Pyrazolylamidino- and Bis(pyrazole)manganese(I) Complexes

Marta Arroyo,[a] Álvaro López-Sanvicente,[a] Daniel Miguel,[a] and Fernando Villafañe*[a]

Keywords: Manganese / N ligands / Pyrazole / Pyrazolylamidino ligands

The pyrazolylamidino complexes *fac*-[MnBr(CO)$_3${NH=C(R)-pz-κ^2*N*,*N*}] or *fac*-[MnBr(CO)$_3${NH=C(R)dmpz-κ^2*N*,*N*}] (R = CH_3, C_6H_5) are obtained by reaction of *fac*-[MnBr(CO)$_3$-(NCR)$_2$] and equimolar amounts of pzH or dmpzH (dmpz = 3,5-Me_2pz), although these reactions also afford the bis(pyrazole) complexes as by-products. The bispyrazole complexes *fac*-[MnBr(CO)$_3$(pzH)$_2$] or *fac*-[MnBr(CO)$_3$(dmpzH)$_2$] are selectively obtained from [MnBr(CO)$_5$] and two equivalents of pzH or dmpzH. Their solid-state structures, determined by X-ray diffraction methods, show the N-bound hydrogens of the pyrazoles pointing towards the bromine atom. The pyrazolylamidino complexes can also be prepared by reactions of equimolar amounts of the bispyrazole and the bisnitrile complexes. The solid-state structures of the pyrazolylamidino complexes containing the dmpz fragment were determined by X-ray diffraction methods.

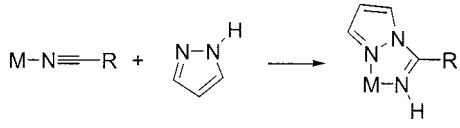
Introduction

An increasing interest is being dedicated to pyrazole-containing chelating ligands.[1] Among them, those containing pyridyl and pyrazolyl fragments are receiving the highest attention, probably because they are involved in different and interdisciplinary aspects, such as the synthesis of supramolecular assemblies or the design of molecules displaying physical properties of interest.[2,3] At the opposite side concerning the attention received are pyrazolylamidines, since only molybdenum, iridium, ruthenium, and platinum complexes containing these ligands have been described so far.[4] However, amidino has been found to be a promising ligand,[5] which may be attributed to several special features of pyrazolylamidino complexes: (a) the different properties of the two donor atoms and the electron delocalization within the ligand makes them potentially interesting for electron-transfer processes and related physical properties, as occurs for the related pyridyl- and pyrazolyl-containing polydentate ligands; (b) the pyrazolylamidino ligands are synthesized in situ (Scheme 1), thus using different nitriles and pyrazoles allows the opportunity of controlling both the electronic and steric properties of the metal complexes, in contrast with most of the ligands, which must be previously synthesized; (c) the NH group may be deprotonated, giving rise to further reactivity by attack of different electrophiles including metal fragments, which would afford heterometallic complexes.



Scheme 1. General method for the synthesis of pyrazolylamidino complexes.

As part of our studies on the chemistry of group 6 and 7 complexes with N-donor chelating ligands,[6] we decided to study the coordination of the pyrazolylamidino ligand to these metals, which has not been explored so far. The first pyrazolylamidinomanganese complexes are reported here.[7] During the course of this work we unexpectedly obtained bis(pyrazole) manganese complexes, which had not been previously reported, therefore their selective syntheses are also described.

The chemistry of bis(pyrazole) complexes is also attracting our attention,[8] since both their structures and reactivity are promising aspects. Concerning their structures, the N-bound hydrogen of pyrazole complexes is commonly involved in hydrogen bonds that give rise to supramolecular arrangements.[9,10] Concerning their reactivity, terminal pyrazole ligands are very useful precursors for bridging pyrazolate homo- or heterobimetallic complexes, which may be obtained by deprotonating the N-bound hydrogen of the coordinated pyrazole when a second metallic substrate is present. This strategy has been successively used by different groups, mainly with middle and late transition elements.[11]

Results and Discussion

Synthesis and Characterization of Bis(pyrazole)manganese Complexes

The bis(pyrazole)manganese(I) complexes *fac*-[$MnBr(CO)_3(pzH)_2$] (**1a**) and *fac*-[$MnBr(CO)_3(dmpzH)_2$] (**1b**) were obtained when [$MnBr(CO)_5$] was treated with a twofold excess of pzH or dmpzH in warm CH_2Cl_2. A white insoluble solid was detected in the reactions with pzH, although the yield of **1a** is still high.[12]

The *fac* geometry of both complexes is evident from their IR spectra in the C–O stretching region, which show three absorptions. The C–O frequencies are slightly higher for **1a** than for **1b**, as is to be expected considering that Hdmpz is a better donor than Hpz. This geometry is supported by the NMR spectroscopic data, as both pyrazole ligands are equivalent. The broadness of the HN signal must be due to a protolysis process involving this proton, which is common in pyrazole complexes. Homodecoupling experiments at low temperature carried out on previously reported complexes have allowed the unequivocal assignment of the signals of the pyrazolic hydrogens.[8a] However, this assignment cannot be unequivocally extended to the complexes described herein, since the chemical shifts of the hydrogens or methyl groups in positions 3 and 5 seem to be affected by different factors that are difficult to evaluate: whether the hydrogen (or methyl) group at position 3 resonates at higher field than that at position 5, or vice versa, may vary in the same family of complexes,[11g] or even depending on the solvent used.[13] Therefore, the assignment proposed for the rest of complexes in the Experimental Section shoud be considered as tentative.

Structure reports of pyrazolemanganese(II) complexes are quite common, but we have only been able to find one report of a crystal structure of a pyrazolemanganese(I) complex,[14] therefore the geometries of complexes **1** were determined by X-ray diffractometric studies. The structures are shown in Figure 1 and relevant distances and angles are collected in Table 1.[15] The distances and angles are very similar in both complexes, and the latter are also similar to those found in previously reported structures of halotricarbonylmanganese(I) complexes containing two monodentate N-donor ligands, which show a slightly distorted octahedral geometry.[16] These distortions are evidenced by the slight deviation from linearity shown by the ligands coordinated *trans* [174.84(17)–176.7(2)°], as well as by the angles formed by the ligands coordinated *cis* [85.71(13)–96.3(2)°]. In both structures the smaller angles are those formed by the two pyrazoles, as occurs in the related manganese(I) complexes containing two monodentate N-donor ligands indicated above.[16]

The N-bound hydrogens of the pyrazoles point to the bromine atom, which may be attributed both to steric and electronic reasons. Steric factors are obviously more important in **1b**, where this orientation brings the methyl groups bound to the 5-carbon close to a carbonyl group, which is smaller than the bromine atom. Therefore, this orientation

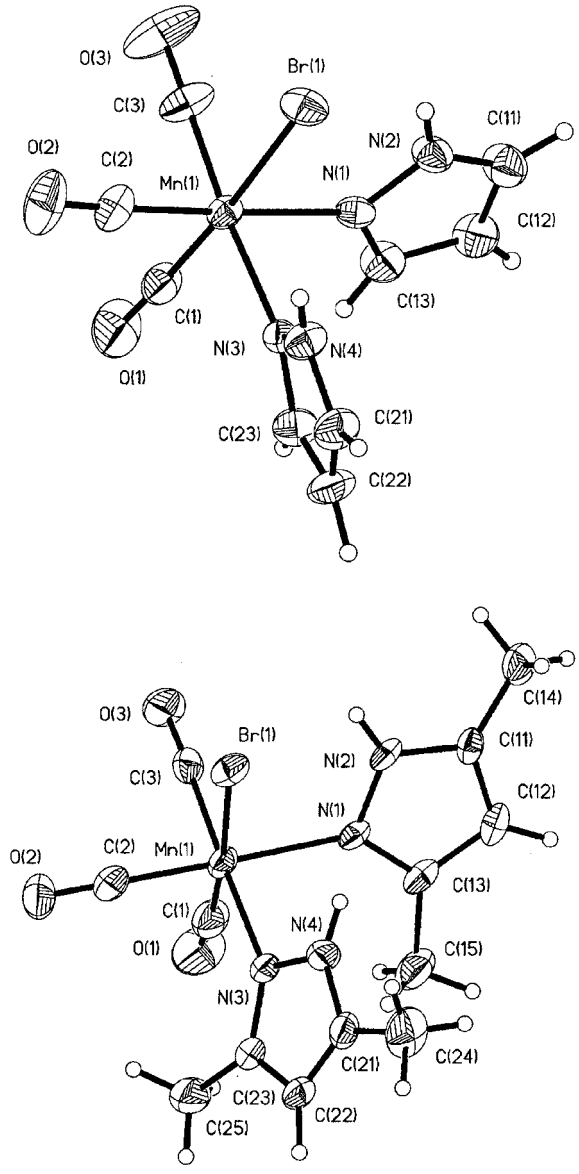

Figure 1. Perspective views of *fac*-[$MnBr(CO)_3(pzH)_2$] (**1a**, top), and *fac*-[$MnBr(CO)_3(dmpzH)_2$] (**1b**, bottom), showing the atom numbering.

reduces the steric hindrance, since the methyl groups bound to the 5-carbon and the bulky bromine atom are at opposite sides of the molecule. Steric hindrance is also responsible for the tilting of the Hdmpz ligands, which are bent in the same sense around the Mo–N bonds, as has been found in other bis(Hdmpz) complexes.[8b] The average dihedral angles are 37(1)° and 34(1)°, so they are close to the planes that bisect the angles between the *cis* substituents. This tilting is not observed in **1a**, where the deviation of the Hpz ligands from the plane perpendicular to that containing the metal and the nitrogen donor atoms is much lower [23(1)° and –10(1)°]. The second difference between the pyrazole ligands in **1a** and **1b** concerns their relative orientation: in **1b** they are tilted in the same direction in order to reduce their steric hindrance, whereas in **1a** the Hpz ligands are

N(1)–Mn(1)–Br(1)	90.26(10)	88.01(11)

tilted slightly such that the C5-bound hydrogens are closer than the N-bound hydrogens.

Electronic factors also explain why these hydrogens point to the bromine atom, since they are involved in weak intermolecular hydrogen bonds. In **1a**, only intramolecular hydrogen bonds are detected: 2.66 Å for H(2)···Br and 2.57 Å for H(4)···Br. These and the corresponding N···Br distances [3.206(1) and 3.212(1) Å] confirm the presence of a hydrogen bond, which may be considered as "weak".[17] The bromine atom in **1b** is also involved in two weak intramolecular hydrogen bonds with the N-bound hydrogens [2.62 Å for H(2)···Br and 2.57 Å for H(4)···Br], the corresponding N···Br distances being 3.218(1) and 3.191(1) Å, and by a weak intermolecular hydrogen bond to one of the N-bound hydrogen atoms of an adjacent molecule [2.68 Å for H(2)···Br, with N···Br = 3.519(1)]. Similar hydrogen bond lengths have been found for other bromo complexes containing pyrazoles.[8a,18]

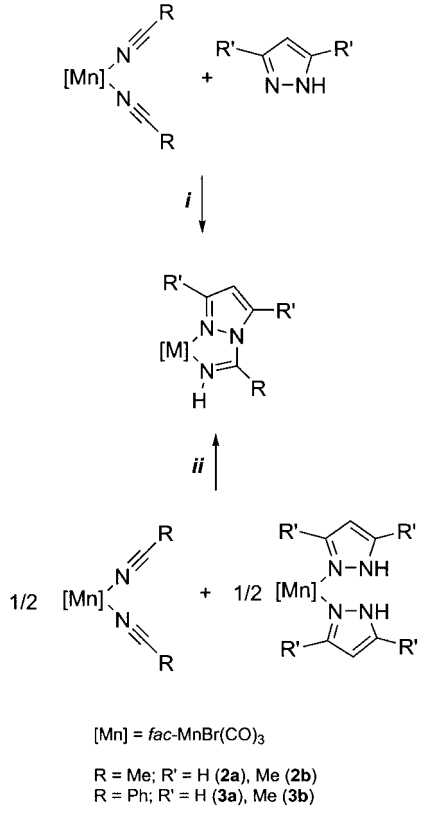
The structure of the related rhenium complex *fac*-[ReBr(CO)$_3$(pzH)$_2$][18a] shows some analogies and differences with those reported here: the relative orientation of the pzH ligands is similar to that of Hdmpz in **1b**, but only one of the N-bound hydrogens in the rhenium complex is involved in a intermolecular hydrogen bond.

Synthesis and Characterization of Pyrazolylamidinomanganese Complexes

The synthesis of pyrazolylamidinomanganese(I) complexes was carried out by reacting equimolar amounts of the corresponding bis(nitrile) complexes and pyrazole (Scheme 1). Nucleophilic addition to metal-activated nitriles is a well-known reaction that has been extensively used to obtain a wide variety of ligands.[19]

The acetonitrile complex *fac*-[MnBr(CO)$_3$(NCMe)$_2$], which was first described more than thirty years ago,[20] was synthesized by heating [MnBr(CO)$_5$] in acetonitrile under controlled conditions in order to avoid bromide displacement to yield the cationic product. It is well known that the carbonyls are ejected before the substitution of the bromide when a thermal process is carried out.[21] A similar method was used to obtain *fac*-[MnBr(CO)$_3$(NCPh)$_2$] (see Exp. Sect.), for which we have not been able to find any previous report.[22]

The reactions of the bis(nitrile) complexes and pyrazole (Scheme 2, route *i*) afford the desired pyrazolylamidino complexes *fac*-[MnBr(CO)$_3${*N*H=C(R)pz-κ^2*N*,*N*}] (R = CH$_3$, **2a**; Ph, **3a**) or *fac*-[MnBr(CO)$_3${*N*H=C(R)dmpz-κ^2*N*,*N*}] (R = CH$_3$, **2b**; Ph, **3b**). However, variable amounts of the bis(pyrazole) complexes **1** are also obtained as by-products. The presence of the bispyrazole complexes could be due to the instability of the bisnitrile complexes under these reaction conditions, which would decrease the amount of available manganese and therefore would increase the manganese/pyrazole ratio. Thus, we decided to attempt the syntheses of the pyrazolylamidino complexes by reacting equimolar amounts of the bis(nitrile) and bis(pyrazole) complexes (Scheme 2, route *ii*) as we believed this would increase the amount of manganese present in the mixture and would not increase the manganese/pyrazole ratio. However, this method did not improve the selectivity of the



Scheme 2. Synthesis of pyrazolylamidino complexes.

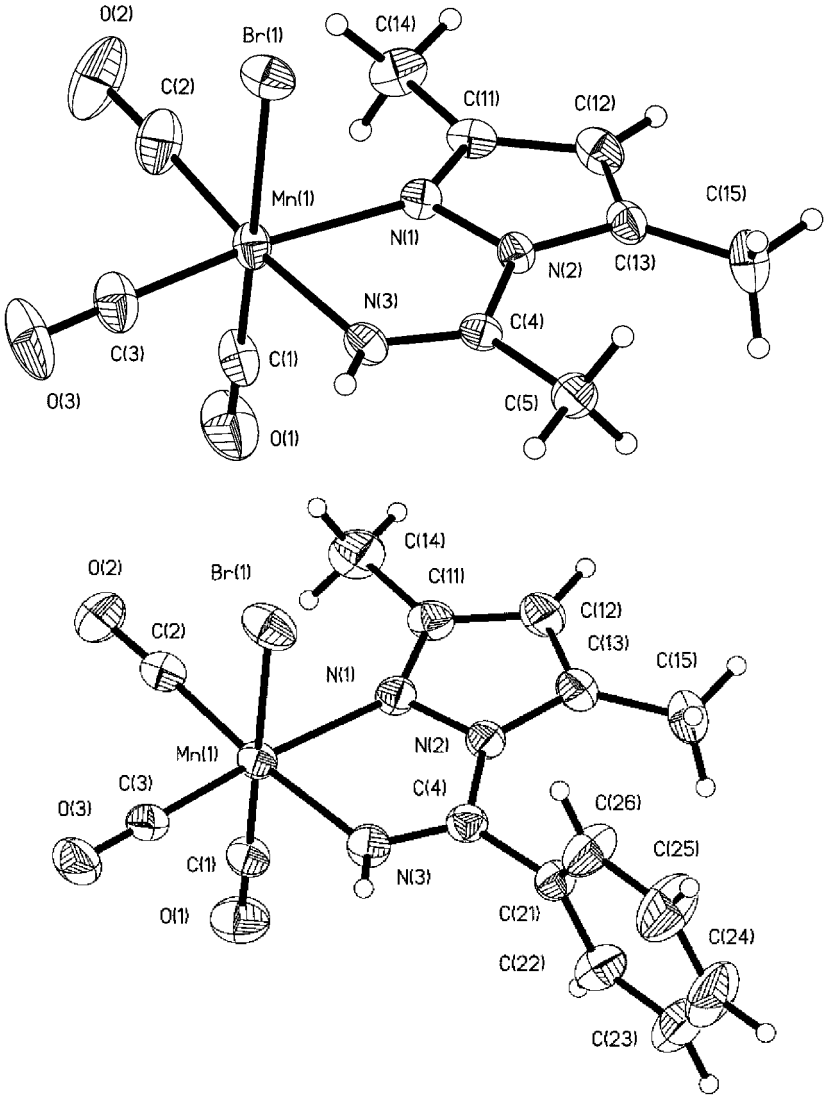

Figure 2. Perspective views of *fac*-[MnBr(CO)$_3${*N*H=C(Me)dmpz-κ^2*N*,*N*}] (**2b**, top) and *fac*-[MnBr(CO)$_3${*N*H=C(Ph)dmpz-κ^2*N*,*N*}] (**3b**, bottom) showing the atom numbering.

process since it afforded similar mixtures of **1** and **2** (see Exp. Sect.).

The C–O stretching region of **2** in the IR spectra also shows three absorptions, as expected for a *fac* geometry. The C–O frequencies follow the expected trends considering the better donor properties of (a) Hdmpz compared to Hpz, and (b) amidino ligands derived from acetonitrile compared to those derived from benzonitrile. The C–N stretching absorption of the amidine ligand is also evident in the IR spectra. The C–N frequencies are slightly higher for complexes **2** than for complexes **3**, which could point to a higher delocalization in the latter due to the presence of a phenyl group instead of a methyl.

The NMR spectroscopic data do not provide structural information, therefore one of each type of complex was subjected to a crystallographic study. The structures are shown in Figure 2 and relevant distances and angles are collected in Table 2. The structural data are essentially the same in both complexes, and very similar to those found in previously reported structures of halotricarbonylmanganese(I) complexes containing a bidentate N-donor ligand.[23] The distances and angles found in the pyrazolylamidino ligands are also similar to those found in other pyrazolylamidino complexes.[4]

The N-bound hydrogen atoms of both structures are involved in intermolecular hydrogen bonds, with the bromine atom in **2b** [H(3)···Br = 2.66 Å; N(3)···Br = 3.483(1) Å], which may be considered as "weak",[17] whereas in **3b** they are linked to a molecule of tetrahydrofuran present in the lattice [H(3)···O(90) = 1.90 Å; N(3)···O(90) = 2.873(7) Å] by a hydrogen bond which may be considered as "moderate".[17]

Experimental Section

General Remarks: All manipulations were performed under N_2 by conventional Schlenk techniques. Filtrations were carried out with dry Celite under N_2. Solvents were purified according to standard

procedures.[24] *fac*-[MnBr(CO)$_3$(NCMe)$_2$] was obtained as described below and its CO stretching bands were compared with those described previously.[20] *fac*-[MnBr(CO)$_3$(NCPh)$_2$] was obtained as described below and its CO stretching bands were compared with those displayed by a sample of *fac*-[MnBr(CO)$_3$-(NCPh)$_2$] obtained by the method previously described for the MeCN complex.[20] All other reagents were obtained from the usual commercial suppliers and used as received. IR spectra were recorded with a Perkin–Elmer RX I FT-IR apparatus as KBr pellets from 4000 to 400 cm^{-1}. NMR spectra were recorded with Bruker AC-300 or ARX-300 instruments in $(CD_3)_2CO$, at room temperature unless otherwise stated. NMR spectra are referenced to the internal residual solvent peak for ^{1}H and ^{13}C{^{1}H} NMR. Assignment of the ^{13}C{^{1}H} NMR spectroscopic data was supported by DEPT experiments and relative intensities of the resonance signals. Elemental analyses were performed on a Perkin–Elmer 2400B microanalyzer.

***fac*-[MnBr(CO)$_3$(Hpz)$_2$] (1a):** Hpz (0.041 g, 0.6 mmol) was added to a solution of [MnBr(CO)$_5$] (0.082 g, 0.3 mmol) in CH_2Cl_2 (20 mL). The solution was stirred at 40 °C for 2 h, during which time a white solid precipitated. The solvent was removed in vacuo and the yellow residue was extracted with THF (ca. 20 mL) and filtered. Hexane was added (ca. 20 mL) and the solution was concentrated and cooled to –20 °C to give a yellow-orange microcrystalline solid, which was decanted, washed with hexane (3 × 3 mL approximately), and dried in vacuo to yield 0.094 g (88%) of **1a**. IR (THF): $\tilde{\nu}$ = 2030 cm^{-1} vs, 1940 vs, 1910 vs. IR (KBr): $\tilde{\nu}$ = 3341 cm^{-1} m, 3302 m, 3144 w, 2921 w, 2035 vs, 1940 vs, 1918 vs, 1468 w, 1352 w, 1139 w, 1127 m, 1056 m, 763 m, 676 w, 634 w, 602 w, 583 w, 512 w. ^{1}H NMR (300 MHz): δ = 6.47 (s, 2 H, *H*^{4} Hpz), 7.81 (s, 2 H, *H*^{3} Hpz), 7.89 (s, 2 H, *H*^{5} Hpz), 12.16 (br., 2 H, *H*N) ppm. ^{13}C{^{1}H} NMR (75.78 MHz): δ = 107.9 (s, *C*^{4} Hpz), 132.6 (s, *C*^{3,5} Hpz), 144.2 (s, *C*^{5,3} Hpz), 222.8 (br., *C*O) ppm. $C_9H_8BrMnN_4O_3$ (355.03): calcd. X-ray Crystallographic Study of 1a, 1b, 2b, and 3b: Crystals were grown by slow diffusion of hexane into concentrated solutions of the complexes in CH_2Cl_2 (for **1a** and **1b**) or THF (for **2b** and **3b**) at –20 °C. Relevant crystallographic details are given in Table 3. A crystal was attached to a glass fiber and transferred to a Bruker AXS SMART 1000 diffractometer with graphite-monochromated Mo-K_α radiation and a CCD area detector. A hemisphere of the reciprocal space was collected up to 2θ = 48.6°. Raw frame data were integrated with the SAINT program.[25] The structure was solved by direct methods with SHELXTL.[26] A semi-empirical absorption correction was applied with the program SADABS.[27] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were set in calculated positions and refined as riding atoms, with a common thermal parameter. All calculations and graphics were made with SHELXTL.

CCDC-266383 (for **1a**), -266384 (for **1b**), -266385 (for **2b**), and -266386 (for **3b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Guanidinate Complexes of Heavier Alkaline-Earth Metals (Ca, Sr): Syntheses, Structures, Styrene Polymerization and Unexpected Reaction Behaviour

Florian Feil[b] and Sjoerd Harder*[a]

Keywords: Alkaline earth metals / Amides / Amidinates / Guanidinates / Polystyrene

The guanidinate complex [Ca{(Cy)N–C{N(SiMe$_3$)$_2$}–N(Cy)}$_2$] can be prepared in good yields and in crystalline purity by two different routes: 1) addition of [Ca{N(SiMe$_3$)$_2$}$_2$] to (Cy)-N=C=N(Cy) or 2) addition of KN(SiMe$_3$)$_2$ to (Cy)N=C=N(Cy) followed by a metathesis reaction of the obtained potassium guanidinate complex with CaI$_2$. Crystallization from Et$_2$O yielded [Ca{(Cy)N–C[N(SiMe$_3$)$_2$]–N(Cy)}$_2$·(Et$_2$O)] (**1**), which shows a C_2-symmetric structure in the crystal. A Sr analogue could be prepared likewise and also crystallizes as the mono-etherate [Sr{(Cy)N–C{N(SiMe$_3$)$_2$}–N(Cy)}$_2$·(Et$_2$O)] (**2**) with a very similar crystal structure. The Schlenk equilibrium between (**1**) and [Ca{α-(Me$_3$Si)-*o*-(Me$_2$N)-benzyl}$_2$·(THF)$_2$] (**3**) in benzene is not completely on the heteroleptic side; however, an excess of (**1**) yields predominantly the heteroleptic benzylcalcium complex [Ca{(Cy)N–C{N(SiMe$_3$)$_2$}–N(Cy)}{α-(Me$_3$Si)-*o*-(Me$_2$N)-benzyl}] (**4**). Styrene polymerization with this mixture results largely in atactic polystyrene of which the molecular weight distribution shows a tailing in the lower range. This could be due to decomposition of the guanidinate ligand under the given polymerization conditions. It is shown that heating a mixture of **1** and **3** gives the crystalline decomposition product [Ca{(Cy)N–C{N(SiMe$_3$)$_2$}–N(Cy)}{(Cy)-(TMS)N}] (**5**), which crystallizes as a dimer with bridging amide ligands.

Introduction

The coordination chemistry of amidinates and the related guanidinates has been well-explored for main-group metals as well as for transition metals.[1–9] These powerful electron-donating ligands not only coordinate to a remarkably wide range of metal ions from all parts of the periodic table, but also show a rich variety of coordination modes.[1–3] Other advantages of this class of ligands are their easy accessibility and the possibility of substituent variation, which allows for tuning of their steric and electronic properties. The latter advantage makes these ligands well-suitable as spectator ligands in catalysis and this opportunity has been well-exploited in the design of polymerization catalysts.[10–22]

In the course of our studies on polymerization catalysts based on alkaline-earth metals,[23–27] we have now prepared guanidinate complexes of the heavier alkaline-earth metals Ca and Sr and explored their structures, reactivity and their behaviour in styrene polymerization.

Results and Discussion

The homoleptic calcium bis(guanidinate) complex (**1**) was prepared by two alternative routes (Scheme 1): i) direct addition of [Ca{N(SiMe$_3$)$_2$}$_2$] to 1,3-dicyclohexylcarbodiimide or ii) addition of KN(SiMe$_3$)$_2$ to 1,3-dicyclohexylcarbodiimide and subsequent reaction of the potassium guanidinate with CaI$_2$. The analogous strontium bis(guanidinate)

complex **2** was synthesized by reaction of the potassium guanidinate with SrI_2.

The calcium bis(guanidinate) complex **1** crystallizes as a mono-etherate. The crystal structure has two independent molecules in the asymmetric unit, which are geometrically similar within their standard deviations (Figure 1). Both molecules show crystallographic C_2-symmetry with the C_2-axis going through Ca and O.

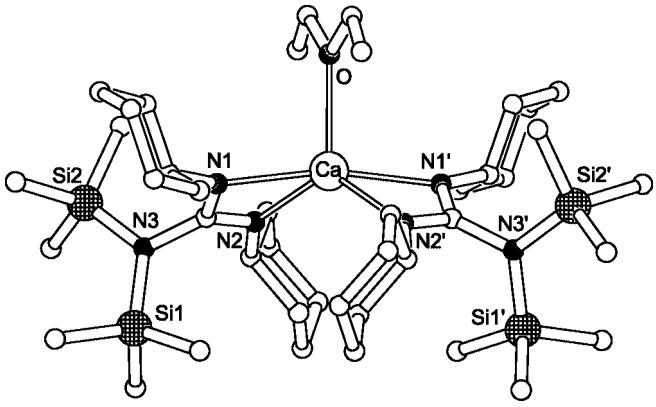

Figure 1. (a) Crystal structure of **1**. Hydrogen atoms have been omitted for clarity and only one of the two crystallographic independent, but very similar, molecules is shown. Selected bond lengths [Å] and angles [°] (values for the other independent molecule are given in square brackets): Ca–N1 2.387(2) [2.369(3)], Ca–N2 2.380(3) [2.388(3)], Ca–O 2.424(3) [2.421(3)]; N1–Ca–N2 56.12(8) [56.47(8)]. The strontium complex **2** is isostructural with **1**; selected bond lengths [Å] and angles [°]: Sr–N1 2.534(3) [2.526(3)], Sr–N2 2.514(3) [2.520(3)], Sr–O 2.559(3) [2.559(3)]; N1–Sr–N2 53.01(9) [53.13(9)].

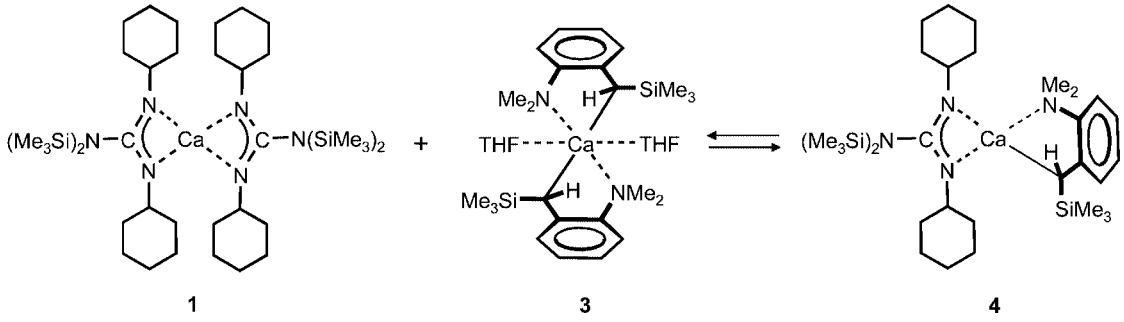
The N_3C units of the guanidinate ligands are planar (maximum deviations from their least-squares planes are 0.004 and 0.008 Å). The $N(SiMe_3)_2$ substituents oriented themselves perpendicular to the NCN plane with dihedral Si_2N/NCN angles of 96.1(1)° and 91.7(1)°, thus preventing N(*p*)–$CN_2(\pi)$ interactions. A similar conformation has been observed in the alkali-metal salts of the (Cy)N–C{N-$(SiMe_3)_2$}–N(Cy) anion.[9]

The guanidinate ligands act as bidentate ligands with an average bite angle of 56.3(8)° and are twisted with respect to each other, which gives rise to C_2-chirality of the molecule. The two independent molecules in the asymmetric cell are nearly mirror images. The coordination geometry of the Ca metal is not clear-cut due to the small bite angle of the guanidinate ligands.

The Ca^{2+} ion is located slightly out of the N_3C planes by 0.301 and 0.358 Å. The Ca–N bond lengths [average 2.381(3) Å] are shorter than those in the structure of the calcium amidinate complex [Ca{Me_3SiN–C(Ph)–$NSiMe_3$}$_2$·$(THF)_2$] for which an average Ca–N bond of 2.431(2) Å has been reported.[28] The longer amide–metal coordination in the latter can be explained by the presence of two neutral ether donor ligands instead of one. The steric bulk of the two guanidinate ligands in **1** allows only one ether molecule in the coordination sphere of Ca and is therefore comparable to the steric bulk of 1,3-$(SiMe_3)_2Cp^-$ or *i*$Pr(Me)_4Cp^-$. Both these Cp ligands form calcocenes also with only one Et_2O molecule in the coordination sphere of Ca.[29]

The strontium bis(guanidinate) complex **2** likewise crystallizes as a mono-etherate complex which is isostructural to **1** (Figure 1). The Sr–N and Sr–O bond lengths are, on average, 0.143 Å and 0.137 Å longer than those in the Ca analogue, which nicely represents the difference of 0.13 Å in the ionic radii of the two alkaline-earth metals. The Sr–N bond lengths in **2** [average 2.524(3) Å] are somewhat shorter than those in the strontium amidinate complex [Sr{Me_3SiN–C(Ph)–$NSiMe_3$}$_2$·$(THF)_2$] for which the average Sr–N bond measures 2.583(9) Å.[30] The longer metal–ligand bond length in the latter complex can again be explained by the presence of one extra donor molecule. The N–Sr–N′ bite-angle in **2** [53.1(1)°] is, however, very similar to that in the amidinate complex [Sr{Me_3SiN–C(Ph)–$NSiMe_3$}$_2$·$(THF)_2$] [53.3(3)°].

Our continuing interest in the use of benzylcalcium complexes for the living and syndiotactic polymerization of styrene spurred us to prepare heteroleptic benzylcalcium complexes containing the chelating guanidinate ligand. Such heteroleptic initiators were prepared by ligand exchange between homoleptic **1** and the dibenzylcalcium complex **3** (Scheme 2). Mixing benzene solutions of **1** and **3** does not result in complete ligand exchange, but a Schlenk equilibrium between homoleptic (**1** and **3**) and heteroleptic (**4**) species is observed. NMR studies in [D_6]benzene show that the equilibrium constant at 20 °C amounts to about 6. For this reason, further polymerization studies were performed with



1 **3** **4**

Scheme 2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mixtures of **1** and **3** in which homoleptic **1** is in excess. This largely results in the formation of heteroleptic **4** mixed with homoleptic **1**. Since the latter is not an active initiator in styrene polymerization, the polymerization is mainly initiated by the heteroleptic benzylcalcium species **4**.

Styrene polymerizations (see Exp. Sect. for details) with 2:1 or 4:1 mixtures of **1** and **3** both yield predominantly atactic polystyrene (also in the absence of solvent). Although the guanidinate ligand has no effect on the stereoselectivity of the polymerization, it has a distinct accelerating influence on the polymerization rate. Styrene polymerization with a 2:1 mixture of **1** and **3** (k = $5.7 \pm 0.3\ L\,mol^{-1}\,s^{-1}$) is more than twice as fast as styrene polymerization with **3** ($k = 2.48 \pm 0.11\ L\,mol^{-1}\,s^{-1}$). This increased polymerization rate could be the consequence of the excellent donor properties of the chelating bidentate guanidinate ligand: this would weaken the benzylcalcium bond and increase the nucleophilicity of the propagating chain-end. Although fast propagation is advantageous for a stereoselective polymerization (the competing inversion of the chiral chain-end results in racemization and therefore loss in stereocontrol)[24] we find essentially atactic polymer. Apparently the guanidinate ligand also increases the rate of inversion of the chiral chain-end.

The molecular-weight distributions of the obtained polymers all show relatively large dispersion indices (>1.5) and a very pronounced tailing in the low molecular weight range. This could be an indication of decomposition of the propagating species during the polymerization experiment. Since it is known from our earlier work that the benzylic group in heteroleptic benzylcalcium compounds can react with the spectator ligand,[27,31] we investigated a benzene solution of **1** and **3** at higher temperatures, i.e. the conditions of the polymerization experiment. Keeping the initiator solution overnight at 80 °C yielded, after subsequent concentration and cooling, a colourless crystalline product (**5**), which dissolves badly in benzene. Analysis of these crystals by X-ray diffraction revealed that one of the guanidinate ligands had decomposed into the amide (Cy)-$(Me_3Si)N^-$, which forms a heteroleptic complex with the original guanidinate ligand (Figure 2). In the solid state, this complex forms a centrosymmetric dimer in which the amide ligands bridge the Ca^{2+} ions and the guanidinate anions act as bidentate ligands located in terminal positions.

The geometry of the guanidinate ligand in **5** is very similar to that observed in **1** and **2**: the N_3C unit is planar (maximum deviation from the least-squares plane is 0.005 Å) and the $(Me_3Si)_2N$ substituent is oriented perpendicular to this plane [the dihedral Si_2N/NCN angle is 87.1(1)°]. The Ca^{2+} ion is located only 0.023 Å out of the N_3C plane. The bite angle of the chelating bidentate guanidinate ligand amounts to 57.6(1)° and is similar to that in **1**. As can be seen from the somewhat shorter Ca–N bond lengths [average 2.337(3) Å], the guanidinate ligand in **5** binds slightly more strongly to the metal than that in **1**. The Ca–N bond lengths to the bridging amides are longer [average 2.435(3) Å].

The formation of $(Cy)(Me_3Si)N^-$ can only be explained by assuming a 1,3-shift of the Me_3Si substituent as the first step (a precedent for a similar shift in an amidinate ligand[22] is known). A possible mechanism for the formation of the amide is proposed in Scheme 3. Ring-flip of the cyclohexane substituents brings the attached N into the axial position and creates more space for the $(Me_3Si)_2N$ substituent in the backbone of the ligand. This allows for rotation of the $(Me_3Si)_2N$ group and delocalization of the N lone-pair into the π-system. Such a resonance structure with enhanced ligand basicity is known for guanidinate ligands with smaller substituents in the backbone.[5,8] A 1,3-shift of the Me_3Si substituent gives a new guanidinate ligand, which could be in equilibrium with $(Cy)(Me_3Si)N^-$ and (Cy)-N=C=N–$SiMe_3$. Such an equilibrium would be strongly on the side of the guanidinate ligand. However, trapping of the

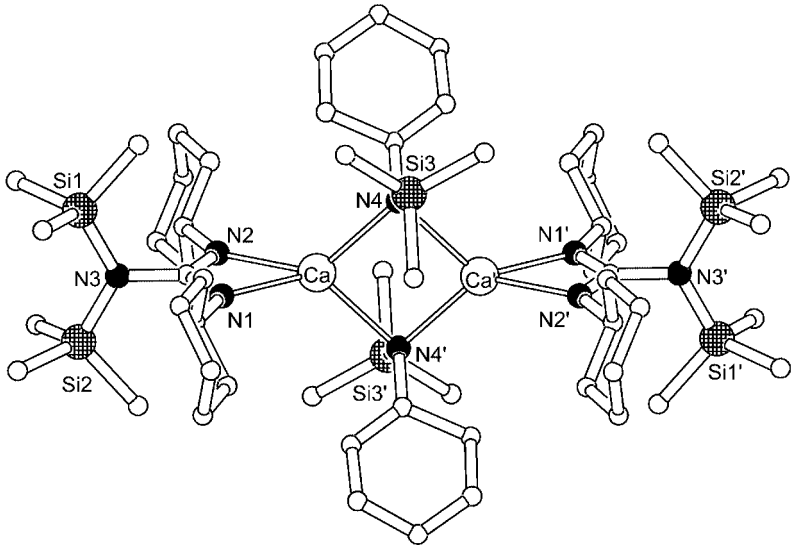


Figure 2. (a) Crystal structure of centrosymmetric **5**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ca–N1 2.316(4), Ca–N2 2.357(3), Ca–N4 2.422(3), Ca–N4′ 2.447(3); N1–Ca–N2 57.6(1), N4–Ca–N4′ 90.1(1).

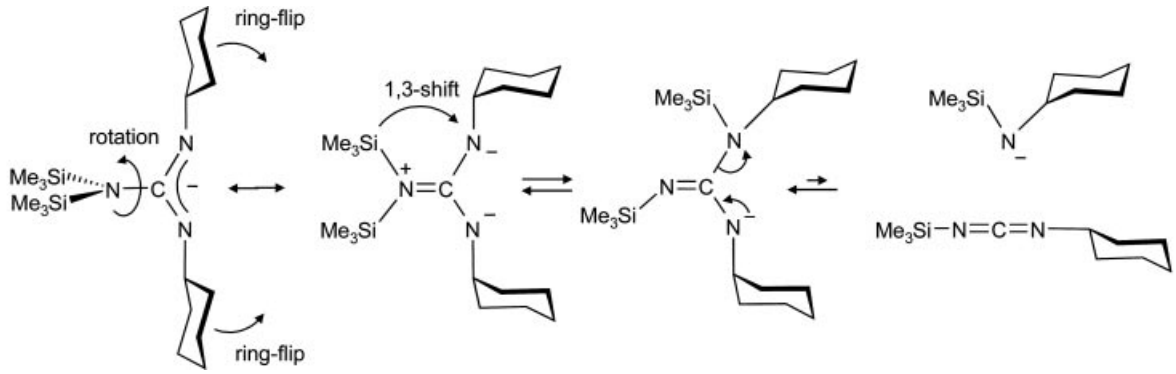

Scheme 3.

carbodiimide by-product by addition of the α-(Me_3Si)-*o*-(Me_2N)-benzyl anion to the C=N bond would result in formation of (Cy)(Me_3Si)N^-.[38] A similar mechanism during the polymerization of styrene would result in partial degradation of the guanidinate ligand and partial quenching of the polystyryl chain-end due to reaction with the carbodiimide.

Conclusions

The homoleptic calcium bis(guanidinate) complex **1** can be prepared in high yields and crystalline purity by two routes, both based on addition of an organometallic compound to a carbodiimide. The analogous strontium complex **2** was obtained likewise. Both the Ca and the Sr complex crystallize as C_2-symmetric mono-etherates. This indicates that the steric bulk of the anionic (Cy)N–C{N-($SiMe_3$)$_2$}–N(Cy) ligand is similar to that of 1,3-($SiMe_3$)$_2$-Cp^- or *i*Pr(Me)$_4$$Cp^-$.

The Schlenk equilibrium between homoleptic calcium bis(guanidinate) **1** and [Ca{α-(Me_3Si)-*o*-(Me_2N)-benzyl}$_2$·(THF)$_2$] is mainly, but not completely, on the heteroleptic side. An excess of **1**, however, results in nearly exclusive formation of the heteroleptic benzylcalcium complex. Polymerization of styrene with such mixtures yields atactic polystyrene. Since the molecular-weight distribution of these polymers shows a strong tailing in the low molecular weight range, it is expected that these polymerizations are not completely living. It has been shown that heating mixtures of **1** and **3** results in decomposition of the guanidinate ligand. A similar reaction could be responsible for quenching of the polymer chains during styrene polymerization.

