[35] [35a] A full investigation of our systems (ENDOR) is currently in progress to identify the different couplings, and will be reported in due course. [35b] It can be noted that similar, but very weak shoulders are sometimes observed with monometallic allenylidene complexes, and that simulated spectra are consistent with the coupling of the electron with the ruthenium atom. Thus, the presence of two ruthenium atoms in bis(allenylidenes) gives rise to a more complex system, with different isotope combinations that account here for the increased intensity of the shoulders: S. Choua, P. Turek, S. Rigaut, D. Touchard, unpublished work.

Structural Diversity of Low-Dimensional Compounds in $[M(en)_2]^{2+}/[Re_6Q_8(CN)_6]^{4-}$ Systems (M = Mn, Ni, Cu)

Konstantin A. Brylev,[a] Guillaume Pilet,[b] Nikolai G. Naumov,*[a] Andre Perrin,[b] and Vladimir E. Fedorov[a]

Keywords: Amines / Cluster compounds / Cyanides / Rhenium / Solid-state structures

Five new octahedral chalcocyanide cluster compounds $[\{Mn(H_2O)(en)_2\}\{Mn(en)_2\}Re_6Te_8(CN)_6]\cdot 3H_2O$ (**1**), $[Ni(NH_3)_2(en)_2]_2[\{Ni(NH_3)_4\}Re_6Se_8(CN)_6]Cl_2\cdot 2H_2O$ (**2**), $[Ni(NH_3)_2(en)_2]_2[\{Ni(NH_3)_4\}Re_6Te_8(CN)_6]Cl_2\cdot H_2O$ (**3**), $(NH_4)_2[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]\cdot 6H_2O$ (**4**) and $(Et_4N)_2[Cu(NH_3)(en)_2]_2[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]\cdot 2H_2O$ (**5**) (en = ethylenediamine), have been synthesised. All five compounds have been characterised by single-crystal X-ray diffraction analysis. Compounds **1**–**3** have chain-like polymeric structures, whereas compound **4** exhibits a two-dimensional polymeric structure, with negatively charged $[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]^{2-}_{\infty\infty}$ layers, and compound **5** has an ionic structure where anionic $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ dimers are packed with cationic $[Cu(NH_3)(en)_2]^{2+}$ complexes and Et_4N^+ cations.

Introduction

The coordination chemistry of octahedral rhenium chalcocyanide cluster complexes $[Re_6Q_8(CN)_6]^{4-/3-}$ (Q = S, Se, Te) is in a stage of a rapid development.[1−5] The interaction of these anions with aqua cations of different metals $[M(H_2O)_6]^{n+}$ results in a partial or total replacement of the coordinated water molecules by nitrogen atoms of the more nucleophilic CN ligands. As a rule such interactions lead to three-dimensional polymeric structures where four or all six CN ligands of the cluster anions coordinate to cations through Re−CN−M bridges.[6−12] The number of low-dimensional structures is limited.[13,14]

A set of chain structures and structures with isolated $[\{M(H_2O)_5\}Re_6Q_8(CN)_6]^{2-}$ fragments has been obtained by using large organic cations like Pr_4N^+ or Bu_4N^+ as "spacers" to separate low-dimensional fragments, thus preventing the formation of framework or layered arrays.[15−17] Another approach to obtain low-dimensional structures is to restrict the coordination abilities of the transition metals. This method has been widely used for mononuclear cyanides.[18−26] Recently, this approach has also been applied to octahedral rhenium chalcocyanide cluster anions such as $[Re_6Q_8(CN)_6]^{4-}$. Several types of organic chelate ligands like en (ethylenediamine),[27,28] trien (triethylenetetramine),[29] salen [*N*,*N*′-ethylenebis(salicylideneaminato)],[30,31] OEP (octaethylporphyrinato dianion) and TPP (tetraphenylporphyrinato dianion)[32] were used and it was shown that the coordination of chelating ligands to the metal effectively reduces the dimensionality of the network.

In the present work we continue the study of the interaction of $[Re_6Q_8(CN)_6]^{4-}$ anions with transition metal cations in the presence of the simplest chelating ligand — ethylenediamine. Five new compounds $[\{Mn(H_2O)(en)_2\}\{Mn(en)_2\}Re_6Te_8(CN)_6]\cdot 3H_2O$ (**1**), $[Ni(NH_3)_2(en)_2]_2[\{Ni(NH_3)_4\}Re_6Se_8(CN)_6]Cl_2\cdot 2H_2O$ (**2**), $[Ni(NH_3)_2(en)_2]_2[\{Ni(NH_3)_4\}Re_6Te_8(CN)_6]Cl_2\cdot H_2O$ (**3**), $(NH_4)_2[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]\cdot 6H_2O$ (**4**) and $(Et_4N)_2[Cu(NH_3)(en)_2]_2[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]\cdot 2H_2O$ (**5**) have been prepared and characterised by X-ray diffraction analysis. They demonstrate the structural diversity of compounds formed in the system "$[M(en)_2]^{2+}$ + $[Re_6Q_8(CN)_6]^{4-}$", where M^{2+} is Mn^{2+}, Ni^{2+} or Cu^{2+} and Q is Se or Te.

Results and Discussion

The crystals of compound **1**−**3** were obtained by diffusion of a water solution of $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ (**1**) or aqueous ammonia solutions of $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$ (**2**) or $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ (**3**) into the glycerol solutions of $Mn(OAc)_2\cdot 4H_2O$ (**1**) or $NiCl_2\cdot 6H_2O$ (**2** and **3**) in the presence of ethylenediamine. Compounds **4** and **5** were crystallised by mixing of aqueous ammonia solutions of $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ and $NiCl_2\cdot 6H_2O$ or $CuCl_2\cdot 2H_2O$, respectively, in the presence of ethylenediamine [Bu_4NBr (**4**) or Et_4NBr (**5**) were added to the reacting systems].

In compounds **1**−**5** the structure of the $[Re_6Q_8(CN)_6]^{4-}$ (Q = Se, Te) anions is similar to that in the starting compounds and related complexes.[2−11,14,16,17,27−32] The Re_6 cluster is an almost ideal octahedron, and the Re−Re bond lengths vary from 2.6714(8) to 2.6988(9) Å in **1**, from 2.6270(7) to 2.6330(3) Å in **2**, 2.6828(7) to 2.6880(6) Å in **3**, from 2.677(2) to 2.698(2) Å in **4** and from 2.6862(8) to 2.6937(8) Å in **5**. The chalcogen atoms cap each triangular face of the Re_6 octahedron. The Re−Q bonds range from 2.683(1) to 2.714(1) Å in **1**, from 2.5247(8) to 2.5275(8) Å in **2**, from 2.6927(5) to 2.6984(6) Å in **3**, from 2.688(2) to 2.701(3) Å in **4** and from 2.679(1) to 2.717(1) Å in **5**. Six cyanide ligands coordinate to rhenium atoms through carbon and stick out in pairs in a mutually perpendicular fashion. The Re−C distances range from 2.07(2) to 2.11(2) Å in **1**, from 2.08(1) to 2.104(9) Å in **2**, from 2.063(14) to 2.085(9) Å in **3**, from 2.03(3) to 2.18(3) Å in **4** and from 2.07(1) to 2.11(2) Å in **5**; the C−N distances range from 1.12(2) to 1.17(3) Å in **1**, from 1.15(1) to 1.16(2) Å in **2**, from 1.16(1) to 1.17(2) Å in **3**, from 1.10(4) to 1.22(4) Å in **4** and from 1.14(2) to 1.20(2) Å in **5**.

In the structure of **1** there are two crystallographically independent manganese cations. Each manganese atom is coordinated by two ethylenediamine molecules, which lie in the equatorial plane and occupy four coordination sites, with Mn−N distances ranging from 2.24(3) to 2.32(2) Å. The atoms coordinated in the axial positions differ for each Mn centre: Mn1 is coordinated by the nitrogen atom of a CN group of the cluster anion [Mn−N distance is 2.26(2) Å] and a water molecule, with an Mn−O length of 2.20(1) Å (Figure 1a), whereas the axial coordination sites of Mn2 (Figure 1b) are coordinated by two nitrogens of CN ligands from neighbouring cluster anions, with Mn−N(CN) distances of 2.23(1) Å and 2.25(2) Å, to form a polymeric zig-zag chain of composition $[\{Mn(H_2O)(en)_2\}\{Mn(en)_2\}Re_6Te_8(CN)_6]_\infty$ (Figure 2). The chains are neutral and are connected to each other by hydrogen bonds to solvate water molecules.

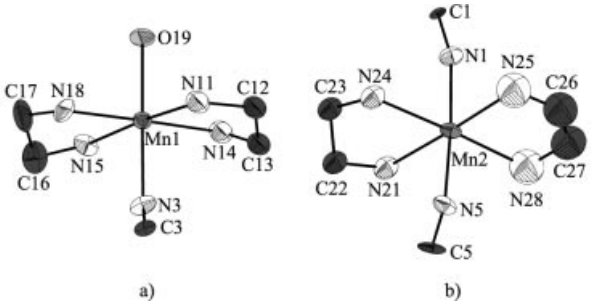

Figure 1. Ligand environment of Mn1 (a) and Mn2 (b) in **1**; displacement ellipsoids are drawn at the 30% probability level; all hydrogen atoms have been omitted for clarity

Compounds **2** and **3** are isostructural. In these compounds there are two crystallographically independent nickel cations. The Ni2 atom and the $[Re_6Q_8(CN)_6]$ clusters have crystallographically imposed *mmm* symmetry, while Ni1 and the Cl atoms have crystallographically imposed 2/*m* and 2*mm* symmetry, respectively. Ni2 is *trans*-coordinated by two nitrogen atoms of CN ligands from neighbouring cluster anions, with Ni2−N(CN) distances of 2.10(1) Å in **2** and 2.06(1) Å in **3**; the four remaining coordination sites are occupied by four molecules of ammonia, with Ni2−N(NH_3) distances of 2.12(2) Å in both compounds (Figure 3a). The Re−CN−Ni2−NC−Re interactions extend along the *a* axis to give infinite negatively charged linear $\{\cdots N{\equiv}C{-}[Re_6Q_8(CN)_4]{-}C{\equiv}N{-}Ni2{-}N{\equiv}C{-}[Re_6Q_8(CN)_4]{-}C{\equiv}N\cdots\}_\infty$ chains (Figure 4a). Ni1 forms the cationic complex *trans*-$[Ni(NH_3)_2(en)_2]^{2+}$ (Figure 3b). The Ni1−N(NH_3) distances are 2.183(8) Å in **2** and 2.187(8) Å in **3**, and the Ni1−N(en) distances are 2.109(6) Å in **2** and 2.108(6) Å in **3**. The structure also contains Cl^- anions surrounded by two $[Ni(NH_3)_2(en)_2]^{2+}$ complex cations [shortest Cl−N(en) distances are 3.41 Å in **2** and 3.47 Å in **3**]. The water molecules are situated near these Cl atoms. The shortest Cl−O distances are 3.15 Å in **2** and 3.27 Å in **3** and correspond to relatively strong Cl···H−O hydrogen bonds.

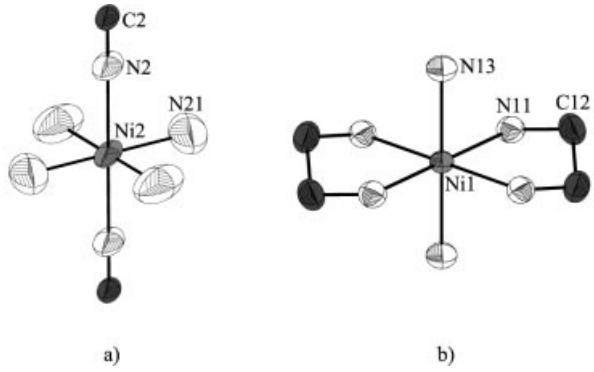

Figure 3. Ligand environment of Ni2 (a) and Ni1 (b) in **2** and **3** (only **2** is shown); displacement ellipsoids are drawn at the 50% probability level; all hydrogen atoms have been omitted for clarity

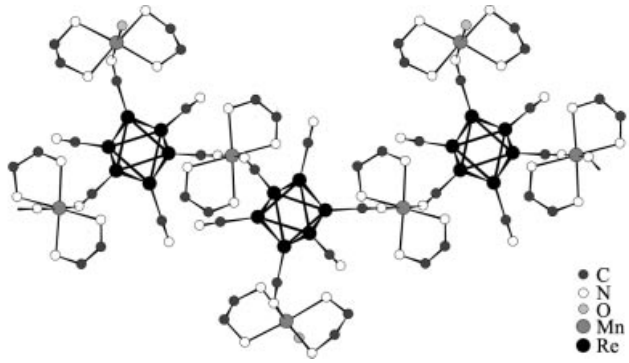

Figure 2. Fragment of the polymer chain $[\{Mn(H_2O)(en)_2\}\{Mn(en)_2\}Re_6Te_8(CN)_6]_\infty$; all hydrogen and tellurium atoms have been omitted for clarity

Infinite anionic chains are located in the same plane and are shifted relative to each other by half a unit cell translation along the *a* axis, as shown in Figure 4b. The distances between chains lying in adjacent planes are 11.822(5) Å in **2** and 12.1078(3) Å in **3**, and 8.078(3) Å in **2** and 8.2025(2) Å in **3** between chains lying in the same plane;

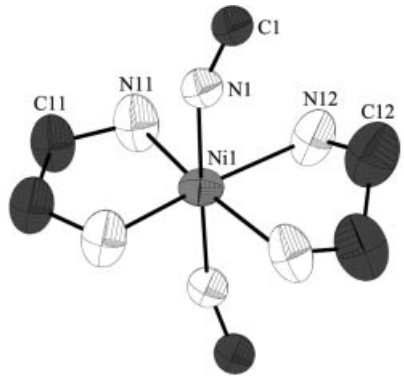

Figure 5. Ligand environment of Ni1 in **4**; displacement ellipsoids are drawn at the 50% probability level; all hydrogen atoms have been omitted for clarity

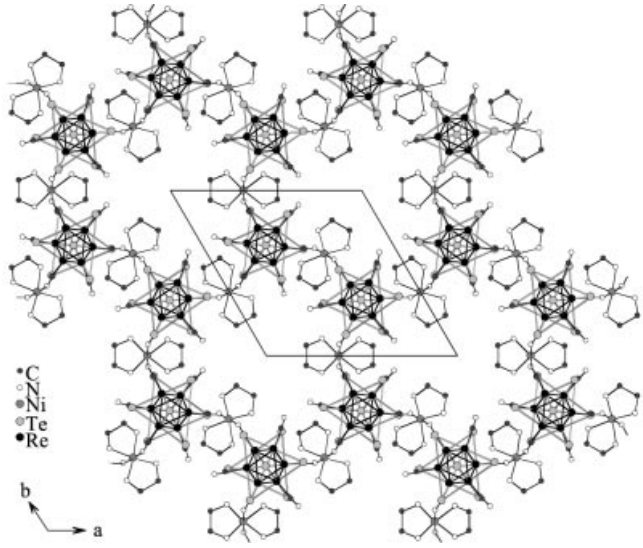

Figure 6. View along [001] of the crystal packing in $(NH_4)_2[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]{\cdot}6H_2O$ (**4**); all hydrogen and tellurium atoms, ammonium cations and water molecules have been omitted for clarity

these values correspond to the *c* and *b*/2 cell parameters, respectively.

In the structure of compound **4** there is one crystallographically independent nickel cation that is located in a special position 3*f* (*x*, 0, 1/2; 0, *x*, 1/2; −*x*, −*x*, 1/2) and has crystallographically imposed C_2 symmetry. It is coordinated by two ethylenediamine molecules lying in the equatorial plane, with Ni−N(en) distances ranging from 2.09(3) to 2.16(3) Å. There are two independent rhenium atoms that belong to the same cluster core. The centre of the cluster anion coincides with the special crystallographic position 2*d* (1/3, 2/3, *z*; 2/3, 1/3, −*z*). Three CN groups from the same face of the Re_6 octahedron take part in the formation of negatively charged infinite wavy $[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]^{2-}_{\infty\infty}$ layers by coordination to cationic $[Ni(en)_2]^{2+}$ units, which are coordinated by one more CN group from neighbouring clusters. The Ni−N(CN) distances are equal to 2.11(3) Å. Finally, the Ni atoms have an octahedral arrangement (Figure 5). In the structure the wavy layers lying in the *ab* plane are packed exactly above each other to form channels with approximate dimensions ranging from 4 Å to 7.2 Å (Figure 6).

Compound **5** contains one cluster anion built from six crystallographically independent rhenium atoms located in general positions and two crystallographically independent copper cations. Cu1 is located in a general position. Its coordination number is equal to five (4 + 1) resulting in the cationic complex $[Cu(NH_3)(en)_2]^{2+}$ (Figure 7a). Four coordination sites of Cu1 are occupied by two ethylenediamine molecules lying in the equatorial plane, with Cu1−N(en) distances in the range from 1.96(2) to 2.02(2) Å, and the fifth coordination site is occupied by ammonia, with a Cu1−N(NH_3) distance equal to 2.32(2) Å. Cu2 is located in the special position 2*c* (0, 1/2, 0; 1/2, 1/2, 1/2) and has imposed $\bar{1}$ symmetry. The coordination number of Cu2 is six (or 4 + 2). Four coordination sites of Cu2 are occupied by two ethylenediamine molecules lying in the equatorial plane, with Cu2−N(en) distances ranging from 2.00(2) to 2.05(2) Å, and the two axial coordination sites are occupied by nitrogen atoms of CN groups of neighbouring clusters, with Cu2−N(CN) distances equal to 2.59(2) Å (Figure 7b). Such a ligand environment of Cu2 results in anionic $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ dimers (Figure 8a). The cationic complexes $[Cu(NH_3)(en)_2]^{2+}$ and cations Et_4N^+ compensate the negative charge of the $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ anions. Inside the structure of $(Et_4N)_2[Cu(NH_3)(en)_2]_2[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]{\cdot}2H_2O$ (Figure 8b) the anionic $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ dimers adopt two orientations. One of these orientations lies nearly along the (b + c) direction, whereas the second

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

orientation is symmetry related and is situated nearly along the (b − c) direction.

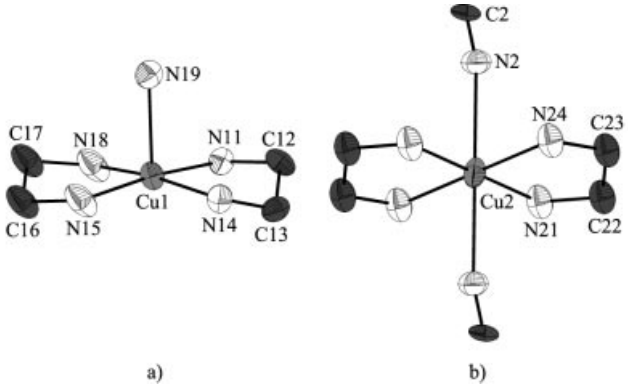

Figure 7. Ligand environment of Cu1 (a) and Cu2 (b) in **5**; displacement ellipsoids are drawn at the 30% probability level; all hydrogen atoms have been omitted for clarity

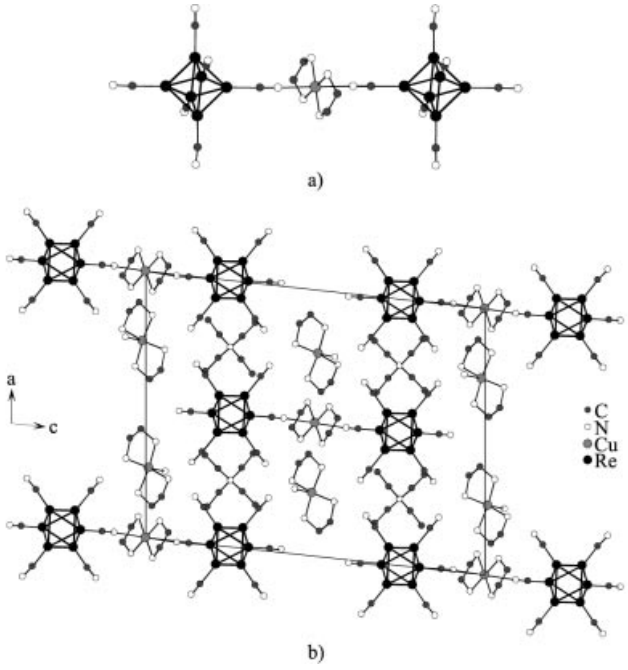

Figure 8. Structure of anionic dimer $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ (a) and view along [010] of the crystal packing in $(Et_4N)_2[Cu(NH_3)(en)_2]_2[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]\cdot 2H_2O$ (**5**) (b); all hydrogen and tellurium atoms and water molecules have been omitted for clarity

As was expected the use of ethylenediamine leads to a decrease in the overall number of M−NC−Re interactions and, hence, to a decrease in the dimensionality of the formed compounds compared to compounds reported earlier for $M^{2+}/[Re_6Q_8(CN)_6]^{4-}$ systems.[6−12] In general, the simultaneous presence of 3d transition metal cations and the chelating ligand ethylenediamine in solution generates different $[ML_{6-2x}(en)_x]^{2+}$ moieties, all of which can serve as building blocks.[27,28,33]

All the structures described here are based on the interaction of cationic $[M(en)_2]^{2+}$ moieties and $[Re_6Q_8(CN)_6]^{4-}$ (Q = Se, Te) anions. The different coordination of $[M(en)_2]^{2+}$ fragments by additional ligands, namely water, ammonia or nitrogen atoms from the cyano groups of the $[Re_6Q_8(CN)_6]^{4-}$ anion, leads to the structural diversity of the compounds. Compounds **1**−**3** have chain-like structures that differ in the binding modes between the cluster anions and metal centres. In **1** the cluster anion $[Re_6Te_8(CN)_6]^{4-}$ is coordinated by three $Mn(en)_2$ fragments (Figure 2), two of which in a *cis*-orientation relative to the Re_6 cluster core, form additional bonds with neighbouring cluster anions. Such binding leads to a zig-zag chain. The third coordinated $Mn(en)_2$ fragment is terminated by a water molecule.

In contrast to **1**, in isostructural **2** and **3** the nickel atoms are bound to *trans*-cyano groups of the anion, which leads to linear chains. Additionally, the nickel atoms are coordinated by four ammonia molecules. The $[Ni(NH_3)_2(en)_2]^{2+}$ cations serve as spacers and are located between the chains along with Cl^- anions, which adjust the charge balance in the structure. It is interesting that in the isomorphous compound $[Co(NH_3)_2(en)_2]_2[\{Co(en)_2\}Re_6Te_8(CN)_6]Cl_2\cdot H_2O$ the transition metal atoms in the polymeric chains are coordinated by ethylenediamine, not by ammonia.[28]

The inclusion of tetraethylammonium cations in **5** results in a change of connectivity in the structure. The structure does not contain infinite chains but only isolated anionic $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ dimer complexes. The formation of such fragments can be described formally as cleavage of $\{\cdots N{\equiv}C{-}[Re_6Q_8(CN)_4]{-}C{\equiv}N{-}M{-}N{\equiv}C{-}[Re_6Q_8(CN)_4]{-}C{\equiv}N\cdots\}_\infty$ chains similar to those found in **2** and **3** due to insertion of the more voluminous Et_4N^+ cations (Figure 9). The influence of cation size on the dimensionality of cyano-bridged clusters has been reported previously.[15,34]

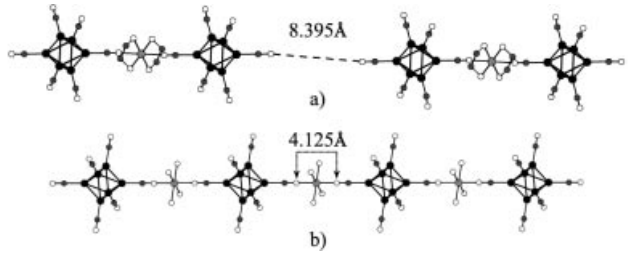

Figure 9. Arrangement of two anionic $[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]^{6-}$ dimers in **5** (a) in comparison with the chain fragment $\{\cdots N{\equiv}C{-}[Re_6Te_8(CN)_4]{-}C{\equiv}N{-}Ni2{-}N{\equiv}C{-}[Re_6Te_8(CN)_4]{-}C{\equiv}N\cdots\}_\infty$ of compound **3** (b)

On the other hand, the use of Bu_4NBr during crystallisation in the Ni/en/$[Re_6Te_8(CN)_6]^{4-}$ system led to intriguing results: the formation of **4** with a two-dimensional framework. Although Bu_4N^+ was not found in the structure of **4**, the presence of Bu_4N^+ in solution is crucial for the formation of this compound, otherwise chain-like compound **3** is formed. In the structure **4** the corrugated $[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]^{2-}_{\infty\infty}$ sheets are stacked exactly above each another. This stacking gives large accessible channels directed along the *c* axis. These channels have a variable profile with dimensions vary from about 4 Å to 7.2 Å based on the estimated van der Waals radii. The CH_2 groups of the ethylenediamine molecules coordinated to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nickel atoms form the narrow section of channels that separate large spherical cavities with a volume of 631 Å^3 (based on calculations performed with PLATON[35]). The cavities centered near the origin (0,0,0) are decorated by six nitrogen atoms from cyano groups of cluster anions. They are filled by solvate water molecules and ammonium cations for charge balance of the framework.

Conclusion

The use of the simplest chelating ligand — ethylenediamine — during co-crystallisation of $[Re_6Q_8(CN)_6]^{4-}$ (Q = Se, Te) with 3d transition metals has resulted in the structural diversity of the formed compounds.

Experimental Section

General: Elemental analyses for C, H, N and S (Carlo Erba 1106) were performed in the Laboratory of Microanalysis of the Institute of Organic Chemistry, Novosibirsk. IR spectra were measured on KBr disks with a Bruker IFS-85 Fourier spectrometer. The starting cluster compounds were synthesised as described previously: $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$ was prepared from polymeric $Re_6Se_8Br_2$;[3] $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ was prepared by adding CsCl to an aqueous solution of the reaction product of polymeric Re_6Te_{15} with molten KCN.[5]

$[\{Mn(H_2O)(en)_2\}\{Mn(en)_2\}Re_6Te_8(CN)_6]\cdot 3H_2O$ (1): The reaction was carried out by layering a solution of $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ (2.0 mg, 0.7 μmol) in water (1 mL) on top of a solution of $Mn(OAc)_2\cdot 4H_2O$ (7 mg, 0.03 mmol) and ethylenediamine (0.01 mL, 0.15 mmol) in glycerol (1 mL). After two weeks, dark red-brown crystals were obtained. These crystals were filtered off and dried on filter paper. The yield was quantitative based on Re. IR: ν_{CN} = 2052s, 2098s and 2112m cm^{-1}. $C_{14}H_{40}Mn_2N_{14}O_4Re_6Te_8$ (2716.5): calcd. C 6.19, H 1.48, N 7.22; found C 6.04, H 1.52, N 7.13.

$[Ni(NH_3)_2(en)_2]_2[\{Ni(NH_3)_4\}Re_6Se_8(CN)_6]Cl_2\cdot 2H_2O$ (2): In a similar manner, layering a solution of $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$ (2.0 mg, 0.94 μmol) in aqueous ammonia (1 mL) on top of a solution of $NiCl_2\cdot 6H_2O$ (7 mg, 0.03 mmol) and ethylenediamine (0.002 mL, 0.03 mmol) in glycerol (1 mL) afforded dark red-brown crystals. The yield was quantitative based on Re. $C_{14}H_{60}Cl_2N_{22}Ni_3O_2Re_6Se_8$ (2564.7): calcd. C 6.56, H 2.36, N 12.02; found C 6.61, H 2.24, N 11.97.

$[Ni(NH_3)_2(en)_2]_2[\{Ni(NH_3)_4\}Re_6Te_8(CN)_6]Cl_2\cdot H_2O$ (3): This compound was synthesised as for **2** by substituting $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ (2.0 mg, 0.7 μmol) for $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$. The resultant dark red-brown crystals were filtered off and dried on filter paper. The yield was quantitative based on Re. $C_{14}H_{58}Cl_2N_{22}Ni_3ORe_6Te_8$ (2935.8): calcd. C 5.73, H 1.99, N 10.50; found C 5.73, H 1.87, N 10.44.

$(NH_4)_2[\{Ni(en)_2\}_3\{Re_6Te_8(CN)_6\}_2]\cdot 6H_2O$ (4): A solution of $NiCl_2\cdot 6H_2O$ (3.33 mg, 0.014 mmol) and ethylenediamine (1.9 μL, 0.028 mmol) in aqueous ammonia (0.5 mL) was added to a solution of $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ (20 mg, 7.0 μmol) and Bu_4NBr (11.28 mg, 0.035 mmol) in aqueous ammonia (10 mL). The resultant solution was kept in a tightly closed vessel at room temperature for two weeks, during which time dark red-brown crystals formed. These crystals were filtered off and dried on filter paper. The yield was quantitative based on Re. IR: ν_{CN} = 2051s, 2091w, 2119m and 2133w cm^{-1}. $C_{12}H_{34}N_{13}Ni_{1.5}O_3Re_6Te_8$ (2634.57): calcd. C 5.47, H 1.30, N 6.91; found C 5.60, H 1.21, N 6.84.

$(Et_4N)_2[Cu(NH_3)(en)_2]_2[\{Cu(en)_2\}\{Re_6Te_8(CN)_6\}_2]\cdot 2H_2O$ (5): A solution of $CuCl_2\cdot 2H_2O$ (12 mg, 0.07 mmol) and ethylenediamine (0.047 mL, 0.7 mmol) in aqueous ammonia (1.5 mL) was added to

a solution of $Cs_4[Re_6Te_8(CN)_6]\cdot 2H_2O$ (20 mg, 7.0 μmol) and Et_4NBr (7.35 mg, 0.035 mmol) in aqueous ammonia (10 mL). The resultant solution was kept in a tightly closed vessel at room temperature for two weeks, during which time dark red-brown crystals formed. These crystals were filtered off and dried on filter paper. The yield was quantitative based on Re. IR: ν_{CN} = 2074s, 2103m and 2141m cm^{-1}. $C_{20}H_{49}Cu_{1.5}N_{14}ORe_6Te_8$ (2735.1): calcd. C 8.78, H 1.81, N 7.17; found C 8.83, H 1.62, N 7.15.

X-ray Crystallographic Study: Selected single crystals were mounted, as usual, on the top of a glass fibre. Diffraction data were collected at room temperature (293 K) with a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Experimental details for complexes **1**−**5** are given in Table 1. The data processing was performed by the Kappa CCD analysis software;[36] the lattice constants were refined by least-square refinement. Absorption corrections based on the crystal shapes were applied to the data sets with the ANALYTICAL program[37,38] for all structures. Structure solution and refinement: Complexes **1** and **5** crystallised in the monoclinic system. The systematic absences led to the $P2_1/n$ *and* $P2/n$ space groups, respectively. For **2** and **3**, the observed systematic absences suggested an orthorhombic crystal system with a *C* lattice. Among the possible space groups, the refinement procedure allowed us to determine unambiguously the *Cmmm* space group. Complex **4** crystallised in the trigonal system with a *P* lattice. The systematic absences led to the *P*321 space group. The structures were solved by direct methods (SIR97 program[39]) combined with Fourier-difference syntheses and refined against *F* using reflections with $I > 3\sigma(I)$ (CRYSTALS program[40]). All atoms were refined anisotropically. CCDC-234060 to -234064 (**1**−**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre (CCDC), 12 Union Road, Cambridge, CB2 1EZ, UK; Fax: + 44-1223-336-033; or deposit@ccdc.cam.ac.uk).

High-Field EPR Study of Frozen Aqueous Solutions of Iron(III) Citrate Complexes

Frédéric Biaso,[a] Carole Duboc,[b] Bernard Barbara,[c] Guy Serratrice,[a] Fabrice Thomas,[a] Denis Charapoff,[a] and Claude Béguin*[a]

Keywords: High-field EPR spectroscopy / Iron / Coordination chemistry / Citrate ligand / Tripodal ligand / Spin crossover

High-field electron paramagnetic resonance spectra have been measured for frozen aqueous solutions of Fe^{III} citrate at acidic and neutral pH values. At high fields (up to 12 T) and high frequencies (95, 190 and 285 GHz), fine-structure peaks due to resonance between Kramers doublets (±1/2, ±3/2, ±5/2) of an $S = 5/2$ species can be observed when the experiments are performed at high temperatures. A full-matrix diagonalisation approach has been used to derive the spin-Hamiltonian parameters for the $S = 5/2$ spin state. In acidic media (pH = 2), the spacing of the fine structure reveals that the value of the axial zero-field splitting (ZFS) parameter D is -0.12 cm^{-1} without rhombicity. A small but significant g anisotropy can be observed which depends slightly on the frequency and the temperature ($g_x = 2.014$, $g_y = 2.014$ and $g_z = 1.983$, at 60 K and 285 GHz). In neutral media (pH = 6), complete rhombic HF-EPR spectra were observed with a fivefold lower $|D|$ value (0.024 cm^{-1}) and $E = 0.008$ cm^{-1}. A satisfactory simulation of the experimental data was obtained with a g value equal to 2.00. The different ZFS parameters obtained under neutral and acidic conditions are discussed in terms of the symmetry of the complex. At low temperatures, a spin transition from 5/2 to 1/2 occurs at all frequencies. The transition temperature is pH- and field-dependent. A model including magnetoelasticity has been suggested in order to interpret the field dependency of the spin transition observed for the two systems.

Introduction

Citric acid is widely known for its abundance in biological fluids and plays key roles in the biochemical processes of bacteria, plants, animals and humans. Its structure, with three carboxylate groups and one hydroxy group, bestows on it unique chemical properties which render it essential in biological media.[1] Besides participation in the Krebs cycle[2] and acting as a component in a number of metalloenzyme active sites,[3] citric acid is a target ligand of a large number of trace metal ions found in biological fluids. Its chelating ability, exemplified in a multitude of coordination modes, plays an important role in metal solubilisation, mobilisation and bioavailability in biological media.[1,4] Among these metal ions, we have a particular interest in ferric ions.[5−7] In humans, citrate is present in blood plasma at a concentration of about 0.1 mM and is believed to be one of the major components of nontransferrin-bound iron (NTBI).[8a,9] It has been proposed that NTBI in the plasma of iron-overloaded patients exists largely in the form of complexes with citrate.[10] Citrate has also been proposed as a component of the cytosolic (or intracellular) iron pool known as the "Labile Iron Pool" (LIP). Other ligands involved in the LIP (which is also called the chelatable pool, transit pool or low molecular weight iron pool) could be AMP, ATP, pyrophosphate, amino acids or nucleoside phosphates.[8b,11] In vivo approaches have been developed to obtain information about the concentration and the nature of this LIP.[8] For a correct interpretation of the biological processes related to the Fe^{III} citrate system, it is necessary to obtain more insight, using noninvasive approaches, into the nature of the chemical species of this system present in aqueous solutions. The dependence of the system on the experimental conditions (stoichiometry, solvent, pH, added ligand or bases etc.) could therefore be easily studied.

High field electron paramagnetic resonance (HF-EPR) experiments performed on aqueous solutions of Fe^{III} citrate should be a good in vitro noninvasive approach. At high frequencies (95, 190 and 285 GHz, i.e. high energy radiation of ca. 3−10 cm^{-1}) and high fields (up to 12 T), we could directly observe EPR resonances between the energy levels. The splitting of these levels depends on the Zero-Field Splitting (ZFS) parameters (Kramers doublets) and on the Zeeman effect. At high fields, the Zeeman interaction is

dominant compared with the ZFS interaction. As a consequence, the ZFS parameters could be determined much more precisely than with conventional X-band EPR spectroscopy (9.4 GHz).[12] By performing measurements at high frequencies, the resonance positions of a Kramer transition may be tracked in order to determine the anisotropy of the *g* tensor even if it is weak (ranging between 1.950 and 2.040 in our case). This might lead to a considerably improved understanding of the symmetries and electronic structures of these biologically relevant Fe^{III} complexes.

The major aim of this study was to measure the ZFS parameters of mononuclear Fe^{III} citrate complexes in aqueous solutions and to find a correlation between the ZFS and the geometry around the iron. Another aim was to confirm, for these experimental conditions, the mononuclear structures of these complexes since the reported coordination chemistry of ferric citrate remains sketchy.[8] The complexes were obtained from solutions where citrate was in excess of the ferric ions (20:1 as respective molar ratio) at two different pH levels. We studied the anions **1** (at pH = 1.95) and **2** (at pH = 6.2) with Na^+ as the counterion. The protonation states of these chemical species cannot be obtained by UV/Vis spectrophotometry or by potentiometric titration. We believe, however, from comparisons with literature data (vide infra), that the structure of **1** is $[Fe(HCit)(H_2Cit)]^{2-}$. Complex **2** has been previously identified using electrospray mass spectrometry as having the structure $[Fe(HCit)(Cit)]^{4-}$ and this was confirmed by X-ray analysis (where Cit is the completely deprotonated citric acid) as shown in Figure 1.[13]

Results

1. High-Field EPR Spectra of 1 and 2 at 60K

The 60 K HF-EPR spectra of **1** and **2**, at frequencies ranging between 95 and 285 GHz, are shown in Figures 2 and 3, respectively. They have been simulated using the spin-Hamiltonian parameters reported in Table 1 (see Exp. Sect. for details). Compound **1** exhibits purely axial symmetry with a *D* value of $|0.12|$ cm^{-1}. The values of the Landé factor vary slightly as a function of the frequency (small increase of $g_\perp$ and small decrease of $g_{//}$ when the frequency decreases, Table 2). All the transitions are shown in Figure 2 with their interpretations using energy level diagrams (e−f in Figure 2). $\Delta M_S = 2$ transitions centred at 1.75 T for 95 GHz can also be recalculated from the energy level diagrams (see d−f in Figure 2).

The negative sign of *D* was determined by careful examination of the intensities of the transitions as a function of temperature (from 20 to 60 K). At 285 GHz, when the temperature increases, the intensities of the [5/2,1/2> to 5/2,3/2>]$_{//}$ and [5/2,1/2> to 5/2,3/2>]$_\perp$ transitions, located at 10.52 T and 9.98 T, respectively, increase, while that of the 5/2,−3/2>$_\perp$ to 5/2,−1/2>$_\perp$ transition decreases at 10.23 T. This agrees with the energy level diagram shown on the right of Figure 2.

For compound **2**, both the high field (Figure 3 and Figure SI1 in the Supporting Information; for Supporting Informations see also the footnote on the first page of this article) and X-band EPR spectra (data not shown) are rhombic. The experimental and simulated 285 GHz EPR spectra recorded at 60 K are shown in Figure 3. At this frequency, the EPR spectrum is constrained between 10.0 and 10.5 T in agreement with a magnitude of *D* five times smaller than that for compound **1** ($|D| = 0.024$ cm^{-1}, with $|E|$ equal to 0.008 cm^{-1}; $\lambda = |E/D| = 1/3$). Since the zfs tensor is completely rhombic, the sign of D has no significance. The different transitions of the $S = 5/2$ paramagnet with their interpretations using energy level diagrams are shown in the Supporting Information (SI1).

2. Evolution of the High-Field EPR Spectra of 1 and 2 as a Function of Temperature from 60 to 5 K

The 285 GHz HF-EPR spectra were found to be temperature-dependent in the 5 to 60 K range (Figure 4) for compound **1** and between 5 and 30 K for compound **2** (Figure SI2 in the Supporting Information). At 5 K, the $S = 5/2$ spectrum was not observed. Instead, an axial $S = 1/2$ signal dominates the spectra of **1** and **2**. The $S = 1/2$ spectra are characterised by a very large line width ($w_{1/2} = 0.5$ T) suggesting a much higher relaxation rate of the $S = 1/2$ species than for the $S = 5/2$ species. However, the line widths of each spin state for compounds **1** and **2** are similar at all frequencies indicating that the frequency has no effect on the relaxation rate of the different species. The $S = 1/2$ signals for compounds **1** and **2** were simulated (see Exp. Sect.) with a small *g* anisotropy in the perpendicular region of the spectra (Table 3). The differences in relaxation rates between the $S = 5/2$ and the $S = 1/2$ spectra are so high that their relative contribution to the spectra could not be precisely obtained. Therefore, it was difficult to evaluate the critical temperature (i.e. T_c, the transition temperature where the molar fractions of the two spin states are equal). However, Figure 4 and SI2 show that the spin conversion is

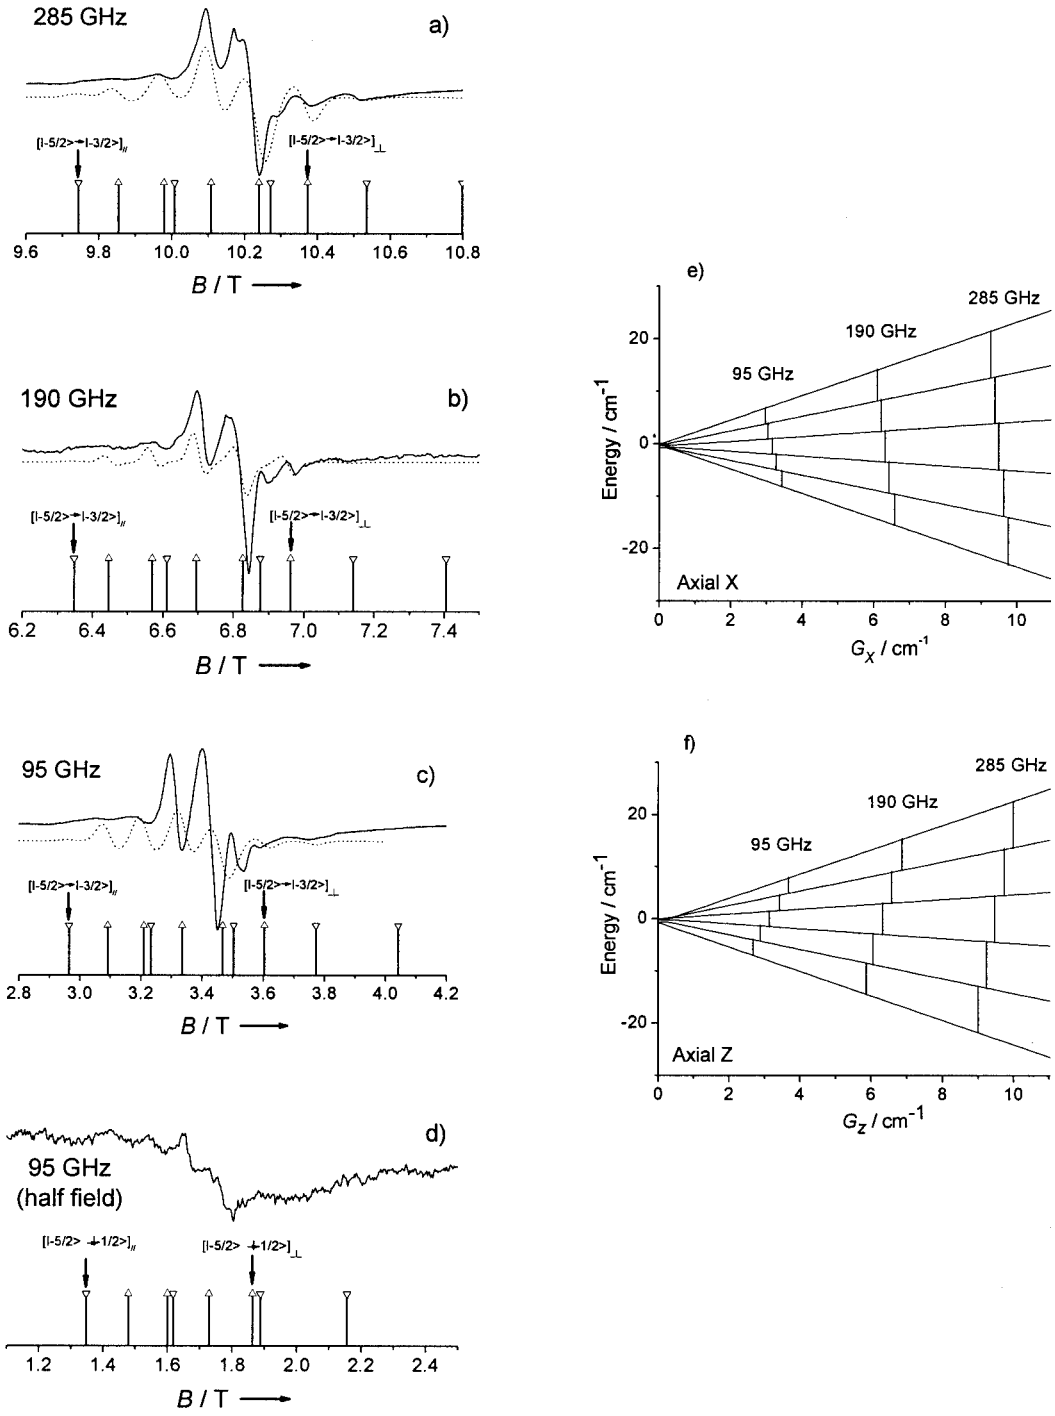

Figure 2. Experimental (bold lines) and simulated (dotted lines, with $D = -0.12$ cm^{-1} and g_x, g_y and g_z according to Table 2) HF-EPR spectra of compound **1** recorded at 60 K and at 285 (a), 190 (b) and 95 GHz (c and d); the assignments of the different transitions are represented as sticks (// parallel and ⊥ perpendicular); in the right-hand part, energy levels calculated for the axial spin-Hamiltonian (see Exp. Sect.) as a function of G_q ($g_q\beta B_o$) are shown; the expected resonances at 95, 190 and 285 GHz are indicated by vertical bars (e) for G_x and (f) for G_z

not abrupt for **1** and **2** but they do not show the presence of a hysteresis loop around T_c.

In Figure 5, the frequency dependence of the HF-EPR spectra of compound **1** is shown at 12.5 K. The $S = 5/2$ component dominates the spectrum with a minor $S = 1/2$ component at 95 GHz, whereas the reverse is true at 285 GHz with a major contribution to the spectrum from the $S = 1/2$ species. This reveals that T_c increases as the field increases. Another way to illustrate this phenomenon is to look at HF-EPR spectra recorded at different frequencies and at different temperatures which appear with similar shapes as shown in Figure 6. At the particular tem-

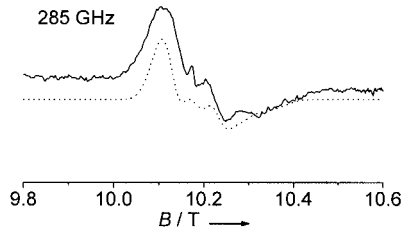

Figure 3. Experimental and simulated HF-EPR spectra for compound **2** at 60 K and at 285 GHz

peratures of 5.0, 9.0 and 12.5 K for 95, 190 and 285 GHz, respectively, the relative intensities of the signals corresponding to the two spin states appear almost equivalent. Thus, these temperatures can be an estimate of the T_c at each frequency, demonstrating that T_c increases almost linearly with the external magnetic field (Figure SI3, Supp. Inf.).

At 285 GHz, the estimate of T_c for compound **2** is much lower than for compound **1** since the $S = 5/2$ spectrum can be observed even at 5 K.

Table 1. Energy matrix of 6 × 6 elements for the $S = 5/2$ spin state characterised by a rhombic zero-field splitting with an external magnetic field B_0, oriented along the molecular axis of the complex, according to the Cartesian components B_x, B_y and B_z; the notations are $G_z = \beta g_z B_z$, $z = G_x + iG_y$ and $z^* = G_x - iG_y$ with $G_x = \beta g_x B_x$ and $G_y = \beta g_y B_y$; all parameters (D, E, G_x, G_y and G_z) have to be treated with the same energy unit (cm^{-1})

Discussion

1. Comparison of the Zero-Field Splitting Parameters with Literature Data

Values of ZFS parameters for high-spin Fe^{III} complexes have been reported in the literature only recently due to the development of high-field EPR techniques. A very early (1973!) paper by Y. Alpert et al. has indisputably been the classic in biological HF-EPR spectroscopy with measurements at various microwave frequencies in the millimetre region (called far-infra red magnetic resonance by some authors).[14] In some cases, measurements of spectra as a function of temperature give the sign of *D*. EPR measurements at X- or Q-band frequencies (with an appropriate treatment of the data), magnetic susceptibility measurements or Mössbauer experiments have also been reported as giving *D* values usually without sign determination.

In Table 4, we have gathered several *D* and λ values determined for low molecular weight mononuclear Fe^{III} complexes or metalloproteins. Absolute *D* values vary from very small up to 12 cm^{-1} while those of λ vary from 0 (complete axial symmetry) to 0.33 (complete rhombic symmetry). We discuss the data in three main groups.

(i) The first group concerns the non-heme octahedral Fe^{III} complexes. The complexes $[Fe(dpm)_3]$, $K_3[Fe(malonate)_3]$, $K_3[Fe(oxalate)_3]$, $K_3[Fe(acac)_3]$ and ferrichrome A have three bidentate ligands for which the denticity only originates from oxygen atoms.[15−18] They are characterized by small *D* values ($|D| < 0.3$ cm^{-1}). Three of these complexes exhibit a quasi-axial ZFS ($\lambda < 0.055$) while the other two show a moderate rhombicity with $\lambda \approx 0.25$. Since a discrepancy in *D* appears in the literature for ferrichrome A we retained, in Table 4, only the values extracted from HF-EPR measurements.[17,18] When nitrogen atoms are present in the coordination shell of Fe^{III}, the magnitude of *D* (0.3−1.7 cm^{-1}) increases in comparison with the values for the previous complexes. The coordination mode varies between $[N_2O_4]$,[19−22] $[N_4O_2]$[23] and $[N_5O]$.[24] EPR measure-

ments performed at several high frequencies are well documented for the Fe^{III}-EDTA complex.[21] For all these octahedral complexes, the $|D|$ values increase as a function of the nature of the coordinating atoms in the order: $[O_6] < [N_2O_4] < [N_4O_2] < [N_5O] < [S_6]$. Among the non-heme proteins, only three iron sites have been studied and the magnitude of D is < 3 cm^{-1}. In the case of transferrin, rhombic spectra have been correlated with the distorted octahedral structure found in the enzyme.[19−21] The iron is coordinated by four monodentate amino acid residues and one bidentate carbonate anion giving an $[NO_5]$ set of donor atoms.[8c] For lipoxygenase, EPR measurements both at low (X band) and high frequencies have been made and give the same magnitude of D (sign determined at high frequencies).[25−26] The corresponding structural data show an $[N_3O_3]$ coordination mode.[27] In the case of the bacterial Fe-superoxide dismutase (Fe-SOD), attention must be drawn to the detailed X-band EPR study. From a precise temperature-dependent spectroscopic analysis, the magnitude and sign of D were obtained.[28] The observed rhombicity ($\lambda = 0.23$) can be explained in relation to the X ray structure of the Fe-SOD from *E. coli* which reveals that the active site is a pentacoordinate complex. The iron atom is coordinated by three histidines, one aspartate and a hydroxide anion resulting in a distorted structure.

(ii) The second group concerns Fe^{III} complexes characterised by a C_{4v} geometry in the coordination sphere. All of these complexes possess halogen ligands. The magnitude of D varies in a large range (2 to 10 cm^{-1}) and has been correlated with the nature of the halogen ligand. For instance, D increases from -2 to $+7$ cm^{-1} when the chloride ligand is replaced by a bromide ligand in $[(R_2NCS_2)_2FeX]$ [R_2NCS_2 is a bis(dithiocarbamate)].[17] The other chloro iron complex [chlorobis(*N*-methylbenzothiohydroamato)Fe^{III}] is characterised by a larger D value (between 7 and 10 cm^{-1}).[29−30] From the X-ray structures determined for several complexes, the magnitude of D can be correlated with the distance between the iron ion and the plane formed by the four equatorial ligands along the axis formed by the fifth ligand and the metal atom. $|D|$ increases when the distances become smaller.

(iii) The third group concerns the (heme)Fe^{III} complexes such as (porphyrin)Fe^{III} and (protein)Fe^{III} complexes such as metmyoglobin and hemoglobin.[14,17,21,31−34] The systematic axial symmetry originates from the conjugated electronic structure of the haeme. When the metal atom lies in the heminic plane, the D values are in the range of 9 to 12 cm^{-1}.[14,17,31−34] On the other hand, when the iron atom lies above the heme plane, the D values become smaller, between 5 and 10 cm^{-1}.[14,17,31−34] The shift of the iron atom above the plane occurs when an additional ligand coordinates to the iron site giving a sixth coordination site. Recently, the sign of D was clearly obtained as being positive for metmyoglobin.[21]

In conclusion, compounds **1** and **2** can be compared with the non-heme octahedral complexes. The D value of 0.12 cm^1 determined for **1** is in the range found for complexes characterised by a $[O_6]$ coordination sphere ($0.12 < D <$ 0.28 cm^1). For compound **2**, the D value of 0.024 cm^{-1} is smaller but can be closely compared with the other complexes extending the previous range. However, all these D values are smaller than those of the other octahedral complexes in which the coordination spheres contain other heteroatoms as for the EDTA complex ($[N_2O_4]$) with $D = 0.8$ cm^{-1}. In our case, the pH change between compounds **1** and **2** leads to a drastic evolution of λ from a purely axial to a totally rhombic system.

2. Zero-Field Splitting Parameters and Structures of Compounds 1 and 2

It is interesting to compare the ZFS parameters with structural data. Different chemical species have been identified in aqueous solutions depending on the pH. In solutions containing 1 μM Fe^{3+} and 0.1 mM citrate at pH = 5−6, $[Fe(citH)_2]^{3-}$ and $[Fe(cit)]^-$ were observed.[35] More recently, different complexes formed from Fe^{III} and citric acid in the pH range 1−13 have been studied by magnetic susceptibility measurements.[36]

The crystal structures of several mononuclear dicitrate complexes with metal(III) ions, with different degrees of protonation, have been obtained in our laboratory. From these results, we should be able to suggest likely structures for compounds **1** and **2**.

At pH = 7, $(NH_4)_5[Fe(Cit)_2]\cdot 2H_2O$ was isolated.[13] The structure is centrosymmetric with the Fe^{III} ion located on an inversion centre. The coordinated oxygen atoms with the similar chemical functions of each citrate are in *trans* positions. This coordination mode involves the formation of a seven-, a six- and a five-membered coordination ring. The remaining terminal carboxylates are noncoordinating. These results are in agreement with those reported in the literature at almost the same pH.[37] The shortest Fe−O bond is 1.942 Å for the Fe−O (alkoxide) bond. The other distances are 1.995 Å for the Fe−O (central carboxylate) bond and 2.055 Å for the Fe−O (terminal carboxylate) bonds.[13]

At pH = 6, single crystals of $(NH_4)_4[Fe(HCit)(Cit)]\cdot 3H_2O$ were isolated.[13] Since the protonation state of each ligand is different, the Fe^{III} ion is no longer located on an inversion centre thus inducing a pseudo-centrosymmetrical complex. The proton in the (Hcit) ligand is located on the pendant terminal carboxylic acid. The Fe−O bond lengths are nevertheless in the same range as those of the previous complex $(NH_4)_5[Fe(Cit)_2]\cdot 2H_2O$. The values of the Fe−O bond lengths are: 1.932 and 1.944 Å for the Fe−O (alkoxide) bonds, 2.007 and 2.019 Å for the Fe−O (central carboxylate) bonds, and 2.035 Å and 2.064 Å for the Fe−O (terminal carboxylate) bonds, for the nonprotonated and protonated ligands in each case, respectively. No crystals could be obtained at other acidic pH values.

Crystal structures of related complexes found in the literature give an idea of the structure of compound **1**. The structure of $(NH_4)_4[Fe(HCit)(Cit)]\cdot 3H_2O$ is isostructural with $(NH_4)_4[Al(HCit)(Cit)]\cdot 3H_2O$ and $(NH_4)_4[Ga(HCit)(Cit)]\cdot 3H_2O$ which have been previously characterised.[38]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The Ga−O bond lengths are 1.893 and 1.900 Å for the Ga−O (alkoxide) bonds, 1.976 and 1.983 Å for the Ga−O (central carboxylate) bonds, and 2.022 and 2.058 Å for the Ga−O (terminal carboxylate) bonds, for the nonprotonated and protonated ligand in each case, respectively. The $[Ga(HCit)(H_2Cit)]^{2-}$ species was recently characterised in the laboratory at pH = 1.5.[39] This complex has two pendant terminal carboxylic acid functions and the Ga^{III} centre is linked to an alkoxide oxygen atom for the monoprotonated ligand and an alcoholic oxygen atom for the diprotonated ligand. The Ga−O bond lengths are 1.878 Å for the Ga−O (alkoxide) bond and 2.038 Å for the Ga−O (alcoholic) bond, the other distances are 1.945 and 1.936 Å for the Ga−O (central carboxylate) bonds, and 2.013 and 2.003 Å for the Ga−O (terminal carboxylate) bonds. These results unambiguously demonstrate that protonation of the alkoxide oxygen increases the Ga−O bond distance.

We therefore suggest that the geometry of compound **2** is strongly related to that of $(NH_4)_4[Fe(HCit)(Cit)]\cdot 3H_2O$. The only difference comes from the difference in the counterion (Na^+ instead of NH_4^+). All of the Fe−O bonds distances are in the range of 1.932 to 2.035 Å, within an interval of 0.1 Å suggesting a rhombic octahedral geometry around the Fe^{III} ion. Although the geometry of compound **1** is still unknown, a comparison of isostructural Ga^{III} and Fe^{III} citrates with different degrees of protonation suggests that the protonation of one or two alcoholic oxygen atoms increases the Fe−O (alcoholic) bond distances leading to an axial octahedron with a long O(alcoholic)−Fe−O(alcoholic) axis. This change of structure related to the variation in the acidity of the medium can therefore be correlated with the strong evolution of the ZFS parameters, extracted from the high-field EPR spectra, when the pH of the medium shifts from 6 to 2.

3. Spin Crossover in 1 and 2

All of our results suggest that complexes **1** and **2** are mononuclear, and we will attempt to explain the different phenomena that we observed starting with the following hypothesis.

We therefore exclude to interpret our data on the basis of two different spin states originating from a trinuclear high-spin Fe^{III} complex. For instance, in the literature, the $[Fe_3S_4]^+$ sites of ferredoxins were characterised by an S = 1/2 ground state and an S = 5/2 excited state. The spin ground state S = 5/2 or S = 1/2 depends on the magnitude of the different antiferromagnetic exchange couplings between the three iron sites.[40] Nevertheless, it has been found by Girerd et al., that in a certain temperature range, an S = 3/2 species becomes stabilised for such trinuclear iron−sulfur complexes. In our case, no evidence of an S = 3/2 spectrum arising from a trinuclear Fe^{III} complex has been found in our experimental data.

Moreover, the observation of such a spin crossover for our $[O_6]$-coordinated iron(III) complexes was quite unpredictable.[41] Indeed, no critical temperature of a spin transition has been described for such compounds. Nevertheless, a spin transition has been established for an iron(III)-substituted acac complex by magnetic moment measurements.[42] From a general point of view, iron(III) spin-crossover compounds are less common than those of iron(II).[41,43] However, early studies on tris(dithiocarbamato)iron(III) complexes $[Fe(S_2CNRR')_3]$ indicated that, depending on the nature of R and R′, the iron(III) is high or low spin or spin crossover in this $[S_6]$ coordination sphere.[41,44] In the case of porphyrinic systems, including ferric haemo proteins, characterised by a $[N_4L_2]$ coordination sphere, spin crossover has been observed (L represents different types of monodentate ligands).[41,45] The origin of this phenomenon has been related to a spin state stereochemical relationship. Spin crossover has also been seen for complexes with $[N_6]$ and $[N_4O_2]$ coordination spheres.[46−47]

Spin Transition Equilibrium and Critical Temperature T_c

At 5 K, the 1/2 spin state corresponds to the major species in solution. When the temperature is increased, the S = 5/2 species appears at the expense of the 1/2 species (Figure 4). Since the relaxation properties of the two species differ strongly, it is difficult to evaluate the critical temperature T_c. Comparing the relative appearance of the two spectra it is possible, however, to characterise the variation of these T_c values as a function of the nature of the complex and the field (see below). For instance, at 285 GHz, T_c is smaller for the complex in a neutral medium ($T_c < 10$ K) than it is under acidic conditions (T_c = 12.5 K) (Figure 4 and SI2, Supp. Inf.). For the compounds **1** and **2**, their T_c values are, by far, smaller than that those already found in the literature for Fe^{III} complexes with $[S_6]$, $[N_6]$ or $[N_4O_2]$ coordination shells. For these last compounds, the T_c values are in the range from room temperature to 70 K.[41]

The experimental data are reproducible even if measurements are performed by increasing or decreasing the temperature, implying that no hysteresis phenomena occur. Thus, we have interpreted the presence of these two paramagnetic species as a thermal spin transition (or spin-crossover) of a unique chemical species changing from the 1/2 spin state to the 5/2 spin state according to the following equilibrium:

$$LS\ (^2T_2) \rightleftarrows HS\ (^6A_1)$$

The spin-state interconversion seems to be "prepared" below T_c. Indeed, the evolution of the g anisotropy of the S = 1/2 species with temperature (seen at 285 GHz in Figure 4) can be attributed to small structural modifications around the metal. These slight changes are likely related to the spin transition. Changes in metal−ligand bond lengths accompanying a spin state transition can be obtained from X-ray crystallography. As an example, for Fe^{III} complexes, differences of 0.17 Å can be found for the Fe−N distances but of only 0.04 Å for the Fe−O distances in a series of hexadentate ligands derived from triethylentetramine with a $[N_4O_2]$ donor set.[48]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The rate of the spin-state interconversion for each compound is slower at all temperatures than the EPR time scale (ca. 10^{11} s^{-1}), but chemically fast. At first sight, it seems strange that at these temperatures the reaction rates are fast. In the literature, however, Buhks et al. suggested that dynamics in spin-crossover should be treated as a nonadiabatic process within the theory of radiationless multiphonon relaxation.[49] They predicted that the LS/HS relaxation would be a thermally activated process at elevated temperatures with a nonvanishing tunnelling rate at cryogenic temperatures. Recently, these relaxation rate constants were measured for several Fe^{III} complexes using laser flash photolysis experiments.[50] Two temperature domains were observed. Clearly, the general temperature behaviour consisting of a thermally activated process at elevated temperatures and a tunneling at low temperatures was experimentally observed. Therefore, even at low temperatures, the LS to HS relaxation rate constant remains high. Under these conditions, the equilibrium between the low-spin (LS) and the high-spin (HS) complexes can thus be instantaneously obtained.

Influence of the External Magnetic Field on Spin Crossover

It can be seen from Figure 5 that the critical temperature is also field dependent and T_c increases as the magnetic field increases. To explain this phenomenon, we have treated the spin transition as an equilibrium reaction between two chemical species, the LS and the HS complexes, with x as the molar fraction of the high-spin complex.

$$\begin{array}{lcl} \text{LS} & \leftrightarrows & \text{HS} \\ (1-x) & & x \end{array}$$

Three different situations can be considered:

(i) In the absence of a magnetic field, the molar free enthalpy (Gibbs free energy, G per mol) for this reaction can be written as the weighted sum of the standard free enthalpy ($G_H°$ and $G_L°$) of the pure HS and LS systems in the absence of any cooperative interaction terms, plus two other terms accounting for the mixing entropy (S_{mix}) and the interactions [$I(x)$]:

$$G = xG_H° + (1-x)G_L° - T\,S_{mix} + I(x) \quad (1)$$

If a regular solution of molecules is assumed for the two states, the mixing entropy S_{mix} for the mixing of the chemical species, according to Guggenheim is:[51]

$$S_{mix} = -R[x\ln x + (1-x)\ln(1-x)] \quad (2)$$

The interaction term can be treated by following a model initially introduced by Slichter, then later modified by König and revisited by Kahn, as:[52−54]

$$I(x) = \gamma_{LL}(1-x)^2 + 2\gamma_{LH}(1-x)x + \gamma_{HH}x^2 \quad (3)$$

where γ_{LL}, γ_{LH} and γ_{HH} are pair interaction terms between two LS ions, a LS and a HS pair, and two HS ions, respectively. These terms are likely related to the magnetoelastic coupling between each cell of the two types of spin (mean field approximation). For convenience, $I(x)$ can be rewritten as:

$$I(x) = \gamma_0 + \gamma_1 x + \gamma_2 x^2 \quad (4)$$

with $\gamma_0 = \gamma_{LL}$, $\gamma_1 = 2(\gamma_{LH} - \gamma_{LL})$ and $\gamma_2 = \gamma_{LL} - 2\gamma_{LH} + \gamma_{HH}$.[52−54] If we introduce equilibrium conditions, the differentiation of the free enthalpy as a function of the molar fraction of the high-spin species gives the following equation:

$$\partial G/\partial x = 0 = \Delta G° + \gamma_1 + 2\gamma_2 x + RT\ln[x/(1-x)] \quad (5)$$

where $\Delta G° = G_H° - G_L°$ is the molar standard free enthalpy of the reaction. This expression gives the equilibrium molar fraction x as a function of temperature with $\Delta G° = \Delta H° - T\Delta S°$ where $\Delta H°$ and $\Delta S°$ are the standard molar enthalpy and entropy of the equilibrium reaction, respectively. $\Delta S°$ for the reaction is positive and is much larger than the entropy variation associated with the mere change of spin state, i.e. $R[x\ln(2S_H + 1) + (1-x)\ln(2S_L + 1)] = R\ln(3) = 9.1$ $J\cdot K^{-1}\cdot mol^{-1}$, where S_H and S_L are the total spin value of the high-spin and low-spin states, respectively.

We now defined the critical temperature of the spin-transition in the absence of an external magnetic field $T_c(0)$, from this equation, for $x = 0.5$:

$$T_c(0) = (\Delta H° + \gamma_1 + \gamma_2)/\Delta S\Theta \quad (6)$$

(ii) The application of a static magnetic field, B, to this sample can be described by adding into Equation (1) a Zeeman energy term ΔG_Z ($= -MB/2$). The total magnetisation is the weighted sum of the magnetisation of the two paramagnetic species as:

$$M = x\chi_H B + (1-x)\chi_L B = [\chi_L + x\Delta\chi)]B = [C_L + x\Delta C]B/T \quad (7)$$

where χ_L and χ_H are the high-spin and low-spin susceptibilities and $\Delta\chi = \chi_H - \chi_L$ and $\Delta C = C_H - C_L$. In this last term, C_H and C_L represent the Curie constants of the two species ($\chi = C/T$).

The Zeeman energy term follows as:

$$\Delta G_Z = -[C_L + x\,\Delta C]B^2/2T \quad (8)$$

With this added term, the equilibrium Equation (5) becomes:

$$\partial G/\partial x = 0 = \Delta G° + \gamma_1 + 2\gamma_2 x + RT\ln[x/(1-x)] - (\Delta C/2T)B^2 \quad (9)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

For $x = 0.5$, the critical temperature of the spin-transition, T_c, is now field-dependent, according to:

$$(\partial G/\partial x)_{x=0.5} = \Delta H^\circ - T_c\Delta S^\circ + \gamma_1 + \gamma_2 - (\Delta C/2T_c)B^2 = 0 \quad (10)$$

giving two solutions (see appendix): (a) one around $T_c(0)$ $T_c = T_c(0) - a'B^2$ with

$$a' = [\Delta C/(2T_c(0)\Delta S^\circ)] \quad (11)$$

This model predicts a parabolic decrease in the critical temperature when the external magnetic field increases. This type of variation has already been observed in good agreement with the predictions for several transition metal ion compounds [$LaCo^{III}O_3$ and $[Fe^{II}(Phen)_2(NCS)_2]$ (Phen: 1,10-phenanthroline)][55−56] and particularly with very high B values from pulsed magnetic fields for $[Fe^{II}(Phen)_2(NCS)_2]$ and $[(Mn^{III}(pyrrol)_3(tren)]$ [pyrrol: pyrrole-2-carboxaldehyde; tren: 2,2′,2′′-tris(ethylamino)-amine)].[57−58] These effects are characterised by a relatively small amplitude (1.5 K from 0 to 23 T). These experiments have been recently reviewed.[59] (b) The other solution gives values at very low temperatures:

$$T_c = a'B^2 \quad (12)$$

This model predicts a parabolic increase in the critical temperature when the external magnetic field increases. However, this effect should be small since a′ is the same coefficient as in Equation (11). In our experiments, however, no such phenomena were observed. In our systems, the variation in the T_c value of the spin-transition as a function of the external magnetic field B is completely different. Instead of becoming saturated, at very low temperature, we found a relatively large and almost linear dependence and as shown in SI2 (Supporting Information; 7.5 K from 3.4 to 10.2 T). The main discrepancy is that Equation (12) is related to a transition between high-spin and low-spin states which is contrary to our observations (always a low-spin state at low temperatures for each field). This behaviour cannot be understood in terms of the framework of the model given above even through the pair interactions γ_{LL}, γ_{LH} and γ_{HH}.

In order to interpret our results we introduced another effect, namely the magnetoelastic coupling associated with low-spin and high-spin volume anomalies.

(iii) We now take into account a magnetoelastic term, according to which the local moment is coupled to the volume of each coordination sphere leading to the fact that the magnetoelastic term of a low spin is different from that of a high spin. The free energy related to this magnetoelasticity for a chemical species can be shown to be proportional to $(\delta V/V_o)$ and M^2 as:[60]

$$\Delta G_{ms} = k_{ms}(\delta V/V_o)M^2 \quad (13)$$

where $\delta V/V_o$ (noted below as ε) represents the relative variation of volume between the ordered and disordered states (also called anomaly of volume), M is the magnetisation in the external magnetic field and k_{ms} is a constant. This is a local coupling which does not imply a cooperative mechanism. In our case, we have a mixture of two species and the total free energy related to the volume anomaly is the weighted sum of the terms of the magnetisation relative to the two species (neglecting the interfacial energies).[54]

$$\Delta G_{ms} = k_{ms}[(1 - x)\varepsilon_L M_L^2 + x\varepsilon_H M_H^2] = k_{ms}[\varepsilon_L C_L^2 + x(\varepsilon_H C_H^2 - \varepsilon_L C_L^2](B/T)^2 \quad (14)$$

with M being $(C/T)B$. By adding this term, Equation (9) becomes:

$$\partial G/\partial x = \Delta G^\circ + \gamma_1 + 2\gamma_2 x + RT[\ln(x/(1 - x)] - (\Delta C/2T)B^2 + k_{ms}[\varepsilon_H C_H^2 - \varepsilon_L C_L^2](B/T)^2 = 0 \quad (15)$$

and $(\partial G/\partial x)_{x=0.5}$ has two solutions for low temperatures (see appendix):

a) field-independent:

$$T_c = 2k_{ms}[\varepsilon_H C_H^2 - \varepsilon_L C_L^2]/\Delta C \quad (16)$$

and b) second-order field-dependent:

$$T_c = \{\Delta C/[2\Delta S^\circ T_c(0)^2] - k_{ms}[\varepsilon_H C_H^2 - \varepsilon_L C_L^2]/[\Delta S^\circ T_c(0)^3]\}B^2 \quad (17)$$

The unknown values of all these parameters prevent further progress at this stage. Nevertheless, it seems that this treatment can be in agreement with the observation of the low-spin state for each field at low temperatures. A more sophisticated treatment is now in progress. The contribution of the magnetoelasticity term in our systems compared with those systems where it was not observed,[55−60] probably originates from the fact that our experiments were performed in frozen solutions as opposed to in the solid-state used in previous studies. Moreover, in our studies, complexes **1** and **2** present very flexible structures because of the nature of the ligands, allowing for the development of volume anomalies.

Conclusion

Our analysis of the HF-EPR spectroscopic data of the two studied complexes has shown that the ZFS parameters strongly depend on the symmetry of the metal ions in the complexes. Conversely, measurements of these ZFS parameters can give information on the symmetry in solution when no other methods give any data. Surprisingly, this work has revealed a spin-crossover (from spin 1/2 to spin 5/2 species) at low temperatures. Another surprise was the observation that the critical temperature of the spin transition was field-dependent but in a somewhat unconven-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tional manner (large positive change instead of small negative one). This phenomenon is likely related to the magnetoelastic properties of the mixture of the two species with their different spin states. Further magnetic studies are in progress to interpret these observations.

Experimental Section

Preparation of the Solutions: Complex **1** was prepared from a 0.1 M aqueous solution of ferric perchlorate [$Fe(ClO_4)_3 \cdot 9H_2O$] (Aldrich) and a 2 M solution of citric acid (Aldrich). The pH was adjusted to 1.95 with sodium hydroxide solution. Complex **2** was prepared from a 0.09 M aqueous solution of ferric perchlorate and a 1.8 M solution of citric acid. The pH was adjusted to 6.25 with sodium hydroxide solution. 1 mL of the respective solution was inserted into an appropriate flask for introduction into the EPR spectrometer.

EPR Instrumentation: High-frequency and high-field EPR spectra were recorded with a laboratory-built spectrometer,[61−62] using frozen solutions. Gunn diodes operating at 95 GHz and equipped with a second and third harmonic generator were used as the radiation source. The high magnetic field was produced by a superconducting magnet (0−12 T). We used a temperature regulation apparatus to maintain the temperature between 4 K and room temperature. Measurements were performed in unsaturated conditions.

Theory for the High-Spin Ferric Ion EPR Spectra

(i) Review of the Spin Hamiltonian for High-Spin Ferric Iron (S = 5/2) in Octahedral Symmetry: This review is given as an introduction to the treatment of the data in the frozen solution state. EPR spectra of paramagnetic complexes under the effect of an external magnetic field and as a function of temperature can adequately be described in the framework of the spin-Hamiltonian parametrisation. This was originally introduced by Abragam and Pryce[63] and then systematically discussed in the book of Abragam and Bleaney.[12] For the high spin iron(III) complexes, the ion ($3d^5$) is in a $^6S_{5/2}$ state. We recall, that in this system with an odd numbers of electrons, at least a twofold degeneracy must remain in the absence of a magnetic field. Thus, the ZFS gives pairs of states (Kramers doublets) related by a time-reversal operator.[12a,64] In EPR experiments, the spin-Hamiltonian therefore has two terms, the Zeeman and the ZFS terms, expressed with the Steven's spin operator equivalents of appropriate symmetry, O_n^m, as:

$$\mathbf{H} = \beta \boldsymbol{B_0 g S} + \sum_{0<n<2S}^{n} \sum_{|m|\leq n}^{m} B_n^m \mathbf{O_n^m} \qquad (18)$$

where B_n^m are parameters to be determined, S is the total electron spin, and n and m are integers with the following constraints: $0 < n < 2S$ (terms with odd n disappear due to time-reversal symmetry)[12a] and the only nonzero terms have $m = lp$ (where l is integral or zero) when the highest rotational symmetry axis is p-fold.[12,65−66] The spin operators O_n^m and the corresponding matrix elements $<M_S|O_n^m|M_{S'}>$ (with M_S, $M_{S'}$ spanning the six values −5/2, −3/2, −1/2, 1/2, 3/2 and 5/2) have been tabulated.[12b] It should be noted that nonzero elements only occur when $|M_S - M_{S'}| = m$ for each $B_n^m O_n^m$ term. The general spin-Hamiltonian for high spin iron(III) can therefore be written as:

$$\mathbf{H} = \beta \boldsymbol{B_0 g S} + B_2^0 \boldsymbol{O_2}^0 + B_2^2 \boldsymbol{O_2}^2 + B_4^0 \boldsymbol{O_4}^0 + B_4^2 \boldsymbol{O_4}^2 + B_4^3 \boldsymbol{O_4}^3 + B_4^4 \boldsymbol{O_4}^4 \qquad (19)$$

The occurrence of the different terms of the ZFS depends on the symmetry around the Fe^{III} centre in the complex. For complexes with pure cubic symmetry, only terms related to $\boldsymbol{O_4}^0$ and $\boldsymbol{O_4}^4$ [12c] occur, as in $Fe^{III}(H_2O)_6$.[67] It will be seen, as in our Fe^{III} citrate system, that the fourth-order terms B_4^m in the spin-Hamiltonian can be neglected and that only the effects of B_2^0 and B_2^2 need to be considered (with the notations $D = B_2^0/3$ and $E = B_2^2$).[68] Under these conditions, the spin-Hamiltonian can be rewritten as:

$$H = \beta B_0 g S + D[\boldsymbol{S_z}^2 - 1/3S(S+1)] + E[\boldsymbol{S_x}^2 - \boldsymbol{S_y}^2] \qquad (20)$$

where D is the axial ZFS and E gauges the rhombic ZFS. For a complex with pure axial symmetry, $E = 0$. When the anisotropy of the Landé tensor g occurs in the same axis as the ZFS, a complete expression of the spin-Hamiltonian for this 6S5/2 state is:

$$H = (G_x/2)[\boldsymbol{S_+} + \boldsymbol{S_-}] - (iG_y/2)[\boldsymbol{S_+} - \boldsymbol{S_-}] + G_z \boldsymbol{S_z} + D[\boldsymbol{S_z}^2 - 1/3S(S+1)] + E/2[\boldsymbol{S_+}^2 + \boldsymbol{S_-}^2] \qquad (21)$$

where $Gq = \beta g_q B_{oq}$, with $q = x$, y or z. The corresponding energy matrix containing 6 × 6 elements $<M_S|H|M_{S'}>$ is shown in Table 1, with $\boldsymbol{z} = G_z + iG_y$ and $\boldsymbol{z^*} = G_z - iG_y$. The locations of $\boldsymbol{S_z}$, $\boldsymbol{S_+}$ (or $\boldsymbol{S_-}$) and $\boldsymbol{S_+^2}$ (or $\boldsymbol{S_-^2}$) are, respectively, the origin of the elements on the diagonal line, on one line above (or under) the diagonal and on two lines above (or under) the diagonal.

(ii) Principle of the Treatment of the Data: The corresponding eigenvalues ε_j and the eigenstates $|\varphi_j>$, with j from 1 to $2S + 1 = 6$, can be obtained by diagonalising the matrix. For the pure axial case, with $E = 0$, two diagonalisations have to be made, one for the orientation according to z, with $z = 0$ (written for this case as a diagonal matrix) and the other, for the orientation according to x or y, with $G_z = 0$ and $z = G_x$. For the rhombic case, where E is different from 0, three diagonalisations have to be made, the first for the orientation according to z, with $z = 0$, the second is made for the orientation according to x, with $G_z = 0$ and $z = G_x$ and the third, for the orientation according to y, with $G_z = 0$ and $z = iG_y$ (diagonalisation of a 6 × 6 matrix with imaginary number elements). In each case, five transitions related to the change of Zeeman level states from −5/2 to −3/2, −3/2 to −1/2, −1/2 to 1/2, 1/2 to 3/2 and 3/2 to 5/2 can be expected. These levels are clearly defined when the Zeeman term is large compared with the ZFS term. For the randomly orientated molecules of the frozen aqueous solutions, the intensity of absorption varies from those parallel to the magnetic field to those perpendicular to the magnetic field (which are more numerous by far). For the axial systems, the perpendicular transitions are only of one type whereas for the rhombic systems, the x and y orientations have to be distinguished. In the axial systems, a qualitative interpretation of the spectra can be made when $g\beta B_o >> D$ (high-field limit). The five ($2S$) permitted M to $M + 1$ transitions between the 6 ($2S + 1$) energy levels can be observed for the following resonance field: $B_r(M) = g_e/g[B_o + (M + 1/2)D']$, where $D' = (3\cos^2\theta - 1)D/(g_e\beta)$ and θ is the angle of the external magnetic field with respect to the main axis of symmetry of the complex.[69] Therefore, when the external magnetic field is parallel to the axis, the neighbouring lines are separated by $2|D|$ and centred at $B_{r//} = g_e B_o/g_{//}$ while they are separated by $|D|$ and centred at $B_{r\perp} = g_e B_o/g_\perp$ when it is perpendicular to the axis.

(iii) Treatment of the Spectroscopic Data for the High-Spin Ferric Ion: In Figure 2, we compare the field location of the transitions

in the experimental spectra with those of the transitions obtained in the energy level diagrams for compound **1**. In the left-hand section (Figure 2, a−d), the experimental spectra are displayed along with the simulations calculated using the program available from Weihe et al.[70] The same simulations can be obtained when the X-Sophe software from Bruker is used.[71] Marks have been added to point out the pure z transitions centred at $B_{0//} = \nu_0/\beta g_{//}$ and the pure x, y transitions centred at $B_{0\perp} = \nu_0/\beta g_{\perp}$. In the right-hand section (e−f in Figure 2), we show the energy level diagrams as a function of the product $g\beta B_0$ in cm^{-1} and the allowed $\Delta M_s = \pm 1$ transitions for the zero-field splitting parameter, D, obtained above. The same type of information is given for compound **2** in Figure SI1 (Supporting Information). These diagrams show the energy value (in cm^{-1}) as a function of $G_q = g_q\beta B_o$ with q for x, y or z (G in cm^{-1}). These energy values are eigenvalues of the energy matrix reported in Table 1. The diagonalisations of the real or imaginary, hermitian and symmetric 6×6 matrices were carried out using the Jacobi method, as described in "Numerical Recipes in Fortran"[72] and using the C programming language with a Linux System. We tried several values for the D and E parameters. The segments related to the five transitions according to the parallel or perpendicular axis for axial systems (e−f in Figure 1) or those related to the five transitions according to the x, y or z axis for rhombic systems (Figure SI 1, Supporting Information) were calculated using Mathmab for each frequency (9.507, 6.338 and 3.169 cm^{-1} related to the 285, 190 and 95 GHz measurement frequencies, respectively). The field positions of these calculated transitions are reported in Figure 2 (a−d) under each experimental spectrum taking into account the $g_{//}$ and $g_{\perp}$ values for the axial systems and in Figure SI1 (Supporting Information) with the g_x, g_y and g_z values for the rhombic systems. These g_q values were evaluated from the field positions of the centres of the set of the five transitions related to each orientation relative to the field. With a negative value of D, in the axial system, Figure 2 (e−f) show that the parallel transition from the lowest level ($M_s = -5/2$) can be observed at low field compared with the centre of the set of the five parallel transitions whereas the perpendicular one is at high field. The agreement seems to be satisfactory both for the field positions and for the evolution of the intensities of the transitions as a function of the temperature.

Appendix

(i) Equation (10) can be resolved as a second order equation with $u = T_c/T_c(0)$:

$(\partial G/\partial x)_{x=0.5} = u^2 - u + a = 0$

with $a = (\Delta C/2\Delta S^\circ)[B/T_c(0)]^2$. The general solution is $u = [1 \pm (1 - 4a)^{1/2}]/2$. The solution for T_c around $T_c(0)$ is, with sign "+" for $\pm$, $u = 1 - a$, i.e.:

$T_c = T_c(0) - a'B^2$
with $a' = (\Delta C/[2T_c(0)\Delta S^\circ)]$.

The second solution, for very low temperatures (sign "−" for $\pm$), is $u = a$, i.e. with the same coefficient a':

$T_c = a'B^2$

(ii) Equation (15) can be resolved as a third-order equation with $u = T_c/T_c(0)$:

$(\partial G/\partial x)_{x=0.5} = u^3 - u^2 + bu - c = 0$

with $b = b'B^2$, $b' = \Delta C/[2\Delta S^\circ T_c(0)^2]$ and $c = c'B^2$, $c' = k_{ms}[\varepsilon_H C_H{}^2 - \varepsilon_L C_L{}^2]/(\Delta S^\circ T_c(0)^3]$.
At low temperatures, around 0 K, i.e. and with $u = \varepsilon$, we obtain the solution for the first-order treatment:

$u = c'/b' = 2k_{ms}[\varepsilon_H C_H{}^2 - \varepsilon_L C_L{}^2]/[\Delta C T_c(0)]$

and for the second-order treatment, the only likely solution is:

$u = (c' - b')\ B^2$

Supporting Information (see also footnote on the first page of this article): Figure SI1 shows simulated and experimental 285 GHz HF-EPR spectra of compound **2** recorded at 60 K with the assignments of the different transitions presented as well as energy level diagrams. Figure SI2 shows the experimental 285 GHz-EPR spectra of compound **2** recorded between 5 and 30 K. Figure SI3 shows the plot of the observed T_c of the 1/2 to 5/2 spin transition of compound **1** as a function of the field.

Acknowledgments

The authors thank Professor Jean-Louis Pierre for his interest in this study and as the initiator of this research in iron in biology. We thank Dr. Yves Frapart (Chimie et Biochimie Pharmacologiques et Toxicologiques, University of Paris V), Dr. Geneviève Blondin (Institut de Chimie Moléculaire d'Orsay, University of Paris XI) and Dr. P. Höfer (Bruker Industry, Wissembourg) for providing X-Sophe simulations. C. B. thanks Prof. Jean-Paul Bertrandias (Institut de Mathématiqes Appliquées, UJF) and Dr. André Eberhard (Laboratoire Modélisation et Calcul, UJF) for their help with the mathematics and the use of Mathlab software, respectively. C. B. thanks Prof. I. Gautier-Luneau (Laboratoire de Cristallographie, UJF) for discussions on the X-ray data for compounds related to those studied here and for fruitful discussions about the influence of the state of protonation on the geometries of complexes of Fe^{III} and Ga^{III} with organic ligands. C. B. thanks also Prof. Andreas Hauser (Département de Chimie Physique, University of Geneva), Prof. M. Cyrot (Laboratoire Louis Néel, UJF) and Dr. M. Guillot (HMFL) for general fruitful discussions. We thank also the "Centre National de la Recherche Scientifique" for support through the GdR 1879 "Deregulation of Iron Metabolism: Chemistry, Biology and Therapeutics".

Anion and Solvent Effects upon the Structures of Platinum(II) Complexes with Thiacrown Ligands: The Crystal Structures of $[Pt(9S3)_2](PF_6)_2 \cdot 2\ CH_3NO_2$, $[Pt(9S3)_2](BF_4)_2 \cdot 2\ CH_3NO_2$, $[Pt(9S3)_2](OTf)_2 \cdot 2\ CH_3NO_2$, and $[Pt(18S6)](BF_4)_2$

Keywords: S ligands / Platinum

The synthesis and crystal structures of four mononuclear Pt^{II} homoleptic complexes with two thiacrown ligands are presented. The binding mode for both macrocycles to the platinum center contrasts with previous structural reports involving identical complex cations but differing anions or crystallization solvents. All three bis(1,4,7-trithiacyclononane(9S3))platinum(II) complexes (with tetrafluoroborate, hexafluorophosphate, and triflate as counterions) are centrosymmetric, with *endodentate* binding of the trithioether resulting in $[S_4 + S_2]$ coordination. The Pt^{II} complex of 1,4,7,10,13,16-hexathiacyclooctadecane(18S6) shows an elongated square pyramidal structure with one *exodentate* sulfur in a $[S_4 + S_1]$ mode. Our work illustrates how changes of counterion and solvent dramatically affect the crystal structures for such complexes, suggesting that packing forces are more important than ligand conformation in determining solid-state structures. In addition, the full spectroscopic and electrochemical properties of the complex $[Pt(18S6)](BF_4)_2$ are reported. The electronic spectrum shows a d–d transition near 430 nm, and an irreversible Pt^{II}/Pt^{III} couple occurs at +564 mV vs. Fc/Fc^+ in cyclic voltammetry. Both these data are consistent with other hexakis(thioether) Pt^{II} complexes. ^{13}C NMR measurements show a non-fluxional 18S6 ligand in the complex while the platinum-195 NMR resonance at –4152 ppm indicates a mixed orientation of lone pair electrons on the sulfur donors.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The complexation of both transition metal and main group metal ions by thiacrown ligands, such as 1,4,7-trithiacyclononane (9S3) and 1,4,7,10,13,16-hexathiacyclooctadecane (18S6), has been well researched over the past decade.[1–5] Complexes involving Pt^{II} and Pd^{II} with these macrocycles have been a particularly active area.[6–12] Such complexes are quite stable due to coordination of the soft metal center by the soft thioether ligand. The unique spectroscopic and electrochemical properties of crown thioether complexes containing the two divalent metal ions are a further impetus for research. Unusual d–d electronic transitions in the visible region result in atypical colors for both Pt^{II} (orange) and Pd^{II} (blue-green) complexes. Furthermore, the complexes exhibit a fully reversible M^{II}/M^{III} couple, observed in non-aqueous cyclic voltammetry; they also display fluxional trithioether ligands whose barriers of conversion are exceedingly small (near the limit of NMR detection of dynamic processes).[13] These physicochemical properties arise from the long M–S axial interactions between the metal ion and the sulfur donors of the thiacrown; long M–S interactions in solution have been correlated with the conformational preferences of individual crown thioether ligands.[14] Figure 1 shows the three distinct binding modes of thiacrowns to Pd^{II} and Pt^{II}, involving zero, one, and two long metal–sulfur interactions. These long interactions fall in the range 2.7–3.2 Å, which is longer than typical divalent palladium and platinum thioether sulfur bond lengths (2.3–2.4 Å), but less than the corresponding metal–sulfur Van der Waals distances.[15] Also, the electronic nature of these interactions is of considerable theoretical interest as they serve as intermediate cases between bonding and non-bonding situations.[16]

The initial report of the crystal structure of the complex $[Pt(9S3)_2](PF_6)_2$ revealed, surprisingly,[6] an elongated

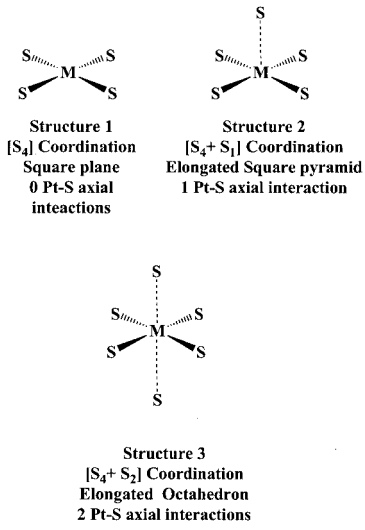

Figure 1. Three coordination modes of d^8 metal ions displayed by thiacrowns

square pyramidal structure ([S_4 + S_1], Figure 1, Structure 2) rather than the more common, and anticipated, elongated octahedral structure ([S_4 + S_2], Figure 1, Structure 3). In the reported structure, the two 9S3 ligands were not centrosymmetrically bound to the Pt^{II}. One 9S3 was positioned *endodentate* to the metal ion while the second ligand was in an uncommon *exodentate* conformation. The *exodentate* conformation of 9S3 contrasts with that of the identical bis Pd^{II} analog.[8] Indeed, to the best of our knowledge, only one other *exodentate* binding case of 9S3 in a Pt^{II} structure has been reported.[17] Therefore, we undertook the current crystallographic study of the $[Pt(9S3)_2]^{2+}$ cation with various anions to see if this atypical 9S3 complex structure might be duplicated. The length of the axial sulfur−metal interaction serves as a sensitive probe for the examination of anion and solvent effects.[18a−18e] For example, dramatic solvent effects on Pd^{II} complexes containing thiacrown ligands have been reported for the analogous thiacrown 10S3 (1,4,7-trithiacyclodecane).[19,20] Interestingly, the linkage isomer obtained for the $[Pd(10S3)_2]^{2+}$ complex, reported by McAuley, has a six-membered chelate ring between the equatorial sulfurs, while our structure contains a five-membered chelate ring between the sulfurs. The switch in linkage isomer appears to be due to packing forces associated with a particular solvent (nitromethane vs. acetonitrile); this solvent−complex interaction has been confirmed via low temperature ^{13}C NMR studies. Similarly, macrocyclic hexathioether 18S6 complexes with Pd^{II} to form two different salts with different solid-state structures. The tetraphenylborate salt of $[Pd(18S6]^{2+}$ is yellow-brown while the hexafluorophosphate salt is green.[1,9] In addition, the Pd−S bond lengths and conformations of ethylene linkages also differ, illustrating how counterion effects can alter structures. As the spectroscopic and electrochemical properties of $[Pt(18S6]^{2+}$ have not been reported, those data are included here, along with our X-ray structure of the tetrafluoroborate salt.[9] Control of complex cation structure by solvent and counterion could have important implications in crystal engineering applications. Both Pd^{II} and Pt^{II} complexes of thiacrowns have been used by the Schröder and Lippolis groups as templates for control and the self-assembly of three-dimensional structures.[21,22]

Results and Discussion

Structures of $[Pt(9S3)_2]^{2+}$ Complexes

The tetrafluoroborates and hexafluorophosphates both crystallize in the monoclinic space group, $P2_1/c$ (No. 14), while the triflate salt crystallizes in the orthorhombic space group, *Pbca* (No. 61). The asymmetric unit in all three lattices consists of the platinum(II) center, situated on an inversion center, one 9S3 ligand, one anion, and one nitromethane solvent molecule, each occupying general positions within the cell. For the hexafluorophosphate salt, both 9S3 ligands are centrosymmetrically bound to the Pt^{II} ion in the three structures (Figure 2), and the ligand shows an *endodentate* conformation with a [S_4 + S_2] coordination mode. There are four equatorial Pt−S bonds and two long distance Pt−S axial interactions forming an elongated octahedral structure. Notably, all three structures contrast with the prior structure of $[Pt(9S3)_2](PF_6)_2$, which shows one *exodentate* sulfur, non-centrosymmetrical binding of the two ligands, and no solvent molecules.[6] Our structural results, therefore, do not support the hypothesis that [S_4 + S_1] binding of 9S3 to Pt^{II} is its common and preferred coordination mode due to the conformation of the ligand.[11] Rather, packing effects, which depend upon the specific counterion and crystallization solvent, control whether [S_4 + S_2] or [S_4 + S_1] coordination is observed in structures of 9S3 and related macrocycles with d^8 metal ions such as Pt^{II} and Pd^{II}.

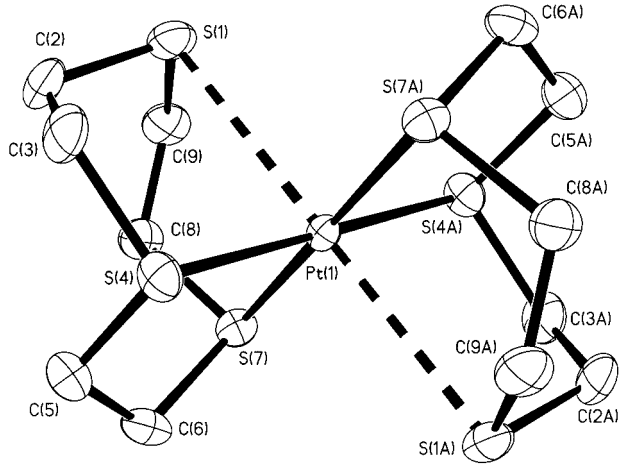

Figure 2. Thermal ellipsoid perspective (50% probability) of cation in $[Pt(9S3)_2]](PF_6)_2 \cdot 2\ CH_3NO_2$

Equatorial Pt−S bond lengths increase only very slightly, in the order $BF_4^- < PF_6^- < OTf^-$. Greater variation is seen, not unexpectedly, in the Pt−S axial distances, with the triflate showing a larger distance (over 0.1 Å) than the other two structures. However, the Pt−S distance is markedly

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

greater, over 0.3 Å, than for the earlier $[Pt(9S3)_2](PF_6)_2$ structure − a dramatic effect arising from packing forces.[6] S−Pt−S chelate bite angles in the three structures are slightly less than 90°, with a commensurate expansion of the non-chelate angle to slightly above 90°. This effect is also seen in the $S_{equatorial}-Pt-S_{axial}$ angles (Table 1), which are less than 90°, showing the axial sulfur bending towards the metal center.

Structure of $[Pt(18S6)]^{2+}$

The structure crystallizes in a triclinic cell with space group, $P\bar{1}$ (No. 2); Figure 3 shows a thermal ellipsoid perspective. The asymmetric unit consists of one $[Pt(18S6)]^{2+}$ cation and two BF_4^- anions, all occupying general positions within the cell. Note that, unlike the three 9S3 structures, there are no solvent molecules incorporated into the lattice. The 18S6 forms an elongated square pyramidal structure (Figure 1, Structure 2) with $[S_4 + S_1]$ coordination. One long Pt−S axial interaction is observed [2.809(3) Å], but the sixth sulfur donor is oriented *exodentate* to the Pt^{II} and at too great a distance [4.099(3) Å] to interact. Notably, our structure contrasts with the earlier $[Pt(18S6)]^{2+}$ structure with tetraphenylborate, which shows a symmetrical $[S_4 + S_2]$ binding of the 18S6.[9] As seen in the 9S3 structures, the coordination mode of the 18S6 can be switched between $[S_4 + S_2]$ and $[S_4 + S_1]$ depending upon crystal packing forces that arise from the counterion or crystallization solvent. Although the preferred conformation of the ligand is generally important in determining how it will bind to a metal ion, there appears to be some limited flexibility in coordination modes towards d^8 metal ions like Pt^{II} and Pd^{II}. For exclusively ethylene bridged thioether macrocycles like 9S3 and 18S6, the coordination mode can switch between $[S_4 + S_2]$ and $[S_4 + S_1]$, depending upon the solvent or anion. In that regard, our recent report of homoleptic Pt^{II} and Pd^{II} complexes of 12S3 (1,5,9-trithiacyclodecane, exclusive propylene bridges) shows examples of both $[S_4]$ and $[S_4 + S_1]$, but never $[S_4 + S_2]$ coordination.[10] The all-sulfur *exodentate* conformation of the12S3 ligand precludes its forming two Pt−S axial interactions, but it, too, has limited flexibility in its ability to coordinate these ions.

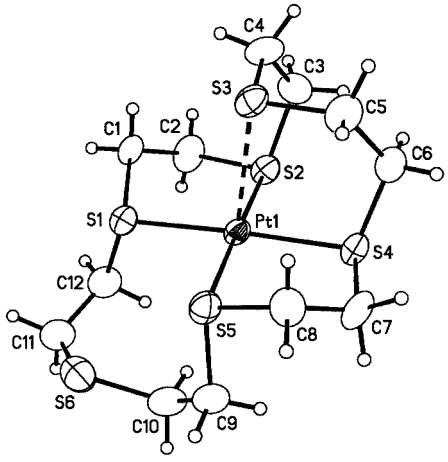

Figure 3. Thermal ellipsoid perspective (50% probability) of cation in $[Pt(18S6)](BF_4)_2$

The five-sulfur square pyramidal portion of the 18S6 ligand is in the eclipsed conformation, but strain within the macrocycle causes the remaining portion (involving the one *exodentate* sulfur atom) to adopt a staggered conformation. Previous 18S6 structures with Pd^{II} and Pt^{II} reported exclusively staggered or eclipsed conformers, so our structure represents an interesting intermediate case.[1,9] S−Pt−S chelate bite angles in the 18S6 structure are even smaller than the for the three 9S3 structures at slightly less than 89°. The four sulfur atoms in the equatorial plane (S1, S2, S4, and S5) are co-planar to within 0.126 Å. The Pt^{II} ion is displaced by 0.067(2) Å above the mean square plane and is directed towards the axial sulfur donor, S3. Equatorial distances are longer by 0.02 Å than in the earlier tetrafluoroborate structure, but the axial distance is surprisingly short. Indeed this is the shortest Pt−S axial distance observed in a homoleptic thioether complex of platinum(II). A full listing of Pt−S equatorial and axial distances for Pt^{II} thiacrown complexes that exhibit these two types of structures appears in Table 2. The two shortest Pt−S axial distances are observed, notably, for the two $[S_4 + S_1]$ structures, and both $[S_4 + S_1]$ structures show the platinum displaced towards the axial sulfur above the least-squares plane of the four sulfur donors. In general, the average Pt−S equatorial bond lengths show little variation, but there is a large difference in Pt−S axial distances.

Although there are no interionic contacts shorter than van der Waal's radii sums, there are interesting S···F contacts involving all six sulfur atoms, with distances ranging from 3.31(1) to 3.52(1) Å (average of 3.43(9) Å] − just outside the van der Waal's sum for sulfur and fluorine (S 1.80 Å; F 1.47 Å).[23] These contacts are roughly co-linear with the Pt−S bonds (range of Pt−S···F angles: 144(1)−175(1)°; average 166(11)°] and approximately along the line expected

$[Pt(10S3)_2]^{2+}$	PF_6^-	S_4 + S_2	2.30 Å	3.21 Å	[11]
$[Pt(10S3)_2]^{2+}$	PF_6^-	S_4 + S_2	2.30 Å	3.23 Å	[14]
$[Pt(18S6)]^{2+}$	BPh_4^-	S_4 + S_2	2.30 Å	3.38 Å	[9]

for a lone-pair on fluorine (range of B−F···S angles: 127(1)−149(1)°; average 136(9)°], suggesting a weak donor−acceptor character of these interactions. Indeed, we observe very similar behavior in the tetrafluoroborate salt of $[Pt(9S3)_2]^{2+}$, which also has S···F contacts in the range 3.49(3)−3.61(3) Å, which are approximately co-linear with the Pt−S bonds (Pt−S···F angles: 165°−169°). In our hexafluorophosphate structure, we observe very short S···F contacts between the fluorides of the anion and the axial sulfur. At 3.191(8) Å, these are shorter than the van der Waal's sum. There is also a short contact between the axial sulfur and one oxygen of the nitromethane solvent at 3.34 Å. The two hexafluorophosphate structures of $[Pt(9S3)_2]^{2+}$ show noticeable differences in the nature of the S···F contacts. The previous structure shows one short S···F contact (3.43 Å) between the *exodentate* sulfur and a fluorine atom in one hexafluorophosphate anion.[6] A second fluorine in the same anion, *cis* to this first fluorine, links to an equatorial sulfur in a different cation at 3.23 Å. For the triflate structure, the anions and solvent lie along the open side of the complex cation, away from the axial sulfur position. We feel that the solid-state structures obtained for this series of compounds can be influenced by weak donor−acceptor interactions between the sulfur atoms of the thioether macrocycle and anions or solvent.

Spectroscopic and Electrochemical Measurements

A d−d electronic transition at 426 nm results in the orange color of the $[Pt(18S6)]^{2+}$ complex. The relatively small extinction coefficient confirms that this absorption band is a d−d transition. The analogous Pt^{II} complexes, $[Pt(9S3)_2]^{2+}$ and $[Pt(10S3)_2]^{2+}$, also show similar transitions near 430 nm.[8,11,14] Note that these three ligands are the ones whose complexes have the shortest platinum−sulfur axial interactions. When these strong axial interactions are not present, the color of the complex is dominated by the position of charge-transfer bands, and may range from yellow to colorless.[10,14]

Carbon NMR spectroscopy was undertaken on the 18S6 complex to see if there was evidence for fluxionality in solution, as observed for trithioether complexes of Pt^{II}. The $^{13}C\{^1H\}$ NMR spectra in two different solvents both show a simple three-line carbon spectrum consistent with a centrosymmetric binding of 18S6. There is little change in the appearance of the spectrum with temperature, even up to 150 °C, and so we do not see evidence for fluxionality of the coordinated 18S6 ligand. The simple NMR spectrum is not consistent with the [S_4 + S_1] binding mode in the crystal structure, but rather the symmetrical [S_4 + S_2] structure shown by the tetraphenylborate salt.[9] Our NMR spectroscopic data suggest that the ligand, in solution, forms an S-shaped elongated octahedral structure, and that packing effects during crystallization result in the [S_4 + S_1] structure seen in our X-ray data. Another important result from the NMR study is the lack of fluxionality for the 18S6 ligand. Virtually every known 9S3 and 10S3 Pt^{II} complex shows fluxionality of the trithioether ligand. However, the 18S6 does not. The lack of fluxionality of the 18S6 may be due to the increased number of platinum−sulfur interactions (six vs. three) with the larger hexathioether macrocycle, supporting the 1,4-metallotropic shift exchange mechanism.[13]

Under the conditions of our cyclic voltammetry study, the complex $[Pt(18S6)]^{2+}$ exhibits an irreversible oxidation wave at +0.564 V and a second irreversible oxidation wave at +1.358 V. (both vs. Fc/Fc^+). Both are metal-centered oxidations and are assigned as a Pt^{II}/Pt^{III} couple and a Pt^{III}/Pt^{IV} couple, respectively. The electrochemical behavior resembles $[Pt(9S3)_2]^{2+}$ and $[Pt(10S3)_2]^{2+}$, but with two distinctions. First, the oxidation wave in the 18S6 complex appears at a higher positive potential, indicating greater difficulty in oxidizing the Pt^{II} center. Second, the +2/+3 couple for the trithioether complexes is fully reversible − not irreversible as observed for the 18S6 complex. We propose that the less flexible 18S6 cannot re-orient to facilitate oxidation of the Pt^{II}, thereby accounting for the greater difficulty of its oxidation and lack of reversibility in the electron transfer.

Lastly, the ^{195}Pt NMR spectrum of $[Pt(18S6)]^{2+}$ shows a single resonance at $\delta = -4152$ ppm, confirming the presence of a single complex in solution. The chemical shift is consistent with the hypothesis, regarding lone pair orientation on sulfur donors in macrocyclic thioether complexes,[10,12] that complexes with a mixed (half up, half down) orientation of lone pairs show values in the −4000 to −4300 ppm range, while those with all lone pairs on the sulfur donors oriented in the same direction have Pt resonances shifted upfield by ca. 500 ppm. Thus, the ^{195}Pt NMR chemical shift value agrees with the mixed lone pair orientation on the sulfur donors in the coordinated 18S6 ligand, as confirmed in our carbon-13 NMR work. We believe

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

there is sufficient ^{195}Pt NMR spectroscopic data to establish a definite correlation between chemical shift and sulfur lone pair orientation in this series of complexes.

Conclusion

The crystal structures of four mononuclear Pt^{II} homoleptic complexes with two thiacrown ligands contrast with previous structural reports involving identical complex cations but differing anions or crystallization solvents. In the solid state, both [S_4 + S_1] and [S_4 + S_2] coordination of Pt^{II} by 9S3 and 18S6 are observed, depending upon packing forces. Our work illustrates how changes of counterion and solvent can have dramatic effects on the crystal structures for their complexes, suggesting that packing forces play a more dominant role than ligand conformation in determining specific solid-state structures. The spectroscopic and electrochemical properties of the complex $[Pt(18S6)](BF_4)_2$ are consistent with the presence of two Pt−S axial interactions in solution. The 18S6 ligand is non-fluxional in solution, in contrast to the trithiacrowns, and the ^{195}Pt NMR chemical shift indicates an alternating orientation of lone pair electrons on the sulfur donors.

Experimental Section

Materials: Thioether ligands 9S3 and 18S6, inorganic salts and K_2PtCl_4, and all solvents were purchased from the Aldrich Chemical Company, and used as received. The starting complex $[PtCl_2(C_2H_5CN)_2]$ was prepared according to the literature method.[24]

Measurements: Elemental analyses were performed by Atlantic Microlab, Inc. of Atlanta, Georgia. Fourier transform infrared spectra were obtained using a Galaxy FT IR 5000 spectrophotometer and ultraviolet-visible spectra were obtained on a Varian DMS 200 UV/Visible spectrophotometer. $^{13}C\{^1H\}$ and ^1H NMR spectra were recorded on a Varian Gemini 300 NMR spectrometer using CD_3NO_2 for both the deuterium lock and reference. $^{195}Pt\{^1H\}$ NMR spectra were recorded near 64.208 MHz using aqueous solutions of $[PtCl_6]^{2-}$ (δ = 0 ppm) as an external reference and a delay time of 0.01 s. Referencing was verified versus authentic samples of $[PtCl_4]^{2-}$, which had a chemical shift at δ = −1626 ppm, in agreement with its reported value of −1624 ppm.[25] A Biological Analytical Systems 50 Analyzer was used for all electrochemical measurements. The supporting electrolyte was 0.1 M $(Bu)_4NBF_4$ in CH_3CN, and sample concentrations were 1 mM. Voltammograms were recorded at a scan rate of 100 mV s^{-1}. The standard three-electrode configuration was as follows: platinum working electrode, Pt-wire auxiliary electrode, and Ag/AgCl reference electrode. All potentials were referenced against a Fc/Fc^+ couple.

Synthesis of $[Pt(9S3)_2]^{2+}$ Complex Salts

$[Pt(9S3_2](BF_4)_2$: A mixture of $K_2[PtCl_4]$ (100.8 mg, 0.243 mmol) and 1,4,7-trithiacyclononane (88.5 mg, 0.491 mmol) was boiled under reflux in a 2:1 methanol/distilled water solution (26 mL). The resultant brownish-orange reaction mixture was allowed to cool and was then partitioned into two equal volumes for the subsequent addition of counterion. $NaBF_4$ (56.3 mg, 0.513 mmol) was added to one aliquot and then cooled to 0 °C. Orange crystals thus formed were filtered off, washed with cold methanol (3 × 15 mL) and diethyl ether (3 × 15 mL) to yield bis(1,4,7-trithiacyclononane)-platinum(II) tetrafluoroborate (76.2 mg, 86.3%). FT-IR (KBr): $\tilde{\nu}$ = 2980, 2935, 2832, 1427, 1401, 1320, 1285, 1225, 1165, 1061(s, BF_4^-), 834, 646, 526 cm^{-1}. $C_{12}H_{24}B_2F_8PtS_6$ (729.38): calcd. C 19.76, H 3.32, S 26.37; found C 19.99, H 3.25, S 26.25. Slow diffusion of diethyl ether into a nitromethane solution yielded X-ray quality crystals as a nitromethane solvate.

$[Pt(9S3)_2](BPh_4)_2$: $NaBPh_4$ (167.2 mg, 0.4886 mmol) was added to the remaining aliquot of $[Pt(9S3)_2]^{2+}$ and the resultant mixture chilled to 0 °C. The so-obtained dark orange crystals were then filtered off, washed with cold methanol (3 × 15 mL) and diethyl ether (3 × 15 mL) to yield bis(1,4,7-trithiacyclononane)platinum(II) tetraphenylborate (130 mg, 89.7%) as a dark orange solid. FT-IR (KBr): 3050, 2985, 1577, 1476, 1155, 746, and 608 cm^{-1}. Poor solubility of the complex in common solvents limited additional study. $C_{60}H_{64}B_2PtS_6$ (1194.25): calcd. C 60.34, H 5.40, S 16.11; found C 60.04, H 5.55, S 15.99.

$[Pt(9S3_2](PF_6)_2$: This compound has been previously reported, and a crystal grown from acetonitrile.[6] We were interested in repeating the crystallization using nitromethane. A mixture of $K_2[PtCl_4]$ (206 mg, 0.497 mmol) and 9S3 (195 mg, 1.00 mmol) were boiled under reflux in 2:1 methanol−water (v/v, 49 mL) solution for 19 h. The resulting yellow solution was filtered off and concentrated to 2/3 of its original volume. Upon addition of NH_4PF_6 (176 mg, 0.491 mmol), yellow crystals of the complex formed. After cooling to 0 °C, the crystals were filtered off, washed with cold methanol (3 × 15 mL), anhydrous diethyl ether (3 × 15 mL), and air-dried. The reaction produced bis(1,4,7-trithiacyclodecane)platinum(II) hexafluorophosphate (334 mg, 79.3%) as an orange crystalline solid. FT-IR (KBr): 2995, 2944, 2925, 2848, 1444, 1410, 1290, 1272, 932, 837 (s, PF_6^-), 558 cm^{-1}. The electronic absorption spectrum measured in acetonitrile showed three λ_{max}s, at 430 (ε = 120), 287 (ε = 11,000) and 250 nm (ε = 15,000), matching its literature spectrum.[6] Slow diffusion of diethyl ether into a nitromethane solution yielded X-ray quality crystals as a nitromethane solvate.

$[Pt(9S3_2](OTf)_2$: Silver triflate, AgOTf, $AgSO_3CF_3$ (277 mg, 1.08 mmol) was added to a solution of $[PtCl_2(C_2H_5CN)_2]$ (193 mg, 0.513 mmol) dissolved in dichloromethane (3.5 mL) and propanenitrile (0.10 mL). This suspension was stirred vigorously for 5 h and the resultant white AgCl precipitate removed by filtration to yield a light yellow solution. The AgCl precipitate was then washed twice with additional CH_2Cl_2 (2 mL). 9S3 (200 mg, 1.11 mmol) was quickly added and stirred overnight. If too much time lapses before the addition of the 9S3 ligand, the Pt solution turns blue, evidently due to the formation of an aqua complex.[24] Diethyl ether was then added drop-wise to precipitate orange crystals of $[Pt(9S3_2](OTf)_2$ (129 mg, 29.6% yield). $C_{14}H_{24}F_6O_6PtS_8$ (853.90): calcd. C 19.69, H 2.83; found C 19.61, H 2.86. The visible electronic absorption spectrum measured in acetonitrile showed one λ_{max} at 420 nm (ε = 110). Slow diffusion of diethyl ether into a nitromethane solution yielded X-ray quality orange prismatic crystals as a nitromethane solvate. The crystals readily desolvate in air, but are quite stable when protected.

Synthesis of $[Pt(18S6]^{2+}$ Salts

A mixture of $K_2[PtCl_4]$ (315 mg, 0.759 mmol) and 18S6 (278 mg, 0.771 mmol) was boiled under reflux in a methanol−water (2:1 v/v, 84 mL) solution for 17.5 h. The resulting yellow solution was filtered and then concentrated to 40 mL. Four 10 mL portions of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the solution were then divided and used for subsequent anion metathesis reactions.

[Pt(18S6](BF$_4$)$_2$: An aliquot of the [Pt(18S6]$^{2+}$ solution (10 mL) was mixed with $NaBF_4$ (42.2 mg, 0.384 mmol), and the resultant solution filtered. Slow evaporation of the filtrate yielded crystals (36.0 mg, 26.0% yield) of 1,4,7,10,13,16-hexathiacyclooctadecaneplatinum(II) tetrafluoroborate suitable for X-ray diffraction studies. IR (KBr): 2990, 2945, 2844, 1427, 1320, 1285, 1234, 1177, 1075−1033 (s, BF_4^-), 925, 808, 656, 574, 564 cm^{-1}. $C_{12}H_{24}B_2F_8PtS_6$ (729.38): calcd. C 19.76, H 3.32, S 26.37; found C 20.04, H 3.27, S 26.18.3

[Pt(18S6](PF$_6$)$_2$: An aliquot of the [Pt(18S6]$^{2+}$ solution (10 mL) was mixed with NH_4PF_6 (59.5 mg, 0.365 mmol), and the solution was chilled in an ice bath for 1.5 hours to afford light orange crystals that were filtered off and washed with chloroform (5 mL) to yield 1,4,7,10,13,16-hexathiacyclooctadecaneplatinum(II) hexafluorophosphate (126 mg, 78.4%) as an orange crystalline solid. IR (KBr): 2991, 2952, 2850, 1430, 1285, 1244, 1180, 1077, 1056, 841 (s, P−F), 651, 574, 558 cm^{-1}. $C_{12}H_{24}P_2F_{12}PtS_6$ (845.70): calcd. C 17.04, H 2.86, S 22.75; found C 17.15, H 2.85, S 22.66. As this salt offered the best solubility properties, most solution work was performed on it. The electronic absorption spectrum measured in acetonitrile showed two λ_{max}s, at 426 nm (ε = 84) and at 235 (ε = 28222). The electrochemistry of the complex showed one irreversible oxidation wave at +564 mV and a second irreversible oxidation wave at +1358 mV vs. Fc/Fc$^+$. ^{1}H NMR (300 MHz, CD_3CN, 25 °C): broad, poorly resolved resonances from 2.8 to 3.6 ppm. $^{13}C\{^1H\}$ NMR (75 MHz, CD_3CN, 25 °C): three peaks of approximately equal intensity at 27.54, 38.86, and 42.59 ppm. These were all confirmed to be methylene resonances by a DEPT experiment. $^{195}Pt\{^1H\}$ NMR (64.4 MHz, CD_3NO_2, 25 °C), δ ($\nu_{1/2}$): singlet at δ = −4152 ppm (91 Hz).

[Pt(18S6](BPh$_4$)$_2$: The synthesis and X-ray structure of this compound has been reported previously.[1] An aliquot of the [Pt(18S6]$^{2+}$ solution (10 mL) was mixed with $NaBPh_4$ (131 mg, 0.383 mmol), and the solution was then chilled in an ice bath for 1.5 hours to give light orange crystals that were filtered off and washed with chloroform (5 mL) to yield 1,4,7,10,13,16-hexathiacyclooctadecaneplatinum(II) tetraphenylborate (55.0 mg, 24.7%). IR (KBr): 3090, 3050, 2993, 2954, 1430, 1285, 1244, 1180, 1077, 1056, 750, 750, 670, 574 cm^{-1}. The electronic absorption spectrum measured in acetonitrile matched the reported literature spectrum.[1]

[Pt(18S6](ClO$_4$)$_2$: An aliquot of the [Pt(18S6]$^{2+}$ solution (10 mL) was mixed with $NaClO_4$ (53.9 mg, 0.440 mmol), and the solution was allowed to slowly evaporate to afford light orange crystals that were filtered off. These crystals were then washed with chloroform (5 mL) to yield 1,4,7,10,13,16-hexathiacyclooctadecaneplatinum(II) perchlorate (32.0 mg, 22.3%). IR (KBr): 2981, 2945, 2914, 1430, 1285, 1094−1074 (s, ClO_4^-), 925, 777, 623, 574 cm^{-1}. $C_{12}H_{24}Cl_2O_8PtS_6$ (754.68): calcd. C 19.10, H 3.21, Cl 9.40, S 25.44; found C 19.18, H 3.19, Cl 9.45, S 25.57. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]DMSO, 25 °C): three broad peaks of approximately equal intensity at δ = 25.8, 27.2, and 40.7 ppm.

Caution! Although the perchlorate salt prepared in this report did not appear to be shock-sensitive, they should always be handled with caution and used only in very small quantities.

X-Ray Data Collection and Processing

Suitable crystals of all complexes were grown by slow diffusion of diethyl ether into a nitromethane solution. Table 3 summarizes the key crystallographic details for the structures.

9S3 Complexes: For the tetrafluoroborate and hexafluorophosphate structures, intensity data were collected at low temperature

on a Siemens SMART 1 K CCD diffractometer[26,27] equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Structures were solved by direct methods,[26] and refinement was done using full-matrix least-squares techniques (on F^2). Structure solution, refinement and the calculation of derived results were performed with the SHELXTL[28] package of computer programs. For the triflate structure, intensity data were measured at room temperature with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Rigaku AFC-8 diffractometer[29,30] equipped with a 1 K mercury CCD detector.

18S6 Complex: Intensity data were measured at room temperature with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Rigaku AFC7R diffractometer. Data were corrected for Lorentz and polarization effects, and for absorption, using semi-empirical methods. The structure of the 18S6 complex was solved by direct methods and refined by using full-matrix least-squares techniques (on F^2). All non-hydrogen atoms were refined anisotropically; hydrogen atoms were placed in optimized positions (d_{C-H} = 0.96 Å) with assigned thermal parameters equal to 120% of the U_{eq} value of their host atom. Structure solution, refinement and the calculation of derived results were performed with the SHELXTL[28] package of computer programs. Neutral atom scattering factors were those of Cromer and Waber,[31a] and the real and imaginary anomalous dispersion corrections were those of Cromer.[31b]

Tetracyanoquinodimethanido Derivatives of (Terpyridine)- and (Phenanthroline)metal Complexes − Structural and Magnetic Studies of Radical-Ion Salts[‡]

Cristina Alonso,[a] Loreto Ballester,[a] Angel Gutiérrez,*[a] M. Felisa Perpiñán,[a] Ana E. Sánchez,[a] and M. Teresa Azcondo[b]

Keywords: Radical ions / Stacking interactions / Supramolecular chemistry / Magnetic properties

Several derivatives of formulae $[M(terpy)_2](TCNQ)_2$ or $[M(terpy)_2](TCNQ)_3$ (M = Ni, Cu, Zn; terpy = 2,2′:6′,2"-terpyridine; TCNQ= 7,7,8,8-tetracyanoquinodimethane) and $[M(phen)_3](TCNQ)_2$ or $[M(phen)_3](TCNQ)_4$ (M = Fe, Ni; phen = 1,10-phenanthroline) have been obtained. The crystal structures of $[M(terpy)_2](TCNQ)_2$ (M = Ni, Cu) show that the metal is surrounded by the terpyridine nitrogen atoms in a closed octahedral environment and the TCNQ anions are dimerised by π overlap. The cationic $[M(terpy)_2]^{2+}$ and the anionic $[TCNQ]_2^{2-}$ groups alternate in the crystal. For the derivatives with three TCNQ groups, the existence of a stack of trimeric $[TCNQ]_3^{2-}$ ions having electronic delocalisation is proposed. The compound $[Fe(phen)_3](TCNQ)_2$, which shows a strong interaction between TCNQ anions, led to the formation of a σ bond in the diamagnetic species [TCNQ–TCNQ], while the nickel analogue is expected to have a localised structure formed by alternation of cationic metal complexes and dimeric $[TCNQ]_2^{2-}$ anions similar to those observed in the analogous terpy derivatives. The derivatives having four TCNQ groups also show electronic delocalisation and a 1D stack based on the magnetic data is proposed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

In the field of molecular networks containing organic radicals, macroscopic properties such as magnetic order or electric conductivity can be produced when the appropriate supramolecular arrangement is achieved.[1,2] On this basis, when paramagnetic metallic centres are integrated within organic radicals as building blocks in molecular networks, "hybrid" materials combining the properties of the organic and inorganic components can be formed.[3,4]

Special attention has been given to the assembly of organonitrile radical complexes with transition metals because of their rich interaction possibilities. One of the most extensively used radicals in these studies has been the planar organic molecule 7,7,8,8-tetracyanoquinodimethane (TCNQ) since it shows a low reduction potential which makes it a suitable acceptor in charge transfer processes and also shows, in its anion-radical form, a high σ-donor ability for coordinating to transition metals.[5−8] Another typical feature of this acceptor is the tendency to overlap its π-delocalised system with neighbouring molecules to form stacks with different degrees of electronic delocalisation.[9−12]

The compounds having vacant positions around the metal react with TCNQ salts forming new compounds where the anion-radical is coordinated via one or more of its nitrile groups.[6,8,13−15] When complexes with a fully coordinated metal environment are used, new species without direct bonding interactions between the metal and the TCNQ are formed. When TCNQ is fully reduced, dimerisation to $[TCNQ]_2^{2-}$ is usually observed[7,8,16] but when TCNQ is partially reduced, a greater electronic delocalisation along with the formation of infinite stacks is observed.[9−12]

The present work reports our studies on the interactions of TCNQ in different formal oxidation states with closed shell first row transition metal complexes aimed at looking for electronic delocalisation in our systems. We have used nitrogen donor ligands with aromatic rings such as terpy (2,2′:6′,2"-terpyridine) or phen (1,10-phenanthroline) which are susceptible to forming weak π interactions with the TCNQ rings.[17−26] These interactions are more common when neutral TCNQ is present and can modulate the TCNQ overlap responsible for the stacking.

Results and Discussion

All metallic compounds were obtained by metathesis reactions from the parent derivatives. When only anionic TCNQ was added to the reaction mixture in the form of LiTCNQ, the compounds $[M(terpy)_2](TCNQ)_2$, (M = Ni, **1**; Cu **2**; Zn, **3**) or $[M(phen)_3](TCNQ)_2$, (M = Fe, **7**, Ni **8**) were obtained. TCNQ is in the anionic form in each case since it must neutralise the two positive charges on the metal ion. The tendency for TCNQ to dimerise means that the anions appear as dimers, i.e. $[TCNQ]_2^{2-}$. The exception to this behaviour is $[Fe(phen)_3](TCNQ)_2$ where the π interaction between the radical anions is so strong that a σ-carbon−carbon bond is formed. The formation of this σ-dianion (TCNQ−TCNQ) has previously been observed only in a few cases.[27−31]

In the reaction with $(NEt_3H)(TCNQ)_2$, with both neutral and anionic TCNQ present, the derivatives obtained correspond to the formulae $[M(terpy)_2](TCNQ)_3$ (M = Ni **4**; Cu **5**; Zn **6**) or $[M(phen)_3](TCNQ)_4$ (M = Fe **9**; Ni **10**). The TCNQ species in these compounds show an average formal charge of 0.66 e^- and 0.5 e^-, respectively, suggesting some degree of electronic delocalisation, a fact that is usually reflected in the formation of 1D TCNQ chains resulting from overlap of the π clouds of adjacent units.[11,12,32−38]

The new compounds are only slightly soluble in polar solvents such as acetonitrile or dimethyl sulfoxide. These solvents break any interactions between the metal cations and the TCNQ units which could be present in the solid state. For this reason, the solutions behave as a mixture of the metallocations and TCNQ, either in anionic or in neutral form. The spectroscopic and electrochemical data of these solutions do not give any additional information to that obtained for solid state samples, as previously described.[8,11,14] The spectroscopic data from solid-state samples will be commented upon below.

Crystal Structures

$[Ni(terpy)_2](TCNQ)_2$ (1)

This compound crystallises in the $P2_1/n$ space group. Figure 1 shows an ORTEP view of the molecular unit. The crystal structure can best be described as formed from alternating $[Ni(terpy)_2]^{2+}$ cations and dimeric $[TCNQ]_2^{2-}$anions. The nickel atom is hexacoordinated by the nitrogen atoms of the two terpy ligands in a *mer* arrangement which is expected for the ligand geometry. The nickel−nitrogen distances range between 1.994(1) and 2.132(1) Å with the shortest distances corresponding to the central nitrogen of each terpy ligand due to the strain imposed by the coordination.[39−41]

There are two crystallographically independent TCNQ molecules, A and B, in the asymmetric unit. The carbon−carbon bond lengths in the TCNQ rings are characteristic of the fully reduced radical-anion.[42] This is expected since the two positive charges in the metallic cation must be neutralised. Every $TCNQ_A$ overlaps with a $TCNQ_B$ in the ring-over-ring mode, thereby forming

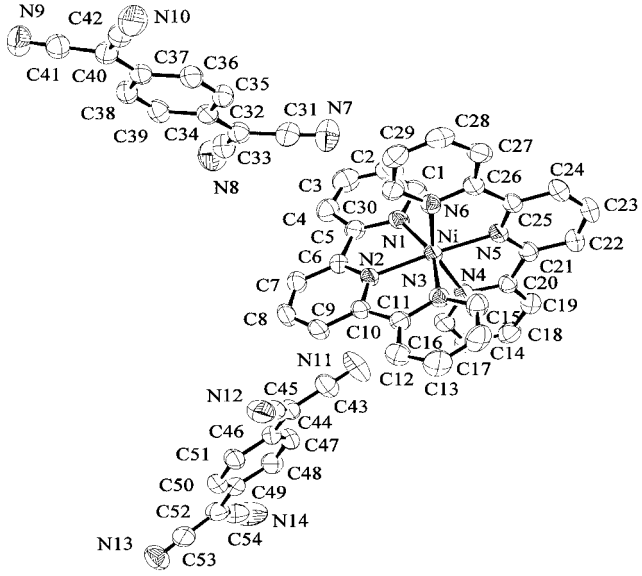

Figure 1. ORTEP view and labelling scheme of $[Ni(terpy)_2](TCNQ)_2$ (**1**); the atom labelling of the copper compound (**2**) is identical

$[TCNQ]_2^{2-}$ dianions with the shortest interplanar distance being 3.28(1) Å. The TCNQ planes are parallel to within 1.38(6)°. These planes form an angle of 31.32(6)° with one of the terpy ligands but no short contacts (less than 3.4 Å) could be found, suggesting that the cations and anions only interact by electrostatic forces in the crystal (Figure 2).

$[Cu(terpy)_2](TCNQ)_2$ (2)

This compound crystallises in the $P2_1/c$ space group. Its labelling scheme is identical to that shown in Figure 1 for the nickel derivative.

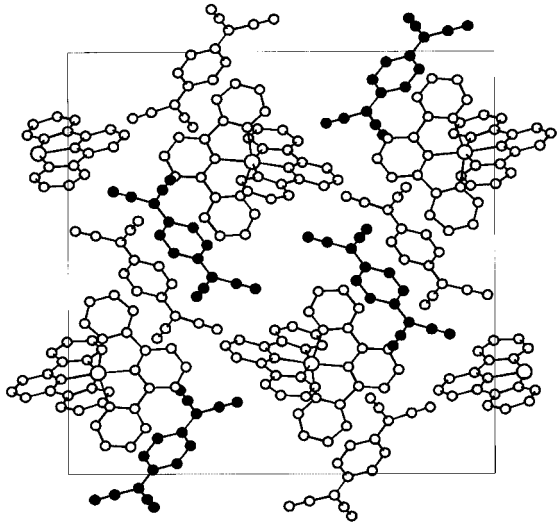

Figure 2. Unit cell contents for $[Ni(terpy)_2](TCNQ)_2$ (**1**); atoms in TCNQ A are shown as white circles and in TCNQ B as black circles

The metal environment is similar to that of the nickel derivative but the Cu−N distances vary more due to the Jahn−Teller effect which is expected for the copper centre.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This induces a rhombic distortion with opposite distances of 1.956(6) and 2.016(7) Å for the central nitrogen atoms, 2.103(6) and 2.137(7) Å for one pair of extreme nitrogen atoms and 2.250(7) and 2.277(7) Å for the other pair. A similar distortion has been observed in the structure of the parent nitrate and in related derivatives.[43−45] In accordance with these data the EPR spectrum of this compound at room temperature shows a rhombic pattern with *g* values of 2.20, 2.12 and 2.02.

There are also two crystallographically independent TCNQ anions in the cell, namely A and B, but in contrast with the nickel derivative each TCNQ overlaps with a symmetry related anion giving rise to two different $[TCNQ_A]_2^{2-}$ dimers with a ring-over-external bond overlap and a shortest interplanar distance of 3.14(1) Å and a $[TCNQ_B]_2^{2-}$ dianion overlapping in the ring-over-ring mode with a shortest distance of 3.19(1) Å (Figure 3).

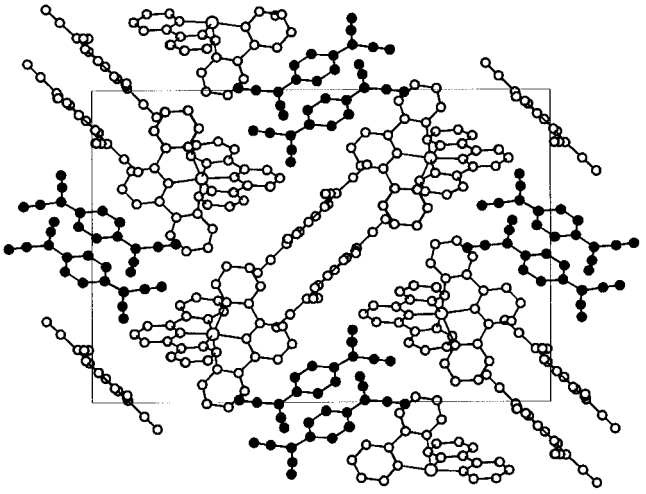

Figure 3. Unit cell contents for $[Cu(terpy)_2](TCNQ)_2$ (**2**); atoms in TCNQ A are shown as white circles and in TCNQ B as black circles

The $TCNQ_A$ dimers are isolated from the $[Cu(terpy)_2]^{2+}$ cations although the $TCNQ_B$ centres do overlap with the terpy rings of different cations through their external bonds (Figure 4) with shortest distances of 3.29(1) and 3.31(1) Å. The angle formed between the terpy and the $TCNQ_B$ is 28.0(2)°. These overlaps allow a small degree of electronic delocalisation along the tetrameric terpy·$TCNQ_B$·$TCNQ_B$·terpy stack. The stack does not continue through the solid, thus limiting possible delocalisation.

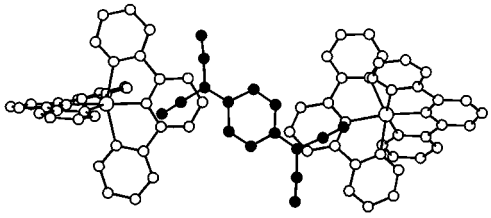

Figure 4. View of the overlap between $TCNQ_B$ and the terpy ligands of two adjacent $[Cu(terpy)_2]$ cations

[Fe(phen)$_3$](TCNQ−TCNQ) (7)

This compound crystallises in the *Cc* space group. Figure 5 shows the molecular unit with the labelling scheme. The structure can be described as formed from alternating sheets of $[Fe(phen)_3]^{2+}$ cations and σ-dimerised $[TCNQ-TCNQ]^{2-}$ anions. In the cations, the iron atom is hexacoordinated by the nitrogen atoms of three phen ligands with iron-nitrogen distances between 1.95 and 2.01 Å which is in the range usually found in other iron−phen derivatives.[46,47] The dimerised anion is obtained through the formation of a long bond between two exocyclic carbons. The carbon−carbon distance of 1.645(7) Å is similar to that found in the few cases in which this σ dimerization has been observed.[27−31] The formation of this bond is reflected in the tetrahedral conformation adopted by the linked carbon atoms, with angles between the ring plane

and the $C(CN)_2$ plane of 49.4(7) and 46.4(7)°, while the rest of the molecule is essentially planar.

The anions and cations are packed (Figure 6) in alternating sheets parallel to the *ab* plane and no interactions other than the usual van der Waals contacts can be found between them. Inside the anionic sheets the [TCNQ−TCNQ] units are arranged in chains along the [−1 1 0] direction with shortest contacts of 3.37(2) Å between C45 and C56.

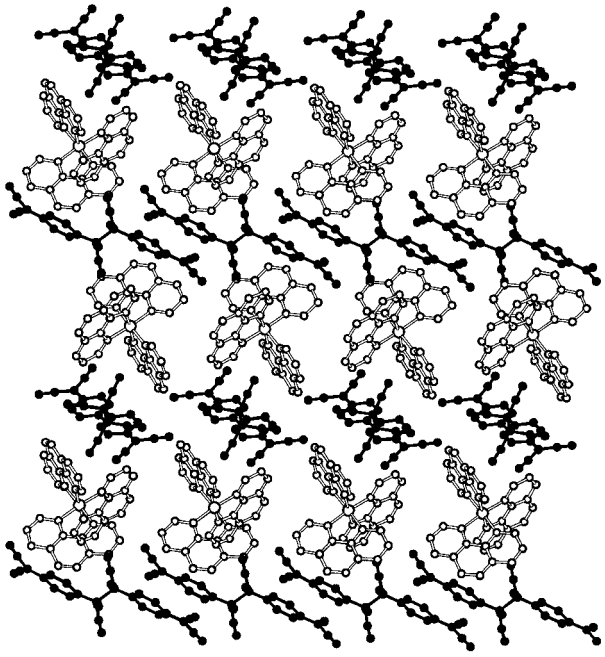

Figure 6. View of the alternating sheets of $[Fe(phen)_3]^{2+}$ cations and $[TCNQ-TCNQ]^{2-}$ anions in the structure of **7**

Spectroscopic Studies

The IR spectra of the studied derivatives show the typical features found in other uncoordinated TCNQ compounds.[48−50] The most significant bands for the neutral TCNQ are ν(CN) = 2228 cm^{-1}, $\nu_{20}(b_{1u})$ = 1530 cm^{-1} and $\nu_{50}(b_{3u})$ = 860 cm^{-1}. These bands are shifted to lower frequencies on increasing the electronic charge on the TCNQ.

The derivatives with two TCNQ units per metal atom, **1**−**3** and **8**, show these bands with typical values for the uncoordinated anion-radical, in accord with the localised picture of dimeric $[TCNQ]_2^{2-}$ anions alternating with cationic $[MN_6]^{2+}$ units in the solid structure, as the crystal structure of **1** and **2** revealed.

The spectrum of **7** shows different features attributable to the formation of a TCNQ−TCNQ σ bond. Thus, in the ν(CN) region there are two bands, the first appears at 2172 cm^{-1} and is composed of several component bands as a consequence of the lowering of the symmetry imposed by the bond formation. The second band, however, appears at 2125 cm^{-1}, a value shifted to lower frequency compared with those usually found in the anion radical. The out of plane bending mode ν_{50} also appears at 805 cm^{-1} and has been suggested as characteristic of the presence of the σ dimer,[30] since the usual value for the monoanionic species is 825 cm^{-1}.

The derivatives with three or four TCNQ units per metal atom always have the organic acceptor partially reduced, forming stacks with some degree of electronic delocalisation. This fact is reflected in the IR spectra of these species whose main feature is the presence of the tail of a low energy electronic absorption (CT_2) with broad vibrational bands superimposed on it.[51−53] The frequency values, especially the ν_{50} band, are intermediate between the usual values of the neutral and monoanionic TCNQ, suggesting that the acceptor has a formally nonintegral oxidation state. The low energy electronic transition (CT_2) appears in our compounds in the 3500−5000 cm^{-1} region and can be attributed to a charge transfer between adjacent radical anionic and neutral TCNQ groups, the lower the value the higher the electronic delocalisation.

As a consequence of this delocalisation, these compounds show semiconducting behaviour with relatively high values of electrical conductivity at room temperature and low activation energies which can be correlated with the frequency of the CT_2 electronic charge transfer as can be seen in Table 1. The activation energy was obtained by always assuming an Arrhenius dependence of the conductivity on temperature.

As expected, the derivatives with two TCNQ molecules per formula unit have localised electronic charges leading to very low conductivity values. The terpy derivatives with three TCNQ groups are much better semiconducting species. This fact can be explained if we attribute, to these compounds, a solid-state structure consisting of infinite stacks of TCNQ units separated by rows of $[M(terpy)_2]^{2+}$ cations. Every acceptor molecule in the stack would bear a negative charge of 0.66 giving rise to the formation of overlapping $[TCNQ]_3^{2-}$ trimers with partial electronic delocalisation. This structure has been previously observed in related derivatives exhibiting similar properties but with three TCNQ groups per metal atom.[11,12]

Table 1. Electronic spectra and electrical conductivity data of some representative compounds

Compound	CT_2 [cm^{-1}]	σ [S cm^{-1}] (298 K)	E_a [eV]
$[Ni(terpy)_2](TCNQ)_2$ (**1**)		$1.1\ 10^{-10}$	1.12
$[Ni(terpy)_2](TCNQ)_3$ (**4**)	3754	$1.9\ 10^{-2}$	0.25
$[Zn(terpy)_2](TCNQ)_3$ (**6**)	4378	$3.6\ 10^{-3}$	0.38
$[Ni(phen)_3](TCNQ)_4{\cdot}2CH_3CN$ (**10**)	4630	$1.8\ 10^{-4}$	0.41

The derivatives with four TCNQ groups per metal atom also show electronic delocalisation since the formal charge on every acceptor is 0.5. The reported structures of derivatives consisting of $TCNQ^{0.5-}$ show these anions stacked in nonuniform columns either forming dimerised ($[TCNQ]_2^{-}$)[38,54] or tetramerised ($[TCNQ]_4^{2-}$)[33,34,36,55] units. Both pictures correspond to a semiconductor and could suggest, for our derivatives **9**−**10**, a similar structure in the solid state.

Magnetic Properties

The bulk magnetic susceptibilities of the new compounds have been measured in the temperature range 2−300 K.

The magnetic moments of the nickel derivatives **1** and **4** follow the Curie law above 25 K with an abrupt descent in their values below this temperature as is shown for the former in Figure 7. This fact can be attributed to an anisotropic distortion of the nickel(II) environment which results in a zero field splitting of the ground state.[56] Equation (1) for the average magnetic susceptibility takes into account this single-ion anisotropy, where g_{Ni} is the Landé g factor for the nickel ion, k_B is Boltzmann's constant, β is the Bohr magneton, $x = D/k_BT$ with the parameter D measuring the zero-field splitting and $N\alpha$ is the temperature-independent paramagnetism.

$$<\chi>=(2Ng_{Ni}^2\beta^2/3k_BT)\{[2-2\exp(-x)]/x+\exp(-x)\}/[1+2\exp(-x)]+N\alpha \qquad (1)$$

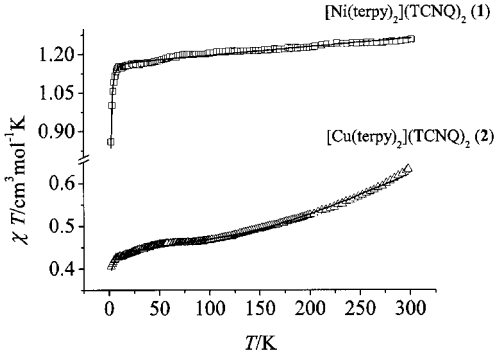

Figure 7. Temperature dependence of χT for **1** and **2**; the solid lines represent the best fit using the equations described in the text

The best fit was obtained when $g_{Ni} = 2.156$, $D = 3.34$ cm^{-1} and $N\alpha = 3.3\times10^{-4}$ cm^3mol^{-1} for **1,** and 2.07, 3.87 cm^{-1} and 9×10^{-5} cm^3mol^{-1}, respectively, for **4**. In both cases the values are typical of slightly distorted octahedral nickel(II) environments with no contribution to the magnetic moment from the organic radical anions. This is consistent with the presence of the dimerised anion-radical. The formation of dimeric $[TCNQ]_2^{2-}$ implies a strong antiferromagnetic coupling of both spins which renders the dianion diamagnetic at room temperature. The magnetic susceptibility variation can then be exclusively attributed to the contribution of the isolated metal ion. In accord with this behaviour, the zinc derivatives **3** and **6** are diamagnetic since no magnetic contribution can be expected from the metal ion.

The copper derivative **2** shows a steady increase in its χT value on increasing the temperature (Figure 7). The small decrease in the value at low temperatures can be ascribed to very weak antiferromagnetic interactions between the almost isolated copper(II) centres and can be fitted with the Curie−Weiss law. The increase in the χT value above 125 K is due to a small contribution from the TCNQ dimers which show a lower antiferromagnetic coupling than exhibited by the nickel and zinc derivatives. The lower value of the coupling implies that the triplet state is thermally accessible and populated near room temperature, giving rise to the contribution from the radicals to the magnetic susceptibility. Taking these two contributions into account, the molar magnetic susceptibility was fit, using Equation (2), to the sum of the Curie−Weiss law for the copper(II) ion and the Bleaney−Bowers equation[57] for the antiferromagnetically interacting TCNQ radicals, where g_{Cu} is the Landé g factor for the copper ion, J is the exchanging coupling constant for the TCNQ dimers, g is the Landé g factor for the TCNQ radicals and is assumed to be 2.003.

$$\chi=\frac{Ng_{Cu}^2\beta^2}{4k_B(T-\theta)}+\frac{Ng^2\beta^2}{k_BT}\left[\frac{2}{3+\exp(-J/k_BT)}\right]+N\alpha \qquad (2)$$

The rest of the parameters are the same as in Equation (1). The best fit for the experimental data, represented as a solid line in Figure 7, corresponds to $g_{Cu} = 2.161$, $\theta = -0.21$ K, $J = -278$ cm^{-1} and $N\alpha = 3.2\times10^{-4}$ cm^3mol^{-1}.

In contrast, compound **5** does not show any contribution from the organic radicals to the magnetic susceptibility which can be fit to the sum of the Curie−Weiss contribution from the copper ion, the first term in Equation (2) and the temperature-independent paramagnetism. The values obtained are $g_{Cu} = 2.26$, $\theta = -0.9$ K and $N\alpha = 8.4\times10^{-4}$ cm^3mol^{-1}. The high value of the TIP compared with those of the other compounds can probably be attributed to an incomplete diamagnetic correction although it is also plausible that it is due to a Pauli contribution originating from the delocalised electron of the anion radicals since the value is in the range of the paramagnetism observed in other conducting radical salts.[12,58] On the other hand, the low θ value for both copper derivatives indicates that the exchange between neighbouring copper spins can be considered negligible.

The phen derivatives show different behaviour, especially those showing electronic delocalisation. The iron derivative **7** is diamagnetic and corresponds to the presence of a low spin iron(II) and coupling between the two electrons with the formation of a TCNQ−TCNQ σ-bond. The magnetic susceptibility of the nickel derivative **8** is characteristic of isolated S = 1 spins and can be fitted to Equation (1) with values of $g_{Ni} = 1.94$, $D = 1.28$ cm^{-1} and $N_\alpha = 10^{-4}$ cm^3mol^{-1}.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The magnetic susceptibilities of the derivatives **9** and **10**, with four TCNQ units per metal atom, show the contribution of the organic radicals which only partially couple in an antiferromagnetic manner.

The iron derivative **9** is weakly paramagnetic and this paramagnetism can only be attributed to the organic radicals since the low spin iron(II) has no unpaired electrons. The susceptibility dependence with temperature (Figure 8) can be interpreted as the sum of three contributions: (i) the contribution of the spins located on the TCNQ which can be adjusted to a 1D antiferromagnetic chain of S = 1/2 spins and which is responsible for the maximum around 65 K, (ii) a Curie contribution from a paramagnetic impurity which may arise from isolated radicals in the structure which gives the increase in susceptibility at lower temperatures and (iii) temperature-independent paramagnetism. The first contribution has been fit with a Heisenberg linear chain model using the expression derived by Hatfield et al.[59] and constitutes the first term of Equation (3) where $x = |J|/k_BT$ and A, B, C, D, E and F are functions of α, a parameter that takes into account the distortion in the chain and can vary from $\alpha = 0$ (corresponding to isolated $TCNQ^-$ dimers) to $\alpha = 1$ (corresponding to a uniform chain of S = 1/2 spins). The second term of Equation (3) is the Curie contribution from the impurities with C being the Curie constant, while the final term is the TIP. The other parameters have the same meaning as in Equations (1) and (2).

$$\chi = \frac{Ng^2\beta^2}{k_BT}\left[\frac{A+Bx+Cx^2}{1+Dx+Ex^2+Fx^3}\right]+\frac{C}{T}+N\alpha \quad (3)$$

The best fit has been obtained assuming $g = 2.003$ for the TCNQ group and affords $J = -44$ cm^{-1}, $\alpha = 0.67$, $C = 0.007$ cm^{3}mol^{-1}K and $N\alpha = 1.5\times10^{-4}$ cm^{3}mol^{-1}. These parameters indicate the presence of a 2% of paramagnetic impurity and that the TCNQ units are probably stacked into infinite chains. The low values of the exchange constant and the α parameter suggest that these molecules can form dimeric $[TCNQ]_2^-$ units with poorer π overlap between adjacent dimers than can be found inside the dimer. Similar behaviour was found in [Fe(cyclam)(NCS)$_2$](TCNQ)$_2$ [38] with a similar J value (-43 cm^{-1}) but with a more uniform stack reflected in a higher α value (0.85) and also in [Zn(phen)$_3$](TCNQ)$_2$[5] which shows only half of the TCNQ anions stacked in an alternating chain ($J = -41$ cm^{-1}, $\alpha = 0.8$).

The nickel derivative **10** shows different magnetic behaviour. The general variation of χT (Figure 9) shows typical values for a nickel(II) ion in the 15−50 K range with a pronounced decrease at low temperatures which can be interpreted in terms of the zero-field splitting induced by the anisotropy in the nickel environment and an increase in χT values at higher temperatures, attributable to the contribution of the stacked TCNQ units. The data below 50 K were then fit to Equation (1) affording the values $g_{Ni} = 2.139$, $D = 1.54$ cm^{-1} and $N\alpha = 2.1\times10^{-4}$ cm^{3}mol^{-1}, while the data above 50 K were treated as consisting of three contributions: that of the nickel ion, the contribution from the antiferromagnetically interacting TCNQ radicals and the temperature-independent paramagnetism [Equation (4)]. In this temperature range we have ignored the contribution from the nickel zero field splitting since the low value previously found can be considered negligible. For this reason the nickel contribution is simply that obtained by the Curie law. The TCNQ groups have been assumed to be showing behaviour similar to that found in the iron derivative and their contribution has therefore been fit to a Heisenberg linear chain model where χ_{TCNQ} corresponds to the first term of Equation (3).

$$\chi = \frac{2Ng_{Ni}^2\beta^2}{3k_BT}+\chi_{TCNQ}+N\alpha \quad (4)$$

The best fit, shown in Figure 9 as a solid line, affords the following values $g_{Ni} = 2.14$, $J = -103$ cm^{-1}, $\alpha = 0.36$ and $N\alpha = 5\times10^{-4}$ cm^{3}mol^{-1}. The picture given by these data suggests an even less uniform chain in this compound which shows pairs of S = 1/2 spins coupling strongly in an antiferromagnetic way with weaker coupling between adjacent pairs. However, the lack of crystal structures precludes closer conclusions being drawn between the nonuniform 1D TCNQ stack deduced from magnetic observations and the actual structure in the solid state.

Concluding Remarks

The formation TCNQ derivatives with different stoichiometries can be seen as the result of the combination of two factors, namely the electrostatic interaction resulting from the neutralisation of the positive charges in the metallic fragment by the $TCNQ^-$ anion-radicals and the steric requirements that the cationic fragment imposes.[36] In derivatives having only monoanionic TCNQ, namely $[M(terpy)_2](TCNQ)_2$ and $[M(phen)_3](TCNQ)_2$, the tendency of the anion-radical to dimerise gives rise to the formation of S = 0 dianions $[TCNQ]_2^{2-}$. Since the metal coordination environment is saturated, no direct interaction with the TCNQ can be observed and the packing of metal cations surrounded by dimeric dianions is the structural motif which describes the solid state arrangement. This is also true when the strong interaction between adjacent TCNQ gives rise to the formation of a σ-bonded dimer in $[Fe(phen)_3](TCNQ)_2$. The strong coupling inside the $[TCNQ]_2^{2-}$ dimer leads to a diamagnetic state for the organic acceptors which do not contribute to the magnetic susceptibility. The exception is $[Cu(terpy)_2](TCNQ)_2$, for which the dimer excited triplet state becomes thermally accessible. This fact can be attributed to a weakening in the antiferromagnetic intradimer coupling as a consequence of the π interactions between $TCNQ^-$ and the aromatic ring of one terpy ligand found in the crystal structure of this compound. This is not observed in the analogous nickel derivative. In previous reports, the isolated $[TCNQ]_2^{2-}$ never contributes to the magnetic susceptibility[8,12,13,50] but when the dimers overlap with adjacent π systems, a weaker coupling can be observed.[11,50,55,60] In the previous cases, the dimeric dianion overlapped with a more or less neutral TCNQ but the unprecedented situation in this complex is that this role is assumed by one of the aromatic rings of the ligand.

In the derivatives with TCNQ in nonintegral oxidation states two compositions have been found, namely $[M(terpy)_2](TCNQ)_3$ and $[M(phen)_3](TCNQ)_4$. The magnetic properties of these derivatives are in accordance with the presence of 1D stacks of either trimeric $[TCNQ]_3^{2-}$ or tetrameric $[TCNQ]_4^{2-}$ units. Thus, in derivatives with $TCNQ^{0.66-}$, no contribution from the organic acceptor is usually observed,[12] whereas with stacked $TCNQ^{0.5-}$ units, linear chain magnetic behaviour from the organic part has been proposed.[38,61] The different stoichiometry for these derivatives can be explained in terms of the size of the metal cation and on the basis that only electrostatic interactions can occur between the cationic units and the negative TCNQ stacks. Assuming that the cations behave as rigid spheres which do not interpenetrate, we can estimate the diameter of the $[M(terpy)_2]^{2+}$ unit as ca. 11.3 Å, i.e. as measured in **1** (in fact the measured nickel-nickel distance of 11.8 Å matches well with this assumption), while a diameter for the $[M(phen)_3]^{2+}$ unit of ca. 13.4 Å has been estimated from the crystal structure of **7**. The TCNQ stack must then accommodate the three or four TCNQ units, bearing the two negative charges, in the same space occupied by the counterion. Since the stacking distances between adjacent TCNQ units appear in the 3.10−3.25 Å range, three TCNQ units will occupy 9.3−9.75 Å, while four TCNQ units need 12.4−13.0 Å in the stack. According to this picture, three TCNQ derivatives will form next to a dipositive cation of less than ca. 12 Å in diameter whereas the four TCNQ unit derivative must be obtained with bigger cations.

Experimental Section

General Remarks: All reactions were carried out under oxygen-free nitrogen. The parent reagents $[M(terpy)_2](NO_3)_2$,[43,62] $[M(phen)_3](NO_3)_2$,[63] LiTCNQ[64] and $(NEt_3H)(TCNQ)_2$ [64] were obtained by the published methods and their purities were checked by elemental analysis. Elemental analyses were carried out by the Servicio de Microanálisis of the Universidad Complutense de Madrid. Infrared spectra were recorded as KBr pellets with a Nicolet Magna-550 FT-IR spectrophotometer. Electronic spectra were recorded using a Cary-5 spectrophotometer. The spectra were recorded either in solution or in the solid state. The solid samples were prepared by rubbing the sample on optical glass. Magnetic experiments were carried out on polycrystalline samples using a SQUID magnetometer MPMS-XL-5 manufactured by Quantum Design. The temperature dependence of the magnetisation in the range between 2 and 300 K was recorded using a constant magnetic field of 0.5 T. The experimental data were corrected for the magnetisation of the sample holder and for atomic diamagnetism as calculated from Pascal's constants. Electrical conductivity data were measured by the two points method on single crystals using an APD cryogenics INC HC2 helium cryostat.

Preparation of the $[M(terpy)_2](TCNQ)_2$ Derivatives: All compounds of this type were obtained by the same procedure. A solution containing LiTCNQ (0.15 mmol) in methanol (15 mL) was added dropwise to a solution of the starting nitrate (0.075 mmol) in a mixture of methanol (15 mL)/water (5 mL). After complete mixing a blue solid appeared which was filtered, washed with methanol and dried under vacuum.

ated with resin epoxy and mounted on a Bruker Smart CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) operating at 50 kV and 25A. Data were collected over a reciprocal space hemisphere by combination of three exposure sets. Each frame exposure time was 20 s covering 0.3° in ω. The cell parameters were determined and refined by least-squares fits of all reflections collected. The first 50 frames were recollected at the end of the data collection to monitor crystal decay but no appreciable decay was observed. The structures were solved by direct and Fourier methods and refined by applying full-matrix least squares on F^2 with anisotropic thermal parameters for the non-hydrogen atoms. The hydrogen atoms were included with fixed isotropic contributions in their calculated positions determined by molecular geometry. The calculations were carried out with the SHELX97 software package.[65] CCDC-238898 (**1**), -238899 (**2**) and -238900 (**7**) contain the supplementary crystallographic data for this paper. Titanium Dioxide Nanoparticles Functionalized with Pd and W Complexes of a Catecholphosphane Ligand

Nigel T. Lucas,[a] James M. Hook,[a] Andrew M. McDonagh,*[a,b] and Stephen B. Colbran*[a]

Keywords: Palladium / Tungsten / Phosphane ligands / Titanium

Palladium and tungsten complexes containing the bifunctional ligand 4-diphenylphosphanylcatechol (L^1) have been synthesized. The catecholate functionality strongly binds to titanium dioxide nanoparticles, effectively anchoring the complexes to the TiO_2 surface. Solid-state ^{31}P NMR spectroscopy was used to probe the surface-bound compounds. Diffuse reflectance infrared spectroscopy also provided data on surface-bound tungsten carbonyl complexes. Preliminary experiments show that the palladium phosphane complex $[PdBr_2(L^1)_2]$ supported on TiO_2 catalyzes the Sonogashira coupling of phenylacetylene with 4-iodonitrobenzene.

Introduction

Immobilizing materials on metal oxide supports is attracting sustained interest with applications in areas such as catalysis, electrocatalysis, electrochromic display, photodegradation of organic compounds, and photovoltaic power generation.[1−4] Titanium dioxide is a useful support because it is inexpensive, inert, and nontoxic, as well as having an electronic band structure suitable for the aforementioned applications.

Our aim was to use a bifunctional catechol (1,2-dihydroxybenzene)−phosphane compound to anchor transition metal complexes ligated via the P atom to TiO_2 bound by the catecholate group. We envisaged that the soft phosphane donor should preferentially coordinate to soft metal centers,[5−8] and the catechol group, which is a source of the hard catecholate dianion, should preferentially bind to hard Ti^{IV} metal centers.[9−18] Anchoring groups such as carboxylate and phosphonate are regularly used to immobilize molecules on TiO_2 and other metal oxide surfaces. Although it is known that catechol forms a strongly immobilized complex with TiO_2 surfaces,[13,14] the use of catechol as an anchoring substituent for metal complexes has been scarcely documented.[15] The catecholate binding group is "non-innocent" in the sense that it is redox active, able to bind metal centers as catecholate, semiquinone and quinonoid forms.[16−18] Attractively, use of a catechol anchor could potentially increase communication between a surface-immobilized transition metal species and the titania surface.[19] We chose phosphanes as the metal-binding groups because phosphanes are amongst the most common ligands in transition metal chemistry and phosphane complexes of transition metals exhibit a diverse range of desirable photophysical and redox properties in addition to being the largest class of molecular catalysts.[5,6]

Scheme 1 outlines two approaches toward our goal of phosphane-substituted metal complexes on titania. We anticipated that either TiO_2 particles could be functionalized with a phosphanyl-catechol and then treated with transition metal sources or that metal phosphane complexes bearing the free catechol group could be prepared which would directly attach to the TiO_2 surface. Phosphanes bearing phosphonite or alkoxysilane-substituted tethers have been previously employed to immobilize metal complexes on SiO_2,[20−32] but to the best of our knowledge not to titania, and never before has the "non-innocent" catecholate group been employed to anchor a transition metal phosphane complex to a metal oxide surface. Raymond et al.[12] recently reported a catecholphosphane (L^1, see below) that suited our purposes. In this paper, we present the results of investigations on L^1 and transition metal complexes of L^1 immobilized on nanocrystalline TiO_2 particles.

Results and Discussion

Syntheses

The precursor 4-(diphenylphosphanyl)veratrole (L^2) was prepared using an adaptation of the method of Schmid et

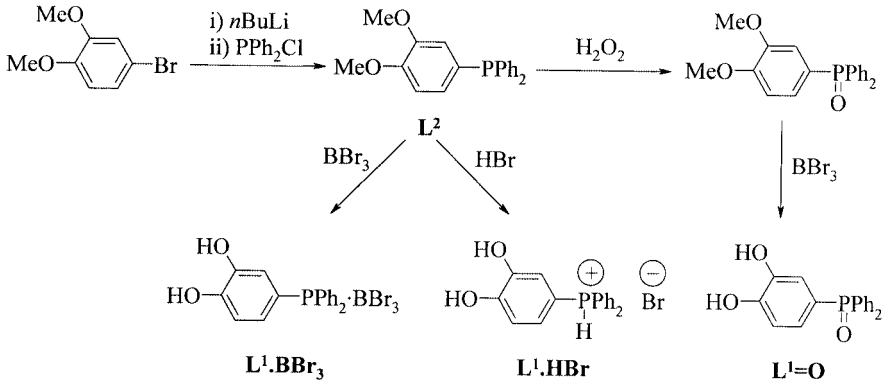

Scheme 2. Preparation of derivatives of catecholphosphane L^1

al.[33] Lithiation of 4-bromoveratrole in tetrahydrofuran using *n*-butyllithium and subsequent reaction with chlorodiphenylphosphane gave L^2 in 95% yield (Scheme 2). Attempted demethylation of L^2 to afford L^1 using boron tribromide yielded instead the boron tribromide adduct $L^1{\cdot}BBr_3$. The ^{31}P NMR spectrum of $L^1{\cdot}BBr_3$ has four peaks of equal intensity because of ^{31}P-^{11}B scalar coupling (^{11}B: $I = {}^3/_2$, 80.4% abundance). The chemical shift, $\delta = -2.4$ ppm, is consistent with other $P(Ar)_3BBr_3$ adducts.[34] The P−B bond was found to be quite stable and we were unable to cleanly displace the boron tribromide by reaction with strong Lewis bases such as di- and triethylamine, or by hydrolysis with aqueous hydroxide. Demethylation of L^2 was achieved by the procedure of Raymond et al.[12] to yield the catecholphosphane hydrobromide, $L^1{\cdot}HBr$. Oxidation of L^2 with hydrogen peroxide followed by demethylation with boron tribromide afforded the catecholphosphane oxide $L^1{=}O$ in 81% overall yield.

The reaction of $[PdCl_2(PhCN)_2]$ with L^2 gave $[PdCl_2(L^2)_2]$ in 80% yield (Scheme 3). Treatment of this complex with boron tribromide did not yield the desired catecholphosphane complex, $[PdBr_2(L^1)_2]$ (**1**), but the bromide-bridged bi-metallic complex $[Pd_2Br_4(L^1)_2]$, which was isolated in 70% yield. The ^1H and ^{31}P NMR spectra, ESI-MS, and elemental microanalysis are all consistent with the dimeric structure for $[Pd_2Br_4(L^1)_2]$. The presence of the adduct $L^1{\cdot}BBr_3$ in the crude reaction mixture (about 1:1 by ^1H NMR spectroscopy) suggests that one of the phosphane groups is captured by boron tribromide resulting in a coordinatively unsaturated palladium species. Combination of two such species would give the stable bromide-bridged dimer. A similar reaction has been previously reported by Sembiring et al.[35] Complex **1** was eventually and conveniently obtained in 70% yield from the reaction of $[PdCl_2(PhCN)_2]$ with $L^1{\cdot}HBr$ followed by treatment with excess KBr. During this reaction, bromide for chloride li-

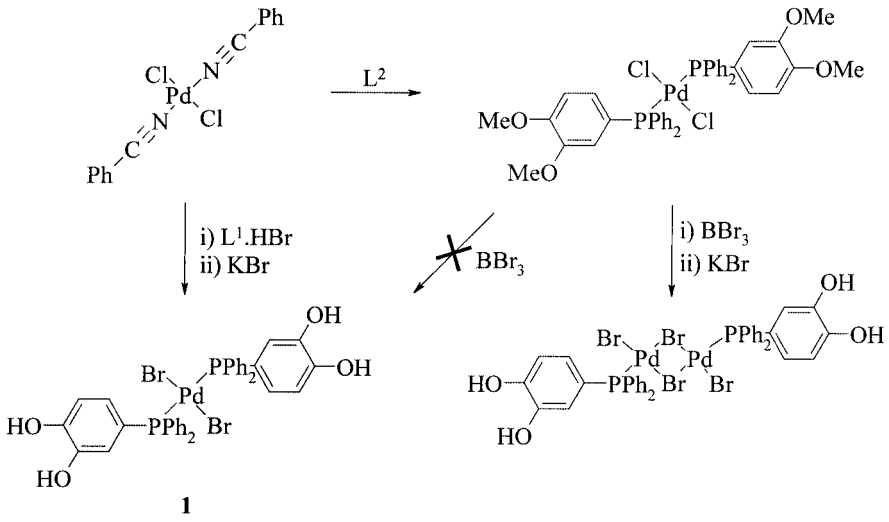
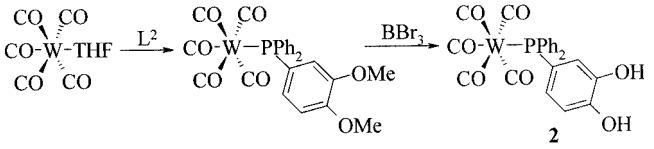


Scheme 3. Preparation of catecholphosphane palladium(II) complexes

gand metathesis occurs and stirring the crude reaction mixture with excess potassium bromide ensures that the amount of chloride-containing complex in the product is negligibly small.

The tungsten(0) carbonyl complex $[W(CO)_5(L^2)]$ was prepared by the in situ reaction of L^2 with freshly prepared $[W(CO)_5(THF)]$ (THF = tetrahydrofuran) (Scheme 4). Boron tribromide effected cleavage of the methyl groups in $[W(CO)_5(L^2)]$, without significant decomplexation of the phosphane from the tungsten, to afford the tungsten(0) carbonyl derivative $[W(CO)_5(L^1)]$ (**2**) in 72% yield.



Scheme 4. Preparation of catecholphosphane tungsten(0) complexes

Preparation of TiO_2-Bound Catecholphosphane Compounds

The TiO_2-bound compounds were prepared by stirring a solution of the compound with TiO_2 nanoparticles (Degussa P-25). The particles were then filtered and rinsed successively with a number of solvents to ensure that no free compound remained before drying in vacuo at room temperature.

Solid-State ^{31}P NMR Studies of TiO_2-Bound Catecholphosphane Compounds

Solid state $^{31}P\{^1H\}$ NMR spectra have been acquired of the catecholphosphane L^1, its oxide $L^1{=}O$, and its metal complexes, **1** and **2**, adsorbed onto titanium dioxide nanoparticles as well as in their pure form. Spectra were obtained using cross-polarization to enhance the NMR sensitivity of the dilute species bound to titania.

The CP/MAS ^{31}P NMR spectrum of $L^1{\cdot}HBr$ (Figure 1, a) shows an isotropic signal at $\delta_P = -3.6$ ppm, (linewidth, $\nu_{1/2} = 450$ Hz, chemical shift anisotropy, $\Delta\sigma = 100$ ppm) little shifted from the solution value, $\delta_P = -6.73$ ppm ([D_7]dimethylformamide).[12] In contrast, the CP/MAS ^{31}P NMR spectrum of the phosphane oxide $L^1{=}O$ (Figure 1, e) yields two values for the isotropic chemical shift, δ_P =

36.0 and 33.9 ppm, suggestive of two chemically distinct phosphorus environments either within the crystal lattice or in two crystal polymorphs. The chemical shift anisotropy, $\Delta\sigma$ = 200 ppm, is indicative of a less isotropic electronic distribution about the phosphorus(v) atom in L^1=O than about the phosphorus(iii) atom in L^1·HBr. The magnitude of the chemical shift anisotropy for L^1=O is identical to the literature value for $OPPh_3$.[20] Interestingly, the linewidths for L^1=O, $\nu_{1/2}$ = 145 Hz, are appreciably narrower than those for L^1·HBr, perhaps reflecting increased crystallinity for the L^1=O sample.

It was anticipated that immobilization of L^1 on the TiO_2 surface would provide titania particles functionalized with phosphane groups. The spectra of L^1·HBr adsorbed to TiO_2 (Figure 1, b) yielded an isotropic chemical shift, δ_P = −2.8 ppm, similar to that for unbound L^1·HBr. The spectra show no peaks for the phosphane oxide L^1=O (see below). Clearly, the catechol group effectively immobilizes L^1 on the TiO_2 surface without significant oxidation of the phosphane functionality. The linewidth of L^1 on TiO_2, $\nu_{1/2}$ = 750 Hz, is of a comparable order of magnitude to that for pure L^1·HBr, $\nu_{1/2}$ = 400 Hz. Likewise, the CP/MAS ^{31}P NMR spectrum of pure **2** shows an isotropic signal at δ_P = 20.1 ppm (Figure 1, c), while that of TiO_2-bound **2** (Figure 1, d) is at δ_P = 19.9 ppm. Again the linewidths of **2**, $\nu_{1/2}$ = 370 Hz, and TiO_2-bound **2**, $\nu_{1/2}$ = 260 Hz, are comparable. The relatively invariant chemical shift dispersion upon immobilization of ligand L^1 or complex **2** is indicative of the surface-bound species, in each case, occupying near identical environments on the TiO_2 surface. In each case, the surface sites occupied by the immobilized species appear remarkably the same.

The CP/MAS ^{31}P NMR spectrum of phosphane oxide L^1=O adsorbed to TiO_2 (Figure 1, f) yields an isotropic chemical shift, δ_P = 39.7 ppm, and chemical shift anisotropy, $\Delta\sigma$ = 200 ppm, suggesting the local environment of the phosphorus atom does not appreciably change upon binding to TiO_2. The linewidth for TiO_2-bound L^1=O, $\nu_{1/2}$ = 1.5 kHz, however, is substantially broader than anticipated. Phosphane oxides are known to bind to TiO_2 surfaces,[36−38] and it is possible that, for TiO_2-bound L^1=O, the phosphane oxide oxygen atom also binds to the surface, which leads to disordered surface environments and consequently to substantial chemical shift dispersion. This is in agreement with the trend observed for solid PPh_3 and $OPPh_3$ bound to silica surfaces.[20−23,25−30,32,36−38]

Infrared Experiments on TiO_2-Bound Tungsten Complexes

The strong infrared-active carbonyl absorption bands of the tungsten(0) carbonyl **2** make it an appropriate probe for the binding of the catechol group of L^1 to titania. Figure 2 shows solution and diffuse reflectance infrared spectra of **2**. The solution spectrum of **2** (Figure 2, a) is characteristic of complexes of the type $[W(CO)_5(PAr_3)]$. The bands at approximately 2070 and 1935 cm^{-1} are assigned to the A_1^{eq} and E vibrational modes,[39] respectively, and are associated with the four equivalent carbonyl ligands.

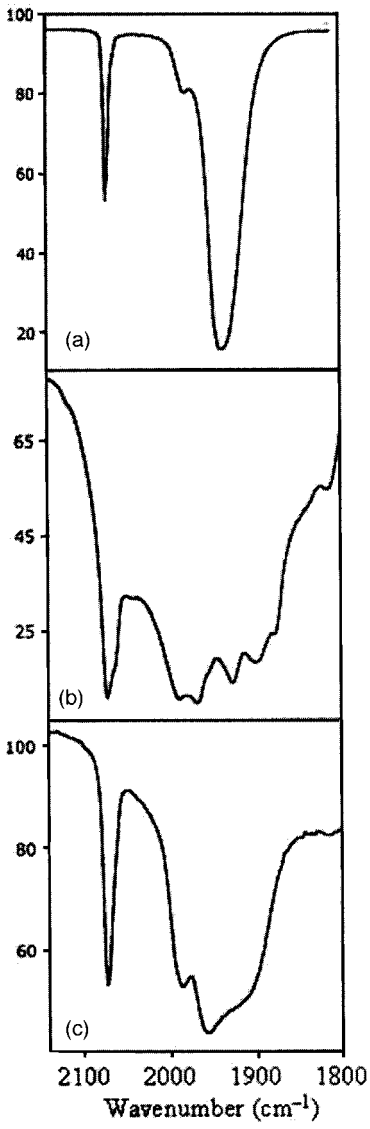

Figure 2. (a) FTIR spectrum of **2** in dichloromethane solution; (b) diffuse reflectance FTIR spectrum of solid **2**; (c) diffuse reflectance FTIR spectrum of TiO_2-supported **2**

The diffuse reflectance infrared spectrum of a solid sample of **2** is shown in Figure 2, b. The A_1^{eq} band appears at 2071 cm^{-1}, a value similar to that observed in the solution spectrum. Most noticeable is the splitting of the E infrared modes, with peaks at 1967, 1926, and 1900 cm^{-1}, due to different carbonyl environments created by packing in the solid state.

The diffuse reflectance infrared spectrum of TiO_2-bound **2** is shown in Figure 2, c. The A_1^{eq} band is seen at 2073 cm^{-1}, almost unchanged from the previous two spectra. A broad E band with a transmittance minimum at approximately 1956 cm^{-1} is observed with a much less symmetrical shape than that in the solution spectrum. This may also be attributed to packing-induced anisotropy and indicates the TiO_2-bound **2** also experiences different carbonyl environments, created by packing and orientation on the surface.

To explore if TiO_2 particles treated with L^1·HBr react with a metal center, we treated $[W(CO)_5(THF)]$ with TiO_2 particles bearing surface-bound ligands. The diffuse reflectance infrared spectrum was recorded. Bands at 2072, 1984 and a broad strong band at approximately 1955 cm^{-1} may be attributed to successful reaction between $[W(CO)_5(THF)]$ and L^1-derivatized TiO_2 to afford TiO_2-bound **2**. We also found that stirring $[W(CO)_5(THF)]$ with untreated TiO_2 particles followed by washing resulted in a surface-bound tungsten carbonyl species. The diffuse reflectance infrared spectrum of this species exhibits characteristic carbonyl stretching bands. Comparison with solution infrared spectra of $[W(CO)_5OH]^-$ [40,41] gives some indication of the nature of the bound tungsten carbonyl species.

These spectra are similar to the surface-bound tungsten carbonyl species formed upon reaction of $[W(CO)_5(THF)]$ with TiO_2. It appears that the species formed involves a Ti−O−W bond such as that illustrated in Figure 3.

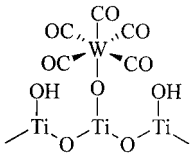

Figure 3. A possible surface-bound tungsten carbonyl species resulting from the reaction of $[W(CO)_5(THF)]$ and TiO_2

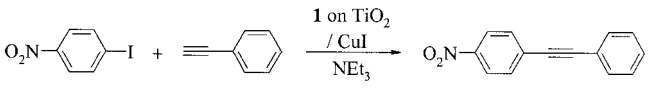
Coupling of Phenylacetylene with 4-Iodonitrobenzene Catalyzed by $[PdBr_2(L^1)_2]$ Supported on TiO_2

Palladium complexes are effective catalysts in the coupling reaction between aryl halides and terminal alkynes (Sonogashira coupling).[42−43,44,45] In order to establish the potential of surface-immobilized catecholphosphane metal complexes in catalysis, a preliminary study of the coupling between 4-iodonitrobenzene and phenylacetylene in the presence of the palladium complex **1** supported on TiO_2 (Scheme 5) was undertaken.



Scheme 5. Coupling reaction between 4-iodonitrobenzene and phenylacetylene catalyzed by CuI and TiO_2-supported **1**

The supported catalyst was prepared by stirring a dichloromethane solution of **1** with TiO_2 at room temperature for 24 h (no special treatment was undertaken to remove any TiO_2 surface-bound water). The suspension was filtered and rinsed successively with dichloromethane, acetone, methanol and diethyl ether to ensure that no unbound material remained. The estimated loading of **4** on titania was 1−2% w/w. The TiO_2-supported **1** was added to a triethylamine solution of 4-iodonitrobenzene and phenylacetylene, together with a cocatalyst, copper(I) iodide. The reaction proceeded to completion after stirring at room temperature for 24 h (^1H NMR spectroscopy showed quantitative conversion of 4-iodonitrobenzene to (4-nitrophenyl)phenylethyne). The reaction mixture was decanted from the settled catalyst, and fresh solvent, reactants, and copper(I) iodide were added. After the same reaction time and conditions as the first batch, the reaction had again proceeded to completion (as evidenced by ^1H NMR spectroscopy). The process was repeated a third time whereupon the reaction reached about 75% completion after the same reaction time, because of the deactivation of the palladium catalyst. A control reaction was also performed where unmodified TiO_2 was added to a triethylamine solution of 4-iodonitrobenzene and phenylacetylene, together with a cocatalyst, copper(I) iodide. After 24 h, no coupling was detected using ^1H NMR spectroscopy.

These preliminary results suggest that palladium complexes anchored to TiO_2 by catecholphosphane ligands do function as catalysts, although with limited turnover cycles. A full study is required to establish the cause of deactivation of the palladium catalyst as well as comparative studies with existing catalysts. Overall, the amount of palladium employed is no larger than that used in conventional homogeneous catalysis (typically 1−5 mol %). Because of the ease of catalyst separation (simple filtering from the reaction mixture) this TiO_2-confined catalyst may be useful in situations where product and catalyst are difficult to separate such as where the reagents and products have highly polar groups and are difficult to purify by the usual chromatographic procedures.

Conclusion

Our results reveal that TiO_2-immobilized transition metal−phosphane complexes are readily accessible starting from catecholphosphanes. Infrared experiments indicate binding of a pre-formed catecholphosphane complex to TiO_2 to give a more precisely defined material than does sequential surface derivatization with the catecholphosphane ligand and subsequent reaction with a metal precursor. Further investigations of applications, such as those summarized in the Introduction, are clearly warranted.

Experimental Section

General Remarks: Reactions were carried out under nitrogen by using Schlenk techniques. All solvents were analytical grade (AR). The following reaction solvents were dried and distilled under nitrogen using standard methods: dichloromethane over calcium hydride; tetrahydrofuran over sodium or potassium benzophenone ketyl. Acetone, diethyl ether, absolute ethanol and triethylamine were used without drying but were purged with nitrogen prior to use. Column chromatography was performed using Merck silica gel 60 of particle size 0.040−0.063 mm (230−400 mesh ASTM). Analytical TLC was carried out on Merck aluminum sheets coated with 0.25 mm silica gel 50 PF_{254}.

The reagents 4-bromoveratrole, *n*-butyllithium, boron tribromide, tungsten hexacarbonyl, phenylacetylene (Aldrich), hydrogen peroxide (20%), MnO_2, KBr, 4-nitroiodobenzene and CuI were purchased commercially and used as received. Chlorodiphenylphos-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phane (Aldrich) was distilled before use. The titanium dioxide (TiO_2) was Degussa P25 (ca. 25-nm particles). Literature procedures were used to prepare 4-(diphenylphosphanyl)catechol hydrobromide (L^1·HBr),[12] and $[PdCl_2(NCPh)_2]$.[46]

^1H and ^{31}P NMR solution spectra were recorded in $CDCl_3$ (Cambridge Isotope Laboratories or Aldrich) or [D_6]acetone (Aldrich) using a Bruker Avance 300 spectrometer (at 300 MHz for ^1H, 121 MHz for ^{31}P). The ^1H NMR spectra were referenced internally to residual protic solvent, and ^{31}P to external 85% H_3PO_4.

Solid state ^{31}P NMR spectra were obtained using a Varian Inova 300 NMR spectrometer at 121.395 MHz using Chemagnetics cross-polarization magic-angle spinning (CP/MAS) probes. The samples were packed into 4 mm or 7.5 mm o.d. zirconia rotors and spun at between 3 and 5 kHz. Spectra were recorded at 303 K and referenced to the CP/MAS spectrum of external solid ammonium dihydrogen phosphate, $\delta_P = 1.0$ ppm.[47] Cross-polarized spectra were obtained after optimizing by using the following parameters: recycle time, 20−120 s; contact time, 4−5 ms; ^1H 90° pulse width, 5−6 μs.

Infrared spectra were recorded on a Nicolet Avatar 320 FT-IR spectrometer in a solution cell or using a diffuse reflectance infrared FT (DRIFTS) attachment. The background for DRIFTS samples was air (for neat samples) or oven-dried TiO_2 (for supported samples). Electrospray ionization mass spectra (ESI-MS) were acquired on a VG Quattro mass spectrometer with a capillary voltage of 4 kV and a cone voltage of 30 V. Elemental microanalyses were carried out by the Microanalytical Service Unit at the Research School of Chemistry, Australian National University.

Synthesis of 4-(Diphenylphosphanyl)veratrole (L^2): A solution of 4-bromoveratrole (4.00 mL, 27.8 mmol) in freshly distilled tetrahydrofuran (110 mL) was cooled to −78 °C and *n*-butyllithium solution (1.55 M) was added dropwise over 3 min. After stirring for 15 min, chlorodiphenylphosphane was added dropwise to the cooled solution. The stirred solution was allowed to warm to room temperature over 17 h after which all volatile materials were removed in vacuo. The white residue was extracted several times with dichloromethane and the washings taken to dryness in a rotary evaporator. The crude material was loaded onto a 15 × 3 cm silica column and eluted with petroleum spirit/dichloromethane (up to 1:1) with the collection of fractions. Fractions containing the product (as identified by analytical TLC, $R_f = 0.55$, petroleum ether/dichloromethane, 1:1) were combined and taken to dryness using a rotary evaporator to afford white−pale green crystals identified as 4-(diphenylphosphanyl)veratrole (L^2) (8.50 g, 26.4 mmol, 95%).[5,11] ^1H NMR ($CDCl_3$): δ = 3.76 (s, 3 H, Me), 3.92 (s, 3 H, Me), 6.92−6.86 (m, 3 H, C_6H_3), 7.37−7.28 (m, 10 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = −3.2 ppm.

Attempted Synthesis of 4-(Diphenylphosphanyl)catechol (L^1): A solution of 4-(diphenylphosphanyl)veratrole (982 mg, 3.0 mmol) in dichloromethane (20 mL) was cooled to −78 °C and BBr_3 (1.05 mL, 11.1 mmol) was added dropwise with stirring. The mixture was stirred for a further 10 min before the cooling bath was removed and the mixture allowed to warm to room temperature over 3 h. Methanol (1 mL) was carefully added to quench the excess BBr_3, followed by water (5 mL), and the mixture was transferred to a separating funnel. The aqueous phase was neutralized and the dichloromethane phase collected, dried with $MgSO_4$, filtered, and taken to dryness on a rotary evaporator. A fluffy white solid was isolated and identified as the adduct, 4-(diphenylphosphanyl)catechol−boron tribromide (L^1·BBr_3) (1.38 g, 83%). ^1H NMR ([D_6]acetone): δ = 7.04 (dd, $^1J_{H,H}$ = 8, $^2J_{PH}$ = 3 Hz, 1 H, 6-C_6H_3), 7.14 (ddd, $^1J_{PH}$ = 11, $^1J_{H,H}$ = 8, $^2J_{H,H}$ = 2 Hz, 1 H, 5-C_6H_3), 7.38 (dd, $^1J_{PH}$ = 12, $^2J_{H,H}$ = 2 Hz, 1 H, 3-C_6H_3), 8.70 (br. s, 1 H, OH), 7.95−7.57 (m, 10 H, Ph), 8.92 (br. s, 1 H, OH) ppm. ^{31}P NMR ($CDCl_3$): δ = −2.4 (1:1:1:1 q, J_{BP} = 149 Hz).

Synthesis of L^2=O: A solution of L^2 (1.02 g, 3.2 mmol) in acetone (50 mL) was cooled to 0 °C and hydrogen peroxide solution (3.5 mL) was added dropwise with stirring. The mixture was stirred at 0 °C for 2 h at which point TLC indicated that the reaction was complete. MnO_2 was added in batches until no effervescence was observed, then the suspension was stirred for a further 1 h. The brown residue was removed by paper filtration, the filtrate tested for peroxides before being taken to dryness in a rotary evaporator to yield a cream colored solid identified as L^2=O (0.90 g, 84%).[10,11] ^1H NMR ($CDCl_3$): δ = 3.83 (s, 3 H, Me), 3.90 (s, 3 H, Me), 6.87 (dd, $^1J_{H,H}$ = 8, $^2J_{PH}$ = 3 Hz, 1 H, 6-C_6H_3), 7.01 (ddd, $^1J_{PH}$ = 12, $^1J_{H,H}$ = 8, $^2J_{H,H}$ = 2 Hz, 1 H, 5-C_6H_3), 7.28 (dd, $^1J_{PH}$ = 12, $^2J_{H,H}$ = 2 Hz, 1 H, 3-C_6H_3), 7.39−7.54 (m, 6 H, Ph), 7.59−7.67 (m, 4 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 32.0 ppm.

Synthesis of L^1=O: A solution of L^2=O (900 mg, 2.7 mmol) in dichloromethane (80 mL) was cooled to −78 °C and BBr_3 (0.80 mL, 8.4 mmol) was added dropwise with stirring. The mixture was allowed to warm to room temperature over 18 h. Dilute NaOH solution was carefully added to destroy excess BBr_3, then the reaction mixture was transferred to a separating funnel, acidified with HCl (5 M), and the dichloromethane layer was collected. The aqueous phase was extracted again with dichloromethane (2 × 25 mL). The dichloromethane washings were combined and washed with dilute acid (ca. 0.1 M HCl, 20 mL), dried with $MgSO_4$, filtered, and taken to dryness in a rotary evaporator. A cream-colored powder was isolated and identified as the hydrate of the product, L^1=O·H_2O (800 mg, 96%). ^1H NMR ($CDCl_3$): δ = 6.61 (ddd, $^1J_{PH}$ = 12, $^1J_{H,H}$ = 8, $^2J_{H,H}$ = 2 Hz, 1 H, 5-C_6H_3), 6.85 (dd, $^1J_{H,H}$ = 8, $^2J_{PH}$ = 4 Hz, 1 H, 6-C_6H_3), 7.40−7.65 (m, 10 H, Ph), 8.00 (br. m, 2 H, OH), 7.81 (dd, $^1J_{PH}$ = 13, $^2J_{H,H}$ = 2 Hz, 1 H, 3-C_6H_3) ppm. ^{31}P NMR ($CDCl_3$): δ = 35.3 ppm. ^{31}P CP/MAS NMR: δ = 33.9, 36.1 (about 3:1). $C_{18}H_{15}O_3P$·H_2O (328.30): calcd. C 65.85, H 5.22; found C 66.82, H 4.87.

Synthesis of $[PdCl_2(L^2)_2]$: A solution of $[PdCl_2(NCPh)_2]$ (500 mg, 1.30 mmol) in dichloromethane (15 mL) was added to a solution of L^2 (890 mg, 2.76 mmol) in dichloromethane (15 mL) at room temperature. The resulting clear yellow solution was stirred for 30 min, the volume was reduced to about 10 mL, and methanol was added dropwise to give a yellow precipitate. The mixture was cooled in ice, and the precipitate was collected on a sintered glass funnel, washed with methanol and dried at the pump. Slow diffusion of diethyl ether into an acetone solution of the crude material yielded yellow-orange prisms of $[PdCl_2(L^2)_2]$ (862 mg, 80%). ^1H NMR ($CDCl_3$): δ = 6.86 (br. d, 2 H, C_6H_3), 3.89 (s, 6 H, Me), 3.75 (s, 6 H, Me), 7.11−7.18 (m, 2 H, C_6H_3), 7.33−7.45 (m, 12 H, Ph), 7.54−7.59 (m, 2 H, C_6H_3), 7.71−7.63 (m, 8 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 25.3 ppm. $C_{40}H_{38}Cl_2O_4P_2Pd$ (822.01): calcd. C 58.45, H 4.66; found C 57.55, H 4.72.

Synthesis of $[PdBr_2(L^1)_2]$ (1): A solution of $[PdCl_2(NCPh)_2]$ (240 mg, 0.63 mmol) in acetone (20 mL) was added to a stirred suspension of L^1·HBr (496 mg, 1.32 mmol) in acetone (30 mL) at room temperature. The resulting clear orange solution was stirred for a further 1 h, then KBr (6.30 g, 53 mmol) was added and the suspension stirred vigorously for 16 h. The mixture was filtered and taken to dryness to yield $[PdBr_2(L^1)_2]$ (**1**) (375 mg, 70%) as a yellow solid. ^1H NMR ([D_6]acetone): δ = 6.92 (br. d, 2 H, C_6H_3), 7.16−7.28 (m, 4 H, C_6H_3), 7.37−7.45 (m, 12 H, Ph), 7.64−7.72

(m, 8 H, Ph) ppm. ^{31}P NMR ([D$_6$]acetone): δ = 23.7 ppm. Negative ion ESI-MS (methanol): 935 ([M + Br]$^-$, 100), 854 ([M − H]$^-$, 55). Positive ion ESI-MS (methanol): 775 ([M − Br]$^+$, 100). $C_{36}H_{30}Br_2O_4P_2Pd$ (854.81): calcd. C 50.59, H 3.54; found C 49.64, H 4.07.

Reaction of [PdCl$_2$(L^2)$_2$] with BBr$_3$: A solution of [PdCl$_2$(L^2)$_2$] (1.00 g, 1.2 mmol) in dichloromethane (30 mL) was cooled to −80 °C, and BBr_3 (0.56 mL, 5.9 mmol) was added dropwise. The reaction mixture was allowed to warm to room temperature overnight, the excess BBr_3 quenched with water, and the mixture was transferred to a separating funnel. Diethyl ether was added, and the organic phase was washed with brine (acidified with HCl), dried, filtered and taken to dryness. The crude material was dissolved in acetone (30 mL), KBr (5.8 g, 4.9 mmol) was added, and the suspension was stirred vigorously for 16 h. The mixture was transferred to a separating funnel, diethyl ether (30 mL) was added, and the resulting organic layer was washed twice and then dried over $MgSO_4$. The mixture was filtered and taken to dryness to give an orange solid identified as [Pd$_2$Br$_4$(L^1)$_2$] (375 mg, 70%). ^{1}H NMR ([D$_6$]acetone): δ = 6.95 (dd, $^1J_{H,H}$ = 8, $^2J_{PH}$ = 3 Hz, 2 H, 5-C$_6$H$_3$), 7.08−7.17 (m, 2 H, 6-C$_6$H$_3$), 7.28 (dd, $^1J_{PH}$ = 13, $^2J_{H,H}$ = 2 Hz, 2 H, 3-C$_6$H$_3$), 7.43−7.59 (m, 12 H, Ph), 7.67−7.77 (m, 8 H, Ph), 8.67 (s, 4 H, OH) ppm. ^{31}P NMR ($CDCl_3$): δ = 36.8 ppm. Negative ion ESI-MS (methanol): 1121 ([M]$^-$, 100). Positive ion ESI-MS (methanol): 775 ([M/2]$^+$, 45). $C_{36}H_{30}Br_4O_4P_2Pd_2$ (1121.04): calcd. C 38.57, H 2.70; found C 38.39, H 2.68.

Synthesis of [W(CO)$_5$(L^2)]: L^2 (1.38 g, 4.3 mmol) was added to a rapidly stirred yellow solution of [W(CO)$_5$(THF)], obtained by irradiating [W(CO)$_6$] (1.50 g, 4.3 mmol) in tetrahydrofuran (60 mL) with a mercury lamp for 3 h (with N_2 purge). The mixture was stirred at room temperature for 2 h after which all the volatile materials were removed in vacuo. The pale yellow residue was purified on a silica column by eluting with petroleum spirit/dichloromethane mixtures (up to 1:1). Fractions were collected and compared by using analytical thin-layer chromatography; the major band (pale yellow) was evaporated to dryness to give a pale yellow solid, identified as [W(CO)$_5$(L^2)] (1.69 mg, 61%). ^{1}H NMR ($CDCl_3$): δ = 3.79 (s, 3 H, Me), 3.91 (s, 3 H, Me), 6.87−6.98 (m, 2 H, 5,6-C$_6$H$_3$), 7.07 (br. d, $^1J_{PH}$ = 13 Hz, 1 H, 3-C$_6$H$_3$), 7.41−7.47 (m, 10 H, Ph); ([D$_6$]acetone): δ = 3.74 (s, 3 H, Me), 3.88 (s, 3 H, Me), 6.98−7.15 (m, 3 H, C$_6$H$_3$), 7.48−7.57 (m, 10 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 23.0 (J_{WP} = 242 Hz) ppm; ([D$_6$]acetone): δ = 21.9 (J_{WP} = 242 Hz) ppm. $C_{25}H_{19}O_7PW$ (646.25): calcd. C 46.46, H 2.96; found C 46.82, H 2.93.

Synthesis of [W(CO)$_5$(L^1)]: A solution of [W(CO)$_5$(L^2)] (615 mg, 0.95 mmol) in dichloromethane (10 mL) was cooled to −80 °C, and BBr_3 (0.30 mL, 3.2 mmol) was added dropwise. The mixture was allowed to warm to about −10 °C over 1.5 h, before it was cooled again to −80 °C, and NEt_3 (1 mL) and methanol (1 mL) were added to quench the excess BBr_3. After warming to room temperature, water (1 mL) was carefully added, and the mixture was transferred to a separating funnel and washed with dilute HCl solution (3 × 20 mL). The organic phase was dried over $MgSO_4$, filtered and taken to dryness to yield [W(CO)$_5$(L^1)] (**2**) (425 mg, 72%) as a cream-colored powder. ^{1}H NMR ([D$_6$]acetone): δ = 6.91−7.03 (m, 3 H, C$_6$H$_3$), 7.47−7.55 (m, 10 H, Ph), 8.41 (s, 1 H, OH), 8.53 (s, 1 H, OH) ppm. ^{31}P NMR ([D$_6$]acetone): δ = 20.8 (J_{WP} = 241 Hz). ^{31}P CP/MAS NMR: δ = 20.1 ppm. Negative ion ESI-MS (methanol): 1236 ([2M]$^-$ dimer, 100). $C_{23}H_{15}O_7PW$ (618.19): calcd. C 44.69, H 2.45; found C 44.98, H 2.45.

Adsorption of Phosphanylcatechol-Containing Compounds onto TiO$_2$

L^1 on TiO$_2$: L^1·HBr (320 mg, 0.85 mmol) was added to a rapidly stirred suspension of TiO_2 (3.4 g) in methanol (150 mL). The color of the particles changed rapidly from white to pale orange. After stirring at room temperature for 1 h, triethylamine (0.5 mL, 3.6 mmol) was added, and the stirring was continued for a further 3 h. The suspension was then allowed to settle, and the colorless solution was removed using a cannula. The material was washed with methanol (150 mL), then filtered and rinsed successively with methanol (150 mL), acetone (2 × 50 mL), tetrahydrofuran (2 × 50 mL), dichloromethane (2 × 50 mL), and diethyl ether (2 × 15 mL), and then dried in vacuo at room temperature for 8 h. ^{31}P CP/MAS NMR: δ = −2.8 ppm.

L^1=O on TiO$_2$: TiO_2 (1.50 g) was added to a colorless solution of L^1=O (203 mg, 0.65 mmol) in methanol (30 mL), and the suspension was stirred at room temperature for 18 h. The pale orange suspension was filtered and rinsed successively with methanol (3 × 15 mL) and diethyl ether (10 mL), and then dried in vacuo at room temperature for 6 h. ^{31}P CP/MAS NMR: δ = 40.1 ppm.

[W(CO)$_5$(L^1)] on TiO$_2$: TiO_2 (1.0 g) was added to a solution of [W(CO)$_5$(L^1)] (100 mg, 0.16 mmol) in dichloromethane (100 mL), and the suspension was stirred at room temperature for 24 h. The pale orange suspension was then filtered and rinsed successively with dichloromethane (5 × 20 mL), acetone (2 × 20 mL), and diethyl ether (2 × 20 mL), then dried in vacuo at room temperature for 3 h. ^{31}P CP/MAS NMR: δ = 19.91 ppm.

[W(CO)$_5$(THF)] on TiO$_2$: Photolytically generated [W(CO)$_5$(THF)] (10 mL, 28.4 mM in tetrahydrofuran, 0.284 mmol) was added to TiO_2 (1.0 g) and the suspension was stirred at room temperature for 24 h. The white-gray suspension was then filtered and rinsed successively with tetrahydrofuran (3 × 40 mL), acetone (2 × 40 mL), and diethyl ether (2 × 40 mL), then dried in vacuo at room temperature for 3 h.

[PdBr$_2$(L^1)$_2$] on TiO$_2$: TiO_2 (1.50 g) was added to an orange-yellow solution of [PdBr$_2$(L^1)$_2$] (150 mg, 0.18 mmol) in dichloromethane (100 mL), and the suspension was stirred at room temperature for 24 h. The suspension was then filtered and rinsed successively with dichloromethane (2 × 20 mL), acetone (2 × 15 mL), methanol (2 × 15 mL), and diethyl ether (2 × 15 mL), then dried in vacuo at room temperature for 8 h.

Catalytic Studies

Coupling of Phenylacetylene with 4-Iodonitrobenzene Catalyzed by [PdBr$_2$(L^1)$_2$] Supported on TiO$_2$: Phenylacetylene (0.15 mL, 1.3 mmol), CuI (10 mg, 0.05 mmol) and [PdBr$_2$(L^1)$_2$]-TiO_2 (800 mg, ca. 1% w/w) was added to a solution of 4-iodonitrobenzene (80 mg, 0.32 mmol) in triethylamine (30 mL, N_2-purged), and the suspension was stirred at room temperature for 24 h. The particles were allowed to settle, and the solution was transferred to a second flask using a cannula. The solid residue was washed with triethylamine (20 mL). The combined reaction solution and washing was taken to dryness, and the crude residue was passed through a short silica plug by using CH_2Cl_2/hexane (3:7) eluent. The ^{1}H NMR spectrum of the resulting pale yellow solid indicated quantitative conversion of 4-iodonitrobenzene to the product (4-nitrophenyl)phenylethyne[48] (<1% of the homo-coupled tolane product was also observed). A second batch of reactants and CuI catalyst (same scale) was added to a triethylamine (30 mL) suspension of the same Pd catalyst from above. Again, quantitative conversion into (4-nitrophenyl)phenylethyne was observed. The cycle was repeated a third time using the same Pd catalyst with a reduction of conversion to 75%.

Preparation and Characterisation of Cd^{II}, Hg^{II} and Pb^{II} Complexes of a Macrodinucleating Hexaaza-dithiophenolate Ligand

Vasile Lozan[a] and Berthold Kersting*[a]

Keywords: Macrocyclic ligands / Cadmium / Mercury / Lead / Complexes

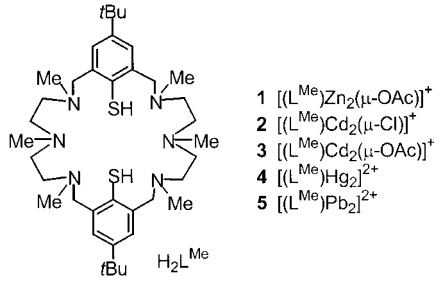
The ligating properties of a Robson-type 24-membered macrodinucleating hexaaza-dithiophenolate ligand towards the heavy metal ions Cd^{II}, Hg^{II} and Pb^{II} have been examined. The complexation of H_2L^{Me} with $CdCl_2$ or $Cd(OAc)_2$ in the presence of triethylamine leads to monocationic $[(L^{Me})Cd_2(\mu\text{-}L')]^+$ complexes bearing additional coligands [L′ = Cl^- (**2**) or OAc^- (**3**)]. With $Hg(OAc)_2$ and $Pb(OAc)_2$, the respective dicationic complexes $[(L^{Me})Hg_2]^{2+}$ (**4**) and $[(L^{Me})Pb_2]^{2+}$ (**5**) were obtained. The latter show no tendency to bind to further coligands. The crystal structure determinations of **2**·BPh_4 and **3**·BPh_4 revealed the presence of bowl-shaped, calixarene-like $[(L^{Me})Cd_2(\mu\text{-}L')]^+$ cations featuring six-coordinate Cd^{II} ions with N_3S_2Cl (**2**) or N_3S_2O (**3**) environments. The metal ions in the dications **4** and **5** display highly irregular N_3S coordination environments, presumably as a consequence of the steric constraints imposed by the rigid macrocyclic nature of $(L^{Me})^{2-}$. All complexes could also be fully characterised by ^1H and ^{13}C NMR spectroscopy. These results have thus established the ability of the macrodinucleating polyaza-dithiophenolate ligand to support the formation of stable dinuclear complexes of toxic heavy metals.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

It is well established that macrodinucleating ligands of the Robson type[1] are ideally suited to the formation of kinetically and thermodynamically stable complexes of the 3d elements.[2] Since these ligands also bind strongly to a range of toxic and precious heavy metal ions,[3−5] they may serve as complexing or extracting agents for biological, environmental or recycling purposes.[6−8] With regards to the soft characteristics of the heavy metal ions,[9] it could be advantageous to use macrocyclic ligands with mixed nitrogen-sulfur donor sets to improve their metal-ion selectivity. Consequently, a large number of N,S-based macrocycles have been reported and their binding properties towards environmentally important elements have been investigated.[10,11] To the best of our knowledge, the thiophenolate derivatives[12−14] of Robson-type macrocycles have not yet been tested in this respect. This led us to investigate the ligating properties of the dinucleating hexaaza-thiophenolate ligand $(L^{Me})^{2-}$ (see Scheme 1)[15,16] towards the metal ions Cd^{II}, Hg^{II} and Pb^{II}.

Herein we demonstrate that such metal ions can be readily accommodated in the two binding pockets of H_2L^{Me}. In each case we have obtained single crystals suitable for X-ray structure determinations. It has therefore been possible to study, in detail, the binding of the metal ions to the octadentate N_6S_2 macrocycle H_2L^{Me}. The results of IR and NMR spectroscopic investigations are also reported.



Scheme 1. Structure of the ligand H_2L^{Me}

Results and Discussion

Preparation

The synthesised compounds and their labels are collected in Scheme 1 with Scheme 2 depicting the synthetic procedures. The complexation reactions of the free macrocycle H_2L^{Me}·6HCl with $CdCl_2$, $Cd(OAc)_2$, $Hg(OAc)_2$ and $Pb(OAc)_2$ were all carried out in methanol in the presence of triethylamine. All reactions proceeded smoothly and produced clear solutions from which, upon addition of an excess of $LiClO_4$, the highly crystalline salts $[(L^{Me})Cd_2(\mu\text{-}Cl)]ClO_4$ (**2**·ClO_4), $[(L^{Me})Cd_2(\mu\text{-}OAc)]ClO_4$ (**3**·ClO_4), $[(L^{Me})Hg_2](ClO_4)_2$ (**4**·ClO_4) and $[(L^{Me})Pb_2](ClO_4)_2$ (**5**·ClO_4) precipitated in good to excellent yields. Complex **3** was also

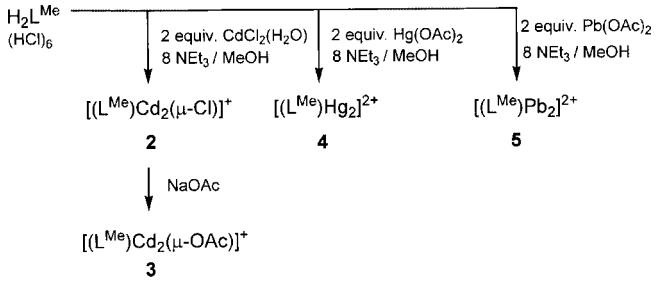
accessible from $[(L^{Me})Cd_2(\mu\text{-}Cl)]ClO_4$ (**2**·ClO_4) and sodium acetate.



Scheme 2. Synthesis of complexes and their labels; the complexes were either isolated as ClO_4^- or BPh_4^- salts

The new compounds are colourless to pale-yellow solids and dissolve readily in polar protic solvents such as methanol or ethanol. With the exception of complex **2**, which fixes carbon dioxide from air to give the methyl carbonate complex $[(L^{Me})Cd_2(\mu\text{-}O_2COMe)]^+$, all compounds are stable in air both in solution and in the solid state. All compounds gave satisfactory elemental analyses and were characterised by spectroscopic methods (IR, ^1H and ^{13}C NMR spectroscopy) and X-ray crystallography.

Spectroscopic Characterisation

Infrared Spectroscopy

The infrared spectra of all compounds are dominated by the absorptions of the $[(L^{Me})M_2]^{2+}$ fragments and the counterions (ClO_4^- or BPh_4^-).[17] The IR spectrum of **3**·ClO_4 shows two bands at 1577 and 1422 cm^{-1} which can be assigned to the asymmetric $[\nu_{asym}(OAc^-)]$ and symmetric stretching modes $[\nu_{sym}(OAc^-)]$ of the acetate group, respectively.[18] These values are very similar to those of the zinc complex $[(L^{Me})Zn_2(\mu\text{-}OAc)]^+$ (**1**),[16] indicating that the acetate group in the cadmium complex **3** is also in the $\mu_{1,3}$-bridging mode. The IR spectra of complexes **4** and **5** lack these two bands which is in good agreement with the presence of unligated $[(L^{Me})M_2]^{2+}$ dications. The IR spectra of **4** and **5** were otherwise not very informative with regards to the compositions and structures of the complexes.

NMR Spectroscopy

All of the new complexes were further characterised by ^1H and ^{13}C NMR spectroscopy. Table 1 lists selected NMR spectroscopic data for complexes **2**−**5**. The data for complex **1** have been reported previously and are included for comparative purposes. As can be seen, the ^1H NMR spectroscopic data of the acetato-bridged complexes **1** and **3** are very similar. Both complexes display only one set of signals, indicating that both exist as single isomers in solution. Furthermore, the four aromatic protons (ArH), the methyl protons on the benzylic nitrogens ($N^{Bz}CH_3$), the methyl protons on the central amine nitrogen of the linking diethylene triamine units (NCH_3) and the *tert*-butyl protons $[C(CH_3)_3]$ appear as singlets, indicative of C_{2v} symmetry for the $[(L^{Me})M_2(\mu\text{-}OAc)]^+$ cations in solution. This is further supported by the fact that the $[(L^{Me})M_2]^{2+}$ fragments give rise to only eleven ^{13}C signals (7 for the aliphatic and 4 for the aromatic carbon atoms). Of note is the appearance of the ^1H NMR signals for the methyl protons of the acetato coligands in **1** and **3** at $\delta = 0.85$ and $\delta = 0.98$ ppm, respectively. The signals are shifted considerably to high-field compared with the value recorded for free sodium acetate in the same solvent ($\delta = 1.83$ ppm). This provides strong

evidence that the coordinated acetate groups sense the ring-currents of the two flanking phenyl rings of $(L^{Me})^{2-}$. As can be seen from Figure 2 (see below), the methyl protons of the acetate groups are positioned in the binding cavity of the $[(L^{Me})M_2]^{2+}$ fragment slightly above the centre of the two phenyl rings in the shielded region. Since the angle between the phenyl rings in the zinc complex **1** (80.0°)[16] is much smaller than in the cadmium complex **3** (94.4°), the distance of the methyl protons to the centre of the phenyl rings is smaller in the former and hence the shielding effect is more pronounced in this compound. These spectroscopic findings thus clearly show that the coligands in **1** and **3** remain attached to the metal ions in solution with retention of their solid-state structures.

The ^{1}H NMR spectroscopic data of the dicadmium complex **2** are very similar to those of **3**. Again, the ArH, $N^{Bz}CH_3$, NCH_3 and $C(CH_3)_3$ protons all appear as well-resolved singlets. Likewise, there are only eleven signals in the ^{13}C spectrum. On the basis of these data, one can also conclude the existence of C_{2v} symmetry in the $[(L^{Me})Cd_2(\mu\text{-}Cl)]^+$ cation. The most striking feature in the ^{1}H NMR spectrum of **2**·ClO_4 is the rare observation of satellites for the $ArCH_2N$ and the $N^{Bz}CH_3$ protons that presumably arise from three-bond $^1H-^{111,113}Cd$ couplings [$^3J(^{111,113}Cd-^1H)$ = 4.6 Hz and 4.0 Hz, respectively].[19] This reflects kinetic inertness of the complex cation in solution as well as a degree of covalency in the Cd−ligand bonds. Similar findings have been observed for other cadmium complexes of macrocyclic ligands.[10,20]

The ^{13}C NMR spectroscopic data of the mercury complex **4** differ significantly from those of the compounds above and, as we will show below, this complex exhibits C_1 symmetry in the solid state. This symmetry arises because of different configurations for the two chiral amine donors in the two opposing diethylene triamine units [e.g. (*R*)-N(1), (*R*)-N(3) vs. (*S*)-N(4), (*R*)-N(6), see Figure 3 below]. This in turn renders all carbon atoms of the present complex chemically inequivalent and, given that its solid-state structure is maintained in solution, a total of 34[21] resonances (12 aromatic C atoms, 4 benzylic C atoms, 8 ethylene C atoms, 4 *tert*-butyl C atoms and 6 *N*-methyl C atoms) are, in principle, observable. The experiment clearly shows that this is indeed the case (see Table 1). At 75 MHz, the differences in the ^{13}C chemical shift values are sufficiently large for all the expected 34 resonances to be resolved. The 12 aromatic carbon atoms resonate in the region δ = 150−120 and the 22 aliphatic carbon atoms can be observed between 70 and 30 ppm. The fact that **4** is a C_1-symmetric species is also supported by ^{1}H NMR spectroscopy. In the case of the benzylic CH_2 and the ethylenic CH_2 protons the chemical shift differences are too small for full resolution of all expected 16 resonances. However, the expected 14 signals for the four aromatic protons, the four CH_3 groups on the benzylic nitrogen atoms, the two CH_3 groups on the central amine N atoms of the diethylene triamine units and the two *tert*-butyl groups are all observable with the correct intensity ratios. It can therefore be concluded that **4** maintains its solid-state structure in solution.

The lead complex **5** displays only half as many ^{13}C NMR signals as **4** but the total number of 17 resonances is still larger than the 11 resonances observed for **3**, indicating symmetry higher than C_1 but lower than C_{2v}. The ^{1}H NMR spectroscopic data suggest that it is C_2 symmetry which was observed in the solid state. The higher symmetry of **5** (relative to **4**) is easily detectable in the identical configurations for the four benzylic amine nitrogen donors in the two opposing diethylene triamine units [e.g. (*S*)-N(1), (*S*)-N(3), (*S*)-N(4), and (*S*)-N(6), see Figure 4, below]. In summary, the NMR spectroscopic investigations have clearly established that all complexes exist as discrete and stable species in solution.

X-ray Crystallography

Further confirmation regarding the composition and structures of the complexes was provided by X-ray diffraction studies. Single crystals of X-ray quality were obtained for the tetraphenylborate salts of **2**−**4** and for the diperchlorate salt of **5**. The molecular structures of the complexes are displayed in Figures 1−4 and selected bond lengths and angles are given in Tables 2 and 3.

Description of the Crystal Structures

*[(L^{Me})Cd_2(μ-Cl)]BPh_4·1.5MeOH (**2**·BPh_4·1.5MeOH)*

This salt crystallises in the triclinic space group $P\bar{1}$. The structure revealed the presence of discrete dinuclear $[(L^{Me})Cd_2(\mu\text{-}Cl)]^+$ cations, tetraphenylborate anions and methanol solvate molecules. The dicadmium complex exhibits idealized C_{2v} symmetry as was established by NMR spectroscopy. As can be seen in Figure 1, the cadmium(II) ions are coordinated in a distorted octahedral fashion by three *facially* oriented nitrogen atoms, two bridging thiophenolate sulfur atoms and a bridging halide ion. The minimum and maximum deviations from the ideal 90° and 180° bond angles of a perfect octahedron are −14.8° for N(1)−Cd(1)−N(2) and −10.4° for Cl−Cd(2)−N(5), respectively. The mean cadmium−ligand bond lengths (Cd−N 2.421 Å, Cd−S 2.677 Å, Cd−Cl 2.703 Å) show no unusual features and compare well with those in **3** (see below) and related complexes with mixed N and S ligation.[20,22] It is also worth mentioning that the macrocycle in **2** adopts the "conical" calixarene-like conformation which differs from the alternative "partial cone" conformation seen in the related complexes $[(L^{Me})M_2(\mu\text{-}Cl)]^+$ of the lighter 3d elements Co^{II}, Ni^{II} and Zn^{II}.[15,24] The preference of the latter for adopting the "partial cone" conformation is presumably due to the smaller ionic radii of these metal ions (Co^{II}: 0.885 Å, Ni^{II}: 0.83 Å, Zn^{II}: 0.88 Å vs. 1.06 Å for Cd^{II})[23] and presumably also due to the rigid nature of the 24-membered macrocycle.

*[(L^{Me})Cd_2(μ-OAc)]BPh_4·2MeCN·MeOH (**3**·BPh_4·2MeCN·MeOH)*

The crystal structure determination of the title compound showed the structure of the dinuclear $[(L^{Me})Cd_2(\mu\text{-}OAc)]^+$ complex to be isostructural with the zinc complex $[(L^{Me})Zn_2(\mu\text{-}OAc)]^+$ (**1**).[16] The hexaaza-dithiophenolate ligand assumes a bowl-shaped "calixarene-like" conformation which is typical for carboxylato-bridged complexes of this ligand.[24] The acetate ion bridges the two cadmium ions in a symmetrical fashion [O(1)−C(39) 1.222(4) Å, O(2)−C(39) 1.232(4) Å] with a Cd···Cd distance of 3.402(2) Å. It is deeply buried in the binding cavity of the $[(L^{Me})Cd_2]^{2+}$ fragment. As a consequence, its methyl protons are positioned above the centre of the two phenyl rings in the shielding region. The angle between the planes through the two phenyl rings of 94.4° is larger than in **1** (80.0°). This explains why the acetate protons in **1** experience a larger high-field shift compared with those in **3** (vide supra). The average Cd−N bond length of 2.439 Å is normal for six-coordinate cadmium complexes with amine donor ligands.[25,26] The same holds for the average Cd−S distance of 2.669 Å and the average Cd−O distance of 2.238 Å.[27,28] As expected, the metal-ligand bond lengths in **3** are larger than those in **1**. The mean difference of 0.13 Å is close to the difference between the ionic radii of the two elements.

*[(L^{Me})Hg_2](BPh_4)$_2$·MeCN [**4**·(BPh_4)$_2$·MeCN]*

The crystal structure determination of **4**·$(BPh_4)_2$·MeCN unambiguously confirmed the identity of the dimercury(II) complex **4**. Its molecular structure is illustrated in Figure 3. The $[(L^{Me})Hg_2]^{2+}$ dication bears no additional coligands and has an intramolecular Hg···Hg separation of 3.725(1) Å. The Hg^{II} ions are surrounded by three nitrogen and two sulfur donor atoms from $(L^{Me})^{2-}$ in highly irregular N_3S_2 coordination environments (coordination number of Hg^{II}: 4 + 1). The intramolecular separations Hg(1)···S(1) of 2.897(2) Å and Hg(2)···S(2) of 3.313(2) Å are much longer than the other two Hg−S distances of 2.383 and 2.395 Å, indicating that the latter exhibit more covalent character while the former are more electrostatic in nature. The diethylene triamine units are *facially* coordinated with one large and two smaller N−Hg−N bond angles, this being the most commonly observed situation in complexes with this tridentate unit.[29] The Hg−N bond lengths (mean value: 2.413 Å) are somewhat longer in comparison with the more covalent Hg−S bonds but are similar to those in related mercury complexes.[30,31] In $[Hg(en)_2](ClO_4)_2$ for example (en = ethylene diamine), an average Hg−N distance of 2.32 Å has been reported.[32]

[a] Average values.

It should be noted that the configurations of the benzylic nitrogen atoms in the opposing diethylene triamine are different. Thus, the configurations are (*R*)-N(1) and (*R*)-N(3) for one diethylene linker, whereas they are (*S*)-N(4) and (*R*)-N(6) for the other. The differences in the secondary Hg···S interactions [i.e. Hg(2)···S(2), Hg(2)···S(1)] are, at least in part, a consequence of these different N configurations. They are also responsible for the C_1 symmetry of the $[(L^{Me})Hg_2]^{2+}$ dication.

[(L^Me)Pb2](ClO4)2·MeCN [5·(ClO4)2·MeCN]

This structure contains discrete $[(L^{Me})Pb_2]^{2+}$ cations, perchlorate anions and acetonitrile solvate molecules. Figure 4 shows the structure of the cation **5** together with the atomic numbering scheme. Similar to **4**, the dication is not bound to any further coligands. Complex **5** exhibits no crystallographically imposed symmetry but has idealized C_2 symmetry. The coordination environment of each lead(II) ion consists of three tertiary amine donors and one thiophenolate sulfur atom. The coordination geometry is best considered as distorted square pyramidal, with the lead ion sitting ca 1.3 Å above the plane formed from the four donor atoms [mean deviation from the planes N(1)N(2)N(3)S(2): 0.32 Å, N(4)N(5)N(6)S(1): 0.31 Å]. The empty space above the lead(II) ion on the apex of the pyramid is indicative of a stereochemically active lone pair as in PbO (yellow modification).[33] In contrast to the dimercury complex **4**, the diethylene triamine units bind in a meridional fashion which results in larger N(1)−Pb(1)−N(3) [137.0(3)°] and N(4)−Pb(2)−N(6) [139.3(3)°] angles. This has also been observed in lead complexes of macrodinucleating polyazaphenolate ligands.[34] The average Pb−N bond length of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2.526 Å is normal for lead(II) complexes.[35,36] The same is true for the Pb−S distances.

Conclusion

The main findings of the present work can be summarised as follows: a) The 24-membered hexaaza-dithiophenolate macrocycle H_2L^{Me} supports the formation of dinuclear complexes of Cd^{II}, Hg^{II} and Pb^{II}. b) The complexes dissolve in organic solvents without decomposition. c) The dicadmium complexes $[(L^{Me})M_2(\mu\text{-}L')]$ differ from the Hg and Pb complexes in that they bind additional coligands. This offers the opportunity to selectively recognise or separate Cd from a mixture of the three elements. d) The structures of $[(L^{Me})Hg_2]^{2+}$ and $[(L^{Me})Pb_2]^{2+}$ have clarified the binding preferences of the two toxic heavy metal ions towards the donors of H_2L^{Me}. This can now be used as a guide for fine-tuning the ligand to achieve high metal-ion selectivity. Current studies in this laboratory are focusing on the determination of the complex stability constants and on methods of metal-ion extraction.

Experimental Section

General: Unless otherwise noted, the preparations of the metal complexes were carried out under argon using standard Schlenk techniques. The compound $H_2L^{Me}\cdot 6HCl$ was prepared as described in the literature.[15,37] All other compounds and reagents were purchased. Melting points were determined in capillaries and are uncorrected. ^1H and ^{13}C NMR spectra were recorded with a Bruker AVANCE DPX-200 or a Varian 300 unity spectrometer. Elemental analyses were performed with a Vario EL analyser (Elementaranalysensysteme GmbH). IR spectra were recorded with a Bruker VECTOR 22 FT-IR spectrometer as KBr pellets.

Safety Note: *Caution; perchlorate salts of transition metal complexes are hazardous and may explode; only small quantities should be prepared and great care should be taken!*

$[(L^{Me})Cd_2(\mu\text{-}Cl)]ClO_4$ (2·ClO_4): To a suspension of $H_2L^{Me}\cdot 6HCl$ (890 mg, 1.00 mmol) in methanol (40 mL) was added solid $CdCl_2\cdot H_2O$ (403 mg, 2.00 mmol). A solution of triethylamine (808 mg, 8.00 mmol) in methanol (2 mL) was then added to give a colourless solution. After stirring at room temperature for 3 h, solid $LiClO_4\cdot 3H_2O$ (2.50 g, 15.6 mmol) was added to give the perchlorate salt **2**·ClO_4 as a white microcrystalline solid. This material was filtered, washed with cold ethanol (5 mL) and diethyl ether (5 mL), and dried in vacuo. Yield 876 mg (85%). M.p. 302−303 °C (decomposes without melting). IR (KBr pellet): $\tilde{\nu}$ = 3446 s br, 2958 s, 2865 s, 1630 m, 1457 s, 1394 w, 1365 m, 1314 m, 1291 m, 1267 m, 1234 m, 1203 w, 1168 w, 1158 w, 1100 vs. [$\nu(ClO_4)$], 1046 s, 1012 w, 1000 w, 978 m, 928 m, 910 m, 887 m, 815 s, 802 m, 746 m, 686 w, 664 w, 624 s, 593 w, 555 w, 484 w cm^{-1}. ^1H NMR (300 MHz, CD_3CN, 25 °C, TMS): δ = 7.20 (s, 4 H, ArH), 4.70 [d, ^2J = 11.5, $^3J(^{111,113}Cd\text{-}^1H)$ = 4.6 Hz, 4 H, $ArCH_2$], 3.42 (m, 4 H, NCH_2), 3.24 (m, 4 H, NCH_2), 2.88−2.78 (m, 4 H +4 H, NCH_2+$ArCH_2$), 2.84 (s, 6 H, NCH_3), 2.50 (m, 4 H, NCH_2), 2.33 [s, $^3J(^{111,113}Cd\text{-}^1H)$ = 4.6 Hz, 12 H, *Bz*NCH_3], 1.26 [s, 18 H, $C(CH_3)_3$] ppm. $^{13}C\{^1H\}$ NMR (75.42 MHz, $[D_3]CH_3CN$, 25 °C, TMS): δ = 147.1, 141.8, 135.8 (CH), 131.0 (CH) (aromatic carbon atoms), 63.8, 60.8, 58.0 (all CH_2), 50.1, 46.0 (all NCH_3), 34.7 [$C(CH_3)_3$], 31.6 [$C(CH_3)_3$] ppm. $C_{38}H_{64}Cd_2Cl_2N_6O_4S_2$ (1028.81): calcd. C 44.36, H 6.27, N 8.17, S 6.23; found C 43.92, H 6.12, N 8.00, S 5.77. The tetraphenylborate salt, $[(L^{Me})Cd_2(\mu\text{-}Cl)]BPh_4$ (**2**·BPh_4), was prepared by adding a solution of $NaBPh_4$ (198 mg, 0.580 mmol) in methanol (3 mL) to an argon-purged solution of **1**·ClO_4 (103 mg, 0.100 mmol) in methanol (50 mL). The resultant colourless precipitate was isolated by filtration, washed with 5 mL of cold methanol and dried in air. Yield 112 mg (90%). M.p. 293−294 °C (decomp.). IR (KBr pellet): $\tilde{\nu}$ = 3053 m, 3032 w, 2996 w, 2964 s, 2925 w, 2900 w, 2862 m, 2835 w, 2807 w, 1477 m, 1457 s, 1425 m, 1394 m, 1365 m, 1352 w, 1313 m, 1290 m, 1267 m, 1232 m, 1203 w, 1181 w, 1170 w, 1157 m, 1131 w, 1114 w, 1083 s, 1044 s, 1011 w, 1000 w, 981 w, 927 w, 910 m, 887 m, 844 m, 815 m, 802 m, 734 s, 705 s [$\nu(BPh_4^-)$], 625 m, 612 m, 555 w, 475 w cm^{-1}. The tetraphenylborate salt was additionally characterised by X-ray crystallography.

$[(L^{Me})Cd_2(\mu\text{-}OAc)]ClO_4$ (3·ClO_4): To a solution of **2**·ClO_4 (103 mg, 0.100 mmol) in methanol (50 mL) was added a solution of sodium acetate (12.3 mg, 0.150 mmol) in methanol (5 mL). After the reaction mixture had been stirred for 3 h, a solution of $LiClO_4\cdot 3H_2O$ (802 mg, 5.00 mmol) in methanol (2 mL) was added. The resultant colourless microcrystalline solid was isolated by filtration, washed with methanol and dried in air. Yield 91 mg (86%). M.p. 352−353 °C (decomp.). IR (KBr, pellet): $\tilde{\nu}$ = 2960 s, 2900 m, 2865 s, 2837 sh, 2806 m, 1577 s [$\nu_{as}(OAc^-)$], 1456 s, 1422 s [$\nu_s(OAc^-)$], 1396 w, 1365 m, 1314 w, 1293 m, 1267 m, 1230 m, 1203 m, 1170 w, 1155 w, 1093 vs. [$\nu(ClO_4^-)$], 1044 s, 1012 w, 1000 w, 981 w, 925 w, 911 m, 884 m, 816 s, 802 m, 744 m, 684 w, 654 m, 624 s, 596 w, 555 w, 535 w cm^{-1}. ^1H NMR (200 MHz, $[D_3]CH_3CN$, 25 °C, TMS): δ = 7.12 (s, 4 H, ArH), 4.54 (d, ^2J = 11.5 Hz, 4 H, $ArCH_2$), 3.40 (m, 4 H, CH_2), 3.18 (m, 4 H, CH_2), 2.84 (s, 6 H, NCH_3), 2.82 (m, 4 H, CH_2), 2.74 (d, 4 H, $ArCH_2$), 2.48 (m, 4 H, CH_2), 2.36 (s, 12 H, NCH_3), 1.23 (s, 18 H, CH_3), 0.98 (s, 3 H, O_2CCH_3) ppm. ^{13}C NMR (75.42 MHz, $[D_3]CH_3CN$, 25 °C, TMS): δ = 176.3 (OAc), 146.4, 141.5, 136.1, 130.5, 63.0 (CH_2), 60.4 (CH_2), 57.9 (CH_2), 50.3 (NCH_3), 46.7 (NCH_3), 34.7 (*C*), 31.6 [$C(CH_3)_3$], 23.2 (OAc) ppm. The tetraphenylborate salt, $[(L^{Me})Cd_2(\mu\text{-}OAc)]BPh_4$ (**3**·BPh_4), was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of **3**·ClO_4 (103 mg, 0.100 mmol) in methanol (50 mL). The resultant colourless solid was recrystallised from a mixed acetonitrile/methanol (1:1) solvent system. Yield 116 mg (91%). M.p. 304−305 °C (decomp.). IR (KBr pellet): $\tilde{\nu}$ = 3055 m, 3034 m, 2908 sh, 2963 s, 2924 m, 2899 m, 2866 m, 2836 m, 2804 w, 1576 s [$\nu_{asym}(OAc^-)$], 1476 w, 1455 s, 1425 s [$\nu_{sym}(OAc^-)$], 1395 w, 1364 w, 1353 w, 1313 w, 1291 w, 1267 w, 1230 w, 1203 w, 1181 w, 1170 w, 1155 m, 1133 w, 1116 w, 1082 s, 1045 s, 1012 w, 996 w, 981 w, 924 m, 911 m, 886 m, 842w, 815 s, 800 m, 744 m, 734 s, 704 s [$\nu(BPh_4^-)$], 653 w, 625 m, 612 m, 594 w, 556 w cm^{-1}. $C_{64}H_{87}BCd_2N_6O_2S_2$ (1272.18): calcd. C 60.42, H 6.89, N 6.61, S 5.04; found C 60.24, H 6.72, N 6.47, S 4.94. This salt was additionally characterised by X-ray crystallography.

$[(L^{Me})Hg_2](ClO_4)_2$ [4·$(ClO_4)_2$]: To a suspension of $H_2L^{Me}\cdot 6HCl$ (890 mg, 1.00 mmol) in methanol (40 mL) was added a solution of $Hg(CH_3COO)_2$ (637 mg, 2.00 mmol) in methanol (10 mL). A solution of triethylamine (808 mg, 8.00 mmol) in methanol (5 mL) was then added to give a colourless solution. The reaction mixture was stirred for 12 h after which time a solution of $LiClO_4\cdot 3H_2O$ (802 mg, 5.00 mmol) in methanol (2 mL) was added. The resultant colourless microcrystalline solid was isolated by filtration, washed with methanol and dried in air. Yield 901 mg (71%). M.p. 246−247 °C (decomp). IR (KBr pellet): $\tilde{\nu}$ = 2958 s, 2902 w, 2864 s, 1463 m, 1394 w, 1366 m, 1307 w, 1290 w, 1266 w, 1231 m, 1202 w, 1183 w,

Crystal Structure Determinations: Single-crystals suitable for X-ray structural analyses were grown by recrystallisation from methanol (**2**·BPh_4·1.5MeOH), acetonitrile [**4**·(BPh_4)$_2$·MeCN, **5**(ClO_4)$_2$·MeCN] or a mixed acetonitrile/methanol solvent system (**3**·BPh_4·2MeCN·MeOH). The crystals were mounted on glass fibres using perfluoropolyether oil. Intensity data were collected at 210(2) K using a Bruker SMART CCD diffractometer. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. The data were processed with SAINT and corrected for absorption using SADABS[38] (transmission factors: 1.00−0.95 for **2**·BPh_4, 1.00−0.85 for **3**·BPh_4, 1.00−0.64 for **4**·(BPh_4)$_2$ and 1.00−0.70 for **5**·(ClO_4)$_2$]. The structures were solved by direct methods using the program SHELXS-86[39] and refined by full-matrix least-squares techniques against F^2 using SHELXL-97.[40] The SHELXTL version 5.10 program package was used for the structure solutions and

refinements.[41] PLATON was used to search for higher symmetry.[42] ORTEP3 was used for generating the ORTEP diagrams.[43] Unless otherwise noted, the anisotropic thermal parameters of all nonhydrogen atoms were refined. Hydrogen atoms were included in calculated positions with their bond lengths and thermal parameters 1.2 times (1.5 times for CH_3 groups) the thermal parameter of the atoms to which they are attached. Selected details of the data collection and refinements are given in Table 4. In the crystal structure of **2**·BPh_4·1.5MeOH one *tert*-butyl group was found to be disordered over two positions. A split atom model was applied for the disordered *t*Bu groups. The site occupancies of the two orientations were refined as 0.67(1)/0.33(1) [for C(36a/c), C(37a/c), C(38a/c)]. In the crystal structure of **3**·BPh_4·2MeCN·MeOH the methanol solvent molecule of crystallisation was found to be disordered over two positions. The site occupancies of the two orientations were fixed at half occupancy. The C and O atoms of this molecule were refined isotropically. In the crystal structure of **4**·$(BPh_4)_2$·MeCN, the *tert*-butyl groups were found to be disordered over two positions. A split atom model was applied for these alkyl groups. The site occupancies of the two orientations were refined as 0.66(3)/0.34(3) [for C(32a/c), C(33a/c), C(34a/c)] and 0.56(2)/0.44(2) [for C(36a/c), C(37a/c), C(38a/c)]. The non-hydrogen atoms of the disordered *t*Bu groups and the acetonitrile solvate molecule were refined isotropically. No hydrogen atoms were calculated for these two residues. In the crystal structure of **5**·$(ClO_4)_2$, the acetonitrile molecule of solvation and one of the two perchlorate anions were found to be disordered over two positions. The site occupancy factors of the two orientations of the acetonitrile molecule were fixed at 0.50 and its C and N atoms were refined isotropically. No hydrogen atoms were calculated for the MeCN molecule. The site occupancy factors of the two orientations of the perchlorate anion were refined as 0.68(2) and 0.32(2) for O(5)O(6a)O(7a)O(8a) and O(5)O(6b)O(7b)O(8b). These atoms could not be refined anisotropically and, for this reason, were treated as isotropic scatterers. CCDC-243454 (**2**), -243455 (**3**), -243456 (**4**) and -243457 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are particularly grateful to Prof. Dr. H. Vahrenkamp for providing facilities for NMR spectroscopic and X-ray crystallographic measurements. Financial support of this work from the Deutsche Forschungsgemeinschaft (Priority programme "Sekundäre Wechselwirkungen", KE 585/3-1,2) and the Wissenschaftliche Gesellschaft in Freiburg is gratefully acknowledged.

Synthesis of Group 14 Metal Enamido, Alkenyl, Imido and Alkenyl-Amido Complexes from a Monoanionic Pyridyl-1-azaallyl Ligand

Wing-Por Leung,*[a] Cheuk-Wai So,[a] Yuen-Sze Wu,[a] Hung-Wing Li,[a] and Thomas C. W. Mak[a]

Keywords: Germanium / Group 14 elements / Lead / N ligands / Tin

The reactivity of the lithium pyridyl-1-azaallyl complex [Li{N(SiMe$_3$)C(Ph)C(R)(C$_5$H$_4$N-2)}]$_2$ [R = SiMe$_3$ (**1**) or H (**10**)] with group 14 metal halides has been studied under various conditions. It undergoes a salt-elimination reaction with MCl$_2$ (M = Ge, Sn or Pb) to form [Ge{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)$_2$}{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}] (**2**), [M{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}$_2$] [M = Sn (**3**), Pb (**4**)], and [M{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}Cl] [M = Ge (**5**), Sn (**6**), Pb (**7**)], where the azaaalyl moiety acts as a monodentate ligand. However, the reaction of **1** with GeCl$_4$ or HSiCl$_3$ forms [Ge{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)}Cl$_2$]$_2$ (**8**) or [{(C$_5$H$_4$N-2)C(SiMe$_3$)C(Ph)N}(μ-SiHCl)]$_2$ (**9**), respectively, by elimination of both the lithium salt and Me$_3$SiCl; the reaction of **10** with GeCl$_4$ gives [{(C$_5$H$_4$N-2)C(H)C(Ph)N}(μ-GeCl$_2$)]$_2$ (**11**) in a similar manner. X-ray structural analysis of compounds **2**–**5**, **7**–**9** and **11** showed that the pyridyl-1-azaallyl ligand bonds to the metal center in enamido, alkenyl, alkenyl-amido, and imido bonding modes. A mechanism for the formation of these compounds is proposed and discussed.

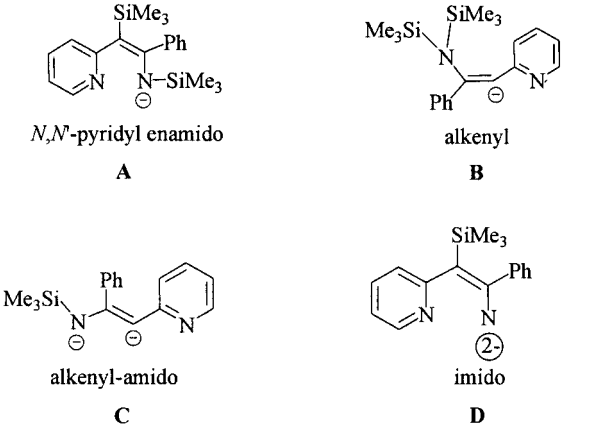
Introduction

Alkali metal 1-azaallyl complexes are commonly used as monoanionic ligand-transfer reagents in the synthesis of main-group, transition-metal, and lanthanide complexes.[1] For example, [Ni{N(R)C(Ph)C(H)(R)}$_2$],[2] [Mg{N(R)C(*t*Bu)C(H)(R)}$_2$],[3] [Cu{μ-N(R)C(*t*Bu)C(H)(R)}]$_2$,[4] [Al{N(R)C(Ph)C(R)$_2$}Cl$_2$],[5] and [Yb{N(R)C(*t*Bu)C(H)(R)}$_2$][6] (R = SiMe$_3$) have been prepared. 1-Azaallyllithium complexes can be prepared by insertion of Li(CH$_{3-n}$R$_n$) (n = 1, 2 or 3; R = SiMe$_3$) into an α-H-free nitrile R′CN (R′ = *t*Bu, Ph or 2,6-Me$_2$C$_6$H$_3$). Other alkali metal 1-azaallyl complexes can be derived from the metathesis reaction of lithium complexes with MO*t*Bu (M = Na or K).[7]

We have reported the synthesis of [MCl$_2${N(SiMe$_3$)C(Ph)C(H)(C$_9$H$_6$N-2)}] (M = Hf and Zr) from the reaction of MCl$_4$ with the quinolyl-1-azaallyllithium complex [Li{N(SiMe$_3$)C(Ph)C(H)(C$_9$H$_6$N-2)}]$_2$ previously.[8] In this paper we report different reactivities of the pyridyl-1-azaallyllithium compound [Li{N(SiMe$_3$)C(Ph)C(R)(C$_5$H$_4$N-2)}]$_2$ [R = SiMe$_3$ (**1**) or H (**10**)][9] with a variety of Group 14 metal halides. It acts as both a monoanionic and dianionic ligand by using the SiMe$_3$ group as the leaving group during the metathesis reaction. The pyridyl-1-azaallyl ligand can bind to a metal in bonding modes **A**−**D** (Scheme 1).



Scheme 1

Results and Discussion

Synthesis of Group 14 Metal Pyridyl-1-azaallyl Complexes

Treatment of [Li{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}]$_2$ (**1**) with an equimolar amount of GeCl$_2$·dioxane in Et$_2$O afforded [Ge{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)$_2$}{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}] (**2**) (Scheme 2). The X-ray structure shows that the germanium(II) center in **2** is bonded to an *N*,*N*′-pyridyl-enamido ligand and an η^1-alkenyl ligand, which suggests that the smaller size of the germanium

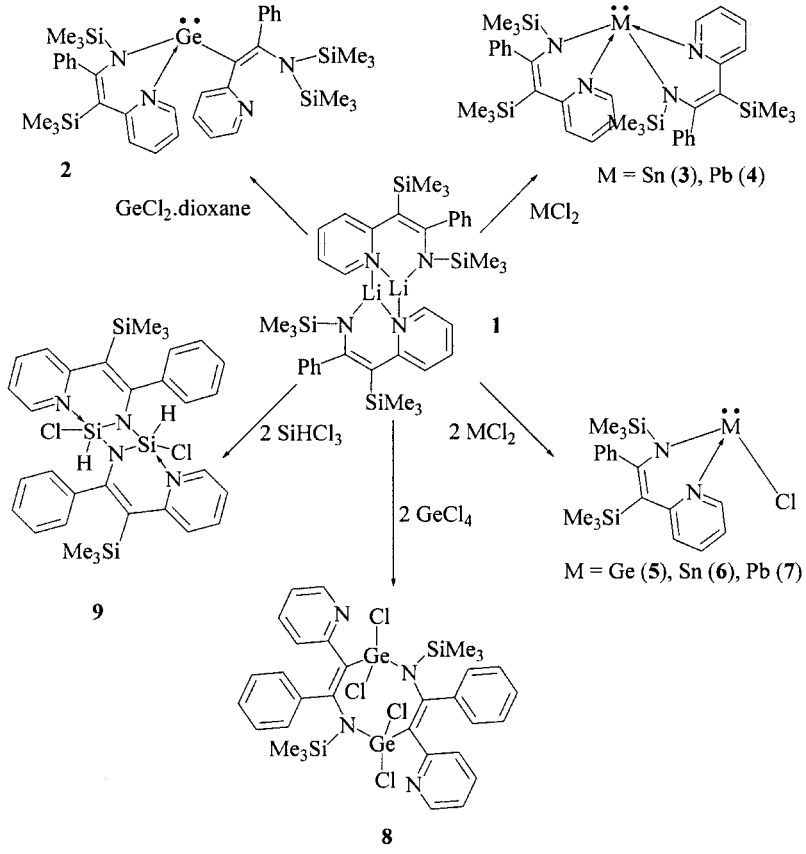


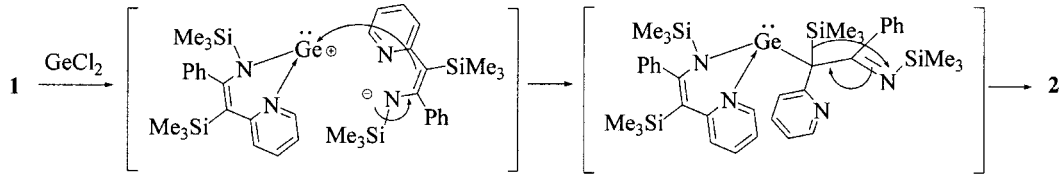
Scheme 2

center prevents both pyridyl-1-azaallyl ligands from bonding in an *N*,*N*′-chelate fashion. One of the ligands has undergone a 1,3-silyl migration in order to release the steric crowding at the germanium(II) center (Scheme 3). A similar silyl migration has been reported in the thermal isomerization of the ketimine $[Me_3SiN{=}C(CMe_3)CH(SiMe_3)_2]$ to the enamine $[(Me_3Si)_2NC(CMe_3){=}CH(SiMe_3)]$.[10] In another example, a 1,2-silyl migration on the 1-azaallyl ligand backbone results in the formation of the asymmetric distannene [{1-[N(*t*Bu)C(SiMe$_3$)C(H)]-2-[N(*t*Bu)CC(H)]C$_6$H$_4$}-Sn→Sn{1,2-[N(*t*Bu)(SiMe$_3$)CC(H)]$_2$C$_6$H$_4$}].[11]

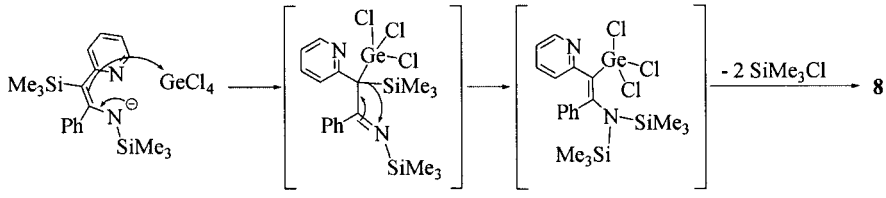
A similar reaction of **1** with MCl_2 (M = Ge, Sn or Pb) in a 1:1 or 1:2 ratio gave the metal enamides [M{N(SiMe$_3$)-C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}$_2$] [M = Sn (**3**) and Pb (**4**)] or [M{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}Cl] [M = Ge (**5**), Sn (**6**) and Pb (**7**)], respectively (Scheme 2).

The reaction of **1** with two equivalents of $GeCl_4$ in THF, however, afforded [Ge{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)}Cl$_2$]$_2$ (**8**). The X-ray structure of **8** shows that the germanium center is bonded to two alkenyl-amido ligands to form an eight-membered heterocyclic ring. The pyridyl-1-azaallyl ligand acts here as a *C*-centered nucleophile, and undergoes 1,3-silyl migration and elimination of Me_3SiCl to form **8** (Scheme 4).

Treatment of **1** with two equivalents of $HSiCl_3$ in THF afforded [{(C$_5$H$_4$N-2)C(SiMe$_3$)C(Ph)N}(μ-SiHCl)]$_2$ (**9**).

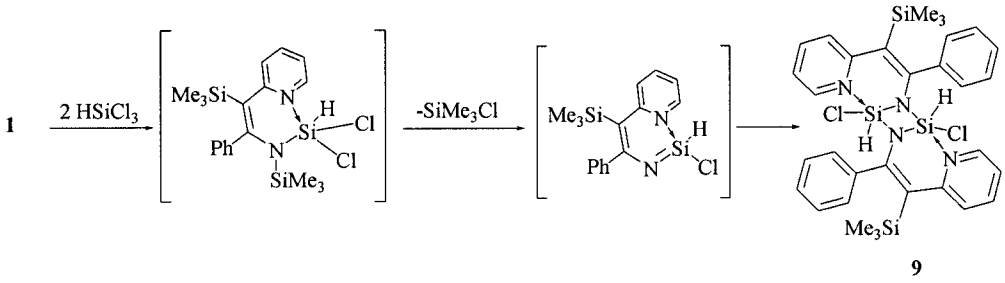


Scheme 3



Scheme 4

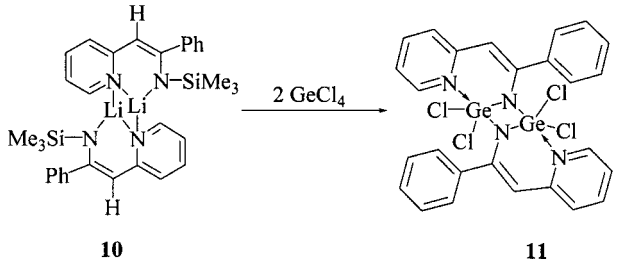
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5

The X-ray structure of **9** shows that the pyridyl-1-azaallyl ligand acts as an *N*-centered nucleophile rather than a *C*-centered towards $HSiCl_3$. The intermediate $[HSi\{N(SiMe_3)C(Ph)C(SiMe_3)(C_5H_4N\text{-}2)\}Cl_2]$ eliminates Me_3SiCl and dimerizes to form compound **9** (Scheme 5). Each silicon center is bonded to two imido ligand to form a four-membered ring. A similar result has been reported in the synthesis of $ClPN(R)P(Cl)NR$ [R = C(*t*Bu)=C(H)$SiMe_3$] from the reaction of $[Li\{N(SiMe_3)C(tBu)C(H)(SiMe_3)\}]_2$ and PCl_3.[10]

In contrast, the reaction of $[Li\{N(SiMe_3)C(Ph)C(H)(C_5H_4N\text{-}2)\}]_2$ (**10**) with two equivalents of $GeCl_4$ in THF gave $[\{(C_5H_4N\text{-}2)C(H)C(Ph)N\}(\mu\text{-}GeCl_2)]_2$ (**11**), with a structure similar to that of **9** (Scheme 6). The $C_{alkenyl}-H$ bond is much stronger than the $C_{alkenyl}-SiMe_3$ bond, therefore a 1,3-H shift is less feasible than a 1,3-silyl migration. The pyridyl-1-azaallyl ligand preferably acts as an *N*-centered nucleophile; the formation of **11** is similar to that of **9**.



Scheme 6

Spectroscopic Properties

Compounds **2**−**9** and **11** are yellow crystalline solids that are soluble in Et_2O, toluene, and THF, and sparingly soluble in hydrocarbon solvents. The ^1H and ^{13}C NMR spectra of **2** display three sharp singlets in ratio of 1:1:2 assignable to the three types of $SiMe_3$ groups, this is consistent with the solid-state structure.

The ^1H and ^{13}C NMR spectra of **3**−**7** show a similar pattern and display one set of signals due to the pyridyl-1-azaallyl ligand. The chemical shifts of the ^{119}Sn NMR signals of **3** (δ = −140.0 ppm) and **6** (δ = −197.95 ppm) are similar to those of four-coordinate $[Sn\{N(SiMe_3)C(Ph)NC(Ph)=C(SiMe_3)_2\}_2]$ (δ = −141.4 ppm)[12] and three-coordinate $[\{HC(CMeNAr)_2\}SnCl]$ (δ = −224.0 ppm),[13] respectively.

The ^1H NMR spectra of **8**, **9** and **11** show one set of signals due to the pyridyl and phenyl rings. In the ^1H NMR spectrum of **9**, the Si−H chemical shift (δ = 5.46 ppm) is similar to that in $[SiH\{(C_{10}H_6\text{-}2)(NMe_2)\}_3]$ (δ = 6.61 ppm)[14] and $[SiH_2\{(C_6H_3\text{-}2,6)(NMe_2)_2\}]$ (δ = 4.87 ppm).[15] In the ^1H NMR spectrum of **11** the *H*-C=C signal (δ = 5.09 ppm) is shifted upfield relative to the value of δ = 6.24 ppm in $[Li\{N(SiMe_3)C(Ph)C(H)(C_5H_4N\text{-}2)\}]_2$ (**10**).

X-ray Crystal Structures

Compound **2** (Figure 1, Table 1) is a monomeric, heteroleptic germylene complex. The germanium center is bonded to an *N*,*N*′-pyridyl-enamido chelate and a monohapto η^1-alkenyl ligand. The Ge−C(26) bond length of 2.039(2) Å is similar to the Ge−C single bond lengths of 2.067 Å and 2.012 Å in $[Ge\{CH(SiMe_3)_2\}\{C(SiMe_3)_3\}]$[16] and 2.116 Å in $[Ge\{CPh(SiMe_3)C_5H_4N\text{-}2\}_2]$.[17] The Ge−N(2) bond length of 1.940(2) Å in **2** is comparable to those of 2.096(1) Å and 2.088(6) Å in $[Ge\{N(SiMe_3)_2\}_2]$[18] and 1.90(1) Å and 1.87(1) Å in $[Ge\{NCMe_2(CH_2)_3CMe_2\}_2]$.[19]

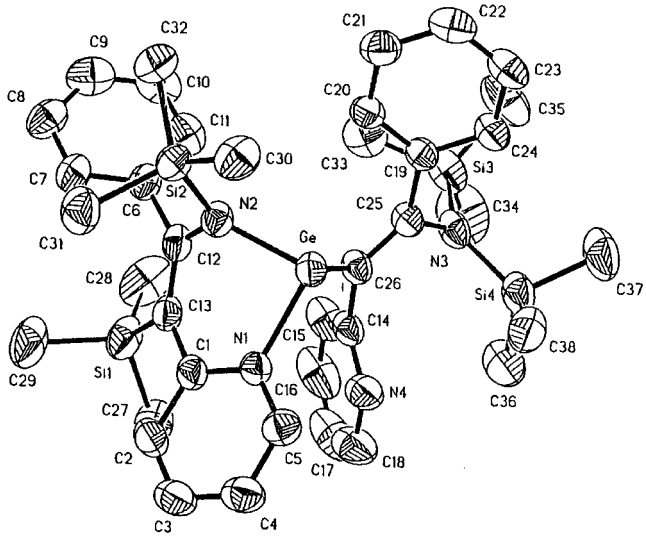


Figure 1. Molecular structure of **2**

Compounds **3** and **4** (Figure 2, Table 2) are isostructural. The $Sn-N_{amide}$ bond lengths of 2.162(2) Å and 2.174(2) Å in **3** are similar to that of 2.130 Å in the κ^1-enamidotin(II)

complex [Sn{N(SiMe$_3$)C(*t*Bu)C(H)C$_6$H$_3$Me$_2$-2,5}$_2$], but significantly shorter than that of 2.510(2) Å in the η^3-(1-azaallyl)tin(II) complex [Sn{N(SiMe$_3$)C(*t*Bu)C(H)(SiMe$_3$)}$_2$].[20] The Pb−N$_{amide}$ bond lengths of 2.277(7) Å and 2.275(7) Å in **4** are shorter than that of 2.381(7) Å in the η^3-(1-azaallyl)lead(II) complex [Pb{N(SiMe$_3$)C(Ph)C(SiMe$_3$)$_2$}Cl].[21] The short C(6)−C(10) and C(25)−C(29) and long N(2)−C(10) and N(4)−C(29) bond lengths correspond to double and single bonds, respectively. Thus, the bonding within the NCCCN ligand backbone is localized, and the pyridyl-1-azaallyl ligand bonds to the metal center in an enamido bonding mode.

Compounds **5** and **7** (Figure 3, Table 3) are isostructural. The metal−amide bond lengths of 1.920(2) Å and 2.279(7) Å in **5** and **7** are similar to those in **2** and **4**, respectively. The Ge−Cl bond length of 2.283(9) Å in **5** is similar to that of 2.203(10) Å in [Ge(C$_6$H$_3$-2,6-Trip$_2$)Cl][22] (Trip = C$_6$H$_2$-2,4,6-*i*Pr$_3$) and 2.295(12) Å in [{HC(CMeNAr)$_2$}GeCl].[13]

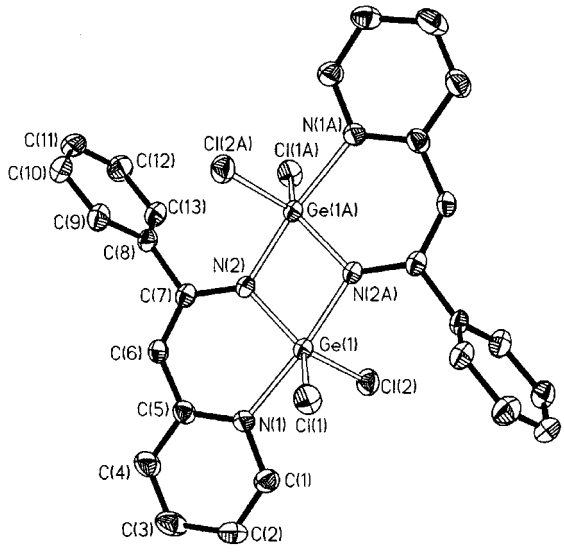

Figure 6. Molecular structure of **11**

larger than the N−Ge−C angle of 105.2(2)° in **2**. The Ge(1)−C(1) [1.924(7) Å] and Ge(1)−N(2) [1.813(6) Å] bond lengths in **8** are shorter than the Ge−C and Ge−N distances of 2.039(2) Å and 1.942(17) Å, respectively, in **2**.

The molecular structures of **9** (Figure 5, Table 4) and **11** (Figure 6, Table 4) are similar. They are centrosymmetric with the metal centers bonded to two imino nitrogen atoms to form a planar N_2M_2 ring [M = Si (**9**), Ge (**11**)]. The geometry around the metal center is trigonal bipyramidal with the N-donor at the axial position. The average bond length of 1.802 Å within the Si_2N_2 ring in **9** is longer than that of 1.750 Å in [{μ-MesN}Si(H)(*t*Bu)]$_2$ [23] and 1.770 Å in [Me_2Si(μ-*N*-C_9H_6N)(μ-*N*-C_9H_6N)SiMe_2].[24] The Ge−N_{imino} bond lengths of 1.843(2) Å and 1.944(2) Å in **11** are longer than those reported in similar Ge_2N_2 ring systems, such as [{N(CH_3)CH_2CH_2N(CH_3)}Ge{μ-NSi(O*t*C_4H_9)}]$_2$ (1.836 Å and 1.843 Å).[25]

Conclusion

A series of Group 14 metal pyridyl-1-azaallyl complexes has been synthesized: [Ge{C(C_5H_4N-2)C(Ph)N($SiMe_3$)$_2$}-{N($SiMe_3$)C(Ph)C($SiMe_3$)(C_5H_4N-2)}] (**2**), [M{N($SiMe_3$)C-(Ph)C($SiMe_3$)-(C_5H_4N-2)}$_2$] [M = Sn (**3**), Pb (**4**)], [M{N($SiMe_3$)C(Ph)C($SiMe_3$)(C_5H_4N-2)}Cl] [M = Ge (**5**), Sn (**6**), Pb (**7**)], [Ge{C(C_5H_4N-2)C(Ph)N($SiMe_3$)}Cl_2]$_2$ (**8**), [{(C_5H_4N-2)C($SiMe_3$)C(Ph)N}(μ-SiHCl)]$_2$ (**9**) and [{(C_5H_4N-2)C(H)C(Ph)N}(μ-$GeCl_2$)]$_2$ (**11**). The results show that the pyridyl-1-azaallyl ligand bonds to the metal center in enamido and alkenyl bonding modes in compound **2**, an enamido mode in compounds **3**−**7**, an alkenyl-amido mode in compound **8**, and an imido mode in compounds **9** and **11**.

Experimental Section

General Remarks: All manipulations were performed under an inert atmosphere of dinitrogen gas by standard Schlenk techniques. Solvents were dried over and distilled from CaH_2 (hexane) and/or Na (Et_2O, toluene and THF). Anhydrous $SnCl_2$, $PbCl_2$, $GeCl_4$, and $HSiCl_3$ were purchased from Aldrich Chemicals and used without further purification. $GeCl_2$·dioxane[26] and [Li{N($SiMe_3$)C-(Ph)C(R)(C_5H_4N-2)}]$_2$ (R = Ph, H)[9] were prepared by literature procedures. The ^{1}H, ^{13}C and ^{119}Sn NMR spectra were recorded on Bruker WM-300 or Varian 400 instruments. All spectra were recorded in [D_6]benzene or [D_8]THF, and the chemical shifts are quoted relative to $SiMe_4$ and $SnMe_4$ for ^{1}H/^{13}C and ^{119}Sn, respectively.

[Ge{C(C_5H_4N-2)C(Ph)N($SiMe_3$)$_2$}{N($SiMe_3$)C(Ph)C($SiMe_3$)-(C_5H_4N-2)}] (2): A solution of **1** (3.75 g, 5.41 mmol) in Et_2O (30 mL) was added slowly to a suspension of $GeCl_2$·dioxane (1.25 g, 5.41 mmol) in Et_2O (25 mL) at 0 °C. The orange mixture was warmed to ambient temperature and stirred for 16 h. The solvent was then removed under reduced pressure and the residue was extracted with toluene (50 mL). The precipitate was filtered and the orange filtrate was concentrated. *n*-Hexane (5 mL) was added and the solution was kept at 4 °C for 1 day to yield orange crystals of **2**. Yield: 2.55 g (62%); m.p.: 206−208 °C (dec.). $C_{38}H_{54}GeN_4Si_4$: calcd. C 60.75, H 7.19, N 7.46; found C 60.69, H 7.19, N 7.70. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = −0.04 (s, 9 H, $SiMe_3$), 0.06 (s, 18 H, $SiMe_3$), 0.21 (s, 9 H, $SiMe_3$), 6.52 (t, J = 6.3 Hz, 1 H, py), 6.67 (br, 1 H, py), 7.05 (m, 5 H, Ph), 7.12 (br, 3 H, py), 7.50 (m, 5 H, Ph), 7.77 (d, J = 6.9 Hz, 2 H, py), 8.59 (d, J = 4.8 Hz, 1 H, py) ppm. ^{13}C{^{1}H} NMR (300 MHz, C_6D_6, 25 °C): δ = 2.94, 3.02, 3.11 ($SiMe_3$), 114.21 (*C*$SiMe_3$), 117.93, 118.98, 119.13, 123.73, 124.20, 124.96, 125.59, 127.39, 127.79, 128.33, 128.79, 129.00, 130.69, 131.13, 135.05, 136.66, 144.09, 145.31, 147.22, 147.99, 150.80, 153.57 (Ph and Py), 155.88 (py*C*Ge), 166.79, 171.46 (N*C*Ph) ppm.

[Sn{N($SiMe_3$)C(Ph)C($SiMe_3$)(C_5H_4N-2)}$_2$] (3): A solution of **1** (0.71 g, 1.02 mmol) in Et_2O (30 mL) was added slowly to a suspension of $SnCl_2$ (0.19 g, 1.02 mmol) in Et_2O (25 mL) at 0 °C. The yellow mixture was then warmed to ambient temperature and stirred for 16 h. The solvent was removed under reduced pressure and the residue was extracted with toluene (50 mL). The precipitate was filtered and the yellow filtrate was concentrated. *n*-Hexane (5 mL) was added and kept at 4 °C for 1 day to yield yellow crystals of **3**. Yield: 0.42 g (52%); m.p.: 149−151 °C (dec.). $C_{38}H_{54}N_4Si_4Sn$: calcd. C 57.20, H 6.82, N 7.02; found C 56.82, H 6.83, N 6.94. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = −0.16 (s, 9 H, $SiMe_3$), −0.03 (s, 9 H, $SiMe_3$), −0.01 (s, 9 H, $SiMe_3$), 0.22 (s, 9 H, $SiMe_3$), 6.49 (br, 1 H, py), 6.57 (m, 2 H, py), 7.08 (m, 5 H, Ph), 7.49 (m, 3 H, py), 7.75 (d, J = 6.90 Hz, 5 H, Ph), 8.83 (br, 1 H, py), 9.09 (br, 1 H, py) ppm. ^{13}C{^{1}H} NMR (300 MHz, C_6D_6, 25 °C): δ = 1.38, 2.41, 3.65, 4.59 ($SiMe_3$), 118.08, 118.77 (*C*$SiMe_3$), 118.87, 123.91, 124.10, 124.80, 125.64, 127.23, 127.68, 128.56, 129.28, 130.47, 131.12, 135.20, 135.58, 137.07, 141.95, 144.29, 146.06, 147.51, 147.68, 147.98, 151.68, 158.76, 159.24 (Ph and Py), 168.17, 173.09 (N*C*Ph) ppm. ^{119}Sn{^{1}H} NMR (149 MHz, C_6D_6, 25 °C): δ = −140.00 ppm.

[Pb{N($SiMe_3$)C(Ph)C($SiMe_3$)(C_5H_4N-2)}$_2$] (4): A solution of **1** (0.96 g, 1.38 mmol) in Et_2O (20 mL) was added slowly to a solution of $PbCl_2$ (0.38 g, 1.38 mmol) in Et_2O (20 mL) at −90 °C in the absence of light. The yellow suspension was warmed to ambient temperature and stirred for 18 h. The precipitate was then filtered. *n*-Hexane was added to the filtrate, concentrated under reduced

pressure and stored at −30 °C. Compound **4** was obtained as yellow crystals. Yield: 0.45 g (37%); m.p.: 201−203 °C. $C_{38}H_{54}N_4PbSi_4$: calcd. C 51.49, H 6.14, N 6.32; found C 51.12, H 6.06, N 6.27. ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): δ = −0.28 (s, 9 H, $SiMe_3$), −0.21 (s, 9 H, $SiMe_3$), 6.95−7.01 (m, 1 H, 5-py), 7.18−7.24 (d, J = 8.0 Hz, 1 H, 3-py), 7.35−7.41 (m, 3 H, Ph), 7.42−7.48 (m, 2 H, Ph), 7.55−7.64 (m, 1 H, 4-py), 8.45 (d, J = 4.1 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]THF, 25 °C): δ = 1.17, 2.34 ($SiMe_3$), 119.48 (*C*$SiMe_3$), 121.80, 123.43, 125.29, 128.52, 129.64, 131.79, 135.90, 142.62, 148.02, 150.03, 159.77 (Ph and Py), 164.63 (N*C*Ph).

[Ge{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}Cl] (5): A solution of **1** (0.94 g, 1.36 mmol) in Et_2O (30 mL) was added slowly to a solution of $GeCl_2$·dioxane (0.66 g, 2.85 mmol) in Et_2O (30 mL) at 0 °C. The yellow suspension was warmed to ambient temperature and stirred for 18 h. The precipitate was then filtered. Hexane was added to the filtrate and concentrated, yielding pale-yellow crystals of **5**. Yield: 0.76 g (62%); m.p.: 124−125 °C. $C_{19}H_{27}ClGeN_2Si_2$: calcd. C 50.98, H 6.08, N 6.25; found C 50.77, H 5.91, N 6.13. ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): δ = −0.22 (s, 9 H, $SiMe_3$), −0.18 (s, 9 H, $SiMe_3$), 7.33−7.40 (m, 4 H, Ph), 7.41−7.49 (d, 1 H, 5-py), 7.49−7.63 (m, 1 H, Ph), 7.63−7.66 (d, J = 7.4 Hz, 1 H, 3-py), 7.95 (t, J = 7.1 Hz, 1 H, 4-py), 8.70 (d, J = 5.5 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]THF, 25 °C): δ = 1.62, 3.08 ($SiMe_3$), 95.62 (*C*$SiMe_3$), 120.69, 126.33, 127.97, 129.28, 130.06, 131.11, 133.53, 140.47, 144.38, 145.61, 155.57 (Ph and Py), 164.94 (N*C*Ph) ppm.

[Sn{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}Cl] (6): A solution of **1** (0.86 g, 1.23 mmol) in Et_2O (30 mL) was added slowly to a solution of $SnCl_2$ (0.47 g, 2.47 mmol) in Et_2O (30 mL) at 0 °C. The yellow suspension was warmed to ambient temperature and stirred for 18 h. The precipitate was then filtered. The filtrate was removed under reduced pressure and the residue was extracted with THF/*n*-hexane (1:10) and concentrated to yield **6** as a yellow solid. Yield: 0.51 g (42%); m.p.: 210−213 °C. $C_{19}H_{27}ClN_2Si_2Sn$: calcd. C 46.22, H 5.51, N 5.67; found C 46.29, H 5.58, N 5.88. ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): δ = −0.28 (s, 9 H, $SiMe_3$), −0.27 (s, 9 H, $SiMe_3$), 7.13−7.26 (m, 1 H, 5-py), 7.30−7.35 (m, 3 H, Ph), 7.35−7.40 (m, 2 H, Ph), 7.44−7.47 (m, 1 H, 4-py), 7.56−7.59 (d, J = 8.7 Hz, 1 H, 3-py), 8.48 (d, J = 6.0 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]THF, 25 °C): δ = 0.96, 1.96 ($SiMe_3$), 100.12 (*C*$SiMe_3$), 118.72, 127.56, 128.69, 130.89, 135.14, 140.72, 147.36, 160.03 (Ph and Py), 162.93 (N*C*Ph) ppm. ^{119}Sn{^{1}H} NMR (149 MHz, [D$_8$]THF, 25 °C): δ = −197.95 ppm.

[Pb{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}Cl] (7): A solution of **1** (1.25 g, 1.80 mmol) in THF (20 mL) was added slowly to a solution of $PbCl_2$ (1.10 g, 3.96 mmol) in THF (20 mL) at −90 °C. The yellow suspension was warmed to ambient temperature and stirred for 18 h. The volatiles were then removed under reduced pressure and the residue was extracted with toluene. The yellow mixture was filtered and concentrated to give yellow crystals of the title compound. Yield: 0.73 g (69%); m.p.: 190−192 °C. $C_{19}H_{27}ClN_2PbSi_2$: calcd. C 39.19, H 4.67, N 4.81; found C 38.94, H 4.53, N 4.73. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = −0.07 (s, 9 H, $SiMe_3$), −0.08 (s, 9 H, $SiMe_3$), 6.40 (m, 1 H, 5-py), 6.90 (m, 1 H, 3-py), 7.07 (m, 1 H, 4-py), 7.23−7.27 (m, 2 H, Ph), 7.47−7.50 (m, 3 H, Ph), 8.24 (d, J = 4.1 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, C_6D_6, 25 °C): δ = 2.07, 2.94 ($SiMe_3$), 89.40 (*C*$SiMe_3$), 120.50, 123.30, 128.63, 129.00, 130.67, 130.79, 138.33, 145.26, 159.49 (Ph and Py), 166.23 (N*C*Ph) ppm.

[Ge{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)}Cl$_2$]$_2$ (8): A solution of **1** (1.48 g, 2.13 mmol) in THF (30 mL) was added slowly to a solution of $GeCl_4$ (0.54 mL, 4.69 mmol) in THF (20 mL) at −90 °C. The yellow solution was warmed to ambient temperature and stirred for two days. The volatiles were removed under reduced pressure and the residue was extracted with toluene. The yellow mixture was filtered and concentrated to give yellow crystals of the title compound. Yield: 0.84 g (48%); m.p.: 226−227 °C. $C_{32}H_{36}Cl_4Ge_2N_4Si_2$: calcd. C 46.88, H 4.43, N 4.83; found C 46.51, H 4.31, N 4.63. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.03 (s, 4 H, $SiMe_3$), 0.31 (s, 5 H, $SiMe_3$), 6.86 (t, J = 7.1 Hz, 1 H, 5-py), 6.98 (d, J = 7.1 Hz, 1 H, 3-py), 7.08−7.15 (m, 3 H, Ph), 7.17−7.22 (m, 2 H, Ph), 7.41 (t, J = 7.7 Hz, 1 H, 4-py), 7.73 (d, J = 5.5 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, C_6D_6, 25 °C): δ = 2.60 ($SiMe_3$), 119.13 (*C*$SiMe_3$), 122.97, 126.04, 127.80, 128.91, 129.67, 132.07, 133.09, 139.98, 145.62 (Ph and Py), 167.73 (N*C*Ph) ppm.

[{(C$_5$H$_4$N-2)C(SiMe$_3$)C(Ph)N}(μ-SiHCl)]$_2$ (9): A solution of **1** (1.28 g, 1.84 mmol) in THF (30 mL) was added slowly to a solution of $HSiCl_3$ (0.41 mL, 4.05 mmol) in THF (20 mL) at −90 °C. The yellow solution was warmed to ambient temperature and stirred for two days. The volatiles were removed under reduced pressure and the residue was extracted with toluene. The yellow mixture was filtered and concentrated to give yellow crystals of the title compound. Yield: 0.97 g (79%); m.p.: 232−233 °C. $C_{32}H_{38}Cl_2Si_4N_4$: calcd. C 58.07, H 5.79, N 8.46; found C 58.55, H 5.62, N 7.64. ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): δ = −0.16 (s, 6 H, $SiMe_3$), 0.41 (s, 3 H, $SiMe_3$), 5.46 (s, 1 H, SiH), 6.92−6.96 (t, J = 6.0 Hz, 1 H, 5-py), 6.99−7.02 (d, J = 7.4 Hz, 1 H, 3-py), 7.11−7.19 (m, 2 H, Ph), 7.36−7.37 (m, 3 H, Ph), 7.41−7.44 (m, 1 H, 4-py), 7.80−7.82 (d, J = 5.8 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, [D$_8$]THF, 25 °C): δ = 2.90, 3.13 ($SiMe_3$), 101.36 (*C*$SiMe_3$), 118.44, 123.80, 126.05, 127.92, 128.35, 128.91, 129.59, 139.36, 141.80, 155.89 (Ph and Py) 162.51 (N*C*Ph) ppm.

[{(C$_5$H$_4$N-2)C(H)C(Ph)N}(μ-GeCl$_2$)]$_2$ (11): A solution of **10** (0.84 g, 1.53 mmol) in THF (30 mL) was added slowly to a solution of $GeCl_4$ (0.38 mL, 3.36 mmol) in THF (20 mL) at −90 °C. The yellow suspension was warmed to ambient temperature and stirred for two days. The volatiles were removed under reduced pressure and the residue was extracted with toluene. The yellow mixture was filtered and concentrated to give yellow crystals of the title compound. Yield: 0.39 g (37%); m.p.: 210−211 °C. $C_{26}H_{36}Cl_4Ge_2N_4$: calcd. C 46.23, H 2.90, N 8.29; found C 46.03, H 3.08, N 8.23. ^{1}H NMR [300 MHz, C_6D_6/[D$_8$]THF (2:1), 25 °C]: δ = 5.09 (s, 1 H, *H*CC), 6.57 (t, J = 6.6 Hz, 1 H, 5-py), 6.68 (d, J = 8.5 Hz, 1 H, 3-py), 6.91 (t, J = 8.0 Hz, 1 H, 4-py), 7.10−7.14 (m, 5 H, Ph), 8.65 (d, J = 6.3 Hz, 1 H, 6-py) ppm. ^{13}C{^{1}H} NMR (300 MHz, C_6D_6/[D$_8$]THF 2:1, 25 °C): δ = 96.51 (H*C*C), 116.70, 119.56, 121.62, 124.71, 125.92, 126.85, 129.69, 130.36, 139.85, 142.27, 145.48 (Ph and Py), 155.79 (N*C*Ph) ppm.

X-ray Crystallographic Study: Single crystals were sealed in Lindemann glass capillaries under nitrogen. The X-ray data of **2**−**5**, **7**−**9**, and **11** were collected on a Rigaku R-AXIS II imaging plate using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) from a rotating-anode generator operating at 50 kV and 90 mA. Crystal data for **2**−**5**, **7**−**9**, and **11** are summarized in Table 5 and 6. The structures were solved by direct phase determination using the computer program SHELXTL-PC[27] on a PC 486 and refined by full-matrix least-squares with anisotropic thermal parameters for the non-hydrogen atoms. Hydrogen atoms were introduced in their idealized positions and included in structure factor calculations with assigned isotropic temperature factor calculations.

CCDC-250383 to -250390 (**2**−**5**, **7**−**9** and **11**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/

Sonochemical Reaction of $[Fe(CO)_5]$ with 1-Methylimidazole in An Ionic Liquid: Formation of $[(1\text{-Methylimidazole})_6Fe^{II}](PF_6)_2$

David S. Jacob,[a] Volker Kahlenberg,[b] Klaus Wurst,[c] Leonid A. Solovyov,[d] Israel Felner,[e] Linda Shimon,[f] Hugo E. Gottlieb,[a] and Aharon Gedanken*[a]

Keywords: Ionic liquid / Sonochemistry / Iron imidazole complex

The ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate, $(BMI^+)(PF_6^-)$, has been used as a solvent in the sonochemical reaction of 1-methylimidazole and $[Fe(CO)_5]$ at 40–50 °C under air. The reaction afforded $[(1\text{-methylimidazole})_6Fe^{II}](PF_6)_2$, the structure of which was determined at 293 K by single-crystal X-ray diffraction methods. The salt crystallizes in the trigonal space group $P\bar{3}$ with unit-cell parameters of a = 11.4603(16) Å, c = 8.0172(11) Å, and Z = 1. The crystals showed twinning by merohedry, which was accounted for in the structure determination and refinement calculations. All the 1-methylimidazole ligands are equivalent, with a Fe–N bond length of 2.204(3) Å. Mössbauer spectroscopy confirmed the presence of Fe^{2+}.

Introduction

Ionic liquids are generally considered to be noncoordinating green solvents in organic synthesis and catalysis.[1] However, there are few examples where ionic liquids behave as templates or charge-compensating groups in the reactions. Xiao et al.[2] were the first to report the in situ formation of 1-butyl-3-methylimidazole-2-ylidene (bmiy) complexes of palladium $[Br(\mu\text{-}Br)(bmiy)Pd]_2$ and $[Br_2(bmiy)_2Pd]$ in 1-butyl-3-methylimidazolium bromide ionic liquid. Welton et al.[3] have studied the in situ formation of the mixed phosphane imidazolylidene palladium complexes $[(PPh_3)_2Pd(bmimy)X](BF_4^-)$ at room temperature in 1-butyl-3-methylimidazolium tetrafluoroborate ionic liquid (where X = Cl, Br). These references show the solvent incorporation behavior of the ionic liquid in the final product. Aggarwal et al.[4] have reported unexpected side reaction of imidazole-based ionic liquids in the base-catalysed Baylis–Hillman reaction. Zaworotko et al.[5] synthesized *trans*-$[(1\text{-Meim})_4F_2Fe]BF_4$ in 1-methylimidazolium tetrafluoroborate ionic liquid as a reactant. In the solvothermal synthesis of the coordination polymer $[Cu^I(bpp)]BF_4$, using 1-butyl-3-methylimidazolium tetrafluoroborate ionic liquid as solvent, Li et al.[6] found that BF_4^- anions entered the final structure as a charge-compensating species.

Although ionic liquids have several important properties that could make them useful in various chemical processes,[1,7–16] experimental evidence is lacking in the field of coordination chemistry, wherein ionic liquids act as clean, effective solvents for the crystallization of complexes. To explore the reactions in ionic liquids, we report here the inorganic synthesis of (1-methylimidazole)iron complex in ionic liquid (as solvents) under sonochemical conditions.

Transition metals and imidazole play an important role as an active centre of metalloproteins, as well as in many other biological systems such as hemoglobin, vitamin B_{12},[17] and F_{430}. The interaction between imidazole ligand and transition metal ions[17–20] forms well-defined complexes whose stoichiometry is $M(Im)_6X_2$, M = Fe^{II}, Co^{II}, Ni^{II}, and Cu^{II} ions.[18,19] The structures of known *N*-substituted imidazole complexes of transition metal ions have been studied extensively.[21] An $[(1\text{-methylimidazole})_6Fe^{II}]^{2+}$ complex has been prepared using iron(II) salts as precursors for iron.[21b,21c]

A further literature survey revealed a reaction of ferrocene and cyclopentadienyl irondicarbonyl with imidazole

(unsubstituted), yielding $Fe(N_2C_3H_3)\cdot 0.71N_2C_3H_4$ with fourfold, as well as sixfold, coordinated metal ions.[22] For substituted imidazole, only a fourfold coordinated iron is detected.[22]

In 1980 a paper reported on the reaction of 1-methyl-, 1-ethyl-, 1,2-dimethyl- and 1,2,3,4-tetramethylimidazole with $[Fe(CO)_5]$, yielding $(FeIm_6)[Fe(CO)_8]$, $(FeIm6)[Fe(CO)_4]_2$, $(FeIm_4)[Fe(CO)_4]$ and $Fe(Im)(CO)_2$, respectively, (Im = substituted imidazole).[23] The reaction product of $[Fe(CO)_5]$ with 2-ethylimidazole shows that the anion is $[HFe(CO)_5]^-$ rather than $[Fe(CO)_4]^-$, as proposed by Seel et al.[23,24]

The ionic liquid used in our system is composed of an asymmetric 1-butyl-3-methylimidazolium cation (BMI^+) with a bulky hexafluorophosphate (PF_6^-) anion. Ionic liquids exhibit unique properties, including high thermal stability, a large liquid range, and negligible vapour pressure.[25] The latter property could change the characteristics of acoustic cavitation and make ionic liquids potentially attractive for use in sonochemical reactions. Acoustic cavitation, i.e., the formation, growth and implosive collapse of bubbles in a liquid medium, is principally responsible for sonochemistry.[26] The collapse of such bubbles creates hot spots ($\approx$ 5000 °C), high pressures (1000 atm), and very high cooling rates (10^{10} K·s^{-1}),[27] leading to the extreme conditions responsible for various chemical and physical effects.

Upon cavitational collapse, vapours inside the bubble undergo a gas-phase reaction. It is of great importance that only vapours of the volatile solutes, and not of the solvent, are inside the collapsing bubble, and so low vapour pressure solvents such as decalin, hexadecane, and isodurene are common in sonochemistry.[28] Suslick et al. have shown that sonication of $[Fe(CO)_5]$ in decane (for 3 h in a dry-ice acetone bath) affords amorphous iron that contains 3% carbon, 2% hydrogen, and 1% oxygen, by weight.[29] The amount of contaminants was reduced sharply upon a shorter sonication time.[30] Such contaminants originate from the small amount of decane vapour found inside the collapsing bubble. The search for low vapour solvents has led recently to the use of diphenylmethane.[31] Ionic liquids are good candidates for this purpose due to their low vapour pressure.

Recently, Suslick et al. have studied the effect of acoustic cavitation on pure ionic liquids sonicated at 20 kHz, and at ca. 60 W·cm^{-2} for 3 h at 85−135 °C. The reaction led to the decomposition of the ionic liquid and the products in the headgas were analyzed by gas-chromatography.[32] The ionic liquid decomposed at 1.9−3.8 μmol·min^{-1}, so that after 180 min less than 1% of the ionic liquid had decomposed. $[Fe(CO)_5]$ yields amorphous iron nanoparticles upon sonication under argon, wheras sonication under air affords nanosized amorphous Fe_2O_3.[33,28] Decalin was used as solvent for both sonications.

The current paper reports an *inorganic* sonochemical reaction carried out in an ionic solvent. $[Fe(CO)_5]$ (reactant I), and 1-methylimidazole (reactant II) were reactants, while the ionic solvent was 1-butyl-3-methylimidazole hexafluorophosphate (BMI^+)(PF_6^-). The product was composed of iron originating from reactant I, 1-methylimidazole from reactant II, and the PF_6^- anion from the ionic liquid. This product differs from the sonochemical product obtained in the dissociation of $[Fe(CO)_5]$ in organic solvents such as decalin or hexadecane.[28,29a] Products of all the reactions conducted using transition metal carbonyls were amorphous. This due to the fast cooling rates obtained when the bubble collapses, which prevent crystallization of the product. Here, our focus is on the crystalline product obtained after the sonication reaction. The possibility of producing crystalline products under sonochemical reaction makes our research especially interesting. The structure of the complex was characterized by single crystal and powder X-ray diffraction (XRD) analysis.

Results and Discussion

The single-crystal structure analysis shows that the Fe^{2+} atoms are coordinated by six 1-methylimidazolium groups with an equivalent Fe−N (2.204(3) Å) bond length. This distance is within the range observed for other reported Fe−N distances.[5,21a,21c] Two PF_6^- ions balance the positive charge. The coordination polyhedron around the P atom is slightly disordered and the fluorine atoms were refined with an occupancy factor of 0.333. Figure 1 shows an ORTEP perspective of the [(1-methylimidazole)$_6$Fe^{II}](PF$_6$)$_2$. Table 1 presents crystal and structure refinement data.

Table 1. Crystal and structure refinement data for [(1-methylimidazole)$_6$Fe^{II}](PF$_6$)$_2$

Empirical formula	$C_{24}H_{36}F_{12}FeN_{12}P_2$
Molecular mass	838.44
Temperature	293(2) K
Wavelength	0.71073 Å (Mo-K_α)
Crystal system	trigonal
Space group	$P\bar{3}$ (No.147)
Unit cell dimensions	a = 11.4603(16) Å; α = 90 deg.
b = 11.4603(16) Å; β = 90 deg.	
c = 8.0172(11) Å; γ = 120 deg.	
Volume	911.9(2) Å^3
Z, calculated density	1, 1.527 Mg/m^3
Absorption coefficient	0.599 mm^{-1}
F(000)	428
Color, habit	colorless, needle
Crystal size	0.02 × 0.02 × 0.4 mm
Theta range for data collection	2.05−25.17 deg.
Limiting indices	$-13 \le h \le 12$, $-13 \le k \le 13$, $-9 \le l \le 9$
Reflection collected/unique	5824/1078 [$R_{(int)}$ = 0.0806]
Reflections with $I > 2\sigma(I)$	890
Absorption correction	none
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	1078/0/116
Goodness-of-fit on F^2	1.116
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0440, $wR2$ = 0.0718
R indices (all data)	$R1$ = 0.0597, $wR2$ = 0.0764
Largest diff. Peak and hole	0.159 and −0.198 Å^{-3}

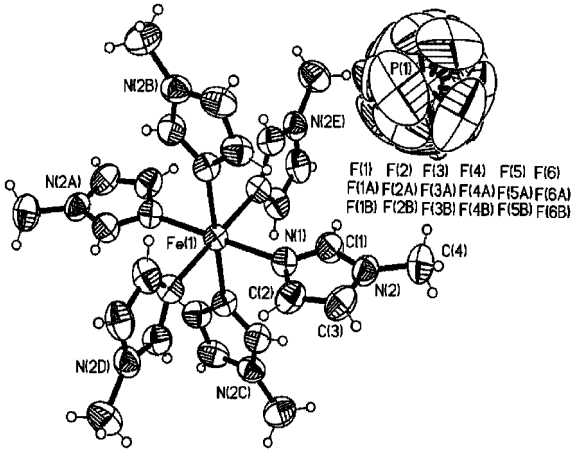

Figure 1. Perspective ORTEP view of [(1-methylimidazole)$_6$Fe^{II}]-(PF_6)$_2$ (50% probability displacement ellipsoids); hydrogen atoms omitted for clarity

In parallel, powder XRD (PXRD) structural investigations of the bulk sample reproduced the single crystal results, and confirmed the single-phase purity of the product. Figure 2 illustrates the final agreement between the experimental and calculated PXRD profiles. All observed PXRD peaks are explained fairly well by the refined structure model.

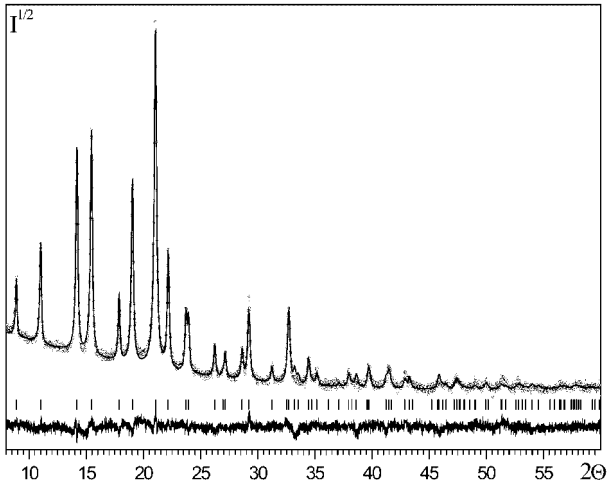

Figure 2. Weighted experimental (circles), calculated (solid line) and difference (bottom curve) PXRD profiles for [(1-methylimidazole)$_6$Fe^{II}](PF_6)$_2$. Reflection positions are marked by ticks

Vibrational bands in the Raman and IR absorption spectra of the complex (Figure 3) are assigned in Table 2. The vibrational bands of the ligands are shifted, as reported previously by Reedijk,[34] Perchard and Novak.[35] M−N vibrations in the Raman spectrum below 300 cm^{-1} are in accordance with the literature values.[34] The intense Raman line at 739 cm^{-1} is assigned to the symmetric ν_1 mode of the PF_6^- ion.[36]

NMR studies of ^{31}P and ^{19}F confirm the presence of PF_6^- anions (Figure 4). The ^{31}P NMR spectrum shows septet with respect to fluorine and the ^{19}F NMR spectrum

Table 2. Raman and IR vibration bands (cm^{-1}) for Fe^{II}(1-methylimidazole)$_6$(PF_6)$_2$ (w = weak, m = medium, s = strong and br. = broad)

Assignments	Vibration frequency [$(C_4H_6N_2)_6$Fe](PF_6)$_2$

C−N deformation	−	237 m

shows the doublet with respect to phosphorus (where I_P = 1/2 and I_F = 1/2).

Mössbauer spectroscopic data confirm the +2 oxidation state of iron with an isomeric shift (IS) = 1.041 mm s^{-1} and a quadrupole splitting (QS) = 0.769 mm s^{-1}, which agree with the literature values.[19,23] The Mössbauer spectrum does not show Fe^{III} impurities. The mass spectrum of the complex, obtained by desorption chemical ionization (DCI) using methane, shows the 1-methylimidazole peak at m/z = 82. The PF_6^-anion of the complex appears at m/z = 145 under fast atom bombardment (FAB)-glycerol in methanol. Elemental analysis for [(1-methylimidazole)$_6$Fe^{II}](PF_6)$_2$ also matches the calculated theoretical values.

Following previous sonochemical experiments,[29] we assume that the first stage of the current reaction involves the decomposition of [Fe(CO)$_5$] to Fe and CO. The CO is then released from the sonication cell, while the Fe(0) is oxidized by air to Fe^{2+} ions in the (BMI^+)(PF_6^-) ionic liquid. Sonication of [Fe(CO)$_5$] under the same conditions in decalin gave amorphous Fe_2O_3.[28] Unlike the reaction in decalin, here the surrounding environment of the 1-methylimidazole and the ionic liquid (BMI^+)(PF_6^-) prevented complete oxidation of the iron. Our first assumption is, following earlier reports,[2−6] that the ionic liquid is the source of the imidazole ring and the counterion (PF_6^-) in the product, while losing a 1-butyl group during the reaction. This assumption might also agree with the decomposition product of the sonication of (BMI^+)(PF_6^-) under argon[32] where the cation of the ionic liquid (BMI^+)(PF_6^-) loses a butyl/methyl group. ^{1}H and ^{13}C NMR analysis of the product of the ionic liquid reaction indicates the presence of a 1-methylimidazole, but no butyl group. This means that the 1-meth-

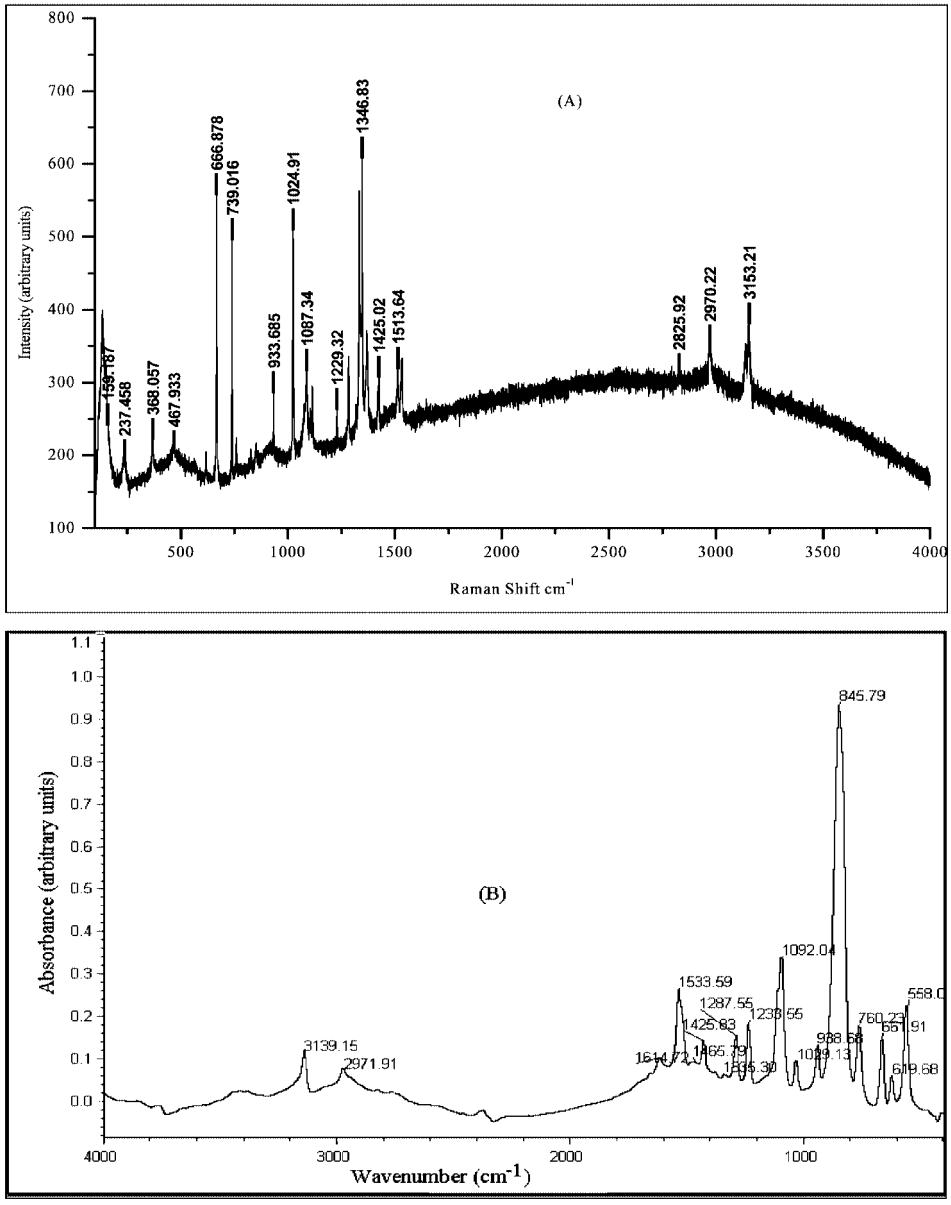

Figure 3. Raman (A) and IR (B) absorption spectrum of [(1-methylimidazole)$_6$Fe^{II}](PF$_6$)$_2$

ylimidazole source is not the ionic liquid, but the reactant II. Conversely, the anions in the product originate from the ionic liquid.

To investigate the purity of the ionic liquid, (BMI$^+$)(PF$_6^-$), its thermal decomposition[37] was studied by TGA (Thermo Gravimetric Analysis) between 25 and 1000 °C at 3 °C min^{-1} in a N_2 flow. Water, as an impurity, causes the partial decomposition of the ionic liquid, with the formation of phosphate, HF and transition metal fluorides.[38] The (BMI$^+$)(PF$_6^-$) was thermally stable at 330 °C and decomposed completely at 516 °C, confirming that it is stable at the reaction temperature, without forming metal fluorides, and that it undergoes a chemical reaction only due to the temperature developed as a result of the bubble collapse.

A control reaction sonicating the same concentration of [Fe(CO)$_5$] in the ionic liquid (BMI$^+$)(PF$_6^-$) (without 1-methylimidazole) under an air atmosphere at 40−50 °C yielded a very small amount of an amorphous product (6 mg). A second control reaction, conducted by sonicating [Fe(CO)$_5$] in 1-methylimidazole (no ionic liquid), gave an amorphous product. After crystallization Fe_2O_3 was identified (PXRD) as the product. This is a main difference between the sonochemical reaction and that in ref.[23], which produces a crystalline product. The time and temperature of the reaction (30 min, 40−50 °C here) also differ (3−6 h, 60−80 °C[23]). The difference between a regular reaction[23] and that of [Fe(CO)$_5$] and imidazole in an ionic liquid is that sonication leads to the loss of CO while the products of a regular reaction contain the carbonyl. Moreover, the

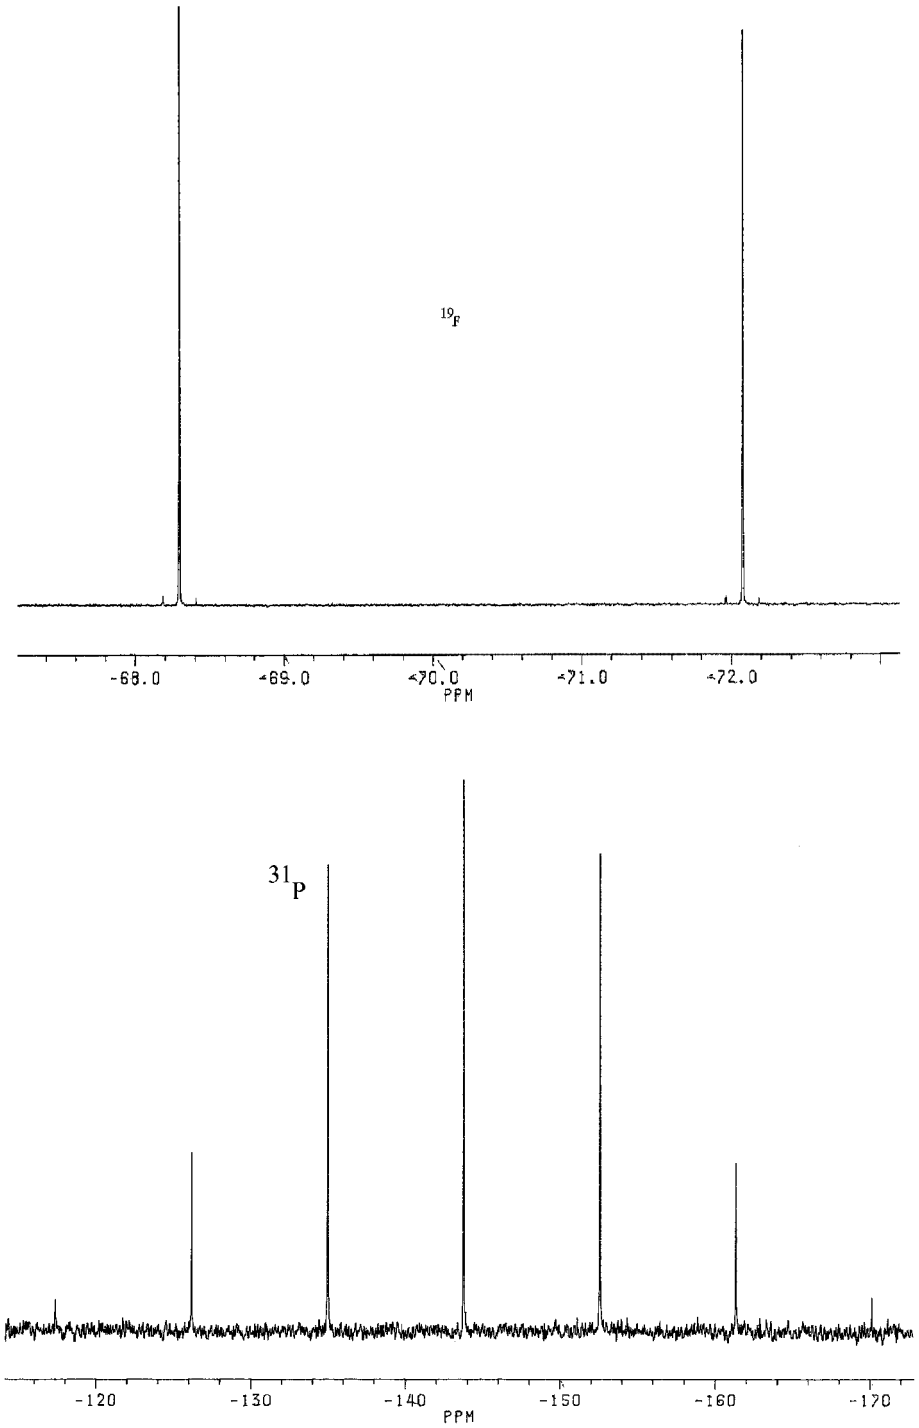

Figure 4. ^{19}F and ^{31}P NMR spectrum of [(1-methylimidazole)$_6$Fe^{II}](PF$_6$)$_2$

negative ions originate from the ionic liquid in our reaction, while [Fe(CO)$_5$] is their source in a regular reaction.[23]

Conclusions

The sonication product of 1-methylimidazole and [Fe(CO)$_5$] in (BMI$^+$)(PF$_6^-$) (which acts as a solvent) gives a complex of [(1-methylimidazole)$_6$Fe^{II}](PF$_6$)$_2$ under air. Unlike ref.[2,3,5], where the cation and the anion contribute to the structure of the final product, here only the anion is part of the product, which is similar to ref.[6]. In this sonochemical reaction, Fe^{2+} ion is coordinated octahedrally by six 1-methylimidazole. PF_6^- acts as a charge-stabilizing agent in the formation of the crystal salt, which is characterized by a trigonal crystal lattice with a $P\bar{3}$ space

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

group. To probe the effect of the ionic liquid as a solvent on sonochemical reactions, studies on similar systems using different ionic liquids and transition metal carbonyls are in progress and will be reported soon.

Experimental Section

General Remarks: Ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate [(BMI$^+$)(PF$_6^-$)] (Aldrich, 96%), 1-methylimidazole (Aldrich, 99%), and pentacarbonyliron (Strem chemicals, USA, 99.5%, refer to MSDS for safety precaution) were purchased from the Aldrich Chemical Co. and used without further purification.

Synthesis of Complex: Pentacarbonyliron [Fe(CO)$_5$] (1.49 g, 6.08 mmol) and 1-methylimidazole (2 g, 24.3 mmol) were dispersed in the ionic liquid (BMI$^+$)(PF$_6^-$) (5 g, 17.6 mmol) under ultrasonic conditions. Sonication was carried out with a high intensity ultrasonic horn (Sonics and Materials Model VC-600, Ti-horn, 20 kHz, 40 W·cm^{-2}) for 30 min under an air atmosphere. The reaction cell was placed in the exhaust hood so that CO was not released into the laboratory (please refer to MSDS for correct handling of these chemicals). The temperature was maintained at around 40−50 °C using a (Julabo FT 901) acetone cooler bath, as the reaction temperature in ionic liquids rises to about 200 °C without cooling. After completion of the reaction, the ionic liquid changed from clear brown to black. Ethanol was used to precipitate a grey powder and to develop the transparent crystals. The amount of product collected after 30 min of sonication was 1.414 g (1.68 mmol). The yield with respect to iron was 28%.

X-ray Crystallographic Study

Single Crystal XRD: A needle-shaped crystal (0.02 × 0.02 × 0.40 mm^3) was mounted on the tip of a glass fiber. Diffraction data were recorded on a Stoe imaging plate detector system (IPDS-II). The diffraction symmetry was consistent with Laue group $\bar{3}$. Since no systematically extinct reflections were observed, space groups $P3$ and $P\bar{3}$ were taken into consideration. Subsequent structure determination confirmed the adequacy of the centrosymmetric space group. Due to the low linear absorption coefficient of the material (μ = 0.6 mm^{-1}) for Mo-K_α radiation, no absorption correction has been applied. Data reduction included Lorentz and polarization corrections. The structure was solved by direct methods using the SHELXS-86 program system.[39] Subsequent refinement calculations were also performed with SHELXL-97,[40] using neutral atomic scattering factors. In the initial stages of the structure determination, several models were obtained that were less satisfactory from a crystal chemical point of view. Finally, a possible twinning of the crystal was considered to explain these difficulties. Since the differences between the internal residuals for merging the data in the two Laue groups $\bar{3}$ and 6/m were not very pronounced (0.078 and 0.109, respectively), a twinning according to m$_{[001]}$ was assumed. This type of twinning results in an exact superposition of the reciprocal lattices of the two twin domains. The twinning model was introduced into the refinements and resulted in a significant improvement. The volume fraction of the twin component I was refined to 0.438(3). For the final, least-squares cycles, anisotropic displacement parameters were used for the non-hydrogen atoms. Hydrogen atoms were added geometrically, and refined using a riding model with isotropic displacement parameters 1.2 or 1.5 times higher than U_{eq} of the aromatic or methyl carbon atoms.

Powder-XRD: PXRD data were collected in Bragg−Brentano geometry using a DRON-4 diffractometer with graphite secondary monochromator (Cu-K_α radiation) and scintillation counter. Measurements were taken at room temperature in air. The unit cell parameters of the crystalline powder product were determined from the PXRD peak positions. A preliminary structure model was estimated by searching the Cambridge Structure Database.[41] Several structures were found with similar crystal lattice dimensions and cognate structure units to those expected for the studied compound: hexakis(*N*-methylimidazole)ruthenium(II) bis(trifluoromethanesulfonate), hexakis(2-methyltetrazole)nickel(II) bis(tetrafluoroborate), and hexakis(5-methylpyrazole)nickel diperchlorate.[42] Considering the synthesis mixture composition and the analogous structures, the formula of the studied compound was assumed to be hexakis(*N*-methylimidazole)iron(II) bis(hexafluorophosphate). A trial structure model was built based on the atomic coordinates of the analogues. Further full-profile PXRD structure refinement utilizing the Rietveld[43] method confirmed the structure model, which was identical to that obtained from the single-crystal study.

Instrumentation: A Raman absorption spectrum of the title compound was recorded with a Jobin Yvon Horiba Raman spectrometer using a 514.532 nm laser in the range 100−4000 cm^{-1}. An IR absorption spectrum was recorded with a Nicolet (Impact 410) spectrometer in the range 400−4000 cm^{-1}. For IR measurements, a pellet containing 200 mg of KBr and 1 mg of the product was prepared. NMR spectra were recorded with an AC Bruker 200 instrument. Mass spectra were recorded with a VG-autospec instrument.

[(1-Methylimidazole)$_6$Fe^{II}](PF$_6$)$_2$: ^{1}H NMR ([200.1 MHz, [D$_6$]DMSO, ppm): δ = 3.59 [s, 3 H, N−CH$_3$], 6.86 [s, 1 H, H(5)], 7.06 [s, 1 H, H(4)], 7.55 [s, 1 H, H(2)].^{13}C NMR (50.3 MHz, [D$_6$]DMSO, ppm): δ = 33.66 [N−CH$_3$)], 121.61 [C(5)], 128.55 [C(4)], 138.57 [C(2)]. ^{31}P NMR (81.0 MHz, [D$_6$]DMSO, ppm): δ = −143.85 (septet, J_{PF} = 709 Hz). ^{19}F NMR (188.3 MHz, [D$_6$]DMSO, ppm): δ = −70.21 (d, J_{PF} = 709 Hz). $C_{24}H_{36}F_{12}FeN_{12}P_2$ (838.44): calcd. C 34.34, N 20.03, H 4.29; found C 34.61, N 19.98, H 4.33.

CCDC-228751 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Keywords: Solid state structures / Platinum / Sulfates / Metal−metal bonds / IR data

The reaction of $Pt(NO_3)_2$ with concentrated sulfuric acid in sealed glass ampoules at 400 °C causes reduction of the nitrate ion to NH_4^+ and leads to single crystals of $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ [triclinic, $P\bar{1}$, $Z = 1$, $a = 749.96(9)$, $b = 754.2(1)$, $c = 765.4(1)$ pm, $\alpha = 102.15\ (1)°$, $\beta = 110.23(1)°$, $\gamma = 100.87(1)°$, $R_{all} = 0.0677$]. In the crystal structure, Pt_2 dumbbells are coordinated by four bidentate-bridging sulfate ions and two axial H_2O molecules. The replacement of the axial H_2O molecules with SO_4^{2-}, which can be observed in the crystal structure of $K_4[Pt_2(SO_4)_5]$ [triclinic, $P\bar{1}$, $Z = 2$, $a = 975.6(1)$, $b = 1331.8(1)$, $c = 1491.0(1)$ pm, $\alpha = 101.156(8)°$, $\beta = 96.278(8)°$, $\gamma = 102.849(8)°$, $R_{all} = 0.0459$], causes a connection of the dumbbells into chains of the composition $^1_\infty[Pt_2(SO_4)_{4/1}(SO_4)_{2/2}]^{4-}$. $K_4[Pt_2(SO_4)_5]$ has been obtained from the reaction of $K_2[PtCl_4]$ and concentrated H_2SO_4 at 400 °C in sealed glass tubes. The same reaction with $Cs_2[PtCl_4]$ instead of $K_2[PtCl_4]$ leads to $Cs[Pt_2(SO_4)_3(HSO_4)]$ [monoclinic, $P2_1/c$, $Z = 4$, $a = 1724.8(2)$, $b = 881.28(9)$, $c = 935.1(1)$ pm, $\beta = 100.397(8)°$, $R_{all} = 0.0458$]. In the crystal structure, part of the bidentate-bridging sulfate ions of the $[Pt_2(SO_4)_4]$ core act as monodentate ligands to further Pt_2 dumbbells leading to anionic layers of the composition $^2_\infty[Pt_2(SO_4)_{4/2}(SO_4)_{2/1}]^{2-}$ and neutral units with the formula $^2_\infty[Pt_2(SO_4)_{4/2}(HSO_4)_{2/1}]$. The two types of layers are stacked alternatingly with the ten coordinate Cs^+ ions.

Introduction

The dumbbell shaped Pt_2^{6+} ion was reported for the first time by Muraveiskaya et al. in the complex salt $K_2[Pt_2(SO_4)_4(H_2O)_2]$.[1,2] In the crystal structure of the latter, Pt_2^{6+} is coordinated by four bidentate-bridging sulfate groups and two monodentate water molecules which are located in the axial positions of the dumbbell. This motif has been extensively varied by Cotton and co-workers and other groups[3−10] by introducing other bridging ligands, for example HPO_4^{2-}. Furthermore the H_2O molecules in the axial positions can be replaced by other ligands, for example DMSO or pyridine but also by anions such as Cl^- and OH^-.[11] In all of the compounds which have been structurally characterised so far, the complexes remain monomeric, i.e. they are binuclear anions such as $[Pt_2(SO_4)_4(H_2O)_2]^{2-}$ or $[Pt_2(SO_4)_4Cl_2]^{4-}$. Recently we have shown that a linkage of the $[Pt_2(SO_4)_4]$ entities is possible if the axial positions of the Pt_2 dumbbell are occupied by further sulfate ions. For example, in $Pt_2(HSO_4)_2(SO_4)_2$, the SO_4^{2-} ions act as bidentate-bridging ligands to one platinum dumbbell and as monodentate ligands to the next Pt_2^{6+} ion so that layers of formula $^2_\infty[Pt_2(SO_4)_{4/2}(HSO_4)_{2/1}]$ are formed.[12] Another linkage may be found in the unique structure of $(NH_4)_4[Pt_{12}O_8(SO_4)_{12}]$ which shows six Pt_2^{6+} ions linked by sulfate groups and oxide ions into the cluster anions $[Pt_{12}O_8(SO_4)_{12}]^{4-}$ with a distorted icosahedral Pt_{12} core.[13] As an extension of our work we present, in this paper, the first example of the linkage of $[Pt_2(SO_4)_4]$ units into chains as observed in the crystal structure of $K_4[Pt_2(SO_4)_5]$. Furthermore, we were able to characterise a second example with $[Pt_2(SO_4)_4]$ groups connected into sheets, namely the new sulfate $Cs[Pt_2(SO_4)_3(HSO_4)]$. Finally we report the crystallographic data for $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ as a representative of the monomeric species.

Results and Discussion

As described recently, the reaction of $Pt(NO_3)_2$ with concentrated sulfuric acid in sealed glass ampoules at 400 °C leads to deep red single crystals of $(NH_4)_4[Pt_{12}O_8(SO_4)_{12}]$.[13] As a side product of this reaction, yellow single crystals were also observed. According to an X-ray investigation, this side product is $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$. This compound has been reported previously, however, but without accompanying crystallographic data.[2,5] It is worth-

while mentioning that the NH_4^+ ion originates from the reduction of the initial nitrate, clearly by Pt^{2+}.

$(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ crystallizes in the form of yellow plates and can be easily separated from the deep red single crystals of $(NH_4)_4[Pt_{12}O_8(SO_4)_{12}]$. $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ is isotypic with $K_2[Pt_2(SO_4)_4(H_2O)_2]$ as can be expected from the comparable radii of K^+ and NH_4^+. The compound contains the typical lantern shaped $[Pt_2(SO_4)_4(H_2O)_2]^{2-}$ anion as can be seen in Figure 1. The Pt−Pt distance within the ion was found to be 246.3(1) pm which is not significantly different from the values reported previously for similar compounds.[1−11] The four sulfate groups act as bidentate-bridging ligands with the Pt-O distances being uniformly around 200 pm (Table 2). The S−O distances within the SO_4^{2-} ions differ remarkably. Those to the oxygen atoms which are attached to platinum atoms lie between 151.2(11) and 154.7(13) pm, the noncoordinated oxygen atoms can be found at distances from 142.1(15) up to 144.3(12) pm. The significant differences in the bond lengths also affect the energies of the IR bands (Table 5). For an ideal SO_4^{2-} tetrahedron (T_d symmetry), four vibrations can be theoretically predicted but only the two of symmetry species F_2 can be observed in the IR spectrum at around 1100 [ν_{as}(S−O)] and 610 cm^{-1} [$\delta_{as}(SO_4)$], respectively. In the present case, the SO_4^{2-} ions exhibits only C_1 symmetry and a factor group splitting must also be assumed. Thus, many more bands may be found covering quite a wide range from 1284 down to 850 cm^{-1} [ν(S−O)] and from 651 to 453 cm^{-1} [$\delta(SO_4)$]. In particular, the symmetric stretching vibrations are shifted remarkably to lower wavenumbers compared with the values usually found for sulfates. This can be expected owing to the very long S−O distances of up to almost 155 pm. Such distances are more typical of hydrogensulfates (S−OH) and, for the latter, stretching vibrations around 870 cm^{-1} are not unusual.[14,15]

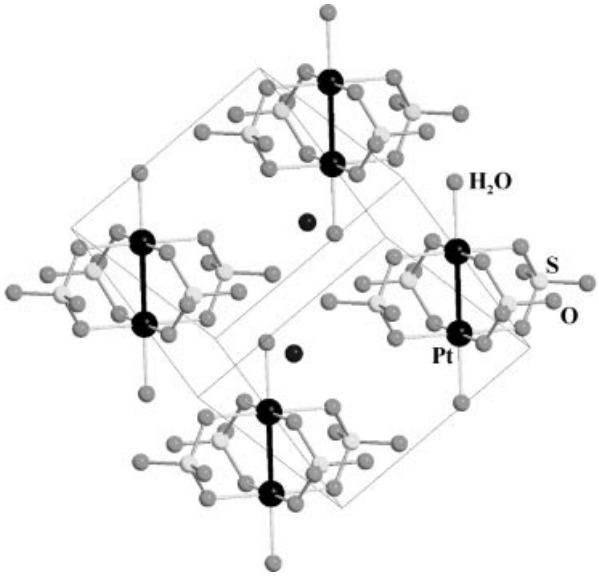

Figure 1. Crystal structure of $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$. The Pt−Pt distance within the lantern shaped complex anion is 246.3(1) pm.

The oxygen stoms of the water molecules (O1) in the axial positions of the Pt_2 dumbbell are at a distance of 209.9(11) pm from the platinum centres and the angle Pt−Pt′−O(1) is 179.3(4)°. According to the space group symmetry of the compound, the $[Pt_2(SO_4)_4(H_2O)_2]^{2-}$ anion should belong to the point group C_i with the inversion centre in the mid-point of the Pt−Pt bond but in fact it has nearly C_{4h} symmetry. The NH_4^+ ions which act as charge compensators are in ninefold coordination environments of oxygen atoms with the NH_4−O distances ranging from 282(2) up to 333(4) pm (Table 2). Besides the findings from the X-ray investigation, the presence of NH_4^+ is also clear from the IR spectra which display typical bands at 3245 cm^{-1} [ν(N−H)] and 1431 cm^{-1} [$\delta(NH_4)$].

The replacement of the axial water molecules in the $[Pt_2(SO_4)_4(H_2O)_2]^{2-}$ anion by monodentate SO_4^{2-} ions can be observed in the crystal structure of $K_4[Pt_2(SO_4)_5]$. This species can be obtained as orange prismatic single crystals from the reaction of $K_2[PtCl_4]$ with concentrated H_2SO_4. Like $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$, $K_4[Pt_2(SO_4)_5]$ is quite stable towards moisture but in contrast to the former, only slightly soluble in water. The four crystallographically different $[Pt_2(SO_4)_4]$ cores of the compound remain nearly unchanged compared with those in $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$. The respective Pt−O distances lie in the same range from 200.6(6) up to 202.6(5) pm and the sulfate groups also show the same significant bond length differences for coordinating ($d_{av.}$ = 143.3 pm) and noncoordinating oxygen atoms ($d_{av.}$ = 152.9 pm), respectively. Accordingly, the findings of the IR spectroscopic measurements (Table 5) are almost the same as those discussed for $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$.

The Pt−O distances to the axial oxygen atoms range from 211.0(5) up to 213.2(5) pm. These distances are slightly longer than observed in $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$. Furthermore, in contrast to the related angles mentioned previously, the Pt−Pt′−O angles in this species involving the axial oxygen atoms show slight but significant deviations from linearity with values between 171.9(1) and 173.7(1)°. The axial oxygen atoms belong to the sulfate groups $S(8)O_4^{2-}$ and $S(10)O_4^{2-}$. These anions link the $[Pt_2(SO_4)_4]$ units into two crystallographically different infinite chains according to the formula $^1_\infty[Pt_2(SO_4)_{4/1}(SO_4)_{2/2}]^{4-}$ (Figure 2) which are oriented in the [110] direction (Figure 3). The linking sulfate groups show the same characteristics as observed for the bidentate-bridging sulfate groups. Thus, the S−O distances to the oxygen atoms which are coordinated to the platinum atoms are about 10 pm longer than the respective values for the noncoordinating oxygen atoms. The charge compensation for the $^1_\infty[Pt_2(SO_4)_{4/1}(SO_4)_{2/2}]^{4-}$ chains is achieved by eight crystallographically different K^+ ions which show coordination numbers between 7 and 11 if distances up to 339.5(6) pm from these centres are taken into account (Table 3).

The linkage of $[Pt_2(SO_4)_4]$ units into layers can be seen in the crystal structure of $Cs[Pt_2(SO_4)_3(HSO_4)]$ which is formed from the reaction of $Cs_2[PtCl_4]$ and concentrated H_2SO_4. The plate-shaped red single crystals of

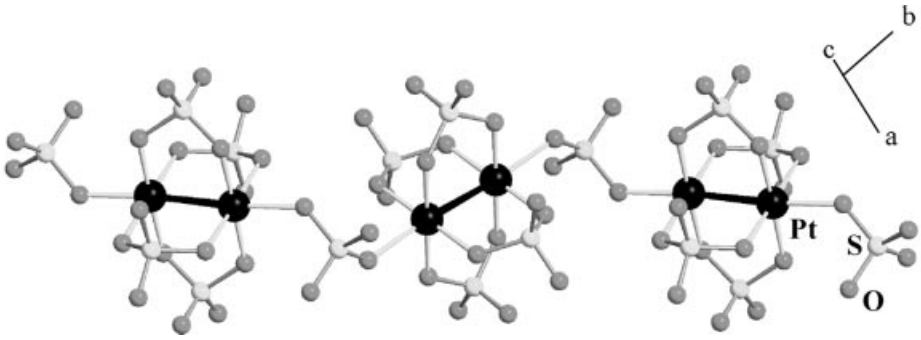

Figure 2. Connection of $[Pt_2(SO_4)_4]$ units via sulfate ions to anionic chains with the formula $^1_\infty[Pt_2(SO_4)_{4/1}(SO_4)_{2/2}]^{4-}$ in the crystal structure of $K_4[Pt_2(SO_4)_5]$. There are two crystallographically different chains which, however, do not differ significantly. The linking SO_4^{2-} ions act as bidentate bridging ligands and the O−S−O angles between their coordinated oxygen atoms and the sulfur atoms are 104.2(3)° and 108.4(3)°, respectively.

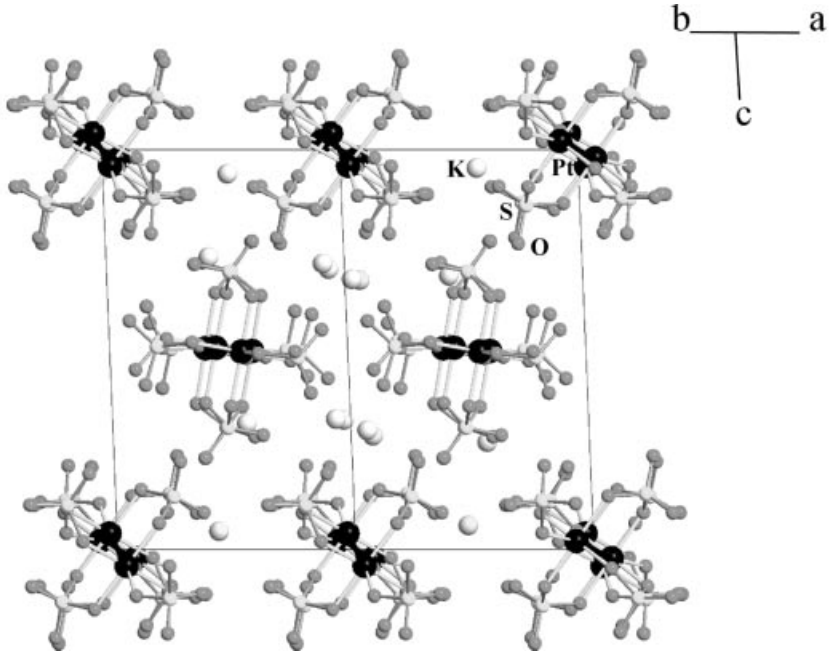

Figure 3. Arrangement of the $^1_\infty[Pt_2(SO_4)_{4/1}(SO_4)_{2/2}]^{4-}$ chains shown in Figure 2 along the [110] direction in the triclinic unit cell of $K_4[Pt_2(SO_4)_5]$. The K^+ ions take act as charge compensators and exhibit coordination numbers between 7 and 11.

$Cs[Pt_2(SO_4)_3(HSO_4)]$ are extremely moisture sensitive and turn immediately cloudy when exposed to air. As described for $K_4[Pt_2(SO_4)_5]$, the Pt_2^{6+} dumbbells in this compound are also coordinated by four bidentate-bridging and two monodentate tetrahedra. The Pt−O distances are comparable to those observed in $K_4[Pt_2(SO_4)_5]$ and lie between 199.2(4) and 202.0(4) pm for the bidentate-bridging ligands and at 212.2(4) and 215.6(4) pm for the monodentate ones (Table 4). In contrast to $K_4[Pt_2(SO_4)_5]$, the axial sulfate groups do not act as *monodentate* but as *bidentate-bridging* ligands towards further Pt_2^{6+} ions and, vice versa, two of the bidentate-bridging tetrahedra are monodentate towards neighbouring Pt_2 dumbbells. The remaining two bidentate-bridging tetrahedra are not bonded to further platinum atoms. The connection leads to layers as depicted in Figure 4. Two different layers can be distinguished crystallographically. One can be formulated as $^2_\infty[Pt_2(SO_4)_{4/2}(SO_4)_{2/1}]^{2-}$ while for the second, half of the tetrahedra can be clearly viewed as hydrogensulfate ions leading to neutral sheets with the composition $^2_\infty[Pt_2(SO_4)_{4/2}(HSO_4)_{2/1}]$. The identification of HSO_4^- ions can be carried out unambiguously with respect to the S−O distances which range from 140.7(4) up to 147.8(4) pm for the oxygen atoms which are not attached to platinum atoms and from 150.1(4) up to 152.7(4) pm for the Pt coordinated oxygen atoms. The only exception is O42 which shows a distance of 150.9(4) pm to the sulfur atom *without* being attached to a platinum atom itself. Furthermore, the hydrogen atom of the HSO_4^- ion can be found in the difference Fourier map. It is involved in a short hydrogen bond with O21 as the acceptor atom

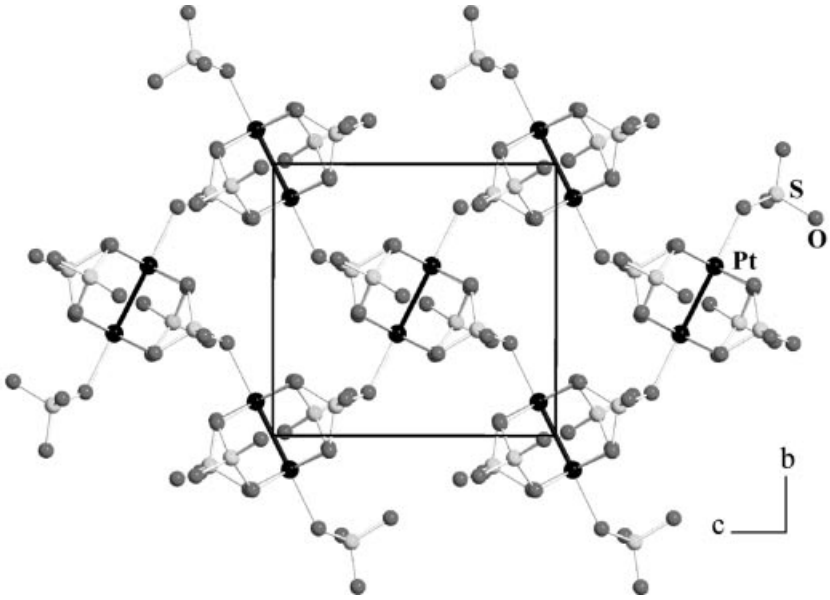

Figure 4. Connection of $[Pt_2(SO_4)_4]$ units by sulfate ions to anionic layers of forumla to $^2_\infty[Pt_2(SO_4)_{4/2}(SO_4)_{2/1}]^{2-}$ in the crystal structure of $Cs[Pt_2(SO_4)_3(HSO_4)]$. One half of the sulfate ions acts as bidentate-bridging ligands, the other half of them are bidentate-bridging to one Pt_2 dumbbell and monodentate to the next. In a second very similar layer, the two uniquely bidentate-bridging sulfate groups are replaced by HSO_4^- ions leading to neutral sheets with the composition $^2_\infty[Pt_2(SO_4)_{4/2}(HSO_4)_{2/1}]$.

with a short distance of 246.7(6) pm from O42 and an angle O42−H−O21 of 167(2)°. With respect to the donor−acceptor distance, the hydrogen bond can be classified as strong.[16,17] It is worthwhile pointing out that the observed O−H−O angle is relatively small for a strong hydrogen bond which usually show values around 180°. However, similar observations of other compounds have been made and a fairly recent neutron diffraction study on NaH_2PO_4 (donor−acceptor distance: 248.5 pm, angle O−H−O: 167.7°) may serve as an example.[17,18] Interestingly, the structural characteristics of the neutral $^2_\infty[Pt_2(SO_4)_{4/2}(HSO_4)_{2/1}]$ sheets are identical to those recently reported for $Pt_2(SO_4)_2(HSO_4)_2$.[12] Thus, the structure of $Cs[Pt_2(SO_4)_3(HSO_4)]$ might be described as a composite of $Pt_2(SO_4)_2(HSO_4)_2$ and the hitherto unknown sulfate $Cs_2[Pt_2(SO_4)_4]$. The neutral and anionic layers are stacked in the [100] direction and alternate with the Cs^+ ions (Figure 5). The latter are in tenfold coordination environments of oxygen atoms with the Cs−O distances ranging from 295.2(4) up to 366.9(5) (Table 4).

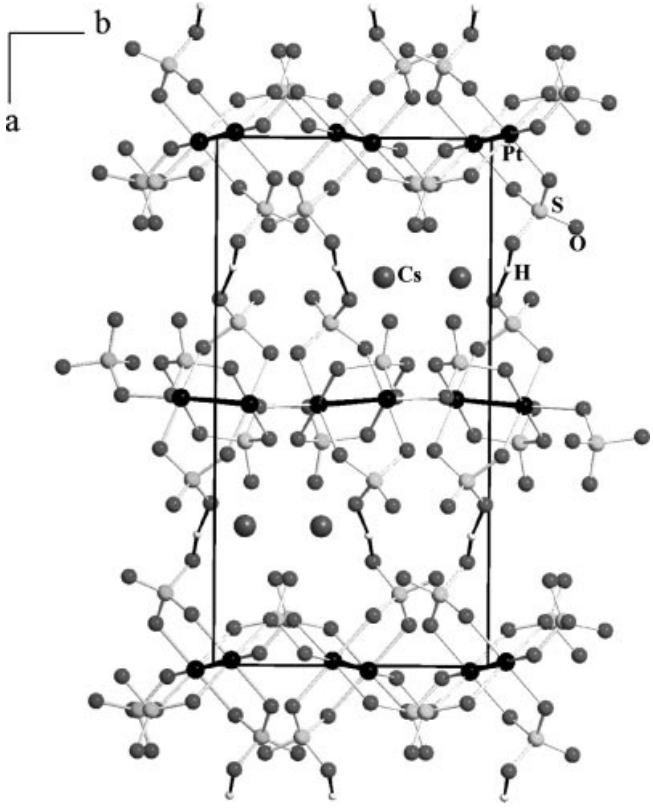

Figure 5. Stacking of the two different layers in the crystal structure of $Cs[Pt_2(SO_4)_3(HSO_4)]$ along the [100] direction. The layers are connected by Cs^+ ions in tenfold coordination environments of oxygen atoms and short hydrogen bonds with a donor (O42) acceptor (O21) distance of 246.7(6) pm.

Experimental Section

Synthesis: All reactions were carried out in sealed thick-walled (2 mm) glass ampoules (ϕ = 10 mm, l = 100 mm) which were placed in a resistance furnace at a temperature of 400 °C. In all cases 2 mL (37.31 mmol) of concentrated sulfuric acid were used. For the synthesis of $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ the platinum source was $Pt(NO_3)_2$ (0.7 g, 5.59 mmol, ABCR, 99.99%) which was used as purchased. For the preparation of $K_4[Pt_2(SO_4)_5]$ and $Cs[Pt_2(SO_4)_3(HSO_4)]$ $K_2[PtCl_4]$ (0.5 g, 1.20 mmol) and $Cs_2[PtCl_4]$ (0.5 g, 0.83 mmol), respectively, were used in the reactions. $K_2[PtCl_4]$ was synthesised from elemental platinum according to literature procedures.[19] $Cs_2[PtCl_4]$ cannot be obtained in the same way due to the very low solubility of $Cs_2[PtCl_6]$. Instead, it was precipitated from a solution of $H_2[PtCl_4]$ which was obtained by reducing $H_2[PtCl_6]$ with $(N_2H_6)Cl_2$. The preparation of $H_2[PtCl_6]$

is well-known.[19] $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ crystallises in the form of yellow plates which can be easily separated from the deep red single crystals of $(NH_4)_4[Pt_{12}O_8(SO_4)_{12}]$ which are formed in the same reaction.[13] $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ is the minor product of the reaction and the yield is about 20% with respect to the initial nitrate. With respect to the X-ray powder patterns of the products, the other two compounds are the only phases to be formed in the reactions. They were obtained in a 50% yield with respect to the initial chlorides. The single crystals of $K_4[Pt_2(SO_4)_5]$ and $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ can be handled under ambient conditions while $Cs[Pt_2(SO_4)_3(HSO_4)]$ is extremely moisture sensitive.

X-ray Diffraction: Several single crystals of each compound were selected under sodium dried paraffin and mounted in glass capillaries. Their quality was checked with the help of a precession camera equipped with an image plate system. For the best specimens, intensity data were collected with an image plate diffractometer (STOE IPDS II). A numerical absorption correction was applied to the data using the programs X-SHAPE and X-RED in each case.[20,21] The solutions of the crystal structures were successful using direct methods provided by the program SHELXS-97.[22] For the refinements of the structures the program SHELXL-97[23] was used, introducing anisotropic thermal parameters for all nonhydrogen atoms. The position of the H atom in $Cs[Pt_2(SO_4)_3(HSO_4)]$ was observed in the final difference Fourier map. It was refined isotropically without restrains. Further details of the data collection and relevant crystallographic data are summarised in Table 1−4. Furthermore, the data have been deposited with the Fach-

informationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen (crysdata@FIZ-Karlsruhe.de) and are available on quoting the deposition numbers given in Table 1.

IR Spectroscopy: For the collection of IR data several single crystals of $(NH_4)_2[Pt_2(SO_4)_4(H_2O)_2]$ and $K_4[Pt_2(SO_4)_5]$ were selected and prepared in KBr pellets. No IR data for $Cs[Pt_2(SO_4)_3(HSO_4)]$ could be gained due its extreme moisture sensitivity. Data collection was performed with a Bruker IFS66v/s IR spectrometer in the range from 400 to 4000 cm^{-1}. Data are summarised in Table 5.

A New Organic-Inorganic Hybrid Gallophosphate Prepared in the Presence of Glycine

Mohammed Abdelkrim Hasnaoui,[a,c] Angélique Simon-Masseron,*[a] Volker Gramlich,[b] Joël Patarin,[a] and Abdelkader Bengueddach[c]

Keywords: Gallium / Gallophosphate / Glycine / Hydrothermal synthesis / Fluorides

A new layered gallophosphate, $Ga_4P_4O_{16}(C_2H_5NO_2)_4$, known as Mu-32 has been synthesised hydrothermally using the amino acid glycine ($H_2NCH_2CO_2H$) as an original template. Such a template has never been used before for the synthesis of microporous and phosphate-based materials such as gallophosphates. The structure was determined by a single-crystal X-ray diffraction study and further characterised by scanning electron microscopy, elemental and thermal analyses and by ^{13}C and ^{31}P solid-state NMR spectroscopy. The compound crystallises in the monoclinic space group $P2_1/c$ with a = 9.177(2), b = 5.1540(10), c = 12.513(3) Å and β = 90.67(3)°. The inorganic layer is built up from four-membered rings sharing T–O–T bonds. In addition to the nature of the template, the original properties of this new gallophosphate come from the coordination environment of the Ga which is only pentacoordinated with oxygen atoms and has strong bonds (Ga–O–C) between the organic template and the inorganic sheet.

Introduction

During the last decade, extensive investigations by numerous researchers have given rise to many new open-framework materials.[1] Among these, the aluminophosphates,[2−6] gallophosphates[7−13] and zincophosphates[14−18] appear to be the most studied. These materials are typically synthesised under hydrothermal or solvothermal conditions in the presence of various organic amines as structure-directing agents. In several cases, the introduction of fluoride ions is crucial for the formation of the phosphate-based material.[19] F^- can act as a mineraliser, it can become trapped in the cages of the framework playing a templating role as shown in the fluorogallophosphate cloverite[20] or it may form a bridge between the atoms of the framework.[21] The amine molecules occupy the cavities or the channels of the framework and are usually removed by calcination of the synthesised sample. Most of the time, the organic molecules are hydrogen-bonded to the inorganic framework. They can also be directly linked to the inorganic structure via T−N or T−O−C bonds (T = Al, Zn,Ga, ...).[22,23] Such connections can be found, for instance, in the oxalate-phosphate[24,25] and -phosphonate systems where a P atom is directly linked to the carbon atom in PO_3R.[26−28] Aluminophosphates and gallophosphates showing such organic-inorganic bonds are rarely encountered. However, the use of the cyclam molecule (1,4,8,11-tetraazacyclotetradecane) as a structure-directing agent in these systems induces the crystallisation of such compounds (STA-6,[29] Cyclam-Co-$AlPO_4$,[30] Mu-5[31] and Mu-6[32]). It was shown, in the $AlPO_4$-SOD material synthesised in the presence of dimethylformamide, that the organic template is bonded to the inorganic framework via Al−O−C bonds.[33] More recently, bipyridine-gallophosphate hybrid materials have also been obtained.[34,35] In these compounds, Ga−N, F−N or Ga−O−Co−cyclam bonds have been revealed. The majority of the open-framework metal phosphates were synthesised in the presence of amines. To the best of our knowledge, there are no open-framework metal phosphates which have been prepared with bifunctional molecules such as amino acids (NH_2−R−COOH) as structure-directing agents.

In this paper, we describe the structure of a new layered gallophosphate, Mu-32, prepared with the amino acid glycine as an organic template. Its characterisation by thermal analysis, scanning electron microscopy and solid-state NMR spectroscopy is also reported.

Results and Discussion

Synthesis and Crystal Morphology

The most characteristic synthetic results are summarised in Table 1. It has been shown that strongly acidic media are unfavourable for the formation of the gallophosphate Mu-32. Indeed a starting mixture with a pH of 1 induces the formation of a material called the "S phase" which is related to the mineral strengite (sample A, Table 1). Therefore TriPA was added in order to increase the initial pH to ca. 4−5.

With a TriPA/Ga_2O_3 molar ratio of 1.5 at 130 °C, the strengite phase crystallises (sample B, Table 1). It was necessary to increase the temperature to 170 °C in order to obtain large crystals of pure Mu-32 (sample C, Table 1). The influence of the gallium source was also studied. Instead of β-Ga_2O_3, the use of GaOOH (prepared by heating a gallium nitrate solution at 250 °C for 24 h) induces formation of larger crystals of Mu-32 but in this case, traces of an impurity can also be detected by XRD (sample D, Table 1). It should be noted that the presence of fluoride ions is of prime importance for the formation of Mu-32. They act as catalysts since their presence cannot be detected in the finally prepared material. On the other hand, β-Ga_2O_3 (sample E, Table 1) or a quartz-type gallophosphate is obtained (sample F, Table 1) in the absence of fluoride anions under similar reaction conditions and pH. Large crystals of Mu-32 display a hexagonal prismatic morphology as shown in Figure 1. Their average sizes are 150 × 830 × 980 μm.

The experimental XRD pattern of Mu-32 is reported in Figure 2 (a). For comparison, the simulated pattern calculated from the structural data is given in Figure 2 (b).

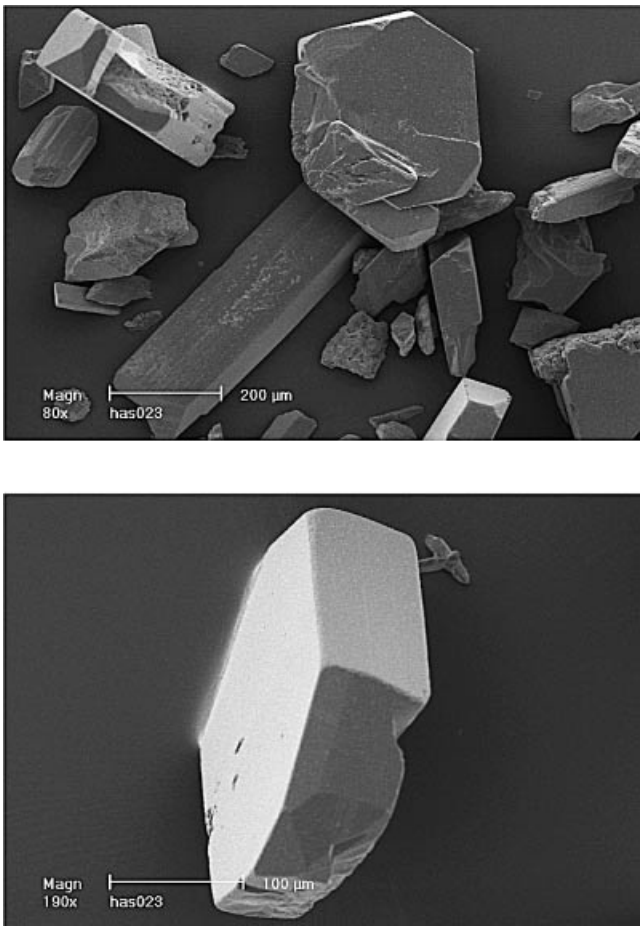

Figure 1. Scanning electron micrographs of some crystals of the gallophosphate Mu-32

Chemical Formula Determination

According to the microprobe and chemical analyses, the synthesised Mu-32 sample has Ga/P and C/N molar ratios close to 1 (Ga/P exp = 1.06) and 2 (C/N exp = 2.08), respectively. No fluoride was detected by scanning electron microprobe analysis.

The thermal behaviour of Mu-32 was investigated by TG/DTA thermal analyses. The TG and DTA curves of the material are given in Figure 3. The total weight loss occurs in two steps. The first occurs between 380 and 480 °C (23.8 wt%) and the second between ca. 480 °C and 1100 °C (3.8 wt%). The first weight loss is associated with the oxidation of the template (exothermic component on the DTA curve), consistent with the structure determination (weight loss expected: 27 wt%) and with a collapsing of the structure. The latter was confirmed by XRD analyses (not reported) recorded on an Mu-32 sample previously heated to 450 °C and by the presence in the DTA curve (reproducible) of an endotherm at about 450 °C. The second weight loss may correspond to dehydroxylation reactions including hydroxyl groups probably formed during the oxidation of the template by cleavage of the C(1)−O(3)−Ga(1) bonds (see struc-

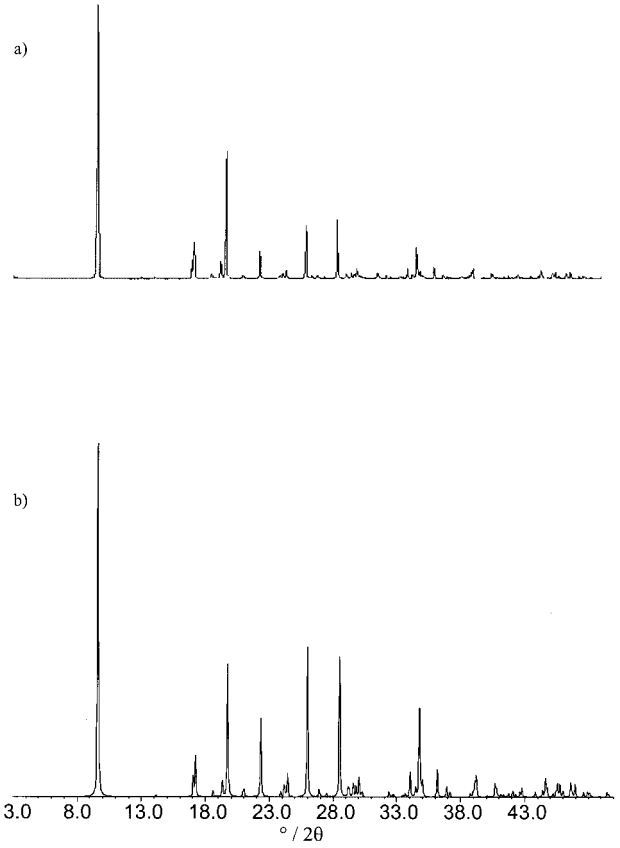

Figure 2. Experimental (a) and calculated (from crystal data) (b) XRD patterns of the gallophosphate Mu-32

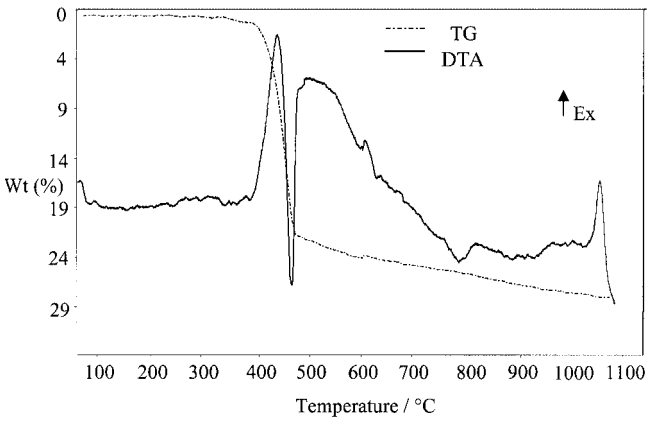

Figure 3. Thermal analyses (TG and DTA) of the gallophosphate Mu-32 under air

ture determination). After heating to 1000 °C, the XRD pattern of the sample showed that a cristobalite-type gallophosphate was formed (ICDD 89-3606). Its formation might also be the cause of the exothermic signal on the DTA curve at about 1050 °C. Taking into account the results of these analyses, the following unit cell formula can be proposed for the gallophosphate Mu-32: $Ga_4P_4O_{16}$-$(C_2H_5NO_2)_4$.

Structure Description

The framework of Mu-32 exhibits only four-membered rings formed by the alternation of Ga-centred trigonal pyramids (GaO_5) with P-centred tetrahedra (PO_4). This alternating pattern leads to the formation of an inorganic sheet parallel to the *bc* plane [Figure 4 (a)].

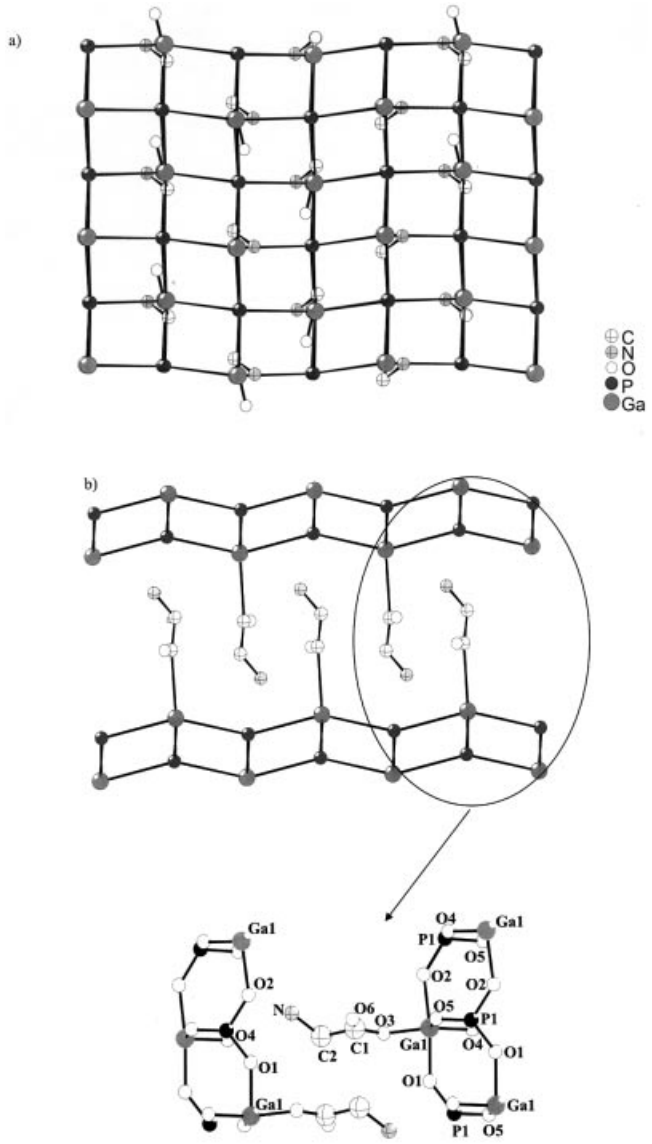

Figure 4. View along the [100] (a) and the [010] directions (b) of the framework of the gallophosphate Mu-32; oxygen atoms of the inorganic sheet are omitted for clarity

The most striking feature of this structure is the coordination sphere of each gallium atom. They are in pentacoordinate environments of oxygen atoms. Four oxygen atoms are shared with P-centred tetrahedra and the remaining one comes from the glycine template. The inorganic sheet interacts with the template via a hydrogen bond between its nitrogen atom and the O2 framework oxygen (bond length N···O2 = 2.821 Å) but also via a strong bond between its O3 oxygen (from OH group in the free glycine molecule) and the gallium atom of the inorganic layer (bond length

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

O3···Ga1 = 1.913 Å) [Figure 4 (b)]. A bond valence calculation[36] performed on this O3 oxygen atom shows clearly that it corresponds to an oxygen atom and not to an OH group (Σs = 2.02, Table 2). The trigonal-pyramidal GaO_5 is quite regular since its angles, shown in Table 3, are close to the expected values of 90°, 120° and 180°. Nevertheless, it should be noted that the axial bonds of the pyramids, i.e. Ga1−O1 and Ga1−O2, are relatively longer than the equatorial ones, Ga1−O3, Ga1−O4 and Ga1−O5. In addition, the equatorial bond length Ga1−O3 is slightly longer than Ga−O4 and Ga−O5 since O3 bridges the gallium to the carbon atom C1. The phosphorus tetrahedra are quite regular with O−P−O angles in the range of 105.3(3)−111.9(3)°.

Table 2. Bond valence analysis of the gallophosphate Mu-32, according to Brown;[36] the results refer to the equation: $s = \exp[(R_0 - d)/B]$ with d = experimental distance, R_0 = 1.62, B = 0.36 for P−O and R_0 = 1.73, B = 0.38 for Ga−O; for C−O, $s = (d/R_0)^{-N}$ with R_0 = 1.37 and N = 4.4

Atoms	Ga1	P1	C1	Σs	Expected valence
O5	0.68	1.27		1.95	2
O4	0.67	1.22		1.89	2
O3	0.61		1.40	2.02	2

O2#1−P1−O5#2	111.92(14)		

The structure of Mu-32 can be compared with that of the fluorogallophosphate ULM-9.[37] Although these 2D structures have different crystallographic data, they do have similar frameworks. Besides the conditions for their synthesis (structure-directing agent, ...), a difference can be observed in one of the equatorial bonds of the pentacoordinate gallium atom: the Ga−O−C bonds in Mu-32 are replaced by $Ga-F_{terminal}$ bonds in ULM-9.

NMR Spectroscopy

The ^{13}C CP MAS NMR spectra of the gallophosphate Mu-32 recorded at 4 kHz and 744 Hz display two isotropic chemical shifts at 45 (CH_2) and 160 ppm (C=O, oxygen O6) [Figure 5 (a and b)]. The resultant tensor associated with the carbonyl group cannot be decomposed into only one tensor. At least two tensors are necessary to reconstruct this part of the spectrum. Thus, the ^{13}C NMR spectrum enables the distinguishing of at least two kinds of carbonyl groups associated with the same isotropic chemical shift. It could reveal two different delocalisations of the electronic charge in the O6−C1−O3 bonds. Such a distinction cannot be observed by single-crystal XRD analysis.

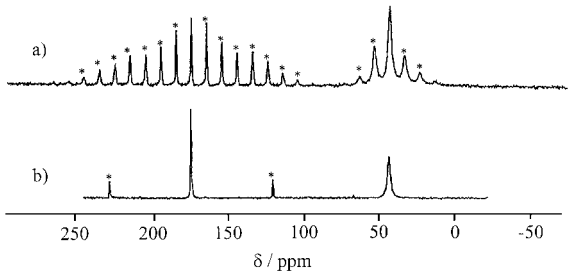

Figure 5. ^{13}C CP MAS NMR spectra of the gallophosphate Mu-32 recorded at 744 Hz (a), 4 kHz (b); * spinning side bands

The ^1H MAS NMR spectrum exhibits two signals at δ = 7.6 and 3.9 ppm (Figure 6). A decomposition allows the determination of the proportion of the different populations as 58 and 42%, respectively. These can be attributed to NH_3^+ and CH_2 groups, respectively, in agreement with the structure determination. The ^1H MAS NMR spectrum does not display a signal corresponding to an OH group (between δ = 9 and 12 ppm) which confirms that the glycine template is strongly bonded to the inorganic layer

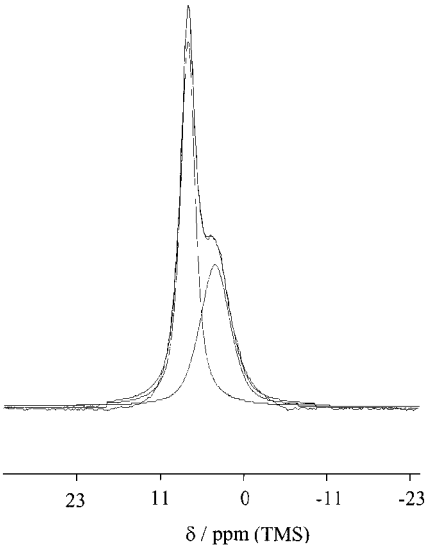

Figure 6. ^1H MAS NMR spectrum of the gallophosphate Mu-32; the two inner curves represent the decomposition of the spectrum

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

through its oxygen atom O3 (OH group in the free glycine molecule).

The ^{31}P MAS NMR spectrum of Mu-32 displays only one signal located at $\delta = -9.2$ ppm (Figure 7) in agreement with the structural data in which only one crystallographic phosphorus site is present. Such a chemical shift value is similar to those traditionally observed for PO_4 groups in gallophosphates.[9,10]

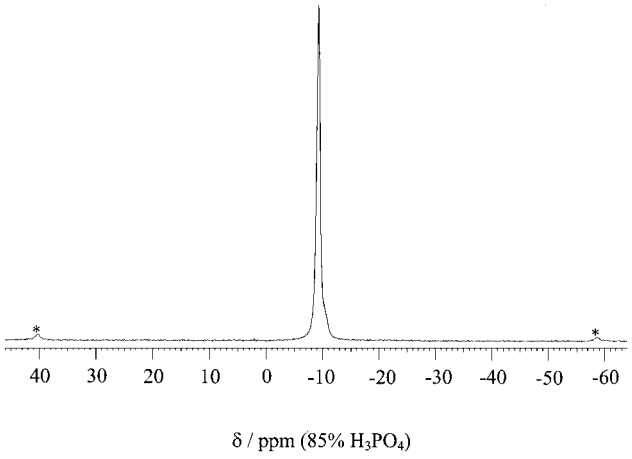

Figure 7. ^{31}P MAS NMR spectrum of the gallophosphate Mu-32; * spinning side bands

Conclusion

The gallophosphate Mu-32 shows several original features. The first is the nature of the template, i.e. the amino acid glycine, which has never been used before as a structure-directing agent in the synthesis of microporous and phosphate based materials such as gallophosphates. This work shows that under certain particular synthetic conditions, such an organic molecule can have a templating effect. The second feature comes from the coordination sphere of the gallium atoms. They are in pentacoordinate environments of oxygen atoms. Four oxygens are shared with P-centred tetrahedra and the last oxygen comes from the glycine template. The latter is, therefore, part of the framework.

Experimental Section

Synthesis: The reactants were glycine (Gly) (Fluka, 99%), phosphoric acid (Labosi, 85%) and hydrofluoric acid (Prolabo, 40%). The gallium source was the oxide β-Ga_2O_3 (ICDD 41-1103) obtained by heating a gallium nitrate solution to 250 °C for 24 h followed by calcination at 1000 °C for 6 h. Tripropylamine (TriPA) (Fluka, purum >98%) was used as a pH modifier. Previous experiments indicated that this amine does not play a templating role in the synthesis of gallophosphates in fluoride media.[31] Mu-32 was obtained by hydrothermal synthesis at 170 °C in a fluoride medium. The starting molar composition of the gel was: 1 Ga_2O_3/1 P_2O_5/1 HF/1 Gly/1.5 TriPA/160 H_2O. The gel was prepared by adding H_3PO_4 to the mixture of the gallium source and water with stirring. After a homogenisation time of 10 min, the amino acid glycine was introduced. Finally, the pH was adjusted to 4−5 with tripropylamine. The resultant gel was mixed at room temperature for 2 h and transferred to a 20-mL PTFE-lined stainless steel autoclave. The crystallisation was carried out at 170 °C under static conditions. After 3 d of heating, the product was recovered, washed with distilled water and dried at 60 °C overnight.

Structure Determination: On the basis of Weissenberg photographs, the powder XRD pattern of Mu-32 reported in Figure 2 (a) was indexed to the monoclinic crystal system, space group $P2_1/c$, with the following unit cell parameters: $a = 9.1766(3)$ Å, $b = 5.1520(16)$ Å, $c = 12.5093(4) =$ Å and $\beta = 90.6685(16)$. The structure was then determined by a single-crystal X-ray diffraction study using direct methods. A crystal with dimensions 200 × 90 × 50 μm was selected from the batch and mounted on a Picker 4-circle STOE diffractometer. 1036 reflections were recorded from 3.26° up to 24.95° in θ in the ω-scan mode, of which 1004 fulfilled the condition $I > 2\sigma(I)$. A summary of the experimental and crystallographic data is reported in Table 4. The structure was solved by direct methods using SHELXS-86[38] and refined using SHELXL-93.[39] The refinement converged to $R_1 = 0.0293$ $\{R_1 = \Sigma(F_o - F_c)/\Sigma F_o]$ and $wR_2 = 0.1041$ $\{R_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}\}$ for 1004 reflections $[I > 2\sigma(I)]$. Using direct methods, the positions of the Ga and P atoms were revealed and all the remaining atoms, except the hydrogen atoms, were located from successive Fourier maps. Hydrogen atoms were placed with geometrical constraints. None of the hydrogen atoms were refined with anisotropic displacement parameters. CCDC-236894 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail:

Characterisation: The powder XRD patterns were recorded with a STOE STADI-P diffractometer equipped with a curved germanium (111) primary monochromator and a linear position-sensitive detector using Cu-$K_{\alpha 1}$ radiation (λ = 1.5406Å). The morphology and size of the crystals were determined by scanning electron microscopy using a Philips XL30 microscope. Thermogravimetric (TGA) and differential thermal analyses (DTA) were performed under air with a Setaram Labsys thermoanalyser with a heating rate of 5 °C/min up to 1100 °C. At this final temperature, a white product was obtained indicating that the total amount of the organic template had been eliminated. The amounts of Ga, F and P in the gallophosphate Mu-32 were determined by scanning electron microprobe analysis with a Castaing type (CAMEBAX) electron microscope. Carbon and nitrogen quantities were determined by coulometric and catharometric methods, respectively. The ^{13}C CP MAS NMR spectrum was recorded with a Bruker MSL 300 spectrometer and the ^{1}H and ^{31}P MAS NMR spectra with a Bruker DSX 400 spectrometer. The recording conditions of the CP MAS and MAS spectra are given in Table 6.

Aerogel and Xerogel Catalysts Based on θ-Alumina Doped with Silicon for High Temperature Reactions

Aurelien Florin Popa,[a] Laurence Courthéoux,[b] Eric Gautron,[b] Sylvie Rossignol,*[b] and Charles Kappenstein[b]

Keywords: Aerogel / Xerogel / Catalyst / Platinum / Alumina

Numerous materials (supports and catalysts) based on alumina have been prepared using the sol-gel process and carbon dioxide supercritical drying. In this work two types of solids, i.e. xerogels and aerogels, were systematically compared and a way of introducing platinum metal with a content of 5% percent by weight was examined. The structural data, the surface area, Pt dispersion and catalytic activity for the decomposition of the propellant were measured for the various samples. The $(Al_2O_3)_{0.88}(SiO_2)_{0.12}$ samples prepared show very interesting porosity values, especially for the aerogel. For this reason, they were chosen as supports for the synthesis of 5 wt% platinum on alumina catalysts. The results presented in this work allowed us to obtain an overall view of the influence of the preparation mode on the properties of platinum on alumina supported catalysts. The dispersion of the metal phase is directly dependent on the specific surface of the support. A significant value for the surface area implies a large amount of centers for interaction with the metal precursor and, consequently, the appearance of more centres of simultaneous germination. Although aerogels obtained by carbon dioxide supercritical drying always show superior properties compared with xerogels, for catalytic decompositions the xerogels still remain superior.

Introduction

The sol-gel method represents a way of synthesising materials which display excellent properties suitable for many applications such as catalysis, ceramics and glasses, and nano-materials.[1] Therefore, numerous catalyst supports or catalysts have been prepared by this procedure which leads to high purity, homogeneous materials with large surface areas. These properties are key factors for the application of these materials.[2,3] Their properties are comparable and, in some cases, superior to some catalysts prepared using conventional procedures such as co-precipitation or conventional ceramic methods. In particular, we have focussed our interest in recent years on the preparation and evaluation of alumina-based catalysts for applications concerning the decomposition of monopropellants.[4] For this specific purpose, it is important to obtain catalytic materials or supports displaying high thermal stability (i.e. at 1200 °C or even higher). The selected supports for achieving this purpose are aerogel aluminas[5] or doped aluminas. In the latter case, the doping element (lanthanum, praseodymium, barium or silicon) can be introduced during the sol-gel process.[6−10] Moreover, for catalytic applications, it is generally necessary to add an active phase (a metal phase such as platinum, palladium etc.) to improve the properties.

Numerous authors have used alumina-supported platinum catalysts, prepared generally by the impregnation of commercially available supports. The literature concerning the sol-gel method was less important until the 1990′s during which time more papers appeared. Samples have been generally prepared by conventional drying processes (293 to 393 K) leading to xerogels. The use of supercritical drying, generally in carbon dioxide, leads to aerogels but the corresponding reports are much less numerous and focus mainly on pure alumina supports. The first paper concerning a Pt catalyst supported on alumina (aerogel and xerogel) and prepared by the sol-gel method was published in 1993 by Balakhrishnan et al.[11] The alumina precursor used was aluminium tri-*sec*-butoxide Al(O-*sec*-$C_4H_9)_3$ (ATB) following the work of Yoldas[12] and the platinum was introduced during the sol-gel transformation using H_2PtCl_6 as a precursor. The supercritical conditions for obtaining the aerogels were T = 295 °C and P = 85 bar with methanol. The samples were then treated at 773 K under helium. The main conclusions from this work were: (i) during the treatment, a reduction of the surface area can be observed and (ii) aerogels display a lower Pt metal dispersion in comparison with xerogels of similar loading. In 1998, Cho et al.[13] prepared the same materials using aluminium tripropoxide Al-

$(OC_3H_7)_3$ (ATP) and H_2PtCl_6, with a final treatment at 773 K. They demonstrated that the sol-gel (xerogel) catalyst displays a higher thermal stability of the metal particles than the conventionally impregnated catalyst. For the sol-gel sample, the exposed Pt metal particles are anchored to the alumina surface by metal−oxygen bonding. Other xerogel Pt/Al_2O_3 catalysts prepared by Castillo et al.[14] and Manasilp et al.[15] using the same precursors (ATB-ATP, H_2PtCl_6) and treated at 823 K and 773 K, respectively, demonstrate that the co-gelation of alkoxides and noble metals induces the stabilisation of the metallic phase and its incorporation into the alumina network producing better metal-support interactions. Recently, using ATB with acetylacetonate and $LiBH_4$ as precursors, Sault et al.[16] demonstrated that after calcination at 873 K, the metal particles are not encapsulated or occluded into the support. All these observations confirm that the metal-support interactions strongly depend on the precursors used, on the thermal treatment and on the method of drying. In order to extend the use of such samples to high temperature applications, it seemed important to study the influence of the drying conditions and to then compare xerogels and aerogels.

In this paper, we present our results on the sol-gel preparation of alumina or alumina doped with silica as a support. A systematic comparison has been made between support samples dried under conventional conditions (xerogels) and under supercritical conditions using CO_2 (aerogels) including the behaviour after the thermal treatment. The introduction of platinum was carried out using the conventional impregnation of dried or calcined sol-gel supports or during the sol-gel process. Powder X-ray diffraction (XRD), transmission electron microscopy (TEM) and thermal analyses (TDA-TGA) were used to determine the structural properties. To determine the effects of the synthesis on the catalytic activity, an evaluation of the properties of the catalyst towards the propellant decomposition has been performed with aqueous solutions of hydroxylammonium nitrate $NH_3OH^+ NO_3^-$ (HAN). The preliminary results are presented here.

Results and Discussion

A. Supports

The diffraction patterns of the four different types of supports, after drying, are presented in Figure 1. They are all composed of nanocrystalline hydrated boehmite γ-$AlO(OH)\cdot nH_2O$, see PDF file 21−1307 mentioned in ref.[17] The peak positions are essentially identical for all samples which also show the same cell parameters. The shift of the first diffraction peak has been discussed previously.[18]

The thermal analyses curves (Figure 2) indicate two major weight losses accompanied by endothermic effects which correspond firstly to the dehydration of the hydrated boehmite and then to the transformation of boehmite into gamma alumina. Assuming that at the end of the analyses the final product is the anhydrous α-alumina, the TG curves enable the determination of evolved water and thus the formula of the initially dried solids. At the beginning of the measurements, the dried samples always contain an excess of water and are known as hydrated boehmites. For both samples presented in Figure 2, the complete formulas are $AlOOH\cdot 0.94H_2O$ and $(AlOOH)_{0.94}\text{-}(SiO_2)_{0.06}\cdot 1.0H_2O$. Therefore, in the low temperature range (20−800 °C), the behaviour of the doped samples is similar to that of pure boehmites. On the other hand, the TDA curves reveal an important difference at high temperature: the exothermic peak at about 1200 °C which characterises the transformation into alpha alumina is clearly visible in the case of the pure boehmites but is shifted to a higher temperature for the doped samples. In this case, the boehmite is transformed into transition alumina but its structure is more stable and leads to alpha alumina at much higher temperatures (>1350 °C). This thermal behaviour is the same for the aerogel and xerogel samples. Consequently, we expected that the doped samples would not be transformed into alpha alumina, even after a hard thermal treatment (5 h calcination at 1200 °C).

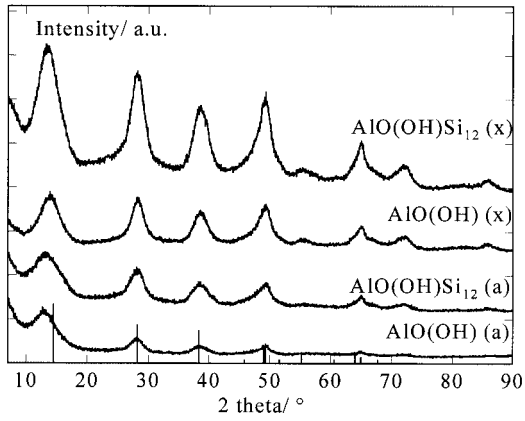

Figure 1. X-ray diffraction patterns of pure and doped boehmites, xerogels and aerogels (lines: PDF file 21−1307).

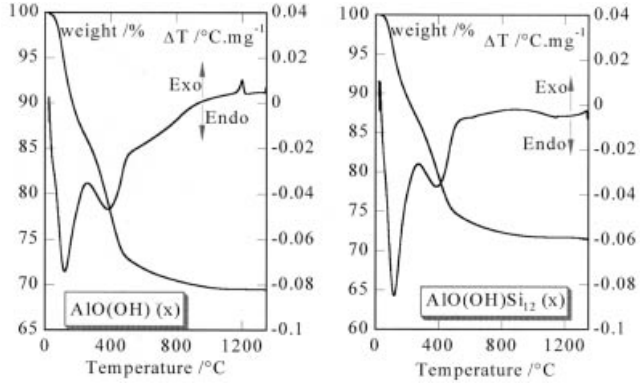

Figure 2. Thermal analyses of dried samples of AlO(OH) (x) and $AlO(OH)\text{-}Si_{12}$ (x)

The diffraction patterns of the calcined supports (Figure 3) confirm this fact, revealing that the transformation into alpha alumina is delayed by doping. After the thermal treatment, the structure of the Al_2O_3Si12 xerogel or aerogel corresponds to θ alumina (monoclinic, PDF file 23−1009) with a well ordered structure. By comparison, the nondoped aerogel (Al_2O_3) is entirely transformed into alpha alumina after the same treatment (Figure 7).

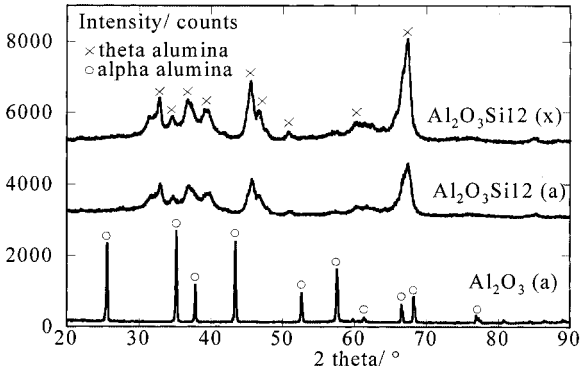

Figure 3. X-ray diffraction patterns of doped samples of Al_2O_3-Si12 (a) and (x) and nondoped Al_2O_3 (a), calcined at 1200 °C for 5 h (θ Al_2O_3, PDF: 23−1009; α Al_2O_3, PDF: 46−1212)

The values found for the BET surface area of the samples (Table 1) confirm that the doping retards the transformation into alpha alumina. The doped xerogel retains a good specific surface area (65 $m^2 \cdot g^{-1}$) whereas the aerogel has a much better value of 120 $m^2 \cdot g^{-1}$ (compared with 1−3 $m^2 \cdot g^{-1}$ for the nondoped alumina). This value is similar to that published by Mizushima,[8,9] (114 $m^2 \cdot g^{-1}$) for a 10% doped sample prepared in an alcoholic medium. The porous volume is slightly larger for the ASi12 (a) sample (0.24 $cm^3 \cdot g^{-1}$) than for the ASi12 (x) sample (0.16 $cm^3 \cdot g^{-1}$). The mean pore sizes of the two doped aluminas are comparable at 9.5 and 9.7 nm, respectively.

The transmission electron microscopy images enabled us to analyse the morphology of these calcined supports. Furthermore, the X-ray mapping revealed the atomic distribution of Al and Si across the samples. For the sake of clarity, we present a previously published diagram (Figure 4).[17] For ASi12 (a) (aerogel sample) we can see that the distribution of both aluminium and silicon atoms is homogeneous over the entire zone of the sample which was analysed. Other explored zones show that this homogeneity is a characteristic of the aerogel samples (see 2 in Figure 4). Xerogel sample ASi12 (x) contains some zones showing obvious microscale heterogeneity (see 1 Figure 4). This latter sample contains domains where the silicon concentration is enhanced. From EDX analyses, the Si and Al atomic compositions were quantified. For the aerogel, the atomic Si:Al ratio of 6:94 is in excellent agreement with the expected value (6.3:93.7). For the xerogel, this ratio strongly depends on the analysed zone (200 nm). In Figure 4 (1), the analysed zone exhibits a very important excess of silicon: Si:Al = 33:67. In fact, the large (200 nm) dark particle clearly visible on the image of the xerogel (see 2 in Figure 4) contains only silicon and oxygen atoms which correspond to pure amorphous silica. The aluminium content is smaller in the zones where this silicon agglomeration appears. In compensation, other zones are reduced in their silicon content leading to a higher content of aluminium in comparison with the calculated value. In these zones, the aluminium content can reach values as high as 95.7%.

The silica segregation can explain the lower specific surface area (Table 1) of the xerogel sample 1-Asi12(x) after the thermal treatment at high temperature. During the transformation of alumina into the alpha form, small sites are first formed by a nucleation process. The corundum formation then continues by a growing and sintering process which requires contact between the former crystallites and migration of cations or cationic vacancies from the alumina particles of the previous transition.[25]

The stabilising effect of silicon occurs at the surfaces of the crystallites. When the silicon distribution is homogeneous, the silicon atoms are bonded tetrahedrally through μ-oxo bridges Al−O−Si−O−Al− and cannot take part at the sintering process because the α-Al_2O_3 structure contains the cations in octahedral sites. It is much more difficult for these sites to be occupied by silicon. The surface silicon layer behaves as a barrier between the growing areas and limits the transformation. Another explanation for the delay of the transformation into alpha alumina is related to the crystalline structure of the transition alumina. Beyond 600−700 °C, the quantity of surface OH groups contained in alumina is no longer sufficient to maintain the stability of the structure. The removal of these hydroxyl groups leads to the formation of tetrahedral vacancies which destabilise the structure. In the presence of well distributed silicon atoms, the influence of these tetrahedral vacancies is lowered and the transformation is delayed.[19−22]

The diffraction peaks of the two samples after the high temperature treatment have been enlarged to focus on the peak displacement (Figure 5). We observed a systematic and slight but visible displacement of the aerogel peaks to higher 2θ values. This displacement varies between 0.09 and 0.29° and can be explained by the cell parameters shrinking due to the replacement of aluminium by silicon atoms in the structure. Silicon atoms are slightly smaller than Al atoms (bond length Si−O = 1.91 Å compared with Al−O = 2.03 Å).[23] If the structure of θ−Al_2O_3 can be viewed as a distorted spinel structure,[24] we can approximate the peak displacement on the basis of a cubic structure. Assuming that all the silicon atoms are located in the tetrahedral sites of the θ−Al_2O_3 structure, we can estimate the 2θ displacement from the bond length difference to be of the order of 0.2 to 0.5°. The experimental shifts between the aerogel and the xerogel peak positions range from 0.1 to 0.3°, indicating that the silicon content incorporated into the structure is far superior in the case of the aerogel (of the order of 50%).

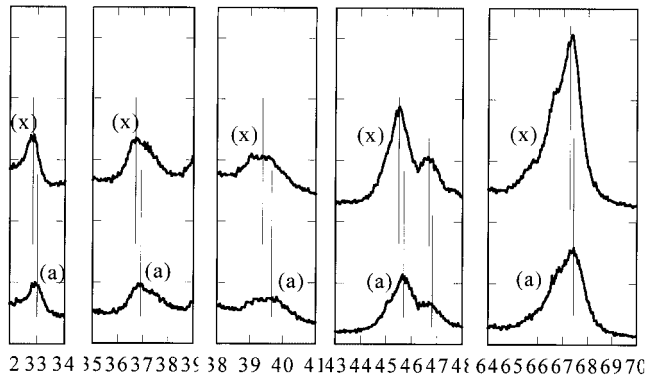

Figure 5. Enlargement of the diffraction patterns of the Al_2O_3Si12 samples X: (a) = aerogel, (x) = xerogel

This cell parameter difference does not exist for the non-calcined samples displaying the boehmite pattern (Figure 1). No displacements can be seen, in agreement with the boehmite structure which displays only octahedral aluminium sites. These sites are able to host aluminium atoms but not silicon atoms. During the sol synthesis, boehmite nanocrystallites are formed first by hydrolysis of the aluminium precursor. After addition of the silicon precursor, hydrolysis occurs later and produces silicon species which may be bonded to the surface aluminium atoms of the boehmite particles by a μ_2-oxo bridge, this being a consequence of an oxolation reaction: $-Si-OH + HO-Al- \rightarrow -Si-O-Al- + H_2O$

Thus, before calcination, silicon atoms are located mainly at the surface of the crystallites and only during the transformation of boehmite into γ alumina can they participate in the transition γ-alumina structure by substituting tetrahedral aluminium atoms. In Figure 6, which shows a possible structural rearrangement during the transformation of boehmite, the surface Si atom is linked to a surface HO group of boehmite and to an external hydroxyl group. The transformation of the hydroxyl group and a slight silicon displacement leads to the position of silica in a tetrahedral site of the transition alumina. The presence of these silicon atoms stabilises the alumina defect structure and can explain the delay in the transformation into corundum.

The results presented in this section show that the drying technique has an important influence on the features of doped alumina. The morphology, thermal stability, homogeneity, fine structure and the textural properties are depen-

dent on this. The ASi12 samples prepared show very interesting porosity values, especially for the aerogel. For this reason, they were chosen as supports for the synthesis of 5 wt.-% platinum on alumina catalysts.

B. Catalysts

1. Effective Catalyst Metal Load

For a selection of catalysts (6 samples), the platinum content was analysed in order to establish precisely the effective metal load after the thermal treatment. For two other samples, SG-Pt-B-c (x) and Pt-A-r (a), the metal load was estimated from a quantitative analysis of the X-ray diffraction patterns with respect to their homologues SG-Pt-B-c (a) and Pt-A-r (x).[25] The results are presented in Table 1. The metal content is between 47 and 71% of the calculated value, so that a quantity of platinum is lost during the preparation of the catalysts. This loss probably takes place during the thermal treatment processes (calcination and reduction).[26] During the introduction of the platinum precursor, the anions present in solution ($[PtCl_6]^{2-}$, $[Pt(H_2O)Cl_5]^-$ or others) are adsorbed into the surfaces of the crystallites and this fixation is mainly due to electrostatic interactions between negative complexes and surface OH_2^+ groups of the support present in acidic solutions or to ligand substitution around the platinum atoms (Cl^- by surface OH groups). The fraction of platinum atoms which is not firmly anchored on the surface can become detached and leave during the thermal treatments, probably in the form of more volatile oxychloride species. Nevertheless, hexachloroplatinic acid remains the best precursor because it allows the preparation of catalysts with high metal dispersions.[11,27] We expect also a lower metal percentage for the materials displaying the α-Al_2O_3 structure due to the strong decrease of the BET surface area (Table 1).

For the samples supported on doped alumina, this platinum content decrease could be related to the surface Si−OH groups which can prevent the metal from bonding firmly to the surface.[28]

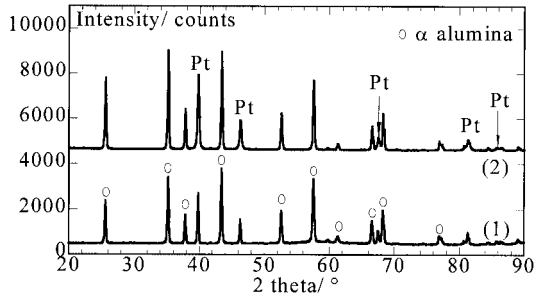

Figure 7. Diffraction patterns of catalysts on nondoped supports: (1) SG Pt-B-c (a) sample; (2) Pt-A-r (a) sample. (PDF: Pt: 04−0802; αAl_2O_3: 46−1212)

2. Physico-Chemical Characterisation

a) Catalysts on Nondoped Supports

The diffraction patterns of both aerogel catalysts (sol-gel and impregnated) are presented in Figure 7. As expected, the structure of the support is α-Al_2O_3 and the metal phase appears as large sized crystallites. The average size values calculated from peak breadths are around 70 nm for the sol-gel catalyst and 26 nm for the impregnated one. For the xerogel sample, the respective values are of the same order (Table 1). The sintering is slightly more pronounced for the sol-gel samples compared with the samples prepared by impregnation.

For the Pt-A-r (a) sample, transmission electron microscopy agrees well with this average size. The image reveals a rather large distribution of the crystallite sizes, ranging from a few tenths to several hundred angstroms. We present two different characteristic zones of the sample in Figure 8.

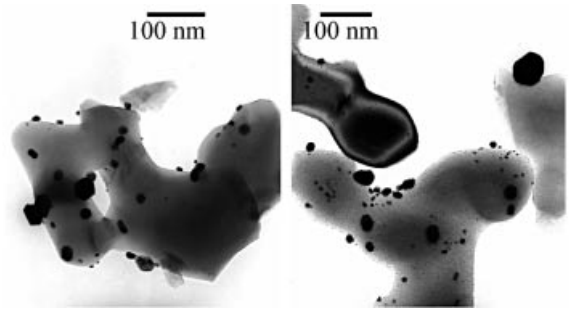

Figure 8. Two transmission electron microscopy images of the Pt-A-r (a) sample

b) Catalysts on Doped Supports

Catalysts Prepared by Sol-Gel Synthesis: The diffraction patterns indicate the presence of θ alumina for the support and the same large metal crystallites (Figure 9) of average size 43 nm for the xerogel and 56 nm for the aerogel. This is the only case when the aerogel crystallites are larger than the xerogel ones. This fact is probably related to the particular texture of the sample of SG Pt−BSi12-c (a). In fact, the precursor anions can be adsorbed onto the boehmite sites concurrently with the silicon species. As a consequent, the

surface nature and the interactions between crystallites may be different from the case of a pure boehmite sol.

After the thermal treatment at 1200 °C, the sample SG Pt-BSi12-c (a) exhibits the largest specific surface area (130 $m^2 \cdot g^{-1}$), compared with only 41 $m^2 \cdot g^{-1}$ for its xerogel homologue SG Pt-BSi12-c (x). The porous volume is 0.45 $cm^3 \cdot g^{-1}$, five times larger than for the xerogel (0.09 $cm^3 \cdot g^{-1}$) and the mean pore sizes are 14 and 7 nm, respectively. Consequently, the platinum crystallites located inside the aerogel pores can develop and reach larger sizes.

The TEM pictures (Figure 10) show, for the xerogel sample, some zones with a normal aspect of the porous support and metal crystallites with sizes ranging from 7 to 100 nm and some other singular zones particles with different textures can be observed. In order to identify the nature of the particles visible on the B image, we recorded three EDX spectra, shown in Figure 11. The first (a) corresponds to a homogeneous zone. We could establish the presence of aluminium and silicon but not platinum. The second reveals platinum crystallites and, finally, the third (c) indicates a large particle containing only aluminium atoms. The appearance of such particles can be explained by the presence of the metal precursor in the boehmite sol in the earlier stages of the synthesis. The competition of adsorption on boehmite crystallites between the platinum and silicon species leads to crystallites covered by more platinum and less silicon. The X-ray analysis reveals that a small fraction of platinum atoms is rather well dispersed over the sample but the other fraction exists as isolated crystallites. In the same way as observed for the supports, some zones with a silicon agglomeration can be identified.

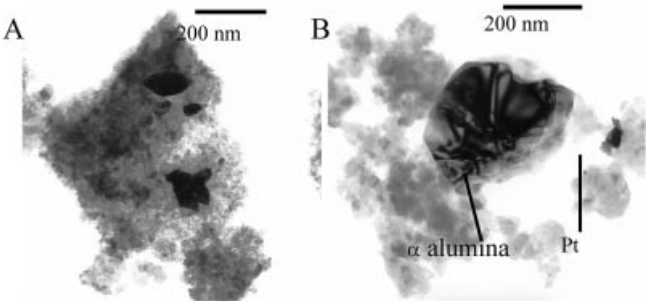

Figure 10. Two transmission electron microscopy images for the sample SG Pt-BSi12-c (x)

For the aerogel, we observed similar behaviour with platinum isolated crystallites and α-Al_2O_3 particles. The X-ray mapping, performed on a zone around the α alumina particle, revealed a better silicon repartition compared with the xerogel. Instead, the signal due to the platinum atoms is practically invisible over the zone showing that the metal is present only as isolated crystallites.

Catalysts Prepared by Impregnation on Doped Alumina: The diffraction patterns of the catalysts impregnated on doped alumina are presented in Figure 12. In the case of the aerogel, the peaks corresponding to platinum are practically indiscernible from the background indicating a very small crystallite size. For the xerogel, the platinum peaks are weak but visible. By comparing the intensity of the isolated (311) peak (36 counts degree) with the SG-Pt-BSi12 c (x) sample (which has practically the same metal load, 304 counts degree) we can estimate that only about 10 wt% of the platinum contributes to the diffraction peaks in the Pt-ASi12-r (x) sample. By using the width of the (311) peak, which appears well isolated at $2\theta = 81.3°$, we can estimate a size of 40 nm. In fact, for a large size distribution, the mean value calculated on the basis of peak's width is largely overestimated since the small crystallites make very little contribution and the peak profile is mainly influenced by the large crystallites.[27,29] We can therefore assume that a large part of the crystallites are small in size and only a small other part of the better developed crystallites will be responsible for the diffraction signal.

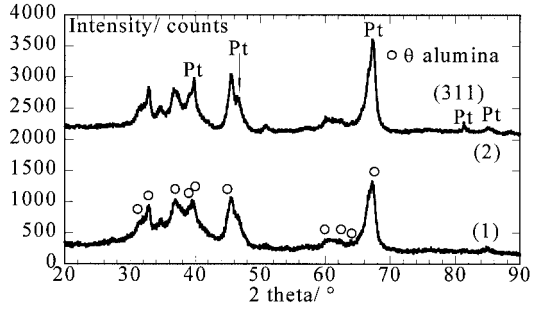

Figure 12. Diffraction patterns of the (1) Pt-ASi12-r (a) and (2) Pt-ASi12-r (x) samples (the circles correspond to θ Al_2O_3, PDF: 23−1009)

The specific surface areas of these catalysts are 68 $m^2 \cdot g^{-1}$ for the xerogel and 120 $m^2 \cdot g^{-1}$ for the aerogel. This is practically the same as in the supports and indicates no pore blocking which is in agreement with the small sizes of most of the crystallites.

Transmission electron microscopy confirmed these results. For the aerogel, almost all the platinum particles are smaller than 4 nm (Figure 13, left). The xerogel exhibits a

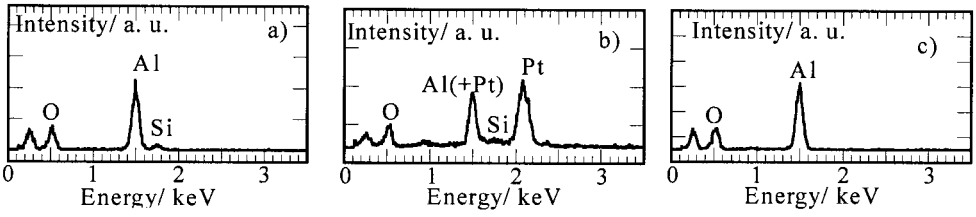

Figure 11. EDX spectra corresponding to different zones of the sample SG Pt-BSi12-c (x)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

larger size distribution with crystallites smaller than 4 nm but with larger particles (Figure 13, right). Both histograms are shown in Figure 14 as well as the average crystallite sizes. From the metal dispersion measurements, an average surface crystallite size can be determined (Table 2). Two models may be used used, a cubic model with one face in contact with the support and a hemispherical model. The average sizes refer to the cube parameter or the diameter. The results for the aerogel are in good agreement with the average sizes determined from the electron microscopy histogram. For the xerogel, this agreement is poorer because of the larger size distribution revealed by electron microscopy and X-ray diffraction (90% of the platinum appears as crystallites with average sizes of about 4 nm, i.e. 10% larger and visible by XRD). It is also possible that a part of the metal crystallites, located in closed pores, is not accessible for the hydrogen adsorption.[30,16]

$$\overline{T_V} = \frac{\sum_{i=0}^{n} T_i \cdot V_i}{\sum_{i=0}^{n} V_i} = \frac{\sum_{i=0}^{n} T_i^4}{\sum_{i=0}^{n} T_i^3}$$

$\overline{T_V}$ = volume weighted mean crystallite size (Å)
T_i = size of a particle i (Å)
V_i = volume of a particle T_i (Å^3)
n = number of particles

C. Discussion

1. Influence of the Preparation Mode by Impregnation versus the One-Step Method (Sol-Gel)

For the samples prepared by the sol-gel method, the calcination at 1200 °C induces an important sintering of the metal phase, whatever the nature of the support (xerogel or aerogel). The SG Pt-BSi12-c (a) sample is of particular note, displaying a very large specific surface area of 130 $m^2 \cdot g^{-1}$. This important difference is due to the specific synthetic conditions (simultaneous presence of silicon and platinum species in the sol) as well as to the supercritical drying which allows the retention of the gel morphology. The metal dispersion is not related to the porosity of the support because the mean size of the platinum crystallites for the SG Pt-BSi12-c (a) sample is still greater than 50 nm. Therefore, the metal dispersion is mainly determined by the growth and sintering of the particles.

In contrast, the catalysts prepared by impregnation on calcined alumina contain smaller metal particles because sintering cannot occur during the reduction process. In this case, the dispersion of the metal phase is directly dependent on the specific surface of the support. A large value of the surface area implies a large amount of adsorption centers within the metal precursor (i.e. H_2PtCl_6) and, consequently, the formation of numerous centers for germination of platinum particles during the reduction. The catalysts supported on doped alumina also exhibit special characteristics, especially for the aerogel sample Pt-ASi12-r (a), namely a specific surface area higher than 120 $m^2 \cdot g^{-1}$ after thermal treatment, good metal dispersion (> 50%) and a homogeneous distribution of silicon and platinum atoms over the sample. As a consequence, this sample could be tested as an interesting catalytic material for applications requiring high temperatures.

Nevertheless, it must be stated that the great difference in dispersion between sol-gel and impregnated catalysts is related to the temperature difference applied to the plati-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

num precursor. For the sol-gel samples, the platinum precursor is decomposed to platinum crystallites during the high temperature treatment (1200 °C, 5 h) in an oxidising atmosphere leading to a strong sintering effect. In the other case, the impregnated sample is reduced at low temperatures (see Exp. Sect.) and the maximum temperature experienced by the platinum particles is only 400 °C. To confirm the critical role of the temperature, the xerogel sample (Pt-ASi12-r (x)) was treated with the same high temperature conditions after reduction at 400 °C. A small decrease in the surface area could be observed from 68 $m^2 \cdot g^{-1}$ to 43 $m^2 \cdot g^{-1}$, accompanied by a strong sintering of the platinum particles. The average size was between 4 nm and 30 nm before treatment and 40 nm after treatment. It must be said that the real catalytic conditions used will not be so drastic, the high temperatures being reached over very short time ranges.

2. *Influence of the Drying Mode: Xerogel versus Aerogel*

The main advantage of the supercritical drying is the possibility of maintaining the microporosity of the wet gel and obtaining materials with high specific surfaces and porosities. Indeed, the specific surface area of the aerogel supports and catalysts is about 120 $m^2 \cdot g^{-1}$even after a thermal treatment at 1200 °C (5 h). By comparison, the xerogel catalysts reveal a specific surface area respectively for the sol-gel, 41 $m^2 \cdot g^{-1}$ and for the impregnated, 68 $m^2 \cdot g^{-1}$. Those values are related to the high porosity of the aerogel materials (0.24 $cm^3 \cdot g^{-1}$ for the doped alumina and only 0.16 $cm^3 \cdot g^{-1}$ for the corresponding xerogel). An other important aspect is the platinum size distribution which is shorter for the catalyst prepared by impregnation on doped aerogel than for the xerogel catalyst. Furthermore, the platinum particles are more homogeneously distributed on the aerogel support. All these remarks display the importance of the drying mode for the final properties of the materials.

D. *Catalytic Tests*

The decomposition temperatures of the HAN/water mixtures, with and without the presence of supports or catalysts are reported in Figure 15. For the catalysts, the effective platinum content is also reported. The decomposition of the $HAN_{79\%}$/water mixture alone appears at a temperature of 165 °C.

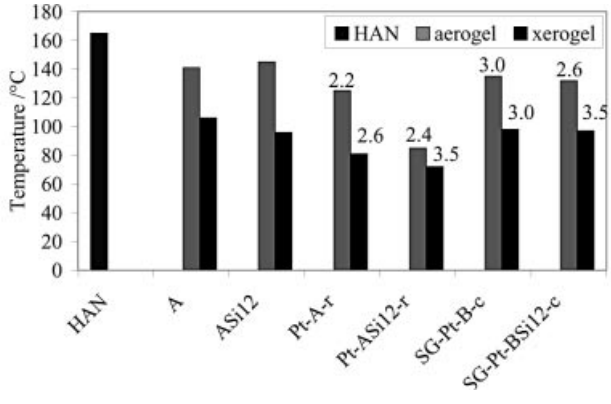

Figure 15. Decomposition temperatures of HAN/water mixtures with and without supports or catalysts and metal content for aerogels and xerogels materials

All the supports (without the active phase) display a catalytic effect. This effect is more pronounced in the case of the xerogel samples (106 °C for A (x) and 96 °C for ASi12 (x)). For the aerogels, the decomposition temperatures are higher and similar for each sample (140 °C). The very strong difference in the surface area between nondoped and Si-doped alumina seems to have a limited influence on this reaction. The introduction of platinum leads to a further catalytic effect in the case of the impregnated catalysts. A further decrease in the decomposition temperature, in comparison with the support, is of the order of 25 °C except for the Si-doped aerogel which display a decrease of 60 °C. For the sol-gel catalysts, the effect of platinum is much more limited.

With regard to the supports, the effect of the surface area remains very limited for the catalysts except for the impregnated aerogel samples Pt-ASi12-r (x) which display an important decomposition temperature decrease (from 125 °C to 85 °C) related to the surface area increase (1 $m^2 \cdot g^{-1}$ to 68 $m^2 \cdot g^{-1}$). For both samples the platinum is of the same order. The higher decomposition temperatures of the sol-gel catalysts compared with the impregnated catalysts are mainly due to the platinum particles sintering during the calcinations leading to a very low platinum accessibility. This effect is clearly observed for the samples Pt-ASi12-r (x) and SG-Pt-BSi12-c (x) which have the same effective metal content (3.5%) but exhibit a decomposition temperature difference of 20 °C. This indicates the importance of the preparation mode.

The comparison between aerogel and xerogel supports and catalysts shows that the xerogel samples are always more efficient (Figure 15). A possible explanation for this difference can be related to the higher insulation properties of the aerogels.[31] Due to its lower thermal conductivity and higher porosity, the temperature within the aerogel is lower than the measured crucible temperature, leading to a temperature difference higher than for xerogels and thus to a higher measured decomposition temperature. Moreover, when the exothermic decomposition starts on the external surface of the catalyst powder, the release energy propagates more slowly to the centre of the aerogel powder resulting in a delay in the decomposition reaction of the monopropellant.

Catalysts supported on silicon-doped alumina are promising for high temperature applications. Moreover, xerogel catalysts have been revealed to be better than aerogel catalysts despite the heterogeneous dispersion of silicon. To confirm this hypothesis, studies must be carried out on the decomposition characteristics, i.e. the temperature increase, pressure increase and ignition delay.

Conclusion

We have synthesised sol-gel materials based on pure or doped alumina using classical and supercritical drying con-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ditions. For the supports, the morphology, thermal stability, homogeneity and the structure depend strongly on the drying technique used. The ASi12 sample displays a high parosity and it was selected as support of catalyst.

A general characteristic of all catalysts is that a fraction of the platinum is lost during the preparation of the catalysts and the real metal content is between 47 and 71% of the calculated value (5 wt.-%).

The comparison between the aerogel and xerogel samples displays, respectively, a fine distribution on the surface and a heterogeneous distribution of the metallic phase. This feature can be linked to the larger specific surface area of the aerogels.

The introduction mode of platinum by impregnation leads to smaller particles which are well dispersed. On the other hand, the sol-gel method results in the formation of large particles.

Finely, from our evaluation experiments on HAN solutions, the best catalytic activity is displayed by platinum catalysts prepared by impregnation on Si-doped xerogel alumina.

Experimental Section

A. Preparations

a) Support: Pure Alumina and Doped Alumina

The preparation procedure for pure alumina and Si-doped alumina $[(Al_2O_3)_{0.88}(SiO_2)_{0.12}]$ by the sol gel method has been described in previous work and is shown in Figure 16.[6] The ASi12 label for this material (Table 1) indicates the final molar composition (after drying and firing) as $SiO_2/(SiO_2+Al_2O_3) = 0.12$. The silica weight percent in the dried sample is 7.4%, corresponding to an atomic ratio Si:Al = 6.3:93.7.

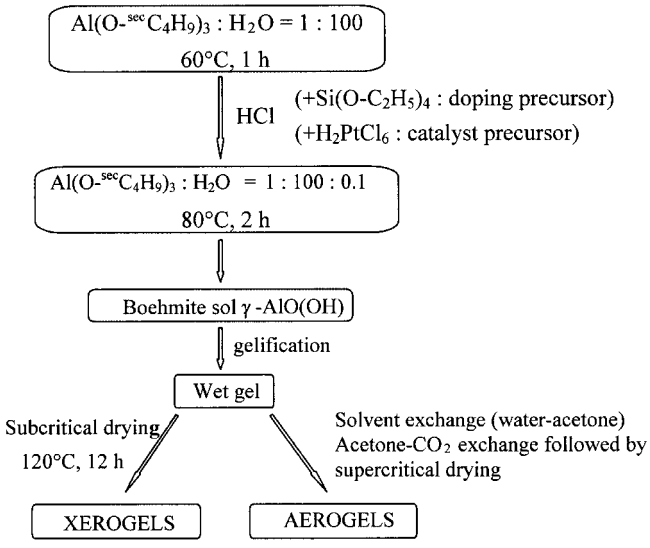

Figure 16. Scheme of the sol-gel preparation procedure

To prepare 2 g of support, aluminium tri-*sec*-butoxide (8.48 g, 0.0334 mol, 97%, Aldrich) and pure water (60.1 g, 3.34 mol) were stirred at 60 °C for 1 h. Concentrated hydrochloric acid (0.28 mL, 3.3 10^{-3} mol, 12 mol·L^{-1}) and, if necessary, tetraethoxysilane (0.51 mL, 2.24 10^{-3} mol, 98%, Aldrich) as a doping precursor were then added and the temperature was raised and maintained at 80 °C for 2 h.

The xerogel samples were obtained after drying overnight at 120 °C in a ventilated oven. For the aerogel samples, about 75% of the water content evaporated at 80 °C over 3 h affording a viscous sol which was poured in the drying mould (stainless steel, $d = 3.6$ cm, $h = 3.5$ cm). A 5-mm hole in the bottom of the mould enables the solvent exchange. After 15 h, the solvent exchange started: water was replaced first by acetone (complete miscibility) and then acetone was replaced by CO_2 just before the supercritical drying. The solvent exchange procedure was as follows: the wet gel was covered with acetone (about 25 mL) and the solvent was evacuated through the bottom hole before the addition of acetone (25 mL, three times a day over 5 days). The mould was then introduced into the autoclave (300 mL, Parr Instruments) and acetone (100 mL) was added. The autoclave was equipped with two entries (liquid CO_2 and argon) and two outflows (gas and liquid) and the temperature and the pressure can be controlled as shown in Figure 17.

The reactor was filled with liquid carbon dioxide using several filling and purging steps in order to quantitatively evacuate the acetone and the air contained in the autoclave. Upon completely filling the autoclave with liquid CO_2, a temperature difference was obtained between the bottle (room temperature) and the autoclave (water cooling system). The temperature difference (about 4−5 °C) was sufficient to push liquid CO_2 into the reactor because the pressure in the bottle (55 bar at 20 °C) exceeded the equilibrium pressure in the reactor (49 bar at 14 °C). After complete filling, the pressure was about 55 bar (Figure 18, point 1). The reactor was isolated and the temperature increased from 15 °C to 40 °C which led to an important pressure increase (step 1−2) up to 140−150 bar (inside the supercritical domain). After 1 h, the supercritical fluid was evacuated over 1 h at the same temperature and the pressure was decreased to 1 bar (step 2−3). The heating was then turned off and argon was flushed through the reactor (step 3−4). The aerogel was then taken out of the reactor.

Pure boehmites and Si-doped boehmites (aerogels and xerogels) were calcined at 1200 °C under air for 5 h (ramp of 5 °C·min^{-1}) to obtain pure or doped aluminas.

$$2\ AlOOH\ (s) \xrightarrow{1200°C} Al_2O_3\ (s) + H_2O\ (g) \quad (2)$$

b) Supported Platinum Catalysts (5 wt.-%)

The catalysts were prepared by two procedures: (i) a one step procedure using the sol-gel method or (ii) an impregnation procedure on a calcined support (pure or doped alumina).

Sol-Gel Procedure: The platinum precursor solution (H_2PtCl_6) was introduced during the preparation of the support in the sol with the hydrochloric acid (see Figure 16). The preparation procedure follows the same steps used for the support (drying, calcination at 1200 °C). The high temperature calcination induces the formation of metal by a redox reaction:[1]

$$H_2PtCl_6 \xrightarrow{1200°C} Pt^0\ (s) + 2\ Cl_2\ (g) + 2\ HCl\ (g) \quad (3)$$

Impregnation Procedure: A volume of the metallic solution (H_2PtCl_6) corresponding to the porous volume of the support

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

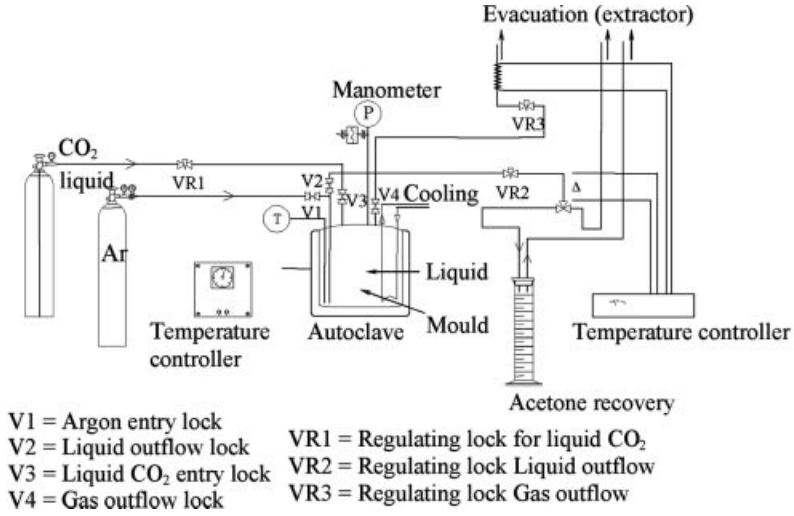

Figure 17. Diagram of the supercritical drying apparatus

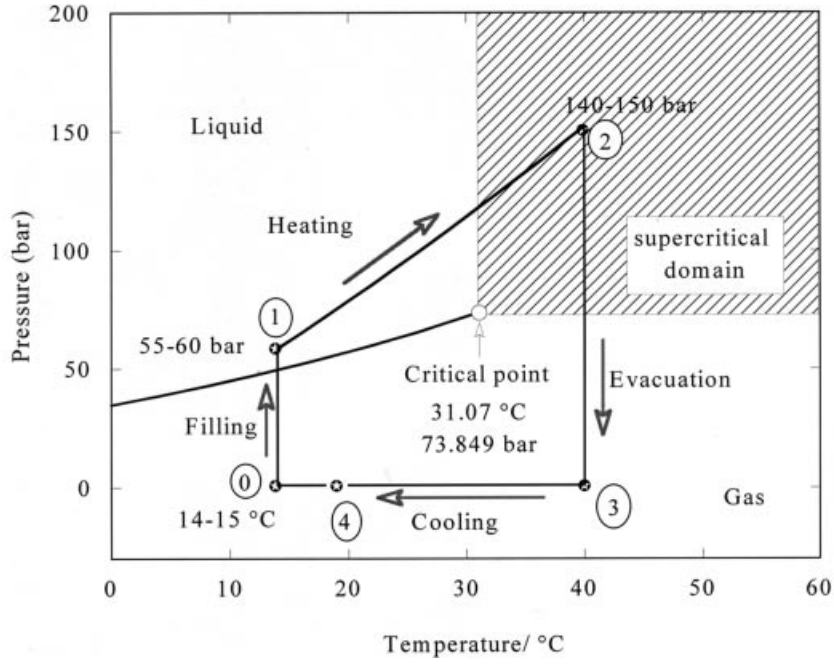

Figure 18. Diagram of the pressure and temperature for supercritical drying

(1.5 mL·g^{-1}) was added to the alumina (wetness impregnation). The concentration of the solution was then calculated giving a metal content of 5 wt.-%. The catalysts were dried overnight at 120 °C, calcined at 400 °C for 3 h under air (20 mL·min^{-1}) and reduced under H_2 (20 mL·min^{-1}) for 1 h at 200 °C and 2 h at 400 °C to obtain platinum supported alumina.

$$H_2PtCl_6\,(l) + 2\,H_2\,(g) \xrightarrow{400°C} Pt\,(s) + 6\,HCl\,(g) \quad (4)$$

Whatever the procedure, the introduction of the metallic precursor did not affect the acidity (pH near 1).

B. Characterisations

The effective metal load was determined from the CNRS analyses. The specific surface areas of the samples were determined by the BET method from the nitrogen adsorption isotherms at −196 °C in an automated Micromeritics ASAP 2000 apparatus after evacuation for 1 h 30 min at 350 °C. The method used is a simple BET 7 points procedure with P/P_0 values between 0.05 and 0.25. The complete adsorption and desorption isotherm was obtained for a few samples leading to the porous volume values.

Differential thermal analyses (DTA) and thermogravimetric analyses (TGA) were recorded in order to characterise the supports after

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drying. TDA-TGA experiments were carried out between 25 and 1350 °C using a thermal analyst 2100 TA instrument with platinum crucibles. The samples were heated in a nitrogen flow (100 mL·min^{-1}) with a ramp of 10 °C·min^{-1}.

Diffraction patterns and particles sizes were determined by X-ray diffraction (XRD) experiments performed on a Siemens D 5005 powder θ-θ diffractometer using the Cu-*Kα* radiation ($\lambda_{K\alpha}$ = 0.15186 nm) and a graphite monochromator. The diffraction patterns were obtained under the following conditions: dwell time: 2 s, step: 0.04°, constant divergence slit: 1°.

Crystalline phases were identified by comparison with PDF standards (Powder Diffraction Files) from ICDD. (AlOOH: 21−1307, α-Al_2O_3: 46-1212, θ-Al_2O_3: 23−1009, Pt: 04−0802)

The average crystallite sizes (D) were determined from the Scherrer equation: $D = (0.9\cdot\lambda)/(B\cdot\cos\theta)$, $\lambda = 0.15186$ nm, B is the width at half maximum and θ the Bragg angle for the peak in question (rad). For boehmite, the peak (020) was used without any correction due to the very small size of the particles. For platinum, the peaks (311) and (222) were used and a width correction was introduced, i.e. $B_{cor} = (B_{exp}^2 - B_{inst}^2)^{1/2}$. To determine B_{inst}, the analysis of standard LaB_6 powder was performed under the same conditions. The widths of the peaks were obtained by profile analyses using a pseudovoigt function from the diffract AT software (socabim, France).

The structural pictures were obtained using the software CaRine Crystallography.[32]

The platinum dispersion was obtained by hydrogen chemisorption at room temperature with a lab-build apparatus using pressure measurements. The samples (300 to 500 mg) were reduced at 400 °C over 1 h under a static pressure of hydrogen, degassed at this temperature over 1 h and cooled to ambient temperature. The adsorption isotherms enabled the determination of reversibly and irreversibly adsorbed hydrogen. The dispersion was calculated using the stoichiometric ratio H/Pt = 1.[4]

Platinum particle sizes and size distributions were obtained from transmission electron microscopy using a Philips CM 120 microscope with a linear resolution of 3.5 Å. Analyses by EDX enabled us to determine the distribution and quantification of atomic species (Al, Si and Pt). The lines used were *Lα* at 9.441 keV (Pt), *Kα* at 1.486 keV (Al) and *Kα* at 1.739 keV (Si), respectively.

C. Catalytic Tests

All samples were tested by the decomposition of an aqueous solution of HAN (hydroxylammonium nitrate, 79 wt.-%) prepared by water evaporation of a 20 wt.-% HAN solution [from SME (SME: French society of explosive materials)] in a rotating evaporator apparatus at 50 °C under vacuum conditions (water pump), the concentration was controlled by density measurements. The experiments were carried out in a TDA-TGA apparatus which gives a good estimation of the decomposition temperature.[4] The procedure was as follows. After placing the sample (15 mg) in an aluminium pan with a cover, the propellant was added with a micropipette (10 μL). The system was heated (10 °C·min^{-1}) to 250 °C under an argon flow (100 cm^3·min^{-1}). An example of the catalytic decomposition is given in Figure 19. The inflexion point of the temperature curve indicates the decomposition temperature. The analyses by TDA-TGA allowed us to obtain the following information: (i) the onset temperature of the decomposition, (ii) the concentration of the HAN solution at decomposition and (iii) the efficiency of the catalyst, i.e. the exothermic peak. The weight loss after a completed reaction is often different from the expected value due to the high exothermicity of the decomposition which destroys a small amount of catalyst.

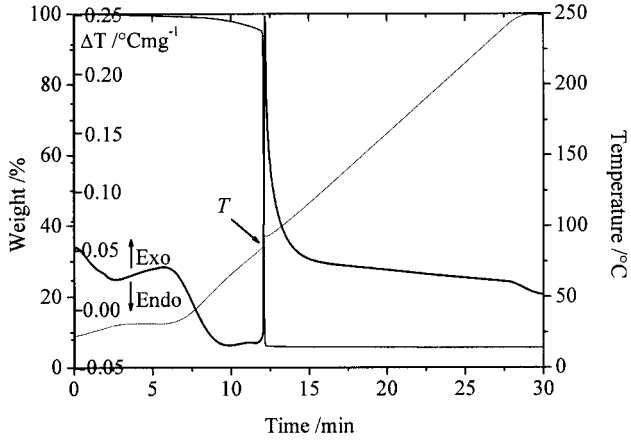

Figure 19. Example of the catalytic decomposition temperature of a HAN/water mixture on Pt-ASi-r (x)

Outer-Sphere Hydration and Liquid−Liquid Partition of Metal(III) Chelates − Density Functional Calculations

Marian Czerwiński*[a] and Jerzy Narbutt[b]

Keywords: Metal chelates / Outer-sphere hydration / Hydrogen bonding / Aqueous solution / Liquid−liquid partition / Enthalpy of transfer / Density functional calculations / Solvent effects / Implicit solvation model

Hydration of two coordinatively saturated metal chelates, tris(propane-1,3-dionato)scandium(III) and tris(propane-1,3-dionato)cobalt(III), was studied theoretically using the density functional method with a three-parameter B3LYP implementation at different variants for calculating the hydration energy, including corrections for ZPVE, BSSE, polarisation functions, temperature and the number of hydrating water molecules in the system. Formation of hydrates was demonstrated, with water hydrogen-bonded to ligands (outer-sphere hydration). After corrections for side effects, good correlations were found between the energy and the length of these hydrogen bonds in the hydrates of both chelates. Also, the calculated changes in charge distribution on the atoms of hydrogen-bonded water in these model chelates qualitatively agree with the experimental ^{1}H NMR spectroscopic data for the analogous tris(pentane-2,4-dionato)cobalt(III) species. An implicit solvation model (SCI-PCM) was used to take into account solvent effects of water and heptane on the energies of the model chelates studied and to calculate their enthalpies of transfer from heptane to water. In spite of simplifications in the model, satisfactory agreement was found between the calculated values and the experimental standard enthalpies of transfer of the analogous chelates, namely the tris(pentane-2,4-dionates) of scandium and cobalt(III).

Introduction

Interactions between amphiphilic molecules and water play an important role in numerous chemical and biochemical processes. References cited in ref.[1] are devoted to theoretical studies on hydrogen bonding in systems consisting of relatively simple molecules. Theoretical chemistry well describes simple hydrogen bonded systems composed of two small molecules.[2] On the other hand, large hydrogen-bonded structures are of greater interest not only because of their chemical complexity but also due to their practical importance. Theoretical calculations make it possible to quantify hydrogen-bonding interactions in large supermolecular systems with light atoms (organic species), not only in vacuo but also in solvent-modelling environments.[3] Less common are theoretical studies on hydrogen bonding in metal complexes. Because of computational problems, investigations on such systems develop rather slowly, although fast and efficient methods based on density functional theory (DFT), supplemented by using polarisation functions, have been successfully applied to solve various chemical problems dealing with *d*- and *f*-electron metal ions.[4−8] DFT calculations were used to study the effect of hydrogen bonding between solvent molecules and ligands on the stability of copper(I) thiocyanate complexes. However, scarce information is available on the calculation details.[9] More informative in this context are extensive theoretical studies on the hydrogen bonding of various proton donors to metal hydrides.[10]

With only moderate success gained from theory, experimental methods still predominate in studying large hydrogen-bonded, metal containing structures. From the numerous problems intensively studied in this field, we have focussed on the interactions of amphiphilic metal chelates with solvent water. Hydrogen bonding is responsible for two effects observed in aqueous solutions of the chelates: (1) Hydrophobic hydration which makes the thermodynamic activity of the solute (chelate molecule) higher because of promotion of the local structure of water around the hydrocarbon fragments of ligands, resulting from hydrogen bonding between neighbouring water molecules and (2) outer-sphere hydration of metal chelates, i.e. hydrogen bonding of water molecules to hydrophilic fragments of coordinated ligands, in particular to electron-donor oxygen atoms that coordinate to the central metal ion. The latter process, resulting in a decrease in the thermodynamic activity of the

solute, has been observed and comprehensively studied in a series of experimental studies by our group.[11]

All these aqueous-phase interactions influence liquid−liquid partition of metal chelates and play an important role in solvent extraction of metal ions. Unfortunately, as shown in our recent review,[12] many researchers who studied solvent extraction processes by computational modelling, focused their attention on the complex formation step and neglected hydration phenomena. The aims of the present work were: (1) To point out importance of the outer-sphere hydration, by supplying theoretical evidence for hydrogen bonding between molecules of water and coordinatively saturated metal chelates, (2) to reproduce properties of these hydrogen-bonded systems in terms of energy and (3) to evaluate the effects of various calculation approaches, including models, basis sets, polarisation functions and temperature, etc on the reliability of the calculation results.

A supermolecular approach[13] was used in this work which assumes formation of molecular adducts, i.e. the outer-sphere hydrates of metal chelates. Model molecules were studied with a fewer number of ligand CH_2 groups than in real chelates. Apart from the energies of adduct formation in the gas phase, standard enthalpies of transfer (heptane → water) of the model molecules were calculated and compared with experimental data for two coordinatively saturated metal acetylacetonates. Therefore, solvent effects were included in the calculations by modelling both liquid phases (heptane and water) with continuous electrostatic fields which surrounded the molecules studied. In the next section, various approaches used for the calculation of total energies of all the species studied after optimisation of their structures in the gas phase are presented.

Calculation Method

Let us assume that two molecules, X and HY, form a hydrogen-bonded adduct (hydrate) X···HY, accompanied by some deformation of the original molecules. The relative positions of X and HY in the hydrate can be described by the system of intermolecular coordinates, R. The internal coordinates of X and HY in the hydrate, r_X and r_{HY}, differ from the respective equilibrium values in the free molecules, r_Xf and r_{HY}f. According to the supermolecular approach, a fundamental formula for the energy of interaction (at 0 K) between X and HY is:

$$E_{int} = E_{XHY}(R,r_X, r_{HY}) - E_X(r_X f) - E_{HY}(r_{HY} f) + \Delta ZPVE \quad (1)$$

where $E_{XHY}(R,r_X,r_{HY})$ is the total energy of the hydrate and $E_X(r_X f)$ and $E_{HY}(r_{HY} f)$ are the total energies of the chelate and water molecules (fully optimised). The E_{int} value must be corrected for the difference between the zero-point vibrational energies (ZPVE − energy of molecular vibrations at 0 K) of the hydrate and its free components, ΔZPVE. If polarisation functions are included in the basis sets used, we denote the energies with *, e.g. E^*_{int}.

Because Equation (1) overestimates the intermolecular attraction, the interaction energy in weakly bound supermolecules should be corrected for the basis set superposition error (BSSE). We applied the counterpoise procedure described by Boys and Bernardi[14] and calculated total energies of the X and HY molecules in the hydrate geometry and in the hydrate basis set: $E_{X(HY)}(R,r_X,r_{HY})$ and $E_{HY(X)}(R,r_X,r_{HY})$:

$$E^0_{int.} = E_{XHY}(R,r_X,r_{HY}) - E_{X(HY)}(R,r_X,r_{HY}) - E_{HY(X)}(R,r_X,r_{HY}) + \Delta ZPVE \quad (2)$$

In many systems this correction, BSSE = $E^0_{int} - E_{int}$, is larger than the energy difference which results from the Born-Oppenheimer approximation and from neglecting anharmonicity.

The calculations [Equations (1)−(2)] refer to 0 K. In order to predict the energy of the system at a nonzero temperature T, terms for a thermal energy correction must be added to the total energies, i.e. E_A (A = XHY, HY, or X) which includes the effects of molecular vibration $E_{A,vib}$, rotation $E_{A,rot}$ and translation $E_{A,transl}$:

$$E^T_A = E_A + E_{A,vib} + E_{A,rot} + E_{A,transl} \quad (3)$$

The energy of interaction can then be calculated without the zero-point correction:

$$E^T_{int.} = E^T_{XHY} - E^T_X - E^T_{HY} \quad (4)$$

All the energies calculated for the gas phase are not directly comparable with the experimental data which refer to the process of the chelate transfer from heptane to water. To make such a comparison plausible, solvent effects of the liquid environment on the solute energy must be taken into account in the calculations, e.g. by use of a Self-Consistent Isodensity Polarised Continuum Model (SCI-PCM).[15] This procedure locates the solute molecule within a cavity formed in the field with the dielectric constant of a given liquid, either water (ε_w = 78.3) or heptane (ε_h = 1.92), and then the electron density is determined which minimises the energy of the whole system. The optimised gas-phase structures of all the species (hydrate, chelate and water molecules) were used.

From the thermodynamic point of view, the process of aqueous-phase hydration of a solute molecule (e.g. metal chelate) originally present in another phase (e.g. heptane) can be divided into two steps: (1) Transfer of the chelate molecule to the aqueous solution, followed by (2) addition of water molecule(s) present in bulk water to the chelate by, for example, hydrogen bonding, i.e. formation of a supermolecule (hydrate) in the aqueous phase. The energy change (at 0 K) corresponding to formation of the 1:1 adduct is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$E_{h-w} = E_{XHY}(w) - E_X(h) - E_{HY}(w) + \Delta ZPVE \quad (5)$$

where the total energies of the molecules (defined by the indexes) are calculated in the field of either water (w) or heptane (h). Assuming that the small temperature correction, $\Delta E^T = E^T_{int.} - E_{int}$, does not depend on the environment, the energy change at temperature T is equal to $E^T_{h-w} = E_{h-w} + \Delta E^T$ and (with the definition $H^T_A = E^T_A + RT$) the enthalpy change for the 1:1 adduct formation is $\Delta H^T_{h-w} = E^T_{h-w} - RT$. The same also holds for the 1:3 adduct, assuming that one of its components is a single molecule of a water trimer.

The calculations were first carried out in the model systems consisting of a molecule of water and a molecule of the metal chelate, i.e. M(mala)$_3$ = tris(propane-1,3-dionato)scandium(III) or tris(propane-1,3-dionato)cobalt(III). The ligand was a deprotonated enol form of malonaldehyde, [O=CH−CH=CH−O]$^-$, abbreviated as mala$^-$, which we assumed to be a suitable model for the pentane-2,4-dionate (acetylacetonate) anion. The metal ions scandium and cobalt(III) were selected for this study because their tris(acetylacetonates), M(acac)$_3$, have been experimentally[11d,11c] characterised as having the highest and the lowest standard enthalpies of transfer (see Table 5) within the whole series of 3d metal(III) ions. In other calculation systems, more water molecules were then used (see below). In all cases, the addition of water molecule(s) to the chelates resulted in the formation of the water adducts, either M(mala)$_3$·H$_2$O or M(mala)$_3$·3H$_2$O, further referred to as hydrates.

The present calculations were based on the Density Functional Theory (DFT),[16] using the Lanl2dz double-ζ basis set[17] and the three-parameter Becke functionals of the B3LYP[18] type. The Berny geometry-optimisation algorithm[19] was applied to calculate the geometries of the neutral metal chelates, water and its multimers, as well as the 1:1 and 1:3 hydrates. The system Hessian with $(3n-6)$ eigenvalues confirms that the minimum energies were found for all the compounds. The calculations have also been performed with the use of the Huzinaga polarisation functions on each atom.[20] All the calculations were carried out by means of the Gaussian 94 package[21] using Cray J90 and Cray Y-MP supercomputers.

Results and Discussion

Geometry and Charge Distribution

Table 1 shows some selected B3LYP geometrical parameters of the model chelate molecules [distorted octahedral Sc(mala)$_3$ and Co(mala)$_3$] in the gas phase and the charge distributions on some of their atoms. The geometries mirror the experimental data for their crystalline analogues, Sc(acac)$_3$ and Co(acac)$_3$, within an acceptable error. The calculated M−O distances are somewhat shorter (by 0.02 - 0.03 Å). This is in accordance with the temperature difference (room temp. vs. 0 K for the calculations) and with the difference in the structure of the ligands, i.e. lack of two electron-releasing methyl groups in each mala$^-$ ligand in comparison with acac$^-$. The much larger span of the calculated atomic charges on Sc−O compared with Co-O (Table 1) can be interpreted in terms of a stronger covalent nature of the Co−O bond. The full set of calculation data for all components studied, including the hydrates (see below), is given in the Supporting Information (Table 8; for Supporting Information see also the footnote on the first page of this article).

The interaction between water and the metal chelates leads to formation of the adducts (hydrates) which can be considered to be supermolecules. Theoretical calculations of the structures of these adducts were carried out by minimising the energy of systems consisting of one molecule of a given chelate and one (or more) water molecule(s) in the gas phase (vacuum). The initial position(s) of the water molecule(s), i.e. the initial distance between the central metal ion M and the oxygen atom of water (or of a water molecule in a cyclic multimer), O$_w$, was varied. For the 1:1 adducts, three different cases were considered: (1) d(M−O$_w$) < 2.5 Å, the water molecule would be expected to coordinate directly to the M^{3+} ion by means of a lone electron pair on the O$_w$ atom, thus increasing the coordination number (CN) of M^{3+}. This model corresponds to the inner-sphere hydration of the chelate. Optimisation of such a structure led to strong deformations and eventually "decomposition" of the water molecule which is inconsistent with the experiments on tris(acetylacetonates) of scandium[11d] and cobalt(III).[11c] This result confirms our basic assumption that the chelates studied are coordinatively saturated. (2) d(M−O$_w$) > 4.5 Å, the water molecule approached the CH groups or π-electrons of the ligand,

weakly interacting with them. However, the total energy of such systems was rather high, therefore this was not the case of interest. (3) 4.0 Å < d(M−O_w) < 4.5 Å, the system attained the lowest energy. The water molecule formed a hydrogen bond with one of the oxygen atoms of a ligand in the M(mala)$_3$ molecule. The reliability of our model of the outer-sphere hydration of the chelates has been confirmed this way. Additional calculations of the second derivatives of the energies for Sc(mala)$_3$ − H_2O and Co(mala)$_3$ − H_2O systems confirmed that the true energy minimum was attained. The optimised structure of the Co(mala)$_3$·H_2O adduct in the gas phase is given in Figure 1.

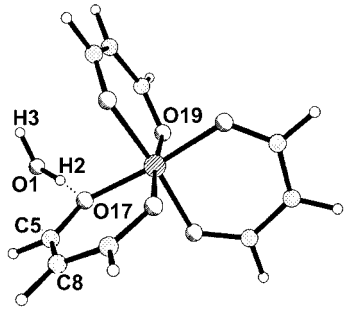

Figure 1. The optimised gas-phase structure of monohydrate Co(mala)$_3$·H_2O. The metal ion occupies the central position. The other atoms mentioned in the text are numbered. Full numbering is given in the Supporting Information (Figure 8.2). The hydrogen bond between the water molecule and a ligand oxygen atom is shown by a dotted line.

Table 2 shows some selected geometrical parameters of the 1:1 hydrates and the changes in the charge distribution on selected atoms due to the hydrate formation. In both hydrates the oxygen atom of the water molecule is located at a short distance (ca. 2.8 Å typical for hydrogen bonding) from one of the oxygen atoms (O17 − For numbering of atoms in the hydrates see Figure 1 and Figure 2 and also Supporting Information, Figures 8.2 and 8.3) of a mala$^-$ ligand. The angles α (O1−H2−O17), β (O1−O17−C5) and γ (C8−C5−O17−O1) deviate slightly (by less than 10°-20°) from the expected values (sp^2 hybridisation of the ligand oxygen atoms was assumed): 180°, 120° and 180°, respectively. This shows that the hydrogen bond O1−O17 is nearly linear and only slightly deviates from the direction of the lone electron pair on the O17 atom. The small difference between O1−O17 distances in Co(mala)$_3$·H_2O and in Sc(mala)$_3$·H_2O points to a stronger hydrogen bond in the former hydrate, in spite of much less negative charge on the oxygen atoms in Co(mala)$_3$ than that in Sc(mala)$_3$ (Table 1). The electrostatic model of hydrogen bonding is, therefore, inapplicable for the hydrates studied.

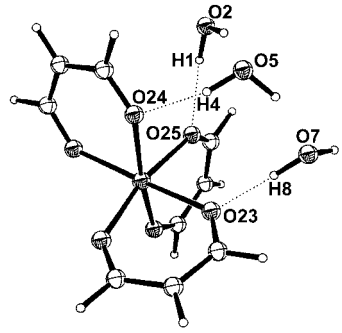

Figure 2. The optimised gas-phase structure of the trihydrate Sc(mala)$_3$·3H_2O. The metal ion occupies the central position. The other atoms mentioned in the text are numbered. Full numbering is given in the Supporting Information (Figure 8.3). The hydrogen bonds between water molecules and ligand oxygen atoms are shown by dotted lines.

Formation of the $M(mala)_3 \cdot nH_2O$ adducts is accompanied by small changes in the geometries of the original molecules and in the charge distributions on their atoms (Table 2 and Table 3, as well as Table 8 in Supporting Information). For example, in the 1:1 adducts, the Sc−O17 distance increases by about 0.03 Å, while the Co-O17 distance increases only by 0.004 Å. This difference may be explained in terms of a stronger covalency and greater strength of the Co−O bond compared with the Sc−O distance. The other M−O distances remain practically unchanged. In both systems the O1−H2 distances increase by about 0.01 Å and the angles H3−O1−H2 slightly decrease. The electron densities increase on the hydrogen-bonded oxygen atoms (O17, O1) and decrease on the hydrogen (H2). The summed-up decrease in the electron density on all hydrogen atoms of water in the hydrates is consistent with the significant downfield shift of the water proton resonance observed in the ^1H NMR spectrum of the $Co(acac)_3$ solution.[11b] All the results give us a picture of the hydrogen bonded systems which is in accordance with the hypothesis of outer-sphere hydration of metal chelates, based on the earlier experiments.[11]

Quite surprisingly, the analysis of the geometries of the hydrates has shown that apart from the expected hydrogen bond between the water molecule and a donor oxygen atom in the ligand of each chelate, an additional hydrogen bond has been detected in the scandium (but not the cobalt) hydrate. The relatively short O1−O19 distance in $Sc(mala)_3 \cdot H_2O$, equal to 3.24 Å, can be considered as evidence for a very weak hydrogen bond between the water molecule and another ligand in the chelate. The corresponding distance of 3.50 Å in $Co(mala)_3 \cdot H_2O$ is too long for hydrogen bonding. This additional interaction may explain why the total decrease in the electron density on the whole hydrogen bonded water molecule is larger in $Sc(mala)_3 \cdot H_2O$ ($\Delta q = +0.016$) than in $Co(mala)_3 \cdot H_2O$ ($\Delta q = +0.011$).

Since each chelate molecule in question has more than one hydrophilic site, we also studied its hydration taking into account more than one water molecule. Earlier semiempirical and ab initio calculations have shown that the lowest energy of a system consisting of a number of H_2O molecules in the gas phase is attained when the water molecules form cyclic multimers.[24,25] We have optimised the structures of the cyclic multimers consisting of three, six and nine H_2O molecules. After placing each multimer close to the chelate molecule [4.0 Å $< d(M\text{-}O_w) <$ 4.5 Å, where O_w denotes one of the oxygen atoms in the multimer], the systems were optimised again until the global minimum for each system (hydrate) was attained. Full optimisation of the 1:3 hydrates resulted in strong structural changes in the cyclic water trimer, i.e. breaking one of its hydrogen bonds, stretching the resultant chain and attaching it by means of hydrogen bonding to three oxygen atoms in the three mala ligands (Figure 2).

These structural changes may be considered to be a template effect. Optimisation of the systems with the water hexamer and nonamer led to formation of the 1:3 hydrate as well. The remaining water molecules were separated from the hydrate and moved away.

Table 3 shows some selected geometrical parameters (B3LYP) of the 1:3 hydrates and changes in the charge distributions on chosen atoms due to the hydrogen bonding. The average length of hydrogen bonds formed between the water molecules and the three mala ligands is somewhat shorter in $Co(mala)_3 \cdot 3H_2O$ (2.86 Å) than in $Sc(mala)_3 \cdot 3H_2O$ (2.87 Å) although the difference is small. In contrast, the deformation of the original water trimer is much stronger in the former hydrate. This is evidenced by longer distances between the neighbouring oxygens in the trimer chain in $Co(mala)_3 \cdot 3H_2O$ than in $Sc(mala)_3 \cdot 3H_2O$, 2.84 Å versus 2.73 Å on average. Both distances have significantly increased from the original 2.58 Å calculated for the cyclic water trimer (see Supporting Information, Table 8.5).

The summed-up decrease in the electron density on the three hydrogen bonded water molecules is greater in $Sc(mala)_3 \cdot 3H_2O$ ($\Delta q = +0.051$) than in $Co(mala)_3 \cdot 3H_2O$ ($\Delta q = +0.030$). This agrees very well with the respective changes on the single water molecules in the corresponding monohydrates, which are three times less (see above).

Energy of Hydrogen Bonding

The next challenge was to explain, at least at a model level, a possible reason for the stronger hydration (in aqueous solution) of $Co(acac)_3$ compared with $Sc(acac)_3$,[11d] something which was unexpected from the viewpoint of the electrostatic model of hydrogen bonding (see above). Therefore, the energy of hydrogen bonding between $M(mala)_3$ and water molecule(s) was calculated. It was assumed to be

the energy of interaction between the given molecules in the gas phase at 0 K (Table 4).

Since the DFT method takes into consideration a significant part of the electron correlation energy,[26] we could expect high accuracy and reliability from the calculations. Furthermore, the method was verified based on the comparison of the results obtained by the density functional calculations (using BLYP and BP functionals) with the exact solution of the Schrödinger equation for the helium atom in a model of harmonic interactions (Hooke model). Within the BLYP functional, the error in the total energy amounted to 0.87%, which was a half the error resulting from the Hartree−Fock method, while the BP functional energy error was only 0.08%.[27] This means that the DFT method with various correlation potentials is quite effective.

For the 1:1 hydrates the calculations were carried out in different variants, including (or not) corrections for the BSSE, ZPVE and temperature using (or not) the polarisation functions on each atom. Corrections for BSSE made the results even worse. An improvement was obtained using calculations with the polarisation functions. The temperature corrections gave negligible effects. On the other hand, a correction for the energy of the additional H-bond in $Sc(mala)_3{\cdot}H_2O$ (see above) appeared to be very important. This was calculated as the difference between the total energy of the optimised $Sc(mala)_3{\cdot}H_2O$ molecule, E_{XHY}, and the total energy of the same molecule with a somewhat distorted geometry, E_{XHY}', i.e. where the water molecule was twisted around the O1−O17 axis enough to break this additional bond but keeping unchanged all other important interactions, in particular the length of the main (O1−O17) hydrogen bond. The magnitude of this correction, E_{HB}', depended on the calculation variant (see Table 4−5 and Supporting Information, Table 6). The energy of formation of the main H-bond, E_{HB}, in $Sc(mala)_3{\cdot}H_2O$ was calculated by subtracting the E_{HB}' value from the interaction energy, e.g. E_{int}, while in $Co(mala)_3{\cdot}H_2O$ the E_{HB} value was equal to E_{int}. This led to a significant improvement in the results. The differences between the E_{HB} values in $Sc(mala)_3{\cdot}H_2O$ and $Co(mala)_3{\cdot}H_2O$ became positive, independently of the calculation variant (in particular, corrections for polarisation functions appeared negligible). In this way, the expected relationship between the calculated energies and lengths of the hydrogen bonds was achieved.

For the 1:3 hydrates, the calculations were carried out only in the simplest variant with no corrections for BSSE, ZPVE and temperature. In contrast to the expectation that three water molecules would bind to the chelate much more strongly than one, the calculated energies of gas-phase interactions of the chelates with the water trimer appeared comparable with those calculated in the same variant for the single H_2O molecule (Table 4, two last Entries). Moreover, the negative $\Delta E_{Sc/Co}$ values observed for the formation of the trihydrates, $Sc(mala)_3{\cdot}3H_2O$ and $Co(mala)_3{\cdot}3H_2O$, again led to incorrect correlation between the formation energy and the average length of the three hydrogen bonds in the trihydrates considered. This inconsistency is probably due to the significant energy required to break one hydrogen bond in the original cyclic water trimer and to stretch out the remaining two. Geometrical considerations (see above) showed that the energy must be larger in $Co(mala)_3{\cdot}3H_2O$ than in $Sc(mala)_3{\cdot}3H_2O$ because of stronger distortions of the water trimer in the former hydrate. Subtracting these contributions from the formation energies of the trihydrates would make the energies of hydrogen bonding much more negative (as expected) and restore the correct length-energy correlation. These conclusions were corroborated by the energies calculated in the SCI-PCM field.

Chelate Hydration in an Aqueous Medium. Enthalpy of Chelate Transfer

The final goal of the present work was to verify the calculated energies by comparison with the experimental data. The energies calculated for the gas phase can hardly be used for this purpose because the interaction energy significantly depends on the environment of the interacting species. The experimental values we can use for the comparison are standard enthalpies of transfer (heptane → water) of the tris(acetylacetonates) $Sc(acac)_3$ [11d] and $Co(acac)_3$ [11c] at 298 K which include the energy changes due to chelate hydration in the aqueous phase.

In order to compare these values, the enthalpy of transfer of $M(mala)_3$ chelates was calculated, taking into account solvent effects of the aqueous and heptane environments as was discussed above. The reasons why only the enthalpies and not the Gibbs free energies were used for the comparison of hydrogen bonding of water molecule(s) with the

Table 5. Enthalpies of transfer (heptane → water) of $M(mala)_3$ chelates [$kJ{\cdot}mol^{-1}$]. The energies of the species were calculated (DFT-B3LYP) in the SCI-PCM field corresponding to either water (H_2O and hydrates) or heptane (chelates); no BSSE correction

Model[a]	T, K	ΔH_{Sc}	ΔH_{Co}	$\Delta(\Delta H)_{Sc/Co}$
Field only, no hydrate formation	0 K	−36.8	−41.7	+4.9

model and real chelates differing in the number of CH_2 groups in the ligands were as follows: (1) It was experimentally shown that for similar, coordinatively saturated beryllium β-diketonates with ligands belonging to the homologous series of acetylacetone, the enthalpies of transfer did not practically differ,[11a,28] while the free energies regularly increased with each CH_2 group added. (2) The implicit solvation model, SCI-PCM, used in the calculations does not take into account the interactions of the solute with solvent molecules which leads to formation of a solvation shell around the solute.[12] This is particularly important for aqueous solutions where the entropy term, related to this specific hydration, strongly contributes to the Gibbs energy. Therefore, to calculate the free energy of hydration of neutral molecules a special approach[29] must be used.