Experimental Section

General Comments: All experiments were carried out under argon using predried solvents and Schlenk techniques. [Ca{N-($SiMe_3$)$_2$}$_2$][32] and [Ca{(2-Me_2N-α-Me_3Si-benzyl)}$_2$·(THF)$_2$][23] were prepared according to literature procedures. NMR spectra were recorded on Bruker AC250 and AMX600 machines. Polymerizations of styrene were performed in a thermostatted 100-mL, stainless-steel reactor at normal pressure. Polymerizations were carried out either in cyclohexane (0.1 M styrene solution, 0.1 mM catalyst, 50 °C) or in pure styrene (0.1 mM catalyst, 20 °C). In a typical polymerization experiment, the reactor was loaded with 90 mL of dry cyclohexane and 11.5 mL (ca. 100 mmol) of freshly distilled (from alox-perls) styrene. A solution of the initiator (0.05 mmol **3** and 0.1 or 0.2 mmol of **1**) in 1.0 mL of benzene/cyclohexane was added through a port. The usual appearance of a red colour indicated that the polymerization started immediately. After a polymerization time of 30 min, the mixture was quenched with oxygen-free methanol. Evaporation of all solvents yielded the polymer in quantitative yields. The polymers were analyzed by GPC and high temperature ^{1}H and ^{13}C NMR spectroscopy (solvent: [D_2]tetrachloroethane). The tacticity of the polymer was checked by analyzing the ^{13}C NMR signal for the C_{ipso} in the phenyl ring.[33]

Synthesis of [K{(Cy)NC{N($SiMe_3$)$_2$}N(Cy)}]: A solution of dicyclohexylcarbodiimide (1.00 g, 4.85 mmol) and KN($SiMe_3$)$_2$ (0.97 g, 4.85 mmol) in 30 mL of Et_2O was stirred overnight at room temperature. The solvents were removed under vacuum and the precipitate was washed twice with 10 mL portions of hexane. The residue was dried under vacuum (0.01 Torr, 50 °C, 30 min). The remaining white powder was identified by NMR analysis as [K{(Cy)-NC{N($SiMe_3$)$_2$}N(Cy)}] (1.92 g, 98%). ^{1}H NMR ([D_6]benzene/[D_8]THF (9:1), 600 MHz, 20 °C): δ = 0.31 (s, 18 H, Me_3Si), 1.30 (m, 4 H, Cy), 1.38 (m, 2 H, Cy), 1.51 (m, 4 H, Cy), 1.64 (m, 4 H, Cy), 1.79 (m, 2 H, Cy), 1.90 (m, 4 H, Cy), 3.26 (m, 2 H, Cy) ppm. ^{13}C NMR ([D_6]benzene/[D_8]THF (9:1), 62.86 MHz, 20 °C): δ = 2.9 (Me_3Si), 26.8 (Cy), 27.1 (Cy), 39.1 (Cy), 56.1 (Cy), 157.5 (NCN) ppm.

Synthesis of [Ca{(Cy)NC{N($SiMe_3$)$_2$}N(Cy)}$_2$·(Et_2O)] (1): This complex was prepared by two different methods. **Method A:** A suspension of [K{(Cy)NC{N($SiMe_3$)$_2$}N(Cy)}] (1.46 g, 3.60 mmol) and CaI_2 (0.53 g, 1.80 mmol) in 30 mL of Et_2O was stirred for three days at room temperature. The solvent was removed under vacuum and the product was extracted with two 20-mL portions of hexane. The hexane layers were concentrated to 15 mL and 2 mL of Et_2O was added. Slow cooling of the remaining solution to –30 °C yielded large colourless crystals of **1** (yield: 0.98 g, 65%). **Method B:** A solution of dicyclohexylcarbodiimide (1.98 g, 9.60 mmol) and [Ca{N($SiMe_3$)$_2$}$_2$] (1.73 g, 4.80 mmol) in 30 mL of Et_2O was stirred overnight at room temperature. After removing the solvent under vacuum a white residue remained, which was recrystallized from 20 mL of hexane and 2 mL of Et_2O at –30 °C (yield: 3.10 g, 76%). Decomposition temperature: approx. 185 °C. $C_{42}H_{90}CaN_6OSi_4$ (847.65): calcd. C 59.51, H 10.70; found C 59.23, H 10.61. ^{1}H NMR ([D_6]benzene, 600 MHz, 20 °C): δ = 0.37 (s, 36 H, Me_3Si), 1.20 (t, J = 7.1 Hz, 6 H, Et_2O), 1.27 (m, 4 H, Cy), 1.36 (m, 8 H, Cy), 1.45 (m, 8 H, Cy), 1.70 (m, 4 H, Cy), 1.86 (m, 8 H, Cy), 1.92

(m, 8 H, Cy), 3.34 (m, 4 H, Cy), 3.35 (q, J = 7.0 Hz, 4 H, Et_2O) ppm. ^{13}C NMR ([D$_6$]benzene, 62.86 MHz, 20 °C): $δ$ = 2.8 (Me_3Si), 14.6 (Et_2O), 26.6 (Cy), 26.8 (Cy), 39.1 (Cy), 55.0 (Cy), 66.3 (Et_2O), 159.2 (NCN) ppm.

Synthesis of [Sr{(Cy)NC{N(SiMe$_3$)$_2$}N(Cy)}$_2$·(Et$_2$O)] (2): A mixture of [K{(Cy)NC{N(SiMe$_3$)$_2$}N(Cy)}] (1.41 g, 3.48 mmol) and SrI_2 (0.59 g, 1.74 mmol) in 50 mL of Et_2O was stirred for five days at room temperature. The resulting suspension was centrifuged and the mother liquor was isolated. The solid residue was extracted with 20 mL of Et_2O and the solvent of the combined ether fractions was removed under vacuum. The solid product was dissolved in 10 mL of hexane and 10 mL of Et_2O and the solution was concentrated at 30 °C to a volume of about 8 mL. Slow cooling to room temperature yielded large colourless crystalline cubes of **2** (yield: 0.98 g, 68%). Decomposition temperature: approx 168 °C. $C_{42}H_{90}N_6OSi_4Sr$ (895.19): calcd. C 56.35, H 10.13; found C 55.98, H 9.98. ^{1}H NMR ([D$_6$]benzene/[D$_8$]THF (9:1), 600 MHz, 20 °C): $δ$ = 0.33 (s, 36 H, Me_3Si), 1.06 (t, J = 7.0 Hz, 6 H, Et_2O), 1.25 (m, 12 H, Cy), 1.40 (m, 8 H, Cy), 1.68 (m, 4 H, Cy), 1.81 (m, 8 H, Cy), 1.84 (m, 8 H, Cy), 3.27 (q, J = 7.0 Hz, 4 H, Et_2O), 3.33 (m, 4 H, Cy) ppm. ^{13}C NMR ([D$_6$]benzene/[D$_8$]THF (9:1), 62.86 MHz, 20 °C): $δ$ = 3.0 (Me_3Si), 14.6 (Et_2O), 26.8 (Cy), 27.0 (Cy), 39.3 (Cy), 55.5 (Cy), 66.3 (Et_2O), 162.4 (NCN) ppm.

Reaction of 1 with 3: A solution of **1** (0.30 g, 0.36 mmol) and [Ca{α-(Me_3Si)-*o*-(Me_2N)-benzyl}$_2$·(THF)$_2$] (**3**; 0.22 g, 0.37 mmol) in 10 mL of benzene was heated overnight at 80 °C. Concentration of the solution to 50% of its original volume yielded, after cooling to 5 °C, a batch of nicely formed colourless crystals of **5** (54 mg, 0.047 mmol, 26% yield). Decomposition temperature: approx. 160 °C. $C_{56}H_{120}Ca_2N_8Si_6$ (1154.3): calcd. C 58.27, H 10.48; found C 58.04, H 10.21. The crystals are only sparingly soluble in benzene or THF and NMR spectra in both solvents give broad signals also at higher temperatures. ^{1}H NMR ([D$_6$]benzene, 250 MHz, 50 °C): $δ$ = 0.25 (s, 18 H, Me_3Si), 0.33 (s, 36 H, Me_3Si), 1.03–2.15 (broad m's, 60 H, Cy), 3.31 (broad m's, 6 H, Cy) ppm. ^{13}C NMR spectroscopic data could not be recorded due to the low solubility of the complex and broad signals as a consequence of dynamic processes.

Crystal Structures: Crystal diffraction data were measured on an Enraf–Nonius CAD4 diffractometer (crystal data are given in Table 1). All crystal structures were solved with DIRDIF[34] and refined with SHELXL-97.[35] Absorption correction was applied for **2** using the psi-scans method incorporated in PLATON,[36] which was also used for geometry calculations and graphics for all structures described here. For all structures, hydrogen atoms were placed at calculated positions and were refined isotropically. The bridging amide in **5** shows disorder in the cyclohexane substituent but no appropriate disorder model could be found and the disordered molecule is described by large anisotropy in the ring atoms. Crystals of **5** also contain one equivalent of disordered benzene which was treated with the SQUEEZE procedure[37] incorporated in PLATON.

CCDC-272452–272454 (for **1**, **2** and **5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We thank the DFG for financing this project and are grateful to the BASF AG (Ludwigshafen, Germany) for their interest and for GPC analyses of the polymers. Mrs. Anke Friemel is thanked for measuring 600-MHz spectra.

COVER PICTURE

The cover picture shows the postulated catalytic cycle for the pH-dependent, enantioselective transfer hydrogenation of acetophenone to give phenylethanol in water, using formate as hydrogen donor and (arene)ruthenium(*trans*-diaminocyclohexane) as chiral catalyst. This work illustrates the increasing interest for water-soluble enantioselective catalysts operating in aqueous solution. Details are discussed in the article by G. Süss-Fink et al. on p. 4493ff.

Synthetic Routes to the Encapsulation of II–VI Semiconductors in Mesoporous Hosts

Elizabeth A. Turner,[a] Yining Huang,*[a] and John F. Corrigan*[a]

Keywords: Mesoporous materials / Semiconductors / Host–guest systems / Nanostructures

Ordered mesoporous silicate materials, such as MCM-41 and SBA-15, offer a nanometre-sized environment for the inclusion of quantum-confined materials. The channel walls of the framework hinder cluster-cluster interactions thereby restricting particle growth and thus limiting the size of the enclosed particles to the nanometre-size regime. In particular, the past decade has seen substantial progress in the synthesis and encapsulation of II–VI nanoparticles within MCM-41 and SBA-15. This microreview highlights the recent developments in this area, with notable emphasis on the synthetic routes used in the growth and anchoring of CdS, CdSe and ZnS nanoparticles within a mesoporous host. Of relevance are the methods of ion-exchange, interior pore wall modification, quantum-dot doping, incorporation of preformed nanoparticles and clusters and external surface passivation through organic functionalization. In addition to synthetic methods employed, the interesting photochemical properties of the composite materials are discussed.

Introduction

Ordered porous silicate materials have been the subject of intense investigation over the past several decades.[1] These materials are generally categorized according to pore size, corresponding to the spherical diameter of the aperture. IUPAC has defined three classifications of porous materials which include microporous (< 2 nm in diameter), mesoporous (2–50 nm) and macroporous (> 50 nm).[2] Although microporous materials have been successfully used in the formation of inorganic–organic hybrid materials, the advent of the first ordered mesoporous materials[3] marked a pivotal moment in the advancement of host–guest chemistry.

Since the development of MCM-41 (**M**obil's **c**omposition of **m**atter) in the early nineties[3] and the subsequent discovery of SBA-15 (**S**anta **B**arbar**a**) in 1998,[4] a considerable amount of work has focused on understanding both the mechanistic formation[5] and characterization[6] of these intriguing silicate/aluminosilicate materials. Recognizing that

Elizabeth A. Turner (centre) was born in Halifax, Nova Scotia, Canada in 1980. She obtained her B. Sc. (Honours) from Saint Mary's University in Halifax, Nova Scotia in 2002. She is currently pursuing her Ph. D. at The University of Western Ontario in London, Ontario under the supervision of Dr. John F. Corrigan and Dr. Yining Huang. Her research interests are in the synthesis and characterization of ternary metal–metal chalcogenides in mesoporous materials and the development of new binary chalcogenide reagents. Yining Huang (right) was born in Beijing, P. R. China. He earned his B.Sc., M.Sc. from Peking University and his Ph. D. from McGill University with Ian S. Butler and Denis F. R. Gilson. He was a NSERC post-doctoral fellow with Colin A. Fyfe at the University of British Colombia. He started his academic career at Laurentian University as an Assistant Professor in 1995 and then moved to The University of Western Ontario in 1997 where he is currently Professor of Chemistry. His major research interests include characterization of nanoporous materials and the host–guest interactions in these systems. John F. Corrigan (left) was born in Oshawa, Ontario, Canada. He obtained his B.Sc. (Chemistry Specialist) from the University of Toronto in 1990 and his Ph. D. degree from the University of Waterloo in 1995 with Arthur J. Carty. After a NSERC post-doctoral fellowship at the University of Karlsruhe with Dieter Fenske, he joined the faculty at The University of Western Ontario in 1997 where he is currently an Associate Professor. His current research interests focus on metal chalcogenolate and chalcogenide complexes, from coordination complexes to nanomaterials.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

the distinctive hexagonal array of uniform mesoporous channels can be used in inclusion chemistry,[7] the past decade has seen an explosion of growth in the use of mesoporous materials as a host environment for catalysis,[8] adsorption/separation,[9] polymerization,[10] and in particular, the subject of this microreview, quantum-confined materials.

The original synthesis for purely siliceous MCM-41 is done under acidic conditions with the use of alkyltrimethylammonium halide as an organic structure directing agent and sodium silicate as a silica source.[3] A liquid-crystal templating method (Figure 1) has been proposed for the formation of MCM-41, where surfactant species form micellar rods in aqueous solution which can align in a hexagonal array.[3,5] The addition of an anionic inorganic species into the aqueous domain initiates the formation of inorganic walls between the surfactant micelles in an effort to balance the cationic charge of the hydrophilic micelle. Increasing the alkyl chain length of the surfactant and the use of an organic auxiliary swelling agent (e.g. 1,3,5-trimethylbenzene) have been found to result in pore-size expansion, further supporting the proposed liquid-crystal templating mechanism. The porous silica skeleton is obtained through calcination of the surfactant-silica material at 540 °C, thus removing all organic components from the interior pore.

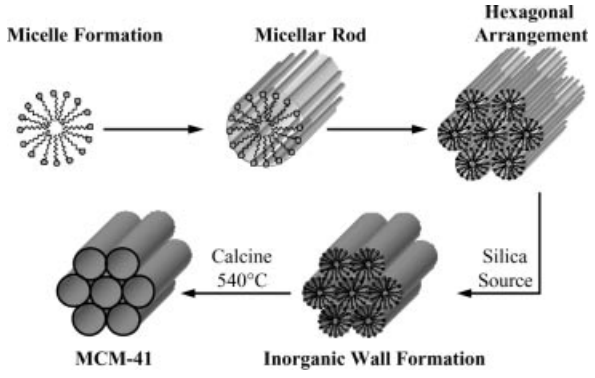

Figure 1. Proposed liquid-crystal templating method for the formation of mesoporous MCM-41.

Although the pore size of MCM-41 can range from 1.6–10 nm, the larger pore systems generally show decreased regularity of the hexagonal array as observed by transmission electron microscopy (TEM), Figure 2, a–b. In addition, the thin walls of MCM-41 (1–1.5 nm) are not strong enough to retain the framework structure upon hydrothermal treatment. The pore walls can be strengthened using a secondary crystallization technique,[11] modified reaction conditions[12] and post-synthesis restructuring.[13] These approaches, however, result in a pore-wall thickness having an upper limit of ca. 3 nm. On the other hand, SBA-15[4] is a thicker-walled mesoporous material (3.1–6.4 nm) with pore sizes spanning 4.7–30 nm. Although SBA-15 has a similar hexagonal arrangement of mesoporous channels to MCM-41, the material is formed from a nonionic triblock copolymer of poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide). Pore-size engineering can be accomplished by adjusting the reaction temperature (35–140 °C) and time (11–74 h), as well as by altering copolymer composition or through the addition of an organic swelling agent. The increased pore thickness enables SBA-15 to exhibit greater hydrothermal stability as compared to its MCM-41 counterpart. Furthermore, SBA-15 displays increased regularity in pore size uniformity as is shown in Figure 2c–d.

Stucky, Science 1998, 279, 548–552. Copyright 1998, AAAS).

One of the many attractive features of MCM-41 and SBA-15 is the relatively high surface area offered by the mesoporous framework, typically ranging between 700 and 1000 $m^2 g^{-1}$, thus rendering these surfaces available for guest molecule inclusion. Upon occupying the host with a guest species a notable decrease in surface area is observed. Nitrogen adsorption is the most commonly used technique to monitor changes in pore size, surface area and pore volume.[14] Type-IV isotherms[2] are observed for both MCM-41 and SBA-15 and are marked with a sharp inflection point at a value P/P_0, corresponding to capillary condensation within the primary mesopores (Figure 3). The surface area is calculated based on the Brunauer–Emmett–Teller (BET) method,[15] where a decrease in BET surface area is characterized by a decrease in the P/P_0 position for capillary condensation. The results from nitrogen adsorption can also be used in the calculation of pore size distribution based on the Barrett–Joyner–Halenda (BJH) method.[16] It is important to note, however, that the BJH calculation tends to underestimate the pore size by approximately 1 nm for pore dimensions less than 4 nm.[17] Nonetheless, the trend in decreasing pore size as a result of pore filling can be monitored using this calculation.

Upon enclosing guest molecules within the host material it is essential that the siliceous framework remains intact both during and after inclusion of the desired species. The hexagonal array is unambiguously monitored by TEM, however, powder X-ray diffraction (PXRD) is another useful tool in surveying the framework structure. MCM-41 displays a very strong d_{100} spacing at low angle with slightly weaker reflections corresponding to lattice planes (110) and

(200) at higher angle, as seen in Figure 4 (a).[3] Similarly, SBA-15 displays a predominant d_{100} spacing with three additional well-resolved peaks related to the (110), (200) and (210) lattice planes at higher angles (Figure 4, b).[4] Retention of these peaks upon guest-molecule inclusion is indicative of framework stability. Typical pore filling is accompanied by a reduction in peak intensity of the composite material in the corresponding PXRD pattern. This results from a decrease in scattering contrast between the pores and the walls of the mesoporous material upon pore filling. In addition, the position of the d_{100} peak is often shifted to lower angles as pore size decreases.

The field of quantum-confined nanocrystals has grown tremendously with the discovery of the size-dependent chemical, electronic and physical properties of semiconductor materials.[18] Conventional semiconductors are characterized by a filled valence band and empty conduction band separated by a discrete bandgap energy. The progression to smaller-sized particles (smaller than the Bohr radius[19]) having the same chemical composition as that of the bulk material results in an increase in bandgap energy, coupled with the quantization of both the valence and conduction bands (Figure 5). Upon entering this nanometre size regime, the Bohr radius of the exciton exceeds the size of the particle itself and thus, the exciton "fits" into the given particle by adopting a higher kinetic energy. As such, an increase in bandgap energy is observed as a result of quantum-confinement effects. These effects are readily monitored using UV/Vis absorption spectroscopy where shifts to higher energy with decreasing size vs. the bulk material are observed. Thus UV/Visible spectroscopy can be used to demonstrate the effects of quantum confinement in II–VI particles of various sizes, highlighted by the systematic shift of the excitonic transition to higher energy with decreasing particle size. These materials are composed of metal atoms from group 12 (Zn, Cd, Hg) and chalcogen atoms from group 16 (S, Se, Te). Hence, a blue shift in absorbance onset from that of the bulk material is observed.[18c] The photoluminescence (PL) of II–VI nanoparticles occurs as two types; band-edge PL and deep-trap PL. Band-edge emission occurs due to the recombination of trapped charge carriers from shallow trap states within the particle, and this results in a slight red shift with respect to the absorption due to the relaxation of the trapped charge carrier into lower lying energy states prior to recombination. Deep-trap emission occurs through recombination of trapped localized carriers from deep mid-gap trap states, which are usually hole traps at the surface of the particle. Trapped emission is characterized by a broad line width which is shifted significantly to the red of the excitonic absorption.[18,19]

One of the challenges in obtaining monodisperse nanoparticles is in controlling their growth and thus preventing their aggregation to the bulk state. In particular, there has been substantial interest in developing suitable chemical capping agents for these nanometre-sized particles. Recent efforts have focused on the use of polymers,[20] organic ligands[21] and inorganic functionalization in core/shell materials[22] to passivate the nanoparticle surface, although particle size distribution is inevitable within these systems. An alternative method potentially leading to monodisperse or nearly monodisperse particles is through the use of an ordered mesoporous host such as MCM-41 and SBA-15. The pore-size structure of these materials is ideal for the growth of nanoparticle semiconductor materials, where the confining nanosized environment hinders particle–particle interactions thus preventing cluster aggregation.

Perhaps the most extensively studied class of semiconductor materials is that referred to as the II–VI semi-

conductors. Two polymorphs of these metal chalcogenide materials are known, referred to as zinc blende (or sphalerite) and wurtzite, where both M^{2+} (M = Zn, Cd, Hg) and E^{2-} (E = S, Se, Te) are tetrahedrally coordinated.[23] Zinc blende can be represented as two interpenetrating face-centred cubic lattices, where the anion occupies one cubic lattice in which a quarter of the tetrahedral holes are populated by the cation of a second cubic lattice. In contrast, the wurtzite structure has hexagonal symmetry where anions form a hexagonal closest-packed arrangement in which half of the tetrahedral holes are occupied by metal atoms of a second hexagonal closest-packed array. For some metal chalcogenides both polymorphs are observed where one form is thermodynamically favoured over the other.[24] For metal sulfides, both forms occur naturally, however, zinc blende is more stable for ZnS, whereas the thermodynamically favoured wurtzite structure is observed for CdS. In comparison, both structures are observed in the case of CdSe (preferentially wurtzite), while ZnSe is only found in the zinc blende form. The reverse is true for metal tellurides, where CdTe is found only as a zinc blende structure, while for ZnTe the zinc blende form is preferred but it also displays the wurtzite structure.

It is the intention of this microreview to discuss the various synthetic strategies employed in the formation of II–VI materials within a mesoporous host with emphasis on the quantum-confinement effects observed within these composite materials.

Ion-Exchange Method for the Synthesis of II–VI Mesoporous Materials

Prior to the discoveries of mesoporous MCM-41[3] and SBA-15,[4] the importance of confining the dimensions of II–VI semiconductor materials in a suitable size-restricting host had been recognized. The microporous nature of zeolites provides an ideal environment for the inclusion of nanosized semiconducting materials. The ionic character of these zeolites offers the opportunity to exchange host cations for desired metal cations in the pursuit of enclosing binary metal chalcogenides within the framework cages. As such the ion-exchange method for the synthesis of II–VI materials in zeolites was developed for the synthesis of CdS in zeolites-X, Y and A.[25] Since that time there have been numerous studies investigating the synthesis of CdS,[26] CdTe[27] and ZnS[28] in various zeolite hosts using this general approach.

The typical procedure uses the sodium form of the respective zeolite. Sodium cations within the framework can be exchanged for preferred metal cations through mechanical mixing of the zeolite with a given metal salt. Generally nitrate salts are used,[25,26a–26c,27,28c] although chloride[26d,26e,28a,28b] and sulfate[28b] salts and even Me_2M (M = Zn, Cd)[28d] have also found utility. The ion-exchanged materials are often calcined at 400 °C and, in the case of the sulfides, are treated with a flow of H_2S at 100 °C. Sulfidization has also been achieved using thiourea[26e] and Na_2S.[28c] An alternative approach has been employed in the formation of CdTe, where tellurium metal is incorporated into the framework of zeolite-A at high temperature prior to cation exchange.[27] A wide variety of zeolites have been investigated in this manner and include zeolite-A,[25b,25c,26c,27] zeolite-X,[25b,25c,26e] zeolite-Y,[25,26d] mordenite[26a,26b,28] and SAPO-5.[26c]

The microporous environment of zeolites used for the encapsulation of semiconducting materials often leads to composite materials which show broad particle size distributions. This generally results from poor channel filling from ion-exchange, ultimately leading to a high density of defect sites. There are reports that clusters, superclusters and aggregates can co-exist within the same host,[26e] and in some instances larger particles are found to passivate the external surface.[28a] Although in most cases quantum-confinement effects are noted by the blue shift in the absorption edge,[26–28] identifying metal chalcogenide material within the host through PXRD is hindered by the overlapping of diffraction peaks of the II–VI material with those of the zeolite framework.[26–28]

Mesoporous materials offer a larger pore diameter for the inclusion of semiconductor materials and may thus offer better control over particle size. The improvement over microporous zeolites is illustrated by a similar ion-exchange method with a commercially available mesoporous zeolite.[29] Using the sodium form of the zeolite, Na^+ is exchanged for Cd^{2+}, and the material is sulfidized with Na_2S at room temperature. Size and loading of CdS can be controlled by varying the amount of Cd^{2+} introduced during the exchange process. From the wide-angle XRD pattern (Figure 6) the observed diffraction peaks are indexed to cubic crystalline zinc blende CdS, where the peaks become sharper as the Cd^{2+} concentration is increased in the material, thus leading to an increase in particle size as determined by the Scherrer formula.[30]

Quantum-confinement effects are readily observed in the photoluminescence (PL) and photoluminescence excitation (PLE) spectra, where two bands are observed in the PL spectra and three bands are present in the PLE spectra. In both, the bands are found to blue shift as particle size de-

creases. In the PL spectra the strong Stokes-shifted band at 550 nm arises from trapped luminescence at the surface while a shoulder at 420 nm is assigned to band-edge emission (Figure 7).

With the advent of MCM-41 and SBA-15 new methods for the incorporation of II–VI materials within a mesoporous framework have been pursued. Typically MCM-41 and SBA-15 are used in their purely siliceous forms, and thus there are no counter-cations that can be exchanged for desired metal ions, hence a modified route to developing metal chalcogenides within the mesopores through ion-loading was designed. Of recent interest has been the synthesis of manganese-doped II–VI semiconductors within a mesoporous host through the use of this method.[31–33] In particular $Zn_{1-x}Mn_xS$,[31] $Cd_{1-x}Mn_xS$[32] and $Cd_{1-x}Mn_xSe$[33] have been synthesized in MCM-41 and SBA-15 to investigate their unique optical and magnetic properties. In this approach metal acetate salts of Zn or Cd are mixed with $Mn(OAc)_2$ and solution loaded into both MCM-41 and SBA-15. Treatment with either H_2S or H_2Se at 100 °C leads to the formation of sulfides and selenides, respectively.

As determined from electron paramagnetic resonance (EPR) spectroscopy, when $x = 0.01$ the resulting encapsulated nanowires are of the zinc blende structure, while in cases where $x > 0.01$ the materials are characteristically found to display the wurtzite structure. This is true in the case of both Zn- and Cd-based materials. The X-ray absorption near-edge structure (XANES) region of the X-ray absorption spectra suggest that Mn^{2+} is present within the composite materials but not in the form of MnS. The results from XANES analyses suggest rather that Mn^{2+} is found to substitute for M^{2+} (M = Zn, Cd) sites within the ME (E = S, Se) structure, thus becoming intimately incorporated within the material. XANES spectra also indicate that only a small percentage of Mn^{2+} is found on the surface of the ME structure. All of the composite materials show quantum-confinement effects that increase with decreasing wire diameter (where the diameter is controlled by the chosen mesoporous host). These quantum-confinement effects ultimately lead to an increase in the direct bandgap energy.

Typically II–VI composite materials prepared using ion-exchange/loading as well as surface functionalization of the mesoporous material (vide infra) are in microcrystalline (powder) form. Although it is important to develop the chemistry using powder-based composites, these powders are generally unfavourable for their application in non-linear optics and optical characterization, where diffuse reflectance techniques are often employed. Thus there has been an emergence in the development of mesoporous thin films,[34–36] monoliths[34] and membranes[37] incorporating II–VI materials. Specifically, CdS[34,35,37] CdSe[35] and CdTe[36] have been prepared in these forms using a similar ion-loading technique, where a cadmium salt is introduced to the mesopores typically during the synthesis of the framework. The general procedure involves the use of alkyl-(ethylene oxide) as the structure-directing agent of which a sol is formed under acidic conditions in the presence of tetraethoxysilane. Cadmium nitrate[34] (or acetate[35]) salts are added to the sol from which thin films are formed by dip-coating, and monoliths are prepared by spreading the sol over a glass slide. Metal chalcogenides are thus formed through exposure to H_2E. An alternative approach used in the synthesis of mesoporous CdTe thin films utilizes the electrochemical codeposition of cadmium sulfate and tel-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lurium dioxide.[36] Prior to electrodeposition, the salts are incorporated into a lytropic liquid crystalline domain composed of octaethyleneglycol monohexadecyl ether as the templating agent. Using a similar synthetic approach as detailed above, porous alumina membranes are used as a template in the formation of CdS mesoporous structures.[37] Using this route, surfactant, silica and cadmium salts are incorporated into the channels of the alumina membrane, followed by H_2S treatment. Much like their powder counterparts, these materials have particle sizes on the order of 2.5 nm when formed in thin films and monoliths and ca. 6 nm when synthesized as a membrane structure. In addition, all enclosed materials display similar quantum-confinement effects to those observed in MCM-41 and SBA-15.

Surface Modification of Mesoporous Hosts for the Synthesis of II–VI Materials

Organic functionalization of the interior pore structure of a mesoporous material has been studied extensively, resulting in the formation of inorganic–organic hybrid materials.[38] Pore modification can be achieved through either a direct co-condensation method[38d–38f] or post-synthesis grafting.[38g–38j] The method of post-synthesis grafting is most often utilized in the inclusion of II–VI semiconductor species within a mesoporous host. This modification procedure exploits the presence of multiple reactive silanol moieties populating the surface of the pore walls. Through condensation reaction with a designated alkoxysilane, the organic functional group is effectively anchored to the pore surface by the formation of silicon–oxygen bonds (Figure 8). Thiol[39] and ethylenediamine[40] moieties can be incorporated into the pore structures of MCM-41 and SBA-15 and have been used as a method of developing and/or confining metal sulfide nanoparticles within the host framework.[41–46] In this vein, these organic groups can meet several objectives which include acting as an anchor for the prepared metal sulfide, enhancing the hydrophobicity of the interior pore structure and, in the case of the anchored thiol moiety, pre-positioning the sulfide source.

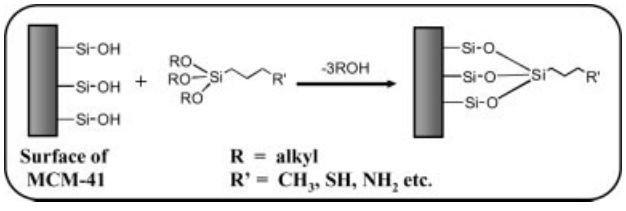

Figure 8. General reaction scheme used in the surface modification of siliceous mesoporous materials, utilizing an alkoxysilane. The rectangular area represents the pore wall of MCM-41 (or SBA-15) populated by surface silanol groups.

Cadmium sulfide is the most comprehensively studied II–VI material that has been encapsulated in a mesoporous host. In particular, the method of organic functionalization has found utility in both the synthesis and constriction of the resulting CdS particles. In studies pertaining to both MCM-41 and SBA-15, the interior pore surface is initially functionalized with 3-(mercaptopropyl)trimethoxysilane in either refluxing or room temperature solvent.[41–43] The degree of functionalization has been shown to be dependant on reaction temperature, where the higher the temperature the greater the extent of modification (as monitored by nitrogen adsorption and IR spectroscopy).[41] Cd^{2+} is adsorbed into the pores through stirring a methanolic solution of $Cd(OAc)_2{\cdot}2H_2O$ with the organo–mesoporous material. The resulting material is treated either with a stream of 5 vol-% H_2S in nitrogen[41,42] or calcined at 300 °C in nitrogen[43] resulting in the formation of CdS nanorods, as depicted in Figure 9.

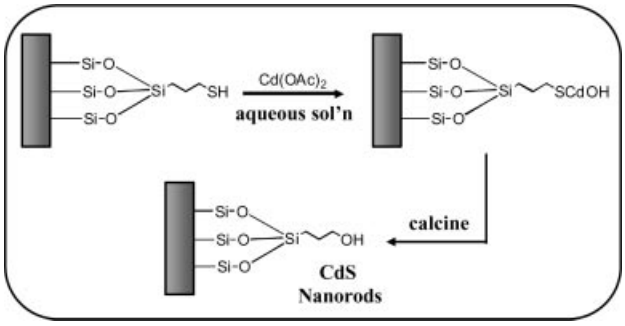

Figure 9. Formation of CdS nanorods in thiol-modified SBA-15 through the addition of $Cd(OAc)_2$ followed by calcination under nitrogen.

The incorporation of CdS nanoparticles within the porous structure is confirmed by wide-angle PXRD and diffuse reflectance UV/Vis spectroscopy. From PXRD analysis, the wide-angle peaks are indexed to the hexagonal cell (wurtzite structure) of CdS, shown in Figure 10, as opposed to the cubic form of CdS generated from the ion-exchange method. The UV/Vis spectra indicate a blue shift in the absorption edge (305–485 nm) of the resulting CdS–mesoporous materials compared to bulk CdS (515 nm), and this blue shift is consistent with the enclosed particles exhibiting quantum-confinement effects. CdS–SBA-15 composite materials are found to show a smaller blue shift of the exciton peak given the larger diameter of the pore, consistent with larger-sized particles confined within the framework.[42] The size, however, of the CdS particles grown in SBA-15 is strictly dependent on the synthetic method employed: H_2S treatment produces smaller-sized particles (3.4 nm),[42] while post-synthesis calcination is found to produce larger-sized particles (6 nm).[43] The sizes for both particles are calculated from the PXRD data using the Scherrer formula.

It has also been demonstrated that the size of the CdS particles grown inside MCM-41 is dependent on both the degree of organic functionalization and the temperature of H_2S treatment.[41] CdS particles grown in MCM-41 with the greatest coverage of thiol moieties are found to grow from 1.2 to 2.2 nm upon changing the temperature of formation from 30 °C to 230 °C. At the highest temperature of formation the particles are found to grow to the available

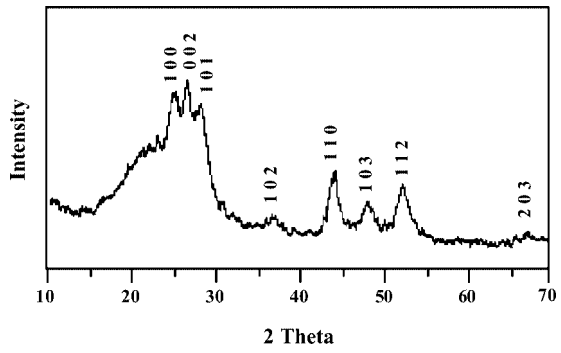

Figure 10. Wide-angle XRD pattern of wurtzite CdS nanorods synthesized within SBA-15. (Figure reprinted and modified from ref.[43], in situ Adsorption Method for Synthesis of Binary Semiconductor CdS Nanocrystals Inside Mesoporous SBA-15, Copyright 2002, with permission from Elsevier).

pore diameter, while at lower temperature there is stronger interaction of Cd^{2+} with the thiol groups, consequently leading to impeded mobility of the metal ions. Conversely, the size of the nanoparticles is found to decrease with increasing surface functionalization, as confirmed by the blue-shifted exciton peak (430 to 320 nm). This result can be correlated with the decreased pore diameter of the functionalized materials with increasing the temperature of modification, thereby reducing the available pore space for nanoparticle growth.

Although the majority of published reports study the incorporation of cadmium chalocogenides in a mesoporous host, there have been fewer cited examples of encapsulated nanosized zinc sulfide. Of these, there are several that utilize organic functionalization of MCM-41 with ethylenediamine as a means of forming ZnS nanoparticles within the framework.[44,45] Surface modification is achieved through refluxing calcined MCM-41 with *N*-[3-(trimethoxysilyl)propyl]ethylenediamine in dry toluene. The anchored chelating group provides the ability to adsorb Zn^{2+} from an ethanolic solution of $Zn(OAc)_2{\cdot}2H_2O$ while stirring at room temperature.

The desired ZnS nanoparticles can then be generated through several approaches. One method involves calcining the resulting Zn–MCM-41 material at 600 °C in air, thus removing all organic constituents from the pore while retaining the adsorbed Zn^{2+}, present in the host as ZnO as a result of calcination.[44] Similar to the formation of CdS materials within MCM-41, both Zn–MCM-41 modified with ethylenediamine and ZnO–MCM-41 are treated with H_2S for up to 6 hours leading to the synthesis of ZnS nanoparticles.[44] Six hours of exposure to H_2S is required to ensure the ratio between Zn and S reaches ca. 1:1, as confirmed by energy dispersion X-ray (EDX) analysis. An alternative method involves mixing the organically modified Zn–MCM-41 with an ethanolic solution of carbon disulfide at room temperature, thus producing ZnS within the pores of MCM-41.[45] In this method, however, no diffraction peaks in the wide-angle XRD are observed for ZnS thus suggesting the incomplete formation of ZnS crystallites at room temperature, however, the ratio of Zn to S is still found to be close to 1:1. This is quite different to the ZnS nanoparticles formed from H_2S treatment,[44] where the diffraction peaks in the wide-angle XRD are indexed to zinc blende ZnS. From this XRD study the ZnS nanoparticles are found to be less than 2.5 nm in size, as determined from the Scherrer formula.

Confirmation that the synthesized particles were located in the interior of the framework vs. the exterior surface was attained from TEM analysis and from thermal treatment of the ZnS–MCM-41 materials.[44] The TEM images show no indication of the formation of ZnS on the exterior pore surface whether the electron beam is parallel or perpendicular to the channel direction. ZnS particles in the pores of MCM-41, however, are not observed directly using TEM, likely due to the weak contrast between ZnS and the silica framework. In the event ZnS particles formed on the external surface of MCM-41, thermal treatment of the composite material should result in the generation of larger-sized particles, given that the exterior pore surface provides no restriction to particle growth. Treating the materials at 150 °C while under vacuum results in no obvious change in the wide-angle XRD, therefore suggesting that all ZnS nanoparticles are confined to the pores of MCM-41 and as such their growth is impeded.

As observed for CdS formed in organically modified mesoporous materials,[41–43] the absorption edge of ZnS confined in MCM-41 (ca. 350 nm) is found to be blue-shifted from that of bulk ZnS (410 nm). Variation in the synthetic method does not result in any appreciable change in the absorption edge whereby the exciton peak of calcined ZnS–MCM-41 is found to be red-shifted by 10–20 nm from that of Zn–MCM-41-containing anchored ethylenediamine. This blue shift from the bulk material is indicative of the resulting materials exhibiting quantum-confinement effects. In both studies[44,45] the photoluminescence properties of the composite materials were investigated. From the PL spectra, the ZnS-MCM-41 materials are found to emit in the blue between 430 and 475 nm, and this has been assigned to defects associated with sulfur vacancies.[44]

Despite the ethylenediamine moiety within the framework, the resulting ZnS nanoparticles are found to leach out of the pores (as observed with TEM analysis) upon stirring for more than 4 hours in aqueous solution, consequently growing into larger-sized particles (Figure 11).[44] This problem is even more pronounced in the case where the ethylenediamine moiety is removed through calcination. To circumvent this problem with leaching, bifunctional mesoporous materials have been designed and offer advantages over monofunctionalized mesoporous materials, especially in the formation of II–VI nanoparticles within the host.[46] This synthesis uses two methods of grafting, where initially ethylenediamine-modified MCM-41 is formed through direct co-condensation[47] followed by post-synthesis grafting of a thiol moiety. The post-synthesis grafting is carried out in supercritical fluid to ensure uniform distribution of the organic groups. CdS nanoparticles are then prepared in the same manner as already described using thioacetamide as the source of S^{2-}. It is believed that the ethyl-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

enediamine group strongly chelates Cd^{2+}, while the thiol moiety anchors the formed CdS particles. By releasing Cd^{2+} from ethylenediamine more Cd^{2+} can be adsorbed, ultimately until the pores of MCM-41 are filled entirely with CdS. It is thought that these bifunctional MCM-41 materials can offer a stronger host–guest interaction over conventional monofunctionalized materials[44] while allowing a greater density of binary semiconductor material to fill the pore structure.

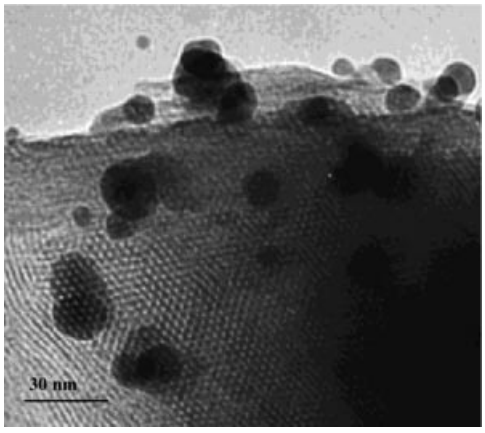

Figure 11. Transmission electron microscope image of ZnS particles leaching out of ethylenediamine-modified MCM-41 after ethanolic treatment. It is apparent from the image that particles aggregate to larger species upon leaching from the channel structure. (Figure reprinted with permission from ref.[44]. Surface Functionalization Used to Incorporate Preformed Nanoparticles

In addition to the synthesis of II–VI nanoparticles within a mesoporous host, surface functionalization has also found utility in directing the incorporation of preformed nanoparticles within the modified framework.[48–51] In particular, post-synthesis grafting of an organic thiol is often used to develop a hydrophobic interior to the pore structure, thus promoting the delivery of II–VI nanoparticles into the host. Recent efforts have focused on the synthesis of semiconducting nanoparticles within the hydrophilic core of reverse micelles.[52] The columnar structure of the reverse micelles makes these ideal candidates for their inclusion within MCM-41 and SBA-15. The passivation of the mesoporous surface with a hydrophobic moiety ultimately facilitates the inclusion of the reverse micelles and consequently semiconducting nanoparticles within the siliceous framework.

Cadmium[48–50] and zinc sulfide,[51] formed from reverse micellar solutions, have been encapsulated within MCM-41. The typical procedure uses a reverse micellar solution containing bis(2-ethylhexyl)sulfosuccinate (AOT), water and isooctane. A reverse micellar solution of a specified water content (W_o = [H_2O]/[AOT]) containing either $Cd(NO_3)_2$ or $ZnSO_4$ is added rapidly to a second micellar solution, of equal water content, containing Na_2S. Within minutes the MS (M = Zn, Cd) nanoparticles form and the mesoporous material, modified through post-synthesis grafting of a propyl thiol group, is added to solution. The percent incorporation of MS into the mesoporous host is determined by subtracting the absorbance of MS in the supernatant of the reaction from that of the original reverse micellar solution. The use of large-pore MCM-41 leads to the inclusion of all preformed nanoparticles, as observed by the lack of absorbance for MS in the supernatant.