The electrostatic fields, used in modelling the liquid phases, modified the energies of interaction of the chelates with water to a different extent which made the energy in the cobalt system distinctly more negative than that in the scandium case, in line with the experimental observations.

Table 5 shows the enthalpies of transfer (heptane → water) of the model chelates, calculated for three different cases which refer to the species in the field of water, the species being the chelate molecule alone (no hydrate formation), the 1:1 hydrate and the 1:3 hydrate. The results shown relate to some selected variants, while the energies of transfer for the case of formation of monohydrates, calculated in all variants including BSSE corrections, the use of polarisation functions etc. are shown in Supporting Information, Table 7. The numerical values calculated with polarisation functions are somewhat less negative than the corresponding values given in Table 5, but the respective differences are very close to those in Table 5. The calculated enthalpies of transfer became more negative when more water molecules were involved in hydrogen bonding with the chelates, according to expectations. A comparison of the calculated enthalpies with the experimental standard enthalpies of transfer of the analogous tris(acetylacetonates) shows that all the values are similar, even those calculated for the case which assumed only the effect of the environment (field) with no hydrate formation. The latter result, which was rather unexpected, shows that the implicit solvation model used estimates the energy of the solute-solvent interactions in aqueous solutions very well. The calculated energy of transfer of the chelate ("solute") molecules to the field modelling water is only by about 10−20 kJ·mol^{-1} higher than the values which include the energy of hydrogen bonding of the chelate with individual (explicit) water molecule(s) which form a solvation shell around the "solute". Simply, the interactions of the "water field" with the hydrophilic sites of all "solutes" produce negative contributions to the total energies of the solutes. If these hydrophilic sites are already hydrated, the contributions are smaller. That is why the energies of chelate hydration calculated in the water field are higher than those calculated in the gas phase. (This is also in line with the observation that the E_{HB}' corrections calculated in the SCI-PCM field are distinctly smaller than those calculated in the gas phase.) Most probably, the water field interacts with the hydrated hydrophilic sites via the attached water molecule(s). The more "open" the structure of the site, the stronger the interactions. This is the case with both hydrates of $Co(mala)_3$: the lack of additional hydrogen bonding in the monohydrate and a more distorted structure of the water trimer in the trihydrate. Stronger interactions with the water field of these structures, more "open" that those in the hydrates of $Sc(mala)_3$, restore the correct relationship between the calculated energies of hydration (enthalpies of transfer) of both chelates. This consistency confirms that the model used in this work may be considered not only qualitatively but also quantitatively reliable.

In all cases, the differences between the calculated enthalpies of transfer, $\Delta(\Delta H)_{Sc/Co}$, are significantly smaller than the experimental value (Table 5) but because of simplifications in the model, they seem to be acceptable. It has been shown, therefore, that theoretical calculations can be used to evaluate the thermodynamic functions (at least the enthalpy) of the partition of neutral molecules of coordinatively saturated metal chelates between water and organic solvents. This possibility is particularly important when studying solvent extraction of metal ions.[12]

Conclusions

The calculations by means of the DFT B3LYP method on large hydrogen bonded systems, i.e. hydrates of two neutral, coordinatively saturated chelates of scandium and cobalt(III), confirm our earlier assumption that hydration of the chelates takes place in their outer coordination spheres by ligand hydration through hydrogen bonding. Simple calculations for the gas phase at 0 K result, however, in incorrect correlations between the length and the energy of the hydrogen bonds for the two hydrates. More careful examinations of the systems studied, allowed us to find interactions other than the expected hydrogen bonding which contributed to the energy of hydrate formation and disturbed the correlation. These were (1) an additional hydrogen bond in the 1:1 hydrate of the scandium (but not cobalt) chelate and (2) different distortions of the original water trimer in the 1:3 hydrates. Subtracting these contributions from the energy of hydrate formation restored the correct length vs. energy relationship for the hydrogen bonds considered.

However, the calculations of the interaction energy in the gas phase do not correctly reflect the interactions in aqueous solution because solvent effects to a different degree contribute to the total energy of the solutes (hydrates). The use of an implicit solvation model, SCI-PCM, allowed us to compare the energies calculated for this model system with the experimental standard enthalpies of transfer (heptane → water) of two analogous chelates, namely tris(acetylacetonates) of scandium and cobalt(III). In spite of simplifications in the models used and discussed in the paper, a good agreement was observed. Therefore, a correct understanding of phenomena related to the outer-sphere hydration and their quantitative description became possible.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In particular, standard enthalpies of partition of simple, coordinatively saturated metal chelates in solvent extraction systems (water/organic solvent) can be evaluated. Moreover, even the use of the most simplified solvation model, consisting of the electrostatic field alone without assuming hydrate formation, resulted in a quite satisfactory agreement with solvent extraction experiments, as far as the enthalpy of transfer was concerned.

General conclusions can also be drawn, namely (1) the present-day state of computational chemistry makes possible reliable calculations of hydrogen bonding energies in large metal-containing systems, (2) the supermolecular model well describes hydrogen bonding interactions between metal chelates and water molecules and (3) the implicit solvation model (SCI-PCM) is an adequate tool for calculating the energy of solute-solvent interactions of coordinatively saturated metal chelates and water and, in particular, standard enthalpies of transferring the chelates from an organic solvent to water.

Acknowledgments

The numerical calculations were carried out at the Interdisciplinary Centre for Mathematical and Computational Modelling, Warsaw, the Poznań Supercomputing & Networking Centre and the WCSS of the Technical University of Wrocław, Poland. We acknowledge access to the computer resources and the kind cooperation of the staff.

Alkali-Metal Salts of Aromatic Carboxylic Acids: Liquid Crystals without Flexible Chains

Rik Van Deun,[a] Jan Ramaekers,[a] Peter Nockemann,[a] Kristof Van Hecke,[a] Luc Van Meervelt,[a] and Koen Binnemans*[a]

Keywords: Alkali metals / Layered compounds / Liquid crystals / Metallomesogens / Smectic mesophases

The alkali-metal salts of *meta*-substituted benzoic acids exhibit a smectic A mesophase at high temperatures. These compounds are examples of liquid crystals without terminal alkyl chains. The influence of the metal ion and of the type of substituents on the transition temperatures is discussed. Compounds with the substituent in the *ortho*- and *para*-positions are non-mesomorphic. The crystal structures of the compounds $Rb(C_7H_4ClO_2)(C_7H_4ClO_2H)$, $Na(C_7H_4IO_2)(H_2O)$, $K(C_7H_4ClO_2)(C_7H_4ClO_2H)$ and $Rb(C_7H_4BrO_2)(C_7H_4BrO_2H)$ have been determined by X-ray crystallography. These compounds possess a layerlike structure in the solid state.

1 Introduction

In the classic picture, liquid crystals are either calamitic (rodlike) or discotic (disklike) molecules. However, many types of liquid crystals cannot be classified as rodlike or disklike, and several intermediate forms are possible.[1,2] In general, the rodlike mesogenic molecules have one or two terminal alkyl chains. The function of these flexible chains is not only to stabilize the mesophase, but also to reduce the melting point. This may give the wrong impression that such flexible chains are necessary to obtain liquid crystals, as some compounds without a flexible chain are able to form a mesophase as well. Typical examples are the *para*-oligophenyls, such as *para*-quinquephenyl and *para*-sexiphenyl.[3−6] Tschierske and co-workers[7] have investigated semi-rigid substituted benzyloxybiphenyl compounds with diol head groups. The indenes and pseudo-azulenes with peripheral chloro groups reported by Barbera et al.[8] were the first examples of mesomorphic discotic molecules without a flexible chain. The rodlike or disklike shape of all these molecules is very distinct. We can therefore ask ourselves what happens if the length of the rodlike molecules is reduced. Do simple aromatic compounds consisting of one phenyl ring exhibit a mesophase? The answer is no; compounds such as benzoic acid, phenol, aniline, chlorobenzene are not liquid crystals. However, the situation changes when alkali-metal salts of aromatic carboxylic acids (for example sodium benzoate) are considered. The liquid-crystalline behaviour of these compounds was discovered in 1910 by the great pioneer in liquid-crystal research, Daniel Vorländer,[9,10] Vorländer investigated the lithium, sodium, potassium and rubidium salts of benzoic acid. In addition, he investigated the alkali-metal salts of the *ortho*-, *meta*- and *para*-isomers of chlorobenzoic acid, bromobenzoic acid, iodobenzoic acid, methylbenzoic acid and nitrobenzoic acids. The sodium and potassium salts were prepared for all these compounds and a few lithium, rubidium and cesium salts as well. Vorländer mentions only the presence and absence of a mesophase, but gives no mesophase identification. These mesophases often have a low viscosity, and approximate transition temperatures were given for a limited number of compounds only. Demus and co-workers[11] re-examined some of the compounds described by Vörlander — the lithium, sodium, potassium, rubidium and cesium salts of 3-bromobenzoic acid, and the potassium salt of 3-iodobenzoic acid — in 1970. In some instances they used the original samples prepared by Vorländer sixty years before, and they found no signs of deterioration. These authors determined the transition temperatures by optical microscopy and identified the mesophase as a "neat" phase (smectic A). In addition, they constructed binary phase-diagrams by mixing the compounds with other aliphatic and aromatic carboxylate salts. Unfortunately, there is not complete agreement between the results of Vorländer and Demus: transition temperatures for the same compound reported by the two authors differ by up to 35 °C in some cases, and for cesium 3-bromobenzoate Vorländer found a mesophase, whereas Demus and co-workers didn't.

Given the intrinsic scientific interest of these low-molecular-weight liquid crystals, we reinvestigated the compounds described by Vorländer in order to obtain more detailed quantitative thermodynamic and structural data. The com-

E-mail: Koen.Binnemans@chem.kuleuven.ac.be

pounds were investigated by polarizing optical microscopy (POM) and by differential scanning calorimetry (DSC), and some compounds by high-temperature X-ray diffraction. This work extends Vorländer's work by including some alkali-metal salts of substituted benzoic acids not studied by Vorländer, for instance salts of the *ortho*-, *meta*- and *para*-isomers of fluorobenzoic acid and methoxybenzoic acid. In addition, we have determined the crystal structures of four alkali-metal salts.

Results and Discussion

The first series of compounds we prepared were the alkali-metal salts of benzoic acid. These compounds have much higher transition temperatures than benzoic acid, which melts at 122 °C. The melting points of the corresponding alkali-metal salts range from 369 °C (lithium benzoate) to 444 °C (rubidium benzoate). While benzoic acid does not exhibit liquid-crystalline behaviour, sodium benzoate is an enantiotropic liquid crystal. The other salts (the lithium, potassium, rubidium and cesium benzoates) do not exhibit mesomorphism. The optical texture of the sodium benzoate shows the typical features of a smectic A phase (SmA): bâtonnets appear from the isotropic liquid and coalesce to a fan-shaped texture with homeotropic regions. If the sample is quickly cooled after isotropisation, thermal decomposition can be limited and formation of a mesophase can be observed upon cooling, thus illustrating the enantiotropic nature of the SmA mesophase. The DSC thermogram (first heating run) of sodium benzoate is shown in Figure 1. The thermal behaviour of the alkali-metal benzoates is summarised in Table 1.

Table 1. Thermal behaviour of benzoic acid and its alkali-metal salts

Compound	Transition temperatures (°C)[a]
Benzoic acid	Cr·122·I
Lithium benzoate	Cr·369·I
Sodium benzoate	Cr·431·SmA·451·I
Potassium benzoate	Cr·439·I
Rubidium benzoate	Cr·444·I
Cesium benzoate	Cr_I·383·Cr_{II}·398·I

[a] Cr, Cr_I, Cr_{II}: solid crystalline phases; SmA: smectic A phase; I: isotropic phase.

These findings are in partial disagreement with the data of Vorländer, who reported that the lithium, sodium, potassium and rubidium salts of benzoic acid are all enantiotropic liquid crystals, while benzoic acid is not liquid-crystalline. He described the texture as small rods which flow together to form drops. The transition temperatures of sodium benzoate were given (melting point: 410 °C, clearing point: 430 °C), but not for the other unsubstituted alkali-metal benzoates. Vorländer had problems to record the transition temperatures of these high-melting solids accurately due to their thermal decomposition at high temperatures. For rubidium benzoate, Vorländer wrote that this

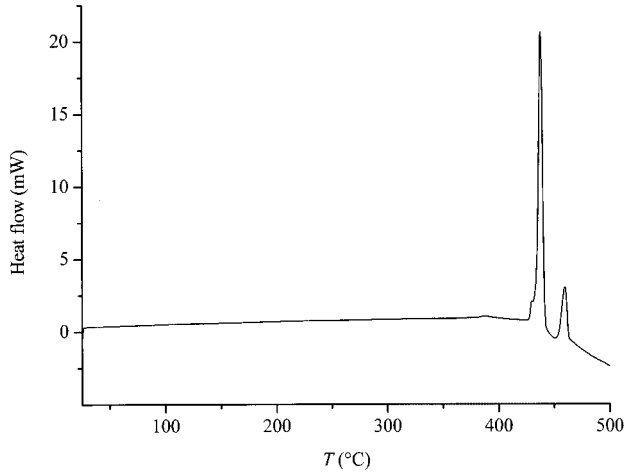

Figure 1. DSC thermogram (first heating) of sodium benzoate; endothermic peaks are pointing upwards

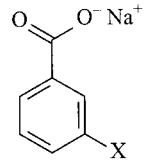
compound decomposed before the clearing point had been reached. Modern techniques indicate that only the sodium salt is a liquid crystal, and the other salts of benzoic acid melt to an isotropic liquid without showing a mesophase, just like benzoic acid itself. No evidence for monotropic mesophases was found.

A second group of compounds we investigated are the sodium salts of different *meta* (or 3)-substituted benzoic acids: sodium 3-fluorobenzoate, sodium 3-chlorobenzoate, sodium 3-bromobenzoate, sodium 3-iodobenzoate, sodium 3-methylbenzoate and sodium 3-methoxybenzoate (Figure 2). Their thermal behaviour was compared to that of unsubstituted sodium benzoate; the data are summarised in Table 2. As can be seen, all *meta*-substituted sodium benzoates are



X = H, F, Cl, Br, I, CH_3, OCH_3

enantiotropic liquid crystals. For the *meta*-halogen-substituted compounds, the melting points decrease with increasing size of the halogen substituent in the *meta*-position, as is also the case for the clearing points (Figure 3). However, the melting points decrease in a more pronounced way than the clearing points, which results in an increase of the mesophase range.

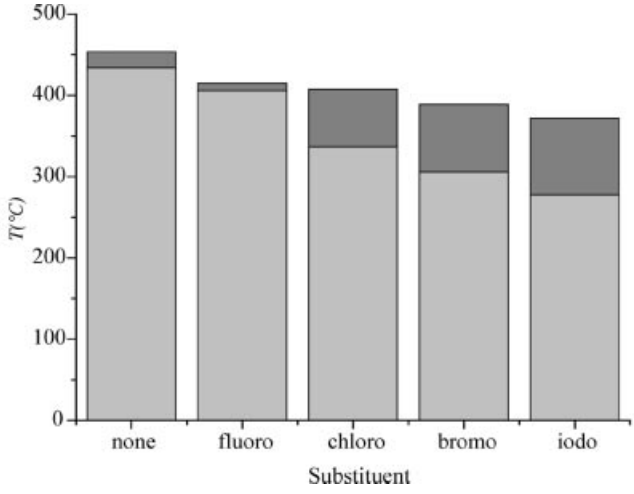

Figure 3. Influence of the size of the halogen atom on the transition temperatures of the sodium salts of *meta*-halogen-substituted benzoic acids; the light-grey shading represents the solid state and the dark-grey shading the smectic A phase

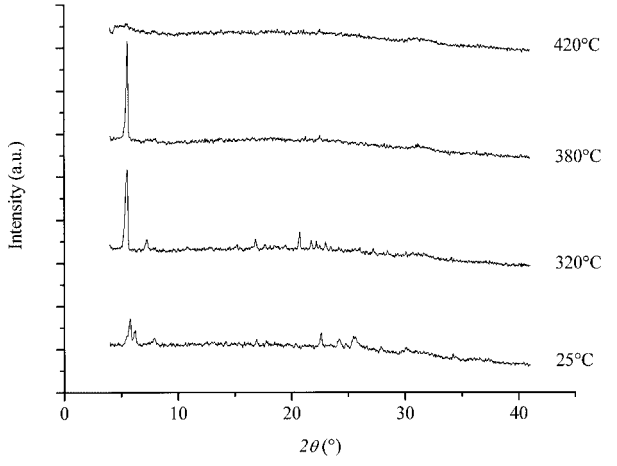

Figure 4. X-ray diffractograms of sodium 3-chlorobenzoate recorded at different temperatures

Figure 4 shows the X-ray diffractograms of sodium 3-chlorobenzoate. The bottom trace is that of a powder diffractogram at room temperature. At small diffraction angles, the diffraction peaks indicate a rather long-distance ordering, while the peaks at wider diffraction angles (around $2\theta = 25°$) result from an ordering at low dimensions. The observation of a number of diffraction peaks in the X-ray diffractogram confirms the crystallinity of the compound at room temperature. The second-from-bottom trace shows the compound after heating to 320 °C. The compound is still in the solid state, but evidence of a layered structure is already given by the first-order diffraction peak at around $2\theta = 6°$, which is of a rather high intensity. The third trace shows the situation at 380 °C, where the compound is in the SmA mesophase. Only the long-range order of the layered smectic phase remains, as witnessed by the absence of all but the first-order peak in the diffractogram. This is a typical diffractogram of a disordered smectic phase. The upper trace is of the sample in the isotropic liquid. No order remains, as can be seen from the absence of sharp diffraction peaks. The identification of the mesophase was supported by the observation of the texture given in Figure 5, which shows the formation of bâtonnets, which is typical for a smectic A phase. The thermal stability of the compounds at high temperatures is limited, as can be seen from the DSC curve of sodium 3-chlorobenzoate shown in Figure 6. Although the melting and clearing peaks are

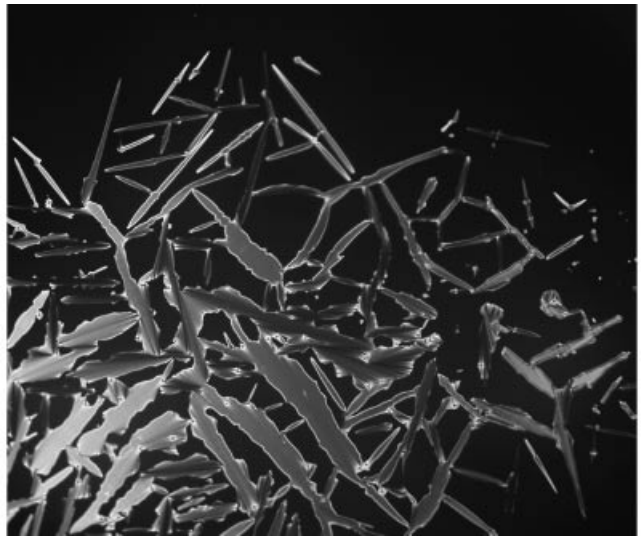

Figure 5. Texture of sodium 3-bromobenzoate at the clearing point at 389 °C, after cooling down from the isotropic liquid

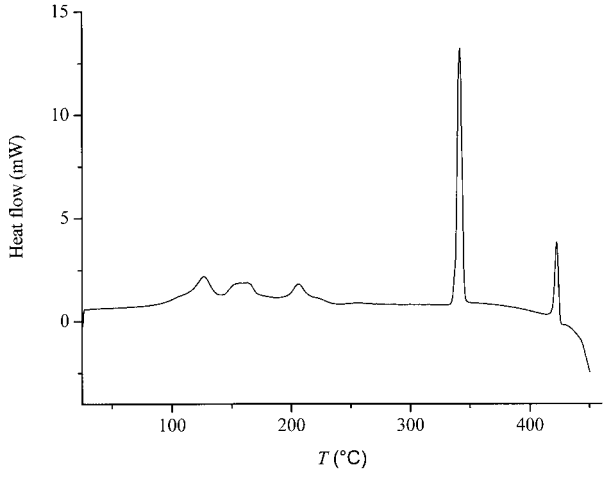

Figure 6. DSC thermogram of sodium 3-chlorobenzoate (first heating); endothermic peaks are pointing upward; the transitions between 100 and 250 °C are crystal−crystal transitions

sharp, which indicates a high purity, decomposition of the sample occurs already at temperatures below 400 °C.

The potassium salts of *meta*-substituted benzoic acids form a third group of compounds. The general trends observed for the sodium salts remain the same for the potassium salts: the melting and clearing temperatures decrease with increasing size of the *meta*-halogen substituent, whereas the mesophase range increases in the same way. However, unsubstituted potassium benzoate does not show a mesophase (see discussion of unsubstituted alkali-metal benzoates and Table 1), and neither does potassium 3-fluorobenzoate. Generally speaking, the transition temperatures of the potassium salts are lower than those of the corresponding sodium salts, and the mesophase range for an analogous potassium salt is narrower than that of the comparable sodium salt. The thermal behaviour of the potassium *meta*-substituted benzoates is summarised in Table 3.

Table 3. Thermal behaviour of *meta*-substituted potassium benzoates

Compound	Transition temperatures (°C)[a]

The fourth and fifth group, consisting of the rubidium and cesium salts of *meta*-substituted benzoates, respectively, follow the same trend as the second and third group: the melting and clearing points decrease with increasing size of the halogen substituent. However, the mesophase range decreases with increasing size for the rubidium salts, whereas the opposite was true for the sodium and potassium salts. Neither unsubstituted rubidium benzoate nor rubidium 3-fluorobenzoate show mesomorphism. Neither do any of the cesium salts. The thermal data of the rubidium and cesium salts of *meta*-substituted benzoates are given in Table 4 and 5, respectively.

A sixth group of compounds comprises the lithium salts of the *meta*-substituted benzoates. The reason why they have not been discussed first is the aberrant behaviour of lithium in the alkali-metal series. The lithium−oxygen bonds are less ionic than the metal−oxygen bonds of the other alkali-metal ions. As a result, the thermal data of the lithium series are not in line with the results of the other *meta*-substituted benzoate salts. The mesophase range of the corresponding *meta*-chlorobenzoate increases in the same way, from 0 °C for the cesium salt (which is non-mesopmorphic) through 26 °C for the rubidium salt and 61 °C for the potassium salt to 71 °C for the sodium salt. Looking only at the ionic radius of the alkali-metal ion, one would expect an even wider mesophase range for the lithium salt. This is not the case: lithium 3-chlorobenzoate has a mesophase range of 64 °C. The mesophase of lithium 3-iodobenzoate could not be identified (although it is very likely a highly ordered smectic phase). No nice texture could be observed under the microscope for any of the synthesised compounds. A very viscous mesophase is formed upon cooling the isotropic liquid, with no easily recognisable features present. This viscous phase does not crystallise when cooling further. This behaviour was observed in the DSC thermogram by the absence of a crystallisation peak in the first cooling run and a ''cold'' recrystallisation peak in the second heating run. The thermal behaviour of the lithium *meta*-substituted benzoates is summarised in Table 6.

The *ortho*- and *para*-substituted benzoates have also been studied. None of the *ortho*- (or 2-) or *para*- (or 4-)substituted benzoates shows mesomorphism. They all melt directly from the solid crystalline state to the isotropic liquid state. The melting points of the *para*-substituted salts are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

higher than those of the *ortho*-substituted salts. Within the series of the *ortho*-substituted salts, the melting points decrease with increasing size of the halogen substituent. The same is true for the *para*-substituted series, although here the melting points of the 4-chloro-, 4-bromo- and 4-iodobenzoates are virtually the same. The thermal data for these compounds are collected in Table 7.

[a] Cr: solid crystalline phases; SmA: smectic A phase; I: isotropic phase.

The layer-like structure of the compounds in the smectic A phase indicates that a layer structure is also present in the solid state, as it is very unlikely that a layered structure is formed upon melting of these compounds. In the absence of a layered structure in the solid phase, the compound will directly melt to an isotropic liquid. Surprisingly few crystal-structure data of alkali-metal benzoates are available, and most of the structures described in the literature are those of acid salts (obtained by partial neutralisation of 1 mol of the benzoic acid with 0.5 mol of alkali-metal hydroxide).[12,13] To the best of our knowledge, only one crystal structure of an anhydrous alkali-metal benzoate is known: anhydrous lithium benzoate.[14] The lithium benzoate molecules form a two-dimensional structure consisting of a grid of lithium and carboxylate oxygen atoms, with the phenyl groups forming a covering layer on each side. The polymeric layers are stacked, with the CH groups in the *para*-position pointing towards each other, so that a bilayer structure is formed. The layers are held together by weak van der Waals forces. The authors relate the presence of the weak van der Waals forces to the easy cleavability of the sheetlike crystals.

The thermal behaviour of the alkali-metal benzoates can be described as follows: at the melting point the van der Waals bonds between the phenyl rings are broken, so that the layers can move relative to one another. Hence, we observe a smectic A mesophase. Most probably, the ionic layer containing the alkali-metal ions is partially destroyed too, otherwise the viscosity of the mesophase would be much higher than what we observe. At the clearing point, the polymeric ionic layer is totally broken into pieces, so that an ionic melt is formed. The substituents in the *ortho*-, *meta*- or *para*-position will have an influence on the stacking of the molecules. This effect will be most pronounced for compounds with substituents in the *ortho*-position, and less so for compounds with substituents in the *meta*-position and in the *para*-position.

Although we tried out different routes, we were not able to obtain the anhydrous alkali-metal benzoates as single crystals of a quality high enough for X-ray diffraction. When an organic solvent was chosen as the crystallisation solvent only a fine polycrystalline precipitate was formed. Crystallisation from an aqueous solution resulted either in the formation of hydrated salts or of acid salts. The fact that those acids salts are formed in water, even though we started from pure alkali-metal benzoates, can be rationalised from the fact that, in water, partial hydrolysis occurs and the carboxylate groups get protonated. Nevertheless, these hydrated salts and acid salts do show the presence of a layered structure in the solid phase.

Single crystal data were obtained for four compounds: $Rb(C_7H_4ClO_2)(C_7H_4ClO_2H)$ (**1**), $Na(C_7H_4IO_2)(H_2O)$ (**2**), $K(C_7H_4ClO_2)(C_7H_4ClO_2H)$ (**3**) and $Rb(C_7H_4BrO_2)(C_7H_4BrO_2H)$ (**4**). All these compounds are salts of *meta*-substituted benzoic acids. The crystal data of compounds **1**−**4** are summarised in Table 8. Compounds **1**, **3** and **4** crystallised in the space group $C2/c$, whereas compound **2** crystallised in $P\bar{1}$ with two extra water molecules in the asymmetric unit. Consequently, the crystal packing of compounds **1**, **3** and **4** is isotypic, whereas compound **2** is differently packed. For compounds **1**, **3** and **4** the *meta*-chloro/bromobenzoic acid residues are linked together by a short, strong hydrogen bond across a centre of symmetry. The atom H7 lies on a centre of symmetry and bridges O2 and O2′ of two centrosymmetrical equivalent residues (see Figure 7). The distances for this hydrogen bond (O···H···O distance) are 2.448(2), 2.438(3) and 2.434(9) Å for compounds **1**, **3** and **4** respectively. A search of the CSD[15] for benzoic acid compounds that exhibit a strong hydrogen bond with the hydrogen atom on a centre of symmetry gave an average distance of 2.451 Å, with a range of 2.432−2.480 Å, for 12 structures. No such hydrogen bonds were found for compound **2** (see Figure 8). The dihedral angles between the plane formed by the atoms of the planar phenyl ring and the plane through the carboxylic group are 8.4(1), 7.9(2) and 8.4(4)° for compounds **1**, **3** and **4** respectively. For compound **2** the carboxylic groups lie nearly perfectly in the plane of their respective phenyl rings. The angles are 0.56(17) and 0.73(17)° respectively.

For compounds **1**, **3** and **4** the coordination sphere of the alkali-metal ions (potassium or rubidium) can be described by a distorted octahedron. Each alkali-metal ion is surrounded by six carboxylate oxygen atoms from different benzoic acid residues. These six oxygen atoms actually consist of four O1 and two O2 atoms. Thus, every carboxylic O1 atom coordinates to two alkali-metal ions and every O2 atom to only one alkali-metal ion. The alkali metal−oxygen distances vary for the rubidium compounds in the range of 2.838(2)−3.043(2) and 2.845(7)−3.068(7) Å for compounds **1** and **4**, respectively, and for the potassium compound **3** from 2.724(4)−2.885(3) Å. Notice that the distances of the latter are a little shorter than for the rubidium compounds due to the smaller ionic radius. For compound **2** the asym-

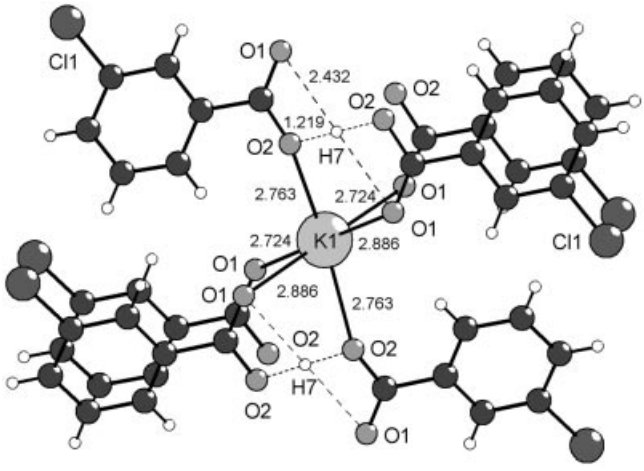

Figure 7. Crystal structure of compound **3** showing the coordination environment of the potassium ion; compounds **1** and **4** are isostructural

metric unit contains two alkali-metal (sodium) atoms. The coordination sphere of Na1 can be described by a distorted octahedron, which consists of six oxygen atoms, three from coordinated water molecules (O6 and two O5 atoms) and three from carboxylate oxygen atoms (O3, O2 and O4). The alkali metal−oxygen distances vary in the range 2.290(5)−2.609(5) Å. However, two additional longer contacts with O1 [2.903(6) Å] and O4′ of another equivalent residue [2.995(5) Å] could be noticed. Na2 also exhibits an octahedral coordination sphere, although it is less distorted than for Na1. The alkali metal−oxygen distances vary in the range 2.308(5)−2.831(5) Å with no additional contacts appearing. For compounds **1**, **3** and **4** the overall structure is built up by strands along the (010) direction, which are formed by the carboxyl O1 atom bridging the alkali-metal ions (see Figure 9). These strands are linked together in the (001) direction with the carboxylic groups acting as bridges (via O1) and with strong hydrogen-bonding between the O2 and O2′ atoms of equivalent residues. As a result, a two-dimensional coordination polymer is formed. In the (100) direction only van der Waals forces are observed between these coordination polymer units: the shortest distance is between two Cl/Br atoms [3.503(3), 3.532(5) and 3.597(6) Å for compounds **1**, **3** and **4** respectively]. For compound **2**, however, a strand of sodium atoms is formed by the carboxylic O2 and O4 atoms, which bridge Na1 and Na2 along the (010) direction (see Figure 10). The carboxylic O1 and O3 atoms form additional contacts with Na1. Thus, in the (010) direction two different carboxylic groups bridge two strands of sodium ions. These double strands of sodium ions are linked together in the (100) direction by water molecules (O5 and O6), each contacting Na1 and Na2, which results in a two-dimensional coordination polymer. In the (001) direction no contacts other than van der Waals contacts could be observed; the shortest distance between two iodine atoms is 4.158(5) Å. The position of the benzoic acid substituent does not influence the overall crystal packing.

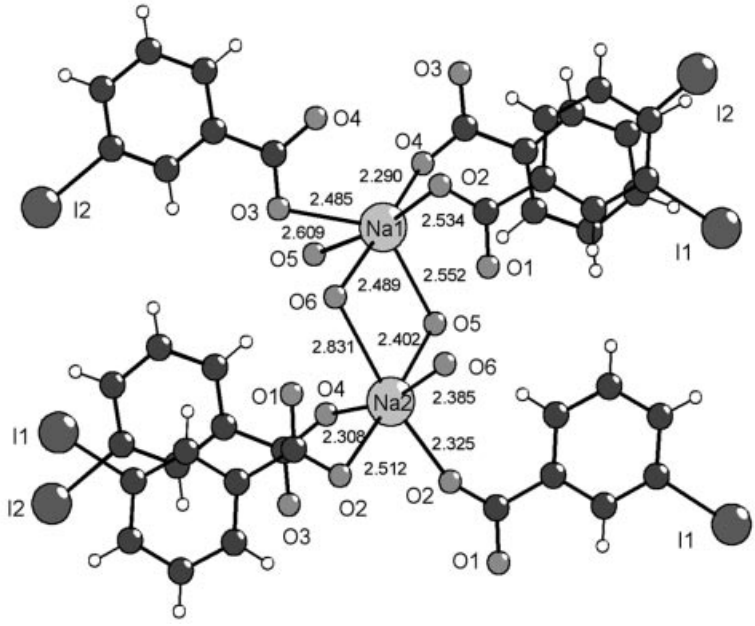

Figure 8. Crystal structure of compound **2** showing the coordination environment of the sodium ions

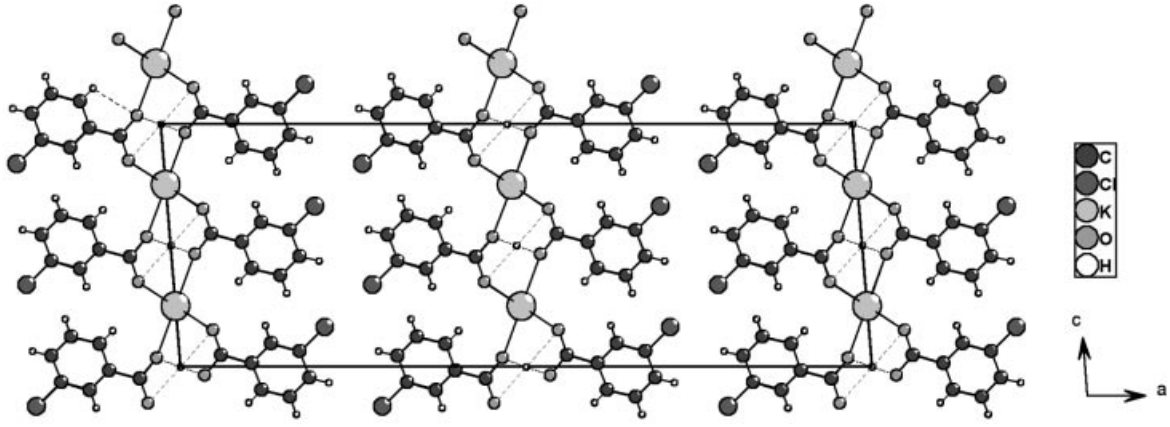

Figure 9. Crystal packing of compounds **1**, **3** and **4**

Indeed, for CSD[15] entry BINZAZ,[16] with a fluorine atom in the *para*-position, and for KHPHBZ10,[17] with a hydroxyl group in the *para*-position, a similar packing is observed. The latter crystallises in *P*2/*c* instead of *C*2/*c* (the *a*-axis is reduced to half length resulting in a similar packing) and contains one water molecule not in contact with the alkali-metal ion. Water molecules in contact with the alkali-metal ion influence the packing, as in compound **3**. The layered structures found for compounds **1**−**4** give an indication that it is likely that the anhydrous alkali-metal salts also have a layerlike structure in their solid phase. This idea is also supported by the fact that a layerlike structure is observed for lithium benzoate.[14] On the other hand, no layer structure is observed for benzoic acid. This compound forms dimers by intramolecular hydrogen bonding.[18] These dimers are not packed into layers, but are stacked on each other. The structure as a whole is built up by such stackings which alternate perpendicularly to one another. When the crystal melts, each dimer behaves as a separate entity, but its length-to-width ratio is too small to form a mesophase. Therefore, benzoic acid and the substituted benzoic acids melt directly to the isotropic liquid without passing through a mesophase.

Due to the absence of alkyl chains, the transition temperatures of the compounds are very high. At these high temperatures, the thermal energy of the molecules is high as well and only compounds with a strong interaction between the metal and carboxylate groups will exhibit a mesophase. Based on the concept of the hardness of Lewis acids and Lewis bases,[19] the strength of the metal−carboxylate bond decreases in the order $Na^+ > K^+ > Rb^+ > Cs^+$. Therefore, sodium compounds have the highest tendency to form a mesophase. This is indeed observed experimentally. The high transition temperatures result in several compounds starting to decompose in the mesophase (or even before the mesophase is reached). Lithium compounds are an exception, because the lithium−oxygen bond has a higher covalent contribution than the same bond in the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

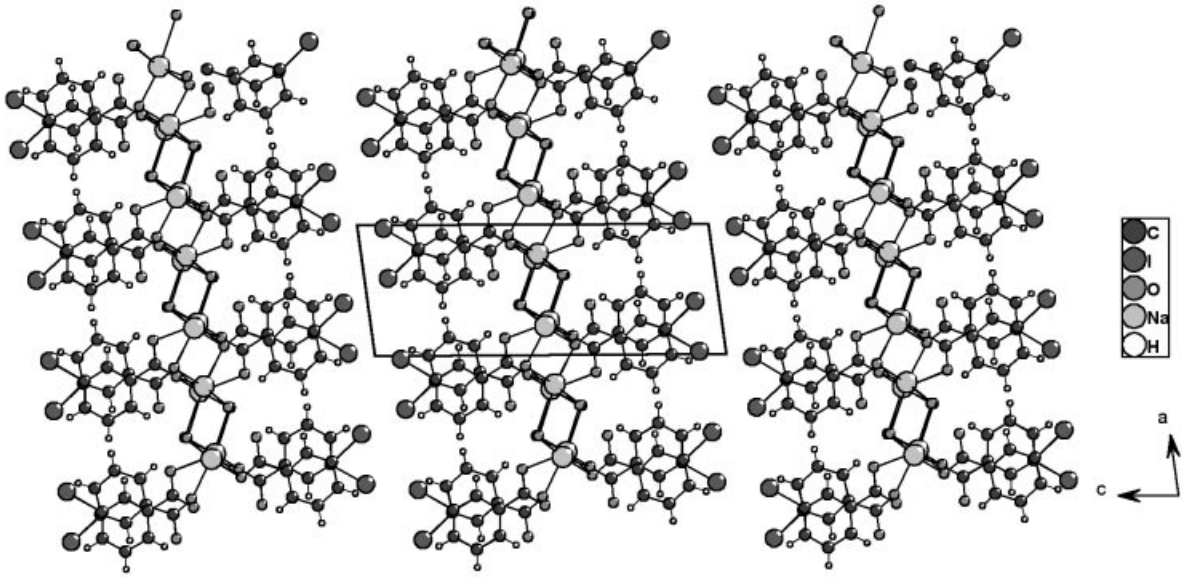

Figure 10. Crystal packing of compound **2**

other alkali metals. The higher the transition temperatures, the higher the chance that the compounds will melt from the solid state directly to the isotropic liquid. This is especially true when the strength of the ionic layer is weakened by (bulky) substituents in the *ortho*-position of the benzene ring. Bulky groups in the *para*-position prevent the formation of a mesophase, because the molecules will experience larger van der Waals forces or even dipole−dipole interactions, and because the bulky groups make it more difficult for the layers to glide along one another (and thus also give a higher viscosity). From this viewpoint, it is understandable that the most stable mesophases are formed for the alkali-metal salts of the *meta*-substituted benzoic acids. No mesophase is expected for the alkali-metal salts of terephthalic acid, because in this case no layer structure with an alternation of layers with ionic and van der Waals forces will be formed, but a succession of ionic layers.

Conclusion

Although the alkali-metal salts of aromatic carboxylic acids don't have the rodlike or disklike shape of conventional liquid crystals, they can form a mesophase at high temperatures. This has been illustrated for the salts of different substituted benzoic acids. The position of the substituent is of prime importance, since only the salts of *meta*-substituted benzoic acids exhibit mesomorphism. No liquid-crystalline behaviour was observed for *ortho*- and *para*-substituted compounds. The mesomorphism not only depends on the type of substituent and its position, but also on the type of alkali metal. The most stable mesophases were observed for the sodium salts, and of the salts of unsubstituted benzoic acid, only sodium benzoate is mesomorphic. Investigation by polarizing optical microscopy and by high-temperature X-ray diffraction shows that the structure of the mesophase is similar to that of the smectic A phase of conventional organic liquid crystals. Crystal structures of similar, but hydrated or solvated compounds show that a layer-like structure is already present in the solid state.

Experimental Section

The alkali-metal salts were prepared by a neutralisation titration of an ethanolic solution of the carboxylic acid with an aqueous standard solution (0.5 M) of the corresponding alkali-metal hydroxide (LiOH, NaOH, KOH, CsOH or RbOH), with phenolphthalein as the indicator. After reaching the equivalence point, the carboxylate salts were recovered by evaporation of the solvent under reduced pressure. The compounds were redissolved in a small amount of ethanol at room temperature and were reprecitated by addition of acetone or a mixture of acetone and diethyl ether. An acetone/diethyl ether mixture was used for the precipitation of the rubidium and the cesium salts of sodium 2-chlorobenzoate and sodium 2-bromobenzoate. The precipitate was filtered off on a Buchner funnel, washed with acetone and dried in vacuo at 120 °C. The purity of the samples could not be checked by CHN elemental analysis, because the carbon dioxide, resulting from the combustion of the benzoic acids in the CHN apparatus, reacts with the alkali metals to form alkali-metal carbonates, which are very stable at high temperatures, resulting in a too low measured carbon content. All samples were prepared in triplicate to check the reproducibility of the transition temperatures. Infrared measurements were performed to check the absence of free carboxylic acid.

Differential scanning calorimetry (DSC) measurements were performed on a Mettler-Toledo DSC821e module (scan rate 10 °C min^{-1} under a helium flow of 35 mL min^{-1}). The reported transition temperatures are onset temperatures. The optical textures of the mesophases were observed with an Olympus BX60 polarizing optical microscope equipped with a Linkam THMS600 hot stage and a Linkam TMS93 programmable temperature controller. In order to avoid or reduce the oxidative degradation of the compounds, the hot stage was flushed with a stream of nitrogen gas. High-temperature X-ray diffraction was measured on a STOE Transmission Powder Diffractometer System STADI P, with a high temperature attachment version 0.65.1 (temperature range from

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

room temperature to 1000 °C). Monochromatic Cu-$K_{\alpha 1}$ radiation (λ = 1.5406 Å) was obtained with the aid of a curved germanium primary monochromator. The diffracted X-rays were measured by a linear Position Sensitive Detector (PSD). The sample was placed in a quartz glass capillary (outer diameter 0.3 mm, wall thickness 0.01 mm) and spun during the measurement.

Crystals of salts of the *meta*-substituted benzoates of a quality suitable for X-ray diffraction were obtained for $Rb(C_7H_4ClO_2)(C_7H_4ClO_2H)$ (**1**), $Na(C_7H_4IO_2)(H_2O)$ (**2**), $K(C_7H_4ClO_2)(C_7H_4ClO_2H)$ (**3**) and $Rb(C_7H_4BrO_2)(C_7H_4BrO_2H)$ (**4**) by slow evaporation of the solvent from an H_2O/EtOH (1:1) mixture at room temperature, and mounted in a nylon loop for data collection at 100 K on a SMART 6000 diffractometer equipped with a CCD detector using Cu-K_α radiation (λ = 1.54178 Å). The images were interpreted and integrated with the program SAINT from Bruker.[20] The four structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL program package.[21] Non-hydrogen atoms were refined anisotropically and the hydrogen atoms were refined in the riding mode with isotropic temperature factors fixed at 1.2-times *U*(eq) of the parent atoms, except for compound **1**, where the positions of all hydrogen atoms could be localised from the difference Fourier maps without applying any further restraints. For compounds **1**, **3** and **4** the H atoms occur on special positions — the H7 atom bridges O2 and O2′ of a symmetry-equivalent molecule. Only for compound **4** could this H atom not be localised from the difference Fourier maps; it was modelled by assigning the coordinates of the special position. Compound **3** is essentially the same as the one found in the CSD[15] with code KHCBZO10,[12] but in the latter one aromatic hydrogen atom and the one at the special position are not included in the structure.

CCDC-256797 (**1**), -256798 (**2**), -256799 (**3**) and -256800 (**4**) contain the supplementary crystallographic data for this paper. Causes of Nonplanarity in Fluorinated 1,3λ⁴δ²,2,4-Benzodithiadiazines: Gas-Phase Electron Diffraction, Ab initio and DFT Structures

Andrew R. Turner,[a] Frank Blockhuys,[b] Christian Van Alsenoy,[b] Heather E. Robertson,[a] Sarah L. Hinchley,[a] Andrey V. Zibarev,[c] Alexander Yu. Makarov,[c] and David W. H. Rankin*[a]

Keywords: Antiaromaticity / Fluorinated 1,3λ⁴δ²,2,4-benzodithiadiazines / Molecular structure / Ab initio calculations / Density functional calculations

The gas-phase molecular structures of 6,8-difluoro-1,3λ⁴δ²,2,4-benzodithiadiazine and 5,6,7-trifluoro-1,3λ⁴δ²,2,4-benzodithiadiazine have been determined using quantum chemical calculations and electron diffraction via the SARACEN method of structural analysis. Of particular interest was the planarity or nonplanarity of the heterocyclic fragments of the molecules. It was shown that the difluoro compound is planar with respect to the heterocyclic fragment [folding angle: 0.0(5)° (figures in parenthesis indicate e.s.d.s in the final digits)] and that the trifluoro compound probably deviates from planarity to a small extent [folding angle: 4.0(–30;+3)°; the large uncertainty in the value of this angle is due to the low-frequency, large-amplitude vibrational motion associated with the folding of the heterocyclic fragment]. Pertinent structural parameters from the electron diffraction data (r_{h1} structure) of the difluoro compound are *av*[*r*(S=N)] = 155.7(7) pm, *r*(S–N) = 175.8(5) pm, *r*(C–S) = 176.6(8) pm and *r*(C–N) = 141.6(2) pm. For the trifluoro compound the equivalent structural parameters are *av*[*r*(S=N)] = 155.5(7) pm, *r*(S–N) = 170.7(6) pm, *r*(C–S) = 180.6(8) pm and *r*(C–N) = 140.6(2) pm. The gas-phase electron diffraction structures have been compared with results from ab initio and DFT calculations and also with experimental solid-state structures.

Introduction

Antiaromatic structures (i.e. those with 4*n* π-electrons) containing a benzenoid ring fused to a heterocyclic ring have been the subject of recent scrutiny due to their unusual structural properties.[1−4] Of particular interest have been 1,3λ⁴δ²,2,4-benzodithiadiazine and its fluorinated derivatives. The basic structural unit of these compounds consists of a benzene ring fused to a S_2N_2 fragment to give a 12 π-electron system. A gas-phase electron diffraction (GED) study of the parent compound 1,3λ⁴δ²,2,4-benzodithiadiazine (**1**)[3] showed that the heterocyclic fragment adopts a nonplanar conformation in the gas phase. In the same study it was shown that the tetrafluoro derivative (5,6,7,8-tetrafluoro-1,3λ⁴δ²,2,4-benzodithiadiazine, compound **2**) has a planar heterocyclic fragment in the gas phase. The nonplanar conformation of compound **1** was rationalised as a pseudo-Jahn−Teller distortion[5] which minimises the destabilisation caused by the antiaromaticity. For the tetrafluoro derivative it was postulated that a π-fluoro effect, due to the fluorine substituted in the 8-position, would counteract the pseudo-Jahn−Teller distortion leading to a planar conformation.

The study also revealed an unexpected conflict in the conformation predicted for compound **2** by ab initio molecular orbital (MO) methods and DFT calculations. The DFT calculations predicted the planar conformation as seen in the refined GED structure, whilst the MO calculations predicted the nonplanar conformation. This work extends the study by employing both GED and theoretical structural studies to deduce the gas-phase structures of the 6,8-difluoro derivative **3** and the 5,6,7-trifluoro derivative **4**. From the π-fluoro hypothesis we would expect compound **3** to show a planar conformation with respect to the heterocyclic fragment and compound **4** to show a nonplanar conformation. Along with **1** and **2**, these are the simplest accessible compounds that can be used to investigate the influence of fluorine substitution at position 8.

Preparation and Characterisation

Compounds **3** and **4** were prepared, purified and structurally characterised by single-crystal X-ray diffraction

studies as described in reference 4. IR spectra of the compounds in KBr were recorded on an FT Bruker Vector 22 spectrometer. Raman spectra were recorded with an FT Bruker IFS 66 spectrometer equipped with a Nd/YAG laser with an excitation line at 1064 nm.

GED Measurements

Electron diffraction data were captured with Kodak Electron Image photographic films using the Edinburgh gas-phase electron diffraction apparatus.[6] For compound **3**, at the short camera distance, the sample was maintained at a temperature of 423 K whilst the nozzle temperature was held at the higher temperature of 443 K to prevent sample condensation in the nozzle. At the long camera distance, the sample temperature was 381 K whilst the nozzle temperature was 413 K. The four corresponding temperatures for compound **4** were 431, 450, 386 and 413 K, respectively. The vapours were injected into the diffraction chamber through a metal nozzle with camera distances of approximately 98 mm and 250 mm. The electron accelerating voltage was approximately 40 kV, giving an electron wavelength close to 6 pm. The precise camera distances (d) and electron wavelengths (λ) were determined from scattering patterns for benzene vapour recorded immediately before or after the sample patterns. Details are given in Table 1, together with the weighting functions used to set up the diagonal elements of the weight matrix used in the least-squares refinement process (sw_1, sw_2), the s-ranges ($s_{min.}$, $s_{max.}$), the scale factors (k) and the correlation parameters (ratio of the off-diagonal terms to the diagonal terms of the weight matrix, q) which were used to define the immediate off-diagonal elements of the weight matrix.[7] The remaining elements of the weight matrix were set to zero.

Table 1. GED experimental details; figures in parentheses are the estimated standard deviations of the last digits

	d [mm]	Weighting functions [nm^{-1}]					q	k	λ [pm]
		Δs	$s_{min.}$	sw_1	sw_2	$s_{max.}$			
3	97.69	4	100	120	264	308	0.4406	0.673(15)	6.020
	256.19	2	20	40	128	150	0.3511	0.872(7)	6.020
4	97.85	4	100	120	264	308	0.4692	0.691(11)	6.020
	251.21	2	20	40	136	158	0.4009	0.861(7)	6.020

Details of the electron scattering patterns were converted into digital form using a PDS densitometer at the Institute of Astronomy in Cambridge. For compound **3**, the results spanning the ranges 20 nm^{-1} ≤ s ≤ 150 nm^{-1} and 100 nm^{-1} ≤ s ≤ 308 nm^{-1} and for compound **4**, the results spanning the ranges 20 nm^{-1} ≤ s ≤ 158 nm^{-1} and 100 nm^{-1} ≤ s ≤ 308 nm^{-1} were reduced and analysed using the ed@ed program[8] employing the scattering factors tabulated by Ross et al.[9]

Results and Discussion

Theoretical Studies

Calculations were performed at various levels, using the Gaussian98 suite of quantum chemistry programs,[10] to gauge the effects of different methodologies and basis sets on the structures. They also provide guidelines for the uncertainties of the SARACEN restraints[11] in the GED structure refinements (see GED Structure Refinements). The results are listed in Table 2 for compound **3** and in Table 3 for compound **4**.

The most obvious feature of the calculations is the disagreement between the ab initio results (MP2, 2nd order Møller-Plesset perturbation theory[12]) and the DFT results (B3LYP hybrid functional[13]) in the conformation predicted for compound **3**. The DFT calculations all agree on the planar conformation for the heterocyclic fragment while the ab initio calculations predict a nonplanar conformation. Although the two methods agree on the nonplanar conformation for compound **4**, the largest differences between the DFT and ab initio calculations are in the geometry of the heterocyclic fragment. The same patterns were noted and explained in a previous study of compounds of this type.[3] In short, the DFT results seem to agree consistently and more closely with previous GED experiments than the ab initio results.

GED Structure Refinements

6,8-Difluoro-1,3λ⁴δ²,2,4-benzodithiadiazine (3)

The refined structure and associated atom numbering scheme for compound **3** are shown in Figure 1. The molecular model was constructed in C_1 symmetry, thus allowing for the out-of-plane movement of the heterocyclic fragment. The $C_6H_2F_2$ fragment was assumed to be planar since all of the ab initio and DFT calculations show negligible deviations from planarity. Twenty-eight independent geometrical parameters were used to describe the molecular structure and these are defined in Table 4. Eleven of the parameters correspond to bond angles and four to torsional angles. The remaining thirteen describe the various bond lengths in the molecule. The two C−H distances are described by a single parameter (p_8) as are the two C−F distances (p_9). In both of these cases the calculations indicated insignificant differences between the two different occurrences of the bonds. The parameter p_1 corresponds to the mean of all the C−C and C−N bond lengths, with p_2 to p_7 corresponding to various combinations of differences between these distances. The mean and the difference between the S(12)−N(13) and S(12)−N(11) bond lengths are given by p_{12} and p_{13},respectively, since these distances are similar according to the ab initio and DFT calculations.

A force field in Cartesian coordinates, calculated using the DFT method with a B3LYP functional and a 6-311+G* basis set,[14] was used (after scaling, see below) to compute values for the root-mean-square (RMS) amplitudes of vibration (u_{h1}) and perpendicular distance corrections (k_{h1}) using the methods of Sipachev.[15] This takes account of the curvilinear motions of the atoms in the molecular vibrations and yields the r_{h1} structure from the refinement process.

IR and Raman spectra were recorded and used to scale the calculated force field to obtain the most realistic esti-

[a] Ref.[14] [b] Dunning correlation-consistent triple-ζ with diffuse functions.[16]

mates for the u_{h1} values. Table 5 lists the experimental frequencies as well as the scaled theoretical frequencies. The scaling factors for the theoretical frequencies were 0.92 for CH stretching modes, 0.98 for CH out-of-plane bending modes and 0.97 for the CC stretching modes. The RMS difference between the experimental and theoretical frequencies is 9 cm^{-1} and the largest difference is 17 cm^{-1}.

The refinement was carried out using the ed@ed program.[8] SARACEN restraints were applied to a large number of the independent parameters in order to allow all similar distances to be refined simultaneously. All the restraints are listed in Table 4. Reasonably tight restraints were applied to all the parameters describing the carbocyclic fragment since the consistency of the calculations gave us a large amount of confidence in the computed values for these parameters. Restraints were also placed on the C−H distance and C−F distance parameters (p_8 and p_9, respectively). The only restraints applied to the heterocyclic fragment were to the S−N distance average and difference parameters (p_{12} and p_{13}, respectively). The starting values for the refinement and the values for the restraints were taken from a DFT calculation using the B3LYP functional with a Dunning correlation-consistent basis set of triple-ζ quality, augmented by one diffuse function on each atom.[16]

It is immediately obvious that the positions of the hydrogen atoms are determined almost entirely by the restraints, with the exception of the C−H bond length. All of the difference parameters pertaining to the structure of the carbocycle (p_2−p_7) are also determined by the restraints (indicated by the equivalence of the parameter estimated standard deviation, e.s.d., and the restraint uncertainty). The unrestrained parameter p_1 (the average of the C−C and C−N distances) differs by just 0.5 pm from the computed value (DFT/B3LYP/aug-cc-pVTZ). The remaining restrained parameter values fall within the restraint uncertainties apart from p_{20}, the value of which lies just outside the uncertainty range of the restraint.

Restraints were also applied to the RMS amplitudes of vibration which could not be refined independently. Values for these restraints were calculated directly from the DFT force field, with uncertainties of 10% in the absolute computed values. With these restraints in place, all the significant RMS amplitudes of vibration were refined. The full set of refined RMS amplitudes of vibration is presented as Supporting Information (Table S1; for Supporting Informations see also the footnote on the first page of this article) along with their associated interatomic distances. The final R_G factor for the refinement was 0.049 (for the individual datasets: $R_G^{(long)} = 0.155$; $R_G^{(long)} = 0.032$). The molecu-

lar scattering intensities are available in the Supporting Information (Figure S1) and the final RDCs are shown in Figure 2.

The parameters describing the folding of the heterocyclic ring ($p_{25}-p_{28}$), a key aspect of this study, were initially held fixed in the computed geometry (i.e. a planar conformation). Once this constrained refinement had been completed, the four folding parameters were combined into one parameter describing the folding motion (p_{25}), the other three parameters being determined from it by fixed ratios (as in Blockhuys et al.[3]). The ratios were determined from the displacements of the atoms of the heterocycle for the lowest-frequency folding mode calculated from the DFT force field [$p_{26} = 3.05 \times p_{25}$; $p_{27} = -3.46 \times p_{25}$; $p_{28} = (0.39 \times p_{25}) - 180$]. This folding parameter was then fixed at various nonzero values and the refinement repeated. The variation of the R_G factor with folding angle was monitored and is plotted in Figure 3. It is immediately obvious that the molecule adopts the planar conformation in the gas phase. The tables of Hamilton[17] were used to compute the 99.5% confidence limit (ca. 3σ) in order to determine the estimated standard deviation for the folding angle, leading to a value of 0.0(5)° (where the figure in parentheses indicates the e.s.d. in the last digit). The refined values of the structural parameters (r_{h1} structure) of this conformation are shown in Table 4. The planar conformation is in agreement with both the predictions of the π-fluoro hypothesis and those of the DFT calculations.

The Supporting Information (see also footnote on the first page of article) contains numerical data corresponding to the molecular scattering intensity curves (Table S2) and

the R_G factor plot (Table S3) along with the Cartesian coordinates of the final refined structure (Table S4) and the least-squares correlation matrix (Table S5).

5,6,7-Trifluoro-1,3λ⁴δ²,2,4-benzodithiadiazine (4)

The model for compound **4** was constructed in an analogous way to that for compound **3**. Figure 4 shows the refined structure and atom numbering scheme for compound **4**. The differences between the models are listed below:

p_8 now describes only one C−H bond length.

p_9 now describes three C−F distances.

p_{19} now describes an F−C−C angle.

IR and Raman spectra were recorded and used to scale the calculated force-field (computed in an analogous way to that for compound **3**) to obtain the most realistic estimates of the u_{h1} values. Table 6 lists the experimental frequencies as well as the scaled theoretical frequencies. The scaling factors for the theoretical frequencies were 0.92 for CH stretching modes, 0.98 for CH out-of-plane bending modes and 0.97 for the CC stretching modes. The RMS difference between the experimental and theoretical frequencies is 9 cm^{-1} and the largest difference is 17 cm^{-1}.

Once again, SARACEN restraints were applied to many of the independent parameters in order to allow all similar distances to be refined simultaneously. All the restraints are listed in Table 7. Restraints were also placed on the C−H distance and C−F distance parameters (p_8 and p_9, respectively). The only restraints applied to the heterocyclic fragment were on the S−N average distance parameter and the S−N distance difference parameter (p_{12} and p_{13}). The starting values for the refinement and the values for the restraints were taken from a DFT calculation using the B3LYP functional with a Dunning correlation-consistent basis set of triple-ζ quality augmented with one diffuse function on each atom.

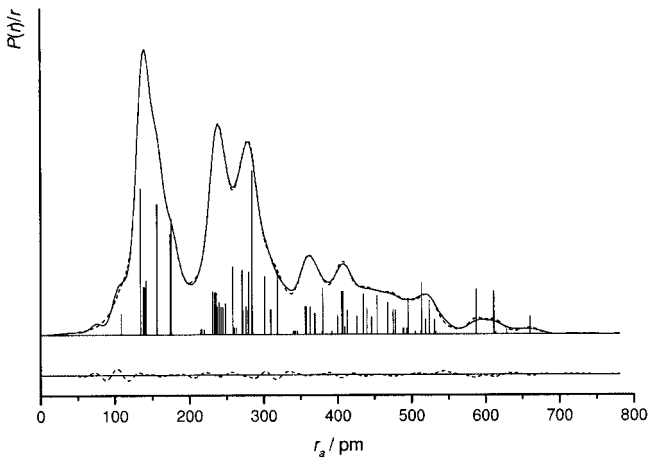

Figure 2. Radial distribution and difference curves for compound **3**; solid curve: observed radial distribution curve; dashed curve: calculated radial distribution curve at refined geometry; lower dashed curve: difference between observed and calculated radial distribution curves; before Fourier inversion all data were multiplied by $s[\exp(-0.00002s^2)/(Z_S - f_S)(Z_F - f_F)]$

Restraints were also applied to the RMS amplitudes of vibration which could not be refined independently. Values for these restraints were calculated directly from the DFT force field, with uncertainties of 10% in the absolute computed values. With these restraints in place, all the significant RMS amplitudes of vibration were refined. The full set of refined RMS amplitudes of vibration is available in the Supporting Information (Table S6) along with their associated interatomic distances. The final R_G factor for the refinement was 0.039 (for the individual data sets: $R_G^{(short)} = 0.112$; $R_G^{(long)} = 0.025$). The molecular scattering intensities are available in the Supporting Information (Figure S2) and the final RDCs are shown in Figure 5. Once again, all of

the difference parameters defining the structure of the carbocycle (p_2−p_7) are determined entirely by the restraints. The unrestrained parameter describing the average of the C−C and C−N distances (p_1) differs by just 0.3 pm from the computed value (DFT/B3LYP/aug-cc-pVTZ).

As for compound **3**, we were particularly interested in the planarity or nonplanarity of the heterocyclic fragment. In order to investigate this, the four parameters describing the folding of the heterocyclic fragment were combined into just one folding parameter (p_{25}). The ratios were determined from the displacements of the atoms of the heterocycle for the lowest-frequency folding mode calculated from the DFT force field [$p_{26} = 3.05 \times p_{25}$; $p_{27} = -3.16 \times p_{25}$; $p_{28} = (0.49 \times p_{25}) - 180$]. This parameter was fixed at various values and the refinement repeated. The variation of the R_G factor with folding angle is presented in Figure 6 along with the 99.5% confidence limit, calculated as described above. The graph indicates that the folding angle parameter can take effectively any value between 0° (planar) and about 6°. The variation of the R_G factor from its minimum value of 0.038 (4.0°) up to its value of 0.042 at 6° is just 0.004. Nevertheless, the R_G factor analysis suggests a folding angle of 4.0(−30;+3)°. More evidence for the slightly nonplanar geometry of the heterocyclic fragment comes from the fact that in the refinement at the planar geometry, some of the parameter values lie outside their SARACEN restraint uncertainties. In the nonplanar geometry refinement the parameter values lie within the restraint uncertainties.

The Supporting Information contains numerical data corresponding to the molecular scattering intensity curves (Table S7) and the R_G factor plot (Table S8) along with the Cartesian coordinates of the final refined structure (Table S9) and the least-squares correlation matrix (Table S10).

Structural Comparisons

Table 8 enables a comparison of the available experimental and theoretical structural data (DFT/B3LYP/aug-cc-pVTZ) for compound **3** and Table 9 shows the same comparison for compound **4**.

For compound **3**, both GED and theory agree on a planar conformation with respect to the heterocyclic ring in the gas phase, while the XRD study shows that the compound is bent in the crystal. The major differences between the GED structure and the theoretical structure are in the S(14)−N(13) and C(1)−S(14) bond lengths. In the GED structure, the S(14)−N(13) bond is 6.9 pm longer than the theoretical value and the C(2)−S(14) bond length is 5 pm shorter than the theoretical value. Refinements with the bond lengths restrained to the theoretical distances show significantly larger R_G factors than for the final refined structure. 1st row to 2nd row *p*-block bond lengths have been found to be particularly difficult to determine using ab initio techniques.[18]

For compound **4**, the theoretical structure shows a bent conformation for the heterocyclic ring and the XRD study shows that the heterocycle is almost flat in the crystal. In the gas phase, the indications are that the heterocyclic ring is slightly bent. This is supported by the fact that generally, the GED structural parameters agree more closely with the theoretical (bent) structure than with the XRD (almost planar) structure. All the S−N bond lengths and the C−S bond length agree to within 1 pm. The magnitude of the folding angle is also very similar in the GED and theoretical structures.

Table 10 shows a comparison of the relevant structural parameters for compounds **1**, **2**, **3** and **4** as determined by GED. The major differences between the compounds are in the S(14)−N(13) and C(2)−S(14) bond lengths. For the S(14)−N(13) bond, the largest difference is 6.1 pm (between compound **1** and compound **3**) and for the C(2)−S(14) bond length, the largest difference is 4.6 pm (between compound **2** and compound **3**). It is worth noting that although the S=N bond lengths [N(11)−S(12), S(12)−N(13)] stay

reasonably consistent over all the compounds, the S−N bond length [S(14)−N(13)] is slightly greater in the two planar compounds. The lack of other obvious trends in the structures is indicative of the complex effects that different fluorine substitution patterns have on the structures of the compounds. Although the calculations predict that both the S(14)−N(13) and C(2)−S(14) bond lengths should be similar in both compounds **3** and **4**, the GED results do not replicate this trend. To assess whether or not this is a real effect we restrained the values in the GED refinement to the theoretical values. In both compounds this resulted in the values lying well outside the restraint uncertainties and a large increase in the R_G factors showing that the experimentally determined values are indeed correct.

Our studies show that compound **3** is planar and that compound **4** is slightly nonplanar, in line with the π-fluoro hypothesis. The energy difference between the planar and nonplanar conformations of compound **4** has been calculated using a number of different methods and the results are shown in Table 11. These values have been corrected by adding the calculated zero-point vibrational energies (scaled according to the constants of Wong et al.). All of the energy differences between the bent and flat conformers are effectively zero, reflecting the low-frequency, large-amplitude nature of the out-of-plane bending mode. At the temperature of the GED experiment we would expect the vibrational mode corresponding to the folding of the heterocyclic ring to have a large amplitude, leading to the very large uncertainties we see in the value of the folding angle.

Table 11. Calculated energy differences between bent and flat conformations of compound **4**; all energy differences include scaled zero-point vibrational energy corrections

Method	Energy difference [kJ·mol^{-1}]

DFT/B3LYP/aug-cc-pVDZ	0.9
DFT/B3LYP/aug-cc-pVTZ	0.07

Conclusion

We have successfully used the new graphical structural refinement program ed@ed to obtain the SARACEN gas-phase structures of 6,8-difluoro-1,3λ^{4}δ^2,2,4-benzodithiadiazine (**3**) and 5,6,7-trifluoro-1,3λ^{4}δ^2,2,4-benzodithiadiazine (**4**) from GED data.

These GED structures have been compared with both the theoretical and crystal structures and the differences, in particular the conformations of the heterocyclic fragments, have been noted and discussed. Compound **3** is planar in the gas phase with respect to the heterocyclic fragment and compound **4** is slightly nonplanar, as predicted by the π-fluoro hypothesis postulated by Blockhuys et al.[3] The large uncertainties in the folding of the heterocyclic fragment for compound **4** are due to the low-frequency bending mode of the heterocyclic fragment. On the whole, this work and Blockhuys et al.[3] describe and explain interesting stereoelectronic effects in benzo-fused sulfur-nitrogen antiaromatic heterocycles. In particular, it has been shown that for free molecules, the conformation of the heterocyclic ring can be affected by substitutions on the carbocyclic fragment.

Ionic Liquids as Reaction Media for Palladium-Catalysed Cross-Coupling of Aryldiazonium Tetrafluoroborates with Potassium Organotrifluoroborates

Vito Gallo,[a] Piero Mastrorilli,*[a] Cosimo F. Nobile,[a] Rossella Paolillo,[a] and Nicola Taccardi[a]

Keywords: C-C coupling / Diazonium salts / Homogeneous catalysis / Ionic liquids / Organotrifluoroborates

The system comprising a palladium complex in a 1-butyl-3-methylimidazolium tetrafluoroborate/methanol mixture efficiently catalyses the cross-coupling reaction between *p*-tolyldiazonium tetrafluoroborate and potassium phenyltrifluoroborate at room temperature. The presence of methanol (or water) in the reaction mixture is necessary in order to achieve quantitative conversions, due to its scavenging behaviour towards the BF_3 formed during the reaction. Yields higher than 90% were obtained using $Pd_2(dba)_3$ or the azapalladacycle **10** as the palladium source. With the latter complex a turnover frequency of about 6000 h^{-1} was attained in the coupling of aryldiazonium tetrafluoroborates with potassium vinyltrifluoroborate. Recycling of the catalytic solution could be performed provided that a slight excess of diazonium salt was used in the first run.

Introduction

Palladium-catalysed cross-coupling utilizing organoboron compounds (the Suzuki reaction) is a powerful tool for the formation of carbon−carbon bonds.[1,2] The practical advantages of this reaction are mainly related to the wide range of functionalized substrates that can be used under mild conditions. Typical reaction protocols exploit aryl iodides, bromides and triflates, which are not as cheap and readily available as aryl chlorides, although the latter are less reactive. It has been demonstrated[3−8] that aryldiazonium tetrafluoroborates derived from inexpensive and easily accessible anilines can be efficiently used in the cross-coupling with organoboronic acids or esters. Moreover, the cross-coupling has also been performed at room temperature and without added base using potassium organotrifluoroborates, which are more stable and reactive than the corresponding boronic acid derivatives.[9]

Ionic liquids (ILs) have emerged as potentially useful reaction media in catalysis because of their peculiar physical and chemical properties.[10] The latest efforts of the scientific community have been addressed towards finding new, possibly recyclable catalytic systems that exhibit higher activity than with classical solvents.

The palladium-catalyzed Suzuki reaction between boronic acids and aryl halides has been successfully carried out in ILs. Welton et al.[11−13] have demonstrated that, under suitable conditions, the use of imidazolium-based IL/H_2O mixtures leads to increased reactivity and selectivity compared to conventional reaction media and permits the recycling of the catalytic solutions. Other catalytic systems employed for the same reaction include $PdCl_2$ in alkylammonium tetrafluoroborate/H_2O mixtures,[14] $Pd_2(dba)_3$ in a ternary system made up of tetradecyltrihexylphosphonium chloride, water and toluene[15] and phosphane-free $Pd(OAc)_2$ or bisimidazolin-2-ylidene palladium complex in IL/MeOH mixtures under ultrasonic irradiation.[16]

In the framework of our studies on metal-catalysed carbon−carbon bond forming reactions in ILs[17−20] we decided to investigate the palladium-catalysed cross-coupling of aryldiazonium salts with organotrifluoroborates. Figure 1 shows the ILs used in this work.

Results and Discussion

Optimisation of the Solvent

The cross-coupling reaction between *p*-tolyldiazonium tetrafluoroborate (**1a**) and potassium phenyltrifluoroborate (**2**) was chosen as the model system (Reaction 1).

Reaction 1. Cross-coupling between *p*-tolyldiazonium tetrafluoroborate and potassium phenyltrifluoroborate

Table 1 summarises the results obtained when carrying out reaction 1 in several ILs with 2.0 mol % $Pd(OAc)_2$ as catalyst, which is a palladium loading less than half of that used in previous works.[9]

Table 1. Solvent screening; reaction conditions: IL: 10 mmol; $Pd(OAc)_2$: 0.02 mmol; **1a**: 1.0 mmol; **2**: 1.2 mmol

Entry	Solvent	Time [h]	Conv.[a] (%)	Isolated yield (%)
1-1	[bmim]BF_4	6	51	49
2-1	[bmim]$N(SO_2CF_3)_2$	6	60	38
3-1	[bmim]PF_6	14	50	41
4-1	[bmmim]BF_4	12	53	45
5-1	[bbim]BF_4	12	45	34

[a] Calculated at the time at which a plateau was reached in the consumption of the diazonium salt.

The results show that there is an effect of the IL used on the course of the reaction. Using [bmim]BF_4 (bmim = 1-*n*-butyl-3-methylimidazolium) gave 51% conversion after 6 h with 96% selectivity towards **3a** (Entry 1-1). Catalysis in [bmim]$N(SO_2CF_3)_2$ was more efficient (60% conv. after 6 h) but significantly less selective (63%, Entry 2-1), whereas when [bmim]PF_6 was used as solvent a drop in both activity (50% conv. after 14 h) and selectivity (82%) was observed (Entry 3-1 vs. Entry 1-1). The effect of the cation of the IL is shown in Entries 1-1, 4-1 and 5-1, from which it is apparent that comparable yields of **3a** were obtained after significantly different times. Among all the ILs tested [bmim]BF_4 gave the best results in terms of both activity and selectivity and was chosen as solvent for further investigations.

A common point which emerges from Table 1 is that, after variable times, the reactions did not reach completion but stopped when the conversion was about 50−60%. Figure 2 shows the reaction course in the case of Entry 1-1.

Such a behavior could, in theory, be ascribed to two causes: a) catalyst deactivation, or b) formation of a product that inhibits the reaction.

The first hypothesis was ruled out by the observation that the conversion did not improve significantly when performing the reaction with a higher amount of palladium: carrying out the catalysis with 5 or 10 mol % Pd resulted in 65% or 70% conversion, respectively.

In search of the reaction product that could act as inhibitor for the reaction we focused our attention on BF_3. It is known[21,22] that BF_3 reacts with **2** in halogenated solvents to afford potassium tetrafluoroborate and phenyldifluoroborane (Reaction 2).

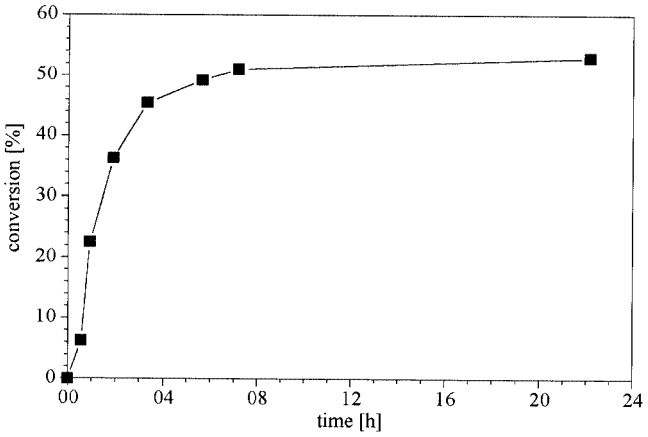

Figure 2. Reaction course of Entry 1-1

$$BF_3 + KPhBF_3 \rightarrow PhBF_2 + KBF_4$$

Reaction 2

This reaction could therefore be responsible for unsatisfactory conversions as the formed $PhBF_2$ is inactive in Suzuki cross-coupling.

The detrimental effect of BF_3 on the reaction course was circumvented by using MeOH as a BF_3 scavenger. In fact, reactions performed in [bmim]BF_4/MeOH mixtures gave quantitative conversions. Figure 3 shows the effect of the molar fraction (x_{MeOH}) of added methanol on the catalysis performed in [bmim]BF_4. Isolated yields of **3a** and reaction times are dependent on the molar fraction of MeOH. At x_{MeOH} = 0.25 the reaction reaches completion in 120 min with a 68% yield of **3a**. The discrepancy between yield and conversion is due to decomposition of the diazonium salt, since only traces of homo-coupling products (biphenyl and 4,4′-dimethylbiphenyl) were formed. At x_{MeOH} = 0.75 a 67% yield of **3a** was achieved along with the formation of biphenyl (25%) and 4,4′-dimethylbiphenyl (6%) by-products. The reaction carried out in pure MeOH was very fast and exothermic but poorly selective, giving only 47% yield of **3a**, 30% of biphenyl and 16% of 4,4′-dimethylbiphenyl. Hence, MeOH has the side effect of accelerating the decomposition of the diazonium salt over long reaction times when used at low molar fractions; at high x_{MeOH} the selectivity of the reaction is strongly reduced, mainly owing to formation of homocoupling by-products. Carrying out the reaction with a x_{MeOH} of 0.50 gave the best result (83% yield of **3a** after 30 min). In this case the formation of

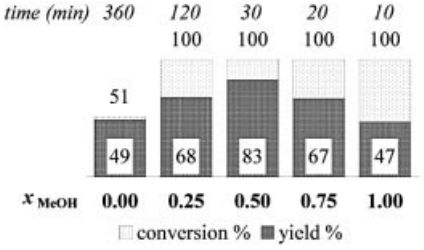

Figure 3. Effect of the MeOH molar fraction

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

homo-coupling products was negligible and the decomposition of diazonium salt minimised.

Palladium Source

Results obtained using several Pd sources in [bmim]BF_4/MeOH (x_{MeOH} = 0.50) as catalysts for reaction 1 are summarized in Table 2. A comparison of Entry 1-2 with Entry 2-2 clearly shows the strong influence exerted by the anion of the Pd^{II} salt on the catalysis: $PdCl_2$ gave only 40% conversion and 15% yield of **3a** after 28 h. The reactions involving Pd^0 complexes gave nearly quantitative conversions. In particular, $Pd_2(dba)_3$ gave a higher yield (90%) than that (63%) obtained with $Pd(PPh_3)_4$, but needed a longer reaction time (Entries 3-2 and 4-2).

Table 2. Screening of palladium source; reaction conditions: degassed solvent mixture IL/MeOH (x_{MeOH} = 0.50): 2.0 mL; Pd: 0.02 mmol; **1a**: 1.0 mmol; **2**: 1.2 mmol

Entry	Catalyst	Time [min]	Conv. (%)	Isolated yield (%)
1-2	$Pd(OAc)_2$	30	100	83
2-2	$PdCl_2$	1680	40	15
3-2	$Pd_2(dba)_3{\cdot}CHCl_3$	330	95	90
4-2	$Pd(PPh_3)_4$	150	100	63

10-2	**9**	10	100	84
11-2	**10**	30	100	93
12-2	**10**[a]	15	100	55
13-2	**10**[b]	120	96	87
14-2	**10**[c]	720	83	67

[a] Pure methanol (4 mL) as solvent. [b] Solvent mixture: 4 mL; Pd: 5.0×10^{-3} mmol; **1a**: 2.0 mmol; **2**: 2.4 mmol. [c] Pd: 1.0×10^{-3} mmol.

Several palladium(II) acetate derivatives (Figure 4) were tested. Mononuclear complexes bearing chelating ligands gave unsatisfactory results: 2,2′-bipyridyl complex **4** gave a 44% yield of **3a** while the 1,2-bis(diphenylphosphanyl)-ethane complex **5** was almost inactive (Entries 5-2 and 6-2). Conversely, dinuclear phosphapalladacycles were found to be active catalysts for reaction 1: complex **6** gave 64% conversion together with 54% yield after 22 h (Entry 7-2), while **7** gave a quantitative conversion and 86% yield in a shorter reaction time (Entry 8-2). The dinuclear azapalladacycles **8**−**10** were found to be the most active catalysts. In all cases quantitative conversions were obtained in 30 min or less, with selectivities towards the desired product **3a** ranging from 65% obtained with the 8-methylquinoline derivative **8** (Entry 9-2) to 93% obtained with the azobenzene derivative **10** (Entry 11-2). A remarkably short reaction time was observed with the iminopalladacycle **9**, which afforded an 84% yield in less than 10 min (Entry 10-2). Complex **10** was also used for comparison in pure methanol, giving only 55% yield after 15 min (Entry 12-2).

$Pd(OAc)_2$ and complexes **6**−**10** were also used in an equimolar mixture of [bmim]BF_4 and H_2O. In all cases quantitative conversions were achieved owing to the ability of water to act as a BF_3 scavenger. $Pd(OAc)_2$ gave 65% yield of **3a** after 2 h whereas the yields obtained with complexes **6** and **7** were 85% and 87%, respectively, after 20 h. Complexes **8**−**10** gave 64%, 60% and 70% isolated yields, respectively, in less than 30 min. Figure 5 shows a comparison of the results obtained with $Pd(OAc)_2$ and complexes **6**−**10** in IL/MeOH with those in IL/H_2O. All the catalysts shown in Figure 5, except phosphapalladacycles **6** and **7**, were more selective when the cosolvent was MeOH.

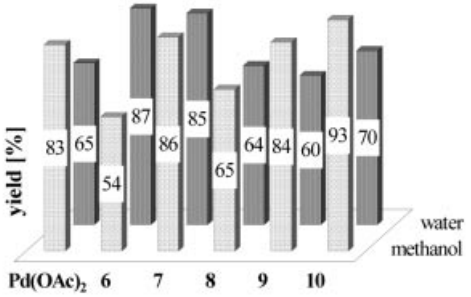

Figure 5. Performance of catalysts **4**−**10** in equimolar [bmim]BF_4/cosolvent mixtures

Palladium Loading and Recycling

The effect of palladium loading was investigated using complex **10** in an equimolar [bmim]BF_4/MeOH mixture. At 0.5% Pd loading (0.25 mol % of the dinuclear complex) the catalyst was still active and selective, reaching nearly quantitative conversion with an 87% yield after 2 h (Entry 13-2); at 0.1% loading the reaction afforded 67% of **3a** with an 83% conversion after 12 h (Entry 14-2).

Optimization tests aimed at recycling the catalytic solution, performed with complex **10** in IL, showed that an excess of the aryldiazonium **1a** was necessary in order to obtain a recyclable catalytic solution. When a 20% excess of phenyltrifluoroborate **2** was employed the second cycle did

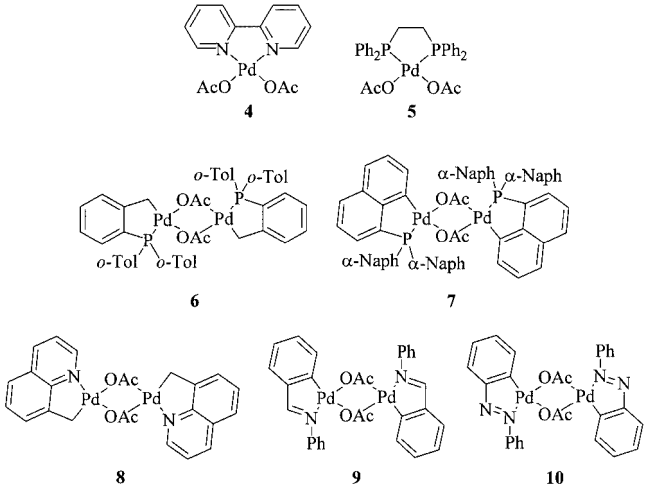

Figure 4. Palladium acetate derived catalysts; Naph = naphthyl

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

not reach completion (60% conv. after 3 d), giving only 37% of **3a**; the catalyst decomposed into Pd black (formation of Pd black during the reaction was observed in almost all the reactions described so far). On the other hand, when a 20% excess of **1a** was used no Pd black formed after the first run and the catalytic solution was recyclable (Figure 6). The excess of **1a** renders the catalytic system less efficient as, with an excess of **2**, a 93% yield was achieved after 30 min (Entry 11-2), whereas with **1a** in excess a 72% yield was achieved after 2 h.

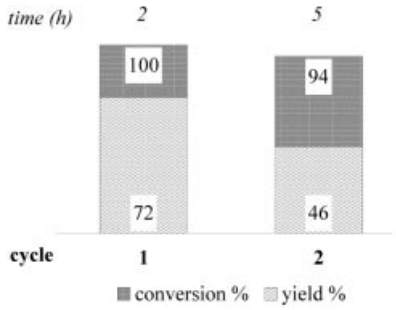

Figure 6. Recyclability of the catalytic solution (initial **1a**/**2** molar ratio = 1.2)

Possible Active Species: Preliminary Investigations

Mechanistic investigations on Suzuki coupling involving aryldiazonium salts have not been performed so far. However, different active species have been suggested for "classical" Suzuki reactions in ILs. Zou et al. have proposed that the catalytic activity observed in alkylammonium tetrafluoroborate/H_2O mixtures is due to palladium metal stabilised by the reaction medium.[14] On the other hand, Srinivasan's group has ruled out colloidal Pd nanoparticles as the active species in the Suzuki reaction performed in imidazolium-based IL/MeOH mixtures.[16] Welton et al.[12] have suggested the intermediacy of mixed (carbene)(phosphane)Pd^{II} complexes formed by reaction of $Pd(PPh_3)_4$ with [bmim]BF_4 in the presence of aryl halide and a halide salt under basic conditions.

Although palladium nanocolloids are known to catalyze the strictly related Heck reaction in ILs,[23] in our case the progressive formation of palladium black observed nearly invariably during catalysis is more probably the consequence of catalyst decomposition, since no Pd black formed in the catalytic solutions that could be successfully recycled. That palladium metal is not involved in the catalytic act is further demonstrated by poisoning experiments with Hg metal.[24] When performing reaction 1 catalyzed by complex **10** in the presence of added Hg (Hg/Pd = 150 mol/mol) no inhibition was observed (Entry 1-3, Table 3). This result suggests that palladium nanocolloids are not involved in the catalytic cycle and that a homogeneous mechanism should be operating.

Table 3. Reaction conditions: degassed solvent mixture LI/MeOH (x_{MeOH} = 0.50): 2.0 mL; Pd: 0.02 mmol; **1a**: 1.0 mmol; **2**: 1.2 mmol

Entry	Catalyst	Time [min]	Isolated yield (%)[a]
1-3[b]	**10**	30	85
2-3	**11**	260	65
3-3	**12**	1600	45
4-3	**13**	480	55
5-3[c]	**10**	40	90

[a] Quantitative conversions. [b] Hg added; Hg/Pd = 150 mol/mol. [c] Reaction performed in [bmmim]BF_4/MeOH.

Among the possible candidates for the active species in the present reaction we focused our attention on (carbene)Pd^{II} species. According to Wasserscheid,[10] three simple experiments should be carried out to verify the intermediacy of carbene complexes as catalytically active species in ILs, namely variation of the ligands, tests with independently prepared, well-defined (carbene)Pd^{II} complexes, and reactions in ILs that are not capable of carbene formation. Replacing the bridging acetates with bridging bromides (Figure 7) in complex **10** resulted in a drop of activity (Entry 11-2 vs 2-3); this might be rationalised by invoking the inability of bromide to generate carbene species by abstraction of the acidic proton in the 2-position of the imidazolium ring. However, reactions performed with the preformed carbene complexes **12** and **13** (Entries 3-3 and 4-3) were much slower than that performed with complex **10** (Entry 11-2). This seems to indicate that, even if they form in the reaction mixture, carbene species are not mainly responsible for the catalytic activity observed with azapalladacycles. Accordingly, replacing [bmim]BF_4 with [bmmim]BF_4, an imidazolium-based IL that is not capable of carbene formation due to the presence of the methyl group in the 2-position, gave essentially equal activity and selectivity (see Entries 11-2 and 5-3).

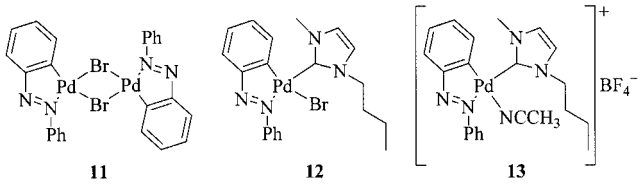

Figure 7. (Azobenzene)Pd^{II} complexes

The above-mentioned detrimental effect of bromides on catalysis could, therefore, be due to the strong coordinating ability of halide species towards palladium. This strong tendency to bind palladium could also be held responsible for the difference in activity between bromo complex **12** and acetonitrile complex **13**, and can also rationalize the sluggishness of the reaction catalyzed by $PdCl_2$ (Entry 2-2).

At this stage, the following points seem to emerge: (i) catalysis is molecular and influenced by the ligands on the palladium atom; (ii) the presence of easily dissociable li-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gands in palladium(II) precatalysts has a beneficial effect on catalysis (compare activities of acetate complex **10** vs. bromide complex **11** or of acetonitrile complex **13** vs. bromide complex **12**). Although no definitive conclusion can be drawn about the active species that triggers the catalysis starting from azapalladacycle **10**, these observations lead us to suggest, on the basis of the commonly accepted Pd^0/Pd^{II} cycle, the anionic Pd^0 complex depicted in Figure 8 as the possible active species. Such a species, which could be generated by reduction of **10** by **2**, might start the catalytic cycle by forming an arylpalladium complex by reaction with the diazonium salt.

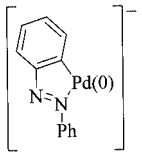

Figure 8. Possible active species in reactions catalysed by complex **10**

Anionic Pd^0 complexes have been suggested as active species in related cross-coupling reactions. Amatore et al.,[25] for example, have demonstrated that $[Pd(PPh_3)_2(OAc)]^-$, formed from $Pd(OAc)_2$ and PPh_3, is an active species for the catalytic cycle of Heck reactions between aryl halides and olefins, and Hermann et al.[26] have proposed the palladacycle [(di-*o*-tolylphosphanyl)benzyl]-palladate(0) as the active species in Heck couplings catalyzed by complex **6**.

Screening of Substrates

The reactivity of several substrates was explored (Table 4). Substituted aryldiazonium salts (Reaction 3) gave fair to good yields: 4-methoxybiphenyl was obtained with a 78% yield after 3 h (Entry 1-4) while aryldiazonium salt **1c**, containing an electron-withdrawing group (Entry 2-4), reacted faster to give the relevant biphenyl in 82% yield. Halogen-substituted substrates **1d** and **1e** were less reactive and required 4% palladium to give quantitative conversions and 79% and 95% yields, respectively (Entries 3-4 and 4-4). Vinyltrifluoroborates were far more reactive than the aromatic ones (Reaction 4): quantitative conversions and yields of up to 83% were obtained after 10 min using as little as 0.1% palladium (turnover frequency $\approx$ 6000 h^{-1}; Entries 5-4 and 6-4).

Table 4. Screening of substrates; reaction conditions: degassed solvent mixture LI/MeOH (x_{MeOH} = 0.50): 2 mL; ArN_2BF_4: 1.0 mmol; $KRBF_3$: 1.2 mmol; quantitative yields were obtained

Reaction 4

Conclusion

This study demonstrates that ILs are suitable solvents for the title reaction. Used neat, ILs give high selectivities for the cross-coupling product. High activity and selectivity were shown by catalytic systems comprised of azapalladacycles in $[bmim]BF_4$/MeOH mixtures. Using a slight excess of diazonium salt with respect to aryltrifluoroborate allowed the recycling of the catalytic solution. Preliminary mechanistic studies carried out with the precatalyst **10** indicate that a homogeneous process takes place and that carbene species are not the main active species. Further studies on this subject are in progress.

Experimental Section

General: Unless otherwise specified all the manipulations were conducted under an inert gas (nitrogen) using standard Schlenk techniques. Flash-chromatography was performed on SiO_2 Kieselgel 230−400 mesh. The NMR spectra were recorded with a Bruker AX400 spectrometer (400 MHz for ^1H) at 295.0 K; chemical shifts are reported in ppm referenced to $SiMe_4$ for ^1H and ^{13}C, and $CFCl_3$ for ^{19}F. LC-MS analyses of complexes **11**, **12** and **13** were performed with an Agilent HPLC system equipped with DAD, autosampler and MS systems (Agilent 1100 LC-MS SL series). All samples were dissolved in the same HPLC-grade solvent that was used as eluent. The used interfaces were APCI for neutral complexes **11** and **12**, and ESI for cationic complex **13**. APCI conditions: positive-ion mode, flow rate 0.5 mL/min, nitrogen as nebulizing and drying gas, nebulizer pressure 4 atm, vaporizer temperature 350 °C, corona current 4.0 μA, drying-gas flow 5 L/min, drying-gas temperature 350 °C, capillary voltage 4000 V. ESI conditions: positive-ion mode, flow rate 0.3 mL/min, nitrogen as nebulizing and drying gas, nebulizer pressure 2 atm, capillary voltage 4000 V. Mass spectrometry data were acquired in the scan mode (mass range m/z = 50−3000). C, H, N elemental analyses were carried out with a Eurovector CHNS-O Elemental Analyser. Pd analyses were performed with a Perkin−Elmer SIMAA6000 Atomic Absorption spectrometer. The IR spectra were recorded with a Bruker Vector 22 FT-IR spectrometer. GC analyses were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

performed with an HP5890 instrument equipped with a Supelco SPB-1 capillary column (30 m × 320 μm × 0.25 μm). GC-MS analyses were performed with an HP6890-HP5973MSD instrument equipped with an HP-5MS capillary column (30 m × 250 μm × 0.25 μm). The halide content of the ionic liquids was determined in aqueous solution by a potentiometric automatic titration using a Metrohm 716 DMS Titrino (300 mg sample, ca. 30 mL deionized water, three runs) while the water content was determined by the Karl−Fischer method using a Metrohm 716 DMS Titrino equipped with a 703 titration stand using sodium tartrate-2-hydrate as standard and dry methanol as solvent (1 g sample, ca. 30 mL MeOH, three runs). All commercial reagents were used as received without further purification. Solvents were dried and distilled under nitrogen according to standard procedures; water (resistivity $> 17.5 \cdot M\Omega\ cm^{-1}$) was deionized with a Millipore Simplicity unit. [bmim]Cl,[27] [bmmim]Cl,[27] [bbim]Br[28] and [bmim]Br[29] were synthesised from 1-chlorobutane or 1-bromobutane and the relevant imidazole salt according to literature procedures. [bmim]Cl, [bmmim]Cl and [bmim]Br were purified by crystallisation from acetonitrile/ethyl acetate (1:4) until a colourless mother liquor was obtained, and then filtered and dried under vacuum; all compounds were obtained as white solids. [bbim]Br was obtained as a viscous brown liquid, washed with CH_2Cl_2/diethyl ether (1:4) and dried under vacuum. All compounds were stored under nitrogen. [bmim]BF_4, [bmim]PF_6, [bmim]$N(SO_2CF_3)_2$, [bmmim]BF_4, [bbim]BF_4 were synthesised by metathesis from the corresponding alkali metal salts in dichloromethane; the resulting suspension was filtered through Celite and washed with the minimal amount of water until the $AgNO_3$ test on the aqueous layer was negative. The solvent was then evaporated and the resulting IL was dried at 40−50 °C under vacuum for 48 h and stored under nitrogen. The ionic liquids were obtained as pale-yellow or colourless liquids and fully characterised by multinuclear NMR spectroscopy. Their water content was less than 460 ppm whereas their halide content was below the detection limit of 0.38 mg/L. Complexes **4**,[30] **5**,[31] **6**,[26] **7**,[32] **8**,[33] **9**[34] and **10**[35] were synthesised according to literature procedures.

Di-μ-bromo-bis[*o*-(phenylazo)phenyl]dipalladium(II) (11): Complex **10** (0.173 g, 0.25 mmol) and tetrabutylammonium bromide (0.167 g, 0.52 mmol) were dissolved in dry dichloromethane (10 mL). After stirring for 3 h, the volume was reduced in vacuo to a half and dry methanol (50 mL) was added. The resulting red solid was filtered off, washed with methanol (3 × 5 mL) and hexane (15 mL) and dried in vacuo to afford **11** as a red powder (0.151 g, 82%); m.p. > 250 °C. IR (KBr): $\tilde{\nu}_{max}$ = 1575 (m), 1553 (w), 1482 (w), 1458 (w), 1444 (w), 1393 (m), 1318 (w), 1306 (w), 1263 (w), 1242 (w), 762 (m), 753 (m), 706 (w), 691 (m), 595 (w), 550 (w), 525 (w) cm^{-1}. ^1H NMR ([D]$_6$DMSO): δ = 7.07 (t, J = 7.31 Hz, 1 H), 7.17 (t, J = 7.31 Hz, 1 H), 7.44 (m, 3 H), 7.65 (m, 2 H), 7.86 (d, J = 7.31 Hz, 1 H), 7.89 (d, J = 7.92 Hz, 1 H) ppm. ^{13}C NMR ([D]$_6$DMSO): δ = 124.36, 126.06, 128.84, 130.24, 131.38, 132.22, 139.12, 150.88, 153.88, 164.13 ppm. LC-MS (CH_3CN/CH_2Cl_2, 9:1): exact mass calcd. for $C_{24}H_{18}Br_2N_4Pd_2$: 731.80; found 732 $[M]^+$, 773 $[M + CH_3CN]^+$. $C_{24}H_{18}Br_2N_4Pd_2$: calcd. C 39.21, H 2.47, N 7.62, Pd 28.95; found C 39.65, H 2.70, N 7.41, Pd 28.79.

Bromo(1-butyl-3-methylimidazolin-2-ylidene)[*o*-(phenylazo)phenyl]-palladium(II) (12): Complex **10** (0.39 g, 0.56 mmol) and [bmim]Br (0.25 g, 1.13 mmol) were dissolved in dry THF (50 mL) in a round-bottomed flask. After refluxing under nitrogen for 3 h and cooling to ambient temperature, the solvent was evaporated in vacuo to give an orange solid. Crystallization from acetone/hexane afforded **12** as a dark-orange, microcrystalline solid (0.470 g, 82%); m.p. 202−205°. IR (KBr): $\tilde{\nu}_{max}$ = 3156 (w), 3124 (m), 3042 (w), 2954 (m), 2929 (m), 2870 (m), 1574 (m), 1551 (m), 1460 (m), 1445 (m), 1388 (m), 1254 (m), 1233 (m), 1204 (w), 1107 (w), 774 (s), 731 (m), 716 (m), 691 (s), 584 (w), 547 (w), 522 (w) cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 0.80 (t, J = 7.31 Hz, 3 H, CH_2CH_3), 1.25 (m, 2 H, $CH_2CH_2CH_3$), 1.77 (m, 2 H, $CH_2CH_2CH_2$), 3.78 (s, 3 H, NCH_3), 4.18 (m, 2 H, NCH_2), 6.12 (d, J = 7.92 Hz, 1 H), 7.00 (m, 3 H), 7.16 (t, J = 7.31 Hz, 1 H), 7.41 (m, 3 H), 7.94 (d, J = 6.7 Hz, 1 H), 7.99 (m, 2 H, NC*H*) ppm. ^{13}C NMR (CD_2Cl_2): δ = 13.40 (CH_3), 19.78 ($CH_2CH_2CH_3$), 32.20 ($CH_2CH_2CH_2$), 38.40 (NCH_2CH_2), 51.12 (NCH_3), 121.44, 122.54, 124.66, 125.14, 127.86, 130.35 (NC*H*), 130.48 (NC*H*), 132.57, 135.45, 151.93, 155.82, 164.54, 169.35 (N*C*N) ppm. LC-MS (CH_3CN/CH_3OH 99:1): exact mass calcd. for $C_{20}H_{23}BrN_4Pd$: 504.00; found 505 $[M + H]^+$, 465 $[M - Br + CH_3CN]^+$, 424 $[M - Br]$. $C_{20}H_{23}BrN_4Pd$: calcd. C 47.50, H 4.58, N 11.08, Pd 21.04; found C 47.78, H 4.75, N 10.86, Pd 20.96.

Acetonitrile(1-butyl-3-methylimidazolin-2-ylidene)[*o*-(phenylazo)-phenyl]palladium(II) Tetrafluoroborate (13): $AgBF_4$ (0.110 g, 0.57 mmol) dissolved in dry acetonitrile (5 mL) was added to a THF (30 mL) solution of complex **12** (0.286 g, 0.57 mmol). After stirring for 45 min, the solvent was evaporated in vacuo. The pale-orange residue was extracted with dry dichloromethane (30 mL) and the resulting suspension filtered through Celite. Crystallization from THF/hexane gave **13** as a pale-orange powder (0.276 g, 88%) m.p. 168° (dec.). IR (nujol mull): $\tilde{\nu}_{max}$ = 3167 (w), 3136 (w), 2318 (w) [ν(C≡N)], 2290 (w) [ν(C≡N)], 1575 (w), 1555 (w), 1463 (s), 1401 (w), 1377 (m), 1257 (w), 1236 (m), 1056 (vs) [ν(B−F)], 773 (m), 713 (m), 696 (m), 588 (w), 548 (w), 523 (w) cm^{-1}. ^1H NMR (CD_2Cl_2): δ = 0.81 (br. t, J = 7.31 Hz, 3 H, CH_2CH_3), 1.25 (br. sext, J = 7.31, 2 H, $CH_2CH_2CH_3$), 1.76 (br. quint, J = 7.31 Hz, 2 H, $CH_2CH_2CH_2$), 2.13 (s, 3 H, $NCCH_3$), 3.83 (s, 3 H, NCH_3), 4.15 (br. t, J = 7.31 Hz, 2 H, NCH_2), 6.03 (d, J = 7.31 Hz, 1 H), 7.00 (t, J = 7.31 Hz, 1 H), 7.14 (s, 1 H, NC*H*), 7.18 (s, 1 H, NC*H*), 7.22 (t, J = 7.31 Hz, 1 H), 7.51 (br. s, 3 H), 7.72 (m, 2 H), 7.97 (d, J = 7.31 Hz, 1 H) ppm. ^{13}C NMR (CD_2Cl_2): δ = 2.78 ($NCCH_3$), 13.35 (CH_2CH_3), 19.62 ($CH_2CH_2CH_3$), 32.64 ($CH_2CH_2CH_2$), 38.45 (NCH_2CH_2), 51.18 (NCH_3), 122.48, 122.75, 123.98, 129.03, 131.51 (NC*H*), 131.62 (NC*H*), 133.25, 136.17, 151.22, 151.56, 164.92, 165.04 ppm. LC-MS (CH_3CN): exact mass calcd. for the cation $C_{22}H_{26}N_5Pd$: 466.12; found 466 $[M]^+$, 425 $[M - CH_3CN]^+$. $C_{22}H_{26}BF_4N_5Pd$: calcd. C 47.72, H 4.73, N 12.65, Pd 19.22; found C 47.61, H 4.85, N 12.74, Pd 19.12.

Substrates: The aryldiazonium tetrafluoroborates **1a**−**1f** were synthesised as reported in the literature[36] and characterised by ^1H and ^{13}C NMR (CD_3CN) and IR (nujol mull) spectroscopy. Potassium aryltrifluoroborate **2** and vinyltrifluoroborate **14** were also synthesised according to a literature procedure.[9]

General Procedure for the Catalytic Reactions: All catalytic runs were repeated at least three times and yields and conversions were reproducible within ±3%. The course of the reactions was monitored by measuring the evolution of N_2 vs. time by means of a mercury gas-burette. Reactions were stopped when no further gas evolution was observed. In neat ILs, the decomposition of diazonium salt was negligible (4−5% per day) as demonstrated by blank tests.

Typical Reaction in Neat IL: Compounds **2** (221 mg, 1.2 mmol) and **1a** (206 mg, 1.0 mmol) were added, with vigorous stirring, to a suspension of $Pd(OAc)_2$ (4.48 mg, 0.02 mmol) in [bmim]BF_4 (2.260 g, 10 mmol) in a 10-mL Schlenk tube. At the end of reaction, the mixture was diluted with water (100 mL) and the products were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

extracted with diethyl ether (3 × 25 mL); the organic phases were collected and dried with Na_2SO_4. The products were purified by flash chromatography and characterised by GC-MS and the selectivity assessed by GC using naphthalene as internal standard.

Reactions in [bmim]BF_4/Cosolvent: 2 mL of the degassed solvent mixture was poured into a 10-mL Schlenk tube containing Pd catalyst (0.02 mmol of Pd), $KRBF_3$ (1.2 mmol) and ArN_2BF_4 (1.0 mmol) and stirred vigorously.

Recycle: Compounds **2** (184 mg, 1.0 mmol) and **1a** (247 mg, 1.2 mmol) were added, with vigorous stirring, to a suspension of **10** (6.93 mg, 0.01 mmol) in [bmim]BF_4 (2.260 g, 10 mmol) and MeOH (405 μL 10 mmol) in a 10-mL Schlenk tube. At the end of reaction, the MeOH was evaporated off in vacuo and the products were extracted with dry *n*-hexane (6 × 3 mL); after evaporation of the solvent, fresh MeOH (405 μL, 10 mmol), **2** (184 mg, 1.0 mmol) and **1a** (206 mg, 1.0 mmol) were added to the resulting catalytic solution.

Acknowledgments

Dr. G. Ciccarella is gratefully acknowledged for performing the LC/MS experiments. We also thank Mr. G. Di Gregorio for experimental assistance and Engelhard for a generous loan of palladium acetate. The Polytechnic of Bari is acknowledged for financial support (F.R.A. ex 60%).

Gold(0) and Gold(III) Reactivity towards the Tetraphenyldithioimidodiphosphinic Acid, $[Ph_2P(S)NHP(S)Ph_2]$

G. Luca Abbati,[a] M. Carla Aragoni,[b] Massimiliano Arca,[b] M. Bonaria Carrea,[b] Francesco A. Devillanova,[b] Alessandra Garau,[b] Francesco Isaia,*[b] Vito Lippolis,[b] Marco Marcelli,[b] Cristian Silvestru,[c] and Gaetano Verani[b]

Keywords: Gold(I) complexes / S ligands / Bridging ligands / Iodine / Density functional calculations

The reaction of gold powder with the iodine adduct of $Ph_2P(S)NHP(S)Ph_2$ (H**L**) in Et_2O gave the complex $[Au(\mathbf{L})I_2]$ under mild reaction conditions. Its crystal structure is comprised of discrete, monomeric molecules with a central Au^{III} ion bonded to two sulfur atoms by an anionic ligand **L** and two iodide anions in a slightly distorted square-planar coordination geometry. From the reaction of $[AuCl_3(tht)]$ with H**L** in CH_2Cl_2 it is possible, besides the main complex $[Au(\mathbf{L})]_2$, to separate the neutral Au^{I} complex $[Au(\mathbf{L}'_2H)]$, **L**′ = $[Ph_2P(S)NP(O)Ph_2]^-$, the crystal structure of which features a Au^{I} ion linearly coordinated to two sulfur atoms and a proton bridging two oxygen atoms of the PO groups. ^{31}P NMR CP MAS spectroscopy is in accordance with the nature of the ligands in the complex. The reaction chemistry of $[Au(\mathbf{L}'_2H)]$ in CH_2Cl_2 towards the acid CF_3COOH and the organic base 1,8-bis(dimethylamino)naphthalene is reported.

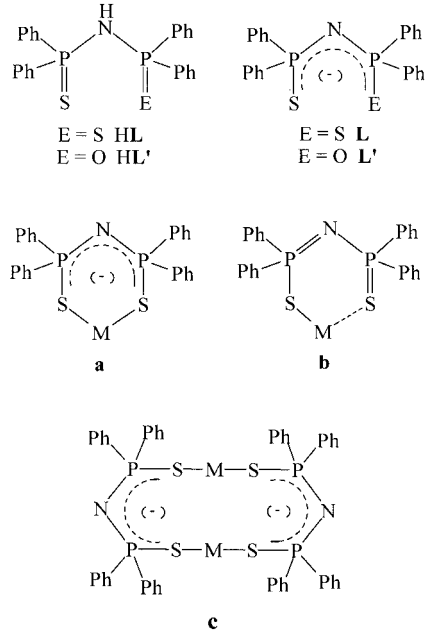
Introduction

The transition metal chemistry of tetraphenyldithioimidodiphosphinic acid, $Ph_2P(S)NHP(S)Ph_2$ (H**L**), has received great attention during the past years[1] and continues to remain an area of interest since the ligand H**L** has found applications as a selective extraction agent for metals,[2] as a lanthanide NMR shift reagent[3] and more recently in catalysis.[4] The reaction of H**L** with metal ions usually leads to deprotonation of the NH group and concomitant formation of the anionic tetraphenyldithioimidodiphosphinate ligand $[Ph_2P(S)NP(S)Ph_2]^-$ (**L**) which features the negative charge delocalised throughout the SPNPS skeleton.[1] A vast body of results show that **L** commonly coordinates to the metal atom through both sulfur atoms, either symmetrically or asymmetrically,[1] resulting in chelate structures (see **a** and **b** in Scheme 1). Alternatively, supramolecular polymeric structures and bridging modes such as **c** (Scheme 1) with formation of homobimetallic compounds are possible.[1]



Scheme 1

The chemistry of H**L** with gold(I) and gold(III) ions has yielded only two X-ray characterised complexes, i.e. $[Au(\mathbf{L})Cl_2]$ (**1**), in which the Au^{III} centre is tetracoordinated in a square-planar fashion[5] and $[(Ph_3P)Au(\mathbf{L})]$ which con-

tains a three-coordinate Au^{I} atom.[6] A few other complexes obtained from the reaction of H**L** with [RAu(tht)], [AuCl(tht)] or $[R_2AuCl]_2$ (R = C_6F_5; tht = tetrahydrothiophene) and containing the ligand in its deprotonated form were only partially characterised.[7,8] As part of an ongoing study on the coordination ability of H**L**,[9–12] we have further explored its reactivity towards the complex $[Au^{III}Cl_3(tht)]$ in CH_2Cl_2 and tested the oxidation in diethyl ether at room temperature of Au^0 metal powder with I_2 in the presence of H**L**. In addition, the structures of the neutral complexes $[Au^{III}(\mathbf{L})I_2]$ (**2**) and $[Au^{I}(\mathbf{L}'_2H)]$ (**3**) {$\mathbf{L}'$ = $[Ph_2P(S)NP(O)Ph_2]^-$}, the latter being obtained as a by-product from the reaction of H**L** with $[AuCl_3(tht)]$, have been determined by single-crystal X-ray diffraction studies.

Results and Discussion

Oxidation of Gold Powder by the Adduct HL·I_2

The oxidation/complexation reaction of metal powders by the iodine adducts of phosphane,[13] thiophosphane[9–12] and polyfunctional thione donors[14–17] has been well documented in recent years. The numerous papers on the subject have shown this synthetic route to be a useful tool in obtaining coordination compounds with unusual geometries, stoichiometries and oxidation numbers at the metal centre. In particular, the I_2 and IBr adducts of *N*,*N*′-dimethyl-perhydro-diazepine-2,3-dithione[15–17] have been applied successfully to noble metals such as gold and platinum for the recovery of these precious metals from waste materials.

The reaction between the adduct H**L**·I_2, generated in situ, and Au metal powder (1:1 molar ratio; H**L** = 2.22×10^{-3} mol·dm^{-3}, 25 °C) in anhydrous Et_2O yielded a dark-red solution from which air-stable dark-red crystals of formula $[Au(\mathbf{L})I_2]$ (**2**) could be separated (yield 20% based upon Au). Concentration of the filtrate solution to dryness yielded a sticky red oil, the FT-Raman spectrum of which showed intense peaks in the low frequency region at 169, 144 and 112 cm^{-1}. The peaks at 112 and 144 cm^{-1} indicate the presence of asymmetric I_3^-, while the peak at 169 cm^{-1} is due to weakly perturbed I_2 molecules.[18] The course of the reaction was also monitored by ^{31}P NMR spectroscopy over a three-week period. As the adduct H**L**·I_2 in Et_2O (δ = 57.4 ppm) reacts with the gold powder, a new species appears which shows a signal at δ = 37.4 ppm. The assignment of this signal to complex **2** is straightforward and supported by a comparison with the spectrum of the neat compound recorded in $CDCl_3$, δ = 36.4 ppm. During the course of the reaction the signal related to H**L**·I_2 decreases in intensity and, since complex **2** has a low solubility in Et_2O, the separation of a dark-red fine powder can be observed during this time. Though the synthesis of complex **2** occurs in low yield (Equation 1), the mixture of H**L** with I_2 can oxidise Au^0 to Au^{III} (Equation 1). The influence of this mixture on the process of oxidation is not yet fully understood, though there is no doubt that the reaction of gold powder with either H**L** or I_2 alone leaves the gold unchanged.

$$\mathbf{HL} + 1.5I_2 + Au \xrightarrow[\text{r.t.}]{Et_2O} Au(\mathbf{L})I_2 + HI + \text{other products} \quad (1)$$

On the basis of cyclic voltammetry (CV) measurements, presented in a previous paper,[10] we have shown that neither iodine ($I_2/2I^-$, E_{pc} = −0.05 V) nor the adduct H**L**·I_2 (H**L**·$I_2/2I^-$, E_{pc} = −0.19 V) have reduction potentials capable of matching those of noble metals such as Pd, Pt, or Au. Presumably, however, the simultaneous presence of H**L** and I_2 lowers the oxidation potentials of the metals allowing their oxidation, dissolution and complexation. Similar conclusions have also been reached by other researchers employing iodine adducts of sulfur-containing ligands on metal(0) powders or thin sheets.[17] Although complex **2** is known in the literature,[5] its crystal structure has not yet been reported. The results of our single-crystal X-ray structural analysis are reported in Figure 1 as an ORTEP plot, while crystal data and selected geometric parameters of the compound are listed in Table 1 and Table 2, respectively.[19–24] Complex **2** shows a molecular structure similar to that of **1** reported by Laguna et al.,[5] despite showing marked differences in unit cell parameters. It consists of a central Au^{III} ion bonded to two sulfur atoms from an anionic ligand **L** and two iodide anions in a slightly distorted square-planar coordination geometry, showing a maximum deviation from the Au(1)S(1)S(2)I(1)I(2) mean plane of 0.0769(4) Å and a dihedral angle between the I(1)Au(1)I(2) and S(1)Au(1)S(2) planes of 4.70(5)°. A comparison of the structures of **1** and **2** shows some differences, mainly due to the arrangement of the bulky iodide ions around the central Au^{III} ion (Table 3). As already observed in **1**, as well as in various other metal-dichalcogenoimidodiphosphinate complexes,[1] the anionic ligand **L** adopts a pseudo-boat conformation where S(1) and P(2) act as "bow" and "stern", with deviations of 1.1839(12) and 0.6131(3) Å, respectively, from the mean Au(1)P(1)N(1)S(2)

plane and dihedral angles between the Au(1)P(1)N(1)S(2) and Au(1)S(1)P(1) [S(2)P(2)N(1)] planes of 57.46(3) [41.33(10)]°. Some extent of π-electron delocalisation can be observed over the whole nonplanar [Au(SP)$_2$N] ring, as indicated by the shorter P−N and longer P−S bond lengths observed in **2** [1.593(3)−1.584(3) and 2.0456(14)−2.0603(13) Å, respectively] with respect to those in the free ligand H**L** [1.672(2)−1.683(2) and 1.937(1)−1.950(1) Å, respectively].[25] The presence of a metal-bonded iodide acting as a terminal ligand is not very common among gold(III) compounds containing a sulfur-bonded metal ion, as observed in **2**. To the best of our knowledge, a similar feature has been observed only in the square-planar cation [Au(**D**)I$_2$]$^+$ (**D** = *N*,*N*′-dimethylperhydrodiazepine-2,3-dithione), obtained by oxidation of gold powder employing a **D**·2I$_2$ adduct[15,17] and in [Au$_2^{I,III}$I$_2$(C$_6$H$_3$-2-PPh$_2$-5-Me)(S$_2$CN*n*Bu$_2$)] which is a mixed-valence complex featuring a square-planar, iodide-bound Au^{III} ion bridged by the C$_6$H$_3$-2-PPh$_2$-5-Me group to a linear [Au^I−I] moiety.[26]

Gold(III) Reactivity towards HL, Crystal Structure of [Au(L′$_2$H)]

The reaction between [Au^{III}Cl$_3$(tht)] and H**L** in CH$_2$Cl$_2$ has been partly studied by Laguna et al.[5] who were able to separate the complexes [Au^{III}(**L**)Cl$_2$] (**1**) and [Au^I(**L**)]$_2$ (**4**) using reagent molar ratios of 1:1 and 1:2, respectively. In order to further investigate the reduction reaction of Au^{III} during the formation of complex **4**, we have reconsidered the reaction between [Au^{III}Cl$_3$(tht)] and H**L** in CH$_2$Cl$_2$ using a 1:2 molar ratio. The red colour of the reaction mixture disappeared after a few hours with concomitant formation of buff-coloured fine powder which proved to be elemental sulfur. The subsequently formed insoluble white powder proved to be the expected gold(I) complex **4**. The ^{31}P NMR spectrum of the filtered solution revealed the presence of further phosphorus-containing species besides very small amounts of **4**. In fact, the solvent was slowly evaporated to firstly give a white powder which, on the basis of elemental analysis and ^{31}P NMR spectroscopy [δ = 57.5 and 21.6 ppm; d, $^2J_{P,P}$ = 16.5 Hz, CH$_2$Cl$_2$], was identified as the unsymmetrical oxygen/sulfur containing ligand Ph$_2$P(S)NHP(O)Ph$_2$, (H**L**′).[27,28] Secondly, white stable crystals of a new compound (**3**) were formed which, on the basis of elemental analysis, were tentatively assigned as the neutral Au^I complex [Au(**L**′)(H**L**′)] containing the ligand H**L**′ (Scheme 1) in both the protonated and deprotonated forms. In the Au^{III} to Au^I redox reaction the ligand H**L** has, therefore, a double role acting firstly as a reducing agent with production of the oxidised species H**L**′ and elemental sulfur and consequently as a complexing agent towards the Au^I ion. However, the solid state ^{31}P CP MAS spectrum of **3** which shows peaks at δ = 33.6 ($\Delta\nu_{1/2}$ = 143 Hz), 25.6

($\Delta\nu_{1/2}$ = 180 Hz) and 18.4 ppm ($\Delta\nu_{1/2}$ = 212 Hz) with a relative intensity ratio of 1:1:2 does not support the presence of **HL′** in its neutral form in the complex since no signal in the 50−60 ppm range was detected (**HL′**, ^{31}P CP MAS: δ = 57.9 and 20.0). Fortunately, we have obtained good quality crystals of **3** for a single-crystal X-ray diffraction study. The molecular structure of **3** is shown in Figure 2, while selected structural parameters are listed in Table 4. The crystal lattice is made up of an Au^{I} complex featuring a quite distorted linear coordination geometry with the sulfur atoms of two ligand molecules [S−Au−S angle 170.24(12)°; average Au−S bond length 2.286(7) Å; nonbonding Au···O distances of 3.212(10) and 4.321(11) Å, for O(1) and O(2), respectively]. Both ligand molecules show a *syn* conformation of the sulfur and oxygen atoms with respect to the PNP fragment, with dihedral angles S(1)P(1)N(1)[O(1)P(2)N(1)]−P(1)N(1)P(2) and S(2)P(3)-N(2)[O(2)P(4)N(2)]−P(3)N(2)P(4) of 9(2) [49.8(12)] and 59.7(11) [55.4(15)]°, respectively, and deviations from the corresponding PNP basal planes in the ranges 0.27(4)−1.52(3) Å for sulfur [S(1) and S(2), respectively] and 1.02(3)−1.12(2) Å for the oxygen atoms [O(1) and O(2), respectively]. This arrangement of ligand moieties gives rise to a nonplanar Au[SO(P$_2$N)]$_2$ ring [deviations from the average atom plane ±1.479(5) Å] which can also be regarded as the connection of two almost planar fragments, namely S(1)Au(1)S(2)P(3) and P(4)O(2)O(1)P(2)N(1) (deviations from the mean plane of ±0.023(2) and ±0.062(7) Å, respectively) by the N(2) and P(1) ′bridging′ atoms. The absence of any counterion in the lattice is the most intriguing feature of the structure since it requires the simultaneous presence, in the molecule, of the ligand both in its neutral (**HL′**) and anionic (**L′**) forms to achieve electroneutrality. In the chemistry of metal tetraorganodichalcogenoimidodiphosphinate complexes, the presence of differentially protonated ligands in the same molecule is quite uncommon and, to the best of our knowledge, only two examples have been reported so far, namely the cationic complex [Pd{*i*Pr$_2$P(S)NHP(S)*i*Pr$_2$}{*i*Pr$_2$P(S)NP-(S)*i*Pr$_2$}]$^+$ [29] and [Au{Ph$_2$P(S)NP(O)Ph$_2$-*S*}{Ph$_2$PNHP-(O)Ph$_2$-*P*}] (**5**)[30] which shows a phosphorus-coordinated Au^{I} ion. Interestingly, in both complexes, the neutral ligands feature an N−H group and effectively retain the hy-

[a] Hydrogen atoms in calculated positions.

drogen atom topology shown by the corresponding free molecules.[27,31] This seems not to be true in the case of **3**. Although the metric parameters of the two ligands are substantially equivalent and do not allow the identification of a protonated molecule, they do indeed reveal a surprisingly short O(1)···O(2) distance of 2.399(15) Å which strongly suggests the presence of an *intramolecular* hydrogen bond between the two oxygen atoms. Though experimental detection of a bridging hydrogen atom is not possible due to the quality of the solid-state structural determination, such a feature would be reasonable. The presence of a strong negative-Charge Assisted Hydrogen Bond[32] would in fact involve a negative charge-sharing between the two oxygen atoms and explain the equivalence, to within 3σ, of the P−O and N−P bond lengths in the ligands as well as the presence of P−O bonds significantly longer [1.496(10)−1.542(11) Å] than the usual P=O distances [1.47−1.50 Å][25,33,34] observed in *both* ligand fragments of the molecule of **3**. The latter bond length, in particular, could not be ascribed to other intramolecular interactions since the oxygen atoms show only weak nonbonding C−H···O interactions at distances of about 2.7 Å. On the basis of these structural data it is therefore possible to explain the solid state ^{31}P NMR spectroscopic data. The values at δ 33.6 and 25.6 reflect the different phosphorus environments of the *P*S groups in the complex, whereas the broad band at δ = 18.4 ppm reflects the similarity of the two *P*O groups.

It is worthy of note that the presence of strong *intramolecular* hydrogen bonds is not unusual in phosphane-derived compounds. Some examples reported in the literature include complex **5**[30] which features a (N−H···O$^-$) bridge, the chloro-bridged platinum(III) dimer $[PtCl(Ph_2PO)_2H]_2$ [35] and $[(Ph_2PO)_2H(Ph_3PO)]^+I_3^-$ in which an *intramolecular* hydrogen bond drives the cation conformation[36a] and the salts $[(Ph_3PO)H(Ph_3PO)]^+[AuCl_4]^-$[36b] and $[(Ph_3PO)H(Ph_3PO)]^+[ICl_4]^-$.[36c]

Further support of the structural data of **3** and of the stabilisation exerted by the *intramolecular* hydrogen bond between O(1)···O(2) comes from DFT calculations. Starting from the structural data of **3**, the geometry of the model complex $[Au(\mathbf{L}'')_2]^-$ was optimised, {[H**L**′′ = $H_2P(S)NHP(O)H_2$; **L**′′ = $H_2P(S)NP(O)H_2]^-$}. Subsequently, a hydrogen atom was positioned on the nitrogen or on the oxygen atom of an **L**′′ unit so as to form the model complexes [Au(H**L**′′)(**L**′′)] and [Au(**L**′′$_2$H)], respectively, and these complexes were then optimised. While the calculated structure of [Au(H**L**′′)(**L**′′)] is markedly different from that of **3**, the one related to [Au(**L**′′$_2$H)] features a P−O···H···O−P bridge with a calculated O−O bond length of 2.401 Å which agrees well with the experimental value of 2.399(15) Å found in **3**. Moreover, the energy of the model complex [Au(**L**′′$_2$H)] was found to be 20 kcal/mol more stable than that of [Au(H**L**′′)(**L**′′)]. An NBO analysis of [Au(**L**′′$_2$H)] showed that the two ligand units **L**′′ feature a similar charge distribution (differing by 0.09 e) and that the bridging hydrogen has a strong positive charge (0.539 e); see also Supplementary Information.

Acid/Base Behaviour of Complex 3

The protonation and deprotonation reactions of complex **3** were investigated by ^{31}P NMR spectroscopy. The solution ^{31}P NMR spectrum of **3** (CH_2Cl_2)[37] features a pair of doublets with the same integrated intensity at δ(*P*S) 32.8 ppm and δ(*P*O) 18.4 ppm (Table 5). The similarity of these values to those reported for the solid-state sample indicates that the structure of **3** is retained in solution with the proton bridging the two oxygen atoms. Treatment of complex **3** dissolved in CH_2Cl_2 with increasing amounts of a very strong base, 1,8-bis(dimethylamino)naphthalene (DMAN), produced the broadening and lowering of peaks related to **3** and the concomitant formation of two new peaks at δ = 29.0 ppm and 12.7 ppm. Notably, these values are similar to those previously observed for the **L**′ moiety in [Au{$Ph_2P(O)NP(S)Ph_2-S$}{$Ph_2P(O)NHPPh_2-P$}] [δ(*P*S) 28.5 ppm, δ(*P*O) 14.0 ppm, $CDCl_3$] in which **L**′ coordinates to the gold ion *via* the sulfur atom only, leaving the PO group pendant. This indicates that DMAN is able to deprotonate complex **3** with formation of the anionic complex $[Au(\mathbf{L}')_2]^-$ in which the metal ion is coordinated only by the sulfur atoms of two **L**′ ligands leaving, in this case also, the PO groups as pendants. This also agrees very well with the fact that the variation of the chemical shifts of (*P*O) is more pronounced with respect to that observed for (*P*S).

Table 5. ^{31}P NMR spectroscopic data for complex **3**, H**L**′ and related reactions

Compound/reaction[a]	δ(*P*S) / ppm	δ(*P*O) / ppm	$^2J(P_SP_O)$ / Hz
3 (solid state)	33.6 25.6	18.4	
3 (CH_2Cl_2)	32.8	18.4	2.5
3 + DMAN[b][c] (CH_2Cl_2)	29.0	12.7	
3 + CF_3COOH[b][d] (CH_2Cl_2)	56.4	26.8	14
H**L**′ (CH_2Cl_2)	57.5	21.6	16.5
H**L**′ + CF_3COOH[b][e] (CH_2Cl_2)	57.4	28.8	15.9

[a] All measurements carried out at 25 °C. [b] In situ reaction. [c] **3**/DMAN 1:2 molar ratio; **3** = 5×10^{-2} mol·dm^{-3}. [d] **3**/CF_3COOH 1:1 molar ratio; **3** = 5×10^{-2} mol·dm^{-3}. [e] H**L**′/CF_3COOH 1:1 molar ratio; H**L**′ = 5×10^{-2} mol·dm^{-3}.

The addition of an equivalent of CF_3COOH to a solution of **3** in CH_2Cl_2 resulted in a considerable change in the ^{31}P NMR spectrum of the complex with both the (*P*S) and (*P*O) resonance signals shifted to higher values of δ = 56.4 ppm and 26.8 ppm, respectively. The value of δ(*P*S) at 56.4 ppm, which is strongly indicative of *N*-protonation of the ligands in the complex, agrees well with the signal observed for the neutral complexes $[Pd(HL)I_2]$[10] [δ(*P*S) 56.5 ppm, $CHCl_3/CH_3CN$, v:v, 1:1] and $[Hg(HL)I_2]$[38] [δ(*P*S) 57.8 ppm, CH_2Cl_2] and for *cis*-[Pd{$Ph_2P(O)NHP(S)Ph_2-O,S$}$_2$][BF_4]$_2$ [δ(*P*S) 57.6 ppm, δ(*P*O) 45.9 ppm, d,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$^2J_{P,P}$ = 7.0 Hz), $CDCl_3$] in which the ligand acts in an *O*,*S*-bidentate manner thus forming a six-membered Pd−O−P−N−P−S ring. It is interesting to note that the (*P*O) signal for the protonated complex **3** is very different from that observed for the palladium complex *cis*-$[Pd\{Ph_2P(O)NHP(S)Ph_2\text{-}O,S\}_2][BF_4]_2$, while it is comparable with that measured for an acidic solution of H**L**′′ [δ(*P*O) 28.8 ppm, CH_2Cl_2] (Table 5). Hence it is reasonable to hypothesise that in acidic media the PO groups in **3** remain uncoordinated to the metal and protonated, and that the variation observed at the δ(*P*O) depends on the *N*-protonation of the ligands.

Conclusion

It has been demonstrated that the adduct H**L**·I_2 in Et_2O can oxidise Au^0 powder to produce the complex $[Au^{III}(\mathbf{L})I_2]$ under mild conditions in a single step. This reaction indicates that the oxidation of Au^0 by charge transfer adducts of iodine can be accomplished using very different donor molecules and, consequently, it may be of some importance in the gold-based technology of semiconductor devices since it avoids the use of unattractive reagents in the etching process. As a result of an interest in the reactions between $[Au^{III}Cl_3(tht)]$ with H**L**, it has been shown that the reducing agent is the ligand HL and the products are the complex $[Au^{I}(\mathbf{L})]_2$, sulfur, the free ligand $Ph_2P(S)NHP(O)Ph_2$ (H**L**′) and a very small amount of its Au^I complex. The nature of this unusual complex has been investigated by X-ray crystallography and ^{31}P CP MAS spectroscopy. Interestingly, this complex shows a structure similar to that depicted in Scheme 1 (see **c**), with an Au^I ion bridging two sulfur atoms of two anionic ligands **L**′ and a proton bridging two oxygen atoms of the PO groups. The nature of this complex is also supported by DFT calculations. The protonation and deprotonation reactions of $[Au(\mathbf{L}'_2H)]$ leave the coordination environment of the Au^I centre unaffected. ^{31}P NMR spectroscopic data suggest that in the case of protonation, both ligands are protonated at the nitrogen atoms.

Experimental Section

Materials and Instrumentation: Reagents were used as purchased from Aldrich. Diethyl ether was distilled form $LiAlH_4$ shortly before use.

$^{31}P\{^1H\}$ NMR spectra were recorded on a Varian Unity 400 MHz spectrometer. Chemical shift values were referenced to an external standard of 85% H_3PO_4 (δ_{31P} = 0.0) inserted in a sealed co-axial tube. All solution NMR experiments were carried out in NMR tubes with PTFE valves (Aldrich). ^{31}P NMR CP MAS spectra were calibrated indirectly through the 85% H_3PO_4 peak (δ_{31P} = 0.0). IR spectra were measured as KBr (4000−400 cm^{-1}) and polyethylene pellets (400−50 cm^{-1}) on a Bruker Equinox 55 FT-IR spectrometer. FT-Raman spectra were recorded on a Bruker FRS 100/S Fourier transform Raman spectrometer operating with a diode-pumped Nd:YAG exciting laser emitting at 1064 nm.

Syntheses: Compounds $[Ph_2P(S)NHP(S)Ph_2]$ (H**L**) and $Cs[Ph_2P(S)NP(S)Ph_2]$ (Cs**L**) were prepared according to ref.[39] and ref.[11], respectively. Complexes [AuCl(tht)] and $[AuCl_3(tht)]$ were prepared according to ref.[7]; complex $[Au(\mathbf{L})Cl_2]$ was prepared according to ref.[5]

[Au(L)I_2] (2): A mixture of H**L** (0.100 g, 0.222 mmol) and I_2 (0.084 g, 0.333 mmol) in diethyl ether (200 mL) was stirred at 25 °C under N_2 until the reagents were completely dissolved. Gold metal powder (100 mesh) (0.044 g, 0.222 mmol) was added with stirring. Stirring was continued at room temperature for ca. 3 weeks. The resultant red-black solid and crystals were collected by suction filtration, washed with a mixture of CH_2Cl_2 and *n*-hexane (1:5, v:v) and dried in vacuo. Yield 0.040 g, 20%. m.p. 230−232 °C. Elemental analysis for $C_{24}H_{20}AuI_2NP_2S_2$ (899.24): calcd. C 32.06, H 2.24, N 1.56, S 7.13; found C 32.5, H 2.4, N 1.8, S 7.6. ^{31}P NMR ($CDCl_3$): δ = 36.4 ppm. IR (KBr): $\tilde{\nu}$ = 3051 w, 1476 w, 1436 s, 1308 w, 1187 s, 1172 vs, 1108 vs, 1026 w, 997 w, 923 w, 827 m, 746 s, 721 s, 700 vs, 690 vs, 567 vs, 554 vs, 523 m, 511 s, 491 m cm^{-1}.

[Au(L′$_2$H)] (3): $Ph_2P(S)NHP(S)Ph_2$ (0.233 g, 0.520 mmol) was added to a solution of $AuCl_3(tht)$ (0.100 g, 0.260 mmol) in dichloromethane (50 mL) and the mixture was stirred for 2 h at room temperature. The cloudy mixture was then filtered to separate a fine buff-coloured powder (sulfur) and, after 48 hours, filtration was again carried out to separate complex **4**. The filtrate was reduced by two-thirds to give the white compound $Ph_2P(S)NHP(O)Ph_2$. Further evaporation of the solvent to almost dryness yielded white crystals of **3**, yield 5%, m.p. 208−210 °C. Elemental analysis for $C_{48}H_{41}AuN_2O_2P_4S_2$ (1062.79): calcd. C 54.24, H 3.89, N 2.64, S 6.03; found C 54.6, H 4.0, N 2.8, S 6.5. ^{31}P NMR (CH_2Cl_2): δ(*P*S) 32.8, δ(*P*O) 18.4 ppm, $^2J_{PSPO}$ = 2.5 Hz. IR (KBr): $\tilde{\nu}$ = 3055 m, 1591 w, 1481 m, 1436 s, 1253 br, 1179 m 1124 s, 1110 s, 1067 m, 1027 m, 1000 m, 889 br, 746 ms, 722 s, 691 vs, 618 w, 579 s, 565 s, 546 s, 509 s cm^{-1}.

X-ray Crystallography: X-ray quality crystals of **2** and **3** were obtained directly as described above. The structures were solved by direct methods (SIR-97[20] and SHELXS-97[21] for **2** and **3**, respectively) and refined using the SHELXL-97 program[21] implemented in the WINGX suite.[22] Details of the crystal data and structural refinements are reported in Table 1. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were treated as idealised contributors in calculated positions and refined isotropically. Selected interatomic distances and angles can be found in Table 2 and Table 4. CCDC-233084 (for **2**) and -233085 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Complex 2: Diffraction data were collected at room temperature on an Bruker SMART-CCD system automatic diffractometer equipped with a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) in the range $3.6 < 2\theta < 66.6°$. Refinement of 290 parameters on 9953 independent reflections gave *R1* [*wR2*] = 0.0327 [0.0819] on $I > 2\sigma(I)$ [all data]. The maximum and minimum residual electron densities on the final ΔF map were 0.95 and −1.06 e·Å^{-3}.

Complex 3: A 0.58 × 0.22 × 0.10 mm crystal was mounted at room temperature on a Siemens P4-RA automatic diffractometer equipped with graphite-monochromated Mo-K_α radiation (a = 0.71073 Å). A total of 10515 reflections (8424 unique) were col-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lected in the range $3.8 < 2\theta < 50.1°$. Intensities were corrected for Lorentz-polarisation effects and an empirical absorption correction was applied (ψ-scan).[23] Refinement of 532 parameters gave *R1* [*wR2*] = 0.0820 [0.2506] on $I > 2\sigma(I)$ [all data]. The maximum and minimum residual electron densities on the final ΔF map were 1.59 and −0.83 e·Å^{-3}.

Computations: Density Functional Calculations (DFT) were carried out on the model complexes [Au(**L**′′)$_2$]$^-$, [Au(H**L**′′)(**L**′′)] and [Au(**L**′′$_2$H)] using the Gaussian 98 suite of programs (Rev. A11)[40] with the hybrid Becke3LYP functional[41−43] and the LanL2DZ basis set for C, H, N, O, P, S and Au. The NBO charge distribution[44] was calculated for all the examined compounds. The results were examined with the Molden 3.9 program.[45]

Synthesis and Metal-Complexation Properties of a New Hydroxypyrimidinone-Functionalized Sepharose

M. Alexandra Esteves,*[a] Anabela Cachudo,[a] Sílvia Chaves,[b] and M. Amélia Santos[b]

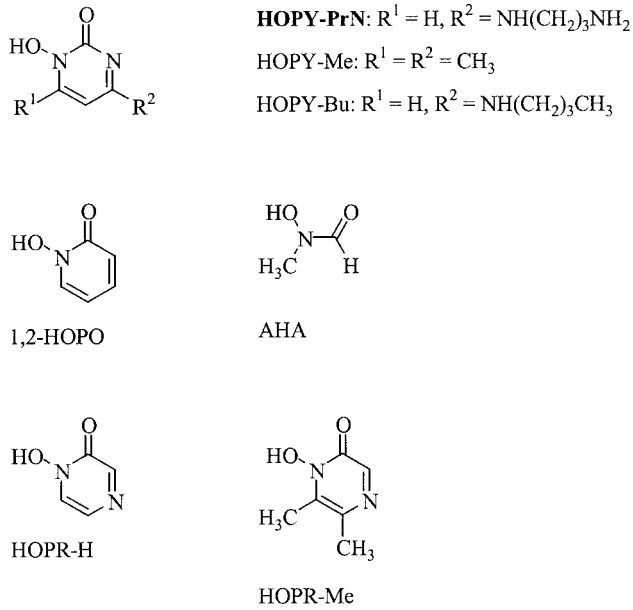
Keywords: Actinides / Chelates / Environmental chemistry / O ligands / Functionalized sepharose

The 1-hydroxy-2-(1*H*)-pyrimidinone derivative 4-(3-aminopropylamino)-1-hydroxy-2-(1*H*)-pyrimidinone (HOPY-PrN) was synthesized and its acid-base and complexation properties towards a set of metal ions (Fe^{III}, Al^{III}, and Th^{IV}) were studied by potentiometry and spectrophotometry. The ligand was further immobilized in an epoxy-activated sepharose by chemical coupling through the aminoalkyl pendent group with the aim of improving its sequestering capacity for residual amounts of metals. The new hydroxypyrimidinone-functionalized sepharose shows a high chelating capacity for metal ions in the pH range 3–8, thus suggesting good perspectives for potential environmental applications.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The need to manage, safely store, and limit the potential environmental or injurious effects of toxic metal ions, such as the actinides (e.g.: plutonium) produced from nuclear reactors, is becoming increasingly urgent.[1] Accordingly, the requirement for effective metal-sequestering agents, namely solid supports functionalized with specific chelators, has increased.[2,3] Those materials can find practical applications as extraction agents for the removal of residual amounts of actinides and other hazardous metal ions from waste waters. Immobilized chelators have also been used in biological and pharmacological applications, such as the removal of metal contaminants from biological systems, and as supports for affinity chromatography.[4]

For all these purposes the functionalized solid matrix should have an adequate hydrophilicity and stability, in order to guarantee a good interaction with water, and a low bleeding potential to prevent the introduction of further contaminants into the environment. On the other hand, immobilized metal-chelators should also have important properties such as a high affinity for a specific metal ion (or group of metal ions) and adequate spacer groups to avoid steric hindrance. A variety of supports are known for chelator immobilization, such as silicas, organic polymers, agaroses, and celluloses.[5] The search for specific chelators for hard metal ions has been quite active, and has been especially aimed at finding substitutes for Desferrioxamine B (a hydroxamate-based medicinal chelating drug with limitations due to oral inactivity)[6] and also substitutes of hydroxamate-immobilized matrices for potential environmental applications without their inherent problems of instability and re-usability.[7] *N*-Hydroxyamide-containing heterocycles, such as 1-hydroxy-2-pyridinones (1,2-HOPO),[8] hydroxypyrimidinones (HOPY),[9,10] and hydroxypyrazones (HOPR)[11] (see Scheme 1), have been



Scheme 1. Structural formulae for 4-(3-aminopropylamino)-1-hydroxy-2-(1*H*)-pyrimidinone (HOPY-PrN), 1-hydroxy-4,6-dimethyl-2(1*H*)-pyrimidinone (HOPY-Me), 1-hydroxy-4-(*N*-butylamino)-2(1*H*)-pyrimidinone (HOPY-Bu), 1-hydroxy-2(1*H*)-pyridinone (1,2-HOPO), acetohydroxamic acid (AHA), 1-hydroxy-2(1*H*)-pyrazinone (HOPR-H), and 1-hydroxy-5,6-dimethyl-2(1*H*)-pyrazinone (HOPR-Me)

considered of great interest owing to their effectiveness in the selective sequestration of hard metal ions, particularly Fe^{III}, those of group IIIA, and some actinides (e.g. Pu^{IV} and Th^{IV}).[1] These *N*-hydroxyamide-containing mono- and diazines can be regarded as hydroxamic acids (HAs), but with endocyclic structures, which makes them much more stable in aqueous medium than linear or exocyclic HAs. On the other hand, their π-electron-deficient ring system allows a considerable amount of electron delocalization, which contributes to the high stability of the metal complexes.

Although some 1-hydroxy-2-pyridinone derivatives have already been studied in terms of chelating properties and immobilization onto polystyrene supports for the removal of hard metal-ions (e.g. Pu^{IV}) from water streams,[2,12,13] only a few published data are available on the coordination chemistry of hydroxypirimidinone derivatives.[11,14] Also, to the best of our knowledge, there are no reports of the immobilization of this kind of ligand on solid supports. Hydroxypyrimidinones have an extra nitrogen atom in the heterocyclic ring, which makes them less toxic and more promising compounds for environmental and biomedical applications[9,15−17] by increasing their acidity and water solubility.

As part of an ongoing project on hydroxypyrimidinone-based chelating resins, we present herein the synthesis and study of a water-soluble hydroxypyrimidinone and its sepharose-supported derivative. Thus, 4-(3-aminopropylamino)-1-hydroxy-2-(1*H*)-pyrimidinone (HOPY-PrN) was synthesized and studied in terms of its acid-base and chelating properties towards Fe^{III}, Al^{III}, and Th^{IV}, in aqueous solution, by potentiometric and spectrophotometric techniques. This ligand was further immobilized in an epoxy-activated sepharose and then the new functionalized support was studied with regards to its ligand density, stability, and capacity for the removal of some hard metal ions from aqueous medium. In these studies, Th^{IV} was chosen as a model of Pu^{IV}. In fact, isotopes of thorium are formed as daughter products of the most important isotopes of uranium, and although thorium is also a potential contaminant in the reprocessing of nuclear fuels, it has a very low specific radioactivity and so it is a quite safe actinide ion for model studies.

Results and Discussion

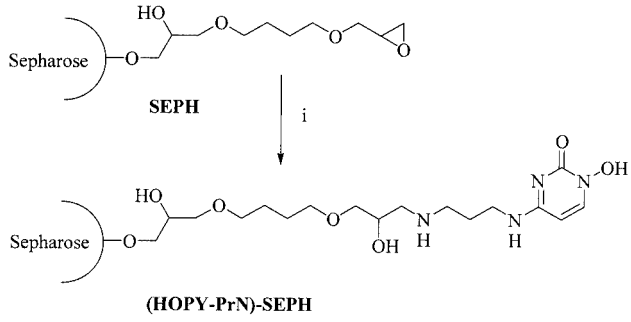
Synthesis of HOPY-PrN

The general procedure for the synthesis of HOPY-PrN is outlined in Scheme 2.

1-(Benzyloxy)uracil (**1**), which was synthesized by a previously reported procedure,[11] was condensed with 1,2,4-triazole in the presence of 4-chlorophenyldichlorophosphate in dry pyridine[18] to give 1-(benzyloxy)-4-(1′,2′,4′-triazol-1′-yl)-2(1*H*)-pyrimidinone (**2**) in 50% yield. To enable the posterior coupling of the ligand to the solid support, an *N*-protected alkylamine segment was introduced as a heterocyclic substituent group by reacting **2** with 3-[(benzyloxycarbonyl)amino]propylamine[19] in refluxing THF to give 4-{3-[(benzyloxycarbonyl)amino]propylamino}-1-(benzyloxy)-2(1*H*)-pyrimidinone (**3**) in 80% yield. Finally, HOPY-PrN was obtained by removing the protecting benzyl groups from both benzyloxycarbonyl/amino and hydroxyl groups of **3** by standard catalytic hydrogenolysis in methanol.[11]

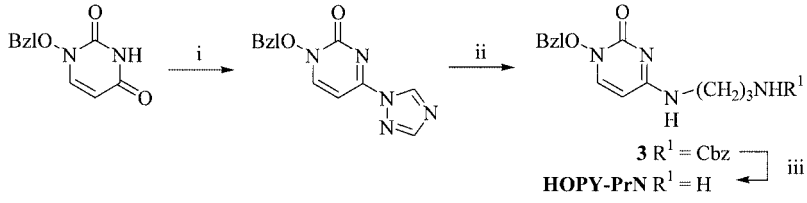
Immobilization of HOPY-PrN

The coupling reaction of the ligand to the commercially available 6B epoxy-sepharose (SEPH, Scheme 3) was carried out under slightly basic conditions according to a published procedure.[20] Care was taken in the selection of the pH for the coupling reaction because it should be just high enough to ensure the deprotonation of the amino group but not so high to promote coupling of the hydroxyl group or even the degradation of the ligand. Therefore, the epoxy sepharose gel was added to a solution of HOPY-PrN in a buffer solution at pH 9 and the mixture was shaken in a water bath at 40 °C for 48 h.



Scheme 3. Immobilization of HOPY-PrN in epoxy-activated 6B sepharose (SEPH): (i) universal buffer, pH 9, $T = 40$ °C (48 h)

A series of preliminary coupling reactions were performed to find the dependence of the ligand concentration on the extent of the HOPY-PrN immobilization. As is shown in Figure 1, a 60-fold ligand excess, relative to the expected amount of active sites in the epoxy-sepharose (ca. 103 μmol active sites per gram dry gel with additives),[20]



Scheme 2. Synthesis of HOPY-PrN: (i) 1,2,4-triazole, 4-chlorophenyldichlorophosphate, pyridine; (ii) $NH_2(CH_2)_3NHCbz$, THF, Δ; (iii) 10% Pd/C, H_2, MeOH

gave the highest (HOPY-PrN)-SEPH density [263 μmol ligand per gram (dry weight)], which corresponds to 54% conversion of the active sites. The ligand density in the functionalized sepharose was easily calculated from the nitrogen amount determined by elemental analysis, since the ligand is the only source of this element in the matrix.

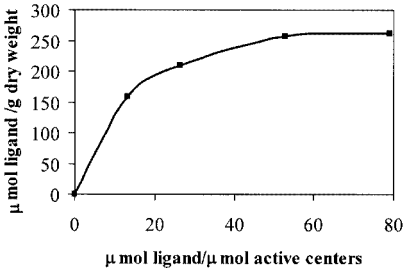

Figure 1. Plot of ligand density in (HOPY-PrN)-SEPH vs. ligand concentration in the coupling reaction

Stability of the Functionalized Support (HOPY-PrN)-SEPH

The stability of the functionalized support in aqueous solution was tested under different pH conditions (pH 3, 7, and 9) at room temperature. The support was added to buffered aqueous solutions at the selected pH and the suspensions were left shaking at room temperature for 24 h. To calculate the amount of ligand released into solution the suspensions were periodically centrifuged during the experiment and the absorbance of the supernatants was measured at the maximum absorption wavelength (λ_{max} = 318 nm) for HOPY-PrN. Plots of percentage of ligand released vs. time (Figure 2) showed that, after 24 h, less than 0.5% of the ligand had been released from the solid matrix for all the experimental pH values, thus indicating that the functionalized sepharose is quite stable.

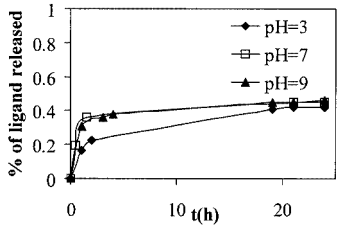

Figure 2. Plot of the percentage of ligand released from the functionalized sepharose vs. time in aqueous solution at pH 3, 7, and 9

Equilibrium Solution Studies

Acid-Base Properties

The ligand was obtained as a neutral species even though, in the fully protonated form, it has three dissociable protons. The corresponding protonation constants were determined from the fitting analysis of the potentiometric titration curve, and its protonation sequence was deduced from the ^{1}H NMR titration curves (Figure 3). The protonation sequence of the ligand is in agreement with the chemical evidence, namely the downfield shifts of the labile protons, which follow the order terminal *N*-amine group (at pD ≈ 10.1−12.5 peaks *c*, *d*, *e*), hydroxy group (at pD ≈ 6−8.8 peaks *a* and *b*), and 4-imine group (at pD ≈ 1.5−4.1 all the peaks, but mostly on *a* and *b*, probably due to the enamine-imine equilibrium). This ^{1}H NMR titration was checked for reversibility and the ligand proved to be stable under both acidic and basic pH conditions.

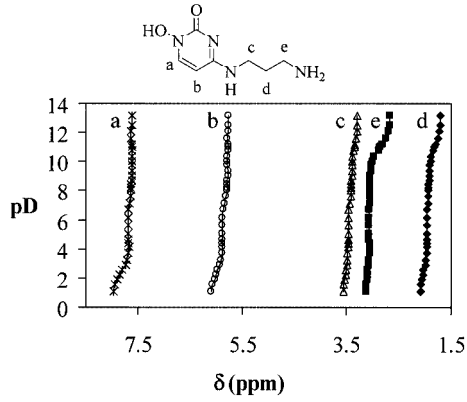

Figure 3. ^{1}H NMR titration curves for HOPY-PrN

The calculated protonation constants (log K_i,) for the ligand are reported in Table 1, which also includes the corresponding values for some analogous compounds, namely 1-hydroxy-4,6-dimethyl-2(1*H*)-pyrimidinone (HOPY-Me),[14] 1-hydroxy-2(1*H*)-pyridinone (1,2-HOPO),[8,21] 1-hydroxy-2(1*H*)-pyrazinone (HOPR-H),[9] 1-hydroxy-5,6-dimethyl-2(1*H*)-pyrazinone (HOPR-Me),[9] and acetohydroxamic acid (AHA).[22]

Table 1. Stepwise protonation constants (log K_i) of HOPY-PrN and other ligands, for comparison, as well as global formation constants (log $\beta_{M_mH_hL_l}$) of the corresponding Fe^{3+}, Al^{3+}, and Th^{4+} complexes (I = 0.1 M KNO_3, T = 25.0 ± 0.1 °C)

The terminal *N*-amine group of HOPY-PrN is slightly more acidic (log K = 10.11) than that of propylamine (10.57)[23] or 1,3-diaminopropane (10.49)[24] due to the electron-withdrawing effect of the pyrimidinone ring. The log K_2 value (6.84), which corresponds to the protonation of the hydroxy group, is lower than that of an aliphatic hydroxamic acid, such as acetohydroxamic acid (log K = 9.36),[22] due to the stabilization of the negative charge of the conjugated base by the electron-withdrawing and resonance effects of the aromatic ring. It is also lower than that of HOPY-Bu (7.5)[11] due to the electron-donating effect of the butyl group. However, log K_2 is higher than the reported values for the corresponding hydroxy groups of HOPY-Me (6.1), 1,2-HOPO (5.78,[8] 5.86[21]), HOPR-Me (4.7), and HOPR-H (4.4) due to the interplay of different effects such as the inductive/electron-donating effect of the substituting groups at the C-4 position, the electron-withdrawing effect of the additional ring-nitrogen atom and its different positioning relative to N-OH group (e.g. *meta*- or *para*-positioned for HOPY and HOPR derivatives, respectively, with a concomitant difference in the resonance stabilization). From the ^{1}H NMR titration curves there is also evidence of a third labile proton (log K_3 = 2.21), which was determined after addition of excess of mineral acid. It is attributed to the 4-amino group, and its high acidity should be due to the enamine/imine equilibrium and the electron-withdrawing resonance effect of the aromatic ring.

Complexation Studies

The stability constants of the M^{3+} (M = Fe, Al) and Th^{4+} complexes with HOPY-PrN were determined by potentiometric and spectrophotometric techniques; they are collected in Table 1, together with reported values for some structural analogs (HOPY-Me, 1,2-HOPO, HOPR-H, HOPR-Me, AHA), all of which form five-membered chelate rings through the adjacent *N*-hydroxy- and keto-oxygen atoms. For all M/(HOPY-PrN) systems studied herein, the potentiometric titration curves show that the complex formation is already underway at the beginning of the titration. They also indicate the existence of a break at a = 0 (a = mol of base per mol of ligand), which suggests the non-involvement of the appended amine groups in the metal coordination, and also the apparent formation of mixed hydroxo-ligand complexes before the complete deprotonation of the fully coordinated complex species. At the beginning of the titration of the Fe^{3+}/HOPY-PrN or Th^{4+}/HOPY-PrN systems the extent of complexation was too high to allow the use of a direct potentiometric method. Therefore, spectrophotometric titrations at 1:1 metal-to-ligand molar ratios were performed in order to determine the formation constants of the corresponding MHL (L being the fully deprotonated form of a ligand) species. On the other hand, since precipitation started at around pH 4 during the potentiometric titration of the Fe^{3+}/ligand system with a 1:3 metal-to-ligand molar ratio, the formation constants of the bis- and tris-chelated species were obtained from the fitting analysis of the spectrophotometric titration data for a 10-fold ligand excess, but keeping the previously determined log β_{FeHL} value constant. Figure 4 shows the pH dependence of the spectrum during this titration. There is a blue shift of the absorption band with increasing pH, thus indicating a concomitant increase of the coordination number. Along the range of pH 2.5−5, there is one isosbestic point at around $\lambda \approx 510$ nm, which is associated with the interconversion from bis- to tris-chelated complexes. Over the range of pH 5.3−7.7 there is no apparent change in the λ_{max} value, thus indicating the presence of the same chromophoric species. The observed spectral parameters (λ_{max} = 465 nm, ε = 5624 $M^{-1}\cdot cm^{-1}$) are comparable to the reported values for the charge-transfer (CT) bands of ferric tris-chelated complexes with hydroxypyrimidinone analogs (HOPY, HOPR),[9,11] which indicates the existence of a tris-chelated species, although with different protonation extents. Above a pH of about 8 the formation of Fe^{3+} ligand-hydroxide mixed complex species and their precipitation is indicated by the intensity decay and hypsochromic shift of the absorption bands.

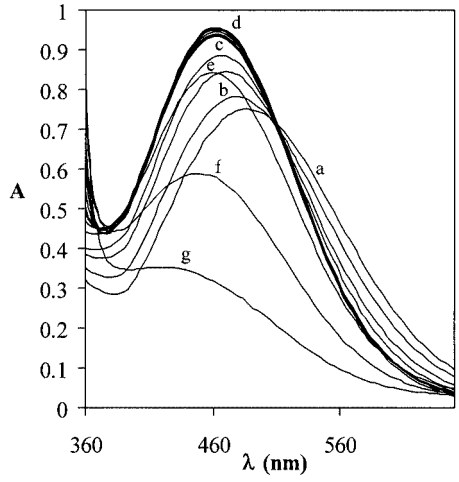

Figure 4. Spectrophotometric absorbance curves at various pH values (a = 2.53, b = 2.78, c = 3.42, d = 5.31−7.72, e = 8.56, f = 9.04, g = 9.31) for the Fe^{3+}/HOPY-PrN system (C_L/C_{Fe} = 10, $C_L = 1.7 \times 10^{-3}$ M)

For the Th^{4+}/HOPY-PrN system the stability constants of the complexes with 1:2, 1:3, and 1:4 metal-to-ligand stoichiometries were evaluated from the potentiometric titration curves for 1:4 and 1:8 metal-to-ligand molar ratios while holding constant the β_{ThHL} value previously determined by spectrophotometry.

The stability constants for the Al^{3+}/HOPY-PrN system were determined by a fitting analysis of the potentiometric data obtained for the 1:1, 1:3, and 1:6 stoichiometries.

A rough comparison between the stability constants of the ligand-metal complexes and the corresponding values for the analogous systems (see Table 1) can be made, assuming that the terminal amine group in the ligand is not

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

involved in the coordination and so $\log \beta_{MHL} = \log \beta_{ML} + \log K_1$. Analysis of Table 1 indicates that the stability constants for the ligand-metal complexes follow the order Fe > Th > Al, in accordance with the corresponding log K_{MOH} values reported for the same metal ions (11.8, 10.8, and 9.0 respectively).[25] This feature reflects the ionic nature of this type of complex, with no preponderance of the crystal-field stabilization effect. The speciation at different pH values for the ligand (HOPY-PrN) and the corresponding ligand/metal-ion systems are illustrated in Figure 5. For all the metal/ligand systems studied herein, Figure 5 clearly evidences the strong chelating capacity of HOPY-PrN, with the complexation starting in quite acidic conditions (even at pH ≈ 2, for M = Fe^{3+} and Th^{4+}). The speciation curves for the iron and thorium systems confirm that, at pH 2, MHL is already formed, thus rendering impossible the determination of log β_{MHL} by potentiometry, as stated above.

Analysis of the speciation curves further shows the existence of a stepwise formation of $M(HL)_i$ species whose metal-ligand binding mode can be derived from chemical evidence, namely a protonated ligand molecule with the hydroxypyrimidinone moiety coordinated to the metal ion but the terminal amino groups protonated. For the thorium system there is a minor species present above pH 5 which can be ascribed either to a partially amino-deprotonated tris-chelated species or to a hydroxo-ligand mixed complex such as $[Th(HL)_3(OH)]$. However, those species are indistinguishable by potentiometry and they are just assigned as ThH_2L_3.

Since comparison between the metal-binding affinity of different ligands must take into account their distinct proton concentration dependency, pM values (pM = −log [M] for $C_L/C_M = 10$ and $C_L = 10^{-5}$ M) have been calculated at different pH conditions for HOPY-PrN and its analogs. Plots of pM (M = Fe, Al) versus pH have been calculated and are shown in Figure 6 and 7. It must be mentioned that these pM values were calculated based on the complex stability and ligand-protonation constants calculated herein or reported in the literature (Table 1), as well as the corresponding hydrolytic species used above for the equilibrium models, but neglecting effects of different ionic strengths and temperatures (as in the case of AHA) on the complexation models and assuming that no precipitation takes place.

Analysis of Figure 6 shows that all these *N*-hydroxamide compounds present a steady variation of pFe with pH. Furthermore, among these compounds (excluding 1,2-HOPO which clearly presents the highest pFe value), HOPY-PrN seems to be the most promising chelating agent in the pH range 2−3.9 and above 5. For pH values between 3.9 and 5 HOPR-Me has slightly higher pFe values, probably due to the electron-donation effect of the ring methyl groups. Therefore the inclusion of methyl groups as substituents in the HOPY-PrN ring should also be expected to improve the chelating capacity of the ligand; this will be a challenge for future work.

Figure 7 indicates that although 1,2-HOPO presents higher pAl values than HOPY-PrN in the acid region, under neutral and basic pH conditions both these ligands and AHA possess the same aluminum-complexation strength.

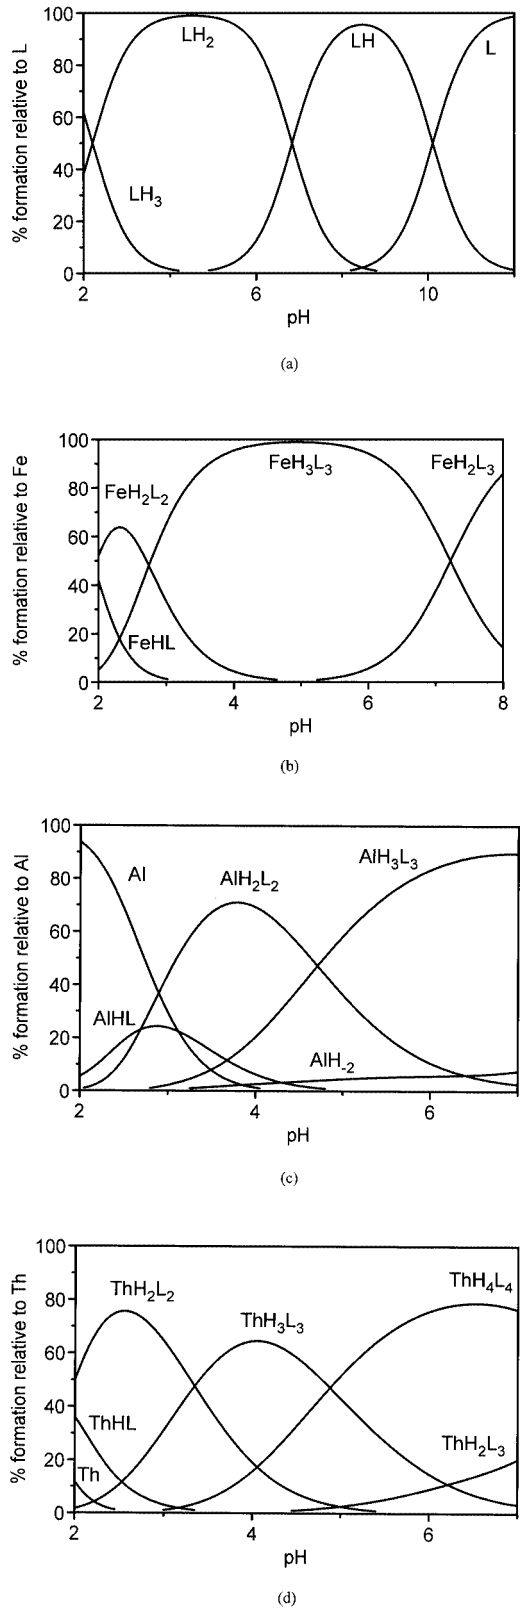

Figure 5. Species-distribution diagrams for HOPY-PrN (a) and M/HOPY-PrN systems with M = Fe^{3+} ($C_L/C_{Fe} = 10$; b); M = Al^{3+} ($C_L/C_{Al} = 3$; c); M = Th^{4+} ($C_L/C_{Th} = 4$; d); $C_L = 2 \times 10^{-3}$ M

Chelating Capacity of (HOPY-PrN)-SEPH

To evaluate the chelating capabilities of (HOPY-PrN)-SEPH towards Fe^{III}, Al^{III}, and Th^{IV}, batch experiments were used. Typically, for Fe^{III}, the functionalized support was added to a universal buffer solution at pH 7 containing Fe^{III}-citrate in fourfold excess relative to the amount of ligand immobilized in the solid matrix, and the mixture was shaken at room temperature for 4 h. During the experiment it could be observed that the solid support gained the characteristic red color of the iron complex almost immediately upon addition of the iron solution. After filtration and careful washing of the functionalized support to remove the excess of metal ions, the Fe^{III} retained on (HOPY-PrN)-SEPH was released by treatment with an acidic solution. The Fe-chelating capacity of the support was calculated from the iron content of the collected filtrates, which was determined by atomic absorption spectrophotometry (AAS). The obtained values (Table 2) indicate that the metal complexes possess an approximate 1:1 ligand-Fe^{III} stoichiometry. Comparison of the ligand density in the modified sepharose with the corresponding chelating capacity indicates that, at neutral pH, (HOPY-PrN)-SEPH is 100% efficient in iron removal, but at pH 3 its chelating efficiency is slightly lower, as expected from the pH dependence of the pM (Figure 6). However, it should be emphasized that the presence of the citrate buffer at pH 3 could be responsible for some underevaluation of the chelating efficacy of these functionalized supports because citrate can also compete with the ligand for the metal ions.

Table 2. Chelating capacity of (HOPY-PrN)-SEPH towards Fe^{III}, Al^{III}, and Th^{IV} at pH 3 and 7

Ligand density (μmol/g dry weight)	pH	Chelating capacity (μmol/g dry weight)		
		Fe^{III}	Al^{III}	Th^{IV}
263 ± 8	3	(16 ± 1) × 10	<70	90 ± 8
263 ± 8	7	(26 ± 1) × 10	(24 ± 2) × 10	(25 ± 2) × 10

The chelating capacities of the functionalized sepharose for Al^{III} and Th^{IV} were also calculated by following the same procedure; the results show that the complexation behavior of the supported hydroxypyrimidinone towards these metal ions is similar to that found for Fe^{III}. Interestingly, the metal chelating capacities at pH 7 follow the same order ($Fe^{III} > Th^{IV} > Al^{III}$) found for the stability constants of the corresponding metal-ligand complexes in aqueous solution (Table 1). So, although comparisons between the solution and the two-phase conditions have to be made with care, the eventual formation of ligand-hydroxo mixed species in the solid phase is only expected at pH values above 8, but without the precipitation problems found in the solution studies, which means that this functionalized resin can be used in the pH range 3−8. The fact that both the ligand and the functionalized resin proved to be very stable under acid conditions is noteworthy. Furthermore, an extra experiment showed that, upon removal of the iron under very acidic conditions, the iron-chelating capacity was kept constant (within the experimental error range) and so there are good perspectives for its reutilization. This feature is very important and it represents an advantage of this chelating support over other ones, such as the linear hydroxamate-based supports, because these groups are easily hydrolysable under such acidic conditions.

Conclusion

Solution studies of a 1-hydroxy-2-(1*H*)-pyrimidinone substituted with an alkylamino group at the C-4 position, HOPY-PrN, by potentiometry and spectrophotometry have shown a strong metal-binding affinity for hard metal-ions, particularly Fe^{III}, Al^{III}, and Th^{IV}, and its ability to compete with other analogous *N*-hydroxamide ligands. This compound was then immobilized in an epoxy-activated sepharose by chemical coupling through the aminoalkyl pendent group. This new hydroxypyrimidinone-functionalized sepharose shows high stability in water over a wide pH range (3−9), a high sequestering capacity for this type of hard metal-ions at mildly basic or even acidic pH conditions, and an ability for reutilization. Therefore, there are good perspectives for its potential use for the removal of traces of toxic hard metal-ions from aqueous media, and thus for environmental purposes.

Experimental Section

Materials: 6B Epoxy-sepharose was purchased from Amersham Pharmacia Biotech. All reagents were analytically pure. Thin Layer Chromatography (TLC) was performed on silica gel 60 F254 plates with 0.2 mm layer thickness from Macherey−Nagel and the compounds visualized by illumination under UV light at 254 nm. Column chromatography (CC) was carried out with Macherey−Nagel Si gel 60 (230−400 mesh). Whenever necessary, solvents were dried according to standard methods.[26] 1-(Benzyloxy)uracil (**1**) was prepared according to the literature.[11]

The 0.050 M Al^{3+} and Th^{4+} solutions were prepared from the corresponding nitrate salts and were standardized by atomic absorption and inductively coupled plasma emission, respectively. The 1000 ppm $Fe(NO_3)_3$ standard solution was purchased from Merck. The solutions of trivalent metal ions were prepared with an excess of nitric acid to prevent hydrolysis. The exact concentration of HNO_3 in each solution was determined by titration with 0.1 M HNO_3 (Titrisol, 0.1 M HNO_3 ampoules) for values of pH ≥ 2. The titrant was prepared from carbonate-free commercial concentrate (Titrisol, KOH 0.1 M ampoules) and was standardized by titration with a solution of potassium hydrogenphthalate. KOH solutions were discarded whenever the percentage of carbonate, determined by Gran's method,[27] was superior to 0.5% of the total amount of base.

Instrumentation and General Information: FTIR spectra were recorded on a Perkin−Elmer 1725 spectrometer and UV/Vis spectra on a Hitachi 150−20 spectrophotometer. Melting points were determined on a Reichert Thermovar melting-point apparatus and are uncorrected. Fourier transform (FT) NMR spectra were run at ambient temperature on a General Electric QE-300 spectrometer with a resonance frequency of 300.65 for ^1H and 75.6 MHz for ^{13}C, using an appropriate solvent. The chemical shifts are reported in δ (ppm) relative to internal references (TMS for organic solvents or sodium 3-trimethylsilyl-D_4-propionate for aqueous solutions). Coupling constants (J) are expressed in hertz. Electrospray ionization mass spectra (ESI-MS) were determined on a Bruker Esquire 3000 mass spectrometer.

1-(Benzyloxy)-4-(1′,2′,4′-triazol-1′-yl)-2(1*H*)-pyrimidinone (2): 1,3,4 Triazole (0.509 g, 7.28 mmol) was added to a solution of 1-(benzyloxy)uracil (**1**; 0.500 g, 2.46 mmol) in dry pyridine (32 mL) at room temperature. Then, 4-chlorophenyldichlorophosphate (0.50 mL, 3.69 mmol) was added and the reaction mixture stirred for 3 d at room temperature. Water was added to the mixture and the solvents evaporated. A saturated $NaHCO_3$ solution was added to the residue and this aqueous suspension extracted with $CHCl_3$ (5 × 50 mL). The combined organic extracts were dried over anhydrous Na_2SO_4. After evaporation of the solvent, the resulting residue was purified by CC on silica gel using a mixture of ethyl acetate/*n*-hexane (2:1) as eluent to give pure **2** as a yellowish solid (0.443 g; yield 67%), m.p. 202−205 °C (206−209 °C).[11] ESI-MS: m/z = 270 $[M^+ + 1]^+$. FT-IR (KBr): $\tilde{\nu}$ = 1453, 1541, 1616, 1692, 2930, 3099 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 5.38 (s, 2 H, $PhCH_2O$), 6.73 (d, J = 8.5 Hz, 1 H, 5-H), 7.39 (s, 5 H, ArH), 7.50 (d, J = 8.5 Hz, 1 H, 6-H), 8.09 (s, 1 H, 3′-H or 5′-H), 9.22 (s, 1 H, 5′-H or 3′-H) ppm.

4-{3-[(Benzyloxycarbonyl)amino]propylamino}-1-(benzyloxy)-2(1*H*)-pyrimidinone (3): A solution of **2** (0.50 g, 1.86 mmol) and 3-[(benzyloxycarbonyl)amino]propylamine[19] (0.50 g, 2.4 mmol) in dry THF (15 mL) was stirred overnight at reflux temperature, under N_2. The solvent was then evaporated and H_2O added to the residue. The aqueous layer was extracted with $CHCl_3$ (5 × 20 mL) and the combined organic extracts were washed successively with 5% citric acid solution, H_2O, and brine, and dried over anhydrous Na_2SO_4. The solvent was evaporated and the crude product recrystallized from MeOH to afford **3** as a pale-yellow solid (0.60 g; yield 80%), m.p. 154−156 °C. ESI-MS: m/z = 408 $[M + H]^+$, 301 $[M - 107]^+$. ^1H NMR ($CDCl_3$): δ = 1.74 (quin, J = 6.15 Hz, 2 H, $CH_2CH_2CH_2$), 3.28 (q, J = 6.30 Hz, 2 H, $NHCH_2$), 3.53 (q, J = 6.30 Hz, 2 H, CH_2NH), 5.11 (s, 2 H, $PhCH_2O$), 5.22 [s, 2 H, $NHC(O)OCH_2$], 5.91 (m, 1 H, 5-H), 6.89−6.92 (m, 1 H, 6-H), 7.36−7.39 (m, 10 H, 2 ArH) ppm. ^{13}C NMR ($CDCl_3$): δ = 29.2 ($CH_2CH_2CH_2$), 38.0 ($NHCH_2$), 38.1 (CH_2NH), 66.8 [$C(O)OCH_2$], 78.5 (OCH_2), 94.4 (C-5), 128.0, 128.2, 128.6, 128.9, 129.5, 130.3 (ArCH),142.6 (C-6), 154.6 (C-2), 157.7 [C(O)O], 162.8 (C-4) ppm. $C_{22}H_{24}N_4O_4$ (408.45): calcd. C 64.69, H 5.92, N 13.72; found C 64.66, H 5.89, N 13.52.

4-(3-Aminopropylamino)-1-hydroxy-2-(1*H*)-pyrimidinone (HOPY-PrN): A suspension of 10% Pd/C (0.23 g) in dry MeOH (50 mL) was prehydrogenated with H_2 (1 atm) for 30 min. A solution of **3** (0.40 g; 1.06 mmol) in dry MeOH (200 mL) was added to this suspension and the mixture stirred under H_2 (1 atm) for 3 h at room temperature. The catalyst was removed by filtration and the solvent evaporated under reduced pressure. The residue obtained was recrystallized from H_2O/MeOH to afford pure HOPY-PrN (0.185 g; yield 95%), m.p. 216−218 °C. ESI-MS: m/z = 185 $[M + H]^+$, 168 $[M - 16]^+$. FT-IR (KBr): $\tilde{\nu}$ = 2926−3401, 1626, 1524 cm^{-1}. ^1H NMR (D_2O): δ = 1.82 (quin, J = 5.30 Hz, 2 H, $CH_2CH_2CH_2$), 2.93 (t, J = 5.30 Hz, 2 H, CH_2NH_2), 3.31 (t, J = 4.80 Hz, 2 H, $NHCH_2$), 5.64 (dd, J = 7.2, 1.9 Hz, 1 H, 5-H), 7.48 (dd, J = 7.2, 1.9 Hz, 1 H, 6-H) ppm. ^{13}C NMR (D_2O): δ = 29.6 ($CH_2CH_2CH_2$), 39.2 (CH_2NH_2), 39.4 ($NHCH_2$), 95.1 (C-5), 147.2 (C-6), 160.1 (C-2), 163.4 (C-4) ppm. $C_7H_{12}N_4O_2$ (184.20): calcd. C 45.64, H 6.57, N 30.42; found C 45.52, H 6.66, N 30.20.

General Procedure for the Preparation of (HOPY-PrN)-SEPH: Epoxy-activated sepharose 6B freeze-dried powder (500 mg) was washed with distilled H_2O (100 mL) in a sintered glass filter and then suspended in coupling buffer (10 mL of universal buffer, pH 9).[28] HOPY-PrN (500 mg) was dissolved in coupling buffer and added to the matrix suspension. The coupling mixture was adjusted to pH 9 and then shaken in a shaker water bath at 40 °C for 48 h. After that time, the mixture was filtered and the excess ligand was washed away with coupling buffer, distilled H_2O, or, alternatively, with 0.1 M $NaHCO_3$ containing 0.5 M NaCl (pH 8) and 0.1 M acetate buffer containing 0.1 M NaCl, (pH 4) at least three times. The functionalized gel obtained was freeze-dried and stored at 0−4 °C.

Stability Studies of (HOPY-PrN)-SEPH: Freeze-dried (HOPY-PrN)-SEPH (15 mg) was placed in distilled water at pH 3, 7, and 9 and the suspensions shaken at room temperature for 24 h. Aliquots (3 mL) were taken several times, diluted with water, and the absorbance of the resulting solutions measured at λ = 318 nm. Plots of percentage of ligand released from the solid support vs. time were obtained from the values of ligand concentration in solution for each aliquot calculated from a calibration curve.

^1H NMR Titration of HOPY-PrN: ^1H NMR spectra were recorded with a Varian Unity 300 spectrometer at probe temperature. Solutions of HOPY-PrN (approx. 0.02 M) were prepared in D_2O using DSS as internal reference. The pD was adjusted by addition of DCl or CO_2-free KOD, using a Crison 2001 instrument fitted with a combined Mettler Toledo U402-M3 S7/200 microelectrode. This microelectrode was previously calibrated with standard buffered aqueous solutions; $-\log[D^+]$ was measured in the NMR tubes. The final values of pD were determined from the equation pD = pD*

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

+ 0.40,[29] in which pD* corresponds to the reading of the pH meter previously calibrated with aqueous buffers at pH 4 and 7.

Potentiometric Measurements: The equipment used has been described before.[30] All the potentiometric measurements were carried out under thermostatted conditions ($T = 25.0 \pm 0.1$ °C) at an ionic strength, I, of 0.10 M (KNO_3); the experiments were monitored by computer. Atmospheric CO_2 was excluded from the cell during the titration by passing purified N_2 across the top of the experimental solution in the reaction cell. The potentiometric measurements were performed at ligand concentrations of 2.0×10^{-3} M, first in the absence of metal ions and then in the presence of each metal ion with corresponding C_M/C_L ratios (1:3 for Fe^{3+}; 1:3 and 1:6 for Al^{3+}; 1:4 and 1:8 for Th^{4+}). The $[H^+]$ of the solutions was determined by measuring the electromotive force of the cell, as described previously;[31] the determined value of K_w used in the computations was $10^{-13.80}$.
At the beginning of the titrations of the ligand with Fe^{3+} and Th^{4+}, the extent of formation of the metal complexes was too high to allow the use of the direct potentiometric method, therefore spectrophotometric titrations were performed.

UV Spectrophotometric Measurements: Electronic spectra were recorded with a Perkin−Elmer model Lambda 9 spectrophotometer, using aqueous solutions of the complexes, in 1 cm path-length cells. The temperature of the solutions was kept at 25.0 ± 0.1 °C, using a Grant W6 thermostat, and $I = 0.10$ M (KNO_3). The spectra were recorded in the range 250−350 or 350−650 nm for the Th^{4+} and the Fe^{3+} systems, respectively. The solution of the Fe^{3+} complex (1:10 stoichiometry) was prepared as indicated for potentiometric measurements. For the 1:1 Fe^{3+}/ligand and Th^{4+}/ligand systems, the measurements were made for $0.8 \leq pH \leq 2$ and the amount of acid to be added (from standard solutions of 0.097 or 1 M HNO_3) was calculated for the total volume solution under study.

Calculation of Equilibrium Constants: Ligand protonation constants, $K_i = [H_iL]/[H_{i-1}L][H]$, were calculated by fitting the potentiometric data obtained for the free ligand using the program HYPERQUAD version 2.1.[32] Stability constants of the metal-ion complexes formed in solution were determined from the experimental data corresponding to the titration of solutions with different ligand and metal-ion ratios, also with the aid of the same program. Whenever a high extent of formation of the metal complexes at the beginning of the titration was present, the PSEQUAD program[33] was used to treat the spectrophotometric data. The results were obtained in the form of overall stability constants or $\beta_{M_mH_hL_l} = [M_mH_hL_l]/[M]^m[H]^h[L]^l$. In the analysis of the potentiometric as well as the spectrophotometric data, the hydrolytic species[31,34−36] of the respective metal ions were considered. Species-distribution curves were plotted with the HYSS program.[32] The errors quoted are the standard deviations of the overall stability constants given directly by the program. In the case of K_i, the standard deviations were determined by the normal propagation rules and do not represent the total experimental errors.

Determination of the Chelating Capacity of (HOPY-PrN)-SEPH: To evaluate the Fe^{III} chelation, (HOPY-PrN)-SEPH freeze-dried gel (50 mg) was placed in a buffer solution at pH 7 containing 90 ppm Fe^{III} citrate, and the suspension was shaken at room temperature for 4 h. The gel was filtered, washed with deionized water, and HNO_3 was added to the filtrate solution. Then, the gel was washed with an acidic solution of HNO_3 to release the complexed Fe^{III}. The Fe^{III} chelating capacity of the gel was calculated from the difference in the iron content of the filtrate solutions determined by AAS. To determine the Al^{III} chelation, a procedure identical to that described above was followed but with Al^{III} citrate[37] instead of Fe^{III} citrate. As for the evaluation of the Th^{IV} chelation, the same technique used for the Fe^{III} system was applied, but the Th^{IV} citrate was generated by preparing an aqueous solution containing equimolar amounts of Th^{IV} nitrate and citric acid (1.72×10^{-3} M).

Solid-State Structure, Quantum Calculations and Spectroscopic Characterization of the Hydrogen-Bonded Complex $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)][PF_6]_2$

Claudio Garino,[a] Roberto Gobetto,*[a] Carlo Nervi,[a] Luca Salassa,[a] Gianluca Croce,[b] Marco Milanesio,[b] Edward Rosenberg,[c] and J. B. Alexander Ross[c]

Keywords: Density functional calculations / Hydrogen bonds / N ligands / NMR spectroscopy / Osmium

The new H-bonded complex $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)][PF_6]_2$, where DMAP = 4-(dimethylamino)pyridine and bpy = 2,2′-bipyridine, has been synthesized and characterized by X-ray diffraction, IR, solution and solid-state NMR spectroscopy. The complex shows a strong hydrogen bond between the protonated DMAP moiety and the deprotonated ethanolic group directly bonded to the Os atom. High-speed (28 KHz) solid-state ^1H MAS NMR spectroscopy and quantum-mechanical calculations were used to assess the location of the hydrogen atom involved in the H-bond. Both confirmed a proton characteristic of an N–H···O–Y hydrogen bond. A molecular orbital analysis was performed to elucidate the IR CO stretching frequency red shift of the H-bonded complex with respect to $[Os(bpy)_2(CO)O(H)Et][OTf]_2$. Absorption spectra indicate that the H-bond is present both in water and dichloromethane solutions. However, no direct evidence of the H-bond interaction in solution is observed from the ^1H NMR spectrum (CD_2Cl_2) between 298 and 193 K.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The complex $[Os(bpy)_2(CO)(OTf)][OTf]$, where OTf = $CF_3SO_3^-$, was first synthesized in the 1980s as a potential reactive intermediate for the chemically mild synthesis of a new series of metal-ligand complexes with strong ligand-field donor ligands. Many nitrile and isocyanide derivatives were produced and their excited-state properties explored.[1,2]

Following our earlier studies devoted to the synthesis of new $[Os(bpy)_2(CO)L]^{n+}$ complexes with interesting and potentially useful fluorescence properties,[3] we investigated the substitution of OTf[4−7] with alcohols. Many structures of $Ru(bpy)_2$ derivatives (bpy = 2,2′-bipyridine) have been reported in the literature, but few $Os(bpy)_2$ structures can be found in the Cambridge Structural Database (CSD),[8] as summarized in our recent paper.[9]

In an attempt to extend the reactivity of the $[Os(bpy)_2(CO)(OTf)][OTf]$ complex, we found that DMAP[10−14] [4-(dimethylamino)pyridine] has an active role in its reaction with alcohols. We have characterized the resulting $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)][PF_6]_2$ (**1[PF$_6$]$_2$**) complex by X-ray crystallography and solid-state ^1H NMR and solution spectroscopic techniques. We have also examined the solution properties of the triflate analog **1[OTf]$_2$**. The main feature of these complexes is the presence of a strong N−H···O hydrogen bond between a protonated dimethylaminopyridine moiety ($H\text{-}DMAP^+$) and an alkoxide group directly bonded to the Os atom.

It is significant that the heteronuclear N−H···O bond plays a central role not only in protein folding and DNA base-pairing, but also in the ever-growing areas of molecular recognition and crystal-engineering research.[15−20] Important reviews in recent decades have highlighted the field of strong H-bonds,[21−24] and the electrostatic versus covalent nature of the H-bond has been extensively debated and investigated.[22,25−30] A new model, the Electrostatic-Covalent H-Bond Model (ECHBM),[31−33] has been developed to rationalize the electrostatic nature of weak homonuclear O−H···O H-bonds and the covalent nature of strong ones. The ECHBM has been applied to heteronuclear cases with good results, although additional aspects require further investigation.[34]

Recent studies of *intramolecular* X−N−H···O−Y hydrogen bonds[35,36] in ketohydrazone-azoenol systems demonstrated the presence of very strong H-bonds. The H-bond is stronger if the two resonance forms X−N−H···O−Y and

X−N···H−O−Y have similar energy, a condition that occurs when the intrinsic proton affinity (PA) of the N atom is reduced.[34] Thus, a weak hydrogen bond can be strengthened by introducing chemical substituents that reduce the PA difference between the H-bond donor and acceptor atoms and cause the resonance forms to become isoenergetic. This observation helps to explain the behavior of the homonuclear H-bond.

There are three classes of strong intramolecular H-bonds: (i) (−)CAHB, a negative-charge-assisted H-bond; (ii) (+)CAHB, a positive-charge-assisted H-bond; and (iii) RAHB, a resonance-assisted H-bond. These classifications can be extended to *intermolecular* interactions as well, as demonstrated by an extensive analysis of *intermolecular* N−H···O/N···H−O bonds[34] using the Cambridge Crystallographic Database (CSD).[8] In most examples of intermolecular H-bonds, the H-bond results from an acid-base equilibrium, usually referred to as "a salt bridge" in the biochemical literature.[24] For example, Jerzykiewicz et al. have reported an intriguing case of a strong *intermolecular* N−H···O/N···H−O bond in the complex between 3,5-dimethylpyridine and 3,5-dinitrobenzoic acid (DMP-DNB) that is characterized by an almost linear N−H···O angle (177°) and a nitrogen−oxygen distance of about 2.550 Å.[37]

In this paper we report the study of the heteronuclear H-bond of $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)]^{2+}$ using several complementary physical techniques in combination with quantum-mechanical calculations. Furthermore, we describe how theoretical computation can play a critical role in developing an understanding of the structural properties of the complex and in rationalization of the spectroscopy data.

The goal is to identify where the observed strong hydrogen bond fits into the currently available hydrogen bonding models and to understand how the d-orbital energies and electron distributions are impacted by this bond relative to previously reported $Os(bpy)_2(CO)(L)$ systems.

Results and Discussion

Crystal Structure of $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)][PF_6]_2$

The dissolution of $[Os(bpy)_2(CO)(OTf)][OTf]$[38] in ethanol in the presence of a tenfold excess of DMAP gave a dark-red solution that slowly changed to violet. The crystalline product **1[PF$_6$]$_2$**, which was obtained after purification and careful recrystallization, was analyzed by single-crystal X-ray diffraction (see Exp. Sect.).

The structure determined for the complex is illustrated in Figure 1 and the crystallographic data are given in the Exp. Sect. The most interesting feature of **1[PF$_6$]$_2$** is the strong N−H···O hydrogen bond (dotted line in Figure 1) between the H-DMAP$^+$ moiety and a deprotonated ethanol molecule directly bonded to the Os atom.

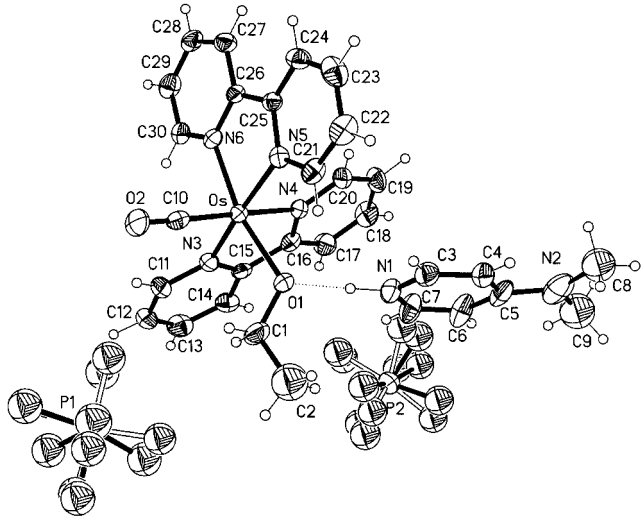

Figure 1. Molecular structure of $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)][PF_6]_2$ showing the adopted labeling scheme, with displacement ellipsoids drawn at the 25% probability; the PF_6^- moiety is disordered with black and white bonds indicating the two possible positions

The strength of the N−H···O interaction is implied by the geometric features of the hydrogen bond, as summarized in Table 1. The H-bond is close to linear [N−H···O angle is approximately 175(1)° both from X-ray data and theoretical calculations, see below] and the donor−acceptor distance is short [2.614(9) Å] and close to the values observed in two-center hydrogen bonds[35,37] in which the hydrogen is approximately midway between the two electronegative atoms (O1 and N1 in Figure 1). It is worth noting that the O atom of the ethanol ligand is tightly bonded to the Os atom while the methyl group is rather mobile, as indicated by their anisotropic displacement parameters

Table 1. Geometric features of the strong N−H···O hydrogen bond in the crystal structure of $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP)][PF_6]_2$ and from theoretical calculations at the B3LYP/BS3//B3LYP/BS3 level of theory, with LACVP ECP on the Os atom

(ADP) (depicted at 25% of probability in Figure 1). Atom O1 shows a small averaged ADP [0.058(2) Å^2], while the very mobile C2 atom has a significantly larger ADP value [0.152(7) Å^2] and C1 has intermediate mobility, its ADP value being 0.087(4) Å^2. Similarly, in the case of the H-DMAP$^+$ moiety the atoms of the molecule showing smaller ADPs are those closest to the N−H bond and those directly bound to the Os complex through the N−H···O hydrogen bond. This is illustrated by the monotonic increase in the ADPs going from N1 to C8 [ADP = 0.066(2), 0.070(3), 0.077(3), 0.085(4), 0.114(4), 0.130(6) for atoms N1, C3, C4, C5, N2, and C8, respectively].

The crystal packing of the osmium complex is driven by various intermolecular interactions. First, the positively charged Os complex and the H-DMAP$^+$ moiety are bound together by the previously described strong N−H···O hydrogen bond. Next, the negative PF_6^- anions are bound to the positive Os-containing moiety and to the H-DMAP$^+$ by ionic forces. Finally, weak interactions are present between the C−H groups belonging to the bpy groups and to the H-DMAP$^+$ moiety and those of the hydrogen-bond acceptors [CO bonded to Os and F belonging to PF_6^- anions; H···F and H···O contacts ranging from 2.42(1) to 2.91(1) Å]. As already observed in other PF_6^--containing crystal structures,[9] each PF_6^- moiety is disordered over two positions (black and white bonds in Figure 1 for the major and the minor components, respectively).

Defining the location of the H1 position was not straightforward and different strategies for the X-ray data refinement were carefully checked. As discussed below, an Os−O distance of 2.083(6) Å is consistent with both the alcohol and the alkoxide form. Nevertheless, in the Fourier difference map, after location of all the non-hydrogen atoms and of all the H-atoms (whose locations were calculated using the program XP as implemented in SHELX-TL)[39] except H1, a well-defined peak was observed at about 1.0 Å from N1. With unconstrained refinement, the H1-atom coordinates retain a position consistent with the alkoxide form. Moreover, if in the initial model an H-atom is bonded to O1 to obtain an N···H−O alcohol form, refinement moves the H atom towards N1, into the position expected for formation of an N−H···O alkoxide. We are aware, however, that it is difficult to determine the precise location of an H-atom only on the basis of X-ray data, particularly considering that $wR2 = 0.12$ for the refined structure of **1[PF$_6$]$_2$**. Therefore, to compare the stability of the two different forms (**1a** and **1b**) depicted in Scheme 1, and to give a more general overview of the literature on such inorganic systems, we carried out theoretical calculations and also performed an extensive search in the Cambridge Structural Database (CSD).[8] This search of the two alkoxide-containing fragments **3** and **4** depicted in Scheme 2, where the oxygen atom can be protonated or deprotonated, returned 51 structures. The alcohol-alkoxide geometric features were indirectly analyzed by monitoring the Os−O distance in these structures, thus avoiding a comprehensive study of distances and angles involving H-atoms whose exact location cannot be defined from X-ray analysis. The Os−O bond lengths are obviously dependent on the presence of the ancillary ligands. Nevertheless, distances shorter than 2.00 Å are generally consistent with the alkoxide form, as reported, for example, by Richter-Addo et al.,[40] where the Os−O distance is 1.89(2) Å in (octaethylporphyrinato)Os(NO)(OEt). Conversely, Os−O distances larger than 2.20 Å are always attributed to the alcohol form as, for example, in the [*N*,*N*′-bis(salicylidene)-*o*-phenylenediamine](methanol)(nitrido)-osmium(VI) perchlorate complex reported by Tsz-Wing et al.,[41] where the Os−O distance is 2.265 Å. Os−O distances in the range 2.00−2.20 Å have been attributed to either form. For example, in the tetraphenylarsonium pentachloroosmium ethanol solvate, [AsPh$_4$][OsCl$_5$EtOH]·EtOH, reported by Lang et al.,[42] the acceptor is a second ethanol molecule where the located hydrogen is clearly much closer to the EtOH in the first coordination sphere. Thus, the alkoxide form can be excluded, even if the Os−O distance (2.078 Å) is short. Also, several alkoxide-like complexes that have the alkoxy group in a bridged coordination show Os−O distances around 2.10 Å, as reported, for example, in the nonacarbonyl(μ-σ-η-dimethylamino-1-methoxy-1-

oxobut-2-ene-2,4-diyl)(μ-methoxo)triosmium dichloromethane solvate complex by Adams et al.[43] Finally, the Os−O distance can be substantially larger {up to 2.40 Å as in the [diethylsilylene(tetrahydrofuran-*O*)](tetrahydrofuran)[*meso*-(tetra-*p*-tolyl)porphyrin]osmium tetrahydrofuran solvate complex reported by Woo et al.}[44] when the ligand is bound to the Os atom in the alcoholic form.

Theoretical Calculations of the Hydrogen-Bond Geometry

Because the observed Os−O distance in our crystal structure (2.078 Å) is consistent with the two possible forms (alcohol and alkoxide) depicted in Scheme 2, theoretical calculations were carried out to better understand this situation in **1[PF$_6$]$_2$**. However, the quantum treatment of a charged H-bonded complex containing a third-row transition metal is not straightforward. Consequently, several different strategies were adopted for evaluation of the electron correlation effects and the basis-set superposition error (BSSE).[45] The geometric optimization was carried out first at the Hartree−Fock (HF) level of theory, employing the BS1 basis set and then employing the density functional method, with the B3LYP and B3PW91 schemes and different basis sets (see Table 2). Finally, a single-point calculation was carried out employing the post-SCF local MP2 correction (L-MP2 in Table 2), as implemented in the Jaguar software, using the BS3 basis set, on the geometry optimized at the HF/BS1 level. At this level of calculation, the electron-correlation effects can be treated correctly at a fraction of the computational time of a "normal" MP2 calculation, and the BSSE should be of limited importance. The energy values reported in Table 2 indicate that the Hartree−Fock method is inadequate for estimating the energy difference between the alcohol and the alkoxide forms (unique negative ΔE in Table 2). On the other hand, the DFT methods give results in keeping with the L-MP2 value, which suggests a slight energetic preference for the alkoxide form.

In compound **1**, the geometric features and the small energy difference between the two forms indicate that the N−H···O interaction is a rather strong, almost linear, resonance-assisted hydrogen bond. Nevertheless, it cannot be considered a three-center hydrogen bond because the O···N distance is too long [2.614(9) Å, which is longer compared, for example, to the 2.550(2) Å of the DMP-DNB complex reported by Jerzykiewicz et al.].[37] Indeed, the N−H···O hydrogen bond is sufficiently strong to be stable in solution, as indicated by spectroscopic measurements (see below).

Table 2. Energy (ΔE) of the alcohol form (N···H−O hydrogen bond present), with respect to the alkoxide one (N−H···O hydrogen bond present); the LACVP ECP was employed for the Os atom in all calculations, while different basis sets (see computational details) were adopted; ΔE is calculated taking the energy of the alkoxide form as reference

Level of the calculation	ΔE [kJ/mol]
HF/BS1//HF/BS1	−21.2
HF/BS1//L-MP2/BS3	3.8
B3LYP/BS1	4.7
B3LYP/BS3	2.9
B3PW91/BS1	4.7
B3PW91/BS2	6.3
B3PW91/BS3	10.0

The case of the EtO−H···DMAP couple was also considered at the B3LYP/BS3 level of calculation. We attempted to optimize the geometry of the complex $EtO^-\cdots H\text{-}DMAP^+$, but the proton moved toward the alcoholic oxygen. The uncomplexed DMAP−EtOH complex has a nitrogen−oxygen distance that is longer than in models **1a** and **1b** (Scheme 1) due to withdrawal of electron density from the oxygen by the metal center. The acid-base equilibrium between a nitrogen base and an organic or inorganic acid can be described in terms of a positive/negative-charge-assisted H-bond, (±)CAHB; the approximate proton position can be estimated from the pK_a values (or the PA). The pK_a values for ethanol and $H\text{-}DMAP^+$ in water are about 16 and 9.2, respectively. This difference accounts for the large d(N−O) in the EtO−H···DMAP couple and for the failure of all attempts to optimize the geometry of the hypothetical $EtO^-\cdots H\text{-}DMAP^+$ complex, thus confirming that when the ethanol is not bonded to an organometallic moiety, a stable alkoxide structure is not formed. The ethanol bonded to the osmium should possess a lower pK_a value, and consequently the ΔPA moves toward zero, shortening the N−O distance.

Spectroscopic Measurements

In order to corroborate the conclusions drawn from the solid-state structure determination and the theoretical calculations we made a detailed investigation of the spectroscopic properties of **1[OTf]$_2$** and $[Os(bpy)_2(CO)(EtOH)(OTf)_2]$ (**2[OTf]$_2$**). Solid-state ^{1}H NMR spectroscopy offers an alternative method for detecting the presence of an H-bond when dynamic behavior or the presence of trace moisture can mask its presence in solution. The main constraint of this approach with organic solids, however, is the presence of strong dipole-dipole interactions that cause line broadening of up to some tens of kilohertz. This homonuclear dipolar interaction is only partly averaged by the rotation of the solid sample at the spinning speeds routinely used in magic angle spinning (MAS) experiments. Nevertheless, relatively high resolution can be achieved in many cases at high magnetic fields by rotating the sample at very high spinning speeds (28−30 KHz). The solid-state ^{1}H NMR spectrum of **1[OTf]$_2$**, recorded under these experimental conditions, is shown in Figure 2.[46−48] The peaks at δ = 0.6 and 2.8 ppm are readily assigned to the CH_3 and CH_2 groups of the ethanol ligand, respectively, whereas the resonance at δ = 2.3 ppm is assigned to the methyl groups of DMAP (small differences between solution and solid-state proton chemical shifts are accepted due to the bulk magnetic susceptivity and crystal-packing effects).[46−48] The spectrum is dominated by the strong signal centered at δ = 7.4 ppm, which is attributed to the large array of aromatic protons. At chemical shifts greater than δ =

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

11.0 ppm, a broad resonance is evident as a shoulder of the aromatic peaks. This resonance does not have any counterparts in the solution spectrum, and it is in the region expected for an N−H···O proton involved in an alkoxide hydrogen bond. Indeed, the proportion of aromatic, aliphatic, and hydrogen-bond protons, as determined by integration of the peaks, well agrees with the proposed assignment. A magnetic shielding calculation using the GIAO method gave a value of δ = 13.17 ppm, which also confirms the proposed assignment.

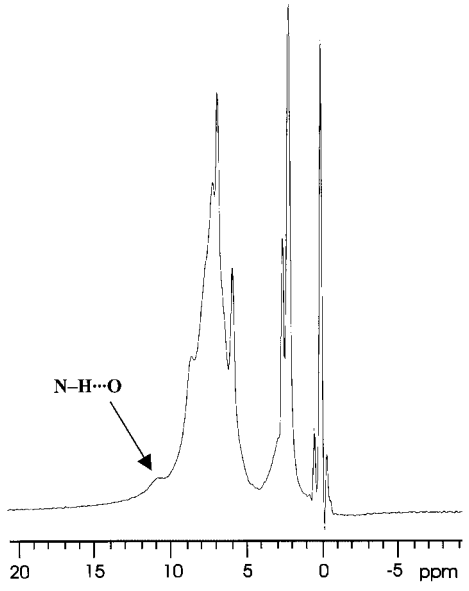

Figure 2. ^{1}H MAS NMR spectrum of **1** measured at 499.7 MHz, 64 transients, pulse delay 10 s, rotational speed 28 kHz

Evidence of formation of the H-bonded complex in solution is inferred from the initial rapid change in the color of the solutions of **2[OTf]$_2$** during the addition of DMAP. A comparison of the color of **1[OTf]$_2$** and **2[OTf]$_2$**, either in the reaction solvent (ethanol) or in CH_2Cl_2, confirms that an interaction between the osmium moiety and DMAP persists in solution. Prior to addition of DMAP to carefully dried dichloromethane solutions of **2[OTf]$_2$** a broad peak is detected at δ = 2.17 ppm in the ^{1}H NMR spectrum; this indicates the presence of coordinated ethanol as opposed to an alkoxide complex for this species. On addition of DMAP this resonance disappears and the characteristic color change to violet is observed. Although direct observation of the H-bond was not possible using solution NMR techniques in the range of temperature we investigated (298−193 K), these spectra contain the following features that suggest the interaction is maintained in CD_2Cl_2: (i) the two diastereotopic CH_2 protons of the coordinated ethanol are well separated both in **1[OTf]$_2$** and in **2[OTf]$_2$** (Figure 3); (ii) although the signal pattern is practically equivalent, the coupling constants are different (**1[OTf]$_2$**, ^2J = 10.55, ^3J = 6.42, ^3J = 6.86 Hz; **2[OTf]$_2$** ^2J = 10.88, ^3J = 7.10, ^3J = 7.09 Hz); (iii) for **1[OTf]$_2$** and **2[OTf]$_2$** the methyl protons and aromatic protons have different chemical shifts, and (iv) the coordinated DMAP signals are clearly different

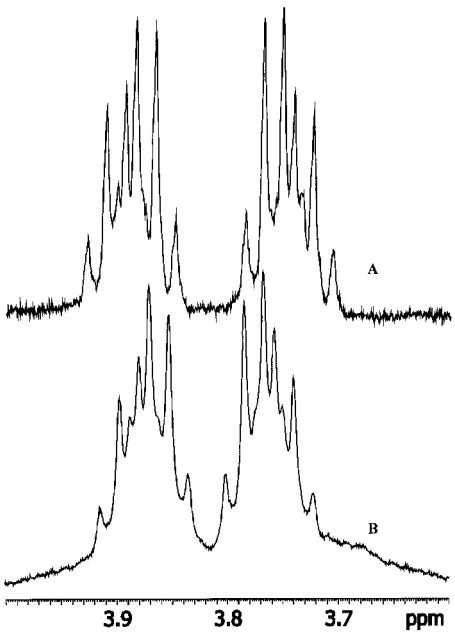

Figure 3. Expansion of the ^{1}H NMR spectra for the diastereotopic CH_2 protons of the coordinated ethanol group in **1** (**A**) and **2** (**B**); the spectra were recorded in CD_2Cl_2 solution at 399.78 MHz and 298 K

from those of free DMAP. In the former case, the signals occur at δ = 3.09 ppm (methyl group, 6 H), 6.61 ppm (*meta*, 2 H), and 7.67 ppm (*ortho*, 2 H), whereas in the latter case they fall at δ = 2.95, 6.46, and 8.15 ppm, respectively. From the literature,[34] we would expect a value of $\delta_{NH\cdots O}$ in the range 9.28−14.18 ppm. A broad signal can be observed in the solution ^{1}H NMR spectrum in the range δ = 5.90−6.75 ppm, and its chemical shift changes markedly with temperature. A possible explanation for this behavior could be rapid equilibria involving traces of water. This is also consistent with the lack of the O−D signal in the ^{2}H NMR spectrum of [Os(bpy)$_2$(CO)(CD_3CD_2O···D−DMAP)][OTf]$_2$. According to the previously reported studies of Limbach and co-workers, the inability to detect the H-bond resonance could be related to fast exchange of the hydrogen-bonded ligand with water.[49] Lowering the temperature could be a way to overcome the fast exchange.[50,51] We measured spectra at 193 K, but it still did not resolve the anticipated resonance due to the strong hydrogen bond. Apparently, the hypothesized equilibria are not sufficiently slow at this temperature, either for the protonated or deuterated complex. Attempts to rigorously dry solid samples prior to dissolution in carefully dried NMR solvents did not eliminate all traces of water.

The IR spectrum of **1[OTf]$_2$** in KBr, prepared under anhydrous conditions, shows two sets of adsorptions in the region around 3000 cm^{-1}, which are typical for C−H stretching modes. It also shows a broad band at 3273 cm^{-1} that can be attributed to the hydrogen-bond interaction; this broad band is not present in the IR spectrum of the deuterated analog [Os(bpy)$_2$(CO)(CD_3CD_2O···D−DMAP)][OTf]$_2$. The presence of the H-bond between the osmium moiety and DMAP can also be indirectly deter-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mined by the shift of the CO frequency. The CO stretching in **1[OTf]$_2$** falls at 1929 cm^{-1} whereas in **2[OTf]$_2$** it appears at 1939 cm^{-1}, showing a red shift due to the presence of the hydrogen bond, in agreement with the theoretical calculations (see discussion below). The electronic absorption spectra of **1[OTf]$_2$** and **2[OTf]$_2$** are quite different (λ_{max} = 280, 340, and 455 nm for **1** and 266, 302, 352, and 444 nm for **2**). Solutions of **1[OTf]$_2$** give a barely detectable emission at 549 nm when excited at 450 nm while solutions of **2[OTf]$_2$** give a more-pronounced emission at 557 nm. This difference in behavior could result from the quenching of the MLCT excited of the complex by the electron-donating DMAP group.[2,52]

Electron Distribution on the Os-Containing Moiety

The electron distribution on the Os−CO and Os−OEt moieties was investigated by employing the calculated and experimental vibrational data and the NBO[53] orbital analysis, using the three models proposed above (**1a, 1b** and **2** in Scheme 1). As described above, the calculations were carried out at the B3LYP/BS3//B3LYP/BS3 (with LACVP ECP for Os atom) level of theory with the Jaguar software.

The CO stretching frequency (ν_{CO}) is a traditional diagnostic tool that has been used to estimate electron availability in a metal complex.[54,55] As shown in Table 3, comparing model **2**, which lacks the hydrogen bond, to model **1a**, which has the hydrogen bond, we observe that the strength of the Os−O interaction is increased and the strength of the CO bond decreased, as a consequence of the H-bond formation. This is indicated by a shortening of the Os−O bond, a lengthening of the CO bond, and a red shift of the calculated and experimental ν(CO) frequencies (even if the calculated frequencies show the expected systematic over-estimation error). In **1a**, the proton is further removed from the ethanolic oxygen and the ν(CO) is further red-shifted. Also, the trend in the Os−C and C−O bond lengths is in keeping with the proposed explanation in which the electron density on the metal center increases on passing from model **1b** to model **1a**.

Additional details can be observed by employing the NBO approach. The Os−O interaction is described in the same way for the three models depicted in Scheme 1, with the electron density confined to the two lone-pairs localized on the oxygen atom, which have about 30% s and about 70% p character. It is worth noting that no NBOs can be found that give rise to two-center bonds (referred to as BD in NBO nomenclature).[53] In fact, the Os−O interaction is described by electron donation from the oxygen lone-pairs to two empty osmium d-orbital NBOs. The lowest-energy osmium NBO has 99% d character whereas the next-highest-energy d-orbital has about an 80% s and a 20% d character. The energy stabilization arising from this delocalization can be estimated using Perturbation Theory Analysis as provided in the NBO package. The decrease in the Os−O distance is reflected in the stabilization energies, which are 293.80, 357.27, and 537.76 kJ/mol for models **2**, **1b** and **1a**, respectively. A similar trend can be observed for the Os−C and C−O bonds (see Table 3). In the latter case the C−O bond is described by a single BD NBO. Again, application of Perturbation Theory Analysis results in donation of electrons from two oxygen lone-pairs to two vacant carbon NBOs, which again gives stabilization energies following the trend **2** > **1b** > **1a** (see Table 3). This trend is also in agreement with the H-bond-induced red shift of the CO stretching measured experimentally and confirmed by the theoretical calculations.

The slight increase in electron density at the metal with the introduction of the H-bond is entirely consistent with the expected increase in the lone pair π-donor ability of the O-atom resulting from partial deprotonation. This, in turn, increases back-donation by the metal to the CO ligand and results in the observed slight red-shift of the CO stretching frequency.

Table 3. Selected distances [Å], calculated C≡O frequency [cm^{-1}], and stabilization energy [kJ/mol] for the three models of Scheme 1 at the B3LYP/BS3//B3LYP/BS3 level of theory, with LACVP ECP on the Os atom

	d(Os−O)	*d*(Os−C)	*d*(C≡O)	ν(C≡O)	*E*(Os−O)	*E*(C≡O)
1a	2.125	1.8791	1.161	2043	537	1895
1b	2.169	1.883	1.160	2065	357	1919
2	2.213	1.887	1.158	2065	293	1946

Conclusion

The strong N−H···O hydrogen bond formed between the protonated DMAP moiety and the deprotonated ethanolic group in the complex $[Os(bpy)_2(CO)(EtO\cdots H\text{-}DMAP][PF_6]_2$ has been investigated by a combination of single-crystal X-ray diffraction analysis, spectroscopic techniques, and theoretical quantum calculations. The dominance of the alkoxide form over the alcoholic one in the solid state has been supported by the results from different, complementary experimental and theoretical approaches. The ^1H MAS NMR spectrum, recorded at very high spinning speeds, is characterized by the presence of a broad proton signal in the expected N−H region. Although discrimination between the two possible forms **1a** and **1b** was not possible from the solution data alone, IR and ^1H NMR spectra also support the persistence of the H-bonded complex in solution.

The theoretical and experimental studies clearly show that the hydrogen atom is closer to N than to O, but the closeness in energy of the alcohol and alkoxide forms realized from the calculations suggest that the hydrogen bond in **1** is a resonance-assisted hydrogen bond. However, the resonance contribution of the nitrogen moiety to this strong hydrogen bond must await a survey of the PAs of the nitrogen bases employed. The experimental and theoretical data also support a significant perturbation of the electronic environment at the Os atom of **1** relative to **2** and that the alcohol ligand is in a predominantly alkoxide form. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

latter is exactly the opposite of the case for the free alcohol H-bonding to DMAP and points to the importance of the metal complex in establishing the observed hydrogen bond.

Preliminary results prompt us to believe that the reactivity generated by formation of this strong hydrogen bond could be widely extended by using different alcohols (or amines), different bases, and different metal triflate complexes. For example, the principles underlying the chemistry of the strong hydrogen bond could be adapted to different reactants with relevant biological roles, such as purinic and pyrimidinic bases in DNA or RNA, or nucleophilic amino acids in proteins or polypeptides. Such investigations could assume relevance in the anti-tumour drug field. For example, different ruthenium-based metal complexes have been studied for their anti-tumour properties,[56−59] but only one complex with covalently coordinated DNA bases at the metal center has been reported in the literature.[60]

Experimental Section

General Remarks: $(NH_4)_2OsCl_6$ was purchased from Novachimica. 2,2′-Bipyridine, obtained from Aldrich, was purified by crystallization from hexane and dried under vacuum over P_2O_5.[61] Neutral alumina for chromatography was obtained from Aldrich. All other reagents were reagent grade and used as received without further purification.

Spectroscopic Methods: The NMR spectra were recorded with a JEOL EX 400 spectrometer (operating at 399.78 MHz for ^1H) with chemical shifts referenced to residual protons of the solvent (CD_2Cl_2). VT NMR experiments were performed according to standard procedures. ^1H MAS measurements were performed with a Varian InfinityPlus 500 spectrometer operating at 499.7 MHz for ^1H. Powdered samples were spun at 28 KHz in a Varian 2.5 mm HX probe (courtesy of Department of Chemistry, University of Durham, UK). Spectra were acquired using a π/2 pulse of 2.8 μs in duration and a pulse delay of 10 s over a spectral width of 150 KHz. A total of 64 transients were collected for each spectrum. Proton chemical shifts were referenced to the resonance of PDMSO [poly(dimethylsiloxane)] at $\delta = 0.14$ ppm relative to tetramethylsilane (TMS). UV/Vis absorption spectra were measured at room temperature in deionized water, using a Hitachi U-3210 double-beam spectrophotometer, and emission spectra were measured using a SLM 4800 spectrofluorimeter. The IR spectra were measured as either KBr pellets or in CH_2Cl_2 or CD_2Cl_2 solution using a Bruker Equinox 55 FT-IR spectrophotometer with a resolution of 1 cm^{-1} and an accumulation of 64 scans.

$[Os(bpy)_2(CO)(EtO\cdots H-DMAP)][OTf]_2$ (1[OTf]$_2$): $[Os(bpy)_2(CO)(OTf)][OTf]$[38] (OTf = $CF_3SO_3^-$; 25 mg) was dissolved in ethanol and a tenfold excess of DMAP was added. The solution rapidly changed color from yellow to dark red. The solution was stirred for approximately 48 h and finally became violet. The solvent was then evaporated and the compound was suspended in a toluene solution to dissolve the free DMAP. Finally, the solid was separated and washed several times with diethyl ether. Conversion of the starting complex to the H-bonded product was essentially quantitative; yield 91% (27.4 mg). ^1H NMR (CD_2Cl_2): $\delta = 1.01$ (t, 3 H, CH_3CH$_2$OH), 3.10 (s, 6 H, DMAP), 3.75 (m, 1 H, CH$_3$CH$_2$OH), 3.89 (m, 1 H, CH$_3$CH$_2$OH), 6.60 (d, 2 H, DMAP), 7.20 (d, 1 H), 7.26 (m, 2 H), 7.67 (d, 2 H, DMAP), 7.85 (m, 2 H), 7.97 (t, 1 H), 8.04 (m, 3 H), 8.37 (t, 1 H), 8.41 (d, 1 H), 8.47 (d, 1 H), 8.58 (d, 1 H), 8.65 (d, 1 H), 9.34 (d, 1 H), 9.49 (d, 1 H) ppm. Selected ^{13}C NMR spectroscopic data (CD_2Cl_2): $\delta = 19.82$ (*C*H$_3$CH$_2$OH), 39.70 (CH$_3$, DMAP), 69.46 (CH$_3$*C*H$_2$OH), 106.84 (*meta*, DMAP), 140.97 (*ortho*, DMAP), 177.99 (CO) ppm. Selected IR data (KBr): $\tilde{\nu} = 1929$ (CO); (CH_2Cl_2): $\tilde{\nu} = 1945$ (CO); (CD_2Cl_2): $\tilde{\nu} = 1951$ cm^{-1} (CO). Absorption spectrum (H_2O): $\lambda_{max} = 280, 340, 455$ nm. Emission spectrum (H_2O, $\lambda_{exc} = 450$ nm): weak emission with $\lambda_{max} = 549$ nm.

$[Os(bpy)_2(CO)(EtO\cdots H-DMAP)][PF_6]_2$ (1[PF$_6$]$_2$): Crystals of the complex were obtained by precipitating the ethanol solution of **1[OTf]$_2$** with a saturated solution of $(NH_4)PF_6$. ^1H NMR (CD_2Cl_2): $\delta = 1.03$ (t, 3 H, CH_3CH$_2$OH), 3.13 (s, 6 H, DMAP), 3.83 (m, 1 H, CH$_3$CH$_2$OH), 3.93 (m, 1 H, CH$_3$CH$_2$OH), 6.61 (d, 2 H, DMAP), 7.16 (d, 1 H), 7.52 (d, 2 H, DMAP), 7.27 (m, 2 H), 7.71 (t, 1 H), 7.83 (d, 1 H), 7.96 (t, 1 H), 8.03 (m, 2 H), 8.29 (m, 3 H), 8.38 (t, 1 H), 8.47 (d, 1 H), 8.52 (d, 1 H), 9.31 (d, 1 H), 9.50 (d, 1 H) ppm. Selected IR data (CH_2Cl_2): $\tilde{\nu} = 1945 cm^{-1}$ (CO).