Nanoparticles of cadmium sulfide are only found to insert into the mesoporous channel if the pore wall has been functionalized with a propyl thiol moiety. The presence of the organic thiol promotes bonding between itself and the encapsulated CdS nanoparticles.[48,49] Although incorporation of CdS is easily achieved in larger-pore systems (ca. 4 nm), the percent incorporation is found to be strongly dependant on the micellar water content (W_o) in medium-pore systems (ca. 3.5 nm) and not at all dependant on W_o in smaller-pore systems (2 nm).[48,49] It is suggested that in large- and medium-pore MCM-41 a particle-sieving effect is observed where percent incorporation decreases with increasing W_o. This can be directly correlated with observed particle size, where smaller-sized particles are formed in micellar solutions with low water content. Consequently, the pore diameter dictates the size of CdS nanoparticles that can enter the framework, where particles exceeding the diameter of the pore will not be encapsulated. Conversely, for smaller-pore MCM-41, all values of W_o lead to more than 90% inclusion of CdS within the framework despite the size of the preformed nanoparticles exceeding the pore diameter. It is believed that these nanoparticles are immobilized in the macropores of MCM-41 (20–40 nm) and on the surface of the framework.

A mechanism for the incorporation of II–VI nanoparticles from reverse micellar solutions into mesoporous frameworks has been proposed.[49] It is believed that water droplets from the reverse micellar solution are absorbed into the pores of the given framework. As such, these droplets contain preformed MS nanoparticles which are transfixed to the pore through anchored thiol groups. Increased loading amounts of MS in the pore structure can be achieved through additional treatment with a second MS micellar solution.[49,51] Exchange of MS-free water droplets for MS-containing water droplets facilitates this process. Although sequential treatment with a MS micellar solution leads to an increased cumulative amount of MS within the framework, the successive increase in MS loading decreases with each treatment.

Diffuse reflectance UV/Vis spectroscopy of the composite MCM-41 materials reveals a blue shift in the absorption onset for CdS (450 nm) and ZnS (272 nm) from the parent bulk materials.[50,51] Although the absorption is very broad, possibly resulting from a distribution of exciton states due to varying particle sizes, these observed blue shifts in absorption onset are consistent with the enclosed particles demonstrating quantum-confinement effects. ZnS particles are found to be ca. 2 nm,[50] while CdS particles are found

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to range between 3–3.4 nm[48,50] In all cases, the size of the enclosed particles does not exceed the diameter of the MCM-41 pore.

The PL spectrum (Figure 12) of encapsulated CdS shows two broad emission bands at 430 nm (sub-band I) and 530 nm (sub-band II).[50] The authors attribute the emission at 430 nm to band-edge emission, caused by excitonic recombination, while the largely Stokes-shifted emission at 530 nm is the result of surface-defect states. The emission of sub-band I is blue-shifted (420 nm) upon calcination of the composite material (to remove all organic constituents), as observed in Figure 12b, while the emission of sub-band II is red-shifted (560 nm). These changes in the PL spectrum are associated with the slight reduction of particle size upon calcination. On the other hand, ZnS emits in the spectral region associated with the emission resulting from the modified MCM-41 framework (390 nm), however, the emission due to confined ZnS (373 nm) can be distinguished from that of MCM-41 due to its increased intensity.[51] The emission of ZnS is also found to be enhanced with sequential treatment of ZnS–micellar solutions (Figure 13). Unlike the broad blue emission associated with ZnS formed within modified MCM-41,[44] these enclosed ZnS particles show emission in the UV. Luminescence does thus not result from surface sulfur vacancies but rather from recombination processes at core lattice sulfur vacancies. This is further confirmed by the PLE spectrum that is centred at 308 nm, and hence the observed emission is Stokes-shifted from the corresponding PLE spectrum. Confined CdS is found to have both fast (ca. 0.1 ns) and slow (5–13 ns) lifetime components associated with band-edge and Stokes-shifted emission, respectively, while encapsulated ZnS was found to have a single recombination lifetime of 1.3 ns resulting from a highly selective emission state.[50,51]

Surface modification of the silicate framework is not necessary to encapsulate II–VI nanoparticles prepared in reverse micelles into the mesoporous host if a gas antisolvent technique (supercritical CO_2) is used, rather than solution loading of the reverse micelles.[53] It has been found that by adding compressed CO_2 to a MS–micellar solution leads to the removal of MS nanoparticles from the hydrophilic core of the micelle.[54] ZnS has been loaded into MCM-41 using this technique, where CO_2 is added to a dispersion of ZnS–reverse micelles and calcined MCM-41.[53] Upon removing ZnS from the reverse micelles, the nanoparticles can diffuse into the pores of MCM-41 and are thus absorbed by the pore wall. In the absence of CO_2, ZnS is not found to be enclosed within the pores of MCM-41 and therefore the antisolvent behaviour of CO_2 is necessary for their inclusion.

In addition to modifying the framework with propyl thiol groups, to be used to attach preformed CdS to the mesoporous host, other organic modifiers have been used. Zn-doped SBA-15 has been modified with an alkane dithiol moiety, where Zn–S bond formation anchors the organic to the pore wall.[55] The pendant thiol provides a hydrophobic interior to the pore structure thus allowing the movement of CdS–reverse micelles into the framework. The incorporation of Zn is required to enhance the photocatalytic activity for H_2 generation of the resulting composite materials.

The utility of functionalizing the pore wall to promote nanoparticle attachment has shown promise in the field of stimuli-responsive controlled-release drug-delivery systems.[56] A mesoporous silica nanosphere (having MCM-41

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

type hexagonally packed mesopores) can be modified with (2-propyldisulfanyl)ethylamine, following which drug molecules such as vancomycin can be absorbed by the material. The openings of the nanosphere are then capped by mercaptoacetic acid-derived CdS through the formation of amide bonds to the organic anchor. The lability of the disulfide bond existing between the nanosphere and CdS allows for facile bond cleavage with various disulfide reducing agents (e.g. mercaptoethanol, dithiothreitol) thereby allowing controlled release of the absorbed drug molecules to the targeted area.

Preformed Clusters Used for the Formation of II–VI Materials in Mesoporous Hosts

Incorporating clusters within mesoporous frameworks has been studied extensively,[57] and the development of condensed nanoparticle structures within the framework from these cluster precursors is also of interest.[57a–57d] Recently, it was demonstrated that $[Cu_6(TePh)_6(PPh_2Et)_5]$ can be loaded into the pores of MCM-41 at 110 °C.[58] As a discrete molecule, the cluster is known to undergo a series of condensation reactions through photochemical elimination of Ph_2Te to yield $[Cu_{50}(TePh)_{20}Te_{17}(PPh_2Et)_8]^{4-}$.[59] This same photochemical behaviour was observed for the Cu_6 cluster enclosed in MCM-41 as marked by the red shift (440 nm) in the UV/Vis absorption spectrum upon irradiation, from that of the original Cu_6 cluster (249 nm). Thermal condensation of the cluster is found to lead to the formation of Cu_2Te nanoparticles within the host.[58b]

The hexagonally arranged channel structure of MCM-41 and SBA-15 makes these materials ideal candidates for the formation of nanowire arrays.[60] The siliceous framework acts as a hard-surface template that can be removed after formation of the desired nanowire assemblies. This template technique has been employed in the formation of CdS nanowires within SBA-15.[61,62] The method initially requires impregnation of a precursor cluster, containing both Cd and S within a single source. The resulting materials are treated thermally to promote cluster decomposition to CdS, upon which the siliceous framework is etched away from the surface of the CdS nanowires through treatment with aqueous NaOH.

In one method, $Cd(NO_3)_2{\cdot}4H_2O$ is combined with thiourea in an ethanolic solution to which a suspension of SBA-15 is added.[61] The mixture of $Cd(NO_3)_2$ with thiourea leads to the formation of complex cadmium–thiourea precursors. Upon evaporating ethanol from the suspended materials, the cadmium–thiourea precursors are incorporated into the channels of SBA-15 by capillary condensation. In heating the materials to 150 °C, (cubic) zinc blende CdS nanowires are formed, as confirmed by wide-angle XRD and high-resolution TEM analysis. Alternatively, cadmium thioglycolate $[Cd_{10}S_{16}C_{32}H_{80}N_4O_{28}]$ has been used as a Cd–S single source precursor in SBA-15, followed by thermal treatment thus leading to the formation of (hexagonal) wurtzite CdS as observed by wide-angle XRD and selected area electron diffraction (SAED).[62] From TEM analysis, the CdS assembly appears as a hexagonal array of nanowires having a diameter of ca. 6 nm and a particle spacing of ca. 3 nm. TEM analysis also indicates that the nanowire array is exactly an inverse replica of SBA-15. EDX confirmed the 1:1 ratio between Cd and S with negligible contribution from Si.

A similar single-source-precursor approach has also been utilized in the formation of CdS within Al–MCM-41 and zeolitic mordenite.[63] Initially $CdCl_2$ and thiourea are added to the silica materials and then treated thermally to promote the formation of CdS. EDX results, however, suggest lower sulfur content than the expected (1:1, Cd:S), which could potentially lead to vacancies and defects within the materials. In these materials the siliceous framework is maintained, and as a result a broad size distribution of nanoparticles is observed. Smaller-sized particles are found to be enclosed within the Al–MCM-41 host, while larger particles are immobilized on the external surface. Conversely, the zeolite is only found to contain CdS on the exterior surface.

In the revision stage of this microreview a new synthetic methodology exploiting a molecular single-source-precursor approach in the formation of cadmium chalcogenides was reported.[64] Using melt permeation, the molecular precursors TMEDA-$Cd(EPh)_2$ (where TMEDA = tetramethylethylenediamine and E = S, Se, Te) are incorporated into the mesopores of SBA-15. Through subsequent pyrolysis of the encapsulated precursors, CdS, CdSe and CdTe nanoparticles are formed within the pores of SBA-15, having a particle size of roughly 7 nm. The given cadmium chalcogenide forms in the most thermodynamically favoured polymorph; CdS as wurtzite, CdTe as zinc blende and CdSe as a mixture of both the wurtzite and zinc blende forms.

Quantum-Dot Doping in Mesoporous Materials

The recent use of quantum dot (QD) and quantum wire (QW) cadmium chalcogenides in device fabrication has led to the development of LEDs, biological probes and field-effect thin-film transistors with tunable properties.[65] One of the major obstacles in fostering new devices of one-, two-, and three-dimensional QD arrays is being able to manipulate and control their spatial orientation. As such, mesoporous hosts offer an ideal environment for controlling the organization of QDs.[66,67]

A recent example has been detailed, where CdSe nanoparticles are synthesized in the pores of MCM-41, combining the methods of solution loading and hot injection into a coordinating medium.[66] There have been many examples on the growth of nanoparticles in a highly coordinating solvent (e.g. trioctylphosphane oxide – TOPO)[18b,68] but none that has extended this technique to the inclusion of such nanoparticles within MCM-41. In this approach, Me_2Cd and Se (dissolved in tributylphosphane) are encapsulated into the pores of MCM-41. The wet suspension is rapidly injected into hot TOPO (325 °C), thereby initiating the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

growth of CdSe. Upon completion the materials are washed repeatedly with toluene to remove excess TOPO and larger CdSe nanoparticles that may have grown on the exterior surface. UV/Vis spectroscopy of the resulting composite material indicates a blue shift in absorption maxima from that of bulk CdSe suggesting the encapsulated nanoparticles exhibit characteristic quantum-confinement effects. X-ray photoelectron spectroscopy (XPS) of Cd and Se show broad asymmetric peaks indicating there could possibly be multiple bonding domains. Either Cd or Se could react with surface silanols of MCM-41, hence Si–O–Cd or Si–O–Se bonding interactions have been proposed.

Preformed core–shell QDs of ZnS-capped CdSe have been loaded into the pores of mesoporous beads whose surface is covered with hydrocarbons.[67] The QDs are confined into the pores through interdigitation of the hydrocarbon and surface TOPO on the nanoparticle. These materials were found to exhibit higher luminescence than latex and nonporous polystyrene beads doped with similar QDs.

Preventing Particle Aggregation with Exterior Surface Functionalization

One limitation to the approaches used to incorporate II–VI materials within a mesoporous host is the potential to form large aggregated nanoparticles on the exterior surface. Recent efforts have focused on the selective functionalization of mesoporous materials, where exterior functionalization can be performed prior to removal of the structure-directing agent (surfactant).[69] Upon removing the surfactant, internal grafting can be achieved in a similar manner as has been described earlier (vide supra).

The success of external grafting has led to its use in the inclusion of II–VI materials within MCM-41 and SBA-15.[70–73] External grafting has demonstrated utility in both the ion-exchange approach[70,71] as well as in the internal pore functionalization method.[72,73]

Cadmium sulfide has been synthesized in a mesoporous host using an ion-exchange approach that incorporates exterior surface modification with phenyltrimethoxysilane.[70,71] Removal of the protonated surfactant renders cationic vacancies within the framework that can be filled by Cd^{2+} in the form of $Cd(OAc)_2$. Similar to the conventional ion-exchange method, this Cd^{2+}–mesoporous material is subsequently sulfidized with H_2S forming CdS exclusively within the pores of both MCM-41[70] and SBA-15.[71] The motivation of this method is that the surface phenyl groups create a hydrophobic coverage of the outer pore surface, and thus the pore interior is the only environment to which Cd^{2+} absorbs. The UV/Vis spectra for CdS, formed in both MCM-41 and SBA-15, show a blue shift in the absorption onset (450 nm and 470 nm, respectively) suggesting that the confined materials exhibit quantum-confinement effects. In addition, the wide-angle XRD of both composite materials indicate the formation of cubic crystalline CdS having a size of < 2.5 nm and 3 nm in MCM-41 and SBA-15, respectively, as determined by the Scherrer formula.

External passivation of SBA-15 with chlorotrimethylsilane, followed by internal functionalization with (3-aminopropyl)triethoxysilane (Figure 14) has led to the successful incorporation of quantum-confined CdSe[72] and CdS.[73] In the case of CdSe, $Cd(NO_3)_2$ is solution-loaded into amino-functionalized SBA-15 that has previously undergone surface functionalization, thus promoting the complexation of Cd^{2+} with the NH_2 groups. After incorporation of Cd^{2+}, the composite material is exposed to sodium selenosulfate (Na_2SeSO_3) under basic conditions (pH, 8). In the presence of a basic medium, Cd^{2+} is converted to $Cd(OH)_2$, while $SeSO_3^{2-}$ gradually releases Se^{2-} within the pores. Se^{2-} readily replaces the hydroxy groups bound to Cd^{2+} due to the lower solubility of CdSe vs. $Cd(OH)_2$. Alkaline conditions are required to promote the formation of CdSe, as similar attempts using a pH < 8 resulted in no reaction.

In a slightly modified procedure, CdS[73] was incorporated into SBA-15 with exterior modification and interior amino functionalization. In this example the chalcogen is added to the framework prior to the metal: Mercaptoacetic

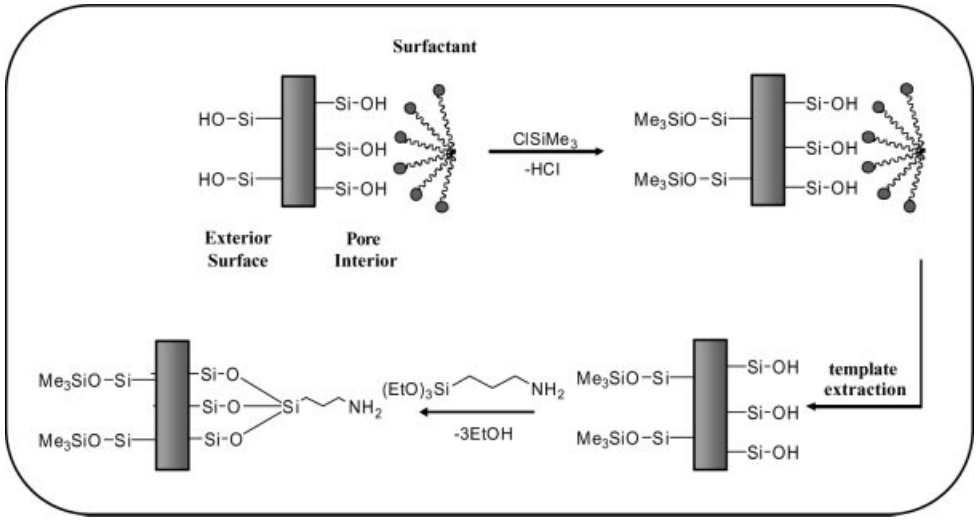

Figure 14. Synthetic pathway used for exterior functionalization followed by interior pore modification with a second organic molecule.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

acid in KOH is added to surfactant-free SBA-15. The FTIR spectrum of thiol-SBA-15 indicates the appearance of two stretching vibrations associated with $–COO^–$ that are slightly blue-shifted (1380 and 694 $cm^{–1}$) accompanied by an additional red-shifted peak (1630 $cm^{–1}$) related to $–NH_3^+$ distortion. The shift in these three IR peaks suggests binding of $COO^–$ and NH_3^+. The authors report that mercaptoacetic acid ionizes H^+, which combines with amine to form $–NH_3^+$. This observed coordination between $–COO^–$ and $–NH_3^+$ is what effectively anchors the sulfur source to the framework. Solution loading of $Cd(NO_3)_2$ followed by calcination at 300 °C leads to the formation of CdS.

The UV/Vis spectra for both CdS (519 nm) and CdSe–SBA-15 (622 nm) materials thus prepared show a blue shift in the absorption onset from that of the parent bulk materials; 550 nm and 698 nm, respectively. If no surface modification is employed in the case of CdSe, the absorption onset is only slightly shifted (660 nm) from that of the bulk material, indicating the formation of larger particles. Thus, the overall effect of exterior functionalization leads to smaller particles (5 and 7 nm for CdS and CdSe, respectively) that are found solely within the pores of the host framework.

Conclusions

Mesoporous environments, such as MCM-41 and SBA-15, have been readily used in the quantum confinement of II–VI materials. The unique nanosized siliceous channels are ideal for the inclusion of nanoparticle species. As such, there are several routes that can be employed in the synthesis of II–VI composites, in particular those accessing CdS, CdSe and ZnS particles. The ionic nature of these mesoporous hosts enables ion-exchange of framework ions for desired metal cations that can be successively used to form sulfide and selenide binary materials within the channel structure. An alternative route exploits the multiple silanol moieties populating the interior pore surface, whereby the choice of an appropriate alkoxysilane leads to the formation of new Si–O–Si bonding interactions, thus effectively anchoring an organic functional group to the pore walls. Anchored organic moieties have shown to be valuable in synthesizing, securing and directing II–VI nanoparticles into the interior pore structure. Perhaps a limitation of both these methods is the potential to form aggregated species on the exterior pore surface. In an effort to circumvent this issue and possibly access monodisperse or nearly monodisperse particles within the framework, exterior surface modification has been combined with the methods of ion-exchange and interior pore functionalization. Thus the exterior surface is protected by a hydrophobic layer thereby preventing M^{2+} from adsorbing to the exterior pore walls.

All of the described synthetic routes lead to quantum-confined materials which can be monitored by the blue shifts in the absorption onset from that of the bulk II–VI material. In addition, depending on the synthetic method employed, different polymorphs of the same binary material can be obtained. Although the above methods have been met with a significant amount of success, there is still a tremendous need to develop and explore this field fully. In particular, future studies should be geared towards rationally developing nanoparticle vs. nanowire assemblies within the mesoporous host. As such, researchers need to devise specific synthetic routes that will ultimately generate either nanowire or nanoparticle materials.

The developments presented in this microreview have pioneered the field of quantum-confined materials within mesoporous hosts. With the rapidly and vastly growing interest in nanoparticle construction, the next few years will see an evolution in the area of mesoporous encapsulated II–VI materials.

Norcorrole and Dihydronorcorrole: A Predictive Quantum Chemical Study

Abhik Ghosh,*[a] Ingar H. Wasbotten,[a] Wade Davis,[b] and Jannie C. Swarts[b]

Dedicated to Professor Emeritus Dr. Dr. h. c. Emanuel Vogel

Keywords: Norcorrole / Quantum chemical calculations

DFT calculations indicate norcorrole (NCH_2), a 16π-electron doubly contracted porphyrin, to be a promising synthetic target, especially when complexed to a small cation such as Ni^{II}. The relative stability of norcorrole derivatives appears to reflect the fact that they are not antiaromatic, but should rather be viewed as bis(dipyrrins). However, norcorrole (NC) complexes are expected to be prone to reduction and we predict that high-valent transition metal dihydronorcorrole (DHNC) derivatives should exist as reasonably stable substances. Our calculations further predict that both NC and DHNC complexes should exhibit short metal–nitrogen distances and moderate to strong doming of the macrocycle. Overall, a number of calculated results suggest that NC and DHNC derivatives should be of unique electronic-structural interest, as conceptual links between aromatic tetrapyrroles such as porphyrin and corrole on the one hand and open-chain pyrrole-based ligands such as dipyrrins and biliverdines on the other.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

The study of porphyrin analogues such as expanded and contracted porphyrins and heteroatom-substituted porphyrins (e. g. porphyrazines and corrolazines) has been a major new direction of porphyrin-related research.[1] In many cases, the new macrocycles have resulted in new metal spin states and novel chemical behavior, relative to the analogous porphyrin complexes. In 2002, Professor Emanuel Vogel encouraged one of us (AG) to investigate by theoretical means the question of stability of the doubly contracted porphyrin shown in Figure 1, for which we have used the trivial name norcorrole (NCH_2; "nor" signifying one fewer carbon than in corrole), as well as its potential as a ligand in coordination chemistry. Given the 16π-electron, possibly antiaromatic, nature of the ring system and the extremely contracted nature of the central N_4 core, we were not optimistic about the prospects. Nonetheless, we undertook a DFT[2] investigation of the problem and have been pleasantly surprised by the results, which seem quite promising, as described below.[3–5]

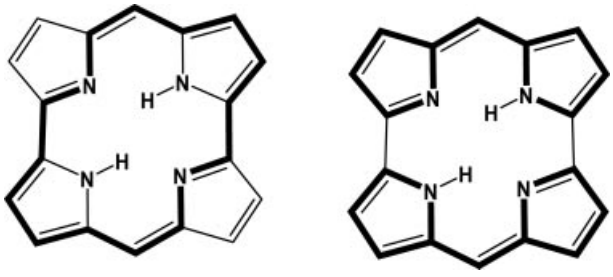

Figure 1. Two views of norcorrole. Left: antiaromatic; right: a bis(dipyrrin) structure.

Despite the small N_4 core size, a geometry optimization indicated an essentially planar, near-C_{2h} geometry for NCH_2, some highlights of which are depicted in Figure 2. Note the compact N_4 core and the short N–H···N hydrogen bonds.[6] Remarkably, the optimized NCH_2 structure does not exhibit the strong bond length alternation for the various skeletal CC and CN bonds that one might expect for

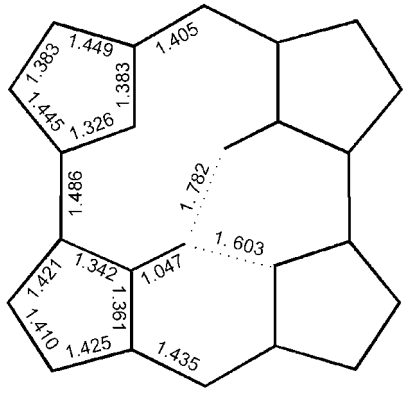

Figure 2. Selected symmetry-unique bond lengths [Å] in free-base norcorrole. Note the crowded core and the short N–H···N hydrogen bond.

an antiaromatic system. Thus, adjacent C_α–C_{meso} distances differ by only 0.03 Å. The long, nearly single bond-like, C_α–C_α distance of 1.486 Å provided the key insight into this structure, namely that NCH_2 should not be viewed as antiaromatic but rather as a cyclic bis(dipyrrin),[7,8] and indeed as a unique conceptual link between aromatic tetrapyrroles on the one hand and dipyrrins and other open-chain oligopyrroles on the other.[9]

Might NCH_2 serve as a macrocyclic ligand and exhibit interesting coordination behavior? Given the small size of the low-spin Ni^{II} cation, Ni(NC) (S = 0) seemed like an ideal candidate for a DFT study. A C_2 symmetry-constrained geometry-optimization yielded a near-C_{2v} geometry, the essential symmetry-equivalence of the four pyrrole units once again signifying that the structure is best viewed as a bis(dipyrrin) complex. The optimized geometry, depicted in Figure 3, exhibits a significant doming, but is otherwise quite strain-free. The Ni–N distances of 1.85 Å are short (but not exceptionally so), and the direct C_α-C_α linkages are once again nearly single bond-like in length

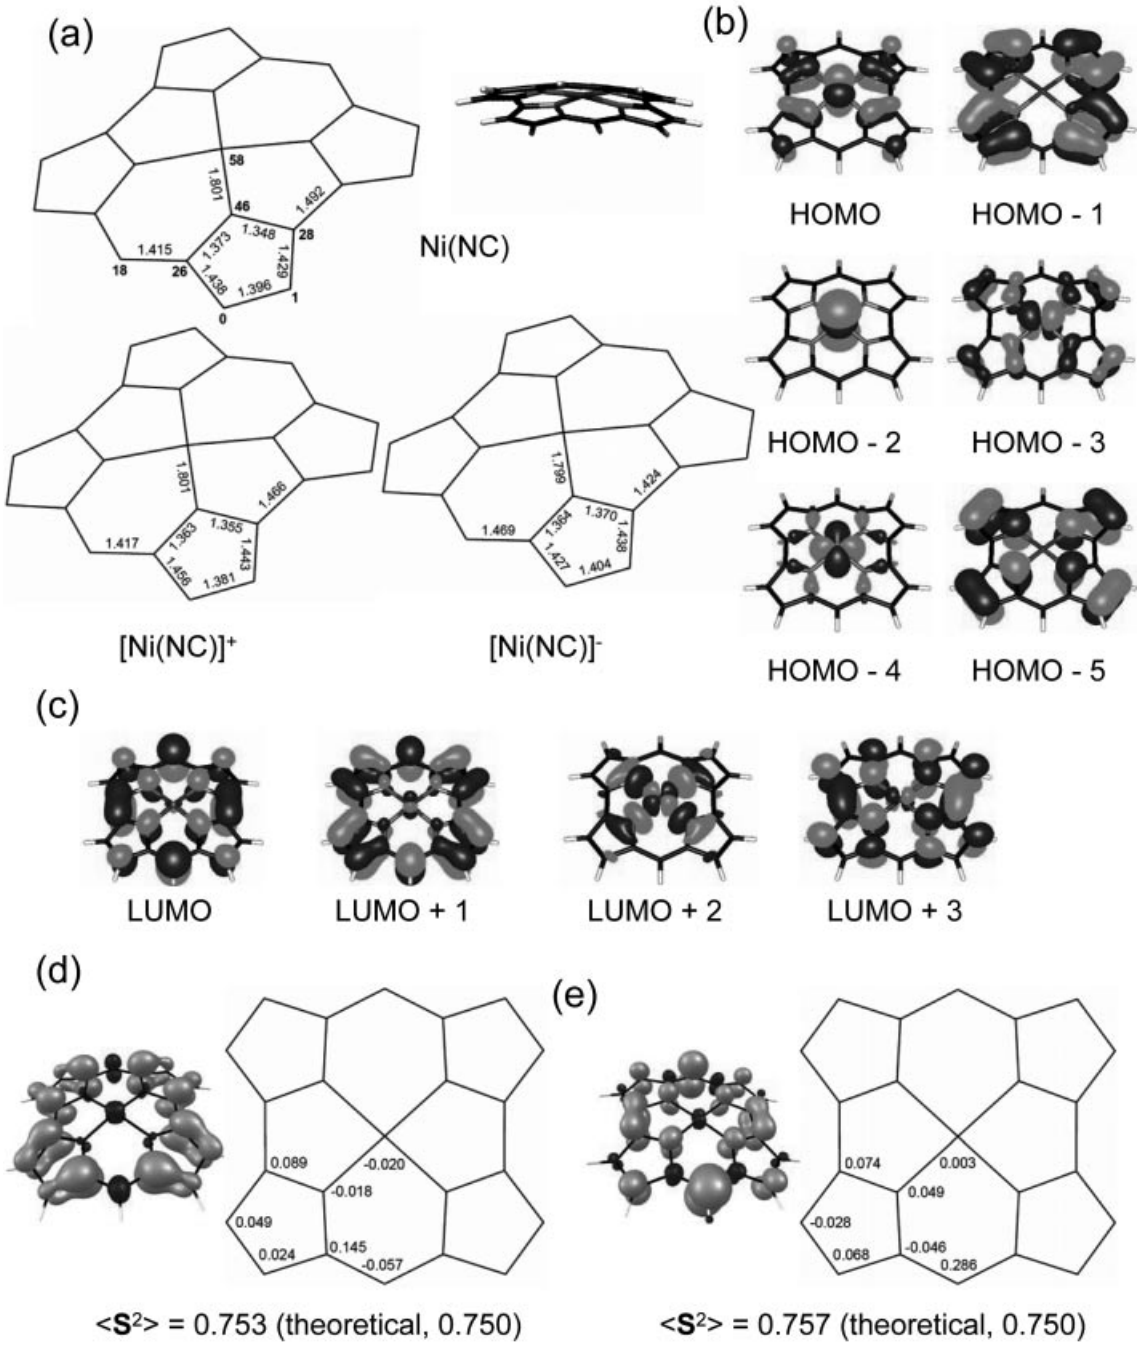

Figure 3. Selected computed results on Ni(NC): (a) Optimized structures [Å], (b) HOMOs, (c) LUMOs, (d) spin density for $[Ni(NC)]^+$, (e) and spin density for $[Ni(NC)]^-$. In part (a), the numbers in bold indicate the "elevation" of the atoms in question in pm "above" the "lowest" β-carbons, to give an estimate of the amount of doming.

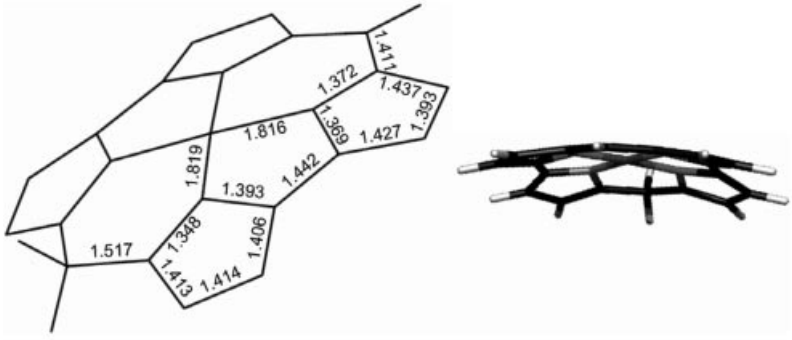
(1.493 Å). Overall, the geometry parameters of Ni(NC) are similar to those of a typical Ni(dipyrrin)$_2$ complex.[7]

Figure 3 also depicts several frontier MOs of Ni(NC), including the HOMO and LUMO, which are both macrocycle-based π MOs, as well as geometrical highlights and spin density profiles for the cationic and anionic states of Ni(NC), for which we also carried out geometry optimizations. Note the strong C_α–C_α bonding interaction in the Ni(NC) LUMO and the shortening of these bonds ($d_{C\alpha-C\alpha}$ = 1.469 Å) in the Ni(NC)$^-$ anion. The calculations on the ionized states yielded an adiabatic ionization potential of 6.91 eV and an adiabatic electron affinity of 2.47 eV for Ni(NC). The ionization potential is roughly comparable to that of a typical metalloporphyrin (e. g. zinc porphyrin[4a,10]), indicating that Ni(NC) should not be particularly sensitive to oxidative degradation. However, the electron affinity is extremely high (compared to about 1.2–1.5 eV for typical porphyrins[4a,11]), suggesting that norcorrole derivatives should be very prone to reduction. The high amplitude of the LUMO at the *meso* positions suggests that either of these positions is a plausible site of nucleophilic attack. We therefore carried out some exploratory DFT studies on dihydronorcorrole (DHNC) complexes, featuring one *meso* CH_2 unit.

By analogy with the corroles and biliverdines,[12,13] we suspected that the trianionic DHNC^{3-} ligand might form highly oxidized transition-metal complexes and our calculations suggest that it indeed should do so. Figure 4 depicts the optimized geometry Cu(DHNC), which exhibits a clear singlet "Cu^{III}" ground state, the lowest S = 1 Cu^{II} π-cation radical state being at least several tenths of an eV higher in energy. Clearly, the highly contracted N_4 core favors the smaller Cu^{III} ion ($d_{CuN} \approx 1.82$ Å, Figure 4) over the significantly larger Cu^{II} ion. The optimized structure of Cu(DHNC) exhibits the same kind of strain-free doming as Ni(NC), but note that the C_α-C_α linkages are significantly shorter (1.44 Å) than in Ni(NC), indicating reasonably effective conjugation across the entire π-system.

The extreme stabilization of the Cu^{III} state in Cu(DHNC) is probably most reminiscent of Cu^{III} corrolazines, where Goldberg[14] and co-workers have experimentally shown that a Cu^{III} ground state is also clearly favored over a Cu^{II} ligand π-cation radical state.[15] In contrast, using temperature-dependent NMR measurements (as well as DFT calculations[4]), we[16,17] and others[18,19] have shown that the Cu^{III} and the Cu^{II} ligand π-cation radical states are essentially isoenergetic for corroles, whereas Cu biliverdines clearly exhibit Cu^{II} ligand π-cation radical ground states. As in the DHNC case, the stability of the Cu^{III} state for corrolazines seems readily ascribable to their significantly tighter N_4 cores, compared with corroles. Interestingly, DFT calculations predict that Cu isocorroles, whose central cavities are expected to be only slightly smaller relative to Cu corroles, should also exhibit clear Cu^{III} ground states.[20]

We have carried out DFT calculations for a number of additional high-valent DHNC complexes, namely Fe(DHNC)Cl (Figure 5), Mn(DHNC)Cl (Figure 6),



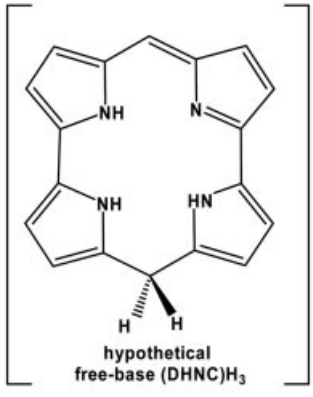


Figure 4. Highlights [Å] of the optimized structure of Cu(DHNC). For clarity, only the *meso* C–H bonds are explicitly shown in the diagram to the left. Note the structure of the hypothetical free-base dihydronorcorrole.

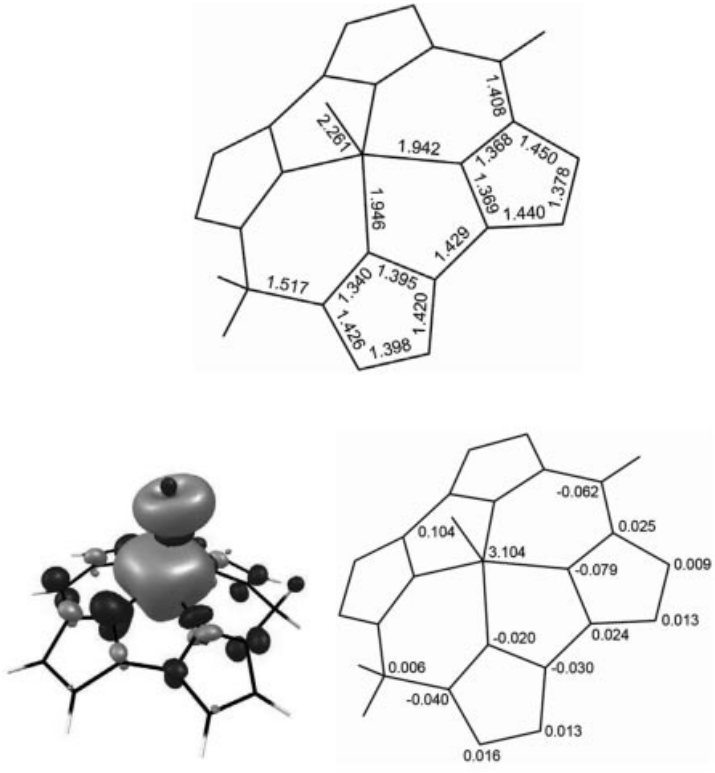

Figure 6. Selected computed results on Mn(DHNC)Cl; top: optimized geometry [Å], bottom: spin density and populations.

Fe(DHNC)Ph (Figure 7), Mn(DHNC)Ph (Figure 8), and Co(DHNC)Ph (Figure 9). The corrole analogues of these complexes have also been studied by DFT and, in some cases, also experimentally, which allows us to make some interesting comparisons.[4–6] Our main findings on these molecules are as follows.

All the five-coordinate DHNC complexes exhibit short metal–nitrogen distances, which are shorter than those in

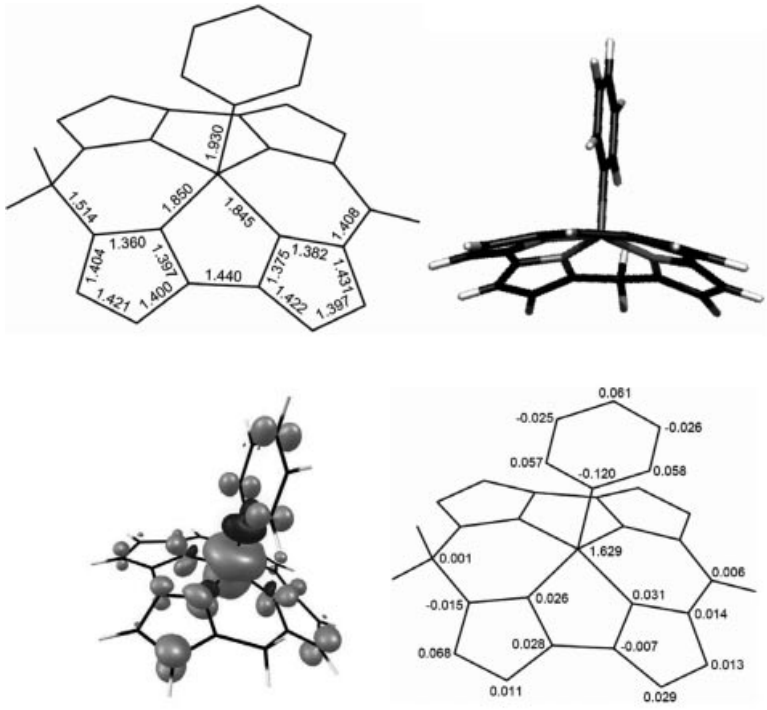

Figure 7. Selected computed results on Fe(DHNC)Ph; top: optimized geometry [Å], bottom: spin density and populations.

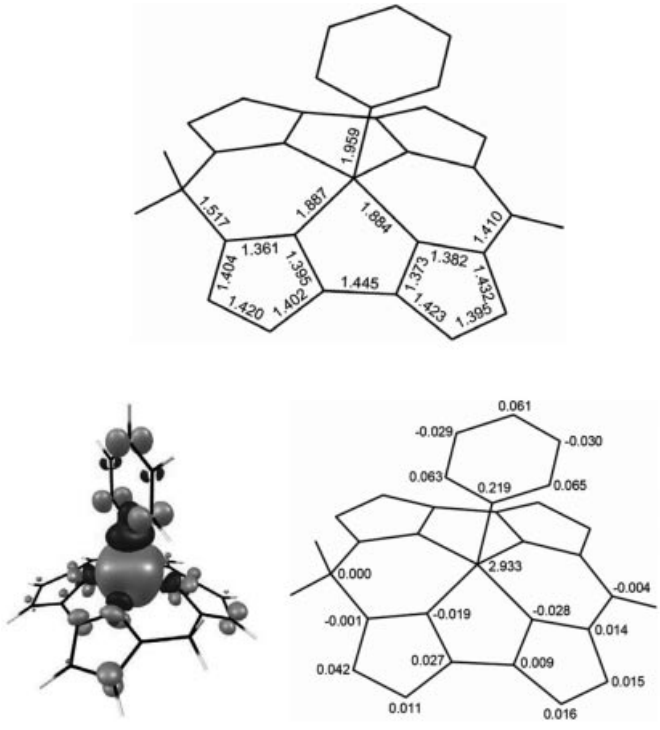

Figure 8. Selected computed results on Mn(DHNC)Ph; top: optimized geometry [Å], bottom: spin density and populations.

corroles, and considerable doming, which is more pronounced than in Ni(NC) and Cu(DHNC). Thus, the metal atom in Fe(DHNC)Cl, Mn(DHNC)Cl, Fe(DHNC)Ph, and Mn(DHNC)Ph is above the DHNC N_4 plane by 0.590, 0.650, 0.400, and 0.444 Å, respectively.