$[Os(bpy)_2(CO)O(H)Et][OTf]_2$ (2[OTf]$_2$): This complex was prepared by dissolving 25 mg of $[Os(bpy)_2(CO)(OTf)][OTf]$ in ethanol and stirring the solution for 5 d. After evaporation of the solvent, the orange solid was characterized spectroscopically; yield 82% (21.6 mg). ^1H NMR (CD_2Cl_2): $\delta = 1.15$ (t, 3 H, CH_3CH$_2$OH), 2.17 (br, CH$_3$CH$_2$O*H*), 3.77 (m, 1 H, CH$_3$CH$_2$OH), 3.87 (m, 1 H, CH$_3$CH$_2$OH), 7.27 (d, 1 H), 7.33 (t, 1 H), 7.49 (t, 1 H), 7.80 (m, 2 H), 7.94 (t, 1 H), 8.00 (t, 1 H), 8.13 (t, 1 H), 8.14 (t, 1 H), 8.38 (t, 1 H), 8.48 (t, 2 H), 8.57 (d, 1 H), 8.65 (d, 1 H), 9.10 (d, 1 H), 9.45 (d, 1 H) ppm. Selected IR data (KBr): $\tilde{\nu} = 1939$ (CO); (CH_2Cl_2): $\tilde{\nu} = 1956$ (CO); (CD_2Cl_2): $\tilde{\nu} = 1963$ cm^{-1} (CO). Absorption spectrum (H_2O): $\lambda_{max} = 266, 302, 352, 444$ nm.

X-ray Crystallographic Study: The crystal structure of **1[PF$_6$]$_2$** was solved by single-crystal X-ray diffraction analysis. Suitable crystals were obtained by slow evaporation of the solvent from a water/ethanol solution. Diffraction data were collected at room temp. with a Bruker SMART-APEX CCD[62] area detector diffractometer, using graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation. Absorption correction was performed using SADABS.[63] The structure was solved by direct methods (SIR97)[64] and refined by full-matrix least squares (SHELX97).[39] All hydrogen atoms except H1 were generated in their calculated positions with the XP[65] software. Because the location of atom H1, which is involved in the strong hydrogen bond, is not straightforward, different refining techniques were adopted. These results were compared to those from theoretical quantum calculations, as described in the crystal structure section. Crystallographic data and details of data collections and refinements are given in Table 4. CCDC-244832 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: All the calculations on the osmium complex were performed on the cationic complexes (**1a**, **1b**, **2**; see Scheme 1) using the Jaguar software,[66] except for the magnetic shielding tensor calculations, which were calculated with the Gaussian 98 (G98)[67] program. The Hartree−Fock (HF)[68] and density-functional theory (DFT) methods were adopted for geometry optimization. DFT calculations were carried out using Becke's[69] three-parameter hybrid functional and either the Lee−Yang−Parr[70] or Perdew−Wang[71] gradient-corrected correlation functional. The

importance of the electron correlation effects was then taken into account by performing calculations that use the local MP2 (L-MP2) method[72−75] as implemented in the Jaguar software. The Los Alamos Effective Core Potential (ECP) Double-ζ (LanL2Dz) was used for the Os atom in the Gaussian 98 calculations, while the LANL ECP named LACVP[76] was employed for all calculations carried out with the Jaguar program. Different basis sets were employed for the geometry optimizations (main results summarized in Tables 1 and 3) and for the calculations of the energetic features (Table 2), i.e. 6-31G(d,p), 6-31+G(d,p), 6-31++G(d,p), and 6-311++G(2d,p),[68] hereafter named BS1, BS2, BS3, and BS4, respectively. For the NMR calculations on model **1a**, a B3LYP/BS3//B3LYP/BS4 (geometry optimization//NMR calculation) level of theory was used, employing the GIAO[77] method as implemented in Gaussian 98. The σ values were converted into proton chemical shifts, δ, relative to the magnetic shielding of TMS computed with the corresponding basis set. The vibrational frequencies were then calculated (without applying any scaling factor) for the CO groups at the B3LYP/BS3//B3LYP/BS3 levels (with the LACVP ECP for Os atom), using numerical algorithms implemented in the Jaguar software. The Natural Bonding Orbital (NBO)[53] analysis was carried out with the Jaguar software to rationalize, by means of geometric features and orbital analysis, the IR spectral characteristics of **1a**, **1b** and **2**. Finally, a geometry optimization calculation on the two possible forms of the non-metal-containing organic couple formed by ethanol and DMAP ($EtOH\cdots DMAP$ and $EtO^-\cdots H-DMAP^+$) was performed at the B3LYP/BS3 level of theory. All attempts to optimize the geometry of the hypothetical $EtO^-\cdots H-DMAP^+$ complex failed.

Acknowledgments

This work was supported by Italian MURST (FIRB RBAU015MJ9 004). J. B. A. R. gratefully acknowledges support by NIH grants R01-CA63317 and P20-RR15583, and by NSF grant EPS-0091995. E. R. and J. B. A. R. both thank the BRIN faculty Travel Program, and E. R. thanks the DOE for support. The authors acknowledge Prof. D. Viterbo (Università del Piemonte Orientale, Italy) and Prof. P. Ugliengo (Università di Torino, Italy) for useful discussions. Finally, we are indebted to Prof. R. K. Harris and Dr. D. Apperley (Durham University, UK) for performing the high-speed ^{1}H MAS NMR measurements.

COVER PICTURE

The cover picture shows the X-ray crystal structure of bis(1,3-di-*tert*-butylcyclopentadienyl)thulium(tetrahydrofuran), a new organothulium(II) complex and the first one with all-carbon π-ligands. Two new and particularly stable phospholylthulium(II) complexes are also described. The very existence and relative ease of formation of the so far described thulium(II) molecular compounds strongly suggest that many more such compounds can be prepared, provided that adequate steric and/or electronic protection of the thulium(II) ion can be archieved, thus paving the way to new and hopefully exciting studies in the field of thulium(II) chemistry. Details are discussed in the article by F. Nief et al. on p. 637 ff. The cover picture was rendered in POVRAY 3.5, and the initial input file was obtained with Louis J. Farrugia's ORTEP-III for Windows programme.

Formation of ArPdXL(amine) Complexes by Substitution of One Phosphane Ligand by an Amine in *trans*-ArPdX(PPh_3)$_2$ Complexes

Anny Jutand,*[a] Serge Négri,[a] and Anna Principaud[a]

Keywords: Amines / Phosphanes / Palladium / Ligand substitution

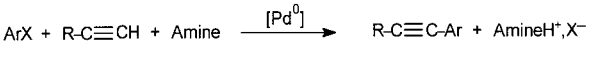
Amines (piperidine, morpholine, diisopropylamine, terbutylamine), which may be used as bases in copper-free palladium-catalyzed Sonogashira reactions, substitute one phosphane PPh_3 in *trans*-ArPdX(PPh_3)$_2$ complexes (Ar = Ph, 4-NC–C_6H_4, 4-MeOC–C_6H_4, 2-thienyl; X = I, Br, Cl) to generate ArPdX(PPh_3)(amine) complexes in a reversible reaction whose equilibrium constant is determined in chloroform, THF, and DMF. The equilibrium constant depends on Ar, X, the basicity, and the steric hindrance of the amine.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Palladium-catalyzed Sonogashira reactions (Scheme 1) require the presence of a base, which is very often an amine.[1,2]

Scheme 1.

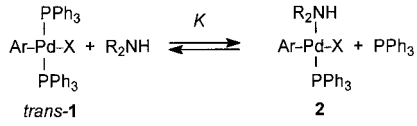
In copper-free Sonogashira reactions (Scheme 2), the role of the base is crucial, and specific amines are required.[3–10] Among them, secondary amines such as piperidine,[3,6,8–10] morpholine,[10] and diisopropylamine[8,10] proved to be very efficient. The amines are usually used in excess,[5,6,8,9] even as the solvent.[3,6,7] PPh_3 is often a ligand of the palladium catalyst when aryl iodides, bromides or triflates are used.[3,4,7–9]



Scheme 2.

The mechanism of the copper-free reaction is not well known. The first step of the reaction is an oxidative addition of ArX to a Pd^0 complex, which generates $ArPdXL_2$ complexes (e.g. L = PPh_3). However, the second step of the reaction is under debate. The amines employed in such reactions (e.g. piperidine, morpholine, etc.) are usually not able to deprotonate the alkyne to generate the anionic nucleophile RC≡C$^-$ that is able to react with $ArPdXL_2$ in a transmetallation step. It is for this reason that complexation of the alkyne to the *trans*-$ArPdXL_2$ complexes is supposed to proceed first with displacement of one ligand to give intermediate complexes: ArPdXL(η^2-HC≡CR).[10] The ligated alkyne would then be more easily deprotonated by the amine, and a new complex would be formed ArPd(–C≡CR)L_n (n = 1 or 2), which gives the coupling product ArC≡CR by reductive elimination. In the absence of any amine, a carbopalladation step[11,12] takes place, which leads to R–C($PdXL_2$)=CH–Ar complexes,[12] presumably by formation of ArPdXL(η^2-HC≡CR) complexes.[11]

Herein we report that amines react with *trans*-ArPdX(PPh_3)$_2$ (**1**) complexes by substitution of one PPh_3 to generate ArPdX(PPh_3)(amine) (**2**) complexes (Scheme 3). In other words, competition between the amine and the alkyne for the substitution of one phosphane group in ArPdX(PPh_3)$_2$ complexes may occur in palladium-catalyzed copper-free Sonogashira reactions.



Scheme 3.

The reactions of the secondary (piperidine, morpholine, and diisopropylamine) and primary amines (terbutylamine) with **1** were monitored by ^1H and ^{31}P NMR spectroscopy in DMF, THF, acetone, and chloroform, after successive additions of known amounts of amine. Besides the set of the ^1H NMR signals for the protons of the Ar group in **1**, a new set of signals appears at lower field, suggesting that a new complex **2** is formed. The magnitude of the ^1H NMR signals of **2** increases at the expense of those of complexes **1** as the amine concentration is increased. Concomitant ^{31}P NMR spectroscopy performed on the same solutions shows that signals for free PPh_3[13] are detected in the ^{31}P NMR spectra, together with a new singlet (δ_2 in Table 1) located

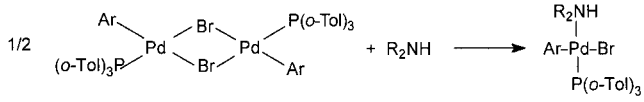
[a] δ_2 is the shift of the major isomer. [b] A minor isomer (16%) was observed at δ = 30.52 ppm. [c] A minor isomer (6%) was observed at δ = 32.22 ppm. [d] A minor isomer (11%) was observed at δ = 27.62 ppm. [e] Two other isomers (11%) were observed at δ = 28.20 and 30.10 ppm. [f] A minor isomer (13%) was observed at δ = 33.82 ppm.[g] A minor isomer (27%) was observed at δ = 31.31 ppm. [h] A minor isomer (40%) was observed at δ = 31.62 ppm. [i] A minor isomer (39%) was observed at δ = 31.42 ppm. [j] None determined because of the very low solubility of *trans*-PhPdI(PPh_3)$_2$ in acetone. [k] None determined because of the presence of some triphenylphosphane oxide. [l] Th means thienyl.

at lower field than those of the initial complexes **1** (δ_1 in Table 1). The magnitude of the singlet for free PPh_3 is similar to those of the new complexes **2** and both increase concomitantly at the expense of those of **1** as the amine concentration is increased. These experiments establish that one PPh_3 group is substituted by one amine group (Scheme 3).[14–18] The coordinated amine was characterized by its ^1H and ^{13}C NMR signals in isolated complexes **2**.

The reversibility of the substitution is proved by the fact that the amount of **2** increases at the expense of **1** when the amine concentration is increased, and addition of PPh_3 to solutions containing both complexes **1** and **2** results in an increase in the amount of **1** to the detriment of **2**. Addition of PPh_3 to the isolated complex 2-ThPdI(PPh_3)(piperidine) (Th = thienyl) results in the formation of *trans*-2-ThPdI(PPh_3)$_2$, and the release of the free piperidine is clearly detected by the ^1H NMR spectroscopy – further evidence of the equilibrium in Scheme 3. Complexes **1** and **2** are involved in equilibria that are slow relative to the time scale of NMR spectroscopy.

The substitution of the two PPh_3 was never observed,[19] even in the presence of a large amount of amine. Indeed, the integration of the ^{31}P NMR signal for the free phosphane never exceeded that of the monosubstituted complex ArPdX(PPh_3)(amine).

The substitution of PPh_3 in *trans*-ArPdX(PPh_3)$_2$ (**1**) by the amine occurs irrespective of the identity of X (= I, Br, Cl) and the aryl groups (Ar = Ph, 2-thienyl, 4-NC–C_6H_4, 4-MeOC–C_6H_4) investigated here (Table 1). One major complex of type **2** is generally generated (Table 1). Its structure, given in Scheme 3, was deduced from its ^{13}C NMR spectrum, in agreement with the value of the J_{CP} coupling, characteristic of a phosphane *cis* to the aryl group. In some cases, a second minor singlet near that observed at δ_2 is detected (Table 1), which suggests isomerisation of the ligands of **2** around the Pd^{II} centre, as observed for the P(*o*-Tol)$_3$ (*o*-Tol: *ortho*-tolyl) ligand.[20] Indeed, related complexes ArPdBr(amine)(P[*o*-Tol]$_3$) have been synthesized by a quite different reaction, not by ligand substitution but by cleavage of the bromide bridges by the amine in dimeric [ArPdBr(P[*o*-Tol]$_3$)]$_2$ complexes (Scheme 4).[20,21] The major isomer ArPd(amine)(P[*o*-Tol]$_3$) has the same structure as complexes **2** with the phosphane *trans* to the amine group.[20] Two other minor isomers only characterized by ^{31}P NMR singlets are also observed.[20]



Scheme 4.

The complexes ArPdX(PPh_3)(amine) **2** generated in situ were rather stable with time in chloroform. After some days, phosphane oxide was detected as a by-product, with the effect that the amount of complexes **2** had increased relative to that of complexes **1**, by the shift of the equilibrium in Scheme 3 to the right as a result of the oxidation of PPh_3. As an isolated complex, PhPdI(PPh_3)(piperidine) was stable for at least four days in chloroform.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The value of the equilibrium constant in Scheme 3, K = [**2**][PPh_3]/[**1**][amine] was determined by ^{31}P NMR spectroscopy by using the respective integration of the singlets of complexes **1** and **2**;[22] $K = x^2/(1-x)(n-x)$, where x is the molar fraction of **2** in the equilibrium: $x = 2S_2/(S_1 + 2S_2)$ [S_1 and S_2: magnitude of the singlet of **1** and **2**, respectively], n is the equiv. of amine added to **1**. The plot of x^2 versus $(1-x)(n-x)$ is linear, and K is determined from the slope of the straight line (Figure 1,Table 1).

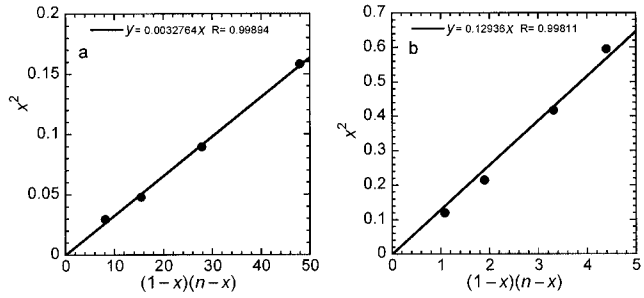


Figure 1.Determination of the equilibrium constant K between *trans*-ArPdX(PPh_3)$_2$**1** and ArPdX(PPh_3)(amine) **2** (Scheme 3) as monitored by ^{31}P NMR spectroscopy; plot of x^2 versus $(1-x)(n-x)$ [x is the molar fraction of **2** in the equilibrium; n is the equiv. of amine added to **1**]; K is determined from the slope; a) equilibrium between *trans*-(4-NC–C_6H_4)PdBr(PPh_3)$_2$ (initially 30 mM) and (4-NC–C_6H_4)PdBr(PPh_3)(morpholine) in $CDCl_3$ (n = 10, 20, 40, 80); b) equilibrium between *trans*-PhPdI(PPh_3)$_2$ (initially 20 mM) and PhPdI(PPh_3)(piperidine) in [D_8]THF (n = 2, 4, 10, 20)

The value of K is less than 1 (Table 1), which means that, under identical concentrations of ArPdX(PPh_3)$_2$ and amine, the equilibrium lies in favor of ArPdX(PPh_3)$_2$. However, in catalytic reactions where the concentration of the amine is always considerably higher than that of the catalytic palladium species, the equilibrium will be shifted toward the formation of ArPdX(PPh_3)(amine). As an example, if the concentration of the piperidine is 50 times higher than that of *trans*-PhPdI(PPh_3)$_2$ in DMF (corresponding to a catalytic reaction run with 2% of catalyst), then, with K = 0.095 (Table 1), one calculates that the concentration of PhPdI(PPh_3)(piperidine) will be 5.5 times higher than that of *trans*-PhPdI(PPh_3)$_2$.

The ligand substitution was studied under reversible conditions. We only have the thermodynamic data for the formation of complexes **2**. From the values of the equilibrium constant K collected in Table 1, it can be seen that for a given Ar group and X, K increases, and consequently the substitution is favored as the amine basicity[23] increases within the cyclic series (piperidine and morpholine: compare entries 4 and 5, 8 and 9, 10 and 11, 12 and 13, and 14 and 15). However, the magnitude of K follows the order (compare entries 4–7): piperidine > morpholine > $tBuNH_2$ >> iPr_2NH.

This does not reflect the amine basicity order since on one hand morpholine is less basic than tBuNH$_2$ and iPr$_2$NH, and on the other hand iPr$_2$NH is slightly more basic than tBuNH$_2$.[23] The steric hindrance of the amine may also affect the substitution. Indeed, *N*-methylmorpholine, even when used at high concentrations, could not displace the phosphane. The equilibrium constant is not significantly affected by the solvent (entries 1,2,4).

For a given X, amine and solvent, K decreases when the *para* substituent on the aryl group is an electron acceptor (entries 4 and 12, 5 and 13, 8 and 14, and 9 and 15).[24,25] The reaction was not tested with an electron-donor substituent because of the instability of the related *trans*-ArPdX(PPh_3)$_2$ due to scrambling between the Ph group of the ligand and the Ar group.[26,27]

The influence of X (X = I, Br, Cl) on the substitution was tested for a given Ar group, amine and solvent. Whereas for the substitution of PPh_3 by the piperidine K follows the order: Br > Cl > I (entries 4, 8,10; entries 12, 14), a reverse order: I > Br ≈ Cl (entries 5, 9, 11; entries 13,15) is found for the substitution by morpholine. The effect of the halides is hard to rationalize, since they cannot have a *trans* influence on the substitution of the phosphane due to the structure of the initial complexes **1**.[24,25]

In conclusion, ArPdX(PPh_3)(amine) complexes were generated by the reaction of amines with *trans*-ArPdX(PPh_3)$_2$ complexes. The reversible substitution of one PPh_3 group by one amine was characterized by the determination of the equilibrium constant between the two complexes. These results establish that in copper-free Sonogashira reactions, the formation of ArPdX(PPh_3)(amine) complexes has to be taken into account. There will be an evident competition between the alkyne and the amine for the substitution of one PPh_3 group in ArPdX(PPh_3)$_2$ complexes. The fact that the amine is often used in large excess[5,6,8,9] or as the solvent[3,6,7] encourages the substitution of the phosphane by the amine group. Work is in progress to better define the contribution of such new amine complexes in the mechanism of palladium-catalyzed reactions involving amines in copper-free Sonogashira reactions.

Experimental Section

General: All experiments were conducted under argon. The deuterated solvents DMF, THF, acetone and chloroform were obtained commercially and degassed just before use. The amines (piperidine; morpholine, diisopropylamine, terbutylamine), phenyl halides (X = I, Br, Cl), 4-NC–C_6H_4–X (X = Br, Cl), 4-MeOC–C_6H_4–Br, 2-iodothiophene were obtained commercially. The complexes *trans*-ArPdX(PPh_3)$_2$ were synthesized by reacting aryl halides with $Pd^0(PPh_3)_4$.[28–30]

General Procedure for the Ligand Exchange as Monitored by ^1H and ^{31}P NMR Spectroscopy: *trans*-PhPdI(PPh_3)$_2$ (8.3 mg, 0.01 mmol) was introduced in $CDCl_3$ (0.5 mL). The ^1H and ^{31}P NMR spectra were recorded at room temperature. Piperidine (2 μL, 0.02 mmol) was first added, followed by further additions of piperidine (0.02, 0.06 and 0.10 mmol, respectively). ^1H and ^{31}P NMR spectra were recorded after each addition of piperidine.

General Procedure for the Synthesis of ArPdX(PPh_3)(amine): Piperidine (500 μL, 5 mmol) was added to *trans*-PhPdI(PPh_3)$_2$ (83 mg, 0.1 mmol) in chloroform (5 mL). After 30 min, the solution was concentrated under vacuum. Precipitation in pentane gave 48 mg of PhPdI(PPh_3)(piperidine), as a gray-white solid (72 % yield). The isolated complex exhibits the same ^1H and ^{31}P NMR spectra as those recorded during ligand exchange in the NMR tube, but the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protons of the ligated piperidine are more clearly detected because of the absence of excess piperidine. A ^{13}C NMR spectrum was also recorded on the isolated complex to elucidate its structure.

The complexes with morpholine, $ArPdX(PPh_3)$(morpholine), could not be isolated as pure compounds because the equilibrium lies less in favor of their formation than for the formation of $ArPdX(PPh_3)$(piperidine). The reversibility explains the difficulty in their isolation. Consequently, most of them were characterized in situ in solution.

***trans*-PhPdI(PPh$_3$)$_2$:**[28] ^1H NMR (250 MHz, $CDCl_3$, TMS): δ = 6.21 (t, J = 7 Hz, 2 H, *m*-H of Ph), 6.33 (t, J = 7 Hz, 1 H, *p*-H of Ph), 6.60 (d, J = 7 Hz, 2 H, *o*-H of Ph), 7.23 (t, J = 7 Hz, 12 H, *m*-H in PPh_3), 7.32 (t, J = 7 Hz, 6 H, *p*-H in PPh_3), 7.50 (dd, J = 7, J = 6 Hz, 12 H, *o*-H in PPh_3) ppm. ^{13}C NMR (62.89 MHz, $CDCl_3$, TMS): δ = 127.76 (t, J_{C3P} = 5 Hz, C_3 of Ph in PPh_3), 127.90 (t, J_{C3P} = 4 Hz, C_3 of Ph–Pd), 129.69 (s, C_4 of Ph in PPh_3), 131.31 (s, C_4 of Ph–Pd), 132.21 (t, J_{C1P} = 23 Hz, C_1 of Ph in PPh_3), 134.65 (t, J_{C2P} = 6 Hz, C_2 of Ph–Pd), 134.89 (t, J_{C2P} = 6 Hz, C_2 of Ph in PPh_3), 136.03 (t, J_{C1P} = 5 Hz, C_1 of Ph–Pd) ppm. ^{31}P NMR (101 MHz, $CDCl_3$, H_3PO_4): δ = 23.03 (s) ppm.

New Complexes of Divalent Thulium with Substituted Phospholyl and Cyclopentadienyl Ligands

François Nief,*[a] Brice Tayart de Borms,[a] Louis Ricard,[a] and Duncan Carmichael[a]

Keywords: Phosphorus heterocycles / Lanthanides / Subvalent compounds / Thulium / Cyclopentadienyl ligands

In order to try to stabilise the Tm^{II} ion with phospholyl ligands lacking methyl groups at the 3 and 4 positions, the following ligand precursors were prepared: sodium 2,5-di-*tert*-butylphospholyl [Na(Htp)] (**3**) and sodium 2,5-bis(trimethylsilyl)phospholyl [Na(Hsp)] (**8**). Because of its similar steric bulk, we also decided to use sodium di-*tert*-butylcyclopentadienyl [$NaCp^{tt}$] (**9**) as a ligand precursor. Compound **3** was obtained by sodium cleavage of the P–P bond of 2,5,2′,5′-tetra-*tert*-butyl-1,1′-diphosphole (**2**). Halogen-lithium exchange in 1,4-diiodo-1,4-bis(trimethylsilyl)buta-1,3-diene (**4**) followed by reaction with $PhPCl_2$ afforded 1-phenyl-2,5-bis(trimethylsilyl)phosphole (**5**). Treatment of **5** with lithium metal followed by oxidative treatment with iodine gave 2,5,2′,5′-tetrakis(trimethylsilyl)-1,1′-diphosphole (**7**) which could be transformed into **8** by treatment with sodium. Treatment of **3**, **8** and **9** with $[TmI_2(THF)_3]$ in diethylether yielded three new organothulium(II) complexes $[Tm(Htp)_2(THF)]$ (**10**), $[Tm(Hsp)_2(THF)]$ (**11**) and $[Tm(Cp^{tt})_2(THF)]$ (**12**), respectively, which could be isolated pure as crystalline solids in low to moderate yields. Complexes **10**, **11** and **12** were studied by X-ray crystallography and their structures compared with those of two previously described complexes, $[Tm(Cp'')_2(THF)]$ **1** [Cp′′ = 1,3-bis(trimethylsilyl)cyclopentadienyl] and $[Tm(Dtp)_2(THF)]$ (**13**) (Dtp = 3,4-dimethyl-2,5-di-*tert*-butylphospholyl). Although the phospholyl ligands may be slightly more bulky than their cyclopentadienyl counterparts, the structures of **1**, **10**, **11** and **12** are remarkably similar and are substantially different from that of the more bulky **13**.

Introduction

For a long time, the coordination chemistry of divalent lanthanide (Ln) ions has been limited to the classical Eu^{II}, Yb^{II} and Sm^{II}.[1] Although other Ln^{II} species can exit in the solid state, these ions were until recently considered too reactive to be isolated as molecular compounds.[2]

However, this statement has been challenged very recently by the isolation of molecular solvates of the type $[MI_2(solv.)_n]$ where M = Nd, Dy or Tm and solv. is a donor solvent such as THF or dimethoxyethane (DME).[3–7] As expected, these species are highly reducing. While solvated TmI_2[3,4] is reasonably stable, solvated DyI_2[6] and NdI_2[7] are highly reactive complexes which are only stable below room temperature.

In coordination chemistry, no other complexes of Nd^{II} and Dy^{II} have been isolated up to now although their transient nature has been postulated in trapping reactions. Likewise, some transient Tm^{II} complexes have also been observed this way. For instance the M^{II} cations can be trapped with nitrogen, forming [μ-(N_2^{2-})] complexes[8–10] or by oxidative splitting of the coordinated solvent[8,11] or the ligand[12] thus yielding M^{III} complexes. They are also able to reduce aromatic hydrocarbons[6,13] or acetonitrile.[14] Interestingly, reduction of Ho^{III} or Y^{III} amides in the presence of nitrogen also yields products in which N_2 has been activated.[15]

In the case of Tm^{II}, however, after some unsuccessful attempts, Evans et al. isolated the first structurally characterised organometallic complex of thulium(II), $[TmCp''_2(THF)]$ (**1**) [Cp′′ = $C_5H_3(SiMe_3)_2$].[8] Since then, by using very bulky phospholyl or arsolyl ligands, we have been able to isolate several other Tm^{II} compounds[16,17] including a homoleptic complex.[17] The chemistry of the "new" divalent lanthanides has been very recently reviewed.[18]

The phospholyl and arsolyl ligands appear particularly suitable for the stabilisation of low-valent complexes because of their reduced π-donating ability. So far, we have used the following ligands around Tm^{II}: Dsp = $PC_4Me_2(Tms)_2$, Dsas = $AsC_4Me_2(Tms)_2$ and Dtp = $PC_4Me_2tBu_2$. These ligands differ from the Cp′′ ligand by the presence of the heteroatom in the ring but also by their higher bulkiness due to the presence of two extra methyl groups as substituents.

At this point, we wanted to expand the scope of Tm^{II} chemistry by synthesising new complexes which would be sterically more similar to that of Evans (**1**).[8] Thus, we decided to attempt to stabilise the Tm^{II} ion with phospholyl

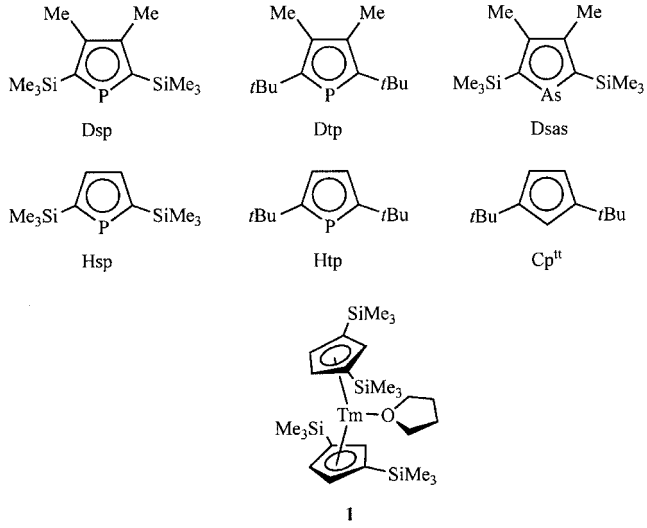
ligands lacking the two methyl groups on the rings which are present in Dsp and Dtp. These ligands are Hsp = $PC_4H_2(Tms)_2$ and Htp = $PC_4H_2tBu_2$. In order to have a complete picture, we also decided to use the well known Cp^{tt} ligand [Cp^{tt} = $C_5H_3tBu_2$] (Scheme 1). Interestingly, Lappert has recently characterised an unusual La^{II} anionic complex with this ligand, namely [K(18-crown-6)(η-$C_6H_6)_2$][$(LaCp^{tt}_2)_2$(μ-C_6H_6)] by reduction of the trivalent precursor [$(LaCp^{tt}_2)_3$].[19]



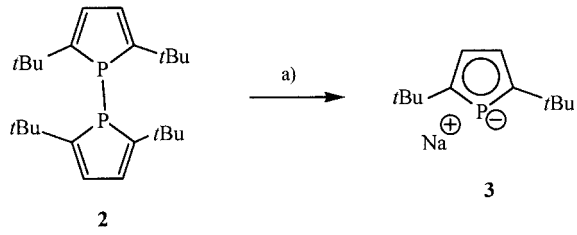
Scheme 1. Ligands and complexes in Tm^{II} chemistry

In this paper we report the synthesis of the new ligand Hsp, the synthesis of three new Tm^{II} complexes with the Hsp, Htp and Cp^{tt} ligands, and a structural study of these complexes by comparison with that of **1**.

Results and Discussion

Ligands

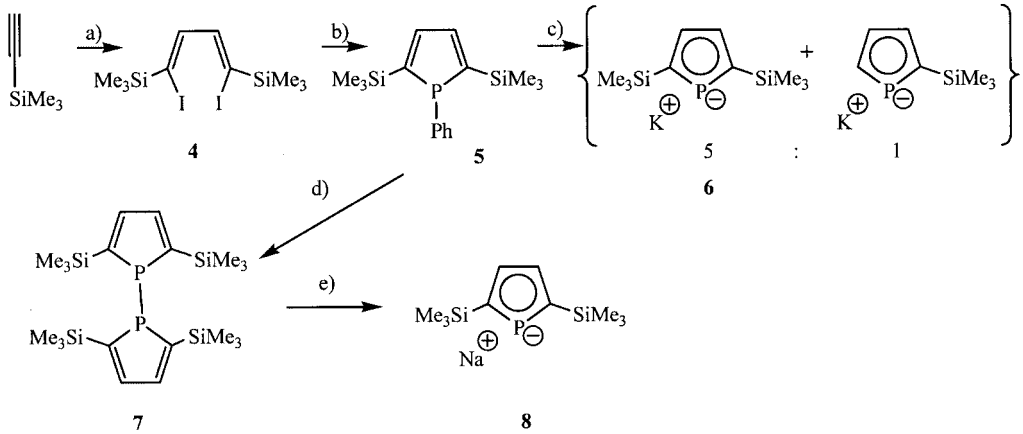
The synthesis of 2,5,2′,5′-tetra-*tert*-butyl-1,1′-diphosphole $(Htp)_2$ (**2**) has been described in the literature.[20] The new ligand precursor [Na(Htp)] (**3**) was simply obtained in good yield by sodium cleavage of the P–P bond in **2** (Scheme 2).



Scheme 2. Synthesis of Na(Htp) (**3**); reagents and conditions: a) excess Na, THF, room temp., 85%

The Hsp ring has not been described in the literature although Sato et al. have recently described a silole (silacyclopentadiene) possessing the same substituents on the heterocyclic ring. These authors, using trimethylsilylacetylene as a starting material, employed Ti^{II}-based chemistry in order to prepare 1,4-diiodo-1,4-bis(trimethylsilyl)buta-1,3-diene (**4**) as a key intermediate. Further iodine-lithium exchange followed by treatment with $Si(OEt)_4$ allowed them to isolate 1,1-dimethoxy-2,5-bis(trimethylsilyl)silole.[21]

Compound **4** was prepared with slight modifications to the original procedure due to scale-up. Iodine-lithium exchange in **4** with *n*BuLi in Et_2O followed by treatment with $PhPCl_2$ gave 1-phenyl-2,5-bis(trimethylsilyl)phosphole (**5**) in fair yield. Further treatment of **5** with potassium metal under the conditions previously used for the synthesis of [K(Dsp)][16] was less satisfactory and although [K(Hsp)] (**6**) was obtained as the major product, it was invariably contaminated with up to 20% of a product resulting from desilylation, i.e. [K{$PC_4H_3(SiMe_3)$}] (^{31}P NMR: δ = 116 ppm). Although repeated extraction of the crude solid with Et_2O could reduce the side product content of **6** to less than 10%, we nevertheless sought a better synthesis of the Hsp anion. We found that no concomitant desilylation took place when **4** was treated with lithium instead of potassium and the



Scheme 3. Synthesis of Na(Hsp) (**8**); reagents and conditions: a) $Ti(OiPr)_4$ + *i*PrMgCl, Et_2O, –78 °C to –50 °C, 2 h, then I_2, –50 °C to room temp., 2 h, 67%; b) 2 *n*BuLi, Et_2O, –78° to room temp., 1h, then $PhPCl_2$, –78° to room temp., 30 min, 42%; c) excess K, DME, 70 °C, 2h; d) excess Li, THF, room temp., 3 h, then $AlCl_3$, 0 °C, 30 min, then I_2, room temp., 15min, 66%; e) excess Na, THF, room temp., 79%

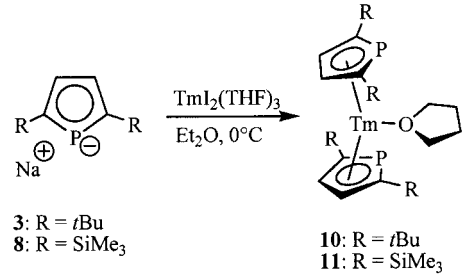
resultant [Li(Hsp)] could be transformed, in situ, into $(Hsp)_2$ (**7**) by treatment with iodine. Pure [Na(Hsp)] (**8**) was then obtained by treatment of **7** with sodium in THF (Scheme 3).

Finally, 1,3-di-*tert*-butylcyclopentadiene (HCp^{tt}) was prepared by literature methods[22] and transformed into [$NaCp^{tt}$] (**9**) by treatment with $NaNH_2$ in THF.[23]



Scheme 4. Synthesis of Tm^{II} phospholyl complexes

New Complexes of Thulium(II)

We then tried to synthesise Tm^{II} complexes of the Htp, Hsp and Cp^{tt} ligands by utilising their sodium salts (**3**, **8**, and **9**, respectively) in reactions with [$TmI_2(THF)_3$], in a 2:1 mole ratio, at 0 °C and with diethylether as a solvent. With the phospholyl anions **3** and **8**, the reaction mixtures quickly turned dark green. After 1 hour, the solutions were checked by ^{31}P NMR spectroscopy and the spectra showed complete disappearance of the starting anions and the presence of two new, broad peaks at δ = –290 and –235 ppm, respectively, with Htp and Hsp as the ligands. These signals provided good evidence for the presence of Tm^{II} phospholyl complexes, their chemical shifts being similar to those of the already described [$Tm(Dtp)_2(THF)$] and [$Tm(Dsp)_2$-(THF)].[16] Complexes formulated as [$Tm(Htp)_2(THF)$] (**10**) and [$Tm(Hsp)_2(THF)$] (**11**) could be subsequently isolated as dark green crystalline powders from pentane at –30 °C (Scheme 4).

Complexes **10** and **11** exhibit reasonably well-resolved (and quite similar) proton NMR spectra in C_6D_6. Whilst the methyl groups could be clearly identified at low field (δ = 57 ppm for **10** and 43 ppm for **11**), the remaining signals (corresponding to the coordinated THF and the β-protons on the ring) were present as three sets of broad humps at high field which were difficult to integrate accurately due to their large width and baseline roll. In order to simplify this situation, we decided to prepare an analogue of **10** in which the THF was replaced by perdeuterated THF. This was accomplished by allowing **3** to react with unsolvated TmI_2 in diethylether in the presence ofca. 0.1 mL of [D_8]THF. Afterstandard workup, [$Tm(Htp)_2$([D_8]THF)] (**10-d**) could be isolated and its proton spectrum is presented below together with that of **10** (Figure 1).

A comparison of these spectra suggests that the signals around –30 ppm and –45 ppm in **10** belong to the THF solvent and that the peak at highest field around –70 ppm corresponds to the β-protons on the phospholyl ring. The assignment of the high-field signals in the spectrum of **11** was inferred accordingly (see experimental section). Finally, magnetic susceptibility measurements confirmed the +II oxidation state of thulium in **10** and **11**.

The reaction of **9** with [$TmI_2(THF)_3$] proceeded similarly to those described above but the solution colour was purplish-red. Evaporation to dryness of the filtered solution induced some apparent decomposition of the product since further extraction with pentane invariably resulted in the

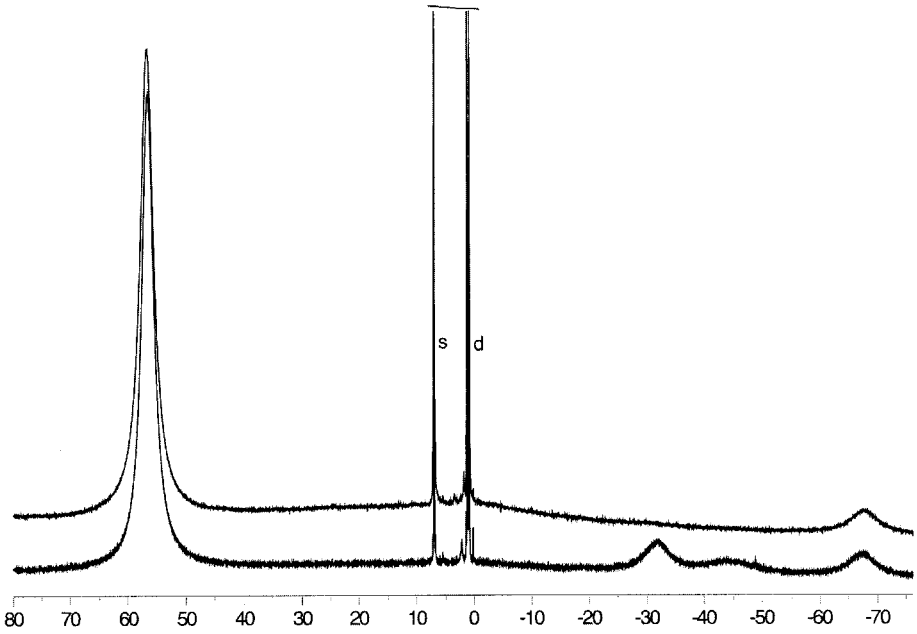


Figure 1. Proton NMR spectra (C_6D_6 solutions, ppm values) of **10**–**d** (upper trace) and **10** (lower trace) (s = C_6D_5H, d = diamagnetic impurities)

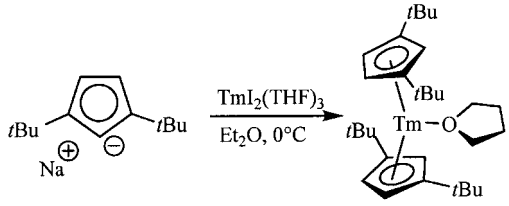
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

precipitation of large amounts of white, insoluble material (this was not the case with the phospholyl compounds). We found that a red crystalline solid, formulated as [Tm(Cp^{tt})$_2$(THF)] (**12**) could be obtained in low yield by concentrating the filtered reaction mixture by evaporation of diethylether and allowing the solution to stand at –30 °C for two days. The proton NMR spectra of a solution of these crystals in [D_6]benzene or [D_{12}]cyclohexanedisplayed a peak at δ = 63 ppm which can reasonably be attributed to the methyl groups but the other parts of the spectra were less clear. We found that for **12** μ_{eff}= 4.6 μ_B, a value which is compatible with Tm^{II} (Scheme 5).



9 **12**

Scheme 5. Synthesis of a Tm^{II} cyclopentadienyl complex

Diethyl ether solutions of **10**, **11** and **12** were then exposed to 1atm. of nitrogen. In the case of **10** and **11**, no reaction had taken place after 24h at room temperature. In contrast, in the case of **12**, a colour change to light brown occurred within a few minutes. Unfortunately, however, despite several attempts, we could not isolate any crystalline product from this reaction mixture. Thus, no definite compounds could be isolated from the reaction of our new Tm^{II} complexes with N_2. Nevertheless, we can confirm that coordination of the phospholyl ligand considerably lessens the reactivity of thulium(II).

X-ray Crystal Structures

Suitable crystals of **10**, **11** and **12** were obtained by low-temperature crystallisation. A summary of the X-ray data is presented in Table 1 and Figure 2 shows ORTEP plots of one molecule each of **10**, **11** and **12**, respectively.

In the structures of **11** and **12**, the Tm–O bond coincides with a crystallographic symmetry axis. In addition, in **12**, the coordinated THF molecule is disordered over two positions and only one is presented in Figure 2. Table 2 displays relevant distances and angles for **10**, **11** and **12** together with relevant data for **1**[8] (the trimethylsilyl analogue of **12**) and [Tm(Dtp)$_2$(THF)] **13**[16] (analogue of **10** with two methyl substituents on the phospholyl ring).

The structures of **1**, **10**, **11** and **12** are strikingly similar. The Tm–O bond lengths and the ligand bending, as indicated by both the centroid-Tm-centroid angles and the dihedral angles between the mean planes of the π-ligands (referred to as ligand plane angles in Table 2), are almost identical in these four complexes. The main difference between the phospholyl complexes **10** and **11** and their cyclopentadienyl analogues (**12** and **1**, respectively) is that in **10** and **11** the C–Tm bonds are longer. This is probably due to the fact that the phospholyl complexes have to accommodate a long P–Tm bond in the Tm^{II} coordination sphere. Incidentally, this bond length in **10** and **11** falls in the range of the tabulated values for Yb^{II}–P bonds[24] (the ionic radii of Yb^{II} and Tm^{II} are similar). On these grounds, the steric bulk of the Hsp and Htp ligands should be larger than their all-carbon counterparts (Cp'' and Cp^{tt}, respectively). However, this is not reflected by the Tm–O distances and ligand bending in **1**, **10**, **11** and **12**. On the contrary, in **13**, all parameters relevant to steric crowding (Tm–O and Tm–C bond lengths, cnt–Tm–cnt and ligand plane angles) are higher than in **1**, **10**, **11** and **12**. This is most likely due to inter-

ring steric repulsion of the methyl groups in **13**. Thus, adding methyl groups to the ring induces more structural changes than a CH ↔ P substitution.

Conclusions

In this report, we have described access to the new 2,5-bis(trimethylsilyl)phospholyl (Hsp) ring system and the successful isolation of two new Tm^{II} phospholyl complexes, [$Tm(Htp)_2(THF)$] (**10**) and [$Tm(Hsp)_2(THF)$] (**11**) as well as the second Tm^{II} cyclopentadienyl complex, [$Tm(Cp^{tt})_2$-(THF)] (**12**). Preliminary studies seem to indicate that the reactivity of **12** is higher than that of **10** and **11**.

We feel that organothulium(II) π complexes can no longer be considered as rarities. They are not especially difficult to isolate as long as the ligands provide adequate steric protection of the Tm^{II} environment and oxygen, nitrogen and water are excluded during their synthesis. We are convinced that many more Tm^{II} compounds can be made, thus opening the way to more studies of the chemistry of divalent thulium.

Experimental Section

General Remarks: All manipulations involving lanthanide complexes were performed on a vacuum line or in a drybox under argon using dry, oxygen-free solvents. All other reactions were performed in Schlenk glassware under nitrogen. Diphosphole (**2**)[20] and TmI_2[17] were prepared as described previously. [$TmI_2(THF)_3$] was obtained by extraction of TmI_2 with THF. All other reagents were commercial and used as received from the suppliers. Magnetic susceptibility data were obtained by the Evans NMR method. Elemental analyses were performed at the Service de microanalyse du CNRS, Gif-sur-Yvette, France, and at the Service de microanalyse de l′université de Dijon, Dijon, France.

Phospholyl 3: To a solution of diphosphole **2**[20] (1.5 g, 3.84 mmol) in THF (30 mL) at room temperature was added excess sodium in small pieces (0.35 g). After 3 h, the remaining sodium was removed from the reaction mixture which was then evaporated to dryness under vacuum. The residue was rinsed with hexane and sodium 2,5-di-*tert*-butylphospholyl (**3**) was obtained as an air-sensitive white powder which was dried in vacuo (1.43 g, 6.55 mmol, 85%). ^{1}H NMR (300 MHz, [D_8]THF): δ = 1.32 (s, 18 H, CH_3), 6.47 ppm (d, J_{HP} = 4 Hz, 2 H, CH). ^{13}C NMR (75.5 MHz, [D_8]THF): δ = 35.2 (d, J_{CP} = 18 Hz, C), 35.3 (d, J_{CP} = 8 Hz, CH_3), 113.1 (d, J_{CP} = 2 Hz, C3), 160.3 ppm (d, J_{CP} = 47 Hz, C2). ^{31}P NMR (122 MHz, [D_8]THF): δ = 56 ppm.

Diiodide 4:[21] This was prepared by a modification of the literature procedure. To a diethylether (300 mL) solution of $Ti(OiPr)_4$ (18 mL, 17.28 g, 60.7 mmol) and TmsCCH (14 mL, 9.94 g, 103 mmol) at –70 °C was added an ether solution of *i*PrMgCl (60 mL of 2 M soln., 120 mmol) The mixture was warmed to –50 °C over 1 h. After stirring for an additional 1 h, I_2 (31.75g, 125 mmol) was added as a solid to the mixture at –50 °C. The mixture was warmed to room temperature and stirred for 2 h. A saturated aqueous solution of $Na_2S_2O_3$ was then added and the mixture was extracted with hexane. The extract was dried with $MgSO_4$, filtered and evaporated whereupon the resultant oil partially crystallised. The residue was recrystallised from methanol at 0 °C and 1,4-diiodo-1,4-bis(trimethylsilyl)buta-1,3-diene (**4**) (15.15g, 33.6 mmol, 67%) was obtained as tan crystals. ^{1}H NMR (300 MHz, C_6D_6): δ = 0.14 (s, 18 H, CH_3), 7.31 ppm (s, 2 H, CH).

Phosphole 5: A solution of diiodide **4** (9 g, 20 mmol) in diethylether (80 mL) was cooled to –78 °C and a solution of *n*BuLi in hexane (30 mL of 1.33 M soln., 40 mmol) was added dropwise. After 1 h stirring at this temperature, a solution of $PhPCl_2$ (4.5 g, 25 mmol)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in hexane (20 mL) was added dropwise and the reaction mixture was allowed to warm to room temperature. The solution was then evaporated to dryness and taken up in a 1:1 hexane/satd. aq. $NaHCO_3$ mixture (200 mL). This mixture was decanted, the aqueous phase extracted with hexane, the combined organic phases dried with $MgSO_4$ and the solvents evaporated to dryness. The residue was chromatographed on silica gel using hexane as the eluent. The compound 1-phenyl-2,5-bis(trimethylsilyl)phosphole (**5**) was obtained as a colourless oil (2.55 g, 8.37 mmol, 42%). ^{1}H NMR (300 MHz, C_6D_6): δ = 0.11 (s, 18 H, CH_3) 6.95 (m, 3 H, Ph), 7.21 (d, J_{HP} = 19.5 Hz, 2 H, CH), 7.25 ppm (m, 2 H, Ph). ^{13}C NMR (75.5 MHz, C_6D_6): δ = 0.18 (d, J_{CP} = 2.5 Hz, CH_3), 128.4 (d, J_{CP} = 9.0 Hz, C *meta*-Ph), 129.8 (d, J_{CP} = 1.5 Hz, C *para*-Ph), 131.0 (d, J_{CP} = 8.5 Hz, C *ipso*-Ph), 135.0 (d, J_{CP} = 20.5 Hz, C *ortho*-Ph), 144.9 (d, J_{CP} = 10.5 Hz, C3), 158.4 ppm (d, J_{CP} = 31.5 Hz, C2). ^{31}P NMR (122 MHz, C_6D_6): δ = 38.5 ppm. MS (70 eV, CI/NH_3): *m*/*z* (%) 305 $[M + H]^+$ (100). $C_{16}H_{25}PSi$ (304.5): calcd. C 63.1, H 8.3; found C 63.0, H 8.3.

Diphosphole 7: A solution of phosphole **5** (1 g, 3.28 mmol) in THF (30 mL) was treated with lithium metal (0.18 g, excess). After 3 h at room temperature, the excess lithium was removed and the solution was treated with $AlCl_3$ (0.15 g, 1.1 mmol). After 30min at room temperature, solid iodine (0.42 g, 1.64 mmol) was added to the reaction mixture which was then evaporated to dryness under vacuum. The crystalline residue was dissolved in hexane, the solution was evaporated and the resultant solid recrystallised from methanol. The product 2,5,2′,5′-tetrakis(trimethylsilyl)-1,1′-diphosphole (**7**) was obtained as pale yellow crystals (0.49 g, 2.16 mmol, 66%). ^{1}H NMR (300 MHz, C_6D_6): δ = 0.27 (s, 36 H, CH_3), 7.22 ppm (pseudo-t, $J_{HP(app.)}$ = 22 Hz, 4 H, CH). ^{13}C NMR (75.5 MHz, C_6D_6): δ = 0.63 (s, CH_3) 144.6 (pseudo-t, $J_{CP(app.)}$ = 16 Hz, C3), 152.1 ppm (pseudo-t, $J_{CP(app.)}$ = 37 Hz, C2). ^{31}P NMR (122 MHz, C_6D_6): δ = –3 ppm. MS (70 eV, CI/NH_3) *m*/*z* (%) 455 $[M + H]^+$ (100). $C_{20}H_{40}P_2Si_4$ (454.8): calcd. C 52.8, H 8.9; found C 52.7, H 9.0.

Phospholyl 8: This was prepared similarly to **3** by cleavage of diphosphole **7** (0.3 g, 0.66 mmol) with sodium (0.15 g, excess) in THF solution (10 mL). Yield: 0.26 g (1.04 mmol, 79%) of sodium 2,5-bis(trimethylsilyl)phospholyl (**8**) as an air-sensitive white powder. ^{1}H NMR (300 MHz, [D$_8$]THF): δ = 0.19 (s, 18 H, CH_3), 7.14 ppm (d, J_{HP} = 8.5 Hz, 2 H, CH). ^{13}C NMR (75.5 MHz, [D$_8$]THF): δ = 2.50 (d, J_{CP} = 2 Hz, CH_3) 127.5 (d, J_{CP} = 2 Hz, C3), 144.4 ppm (d., J_{CP} = 67.5 Hz, C2). ^{31}P NMR (122 MHz, [D$_8$]THF): δ = 145 ppm. $C_{10}H_{20}NaPSi_2$ (250.4): calcd. C 48.0, H 8.0; found C 48.0, H 7.6.

General Method for the Synthesis of the Tm^{II} Complexes: Dry diethylether was condensed at –78 °C onto a mixture of $TmI_2(THF)_3$ (1 equiv.) and the anions **3**, **8** or **9** (2 equiv.). The reaction mixture was stirred at 0 °C for 2 h then worked up as described below.

Complex 10: This was prepared from $TmI_2(THF)_3$ (0.150 g, 0.23 mmol) and **3** (0.102 g, 0.47 mmol). The dark green solution was evaporated to dryness and the residue extracted with pentane. The pentane solution was evaporated to dryness and the residue rinsed with cold pentane. Yield 0.056 g of **6** as dark green crystals (0.089 mmol, 38%). ^{1}H NMR (300 MHz, C_6D_6): δ = –68 (br., 4 H, CH), –44 (br., 4 H, THF), –32 (br., 4 H, THF), 57 ppm (br., 36 H, CH_3). ^{31}P NMR (122 MHz, C_6D_6): δ = –290 ppm (br). μ_{eff} = 4.7 μ_B.

Complex 11: This was prepared from $TmI_2(THF)_3$ (0.128 g, 0.200 mmol) and **8** (0.100 g, 0.40 mmol). The dark green solution was filtered, evaporated to dryness and the residue dissolved in pentane. The pentane solution was filtered, concentrated to a small volume and cooled to –30 °C whereupon the product crystallised. Complex **11** was obtained as dark green crystals (0.067 g, 0.096 mmol, 48%). ^{1}H NMR (300 MHz, C_6D_6): δ = –63 (br., 4 H, CH), –52 (br., 4 H, THF), –34 (br., 4 H, THF), 43 ppm (br., 36 H, CH_3). ^{31}P NMR (122 MHz, C_6D_6): δ = –240 ppm (br. s). μ_{eff} = 4.7 μ_B.

Complex 12: This was prepared from $TmI_2(THF)_3$ (0.200 g, 0.31 mmol) and **9** (0.26 g, 0.62 mmol). The purplish-red solution was filtered and concentrated to a small volume and this solution was kept for 2 days at –30 °C whereupon the product crystallised. Complex **11** was obtained as a dark reddish-purple powder (0.036 g, 0.06 mmol, 19%). ^{1}H NMR (300 MHz, C_6D_6): δ = 63 ppm (br. s, CH_3). Other small peaks were present at 89, 83 and –77 ppm. μ_{eff}= 4.6 μ_B.

X-ray Crystallographic Study: Suitable single-crystals of **10** and **11** were obtained from saturated pentane solutions at –30 °C and those of **12** were obtained from a saturated diethylether solution at –30 °C. X-ray intensities were measured with a Nonius KappaCCD diffractometer at 150(1) K using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). A summary of the crystal structure determinations is presented in Table 1. CCDC-250697–250699 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Azaferrocenophanes with Azobenzene-Containing Ligands − Protonation and Electrochemical Oxidation of the Molecule Influences the Absorption Spectra and *cis*−*trans* Isomerization of the Azobenzene Group

Tatsuaki Sakano,[a] Masaki Horie,[a] Kohtaro Osakada,*[a] and Hidenobu Nakao[b]

Keywords: Azobenzene / Chromophores / Ferrocene / Photochemistry / Redox chemistry

N-{4-(Phenylazo)phenyl}aminophenyl-2-aza-[3]-ferrocenophane (**4**) and *N*-{3-(phenylazo)phenyl}aminophenyl-2-aza-[3]-ferrocenophane (**5**) have been prepared by C–N bond-forming reactions catalyzed by Ru and Pd complexes. The absorption peaks due to the π–π^* transition of the *trans*-azobenzene group of **4** and **5** appear at 442 and 426 nm, respectively, in toluene. Photoirradiation of solutions of **4** and **5** at 420 nm causes partial isomerization of the *trans*-azobenzene group to *cis*-azobenzene and reaches a photostationary state. The compounds at the photostationary state undergo thermal isomerization of the *cis*-azobenzene group to the *trans* isomer. The isomerization after one-electron oxidation of the compounds takes place more rapidly than that without electrochemical oxidation.

Introduction

Several organometallic compounds have potential utility as materials for opto-electronic devices which exhibit electroluminescence, liquid-crystalline properties, and perform as biosensors.[1] The introduction of functional groups to the cyclopentadienyl ligands of ferrocene forms ferrocene derivatives, which can be utilized as a mediator and electron donor in electrochemical reactions and electron-transfer systems.[2] Since azobenzene changes its molecular shape and the absorption peak positions upon photoirradiation or heating,[3] binding the ferrocene and azobenzene with a suitable linker would provide compounds where the electrochemical properties of the Fe center and the optical response of the organic group are linked to each other.[4] Nishihara has reported the unique properties of *m*-ferrocenylazobenzene, in which azobenzene is directly bonded to a cyclopentadienyl ligand.[5] One-electron oxidation of the compound led to the formation of a *trans*-rich mixture in the Fe^{III} state upon irradiation with a single green light, while it was converted to a *cis*-rich mixture upon electrochemical reduction to Fe^{II}.

Recently we have prepared ferrocene derivatives with an aminomethyl substituent at the cyclopentadienyl ligand and found electrochemical communication between the ferrocene and the organic group of the ligand by electron transfer between the Fe center and the N atom.[6] N-Substituted 2-aza-[3]-ferrocenophanes also undergo similar electron transfer between the metal center and the organic group of the ligand.[7,8] These compounds may show cooperative responses to a photo- or electrochemical stimulus. In this paper we report the preparation of new 2-aza-[3]-ferrocenophanes containing azobenzene in the ligand, as well as their molecular structures and their absorption spectra, which change upon protonation and electrochemical oxidation. Part of this work has been reported in a preliminary form.[9]

Results and Discussions

Preparation and Characterization

The synthesis of the new ferrocenophanes with an azobenzene group is summarized in Scheme 1. Dehydrative condensation of 1,1′-ferrocenedimethanol with 4-aminoazobenzene catalyzed by $[RuCl_2(PPh_3)_3]$[10] produces *N*-{4-(phenylazo)phenyl}-2-aza-[3]-ferrocenophane (**1**). Similar reactions with 4-bromoaniline and with 3-bromoaniline form *N*-(4-bromophenyl)-2-aza-[3]-ferrocenophane (**2**) and *N*-(3-bromophenyl)-2-aza-[3]-ferrocenophane (**3**), respectively. The ferrocenophanes react with 4-(phenylamino)azobenzene in the presence of $Pd_2(dba)_3$/P*t*Bu$_3$ [dba = di-(benzylidene)acetone] catalyst and NaO*t*Bu to afford *N*-{4-(phenylazo)phenyl}-2-aza-[3]-ferrocenophane (**4**) and *N*-{3-(phenylazo)phenyl}-2-aza-[3]-ferrocenophane (**5**), respectively. Analogous Pd-catalyzed cross-coupling reactions of bromoarene with secondary amines have been reported to form a new C−N bond.[11−13]

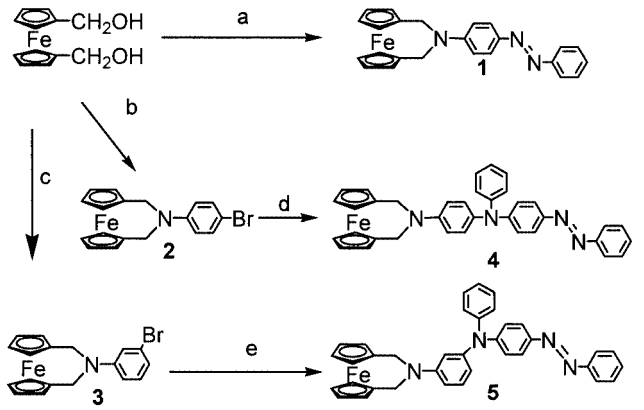

Scheme 1. (a) 4-phenylazoaniline (1 equiv.), $[RuCl_2(PPh_3)_3]$ (5 mol %), 180 °C, NMP; (b) 4-bromoaniline (1 equiv.), $[RuCl_2(PPh_3)_3]$ (5 mol %), 180 °C, NMP; (c) 3-bromoaniline (1 equiv.), $[RuCl_2(PPh_3)_3]$ (5 mol %), 180 °C, NMP; (d) 4-phenylazodiphenylamine (1 equiv.), $[Pd_2(dba)_3]$ (1.3 mol %), NaO*t*Bu (1.5 equiv.), P(*t*Bu)$_3$ (7.5 mol %), 100 °C, toluene

The ferrocenophanes with azobenzene-containing ligands (**1**, **4**, and **5**) were characterized by NMR spectroscopy and X-ray crystallography. Figure 1 depicts the molecular structures of **1**, **4**, and **5**, as determined by X-ray crystallography. The two cyclopentadienyl ligands have a staggered conformation, similar to other structurally characterized [3]-ferrocenophanes.[8,9] The diazene moiety (N=N bond) in the compounds has a *trans* conformation [N=N bond lengths: **1**: 1.276(7) Å; **4**: 1.232(7) and 1.197(7) Å; **5**: 1.227(5) Å; C−N=N bond angles: **1**: 113.3(6) and 116.2(6)°; **4**: 113.0(6), 110.4(6), 109.7(6), and 109.1(6)°; **5**: 112.1(5) and 113.2(5)°]. The N−C(phenyl) bond in the ferrocenophane ring [**1**: 1.355(8) Å; **4**: 1.393(8) and 1.398(8) Å; **5**: 1.384(4) Å] is shorter than the N−CH_2 bond (1.45−1.48 Å), which suggests a partial double-bond character of the former.[14]

Absorption Spectra and trans−cis Isomerization

Figure 2 shows the absorption spectra of **1**, **4**, and **5**. These complexes have peaks due to the π−π* transition of the *trans*-azobenzene group at 413 nm (**1**; ε = 19900 $M^{-1}\cdot cm^{-1}$), 442 nm (**4**; ε = 28000 $M^{-1}\cdot cm^{-1}$), and 426 nm (**5**; ε = 31500 $M^{-1}\cdot cm^{-1}$). The order of wavelengths of the π−π* transition, **4** > **5** > **1**, can be attributed to different degrees of π-conjugation of the azobenzene-containing ligands. Compound **4**, with a *p*-diaminophenylene group bonded to the phenylaminoazobenzene group, has the absorption peak at longer wavelength than **1**, without a diaminophenylene group, and **5**, with a *m*-diaminophenylene group.

The *trans*-azobenzene group of **4** undergoes partial isomerization to the *cis* form upon irradiation at 420 nm (Xenon lamp). Figure 3a shows change of the absorption spectra during the reaction at 25 °C in toluene. The peak intensity of the π−π* band of the *trans*-azobenzene group of **4** decreases in intensity and is accompanied by a shift of the peak to 457 nm. The new minor absorption is assigned to the n−π* transition of the *cis*-azobenzene group formed by photo-induced isomerization. The intensity of the ab-

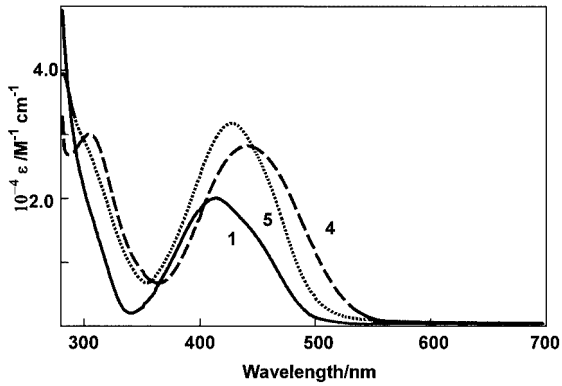

Figure 2. Absorption spectra of **1** (2.5×10^{-5} M in $CHCl_3$, solid line), **4** (2.5×10^{-5} M in toluene, dashed line), and **5** (2.5×10^{-5} M in toluene, dotted line) at 25 °C; wavelength at maximum absorbance and absorption coefficients are determined as: λ_{max} = 413 nm and ε = 19900 $M^{-1}\cdot cm^{-1}$ (**1**); λ_{max} = 442 nm and ε = 28000 $M^{-1}\cdot cm^{-1}$ (**4**); λ_{max} = 426 nm and ε = 31500 $M^{-1}\cdot cm^{-1}$ (**5**)

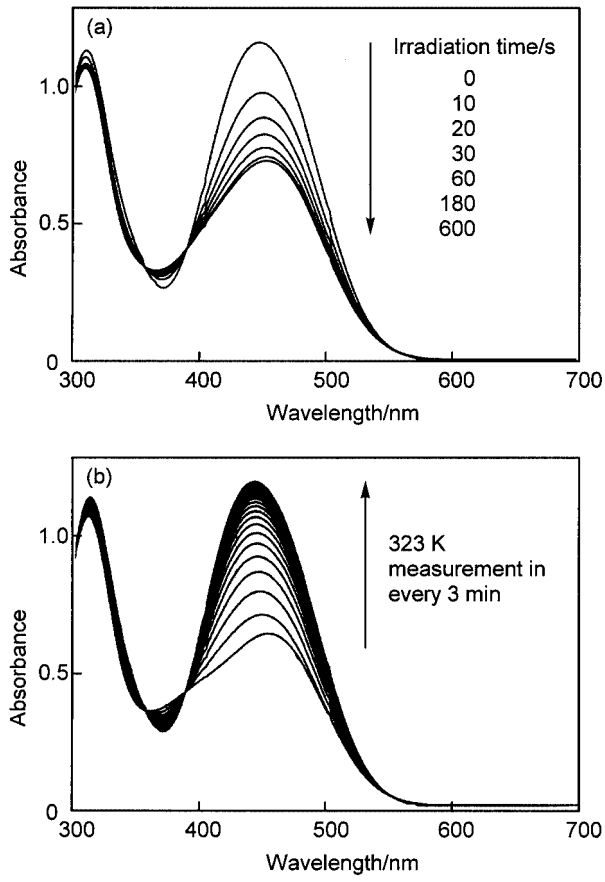

Figure 3. Change of the absorption spectrum of **4** caused by (a) photoisomerization with irradiation at 420 nm at 25 °C in toluene, and (b) thermal isomerization of the photostationary state at 50 °C in toluene

sorbance at 442 nm decreases to 41% of the original spectrum of **4**.

Heating the solution of **4** at the photostationary state in the dark at 50 °C causes growth of the π−π* band of *trans*-azobenzene group (Figure 3b). Recovery of the absorbance of **4** with all the azobenzene groups *trans* takes 30 min at this temperature. The spectra taken during the photo-induced isomerization of the *trans*-azobenzene group to *cis* the structure and thermal isomerization in the reverse direction contain isosbestic points at 335 nm and 387 nm, respectively. Table 1 summarizes the kinetic data of the thermal isomerization of **4** monitored by the increase of the absorbance at 430 nm at 30−70 °C. The reaction obeys first-order kinetics with respect to the concentration of the *cis*-azobenzene group. The reaction enthalpies are estimated to be 9.5 kcal·mol^{-1} in toluene and 7.9 kcal mol^{-1} in MeCN. Compound **5** also undergoes photochemical isomerization of the *trans*-azobenzene group to the *cis* form and thermally induced isomerization of the *cis*-azobenzene group to the *trans* form. The reaction enthalpies of the latter reaction were determined to be 13.5 kcal mol^{-1} and 7.0 kcal mol^{-1} in toluene and in MeCN, respectively. The rate constants of the reaction in toluene are larger than those in MeCN.

Table 1. Kinetic data of the thermally induced *cis*-to-*trans* isomerization

	Solvent	10^3 k_{obs} (s^{-1})			$\Delta H^{\ddagger}$ (kcal mol^{-1})
		323 K	333 K	343 K	
4	toluene	1.02	2.63	5.99	9.5
4	MeCN	0.83	1.93	3.81	7.9
5	toluene	4.01	5.30	10.3	13.5
5	MeCN	0.48	0.92	1.88	7.0

Protonation of 1 and 4

Addition of CF_3COOH to $CHCl_3$ solutions of **1** and **4** with *trans*-azobenzene groups causes a significant change of the spectra, as shown in Figure 4. Addition of CF_3COOH to the solution of **1** causes a decrease in the intensity of the π−π* transition peak at 398 nm and the growth of a new peak at 550 nm (Figure 4a). An isosbestic point at 460 nm is observed throughout the reaction. The new peak can be assigned to a diazaquinoid structure by comparison of the peak position with those of oxidized species of polyaniline and *p*-bis(dimethylamino)benzene.[15] Protonation of 4-(phenylamino)azobenzene with CF_3COOH also results in a decrease of the intensity of the initial peak at 400 nm and the growth of a new peak at 541 nm. Scheme 2 shows a plausible pathway to account for the change of the spectra. Initial protonation takes place either at the nitrogen of the ferrocenophane or the nitrogen of azobenzene. The two species formed can be transformed reversibly into each other by proton transfer. The species protonated at the azobenzene nitrogen is stabilized by a contribution from structure **A**, with a diazaquinoid group. The absorption of the protonated compound at 550 nm is attributed to structure **A**.

Protonation of compound **4** occurs in a stepwise manner, as shown in Figure 4b. Initial addition of CF_3COOH causes a shift of the peak at 450 nm to 405 nm, which is a similar position to **1**. Further addition of CF_3COOH causes a decrease of the intensity of the peak at 405 nm with concomi-

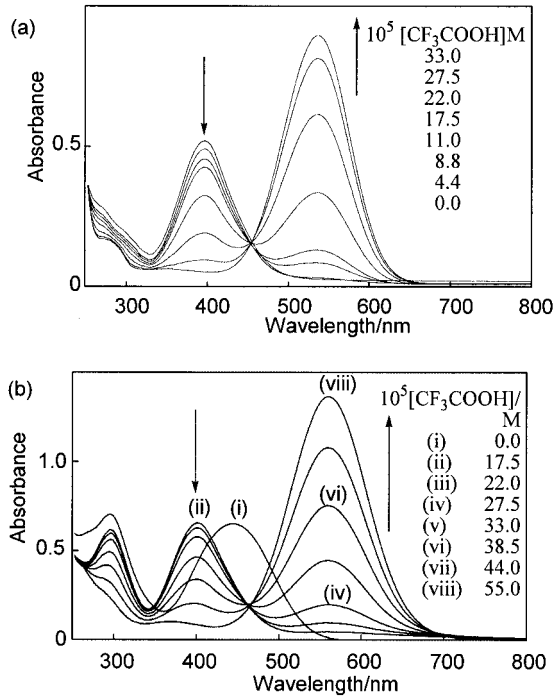

Figure 4. Change in the absorption spectra of (a) **1** (2.5×10^{-5} M in $CHCl_3$) and (b) **4** (2.5×10^{-5} M in $CHCl_3$) upon addition of CF_3COOH

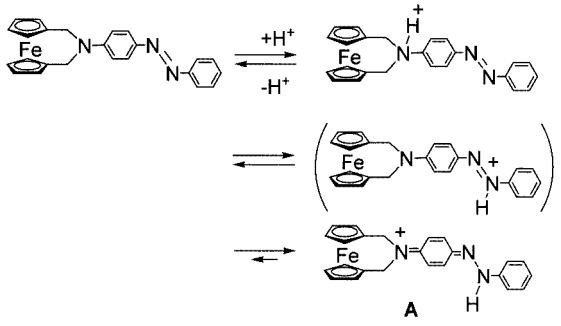
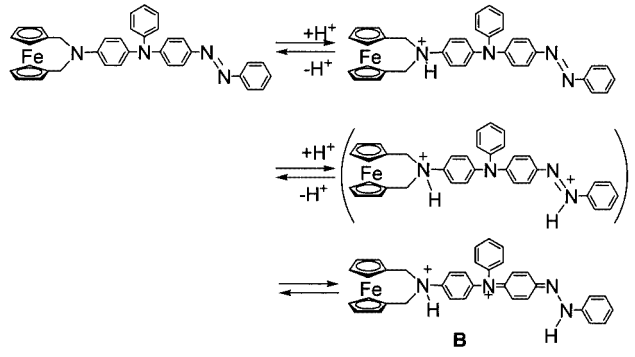


Scheme 2

tant growth of a peak at 570 nm with an isosbestic point at 472 nm. A plausible mechanism for the stepwise protonation of **4** is summarized in Scheme 3.

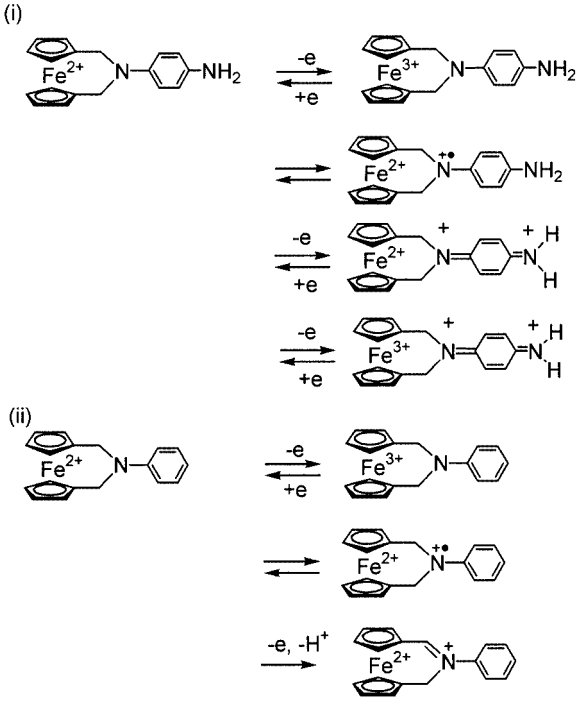


Scheme 3

Initial protonation occurs at the nitrogen atom in the ferrocenophane ring, which restricts π-conjugation of the *p*-diaminophenyelene group and causes a shift of the π−π* transition peak to a higher energy level. Further protonation of the azobenzene nitrogen causes formation of a tautomeric dication **B**. A resonance structure with a diazaquinoid group in the ligand serves to generate a π-conjugated system which shows an intense π−π* absorption at 570 nm.

Electrochemical Oxidation

Previously we have reported the electrochemical oxidation of various 2-aza-[3]-ferrocenophane derivatives.[7,8] The compounds with 4-hydroxyphenyl and with 4-aminophenyl substituents at the nitrogen atoms exhibit three reversible cycles of oxidation and reduction in the cyclic voltammograms, while those with phenyl or alkyl substituents undergo one reversible and one irreversible oxidation reaction. These results suggest a different structure for the product of the second oxidation, as shown in Scheme 4. The ferrocenium species formed upon initial oxidation of the Fe center is in equilibrium with the Fe^{II} species having a cation radical at the nitrogen within the ferrocenophane ring. The cation radical formed in Scheme 4(i) undergoes further electrochemical oxidation to produce the stable quinodiimine. The formed cation radical would release both a proton and an electron under the oxidation conditions to form an iminium-containing product. Similar electron transfer between an Fe center and an amino group, followed by irreversible reaction has been discussed previously for the electrochemical oxidation of ferrocenophanes containing pendant amino groups.[7]



Scheme 4

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The cyclic voltammograms of **1**, **4**, and **5** in CH_2Cl_2 are shown in Figure 5. Compound **1** undergoes a reversible reduction at $E_{1/2}$ = +0.05 V and an irreversible oxidation at E_{pa} = +0.75 V. The former was assigned to the redox potential of the ferrocenophane group, based on a comparison of the reduction potential of ferrocene ($E_{1/2}$ = +0.08 V). The CV peak at +0.75 V is due to further electrochemical oxidation of the organic group in the molecule.[6,16] The cyclic voltammogram of **4** in CH_2Cl_2 solution (see b in Figure 5) exhibits three redox peaks at $E_{1/2}$ = +0.17, +0.41, and +0.92 V. The second electrochemical oxidation occurs more easily than the second oxidation of **1**. Scheme 5 summarizes a plausible mechanism for the total electrochemical reaction. The oxidation of the ferrocene group ($E_{1/2}$ = +0.17 V) leads to formation of the ferrocenium cation, which is in equilibrium with the species with Fe^{II} and a cation radical at the nitrogen atom. The second oxidation occurs easily at the nitrogen bonded to three benzene rings (+0.41 V) to afford the stable dicationic quinodiimine structure. Further reversible oxidation (+0.92 V) occurs at the Fe^{II} center of the product of the second oxidation to afford the dicationic Fe^{III} product.

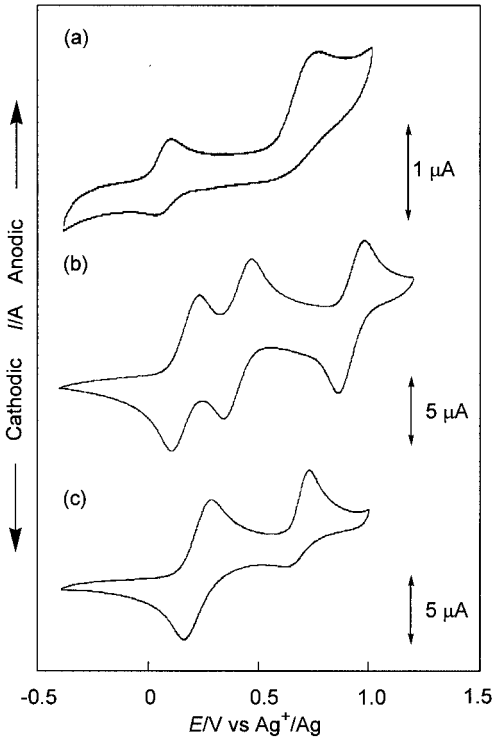


Figure 5. Cyclic voltammograms of (a) **1** (1.0 mM) in CH_2Cl_2 containing 0.10 M Et_4NBF_4 ($E_{1/2}$ = 0.05 V and E_{pa} = 0.75 V), (b) **4** (1.0 mM) in CH_2Cl_2 containing 0.10 M Et_4NBF_4 ($E_{1/2}$ = 0.17 V, 0.41 V, and 0.92 V), and (c) **5** (1.0 mM) in CH_2Cl_2 containing 0.10 M nBu_4NPF_6 ($E_{1/2}$ = 0.22 V and E_{pa} = 0.73 V); sweep rate: 0.10 V s^{-1}; measurement was carried out at 25 °C

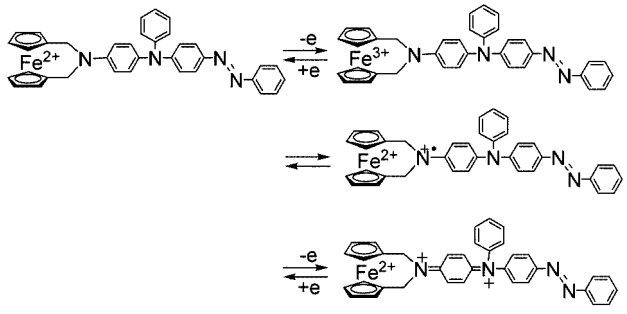

Scheme 5

The cyclic voltammogram of **5** contains a reversible redox peak at $E_{1/2}$ = +0.22 and a quasi-reversible oxidation peak at E_{pa} = +0.73 V. The second oxidation accompanies loss of a proton from the CH_2CN group to form a *meta*-azaquinoid structure.

Figure 6 (a) depicts the change of the absorption spectra during the electrochemical oxidation of **4** in a flow electrolysis cell. Spectrum (i) shows the absorption peak due to **4** (440 nm) exclusively. Spectra (ii) (obtained at −0.1 V) and (iii) (0.3 V) contain peaks at 440 nm and 770 nm, respectively. The latter peak is assigned to the radical cation in Scheme 5. The peak position suggest delocalization of the radical within the π-conjugated ligand. Spectrum (iv) (at 1.0 V) exhibits a new absorption band at 550 nm, which is ascribed to the species with a quinodiimine structure. The change of the absorbance at 440 nm, 550 nm, and 770 nm is shown in part b of Figure 6. It is consistent with the re-

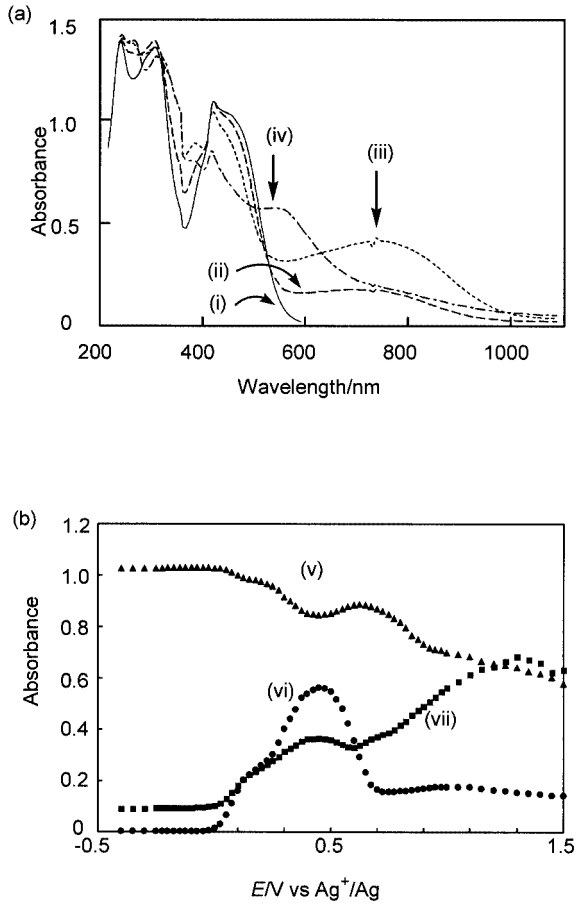

Figure 6. (a) Changes of absorption spectra of **4** (0.05 mM) in acetonitrile solution of 0.1 M Et_4NBF_4 at (i) −0.4 V, (ii) −0.1 V, (iii) 0.3 V, and (iv) 1.0 V (vs Ag^+/Ag); (b) relative intensity changes of absorption spectra of **4** induced by oxidation potentials (v) at 440 nm, (vi) at 550 nm, and (vii) at 770 nm

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sults of CV (see b in Figure 5) and the proposed mechanism of the reaction shown in Scheme 5: the peaks at 770 nm and at 550 nm grow upon oxidation at −0.05−0.3 V and that at 0.3−0.4 V, respectively. Attempts to obtain clear ^{1}H NMR spectra of the oxidized species did not succeed due to significant broadening of the signals.

Electrochemical oxidation of **4** and **5**, both with the azobenzene group *trans*, at 0.30 and 0.40 V (vs Ag^+/Ag), causes little change in the positions of the π−π* transition peaks compared to those before electrolysis. Irradiation of the solutions at 420 nm after electrolysis causes a slight decrease of the peak intensity [approximately 5% (**4**) and 8% (**5**) of the original absorbance], as shown in Figure 7, which suggests that the photostationary states of the oxidized compounds contain *cis*-azobenzene as the minor components. The spectra returned rapidly to the original spectra containing the *trans*-azobenzene group. This can be ascribed to the higher stability of the *trans*-azobenzene group than the *cis*-azobenzene group even during photoirradiation, or faster, thermally induced isomerization of the *cis*-azobenzene group to the *trans* than the photo-assisted isomerization in the reverse direction. In order to obtain further insights, thermal isomerization of the *cis*-azobenzene obtained in the photostationary state of **4** and **5** was conducted after electrochemical oxidation.

Figure 8 compares the kinetic data of the thermal isomerization of the *cis*-azobenzene group to the *trans* form before and after electrolysis, which was monitored by the change in the absorbance at 430 nm. The rate of thermal isomerization actually increases with the electrochemical oxidation. The thermal isomerization was monitored by the spectroscopic change at 10 °C; it is complete within 5 min at this temperature.

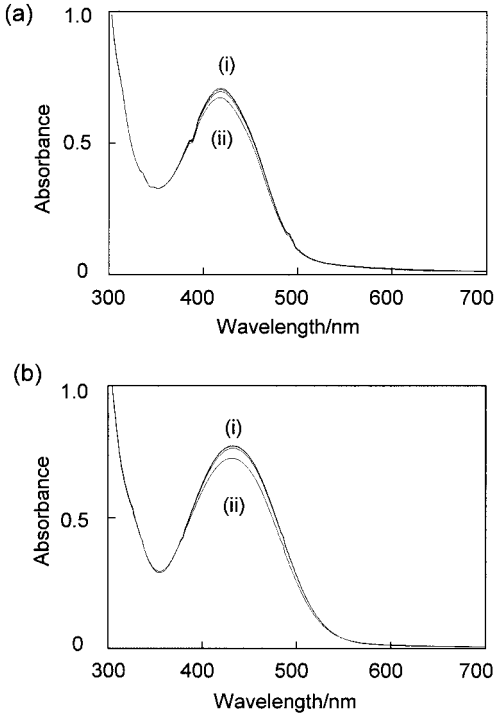

Figure 7. (a) Absorption spectra of **4** (i) before and (ii) after irradiation at 420 nm from a cut-off filtered Xenon lamp for 1 h at 20 °C in toluene; (b) absorption spectra of **5** (i) before and (ii) after irradiation; the data were obtained by flow-electrolysis at 0.3 V (a) and at 0.4 V (b)

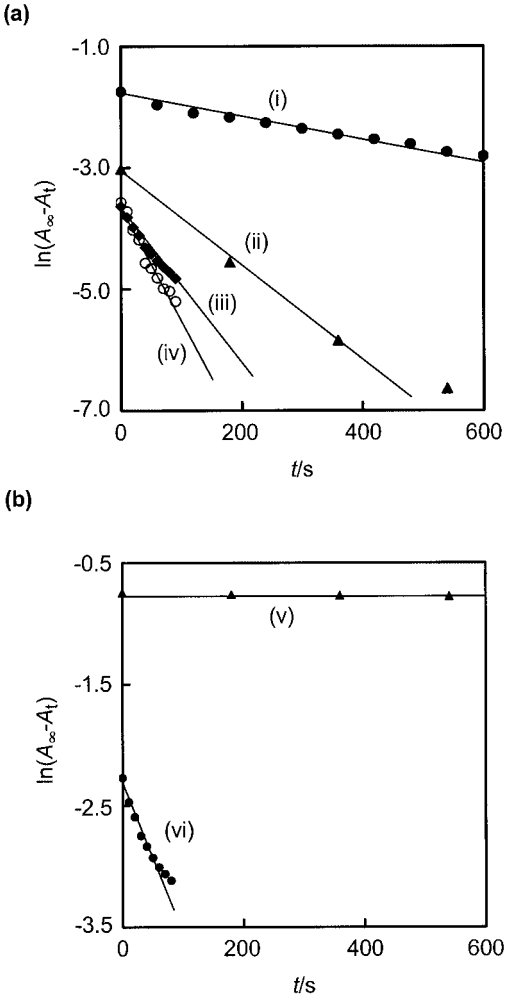

Figure 8. First-order plots of thermal isomerization (283 K) of (a) **4** in the photostationary state (i) without oxidation, (ii) after oxidation at 0.3 V, (iii) 0.6 V and (iv) 1.0 V, and (b) **5** in the photostationary state (iv) without oxidation and (v) after oxidation at 0.4 V; A_t denotes the absorption at 440 nm

Scheme 6 summarizes a mechanism that accounts for the rapid isomerization of the oxidized species. One-electron oxidation of **4** and **5**, with the azobenzene group *cis*, forms the Fe^{III} center, which is in equilibrium with the species having an Fe^{II} center and a cation radical at the N atom[16] due to electron transfer between the Fe and two N atoms.[7] This intermediate is responsible for the rapid isomerization of the *cis*-azobenzene to the *trans* form.[17] The positive charge at the N atom attached to the azobenzene unit enhances the isomerization of the N=N bond significantly due to rapid N−N bond rotation of the oxidized form. A canonical structure containing a diazaquionid moiety and a radical at an azobenzene nitrogen is involved in the oxidized species. Although the amount of the intermediate is small, rapid rotation of the N−N bond due to the single-bond

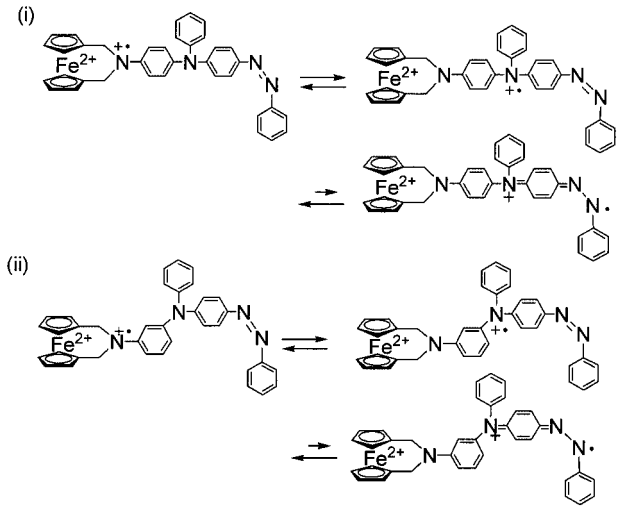

Scheme 6

character of the azobenzene group and intermolecular transfer of the positive charge at the organic ligand renders thermally induced isomerization facile.

In summary, the synthesis of new ferrocenophanes containing an azobenzene group has been achieved by using two types of bond-forming reactions catalyzed by transition metal complexes. The introduced azobenzene group performs as a redox-active site and as a chromophore that varies its absorption upon treatment with protic acid. The presence of ferrocenophane does not influence the optical properties of the azobenzene group significantly. Reversible multi-step redox reactions of **1** and **4** and the color change caused by addition of H^+ suggest a potential use of these compounds as electron- or acid-responsive organic materials.

Experimental Section

General Methods: $RuCl_2(PPh_3)_3$,[18] 1,1′-ferrocenedimethanol,[19] and $Pd_2(dba)_3$ [20] were prepared according to the literature. Preparation of the complexes and ferrocenophanes was carried out under nitrogen or argon using standard Schlenk techniques. Solvents were distilled from CaH_2 and stored under argon. The IR spectra were obtained with a JASCO-IR810 spectrophotometer. The ^1H and ^{13}C NMR spectra were recorded with a JEOL EX-400 spectrometer at 25 °C unless otherwise stated. A YANACO MT-5 CHN Autocorder was used for the elemental analyses. Cyclic voltammetry was recorded with a MeCN solution of 0.10 M Et_4NBF_4 with an ALS Electrochemical Analyzer Model-600A. The potentials were referenced to Ag^+/Ag. Spectroscopic measurements of the electrochemically oxidized species were carried out by using a combination of a flow-through electrolysis cell, ALS Electrochemical Analyzer Model-600A and EYELA peristaltic pump SMP-11, and JASCO V-530 UV/Vis spectrometer. Details of apparatus have been reported previously.[8,21]

Preparation of 1: 4-Phenylazoaniline (429 mg, 2.2 mmol) and then 1,1′-ferrocenedimethanol (536 mg, 2.2 mmol) were added at room temperature to a solution of $[RuCl_2(PPh_3)_3]$ (139 mg, 0.15 mmol) in 1-methyl-2-pyrrolidone (NMP) (3 mL) under nitrogen. The mixture was heated for 48 h at 180 °C. After removal of the solvent under vacuum, the product was extracted with ethyl acetate and purified by column chromatography (silica gel; hexane/ethyl acetate, 3:1). The yellow solid thus obtained was recrystallized from a dichloromethane/methanol mixture to afford **1** as orange crystals (253.0 mg, 38%). $C_{24}H_{21}FeN_3 \cdot 0.5C_6H_{14}$ (450.38): calcd. C 71.95, H 6.22, N 9.33; found C 72.11, H 6.07, N 9.33. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.95 (s, 4 H, Cp-CH_2-N), 4.00, 4.15 (t, J = 2 Hz, 8 H, Cp), 6.95 (d, J = 10 Hz, 2 H, *meta*-N=NC$_6$H$_4$-), 7.37 (t, J = 7 Hz, 1 H, *para*-C$_6$H$_5$N=N-), 7.41 (t, J = 8 Hz, 2 H, *meta*-C$_6$H$_5$N=N-), 7.78 (d, J = 9 Hz, 2 H, *ortho*-N=NC$_6$H$_4$), 7.83 (d, J = 9 Hz, 2 H, *ortho*-C$_6$H$_5$N=N) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): δ = 45.8 (Cp-*C*H$_2$-N), 69.4 (Cp), 70.0, 83.4 (*Cp*-CH$_2$-), 112.0 (*para*-C$_6$H$_5$N=N-), 122.2 (*ortho*-C$_6$H$_5$N=N), 125.4 (*ortho*-C$_6$H$_4$N=N), 129.0 (*meta*-C$_6$H$_5$N=N-), 129.5 (*para*-C$_6$H$_5$N=N-), 144.2 (*ipso*-C$_6$H$_4$N=N), 151.1 (*para*-N=N C$_6$H$_4$-), 153.2 (*ipso*-C$_6$H$_5$N=N) ppm.

Preparation of 2: 4-Bromoaniline (571 mg, 3.3 mmol) and then 1,1′-ferrocenedimethanol (817 mg, 3.3 mmol) were added at room temperature to a solution of $[RuCl_2(PPh_3)_3]$ (139 mg, 0.15 mmol) in NMP (5 mL) under nitrogen. The mixture was heated for 24 h at 180 °C. After removal of the solvent under vacuum, the product was extracted with acetone. Column chromatography (silica gel; hexane/ethyl acetate, 1:1) of the extract gave a yellow solid which was recrystallized from a dichloromethane/methanol mixture to afford **2** as yellow crystals (883 mg, 70%). $C_{18}H_{16}BrFeN$ (382.08): calcd. C 56.58, H 4.22, Br 20.91, N 3.67; found C 56.85, H 4.06, Br 21.21, N 3.69. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.84 (s, 4 H, Cp-CH_2-N), 4.06, (t, J = 2 Hz, 8 H, Cp), 6.83 (t, J = 9 Hz, 2 H, *meta*-BrC$_6$H$_4$), 7.32 (d, J = 9 Hz, 2 H, *ortho*-BrC$_6$H$_4$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): δ = 46.1 (Cp-*C*H$_2$-N), 69.3, 70.0 (Cp), 84.0 (*Cp*-CH$_2$-), 113.1 (*ipso*-BrC$_6$H$_4$), 115.0 (*meta*-BrC$_6$H$_4$), 132.1 (*ortho*-BrC$_6$H$_4$), 148.3 (*para*-BrC$_6$H$_4$) ppm.

Preparation of 3: 3-Bromoaniline (571 mg, 3.3 mmol) and then 1,1′-ferrocenedimethanol (817 mg, 3.3 mmol) were added at room temperature to a solution of $[RuCl_2(PPh_3)_3]$ (139 mg, 0.15 mmol) in NMP (5 mL) under nitrogen. The mixture was heated for 24 h at 180 °C. After removal of the solvent under vacuum, the product was extracted with acetone. Column chromatography (silica gel; hexane/ethyl acetate, 1:1) of the extract gave a yellow solid which was recrystallized from a dichloromethane/methanol mixture to afford **3** as yellow crystals (857 mg, 68%). ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.84 (s, 4 H, Cp-CH_2-N), 4.06, 4.18 (t, J = 2 Hz, 8 H, Cp), 6.84 (d, J = 7 Hz, 1 H, *para*-BrC$_6$H$_4$), 6.85 (s, 1 H, *ortho*-BrC$_6$H$_4$), 7.08 (dd, J = 7 Hz, 1 H, *meta*-BrC$_6$H$_4$), 7.09 (d, J = 7 Hz, 1 H, *ortho*, BrC$_6$H$_4$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): δ = 46.0 (Cp-*C*H$_2$-N), 69.3, 69.9 (Cp), 83.8 (*Cp*-CH$_2$-), 111.7 (*para*-BrC$_6$H$_4$), 115.9 (*ortho*-BrC$_6$H$_4$-N), 119.8 (*ortho*-BrC$_6$H$_4$), 123.7 (*ipso*-BrC$_6$H$_4$), 130.6 (*meta*-BrC$_6$H$_4$), 150.4 (*meta*-BrC$_6$H$_4$-N) ppm.

Preparation of 4: A mixture of **2** (382 mg, 1.0 mmol) and 4-phenylazodiphenylamine (273 mg, 1.0 mmol) was dissolved in toluene (20 mL). NaO*t*Bu (145 mg, 1.5 mmol), $Pd_2(dba)_3$ (12 mg, 0.013 mmol), and P(*t*Bu)$_3$ (15 mg, 0.075 mmol) were then added to the solution, which was stirred at 100 °C for 40 h under argon. After cooling, the reaction mixture was quenched by adding NH_4OH. The product was extracted with $CHCl_3$ and purified by column chromatography (silica gel; hexane/$CHCl_3$, 1:1) to give a red-orange solid. Recrystallization from a $CHCl_3$/hexane mixture gave **4** as red crystals (471 mg, 82%). $C_{36}H_{30}FeN_4$ (574.50): calcd. C 75.26, H 5.26, N 9.75; found C 74.99, H 5.17, N 9.71. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.86 (s, 4 H, Cp-CH_2-N), 4.11, 4.22 (d, J = 2 Hz, 8 H, Cp), 6.95 (d, J = 9 Hz, 2 H, *meta*-CH$_2$NC$_6$H$_4$),

Preparation of 5: A mixture of **3** (382 mg, 1.0 mmol) and 4-phenylazodiphenylamine (273 mg, 1.0 mmol) was dissolved in toluene (20 mL). NaO*t*Bu (145 mg, 1.5 mmol), $Pd_2(dba)_3$ (12 mg, 0.013 mmol), and P(*t*Bu)$_3$ (15 mg, 0.075 mmol) were then added to the solution, which was stirred at 100 °C for 40 h under argon. After cooling, the reaction mixture was quenched by adding NH_4OH. The product was extracted with $CHCl_3$ and purified by column chromatography (silica gel; hexane/$CHCl_3$, 1:1) to give a red-orange solid. Recrystallization from a $CHCl_3$/hexane mixture gave **5** as red crystals (448 mg, 78%). $C_{36}H_{30}FeN_4$ (574.50): calcd. C 75.26, H 5.26, N 9.75; found C 75.14, H 5.13, N 9.65. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.81 (s, 4 H, Cp-C*H*$_2$-N), 4.07, 4.17 (d, J = 2 Hz, 8 H, Cp), 7.87−6.55 (aromatic protons) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): δ = 45.9 (Cp-*C*H_2-N), 69.2, 69.9 (Cp), 84.3 (*Cp*-CH_2-), 109.7, 111.1, 115.5, 121.3, 122.5, 123.9, 124.2, 125.4, 129.0, 129.4, 130.1, 130.4, 147.0, 148.2, 150.4, 150.7, 153.0 ppm.

X-ray Structure Analyses: Crystals of **1**, **4**, and **5** suitable for an X-ray diffraction study were obtained by recrystallization from CH_2Cl_2/MeOH and mounted in glass capillaries under argon. Data were collected at 23 °C on a Rigaku AFC-5R automated four-circle diffractometer equipped with monochromated Mo-K_α radiation (λ = 0.71073 Å). Calculations were carried out with the program package teXsan for Windows.[22] The structures were solved by direct methods and subsequent Fourier techniques. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located by assuming an ideal geometry, and are included in the structure calculation without further refinement of the parameters. Crystallographic data and details of refinement are summarized in Table 2.

CCDC-242244 (for **1**), -213721 (for **4**), and -213722 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Solvothermal Synthesis of NiS 3D Nanostructures

Wanqun Zhang,[a] Liqiang Xu,[a] Kaibin Tang,[a] Fanqing Li,[a] and Yitai Qian*[a,b]

Keywords: Nickel sulfide / Nanostructures / Complexes / Crystal growth

Highly uniform urchin-like nanostructures (in the structures, nanoneedles or nanobelts grow radially from the core particles) of NiS (millerite) were successfully prepared by a solvothermal synthetic route using $Ni(Ac)_2{\cdot}6H_2O$ and dithizone as reagents and ethylenediamine as solvent in the temperature range of 220–240 °C. The prepared nickel sulfides with urchin-like 3D architectures were characterized by X-ray diffraction (XRD), field emission scanning electron microscopy (FE-SEM) and high-resolution transmission electron microscopy (HRTEM). The reaction temperature, sulfur sources, and solvent are of great importance on the final urchin-like structures. On the basis of the experimental results, a possible growth mechanism of the urchin-like NiS crystals is proposed, which is supported by the technical characterizations.

Introduction

Many properties of crystalline materials depend on the crystallographic direction, for example, the spontaneous polarization in ferroelectrics and the magnetic coercivity and remanence in ferromagnets.[1] Over the past few years, there has been growing interest in low dimensional nanostructure semiconductors because of their novel electrical and optical properties, and potential applications in nanodevices.[2] Recently, research is expanding into the assembly of nanoparticles in two-dimensional and three-dimensional ordered superstructures.[3] Much effort has been made to construct patterns of well-arranged nanocrystallites, especially arrangements of nanotubes and nanorods due to their interesting physical properties and potential applications in many areas.[4] To obtain highly oriented growth of nanorods, solid templates are usually required, such as porous alumina, polymer nanotubes, and patterned catalysts, to control the directional growth.[5] However, the introduction of templates and substrates introduces heterogeneous impurities, increases the production cost, and thus leads to the difficulty for scale-up production. The development of facile, mild, easily controlled, and template-free methods to create novel patterns on self-generated homogeneous substrates therefore is of great significance.

Nickel monosulfide (NiS) has been the subject of considerable interest because of its properties as a metal insulator, paramagnetic–antiferromagnetic phase-changing material, and its use in hydrosulfurization catalysts and solar storage.[6] In this paper, we present the synthesis of highly uniform urchin-like 3D nickel sulfide nanostructures by the reaction between nickel acetate and dithizone (H_2DZ, $C_{13}H_{12}N_4S$) in ethylenediamine without the use of any template, polymer, and surfactant. Although Xie's group synthesized 3D NiS with flowerlike architectures via a polymer assistant, recently NiS (millerite) nanorods and triangular nanoprisms were synthesized, and other several geometrical urchin-like patterns have also been presented.[7] Up to now, there has not been a report on these kind of urchin-like 3D nickel sulfides nanostructures (in the structures, nanoneedles or nanobelts grow radially from the core particles) synthesized by a simple, efficient method under mild conditions. As a catalyst, the urchin-like nanostructures, which have highly specific area on the surface of the particles, may provide directional catalyst ability and realize region-dependent surface reactivity.

Results and Discussion

Figure 1 shows the XRD patterns of NiS obtained at 220 °C for 5 h. All the peaks in Figure 1 can be indexed as pure millerite NiS (space group: *R*3*m*) with cell parameters a = 9.63 Å, c = 3.15 Å, which are close to the literature data (JCPDS file number: 12–0041). Similar XRD patterns were obtained from other products of the comparison experiment, all of which exhibited millerite NiS.

The morphology of the product was determined by FR-SEM and TEM. Figure 2 shows the obtained urchin-like nanostructures synthesized at 220 °C for 5 h. After careful observation (Figure 2, b, c), it has been found that the ur-

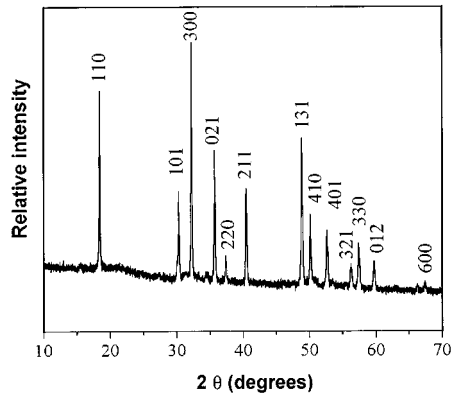

Figure 1. XRD pattern of the synthetic millerite NiS at 220 °C for 5 h

chin-like pattern usually has a diameter of about 30 μm with acicular crystallites radiating from the center in a uniform size distribution. The nanoneedles grown from the center have almost uniform diameters: the bottom of the nanoneedles is about 150 nm; the tip of the nanoneedles is about 50 nm. The nanoneedles were investigated in more detail by high-resolution transmission electron microscopy (HRTEM) (Figure 2, d) and by the SAED pattern (inset in Figure 2, d). The HRTEM image of an individual nanoneedle in Figure 2 (d) shows that lattice spacing of about 0.48 nm and 0.29 nm correspond to the (110) and (011) planes, respectively, of rhombohedral phase NiS. The obtained ED spots projected along the [1 $\bar{1}$ 1] zone axis could be indexed as millerite NiS (110) and (011) planes. The HRTEM and SAED images indicate that the nanoneedles are single crystals grown in the direction parallel to the (110) lattice planes. With a raised temperature of 240 °C, we obtained nanobelts with high aspect ratios, grown radially from the core particles. As shown in Figure 3 (a), these nanobelts have widths ranging from 20 nm to 70 nm and lengths of up to 12 μm. We have characterized these NiS nanobelts by HRTEM and SAED (Figure 3, b). The nanobelts exhibit lattice planes with a spacing of 0.48 nm parallel to the long axis of the nanobelt, which corresponds to the *d* spacing of the (110) planes of NiS (millerite). HRTEM images reveal that the nanobelts grow along the direction parallel to the (110) planes of NiS, which is similar to the nanoneedles. The inset image in Figure 3 (b) shows a typical SAED of the millerite NiS nanobelt, which was obtained by focusing the electron beam along the [0 $\bar{2}$ 1] zone axis of this nanobelt. The SAED pattern further confirms that this nanobelt is a single crystal of millerite NiS.

It is well known that H_2DZ is a good linker ligand, which can form $Ni(HDz)_2$ with Ni^{2+} under alkaline conditions.[8] The reaction in the present system is based on the formation of Ni-dithizone complexes followed by thermal decomposition of these complexes to obtain the final product. The whole reaction process may be expressed as follows:

$$Ni^{2+} + C_{13}H_{12}N_4S \rightarrow Ni(C_{13}H_{11}N_4S)_2 \rightarrow NiS$$

Different sulfur reagents were tested to reveal the dithizone effect, and the results showed that the dithizone was the optimum. When Na_2S was used, the product is a mixture of bulky particles of NiS and Ni_3S_2. When using thio-

urea, podgy rods of NiS (millerite) were obtained. It is ordinarily accepted that dithizone metal complexes prevent the production of large free metal ions and sulfur ions, and thus are favorable for the oriented growth of the final product.

Generally, the growth process of crystals can be separated into two steps: an initial nucleating stage and a subsequent crystal growth process. At the initial nucleating stage, the crystalline phase of the seeds is critical for directing the intrinsic shapes of the crystals due to its characteristic symmetry and structure. In the subsequent step, the crystal growth stage is a kinetically and thermodynamically controlled process that can yield 1D and other more complicated shapes with some degree of shape tenability through changes in the reaction parameters such as temperature, reaction time, concentration, and so on.[9] In the present system, we find that the reaction temperature is undoubtedly vital in the formation of the unique urchin-like patterns of NiS nanoneedles and nanobelts. To investigate the influence of reaction temperature, the reactions were carried out at different temperatures, and the results are listed in Table 1. It is generally believed that temperature can affect crystal growth in several ways, all of them resulting in a smaller crystal size at lower temperatures. From our experiments, it can be clearly seen that a higher temperature is preferable for the anisotropic growth of crystal and results in the product with high aspect ratios (Figure 3, a). Meanwhile, at lower temperatures of 160 °C and 180 °C, only podgy rods and nail-like crystals with lower aspect ratios are obtained. Based on FE-SEM studies, by changing the reaction time a possible formation mechanism of 3D urchin-like NiS nanostructure can be obtained and is described as follows: at the beginning of the reaction, some nuclei are formed. These nuclei rapidly develope into aggregated particles (Figure 4, a). ED patterns of the aggregated particles confirm that the aggregated particles are polycrystal. All the diffraction rings in the ED patterns can be indexed to millerite NiS (inset in Figure 4, a). Because the initial growth may be too rapid to be separated from the nucleation,[10] sheets are formed on the surface of the aggregated particles (Figure 4, b), and then at elevated temperature and pressure, the layer structures directly collapse into nanorods (Figure 4, c).[11] During the following solvothermal process, the shorter nanorods may redissolve into the solution phase, and the longer nanorods grow much longer (Figure 4, d), which is similar to the formation process of silver nanowires.[12] With the rapid growth of nanorods, the concentration of the reactants decreases, which does not completely satisfy the growth of nanorods and finally results in the formation of needlelike nanocrystals (Figure 2, a). Further studies are necessary to understand the exact formation mechanism of 3D NiS nanocrystals.

Ethylenediamine also played an important role in the formation of urchin-like NiS. When Ethylenediamine was substituted by ammonia, ethylamine (65−70%), or 1,6-hexanediamine, the results, shown in Table 2, indicated that neither NiS (millerite) nor urchin-like morphology was obtained. Therefore, it is believed that the solvent affected the phase formation in the reaction system. The exact influence of the solvent undoubtedly needs further investigation.

Table 1. The relationship between temperature and different morphology products

Temperature	Time	Phase	Morphology	Figures	Aspect ratio
160 °C	5 h	–	–	–	–
160 °C	96 h	NiS	podgy rod	–	low
180 °C	5 h	NiS	nail-like	–	lower
220 °C	5 h	NiS	urchin-like (nanoneedles)	2, a	high
240 °C	5 h	NiS	urchin-like (nanobelts)	3, a	higher

Table 2. Results of the reaction of $Ni(AC)_2 \cdot 6H_2O$ and dithizone at 220 °C for 5h

Solvent	Product	Morphology
ammonia/water	Ni_3S_2	irregular
ethylamine (65−70%)	Ni_3S_2, Ni_7S_6	−
1,6-hexanediamine	Ni_3S_2	spherical

Conclusion

In summary, in this paper we have developed a facile solvothermal method for the preparation of highly uniform urchin-like 3D nickel sulfide nanostructures by altering the reaction temperature. A possible mechanism was proposed to explain their formation. This low-temperature synthetic route, free of templates, polymer and surfactant, can be easily adjusted to prepare urchin-like 3D nickel sulfides and might be expanded to the preparation of other low-dimension nanomaterials.

Experimental Section

Preparation of Uniform Urchinlike Nanostructures: All the reagents were analytical grade and purchased from Shanghai Chemical. In a typical synthesis, equivalent molar amounts of $Ni(Ac)_2 \cdot 6H_2O$ and H_2DZ (1.2 mmol) were placed in ethylenediamine (50 mL), and the mixture was stirred strongly for about 1 hour to form a homogeneous solution. The resulting solution was transferred into a 60 mL Teflon-lined autoclave, which was sealed and maintained between 220−240 °C for 5 h, before being left to cool to room temperature naturally. The precipitate was filtered off, and washed with distilled water and absolute ethanol several times, and dried in vacuo at 60 °C for 4 h.

Sample Characterization: SEM images were obtained on a Hitachi (X-650) scanning electron microanalyzer and a JSM-6700F field emission scanning electron microscope (FE-SEM). XRD patterns of the products were recorded by employing a Philips X'pert X-ray diffractometer with Cu-K_α radiation (λ = 1.54187 Å). The electron diffraction (ED) patterns and high-resolution transmission electron microscopy (HRTEM) images were carried out on a JEOL-2010 TEM at an acceleration voltage of 200 kV.

Keywords: Rhenium / Cluster compounds / Ligand exchange / Organic ligands / Structure elucidation / Laser fluorescence spectroscopy

Two new octahedral rhenium cluster complexes, $[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2 \cdot 3,5\text{-}Me_2PzH$ (**1**) and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2 \cdot 3,5\text{-}Me_2PzH$ (**2**), with the organic ligand 3,5-dimethylpyrazole (3,5-Me_2PzH), have been synthesised by reaction of rhenium chalcobromides $Cs_3[Re_6(\mu_3\text{-}Q_7Br)Br_6]$ (Q = S, Se) with molten dimethylpyrazole. During the reaction, all six apical bromine ligands of the cluster complexes are substituted by the organic ligand, which is coordinated through the aromatic nitrogen atom N2. Additionally, the inner ligand μ_3-Br in the cluster core $[Re_6(\mu_3\text{-}Q_7Br)]^{3+}$ is substituted by oxygen, giving cluster cores $[Re_6(\mu_3\text{-}Q_7O)]^{2+}$ with mixed chalcogen/oxygen ligands. Compounds **1** and **2** have been characterised by single-crystal X-ray diffraction analysis. They are isostructural and crystallise with four formula units in the unit cell. Absorption spectra and luminescence characteristics of these two cluster compounds have been investigated in methanol. Absorption starts below 400 nm. For both compounds, broad emissions were found. The fluorescence decays of the two compounds follow a diexponential decay behaviour. The main fluorescence intensity decays have longer fluorescence lifetimes of 3.07 ± 0.03 (**1**) and 3.96 ± 0.02 μs (**2**). Studying the thermal stability of both compounds in vacuo showed that the release of 3,5-dimethylpyrazole ligands begins near 200 °C, and decomposition, with the removal of 7 molecules of 3,5-Me_2PzH, is complete at 330 °C.

Introduction

The chemistry of the rhenium octahedral cluster compounds with the cluster core $\{Re_6Q_8\}^{2+}$ (Q = S, Se) coordinated by organic N- and P-donor ligands is in a stage of rapid development.[1−14] Such organic−inorganic hybrids show interesting electronic, optical and structural properties. Synthetic strategies span both simple cluster modification and more demanding programmed supramolecular arrays. The latter includes hydrogen-bonded and metal-assisted supramolecular networks based on rhenium clusters possessing nicotinamide, isonicotinamide, 3,5-pyridinedicarboxylic acid and 4,4′-dipyridine as apical organic ligands. Furthermore, the dendritic encapsulation of rhenium clusters by polyetheraryl dendrons having pyridine and pyridone units at the focal point has been realised. In all, there is an almost infinite variability regarding the structural modification of such rhenium clusters. This provides the opportunity to achieve properties useful for possible in vivo applications. Thus, it is very appealing to develop metallic drugs based on rhenium clusters. In this context, particularly porphyrin and modified dendritic rhenium clusters show promising luminescence properties for the development of photosensitizers that could be applied to photodynamic therapy.[15,16] Furthermore, rhenium clusters may play an important role as agents in photon activation therapy (PAT).[17] This relatively new treatment paradigm in cancer therapy requires a sufficiently high density of metals in target regions. This could be achieved by organic-inorganic rhenium cluster complexes.

Because of this background, we are especially interested in an efficient synthetic procedure to introduce organic ligands into the rhenium cluster core. Thus, a new synthetic

approach for grafting N-donor ligands to octahedral rhenium cluster compounds has been developed. Here we report the preparation and crystal structures of two new rhenium octahedral cluster complexes, $[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**1**) and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**2**), which were synthesised by the reaction of rhenium chalcobromides $Cs_3[Re_6(\mu_3\text{-}Q_7Br)Br_6]$ (Q = S, Se) with molten 3,5-dimethylpyrazole (3,5-Me_2PzH). The spectroscopic, photophysical and thermal properties of these cluster compounds are also discussed.

Results and Discussion

Syntheses

As a general rule, rhenium cluster compounds containing cluster cores $\{Re_6Q_8\}^{2+}$ (Q = S, Se) and apical organic ligands have been prepared by solution chemistry. A disadvantage of solution chemistry in such syntheses is the rather low rate of interaction and possible hydrolysis (in the case of aqueous solutions or non-anhydrous organic solvents), which limit synthetic resources for preparation of desirable compositions. To overcome these difficulties, we employed a new approach using molten ligands as reaction media for the synthesis of cluster complexes with organic ligands. We applied this method to the reaction of the rhenium cluster compounds $Cs_3[Re_6(\mu_3\text{-}Q_7Br)Br_6]$ (Q = S, Se) with 3,5-dimethylpyrazole as the organic ligand. In the anionic rhenium complexes $[Re_6(\mu_3\text{-}Q_7Br)Br_6]^{3-}$ (Q = S, Se) used, the octahedron Re_6 is surrounded by a cube of eight (μ_3-Q_7Br) atoms (so-called "inner" ligands). Such an "octahedron into cube" forms the cluster core $\{Re_6(\mu_3\text{-}Q_7Br)\}^{3+}$. The six apical positions in the cluster complexes $[Re_6(\mu_3\text{-}Q_7Br)Br_6]^{3-}$ are fully occupied by Br atoms, which are called "outer" ligands. The outer bromide ligands in similar complexes possess anticipated substitutional lability, whereas inner ligands are bonded more strongly. So we expected that in reactions of these clusters with dimethylpyrazole, the apical ligands could be substituted by organic ligands without any change in the cluster core $\{Re_6(\mu_3\text{-}Q_7Br)\}$ as the fundamental building block.

Experimental results show that indeed all apical Br atoms are substituted by organic ligands. On the other hand, an interesting feature of these reactions is an unexpected ligand exchange in the octahedral cluster core, namely the replacement of the inner μ_3-Br ligand by an oxygen atom. Such a substitution is rather unusual in the chemistry of octahedral clusters. The possible source of oxygen for such a substitution is the solvated molecules of H_2O in the starting complexes.

Few examples are known of the substitution of one or two μ_3-Cl ligands by oxygen in the cluster core of octahedral rhenium chalcohalide complexes, and examples of μ_3-Br substitution with oxygen were not found in the literature. The complexes containing two O atoms in the cluster cores $\{Re_6Se_4O_2Cl_2\}^{4+}$ [18] and $\{Re_6S_6O_2\}^{2+}$ [3] were obtained starting from $Re_6Se_4Cl_{10}$ and $[Re_6S_6Cl_8]^{2-}$, respectively. Complexes with the cluster core $\{Re_6S_5OCl_2\}^{2+}$ containing one O atom were obtained from the cluster anion $[Re_6S_5Cl_9]^-$.[19–21] There are two typical sources of oxygen in these reactions: $OSiMe_3$[3,19] or water. Water either came from wet solvent[18] or was added directly to the reaction mixture.[18,20] Here we succeeded in the preparation of oxochalcogenide complexes with a cluster core having the composition $\{Re_6Q_7O\}^{2+}$.

Structures

Compounds **1** and **2** have been characterised by single-crystal X-ray diffraction. The compounds are isostructural. The cluster cations $[Re_6Q_7O(3,5\text{-}Me_2PzH)_6]^{2+}$ (Q = S, Se) contain the Re_6 octahedron residing in a Q_7O pseudocube. There is no disorder in the present structures: seven corner positions of the Q_7O cube are occupied exclusively by S (**1**) or Se (**2**) atoms and one by an O atom. Due to the presence of the O atom in the cluster core $\{Re_6Q_8\}$, the Re_6 octahedrons in both compounds are slightly irregular. Re–Re distances between Re atoms coordinated by the μ_3-O atom are shorter than those for other Re atoms. Each Re atom is coordinated by a 3,5-Me_2PzH. The structure of a complete molecule is shown in Figure 1. The Re–Re distances range from 2.5210(7) to 2.5995(7) Å in **1** and from 2.5465(13) to 2.6386(14) Å in **2**; the Re–Q distances range from 2.392(3) to 2.417(3) Å in **1** and from 2.509(2) to 2.544(2) Å in **2**; the Re–O distances range from 2.114(8) to 2.129(8) Å in **1** and from 2.022(8) to 2.036(8) Å in **2**; the Re–N distances are 2.13(1)–2.16(1) (**1**) and 2.16(2)–2.21(2) Å (**2**). The Re–O distances in **1** are slightly longer than those found in $(Bu_4N)_2[Re_6S_5OCl_8]$ [2.08(1)–2.09(1) Å][19] or $(Bu_4N)_4[(Re_6S_5OCl_7)_2O]$ (average Re–O: 2.087(6) Å)[20] and shorter than in $[Re_6S_6O_2(PPr_3)_6][Re_6S_6Cl_8]$, where Re–O distances are in

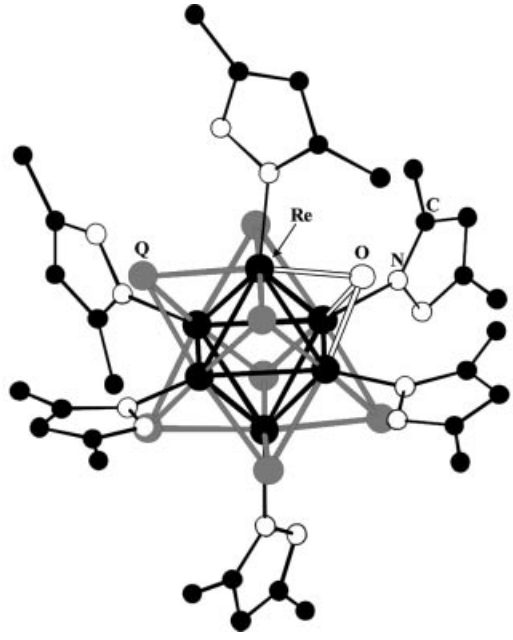

Figure 1. Structure of the cluster cation $[Re_6Q_7O(3,5\text{-}Me_2PzH)_6]^{2+}$ [Q = S (**1**), Se (**2**)]; all hydrogen atoms are omitted for clarity

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the range 2.192(11)−2.226(11) Å.[3] The Re−O distances in **2** are the shortest among all known compounds of this type. Average Re−O distances in α- and β-$(Pr_4N)_2[Re_6Se_4O_2Cl_8]$ are equal to 2.083(14) and 2.094(19) Å, respectively.[18] There are two types of Br atoms in the structure: one bromine atom, Br1, is connected by hydrogen bonds to one cluster (Br···H−N distances are 3.25 and 3.31 Å in **1** and 3.24 and 3.28 Å in **2**) (Figure 2, a), whereas the other one, Br2, is bridged between two cluster cations with Br···H−N distances ranging from 3.41 to 3.68 Å in **1** and from 3.43 to 3.66 Å in **2** to form extended chains along the *a*-axes (Figure 2, b). Both compounds have additional noncoordinated molecules of $3,5\text{-}Me_2PzH$.

Absorption Spectra and Luminescence Characteristics

Solutions (1.0×10^{-5} M) of the two compounds were prepared in methanol. Absorption spectra were recorded in the wavelength range from 190 to 500 nm. The absorption of light starts at around 400 nm. For compound **1**, absorption maxima were located at 221, 247, 272, 294 and 321 nm. Compound **2** had absorption maxima at 211, 241, 260, 277, 294 and 338 nm (Figure 3).

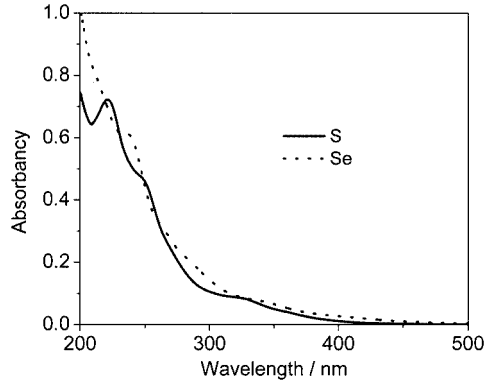

Figure 3. Absorption spectra of $[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**1**) and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**2**)

For excitation of the luminescence, a Nd:YAG laser with fourth harmonic generation (266 nm) was used. To avoid destruction of the compound, the applied laser energy was set to be less than 300 μJ per pulse. The emission spectra were recorded in the wavelength range 560−785 nm. For both compounds broad emission spectra were found. The light emission of **2** was shifted about 30 nm to the red, relative to **1**. Figure 4 shows the emission spectra of the two compounds in methanol solution. Both emission spectra were fitted with two Gaussian peaks (Table 1). For the determination of the fluorescence decay constants, the fluorescence intensity was integrated in the wavelength range from 560 to 785 nm. The resulting fluorescence decay as a function of the increasing time between the laser pulse and the detection of the fluorescence is shown in Figure 5. The derived fluorescence decay times are summarised in Table 1. For compound **1**, the longer fluorescence decay time corresponds to 84.0% of the fluorescence intensity at time $t = 0$, and for compound **2** to 72.5%. Compound **2** shows a somewhat longer fluorescence decay time than **1**. However, the two Gaussian emission distributions found for each compound do not show any remarkable difference in their fluorescence decay behaviour.

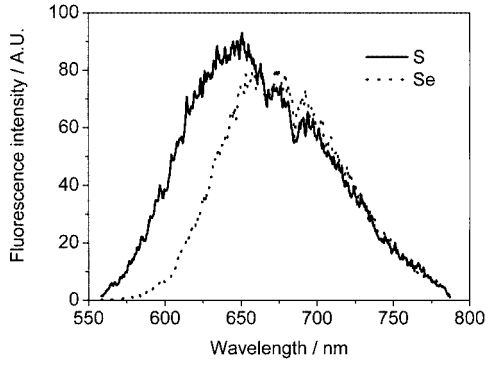

Figure 4. Emission spectra of $[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**1**) and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**2**) in methanol

Table 1. Fluorescence spectroscopic data

Compound	Fluorescence decay time [μs]/ Fluorescence emission maxima [nm]	
1	0.61±0.06/632.4 (49%)	3.07±0.03/692.8 (51%)
2	0.49±0.02/650.0 (24%)	3.96±0.02/688.3 (76%)

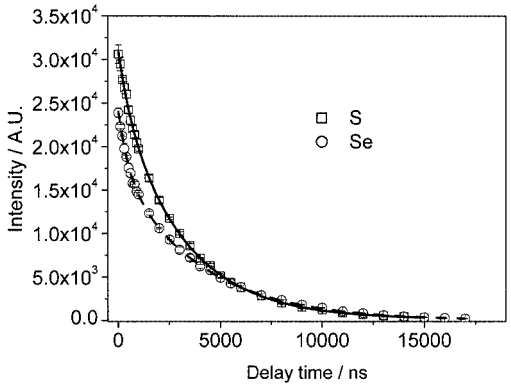

Figure 5. Fluorescence decay of $[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**1**) and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (**2**) in methanol

The emissive properties of these clusters could be used in photodynamic therapy. This phenomenon will be the subject of our future investigations.

Thermal Properties

Studying the thermal stability of both compounds in vacuo showed that the release of 3,5-dimethylpyrazole ligands begins near 200 °C; decomposition with complete removal of 7 mol-equiv. of 3,5-Me_2PzH is finished at 330 °C; however, it is not possible to mark out separate steps of mass loss on the TG curve.

Conclusion

An original method for the synthesis of organic−inorganic rhenium cluster compounds has been demonstrated using the molten organic ligand 3,5-dimethylpyrazole as the reaction medium for the replacement of the apical bromide atoms in the cluster core. Two new octahedral rhenium cluster complexes, having the composition $[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$, were synthesised in a high yield and their structures have been solved and refined. An interesting feature of the chemistry of these compounds is the unexpected ligand exchange in the octahedral cluster core $\{Re_6(\mu_3\text{-}Q_7Br)\}^{3+}$, namely the replacement of the inner μ_3-Br^- ligand by an oxygen ion O^{2-}, which results in the formation of the cluster core $\{Re_6(\mu_3\text{-}Q_7O)\}^{2+}$. Such a substitution is rather unusual in the chemistry of octahedral clusters. The cluster compounds investigated show promising spectroscopic and photophysical properties. The great variety of organic ligands grafting on the cluster core offers abundant opportunities to modify the spectroscopic and photophysical properties, and the organic shell can make the cluster molecule bioavailable. In this nexus, coupling of target-seeking biomolecules to the cluster moiety seems to be an interesting line of future research. Such organic−inorganic hybrids have great inherent potential as diagnostically and therapeutically relevant compounds.

Experimental Section

Materials and Syntheses: All reagents were used as purchased. $Cs_3[Re_6(\mu_3\text{-}Se_7Br)Br_6]\cdot H_2O$ was prepared as described.[22] $Cs_3[Re_6(\mu_3\text{-}S_7Br)Br_6]\cdot H_2O$ was synthesised similarly. Microanalyses for C, H, N, S were performed at the Laboratory of Microanalysis of Vorozhtsov Institute of Organic Chemistry, Siberian Branch RAS with a Vario EL from Elementar Analysensysteme GmbH. FTIR: Bruker IFS-85, Perkin−Elmer 1760X. UV/Vis spectra were recorded in methanol solution with a Cary 5G spectrophotometer (Varian). Emission spectra of these solutions were obtained by use of time-resolved laser-induced fluorescence spectroscopy (TRLFS). The setup is described elsewhere.[25] For excitation, a diode-pumped Nd:YAG laser with fourth harmonic generation (266 nm) was used (DIVA II; Soliton). The repetition rate was 20 Hz and the energy of the laser was set to be 300 μJ per pulse. Thermal properties were studied using Thermoanalyser TA-7000 in vacuo in the temperature interval 25−500 °C with a rate of about 10 K/min.

$[Re_6S_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (1) and $[Re_6Se_7O(3,5\text{-}Me_2PzH)_6]Br_2\cdot 3,5\text{-}Me_2PzH$ (2): Synthetic procedures for both compounds were analogous. Crystals, suitable for X-ray structure determination, were separated manually from the reaction mixture. For preparation of **1**, $Cs_3Re_6S_7Br_7\cdot H_2O$ (0.2 g, 0.0863 mmol) and 3,5-dimethylpyrazole (0.2 g, 2.08 mmol) were heated in a sealed glass ampoule at 200 °C for 2 d. The ampoule was cooled at a rate of about 20 °C/h, then the excess of dimethylpyrazole was removed by washing with diethyl ether. CsBr, formed during the reaction, was removed by washing with water. Yield 95% (180 mg, 0.0819 mmol). Compound **2** was prepared in the same way: $Cs_3Re_6Se_7Br_7\cdot H_2O$ (0.2 g, 0.0756 mmol) was heated with 3,5-dimethylpyrazole (0.2 g, 2.08 mmol). Yield: 93% (177 mg, 0.0703 mmol). $C_{35}H_{56}Br_2N_{14}ORe_6S_7$ (**1**) (2190.44): calcd. C 19.2, H 2.6, N 9.0 S, 10.2; found C 19.0, H 2.6, N 8.9, S 10.1. $C_{35}H_{56}Br_2N_{14}ORe_6Se_7$ (**2**) (2518.68): calcd. C 16.7, H 2.2, N 7.8; found C 16.8, H 2.1, N 7.7. The IR spectra (400−4000 cm^{-1}) of **1** and **2** show all the peaks expected for 3,5-Me_2PzH. In the spectrum of **1** the peak at 415 cm^{-1} was assigned to Re−(μ_3-S) vibration.

Structure Determination: Single-crystal X-ray diffraction data were collected with the use of graphite-monochromatised Mo-K_α radiation (λ = 0.71073 Å) at 293 K with a Bruker SMART diffractometer, equipped with a CCD area detector. The structures were solved by direct methods using SHELXS-90[23] and refined with SHELXL-97.[24] An empirical absorption correction (Ψ-scan) was applied. All non-hydrogen atoms were refined anisotropically. In both structures there are 65 crystallographically independent non-hydrogen atoms which reside at general positions. The positions of hydrogen atoms were calculated corresponding to their geometrical conditions and refined using the riding model. CCDC-231769 (**1**) and -231770 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.uk/data_request/cif.

Syntheses, Structures and Magnetic Properties of Layered Metal(II) Mandelates

Adel Beghidja,[a,b] Sylvain Hallynck,[a] Richard Welter,*[b] and Pierre Rabu*[a]

Keywords: Carboxylate ligands / Layered compounds / Magnetic properties / Transition metals / X-ray powder diffraction

A series of Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} and Cu^{II} layered mandelates has been synthesised in the form of crystalline powders by a hydrothermal route. The five compounds are isostructural with the copper analogue, also obtained in a single crystal form, except that the latter shows a strong Jahn–Teller distortion of the coordination spheres around the Cu^{II} centres. The complexes crystallise in the monoclinic centrosymmetric space group $P2_1/a$ and their structures consist of layers of six-coordinate metal(II) ions interconnected through carboxylato bridges in a diamond-like network. The magnetic data indicate very small antiferromagnetic in-plane couplings for **1**, **2**, **3** and **5**, with $J/k_B = -0.122$ K for **1**. The Ni^{II} compound **4** exhibits ferromagnetic coupling within the layers ($J/k_B = +1.213$ K) and ferromagnetic 3D ordering can be observed at $T_C = 2.7$ K.

Introduction

Correlations between the magnetic properties of molecule-based solids and their structures together with the nature of the chemical bond are useful in the design of new magnetic materials.[1,2] In this respect, low dimensional systems in which the magnetic centres interact within chains (1D) or planes (2D) are of particular interest since their physics may be approximated and analysed to a high degree. This has been possible thanks to the development of a substantial amount of experimental and theoretical work in the area over several decades[3–6] and to the efforts of synthetic chemists in providing model compounds, particularly through the molecular approach, i.e. by using molecular building blocks for the design of new interconnected networks,[7,8] involving several kinds of metallic ions or radicals, which exhibit predictable magnetic properties.[9–11] Focusing on 2D systems, as found in layered transition metal compounds, it has been shown that the occurrence of 3D magnetic ordering is mainly driven by the divergence of the correlation length within the layers which depends on the in-plane magnetic exchange coupling and on the topology of the magnetic centres.[4,6,12,13] Recent results on organic-inorganic layered magnets have shown that it is possible to tune the coupling between spin layers by using suitable organic ligands separating or connecting transition metal based layers.[14] Striking results have been obtained in the field of low dimensional magnetic materials exhibiting unusual behaviour, by carrying out solvothermal reactions.[15–19] In particular, recent reports have been concerned with the use of carboxylate moieties as bridging ligands between paramagnetic transition metal ions with the versatility of the carboxylate coordination group leading to magnetic networks with various topologies.[20–23]

Our recent investigation of Co^{II} alkanoates $[Co(O_2C(CH_2)_nCH_3)_2(H_2O)_2]_n$ has shown that for long alkane chains, layered structures are obtained when the magnetic layers consist of chains of Co^{II} ions interconnected through carboxylate bridges in a *syn-anti* configuration. This leads to weak antiferromagnetic coupling.[24] On the other hand, results on transition metal phenoxyalkanoate hydrates $[M(O_2C(CH_2)OC_6H_4R)_2(H_2O)_2]_n$ (M = Mn, Co; R = H, Cl, F, ...), the structures of which consist of stacked metal(II) carboxylate layers separated by an organic subnetwork of phenyl rings, provided suitable examples of square planar arrays of magnetic centres.[25,26] The diaquabis(phenoxyacetato)manganese(II) derivative exhibits typical behaviour for an antiferromagnetic 2D square-planar $S = 5/2$ system down to $T_C = 1.633$ K where a 3D ordered spin state leads to weak ferromagnetism. Magnetic data for the Co^{II} analogue suggest the presence of ferromagnetic interactions.[27]

As a continuation of our investigations of layered systems, the present work is concerned with the synthesis, through a hydrothermal route, of a series of layered transition metal (M) carboxylates obtained using the chiral mandelate ion $C_6H_5CH(OH)CO_2^-$ (M = Mn, Fe, Co, Ni, Cu) and an analysis of their crystal structures and magnetic

behaviour. Some molecular complexes of transition metals (Cu, Co, V) have been reported in the literature in which the mandelate anion acts as a co-ligand with lactic acid derivatives such as phenanthroline or bipyridine, resulting in peculiar coordination geometries.[28−31] Noble metal complexes were also prepared.[32] It is worth noticing, however, that very few results have been reported in the literature on compounds involving only the mandelate ion and most of these studies have concerned the solubility, vibrational spectroscopic properties and optical activities of the isolated metal complexes.[33] Only one very recent work reports the crystal structure and magnetic susceptibility measurements of a Co^{II} derivative.[34]

Results and Discussion

Synthesis and Structural Analysis

A series of five transition metal mandelates has been synthesised through a hydrothermal method by treating metal chlorides with mandelic acid and NaOH in water (see Experimental Section). The complexes of manganese (**1**), iron (**2**), cobalt (**3**) and nickel (**4**) were obtained as crystalline powders consisting of very thin platelets. The Fe^{II} solid **2** contains a small amount of a magnetic impurity, namely iron oxide, which was revealed by the magnetic measurements. The copper(II) analogue **5** crystallises from the mother solution (resulting from hydrothermal treatment) as thick single crystals suitable for X-ray analysis. It is worth noticing also that reactions under standard conditions at room temperature led, for the five metal ions, to the same products but only as fine and less crystalline powders. This highlights the importance of an interest in the hydrothermal method. The structure of **5** has been solved by a single-crystal X-ray diffraction analysis (see crystallographic section) and is similar to that reported in the literature for the Co^{II} analogue[34] except that an accurate Fourier analysis ascertained the presence of the hydrogen of the α-hydroxide coordinated to the copper(II) centres, whereas this was not considered for the cobalt species. The compound can be described as a (diaqua)copper(II)−μ-mandelate polymer, the asymmetric unit of which is displayed in Figure 1. Each Cu^{II} atom is coordinated to six oxygen atoms forming elongated octahedra. In the equatorial plane, they are surrounded by two mandelate ligands each chelating the metal through one oxygen atom of the carboxylate group [Cu−O1 1.924(2) Å] and the α-OH [Cu−O2 1.987(2) Å]. Two other mandelate groups complete the octahedral site with monodentate oxygen atoms from their carboxylate functions in apical positions [Cu−O3#1 2.418(2) Å] resulting in a distorted environment (Figure 1) similar to the Co^{II} case but with strong additional distortion of the octahedral sites around metal ions due to the Jahn−Teller effect (see Table 1).

Within the *a*,*b* planes, the copper atoms are connected to four neighbours by carboxylato bridges in a *syn-anti* conformation (Figure 1), thus forming square-planar magnetic arrays separated by a double layer of mandelate anions

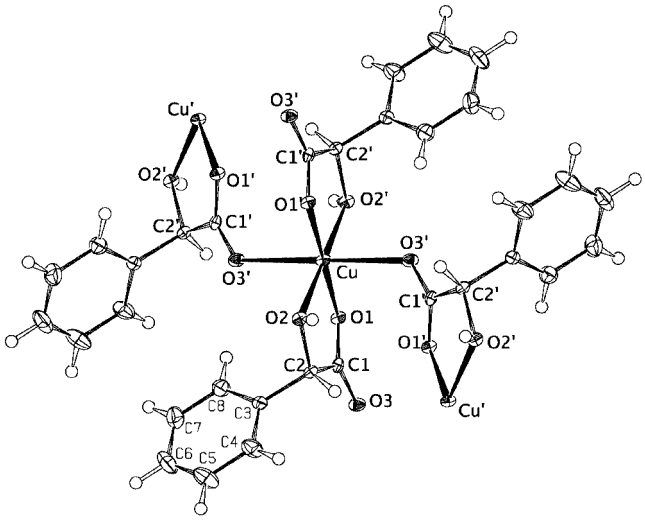

Figure 1. ORTEP plot of the structure of **5** showing coordination of the Cu^{II} atoms by the mandelate ligands and interconnection through carboxylato bridges

Table 1. Bond lengths [Å] and angles [°] in the copper dimandelate compound

Atoms	Distances	Atoms	Angles
Cu−O1	1.924(2)	O1−Cu−O2	83.41(10)
Cu−O2	1.987(2)	O1−Cu−O2#2	96.59(10)
Cu−O3#1	2.418(2)	O1−Cu−O3#1	95.18(9)
O1−C1	1.299(4)	O1#2−Cu−O3#1	84.82(9)
C1−C2	1.530(5)	O2−Cu−O3#1	95.18(9)

C2−C3	1.506(4)	C1−O1−Cu	115.72(19)
		C2−O2−Cu	113.32(18)
O1#3−O2#2	2.752(4)	O3−C1−O1	123.5(3)
(intermolecular)		O3−C1−C2	119.1(3)

#1: $-x + 1/2, y + 1/2, -z + 1$; #2: $-x + 1, -y, -z + 1$; #3: $-x + 1, -y + 1, -z + 1$

(Figure 2). The Cu−Cu distances across the carboxylato bridges are 5.325(5) Å which correspond to the exchange pathways schematised in Figure 3. Moreover, intermolecular hydrogen bonds can be identified [O1#3−O2#2 2.752 (4) Å, O1−H1−O2 171°], the CuO_6 octahedra thus being connected by two O1−O2 hydrogen bonds along the *b* axis. All the mandelates are positioned quasi-perpendicular to the copper layers which are 15.12(1) Å apart. In addition, a detailed examination of the structural stacking prompts a consideration of the existence of σ−π interactions between the phenyl rings related symmetrically by the crystallographic *a* mirror plane. (Figure 2).[35] These cycles form an angle of 87° and the centroid−centroid distance is 5.21 Å. The shortest distances for σ-π interactions are: C4−C8 3.70 Å, C4−C7 3.74 Å, C5−C7 3.93 Å and C5−C6 4.19 Å.

It is apparent that the structure is centrosymmetric. Accordingly, the present compounds exhibit no circular dichroism and involve both (*R*) and (*S*) enantiomers of the mandelate ligand although the pure (*R*) enantiomer was used as a starting ligand. This was also observed in the

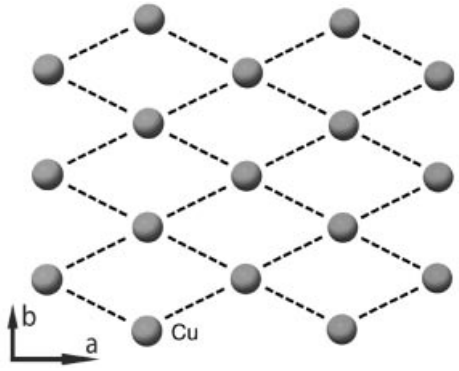

Figure 3. Drawing of the diamond-like M^{II} network in the (*a*,*b*) planes; each metal ion interacts with its four nearest neighbours as in a square planar system

cobalt(II) analogue.[34] For the latter, it was pointed out that this racemisation, on the basis of previous studies on α-hydroxycarboxylic acids, is favoured by the use of an alkaline medium.[36] It is worth noticing here that the present copper(II) analogue, contrary to all the other metal derivatives, can be obtained without addition of an alkaline base. Similarly, the same compound can be obtained as a powder from the reaction under ambient rather than hydrothermal conditions. It thus appears that significant racemisation may also occur in an acidic or neutral medium, perhaps with different kinetics however.[37]

The other M^{II} compounds were obtained as powders or very thin crystals which somewhat frustrated characterisation by single-crystal diffraction methods. However, the corresponding spectroscopic characterisations (Figure 4) and elemental analyses confirm that all complexes are isostructural with the copper(II) and cobalt(II) dimandelates described above. This was further confirmed by a comparison between their powder X-ray patterns shown in Figure 5. The powder diffraction patterns were fully indexed and the crystallographic cell parameters for the series of compounds

have been refined (Table 2) by means of a full pattern matching procedure using the Fullprof software package.[38]

Spectroscopic Properties

The IR and UV data collected for the five compounds were easy to analyse on the basis of the crystal data (see Exp. Sect.). The IR spectra exhibit characteristic bands of the mandelate ligand. The frequency difference between the symmetric and asymmetric carboxylate vibrations, $\Delta\nu$ = 150−165 cm^{-1}, is much smaller than that observed in the corresponding acid ($\Delta\nu_i \approx 270$ cm^{-1}) in agreement with the bidentate coordination mode of the carboxylate groups.[39] The presence of broad νO−H bands in the range 3200−3400 cm^{-1} is related to the mandelate OH moieties bonded to the metal ions. Interestingly, whereas the IR spectra of the Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} compounds are almost identical, thus confirming very similar local structures, significant shifts of the νO−H and carboxylate bands can be observed for Cu^{II} species. The latter is merely related to the distortion of the coordination sphere around the copper atoms due to the Jahn−Teller effect, as found from the single-crystal structure analysis (Table 1). The UV spectra are also consistent with the presence of octahedral geometries for the M^{II} ions.[40,41] The values of Dq and the Racah parameter B have been calculated for the d^7 and d^8 ions giving Dq = 985 cm^{-1}, B = 710 cm^{-1} and Dq/B = 1.4 for the Co^{II} and Dq = 811 cm^{-1}, B = 977 cm^{-1} and Dq/B = 0.83 for the Ni^{II} compound in accordance with weak crystal field and high-spin configurations.[42] For Co^{II}, admixture of forbidden d-d transitions at 480 nm (20833 cm^{-1}) and 505 nm (19801 cm^{-1}) results in a multiple structured band. A value of Dq = 939 cm^{-1} can be deduced for the iron(II) ions and a shoulder at λ = 1260 nm (7936 cm^{-1}) can be attributed to splitting of the ^5E_g state. The UV spectrum of the Cu^{II} derivative exhibits the usual broad band (λ = 745 nm/13422 cm^{-1}) due to transitions from the t_{2g} components to the x^2-y^2 level.

Magnetic Properties

The magnetic properties of **1**, **2**, **3**, **4** and **5** were investigated in the temperature range 2−300 K. The temperature dependence of the magnetic susceptibilities χ above 2 K is shown in Figure 6 as χT vs. T plots for **1**, **2**, **3** and **4**, after correction for diamagnetic contributions. The iron(II) compound **2** contains small amounts of an impurity which is ferromagnetic at ambient temperature. Consequently, the susceptibility displayed in Figure 6 for this compound corresponds to the data corrected using the constant ferromagnetic moment deduced from variations in room temperature magnetisation as a function of the field.

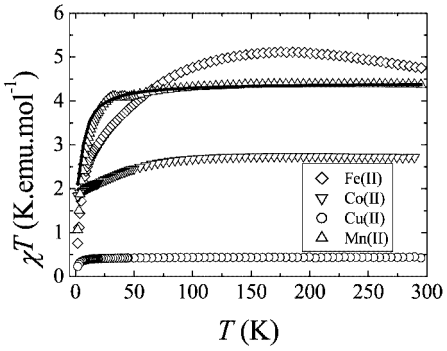

Figure 6. Temperature variation of the magnetic susceptibilities of the compounds **1**, **2**, **3** and **5** as χT vs. T plots; the full line corresponds to the fit of the data for the Mn^{II} compound **1**, as detailed in the text

The four compounds exhibit paramagnetic behaviour corresponding to quasi-isolated metal centres. The inverse-susceptibility versus T curves are linear above 200 K and were fitted using the Curie−Weiss law. The corresponding values of the Curie constants and Weiss temperatures are given in Table 3 and the corresponding values of the effective moments $\mu_{eff} = (8C)^{1/2}$ agree well with those expected for M^{II} ions in an octahedral crystal field.

Upon cooling, the χT product of the Co^{II} compound **3** exhibits a regular decrease from 2.85 $cm^3 \cdot K \cdot mol^{-1}$ at 300 K to 1.8 $cm^3 \cdot K \cdot mol^{-1}$ at 10 K. The decrease of the χT product is well understood as being due to the spin-orbit coupling effects for octahedral Co^{II} ions.[43] Indeed, high-spin octahedral Co^{II} has a $^4T_{1g}$ ground state and, as a consequence, exhibits unquenched spin-orbit coupling in addition to a zero-field splitting which dominates at low temperature and stabilises a doublet ground state. It should be pointed out that for isolated octahedral Co^{II} ions, a minimum value of $\chi T \approx 1.8$ $cm^3 \cdot K \cdot mol^{-1}$ can be expected corresponding to a pseudo spin S = 1/2 and $g \approx 4.4$. Moreover, the magnetisation vs. field variation at 2 K (not shown) is consistent with paramagnetic-like behaviour, indicating that no significant coupling takes place. The saturation moment, Ms = 2.25 $\mu_B \cdot mol^{-1}$, is in agreement with the expected value for octahedral high spin Co^{II} ions (2−3 μ_B per cobalt atom).[9]

Table 3. Main magnetic data of the first row transition metal dimandelates

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Although the corrected data for compound **2** are approximate owing to the presence of the magnetic impurity, the general behaviour of the susceptibility is in agreement with that expected for quasi-isolated Fe^{II} ions exhibiting spin-orbit coupling effects similar to the Co^{II} analogue above.

The copper(II) derivative show a quasi-constant χT product in the whole temperature range and is paramagnetic, whereas the Mn^{II} compound **3** exhibits a significant decrease below 30 K indicating short-range antiferromagnetic in-plane coupling. No long-range order is evident from either susceptibility or magnetisation measurements for this compound. The magnetic behaviour of **3** was modelled with the 2D Heisenberg approach in an effort to evaluate the magnitude of the nearest-neighbour exchange interaction. The susceptibility data were fit between 2 and 300 K with the high-temperature series expansion reported by Rushbrooke and Wood[44,45,46] for an antiferromagnetic 2D Heisenberg square planar system [Equation (1)],[47] giving g = 2.01(1) and $J/k_B = -0.122(4)$ K, Figure 6. The coupling is characteristic of very weak antiferromagnetic interactions across the three-atom dicarboxylate bridge.

$$\chi_{sp}(T) = \frac{S(S+1)Ng^2\mu_B^2}{3k_BT} \times \sum_n a_n x^n \quad (1)$$

The Ni^{II} compound **4** exhibits very different behaviour. Ferromagnetic interactions are implied by the inverse susceptibility $1/\chi$ vs. T variation (not shown) with a positive Curie−Weiss temperature (Table 3). As shown in Figure 7, the temperature variation of the dc magnetic susceptibility implies the existence of a significant ferromagnetic coupling between neighbouring nickel(II) ions within the plane, with an increase in χT from 1.21 K·emu·mol^{-1} at 295 K to 47.5 K·emu·mol^{-1} at 2 K. Ferromagnetic long range order between the layers is demonstrated by the occurrence of a peak in the out-of-phase signal χ'' of the ac susceptibility shown in the inset of Figure 7. The Curie temperature value $T_C \approx 2.5$ K can be deduced from the maximum of χ' where an onset of the imaginary part of the susceptibility χ'' occurs.

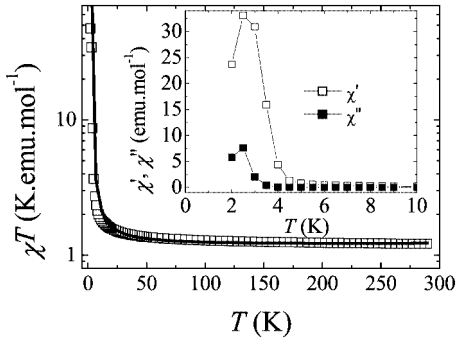

Figure 7. Temperature variation of the magnetic susceptibility of the Ni^{II} mandelate **4** as a χT vs. T plot; the full line corresponds to the fit of the data, as detailed in the text; the inset shows the variation of the real and imaginary parts of the ac susceptibility recorded in a 3.5 Oe/30 Hz magnetic field

Figure 8 shows a magnetisation loop measured at 2 K exhibiting a sharp increase in the magnetisation at low field, up to ca. the half of the saturation value. No hysteresis (at least within a few Gauss) was observed, in accordance with the isotropic character of the Heisenberg Ni^{II} ions and the magnitude of T_C. The saturation moment tends to $2\mu_B$ per Ni^{II} at 5 T which is expected at full saturation for $S = 1$ spin moments. It is important to notice, however, that M vs. H shows a smooth and quasi-linear variation in the high-field region which suggests that small canting between moments might occur, thereby explaining such particular features and leading to rather small residual moments.

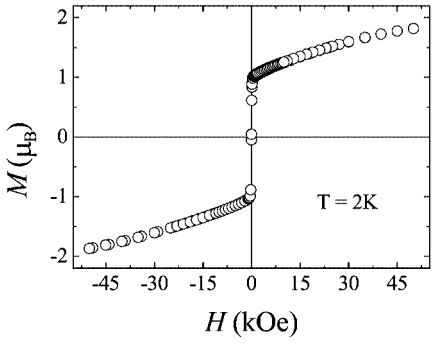

Figure 8. Magnetisation vs. field hysteresis loop for the Ni^{II} mandelate **4**, recorded at 2 K

A fit of the magnetic susceptibility above T_C was carried out using the high temperature series expansion for a ferromagnetic square planar array of $S = 1$ spins, the expression of which is similar to Equation (1) above.[48] In this expression, the zero-field splitting (D) for Ni^{II} ions is neglected although it is known to be effective in the low temperature range, typically below 10 K.[9] Within this approximation, the data are very well fit in the full temperature range with $g = 2.15(1)$ and $J/k_B = +1.213(4)$ K, Figure 7. Finally, the occurrence of 3D magnetic ordering can be undoubtedly established by the temperature variation of the specific heat recorded at low temperature, Figure 9. The curve shows a typical lambda anomaly, the maximum of which enables a

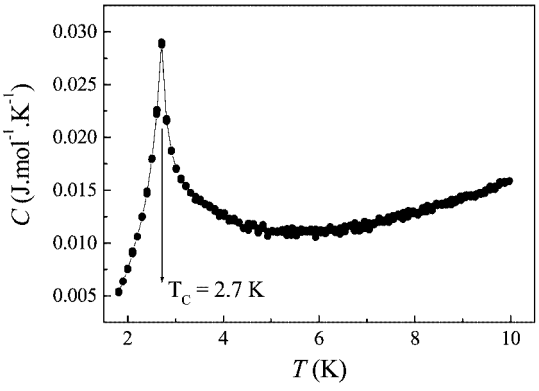

Figure 9. Low-temperature variation of the specific heat of the Ni^{II} mandelate **4**

precise determination of the Curie temperature T_C = 2.7(1) K.

Conclusion

A series of Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} and Cu^{II} mandelates has been crystallised and structurally and magnetically characterised. Although the starting mandelate was enantiomerically pure, the ligand was found to racemise during the synthetic process. The five compounds are isostructural with the copper analogue, the latter having been obtained as single crystals and showing a strong Jahn−Teller distortion of the coordination spheres around the Cu^{II} centres. Their solid-state structures consist of layers of six-coordinate metal(II) ions, thus forming planar arrays of octahedra interconnected through carboxylato bridges in a diamond-like network. The planes are separated by double layers of phenyl groups from the mandelate ligands resulting in a 2D system. From a magnetic point of view, it has been shown that the in-plane exchange pathways between neighbouring magnetic centres form a square-like planar array. The exchange coupling involving bridging carboxylate ligands in a *syn-anti* conformation is known to promote antiferromagnetic interactions between neighbouring M^{II} ions[49] and to be more favourable than the *anti-anti* conformation.[24] This agrees with the observed behaviour of the χT product for the series of transition metal mandelates except for the nickel derivative for which ferromagnetic behaviour is observed with ferromagnetic 3D ordering at $T_C = 2.7$ K.

Experimental Section

General Remarks: Thermogravimetric experiments were performed using a Setaram TG92 instrument (heating rate of 3 °C/min, air stream). FT-IR studies were performed with an ATI Mattson Genesis computer-driven instrument (0.1 mm thick powder samples in KBr). UV/Vis/NIR studies were performed with a Perkin−Elmer Lambda 19 instrument (spectra recorded by reflection with a resolution of 4 nm and a sampling rate of 480 nm/min). Elemental analyses were performed using a Thermo-Finnigan EA 1112 setup (Service d'analyses, ICS, Strasbourg, France). Magnetic studies were carried out using a Quantum Design SQUID MPMS-XL magnetometer (±5 T, 2−300 K) on several sets of crystalline or powdered samples. Low temperature specific heat measurements were carried out using a MagLab HC Oxford Instrument. Powder X-ray diffraction patterns for the whole series where obtained using Bragg−Brentano Siemens D500 (Co-$K_{\alpha 1}$, λ = 1.78897 Å) and D5000 (Cu-$K_{\alpha 1}$, λ = 1.5406 Å) diffractometers equipped with primary beam monochromators. All the powder X-ray patterns exhibit large preferential orientations of the crystallites parallel to the stacking axis *c*.

X-ray Crystallographic Study: A single crystal of the copper mandelate **5** was mounted on a Nonius Kappa-CCD area detector diffractometer (Mo-K_α, λ = 0.71073 Å). The complete conditions of data collection (Denzo software) and structure refinements are given below. The cell parameters were determined from reflections taken from one set of 10 frames (1.0° steps in φ angle), each with an exposure time of 20 s. The structure was solved by direct methods (SHELXS-97) and refined against F^2 using the SHELXL-97 software.[50] The absorption was corrected empirically with Sortav.[51] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated according to stereochemistry and refined using a riding model in SHELXL-97. CCDC-236368 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]. Green-blue crystal, crystal dimension: 0.13 × 0.10 × 0.02 mm, $C_{16}H_{14}CuO_6$, M = 365.81 g·mol^{-1}, monoclinic space group $P2_1/a$, a = 9.454(5) Å, b = 4.905(5) Å, c = 15.495(5) Å, β = 102.564(5)°, Z = 2, $D_{calcd.}$ = 1.732 g·cm^{-3}, μ (Mo-K_α) = 1.588 mm^{-1}, $T_{min.}$ = 0.890, $T_{max.}$ = 0.970 mm, a total of 2406 reflections, 2.69° < θ < 31.96°, 2406 independent reflections with 1833 having $I > 2\sigma(I)$, 106 parameters, Final results: R_1 = 0.0817, wR_2 = 0.1349, *Gof* = 1.16, maximum residual electronic density = 1.152 e·Å^{-3}.

Manganese(II) Dimandelate, $C_{16}H_{14}O_6Mn$ (1): $C_{16}H_{14}O_6Mn$ (**1**) was synthesised by a hydrothermal method from $MnCl_2{\cdot}4H_2O$ (99% Aldrich), (*R*)-mandelic acid (98% Acros) and NaOH (Merck). The starting mixture, which consisted of [$MnCl_2{\cdot}4H_2O$], $C_8H_8O_3$, NaOH and H_2O in a ratio of 2:4:4:20, was homogenised and transferred to a sealed Teflon lined hydrothermal bomb (120-mL bomb volume). After heating at 170 °C for 120 h under autogenous pressure, a white, slightly pink crystalline powder was obtained which was washed and rinsed with distilled water and absolute ethyl alcohol (yield: 0.43 g, 60% on the basis of $MnCl_2{\cdot}6H_2O$). The purity was confirmed by elemental analysis [$C_{16}H_{14}O_6Mn$ (361.21): calcd. C 53.80, H 3.95; found C 53.21, H 3.85] and oxidising pyrolysis [heating in air from 20 to 700 °C at 3 °C/min, at 700 °C for 30 min to transform manganese into Mn_2O_3 and cooling to 20 °C at 10 °C/min: calcd. Mn 15.38%; found 17.16%]. IR (KBr pellet): $\tilde{\nu}$ = 3237 cm^{-1} (νOH), 1560 cm^{-1} (ν_{asym}CO) and 1413 cm^{-1} (ν_{sym}CO).

Iron(II) Dimandelate $C_{16}H_{14}O_6Fe$ (2): $C_{16}H_{14}O_6Fe$ (**2**) was synthesised by a hydrothermal method according to the same process as for the manganese analogue **1** but using $FeCl_2{\cdot}6H_2O$ instead of Mn^{II} dichloride. A very pale green crystalline powder was obtained, washed and rinsed with distilled water and absolute ethyl alcohol (yield: 0.36 g, 50% on the basis of $FeCl_2{\cdot}6H_2O$). The purity was checked by elemental analysis [$C_{16}H_{14}O_6Fe$ (358.12): calcd. C 53.66, H 3.94; found C 53.63, H 3.91] and oxidising pyrolysis [heating in air from 20 to 700 °C at 2 °C/min, at 700 °C for 30 min to transform into Fe_3O_4 and cooling to 20 °C at 10 °C/min: calcd. Fe 15.59%; found 18.85%]. IR (KBr pellet): $\tilde{\nu}$ = 3247 cm^{-1} (νOH), 1565 cm^{-1} (ν_{asym}CO) and 1417 cm^{-1} (ν_{sym}CO). UV/Vis (reflectance for octahedral coordination of Fe^{II}): λ = 1065 nm ($^5E_g \rightarrow {}^5T_{2g}$).

Cobalt(II) Dimandelate $C_{16}H_{14}O_6Co$ (3): $C_{16}H_{14}O_6Co$ (**3**) was synthesised similarly to the above procedure but starting from $CoCl_2{\cdot}6H_2O$ (98% Acros). Very thin pink platelet-like crystals were obtained, washed and rinsed with distilled water and absolute ethyl alcohol (yield: 0.47 g, 65% on the basis of $CoCl_2{\cdot}6H_2O$). The purity was confirmed by elemental analysis [$C_{16}H_{14}CoO_6$ (361.21): calcd. C 53.20, H 3.91; found C 52.84, H 3.85] and oxidising pyrolysis [heating in air from 20 to 700 °C at 3 °C/min, at 700 °C for 30 min to transform into Co_3O_4 and cooling to 20 °C at 10 °C/min: calcd. Co 16.32%; found 16.78%]. IR (KBr pellet): $\tilde{\nu}$ = 3255 cm^{-1} (νOH), 1573 cm^{-1} (ν_{asym}CO) and 1408 cm^{-1} (ν_{sym}CO). UV/Vis (reflectance for octahedral coordination of Co^{II}): λ = 1140 nm ($^4T_{1g} \rightarrow {}^4T_{2g}$), 645 nm ($^4T_{1g} \rightarrow {}^4A_{2g}$), 545 nm [$^4T_{1g} \rightarrow {}^4T_{1g}$ (P)].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Nickel(II) Dimandelate $C_{16}H_{14}O_6Ni$ (4): $C_{16}H_{14}O_6Ni$ (**4**) was synthesised in the same manner as above from $NiCl_2{\cdot}6H_2O$ (99.99% Sigma). A green powder was obtained, washed and rinsed with distilled water and absolute ethyl alcohol (yield: 0.5 g, 70% on the basis of $NiCl_2{\cdot}6H_2O$). The purity was confirmed by elemental analysis [$C_{16}H_{14}NiO_6$ (360.97): calcd. C 53.24, H 3.91; found C 53.15, H 3.87] and oxidising pyrolysis [heating in air from 20 to 700 °C at 3 °C/min, at 700 °C for 30 min to transform into NiO, and cooling to 20 °C at 10 °C/min: calcd. Ni 16.26%; found 17.48%]. IR (KBr pellet): $\tilde{\nu}$ = 3245 cm^{-1} (νOH), 1577 cm^{-1} ($\nu_{asym}CO$) and 1411 cm^{-1} ($\nu_{sym}CO$). UV/Vis (reflectance for octahedral coordination of Ni^{II}): λ = 410 nm ($^3A_{2g}\rightarrow{}^3T_{2g}$), 685 nm ($^3A_{2g}\rightarrow{}^3T_{1g}$), 745 nm ($^3A_{2g}\rightarrow{}^1E_g$), 1235 nm [$^3A_{2g}\rightarrow{}^3T_{1g}$(P)].

Copper(II) Dimandelate $C_{16}H_{14}O_6Cu$ (5): $C_{16}H_{14}O_6Cu$ (**5**) was synthesised from $CuCl_2{\cdot}2H_2O$ (99% Aldrich) and (*R*)-mandelic acid (98% Acros). The starting mixture, corresponding to $CuCl_2{\cdot}2H_2O$, $C_8H_8O_3$ and H_2O in a molar ratio of 2:4:20, was homogenised and transferred to a sealed, Teflon-lined hydrothermal bomb (120-mL bomb volume). Hydrothermal treatment (170 °C, 72 h, autogenous pressure) led to white-yellow crystals and a blue-green solution. These crystals were left to dissolve in the mother liquor. After 6 d, large green-blue crystals of **5** suitable for single-crystal X-ray diffraction analysis were obtained. The crystals were washed with distilled water and absolute ethyl alcohol. (yield: 0.38 g, 52% on the basis of $CuCl_2{\cdot}2H_2O$). The purity was confirmed by elemental analysis [$C_{16}H_{14}O_6Cu$ (365.82): calcd. C 53.66, H 3.94; found C 53.63, H 3.91] and oxidising pyrolysis [heating in air from 20 to 700 °C at 3 °C/min, at 700 °C for 30 min to transform into CuO and cooling to 20 °C at 10 °C/min: calcd. Cu 17.37%; found 16.99%]. IR (KBr pellet): $\tilde{\nu}$ = 3133 cm^{-1} (νOH), 1635 cm^{-1} ($\nu_{asym}CO$) and 1456 cm^{-1} ($\nu_{sym}CO$). UV/Vis (reflectance for octahedral coordination of Cu^{II}): λ = 745 nm (transition from t_{2g} components to x^2-y^2).

Improvements of and Insights into the Isolation of Bismuth Polycations from Benzene Solution – Single-Crystal Structure Determinations of $Bi_8[GaCl_4]_2$ and $Bi_5[GaCl_4]_3$

Martin Lindsjö, Andreas Fischer[a] and Lars Kloo*[a]

Keywords: Bismuth / Cluster compounds / Polycations / Subvalent compounds

The synthesis, crystal growth and structure are reported for the two salts $Bi_5[GaCl_4]_3$ and $Bi_8[GaCl_4]_2$. The compounds are prepared from a solution of $BiCl_3$ and $GaCl_3$ in benzene, using gallium metal as reducing agent. $Bi_8[GaCl_4]_2$ contains a Bi_8^{2+} polycation that, essentially, adopts an ideal square antiprismatic geometry. The compound crystallizes in the $P6_3$ space group; a = 17.760(2) Å and c = 12.979(3) Å. $Bi_5[GaCl_4]_3$ crystallizes in the $R3c$ space group, a = 11.814(2) Å, c = 29.974(3) Å, and contains a Bi_5^{3+} cation adopting a trigonal-bipyramidal geometry. The cation is slightly distorted from the ideal D_{3h} symmetry.

Introduction

Main group clusters constitute an odd group of molecular and ionic species that have long intrigued chemists. Within this group, bismuth polycations have been one of the most studied families of species, primarily because several subvalent cations have been observed, e.g. Bi^+, Bi_5^{3+}, Bi_8^{2+} and Bi_9^{5+}.[1,2]

There are several synthetic schemes practicable for producing bismuth polycations. In early studies, syntheses were performed at high temperature by dissolving bismuth metal in liquid BiX_3 and/or AlX_3 (X = Cl, Br, I).[3–9] In these systems, several polycations were identified in solid state or in solution, mainly using X-ray diffraction and spectroscopy. In particular, both Bi_5^{3+} and Bi_8^{2+} are observed when Bi metal is dissolved in liquid $BiCl_3$–$3AlCl_3$. The major product is controlled by the acidity of the system, which, in turn, is controlled by an excess of $AlCl_3$. Due to slow equilibration, supercooling phenomena and problems with twinning, no single crystals were obtained containing either Bi_5^{3+} or Bi_8^{2+} in these early investigations. Therefore, this route was later reconsidered and refined with the purpose of obtaining single crystals of high quality, which allowed better characterization of the two salts $Bi_5[AlCl_4]_3$ and $Bi_8[AlCl_4]_2$.[10–12] Recently, this type of route has again been utilized in the synthesis of $Bi_8[InBr_4]_2$ [13] and $Bi_8[Ta_2O_2Br_7]_2$.[14]

A second synthetic route to subvalent bismuth cations was later proposed, when evidence for the formation of Bi_5^{3+} and Bi_8^{2+} in superacidic media was found.[15] For such media, the products contain, predominantly, Bi_5^{3+}, while Bi_8^{2+} could be observed as an intermediate.

A decade ago, a third method suitable for the production of bismuth polycations was presented; on adding bismuth metal to a $GaCl_3$–benzene solution, spectroscopic evidence of a dissolved subvalent bismuth species, Bi_5^{3+}, was obtained.[16] This was later supplemented by the isolation of a cubic modification of $Bi_5[GaCl_4]_3$, as a powder, by mixing the Bi–$GaCl_3$–benzene solution with *n*-heptane.[17] The advantage of this route is that it is conducted at room temperature using standard chemicals, while still being reasonably quick. However, only one bismuth polycation has been isolated, and it has been possible to crystallize the solid compound only as powder and not as single crystals. To improve the applicability of this synthetic route, methods for obtaining large single crystals have to be devised. Furthermore, as different bismuth polycations have been isolated from very similar conditions using solid-state techniques, small modifications in the conditions could also generate polycations other than Bi_5^{3+} when using arene reaction media. This hypothesis is additionally supported by quantum chemistry calculations that show several small bismuth clusters, so far not isolated experimentally, to be electronically stable.[18]

We report here a successful method for obtaining high-quality single crystals of subvalent bismuth species in benzene solution. This procedure has been used to isolate a new compound, $Bi_8[GaCl_4]_2$, for which the structure is reported. A re-determination of the structure of trigonal $Bi_5[GaCl_4]_3$ is also reported, together with a discussion on the existence and nature of the cubic modification of $Bi_5[GaCl_4]_3$.

Results and Discussion

Synthesis and Crystal Growth

The original procedure for the synthesis of Bi_5^{3+} in $GaCl_3$–benzene solution used bismuth metal as starting material, which was to be oxidized by $GaCl_3$ to subvalent bismuth species. However, an alternative route is feasible using $GaCl_3$–benzene solution; instead of oxidizing bismuth metal, $BiCl_3$ can be reduced to subvalent species by Ga[$GaCl_4$], mimicking the reaction of Ga–$GaCl_3$–$BiCl_3$ in melts.[19] In this work, the primary procedure has been the reductive route, i.e. the reduction of $BiCl_3$ using Ga[$GaCl_4$]. This alternative is faster and also allows control of bismuth concentration.

As mentioned above, $Bi_5[GaCl_4]_3$ can be precipitated from the prepared benzene solution by shaking this solution with an alkane (e.g. *n*-heptane), producing a red powder.

If larger crystals are desired, a lower rate of mixing with the alkane, e.g. by applying diffusion techniques, could be effective. However, with a Bi–$GaCl_3$–benzene solution, the use of slow diffusion with an alkane normally ends in the solidification of a deeply red, glass-like phase at the bottom of the reaction vessel, together with some red powder. Nevertheless, in rare cases, brown, crystal-like cubes have been obtained using this method. The unit cell has been found to be *F*-centered cubic with a cell parameter of 17.1 Å. This corresponds well to the parameters of the cubic modification of $Bi_5[GaCl_4]_3$, which has previously been reported as the product of this reaction.[17] However, as with the powder data, only low-angle reflections are detected in X-ray diffraction experiments on the single crystals, indicating a disordered structure. The nature of this phase, and its relation to trigonal $Bi_5[GaCl_4]_3$, which has been more satisfactorily characterized, will be further discussed below.

Thus, the use of solely aliphatic hydrocarbons to obtain large single crystals from a Bi_n^{x+}–$GaCl_3$–benzene solution has clearly proved to be at best very unreliable. This is due to the extremely small solubility of the subvalent bismuth species in non-aromatic solvents. For quicker and more reproducible results, other ways have to be explored.

In this case, the obvious choice is to try aromatic hydrocarbons similar to benzene but exhibiting a lower solubility of $GaCl_3$ and Bi_n^{x+}, thus creating a less dramatic decrease in solubility using diffusion techniques. In this particular work, mesitylene has been used for this purpose.

If mesitylene is added on top of a *saturated* Bi_n^{x+}–$GaCl_3$–benzene solution, single crystals are formed, within a couple of days, in the upper part of the benzene phase. Saturation of the benzene solution is important because of the moderately high solubility of the polycations in mesitylene; otherwise only dilution, and no crystallization, will occur. The benzene phase is saturated by an initial extraction (referring mainly to excess $GaCl_3$) using *n*-heptane, but carefully avoiding the precipitation of cubic $Bi_5[GaCl_4]_3$.

Using this procedure, two different types of crystals can be isolated, i.e. black cylinders and red square plates. The black cylinder-shaped crystals consist of $Bi_8[GaCl_4]_2$, a previously uncharacterized compound. The crystals are of varying sizes, the largest being around 0.5 mm.

The red crystals, however, are often very small, <0.1 mm, and tend to form aggregates, making it difficult to select a suitable single crystal for crystallographic investigation. Even so, it has been possible to establish these crystals as trigonal $Bi_5[GaCl_4]_3$, which has previously been synthesized by a solid state route. This structure has so far only been characterized using powder data.[20]

Hence, as for the solid-state and superacid-based methods mentioned above, it can be observed that there is a special relationship between the two cations Bi_5^{3+} and Bi_8^{2+}, and different cations may appear in systems having only slightly different conditions. This is not very controversial, merely reinforcing the proposition that the $GaCl_3$–benzene system can be regarded as a "pseudo-melt".[21]

Of the two cations, Bi_5^{3+} is obviously the most stable in solution; no traceable amounts of Bi_8^{2+} were discovered using UV/Vis spectroscopy in earlier studies on this system. Likewise, only $Bi_5[GaCl_4]_3$ is formed when precipitating using an alkane. However, in contrast, the more abundant product from the approach reported above is $Bi_8[GaCl_4]_2$, while synthetic efforts aimed to generate $Bi_5[GaCl_4]_3$ exclusively in most cases have failed. Instead, red crystals of this compound are most frequently found when the two crystal types are formed in the same experiment. Again, this indicates the very subtle shifts in concentration, of one or more of the reactants, needed to render different solid products. In particular, $Bi_5[GaCl_4]_3$ displays a very narrow window of concentration in which single crystals will be formed. Exactly how this equilibrium is controlled and the mechanism for the formation and crystal growth of $Bi_8[GaCl_4]_2$ from a solution dominated by Bi_5^{3+} are questions for future research. Furthermore, it is puzzling that only these two polycations are formed as calculations have shown that several other bismuth polycations should be isolable.[18]

The route described in this work offers a very easy and good alternative way of producing high-quality crystals containing the Bi_8^{2+} polycation. The crystals can be obtained at room temperature after only a couple days of treatment. However, findings of $Bi_5[GaCl_4]_3$ crystals are far sparser, demonstrating that the optimal conditions for their isolation have very narrow borders, which need to be clarified in order for the described route to this compound to be reliable. The general usefulness of the above method has already been proven with the successful synthesis and crystal growth of $Sb_8[GaCl_4]_2$ – the first structural characterization of an antimony polycation.[22]

Crystal Structure of $Bi_8[GaCl_4]_2$

Table 1 gives the atomic parameters for this compound. The structure consists of Bi_8^{2+} polycations and tetrahedral $GaCl_4^-$ anions (Figure 1). The Bi_8^{2+} polycation geometry is very close to an ideal square antiprism (D_{4d} symmetry), although its crystallographic symmetry is only C_1. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure is very similar to that reported earlier for $Bi_8[AlCl_4]_2$.[10,12] However, the space group chosen for the current chlorogallate structure is $P6_3$ while the aluminate structure was refined in space group $P6_3/m$. In the current structure the anions are all aligned and ordered, in contrast to $Bi_8[AlCl_4]_2$ in which they are reported to be disordered. Notably, all $GaCl_4$ tetrahedra on the *c* axis possess one corner pointing into the positive *c* direction (Figure 2). Adding a mirror plane perpendicular to *c* to this structure would necessarily cause disorder of the anions, leaving the cations essentially unchanged because the latter need only a minor distortion to accommodate such a mirror plane. The choice of space group $P6_3$ therefore appears unambiguous, leaving open the question of whether the chloroaluminate and chlorogallate really adopt slightly different structures or if a redetermination of the chloroaluminate in space group $P6_3$ might lead to an improved structure model without anion disorder.

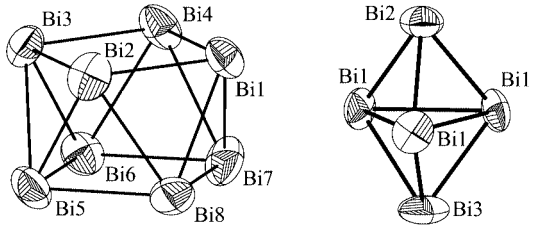

Figure 1. Polycations Bi_8^{2+} in $Bi_8[GaCl_4]_2$ (left) and Bi_5^{3+} in $Bi_5[GaCl_4]_3$ (right); thermal ellipsoids drawn at a 70% probability level

As expected, the Bi–Bi distances of the polycation are very similar to those of the previously reported structure; the bond lengths vary in the range 3.07–3.12 Å (Table 2). The average bond length within the square faces is 3.09 Å and the average bond length between the two squares is 3.10 Å (3.09 and 3.11 Å, respectively, in $Bi_8[AlCl_4]_2$). Quantum chemical calculations have previously suggested that the bonding within the square faces are more localized relative to the bonding between the squares.[18] However, in the optimized theoretical structure, the difference between the inter- and intra-square distances is larger than in the experimentally found polycations; the inter/intra distance ratio is 1.025 theoretically and 1.004 in the structure presented here. This deviation in bond length ratio may indicate that the bonding of the polycation is more extensively delocalized than the calculations predict. The Ga–Cl distances in the anions show a small variation, 2.08–2.18 Å, with the exception of one distance of 2.01 Å. The shortest Bi–Cl distance is 3.44 Å, indicating that the cation–anion interactions are weak.

Table 3 and the unit cell is displayed in Figure 3. Bi_5^{3+} is almost a perfect trigonal bipyramid (Figure 1). This compound has previously been characterized from powder data[20] and, furthermore, it exists in an analogous aluminate structure, $Bi_5[AlCl_4]_3$.[6,11] However, the space group of the structure in the present work was found to be $R3c$, while the earlier studies found it to be $R\bar{3}c$. Even in this study on $Bi_5[GaCl_4]_3$, a structural model could be obtained in space group $R\bar{3}c$. The final result of the structure refinement yielded a much poorer result, though, with significantly larger R factors and difference-Fourier peaks in the range –5 to 5 e Å^{-3} in the proximity of the Bi cation. Additionally, the geometry of the cation changed significantly when the structure was refined in $R3c$. The apical bismuth atoms, which were crystallographically equivalent in $R\bar{3}c$, were refined to rather different final positions in space group $R3c$. This yields a cluster cation with two significantly different bond lengths between the equatorial atoms and the two apical ones, i.e. 2.97 and 3.02 Å, respectively.

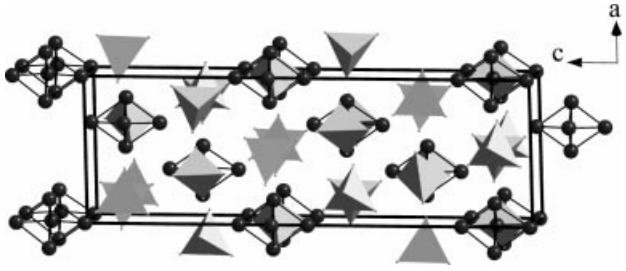

Figure 3. Unit cell of $Bi_5[GaCl_4]_3$ in a view along the *b* axis

To resolve unambiguously the choice of space group in this case, an experimental proof of noncentrosymmetry would be welcome. Unfortunately, so far, such an experiment has proved impossible due to the difficulties in controlling the production of $Bi_5[GaCl_4]_3$ single crystals, as described above. The ultimate choice of the non-centrosymmetric space group is mainly based on the fact that a removal of the centre of symmetry allows a refinement of a structural model that fits the diffraction data considerably better. Table 4 summarizes the bond lengths in $Bi_5[GaCl_4]_3$ and $Bi_5[AlCl_4]_3$.

Table 4. Comparison of unit cell parameters [Å] and distances [Å] in trigonal $Bi_5[GaCl_4]_3$ and $Bi_5[AlCl_4]_3$; atom labels are given in Figure 1

Parameter	$Bi_5[GaCl_4]_3$	$Bi_5[AlCl_4]_3$[11]

Bi(1)–Bi(3)	2.968(4)	3.007(2)

In the $R3c$ space group the symmetry of the cluster cation is lowered from the theoretically predicted D_{3h}, which is predestined with the centric space group, to C_{3v}, as described above. A similar small deviation from the ideal geometry has previously been reported for the isoelectronic Sn_5^{2-}, while Pb_5^{2-} retained the D_{3h} symmetry.[23]

Cubic Modification of $Bi_5[GaCl_4]_3$

As mentioned above, brown, cube-shaped crystallites have on rare occasions been obtained from benzene solution using a slow diffusion technique with *n*-heptane. These crystallites have an F-centered cubic unit cell with a cell parameter of 17.1 Å, corresponding well to the previously reported cubic modification of $Bi_5[GaCl_4]_3$.

This biphasic nature of $Bi_5[GaCl_4]_3$ is puzzling – is the cubic form really a separate phase or is it simply a twinned form of the hexagonal modification? Powder diffraction clearly indicates that the two phases are distinct,[17] but if the trigonal form is cast in a rhombohedral setting it yields cell parameters that differ from the cubic form only by 0.1 Å and 1°. Considering the quality of the data from the cubic modification, such a deviation is not unreasonable; the reflection profiles are very broad. Moreover, the atomic positions in the trigonal form nearly match onto those of the solution of the cubic structure, showing that the two are clearly locally very similar. Hence, in some aspects, the cubic form can reasonably be assumed to represent a microtwinned variety of the trigonal form. The slight mismatch of cell parameters is then explained by the strain caused by the clamping of slightly dissimilar dimensions onto each other.

Does this mean that the two forms are really different phases? Probably yes. The extensive broadening of the reflections in the cubic phase and the lack of high-angle reflections imply that the average domain size is very small, i.e. twinning occurs close to the unit cell level. The two forms are expected to have different heats of formation because of this (they clearly have different diffraction patterns) and they will form at slightly different temperatures and/or solvent conditions. However, no transition between the two phases could be found by thermal analysis (differential scanning calometry) before the compounds decomposed (disproportionation at ca. 170–190 °C).

Conclusions

We have presented an easy route to high-quality single crystals containing bismuth polycations that were previously very difficult to obtain, demanding high temperature and long annealing times. By the stratification of mesitylene on top of a polycation-containing benzene solution, single crystals are formed. Two different crystal structures have been isolated; the previously uncharacterized compound $Bi_8[GaCl_4]_2$ and $Bi_5[GaCl_4]_3$, which has previously been characterized using powder diffraction. It is suggested that the space group of both current chlorogallate structures differs somewhat from that of known aluminate compounds.

The formation of large single crystals of $Bi_5[GaCl_4]_3$ appears to demand very special conditions; the abundant product of the approach described here is, therefore, $Bi_8[GaCl_4]_2$. This is somewhat surprising considering that the dominant polycation in benzene solution is clearly Bi_5^{3+}.

As to whether a cubic $Bi_5[GaCl_4]_3$ phase really exists, it is suggested that this phase is a likely consequence of microtwinning of the trigonal modification.

Experimental Section

General: $GaCl_3$ (Aldrich, anhydrous, 99.99%), $BiCl_3$ (Alfa, anhydrous, 99.999%) and gallium metal (Alfa, 99.999%) were used as received. Benzene (Fluka, 99.5%), heptane (Merck, 99%) and mesitylene (Janssen, 99%) were dried using molecular sieves. Due to the air and moisture sensitivity of the reactants and products, all synthetic work was performed in a glove-box under nitrogen (<1 pm H_2O and O_2).

Preparation of Bismuth Polycation Solutions: A standard reductive-route experiment was performed as follows: $BiCl_3$ (0.22 g, 0.70 mmol) was added to $GaCl_3$ (0.66 g, 3.7 mmol) dissolved in benzene (1.0 mL) in a standard NMR tube. A second solution was produced by adding gallium metal (0.080 g, 1.1 mmol) to a solution of $GaCl_3$ (0.66 g, 3.7 mmol) in benzene (1.0 mL). After 24 h, undissolved gallium metal was removed from the latter solution, and the two solutions were mixed and left overnight. The final solution was deep red.

Isolation of Single Crystals: The solution was first concentrated by gentle extraction using *n*-heptane (2 mL), carefully avoiding precipitation. The heptane phase was then removed and mesitylene (2 mL) was stratified on top of the red solution. After 24–48 h, after one exchange of the mesitylene phase, crystals had formed on the glass wall of the NMR tube, near the phase border. Most of the crystals were black cylinders, but smaller, plate-shaped, red crystals could also be obtained above the black ones, i.e. closer to the mesitylene phase.

Thermal Analysis: Differential scanning calorimetry (DSC) was performed using a Perkin-Elmer DSC 7 instrument. Samples were sealed in aluminium capsules inside the glove box prior to the measurements.

X-ray Crystallographic Data and Refinement of the Structures: Table 5 summarizes the crystallographic data for $Bi_8[GaCl_4]_2$ and $Bi_5[GaCl_4]_3$. The crystals were sealed in 0.5 mm Lindemann capillaries under dry nitrogen. Diffraction data were collected with a Bruker-Nonius KappaCCD diffractometer.

$Bi_8[GaCl_4]_2$: The compound crystallizes in the hexagonal system, Laue group 6/*m*. The systematic absences (00*l*, *l* = 2*n*) led to the possible space groups $P6_3$ and $P6_3/m$ of which the former, noncentrosymmetric one was confirmed during structure determination. The structure was refined assuming an inversion twin (ratio of the twin components: 0.8:0.2).

$Bi_5[GaCl_4]_3$: The compound crystallizes in the rhombohedral system, Laue group –3*m*. Systematic absences led to the possible space groups *R*3*c* and $R\bar{3}c$. A structure model could be obtained in space group $R\bar{3}c$. After the refinement, rather large peaks (+5/–5 e Å^{-3}) were still present in the difference-Fourier map close to the Bi atoms and on opposite sides of them. The symmetry was therefore lowered to *R*3*c*. Upon re-refinement of the structure, the geometry of the cation changed slightly, but significantly: Bond lengths in the equatorial plane decreased from 3.284(5) to 3.269(5) Å. The structural change along the *c* axis is even more significant: The two apical Bi atoms, which were crystallographically related by a two-fold rotation axis in space group $R\bar{3}c$, become independent and the bond lengths between them and the equatorial Bi atoms change [Bi(1)–Bi(3) is 2.977(4) Å and Bi(1)–Bi(2) is 3.037(4) Å]. The difference between these interatomic distances is thus 15σ. Additionally, the maximum and minimum difference-Fourier peaks shrunk to more reasonable levels (1.77/–2.25 e Å^{-3}), which makes the description of the structure in space group *R*3*c* appear more appropriate.

All atoms were refined using anisotropic temperature parameters. Numerical absorption corrections were applied.[24] All structures were solved and refined using direct methods and difference Fourier techniques using SHELXS97/SHELXL97.[25,26] Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD-414089 ($Bi_5[GaCl_4]_3$) and CSD-414090 ($Bi_8[GaCl_4]_2$).

Synthesis, Characterisation of Carbon-Bridged (Diphenolato)lanthanide Complexes and Their Catalytic Activity for Diels–Alder Reactions

Xiaoping Xu,[a] Mengtao Ma,[a] Yingming Yao,*[a] Yong Zhang,[a] and Qi Shen*[a]

Keywords: Lanthanides / O ligands / Structure elucidation / Catalysis / Diels–Alder reaction / Cyclopentadiene

The synthesis and structures of new lanthanide complexes supported by the carbon-bridged diphenolato ligand 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato) ($MBMP^{2-}$) are described. Reactions of anhydrous lanthanide trichlorides with Na_2MBMP in a 1:2 molar ratio in THF at room temperature afforded the corresponding "ate" (diphenolato)lanthanide complexes $[(THF)_nLn(MBMP)_2Na(THF)_2]$ [Ln = Nd (**1**), Sm (**2**), n = 2; Ln = Yb, n = 1 (**3**)]. Recrystallisation of complexes **1**–**3** from toluene in the presence of DME gave the discrete ion-pair complexes $[(MBMP)_2Ln(THF)_2][Na(DME)_2(THF)_2]$ [Ln = Nd (**4**), Sm (**5**), Yb (**6**)]. These complexes have been fully characterised. The single-crystal structural analyses of **1**, **3** and **6** revealed that the coordination geometries of the lanthanide ions can be best described as distorted octahedral in complexes **1** and **6** and distorted trigonal-bipyramidal in complex **3**. It was found that these lanthanide complexes are able to act as Lewis acids to catalyse the Diels–Alder reactions of cyclopentadiene with substituted dienophiles with good activity and stereoselectivity.

Introduction

Of the possible alternatives to the traditional ancillary bis(cyclopentadienyl) ligand set in lanthanide chemistry, alkoxides (aryloxides) have received much attention and become increasingly popular since they are easily available, tuneable and even potentially recyclable ancillary ligand sets for mediating the reactivity of electropositive cations.[1] The synthesis and structural characterisation of a variety of di-[2] and trivalent[3] lanthanide complexes supported by monodentate aryloxides have been published and some of them have shown good catalytic activities for the polymerisation of polar and nonpolar monomers.[4] To date, the chelate diphenolates have been seldom used as ancillary ligands in lanthanide chemistry.[5]

Chelate ligands have played a remarkable role in the development of coordination chemistry. They may stabilise complexes either by thermodynamic or kinetic means and they may serve in the exploration of reaction mechanisms.[6] Carbon-bridged diphenols such as 2,2′-methylenebis(6-*tert*-butyl-4-methylphenol) ($MBMPH_2$) and 2,2′-ethylidenebis(4,6-di-*tert*-butylphenol) ($EDBPH_2$) have been found to be able to act as dianionic ligands which have the advantage of avoiding ligand redistribution reactions and providing a stereochemically rigid framework for the metal centre which could affect stereospecific transformations. The use of these carbon-bridged diphenolato ligands in transition and main-group metal complexes has attracted considerable attention in recent years and some of these complexes have shown interesting catalytic activity.[7] For example, the corresponding titanium complexes are able to catalyse not only the polymerisation of α-olefins in the presence of MAO[7a,7c,7d] but also the living anionic polymerisation of ε-caprolactone.[7b] The aluminium complexes can effectively catalyse the controllable polymerisation of propylene oxide[7f] and ε-caprolactone[7g,7h,7k] as well as MPV hydrogen transfer reactions.[7i] In view of this, it can be anticipated that organolanthanide complexes supported by carbon-bridged diphenolato ligands could lead to the activation of a range of small molecules and act as new types of Lewis acid catalysts for organic synthesis. However, these kinds of ligands have not been used in lanthanide coordination chemistry except for our recent report of the synthesis of divalent lanthanide complexes.[5i] Here we report the synthesis and characterisation of trivalent lanthanide complexes supported by the $MBMP^{2-}$ group and their catalytic activity for Diels–Alder reactions.

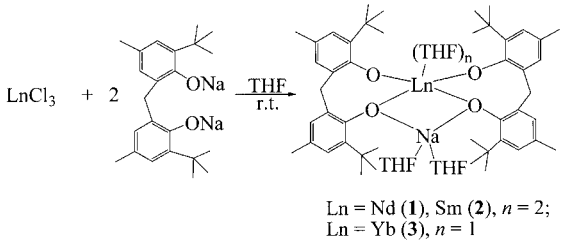
Results and Discussion

Synthesis and Characterisation of Carbon-Bridged (Diphenolato)lanthanide Complexes

Since the organolanthanide or organolanthanoid chlorides are important precursors for lanthanide derivatives, we tried to synthesise the mono(diphenolato)neodymium complex $[(MBMP)NdCl(THF)_x]$ by the general salt metath-

 DOI: 10.1002/ejic.200400519

esis reaction of anhydrous $NdCl_3$ with $MBMPNa_2$ in a 1:1 molar ratio in THF at ambient temperature but this attempt was unsuccessful. The resultant complex, isolated in moderate yield, was characterised as a ligand-redistributed product $[(THF)_2Nd(MBMP)_2Na(THF)_2]$ (**1**). The reaction was repeated with the stoichiometry appropriate for complex **1** and a yield of >78% was obtained. Thus, the isostructural complexes $[(THF)_nLn(MBMP)_2Na(THF)_2]$ [Ln = Sm (**2**), n = 2; Yb (**3**), n = 1] were synthesised by the reaction of $LnCl_3$ with $MBMPNa_2$ in 1:2 molar ratio in THF as shown in Scheme 1.

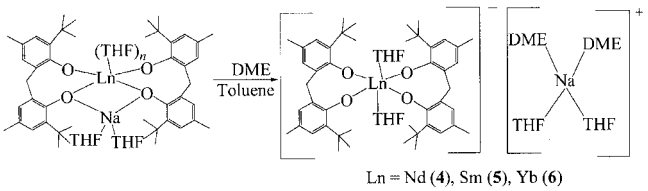


Ln = Nd (**1**), Sm (**2**), n = 2;
Ln = Yb (**3**), n = 1

Scheme 1.

These complexes gave satisfactory elemental analyses and the lanthanide and sodium analyses indicated a molar ratio of 1:1 for Ln and Na in these complexes. The definitive structures of complexes **1** and **3** were determined by X-ray diffraction studies which revealed them to be "ate" complexes in which a sodium atom is connected to one oxygen atom from each of the diphenolato ligands.

It is interesting that recrystallisation of complexes **1**–**3** from toluene in the presence of DME gave the discrete ion-pair complexes $[(MBMP)_2Ln(THF)_2][Na(DME)_2(THF)_2]$ [Ln = Nd (**4**), Sm (**5**), Yb (**6**)] which were confirmed by elemental analysis and ^1H NMR spectroscopy as well as by a structural determination in the case of **6**.[8] In the anionic (aryloxo)lanthanide complexes, most of the anions are connected to the cations by bridging ligands and the ion-pair complexes are rare. Previously reported ion-pair (aryloxo) lanthanide complexes are limited to $[Na(DME)_3][Ln(OC_6H_3\text{-}Ph_2\text{-}2,6)_4]$, $[Na(diglyme)_2][Ln(OC_6H_3\text{-}Ph_2\text{-}2,6)_4$ [diglyme = bis(2-methoxyethyl) ether, Ln = Nd, Er],[3e] $[Nd(OC_6H_3\text{-}tBu_2\text{-}2,6\text{-}Me\text{-}4)_4][Na(THF)_6]$[3d] and $[(C_5Me_5)Y(OC_6H_3\text{-}Me_2\text{-}2,6)_3][Na(THF)_6]$.[9] Due to the competition between coordinating solvents and oxygen atoms in the $MBMP^{2-}$ groups for complexation of the sodium atom, addition of DME broke the bridges between the sodium atom and the diphenolato ligands and formed a sodium cation coordinated by two DME groups and two THF groups as shown in Scheme 2. This can be attributed to the fact that the bidentate DME has a relatively stronger coordinating ability than the bridging phenolate.[3e]



Ln = Nd (**4**), Sm (**5**), Yb (**6**)

Scheme 2.

Complexes **1**–**3** are moderately air- and moisture-sensitive. The crystals can be exposed to air for a few hours without apparent decomposition but the colours of the solutions changed gradually in a few minutes. However, complexes **4**–**6** are air- and moisture-sensitive and the crystals decompose in a few minutes when exposed to air. These complexes are freely soluble in donor solvents such as THF and DME, slightly soluble in toluene and benzene but insoluble in hexane. The neodymium complexes (**1** and **4**) did not provide any resolvable ^1H NMR spectra due to the strong paramagnetism of the neodymium ion.

Crystal Structure Analyses

Although there are many structurally characterised (dinaphtholato)lanthanide complexes in the literature,[5c,10] there are only a few examples of structurally characterised lanthanide complexes supported by diphenolato ligands. The diphenolato ligand $[1,1'\text{-}(2\text{-}OC_6H_2\text{-}tBu_2\text{-}3,5)]_2$, in which two phenols are linked directly, was first used as an ancillary ligand in organolanthanide chemistry.[5a] Recently, other (diphenolato)lanthanide complexes containing donor-functionalised linkers have been reported.[5c–5h] The crystal structures of trivalent lanthanide complexes supported by carbon-bridged diphenolate have not been reported until now.[5i] To elucidate the influence of the carbon-bridged diphenolates on the lanthanide coordination spheres, the X-ray crystal structures of complexes **1**, **3** and **6** were determined.

Crystals of complex **1** suitable for an X-ray diffraction study were grown by cooling a concentrated toluene solution to –10 °C. An ORTEP diagram with the atom-numbering scheme of **1** is shown in Figure 1, selected bond lengths and angles are given in Table 1. Complex **1** has a C_2-symmetric dinuclear structure. The overall molecular geometry consists of a six-coordinate neodymium metal centre which is coordinated by the four oxygen atoms of the two $MBMP^{2-}$ groups and two oxygen atoms from the THF molecules in a distorted octahedron as well as a four-coordinate sodium cation which is coordinated by two oxygen atoms from the $MBMP^{2-}$ groups and two THF ligands in a distorted tetrahedron. The coordination geometry around the neodymium atom is similar to that of the yttrium atom in $[(2,6\text{-}Me_2\text{-}C_6H_3O)_2Y(THF)_2(\mu\text{-}OC_6H_3\text{-}Me_2\text{-}2,6)_2(THF)_3]$.[9] The terminal phenolate [O(2), O(2_2)], one bridging phenolate [O(1)] and one THF molecule [O(3)] can be viewed as occupying equatorial positions within the octahedron about the neodymium centre with Σ(O–Nd–O) = 360.53°. The oxygen atom from another bridging phenolate ligand [O(1_2)] and one oxygen atom from the THF [O(3_2)] occupy axial positions and the O(1_2)–Nd–O(3–2) angle is slightly distorted away from the idealised 180° to 172.466(4)°.

The terminal Nd–O(Ar) bond lengths are 2.278(2) Å which compare well with the previously reported terminal

Table 1. Selected bond lengths [Å] and angles [°] for complex **1**.

Nd(1)–O(1)	2.315(2)	Nd(1)–O(2)	2.278(2)
Nd(1)–O(3)	2.559(3)	Nd(1)–Na(1)	3.543(2)
C(1)–O(1)	1.352(4)	C(7)–O(2)	1.339(4)
Na(1)–O(1)	2.305(2)	Na(1)–O(4)	2.287(3)
O(1)–Nd(1)–O(2)	95.51(8)	O(2)–Nd(1)–O(3)	90.09(8)
O(3)–Nd(1)–O(2_2)	77.92(6)	O(1)–Nd(1)–O(2_2)	97.61(6)
O(1_2)–Nd(1)–O(3_2)	172.466(4)	Nd(1)–O(1)–C(1)	127.3(2)
Nd(1)–O(2)–C(7)	158.5(2)		

Nd–O(Ar) distances when the difference in coordination number is considered.[3d] The bridging Nd–O(Ar) bond length is only 0.04 Å longer than the terminal Nd–O(Ar) bond length which is comparable with that in [Na{Nd(OC_6H_3-Ph_2-2,6)$_4$}][3e] but apparently shorter than that in [(THF)La(OC_6H_3-*i*Pr_2-2,6)$_2$(μ-OC_6H_3-*i*Pr_2-2,6)$_2$Na-$(THF)_2$].[3] The O(2)–Nd–O(2_2) bond angle between the two terminal phenolato ligands is 162.90(6)° whereas the O(1)–Nd–O(1_2) angle between the two bridging phenolato ligands is dramatically smaller at 79.62(5)°. The Nd(1)–O(1)–C(1) bond angle for the bridging phenolato ligand is rather acute at 127.3(2)° reflecting its interaction with the sodium cation while the Nd(1)–O(2)–C(7) bond angle for the terminal phenolato ligand is more obtuse [158.5(2)°] and is comparable with the corresponding bond angles in K[Nd(OC_6H_3-*i*Pr_2-2,6)$_4$].[3i] The bite angle O(1)–Nd–O(2) of 95.51(8)° for the diphenolato ligand is apparently larger than those found in [{Ln[P1,1′-(2-OC_6H-*t*Bu-3-Me_2-5,6)$_2$][N($SiHMe_2$)$_2$](THF)}$_2$] [Ln = Y 88.79(6)°; La 88.83(7)°][5b] and [La{1,1′-(2-OC_6H_2-*t*Bu_2-3,5)$_2$}{CH-($SiMe_3$)$_2$}($THF)_3$] [88.1(3)°][5a] reflecting the fact that addition of a methylene linker between two phenolates increases the flexibility of the diphenolato ligand. Nd(1), Na(1), O(1) and O(1_2) are exactly coplanar (plane 1) as required by the crystallographic symmetry. The dihedral angles between plane 1 and plane 2 [C(1) to C(6)], and between plane 1 and plane 3 [C(7) to C(12)] are 90.64(8) and 81.79(9)°, respectively, indicating that the orientations of plane 1 and the arene rings of the diphenolato ligands are approximately perpendicular. The dihedral angle between two arene rings of the $MBMP^{2-}$ group is 68.9(1)°.

The sodium cation is coordinated to two THF oxygen atoms and an oxygen atom from each of the two $MBMP^{2-}$ groups. This coordination geometry is different from that in [(THF)La(OC_6H_3-*i*Pr_2-2,6)$_2$(μ-OC_6H_3-*i*Pr_2-2,6)$_2$Na-$(THF)_2$], in which one carbon atom from one of the bridging aryloxide ligands is directed to the fifth coordination site of the sodium cation,[3] as well as in [Na{Nd(OC_6H_3-Ph_2-2,6)$_4$}], in which the sodium atom is surrounded by three bridging aryloxide oxygen atoms and three phenyl groups.[3e] The Na–O(Ar) bond length of 2.305(2) Å lies within the range previously reported for Na–O(Ar) bond lengths.[3] The O(1)–Na–O(1_2) bond angle between the bridging phenolato ligands is 80.02(7)° while the O(4)–Na–O(4_2) bond angle between two THF molecules is 88.40(9)°.

Crystals of complex **3** suitable for an X-ray diffraction study were obtained from a concentrated toluene solution at room temperature. The molecular structure of complex **3** is shown in Figure 2 with selected bond lengths and bond angles listed in Table 2. The difference in the molecular

Yb(1)–O(4)–C(30)	149.6(3)	156.7(5)	155.7(5)

structures of complexes **3** and **1** is that only one THF molecule is coordinated to the central metal atom in the former. Thus, the ytterbium centre is five-coordinate by four oxygen atoms from the two $MBMP^{2-}$ groups and one oxygen atom from a THF molecule in a somewhat distorted trigonal-bipyramidal geometry. The oxygen atoms O(5) and O(3) occupy axial positions and the oxygen atoms O(2), O(4) and O(1) can be considered to occupy equatorial positions. The overall molecular structure is similar to that of the previously reported $[(THF)La(OC_6H_3\text{-}i\text{Pr}_2\text{-}2,6)_2(\mu\text{-}OC_6H_3\text{-}i\text{Pr}_2\text{-}2,6)_2Na(THF)_2]$.[3] The coordination geometry of the sodium cation is identical to that observed in complex **1**.

The terminal Yb–O(Ar) bond lengths are 2.059(3) and 2.088(3) Å, respectively, giving an average of 2.073(8) Å which is comparable with those previously reported terminal Yb–O(Ar) bond lengths.[3b] Yb–O(Ar) distances to the bridging ligands are, as expected, somewhat longer at 2.147(3) Å (av.). The Na–O(Ar) and Na–O(THF) bond lengths are comparable with those found in complex **1**. As previously observed in the structure of complex **1**, the O–Yb–O angle between the bridging phenolato ligands [O(1)–Yb(1)–O(3) = 82.2(1)°] is apparently smaller than that between the two terminal phenolato ligands [O(2)–Yb(1)–O(4) = 112.6(1)°]. The average Yb–O–C bond angle for the bridging phenolato ligands is 135.1(3)° while the Yb–O–C angles for the terminal phenolato ligands average 150.6(2)° which is comparable with the corresponding bond angles in complex **1**. The dihedral angles between two arene rings in the $MBMP^{2-}$ groups are quite different, i.e. 57.4(1)° for the ligand containing O(1) and O(2) but 94.8(2)° for that containing O(3) and O(4).

Crystals of complex **6** suitable for an X-ray diffraction study were obtained from a toluene/DME solution at –5 °C. This complex is composed of a discrete six-coordinate $[(MBMP)_2Yb(THF)_2]^-$ anion and an $[Na(DME)_2(THF)_2]^+$ cation. Complex **6** crystallises with two crystallographically independent but chemically similar molecules (**6a** and **6b**) in the unit cell. The selected bond lengths and angles are provided in Table 2 for both molecules. The structure of the anion of complex **6a** with the atom-numbering scheme is shown in Figure 3.

In the cation, the sodium atom is coordinated to four oxygen atoms from two DME molecules and two oxygen atoms from two THF molecules to form a slightly distorted octahedral geometry. In the anion, the coordination geometry around the ytterbium atom is different from that in complex **3**. The ytterbium atom is located in the centre of an octahedron comprised of two $MBMP^{2-}$ groups and two THF molecules in which the oxygen atoms from the $MBMP^{2-}$ groups [O(1), O(3), O(4)] and one THF molecule

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

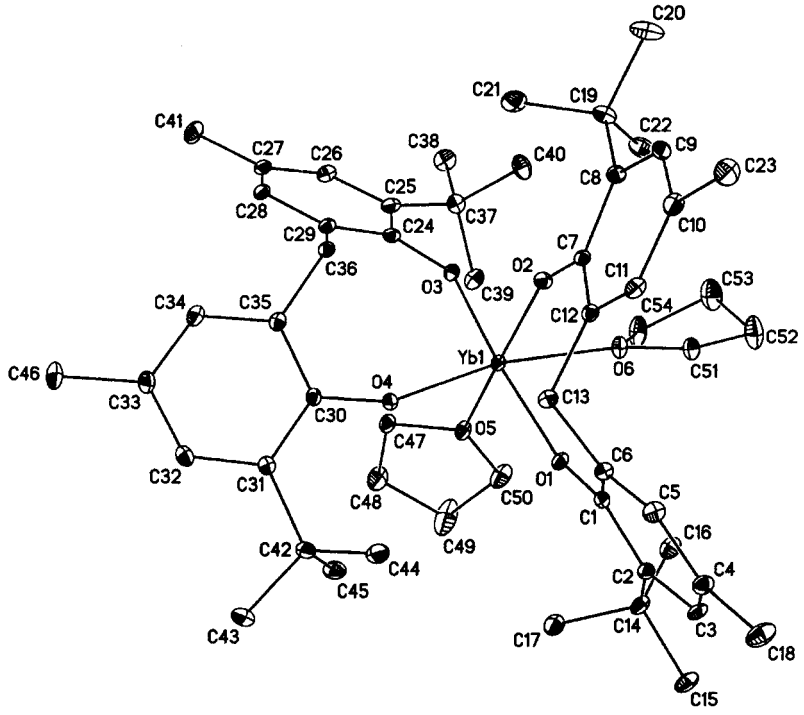

Figure 3. ORTEP diagram of the anion of **6a** showing atom-numbering scheme. Thermal ellipsoids are drawn at the 10% probability level and hydrogen atoms are omitted for clarity.

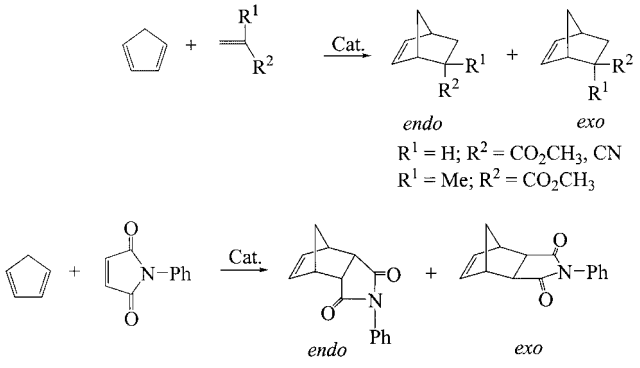
[O(6)] can be considered as occupying equatorial positions with Σ(O–Yb–O) = 359.0°. Two oxygen atoms from one $MBMP^{2-}$ group [O(2)] and the THF molecule [O(5)] occupy axial positions.

The Yb–O(Ar) bond lengths range from 2.119(5) to 2.157(5) Å, giving an average of 2.140(6) Å which is comparable with the terminal Yb–O(Ar) bond lengths in complex **3** when the difference in coordination number is considered but it is slightly longer than that in $[Na(THF)_6][(C_5Me_5)Y(OC_6H_3\text{-}Me_2\text{-}2,6)_3]$ (2.094 Å).[9] The bite angles of O–Yb–O in complex **6a** are 90.45(19)° and 95.72(19)°, respectively, which are comparable with that in complex **1**. The average Yb–O–C bond angle is 152.5(5)° which is similar to the corresponding bond angles in complexes **1** and **3**. The dihedral angles between the arene rings in the two $MBMP^{2-}$ groups are 53.9(3)° and 56.5(2)°, respectively.

A comparison of the structural geometry of the (diphenolato)lanthanide complexes with those of the structurally characterised monodentate aryloxide examples enables an evaluation of the $MBMP^{2-}$ ligand set compared with two ArO^- ligands. The yttrium centre is six-coordinate in $[(2,6\text{-}Me_2\text{-}C_6H_3O)_2Y(THF)_2(\mu\text{-}OC_6H_3\text{-}Me_2\text{-}2,6)_2(THF)_3]$ and $[Na(THF)_6][(C_5Me_5)Y(OC_6H_3\text{-}Me_2\text{-}2,6)_3]$[9] whereas the lanthanum centre is only five-coordinate in $[(THF)La(OC_6H_3\text{-}i\text{Pr}_2\text{-}2,6)_2(\mu\text{-}OC_6H_3\text{-}i\text{Pr}_2\text{-}2,6)_2Na(THF)_2]$[3] and the neodymium centre is four-coordinate in $[Na(THF)_6][Nd(OC_6H_3\text{-}t\text{Bu}_2\text{-}2,6\text{-Me-}4)_4]$,[3d] [Na(diglyme)][$Nd(OC_6H_3\text{-}Ph_2\text{-}2,6)_4$], $Na[Nd(OC_6H_3\text{-}Ph_2\text{-}2,6)_4]$[3e] and $K[Nd(OC_6H_3\text{-}i\text{Pr}_2\text{-}2,6)_4]$.[3i] However, in these (diphenolato)lanthanide complexes, the central metal atom is five- or six-coordinate. Thus, the diphenolato ligand $MBMP^{2-}$ is sterically less demanding than the two monodentate aryloxide groups $[OC_6H_3\text{-}t\text{Bu}_2\text{-}2,6\text{-Me-}4]^-$, $[OC_6H_3\text{-}Ph_2\text{-}2,6]^-$ and $[OC_6H_3\text{-}i\text{Pr}_2\text{-}2,6]^-$ but is comparable with two less bulky aryloxide groups $[OC_6H_3\text{-}Me_2\text{-}2,6]^-$. It is because of the sterically less demanding nature of $MBMP^{2-}$ that the desired (diphenolato)lanthanide chloride $[(MBMP)LnCl(THF)_x]$ could not be achieved by the general salt metathesis reaction.

Diels–Alder Reactions Catalysed by the (Diphenolato) lanthanide Complexes

In recent years, as a result of the importance of Diels–Alder reactions in the synthesis of natural products and physiologically active molecules, increased interest has been directed towards the development of efficient methods for



Scheme 3.

18	**1**	*N*-phenyl maleimide	1:10	8	65	35

the purpose of improving the reaction rates and/or stereoselectivities of cycloaddition reactions.[11] As Lewis-acidic catalysts, lanthanide complexes are well established and have been found to be effective catalysts in numerous Diels–Alder reactions.[12] We found that these carbon-bridged (diphenonato)lanthanide complexes can also catalyse the Diels–Alder reactions of cyclopentadiene with methyl acrylate, methyl methacrylate, acrylonitrile and *N*-phenylmaleimide with relatively good activities and stereoselectivities as shown in Scheme 3 with preliminary results listed in Table 3.

As shown in Table 3, these (diphenolato)lanthanide complexes accelerate the Diels–Alder reactions of cyclopentadiene with these dienophiles and the product yields increased as a function of time whereas the stereoselectivities remained essentially the same at all reaction times. Reactions with substituted dienophiles produced a mixture of *endo* and *exo* isomers although the stereoselectivity (*endo*/*exo* ratio) is apparently dependent on the dienophile. For reactions with asymmetrically substituted dienophiles, the reaction with methyl acrylate afforded the best stereoselectivity. The *endo*/*exo* ratio of 4.6 can be achieved for this reaction at 40 °C in the presence of 10 mol-% of complex **1** as the catalyst (the *endo*/*exo* ratio is 2.7 for the blank reaction, runs 1 and 2). In comparison with other lanthanide catalysts, the activities and stereoselectivities exhibited by the (diphenolato)lanthanide complexes for the reaction of cyclopentadiene with methyl acrylate are higher than that of anhydrous lanthanide chlorides[13a] and are comparable with those of SmI_2[13b] and $Sc(OTf)_3$ if toluene is used as solvent (using $scCO_2$ as solvent, the *endo*/*exo* ratio is up to 10)[13c] but are lower than those of other Lewis acid catalysts such as aluminium,[14a–14c] copper[14d] and ruthenium[14e] complexes. It is worthy to note that the reaction of cyclopentadiene with methyl methacrylate catalysed by complex **1** is *endo*-selective and gave products with an *endo*/*exo* ratio of 2.2. The Diels–Alder reaction of cyclopentadiene with methyl methacrylate normally gave a higher amount of the *exo* stereoisomer[15a] and some organic and inorganic reagents can increase the yield of the *endo* stereoisomer.[15b,15c] Recently, there has been one example reported in which this *exo*-selective reaction can be converted to an *endo*-selective process in chloroaluminate ionic liquids.[15d] Complex **1** showed poor activity and stereoselectivity for the reaction of cyclopentadiene with acrylonitrile, although the result was similar to those reported in the literature.[16] For the symmetrically substituted dienophile *N*-phenylmaleimide, excellent stereoselectivity was obtained. The reaction with *N*-phenylmaleimide using complex **1** as catalyst gave the *endo* stereoisomer as the major product but the selectivity was lower than those of montmorillonite and alumina.[17]

Conclusions

In summary, we have successfully synthesised a series of new soluble carbon-bridged (diphenolato)lanthanide complexes and characterised some of their structural features by X-ray crystallography. Moreover, it was found that coordinated solvents dramatically affect the solid-state structures of the (diphenolato)lanthanide complexes. Crystallisation from toluene in the presence of THF afforded the "ate" complexes while in presence of DME discrete ion-pair complexes were formed. Preliminary results revealed that these "ate" (diphenolato)lanthanide complexes have good activities and stereoselectivities for the Diels–Alder reactions of cyclopentadiene with some substituted dienophiles. Further studies of these reactions are in progress in our laboratory.