As shown in Figure 5, the Fe(DHNC)Cl results show considerable spatial separation of the majority and minority spin densities. In other words, the calculations suggest that electronic structure might best be described as involving an $S = 3/2$ Fe^{III} center antiferromagnetically coupled to a

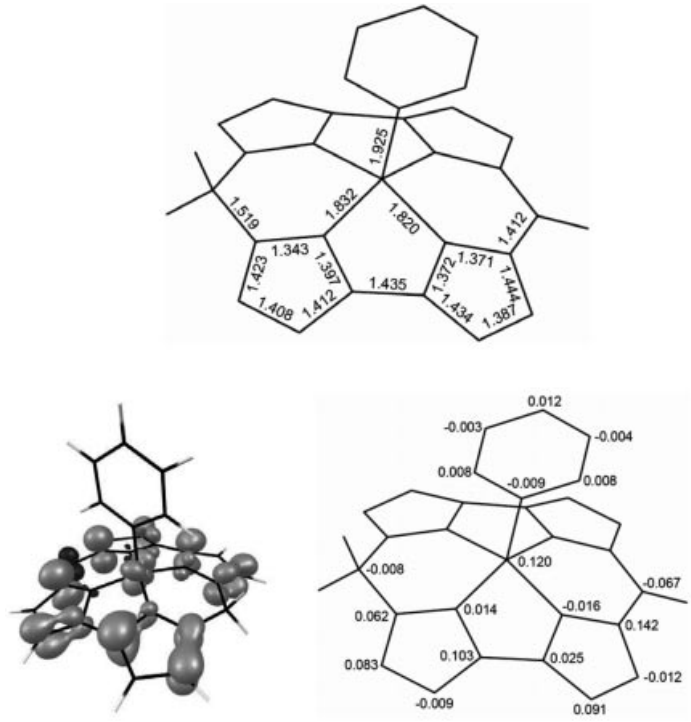

Figure 9. Selected computed results on Co(DHNC)Ph; top: optimized geometry [Å], bottom: the spin density.

$DHNC^{2-\cdot}$ radical. A similar electronic-structural description has also been found for FeCl corrole derivatives on the basis of ^1H NMR spectroscopy and DFT calculations.[5,6,21,22]

Compared to Fe(DHNC)Cl, we found only small amounts of minority spin on the DHNC ligand in Mn(DHNC)Cl (Figure 6). According to our calculations, Mn(DHNC)Cl therefore seems best viewed as a "true" Mn^{IV} complex. In contrast, we found approximately the same amount of ligand radical character (noninnocence) for MnCl corrole as we did for FeCl corrole.[4] In other words, there are both qualitative similarities and intriguing differences between the ways ligand noninnocence plays out in corroles vs. DHNC derivatives.

The spin density profiles of Fe(DHNC)Ph (Figure 7) and Mn(DHNC)Ph (Figure 8) are similar to those of Fe(Cor)Ph and Mn(Cor)Ph, respectively, in the following way.[23] Unlike Fe(DHNC)Cl and Fe(Cor)Cl, Fe(DHNC)Ph and Fe(Cor)Ph do not exhibit significant spatial separation of majority and minority spin densities; in both cases, 80–90% of the majority spin is localized on the Fe, the remainder being distributed over selected sites on both the macrocycle and the phenyl group. In contrast, Co(DHNC)Ph exhibits only a small spin population on the metal but almost pure majority-spin radical character for the DHNC ligand. In other words, the Co compound is best viewed as made up of a $Co^{III}Ph$ center and a $DHN^{2-\cdot}$ ligand.[20] Overall, all the phenyl complexes exhibit very close to the theoretically expected values of $<\mathbf{S}^2>$.

In conclusion, our calculations clearly point to norcorrole as a promising synthetic target, especially when complexed to a small cation such as Ni^{II}. However, NC complexes should be prone to reduction and we predict that high-valent metal-DHNC complexes should exist as reasonably stable substances. However, the successful preparation of NC and DHNC derivatives is likely to be much more than a synthetic exercise: These molecules may be viewed as conceptual links between aromatic tetrapyrroles such as porphyrin and corrole on the one hand and open-chain pyrrole-based ligands such as dipyrrins and biliverdines on the other and detailed studies of their electronic structure is likely to be of unusual interest.

Acknowledgments

As mentioned, one of us (AG) is indebted to Prof. Emanuel Vogel for prompting us to undertake this research. This work was supported by a grant of computer time from the Norwegian Research Council as well as by travel support from the National Research Fund of the Republic of South Africa.

Crystal Structure and Magnetic Behaviour of the New Gadolinium Complex Compound $Gd_2(ClH_2CCOO)_6(bipy)_2$

Daniela John[a] and Werner Urland*[a]

Keywords: Gadolinium / Carboxylate ligands / N ligands / X-ray diffraction / Crystal structure / Magnetic properties

Single crystals of the title compound have been obtained by reaction of $Gd_3(ClH_2CCOO)_9(H_2O)_5$ with 2,2′-bipyridyl (bipy) in a solution of ethanol and water. $Gd_2(ClH_2CCOO)_6(bipy)_2$ crystallises in the triclinic space group $P\bar{1}$ ($Z = 2$) with a = 959.5(3) pm, b = 980.9(3) pm, c = 1163.9(4) pm, α = 68.67(3) °, β = 84.82(4)° and γ = 82.47(4)°. The crystal structure is built up of discrete molecules of dinuclear Gd^{3+}–Gd^{3+} units. The corresponding residual (all data) for the refined structure is 4.46 %. The magnetic behaviour of the compound was investigated in the temperature range of 1.76–300 K. The magnetic data were interpreted considering exchange interactions within the dimeric unit (J_{ex} = –0.020 cm^{-1}).

Introduction

The research on molecular magnetic materials with lanthanides (Ln) is up to now mostly focused on the interaction of transition metal with lanthanide ions. There are several publications[1–5] concerning magnetic interactions in Ln–Cu, Ln–Ni and Ln–Fe units but only few Ln-Ln interactions in molecular magnetic materials have been studied yet.[6–10] There are no simple rules, such as the ones of Goodenough and Kanamori for compounds of d elements, to predict the occurrence of ferro- or antiferromagnetic coupling.[11] In order to fill this lack of knowledge we synthesised the title compound and determined the magnetic behaviour. The magnetic data were interpreted considering magnetic exchange coupling in the dinuclear Gd^{3+}–Gd^{3+} unit.[11,12]

Results and Discussion

The crystal data and details of the refinements for $Gd_2(ClH_2CCOO)_6(bipy)_2$ are summarised in Table 1, selected bond lengths can be found in Table 2.

The title compound crystallises in the triclinic space group $P\bar{1}$ ($Z = 2$) with a = 959.5(3) pm, b = 980.9(3) pm, c = 1163.9(4) pm, α = 68.67(3)°, β = 84.82(4)° and γ = 82.47(4)°. The crystal structure is shown in Figure 1 (H atoms are not displayed). The structure is built up by discrete dimers (Gd^{3+}–Gd^{3+}-distance: 399.0 pm) with two kinds of bridging carboxylate groups (μ_2-carboxylato-κ^1O:κ^1O' and μ_2O';κ^2O,O') and besides a chelating monochloroacetate ion (Figure 2).[13] The Gd^{3+} ion is ninefold coordinated by seven oxygen atoms originating from the carboxylate groups (Gd^{3+}–O distances: 236.3 pm to 260.3 pm) and two nitrogen atoms stemming from a 2,2′-bipyridyl molecule (Gd^{3+}–N distances: 255.1 pm and 258.5 pm).

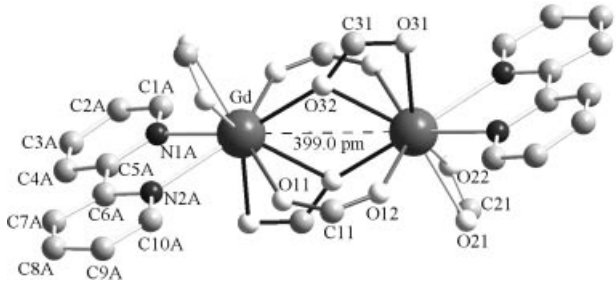

Figure 2. Dimeric unit in $Gd_2(ClH_2CCOO)_6(bipy)_2$; Gd atoms, carboxylate groups and 2,2′-bipyridyl molecules are given. The dashed line shows the Gd^{3+}–Gd^{3+}-distance, dark-grey lines indicate the μ_2-carboxylato-κ^1O:κ^1O'- and the black ones the μ_2O';κ^2O,O'-bridging mode.

The extended structure is formed by π–π stacking of the ligating 2,2′-bipyridyl molecules (Figure 3).[14,15] The shortest orthogonal distance between two aromatic fragments is 345.0 pm.

Former results have shown, that the μ_2O';κ^2O,O'- is responsible for a ferromagnetic interaction whereas the μ_2-carboxylato-κ^1O:κ^1O'-bridging mode leads to an antiferromagnetic interaction.[13,16–20] The title compound with the obtained crystal structure is interesting for magnetic investigations in order to study the influence of the coexistence of both bridging modi.

The presentation of the magnetic data follows the recommendation of S. Hatscher et al.[21] Figure 4 displays the measured effective Bohr magneton number (μ_{eff}) of the $Gd_2(ClH_2CCOO)_6(bipy)_2$ in the temperature range between 1.76 and 300 K ($H^{(ir)}$ = 500 Oe). The curve progression shows an antiferromagnetic behaviour. The measured magnetic susceptibility ($\chi_m^{(ir)}$) is interpreted by Equation (1) given below, where the intramolecular interaction within the dimeric unit is described by the Heisenberg model with a spin Hamiltonian $\hat{H}_{ex} = -2J_{ex}\hat{\boldsymbol{S}}_{Gd1}\cdot\hat{\boldsymbol{S}}_{Gd2}$ ($S_{Gd1} = S_{Gd2} = 7/2$), where N_A is the Avogadro constant, μ_B the Bohr magneton, g the Landé factor, k_B the Boltzmann constant, T the absolute temperature and J_{ex} the magnetic exchange parameter.[12]

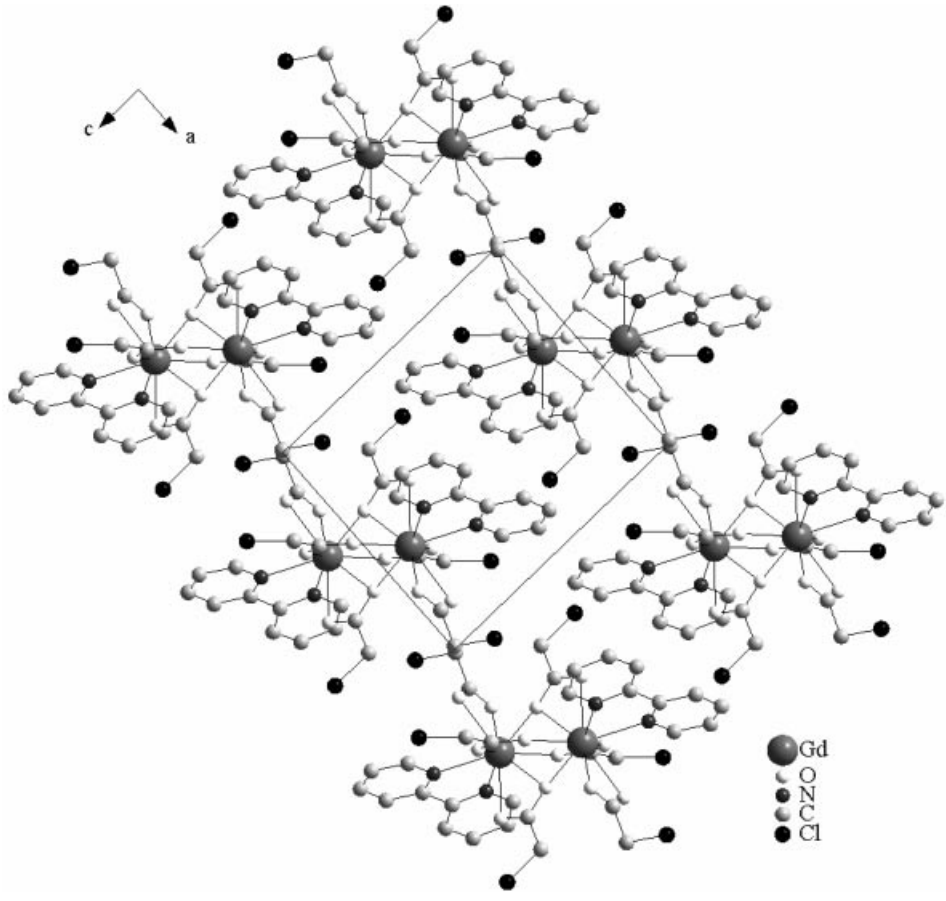

Figure 1. Crystal structure of $Gd_2(ClH_2CCOO)_6(bipy)_2$. The triclinic unit cell is given; H atoms are not displayed.

$$\chi_m^{(ir)} = \frac{N_A \mu_B^2 g^2}{k_B T} \cdot \frac{e^{2x} + 5e^{6x} + 14e^{12x} + 30e^{20x} + 55e^{30x} + 91e^{42x} + 140e^{56x}}{1 + 3e^{2x} + 5e^{6x} + 7e^{12x} + 9e^{20x} + 11e^{30x} + 13e^{42x} + 15e^{56x}}$$

with $x = J_{ex} / k_B T$ (1)

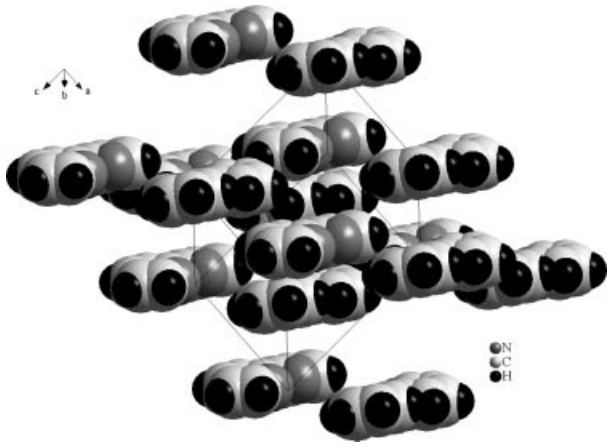

Figure 3. π–π Stacking of the 2,2′-bipyridyl molecules in $Gd_2(ClH_2CCOO)_6(bipy)_2$. The unit cell is given.

The fitting procedure leads to J_{ex} = –0.020 cm^{-1}, with g = 2.00. The accordance of the measured and calculated μ_{eff} values is shown in Figure 4.

The value of J_{ex} for the title compound is comparable with the ones of other carboxylates containing Gd^{3+} (cf. Table 3). The coexistence of the $\mu_2O';\kappa^2O,O'$- and the μ_2-carboxylato-$\kappa^1O:\kappa^1O$-bridging mode in $Gd_2(ClH_2CCOO)_6(bipy)_2$ leads to a negative exchange parameter, meaning a dominating antiferromagnetic interaction, as found in (**2**).[20]

Experimental Section

Transparent, colourless, air-stable, single crystals of $Gd_2(ClH_2CCOO)_6(bipy)_2$ have been obtained by reaction of $Gd_3(ClH_2CCOO)_9(H_2O)_5$ with 2,2′-bipyridyl (Fluka, ≥ 98.0%%) (molar ratio 2:1) in a solution of ethanol and water (1:1). The starting compound $Gd_3(H_2ClCCOO)_9(H_2O)_5$ was prepared as given in the literature.[22]

Well grown single crystals were mounted on a STOE imaging plate diffractometer. The data collection was carried out at room temperature. The structure was solved by Patterson methods and were refined with anisotropic displacement parameters based on F^2 using SHELXS-97[23] and SHELXL-97[24] programs. Data analysis indicate the space group $P\bar{1}$. The final refinement yielded R_1 (all data) = 4.46%. Hydrogen atoms were included using a riding model. The crystal data and details of the refinement are summarised in Table 1 and selected bond lengths can be found in Table 2. Elemental analysis (Vario EL, Elementar Analysesysteme GmbH, Hanau, Germany) for $C_{16}H_{20}Cl_3GdN_2O_6$ (593.91): calcd. C 32.36, H 2.38, N 4.72; found C 32.29, H 2.47, N 4.69.

Pulverised single crystals of the title compound were measured with a SQUID magnetometer (MPMS5, Quantum Design) in a temperature range of 1.76 to 300 K at magnetic fields ($H^{(ir)}$) of 500 and 1000 Oe. No field dependence of the magnetic data was observed. The sample was weighed into the lid of a gelantine capsule. To avoid orientation effects during the measurement, another gelantine capsule was pressed on the sample to fix it. Subsequently the container was sewn in a plastic straw. Using the increments of Haberditzl, the raw magnetic data were corrected for diamagnetism of the sample carrier and the sample.[25]

Significance of Intermolecular S···C(π) Interaction Involving M–S and –C=O Centers in Crystal Structures of Metal Thiolate Complexes

Janusz Lewiński,*[a] Wojciech Bury,[a] and Iwona Justyniak[b]

Keywords: Database analysis / Noncovalent interactions / Thiolates / Metal complexes

The database analysis of intermolecular S···C(π) distances involving a metal-bonded thiolate sulfur atom and various C(π)-centered Lewis acid domains provided evidences for M–S···C(π) contacts as resulting from specific noncovalent interactions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

A plethora of noncovalent interactions account for a number of known binding and structural motifs in biological systems, synthetic catalysis and supramolecular chemistry.[1] In this regard hydrogen bonding plays a dominant role,[2] but many other less conventional noncovalent forces like the C–H···π,[3] cation···π,[4] and anion···π interactions,[5] π–π aromatic stacking,[6] halogen bonding,[7] or chalcogen–chalcogen[8] interactions have been identified and extensively explored recently. Nevertheless, some structural and functional aspects of biomolecular or catalytic functions remain an active problem which partly results from the fact that less obvious specific forces involving different chemical entities are only rarely encountered. In this regard, studies on identifying and characterizing noncovalent interactions are essential for a more complete understanding of biochemical processes and could provide useful tools in the field of molecular recognition. One of such emerging areas of research are interactions between divalent sulfur centers and electron-deficient π-systems. It is over 30 years since the seminal work of Dunitz et al. revealed that a large number of the close contacts between an electrophilic carbonyl group and a nucleophilic group exist in the crystal structures of small organic molecules, and based on the correlation analysis the authors mapped out reaction pathways of the nucleophilic addition to a carbonyl group.[9] More recently, it has been found that the nucleophilic attack by an amino acid S-terminal side chain on a peptide carbonyl atom is the crucial step in the mechanism of self-catalyzed peptide bond rearrangement.[10] An attractive intramolecular interaction between the thiolate group of a metal-bound cysteine and a carbonyl carbon atom of a peptide group is also essential in the determination of metalloprotein structures.[11–13] Nevertheless, the chemistry of specific weak interactions involving a thiolate center in metal complexes and metalloproteins has been so far explored only fleetingly.[14] Very recently, we have revealed that the intermolecular S···C(π) interaction between an M–S thiolate unit and the π-surface of an ester functionality can compete with the potential sulfur–metal dative bond of group 13 metal–alkyl compounds derived from methyl thiosalicylate, $Me_2M(SC_6H_4\text{-}2\text{-}CO_2Me)$ (cf. structures **I** and **II**; Figure 1).[15] In order to verify the significance of the M–S···C(π) interaction between the M–S–C thiolate sulfur atom and the carbonyl carbon atom as an intermolecular force, we have performed detailed structural analysis of intermolecular contacts for various types of metal thiolate complexes retrieved from the Cambridge Structural Database (CSD).

Results and Discussion

The collection of structural data was obtained through the systematic search of the CSD using CCDC software (version 5.25).[16] The searches were performed for structures containing a sulfur atom bonded to any metal atom and carbonyl group moieties of the type X–C=O (where X = C, N, O, S). Only the intermolecular contacts between the sulfur atom and the carbonyl carbon atom were examined (the S···C=O intermolecular contact). The coordinate system, the atom labeling scheme and the resulting geometric parameters used in our analysis are sketched in Figure 2.

The position of the sulfur atom relative to the carbonyl group plane is specified in spherical polar coordinates by two angles, φ and θ and the distance r. The carbonyl group lies in the xy plane and the vector C=O defines the direction of the X axis. The search was subjected to the following criteria: S···C intermolecular contacts up to 4.0 Å, R-factor less than 0.075 and error free, the position of the sulfur atom was specified relative to the π-phase of C=O moieties in spherical polar coordinates. The restricted searches revealed 101 compounds and the total data set used for the correlation analysis was 141 data points. In our analysis were excluded all intermolecular contacts between the sulfur atom and a carbonyl group corresponding to the S···O=C interaction between a C–S–C unit and a carbonyl oxygen atom.[8b] A survey of available crystal structures shows several types of functional groups acting as the C(π)-centered Lewis acid domains. In total 27 contacts were found in which the sulfur lone pair is directed to the carbon atom of the carboxylate group bonded to a metal center, 48 contacts involve metal-bonded thiocarboxylates, 23 amides, 21 esters, and 22 ketones. The corresponding histogram plots of the S···C=O distances for various type of X–C=O carbonyl moieties are offset essentially regularly (Figure 2). This observation is consistent with the expectation taking into account that the functional groups in question are both bound (or not bound at all) to various metal centers and with various coordination modes, and thus the metal–ligand interactions have a different character which affects the Lewis acidity of the X–C=O carbon center. Not surprisingly, the effect is most pronounced for the carboxylate groups which exhibit the greatest metal–ligand bonding diversity.[17] Interestingly, it appears from the considered data set that in the short range of contacts (i.e., below 3.5 Å) there are interactions involving essentially all types of functional groups except the ester group. Thus, this fact suggests that the ester group Lewis acid domain is one of the weakest acidity. On the other hand, the S···C(π) distance recently found by us for $Me_2Al(SC_6H_4\text{-}2\text{-}CO_2Me)$ is one of the shortest intermolecular contacts observed to date between the M–S center and the carbon atom of the ester group. Furthermore, the analysis of angular attributes of the S···C(π) interactions clearly show the directional nature of this novel noncovalent force, Figure 3 (see also Figures S3 and S4 of the Supporting Information).

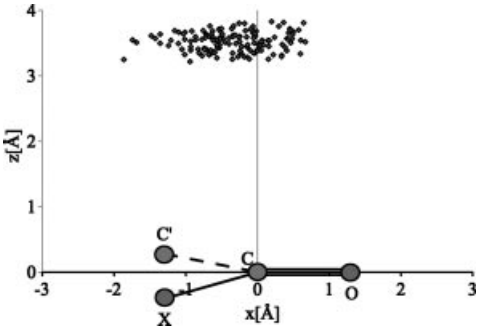

Figure 3. Distribution of the axial positions for the sulfur atom of a metal thiolate unit position relative to the X–C=O π-face projected on the xz plane.

In conclusion, detailed structural analysis was performed for crystal structures of metal thiolate complexes retrieved from the CSD which demonstrates that the intermolecular S···C(π) interactions involving a metal-bonded thiolate sulfur atom and various C(π)-centered Lewis acid domains appear very frequently and play a crucial role in the molecular assembly of these compounds in the solid state {cf. the crystal structures of $[Co(SC_6H_4\text{-}2\text{-}CO_2)N(C_2H_4NH_2)_3]ClO_4$ (**III**)[18] and $Zn(SC_6F_5)_2(C_5H_4N\text{-}2\text{-}COCH_3)$ (**IV**)[19] see Figure 4}.

There are already more than 100 crystal structures deposited in the CSD and surprisingly the S···C(π) interaction as well its role on the supramolecular structure of various

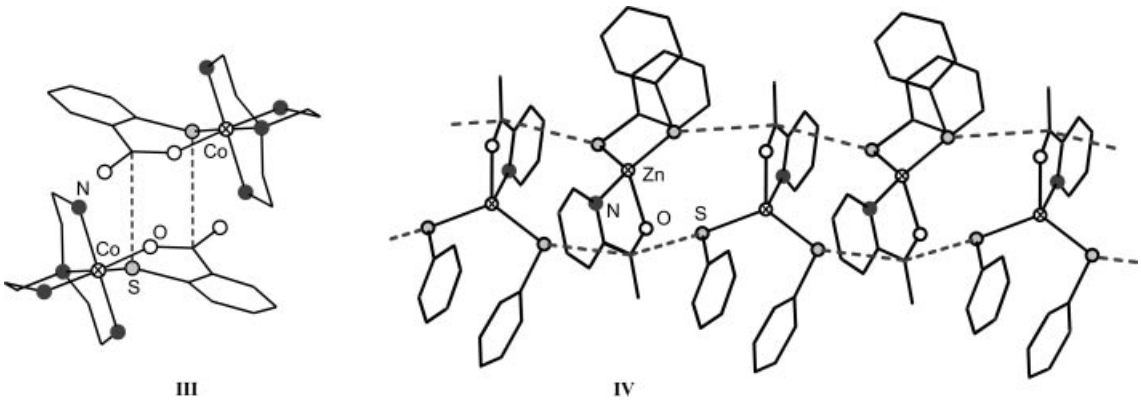

Figure 4. Structures of non-covalently bonded dimer $[Co(SC_6H_4\text{-}2\text{-}CO_2)N(C_2H_4NH_2)_3]ClO_4$ (**III**) and polymer chain of $Zn(SC_6F_5)_2(C_5H_4N\text{-}2\text{-}COCH_3)$ (**IV**).

complexes has not been recognized in any case by the original authors. Furthermore, it is reasonable that the M–S···C=O interactions may be expected to be responsible for the high bioactivity of sulfur, because such an interaction may occur at an early stage along the reaction coordinate or stabilize the folded protein structure as well as it might be a controlling factor in regulating the reactivity and specificity of metal–thiolate bonds.[20] The fact that the chemistry of specific weak interactions involving a thiolate center in metalloenzymes has been often underestimated in model studies is well expressed by the investigation involving the above-mentioned complex **IV**.[19] Further studies on both the relationship between dative bonds in metal complexes and secondary interactions, and the significance of the intermolecular S···C(π) interaction between M–S thiolate units and the π-surface of a carbonyl functionality in various systems are in progress.

Supporting Information (see footnote on the first page of this article) is available online for this manuscript, including parameterization data, histograms, scatter plots based on analyzed datasets and CCDC reference codes used in the database analysis can be found there.

Water-Soluble Arene Ruthenium Complexes Containing a *trans*-1,2-Diaminocyclohexane Ligand as Enantioselective Transfer Hydrogenation Catalysts in Aqueous Solution

Jérôme Canivet,[a] Gael Labat,[a][‡] Helen Stoeckli-Evans,[a][‡] and Georg Süss-Fink*[a]

Keywords: Ruthenium complexes / Transfer hydrogenation / Enantioselective catalysis

The cationic chloro complexes $[(arene)Ru(H_2N\cap NH_2)Cl]^+$ (**1**: arene = C_6H_6; **2**: arene = *p*-MeC_6H_4iPr; **3**: arene = C_6Me_6) have been synthesised from the corresponding arene ruthenium dichloride dimers and enantiopure (*R*,*R* or *S*,*S*) *trans*-1,2-diaminocyclohexane ($H_2N\cap NH_2$) and isolated as the chloride salts. The compounds are all water-soluble and, in the case of the hexamethylbenzene derivative **3**, the aqua complex formed upon hydrolysis $[(C_6Me_6)Ru(H_2N\cap NH_2)OH_2]^{2+}$ (**4**) could be isolated as the tetrafluoroborate salt. The molecular structures of **3** and **4** have been determined by single-crystal X-ray diffraction analyses of $[(C_6Me_6)Ru(H_2N\cap NH_2)Cl]Cl$ and $[(C_6Me_6)Ru(H_2N\cap NH_2)OH_2][BF_4]_2$. Treatment of $[Ru_2(arene)_2Cl_4]$ with the monotosylated *trans*-1,2-diaminocyclohexane derivative ($TsHN\cap NH_2$) does not yield the expected cationic complexes, analogous to **1**–**3** but the neutral deprotonated complexes $[(arene)Ru(TsN\cap NH_2)Cl]$ (**5**: arene = C_6H_6; **6**: arene = *p*-MeC_6H_4iPr; **7**: arene = C_6Me_6; **8**: arene = C_6H_5COOMe). Hydrolysis of the chloro complex **7** in aqueous solution gave, upon precipitation of silver chloride, the corresponding monocationic aqua complex $[(C_6Me_6)Ru(TsHN\cap NH_2)(OH_2)]^+$ (**9**) which was isolated and characterised as its tetrafluoroborate salt. The enantiopure complexes **1**–**9** have been employed as catalysts for the transfer hydrogenation of acetophenone in aqueous solution using sodium formate and water as a hydrogen source. The best results were obtained (60 °C) with **7**, giving a catalytic turnover frequency of 43 h^{-1} and an enantiomeric excess of 93 %.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Water-soluble organometallic complexes continue to attract growing interest for applications in catalysis because of environmentally friendly processing, simple product separation and pH dependent selectivity in aqueous media.

The first arene ruthenium aqua complexes were observed by NMR spectroscopy in 1972 when Zelonka and Baird dissolved $[(C_6H_6)Ru_2Cl_4]$ in D_2O.[1] The osmium complex $[(C_6H_6)Os(H_2O)_3]^{2+}$ was synthesised in an analogous manner and characterised spectroscopically by Hung et al.[2] Stebler-Röthlisberger et al. finally succeeded in isolating the first cationic benzene aqua complexes $[(C_6H_6)Ru(H_2O)_3]^{2+}$ and $[(C_6H_6)Os(H_2O)_3]^{2+}$ as the tosylate salts. The structure of the triaqua(benzene)ruthenium(II) cation was confirmed by a single-crystal X-ray structure analysis of the sulfate.[3]

Since these early reports, the chemistry of organometallic aqua ions of the transition metals has steadily grown during the 1980s and this topic was comprehensively reviewed by Koelle.[4] Related reviews deal with water-soluble organometallics complexed by hydrophilic ligands,[5] metal-mediated organic synthesis in water[6] and catalysis by water-soluble organometallic complexes in biphasic systems.[7] Recently, Ogo reported the transfer hydrogenation of ketones with HCO_2Na as a hydrogen donor, catalysed by achiral water-soluble Ru(II) complexes.[8] The intermediary formato and hydrido complexes $[(C_6Me_6)Ru(bipy)(OCHO)]^+$ and $[(C_6Me_6)Ru(bipy)H]^+$ could be isolated and structurally characterised.[8,9] We have also described the synthesis and catalytic activity of cationic arene ruthenium complexes containing 1,10-phenanthroline and its derivatives as chelating *N*,*N*-donor ligands.[10]

Several recent reports deal with asymmetric transfer hydrogenation of ketones with formate in aqueous media using active catalytic systems based on $[(p\text{-}MeC_6H_4iPr)RuCl_2]_2$ and *N*-(*p*-toluenesulfonyl)-1,2-diphenyl-ethylenediamine and its derivatives[11–14] 2-(*N*-anilinocarboxy)-pyrrolidine[15] or aminoethanol attached to cyclodextrin.[16] These catalytic systems show good activities and enantioselectivities but the catalysts are formed in situ from precursors and are not isolated. 1,2-dephenylethylendiamine ("Noyori's ligand")[17,18] and also *trans*-1,2-diaminocyclohexane form, in combination with $[(p\text{-}MeC_6H_4iPr)RuCl_2]_2$, an active catalytic system for the transfer hydrogenation of ketones in 2-propanol or in an Et_3N/HCOOH azeotropic mixture.[19]

In this paper we report a series of water-soluble arene ruthenium complexes containing enantiopure *trans*-1,2-di-

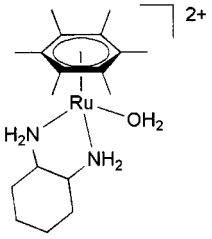
aminocyclohexane and derivatives thereof as chelating *N*,*N*-donor ligands. We also describe the catalytic activity of these complexes in the transfer hydrogenation of aromatic ketones to give the corresponding chiral secondary alcohol with sodium formate as a hydrogen donor in aqueous solution.



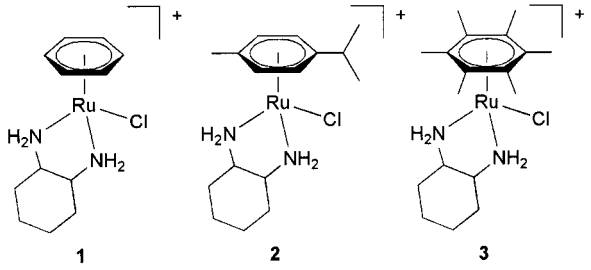
4

Results and Discussion

Synthesis of Enantiopure Arene Ruthenium Complexes Containing the *trans*-1,2-Diaminocyclohexane Ligand (1–4)

The monocationic chloro complexes $[(arene)Ru(H_2N\cap NH_2)Cl]^+$ (**1**–**3**) containing the *N*,*N* donor as a chelating ligand are accessible by treatment of the dimeric arene ruthenium complexes $[(arene)RuCl_2]_2$ with enantiopure (*R*,*R* or *S*,*S*) *trans*-1,2-diaminocyclohexane ($H_2N\cap NH_2$) at room temperature in dichloromethane solution [Equation (1)].

$$0.5\ [(arene)RuCl_2]_2 + H_2N\cap NH_2 \rightarrow [(arene)Ru(H_2N\cap NH_2)Cl]^+ + Cl^- \quad (1)$$



1 **2** **3**

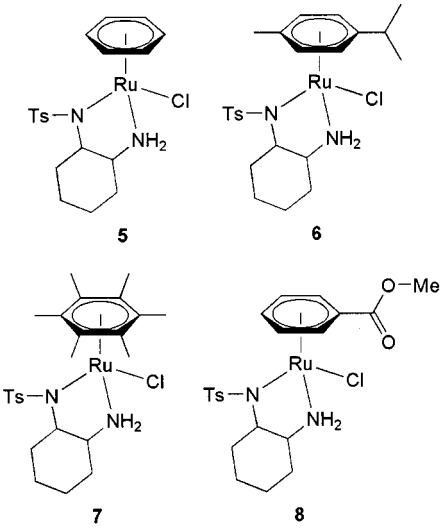
The chloride salts of **1**–**3** are orange solids that dissolve well in water, a property which can be used to remove unreacted materials. Since there is a risk of hydrolysis in water, the aqueous solutions were filtered immediately and then evaporated to dryness to give the analytically pure salts [**1**–**3**]Cl. All compounds were obtained for both *trans*-1,2-diaminocyclohexane enantiomers (*R*,*R* or *S*,*S*) and were subsequently characterised by ^1H and ^{13}C spectroscopy, mass spectroscopy and elemental analysis. The molecular structure of **3** has been confirmed by a single-crystal X-ray structure analysis.

The chloro complex $[(C_6Me_6)Ru(H_2N\cap NH_2)Cl]^+$ (**3**) undergoes hydrolysis in aqueous solution and gives, upon precipitation of silver chloride, the enantiopure dicationic aqua complex $[(C_6Me_6)Ru(H_2N\cap NH_2)(OH_2)]^+$ (**4**). Both enantiomers (*R*,*R* or *S*,*S*) have been isolated as tetrafluoroborate salts and characterised by ^1H and ^{13}C spectroscopy, mass spectroscopy, elemental analysis and single-crystal X-ray structure analysis.

Synthesis of Enantiopure Arene Ruthenium Complexes Containing the *N*-Tosyl-*trans*-1,2-diaminocyclohexane Ligand (5–9)

The reaction of $[Ru_2(arene)_2Cl_4]$ with the monotosylated *trans*-1,2-diaminocyclohexane[20] ($TsHN\cap NH_2$) at room temperature in dichloromethane solution does not give the expected cationic complexes, analogous to **1**–**3**, but the deprotonated neutral complexes $[(arene)Ru(TsN\cap NH_2)Cl]$ (**5**–**8**) [Equation (2)].

$$0.5\ [(arene)RuCl_2]_2 + TsHN\cap NH_2 \rightarrow [(arene)Ru(TsN\cap NH_2)Cl] \quad (2)$$



5 **6** **7** **8**

Similar to the known complex **6**,[21] complexes **5**, **7** and **8** are orange solids. The products obtained are quite soluble in water but in order to avoid hydrolysis they were purified by column chromatography on aluminium oxide using methanol as eluent. All compounds were obtained for both the *N*-Tosyl-*trans*-1,2-diaminocyclohexane enantiomers (*R*,*R* or *S*,*S*) and were subsequently characterised by ^1H and ^{13}C spectroscopy, mass spectroscopy and elemental analysis.

The chloro complex $[(C_6Me_6)Ru(TsN\cap NH_2)Cl]$ (**7**) undergoes hydrolysis in aqueous solution and gives, upon precipitation of silver chloride, the enantiopure monocationic aqua complex $[(C_6Me_6)Ru(TsN\cap NH_2)(OH_2)]^+$ (**9**). Both enantiomers (*R*,*R* or *S*,*S*) were isolated as the tetrafluoroborate salts and characterised by ^1H and ^{13}C spectroscopy, mass spectroscopy and elemental analysis.

Molecular Structures of $[(C_6Me_6)Ru(R,R\text{-}H_2N\cap NH_2)Cl]^+$ (*R*,*R*-3) and $[(C_6Me_6)Ru(S,S\text{-}H_2N\cap NH_2)(OH_2)]^{2+}$ (*S*,*S*-4)

The compound $[R,R\text{-}3][Cl]\cdot 2CHCl_3$ crystallises in the orthorhombic non-centrosymmetric space group $P2_12_12_1$. The molecular structure of $[R,R\text{-}3][Cl]\cdot 2CHCl_3$ is depicted in Figure 1. The structure of the cation consists of a pseudo-tetrahedral arrangement of a ruthenium atom coordinated to the η^6-hexamethylbenzene ligand, the two nitrogen atoms of the (*R*,*R*) *trans*-1,2-diaminocyclohexane ligand and a chlorine atom. Ru–C distances fall within the range 2.183(2)–2.218(2) Å. As expected, the two amino groups of the (*R*,*R*) *trans*-1,2-diaminocyclohexane ligand are in equatorial positions which is the more stable conformation.

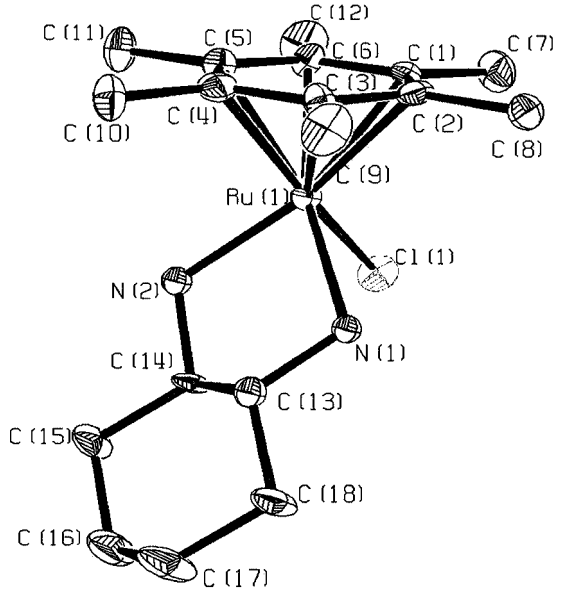

Figure 1. Molecular structure of *R*,*R*-**3**; displacement ellipsoids are shown at the 50% probability level; hydrogen atoms, the chloride counter anion and chloroform molecule are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru(1)–N(1) 2.129(4), Ru(1)–N(2) 2.130(4), Ru(1)–Cl(1) 2.4052(16); N(1)–Ru(1)–N(2) 79.26(16), N(1)–Ru(1)–Cl(1) 83.06(15), N(2)–Ru(1)–Cl(1) 84.89(14).

The compound $[S,S\text{-}4][BF_4]_2\cdot H_2O$ crystallises in the orthorhombic noncentrosymmetric space group $P2_12_12_1$. The molecular structure of $[S,S\text{-}4][BF_4]_2\cdot H_2O$ is depicted in Figure 2. The structure of the cation consists of a pseudo-tetrahedral arrangement of a ruthenium atom coordinated to the η^6-hexamethylbenzene ligand, the two nitrogen atoms of the (*S*,*S*) *trans*-1,2-diaminocyclohexane ligand and a water molecule. Ru–C distances fall within the range 2.183(2)–2.218(2) Å. As expected, the two amino groups of the (*S*,*S*) *trans*-1,2-diaminocyclohexane ligand are in equatorial positions which is the more stable conformation.

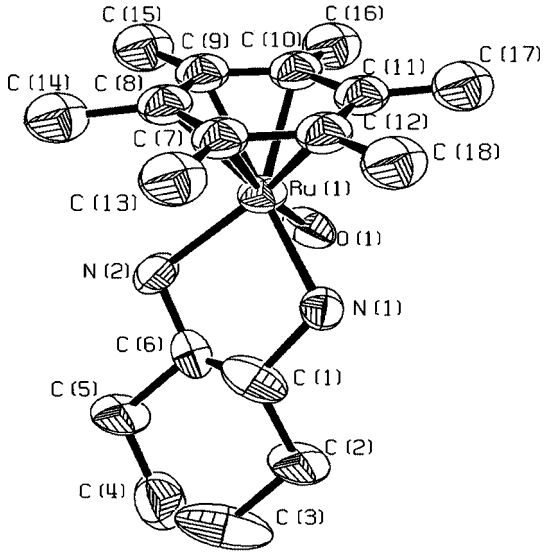

Figure 2. Molecular structure of *S*,*S*-**4**; displacement ellipsoids are shown at the 50% probability level; hydrogen atoms, tetrafluoroborate counter anions and water molecule are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru(1)–N(1) 2.127(10), Ru(1)–N(2) 2.125(11), Ru(1)–O(1) 2.188(7); N(1)–Ru(1)–N(2) 78.8(3), N(1)–Ru(1)–O(1) 81.9(4), N(2)–Ru(1)–O(1) 82.6(4).

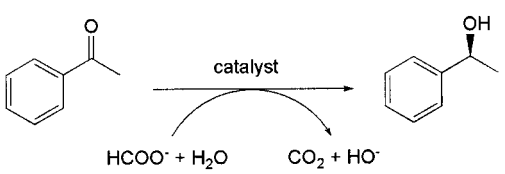
Catalytic Application of 1–9 for the Transfer Hydrogenation of Acetophenone and Derivatives with Sodium Formate in Aqueous Solution

Based on the studies using a catalytic system composed of the tosylated diphenylethanediamine (TsDPEN) with $[(p\text{-}MeC_6H_4iPr)RuCl_2]_2$ for the asymmetric transfer hydrogenation of ketones with sodium formate as hydrogen donor in water,[11–14] we evaluated the catalytic potential of the *trans*-diaminocyclohexane complexes **1**–**9** for this reaction using acetophenone as a test substrate. The solubility of the catalysts in water varies from 10 $\mu mol\,mL^{-1}$ for the neutral complexes **5**–**8** to 40 $\mu mol\,mL^{-1}$ for the ionic compounds **1**–**4** and **9** at 60 °C.



All *trans*-diaminocyclohexane complexes **1**–**9** (both *R*,*R* *and* *S*,*S* enantiomers) were found to catalyse the transfer hydrogenation reaction of acetophenone to give phenylethanol in aqueous solution with sodium formate as a hy-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drogen source (Table 1). However, the tosylated derivatives **5**–**7** and **9** shown higher activities and selectivities than the non-tosylated complexes. The contribution of the donor effect of the substituents on the arene ligand is also obvious as the enantiomeric excess (*ee*) increases from 54% for the benzene complex **5** to 93% for the hexamethylbenzene complex **7**. This result is also consistent with the CH/π attraction model reported by Noyori.[22] The beneficial effect of the donor substituents at the arene ligand was confirmed by the use of complex **8** which gave a lower activity and selectivity than those observed for the benzene complex **5**.

Table 1. Catalytic enantioselective transfer hydrogenation of acetophenone using the (1*R*,2*R*)-diaminocyclohexane ruthenium complexes as catalysts and HCOONa as a hydrogen donor in water.[a]

Catalyst	Conversion % (h)[b]	*ee* %[b]	TOF [h^{-1}][c]
1	74 (16)	29	4.6
2	89 (16)	17	5.6
3	82 (16)	47	5.1
4	86 (16)	38	5.4
5	94 (2)	54	47
6	93 (2)	81	46.5
7	86 (2)	93	43
8	7 (2)	44	3.5
9	85 (2)	91	42.5

[a] Conditions: Reactions were carried out at 60 °C, pH = 9, in 5 mL of water and with acetophenone (1 mmol); the ratio catalyst/substrate/formate was 1:100:500. [b] The conversion and the enantiomeric excesses were determined by chiral HPLC analysis. [c] TOF: turnover frequencies (mol of acetophenone converted to phenylethanol per mol of catalyst per hour) were taken after 60% conversion.

It may be assumed that the chloro complexes **1**–**3** and **5**–**8** undergo hydrolysis to the corresponding aqua complexes under catalytic conditions. Thus, the isolated aqua complex **9** shows the same activity and selectivity as the corresponding chloro complex **7**. We believe that the aqua complexes react with the formate anion to give the corresponding formato complexes as the catalytically active species. A proposed catalytic cycle for derivative **9**, based on the pioneering work of Noyori[17c] and Ogo[8] is shown in Figure 3.

The hypothesis of an η^4 transition state (Figure 3) postulated by Ogo, in the case of the $[(C_6Me_6)Ru(bipy)(OH_2)]^{2+}$ complex[8] (bipy = 2,2' bipyrimidine) is substantiated by the arene substituent dependence of the catalytic activity described above. Indeed, complex **7** containing donor substituents on the arene ligand (arene = C_6Me_6, TOF = 43 h^{-1}), which would stabilise the transition species, shows activity more than ten times greater than that of the analogue **8** with an electron-withdrawing substituent at the arene ligand (arene = $C_6H_4CO_2Me$, TOF = 3.5 h^{-1}).

The pH dependence of the catalytic activity[8,10] of **7** was studied for the transfer hydrogenation of acetophenone to give phenylethanol in aqueous solution. As Figure 4 reveals, the best pH conditions were found to be around 9 which corresponds to the pH obtained by addition of sodium formate in water under catalytic conditions.

The temperature dependence of the catalytic activity of **7** was also studied for the same reaction. The curve obtained (Figure 5) clearly shows that the catalytic conditions for the activity of this reaction were found to be the best at 60 °C without significant modification to the selectivity.

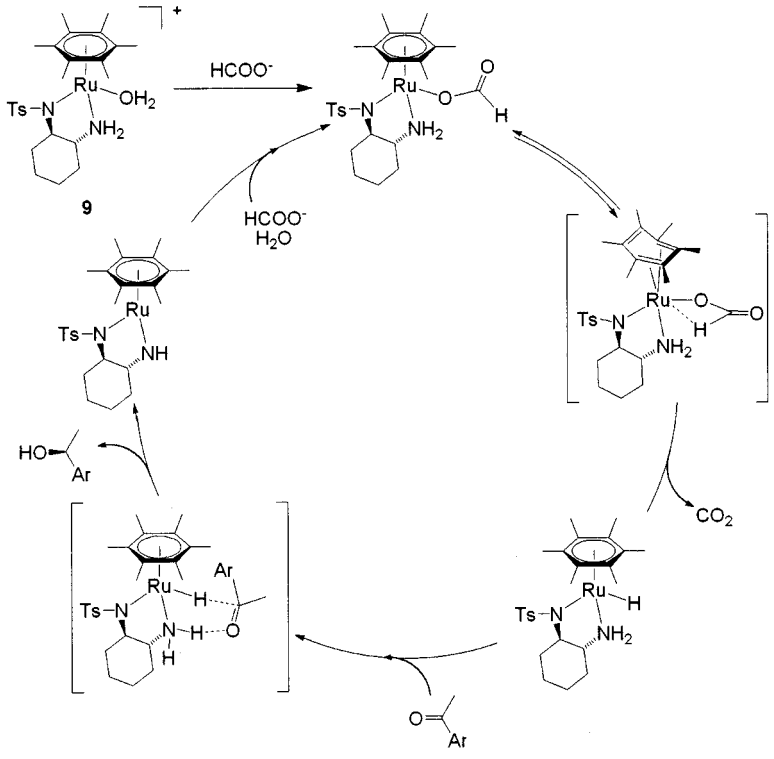


Figure 3. Postulated catalytic cycle for transfer hydrogenation catalysed by **9**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

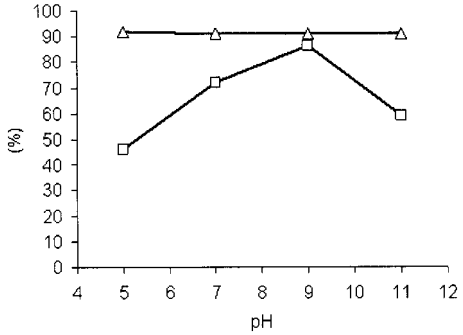

Figure 4. pH-dependent profile of conversion (□) and enantiomeric excess (ρ) for transfer hydrogenation of acetophenone (1 mmol) using complex **7** as the catalyst and HCOONa as a hydrogen donor in water (5 mL), at 60 °C, for 2 h, the catalyst/substrate/formate ratio being 1:100:500.

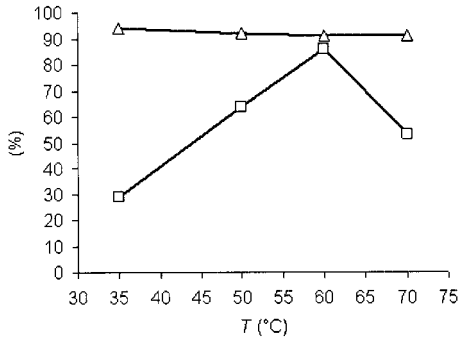

Figure 5. Temperature-dependent profile of conversion (□) and enantiomeric excess (Δ) for transfer hydrogenation of acetophenone (1 mmol) using complex **7** as catalyst and HCOONa as hydrogen donor in water (5 mL), at pH = 9, for 2 h, the catalyst/substrate/formate ratio being 1:100:500.

The kinetic plot (Figure 6) shows that under these conditions the reaction is almost complete after 3 h. The turnover frequency calculated in this case, using the best catalyst precursor **7**, is 43 h^{-1}, comparable to those found for the TsDPEN catalysts.[11–14]

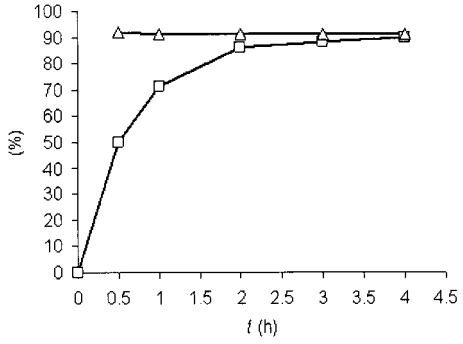

Figure 6. Time dependence of conversion (□) and enantiomeric excess (Δ) for transfer hydrogenation of acetophenone (1 mmol) using complex **7** as catalyst and HCOONa as hydrogen donor in water (5 mL), at 60 °C, pH = 9, the catalyst/substrate/formate ratio being 1:100:500.

The catalytic activity and selectivity of complex **7** have also been determined for the transfer hydrogenation reaction of *para*-substituted acetophenone under the same catalytic conditions (Table 2).

Table 2. Enantioselective catalytic transfer hydrogenation of *para*-substituted acetophenone using complex **7** as catalyst and HCOONa as a hydrogen donor in water.[a]

Substituent	Conversion % (h)	*ee* %	TOF [h^{-1}][d]
CF_3	70 (2)[c]	90[c]	35
NO_2	57 (2)[c]	79[c]	28.5
Br	88 (2)[b]	90[b]	44
Me	84 (2)[b]	92[b]	42
OMe	65 (2)[c]	93[c]	32.5

[a] Conditions: reactions were carried out at 60 °C, at pH = 9, in 5 mL of water, acetophenone (1 mmol), the ratio catalyst/substrate/formate being 1:100:500. [b] The conversion and the enantiomeric excess were determined by chiral HPLC analysis. [c] The conversion and the enantiomeric excess were determined by chiral GC analysis. [d] TOF: turnover frequencies (mol of acetophenone converted to phenylethanol per mol of catalyst per hour) were taken at 50% conversion.

The catalytic system is rather tolerant with respect to the substrate. There is no substantial limitation by electronic effects of the substituents at the substrate molecule. Thus, the enantioselectivity varies only slightly from 79% (*para*-nitroacetophenone) to 93% (*para*-methoxyacetophenone) with dramatically varying electronic densities in the aromatic rings of the substrates. The variation of the catalytic activity from 28.5 h^{-1} (*para*-nitroacetophenone) to 44 h^{-1} (*para*-bromoacetophenone) is also not very pronounced.

Conclusions

In conclusion, we report here nine water-soluble chiral arene ruthenium complexes containing *trans*-1,2-diaminocyclohexane or derivatives thereof as chelating ligands. All these complexes were found to catalyse the enantioselective transfer hydrogenation of acetophenone to give 1-phenylethanol using sodium formate as a hydrogen source in aqueous solution. The best results were obtained for **7** at 60 °C, giving a turnover frequency of 43 h^{-1} and an enantiomeric excess of 93%. The corresponding aqua complex **9**, presumed to be the catalytic species, has been isolated and characterised as its tetrafluoroborate salt.

Experimental Section

General: All manipulations were carried out in an inert atmosphere using standard Schlenk techniques and freshly distilled solvents saturated with nitrogen prior to use. The starting dimer [(arene)Ru-$Cl_2]_2$[23,24] and the monotosylated diaminocyclohexane ($TsHN\cap NH_2$)[20] were prepared according to the published methods. All other reagents were commercially available and were used without further purification. NMR spectra were recorded on a Bruker 400 MHz spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate in D_2O as a ^{13}C locking agent. Electrospray mass spectra were obtained in the positive-ion mode with an LCQ Finnigan mass spectrometer. Microanalyses were carried out by the Laboratoire de Chimie Pharmaceutique, Université de Genève

(Switzerland). All chemical characterisations given below were found for both *R,R* and *S,S* enantiomers.

Preparation of the Enantiopure Chloro Complexes [(arene)-Ru($H_2N\cap NH_2$)Cl]$^+$ (arene = C_6H_6, *p*-MeC_6H_4iPr or C_6Me_6; $H_2N\cap NH_2$ = *trans*-1,2-diaminocyclohexane): Two equiv. (0.30 mmol) of the appropriate enantiomer of *trans*-1,2-diaminocyclohexane ($H_2N\cap NH_2$) were added to a suspension of [(arene)-$RuCl_2]_2$ (0.15 mmol) in dichloromethane (30 mL). The mixture was stirred for 4 h at room temperature, during this time the orange colour became darker. After evaporation to dryness, the residue was dissolved in water (20 mL). The solution was filtered, washed with diethyl ether (2× 10 mL), and the aqueous solution was evaporated to dryness giving the product in 75–85% yield.

[(C_6H_6)Ru($H_2N\cap NH_2$)Cl]Cl ([1]Cl): Yield 74%, 80.8 mg. ^{1}H NMR (400 MHz, D_2O, 21 °C): δ = 1.03 (m, CH_2), 1.18 (m, $^3J_{cis}$ = 3.96, $^3J_{trans}$ = 11.36 Hz, CH), 1.57 (m, CH_2), 1.83 (m, $^3J_{cis}$ = 3.72, $^3J_{trans}$ = 12.28 Hz, CH), 1.94 (m, CH_2), 5.78 (s, C_6H_6) ppm. ^{13}C NMR (200 MHz, D_2O, 21 °C): δ = 24.1 (CH_2), 24.3 (CH_2), 32.9 (CH_2), 34.4 (CH_2), 56.7 (CH), 61.0 (CH), 84.4 (C_6H_6) ppm. MS (ESI): *m*/*z* = 520 [M – Cl]$^+$. $C_{22}H_{30}ClN_2O_4RuS$ (555): calcd. C 47.60, H 5.45, N 5.05; found N 47.48, H 5.28, N 4.96.

Preparation of the Enantiopure Aqua Complex [(C_6Me_6)-Ru($H_2N\cap NH_2$)(OH_2)]$^{2+}$ (4) and [(C_6Me_6)Ru(TsN∩NH_2)(OH_2)]$^+$ (9) ($H_2N\cap NH_2$ = *trans*-1,2-diaminocyclohexane; TsHN∩NH_2 = *N*-tosyl-*trans*-1,2-diaminocyclohexane): To an aqueous solution of the appropriate chloro complex, [(arene)Ru($H_2N\cap NH_2$)Cl]$^+$ or [(arene)Ru(TsN∩NH_2)Cl], was added one equiv. of silver sulfate (0.30 mmol, 93.6 mg) in water (30 mL). After stirring for 1 h in the dark at room temperature the white precipitate (AgCl) was removed by filtration from the yellow solution. Solid $NaBF_4$ was added until saturation and a yellow precipitate appeared. The suspension was then centrifuged, the solid dissolved in dry acetonitrile (10 mL) and the resultant solution filtered through celite to eliminate the excess $NaBF_4$. After evaporation of the solvent, the tetrafluoroborate salt was obtained as a yellow-orange powder in quantitative yield.

[(C_6Me_6)Ru($H_2N\cap NH_2$)(OH_2)](BF_4)$_2$ ([4](BF_4)$_2$): Yield 98%, 167.6 mg. ^{1}H NMR (400 MHz, D_2O, 21 °C): δ = 1.09 (m, CH_2), 1.22 (m, CH), 1.63 (m, CH_2), 1.85 (m, CH), 1.89 (m, CH_2), 2.12 (s, $C_6(CH_3)_6$). ^{13}C NMR (200 MHz, D_2O, 21 °C): δ = 15.2 ($C_6(CH_3)_6$),

Single Crystal X-ray Structure Analyses: A yellow crystal of compound [*R*,*R*-**3**][Cl]·2$CHCl_3$, obtained from recrystallisation of [*R*,*R*-**3**][Cl] with chloroform by slow evaporation, was mounted on a Stoe Imaging Plate Diffractometer System (Stoe & Cie, 1995) equipped with a one-circle φ goniometer and a graphite-monochromator. Data collection was performed at –100 °C using Mo-K_α radiation (λ = 0.71073 Å). 133 exposures (6 min per exposure) were obtained at an image plate distance of 70 mm with $0 < \varphi < 198°$ and with the crystal oscillating through 1.5° in φ. The resolution was D_{min}–D_{max} 12.45–0.81 Å. This compound crystallised in a noncentrosymmetric orthorhombic cell [$P2_12_12_1$, Flack parameter x = 0.00(5)]. The molecular formula of this compound is {[RuCl($C_{12}H_{18}$)($C_6H_{14}N_2$)]Cl($CHCl_3$)$_2$}. The structure was solved by direct methods using the program SHELXS-97[25] and refined by full-matrix least-squares on F^2 with SHELXL-97.[26] The positions of the protons N2H3 and N2H4 were derived from difference Fourier maps and refined with the N–H distance constrained to the theoretical value, the remaining hydrogen atoms were included in calculated positions and treated as riding atoms using SHELXL-97 default parameters. All non-hydrogen atoms, were refined anisotropically. A semi-empirical absorption correction was applied using MULABS (PLATON03, $T_{min.}$ = 0.804, $T_{max.}$ = 0.839). Selected crystallographic data for the complex are summarised in Table 3.

A yellow crystal of compound [*S*,*S*-**4**][BF_4]$_2$·H_2O, obtained by recrystallisation of [*S*,*S*-**4**][BF_4]$_2$ from water, was mounted on a Stoe Mark II-Imaging Plate Diffractometer System (Stoe & Cie, 2002) equipped with a graphite monochromator. Data collection was performed at –100 °C using Mo-K_α radiation (λ = 0.71073 Å). 171 exposures (6 min per exposure) were obtained at an image plate distance of 135 mm, 171 frames with φ = 0° and $0 < \omega < 171°$, with the crystal oscillating through 1° in ω. The resolution was $D_{min.} - D_{max.}$ 17.78–0.72 Å. This compound crystallises in a noncentrosymmetric space group with an orthorhombic cell ($P2_12_12_1$). The absolute structure could not be defined [Flack parameter = 0.16(12)]. The molecular formula of this compound is {[Ru($C_{12}H_{18}$)($C_6H_{14}N_2$)(H_2O)](BF_4)$_2$.(H_2O)}. As a result of the high disorder found in the anions and solvent molecules, the SQUEEZE instruction in PLATON03[27] was used to calculate the remaining potential solvent accessible area in the unit cell; 602.1 Å^3 was calculated containing about 173 electrons. Therefore, one BF_4 (4×41 electrons) per asymmetric unit was included in all further calculations. The structure was solved by direct methods using the program SHELXS-97[25] and refined by full-matrix least-squares on F^2 with SHELXL-97.[26] The hydrogen atoms were included in calculated positions and treated as riding atoms using SHELXL-97 default parameters. All non-hydrogen atoms were refined anisotropically.

tropically. Selected crystallographic data for the complex are summarised in Table 4.

CCDC-273653 (for [**3**]Cl·2CHCl$_3$) and -273652 (for [**4**](BF$_4$)$_2$·H$_2$O) contain supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/data_request/cif, by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336033.

Transfer Hydrogenation Catalysis: The transfer hydrogenation reactions of acetophenone (1 mmol), using **1–9** as their chloride (**1–3** and **5–8**) or sulfate (**4** and **9**) salts (10 μmol) with HCOONa (5 mmol), were carried out in water (5 mL) in an inert atmosphere. The reactions were quenched by cooling the mixtures to 0 °C. The products were extracted with Et$_2$O, filtered through silica and identified (and conversion and enantiomeric excesses were determined) by HPLC on a Chiracel OB-H capillary column for acetophenone and its Br and Me *para*-substituted derivatives or by gas chromatography on a 6-*tert*-butyl-2,3-diethyl-β-cyclodextrin (30% in 5% phenyl polymer) capillary column for the CF_3, NO_2 and MeO *para*-substituted substrates. The pH was monitored using a pH meter (Mettler Toledo InLab® 413) and adjusted using HNO_3 (for pH = 4 to 9) or NaOH (for pH = 10).

Acknowledgments

Financial support of this work from the Swiss National Science Foundation and a generous loan of ruthenium(III) chloride hydrate from the Johnson Matthey Research Centre are gratefully acknowledged.

Synthesis and Binding Properties of Dendritic Oxybathophenanthroline Ligands towards Copper(II)

Holger Stephan,*[a] Gerhard Geipel,[b] Gert Bernhard,[b] Peter Comba,[c] Gopalan Rajaraman,[c] Uwe Hahn,[d] and Fritz Vögtle*[d]

Keywords: Dendrimers / Phenanthroline / Copper(II) / Solvent extraction / Laser fluorescence spectroscopy

Dendritic oxybathophenanthroline ligands (generation 0 to 3) have been synthesized by treatment of 4,7-bis(4′-hydroxyphenyl)-1,10-phenanthroline with the corresponding Fréchet-type dendrons carrying a benzylic bromide function at the focal point. The complexation of copper(II) has been studied by liquid–liquid extraction using the radioisotope ^{64}Cu and time-resolved laser-induced fluorescence spectroscopy (TRLFS) in organic media indicating the formation of 1:3 complexes (Cu:dendritic ligand). Electronic and EPR spectroscopy were used to characterize the copper(II) chromophore, which is shown to have the expected distorted square-planar geometry with two phenanthroline donors coordinated to the copper(II) center. The third dendritic ligand therefore is proposed to be bound by secondary interactions. The stability constants of the 1:3 complexes were found to be in the order of log $K \approx 16$ in $CHCl_3$. On the other hand, increasing generation of the dendritic Fréchet-type branches leads to enhanced shielding of the copper ion from the environment. Additional information about this behaviour was obtained by the fluorescence lifetimes, which are much less influenced upon addition of copper(II) salt to solutions of the higher generation ligands.

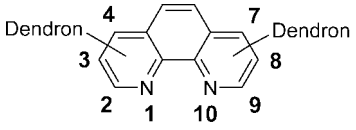
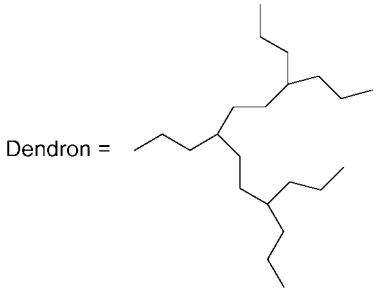
Introduction

Derivatives of 1,10-phenanthroline and their metal complexes are of considerable interest in bioinorganic chemistry, biology and medicine.[1] Oxidative substitutions of 1,10-phenanthroline give versatile 5,6-disubstituted intermediates for the introduction of less bulky groups into the chelating unit. Such 5,6-substituted phenanthrolines play an important role as hydrophobic DNA intercalators (dipyridophenazine[2]), and most representatives of chromophore-containing derivatives base on this substitution pattern.[3] Also, metallodendrimers consisting of ruthenium(II) complexes with bisphenanthroline ligands bridged in the 5,6-positions have been described as robust, structurally rigid and well-defined nanoscopic complexes.[4] Dendritic modifications gain in importance as they open the way for tailoring nano dimension, solubility or complexation behaviour (complex stability, kinetics of formation) in manifold directions.[5] Due to steric reasons, the attachment of highly branched units particularly in the 4,7- and 3,8-positions of the 1,10-phenanthroline core seems to be suited in this respect (Scheme 1). In addition Fréchet-type dendrons being attached adjacent to the metal coordination centre (2,9-positions) have also been presented.[6]





Scheme 1. Suitable positions for dendritic modification of 1,10-phenanthroline.

Ruthenium(II) complexes containing 4,7-bis(benzyloxy)-1,10-phenanthroline units[7] and also dendritic rutheni-

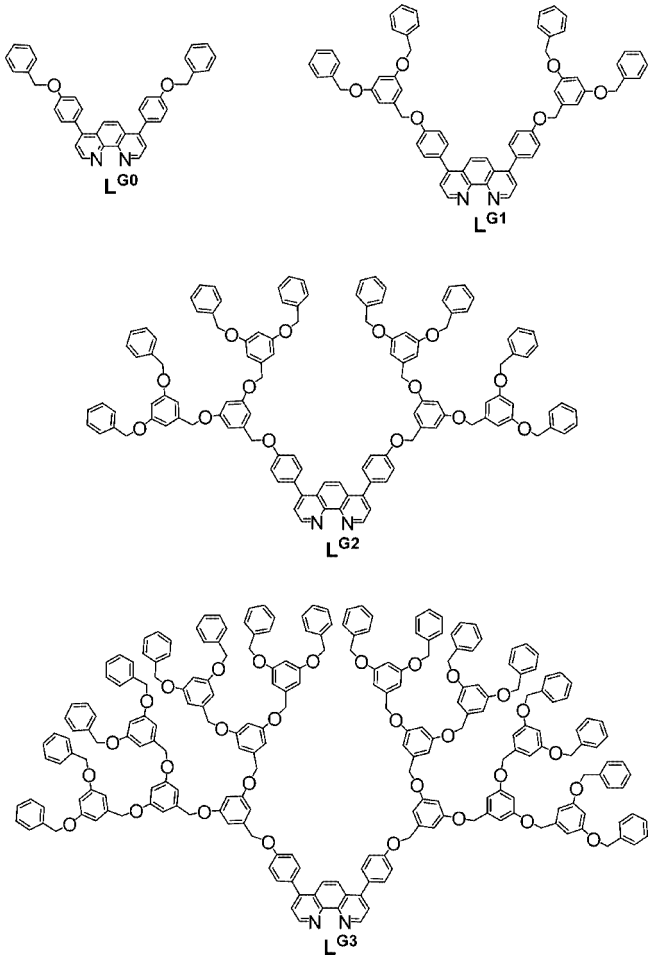
um(II) complexes bearing bis-substituted 2,2′-bipyridine moieties have been reported to exhibit interesting luminescence and redox properties.[8] Ruthenium(II) dendrimers containing carbazole-based chromophores as branches in the 4,7-positions of phenanthroline exhibit significant absorption and luminescence characteristics.[9] Complexation of appropriate metals with phenanthroline ligands carrying branched units in the 3,8-positions induces the formation of supramolecular self-assemblies with tuneable coordination geometry.[10] In this respect, we are interested to characterize the self-assembly system involving novel dendritic compounds and copper(II). Here, we report the synthesis of 1,10-phenanthroline ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$ with attached Fréchet-type dendrons (generation 0 to 3) in the 4,7-positions (Scheme 2). The complexation behaviour of these hydrophobic dendritic oxybathophenanthroline derivatives towards Cu^{II} has been studied by liquid-liquid extraction experiments, time-resolved laser-induced fluorescence spectroscopy and electronic as well as EPR spectroscopy.

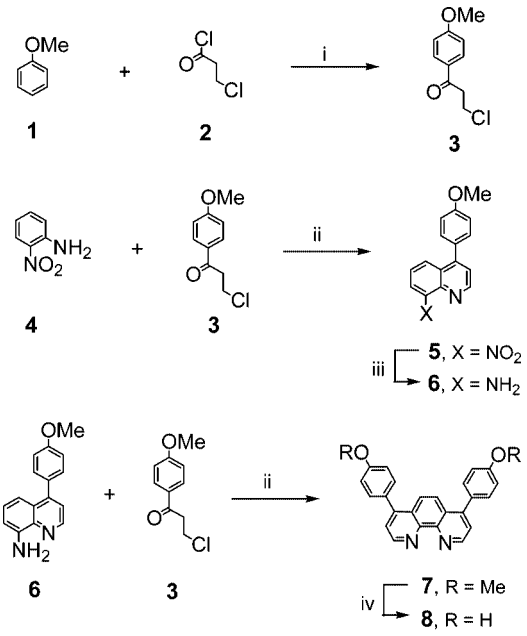


Scheme 2. Constitutions of the investigated dendritic OBP ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$.

Results and Discussion

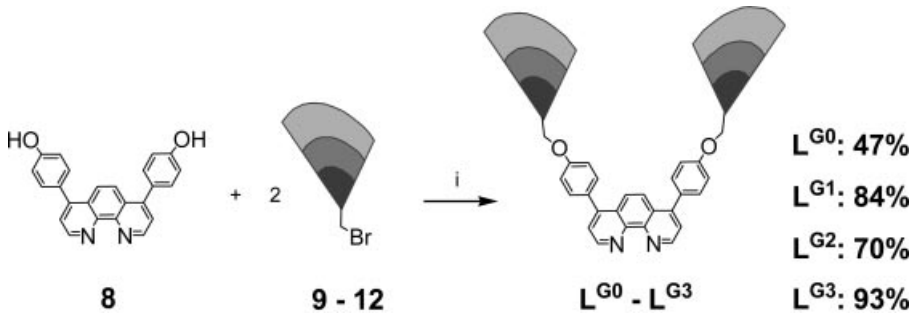
Syntheses

The parent phenanthroline ligand **8** with two *p*-hydroxyphenyl groups in the positions 4 and 7 was synthesized in a multi-step sequence (Scheme 3).[11] The β-chloro ketone **3** was prepared by a Friedel–Crafts acylation of 3-chloropropionyl chloride (**2**) and anisole (**1**) in dry 1,2-dichloroethane at 0 °C in the presence of anhydrous aluminum chloride to yield a colourless solid. The reaction of the β-chloro ketone **3** with *o*-nitroaniline (**4**) under the conditions of the Yale modification of the Skraup quinoline synthesis, gave the 4-substituted 8-nitroquinoline **5** as a yellow solid. The nitro group was subsequently reduced with tin(II) chloride dihydrate in dry ethanol under reflux conditions to form the 4-(4′-methoxyphenyl)-8-aminoquinoline **6** as a yellow solid. The 4,7-disubstituted 1,10-phenanthroline **7** was obtained by a second Skraup reaction of aminoquinoline **6** and β-chloro ketone **3** using again the conditions of the Yale modification. Demethylation of the bisanisyl-1,10-phenanthroline (**7**) was performed in dry dichloromethane at –20 °C by treatment with boron tribromide to yield the phenanthroline building block **8** carrying two hydroxy functions to which the various dendritic wedges could be attached.[12]



Scheme 3. Preparation of the 4,7-bis(*p*-hydroxyphenyl)-1,10-phenanthroline (**8**); (i) 0 °C, 3 h, 1,2-dichloroethane; (ii) addition of **3** at 100–120 °C, aq. As_2O_5 (80%), concd. H_3PO_4, 140 °C, 1 h, (iii) $SnCl_2{\cdot}2H_2O$, reflux, 4 h, EtOH, (iv) addition of BBr_3 at –20 °C, 2 h, room temp., CH_2Cl_2.

The dendritic oxybathophenanthroline (OBP) ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$ were synthesized according to Scheme 4. Thus, 1 equiv. of 4,7-bis(4′-hydroxyphenyl)-1,10-phenanthroline (**8**) was dissolved in DMF and deprotonated by treatment with sodium hydride. Addition of 2 equiv. of benzyl bromide (**9**) or the corresponding dendritic benzyl bromides[13] **10**–**12** followed by purification on silica gel gave the products in medium to high yields as colourless solids in the case of the benzyl derivative, or as viscous oils for the higher generations. The medium yield for the benzyl-substituted derivative $\mathbf{L^{G0}}$ may be explained by the formation of a *N*,*O*-



Scheme 4. Schematic representation for the preparation of the dendritic oxybathophenanthroline (OBP) ligands; (i) NaH (60% in paraffin), room temp., 1 d, DMF.

dibenzyl derivative, in which one nitrogen of the phenanthroline unit is substituted by a benzylic moiety.[14] Due to the small size of benzyl bromide such a cyclohexa-2,5-dienone derivative can be formed in higher quantities. But for the dendritic generations with an increased steric demand this side reaction seems to be less favoured and leads therefore to higher yields. Additionally, the purification of $\mathbf{L^{G0}}$ on silica gel was more difficult as a result of the higher polarity of the phenanthroline unit. Substitution of the phenanthroline building block **8** with dendritic units of a various size leads to an increased lipophilicity of the ligands and thus to easier purification by column chromatography. The structures of all new oxybathophenanthroline ligands could be readily deduced from ^1H and ^{13}C NMR spectra as well as from mass spectrometric analysis.

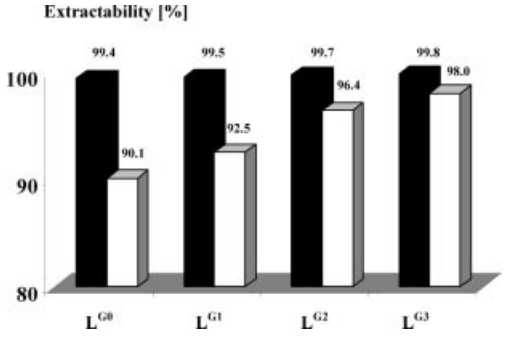


Figure 1. Extractability of copper(II) by dendritic OBP ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$; black bars $c_{Cu(NO_3)_2} = 1\times10^{-4}$ M, $c_{HPic} = 5\times10^{-3}$ M, pH = 5.3 (MES/NaOH); white bars $c_{Cu(NO_3)_2} = 1\times10^{-4}$ M, pH = 5.3 (MES/NaOH); $c_{\text{dendritic ligand}} = 1\times10^{-3}$ M in $CHCl_3$, time = 30 minutes.

Liquid–Liquid Extraction

1,10-Phenanthroline is known to form strong complexes with copper(II). Depending on the experimental conditions, the resulting complexes may have 1:1, 1:2 or 1:3 stoichiometry (metal/ligand), and show different coordination geometries.[15] Due to the Jahn–Teller lability 1:3 stoichiometry (pseudo-octahedral coordination geometry) is unlikely with the rigid phenanthroline-type chelates. By virtue of the high lipophilicity of the dendritic oxybathophenanthrolines, liquid–liquid extraction experiments have been chosen to characterise the binding properties of the OBP ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$ towards Cu^{II} in the aqueous-organic system $Cu(NO_3)_2$/buffer/H_2O/dendritic ligand/$CHCl_3$. Precise data of the efficiency of complex formation and the stoichiometry of the copper(II) complexes with the ligands investigated were obtained using the radiotracer technique with ^{64}Cu as radioisotope.[16] First extraction experiments have been performed in the presence of the lipophilic picrate anion (Figure 1). In this case the extractability of Cu^{II} is almost quantitative for all ligands. But also in the absence of the picrate anion, Cu^{II} is very efficiently extracted into the organic phase. Here, a dendritic effect is clearly visible caused most likely by the increasing lipophilicity of the complexes formed.

Interestingly, a rapid attainment of extraction equilibrium (within few minutes) was observed. Even in the case of the most bulky ligand $\mathbf{L^{G3}}$ the equilibrium was attained after 10 minutes.[17] As expected, the Cu^{II} extraction is enhanced with increasing pH accompanied by decreasing protonation of the chelating moiety.[18] Information about the overall stoichiometry of the complexation was obtained by measuring the distribution ratio D_{Cu}[19] as a function of the ligand concentration in the organic solvent (Figure 2).

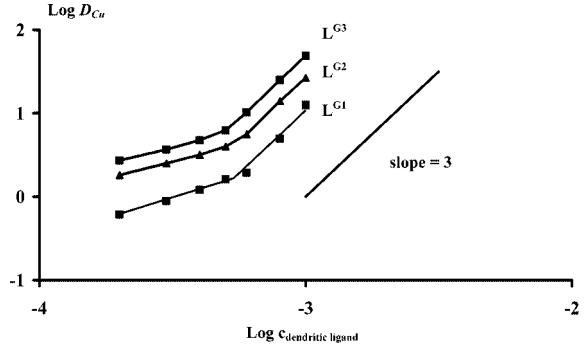

Figure 2. Variation of log D_{Cu} with ligand concentration for the extraction of copper(II) with dendritic OBP ligands $\mathbf{L^{G1}}$–$\mathbf{L^{G3}}$; $c_{Cu(NO_3)_2} = 1\times10^{-4}$ M, pH = 5.3 (MES/NaOH), time = 30 minutes, $c_{\text{dendritic ligand}} = 2\times10^{-4}$ M to 1×10^{-3} M in $CHCl_3$.

Surprisingly, in all cases, the slopes of the lines in the log D_{Cu}/logc_{ligand} plots were 3 if the ligand excess is high enough compared to the copper concentration. This finding indicates the formation of 1:3 complexes (Cu^{II}: dendritic ligand).[20] However, this is not an indication for three phenanthroline donors, coordinated to the copper(II) centers (see below).[21]

Luminescence Characteristics

The fluorescence properties of the ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$ are summarized in Table 1. The time-resolved fluorescence spectrum of $\mathbf{L^{G0}}$ is shown in Figure 3 as an example.

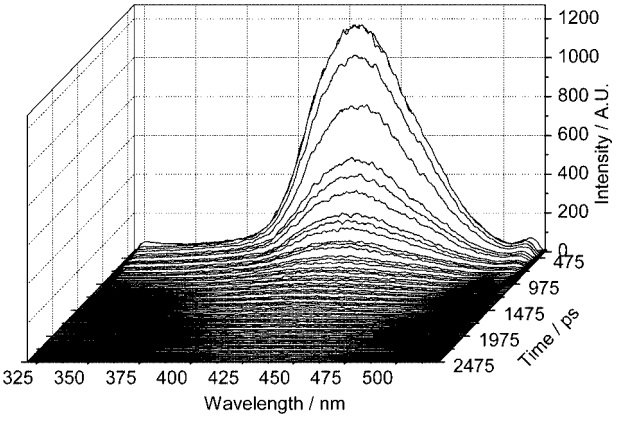

Figure 3. Time-resolved fluorescence spectrum of the dendritic OBP ligand $\mathbf{L^{G0}}$, $c_{dendritic\ ligand} = 1 \times 10^{-5}$ M in $CHCl_3$.

For all four ligands a two-exponential fluorescence decay behaviour was observed in the absence of Cu^{II}. The component with the shorter fluorescence decay time shows the higher fluorescence intensity. The maximum of this fluorescence emission is located at ca. 430 nm. The fluorescence maximum for the second emitting component was found at ca. 420 nm. Additionally the fluorescence decay time of this component depends on the size of the dendritic wedges. Going to higher generations the fluorescence decay times decrease. This may be due to an increasing number of deactivation channels.

Addition of copper(II) to the solution of the ligands leads to a decrease in fluorescence intensity (static fluorescence quenching). As expected, the complexes formed do not show any fluorescence. The fluorescence with the shorter fluorescence lifetime was mainly influenced by the formation of the complexes (see Table 1 in the Supporting Information; for details see the footnote on the first page of this article). At Cu^{II}/ligand ratios of 1:3 the fluorescence of the 430 nm component disappears. This behaviour is in agreement with the results of the liquid–liquid extraction (1:3 complexes). The ligand $\mathbf{L^{G2}}$ shows a somewhat different behaviour. Here, the fluorescence disappears at a 1:2 ratio of Cu^{II} to ligand. In a separate measurement with a metal to ligand ratio of 1:3 only a monoexponential fluorescence decay with the longer fluorescence lifetime was observed. This is strong evidence that also a 1:3 adduct is formed.

In addition the fluorescence intensities were used to confirm complex formation. Due to the observation that mainly the fluorescence intensity of the component with the shorter fluorescence lifetime is influenced by the complex formation these data were evaluated for the stability of the complexes. The species concentration can be calculated from the fluorescence intensities of the free ligand. The resulting stability constants are summarized in Table 2.

Table 2. Stability constants of the formed Cu^{II} complexes.

Ligand	Metal	Stoichiometry	log K	Solvent
$\mathbf{L^{G0}}$	Cu^{II}	3:1	16.4 ± 0.8	$CHCl_3$
$\mathbf{L^{G1}}$	Cu^{II}	3:1	17.5 ± 0.9	$CHCl_3$
$\mathbf{L^{G2}}$	Cu^{II}	3:1	15.6 ± 0.7	$CHCl_3$
$\mathbf{L^{G3}}$	Cu^{II}	3:1	16.6 ± 0.7	$CHCl_3$

It was found that the fluorescence decay times of the longer decay component decrease with increasing size of the dendritic branches if no copper(II) is added. The addition of copper(II) influences the fluorescence lifetime (Supporting Information, Table 2). However, this effect decreases with increasing size of the dendritic wedge. The longer fluorescence lifetime as function of the cooper(II) concentration shows no clear behaviour. For the ligand $\mathbf{L^{G0}}$ a clear dynamic quench effect was observed, which is much less remarkable for the ligand $\mathbf{L^{G1}}$. The ligand $\mathbf{L^{G2}}$ shows an increase of the fluorescence lifetime. For the ligand $\mathbf{L^{G3}}$ addition of copper(II) resulted in much less influence. However, also intermediate deviations from this trend were observed. A profound explanation of this behaviour is not possible at this time. The fluorescence lifetime of the second component with the shorter lifetime is also influenced by the addition of Cu^{II}. This behaviour can be explained by a less pronounced dynamic quenching effect of the Cu^{II} or in reverse, that the increasing generation of the dendritic structure leads to an increased shielding effect on the deexcitation channels of the copper(II).

Geometry of the Copper(II) Chromophores

Due to the Jahn–Teller lability of the d^9 copper(II) ions the formation of stable $[Cu(L)_3]^{2+}$ complexes, where L is a

Table 1. Fluorescence properties of the dendritic OBP ligands.

Ligand	Center of gravity (1) nm	Fluorescence decay time (1) ps	Center of gravity (2) nm	Fluorescence decay time (2) s	Intensity ratio (1)/(2)	Intensity relative to L^0
$\mathbf{L^{G0}}$	430.1	160 ± 2	423.7	1860 ± 10	22.6	1
$\mathbf{L^{G1}}$	430.3	270 ± 2	417.0	1080 ± 10	3.3	1.45
$\mathbf{L^{G2}}$	431.8	240 ± 2	419.9	990 ± 10	3.6	1.57

bidentate ligand, is not likely, specifically with L = 1,10-phenanthroline derivatives. One would rather expect the stabilization of a distorted square planar (tetragonally distorted octahedral or square pyramidal) chromophore derived from $[Cu(L)_2(X)_n]^{2+}$, where X may be OH_2 and n = 0, 1, 2. The third dendritic phenanthroline ligand found in the extraction and luminescence experiments may then be bound by secondary interactions (outer sphere coordination) to the distorted square-planar complex. The type of chromophore was analyzed by electronic and EPR spectroscopy and supported by molecular mechanics modeling.