Experimental Section

General Procedures: All manipulations were performed under argon using standard Schlenk techniques. THF, DME and toluene were distilled from sodium benzophenone ketyl before use. Anhydrous lanthanide trichlorides were prepared according to the literature procedures[18] and $Na_2(MBMP)$ was prepared from the reac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion of $MBMPH_2$ with Na in THF [$MBMPH_2$ = 2,2′-methylenebis(6-*tert*-butyl-4-methylphenol)]. Lanthanide analyses were performed by EDTA titration with xylenol orange indicator and hexamine buffer[19] and chloride analyses were carried out using the Volhard method. The sodium content was determined with a Hitachi 180-80 polarised Zeeman atomic absorption spectrophotometer. Carbon and hydrogen analyses were performed by direct combustion with a Carlo–Erba EA-1110 instrument. IR spectra were recorded with a Nicolet-550 FTIR spectrometer as KBr pellets. Uncorrected melting points of crystalline samples in sealed capillaries (under argon) are reported as ranges. Methyl acrylate, methyl methacrylate and acrylonitrile were washed with diluted NaOH solution three times, dried with anhydrous $NaSO_4$ for 24 h and distilled before use. *N*-Phenylmaleimide was prepared according to the literature.[20] Cyclopentadiene was freshly prepared by thermally cracking dicyclopentadiene. Other reagents were commercially available.

Synthesis of [(THF)$_2$Nd(MBMP)$_2$Na(THF)$_2$] (1). Method A: To a suspension of $NdCl_3$ (1.63 g, 6.50 mmol) in THF (50 mL) was slowly added a THF solution of Na_2(MBMP) (27.6 mL, 6.50 mmol) at room temperature. After being stirred for 24 h, the precipitate was separated from the reaction mixture using a centrifuge, the solvent was completely removed in vacuo and toluene was added to extract the product. The dissolved portion was removed with a centrifuge. Light-blue microcrystals were obtained from the concentrated toluene solution. Yield: 2.41 g, 32%. M.p. 165–166 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2955 (s), 2871 (m), 1632 (m), 1474 (s), 1389 (m), 1055 (w), 861 (m) cm^{-1}. $C_{62}H_{92}NaO_8Nd$ (1132.64): calcd. C 65.75, H 8.19, Nd 12.73, Na 2.03; found C 65.43, H 8.01, Nd 12.55, Na 1.91. **Method B:** To a suspension of $NdCl_3$ (1.28 g, 5.10 mmol) in THF (40 mL) was slowly added a THF solution of Na_2(MBMP) (43.3 mL, 10.2 mmol) at room temperature. After the reaction solution had been stirred for 24 h, complex **1** was isolated as described above (4.53 g, 78%).

Synthesis of [(THF)$_2$Sm(MBMP)$_2$Na(THF)$_2$] (2): The synthesis of complex **2** was carried out as described above for complex **1** (Method B) but anhydrous $SmCl_3$ (1.3 g, 5.06 mmol) was used instead of $NdCl_3$. Colourless microcrystals were obtained from toluene. Yield: 4.21 g, 73%. M.p. 144–145 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2955 (s), 2920 (s), 2870 (m), 1604 (w), 1435 (s), 1385 (m), 1250 (s), 1087 (w), 860 (m) cm^{-1}. ^{1}H NMR (C_6D_6): δ = 1.47 [36 H, C(CH_3)$_3$], 2.01–2.58 (br., 28 H, THF and ArCH_3), 3.66 (16 H, THF), 3.78 (4 H, ArCH_2), 6.93–7.08 (4 H, C_6H_2) ppm. $C_{62}H_{92}NaO_8Sm$ (1138.76): calcd. C 65.39, H 8.14, Sm 13.18, Na 2.02; found C 65.27, H 7.93, Sm 13.47, Na 1.98.

Synthesis of [(THF)Yb(MBMP)$_2$Na(THF)$_2$] (3): The synthesis of complex **3** was carried out as described for complex **1** but anhydrous $YbCl_3$ (1.31 g, 4.69 mmol) was used instead of $NdCl_3$. Yellow microcrystals were obtained from toluene. Yield: 4.07 g, 75%. M.p. 142–143 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2954 (s), 2909 (s), 2869 (m), 1605 (m), 1526 (m), 1434 (s), 1240 (s), 1156 (s), 1050 (m), 862 (m) cm^{-1}. ^{1}H NMR (C_6D_6): δ = 1.45 (48 H, C(CH_3)$_3$ and THF), 2.17 (12 H, ArCH_3), 3.42–3.81 (br., 16 H, THF and ArCH_2), 6.93–7.08 (8 H, C_6H_2) ppm. $C_{58}H_{84}NaO_7Yb$ (1089.33): calcd. C 63.95, H 7.77, Yb 15.88, Na 2.11; found C 63.56, H 7.74, Yb 15.60, Na 1.93.

Synthesis of [(THF)$_2$Nd(MBMP)$_2$][Na(DME)$_2$(THF)$_2$] (4): To a solution of complex **1** (3.27 g, 2.8 mmol) in toluene (50 mL) was added DME (1 mL). After stirring the solution for about 30 min, blue-purple microcrystals were obtained upon concentration and subsequent cooling of the solution to –5 °C for 3 d. Yield: 3.11 g, 85%. M.p. 109–110 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2951 (s), 2912 (s), 1608 (w), 1466 (s), 1435 (s), 1385 (m), 1084 (s), 860 (m) cm^{-1}. $C_{70}H_{112}NaO_{12}Nd$ (1312.88): calcd. C 64.04, H 8.60, Nd 10.99, Na 1.75; found C 63.74, H 8.39, Nd 10.72, Na 1.68.

Synthesis of [(THF)$_2$Sm(MBMP)$_2$][Na(DME)$_2$(THF)$_2$] (5): To a solution of complex **2** (2.84 g, 2.5 mmol) in toluene (50 mL) was added DME (1 mL). After stirring the solution for about 30 min, pale-yellow microcrystals were obtained upon concentration and subsequent cooling of the solution to –5 °C for 2 d. Yield: 2.83 g, 86%. M.p. 98–99 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2951 (s), 2921 (s), 2870 (m), 1605 (w), 1466 (s), 1431 (s), 1385 (m), 1292 (s), 1084 (s), 860 (m) cm^{-1}. ^{1}H NMR (C_6D_6): δ = 1.47 [36 H, C(CH_3)$_3$], 1.97 (16 H, THF), 2.17 (12 H, ArCH_3), 2.78–3.61 (br., 40 H, DME, THF and ArCH_2), 6.93 (4 H, C_6H_2), 7.08 (4 H, C_6H_2) ppm. $C_{70}H_{112}NaO_{12}Sm$ (1319.01): calcd. C 63.76, H 8.56, Sm 11.41, Na 1.74; found C 63.83, H 8.63, Sm 11.02, Na 1.62.

Synthesis of [(THF)$_2$Yb(MBMP)$_2$][Na(DME)$_2$(THF)$_2$] (6): To a solution of complex **3** (3.21 g, 2.95 mmol) in toluene (50 mL) was added DME (1 mL). After stirring the solution for about 30 min, light-yellow microcrystals were obtained upon concentration and subsequent cooling of the solution to –5 °C for 2 d. Yield: 2.28 g, 61%. M.p. 62–63 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2955 (s), 2920 (m), 2870 (m), 1635 (w), 1466 (m), 1442 (s), 1234 (m), 1157 (m), 1049 (w), 864 (m) cm^{-1}. ^{1}H NMR (C_6D_6): δ = 1.45 [36 H, C(CH_3)$_3$], 1.87 (16 H, THF), 2.16 (12 H, ArCH_3), 3.12–3.85 (br., 40 H, THF DME and ArCH_2), 6.92 (4 H, C_6H_2), 7.07 (4 H, C_6H_2) ppm. $C_{70}H_{112}NaO_{12}Yb$ (1341.68): calcd. C 62.66, H 8.41, Yb 12.91, Na 1.71; found C 63.03, H 8.81, Yb 12.98, Na 1.68.

Diels–Alder Reactions Catalysed by the (Diphenolato)lanthanide Complexes: In a typical run, methyl acrylate (0.25 mL, 2.7 mmol) was added to a toluene solution of the catalyst (3.7 mL, 0.27 mmol). After stirring the solution at 40 °C for 5 min, freshly cracked cyclopentadiene (0.30 mL, 3.3 mmol) was added with a syringe and stirring was continued for the desired time. Methanol was added to the mixture to terminate the reaction and acetylbenzene was immediately added as an internal standard for quantitative analysis. The product yields and *endo*/*exo* ratios were determined using GC or NMR spectroscopy as described in the literature for different dienophiles.[13a,15c,16a,17]

X-ray Crystallography: Crystals of complexes **1**, **3** and **6** suitable for X-ray diffraction were sealed in thin-walled glass capillaries under argon. Diffraction data were collected with a Rigaku Mercury CCD area detector. The structures were solved by direct methods and refined by full-matrix least-squares procedures based on $|F|^2$. All non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms were treated as idealised contributions. The structures were solved and refined using the CRYSTALS (for **1** and **3**) and SHELXS-97 (for **6**) programs. Crystal and refinement data are listed in Table 4. CCDC-239852 to -239854 for **1**, **3** and **6**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

A Study of the Magnetic Structure of $LaMn_2O_5$ from Neutron Powder Diffraction Data

Angel Muñoz,*[a] Jose A. Alonso,[b] María T. Casais,[b] María J. Martínez-Lope,[b] Jose L. Martínez,[b] and María T. Fernández-Díaz[c]

Keywords: Lanthanides / Magnetic properties / Neutron diffraction / Spin glass / Superexchange interaction

Polycrystalline $LaMn_2O_5$ has been studied by neutron powder diffraction in conjunction with magnetization data. The crystal structure of this oxide contains infinite chains of edge-sharing $Mn^{4+}O_6$ octahedra, interconnected by $Mn^{3+}O_5$ pyramids and LaO_8 units. Susceptibility measurements show that $LaMn_2O_5$ presents an antiferromagnetic order below a T_N value of about 31 K. Neutron diffraction experiments confirm the long-range ordering below this temperature in a magnetic structure characterized by the propagation vector **k** = (0,0,1/2). The magnetic arrangement is defined by the basis vectors (G_x,A_y,0) and (0,0,C'_z) for the Mn^{4+} and Mn^{3+} ions, respectively. At 3.5 K, the magnetic moments are 2.59(4) and 1.61(7) μ_B for the Mn^{3+} (4h site) and Mn^{4+} ions (4f site), respectively. Superexchange interactions between the Mn^{4+} ions through Mn^{4+}–O–Mn^{4+} paths are considered in order to explain the commensurate character of the magnetic structure in comparison with the incommensurate structures observed for most of the RMn_2O_5 (R = rare earth metal) compounds. A spin-glass-type behaviour, which probably involves the short-range order in the Mn^{3+} sublattice, is observed above T_N.

Introduction

The discovery of a colossal magnetoresistance effect in the hole-doped rare-earth manganites $R_{1-x}A_xMnO_3$ (A = alkaline-earth metal)[1,2] has triggered the investigation of related oxides which could also present similar phenomena, in particular complex oxides containing manganese ions in a mixed-valence state. The RMn_2O_5 (R = rare-earth metal, Y or Bi) family of oxides is appealing since it contains two different oxidation states for Mn, which are located at crystallographically distinct oxygen environments. According to the first crystallographic studies devoted to the RMn_2O_5 series in the 1960s, they present an orthorhombic crystallographic structure (*Pbam*),[3,4] which was confirmed by a recent high-resolution neutron powder diffraction study[5,6] for most of the compounds of the family. The two different sites for Mn − 4f and 4h − correspond to the Mn^{4+} and Mn^{3+} oxidation states, respectively. The Mn^{4+} ions are octahedrally coordinated by oxygen atoms, and the Mn^{3+} ions are bonded to five oxygen atoms in a distorted tetragonal pyramid. Along the *c* axis the crystallographic structure contains infinite chains of edge-sharing $Mn^{4+}O_6$ octahedra. The different chains are interconnected by dimer units of the $Mn^{3+}O_5$ pyramids. The R^{3+} cations form RO_8 units, which can be considered as bicapped trigonal prisms.

As regards the magnetic properties of the RMn_2O_5 oxides, initial reports[7,8] indicated an antiferromagnetic (AFM) behaviour below 40 K. In particular, for R = Nd, Tb, Ho, Er and Y the magnetic structure is characterized by the propagation vector **k** = (1/2,0,τ) and the Mn spins are ordered according to a helicoidal structure, with the magnetic moments lying in the *ab* plane. In some of these compounds a magnetic ordering is also observed for the rare-earth moments, but at a significantly lower temperature. It seems that the R^{3+} magnetic moments present a sinusoidal magnetic structure. A further study for the compounds with R = Er and Tb[9] indicated that the magnetic structure for the Mn ions is also sinusoidally modulated. Some compounds of the family, such as $DyMn_2O_5$, present a more complicated ordering;[10] its magnetic structure is defined by two propagation vectors, $\mathbf{k_1}$ = (1/2,0,0) and $\mathbf{k_2}$ = (1/2,0,τ). The magnetic structure of $EuMn_2O_5$ has also been analysed to a certain degree. Its magnetic structure is characterised by **k** = (1/2,0,τ); τ varies with the temperature and remains constant for $T < 6$ K on achieving the commensurable value τ = 1/3.[11] Unlike most of the RMn_2O_5 compounds, $BiMn_2O_5$ presents a commensurate magnetic structure,[12,13] defined by **k** = (1/2,0,1/2).

Dielectric and magnetoelectric studies[14,15] carried out on the RMn_2O_5 oxides indicate the presence of ferroelecticity in these compounds. Many studies have been performed

in order to characterize the coexistence of ferroelectricity and magnetism, in particular the effect on the ferroelectric properties when a magnetic field is applied. Very recently,[16] in the multiferroic $TbMn_2O_5$ compound, a strong interplay between electrical polarization and the applied magnetic field has been reported, even for small fields. This striking behaviour implies a new possible device application consisting of magnetically recorded ferroelectric memory.

The preparation and crystal structure of $LaMn_2O_5$ has not been described until recently,[6] since its synthesis requires the use of high oxygen pressure. The aim of this paper is to report on the magnetic ordering and its thermal evolution from neutron diffraction measurements for this material, in conjunction with magnetic susceptibility measurements. A comparison with the magnetic structure of other compounds of the series is also established.

Results

Magnetic Measurements

The dc magnetic susceptibility curves recorded under zero-field-cooling (ZFC) and under field-cooling (FC) conditions are shown in Figure 1. Both curves present a similar behaviour above a T_N value of about 31 K; they diverge below this temperature [see inset (a) of Figure 1]. As will be shown for the neutron diffraction results, this temperature coincides with the establishment of the long-range magnetic ordering in $LaMn_2O_5$. The evolution of the FC susceptibility below T_N corresponds to the onset of an AFM ordering. Another important feature of the dc susceptibility curve is the presence of a very broad maximum at low temperature, which is centred at around 45 K (T_{SG}). A broad maximum is also observed in the real part of the ac susceptibility (see Figure 2). As is shown in inset (a) of Figure 2, the thermal evolution of the ac curve strongly depends on the frequency, which suggests a spin-glass-like behaviour at low temperature. It is well known that irreversibility in the spin-glass behaviour leads to a non-zero out-of-phase component, χ'' (imaginary part of the ac susceptibility). This can clearly be seen in inset (b) of Figure 2, which shows χ''. This confirms the spin-glass behaviour, and the presence of two peaks indicates that the freezing of the spin-glass state takes place in a complicated way.

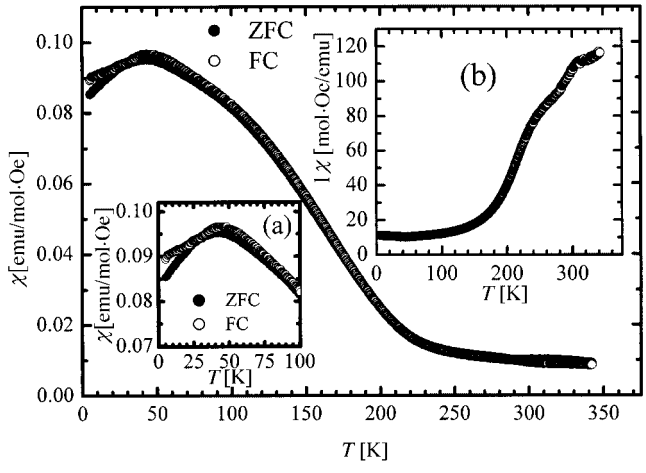

Figure 1. Thermal variation of the dc susceptibility under zero-field cooling (ZFC) and field-cooling (FC) conditions (H = 1 kOe); inset: (a) close-up of the low-temperature region; (b) plot of the reciprocal susceptibility (FC) versus temperature

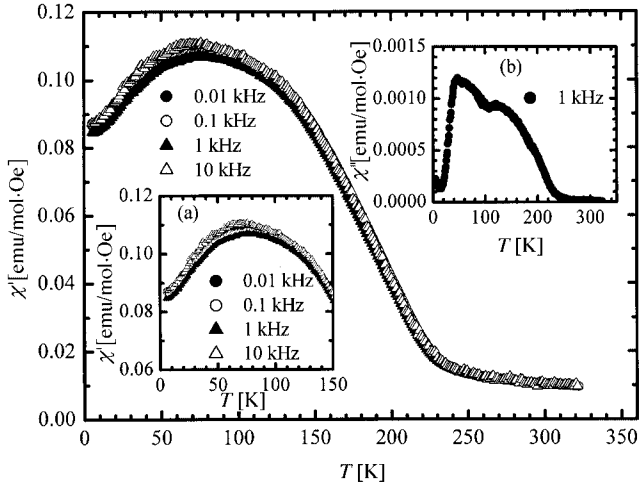

Figure 2. Real ac susceptibility curve; inset: (a) close-up of the low-temperature region; (b) imaginary component of the ac susceptibility

As regards the thermal variation of the dc susceptibility at high temperature, a linear behaviour in the reciprocal susceptibility is not observed below 300 K [inset (b) of Figure 1]. Applying the Curie–Weiss law in the temperature range 317–342 K gives a paramagnetic temperature, Θ_P, of –225 K and an effective magnetic moment of 6.25 μ_B. The effective magnetic moment is in good agreement with the theoretical value, determined as $\mu = [\mu^2(Mn^{3+}) + \mu^2(Mn^{4+})]^{1/2}$, of 6.24 μ_B, where the spin-only values of 4.90 and 3.87 μ_B are considered for the Mn^{3+} and Mn^{4+} ions, respectively. The magnetization curves displayed in Figure 3 show a negligible magnetization at low temperatures, discarding the presence of a weak ferromagnetism effect. We suggest that the change in the slope observed in the inverse of the susceptibility at around 275 K is due to crystal-field effects.

Magnetic Structure from Neutron Diffraction Measurements

A set of neutron powder diffraction (NPD) patterns acquired in the temperature range 3.5–98.8 K, with λ = 2.40 Å, has been used to determine the magnetic structure and study its thermal evolution. For the high-temperature NPD patterns, all the Bragg reflections can be indexed in the orthorhombic *Pbam* space group. The lattice parameters at 98.8 K refined to a = 7.6121(8) Å, b = 8.6372(8) Å and c = 5.6691(6) Å. On decreasing the temperature to below 31 K new peaks appeared in the patterns, thus confirming the onset of a magnetic ordering with a T_N value of 31 K (see Figure 4). The new peaks can be indexed with the propagation vector **k** = (0,0,1/2), which implies a commensurable magnetic structure with a magnetic unit-cell that doubles the chemical one along the c direction. As can be seen in Figure 5, the intensity of the magnetic reflections increases monotonically below T_N and reaches saturation at low temperature, with no anomalies that could indicate a modification of the long-range spin arrangement. Therefore, the magnetic structure seems to remain stable down to 3.5 K.

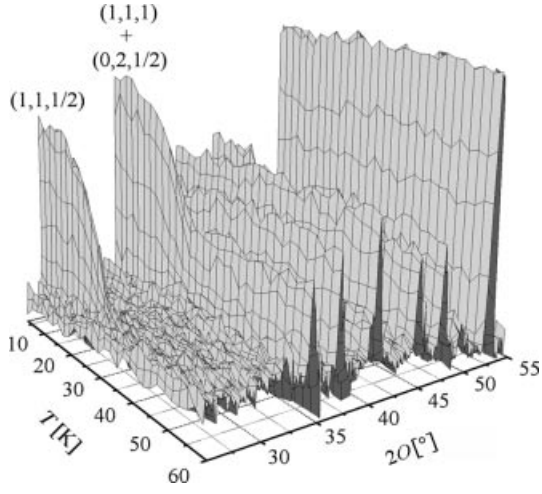

Figure 4. Thermal evolution of the NPD patterns for 3.5 < T < 60 K and 25° < 2θ < 55°

For the resolution of the magnetic structure, the solutions compatible with the symmetry of $LaMn_2O_5$ have been taken into consideration. The possible solutions were determined by a representation analysis of group theory technique described by Bertaut.[17] For **k** = (0,0,1/2), the irreducible representations of the G_k group are those given in Table 1, which have been taken from Kovalev's tables.[18] The basis vectors associated with each irreducible representation are reported in Table 2. The basis vectors define the different possible magnetic structures and were obtained by the projection operator technique. The notation for the Mn1 atoms located at the 4h site is 1(x,y,1/2), 2(–x,–y,1/2), 3(–x + 1/2,y + 1/2,1/2) and 4(x + 1/2,–y + 1/2,1/2). The Mn2 atoms of the 4f site are labelled as 5(1/2,0,z), 6(1/2,0,–z), 7(0,1/2,z) and 8(0,1/2,–z).

Γ_4	(C_x,F_y,0)	(A'_x,G'_y,0)
Γ_5	(0,0,G_z)	(C'_x,F'_y,0)
Γ_6	(F_x,C_y,0)	(G'_x,A'_y,0)
Γ_7	(A_x,G_y,0)	(0,0,F'_z)
Γ_8	(0,0,C_z)	(0,0,A'_z)

[a] F = m1 + m2 + m3 + m4; C = m1 + m2 – m3 – m4; A = m1 – m2 – m3 + m4; G = m1 – m2 + m3 – m4. [b] F' = m5 + m6 + m7 + m8; C' = m5 + m6 – m7 – m8; A' = m5 – m6 – m7 + m8; G' = m5 – m6 + m7 – m8.

After checking the different solutions, the magnetic structure that shows the best agreement with the experimental data is defined by the basis vectors (G_x,A_y,0) for Mn1 atoms (site 4h) and (0,0,C'_z) for Mn2 atoms (site 4f). The calculated and observed NPD patterns for this solution at 3.5 K are compared in Figure 6. In the fitting, the atomic positions of $LaMn_2O_5$ are fixed to those given in Table 4 in the Exp. Sect. At 3.5 K, the magnetic moments are 2.59(4) and 1.61(7) μ_B for the Mn1 and Mn2 atoms, respectively (see Table 3). These values are significantly lower than those expected for the oxidation states Mn^{3+} at 4h sites (electronic

configuration $t_{2g}^3e_g^1$, expected moment of 4 μ_B) and Mn^{4+} at 4f sites (electronic configuration t_{2g}^3, with 3 μ_B). This reduction could be due to covalency effects.

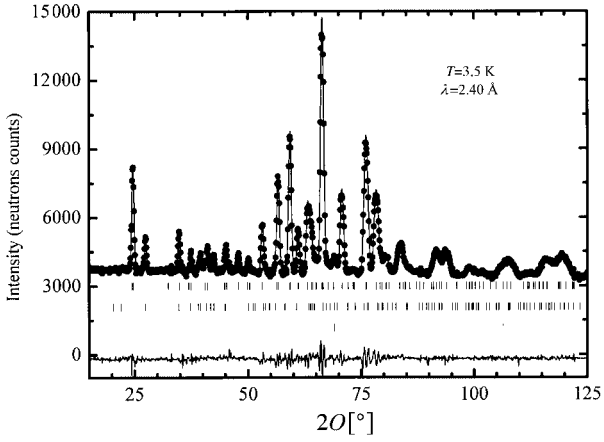

Figure 6. Observed (solid circles) and calculated (solid line) NPD patterns at 3.5 K; the first series of tick marks corresponds to the nuclear Bragg reflections of $LaMn_2O_5$, the second one to the magnetic reflections and the third one to the vanadium sample holder; the solid line at the bottom is the difference between the observed and calculated NPD patterns

The thermal evolution of the magnetic moments below T_N is displayed in Figure 7. On cooling, both the Mn1 and Mn2 ordered moments increase monotonically and reach saturation at low temperature. A view of the magnetic structure is presented in Figure 8. The magnetic moments of the Mn^{4+} ions are arranged along the *c* direction, whereas for the Mn^{3+} ions the moments are oriented in the *ab* plane. On the other hand, as displayed in Figure 8, the magnetic moments of the $z = z_0$ [$z_0 = 0.2610(8)$] and $z = -z_0$ layers, which are separated by a layer of La atoms, are ferromagnetically coupled. In contrast, the $z = z_0$ and $z = 1 - z_0$ layers, which are separated by a layer of Mn^{3+} ions, are antiferromagnetically coupled.

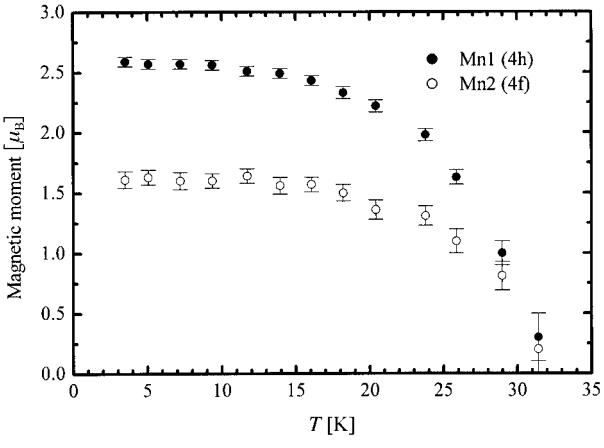

Figure 7. Thermal evolution of the magnetic moments for the Mn^{3+} (4h site) and Mn^{4+} (4f site) ions

The sequential refinement of the NPD patterns allowed us to determine the thermal evolution of the unit-cell parameters. The thermal variation of the *a* and *c* lattice parameters below 100 K is represented in Figure 9a. On decreasing the temperature below 100 K, the *c* lattice parameter decreases almost linearly and, below T_N, it remains virtually constant. Surprisingly, the *a* parameter increases with a sigmoidal shape when the temperature de-

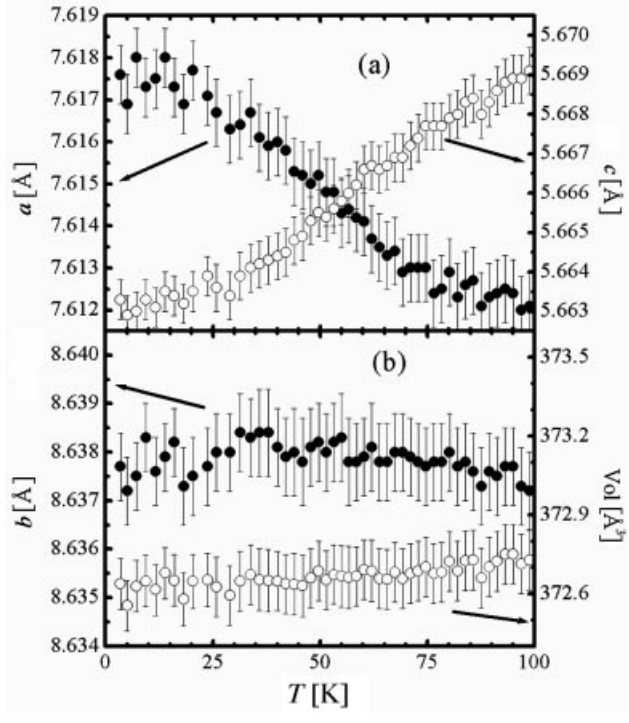

Figure 9. Thermal variation of the *a*, *b* and *c* lattice parameters and unit-cell volume

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

creases. The *b* lattice parameter variation (Figure 9b) also shows a slight anomaly around T_N, which suggests a subtle magnetostrictive effect. The unit-cell volume, averaging the trends of *a* and *c* parameters, remains constant over the whole temperature range.

Discussion

The neutron diffraction measurements have shown that $LaMn_2O_5$ orders below 31 K with a magnetic structure characterized by the propagation vector **k** = (0,0,1/2) and defined by the basis vectors $(G_x,A_y,0)$ and $(0,0,C'_z)$ for the Mn^{4+} and Mn^{3+} ions, respectively. For a better understanding of the spin arrangement it is very useful to bear in mind a description of the crystallographic structure. It consists of chains of edge-sharing $Mn^{4+}O_6$ octahedra arranged along the *c* axis. Along the chain direction, the $Mn^{4+}O_6$ octahedra (Mn2) are interleaved either by a layer of La^{3+} ions or by a layer of Mn^{3+} ions (Mn1). This implies that, for a given $Mn^{4+}O_6$ octahedron, there are two closer $Mn^{4+}O_6$ octahedra, one at $d_1 = 2z_0$ (separated by La^{3+} ions) and one at $d_2 = 1 - 2z_0$ (separated by Mn^{3+} ions). For $LaMn_2O_5$ the Mn2–Mn2 distances are d_1 = 2.987 Å and d_2 = 2.735 Å (Table 4). The different chains are interconnected by $La^{3+}O_8$ and $Mn^{3+}O_5$ units; these latter polyhedra mediate the magnetic coupling between neighbouring $Mn^{4+}O_6$ chains. In fact, the $Mn^{3+}O_5$ units form dimers of two pyramids related by an inversion centre. For $LaMn_2O_5$, the distance between the two Mn^{3+} ions within the dimer is 2.894 Å. The chains of $Mn^{4+}O_6$ octahedra, separated by a lattice parameter along *a* or *b*, are connected by a dimer. On the other hand, every chain has four closer chains interconnected by a single $Mn^{3+}O_5$ pyramid. This arrangement is displayed in Figure 10.

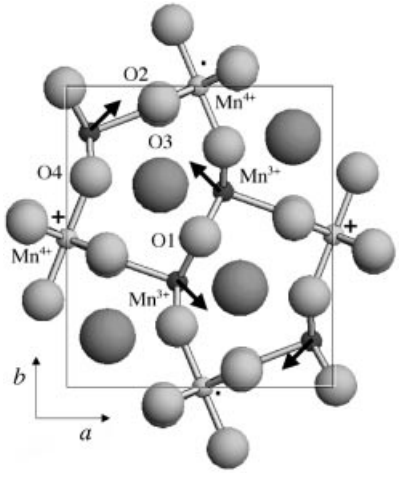

Figure 10. Projection of the crystallographic structure in the *ab* plane; the Mn^{3+} and Mn^{4+} ions are in the $z = 1/2$ and $z = 1 - z_0$ planes, respectively; the arrows indicate the direction of the Mn^{3+} magnetic moments in the *ab* plane; the + and – symbols indicate Mn^{4+} magnetic moments oriented parallel or antiparallel, respectively, to the direction of the *c* axis

In the magnetic structure, the magnetic moments of the Mn^{4+} ions are directed along *c* in the chains of $Mn^{4+}O_6$ octahedra (Figure 8). Within a single chain, the coupling between the Mn^{4+} ions of two adjacent octahedra separated by a La^{3+} layer is ferromagnetic, whereas those separated by a Mn^{3+} layer are antiferromagnetically coupled. Therefore, we have alternating FM and AFM couplings along the chains. To understand the observed magnetic arrangement, we must consider the following interactions: i) the superexchange interaction between the Mn^{4+} ions separated by an La^{3+} layer (with an Mn2–Mn2 distance, d_1, of 2.986 Å), across an Mn^{4+}–O2–Mn^{4+} path (with a bonding angle of 100.1°), assigned to the J_1 superexchange parameter; ii) the superexchange interaction between the Mn^{4+} ions separated by an Mn^{3+} layer, characterized by an Mn2–Mn2 distance, d_2, of 2.735 Å, across the superexchange path Mn^{4+}–O3–Mn^{4+} (bonding angle 93.3°), labelled J_2; and iii) the indirect superexchange interaction involving the $Mn^{3+}O_5$ units, across Mn^{4+}–O2–Mn^{3+}–O4–Mn^{4+} paths, characterized by J_3. If the indirect superexchange interaction is isotropic, J_3 would tend to couple the two Mn^{4+} ions placed at both sides of the Mn^{3+} layer ferromagnetically, as both these Mn^{4+} ions are symmetrically arranged with respect to the Mn^{3+} layer. The experimental results indicate that the coupling is AFM, which implies that J_2 must be negative and much greater than J_3. In the same way, J_1 must be positive, as the coupling between the Mn^{4+} ions separated by a La^{3+} layer is ferromagnetic. The presence of two superexchange interactions of different sign along *c* accounts for the propagation vector **k** = (0,0,1/2). Furthermore, it seems that a short Mn2–Mn2 distance along the chains favours an AFM interaction, whereas a long distance implies a ferromagnetic interaction. The J_1 and J_2 values depend on the distances d_1 and d_2, respectively. These distances are determined by the z_o position parameter for the Mn2 atoms (4f site). In the RMn_2O_5 series, on decreasing the R^{3+} ionic radius, d_1 tends to decrease; this changes makes possible the fulfilment of the condition $|J_1| < 4|J_2|$, which can give place to the incommensurate magnetic structure found in most of the RMn_2O_5 compounds ($k_z = \tau$).

On the other hand, every chain is antiferromagnetically coupled to four closer ones. In the dimers, the two Mn^{3+} ions are antiferromagnetically coupled and the magnetic moments are oriented in the *ab* plane in such a way that the moment direction is nearly perpendicular to the base of the pyramid. The path for the superexchange interaction between the Mn^{3+} ions of the dimer is Mn^{3+}–O1–Mn^{3+}, with a bonding angle of 97.5°. Taking into account the expected electronic configuration for Mn^{4+} and Mn^{3+} ions – t_{2g}^3 and $t_{2g}^3e_g^1$, respectively – the superexchange interaction across Mn^{4+}–O2–Mn^{4+} paths (along the chains) takes place via t_{2g}–t_{2g} orbitals, whereas for Mn^{3+}–O3–Mn^{3+} (within the dimers) it takes place via e_{2g}–e_{2g} orbitals. Given the directionality of the d orbitals, the latter superexchange interaction (via e_{2g}–e_{2g} orbitals) is, in general, stronger than that observed via t_{2g}–t_{2g} orbitals; this fact suggests that the coupling between Mn^{3+} moments within the dimers would take place at higher temperatures. We can consider a sce-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nario consisting of the appearance of an AFM coupling in each dimer at temperatures well above T_N. This short-range ordering, with no coherence across the crystal, would be responsible for the spin-glass-type behaviour described above. On decreasing the temperature, the strengthening of the superexchange interactions between the Mn^{4+} ions (along the chains) and between Mn^{3+} and Mn^{4+} moments would give rise to the establishment of a long-range order below T_N.

It is worthwhile to compare the magnetic structure of $LaMn_2O_5$ with those of other members of the RMn_2O_5 family. For most RMn_2O_5 oxides the magnetic structure is defined by the propagation vector $\mathbf{k} = (1/2,0,\tau)$, except for $BiMn_2O_5$, where $\mathbf{k} = (1/2,0,1/2)$, and $DyMn_2O_5$, where $\mathbf{k_1} = (1/2,0,0)$ and $\mathbf{k_2} = (1/2,0,\tau)$. Thus, for all of them the magnetic structure propagates antiferromagnetically along the *a* direction, whereas for $LaMn_2O_5$, with $\mathbf{k} = (0,0,1/2)$, the propagation is ferromagnetic. As regards the orientation of the magnetic moments, in $LaMn_2O_5$ the moments of the Mn^{4+} ions are parallel to the *c* direction and for the rest of the compounds of the series the moments are in the *ab* plane. The magnetic anisotropy is mainly given by the symmetry of the ion environment, in this case by the symmetry of the $Mn^{4+}O_6$ octahedra. The Mn–O distances in the octahedra become more different as the R^{3+} ionic radius increases, so that the higher symmetry of the octahedra is found for $LaMn_2O_5$. The coupling of the magnetic moments of the Mn^{4+} ions along the *c* direction is also worth discussing. For RMn_2O_5 compounds with $\mathbf{k} = (1/2,0,\tau)$ two models[8] for the magnetic structure can be considered. In one of them, the coupling of the magnetic moments for the Mn^{4+} ions separated by an Mn^{3+} plane is ferromagnetic, and for those Mn^{4+} ions separated by an R^{3+} plane the magnetic moments form a certain angle, φ. In the second model, the coupling is simply the inverse. In fact, both $BiMn_2O_5$ and $LaMn_2O_5$ follow both models, but with $\varphi = 180°$ for $BiMn_2O_5$ (first model) the coupling of the magnetic moments for the Mn^{4+} ions separated by a R^{3+} plane is perfectly antiferromagnetic, whereas for $LaMn_2O_5$ the coupling is the opposite and follows the second model.

Conclusions

Both dc and ac magnetic susceptibility measurements show that $LaMn_2O_5$ undergoes an AFM ordering below 31 K (T_N), and also suggest a spin-glass-like behaviour above T_N. Neutron diffraction experiments allowed us to characterize the low-temperature magnetic arrangement: the magnetic structure is defined by the propagation vector $\mathbf{k} = (0,0,1/2)$, and the spin coupling is given by the basis vectors $(G_x,A_y,0)$ and $(0,0,C'_z)$ for the Mn^{4+} and Mn^{3+} spins, respectively. Within the chains of $Mn^{4+}O_6$ octahedra, the magnetic moments of the Mn^{4+} ions are directed along *c*; each Mn^{4+} moment displays an FM and an AFM coupling with neighbouring Mn^{4+} spins to account for the observed propagation vector. Adjacent chains are antiferromagnetically coupled. Within the dimer units of $Mn^{3+}O_5$ pyramids, the two Mn^{3+} spins also show an AFM coupling, with the magnetic moments lying in the *ab* plane. The magnitude of the two superexchange parameters defined along the chains, J_1 and J_2, is related to the two different distances between Mn2 atoms; the different sign and magnitude of J_1 and J_2 accounts for the commensurate character of the magnetic structure. We suggest that the two Mn^{3+} ions of each dimer unit are antiferromagnetically coupled above T_N, given the superior strength of the superexchange interactions through the e_{2g}–e_{2g} orbitals, which would cause a short-range magnetic order within the Mn^{3+} dimers, with no long-range coherence across the crystal. This effect would be responsible for the spin-glass-type behaviour observed in the magnetization measurements.

Experimental Section

$LaMn_2O_5$ was obtained as a dark-brown, polycrystalline powder starting from precursors previously synthesized by a wet-chemistry technique, followed by oxygenation at 1000 °C under 200 bar of oxygen pressure, as described elsewhere.[6] It is important to underline that the final treatment under high oxygen pressure is essential for the stabilization of monophase $LaMn_2O_5$. This material could not be obtained at ambient pressure starting either from citrate precursors or ceramic mixtures since the competitive, very stable $LaMnO_{3+\delta}$ perovskite was always present in the final product.

The magnetic measurements were performed in a PPMS (Quantum Design) system. The dc susceptibility curves were obtained under a 1 kOe magnetic field, under both zero-field cooling (ZFC) and field cooling (FC) conditions, for temperatures between 5.2 and 342.1 K. The ac susceptibility was measured in the temperature range 5–322 K under a small oscillating magnetic field of frequencies 0.01, 0.1, 1 and 10 kHz. Different isothermal magnetization curves were obtained at 5, 35 and 99 K in a magnetic field of between 0.05 and 45 kOe.

The study of the magnetic structure of $LaMn_2O_5$ was carried out from a set of neutron powder diffraction (NPD) patterns, collected at the high flux D20 diffractometer of the Institut Laue-Langevin in Grenoble (France). The patterns were dynamically acquired in the temperature range 3.5–98.8 K with a wavelength, λ, of 2.40 Å. The NPD data were analysed by the Rietveld method,[19] using the FULLPROF[20] program. The line-shape of the diffraction peaks was simulated by a Gaussian function and the background was fitted to a fifth-degree polynomial function. In the magnetic refinements, the atomic parameters were fixed to the values given in ref.[5], previously refined from high resolution NPD data, measured in the D2B diffractometer at the ILL-Grenoble on the same sample used in the present experiments. The atomic coordinates and main interatomic distances of $LaMn_2O_5$ taken from this reference are listed in Table 4.

Iron(II) Formate $[Fe(O_2CH)_2]\cdot 1/3HCO_2H$: A Mesoporous Magnet − Solvothermal Syntheses and Crystal Structures of the Isomorphous Framework Metal(II) Formates $[M(O_2CH)_2]\cdot n$(Solvent) (M = Fe, Co, Ni, Zn, Mg)

Martin Viertelhaus,[a] Peter Adler,[a] Rodolphe Clérac,[b] Christopher E. Anson,[a] and Annie K. Powell*[a]

Keywords: Iron / Solvothermal synthesis / Framework material / Magnetic properties / Mössbauer spectroscopy

Recrystallisation of iron(II) formate dihydrate from formic acid under solvothermal conditions results in single-crystals of the iron(II) formate, α-$Fe(O_2CH)_2\cdot 1/3HCO_2H$. The crystal structure of this phase has been determined by X-ray diffraction and reveals an open framework structure with formic acid molecules occupying channels in the lattice which is stable even after removal of the solvent molecules. Magnetic susceptibility and Mössbauer measurements show that the compound undergoes 3D magnetic ordering below $T_C = 16$ K. α-$Fe(O_2CH)_2\cdot 1/3HCO_2H$ and the corresponding magnesium, cobalt, nickel and zinc formates form an isomorphous series. In contrast to the iron compound, the magnetic behaviour of the cobalt analogue is dominated by antiferromagnetic interactions.

Introduction

The versatility of carboxylate anions as units for ligating and connecting metal centres has led to extensive research on the structures and properties of carboxylato complexes. Among the many fascinating examples in the literature are molecular entities such as the well-known oxo-centred trinuclear complexes,[1] the "Single Molecule Magnet" $[Mn_{12}O_{12}(O_2CCH_3)_{16}(OH_2)_4]\cdot 4H_2O\cdot 2CH_3CO_2H$ and related clusters[2,3] as well as extended systems, often produced using solvothermal synthesis, where the presence or absence of template molecules leads to open framework structures such as $Mn_4(PO_4)_2(C_2O_4)(H_2O)_2$[4] or very densely packed materials such as β-$Mn(O_2CMe)_2$.[5] Of particular current interest is the possibility of synthesising dual functionality materials where, for example, a mesoporous structure could also display a second useful physical property, such as cooperative magnetic behaviour.[6] These could be used to isolate and store paramagnetic molecules including gases such as dioxygen. Of the compounds which have so far been shown to display magnetic ordering and a microporous structure,[6b−6g] only $Co_3[Co(CN)_5]_2$,[6a] has displayed hysteresis and can be described as a ferrimagnet with $T_N = 38$ K. It has a defect Prussian Blue structure on the basis of its X-ray powder pattern.

We have been exploring the crystal structures and properties of compounds with the formate anion as a carboxylate linking unit, produced using solvothermal conditions.[7] Although the formate anion is the simplest carboxylate, most compounds described in the literature which have been structurally characterised using single-crystal X-ray diffraction have been synthesised using acetates and higher homologues. For most transition metal(II) formates, only single-crystal structure determinations for the dihydrates have been reported. The divalent 3*d*-transition metals, together with magnesium and cadmium, form an isomorphous series of metal(II) formate dihydrates.[8] Single-crystal structures of anhydrous diformates of these metals have only been determined for copper,[9] cadmium[10] and manganese.[11] This lack of knowledge concerning the structures of anhydrous transition metal(II) formates is comparable with that for the corresponding anhydrous nitrates or acetates[11] and is in contrast to the extensive research on the properties of such materials characterised only by X-ray powder diffraction (Mg,[12] Mn,[13] Fe,[14] Co,[15] Ni,[16] Zn[17]) and IR spectroscopy.[18] The kinetics and thermodynamics of the dehydration reactions of the dihydrates and the rehydration of the anhydrous products of dehydration[19] have been studied as well as the use of the dihydrates as precursors for dehydrogenation catalysts.[20] As far as the anhydrous metal(II) formates, $M(O_2CH)_2$, are concerned the Cu^{II} and Cd^{II} examples were synthesised at temperatures around 60−80 °C by slow evaporation of the solvent consisting of a mixture of water and formic acid. Single-crystals of other anhydrous

formates are not available using this synthetic route, although Vassileva and Karapetkova were able to isolate anhydrous formates of manganese, iron and zinc under ambient conditions as microcrystalline solids.[21]

We recently described the single-crystal X-ray structure of the new anhydrous formate $[Mn(O_2CH)_2]$ which can be prepared either using modified solvothermal conditions or by an unusual topotactic solid-state dehydration of the corresponding dihydrate.[11] As part of our survey of metal(II) formates we also found an isomorphous series of mesoporous framework compounds of general formula $M(O_2CH)_2\cdot 1/3HCO_2H$ for M = Fe, Co, Ni, Zn and Mg,[7] the synthesis, structures and properties of which we report here with particular reference to the Fe^{II} compound and its magnetic behaviour. Whilst we were investigating these magnetic properties, the structures of $Mn(O_2CH)_2\cdot 1/3C_4H_8O_2$ and $Mn(O_2CH)_2\cdot 1/3CH_3OH\cdot 1/3H_2O$ were reported both of which are isomorphous compounds with the same metal-formate framework we have observed.[22]

Results and Discussion

Syntheses

Recrystallisation of iron(II) formate dihydrate, $Fe(O_2CH)_2\cdot 2H_2O$, from formic acid under solvothermal conditions yields transparent green crystals of α-$Fe(O_2CH)_2\cdot 1/3HCO_2H$, suitable for X-ray diffraction (Scheme 1). The crystal structure was determined at 200 K and crystallographic details are summarised in Table 1. The same product, with a higher degree of purity but in a microcrystalline form, can be obtained in quantitative yield using milder conditions. Vassileva and Karapetkova had already observed this anhydrous iron(II) formate phase in the ternary system $Fe(O_2CH)_2-H_2O-HCO_2H$ at 25 °C with concentrations of formic acid higher than 83%.[21] The powder diffraction pattern of this product was different from the powder pattern of the product from direct dehydration of $Fe(O_2CH)_2\cdot 2H_2O$.[23] Vassileva and Karapetkova called their product anhydrous iron formate. As will be shown below, they had not prepared a pure formate free of solvent but, rather, an open framework structure with formic acid molecules occupying channels in the lattice. Since it is possible to desolvate the crystals, we refer to the synthesised or primary product $Fe(O_2CH)_2\cdot 1/3HCO_2H$ as α-FeFA·$1/3HCO_2H$. The stable crystalline network structure with-

[a] This work. [b] This structure was published in the alternative space group setting $P2_1/c$. The appropriately transformed cell is given in the above table for consistency with the other structures.

out solvate molecules is thus α-FeFA. In the course of our work, we have also characterised two further anhydrous and solvent-free iron(II) formates, namely β- and γ-FeFA (see Scheme 1) which will be published separately.[24] The three different compounds thus necessitate use of the prefixes α, β and γ.

Similar synthetic methods were used to obtain α-MFA·1/3HCO_2H (M = Zn, Mg) and α-CoFA·1/3HCO_2H·1/3H_2O. Although the magnesium compound could only be obtained as a microcrystalline material, the solvent molecules could be identified from the IR spectrum. The nickel analogue could also be prepared but was highly unstable when removed from the mother liquor. The unit cell could be determined from a sample prepared in situ in a glass capillary, demonstrating that the nickel complex is indeed isomorphous with the other compounds but the precise solvent content of the crystals of the nickel formate remains uncertain. For convenience, the unit cell parameters for all the compounds reported here, as well as the recently reported Mn^{II} complexes,[22] are listed in Table 2.

Framework Structure

α-Fe(O_2CH)$_2$·1/3HCO_2H crystallises in the monoclinic space group $P2_1/n$ with $Z = 12$. Selected geometrical parameters are listed in Table 3. The structure of the isomorphous Mn^{II} analogue has been discussed[22] with reference to its open framework structure, where it was described as a diamondoid network of metal centres, although the channels only run through the network in one direction, rather than in the four directions implied by this description. Since we were particularly interested in investigating the magnetic behaviour of the system, which turned out to be fairly complicated, our structural description concentrates on the metal ion coordination spheres and the chemical links between the metal centres which could mediate possible magnetic interactions.

The asymmetric unit of α-FeFA·1/3HCO_2H contains four independent iron centres with Fe(1) and Fe(2) on general positions, and Fe(3) and Fe(4) representing inversion centres. All four have distorted octahedral coordination spheres of oxygen atoms from formate ions with angles in the ranges 78.00−97.34° and 164.19−180° (Table 3). Each of the six independent formate ligands forms a μ_3-(*syn,syn-anti*) carboxylate bridge between three Fe centres and for convenience the numbering is such that the odd-numbered oxygen forms the (μ_2-η^1) bridge, while the even-numbered oxygen is monodentate. The Fe−O bond lengths (Table 3) are, on average, slightly longer for the bridging oxygen atoms being in the range 2.080(4)−2.174(4) Å (mean value 2.142 Å), whereas those involving a monodentate oxygen lie in the range 2.072(4)−2.154(4) Å (mean 2.098 Å).

The framework structure is generated firstly from chains of Fe(1) and Fe(2) running along the 2_1-screw axes {Fe(1)−Fe(2)−Fe(1a)−Fe(2a)...} (Figure 1). Within the chains, pairs of iron atoms are linked by one *syn*,*syn*-for-

mate bridge with O(5) and O(7) joining Fe(1) and Fe(2), and two μ-bridging oxygen atoms with O(9) and O(11) joining Fe(1) and Fe(2a). The coordination polyhedra of Fe(1) and Fe(2) can thus be described as edge-sharing octahedra, with the shared edges defined by these four oxygens (Figure 1). This leads to two alternating crystallographically distinct, although geometrically rather similar Fe···Fe linkages. Of particular interest in terms of the magnetic behaviour is that the Fe−O−Fe angles at O(5), O(7), O(9) and O(11) all lie in the range 96.08−99.42° (Table 3) and might therefore be expected to mediate rather similar magnetic interactions (vide infra).

The chains are cross-linked via further Fe^{II} centres, namely Fe(3) and Fe(4) in the *ac*-plane (Figure 2 and Figure 3). The linkages from Fe(1) to either Fe(3) or Fe(4) both involve a single μ-oxygen bridge [O(1) and O(3), respectively] and two *syn*,*syn*-formate bridges. In contrast, Fe(2) is only linked to Fe(3) and Fe(4) through single *syn*,*anti*-formate bridges. The Fe−O−Fe angles at the bridging oxygens O(1) and O(3) are similar and significantly larger than those forming the bridges within the chains at 111.84° and 113.54°, respectively, and could thus mediate magnetic interactions similar to each other but significantly different from the intrachain linkages.

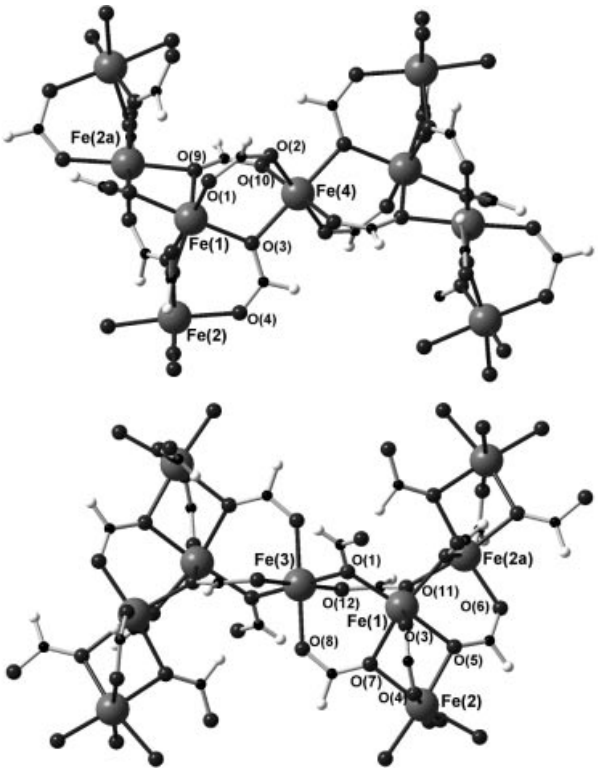

Figure 2. The interchain linkages through Fe(4) (upper) and through Fe(3) (lower); atom key and symmetry code as in Figure 1

Of further interest in terms of the magnetic behaviour is the presence of any distortion in the coordination spheres of the Fe^{II} centres which can affect the zero-field splitting and ground state term. Fe(3) and Fe(4) each show slight tetragonal elongations along one axis, with Fe−O distances of 2.175(4) and 2.159(4) Å, respectively, compared with the shorter distances in the range 2.082(4) −2.120(4) Å. However, Fe(1) and Fe(2) show no such pattern and indeed for Fe(2) the longest Fe−O distance is *trans* to the shortest.

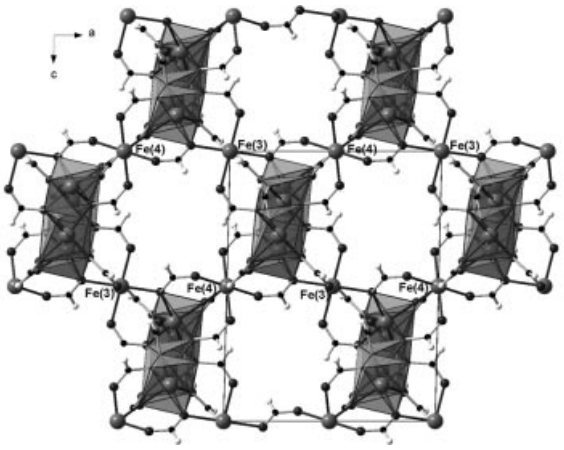

Figure 3. The structure of α-FeFA·1/3HCO_2H viewed along the *b*-direction showing its channel structure; Fe(1) and Fe(2), which form the chains bridged by pairs of μ-oxygen bridges, are shown as coordination polyhedra; Fe(3) and Fe(4) and their symmetry-equivalents, which form linkages between the chains, are shown as conventional atoms; formic acid molecules inside the channels are omitted for clarity

Mesoporous Behaviour

An examination of the stabilised open framework structure of α-FeFA·1/3HCO_2H using PLATON[25] showed that the accessible volume of the channels amounts to 505 $Å^3$ per unit cell, or 30.5% of the unit cell volume which is in good agreement with the values for the manganese compounds.[22] It has been shown that the manganese-based-framework can accommodate a wide variety of guest molecules. The channels in the synthesised iron compound contain formic acid molecules. In the structure, these solvent molecules are twofold disordered with the overlapping half-molecules occupying one general position. This results in one third of a formic acid molecule per iron atom in the formula, i.e. α-FeFA·1/3HCO_2H. The presence of formic acid in the lattice was confirmed by the IR spectrum (Table 4). In addition to the expected bands from the for-

mate ligands, a single band at 3430 cm^{-1}, a stronger band at 1742 cm^{-1} and a pair of bands at 1163 and 1144 cm^{-1} can be assigned to free formic acid molecules.[26] There was no evidence in the spectrum for the presence of water molecules. The stoichiometry of the formic acid can be verified by STA-experiments on a briefly-dried sample from the solvothermal synthesis. The sample loses mass in several unresolved processes between room temperature and 160 °C. The overall mass loss for these steps is 9.2% which is in good agreement with the theoretical mass loss of 9.5% for $1/3HCO_2H$ per iron atom to give α-FeFA. Between 160 and 270 °C, α-FeFA decomposes exothermally to amorphous Fe_2O_3 with a further mass loss of 39.7% (calcd. 40.9%).

Pure desolvated α-FeFA can be obtained by heating the powder α-FeFA·$1/3HCO_2H$ to 120 °C for several hours. The desolvation can be monitored by X-ray powder diffraction. For example, on heating the sample, the 002 reflection increases in intensity, whereas the $\bar{1}11$, 200 and 112 reflections decrease (Figure 4). To further verify this, the powder pattern calculated from the crystal structure of α-FeFA·$1/3HCO_2H$ was compared with the pattern calculated from the same structure with the atoms of the formic acid molecule removed. As can be seen in Figure 4, these patterns show the same trends as the experimentally measured patterns and that calculated from the structure with the formic acid atoms deleted is essentially identical to the final experimental powder pattern in which all peaks could be indexed. The structural framework is thus not merely stable to removal of the solvent but also maintains its structure with minimal changes in geometry. In contrast, if a sample of α-FeFA·$1/3HCO_2H$ is kept in vacuo for several days, no significant change in the powder diffraction pattern can be observed, indicating that heating is necessary to remove the formic acid solvent molecules.

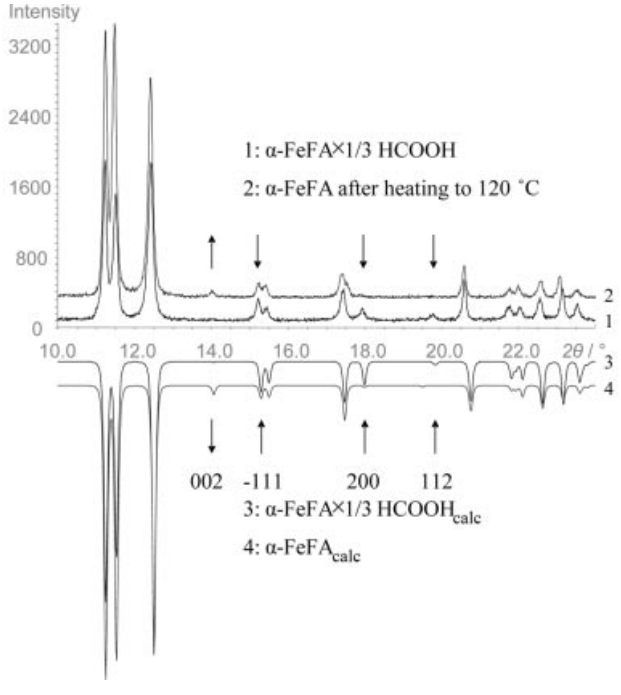

Figure 4. X-ray powder diffraction with Co-$K\alpha_1$ radiation shows the stability of the channel structure of α-FeFA on removal of the solvent molecules; significant changes in intensities on heating are marked with arrows; for comparison the calculated patterns are shown

The IR spectra of the magnesium and zinc formates show no evidence for the presence of water molecules in the lattices. STA results for the zinc and magnesium compounds indicate mass losses of 9.1 and 9.7%, respectively, in agreement with the theoretical value for loss of $1/3HCO_2H$ per metal atom (9.0 and 10.7%, respectively). We have therefore formulated both these compounds analogously to the iron formate, i.e. as α-MFA·$1/3HCO_2H$ (M = Zn, Mg). In contrast, the IR spectra of the cobalt analogue show, in addition to bands from the bridging formate ligands and formic acid solvent molecules as found for the other three complexes, two additional bands in the 3300−3200 cm^{-1} region which indicate that water molecules are present in the channels in addition to formic acid. The expected band at ca. 1630 cm^{-1} for the deformation mode of water is obscured by the very strong formate bands. The additional presence of water in the solvent lattice was confirmed by the STA results. The mass loss on heating to 140 °C is significantly higher than for the iron complex with a mean value of 13.2% which can be compared with the calculated mass losses per Co atom of 9.1% for $1/3HCO_2H$ and 12.5% for $1/3HCO_2H + 1/3H_2O$. In the crystal structure, the solvent could readily be refined as a slightly disordered formic acid molecule and a water molecule disordered between two adjacent sites. We have thus formulated the cobalt formate as α-CoFA·$1/3HCO_2H\cdot 1/3H_2O$ and note the similar formulation of MnFA·$1/3CH_3OH\cdot 1/3H_2O$ found for the compound described in ref.[22b]

Magnetic Properties

The χT product of α-FeFA·$1/3HCO_2H$ shown in Figure 5 continuously increases from 4.72 emu K mol^{-1} at 300 K up to a value of 28 emu K mol^{-1} at 20 K. Above this temperature the paramagnetic behaviour can be satisfactorily reproduced by a Curie−Weiss law with a Curie constant of 4.5 emu K mol^{-1}, corresponding to an average g value of 2.45, in agreement with typical values for high spin Fe^{II} metal ions in a distorted octahedral geometry.[27] The positive

Weiss constant of +16 K is indicative of dominant ferromagnetic interactions within the framework. Below 20 K, the susceptibility, χ, increases dramatically and reaches a saturation value of 10.6 emu mol^{-1} at around 5 K. This behaviour is typically associated with the onset of spontaneous magnetisation and therefore with the stabilisation of magnetic 3D order. Heat capacity measurements made on a pressed pellet of α-FeFA·1/3HCO_2H confirmed the magnetic transition observed (Figure S1). A lambda peak indicative of a second order phase transition was obtained at 16 K.

In order to obtain more insight into the low temperature magnetic phase, the field dependence of the magnetisation was investigated. As shown in Figure 6, the magnetic moment (M) increases very rapidly in small magnetic fields below 15 K. This increase slows at around 2000 Oe, when the moment reaches about 2.2 μ_B/per Fe^{II} at 1.8 or 5 K. As the field increases, M increases in a quasi-linear fashion without saturation even at 50 kOe. Hysteresis loops are obtained at 15 K and below, with coercive fields up to 1000 Oe at 1.8 K.

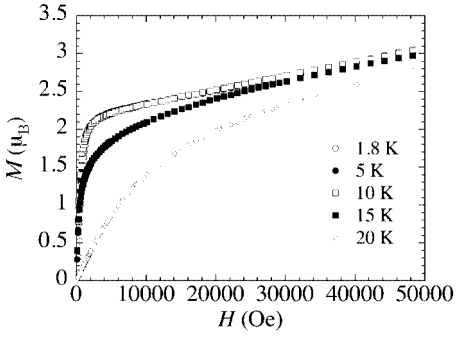

Figure 6. First magnetisation of the magnetic moment per Fe^{II} for α-FeFA·1/3HCO_2H

Fe(3) and Fe(4) each link to two Fe(1) chain centres via a single oxygen bridge (with Fe−O−Fe angles 111.84 or 113.54°) and two *syn*,*syn*-carboxylate bridges. Geometries corresponding to the interchain pathways have been previously observed in a small number of Fe^{II} complexes: $Ba_4(C_2O_4)Cl_2[\{Fe(C_2O_4)(\mu\text{-}OH)\}_4]$[28] which has an Fe−O−Fe angle of 122° and J/k_B = −9 K, $[Fe_2(\mu\text{-}OH)(\mu\text{-}OAc)_2(Me_3TACN)_2](ClO_4)$[29] (where Me_3TACN is 1,4,7-trimethyl-1,4,7-triazacyclononane) with an Fe−O−Fe angle of 113.2° and J/k_B = −18.7 K, $[Fe_2(\mu\text{-}OH)(\mu\text{-}Ph_3CCO_2)_2(Me_3TACN)_2](OTf)$[30] which displays an Fe−O−Fe angle of 119.1° and J/k_B = −17.4 K, and finally deoxyhemerythrin for which the Fe−O−Fe angle is not precisely known but for which J/k_B has been variously reported to be in the range −17 to −55 K[31] or as −21 K.[32] In all these compounds, the magnetic interactions are mediated by a single oxygen and two *syn, syn*-carboxylate bridges and have been found to be always antiferromagnetic. Due to the similarity of the geometries of these bridges to the interchain pathways in α-FeFA·1/3HCO_2H and in particular for the acetate-bridged dinuclear complex, these results enable us to conclude that our interchain linkages Fe(1)−Fe(3,4) are antiferromagnetic. Since the Weiss constant indicates that the dominant interactions in α-FeFA·1/3HCO_2H are ferromagnetic, the intrachain interaction must therefore be ferromagnetic and larger in magnitude than the antiferromagnetic interchain interaction. Unfortunately, to the best of our knowledge, no complex in which two Fe^{II} ions are linked via two oxygen bridges and one *syn, syn*-carboxylate bridge, which could confirm this conclusion, has been reported to date. However, based on this analysis, the magnetic structures of α-FeFA·1/3HCO_2H and MnFA[22b] are similar and composed of ferromagnetically-coupled Fe^{II} chains in which the magnetic moments are parallel and the linking Fe(3) and Fe(4) centres have antiparallel spins. Since the different metal centres occur in the ratio Fe(1):Fe(2):Fe(3):Fe(4) = 2:2:1:1 in the structure, this gives rise to the net magnetic moment. The saturation moment in the magnetic phase should thus be 1.6 μ_B per Fe^{II} or 9.8 μ_B per 6 Fe^{II}, based on g = 2.45 deduced from the high temperature susceptibility.

As shown in Figure 7, a rapid increase in the magnetisation with applied field is observed for low fields, as expected for a magnet. However, the magnetisation reaches 2.2 μ_B per Fe^{II} which is greater than the expected value of 1.6 μ_B. There are two possible causes for this behaviour which are not necessarily mutually exclusive: either the spins on Fe(3) and Fe(4) are not completely antiparallel to those on Fe(1) and Fe(2) or the g values for Fe(3) and Fe(4) might be smaller than for Fe(1) and Fe(2). In either or both cases, the magnetic moment of the magnetic phase is increased by an incomplete compensation of two of the four Fe(1,2) spins by the two Fe(3,4) spins. At higher fields (Figure 7) the magnetisation increases linearly with the applied magnetic field to reach ca. 3 μ_B per Fe^{II} at 5 T. This behaviour is consistent with the progressive alignment of the antiparallel magnetic spins on Fe(3,4) within the field. From the magnetic data discussed so far α-FeFA·1/3(HCO_2H), as for MnFA,[22b] can be understood in terms of ferromagnetic interactions within the chains and antiferromagnetic interchain interactions resulting in what can be described here, as in ref.[22b], as ferrimagnetic behaviour even though there is only one type of spin in the structure. This is in accordance with the definition of Néel that in a ferrimag-

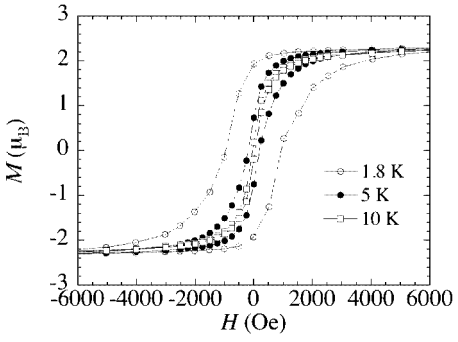

Figure 7. Hysteresis loops of the magnetic moment per Fe^{II} for α-FeFA·1/3HCO_2H obtained at a field sweep rate of 12 Oe/s

netic material, the magnetic moments of different sublattices do not compensate and a spontaneous magnetisation remains. For the iron complex, the ordering temperature T_c is 16 K and this is considerably higher than the maximum value of 8 K reported for the series of Mn^{II} compounds in ref.[22b]

To confirm this magnetic ordering, the temperature dependence of the in-phase (χ') and out-of-phase (χ'') magnetic susceptibilities have been measured (Figure 8). Both components exhibit a peak at 1 Hz at temperatures of 15 and 12 K for χ' and χ'', respectively. Independent of the frequency, χ'' becomes nonzero around 16 K in agreement with the ordering temperature already estimated by the heat capacity and *d.c.* measurements (vide supra). Closer analysis of the *a.c.* data reveals a slight frequency dependence for both the maximum and the breadth of the peaks. The positions of the χ' and χ'' peaks increase by less than 0.5 K and ca. 1.3 K, respectively, when the frequency is increased from 1 to 1500 Hz. Mydosh established that the frequency dependence of the *a.c.* measurements can quantify the degree of glassiness in a material by the parameter γ.[33] Such analysis of the data presented here leads to a γ value of 0.015, indicating that the magnetic order observed below 16 K involves a slight degree of glassiness.

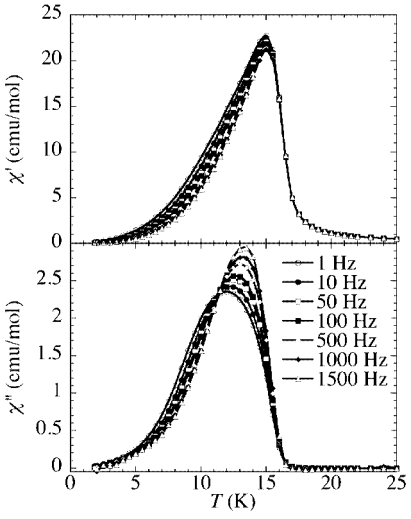

Figure 8. Temperature-dependence of the in-phase, χ', and out-of-phase, χ'', ac susceptibilities per Fe^{II} in α-$FeFA\cdot 1/3HCO_2H$ for a range of ac frequencies: dc field zero; ac field of amplitude 3 Oe

In contrast to the iron compound, the magnetic behaviour of the cobalt analogue is dominated by antiferromagnetic interactions and no magnetic order has been observed down to 1.8 K. The plot of χ^{-1} against T can be fitted (using data above 70 K) to the Curie−Weiss law with a Curie constant of 3.30 emu K mol^{-1} and a negative Weiss constant of −14.8 K. The Curie constant is in good agreement with typical values for high spin octahedral Co^{II} (S = 3/2).[27a] As indicated by the Weiss constant, dominant antiferromagnetic interactions are present between Co^{II} centres in α-$CoFA\cdot 1/3HCO_2H\cdot 1/3H_2O$. Nevertheless, a contribution from spin-orbit coupling of Co^{II} is also expected and probably enhances the Weiss constant extrinsically. In an octahedral ligand field the $^4T_{1g}$ ground state of the S = 3/2 Co^{II} metal ions is split by spin-orbit coupling into a set of three levels with an effective S = 1/2 ground state and leads to the possibility of large g values.[34]

Mössbauer Spectra

In order to investigate the relationship between electronic structure and magnetism in more detail, Mössbauer spectra of α-$FeFA\cdot 1/3HCO_2H$ were collected between 4 and 295 K (Figure 9). The spectra reflect the different iron sites in the crystal structure and are in agreement with the development of 3D magnetic order, as indicated by the pronounced changes in the shape of the spectra around 16 K (Figure 9).

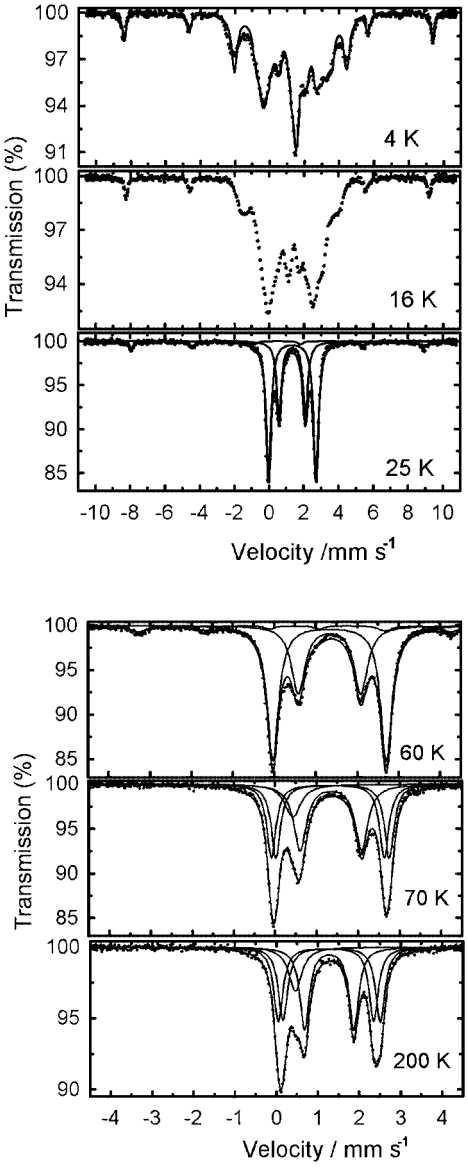

Figure 9. Mössbauer spectra of α-$FeFA\cdot 1/3HCO_2H$ in the temperature range of the magnetic phase transition (top) and in the paramagnetic phase (bottom); solid lines correspond to the best fits and the constituent subspectra

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The spectra of the paramagnetic phase above 16 K (e.g. the 25 K spectrum) essentially consist of two quadrupole doublets with an intensity ratio of roughly 2:1. Their isomer shifts *IS* (see Table 5) are nearly identical and typical for high spin Fe^{2+} sites. From the relative intensities, the outer doublet with the larger quadrupole splitting ΔE_Q can be assigned to the chain Fe(1) and Fe(2) sites with the second doublet showing the smaller ΔE_Q corresponding to the bridging Fe(3) and Fe(4) atoms. In the spectrum at 25 K, in addition to the major component arising from the Fe^{2+} paramagnetic signals, a hyperfine sextet with an isomer shift and a hyperfine field B_{hf} typical of Fe^{3+} can be observed (Table 5). The six-line pattern indicative of a magnetically-ordered phase persists up to about 60 K above which it collapses into a broad single line. This subspectrum can be attributed to the presence of about 8% of the cubic Fe^{III} formate $Fe(O_2CH)_3{\cdot}HCO_2H$ (subsequently identified by X-ray powder diffraction) which becomes antiferromagnetically ordered near 60 K and will be described elsewhere.[28] Below 60 K only two of the six lines fall within the region of the spectrum of α-FeFA·1/3HCO_2H and their shapes can be determined accurately from the four falling outside this region so that fitting the α-FeFA·1/3HCO_2H spectrum was essentially unaffected by the presence of this impurity.

Table 5. Mössbauer parameters of α-FeFA·1/3HCO_2H in the paramagnetic region at selected temperatures; the Fe(1,2) sites are described by one quadrupole doublet at 25 K and two doublets [Fe(1,2) a and b] for $T \geq 70$ K, whereas the Fe(3,4) sites were always modelled by a single somewhat broadened quadrupole doublet; errors are less than 1 in the last digit if not given explicitly in parentheses

T (K)	site	IS (mm·s^{-1})	ΔE_Q (mm·s^{-1})	Rel. area (%)
25	Fe(1,2)	1.35	2.73	60
	Fe(3,4)	1.35	1.52	32
	Fe^{3+}	0.50	–	8
70	Fe(1,2)a	1.33	2.84	56[a]
	Fe(1,2)b	1.33	2.61	
	Fe(3,4)	1.35	1.48	33
	Fe^{3+}	0.43	–	11
295	Fe(1,2)	1.22	2.14	25(2)
	Fe(1,2)b	1.20	1.85	29(2)
	Fe (3,4)	1.21	1.00	34
	Fe^{3+}	0.40	–	12

[a] Total Fe(1,2) area. The areas of Fe(1,2)a and Fe(1,2)b were assumed to be equal.

A more detailed inspection of the spectra recorded in the paramagnetic region (Figure 9) revealed that the Fe(1) and Fe(2) sites in the crystal structure of α-FeFA·1/3HCO_2H can be distinguished since their quadrupole splittings are somewhat different. This is particularly apparent from the shape of the spectrum recorded at 200 K (the temperature of the crystal structure determination). Thus, the Fe^{2+} part of the spectrum was modelled by three doublets. Although the Fe(3,4) sites cannot be similarly resolved, a certain line broadening at low temperatures indicates slightly different quadrupole splittings. As expected for $3d^6$ high spin Fe^{2+} ions, ΔE_Q is temperature dependent (Figure 10) for the Fe(1,2) as well as for the Fe(3,4) sites reflecting the aspherical electron distribution arising from the splitting of the octahedral t_{2g} orbitals in the lower symmetry ligand field. The rather small value for ΔE_Q of ca. 1.5 mm·s^{-1} for the Fe(3,4) sites even at 25 K suggests that their electronic structures result from the orbital splitting of an elongated octahedron, in agreement with the structural data (vide supra) where the d_{xz} and d_{yz} orbitals are below the d_{xy} orbital.[35] In addition, the degeneracy of the d_{xz} and d_{yz} orbitals is likely to be lifted because the equatorial bond lengths are different. The much larger ΔE_Q for the Fe(1,2) sites suggests a different sequence of orbitals for these more distorted sites but a more detailed analysis would need to take the effects of spin-orbit coupling into account.

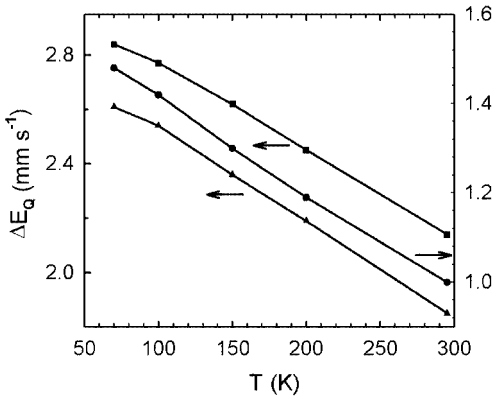

Figure 10. Temperature dependence of the quadrupole splitting for the Fe(1,2) sites (left scale) and the Fe(3,4) sites (right scale); solid lines are guides for the eye

The shape of the 4 K spectrum is completely different from that of the high temperature spectra and indicates that all the Fe^{2+} sites are magnetically ordered. Modelling of the spectrum is complicated by the fact that for Fe^{2+} compounds, electric quadrupole and magnetic hyperfine interactions are generally of comparable size and it is not possible to analyse the spectra in terms of six line patterns with an intensity ratio 3:2:1:1:2:3. Accordingly, the 4 K spectrum was modelled with the software package Recoil[36] employing the full static Hamiltonian for mixed hyperfine interactions with four Fe^{2+} sites and one Fe^{3+} site (to account for the impurity) included in the calculations. This data treatment resulted in a large number of parameters which cannot all be deduced unambiguously from powder spectra since each iron site is characterised by (i) its isomer shift *IS* (ii) the hyperfine field B_{hf} (iii) the quadrupole interaction parameter $\varepsilon = eQV_{ZZ}/2$ (where V_{ZZ} is the Z component of the diagonalised electric field gradient (efg) tensor, Q = quadrupolar moment of the iron nucleus) (iv) the asymmetry parameter η of the efg tensor ($0 \leq \eta \leq 1$) and (v) the polar and azimuthal angles Θ and Φ describing the orientation of $\mathbf{B_{hf}}$ in the efg principal axes coordinate system. For this reason it was assumed that the values for the *IS* and quadrupole splittings $\Delta E_Q = (V_{ZZ}Q/2)(1 + \eta^2/3)^{1/2}$

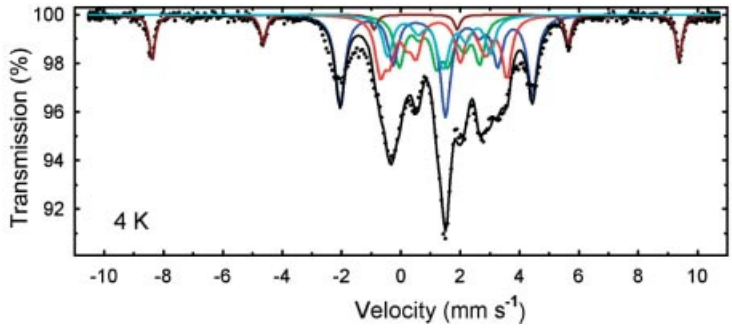

Figure 11. Analysis of the 4 K Mössbauer spectrum using the full Hamiltonian for combined quadrupole and magnetic hyperfine interactions; the black solid line corresponds to a theoretical spectrum obtained with the parameters given in Table 6; blue and red lines correspond to the Fe(1,2) subspectra, green and cyan lines to the Fe(3,4) subspectra; see text for more details

in the paramagnetic phase at 25 K and in the magnetically ordered phase at 4 K are identical. A reasonable description of the overall shape of the spectrum (Figure 11) was obtained with the parameters summarised in Table 6. In this model, the efg of the Fe(3,4) sites was assumed to be axially symmetric so that the spectra do not depend on the azimuthal angles Φ which were set to zero for these as well as for the Fe(1,2) sites. The negative value of V_{ZZ} for the Fe(3,4) sites is in agreement with an orbital doublet ground state. The best simulation of the overall shape of the spectrum was obtained also by using a negative value of V_{ZZ} for the Fe(1,2) sites, although a positive value cannot be ruled out. The experimental spectrum reveals considerable line broadening at higher velocities indicating a distribution of hyperfine fields. This was not taken into account in the data analysis and points to disorder effects which are also believed to be the origin of the frequency dependence of the *a.c.* susceptibility data (vide supra).

Table 6. Mössbauer parameters of α-$FeFA\cdot 1/3HCO_2H$ obtained from the analysis of the 4 K spectrum with the full hyperfine Hamiltonian; the full width at half maximum was set to 0.4 $mm\cdot s^{-1}$ for all Fe^{2+} sites and to 0.24 $mm\cdot s^{-1}$ for the Fe^{3+} site; the azimuthal angle Φ was kept at zero for all sites; Fe(1,2) and Fe(3,4) are split into two sites a and b, respectively

Site	IS ($mm\cdot s^{-1}$)	ε ($mm\cdot s^{-1}$)	η	B_{hf} (Tesla)	Θ (°)	rel. Area (%)

Fe(3,4)a	1.35[a]	−1.5[a]	0[b]	4.7	44	19
Fe(3,4)b	1.35[a]	−1.5[a]	0[b]	7.5	45	15
Fe^{3+}	0.50[a]	–	–	55.1	–	9

[a] Parameters taken from the 25 K spectrum. Note that $\Delta E_Q = (eQV_{ZZ}/2)(1 + \eta^2/3)^{1/2} = \varepsilon(1 + \eta^2/3)^{1/2}$. A negative sign for V_{ZZ} was assumed for both sites. [b] Parameter was not varied during fitting but analysis was performed for different η values.

The range of B_{hf} values found from this analysis for the various Fe sites in α-$FeFA\cdot 1/3HCO_2H$ (Table 6) is similar to those of other Fe^{2+} compounds.[37] The observed hyperfine field is a sum of three contributions:

$$B_{hf} = B_C + B_L + B_D$$

where B_C is the isotropic Fermi contact contribution and B_L and B_D correspond to the anisotropic dipolar interactions between the nuclear momentum and the electronic angular and spin momentum, respectively. According to a common rule of thumb,[38] the $S = 2$ state of Fe^{2+} can be expected to lead to a B_C value of roughly −44 T which is compensated by positive B_L and B_D contributions with B_L being dominant and proportional to the expectation value $<L>$ of the angular momentum. The value of $<L>$ and therefore B_L is expected to be larger for the more symmetric Fe(3,4) than for the more distorted Fe(1,2) sites implying that the sign of B_{hf} is negative for the Fe(1,2) and positive for the Fe(3,4) sites. The small hyperfine field values are evidence for the importance of the angular contribution to the magnetic moment for both kinds of Fe sites in the crystal structure of α-$FeFA\cdot 1/3HCO_2H$ and the resultant magnetic anisotropy will also influence the detailed spin structure in the magnetically ordered phase.

Finally, we note that the 16 K spectrum (Figure 9) corresponds to a superposition of magnetically ordered and paramagnetic phases in good agreement with a T_C value of 16 K derived from the magnetic susceptibility measurements. Mössbauer spectra in an external magnetic field could shed more light on the electronic structure and magnetic exchange interactions of the various Fe sites in the present compound and elastic neutron scattering studies would be a further means of probing the magnetic structures. However, based on what is already in the literature[22,29−33] and the complementary susceptibility and Mössbauer studies we have presented here, we feel that our proposed model for the spin structure is probably justified.

Conclusion

We have described the synthesis, structure and the magnetic properties of the mesoporous compound $Fe(HCO_2)_2\cdot 1/3HCO_2H$ which is a magnet below 16 K. As the member with the highest T_C of a newly-discovered family of M^{II} formate framework structures with high stabilities

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and the ability to take up specific gas molecules, it points to a promising way forward in combining magnetic and porous properties which could find applications in separation techniques.

Experimental Section

FeFD, CoFD, NiFD, ZnFD and MgFD were synthesised as reported previously.[39]

Synthesis of α-$Fe(O_2CH)_2$·1/3HCO_2H: In a typical experiment $Fe(O_2CH)_2$·2H_2O (0.1 g, 0.5 mmol) was heated in formic acid (7 mL) to 70 °C in a steel autoclave with a Teflon-insert of internal volume 10 mL for a period of 8 hours. After slow cooling, α-FeFA·1/3HCO_2H was obtained in quantitative yield. The polycrystalline product was washed with formic acid, dried and stored under an inert atmosphere. The product was shown to be a single-phase by powder diffraction except in the case of the sample used for the Mössbauer measurements which contained about 8% of the Fe^{III} impurity $Fe(O_2CH)_3$·HCO_2H as described in the text.
Single-crystals of α-FeFA·1/3HCO_2H could obtained when formic acid was allowed to evaporate slowly under solvothermal conditions. $Fe(O_2CH)_2$·2H_2O (60 mg, 0.3 mmol) was heated in formic acid (8 mL) for 12 hours at 170 °C. The mixture was then cooled to 110 °C over 2 hours, maintained at this temperature for a further 28 hours then slowly cooled to room temperature. In this preparation, the autoclave lid was not closed tightly, allowing very slow loss of solvent from the autoclave.

Synthesis of α-$Co(O_2CH)_2$·1/3HCO_2H·1/3H_2O: The synthesis of polycrystalline material was as for α-FeFA·1/3HCO_2H. Single-crystals of α-CoFA·1/3HCO_2H·1/3H_2O could be obtained under solvothermal conditions by the modification described for α-FeFA·1/3HCO_2H. $Co(O_2CH)_2$·2H_2O (200 mg, 1 mmol) was heated in formic acid (4 mL) for 100 hours at 160 °C.

Synthesis of α-$Zn(O_2CH)_2$·1/3(HCO_2H): A quantitative yield of α-$Zn(O_2CH)_2$·1/3HCO_2H was obtained by recrystallisation of $Zn(O_2CH)_2$·2H_2O (4.88 g, 25.5 mmol) with formic acid (6 mL) at 120 °C for 120 hours. The autoclave lid was not closed tightly, allowing very slow loss of solvent from the autoclave.

Synthesis of α-$Ni(O_2CH)_2$·*x*HCO_2H·*y*H_2O: A 0.5 mm i.d. glass capillary tube was filled to a depth of 1 cm with $Ni(O_2CH)_2$·2H_2O and formic acid and was placed together with formic acid (2.5 mL) in the Teflon insert of the autoclave and heated at 170 °C for 17 hours. After cooling, the capillary tube was sealed and the X-ray powder pattern was measured.

Synthesis of α-$Mg(O_2CH)_2$·1/3HCO_2H: $Mg(O_2CH)_2$·2H_2O (1.22 g, 16.2 mmol) and formic acid (2 mL) were heated for 105 hours to 120 °C. The resultant polycrystalline powder was separated from the solvent by filtration and dried in air.

Single-Crystal X-ray Diffraction Studies: Data were measured on Stoe IPDS or Stoe IPDS II image plate area detector diffractometers using graphite-monochromated Mo-*Kα* radiation (λ = 0.71073 Å). Structures were solved by direct methods and refined by full-matrix least-squares against F^2 (all data) using the SHELXTL software package.[40] Nonhydrogen atoms were assigned anisotropic thermal parameters. Hydrogen atoms were fully refined with isotropic temperature factors (Co and Zn) or positionally refined with U set at 1.2U_{eq} for the carbon atom (Fe). Crystal data and experimental details are summarised in Table 1. CCDC-238105 to -238107 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

X-ray Powder Diffraction: X-ray powder patterns were measured at ambient temperature on a Stoe STADI-P diffractometer using Co-$K\alpha_1$ radiation (Ge monochromator) and Debye−Scherrer geometry. The sample was held between sheets of amorphous polyacetate foil. Data analysis was carried out with the WinXPow 1.07 software suite.
The unit cell for α-$Ni(O_2CH)_2$·*x*HCO_2H·*y*H_2O was determined from powder diffraction measurements made on the ANKA-DIFF beamline at the ANKA synchrotron source at the Forschungszentrum Karlsruhe at ambient temperature and using radiation of wavelength 1.58845(3) Å.

Thermal Analyses: The differential thermal analyses (DTA) and the thermogravimetric (TG) experiments were carried out using a Netzsch STA 409C system. Samples were heated in Al_2O_3 crucibles with a heating rate of 1 K min^{-1} up to 600 °C under a nitrogen atmosphere with a flow rate of 30 L h^{-1}.

Susceptibility Measurements: The magnetic susceptibility measurements were obtained with the use of a Quantum Design SQUID magnetometer MPMS-XL. Measurements were performed on finely ground polycrystalline samples of α-FeFA·1/3HCO_2H (13.13 mg) and α-CoFA·1/3HCO_2H·1/3H_2O (5.1 mg) in the temperature range 1.8−300 K with fields up to 7 T. The magnetic data were corrected for the sample holder and the diamagnetic contribution calculated from Pascal's constants.[41]

^{57}Fe Mössbauer Spectroscopy: Temperature dependent Mössbauer spectra of powdered samples of α-FeFA·1/3HCO_2H (about 10 mg natural iron per cm^2 with the samples diluted with polyethylene to ensure homogeneous distribution of the sample in the plexiglass container) were measured in an Oxford flow cryostat with a conventional Mössbauer spectrometer operating with a sine-type drive signal. All spectra were referenced to α-Fe.

Heat Capacity Measurements: The heat capacity measurements were performed on a Quantum Design PPMS system. A pressed pellet of the sample was mounted using grease on the heat capacity sample holder.

IR Spectroscopy: FTIR spectra were measured using KBr pellets of the sample in the range from 4000 to 400 cm^{-1} with a Perkin−Elmer Spectrum One instrument.

Acknowledgments

We acknowledge the ESF "Molecular Magnets" program for funding the short scientific stays of Rodolphe Clérac. R.C. thanks the CNRS, the University of Bordeaux 1 and the Conseil Regional d'Aquitaine for financial support. M. V., P. A., C. E. A. and A. K. P. thank the DFG Centre for Functional Nanostructures (CFN) for financial support. We thank W. Hölle for technical assistance with the measurement of the Mössbauer spectra performed at the Max-Planck-Institut für Festkörperforschung, Stuttgart. We thank Stephen Doyle for the measurement of the high resolution X-ray powder data at the ANKA-DIFF beamline, Forschungszentrum Karlsruhe.

Stereochemical Investigation of Palladium(II) Complexes with Phenanthroline Ligands: A Molecular Mechanics Approach

Mario Calligaris,[a] Ennio Zangrando,*[a] and Barbara Milani,[a] Angelica Marson[a,‡]

Keywords: Stereochemistry / Molecular mechanics / Copolymerisation / Phenanthroline / Palladium

Specific force field parameters have been derived through an optimisation procedure based on crystal structure data to describe the geometry of Pd^{II}-phenanthroline complexes. The X-ray structure of $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2][OTf]$ is also reported. Molecular mechanics calculations show that intramolecular steric interactions yield severe distortions from a square-planar geometry of the metal atom, both in bischelated $[Pd(3\text{-R-phen})_2]^{2+}$ and monochelated $[Pd(CH_3)(3\text{-R-phen})_2]^+$ complexes. A complete stereochemical analysis of the possible diastereoisomers of this last complex (R = *s*Bu) allows the rationalisation of its fluxional behaviour observed in solution. Complexes like $[Pd(H)(3\text{-tmp-phen})_2]^+$ and $[Pd\{CH(C_6H_5)CH_2C(O)OCH_3\}(3\text{-tmp-phen})(CH_3OH)]^+$ (tmp = 1,2,2-trimethylpropyl) have also been investigated as species reasonably involved in the copolymerisation reactions. It is suggested that the remarkable increase of the copolymer molecular weight obtained with the 3-tmp-phen ligand derives from the steric destabilisation of an intermediate species postulated for the termination reaction.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Bischelated palladium(II) compounds with bidentate nitrogen-donor ligands, such as 1,10-phenanthroline (phen) and its derivatives, have been shown to act as efficient precatalysts in the CO/styrene copolymerisation reaction.[1–3] Some stereochemical aspects of these complexes have been investigated both in solution and in the solid state, providing some information about the conformational flexibility of the bischelated $[Pd(phen)_2]^{2+}$ complex,[1,4] and the fluxional behaviour of the monocationic derivatives, $[Pd(R)(phen)_2]^+$ (R = CH_3,[5] and CH_2NO_2[6]), where one phen ligand is monocoordinated.

In order to rationalise the observed structural properties of this kind of complexes, a thorough molecular mechanics (MM) investigation has been undertaken, on the basis of a specific force field. The force field parameters have been derived from the available crystal data for $[Pd(phen)_2][OTf]_2$ (**1**),[7] $[Pd(3\text{-}i\text{Pr-phen})_2][PF_6]_2$ (**2**),[8] $[Pd(3\text{-}n\text{Bu-phen})_2][PF_6]_2$ (**3**),[8] and $[Pd(CH_3)(phen)_2][PF_6]$ (**4**),[5] besides those presented in this paper for $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2][PF_6]$ (**5**) (OTf = triflate, 3-*i*Pr-phen = 3-isopropyl-phenanthroline, 3-*n*Bu-phen = 3-normal-butyl-phenanthroline, 3-*s*Bu-phen = 3-secondary-butyl-phenanthroline). The crystal structure of the latter has been determined in order to examine the influence of a bulky group in position 3 of phen on the overall geometry of the organometallic cation.

The MM study has been extended to the diastereoisomers of the hydride complex, $[Pd(H)(phen)_2]^+$, and of its 3-(1,2,2-trimethylpropyl) derivative, $[Pd(H)(3\text{-tmp-phen})_2]^+$, in order to get some insight into the structure of species proposed to be present in the catalytic copolymerisation process.[1,2] The 3-tmp group has been considered in view of the significant increase of both productivity and polymer molecular weight obtained after introduction of this side group in the phen ligand.[3] Furthermore, models of the copolymer chain-initiating species, like $[Pd\{CH(C_6H_5)CH_2C(O)OCH_3\}(N\text{–}N)(CH_3OH)]^+$, have also been investigated with N–N = phen and 3-tmp-phen with the aim of elucidating the role of the side group in the chain growth process.

Results and Discussion

Force Field

The molecular strain energy, *E*, has been calculated according to the AMBER force field,[9] as the sum of the harmonic deformation functions for bond lengths (d), bond angles (θ), torsion angles (including improper-torsion angles, which model out-of-plane displacements) (ψ), and the van der Waals and electrostatic energy contributions [Equation (1)].

E-mail: zangrando@univ.trieste.it
[‡] Current address: Institute of Molecular Chemistry, Homogeneous Catalysis, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

$$E = \Sigma_b[k_b(d - d°)^2] + \Sigma_a[k^\theta(\theta - \theta°)^2] + \Sigma_t\{\tfrac{1}{2}V_n[1 + \cos(n \cdot \psi - \psi°)]\} + \Sigma_{ij}[(a_{ij}/r_{ij}^{12}) - (b_{ij}/r_{ij}^{6}) + (q_i \cdot q_j/D \cdot r_{ij})] \quad (1)$$

Summations in (1) are extended over all bonds, angles, torsions and pairs of non-bonded atoms *i*–*j*, separated by the distance r_{ij} . In the last summation, $a_{ij} = (\varepsilon_i\varepsilon_j)^{1/2}(r_i* + r_j*)^{12}$, $b_{ij} = 2(\varepsilon_i\varepsilon_j)^{1/2}(r_i* + r_j*)^6$, where r_i* is the van der Waals radius of atom type *i*, and ε_i is the well depth for two atoms of type *i*; q_i and q_j are the atomic charges and *D* is the dielectric constant, here treated as a distance-dependent variable ($D = r_{ij}$). Electrostatic and nonbonded atom interactions have both been reduced by a scale factor of 0.5 when atoms are only separated by three bonds. In all calculations, the trigonal carbon and nitrogen atoms have been treated using the improper torsion parameters of aromatic carbon atoms given in AMBER.[9] As in previous computations,[10,11] torsion barriers around the coordination bonds have been fixed to zero.

Energy calculations have been performed with a Pentium III PC, using the HyperChem. 6.01 molecular modelling system.[12] The Polak–Ribiere version of the conjugate gradient method has been used in all energy minimisation calculations with a convergence criterion of 0.001 kcal mol^{-1} Å^{-1} (1 kcal = 4.184 kJ). Atomic charges have been calculated by the semi-empirical ZINDO/1 method, suitable for the molecular orbital calculations of second-row transition metal complexes.[12] A local program has been used for all the geometrical calculations.[13]

Because phenanthroline and palladium atom types were not available in AMBER, the force field has been implemented with the addition of the new atom types (Figure SA in the Supporting Information) and the relative force field constants (Tables SA and SB in the Supporting Information). The "stretching" potential constants (k^d) for the *i*–*j* bonds have been calculated according to the Badger's rule,[14] $k^d_{ij} = 71.94 \cdot [(A_{ij} - D_{ij})/(d°_{ij} - D_{ij})]^3$ kcal mol^{-1} Å^{-2}, using the A_{ij} and D_{ij} parameters proposed by Herschbach and Laurie.[15] The $d°$ values for the phenanthroline C–N and C–C bonds have been derived from the mean values, calculated from the accurate crystal structure data of complexes **1–3**, while the $d°$ values for the Pd–N and Pd–C bonds (Table SA), together with the ε_{Pd} (0.693 kcal mol^{-1}) and $r*_{Pd}$ (1.928 Å) van der Waals parameters, have been optimised according to the Simplex-method procedure, already used for the derivation of force field constants in ruthenium(II)[10] and cobalt(III) [11] metal complexes. The minimised function is GOF = $[\Sigma_i w_i\Delta_i^2/(n_{obs} - n_p)]^{1/2}$, where the summation is extended to all the differences, Δ_i , between each observed and calculated value of the n_{obs} data (522 in the present case); w_i is the weight ($1/\sigma_i^2$) of each observation, and n_p is the total number of variable parameters (7, in the present case). The "bending" constants (k^θ) for the *i*–*j*–*k* bond angles have been calculated according to the Halgren's equation:[16] $k^\theta_{ijk} = 125.9 \cdot \{Z_iC_jZ_k(d°_{ij} + d°_{ik})^{-1}(\theta°_{ijk})^{-2}\exp[-2(d°_{ij} - d°_{jk})^2/(d°_{ij} + d°_{ik})^2]\}$ kcal mol^{-1} rad^{-2}.

The values of the *C* and *Z* parameters for palladium (1.3267 and 3.2039, respectively) have been obtained by the optimisation procedure described above, whereas for the carbon, nitrogen and hydrogen atoms, the Halgren's values have been used. No restraint has been included in the energy minimisation during the force field parameter optimisation procedure.

Because of the lack of suitable experimental structural data, the stretching (Table SA) and bending (Table SB) force constants of the Pd–H and Pd–O bonds have been simply calculated by the Badger's and Halgren's equations, assuming $d°$(Pd–H) = 1.6 Å, and $d°$(Pd–O) = 2.01 Å.

Minimum energy structures have been found by the Conformational Search routine of HyperChem[12] and the conformational analysis has been carried out with local Excel© Macro functions that allow the minimisation of the strain energy as the conformation of the cation is varied through rotation around the Pd–N bond of the monocoordinated phen ligand.

As shown in Table 1, the agreement between observed and calculated bond lengths and angles for the five complexes, **1–5**, used for the optimisation of the force field parameters, is quite satisfactory, specially after imposing a restraint on the Pd···N(apical) distance in the methyl derivatives **4** and **5** (see below). In fact, the average differences, $<\Delta>$, between observed and calculated values, are low enough to show the absence of large systematic errors, and the weighted root-mean-square deviations (wrms = $[(\Sigma_i w_i\Delta_i^2)/\Sigma_i w_i]^{1/2}$) are lower than the mean ranges of chemically equivalent structural parameters, observable in the crystal structures of **1–3** (e.g. 0.022, 0.018, and 0.023 Å for the Pd–N, N–C, and C–C bond lengths).

Table 1. Average differences $<\Delta>$ between observed and calculated bond lengths and angles, weighted root-mean-square values (wrms), and number of observations (*n*) used in the force field parameter optimisation procedure for structures **1–5**. X, Y and Z represent carbon and nitrogen atoms.

Distances [Å]	$<\Delta>$[a]	$<\Delta>$[b]	wrms[a]	wrms[b]	*n*
Pd–X	–0.010	–0.008	0.016	0.015	20

Pd–X–Y	0.6	0.6	1.0	0.9	36
X–Y–Z	0.3	0.3	1.4	1.3	252

[a] No restraint. [b] Pd···N distance restrained to 2.730 Å with a force constant of 1000 kcal mol^{-1}.

Moreover, the overall shape of the minimised structures of the cations, $[Pd(phen)_2]^{2+}$ (**1**) and $[Pd(3\text{-R-phen})_2]^{2+}$ (R = *i*Pr for **2** and *n*Bu for **3**), is reasonably close to that found in the crystal structures (Table 2), the differences being attributable to the different packing environments.

The consistency of the force field is further illustrated by its ability to reproduce, in the methyl derivatives **4** and **5**, the increase of the Pd–N bond lengths on going from the chelate to the monocoordinated ligand, and the increase of the Pd–N bond length *trans* to the methyl group (Table 3). The deformation of the Pd–N–C bond angles in the monocoordinated phenanthroline ligand is also well reproduced, as well as the orientation of the ligands, shown by the tor-

Molecular and Crystal Structures

$[Pd(phen)_2]^{2+}$ and $[Pd(3\text{-R-phen})_2]^{2+}$ Complexes

Previous structural investigations of $[Pd(phen)_2]^{2+}$ complexes showed that the cations are characterised by significant ligand distortions due to the steric repulsion between the α-hydrogen atoms.[1,4,7,17] In most cases, the steric crowding is relieved by a tetrahedral distortion of the PdN_4 core yielding a *twist* conformation, in which the dihedral angle, α, between the PdN_2 planes (π_1 and π_1' in Figure 1) ranges from 18° to 25°, depending upon the nature of the anion (Table 2).[1,7,17] A similar conformation has also been found in the phenanthroline-substituted cations $[Pd(3\text{-R-phen})_2]^{2+}$ (α = 18.8 and 23.2°, for R = *i*Pr and *n*Bu, respectively),[8] and in the platinum(II) complex $[Pt(phen)_2][Cl]_2\cdot 3H_2O$ (α = 20.9°).[18] On the other hand, in the case of $[Pd(phen)_2][PF_6]_2$, the repulsive interactions are partly alleviated by a bending on opposite sides of the π_1, π_2 and π_1', π_2' planes (dihedral angles β, β') giving rise to a *step* geometry (α = 0°, $\beta = \beta'$ = 16.2°), with the five-membered rings in an *envelope* conformation.[4] This deformation is accompanied by a tilting, towards the same side, of the π_3, π_4 planes (dihedral angle γ = 13.4°) so that each phen ligand exhibits a *bow* conformation, and the cation acquires an overall *bow-step* shape.[4] However, inspection of Table 2 shows that also in the *twist* conformations there can be some "s*tepping*" and "*bowing*", like in $[Pd(3\text{-}i\text{Pr-phen})_2][PF_6]_2$ (β = 7.4° and γ = 5.0°) and in $[Pd(phen)_2][OTf]_2$, where, for one ligand, β = 5.6° and γ = 5.2°. Interestingly, in $[Pd(phen)_2][BF_4]_2$,[1] β and γ are much smaller, probably because of weaker intermolecular interactions, due to the lack of any Pd···O or Pd···F coordinating interaction, present in the other compounds.[7,17] This is in agreement with the observation that the β and γ values found in the BF_4 compound are close to those calculated for the three isolated cations, $[Pd(phen)_2]^{2+}$, $[Pd(3\text{-}i\text{Pr-phen})_2]^{2+}$ and $[Pd(3\text{-}n\text{Bu-phen})_2]^{2+}$ (Table 2), in the absence of any packing effect.

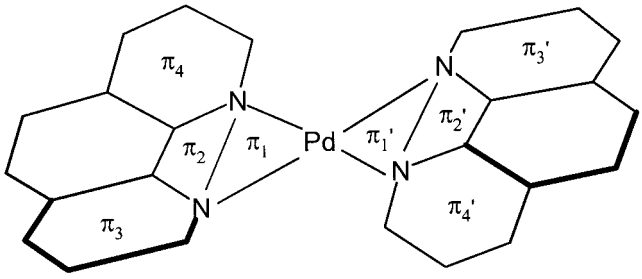

Figure 1. Planes (π_i) used to describe the conformation of the $[Pd(phen)_2]^{2+}$ complex; the dihedral angle α, between π_1 and π_1', defines the "twisting" of the two ligands, β (β'), between π_1, π_2 (π_1', π_2'), defines the "step", and γ (γ'), between π_3, π_4 (π_3', π_4'), defines the "bow".

The present MM calculations show that the $[Pd(phen)_2]^{2+}$ cation in the *twist* conformation exhibits a total strain energy about 3.7 kcal mol^{-1} lower than that in the *bow-step* conformation, mainly because of a lower torsional energy contribution. This indicates that the *bow-step* conformation is only slightly less stable, confirming the hypothesis that, in the solid state, it can be stabilised by van der Waals and electrostatic forces, without the need for particular stacking interactions.[1]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

It is interesting to observe that the *twist* distortion gives a two-bladed propeller shape to the $[Pd(phen)_2]^{2+}$ cation (C_2 point group symmetry), whose chirality can be assigned using the Δ, Λ descriptors.[19] On the contrary, the *bow-step* conformation is achiral being characterised by a C_{2v} symmetry.

Finally, it is worth noting that, in the solid state, the $[Pd(3\text{-}i\text{Pr-phen})_2]^{2+}$ and $[Pd(3\text{-}n\text{Bu-phen})_2]^{2+}$ complexes, have the side groups placed on the same side, in a *syn* geometry. In fact, MM calculations show that this isomer, for both of the isolated cations, exhibits a strain energy slightly lower than that of the *anti* isomer (*i*Pr, 0.8 kcal mol^{-1}; *n*Bu, 1.1 kcal mol^{-1}). This is qualitatively in agreement with the results of a DFT study performed on the same derivatives.[8] However, the energy differences are rather low, suggesting that the stabilisation of the *syn* isomers in the solid state is probably due to packing effects.

$[Pd(CH_3)(phen)_2]^+$ and $([Pd(CH_3)(3\text{-R-phen})_2]^+$ Complexes

The most interesting structural feature in the crystals of the $[Pd(CH_3)(phen)_2]^+$,[5] and $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$ (Figure 2) cations is the distorted square-planar geometry of the Pd atoms with one phenanthroline molecule acting as a monocoordinated ligand. The orientation of this phen group is such that the uncoordinated nitrogen atom, through rotation around the Pd–N bond, occupies a pseudo-apical position at 2.73(1) Å from the metal atom. The rotation around the Pd–N bond is measured by the torsion angle ψ (N[2]–Pd–N(3)–C(14) in Figure 2), which is 90.5° and 103.0° in $[Pd(CH_3)(phen)_2]^+$[5] and $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$, respectively (Table 3). The two phenanthroline ligands are nearly perpendicular to each other in the phen complex (dihedral angle τ = 89.4°);they form a narrower angle in the 3-*s*Bu-phen derivative (τ = 75.5°). A similar structure has been found in the related complex $[Pd(CH_2NO_2)(phen)_2][PF_6]$, where the Pd···N distance is 2.674(3) Å and τ = 88.9°.[6]

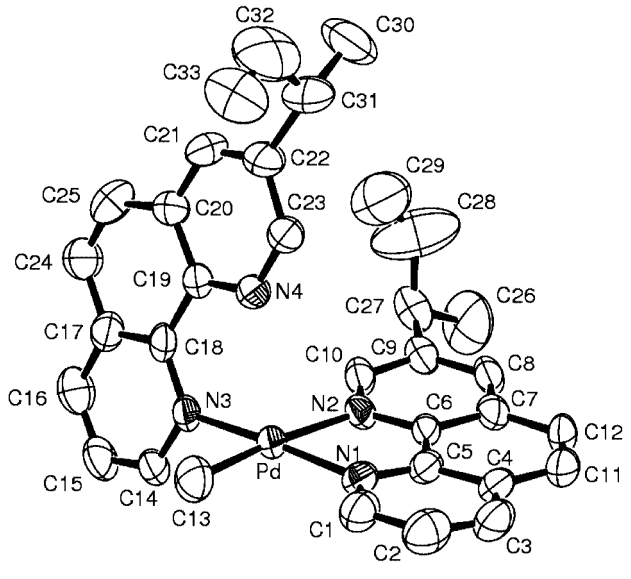

Figure 2. ORTEP drawing of the $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$ cation (thermal ellipsoids at 40% probability level).

The strain energy minimisation (without any restraint), starting from the crystal structure coordinates of $[Pd(CH_3)(phen)_2]^+$, yields for the calculated structures ψ = 106.9° and τ = 73.7°, and, in the case of $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$, ψ = 110.2° and τ = 69.4°, not too far from the solid-state values. This indicates that the orientation of the monocoordinated ligand is essentially determined by intramolecular van der Waals and electrostatic interactions. On the other hand, in the minimum-strain-energy structures, the average Pd···N distance is 2.985(1) Å. Interestingly, this distance is significantly shorter than the sum of the assumed van der Waals radii (1.93+1.82 = 3.75 Å), but much longer than the experimental distances, which suggests the presence of some Pd–N valence-bonding interaction not modelled in the present force field (no specific d^o and k^b values). In this respect, we must observe that the van der Waals radius of 1.93 Å, derived for Pd^{II} in the present force field, in correspondence with ε_{Pd} = 0.69 kcal mol^{-1}, is somewhat intermediate between the previously proposed values of 1.65 Å[20] and 2.60 Å,[21] and not far from 1.7 Å (ε_{Pd} = 0.2 kcal mol^{-1}) reported by Hambley, from MM modelling of nonbonded Pd···H and Pd···S interactions.[22] In fact, this last value might be an underestimate in the case of weakly attractive (agostic) interactions with the metal atom.[22]

The presence of a bonding contribution is further indicated by the displacement of the palladium atom from the coordination mean plane (Table 3). In fact, by restraining the Pd···N distance to 2.730 Å a remarkable improvement of the Pd out-of-plane distance is obtained, as well as of ψ and τ (Table 3). On the basis of these results, we can assume that the palladium coordination polyhedron is intermediate between a square-planar and a square-pyramidal geometry, even though, in this last case, a Pd–N distance of about 2.347 Å should be expected for an apical bond.[23] However, a constraint on such a value for the Pd···N distance causes a dramatic increase of the strain energy (≈ 75 kcal mol^{-1}), essentially because of the increase of the van der Waals energy term. Thus, the attractive bonding interaction between the Pd and N atoms seems to be in balance with significant intraligand repulsive forces.

^{1}H NMR spectroscopy has shown the equivalence, in solution, of the two phen ligands, indicating the presence of a dynamic process, which involves either the exchange between the unbound nitrogen atom of the monocoordinated ligand and that of the chelate ligand *trans* to the methyl group (*opening-closure*), or the exchange of the two nitrogen atoms at the same coordinating site (*flipping*).[5]

In order to investigate the steric aspects of this process, we have undertaken an analysis of the strain energies of the species possibly involved. From a structural point of view, we have only one stereoisomer in the case of the phen ligand ($[Pd(CH_3)(phen)_2]^+$) and four distinct diastereoisomers in the case of the 3-alkyl-phen ligands ($[Pd(CH_3)(3\text{-R-phen})_2]^+$, with R = *i*Pr and *s*Bu), depending on the relative position of the substituents (Figure 3).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

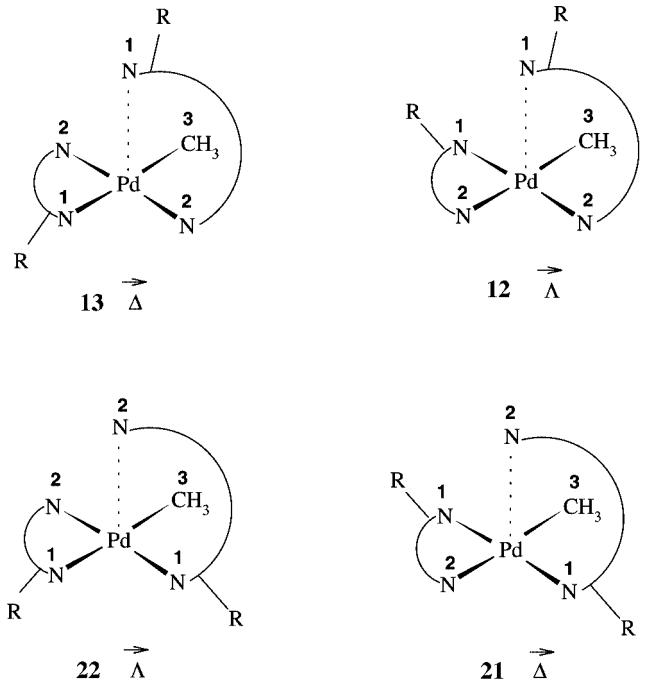

Figure 3. Sketch of the stereoisomers of the $[Pd(CH_3)(3\text{-R-phen})_2]^+$ cations, with their stereochemical descriptors; ranking numbers are also reported.

The different diastereoisomers are identified by a two-digit configuration index formally assuming a bischelated complex with a square pyramidal geometry.[19] For the 3-R-phen complexes, the priority of the ligating atoms decreases in the order N(–R) > N > C, with ranking numbers 1, 2 and 3, respectively (Figure 3). The chirality of these complexes (C_1 symmetry) can be conveniently described by the "oriented-skew-lines" reference system, considering the N···N lines of the 3-R-phen ligands oriented from N(–R) to N.[24]

It is to be noted that the change of the apical position implies an inversion of the complex configuration, with inversion of the sign of ψ. Furthermore, because of the approximate coplanarity of the atoms in the phenanthroline ligands and in the coordination basal plane, the variation of ψ implies a variation of the dihedral angle τ such that $|\psi| + \tau \approx 180°$ (Table 4). Therefore, the rotation of the phen ligand around the Pd···N axis corresponds to the swinging of the ligand plane around the Pd···N "hinge".

In order to investigate the isomer stability, we have calculated the strain energy for the four diastereoisomers of $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$, with different combinations of the *R*/*S* chirality of the *s*Bu groups (Table 4). ΔE and ψ (configuration $\vec{\Delta}$) values have been calculated with and without the restraint on the Pd···N distance. However, inspection of Table 4 shows that there are small energy differences between the two cases. It is worthy of note that after introduction of the restraint, the lowest energy is exhibited by isomer **13**, in which the asymmetric carbon atoms of the *sec*-butyl group in the chelated and that in the monocoordinated phen ligands have opposite configurations, as in the diastereoisomers **13** (*R*–*S*) and **13** (*S*–*R*). In fact, the former isomer has been found in the crystal. This shows once again that the introduction of the Pd···N restraint is necessary for the best description of the structural properties of these complexes. As shown in Table 4, in each diastereoisomer, ΔE is nearly unaffected by the chirality of the *s*Bu groups, while it increases slightly, in the order **13** < **22** < **21** < **12**, with a maximum energy difference of about 1.3 kcal mol^{-1}. Finally, calculations show that changes in the conformation of the *s*Bu groups (φ angles) cause small changes in ΔE.

Table 4. Scaled strain energies [kcal mol^{-1}] for the four diastereoisomers of $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$, all in configuration $\vec{\Delta}$ considering the possible combinations of the ligand chirality; ΔE represents the strain energy differences with respect to the lowest-energy isomer; some conformational parameters (see Figure 2 for labels) are also reported for the "restrained" structures.

As shown in Table 4, the minimum energy structures are provided by *gauche*-like conformations ($\varphi \approx \pm 60°, \pm 120°$).

The possibility of rotation of the monocoordinated phen ligand around its Pd–N bond (torsion angle ψ) has been investigated through a conformational analysis of the $[Pd(CH_3)(phen)_2]^+$ and $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$ cations, imposing the Pd···N restraint, and considering the enantiomeric species with $\psi > 0$, in the range between 50° and 130°.

As shown in Figure 4, in the case of the phen complex, "free" rotation is limited to a ψ range between 65° and 115°, in correspondence of the broad low-energy region ($\Delta E < 1$ kcal mol^{-1}), with two minima around $\psi = 80°$ and $\psi = 100°$, the second one with an energy only 0.2 kcal mol^{-1} higher. A similar behaviour is found for the **22** $\vec{\Delta}$ (*R*–*S*) isomer of the 3-*s*Bu-phen derivative ($\Delta E = 0.3$ kcal mol^{-1}), whereas its other *R*–*S* diastereoisomers, as well as all those of the **12** and **21** isomers, exhibit the opposite trend, having the deepest minimum at $\psi \approx 100°$–$105°$, with ΔE values varying from 0.1 to 0.3 kcal mol^{-1}. Calculations show that in the case of isomer **13** $\vec{\Delta}$, the energy at $\psi \approx 80°$ slightly increases in the order (*R*–*R*) < (*S*–*S*) < (*S*–*R*) < (*R*–*S*), with ΔE in the range 0.4–0.6 kcal mol^{-1}.

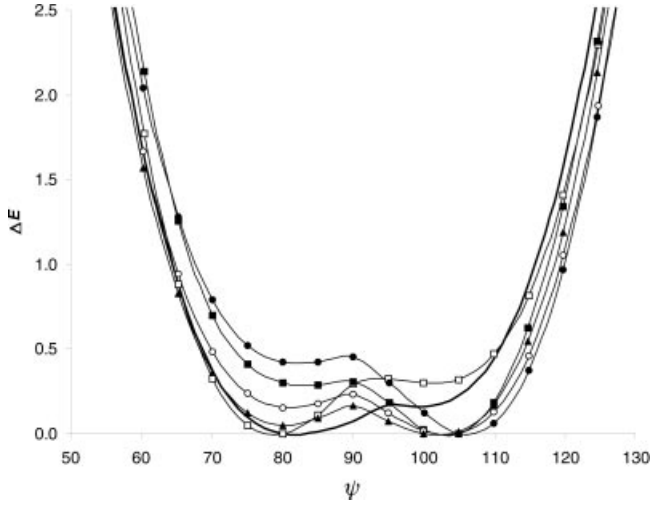

Figure 4. Plot of ΔE [kcal mol^{-1}] vs. the rotation angle ψ [°] (Pd···N restraint) for $[Pd(CH_3)(phen)_2]^+$ (thick line), and for some isomers of $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2]^+$: **22** $\vec{\Lambda}$ (*R*–*S*) (□), **22** $\vec{\Lambda}$ (*R*–*R*) (■), **12** $\vec{\Lambda}$ (*R*–*R*) (#9650;), **21** $\vec{\Delta}$ (*R*–*R*) (○), and **13** $\vec{\Delta}$ (*R*–*R*) (●).

The small differences calculated for the strain energies (Table 4) account for the fluxional behaviour in solution of this kind of complexes, and the proposed ligand exchange mechanism.[5] In fact, the *flipping* process yields the equilibration between isomers **13** and **22** ($E_{22} - E_{13} \approx 0.4$ kcal mol^{-1}), the last one also being in equilibrium with **12**, through an *opening-closure* process ($E_{12} - E_{22} \approx 0.9$ kcal mol^{-1}). Finally, a *flipping* process converts **12** into **21** ($E_{12} - E_{21} \approx 0.2$ kcal mol^{-1}). Furthermore, the *opening-closure* process converts isomer **21** into its enantiomeric form. NMR spectra show the complete equivalence of the phenanthroline ligands, indicating the presence in solution of all the isomers, but say nothing about their relative populations. On the basis of such energy differences it may be expected that the isomers are present in solution, at room temperature, in approximately equimolar ratios.

[Pd(H)(phen)$_2$]$^+$ and [Pd(H)(3-tmp-phen)$_2$]$^+$ Complexes

A palladium hydride intermediate, such as [Pd(H)(N–N)(S)]$^+$, where S represents a coordinating solvent molecule, has been proposed to be present in the termination step of the copolymerisation reaction mechanism.[2] Depending upon the reaction conditions, the Pd-hydride can be reoxidised to the catalytically active species, or can insert the olefin starting a new polymeric chain. Eventually, it can evolve to palladium metal. The stability of the active species increases with an excess of the phenanthroline ligand, probably because of the formation of species like [Pd(H)-(phen)$_2$]$^+$, which should prevent the Pd-hydride intermediate from decomposing to palladium metal.[2]

Assuming for this last complex the pseudo-square-pyramidal structure found in the methyl derivatives, MM calculations have been performed for both the phen and the 3-tmp-phen complexes, in order to get some information about their structural behaviour. Inspection of Table 5 shows that, like in the 3-*s*Bu-phen methyl complex, the strain energy slightly increases from isomer **13** to isomer **22**, while **12** and **21** exhibit slightly higher energies. However, the energy trends, as a function of the ligand chirality, are different, and the energy changes are larger.

Table 5. Scaled strain energies [kcal mol^{-1}] for the four diastereoisomers of $[Pd(H)(3\text{-tmp-phen})_2]^+$, all in configuration $\vec{\Delta}$, considering the possible combinations of the ligand chiralities; the torsion angle ψ [°] and the dihedral angle τ [°] are also reported (see footnotes h, i in Table 3).

Isomer	Chirality[a]	ΔE[b]	ψ[b]	τ[b]
13	*S*–*R*	0.0	104.6	74.7

phen ligands, and L = CH_3OH or a monocoordinated N–N molecule, are models of possible species involved in the initiation steps of the reaction mechanism for the CO/styrene copolymer chain growth.

In the case of the $[Pd\{CH(C_6H_5)CH_2C(O)OCH_3\}(3\text{-tmp-phen})(CH_3OH)]^+$ derivative, two isomers (*cis* and *trans*) are possible, depending on the relative positions of the growing polymer chain and the nitrogen atom close to the tmp group (Figure 5); while in the case of L = N–N, we have the same isomers of the methyl complexes mentioned above.

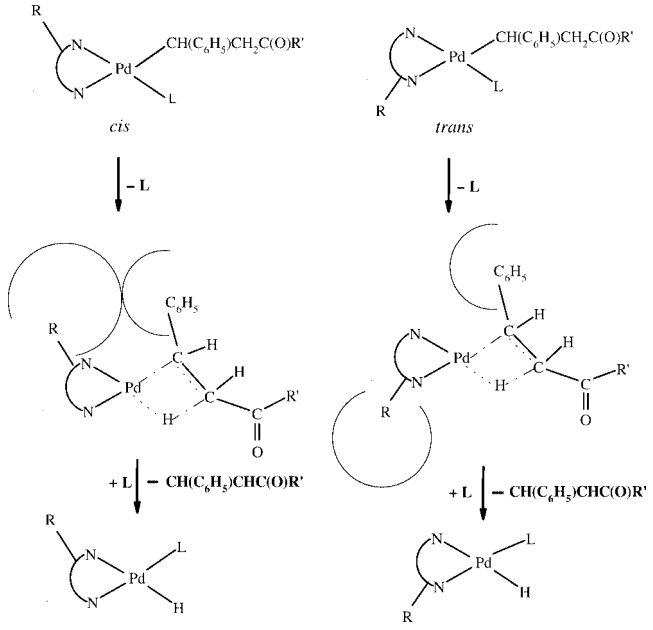

Figure 5. Sketch showing the formation of the transition states for the β-hydrogen elimination process, yielding the termination of the CO/styrene copolymer chain growth; L represents a coordinating solvent or a monocoordinated phen ligand; R′ = OCH_3 or the growing polymer chain; bonds under cleavage or formation are drawn as dotted lines; the arcs depict the steric encumbrance of the R and phenyl groups during their rotation around the C–C bonds.

Examination of molecular models shows that there is no particular difference between the phen and the 3-tmp-phen complexes, as to their steric hindrance to the attack of a further styrene molecule, both in the case of the square-planar (L = CH_3OH) and of the pseudo-square-pyramidal (L = N–N) complexes. Therefore, there is no apparent reason for the observed differences in the copolymerisation reaction, attributable to steric effects in the chain initiation steps.

As a matter of fact, the observation that increasing the bulkiness of the 3-alkyl group remarkably increases the molecular weight of the polymer chains[3] suggests that the bulkiness of the group could play an important role in the chain termination step, which proceeds through a β-hydrogen elimination reaction.[2] As depicted in Figure 5, the reaction intermediate obtained from the *cis* isomer (*cis*-β-H) is destabilised with respect to that obtained from the *trans* isomer (*trans*-β-H) by the steric interactions between the phenyl and the tmp groups, which, at the reaction temperature (≈ 50 °C), can be considered to be freely rotating around their respective single C–C bonds. Because this intermediate leads to the detachment of the copolymer chain, it seems likely that the molecular weight of the copolymer will increase to the extent the β-hydrogen elimination reaction is retarded.

Anyhow, inspection of molecular models (Figure 6, top) indicates that in the *cis*-β-H complex, the repulsive effects are efficient only when the chiral carbon atom of the tmp group and that of the Pd-bound chain exhibit opposite configurations (*R* and *S*, respectively, in Figure 6), displaying the two groups on the same side of the coordination plane. On the contrary, in the case of the *trans*-β-H intermediate (Figure 6, bottom), the two groups are sufficiently distant, even in the case of homochiral groups.

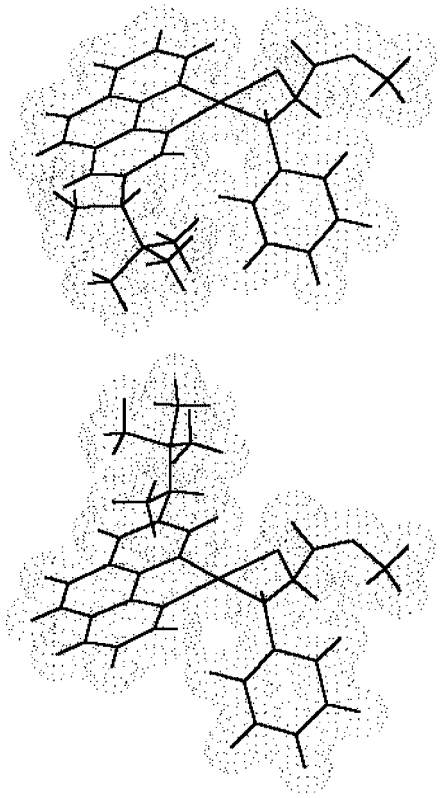

Figure 6. Sketch of the (*R*–*S*)-β-hydrogen elimination intermediate, from the *cis* (top) and *trans* (bottom) isomer of $[Pd\{CH(C_6H_5)CH_2C(O)OCH_3\}(3\text{-tmp-phen})(L)]^+$.

On this basis, it is expected that the termination reaction can occur more easily with the phen complexes rather than with the 3-tmp-phen complexes. In this last case, in fact, the *R*–*S* and *S*–*R* diastereoisomers of the *cis* complex are destabilised by steric interactions, reducing the concentration in solution of the palladium species prone to forming the β-H reaction intermediate.

Conclusions

The stereochemistry of Pd-phenanthroline complexes $[Pd(3\text{-R-phen})_2]^{2+}$ (R = H, alkyl group) has been investi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gated in relation with their action as precatalysts in the CO/styrene copolymerisation process.

The results of the MM investigation have shown that the specific force field, derived here, is suitable for a description of the molecular structure of the above dications and of organometallic complexes like $[Pd(CH_3)(3\text{-R-phen})_2]^+$. In the first case, steric effects are shown to determine severe distortions from a square-planar coordination geometry of the metal atom. This can explain the instability of the dications, which in solution of coordinating solvents, undergo dissociation of one chelate ligand and substitution with solvent and/or monocoordinated phen molecules, giving rise to the catalytically active species. In the methyl monocations, the coordination polyhedron results to be intermediate between square planar and square pyramidal, one phenanthroline ligand having one nitrogen atom loosely bound to Pd, in a pseudo apical position. The comparison of the strain energies of all the possible diastereoisomers, together with the results of conformational analyses, account for the possible exchange between the various isomers, in agreement with the fluxional behaviour detected in solution by NMR spectroscopy.

Molecular modelling suggests that peculiar steric effects can be displayed by bulky alkyl groups in 3-R-phen complexes during the termination step of the CO/styrene copolymerisation reaction. In fact, the β-hydrogen elimination reaction appears to be hindered in the presence of a bulky group, such as 1,2,2-trimethylpropyl, allowing the formation of longer copolymer chains.

In order to get a deeper insight into the Pd–N bonding in the square pyramidal methyl derivatives, a quantum chemical investigation appears of interest. Of great importance would also be the quantum chemical investigation of the structure of the intermediate species involved in the β-hydrogen elimination reaction, checking the influence of the phenanthroline side groups. These, in fact, cannot be properly treated by MM methods.

Experimental Section

Materials and Instrumentation: The analytical grade solvents and chemicals (Carlo Erba and Aldrich) were used without further purification for synthetic purposes. The dichloromethane used for the synthesis was purified through distillation over $CaCl_2$ and stored under an inert atmosphere. $[Pd(CH_3COO)_2]$ was a loan from Engelhard Italiana SpA. The 3-*s*Bu-phen, in the racemic form, was prepared by Serafino Gladiali from the University of Sassari. ^1H NMR spectra were recorded at 400 MHz with a JEOL EX 400 spectrometer; the resonances were referenced to the solvent peak versus TMS: $CDCl_3$ at δ = 7.26 ppm.

Synthesis of Complexes: All manipulations were carried out under argon and at room temperature by using Schlenk techniques. Elemental analyses (C, H, N), performed at Dipartimento di Scienze Chimiche (Università di Trieste), were in perfect agreement with the proposed stoichiometry. The compound $[Pd(CH_3)(CH_3CN)(3\text{-}s\text{Bu-phen})][OTf]$ was synthesised as previously reported.[5]

Synthesis of $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2][OTf]$: *rac*-3-*s*Bu-phen (0.26 mmol) was added to a suspension of $[Pd(CH_3)(CH_3CN)(3\text{-}s\text{Bu-phen})][OTf]$ (0.20 mmol) in chloroform (20 mL) (Pd/3-*s*Bu-phen = 1:1.3) yielding an orange solution. After 10 min, the solution was filtered through fine paper and concentrated under vacuum to induce precipitation of the product as an orange solid. The solid was removed by filtration, washed with diethyl ether and vacuum dried. Yield: 80 %. $C_{34}H_{35}F_3N_4O_3PdS$: calcd. C 54.95, H 4.75, N 7.54; found C 54.6, H 4.71, N 7.60. ^1H NMR ($CDCl_3$): δ = 8.73 (br., 2 H, H^9), 8.69 (br., 2 H, H^2), 8.51 (d, 2 H, H^7), 8.30 (s, 2 H, H^4), 8.02 (s, 4 H, $H^{5,6}$), 7.70 (dd, 2 H, H^8), 0.96 (s, 3 H, CH_3), 0.98 (s, 3 H, CH_3) ppm.

Crystallography: Diffraction data for $[Pd(CH_3)(3\text{-}s\text{Bu-phen})_2][PF_6]\cdot CH_2Cl_2$ were collected at room temperature with the $\omega/2\theta$ scan technique on a CAD4 Enraf–Nonius diffractometer, equipped with graphite-monochromator and Mo-K_α radiation (l = 0.71073 Å). Intensity data were corrected for Lorentz polarisation effects and also for absorption, based on an empirical ψ-scan method. The structure was solved by conventional Patterson and Fourier techniques,[25] and refined by the full-matrix least-squares method based on F^2.[25] The fluorine atoms of the PF_6^- anion were found to be disordered over two positions [refined occupancies of 0.75(2) and 0.25(2)]. A difference Fourier map allowed to detect a disordered molecule of CH_2Cl_2. All the calculations were performed with the WinGX System, Ver 1.64.05.[26] Crystal data: $C_{34}H_{37}Cl_2F_6N_4PPd$, M = 823.95, triclinic, space group $P\bar{1}$ (No. 2), a = 11.002(4), b = 12.508(4), c = 14.502(4) Å, α = 80.67(3), β = 82.37(2), γ = 65.37(3)°, V = 1785.4(10) Å^3, Z = 2, $\rho_{calcd.}$ = 1.533 g cm^{-3}, μ(Mo-K_α) = 0.776 mm^{-1}, F(000) = 836; 7670 reflections collected ($2\theta_{max}$ = 53°), 7367 unique [R(int) = 0.0363], 3332 observed reflections $I > 2\sigma(I)$, 458 parameters, $R1$ = 0.0658, $wR2$ = 0.1658, GoF = 1.017; hydrogen atoms in idealised geometry; max positive and negative peaks in ΔF map 0.561 and –0.637 e Å^{-3}, respectively. CCDC-232498 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Preparation and Coordination Chemistry of *n*-Allylaminophosphane

Alexandra M. Z. Slawin,[a] Joanne Wheatley,[a] and J. Derek Woollins*[a]

Keywords: Phosphanes / Alkenes / Hemilabile complexes / X-ray structures

Reaction of allylamine with 1 equiv. of Ph_2PCl in the presence of NEt_3, proceeds in THF to give (allylamino)phosphane **1**. **1** has been coordinated as a monodentate *P* ligand with Au, Pd, Pt, Ru, Rh, Ir and as a bidentate *P,allyl* ligand to Pt. Reaction of KO*t*Bu with $[PtCl_2\{Ph_2PNH(C_3H_5)\}_2]$ in methanol gives $[Pt\{Ph_2PNH(C_3H_8O)\}_2]$. The X-ray structures of **1**.Se and four demonstrative monodentate complexes all reveal intramolecular N–H···Cl hydrogen bonding. The structure of $[Pt\{Ph_2PNH(C_3H_8O)\}_2]$ consists of an N–H···O hydrogen-bonded dimer in the solid state.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Phosphane–alkenes have the potential to coordinate with the phosphorus atom or through the olefin moiety. For example, Coutinho et al.[1] treated a variety of phosphido-bridged complexes, $[(OC)_4M(\mu\text{-}PPh_2)_2RhH(CO)(PPh_3)]$, with the phosphanylalkenes $Ph_2P(CH_2)_nCH{=}CH_2$ (M = Cr, Mo or W; n = 1–3); in these reactions the olefin undergoes hydroformylation, which is of great interest today in commercial processes including the Rhone-Poulenc/Ruhr Chemie aqueous-based system.[2] Furthermore, work continues to prepare ligands that lead to greater regioselectivity and/or enantioselectivity.[3] It is of interest to investigate other potentially hemilabile ligands to increase the success and efficiency of current processes and in early work the olefinic fragment was used as a stabilising group with strongly bonding phosphane ligands.[4] More recently the study of phosphane–alkene ligands has focused on the weakly ligating nature of the alkene, for example, Brookes[4] displaced the olefinic groups of a rhodium complex with a tetraphenylborate anion to yield a piano stool metal complex. Lindner et al.[5] showed that the furan ring in (phopshanylalkyl)furan ligands could ligate to metal centres in an η^1-fashion through the oxygen atom or by an η^2-fashion through the C=C double bonds. The most favoured coordination mode of these types of phosphane–alkene ligands was shown to be the η^2-fashion as the partial donation of the lone pair from the oxygen atom makes the η^1-fashion coordination less favourable due to the oxygen atom being a poorer σ-donor than the olefinic groups. Diphenyl(vinyl) phosphane (DPVP) was shown by the Barthel-Rosa research group to be a hemilabile ligand when coordiniated to ruthenium(II) centres.[5] They showed that the (η^3-DPVP) ruthenium(II) complex could react both reversibly and irreversible depending on the small molecule that was used in the reaction. A reversible reaction was observed when acetonitrile was used; however, in the presence of CO the reaction was found to be irreversible but in both instances the DPVP ligand underwent an η^3- to η^1-shift that opened up a coordination site on the metal centre. It is clear that there is a potentially rich and diverse coordination chemistry available for phosphane–alkenes.

Here, we report the preparation of an aminophosphane which contains an olefinic side chain and thus the potential to act as a hemilabile ligand. Illustrative coordination complexes have been prepared.

Results and Discussion

Reaction of allylamine with 1 equiv. of Ph_2PCl in the presence of NEt_3, proceeds in THF to give **1** which was isolated (41 % yield) by filtration from $Et_3NH^+Cl^-$ as a colourless oil that was purified by distillation (132 °C/0.2 Torr). After storing under nitrogen at –18 °C a colourless waxy solid formed (41 % yield). The $^{31}P\{^1H\}$ NMR spectrum of **1** consists of a singlet at δ_P = 42.5 ppm. The EI^+ mass spectrum gave the expected fragmentation pattern and parent ion observed at *m*/*z* 242. The microanalysis gave satisfactory results for the suggested structure. The chalcogenides of $Ph_2PNH(C_3H_5)$ were prepared easily [Equation (1)].

E-mail: jdw3@st-and.ac.uk

 DOI: 10.1002/ejic.200400447 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The oxide $Ph_2P(O)NH(C_3H_5)$ (**2**) was prepared by addition of urea/hydrogen peroxide to a dichloromethane solution of **1** whilst the sulfur and selenium analogues **3** and **4** were prepared by the addition of elemental S or Se to the ligand in toluene. Microanalysis and EI^+ mass spectroscopic data for all the chalcogenides prepared were satisfactory and the $^{31}P\{^1H\}$ NMR showed single resonances ($CDCl_3$) at δ_P = 24.4 and 60.5 ppm for the oxide and sulfide, respectively. The selenium analogue exhibited a single $^{31}P\{^1H\}$ NMR resonance ($CDCl_3$) at δ_P = 58.1 ppm with selenium satellites [$^1J(^{31}P\text{-}^{77}Se)$ = 756 Hz] which is typical for a P=Se group.[6]

The crystal structure of **4** (Figure 1, Table 1). shows that in the solid state the molecule forms hydrogen-bonded dimers. The NH proton of one molecule is hydrogen-bonded to the selenium atom of a second and the selenium atom of the second interacts with the NH proton of the first, leading to a head to tail type arrangement of the molecules [H(2)···Se(1A) 2.63, N(2)···Se(1A) 3.61 Å, N(2)–H(2)···Se(1A) angle of 174°].

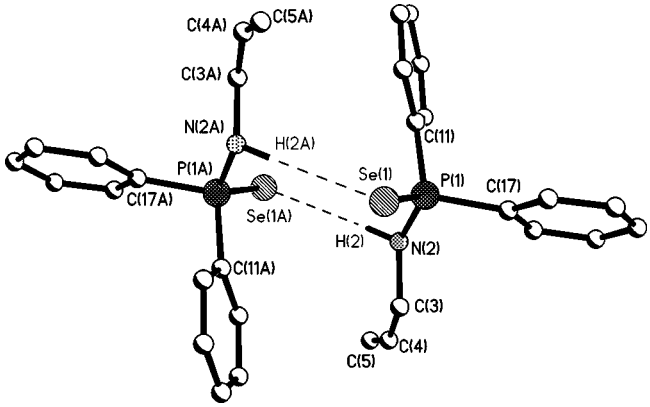

Figure 1. The X-ray structure of $Ph_2P(Se)NH(C_3H_5)$ (**4**) showing hydrogen bonding

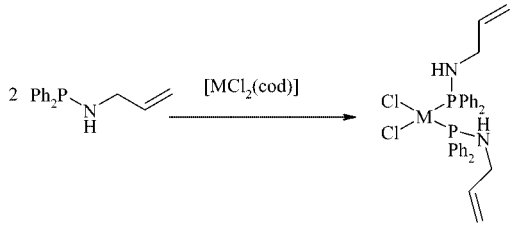
Table 1. Selected bond lengths [Å] and angles [°] for $Ph_2P(Se)NH(C_3H_5)$ (**4**)

	4
P(1)–N(2)	1.657(4)
Se(1)–P(1)	2.1082(12)
P(1)–C(11)	1.806(4)
P(1)–C(17)	1.814(4)
N(2)–P(1)–C(11)	103.30(19)
N(2)–P(1)–C(17)	103.49(18)
C(11)–P(1)–C(17)	105.86(18)
C(11)–P(1)–Se(1)	113.32(13)
C(17)–P(1)–Se(1)	112.20(14)
N(2)–P(1)–Se(1)	117.48(15)
P(1)–N(2)–H(2)	116(3)

Coordination of **1** as a monodentate ligand was established in a number of cases. Thus, reaction of [AuCl(tht)] with **1** gave the expected product [$AuCl\{Ph_2PNH(C_3H_5)\}$] (**5**) [Table 2 summarises spectroscopic data], and reaction of [$PtCl_2$(cod)] with **1** in a 1:2 molar ratio gave [$PtCl_2\{Ph_2PNH(C_3H_5)\}_2$] (**6**) in very good yield (90 %). The FAB mass spectrum of **6** showed the expected parent ion and fragmentation pattern and the complex displays a single resonance with platinum satellites in the $^{31}P\{^1H\}$ NMR spectrum [δ_P = 34.8 ppm, $^1J(^{31}P\text{-}^{195}Pt)$ = 3949 Hz, Table 2] which indicates the presence of Cl^- *trans* to P. The IR spectrum has ν_{NH} at 3054 cm^{-1}, $\nu_{C=C}$ and ν_{PN} at 1642 and 1000 cm^{-1}, respectively, and two ν_{PtCl} bands at 305 and 288 cm^{-1} which support the *cis* geometry.

The crystal structure of **6** (Table 3, Figure 2) shows that the molecule is square-planar at Pt. The P(21)–Pt(1)–P(1) [98.81(4)°] and Cl(1)–Pt(1)–Cl(2) [84.53(4)°] angles are significantly distorted from the ideal 90° due to the bulky phosphane groups. The Pt–P bond lengths are in the normal range. In the solid state the X-ray structure displays two intramolecular N–H···Cl hydrogen bonds that result in two five-membered rings [N(13)–H(13)···Cl(1) 2.34(4) Å N(13)–H(13)···Cl(1) 127(4)°, N(33)–H(33)···Cl(2) 2.34(4) Å, N(33)–H(33)···Cl(2) angle of 128(4)°].

[$PdCl_2\{Ph_2PNH(C_3H_5)\}_2$] (**7**) was prepared in a similar way to **6**. The expected fragmentation pattern and parent ion was observed in the FAB mass spectrum whilst the $^{31}P\{^1H\}$ NMR spectrum showed two peaks at δ = 58.8 and 46.2 ppm which is indicative of a mixture of *cis* and *trans* isomers. The IR bands observed at 3054, 1643 and 997 cm^{-1} represent ν_{NH}, $\nu_{C=C}$ and ν_{PN}, respectively [Equation (2)].



M = Pt **6**, Pd **7**
cod = 1,5-cyclooctadiene (2)

Reaction of of [{PtCl(μ-Cl)(PEt_3)}$_2$] with **1** gave [$Pt(PEt_3)Cl_2\{Ph_2PNH(C_3H_5)\}$] (**8**) in a yield of 59 %; δ_{PA} = 34.2 ppm, δ_{PX} = 7.3 ppm, $^1J(^{31}P_A\text{-}^{195}Pt)$ = 3979, $^1J(^{31}P_X\text{-}^{195}Pt)$ = 3479, $^2J(^{31}P_A\text{-}^{31}P_X)$ = 19 Hz, which is typical for complexes of this type. The PMe_2Ph analogue **9** was obtained in a similar fashion. The molecular structures of **8** and **9** (Table 4, Figure 3) confirm that the complexes contain one ligand bound to the platinum atom through the phosphorus atom; the hydrogen bonding motif is observed [in **8**: N(2)–H(2)···Cl(2) 2.74(4) Å, N(2)–H(2)···Cl(2) angle of 110(3)°].

[$PdCl(C_{10}H_8N)\{Ph_2PNH(C_3H_5)\}$] (**10**) was prepared from **1** and [{$PdCl(C_{10}H_8N)\}_2$] ($C_{10}H_8N$ = metallated naphthylamine ligand) whilst [RuCl(μ-Cl)(η^6-*p*-MeC_6H_4-*i*Pr)$\{Ph_2PNH(C_3H_5)\}$] (**11**) was prepared from [{RuCl(μ-Cl)(η^6-*p*-MeC_6H_4 *i*Pr)}$_2$] and **1** (85 % yield). The X-ray structure of **11** (Table 5, Figure 4) confirms that the complex contains one ligand and is bound to the ruthenium

(4)

In an interesting transformation, [Pt{Ph$_2$PNH(C$_3$H$_8$O)}$_2$] (**16**), was obtained by reaction of KO*t*Bu in methanol with **6** (51 % yield). The reaction probably proceeds by nucleophillic attack of methoxide though we have not observed this reaction for other complexes. The ^{31}P{^{1}H} NMR spectrum showed a single peak at δ_P = 91.4 ppm with platinum satellites at $^1J(^{31}P\text{-}^{195}Pt)$ = 2294 Hz. The IR spectrum shows absorptions at 2873–2809 cm^{-1}, which corre-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spond to ν_{OMe} vibrations along with vibrations at 3069 and 997, which are assigned to ν_{NH} and ν_{PN}, respectively. The FAB mass spectral analysis gave the appropriate parent ion and fragmentation pattern and the microanalysis shows good results for the suggested structure. The crystal structure of **16** (Table 6, Figure 5) shows that in the solid state the molecule occurs as hydrogen-bonded dimers. [H(1N)···O(5) 2.241(19) Å, N(1)···O(5) 3.164(4) Å, N(1)–H(1N)···O(5) angle of 157(4)°].

This paper clearly demonstrates the ability of (allylamino)phosphane to behave as a monodenate and bidentate ligand and illustrates a potentially useful nucleophilic addition at the allyl group.

Experimental Section

General: General conditions were as described previously.[7] Unless otherwise stated, all reactions were carried out under oxygen-free nitrogen using standard Schlenk techniques. Diethyl ether and THF were purified by reflux in the presence of sodium/benzophenone and distillation under nitrogen. Dichloromethane was heated to reflux in the presence of calcium hydride and distilled under nitrogen. Toluene and hexane were heated to reflux in the presence of sodium and distilled under nitrogen. The complexes [PtMeX(cod)] (X = Cl or Me),[8] [{Pd(μ-Cl)(η^3-C_3H_5)}$_2$],[9] [Cu(MeCN)$_4$][PF_6],[10] [AuCl(tht)] (tht = tetrahydrothiophene),[11] [MCl_2(cod)] (M = Pt or Pd),[12,13] [{RuCl(μ-Cl)(η^6-p-MeC_6H_4-*i*Pr)$_2$}],[14] [{Rh(μ-Cl)(cod)}$_2$],[15] [{MCl(μ-Cl)(η^5-C_5Me_5)}$_2$] (M = Rh or Ir),[16] [{PtCl(μ-Cl)(PMe_2Ph)}$_2$],[17] [{PtCl(μ-Cl)(PMe_2-Ph)}$_2$][18] and [{Pd(μ-Cl)($C_{10}H_8N$)}$_2$][19] were prepared according to literature procedures. Chlorodiphenylphosphane and allylamine were distilled prior to use. Et_3N (99 % purity), *t*BuOK (95 % purity), H_2O_2 (30 wt.% in H_2O) and reagent grade KBr were used without further purification. IR spectra were recorded as KBr discs in the range 4000–200 cm^{-1} with a Perkin–Elmer 2000 FTIR/RAMAN spectrometer. NMR spectra were recorded with a Gemini 2000 spectrometer (operating at 121.4 MHz for ^{31}P and 300 MHz for ^1H). Microanalyses were performed by the St. Andrews University service and mass spectra by the Swansea Mass Spectrometer Service.

$Ph_2PNH(C_3H_5)$ (1): Allylamine (3.671 g, 64.3 mmol) and triethylamine (6.831 g, 67.5 mmol) were added together in dry THF (50 mL). Chlorodiphenylphosphane (14.894 g, 67.5 mmol) in dry THF (50 mL) was added dropwise with stirring overnight. Triethylamine hydrochloride was removed by filtration under nitrogen and the solvent removed in vacuo to yield a colourless oil which was purified by distillation (132 °C/0.2 Torr) and storing under nitrogen in the freezer which yielded a colourless waxy solid. Yield 6.283 g, 41 %. $C_{15}H_{16}NP$ (241.3): calcd. C 74.67, H 6.68, N 5.81; found C 74.27, H 7.37, N 5.58. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 42.5 ppm. ^1H NMR ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.8 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2) and 1.9 (s, 1 H, NH) ppm. EI^+ MS: *m*/*z* = 242 $[M + 1]^+$.

$Ph_2P(O)NH(C_3H_5)$ (2): $Ph_2PNH(C_3H_5)$ (461 mg, 1.9 mmol) was dissolved in dichloromethane (10 mL). Urea/hydrogen peroxide (180 mg, 1.9 mmol) was added and the reaction mixture was stirred overnight. The product was extracted from the CH_2Cl_2 by addition of distilled water, washed with CH_2Cl_2 (3 × 5 mL), dried with magnesium sulfate and the solvents were evaporated to dryness to yield a colourless solid. Yield 338 mg, 67 %. $C_{15}H_{16}NOP$ (257.3): calcd. C 70.03, H 6.27, N 5.44; found C 69. 74, H 6.22, N 5.15. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 24.4 ppm. ^1H ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.9 (m, 1 H, CH), 5.3 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2) and 2.9 (br.s, 1 H, NH) ppm. EI^+ MS: *m*/*z* = 257 [M]. IR (KBr disc): $\tilde{\nu}$ = 3189, 1641, 1181, 993 cm^{-1}.

$Ph_2P(S)NH(C_3H_5)$ (3): $Ph_2PNH(C_3H_5)$ (420 mg, 1.7 mmol) and elemental sulfur (56 mg, 1.7 mmol) were dissolved in dry toluene (10 mL) to yield a yellow solution which was stirred overnight. The solvent was reduced to 1 mL before addition of hexane (10 mL) to precipitate a colourless solid that was isolated by filtration. Yield 246 mg, 52 %. $C_{15}H_{16}NPS$ (273.3): calcd. C 65.91, H 5.90, N 5.12; found C 66.01, H 6.09, N 5.11. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 60.5 ppm. ^1H NMR ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.9 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2) and 2.4 (br. s, 1 H, NH) ppm. EI^+ MS: *m*/*z* = 273 [M]. IR (KBr disc): $\tilde{\nu}$ = 3170, 1642, 997, 689 cm^{-1}.

$Ph_2P(Se)NH(C_3H_5)$ (4): $Ph_2PNH(C_3H_5)$ (235 mg, 1.0 mmol) and grey selenium (77 mg, 1.0 mmol) were refluxed in dry toluene (10 mL) for 1 h before cooling to room temperature and filtering through a Celite plug to remove any insoluble material. The solvent was reduced to 1 mL to yield a colourless solid that was isolated by suction filtration and dried in vacuo. Yield 269 mg, 86 %.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$C_{15}H_{16}NPSe$ (320.2): calcd. C 56.07, H 5.02, N 4.36; found C 55.97, H 5.25, N 4.43. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 58.1 ppm [$^1J(^{31}P\text{-}^{77}Se)$ = 756 Hz]. ^1H NMR ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.9 (m, 1 H, CH), 5.3 (q, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2) and 2.3 (br. s, 1 H, NH) ppm. EI^+ MS: *m*/*z* = 322 [M]. IR (KBr disc): $\tilde{\nu}$ = 3177, 1644, 991, 573 cm^{-1}.

[AuCl{Ph$_2$PNH(C$_3$H$_5$)}] (5): $Ph_2PNH(C_3H_5)$ (78 mg, 0.3 mmol) and [AuCl(tht)] (103 mg, 0.3 mmol) were dissolved in CH_2Cl_2 (5 mL) and the mixture stirred overnight in the dark. Hexane (20 mL) was added to precipitate a colourless solid that was isolated by suction filtration. Yield 44 mg, 29 %. $C_{15}H_{16}AuClPN$ (473.7): calcd. C 38.03, H 3.40, N 2.96; found C 37.98, H 2.76, N 3.07. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 64.9 ppm. ^1H NMR ($CDCl_3$): δ = 7.4 (m, 10 H, aromatic), 5.9 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.6 (m, 2 H, NCH_2), 2.5 (br.s, 1 H, NH) ppm. FAB^+ MS: *m*/*z* = 496 [M + Na]$^+$, 473 [M]$^+$, 438 [M – Cl]$^+$. IR (KBr disc): $\tilde{\nu}$= 3069, 1643, 996, 323 cm^{-1}.

[PtCl$_2${Ph$_2$PNH(C$_3$H$_5$)}$_2$] (6): $Ph_2PNH(C_3H_5)$ (161 mg, 0.7 mmol) and [$PtCl_2$(cod)] (125 mg, 0.3 mmol) were dissolved in dry CH_2Cl_2 (10 mL) to yield a colourless solution which was stirred overnight before reducing the solvent volume to 0.5 mL and addition of diethyl ether (20 mL) to precipitate a colourless solid which was isolated by suction filtration and dried in vacuo. Yield 226 mg, 90 %. $C_{30}H_{32}P_2N_2PtCl_2$ (748.5): calcd. C 48.14, H 4.31, N 3.74; found C 48.23, H 4.10, N 3.65. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.8 ppm [$^1J(^{31}P\text{-}^{195}Pt)$ 3949 Hz]. ^1H NMR ($CDCl_3$): δ = 7.4 (m, 20 H, aromatic), 5.5 (m, 2 H, CH), 5.0 (m, 2 H, CH_2), 4.9 (m, 2 H, CH_2), 4.1 (br.s, 2 H, NH) and 3.5 (m, 4 H, NCH_2) ppm. FAB^+ MS: *m*/*z* = 713 [M – Cl]$^+$, 677 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$= 3054, 1642, 1000, 305, 288 cm^{-1}.

[PdCl$_2${Ph$_2$PNH(C$_3$H$_5$)}$_2$] (7): $Ph_2PNH(C_3H_5)$ (179 mg, 0.7 mmol) and [$PdCl_2$(cod)] (106 mg, 0.4 mmol) were dissolved in CH_2Cl_2 (10 mL) and stirred overnight. The solvent volume was reduced to 0.5 mL before addition of hexane (20 mL) to precipitate a yellow solid that was isolated by filtration and dried in vacuo. Yield 224 mg, 91 %. $C_{30}H_{32}Cl_2N_2P_2Pd$ (659.9): calcd. C 54.61, H 4.89, N 4.25; found C 54.80, H 4.67, N 4.06. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 58.8 and 46.2 ppm, *cis* and *trans* isomers. ^1H NMR ($CDCl_3$): δ = 7.5–7.2 (m, 20 H, aromatic), 5.6 (m, 2 H, CH), 5.2 (m, 2 H, CH_2), 5.1 (m, 2 H, CH_2), 3.5 (m, 4 H, NCH_2) and 4.1 (br.s, 2 H, NH) ppm. FAB^+ MS: *m*/*z* = 624 [M – Cl]$^+$, 588 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$= 3054, 1643, 997, 297, 277 cm^{-1}.

[Pt(PEt$_3$)Cl$_2${Ph$_2$PNH(C$_3$H$_5$)}] (8): To a CH_2Cl_2 (10 mL) solution of [{PtCl(μ-Cl)(PEt_3)}$_2$] (56 mg, 0.07 mmol) was added dropwise a CH_2Cl_2 (10 mL) solution of $Ph_2PNH(C_3H_5)$ (35 mg, 0.1 mmol) with stirring to yield a pale yellow solution. After 30 minutes the solvent was reduced to 1 mL before addition of diethyl ether (20 mL) to precipitate a colourless solid that was isolated by suction filtration. Yield 54 mg, 59 %. $C_{21}H_{31}Cl_2NP_2Pt$ (625.4): calcd. C 40.38, H 5.01, N 2.24; found C 40.61, H 4.38, N 2.49. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta(P_A)$ = 34.2 (d) ppm [$^1J(^{31}P_A\text{-}^{195}Pt)$ = 3979 Hz]; $\delta(P_X)$ = 7.3 (d) ppm [$^1J(^{31}P_X\text{-}^{195}Pt)$ = 3479 Hz, $^2J(^{31}P_A\text{-}^{31}P_X)$ =19 Hz]. ^1H NMR ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.7 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.0 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2), 3.2 (br.s, 1 H, NH), 1.5 (m, 6 H, PCH_2) and 0.9 (m, 9 H, Me) ppm. ES^+ MS: *m*/*z* = 590 [M – Cl]$^+$. IR (KBr disc): $\tilde{\nu}$= 3072, 1641, 1002, 309, 283 cm^{-1}.

[Pt(PMe$_2$Ph)Cl$_2${Ph$_2$PNH(C$_3$H$_5$)}] (9): $Ph_2PNH(C_3H_5)$ (33 mg, 0.1 mmol) in CH_2Cl_2 (10 mL) was added dropwise to a CH_2Cl_2 (10 mL) solution of [{PtCl(μ-Cl)(PMe_2Ph)}$_2$] 56 mg, 0.07 mmol) over 10 minutes with stirring. The solution was stirred for a further 30 minutes before reduction of the solvent to 1 mL and addition of diethyl ether (20 mL) to precipitate a colourless solid that was isolated by suction filtration and dried in vacuo. Yield 55 mg, 62 %. $C_{23}H_{27}Cl_2NP_2Pt$ (645.4): calcd. C 42.85, H 4.22, N 2.17; found C 42., H 2.26, N 2.08. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta(P_A)$ = 35.3 (d) ppm [$^1J(^{31}P_A\text{-}^{195}Pt)$ = 3878 Hz]; $\delta(P_X)$ = –14.2 (d) ppm [$^1J(^{31}P_X\text{-}^{195}Pt)$ = 3625 Hz. $^2J(^{31}P_A\text{-}^{31}P_X)$ 19 Hz]. ^1H NMR ($CDCl_3$): δ = 7.4 (m, 15 H, aromatic), 5.6 (m, 1 H, CH), 5.1 (m, 1 H, CH_2), 4.9 (m, 1 H, CH_2), 4.5 (br.s, 1 H, NH), 3.1 (m, 2 H, NCH_2) and 1.7 [d, 6 H, $^3J(^{195}Pt\text{-}^1H)$ = 32 Hz, $^2J(^{31}P\text{-}^1H)$ = 11 Hz, PMe] ppm. ES^+ MS: *m*/*z* 645 = [M + H]$^+$, 610 [M – Cl]$^+$, 575 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$= 3053, 1642, 1000, 313, 283 cm^{-1}.

[PdCl(C$_{10}$H$_8$N){Ph$_2$PNH(C$_3$H$_5$)}] (10): To a CH_2Cl_2 (10 mL) suspension of [{PdCl($C_{10}H_8N$)}$_2$] (61 mg, 0.1 mmol) was added dropwise a CH_2Cl_2 solution of $Ph_2PNH(C_3H_5)$ (52 mg, 0.2 mmol) over 10 minutes to yield a colourless solution. After stirring for a further 30 minutes the solution was filtered through a Celite plug to remove any insoluble material remaining before reducing the solvent volume to 1 mL and addition of diethyl ether (20 mL) to precipitate a tan coloured microcrystalline solid that was isolated by filtration. Yield 78 mg, 69 %. $C_{25}H_{24}ClN_2PPd$ (525.3): calcd. C 57.16, H 4.60, N 5.33; found C 56.93, H 3.93, N 5.24. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 65.0 ppm. ^1H NMR ($CDCl_3$): δ = 9.6–7.8 (m, 6 H, naphthalene aromatic), 7.3 (m, 10 H, aromatic), 5.7 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.0 (m, 1 H, CH_2), 4.5 (br.s, 1 H, NH), 3.4 (m, 2 H, NCH_2), 2.8 [d, $^2J(^{31}P\text{-}^1H)$ 5 Hz, 2 H, CH_2] ppm. ES^+ MS: *m*/*z* = 489 [M – Cl]$^+$. IR (KBr disc): $\tilde{\nu}$= 3049, 1639, 993, 28 cm^{-1}.

[RuCl(μ-Cl)(η^6-*p*-MeC$_6$H$_4$ *i*Pr){Ph$_2$PNH(C$_3$H$_5$)}] (11): $Ph_2PNH(C_3H_5)$ (170 mg, 0.7 mmol) and [{RuCl(μ-Cl)(η^6-*p*-MeC_6H_4 *i*Pr)}$_2$] (54 mg, 0.1 mmol) were dissolved in CH_2Cl_2 (5 mL) to yield a dark red solution that was stirred for 30 min. The solvent was reduced to 0.5 mL before addition of hexane (10 mL to precipitate an orange microcrystalline solid that was isolated by suction filtration and dried in vacuo. Yield 82 mg, 85 %. $C_{25}H_{30}Cl_2NPRu$ (547.5): calcd. C 54.85, H 5.52, N 2.56; found C 55.71 54.85, H 5.62, N 2.71. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 61.3 ppm. ^1H NMR: δ = 7.3 (m, 14 H, aromatic), 5.5 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2), 2.9 (br. s, 1 H, NH), 2.6 (m, 1 H, CH), 1.2 (m, 3 H, CH_3), 0.8 (m, 6 H, CH_3) ppm. FAB^+ MS: *m*/*z* = 570 [M + Na]$^+$, 547 [M]$^+$, 512 [M – Cl]$^+$, 476 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$ = 3051, 1642, 996, 290, 283 cm^{-1}.

[RhCl(μ-Cl)(η^5-C$_5$Me$_5$){Ph$_2$PNH(C$_3$H$_5$)}] (12): $Ph_2PNH(C_3H_5)$ (45 mg, 0.2 mmol) and [{RhCl(μ-Cl)(η^5-C_5Me_5)}$_2$] (58 mg, 0.1 mmol) were dissolved in CH_2Cl_2 (10 mL) to yield a blood red solution that stirred for 30 min before reducing the solvent to 1 mL and addition of diethyl ether (20 mL) to precipitate a red microcrystalline solid that was isolated by suction filtration and dried in vacuo. Yield 69 mg, 67 %. $C_{25}H_{31}Cl_2NPRh$ (550.3): calcd. C 54.56, H 5.68, N 2.55; found C 54.32 , H 5.78, N 2.44. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 66.4 ppm [$^1J(^{31}P\text{-}^{103}Rh)$ = 148 Hz]. ^1H NMR ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.6 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.3 (m, 2 H, NCH_2), 3.2 (br. s, 1 H, NH), 1.3 (s, 15 H, CH_3) ppm. FAB^+ MS: *m*/*z* = 572 [M + Na]$^+$, 514 [M – Cl]$^+$, 474 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$ = 3063, 1642, 995, 279, 267 cm^{-1}.

[IrCl(μ-Cl)(η^5-C$_5$Me$_5$){Ph$_2$PNH(C$_3$H$_5$)}] (13): $Ph_2PNH(C_3H_5)$ (42 mg, 0.2 mmol) and [{IrCl(μ-Cl)(η^5-C_5Me_5)}$_2$] (69 mg, 0.1 mmol) were dissolved in CH_2Cl_2 (10 mL) to yield an orange solution. The solvent was reduced to 1 mL before diethyl ether was added to precipitate a yellow microcrystalline solid that was isolated by filtration and dried in vacuo. Yield 72 mg, 65 %. $C_{25}H_{31}Cl_2IrNP$ (639.6): calcd. C 46.95, H 4.89, N 2.19; found C 47.07, H 4.85, N 2.13. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.5 ppm. ^1H

NMR ($CDCl_3$): δ = 7.3 (m, 10 H, aromatic), 5.6 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2), 3.2 (br. s, 1 H, NH), 1.3 (s, 15 H, CH_3) ppm. FAB$^+$ MS: m/z = 604 [M – Cl]$^+$, 568 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$ = 3058, 1640, 994, 291, 280 cm^{-1}.

[$PdCl_2${$Ph_2PNH(C_3H_5)$}] (14): $Ph_2PNH(C_3H_5)$ (52 mg, 0.2 mmol) in CH_2Cl_2 (5 mL) was added dropwise to CH_2Cl_2 (5 mL) solution of [$PdCl_2$(cod)] (53 mg, 0.2 mmol). After stirring for 30 min, the solvent was reduced in vacuo to 0.5 mL before precipitating a yellow microcrystalline solid upon addition of hexane (10 mL) and isolation by suction filtration. Yield 65 mg, 83 %. $C_{15}H_{16}PNPdCl_2$ (418.6): calcd. C 43.04, H 3.85, N 3.35; found C 43.95, H 4.26, N 2.70. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 93.6 ppm. ^1H NMR (CD_2Cl_2): δ = 7.35 (m, 10 H, aromatic), 5.6 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2) and 4.1 (br. s, 1 H, NH) ppm. FAB$^+$ MS: m/z = 382 [M – Cl]$^+$, 347 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$ = 3054, 996, 318, 281 cm^{-1}.

[$PtCl_2${$Ph_2PNH(C_3H_5)$}] (15): $Ph_2PNH(C_3H_5)$ (43 mg, 0.2 mmol) in CH_2Cl_2 (5 mL) was added dropwise to a CH_2Cl_2 (5 mL) solution of [$PtCl_2$(cod)] (58 mg, 0.2 mmol) over 2.5 h. The solvent was reduced to 1 mL before addition of hexane (10 mL) to yield an off-white sticky solid on reduction of solvent. The sticky solid was subsequently dissolved in CH_2Cl_2 (0.5 mL) before addition of petroleum ether (40–60°C) (10 mL) to yield a colourless solid that was isolated by suction filtration. Yield 51 mg, 65 %. $C_{15}H_{16}Cl_2NPPt$ (507.2): calcd. C 35.52, H 3.18, N 2.76; found C 36.53, H 2.99, N 2.60. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 63.5 ppm [$^1J(^{31}P\text{-}^{195}Pt)$ = 3481 Hz]. ^1H NMR (CD_2Cl_2): δ = 7.35 (m, 10 H, aromatic), 5.5 (m, 1 H, CH), 5.2 (m, 1 H, CH_2), 5.1 (m, 1 H, CH_2), 3.5 (m, 2 H, NCH_2) and 4.1 (br. d, J = 8 Hz, 1 H, NH) ppm. FAB$^+$ MS: m/z = 472 [M – Cl]$^+$, 436 [M – 2 Cl]$^{2+}$. IR (KBr disc): $\tilde{\nu}$ = 3055, 998, 328, 289 cm^{-1}.

[Pt{$Ph_2PNH(C_4H_8O)$}$_2$] (16): To a CH_3OH (10 mL suspension of [$PtCl_2${$Ph_2PNH(C_3H_5)$}$_2$] (100 mg, 0.1 mmol) was added potassium *tert*-butoxide (30 mg, 0.2 mmol) with stirring to yield a colourless precipitate after 1 h. This microcrystalline solid was subsequently isolated by suction filtration and dried in vacuo. Yield 46 mg, 51 %. $C_{32}H_{38}N_2O_2P_2Pt$ (739.7): calcd. C 51.96, H 5.18, N 3.79; found C 52.06, H 4.60, N 3.70. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 91.4 ppm [$^1J(^{31}P\text{-}^{195}Pt)$ = 2294 Hz]. ^1H NMR ($CDCl_3$): δ = 7.4 (m, 20 H, aromatic), 5.9 (m, 2 H, CH), 5.2 (m, 2 H, CH_2), 5.1 (m, 2 H, CH_2), 3.6 (m, 4 H, NCH_2), 2.5 (br. s, 2 H, NH), 1.5 (s, 6 H, MeO) ppm. FAB$^+$ MS: m/z = 740 [M]$^+$. IR (KBr disc): $\tilde{\nu}$ = 3069, 3045, 2873–2809 (m), 997 cm^{-1}.

X-ray Crystallography: X-ray diffraction studies were performed using a Bruker SMART diffractometer with graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods, non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms bound to carbon atoms were idealised, the NH protons were located by a ΔF map. Structural refinements were made by the full-matrix least-squares method on F^2 using SHELXTL.[20] Details are given in Table 7. Full lists of structure refinement data, atomic coordinates, bond lengths and angles, anisotropic displacement parameters and hydrogen atom parameters have been deposited as supplementary material, CCDC-239884 to –239889 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The Reactions of Elemental Iron with Dipicolinic Acid (H_2dipic) and Quinaldic Acid (Hquin) – X-ray Crystal Structures of $[C_5H_5NH][Fe(Dipic)(Hdipic)(C_5H_5N)_2]\cdot 3C_5H_5N$, $[Fe_2(\mu\text{-}O)(Dipic)_2(C_5H_5N)_4]\cdot 2C_5H_5N\cdot 2H_2O$ and *trans*-$[Fe(Quin)_2(MeOH)_2]$

Sneh L. Jain,[a] Alexandra M. Z. Slawin,[a] J. Derek Woollins,*[a] and Pravat Bhattacharyya[a]

Keywords: Iron / Dipicolinic acid / Carboxylates / Quinaldic acid / Gif chemistry

Iron powder reacts with dipicolinic acid (H_2dipic) in pyridine at 110 °C to give the heptacoordinate iron(II) complex $[C_5H_5NH][Fe(dipic)(Hdipic)(C_5H_5N)_2]$; the $(Hdipic)^-$ ligand binds to the metal centre *solely* through the oxygen atoms of one carboxylate group, the first example of this coordination mode at iron. Upon dissolution in pyridine under aerobic conditions this complex transforms into the oxo-bridged di-iron(III) species $[Fe_2(\mu\text{-}O)(dipic)_2(C_5H_5N)_4]$, which possesses a linear Fe–O–Fe axis. Quinaldic acid (Hquin) reacts with iron powder in pyridine at 110 °C to give $[Fe(quin)_2(C_5H_5N)_2]$, analogous to the corresponding reactivity of picolinic acid. This complex is converted into *trans*-$[Fe(quin)_2(MeOH)_2]$ or $[Fe_2(\mu\text{-}O)(quin)_4(dmf)_2]$ in methanol or DMF respectively. The formation of an iron(II) complex in the reaction with methanol differs markedly from the picolinate system.

Introduction

Picolinic acid (Hpic) is a highly efficient promoter of Gif-type catalytic oxygenation of methylene groups in cycloalkane substrates using iron complexes ($GoAgg^{III}$ conditions).[1] The active catalyst in $GoAgg^{III}$ is proposed to be an iron-hydroperoxy complex, although the processes involved in the construction of this species are poorly understood. Stavropoulos[2] has reported that iron powder reacted with Hpic at room temperature to give polymeric $[Fe(pic)_2]_n$ (in dichloromethane) or $[Fe(pic)_2(C_5H_5N)_2]$ (in pyridine), from which an array of mono- and bimetallic systems was readily generated by treatment with coordinating solvents (DMF, methanol, water) and/or aerobic oxidation. The catalytic oxygenation profiles of adamantane using these picolinate complexes lend valuable support to the radical-based mechanism believed to operate in Gif chemistry. Also, Shova et al. have reported that the reaction of iron powder with Hpic in water leads to $[Fe(pic)_2(H_2O)_2]$.[3]

The richness of the iron(0)-Hpic system prompted us to investigate the behaviour of dipicolinic and quinaldic acids (H_2dipic and Hquin respectively) with elemental iron. Ferrous and ferric complexes with dipicolinate[4–14] and quinaldinate[15–21] ligands have hitherto been prepared from iron salts, however the use of iron in elemental form as a substrate with the parent acids has not been explored. There is precedent for the use of iron-dipicolinate complexes as $GoAgg^{III}$ oxygenation catalysts,[12] although doubts were later cast on the validity of these results,[10] since these complexes have a tendency to interconvert in solution. Access to a range of structurally and spectroscopically characterised iron derivatives containing dipicolinate and quinaldinate ligands is thus eminently desirable in order to evaluate their catalytic potential.

Results and Discussion

Dipicolinate Complexes

Initial attempts at the iron(0)-H_2dipic reaction in dichloromethane, both at room temperature and under reflux, showed no visual evidence for any reaction, as the supernatant solution remained colourless throughout, with insoluble H_2dipic and iron powder present c.f. Hpic reacts at room temperature with Fe^0 to give $[Fe(pic)_2]_n$ in 63 % yield after four days.[2] The use of pyridine as the reaction solvent proved to be more profitable.

Refluxing a mixture of H_2dipic and iron powder (molar ratio 2:1) in pyridine for 5 h under argon produces a deep red solution from which unreacted iron is removed by anaerobic filtration whilst hot. Upon cooling the filtrate to –20 °C for 24 h a red crystalline solid is deposited. The molecular structure of the complex was determined crystallographically to be $[C_5H_5NH][Fe(dipic)(Hdipic)(C_5H_5N)_2]\cdot$

$3C_5H_5N$ (**1**·$3C_5H_5N$, Figure 1) in which dipic^{2-} is coordinated in tridentate fashion to Fe(1) via the N(1), O(7) and O(8) atoms, while (Hdipic)$^-$ is bound via O(16) and O(17) of one carboxylate group to give a four-membered metallacycle with the N(11), O(18) and O(19) atoms oriented away from Fe(1). **1** is the first iron complex in which the 2,6 isomer of (Hdipic)$^-$ is solely *O*,*O*′-bidentate through one carboxylate group. Fe(1) has a pentagonal bipyramidal geometry, with equatorial [NO_4] donor atoms being supplied by dipicolinate ligands and axial pyridines completing the coordination sphere. By analogy with Stavropoulos' iron(0)-Hpic system[2] and our own rigorous exclusion of dioxygen and moisture during the reaction, we assign a +2 oxidation state to the iron centre. Magnetic susceptibility measurements of powdered samples reveal $\mu_{eff} \approx 4.7$ B.M at room temperature, confirming a high-spin iron(II) species. The ^{1}H NMR spectrum of **1** in [D_5]pyridine at room temperature comprises broad singlets at $\delta_H = 75.5$, 52.7 and 4.7 ppm. The bond lengths and angles in **1** concur with other (dipicolinato)iron complexes,[8–11,13] with O(16)–Fe(1)–O(17) 58.11(7)°, the Fe(1)–O lengths span the range 2.1614(19)–2.2905(19) Å. The pyridinium counterion and one of the solvate pyridine molecules hydrogen-bond to the iron complex [H(51)···O(8) 1.81(2) Å, N(51)···O(8) 2.737(3) Å, N(51)–H(51)···O(8) 156(4)°; H(19)···N(41) 1.62(1) Å, O(19)···N(41) 2.598(4) Å, O(19)–H(19)···N(41) 177(4)°]. This interaction between O(8) and the pyridinium cation lengthens Fe(1)–O(8) by ca. 0.04 Å compared to Fe(1)–O(7).

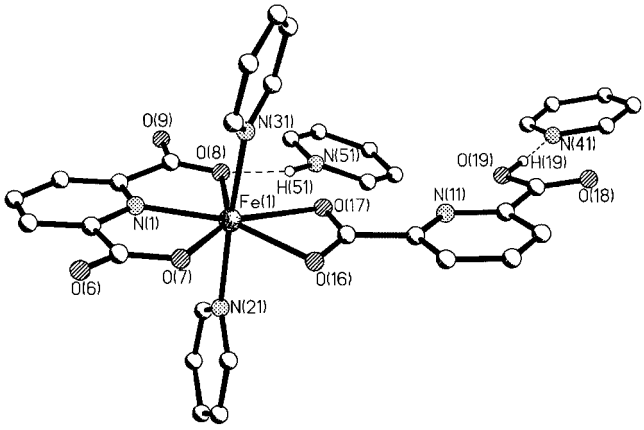

Figure 1. Molecular structure of **1**·$3C_5H_5N$ (hydrogen atoms and non-H bonded solvate molecules omitted for clarity); selected bond lengths (Å) and angles (°): Fe(1)–N(1) 2.133(2), Fe(1)–O(7) 2.1614(19), Fe(1)–O(8) 2.2095(18), Fe(1)–N(31) 2.218(2), Fe(1)–N(21) 2.234(2), Fe(1)–O(17) 2.246(2), Fe(1)–O(16) 2.2905(19), N(1)–Fe(1)–O(7) 73.49(8), N(1)–Fe(1)–O(8) 72.36(8), O(7)–Fe(1)–O(8) 145.71(7), N(1)–Fe(1)–N(31) 95.14(8), O(7)–Fe(1)–N(31) 90.12(8), O(8)–Fe(1)–N(31) 90.00(8), N(1)–Fe(1)–N(21) 88.21(8), O(7)–Fe(1)–N(21) 90.04(8), O(8)–Fe(1)–N(21) 91.80(8), N(31)–Fe(1)–N(21) 176.55(9), N(1)–Fe(1)–O(17) 147.06(8), O(7)–Fe(1)–O(17) 139.39(7), O(8)–Fe(1)–O(17) 74.71(7), N(31)–Fe(1)–O(17) 84.92(8), N(21)–Fe(1)–O(17) 92.72(8), N(1)–Fe(1)–O(16) 154.74(8), O(7)–Fe(1)–O(16) 81.54(7), O(8)–Fe(1)–O(16) 132.74(7), N(31)–Fe(1)–O(16) 88.50(8), N(21)–Fe(1)–O(16) 88.12(8), O(17)–Fe(1)–O(16) 58.11(7)

Compound **1** is stable for prolonged periods in the solid state under an inert atmosphere. The pyridine solvate molecules are lost upon removal of crystals from the mother liquor, thermogravimetric analysis shows that at 118 °C a sample of the freshly crystallised complex loses 27.8 % of its mass, c.f. for **1**·$3C_5H_5N$ the solvent of crystallisation constitutes 27.5 % by mass. The FAB$^+$ mass spectrum contains a peak at *m*/*z* = 388 corresponding to [Fe(dipic)]$^+$, peaks at higher *m*/*z* ratios could not be assigned.

Following dissolution of **1** in wet pyridine under aerobic conditions, [$C_5H_5NH]_2$[dipic] (^{1}H NMR and infra-red spectroscopic evidence) is precipitated. Upon filtration and standing in air overnight, deep red crystals deposit from the filtrate. X-ray crystallography reveals the product to be the diiron(III) complex [Fe_2(μ-O)(dipic)$_2$($C_5H_5N)_4$] (**2**) (Figure 2) in which dipic^{2-} is tridentate at Fe(1) via the N(7), O(11) and O(11B) atoms with N(7) *trans* to the μ-oxo atom O(1); the complex co-crystallises with molecules of pyridine and water. The octahedral coordination at Fe(1) is completed by pyridine ligands bound axially through N(1) and N(1B). The oxo atom O(1) lies on an crystallographic inversion centre, hence the Fe(1)–O(1)–Fe(1A) axis is 180°. The acute bite angle of dipic^{2-} distorts the geometry at Fe(1), thus O(11)–Fe(1)–O(11B) and O(1)–Fe(1)–O(11) are 150.67(18)° and 104.67(9)°, respectively. The shortness of Fe(1)–O(1) [1.7808(8) Å] compared to Fe(1)–O(11) [2.048(3) Å] suggests significant π-bonding within the Fe(1)–O(1) linkage. The *trans* influence of O(1) lengthens Fe(1)–N(7) [2.106(6) Å] compared with [Fe(dipic)$_2$]$^-$ species [2.037(3)–2.076(3) Å],[8,9,22] Fe(1)–O(11) [2.048(3) Å] being marginally longer than in the homoleptic complexes [2.001(2)–2.035(2) Å]. The Fe(1)–N(1) bonds [2.218(5) Å] are identical in length to **1** [2.218(2), 2.234(2) Å]. The solv-

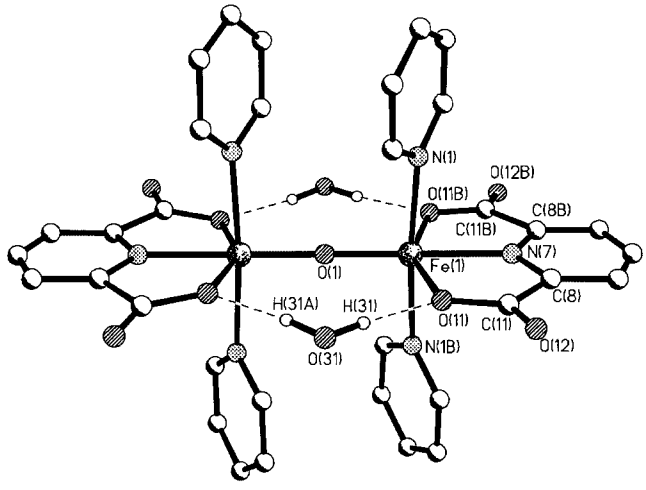

Figure 2. Molecular structure of **2**·$2C_5H_5N$·$2H_2O$ (C–H bonds and pyridine solvate molecules omitted for clarity); selected bond lengths (Å) and angles (°): Fe(1)–O(1) 1.7808(8), Fe(1)–O(11) 2.048(3), Fe(1)–N(7) 2.106(6), Fe(1)–N(1) 2.218(5), O(10)–Fe(1)–O(11) 104.67(9), O(11)–Fe(1)–O(11B) 150.67(18), O(1)–Fe(1)–N(7) 180.0, O(11)–Fe(1)–N(7) 75.33(9), O(11)–Fe(1)–N(1) 87.72(12), N(7)–Fe(1)–N(1) 87.45(10), O(1)–Fe(1)–N(1) 92.55(10), O(11B)–Fe(1)–N(1) 90.99(12), N(7)–Fe(1)–N(1) 87.45(10), N(1B)–Fe(1)–N(1) 174.9(2), Fe(1)–O(1)–Fe(1A) 180.0

ate water molecule hydrogen bonds to the dipicolinate [H(31)···O(11) 1.895(11) Å, O(31)···O(11) 2.868(5) Å, O(31)–H(31)···O(11) 172(5)°], O(31) being essentially coplanar with this ligand. There are no other significant intermolecular contacts. In its infra-red spectrum, the band for the asymmetric ν_{FeOFe} stretch appears at 862 cm^{-1}.

Upon storage in a sample vial for several days the deep red crystals of **2** transform into a pale brown solid with the release of pyridine vapour (olfactory evidence). Microanalysis suggested the stoichiometry $[Fe_2O(dipic)_2(H_2O)_4]$ i. e. the pyridine ligands and solvate molecules are lost upon removal from contact with the mother liquor. We propose that the μ-oxo bridge is retained during this process and that the new aqua complex is isostructural with $[Fe_2(\mu\text{-}O)(4\text{-}Cl\text{-}dipic)_2(H_2O)_4]$ (4-Cl-dipic = 4-chlorodipicolinate, Figure 3), which is accessible from iron(III) chloride hexahydrate, the diethyl ester of 4-Cl-dipicH_2 and urea.[5] Pyridine loss is suppressed when **2** is stored in a sample vial housed within a larger one containing a small volume of this solvent. The lability of the pyridine ligands in **2** suggests that this compound may be a useful synthon for new complexes with the $Fe_2(\mu\text{-}O)(dipic)_2$ subunit.

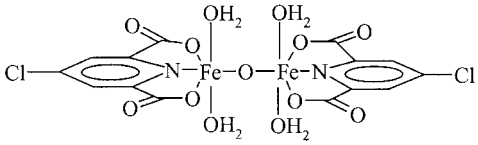

Figure 3. The structure of $[Fe_2(\mu\text{-}O)(4\text{-}Cl\text{-}dipic)_2(H_2O)_4]$;[5] complex $[Fe_2(\mu\text{-}O)(dipic)_2(H_2O)_4]$ is proposed to be isostructural

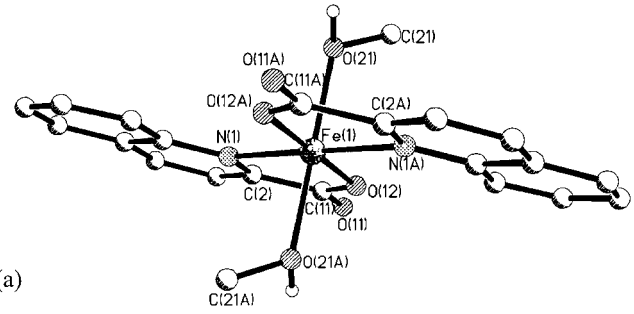
Quinaldinate Complexes

The reaction of Hquin with elemental iron has not been reported elsewhere. We have found that Hquin reacts with iron powder (molar ratio 2:1) under identical conditions to those used to synthesise **1** to give $[Fe(quin)_2(C_5H_5N)_2]$ (**3**). The ν_{COO} bands in **3** (1652, 1361 cm^{-1}) are comparable to $[Fe(pic)_2(C_5H_5N)_2]$ (1645, 1348 cm^{-1}),[2] microanalytical data confirms the proposed stoichiometry although the FAB^+ mass spectrum contains no peaks which are assignable to a molecular ion or daughter fragments. Compound **3** is air- and moisture-stable in the solid state under ambient conditions. We have been unable to obtain crystals suitable for X-ray crystallographic analysis in order to establish its geometry. As with **1**, there is paramagnetic shifting of the signals in the ^1H NMR spectrum.

Complex **3** is more stable towards methanol under aerobic conditions than its picolinate counterpart. Whereas $[Fe(pic)_2(C_5H_5N)_2]$ reacts with methanol at room temperature to give a diiron(III) complex $[Fe_2(\mu\text{-}OMe)_2(pic)_4]$,[23] refluxing a methanolic suspension of **3** for four days is sufficient only to displace the coordinated pyridine ligands and generate the iron(II) species $[Fe(quin)_2(MeOH)_2]$ (**4**). The sluggishness of this reaction reflects the greater steric bulk of quinaldinate compared with picolinate and, possibly, that **3** is polymeric. The directing influence of the pyridine ligands on the course of the picolinate reactions is crucial, as under anaerobic conditions $[Fe(pic)_2]_n$ reacts at room temperature with methanol to give $[Fe(pic)_2(MeOH)_2]$.[2]

Crystals of **4** suitable for X-ray analysis were deposited from the reaction mixture. The molecular structure (Figure 4) reveals a centrosymmetric geometry at the iron centre, with an FeN_2O_4 core comprising methanol ligands in axial positions and *N,O*-chelating quinaldinate anions with a *trans*-arrangement in the equatorial plane. The geometric parameters of **4** and the formation of one-dimensional hydrogen-bonded chains between carbonyl oxygen atoms and methanol ligands in adjacent molecules [H(21O)···O(11′) 1.650(6) Å, O(21)···O(11′) 2.621(1) Å, O(21)-H(21O)··· O(11′) 170(3)°] correspond with the diaqua, diethanol and di(*n*-propanol) analogues, as well as $[Fe(pic)_2(MeOH)_2]$.[2,17,18,21] Additionally, there are only very modest dimensional differences between **1, 2** and **4**. In the infra-red spectrum ν_{OH} appears at 3180 cm^{-1} and ν_{COO} at 1635 and 1387 cm^{-1}. Complex **4** is stable towards moisture and oxidation over several months in the solid state.



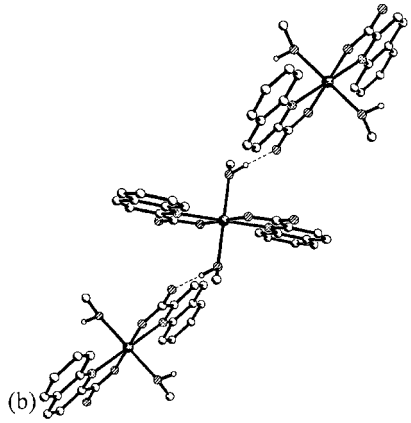


Figure 4. (a) Molecular structure of **4** (C–H bonds omitted for clarity); selected bond lengths (Å) and angles (°): Fe(1)–O(12) 2.0534(14), Fe(1)–O(21) 2.1624(14), Fe(1)–N(1) 2.2571(17), O(21)–C(21) 1.439(2), O(12)–Fe(1)–N(1) 76.39(6), N(1A)–Fe(1)–N(1) 180.0, O(21A)–Fe(1)–N(1) 88.98(6), O(21)–Fe(1)–N(1) 91.02(6), O(21A)–Fe(1)–O(21) 180.0, O(12A)–Fe(1)–O(12) 180.00(3), O(12)–Fe(1)–O(21) 91.48(5), O(12)–Fe(1)–N(1A) 103.61(6), O(12)–Fe(1)–O(21A) 88.52(5); (b) hydrogen-bonding networks in **4**

O)(quin)$_4$(dmf)$_2$] (**5**). This conversion mirrors the behaviour of [Fe(pic)$_2$(C$_5$H$_5$N)$_2$] towards dmf, which affords [Fe$_2$(μ-O)(pic)$_4$(dmf)$_2$].[2] The asymmetric ν_{FeOFe} and ν_{COO} vibrations in **5** (882, 1676, 1315 cm^{-1}) differ by 15–30 cm^{-1} from the picolinate complex (867, 1653, 1344 cm^{-1}). The insolubility of this complex in organic solvents prevented acquisition of ^{1}H NMR and mass spectra.

Although Hquin and Hpic behave in a similar fashion towards iron powder, there is a significant difference towards iron(III) salts. Whereas Hpic gives [Fe(pic)$_3$],[2] the corresponding reaction with Hquin in methanol at room temperature gives the binuclear complex [Fe$_2$(μ-OH)$_2$(quin)$_4$] (**6**).[15,20] Presumably steric constraints preclude tris(chelation) of quin$^-$ at an iron(III) centre, since [M(quin)$_3$] complexes exist for bismuth(III) and lanthanide(III) ions.[24,25]

Summary

The reaction of H$_2$dipic with iron powder in pyridine affords [C$_5$H$_5$NH][Fe(dipic)(Hdipic)(C$_5$H$_5$N)$_2$], in which the deprotonated acid exhibits two different coordination modes. In wet pyridine this complex converts into the oxo-bridged diiron(III) species [Fe$_2$(μ-O)(dipic)$_2$(C$_5$H$_5$N)$_4$] whose coordinated solvent molecules are susceptible to displacement by atmospheric water in the solid state. Hquin reacts with iron powder to give [Fe(quin)$_2$(C$_5$H$_5$N)$_2$], whose pyridine ligands are displaced under forcing conditions by methanol or at room temperature by dmf, affording *trans*-[Fe(quin)$_2$(MeOH)$_2$] and [Fe$_2$(μ-O)(quin)$_4$(dmf)$_2$] respectively.

The detailed investigation of (dipicolinato)iron complexes in aqueous media by Gourdon et al. demonstrates that several structural motifs can be readily derived.[4,7,10,11] The chemistry of (Hdipic)$^-$ and dipic^{2-} is enriched by the capacity of the carbonyl oxygens of the carboxylate groups to bind to adjacent metal centres, generating polynuclear structures.[27–30] A recent example illustrates that the carboxylate oxygen atom can also engage in hydrogen-bonding interactions with coordinated water molecules to form supramolecular networks.[31] That (Hdipic)$^-$ binds to iron(II) in **1** without the formation of a polymeric structure via the pendant carboxylate group is unusual, instances of this *O*,*O*′ mode at europium(III) and silver(I) generate infinite chains wherein both of the acid groups link metal ions.[32,33] 2,6-H$_2$dipic is the sole positional isomer of this ligand for whom geometric constraints do not preclude *N*,*O*,*O*′ chelation to a single metal centre. Studies using other isomers where such tridentate chelation is prohibited by the disposition of the acid groups lead to coordination polymers.[34–37] Investigations into how these other diacids react with elemental iron are currently underway in our laboratory.

The lability of the coordinated solvent molecules in **1**–**3** suggests that these complexes could be valuable precursors to new mono- and polyiron dipic/quin species, which will benefit investigations into Gif chemistry. The facility of the reactions of H$_2$dipic and Hquin with elemental iron also indicates that reactions of these acids with other electropositive metals will undoubtedly deliver complexes with new structural motifs.

Experimental Section

Materials and Instrumentation: Syntheses and work-up procedures were conducted under argon or oxygen-free dinitrogen using Schlenk line techniques, unless stated otherwise. Pyridine was distilled from calcium hydride, all other solvents and reagents were used as supplied. Infra-red spectra were recorded as pressed KBr discs with Perkin–Elmer System 2000 and Nicolet Nexus FTIR/Raman spectrometers, microanalyses were carried out by the University of St. Andrews and UMIST Microanalytical Services. FAB mass spectra (positive ionisation mode, 3-nitrobenzyl alcohol matrix) were recorded by the EPSRC National Mass Spectrometry Service (Swansea), ^{1}H NMR spectra (200.0 MHz) were recorded with a Bruker DPX 200 spectrometer.

Synthesis of Complexes 1–6

[C$_5$H$_5$NH][Fe(dipic)(Hdipic)(C$_5$H$_5$N)$_2$] (1): Iron powder (320 mg, 5.7 mmol) and H$_2$dipic (1.80 g, 10.8 mmol) were heated in pyridine (50 cm^3) at 110 °C under argon for 5 h. The red solution was filtered anaerobically while hot to remove unreacted iron, and the filtrate was cooled to –20 °C overnight. Red crystals of **1**·3C$_5$H$_5$N suitable for X-ray analysis were collected by filtration under argon, concentration of the filtrate in vacuo gave a second crop of complex. Yield 2.29 g (74 %). C$_{24}$H$_{17}$FeN$_4$O$_8$ (545.2): calcd. C 52.87, H 3.14, N 10.28; found C 52.24, H 3.19, N 9.85. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 3435 s (ν_{OH}), 1673 s, 1648 s, 1368 s, 1350 s (ν_{COO}). MS: *m*/*z* = 388 [Fe(dipic)]$^+$. ^{1}H NMR ([D$_5$]pyridine): δ = 75.5 (br), 52.7 (br), 4.7 (br) ppm.

[Fe$_2$(μ-O)(dipic)$_2$(C$_5$H$_5$N)$_4$] (2): Under aerobic conditions **1** (200 mg) was dissolved in pyridine (10 cm^3) with sonication, giving a red solution with a colourless precipitate of [C$_5$H$_5$NH]$_2$[dipic]. The solution was filtered and the filtrate left open to air for 12 h, after which time deep red crystals of **2**.2C$_5$H$_5$N·2H$_2$O (118 mg) suitable for X-ray analysis had deposited. C$_{34}$H$_{26}$Fe$_2$N$_6$O$_9$ (774.2): calcd. C 52.7, H 3.4, N 10.9; found C 52.1, H 2.9, N 10.4. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 1674 s, 1367 m (ν_{COO}), 862 m ($\nu_{FeOFe(asym)}$). Crystalline **2** changed colour from dark red to beige with the release of pyridine over four days at room temperature upon storage in a sample vial. Microanalysis suggested conversion to [Fe$_2$(μ-O)(dipic)$_2$(H$_2$O)$_4$]. C$_{14}$H$_{14}$Fe$_2$N$_2$O$_{13}$ (529.9): calcd. C 31.73, H 2.66, N 5.28; found C 31.91, H 2.43, N 5.24. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 3462 s, 2923 s (ν_{OH}), 1656 s, 1626 s, 1379 s, 1366 s (ν_{COO}), 924 m ($\nu_{FeOFe(asym)}$).

[Fe(quin)$_2$(C$_5$H$_5$N)$_2$] (3): Iron powder (75 mg, 1.35 mmol) and Hquin (352 mg, 2.03 mmol) were heated in pyridine (40 cm^3) at 110 °C for 3.5 h under argon. Unreacted iron powder was filtered off anaerobically whilst hot, **3** precipitated as a purple solid from the filtrate upon cooling to room temperature and was collected by filtration under argon. Yield 370 mg (49 %). C$_{30}$H$_{22}$FeN$_4$O$_4$ (558.3): calcd. C 64.53, H 3.97, N 10.03; found C 63.92, H 3.99, N 9.80. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 1652 s, 1361 m (ν_{COO}). ^{1}H NMR (CDCl$_3$): δ = 42.0 (br), 37.9 (br), 32.6 (br), 30.8 (br), 29.5 (br), 28.6 (br), 26.3 (br), 25.4 (br), 13.0 (br), 10.4 (br) ppm.

***trans*-[Fe(quin)$_2$(MeOH)$_2$] (4):** Under aerobic conditions a suspension of **3** (140 mg, 0.25 mmol) in methanol (20 cm^3) was heated at reflux for four days. The resulting brown microcrystalline solid was filtered off and washed with diethyl ether. Yield 89 mg (76 %).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Crystals amenable to X-ray crystallographic analysis were obtained directly from the reaction. $C_{22}H_{20}FeN_2O_6$ (464.2): calcd. C 56.9, H 4.0, N 6.0; found C 56.0, H 4.4, N 6.1. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 3180 s (ν_{OH}), 1635 s, 1387 s (ν_{COO}). ^1H NMR ([D_7]DMF): δ = 34.1 (br), 32.1 (br), 12.0 (br), 4.4 (br), 2.3 (br) ppm.

[Fe_2(μ -O)(quin)$_4$(dmf)$_2$] (5): Under aerobic conditions a solution of **3** (84 mg, 0.15 mmol) in DMF (5 cm^3) was vapour-diffused with diethyl ether. After three days golden-brown needles of **5** were deposited. Yield 51 mg (67 %). $C_{50}H_{38}Fe_2N_6O_{11}$ (1010.5): calcd. C 59.4, H 3.8, N 8.3; found C 59.2, H 3.6, N 8.4. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 1676 s, 1315 m (ν_{COO}), 882 m ($\nu_{FeOFe(asym)}$).

[Fe_2(μ -OH)$_2$(quin)$_4$] (6): Under aerobic conditions, Hquin (256 mg, 1.45 mmol) was added to iron(III) nitrate nonahydrate (194 mg, 0.48 mmol) in methanol (10 cm^3), giving a yellow solution. Addition of diethyl ether precipitated **6** as a yellow solid. Yield 295 mg (80 %). $C_{40}H_{26}Fe_2N_4O_{10}\cdot 2H_2O$ (870.3): calcd. C 55.20, H 3.47, N 6.44; found C 55.71, H 3.03, N 6.37. Selected IR bands (cm^{-1}): $\tilde{\nu}$ = 3456 m (ν_{OH}), 1663 s, 1372 s (ν_{COO}). MS: m/z = 802 $[Fe_2(quin)_4]^+$.

X-ray Crystallography: Diffraction studies on **1**·3C_5H_5N and **2**·2C_5H_5N·2H_2O were performed using a Bruker SMART-CCD diffractometer, for **4** a Rigaku MM007/Saturn was used, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) in each case. All data were corrected for Lorentz polarisation and long-term intensity fluctuations. The structures were solved by direct methods, non-hydrogen atoms were refined with anisotropic displacement parameters, all hydrogen atom positions were idealised. In **2** ·2C_5H_5N·2H_2O the disordered pyridine solvate molecules were refined with all of the ring atoms as carbons and the hydrogen atoms distributed over all of the possible sites. Structural refinements were by the full-matrix least-squares method on F^2 using the program SHELXTL-PC.[26] CCDC-225950 (for **2**), -225951 (for **1**) and -248948 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

1·3C_5H_5N: $C_{44}H_{38}FeN_8O_8$, T = 125(2) K, M = 862.67, monoclinic, space group $P2_1/n$, a = 9.5494(11) Å, b = 20.107(2) Å, c = 21.744(3) Å, β = 98.873(2)°, V = 4124.0 $Å^3$, Z = 4, D_c = 1.389 Mg·m^{-3}, μ = 0.430 mm^{-1}, F_{000} = 1792. Green Light Luminescence from ZnO/Dodecylamine Mesolamellar Nanocomposites Synthesized by Self-Assembly

Yu-de Wang,*[a] Shuo Zhang,[a] and Xing-hui Wu[a]

Keywords: Mesoporous materials / Nanocomposites / Luminescence / Interfacial interactions

The synthesis, structural characterization and optical properties of a semiconducting zinc oxide based dodecylamine surfactant, mesolamellar zinc oxide/surfactant nanocomposite (Zn-L) are described. XRD and TEM results showed the formation of a lamellar mesostructure with two layer spacings ca. 28 Å. A red-shift in the absorption band edge of absorption spectrum and the green light photoluminescence of the resulted nanocomposite were observed at room temperature. The red-shift of the absorption band edge and the room temperature photoluminescence (RTPL) of the Zn-L nanocomposite might be induced by the dielectric confinement effect and the interfacial interaction between the ZnO and the surfactant, respectively.

Introduction

Recent developments in the synthesis of self-assembled inorganic/organic surfactant composites have opened up a new field in the study of composite materials.[1] Lamellar inorganic species/surfactant composite consist of surfactant layers, alternating with inorganic layers. When the inorganic layers are semiconducting materials, a novel nanostructured semiconductor–surfactant superlattice may result with, possibly,novel properties.[2] A novel chemical synthetic approach based on self-assembly between inorganic species and surfactant has been presented for inorganic species and organic surfactant into two- and three-dimensional superlattice structures,[3,4] and has been successfully extended to numerous ordered inorganic–organic composites with nanometer scale periodicities.[2,5] To date, a series of semiconductor lamellar mesophase in which a semiconductor oxide is sandwiched between organic components has been successfully synthesized.[6–8] Zinc oxide is a promising luminescent material with a wide bandgap (3.37 eV), large exciton binding energy (60 meV) and is used for various applications such as vacuum fluorescent displays due to its nonlinear optical properties and room temperature ultraviolet emission.[9] As a large-bandgap semiconductor and luminescence material, nanostructured ZnO (nanoparticles, nanowires, nanobelts, and nanotuble) has been widely studied.[10–12] However, to the best of our knowledge, ZnO lamellar mesophase, relative to its room temperature photoluminescence, has rarely been mentioned. In this letter, we report the synthesis and room temperature photoluminescence of a mesolamellar zinc oxide/surfactant nanocomposite, the morphology of which appears to be distinctively different from those previously reported.

Results and Discussion

Powder XRD data clearly demonstrate the ordered lamellar mesostructure of the zinc oxide/surfactant composite (Figure 1): a series of equally spaced peaks appear in the low-angle region. Similar to lamellar silicate, aluminophosphate, and TiO_2 mesophase,[1,2] the peaks are attributed to the 00*l* rational reflections, characteristic of a lamellar structure. The first diffraction peak, assumed to be (001), corresponds to a *d*-spacing of about 28.5 Å. Reflections up to the 5th order of the (001) diffraction are observed. Besides the (00*l*) series, other diffraction peaks in the low-angle diffraction region are best assigned to positional ordering of the dodecylamine molecules within the bilayer. The fully extended dodecylamine bilayer can be estimated to be about 39 Å long. Crystalline dodecylamine displays a very similar XRD patter in this range.

The powder XRD pattern of the Zn-L composite clearly displays the characteristics of a well-ordered layered structure with evidence of registry between the sheets. The flaky morphology of Zn-L the composite, displayed in the SEM image, Figure 2(a), supports this proposal. The lamellar composite is further confirmed by a TEM study. Well-defined parallel lines [Figure 2(b)] confirm that the Zn-L composite is a lamellar structure[3] – consistent with the results of XRD. The inter-lamellar distance is 28 Å, in accordance with the *d*-spacing calculated from the first diffraction peak in the XRD pattern.

The FT-IR spectrum of the Zn-L composite shows a zinc–oxygen stretching band in the region 500–1000 cm^{-1}

 DOI: 10.1002/ejic.200400450 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

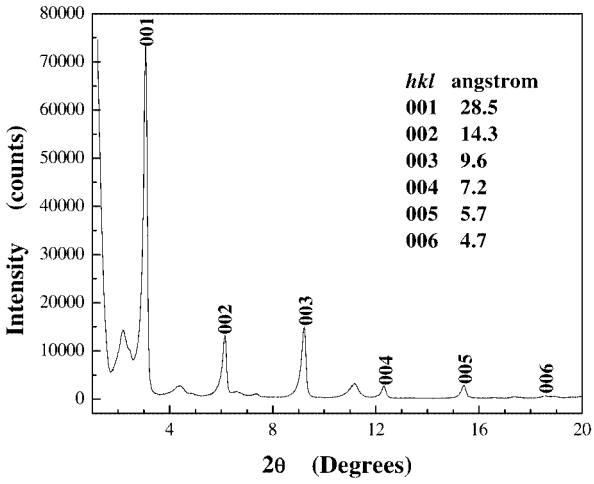

Figure 1. XRD pattern of as-synthesized Zn-L composite.

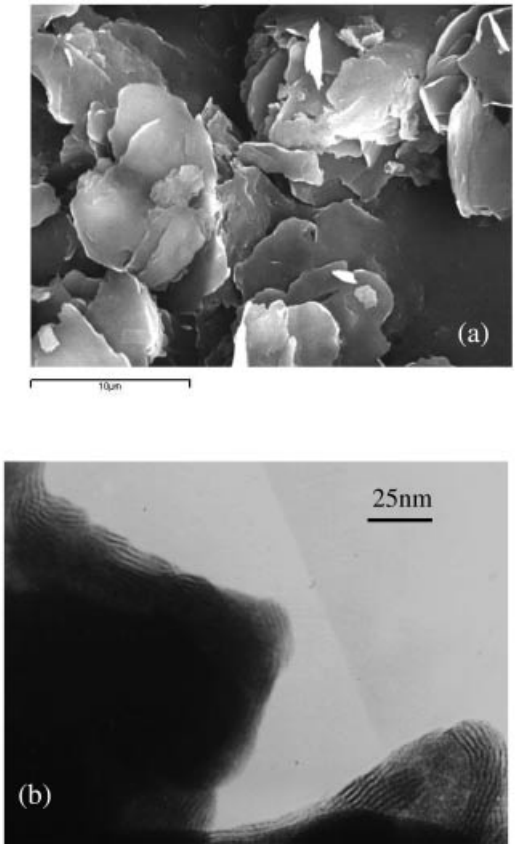

Figure 2. (a) Representative SEM image of Zn-L composite. (b) TEM image to the Zn-L composite showing the lamellar.

(Figure 3). Some bands in the region 3300–3500 cm^{-1} are due to N–H stretches of DDA, and sharp bands at 2853 and 2913 cm^{-1} are due to C–H stretches of the hydrocarbon chain of DDA. Sharp bands in the region 1370–1600 cm^{-1} are attributed to the deformation of $–CH_2–$ and $–CH_3$ of the incorporated DDA. The CH_2 stretching vibrations are considered to be related with the physical state (monomer, micelle or solid) of dodecylamine. These band vibrations indicate that the dodecylamine is present in the as-synthesized nickel oxide mesostructure. They provide evidence for the incorporation of dodecylamine into the hydrous oxide.[13] Figure 3 also reveals a C–N band at 1333 cm^{-1}, which is blue-shifted by 33 cm^{-1} compared with the spectrum of DDA (C–N at 1300 cm^{-1}). The affinity of Zn^{2+} ions to amine and imine ligands is well known. This allows us to assume chemical interaction between NHgroups of the DDA chains and surface Zn^{2+} ions of the Zn-L nanocomposites. It can be inferred that the formation of new surface states may results from chemical binding between the components of the neighbouring layers.

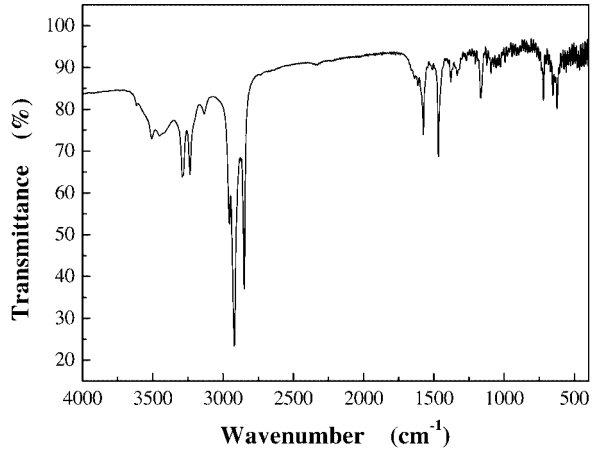

Figure 3. FTIR spectrum of Zn-L nanocomposite.

The two XPS spectrum peaks [Figure 4(a)], of $2p_{\frac{3}{2}}$ and $2p_{\frac{1}{2}}$ at 1022.9 eV and 1045.9 eV, with a better symmetry, are assigned to lattice zinc in zinc oxide. The peaks are 23.0 eV apart. The values correspond to a 2p3 binding energy of Zn^{II} ion (indexed Standard ESCA Spectra of the Elements and Line Energy Information, Φ Co., USA). The small shift in the $2p_{\frac{3}{2}}$ peak position from the crystalline ZnO to the mesolamellar structure ZnO, from 1021.7 eV (indexed Hand of X-ray photoelectron spectroscopy) to 1022.9 eV, indicates a change of microenvironments for zinc. This shift (1.2 eV) confirms that most Zn atoms remain in Zn-L nanocomposites, in the same formal valence state of Zn^{2+} within an oxygen deficient ZnO_{1-x} matrix.[14,15] This Zn enrichment or oxygen defects is due to the strong interaction between the dodecylamine and ZnO and to the weakly crystalline nature of the hydrous zinc oxide composite. Figure 4(b) shows that the O_{1s} XPS is asymmetric (the left-hand side is wider), indicating that there at least two kinds of oxygen species in the near surface region. The peak at about 531.6 eV is due to the ZnO crystal lattice oxygen, while that at about 533 eV is due to chemisorded oxygen.[16]

The lamellar mesostructured zinc oxide/surfactant composite displays interesting optical properties. UV/Vis spectroscopy was used to characterize the optical absorbance of the Zn-L nanocomposite. The absorption spectrum of Zn-L was carried out to resolve the excitonic or interband (valence-conduction band) transition of Zn-L, which allows us to calculate the bandgap. The absorption and corresponding bandgap energy of bulk ZnO is λ = 367 nm and E_g = 3.36 eV. The UV/Vis absorption spectrum of the as-synthe-

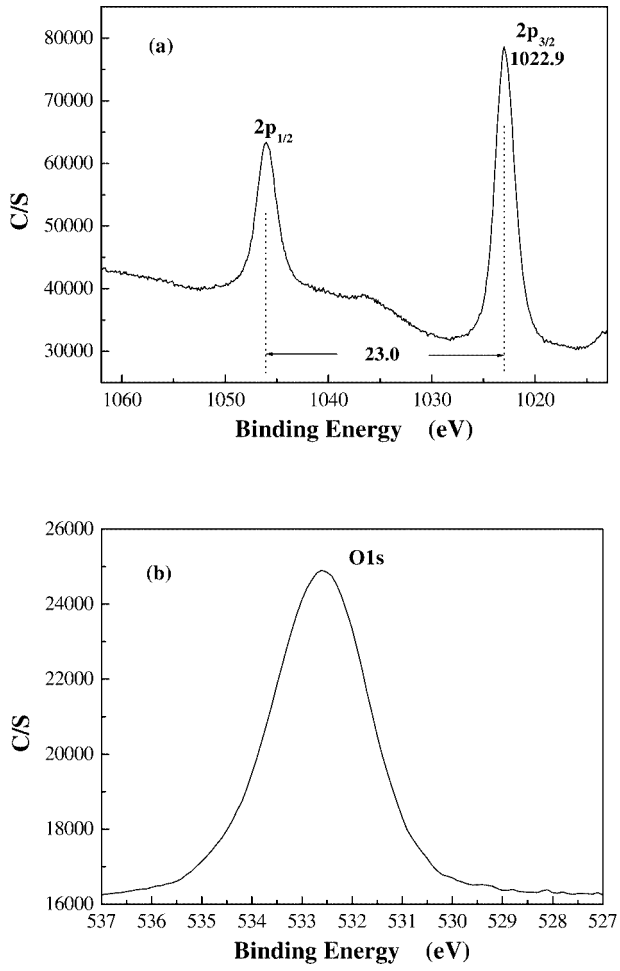

Figure 4. XPS spectra of ZnO/surfactant nanocomposites: (a) Zn2p and (b) O1s.

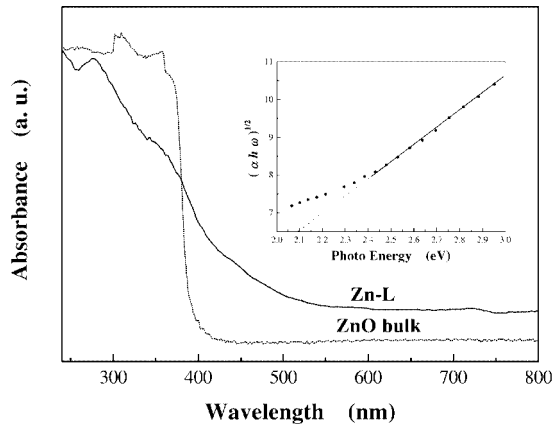

Figure 5. Absorption spectra of Zn-L composite and ZnO bulk. Inset: apparent energy gap of the Zn-L composite.

sized compositeshows a strong band edge absorption in the region above 370 nm (Figure 5). The absorption edge of Zn-L composite is red-shifted from the absorption edges of wurtzite ZnO dendrites (377 nm)[17] and bulk ZnO (367 nm). Absorption at longer wavelengths, the absorption red-shift, was also observed by Wang et al.[18] with sodium dodecylbenzenesulfonate (DBS) capped ZnO nanoparticles. The authors attributed this red-shift to intraband surface states formed by surfactant molecules chemically bound on the ZnO surface.

The absorption coefficient of an amorphous semiconductor has a characteristic relation:[19]

$$[d\hbar\omega]^{1/2} = A[\hbar\omega - E_g]$$

in which $\hbar\omega$ is the photon energy, E_g is the apparent optical bandgap, A is a constant characteristic of the amorphous semiconductor, and a is the absorption coefficient. Therefore, the E_g of zinc oxide/surfactant composite can be obtained by extrapolating the above relation to 2.09 eV (Figure 5 inset). A red-shift of ca. 1.27 eV relative to bulk ZnO is evident for the zinc oxide/surfactant inorganic–organic composite. This is contrary to the quantum size effect, which leads to a blue-shift of E_g with decreasing particle size, and has been observed in many nanometer-sized semiconductor materials.[20] Notably, however, the red-shift of absorption spectrum or apparant optical bandgap here would arise from the interface between zinc oxide and surfactant. As for the band edge shift of optical absorption of semiconductor nanoparticals in different surrounding mediums with a smaller dielectric constant than that of the semiconductors, Takagahara[21] attributes it to the dielectric confinement effect. He expressed, approximately,the bandgap of the semiconductor nanoparticles in the different surrounding mediums as

$$E_g = E_0 + \frac{\pi^2}{\bar{R}^2} - \frac{3.572}{\bar{R}} - \frac{0.248\varepsilon_1}{\varepsilon_2}$$

where E_0 is the bandgap of bulk semiconductor, $\bar{R} = R/a_B$ (R is semiconductor nanoparticles radius, a_B is exciton Bohr radius),and ε_1 and ε_2 are the dielectric constants of the semiconductor and surrounding medium, respectively. The second term is the quantum confinement energy, leading to the absorption band edge blue-shift as the size of particle radius reduces; the third term is the direct Coulomb interaction between an electron and a hole, leading to red-shift. The last term is usually called the surface polarization energy, which arises from the difference in dielectric constant between the semiconductor nanoparticles and the surrounding medium, leading to a red-shift. The dielectric confinement has a significant effect on the excition energy and can not be treated as a minor perturbation.[21] Therefore, the smallerthe semiconductor nanoparticles and the greater the difference between ε_1 and ε_2 , the greater the dielectric confinement effect becomes. For the Zn-L nanocomposites, the surfactant DDA has a smaller dielectric constant ($\varepsilon_1 \approx 1.5$) than ZnO ($\varepsilon_2 \approx 12$). The dielectric-constant ration $\varepsilon_2/\varepsilon_1$ is 8 and the dielectric confinement effect would be significant. When the dielectric confinement effect emerges, the screening effect is reduced and the Coulomb interaction between charged particles becomes enhanced, resulting in enhancement of the exciton binding energy and the exciton

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oscillation strength; thus the surface polarization energy becomes the key factor influencing the absorption band edge.[21,22] Meanwhile, the quantum confinement energy would become the subordinate factor.