Solutions for the UV/Vis-NIR and EPR spectra ($\mathbf{L^{G0}}$ and $\mathbf{L^{G3}}$) were prepared as those for the liquid–liquid extractions ($[Cu(trif)_2]^{2+}$, H_2O/L, $CHCl_3$; $[Cu^{2+}] \approx 1.0$ mM, $[Cu^{2+}]$:[L] = 1:3). The electronic spectra (Supporting Information) show two broad transitions centered at approx. 708 nm and 925 nm for $\mathbf{L^{G0}}$, and 734 nm and 925 nm for $\mathbf{L^{G3}}$, respectively. The lower energy band is due to the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition and was not well resolved in our spectra (relatively low concentration), the feature at higher energy is due to transitions from d_{xy}, d_{xz}, d_{yz} and therefore is, as expected, very broad. While $[Cu(phen)_3]^{2+}$ (phen = 1,10-phenanthroline) was reported to have transitions at 680 nm and 1250 nm,[22] $[Cu(phen)_2(OH_2)_n]^{2+}$ (n = 0, 1, 2) has transitions at 750–800 nm and ca. 980 nm.[22,23] Addition of up to 3 equiv. of phen did not change the spectroscopic parameters. The assignment of these transitions to CuN_4O_n (n = 0, 1, 2) chromophores is supported by EPR spectra (identical solutions, T = 100 K). The analysis of the spin Hamiltonian parameters (g_x = 2.06, g_y = 2.08, g_z = 2.22, $A_x = A_y$ = 45 G, A_z = 128 G) supports this conclusion (experimental and simulated spectra are given in the Supporting Information): the major features are similar to those reported for the EPR spectra of distorted square planar $[Cu(phen)_2]^{2+}$-type chromophores,[24] the minor features are similar to those of $[Cu(phen)_2(OH_2)](NO_3)_2$ (g_x = 2.02, g_y = 2.13, g_z = 2.23).[25]

The conclusion that the extracted copper(II) species are $[Cu(L)_2(OH_2)_n]^{2+}\cdot L$ is supported by strain energy minimized structures, using the MOMEC program[26] and force field[27] (for structural data and plots of the optimized structures see Supporting Information). The optimized structures ($[Cu(L)_2(OH_2)_2]^{2+}$) have Cu–N distances (ca. 1.97 Å) and tetrahedral distortions of the CuN_4 chromophores (ca. 42°) which are very similar to those of reported $[Cu(phen)_2(OH_2)_n]^{2+}$-type structures.[28]

Conclusions

An efficient synthetic strategy has been developed for the preparation of new dendritic ligands consisting of a 1,10-phenanthroline core unit to which hydrophobic polybenzyl ether dendrons are attached in the 4,7-positions. These oxybathophenanthroline ligands rapidly form very stable 1:3 adducts in organic media with Cu^{II}. Electronic and EPR spectroscopy suggest that two of the ligands are coordinated to copper(II) by the phenanthroline donors, the third ligand probably is bound by secondary interactions. The dendritic ligands are capable to extract Cu^{II} with high efficiency. For extraction experiments a dendritic effect was found most likely caused by the increasing lipophilicity when going to higher generations. As obtained by titration experiments using TRLFS, the dendritic ligands $\mathbf{L^{G0}}$–$\mathbf{L^{G3}}$ form strong 1:3 adducts with copper(II) in $CHCl_3$ ($\log K \approx$ 16). Studies of the fluorescence lifetimes show an increased shielding effect with increasing generation of the dendritic wedge attached to the phenanthroline unit. The results obtained for the copper(II) complexation with hydrophobic dendritic phenanthroline ligands have encouraged us to develop water-soluble analogues having targeting units at the periphery in view of binding and selective transport of the diagnostically and therapeutically relevant radioisotopes ^{64}Cu and ^{67}Cu.

Experimental Section

General Remarks: All starting materials were purchased from commercial sources and used without further purification. The dendritic bromides[13] **9**–**12** and the 4,7-(bisanisyl)phenanthroline[11] (**7**) have been prepared according to literature. The solvents were dried using standard techniques. Reactions were monitored by thin-layer chromatography using TLC plates pre-coated with silica gel $60F_{254}$ (Merck) and compounds detected by UV light (254 nm). Column chromatography was carried out using silica gel (Merck 15101). Melting points were determined with a Reichert Thermovar microscope and were not corrected. ^1H and ^{13}C NMR spectra were recorded using Avance 300 and AM 400 MHz Bruker instruments; the solvent signal was used for internal calibration. Mass spectra were recorded using a MS-50 from A.E.I., Manchester, GB (EI), a Concept 1H from Kratos Analytical Ltd., Manchester, GB (FAB), or a MALDI-TofSpec-E from MICROMASS, GB (MALDI). Electronic spectra were recorded with a JASCOV-570 UV/Vis-NIR spectrophotometer and EPR spectra were obtained from a Bruker ELEXSYS-E-500 instrument (X-band); spin-Hamiltonian parameters were obtained by simulation of the spectra with XSophe (version 1.1.4).[29]

3-Chloro-1-(4′-methoxyphenyl)propan-1-one (3): To a suspension of powdered aluminum chloride (7.23 g, 54.2 mmol) in dry 1,2-dichloroethane (40 mL) were added slowly 3-chloropropionyl chloride (**2**) (4.55 mL, 47.4 mmol) at 0 °C and anisole (**1**) (4.91 mL, 45.2 mmol) under cooling with water. The orange solution was stirred at room temp. for 3 h and left standing for about 12 h. The dark orange solution was poured onto ice (50 g), the organic phase separated and the aqueous phase extracted two times with CH_2Cl_2. The collected organic phases were washed with water, several times with aqueous NaOH (2%, 50 mL) until the organic phase did not turn back to yellow, and then twice with water. The organic phase was dried with $MgSO_4$ and the solvent removed under reduced pressure. Purification by gradient column chromatography [SiO_2, CH_2Cl_2/petroleum ether (40/60), 20:1 to CH_2Cl_2] gave 9.23 g (97% yield) of a colourless solid. R_f = 0.68 (CH_2Cl_2); m.p. 63–64 °C. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.29 (t, J = 7 Hz, 2 H, CH_2Cl), 3.75 (s, 3 H, OCH_3), 3.80 (t, J = 7 Hz, 2 H, $COCH_2$), 6.82 (AA′ part of the AA′BB′ system, 2 H, H_{ar}), 7.82 (BB′ part of the AA′BB′ system, 2 H, H_{ar}) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 39.0, 40.9, 55.5, 113.9, 129.6, 130.4, 163.9, 195.2 ppm. MS (EI, 70 eV): m/z (%) = 198 (12) [$M^{+\cdot}$].

4-(4′-Methoxyphenyl)-8-nitroquinoline (5): To a solution of *o*-nitroaniline (**4**) (1.38 g, 10.0 mmol), aq. As_2O_5 (3.37 g, 80%) and concd. H_3PO_4 (9 mL) was added portionwise β-chloro ketone **3** (2.48 g, 12.5 mmol) at 100 °C in 10 min so that the temperature is not rising above 120 °C. The solution was stirred at 120 °C for 5 min and then heated to 140 °C for 1 h. The deep red solution was cooled to room temp., poured onto CH_2Cl_2 (150 mL) and water (100 mL), and neutralized with aq. KOH (30%). The aqueous phase was extracted several times with CH_2Cl_2, the collected organic phase dried with $MgSO_4$, and the solvent removed under reduced pressure. Column chromatography (SiO_2, CH_2Cl_2) gave 1.56 g (56%) of a yellow coloured solid. R_f = 0.40 (CH_2Cl_2); m.p. 134–135 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.95 (s, 3 H, CH_3), 7.09 (AA′ part of the AA′BB′ system, 2 H, H_{ar}), 7.41 (BB′ part of the AA′BB′ system, 2 H, H_{ar}), 7.43 (d, J = 4 Hz, 1 H, H_{ar}), 7.55 (dd, J = 9, J = 8 Hz, 1 H, H_{ar}), 7.98 (dd, J = 8, J = 1 Hz, 1 H, H_{ar}), 8.17 (dd, J = 9, J = 1 Hz, 1 H, H_{ar}), 9.02 (d, J = 4 Hz, 1 H, H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 55.6, 114.5, 122.9, 123.4, 125.1, 128.1, 129.2, 130.2, 131.0, 140.2, 148.7, 149.0, 152.1, 160.5 ppm. MS (EI, 70 eV): *m*/*z* (%) = 280 (100) [$M^{+\cdot}$].

8-Amino-4-(4′-methoxyphenyl)quinoline (6): A solution of nitrochinoline **5** (1.15 g, 4.1 mmol) and tin(II) chloride dihydrate (2.78 g, 12.3 mmol) in dry ethanol (30 mL) was refluxed for 4 h. The solution was cooled to room temp. and made alkaline with concd. ethanolic NaOH. The precipitate was filtered off, and the solvent removed under reduced pressure. Purification by gradient column chromatography (SiO_2, CH_2Cl_2 to CH_2Cl_2/methanol, 30:1) gave 0.91 g (89%) of a yellow solid. R_f = 0.18 (CH_2Cl_2); m.p. 148–149 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.78 (s, 3 H, CH_3), 4.95 (br. s, 2 H, NH_2), 6.81 (dd, J = 6, J = 3 Hz, 1 H, H_{ar}), 6.93 (AA′ part of the AA′BB′ system, 2 H, H_{ar}), 7.16 (m, 3 H, H_{ar}), 7.24 (BB′ part of the AA′BB′ system, 2 H, H_{ar}), 8.62 (d, J = 4 Hz, 1 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 55.4, 109.9, 114.0, 114.2, 121.7, 127.2, 127.6, 130.8, 131.0, 138.9, 144.3, 147.0, 148.1, 159.8 ppm. MS (EI, 70 eV): *m*/*z* (%) = 250 (100) [$M^{+\cdot}$].

4,7-Bis(4′-methoxyphenyl)-1,10-phenanthroline (7): To a solution of the aminoquinoline **6** (1.43 g, 5.7 mmol), aq. As_2O_5 (1.61, 80%) and concd. H_3PO_4 (9 mL) was added portionwise the β-chloro ketone **3** (1.58 g, 7.1 mmol) at 100 °C in 10 min so that the temperature is not rising above 120 °C. The solution was stirred at 120 °C for 5 min and then heated to 140 °C for 1 h. The deep red reaction mixture was cooled to room temp., poured onto CH_2Cl_2 (150 mL) and water (100 mL) and neutralized with aqueous NaOH (20%). The aqueous phase was extracted several times with CH_2Cl_2, the collected organic phase dried with $MgSO_4$ and the solvent removed under reduced pressure. Column chromatography (SiO_2, CH_2Cl_2) yielded a brownish solid (1.50 g, 67%). R_f = 0.35 (CH_2Cl_2/MeOH, 5:1); m.p. 208–209 °C. ^{1}H NMR (400 MHz, 1:1 $CDCl_3$/CD_3OD, 25 °C): δ = 2.41 (s, 6 H, CH_3), 5.58 (AA′ part of the AA′BB′ system, 4 H, H_{ar}), 5.95 (BB′ part of the AA′BB′ system, 4 H, H_{ar}), 6.10 (d, J = 5 Hz, 2 H, H_{ar}), 6.40 (s, 2 H, H_{ar}), 7.62 (d, J = 5 Hz, 2 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 54.9, 114.0 123.6, 123.9, 126.5, 129.7, 130.8, 146.2, 148.6, 149.1, 160.1 ppm. MS (EI, 70 eV): *m*/*z* (%) = 392 (100) [$M^{+\cdot}$].

4,7-Bis(4′-hydroxyphenyl)-1,10-phenanthroline (8): To a solution of 4,7-bis(4′-methoxyphenyl)-1,10-phenanthroline (**7**) (6.77 g, 17.3 mmol) in dry dichloromethane (90 mL) was added dropwise boron tribromide (4.91 mL, 51.8 mmol) at –20 °C. The red suspension was stirred at room temp. for 2 h, poured onto ice and let stand still for 30 min. The solution was neutralized with aq. KOH (5%), the organic phase separated and the aqueous phase extracted several times with 10:1 CH_2Cl_2/MeOH. The collected organic phase was dried with $MgSO_4$ and the solvent removed under reduced pressure. The remaining solid was three times suspended in CH_2Cl_2 and filtered. The solid was dried to yield a yellow solid (3.20 g, 47%). M.p. 285–288 °C. ^{1}H NMR (400 MHz, [D_6]DMSO, 25 °C): δ = 6.98 (AA′ part of the AA′BB′ system, 4 H, H_{ar}), 7.41 (BB′ part of the AA′BB′ system, 4 H, H_{ar}), 7.65 (d, J = 5 Hz, 2 H, H_{ar}), 7.92 (s, 2 H, H_{ar}), 9.08 (d, J = 5 Hz, 2 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, [D_6]DMSO, 25 °C): δ = 116.1, 124.0, 124.3, 126.3, 128.0, 131.5, 145.9, 148.7, 149.5, 158.6 ppm. MS (EI, 70eV): *m*/*z* (%) = 392 (100) [$M^{+\cdot}$].

General Procedure for the Preparation of Dendritic OBP Ligands (L^{G0}–L^{G3}): To a suspension of 4,7-bis(4′-hydroxyphenyl)-1,10-phenanthroline (**8**) (0.1 mmol) in dry DMF (10 mL) was added NaH (0.22 mmol, 60% in paraffin). The reaction mixture turned to red. After 5 min a solution of the corresponding bromides[13] **9**–**12** (0.21 mmol) in dry DMF (5 mL) was added, and the suspension stirred for 1 d at room temp. The residual NaH was deactivated by slow addition of water at 0 °C. CH_2Cl_2 (30 mL) was added, the suspension neutralized with aq. HCl (2 N), and the aqueous phase extracted several times with CH_2Cl_2. The collected organic phase was washed with concd. aq. $NaHCO_3$, water, dried with $MgSO_4$ and the solvent removed under reduced pressure. The crude product was purified by column chromatography on silica gel.

4,7-Bis(4′-benzyloxyphenyl)-1,10-phenanthroline (L^{G0}): 4,7-Bis(4′-hydroxyphenyl)-1,10-phenanthroline (**8**) (100.0 mg, 0.27 mmol), benzyl bromide **9** (98.6 mg, 0.58 mmol), NaH (24.2 mg, 0.60 mmol, 60% in paraffin) in dry DMF (15 mL). Column chromatography (SiO_2, CH_2Cl_2/MeOH, 50:1 to 20:1) gave a colourless solid (69.8 mg, 47%). R_f = 0.42 (CH_2Cl_2/MeOH, 5:1); m.p. 230–231 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 5.12 (s, 4 H, OCH_2), 7.10 (AA′ part of the AA′BB′ system, 4 H, H_{ar}), 7.30–7.47 (m, 14 H, H_{ar}), 7.52 (d, J = 5 Hz, 2 H, H_{ar}), 7.85 (s, 2 H, H_{ar}), 9.16 (d, J = 5 Hz, 2 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 70.2, 115.1, 123.5, 124.0, 126.5, 127.5, 128.1, 128.7, 130.6, 131.0, 136.7, 147.0, 148.1, 149.7, 159.2 ppm. MS (FAB, NBA): *m*/*z* (%) = 545.2 ([M + H]$^+$, 100), 454.1 (12), 307.0 (18).

4,7-Bis{4′-[3′′,5′′-bis(benzyloxy)benzyloxy]phenyl}-1,10-phenanthroline (L^{G1}): 4,7-Bis(4′-hydroxyphenyl)-1,10-phenanthroline (**8**) (120.0 mg, 0.33 mmol), dendritic Fréchet-type G1 bromide **10** (256.1 mg, 0.69 mmol), NaH (29.0 mg, 0.73 mmol, 60% in paraffin) in dry DMF (15 mL). Column chromatography (SiO_2, CH_2Cl_2/MeOH, 50:1 to 20:1) gave a brownish viscous oil (269.5 mg, 84%). R_f = 0.55 (CH_2Cl_2/MeOH, 10:1). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 5.05 (s, 8 H, OCH_2), 5.08 (s, 4 H, OCH_2), 6.58 (t, J = 2 Hz, 2 H, H_{ar}), 6.72 (d, J = 2 Hz, 4 H, H_{ar}), 7.10 (AA′-part of the AA′BB′-system, 4 H, H_{ar}), 7.26–7.47 (m, 24 H, H_{ar}), 7.51 (d, J = 5 Hz, 2 H, H_{ar}), 7.90 (s, 2 H, H_{ar}), 9.18 (d, J = 5 Hz, 2 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 70.1, 70.2, 101.7, 106.5, 115.1, 123.5, 124.0, 126.5, 127.6, 128.6, 130.6, 131.0, 136.8, 139.3, 147.0, 148.1, 149.7, 159.1, 160.3 ppm. MS (FAB, NBA): *m*/*z* (%) = 969.5 ([M + H]$^+$, 60), 307.1 (100).

4,7-Bis(4′-{3′′,5′′-bis[3′′′,5′′′-bis(benzyloxy)benzyloxy]benzyl}-phenyl)-1,10-phenanthroline (L^{G2}): 4,7-Bis(4′-hydroxyphenyl)-1,10-phenanthroline (**8**) (70.0 mg, 0.19 mmol), dendritic Fréchet-type G2 bromide **11** (325.9 mg, 0.40 mmol), NaH (16.9 mg, 0.42 mmol, 60% in paraffin) in dry DMF (15 mL). Column chromatography (SiO_2, CH_2Cl_2/MeOH, 50:1 to 20:1) gave a brownish viscous oil (246.0 mg, 70%). R_f = 0.51 (CH_2Cl_2/MeOH, 10:1). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 4.86 (s, 8 H, OCH_2), 4.89 (s, 16 H, OCH_2), 4.96 (s, 4 H, OCH_2), 6.58 (t, J = 2 Hz, 6 H, H_{ar}), 6.57 (d, J = 2 Hz, 8 H, H_{ar}), 6.59 (d, J = 2 Hz, 4 H, H_{ar}), 7.00 (AA′ part of the AA′BB′ system, 4 H, H_{ar}), 7.17–7.28 (m, 40 H, H_{ar}), 7.12 (BB′

part of the AA′BB′ system, 4 H, H_{ar}), 7.40 (d, J = 5 Hz, 2 H, H_{ar}), 7.88 (s, 2 H, H_{ar}), 9.08 (d, J = 5 Hz, 2 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 70.0, 70.1, 70.2, 101.7, 101.7, 106.5, 106.6, 115.2, 123.6, 124.0, 126.5, 127.6, 128.1, 128.3, 128.6, 130.6, 131.1, 136.8, 136.9, 139.3, 139.4, 147.0, 148.1, 149.8, 159.1, 160.1, 160.2 ppm. MS (FAB, NBA): m/z (%) = 1818.6 ([M + H]$^+$, 17), 303.1 (100).

4,7-Bis[4′-(3′′,5′′-bis{3′′′,5′′′-bis[3′′′′,5′′′′-bis(benzyloxy)benzyloxy]benzyloxy}benzyl)phenyl]-1,10-phenanthroline (L^{3G}): 4,7-Bis(4′-hydroxyphenyl)-1,10-phenanthroline (**8**) (40.0 mg, 0.11 mmol), dendritic Fréchet-type G3 bromide **12** (381.9 mg, 0.23 mmol), NaH (9.7 mg, 0.24 mmol, 60% in paraffin) in dry DMF (15 mL). Column chromatography (SiO_2, CH_2Cl_2/MeOH, 50:1 to 20:1) gave a brownish viscous oil (360.0 mg, 93%). R_f = 0.55 (CH_2Cl_2/MeOH, 10:1). ^1H NMR (400 MHz, $CDCl_3$): δ = 4.86 (s, 16 H, OCH_2), 4.89 (s, 8 H, OCH_2), 4.92 (s, 32 H, OCH_2), 4.95 (s, 4 H, OCH_2), 6.49 (m, 12 H, H_{ar}), 6.61 (m, 26 H, H_{ar}), 6.65 (d, J = 2 Hz, 4 H, H_{ar}), 7.03 (AA′ part of the AA′BB′ system, 4 H, H_{ar}), 7.18–7.34 (m, 80 H, H_{ar}), 7.36 (BB′ part of the AA′BB′ system, 4 H, H_{ar}), 7.42 (d, J = 5 Hz, 2 H, H_{ar}), 7.84 (s, 2 H, H_{ar}), 9.11 (d, J = 5 Hz, 2 H, H_{ar}) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 70.0, 70.1, 70.2, 70.3, 101.6, 101.7, 101.8 106.5, 106.6, 106.8, 115.2, 123.6, 124.0, 126.5, 127.6, 128.0, 128.6, 130.6, 131.1, 136.9, 139.3, 139.4, 139.5, 147.0, 148.1, 149.8, 159.1, 160.1, 160.2, 160.3 ppm. MS (MALDI-TOF, DHB): m/z = 3515.9 (34) [M + H]$^+$, 1940.7 (24), 1621.5 (100).

Liquid–Liquid Extraction Procedure: Extraction studies were performed at 25 ± 1 °C in 2 cm^3 microcentrifuge tubes by mechanical shaking. The phase ratio $V_{(org)}$:$V_{(w)}$ was 1:1 (0.5 cm^3 each); the shaking period was 30 min. The extraction equilibrium was achieved during this period. All samples were centrifuged after extraction. The copper concentration in both phases was determined radiometrically using γ-radiation [^{64}Cu, NaI(Tl) scintillation counter Cobra II/Canberra Packard]. The aqueous solution was adjusted using 0.05 mol·dm^{-3} 2-[*N*-morpholino]ethanesulfonic acid (MES)/ NaOH (pH = 5.3–5.9).

Time-Resolved Laser-Induced Fluorescence Spectroscopy (TRLFS): Fluorescence measurements were carried out by use of a spectrometer system described elsewhere.[30] The ligands (L^{0G}–L^{3G}) were dissolved in $CHCl_3$. The total concentration of the ligand was $1 \cdot 10^{-5}$ mol·dm^{-3}. The fluorescence of solutions with increasing concentration of added Cu^{II} trifluoromethanesulfonate were measured. The ligand to Cu^{II} ratio was varied from 10:1 to 1:1. The fluorescence of the non-complexed ligand was excited by 130 fs laserpulses at 266 nm. The repetition rate of the laser system was 1 kHz. The emitted fluorescence was focussed into a 270 mm spectrograph (Acton Research) and the spectrum was measured by an intensified CCD (charged coupled device) camera (LaVision). The gate of the camera system was set to be 120 ps and the observed wavelength range was set from 350 nm to 510 nm. The range for time-resolved measurements was limited from 0 to 4000 ps with steps of 25 ps.

Acknowledgments

Financial support by the Saxon State Ministry of Science and Art (project 4–7531.50–03–0370–01/4) is acknowledged with thanks. We are grateful for advice by Dr. H.-J. Josel (Roche Diagnostics) during earlier studies on luminescent complexes.

Synthesis and Linear Optical Properties of Tris(catecholato)metal(III,IV) Complexes with Acceptor-Substituted Ligands

Volker Kriegisch[a] and Christoph Lambert*[a]

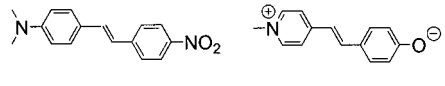
Dedicated to the memory of Prof. Dr. Rüdiger Wortmann (1959–2005)

Keywords: Nonlinear optics / Octupolar complexes / Chromophores / Donors / Acceptors / Catecholate

The synthesis of C_3-symmetric chromophores (**2**–**4**, **9**, **10**, **14**) with acceptor-substituted catecholato ligands and different central metal atoms (Si, Al, Ti) is described. These complexes might serve as octupolar chromophores with first-order nonlinear optical properties. UV/Vis spectroscopic investigations show a red-shift of the lowest-energy charge-transfer band on going from Si^{IV}, Al^{III} to Ti^{IV} complexes, dependent on the increasing ionic character of the M–O bond.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Over the past two decades, there has been considerable interest in the nonlinear optical (NLO) properties of organic and organometallic materials because of their potential application in various fields such as telecommunications, optical data storage and optical information processing. Many organic chromophores possess very high NLO efficiencies which derive from the high polarisability of electrons in unsaturated systems.[1–6] In one-dimensional NLO chromophores, in which a π-system is terminated by an electron acceptor and a donor, the electronic structure can be described by a mixture of a neutral valence-bond structure and a polar charge-separated mesomeric structure. The dipole moments of the ground and the first excited charge-transfer (CT) state depend on the degree of mixing. Those species, in which the neutral mesomeric structure constitutes the major part of the ground-state wave function, have a small ground-state dipole moment but a high dipole moment in the excited state. The prototype is 4-(dimethylamino)-4′-nitrostilbene (DANS).[3,4] Those systems, in which the dipolar mesomeric structure is the one which dominates the ground state, display zwitterionic character in the ground state but have a small dipole moment in the excited state. Brooker's dye is the prototype.[7,8]



DANS Brooker´s dye

While most NLO chromophores are one-dimensional and show, owing to the difference of the ground- and excited-state dipole moments, a strong solvatochromism, there are also D_3-symmetrical two-dimensional "octupolar" NLO chromophores which have the advantage that they do not show solvatochromism and, therefore, no loss of transparency in a polar environment. This is a consequence of the vanishing dipole moments in a D_3-symmetric chromophore.[9–11] Therefore, in recent years many investigations were devoted to this type of NLO chromophore.[2,12–16]

Although Brooker's dye shows exceptionally high quadratic NLO properties, its accurate investigation is hampered because of the sensitivity of the electronic structure to protonation or even because of hydrogen bonding of the phenolate oxygen atom.[17–23] Therefore, the goal of this investigation is to synthesise octupolar chromophores in which the phenolate part of a chromophore ligand is complexed by a metal ion in order to reduce its sensitivity to protic impurities. On the other hand, the metal ion serves as a template to organise three chromophores in a threefold symmetric arrangement. In order to gain thermodynamic stability, we used ligands based on catecholate rather than on phenolate as in Brooker's dye. The metal ions are Al^{III},[24] Ti^{IV},[25–27] and Si^{IV}[28,29] because these ions are known to form stable complexes with catecholate. The ions also form highly polar bonds to oxygen atoms, which will allow the catecholate to retain most of its anionic electronic structure, which is important in order to serve as a good electron donor in the ligand chromophores. The ligands used are given below. While **1** is derived from caffeic acid that has a carboxylic ester function as the electron acceptor, the ligands **8** and **13** have a nitro and a trimethylammonio group, respectively, as the acceptor functionalities. In the

forthcoming sections we describe the syntheses and the linear optical properties of some metal complexes derived from the above-mentioned ligands.

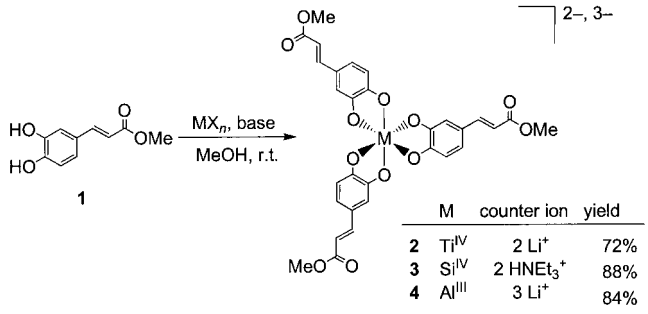
Results and Discussion

Synthesis and Characterisation

The synthesis of the (catecholato)M (M = metal) complexes **2**–**4** is illustrated in Scheme 1. The tris(catecholato)-Ti^{IV} complex **2** has been prepared in high yield using a procedure by Albrecht et al.[25,30]

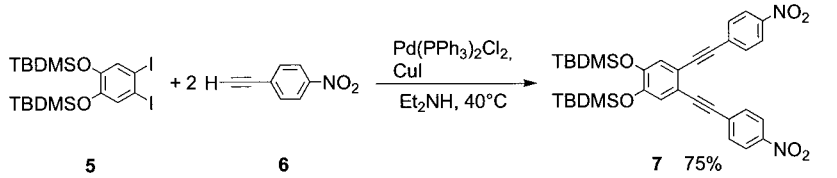


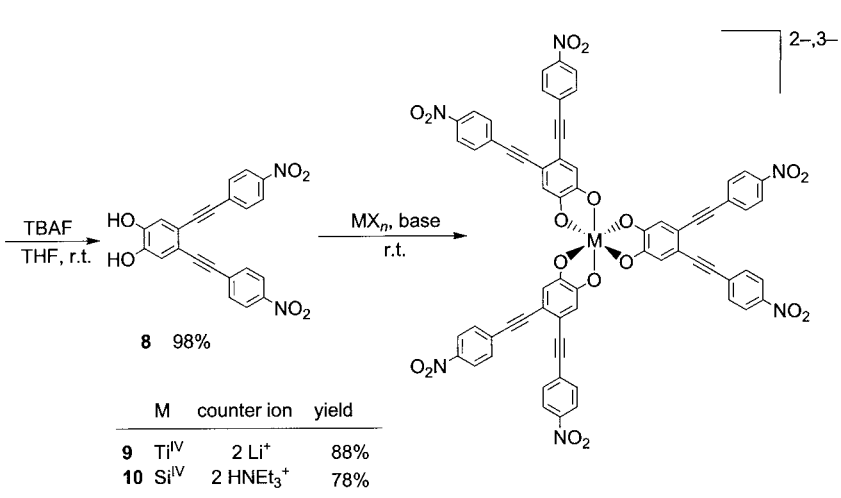
Scheme 1. Synthesis of octupolar (catecholato)M^{IV,III} complexes **2**–**4**.

To explore the preparation of tris(catecholato) complexes with different central atoms, **1** was used as an easily accessible ligand. In case of the Ti^{IV} and Al^{III} complexes Li_2CO_3 was used as the base. For the Si^{IV} complex **3** triethylamine was used as the base for the preparation. NMR and IR spectroscopic investigations confirm the formation of the complexes. An intense band occurs in the IR spectra at about 1200–1300 cm^{-1} which is typical of C–O stretching modes in catecholato–metal structures.[24,31] In the case of the unsymmetrical ligand **1** diastereomeric complexes form which we were unable to separate. These diastereomers are likely to show slightly different optical properties, which are not considered in the following text.

In order to avoid problems with diastomeric mixtures, 4,5-substituted catecholate systems were used to synthesise D_3-symmetrical complexes that will only consist of enantiomers.

The ligands **8** and **13** were prepared starting from the *tert*-butyldimethylsilyl-(TBDMS-)protected diiodo compound **5** which was synthesised according to Lulinski et al. and Kinder et al.[31,32] Using Hagihara coupling reaction conditions, compound **5** and 2 equiv. of **6** gave the 4,5-disubstituted ligand **7** in 75% yield. The reaction time has to be limited to 2 h because of the increasing formation of by-products with a prolonged reaction time. Deprotection of the TBDMS group led to the catechol ligand **8** in high yields (Scheme 2). The Ti^{IV} (**9**) and Si^{IV} complexes (**10**) were prepared in the same way as the caffeic acid complexes. Although the corresponding Al^{III} complex could be synthesised in an analogous manner, we were unable to purify this complex.





Scheme 2. Syntheses of the acceptor-substituted catechol ligand **8** and the corresponding octupolar Ti^{IV} (**9**) and Si^{IV} complexes (**10**).

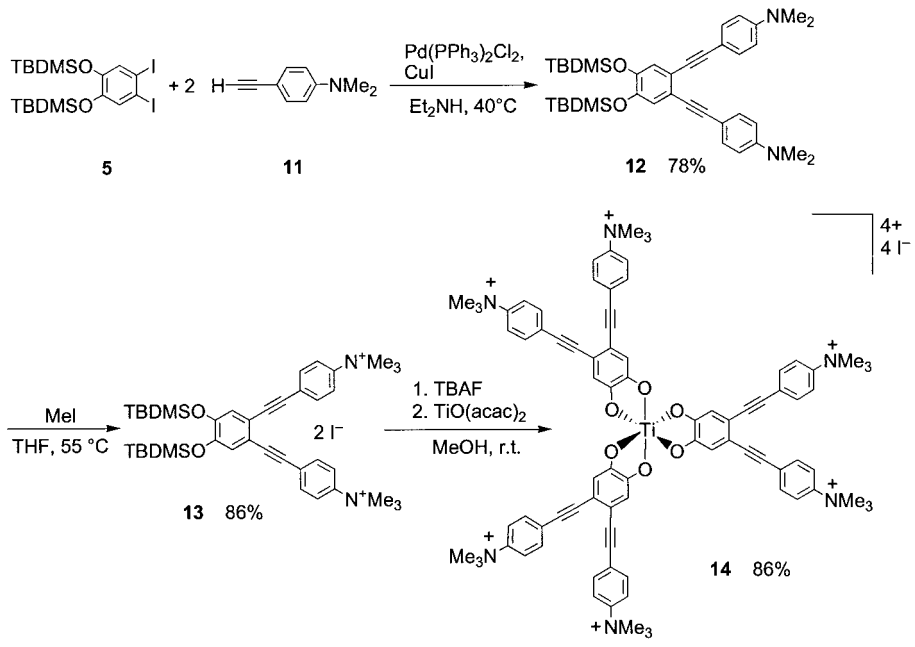

Scheme 3. Syntheses of the TBDMS-protected acceptor-substituted catechol ligand **13** and the corresponding octupolar Ti^{IV} complex **14**.

Ligand **13** was built up in the same way as alkyne **8**: the alkyne **11** was coupled with **5** in a palladium-catalysed reaction to give compound **12**. Subsequently, the amino groups of **12** were quaternised with methyl iodide. The Ti^{IV} complex **14** was prepared by in situ deprotection of **13** and reaction with $TiO(acac)_2$ (Scheme 3).

UV/Vis Absorption Spectra

Owing to the ionic character of all complexes, absorption spectra could only be recorded in relatively polar solvents. The UV/Vis spectra of the free ligand **1** show a concentration-dependent behaviour in DMSO. At high concentrations **1** has an absorption maximum at λ_{max} = 335 nm. Dilution leads to the formation of a new band at 425 nm, associated with an increase of this band (Figure 1).

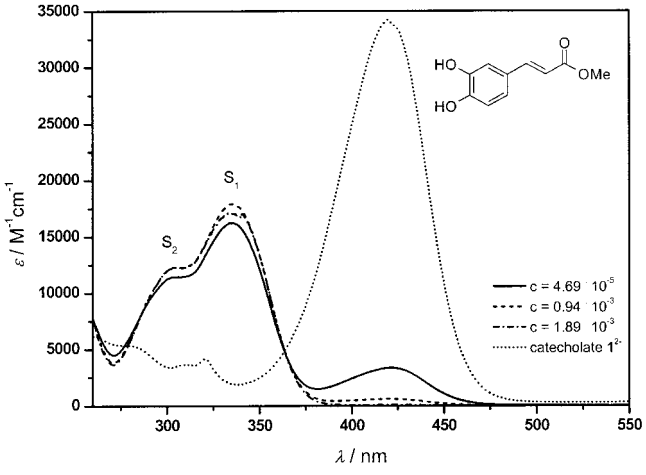

Figure 1. Concentration-dependent UV/Vis spectra of **1** and the catecholate $\mathbf{1}^{2-}$ in DMSO.

The reason for this behaviour is, as for ligand **8**, the concentration-dependent shift of the acid/base equilibrium to the deprotonated species and finally to the catecholate dianion $\mathbf{1}^{2-}$. Quantitative preparation of the catecholate dianion $\mathbf{1}^{2-}$ by adding sodium *tert*-butoxide to a solution of **1** results in a bathochromic shift and in the formation of an intense band at λ_{max} = 420 nm which corresponds to the one observed for **1** at high dilution. In contrast to **1** the UV/Vis spectra of the metal complexes **2**–**4** in DMSO, DMF and MeCN are concentration-independent. Comparison of the UV/Vis spectra of the tris(catecholato)M complexes of **1** in DMSO with that of $\mathbf{1}^{2-}$ shows a hypsochromic shift of the absorption maximum for M = Si^{IV} (**3**) (λ_{max} = 394 nm) over Al^{III} (**4**) (λ_{max} = 404 nm) to Ti^{IV} (**2**) (λ_{max} = 423 nm). The latter shows a maximum at about the same wavelength as the free ligand $\mathbf{1}^{2-}$ (Figure 2). This behaviour reflects the different degree of ionicity in the M–O bond increasing from Si^{IV}–O over Al^{III}–O to Ti^{IV}–O. The high ionicity of the M–O bond concentrates charge on the catecholate oxygen atoms, which become stronger donors the more ionic the bond is. This results in an intraligand CT absorption as observed in, for example, other tris(catecholato)Ti^{IV} complexes.[26] Interestingly, the band width of this CT band is much broader for **2** than for **3** and **4**. Whether this effect has to do with diastereomeric mixtures or is due to electronic effects is presently unclear.

While the spectra of **2**–**4** do not vary much in DMSO, DMF and MeCN, further studies of their possible solvatochromism were hampered by the insolubility in less polar solvents. In MeOH decomposition of **3** was observed and free ligand **1** was formed.

The complexes **9** and **10** show a similar behaviour of the absorption spectra as the complexes **2**–**4** (Figure 3). The spectra of both compounds **9** and **10** are shifted batho-

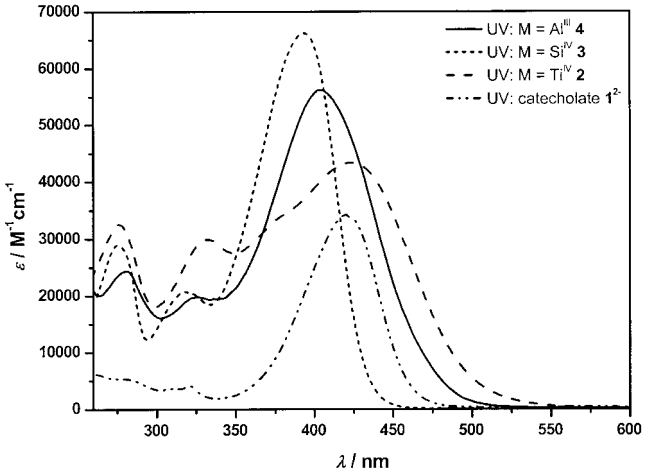

Figure 2. Absorption spectra of tris(catecholato)M complexes **2**–**4** and of catecholate $\mathbf{1}^{2-}$ in DMSO.

chromically vs. the free ligand **8**. Even here the increasing ionic character of the M^{IV}–O bonding is responsible for the red shift of the absorption maximum of the Si^{IV} compound **10** vs. the Ti^{IV} compound **9**. In DMSO the band maximum for **9** is at λ_{max} = 460 nm and for **10** at λ_{max} = 442 nm. Surprisingly, even the absorption maximum of the Ti^{IV} complex **9** does not reach that of the free deprotonated ligand $\mathbf{8}^{2-}$. This contrasts the behaviour of **2**. Neither the free ligand **8** nor the complexes themselves show fluorescence in DMSO, but their absorption is slightly solvatochromic (see Table 1). Ligand **8** shows, as for ligand **1**, a concentration-dependent deprotonation of the hydroxy groups to form the catecholate $\mathbf{8}^{2-}$. Although the Ti^{IV} complex **9** has a higher stability compared to the Si^{IV} species **10**, we observe ligand exchange in methanol.

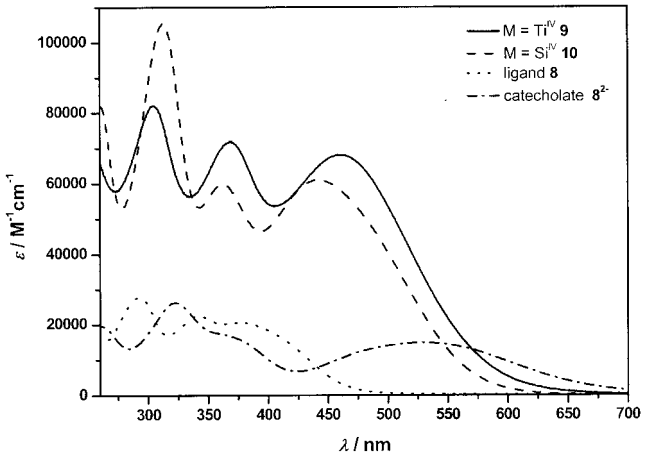

Figure 3. Absorption spectra of the tris(catecholato)M complexes **9**, **10** and the corresponding ligand **8** and catecholate $\mathbf{8}^{2-}$ in DMSO.

The UV/Vis spectrum of **14** in DMSO is similar to the spectrum of **9** but has a maximum at λ_{max} = 391 nm which is blue-shifted vs. **9** due to the R_3N^+ electron acceptor that is weaker than the NO_2 group in **9** (Figure 4).

Table 1. UV/Vis data {λ_{max} [nm] (ε [$M^{-1}cm^{-1}$])} of ligands **1**, **8**, **13**, the corresponding catecholates $\mathbf{1}^{2-}$, $\mathbf{8}^{2-}$ and tris(catecholato)$M^{III,IV}$ complexes **2**–**4**, **9**, **10**, **14**.

Conclusions

Although we could not measure the absorption spectra of the metal catecholates in solvents with strongly different polarity due to solubility/instability problems, the bathochromic shift of the lowest-energy transition for the ligands **1** and **8** on going from Si^{IV} via Al^{III} to Ti^{IV} complexes **2**–**4**, **9**, and **10** supports the assignment to an intraligand charge-transfer transition. The bathochromic shift of this transition reflects the increasing ionic character of the M–O bonding which in turn causes the catecholate oxygen atom to become a stronger donor in the Ti^{IV} complexes than in the Si^{IV} compounds. For this reason the spectroscopic properties of the Ti^{IV} complexes **2** and **9** approach those of the deprotonated free ligands $\mathbf{1}^{2-}$ and $\mathbf{8}^{2-}$. The higher energy transition of Ti^{IV} complex **14** compared to **9** reflects the much weaker electron acceptor strength of the trimethylammonio substituent compared to the nitro group.[33] The former substituent acts by a purely inductive (field) effect while in the latter mesomeric effects also play a role.

In conclusion, we were able to synthesise a series of octupolar chromophores and to characterise their linear optical properties. The metal complexes described in this paper can serve as reasonably stable substitutes for the much more sensitive free-ligand chromophores. Owing to their intense

intraligand CT transitions these complexes might be good candidates as chromophores for first-order nonlinear applications.[34]

Experimental Section

General Remarks: All operations were performed under nitrogen or argon using standard Schlenk-line techniques. All reagents were purchased from commercial sources and used as received. Methyl 3-(3,4-dihydroxy)phenyl-2-propenoate (**1**),[35] 1,2-bis(*tert*-butyldimethylsilyloxy)-4,5-diiodobenzene (**5**),[31] 1-ethynyl-4-nitrobenzene (**6**),[36] and (4-ethynylphenyl)dimethylamine (**11**)[36] were prepared according to literature procedures.