The room temperature emission spectrum of the Zn-L lamellar mesophase (Figure 6) shows that the RTPL of as-synthesized Zn-L exhibits a broad, strong emission band between 440 and 560 nm, centered at 480 nm (2.58 eV), i.e. in the green region of visible range. Compared with ZnO nanowires previously reported[23] and nanosheets,[17] the Zn-L lamellar mesophase shows a peak small shift about 20 nm and 6 nm, respectively. The maximum Stokes shift $\frac{1}{2}\Delta_{max}$ ($\hbar\omega_{ex} - \hbar\omega_{em}$) is 0.327 eV. Figure 6 shows that the board emission band is asymmetric (the right-hand side is wider), indicating that the emission band is made up of at least two overlapping emission bands, and the position of the overall maximum will depend on their intensity ratios. Inner interfacial defects between the ZnO and surfactant contribute to the relatively shorter wavelength of luminescence (<480 nm), while the outmost surfactant can additionally luminescence at long wavelengths (>480 nm).[18] Similar results and discussion have been reported by Lin[2] et al. for mesolamellar TiO_2. The luminescence of the Zn-L nanocomposite is similar to that from ZnO-capped sodium dodecylbenzenesulfonate.[18] The luminescence mechanisms of ZnO have been studied for several decades.[17,23] The ultraviolet peaks can be assigned to the direct recombination of a conduction electron and a hole in the valence band, and the green peaks can be attributed to the deep-trap-mediated emission. The origin of the deep trap in ZnO is not yet clearly understood but is generally attributed to structural defects, single ionized vacancies, and impurities.[23–26]

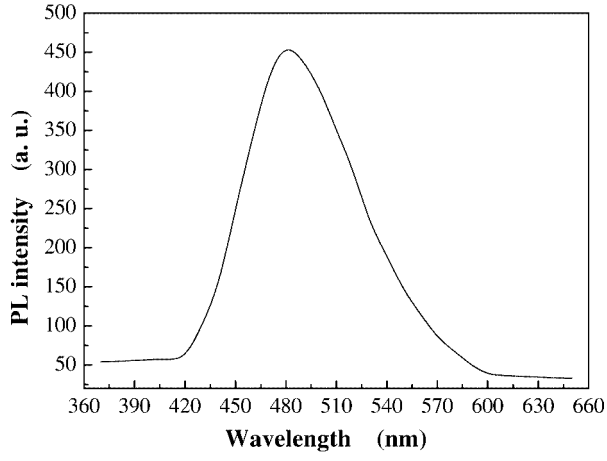

Figure 6. Emission (λ_{ex} = 383 nm) spectra of Zn-L nanocomposites.

In our investigation, the RTPL mechanism of Zn-L composite differs from that of bulk and other nanostructured ZnO. The mesolamellar zinc oxide/surfactant nanocomposites show the ordered structure to form zinc oxide/surfactant superlattices. This peculiar structure might have a profound effect on the chemical and physical properties of zinc oxide. The interfacial effect of zinc oxide/surfactants composites between zinc oxide and organic surfactants might be similar to the ZnO nanoparticles coated with sodium dodecylbenzenesulfonate reported by Wang.[18] X-ray photoelectron spectroscopic analysis indicates that the oxygen vacancies are formed in Zn-L nanocomposites. Many oxygen vacancies mainly located on the interface of the inorganic framework have interactions with interfacial capping surfactants, and surfactants might stabilize F-center-like oxygen vacancies. These interactions will lead to the formation of the trapped state that might form a series of metastable energy levels within the bandgap. Metastable energy levels are relatively long-lived and their optical transitions are dipole allowed. Thus, room temperature photoluminescence can be observed. Therefore, it could be inferred that the RTPL of the zinc oxide/surfactant mesophase might be induced by interfacial effects between the inorganic framework and the surfactants.

Conclusions

An ordered lamellar zinc oxide mesostructure was prepared in the presence of a neutral surfactant by self-assembly. Such Zn-L nanocomposites display new optical properties, such as a red-shift of absorption edge and room temperature photoluminescence. The absorption edge shifts to a low energy region (red-shift) because of the dielectric confinement effect. The interface effect between zinc oxide and surfactant is the main cause of the room temperature photoluminescence. These new optical properties of mesolamellar zinc oxide/surfactant nanocomposites also enhance their applications in optics.

Experimental Section

General: The structure was analyzed and characterized by X-ray diffraction (XRD, Rigaku D/max-RB diffractometer with Cu-K_α radiation, λ = 1.5418 Å). The sample was scanned from 1.2° to 20° (2θ) in steps of 0.02°. The scanning electron microscopy (SEM) photograph was obtained by JSM-6301F. Transmission electron micrographs (TEM) were made on a 200CX transmission electron microscope operated at 200 kV. Fourier transformed infrared (FTIR) spectra (4000–400 cm^{-1}) were recorded on a Perkin-Elmer Spectrum GX infrared spectrophotometer. Samples for FTIR were prepared using the KBr technology, which were calibrated by polystyrene. The composition of the Zn-L nanocomposite was determined by the X-ray photoemission spectra (XPS) recorded on a Perkin–Elmer PHI 5300 ESCA system with an Al-K_α X-ray beam and 250 W power. UV/Vis measurements were made with a UV2100 spectrophotometer. Photoluminescence (PL) measurements were carried out at room temperature using λ = 383 nm as the excitation wavelength with a HITACHI 850 type visible-ultraviolet spectrometer with a Xe laser as the excitation source.

Synthesis of ZnO/Dodecylamine Mesolamellar Nanocomposite: All chemical reagents used in the experiments were obtained from commercial sources as guaranteed-grade reagents and used without further purification or treatment. $ZnCl_2$ and DDA had purities of 98%. The composite was synthesized using a neutral dodecylamine ($C_{12}H_{27}N$, DDA) surfactant and zinc chloride ($ZnCl_2$). $ZnCl_2$ (1.36 g) was dissolved in distilled deionized water (DDW) (28 mL). DDA (0.74 g) dissolved in DDW (28 mL) was then added to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$ZnCl_2$ solution under vigorous stirring. The synthesis mixture, possessing a molar ratio $ZnCl_2$:DDA:H_2O of 1.0:0.4:156, was stirred for 4 h before being aged at room temperature for 48 h. The solid product was then recovered by filtration and washed with water. Dry composite could be exposed to air without oxidation.

Vanadium(IV and V) Complexes of Schiff Bases and Reduced Schiff Bases Derived from the Reaction of Aromatic *o*-Hydroxyaldehydes and Diamines: Synthesis, Characterisation and Solution Studies

Isabel Correia,[a] João Costa Pessoa,*[a] M. Teresa Duarte,[a] M. Fátima Minas da Piedade,[a] Tamás Jackush,[b] Tamás Kiss,*[b] M. Margarida C. A. Castro,[c] Carlos F. G. C. Geraldes,[c] and Fernando Avecilla[d]

Keywords: Vanadium complexes / Schiff bases / Reduced Schiff bases / Crystal structures / Speciation

Several sal_2en-type reduced Schiff bases have been prepared from the reaction of 2 equiv. of salicylaldehyde (or derivatives) with ethylenediamine followed by reduction with $NaBH_4$ and subsequently characterised. The water-soluble ligands $(SO_3\text{-sal})_2en$ and $R(SO_3\text{-sal})_2en$ (SO_3-sal = salicylaldehyde-5-sulphonate) have been studied by pH potentiometry and ^1H NMR spectroscopy and the protonation constants of $R(SO_3\text{-sal})_2en$ have been determined. The Schiff bases are more susceptible to hydrolysis than the corresponding reduced Schiff bases. The crystal structures of $H_2(o\text{-van})_2en$ and $KH(o\text{-van})_2en$ (*o*-van = *o*-vanillin) have been determined by X-ray diffraction. The vanadium(IV) complexes have been prepared and characterised by magnetic measurements and IR, UV/Vis and EPR spectroscopy. The colours, magnetic susceptibilities and IR spectra of the new vanadium(IV) complexes of the reduced Schiff bases now obtained suggest oligomeric/polymeric structures for the compounds while the corresponding $V^{IV}O$–Schiff-base complexes are monomeric. The complexation of $[V^{IV}O]^{2+}$ and $[V^{V}O_2]^{+}$ with $R(SO_3\text{-sal})_2en$ in aqueous solution has been studied by pH potentiometry, UV/Vis as well as by EPR spectroscopy for the $V^{IV}O$ system and ^1H and ^{51}V NMR spectroscopy for the $V^{V}O_2$ system. Complex formation constants have been determined and binding modes have been proposed. *N*,*N*′-ethylenebis(pyridoxylaminato) ($Rpyr_2en$) has also been obtained and the structure of $Na[V^{V}O_2(Rpyr_2en)]\cdot CH_3OH\cdot 3H_2O$ determined by X-ray diffraction. The $Rpyr_2en^{2-}$ ligand coordinates through both the *N*-amine and *O*-phenolate moieties in a symmetrical α-*cis* type coordination mode, i.e. with both *O*-phenolato donors *cis* to the *O*-oxo atoms and *trans* to each other.

Introduction

The presence of vanadium in biological systems, its insulin-enhancing action[1–4] and anticancer activity[5–7] has driven a considerable amount of research. Particular interest has been given to the study of the potential benefits of vanadium compounds as oral insulin substitutes for the treatment of diabetes.[8–12] Coordinated ligands should be able to improve the absorption and intracellular mobility of vanadium, reducing the dose necessary for producing equivalent effects. Several vanadium complexes of the dianionic tetradentate Schiff base sal_2en (*N*,*N*′-disalicylideneethylenediamine) type ligands have been proposed for use as insulin-enhancing agents and for treatment of obesity and hypertension.[13–15] Saminathan and Durai[13] reported the ability of $V^{IV}O(sal_2en)$ to reverse the hyperglycaemic condition of alloxan-induced diabetic rats, thereby exerting insulin-like action. However, the rats tended to become hypoglycaemic and withdrawal of treatment brought an immediate return of hyperglycaemia.

The sal_2en-type ligands present versatile steric, electronic and lipophilic properties. They may be easily prepared by the condensation of two compounds, namely an aromatic *o*-hydroxyaldehyde and a diamine, the hydrophilic-lipophilic balance being easily fine-tuned by choosing the appropriate amine precursors and ring substituents of the aldehyde.

In solution, Schiff base (SB) ligands have the disadvantage of their potential for hydrolysis. This instability can be overcome by reduction of the SB to give an amine. This presents interesting possibilities since the reduced SB will be more flexible and not forced to remain planar when coordinated to a metal centre. In this paper, we report the preparation of the SB and reduced SB ligands of salicylaldehyde, *o*-vanillin (*o*-van) and salicylaldehyde-5-sulphonate

(SO_3-sal) with ethylenediamine and the preparation of their $[V^{IV}O]^{2+}$ complexes which were characterised in the solid state and in solution.

Most of vanadium's biologically important reactions occur in water-based environments such as blood plasma and intracellular fluids. A knowledge of the distribution and chemical speciation of the vanadium compounds in aqueous solution is, therefore, of the utmost importance. Most of the sal_2en-type ligands and vanadium complexes prepared so far are not water-soluble. The compounds prepared using SO_3-sal are, however, soluble in water and may, therefore, be particularly useful for therapeutic use.

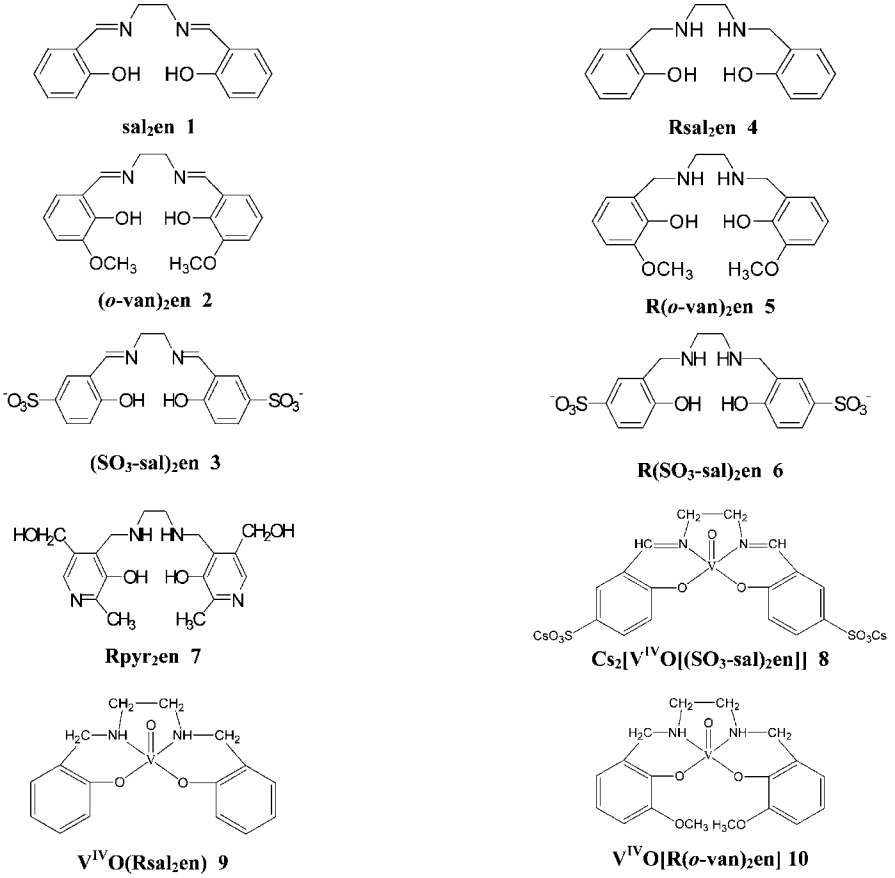
The study of the moderately water-soluble Schiff base of pyridoxal and ethylenediamine (pyr_2en) and its hydrolytically more stable reduced derivative $Rpyr_2en$ was reported in a previous paper.[15] Both proved to be efficient binders of vanadium in the +IV and +V oxidation states. Several $V^{IV}O$– and $V^{V}O_2$–$Rpyr_2en$ complexes were prepared and their properties studied. One of these, $[V^{V}O_2(HRpyr_2en)]$, was isolated in a crystalline form and structurally characterised by X-ray diffraction. Both ligands pyr_2en and $Rpyr_2en$ were found to form basically similar complexes coordinating through two $O_{phenolate}$ centres and two $N_{amine/imine}$ centres. The solution speciation revealed that the reduced SB formed more stable complexes with both $[V^{IV}O]^{2+}$ and $[V^{V}O_2]^{+}$ than the SB itself. EPR ($V^{IV}O$–$Rpyr_2en$ system), ^1H and ^{51}V NMR ($V^{V}O_2$–$Rpyr_2en$ system) spectroscopic studies indicated the presence of various isomeric species in solution.

Some of the vanadium(IV) complexes synthesised and characterised in the present and in the previous study[15] have been tested in vitro for their toxicity and insulin-mimetic behaviour, these are[16] $Cs_2[V^{IV}O(SO_3\text{-sal})_2en]$ (**8**), $[V^{IV}O(Rsal_2en)]$ (**9**), $[V^{IV}O(pyr_2en)]$ and $[V^{IV}O(Rpyr_2en)]$. At vanadium concentrations below 10 μM none of the compounds were toxic and they all proved to be effective with respect to the insulin-mimetic activity which was tested as the ability of vanadium compounds to trigger glucose uptake by cells. In that study, compound **8** was considered one of the most promising compounds with respect to its insulin-mimetic behaviour and low toxicity in the physiological concentration range.[16]

Results and Discussion

Synthesis and Characterisation

The Schiff bases **1**–**3** (see Scheme 1) were prepared in high yields (>75%) by the condensation of 2 equiv. of the appropriate aldehyde derivative with 1 equiv. of ethylenediamine. Treatment of these condensation products with sodium borohydride resulted in the reduction of the two imine bonds, yielding the reduced Schiff bases **4**–**7** (Scheme 1). All compounds gave satisfactory elemental analyses and were



Scheme 1. Ligands and $[V^{IV}O]^{2+}$ complexes prepared and characterised in this work

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

characterised by ^{1}H NMR spectroscopy and mass spectrometry. Two types of crystals suitable for X-ray diffraction studies were obtained for **2**.

By treatment of **3**–**5** with oxovanadium(IV) salts, [$V^{IV}O$] complexes with an N_2O_2 binding mode were obtained in good yields, namely [$V^{IV}O\{(SO_3\text{-sal})_2en\}$] (**8**),[17] [$V^{IV}O$-(Rsal$_2$en)] (**9**) and [$V^{IV}O\{R(o\text{-van})_2en\}$] (**10**). The complexes were characterised by elemental analysis, IR and UV/Vis spectroscopy. All our efforts to characterise the compounds obtained from the reaction of **6** with $[V^{IV}O]^{2+}$ were unsuccessful. Solids were obtained but no satisfactory formulation could be deduced. Compound **11** was obtained after slow concentration of a methanolic solution which contained a V^V salt and compound **7**.

X-ray Diffraction Studies

H_2(o-van)$_2$en (2A) and KH(o-van)$_2$en·2H_2O (2B)

ORTEP diagrams of **2A** and **2B** are presented in Figure 1 and selected bond lengths and angles are given in Table 1. A similar crystal structure for **2A** has already been reported[18] but we have included our data since it is of a better resolution (taking into account the *R* and e.s.d. values; we also included the hydrogen atoms in the refinement). The molecular structure of **2A** agrees with the published data[18] and both exhibit two geometry-determined intramolecular H-bonds between the N_{imine} and the $O_{phenolic}$ centres in both sides of the molecule [O–H···N 2.576(3), 2.608(3) Å with angles of 147.4(2)° and 146.8(2)° which dictate the molecular configuration and an N–C–C–N torsion angle of –163.0(2)° (–160.91° in ref.[18])]. The bond lengths and angles do not show any significant deviation from the expected values in similar compounds.[15,19,20] Another structure for H_2(o-van)$_2$en has recently been reported.[21] However, it is impossible to access this report to make adequate comparisons.[22]

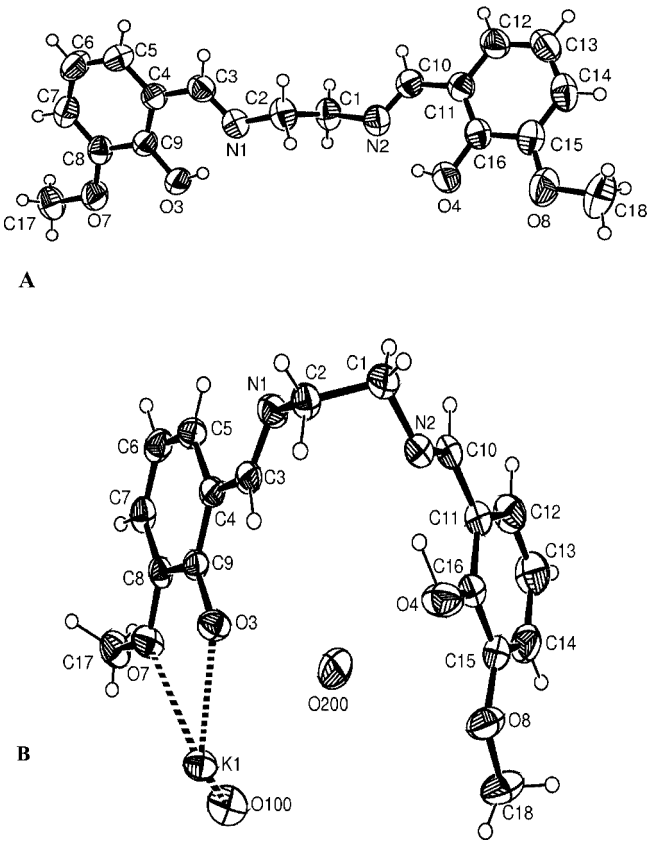


Figure 1. ORTEP diagrams of H_2(*o*-van)$_2$en (**2A**) and KH(*o*-van)$_2$en·2H_2O (**2B**), showing the atom labelling scheme; thermal ellipsoids of the non-hydrogen atoms have been drawn at the 40% probability level

The molecular structure of **2A** is comparable with that of **2B**, the latter being the same organic moiety but crystallised as an ionic pair with K^+ and two water molecules of crystallisation. In **2B**, the presence of K^+ changes the type of intramolecular H-bonds formed, thus promoting a totally different conformation of the organic moiety. One of

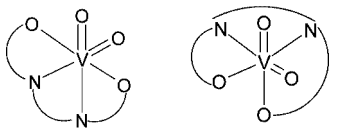
the intramolecular interactions is retained [O(4)-H···N(2) 2.556(5) Å] but the other is lost due to the direct interaction of the phenolic oxygen atom with the K^+ cation. A completely different conformation is thus obtained with an N–C–C–N torsion angle of –71.8(5)°. In the crystal structure of **2B**, the molecules pack as pseudo dimers due to the interactions with the K^+ cations and an extensive H-bonding system is promoted by the water molecules (see section ESI-A of the Supporting information for details).Figure ESI-1 (Supporting information) shows the cubic-like cage formed by the hydroxyl-oxygen, the K^+ ion and the O atoms of the water molecules. The coordination number of K^+ is six and it adopts a twisted trigonal-prismatic geometry (where the O_x···K^+ interactions, with x = hydroxy or water, range from 2.699 to 3.054 Å).

Na[V^VO_2(Rpyr$_2$en)]·CH_3OH·$3H_2O$ (11)

Rpyr$_2$en is stable to hydrolysis and ^{1}H and ^{51}V NMR spectroscopic studies for the V^VO_2–Rpyr$_2$en system indicated the presence of various complexes in solution, namely α-*cis*- and β-*cis*-type isomers[15] (Scheme 2). The pyridinium N atoms of the pyridoxal rings do not take part in the coordination but are involved in acid-base reactions which affect the number, type and relative amount of the isomers of the V^VO_2–Rpyr$_2$en complexes present in solution.[15] DFT calculations provided sensible molecular structures and the energy values for the various α-*cis*- and β-*cis*-type isomeric complexes differ by less than 4 kcal mol^{-1}, confirming that both types may coexist in solution. The α-*cis* isomer is symmetric and corresponds to the structure presently determined by X-ray diffraction.



α-*cis* β-*cis*

Scheme 2. Schematic representation of the binding mode of the α- and β-*cis* isomers in the present VO_2^+ complexes

The structure of [V^VO_2(HRpyr$_2$en)] (**12**) obtained from aqueous solutions at pH ≈ 7 was reported previously.[15] The ligand coordinates to the V^V centre through the two N_{amine} and two $O_{phenolate}$ atoms. The molecule is neutral and only one of the pyridine N atoms is protonated. From methanolic solutions containing the ligand and a different metal precursor (Bu_4NVO_3), a new compound was obtained, namely Na[V^VO_2(Rpyr$_2$en)]·CH_3OH·$3H_2O$ (**11**), its molecular structure is shown in Figure 2 and some selected bond lengths and angles are included in Table 2.Both **11** and **12** correspond to the symmetrical α-*cis*-type complex.[15] The molecular structures are similar and the difference that must be emphasised is that in the present compound **11**, both pyridinic N atoms are deprotonated. Thus, both halves of the ligand become equivalent whereas they are different in **12**. The complex molecule in **11** is anionic and there is an Na^+ counterion in the crystal structure as well as one methanol and three water molecules.

The V–O_{oxo}, V–$O_{phenolate}$ and V–N_{amine} bond lengths are similar in **11** and **12** but (i) the difference between the two V–O_{oxo} internuclear distances is 0.019 Å in **11** (not significant within a 3σ criterion) while it is 0.056 Å in **12** (this is probably due to different H-bonding interactions of the O_{oxo} atoms in **11** and **12**) and (ii) in the two halves of [V^VO_2(Rpyr$_2$en)]$^-$, the two V–$O_{phenolate}$ and V–N_{amine} bond lengths differ by 0.003 (not significant) and 0.02 Å, respectively, while they differ by 0.07 and 0.06 Å, respectively, in [V^VO_2(HRpyr$_2$en)]. This is due to the deprotonation of both pyridine N atoms in **11**. The similarity of both halves of the ligand can also be observed in the mean deviation from the plane of the atoms of the chelating rings which in **11** is the same in both V–O–C–C–C–N chelating rings (0.292 Å) while they are different in **12** (0.282 and 0.300 Å).

The H-bonding network is quite complex. Several atoms are involved in H-bonding with the neighbouring solvent molecules and this is described in section ESI-A (Supporting information). The Na^+ cation interacts strongly with O(4) [Na–O(4) 2.424(6) Å] and the water molecules (see Table 2).

Infrared Spectra

A set of selected IR bands for compounds **1–12** are summarised in section ESI-B (Supporting information). The assignments were made based on refs.[15,23,24] and by comparison of the spectra. While the spectrum of **2** in the powder and crystalline forms shows only one ν(C=N) strong band at 1633 cm^{-1}, the IR spectrum of KH(*o*-van)$_2$en shows two

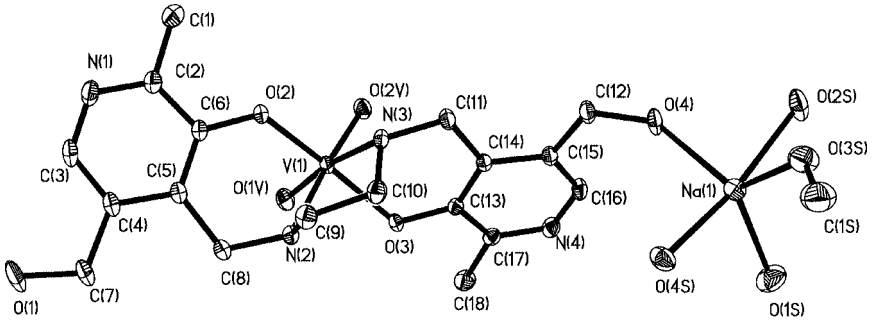


Figure 2. ORTEP diagram of Na[VO_2(Rpyr$_2$en)]·CH_3OH·$3H_2O$ (**11**) showing the atom labelling scheme; thermal ellipsoids have been drawn at the 30% probability level

O4S–H4SB–O3	0.900(2)	2.93(4)	2.868(7)	154(9)

strong bands at 1638 and 1617 cm^{-1}. This may be explained by the different H-bonding networks.

The characteristic ν(V=O) of oxovanadium(IV) complexes appears as a medium-strong band at 960 cm^{-1} in the IR spectrum of **8**, in agreement with the literature.[17] For the $V^{IV}O$ complexes of the reduced SB, the ν(V=O) is shifted to lower wavenumbers by ca. 100 cm^{-1}. These low ν(V=O) values indicate V=O···V=O interactions and this is in agreement with the magnetic susceptibility measurements (see below). The binding of an O_{oxo} atom to an adjacent vanadium atom *trans* to its vanadyl O atom lengthens and weakens the bond, thereby lowering the V=O stretching frequency.

Electronic Absorption Spectra

The electronic absorption spectra of bis(salicylaldimines) and their transition metal complexes have been extensively studied.[25–28] All free Schiff bases **1**–**3** show a broad band centred at ca. 320 nm due to an n→π* transition associated with the azomethine group and another band at around 260 nm which may arise from a transition involving mainly the π molecular orbitals localised on the C=N group and/or the aromatic ring.[26] In the spectra of the reduced SB compounds, the n→π* transition is absent as expected and the 260 nm transition is red-shifted and less intense. Section ESI-C (Supporting information) summarises the UV/Vis data.

Although three (or four) d-d bands can be expected to appear in the spectra of the $V^{IV}O$ complexes in the visible region, they are often overlapping or obscured by strong LMCT bands. The spectra of **8**–**10** show broad bands in the range 500–600 nm (band II: $d_{xy}\rightarrow d_{x^2-y^2}$) and a shoulder at 600–710 nm (band I: $d_{xy}\rightarrow d_{xz}$, d_{yz}).[29] Band III ($d_{xy}\rightarrow d_{z^2}$) occurs below 500 nm and is under much stronger LMCT bands (probably $O_{phenolate}\rightarrow$d orbital).

EPR Spectra

The X-band EPR spectra of frozen solutions (77 K) of the vanadium complexes, dissolved in DMSO (except for **8** which was in water), were measured and simulated with a computer program by Rockenbauer.[30] The EPR parameters obtained are listed in Table 3. All spectra show a small rhombic distortion which can be observed in the perpendicular lines corresponding to M_I = 7/2, 5/2 and 3/2, indicating a distorted geometry around the metal centre. Although the additivity rule[31] was developed to allow the determination of the identity of the equatorial donor groups in complexes of square-pyramidal geometry (or octahedral with a weak sixth ligand), it has been successfully applied to structurally distorted molecules.[32,33] In the present $[V^{IV}O]$ complexes, the EPR parameters fit well with a binding mode involving either two equatorial N_{amine} and two $O_{phenolate}$ centres or two equatorial N_{imine} and two $O_{phenolate}$ centres. However, since the contribution of equatorial DMSO ligands to A_z is ca. 42×10^{-4} cm^{-1}, i.e. close to that of N_{amine},[15] other binding modes cannot be ruled out.

Magnetic Properties

The magnetic susceptibilities of the vanadium complexes **8** and **9** were measured by the Faraday method in the tem-

perature range of 3 to 287 K. Data were corrected for diamagnetic contributions using the Pascal's constants.[34] For both complexes the plot of $1/\chi_P$ vs. T shows deviations from linearity which can be accounted for by assuming a Curie–Weiss law and a temperature-independent paramagnetism (TIP) term. The magnetic susceptibility of compound **8** fits well the Curie–Weiss law. A μ_{eff} of 1.76 μ_B was obtained at room temperature which is typical for compounds with a spin ½, indicating that **8** is monomeric. This is in agreement with the ν(V=O) obtained. Evans[17] also reported a room-temperature magnetic moment of 1.76 μ_B for **8** in aqueous solution at pH = 8.4.

Complex **9** shows temperature dependence for the μ_{eff} values. A smaller μ_{eff} value than the theoretical for S = ½ was obtained (see section ESI-D of the Supporting information). This low magnetic moment indicates that there are V=O···V=O interactions which is in agreement with the low ν(V=O) measured for this complex (see above). Low μ_{eff} and ν(V=O) values were also found for several sal$_2$entype SB vanadium complexes[35–37] including [V^{IV}O-(Rpyr$_2$en)].[15]

Speciation Studies

(SO$_3$-sal)$_2$en (3) and R(SO$_3$-sal)$_2$en (6)

Compounds **3** and **6** are water-soluble and their acid-base behaviour was studied by pH potentiometry and ^{1}H NMR spectroscopy. The protonation constants of **6** are listed in Table 4. For the SB **3**, both the evaluation of the titration curves and the ^{1}H NMR studies indicate the occurrence of hydrolytic processes. For the reduced SB **6**, no hydrolysis could be detected in the whole pH range. The SB sal$_2$en also undergoes hydrolysis in strongly acidic DMSO/water [80:20 (w/w)] solutions.[38] In contrast, the SB *N*,*N*′-*o*-phenylenebis(salicylideneimine) is stable under the same conditions at pH > 2.5.[39]

In order to study the hydrolytic processes of compound **3**, several samples were prepared by dissolving the SB (SO$_3$-sal)$_2$en and either ^{1}H NMR or pH-potentiometric data were collected and evaluated with the computer programs PSEQUAD[40] and SUPERQUAD,[41] respectively. Our objective was to obtain a reasonably quantitative approach for the species which form as the pH is varied, but not very

accurate pK values. From the ^{1}H NMR spectra, all chemical shift values were assigned and then set as constants which were used to determine all the other protonation and formation constants from the pH concentration dependence for each species. The pH dependence of the chemical shifts assigned to the peaks of the free ethylenediamine and aldehyde protons were also used to determine their pK values with PSEQUAD[40] (see ESI-E). The potentiometric data were treated separately.

The species were expressed as $(en)_p(SO_3\text{-sal})_q(H^+)_r$ and the protonation and formation constants of the main products formed were determined. Table 4B contains the protonation and formation constants, section ESI-E (Supporting information) contains information on the calculations and Figure 3 shows a concentration distribution diagram showing the total concentrations of each main compound.

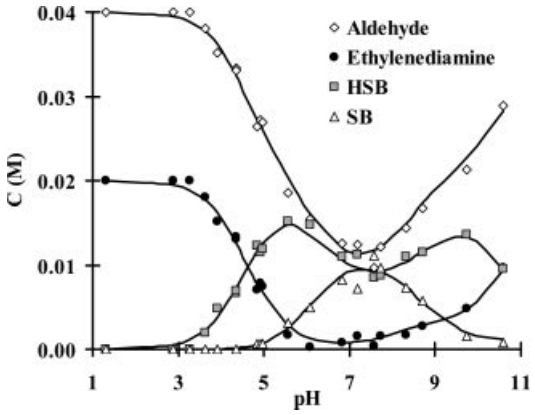

Figure 3. Concentration distribution curves of hydrolytic species formed in solutions containing compound **3** (see Scheme ESI-1 of Supporting information); only the total concentrations of each compound [aldehyde = (SO_3-sal); HSB = (SO_3-sal)en, SB = [SO_3-sal]$_2$en] are represented

We can conclude that for SB **3**, the hydrolysis is very extensive, much more than for pyr$_2$en and occurs in the whole measurable pH range. With pyr$_2$en, hydrolysis was only detected to a small extent at pH $>$ 7.[15]

Vanadium(IV) Complexes

Although potentiometric and spectroscopic studies were carried out with SB **3**, its extensive hydrolysis did not allow a consistent evaluation of the system. For the corresponding reduced SB **6**, the interaction with $[V^{IV}O]^{2+}$ and $[V^{V}O_2]^{+}$ was studied and the corresponding stability constants are also listed in Table 4. With $[V^{IV}O]^{2+}$ the pH-metric data were evaluated only up to pH $\approx$ 9.5 since slow processes occur at higher pH values (oxidation and/or hydrolysis). The species distribution diagram is presented in Figure 4a. The complex formation starts at pH $\approx$ 4 with the formation of the neutral complex $[VOLH_2]$. The ligand forms quite stable 1:1 complexes with $[V^{IV}O]^{2+}$ and the stoichiometry $[VOL]^{2-}$ predominates in the pH range 4.5–9.0. In the basic pH range, the process $[VOL]^{2-} \rightleftarrows [VOLH_{-1}]^{3-} + H^+$ has a pK of ca. 9.5.

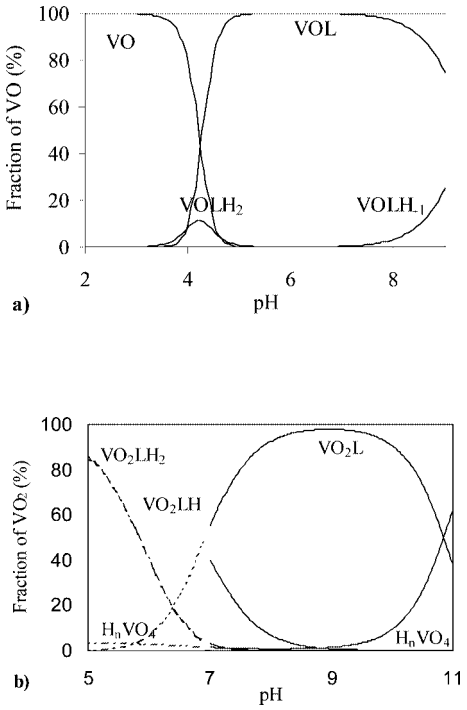

Figure 4. Concentration distribution curves of complexes formed in solutions containing: a) $[V^{IV}O]^{2+}$ and R(SO_3-sal)$_2$en with C_{VO} = 1.0 mM and L/M = 2; b) $[V^{V}O_2]^{+}$ and R(SO_3-sal)$_2$en with C_V = 3.0 mM and L/M = 2, calculated using the stability constants listed in Table 4; the dashed lines indicate that the curves only represent an approximate estimation of the relative concentrations (see text)

Figure 5 shows the high-field region of the X-band EPR spectra of "frozen" solutions containing $[V^{IV}O]^{2+}$ and **6** at several different pH values. The EPR parameters were obtained by computer simulation[30] of the EPR spectra. At pH $<$ 4 the only species present is the (aqua)vanadyl ion. At pH $>$ 4 two new species form. $[VOLH_2]$ only forms in

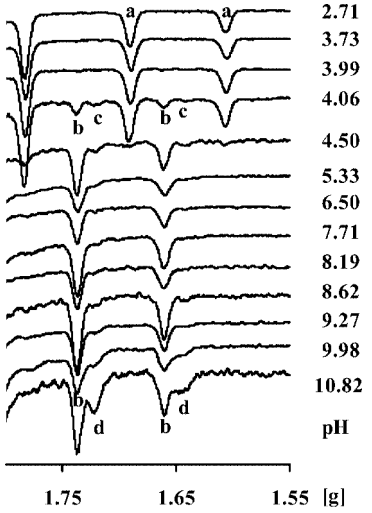

Figure 5. High-field region of the EPR spectra (77K) of frozen solutions containing $[V^{IV}O]^{2+}$ and R(SO_3-sal)$_2$en at several pH values with L/M = 1 and $C_{VO} \approx 0.004$ M; four main components can be detected a: $[VO(H_2O)_5]$, b: VOL, c: $VOLH_2$ and d: $VOLH_{-1}$ (charges omitted)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

low concentration (ca. 10%) and its EPR parameters are $g_z \approx 1.945$ and $A_z \approx 168 \times 10^{-4}$ cm^{-1}. The additivity rule[31] applied to bidentate coordination of the ligand, i.e. through equatorial binding of $O_{phenolate}$, N_{amine} and two H_2O groups yields $A_z^{estim} = 170 \times 10^{-4}$ cm^{-1}, so this is probably the binding mode of $VOLH_2$.

For VOL, the EPR parameters[30] g_x, g_y and g_z are 1.982, 1.976 and 1.957, respectively, and A_x, A_y and A_z are 52, 50 and 159×10^{-4} cm^{-1}. This indicates an equatorial binding mode involving two $O_{phenolate}$ and two N_{amine} centres, $A_z^{estim} = 157 \times 10^{-4}$ cm^{-1}. In all the EPR spectra above pH $\approx$ 4 a second minor component is present which probably corresponds to a binding mode of two equatorial $O_{phenolate}$ centres, one equatorial N_{amine} and one equatorial O_{water} centre as well as one axial N_{amine} centre, $A_z^{estim} = 164 \times 10^{-4}$ cm^{-1}. Therefore, equilibrium between *cis*/*trans* isomers apparently occurs as observed in the $V^{IV}O$–Rpyr$_2$en system.[15] However, in the present system the position of this equilibrium is shifted to the *trans* isomer (which presumably contains the H_2O ligand *trans* to the O_{oxo} atom) and the EPR spectra could be satisfactorily simulated assuming some rhombic distortion from a square-pyramidal structure.

Above pH $\approx$ 9 a new signal could be observed in the EPR spectra corresponding to the hydroxo complex [$VOLH_{-1}$]. The corresponding g_z and A_z parameters are ca. 1.948 and ca. 162×10^{-4} cm^{-1}, respectively. Possible equatorial binding modes are by two N_{amine}, an $O_{phenolate}$ and an OH^- with $A_z^{estim} = 158 \times 10^{-4}$ cm^{-1} and by two $O_{phenolate}$ centres, an N_{amine} and an OH^- with $A_z^{estim} = 156 \times 10^{-4}$ cm^{-1}. The binding mode for [$VOLH_{-1}$] probably corresponds to the first case.

The visible absorption spectra for this system confirm the speciation model obtained by pH potentiometry. At pH = 3.1 the spectrum corresponds to the spectrum of $[V^{I-V}O(H_2O)_5]^{2+}$. In the pH range 5–7 the spectra do not change and the d-d bands at λ_{max} = 535 nm (ε = 112 M^{-1} m^{-1}) and 840 nm ($\varepsilon \approx 50$ M^{-1} m^{-1}) correspond to VOL. Below 400 nm there is a charge-transfer band probably due to transitions between $O_{phenolate}$ and empty d orbitals on the V atom.

Vanadium(V) Complexes

The interaction between R(SO$_3$-sal)$_2$en and V^V was studied by pH potentiometry and ^{1}H and ^{51}V NMR spectroscopy. The species distribution diagram is shown in Figure 4B and Table 4 contains the complex formation constants. The pH-potentiometric titrations were carried out between pH = 11.5 and 2 but due to the slow formation of a small percentage of decavanadate species below pH $\approx$ 5,

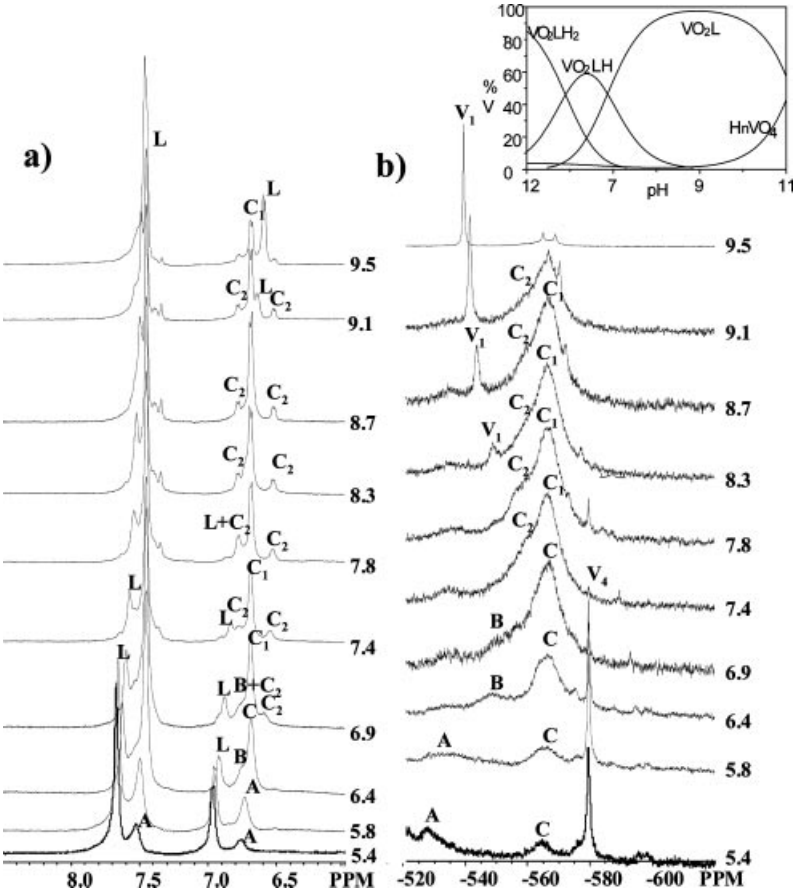

Figure 6. NMR spectra at different pH values of D_2O of solutions containing V^V and R(SO$_3$-sal)$_2$en with C_V = 20 mM and L:M $\approx$ 1.1; a) aromatic region (8.5 < δ < 6.0 ppm) of the ^{1}H NMR spectra and b) ^{51}V NMR spectra; **C** = **C$_1$** + **C$_2$**; inset: concentration distribution curves for the conditions used in the NMR experiments

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the model that showed the best fitting was obtained by considering only data at pH > 5.7. The complexes formed between V^V and **6** are quite stable and correspond to a 1:1 stoichiometry in several protonation states. For an L/M ratio of 2 (and C_V = 3 mM), some hydrolysis occurs only above pH ≈ 10 with the formation of $[HVO_4]^{2-}$ and $[VO_4]^{3-}$ (see Figure 4B).

The ^{51}V NMR spectra (Figure 6B) are quite complex, showing signals corresponding to a variety of V^V species including monovanadate (V_1), its oligomers (V_2 and V_4) and V^V–ligand complexes. Although in the potentiometric studies, decavanadate is formed only below pH ≈ 5, in these ^{51}V NMR studies weak decavanadate signals were detected even at pH ≈ 9 (data not shown). Nevertheless, the spectra clearly show complex formation between ligand **6** and $[VO_2]^+$, e.g. species **A**, **B**, $\mathbf{C_1}$and $\mathbf{C_2}$in Figure 6B. These resonances are broad due to quadrupolar relaxation and the asymmetric coordination environment of the V^V.[43]

The assignment of these ^{51}V NMR signals was done taking into account the respective chemical shift values and peak areas (the peak areas were determined with program NUTS[44] after deconvolution of the signals) and by comparison with the speciation diagram of Figure 4b. The resonance $\mathbf{C_1}$ ($\delta \approx -565$ ppm), observed above pH ≈ 5, corresponds to the α-*cis*-VO_2L complex (see Scheme 2) which predominates between pH ≈ 7 and 9, and the $\mathbf{C_2}$ signal ($\delta \approx -562$ ppm) of lower intensity appears clearly as a shoulder on signal $\mathbf{C_1}$ above pH ≈ 7. This can be assigned to the β-*cis*-VO_2L isomer. The ^{51}V NMR shifts of these resonances are in agreement with a binding mode involving N_2O_2[43] and with previous data obtained with the V^VO_2–Rpyr$_2$en system.[15] A low-intensity, broad resonance **B** ($\delta \approx -550$ ppm) appears at pH ≈ 6.4–6.9 and can be assigned to a VO_2LH species where the monoprotonated ligand coordination is probably tridentate. Several isomers may coexist since the ligand can coordinate through one or two of the N_{amine} and $O_{phenolate}$ atoms, this being a plausible explanation for the broadness of the peak. Resonance **A** ($\delta \approx -530$ ppm), with a maximum intensity at pH ≈ 5.4, is practically absent at pH = 6.4. It should correspond to a VO_2LH_2 complex, in which the coordination of the diprotonated ligand is probably bidentate. Again several isomers may coexist. Between pH = 6.9 and 8.2 a weak broad signal can be observed at $\delta \approx -535$ ppm but its assignment is not straightforward. It is probably an isomer of complex **B** since it appears in the same pH range (see Figure 6b). The ^{51}V shift trend observed as the complex is protonated is in agreement with a decreasing ligand coordination number.[45,46]

^{51}V and ^1H NMR studies for the V^VO_2–Rpyr$_2$en system have shown the existence of equilibria in solution between structural isomers of the α- and β-*cis*-type (see Scheme 2).[15] While the α-*cis* isomer is symmetric, in the β-*cis* isomer the protons of the two half-molecules are not equivalent, with peaks appearing at different chemical shifts for each half-molecule. Complex **11**, with the molecular structure depicted in Figure 2, corresponds to an α-*cis* isomer with V^VO_2L stoichiometry. In aqueous solution its ^{51}V NMR chemical shift is at $\delta \approx -563$ ppm which is close to the value for species $\mathbf{C_1}$ (Figure 6b). Although the ^{51}V NMR spectra for the present system are not as clear as for the V^VO_2–Rpyr$_2$en system, they also display an α-/β-*cis* isomeric equilibrium: the ^{51}V NMR signal for species $\mathbf{C_1}$ shows a shoulder at higher frequency (assigned to $\mathbf{C_2}$ in Figure 6b) but the signal overlap due to the proximity of the chemical shifts makes quantification of the equilibrium difficult. However, in the ^1H NMR spectra (Figure 6a), the presence of the equilibrium is particularly clear for the aromatic proton signals, e.g.at pH = 7.4–9.5, where VO_2L ($\mathbf{C_1}$ and $\mathbf{C_2}$) is the only stoichiometry present, three separate ^1H NMR resonances can be observed (besides the one corresponding to the excess of free ligand in solution, **L**). One corresponds to $\mathbf{C_1}$, the α-*cis* isomer, and the other two to $\mathbf{C_2}$, the β-*cis* isomer. Thus, as in the V^VO_2–Rpyr$_2$en system,[15] while in the α-*cis* complex the protons of each half-molecule are equivalent, in the β-*cis* complex they give rise to two separate signals. Deconvolution of the ^1H NMR peaks gave a rough estimate of the ratio between the α-*cis* and β-*cis* isomers of ca. 80:20 at pH = 7.8 which increases at lower pH. The very low percentage of the $\mathbf{C_2}$ isomer precludes observation of its ^{51}V NMR resonance at pH < 7.4 (upon formation of complexes with other stoichiometries) but at higher pH it is detectable. The small percentage of the β-*cis* species might be due to repulsion between the negative SO_3^- groups which in the β-*cis* complex are closer in space. At pH = 6.9 and lower, the broad ^1H resonances of the protonated **B** and **A** forms can be observed. Thus, in the present case, slow exchange conditions on the NMR time scale prevail, not only between the two isomers of $[VO_2L]$ and L but also with $[VO_2LH]$ and $[VO_2LH_2]$ because, in this case, ligand protonation causes a change of V^V coordination which was not the case for V^VO_2–Rpyr$_2$en in which ligand protonation only resulted in ^1H and ^{51}V chemical shift changes.[15]

Conclusions

The SB ligands sal$_2$en, (*o*-van)$_2$en, (SO$_3$-sal)$_2$en and their reduced derivatives H_2Rsal$_2$en, H_2R(*o*-van)$_2$en and H_2R(SO$_3$-sal)$_2$en were synthesised in good yields and the structures of H_2(*o*-van)$_2$en and KH(*o*-van)$_2$en·2H_2O were determined by X-ray diffraction. As expected, the Schiff bases are more susceptible to hydrolysis than the corresponding reduced SB and ^1H NMR studies in aqueous solutions of (SO$_3$-sal)$_2$en indicated the presence of several hydrolysis products, namely the "half SB", the free ethylenediamine and the free SO$_3$-salicylaldehyde.

For the present set of ligands, there is strong IR and magnetic susceptibility evidence that the Schiff base $V^{IV}O$ complexes form monomeric structures in the solid state and that the corresponding reduced Schiff-base complexes form structures with V=O···V=O-type interactions. The potentiometric and spectroscopic studies demonstrate the high affinity of the reduced SB R(SO$_3$-sal)$_2$en for $[V^{IV}O]^{2+}$ and $[V^VO_2]^+$. The ligand forms stable 1:1 complexes with vanadium in both oxidation states and for the predominant stoi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chiometries in solution, ML (M = $[V^{IV}O]^{2+}$ and $[V^{V}O_2]^{+}$), there is considerable evidence that there are two types of isomers.

The X-ray diffraction characterisation of both $[V^{V}O_2(HRpyr_2en)]$[15] and $Na^{+}[V^{V}O_2(Rpyr_2en)]^{-}$ (**11**) confirmed the formation of $V^{V}O_2$–$Rpyr_2en$ complexes with different degrees of protonation at the *N*-pyridine sites, thus confirming some data from the earlier report for this system.[15]

Complexes **8**, **9** and $[V^{IV}O(Rpyr_2en)]$ were tested for toxicity and insulin-mimetic effects in vitro through studies involving mice fibroblasts.[16] When compared with other compounds tested, $[V^{IV}O(Rpyr_2en)]$ showed relatively low toxicity and complex **8** showed high efficiency in promoting glucose uptake into cells as well as high aqueous solubility. All these characteristics might be important factors for the therapeutic action of the vanadium complexes.

Experimental Section

Preparation of Ligands and Complexes

Synthesis of the Schiff Bases and Reduced Schiff Bases: The Schiff-base ligands were prepared according to literature procedures[47] by reaction of the *o*-hydroxyaldehyde with ethylenediamine (2:1) in methanol, except for **3** in which the solvent was water. All compounds were characterised by elemental analysis, mass spectrometry and ^{1}H NMR spectroscopy.

sal_2en (1): Yield: 0.77g, 95%. $C_{16}H_{16}N_2O_2$ (268.32): calcd. C 71.62, H 6.01, N 10.44; found C 71.6, H 6.0, N 10.5. MS: *m*/*z* = 268 $[M]^+$. ^{1}H NMR (500 MHz, $CDCl_3$ 25 °C): δ = 3.95 (s, 4 H, –CH_2CH_2–), 7.2 (m, 8 H, $CH_{aromatic}$), 8.36 (s, 2 H, C*H* = N) ppm.

(*o*-van)$_2$en (2): Yield: 0.89g, 76%. $C_{18}H_{20}N_2O_4$ (328.37): calcd. C 65.84, H 6.14, N 8.53; found C 65.8, H 6.1, N 8.5. MS: *m*/*z* = 228 $[M]^+$. ^{1}H NMR (500 MHz, $CDCl_3$ 25 °C): δ = 3.89 (s, 6 H, CH_3–O), 3.97 (s, 4 H, –CH_2CH_2–), 6.8 (m, 6 H, $CH_{aromatic}$), 8.33 (s, 2 H, C*H* = N) ppm.

Both the filtrate and the washings were kept at room temperature for several weeks and yellow crystals of two different types were collected and characterised by X-ray diffraction. Crystals of **2A** and **2B** were obtained from the washings and filtrates from the synthesis of the Schiff base, respectively. The source of the K^+ ion was the KOH solution used to increase the pH from 4 to ca. 7.

(SO$_3$-sal)$_2$en (3): The Schiff base was prepared according to a literature procedure.[48] Yield: 1.2 g, 87%.$C_{16}H_{14}N_2Na_2O_8S_2$ (472.40): calcd. C 40.68, H 2.99, N 5.93, S 13.57; found C 40.7, H 3.0, N 5.9, S 13.4.

Rsal_2en (4): To a solution of the SB **1** (0.61 g, 2.27mmol) in dichloromethane (10 mL) at ca. 0 °C was added a methanolic solution of $NaBH_4$ (0.076g, 2.0 mmol, 5 mL containing some drops of concd. KOH solution. The pH was set to 6 and the solution stirred for several hours until the yellow colour had disappeared. The solvent was evaporated to dryness and water (10 mL) was added to the residue. The pH was set to 4–5 by addition of 3 M HCl. The white solid was filtered, washed with cold water, ethanol and diethyl ether and dried under vacuum. Yield: 0.38g, 61%. $C_{16}H_{20}N_2O_2$ (272.35): calcd. C 70.56, H 7.40, N 10.29; found C 70.8, H 7.0, N 10.4. MS: *m*/*z* = 273 $[M]^+$. ^{1}H NMR (500 MHz, $CDCl_3$ 25 °C): δ = 2.85 (s, 4 H,–CH_2CH_2–), 4.00 (s, 4 H, CH_2NH), 7.0 (m, 8 H, $CH_{aromatic}$) ppm.

R(*o*-van)$_2$en (5): The procedure was similar to the one used for **4**. Yield: 0.57g, 75%. $C_{18}H_{24}N_2O_4$·0.2MeOH (459.49): calcd. C 64.52, H 7.38, N 8.27; found C 64.6, H 7.5, N 8.1. MS: *m*/*z* = 333 $[M]^+$. ^{1}H NMR (500 MHz, $CDCl_3$ 25 °C): δ = 2.82 (s, 4 H,–CH_2CH_2–), 3.87 (s, 6 H, CH_3–O), 3.99 (s, 4 H, CH_2NH), 6.7 (m, 6 H, $CH_{aromatic}$) ppm.

R(SO$_3$-sal)$_2$en (6): The procedure was similar to the one for **4** but the solvent used was water. Yield: 0.77g, 88.0%. $C_{16}H_{20}N_2O_8S_2$·1.5H_2O (459.49): calcd. C 41.82, H 5.05, N 6.10, S 13.95; found C 41.7, H 5.1, N 6.0, S 14.3. ^{1}H NMR (500 MHz, D_2O, pH ≈ 5.7, 25 °C): δ = 3.35 (s, 4 H, –CH_2CH_2–), 4.23 (s, 4 H, CH_2NH), 6.97 (d, 2 H, $CH_{aromatic}$), 7.67 (s, 4 H, $CH_{aromatic}$) ppm.

$Rpyr_2en$ (7): The compound was prepared according to a literature procedure.[15] Yield: 0.83g, 60%. $C_{18}H_{26}N_4O_4$ (362.43): calcd. C 59.65, H 7.23, N 15.35; found C 59.5, H 7.3, N 15.4. ^{1}H NMR (500 MHz, D_2O, pH ≈ 4.8, 25 °C): δ = 2.41 (s, 6 H, CH_3), 3.35 (s, 4 H, –CH_2CH_2–), 4.35 (s, 4 H, CH_2NH), 4.63 (s, 4 H, CH_2O), 7.62 (s, 2 H, $CH_{aromatic}$) ppm.

Synthesis of the Vanadium Complexes: All reactions with the $V^{IV}O$ complexes were carried out under nitrogen.

$Cs_2[V^{IV}O\{(SO_3\text{-}sal)_2en\}]$ (8): The synthesis followed a literature procedure.[17] A pink complex was obtained. Yield: 93%. $C_{16}H_{12}N_2O_9S_2VCs_2$·0.5$H_2O$ {formulation: $Cs_2[V^{IV}O\{(SO_3\text{-}sal)_2en\}](H_2O)_{0.5}$} (766.16): calcd. C 25.08, H 1.71, N 3.66, S 8.37; found C 25.2, H 2.0, N 3.6, S 8.4.

$[V^{IV}O(Rsal_2en)]$ (9): Compound **4** (0.27g, 1.0 mmol) was dissolved in methanol/chloroform (10:1, 20 mL) containing sodium acetate (0.30g, 2.2 mmol). An aqueous solution of $VOSO_4$·5H_2O (0.25g, 1.0 mmol) was slowly added and a brownish-orange precipitate immediately formed. This was collected by filtration and washed with methanol:water (8:2), methanol and diethyl ether and then dried under vacuum. Yield: 0.30g, 90%. $C_{16}H_{18}N_2O_3V$ (337.27): calcd. C 56.98, H 5.38, N 8.31; found C 56.8, H 5.3, N 8.4.

$[V^{IV}O\{R(o\text{-}van)_2en\}]$ (10): The procedure was similar to the one used for **9**. Yield: 0.36g, 94%. $C_{18}H_{22}N_2O_5V$·2.1H_2O (435.17) {formulation: $[V^{IV}O\{R(o\text{-}van)_2en\}](H_2O)_{2.1}$}: calcd. C 49.68, H 6.07, N 6.44; found C 49.5, H 6.0, N 6.4.

$Na[V^{V}O_2(Rpyr_2en)]\cdot CH_3OH\cdot 3H_2O$ (11): A mixture of NH_4VO_3 (0.03g, 0.27mmol) and Bu_4NBr (0.09g, 0.27mmol) in methanol (10mL) was heated to reflux for 1 h. The solution turned pale yellow and was filtered to remove the solid materials. After cooling, $Rpyr_2en$ (0.10g, 0.28mmol) was added and the solution became red. As there was no precipitation after 1 h of stirring, the solution was maintained at room temperature for 2 weeks. Yellow crystals were collected and characterised by X-ray diffraction.

Physical and Spectroscopic Studies: ^{51}V and ^{1}H NMR spectra were obtained with a Varian Unity-500 Spectrometer operating at 131.404 MHz and 499.824 MHz, respectively, using a 5-mm broadband probe at 25.0 ± 0.5 °C. The ^{1}H and ^{51}V NMR chemical shifts were referenced relative to TSS [sodium 3-(trimethylsilyl)propane sulphonate] at δ = 0 ppm, and to an external $[VOCl_3]$ solution at δ = 0 ppm, respectively. The ^{51}V NMR acquisition parameters were as follows: 33 kHz spectral width, 30 μs pulse width, 1 s acquisition time and 10 Hz line broadening. A presaturation pulse sequence was used for ^{1}H NMR spectra to eliminate the residual water signal. IR spectra were recorded with a BioRad FTS 3000 MX FTIR spectrometer. Vis spectra were recorded either with a Hitachi U-2000 or with a Perkin–Elmer Lambda 9 UV/Vis/NIR spectrophotometer. The EPR spectra were recorded at 77 K (on glasses prepared by freezing solutions in liquid nitrogen) with a Bruker ESP

[a] The formula of **2B** includes only the hydrogen atoms actually used in the refinement, i.e. H19. Hydrogen atoms of the water molecules were not found or inserted in calculated positions. Taking into account all H atoms, the correct formula for the compound is $C_{18}H_{23}KN_2O_6$.

300E X-band spectrometer. The magnetic susceptibilities were measured in the range 5–296 K using a 7 T F Oxford Instruments system coupled to a Sartorius S3D-V microbalance.

X-ray Crystal Structure Determinations: For compounds **2A** and **2B** data were collected with a TURBOCAD4 Enraf–Nonius diffractometer using Cu-K_α graphite-monochromated radiation. Data were corrected for Lorentz and polarisation effects. No absorption correction was performed. The crystal structures were solved by direct methods (program SIR97[49]) and refined with SHELXL97[50] using the WinGX package Version 1.64.03b.[51] All non-hydrogen atoms were refined anisotropically. In compound **2B**, hydrogen atoms located in the Fourier maps were refined isotropically. In compound **2A**, the hydrogen atoms were included in calculated positions and allowed to refine while riding on the parent C atom except for the hydrogen atoms on C(1), C(2), C(3) and C(4) which were located and refined isotropically. The poor quality of the crystals of compound **2B** precluded better refinement results. Further details of the crystal structure determinations are given in Table 5. Graphical representations were prepared using ORTEP[49] and Mercury 1.1.2.[52] The X-ray data for compound **11** were collected with a Siemens Smart 1000 CCD operating at 25 °C. Data were corrected for Lorentz and polarisation effects and for absorption by semiempirical methods. Structures were refined by full-matrix least squares on F^2. Complex scattering factors were taken from the program package SHELXTL. Of the 15098 reflections measured, 3823 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. Hydrogen atoms were included in calculated positions and were refined in the riding mode except the hydrogen atoms H(2N), H(3N), H(2SA), H(2SB), H(4O), H(4SA) and H(4SB) which were located from a difference electron density map and then fixed to 0.9 Å from the corresponding heteroatom [except H(4O) which was left to refine freely]. Refinement converged with allowance for thermal anisotropy of all non-hydrogen atoms. Crystal data and details of the data collection and refinement are also summarised in Table 5. CCDC-235821, -235822 and -236365 contain the supplementary crystallographic data for this paper for **2A**, **2B**, and **11**, respectively. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Speciation Studies

Spectroscopic Measurements: For preparation of the solutions and pH calibrations we used a special glass vessel with a double wall with entries for the combined electrode (Radiometer "Red Rod" pHC2015-8), thermometer, nitrogen and reagents (e.g. base). A computerised system developed locally was used to control the titration conditions for pH calibrations. The emf measurements were made with a Denver Model 15 pH meter.

pH-Potentiometric Titrations: The purity of the ligands was checked pH-potentiometrically and the exact concentrations of the solutions were determined by the Gran method.[53] A stock solution of [$V^{IV}O$] was prepared and standardised as reported earlier[54,55] and its H^+ concentration was determined by pH potentiometry. The vanadate stock solution was prepared by dissolving KVO_3 in a KOH solution of known molarity. The vanadium content in the commercial KVO_3 was determined as reported earlier[15] and the H^+ concentration in the stock V^V solution was calculated. All solutions were manipulated under high-purity nitrogen or puri-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fied argon. The ionic strength was adjusted to 0.20 M KCl and the temperature was 25.0 ± 0.1 °C. The pH was measured with an Orion 710A precision digital pH meter equipped with an Orion Ross 8103BN type combined glass electrode, calibrated for H^+ concentration as described earlier.[56] The ionic product of water is pK_w = 13.76. Stability constants were determined by pH-metric titration of 10.0-mL samples. The ligand concentrations were in the range 0.002–0.004 M and the metal ion/ligand molar ratio varied from 1:1 to 1:4. Titrations of solutions containing $[V^{IV}O]^{2+}$ were normally carried out with KOH solution of known concentration (ca. 0.2 M) under purified argon from pH = 2.0 up to 11.5 unless very extensive hydrolysis, precipitation or slow equilibration was detected. Titrations of solutions containing V^V were carried out by back-titrations i.e., by titrating samples from basic pH with HCl solutions of known concentration (ca. 0.2 M). The reproducibility of titration points included in the evaluation was within 0.005 pH units in the whole pH range. The protonation constants and the ligand purity were determined with the program SUPERQUAD.[41] The concentration stability constants $\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$ were calculated using the PSEQUAD computer program.[40] The formation of the hydroxo complexes of $[V^{IV}O]$ was taken into account. The following species were assumed: $[V^{IV}O(OH)]^+$ ($\log\beta_{10-1}$ = –5.94), $[(V^{IV}O)_2(OH)_2]^{2+}$ ($\log\beta_{20-2}$ = –6.95), with stability constants calculated from the data of Henry et al.[57] and corrected for the different ionic strength using the Davis equation; $[(V^{IV}O)_2(OH)_5]^-$ ($\log\beta_{20-5}$ = –22.5) and $[V^{IV}O(OH)_3]^-$ ($\log\beta_{10-3}$ =–18.0).[29] For the V^V systems the stability constants were defined as $\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$, where M refers to $[VO_2]^+$ (not to $[HVO_4]^-$ as is usual in the literature). The speciation of vanadate into monomeric, dimeric, tetrameric, pentameric and decameric species was taken into account and the values used for the stability constants were those of Petterson[59] (after correction for the different ionic strength using the Davis equation, and recalculation using $[VO_2]^+$ as M): $[HVO_4]^{2-}$ ($\log\beta_{1,0,-3}$ = –14.93), $[H_2VO_4]^-$($\log\beta_{1,0,-2}$ = –6.76), $[V_2O_7]^{4-}$ ($\log\beta_{2,0,-6}$ = –29.71), $[HV_2O_7]^{3-}$($\log\beta_{2,0,-5}$ = –19.37), $[H_2V_2O_7]^{2-}$ ($\log\beta_{2,0,-4}$ = –10.87), $[V_4O_{13}]^{6-}$ ($\log\beta_{4,0,-10}$ = –37.02), $[HV_4O_{13}]^{5-}$ ($\log\beta_{4,0,-9}$ = –27.67), $[V_4O_{12}]^{4-}$ ($\log\beta_{4,0,-8}$ = –17.80), $[V_5O_{15}]^{5-}$ ($\log\beta_{5,0,-10}$ = –22.63), $[V_{10}O_{28}]^{6-}$ ($\log\beta_{10,0,-16}$ = –17.32), $[HV_{10}O_{28}]^{5-}$ ($\log\beta_{10,0,-15}$ = –10.70), $[H_2V_{10}O_{28}]^{4-}$ ($\log\beta_{10,0,-14}$ = –6.53) and $[H_3V_{10}O_{28}]^{3-}$ ($\log\beta_{10,0,-13}$ = –4.67).

Spectroscopic Measurements

UV/Vis Spectroscopy: For compounds **1–10** the spectra were recorded by dissolving the ligands or complexes in the appropriate solvent (see text). For the $V^{IV}O$–R(SO_3-sal)$_2$en system, the spectra were recorded upon changing the pH, with approximately fixed total vanadium and ligand concentrations. Two sets of measurements were made with an L/M ratio of 1 and with $C_{VO} \approx 4$ and 12 mM (C_{VO} = total metal ion concentration). The temperature was kept at 25.0 ± 0.3 °C with circulating water. In the figures we represent ε_m values vs. λ, [where ε_m = absorption/($b \cdot C_{VO}$), b = optical path (either 0.1- or 1-cm cells were used)]. The spectral range covered was normally 350–900 nm.

EPR Spectroscopy: For the frozen (77 K) aqueous solution spectra in the absence of ethylene glycol, a relatively broad background was obtained. Most spectra were therefore run with solutions containing 5% ethylene glycol. The $V^{IV}O$ EPR spectra were simulated using a program from Rockenbauer.[30] The EPR spectra may help to elucidate which groups coordinate in solution.[31] For the $V^{IV}O$ systems, we used the additivity rule to estimate the hyperfine coupling constant A_z^{estim} (and g_z^{estim}) based on the contributions $A_{z,i}$ (and $g_{\|,i}$) of each of the four equatorial donor groups [e.g. $A_z^{estim} = \sum_{i=1}^{4} A_{z,i}$]. The estimated accuracy of A_z^{estim} is $\pm 3 \times 10^{-4}$ cm^{-1}.[31] These data can be used to establish the most probable binding mode of the ligand in the complexes formed, but care must be taken since the contributions of the donor groups to the hyperfine coupling may depend on their orientation[60] or the charge of the ligand.[61] The influence of the axial donor groups (if any) was not taken into account.

^{1}H and ^{51}V NMR Spectroscopy: All NMR samples were prepared at room temperature immediately before NMR spectroscopic determinations. Ligand solutions for the NMR pH titrations were prepared in D_2O (99.995% D) by weighing the appropriate amount of the ligand in order to have the desired concentration. The pD values of these solutions were adjusted with DCl and CO_2-free NaOD solutions and measured with a Crison MicropH 2002 pH-meter with an Ingold 405-M5 combined electrode calibrated at 20 ± 1 °C with standard buffers at pH = 4.0 and 7.0. The final pH values were corrected for the deuterium isotope effect using pH = pD – 0.4.[62] Solutions containing the V^V complexes were prepared by weighing the appropriate amount of ligand and dissolving it in a H_2O solution of the vanadate salt of known concentration (with 10% D_2O) to obtain ^{51}V NMR spectra, or in a D_2O solution of the V^V salt when the samples were analysed by ^{1}H NMR spectroscopy, in order to have the desired L/M ratios. Several sets of experiments as a function of pH with different L/M ratios and total concentrations were carried out. The signal intensities of the NMR resonances were obtained using the program NUTS.[44] After baseline flattening, an iterative deconvolution subroutine (LF) was used to fit the peaks of the spectrum. This subroutine adjusts several parameters, namely the frequency, height, width at half height and area of the selected peaks. The areas obtained may then be used to calculate, for example, the concentrations of the different species.

Supporting Information (see also footnote on the first page of this article): Hydrogen bonding in H_2(*o*-van)$_2$en (**2A**), KH(*o*-van)$_2$en·2H_2O (**2B**) and Na[V^VO_2(Rpyr$_2$en)]·CH_3OH·3H_2O (**11**) (ESI-A), Some IR data for compounds **1**–**12** (ESI-B), UV/Vis data for the ligands and $V^{IV}O$ complexes prepared (ESI-C), Magnetic susceptibility data for complexes **8** and **9** (ESI-D), Study of the hydrolytic processes for SB **3** in aqueous solution (ESI-E)

[22] Since no cif file is presently available for this crystal structure, neither from CCDC nor from the supplementary data, it was not possible to access these data to make adequate comparisons. We may deduce that the structure is different since only one half of the molecule is found in the asymmetric unit. The molecule itself seems more planar and so the conformation as well as the packing are different.

Synthesis of Chiral, Half-Sandwich Ruthenium Complexes from Weakly Coordinated Solvent Species

Laetitia Jekki,[a] Corinne Pala,[a] Beatrice Calmuschi,[a] and Christian Ganter*[b]

Keywords: Chirality / P ligands / Ruthenium / Sandwich complexes

The bis(acetonitrile) species **7** has been synthesized in a multistep protocol. This chiral phosphaferrocene-containing, half-sandwich ruthenium complex easily provides two coordination sites due to the high lability of the coordinated solvent molecules. Although complex **7** could not be isolated in pure form, it serves as a valuable starting material for the preparation of other half-sandwich complexes with, for example, pyridine (**8**), tmeda (**9**), *N*-(2-dimethylaminoethyl)-morpholine (**10**), or tricyclohexylphosphine (**11**) as ligands. Whereas the morpholine complex **10** was obtained as almost a 1:1 mixture of diastereomers, the mixed MeCN/PCy_3 complex **11** was formed with a high level of diastereoselectivity (90% *de*). The molecular structures of complexes **8**, **10**, and the cyclopentadiene derivative **3a** were determined by X-ray diffraction.

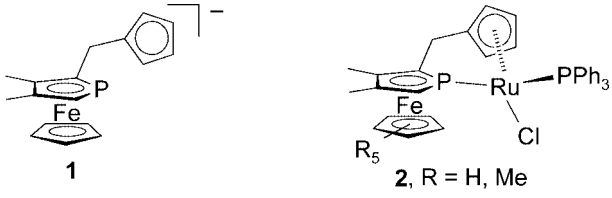
Introduction

In a series of previous papers we have outlined the chemistry of a new type of bidentate ligands that contain a substituted phosphaferrocene moiety as a chiral building block.[1–3] The coordination chemistry employing these new ligands, as well as their applicability in asymmetric catalysis, has been studied by us[1,4] and independently by other groups.[5–11] In a more recent project we have tethered the chiral phosphaferrocene unit to a cyclopentadienyl ring and explored the properties of this anionic ligand system **1** (Scheme 1).[12] For example, the half-sandwich complexes **2** were formed in the reaction of the Na salt of the Cp anion **1** with $[RuCl_2(PPh_3)_3]$.[13] A high diastereoselectivity of 90–99% *de* was observed for the formation of the stereogenic Ru atom in complexes **2**.



Scheme 1.

Furthermore, substitution of chloride in complex **2** for other ligands like I, H or H_2 was easily accomplished and proceeded in a stereospecific manner. However, all attempts to replace the tightly bound PPh_3 ligand by other donor ligands were unsuccessful. In order to have access to a larger array of half-sandwich complexes we set out to develop a new synthetic route based on a weakly coordinated bis(solvent) species that allows the weakly bonded ligands to be easily exchanged. Such bis(solvent) complexes might also be of interest for catalytic asymmetric transformations. Indeed, there is an increasing number of recent literature reports on the application of chiral half-sandwich complexes in catalytic asymmetric reactions.[14–19]

Results and Discussion

Our synthetic strategy had to avoid the presence of strongly binding phosphane ligands throughout the synthesis. Therefore, we chose the half-open ruthenocene **5** as a target, which should be easily converted into the cationic pentadiene complex **6** upon protonation. We hoped to exchange the diene ligand in **6** with two molecules of a donor solvent in the final step to yield the desired species with two potential coordination sites available.

A large number of attempts to prepare the half-open ruthenocene from the sodium salt of **1** were unsatisfactory, the product being obtained in low yields. However, exchange of Na for Tl as the cation gave a straightforward access to excellent yields of complex **5**. For this purpose, the Na derivative was hydrolysed in wet THF and the neutral cyclopentadiene derivative **3** was isolated as a pale-orange solid in 91% yield after chromatography. The NMR spectra indicated that **3** was formed as a 2.5:1 mixture of two isomers that differ in the distribution of the double bonds in the cyclopentadiene ring (Scheme 2).

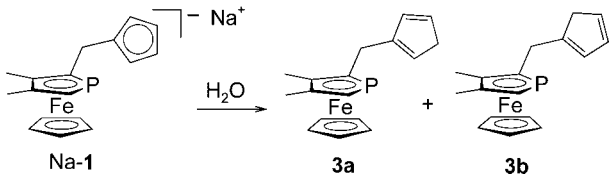

Scheme 2.

Both isomers have the phosphaferrocenylmethyl group attached to an olefinic carbon atom, as indicated by the signals for the CH_2 groups in the DEPT spectra in both cases. The isomers could not be separated by chromatography, but cooling a hexane solution of the mixture afforded crystals of one isomer suitable for X-ray diffraction. The molecular structure of **3a** is depicted in Figure 1 and relevant geometrical data are summarized in Table 1.

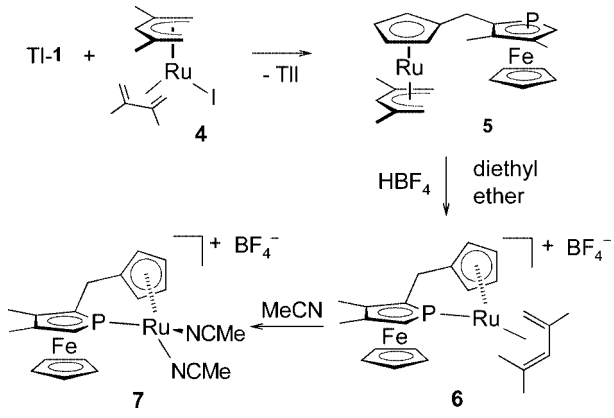
Treatment of a solution of cyclopentadiene **3** in diethyl ether with TlOEt precipitated the thallium cyclopentadienide Tl-**1**, which was isolated as a pale-yellow powder in almost quantitative yield after filtration and drying. The Tl salt was then allowed to react with the ruthenium butadiene iodide **4** [20] to give the half-open ruthenocene **5** (Scheme 3).



Scheme 3.

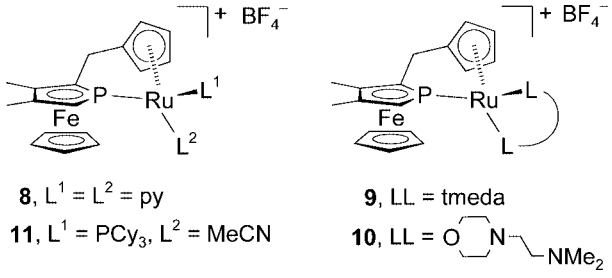
The best yield (76%) was obtained when an equimolar mixture of starting materials was heated as a slurry in toluene overnight. Complex **5** was isolated as a pale-yellow solid after removal of TlI by filtration and chromatography on alumina. The analytical data are in agreement with a half-sandwich structure, with the phosphorus not coordinated to the ruthenium atom. When an ethereal solution of complex **5** was treated dropwise with HBF_4 in diethyl ether, protonation of the pentadienyl ligand occurred at the terminal position to give an η^4-coordinated pentadiene ligand. This transformation is accompanied by the intramolecular coordination of the P atom of the phosphaferrocene moiety to the ruthenium atom, which thereby maintains an 18-electron count in the cationic product **6**. Due to the presence of the chiral phosphaferrocene group, the terminal carbons of the pentadienyl ligand are diastereotopic and the protonation leads to a 1:1 mixture of diastereomeric pentadiene complexes which could not be separated. Accordingly, the ^{31}P NMR spectrum shows two resonances at δ = 50.5 and 43.7 ppm, respectively, which are strongly downfield from the signal at δ = –76.0 ppm for the precursor complex **5** with a non-coordinated phosphorus.

The diene ligand in cationic complex **6** could easily be replaced by acetonitrile by stirring the complex in acetonitrile at room temperature for a couple of hours. Monitoring the reaction progress by ^{31}P NMR spectroscopy revealed that this is not a clean transformation. First, a new signal appears in the spectrum which is attributed to the bis(acetonitrile) species **7**; the intensity of this signal increases with time at the expense of the signals for the two isomeric diene complexes **6**. However, the bis(acetonitrile) complex has a limited stability under the reaction conditions and eventually starts to decompose to uncharacterized products before all the diene complex has been consumed. The reproducibility of the reaction is not very good: repeated experiments under identical conditions led, in some cases, to almost pure solutions of the bis(acetonitrile) species **7**, while in other runs considerable degradation occurred. Variation of the reaction parameters (concentration, temperature, irradiation) did not improve the reaction performance. Attempts to isolate complex **7** in pure form failed and the characteri-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

zation had therefore to be carried out from the reaction solution.

However, the high reactivity of the bis(solvent) complex **7** could be exploited in subsequent substitution reactions (Scheme 4). For example, when the cation **6** was stirred in acetonitrile in the presence of an excess of pyridine for five hours, the respective bis(pyridine) complex **8** could be isolated in 91% yield after precipitation from the solution with diethyl ether. During the reaction, the characteristic signals of **7** are first detected in the ^{31}P NMR spectrum, followed by the appearance of the signal of complex **8**. The use of acetonitrile as solvent is essential for a fast reaction. Indeed, when acetone was used instead of acetonitrile, the reaction proceeded much slower and the conversion was incomplete even after two days. Crystals suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into an acetone solution of bis(pyridine) complex **8**. An ORTEP view of the molecular structure is depicted in Figure 2; relevant geometrical data are summarized in Table 2.



Scheme 4.

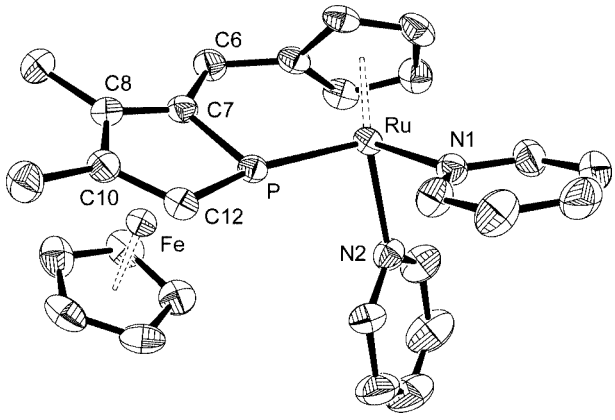


Figure 2. Molecular structure of the cation of complex **8**.

Similarly to the preparation of **8**, the tmeda complex **9** was prepared in 98% isolated yield by treatment of an acetonitrile solution of diene complex **6** with one equivalent of tmeda. When a solution of diene cation **6** in acetonitrile was treated with one equivalent of *N*-(2-dimethylaminoethyl)morpholine complex **10** was formed, with the morpholine derivative coordinated as an *N*,*N* ′-chelate ligand.

In the course of this reaction the ruthenium center becomes stereogenic and complex **10** is formed as two diastereomers in a ratio of approximately 3:2. This poor diastereoselectivity reflects the similar steric demands of the two

different nitrogen donor groups of the morpholine derivative. As the two groups on nitrogen are incorporated into the heterocyclic system of the morpholine the flexibility of this donor is fairly low, and it should therefore be sterically less demanding than the open-chain NEt_2 analogue. Thus, the difference in steric bulk of the morpholine and the dimethylamino donor groups is less pronounced than one would expect at first glance. While a chromatographic separation of the two diastereomeric morpholine complexes **10** was not successful, one diastereomer could be obtained in pure form by crystallization. The molecular structure of this complex was determined by X-ray diffraction and is depicted in Figure 3; relevant geometrical data are summarized in Table 3.

The Ru–P distances in the two cationic complexes **8** (228 pm) and **10** (229 pm) are almost identical and slightly longer than in neutral Ru-phosphaferrocene half-sandwich complexes (224–225 pm).[2,13] As expected, the Ru–N bonds are significantly shorter in the pyridine complex **8** (214 pm) than in the morpholine derivative **10** (221 pm) with its terti-

ary amine donor functions. As is usually observed, on going from an uncoordinated phosphaferrocene derivative (**3a**) to the metal complexes **8** and **10** the C–P–C angle in the phospholyl ring increases slightly from 88.9° (**3**) to 90.9° (**8**) and 90.6° (**10**). Furthermore, the P–C bonds in the phospholyl ring contract slightly on coordination from ca. 178 pm to 175–176 pm.

It was also possible to prepare a mono(acetonitrile) derivative starting from the cationic complex **6**. Thus, when an acetonitrile solution of **6** was treated with one equivalent of tricyclohexylphosphane (PCy_3), the mixed P,N complex **11** was formed in 96% yield. In contrast to the morpholine derivative **10**, a high level of stereodiscrimination (90% *de*) was observed for the formation of complex **11**. This reflects the different steric properties of the acetonitrile and PCy_3 ligands.

Conclusions

A high-yield route to half-sandwich ruthenium complexes with a tethered phosphaferrocene donor and two loosely coordinated acetonitrile molecules has been devised. The bis(acetonitrile) complex is very reactive and easily provides two available coordination sites at the ruthenium. The synthetic value of this approach has been corroborated by the subsequent preparation of some derivatives with mono- and bidentate nitrogen ligands. We are currently trying to extend and improve the results with respect to the stereodiscrimination in the complexation of difunctional ligands and the use of the solvent complex for catalytic applications.

Experimental Section

All experiments were performed under nitrogen using Schlenk and vacuum-line techniques. Hexane and toluene were distilled from sodium; $CHCl_3$ and CH_2Cl_2 from CaH_2. THF and diethyl ether were distilled from sodium/benzophenone. Acetonitrile was dried with P_4O_{10} and distilled from CaH_2. Methanol and acetone were dried with magnesium. The solvents were kept in Schlenk flasks under nitrogen. Silica gel or alumina were heated to 200 °C, cooled to room temperature under vacuum, and stored under nitrogen. Alumina (Riedel-de Haën) was deactivated by addition of 5% water. NMR spectra were measured with Varian Mercury 200, VXR 300 and Unity 500 spectrometers. EI and FAB mass spectra were measured on a Finnigan MAT 95 spectrometer. Elemental analyses were performed by the microanalytical laboratory of the Universität Düsseldorf. Na-**1** [12] and ruthenium iodide **4** [20] were prepared as described in the literature.

Cyclopentadiene 3: Na-**1** was obtained by addition of $NaBEt_3H$ (0.62 mmol, 0.4 mL of a 1.5 M solution in THF) to a solution of 6-(3,4-dimethylphosphaferrocen-2-yl)fulvene (127.7 mg, 0.41 mmol) in diethyl ether/THF (1:1, 30 mL) at room temperature. After stirring for 45 min water (5 mL) was added to the orange solution and the phases were separated. The organic phase was washed with water, dried with Na_2SO_4, and the solvent was removed in vacuum. The crude product was filtered through a short plug of alumina with hexane as eluent. After evaporation of the solvent, **3** (115.7 mg, 0.37 mmol, 91%) was isolated as an orange crystalline powder as a mixture of two isomers in a ratio of ca. 1:2.5. Crystals suitable for X-ray diffraction were obtained by slowly cooling a hexane solution to –18 °C. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.21, 2.14 (s, 3 H, CH_3), 2.93 (m, 4 H, CH_2 in C_5H_5R), 3.26 (m, 4 H, PCC*H*$_2$, major + minor), 3.71 (d, $J_{C,P}$ = 35.7 Hz, 2 H, PCH, major + minor), 4.13 (s, 2 × 5 H, Cp, major + minor), 5.9 (s, 1 H, C_5H_5R, major), 6.24, 6.06 (s, 1 H, C_5H_5R, minor), 6.39 (s, 2 H, C_5H_5R, major + minor), 6.47 (s, 1 H, C_5H_5R, major) ppm. ^{13}C{^{1}H} (125.6 MHz, $CDCl_3$): major isomer: δ = 17.1, 13.7 (s, CH_3), 31.1 (d, $J_{C,P}$ = 20.2 Hz, PC*C*H$_2$), 41.0 (s, *C*H$_2$ in C_5H_5R), 72.0 (s, Cp), 75.6 (d, $J_{C,P}$ = 58.5 Hz, PCH), 93.3 (d, $J_{C,P}$ = 5.7 Hz, *C*CH$_3$), 95.6 (d, $J_{C,P}$ = 6.7 Hz, *C*CH$_3$), 97.4 (d, $J_{C,P}$ = 57.6 Hz, P*C*CH$_2$), 134.4, 133.5, 126.5 (s, CH in C_5H_5R), 146.6 (s, CR in C_5H_5R) ppm; minor isomer: δ = 17.1, 13.7 (s, CH_3), 32.0 (d, $J_{C,P}$ = 22 Hz, PC*C*H$_2$), 43.2 (s, *C*H$_2$ in C_5H_5R), 72.0 (s, Cp), 75.5 (d, $J_{C,P}$ = 57.5 Hz, PCH), 93.3 (d, $J_{C,P}$ = 5.7 Hz, *C*CH$_3$), 95.6 (d, $J_{C,P}$ = 6.7 Hz, *C*CH$_3$), 98.3 (d, $J_{C,P}$ = 57.5 Hz, P*C*CH$_2$), 132.2, 130.7, 127.0 (s, CH in C_5H_5), 149.2 (s, CR in C_5H_5R) ppm. ^{31}P NMR (80.95 MHz, $CDCl_3$): δ = –79.7 (s, minor), –80.1 (s, major) ppm. MS (70 eV): *m*/*z* (%) = 310 (42) [M$^+$], 244.9 (47) [M$^+$ – Cp]. $C_{17}H_{19}FeP$ (310.2): calcd. C 65.83, H 6.17; found C 65.61, H 6.08.

Thallium Salt Tl-1: TlOEt (0.22 mL, 3.06 mmol) was added dropwise to a solution of cyclopentadiene **3** (947 mg, 3.06 mmol) in diethyl ether (10 mL) at room temperature. After stirring for 30 min the precipitate was isolated by filtration, washed with diethyl ether, and dried in vacuo to give 1.74 g (3.03 mmol, 99%) of Tl-**1** as a pale-orange powder. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.23 (s, CH_3), 2.26 (s, CH_3), 3.28 (dd, $J_{H,P}$ = 15.3, $J_{H,H}$ = 7.0 Hz, 1 H, CH_2), 3.49 (m, 1 H, CH_2), 3.66 (d, $J_{H,P}$ = 35.7 Hz, 1 H, PCH), 4.12 (s, 5 H, Cp), 5.84 (m, 2 H, C_5H_4), 5.99 (m, 2 H, C_5H_4) ppm. ^{13}C{^{1}H} (125.6 MHz, $CDCl_3$): δ = 14.2 (s, CH_3), 17.2 (s, CH_3), 29.9 (d, $J_{C,P}$ = 20.9 Hz, CH_2), 72.1 (s, Cp), 75.3 (d, $J_{C,P}$ = 58.1 Hz, PCH), 92.9 (d, $J_{C,P}$ = 4.4 Hz, *C*CH$_3$), 95.8 (d, $J_{C,P}$ = 6.5 Hz, *C*CH$_3$), 105.5 (s, C_5H_4), 106.1 (d, $J_{C,P}$ = 54.9 Hz, P*C*CH$_2$), 108.0 (s, C_5H_4), 132.6 (s, *C*CH$_2$) ppm. ^{31}P NMR (80.95 MHz, $CDCl_3$): δ = –77.7 (s) ppm. SIMS (70 eV): *m*/*z* = 514 [M$^+$], 310.2 [M$^+$ – Tl], 205.1 [Tl$^+$]. $C_{17}H_{18}FePTl$ (513.53): calcd. C 39.76, H 3.53, found C 39.01, H 3.39.

(Dimethylpentadienyl)ruthenium Complex 5: Tl-**1** (1.13 g, 2.21 mmol) was added to a suspension of ruthenium iodide **4** (894 mg, 2.21 mmol) in 35 mL of toluene and the mixture was refluxed overnight. TlI was removed by filtration through Kieselguhr and the filtrate was evaporated to dryness. The residue was extracted with hexane, the solution filtered through alumina, and the solvent was removed in vacuo to yield **5** (849 mg, 1.68 mmol, 76%) as an orange solid. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.29 (d, $J_{H,H}$ = 2.4 Hz, 1 H, H$_{endo}$), 0.31 (d, $J_{H,H}$ = 2.4 Hz, 1 H, H$_{endo}$), 1.87 (s, CH_3), 1.89 (s, CH_3), 1.90 (s, CH_3), 1.92 (s, CH_3), 2.86 (d, $J_{H,H}$ = 2.4 Hz, 1 H, H$_{exo}$), 2.87 (d, $J_{H,H}$ = 2.4 Hz, 1 H, H$_{exo}$), 3.07 (m, 2 H, CH_2), 3.60 (d, $J_{H,P}$ = 36.0 Hz, 1 H, PCH), 3.90 (s, 5 H, Cp), 4.31 (m, 2 H, C_5H_4), 4.56 (m, 2 H, C_5H_4), 5.34 (s, CH) ppm. ^{13}C{^{1}H} (125.6 MHz, $CDCl_3$): δ = 13.9 (s, CH_3), 16.9 (s, CH_3), 27.9 (s, 2 × CH_3), 30.5 (d, $J_{C,P}$ = 20.9 Hz, CH_2), 42.2 (s, =CH_2), 42.3 (s, =CH_2) 72.2 (s, Cp), 76.2 (d, $J_{C,P}$ = 58.8 Hz, PCH), 77.4 (s, RC_5H_4), 78.0 (s, RC_5H_4), 78.5 (s, RC_5H_4), 79.1 (s, RC_5H_4), 92.3 (s, CH_2=*C*), 92.7 (s, CH), 95.7 (d, $J_{C,P}$ = 6.1 Hz, *C*CH$_3$), 98.8 (d, $J_{C,P}$ = 2.8 Hz, *C*CH$_3$), 100.2 (d, $J_{C,P}$ = 58.2 Hz, P*C*CH$_2$) ppm. ^{31}P NMR (80.95 MHz, $CDCl_3$): δ = –76.0 (s) ppm. MS (70 eV): *m*/*z* = 505.8 [M$^+$], 309.9 [M$^+$ – Ru – C_7H_{11}], 244.9 [M$^+$ – Ru – C_7H_{11} – Cp]. HRMS for $C_{24}H_{29}FePRu$: calcd. 506.039346; found 506.039321.

(η^4-2,4-Dimethylpentadiene)ruthenium Complex 6: HBF_4 (0.38 mL, 54% solution in diethyl ether, 2.76 mmol) was added dropwise to a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solution of complex **5** (943 mg, 1.87 mmol) in diethyl ether (50 mL) at –78 °C. After stirring for 30 min at room temperature the precipitate was isolated by filtration, washed twice with diethyl ether, and dried in vacuo to give 1.05 g (1.78 mmol, 95%) of complex **6** as a 1:1 mixture of isomers as an orange powder. ^{1}H NMR (500 MHz, [D$_6$]acetone): isomer 1: δ = 1.46 (d, $J_{H,H}$ = 8.9 Hz, 3 H, CH_3), 2.22 (s, CH_3), 2.28 (s, CH_3), 2.34 (s, CH_3), 2.35 (m, 2 H, =CH_2), 2.40 (s, CH_3), 2.93 (m, 2 H, CH_2), 3.70 (d, $J_{H,P}$ = 32.0 Hz, 1 H, PCH), 3.81 (m, 1 H, =CH-C), 4.63 (m, 1 H, C_5H_4), 4.65 (s, 5 H, Cp), 5.38 (m, 1 H, C_5H_4), 5.61 (m, 1 H, C_5H_4), 5.83 (m, 1 H, C_5H_4) ppm; isomer 2: δ = 1.24 (d, $J_{H,H}$ = 8.4 Hz, 3 H, CH_3), 1.83 (s, CH_3), 1.91 (m, 2 H, = CH_2), 2.30 (s, CH_3), 2.31 (s, CH_3), 2.47 (s, CH_3), 3.01 (m, 2 H, CH_2), 3.38 (m, 1 H, =CH-C), 4.10 (d, $J_{H,P}$ = 32.4 Hz, 1 H, PCH), 4.51 (s, 5 H, Cp), 4.83 (m, 1 H, C_5H_4), 5.25 (m, 1 H, C_5H_4), 5.63 (m, 1 H, C_5H_4), 5.73 (m, 1 H, C_5H_4) ppm. ^{13}C{^{1}H} (125.6 MHz, [D$_6$]acetone): isomer 1: δ = 15.9 (d, $J_{C,P}$ = 6.0 Hz, CH_3), 16.1 (d, $J_{C,P}$ = 5.6 Hz, CH_3), 23.6 (d, $J_{C,P}$ = 15.9 Hz, CH_2), 24.6 (s, CH_3), 26.4 (s, CH_3), 34.3 (s, CH_3), 43.2 (s, =CH_2), 43.3 (s, =*C*H-C), 57.5 (s, PCH), 76.1 (s, Cp), 82.8 (s, RC_5H_4), 85.4 (s, RC_5H_4), 86.9 (s, RC_5H_4), 88.9 (s, RC_5H_4) ppm; isomer 2: δ = 13.9 (s, CH_3), 14.0 (d, $J_{C,P}$ = 5.0 Hz, CH_3), 23.9 (d, $J_{C,P}$ = 16.5 Hz, CH_2), 24.7 (s, CH_3), 26.0 (s, CH_3), 34.0 (s, CH_3), 43.8 (s, =CH_2), 43.9 (s, =*C*H-C), 60.4 (s, PCH), 76.5 (s, Cp), 83.3 (s, RC_5H_4), 83.6 (s, RC_5H_4), 85.8 (s, RC_5H_4), 90.2 (d, $J_{C,P}$ = 4.9 Hz, RC_5H_4) ppm. ^{31}P NMR (80.95 MHz, $CDCl_3$): δ = 50.5 (s, isomer 1), 43.7 (s, isomer 2) ppm. SIMS (70 eV): *m*/*z* = 507 [M$^+$], 411 [M$^+$ – C_7H_{11}]. $C_{24}H_{30}BF_4FePRu$ (593.2): calcd. C 48.59, H 5.10; found C 47.85, H 5.18.

Bis(acetonitrile) Complex 7: A solution of cationic complex **6** (118 mg, 0.20 mmol) in 15 mL of acetonitrile was stirred at room temperature. The reaction progress was monitored by ^{31}P NMR spectroscopy. After 4 h all volatiles were evaporated off under high vacuum to give an orange oil of **7** which was immediately characterized by NMR spectroscopy in CD_3CN. ^{1}H NMR (200 MHz, CD_3CN): δ = 2.20 (s, 6 H, CH_3CN), 2.44, 2.42 (2 × s, 3 H, CH_3), 2.72 (m, 2 H, CH_2), 3.89 (d, $J_{H,P}$ = 34.2 Hz, 1 H, PCH), 4.28 (br. s, 1 H, C_5H_4), 4.52 (s, 5 H, Cp), 5.37, 5.27, 4.71 (3 × br. s, 1 H, C_5H_4) ppm. ^{31}P NMR (202.25 MHz, CD_3CN): δ = 4.2 (s) ppm.

Bis(pyridine) Complex 8: An excess of pyridine (260 µL, 3.21 mmol) was added to a solution of cationic complex **6** (336 mg, 0.57 mmol) in 15 mL of acetonitrile at room temperature. The reaction mixture was stirred for 4 h. The solvents were removed under high vacuum to give an orange oil, which was redissolved in acetone. Complex **8** (338 mg, 0.52mmol, 91%) was isolated as an orange powder upon precipitation with diethyl ether. Red crystals were obtained by diffusion of diethyl ether into an acetone solution. ^{1}H NMR (500 MHz, $[CD_3]_2CO$): δ = 2.27, 2.26 (2 × s, 3 H, CH_3), 2.65 (m, 2 H, CH_2-Phosp.), 3.88 (d, $J_{H,P}$ = 33.3 Hz, 1 H, PCH), 4.11 (s, 5 H, Cp), 5.38, 5.10, 4.73, 4.12 (4 × s, 1 H, C_5H_4R), 7.51, 7.36 (br. t, *J* = 7.0 Hz, 2 H, C_5H_5N-H$_{meta}$), 8.00, 7.88 (2 × br. t, *J* = 7.6 Hz, 1 H, C_5H_5N-H$_{para}$), 8.94 (br. d, *J* = 5.2 Hz, 2 H, C_5H_5N-H$_{ortho}$), 9.19 (br. d, *J* = 4.9 Hz, 2 H, C_5H_5N-H$_{ortho}$) ppm. ^{13}C{^{1}H} (125.6 MHz, $[CD_3]_2CO$): δ = 16.4, 14.3 (2 × s, CH_3), 24.1 (d, $J_{C,P}$ = 16.3 Hz, CH_2), 62.2 (s, C_5H_4), 62.5 (d, $J_{C,P}$ = 36.5 Hz, PCH), 69.9 (s, C_5H_4), 74.8 (s, Cp), 83.2 (d, $J_{C,P}$ = 10.5 Hz, C_5H_4), 85.1 (d, *J* = 5.8 Hz, C_5H_4), 89.2 (s, CR in RC_5H_4), 91.2 (d, *J* = 2 Hz, P*C*CH_2), 111.4 (d, *J* = 7.66 Hz, *C*CH_3), 111.7 (d, *J* = 12.5 Hz, *C*CH_3), 126.6, 126.4 (2 × s, C$_{meta}$-C_5H_5N), 138.3, 138.2 (2 × s, C$_{para}$-C_5H_5N), 158.4, 157.9 (2 × d, $J_{C,P}$ = 7.7 Hz, C$_{ortho}$-C_5H_5N) ppm. ^{31}P NMR (202.25 MHz, $[CD_3]_2CO$): δ = 10.5 (s) ppm. $C_{27}H_{28}BF_4FePN_2Ru$ (655.2): calcd. C 49.49, H 4.31, N 4.28; found C 48.82, H 4.38, N 4.19. FAB MS: *m*/*z* = 490 [cation – py], 411 [cation – 2 py].

Tetramethylethylenediamine Complex 9: tmeda (85 µL, 0.56 mmol) was added to a solution of complex **6** (331.6 mg, 0.56 mmol) in 15 mL of acetonitrile at room temperature. The reaction mixture was stirred for 7 h and the solvent was then evaporated under high vacuum to give **9** as an orange powder (329.4 mg, 96%). ^{1}H NMR (500 MHz, CD_3CN): δ = 2.20, 2.18 (2 × s, 3 H, CCH_3), 2.33 (m, 2 H, C_5H_4-C*H* $_2$), 2.52 (m, 2 H, NCH_2), 2.72 (d, $J_{H,P}$ = 3 Hz, 3 H, NCH_3), 2.72 (m, 1 H, NCH_2), 2.87 (m, 1 H, NCH_2), 3.13 (s, 3 H, NCH_3), 3.15 (d, $J_{H,P}$ = 4 Hz, 3 H, NCH_3), 3.28 (s, 3 H, NCH_3), 3.53 (d, $J_{H,P}$ = 32 Hz, 1 H, PCH), 4.11, 4.09 (2 × m, 1 H, C_5H_4), 4.25 (s, 5 H, Cp), 5.06, 4.64 (2 × m, 1 H, C_5H_4) ppm. ^{13}C{^{1}H} (125.6 MHz, CD_3CN): δ = 14.3 (d, $J_{C,P}$ = 4.8 Hz, CH_3), 16.5 (s, CH_3), 23.8 (d, $J_{C,P}$ = 16.3 Hz, $CpCH_2$), 60.0, 59.4 (2 × s, NCH_3), 61.7 (s, C_5H_4), 61.7 (d, $J_{C,P}$ = 36.5 Hz, PCH), 62.3 (d, *J* = 15.3 Hz, NCH_3), 62.9 (d, *J* = 16.3 Hz, NCH_3), 64.5, 63.8 (2 × s, NCH_2), 66.8 (s, C_5H_4), 75.3 (s, Cp), 77.5 (d, $J_{C,P}$ = 10.5 Hz, C_5H_4), 89.5 (s, C$_{quat.}$), 90.5 (s, C_5H_4), 107.8, 110.6, 117.5 (3 × s, C$_{quat.}$) ppm. ^{31}P NMR (80.95 MHz, CD_3CN): δ = 16.5 (s) ppm. FAB MS (NBA matrix): *m*/*z* = 527 [cation], 87 [BF_4^-]. $C_{23}H_{34}BF_4FeN_2PRu$: calcd C 45.05, H 5.59, N 4.57; found C 45.90, H 5.78, N 3.84.

Morpholine Complex 10: *N*-(2-Dimethylaminoethyl)morpholine (1.3 equiv., 82 µL, 0.48 mmol) was added to a solution of cationic complex **6** (220 mg, 0.37 mmol) in 10 mL of acetonitrile and stirred for 1 d at room temperature. The solvent was evaporated under high vacuum to give **10** as a red powder (223.5 mg, 97%) as a mixture of isomers in a ratio of about 3:2. Crystals suitable for X-ray diffraction were obtained by layering a CH_2Cl_2 solution with hexane. ^{1}H NMR (500 MHz, CD_3CN, mixture of isomers): δ = 2.21, 2.20, 2.20, 2.19 (4 × s, 3 H, CH_3), 3.27, 3.25, 3.24, 3.12 (4 × s, 3 H, NCH_3), 4.24 (s, 5 H, Cp), 4.28 (s, 5 H, Cp) ppm. ^{31}P NMR (202 MHz, CD_3CN): δ = 13.9 (s, major), 12.9 (s, minor) ppm. FAB MS (NBA matrix): *m*/*z* = 569 [cation], 411 [cation – morpholine]. $C_{25}H_{36}BF_4FeN_2OPRu$ (655.3): calcd. C 45.82, H 5.54, N 4.28; found C 45.01, H 5.67, N 4.51.

Tricyclohexylphosphane Complex 11: One equivalent of tricyclohexylphosphane (97 mg, 0.37 mmol) was added to a solution of complex **6** (222 mg, 0.37 mmol) in 10 mL of acetonitrile and stirred for 1 d at room temperature. The solvent was evaporated under high vacuum to give Ru-**9** as an orange foam (291mg, 96%) as a mixture of two isomers in a ratio of about 19:1 (90% *de*). ^{1}H NMR (300 MHz, C_6D_6): major isomer: δ = 1.9–1.1 (m, 36 H, PCy_3 and CH_3CN), 1.94, 1.88 (2 × s, 3 H, CH_3), 2.38 (m, 1 H, $PCCH_2$), 2.59 (m, 1 H, $PCCH_2$), 3.33 (d, $J_{H,P}$ = 32.6 Hz, 1 H, PCH), 3.36 (s, 1 H, C_5H_4), 4.33 (s, 5 H, Cp), 5.01, 5.20, 5.86 (3 × s, 1 H, C_5H_4) ppm. ^{31}P NMR (121.45 MHz, C_6D_6): major isomer: δ = 59.6 (d, $J_{P,P}$ = 55 Hz, PFc), 18.1 (d, $J_{P,P}$ = 55 Hz, PCy_3) ppm; minor isomer: δ = 59.4 (d, $J_{P,P}$ = 48 Hz, PFc), 18.1 (d, $J_{P,P}$ = 48 Hz, PCy_3) ppm.

X-ray Crystallographic Study: Crystal data and details of the structure determination are listed in Table 4. Data collection was performed with a Bruker Smart APEX CCD (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator) area detector. The unit-cell parameters were obtained by the least-squares refinement of 8096 reflections. All the structures were solved by direct methods (SHELXS-97)[21] and refined by full-matrix least-squares procedures based on F^2 with all measured reflections (SHELXL-97).[22] The SADABS[23] program was used for absorption correction of the structures. All non-hydrogen atoms were refined anisotropically. H atoms were in part located from difference Fourier maps; the remaining hydrogens were introduced at their idealized positions [*d*(CH) = 0.98 Å] and were refined using a riding model. The absolute configuration for complex **3a** was confirmed by evaluation of the Flack parameter.[24] CCDC-237071 (for **3a**), -237069

Metal-Directed Stereoselective Syntheses of Homochiral Complexes of *exo*-Bidentate Binaphthol Derivatives

Ruihu Wang,[a,b] Lijin Xu,[a] Jianxin Ji,[a] Qian Shi,[a,b] Yueming Li,[a] Zhongyuan Zhou,[a] Maochun Hong,*[b] and Albert S. C. Chan*[a]

Keywords: Cadmium / N ligands / Palladium / Silver / Zinc

The homochiral *exo*-bidentate ligands (*S*)-2,2′-bis(pyridylmethyleneoxy)-1,1′-binaphthyl [(*S*)-L] and (*R*)-2,2′-bis(pyridylmethyleneoxy)-1,1′-binaphthyl [(*R*)-L] were synthesized and employed for the preparation of coordination complexes with the aim of investigating the effect of an axially chiral 1,1′-binaphthyl connector on self-assembly process. Five homochiral complexes, $[Ag\{(S)\text{-}L\}(ClO_4)]_n$ (**1**), $[Ag\{(R)\text{-}L\}(ClO_4)]_n$ (**2**), $[\{Cd\{(S)\text{-}L\}(H_2O)Cl_2\}(H_2O)_{0.5}]_n$ (**3**), $[(Zn\{(S)\text{-}L\}Cl_2)(DMF)_{0.5}(H_2O)_{0.5}]_n$ (**4**), and $[(Pd_2\{(S)\text{-}L\}_2Cl_4)(H_2O)_{1.5}]_n$ (**5**), have been prepared and characterized by single-crystal X-ray diffraction analyses. The enantiomeric complexes **1** and **2** are isomorphous and are formed through interconnection of ligands and two-coordinate Ag^I centers. Complex **3** possesses a similar structural framework to **1** and is formed with two nitrogen atoms from (*S*)-L coordinating to six-coordinate Cd^{II} in a *trans* mode. The interlocking in part of the adjacent, one-dimensional helix-like chains stabilizes its structure. Complex **4** is a one-dimensional zigzag chain and is formed through interconnection of (*S*)-L and $ZnCl_2$ units. The *exo*-bidentate (*S*)-L ligand in **5** links square-planar Pd^{II} into a homochiral dinuclear metallomacrocycle.

Introduction

The design and construction of well-defined supramolecular architectures through metal-directed self-assembly of metal ions and organic ligands or organometallic substances are important for developing rational approaches to prepare novel metallosupramoleclues with intriguing structural and functional features.[1–4] In this context, the selection of multifunctional organic ligands containing appropriate coordination sites linked by a connector with specific positional orientation and/or functionality is especially crucial.[3,4] Various ligands have been tailored to recognize the intrinsic geometric preferences of specific metal ions or to encode structural constraints upon their coordination to metal ions. Metal–pyridine coordination has proved to be an excellent tool in self-assembly as it is strongly affected by the structural characteristics of the connector groups between the organic bridging ligands and the metal ions. Many pyridine-donor bis-monodentate ligands interconnected by rigid or flexible connectors, such as alkyl[5] or aryl groups,[6] or even organometallic complexes,[7] have been employed to construct metal-organic frameworks. Thus, it is of high interest to establish the rules that control the self-assembly process through chemical programming of suitable components and assembly algorithms.

In our previous study, we prepared a series of pyridine-donor ligands by connecting methylsulfanylpyridyl to aromatic ring connectors; the assembly of such ligands and metal ions resulted in several unique structural motifs, such as a metallosupramolecular cube,[8a] a one-dimensional nanotube,[8b] a dimetallomacrocycle,[8c] square rings with guest molecules,[8d] and a two-dimensional crown-like structure.[8d,8e] From the viewpoint of constructing functional complexes, it may be more valuable to introduce functionalized chiral groups directly into *exo*-bidentate pyridyl ligands as connectors instead of using nonfunctional connectors. Optically active 1,1′-bi-2-naphthol (BINOL) derivatives have been extensively applied to asymmetric synthesis and molecular recognition owing to their conformational stability and molecular flexibility.[9] Moreover, BINOL is also a good chiral connector for the design of new pyridine-donor ligands and the construction of novel, chiral, conjugated materials and fluorescent sensors.[10] We have recently investigated the effect of an axially chiral BINOL backbone on the self-assembly process through the introduction of an optically active BINOL backbone into *exo*-bidentate pyridyl ligands. The preliminary results indicated that the rigidity of the binaphthyl backbone facilitates the transfer of chiral information.[9d] In an effort to elucidate the effect of the coordination geometry of the metal ions on the self-

assembly process, we report herein the syntheses and characterizations of a series of homochiral complexes {[Ag{(*S*)-L}(ClO_4)]$_n$ (**1**), [Ag{(*R*)-L}(ClO_4)]$_n$ (**2**), [{Cd{(*S*)-L}(H_2O)Cl_2}(H_2O)$_{0.5}$]$_n$ (**3**), [(Zn{(*S*)-L}Cl_2)(DMF)$_{0.5}$(H_2O)$_{0.5}$]$_n$ (**4**), and [(Pd_2){(*S*)-L}$_2Cl_4$)(H_2O)$_{1.5}$]$_n$ (**5**) [(*S*)-L = (*S*)-2,2′-bis(pyridylmethyleneoxy)-1,1′-binaphthalene; (*R*)-L = (*R*)-2,2′-bis(pyridylmethyleneoxy)-1,1′-binaphthalene], in which Ag^I, Cd^{II}, Zn^{II}, and Pd^{II} adopt distorted linear, octahedral, tetrahedral, and square-planar geometries, respectively.

(*R*)-L

Results and Discussion

Syntheses

The reaction of (*S*)-1,1′-bi-2-naphthol or (*R*)-1,1′-bi-2-naphthol with 4-picolyl chloride hydrochloride was first carried out in the presence of K_2CO_3 in refluxing acetone under nitrogen for three days to afford *exo*-bidentate (*S*)-L or (*R*)-L in low yields (ca. 15%). The main product of the reaction was a mono-substituted compound (ca. 72%). However, when NaOH was used as the base under the same reaction conditions, (*S*)-L or (*R*)-L was obtained in high yield (88%). These results indicate that the base has a great effect on the yield of (*S*)-L or (*R*)-L. The specific optical rotations of (*S*)-L and (*R*)-L are –54.44° and 54.51° ($[\alpha]_D^{20}$, *c* = 1, THF), respectively. In comparison, the specific optical rotations of (*S*)- and (*R*)-1,1′-bi-2-naphthol are –35.50° and 35.50° ($[\alpha]_D^{20}$, *c* = 1, THF), respectively, thus indicating that the methylpyridine-donor groups in the ligands affect the chiral twist of BINOL. The ligands (*S*)-L and (*R*)-L are soluble in most organic solvents. The reaction of (*S*)-L or (*R*)-L with $AgClO_4$ in a 1:1 molar ratio in MeCN/H_2O (2:1) led to the formation of the corresponding enantiomeric complex **1** or **2**, respectively. As anticipated for (*S*) and (*R*) enantiomers, **1** and **2** possess the same structural framework and equal but opposite optical rotation. It is well known that the coordination geometry of metal ions plays an important role in the construction of supramolecular architectures. Hence, the successful syntheses of **1** and **2** prompted us to go beyond the two-coordinate Ag^I to metal ions of high coordination numbers. The reaction of (*S*)-L with $CdCl_2$ or $ZnCl_2$ in MeCN/H_2O afforded precipitates that were not soluble in any solvent. When a MeOH solution of (*S*)-L was layered on top of an aqueous solution of $CdCl_2$, suitable single crystals were formed. However, crystals of lower quality were produced using $ZnCl_2$ instead of $CdCl_2$ under the same conditions. In contrast, the diffusion of diethyl ether into a DMF/MeCN solution of (*S*)-L and $ZnCl_2$ resulted in crystals suitable for an X-ray single-crystal diffraction study.

Structural Description

[Ag{(S)-L}(ClO_4)]$_n$ (1) and [Ag{(R)-L}(ClO_4)]$_n$ (2)

As anticipated, the enantiomeric complexes **1** and **2** are isomorphous. The single-crystal X-ray structural analyses reveal that they consist of one-dimensional, helix-like chains formed through interconnection of two-coordinate Ag^I centers and homochiral ligands. As shown in Figure 1, Ag^I is in a distorted linear geometry and is coordinated by two nitrogen atoms from different ligands. The Ag–N bond distances (Table 1) are in the range of 2.157(4)–2.162(4) Å, which are typical values for Ag^I–N_{py} coordination distances.[8b,8c] The N(1)–Ag–N(2A) bond angle of 172.65(1)° in **2** is slightly smaller than that of 175.34(15)° in **1**. (*S*)-L in **1** and (*R*)-L in **2** bind in an *exo*-bidentate mode to bridge a pair of adjacent Ag^I centers. As shown in Table 2, the dihedral angles between two naphthyl rings of (*S*)-L and (*R*)-L are 69.3° and 69.8°, respectively, which are approximately equal, thus indicating that the BINOL backbone has hardly been affected. The dihedral angles between the naphthyl rings and their corresponding pyridyl rings are 41.9° and 87.7°, respectively, in **1**. The corresponding angles are 45.1° and 85.6°, respectively, in **2**. The distance between two Ag^I centers bridged by (*S*)-L and (*R*)-L are 4.74 and 4.69 Å, respectively, while the closest distances between two Ag^I centers unsupported by (*S*)-L, (*R*)-L, or the other molecular interactions are 7.28 and 7.32 Å in **1** and **2**, respectively. These slight differences are probably due to packing effects. It is noteworthy that two adjacent homochiral ligands on the same side produce a cleft with the same mean distance of 7.15 Å for **1** and **2**. This dimension is sufficient to recognize suitable aromatic guest molecules. The moiety of ligands in the adjacent helical chains is interlocked into the cleft of each other (Figure 1). The ClO_4^- counteranion, which lies inside the cleft in part through a weak interaction with Ag^I, further fills the void around the metal ions.

[(Cd{(S)-L}(H_2O)Cl_2)(H_2O)$_{0.5}$]$_n$ (3)

Complex **3** is a one-dimensional, left-handed, helix-like chain formed through the interconnection of (*S*)-L and six-coordinate Cd^{II}. As shown in Figure 2, each Cd^{II} center is coordinated by two nitrogen atoms from different (*S*)-L ligands in the apical positions [N(1)–Cd–N(2A) bond angle of 174.6(3)°; Table 1], with two bridging Cl^- ligands in a *cis* mode, a terminal Cl^-, and a water molecule occupying the

equatorial plane. Thus, the coordination environment around Cd^{II} can best be described as a distorted Cl_3N_2O octahedron, which is rare in Cd^{II} complexes. Cd^{II} is approximately coplanar with the atoms in the equatorial plane, with a slight deviation of 0.027 Å. (*S*)-L serves as an *exo*-bidentate ligand, and the dihedral angles between the two naphthyl rings is 110.1°, which is close to those in **1** and **2**. However, the dihedral angle between the naphthyl rings and their corresponding pyridyl rings are 37.4° and 94.9°, respectively (Table 2). Thus, the interconnections of (*S*)-L and the six-coordinate Cd^{II} centers form a one-dimensional, helix-like chain similar to complex **1**. The Cd···Cd distance bridged by (*S*)-L and Cl^- is 5.10 Å. The uncoordinated water molecules stabilize the helix-like chain through hydrogen-bonding interactions between the uncoordinated water molecule and the coordinated water molecule [O(2W)···O(1W)^i = 2.797(12) Å; symmetry code: (i) x, $y + 1$, z,] as well as between the uncoordinated water molecule and terminal Cl^- [Cl(2)···H–O(2) = 3.129(11) Å]. It is noteworthy that the uncoordinated water molecule, coordinated water molecule, terminal Cl^-, and Cd^{II} form a trimetallocentered ten-membered hydrogen bonding ring. The Cd···Cd separation formed by uncoordinated water molecules through hydrogen-bonding interaction is 7.18 Å. The clefts from two adjacent (*S*)-L ligands are 7.04 Å, which is smaller than that in **1**. The complementary interlocking in part of the adjacent chains further stabilizes the chain by efficiently filling the void of the clefts (see b in Figure 2).

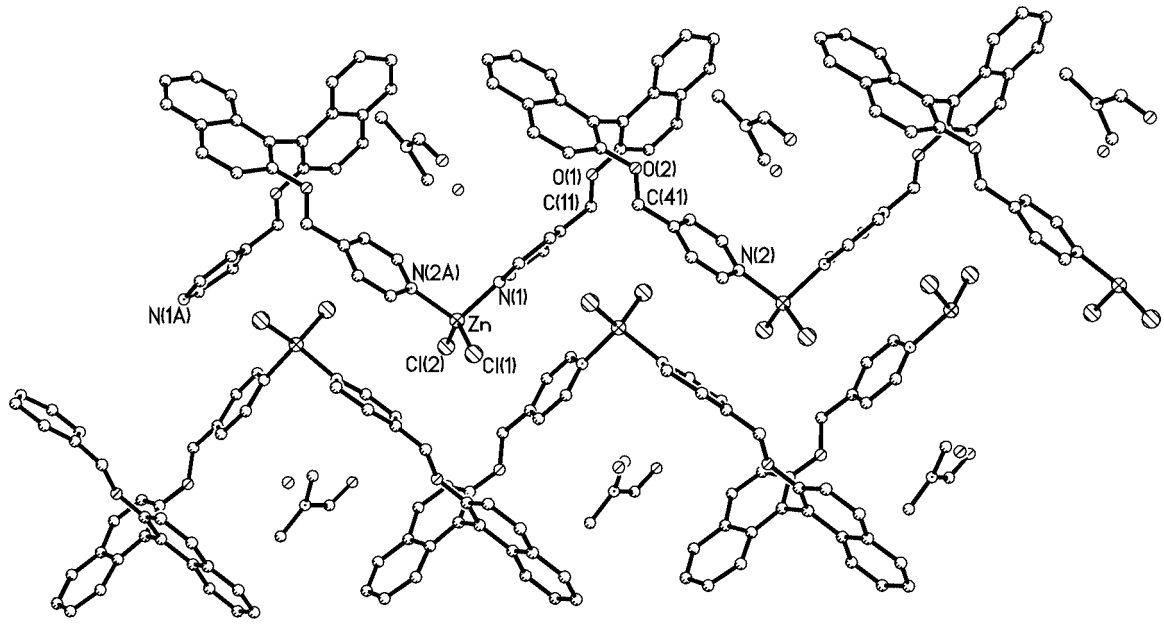

Figure 3. View of the double zigzag chains with guest DMF and water molecules in **4** along the *c* axis

[(Zn{(S)-L}Cl$_2$)(DMF)$_{0.5}$(H$_2$O)$_{0.5}$]$_n$ (4)

The single-crystal X-ray structural analysis reveals that **4** consists of a one-dimensional zigzag chain formed through the interconnection of $ZnCl_2$ units and (*S*)-L. As shown in Figure 3, each Zn^{II} ion is in a distorted tetrahedral geometry and is coordinated by two terminal Cl^- and two nitrogen atoms from different (*S*)-L ligands [Zn–N = 2.006(8) and 2.026(8) Å; N(1)–Zn–N(2A) = 104.1(3)°; Table 1]. The dihedral angle between two pyridyl rings attached to Zn^{II} is 84.5°, thus confirming the approximately perpendicular arrangement of the two coordinated pyridyl rings. All (*S*)-L ligands bind in an *exo*-bidentate mode and lie on the same side of the polymer chain, which is very different from the situation in **1**–**3**. The pyridyl rings are twisted around their naphthyl rings, with the dihedral angles between them being 13.3° and 29.3°, respectively (Table 2). A dramatic twisting between the two naphthyl rings is also observed, with the dihedral angle between them being 76.2°, which is larger than those in **1**–**3**. The combination of these twistings makes the (*S*)-L-connected $ZnCl_2$ units form a one-dimensional polymeric chain. The adjacent Zn···Zn separation bridged by (*S*)-L is 11.30 Å. The other chain with the same chirality fills the chain void between $ZnCl_2$ units in a complementary fashion to stabilize the chain structure. The DMF and water molecules, which lie outside the open cavity formed by the adjacent (*S*)-L ligands, do not generate significant weak interactions.

[(Pd$_2${(S)-L}$_2$Cl$_4$)(H$_2$O)$_{1.5}$]$_n$ 5

Complex **5** has a homochiral, binuclear metallocyclic structure. As shown in Figure 4, both Pd(1) and Pd(2) are in a distorted square-planar geometry and are coordinated by two *trans*-pyridine nitrogen atoms of different (*S*)-L and two *trans* Cl^- ligands, with *cis* angles ranging from 87.7(3)° to 94.9(3)° (Table 1). The average bond distances of Pd–N_{py} and Pd–Cl are 2.008(12) Å and 2.305(4) Å, respectively, which are typical values for Pd–N_{py} and Pd–Cl bond lengths. (*S*)-L acts as an *exo*-bidentate ligand, with its pyridyl rings slightly twisted with respect to their naphthyl rings, with the dihedral angles between them being 30.1° and 64.8° and 29.3° and 87.9°, respectively. The two naphthyl rings are also drastically twisted, with the dihedral angle between them being 81.7° and 82.7°, respectively. The combination of these twistings allows the (*S*)-L ligands to link the $PdCl_2$ units into a thirty-four-membered bimetallic macrocycle. The Pd···Pd separation in the cycle is 4.644 Å. Owing to the high distortion and flexibility of (*S*)-L, no enclathration of guest molecules is observed in **5**; the uncoordinated water molecules lie outside of the macrocycle. There are no other significant weak interactions or short contacts between the adjacent macrocycles.

It is of interest to compare the related structural data of (*S*)-L or (*R*)-L in **1**–**5**. (*S*)-L and (*R*)-L act as *exo*-bidentate ligands, and the difference of the coordinating geometry of the metal ions in **1**–**5** results in different structural topologies. In complexes **1** and **2**, owing to the configurational difference, (*S*)-L and (*R*)-L bridge two-coordinate Ag^I generating left-handed and right-handed helix-like chains, respectively. The frameworks of (*S*)-L and (*R*)-L are not crucially affected by the coordination to metal centers, as shown by the data in Table 2. In complex **3**, two nitrogen atoms from different (*S*)-L ligands occupy the axial positions of a six-coordinate Cd^{II} center, which results in a structural framework similar to **1**. Thus, the dihedral angles between the two naphthyl rings are very close and are the smallest in **1**–**5**. The slight difference between the one-dimensional, helix-like chains is due to free rotation of methylpyridine. However, the distortion angle of the BINOL connector in **4**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

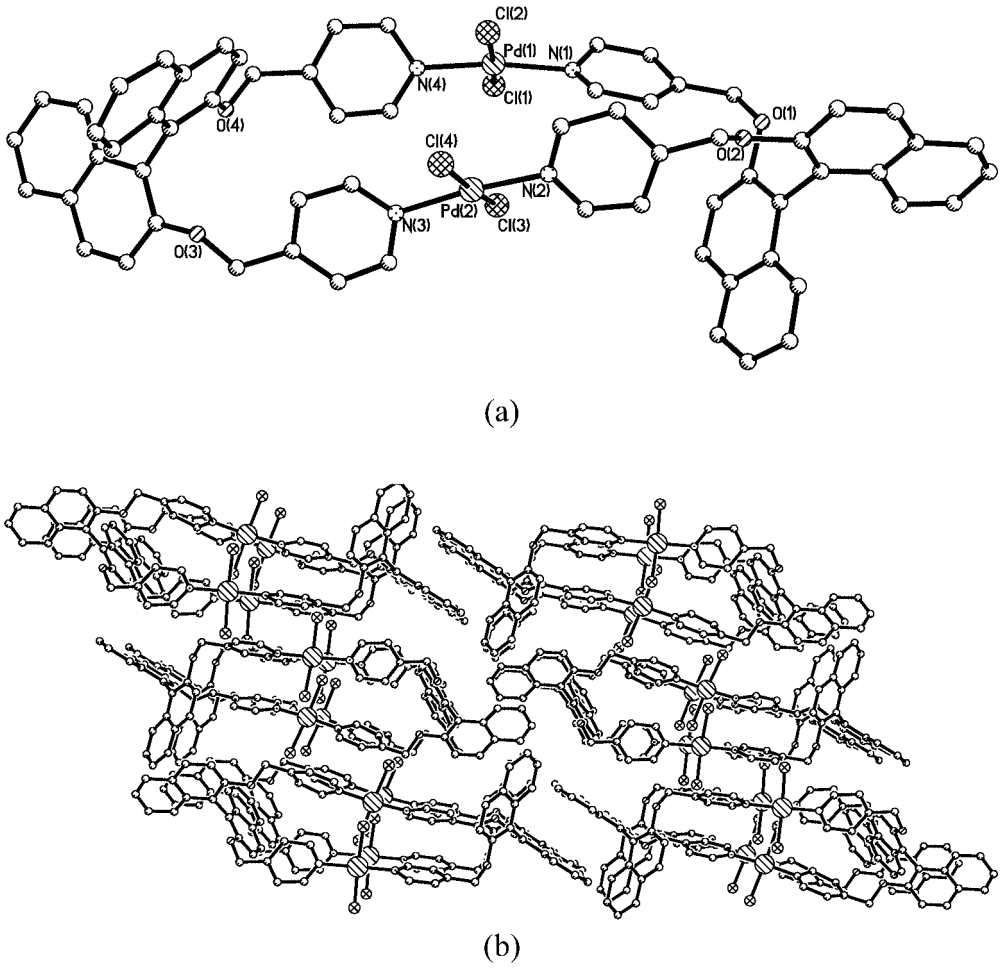

Figure 4. (a) View of the molecular structure of **5**, with uncoordinated water molecules omitted for clarity; (b) view of the packing structure along the *b* axis in **5** showing that there are no other interactions between adjacent macrocycles

(85.1°) is larger than those in **1** and **3**, which results in the formation of a one-dimensional zigzag chain with the (*S*)-L ligands on the same side, with the largest distance between metal centers bridged by (*S*)-L (11.30 Å). The shortest distance is found in dinuclear metallomacrocyclic complex **5** (4.644 Å), in which two Pd^{II} centers are bridged by two (*S*)-L ligands. Therefore, the combination of both the structural characteristics of the BINOL connector and the coordination propensity of the metal ions leads to the formation of the final frameworks of complexes **1**–**5**.

Conclusions

We have successfully synthesized the BINOL-based, homochiral, pyridyl-containing ligands (*S*)-2,2′-bis(pyridylmethyleneoxy)-1,1′-binaphthalene [(*S*)-L] and (*R*)-2,2′-bis(pyridylmethyleneoxy)-1,1′-binaphthalene [(*R*)-L]. Each ligand binds in an *exo*-bidentate mode to bridge two adjacent metal centers. In complexes **1**–**3**, the ligands on different sides link two-coordinate Ag^{I} centers (**1** and **2**) and six-coordinate Cd^{II} centers (**3**) into homochiral helix-like chains, which are stabilized through complementary interlocking in parts of the adjacent chains. In the four-coordinate Zn^{II} complex **4**, the (*S*)-L ligands on the same side link $ZnCl_2$ units into a zigzag chain and the zigzag is stabilized by interlocking with the other chain. However, in the square-planar Pd^{II} complex **5**, the (*S*)-L ligands link *trans*-coordinated $PdCl_2$ units into a homochiral dinuclear metallomacrocycle. The dihedral angle between the two naphthyl rings of the BINOL connector is different in the different structural topologies, thus suggesting that the coordination geometry of the metal ions has an important effect on the framework twisting of the BINOL moiety. It should be noted that the metal ions themselves cannot be considered to be the center of chirality in **1**–**5** as the chirality of these complexes originates from the inherently chiral twisting in the BINOL connector. Thus, assembly of (*S*)-L with Ag^{I} and Cd^{II} results in the formation of left-handed, helix-like complexes **1** and **3**, respectively Correspondingly, the assembly of (*R*)-L with Ag^{I} leads to the formation of the right-handed, helix-like complex **2**. In summary, this research shows that the assembly of dipyridyl ligands with an optically active BINOL connector and metal ions offers an attractive and promising route to generate unique structural motifs that cannot be obtained with other types of normal,

rigid or flexible *exo*-bidentate organic ligands, such as 4,4′-bipy and related organic ligands.

Experimental Section

General: All chemicals were commercially available and were used as received without further purification. (*S*)-L and (*R*)-L were synthesized according to a literature method.[9d] The measurement of the optical rotation was performed with a Polarimeter 341. ESI mass spectra were recorded with a Fisons VG platform. The IR spectra (KBr disk) were recorded with a Magna 750 FTIR spectrophotometer. Elemental analyses were determined with an Elementar Vario ELIII elemental analyzer.

Preparation of [Ag{(*S*)-L}(ClO_4)]$_n$ (1): A solution of $AgClO_4 \cdot H_2O$ (0.021 g, 0.1 mmol) in H_2O (5 mL) was added slowly to a stirred solution of (*S*)-L (0.047 g, 0.1 mmol) in MeCN (10 mL). The reaction mixture was stirred at 60 °C for 3 h and then filtered. Colorless crystals of complex **1** were obtained by allowing the filtrate to evaporate slowly in air for two weeks. Yield (0.062 g, 92%). $C_{32}H_{24}AgClN_2O_6$ (675.9): calcd. C 56.81, H 3.55, N 4.14; found C 56.84, H 3.52, N 4.17. IR (KBr pellet): $\tilde{\nu}$ = 3583 (m, br), 3062 (m), 2922 (m), 1943 (vw), 1672 (vw), 1618 (s), 1592 (s), 1563 (m), 1505 (s), 1466 (w), 1446 (m), 1429 (s), 1357 (vw), 1324 (s), 1287 (s), 1269 (s), 1215 (s), 1151 (vw), 1073 (s, br), 1021 (m), 960 (w), 914 (w), 860 (vw), 804 (m), 746 (m), 669 (vw), 619 (m), 573 (vw), 497 (w), 458 (w), 422 cm^{-1} (w).

Preparation of [Ag{(*R*)-L}(ClO_4)]$_n$ (2): The procedure was similar to the synthesis of complex **1**, except that (*R*)-L was used instead of (*S*)-L. Yield (0.057 g, 84%). $C_{32}H_{24}AgClN_2O_6$ (675.9): calcd. C 56.81, H 3.55, N 4.14; found C 56.89, H 3.63, N 4.16. IR (KBr pellet): $\tilde{\nu}$ = 3585 (m, br), 3060 (m), 2922 (m), 1942 (vw), 1670 (w), 1617 (s), 1592 (s), 1563 (w), 1505 (s), 1468 (w), 1446 (m), 1428 (s), 1356 (w), 1321 (s), 1287 (s), 1269 (s), 1216 (s), 1151 (vw), 1091 (s, br), 1020 (s), 959 (w), 912 (w), 861 (vw), 804 (m), 747 (m), 670 (w), 619 (m), 573 (vw), 497 (w), 459 (w), 422 cm^{-1} (w).

Preparation of [(Cd{(*S*)-L}(H_2O)Cl_2)(H_2O)$_{0.5}$]$_n$ (3): A solution of (*S*)-L (0.047 g, 0.1 mmol) in MeOH (5 mL) was carefully layered on a solution of $CdCl_2 \cdot 2.5H_2O$ (0.023 g, 0.1 mmol) in H_2O (5 mL). Diffusion between the two phases over a period of two weeks produced colorless crystals of **3**. Yield (0.047 g, 69%). $C_{32}H_{27}CdCl_2N_2O_{3.5}$ (678.9): calcd. C 56.56, H 4.00, N 4.12; found C 56.58, H 4.03, N 4.13. IR (KBr pellet): $\tilde{\nu}$ = 3402(m, br), 3053 (m), 2923 (m), 1952 (vw), 1747 (vw), 1619 (s), 1593 (s), 1562(m), 1504 (s), 1467 (w), 1446 (m), 1426 (s), 1356 (w), 1321 (s), 1287 (s), 1268 (s), 1214 (s), 1151 (w), 1089 (s), 1065 (s), 1017 (s), 959 (w), 913 (w), 860 (vw), 803 (s), 746 (m), 669 (vw), 619 (m), 573 (w), 497 (w), 458 (w), 422 cm^{-1} (m).

Preparation of [(Zn{(*S*)-L}Cl_2)(DMF)$_{0.5}$(H_2O)$_{0.5}$]$_n$ (4): A solution of $ZnCl_2$ (0.07 g, 0.1 mmol) in DMF (10 mL) was added slowly to a stirred solution of (*S*)-L (0.047 g, 0.1 mmol) in MeCN (10 mL). The reaction mixture was stirred at 60 °C for 6 h and then filtered. Colorless crystalline complex **4** was obtained in high yield by slow diffusion of diethyl ether into the filtrate over several days. Yield (0.058 g, 89%). $C_{33.5}H_{28.5}Cl_2N_{2.5}O_3Zn$ (650.4): calcd. C 61.86, H 4.38, N 5.38; found C 61.75, H 3.30, N 5.33. IR (KBr pellet): $\tilde{\nu}$ = 3048 (w), 2925 (w), 2858 (w), 1665 (s), 1624 (s), 1594 (m), 1567 (w), 1511 (m), 1384 (w), 1358 (vw), 1322 (m), 1276 (s), 1240 (m), 1219 (m), 1153 (m), 1091 (s), 1066 (s), 1030 (m), 963 (w), 917 (w), 871 (vw), 815 (s), 754 (m), 666 (vw), 636 (w), 605 (vw), 492 (w), 456 (vw), 430 cm^{-1} (vw).

[(Pd_2{(*S*)-L}$_2Cl_4$)(H_2O)$_{1.5}$]$_n$ (5): A solution of [$PdCl_2$(cod)] (0.12 g, 0.1 mmol) in CH_2Cl_2 (5 mL) was added slowly to a stirred solution of (*S*)-L (0.047 g, 0.1 mmol) in CH_2Cl_2 (5 mL). The reaction mixture was stirred at reflux temperature under nitrogen for 3 h and was then evaporated under reduced pressure. Yellow crystals of complex **5** were obtained by slow diffusion of hexane into the resultant solution over several days. Yield (0.055 g, 83%). $C_{64}H_{51}Cl_4N_4O_6Pd_2$ (1326.7): calcd. C 57.94, H 3.84, N 4.21; found C 57.98, H 3.91, N 4.25. IR (KBr pellet): $\tilde{\nu}$ = 3412 (m, br), 3055 (m), 2921 (m), 1925 (vw), 1743 (vw), 1617 (s), 1592 (s), 1563 (m), 1506 (s), 1462 (w), 1445 (m), 1428 (m), 1363 (vw), 1324 (s), 1281

X-ray Crystallography: Intensity data for the five complexes were recorded on a Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature. Empirical absorption corrections were applied with the SADABS program.[12] The structures were solved by direct methods and all calculations were performed using the SHELXL-97 program.[13] The positions of the H atoms in complexes **1**–**5** were generated geometrically (C–H bond fixed at 0.96 Å) and assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. The structures were refined by full-matrix least-squares minimization of $\Sigma(F_o - F_c)^2$ with anisotropic thermal parameters for all atoms except the H atoms. The crystallographic data for complexes **1**–**5** are listed in Table 3.

CCDC-240015 to -240019 (for **1**–**5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Mono-, Di- and Polymeric Calcium and Gadolinium Complexes of the Tripodal Ligand 2,2′,2′′-Nitrilotribenzoic Acid

Stefan Wörl,[a] Igor O. Fritsky,[b] Dieter Hellwinkel,[c] Hans Pritzkow,[a] and Roland Krämer*[a]

Keywords: Calcium / Gadolinium / N,O ligands / Tripodal ligands / X-ray crystallography

Three novel carboxylate-bridged complexes incorporating the tripodal N,O ligand 2,2′,2′′-nitrilotribenzoic acid H_3L of formula $[Ca^{II}(H_2L)(OH_2)_4][(H_2L)]\cdot 4H_2O$ (**1**), $[Ca^{II}(OH_2)_4][Ca^{II}(L)(OH_2)_2]_2\cdot 7H_2O$ (**2**) and $[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2\cdot 13H_2O$ (**3**) were synthesized and characterized by X-ray crystallography. In all three complexes, the ligand H_3L binds to the metal centre only by its three carboxylate donors, leaving the bridgehead nitrogen atom nonbonding. The calcium(II) ion in the monomeric complex **1** is distorted pentagonal-bipyramidal coordinated, the +1 charge of the complex cation $[Ca^{II}(H_2L)(OH_2)_4]^+$ is balanced by an H_2L^- anion and both units are connected by hydrogen bonds. The polymeric compound **2** displays a one-dimensional chain structure, in which two $[Ca^{II}(L)]^{2-}$ units form a dimeric structure and are connected by hydrated Ca^{II} ions. **3** contains two different $[Gd^{III}(L)(OH_2)_n]$ dimers. In one of them the two Gd^{III} ions are linked by two monoatomic carboxylate O-bridges showing a short Gd···Gd distance of 3.99 Å. In the second, a *syn-anti* carboxylate 1,3-bridge with a longer Gd···Gd distance of 4.96 Å is observed. Magnetic measurements of **3** show paramagnetic behaviour with weak antiferromagnetic coupling.

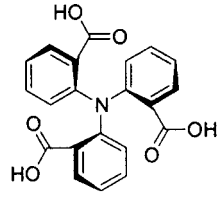
Introduction

The self-assembly of supramolecular architectures by use of metal ion-ligand interactions is one of the most powerful methods to obtain new molecular structures. The carboxylate group is a versatile ligand and favours the formation of oligomeric and polymeric complexes, it can adopt different binding modes, such as terminal monodentate, chelating to one metal center and various modes of bridging coordination of two, three four or even five metal centres.[1] Metal carboxylates have therefore emerged as an important family of supramolecular coordination compounds and inorganic open framework materials.[2] Organic di- and tricarboxylates broaden the availability of such architectures and provide an effective means to design such structures. While dicarboxylates have been extensively studied in this respect, the supramolecular coordination chemistry of ligands carrying three highly preorganized carboxylate groups has been less well explored.

Here we report mono-, oligo and polymeric complexes of the tricarboxylate ligand 2,2′,2′′-nitrilotribenzoic acid H_3L. We have recently described five-coordinate transition metal complexes of H_3L in which the triphenyl nitrogen atom is involved in metal coordination with exception of an octahedral complex $[Fe^{III}(L)(OH_2)_3]$ in which the "hard" Fe^{III} ion is complexed only by the carboxylate groups of L.[3]



H_3L

This study focuses on Ca^{II} and Gd^{III} complexes, which display higher coordination numbers (> 6) of the metal ion and which tend to form polynuclear structures with various bridging modes of the carboxylate donor of H_3L. Studies of Ca^{II} binding to small molecules have led to generalizations about their corresponding binding preferences. Calcium may coordinate to between five and nine atoms, it exhibits irregular geometries and prefers oxygen donor ligands. The distances of Ca–O bonds show a wide variation of 2.20 to 2.80 Å.

Gadolinium coordination compounds are the subject of intense research efforts due to their applications as MRI contrast agents or as precursors for novel magnetic materials.[4] The number of di- and polynuclear Gd^{III} compounds for which structural and magnetic data are available is restricted. In Gd^{III} dimers usually weak antiferromagnetic interactions are reported.[5]

Results and Discussion

Synthesis and Characterization

We were able to characterize two new calcium(II) and one gadolinium(III) coordination compound containing the tripodal N,O-ligand H_3L. The synthesis of H_3L was achieved by a copper-catalyzed Ullman-nitrogen-arylation, followed by a standard base hydrolysis as described previously.[6] Compounds **1**–**3** were synthesized by mixing equimolar amounts of the ligand H_3L and the appropriate metal salt in water. $Ca(OH)_2$ was used as a base to deprotonate H_3L. Crystals suitable for X-ray crystallography were obtained by slow evaporation of the solvent after several days at room temperature. A description of the structures **1**–**3**, together with figures of the complexes is given below. Selected bond lengths and angles are given in Table 1 and Table 2. Crystal data and data collection details are presented in Table 3.

$[Ca^{II}(H_2L)(OH_2)_4][(H_2L)]\cdot 4H_2O$ (1)

Complex **1** contains a $[Ca^{II}(H_2L)(OH_2)_4]^+$ cation, a $[H_2L]^-$ anion and four water molecules (Figure 1). The distorted pentagonal-bipyramidal coordination sphere of the calcium(II) core is composed of the $[H_2L]^-$ ligand that coordinates by two COOH and one COO^- to two equatorial and one axial site, and the four remaining sites are occupied by water molecules. The presence of coordinating COOH groups is supported by the unsymmetric bond distances C14–O3 1.222(1) Å, C1–O4 1.315(1) Å and C21–O5 1.221(1) Å, C21–O6 1.317(1) Å, compared with the nearly

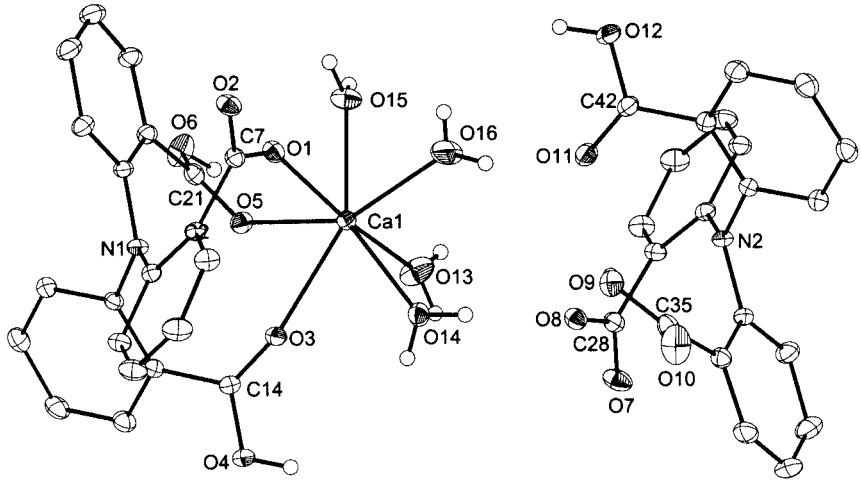

Figure 1. Ellipsoid plot of $[Ca^{II}(H_2L)(OH_2)_4][(H_2L)]$ (**1**). Aryl-H atoms and the H_2O solvent molecules have been omitted for clarity.

symmetric coordinating COO^- group: C7–O1 1.253(1) Å and C7–O2 1.273(1) Å. Also in the nonbonding $[H_2L]^-$ anion two unsymmetric bond distances are found for the COOH group: C35–O9 1.325(1) Å, C35–O10 1.217(1) Å and C42–O11 1.214(1) Å, C42–O12 1.316(1) Å, compared to the nearly symmetric bond distances of the COO^- group: C28–O7 1.265(1) Å and C28–O8 1.260(1) Å. The central nitrogen atom of $[H_2L]^-$ does not coordinate to the calcium ion [Ca1···N1 3.78 Å], resulting in a O3 coordination mode of the ligand. The two equatorial Ca–O bonds are almost identical [2.421(5) and 2.424(1) Å] and the axial Ca–O bond is, as expected, significantly shorter [2.347(1) Å]. The other Ca–O distances lie within the range of 2.336(1) and 2.468(1) Å. Planarization of the triarylamine unit is evident by an average C–N(1)–C angle of 119.0°, underlining the nonbonding property of the nitrogen atom to the calcium ion [average C–N(2)–C angle 118.4 °]. Hydrogen bonds linking $[Ca^{II}(H_2L)(OH_2)_4]^+$ and $[(H_2L)]^-$ are found between H(O16)–O11 [2.023(1) Å] and H(O14)–O8 [1.958(1) Å]. Furthermore, there are other O–H···O interactions between coordinated water and free water molecules.

$[Ca^{II}(OH_2)_4][Ca^{II}(L)(OH_2)_2]_2\ 7H_2O$ (2)

A second calcium complex $[Ca^{II}(OH_2)_4][Ca^{II}(L)(OH_2)_2]_2 \cdot 7H_2O$ (**2**) was isolated out of the reaction mixture yielding complex **1**. In contrast to **1**, the complex is a linear polymer and contains dimeric $[Ca^{II}(L)(OH_2)_2]_2^{2-}$ units, which are bridged by hydrated Ca^{II} ions (Figure 2). In the centrosymmetric $[Ca^{II}(L)(OH_2)_2]_2^{2-}$ unit, each Ca^{II} ion is hepta-coordinated and has a distorted pentagonal-bipyramidal coordination sphere, interacting with L^{3-} by three carboxylate donors. The four remaining sites are occupied by two water molecules and a bidentate bridging carboxylate group of the second $[Ca^{II}(L)]^-$ unit. The resulting –2 charge per $[Ca^{II}(L)(OH_2)_2]_2^{2-}$ unit is balanced by a hexacoordinate Ca^{II} cation. The Ca^{II} ion links the dinuclear units by axial coordination of bridging carboxylates, while its octahedral coordination sphere is completed by four equatorial water molecules. The Ca1–O distances lie in the range of 2.292(1) and 2.572(1) Å. The Ca2–O bond distances are similar to the reported ones for six-coordinate calcium complexes: Ca2–O2 2.335(2) Å, Ca2–O9 2.321(1) Å and Ca2–O10

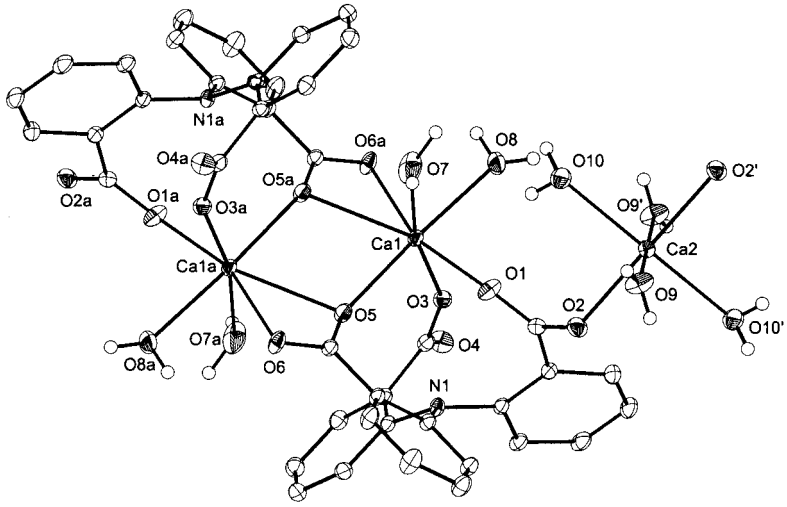

Figure 2. Ellipsoid plot of $[Ca^{II}(OH_2)_4][Ca^{II}(L)(OH_2)_2]_2$ (**2**). Aryl-H atoms and the H_2O solvent molecules have been omitted for clarity.

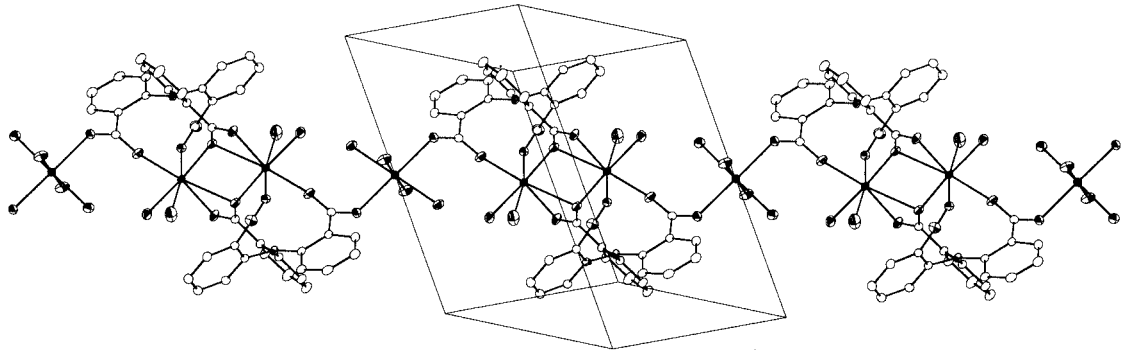

Figure 3. View of the self-assembled one-dimensional supramolecular architecture of **2** emphasizing the catenarian order of the calcium ions; hydrogen atoms and solvate molecules have been omitted for clarity.

2.369(1) Å. The Ca1···Ca1a distance of 4.008(1) Å is relatively long compared to other structurally characterized carboxylate-bridged calcium-dimers with average Ca···Ca distances around 3.8 Å.

$[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2 \cdot 13H_2O$ (3)

H_3L reacts with gadolinium(III) to the complex $[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2 \cdot 13H_2O$ (**3**), incorporating two dimers $[Gd^{III}(L)(OH_2)_3]_2$ and $[Gd^{III}(L)(OH_2)_4]_2$ with different Gd^{III} coordination spheres. The structure of **3** is shown in Figure 4. Two $[Gd^{III}(L)]$ moieties are joined via the carboxylate groups of L^{3-}. The gadolinium ions are eight-coordinate in both structures. The coordination geometry of the metal ion can be described as distorted square-antiprismatic. The remarkable structural feature of **3** is that the flexible ligand H_3L adopts two different coordination modes at the gadolinium(III) ions: In $[Gd^{III}(L)(OH_2)_4]_2$ (Figure 4, left) the two metal ions are bridged by two bidentate carboxylate groups in a *syn-anti* fashion, resulting in a large Gd···Gd distance of 4.959(1) Å. In the second dimer (Figure 4, right), in analogy to the Ca^{II} complex **2**, the bridging carboxylate groups are tridentate with formation of a four-membered chelate ring with one gadolinium ion, resulting in a smaller Gd···Gd distance of 3.996(2) Å; this Gd···Gd′ distance is comparable to that found in other complexes containing Gd_2O_2 rings.[7] The Gd–O distances range from 2.293(1) Å to 2.499(1) Å. The average Gd–O distance at Gd1 is 2.407(1) Å and 2.397(1) Å for Gd2, which is close to other reported Gd^{III} dimers.[8] The angles Gd2–O11–Gd2′ and O11–Gd2–O11′ are 109.96° and 70.04°, respectively. Many lanthanide(III) carboxylate complexes reported in the literature have polymeric structures [9] and only a few are dimeric.[10]

Magnetic Properties of 3

The magnetic susceptibility (χ_M) of **3** was measured in the temperature range 2–300 K. The variations of the inverse of the magnetic susceptibility, χ_M^{-1} and $\chi_M T$ of **3** are shown in Figure 6. The μ_{eff} value of 7.83 μ_B at room temperature is close to the calculated spin-only value (7.94 μ_B). The $\chi_M T$ product at 300 K (30.7 $cm^3 \cdot K \cdot mol^{-1}$) is expected for four isolated Gd^{3+} ions ($^8S_{7/2}$) and remains almost constant to 20 K. Below 10 K the $\chi_M T$ product decreases steeply down to 19.7 $cm^3 \cdot K \cdot mol^{-1}$ at 2 K. Such behaviour indicates paramagnetic behaviour of the Gd centres in **3** with weak antiferromagnetic coupling, as observed before in several binuclear Gd complexes.[11] The experimental points (7–300 K) obey the Curie–Weiss law with a Weiss constant θ = –0.18 K and Curie constant C = 30.731 which corresponds to four Gd^{3+} ions with the average g value

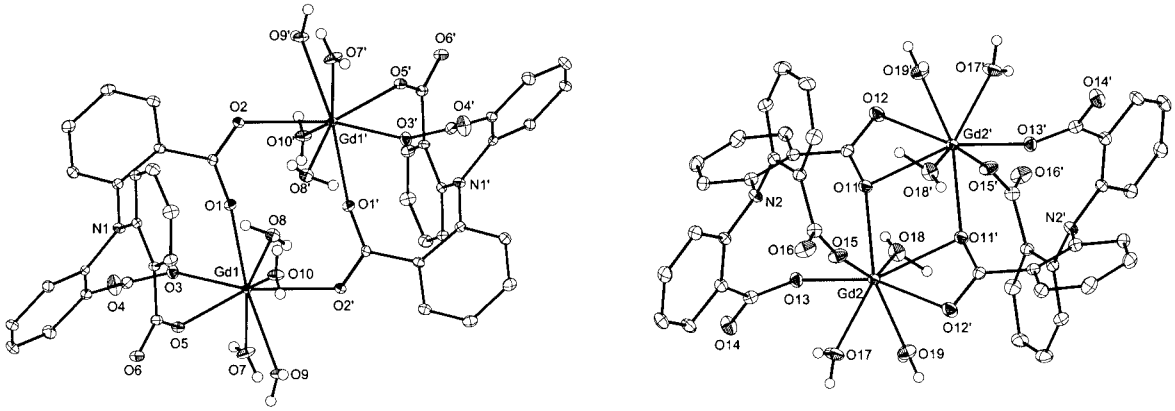

Figure 4. Ellipsoid plot of $[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2 \cdot 13H_2O$ (**3**); aryl-H atoms and the H_2O solvent molecules have been omitted for clarity.

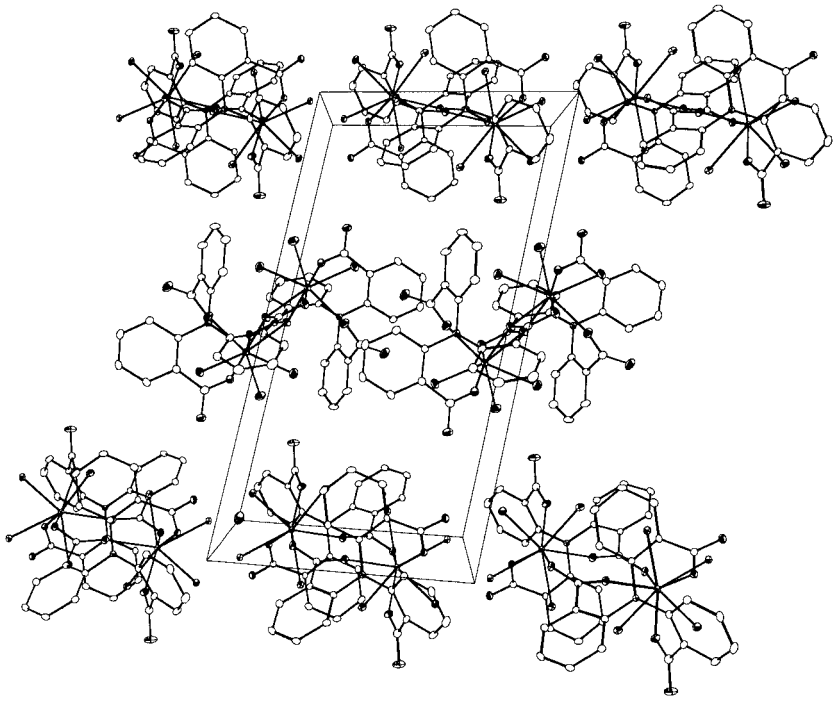

Figure 5. View of $[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2{\cdot}13H_2O$ (**3**) showing the discrete arrangement of the $[Gd(L)]_2$ units.

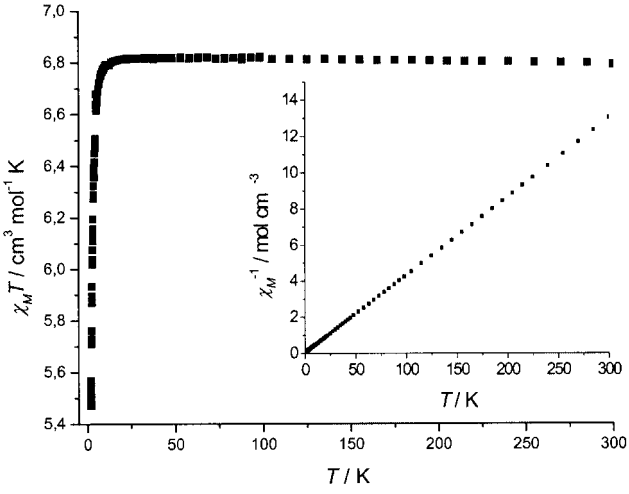

Figure 6. Plot of $\chi_M T$ and χ_M^{-1} vs. T for **3**.

equal to 1.975. Since two inequivalent exchange Gd dimeric units are present and the sample exhibits very weak antiferromagnetic interaction, it is not possible to distinguish the contribution to the observable behaviour from each coupling pattern using an analytical expression. Thus, the susceptibility data were fitted on the basis of the equation deduced from the isotropic Heisenberg model[12] envisaged the presence of an average isotropic coupling parameter $J = (J1 + J2)/2$ ($\boldsymbol{H} = -J \times \boldsymbol{S_1} \times \boldsymbol{S_{1'}} = -J \times \boldsymbol{S_2} \times \boldsymbol{S_{2'}}$, $\boldsymbol{S_1} = \boldsymbol{S_{1'}} = \boldsymbol{S_2} = \boldsymbol{S_{2'}} = 7/2$). A quantitative analysis of the data gave J to be equal to –0.084(2) cm^{-1}, the isotropic g factor to be equal to 1.975. Note, that J values in the range between –0.04 and –0.11 cm^{-1} were reported for other gadolinium dimers.[11,12]

UV/Vis-Spectrophotometric Titrations

Smooth formation of 1:1 complexes is indicated by isosbestic points, when H_3L in water/methanol at pH 7 is titrated with the appropriate metal salts (Figure 7). The UV-band at $\lambda_{max.}$ = 300 nm, that served as a probe for the M···N interaction, is nearly unchanged, in accordance to the crystal structures showing no M···N interactions. Metal coordination of this nitrogen atom is accompanied by a significant decrease of the 300 nm absorbance.[3]

Conclusions

In summary we have characterised new binding modes of lewis-hard metals to the versatile ligand H_3L. With calcium(II) a monomeric species $[Ca^{II}(H_2L)(OH_2)_4][(H_2L)]{\cdot}4H_2O$ (**1**) and a polymeric species $[Ca^{II}(OH_2)_4][Ca^{II}(L)(OH_2)_2]_2{\cdot}7H_2O$ (**2**) is formed, revealing rare examples of calcium(II) complexes with tridentate carboxylate only donor sets in mononuclear complex **1** and in one-dimensional chain-like structure **2**. With gadolinium(III) the complex $[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2{\cdot}13H_2O$ (**3**), incorporating two different dimers with Gd···Gd distances of 4.0 and 5.0 Å, respectively, is formed. The magnetic properties of compound **3** have been studied, revealing paramagnetic behaviour of the gadolinium(III) ions with weak antiferromagnetic coupling. In all three compounds there is no interaction between the bridgehead nitrogen and the metal ions, this is in accordance with UV/Vis spectrophotometric titrations in solution. As observed previously for the iron(II) complex of L,[3] two [ML] units tend to dimerize via two carboxylate bridges in the solid state. The nonbridging car-

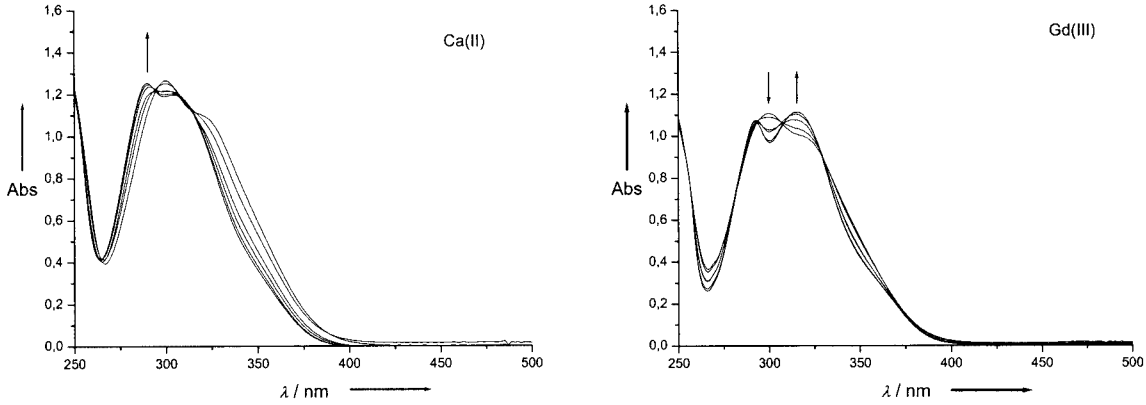

Figure 7. Spectrophotometric titration of H_3L (0.1 mM in MeOH/H_2O, pH 7, 20 mM buffer 3-(*N*-morpholino)propanesulfonic acid, T = 25 °C) with solutions of $Ca(NO_3)_2$ and $Gd(NO_3)_3$, in 0.2 equiv. steps. No further absorbance changes are observed on addition of >1 equiv. metal salt.

boxylate groups in each [ML] unit are available for interaction with "free" metal ions which link the dimers to extended structures, as exemplified by the linear-chain polymer **2**.

Experimental Section

General Remarks: All reactions were carried out in open flasks without exclusion of O_2 or H_2O. Chemicals were purchased from commercial sources (Aldrich and Acros) and were used as received without any further purifications. Electrospray ionization (ESI) mass spectra were recorded with a Q-TOF Micromass/Waters spectrometer. Absorbance UV/Vis spectra were recorded with a Specord S100 spectrophotometer (Carl Zeiss Jena). Magnetic susceptibility data were collected on ground crystals with use of a SQUID-based sample magnetometer (QUANTUM-Design, MPMS-XL-5) in the temperature range 2–300 K with an applied field of 1 T.

Preparation of the Complexes: The ligand 2,2′,2′′-nitrilotribenzoic acid H_3L was synthesised according to published methods.[6]

Synthesis of $[Ca^{II}(H_2L)(OH_2)_4][(H_2L)]\cdot 4H_2O$ (1) and $[Ca^{II}(OH_2)_4]$-$[Ca^{II}(L)(OH_2)_2]_2\cdot 7H_2O$ (2): H_3L (15.0 mg, 0.04 mmol) was dissolved in water (3 mL) and reacted with $Ca(OH)_2$ (4.4 mg, 0.06 mmol). After several days colourless crystals of **1** (monoclinic) and some of **2** (triclinic) were obtained. Yield: 13 mg (72 %). HR-ESI: *m/z*: for **1**: calcd. for $C_{21}H_{14}CaNO_6$ $[Ca(H_2L)]^+$: 416.0447; found: 416.0462; and $C_{42}H_{29}CaN_2O_{12}$ $[\{Ca(H_2L)\}\{H_2L\} + H]^+$: 793.1346; found: 793.1336; and in case of **2**: calcd. for $C_{42}H_{25}Ca_2N_2O_{12}$ $[\{CaL\}_2 + H]^-$: 829.0659; found 829.0655.

Synthesis of $[Gd^{III}(L)(OH_2)_3]_2[Gd^{III}(L)(OH_2)_4]_2\cdot 13H_2O$ (3): H_3L (15.0 mg, 0.04 mmol) was dissolved in water (3 mL) and deprotonated with $Ca(OH)_2$ (4.4 mg, 0.06 mmol). $Gd(NO_3)_3\cdot 6H_2O$ (17.9 mg, 0.04 mmol) in water (3 mL) was added to the solution and after several days colourless crystals were obtained. Yield: 18 mg (65 %). HR-ESI: *m/z*: calcd. for $C_{42}H_{26}GdN_2O_{12}$ $[(GdL)(H_2L)]^-$: 908.0727; found: 908.0725.

X-ray Crystallographic Study: Crystal data and refinement results of complexes **1**–**3** are listed in Table 3. Intensity data were collected with a BRUKER AXS Smart 1000 CCD area detector (Mo-K_α radiation, λ = 0.71073 Å, ω-scan). An empirical absorption correction was applied (SADABS). The structures were solved by direct methods and refined by full-matrix least-squares based on F^2 with all measured reflections.[13] Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in difference Fourier maps and refined isotropically. Some of the solvent molecules in **2** and **3** were disordered. CCDC-243383 (for **1**), -243384 (for **2**) and -243385 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Three-Dimensional Lanthanoid-Containing Coordination Frameworks: Structure, Magnetic and Fluorescent Properties

Hong-Tao Zhang,[a] You Song,[a] Yong-Xiu Li,[a] Jing-Lin Zuo,[a] Song Gao,[b] and Xiao-Zeng You*[a]

Keywords: Lanthanides / Coordination polymers / Magnetic properties / Fluorescence / Solid-state structures

Two lanthanoid-containing 3D coordination polymers, $[Gd_2L_3(H_2O)_2]_n$ (**1**) and $\{[TbL_{1.5}(H_2O)]\cdot 0.5H_2O\}_n$ (**2**) (L = succinate), have been prepared by hydrothermal reaction. The difference in structure between the two 3D coordination polymers is a result of the flexibility of the ligand conformation. The magnetic properties of **1** and **2** have been investigated in the 1.8–300 K range. Both complexes exhibit ferromagnetic interaction between lanthanoid ions. AC magnetic measurements revealed long-range magnetic order in complex **2**. Especially **2** integrates the ferromagnetic, fluorescent and porous properties into a single entity. This motif may be developed to achieve new multifunctional molecular-based materials.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Solid-state assembly of coordination polymers has attracted increasing attention due to their fascinating structure as well as their potential applications in materials science, such as zeolite-like porous structures and optoelectronic properties.[1,2] To construct coordination polymers, polydentate organic ligands are usually employed as space linkers to connect the metal ions.[3,4] The resultant functionality might not only rise from the organic ligand molecules but also from the inorganic metal ions. Accordingly, the wide-ranging functionality of the metal moiety, such as magnetic and optoelectronic properties, can be associated with the ability of the organic ligands to modulate special structural arrangements, to develop new molecular-based materials. Moreover, this supramolecular entity could lead to a multifunctional materials.[5] For this purpose, more new unique 3d- and 4f-metal containing coordination polymers have been investigated.[6–11] Most work involving lanthanoids has focused on the structures and luminescent properties of the complexes rather than on magnetic properties. In these lanthanoid-containing coordination polymers, many organic ligands containing oxygen atoms are employed as a bridge to connect the lanthanoid ions because of the high affinity of the lanthanoid ions for oxygen-containing ligands, such as the terephthalate anion[11d] and 4,4′-bipyridine *N*,*N*′-dioxide.[11a,b] Among them, aromatic polycarboxylate anions are widely used because of their rigid structure.[8,11] However, the structural variation of coordination polymers is ascribed to both the metal–ligand coordination modes and the conformational isomerism of ligands that arises from their flexibility. Generally, for aliphatic carboxylate ligands, the conformational variation of flexibility plays a more remarkable role than that in aromatic carboxylate ligands. As a simple aliphatic dicarboxylate ligand with multi-conformation isomerism, the succinate anions is the better choice to investigate the effect of conformational variation in coordination polymers because of the uncomplicated results. To date, in (succinato)metal coordination polymers, the inorganic species are mostly d-block metals such as Fe^{II} succinate[12d] and several (succinato)cobalt(II) coordination polymers with different structures.[12a–c] Recently, a few (succinato)nickel(II) coordination polymers as porous materials and one example of a (succinato)Sc^{III} 3D coordination polymer as a heterogeneous Lewis acid catalyst have been reported.[13,14] There are only two examples of lanthanoid coordination polymers involving succinate, praseodymium succinate [15a] and lutetium succinate.[15b] In this paper, we present two 3D lanthanoids coordination frameworks, $[Gd_2L_3(H_2O)_2]_n$ (**1**) (L = succinate) and $\{[TbL_{1.5}(H_2O)]\cdot 0.5H_2O\}_n$ (**2**), both of which exhibit ferromagnetic interaction between lanthanoid ions. Moreover, **2** emits an intense green fluorescence in the solid state at room temperature.

Results and Discussion

Crystal Structures

[$Gd_2L_3(H_2O)_2$]$_n$ (1)

A single-crystal X-ray analysis revealed that the solid-state structure of gadolinium(III) succinate differs from that of previously reported praseodymium(III) succinate and lutetium succinate. There are two crystallographically independent gadolinium ions in the asymmetric unit (Figure 1a). Each gadolinium ion is ninefold coordinated by eight oxygen atoms from carboxylate groups of six succinate ions and one oxygen atom from the water molecule. Gd–O bond lengths vary in the range 2.357(8)–2.562(9) Å – in agreement with those of previously reported carboxylate-containing gadolinium complexes (2.308–2.597 Å).[9c] Table 1 gives selected bond lengths and angles. Two Gd^{III} ions are connected by three carboxylate groups, in which one acts as a carboxylate bridge in the usual $\eta^1:\eta^1:\mu_2$ mode while the other two serve as oxo-carboxylate bridges in the less common $\eta^2:\eta^1:\mu_2$ fashion.[9a] Along the *a* axis, the edge-sharing GdO_9 polyhedra extend to a 1D metal oxide like zigzag chain. In the chain, the metal–metal separation for the two symmetrically independent gadolinium ions Gd1–Gd2 is 4.0583(12) Å. The distance between two adjacent symmetrically related Gd^{III} ions is slightly elongated to 4.0595(13) Å [Gd1–Gd2^{I} (I: 1 + *x*, *y*, *z*) or Gd2–Gd1^{II} (II: *x* – 1, *y*, *z*)]. In the lattice, all metal oxide like chains are connected through the carbon–hydrogen chains of the succinate ions to produce 3D lanthanoid coordination frameworks. Notably, there are three conformations in the carbon–hydrogen chains of succinates, which can be observed along the *a* axis (Figure 2). Two of them adopt *gauche*-staggered conformations and extend along the *c* axis, approximately. One such conformation has a torsion angle of 89.5(12)° (C9–C10–C11^{III}–C12^{III}, III: 1 – *x*, 2 – *y*, 1 – *z*) and the other of 70.7(13)° (C5–C6–C7^{IV}–C8^{IV}, IV: 1 – *x*, 2 – *y*, 2 – *z*). The third succinato ligand possesses an *anti*-staggered conformation and extends along the *b* axis, approximately. Here, both carboxylate groups serve as $\eta^2:\eta^1:\mu_2$ mode bridges. In the *gauche*-staggered conformations, however, one carboxylate ion acts as a carboxylate bridge in $\eta^1:\eta^1:\mu_2$ fashion and another as a $\eta^2:\eta^1:\mu_2$ mode bridge.

{[TbL$_{1.5}$(H$_2$O)]·0.5H$_2$O}$_n$ (2)

Complex **2** also has a 3D framework, but differs from complex **1**, containing a mononuclear asymmetric unit that consists of a terbium(III) ion, a coordinating water molecule, 1½ succinate ions as well as ½ a guest water molecule. The terbium(III) ion is also ninefold coordinated by eight oxygen atoms from six carboxylate groups and one water oxygen atom. All oxygen atoms around the Tb^{III} ion form a TbO_9 unit that can be viewed as a tricapped trigonal prism. Tb–O bond lengths are in the range 2.294(4)–2.507(4) Å, which are consistent with that of a previously reported carboxylate-containing terbium complex [2.264(6)–2.533(6) Å].[7b] Table 2 gives selected bond lengths and angles. Along the *b* axis, the TbO_9 polyhedra extend to a 1D zigzag chain by sharing the polyhedron edge. The 1D metal oxide like chains are linked by carbon chains of the ligands to form a 3D metal-organic framework (3D MOF). Although the succinato ligands function in the same modes as in **1**, there are 1D channels that include guest water molecules in the 3D MOF and only one Tb···Tb separation [4.0211(5) Å] in the metal oxide like chains. Guest water molecules are bound to the framework through weak hydrogen bonds, O(2W)–H(2WB)···O(1W) (Table 3). However, the conformations of the carbon–hydrogen chains of the succinato ligands differ slightly from that of **1**. There are just two conformations of the carbon chains in **2** (Figure 3), a *gauche*-staggered with a torsion angle of 72.8(7)° (C1–C2–$C3^V$–$C4^V$, V: x, $y - 1$, $z - 0.5$) and an *anti*-staggered (Table 2). Therefore, the host structural difference between the two complexes is probably caused by the flexibility of the ligand.

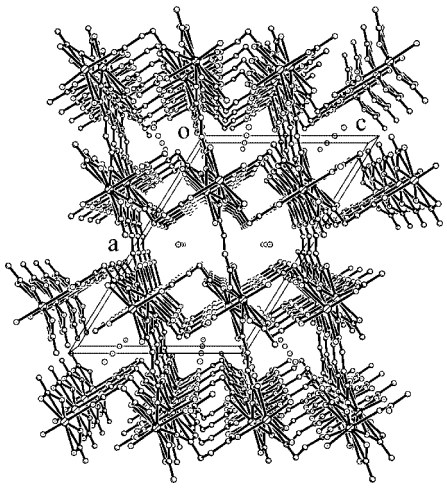

Figure 3. 1D channels including guest water molecules in the 3D frameworks of **2**; all hydrogen atoms omitted for clarity

Thermal Properties

Thermal gravimetric analysis (TGA) is consistent with the X-ray structural results of both coordination polymers. For complex **1**, the gradual weight loss from 115 to 197 °C (5.35%) corresponds to the loss of coordination water molecules (calcd. 5.16%). The complex then decomposes above 404 °C. In contrast, complex **2** shows a sharp weight loss in the range 86–94 °C (3.26%) due to the loss of the guest water (calcd. 2.50%). The thermal analysis curve confirms the presence of guest molecules in the channels of the 3D MOF containing terbium. The second weight-loss (156–202 °C, 5.52%) can be attributed to the loss of coordination water molecules (calcd. 5.13%). Complex **2** decomposes above 400 °C.

Magnetic Properties

The magnetic behavior of complex **1** is represented in Figure 4 as $\chi_M T$ vs. T. At room temperature, $\chi_M T$ is 15.55 $cm^3\,mol^{-1}\,K$, which is close to the value, 15.75 $cm^3\,mol^{-1}\,K$, of two non-interacting Gd^{3+} ions in the $^8S_{7/2}$ ground state. With decreasing temperature, $\chi_M T$ decreases smoothly and reaches a minimum of 15.17 $cm^3\,mol^{-1}$ at 50 K. Below this temperature, $\chi_M T$ increases rapidly, indicating that the ferromagnetic interaction between the Gd^{3+} ions dominates the magnetic properties of complex **1**. This overall feature indicates two conflicting effects. Ferromagnetic interaction between two Gd^{3+} ions increases the molecular magnetism, while some other factors induce the decrease of $\chi_M T$. Similar behavior observed in other lanthanoid-containing complexes[8b,9e] is suggested to arise from the Stark effect caused by the crystal-field perturbation and splitting f orbits. This effect tends to lower the local contributions of the lanthanoid ions.[16] However, the Gd^{3+} ion has a half-filled 4f shell and, to a first approximation, its ground state must not split in ligand fields. Actually, the crystal field distorts the ion symmetry and the degeneracy is broken partly, and a slight splitting always

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

occurs. Generally, the Stark effect for Gd^{III} is of the order of 0.05 cm^{-1}, which is not enough to decrease $\chi_M T$ in the range 50–300 K. In both $GdCl_3$ and $Gd(OH)_3$, both ferromagnetic and antiferromagnetic interactions are present. They arise from the usual Heisenberg form of the exchange plus magnetic-dipole interaction and they do not change appreciably below 77 K.[17–19] The nearest-neighbor (J_{nn}) interactions (*nn* pairs) are antiferromagnetic while those of the next-nearest neighbor (J_{nnn}) interactions (*nnn* pairs) are ferromagnetic. The observed magnetic behavior depends on the dominant interaction. The description of this system closely follows the spin-wave theory used successfully for 3d ions.[19] In complex **1**, the two Gd–Gd separations mentioned above probably make the *nn* and *nnn* pairs, such as Gd1–Gd2 and Gd2–Gd1′. The *nnn* pairs could not, seemingly, be Gd1–Gd1′ or Gd2–Gd2′, because the shortest distance between them is ca. 7.707 Å. Interaction at this distance should be very weak and could be neglected. However, it could not be confirmed as intrinsic source. The nature of the Gd···Gd interaction in **1** is supported by magnetization measurements in the 0–7 T range at 1.83 K. The magnetization plot per Gd^{3+} ion closely follows the Brillouin function with a theoretical *g* factor (g = 2.0) (Figure 5).[20]

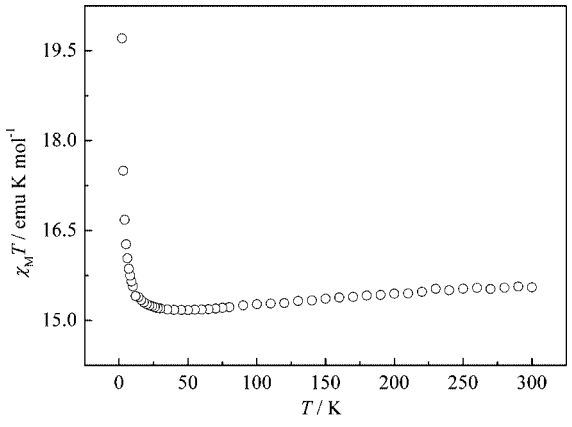

Figure 4. Temperature dependence of $\chi_M T$ for **1**

For complex **2**, $\chi_M T$ increases with decreasing temperature over the whole temperature range (Figure 6), implying that ferromagnetic coupling between Tb^{3+} ions dominates the magnetic properties. At room temperature, $\chi_M T$ is 23.10 $cm^3\ mol^{-1}$ K, which is close to the value of two non-interacting Tb^{3+} ions in the $^7F_6$ ground state (11.82 $cm^3\ mol^{-1}$ per Tb^{3+} ion).[20] $\chi_M T$ increases steadily from 300 to 20 K, and then increases rapidly on further cooling to 1.8 K. All these data indicate a ferromagnetic interaction between two terbium ions in **2**. AC magnetic measurements show a strong temperature dependence of both in-phase magnetization, χ', and out-of-phase magnetization, χ''. Both χ' and χ'' sharply increase below 4 K, suggesting long-range ordering in **1**. The ordering temperature is <1.8 K because no peaks are observed in χ' and χ'' vs. T plots (Figure 7). This appears to be the first observation of long-range ordering in fully structurally characterized lanthanoid-containing coordination compounds that display a ferromagnetic interaction.

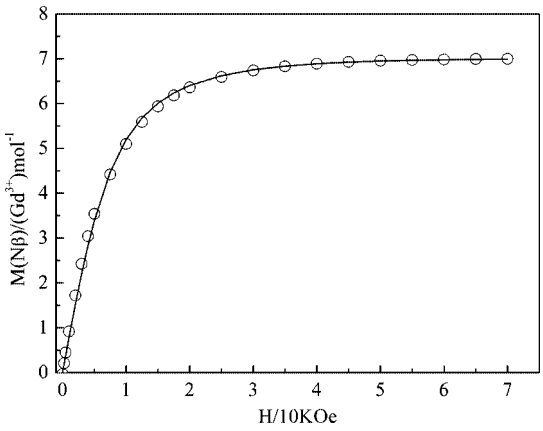

Figure 5. Field dependence of the magnetization for **1** at 1.83 K (circles); the solid line represents the Brillouin function for two magnetically isolated Gd^{III} ions with g = 2.0

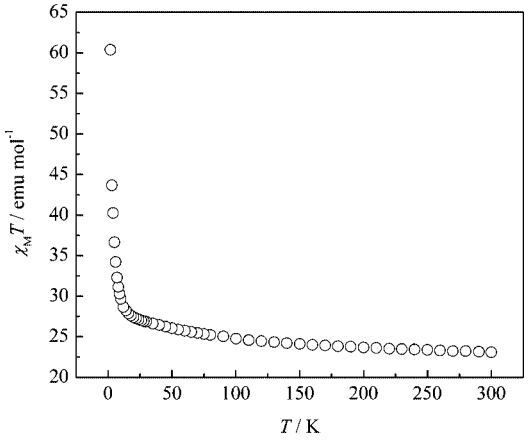

Figure 6.Temperature dependence of $\chi_M T$ for **2**

The magnetic properties of most lanthanoid ions are strongly influenced by their rather large unquenched orbital angular momentum associated with the internal nature of the valence f orbits.[20] This is one reason why lanthanoid compounds are widely applied in magnet technology, but also accounts for the difficulty in studying their magnetic properties. Recent interest has focused on the magnetic behavior of the f-block coordination compounds.[8–10,21] Only two examples of well-characterized lanthanoid complexes containing gadolinium display ferromagnetic interaction between lanthanoid ions;[9c,d] others have observed ferromagnetism in dinuclear triple-decker complexes that include Tb, Dy and Ho, but without structural characterization.[21] The ferromagnetic interaction observed here in the gadolinium carboxylate compound probably arises from the accidental orthogonality between the magnetic orbitals of the two interacting Gd^{III} ions, the angle at the oxo bridge, and the Gd···Gd separation through it.[9c]

Fluorescent Properties

Complex **2** emits an intense green light in the solid state at room temperature. Excitation and emission spectra (Figure 8) show typical Tb^{III} excitation peaks at 319 ($^7F_6 \rightarrow {}^5D_0$), 342 ($^7F_6 \rightarrow {}^5L_7$), 352 ($^7F_6 \rightarrow {}^5L_9$), 370 ($^7F_6 \rightarrow {}^5G_5$) and 379 nm ($^7F_6 \rightarrow {}^5G_6$), indicating that direct excitation of the terbium ion operates in complex **2** when emission at 544 nm is observed. The emission spectra are almost identical when excited at 352 and 370 nm. Emission peaks at 489, 544, 585 and 621 nm can be assigned to $^5D_4 \rightarrow {}^7F_n$ (n = 6, 5, 4, 3) transitions, respectively. The most intense emission, at 544 nm ($^5D_4 \rightarrow {}^7F_5$), is a magnetic dipole transition (ΔJ = ±1). Both excitation and emission spectra agree well with the spectra of a terbium-ion-doped inorganic ceramic.[22]

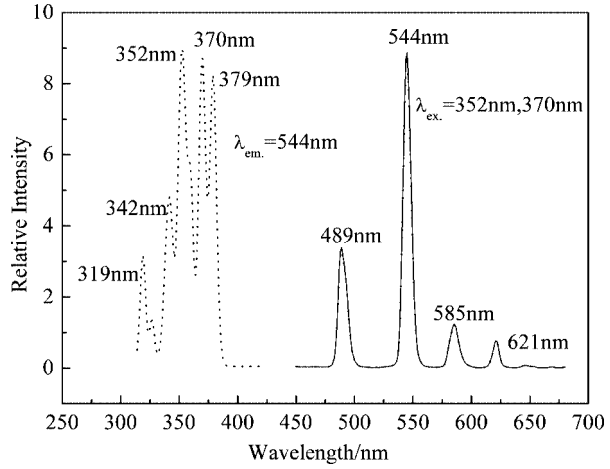

Figure 8. Excitation (dotted line) and emission (solid line) spectra of 2 in the solid state

Conclusions

Magnetic properties of the coordination frameworks in **1** and **2**, along with the fluorescence of **2**, support their structural motif. Functional carriers, such as Gd^{III} or Tb^{III} ions as the spin carriers and Tb^{III} ions as the luminescent centers, can be arranged into a special solid-state structure by the support or connection of the ligands, e.g. a 3D array of 1D chains. Such solids can display properties induced by the metals ions. Especially, the 3D framework consisting of terbium ions integrates ferromagnetic, fluorescent and porous properties into a single entity. This approach probably makes some coordination polymers promising candidates for new multifunctional molecular-based materials.

Experimental Section

Materials and Methods: All starting materials were purchased from China Medicine (Group) Shanghai Chemical Reagent Corporation and used without further purification. Elemental analyses were carried out with a Perkin–Elmer 240C elemental analyzer. IR spectra were recorded with a Bruker VECTOR22 FT-IR spectrometer using the KBr pellet technique. Thermogravimetric analyses (TGA) were performed with a TA-SDT 2960 thermal analyzer at a heating rate of 10 °Cmin^{-1} from room temperature to 600 °C under nitrogen. The solid-state excitation-emission spectrum was acquired with an AMINCO•Bowman Series AB2 Luminescence Spectrometer at room temperature. Magnetic susceptibilities were measured with a Mag Lab2000 system and a SQUID MPMS XL magnetometer. Diamagnetic corrections were made using Pascal's constants.

Syntheses and Characterization

$[Gd_2L_3(H_2O)_2]_n$ (1): A mixture of $Gd(NO_3)_3$•$6H_2O$ (45.3 mg, 0.1 mmol), succinic acid (18 mg, 0.15 mmol), NaOH (12 mg, 0.3 mmol), and H_2O (10 mL) was sealed in a 25-mL stainless-steel reactor with a Teflon liner and heated to 170 °C. After 3 d at 170 °C, the mixture was then cooled to room temperature. Colorless block-like crystals of **1** were obtained in 77.0% yield (53.8 mg) after filtration and washing with water. $C_{12}H_{16}Gd_2O_{14}$ (698.75): calcd. C 20.63, H 2.31; found C 20.62, H 2.37. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3300 (m, br.), 2983 (w), 2947 (w), 2925 (w), 2913(w), 1572 (vs, sh), 1427 (vs, sh), 1304 (s), 1215 (s), 1176 (s), 1002 (m), 909 (m), 691 (s), 652 (s), 572 (m).

$\{[TbL_{1.5}(H_2O)]\cdot 0.5H_2O\}_n$ (2): A mixture of $Tb(NO_3)_3$•$6H_2O$ (45.5 mg, 0.1 mmol), succinic acid (18 mg, 0.15 mmol), NaOH (12 mg, 0.3 mmol), and H_2O (10 mL) was sealed in a 25-mL stainless-steel reactor with Teflon liner and heated to 170 °C, kept at 170 °C for 3 d, then cooled to room temperature. Colorless block-like crystals of **2** were obtained in 69.0% yield (49.7 mg) after filtration and washed with water. $C_{12}H_{18}O_{15}Tb_2$ (720.10): calcd. C 20.02, H 2.52; found C 20.08, H 2.44. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3302 (m, br), 2983 (w), 2948 (w), 2925 (w), 2914 (w), 1576 (vs, sh), 1429 (vs, sh), 1304 (s), 1215 (s), 1176 (s), 1002 (m), 909 (m), 691 (s), 653 (s), 572 (m).

Crystallography

$[Gd_2L_3(H_2O)_2]_n$ (1): A single crystal (0.21×0.16×0.12 mm) was used for structural determination with an Enraf-Nonius CAD-4 diffractometer with graphite-monochromatized Mo-K_α radiation (λ = 0.71073) using an ω-2θ scan mode at 293 K. Intensity data were collected in the θ range 2.75–25.00°, data reduction was made with the MolEN package.[23] Absorption corrections from ψ scans were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

applied. The structure was solved by direct methods using SHELXS-97 [24] and refined on F^2 by full-matrix least squares using SHELXL-97 with anisotropic displacement parameters for all non-hydrogen atoms.[25] Hydrogen atom positions were fixed geometrically at calculated distances and allowed to ride on the parent atoms. Relevant crystallographic data are presented in Table 4.

{[TbL$_{1.5}$(H$_2$O)]·0.5H$_2$O}$_n$ (2): A single crystal (0.20×0.14×0.10 mm) was used for structural determination with a Bruker SMART CCD diffractometer with graphite-monochromatized Mo-K_α radiation (λ = 0.71073) using both Φ- and ω-scan modes at 293 K. Intensity data were collected in the θ range 2.40–25.00°, data reduction was made with the Bruker SAINT package.[26] Absorption corrections were performed using the SADABS program.[27] The structure was solved by direct methods using SHELXS-97 and was refined on F^2 by full-matrix least squares using SHELXL-97 with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were introduced in calculations using the riding model. Table 4 gives the relevant crystallographic data.

CCDC-228741 (**2**) and -28742 (**1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

Addition of Carbenes to an Osmium(VI) Nitride Complex

Chi-Fai Leung,[a] Tsz-Wing Wong,[a] Tai-Chu Lau,*[a] and Wing-Tak Wong[b]

Keywords: Carbenes / N,O ligands / Nitrides / Osmium / Vinylidene ligands

A series of osmium(VI) nitride complexes containing 8-quinolinolato ligands, $[Os^{VI}(N)(X\text{-}Q)_2Cl]$ (X = H, 5-Cl, 5-NO_2, 2-Me; **1a**–**d**), have been synthesized by reaction of HX-Q with $[nBu_4N][Os^{VI}(N)Cl_4]$ in the presence of 2,6-dimethylpyridine. The ν(Os≡N) stretches of these compounds occur at 1056–1075 cm^{-1}, and are within the range (1050–1120 cm^{-1}) found for most osmium nitride species. The structure of **1d** has been determined by X-ray crystallography. The osmium center adopts a distorted octahedral geometry, and the two quinolinolato ligands are *cis* to each other. The three N atoms are in a facial arrangement, and the Os≡N bond distance is 1.644(6) Å. Complex **1c** readily reacts with the carbene precursors bis(1,3-dialkylimidazolidin-2-ylidene) ($L^R{}_2$; R = Me, Et, or CH_2Ph) to produce the osmium(IV) azavinylidene species, $[Os^{IV}(N{=}L^R)(NO_2\text{-}Q)_2Cl]$, which are derived from the formal addition of the carbenes L^R to $Os^{VI}{\equiv}N$. The structure of $[Os^{IV}(N{=}L^{Et})(NO_2\text{-}Q)_2Cl]$ (**2b**) has been determined by X-ray crystallography. The osmium center has a distorted octahedral geometry in which the facial arrangement of the three N atoms is retained. The Os(1)–N(5) distance of 1.875(6) Å is rather long and, together with the rather acute Os(1)–N(5)–C(19) angle of 133.8(5)°, indicates that there is no significant multiple-bond character in the Os(1)–N(5) bond.

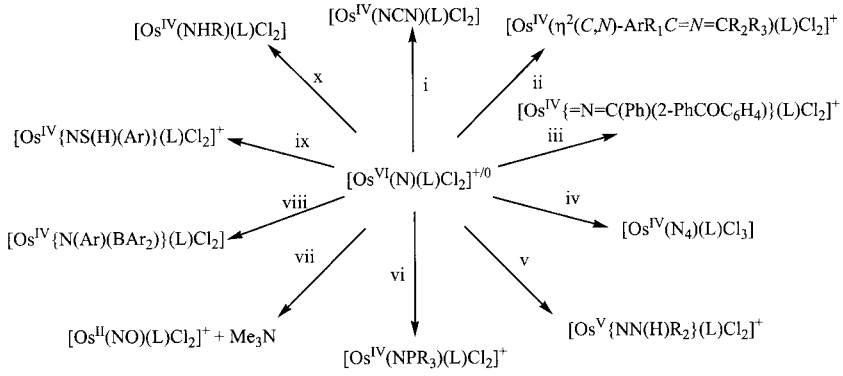
Introduction

Osmium(VI) nitride species containing nitrogen-based ligands, such as *cis*- and *trans*-$[Os^{VI}(N)(tpy)Cl_2]^+$ (tpy = 2,2′:6′,2′′-terpyridine), $[Os^{VI}(N)(tpm)Cl_2]^+$ [tpm = tris(1-pyrazolyl)methane], $[Os^{VI}(N)(Tp)Cl_2]$ [Tp^- = hydrotris(1-pyrazolyl)borate], and $[Os^{VI}(N)(bpy)Cl_3]$ (bpy = 2,2′-bipyridine), have been shown to exhibit novel electrophilic properties.[1–14] A variety of reagents such as phosphanes, amines, cyanide, azide, Grignard reagents, arylboranes, amine *N*-oxides, alkenes, and disubstituted benzenethiols have been reported to add to the nitride ligand.[1–14] These reactions are summarised in Scheme 1.



Scheme 1.Electrophilic reactions of osmium(VI) nitrido complexes: i) L = tpy, CN^-; ii) L = tpy, alkenes; iii) L = tpy, 1,3-diphenylisobenzofuran; iv) L = bpy, N_3^-; v) L = tpy/tpm, HNR_2 [R = Et, 1/2$(CH_2)_4O$, 1/2$(CH_2)_4CH_2$]; vi) L = tpy, PR_3; vii) L = tpy, Me_3NO; viii) L = Tp, arylboranes; ix) L = tpy, ArSH (Ar = 3,5-$Me_2C_6H_3$); x) L = Tp, RMgCl

We are interested in tuning the reactivities of these osmium(VI) nitride complexes by replacing tpy or Tp^- with other chelating ligands. We report here the synthesis of a series of new electrophilic osmium(VI) nitride complexes containing 8-quinolinolato ligands. These are the first examples of high-valent osmium complexes containing 8-qui-

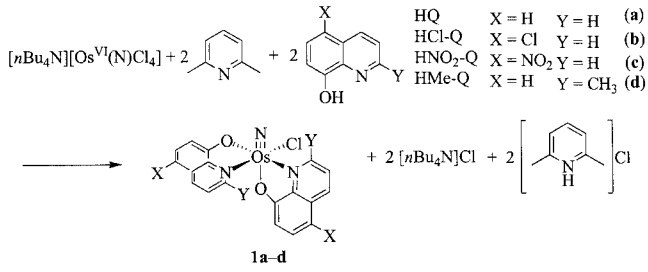
nolinolato ligands. We also report the reaction of the 5-nitro-8-quinolinolato complex with the carbene precursors bis(1,3-dialkylimidazolidin-2-ylidene) (L^R_2; R = Me, Et, or CH_2Ph) to produce (azavinylidene)osmium(IV) species that are derived from the formal addition of the carbenes L^R to $Os^{VI}{\equiv}N$. This is the first example of the addition of a carbene fragment to a nitride ligand, an important "missing" reaction for electrophilic metal nitride species.

Results and Discussion

Complexes **1a**–**d** were prepared in 55–65% yields from the reaction of $[nBu_4N][Os^{VI}(N)Cl_4]$ with the appropriate 8-hydroxyquinoline at room temperature in methanol in the presence of 2,6-dimethylpyridine, which functions as a mild base (Scheme 2).



Scheme 2. Preparation of osmium nitride complexes

These complexes are air-stable, diamagnetic, orange crystalline solids. They were characterized by ^1H NMR and IR spectroscopy, and elemental analysis (see Exp. Sect.). The ν(Os≡N) stretches of these complexes occur at 1056–1075 cm^{-1}, and are within the range (1050–1120 cm^{-1}) found for most osmium nitride species.[15–17] The assignment of the ν(Os≡N) stretches was supported by ^{15}N labeling. The structure of **1d** was determined by X-ray crystallography (Figure 1). The osmium center adopts a distorted octahedral geometry, and the two quinolinolato ligands are *cis* to each other. The three N atoms are in a facial arrangement. The Os≡N bond length of 1.644(6) Å is within the range (1.52–1.70 Å) found for other osmium nitride complexes.[3,17,18] The Os(1)–O(2) and Os(1)–O(1) bond lengths are 2.111(4) and 1.974(4) Å, respectively. The long Os(1)–O(2) distance reflects the rather large *trans* influence of the nitride ligand; it is assumed that **1a**–**c** also have the same configuration as **1d**. This is supported by their ^1H NMR spectra, which show that all four complexes have similar patterns.

The reaction of **1c** with bis(1,3-dialkylimidazolidin-2-ylidene) (L^R_2; R = Me, Et, or CH_2Ph) in CH_2Cl_2 under argon produces the (azavinylidene)osmium(IV) complexes **2a**–**c** as air-stable, dark-red, rod-shaped crystals in 40–46% yield (Scheme 3). However, no reaction occurs between L^R_2 and **1a**, **1b**, or **1d**.Complex **1c** is expected to be the most electrophilic among the four nitride species due to the presence of the electron-withdrawing nitro group in the 8-quinolinolato ligand.

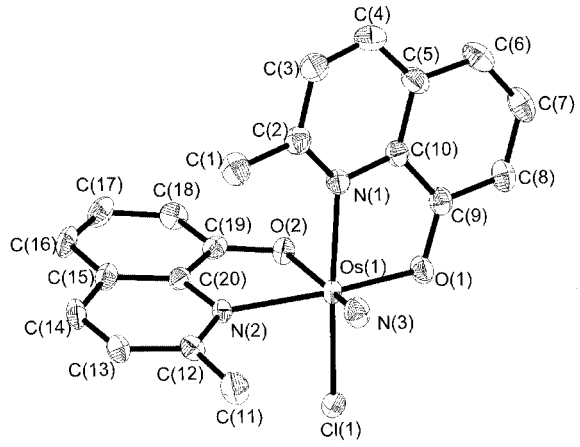


Figure 1.Molecular structure of **1d**

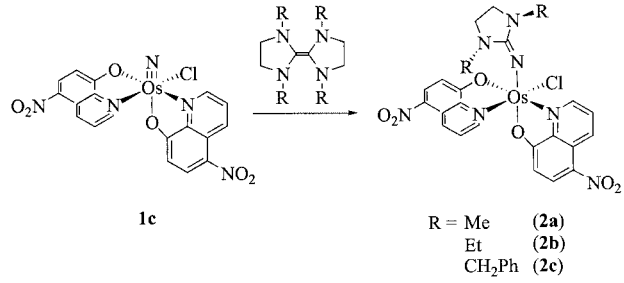

Scheme 3. Reaction of osmium nitride complex **1c** with L^R_2

The IR spectra (KBr) of the osmium(IV) complexes **2a**–**c** exhibit bands at around 2900 cm^{-1}, which correspond to the aliphatic C–H stretches of the alkyl groups on the imidazolin-2-ylidene ring. Complex **2b** has a room-temperature magnetic moment of 2.07 μ_B, which is consistent with its formulation as a d^4 Os^{IV} complex with a $d\pi_1^2$ $d\pi_2^1$ $d\pi_3^1$ electronic configuration. (Phosphoraniminato)osmium(IV) complexes have slightly lower magnetic moments of around 1.8 μ_B.[18,19] These magnetic moments are much lower than the spin-only value of 2.8 μ_B due to spin-orbit coupling.

The structure of **2b** was determined by X-ray crystallography (Figure 2). The osmium center has a distorted octahedral geometry in which the facial arrangement of the three N atoms is retained. The Os(1)–N(5) distance of 1.875(6) Å is within the range found for other (azavinylidene)osmium complexes (1.78–1.88 Å).[13,20] The Os(1)–N(5)–C(19) angle of 133.8(5)° is, however, the smallest among (azavinylidene)osmium complexes (152–176°).[13,20] The similar Os(1)–O(4) and Os(1)–O(1) distances [2.019(3) and 2.048(4) Å respectively] indicate that the *trans* influence of the azavinylidene ligand is negligible.

Complexes **2a**–**c** have extensive redox chemistry. Figure 3 displays the cyclic voltammogram of **2b** in CH_3CN (0.1 M $[nBu_4N][PF_6]$) recorded at a glassy-carbon working electrode. Three reversible waves appear at $E_{1/2}$ = +1.06 V (ΔE_p = 66 mV), +0.05 V (ΔE_p = 56 mV), and –0.95 V (ΔE_p = 64 mV) vs. ferrocenium/ferrocene (Fc^+/Fc), which are assigned to metal-centered $Os^{VI/V}$, $Os^{V/IV}$, and $Os^{IV/III}$ couples, respectively (Figure 3). There is also a quasi-reversible wave

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

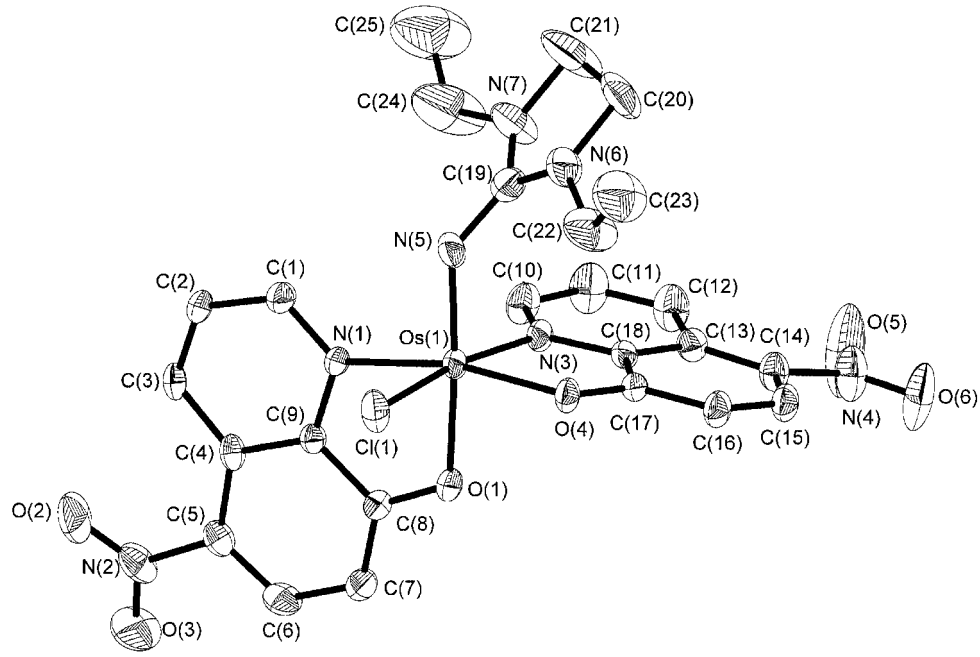

Figure 2. Molecular structure of **2b**

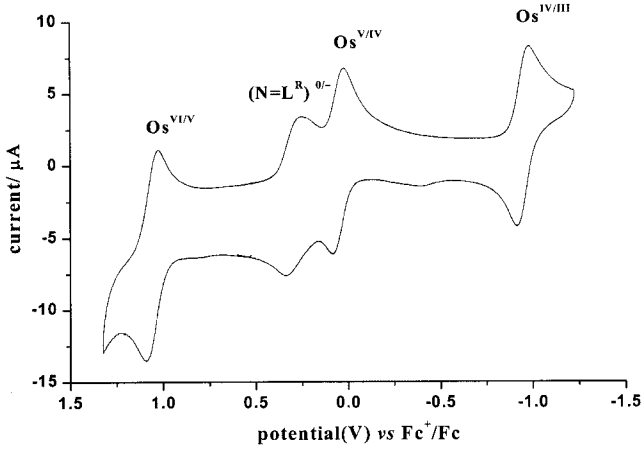

Figure 3. Cyclic voltammogram of $[Os^{IV}(N=L^{Et})(NO_2\text{-}Q)_2Cl]$ (**2b**) in CH_3CN (0.1 M $[nBu_4N][PF_6]$), scan rate = 100 mV s^{-1}

at $E_{1/2}$ = +0.29 V (ΔE_p = 86 mV), which is assigned to oxidation of the azavinylidene ligand, $(N=L^{Et})^- \rightarrow (N=L^{Et})$. The electrochemistry of **2b** is represented by Equation (1).

$$[Os^{VI}\{(N=L^{Et})^0\}(NO_2\text{-}Q)_2Cl]^{3+} \underset{-e}{\overset{+e}{\rightleftharpoons}} [Os^{V}\{(N=L^{Et})^0\}(NO_2\text{-}Q)_2Cl]^{2+} \underset{-e}{\overset{+e}{\rightleftharpoons}}$$
$$[Os^{IV}\{(N=L^{Et})\}(NO_2\text{-}Q)_2Cl] \underset{-e}{\overset{+e}{\rightleftharpoons}} [Os^{III}\{(N=L^{Et})\}(NO_2\text{-}Q)_2Cl] \quad (1)$$

Similar electrochemical behavior is found for **2a** and **2c**; the electrochemical data for **2a**–**c** are collected in Table 1. The $E_{1/2}$ of the quasi-reversible wave shifts from 0.29 V to 0.24 V on going from CH_3 or C_2H_5 to the more electron-rich CH_2Ph substituent, in accordance with its assignment as a ligand-centered redox couple.

Table 1. Electrochemical data for $[Os^{IV}(N=L^R)(NO_2\text{-}Q)_2Cl]$ (**2a**–**c**) in 0.1 M $[nBu_4N][PF_6]/CH_3CN$; scan rate = 100 mV s^{-1}; the errors in the potentials are typically 10 mV

	$E_{1/2}$ [V vs. Fc/Fc^+]			
	$Os^{VI/V}$	$(N=L^R)^{0/-}$	$Os^{V/IV}$	$Os^{IV/III}$
2a (R = Me)	1.06	0.29	0.06	–0.96
2b (R = Et)	1.06	0.29	0.05	–0.95
2c (R = CH_2Ph)	1.05	0.24	0.03	–1.01

The electron-rich alkenes $L^R{}_2$ are well-known carbene precursors; they react with a variety of transition-metal complexes to produce carbene complexes of the type $M=L^R$.[21,22] The work reported here, however, is the first example of the reaction of $L^R{}_2$ with a nitride complex that results in the formal addition of the carbene L^R to the nitride ligand. A similar, but much faster, reaction occurs between **1c** and the stable, commercially available carbene L^R (R = *tert*-butyl, 1,3-di-*tert*-butylimidazol-2-lylidene); however, in this case, attempts to purify the product have so far been unsuccessful. A proposed mechanism for the reaction of Os≡N with $L^R{}_2$, which is similar to that proposed for the formation of (carbene)metal compounds between metal complexes and $L^R{}_2$,[21] is shown in Scheme 4. It is generally believed that $L^R{}_2$ does not dissociate into the free carbene L^R prior to reaction with metal complexes. Hence, we suggest that $L^R{}_2$ reacts directly with Os≡N to produce the (azavinylidene)Os^{IV} compound.

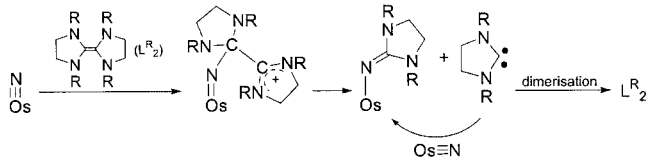

Scheme 4. Proposed mechanism for the reaction of Os≡N with L^R_2

Conclusions

A series of osmium(VI) nitride complexes containing 8-quinolinolato ligands, $[Os^{VI}(N)(X\text{-}Q)_2Cl]$ (X = H, 5-Cl, 5-NO_2, 2-Me; **1a**–**d**), have been synthesized by reaction of HX-Q with $[nBu_4N][Os^{VI}(N)Cl_4]$ in the presence of 2,6-dimethylpyridine. Among these complexes **1c** is the most electrophilic, and it reacts readily with the carbene precursors bis(1,3-dialkylimidazolidin-2-ylidene) (L^R_2; R = Me, Et, or CH_2Ph) to produce a series of (azavinylidene)osmium(IV) species, $[Os^{IV}(N{=}L^R)(NO_2\text{-}Q)_2Cl]$, that are derived from the formal addition of the carbenes L^R to $Os^{VI}{\equiv}N$.

Experimental Section

Reagents and Physical Measurements: The complexes $[nBu_4N][Os^{VI}(N)Cl_4]$ and $[nBu_4N][Os^{VI}(^{15}N)Cl_4]$[23,24] and the electron-rich olefins bis(1,3-dialkylimidazolidin-2-ylidene)[25] were prepared by literature procedures. Acetonitrile was first heated to reflux in the presence of calcium hydride and then distilled under argon. Tetrabutylammonium hexafluorophosphate (Aldrich) was recrystallized three times from boiling ethanol and dried in vacuo at 120 °C for 1 d before use. The 8-hydroxyquinoline ligands were purchased from Aldrich and were used as received. All other chemicals were of reagent grade and used without further purification. IR spectra were obtained from KBr discs with a Bomen MB-120 FTIR spectrophotometer. UV/Vis spectra were recorded with either a Perkin–Elmer Lamda 19 or a Shimadzu UV3100 spectrophotometer. ^{1}H NMR spectra were recorded with a Varian (300MHz) FT NMR spectrometer. The chemical shifts (δ, ppm) are reported relative to tetramethylsilane (TMS). Elemental analyses were performed with an Elementar Vario EL Analyzer. Cyclic voltammograms were obtained with a PAR model 273 potentiostat. A glassy-carbon disk working electrode and an $Ag/AgNO_3$ reference electrode were used. The supporting electrolyte was 0.1 M $[nBu_4N]PF_6$ in CH_3CN.

$[Os^{VI}(N)(Q)_2Cl]$ (1a): 8-Hydroxyquinoline (HQ; 50 mg, 0.34 mmol) was added to a solution of $[nBu_4N][Os^{VI}(N)Cl_4]$ (100 mg, 0.17 mmol) in 10 mL of methanol. After stirring for 15 min, 2,6-lutidine (0.5 mL) was added and the resulting orange solution was stirred for another 30 min. The orange solid was collected by filtration, washed with methanol, and dried in vacuo. Yield 47 mg (53%). $C_{18}H_{12}ClN_3O_2Os$ (528.01): calcd. C 40.95, H 2.27, N 7.96; found C 41.07, H 2.52, N 7.82. UV/Vis (DMF): λ_{max} = 266 nm (ε = 38700 dm^3 mol^{-1} cm^{-1}), 340 (3790), 407 (6710). IR (KBr): $\tilde{\nu}$ = 1573 cm^{-1} (s), 1500 (s), 1464 (s), 1381 (s), 1319 (s), 1056 (w, OsN) [1025 (w, $Os^{15}N$)]. ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 6.57 (d, 1 H), 7.27 (d, 1 H), 7.46 (t, 1 H), 7.61 (m, 3 H), 7.80 (t, 1 H), 7.94 (m, 1 H), 8.32 (d, 1 H), 8.73 (d, 1 H), 8.82 (d, 1 H), 9.25 (d, 1 H) ppm.

$[Os^{VI}(N)(Cl\text{-}Q)_2Cl]$ (1b): This complex was prepared by a procedure similar to that for **1a** using 5-chloro-8-hydroxyquinoline (61 mg, 0.34 mmol). Yield 58 mg (57%). $C_{18}H_{10}Cl_3N_3O_2Os$ (596.92): calcd. C 36.22, H 1.69, N 7.04; found: C, 35.89, H 1.86, N 6.83. UV/Vis (DMF): λ_{max} = 269 nm (ε = 13800 dm^3 mol^{-1} cm^{-1}), 419 (3030). IR (KBr): $\tilde{\nu}$ = 1570 cm^{-1} (w), 1498 (s), 1457 (s), 1368 (s), 1302 (w), 1058 (w, OsN) [1027 (w, OsN^{15})]. ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 6.58 (d, 1 H), 7.61 (d, 1 H), 7.63 (d, 1 H), 7.78 (m, 1 H), 8.54 (d, 1 H), 8.87 (m, 2 H), 8.37 (d, 1 H) ppm.

$[Os^{VI}(N)(NO_2\text{-}Q)_2Cl]$ (1c): This complex was prepared by a procedure similar to that for **1a** using 8-hydroxy-5-nitroquinoline (65 mg, 0.34 mmol). Yield 66 mg (63%). $C_{18}H_{10}ClN_5O_6Os$ (618.01): calcd. C 34.99, H 1.62, N 11.33; found: C, 35.17, H 1.86, N 10.97. UV/Vis (DMF): λ_{max} = 268 nm (ε = 9760 dm^3 mol^{-1} cm^{-1}), 419 (8410). IR (KBr): $\tilde{\nu}$ = 1601 cm^{-1} (w), 1503 (s), 1462 (s), 1298 (vs), 1075 (w, OsN) [1040 (w, $Os^{15}N$)]. ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 6.67 (d, 1 H), 7.75 (d, 1 H), 7.86 (m, 1 H), 8.27 (m, 1 H), 8.60 (d, 1 H), 8.82 (d, 1 H), 8.88 (d, 1 H), 9.48 (d, 1 H), 9.58 (m, 2 H) ppm.

$[Os^{VI}(N)(Me\text{-}Q)_2Cl]$ (1d): This orange complex was prepared by a procedure similar to that for **1a** using 8-hydroxy-5-methylquinoline (54 mg, 0.34 mmol). Yield 57 mg (60%). $C_{20}H_{16}ClN_3O_2Os$ (556.07): calcd. C 43.2, H 2.88, N 7.55; found: C, 43.43, H 3.24, N 7.34. UV/Vis (DMF): λ_{max} = 269 nm (ε = 14100 dm^3 mol^{-1} cm^{-1}), 394 (2110). IR (KBr): $\tilde{\nu}$ = 1563 cm^{-1} (s), 1458 (s), 1324 (w), 1268 (w), 1056 (w, OsN) [1024 (w, $Os^{15}N$)]. ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 2.15 (s, 3 H), 6.40 (d, 1 H), 7.15 (d, 1 H), 7.27 (t, 1 H), 7.50 (m, 3 H), 7.68 (t, 1 H), 8.00 (d, 1 H), 8.55 (m, 2 H) ppm.

$[Os^{IV}(N{=}L^{Me})(NO_2\text{-}Q)_2Cl]$ (2a): Complex **1c** (100 mg, 0.16 mmol) was added under argon to bis(1,3-dimethylimidazolidin-2-ylidene) L^{Me}_2 (31 mg, 0.16 mmol), in 15 mL of CH_2Cl_2, and the mixture was stirred for 24 h to give a red solution. After filtration, the solution was loaded onto a silica-gel column and eluted with acetone/CH_2Cl_2 (1:5). The red solid was recrystallized from CH_3CN/CH_3OH. Yield 49 mg (43%). $C_{23}H_{20}ClN_7O_6Os$ (716.16): calcd. C 38.57, H 2.82, N 13.69; found: C, 38.74, H 2.87, N 13.51. UV/Vis (CH_2Cl_2): λ_{max} = 254 nm (ε = 40300 dm^3 mol^{-1} cm^{-1}), 301 (17400), 393 (16700), 449 (19800), 480 (19600). IR (KBr): $\tilde{\nu}$ = 3105 cm^{-1} (w, CH), 2878 (w, CH), 1593 (w), 1577 (w), 1559 (s), 1503 (s), 1450 (w), 1409 (w), 1286 (vs), 1186 (w), 1145 (w), 1102 (w), 1010 (w).

$[Os^{IV}(N{=}L^{Et})(NO_2\text{-}Q)_2Cl]$ (2b): This complex was prepared by a procedure similar to that for **2a**, using bis(1,3-diethylimidazolidin-2-ylidene) L^{Et}_2 (41 mg, 0.16 mmol). Crystals suitable for X-ray crystallography were obtained from acetonitrile/methanol. Yield 55 mg (46%). $C_{25}H_{24}ClN_7O_6Os$ (744.21): calcd. C 40.35, H 3.26, N 13.18; found C 40.27, H 3.18, N 12.95. UV/Vis (CH_2Cl_2): λ_{max} = 491 nm (ε = 38800 dm^3 mol^{-1} cm^{-1}), 299 (30800), 393 (31000), 254 (72800). IR (KBr): $\tilde{\nu}$ = 2966 cm^{-1} (w), 2925 (w), 2869 (w, CH), 1596 (w), 1562 (w), 1503 (s), 1453 (w), 1288 (vs, NO), 1186 (w), 1145 (w), 1100 (w), 1009 (w).

$[Os^{IV}(N{=}L^{CH_2Ph})(NO_2\text{-}Q)_2Cl]$ (2c): The complex was prepared by a procedure similar to that for **2a**, using bis(1,3-dibenzylimidazolidin-2-ylidene), $L^{CH_2Ph}_2$ (81 mg, 0.16 mmol). Yield 49 mg (39%). $C_{35}H_{28}ClN_7O_6Os$ (868.32): calcd. C 48.41, H 3.26, N 11.29; found C 48.58, H 3.24, N 11.35. UV/Vis (CH_2Cl_2): λ_{max} = 253 nm (ε = 41800 dm^3 mol^{-1} cm^{-1}), 296 (16900), 378 (17800), 496 (22800). IR (KBr): $\tilde{\nu}$ = 3105 cm^{-1} (w), 3060 (w, CH), 1601 (w), 1505 (s), 1299 (vs, NO), 1193 (w), 1148 (w), 1100 (w), 1071 (w).

X-ray Crystallographic Study: Intensity data were collected at ambient temperature using a Rigaku AFC7R diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) in the ω-scan mode. Details of the intensity data collection and crystal data are given in Table 2. Selected bond lengths and angles for **1d** and **2b**

are given in Table 3 and Table 4, respectively. The data were corrected for Lorentz and polarization effects. Absorption corrections by the ψ-scan method or an approximation by inter-image scaling were applied. The structures were resolved by direct methods (SIR92[26] or SHELXS-86[27]), and expanded using Fourier techniques (DIRDIF94[28]). Hydrogen atoms are included but not refined. All calculations were performed using the TeXsan[29] crystallographic software package from Molecular Structure Corporation. CCDC-226391 (**1d**) and -226392 (**2b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

Bis(1-methylimidazol-2-yl)propionates and Bis(1-methylbenzimidazol-2-yl)-propionates: A New Family of Biomimetic *N,N,O* Ligands – Synthesis, Structures and Cu^{II} Coordination Complexes

Pieter C. A. Bruijnincx,[a] Martin Lutz,[b] Anthony L. Spek,[b][‡] Ernst E. van Faassen,[c] Bert M. Weckhuysen,[d] Gerard van Koten,[a] and Robertus J. M. Klein Gebbink*[a]

Keywords: N,N,O ligands / Ligand design / Facial capping / Copper / Carboxylate ligands

A general synthetic route towards new tridentate, tripodal *N,N,O* ligands, bearing one carboxylate group and two of the biologically relevant imidazole moieties, is presented. The parent compounds of this new family of ligands, A[MIm_2Pr] (**1**) and A[$BenzMIm_2Pr$] (**2**) (A = H, K, Bu_4N) were synthesized in two steps and high overall yield. The structures of $HMIm_2Pr$ (**1a**) and $HBenzMIm_2Pr$ (**2a**) were confirmed by X-ray crystal structure determination, both molecules forming infinite one-dimensional hydrogen bonded chains. The synthetic route allows for the fine-tuning of the physical properties of both ligand systems, e.g., solubility and ease of crystallization. The capability of the two ligands to coordinate facially through all donor atoms was investigated and two isostructural mononuclear copper(II) complexes of the type [CuL_2] were obtained. Both [$Cu(MIm_2Pr)_2$]·$2H_2O$ (**3**) and [$Cu(BenzMIm_2Pr)_2$]·$3.12(H_2O)$·$1.74(C_2H_5OH)$ (**4**) have been characterized by X-ray crystallography, ESI-MS, elemental analysis, UV/Vis, IR, and EPR spectroscopy. In both structures the copper atoms are on an inversion center, which results in a tetragonally distorted octahedral coordination geometry. The CuN_4O_2 chromophores consist of four equatorially coordinated imidazole nitrogen atoms and two axially coordinated carboxylate groups. The non-coordinated water molecules of both crystal structures are involved in a one-dimensional hydrogen-bonded network. Two neighboring octahedrons are connected by two water molecules, each water molecule forming two hydrogen bonds with the non-coordinated oxygen atoms of the carboxylate group. This results in the formation of infinite one-dimensional chains. EPR spectroscopy and ESI-MS measurements provide evidence for the integrity of the complexes in solution.

Introduction

The study of synthetic active site analogues has made a vast contribution to the understanding of the structure-function relationship of many metalloenzymes, as has been recently highlighted in a thematic review issue.[1] In particular, the use of tripodal ligand systems has received much attention, the most well-known example probably being the tris(pyrazolyl)borates.[2] Despite their remarkable versatility and the impressive results that have been obtained, these "scorpionates" also illustrate two of the drawbacks associated with many of the reported tripodal ligands. First, most ligand systems are fully symmetrical and provide, for instance, an all-*N* donor set. Second, the *N* donor groups are often found to be non-biologically relevant heterocycles (such as pyrazole or pyridine), which differ both in size, and chemical and electronic properties from the histidyl imidazole-side chain found in biological systems. Since the coordination environment of many metalloenzyme active sites is made up of different donor groups, the interest of synthetic chemists has shifted towards the design of *mixed* ligand systems incorporating different functionalities, i.e. "heteroscorpionates".[3]

We are particularly interested in a group of enzymes exhibiting the so-called 2-His-1-carboxylate motif at their active site.[4,5] This structural motif is found in several crystallographically characterized mononuclear non-heme iron enzymes,[5] like deacetoxycephalosporin C synthase (DAOCS)[6] and naphthalene 1,2-dioxygenase (NDO),[7] in which two histidines and one carboxylate occupy one face of the iron(II) coordination environment. The same facial

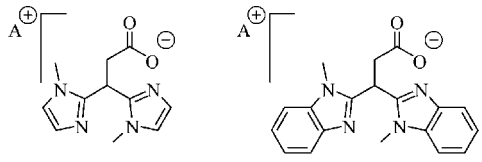
capping by two histidines and one carboxylate is found in several zinc containing enzymes, e.g. carboxypeptidase and thermolysin.[8] This triad is therefore an interesting target for structural modeling.

Most modeling efforts at mimicking this facial triad used either the tridentate tris(pyrazolyl)borato-*N*,*N*,*N* or the tetradentate tris(2-pyridylmethyl)amine-*N*,*N*,*N*,*N*′ ligands.[5,8] However, suitable structural mimics of this triad should preferably be tridentate, tripodal, monoanionic ligands systems with a potentially facially coordinating *N*,*N*,*O* donor set. *N*,*N*,*O* ligands are relatively rare and, to the best of our knowledge, only three tridentate examples have been reported of these mixed ligands bearing a carboxylate group. The bis(pyrazol-1-yl)acetates were introduced by Otero et al.[9] and have been studied by Burzlaff et al. as mimics of the 2-His-1-carboxylate motif.[10] A drawback of this system is the use of the non-biologically relevant pyrazole groups as the two *N* donor groups. The second example is the bis(imidazolyl)propionato ligand (HBIP) already reported in the late 1970s by Joseph et al.[11] This ligand system, however, suffers from a difficult synthetic route, complicating acid-base chemistry, and limited solubility in non-aqueous media. Parkin indirectly constructed an *N*,*N*,*O* donor set by the insertion of carbon dioxide or formaldehyde into the B–H bond of a [bis(pyrazolyl)hydroborato]zinc complex.[12]

Recently, we became interested in biomimetic ligand systems which in principle could accommodate the desired facial coordination geometry and would incorporate the biologically relevant *N*,*N*,*O* donor atom set. A further requirement would be access to a straightforward synthetic route, which would allow for facile modification of the *N*,*N*,*O* ligands and therefore tuneability of their physical properties.

With this in mind, we have developed a new *N*,*N*,*O* ligand family, i.e. the 3,3-bis(1-methylimidazol-2-yl)- and 3,3-bis(1-methylbenzimidazol-2-yl)propionates **1** and **2**, incorporating the biomimetic 1-methylimidazole and carboxylate groups in a tripodal, monoanionic, tridentate ligand framework (Figure 1).



A[MIm$_2$Pr] (1) **A[BenzMIm$_2$Pr] (2)**

Figure 1. *N*,*N*,*O* ligands A[MIm$_2$Pr] (**1**) and A[BenzMIm$_2$Pr] (**2**)

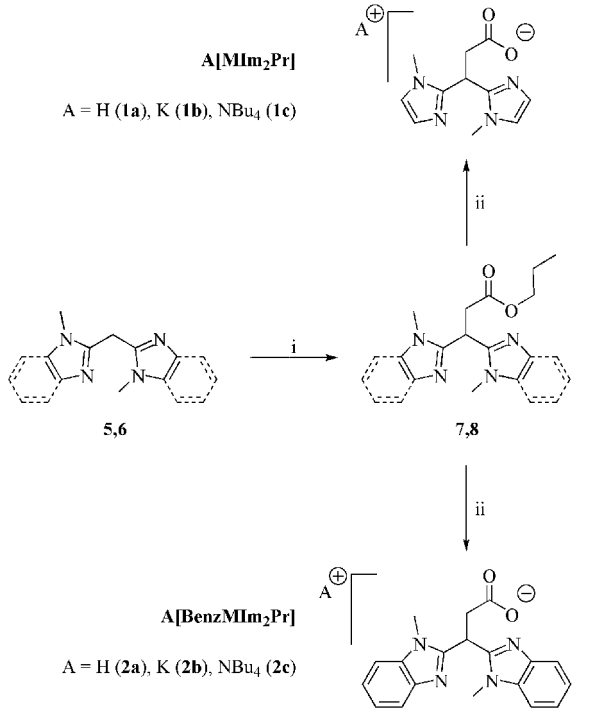
These *N*,*N*,*O* ligands are also of interest in connection with the biomimetic study of copper proteins. Various (polynuclear) copper enzymes are known in which the metal centers are found in an imidazole-rich coordination environment.[13] Furthermore, copper(II) can be used as a probe metal to test the ability of the ligands to facially cap a metal center.[14]

Herein we report the synthesis and structural characterization of two new *N*,*N*,*O* ligands, A[MIm$_2$Pr] (**1**) and A[BenzMIm$_2$Pr] (**2**) (A represents different possible cations), and their copper(II) coordination complexes.

Results

Synthesis and Structural Characterization of the *N*,*N*,*O* Ligands

A general synthetic route for the 3,3-bis(1-methylimidazol-2-yl)- and 3,3-bis(1-methylbenzimidazol-2-yl)propionates was developed (Scheme 1). This route is based on the readily available bis(1-methylimidazol-2-yl)methane framework. Both bis(1-methylimidazol-2-yl)methane (**5**)[15] and bis(1-methylbenzimidazol-2-yl)methane (**6**)[16] can be easily synthesized on a multigram scale.



Scheme 1. i) a. *n*-butyllithium, –78 °C, 1 h, b. propyl bromoacetate, –78 °C → room temp., overnight; ii) a. 1 equiv. KOH, room temp., 3 h, b. 1 equiv. HCl (**1a/2a**); 1 equiv. KOH, room temp., 3 h (**1b/2b**); 1 equiv. [Bu$_4$N]OH, room temp., 3 h (**1c/2c**)

Lithiation of **5** and **6** at the bridging methylene group with *n*-butyllithium at –78 °C in THF and subsequent dropwise addition of propyl bromoacetate resulted in the clean formation of the propyl esters MIm$_2$PrPr (**7**) and BenzMIm$_2$PrPr (**8**). Basic hydrolysis of these ligand precursors in THF with 1 equiv. of a potassium hydroxide solution in water gave the potassium salts of 3,3-bis(1-methylimidazol-2-yl)propionic acid, K[MIm$_2$Pr] (**1b**), and 3,3-bis(1-methylbenzimidazol-2-yl)propionic acid, K[BenzMIm$_2$Pr] (**2b**), in quantitative yields. Likewise, treatment of the esters with [Bu$_4$N]OH resulted in the quantita-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tive formation of the tetrabutylammonium salts [Bu_4N][MIm_2Pr] (**1c**) and [Bu_4N][$BenzMIm_2Pr$] (**2c**). Subsequent addition of 1 equiv. of hydrochloric acid to a solution of the hydrolyzed esters and purification by recrystallization gave 3,3-bis(1-methylimidazol-2-yl)propionic acid, $HMIm_2Pr$ (**1a**), and 3,3-bis(1-methylbenzimidazol-2-yl)propionic acid, $HBenzMIm_2Pr$ (**2a**), in good yields. The propionate salts **1b/1c** and **2b/2c** are very hygroscopic and can only be obtained as fine powders if they are completely solvent-free. This is also reflected in the IR spectra of the compounds. The exact position of the bands depends on the amount of water present in the sample or accumulated during measurement. The carboxylate group asymmetric stretching vibrations $\nu_{as}(COO^-)$ can be found at 1702 (**1a**) and 1716 cm^{-1} (**2a**) for the acids and at 1581 (**1b/1c**) and 1597 (**2c**) for the K and Bu_4N salts. The $\nu_{as}(COO^-)$ of **2b** is split into two bands of equal intensity at 1582 and 1598 cm^{-1}. The symmetric stretch vibration $\nu_s(COO^-)$ is less intense and could only be unambiguously identified for the potassium salts **1b** and **2b** (1393 and 1386 cm^{-1}, respectively).

The molecular structures of acids **1a** and **2a** were studied by single-crystal X-ray diffraction (Figure 2). Suitable single crystals of $HMIm_2Pr$ (**1a**) were obtained by slow vapor diffusion of diethyl ether into a methanolic solution. Recrystallization of the crude product from ethanol/water (95:5) resulted in the formation of a different crystalline phase.[17] Single crystals of $HBenzMIm_2Pr$ (**2a**) were obtained by slow cooling of a hot, saturated solution of **2a** in methanol.

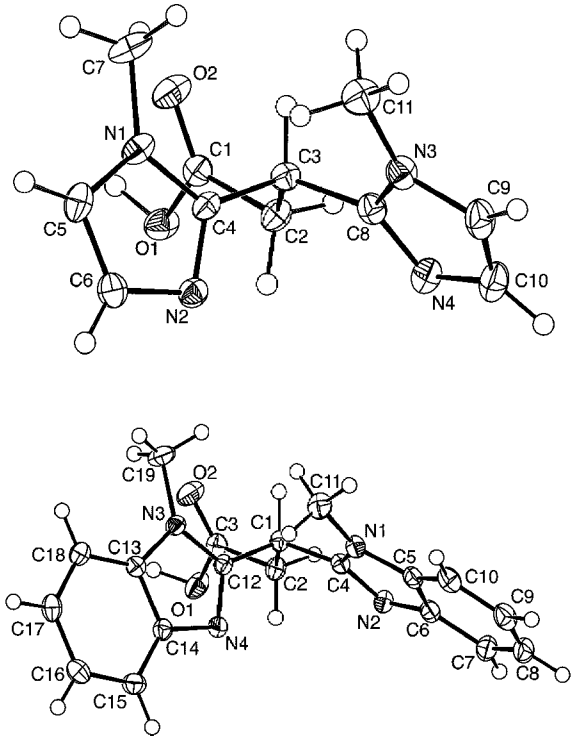


Figure 2. Molecular structure of $HMIm_2Pr{\cdot}MeOH$ (**1a**, top) and $HBenzMIm_2Pr$ (**2a**, bottom) in the crystals; the co-crystallized molecule of methanol (**1a**) has been omitted for clarity; displacement ellipsoids are drawn at the 50 % probability level

The molecular structures of the acids **1a** and **2a** are very similar and their solid-state structures clearly show the general predisposition of tripodal ligands towards facial capping of a metal center.[8b] Rotation around a single C–C bond, i.e. C2–C3 in **1a**, will orient the *N,N,O* lone pairs to a virtual metal center in a facial manner. Interestingly, **1a** and **2a** do not crystallize as zwitterions; the carboxylate oxygen atom O1 is protonated, the imidazole nitrogen atoms are non-protonated. Thus, atom O1 can act as hydrogen-bond donor and the imidazole nitrogen atoms as hydrogen-bond acceptors. In the solid state, molecules of $HMIm_2Pr$ (**1a**) thus form an infinite hydrogen-bonded chain along the crystallographic *c*-axis (Figure 3, Table 1). The co-crystallized methanol solvent molecule is also participating as a hydrogen-bond donor with imidazole nitrogen atom N4 as acceptor. Consequently, both imidazole nitrogen atoms are used for hydrogen bonding. In the crystal structure of **2a**, there are no co-crystallized solvent molecules and therefore only imidazole nitrogen atom N4 accepts hydrogen bonds to form a one-dimensional hydrogen bonded chain along the crystallographic *c*-axis (see Table 1 and Supporting Information). In both crystal structures the non-protonated oxygen atom O2 is not involved in strong hydrogen bonds. Weak C–H···O and C–H···N interactions involve O2 in both structures and nitrogen atom N2 of compound **2a**; π-π stacking interactions between the aromatic systems of the (N1,N2,C4–C10)-benzimidazole rings with average interplanar distances of 3.40 and 3.49 Å are also observed for **2a** (see Supporting Information).

Synthesis of Cu^{II} Complexes

To investigate the facial capping potential of the new *N,N,O* ligands, their coordination chemistry towards copper(II) cations was investigated. Two new, neutral copper complexes of the type [CuL_2] were synthesized and charac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

terized by X-ray crystallography, IR, UV/Vis and EPR spectroscopy, and ESI-MS. The mononuclear copper complex $[Cu(MIm_2Pr)_2]\cdot 2H_2O$ (**3**) was obtained by reaction of 1 equiv. of $CuCl_2\cdot 2H_2O$ with 2 equiv. of $K[MIm_2Pr]$ (**1b**) in hot ethanol. Complex **4**, identified as $[Cu(BenzMIm_2Pr)_2]\cdot 3.12(H_2O)\cdot 1.74(C_2H_5OH)$, with a comparable coordination environment was isolated when $CuCl_2\cdot 2H_2O$ was treated with 2 equiv. of $K[BenzMIm_2Pr]$ (**2b**) in hot ethanol. In both cases, blue single crystals suitable for X-ray diffraction analysis crystallized after several weeks. The complexes can also be obtained directly as powders, nicely illustrating how the judicious choice of solvent and ligand cation can simplify isolation and purification (see Discussion section). In this way, reaction of $CuCl_2$ with 2 equiv. of $[Bu_4N][BenzMIm_2Pr]$ (**2c**) in dry methanol resulted in the formation of the pale blue precipitate $[Cu(BenzMIm_2Pr)_2]$. Separation by centrifugation and purification by simple washings with dichloromethane allowed for the facile isolation of the copper complex.

Description of the Crystal Structures

[Cu(MIm$_2$Pr)$_2$]·2H$_2$O (3)

Two monoanionic MIm_2Pr ligands were found to be arranged centrosymmetrically around the copper ion, coordinating through all three donor groups, i.e. two 1-methylimidazole nitrogen atoms and one carboxylate oxygen atom each, resulting in an elongated octahedral geometry (Figure 4). The four 1-methylimidazole imine nitrogen atoms occupy the equatorial plane [Cu–N 2.0109(18) and 1.9929(18) Å] and the two carboxylate oxygen atoms are located in the axial positions [Cu–O 2.4004(17) Å]. Crystallographic data and selected bond lengths and angles are given in Tables 2 and 3. The Cu–N bond lengths are similar to those found in other CuN_4O_2 chromophores with imidazole nitrogen donors.[18,19] The Cu–O bonds are shorter than those found in, for instance, bis(acetato)tetrakis(imidazole)copper(II),[20] due to ligand constraints.

The non-coordinated water molecules are involved in a one-dimensional hydrogen-bonded network. Two neighboring octahedrons are connected by two water molecules, each water molecule forming two hydrogen bonds to the non-coordinated oxygen atoms of the carboxylate group. This results in the formation of infinite linear chains in the direction of the crystallographic *a*,*b*,*c*-diagonal as shown in Figure 5. The OH stretching vibrations characteristic for hydrogen-bonded water molecules are present in the IR spectrum of **3** at 3347 cm^{-1}. A related $[CuL_2]$ structure was recently reported for $[Cu(bdmpza)_2]\cdot 2H_2O$ [bdmpza = bis(3,5-dimethylpyrazol-1-yl)acetate] by Reedijk et al. in which the two co-crystallized water molecules play an identical role.[20] Copper(II) complexes of the related HBIP ligand have also been reported, but no facial capping of the ligand through all donor atoms was observed.[21]

[Cu(BenzMIm$_2$Pr)$_2$]·3.12(H$_2$O)·1.74(C$_2$H$_5$OH) (4)

Complex **4** was found to have a comparable copper geometry as in complex **3** (Figure 6). Crystallographic data

and selected bond lengths and angles are given in Tables 2 and 3. The replacement of imidazole for benzimidazole hardly affects the *N*,*N*,*O* tridentate coordination to the copper center. However, the Cu–O bond in **4** [2.3476(14) Å] is significantly shorter than the one found in **3** [2.4005(18) Å]. The Cu–N bond lengths compare well to the only other crystallographically characterized CuN_4O_2 chromophore with four benzimidazole donor groups.[22]

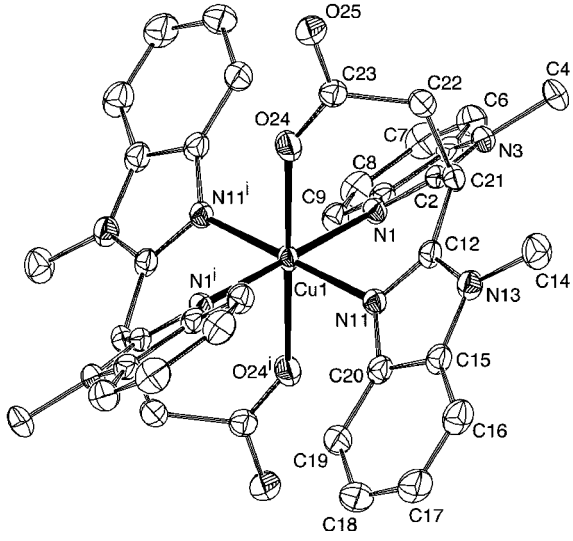

Figure 6. Molecular structure of $[Cu(BenzMIm_2Pr)_2] \cdot 3.12(H_2O) \cdot 1.74(C_2H_5OH)$ (**4**) in the crystal; hydrogen atoms and solvent molecules have been omitted for clarity; displacement ellipsoids are drawn at the 50 % probability level

Also, the hydrogen bonding pattern is similar to the one found in complex **3**. Again two water molecules connect the octahedrons through four hydrogen bonds to form an infinite chain in the direction of the crystallographic *c*-axis. Yet, the water molecules here act also as hydrogen-bond acceptors for co-crystallized ethanol molecules (Figure 7). Additionally, there are water molecules present in the crystal structure which do not participate in the hydrogen bonding. The latter water and ethanol molecule positions in the crystal lattice are not fully occupied (probably due to evaporation), hence the non-integer coefficients in the structural formulation of compound **4**.

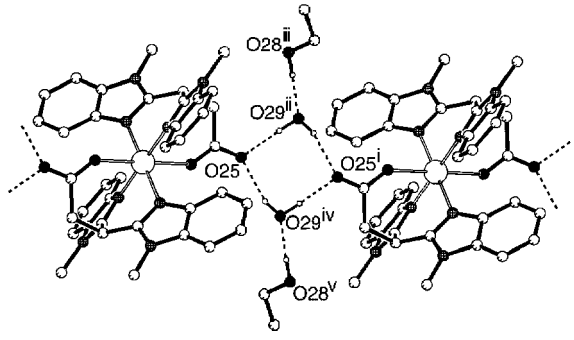

Figure 7. Hydrogen bonding network of **4** resulting in infinite linear chains; C–H hydrogen atoms and water molecules, which do not participate in the hydrogen bonding, have been omitted for clarity; symmetry operations: i: 1 – *x*, 1 – *y*, –*z*; ii: *x*, 0.5 – *y*, *z* – 0.5; iii: *x* – 1, 0.5 – *y*, *z* – 0.5; iv: 1 – *x*, *y* + 0.5, 0.5 – *z*; v: 2 – *x*, *y* + 0.5, 0.5 – *z*

ESI-MS

The ESI mass spectra of **3** and **4** dissolved in a methanol/acetonitrile mixture were recorded and very clean spectra were obtained for both complexes. Also, reference spectra of $K[MIm_2Pr]$ (**1b**) and $K[BenzMIm_2Pr]$ (**2b**) were recorded for comparison. For complex $[Cu(MIm_2Pr)_2] \cdot 2H_2O$ (**3**) only two, equally intense peaks were detected. The peak at *m*/*z* 551.78 corresponds to the $\{[Cu(MIm_2Pr)_2] + Na\}^+$ adduct ion, while the peak at *m*/*z* 529.96 is assigned to $\{[Cu(MIm_2Pr)_2] + H\}^+$. The same adduct ions were found for compound **4**, giving an *m*/*z* of 752.14 for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

{[Cu(BenzMIm$_2$Pr)$_2$] + Na}$^+$ and 730.25 for {[Cu(BenzMIm$_2$Pr)$_2$] + H}$^+$. The observed copper isotope patterns were in good agreement with the calculated ones and furthermore, no free ligand was found in the spectra of both complexes. These data strongly suggest the prevalence of the [CuL$_2$] motif and shows the complexes [Cu(MIm$_2$Pr)$_2$] and [Cu(BenzMIm$_2$Pr)$_2$] as predominant species in solution.

UV/Vis, EPR

The UV/Vis spectrum of **3** in methanol shows three absorption bands at 215, 293 (sh), and 587 nm. The first two bands are also present in reference spectra of the ligand and are therefore assigned to intraligand transitions. The broad absorption centered at 587 nm is assigned to d–d transitions of the copper(II) center. The d–d band for **4** in methanol was found around 666 nm and four intraligand transitions could be detected (228, 252, 271, and 284 nm). Changing the nitrogen donor groups from imidazole to benzimidazole affects the ligand field splitting parameter and results in a red-shift of about 80 nm for complex **4** with respect to complex **3**. This red shift reflects the smaller axial Jahn–Teller distortion and corresponds to the shorter Cu–O bond as found in the crystal structure of complex **4**. The spectral parameters are in the range expected for d–d transitions of tetragonally distorted monomeric CuN_4O_2 chromophores.[18]

The complexes **3** and **4** were studied by EPR as powders at room temperature and as frozen solutions at 77 K (Figure 8). The solid-state EPR spectra of both complexes at room temperature display broad features due to dipolar coupling of the Cu^{II} centers, but are typically axial with $g_\perp$ = 2.06 and $g_\parallel$ = 2.22 for complex **3** and $g_\perp$ = 2.06 and $g_\parallel$ = 2.25 for complex **4**. The hyperfine splitting of the spectrum with the Cu^{II} ion was observed in the parallel region in both cases with $A_\parallel$ = 200 G (**3**) and $A_\parallel$ = 177 G (**4**), the latter being better resolved. This smaller hyperfine coupling $A_\parallel$ of complex **4** is in line with the red shift observed in the UV/Vis spectra. An EPR spectrum of a frozen solution of **3** in methanol/water (1:5, v/v) was also recorded and again an EPR envelope typical for an axially elongated mononuclear Cu^{II} species was observed ($g_\perp$ = 2.04, $g_\parallel$ = 2.24, $A_\parallel$ = 193 G). Additional superhyperfine splitting due to interaction with the ^{14}N nuclei of the ligands is resolved, consistent with four equivalent nitrogens in the equatorial plane ($A_\perp$ = 15.5 G). A frozen methanolic solution of **4** gave a similar EPR spectrum. Again, both the hyperfine and superhyperfine couplings were resolved and the relevant parameters in this case are $g_\perp$ = 2.05, $g_\parallel$ = 2.25, $A_\parallel$ = 187 G, and $A_\perp$ = 14.5 G. The EPR data of the powders and the frozen solutions are consistent with the structure description derived from the X-ray analyses and the ESI-MS measurements, respectively. The spectral parameters for **3** and **4** are characteristic of tetragonally elongated monomeric copper(II) complexes[23] and are comparable to the EPR parameters obtained for other CuN_4O_2 chromophores with four imidazole nitrogen donors.[18,19]

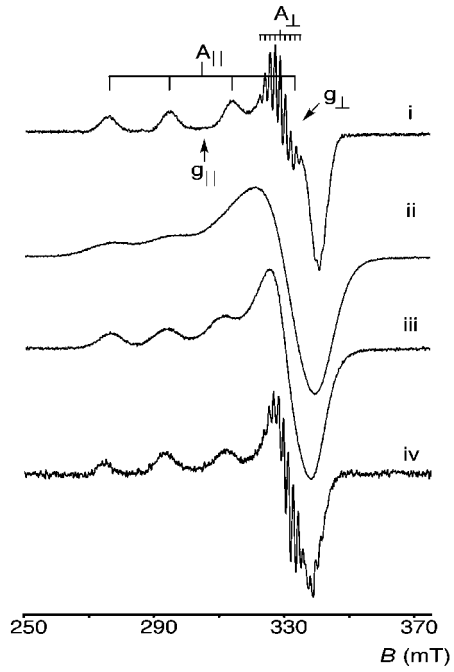

Figure 8. EPR spectra of compounds **3** and **4**; i) frozen methanol/water solution of **3** at 77K, ii) solid **3** at room temp., iii) solid **4** at room temp., iv) frozen methanol solution of **4** at 77K

Discussion and Conclusion

A relatively straightforward, high yielding, two-step route for the synthesis of two new *N*,*N*,*O* ligands on a multigram scale has been developed. Compounds **1** (A[MIm$_2$Pr]) and **2** (A[BenzMIm$_2$Pr]) can be regarded as parent compounds, as the synthetic route offers the possibility of further expansion of this series of ligands. For instance, the bis(heteroaryl)methane synthesis (**5** and **6**) [15,16] allows for the incorporation of (poly)substituted (benz)imidazoles; thus, introduction of other functionalities and further modification of this *N*,*N* backbone is feasible. Both physical properties like solubility, ease of crystallization, and steric requirements as well as the electronic properties of the ligand can therefore be controlled by design. Alterations in the fourth substituent of the central carbon atom [C3 (**1a**) and C1 (**2a**) in Figure 2] and the type of introduced electrophile offer further possibilities for structural variation.

The two cation series of ligands, A[MIm$_2$Pr] and A[BenzMIm$_2$Pr] (A = H, K, and Bu$_4$N), were developed to vary the solubility of one single member of a ligand family and simplify the syntheses and purification of different metal complexes. The reaction of a monoanionic ligand with a metal salt generally results in the formation of two new salts, i.e. the desired complex and an (inorganic) byproduct. The solubility properties of both the desired complex and the byproduct are often comparable and this then hampers purification. Choosing the right cation allows control over the solubility properties of the formed byproduct and therefore purification of the desired metal complexes can in principle be achieved by a simple washing procedure. An example of this approach is described here for the synthesis of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[Cu(BenzMIm$_2$Pr)$_2$] (**4**). The solubility properties of the Bu$_4$N ligands (**1c**, **2c**) also allow the use of relatively apolar solvents, solvents in which the potassium salts (**1b**, **2b**) and acids (**1a**, **2a**) are insoluble.

The ligands **1** and **2** were designed to provide a transition metal with a facial donor array of one carboxylate and two imidazole groups, as found in the enzymes exhibiting the 2-His-1-carboxylate motif.[4,5,8] Using copper(II) as a probe, the neutral [CuL$_2$] complexes **3** and **4** nicely illustrate the facial *N,N,O* capping potential of both new ligands.

This facial capping of the *N,N,O* ligands A[MIm$_2$Pr] (**1**) and A[BenzMIm$_2$Pr] (**2**) renders this new family of ligands suitable candidates for mimicking the 2-His-1-carboxylate motif and we are therefore currently studying the iron and zinc coordination chemistries of these ligands.

Experimental Section

General Remarks: Air-sensitive reactions were carried out under dry, oxygen-free N$_2$ using standard Schlenk techniques. THF was dried with sodium/benzophenone ketyl and distilled under N$_2$ prior to use. Methanol was dried with magnesium methoxide and distilled under N$_2$ prior to use. ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded with a Varian Inova 300 spectrometer at 300 and 75 MHz, respectively, operating at 25 °C. Elemental microanalyses were carried out by the Microanalytisches Laboratorium Dornis and Kolbe, Mülheim a. d. Ruhr, Germany. Infrared spectra were recorded with a Perkin–Elmer Spectrum One FT-IR instrument. ESI-MS spectra were recorded with a Micromass LC-TOF mass spectrometer by the department of Biomolecular Mass Spectrometry, Utrecht University. UV/Vis spectra were recorded with a Cary 50 Varian spectrometer. EPR spectra were measured with a modified Bruker ESP300 spectrometer equipped with an ER4103TM cavity (TM$_{110}$ mode with unloaded Q = 12000). The microwave frequency was near 9.52 GHz and the spectrometer settings involved 4 Gauss field modulation. Bis(1-methylimidazol-2-yl)methane and bis(1-methylbenzimidazol-2-yl)methane were prepared according to literature procedures.[15,16] All other chemicals were commercially obtained and used as received.

Propyl 3,3-Bis(1-methylimidazol-2-yl)propionate, MIm$_2$PrPr (7): A solution of *n*-butyllithium in hexanes (18 mL, 28.8 mmol, 1.6 M in hexanes) was added dropwise to a stirred solution of bis(1-methylimidazol-2-yl)methane (**5**) (5.02 g, 28.5 mmol) in THF (150 mL) at –78 °C. The solution was stirred at –78 °C for 1 h, followed by the dropwise addition of propyl bromoacetate (3.8 mL, 29 mmol). The temperature was allowed to rise to room temperature overnight, resulting in a yellow-white suspension. The reaction mixture was quenched with H$_2$O (25 mL) and all volatiles were evaporated in vacuo. The water layer was extracted with ethyl acetate (4 × 30 mL) and the combined organic layers were dried with magnesium sulfate, filtered, and the solvents evaporated to dryness. The product was obtained as a yellow oil, which solidified upon standing (6.51 g, 83 %). This product can be purified using column chromatography (silica; eluent ethyl acetate/methanol, 9:1), but the crude product is pure enough for further use. ^{1}H NMR (300 MHz, CDCl$_3$, 25 °C): δ = 0.82 (t, $^3J_{H,H}$ = 7.8 Hz, 3 H, OCH$_2$CH$_2$C*H*$_3$), 1.54 (sext, $^3J_{H,H}$ = 7.5 Hz, 2 H, OCH$_2$C*H*$_2$CH$_3$), 3.28 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, CHC*H*$_2$), 3.46 (s, 6 H, NC*H*$_3$), 3.96 (t, $^3J_{H,H}$ = 6.9 Hz, 2 H, OC*H*$_2$CH$_2$CH$_3$), 4.94 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, C*H*CH$_2$), 6.72 (s, 2 H, H_{imid}), 6.88 (s, 2 H, H_{imid}) ppm. ^{13}C{^{1}H} NMR (75 MHz, CDCl$_3$, 25 °C): δ = 10.19, 21.82, 32.81, 34.42, 36.34, 66.32, 121.95, 127.15, 145.29, 171.21 ppm. IR (solid): $\tilde{\nu}$ = 3099.1, 2967.2, 1727.1, 1492.3, 1282.9, 1189.7, 1174.9, 1129.8, 744.0 cm^{-1}. C$_{14}$H$_{20}$N$_4$O$_2$ (276.33) calcd. C 60.85, H 7.30, N 20.28; found C 60.74, H 7.22, N 20.18.

Propyl 3,3-Bis(1-methylbenzimidazol-2-yl)propionate, BenzMIm$_2$PrPr (8): Compound **8** was synthesized using the procedure described above for compound **7**. The product was obtained as an off-white solid (2.89 g, 92 %). This product can be purified using column chromatography (silica; eluent ethyl acetate/methanol, 7:1), but the crude product is pure enough for further use. ^{1}H NMR (300 MHz, CDCl$_3$, 25 °C): δ = 0.86 (t, $^3J_{H,H}$ = 7.5 Hz, 3 H, OCH$_2$CH$_2$C*H*$_3$), 1.58 (sext, $^3J_{H,H}$ = 7.2 Hz, 2 H, OCH$_2$C*H*$_2$CH$_3$), 3.61 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H, CHC*H*$_2$), 3.76 (s, 6 H, NC*H*$_3$), 4.02 (t, $^3J_{H,H}$ = 6.3 Hz, 2 H, OC*H*$_2$CH$_2$CH$_3$), 5.45 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, C*H*CH$_2$), 7.26 (m, 6 H, $H_{benzimid}$), 7.76 (m, 2 H, $H_{benzimid}$) ppm. ^{13}C{^{1}H} NMR (75 MHz, CDCl$_3$, 25 °C): δ = 10.20, 21.84, 30.25, 35.94, 36.19, 66.64, 109.23, 119.74, 122.18, 122.84, 136.44, 142.07, 151.19, 170.89 ppm. IR (solid): $\tilde{\nu}$ = 2973.2, 1733.9, 1467.1, 1439.7, 1389.1, 1179.2, 733.7 cm^{-1}. C$_{22}$H$_{24}$N$_4$O$_2$ (376.45) calcd. C 70.19, H 6.43, N 14.88; found C 69.98, H 6.41, N 14.69.

3,3-Bis(1-methylimidazol-2-yl)propionic Acid, HMIm$_2$Pr (1a): To a solution of ester **7** (2.24 g, 8.1 mmol) in THF (20 mL) was added 1 equiv. of potassium hydroxide in water (8.20 mL, 0.989 M, 8.1 mmol) and the solution was stirred at room temperature for 3 h. Subsequently, 1 equiv. of a hydrochloric acid solution in water (8.11 mL, 1 M, 8.1 mmol) was added to the hydrolysed reaction mixture. Evaporation of the solvents resulted in a white mixture of product and potassium chloride. Most of the KCl was removed after extraction of the powder with dry methanol (3 × 15 mL). Evaporation of the solvent and recrystallization from EtOH/H$_2$O (95:5) gave the product as colorless crystals of composition HMIm$_2$Pr·4H$_2$O (1.6 g, 65 %). Single crystals of the composition HMIm$_2$Pr·CH$_3$OH were obtained by slow diffusion of diethyl ether in a concentrated solution of **1a** in methanol. ^{1}H NMR (300 MHz, CD$_3$OD, 25 °C): δ = 3.16 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, CHC*H*$_2$), 3.62 (s, 6 H, NC*H*$_3$), 5.00 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, C*H*CH$_2$), 6.99 (s, 2 H, H_{imid}), 7.11 (s, 2 H, H_{imid}) ppm. ^{13}C{^{1}H} NMR (75 MHz, CD$_3$OD, 25 °C): δ = 33.63, 33.86, 38.87, 123.88, 125.92, 146.76, 175.17 ppm. IR (solid): $\tilde{\nu}$ = 3130.0, 1701.5, 1491.2, 1348.4, 1285.6, 1266.7, 1220.9, 1135.5, 772.3 cm^{-1}. C$_{11}$H$_{14}$N$_4$O$_2$·4H$_2$O (306.32) calcd. C 43.13, H 7.24, N 18.29; found C 43.31, H 7.16, N 18.34.

3,3-Bis(1-methylbenzimidazol-2-yl)propionic Acid, HBenzMIm$_2$Pr (2a): The acid **2a** was synthesized using the procedure as described above for the acid **1a**. KCl could in this case be removed by washing the product with water (3 × 20 mL). Recrystallization from methanol gave the product as colorless crystals (0.59 g, 64 %). Slow cooling of a hot saturated solution of **2a** in methanol resulted in crystals suitable for X-ray analysis. ^{1}H NMR (300 MHz, CD$_3$OD, 25 °C): δ = 3.53 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H, CHC*H*$_2$), 3.78 (s, 6 H, NC*H*$_3$), 5.40 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, C*H*CH$_2$), 7.28 (m, 4 H, $H_{benzimid}$), 7.48 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H, $H_{benzimid}$) 7.63 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H, $H_{benzimid}$) ppm. ^{13}C{^{1}H} NMR (75 MHz, CD$_3$OD, 25 °C): δ = 30.52 35.27, 37.60 111.01, 119.60, 123.59, 124.25, 137.32, 142.69, 153.46, 174.41 ppm. IR (solid): $\tilde{\nu}$ = 2934.4, 1716.3, 1467.8, 1392.8, 1332.3, 1282.8, 762.1, 739.6 cm^{-1}. C$_{19}$H$_{18}$N$_4$O$_2$ (334.37) calcd. C 68.25, H 5.43, N 16.76; found C 68.15, H 5.49, N 16.83.

General Procedure for the Synthesis of the Potassium and Tetrabutylammonium Salts 1b/c and 2b/c: To a solution of the appropriate ester **7** or **8** in THF (20 mL) was added 1 mol-equiv. of a KOH or [Bu$_4$N]OH solution in water (volumetric standard) and the reaction mixture was stirred at room temperature for 3 h. Evaporation of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the solvents resulted in an oil. Repeated azeotropic drying of the oil with toluene, gave the desired product as a powder in quantitative yield.

Potassium 3,3-Bis(1-methylimidazol-2-yl)propionate, K[MIm$_2$Pr] (1b): Yellowish powder (1.97 g). ^{1}H NMR (300 MHz, CD_3OD, 25 °C): δ = 3.08 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H, CHCH_2), 3.52 (s, 6 H, NCH_3), 4.92 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, CHCH$_2$), 6.83 (s, 2 H, H_{imid}), 6.95 (s, 2 H, H_{imid}) ppm. ^{13}C{^{1}H} NMR (75 MHz, CD_3OD, 25 °C): δ = 35.22, 35.59, 41.09, 123.16, 127.11, 148.34, 178.60 ppm. IR (solid): $\tilde{\nu}$ = 1580.2, 1393.0, 665.2 cm^{-1}. $C_{11}H_{13}KN_4O_2$ (272.34) calcd. C 48.51, H 4.81, N 20.57; found C 48.36, H 4.92, N 20.47. ESI-MS: *m*/*z* = 311.08 {(K[MIm$_2$Pr] +K)$^+$, calcd. 311.03}, 583.04 {(2K[MIm$_2$Pr] + K)$^+$, calcd. 583.10}.

Tetrabutylammonium 3,3-Bis(1-methylimidazol-2-yl)propionate, [Bu$_4$N][MIm$_2$Pr] (1c): White powder (1.97 g). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.92 (m, 12 H, $CH_2CH_2CH_2CH_3$), 1.35 (m, 8 H, $CH_2CH_2CH_2CH_3$), 1.57 (m, 8 H, $CH_2CH_2CH_2CH_3$), 3.06 (d, $^3J_{H,H}$ = 6.5 Hz, 2 H, CHCH_2), 3.26 (m, 8 H, $CH_2CH_2CH_2CH_3$), 3.58 (s, 6 H, NCH_3), 5.08 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H, CHCH$_2$), 6.65 (s, 2 H, H_{imid}), 6.77 (s, 2 H, H_{imid}) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = 13.69, 19.68, 24.04, 33.00, 35.16, 40.80, 58.56, 120.79, 126.53, 148.87, 174.66 ppm. IR (solid) $\tilde{\nu}$ = 2962.5, 2936.7, 1581.6, 1489.7, 1363.2, 1280.6, 1128.0, 770.5 cm^{-1}. $C_{27}H_{49}N_5O_2$ (475.71) calcd. C 68.17, H 10.38, N 14.72; found C 67.89, H 10.31, N 14.63.

Potassium 3,3-Bis(1-methylbenzimidazol-2-yl)propionate, K[BenzMIm$_2$Pr] (2b): Yellowish powder (2.27 g). ^{1}H NMR (300 MHz, CD_3OD, 25 °C): δ = 3.35 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H, CHCH_2), 3.78 (s, 6 H, NCH_3), 5.40 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, CHCH$_2$), 7.23 (m, 4 H, $H_{benzimid}$), 7.44 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, $H_{benzimid}$), 7.61 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, $H_{benzimid}$) ppm. ^{13}C{^{1}H} NMR (75 MHz, CD_3OD, 25 °C): δ = 29.31, 35.47, 39.84, 09.61, 118.42, 122.01, 122.66, 136.21, 141.80, 153.61, 176.78 ppm. IR (solid) $\tilde{\nu}$ = 1598.0, 1581.9, 1385.7, 1282.7, 737.8 cm^{-1}. $C_{19}H_{17}KN_4O_2$ (372.46) calcd. C 61.27, H 4.60, N 15.04; found C 61.05, H 4.68, N 14.86. ESI-MS: *m*/*z* = 327.18 {([BenzMIm$_2$C$_2$H$_2$] + K)$^+$, calcd. 327.10}, 411.12 {(K[BenzMIm$_2$Pr] + K)$^+$, calcd. 411.06}, 783.19 {(2K[BenzMim$_2$Pr] + K)$^+$, calcd. 783.16}.

Tetrabutylammonium 3,3-Bis(1-methylbenzimidazol-2-yl)propionate, [Bu$_4$N][BenzMIm$_2$Pr] (2c): Yellow powder (1.52 g). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.92 (t, $^3J_{H,H}$ = 7.2 Hz, 12 H, $CH_2CH_2CH_2CH_3$), 1.33 (m, 8 H, $CH_2CH_2CH_2CH_3$), 1.53 (m, 8 H, $CH_2CH_2CH_2CH_3$), 3.19 (m, 8 H, $CH_2CH_2CH_2CH_3$), 3.37 (d, $^3J_{H,H}$ = 6.6 Hz, 2 H, CHCH_2), 3.82 (s, 6 H, NCH_3), 5.58 (t, $^3J_{H,H}$ = 6.3 Hz, 1 H, CHCH$_2$), 7.20 (m, 6 H, $H_{benzimid}$), 7.65 (m, 2 H, $H_{benzimid}$) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = 13.56, 19.58, 23.91, 30.21, 36.17, 39.52, 58.65, 109.06, 119.29, 121.29, 121.89, 136.38, 142.41, 154.25, 174.12 ppm. IR (solid) $\tilde{\nu}$ = 2960.0, 2874.0, 1596.5, 1465.8, 1380.2, 1275.5, 736.1 cm^{-1}. $C_{35}H_{53}N_5O_2$ (575.83) calcd. C 73.00, H 9.28, N 12.16; found C 72.89, H 9.38, N 12.22.

[Cu(MIm$_2$Pr)$_2$]·2H$_2$O (3): To a colorless solution of K[MIm$_2$Pr] (**1b**) (414 mg, 1.52 mmol) in hot ethanol (20 mL) was added a solution of $CuCl_2$·$2H_2O$ (129 mg, 0.76 mmol) in hot ethanol (10 mL). The solution immediately turned dark blue and the reaction mixture was heated to reflux for 1 h. Upon cooling of the solution to room temperature, a white precipitate formed (KCl). The solution was filtered and concentrated in vacuo. The resulting dark blue powder was recrystallized from a minimal amount of refluxing ethanol and cooled to 4 °C to give the title compound as blue crystals (201 mg, 47 %). Single crystals formed after three weeks from a concentrated solution of **3** in ethanol upon standing. $C_{22}H_{26}CuN_8O_4$·$2H_2O$ (566.06) calcd. C 46.86, H 5.34, N 19.80; found C 46.60, H 5.44, N 19.72. IR (solid) $\tilde{\nu}$ = 3347.5, 3275.9, 3126.5, 1582.1, 1506.9, 1383.9, 1289.8, 1153.1, 745.9 cm^{-1}. UV/Vis (methanol): λ_{max} = 215, 219, 587 nm. ESI-MS: *m*/*z* = 529.96 {[{Cu(MIm$_2$Pr)$_2$} + H]$^+$, calcd. 530.14}, 551.78 {[{Cu(MIm$_2$Pr)$_2$} + Na]$^+$, calcd. 552.13}.

[Cu(BenzMIm$_2$Pr)$_2$] (4): To a colorless solution of [Bu$_4$N][BenzMIm$_2$Pr] (**2c**) (470 mg, 0.82 mmol) in hot, dry methanol (20mL) was added a solution of $CuCl_2$ (55 mg, 0.41 mmol) in hot, dry methanol (10 mL). Immediately the solution turned green-blue and the reaction mixture was refluxed for 1 h, during which a pale blue precipitate formed. The reaction mixture was allowed to cool to room temperature and the precipitate was collected by centrifugation. The crude product was washed with methanol (1 × 10 mL) and dichloromethane (3 × 10 mL) and dried in vacuo. The title compound was isolated as a light blue powder (162 mg, 54 %). Slow evaporation of the solvent of a concentrated solution of **4** in ethanol resulted in the formation of single crystals of the composition [Cu(BenzMIm$_2$Pr)$_2$]·3.12(H_2O)·1.74(C_2H_5OH) formed after six weeks. $C_{38}H_{34}CuN_8O_4$ (730.27) calcd. C 62.50, H 4.69, N 15.34; found C 62.36, H 4.62, N 15.23. IR (solid) $\tilde{\nu}$ = 3349.8, 1583.1, 1458.0, 1385.5, 1304.1, 1284.8, 742.8 cm^{-1}. UV/Vis (methanol): λ_{max} = 228, 252, 271, 666 nm. ESI-MS: *m*/*z* = 730.25 {[{Cu(BenzMIm$_2$Pr)$_2$} + H]$^+$, calcd. 730.21}, 752.14 {[{Cu(BenzMIm$_2$Pr)$_2$} + Na]$^+$, calcd. 752.19}.

X-ray Crystallographic Study: X-ray intensities were measured with a Nonius KappaCCD diffractometer with rotating anode (graphite monochromator, λ = 0.71073 Å) at a temperature of 150 K. The structures were solved with Direct Methods (compounds **1a**,[24] **2a**,[25] and **4**[24]) or automated Patterson methods (compound **3**[26]). The structures were refined with SHELXL-97[27] against F^2 of all reflections up to $(\sin\theta/\lambda)_{max}$ = 0.65 Å^{-1}. Structure calculations, drawings, and checking for higher symmetry was performed with the PLATON[28] package. Further details are given in Table 3. In crystal structures **1a**, **2a**, and **3** all hydrogen atoms were located in the difference Fourier map. C–H hydrogen atoms were refined as rigid groups. O–H hydrogen atoms were refined freely with isotropic displacement parameters. In crystal structure **4**, the position of water molecule O29 is fully occupied. Water molecule O30 was refined with an occupancy of 56 % and the ethanol molecule with an occupancy of 87 %. All hydrogen atoms were located in the difference Fourier map. C–H hydrogen atoms were refined as rigid groups. O–H hydrogen atoms were kept fixed in the located position. CCDC-249589 (**1a**), -249590 (**2a**), -249591 (**3**) and -249592 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information (see also footnote on the first page of this article): Two figures are included depicting the hydrogen bonding pattern and π-π stacking the crystal structure of HBenzMIm$_2$Pr (**2a**).

First Examples of β-Diketonate Platinum(II) Complexes with Sulfoxide Ligands

Sandra A. De Pascali,[a] Paride Papadia,[a] Antonella Ciccarese,[a] Concetta Pacifico,[b] and Francesco P. Fanizzi*[a]

Keywords: Platinum / β-Diketonate / S ligands

New platinum(II) complexes have been prepared as models for explaining the coordination of multiple β-diketonate ligands to give [Pt(*O,O′*-acac)(γ-acac)L] species. The new compounds containing both an *O,O′*-chelated acetylacetonate ligand and a sulfoxide in the platinum coordination sphere, [PtCl(*O,O′*-acac)(DMSO)] (**1**) and [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (**2**), have been synthesised and characterised by ^{1}H, ^{13}C, ^{195}Pt 1-D and 2-D NMR heteronuclear correlation spectroscopy and, in the case of **2**, by X-ray crystal structure analysis also. Moreover, a new synthetic pathway to obtain the previously reported complex K[Pt(*O,O′*-acac)(γ-acac)$_2$] (**3**) has been developed. The data presented herein are consistent with a reaction mechanism which explains the subsequent steps of the coordination of multiple β-diketonate ligands to platinum(II) complexes, where the first species formed contains one *O,O′*-chelated acac group.

Introduction

Despite the fact that sulfoxides[1,2] and acetylacetone[3] have been widely used in the coordination and organometallic chemistry of platinum, to the best of our knowledge, no platinum(II) complexes containing both ligands have been described so far. In particular, platinum(II) shows a high affinity for sulfur ligands, a large number of complexes with sulfoxides are known and several studies of DMSO complexes dealing with a wide variety of different aspects of these complexes have been carried out.[4] On the other hand, the versatility of acetylacetone as a ligand was first demonstrated by Werner who employed it as a chelating agent.[5] Almost every metal has been found to give acetylacetone complexes which, in many cases, have exhibited interesting stereochemical arrangements. Several reports on acetylacetonatoplatinum(II) complexes have established the presence of two main modes of metal-ligand bonding: oxygen-bonded (chelated) acetylacetonate and carbon-bonded acetylacetonate.[6–9] In many cases, two acetylacetonate (acac) ligands, one of them oxygen-bonded (*O,O′*-chelated) and the other one carbon-bonded (σ-bonded), are coordinated to the same metal centre. Very extensive studies have been performed on the reactions of bis(β-diketonato)palladium(II) and platinum(II) complexes of the type [M(*O,O′*-acac)$_2$] (M = Pd or Pt, *O,O′*-acac = *O,O′*-acetylacetonate) with nitrogen ligands (py and Et_2NH), tertiary phosphanes (PPh_3, PCy_3 and PEt_3) and arsines which resulted in the bonding mode conversion for at least one *O,O′*-chelated β-diketonate anion to other type of coordination modes.[10,11] It was found that the addition of a series of ligands (L) to [Pt(*O,O′*-acac)$_2$] caused the rearrangement of one of the *O,O′*-chelated acac ligands to a σ-bonded form, affording complexes of the type [Pt(*O,O′*-acac)(γ-acac)L] (γ-acac = Cγ-bonded acetylacetonate).[12] The reaction of [Pt(*O,O′*-acac)$_2$] with an excess of pyridine, on the other hand, yielded a complex in which both acetylacetonate ligands are coordinated to platinum through the central carbon atoms, [Pt(γ-acac)$_2$(py)$_2$], in equilibrium with a mono-γ-acac complex, [Pt(*O,O′*-acac)(γ-acac)(py)].[13] Interestingly, reactions giving [Pt(*O,O′*-acac)(γ-acac)L] complexes starting from platinum species other than [Pt(*O,O′*-acac)$_2$] and, in general, lacking an acac ligand previously bound to the metal, appear to be much less common. Representative examples for this latter kind of reaction are the syntheses of K[Pt(*O,O′*-acac)(γ-acac)Cl][6] and [Pt(*O,O′*-acac)(γ-acac)-(Et_2S)][14] starting from $K_2[PtCl_4]$ and [$PtCl_2(Et_2S)_2$], respectively. Furthermore, the subsequent coordination of two acac ligands in the reactions of [$PtCl_2L_2$]-type complexes [L = Et_2S, 1,2-bis(ethylthio)ethane, PEt_3, PPh_3] with thallium(I) β-diketonates has been examined (Scheme 1). The factors favouring each of the two coordination modes, *O,O′*-chelated or Cγ-bonded, when the first acac binds the metal were investigated but no definitive conclusions were drawn about the pathway leading to [Pt(*O,O′*-acac)(γ-acac)-L] complexes.[14]

Scheme 1

In this context, we have synthesised two novel complexes of platinum(II), namely [PtCl(*O,O′*-acac)(DMSO)] (**1**) and [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (**2**), as models for explaining the coordination of multiple β-diketonate ligands to give [Pt(*O,O′*-acac)(γ-acac)L] species. Together with the synthesis and characterisation of the new complexes **1** and **2**, we also report herein a new synthetic pathway for the homoleptic complex K[Pt(*O,O′*-acac)(γ-acac)$_2$] (**3**), previously obtained by Lewis et al.[6] Compounds **1**–**3** (Scheme 2) have been characterised by microanalysis, IR spectroscopy, multinuclear multidimensional NMR spectroscopy and, in the case of **2**, by X-ray diffraction.

Results and Discussion

Synthesis of the Compounds

The synthesis of [PtCl(*O,O′*-acac)(DMSO)] (**1**), containing a single chelate acac, was straightforward since, due to its low solubility in the reaction medium, it precipitates as a pale yellow powder from the reaction mixture of K[$PtCl_3$(DMSO)] with acetylacetone and KOH in water. Complexes **2** and **3** were obtained by treating [$PtCl_2(DMSO)_2$] with acetylacetone and KOH in MeOH and were isolated from their respective reaction mixtures by an appropriate workup procedure reported in the experimental section. In all cases, in order to prevent metal reduction, a slight excess of acetylacetone was used with respect to the calculated stoichiometric amount of KOH based on starting platinum complex. It should be noted that the use of the scarcely soluble [$PtCl_2(DMSO)_2$] as a starting platinum complex for the preparation of **1** in MeOH or water gave unsatisfactory results. Due to the low solubility of [$PtCl_2(DMSO)_2$], the reaction with acetylacetone and KOH in MeOH resulted in an excess of acac in solution, even when using a stoichiometric or substoichiometric amount of acac and always gave a mixture of **1**, **2** and unreacted starting material. On the other hand, the reaction of [$PtCl_2(DMSO)_2$] with acetylacetone and KOH in water, in which both the starting platinum complex and [PtCl(*O,O′*-acac)(DMSO)] are sparingly soluble, gave analytically pure **1** although a longer reaction time was required and a lower yield was obtained. Quadrangular, pale-yellow X-ray quality crystals of [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (**2**) were obtained from a $CHCl_3$/pentane solution.

Characterisation of the Complexes

All complexes were characterised by microanalysis, IR spectroscopy and multinuclear, multidimensional NMR spectroscopy. In the case of compound **2**, the structure assigned on the basis of spectroscopic and microanalytical data was also confirmed by a single-crystal X-ray diffraction analysis. ^{1}H, ^{13}C NMR and ^{195}Pt NMR spectroscopic data are reported in Table 1, Table 2 and Table 3, respectively. Crystal data, data collection and refinement parameters for compound **2** are summarised in Table 4 and Table 5.

In the IR spectrum of complex **1**, the observed stretching frequencies for Cγ-H (above 3000 cm^{-1}), C=C (1570 cm^{-1}) and C=O (1520 cm^{-1}) were indicative of acetylacetonate bonded through oxygen. For chelate acetylacetonate complexes, the highest reported stretching frequencies for C=O are below 1600 cm^{-1}, in agreement with the "aromatic" nature of the system resulting from delocalization of the π elec-

trons in the chelate ring.[7] The IR spectra of **2** and **3**, containing both oxygen-bonded and carbon-bonded acetylacetonate show two sets of absorptions in the C–H stretching region. The IR band above 3000 cm^{-1} was assigned to the Cγ-H vibration of the oxygen-bonded ligand whereas below 3000 cm^{-1}, both CH_3 and Cγ-H absorptions for the σ-bonded acac could be clearly identified. The high frequencies (1680–1630 cm^{-1}) of the C=O stretching modes observed in complexes **2** and **3** are further evidence that the carbonyl groups do not interact with platinum and strongly suggest that the complexes also contain a σ-bonded acac.

The absorption band at 1030 cm^{-1} in the IR spectra of **1** and **2** was assigned to the S=O stretching mode of the DMSO moiety whereas the band at 340 cm^{-1}, unique to the only new chloride complex here reported, was unambiguously attributed to the Pt–Cl stretching mode.

The ^1H NMR spectrum of **1** in $CDCl_3$ shows two singlets at δ = 2.02 and 2.06 ppm for the two methyl groups of the oxygen-bonded acetylacetonate, one singlet at δ = 5.56 ppm relative to the Cγ-H of acac and one singlet at δ = 3.44 ppm with a characteristic $^3J_{H-Pt}$ of 40 Hz for the methyl protons of the DMSO ligand. The resonance pattern is in agreement with an asymmetric *O,O′*-chelated complex which also shows the expected remarkable deshielding of the methyne proton (Cγ-H) due to the aromatic character of the metallacycle. The ^1H NMR spectrum of complex **2** in $CDCl_3$ shows a signal pattern very similar to that observed for compound **1** with only two extra resonances, i.e. one singlet at δ = 2.29 ppm ($^4J_{H-Pt}$ = 5 Hz) and one strongly ^{195}Pt-coupled singlet at δ = 4.80 ppm ($^2J_{H-Pt}$ = 120 Hz) account-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing for six protons and one proton, respectively. The occurrence of the same signal pattern observed for complex **1** also suggests, for complex **2**, the presence of one asymmetric *O,O′*-chelated acac in the platinum coordination sphere (two methyl groups, δ = 2.01 and 1.95 ppm, one Cγ-H proton, δ = 5.53 ppm) and one coordinated DMSO (δ = 3.31 ppm, $^3J_{H-Pt}$ = 40 Hz). The observed two extra signals could be easily assigned to an extra σ-bonded acac, which occupies the fourth square-planar coordination site, on the basis of both the large platinum coupling for the Cγ-H proton at δ = 4.80 ppm and the equivalence of the methyl groups (one singlet at δ = 2.29 ppm). In both **1** and **2**, the two methyl resonances of the asymmetric *O,O′*-chelated acac were assigned to the appropriate halves of the diketonate on the basis of the NOESY cross peaks originating from the interaction of one of them with the *cis*-DMSO ligand observed in the NOESY spectra.

The ^{1}H NMR spectrum of **3** in CD_3OD consists of only four resonances at 1.77, 2.18, 4.75 and 5.39 ppm accounting for six protons, twelve protons, two protons and one proton, respectively. None of the observed signals show ^{195}Pt satellites assignable to coordinated DMSO. On the other hand, the strong ^{195}Pt coupling exhibited by the resonance at δ = 4.75 ppm ($^2J_{H-Pt}$ = 120 Hz) together with proton integration data indicate the presence of two equivalent Cγ-H protons characterised by a $^2J_{H-Pt}$ of 120 Hz and, therefore, two equivalent Cγ-bonded acac groups in the platinum coordination sphere. Two equivalent Cγ-coordinated acac moieties also account for the twelve protons resonating at δ = 2.18 ppm. The other two resonances at δ = 1.77 and 5.39 ppm in the spectrum of **3** were assigned to one symmetric *O,O′*-chelate acac ligand coordinated to the metal. Consistently, the $^2J_{H-Pt}$ values observed for the single and the two equivalent Cγ-bonded acac groups of complexes **2** and **3**, respectively, are very similar due to the presence, in both cases, of an *O,O′*-chelated acac group in the *trans* position.

The ^{13}C NMR spectra of complexes **1**–**3** confirmed the structures assigned on the basis of ^{1}H NMR spectroscopic data. One bond and long range 2-D ^{1}H-^{13}C HETCOR experiments (spectra of **2** in Figure 1) allowed correct assignments for all the ^{13}C resonances. In particular, *O,O′*-chelated and Cγ-bonded acac groups show, for the Cγ atom, very different chemical shifts and ^{195}Pt couplings. The pseudo aromatic Cγ carbons of the acac chelates resonate downfield and with much smaller ^{195}Pt coupling constants (δ = 102.27 ppm, $^3J_{C-Pt}$ = 73 Hz; δ = 102.19 ppm, $^3J_{C-Pt}$ = 64 Hz; δ = 101.97 ppm, for **1**, **2** and **3**, respectively) with respect to the corresponding carbon in the σ-bonded acac (δ = 42.04 ppm, $^1J_{C-Pt}$ = 652; δ = 44.00 ppm, for **2** and **3**, respectively). Carbonyls of the acac chelate involved in the pseudo aromatic metallacycle resonate upfield with respect to those of σ-bonded acac. The long range 2-D ^{1}H-^{13}C HETCOR spectra of **1** and **2**, together with the above mentioned NOESY data, were used to correlate the carbonyls and the methyl groups belonging to the same half of the asymmetric chelate acac. In the case of complex **1**, the two carbonyl resonances observed at δ = 185.06 and 185.87 ppm show $^2J_{C-Pt}$ values of 28 and 16 Hz, respectively, in agreement with the higher *trans* effect exhibited by DMSO compared with that of the chloro ligand.

Interestingly, in the ^{1}H-^{13}C HETCOR spectrum of **2** (in which the Cγ-bonded acac and DMSO are both coordinated to platinum), the positions of the observed cross peaks due to the coupling with the magnetically active spectator nucleus (^{195}Pt) correlate with the number of bonds

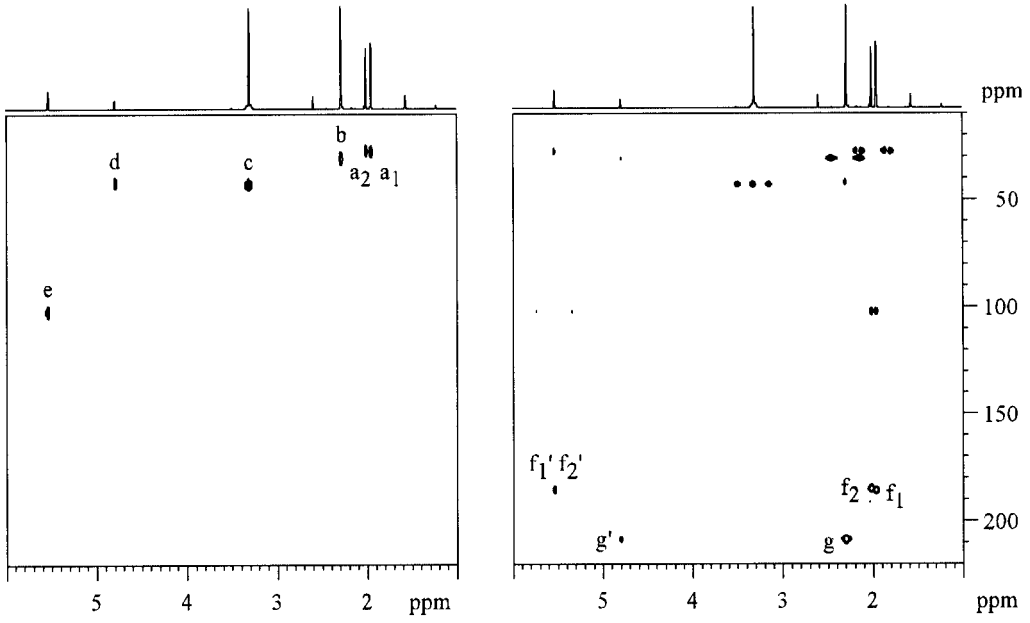

Figure 1. ^{1}H-^{13}C HETCOR (left) and ^{1}H-^{13}C long range HETCOR (right) spectra of **2**. Hydrogen bearing carbon atoms of *O,O′*-chelated acac (a_1, a_2, and e), Cγ-bonded acac (b and d) and DMSO (c) were detected by ^{1}H-^{13}C HETCOR while the carbonyls of the *O,O′*-chelated acac and the Cγ-bonded acac could be assigned according to cross peaks with methyls (f_1, f_2, and g, respectively) or according to cross peaks with Cγ-H (f_1', f_2', and g′, respectively) in the ^{1}H-^{13}C long range HETCOR spectrum

between this latter nuclues and the observed nucleus (^{1}H). The straight line joining the ^{195}Pt cross peaks shows, in the case of the platinum bound Cγ-H acac ($^2J_{H–Pt}$ = 652 Hz) and the DMSO ligand ($^3J_{H–Pt}$ = 56 Hz), a negative and positive gradient, respectively (Figure 2).[15] Another interesting feature of the ^{195}Pt coupling exhibited by [Pt(*O,O′*-acac)(γ-acac)(DMSO)] can be shown by a 2-D ^{1}H-^{195}Pt HETCOR experiment, in which all ^{195}Pt coupled protons result in cross peaks at a single platinum chemical shift (δ = –3198 ppm in $CDCl_3$). Among all the CH_3 resonances for **2**, only the methyl groups of the σ-bonded acac exhibit small cross peaks showing a very small $J_{H–Pt}$ coupling in the ^{1}H-^{195}Pt HETCOR spectrum. This may be due to a through space interaction (Figure 3). The ^{195}Pt NMR spectroscopic data of complexes **1**–**3** are reported in Table 3. The observed ^{195}Pt chemical shifts show that in [Pt(*O,O′*-acac)(DMSO)L] complexes, the shielding effect when L = Cγ-acac is considerably higher than when L = Cl^- ($\Delta\delta$, ^{195}Pt = 738 ppm in CD_3OD), while in [Pt(*O,O′*-acac)(γ-acac)L] the shielding effect is higher when L = DMSO than when L = Cγ-acac ($\Delta\delta$, ^{195}Pt = 629 ppm in CD_3OD).

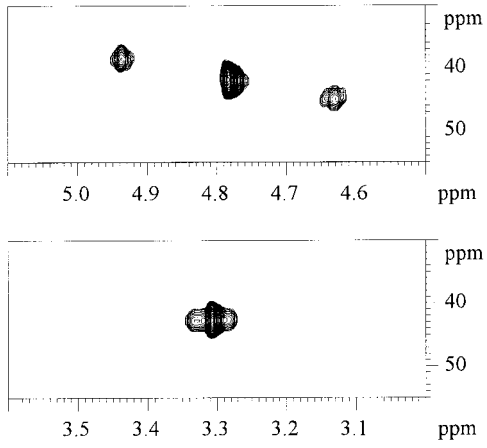

Figure 2. Expansions of ^{1}H-^{13}C HETCOR spectrum of **2** showing ^{195}Pt satellites relative to the Cγ-bonded acac (above) and the DMSO methyl groups (below)

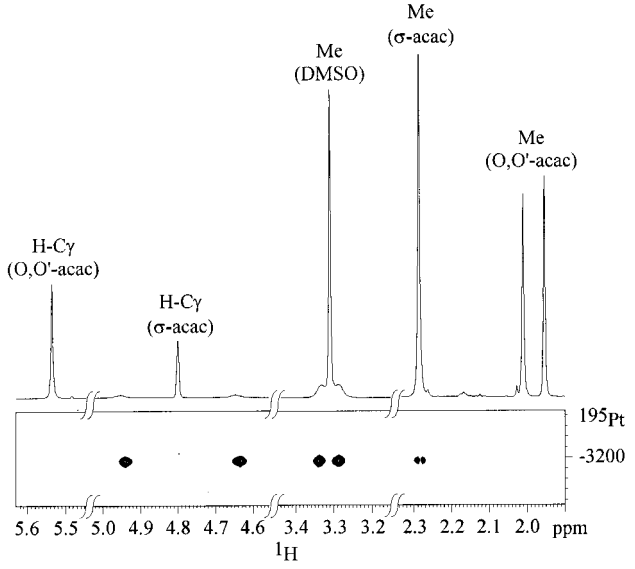

Figure 3. ^{1}H-^{195}Pt-HETCOR spectrum of **2** acquired without ^{195}Pt decoupling during acquisition. For clarity, ^{1}H projections are not on the same vertical scale

Crystal Structure of 2

The crystals obtained for complex [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (Figure 4) contain three molecules in the asymmetric unit (*2*, *2a* and *2b*). The cell dimensions along with other crystallographic details are given in Table 4. In both the neutral [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (**2**) and ionic [Pt(*O,O′*-acac)(γ-acac)Cl]$^-$ (**4**)[16] complexes, the oxygen-bonded acetylacetonate ligand is asymmetrically coordinated. The different Pt–O bond lengths follow the trend expected on the basis of *trans* substituents. The Pt–O lengths for the oxygen atom *trans* to the Cγ-carbon are 2.06[1] and 2.07(1) Å (square brackets indicate average values; parentheses refer to unique values) while those for the oxygen atom *trans* to the sulfur (DMSO) and chlorine atoms (complexes **2** and **4**, respectively) are 2.00[1] and 1.97(1) Å. In the σ-bonded acetylacetonate, the Pt–Cγ bond length for compound **2** is in agreement with the value for the analogous bond previously reported for **4** (2.09[2] and 2.11(2) Å, respectively). Both distances are greater than Pt–C(sp^3) σ-bonds *trans* to oxygen reported for C alkyls.[16,17] The Cγ of the σ-bonded acetylacetonate could be a weak donor, probably due to the cumulative electronegative effects of two carbonyl groups. All three *O,O′*-chelate acac moieties are planar. In all three molecules, the oxygen atoms of DMSO are oriented towards the σ-bonded acetylacetonate ligands. The modulus of the lowest torsional angles X–Pt–S–O (Ψ) (Scheme 3), according to the statistical study by Calligaris and Carugo,[2] indicates that the torsional angles Ψ lie in the low probability range [51.5(4)°, 52.4(5)° and 34.0(5)°]. This orientation of DMSO favours

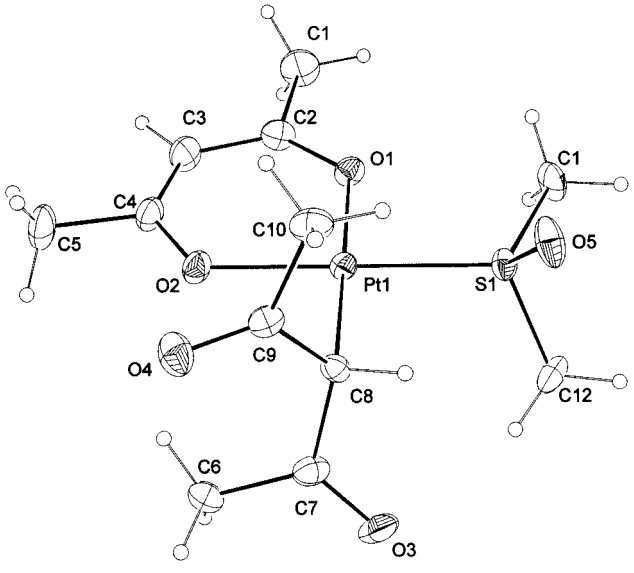

Figure 4. Molecular structure of one out of three independent molecules (molecule *2*) in the asymmetric unit of compound **2**

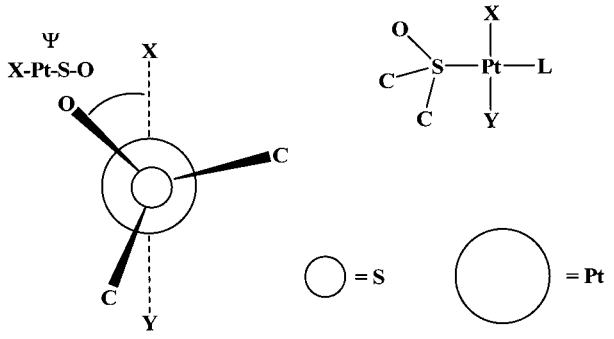
interactions between the oxygen atom of the DMSO and the Cγ hydrogen atom of the σ-bonded acetylacetonate [C(8)···O(5) 3.20(5), H(8)···O(5) 2.55(5) Å, C(8)···H(8)···O(5) 124(1)°].



Scheme 3

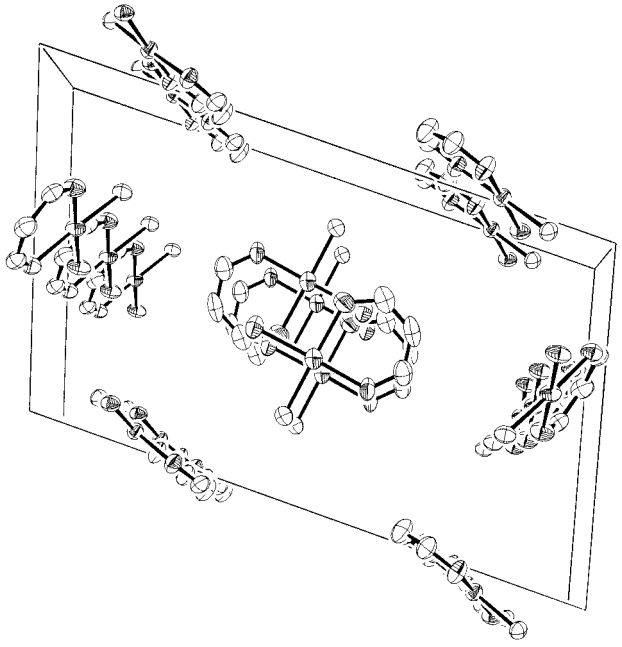


Figure 5. Unit cell projection along the *a*-axis showing alternating *2b* molecules staggered by ca. 180° and stacked inside the channel resulting from the propagation of molecules of *2* (top and bottom) and *2a* (sides). Only ligand atoms in the coordination plane are shown (see Supporting Information, S4 for the same projection with all atoms except hydrogen)

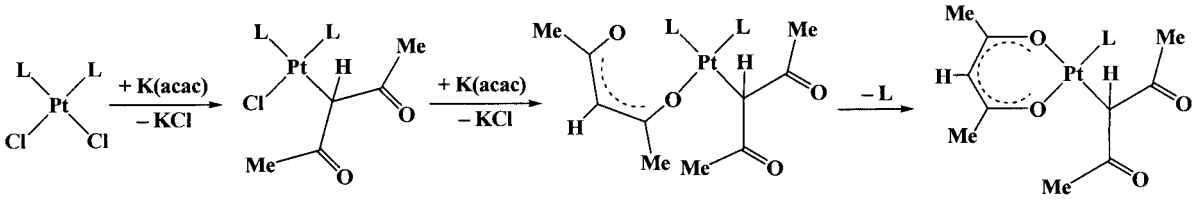
The crystal packing arrangement is shown in Figure 5. The three independent molecules of the unit cell are almost perpendicular and describe a box shape. Interestingly, the crystal structure shows subsequent boxes generating a channel by superimposition along the *a* axis. Alternating *2b* molecules are staggered by ca. 180° and stacked inside the channel created by the propagation of molecules *2* and *2a*. Selected bond distances and angles are listed in Table 5.

Reaction Mechanism

Platinum and palladium complexes of the type [M(*O,O′*-acac)(γ-acac)L] which contain one *O,O′*-chelated and one Cγ-bonded β-diketonate on the same metal together with one of a variety of nitrogen, phosphorus, arsenic and sulfur ligands (L) are well known in coordination chemistry. Usually, such complexes are produced by the addition of the ligand L to [M(*O,O′*-acac)$_2$] which causes the rearrangement of one of the two acac groups from the *O,O′*-chelate mode to the σ-bonded mode to give [M(*O,O′*-acac)(γ-acac)L] species.[12] However, in the course of our study, we have verified that treatment of the bis(β-diketonate)platinum(II) complex [Pt(*O,O′*-acac)$_2$] with excess DMSO or Et_2S[14] does not give [Pt(*O,O′*-acac)(γ-acac)L] even after two weeks. On the other hand, treatment of the starting complexes used in this work, i.e. [$PtCl_2(DMSO)_2$] and K[$PtCl_3$(DMSO)], with an excess of acetylacetone does not give [Pt(*O,O′*-acac)$_2$] in addition to [Pt(*O,O′*-acac)(γ-acac)L] and [Pt(*O,O′*-acac)(γ-acac)$_2$]$^-$. In a few cases, as for complex **2** described in this paper, [M(*O,O′*-acac)(γ-acac)L] complexes could be obtained starting from species lacking acac ligand(s) previously bound to the metal. In the case of platinum chemistry, the syntheses of K[Pt(*O,O′*-acac)(γ-acac)Cl][6] and [Pt(*O,O′*-acac)(γ-acac)(Et_2S)][14] have been reported starting from $K_2[PtCl_4]$ and [$PtCl_2$-(Et_2S)$_2$], respectively. The subsequent coordination of two acac ligands in the reactions of the [$PtCl_2L_2$]-type complexes (L = Et_2S, 1,2-bis(ethylthio)ethane, PEt_3, PPh_3) with thallium(I) β-diketonates has been studied in order to clarify the factors which could favour each of the two coordination modes, i.e. *O,O′*-chelated or Cγ-bonded, when the first acac binds to the metal. The reaction of *cis*-[$PtCl_2(PPh_3)_2$] with acac requires previous removal of the chloro ligands to give [Pt(*O,O′*-acac)(PPh_3)$_2$] while treatment of *trans*-[$PtCl_2(PEt_3)_2$] with an excess of Tl(acac) gave [Pt(*O,O′*-acac)Cl(PEt_3)]. No acetylacetonato complexes were detected in a similar reaction of *cis*-[$PtCl_2(PEt_3)_2$]. On the other hand, the reaction of *cis*- or *trans*-[$PtCl_2(Et_2S)_2$] with Tl(acac) was reported to give[Pt(*O,O′*-acac)(γ-acac)(Et_2S)] in both cases (although with different reaction rates). Interestingly, in both cases it was not possible to isolate intermediate products either by lowering the reaction temperature or by decreasing the acac/platinum complex ratio.[14] Attempts to obtain [Pt(*O,O′*-acac)$_2$] by treatment of [$PtCl_2(Et_2S)_2$] with K(acac) once again gave, after removal of the chloro ligands with silver perchlorate, [Pt(*O,O′*-acac)(γ-acac)(Et_2S)]. When [$PtCl_2$(S-S)] [S-S = 1,2-bis(ethylthio)ethane] was treated with Tl(acac), [PtCl(γ-acac)(S-S)] was exclusively formed and no other products were obtained even when a large excess of the β-diketonate was used. This latter result clearly indicates that the [PtCl(S-S)]$^+$ moiety prefers to bind to the Cγ-carbon rather than the oxygens of acac. Nevertheless, in the reaction of [$PtCl_2(Et_2S)_2$] with Tl(acac), the isolation of [Pt(*O,O′*-acac)(γ-acac)(Et_2S)] as the only product, without evidence of intermediates, does not explain which of the two coordination modes (*O,O′*-chelated or Cγ-bonded) is preferred when the first acac binds to the metal. It has been suggested that in the reaction of [$PtCl_2(Et_2S)_2$] with acac, the first β-diketonate substitutes one chloro ligand by Cγ-binding to the metal. The second β-diketonate then replaces the other

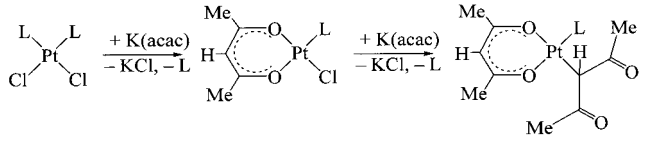
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4

chloride in a *O*-unidentate mode which finally converts to the *O,O′*-acac chelating mode by sulphide elimination (Scheme 4).

Nevertheless, there is another possible mechanism which cannot be ruled out. According to this mechanism, a cationic β-diketonate chelate first forms, i.e. [Pt(*O,O′*-acac)-$(Et_2S)]^+$, which then bonds to the carbon of the second β-diketonate to give [Pt(*O,O′*-acac)(γ-acac)(Et_2S)] (Scheme 5).[14]



Scheme 5

In this context the synthesis reported here for the **1**, with only the *O,O′*-chelated acac ligand, may be considered important evidence for explaining whether the *O,O′*-chelated or the Cγ σ-bonded acac is the first ligand to coordinate to the metal in the reaction of multiple β-diketonates with platinum. In our investigations, we found that the use of stoichiometric or even substoichiometric amounts of acac with respect to platinum in the reactions with $[PtCl_2(DMSO)_2]$, performed in MeOH, always gave mixtures of **1** and **2**. When we used $K[PtCl_3(DMSO)]$ as a starting complex and water as the solvent, it was possible to exclusively obtain complex **1** which could be isolated in good yield. In principle, the reactivity of $[PtCl_2(DMSO)_2]$ and $K[PtCl_3(DMSO)]$ with chelates can be expected to be very similar.[18] It is well known that both $[PtCl_2(DMSO)_2]$ and $K[PtCl_3(DMSO)]$ react with chelating nitrogen ligands to give the cationic species $[PtCl(DMSO)(N\text{-}N)]^+$ via substitution of one chloride *trans* to DMSO as the first reaction step.[19] In the present case, the formation of a mixture of **1** and **2**, when a suspension of $[PtCl_2(DMSO)_2]$ in MeOH was used in the reaction with acac, can be explained in terms of the low solubility of the starting complex in the reaction medium. In the first step of the reaction, one molecule of acac reacts with the platinum complex to give **1** which is soluble in MeOH and therefore accumulates in the reaction medium. It should be noted that in the formation of compound **1**, as in the formation $[PtCl(DMSO)\text{-}(N\text{-}N)]^+$,[19] the higher *trans* effect of DMSO compared with that of chloride is responsible for both the first attack on platinum by one end of the bidentate ligand and further chelation leading to the thermodynamic product. As the reaction proceeds, complex **2** forms since the second molecule of acac reacts with [PtCl(*O,O′*-acac)(DMSO)] (**1**) rather than with $[PtCl_2(DMSO)_2]$ because of the higher availability of compound **1** in the reaction medium. When we used $K[PtCl_3(DMSO)]$ as the starting complex, [PtCl(*O,O′*-acac)(DMSO)] could be obtained in high yield. In fact **1** is scarcely soluble in water and precipitates from the reaction medium immediately after its formation. It should be noted that **1** could also be obtained by carrying out the reaction of $[PtCl_2(DMSO)_2]$ with a stoichiometric amount of acac in water. In this case, however, a longer reaction time was required due to the much lower solubility of $[PtCl_2\text{-}(DMSO)_2]$ in water compared with that of $K[PtCl_3(DMSO)]$. Finally, further treatment of [Pt(*O,O′*-acac)(γ-acac)(DMSO)] with an extra acac led to the formation of [Pt(*O,O′*-acac)(γ-acac)$_2$]. These results confirm the mechanism depicted in Scheme 5 in which the β-diketonate chelate is the first product formed and the *O,O′*-chelation of the first acac then favours Cγ-carbon bonding of the second (and eventually third) β-diketonate.

Conclusions

In this paper we have described the first two examples of platinum(II) complexes containing both acetylacetonate and sulfoxide ligands coordinated to the metal, namely [PtCl(*O,O′*-acac)(DMSO)] (**1**) and [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (**2**). We have also reported a new synthesis of the homoleptic complex K[Pt(*O,O′*-acac)(γ-acac)$_2$] (**3**).[20] The formation of **2** represents a rare example of a reaction giving [Pt(*O,O′*-acac)(γ-acac)L] complexes starting from platinum species other than [Pt(*O,O′*-acac)$_2$] which also, in general, lack an acac ligand initially bound to the metal. Moreover, the isolation of **1** as an intermediate supports a mechanism in which the β-diketonate chelate is the first product formed from the reaction of multiple β-diketonate ligands with platinum. According to the results reported here, the *O,O′*-chelation of the first acac is followed by the Cγ-carbon bonding of the second (and eventually the third) β-diketonate in the platinum coordination sphere.

Experimental Section

Physical Measurements: Elemental analyses were performed using a Carlo–Erba elemental analyser, model 1106. IR Spectra were recorded with a Perkin–Elmer Spectrum 598 spectrometer using KBr as a solid support for pellets. ^1H and ^{13}C NMR spectra as well as ^1H-^1H NOESY, ^1H-^{13}C HETCOR and ^1H-^{195}Pt HETCOR 2-D experiments were performed with a DPX 400 MHz Avance Bruker instrument using $CDCl_3$, CD_3OD or D_2O as the solvent. Chemical shift are referenced to TMS using the residual protic solvent peaks

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as internal references (δ = 7.24 for $CDCl_3$, δ = 3.30 for CD_3OD and δ = 4.65 for D_2O).

Starting Materials: Commercial reagent grade chemicals, acetylacetone and solvents were used without further purification. [Pt(*O,O′*-acac)$_2$],[7] [$PtCl_2(DMSO)_2$][21] and K[$PtCl_3$(DMSO)][22] were prepared by previously reported procedures.

[PtCl(*O,O′*-acac)(DMSO)] (1): A solution of acetylacetone (97.5 mg, 0.973 mmol) and KOH (19.5 mg, 0.487 mmol) in methanol (5 mL) was added dropwise to a solution of K[$PtCl_3$(DMSO)] (204 mg, 0.487 mmol) in water (10 mL) at room temperature with stirring. After few minutes a yellow precipitate separated from the solution. The reaction mixture was left stirring overnight and the pale-yellow precipitate of [PtCl(*O,O′*-acac)(DMSO)] (**1**) was then isolated by filtration and dried under vacuum (yield 149 mg, 75%). $C_7H_{13}ClO_3SPt$ (407.79): calcd. C 20.62, H 3.21; found C 20.73, H 3.28.

Alternatively, a solution containing acetylacetone (97 mg, 0.966 mmol) and KOH (27 mg, 0.483 mmol) in water (5 mL) was added dropwise to a suspension of [$PtCl_2(DMSO)_2$] (204 mg, 0.483 mmol) in water (10 mL) at room temperature with stirring. The reaction mixture slowly became a yellow solution. After 3 h, a pale-yellow solid started to precipitate. The suspension was left stirring for one day and the solid was then filtered and dried under vacuum (yield 27 mg, 26%). $C_7H_{13}ClO_3SPt$ (407.79): calcd. C 20.62, H 3.21; found C 20.51, H 3.18.

[Pt(*O,O′*-acac)(γ-acac)(DMSO)] (2): A solution of acetylacetone (358 mg, 3.576 mmol) and KOH (114 mg, 2.860 mmol) in methanol (5 mL) was added dropwise to a suspension of [$PtCl_2(DMSO)_2$] (302 mg, 0.715 mmol) in methanol (20 mL) at room temperature with stirring. The reaction mixture slowly became a pale yellow solution. After one day, the solvent was evaporated under vacuum and the yellow residue was extracted with $CHCl_3$ (10 mL). The chloroform solution was then filtered to remove KCl and K(acac), pentane (30 mL) was added and the resultant solution kept overnight at 5 °C. Quadrangular pale-yellow crystals of [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (**2**) which separated out from the solution were filtered, washed with pentane and dried under vacuum (yield 168 mg, 50%). $C_{12}H_{20}O_5SPt$ (471.441): calcd. C 30.57, H 4.28; found C 30.73, H 4.34.

K[Pt(*O,O′*-acac)(γ-acac)$_2$] (3): A solution of acetylacetone (332 mg, 3.318 mmol) and KOH (94.8 mg, 2.370 mmol) in methanol (5 mL) was added dropwise to a suspension of [$PtCl_2(DMSO)_2$] (200 mg, 0.474 mmol) in methanol (20 mL) at room temperature with stirring. After 1 h, the suspension became a pale-yellow solution which was left stirring for three days. The solvent was then removed under vacuum and the residual yellow oil was extracted with $CHCl_3$ (10 mL). The chloroform solution was then filtered to separate KCl and K(acac), and pentane (30 mL) was added causing the precipitation of K[Pt(*O,O′*-acac)(γ-acac)$_2$] (**3**) as a yellow solid. The product was separated by filtration, washed with pentane and dried under vacuum (yield 68 mg, 27%). $C_{15}H_{24}KO_6Pt$ (534.524): calcd. C 33.70, H 4.53; found C 33.46, H 4.21.

Alternatively, a solution of acetylacetone (129 mg, 1.284 mmol) and KOH (48 mg, 0.856 mmol) in methanol (10 mL) was added dropwise to a suspension of [Pt(*O,O′*-acac)(γ-acac)(DMSO)] (202 mg, 0.428 mmol) in diethylether (30 mL) at room temperature with stirring. The colour of the solid in the reaction mixture slowly turned from white to pale-yellow. After one day, the solvent was removed under vacuum and the residue was washed with diethyl ether (10 mL) then extracted with chloroform (10 mL). K[Pt(*O,O′*-acac)(γ-acac)$_2$] was obtained as a pale-yellow solid by addition of diethylether (20 mL) to the filtered chloroform solution (yield 65 mg, 28%).

Reaction of [Pt(*O,O′*-acac)$_2$] with DMSO: [Pt(*O,O′*-acac)$_2$] (2 mg, 0.005 mmol), synthesised by a previously reported procedure, was dissolved in $CDCl_3$ (0.5 mL) and the resultant solution placed in an NMR tube. DMSO (1 μL, 1.17 mg, 0.015 mmol) was added and the solution was monitored by recording ^{1}H NMR spectra periodically over a period of two weeks. The spectra did not show any significant change over that period of time.

Single-Crystal X-ray Diffraction Study: Pale-yellow crystals of [Pt(*O,O′*-acac)(γ-acac)(DMSO)] were obtained by crystallisation from $CHCl_3$/pentane. X-ray data were collected using an Enraf–Nonius CAD4 diffractometer. A least-squares algorithm using 25 automatically centred reflections was used to refine the unit cell dimensions. A total of 6726 independent reflections were collected in the range $-10 \le h \le 10$, $-13 \le k \le 14$ and $0 \le l \le 23$. Four reflections were monitored during data collection but no decay was observed. Crystallographic data are summarised in Table 4. The full data set was corrected for Lorentz and polarisation effects and an absorption correction was applied using the DIFABS package[23] at the isotropic stage of refinement. The structure was solved by direct-methods in the $P\bar{1}$ space group. The model was refined by full-matrix least-squares methods. Anisotropic thermal parameters were applied for all non-hydrogen atoms. All hydrogen atoms were placed in their geometrically calculated positions and were included in the full-matrix least-square cycles with isotropic thermal parameters (U) fixed at 1.2 and 1.5 (for methyl group) times the values of *U* of the corresponding carbon atoms. Crystallographic calculations were carried out and molecular graphics designed using the SIR97,[24] SHELXL97,[25] WinGX,[26] ORTEP for Windows[27] and PARST97[28] packages. CCDC-172448 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

COVER PICTURE

The cover picture shows the richness of 1,2-ethanediylbis-(iminomethylene)bis(phosphonic acid) (H_4L) used as a ligand. The left compound is cadmium phosphonate, $Cd_2Cl_2(H_2O)_4(H_2L)$, in which the Cd atoms form dimers through bridging chloride ions. These dimers are, in turn, formed into rows by the phosphonate groups, and the rows are crosslinked by the organic chain of the ligand into layers. The second picture shows $Zn_3Cl_2(H_2L)_2{\cdot}2H_2O$, in which Zn atoms are tetrahedrally coordinated. One of the Zn atoms lies in rows parallel to the *b*-axis, which are sandwiched between rows formed by the two other Zn atoms. The carbon–nitrogen chains crisscross each other forming a three-dimensional structure. The structure of this latest compound is presented in the article by A. Clearfield et al. on p. 829 ff.

η^6:η^6 Coordination of Tetraphenylborate to Ytterbium(II): A New Class of Lanthanoid *ansa*-Metallocenes

Glen B. Deacon,*[a] Craig M. Forsyth,[a] and Peter C. Junk[a]

Keywords: Metallocenes / Ytterbium / Tetraphenylborate / Bis(trimethylsilyl)amide / Pyrazolate

The ytterbium(II) complexes [Yb(*t*Bu$_2$pz)(THF)BPh$_4$] (**2**) (*t*Bu$_2$pzH = 3,5-di-*tert*-butylpyrazole) and [Yb{N(SiMe$_3$)$_2$}BPh$_4$] (**3**) were synthesised by reaction of [Yb{N(SiMe$_3$)$_2$}(THF)BPh$_4$] (**1**) with *t*Bu$_2$pzH or by in situ desolvation of the THF complex **1**. X-ray analysis of **2** and **3** reveals η^6:η^6 binding of chelating BPh$_4^-$ to ytterbium in both cases, generating true metallocene structures. Complex **3** is distinguished by a very short Yb–N bond and an agostic Yb–Me interaction, both indicative of a highly Lewis acidic metal centre.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The recent rapid growth in the chemistry of lanthanoid-π-arene complexes has been fuelled both by an interest in their structures and bonding and by their ability to stabilise unusual oxidation states.[1–3] Readily available tetraphenylborate (BPh$_4^-$) can act as a chelating 12 e$^-$ donor through π bonding of two of the phenyl rings to a metal as in [Nb(RC≡CR)(η^6-Ph)$_2$BPh$_2$],[4,5] but not in lanthanoid tetraphenylborates, which almost exclusively have the BPh$_4^-$ simply in its classical counterion role (recent examples[6–13]). Two exceptions of note are [La(C$_5$Me$_5$){CH(SiMe$_3$)$_2$}BPh$_4$], for which the solid-state NMR spectra shows evidence of La–Ph interactions,[14] and structurally characterised [Sm(C$_5$Me$_5$)$_2$(Ph)$_2$BPh$_2$], which shows two of the Ph groups bound (η^2:η^2) to Sm^{3+}.[15] Both of these lanthanoid(III) complexes have two bulky coligands, which prevent a closer approach of BPh$_4^-$ to the metal centre. We have recently reported the isolation of the lanthanoid(II) tetraphenylborate, [Yb{N(SiMe$_3$)$_2$}(THF)(Ph)$_2$BPh$_2$] (**1**), which also has a bonded BPh$_4^-$ ligand.[16] However, the Yb–BPh$_4$ coordination is labile as indicated by the existence of two solid-state linkage isomers, one that has η^6-Ph:η^4-Ph binding to Yb (**1a**), whilst in the other isomer **1b**, an agostic Yb–Me(Si) bond and an η^1-Yb–Ph interaction replace the η^4-Ph donor.[16] Potentially, higher hapticity binding of the BPh$_4^-$ anion to Yb^{2+} may be induced by reducing either the steric bulk or the number of coligands. Following this design, we now report the synthesis and structures of two new ytterbium(II) tetraphenylborate complexes that show unequivocal η^6:η^6-Yb–Ph$_2$BPh$_2$ coordination.

Results and Discussion

At low temperature, **1** reacts with one equivalent of *t*Bu$_2$pzH (3,5-di-*tert*-butylpyrazole) to give poorly soluble, red-purple [Yb(*t*Bu$_2$pz)(THF)BPh$_4$].2PhMe (**2**). A THF-free derivative of **1** was also prepared by in situ desolvation in PhMe to give purple [Yb{N(SiMe$_3$)$_2$}BPh$_4$] (**3**) (Scheme 1). Both compounds were obtained in moderate to good yields, and were characterised by analytical and spectroscopic data and by single-crystal X-ray structure determinations (see below). Solid-state IR spectra of **2** and **3** exhibit two ν(C=C$_{Ar}$) absorptions near 1580 cm^{-1} as well as three or more δ(C–H$_{Ar}$) bands between 700–800 cm^{-1}, consistent with the presence of both free and Yb-bound B–Ph moieties. However, in C$_6$D$_6$ solution at room temperature, only single Ph environments are observed in the ^{1}H NMR spectra of **2** and **3**. The *o*-H(Ph) resonances [δ: 8.14 (**2**), 7.84 (**3**) ppm] are shifted to higher frequency relative to free BPh$_4^-$, e.g. [Yb(MeCN)$_8$][BPh$_4$]$_2$ δ(CD$_3$CN) = 7.25 ppm[10] {compare also [Na([18]-cr-6)][BPh$_4$]·1.5H$_2$O δ(CD$_2$Cl$_2$) = 7.33 ppm[5]}, as has been observed for coordi-

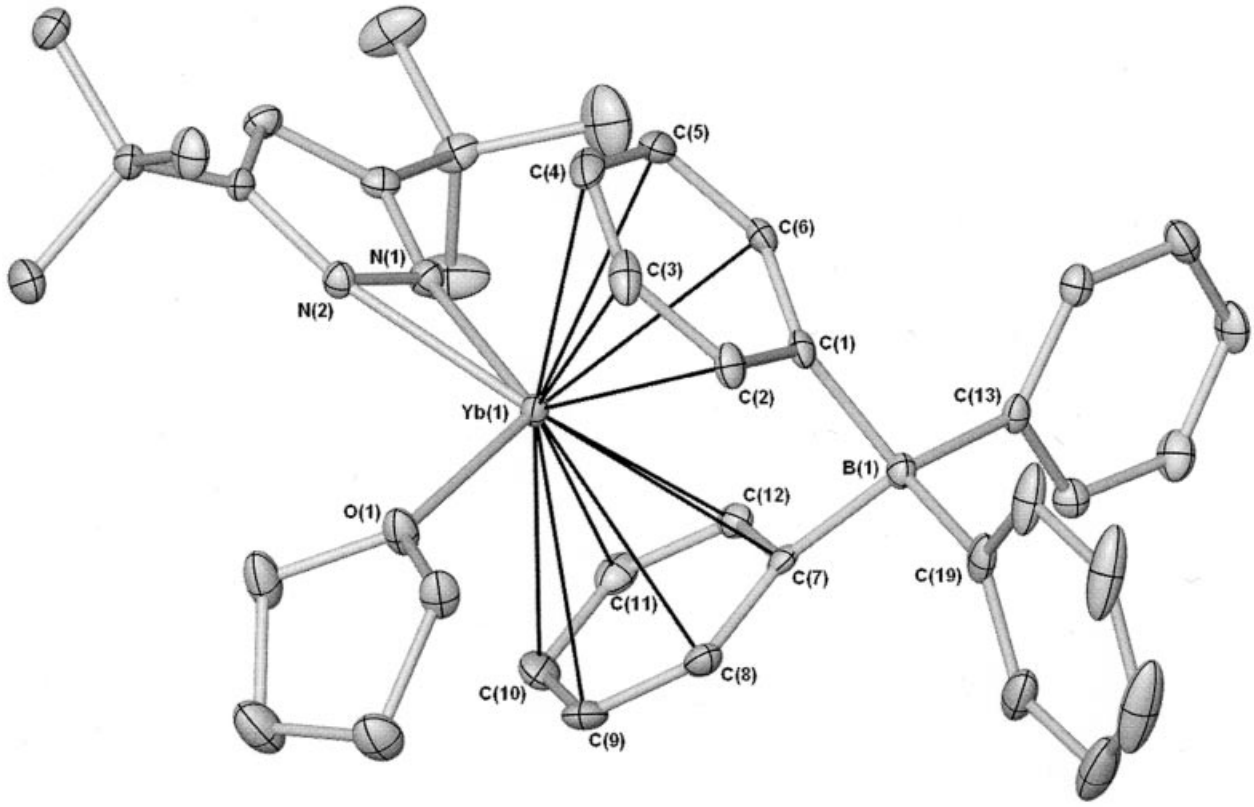

Figure 1. Molecular representation of the X-ray structure of [Yb(*t*Bu$_2$pz)(THF)BPh$_4$]·2C$_6$D$_6$ (**2a**) showing 50% thermal ellipsoids, and with lattice C$_6$D$_6$ molecules and hydrogen atoms omitted for clarity.

nation of BPh_4^- to other d^0 metals {e.g. [Zr(CH_2Ph)$_3$(η^6-Ph)BPh_3] δ_H = 8.25 ppm[17]}. Thus, the data for **2** and **3** suggest that some degree of Yb–Ph coordination occurs in C_6D_6 solution, rather than formation of ion pairs such as [Yb(L)(THF)$_n$(C_6D_6)$_2$][BPh_4] (L = *t*Bu$_2$pz, *n* = 1; L = N($SiMe_3$)$_2$, *n* = 0), but that the system is fluxional. Variable-temperature ^{13}C NMR studies of **3** in C_6D_6/PhMe (1:10) show some line broadening at –40 °C for the aromatic carbon atoms but this is insufficient to resolve the two Ph environments. Further cooling results in significant precipitation of solid **3**, and **2** was insoluble in this medium below room temperature. A ^{171}Yb or ^{29}Si NMR signal for **3** could not be located between –40 and +30 °C.

To clarify the exact bonding mode(s) for BPh_4^- in **2** and **3**, X-ray crystal structures of both complexes were determined. Difficulty was experienced in obtaining single crystals, since at room temperature or with heating, solutions of **2** or **3** slowly decompose, and deposit yellow, insoluble [Yb(BPh_4)$_2$].[18] However, suitable crystals of [Yb(*t*Bu$_2$pz)(THF)BPh_4]·2C$_6$D$_6$ (**2a**) were deposited from a warm C_6D_6 solution, along with the yellow solid, whilst **3** was crystallised by slow evaporation of a cold PhMe solution. The molecular diagrams are shown in Figure 1 and Figure 2, and selected bond distances and angles are listed in Table 1. A key feature of both structures is the unequivocal η^6-binding of *two* phenyl rings from a chelating BPh_4^- anion to each of the central ytterbium atoms. In addition, **2a** has an η^2-*t*Bu$_2$pz$^-$ anion and a coordinated THF molecule, giving a formal coordination number of nine. In contrast, the remaining coordination sphere of **3** is occupied solely by an *N*-bound N($SiMe_3$)$_2^-$ ligand supported for coordination saturation by a short Yb–Me interaction to one of the $SiMe_3$ groups. Thus, the coordination number is eight. Both complexes exhibit distorted pseudotetrahedral coordination geometries, as defined by the centroids of the bound Ph groups, and the THF oxygen atom, and the centre of the N–N bond for **2a** and the amido nitrogen atom and bound $SiMe_3$ carbon atom for **3**.

The Yb–C distance ranges for each interacting Ph ring in **2a** and **3** are narrow (0.12–0.19 Å), and the average Yb–C distances (Table 1) are comparable to those (2.85–2.99 Å) of the single η^6-Ph–Yb moieties of **1a** or **1b**,[16] despite the higher coordination number in the current complexes. The average Yb–C distances in **3** are shorter than those to a substituted neutral arene, e.g. <Yb–C> 2.94 Å in [(Yb(η^6-$C_6Me_3H_3$)($AlCl_4$)$_2$]$_n$·*n*(C_6H_6)[19] or <Yb–C> 2.96, 2.98 Å in [Yb{SC_6H_3-2-(η^6-$C_6H_2Pr^i_3$)-6-($C_6H_2Pr^i_3$)}$_2$].[20] With allowance for differences in coordination number, the upper limit for Yb–C bonding in **2a** and **3** [3.050(2) Å] is comparable with or well below the upper value for the preceding two complexes,[19,20] whilst the current Yb–C distance range (Table 1) is comparable or smaller. In the metallocene complex [Yb{N($SiMe_3$)$_2$}(C_5Me_5)$_2$Na(THF)$_3$],[21] which has an analogous ytterbium coordination environment to that of

N/N*–Yb–O/C	98.4	67.9

[a] Si–C distance for the Me group bound to Yb.

3, the average Yb–C(C$_5$Me$_5$) bond length (2.83 Å) of the bridging (η^5:η^5) C$_5$Me$_5$ ligand is close to the average Yb–C distance in **3** (Table 1).

The amido ligands in both **2a** and **3** are characterised by short Yb–N distances, emphasising the high Lewis acidity of Yb^{2+} in the Yb(Ph)$_2$BPh$_2$ fragment. The two Yb–N distances in **2a** (Table 1) are approximately equivalent, indicating symmetrical binding of the *t*Bu$_2$pz$^-$ ligand, but the values are shorter than those of eight coordinate [Yb(Ph$_2$pz)$_2$(DME)$_2$] [2.414(7)–2.430(7) Å].[22] Similarly, the Yb–N distance in **3** [2.262(6) Å] is remarkably short relative to 2.41(2) Å in the closely related compound [Yb{N(SiMe$_3$)$_2$}(C$_5$Me$_5$)$_2$Na(THF)$_3$].[21] This difference is also likely to be influenced by the decreased steric bulk of **3** (two Ph groups compared with two C$_5$Me$_5$ groups) and the boron linkage in the chelating BPh$_4^-$ ligand, and this results in a more open residual coordination sphere. The centroid–Yb–centroid angle (Ph*–Yb–Ph* 114.0°) is significantly smaller for **3** than for [Yb{N(SiMe$_3$)$_2$}(C$_5$Me$_5$)$_2$Na(THF)$_3$] (Cp*–Yb–Cp* 134°).[21] The Ph*–Yb–Ph* angles are also considerably more acute than for BPh$_4^-$ in [Nb(RC≡CR)(η^6-Ph)$_2$BPh$_2$] (131.6°).[4] Complex **3** has a Yb–C(Me) distance [2.845(8) Å] that is much shorter than a similar interaction in **1b** [3.123(4) Å[16]) but comparable to those of [Yb{N(SiMe$_3$)$_2$}$_2$]$_2$ [2.785(4)–2.823(4) Å], which has several agostic Yb–Me$_3$Si interactions to support the YbN$_3$ coordination.[23] The Yb–Me contact is accompanied by a narrowing of the Yb–N–Si angle from 111.0(1)° in **1a** to 104.6(3)° in **3** and an apparent lengthening of the associated Si–C distance (Table 1).

Conclusions

Through the use of steric engineering that provides an appropriate coligand environment in heteroleptic Yb(L)BPh$_4$ complexes, stronger binding of BPh$_4^-$ to Yb^{2+} has been achieved with the first observation of η^6:η^6-Ph$_2$BPh$_2$ coordination to a lanthanoid. These complexes represent true *ansa*-metallocenes of ytterbium(II) and, in particular, the solvent-free complex **3** parallels the highly catalytically active *ansa*-bis(cyclopentadienyl)lanthanoid(III) species, and we are currently pursuing this aspect.

Experimental Section

General Remarks: All reactions were carried out under dry nitrogen or argon by using dry box and standard Schlenk techniques. Solvents were dried by distillation from sodium wire/benzophenone. Elemental analyses (C,H,N) were performed by the Campbell Microanalytical Service, University of Otago, New Zealand. IR data (4000–650 cm^{-1}) were recorded for Nujol mulls sandwiched between NaCl plates with a Perkin–Elmer 1600 Fourier transform infrared spectrometer. NMR spectra were obtained with a Bruker AC300 MHz spectrometer; [D_6]benzene was degassed and distilled from Na/K alloy prior to use. **1**,[16] [Yb{N($SiMe_3$)$_2$}$_2$(THF)$_2$],[24] Me_3NHBPh_4,[25] and 3,5-tBu$_2$pzH[26] were prepared according to literature procedures.

[Yb(tBu$_2$pz)(THF)BPh$_4$].2PhMe (2): A Schlenk flask was charged with tBu$_2$pzH (0.05 g, 0.25 mmol), **1** (0.18 g, 0.25 mmol), and PhMe (20 mL), and cooled to –40 °C. The reaction mixture was stirred and allowed to warm to 0 °C over approximately 1 h. The resulting purple solution was concentrated to 10 mL and cooled to –73 °C to yield **2** as a red-purple solid, which was collected and dried under vacuum (yield 0.14 g, 67%). IR (Nujol): $\tilde{\nu}$ = 1584 (w), 1570 (w), 1496 (m), 1310 (w), 1272 (w), 1248 (m), 1220 (w), 1184 (m), 1156 (m), 1066 (w), 1030 (m), 1014 (m), 993 (w), 934 (s), 869 (m), 857 (m), 777 (m), 750 (vs), 729 (vs), 714 (vs), 695 (m) cm^{-1}. ^{1}H NMR ([D_6]benzene): δ = 8.14 [br. s, 8 H, *o*-H(BPh)], 7.22 [br. s, 8 H, *m*-H(BPh)], 7.16–7.00 (m, 10 H, *Ph*Me), 6.90 [br. t, J = 7.5 Hz, 4 H, *p*-*H*(BPh)], 6.11 [br. s, 1 H, *H*4(pz)], 2.11 (s, 6 H, Ph*Me*), 1.24 (br. s, 18 H, tBu) ppm. Resonances due to THF at $\delta \approx$ 3.5 and 1.3 ppm (underlying the tBu resonance at δ = 1.24 ppm) were extremely broad with unreliable integration. Analytical data were consistent with loss of lattice toluene molecules: [Yb(t-Bu$_2$pz)(THF)BPh$_4$], $C_{39}H_{47}BN_2OYb$ (744.32): calcd. C 62.9, H 6.4, N 3.8%; found C 62.8, H 6.7, N 3.6% {compare with [Yb(t-Bu$_2$pz)(THF)BPh$_4$]·2PhMe, $C_{53}H_{63}BN_2Yb$ (928.44): calcd. C 68.5, H 6.8, N 3.0%}. Single crystals of [Yb(tBu$_2$pz)(THF)BPh$_4$]·2C_6D_6 (**2a**) were grown from a [D_6]benzene solution of **2**.

[Yb{N(SiMe$_3$)$_2$}BPh$_4$] (3): A Schlenk flask was charged with [Yb{N($SiMe_3$)$_2$}$_2$(THF)$_2$] (0.64 g, 1.0 mmol), Me_3NHBPh_4 (0.38 g, 1.0 mmol), and PhMe (60 mL), and the reaction mixture was stirred for 2 h at –10 °C. The solvent was then removed under vacuum whilst maintaining the solution at –10 °C. PhMe (60 mL) was added to the residue, and the mixture was stirred for a further 1 h at –10 °C before the solvent was again removed, and the cycle was repeated. After the final removal of solvent, PhMe (60 mL) was added, and the resulting purple solution was filtered, concentrated to 5 mL, and hexanes (10 mL) were added. Cooling to –73 °C gave **3** as a purple solid, which was collected and dried under vacuum (yield 0.36 g, 55%). IR (Nujol): $\tilde{\nu}$ = 1583 (w), 1560 (w), 1307 (w), 1249 (m), 1240 (m), 1178 (w), 1156 (m), 1066 (vs), 976 (w), 833 (m), 816 (m), 783 (w), 748 (s), 736 (s), 712 (s) cm^{-1}. ^{1}H NMR (300 MHz, 303 K, [D_6]benzene): δ = 7.84 [br. d, J = 5.8 Hz, 8 H, *o*-*H*(BPh)], 7.06 [br. s, 8 H, *m*-*H*(BPh)], 6.90 [br. s, 4 H, *p*-*H*(BPh)], –0.19 (s, 18 H, SiMe_3) ppm. ^{13}C NMR (75.5 MHz, [D_6] benzene): δ = 135.0 [*o*-*C*H(BPh)], 129.3 [*m*-*C*H(BPh)], 124.6 [*p*-*C*H(BPh)], 4.5 (SiMe_3) ppm. The resonance for the *ipso*-C (bound to B) was not detected. ^{11}B NMR (128.4 MHz, [D_6]benzene): δ = –3.85 ppm. $C_{30}H_{38}BNSi_2Yb$ (652.65): calcd. X-ray Crystallographic Study: Crystals were mounted in an inert atmosphere under viscous oil onto a glass fibre. Low-temperature (123 K) data were collected on an Enraf–Nonius KAPPA CCD area-detector diffractometer (Mo-K_α radiation, λ 0.71073 Å, frames comprised 1.0° or 0.5° increments in φ and ω yielding a sphere of data) with proprietary software (Nonius B.V., 1998). Each data set was corrected for absorption (empirical-SORTAV[27]) then merged (R_{int} as quoted) to N unique reflections. The structures were solved by conventional methods and refined with anisotropic thermal parameter forms for the non-hydrogen atoms by full-matrix least-squares on all F^2 data by using SHELX 97.[28] Hydrogen atoms were included in calculated positions and allowed to ride on the parent carbon atom.

2a: $C_{51}H_{47}D_{12}B_1N_2O_1Yb_1$ (911.92) monoclinic $P2_1/n$, a = 15.0562(1), b = 16.2227(1), c = 18.1395(3) Å, β = 97.296(1) °, V = 4394.7(1) Å^3, $D_{calcd.}$ (Z = 4) 1.378 g cm^{-3}, μ_{Mo} = 2.166 mm^{-1}, F(000) 1848, $T_{min,max}$ = 0.561, 0.653, N_{total} = 50926, N = 10752 (R_{int} = 0.053), R = 0.026, wR_2 = 0.061 (R = 0.038, wR_2 = 0.064 all data). One of the lattice C_6D_6 molecules was disordered over two positions, and the geometries of both components were modelled as rigid hexagons.

3: $C_{30}H_{38}B_1N_1Si_2Yb_1$ (652.64) orthorhombic $Pca2_1$, a = 31.2276(4), b = 9.5779(1), c = 19.6904(3) Å, V = 5889(2) Å^3, $D_{calcd.}$ (Z = 8) 1.472 g cm^{-3}, μ_{Mo} = 3.28 mm^{-1}, F(000) 2624, $T_{min,max}$ 0.549, 0.778, x_{abs} 0.066 (12), N_{total} = 59936, N = 13425 (R_{int} = 0.096), R = 0.047, wR_2 = 0.082 (R = 0.086, wR_2 = 0.094 all data). As modelled in $Pca2_1$, the asymmetric unit comprised a pair of molecules apparently related by a centre of symmetry. However, no further crystallographic symmetry was detected by using the program PLATON,[29] and no sensible solution could be found in the centrosymmetric space group *Pbcm*. The high correlation matrix elements present in the noncentrosymmetric solution as a result of the pseudosymmetry presumably contribute to the relatively large ESDs.

CCDC-255023 and CCDC-255024 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Structural, Spectroscopic, and Reactivity Properties of N_2S_2(thioether)-O(amide)-Ligated Hg^{II} Complexes: The First Examples of Hg^{II}-Mediated Amide Cleavage

Magdalena M. Makowska-Grzyska,[a] Kelly Doyle,[a] Russell A. Allred,[a] Atta M. Arif,[b] Deborah C. Bebout,*[c] and Lisa M. Berreau*[a]

Keywords: Mercury / Amides / NMR Spectroscopy / Zinc / Cadmium

Two mercury(II) complexes [(bmppa)Hg(ClO_4)]ClO_4 {**1**, bmppa = *N,N*-bis(2-methylthio)ethyl-*N*-[(6-pivaloylamido-2-pyridyl)methyl]amine} and [(beppa)Hg(ClO_4)]ClO_4 {**2**, beppa = *N,N*-bis(2-ethylthio)ethyl-*N*-[(6-pivaloylamido-2-pyridyl)-methyl]amine} of N_2S_2(thioether)O(amide)-donor chelate ligands have been prepared and characterized by X-ray crystallography and/or spectroscopic methods. In the solid state, the Hg^{II} ion of **2** exhibits an overall coordination number of six and strong amide oxygen coordination. Comprehensive multinuclear NMR studies of **1** and **2** have yielded the first $J_{^{199}Hg^{1}H}$ and $J_{^{199}Hg^{13}C}$ coupling constants associated with a Hg–$RSCH_3$ methyl group. In the presence of one equivalent of $Me_4NOH{\cdot}5H_2O$ in methanol/acetonitrile solution, the amide appendages of **1** and **2** undergo alcoholysis.

Introduction

The coordination chemistry of the Hg^{II} ion in biologically-relevant ligand environments is an area of current interest. For example, recent biochemical studies have focused on the use of ^{199}Hg NMR techniques in evaluating the active site coordination environments of Hg^{II}-substituted proteins.[1–2]^1H NMR studies of Hg^{II} complexes of tripodal ligands have contributed to our understanding of the interplay of Hg^{II} coordination and spectroscopic properties by providing information regarding the magnitude of $J_{^{199}Hg^{1}H}$ and $J_{^{199}Hg^{13}C}$ coupling constants as a function of the nature of the Hg^{II} ligand environment.[3–7] Herein we outline the synthesis, structural and spectroscopic characterization, and amide cleavage properties of two Hg^{II} complexes of N_2S_2(thioether)O(amide)-donor chelate ligands. This work initiates advancement in two important areas of Hg^{II} coordination chemistry of relevance to biological systems. First, in seeking to expand the breadth of known spectroscopic features associated with Hg^{II} coordination, we have elucidated the first $J_{^{199}Hg^{1}H}$ and $J_{^{199}Hg^{13}C}$ coupling constants for Hg^{II}-$RSCH_3$ interactions. Second, we have commenced investigations into biologically-relevant reactions as a function of the group 12 metal ion present. In this context, we report herein that a Hg^{II} complex will mediate an amide cleavage reaction akin to that observed for zinc and cadmium analogs.[8] To the best of our knowledge, this work represents the first report in the chemical literature of Hg^{II}-mediated amide cleavage.

Results and Discussion

Preparation and Characterization of Hg^{II} Complexes

Mercury(II) complexes of the bmppa {*N,N*-bis(2-methylathio)ethyl-*N*-[(6-pivaloylamido-2-pyridyl)methyl] amine}and beppa {*N,N*-bis(2-ethylthio)ethyl-*N*-[(6-pivaloylamido-2-pyridyl)methyl]amine} ligands were prepared with $Hg(ClO_4)_2{\cdot}3H_2O$ in methanol (Scheme 1). Following crystallization from *i*PrOH/CH_3OH/Et_2O, [(bmppa)Hg(ClO_4)]ClO_4 (**1**) and [(beppa)Hg(ClO_4)]ClO_4 (**2**) were isolated in yields of 73% and 63%, respectively. Formulation of these complexes as having the amide oxygen coordinated to the Hg^{II} ion and one inner sphere perchlorate anion in the solid state is based on the X-ray crystal structure of **2** (vida infra) and the similarity of the solid state infrared spectral features for the amide moiety and perchlorate anions in **1** and **2**.

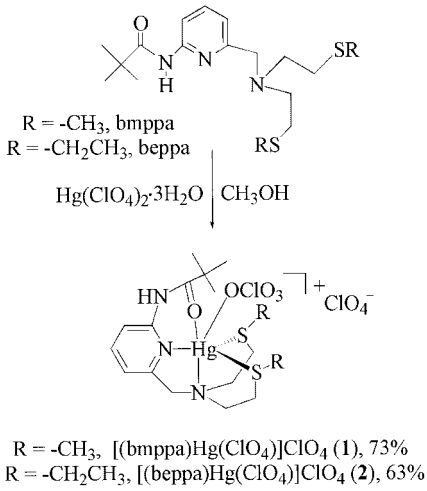

Scheme 1.

X-ray Crystallography

A summary of the X-ray data collection and refinement parameters for **2** is given in Table 1. An ORTEP representation of the cationic portion of **2** is shown in Figure 1. The Hg^{II} ion is well-known in two-coordinate linear or four-coordinate tetrahedral geometries.[9–13] However, the Hg^{II} center in **2** has an overall coordination number of six, with two short interactions involving the amide oxygen [Hg(1)–O(1) 2.271(5) Å; sum of Hg–O covalent radii 2.21 Å] and a thioether sulfur donor [Hg(1)–S(2) 2.4462(17) Å; sum of Hg–S covalent radii 2.50 Å][10] in a bent arrangement [O(1)–Hg(1)–S(2) 132.21(16)°]. As the Hg–O distance in **2** is only slightly longer than the sum of the covalent radii of the atoms, a strong interaction is present in the solid state for this complex. A search of the Cambridge Crystallographic Database revealed a complex of a 2-(pivaloylamido)-appended benzenethiolato ligand having a Hg–O (secondary amide) interaction akin to that in **2**.[14] However, the Hg–O distance in **2** is more than 0.5 Å shorter than the analogous bond length in bis[2,6-bis(pivaloylamido)benzenethiolato]mercury(II) [2.722(6) Å].[14] Typically, Hg^{II}–S(thioether) bond lengths are found in the range of 2.47–2.73 Å.[10–11,15–16] Thus, the Hg(1)–S(2) interaction is consistent with strong coordination to the Hg^{II} center, whereas the Hg(1)–S(1) bond length [2.6674(18) Å] indicates a weaker interaction. The remaining ligands to the Hg^{II} center of **2** are a pyridyl nitrogen [Hg(1)–N(2) 2.343(5) Å], a tertiary amine nitrogen [Hg(1)–N(3) 2.412(6) Å], and a weak Hg–O(perchlorate) interaction (3.01 Å). The Hg–N_{py} and Hg–N_{Am} distances in **2** are similar to the average corresponding distances found in $[(TMPA)HgCl]_2(HgCl_4)_2$ {Hg–N_{py}: 2.40 Å; Hg–N_{am}: 2.43 Å; TMPA = tris[(2-pyridyl)methyl]amine}.[3] Perchlorate coordination to Hg^{II} has been observed in several previously reported complexes.[4,17–21] In these, the Hg^{II}–O(perchlorate) bond lengths generally range from 2.66–2.95 Å. Notably, one of these reported structures has Hg^{II}–S(thioether) bonding as well as a weakly coordinated perchlorate (Hg–O, 3.08 Å) in a sixth coordination position.[18] Finally, key structural features of **2** are reminiscent of those found for the cadmium analog [(bmppa)$Cd(ClO_4)$]ClO_4.[8] Specifically, **2** and the Cd^{II} derivative both exhibit an overall six-coordinate distorted trigonal prismatic structure for the cation, with similar O(1)–M–N(2)–C(Ar) torsion angles {**2**: –13.8°; [(bmppa)$Cd(ClO_4)$]ClO_4: –22.5°} associated with coordination of the amide oxygen.

Spectroscopic Properties of 1 and 2

Infrared Spectroscopy

In the solid state, **1** and **2** have amide carbonyl stretching vibrations at 1652 and 1647 cm^{-1}, respectively, a position

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that is ca. 36–41 cm^{-1} shifted from that observed for the free ligands (bmppa and beppa, $\nu_{C=O} \approx 1687$ and 1688 cm^{-1}, respectively, neat between NaCl plates).[8,22] The reduced energy of the carbonyl vibrations in **1** and **2** is consistent with coordination to the Hg^{II} center. No significant difference is found in the solid state carbonyl stretching vibration as a function of metal ion, as zinc {[(beppa)Zn]$(ClO_4)_2$, 1643 cm^{-1}} and cadmium analogs {[(bmppa)Cd(ClO_4)]ClO_4, 1654 cm^{-1}} have a $\nu_{C=O}$ vibration of similar energy.[8] The acetonitrile solution infrared spectrum of **1**, obtained in a new BaF_2 cell, exhibits a single $\nu_{C=O}$ vibration at 1647 cm^{-1}, indicating that amide oxygen coordination is maintained in solution. Notably, collection of a CH_3CN solution infrared spectrum of **1** in an older KBr cell yields a $\nu_{C=O}$ vibration at 1698 cm^{-1}. This higher energy $\nu_{C=O}$ vibration suggests that the amide oxygen is not coordinated to the Hg^{II} ion under these conditions. Since the solution infrared properties of **1** depend on the nature of the cell used for the infrared measurement, we currently hypothesize that the noncoordinated amide species formed in the KBr cell results from formation of a bromide derivative via anion exchange involving the cell salt.

NMR Spectroscopy

A wide array of 1D (^1H, ^{13}C, ^{199}Hg) and 2D ({^1H,^1H}COSY, {^{13}C,^1H}HMQC) NMR experiments have been used to characterize **1** (Figures S1–S3, Supporting Information) and **2** (Figures S4–S7) in acetonitrile solution. The cations of **1**, **2**, [(beppa)Zn]$(ClO_4)_2$, [(bmppa)Zn]$(ClO_4)_2$, and [(bmppa)Cd(ClO_4)]ClO_4 in acetonitrile solution, all exhibit *tert*-butyl methyl ^1H NMR resonances at a similar chemical shift (1.39–1.41 ppm).[8] Despite differences in the chemical environments of the sulfur alkyl substituents, and the differing Hg–S distances observed in the solid-state structure of **2**, a single sharp set of ^1H NMR resonances is observed for the S-CH_3 and -SCH_2CH_3 protons in CD_3CN solutions of **1** and **2** at ambient temperature. In this regard, we have previously noted a similar spectral appearance for the sulfur methyl protons in [(bmppa)Zn]$(ClO_4)_2$.[8] In this complex, the thioether appendages undergo a rapid inversion process at room temperature (in CD_3OD solution) wherein the two possible directions of -SCH_3 canting (clockwise or counterclockwise) are rapidly interconverted via an intramolecular exchange process (coalescence temperature ca. –65 °C).[23]

A large heteronuclear coupling is evident in the -SCH_3 resonance of **1** [see Figure S1(b) in the Supporting Information, Table 2]. The intensities of the satellites ($\approx$ 17%) in this resonance are consistent with the natural abundance of ^{199}Hg (I = 1/2, 16.85%). To the best of our knowledge, this is the first reported $^3J_{^{199}Hg^1H}$ coupling involving a Hg-$RSCH_3$ methyl group.[10] Coupling between ^{199}Hg and methionine methyl protons has been previously detected indirectly for Hg^{II}-substituted plastocyanin.[1] The only other reported $J_{^{199}Hg^1H}$ values for Hg^{II} thioether complexes range from 36 to 90 Hz and involve methylene protons.[24,25] In nitrogen-only ligated Hg^{II} coordination complexes, a coupling constant of a similar magnitude (Table 2) has been previously reported for the benzylic -CH_2- resonance in the $[Hg(TLA)]^{2+}$ cation {TLA = tris[(6-methylpyrid-2-yl)-methyl]amine}.[6] For the Cd^{II} analog [(bmppa)Cd(ClO_4)]-ClO_4, the $J_{^{111/113}Cd^1H}$ coupling constant in the Cd^{II}-$RSCH_3$ thioether methyl resonance is much smaller.[8,26]

Table 2. Heavy atom/proton coupling constants ($J_{^{199}Hg^1H}$ or $J_{^{111/113}Cd^1H}$) identified in the ^1H NMR spectra of **1**, **2**, and structurally related complexes.

Complex	*H*	*J* [Hz]	Ref.

[Hg(TLA)]$(ClO_4)_2$	benzylic -CH_2-	72	[6]
[(TMPA)Hg]$(ClO_4)_2$	benzylic -CH_2-	36	[3]
[(TMPA)HgCl]Cl	benzylic -CH_2-	45	[3]
[(bmppa)Cd(ClO_4)]ClO_4[b]	-SCH_3	15	[8]
	benzylic -CH_2-	9.6	

[a] Spectra recorded in dry CD_3CN at 25(1) °C on a Bruker ARX-400. [b] JEOL 270 MHz spectrometer.

For both **1** and **2**, benzylic -CH_2- resonances having ^{199}Hg coupling satellites are identifiable in the ^1H NMR spectra of the complexes [Table 2; Figures S1(a) and S4(a)]. These $^{3/4}J_{^{199}Hg^1H}$coupling constants are slightly smaller than those observed in the benzylic proton resonances of [(TMPA)Hg]$(ClO_4)_2$ {TMPA = tris[(2-pyridyl)methyl]-amine} and [(TMPA)HgCl]Cl, but are significantly larger than the $^{3/4}J_{^{111/113}Cd^1H}$ coupling constant found in benzylic -CH_2- resonance of [(bmppa)Cd(ClO_4)]ClO_4.[3,8]

The -SCH_3 resonance in the ^{13}C{^1H} NMR spectrum of **1** exhibits two-bond $^{199}Hg^{13}C$ coupling [Table 3, Figure S2(f)] as does the -SCH_2CH_3 methylene carbon resonance of **2** [Figure S5(e2)]. This methylene carbon resonance was assigned via {^{13}C,^1H}HMQC (Figure S7). For each complex the methylene linker carbons of the thioether arms exhibit $^{2/3}J_{^{199}Hg^{13}C}$ coupling [Figures S2(d) and (e); Figures S5(d) and (e1)]. Notably, the methylene C signal found at ca. 48.4–48.6 ppm in **1** and **2** exhibits a much larger $^{2/3}J_{^{199}Hg^{13}C}$coupling constant than that found for the other methylene linker C atom at about 32–35 ppm (Table 3). Conclusive identification of which of these resonances represents the carbon adjacent to the sulfur donor in the linker arms of each complex has not yet been accomplished.

Finally, ^{199}Hg heteronuclear coupling is found in two pyridyl ring carbon resonances in **1** and **2**. Specifically, an *ortho*-carbon resonance at δ = 153.7 ppm for each complex (Table 3) has a larger coupling constant than a *meta* ring carbon resonance at ~124 ppm. The assignment of these resonances as *ortho*- and *meta*-carbons was achieved via {^{13}C,^1H}HMQC experiments for both complexes.

As **1** and **2** exhibit generally similar solution NMR properties, we examined only **2** via ^{199}Hg NMR spectroscopy. For this complex, a single resonance is found at –1124 ppm, as referenced to an external standard of phenylmercuric acetate in DMSO (–1439.5 ppm). Whereas thiolate-ligated Hg^{II} centers tend to have ^{199}Hg NMR resonances in the region of –100 to –400 ppm, the ^{199}Hg chemical shift found

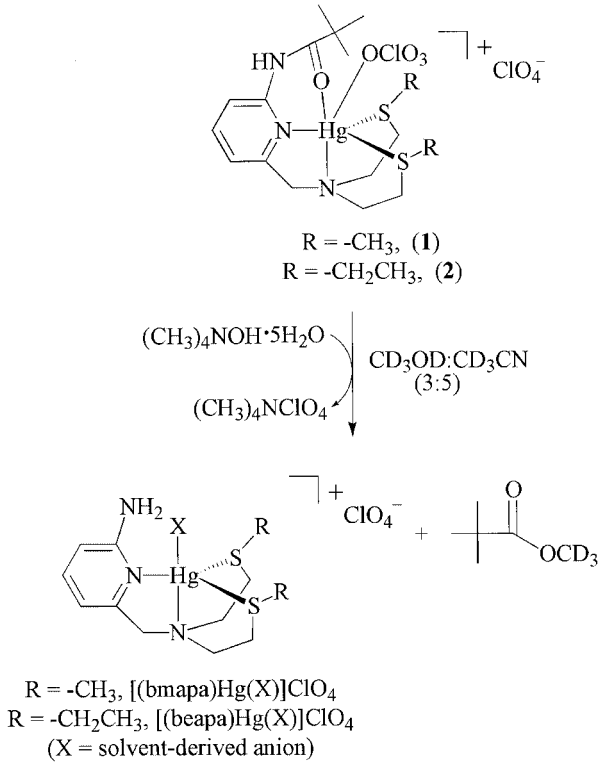
[a] Spectra recorded in dry CD_3CN at 25(1) °C on a Bruker ARX-400. [b] Methylene carbon resonances were not individually assigned.

for **2** is similar to that found for all nitrogen-ligated Hg^{II} complexes (–1200 to –1400 ppm).[1] A comparable result was recently identified for N_2S_2(thioether)-ligated Cd^{II} complexes.[27]

These combined infrared and NMR studies indicate that the nitrogen and sulfur donors of the bmppa and beppa chelate ligands, as well as the amide oxygen, are coordinated to the Hg^{II} centers of **1** and **2** in acetonitrile solution.



Scheme 2.

Amide Cleavage Reactivity

Reaction of **1** with an equimolar amount of $Me_4NOH{\cdot}5H_2O$ in CD_3OD/CD_3CN solution (3:5) at 55(1) °C results in amide alcoholysis of the *tert*-butyl amide moiety to quantitatively yield [D_3]methyl trimethylacetate and a Hg^{II} complex of a primary amine-appended chelate ligand (Scheme 2).

The ester product was identified by ^1H NMR [δ = 1.18 ppm (s, 9 H)] via spectral comparison to an authentic sample of methyl trimethylacetate (Aldrich).[8] One equivalent of Me_4NClO_4 is produced in the amide cleavage reaction of **1** and has been isolated from the reaction mixture in 81% yield as described for the similar amide methanolysis reaction of [(bmppa)Zn]$(ClO_4)_2$.[8] The Hg^{II} product of the amide cleavage reaction of **1** could not be isolated cleanly. This is probably due to the fact that the complex will have one solvent derived anion (OH^- or OCD_3^- or a mixture of both). However, the formation of bmapa-ligand Hg^{II} products is apparent from the ^1H NMR features of the final reaction mixture. Specifically, the signals associated with the *meta*-protons of the primary amine-appended pyridyl donor in the bmapa-ligated product resonate significantly upfield (6.63 and 6.85 ppm) of the same protons in **1**. This is consistent with the chemical transformation from an electron-withdrawing amide group to the electron-donating primary amine substituent on the pyridyl ring. A similar final reaction mixture is obtained following treatment of **2** with $Me_4NOH{\cdot}5H_2O$ in CD_3OD/CD_3CN solution (3:5) at 55(1) °C. Notably, exposure of the free bmppa or beppa ligand to $Me_4NOH{\cdot}5H_2O$ in CD_3OD/CD_3CN solution (3:5) at 55(1) °C does not result in signficant amide cleavage (< 1%) in the time required for complete amide cleavage in **1**, **2**, or the zinc and cadmium analogs that have been previously reported.[8] Further investigations are directed at elucidation of the mechanism of amide cleavage in these systems.

Conclusions

The synthesis and structural characterization of two new Hg^{II} complexes of N_2S_2(thioether)O(amide) donor chelate ligands has been accomplished. Comprehensive solution infrared and NMR studies of these complexes has revealed that strong N_2S_2 and amide oxygen coordination are maintained in CH_3CN solution. Using these complexes, heteronuclear coupling constants ($J_{^{199}Hg^1H}$and $J_{^{199}Hg^{13}C}$) for Hg^{II}–S(thioether) interactions have been determined. Particularly notable is the identification of a large $^3J_{^{199}Hg^1H}$ coupling constant (91 Hz) observed in the methyl proton resonance of a Hg^{II}-$RSCH_3$ interaction. Treatment of these amide-appended Hg^{II} derivatives with $Me_4NOH{\cdot}5H_2O$ in methanol/acetonitrile solution has provided the first examples of Hg^{II}-mediated amide cleavage.

Experimental Section

General Remarks: Reagents and solvents were purchased from commercial sources and were used as received unless otherwise noted. FTIR spectra were recorded on a Shimadzu FTIR-8400 spectrometer as KBr pellets or CH_3CN solutions between BaF_2

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

or KBr plates. ^{1}H, ^{13}C{^{1}H}, {^{1}H,^{1}H}COSY, and {^{13}C,^{1}H}HMQC NMR spectra were recorded in dry CD_3CN at 25(1) °C on a Bruker ARX-400 spectrometer. Chemical shifts (in ppm) are referenced to the residual solvent peaks in CD_3CN (^{1}H: 1.94 (quintet); ^{13}C{^{1}H}: 1.39 (heptet) ppm). ^{199}Hg NMR spectra were recorded at 71.6 MHz on a Varian Mercury VX NMR spectrometer with CH_3CN as the solvent, at concentrations of about 112 mM and about 30 mM. These spectra were referenced to an external standard of 0.5 M phenylmercuric acetate in DMSO (–1439.5 ppm). Fast atom bombardment (FAB) mass spectra were collected at the University of California, Riverside using a VG ZAB2SE high resolution mass spectrometer in a matrix of *m*-nitrobenzylalcohol (NBA). The chelate ligands bmppa and beppa were prepared as previously reported.[8,22]

Caution! Perchlorate salts of metal complexes with organic ligands are potentially explosive. These compounds should be handled in small amounts and should be treated with extreme caution, especially in the solid state.[28]

[(bmppa)Hg(ClO$_4$)]ClO$_4$ (1): Prepared in an identical manner to [(bmppa)Zn](ClO$_4$)$_2$.[8] Recrystallization of a white powder by diethyl ether diffusion into a *i*PrOH/CH_3OH, 1:1 solution yielded colorless blocks (94 mg, 73%). ^{1}H NMR [CD_3CN, 400 MHz, 25(1) °C]: δ = 1.39 (s, 9 H), 2.34 (t, $^3J_{^{199}Hg^1H}$ = 91 Hz, 6 H), 2.95–3.50 (m, 8 H), 4.01 (t, $^{3/4}J_{^{199}Hg^1H}$ = 27 Hz, 2 H), 7.36 (d, $^3J_{H,H}$ = 7.5 Hz, 1 H), 7.42 (d, $^3J_{H,H}$ = 8.1 Hz, 1 H), 8.04 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H), 9.04 (br. s, 1 H, N-*H*) ppm; ^{13}C{^{1}H} NMR [CD_3CN, 100 MHz, 25(1) °C]: δ = 18.0 (t, $^2J_{^{199}Hg^{13}C}$ = 36 Hz), 27.4, 34.2 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 14 Hz), 42.7, 48.4 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 75 Hz), 56.8 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 20 Hz), 118.6, 123.9 (t, $^3J_{^{199}Hg^{13}C}$ = 17 Hz), 143.6, 153.7 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 35 Hz), 154.6, 186.4 (12 signals expected and observed). [(beppa)Hg(ClO$_4$)]ClO$_4$ (2): Prepared in an identical manner to [(beppa)Zn](ClO$_4$)$_2$.[8] Recrystallization of a white powder by diethyl ether diffusion into a *i*PrOH/CH_3OH, 1:1 solution yielded colorless prisms suitable for X-ray diffraction analysis (81 mg, 63%). ^{1}H NMR [CD_3CN, 400 MHz, 25(1) °C]: δ = 1.33 (t, $^3J_{H,H}$ = 7.3 Hz, 6 H), 1.39 (s, 9 H), 2.50–2.90 (m, 4 H), 2.97–3.45 (m, 8 H), 4.02 (t, $^{3/4}J_{^{199}Hg^1H}$ = 26 Hz, 2 H), 7.37 (d, $^3J_{H,H}$ = 7.5 Hz, 1 H), 7.44 (d, $^3J_{H,H}$ = 8.2 Hz, 1 H), 8.04 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H), 9.09 (br., 1 H, N-*H*) ppm; ^{13}C{^{1}H} NMR [CD_3CN, 100 MHz, 25(1) °C]: δ = 14.1 (t, $^3J_{^{199}Hg^{13}C}$ = 46 Hz), 27.4, 30.2 (t, $^2J_{^{199}Hg^{13}C}$ = 32 Hz), 32.0 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 15 Hz), 42.7, 49.2 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 73 Hz), 56.9 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 19 Hz), 118.5, 124.0 (t, $^3J_{^{199}Hg^{13}C}$ = 16 Hz), 143.6, 153.7 (t, $^{2/3}J_{^{199}Hg^{13}C}$ = 33 Hz), 154.7, 186.5 ppm (13 signals expected and observed). ^{199}Hg NMR (CH_3CN, 71.6 MHz) –1124 ppm. FTIR (KBr, cm^{-1}): 3347 (br., ν_{N-H}), 1647 ($\nu_{C=O}$), 1616, 1580, 1533, 1098 (ν_{ClO4}), 625 (ν_{ClO4}); LRFAB-MS (CH_3CN/NBA), *m*/*z* (%): 684 [M – ClO$_4$]$^+$ (60%), 584 [M – 2ClO$_4$–CH_3CN+H]$^+$ (100%). $C_{19}H_{33}Cl_2HgN_3O_9S_2$ (783.10): calcd. C 29.12, H 4.25, N, 5.36; found: C 29.31, H 4.30, N 5.30.

^{1}H-NMR Analysis of Amide Cleavage Reactions of Amide-Appended Hg^{II} Complexes: To a solution of **1** (14.0 mg, 0.019 mmol) in CD_3CN/CD_3OD (500 μL:300 μL) solution was added $(CH_3)_4NOH{\cdot}5H_2O$ (3.4 mg, 0.019 mmol) and an internal standard ($CHPh_3$, 4.5 mg, 0.019 mmol). The resulting mixture was monitored by ^{1}H NMR at 55(1) °C at two-minute intervals for 50 minutes at which point the reaction had reached completion, as indicated by the formation of one equivalent of $(CH_3)_3C(O)OCD_3$. The formation of a bmapa-ligated {bmapa = *N,N*-bis(2-methylthio)-ethyl-*N*-[(6-amino-2-pyridyl)methyl]amine} Hg^{II} product is indicated by the appearance of two upfield-shifted pyridyl ring doublets at δ = 6.63 and 6.85 ppm, respectively {[(bmapa)HgX]ClO$_4$ (X = -OH or -OCD$_3$): ^{1}H NMR [CD_3CN, 270 MHz, 22(1) °C]: δ = 1.98 (s, 6 H), 2.82–3.25 (m, 8 H), 3.81 (s, 2 H), 6.63 (d, $^3J_{H,H}$ = 6.9 Hz, 1 H), 6.85 (d, $^3J_{H,H}$ = 8.6 Hz, 1 H), 7.50–7.55 (m, 1 H) ppm}. This result is very similar to that observed for the amide cleavage reaction of [(bmppa)Zn](ClO$_4$)$_2$, wherein the bmapa ligand has been removed and comprehensively characterized.[8] The reaction of **2** with $(CH_3)_4NOH{\cdot}5H_2O$ under identical conditions proceeds in a similar fashion to give a beapa-ligated {beapa = *N,N*-bis(2-ethylthio)ethyl-*N*-[(6-amino-2-pyridyl)methyl]amine[8]} Hg^{II} complex {[(beapa)HgX]ClO$_4$ (X = -OH or -OCD$_3$): ^{1}H NMR [CD_3CN, 400 MHz, 25(1) °C]: δ = 1.11 (t, $^3J_{H,H}$ = 7.4 Hz, 6 H), 2.32–2.40 (m, 4 H), 2.80–2.95 (m, 6 H), 3.15–3.22 (m, 2 H), 3.70 (t, $^3J_{^{199}Hg^1H}$ = 22 Hz, 2 H), 6.62 (d, $^3J_{H,H}$ = 6.8 Hz, 1 H), 6.84 (d, $^3J_{H,H}$ = 8.5 Hz, 1 H), 7.50–7.55 (m, 1 H) ppm} and $(CH_3)_3C(O)OCD_3$.

Identification and Quantification of [D$_3$]Methyl Trimethylacetate Produced in Amide Alcoholysis Reactions of 1 and 2: Methyl trimethylacetate formation was identified and quantified by ^{1}H NMR as described previously.[8]

Identification and Quantification of $(CH_3)_4NClO_4$ in a Hg^{II}-Mediated Amide Cleavage Reaction: To a solution of **2** (33.4 mg, 4.26×10^{-2} mmol) in methanol (or methanol/acetonitrile) solution (≈ 3 mL) was added $(CH_3)_4NOH{\cdot}5H_2O$ (7.7 mg, 4.25×10^{-2} mmol). The resulting mixture was stirred for ca. 1 minute during which time a white precipitate appeared. The solution was then carefully decanted from the white solid, which was subsequently dried (6.0 mg, 81%) and identified as $(CH_3)_4NClO_4$ by infrared spectroscopy.

X-ray Structure Determination of 2: A colorless prism shaped crystal of **2** was mounted on a glass fiber with traces of viscous oil and then transferred to a Nonius-KappaCCD diffractometer equipped with Mo-*Kα* radiation for data collection. Ten frames of data were collected at 200(1) K with an oscillation range of 1 deg/frame and an exposure time of 20 sec/frame. Indexing and unit cell refinement based on all observed reflections from those ten frames indicated a tetragonal *I* lattice. A total of 16249 reflections were indexed, integrated, and corrected for Lorentz, polarization, and absorption effects using DENZO-SMN and SCALEPACK.[29] The structure was solved by a combination of direct and heavy atom methods using SIR 97.[30] All of the non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms were assigned isotropic displacement coefficients *U*(H) = 1.2 *U*(C) or 1.5 *U*(Cmethyl), and their coordinates were allowed to ride on their respective carbons using SHELXL97.[31] Oxygen atoms of one perchlorate anion were found to exhibit disorder. These oxygen atoms were each split into two fragments [O(6)/O(6′), O(7)/O(7′), O(8)/O(8′), and O(9)/O(9′)] and refined. This refinement led to a 0.51:0.49 ratio in occupancy over two positions for each oxygen atom. Further details of the X-ray data collection and refinement of [(beppa)Hg(ClO$_4$)]ClO$_4$ (**2**) are given in Table 1. CCDC-249460 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also footnote on the first page of this article): Contains figures developed from the 1D and 2D NMR spectra of **1** and **2**.

Ab-initio Powder Structure Determination of Dichloro[1,2-ethanediylbis(iminomethylene)bis(phosphonato)]trizinc Dihydrate

Naima Bestaoui,[a] Ekaterina V. Bakhmutova-Albert,[a] Ana Vega Rodriguez,[b] Ricardo Llavona,[b] and Abraham Clearfield*[a]

Keywords: Metal phoshonates / Zinc

The reaction of zinc chloride with 1,2-ethanediylbis(iminomethylene)bis(phosphonic acid) in acidic conditions yielded dichloro[1,2-ethanediylbis(iminomethylene)bis(phosphonato)]trizinc dihydrate, $Zn_3Cl_2(HO_3PCH_2NHCH_2CH_2NHCH_2PO_3H)_2{\cdot}2H_2O$ which crystallizes in the monoclinic system and space group $P2_1/n$, with the unit cell parameters a = 9.94316(4), b = 10.44577(5), c = 24.3240(1) Å, β = 90.003(1)°, and Z = 4. The crystal structure was determined ab initio from its powder pattern using the programs EXPO and GSAS. The zinc atoms are in tetrahedral environment and form 16-membered rings with the phosphonate groups. The structure is clearly different from that of the corresponding Cd complex in that the Cd is sixfold coordinated and of different ligand to metal ratio.

Introduction

A major effort has been devoted in our laboratory towards the synthesis and characterization of metal phosphonates.[1] Notable studies in this area of research have also been carried out by Alberti et al.,[2] Bujoli and coworkers[3] and in Ferey's laboratory.[4] One general ligand type that we utilized is the α,ω-alkyldiphosphonic acid. These acids formed semi-crystalline products of the general formula $Zr[O_3P(CH_2)_nPO_3]$ with group 4 metals whose morphology and X-ray powder patterns indicate layered structures in which the layers are cross-linked by the alkyl groups.[5] Similar compounds were prepared using Zn and Cu as the metals.[6,7] These latter compounds were sufficiently crystalline that their structures could be determined from X-ray powder data. Indeed the copper structures confirmed the layered nature of the compounds and in these compounds the alkyl chains are perpendicular to the layers.

Interlayer spacings of the zirconium alkylene derivatives indicated that the chains are inclined at about 60° to the mean plane of the layers and that the layer structures differ from those of the transition metal compounds. Subsequently, zirconium diphosphonic acid derivatives in which the alkyl chains contained amino groups were prepared. Although the compounds were amorphous, they exhibited anion exchange and complexing behavior.[8]

Divalent metals often form crystalline phosphonates; it was of interest to prepare cross-linked layered derivatives containing the amino functionality. Determination of such structures would provide a model for understanding the ion exchange and complexation reactions via structural data. In this paper we report the structure of a chloro(ethylenediaminediphosphonato)zinc. The ligand employed was $H_2O_3PCH_2NHCH_2CH_2NHCH_2PO_3H_2$ (H_4L) which exists in solution as a di-zwitterion. In a previous paper[9] we described the synthesis and characterization of chloro(amino)-(phosphonato) cadmium which crystallizes in a monoclinic system and has a layered type structure, the layers being held together by hydrogen bonding. In the cadmium compound the Cd atoms form dimers through bridging chlorides. These dimers are in turn formed into rows by the phosphonate groups and the rows are crosslinked by the organic chain of the ligand into layers.

In this paper, we are presenting the interaction of the same ligand with zinc chloride in an acidic medium. This led to the formation of $Zn_3Cl_2(H_2L)_2{\cdot}2H_2O$, whose structure, quite different from the previous cadmium structure,[9] is presented here as characterized by its X-ray structure derived from powder data and FTIR.

Results and Discussion

Thermogravimetric Studies: The TGA diagram of $Zn_3Cl_2(H_2O)_2(H_2L)_2$, presented in Figure 1, shows three weight losses. The first step begins at 100 °C and indicates the release of two water molecules by 195 °C. The observed weight loss (4.15%) is in agreement with the calculated value (4.53%). The temperature of dehydration indicates that molecules of water are either coordinated with the zinc atom or strongly hydrogen-bonded. The next process is the

decomposition of the organic moieties and phosphonic groups accompanied by the formation of oxychloro derivatives, which begins at 350 °C. The process is completed at 758 °C with the formation of a final residue of 68.93%. The product can be formulated as a 1:1 mixture of $Zn(PO_3)_2$/$Zn_2P_2O_7$ (calcd. residue 66.40%). The total weight loss is 31.07% as compared to the calculated value of 33.43% based on the ideal formula.

Description of the Structure

The structure contains three crystallographic independent Zn atoms; they are all in a tetrahedral environment. Zn1 and Zn3 are both bonded to four oxygen atoms from the phosphonate groups. The Zn–O distances vary between 1.957(8) Å and 2.003(8) Å, and are in the order of a normal Zn–O bond. Zn2 is different as it is connected to two oxygen atoms from the phosphonate groups at distances of 1.967(9) and 2.020(9) Å and two chlorine atoms [2.254(8) Å and 2.379(8) Å].

The four phosphorus atoms are in tetrahedral environments consisting of three oxygen atoms and one carbon atom, divided into two distinct groups. In group P1 and P2, the three oxygen atoms bond to each of the three Zn atoms; in this case the order of the P–O bond is between 1.508(8) and 1.531(9) Å. In the P3 and P4 group, only two of their oxygen atoms each bond to Zn1 and Zn3. In this case the non-bonded oxygen atoms O8 and O11 are located at respective distances of 1.542(9) and 1.533(9) Å. These distances are slightly longer than the bonded P–O distance but similar considering the large e.s.d. values.

Zn1 and Zn3 are connected to each other through O–P–O bridging in both the *a*- and *b*-axis directions. Along the *a*-axis the bridging is by alternating P3 and P4 phosphonate groups and in the *b*-axis direction by P1 and P2 groups (Figure 2). This connectivity results in 16-membered rings (counting all the ring atoms). The Zn2 atoms lie in rows parallel to the *b*-axis sandwiched between the Zn1, Zn3 rows as seen in Figure 3. In the *c*-axis direction, the *z* parameter of the Zn2 atoms is very nearly 0,1/2 (Figure 3). This siting places them at intervals of every two rows of Zn1 and Zn3. The coordination of Zn2 is also tetrahedral but from both chloride ions and O4 from P1 and O6 from P2. The linkage in the *c*-axis direction is to form two sets of 16-membered rings, one involving Zn1 and Zn3 and the other with Zn3 and Zn2 alternating with Zn1, Zn2. The carbon−nitrogen chains criss-cross each other connecting P1 bonded to three Zn atoms to P4 bonded to Zn1 and Zn3 (Figure 4). Similarly, P2 bonds to three Zn atoms and P3 to two forming a three dimensional structure.

The localization of the hydrogen atoms allowed us to characterize the hydrogen bonding in the structure and led us to a better understanding of the structure. The structure show an extensive hydrogen bond network going from the chlorine atoms to the two water molecules, to the nitrogen atoms and to the non-metal-bonded oxygen atoms in phosphonate groups P3–O8 and P4–O11. There are four different nitrogen atoms. The C1–N1–C2 angle is 107.7(6)°

close to the tetrahedral angle of 109°; two hydrogen atoms are located on this nitrogen atom. This shows its tetrahedral symmetry and protonated nature. This atom is hydrogen-bonded to O8 (the free oxygen from P3) through H21. The distance N1···O8 is 2.81 Å on the order of a hydrogen bond length, the bond angle N1–H21···O8 is 130.9° and the distance H21···O8 is 2.04 Å. We could not find any hydrogen atom bonded to O8, therefore O8 is negatively charged. However O8 is also hydrogen-bonded to N2 again as the acceptor. In this case the distance is shorter (2.59 Å), and the interaction between N2 and O8 is much stronger. The angle C3–N2–C7 is 118.2(6)°, close to 120°. However, two hydrogen atoms were localized on this nitrogen atom; this shows the protonated nature of this nitrogen atom and the tetrahedral symmetry. This nitrogen is also hydrogen-bonded to one of the two water molecules (O9w) at a distance of 2.91 Å through H27 with an angle of 152.8°.

The third nitrogen atom is bonded to only one hydrogen atom, the C5–N3–C6 angle is 117.72(7)°; close to 120°. This atom is non-protonated. However it is hydrogen-bonded to O11 through H18. O11 (oxygen from phosphonate group P4), is also protonated (H24), however this proton does not participate into the hydrogen bonding network, O11 is acting as an acceptor in this case and is also hydrogen-bonded with N4 (donor), which is protonated. Two hydrogen atoms (H20 and H28) were localized on this atom and the angle C4–N4–C8 is 108.2(6)° very close to the tetrahedral angle. H28 points towards O10w with an angle of 125.7° and the distance N4···O10w is 2.84 Å. H20 points towards O11 with an angle of 110.8° and the distance N4···O11 is 3.09 Å.

The two water molecules are also hydrogen-bonded to the two chlorine atoms. These two molecules are then stabilized by their multiple hydrogen bonding, which explains why they are thermally removed between 100 °C and 200 °C (thermogravimetric analyses, Figure 1). This loss of water is accompanied by structure collapse.

The distribution of protons from the phosphonate groups to three of the four nitrogen atoms (N1, N2, N4) requires that the two phosphonic acids have different negative charges. The P1, P4 ligand has both nitrogen atoms

protonated as well as O11; therefore it has a charge of minus one. The P2, P3 ligand has only N4 protonated and a charge of minus three.

Spectroscopic Studies

FTIR: The crystal structure of H_4L[13] shows both nitrogen atoms to be protonated. The IR spectrum of this zwitterion is shown in Figure 5a, together with that of the zinc compound. The range of PO vibrations in the IR spectrum of H_4L supports the betaine structure. The spectrum exhibits three strong bands at 1156, 1029 and 939 cm^{-1}, assigned respectively to $\nu_{as}(PO_2)$, $\nu_s(PO_2)$and ν(POH), indicating clearly the presence of PO_3H groups. [10] Furthermore, all the PO bands are low-frequency shifted due to the strong intra- and intermolecular hydrogen bonds with lattice water molecules and NH_2^+ groups. The NH_2^+ bands are expected to give two bands between 3000 and 2700 cm^{-1}, which are usually broad, unresolved and extended to 2273 cm^{-1}. Indeed, the IR spectrum of H_4L shows a broad and shallow band at 2800–2400 cm^{-1} revealing the presence of the protonated NH groups.

The IR spectrum of zinc phosphonate is complicated (see b in Figure 5). Phosphonic groups are coordinated with metal and the ν(P–OH) band observed in H_4L disappears upon coordination. The other vibrations associated with the POH group [ν(PO–H), 2δ(POH)] can still be detected with a decrease of their intensity. Two new sharp bands at 1130 and 1107 cm^{-1} can principally be assigned to both $\nu(PO_2)$ and $\nu(PO_3)$ vibrations. The zwitterionic structure of the compound could also be observed, in the region 3400–2500 cm^{-1} of the spectrum. In fact the NH stretching vibrations band is high-frequency shifted with much higher $\Delta\nu$ (91 cm^{-1}) value than the CdL_2H_2O[9] compound. At the same time, the $\nu(NH_2^+)$ band belonging to acid H_4L is still present in the spectrum. Only a slight decrease in the intensity of this band was observed. The NH_2^+ bending band does not appear in the spectrum. This spectrum can be interpreted in terms of partial protonation of nitrogen atoms and presence of both POH and PO groups, which is in accordance with the structure data.

Conclusions

It is interesting to note that while both the zinc and the cadmium complexes with the ligand H_4L were prepared in a very similar fashion, the stoichiometry and hence the structures are completely different. The Cd complex is octahedrally coordinated[9] by two Cl, two phosphonate oxygen atoms and two water molecules. The chloride ions bridge across two cadmiums while the phosphonate groups connect these dimers into double-stranded chains. In the process the double-stranded chains are crosslinked into layers that are hydrogen-bonded to each other. Both IR and NMR showed that the nitrogen atoms are protonated. In the zinc structure the differences are striking. The Zn atoms are four coordinate in which the chloride ions reside on a single zinc atom and do not bridge across metal atoms. The distribution of the ligand protons is also different, three of the nitrogen atoms are protonated but N3 is not and water molecules are not bonded to zinc. Therefore a moreaccurate formula is $Zn_3Cl_2(O_3PCH_2NH_2^+CH_2CH_2\text{-}NH_2^+CH_2PO_3)(HO_3PCH_2NHCH_2CH_2NH_2^+CH_2PO_3)\cdot 2H_2O$. These studies show that the H_4L ligand can adjust its coordination and behavior in several different as not yet totally explored ways.

Experimental Section

Materials and Methods: All chemicals were obtained from commercial sources and used without further purification. The ethylenediamine-*N,N'*-bis(methylenephosphonic acid) (H_4L) was synthesized as described previously.[9]

Synthesis of $Zn_3Cl_2(H_2L)_2\cdot 2H_2O$: A solution of zinc chloride (EM Science, 10.6 mmol, 15 mL) in water was added to a suspension of H_4L (5.3 mmol, 15 mL) with brisk stirring. The pH was adjusted to 2 with hydrochloric acid (5 M) and the mixture was transferred to a Teflon-lined pressure vessel and kept at 150 °C for 5 days. The lower pH aided the formation of the crystalline powder. The

gravimetric analysis was carried out with a DuPont TGA 951 instrument at a heating rate of 10 °C/min under compressed air. The obtained compounds were characterized by their X-ray powder data collected with either a Rigaku 5000 computer-automated diffractometer with rotating anode or a Bruker advance diffractometer by the step scan method with Cu-K_α radiation (λ = 1.5418 Å).

Analytical Results: Zinc and phosphorus analysis was carried out in-house with a Direct Current Plasma (DCP) spectrometer. A weighed portion of the sample was dissolved in 1 mL of 48% HF and then diluted to 200 mL. Aliquots were then removed and diluted to a composition falling well within the standard curves for Zn and P, respectively. Alternatively these elements were also determined using a Cameca 5 × 50 electron microprobe at an accelerating voltage of 15 kV and operating with a beam current of 20 mA using a wavelength-dispersive spectrometer (WDS). C,H,N analyses were performed by Galbraith laboratories.

In-house X-ray Diffraction

Parameters Determination (high-resolution data): An X-ray powder diffraction pattern was recorded using a Bruker D8 advance, high resolution X-ray diffractometer with Bragg–Brentano θ−2θ geometry (40 kV and 50 mA), using a Ge monochromator with Cu-$K_{\alpha 1}$ radiation (λ = 1.54056 Å). The data were recorded between 5 and 95° in 2θ, with a step size of 0.01° and a count time of 30 s per step. The sample was packed in a flat plastic holder, and was allowed to rotate at 15.00 RPM during the data collection.

Structure Solving and Refinement (intensity data): X-ray powder diffraction patterns were recorded using a Bruker D8 diffractometer with Bragg–Brentano θ–2θ geometry (40 kV and 50 mA), using a graphite monochromator. The data were recorded between 5 and 60° in 2θ, with a step size of 0.01° and a count time of 20 s per step, and 50 to 100° in 2θ, with a step size of 0.01° and a count time of 25 s per step. The sample was packed in a flat plastic holder.

Synchrotron Powder X-ray Diffraction: Powder X-ray diffraction data were collected at ambient temperature on beamline X3B1 of the National Synchrotron Light Source at Brookhaven National Laboratory. X-rays of wavelength 0.70045(1) Å was selected by a double crystal Si(111) monochromator. The sample was sealed in a capillary, which was continuously rotated during data collection. The data collection time increased from 1 s per point at 2 degrees 2θ to 5.7 s at 46.997°, with a step size of 0.003°. The diffracted X-rays are selected by a Ge (111) analyzer crystal on a detector arm, and detected using a commercial NaI scintillation counter; the measured X-ray counts are normalized to the signal from an ionization chamber between the monochromator and the sample in order to correct for decay and fluctuations of the incident beam intensity.

Structure Determination: A first determination of cell parameters was made using Treor90 program[11] on the in-house data. The indexing yielded the cell dimensions: a = 9.942(1), b = 10.445(1), c = 23.317(4) Å, β = 90.001(1)° and V = 2526.46(2) Å^3 as the best solution [M (20) = 51]. The β angle is very close to 90°, the cell parameters are then reflective of an orthorhombic symmetry. The analyses of the systematic absences are consistent with the space group $Pna2_1$. However, we were not able to solve the structure in this space group or in any orthorhombic space group which could reproduce the powder pattern. We considered then a small distortion of the β angle to reflect a monoclinic distortion. The analyses of the systematic absences were consistent with the space group $P2_1/n$. The first attempt to solve this structure in the in-house data, using EXPO,[12] allowed us to localize a few of the atoms. Respectively, three zinc atoms, three of the four phosphorus atoms, and the two chlorine atoms. The calculation of successive Fourier difference maps followed by Rietveld refinement (using the program GSAS[13]) allowed us to locate most of the oxygen atoms and one ligand, but we were not able to go further. For this reason, we recorded a synchrotron data set, which allowed us to localize most of the atoms by direct methods and the rest of them by Fourier difference maps.

The refinement strategy consisted in a first step of a Lebail method refinement for the background (using 12 terms of a Chebychev function), zero shift, cell parameters and peak profile function, considering a dummy hydrogen atom and maintaining a scale factor constant and equal to 1. Once these parameters were satisfactory (Rp = 0.07), they were fixed, the known atoms were entered into the program and the scale factor refined. By successive refinement and Fourier difference maps, all the atoms were located. The following bond constraints were applied: Zn–O (2.0 Å), Zn–Cl (2.6 Å), P–O (1.52Å), P–C (1.80 Å), C–N (1.34 Å), C–C (1.54 Å) and C–H (1 Å) prior to position refinement of the atoms. The bond angles around the phosphorus atom were constrained to idealized tetrahedral angles by applying constraints to the non-bonded O···O (2.5 Å) and O···C (2.7 Å) distances, and tetrahedral angles around the carbon atom. The position for the hydrogen atoms were calculated for the carbon atoms and a final Fourier difference allowed us to localize the remaining hydrogen atoms. The carbon hydrogen atom position were refined but not the nitrogen hydrogen atoms or the water hydrogen. The constraint parameter was first fixed to 500 and then lowered to 100 in the last cycle of the refinement. The atomic positions were refined first, then the temperature factors, and finally all the parameters were refined simultaneously. The last set of refinement yielded a value of R_p = 0.0567, R_{wp} = 0.0733 and R_F = 0.0424.

Figure 6 shows the observed powder pattern, the calculated and the difference curve after the last refinement, from the synchrotron

Catalytic Properties of a Mn^{III}-Salen Complex Immobilised in a Pillared Clay by Simultaneous Pillaring/Encapsulation Procedures

Beatriz Cardoso,[a] João Pires,*[a] Ana P. Carvalho,[a] Manuela B. Carvalho,[a] Iwona Kuźniarska-Biernacka,[b,c] Ana R. Silva,[b] Cristina Freire,*[b] and Baltazar de Castro[b]

Keywords: Clays / Microporous materials / Heterogeneous catalysis / Manganese

The simultaneous encapsulation of a manganese(III)-salen complex, [Mn(salhd)Cl], and pillaring of a montmorillonite clay with aluminium polyoxycations was performed using two methods: method A – the [Mn(salhd)Cl] complex was dissolved in ethanol and added to the oligomer solution at a stage when the oligomeric species had already formed; method B – the complex, also dissolved in ethanol, was added to the clay dispersion. After calcination, both materials were Soxhlet extracted to remove the excess complex, and characterised by XRD, nitrogen adsorption at –196 °C, XPS, atomic absorption and FTIR spectroscopy. In both cases, the manganese(III)-salen complex is mainly physically entrapped within the matrix, although some host–guest interactions with the matrix may be present. Both new materials [Mn(salhd)Cl]@Al-WYO_A and [Mn(salhd)Cl]@Al-WYO_B show catalytic activity in the epoxidation of styrene at room temperature with PhIO as oxygen source in acetonitrile. The solids present high styrene epoxide selectivity, and may be reused at least four times. FTIR spectra of the catalysts after the catalytic reactions suggest that during the reaction no structural changes of the pillared clay (PILC) took place, but low extent complex leaching occurred.

Introduction

Pillared clays (PILCs) are a relatively well-known class of materials, whose preparation methods and catalytic properties were reviewed by different authors.[1–3] Since PILCs were initially developed because of their potential as solids with larger pores than traditional zeolites, namely those used in cracking catalysis, a large number of studies were directed to the study of catalytic reactions that use the acid–base properties of PILCs. In general, this type of reaction occurs under thermal and hydrothermal conditions that partially damage the structure of the pillared clay. These aspects are closely related to the relative unsuccessful use of PILCs as catalysts.

More recently, the use of PILCs as catalyst supports for reactions that occur at mild conditions was considered, particularly those involving transition–metal complexes as homogeneous catalysts.[4–6] The heterogenisation of metal complexes with catalytic activity, within inorganic matrices, is a field that has progressed in recent years[7–13] due to the combination of high chemical selectivity and stability, with relatively easier separation of the catalyst from the reaction media. A relevant reaction in organic chemistry that can be catalysed by transition–metal complexes is the alkene epoxidation reaction − the epoxides formed can be transformed into several different products, sometimes under regio- and stereoselective conditions − which is the most recurrent method for direct transfer of oxygen to the alkene; [14,15] manganese(III) complexes with N_2O_2 Schiff base ligands (usually denoted as salen ligands) efficiently catalyse the epoxidation of unfunctionalised alkenes.[16]

When the synthesis of pillared clays is compared, for instance, with the synthesis of large pore zeolites, the former occurs under much milder conditions of temperature and pH than the latter and thus, the integrity of the metal complexes is expected to be preserved under the conditions of PILCs synthesis. This presents the possibility to encapsulate transition metal complexes simultaneously with the pillaring process, a fact that was already shown by us in a previous study using Cu^{II} acetylacetonate based complexes.[4] In this work, we have studied the simultaneous encapsulation of a manganese(III)-salen complex, [Mn(salhd)Cl], (Scheme 1) and the pillaring of a montmorillonite clay with aluminium polyoxycations. The resulting materials were characterised by several techniques, and the catalytic activity assessed in the epoxidation of styrene. To our best knowledge, this is the first work in which the catalytic activity of a complex encapsulated simultaneously with the pillaring process of a clay was studied.

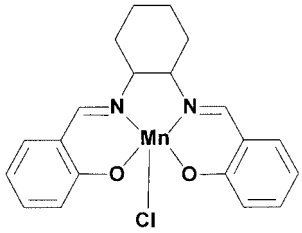

Scheme 1.

Results and Discussion

Material Characterisation

After pillaring (for Al-WYO) or after the pillaring/encapsulation procedure (methods A and B), the solids were calcined at 200 °C; this temperature is lower than that normally used when the main objective is to produce solids with thermally stable pillars (T = 350–500 °C). In this study, the calcination temperature was limited by the decomposition temperature of the complexes, which was verified to be above 200 °C. As a consequence, the stability of the pillared materials obtained at this calcination temperature was assessed by X-ray diffraction before and after the Soxhlet extraction step, since it was not clear if such a treatment could induce some changes in the pillars.

In Figure 1 the X-ray diffractograms of the nonencapsulated sample (Al-WYO) and the samples prepared by methods A and B, before and after Soxhlet extraction, are presented; Table 1 summarises the corresponding d_{001} values. Analysis of the diffractograms clearly shows that all the materials are pillared, and this can be confirmed by the increase in the d_{001} value on going from the parent nonpillared clay (d_{001} = 1.27 nm)[17] to the pillared materials (1.78 $< d_{001} <$ 1.92 nm). Furthermore, from Table 1, it can be seen that: (i) the d_{001} value of Al-WYO is slightly higher than those of the PILCs with encapsulated complexes and, (ii) the d_{001} values of materials subjected to solvent extraction are lower than those of nonextracted materials. The first observation is in contrast with what has been observed in our previous study[4] on the simultaneous pillaring/encapsulation of copper(II) acetylacetonate based complexes, where the larger pentacoordinate complexes have induced an increase in the interlayer distances (acting as templates to the PILC porous structure); the second observation results from some complex exclusion by the purification process. The diffractograms also show, although not in a very pronounced way, that Al-WYO presents a narrower diffraction peak than the samples with metal complexes, which suggest that in the former material the clay particles are better organised.

The isotherms of nitrogen adsorbed at –196 °C in the different samples are presented in Figure 2, and the corresponding values of equivalent surface areas (A_{BET}) and micropore volumes (from t-method[18]) are given in Table 1. The curves show characteristics of isotherm types I and IV, according to the IUPAC classification:[19] they have a steep initial part, typical of microporous solids, but they also present hysteresis. As expected, the A_{BET} and micropore volumes (V_μ) of the PILCs with complexes are lower than those found for Al-WYO. Moreover, the solids submitted to solvent extraction show the lowest A_{BET} and V_μ values of the series. This result is unexpected, although a similar situation was detected in a previous work.[4] In fact, since the Soxhlet extraction is used to remove the complexes that are physically adsorbed at the external surface, it would be expected that the overall surface area would increase. These results lead us to conclude that during Soxhlet extraction some diffusion of the complexes within the cavities of the pillared clay may occur towards the outer surface (probably as a consequence of concentration gradient), leading to a more obstructed structure.

As mentioned above, the presence of the metal complex within the PILC does not impart major differences in the gallery heights (estimated through XRD data) when Al-WYO is used as a reference. In contrast, the distances between the pillars are very difficult to assess, and in order to obtain additional information on the characterisation of the porosity of the materials, a DFT approach [20,21] was applied to the data from the low-temperature nitrogen adsorp-

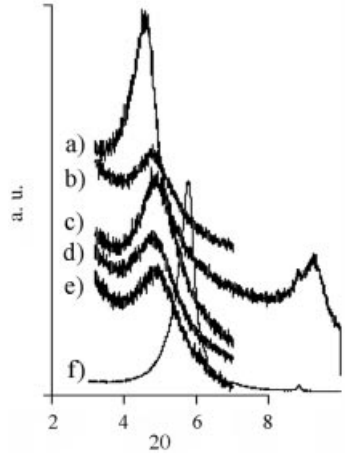

Figure 1. X-ray diffractograms for the Al-WYO sample, a), and for the solids with the [Mn(salhd)Cl] complex encapsulated by method A (b and c) and by method B (d and e). The diffractograms b) and d) refer to samples not subjected to solvent extraction. The curve f) stands for the starting clay.

Table 1. Basal spacing (d_{001}), equivalent surface areas (A_{BET}) and micropore volumes (V_μ) by the t-method, from low-temperature nitrogen adsorption. Mn content obtained by atomic absorption spectroscopy (AA) and X-ray photoelectron spectroscopy (XPS).

	d_{001} [nm]	A_{BET} [m²/g]	V_μ [cm³/g]	Mn content [μmol/g]

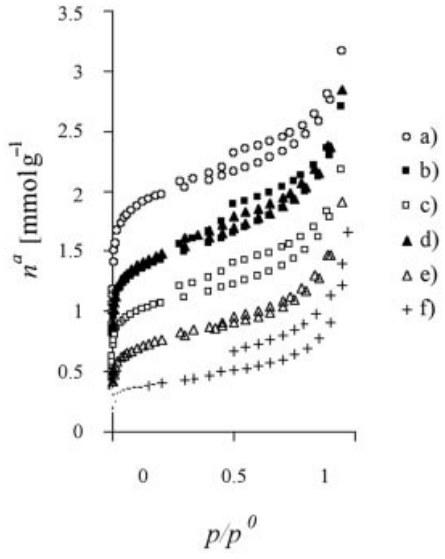

Figure 2. Nitrogen adsorption isotherms at –196 °C for the Al-WYO sample, a), and for the solids with the [Mn(salhd)Cl] complex encapsulated by method A (b and c) and by method B (d and e). The isotherms b) and d) refer to samples not subjected to solvent extraction and the curve f) to the starting clay.

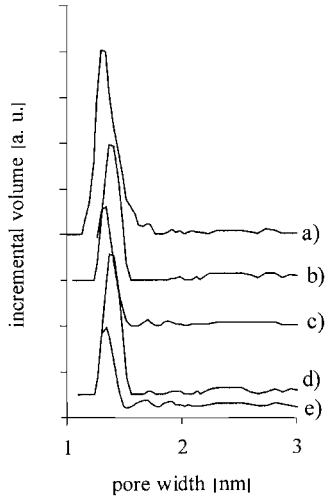

Figure 3. Pore size distributions obtained by DFT for the Al-WYO sample, a), and for the solids with the [Mn(salhd)Cl] complex encapsulated by method A (b and c) and by method B (d and e). The curves b) and d) refer to samples not subjected to solvent extraction.

tion experiments; the results of the pore size distributions obtained in this manner are given in Figure 3. The curves in the micropore region (pore widths <2 nm[19]) cannot be entirely superimposed, and some differences, albeit very small, are expected in the matrix microporosity: the values of the pore widths corresponding to the maximum of the distributions are quite similar for Al-WYO and materials with encapsulated complexes after Soxhlet extraction (1.35 nm), but the distributions obtained for the nonextracted materials are, in fact, slightly shifted to high values. This result has some parallelism with XRD data, and indicates that Soxhlet extraction (removal of adsorbed metal complexes) is essential to the final stabilisation of PILC porosity. We will not pursue the precise significance of the pore widths obtained, since the DFT approach was still not yet widely applied to PILCs; nevertheless, we believe that the results in Figure 3 suggest that the micropore size distribution of materials are, essentially, quite similar, thus confirming that the pillaring process was not significantly perturbed by the presence of the [Mn(salhd)Cl] complex.

Low-resolution XPS spectra of Al-WYO and [Mn(salhd)Cl]@WYO (methods A and B) show the presence of oxygen, silicon, aluminium and magnesium from the aluminium pillared clay lattice at similar values to those published on aluminium pillared clays based on natural Portuguese smectites.[4] The latter materials also show the typical broad Mn $2p_{3/2}$ bands with maxima at about 642 eV, in agreement with the values reported for manganese(III) complexes with salen[22] and porphyrinic[23] ligands. The most relevant surface contents (Al, Si and Mn) are summarised in Table 2. As can be verified, the Al/Si ratio decreases on going from Al-WYO to those materials with metal complexes: the decrease is slightly larger for the material prepared by method B (19%) than that prepared by method A (9%).

Table 2. XPS results for Al-WYO and metal-complex-based PILCs.

	Atomic-%				
Sample	Al	Si	Mn	Al/Si	Mn/Si
Al-WYO	18.84	15.86		1.19	
[Mn(salhd)Cl]@Al-WYO_A	15.95	14.76	0.13	1.08	0.009
[Mn(salhd)Cl]@Al-WYO_B	15.11	15.81	0.11	0.96	0.007

The bulk Mn content of the samples (obtained by AA, Table 1) indicates that almost 25% of the complex initially added was effectively immobilised in the solid matrix; we emphasise the similarity of the values obtained by both methods (A and B). The surface manganese contents obtained by XPS (Table 2) are similar to those obtained by AA, although slightly lower, suggesting that the complex was encapsulated almost homogeneously, throughout the clay during both simultaneous pillaring/encapsulation methods A and B.

It is worth mentioning that simultaneous pillaring/encapsulation methods (A and B) lead to lower Mn loadings than the in situ synthesis of the metal complex within the aluminium pillared clay.[5] This result may be a consequence of the lower pillaring efficiency of the former methods when compared to the latter as both materials present lower surface aluminium contents than Al-WYO (Table 2). However, this result is in contrast with those obtained for the simultaneous aluminium oxide pillaring and encapsulation of copper(II) Schiff base complexes in a Portuguese montmorillonite, in which encapsulation of these complexes induced not only an increase in the surface aluminium content but also higher PILC basal distances than the corresponding aluminium pillared clay prepared without the presence of complex.[4]

FTIR and UV/Vis Spectroscopy

The FTIR spectra of Al-WYO, the free complex and those of the samples obtained by simultaneous pillaring/encapsulation are shown in Figure 4.Similar to [Mn(salhd)CH_3COO]@Al-WYO prepared by an in situ method[5] and to the aluminium pillared clays based on natural Portuguese smectites (Al-BEN) reported by us,[4] the spectrum of Al-WYO shows intense and large bands due to the clay structure: in the region 3700–3300 cm^{-1} (not shown), which are assigned to the surface hydroxyl groups from the acidic Al–OH group,[24–26] at 1626 cm^{-1} and in the range 1300–400 cm^{-1}, assigned to lattice vibrations[5,23] (asymmetric stretching vibrations of SiO_2 tetrahedra).[25] In addition to these strong bands caused by the parent material, the spectra for [Mn(salhd)Cl]@WYO_A and [Mn(salhd)Cl]-@WYO_B also show bands in the 1600–1200 cm^{-1} region, where the Al-WYO matrix does not absorb (Figure 4), and they may be attributed to the presence of the manganese(III)-salen complex. For clarity, only bands for the samples submitted to solvent extraction (which correspond to materials that have been used in the catalytic experiments described below) are seen in the region 1200–1700 cm^{-1}. Due to the low concentration of metal complex inside the PILC, the bands for the encapsulated complex are difficult to detect, but they can be seen in the range 1400–1500 cm^{-1}. These bands are broader and their frequencies are slightly different from those of the free complex, suggesting that the manganese(III)-salen complex might be distorted as a consequence of the physical constraints imposed by the matrix and/or due to host–guest interactions with the PILC framework within the pores, as observed for copper(II) complexes entrapped in aluminium pillared clays.[4]

The diffuse reflectance UV/Vis spectra of [Mn(salhd)Cl]-@WYO obtained by method A and B (not shown) are very similar to the spectra for the parent Al-WYO in the visible range, where the d-d bands due to the complexes are expected to be seen; however, for $\lambda < 350$ nm, new high-intensity bands are observed that can unambiguously be assigned to the metal complex CT bands. The lack of the d-d bands can be due to two combined factors: (i) the small extinction coefficients associated with these electronic transitions in the manganese(III) complex, and (ii) the dilution effect of the manganese(III)-salen complex within the aluminium pillared clay. Thus, no geometrical information about the entrapped manganese(III)-salen complex can be obtained by its electronic spectra.

Catalytic Experiments

The results of the epoxidation of styrene, at room temperature with the use of the manganese(III)-salen heterogeneous catalysts and PhIO as oxygen source in acetonitrile, are summarised in Table 3 and Figure 5; data from homogeneous-phase and blank experiments run under comparable conditions are also included. These results clearly show that these new catalysts are active in the epoxidation reaction and can be reused for up to four cycles, without significant decrease in the catalytic activity.

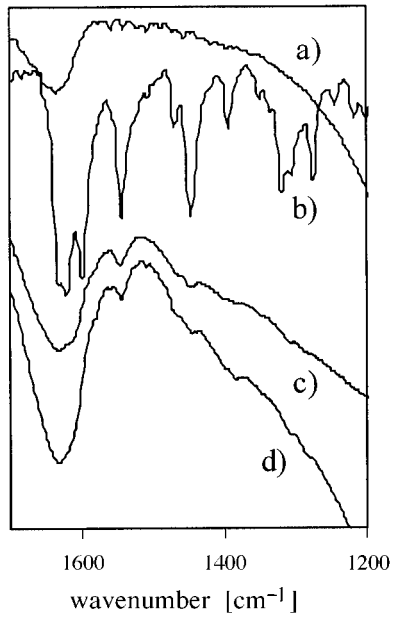

Figure 4. FTIR spectra in the range 1200–1700 cm^{-1} for: a) the Al-WYO pillared clay; b) [Mn(salhd)Cl]; c) and d) are for [Mn(salhd)Cl] encapsulated by methods A and B, respectively.

Both heterogeneous catalysts show high chemoselectivities towards styrene epoxide, which increases slightly with the number of cycles. Nevertheless, these values are lower than that obtained in an experiment run in a homogeneous phase under comparable experimental conditions (Table 3); this may be attributed to some low-extent epoxide-ring opening, owing to support surface acidity and to the higher benzaldehyde selectivity; this occurs by a different catalytic pathway involving the PILC matrix.

The [Mn(salhd)Cl]@Al-WYO_A catalyst shows a styrene conversion quite similar to that of its homogeneous counterpart, whereas for [Mn(salhd)Cl]@Al-WYO_B, styrene conversion is approximately 24% lower. The styrene conversion decreases by 35% and 23% for catalysts prepared by the method A and B, respectively, during further cycles; at the end of the fourth cycle both catalysts show almost the same value. The same trend is observed for the styrene epoxide yield.

Low catalytic activity in the epoxidation of styrene was observed in the filtrate after catalyst removal, indicating that the reaction was not fully catalysed heterogeneously, and that low-extent leaching of the active phase to solution took place; this effect is more perceptible for catalysts obtained by method B. FTIR spectra for both heterogeneous catalysts measured before catalytic reaction and after the fourth cycle show some band intensity decrease in the 1620–1200 cm^{-1} region, which corresponds to the frequency range in which vibration bands for the complex occur; conversely, the bands typical of the Al-WYO matrix do not

show significant changes after the catalytic reaction. These observations suggest that no structural changes of the Al-WYO matrix took place during the consecutive catalytic cycles, but some metal-complex leaching must occur in the catalytic experimental conditions. Thus, the styrene epoxide yield decrease with reuse of the heterogeneous catalysts reported herein, might be correlated with some active phase leaching.

In a previous study,[5] we encapsulated, with the use of the in situ method, the same complex within a previously prepared Al-WYO. This catalyst led to comparable styrene conversions, styrene epoxide selectivity and styrene epoxide yields to those with the catalysts described in this work, under the same experimental conditions; however, no metal-complex leaching was detected. The different behaviour exhibited by the materials in which the complexes were immobilised by different procedures can be explained by considering that the pillars are less rigid (these materials are calcined at 200 °C) in the catalysts prepared by using the simultaneous pillaring/encapsulation process, and thus, a higher degree of swelling will occur during catalytic reaction; this will cause the physically entrapped metal complex to leach more easily. In contrast, the material in which the complex was immobilised by in situ synthesis starts from the pre-prepared aluminium pillared clay (calcined at 350 °C), where the higher temperature of calcination confers higher rigidity to the pillars (very low swelling) preventing metal-complex leaching during the catalytic reaction.

Garcia et al. encapsulated the same chiral manganese(III)-salen complex within the zeolite Y, and observed lower styrene epoxide selectivity (61%) than for the homogeneous counterpart (80%), with NaOCl in dichloromethane at 5 °C. This complex encapsulated within Al-WYO, reported herein, gives rise to higher styrene epoxide selectivity (71%) than within the zeolite Y, notwithstanding the different experimental condition used.[27]

It is noteworthy that when the heterogeneous catalysts were used, the reaction time increased and styrene conversion decreased relative to when homogeneous counterparts were used. The first is a general effect that arises upon immobilisation of metal-complex catalyst in porous matrices and has been attributed to diffusion constraints imposed on substrates and reactants by the porous network of the matrix. The diffusion of the reactants to the metal centre can be particularly hindered for PhIO, a solid with low solubility in acetonitrile, and that solubilisation is controlled by its rate of consumption.[28] The latter effect, lower styrene conversion, must be due to consumption of PhIO in competing reactions involving the matrix.[29]

Conclusions

New heterogeneous catalysts have been prepared by two different methods based on the simultaneous encapsulation of [Mn(salhd)Cl] and the pillaring process. In both cases, the manganese(III)-salen complex is mainly physically entrapped within the matrix, although some host–guest interactions between the complex and PILC can not be ruled out.

The new materials [Mn(salhd)Cl]@Al-WYO_A and [Mn(salhd)Cl]@Al-WYO_B have been tested in the catalytic epoxidation of styrene at room temperature with PhIO as oxygen source in acetonitrile. The heterogeneous catalysts showed similar styrene conversion to their homogeneous counterparts, high styrene epoxide selectivity and can be reused for at least four times, with a small decrease in their catalytic activity. FTIR spectra of the catalysts after the consecutive catalytic reactions suggest that no structural changes of the PILC occur, but some metal-complex leaching must take place, which is responsible for the small decrease in styrene conversion and styrene epoxide yield in further cycles.

Comparison with results from the literature, obtained with other matrices such as zeolites or MCM type materials, [10–13] is not straightforward. However, we believe that the methodology described in this work can be of interest for the immobilization of large complexes. Moreover, this is a cheap methodology, since by using natural clays as the main host there is no need for expensive silica sources or organic templates. In this way, the results obtained in this work show that the simultaneous encapsulation/pillaring procedure is a useful alternative method for the encapsulation of metal complexes within PILCs, since it produces materials that are stable within the oxidative catalytic media, although some solvent swelling is seen, which is typical of nonpillared clays. To overcome complex leaching induced by the swelling of the material during catalytic reaction, metal complexes must be anchored to the PILC matrix. Research work on complex anchoring to the PILC matrix is in progress and will be published elsewhere.

Experimental Section

Synthesis of the [Mn(salhd)Cl] Complex

The Schiff base ligand *N,N′-bis*(salicylaldehyde)cyclohexanediamine (H_2salhd) and the corresponding complex chloro-[*N,N′-bis*(salicylaldehyde)cyclohexanediaminate] manganese(III) ([Mn(salhd)Cl]) were synthesised and characterised as reported elsewhere.[5]

Preparation of the Pillared/Encapsulated Materials

A clay from Wyoming (USA) was used as the starting material. This solid presented a cation exchange capacity of 115 meq/100 g and a structural formula of $(Si_{3.91}Al_{0.09})^{IV}(Al_{1.51}Fe_{0.18}Mg_{0.26})^{VI}(Ca_{/2}, K, Na)_{0.49}$ as described elsewhere.[17,30] The pillaring process was performed using a procedure that was optimised in previous works;[17,30] two solutions were prepared: *solution 1* (which, in fact, is a dispersion) made from clay (1 g) in water (100 mL); and *solution 2*, the oligomer solution. The latter was prepared from aqueous solutions of $AlCl_3$ and NaOH, with an OH/Al ratio of 2, aged for 2 h at 60 °C, after which the pH was increased to 6. The parent pillared clay, denoted as Al-WYO, was prepared by addition of solution 2 dropwise to solution 1 whilst stirring, heated to reflux at 80 °C for 3 h, and kept at 25 °C overnight. The solid was recovered by centrifugation, washed in a dialysis tube until conductivity was lower than 1 $mS\,m^{-1}$, freeze-dried and calcined at 200 °C over

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2 h after a ramp of 1 °C/min. Several methodologies were tried to encapsulate the complexes, but only the two more successful methods are described. In the procedure, hereafter denoted as *method A*, the [Mn(salhd)Cl] complex (0.5 mmol) was dissolved in ethanol and added to the oligomer solution (solution 2) at a stage at which the oligomeric species had already formed, that is, after the aging and pH adjustment to 6. In the case of *method B*, the complex, also dissolved in ethanol, was added to the clay dispersion (solution 1). In both methods, the amount of ethanol used was in the range 50–70 mL, to ensure that the complex would not precipitate after addition to the aqueous solutions. The remaining experimental steps were the same as described above for the preparation of Al-WYO. After calcination at 200 °C, the samples were Soxhlet extracted to remove the excess complex, first with ethanol and then with dichloromethane until a colourless washing was obtained.

Characterisation Methods

X-ray diffractograms were obtained with oriented mounts,[31] with a Philips PX 1820 instrument using Cu-K_α radiation. Nitrogen adsorption isotherms at –196 °C were measured with an automatic apparatus (Asap 2010; Micromeritics). Before the adsorption experiments the samples were outgassed under vacuum over 2.5 h at 150 °C. FTIR spectra were obtained as KBr pellets (Merck, spectroscopic grade) using a Mattson spectrometer, in the range 1800–1300 cm^{-1}; all spectra were collected at room temperature, with a resolution of 4 cm^{-1} and 32 scans. Metal contents were determined by atomic absorption spectroscopy with a Pye Unicam SP9 spectrometer after solubilisation of the samples in an autoclave with a mixture of HF and aqua regia.

X-ray photoelectron spectroscopy was performed at "Centro de Materiais da Universidade do Porto" (Portugal), with a VG Scientific ESCALAB 200A spectrometer using a non-monochromatised Mg-K_α radiation (1253.6 eV). All the materials were compressed into pellets prior to the XPS studies. In order to correct possible deviations caused by electric change of the samples, the C 1s line at 285.0 eV was taken as internal standard.

GC-FID chromatograms were obtained with a Varian CP-3380 gas chromatograph using helium as carrier gas and a fused silica Varian Chrompack capillary column CP-Sil 8 CB Low Bleed/MS (30 m × 0.25 mm i.d.; 0.25 μm film thickness). Conditions used: 60 °C (3 min), 5 °C/min, 170 °C (2 min), 20 °C/min, 200 °C (10 min); injector temperature, 200 °C; detector temperature, 300 °C.

Catalysis Experiments

The catalytic activity of the new materials in the epoxidation of styrene was assessed at room temperature using styrene (substrate, 0.500 mmol), chlorobenzene (GC internal standard, 0.500 mmol), catalyst (0.100 g) and iodosylbenzene (PhIO, 0.250 mmol) as oxidant in of acetonitrile (5.00 cm^3), whilst stirring. During the experiment, aliquots (0.1 cm^3) were taken from solution with a hypodermic syringe, filtered through 0.2 μm syringe filters and directly analysed by GC-FID. After the time needed for total consumption of PhIO (the ratio of areas of iodobenzene and chlorobenzene in chromatogram was constant), the catalyst was centrifuged. To ensure that the epoxidation was only catalysed heterogeneously, a new portion of PhIO (0.25 mmol) was added to the decanted solution, and the composition of reaction media was remonitored. After use, the catalyst was washed/centrifuged with methanol (five times) and with acetonitrile (two times) to remove occluded reactants and products, and then reused using the same experimental conditions described above. The cycle catalysis/washing was performed three times. The acetonitrile solution (after washing) was checked to verify the existence of styrene. To assess the eventual catalytic activity of the support itself in the epoxidation of styrene, reactions using the same experimental conditions (vide supra) were also carried out in the presence of the support (0.1 g); only negligible catalytic activity was found using PhIO as oxidant.

Identification and quantification of products were made by GC-FID analysis (internal standard method). The assignation was made by comparison with authentic samples; the retention times, under the experimental conditions used, are: chlorobenzene 6.4, styrene 7.5, benzaldehyde 9.7, iodobenzene 12.3 and styrene epoxide 13.1 min.

Synthesis of (1,2,4-Oxadiazole)palladium(II) Complexes by [2 + 3] Cycloaddition of Nitrile Oxides to Organonitriles in the Presence of $PdCl_2$

Nadezhda A. Bokach,[a,b] Vadim Yu. Kukushkin,*[b] Matti Haukka,[c] and Armando J. L. Pombeiro*[a]

Keywords: Palladium / 1,2,4-oxadiazole complexes / Nitrile complexes / Nitrile oxide complexes / Cycloaddition

The reaction between the nitrile oxides 2,4,6-$R'_3C_6H_2CNO$ (R′ = Me, OMe) and *trans*-$[PdCl_2(RCN)_2]$, or RCN (R = Me, Et, CH_2CN, NMe_2, Ph) in the presence of $PdCl_2$, proceeded smoothly under mild conditions and allowed the isolation of the 1,2,4-oxadiazole complexes *trans*-$[PdCl_2\{N^a{=}C(R){-}ON{=}C^b(C_6H_2R'_3)(N^a{-}C^b)\}_2]$ (**1**–**8**) in 40–85 % yields. In CH_2Cl_2, the reaction between 2,4,6-$R'_3C_6H_2CNO$ and $[PdCl_2(MeCN)_2]$ furnishes $[PdCl_2(ONCC_6H_2R'_3)_2]$ (**9** and **10**), which are the first representatives of metal compounds where nitrile oxides act as ligands. The 1,2,4-oxadiazole complexes **1**–**8** were characterized by elemental analysis, FAB mass spectrometry, and IR, ^1H and $^{13}C\{^1H\}$ NMR spectroscopy, while **2**, **3**, **7**, and **8** were additionally characterized by X-ray crystallography. The liberation of the heterocyclic species from **1**–**8** was successfully performed by substitution reaction either with 1,2-bis(diphenylphosphanyl)ethane or with an excess amount of $Na_2S{\cdot}7H_2O$ in MeOH; the liberated 1,2,4-oxadiazoles (**11**–**18**) were characterized by positive-ion FAB mass spectrometry and ^1H and $^{13}C\{^1H\}$ NMR spectroscopy.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

1,2,4-Oxadiazoles are an important class of ring systems containing one O and two N atoms.[1] These compounds have widespread applications in biology and medicine insofar as some of them exhibit intrinsic analgesic,[2] anti-inflammatory,[3] and anti-picornaviral[4] effects and show high efficacy as agonists[5] and antagonists[6] for different receptors. Other areas of research in the chemistry of 1,2,4-oxadiazoles include plant protection,[7] their use as liquid-crystalline mesophases,[8] dyeing or printing with 1,2,4-oxadiazole azo dyes,[9] and they are also constituents of fluorescent whiteners.[10] Despite the wealth of chemistry associated with 1,2,4-oxadiazoles in general, the coordination chemistry of these heterocycles has so far been little explored,[11] although the opposite holds true for the *isomeric* 1,3,4-oxadiazoles. Complexes of the latter have been intensively investigated as angular bridging ligands that give unusual coordination polymers[12] and binuclear complexes.[13] In addition, metal complexes with 1,3,4-oxadiazole-derived ligands exhibit important luminescent,[14] electroluminescent,[15] liquid crystal,[16] and magnetic properties.[17]

As a continuation of our project on [2 + 3] cycloadditions[18,19] of dipoles to metal-activated nitriles[20,21] to give heterocyclic systems, we have studied a [2 + 3] cycloaddition of nitrile oxides to nitriles in the presence of a Pd^{II} center and isolated a family of previously unknown (1,2,4-oxadiazole)palladium(II) species. We also observed that the reaction between the nitrile oxides and $[PdCl_2(MeCN)_2]$ in CH_2Cl_2 (instead of MeCN) led to the first representatives of nitrile oxide metal compounds. All these results are reported in this work.

Results and Discussion

Preparation of (1,2,4-Oxadiazole)palladium(II) Complexes

Recently we have studied the reaction of $[PtCl_4(RCN)_2]$ with the nitrile oxides 2,4,6-$R'_3C_6H_2CNO$ which, after [2 + 3] cycloaddition, gives the (1,2,4-oxadiazole)platinum(IV) complexes $[PtCl_4\{N^a{=}C(R)ON{=}C^bC_6H_2R'_3(N^a{-}C^b)\}_2]$.[19] This reaction opens up an easy route to 1,2,4-oxadiazole metal complexes and also allows the preparation of the heterocycles, after liberation of the ligands, under mild conditions. This method to achieve 1,2,4-oxadiazole complexes has been applied here to Pd^{II} systems to obtain a family of previously unknown 1,2,4-oxadiazole complexes.

As dipolarophiles for this study we used the nitrile and dialkylcyanamide palladium(II) complexes *trans*-$[PdCl_2(RCN)_2]$ because it has been shown[20,21] that the Pd^{II}

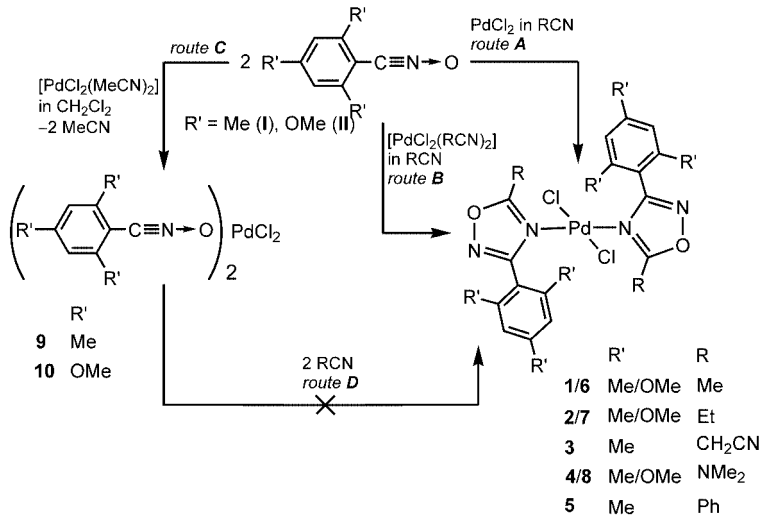

Scheme 1

center strongly activates the ligated nitriles toward the addition of various *nucleophiles* and this type of reactivity can model,[22] to some extent, the [2 + 3] cycloaddition of *dipoles*. Two relatively stable aryl nitrile oxides, i.e. 2,4,6-$Me_3C_6H_2CNO$ (**I**) and 2,4,6-$(MeO)_3C_6H_2CNO$ (**II**),[23] were chosen as dipoles.

In agreement with our expectations, the cycloaddition of **I** or **II** to nitriles in *trans*-$[PdCl_2(RCN)_2]$ to achieve 1,2,4-oxadiazole metal species proceeded smoothly and gave the complexes *trans*-$[PdCl_2\{N^a{=}C(R)ON{=}C^b(C_6H_2R'_3)(N^a–C^b)\}_2]$ (**1**–**8**) in 40–85% yields. The reaction was performed by two rather similar, albeit technically distinct, routes (Scheme 1). In the first route (**A**), both $PdCl_2$ and the nitrile oxide **I** or **II** (3–4 equiv.) were reacted in a suspension of neat nitrile RCN (R = Me, Et, NMe_2, Ph) or, in the case of the solid malonodinitrile (R = CH_2CN) (sixfold molar excess vs. $PdCl_2$), in a CH_2Cl_2 solution. In the second route (**B**), the nitrile complexes *trans*-$[PdCl_2(RCN)_2]$ (R = Me, Et, Ph), dissolved in the corresponding nitrile, were treated with the nitrile oxides **I** or **II** (3–4 equiv.). In both routes the reaction was performed at 40 °C for 12–18 h and the isolated yields for every particular compound, prepared by the two methods, are almost the same. The isolation of the (1,2,4-oxadiazole)palladium(II) products failed only in the case of treatment of the less-reactive (towards the cycloaddition, but more reactive towards the substitution; see below) nitrile oxide **II** with the reactive (but weak ligand) nitriles PhCN and $NCCH_2CN$ at the Pd^{II} center; this reaction gives a mixture of products.

Reaction of $PdCl_2$ with neat RCN is well known and is commonly applied for the preparation of the complexes *trans*-$[PdCl_2(RCN)_2]$.[24] Hence, it is not surprising that the reaction rate and the isolated yields are similar for both routes, because route **A** conceivably includes the formation of $[PdCl_2(RCN)_2]$, upon dissolution of $PdCl_2$ in RCN, followed by the cycloaddition of a nitrile oxide. Despite the similarity of routes **A** and **B**, the obvious advantage of the first method is that it allows the synthesis of complexes **1**–**8** starting directly from $PdCl_2$ and omitting the unnecessary step of the isolation of *trans*-$[PdCl_2(RCN)_2]$.

In order to get a rough estimate of the effect of the Pd^{II} center on the cycloaddition rate, the reaction between $PdCl_2$ (1 equiv.) in EtCN (3 mL) and **I** or **II** (2 equiv.) at 40 °C was compared with the reaction of **I** or **II** and EtCN under the same experimental conditions; only an approximate 1.5-fold acceleration in the metal-mediated vs. metal-free synthesis was observed. It appears that Pd^{II} acts mostly as a trapping center, thus allowing a facile isolation and characterization of 1,2,4-oxadiazoles as metal-bound species.

Binding of the Nitrile Oxides by a Pd^{II} Center

The interaction between $[PdCl_2(MeCN)_2]$ and the nitrile oxides **I** and **II** proceeds in another direction when dichloromethane is used as solvent instead of MeCN: the reaction gives (nitrile oxide)palladium(II) complexes **9** and **10** (Scheme 1, route **C**). In the electrospray mass spectra of both complexes, we observed the $[M + H]^+$ ion with the expected isotopic pattern. Complex **10** gave satisfactory C, H, and N microanalyses, whereas we failed to get reproducible data for the rather unstable **9**. In the IR spectra of both complexes, strong (**9**) or medium (**10**) bands of ν(C≡N) are shifted toward lower frequencies (15 cm^{-1} for **9** and 56 cm^{-1} for **10**) upon coordination. The ^1H NMR spectra display all required resonances with their expected integration. In $CDCl_3$, the complexes exist as a number of conformers probably because of the hindered rotation of the bulky ligands.

Although, to the best of our knowledge, metal complexes with nitrile oxides as ligands are unknown, there are a few reports of 1,3-dipolar cycloadditions where the formation of complexes between Lewis acids and nitrile oxides was assumed, from indirect evidence, to occur.[25,26] The major argument supporting the idea of the formation of (nitrile oxide)[M] complexes is based on the inhibition of the 1,3-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dipolar cycloaddition (sometimes with an increase of selectivity of the reaction[25–29]) in the presence of metal centers, which, in agreement with the authors,[25,26,30] blocks the oxygen atom of the nitrile oxide by coordination. The latter hypothesis was supported in the framework of this study by the lack of formation of (oxadiazole)palladium(II) complexes when **9** or **10** were treated with the corresponding nitriles (route **D**, Scheme 1).

Characterization of the (1,2,4-Oxadiazole)palladium(II) Complexes

Complexes **1**–**8** were characterized by C, H, and N analyses. In their FAB spectra they display the quasi-ion $[M + Na]^+$ (**1**, **2**) and/or the fragmentation $[M - H]^+$ and/or $[M - Cl]^+$ ions (**1**, **2**, **5**, **7**, and **8**); for **3**, **4**, and **6** only deep fragmentation was observed. In their IR spectra, the oxadiazole complexes **1**–**8** exhibit two relatively strong bands in the range of 1537–1658 cm^{-1}. The first one lies in a relatively narrow interval, i.e. 1607–1614 cm^{-1}, for all these complexes, and can be attributed to a ν(C=N) stretching vibration in the oxadiazole ligand. The position of the second band varies and depends on the type of the complex. Thus, medium-to-strong and strong bands at 1537–1585 cm^{-1} (**1**, **2**, **4** derived from **I**) and 1598 cm^{-1} (**6** and **7** derived from **II**) can be attributed to the other ν(C=N) stretching vibration of the heterocycle and/or ν(C=C) stretch of the aromatic ring. In contrast to the alkyl and aryl derivatives of oxadiazoles, the dialkylcyanamide ones (**4** and **8**) do not display strong peaks in the area 1537–1585 cm^{-1} but exhibit a strong band in the range 1657–1658 cm^{-1}. This shift is probably the consequence of a different electron distribution in the dialkylcyanamide-substituted oxadiazole ligands (see below).

In the ^1H and $^{13}C\{^1H\}$ NMR spectra of $[PdCl_2(1,2,4\text{-oxadiazole})_2]$, two (**1**–**4** and **6**–**8**) or five (**5**) sets of each signal (or a group of signals) were detected; this is probably due to the hindered rotation of the bulky oxadiazole ligands around the Pd–N bond, which leads to inequivalence of the protons and carbon atoms. In the $^{13}C\{^1H\}$ NMR spectra, two carbons from the N=C–N and N=C–O moieties were detected at δ = 164–171 and 178–190 ppm, respectively. These assignments are based upon the data for similar platinum(IV) and platinum(II) oxadiazole complexes, i.e. $[PtCl_4\{N^a{=}C(R)ON{=}C^bC_6H_2R'_3)(N^a\text{–}C^b)\}_2]$ and $[PtCl_2\{N^a{=}C(R)ON{=}C^bC_6H_2R'_3)(N^a\text{–}C^b)\}_2]$, where the signals of C from the N*C*N and N*C*O groups can be distinguished by using the long-range selective INEPT technique. In the ^1H NMR spectra of both **4** and **8**, the signal from Me in NMe_2 is broad, apparently because of the hindered rotation of the NMe_2 group (see later).

Crystal Structure Determinations of (1,2,4-Oxadiazole) palladium(II) Complexes

Crystals of **2** (Figure 1), **3** (Figure 2), **7** (Figure 3), and **8** (Figure 4) were obtained directly from the reaction mixtures and their structures were determined by X-ray crystallography.

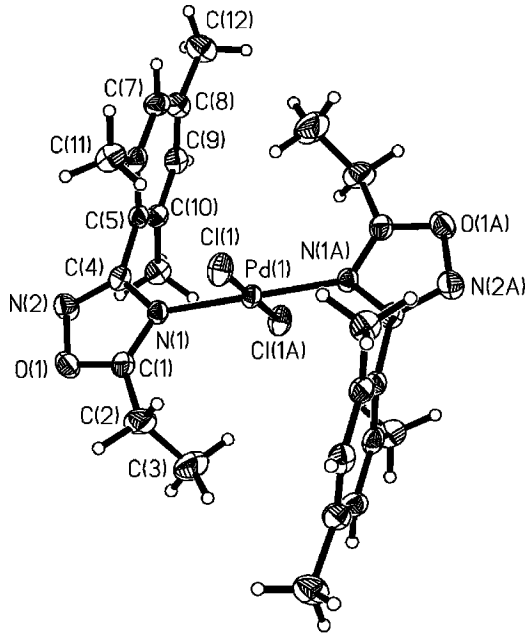

Figure 1. Thermal ellipsoid view of $[PdCl_2\{N^a{=}C(Et)ONC^b(C_6H_2Me_3)(N^a\text{–}C^b)\}_2]$ (**2**)with atomic numbering scheme; thermal ellipsoids are drawn with 50% probability

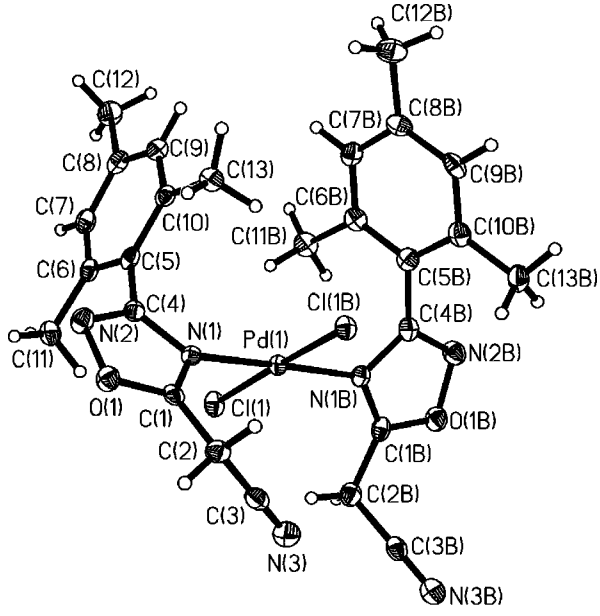

Figure 2. Thermal ellipsoid view of $[PdCl_2\{N^a{=}C(CH_2CN)ONC^b(C_6H_2Me_3)(N^a\text{–}C^b)\}_2]$ (**3**)with atomic numbering scheme; thermal ellipsoids are drawn with 50% probability

The 1,2,4-oxadiazole ligands in all these complexes are coordinated in mutual *trans* positions. In **2**, **7**, and **8** the heterocycles have an antiparallel orientation [angles between N(1)–C(1)–O(1)–N(2)–C(4) planes are 0°, 57.63(9)°, 10.16(14)°, and 0° for **2**, **3**, **7**, and **8**, respectively], while in **3**, they are turned in one direction and the torsion angle is approximately 60°. The geometrical parameters of the heterocycles in **2**, **3**, and **7** are the same within 3σ and are

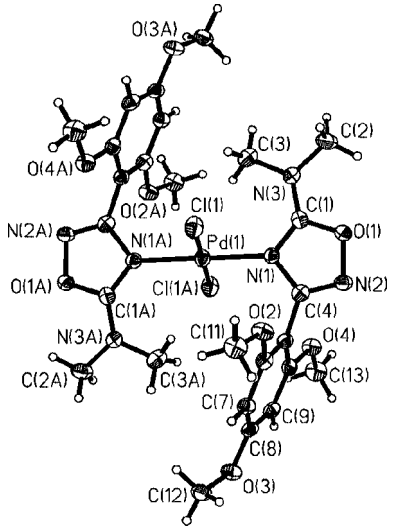

Figure 4. Thermal ellipsoid view of $[PdCl_2\{N^a{=}C(NMe_2)ONC^b(C_6H_2(OMe)_3(N^a{-}C^b)\}_2]$ (**8**)with atomic numbering scheme; thermal ellipsoids are drawn with 50% probability

similar to those in the previously described (1,2,4-oxadiazole)platinum(IV) and -platinum(II) complexes,[19] in 1,2,4-oxadiazole complexes of other metals,[31] and even in the uncomplexed heterocycles.[32–34] The Pd–N and Pd–Cl bond lengths and angles around the Pd center are similar to those given in the literature for $[PdCl_2$(N-coordinated heterocycle)$_2]$-type complexes.[35]

The C=N bond length in the Pd–N=C–N fragment of **8** [1.377(5) Å] is larger than that for the corresponding bond in **2**, **3**, and **7** [1.306(3)–1.314(3) Å] and also larger than those in the free oxadiazoles bearing NRR′ substituents.[36] In addition, the C(1)–N(3) bond length in the *CN*Me$_2$ fragment [1.315(5) Å] is shorter than a normal C–N single bond and even shorter than the C=N bond in the oxadiazole ring; all these facts favor a significant double-bond character in the *CN*Me$_2$ moiety. A possible rationale for the latter observation is the dominance of the right-hand structure (Figure 5) in the mesomeric hybrid of the heterocycle.