Instrumental: ^{1}H and ^{13}C NMR spectra were recorded with a Bruker Avance 400 FT NMR spectrometer. Elemental analyses were obtained from the Institut für Anorganische Chemie of the Universität Würzburg using an apparatus from Leco (CHNS-932). Infrared spectra were recorded in the range 4000–200 cm^{-1} as KBr pellets with a Jasco 410 FT-IR spectrometer. UV/Vis spectra were recorded with a Jasco V-570 UV/Vis/NIR spectrometer using Uvasol® solvents from Merck.

Dilithium Tris{4-[2-(methoxycarbonyl)ethenyl]-1,2-benzenediolato}-titanate(IV) (2): To a mixture of methyl 3-(3,4-dihydroxy)phenyl-2-propenoate (**1**; 250 mg, 1.28 mmol) and Li_2CO_3 (32.0 mg, 433 μmol) in dry MeOH (15 mL) $TiO(acac)_2$ (112 mg, 430 mmol) was added. The solution turned deep red and was stirred at room temperature for 24 h. The solvent was removed in vacuo, the red solid was dissolved in ethyl acetate and carefully covered with a layer of petroleum ether. The crystalline precipitate was filtered off, washed with petroleum ether and dried in vacuo to yield a red solid. Yield 72% (225 mg). ^{1}H NMR (250 MHz, [D$_6$]acetone, 25 °C): δ = 7.49 (d, $^3J_{HH}$ = 15.9 Hz, 1 H, CH=C*H*), 6.72 (dd, $^3J_{HH}$ = 8.2, $^4J_{HH}$ = 2.2 Hz, 1 H, 5-H), 6.56 (d, $^4J_{HH}$ = 2.1 Hz, 1 H, 3-H), 6.23 (d, $^3J_{HH}$ = 7.9 Hz, 1 H, 6-H), 6.06 (d, $^3J_{HH}$ = 15.9 Hz, 1 H, C*H*=CH), 3.67 (s, 3 H, MeO) ppm. ^{13}C NMR (62.9 MHz, [D$_6$]-acetone, 295 K): δ = 168.3, 160.6, 147.9, 125.0, 122.7, 112.2, 111.6, 109.9, 106.1, 51.2 ppm. $C_{30}H_{24}Li_2O_{12}Ti{\cdot}5H_2O$ (728.35): calcd. C 49.47, H 4.71; found C 49.69, H 5.13. IR (KBr): $\tilde{\nu}$ = 3052 (aryl-C–H), 3016 (w, aryl-C–H), 2975 (w, C–H), 1686 (m, C=O), 1624 (m), 1579 (w), 1486 (s), 1436 (m), 1261 (s, C–O), 1197 (w), 1118 (w), 1042 (vw), 977 (vw), 824 (w), 641 (m), 613 (w), 505 (w) cm^{-1}.

Bis(triethylammonium) Tris{4-[2-(methoxycarbonyl)ethenyl]-1,2-benzenediolato}silicate(IV) (3): To a mixture of methyl 3-(3,4-dihydroxy)phenyl-2-propenoate (**1**; 250 mg, 1.28 mmol) and Et_3N (119 mg, 908 μmol) in dry MeOH (5 mL) $Si(MeO)_4$ (63.9 mg, 409 μmol) was added. The solution turned yellow and was stirred at room temperature for 24 h. The solvent was removed in vacuo. The yellow solid was dissolved in dichloromethane and the solution added dropwise to petroleum ether. The precipitate was filtered off, washed with petroleum ether and dried in vacuo. Yield 88% (300 mg) of a yellow solid. ^{1}H NMR (250 MHz, [D$_4$]methanol, 25 °C): δ = 7.53 (d, $^3J_{HH}$ = 15.5 Hz, 1 H, CH=C*H*), 6.86 (s, 1 H, 3-H), 6.72 (d, $^3J_{HH}$ = 7.9 Hz, 1 H, 6-H), 6.53 (dd, $^3J_{HH}$ = 8.0, $^4J_{HH}$ = 1.2 Hz, 1 H, 5-H), 6.13 (d, $^3J_{HH}$ = 15.5 Hz, 1 H, C*H*=CH), 3.72 (s, 3 H, MeO), 3.08 (q, 12 H, CH_3CH_2N), 1.21 (t, 18 H, CH_3CH_2N) ppm. ^{13}C NMR (62.9 MHz, [D$_4$]methanol, 295 K): δ = 170.9, 156.5, 152.6, 149.5, 125.5, 123.6, 111.8, 111.2, 109.2, 50.8, 48.0 (CH_3CH_2N), 9.62 (CH_3CH_2N) ppm. $C_{42}H_{58}N_3O_{12}Si$ (811.00): calcd. C 62.20, H 7.21, N: 3.45; found C 61.32, H 7.15, N 3.46. IR (KBr): $\tilde{\nu}$ = 3057 (aryl-C–H), 3019 (w, aryl-C–H), 2986 (w, C–H), 2949 (w, C–H), 1697 (m, C=O), 1623 (m), 1590 (m), 1497 (s), 1447 (m), 1354 (w), 1259 (s, C–O), 1157 (s), 1117 (m), 1035 (vw), 985 (vw), 926 (vw), 835 (m), 790 (w), 694 (m), 578 (vw), 523 (w) cm^{-1}.

Trilithium Tris{4-[2-(methoxycarbonyl)ethenyl]-1,2-benzenediolato}-aluminate(III) (4): To a mixture of methyl 3-(3,4-dihydroxy)phenyl-2-propenoate (**1**; 300 mg, 1.54 mmol) and Li_2CO_3 (56.2 mg, 758 μmol) in dry MeOH (15 mL) $Al(acac)_3$ (165 mg, 509 μmol) was added. The solution turned yellow and was stirred at room temperature for 24 h. The solvent was removed in vacuo, the remaining yellow solid was suspended in hot ethyl acetate and filtered off. The precipitate was washed twice with hot ethyl acetate and dried in vacuo. Yield 84% (268 mg) of a yellow solid. ^{1}H NMR (250 MHz, [D$_4$]methanol, 25 °C): δ = 7.49 (d, $^3J_{HH}$ = 15.4 Hz, 1 H, CH=C*H*), 6.78 (d, $^4J_{HH}$ = 1.8 Hz, 1 H, 3-H), 6.57 (dd, $^3J_{HH}$ = 7.9, $^4J_{HH}$ = 1.8 Hz, 1 H, 5-H), 6.42 (d, $^3J_{HH}$ = 7.9 Hz, 1 H, 6-H), 6.00 (d, $^3J_{HH}$ = 15.5 Hz, 1 H, C*H*=CH), 3.70 (s, 3 H, MeO) ppm. ^{13}C NMR (62.9 MHz, [D$_4$]methanol, 295 K): δ = 171.3, 162.0, 156.4, 150.3, 123.3, 123.0, 112.9, 110.0, 108.5, 51.6 ppm. $C_{30}H_{24}AlLi_3O_{12}{\cdot}5H_2O$ (714.34): calcd. C 50.44, H 4.80; found C 50.79, H 4.84. IR (KBr): $\tilde{\nu}$ = 3054 (vw, aryl-C–H), 2984 (w, C–H), 1685 (m, C=O), 1622 (m), 1582 (m), 1497 (s), 1437 (m), 1346 (vw), 1269 (s, C–O), 1199 (m), 1166 (m), 1120 (w), 1042 (vw), 980 (w), 929 (vw), 827 (w), 784 (vw), 655 (w), 616 (w) cm^{-1}.

1,2-Bis(*tert*-butyldimethylsilyloxy)-4,5-bis[2-(4-nitrophenyl)ethynyl]-benzene (7): To a mixture of 4,5-bis(*tert*-butyldimethylsilyloxy)-1,2-diiodobenzene (**5**; 189 mg, 320 μmol), $(PPh_3)_2PdCl_2$ (24.0 mg, 34.2 μmol) and $Cu^{I}I$ (4.00 mg, 21.0 μmol) in dry Et_2NH (5 mL) was added 1-ethynyl-4-nitrobenzene (**6**; 100 mg, 680 μmol). The red solution was heated to 60 °C for 1 h, cooled to room temperature and the solvent was evaporated in vacuo. The remaining black solid was purified by flash chromatography on silica gel (dichloromethane/petroleum ether, 2:3) to yield a yellow solid. The solid was dissolved in dichloromethane and the solution added dropwise to petroleum ether. The dichloromethane was removed in a rotary evaporator, the precipitate was filtered and dried in vacuo. Yield 75% (163 mg) of a yellow solid. ^{1}H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 8.22 (AA′, 4 H), 7.65 (BB′, 4 H), 7.03 (s, 2 H, 3-H, 6-H), 1.01 [s, 18 H, $(CH_3)_3CSi$], 0.26 [s, 12 H, $(CH_3)_2Si$] ppm. ^{13}C NMR (62.9 MHz, $CDCl_3$, 295 K): δ = 149.5, 148.2, 133.2, 130.7, 125.3, 124.8, 119.6, 93.3, 91.7, 26.2, 19.2, –3.85 ppm. $C_{34}H_{40}N_2O_6Si_2$ (677.24): calcd. C 64.94, H 6.41, N 4.45; found C 64.69, H 6.24, N 4.52. IR (KBr): $\tilde{\nu}$ = 3041 (vw, aryl-C–H), 2951 (w, C–H), 2930 (w, C–H), 2857 (w, C–H), 2204 (vw, C≡C), 1592 (m), 1536 (w), 1510 (s, NO_2), 1410 (w), 1345 (w), 1336 (s, NO_2), 1256 (m), 1213 (vw), 1105 (w), 1083 (w), 939 (m), 886 (vw), 871 (w), 848 (m), 843 (m), 783 (w), 748 (vw), 684 (vw) cm^{-1}.

1,2-Dihydroxy-4,5-bis[2-(4-nitrophenyl)ethynyl]benzene (8): To a solution of 1,2-bis(*tert*-butyldimethylsilyloxy)-4,5-bis[2-(4-nitrophenyl)ethynyl]benzene (**7**; 95.0 mg, 140 μmol) in dry THF (10 mL) tetrabutylammonium fluoride (101 mg, 386 μmol, 1 M solution in THF) was added. The deep purple solution was stirred at room temperature for 30 min and a cold H_3PO_4 solution (30 mL, 1 M) was added. The mixture was extracted with Et_2O (3 × 30 mL). The organic phases were combined, dried with Na_2SO_4 and the solvent was removed in vacuo. The remaining brown solid was purified by flash chromatography on silica gel (ethyl acetate/*n*-hexane/CH_3COOH, 10:25:1) to yield an orange solid. The solid was dissolved in ethyl acetate and the solution added dropwise to *n*-hexane. The precipitate was filtered off and dried in vacuo. Yield 98% (55.0 mg) of an orange solid. ^{1}H NMR (250 MHz, [D$_6$]acetone, 25 °C): δ = 8.31 (AA′, 4 H), 7.84 (BB′, 4 H), 7.44 (br., 2 H, HO), 7.17 (s, 2 H, 3-H, 6-H) ppm. ^{13}C NMR (62.9 MHz, [D$_6$]acetone, 295 K): δ = 148.0, 147.9, 133.1, 131.0, 124.8, 119.7, 118.0,

Bis(triethylammonium) Tris{4,5-bis[2-(4-nitrophenyl)ethynyl]-1,2-benzenediolato}silicate(IV) (10): To a mixture of 1,2-dihydroxy-4,5-bis[2-(4-nitrophenyl)ethynyl]benzene (**8**; 100 mg, 249 μmol) and Et_3N (16.2 mg, 124 μmol) in dry MeCN (10 mL) a 1 M solution of $Si(MeO)_4$ (12.1 mg, 77.4 μmol) in dry MeCN was added. The solution turned orange and was stirred at room temperature for 24 h. Overnight a solid precipitated which was filtered off, washed with MeCN and dried in vacuo. Yield 78% (76.0 mg) of an orange solid. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25 °C): δ = 8.26 (AA′, 12 H), 7.73 (BB′, 12 H), 6.55 (s, 6 H, 3-H, 6-H), 3.06 (q, 12 H, CH_3CH_2N), 1.16 (t, 18 H, CH_3CH_2N) ppm. ^{13}C NMR (62.9 MHz, [D$_6$]DMSO, 295 K): δ = 154.6, 146.0, 131.7, 130.5, 124.1, 112.8, 111.9, 97.1, 88.9, 45.8, 8.8 ppm. $C_{78}H_{64}N_8O_{18}Si$ (1429.5): calcd. C 65.54, H 4.51, N 7.84; found C 64.13, H 4.38, N 7.56. IR (KBr): $\tilde{\nu}$ = 3071 (w, C–H-aryl), 2197 (m, C≡C), 1591 (s, NO_2), 1498 (s), 1384 (w), 1340 (s, NO_2), 1244 (s, C–O), 1173 (vw), 1105 (w), 1073 (vw), 891 (w), 852 (w), 795 (w), 748 (w), 711 (vw), 687 (vw), 655 (w), 596 (vw), 565 (vw) cm^{-1}.

1,2-Bis(*tert*-butyldimethylsilyloxy)-4,5-bis{2-[4-(dimethylamino)-phenyl]ethynyl}benzene (12): To a mixture of 4,5-bis(*tert*-butyldimethylsilyloxy)-1,2-diiodobenzene (**5**; 189 mg, 320 μmol), $(PPh_3)_2$-$PdCl_2$ (24.0 mg, 34.2 μmol) and Cu^{I}I (4.00 mg, 21.0 μmol) in dry Et_2NH (5 mL) (4-ethynylphenyl)dimethylamine (**11**; 100 mg, 680 μmol) was added. The red solution was heated to 50 °C for 24 h, cooled to room temperature and the solvent was evaporated in vacuo. The remaining brown solid was purified by chromatography on Al_2O_3 (neutral, act. V; dichloromethane/petroleum ether, 1:9) to yield a colourless solid. Yield 78% (156 mg) of a colourless solid. ^{1}H NMR (250 MHz, [D$_6$]acetone, 25 °C): δ = 7.38 (AA′, 4 H), 6.99 (s, 2 H, 3-H, 6-H), 6.72 (BB′, 4 H), 2.99 (s, 12 H, Me_2N), 1.02 [s, 18 H, $(CH_3)_3CSi$], 0.28 [s, 12 H, $(CH_3)_2Si$] ppm. ^{13}C NMR (62.9 MHz, [D$_6$]acetone, 25 °C): δ = 151.6, 148.0, 133.6, 124.7, 121.2, 113.1, 111.2, 94.5, 87.3, 40.5, 26.6, 19.4, –3.50 ppm. $C_{38}H_{52}N_2O_2Si_2$ (625.02): calcd. C 73.03, H 8.39, N 4.48; found C 72.88, H 8.19, N 4.58. IR (KBr): $\tilde{\nu}$ = 3045 (vw, aryl-C–H), 2953 (w, C–H), 2929 (m, C–H), 2885 (w, C–H), 2857 (m, N–Me), 2199 (vw, C≡C), 1608 (s), 1523 (s), 1496 (w), 1362 (s), 1254 (m), 1187 (w), 1136 (w), 929 (m), 887 (vw), 861 (w), 840 (m), 816 (w), 782 (w) cm^{-1}.

1,2-Bis(*tert*-butyldimethylsilyloxy)-4,5-bis{2-[4-(trimethylammonio)-phenyl]ethynyl}benzene Diiodide (13): To a solution of 1,2-bis(*tert*-butyldimethylsilyloxy)-4,5-bis{2-[4-(dimethylamino)phenyl]-ethynyl}benzene (**12**; 1.45 g, 2.31 mmol) in THF (20 mL) methyl iodide (5 mL) was added. The reaction mixture was sealed in a Schlenk tube and heated to 55 °C for 4 d. Excess methyl iodide and the solvent were removed in vacuo. The light yellow solid was dissolved in acetone by heating the mixture to 40 °C, *n*-hexane was added and the acetone was removed in a rotary evaporator. The precipitate was filtered off and washed twice with *n*-hexane to yield a colourless solid. Yield 86% (1.78 g). ^{1}H NMR (250 MHz, [D$_6$]-DMSO, 25 °C): δ = 8.06–8.03 (4 H), 7.79–7.74 (4 H), 7.11–7.00 (2 H, 3-H, 6-H), 3.64 (18 H, Me_3N), 0.98–0.83 [18 H, $(CH_3)_3CSi$], 0.25 to –0.04 [12 H, $(CH_3)_2Si$] ppm. ^{13}C NMR (62.9 MHz, [D$_6$]-DMSO, 25 °C): δ = 147.78, 146.78, 132.51, 132.42, 132.34, 132.24, 124.10, 123.91, 121.29, 121.24, 118.10, 90.26, 89.60, 56.41, 56.34, 25.50, 25.32, 25.26, 18.15, 18.13, 17.72, –3.24, –4.26, –4.54 ppm. $C_{40}H_{58}I_2N_2O_2Si_2$ (908.89): calcd. C 52.86, H 6.43, N 3.08; found C 52.59, H 6.18, N 3.11. IR (KBr): $\tilde{\nu}$ = 3013 (vw, C–H-aryl), 2955 (w, C–H), 2929 (w, C–H), 2885 (vw, C–H), 2857 (w, N–Me), 2210 (vw, C≡C), 1532 (m), 1513 (s), 1492 (m), 1471 (w), 1407 (w), 1357 (m), 1254 (s), 1117 (vw), 1082 (vw), 1013 (vw), 934 (s), 887 (w), 840 (s), 804 (w), 783 (m), 687 (vw), 564 (vw) cm^{-1}.

Tris(4,5-bis{2-[4-(trimethylammonio)phenyl]ethynyl}-1,2-benzenediolato)titanium(IV) Tetraiodide (14): To a solution of 1,2-bis(*tert*-butyldimethylsilyloxy)-4,5-bis{2-[4-(trimethylammonio)phenyl]-ethynyl}benzene diiodide (**13**; 200 mg, 220 μmol) in dry MeOH (13 mL) was added nBu_4NF (151 mg, 578 μmol, 1 M solution in THF) followed by $TiO(acac)_2$ (19.2 mg, 73.2 μmol). The solution turned red and was stirred at room temperature for 24 h. The orange precipitate was filtered off and washed carefully with MeOH. The solid was suspended in MeOH (15 mL) and the suspension added dropwise to a concd. solution of $NH_4(PF_6)$ in MeOH (10 mL). The precipitate was filtered off and the procedure was repeated twice to yield an orange solid. Yield 86% (114 mg). ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25 °C): δ = 7.98 (AA′, 12 H), 7.70 (BB′, 12 H), 6.30 (s, 6 H, 3-H, 6-H), 3.62 (s, 18 H, Me_3N) ppm. ^{13}C NMR (62.9 MHz, [D$_6$]DMSO, 25 °C): δ = 162.1, 146.0, 132.0, 125.4, 121.1, 113.4, 93.4, 88.3, 56.4 ppm. $C_{84}H_{90}I_4N_6O_6Ti{\cdot}4H_2O$ (1901.19): calcd. C 53.07, H 4.87, N 4.42; found C 53.08, H 4.98, N 4.42. IR (KBr): $\tilde{\nu}$ = 3014 (vw, C–H-aryl), 2955 (w, C–H), 2929 (w, C–H), 2885 (w, C–H), 2857 (w, N–Me), 2198 (w, C≡C), 1508 (w), 1479 (s), 1413 (w), 1369 (m), 1278 (w), 1244 (s, C–O), 1200 (w), 1113 (w), 1011 (vw), 955 (vw), 936 (w), 884 (w), 844 (m), 798 (w), 635 (m), 565 (m), 502 (m) cm^{-1}.

A Novel Five-Coordinate Rhodium(I) Complex

Igor O. Koshevoy,[a,b] Olga V. Sizova,[a] Sergey P. Tunik,*[a] Alan Lough,[b] and Anthony J. Poë[b]

Keywords: Solid-state structures / Rhodium / Electronic structure / Phosphane ligands / Carbonyl ligands

An unusual five-coordinate isomer of the mononuclear complex $[Rh(CO)_2(PPh_3)_2I]$ has been isolated, and its crystallographic structure determined. The molecule has a slightly distorted trigonal-bipyramidal structure, with both PPh_3 ligands being in axial positions. A combination of IR and NMR spectroscopy with the results of DFT calculations shows that the complex maintains the same structure in solution.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The adventitious detection[1] of $[Rh(CO)_2(PPh_3)_2Br]$ as a probable product of the reaction of $[Rh_6(CO)_{15}(PPh_3)]$ with Br^- led us to attempt to confirm its structure indirectly by crystallography of its more stable iodo analogue $[Rh(CO)_2(PPh_3)_2I]$ (**1**). This has been prepared more conveniently by reaction of $[Rh_4(CO)_{12}]$ with PPh_3 and NBu_4I under CO, and has been fully characterized by crystallography, IR and NMR spectroscopy. Five-coordinate $[Rh(CO)_2(PR_3)_2(Hal)]$ rhodium complexes had previously been reported[2–5] but were characterized only by NMR and IR spectroscopy. The spectroscopic data obtained for these complexes were not in good agreement but they are all compatible with four symmetrical structures described below. Two structures are based on a trigonal-bipyramidal motif[2–5] with either two COs or two phosphane ligands in the axial positions. Two other possibilities are represented by tetragonal pyramids with *cis* and *trans* arrangement of the ligands in the basal plane.[5] The disagreements in the experimental NMR spectroscopic data can be partially explained by fast exchange between the isomeric species[5] or by dissociative equilibria with the parent square planar $[Rh(CO)(PPh_3)_2(Hal)]$ complexes.[4]

The importance of a clear assignment of the structures of this sort lies in the general significance of five-coordinate Rh^I complexes in terms of the boundary between four-coordinate planar and five-coordinate (usually trigonal bipyramidal, sometimes square pyramidal) d^8 complexes in general, and their occurrence as intermediates in associative substitution reactions of planar Rh^I complexes and in similar reactions proposed for catalytic systems.[6] In particular, it has been clearly shown[5] that occurrence of the $[Rh(CO)_2(PPh_3)_2(Hal)]$ species must be taken into account in catalytic systems that contain the starting square-planar $[Rh(CO)(PPh_3)_2Hal]$ complexes under CO, a typical situation for carbonylation catalysis.

This aspect of the complex's importance is that there are only *two* other five-coordinate Rh^I complexes, the structures of which have been reported quite recently in the Cambridge Structural Database. One is the not exactly analogous $[Rh(PR_3)_2(CO)_3]^+$ cation[7] (trigonal-bipyramid with *trans* P donors), and the other is a closely analogous dinuclear $[Rh(CO)_2X(PP)]_2$ neutral complex, where two Rh^I centers are bridged by two long-chain bidentate diphosphane (PP) ligands. This has a trigonal-bipyramidal structure, with *trans* P donors. In general five-coordinate complexes of Rh^I are rare and/or unstable towards loss of the 5th ligand. In this paper we describe the isolation and detailed characterization (X-ray crystallography, IR, NMR) of the $[Rh(CO)_2(PPh_3)_2I]$ complex. The DFT optimization of the structure, and calculation of the IR spectroscopic characteristics are presented.

Results

The five-coordinate $[Rh(CO)_2(PPh_3)_2I]$ (**1**) complex, can be obtained either by addition of CO to the square-planar $[Rh(CO)(PPh_3)_2I]$[3] or by disproportionation of $[Rh_6(CO)_{15}(PPh_3)]$ in the presence of I^-.[1] In this paper we suggest another high-yield synthesis of **1** by the reaction of $[Rh_4(CO)_{12}]$ with I^- and PPh_3 under CO, according to the proposed stoichiometry:

$$3\,[Rh_4(CO)_{12}] + 4\,PPh_3 + 4\,I^- = 2\,[Rh_5(CO)_{15}I]^{2-} + 2\,[Rh(CO)_2(PPh_3)_2I]$$

The complex is relatively stable in the solid state but in solution it must be kept under CO to prevent decarbonylation and formation of the square-planar $[Rh(CO)(PPh_3)_2I]$ complex as was observed earlier.[3] The solid-state structure of **1** has been characterized by a single-crystal X-ray diffraction study. The IR, ^{31}P, ^{13}C and VT ^{1}H NMR spectroscopic characteristics of **1** in solution were also measured. A very good agreement of the NMR spectroscopic data obtained for **1** and those reported earlier[3] for $[Rh(CO)_2(PPh_3)_2I]$ [^{31}P NMR: δ = 34.0 ppm, ^{1}J(Rh–P) = 91 Hz, ^{13}C: δ = 191.1 ppm, ^{1}J(Rh–C) = 70 Hz, ^{2}J(P–C), CD_2Cl_2, –50 °C] clearly indicates identity of these complexes. An ORTEP view of the molecule is shown in Figure 1 together with its principal structural parameters. The IR and ^{31}P NMR spectroscopic data are presented in the Experimental Section, and the mid-IR spectrum is shown in Figure 2. Quantum Chemical (DFT) calculations have been performed using the GAUSSIAN98 program package.[11] The DFT-B3LYP method,[12] and the basis set LanL2DZ with effective core potentials (ECP) for the Rh, P and I atoms,[13,14] were applied. The geometry optimizations were carried out without any symmetry constraints. The trigonal-bipyramidal structures with axial disposition of either phosphane or CO ligands were used as the starting geometries, but "no symmetry constraints" were imposed. Other feasible structures with the mixed axial/equatorial disposition of CO (PPh_3) ligands were not analyzed because they contradict the NMR spectroscopic data for **1**. In both cases we found local minima on the potential energy surface related to the corresponding structures. Selected results of these calculations are given in Table 1.

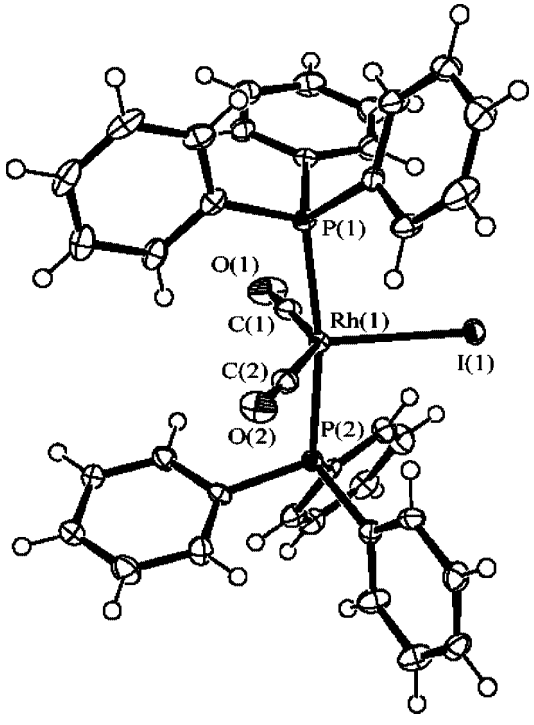

Figure 1. ORTEP plot of the molecular structure of $[Rh(CO)_2(PPh_3)_2I]$ (**1**). Thermal ellipsoids are drawn at the 50% level. Selected bond lengths [Å], Rh(1)–P(1) 2.3385(8), Rh(1)–P(2) 2.3298(7), Rh(1)–C(1) 1.915(3), Rh(1)–C(2) 1.903(3), Rh(1)–I(1) 2.8241(3), O(1)–C(1) 1.148(3), O(2)–C(2) 1.144(3) and angles [°], P(2)–Rh(1)–P(1) 170.34(3), C(2)–Rh(1)–C(1) 143.46(13), C(2)–Rh(1)–I(1) 111.11(9), C(1)–Rh(1)–I(1) 105.42(9).

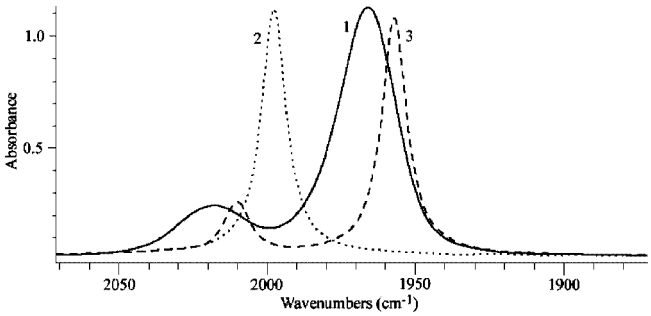

Figure 2. The IR spectroscopic patterns of the two trigonal-bipyramidal isomers of $[Rh(CO)_2(PPh_3)_2I]$. Experimental spectrum of **1** (−). Calculated spectra for the isomer with two axial (-----) and two equatorial (·····) PPh_3 ligands.

Discussion

In the solid state the molecule of **1** forms a trigonal pyramid with two phosphane ligands in the axial positions. The iodide and two carbonyl ligands occupy three equatorial sites. The molecule can be assigned to the C_{2v} idealized symmetry group. Two bonds connecting the phosphorus and rhodium atoms in **1** are slightly bent to form the angle of 170.34(3)°. This distortion from the idealized axial geometry of the phosphanes seems to be dictated by nonbonding interaction of the iodide with the phenyl substituents of the ligands. The angle between Rh–C(O) bonds in the equatorial plane [143.46(13)°] considerably exceeds the I–Rh–C(O) angles [111.11(9)° and 105.42(9)°] to accommodate the phenyl substituents tilted from the iodide to the carbonyl ligands because of the P–Rh–P angle distortion mentioned above. It is worth noting at this point that in the cobalt $[Co(CO)_2(PEt_3)_2I]$[15] and iridium $[Ir(CO)_2(PPh_3)_2I]$[16] congeners the angular distortions are minimal [e.g. P–Co–P and P–Ir–P angles equal to 179.0° and 179.1°, respectively] due to the smaller effective cone angle of the phosphane in the former complex, and to larger metal-to-ligands distances in the latter.

These distortions from an exact trigonal-bipyramidal conformation place **1** on the trajectory involved in a Berry rotation process of the sort usually invoked in scrambling reactions of trigonal-bipyramidal complexes. Because of this it is important to confirm that **1** exists in solution in the same isomeric form as that observed in the solid state. The ^{31}P NMR spectrum displays a doublet resonance (δ = 31.2 ppm [d, ^{1}J(Rh–P) 94.4 Hz]) that points to structurally equivalent phosphane ligands bound to rhodium. The $^{13}C\{^{1}H\}$ spectrum also displays one signal in the carbonyl region, split into doublet of triplets due to the couplings with rhodium [^{1}J(Rh–C) 70.0 Hz] and phosphorus [^{2}J(P–C) 14.5 Hz], the latter being typical of *cis* two-bond coupling. These data are compatible with two structural patterns,

[a] The values of band frequencies are multiplied by the scaling factor 1.03 (see text).

which contain either phosphane or carbonyl ligands in the axial positions of the trigonal bipyramid. Four signals of aromatic carbon atoms between δ = 133 and 128 ppm are indicative of free rotation of the phosphane ligands and their phenyl substituents about the P–C and Rh–P bonds. The proton spectra of **1** display two typical multiplets (2/3 relative intensities) of aromatic protons in the temperature range +25 °C to –40 °C (see Figure S1 in the supporting information; for details see also the footnote on the first page of this article) and this also points to the absence of steric hindrance to rotation in the molecule under these conditions. The latter observations make it more probable that the phosphane ligands are in the axial positions so that nonbonding interactions in the ligand sphere of **1** are minimized. Nevertheless, the NMR spectroscopic data do not allow an unambiguous decision on the stereochemistry of **1**. Analysis of the IR spectroscopic patterns corresponding to the alternative structural hypotheses (see below) showed that this type of spectroscopy provides more reliable background to make a choice in favor of one or another structure. The IR spectrum of **1** in the carbonyl region displays two bands of significant intensity (see Table 1) that is in contrast with the first report on the synthesis of $[Rh(CO)_2(PPh_3)_2I]$[3] where only one carbonyl absorption band was found. The NMR spectroscopic data for **1** are in a good agreement with the data obtained for the above compound[3] [$^{31}P\{^1H\}$ 34 ppm, $^{13}C\{^1H\}$ 191.1 ppm, ^1J(Rh–P) = 91 ppm, ^1J(Rh–C) = 70 Hz, ^2J(C–P) = 16 Hz], and it seems very probable that in the early study[3] the high-frequency band has been missed in the spectrum either because of low sensitivity of the instrument used or due to low concentration of the sample. It has to be also noted that structurally analogous complexes of cobalt[15] and iridium,[16] as well as the chloride and bromide rhodium derivatives[5] $\{[Rh(CO)_2(PPh_3)_2X]\}$ also display two absorption bands in the carbonyl region with essentially similar location and relative intensities. A very similar trigonal-bipyramidal environment of the Rh^I center has been recently found[17] in the dinuclear rhodium complex $[Rh(CO)_2I(PP)]_2$ where two rhodium atoms are bridged by a long-chain diphosphane (PP) ligand with the phosphorus functionalities in axial positions. The structure of this complex found in the solid state must be retained in solution because of the rigidity of the macrocyclic structure of this molecule and two carbonyl absorption bands observed in solution must be associated with the trigonal-bipyramidal structure bearing two phosphorus ligands in the axial positions. Thus the further analysis of geometry of **1** will be based on the presence of two carbonyl absorption bands in its IR spectrum, something that is evidently of crucial importance for a proper assignment of its solution structure.

The DFT calculations of the electronic structure of **1** have shown that the full energy of the isomer with *axial* PPh_3 ligands is slightly lower (1.5 kcal/mol) than that of the form with equatorial phosphanes. Although this small difference cannot be considered as a decisive argument in favor of one or another structure, it would allow for there being as little as ca. 10% of the equatorial isomer to be present in solution. Inclusion of thermochemical corrections does not change this ratio. The bond angles (Table 1), calculated for the isomer with two axial phosphane ligands, are in good agreement with the crystallographic data obtained for **1**. Higher values of the calculated Rh–C, Rh–I and C–O bonds are quite expected because polarizing functions were not included in the basis set of orbitals. Calculation of the IR spectra gave two carbonyl stretch bands (ν_{asymm} and ν_{symm}) for both isomeric forms with, however, essentially different relative intensities. Comparison of the calculated band frequencies with the experimental data shows considerable underestimation of the calculated values. However, this is quite typical for complexes of this sort, and an independent study[18] of another family of five-coor-

dinate carbonyl rhodium compounds ([$Rh(RCOO)(PPh_3)_2(CO)$], R = H, CH_3, CF_3) showed that similar calculations gave consistent values of the band frequencies with the use of scaling factor equal to 1.03. When we applied this factor in the present study it led to much better agreement between experimental and calculated values of the band frequencies. However, in the present case these parameters alone do not allow distinguishing the two possible structures of **1**. Relative intensities of the bands are much stronger discriminative factor due to their well-documented dependence on the angle between carbonyl groups in dicarbonyl complexes.[6,16,19] The greater (O)C–Rh–C(O) bond angle when the CO ligands are both axial resulted in a decrease of the $I_{sym}/I_{antisym}$ value down to ca. 0.01, a value that would actually result in the disappearance of this band from the experimental spectrum. The agreement between experimental and calculated (O)C–Rh–C(O) bond angles when the phosphanes are both axial is completely in line with the excellent fit of the relative intensities of the calculated IR bands and those observed in the experimental spectrum, as shown in Figure 2. Thus, the combination of the spectroscopic data with the calculations described above allows an unambiguous assignment of the solution structure of **1**, which was arguable until the present time.

Experimental Section

General Comments: The complex [$Rh_4(CO)_{12}$] was prepared according to published procedure.[8] [NBu_4]I and PPh_3 (Aldrich) were used as received. Chloroform, hexanes and methanol (Aldrich) were used without additional purification. Tetrahydrofuran was distilled from over Na-benzophenone ketyl under nitrogen prior to use. Infrared spectra were recorded with a Nicolet Magna IR 550 FTIR spectrometer. ^{31}P, ^{1}H and ^{13}C NMR spectra were recorded with Varian Gemini 300 or Unity 500 instruments, and referenced to external 85% H_3PO_4 and residual solvent resonances, respectively.

Preparation of [$Rh(CO)_2(PPh_3)_2I$] (1): [$Rh_4(CO)_{12}$] (206 mg, 0.28 mmol) was dissolved in $CHCl_3$ (10 cm^3) and a slight excess of PPh_3 (97 mg, 0.37 mmol) was added to the solution under nitrogen. After the liberation of gaseous CO was complete, the reaction mixture was degassed (3 freeze-pump-thaw cycles) and saturated with CO. NBu_4I (184 mg, 0.5 mmol) was added to the solution under CO. The course of the reaction was monitored by ^{31}P NMR spectroscopy. After 6–7 hours the ^{31}P NMR spectrum displayed one doublet signal that indicated formation of a phosphorus-containing rhodium complex. The solvent was removed under a flow of gaseous CO. The resulting dark red oily material was first diluted with CO-saturated THF (1 cm^3) and then with CO-saturated methanol (10 cm^3) to give a yellow crystalline precipitate of [$Rh(CO)_2(PPh_3)_2I$] (**1**) and a dark red solution containing anionic cluster species. The suspension obtained was stirred under a flow of CO for 15 minutes to complete precipitation of the product. The mother liquor was then carefully decanted, and the residue was washed with CO-saturated methanol (2×3 cm^3) and dried under a flow of CO to afford 108 mg of **1**. Single crystals of **1** suitable for an X-ray diffraction study were obtained by slow gas-phase diffusion of heptane into a THF/2-propanol solution under CO. IR (CH_2Cl_2, cm^{-1}): ν(CO) = 2018 w br, 1967 s br. $^{13}C\{^1H\}$ NMR (CD_2Cl_2, –80 °C): δ = 191.4 [dt, ^1J(Rh–C) = 70.0, ^2J(P–C) = 14.5 Hz], 134.2 (2 C_{Ph}), 132.9 (multiplet, *ipso*-C_{Ph}), 131.2 (1 C_{Ph}), 128.7 (2 C_{Ph}) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 20 °C): δ = 31.2 ppm [d, ^1J(Rh–P) = 94.4 Hz].

X-ray Structure Determinations: Data were collected with a Nonius Kappa-CCD diffractometer using monochromated Mo-K_α radiation and were measured using a combination of φ scans and ω scans with κ offsets, to fill the Ewald sphere. The data were processed by using the Denzo-SMN software package.[9] The structure was solved and refined using SHELXTL V6.1[10] for full-matrix least-squares refinement that was based on F^2. All H atoms were included in calculated positions and allowed to refine in riding-motion approximation with U_{iso} tied to the carrier atom. Crystallographic data for the compounds is given in Table 2. Selected structural parameters are given in Table 1.

Phase Behaviors of the $ZrMo_{2-x}W_xO_8$ (x = 0.2–2.0) System and the Preparation of an Mo-Rich Cubic Phase

Ling Huang,[a] Qiu-guo Xiao,[a] Hui Ma,[b] Guo-bao Li,[c] Fu-hui Liao,[c] Chuan-min Qi,[a] and Xin-hua Zhao*[a]

Keywords: Calorimetry / Materials science / Phase diagrams / Phase transitions / Zirconium

The phase behaviors of $ZrMo_{2-x}W_xO_8$ (x = 0.2 to 2.0) solid solutions have been studied systematically by variable-temperature X-ray diffraction (XRD) and differential scanning calorimetric (DSC) techniques. A low-temperature (LT) orthorhombic $ZrMo_{2-x}W_xO_8$ (x = 0.2–2.0) phase is formed by dehydration of the precursors $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ (x = 0.2–2.0) within a temperature range from 124 to 203 °C. Among them, the orthorhombic $ZrMo_{2-x}W_xO_8$ solid solutions are able to convert further into metastable cubic phases within an x-dependent temperature range from 502 to 552 °C; the trigonal phases become dominant at higher temperature for Mo-rich solid solutions. However, no trigonal phases are formed in the high-temperature region for W-rich solid solutions. The absence of decomposition of $ZrMo_{2-x}W_xO_8$ (x = 0.2 to 1.6) solid solutions up to 800 °C indicates that the molybdenum substitution leads to a remarkable improvement of the thermal stability in comparison with ZrW_2O_8. Based on the phase behaviors reported in this paper, an approach for the preparation of cubic Mo-rich solid solutions $ZrMo_{2-x}W_xO_8$ with attractive negative thermal expansion (NTE) properties is demonstrated.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The considerable interest in the study of cubic AM_2O_8 (A = Zr, Hf; M = W, Mo) compounds,[1–4] as well as their solid solutions $ZrMo_{2-x}W_xO_8$,[5–8] has been fueled recently by their isotropic negative thermal expansion (NTE) over a very wide temperature range. These compounds are usually synthesized by dehydration of the corresponding hydrate precursors. Typically, $ZrMo_2O_8$ and ZrW_2O_8 are obtained by dehydration of the precursors $ZrMo_2O_7(OH)_2(H_2O)_2$[9] and $ZrW_2O_7(OH)_2(H_2O)_2$,[10] respectively. The similarity in chemical and crystallographic properties between W^{VI} and Mo^{VI} suggests that the compounds ZrW_2O_8 and $ZrMo_2O_8$ should be isomorphic and readily form solid solutions. Solid solutions of $ZrMo_{2-x}W_xO_8$ have indeed been synthesized and the properties of $ZrMoWO_8$, including thermal expansion and oxygen migration at low temperature, have also been reported.[11] However, conspicuous gaps are seen with respect to the temperature-dependent phase behaviors of solid solutions of different compositions.

In this paper, the synthesis and phase behaviors of $ZrMo_{2-x}W_xO_8$ (x = 0.2–2.0) solid solutions are studied using variable-temperature X-ray diffraction (XRD) and different scanning calorimetric (DSC) techniques. It has been found that different structural phases of Mo-rich and W-rich $ZrMo_{2-x}W_xO_8$ solid solutions can be formed under the same heating conditions due to the differences in the thermal stabilities of ZrW_2O_8 and $ZrMo_2O_8$ polymorphs. Cubic, Mo-rich solid solutions of $ZrMo_{2-x}W_xO_8$ (x = 0.2, 0.4, 0.6, 0.7, 0.8) can be synthesized successfully by controlling the temperature within the appropriate range.