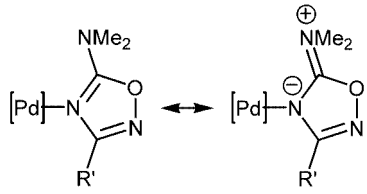

Figure 5. Possible mesomeric forms of the heterocycle in complex **8**

This observation is coherent with the unusual IR data (strong band at 1658 cm^{-1}, see above) and NMR spectroscopic data in solution, where the NMe$_2$ signal is broad probably due to hindered rotation around the partially double CN bond of the CNMe$_2$ functionality.

Liberation of the 1,2,4-Oxadiazoles

Although the activation of nitriles by Pd^{II} toward the cycloaddition is not advantageous from synthetic viewpoint, we still developed a method for liberation of 1,2,4-oxadiazoles from their complexes with the hope of further progress in this area which can be associated with either the application of cationic Pd^{II} complexes or the use of supporting ligands with pronounced π-acceptor properties.[20]

Complexes **1**–**8** are stable and remain intact in an excess of nitrile even at 40 °C for 24 h, thus preventing the reaction from being catalytic. However, the liberation of the oxadiazoles from **1**–**8** was successfully performed by substitution following two routes. In the first one, a solution of **1**–**8** in $CDCl_3$ was treated with two equivalents of 1,2-bis(diphenylphosphanyl)ethane (dppe) and, after 3 h, when the precipitation of the colorless complex $[Pd(dppe)_2]Cl_2$ [$^{31}P\{^1H\}$ ($CDCl_3$): δ = 53.15 ppm (ref.[37] δ = 56.7 ppm)] was complete, the quantitative formation of the free oxadiazoles **11**–**18** was confirmed by ^1H NMR spectroscopy. In the preparative experiment, the precipitate of $[Pd(dppe)_2]Cl_2$ can easily be separated by filtration, and subsequent evaporation of the filtrate gives the 1,2,4,-oxadiazoles in the almost quantitative yield.

In the second route, a solution of **1**–**8** in CH_2Cl_2 was treated with an excess of $Na_2S{\cdot}7H_2O$ in MeOH to immediately give a precipitate of PdS; the free oxadiazoles **11**–**18** remain in solution. After separation of PdS by filtration, the solvent was evaporated from the filtrate and the 1,2,4-oxadiazoles were extracted almost quantitatively from the residue with CH_2Cl_2. The second method is preferable because Na_2S is much cheaper than dppe and the formation of PdS proceeds substantially faster than that of $[Pd(dppe)_2]Cl_2$.

The liberated 1,2,4-oxadiazoles (**11**–**18**) were characterized by positive-ion FAB mass spectrometry − typically the $[M + H]^+$ ion is observed − and ^1H and $^{13}C\{^1H\}$ NMR spectroscopy. The chemical shifts in the ^1H and $^{13}C\{^1H\}$ NMR spectra of **11**–**18** are similar to those for the corresponding (1,2,4-oxadiazole)palladium(II) complexes. However, for **11**–**14** and **16**–**18** each proton or carbon has one set of signals, in contrast to the situation described pre-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

viously for the Pd complexes, i.e. the NMR inequivalence of the oxadiazoles **11**–**14** and **16**–**18** disappears when they are liberated from the corresponding palladium(II) complexes. However, in the case of **15**, five sets of signals are still displayed in the spectra for each proton and carbon atom (in the temperature range from 20 to 50 °C) and we believe that this is due to different conformations of the oxadiazole **15** bearing the two bulky substituents in the ring (Ph and $C_6H_2Me_3$). For all free oxadiazoles **11**–**18**, the N=C–N and N=C–O carbons lie in the ranges δ = 164–168 and 168–180 ppm, respectively.

Final Remarks

The results from this work can be considered from at least two perspectives. From the first one, the developed method, which is based on [2 + 3] cycloaddition of nitriles and nitrile oxides in the presence of a trapping metal center, is an excellent entry to 1,2,4-oxadiazole–metal complexes, whose chemistry is almost unknown, although the opposite holds true for metal compounds of the isomeric 1,3,4-oxadiazole; the latter complexes exhibit a good number of useful properties. From the second perspective, we have found the first example of nitrile oxide–metal complexes and further development of chemistry of this species may shed light on the mechanisms of the still poorly understood metal-mediated 1,3-dipolar cycloaddition of propargyl/allenyl anion type dipoles to nitriles.[19,38] We observed that the more labile Pd^{II} center (as compared to a kinetically inert Pt^{IV} center) reacts to a similar degree with both the dipolarophile and the dipole, and the latter interaction, i.e. ligation of nitrile oxide observed in this work for the first time, inhibits the 1,3-dipolar cycloaddition by blocking the oxygen center of the dipole. The latter points to the need for the selective complexation of metal centers with nitrile dipolarophiles (rather than with nitrile oxide dipoles) to promote the cycloaddition.

Experimental Section

Materials and Instrumentation: Solvents were obtained from commercial sources and used as received. The complexes $[PdCl_2(RCN)_2]$ (R = Me, Et, Ph[24]) and the nitrile oxides 2,4,6-$Me_3C_6H_2CNO$ and 2,4,6-$(MeO)_3C_6H_2CNO$[23] were prepared as described previously. C,H,N elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (NBA) matrices of the samples with 8 keV (ca. 1.28×10^{15} J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Infrared spectra (4000–400 cm^{-1}) were recorded with a JASCO FT/IR-430 instrument in KBr pellets. ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ spectra in $CDCl_3$ were measured with a Varian UNITY 300 spectrometer at ambient temperature.

Cycloaddition of Nitrile Oxides to Pd-Bound Nitriles. Method A: $PdCl_2$ (12 mg, 0.068 mmol, 1 equiv.) and 3–4 equiv. of **I** (32–44 mg, 0.200–0.271 mmol) or **II** (42–56 mg, 0.200–0.271 mmol) were suspended in RCN (R = Me, Et, Ph, NMe_2; 0.3 mL) or in a solution of $NCCH_2CN$ (27 mg, 0.408 mmol) in CH_2Cl_2 (3 mL) and the mixture was heated to 40 °C for 12–18 h. During this period the $PdCl_2$ dissolved to give orange (for **I**) or dark-brown (for **II**) solutions. In the case of complexes **1**–**3** and **6**–**8**, orange crystals were formed at the top of the vial and were removed by filtration (yields are 20–40%). The orange solution (reaction with **I**,complexes **4** and **5**) was evaporated to dryness under vacuum and the orange oil formed was crystallized under a layer of Et_2O to furnish an additional amount (yields are 30–50%) of the cycloaddition product (for **1**–**3**). All oxadiazole complexes (**6**–**8**) derived from **II** were crystallized from the reaction mixture and separated by filtration. The dark reaction mixture formed in the case of nitrile oxide **II** and PhCN and $PhCH_2CN$ contains a number of products and was not further investigated.

Method B: $[PdCl_2(RCN)_2]$ (R = Me, Et, Ph; 15 mg) was suspended with 3–4 equiv. of the nitrile oxides in the corresponding nitrile RCN (R = Me, Et, Ph; 0.3 mL), and the reaction mixture was heated to 40 °C for 12–18 h, whereupon an orange product formed. The isolation procedures are similar to those described above. This method was applied for the preparation of **1**, **2**, and **5**–**7**.

[$PdCl_2${N^a=C(NMe$_2$)ONC^b(C_6H_2(OMe)$_3$)(N^a–C^b)}$_2$] (8): Yield: 20 mg (40%). $C_{24}H_{28}Cl_2N_4O_8Pd$ (735.9): calcd. C 42.43, H 4.66, N 11.42; found C 42.90, H 4.93, N 11.34. FAB$^+$-MS: *m*/*z* = 700 [M – Cl –H]$^+$. IR (KBr, selected bands): 2935 cm^{-1} (mw) and 2845 (w) ν(C–H), 1657 (s) and 1614 (s) ν(C=N) and ν(C=C). ^{1}H NMR (300 MHz, $CDCl_3$; two sets of signals in the approximate ratio 11:1; signal sets for minor isomer are not given because of its low abundance): δ = 3.45 (br. s, 3 H, Me), 3.78 (s, 6 H, *o*-$CH_3C_6H_2$), 3.92 (s, 3 H, *p*-$CH_3OC_6H_2$), 6.19 (s, 2 H, *m*-Ar) ppm. ^{13}C{^{1}H} NMR (75.4 MHz, $CDCl_3$): δ = 39.4 (NMe$_2$), 55.7 (*o*-$CH_3OC_6H_2$), 56.1 (*p*-$CH_3OC_6H_2$), 90.1 (*m*-Ar) ppm; signals for other groups were not detected due to poor solubility of compound.

(Nitrile oxide)palladium(II) Complexes: [$PdCl_2$(MeCN)$_2$] (20 mg, 0.08 mmol) and the nitrile oxides R′CNO [0.20 mmol; R′ = Me$_3$-C_6H_2**I**, (MeO)$_3$$C_6H_2$**II**] were suspended in CH_2Cl_2 (3 mL) and the mixture left to stand at room temperature for 2–4 h. During this period the [$PdCl_2$(MeCN)$_2$] dissolved to give dark-brown solutions. In case of **II** the brown solution remained unchanged after several hours, therefore the solvent was evaporated and the dark oily residue formed was crystallized under a layer of Et_2O. In the case of **I**, after several hours an orange precipitate begin to form and solution become more pale and turned to orange-yellow. The precipitate was removed by decantation and the solution was evaporated under vacuum until dryness and crystallized under a layer of Et_2O. Yield: ca. 60% (**9**) and ca. 30% (**10**).

[$PdCl_2$(ONCC_6H_2Me$_3$)$_2$] (9): ES-MS$^+$: *m*/*z* = 501 [M + H]$^+$. IR (KBr, selected bands): 2967 cm^{-1} (w) and 2922 (mw) ν(C–H), 2278 (s) ν(C≡N) 1792 (ms), 1735 (m), 1608 (s), 1456 (br. ms) [in the free nitrile oxide: 2949 (w) and 2919 (mw) ν(C–H), 2293 (s) ν(C≡N), 1608 (m)]. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.30–2.49 (set of s, 9 H, *o*- and *p*-CH_3C$_6$H$_2$), 6.89–6.94 (set of s, 2 H, C$_6$*H*$_2$) ppm.

[$PdCl_2${ONCC_6H_2(OMe)$_3$}$_2$] (10): $C_{20}H_{22}Cl_2N_2O_8Pd$ (595.9): calcd. C 40.32, H 3.72, N 4.70; found C 40.90, H 4.64, N 4.63. ES-MS$^+$: *m*/*z* = 597 [M + H]$^+$. IR (KBr, selected bands): 2940 cm^{-1} (mw) ν(C–H), 2249 (m) ν(C≡N) 1606 (br. s), 1456 (br. m) [in the free nitrile oxide: 2985 (w) and 2949 (mw) ν(C–H), 2305 (ms) ν(C≡N), 1608 (s), 1582 (s), 1469 (ms)]. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.76–3.94 (set of s, 9 H, *o*- and *p*-CH_3OC$_6$H$_2$), 6.02–6.14 (set of s, 2 H, C$_6$*H*$_2$) ppm.

Liberation of the Oxadiazoles from Complexes 1–8: (*i*) dppe (2 equiv.) was added to a solution of **1**–**8** (15 mg) in $CDCl_3$ (0.5 mL) and the mixture was allowed to stand at 40 °C for 30 min, whereupon colorless [Pd(dppe)$_2$]Cl_2 precipitated. The free oxadiazole was characterized in solution by ^{1}H NMR spectroscopy. Evaporation of the solvent gave **11**–**18** (see later) in almost quantitative yield.(*ii*) A solution of $Na_2S·7H_2O$ (50 mg) in MeOH (1 mL) was added dropwise to a solution of **1**–**8** (10 mg) in CH_2Cl_2 (0.5 mL). The dark-brown PdS precipitated immediately after the addition of ca. 0.15 mL of the sulfide solution (until the yellow color disappeared), whereupon the reaction mixture was evaporated to dryness and the oxadiazole was extracted from the residue with CH_2Cl_2 (1 mL). Yields are almost quantitative.

The oxadiazoles N^a=C(Et)ONC^b(C_6H_2Me$_3$)(N^a–C^b) (**12**), and N^a=C(Et)ONC^b(C_6H_2(OMe)$_3$)(N^a–C^b) (**17**) have been characterized previously.[10]

N^a=C(Me)ONC^b(C_6H_2Me$_3$)(N^a–C^b) (11): FAB$^+$-MS: *m*/*z* = 203 [M + H]$^+$. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.18 (s, 6 H, *o*-CH_3C$_6$H$_2$), 2.33 (s, 3 H, *p*-CH_3C$_6$H$_2$), 2.68 (s, 3 H, Me), 6.94 (s, 2 H, *m*-Ar) ppm. ^{13}C{^{1}H} NMR (75.4 MHz, $CDCl_3$): δ = 12.4 (N=C*Me*), 20.0 (*o*-$CH_3C_6H_2$), 21.2 (*p*-$CH_3C_6H_2$), 128.5 (*m*-Ar), 137.7 (*o*-Ar), 139.6 (*p*-Ar) ppm.

N^a=C(CH_2CN)ONC^b(C_6H_2Me$_3$)(N^a–C^b) (13): FAB$^+$-MS: *m*/*z* = 228 [M + H]$^+$. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.20 (s, 6 H, *o*-CH_3C$_6$H$_2$), 2.34 (s, 3 H, *p*-CH_3C$_6$H$_2$), 4.19 (s, 2 H, CH_2), 6.96 (s, 2 H, *m*-Ar) ppm. ^{13}C{^{1}H} NMR (75.4 MHz, $CDCl_3$): δ = 17.3 (Me), 20.2 (*o*-CH_3C$_6$H$_2$), 21.2 (*p*-CH_3C$_6$H$_2$), 112.0 (C≡N), 122.6 (C_{ipso}), 128.7 (*m*-Ar), 137.8 (*o*-Ar), 140.3 (*p*-Ar), 168.1 (N=C–O), 169.1 (N=C–N) ppm.

X-ray Crystal Structure Determinations: The crystals were immersed in perfluoropolyether, mounted in a cryo-loop and measured at 100 or 110 K. The X-ray diffraction data were collected with a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å). The Denzo-Scalepack program package[39] was used for cell refinements and data reductions. Structures were solved by direct methods using the SHELXS-97 or SIR-97 programs or by Patterson method using DIRDIF-99 with the WinGX graphical user interface.[40–43] An empirical absorption correction was applied to all data using XPREP in SHELXTL v.6.12[44] (T_{min}/T_{max}: 0.12334/0.15440, 0.31972/0.35415, 0.12648/0.15208, and 0.13741/0.17395 for **2**, **3**, **7**, and **8**, respectively). Structural refinements were carried out with SHELXL-97.[41] The asymmetric unit

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

contained only half a molecule in **2** and **8**, whereas in **3** and **7** the asymmetric unit contained a whole molecule. All hydrogens were placed in idealized positions and constrained to ride on their parent atom. The crystallographic data are summarized in Table 1. Selected bond lengths and angles are shown in Table 2.

CCDC-243489 to -243492 (for **2**, **3**, **7**, and **8**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

This work has been partially supported by the FCT (Foundation for Science and Technology, Portugal) and its POCTI program (POCTI/QUI/43415/2001 project; FEDER funded). N.A.B. expresses gratitude to the POCTI program, Portugal (grant SFRH/BPD/11448/2002) and the Center for Natural Sciences (Konkursnii Tsentr Fundamentalnogo Estestvoznaniya), Russia (grant PD03-1.3-28) and the Russian Fund for Basic Research (grant 05-03-32140a) for financial support. M.H. would like to thank the Academy of Finland for financial support. V.Y.K. is very much obliged to the Russian Fund for Basic Research for a grant (03-03-32363), POCTI program (FEDER funded; Cientista Convidado/Professor at the Instituto Superior Técnico, Portugal), the Royal Society of Chemistry for a Grant for International Authors, and the Academy of Finland for support of the cooperation with the University of Joensuu. The authors thank NATO for the Collaborative Linkage Grant PST.CLG.979289.

Open-Framework Polar Compounds: Synthesis and Characterization of Rare-Earth Polyoxometalates $(C_6NO_2H_5)_2[Ln(H_2O)_5(CrMo_6H_6O_{24})]\cdot 0.5H_2O$ (Ln = Ce and La)

Haiyan An,[a] Dongrong Xiao,[a] Enbo Wang,*[a] Yangguang Li,[a] Xinlong Wang,[a] and Lin Xu[a]

Keywords: Rare earth / Polyoxometalates / Open framework / Polar compounds / Magnetic properties

Two unprecedented open-framework polar compounds $(C_6NO_2H_5)_2[Ln(H_2O)_5(CrMo_6H_6O_{24})]\cdot 0.5H_2O$ [Ln = Ce (**1**), La (**2**); $C_6NO_2H_5$ = pyridine-3-carboxylic acid], constructed from Anderson-type polyoxo anions and rare-earth cations, have been synthesized for the first time and characterized by elemental analysis, IR and Raman spectroscopy, TG analysis, and single-crystal X-ray diffraction. Both compounds crystallize in the polar space group $Pmn2_1$ and are made up of $[CrMo_6H_6O_{24}]^{3-}$ polyoxo anions linked by rare-earth cations to form a fascinating 3D open framework with "guest" pyridine-3-carboxylic acid molecules and free water molecules residing in the channels. To the best of our knowledge, this represents the first example of an open-framework polar compound constructed from rare-earth polyoxometalates. The magnetic properties of compound **1** have been studied by measuring its magnetic susceptibility in the temperature range 2.0–300.0 K, indicating the existence of antiferromagnetic interactions.

Introduction

Interest in porous polar inorganicmaterials has increased in recent times, because the potential applications of these materials range from telecommunication, optical storage, and information processing to selective separation and catalysis.[1] Although many covalent three-dimensional inorganic frameworks have been reported, few of them possess polarity.[2] Thus, the designed construction of porous polar inorganic frameworks is one of the most challenging issues in current synthetic chemistry. While the literature abounds in reports of the synthesis and characterization of aluminosilicates and aluminophosphates with polar and porous architectures,[3,4] recently porous polar compounds were extended to systems containing transition-metal oxides because of their particular properties inaccessible in main group systems.[3]

Polyoxometalates (POMs),[7,8] as anionic early transition metal oxide clusters, have been employed as inorganic building blocks for the construction of larger clusters, or one-, two-, and even three-dimensional (3D) extended solid frameworks, owing to their fascinating properties and potential applications in different areas such as catalysis, material science, and biological chemistry. In recent years, several large nanostructured polyoxometalate clusters have been reported by Müller et al.,[9] Pope et al.,[10] and Yamase et al.;[11] a number of 1D and 2D POM-based polymers have also been successfully synthesized by Zubieta et al.[12] and Pope et al.[13] In contrast, the method of assembling POMs into three-dimensional frameworks, especially open frameworks, is still in its infancy, and has been limited to using the 3d-block elements or their coordination complexes as linkers.[14,15] Although rare-earth elements are highly oxophilic and polyoxometalates have oxygen-rich compositions,[16] 3D covalent open frameworks containing both of them remain largely unexplored. In addition, special spectroscopic and magnetic properties of lanthanide ions and their compounds have inspired our research interest.[11,13,17,18]

Hence, our synthetic strategy starts by finding an appropriate POM building block, and then utilizes rare-earth cations as the linker and organic molecules as the template in an attempt to assemble them into a 3D polar network. More recently, we and others, have prepared a few extended structures based on Anderson-type polyoxo anions, ranging from 1D chains to 2D networks.[19,20] The activity of the terminal oxygen atoms on the surface of this kind of POM makes it possible to form 3D covalent structures under an appropriate reaction condition. Furthermore, the employment of low-symmetry organic molecules or complexes as structure-directing agents is promising for the synthesis of new open-framework polar compounds.[4] In this experi-

ment, we chose the acentric pyridine-3-carboxylic acid molecule as the structure-directing agent instead of the widely utilized organic amines, owing to the requirement for acid reaction conditions. With the pyridine-3-carboxylic acid molecule, we have successfully obtained two unprecedented POM-based compounds possessing polarity and open framework characteristics. Herein, the rational synthesis of the two complexes $(C_6NO_2H_5)_2[Ln(H_2O)_5(CrMo_6H_6O_{24})]\cdot 0.5H_2O$ [Ln = Ce (**1**), La (**2**)] by this route and magnetic properties of compound **1** are described. It is notable that the 3D polar framework consists of two intersecting channels, within which pyridine-3-carboxylic acid molecules and free water molecules are situated.

Results and Discussion

The single-crystal X-ray diffraction analyses reveal that both compounds **1** and **2** (Tables 1 and 2) are isostructural and crystallize in the polar space group $Pmn2_1$, therefore we only discussed the structure of **1** herein. The structure of **1** is a unique 3D open framework constructed from $[Cr(OH)_6Mo_6O_{18}]^{3-}$ building blocks and Ce^{3+} cations, with pyridine-3-carboxylic acid molecules and lattice water molecules residing in the channels. The $[Cr(OH)_6Mo_6O_{18}]^{3-}$ cluster is a B-type Anderson structure made up of seven edge-sharing octahedra, six of which are $\{MoO_6\}$ octahedra, arranged hexagonally around the central $\{Cr(OH)_6\}$ octahedron. Four kinds of oxygen atoms exist in the cluster according to the manner of oxygen coordination: the terminal oxygen atom Ot, the terminal oxygen atom Ot′ linked to Ce^{3+}, the double-bridging oxygen atom Ob, and the central oxygen atom Oc. Thus, the Mo–O distances can be grouped into four sets: Mo–Ot 1.683(11)–1.732(11) Å, Mo–Ot′ 1.727(10)–1.732(9) Å, Mo–Ob 1.909(6)–1.958(9) Å, and Mo–Oc 2.254(7)–2.312(8) Å. The central Cr–Oc distances vary from 1.951(11) to 1.980(11) Å. The bond angles of O–Cr–O range from 83.5(3) to 98.1(3)°.

The asymmetric unit (Figure 1) in the structure of **1** consists of two crystallographically independent one-half Anderson anions, in which both chromium ions [Cr(1) and Cr(2)] occupy special positions, linked by the cerium cation. Crystallographically unique cerium(III), residing in a distorted bicapped square-antiprismatic coordination environment, is defined by four terminal oxygen atoms from four $[Cr(OH)_6Mo_6O_{18}]^{3-}$ units [average Ce–O 2.491(9) Å] and six water molecules [average Ce–OH_2 2.626(13) Å]. The average Ce–O bond length is 2.572(11) Å.

In the structure each Anderson anion acts as a quadridentate ligand coordinating to four cerium cations through the terminal oxygen atoms of four $\{MoO_6\}$ octahedra. As shown in Figure 2, firstly these $[Cr(OH)_6Mo_6O_{18}]^{3-}$ clusters are linked by some Ce^{3+} cations to form 1D linear chains, then each chain is connected to two other parallel chains through other Ce^{3+} cations to yield a window-like 2D layer in the *ac* plane. The 2D layer structure built up of polyoxo anions and rare-earth ions is rare. These 2D sheets are further pillared by the $[Cr(OH)_6Mo_6O_{18}]^{3-}$ subunits to form a 3D open framework. It is notable that this kind of connection mode results in the formation of two intersecting channels, which are occupied by the dissociated pyridine-3-carboxylic acid molecules (see Figure 3) and lattice water molecules. The dimensions of the two channels are about 10.0×8.5 Å along the *a* axis (shown in Figure 4) and 10.7×6.2 Å along the *b* axis, respectively (see Figure 5). It is also striking that the structure of compound **1** exhibits extensive hydrogen-bonding interactions among water molecules, pyridine-3-carboxylic acid molecules, and polyoxo anions. The typical hydrogen bonds are O37···O2 2.784, O36···O16 2.641, O37···OW3 2.922, O9···C5 3.119, and O6···C23 2.682 Å (shown in Table S1). It is believed that the extensive hydrogen-bonding interactions between guest molecules and the framework play an important role in stabilizing the 3D structure. Worth mentioning here is that the observed polarity of **1**, indicated by its polar space group $Pmn2_1$, can be partially understood in terms of the molecular recognition between the host framework and guest molecule template through hydrogen bonds.[21,22]

The bond valence sum calculations indicate that the Cr site is in the +3 oxidation state, Ce and La sites are in the +3 oxidation state, and all Mo sites are in the +6 oxidation state.[23]

Table 1. Selected bond lengths [Å] and angles [°] for **1**; symmetry transformations used to generate equivalent atoms: #1: *–x* + 1, *–y*, *–z* + 2; #2: *–x* + 2, *–y*, *–z* + 1

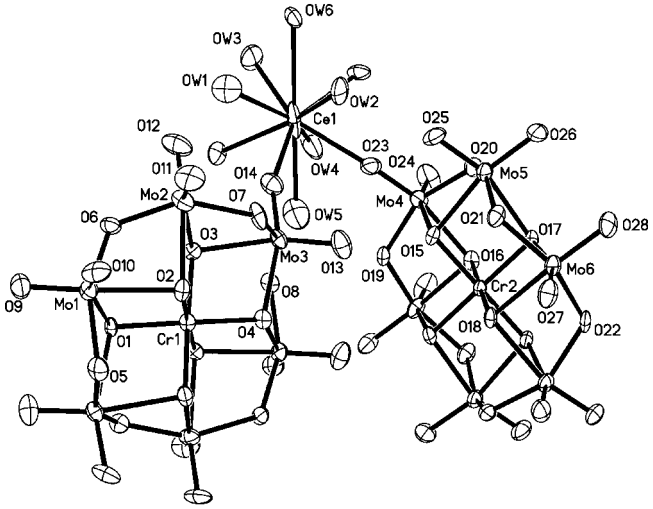

Figure 1. ORTEP drawing of compound **1** with thermal ellipsoids at 50% probability; organic molecules and partial water molecules are omitted for clarity

In the IR spectrum of compound **1**, the features at 3368, 2094, 1635, 1558, 1401, 1374, 1357, and 1304 cm^{-1} can be regarded as characteristic of the pyridine-3-carboxylic acid molecule. The peaks at 946, 909, 879, 759, 649, 578, and 412 cm^{-1} are attributed to ν(Mo–Ot), ν(Mo–Ob), and ν(Mo–Oc) of the $[Cr(OH)_6Mo_6O_{18}]^{3-}$ polyoxo anion. The IR spectrum of compound **2** is similar to that of **1** (see Figures S3a and S3b in the Supporting information). In the

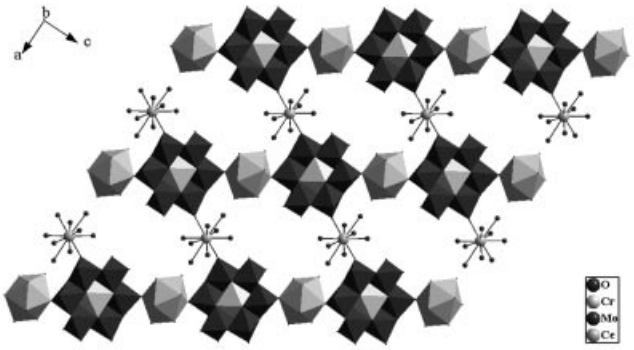

Figure 2. Polyhedral view of the 2D network in **1**

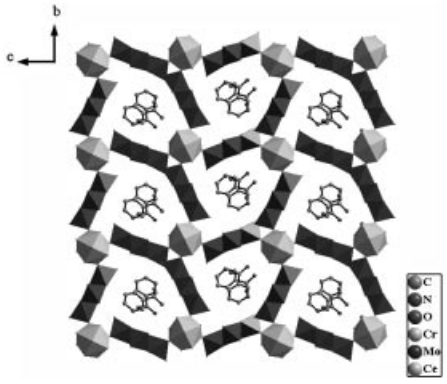

Figure 3. Polyhedral view of the 3D open framework of **1** viewing along the *a* axis, containing pyridine-3-carboxylic acid molecules in the channels

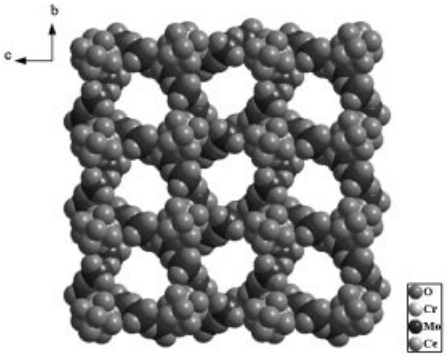

Figure 4. Space-filling diagram of the 3D open framework of **1** along the *a* axis, showing the 1D channels

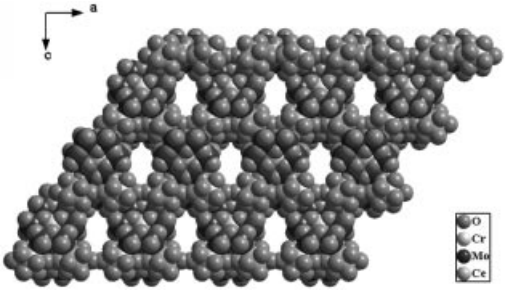

Figure 5. Space-filling diagram of the 3D porous structure of **1** along the *b* axis, representing the 1D channels

Raman spectrum of compound **1**, the bands at 993, 942, 821, 713, 449, 337, and 286 cm^{-1} are ascribed to the $[Cr(OH)_6Mo_6O_{18}]^{3-}$ polyoxo anion. In the Raman spectrum of compound **2**, the features at 993, 929, 908, 850, 823, 550, 333, and 250 cm^{-1} are also attributed to the $[Cr(OH)_6Mo_6O_{18}]^{3-}$ polyoxo anion (shown in Figure S4).

The thermal gravimetric (TG) curve of **1** is shown in Figure S5a. The TG curve gives a total weight loss of 27.24% in the range of 45–750 °C, which agrees with the calculated value of 26.55%. The weight loss of 10.60% at 45–300 °C corresponds to the loss of all noncoordinated and coordinated water molecules (calcd. 10.18%). The weight loss of 16.64% at 340–575 °C arises from the decomposition of organic molecules (calcd. 16.37%). The TG curve of compound **2** exhibits similar weight loss stages to those of compound **1** (see Figure S5b). The whole weight loss (27.16%) is in agreement with the calculated value (26.57%).

Magnetic Properties of Compound 1

The structure of $[Cr(OH)_6Mo_6O_{18}]^{3-}$ clusters bridged by Ce^{3+} cations in compound **1** allows us to predict the existence of magnetic exchange coupling. The thermal variations of $\chi_m T$ and $1/\chi$ of **1** are displayed in Figure 6. The value of $\chi_m T$ continuously decreases as the temperature is lowered from 300.0 to 2.0 K, indicating the presence of an antiferromagnetic interaction. At 300 K, the $\chi_m T$ value is ca. 2.87 emu K mol^{-1} (4.79 μ_B), slightly higher than the total value (2.25 emu K mol^{-1}, 4.24 μ_B) of one uncoupled S = 3/2 spin of the Cr^{3+} atom and one uncoupled S = 1/2 spin of the Ce^{3+} atom. The magnetic susceptibility obeys the Curie–Weiss law in the whole range of 2.0–300.0 K with C = 2.81 emu K mol^{-1}, and θ = –5.79 K, characteristic of an overall antiferromagnetic interaction. It is too difficult to fit the experimental magnetic data of this complex system using a suitable theoretical model, and further studies on magnetic properties of similar systems are ongoing in our laboratory.

Conclusions

In conclusion, we have synthesized the only structurally characterized rare-earth POM complexes featuring an open framework and polarity reported until now, by choosing a suitable POM building block, organic template, and suitable reaction conditions. The success in synthesizing both compounds provides not only innovative examples of open-framework polar compounds, but also a new strategy for the design of polar inorganic materials with channels based on POMs. In contrast to the famous aluminosilicates and metal phosphates with porous polar frameworks, this new type of POM-based polar compound represents another important branch in the field of polarity and open-framework perspectives in the study of these materials. The magnetic properties of **1** have been studied and its antiferromagnetic behavior results from the transformation of O–Mo–O units.

Experimental Section

Materials and General Methods: All chemicals were commercially purchased and used without further purification. $Na_3[CrMo_6H_6O_{24}]\cdot 8H_2O$ was synthesized according to the literature,[24] and characterized by IR spectra and TG analyses. Elemental analyses (C, H, and N) were performed with a Perkin–Elmer 2400 CHN elemental analyzer; Cr, Mo, Ce, and La were analyzed with a PLASMA-SPEC(I) ICP atomic emission spectrometer. IR spectra were recorded in the range 400–4000 cm^{-1} with an Alpha Centaurt FT/IR spectrophotometer using KBr pellets. TG analyses were performed with a Perkin–Elmer TGA7 instrument in flowing N_2 with a heating rate of 10 °C min^{-1}. The Raman spectrum was recorded at ambient temperature with a Spex 1403 Raman spectrometer with an argon ion laser at an excitation wavelength of 514.5 nm. Variable-temperature magnetic susceptibility data were obtained with a SQUID magnetometer (Quantum Design, MPMS-7) in the temperature range of 2.0–300.0 K with an applied field of 10 kG.

Synthesis of 1: In a typical synthesis procedure for **1**, first pyridine-3-carboxylic acid (0.0616 g, 0.5 mmol) and then $Ce(NO_3)_3\cdot 6H_2O$ (0.2171 g, 0.5 mmol) were dissolved in hot water (10 mL). Then an aqueous solution (10 mL) of $Na_3[CrMo_6H_6O_{24}]\cdot 8H_2O$ (0.6155 g, 0.5 mmol) was added to the above solution. The initial pH value of this mixture was 3.00. The mixture was then refluxed at 80 °C for 1 h. The filtrate was kept under ambient conditions for 2 weeks, then yellow block crystals of compound **1** were isolated in about 45% yield (0.338 g, based on Ce). $C_{12}H_{27}CeCrMo_6N_2O_{33.50}$: calcd. C 9.58, Ce 9.32, Cr 3.46, Mo 38.30, N 1.86; found C 9.33, Ce 9.50, Cr 3.23, Mo 36.61, N 1.95. FT IR: $\tilde{\nu}$ = 3368 (s), 2094 (w), 1635 (m), 1558 (m), 1461 (w), 1401 (m), 1374 (m), 1357 (m), 1304 (w), 1109 (w), 946 (s), 909 (vs), 879 (s), 838 (w), 759 (m), 690 (w), 649 (vs), 618 (w), 578 (w), 541 (w), 412 (m) cm^{-1}.

Synthesis of 2: The preparation of **2** was similar to that of **1** except that $La(NO_3)_3\cdot 6H_2O$ was used instead of $Ce(NO_3)_3\cdot 6H_2O$ (0.375 g, yield 50%). $C_{12}H_{27}CrLaMo_6N_2O_{33.50}$: calcd. C 9.59, Cr 3.46, La 9.25, Mo 38.33, N 1.86; found C 9.71, Cr 3.20, La 9.62, Mo 36.55, N 1.68. FT IR: $\tilde{\nu}$ = 3367 (s), 1633 (m), 1563 (m), 1464 (w), 1393 (m), 1303 (w), 1182 (w), 1108 (w), 946 (s), 909 (vs), 887 (s), 838 (w), 760 (m), 649 (vs), 581 (w), 411 (m) cm^{-1}.

Z	4	4
$D_{calcd.}$ [g cm^3]	2.482	2.463
μ [mm^{-1}]	3.278	3.186
R_1[a] [$I > 2\sigma(I)$]	0.0511	0.0637
wR_2[b] [$I > 2\sigma(I)$]	0.1360	0.1535

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]^{1/2}$.

X-ray Crystallography: Suitable single crystals with dimensions of $0.26 \times 0.13 \times 0.05$ mm for **1** and $0.32 \times 0.28 \times 0.03$ mm for **2** were selected for single-crystal X-ray diffraction analysis. Data were collected with a Bruker Smart Apex CCD diffractometer with Mo-K_α (λ = 0.71073 Å) at 293 K using the ω-scan technique. Empirical absorption correction was applied. Systematic absences and the statistics of intensity distribution resulted in the space group $Pmn2_1$. The structures of **1** and **2** were solved by the direct method and refined by the full-matrix least squares on F^2 using the SHELXTL-97 software.[25] All of the non-hydrogen atoms were refined anisotropically except for C22 and O37 in **1** and O4, O18, O19, and O36 in **2**. In **1**, positions of the hydrogen atoms attached to polyanions and to coordinated water molecules except for OW4 were located from difference maps, and those attached to carbon atoms were fixed in ideal positions; the hydrogen atoms attached to OW4, free OW7, and to oxygen atoms of carboxyl groups were not located. In **2**, positions of the hydrogen atoms attached to carbon atoms were fixed in ideal positions and other hydrogen atoms are not located. A summary of the crystallographic data and structural determination for **1** and **2** is provided in Table 3. Selected bond lengths and angles of **1** and **2** are listed in Tables 1 and 2, respectively. CCDC-245443 and -245641 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Structure of Nitrile-Functionalized Alkyltrifluoroborate Salts

Zhaofu Fei,[a] Dongbin Zhao,[a] Tilmann J. Geldbach,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]

Keywords: Anions / Borates / Boron / X-ray structure / Crystal engineering

Two nitrile-functionalized alkyltriflouroborate anion based complexes $[(Ph_3P)_2N][CH_3CH(BF_3)CH_2CN]$ and $[K(18\text{-crown-6})][CH_3CH(BF_3)CH_2CN]$ were synthesized and characterized by spectroscopic methods and single X-ray diffraction analysis. In the former complex no direct cation-anion (F→N or F→P) interactions are observed although F···H–C hydrogen bonds are present. In the later complex all three fluorine atoms interact with the potassium cation and C–H···F hydrogen bonds are also present. The ESI-MS spectra in methanol solution of the potassium complex show similar anion-cation aggregation to that observed for ionic liquids, and comparisons between the two complexes and ionic liquid systems are made.

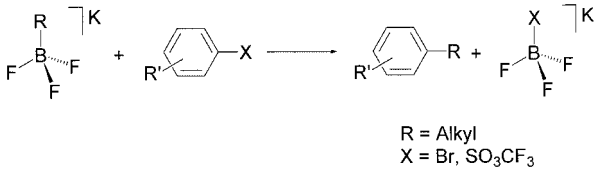
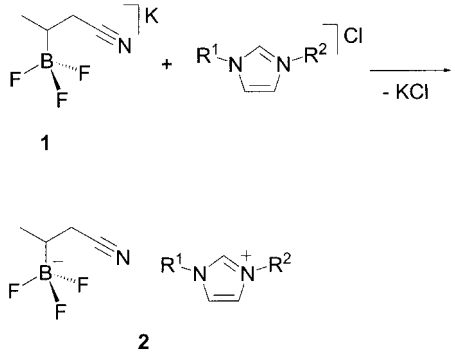
Introduction

Alkyltrifluoroborates are valuable substrates for Suzuki–Miyaura coupling reactions.[1,2] The relatively mild reaction conditions under which they react with arylhalides have made this synthetic approach a highly popular route for the generation of new C–C bonds in organic synthesis, see Scheme 1. Alkyltrifluoroborates are easily prepared on a moderate scale by the addition of KHF_2 to a variety of organoboron intermediates such as boronic acids and esters, organodihaloboranes and organodiaminoboranes, which makes them particularly attractive reagents.[1,2]



Scheme 1

Being structurally and electronically closely related to the BF_4^- anion they can be regarded as potential precursors for the formation of low-melting ionic liquids. The design and synthesis of functionalized ionic liquids is currently attracting a great deal of interest.[3,4,5] In these ionic liquid systems the emphasis lies in the modification of the cationic component, whereas the nature of the anion remains usually unchanged; typically BF_4^- and PF_6^- and to a lesser extent $SO_3CF_3^-$ and $N(SO_2CF_3)^-$ are employed. Recently, we reported on the synthesis of the first imidazolium-based ionic liquids with nitrile-functionalized alkylfluoroborate anions, see Scheme 2.[6] Even in the presence of functional groups on the imidazolium cation, these salts exhibit significantly lower melting points and viscosities relative to the well-established BF_4^- ionic liquids, an effect that has also been noted with the $CF_3BF_3^-$ anion.[7]



Scheme 2

Despite the fact that numerous alkyltrifluoroborate salts have been prepared over the years solid state structural studies of such compounds are extremely sparse. As far as we are aware, only three structures with a sp^3-carbon bound to a BF_3-fragment exist.[8] Apart from these, structures of BF_3-olefin,[9] -aryl,[10] -carbene[11] and -cyclopentadienyl[12] anions are also known.

Structural information of such alkylated trifluoroborates may help to estimate the physical properties of ionic liquids based on such anions. Thus far, efforts to gain insight into

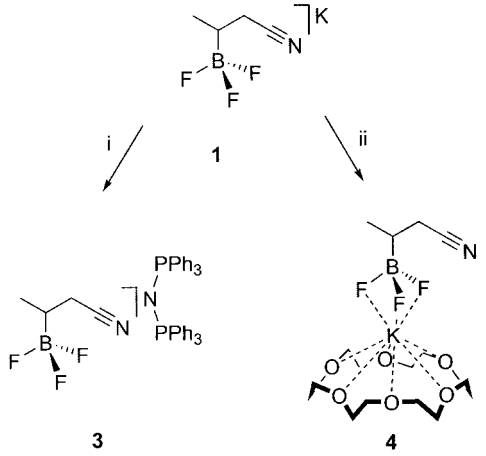
E-mail: paul.dyson@epfl.ch

their structural characteristics have been made using IR and NMR techniques on imidazolium tetrafluoroborate systems,[13] partly because the imidazolium salts with the BF_4^- anion of most interest are liquid at room temperature, which has made it difficult to obtain crystals for X-ray studies. In this paper we present structural investigations on two novel compounds based on the alkylfluoroborate anion $CH_3CH(BF_3)CH_2CN^-$, which provide clues as to how it may interact with imidazolium cations in the liquid phase. This study also illustrates the utility of crown ethers as reagents to facilitate crystallization of anions with small metal counterions which are usually difficult to crystallize.

Results and Discussion

The potassium salt $K[CH_3CH(BF_3)CH_2CN]$, **1**, prepared as a racemic mixture using the literature protocol, crystallized as thin needles which proved unsuitable for single-crystal X-ray diffraction analysis (several attempts to give useful data failed).[6] However, exchange of the potassium cation for $[(Ph_3P)_2N]^+$ or complexation with 18-crown-6 affords compounds **3** and **4**, respectively, as crystalline products that are amenable to X-ray analysis, see Scheme 3.



Scheme 3. Synthesis of compounds **3** and **4**; (i): $[N(PPh_3)_2]Cl$, CH_2Cl_2; (ii): 18-crown-6, THF

Both salts are obtained in essentially quantitative yield. In the case of **3**, the potassium chloride formed from the reaction was separated by filtration and the product obtained after removal of the solvent. This approach, viz. metathesis of a small cation for a large cation is a widely used method to facilitate crystallization of large anions and in some cases is referred to as crystal engineering.[14] For compound **4**, the product was easily obtained by mixing the potassium salt with stoichiometric amounts of 18-crown-6. This strategy essentially converts the small potassium cation into a larger entity by combining it with the crown moiety (rather than replacing it for another anion altogether), and it could prove to be an important way of generating good quality crystals as an alternative to the metathesis approach.

In this manner, the alkyltrifluoroborate anion is obtained either as the "free" anion or in the form of an ion-pair: In **3**, the charge on the cation $[(Ph_3P)_2N]^+$ is delocalized along the P–N–P unit while at the same time beingprotected by six phenyl groups, excluding direct cation-anion charge transfer, F→N or F→P. In contrast, in **4**, complexation by the 18-crown-6 macrocycle leaves the potassium cation accessible enough to interact with the fluorine atoms to form a tight ion-pair. Such potassium 18-crown-6 borate complexes are very rare, the synthesis of the BH_4-analog has been published[15] and the BF_4-salt appears in the patent literature as flame retardant for polycarbonates.[16]

The nitrile stretching frequency, υ_{CN}, is observed at 2233 cm^{-1} in **3** and at 2237 cm^{-1} in **4** [cf. **1** υ_{CN} = 2247 cm^{-1}. The ^1H NMR spectra of both **3** and **4** is of routine nature in that there are no noteworthy differences for protons belonging to the anion relative to the potassium salt **1** and the ionic liquid **2**. In [D_6]acetone, the ^{19}F chemical shift stemming from the BF_3-moiety in **3** and **4** is identical, with $^1J_{FB}$ coupling constants being also very similar, indicating that in this solvent, the cation and anion are solvolysed and do not interact significantly with each other. The electrospray ionisation (ESI) mass spectrum of **3** in methanol shows a parent peak at *m/z* 538 in positive ion mode for the $[(PPh_3)_2N]^+$ cation and *m/z* 136 in the negative ion mode for the $[CH_3CH(BF_3)CH_2CN]^-$ anion. Anion-cation aggregations were observed in neither the positive nor negative spectra in the concentration range of 5–50 ppm. In contrast, the ESI mass spectrum of **4** exhibits some concentration dependence, see Figure 1. At low concentration, ca. 5 ppm, a peak at *m/z* = 303 corresponding to the monomeric cation $[K(18\text{-crown-6})]^+$ dominates, whereas at higher concentration, ca. 50 ppm, the aggregate $[K(18\text{-crown-6})]_2$-$[CH_3CH(BF_3)CH_2CN]$ gives rise to the base peak at *m/z* 742.

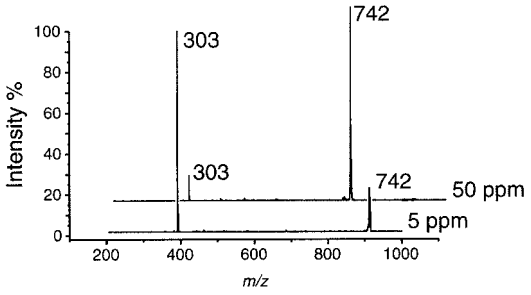


Figure 1. ESI-MS spectrum of **4** in methanol at concentrations of 5 and 50 ppm

Structural Characterization of 3 and 4

The few known structures for alkyltrifluoroborates comprise the potassium salts $K[CF_3BF_3]$[8a] and $K[CH_3BF_3]$[8b] which exhibit extensive potassium-fluorine interactions with K–F distances as short as 2.678(1) Å. The structure of the zwitterionic compound $BF_3CH_2S(O)(CH_3)_2$ has also been reported.[8c]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Single crystals of **3** and **4** suitable for X-ray diffraction studies were grown at –21 °C from dichloromethane-diethyl ether and THF-diethyl ether solution, respectively. The structures of **3** and **4** are illustrated in Figure 2 and Figure 3, respectively, with key bond parameters in the captions. Details of the data collection and the structure determination are provided in the Experimental. There is negligible disorder in the anion of **3**, involving carbon atoms C2 and C3, whereas in **4** there is considerable disorder in the anion, where carbon atoms C2 and C4 are split over two positions with almost identical occupation factors.

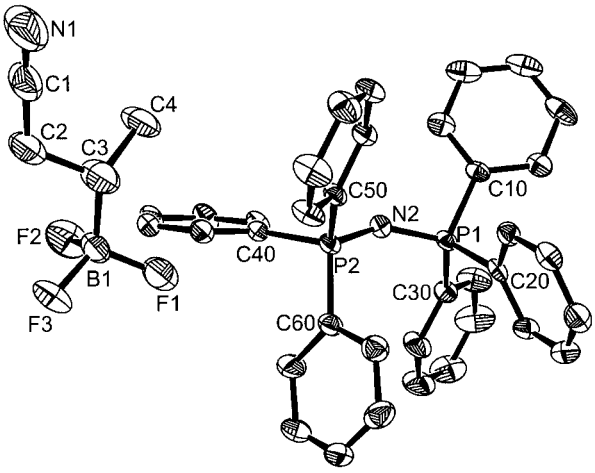

Figure 2. ORTEP-plot of **3** with ellipsoids drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: F1–B1 1.385(5), F2–B1 1.427(5), F3–B1 1.412(5), B1–C3 1.585(6), P1–N2 1.574(3), P2–N2 1.570(3), C1–N1 1.112(6); F1–B1–C3 110.7(3), F2–B1–C3 112.0(3), F3–B1–C3 110.9(4), C2–C3–C4 109.9(4), P1–N2–P2 142.8(2)

In compound **3** the anion adopts a staggered conformation about the B1–C3 bond with an alignment of F1 *anti* to the C3–C2 bond and F3 *anti* to the C3–C4 bond. This conformation influences the B–F distances, which are shorter for F1 and F3 [1.385(5) and 1.412(5) Å, respectively], than for F2 [1.427(5) Å]. In addition, the F2–B1–C3 angle is slightly larger, 112.0(3)°, but all bonding angles around B1 are within 5° of the ideal tetrahedral angle. All fluorine atoms are engaged in intra- and intermolecular hydrogen bonding with H–F distances as short as 2.386 Å (to F1). The B1–C3 distance of 1.585(6) Å is of the same order as in $K[CH_3BF_3]$, viz. 1.575(3) Å,[8b] and markedly shorter than in $BF_3CH_2S(O)(CH_3)_2$, 1.650(2) Å,[8c] reflecting the presence of a localized negative charge on the boron atom. The nitrile moiety, which exhibits a somewhat short C≡N distance of 1.112(6) Å, points away from the fluorine atoms, being almost parallel to the B1–C3 bond. This alignment is probably due to both electrostatic repulsion from the electronegative fluorine atoms and to interactions with phenyl-hydrogen atoms, which come as close as 2.567 Å to N1. The structure of the $[PPN]^+$ cation agrees well with the data reported elsewhere.[17,18] The P–N distances, 1.574(3) Å and 1.570(3) Å, are as expected; the P–N–P angle, 142.8(2)°, is slightly larger than frequently observed but still within the normal range. No close intermolecular contacts to N2 are present.

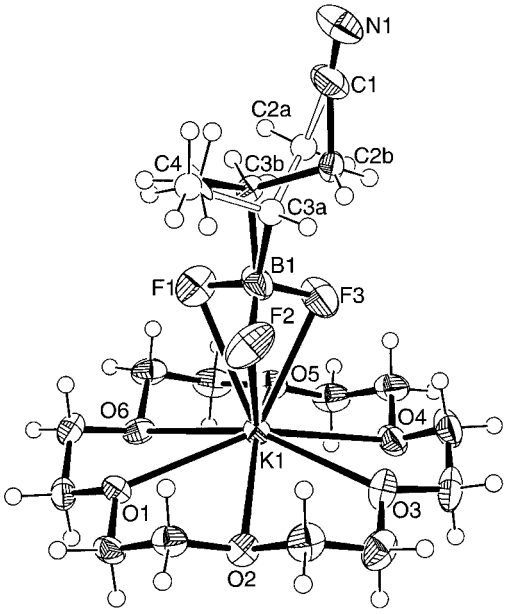

Figure 3. ORTEP-plot of **4** showing the disorder in the alkane moiety; ellipsoids drawn at the 50% probability level. Selected bond lengths [Å]: F1–B1 1.401(3), F2–B1 1.407(3), F3–B1 1.422(3), K1–F1 2.782(1), K1–F2 2.929(1), K1–F3 2.766(1), K1–O1 2.843(1), K1–O2 2.939(1), K1–O3 2.792(2), K1–O4 2.929(2), K1–O5 2.802(2), K1–O6 2.912(1)

Only few structures exist in which a potassium cation is complexed to both a crown ether and fluorine atoms. Most of these salts contain perfluorated silicates as anions,[19] but structures with, for example, hexafluorophosphate[20] and pentafluoroalkyne tungstenate[21] are also known. In addition, a KF adduct of a 21-membered crown ether containing six oxygen atoms and a tethered boronic acid moiety has also been reported.[22] Yet, complex **4** represents the first example of a structure in which a perfluorated boron moiety interacts with a potassium crown ether complex.

Due to the above mentioned disorder, which affects carbon atoms C2 and C4 in the anion in **4**,no quantitative comparison of the anionic structure with **3** is possible. As in **3**, F3 is *anti* to the C3–C4 bond, but the orientation of the C3–C2 bond relative to the fluorine atoms in not unambiguously clear. Despite interaction of the fluorine atoms with the potassium ion, no significant elongation of the B–F bond distances are observed, which range from 1.401(3) to 1.422(3) Å.

The potassium ion lies 0.450 Å above the mean plane defined by the three oxygen atoms O1, O3 and O5 and 0.844 Å above the mean plane defined by the three oxygen atoms O2, O4 and O6. The K–O bonds can accordingly be divided into two groups of three with shorter distances to O1, O3 and O5 [range 2.792(2) to 2.843(2) Å], and longer distances to O2, O4 and O6 [range 2.912(1) to 2.939(1) Å], which is in good agreement with a comparable structure.[23]

The fluorine atoms interact with both intra- and intermolecular hydrogen atoms. Yet, as a result of the bulky

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

crown ether moiety only five intermolecular hydrogen bonds below 3 Å to the fluorine atoms are present, see Figure 4. Such F→H–C hydrogen bonding is very common in imidazolium based systems, where it has been probed by IR and NMR spectroscopic methods, but seldom by single-crystal X-ray analysis.[13] The cation and anion in **4** are held in place by potassium-fluorine interactions with two shorter bonds [2.766(1) and 2.782(1) Å], and one longer bond [2.929(1) Å]. These distances are of the same order as in crystals of potassium tetrafluoroborate[24] and the asymmetry of the bonding is comparable to a related fluorosilicate complex.[19a]

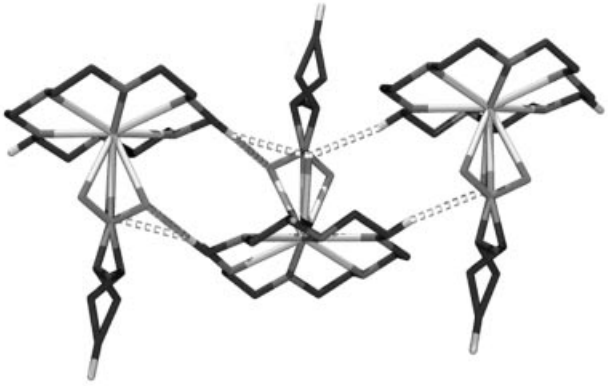

Figure 4. Crystal packing in compound **4**, showing intramolecular hydrogen bonding interactions below 3 Å to the fluorine atoms. For clarity, only those hydrogen atoms involved in the H-bonding are shown

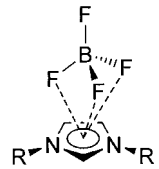
In the context of ionic liquid chemistry it is not unreasonable to propose a similar interaction e.g. with the fluoroborate straddling the face of the imidazolium ring as shown in Scheme 4. This kind of interaction might provide additional rational for the low melting points observed in such compounds in that the intermolecular van-der-Waals forces and C–H···F hydrogen bonding interactions would be reduced.[25]



Scheme 4

In conclusion, the structural studies reported herein provide insight into the bonding characters and substitution effect of one of the F atoms in the BF_4^- anion by a functional group. The information gained is relevant to the Suzuki–Miyaura reaction and to the functionalization of ionic liquid anions. Crown ethers have been used as competitors for ion immobilization in ionic liquids[26] and to increase the solubility of amino acids in ionic liquid,[27]but their function herein was as a crystallization aid, an approach that has been used for some time in crystal engineering.[28]

Experimental Section

The potassium salt **1** was prepared following a published method.[6] Bis(triphenylphosphanyl)iminium chloride and 18-crown-6 were purchased from Aldrich and were used as received. The synthesis of compound **3** was carried out in an inert atmosphere of dry nitrogen and the synthesis of **4** was performed without precautions to exclude air or moisture. IR spectra were recorded on a Perkin–Elmer FT-IR 2000 system. NMR spectra were measured on a Bruker DMX 400 spectrometer. Chemical shifts, δ, are given in ppm and coupling constants, *J*, in Hz. Electrospray ionization mass spectra (ESI-MS) were recorded on a ThermoFinnigan LCQ™ Deca XP Plus quadrupole ion trap instrument on samples diluted in methanol. Samples were infused directly into the source at 5 μL min^{-1} using a syringe pump, the spray voltage was set at 5 kV and the capillary temperature at 50 °C.[29] Elemental analysis were carried out at the Institute of Molecular and Biological Chemistry at the EPFL.

Synthesis of $[(PPh_3)_2N][CH_3CH(BF_3)CH_2CN]$ (3): A mixture of the potassium salt **1** (175 mg, 1.0 mmol) and bis(triphenylphosphanyl)-iminium chloride (574 mg, 1.0 mmol) in dichloromethane (10.0 mL) was stirred at room temperature for 24 hours. The reaction mixture was filtered and the solid washed with dichloromethane (2 × 5.0 mL). The filtrates were combined and the solvent removed under reduced pressure to give the pure product. Yield: 654 mg, 97%, m.p. 140 °C. ESI-MS (MeOH) positive ion *m*/*z*, 538, $[(PPh_3)_2N]^+$; negative ion, 136, $[CH_3CH(BF_3)CH_2CN]^-$. IR (cm^{-1}) 3060 (m), 2938 (m), 2864 (m), 2233 (m), 1588 (m), 1482 (m), 1438 (str.), 1281 (m), 1243 (str.), 1209 (m), 1110 (str.), 1050 (m), 995 (str.), 933 (m),, 910 (m), 802 (m), 721 (str.). ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 7.85–7.68 (m, 18 H), 7.64 –7.55 (m, 12 H); 2.38 (dd, 1 H, ^2J(H,H) = 17.2, $^3J_{H,H}$ = 3.0), 1.85 (dd, 1 H, $^2J_{H,H}$ = 17.0, $^3J_{H,H}$ = 12.0), 0.92 (d, 3 H, $^3J_{H,H}$ = 6.8), 0.59 (m, 1 H).[31] P NMR (161 MHz, [D$_6$]acetone): δ = 21.1 (s). ^{19}F NMR (282 MHz, [D$_6$]acetone): δ = –151.5 (q, $^1J_{FB}$ = 60). $C_{40}H_{36}BF_3N_2P_2$ (674.48): C 71.23, H 5.38, N 4.15; found: C 71.31, H 5.41, N 4.13.

Synthesis of $[K(18\text{-crown-}6)][CH_3CH(BF_3)CH_2CN]$ (4): A mixture of potassium salt **1** (175 mg, 1.0 mmol) and 18-crown-6 (264 mg, 1.0 mmol) in THF (10.0 mL) was stirred at room temperature for 24 hours. The solvent was removed under reduced pressure to give the product in pure form. Yield: 435 mg, 99%, m.p. 145 °C. ESI-MS (MeOH) positive ion, *m*/*z* 303 $[C_{12}H_{24}O_6K]^+$; negative ion, 136, $[CH_3CH(BF_3)CH_2CN]^-$. IR (cm^{-1}) 2899 (str.), 2826 (w), 2237 (m), 1589 (w), 1479 (str.), 1458 (m), 1438 (m), 1351 (str.), 1286 (m), 1249 (str.), 1100 (str.), 1008 (str.), 962 (str.). 931 (m), 838 (m), 720 (m). ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 3.62 (s, 24 H, OCH_2), 2.38 (dd, 1 H, $^2J_{H,H}$ = 17.1, $^3J_{H,H}$ = 3.3), 1.93 (dd, 1 H, $^2J_{H,H}$ = 17.0, $^3J_{H,H}$ = 12.1), 0.93 (d, 3 H, $^3J_{H,H}$ = 6.9), 0.59 (m, 1 H). ^{19}F NMR ([D$_6$]acetone, 282 MHz): δ = –151.5 (q, $^1J_{FB}$ = 59). $C_{16}H_{30}BF_3KNO_6$ (439.32) (%): C 43.74, H 6.88, N 3.19; found: C 43.80, H 6.91, N 3.18.

Structural Characterisation of 3 and 4: Crystals of **3** suitable for X-ray diffraction studies were obtained at –21 °C from in dichloromethane/diethyl ether (1:1) solution, those of **4** (Table 1) under similar conditions from THF/diethyl ether (1:5). Single crystals were mounted on a KUMA KM4/Sapphire CCD diffractometer. Data reduction was performed using CrysAlis RED.[30] Structure solution and refinement was performed using the SHELX97 software package,[31] graphical representations of the structures were made with ORTEP32.[32] Structures were solved by direct methods and successive interpretation of the difference Fourier maps, followed by full-matrix least-squares refinement (against F^2). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were

From Dinuclear Zirconium(+3)-Phosphido Complexes {[$Cp_2ZrP(H)R]_2$} to the First Neutral Zirconocene–Phosphinidene Dimers [$(Cp_2ZrPR)_2$] by P–H Dehydrogenation

Matthias Driess,*[a] Joachim Aust,[b] and Klaus Merz[b]

Dedicated to Professor Michael Veith on the occasion of his 60th birthday

Keywords: Antiferromagnetic coupling / Phosphido complexes / Silylphosphanes / Zirconium / Phosphorus / P–H bonding activation

The syntheses and structures of the new zirconium(+3) silylphosphanido complexes {[$Cp_2ZrP(H)R]_2$} **1a** {Cp = η^5-C_5H_5; R = $SiMe_2C(i\text{Pr})Me_2$}, **1b** (R = $Si i\text{Pr}_3$), and **1c** (R = SiF(*t*Bu)(2,4,6-$i\text{Pr}_3C_6H_2$) are reported. The latter are easily accessible by the reaction of the lithium salts of the corresponding primary silylphosphanes with the Schwartz reagent [$Cp_2Zr(H)Cl$] in THF at –70 °C. They can be isolated in the form of diamagnetic red-black crystals in 68–85 % yield. The central structural motif of the complexes consists of planar (**1a**, **1b**) and slightly puckered Zr_2P_2 rings (**1c**), and contains two d^1-Zr(+3) centers, which are antiferromagnetically coupled (super exchange, through-bond interaction) although the transannular Zr–Zr separation is around 360 pm. Thus, the compounds have a biradicaloid electronic structure. Heating of solutions of **1a–c** in toluene in the presence of Pd/C or [$(Ph_3P)_2Pt(C_2H_4)$] results in catalytic dehydrogenation of the P–H bonds, affording the first neutral zirconocene–phosphinidene dimers [$Cp_2ZrPR]_2$ **3a–c** in the form of deep red crystals in 72–88 % yield. The composition of the products is proven by multinuclear NMR spectroscopy, mass spectrometry and correct C,H-combustion analyses. The molecular structures of **3a** and **3c** were additionally confirmed by X-ray crystal structure analyses, showing that they consist of Zr_2P_2 rings with significantly shorter Zr–P distances than those observed in **1a** and **1c**. Interestingly, the dehydrogenation of the mostly sterically crowded derivative **1c** occurs also in boiling toluene solutions without using a catalyst, but the process is prevented in a H_2 atmosphere. This suggests that the Zr(+3) centers in **1c** can serve as active sites for the P–H bonding activation, which, however, are deactivated in the presence of H_2.

Introduction

Metallocene dihalides of the group 4 transition metals (Ti, Zr, Hf) tend to undergo halogen-reductive substitution by reaction with lithium phosphanides. This has been impressively shown by the reaction of zirconocene dihalides with lithium salts of primary and secondary phosphanes which leads solely to the corresponding dinuclear μ_2-phosphanido-bridged zirconium complexes **A** having two Zr(+3) centers (Scheme 1).[1–4] Although the complexes **A** bear two Zr(+3) atoms with a d^1 electronic configuration and possess relatively large Zr–Zr distances ranging between 381 and 355 pm, they are diamagnetic because of strong "through-space" interactions ($d_{z^2-dz^2}$ bond) and "super exchange" (through ligand coupling) as confirmed by ab initio calculations.[5–7] Alternatively, derivatives of **A** with small organic groups at phosphorus are also formed by oxidative addition of tetraorgano-substituted diphosphanes onto the Zr(+2) centers of two zirconocene molecules, generated in situ by reduction of [Cp_2ZrCl_2] with elemental Mg (Scheme 1).[8]

The preference of other zirconocene derivatives to undergo redox processes [Zr(+4) → Zr(+3)] toward primary and secondary phosphanes is also distinctive for related zirconocene hydrido complexes. Thus, reaction of [$Cp_2Zr(H)Cl$] (Schwartz reagent) with primary phosphanes RPH_2 affords in several ligand-exchange and redox processes **A′**, zirconocene dichloride and the respective diphosphane $R_2P_2H_2$ (Scheme 1).[9] To our surprise, and in contrast to the well-established class of dinuclear Zr(+3) phosphido complexes **A**, related complexes of type **B**, bearing two Cp_2Zr moieties and two μ_2-PR (phosphinidene) bridging ligands, are elusive. They represent dimers of zirconocene–phosphinidene complexes [Cp_2Zr = PR] which are also difficult to detect. Stephan et al. reported in 1991 the first

phosphinidene-bridged zirconocene complex **C**[4] and in 1993 the first isolation of the donor-stabilized zirconocene–phosphinidene complex $Cp_2Zr(PMe_3)$=PR (R = 2,4,6-$C_6H_2tBu_3$) **D**[10] and of the dinuclear complex anion **E** with mixed-valent Zr(+3) atoms (Figure 1).[9,11,12]

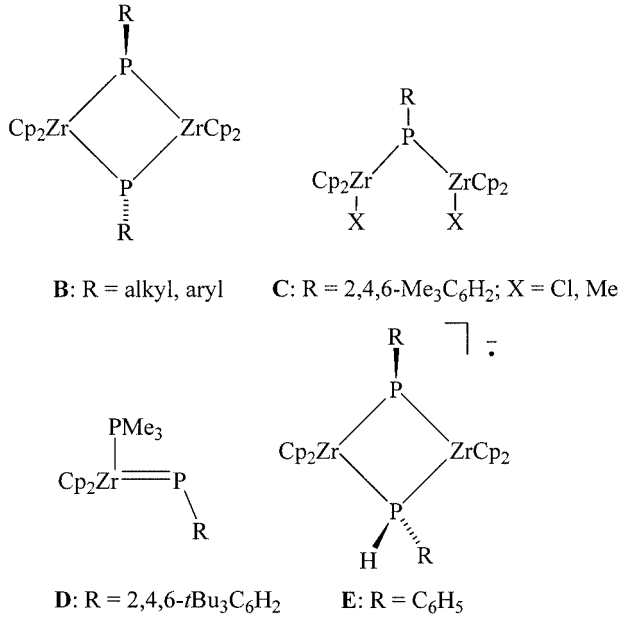

Figure 1. Structural types of zirconocene–phosphinidene complexes.

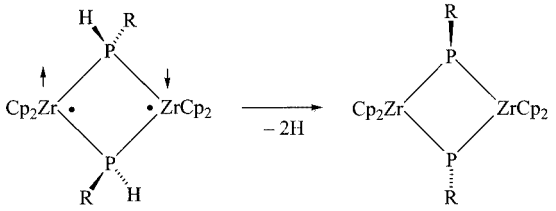
One possibility to synthesize dimeric zirconocene–phosphinidene complexes **B** can be envisioned as the catalytic dehydrogenation of complexes **A** [Equation (1)]. Since the P–H bonds in silylphosphanes are more reactive than those in organophosphanes, we set out to prepare a series of new dinuclear P–H functionalized silylphosphido Zr(+3) complexes **A**, which appeared to be suitable for P–H dehydrogenation experiments according to Equation (1). We report here the synthesis and structural characterization of the latter and their successful conversion into the corresponding dimeric zirconocene–phosphinidene complexes **B**.



Results and Discussion

Synthesis and Structures of 1a–1c

The new bulkily substituted dinuclear Zr(+3) silylphosphanido complexes **1a**–**1c** are easily accessible in 78 (**1a**), 68 (**1b**), and 85% yield (**1c**), by conversion of $[Cp_2Zr(H)Cl]$ with the corresponding lithium silylphosphanides **2a**–**2c** in THF at –70 °C. The complexes were isolated in the form of black-red crystals, which are well soluble in aprotic aromatic solvents. Although the mechanism of the reaction is unknown and no intermediate could be detected by means of NMR spectroscopy, we assume that the initial product is the respective zirconocene-hydrido-phosphanide, which subsequently undergoes dehydrogenative dimerization to the final products **1a**–**1c** [Equation (2)]. The diamagnetic complexes have been characterized by multinuclear NMR spectroscopy and correct elemental analyses. The ^{31}P NMR spectra exhibit doublets relatively upfield with respect to *P*-alkyl-substituted derivatives **A**,[4,9,13] because of the σ-donor effect of the silyl group. However, the magnitudes of $^1J(^{31}P\text{-}^1H)$ coupling constants [236 Hz (**1a**), 228 Hz (**1b**), and 255 Hz (**1c**)] reflect identical electronic features for the P–Zr donor-acceptor bonds. The ^1H NMR spectra of **1a**–**1c** show only one type of C_5H_5 "Cp" protons, which suggests *trans* configuration or fast configurational inversion of the coordinated P atoms. The presence of dynamic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

exchange processes seems unlikely because the VT ^{1}H and ^{31}P NMR spectra are invariant from –75 to +80 °C. In fact, the preference for the *trans* configuration of the silyl groups at phosphorus is confirmed by single-crystal X-ray diffraction analyses (Figure 2, Table 1). The P atoms in **1a**–**1c** have distorted tetrahedral coordinates, and the position of the P–H hydrogen atoms could be localized from the difference Fourier map and refined. The four-membered Zr_2P_2 ring is planar in **1a** and **1b**, but slightly puckered in the case of **1c** (Zr_2P/Zr_2P' angle 3.8°) because of the larger steric demand of the silyl group.

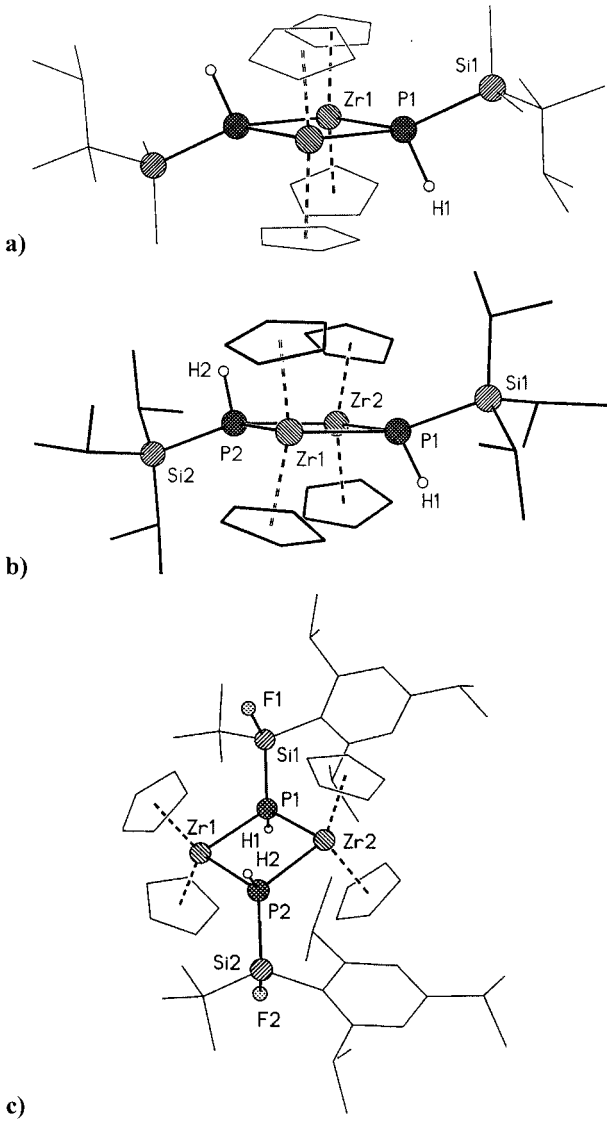


Figure 2. Molecular structures of **1a** (a), **1b** (b), and **1c** (c); the H atoms of the organic groups are omitted for clarity.

This is in contrast to other derivatives with *cis* configuration of the substituents at phosphorus, with folding-angles up to 30.6°.[13] The Zr–P distances as well as the endocyclic Zr–P–Zr and P–Zr–P angles are inconspicuous and practically identical with those in *P*-alkyl-substituted derivatives and related phosphanido-bridged Zr(+3) complexes.[4,5,9,13] The most remarkable geometrical feature is the relatively large Zr–Zr′ separation of 3.64 (**1a**), 3.57 (**1b**), and 3.61 (**1c**), which shows that there is no common transannular bonding between the d^1-Zr centers although the compounds are diamagnetic (singlet ground-state) due to antiferromagnetic coupling by ligand-mediated superexchange. Similar distances were observed in related *P*-alkyl-substituted derivatives.[9,13] According to results of ab initio calculations,[6] the extension of the transannular Zr–Zr distance results from two opposite effects: attractive Zr–Zr through-bond versus repulsive ligand-ligand interactions at the Zr and P atoms. In other words, the hypothetical form **1′** with a "short" Zr–Zr distance and a butterfly-like structure possesses much higher ring strain than the "bond-stretch" isomer **1** (Scheme 2).

Table 1. Selected distances [pm] and angles [°] for **1a**, **1b**, and **1c**.

1a	1b	1c
Zr1–P1 265.7(1)	Zr1–P1 268.0(1)	Zr1–P1 270.0(1)
		Zr1–P2 268.9(1)
P1–Si1 225.4(2)	P1–Si1 228.5(1)	P1–Si1 225.3(2)
Zr1–Zr1A 364.2(3)	Zr1–Zr1A 357.3(3)	Zr1–Zr2 360.8(2)
		Si1–F1 161.9(2)

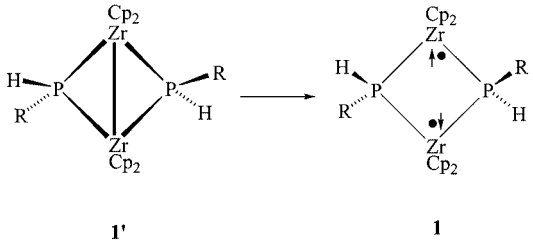
		Zr1–P1–Zr2 84.10(4)
		Zr1–P2–Zr2 84.15(3)



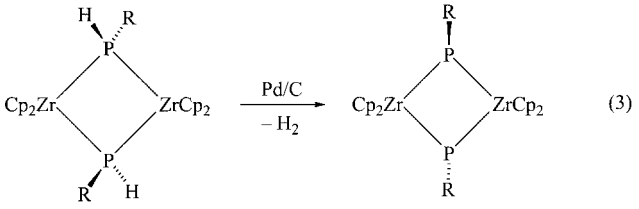
Scheme 2. Bond-stretch isomerization of **1′** to the biradicaloid **1**.

While this situation is widespread in multinuclear transition-metal complexes with unpaired electrons, similar structural and electronic features are scarce in main-group chemistry. The first iso(valence)electronic main-group metal analog, the Sn_2N_2-heterocyclobutane $[ClSn–N(SiMe_3)]_2$, which also has a biradicaloid structure and a singlet ground state, has been discovered only recently.[14]

Formation of the Dimeric Zirconocene–Phosphinidene 3a–3c by P–H Dehydrogenation of 1a–1c

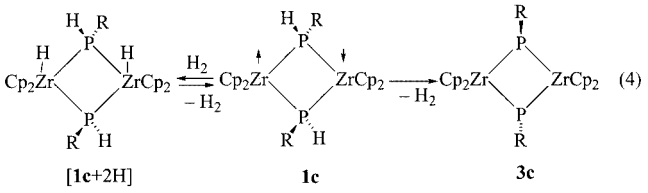
Since the P–H bond in silylphosphanes is more reactive with regard to homolytic and heterolytic fission than that in organophosphanes, we expect that the P–H bonds in **1a**–**1c** can be dehydrogenated by typical dehydrogenation catalysts, leading to the first zirconocene–phosphinidene dimers. In fact, heating of solutions of **1a**–**1c** in toluene at 70 °C in the presence of Pd/C as a dehydrogenation catalystfurnishes the first neutral zirconocene–phosphinidene dimers **3a**–**3c** in good yields [Equation (3)]. Instead of Pd/C, the Pt complex $[(Ph_3P)_2Pt(C_2H_4)]$ can also be used as a catalyst (10^{-2} mol-%).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



(3)

The dehydrogenation is completed after about 8 h and its progress can be monitored by ^{31}P NMR spectroscopy. Surprisingly, the dehydrogenation of the mostly sterically crowded derivative **1c** occurs also in boiling toluene solutions without using a catalyst. This irreversible process is complete after 24 h. In line with that, **3c** is inert toward H_2 in boiling toluene in a sealed tube. However, the conversion of **1c** into **3c** is hampered in a sealed tube or in H_2/D_2 gas at 1 atm without P–H/P–D exchange. Although the mechanism is still unknown we assume the dehydrogenation process involves the Zr(+3) centers as active sites. Apparently, the latter are deactivated in the presence of H_2, affording [**1c** + 2 H] as transient species in a reversible reaction [Equation (4)]. It should be mentioned here that compounds of the type [**1** + 2 H] are also possible transient species for the synthesis of **1a**–**c** [see Equation (2)] but they could not yet be detected.



(4)

The ^{31}P nucleus in **3a** (δ = 238.9 ppm) **3b** (δ = 229.8 ppm) and **3c** (δ = 260.3 ppm) undergoes a drastic downfield shift of $\Delta\delta$ = 337.5 (**3a**), 362.3 (**3b**) and 346.6 ppm (**3c**), respectively. The strong deshielding of the ^{31}P nucleus is characteristic for μ_2-bridging phosphinidene ligands and reflects a higher contribution of the paramagnetic term to the chemical shift.[15] The ^{31}P chemical shifts of **3a**–**3c** are similar to the values of the hitherto only known neutral zirconium phosphinidene complexes **C** (δ = 325.5, 303.0 ppm; see Figure 1).[4,16] The ^{1}H, ^{31}P, and ^{13}C NMR spectra of the products clearly indicate that there is only one configurational isomer present in solution even at low (–75 °C) and high temperatures (+85 °C). The composition of the novel complexes were confirmed by mass spectrometry and correct elemental analyses. In the cases of **3a** and **3c**, the molecular structures were established by X-ray diffraction analyses (Figure 3, Table 2). Compounds **3a** and **3c** crystallize in the monoclinic space group $P2_1/c$ and in the orthorhombic space group *Pbca*, respectively.

Table 2. Selected bond lengths [pm] and angles [°] for **3a** and **3c**.

3a	**3c**
Zr1–P1 259.8 (3)	Zr1–P1 265.2 (4)
Zr1–P1A 261.7 (4)	Zr1–P2 263.0 (4)
P1–Si1 223.4 (5)	P1–Si1 220.8 (4)
Zr1–Zr1A 372.5 (1)	Zr1–Zr2 372.8 (2)
	Si1–F1 162.3 (8)
P1–Zr1–P1A 88.8 (1)	P1–Zr1–P2 89.7 (1)
Zr1–P1–Zr1A 91.2 (1)	P1–Zr2–P2 89.7 (1)
Zr1–P1–Si1 130.6 (2)	Zr1–P1–Zr2 89.6 (1)
Zr1A–P1–Si1 124.4 (2)	Zr1–P2–Zr2 90.0 (1)
	Zr1–P1–Si1 123.0 (2)
	Zr2–P2–Si2 124.3 (2)

Similar to the geometrical features of **1a** and **1c**, the Zr_2P_2 ring is planar in **3a** but is slightly puckered in **3c** because of steric repulsion (folding angle Zr_2P/Zr_2P' 10.6°). The P atoms have distorted pyramidal coordinates, with the sum of bonding angles amounting to 346.3 (**3a**), and 335.1 and 337.4° (**3c**). As expected, the Zr–P separations in **3a** [259.8(3), 261.7(4) pm] and **3c** [263.0(4), 265.2(4) pm] are significantly shorter than those for the Zr–P single bonds in **1a** [265.7(1) pm] and **1c** [268.9(1), 270.0(1) pm]. The values are between those of the Zr–P single bonds in **C** [264.8(3), 264.3(2) pm] and the Zr=P double bond in D [250.5(4) pm] but similar to the values observed for the re-

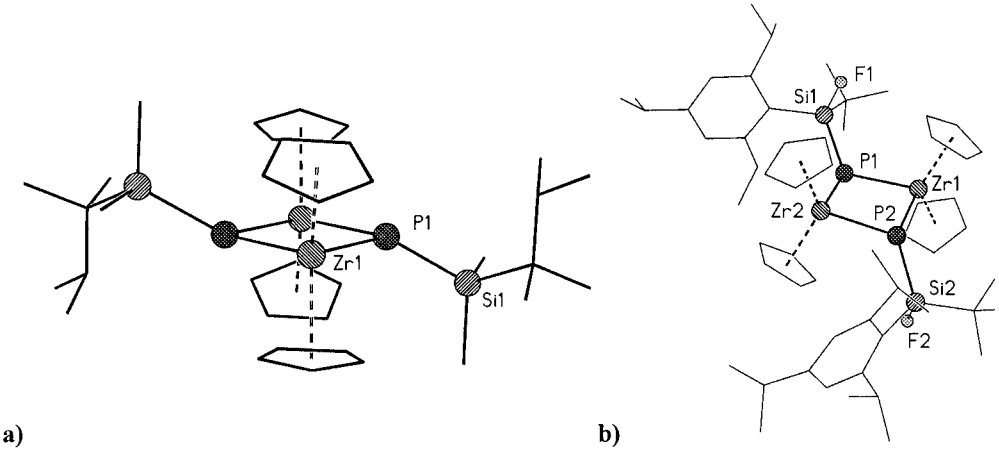


Figure 3. Solid-state structure of **3a** (a) and **3c** (b); H atoms are omitted for clarity.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lated anionic zirconocene–phosphinidene dimer **E** [259.1(5), 256.8(5) pm] (see Figure 1). The transannular Zr–Zr separations in **3a**, and **3c** are approximately 10 pm longer than in the precursors **1a**, and **1c**, but practically identical with the values in **E**.

Conclusions

The dinuclear zirconium(+3) silylphosphanido complexes **1a**–**c** are suitable precursors for the synthesis of the first neutral zirconocene–phosphinidene dimers **3a**–**c**. The latter do not tend to dissociate in hot toluene solutions because of strong Zr–P σ bonds and partial P–Zr π-donor interactions. The desired dehydrogenation of the P–H bonds in **1a**–**c** is an irreversible process which succeeds in the presence of the well-known dehydrogenation catalysts Pd/C and $[(Ph_3P)_2Pt(C_2H_4)]$, and is certainly relieved by the sterically crowded organosilyl groups. Particularly noteworthy is the fact that **1c** undergoes voluntary dehydrogenation even without a catalyst; but the conversion is prevented in the presence of relatively high concentrations of H_2. The results suggest that the Zr(+3) centers in **1c** serve as active sites in the P–H bonding activation process. However, further (kinetic) studies are necessary in order to establish the mechanism. The results led also to the challenging questionywhether or not other Zr(+3) compounds could also be employed as efficient dehydrogenation reagents or catalysts for primary and secondary phosphanes. Respective investigations are currently in progress.

Experimental Section

General Remarks: All manipulations were carried out at anaerobic conditions under dry argon using standard Schlenk techniques. Solvents were refluxed over an appropriate drying agent, distilled and degassed prior to use. NMR spectra were recorded in C_6D_6 at ambient temperature with a Bruker Avance250 spectrometer operating at 250.1 MHz (^{1}H), 101.3 MHz (^{31}P), and 235.4 MHz (^{19}F). Chemical shifts were reported relative to TMS (^{1}H), 85% aqueous H_3PO_4 (^{31}P), and $CFCl_3$ (^{19}F) at δ = 0 ppm. EI-MS measurements were recorded with a Varian MAT CH7 spectrometer at 70eV. Combustion analyses were performed at the Analytical Service Laboratory of the Faculty of Chemistry in Bochum with a CHNO Rapid instrument (Heraeus).

Preparation of $\{(\eta^5\text{-}C_5H_5)_2ZrP(H)SiMe_2C(i\text{Pr})Me_2\}_2$ (1a): A solution of $LiP(H)SiMe_2C(i\text{Pr})Me_2$ (8.79 mmol, freshly prepared from the corresponding silylphosphane with BuLi in THF at –78 °C) in THF (30 mL) was slowly added to a suspension of $[(\eta^5\text{-}C_5H_5)_2Zr(H)Cl]$ (2.26 g, 8.79 mmol) in THF (50 mL) at –70 °C. The reaction mixture was allowed to warm up to room temperature within 8 h and subsequently all volatile components were evaporated off in vacuo (10^{-3} Torr). The solid residue was redissolved in toluene (70 mL), filtered, and the clear red solution was concentrated to about 30 mL to give, after 1d at –20 °C, deep red crystals of **1a**. Yield: 2.7 g (3.43 mmol, 78%). ^{1}H NMR: δ = 4.92 (s, 20 H, C_5H_5), 2.18 [sept, 2 H, $^3J_{H,H}$ = 6.9 Hz, C*H*(CH$_3$)$_2$], 1.26 [s, 12 H, C(C*H*$_3$)$_2$], 1.09 [d, 12 H, $^3J_{H,H}$ = 7.0 Hz, CH(C*H*$_3$)$_2$], 0.51 [s, 12 H, Si(C*H*$_3$)$_2$] ppm. ^{31}P NMR: δ = –106.6 (d, $^1J_{P\text{-}H}$ = 236.8 Hz) ppm. MS: *m*/*z* (%) = 791 [M-H$_2$]$^+$ (1), 708 [M-C(*i*Pr)Me$_2$]$^+$ (1), 621 [791 – 2{C(*i*Pr)Me$_2$}]$^+$ (0.8), 563 [621 – SiMe$_2$]$^+$ (0.8), 85 [C(*i*Pr)Me$_2$]$^+$ (58), 73 [SiMe$_3$]$^+$ (85), 43 [*i*Pr]$^+$ (100). $C_{36}H_{60}P_2Si_2Zr_2$ (793.4): calcd. C 54.50, H 7.60; found C 54.40, H 7.70.

Preparation of $\{(\eta^5\text{-}C_5H_5)_2ZrP(H)Si i\text{Pr}_3\}_2$ (1b): The compound was prepared by a procedure similar to that for **1a**, using the corresponding silylphosphane (2.15 mmol) as starting material. Crystallization in toluene afforded red crystals of **1b**. Yield: 0.6 g (0.73 mmol, 68%). ^{1}H NMR: δ = 4.92 (s, 20 H, C_5H_5), 1.28 [d, 36 H, $^3J_{H,H}$ = 6.8 Hz, CH(C*H*$_3$)$_2$], 1.06 [sept, 6 H, $^3J_{P\text{-}H}$ = 6.9 Hz, C*H*(CH$_3$)$_2$] ppm. ^{31}P NMR: δ = –132.6 (d, $^1J_{P\text{-}H}$ = 228 Hz) ppm. MS: *m*/*z* (%) = 819 [(M-H$_2$)$^+$, 1], 157 [(Si(*i*Pr)$_3$)$^+$, 100], 115 [Si(*i*Pr)$_2$)$^+$, 78], 43 [(*i*Pr)$^+$, 40]. $C_{38}H_{64}P_2Si_2Zr_2$ (821.5): calcd. C 55.55, H 7.85; found C 55.43, H 7.80.

Preparation of $\{(\eta^5\text{-}C_5H_5)_2ZrP(H)SiF(t\text{Bu})(2,4,6\text{-}i\text{Pr}_3C_6H_2)\}_2$ (1c): The compound was prepared by a procedure similar to that for **1a**, using the corresponding fluorosilylphosphane (2.3 mmol) as starting material. Crystallization in toluene afforded prismatic-shaped black crystals of **1b**. Yield: 1.1 g (0.98 mmol, 85%). ^{1}H NMR: δ = 7.33 (s, 4 H, *m*-*H*), 5.08 (s, 20 H, C_5H_5), 3.97 [sept, 4 H, $^3J_{H,H}$ = 6.9 Hz, *o*-C*H*(CH$_3$)$_2$], 2.94 [sept, 2 H, $^3J_{H,H}$ = 6.9 Hz, *p*-C*H*(CH$_3$)$_2$], 1.57 [s, 18 H, C(C*H*$_3$)$_3$], 1.43 [d, 12 H, $^3J_{H,H}$ = 6.9 Hz, *p*-CH(C*H*$_3$)$_2$], 1.36 [d, 24 H, $^3J_{H,H}$ = 6.9 Hz, *o*-CH(C*H*$_3$)$_2$] ppm. ^{31}P NMR: δ = –86.3 (dd, $^1J_{P\text{-}H}$ = 255.2, $^2J_{P\text{-}F}$ = 63.8 Hz) ppm. ^{19}F NMR: δ = –149.8 (d, $^2J_{P\text{-}F}$ = 63.6 Hz) ppm. MS: *m*/*z* (%) = 1119 [(M-H$_2$)$^+$, 1], 307 {[FSi(*t*Bu)(2,4,6-*i*Pr$_3$C$_6$H$_2$)]$^+$, 31}, 203 [(*i*Pr$_3$C$_6$H$_2$)$^+$, 48], 43 [(*i*Pr)$^+$, 100]. $C_{58}H_{86}F_2P_2Si_2Zr_2$ (1121.9): calcd. C 62.09, H 7.72; found C 61.89, H 7.61.

Preparation of $\{(\eta^5\text{-}C_5H_5)_2ZrPSiMe_2C(i\text{Pr})Me_2\}_2$ (3a): A solution of **1a** (0.83 g, 1.05 mmol) in toluene (40 mL) was heated in the presence of Pd/C (0.1 g) at 70 °C for 8 h. After filtration and concentration of the solution to about 20 mL in vacuo, the reaction solution was stored at 6 °C to afford red-black crystals. Yield: 0.6 g (0.76 mmol, 72%). ^{1}H NMR: δ = 6.29 (s, 20 H, C_5H_5), 1.61 [sept, 2 H, $^3J_{H,H}$ = 6.9 Hz, C*H*(CH$_3$)$_2$], 0.91 [d, 12 H, $^3J_{H,H}$ = 7.0 H, CH(C*H*$_3$)$_2$], 0.77 [s, 12 H, C(C*H*$_3$)$_2$], 0.64 [s, 12 H, Si(C*H*$_3$)$_2$] ppm. ^{31}P NMR: δ = 238.9 ppm (s). MS: *m*/*z* (%) = 791 [(M)$^+$, 4], 706 [(M-Thex)$^+$, 3.5], 563 [(M-2(Thex)-SiMe$_2$)$^+$, 2.5], 505 [(M-2(C(*i*Pr)Me$_2$)-2(SiMe$_2$))$^+$, 3.5], 438 [(504-(C$_5$H$_5$))$^+$, 3], 85 [(C(*i*Pr)Me$_2$)$^+$, 25], 73 [(SiMe$_3$)$^+$, 100], 43 [(*i*Pr)$^+$, 35]. $C_{36}H_{58}P_2Si_2Zr_2$ (791.4): calcd. C 54.63, H 7.38; found C 54.46, H 7.30.

Preparation of $\{(\eta^5\text{-}C_5H_5)_2ZrPSi i\text{Pr}_3\}_2$ (3b): The compound was synthesized by a procedure similar to that for **3a**, starting from **1b** (1.50 g, 1.82 mmol). Yield: 1.31 g (1.59 mmol, 87.4%). ^{1}H NMR: δ = 4.98 (s, 20 H, C_5H_5), 1.34 [d, 36 H, $^3J_{H,H}$ = 6.7 Hz, CH(C*H*$_3$)$_2$], 1.11 [sept, 6 H, $^3J_{P\text{-}H}$ = 6.9 Hz, C*H*(CH$_3$)$_2$] ppm. ^{31}P NMR: δ = 229.8 (s) ppm. MS: *m*/*z* (%) = 819 [M]$^+$ (1), 157 [Si(*i*Pr)$_3$]$^+$ (100), 115 [Si(*i*Pr)$_2$]$^+$ (78), 43 [*i*Pr]$^+$ (40). $C_{38}H_{62}P_2Si_2Zr_2$ (819.5): calcd. C 55.69, H 7.62; found C 55.45, H 7.60.

Preparation of $\{(\eta^5\text{-}C_5H_5)_2ZrPSiF(t\text{Bu})(2,4,6\text{-}i\text{Pr}_3C_6H_2)\}_2$ (3c): A solution of **1c** (1.23 g, 1.09 mmol) in toluene (50 mL) was refluxed for 12 h. Concentrating the solution to about 20 mL and cooling at 4 °C afforded brown-red crystals. Alternatively, the desired product was also accessible upon heating the solution for 8 h at 50 °C in the presence of Pd/C (0.1 g). Yield: 0.87 g (0.77 mmol, 71%). ^{1}H NMR: δ = 7.31 (s, 4 H, *m*-*H*), 6.40 (s, 20 H, C_5H_5), 4.59 [sept, 4 H, $^3J_{H,H}$ = 6.9 Hz, *o*-C*H*(CH$_3$)$_2$], 2.79 [sept, 2 H, $^3J_{H,H}$ = 6.9 Hz, *p*-C*H*(CH$_3$)$_2$], 1.02 [s, 18 H, C(C*H*$_3$)$_3$], 1.23 [d, 12 H, $^3J_{H,H}$ = 6.9 Hz, *p*-CH(C*H*$_3$)$_2$], 1.15 [d, 24 H, $^3J_{H,H}$ = 6.9 Hz, *o*-CH(C*H*$_3$)$_2$] ppm. ^{31}P NMR: δ = 260.3 (s) ppm. ^{19}F NMR: δ = –133.6 (s) ppm. MS: *m*/*z* (%) = 1119 [M]$^+$ (1), 307 [FSi(*t*Bu)(2,4,6-*i*Pr$_3$C$_6$H$_2$)]$^+$ (38), 203 [*i*Pr$_3$C$_6$H$_2$]$^+$ (51), 43 [*i*Pr]$^+$ (100). $C_{58}H_{84}F_2P_2Si_2Zr_2$ (1119.9): calcd. C 62.20, H 7.56; found C 62.02, H 7.51.

X-ray Crystallographic Study: Crystals of **1a**, **1b,1c**, **3a**, and **3b** were mounted on top of a thin glass fiber. Data were collected with a Siemens-Stoe AED2 (**1c** and **3b**) and a Bruker-AXS SMART 1000 (**1a**, **1b**, and **3a**) diffractometer with graphite monochromated Mo-$K\alpha$ radiation (λ = 0.71073 Å). The crystal data are summarized in Table 3. Structures were solved by direct methods (SHELX-97) and refined (SHELXL-97) by full-matrix least-squares methods. The positions of the P–H hydrogen atoms were localized in the difference Fourier map and refined. All other hydrogen atoms were introduced at calculated positions (riding model), included in structure factor calculations, and not refined.

CCDC-250811 to -250815 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Addition of (Pyrazol-1-yl)acetyl and (Pyridin-2-yl)acetyl Groups to the Terminal Amino Group of a Phe−Gly Dipeptide Affords ATCUN-Like Copper(II) Binding Sites

Andrew N. Boa,*[a] Jonathan D. Crane,*[a] Radoslaw M. Kowalczyk,[b] and Nayer H. Sultana[a]

Keywords: Bioinorganic chemistry / Copper / Peptides / Tetradentate ligands

(Pyrazol-1-yl)acetic acid (HL^1, **1**) and (pyridin-2-yl)acetic acid have been successfully condensed with the terminal amino group of a Phe−Gly dipeptide to generate the derivatives $PzCH_2$–Phe−Gly (H_3L^2, **7**) and $PyCH_2$–Phe−Gly (H_3L^3, **8**) respectively, which contain ATCUN-like metal ion binding sites. The crystal structures of **1** and the copper(II) complexes $Cu(L^1)_2(H_2O)_2$ (**2**) and $[nBu_4N][Cu(L^2)]$ (**9**) are described. Complex **2** has a tetragonally-elongated, Jahn–Teller distorted octahedral geometry and complex **9** is square-planar. The structural similarity of the copper(II) complexes of **7** and **8** is demonstrated by their almost identical electronic absorption and EPR spectra.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The amino terminal copper(II) and nickel(II)-binding protein motif (H_2N)–Xaa–Xaa–His (ATCUN), where Xaa is an α-amino acid other than Pro, occurs naturally in albumens (human, bovine and rat), histatins, human sperm protamine P2a, and neuromedins (C and K).[1] In the albumens its prominent role is proposed to be the binding and transport of metal ions, usually copper(II) and nickel(II). These ions have been the most extensively studied for ATCUN and ATCUN-like systems.[2–6] The presence of the ATCUN motif in the other proteins raises the possibility that the binding of metal ions may have some influence, presumably adverse, upon the normal function of these systems. It is also worthy of note that although the copper(II) binding sites identified in the prion protein of Creutzfeld–Jakob disease (CJD) are not terminal, they are nevertheless structurally very similar to the ATCUN motif, and it has been proposed that this may indicate the function of the normal cellular form of this protein is copper(II) binding, storage and/or transport.[7]

The investigation of the role of the ATCUN and related motifs in biological systems is well established, but of particular chemical importance are: (i) The observations that both the copper(II) and nickel(II) bound forms of the ATCUN motif are able to mediate oxidative DNA damage, including cleavage and cross-linking, and (ii) even simple ATCUN-like complexes display selective binding to, and cleavage of, DNA and RNA.[1,2] Indeed this has inspired the synthesis and study of ATCUN-containing proteins as selective DNA binding/cleavage systems.[2,5,6] In addition, polydentate ligands predominantly based upon the ATCUN motif have been demonstrated to act as highly selective, fluorescent chemosensors for copper(II).[8,9]

We report herein the synthesis of novel copper(II) binding peptides (Scheme 1) that do not contain a His residue within the amino-terminal protein sequence. In the peptide systems (**7** and **8**) the heterocyclic *N*-donor ligand for the metal ion is provided by the straightforward condensation of (pyrazol-1-yl)acetic acid (**1**) or (pyridin-2-yl)acetic acid with the amino terminal of the peptide. In principle, this approach allows the generation of an ATCUN-like site at the amino terminal of any dipeptide. In the specific examples described here the chosen starting dipeptide was Phe−Gly and in the resulting tetradentate systems the terminal carboxylate group acts as the fourth ligand to the bound, square-planar copper(II) ion.

Results and Discussion

(Pyrazol-1-yl)acetic acid HL^1 (**1**) was prepared in good yield by the alkylation of pyrazole with bromoacetic acid, and X-ray quality crystals were obtained by recrystallisation from water. The structure of **1** (Figure 1) reveals that the pyrazole group is not sufficiently basic for the compound to crystallise in a zwitterionic form; the freely refined acidic proton H(1) is clearly located on the carboxylic acid

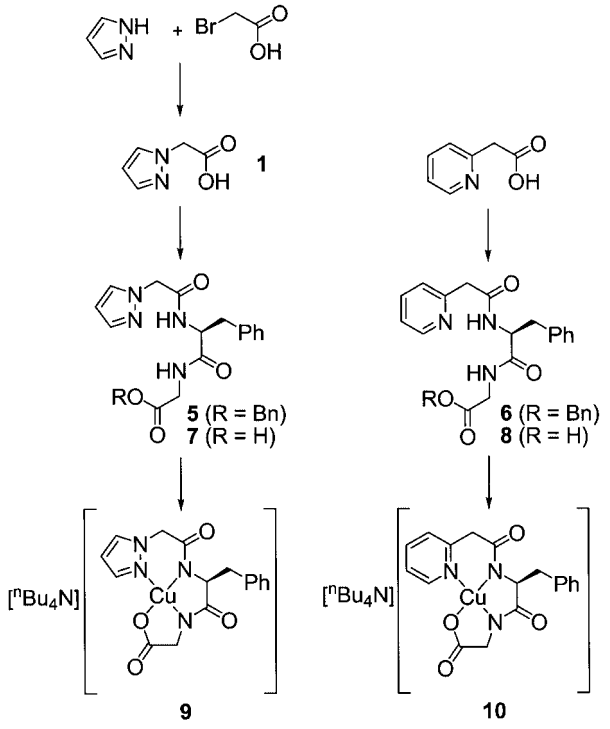

Scheme 1

group with a strong intermolecular hydrogen bond to N(1) of a neighbouring molecule. Thus **1** crystallises as parallel, 1-D, hydrogen-bonded chains that are helical and homochiral (non-centrosymmetric space group $P2_12_12_1$). The least-squares planes of the pyrazole and carboxylic acid groups are almost mutually perpendicular with a dihedral angle of 80.76(6)° and N(2) lies only 0.0276(14) Å out of the plane of the carboxylic group. In all these regards the structure is similar to that reported for the substituted analogue 3,5-dimethyl-(pyrazol-1-yl)acetic acid.[10]

The complexation of **1** with copper(II) yields the Jahn–Teller distorted, centrosymmetric, octahedral structure $Cu(L^1)_2(H_2O)_2$ (**2**), the molecular structure of which is shown in Figure 2. The ligand bite angle is 90.58(7)° and the neutral pyrazole Cu(1)–N(1) bond length of 1.954(2) Å is significantly shorter than the Cu(1)–O(1) bond length of 1.980(2) Å involving the anionic carboxylate ligand. This is consistent with the delocalisation of the carboxylate negative charge over both oxygen atoms as evinced by the similar C(5)–O(1) and C(5)–O(2) bond lengths of 1.274(3) and 1.246(2) Å respectively [Δd = 0.028(4) Å], and this delocalisation is stabilised by the presence of two hydrogen-bonds to the non-coordinated carboxylate oxygen atom O(2). Upon complexation the dihedral angle between the least-squares planes of the pyrazole and carboxylic acid groups has changed from 80.76(6)° in the free ligand (**1**) to 32.35(5)° in **2**. Due to the non-planarity of the ligand the dihedral angle between the pyrazole group and the copper square-plane is 22.55(4)°. The electronic absorption spectrum of **2** in aqueous solution is typical of axially elongated octahedral copper(II) with a single broad absorption band at 14700 cm^{-1} (ε = 32 $M^{-1}cm^{-1}$). There are no reported complexes of either (pyrazol-1-yl)acetic acid (**1**) or its simple derivatives in the literature, however several transition metal complexes (VO^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+} and Cu^{2+}) of the similar ligand imidazol-4-yl-acetic acid have been described.[11–16] The crystal structures of many of these have been reported,[17] but surprisingly not for Cu^{2+}. Furthermore, there is only one unequivocally characterised transition metal complex (Pt^{2+}) of (pyridin-2-yl)acetic acid or its simple derivatives.[18] To date, attempts to prepare and characterise other first row transition metal complexes of **1** have been unsuccessful, thus at present it is difficult to compare di-

rectly the coordination behaviour of these related ligand systems.

The two tetradentate square planar ligands H_3L^2 (**7**) and H_3L^3 (**8**) were prepared in two steps, from **1** and (pyridin-2-yl)acetic acid, respectively, by standard peptide coupling with the dipeptide H–Phe−Gly−OBn, followed by hydrolysis of the benzyl ester. The complexation of **7** with copper(II) yields the deep pink, square-planar complex $[Cu(L^2)]^-$ as the tetra-n-butylammonium salt **9**. The crystal structure of the complex anion of **9** (Figure 3) reveals that the copper(II) centre is close to planar; the sum of the angles subtended at the metal is 360.0° and the maximum deviation from the least-squares coordinate plane for Cu(1) and its four donor atoms is only 0.017(2) Å for N(4). There is a very slight tetrahedral distortion of the Cu(1) coordination geometry with the pairs of opposite donor atoms lying on opposite sides of the least-squares plane and N(1)–Cu(1)–N(4) and N(3)–Cu(1)–O(3) angles of 178.79(6) and 168.71(5)° respectively. As expected, the shortest bond lengths in the copper coordination sphere involve the deprotonated amide nitrogen atoms. The strength of these bonds is further illustrated by the short C=O [average 1.244(2) Å] and long C–N [average 1.324(2) Å] bond lengths within the amide groups showing very little delocalisation of the formal negative charge onto the oxygen atom, and hence relatively little contribution to the electronic structure by the oxy-imine [RN=C(R′)–O⁻] resonance form. Due to the square-planar geometry of the copper centre in **9** and the consequent absence of any axial ligand interactions, the neutral pyrazole Cu(1)–N(1) bond length of 1.9321(13) Å is shorter than in **2**, despite being *trans* to the shortest Cu(1)–N(amide) bond. The carboxylate Cu(1)–O(3) bond length is the longest in the coordination sphere, yet this is also shorter than the similar bond in **2**. In addition the carboxylate C(8)–O bond lengths are more dissimilar [Δd = 0.067(3) Å] than in **2**, consistent with the absence of any stabilisation of negative charge on O(4) by hydrogen bonding. Due to the non-planar nature of the (pyrazol-1-yl)acetyl group the dihedral angle between the pyrazole group and the copper square-plane is 17.81(5)°, similar to that found in **2**. The phenyl substituent of the ligand is positioned above one face of the copper square plane in the solid state and the angle between their respective least-squares planes is 61.59(5)°. Of the three possible staggered conformations about the C(6)–C(10) bond, this is the one that minimises the unfavourable steric interactions between the phenyl ring and the carbonyl oxygen atoms O(1) and O(2). The Flack parameter determined from the structure refinement confirms the known (*S*)-chirality of the ligand at C(6), being derived from (*S*)-phenylalanine. The pink colour of **9** is retained in dichloromethane solution and arises from a single absorption band at 19500 cm^{-1} in the visible region of the electronic absorption spectrum. There is no significant change to the spectrum either in dichloromethane/methanol (1:1) or upon the addition of ten equivalents of a good N-donor ligand (*N*-methylimidazole), indicating that the square-planar geometry is retained under these conditions. In aqueous solution however, the complex is pale violet and the absorption band shifts to 18000 cm^{-1}. This shift of 1500 cm^{-1} to lower energy is similar to that observed for the 1,4-diazacycloheptane (LL) complexes $[Cu(LL)_2]^{2+}$ and $[Cu(LL)_2(H_2O)]^{2+}$,[19] and may therefore indicate the coordination of one water ligand to give a five coordinate, square pyramidal complex in aqueous solution.

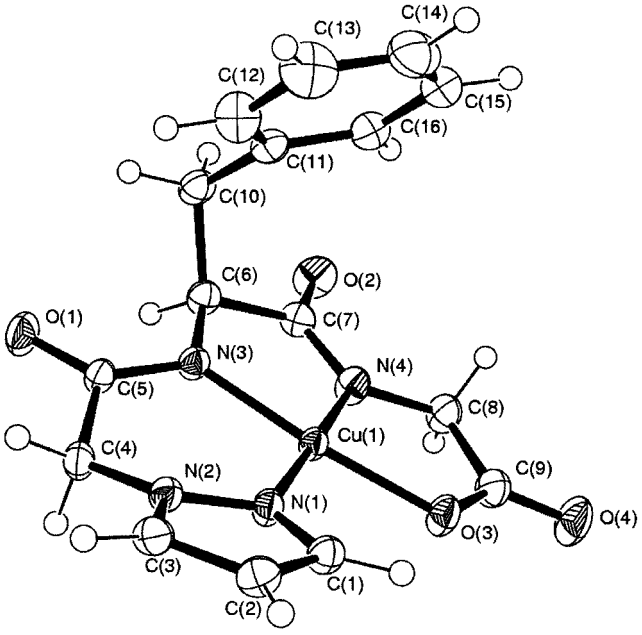

Figure 3. ORTEP[25] view of the structure of the complex cation of **9** with thermal ellipsoids shown at 50 %. Selected bond lengths [Å] and angles [°]: Cu(1)–O(3), 1.9606(12); Cu(1)–N(1), 1.9321(13); Cu(1)–N(3), 1.9299(13); Cu(1)–N(4), 1.8654(13); O(1)–C(5), 1.246(2); N(3)–C(5), 1.325(2); O(2)–C(7), 1.242(2); N(4)–C(7), 1.323(2); O(3)–C(9), 1.298(2); O(4)–C(9), 1.231(2); N(1)–Cu(1)–N(3), 94.42(5); N(3)–Cu(1)–N(4), 84.66(6); O(3)–Cu(1)–N(4), 84.09(6); O(3)–Cu(1)–N(1), 96.85(5).

The (pyridin-2-yl)acetyl analogue, **10**, could be prepared as a pink complex by the same method as used for **9**. Unfortunately, a pure or crystalline sample of **10** could not be obtained due to its slow decomposition during attempted recrystallisation, resulting in a pale green solution. Electronic absorption spectra of **10** in dichloromethane/methanol (3:1) and water were recorded for freshly prepared samples and were found to be almost identical to the corresponding spectra of **9**, consistent with the formation of a structurally very similar complex. Additionally, the negative ion electrospray mass spectrum of complex **10** in dichloromethane solution revealed the desired molecular ion. For further confirmation of the structure of **10**, and for comparison with **9**, the EPR spectra of both were measured at X-band. Complexes **9** and **10** gave near identical spectra in the same solvents systems (Figure 4).

At room temperature the Cu hyperfine (to both isotopes), as well as ligand superhyperfine splittings to ^{14}N and ^{1}H can be resolved, in both aqueous and in CH_2Cl_2 solution. In frozen solution at ca. 110 K (adding ca. 10 % glycerol to H_2O, or ca. 10 % toluene to CH_2Cl_2, to aid glassing) we observed well resolved spectra which are axial within the resolution of the X-band experiment. The ^{14}N

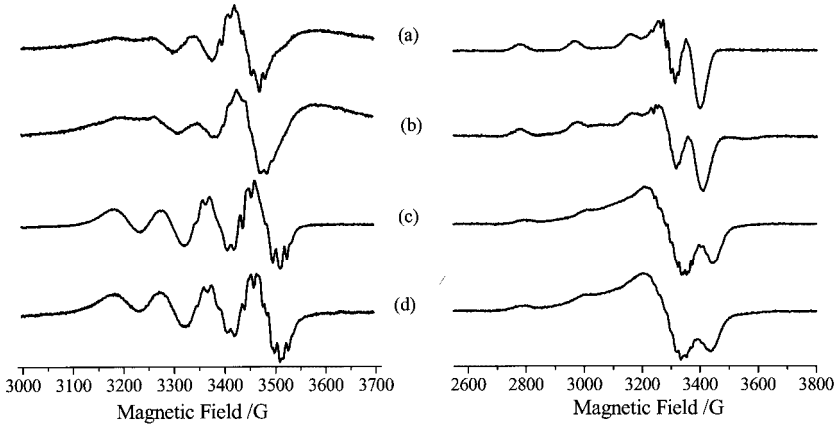

Figure 4. Fluid solution EPR spectra at 290 K and 9.773 GHz (left) and frozen solution EPR spectra at 120 K and 9.457 GHz (right). (a) **9** in H_2O/glycerol; (b) **10** in H_2O/glycerol; (c) **9** in CH_2Cl_2/toluene; (d) **10** in CH_2Cl_2/toluene.

Table 1. Simulation of EPR parameters for complex **9** (A in Gauss). Complex **10** gave nearly identical spectra in the same solvent systems.

Solvent	g_{iso}	A_{iso}^{Cu}	A_{iso}^{3N}	$A_{iso}^{2/3H}$	g_z	g_{xy}	A_z^{Cu}	A_{xy}^{Cu}	A_{xy}^{3N}
H_2O	2.104	79	14	8	2.206	2.040	190	20	16
CH_2Cl_2	2.088	90	16	8	2.165	2.050	216	35	16

Table 2. Comparison of visible and EPR parameters for complexes **9** and related Cu^{II} complexes (data taken from reference 1. *pH = 6.5; HSA, human serum albumin; DSA, dog serum albumin; A values in Gauss).

Complex*	$\lambda_{max.}$ (nm)	$\varepsilon_{max.}$ ($M^{-1}cm^{-1}$)	g_z	g_{xy}	A_z^{Cu}
9 (H_2O)	555	110	2.206	2.040	190
9 (CH_2Cl_2)	513	135	2.165	2.050	216
HSA−Cu^{II}	525	101	2.166	2.051	214
DSA−Cu^{II}	600 (br)	−	2.256	2.059	163
Gly−Gly−His−Cu^{II}	525	103	2.170	2.051	211
Asp−Ala−His−Cu^{II}	525	103	2.167	2.050	211

coupling in the "perpendicular" region of the spectra is also resolved. The frozen solution EPR spectra were modeled assuming coupling of the unpaired electron with Cu and to three equivalent in-plane coordinated ^{14}N nuclei (equivalent within the resolution of the EPR experiment). These simulations were sensitive to both the ^{14}N and Cu hyperfine coupling in the "perpendicular" region (the latter having been estimated initially from the values of A_z^{Cu} and A_{iso}^{Cu}). In order to simulate the isotropic spectra it was also necessary to include coupling to ^1H (this is not resolved in the anisotropic spectra). Simulation parameters are in Table 1. The large values of A_z^{Cu} are consistent with the N_3O in-plane coordination, and the A^N values are typical for (in-plane) N-bound Cu complexes. The important trends are that g_z increases in switching from CH_2Cl_2 to H_2O solution and A_z^{Cu} (and A_{xy}^{Cu}) decreases in going from CH_2Cl_2 to H_2O solution. These trends are consistent with going from a square-planar complex in dichloromethane to square pyramidal species in water and thus support the conclusions drawn from the electronic spectra. The EPR spectroscopic data from **9** in dichloromethane compared with data from human serum albumin, Gly−Gly−His−Cu^{II} and Asp−Ala−His−Cu^{II} are very similar, and are consistent with square-planar coordination in these systems (Table 2). The switch to a square pyramidal structure for complex **9** in water is clearly revealed with the expected changes in g_z, A_z^{Cu} and λ_{max}. Dog serum albumin does not show the ATCUN motif as it does not contain histidine as the third residue from the *N* terminus. The EPR and visible absorption data for this albumin is clearly divergent from the other complexes.

In conclusion, the condensation of (pyrazol-1-yl)acetic acid and (pyridin-2-yl)acetic acid with the terminal amino group of a dipeptide has been shown to generate copper(II) ion binding sites. The extension of this methodology to larger oligopeptides, the investigation of the chemical reactivity of the metal centre, the cytotoxicity of these complexes and their interaction/reaction with DNA are in progress.

Experimental Section

The protected dipeptide [(*S*)-2-*tert*-butoxycarbonylamino-3-phenylpropanoylamino]acetic acid benzyl ester (Boc−Phe−Gly−OBn, **3**) was prepared using standard procedures.[20] Elemental analyses were obtained with a Fisons EA1108 CHNS analyser. IR spectra were recorded as KBr disks with a Perkin–Elmer Paragon-100 FT-IR spectrophotometer. Electronic absorption spectra were recorded

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the range 1100–300 nm with a Perkin–Elmer Lambda-40 spectrophotometer. NMR spectra were recorded with a Jeol JNM-LA400 spectrometer at room temperature (20 °C) and are reported relative to tetramethylsilane. Mass spectra were recorded with a Finnigan MAT-1020 or Thermo Finnigan LCQ ion trap spectrometer. EPR spectra were measured with a Bruker EMX X-band spectrometer.

(Pyrazol-1-yl)acetic Acid (HL^1, 1): Sodium hydroxide (16.2 g, 0.404 mol) was dissolved in water (185 mL) and pyrazole (12.5 g, 0.184 mol) was added. Next bromoacetic acid (28.1 g, 0.202 mol) was added in portions with stirring and the resulting mixture then heated at reflux for 2 hours. After cooling, the mixture was carefully acidified (2 M HCl) to about pH 3 whereupon the product crystallized from the solution. After drying under vacuum, **1** was isolated as a pale yellow crystalline solid. Yield: 15.26 g (67 %). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 4.0–4.5 (br. s, 1 H, OH), 4.95 (s, 2 H, CH_2), 6.25 [dd, ^3J(H,H) = 2.3 and 1.8 Hz, 1 H, PzH], 7.42 (d, $^3J_{H,H}$ = 1.4 Hz, 1 H, PzH), 7.70 (d, $^3J_{H,H}$ = 2.3 Hz, 1 H, PzH) ppm. IR (KBr): $\tilde{\nu}$ = 3423, 2509, 1733, 1071, 780 cm^{-1}. MS (EI): *m*/*z* (%) = 126 (20) [M$^+$].

Synthesis of the Copper(II) Complex $Cu(L^1)_2(H_2O)_2$ (2): A solution of copper(II) acetate (0.39 g, 2 mmol) in water (15 mL) was added to a solution of (pyrazol-1-yl)acetic acid (**1**, 0.50 g, 4 mmol) in water (25 mL) with stirring. The blue solution was filtered and the solvent was evaporated slowly. Large, blue, X-ray quality crystals of the complex **2** deposited. Yield: 0.39 g (56 %). $C_{10}H_{14}CuN_4O_6$ (349.79): calcd. C 34.34, H 4.03, N 16.02; found C 34.11, H 3.98, N 15.86. UV/Vis (H_2O): λ = 14700 cm^{-1} (32 M^{-1}cm^{-1}). IR (KBr): $\tilde{\nu}$ = 3466, 1655, 1415, 1369, 1338, 1284, 1076, 926, 809, 755, 722, 614, 577 cm^{-1}.

(*S*)-[1-(Benzyloxycarbonylmethylcarbamoyl)-2-(phenylethyl)]ammonium Trifluoroacetate (TFA·H–Phe−Gly−OBn, 4): The dipeptide **3** (2.51 g 6.09 mmol) was dissolved in dichloromethane (10 mL) to which was added trifluoroacetic acid (3 mL). The mixture was stirred in an open flask for 2–3 h, and then the solvent and excess trifluoroacetic acid were evaporated in vacuo. The resulting oil was triturated thoroughly with diethyl ether/toluene to give **4** as a white solid. Yield: 2.26 g (87 %). ^{1}H NMR (400 MHz, $CDCl_3$/[D_6]DMSO): δ = 3.18 (ABX, $^2J_{H,H}$ = 13.9, $^3J_{H,H}$ = 6.2, 6.8 Hz, 2 H, $PhCH_2$), 3.98 (d, $^3J_{H,H}$ = 5.6 Hz, 2 H, CH_2NH), 4.31 (br. t, $^3J_{H,H}$ ≈ 6.7 Hz, 1 H, C*H*CH_2), 5.10 (s, 2 H, CH_2O), 7.21–7.47 (m, 10 H, PhH), 8.80 (br. t, $^3J_{H,H}$ ≈ 5.6 Hz, 1 H, NH) ppm.

Benzyl {(*S*)-3-Phenyl-2-[(2-pyrazol-1-yl)acetylamino]propionylamino}acetate ($PzCH_2CO$–Phe−Gly−OBn, 5): A sample of dipeptide **3** (3.0 g, 7.3 mmol) was deprotected as above and the resulting crude oil dissolved in dry dimethylformamide (50 mL). Next (pyrazol-1-yl)acetic acid (**1**, 1.08 g, 8.0 mmol) hydroxybenzotriazole (1.18 g, 8.8 mmol) and diisopropylethylamine (1.52 mL, 9.6 mmol) were added to the solution followed by 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (1.54 g, 8.8 mmol). After stirring at room temperature overnight the dimethylformamide was removed by rotary evaporation under high vacuum and the oil dissolved in dichloromethane/water. After separation, the dichloromethane layer was washed with water, dried with anhydrous sodium sulfate, filtered then the solvent removed in vacuo. The resulting buff-coloured solid was dissolved in the minimum volume of hot ethyl acetate, and upon cooling an amorphous white solid precipitated. Filtration and thorough drying (to remove large amounts of ethyl acetate associated with the solid) under vacuum gave **5**. Yield: 2.34 g (76 %). $C_{23}H_{24}N_4O_4$ (420.18): calcd. C 65.70, H 5.75, N 13.33; found C 65.50, H 5.85, N 13.31. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.02 (ABX, $^2J_{H,H}$ = 13.9, $^3J_{H,H}$ = 6.6, 7.3 Hz, 2 H, $PhCH_2$), 3.98 (ABX, $^2J_{H,H}$ = 18.3, $^3J_{H,H}$ = 5.2, 5.6 Hz, 2 H, CH_2NH), 4.68 (br. q, $^3J_{H,H}$ ≈ 7.3 Hz, 1 H, C*H*CH_2), 4.75 (AB, $^2J_{H,H}$ = 16.8 Hz, 2 H, CH_2Pz), 5.14 (s, 2 H, CH_2O), 6.30 (t, $^3J_{H,H}$ ≈ 2 Hz, 1 H, PzH), 6.63 (br. t, $^3J_{H,H}$ ≈ 5.6 Hz, 1 H, NH), 6.77 (br. d, $^3J_{H,H}$ ≈ 7.8 Hz, 1 H, NH), 7.04–7.06 (m, 2 H, PhH), 7.17–7.26 (m, 3 H, PhH), 7.32–7.39 (m, 6 H, PhH + PzH), 7.58 (d, $^3J_{H,H}$ ≈ 2 Hz, 1 H, PzH) ppm. ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 37.7, 41.3, 54.3, 54.7, 67.2, 106.8, 127.0, 128.4, 128.5(7), 128.6(3), 128.6(5), 129.2, 131.1, 135.1, 136.1, 141.3, 167.5, 169.2, 170.5 ppm. MS (EI): *m*/*z* (%) = 420 (1) [M$^+$]. HRMS found: [M]$^+$ 420.1798; $C_{23}H_{24}N_4O_4$ requires [M]$^+$ 420.1798.

Benzyl {(*S*)-3-Phenyl-2-[(2-pyridin-2-yl)acetylamino]propionylamino}acetate (2-$PyCH_2CO$–Phe−Gly−OBn, 6): A sample of the dipeptide salt **4** (5.0 g, 12.0 mmol) was coupled to (pyridin-2-yl) acetic acid hydrochloride (2.04 g, 12.0 mmol) as described above to give the title compound as a white solid. Yield: 3.40 g (67 %). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.10 (ABX, $^2J_{H,H}$ = 14.0, $^3J_{H,H}$ = 5.9, 7.9 Hz, 2 H, $PhCH_2$), 3.66 (AB, $^2J_{H,H}$ = 15.7 Hz, 2 H, CH_2Py), 4.01 (ABX, $^2J_{H,H}$ = 18.2, $^3J_{H,H}$ = 5.0, 5.9 Hz, 2 H, CH_2NH), 4.77 (br. q, $^3J_{H,H}$ ≈ 8.0 Hz, 1 H, C*H*CH_2), 5.14 (s, 2 H, CH_2O), 7.09–7.20 (m, 8 H, ArH), 7.30–7.38 (m, 5 H, ArH), 7.60 (td, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.7 Hz, 1 H, ArH), 7.76 (br. d, $^3J_{H,H}$ ≈ 7.9 Hz, 1 H, NH), 8.41 (br. d, $^3J_{H,H}$ ≈ 4.8 Hz, 1 H, ArH) ppm. ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 37.4, 41.4, 44.7, 54.4, 67.1, 122.1, 124.0, 126.7, 128.3, 128.5 (two peaks), 128.6, 129.2, 135.2, 136.6, 137.2, 149.0, 155.1, 169.4, 169.6, 171.3 ppm. MS (EI): *m*/*z* (%) = 431 (2) [M$^+$], 340 (20), 239 (45), 120 (100).

{(*S*)-3-Phenyl-2-[(2-pyrazol-1-yl)acetylamino]propionylamino}acetic Acid (H_3L^2, 7): The modified tripeptide **5** (1.0 g, 2.38 mmol) was dissolved in H_2O/ethanol (1:1, 8.0 mL), and to this solution was added 1 M NaOH (7.2 mL, 7.2 mmol). The mixture was stirred at room temperature overnight, then carefully acidified to pH ≈ 2–3 with 2 M HCl causing precipitation of a white fluffy solid. After removal by filtration the solid obtained was dried in vacuo to yield **7**. Yield: 0.546 g (69 %). $C_{16}H_{18}N_4O_4$ (330.34): calcd. C 58.17, H 5.49, N 16.96; found C 58.15, H 5.53, N 16.74. ^{1}H NMR (400 MHz, [D_6]DMSO): δ = 2.90 (ABX, $^2J_{H,H}$ = 13.7, $^3J_{H,H}$ = 4.3, 9.5 Hz, 2 H, $PhCH_2$), 3.77 (d, $^3J_{H,H}$ = 6.1 Hz, 2 H, CH_2NH), 4.57 (br. dt, $^3J_{H,H}$ ≈ 9, 4.2 Hz, 1 H, C*H*CH_2), 4.75 (AB, $^2J_{H,H}$ = 16.0 Hz, 2 H, CH_2Pz), 6.20 (br. t, $^3J_{H,H}$ ≈ 2 Hz, 1 H, PzH), 7.16–7.27 (m, 5 H, PhH), 7.39 (d, $^3J_{H,H}$ = 1.7 Hz, 1 H, PzH), 7.55 (d, $^3J_{H,H}$ = 2.5 Hz, 1 H, PzH), 8.32 (br. d, $^3J_{H,H}$ ≈ 8.5 Hz, 1 H, NH), 8.49 (br. t, $^3J_{H,H}$ ≈ 5.8 Hz, 1 H, NH) ppm. ^{13}C NMR (100.6 MHz, [D_6]DMSO): δ = 37.9, 40.9, 53.6(8), 53.7(1), 106.3, 126.3, 128.1, 129.2, 131.2, 137.5, 138.8, 166.4 (2 peaks), 171.0 ppm. MS (EI): *m*/*z* (%) = 330 (2) [M$^+$].

{(*S*)-3-Phenyl-2-[(2-pyridin-2-yl)acetylamino]propionylamino}acetic Acid (H_3L^3, 8): The modified tripeptide ester **6** (3.0 g, 6.96 mmol) was hydrolysed by the method described for **7** to give three crops of a white solid. Total yield: 1.57 g (66 %). ^{1}H NMR (400 MHz, [D_6]DMSO + $CDCl_3$): δ = 2.77 (dd, $^2J_{H,H}$ = 13.9, $^3J_{H,H}$ = 10.4 Hz, 1 H, PhCH*H*CH), 3.10 (dd, $^2J_{H,H}$ = 13.9, $^3J_{H,H}$ = 3.9 Hz, 1 H, PhCH*H*CH), 3.59 (AB, $^2J_{H,H}$ = 14.6 Hz,, 2 H, CH_2Py), 3.80 (ABX, $^2J_{H,H}$ = 13.9, $^3J_{H,H}$ = 14.6, 14.6 Hz, 2 H, CH_2NH), 4.58 (br. dt, $^3J_{H,H}$ = 8.7, 4.2 Hz, 1 H, C*H*CH_2), 7.07 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, ArH), 7.15–7.24 (m, 6 H, ArH), 7.62 (td, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.7 Hz, 1 H, ArH), 8.42–8.46 (m, 2 H, NH + ArH), 8.52 (br. t, $^3J_{H,H}$ ≈ 5.9 Hz, 1 H, NH), 12.6 (br. s, 1 H, CO_2 H) ppm. ^{13}C NMR (100.6 MHz, [D_6]DMSO + $CDCl_3$): δ = 37.5, 40.7, 44.6, 53.8, 121.6, 123.4, 126.1, 127.9, 129.1, 136.4, 137.8, 148.6, 156.1, 168.8, 171.0, 171.4 ppm. MS (EI): *m*/*z* (%) = 341 (1) [M$^+$], 250 (15), 239 (20), 120 (90).

Synthesis of the Copper(II) Complex [Bu$_4$N][Cu(L^2)] (9): The modified tripeptide **7** (200 mg, 0.606 mmol) was added to potassium hydroxide (102.1 mg, 1.808 mmol) in water (2 mL) to give a pale yellow solution. To this was added dropwise a solution of cupric acetate monohydrate (120.7 mg, 0.606 mmol) in water (2 mL) and then the resulting royal blue solution was filtered through a cotton wool plug. (Tetra-*n*-butyl)ammonium bromide (194.3 mg, 0.606 mmol) was added and the solution evaporated to dryness giving a dark blue solid. Addition of chloroform (10 mL) resulted in the formation of a cherry red solution and white solid, the latter being removed by filtration. The red solution was evaporated and thoroughly dried in vacuo before crystallization from dichloromethane/ethyl acetate (1:6). Yield: 300 mg (78 %). Growth of crystals suitable for single-crystal X-ray diffraction was achieved by slow evaporation of dichloromethane from a dichloromethane/ethyl acetate solution, resulting in the isolation of red needle-like crystals. $C_{32}H_{51}CuN_5O_4$ (633.33): calcd. C 60.69, H 8.12, N 11.06; found C 60.48, H 7.84, N 11.05. MS (APCI): *m*/*z* (%) = 631.3 [M – H]$^+$. UV/Vis (CH_2Cl_2): λ = 19500 cm^{-1} (135 M^{-1} cm^{-1}); (H_2O): 18000 (110). IR (KBr): $\tilde{\nu}$ = 3090 (w), 2964 (m), 2935 (w), 2875 (m), 1623 (m), 1598 (s), 1387 (m), 1338 (m), 1081 (w), 1073 (w), 756 (w), 709 (w), 536 (w), 500 (w) cm^{-1}. EPR: See Table 1 and Figure 4. These spectra are available as Supporting Information (see also the footnote on the first page of this article).

Synthesis of the Copper(II) Complex [Bu$_4$N][Cu(L^3)] (10): The preparation of the copper(II) complex of the modified tripeptide **8** (200 mg, 0.606 mmol) was attempted using the method described above for **9**. Neither a pure sample nor X-ray quality crystals of **10** could be obtained due to the slow decomposition of the complex in solution over several days to give a pale green solution. The EPR and electronic absorption spectra were determined for freshly prepared solutions and the extinction coefficients were calculated with the assumption that all the ligand was successfully complexed to copper(II). UV/Vis [CH_2Cl_2/methanol (3:1)]: λ = 19200 cm^{-1} (125 M^{-1} cm^{-1}); (H_2O): 18000 (110). MS (negative ion electrospray) [CH_2Cl_2]: *m*/*z* (%) = 401.0 (100) ([M]$^-$ Cu^{63}), 403.0 (45) ([M]$^-$, Cu^{65}). EPR: see Figure 4 for the near identical spectra of complexes **9** and **10**. This data is available as Supporting information.

Crystal Structure Determinations: Data for **1**, **2** and **9** were collected at 150(2) K with graphite-monochromated Mo-K_α radiation (wavelength of 0.71073 Å) with a Stoe IPDS II image plate diffractometer (Table 3). Space groups were determined by an examination of the systematic absences in the data, and their correct identification was confirmed by the successful solution and refinement of the structures. Solutions were provided via direct methods using SHELXS-97 and refined by full-matrix least-squares on F^2 using SHELXL-97.[21] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms on carbon were placed in calculated positions with U_{iso} set at 1.2 times the U_{eq} of the parent atom, and the positional and isotropic displacement parameters of all O–H groups were freely refined. Numerical absorption corrections were applied to **2** and **9** using X-RED/X-SHAPE.[22] The analysis of the structures was carried out with PLATON[23] and WinGX.[24]

Supplementary data for **1**, **2** and **9** (CCDC-239525, -239527 and -239526, respectively) are available free of charge from the Cambridge Crystallographic Data Centre (CCDC) via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We acknowledge the University of Hull for financial support of this work and Dr E. J. L. McInnes, of the EPSRC Multi-frequency EPR Service Centre at The University of Manchester, for his contribution to the analysis of the EPR data.

Use of the Di-2-pyridyl Ketone/Acetate/Dicyanamide "Blend" in Manganese(II), Cobalt(II) and Nickel(II) Chemistry: Neutral Cubane Complexes

Giannis S. Papaefstathiou,[a] Albert Escuer,[b] Franz A. Mautner,[c] Catherine Raptopoulou,[d] Aris Terzis,[d] Spyros P. Perlepes,*[a] and Ramon Vicente*[b]

Keywords: Cobalt(II) cubanes / Dicyanamide complexes / Di-2-pyridyl ketone / Magnetic properties / Manganese(II) cubanes / Nickel(II) cubanes

The use of di-2-pyridyl ketone [$(2\text{-py})_2CO$]/dicyanamide "blend" in cobalt(II), manganese(II) and nickel acetate chemistry has yielded neutral cubane clusters. The preparation of $[Mn_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 2(2\text{-py})_2CO\cdot 4H_2O$ (**1**) and $[M_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 10H_2O$ [M = Ni (**2**), Co (**3**)] was achieved by the reaction of $[M(O_2CMe)_2]\cdot 4H_2O$ with $(2\text{-py})_2CO$ and $Na[N(CN)_2]$ in $MeOH/H_2O$ (1:5, v/v) at room temperature. The metal(II)-mediated hydrolysis of $(2\text{-py})_2CO$ to give the coordinated monoanion of the hydrate *gem*-diol form involves a nucleophilic attack of H_2O on the carbonyl group. In the case of the cobalt reaction system, there is a second product. Upon employing an excess of $(2\text{-py})_2CO$, long reaction times, reflux conditions and high dilution, slow oxidation of Co^{II} takes place leading to the isolation of the mononuclear cobalt(III) complex $[Co\{(2\text{-py})_2C(OH)O\}_2][N(CN)_2]\cdot 4H_2O$ (**4**) in yields higher than 70%. The structures of **1**, **2** and **4** have been solved by single-crystal X-ray diffraction studies, while a unit-cell determination indicated that complex **3** is isostructural with **2**. The tetranuclear cluster molecules of **1** and **2** have cubane $[M_4(\mu_3\text{-}OR)_4]^{4+}$ cores with divalent metal atoms and deprotonated oxygen atoms [originating from the $(2\text{-py})_2C(OH)O^-$ ligands] occupying alternate vertices. The centrosymmetric $[Co\{(2\text{-py})_2C(OH)O\}_2]^+$ cation of complex **4** has an octahedral structure with the $(2\text{-py})_2C(OH)O^-$ ligands adopting the tridentate *N*,*O*,*N*′-chelating coordination mode. The magnetic properties of **1**–**3** have been studied by variable-temperature dc magnetic susceptibility techniques. The studies indicate weak antiferromagnetic coupling for **1** and ferromagnetic behaviour for **2** and **3**. A three-*J* model was found to be adequate for describing the thermal variation of the molar magnetic susceptibilities of **1** and **2**. The magnetochemical results have been compared with literature data.

Introduction

There continues to be great interest in the synthesis and study of polynuclear metal complexes (clusters) containing paramagnetic 3d-metals in intermediate oxidation states.[1] There are various reasons for this, not least of which is the aesthetically pleasing nature of some of these species.[2] From an applications point of view, however, efforts in this area are part of the continuing search for new examples of molecular species which can function as nanoscale magnetic particles or so-called single-molecule magnets (SMMs).[3] These zero-dimensional (0D) systems display slow relaxation of their magnetisation vectors as a result of the combination of a large ground state (*S*) and an Ising (or easy-axis) type of magnetoanisotropy.[3] Thus, such molecules exhibit magnetisation hysteresis loops, i.e. the classical behaviour of a magnet. The unusual quantum phenomena[4] such molecules display have also led researchers to propose that the molecules could be used as Qbits in quantum computers.[5] The most studied examples of SMMs are the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ compounds with $S = 10$.[3] Another compound which has been intensely investigated for its SMM behaviour is $[\{Fe_8O_2(OH)_{12}(tacn)_6\}Br_7(H_2O)]Br\cdot 8H_2O$ (tacn = 1,4,7-triazacyclononane),[3] characterised by an $S = 10$ ground state. Since these first discoveries, other oxidation levels[6] in the Mn_{12} family and other Mn_x[2a,2d,3,7] and M_x (M = V^{III},[8] Fe^{II},[9] Fe^{III},[10] Co^{II},[11] Ni^{II}[12]) SMMs, including mixed-metal systems,[13] have been prepared with *S* values ranging from 3 to $5^1/_2$.

The future health of the field of high-spin molecules and the chances of identifying new SMMs will both benefit from the development of new synthetic methodologies for 3d-metal clusters. With this in mind, our group[9b,14,15] and

others[16] have been exploring "*binary* ligand blend" reactions involving (i) the monoanion $(2\text{-py})_2C(OH)O^-$ or the dianion $(2\text{-py})_2CO_2^{2-}$ of the *gem*-diol form of di-2-pyridyl ketone $(2\text{-py})_2CO$ (the formulae of these ligands are shown in Figure 1) *and* carboxylates, and (ii) the monoanion $(2\text{-py})_2C(OR)O^-$ of the hemiacetal form of $(2\text{-py})_2CO$ (Figure 1) *and* carboxylates, with the belief that they might foster formation of discrete polynuclear metal systems. The reactions of $(2\text{-py})_2CO$ with metal ions have been well studied over the years.[15–17] Water and alcohols (ROH) have been shown to add to the carbonyl group upon coordination of the 2-pyridyl ring to the ligands forming the ligands $(2\text{-py})_2C(OH)_2$ [the *gem*-diol form of $(2\text{-py})_2CO$] and $(2\text{-py})_2C(OR)(OH)$ [the hemiacetal form of $(2\text{-py})_2CO$], respectively. The neutral ligands $(2\text{-py})_2C(OH)_2$ and $(2\text{-py})_2C(OR)(OH)$ coordinate to the metal centres as tridentate N,N′,O chelates, with the M–O bond often being weak. Therefore, both neutral ligands do not hold much interest from the cluster formation point of view.[14] Completely different and much more interesting (for cluster chemistry) coordination modes are seen when the ligands $(2\text{-py})_2C(OH)_2$ and $(2\text{-py})_2C(OR)(OH)$ are deprotonated. Upon deprotonation the latter becomes monoanionic, while the former can exist either as monoanionic or dianionic. The presence of deprotonated hydroxyl group(s) leads to a great coordinative flexibility due to the well known ability of the negatively charged oxygen atom to bridge two or three metal ions. The immense structural diversity displayed by the complexes reported stems in part from the ability of $(2\text{-py})_2C(OH)O^-$, $(2\text{-py})_2CO_2^{2-}$ and $(2\text{-py})_2C(OR)O^-$ to exhibit no less than nine distinct bridging coordination modes ranging from μ_2 to μ_5.[14] Carboxylates are employed for two reasons in the above mentioned "ligand blends". Firstly, they are able to deprotonate the hydroxyl group(s) of $(2\text{-py})_2C(OH)_2$ and $(2\text{-py})_2C(OR)(OH)$ under mild conditions (the use of hydroxides often complicates the reactions). Secondly, they are flexible ligands, a consequence of their ability to adopt a number of different ligation modes, both terminal and bridging as well as both monodentate and bidentate. Thus, the $(2\text{-py})_2C(OH)O^-/R'CO_2^-$, $(2\text{-py})_2CO_2^{2-}/R'CO_2^-$ and $(2\text{-py})_2C(OR)O^-/R'CO_2^-$ "blends" (R = Me, Et; R′ = Me, CF_3, Ph) have led to a variety of Mn, Fe, Co, Ni and Cu clusters with nuclearities ranging from three to fourteen and with interesting magnetic properties.[14–16]

Three years ago we decided to incorporate azido ligands, N_3^-, into the 3d-metal carboxylate chemistry of $(2\text{-py})CO_2^{2-}$, $(2\text{-py})_2C(OH)O^-$ and $(2\text{-py})_2C(OR)O^-$, i.e. to study the "*ternary* ligand blend" reaction systems $(2\text{-py})_2C(OH)O^-$, $(2\text{-py})_2CO_2^{2-}$ or $(2\text{-py})_2C(OR)O^-/R'CO_2^-/N_3^-$, as a means of introducing specifically ferromagnetic components into the superexchange schemes, thus increasing the ground state *S* values of the clusters.[9b,18] For example, we reported[9b,18b,18c] that the reactions of $M(O_2CMe)_2{\cdot}xH_2O$ (M = Co, Ni, x = 4; M = Fe, x = 0) with (2-py)CO and N_3^- in DMF or MeCN with heating led to the nonanuclear cages $[M_9(N_3)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}]$ in which the nine M^{II} ions adopt a topology of two square pyramids sharing a common apex. Salient features of the similar structures are

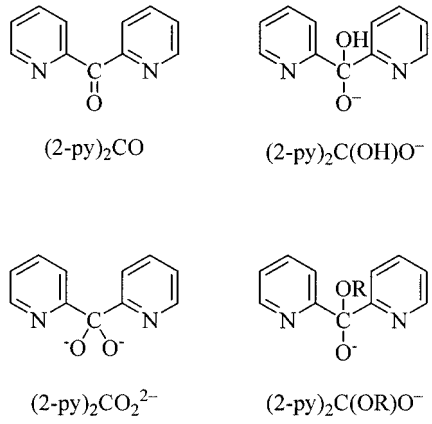

Figure 1. Some of the ligands discussed in the text. Note that the anionic ligands do not exist as free species, they exist only in metal complexes.

the unique $\eta^1{:}\mu_4$ coordination mode of the azido ligands, the μ_5 coordination mode of $(2\text{-py})_2CO_2^{2-}$ and the extremely rare coordination number 8 for the central M^{II} ion lying at the common apex of the pyramids. Magnetic studies revealed ferromagnetic coupling mediated by the azido bridges, giving a ground state total *S* value of seven times the local spin in the case of cobalt(II),[18c] 9 in the case of nickel(II)[18b] and 14 for the iron(II) cluster.[9b] It should be mentioned at this point that Mn^{II}, Co^{II} and Ni^{II} clusters containing *only* various anionic forms of $(2\text{-py})_2CO$ and N_3^- ligands, i.e. non-carboxylate species, are also known.[19]

Very recently we began a program which can be considered as a modification of the above "*ternary* ligand blend" approach. We have been exploring the use of the dicyanamido ligands, $N(CN)_2^-$ (Figure 2) instead of the azido ligands. The great coordinative flexibility and versatility of the $(2\text{-py})_2CO$-based anionic ligands and carboxylates, as well as the μ_2, μ_3, μ_4 or μ_5 potential of $N(CN)_2^-$,[20] prompted us to combine the three ligands to aim for new types of clusters and/or supramolecular architectures involving repeating cluster units. Our belief was that the simultaneous employment of the three classes of ligands in high-nuclearity 3d-metal chemistry would give extraordinary structural flexibility in the mixed $(2\text{-py})_2C(OH)O^-$, $(2\text{-py})_2CO_2^{2-}$ or $(2\text{-py})_2C(OR)O^-/R'CO_2^-/N(CN)_2^-$ ligand systems ("blends"). The loss of some degree of synthetic control[1b] may be more than compensated for by the vast diversity of structures expected using the combination of the three ligands. The advantages of using $N(CN)_2^-$ in place of N_3^- include (i) the possibility of triggering aggregation of preformed species into new, higher-nuclearity products and (ii) the possible diversion of known reaction systems developed using azides to new species as a result of the different flexibility of dicyanamides.

Dicyanamide is currently a ligand of great interest,[20,21] mainly due to the observation of long-range magnetic ordering in the binary α-$[\{M[N(CN)_2]_2\}_n]$ (M = Cr, Mn, Fe, Co, Ni) compounds.[20] Also of particular interest is the generation of new M^{II}-$N(CN)_2^-$ architectures through the introduction of coligands into the structures. These ternary

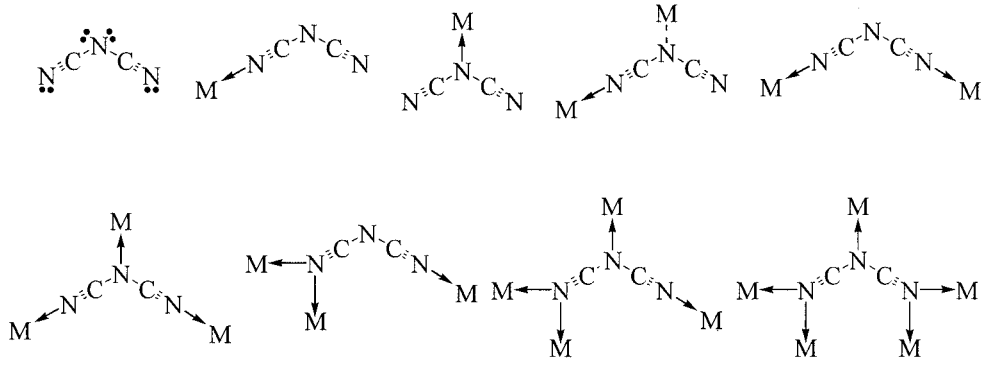

Figure 2. The dicyanamide ion and its crystallographically established coordination modes.

systems exhibit a wide variety of topologies and in a few cases long-range magnetic ordering has been observed at low temperatures.[20] This anion is a versatile ligand[20,22] which has been shown, by crystallography, to coordinate to metal ions in various modes (Figure 2), namely monodentate bonding through a nitrile nitrogen, end-to-end bridging through the two nitrile nitrogen atoms, bidentate bridging through one nitrile and the amide nitrogens or by strong coordination of one nitrile nitrogen and semicoordination of the amide nitrogen, tris(monodentate) bridging (μ_3), end-to-end μ_3 bridging with one nitrile nitrogen atom forming a monoatomic bridge as well as an unusual μ_4 mode where one nitrile nitrogen binds to two metal ions and an extremely rare μ_5 mode where each nitrile nitrogen binds to two metal ions. More generally, however, $N(CN)_2^-$ is also a very interesting ligand in the wider context of coordination chemistry due to its ability to undergo metal ion-assisted nucleophilic addition reactions with alcohols and pyrazole generating interesting polydentate ligands.[23]

The $N(CN)_2^-$ ligand has been used extensively in the synthesis of coordination polymers[20–22] but has been infrequently used for the synthesis of discrete 3d-metal clusters. We herein report the first use of $N(CN)_2^-$ in 3d-metal carboxylate/$(2\text{-py})_2CO$ chemistry which leads to neutral cubane manganese(II), cobalt(II) and nickel(II) clusters. The syntheses, structures, spectroscopic and magnetic properties of these species are described. A synthetically relevant cobalt(III) complex is also reported.

Results and Discussion

Synthesis

Our general synthetic approach for the isolation of heteroleptic $(2\text{-py})_2CO_2^{2-}$ or $(2\text{-py})_2C(OH)O^-$ or $(2\text{-py})_2C(OR)O^-/MeCO_2^-/N(CN)_2^-$ 3d-metal clusters was to treat an excess of the metal acetate with $(2\text{-py})_2CO$ and $N(CN)_2^-$ in various solvents. Obviously "$(2\text{-py})_2C(OH)_2$" and "$(2\text{-py})_2C(OR)(OH)$" can be fully/partially deprotonated by the basic acetate groups and polynuclear $M^{II}/(2\text{-py})_2CO_2^{2-}$, $(2\text{-py})_2C(OH)O^-$ or $(2\text{-py})_2C(OR)O^-/MeCO_2^-/N(CN)_2^-$ complexes may result from the reactions as long as the $MeCO_2^-$ to $(2\text{-py})_2CO$ ratio is high enough to leave an amount of $MeCO_2^-$ in the reaction mixture, given the fact that the anionic forms of $(2\text{-py})_2CO$, acetate and dicyanamide ligands can adopt a variety of terminal and bridging modes.

The preparation of compounds **1**, **2** and **3** can be achieved by the reaction of $M(O_2CMe)_2{\cdot}4H_2O$ with $(2\text{-py})_2CO$ and $Na[N(CN)_2]$ in $MeOH/H_2O$ ($\approx$ 1:5, v/v) at room temperature. The preparation of these complexes can be summarised by the general balanced Equation (1).

The metal(II)-mediated hydrolysis of $(2\text{-py})_2CO$ to give the monoanion of the hydrate *gem*-diol form involves a nucleophilic attack of H_2O on the carbonyl group. In such reactions it might not be necessary for the carbonyl atom to be coordinated to the metal centre. The induced polarisation from the pyridyl nitrogen atoms might be sufficient.[14]

A few features of the general chemical Equation (1) deserve comments. First, the incorporation of uncoordinated $(2\text{-py})_2CO$ molecules in **1** is not common and could not be predicted. Presumably, the presence of these molecules satisfies the requirements of the crystal lattice. However, the existence of ligand molecules in their ketone forms can be explained by the fact that the $(2\text{-py})_2C(OH)_2$ molecules do not exist as free species but exist only within the coordination sphere of metal ions.[14] The presence of lattice $(2\text{-py})_2CO$ has been established crystallographically[24] only in complexes $[Cu_2\{(2\text{-py})_2C(OMe)O\}_2(phen)_2]X_2{\cdot}2(2\text{-py})_2CO$, where phen = 1,10-phenanthroline and $X = PF_6^-$ or ClO_4^-. Secondly, the presence of MeOH in the solvent mixture might imply the presence of the monoanion of the hemiacetal form of di-2-pyridyl ketone, i.e. $(2\text{-py})_2C(OMe)$-

$$4\ M(O_2CMe)_2{\cdot}4H_2O + (4+n)\ (2\text{-py})_2CO + 2\ Na[N(CN)_2] + mH_2O \xrightarrow[20\ ^\circ C]{MeOH/H_2O}$$
$$[M_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]{\cdot}n(2\text{-py})_2CO{\cdot}mH_2O + 2\ NaO_2CMe + 4\ MeCO_2H + 12\ H_2O \quad (1)$$

1: M = Mn^{II}, $n = 2$, $m = 4$
2: M = Ni^{II}, $n = 0$, $m = 10$
3: M = Co^{II}, $n = 0$, $m = 10$

O^- in the complexes. This is a common synthetic feature in $(2\text{-py})_2CO$-based coordination chemistry.[14,17j–17l,19a,19c,19d] However, only $(2\text{-py})_2C(OH)O^-$ ligands are present in complexes **1**–**3**. This can be rationalised on the basis of the crystallisation method used. The complexes were crystallised by slow evaporation at room temperature of a solvent mixture consisting of MeOH and H_2O in a 1:5 volume ratio. This means that precipitation/crystallisation of the clusters was effected from *essentially aqueous media* (i.e., MeOH-free) and, thus, the coordination of *only* $(2\text{-py})_2C(OH)O^-$ might be expected. Thirdly, the "wrong" stoichiometry, i.e. $M(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/Na[N(CN)_2]$ = 2:1:1, employed for the preparation of **1**, **2** and **3** (see Exp. Sect.) compared with that required by Equation (1) was due to our desire to doubly deprotonate the *gem*-diol form of $(2\text{-py})_2CO$ and to prepare complexes of $(2\text{-py})_2CO_2^{2-}$. However, such efforts were in vain. Complexes **1**–**3** were isolated from $MeOH/H_2O$ or $MeCN/H_2O$ even employing a $M(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})CO$ ratio of 3:1. With the identities of **1**–**3** established, the "correct" stoichiometries, i.e. $Mn(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/Na[N(CN)_2]$ = 1:1.5:0.5 and $M(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/Na[N(CN)_2]$ = 1:1:0.5 (M = Co, Ni), were employed and led to pure **1** and **2** but not to pure **3** (vide infra). It is worth mentioning that $(2\text{-py})_2CO_2^{2-}$ complexes are known in $M^{II}/(2\text{-py})_2CO/N_3^-$ chemistry.[18b,18c] Since these complexes contain $\eta^1{:}\mu_4$-azido ligands, the failure to isolate analogous dicyanamide complexes may be in part due to the inability of the $N(CN)_2^-$ anion to adopt an $\eta^1{:}\mu_4$ ligation mode. Lastly, in the case of the cobalt reaction systems *only*, there is a second product. The chemical and structural identity of the product depends on the $Co^{II}/(2\text{-py})_2CO$ ratio, reaction time, temperature and solution concentration. Upon employing an excess of $(2\text{-py})_2CO$, i.e. $Co^{II}/(2\text{-py})_2CO$ = 1:2, long reaction times, reflux conditions and high dilution (to avoid precipitation of the more insoluble tetranuclear Co^{II} cluster), slow oxidation of Co^{II} takes place under the normal laboratory atmosphere leading to the pure mononuclear complex $[Co^{III}\{(2\text{-py})C(OH)O\}_2]\{N(CN)_2\}{\cdot}4H_2O$ (**4**) in very good yields (≈ 70%). The source of the oxidising agent is oxygen from the air, facilitated by the mild reducing nature of Co^{II} in a nitrogen-rich environment. It is likely, as with other reactions in Co chemistry, that the reaction solution contains a mixture of two or more species in equilibrium, with factors such as relative solubility, reaction ratio, lattice energy, crystallisation kinetics and other factors determining the identity of the isolated product. Somewhat to our surprise, an analogous Mn^{III} complex (or a mixed-valent $Mn^{II/III}$ species) was not formed under the conditions employed.

Description of Structures

$[Mn_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]{\cdot}2(2\text{-py})_2CO{\cdot}4H_2O$ (1)

A partially labelled plot of the tetranuclear molecule $[Mn_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]$ present in compound **1** is shown in Figure 3. Selected interatomic distances and angles are listed in Table 1. The solvate $(2\text{-py})_2CO$ and H_2O molecules will not be further discussed.

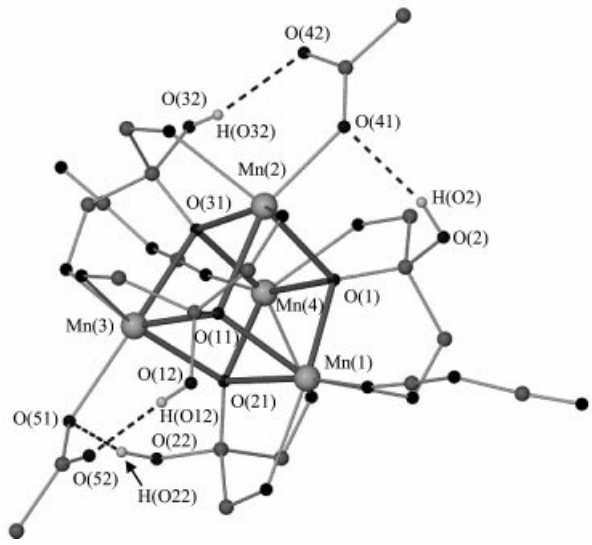

Figure 3. A partially labelled plot of the tetranuclear cluster molecule present in complex **1**. Many carbon atoms of the $(2\text{-py})_2C(OH)O^-$ ligands have been omitted for clarity. The intracubane hydrogen bonds are also shown.

The tetranuclear cluster molecule of **1** has a cubane $[Mn_4(\mu_3\text{-}OR)_4]^{4+}$ core with Mn^{II} and oxygen atoms occupying alternate vertices. Thus, the molecule consists of two interpenetrating tetrahedra, one of four Mn^{II} atoms and one of four μ_3-oxygen atoms originating form the $(2\text{-py})_2C(OH)O^-$ ligands. In addition to three μ_3 oxygen atoms, each Mn^{II} atom is coordinated to two N atoms belonging to two different $(2\text{-py})_2C(OH)O^-$ ligands and a single anion to complete an octahedral coordination environment. For Mn(1) and Mn(4), the anion is a monodentate $N(CN)_2^-$ group bonded through a nitrile nitrogen atom, whereas a monodentate acetate ligand completes the sixth coordination position at Mn(2) and Mn(3). Thus, the chromophores are $Mn(1,4)O_3N_3$ and $Mn(2,3)O_4N_2$. One octahedral face of each Mn^{II} atom is occupied by the three alkoxide-type oxygen atoms and the other contains the remaining donor atoms.

One oxygen atom of each $(2\text{-py})_2C(OH)O^-$ remains protonated and unbound to the metal ions. The resultant monoanion functions as an $\eta^1{:}\eta^3{:}\eta^1{:}\mu_3$ ligand (or as a 3.311 ligand using the Harris notation[25]) forming two five-membered MnNCCO chelating rings with two different metals (these rings share a common C–O edge) and an alkoxide-type bond to a third Mn^{II} atom (Figure 4). This ligation mode is common in the coordination chemistry of hydrated di-2-pyridyl ketone.[14] The large number of ligands involved results in a structure devoid of any point-group symmetry elements.[26]

There are two types for Mn–O (alkoxide-type) bonds for each metal ion: one bond is rather elongated to an average

distance of 2.289 Å, whereas the two other bonds are shorter (average distance 2.179 Å). The cube deviates from the ideal geometry. The internal cube angles (RO–Mn–OR) at the metal vertices average 79.4°, whereas the comparable angles at the alkoxide corners (Mn–OR–Mn) are much larger averaging 99.6°. The Mn···Mn vectors in the complex reflect the different Mn–O (alkoxide-type) bond lengths, with the two Mn(1)···Mn(2) and Mn(3)···Mn(4) [3.274(1) and 3.310(2), respectively] cube face diagonals being shorter than the four other face diagonal vectors [3.385(2)–3.455(2) Å]. The bond distances around the Mn^{II} atoms are typical of those found in octahedrally coordinated high-spin manganese(II) complexes with *O*- and *N*-ligation.[16a,19d,27–29] A few Mn^{II} cubane structures containing $[Mn_4(\mu_3\text{-}OR_4)]^{4+}$ cores have been reported previously.[16a,28,29]

Figure 4. The crystallographically established coordination modes of the ligand $(2\text{-py})_2C(OH)O^-$ present in complexes **1**–**4** and the Harris notation[25] which describes these modes (M = Mn^{II}, Co^{II}, Ni^{II}).

$[Ni_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 10H_2O$ (2)

A partially labelled plot of the tetranuclear molecule present in compound **2** is shown in Figure 5. Selected interatomic distances and angles are listed in Table 2. Complex **2** crystallises in the triclinic space group $P\bar{1}$. Its structure consists of the tetranuclear $[Ni_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]$ moiety and solvate H_2O molecules. The latter will not be further discussed.

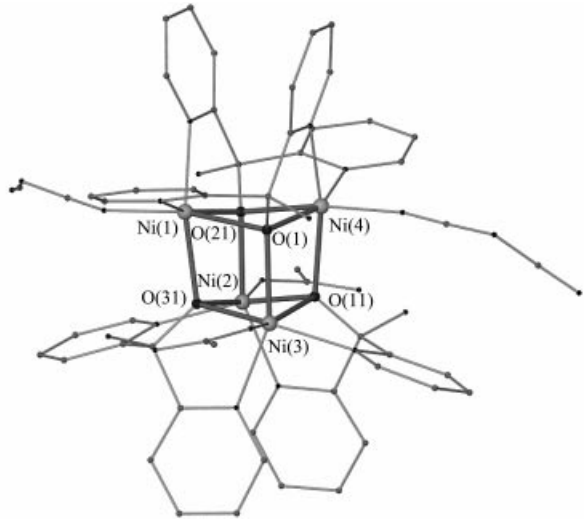

Figure 5. Partially labelled representation of the tetranuclear cluster molecule present in complex **2** emphasising its cubane structure.

The molecular structure of $[Ni_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]$ is very similar to that of the tetranuclear cluster of complex **1**. Clearly, the replacement of Mn^{II} by Ni^{II} has little structural effect. The $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$ core in **2** has almost all the geometric features found in the core of **1**, except that three Ni–O (alkoxide-type) distances are real-

ised for each metal ion. One bond is short with an average distance of 2.022 Å, one bond is relatively long with an average distance of 2.164 Å, while the third bond is of intermediate strength (average Ni–O distance of 2.097 Å). As in **1**, there are two chemically distinct metal sites in **2**. Two of them [Ni(1), Ni(4)] involve monodentate dicyanamides, while the other two [Ni(2), Ni(3)] are each bound to one monodentate acetate. The $\{Ni_4O_4\}$ cube also deviates from ideal geometry. The internal cube angles at the metal (OR–Ni–OR) average 80.0° whereas the analogous angles at the alkoxide-type corners (Ni–OR–Ni) are much larger averaging 99.0°. The Ni···Ni distances on opposite cubic faces are very similar, the pairs with the shortest distances being Ni(1)/Ni(4) and Ni(2)/Ni(3) (both distances are 3.104 Å). Average Ni–N and Ni–O bond lengths of 2.06 and 2.09 Å, respectively, lie well within the range of reported values for the corresponding bond lengths of other tetranuclear cubane Ni^{II} clusters.[2e,12b,12d,16a,26,29–31]

Many $\{Ni_4O_4\}$ cubanes have been reported previously.[2e,12b,12d,16a,26,29–31] Several[2e,29,30] have simple μ_3-alkoxides (CH_3O^-, $C_2H_5O^-$, ...) which provide the four oxygen centres. The first example which we were aware of involves terminal salicylaldehyde and ethanol ligands.[30a] Since that date, terminal ligands attached to the $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$ core have included acetylacetonate,[30b] dibenzoylmethanate[30c,30d] and 6-chloro-2-pyridonate.[30e]

$[Co_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 10H_2O$ (3)

As mentioned in the Experimental Section, the unit-cell determination along with IR and elemental analysis data proved that complex **3** is isostructural with **2**. A full data set was therefore not collected for the cobalt(II) cluster. Compound **3** is a new member of the family containing tetranuclear cobalt(II) cubanes with the $[Co_4(\mu_3\text{-}OR)_4]^{4+}$ core.[11b,15c,16a,29,31b,32]

Intracubane Hydrogen Bonding in 1 and 2

There is a large amount of hydrogen bonding in **1** and **2**. We will briefly comment on the intracubane hydrogen bonds because they reinforce the framework of the cubes.[28a] Details of these bonds are listed in Table 3. Each $(2\text{-py})_2C(OH)O^-$ hydroxyl group is strongly intramolecularly hydrogen bonded to an O atom from an acetate ligand. A notable feature here is that both uncoordinated and coordinated oxygen atoms of the terminal acetate ligands participate in one intracubane hydrogen bond. The intracubane

hydrogen bonds have the effect of lowering the symmetry of the $[M_4(\mu_3\text{-}OR)_4]^{4+}$ core.

Other (2-py)$_2$C(OH)O$^-$-Based Mn^{II}, Co^{II} and Ni^{II} Cubanes

Although several (2-py)C(OH)O$^-$-based, tetranuclear Mn^{II}, Co^{II} and Ni^{II} clusters have been reported,[14] only few have cubane structures in which the four μ_3-oxygen atoms originate from four deprotonated ligands. This group of compounds currently includes $[Co_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$,[15c] $[Mn_4Cl_4\{(2\text{-py})_2C(OH)O\}_4]$,[16a] $[Mn_4(O_2CMe)_3(H_2O)\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$,[16a] $[Co_4(O_2CMe)_3(H_2O)\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$,[16a] $[Ni_4(O_2CMe)_3(H_2O)\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$[16a] as well as **1**, **2** and **3**.

General Information on the Cubane 3d-Metal Clusters

The arrangement of four metal ions and four bridging ligands at alternating corners of a cube is a well-precedented unit in inorganic chemistry.[28d] There is great interest in the synthesis and study of cubanes featuring the first-row transition-metals.[30c,31b] Among the most thoroughly studied members of this class are $\{Fe_4S_4\}^{n+}$ clusters, many of which were prepared and characterised as models for the active site of iron-sulfur proteins.[33] Later, following the proposal of a cubic arrangement of Mn ions and bridging ligands for the oxygen evolving centre (OEC) of photosystem II (PS II),[34] several $\{Mn_4X_4\}^{n+}$ complexes with bridging oxo, chloro or alkoxo ligands were synthesised as models for this postulated unit.[35] More recently,[36] crystallographic data for a cyanobacterial PS II complex at 3.5 Å resolution strongly suggested that the OEC contains a cubane-like $\{Mn_3CaO_4\}$ cluster linked to a fourth Mn by a mono-μ-oxo bridge. However, higher resolution data are required to investigate whether some of the bridging oxygen atoms are protonated. It has also been suggested[31b,37] that these cubanes offer a way to model, and so better understand, the properties of extended networks which are often based on a cubane repeat unit.

[Co{(2-py)C(OH)O}$_2$]{N(CN)$_2$}·4H$_2$O (4)

A labelled plot of the structure of the mononuclear cation $[Co\{(2\text{-py})C(OH)O\}_2]^+$ present in complex **4** is shown in Figure 6. Selected bond lengths, angles and hydrogen bonding details are listed in Table 4 and Table 5, respectively. The structure consists of the above mentioned mononuclear cation, one disordered $N(CN)_2^-$ anion and H_2O solvate molecules; the latter two will not be further discussed. The Co^{III} ion sits on a crystallographic inversion centre.

The geometry of the *trans*-$Co^{III}N_4O_2$ chromophore is nearly octahedral, as would be expected for a Co^{III} species, with the $(2\text{-py})_2C(OH)O^-$ anions adopting the tridentate chelating coordination mode $\eta^1{:}\eta^1{:}\eta^1$ (or, 1.111 using Harris notation[25]) shown in Figure 4. The angle subtended by the off-axis coordination of the oxygen atom [O(1)] with the line normal to the equatorial N_4 plane is very small, with a value of 13.8° The Co–O and Co–N bond lengths agree well with values expected for low-spin Co^{III} in octahedral environments.[17b] There is a hydrogen bonding network among the H_2O molecules, the $N(CN)_2^-$ counterion and both protonated and deprotonated hydroxyl groups of $(2\text{-py})_2C(OH)O^-$ leading to a 2D assembly (Figure 7).

The structure of the cation of **4**, as detailed in the short discussion above and in Table 4, shows remarkable similar-

ity to the structures of the cations in $[Co\{(2\text{-py})C(OH)O\}_2](NO_3)\cdot 2H_2O$,[38a] $[Co\{(2\text{-py})C(OH)O\}_2](ClO_4)\cdot 3H_2O$[38b] and $[Co\{(2\text{-py})C(OH)O\}_2](MeO)\cdot MeOH$.[38c] The latter was obtained from a reaction involving the oxidative degradation of bis[di(2-pyridyl)ethyl]amine in the presence of Co^{II}.

IR Spectra

Complexes **1** and **4** exhibit medium to strong intensity IR bands at 3419 (**1**) and 3500 (**4**) cm^{-1}, and 3329 (**1**) and ca. 3440 (**4**) cm^{-1}, assignable to ν(OH) vibrations for the $(2\text{-py})_2C(OH)O^-$ and H_2O groups, respectively.[15e] The broadness and relatively low frequencies of these bands are both indicative of hydrogen bonding. These two modes coincide at ca. 3450 cm^{-1} in the spectra of the isostructural compounds **2** and **3**.

The spectrum of **1** shows a medium band at 1685 cm^{-1}, suggesting that a certain amount of the organic ligand is present in its ketone form.[17e] This mode is situated at the same wavenumber (1684 cm^{-1}) in the spectrum of free $(2\text{-py})_2CO$, confirming the nonparticipation of the ketone group in the coordination in complex **1**. The spectra of **2**–**4** do not exhibit bands in the region expected for ν(C=O) absorptions, with the nearest strong IR absorptions at 1602 (**2**, **3**) and 1610 (**4**) cm^{-1} which can be assigned as 2-pyridyl stretching modes raised from 1582 cm^{-1} on coordination, as observed earlier[15e,19d] upon complex formation involving hydration of di-2-pyridyl ketone. The strong and rather broad band at 1602 cm^{-1} in **2** and **3** has $\nu_{as}(CO_2)$ character[39] since no other strong band can be observed in the 1600–1515 cm^{-1} region. The $\nu_s(CO_2)$ modes are difficult to assign due to the presence of 2-pyridyl stretching bands at 1440–1415 cm^{-1} and, thus, the application of the spectroscopic criterion of Deacon and Phillips[39] is extremely difficult.

The dicyanamide free anion in $Na[N(CN)_2]$ shows three sharp and medium to strong characteristic stretching bands in the 2290 to 2170 cm^{-1} region attributable to a $\nu_{as}(C\text{–}N) + \nu_s(C\text{–}N)$ combination mode (2286 cm^{-1}), $\nu_{as}(C\equiv N)$ (2232 cm^{-1}) and $\nu_s(C\equiv N)$ (2179 cm^{-1}).[22d] Monodentate coordination has been reported to have a minor effect on these features, whereas the bridging modes of $N(CN)_2^-$ cause a displacement of these bands towards higher frequencies, the effect increasing as one goes from bidentate to tridentate bonding.[22a] In compounds **1**–**3** the three bands occur at 2270–2279, 2210–2231 and 2156–2164 cm^{-1}. These features are indicative of terminal monodentate coordination and are consistent with the X-ray structures of **1** and **2** where $N(CN)_2^-$ was found to coordinate to the metal ions through one of its cyano nitrogen atoms. The $\nu_{as}(C\text{–}N) + \nu_s(C\text{–}N)$ (2275 cm^{-1}), $\nu_{as}(C\equiv N)$ (2238 cm^{-1}) and $\nu_s(C\equiv N)$ (2191 cm^{-1}) vibrations of **4** appear almost at the same frequencies as the corresponding ones in $Na[N(CN)_2]$, confirming the ionic nature of dicyanamide in the Co^{III} complex. The bands at ca. 1350 and 900–950 cm^{-1} in the spectra of **1**–**4** can be assigned to the $\nu_{as}(C\text{–}N)$ and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ν_s(C–N) vibrations, respectively, with a satisfactory degree of certainty.[22a,22g,22i]

Magnetic Studies

Solid-state dc magnetic-susceptibility measurements were performed on polycrystalline samples of **1**–**3** in a 0.1 T field in the range 2.0–300 K. The $\chi_M T$ vs. T and χ_M vs. T plots for **1** are shown in Figure 8. The $\chi_M T$ value is 18.6 $cm^3 mol^{-1} K$ at room temperature, close to the expected value of 17.5 $cm^3 mol^{-1} K$ for four $S = {}^5/_2$ uncoupled spins with $g = 2$. The $\chi_M T$ value decreases slightly in the 300–40 K range and then decreases sharply, reaching a value of 1.0 $cm^3 mol^{-1} K$ at 2.0 K, whereas a maximum of 0.649 $cm^3 mol^{-1}$ in the χ_M vs. T plot is observed at 9 K. The data suggest that the complex appears to possess intramolecular antiferromagnetic interactions. Inspection of the molecular structure (Table 1) reveals that the Mn–O–Mn bond angles in the six faces of the cube are all different. However, if we divide the six faces into three pairs of opposite faces, each member of a given pair has a similar mean Mn–O–Mn bond angle with the other member of the same pair. Thus, the mean Mn–O–Mn bond angles for the faces Mn(1)O(1)Mn(2)O(11), Mn(3)O(21)Mn(4)O(31), Mn(1)O(11)Mn(3)O(21), Mn(2)O(1)Mn(4)O(31), Mn(1)O(1)Mn(4)O(21) and Mn(2)O(11)Mn(3)O(31) are 96.4, 97.5, 101.5, 102.5, 100.5 and 99.3°, respectively. Due to similarities of the mean Mn–O–Mn angles in opposite faces of the cubane motif, the experimental data were fitted using the expression derived from the isotropic Heisenberg Hamiltonian given by Equation (2). The fit of the scheme shown in Figure 9 was performed on $\chi_M$vs. T data by means of the computer program CLUMAG which uses the irreducible tensor operator formalism (ITO).[40] The best fit parameters were $J_1 = -1.71$ cm^{-1}, $J_2 = -0.81$ cm^{-1}, $J_3 = -0.27$ cm^{-1} and $g = 2.10$.

$$H = -J_1(S_1S_4 + S_2S_3) - J_2(S_1S_2 + S_3S_4) - J_3(S_1S_3 + S_2S_4) \quad (2)$$

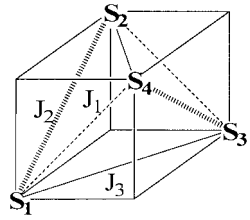

Figure 9. Assignments of J values to M···M interactions for the magnetic model with three coupling constants used for complexes **1** and **2** (M = Mn, Ni).

The J values of **1** are well within the narrow antiferromagnetic range (–0.22 to –4.11 cm^{-1}) reported for other cubane complexes containing the $[Mn_4(\mu_3\text{-}OR)_4]^{4+}$ core.[16a,28a,29]

The $\chi_M T$ vs. T and $\chi_M$vs. T plots for **2** are shown in Figure 10. The $\chi_M T$ value at 300 K is 5.70 $cm^3 mol^{-1} K$. As the temperature is lowered, $\chi_M T$ experiences a very slight increase, reaching a maximum value of 5.79 $cm^3 mol^{-1} K$ at 50 K followed by a much sharper decline at lower temperatures down to 0.84 $cm^3 mol^{-1} K$ at 2 K. On lowering the temperature, χ_M increases without a maximum to a value of 0.42 $cm^3 mol^{-1}$ at 2 K. The overall behaviour of **2** seems to have a ferromagnetic component. The structural parameters of **2** strongly suggest a lower symmetry than T_d for the molecule. As in compound **1**, if we divide the faces of the cube into three pairs of opposite faces, each face of a given pair has a similar mean Ni–O–Ni bond angle with the other member of the same pair. Thus, the mean Ni–O–Ni bond angles for the faces Ni(1)O(1)Ni(2)O(11), Ni(3)O21)Ni(4)O(31), Ni(1)O(11)Ni(3)O(21), Ni(2)O(1)Ni(4(O31), Ni(2)O(11)Ni(3)O(31) and Ni(1)O(1)Ni(4)O(21) are 102.7, 102.0, 99.3, 98.9, 95.6 and 95.7°, respectively. Again, as in **1**, the experimental data were fit using the expression derived from the isotropic Heisenberg Hamiltonian given by Equation (2). The fit on the scheme of Figure 9 was performed on $\chi_M T$ vs. T data by means of the computer program CLUMAG.[40] The best fit parameters were $J_1 = 8.63$ cm^{-1}, $J_2 = -4.43$ cm^{-1}, $J_3 = -0.53$ cm^{-1} and $g = 2.10$.

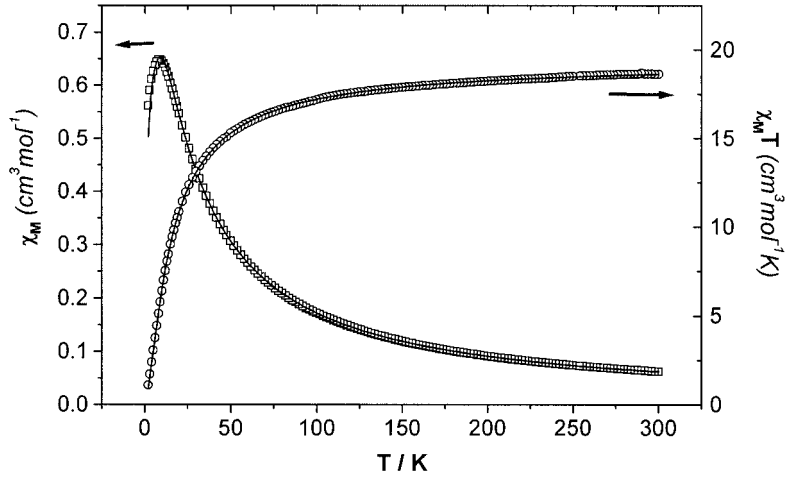

Figure 8. $\chi_M T$ vs. T and χ_M vs. T plots for complex **1**. The solid lines represent the best fit to the data as described in the text.

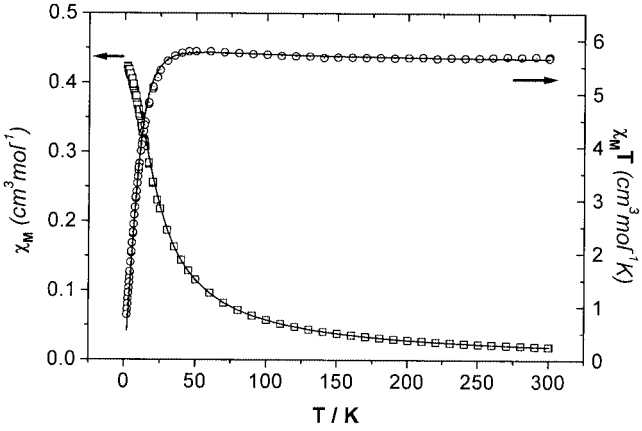

Figure 10. $\chi_M T$ vs. T and χ_M vs. T plots for complex **2**. The solid line represents the best theoretical fit of the data (see text for details).

It should be stressed at this point that the most important parameter in the magnetostructural correlation of tetranuclear nickel(II) complexes possessing the $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$ cubane core has been reported[2e,26,29,30c,31a,41] to be the average Ni–O–Ni angle of a cubane face. A ferromagnetic exchange interaction can be observed for Ni–O–Ni angles lower than 99° and the J value increases as the angle decreases. On the other hand, Ni–O–Ni angles in the vicinity of, and larger than, 99° lead to an antiferromagnetic interaction and the $|J|$ value increases as the angle increases. Accordingly, a linear correlation between J and the Ni–O–Ni angle has been reported.[30c] The differences in sign and in absolute values among the J_1, J_2 and J_3 superexchange interactions are in good agreement with the three different types of faces present in the cubane core of **2** and support the 3-J model used which takes into account the reduced symmetry of the core observed in the X-ray structure of the complex. In **2**, the average Ni–O–Ni angles in the three different sets of faces are 102.4, 99.1 and 95.7°. Thus, the ferromagnetic coupling $J_1 = 8.63\ cm^{-1}$ should be associated with the faces [Ni(2)O(11)Ni(3)O(31), Ni(1)O(1)Ni(4)-O(21)] characterised by the mean angle of 95.7°. The J_2 value of $-4.43\ cm^{-1}$ can be assigned to the faces [Ni(1)O(1)-Ni(2)O(11), Ni(3)O(21)Ni(4)O(31)] with the mean angle of 102.4°, while the very weak antiferromagnetic coupling $J_3 = -0.53\ cm^{-1}$ should be assigned to the remaining two faces with the mean angle of 99.1°. The variable-temperature magnetic susceptibilities for most cubane Ni^{II} complexes have been interpreted on the basis of 1-J or 2-J models.[16a,29,30c,31b] Since the magnetic properties of only few $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$ cubanes have necessitated a 3-J interpretation, Table 6 conveniently summarises some recent members of this small family.

The $\chi_M T$ vs. T plot for **3** is shown in Figure 11. The tetranuclear cluster exhibits a $\chi_M T$ value of $11.85\ cm^3 mol^{-1} K$ at 300 K which is higher than the spin-only value expected ($7.5\ cm^3 mol^{-1} K$) for four uncoupled Co^{II} centres in the $^4T_1$ ground state ($S = {}^3/_2$) with $g = 2$. One reason for this is that the orbital degeneracy of this state is not quenched and, consequently, there is a significant orbital contribution to the magnetic moment.[31b] As the temperature is lowered, $\chi_M T$ slightly increases to reach a broad maximum of $12.35\ cm^3 mol^{-1} K$ at 45 K, then decreases reaching a local minimum at about 25 K and below this temperature it sharply increases to a maximum value of $13.67\ cm^3 mol^{-1} K$ at 6 K, before dropping sharply to $11.58\ cm^3 mol^{-1} K$ at 2 K. χ_M increases continuously upon cooling from a value of $0.0395\ cm^3 mol^{-1}$ at room temperature to a value of $5.79\ cm^3 mol^{-1}$ at 2 K. The overall behaviour of **3** indicates a moderately weak ferromagnetic interaction. The shape of the $\chi_M T$ vs. T plot is probably due to the mixing of phenomena such as the ferromagnetic interaction with the depopulation of the $S = {}^3/_2$ spin levels due to zero-field splitting. The uncommon shape of the $\chi_M T$ vs. T plot is quite reproducible and was confirmed by measurements on different samples (microcrystalline powder, ground crystals, different batches). Analysis of the coupling constants for a high-spin rhombic cobalt(II) tetramer is not possible by me-

Table 6. J [cm^{-1}] as a function of the mean Ni–O–Ni angles [°] for selected $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$-type cubanes the magnetic interpretation of which necessitated the employment of 3-J models.[a]

ans of an effective Hamiltonian based on four $S = {}^3/_2$ spins due to the large anisotropy of this ion.[19c,19d,29] Thus, several measurements were performed in order to characterise the ground state and the sign of the dominant interactions. To rule out any kind of long-range ordering phenomena, ac susceptibility measurements were performed. No out-of-phase response was obtained and dc susceptibility data were also collected under variable external fields (0.3, 0.1 and 0.02 T). The measurements revealed that the low temperature $\chi_M T$ values are field independent indicating a strictly molecular response. Magnetisation experiments show an increase of magnetisation at low fields (M is 6 in Nβ units at 1 T), reaching an Nβ value of 8.3 under the maximum external field of 5 T and clearly indicating a ferromagnetic interaction. Finally, the EPR spectrum of **3** at 4 K shows the typical transition between the ± 2 m_s levels at low fields (g = 15.5).

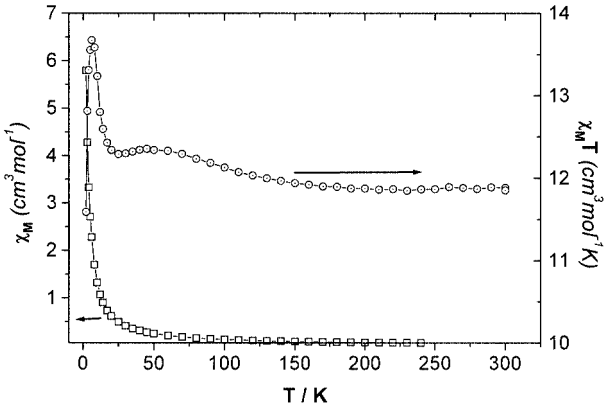

Figure 11. $\chi_M T$ (open circles) vs. T and χ_M (open squares) vs. T plot for complex **3**.

Based on the above data, the ground state of compound **3** can be adequately described as an effective, largely anisotropic, S' = 2 system, obtained from the ferromagnetic coupling of the four low-temperature local spins of the four Co^{II} (S = ½) ions. Complex **3** joins a handful of ferromagnetically coupled tetranuclear complexes consisting of a cubane $[Co_4(\mu_3\text{-}OR)_4]^{4+}$ core.[11b,15c,16a,29,42]

Conclusion and Perspectives

The first use of the dicyanamido ligand in manganese(II), cobalt(II) and nickel(II) acetate chemistry of $(2\text{-py})_2C(OH)O^-$, i.e. the study of the coordination chemistry of the $(2\text{-py})_2C(OH)O^-/MeCO_2^-/N(CN)_2^-$ "ternary ligand blend" has provided access to three new neutral cubane clusters and one mononuclear Co^{III} complex. The three $\{M_4(OR)_4\}$ cubes described are valuable additions to the chemistry of tetranuclear Mn^{II}, Co^{II} and Ni^{II} clusters. With the characterisation of **1**–**3**, the cubane geometry known for the 3d-metal/RCO_2^-/$(2\text{-py})_2C(OH)O^-$ systems can now be considered a feature of 3d-metal/RCO_2^-/pseudohalide/$(2\text{-py})_2C(OH)O^-$ chemistry as well. Complexes **1**–**3** contain low-symmetry cubane cores with different M···M distances and M–O–M angles, resulting in three types of $\{M_2O_2\}$ faces. The lower symmetry of the cubanes has necessitated the use of three discrete exchange parameters for the interpretation of the magnetic properties of **1** and **2**, a fact which is rare in the magnetochemical literature of 3d-metal cubanes. For Ni^{II}, it has recently been emphasised by Chaudhuri, Wieghardt and coworkers[31a] that other structural parameters such as Ni···Ni and Ni···O distances may be important in the magnetostructural correlation for the low-symmetry $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$ cubane core. Thus, more such distorted cubane-type Ni^{II} complexes are needed to resolve this open question.

Analogues of compounds **1**–**3** with other pseudohalides, e.g. N_3^- and NCO^-, are not known, at least to date, and it is currently not evident whether the preparation and stability of these Mn^{II}, Co^{II} and Ni^{II} cubanes are dependent on the particular nature of the pseudohalide ligand. Work is in progress to clarify this matter. The dicyanamido and/or acetate terminal ligands present in **1**–**3** could have future utility as sites for facile incorporation of other monodentate ligands by metathesis or as a means of accessing higher-nuclearity cationic species by using bis(monodentate) bridging aromatic heterocycles. Finally, since the intended bridging behaviour of $N(CN)_2^-$ has not been achieved in **1**–**3**, we are intensively continuing our synthetic efforts to realise the bridging (μ_2-μ_5) potential of $N(CN)_2^-$ in the 3d-metal carboxylate/di-2-pyridyl ketone chemistry.

Experimental Section

Materials and Physical Measurements: All manipulations were performed under aerobic conditions using reagents and solvents (Merck, Aldrich) as received. Elemental analyses (C,H,N) were performed by the University of Ioannina (Greece) Microanalytical Service using an EA 108 Carlo–Erba analyser. IR spectra (400–450 cm^{-1}) were recorded in KBr pellets on Nicolet 520 and Perkin–Elmer PC 16 FTIR spectrometers. Magnetic susceptibility measurements under magnetic fields of approximately 0.1 T in the range 2–300 K and magnetisation measurements (only for complex **3**) in the field range of 1–5 T were performed with a Quantum Design MPMS-XL SQUID magnetometer at the Magnetochemistry Service of the University of Barcelona. All measurements were performed on polycrystalline samples. Pascal's constants were used to estimate the diamagnetic corrections which were subtracted from the experimental susceptibilities to give the corrected molar magnetic susceptibilities. EPR spectra were recorded on a Bruker ES200 spectrometer at X-band frequency.

$[Mn_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 2(2\text{-py})_2CO\cdot 4H_2O$ (1): A solution of $(2\text{-py})_2CO$ (0.099 g, 0.54 mmol) in MeOH (5 mL) was added to a stirred pale yellow aqueous solution (25 mL) of $Mn(O_2CMe)_2\cdot 4H_2O$ (0.270 g, 1.10 mmol) and $Na[N(CN)_2]$ (0.049 g, 0.55 mmol). The resultant yellow solution was stirred for about 10 min and was then allowed to slowly become more concentrated by evaporation at room temperature for a period of 10 days. Well-formed yellow crystals appeared which were collected by filtration, washed with MeOH (5 mL), Et_2O (3 mL) and dried in air. Yield (based on di-2-pyridyl ketone): 0.085 g (55%). $C_{74}H_{66}Mn_4N_{18}O_{18}$ (1715.21): calcd. C 51.8, H 3.9, N 14.7; found C 53.3, H 3.8, N 14.6. IR data (KBR pellet): $\tilde{\nu}$ = 3419 (s), 3329 (s, broad), 3070 (w), 2926 (w), 2270 (m), 2210 (m), 2156 (s), 1685 (m),

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1635 (w), 1600 (s), 1583 (s), 1474 (m), 1435 (m), 1386 (m), 1346 (m), 1320 (m), 1295 (w), 1247 (w), 1222 (m), 1155 (w), 1111 (m), 1080 (s), 1056 (s), 1016 (m), 995 (w), 946 (m), 908 (w), 828 (w), 804 (w), 781 (m), 751 (m), 694 (w), 678 (m), 663 (w), 652 (w), 638 (w), 616 (w), 589 (w), 524 (w), 484 (w), 453 (w) cm^{-1}.

$[Ni_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 10H_2O$ (2): This complex was prepared in a manner completely similar to complex **1** but using $Ni(O_2CMe)_2\cdot 4H_2O$ (0.269 g, 1.08 mmol) in place of $Mn(O_2CMe)_2\cdot 4H_2O$. Green crystals of the product were isolated. Yield (based on di-2-pyridyl ketone): 0.099 g (50%). $C_{52}H_{62}Ni_4N_{14}O_{22}$ (1470.00): calcd. C 42.5, H 4.3, N 13.3; found C 42.4, H 4.3, N 13.4. IR data (KBr pellet): $\tilde{\nu}$ = 3448 (s, broad), 2859 (w), 2279 (m), 2231 (m), 2164 (s), 1602 (s), 1511 (w), 1472 (m), 1438 (m), 1418 (m), 1338 (m), 1292 (w), 1260 (w), 1223 (m), 1157 (w), 1123 (m), 1086 (s), 1062 (m), 1048 (m), 1023 (m), 952 (w), 904 (w), 804 (w), 775 (m), 764 (m), 683 (m), 658 (m), 642 (m), 595 (w), 520 (m), 479 (w) cm^{-1}.

$[Co_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 10H_2O$ (3): A solution of $(2\text{-py})_2CO$ (0.099 g, 0.54 mmol) in MeOH (4 mL) was added to a stirred pink aqueous solution (20 mL) of $Co(O_2CMe)_2\cdot 4H_2O$ (0.269 g, 1.08 mmol) and $Na[N(CN)_2]$ (0.049 g, 0.55 mmol). The resultant red solution was allowed to slowly concentrate at room temperature for a period of 2 days only. X-ray quality reddish-pink crystals formed which were collected by filtration, washed with cold MeOH (3 mL), Et_2O (3 mL) and dried in air. Yield (based on di-2-pyridyl ketone): 0.069 g (35%). $C_{52}H_{62}Co_4N_{14}O_{22}$ (1471.00): calcd. C 42.5, H 4.3, N 13.3; found C 42.6, H 4.2, N 13.3. IR data (KBr pellet): $\tilde{\nu}$ = 3448 (s, broad), 2858 (w), 2279 (m), 2223 (m), 2162 (s), 1602 (s), 1511 (m), 1472 (m), 1436 (m), 1352 (m), 1338 (m), 1292 (w), 1260 (w), 1218 (m), 1157 (w), 1115 (m), 1093 (s), 1065 (m), 1045 (m), 1027 (m), 991 (m), 952 (w), 904 (w), 804 (w), 793 (m), 774 (m), 762 (m), 686 (m), 658 (m), 642 (m), 595 (w), 520 (m), 479 (w) cm^{-1}. In an attempt to obtain a second crop of the reddish-pink crystals of **3** (and thus to increase the yield), the filtrate obtained after separation of **3** was again allowed to slowly become more concentrated at room temperature. A gradual colour change to orange occurred over the course of 2–3 days. After several days reddish-pink and orange crystals were formed. They were carefully collected by filtration and rinsed with a small amount of cold MeOH. The two products were readily separable manually and the reddish-pink and orange crystals proved to be **3** and $[Co^{III}\{(2\text{-py})_2C(OH)O\}_2]\{N(CN)_2\}\cdot 4H_2O$ (4), respectively, by IR spectroscopy (**3**) and crystallography (**4**).

$[Co\{(2\text{-py})_2C(OH)O\}_2]\{N(CN)_2\}\cdot 4H_2O$ (4): A solution of $Co(O_2CMe)_2\cdot 4H_2O$ (0.112 g, 0.45 mmol) in H_2O (30 mL) was slowly added to a stirred solution of $(2\text{-py})_2CO$ (0.184 g, 1.00 mmol) in a mixture of MeOH and H_2O (30 mL, 1:3 v/v). The pink solution obtained was stirred while an aqueous solution (5 mL) of $Na[N(CN)_2]$ (0.049 g, 0.50 mmol) was added. The resultant pink solution was stirred overnight under reflux and during this time a noticeable colour change to orange occurred. Slow concentration of this solution at room temperature gave orange crystals suitable for crystallography. When precipitation was judged to be complete, the crystals were collected by filtration, washed with cold MeOH

Table 7. Crystal data and structure refinements for $[Mn_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 2(2\text{-py})_2CO\cdot 4H_2O$ (**1**), $[Ni_4(O_2CMe)_2\{N(CN)_2\}_2\{(2\text{-py})_2C(OH)O\}_4]\cdot 10H_2O$ (**2**) and $[Co\{(2\text{-py})_2C(OH)O\}_2]\{N(CN)_2\}\cdot 4H_2O$ (**4**).

(1 mL), Et_2O (2× 3 mL) and dried in air. Yields (based on Co) as high as 0.19 g (≈ 70%) were obtained. $C_{24}H_{26}CoN_7O_8$ (599.46): calcd. C 48.1, H 4.4, N 16.4; found C 47.4, H 4.2, N 16.2. IR data (KBr pellet): $\tilde{\nu}$ = 3500 (s, broad), 3442 (m, broad), 3120 (w), 2821 (w), 2275 (m), 2238 (s), 2191 (m), 1642 (sh), 1610 (m), 1470 (sh), 1454 (m), 1390 (w), 1343 (w), 1312 (s), 1249 (s), 1233 (m), 1170 (m), 1029 (s), 950 (w), 903 (w), 824 (m), 762 (s), 699 (m), 683 (m), 573 (m), 525 (w), 494 (w), 479 (w), 455 (w) cm^{-1}.

X-ray Crystallographic Studies: Crystals of **1** and **2** were mounted in capillaries filled with drops of mother liquor while a crystal of **4** was mounted on a glass fibre. Diffraction measurements for **1** and **2** were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo-K_α radiation. Data for **4** were collected on a modified STOE 4-circle diffractometer also with graphite-monochromated Mo-K_α radiation. Complete crystal data and parameters for data collection and refinements are listed in Table 7. Unit-cell dimensions were determined and refined using the angular settings of 25 (for **1** and **2**) or 36 (for **4**) automatically centred reflections in the ranges $11 < 2\theta < 23°$ (for **1** and **2**) or $10 < 2\theta < 15°$ (for **4**). Three standard reflections monitored every 97 (for **1** and **2**) or 100 (for **4**) reflections showed less than 3% variation and no decay. For **1** and **2**, Lorentz, polarisation and Ψ-scan absorption corrections were applied using the Crystal Logic software package whereas for **4** the data were processed without an absorption correction. The structures were solved by direct methods using SHELXS-86[43a] and refined by full-matrix least-squares techniques on F^2 with SHELXL-93[43b] or using the SHELXTL/PC program package[43c] (for **4**). For all three structures the ordered non-hydrogen atoms were refined anisotropically. In the case of **4**, disordered lattice water molecules containing O(4) and O(5) were refined anisotropically with split occupancies of 0.60(2) and 0.40(2), respectively. Further isotropic displacement parameters, split occupancies of 0.50 and geometrical constraints were applied to N(11), C(12), N(13), C(14) and N(15) of the disordered dicyanamide anion. For **1** and **2**, all hydrogen atoms [except those of the acetate ligands which were introduced in calculated positions as riding on their parent carbon atoms] were located from difference maps and refined isotropically. No hydrogen atoms of the solvate molecules were introduced in the refinements. In the case of **4**, hydrogen atoms of water molecules were fixed in positions located from difference maps. The remaining hydrogen atoms were introduced in calculated positions as riding on their parent atoms. Unit-cell determination (at 25 °C) proved that complex **3** is isostructural with **2**. The unit-cell dimensions of **3** are: a = 13.54, b = 19.13, c = 13.16 Å, α = 95.21, β = 111.09, γ = 98.07°, V = 3110 $Å^3$.

CCDC-246277 (for **1**), 246278 (for **2**) and 246279 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

A. E. and R. V. wish to thank the Spanish Ministerio de Ciencia y Technologia (BQU2003/0538 project) and G. S. P. and S. P. P. wish to thank the Research Committee of the University of Patras (K. CARATHEODORY Program No 1941) for financial support of this work. F. A. M. thanks Profs. C. Kratky and F. Belaj (Univ. Graz) for use of equipment.

Coordination Chemistry of the Ditopic Ligand 4-[6-(2-Pyridyl)-2-pyridyl]-6-(2-pyridyl)pyrimidine: Encapsulation of Nitrate by [2×2]Grid Complexes

Larisa Kovbasyuk,[a] Hans Pritzkow,[a] and Roland Krämer*[a]

Keywords: Ligand design / Self-assembly / Nitrate recognition / Grids / Nickel(II) / Cobalt(II)

We describe herein the synthesis, physical properties and crystal structures of metal complexes with the new ligand 6-(2-pyridyl)-4-[6-(2-pyridyl)-2-pyridyl]pyrimidine (**L**). Reactions of **L** with Ni^{II}, Co^{II}, Fe^{II}, Zn^{II} and Cu^{II} nitrates in a 1:1 ratio leads to the self-assembled tetranuclear [2×2] grid complexes **1**–**5** with encapsulated NO_3^- ions, as confirmed by the X-ray crystal structures of $[Ni_4\mathbf{L}_4(DMSO)_2(H_2O)_2](NO_3)(ClO_4)_7\cdot 4\,DMSO\cdot 6\,H_2O$ (**1**) and $[Co_4\mathbf{L}_4(DMF)_4](NO_3)(ClO_4)_7$ (**2**). The mononuclear copper(I) complex $[Cu\mathbf{L}(PPh_3)_2]ClO_4\cdot 2\,(CH_3CN)$ (**6**) and the binuclear $[Cu_2\mathbf{L}_2(CN)(PPh_3)_2]ClO_4$ (**7**) were synthesized from **L** and $[Cu(PPh_3)_3]Cl$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Self-assembly of specially designed metal complexes may afford a variety of unusual topologies, e.g. molecular grids, boxes, ladders and helicates.[1] These highly ordered structures may have well defined cavities which can act as binding pockets for substrates. Self-assembled metal complexes may therefore be useful as receptors, sensors or catalysts. The sizes and shapes of such cavities may be tuned by varying both the ligand structure and the metal ion in order to achieve optimal interaction between the cavity and a substrate.

The development of anion selective receptors is an important topic in chemistry. Reported examples of anion binders based on polynuclear complexes include a "molecular square" assembled from four Ni^{II} ions and tetrazine-derived ligands with a tetrafluoroborate guest,[2] molecular Pd^{II}/Pt^{II} triangles containing ClO_4^- or PF_6^-[3] and a grid-like $Fe^{II}_2Ru^{II}_2$ complex of a 4,6-bis(2,2′-bipyridyl)pyrimidine ligand which encloses chloride in its central cavity.[4] We have recently demonstrated the usefulness of polynuclear metal complexes as ionophores for the construction of anion-selective electrodes.[5]

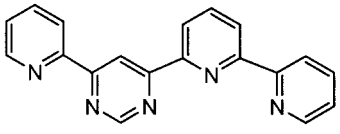
The selective recognition of nitrate is of particular interest since this ion has been implicated in groundwater contamination and is present in high concentrations in certain waste waters. The majority of reported receptors for nitrate are based on H-bonding interactions.[6] Funnel-shaped tri- and hexanuclear Pd^{II}/Pt^{II} complexes incorporating a nitrate at the bottom of the funnel by very weak coordinative bonds are a rare exception.[7] In a recent communication we reported the crystal structure of a tetranuclear nickel(II) complex forming a [2×2] grid structure and incorporating a nitrate in its cavity.[8]

Attempts to isolate the same complex with a Cl^- guest, as observed for the corresponding octahedral M^{II} complexes of the symmetric ligand 4,6-bis(2,2́-bipyridyl)pyrimidine,[4] failed. Interestingly, subtle structural modifications have a significant influence on the host-guest chemistry of the self-assembled complexes.

Herein we present a detailed investigation of the coordination chemistry and metal-induced self-assembly of **L** with the divalent 3d-metal ions Ni^{II}, Fe^{II}, Zn^{II}, Co^{II} and Cu^{II}. In addition, we have explored complex formation of **L** with Cu^{I} ions which prefers a tetrahedral over an octahedral metal coordination as observed in $\mathbf{L}_4M_4$ grid complexes.

Results and Discussion

Details of the synthesis and X-ray structure of the ditopic ligand **L** which has one tridentate and one bidentate metal binding site have been reported elsewhere.[9]



L

Complexes of **L** with Ni^{II}, Co^{II}, Fe^{II}, Cu^{II} and Zn^{II} were prepared by mixing the ligand and suitable metal salts in organic solvents or water. Crystalline compounds were filtered off, washed with isopropanol and dried under high vacuum. Sometimes recrystallisation from different solvents was necessary to obtain crystals suitable for X-ray analysis.

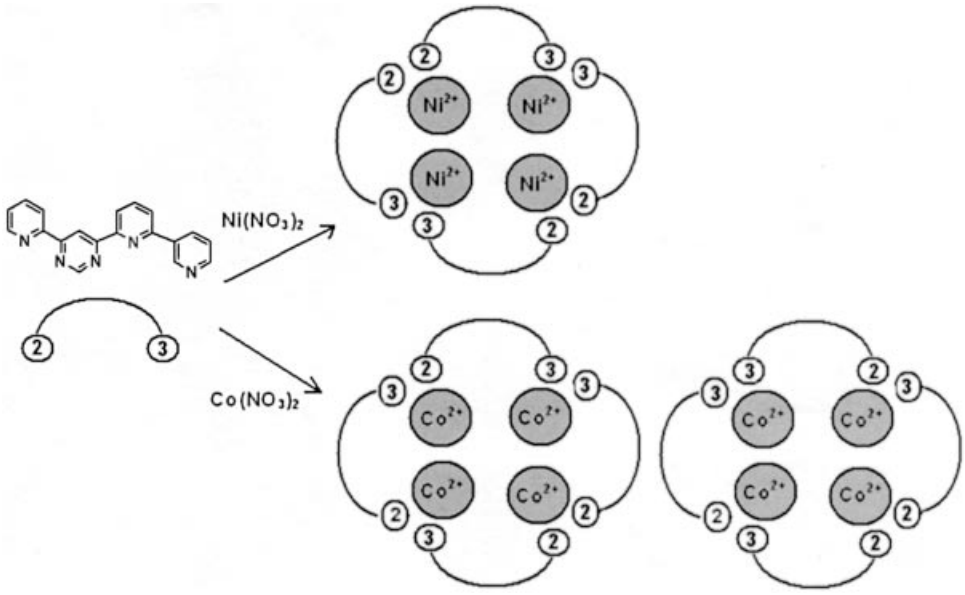

Scheme 1. Tetranuclear grid complexes **1** and **2** are pseudocoordination isomers.

Complex formation is accompanied by a colour change from colourless to yellow in the case of the Ni^{II} complex **1** to red-brown in the case of Co^{II} complex **2**, to dark-blue for the Fe^{II} complex **3** and to blue in the case of the Cu^{II} complex **5**. In the case of the Zn^{II} complex **4**, no significant colour changes were observed. C, H, N analyses of the isolated compounds were in agreement with following formulae: $[Ni_4\mathbf{L}_4(DMSO)_2(H_2O)_2](NO_3)(ClO_4)_7\cdot 4\,DMSO\cdot 6\,H_2O$ (**1**), $[Co_4\mathbf{L}_4(DMF)_4](NO_3)(ClO_4)_7$ (**2**), $[Fe_4\mathbf{L}_4(H_2O)_4](NO_3)(ClO_4)_7\cdot 6\,H_2O$ (**3**), $[Zn_4\mathbf{L}_4(H_2O)_4](NO_3)_4Cl_4\cdot 2\,H_2O$ (**4**) and $[Cu_4\mathbf{L}_4(H_2O)_4](NO_3)_4(ClO_4)_4\cdot 2\,H_2O$ (**5**). For **1** and **2** the tetranuclear structures were confirmed by X-ray analyses. Since **L** is unsymmetrical, isomerism of the metal complexes is possible (Scheme 1).

The complex cation of **1** displays C_2 symmetry and contains two crystallographically independent nickel ions (Figure 1). The four nitrogen atoms of two different molecules of **L** and two oxygen atoms of the *cis*-orientated DMSO and H_2O molecules, respectively, constitute the distorted octahedral environment of Ni(1).[8] Ni(2) is coordinated by six nitrogen atoms of the tridentate sites of two molecules of **L**. Four nickel atoms are arranged at the corners of an almost ideal square [Ni(1)···Ni(2) = 6.170 Å, Ni(1)···Ni(2a) = 6.235 Å, Ni(1)–Ni(2)–Ni(1a) = 88.4°, Ni(2)–Ni(1)–Ni(2a) = 91.6°].

The tetranuclear complex cation of **2**[10] is shown in Figure 2. There is disorder of the ligand connecting Co(1) and Co(2) through its bidentate/tridentate and tridentate/bidentate sites [the site occupation factor for the disordered **L**/DMF ligands on Co(1)–Co(3) is 50:50] and probably for the ligand between Co(2) and Co(3) as well. The DMF ligands could not be localised at these positions. The coordination environments of the cobalt atoms can be described as N_5O or N_6 for Co(1), N_5O or N_6 for Co(2) and N_5O or N_6 for Co(3). The coordination environment of Co(4) is N_4O_2 which is formed from four nitrogen atoms from two

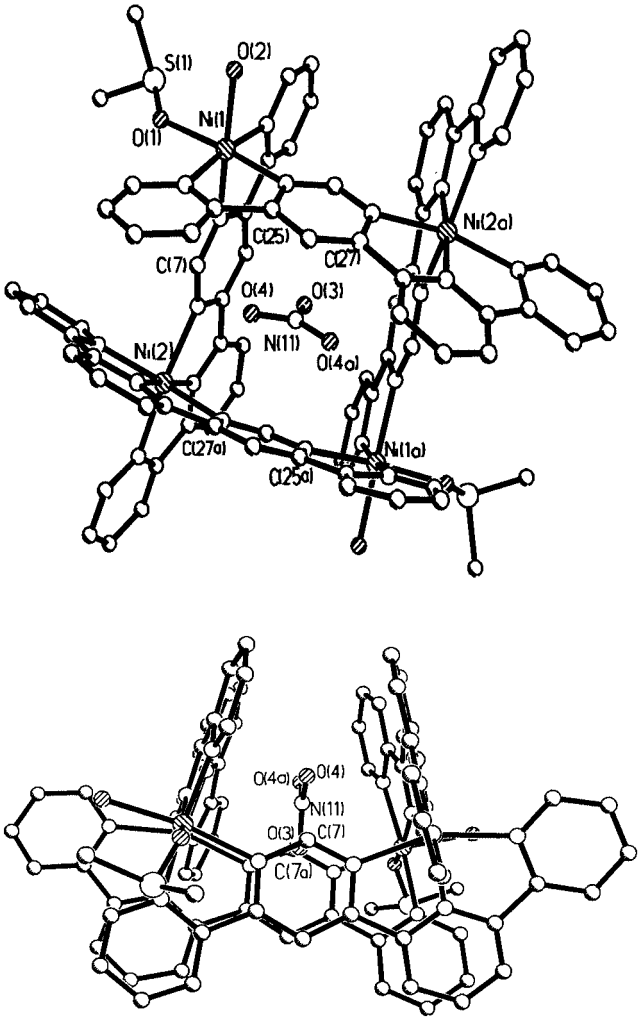

Figure 1. View of the structure of the complex cation of **1** with the enclosed nitrate ion. Hydrogen atoms are omitted for clarity.

different molecules of **L** and two oxygen atoms from DMF molecules.

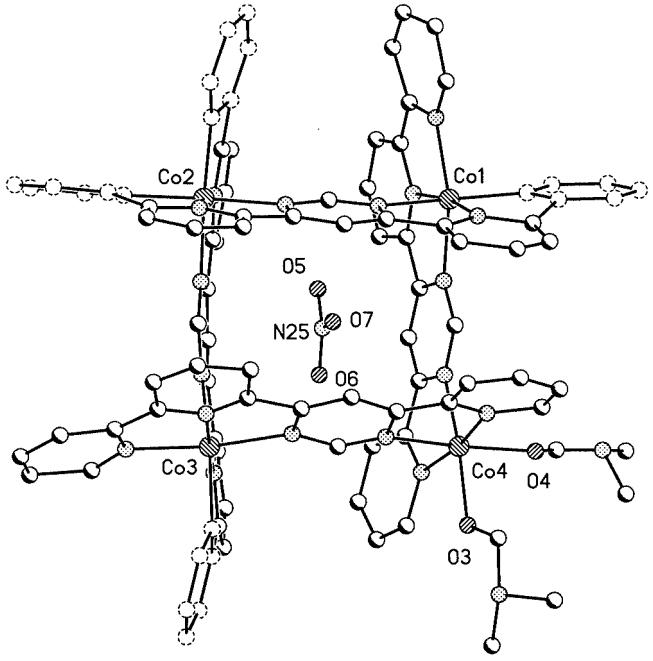

Figure 2. View of the structure of the complex cation of **2** with an enclosed nitrate ion.

The presence of two (depicted in Scheme 1) or more isomers in the crystal of **2** might be the origin of the disorder problems. The Co···Co distances average 6.25 Å which is slightly larger than Ni···Ni distances (6.20 Å) in **1** but significantly shorter than in a related tetracobalt (II) complex derived from a 4,6-bis(2,2′-bipyridyl)pyrimidine ligand (6.49 Å).[11] This illustrates that replacement of one of the two tridentate sites in the latter ligand by a bidentate site has a substantial effect on the cavity size of the self-assembled structure. The difference between the M···M distances in **1** and **2** corresponds to double the difference between the ionic radii of the corresponding metals. Consequently, both a variation in the ligand structure and metal ion size should enable fine tuning of the cavity size in complexes of this type. We have used a series of divalent transition-metals with different atomic radii for construction of [2×2] grids with different cavity sizes for guest binding. Crystallographic data for the Ni^{II} and Co^{II} grids allow us to estimate the M···M distances in the Fe^{II}, Zn^{II} and Cu^{II} [2×2] grids as 6.29, 6.14 and 6.08 Å, respectively, based on the published radii for the high-spin metal ions.[12]

A NO_3^- anion is trapped in the hydrophobic central cavity in both **1** and **2**, the latter being formed from the heterocyclic aromatic rings of the ligands. The molecular plane of the NO_3^- is coplanar to one ligand pair and perpendicular to the second (Figure 1). The close fit of the nitrate in **1** is confirmed by several short van der Waals contacts between the nitrate oxygens with the host, i.e. O(4)···C(25) = 2.814 Å, O(4a)···C(27) = 2.812 Å, O(4)···C(7) = 2.714 Å and O(3)···C(7) = 3.101 Å.[12] It is clear (Figure 1) that the mobility of nitrate within the cage is highly restricted since the two pairs of **L** are not exactly coplanar (interplanar angles are 38.2° and 33.4°) but display a roof-shaped arrangement. Binding of even slightly larger anions should be disfavoured since anion host contacts would be unfavourably short.

In the absence of crystallographic data for compounds **3**, **4** and **5**, a comparison of their solid state infrared spectra indicates that their structures might be related to those of **1** and **2**. Compounds **1**, **2** and **3** show characteristic strong bands of both nitrate (1384, 1384 and 1386 cm^{-1}) and perchlorate (1104, 1102 and 1107 cm^{-1}).[13] In the IR spectrum of **1** two $\nu_{(S=O)}$ peaks appear at 938 and 945 cm^{-1} confirming the presence of coordinated and uncoordinated molecules of DMSO. The presence of DMF molecules in **2** is indicated by presence in the IR spectrum of a strong peak at 1677 cm^{-1} which can be attributed to an amide $\nu_{(C=O)}$ vibration. Strong peaks in the IR spectra of **4** and **5** which are not observed in the spectrum of the free ligand with maxima at 1385, 1378, and 1386, 1378 cm^{-1}, respectively, can be assigned to $\nu_{(N=O)}$ vibrations of the expected two types of nitrate ion. The IR spectrum of **5** also exhibits a strong peak due to the perchlorate ions at 1105 cm^{-1}. All complexes **1**–**5** exhibit, in their IR spectra, a strong peak around 1385 cm^{-1} which in **1** and **2** can be unambiguously attributed to encapsulated nitrate. IR data support the assignment of the related tetranuclear structures of the cations of **3**, **4** and **5** with encapsulated nitrate ions.

To detect magnetic interactions between the metal centres, **2** was subjected to susceptibility measurements in the temperature range 1.7–300 K. Figure 3 shows the temperature dependence of $\chi_m \cdot T$. At 300 K, $\chi_m \cdot T$ equals 9.6 $cm^3 mol^{-1} K$ which roughly corresponds to the expected values for four uncoupled Co^{II} ions (d^7, S =). As T is lowered, $\chi_m \cdot T$ slowly decreases down to 50 K. Below this temperature, $\chi_m \cdot T$ drops abruptly down to 0.5 $cm^3 mol^{-1} K$. This behaviour indicates overall antiferromagnetic interactions between Co^{II} ions. The Curie temperature was evaluated as 23 K. For **3** a ^{57}Fe Mössbauer spectrum recorded at room temperature exhibited a major singlet characteristic of a low spin Fe^{II} species.

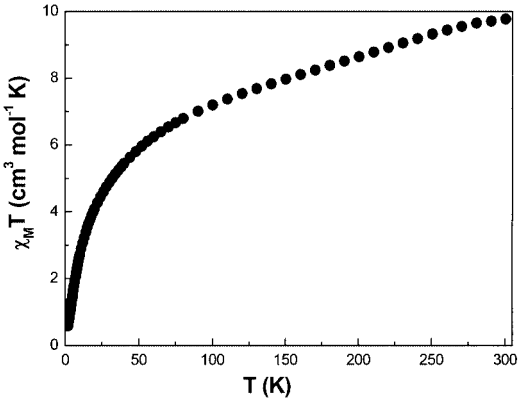

Figure 3. The temperature dependence of $\chi_m \cdot T$ for **2**.

Spectrophotometric titrations of **L** with Co^{II} and Fe^{II} in an acetone/water mixture revealed fast formation of $[\mathbf{L}_2M]^{2+}$ (increase of absorbance at 390 nm) but no further changes were observed immediately after addition of more then 0.5 equiv. of the metal ion (Figure 4). Formation of $\mathbf{L}_2M$ complexes could be confirmed by MALDI mass spectra of solutions containing **L** and M^{II} in a 1:1 ratio. When a MALDI mass spectrum of the Fe^{II} complex solution was recorded several hours after sample preparation, however, new signal corresponding to an $Fe_3\mathbf{L}_2$ fragment appeared.