Results and Discussion

Thermal Analysis

DSC curves were recorded in the temperature range of 40–800 °C for molybdenum-rich (x = 0.2, 0.4, 0.6, 0.7, or 0.8) and tungsten-rich (x = 1.0, 1.2, 1.4, 1.6, or 2.0) $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ precursors. Typical DSC curves of the Mo-rich precursors $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$ and W-rich precursors $ZrMo_{0.4}W_{1.6}O_7(OH)_2(H_2O)_2$ are presented in Figure 1 (parts a and b), respectively. The single endothermic peak appearing in each of these curves (at 127 and 165 °C, respectively) indicates the formation of anhydrous orthorhombic phases due to dehydration in both cases. However, the DSC curve of the Mo-rich solid solution $ZrMo_{1.6}W_{0.4}O_8$ shows two exothermic peaks located at 508 and 562 °C assigned to the formation of a cubic and trigonal phase, respectively, although only one exothermic peak due to the formation of a cubic phase is observed at 542 °C in the DSC curve of the W-rich $ZrMo_{0.4}W_{1.6}O_8$ solid solu-

tion. This difference indicates clearly that there are two distinct phase-transition mechanisms operating during heating of Mo- and W-rich $ZrMo_{2-x}W_xO_8$ solid solutions.

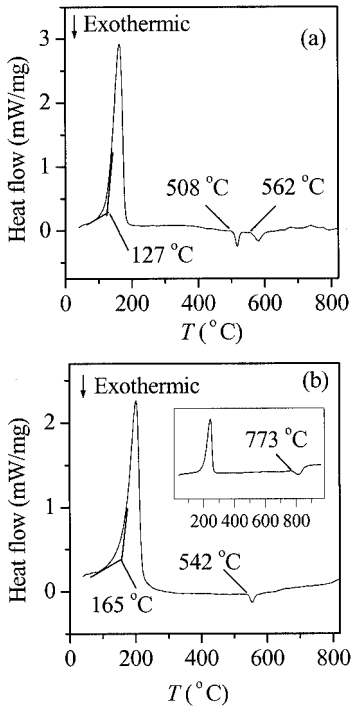

Figure 1. DSC curves of $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$ (a) and $ZrMo_{0.4}W_{1.6}O_7(OH)_2(H_2O)_2$ (b). The DSC of $ZrW_2O_7(OH)_2(H_2O)_2$, which indicates that ZrW_2O_8 decomposes at 773 °C, is given in the inset.

Increasing the tungsten fraction x leads to a gradual shift of the endothermic peak of the solid solutions $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ (x = 0.2–2.0) from 124 up to 203 °C.

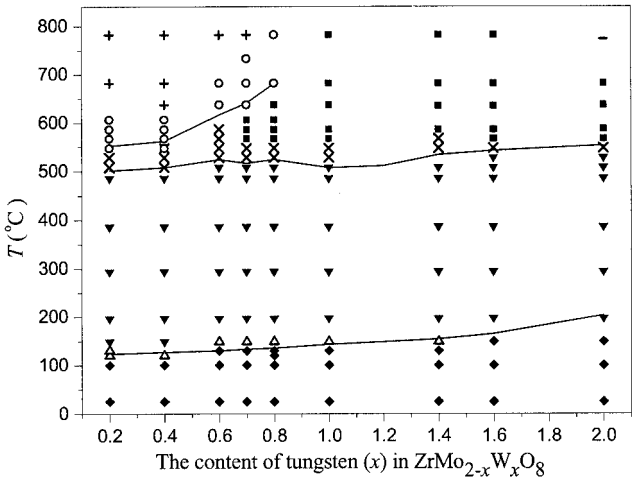

Figure 2. The overall process of phase transition for the $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ system during the heating procedure. The solid lines link the onset peak values of the DSC curves. The crystal structures of precursor (black diamond) and dehydrates of specific composition x at different temperatures are indicated with different symbols: tetragonal: black diamond (♦); orthorhombic: black triangle (▼); tetragonal and orthorhombic: open triangle (Δ); orthorhombic and cubic: ×; cubic: black square (■); cubic and trigonal: open circle (○); trigonal: +; decomposition: –.

Similarly, the increase in x also causes an up-shift of the first exothermic peak from 502 to 552 °C. However, the second exothermic peak of $ZrMo_{2-x}W_xO_8$ ($1 \leq x < 2$) disappears at higher temperature, although it shows a more remarkable shift for solid solutions $ZrMo_{2-x}W_xO_8$ with x less than 1.0 (see Figure 2). The appearance of the exothermic peak in the DSC curve of ZrW_2O_8 suggests its decomposition temperature is located at 773 °C (see the inset in Figure 1, b). This observation indicates that these solid solutions have a higher decomposition temperature than ZrW_2O_8. A similar feature has been observed for the $ZrMo_{2-x}W_xO_8$ solid solution.[6] In addition, no enthalpy changes due to MoO_3 sublimation of $ZrMo_{2-x}W_xO_8$ compounds (x = 0.2–1.6) are detected at temperatures up to 800 °C even though MoO_3 sublimation has been reported to occur for $ZrMo_2O_8$ at 750 °C.[4]

Variable-Temperature XRD Analysis

The composition- and temperature-dependence of the phase behaviors of $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ solid solutions were examined by variable-temperature XRD measurement in real time as they are expected to indicate the mechanism responsible for the phase transition detected by the DSC measurements. Figures 3 and 4 show the variable-temperature XRD patterns of $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$ and $ZrMo_{0.4}W_{1.6}O_7(OH)_2(H_2O)_2$, respectively. Based on refined XRD patterns of $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$, it is evident that precursors at the temperature below the endothermic peak exist in the form of a tetragonal phase. As demonstrated by the typical XRD patterns of $ZrMo_{1.6}W_{0.4}O_8$ in the temperature range 120–508 °C and $ZrMo_{0.4}W_{1.6}O_8$ in the temperature range 197–567 °C, all $ZrMo_{2-x}W_xO_8$ solid solutions (x = 0.2–2.0) formed by precursor dehydration show XRD patterns similar to that observed for o-$ZrMo_{0.4}W_{1.6}O_8$.[12] Hence, the XRD patterns of all $ZrMo_{2-x}W_xO_8$ solid solutions can be indexed using the orthorhombic structure of o-$ZrMo_{0.4}W_{1.6}O_8$ with the space group $Pmn2_1$ as reference; the indexed results are summarized in Table 1.

A close inspection of the XRD pattern of $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$ collected at 120 °C (Figure 3) reveals a shoulder diffraction peak located at 21° (2θ), which seems to be assignable to the 111 diffraction of o-$ZrMo_{1.6}W_{0.4}O_8$. The appearance of this shoulder indicates the beginning of the dehydration of the $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$ precursor; this dehydration process is complete at around 149 °C, as demonstrated by the disappearance of the XRD pattern of the hydrate precursor at this temperature. The accompanied enhancement and sharpening of the XRD peaks upon increasing the temperature from 149 to 486 °C illustrates that o-$ZrMo_{1.6}W_{0.4}O_8$ grows subsequently to the fine crystal. Combing the XRD patterns with the DSC curves displayed in Figure 2 shows that the o-$ZrMo_{1.6}W_{0.4}O_8$ phase converts into the cubic phase c-$ZrMo_{1.6}W_{0.4}O_8$ at 508 °C, which converts, in turn, into the thermodynamically stable trigo-

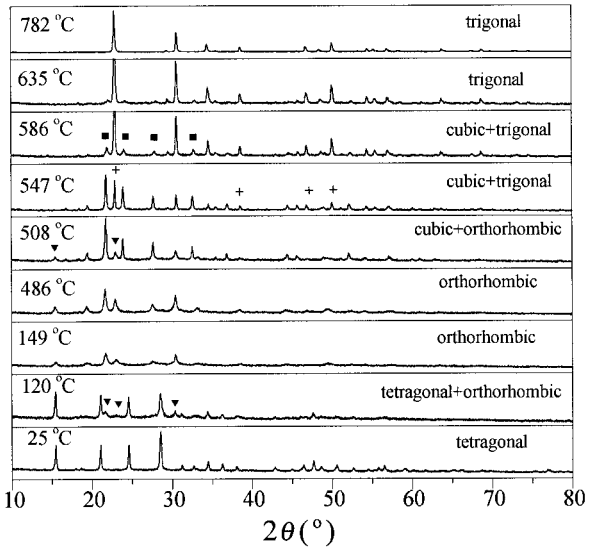

Figure 3. The variable-temperature XRD patterns of $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$ (25 °C) and $ZrMo_{1.6}W_{0.4}O_8$. The diffraction peaks characterizing the polymorphs are marked by a black triangle (▼) (orthorhombic), a black square (■) (cubic), or (+) (trigonal). The denoted temperatures were calibrated against KCl.

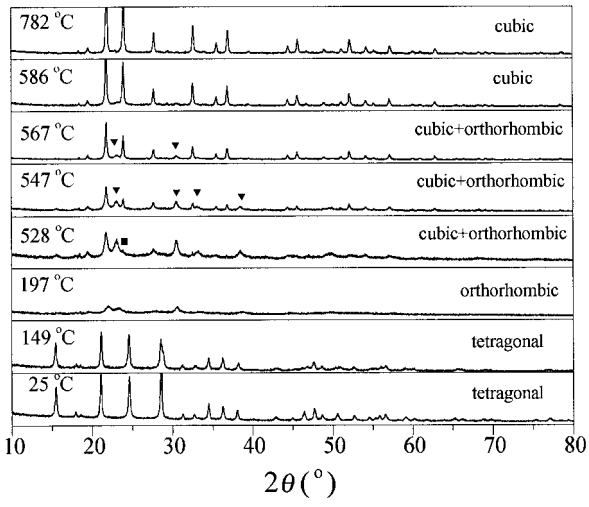

Figure 4. The variable-temperature XRD patterns of $ZrMo_{0.4}W_{1.6}O_7(OH)_2(H_2O)_2$ (≤149 °C) and $ZrMo_{0.4}W_{1.6}O_8$. The diffraction peaks characterizing the polymorphs are marked by a black triangle (▼) (orthorhombic) or a black square (■) (cubic). The denoted temperatures were calibrated against KCl.

nal phase within a narrower temperature "window" of about 54 °C (508–562 °C) at the expense of formation of a pure cubic phase. Therefore, the pure cubic phases of Mo-rich solid solutions can be formed only under carefully controlled temperature conditions.

The pure trigonal $ZrMo_{2-x}W_xO_8$ (x = 0.2–0.7) was prepared at 782 °C and was indexed by using the α′-$ZrMo_2O_8$ model of space group $P\bar{3}m1$[13] rather than α-$ZrMo_2O_8$ of space group $P\bar{3}1c$,[14] because of the absence of 201, 103, and 211 diffractions in the XRD pattern of trigonal $ZrMo_{1.6}W_{0.4}O_8$. The pure trigonal phases of $ZrMo_{2-x}W_xO_8$ (x = 0.2–0.7) are thermodynamically stable up to 800 °C; their lattice parameters are summarized in Table 2.

Table 1. Lattice parameters of o-$ZrMo_{2-x}W_xO_8$ solid solutions at 386 °C.

Table 2. The lattice parameters of the trigonal phase of $ZrMo_{2-x}W_xO_8$ (x = 0.2–0.7) solid solutions at 782 °C.

x	a [Å]	c [Å]	V [Å^3]
0.2	5.824	6.051	177.7
0.4	5.833	6.075	178.9
0.6	5.825	6.040	177.4
0.7	5.823	6.036	177.3

The stability of cubic $ZrMo_{2-x}W_xO_8$ solid solutions (x = 0.2–0.8) increases rapidly with increasing W-fraction (x) from 0.2 to 0.8. As indicated in Figure 2, the metastable pure cubic phases of the solid solutions of x = 0.7 and 0.8 exist over a wide temperature range, and when x is greater than or equal to 1.0 the metastable cubic phase can be found even at temperature up to 800 °C.

Figure 4 indicates that the W-rich solid solution $ZrMo_{0.4}W_{1.6}O_7(OH)_2(H_2O)_2$ converts completely into orthorhombic o-$ZrMo_{0.4}W_{1.6}O_8$ at 197 °C, which is stable up to 528 °C. This observation suggests that the orthorhombic isomorphs of W-rich solid solutions appear to be more stable than those of Mo-rich solid solutions.

The appearance of the small peak located at about 23.8° (2θ) due to the 211 diffraction of the cubic phase in the XRD pattern collected at 528 °C indicates further that W-rich o-$ZrMo_{2-x}W_xO_8$ solid solutions, including o-$ZrMo_{0.4}W_{1.6}O_8$, convert into a cubic phase at 528 °C and that these cubic phases, except x = 2.0, are stable at temperatures up to 782 °C. Since the 310 diffraction of 31° (2θ) disappears at this temperature, the cubic phase can be assigned to the structure type β-ZrW_2O_8. This feature is true for all W-rich solid solutions.

Phase Behaviors of Solid Solutions

Figure 2 displays the phase-transition processes of $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ solid solutions deduced on the basis of the XRD and DSC experiments outlined above. It can be seen that decomposition of the precursors proceeds through a sequential phase-transition process, namely tetragonal → orthorhombic → cubic → trigonal polymorphs. The phase-transition temperatures increase with increasing

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

W-fractions. This dependence is understandable in terms of the bond strength of W–O, which is stronger than that of Mo–O (the bond-dissociation energies for these bonds are 672.0 ± 41.8 and 560.2 ± 20.9 kJ mol^{-1}, respectively).[15]

The difference in phase-transition mechanism of W-rich and Mo-rich solid solutions can be interpreted in terms of trigonal phase formation. Cubic ZrW_2O_8 is metastable over a wide temperature range below 777 °C, whereas the cubic phase of $ZrMo_2O_8$ is dynamically stable only over a narrower window ranging from 480 to 520 °C, above which trigonal $ZrMo_2O_8$ crystallizes.[4] So, it would be expected that the stability of cubic phases of $ZrMo_{2-x}W_xO_8$ solid solutions at high temperature would be greater for W-rich $ZrMo_{2-x}W_xO_8$ solid solutions due to prevention of trigonal phase formation. A close inspection of the phase-composition dependence of behaviors for the $ZrMo_{2-x}W_xO_8$ solid solution reveals indeed that a dynamic equilibrium between these two processes can be established at $x = 1.0$, above which, i.e. $1 \leq x < 2$, the cubic phase is stable at temperatures up to 800 °C; however, the stable cubic phase is difficult to form in solid solutions of $x \leq 0.8$ in the same temperature range.

It is of interest to note that the stability of $ZrMo_{2-x}W_xO_8$ solid solutions can be improved by increasing the Mo fraction. In this way, the decomposition of this solid solution to the corresponding oxides can be prevented even at 800 °C. Therefore, as compared to both ZrW_2O_8 and $ZrMo_2O_8$, $ZrMo_{2-x}W_xO_8$ solid solutions appear to be more stable due to the entropy effect induced by W or Mo doping. Moreover, $ZrMo_{2-x}W_xO_8$ ($1 \leq x \leq 1.6$) solid solutions show a lower phase-transition temperature and have negative expansion coefficients; they are also stable over a wider temperature range. All these factors make solid solutions of this kind more attractive for use in optical and electronic devices.

Preparation of an Mo-Rich $ZrMo_{2-x}W_xO_8$ Solid Solution of a Pure Cubic Phase

Variable-temperature XRD measurements of $ZrMo_{2-x}W_xO_8$ in real time demonstrate that the yield for the orthorhombic → cubic as well as the cubic → trigonal phase-transition depends not only on the system composition and temperature, but also on the temperature-holding time. Hence, strict control of both the temperature and temperature-holding time are crucial for preparation of an Mo-rich cubic phase. The pure cubic phase of $ZrMo_2O_8$ has been synthesized by Lind[4] under rigorously controlled experimental conditions. Following the thermal phase-transition process formulated on the basis of our DSC and XRD data outlined above, we have successfully prepared a pure cubic phase of Mo-rich solid solutions $ZrMo_{2-x}W_xO_8$ with $x = 0.4$, 0.6 and 0.7, 0.8 by holding the temperature at 520 and 530 °C, respectively, for 2 h, followed by rapid cooling to room temperature. It should be noted that a higher temperature is able to accelerate the trigonal phase formation. In addition, a pure cubic phase of $x = 0.2$ cannot be formed in this way, although it can be prepared by two-step heating, i.e. by heating at 365 °C for 12 h and then 5 h at 450 °C. The cubic phases prepared under such conditions do not show a 310 (30.9°) diffraction, and hence are assignable to crystalline β-ZrW_2O_8 type structure, for which the indexed pattern is displayed in Figure 5; lattice parameters of c-$ZrMo_{2-x}W_xO_8$ ($x = 0.2$, 0.4, 0.6, 0.7, and 0.8) are listed in Table 3.

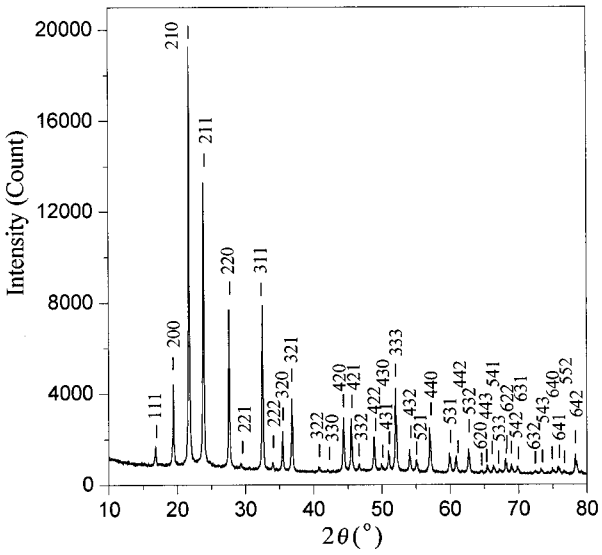

Figure 5. The indexed X-ray diffraction pattern for c-$ZrMo_{1.6}W_{0.4}O_8$.

Table 3. Lattice parameters of c-$ZrMo_{2-x}W_xO_8$ ($x = 0.2$, 0.4, 0.6, 0.7, and 0.8).

x	a [Å]
0.2	9.1311(1)

0.7	9.1318(9)
0.8	9.1317(1)

Conclusions

The precursors $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ ($x = 0.2$–2.0) are converted into a $ZrMo_{2-x}W_xO_8$ orthorhombic phase within an x-dependent temperature range from 124 to 203 °C by removal of three water molecules. The temperature dependence of $ZrMo_{2-x}W_xO_8$ shows two types of phase behavior: the orthorhombic phases of Mo-rich $ZrMo_{2-x}W_xO_8$ ($x = 0.2$–0.8) are able to convert into trigonal phases, with cubic phase formation as the intermediate step, and the metastable pure cubic phases can be prepared by carefully controlling the temperature and temperature-holding time in the appropriate temperature range. However, no trigonal phases can be formed in the W-rich solid solutions $ZrMo_{2-x}W_xO_8$ ($x = 1.0$–1.6). In addition, the solid solutions of this type do not decompose even at temperatures up to 800 °C, even though the decomposition

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature of ZrW_2O_8 is 773 °C. Therefore, doping of tungsten into cubic $ZrMo_2O_8$ increases its stability towards decomposition.

Experimental Section

Preparation and Characterization of $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ Precursors: Precursors $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ were prepared following procedures described previously.[5,7] Briefly, the reactants $Na_2WO_4{\cdot}2H_2O$, $Na_2MoO_4{\cdot}2H_2O$, and $ZrOCl_2{\cdot}8H_2O$ (A.R. grade) were first heated at 800 °C for 6 h and the exact hydration number was re-determined based on the water loss. Dropwise addition of 50 mL of an aqueous solution of 0.5 M Zr^{4+}, together with 50 mL of an aqueous solution of 1 M mixed ionic solution [W^{6+} + Mo^{6+}] with different x (x = 0.2, 0.4, 0.6, 0.7, 0.8, 1.0, 1.2, 1.4, 1.6, or 2.0), into 30 mL of distilled water led to immediate formation of a white precipitate. The white turbid solution formed was then mixed with 182 mL of 6 M aqueous HCl solution with continuous stirring for 4 h and then refluxed for 48 h. The white precipitate was finally separated by centrifugation and washed sequentially with 1.5 M aqueous HCl and distilled water. The obtained products were confirmed to have the desired Zr to W/Mo ratios as indicated by the negligible amounts (<1%) of these ions in the decanted liquid determined by ICP-AES (JY, ULTIMA, France).

The hydration number of the precursors $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ was estimated from the weight-loss percentage of the dried white precipitate measured by TG (Netzsch Sta 409C).

The refined XRD pattern of $ZrMo_{1.6}W_{0.4}O_7(OH)_2(H_2O)_2$, as a typical example, is shown in Figure 6; it indicates that all white or slightly pale $ZrMo_{2-x}W_xO_7(OH)_2(H_2O)_2$ powders are isomorphs of tetragonal $ZrMo_2O_7(OH)_2(H_2O)_2$. The final refinement results are listed in Table 4.

DSC Measurements: DSC curves in the temperature range 40–800 °C were recorded with a DTA-404 PC (Netzsch), under argon, at a heating rate of 10 °C min^{-1}; an empty crucible was used as the reference. The DSC curve of the samples was calibrated using those recorded for a pair of blank platinum crucibles under the same conditions. The peak temperatures were calibrated using the metals In, Sn, Bi, Zn, Al, Ag, Au, and Ni as standard substances and the precision was estimated to be ±1 °C.

X-ray Crystallographic Equipment and Temperature Calibration: The XRD patterns were collected on a Philips X′-Pert MPD diffractometer with X′Celerator detector using Cu-K_α radiation (40 kV, 40 mA). Each ground sample was mounted on a platinum strip, which served as sample holder as well as heater attached with Anton Parr high-temperature units used for variable temperature XRD measurements. The routine XRD patterns were collected within the 2θ range 10–120° with a step width of 0.0167° (2θ) and

step time of 20 s, whereas the variable temperature XRD patterns were recorded within the 2θ range 10–80° with the same step width and a step time of 30 s. The measurements were carried out under argon at temperatures at which the possible phase transition was suggested to occur according to the DSC data. The heating rate between two neighboring temperature was about 2 °C min^{-1} and at each point the temperature was held for 20 min. The temperatures during the measurement were controlled with a TCU 2000 unit and were calibrated using an interpolation technique based on the Pathak equation[16] with KCl as the external standard.

The observed profiles of the XRD patterns for the precursors were refined using the Rietveld method contained in the GSAS program[17] by fitting to tetragonal $ZrMo_2O_7(OH)_2(H_2O)_2$[8] as the model. The refinement was started with lattice parameters and atomic coordinates assigned from the model. The site fraction of Mo/W atom was fixed as the intended ratio according to the precursor formula. The fitting was carried out for the lattice parameters, the scale parameters, background coefficients, and profile coefficients. Finally, the atomic coordinates and the isotropic thermal factors of metals (Zr, Mo, W) were refined.

Analysis and indexing of the XRD patterns for $ZrMo_{2-x}W_xO_8$ were performed using the PowderX program.[18] The zero-point shifts was corrected using the line-pair method. SiO_2 was used as an internal standard to correct the XRD peak positions used to calculate the precise lattice parameters of cubic $ZrMo_{2-x}W_xO_8$.

Synthesis and Structural Characterisation of Group 10 Homo- and Hetero-Dimetallic Sulfur-Bridged Complexes of the [Ni(ema)(μ-*S*,*S*′)M(diphos)] (M = Ni, Pd, Pt) Type

Samantha E. Duff,[a] J. Elaine Barclay,[a] Sian C. Davies,[a] Peter B. Hitchcock,[b] and David J. Evans*[a]

Keywords: Nickel / Palladium / Platinum / Heterometallic complexes

The series of group 10 homo- and hetero-dimetallic sulfur-bridged complexes [Ni(ema)(μ-*S*,*S*′)M(diphos)], [M = nickel, palladium or platinum; diphos = 1,3-bis(diphenylphosphanyl)-propane or 1,2-bis(diphenylphosphanyl)ethane], have been synthesised. Their properties and the crystal structures of five of the series are described. The dinickel complexes are good structural analogues of the dinickel subunit of the nickel-containing enzyme acetyl-CoA synthase.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The nickel enzyme acetyl-CoA synthase catalyses the synthesis of acetyl-CoA. The reaction parallels the industrially important Reppe process for the synthesis of acetic acid, both apparently involving metal–carbonyl, methyl–metal and acyl–metal intermediates.[1] Protein crystallography[2–4] shows at the active site, the A cluster, an Fe_4S_4 cluster bridged through cysteinylthiolate sulfur to a proximal nickel that is then linked to a distal nickel(II) atom in an N_2S_2 coordination environment, Figure 1. The *cis*-planar N_2S_2 coordination is from a deprotonated Cys–Gly–Cys sequence of the protein. Following publication of the crystal structures there has been a renewed vigour in the preparation of dinuclear group 10 complexes as mimics for the dinickel sub-site of the A cluster.[5–10] Herein we report the synthesis and properties of the series of complexes [Ni(ema)(μ-*S*,*S*′)M(diphos)], where M is nickel, palladium or platinum, H_4ema is *N*,*N*′-ethylenebis(2-mercaptoacetamide) and where diphos is 1,3-bis(diphenylphosphanyl)propane (dppp) or 1,2-bis(diphenylphosphanyl)ethane (dppe).

Results and Discussion

Synthesis and Spectroscopy

Previously, we have demonstrated that the homonuclear complexes [Ni(ema)(μ-*S*,*S*′)Ni(dppp)] (**1**) and [Ni(ema)(μ-*S*,*S*′)Ni(dppe)] (**2**) can be readily prepared from the reaction of equimolar amounts of $[NEt_4]_2$[Ni(ema)] and [$NiCl_2$(diphos)] in acetonitrile solution.[5] Here, a similar methodology has been applied to isolate, from the appropriate [MCl_2(diphos)], the heteronuclear dimetallic complexes [Ni(ema)(μ-*S*,*S*′)M(diphos)], M = Pd, diphos = dppp (**3**) or dppe (**4**); M = Pt, diphos = dppp (**5**) or dppe (**6**), in good yield, Equation (1).

$$[NEt_4]_2[Ni(ema)] + [MCl_2(diphos)] \rightarrow [Ni(ema)(\mu\text{-}S,S')M(diphos)] + 2[NEt_4]Cl \quad (1)$$

All complexes have been characterised by EI-MS and the structures of **1**[5] and **3**–**6** have been confirmed by X-ray crystallography. Satisfactory elemental analyses (C, H, N) are obtained for all compounds except **3**, which, for reasons unknown, gave consistently poor results. However, spectroscopic parameters and the mass spectrum of this compound are fully consistent with the crystal structure.

In the solid, complexes **1**–**6** exhibit an infra-red amidocarbonyl stretch in the range 1566–1578 cm^{-1}. The $^{31}P\{H\}$ NMR chemical shifts for solutions in methanol and in dimethyl sulfoxide are consistent with diphosphane chelate ligation and, as expected, depend on the chelate ring size; the chemical shifts observed for five-membered (dppe) chelate rings (ca. 49 to 62 ppm) are larger than those for six-membered (dppp) rings (ca. –5 to 1 ppm).[11] The single resonance observed in each case confirms the equivalence of the phosphorus atoms in solution at ambient temperature. The values for **2** are comparable to those of the related complexes [Ni(L)(μ-*S*,*S*′)Ni(dppe)]$(PF_6)_2$ {L = *N*,*N*′-diethyl-3,7-diazanonane-1,9-dithiolate(2–)} (CD_2Cl_2, 61.1 ppm)[6] and [Ni(CGC)(μ-*S*,*S*′)Ni(dppe)] (CGC = cys–gly–cys) (CD_3CN, 56.7 and 57.5 ppm).[8]

In the solid state the nickel complexes are coloured green, palladium blue-black and platinum red. The electronic absorption spectra of solutions of **1**–**6** exhibit several absorbance peaks as expected, and their parameters are collected in Table 1. The colour in solution is dependent on solvent, Table 2. The nickel and palladium complexes show a dramatic colour difference on changing solvent from acetonitrile to methanol. This is a consequence of the ability of such square-planar complexes to coordinate extra (solvent) ligands in solution to establish an equilibrium between four-, five- and six-coordinate species.[12] However, the NMR in methanol does not support the presence of a six-coordinate, paramagnetic species.

Table 2. Colour of solutions of complexes **1**–**6** in acetonitrile and methanol.

Complex		MeCN	MeOH
[Ni(ema)Ni(dppp)]	(**1**)	emerald green	midnight blue
[Ni(ema)Ni(dppe)]	(**2**)	emerald green	indigo
[Ni(ema)Pd(dppp)]	(**3**)	royal blue	deep red
[Ni(ema)Pd(dppe)]	(**4**)	violet	burgundy
[Ni(ema)Pt(dppp)]	(**5**)	cerise	pink
[Ni(ema)Pt(dppe)]	(**6**)	peach	orange

The cyclic voltammogram of **1** in dichloromethane shows a reversible one electron process at $E_{1/2}$ = –0.42 V (vs. SCE) assigned to a Ni^{II}/Ni^{I} couple of the NiP_2S_2 moiety, a similar process at $E_{1/2}$ = –0.47 V (vs. SCE) has been reported for [Ni(L)(μ-*S*,*S*′)Ni(dppe)]$(PF_6)_2$.[6] A second feature at E_{pc} = –1.39 V (vs. SCE) may be assigned to an irreversible reduction Ni^{I}/Ni^{0} at NiP_2S_2 or an irreversible Ni^{II}/Ni^{I} couple at the other nickel site. The cyclic voltammetry of the complexes **2**–**6** has not been investigated.

It has been observed that 1,10-phenanthroline will chelate and extract the proximal nickel from the acetyl-CoA synthase A cluster.[13] The effect has been observed also in a synthetic analogue, [Ni(PhPepS)(μ-*S*,*S*′)Ni(dppe)] {$PhPepSH_4$ = *N*,*N*′-phenyl(*o*-mercaptobenzamide)}, of the dinickel subsite of the A cluster where it is proposed that the nickel is removed from the NiP_2S_2 unit.[9] The same reaction occurs with complexes **1** and **2**, in dichloromethane solvent, using a ten-fold excess of 1,10-phenanthroline.

There is, however, under similar conditions, no reaction of 1,10-phenanthroline with the heterometallic complexes **3**–**6**, with $[NEt_4]_2$[Ni(ema)] or with the trinickel complex $[NEt_4]_2$-[Ni{Ni(ema)(μ-*S*,*S*′)}$_2$],[5] which provides further confirmation that the phosphine-ligated nickel is lost and that the nickel atom associated with the Ni(ema) moiety is not chelated by 1,10-phenanthroline.

Structures

The crystal structure of **1**·Et_2O[5] (Figure 2) shows that each nickel ligand sphere is slightly distorted square planar, with nickel(1) ligated by the two phosphorus atoms from the dppp ligand and the two sulfur atoms of the ema ligand and the other nickel, (2), ligated by the two nitrogen and two sulfur atoms of the ema ligand. The dppp-ligated nickel atom may be considered to lie within the S_2P_2 mean plane [displaced 0.0035(5) Å from the plane towards the ema-ligated Ni], which is essentially flat [deviations from the mean planes lie in the range –0.0238(9) to 0.0241(9) Å, where the negative sign indicates opposite side of the mean plane]; the most distorted angle about this nickel is 80.93(3)°. This is similar in the other two dppp-ligated metal complexes, with the metal atoms lying within 0.020(2) Å of the S_2P_2 mean planes, which in turn have atoms lying in the ranges –0.017(3) to 0.017(4) and –0.010(2) to 0.010(2) Å from the mean planes in **3** and **5**, respectively. This is, however, different to the arrangement in the dppe-ligated complexes. In these, the S_2P_2 planes are twisted with atoms lying in the ranges –0.2134(13) to 0.2109(13) Å and –0.2556(13) to 0.2590(13) Å in the two independent molecules in **4** and –0.1925(3) to 0.1949(13) in **6**. The metal atoms lie 0.1075(6) and 0.0712(6) Å from the mean planes in **4** and 0.0591(6) in **6**. The ema-chelated nickel atom lies 0.1534(6) Å from the N_2S_2 plane [displaced in the direction away from Ni(1)] with an angle of 169.52(8)° for a N–Ni–S angle being the most distorted. This distortion is similar in all the complexes. The dihedral (hinge) angle at the bridging sulfur atoms in **1** is 111.22°. The Ni–S bond lengths within the chelate ring (2.12 Å) are slightly shorter and the bridge distances (2.28 Å) slightly longer than those observed (2.14–2.19 Å and 2.19–2.24 Å, respectively) for other synthetic sulfur-bridged dinickel complexes such as [Ni(L)(μ-*S*,*S*′)-Ni(dppe)]$(PF_6)_2$.[6] Other angles and bond lengths about the nickel atoms and the Ni···Ni distance [2.6897(5) Å] are similar to those reported for related "Ni(μ-S)$_2$NiN_2" structures.[7]

The Ni(ema) group of the complex forms a curved "wall" around two of the phenyl groups of the dppp ligand, which are orientated "edge-on" to the Ni(ema) group. Within each PPh group, the normals to the second phenyl rings are orientated at 111.3 and 102.6°, respectively, to those of the first two. The complex molecules are arranged with the Ni(ema) groups forming approximate (due to the curved nature of the ema ligands) planes parallel to the crystallographic *bc* plane; viewed along the crystallographic *b* direction, the molecules are arranged in pairs with the Ni(dppp) groups in

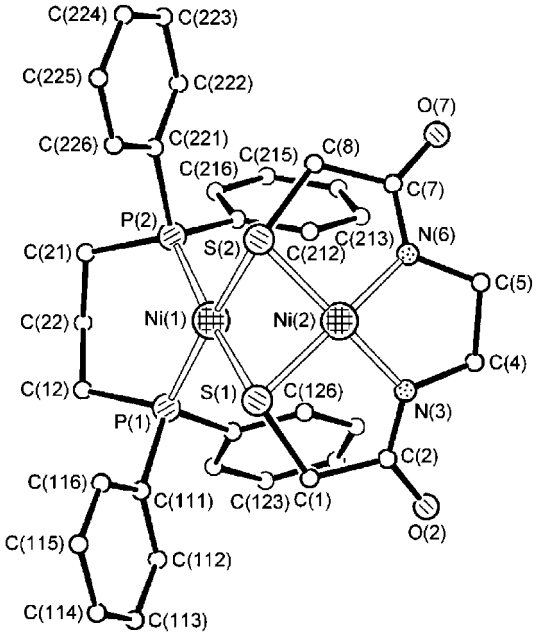

Figure 2. A view of [Ni(ema)(μ-*S*,*S*′)Ni(dppp)] (**1**) showing atom numbering scheme, hydrogen atoms omitted for clarity.

alternating *ab* planes lying on opposite sides of the Ni(ema) planes (Figure 3). This packing arrangement is identical to that in **3** and **5**, while the Ni–ema planes are also found in **4** and **6**. There is a difference in the packing in **6**, however, as the Pt–dppe groups are not "staggered" along the crystallographic *a* vector as they are in the other four arrangements.

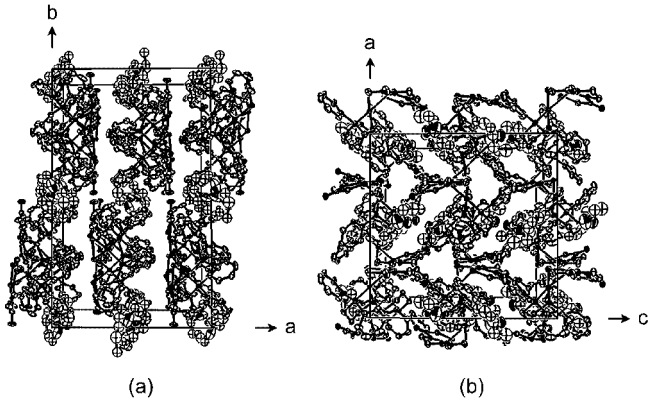

Figure 3. Packing arrangements of [Ni(ema)(μ-*S*,*S*′)Ni(dppp)] (**1**) as viewed along (a) the crystallographic *c* axis and (b) the *b* axis.

The [Ni(ema)(μ-*S*,*S*′)M(diphos)] molecules in complexes **3**, **4**, **5** and **6** have structures similar to complex **1**. In **4** there are two independent molecules within the asymmetric unit. Representative structures of the heterometallic complexes **3** and **4** are shown in Figure 4 and Figure 5, respectively. A comparison of selected bond lengths and angles are given in Table 3. On substitution of nickel(1) by palladium, there is no significant change in the average Ni–N bond length and only a very slight lengthening of the average Ni–S bond length within the Ni(ema); replacement of palladium by

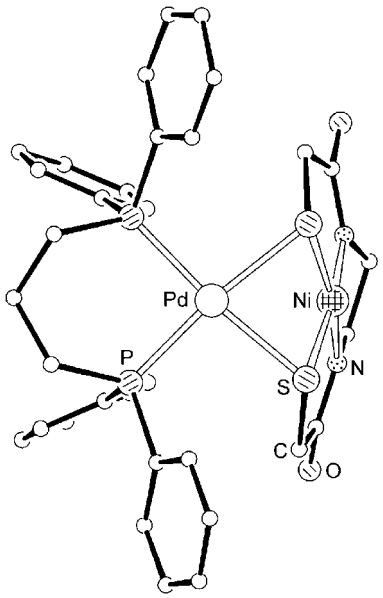

Figure 4. A molecule of [Ni(ema)(μ-*S*,*S*′)Pd(dppp)] (**3**), hydrogen atoms omitted for clarity.

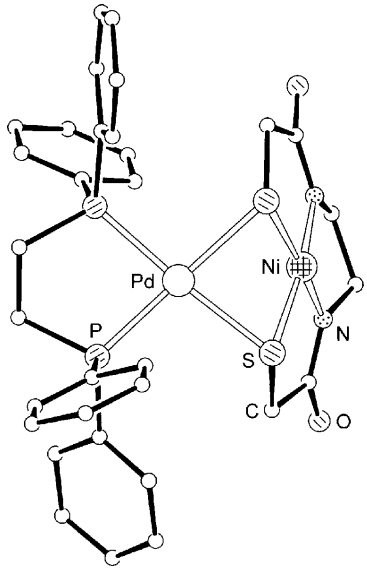

Figure 5. Molecular structure of [Ni(ema)(μ-*S*,*S*′)Pd(dppe)] (**4**), hydrogen atoms omitted for clarity.

platinum leads to no further increase in bond length. Within the NiP_2S_2 fragment there is again an elongation of the M–P and M–S bond lengths on substitution of nickel(1) by palladium (0.08 and 0.13 Å, respectively) but no further change when palladium is replaced by platinum. On changing from dppp to dppe chelation, independent of metal, there is a decrease in the M–P–C(alkane) angle from ca. 116° to ca. 108° that helps maintain the square-planar environment. The dihedral (hinge) angle at the bridging sulfur atoms is similar in all complexes, ranging from 111–117°. The nickel to metal distance increases from 2.6897(8) Å in **1** to 2.780(2) Å in **3**, which is similar to the distance in the heterometallic complexes **4** and **5** and slightly shorter than that in **6** [2.8653(5) Å]. The longer platinum–nickel distance is consistent with the larger hinge angle in the latter complex.

Conclusions

The series of six group 10 homo- and hetero-dimetallic sulfur-bridged complexes of the [Ni(ema)(μ-*S*,*S*′)-M(diphos)] (M = Ni, Pd, Pt; diphos = dppp, dppe) type have been prepared and characterised; five by X-ray crystallography. The geometric parameters about the metal atoms for complex **1** and **3**–**6** resemble those reported for the dinickel subunit of the A-cluster of acetyl-CoA synthase: in complex **1** the nickel(1) and nickel(2) atoms mimic the A cluster distal nickel and proximal nickel, respectively.

Experimental Section

General: All manipulations were performed under dinitrogen, unless otherwise stated, using either Schlenk or vacuum-line techniques. Solvents were dried with appropriate drying agents and distilled under dinitrogen prior to use. [$NiCl_2$(dppp)] was purchased from Aldrich and [Pd(1,5-cylcooctadiene)Cl_2], [Pt(1,5-cylcooctadiene)Cl_2] and [$PdCl_2$(dppe)] were purchased from Alfa Aeser. [NEt_4]$_2$-[Ni(ema)],[14] [$PtCl_2$(dppp)], [$PtCl_2$(dppe)] and [$PdCl_2$(dppp)] were obtained by adaptation of published procedures.[15] [Ni(ema)(μ-*S*,*S*′)Ni(dppp)] (**1**) and [Ni(ema)(μ-*S*,*S*′)Ni(dppe)] (**2**) were prepared as we recently reported.[5] IR spectra were recorded with a Shimadzu FTIR-8000 spectrophotometer and UV/Vis spectra with a Perkin–Elmer Lambda 25. ^{31}P NMR were obtained with a Jeol Lambda 400 spectrometer. Electrospray ionisation mass spectra, in methanol solution, were measured with a Deca XP_{plus} ion trap mass spectrometer from Thermo Finnigan. Elemental analyses were by Medac Ltd, Egham, Surrey, UK.

Preparations

[Ni(ema)(μ-*S*,*S*′)Pd(dppp)] (3): A slurry of [$PdCl_2$(dppp)] (0.146 g, 2.49×10^{-4} mol) in MeCN (20 mL) was added to a stirred solution of [NEt_4]$_2$[Ni(ema)] (0.130 g, 2.49×10^{-4} mol) in MeCN (10 mL). The resultant black solution was stirred at room temp. for 12 h, then diethyl ether (10 mL) was added dropwise. Within 4 h blue-black crystals were formed and collected by filtration (0.12 g, 62%). IR (KBr): $\tilde{\nu}_{max}$ = (CO) 1578 cm^{-1}. ^{31}P NMR (162 MHz. CD_3OD; ref. H_3PO_4): δ = –5.11 (s) ppm, ([D_6]DMSO): δ = 5.22 (s) ppm. MS: *m*/*z* = 783 (100) [$M^+ + H^+$].

[Ni(ema)(μ-*S*,*S*′)Pd(dppe)] (4): To a slurry of [$PdCl_2$(dppe)] (0.300 g, 5.22×10^{-4} mol) in MeCN (10 mL) was added solid [NEt_4]$_2$-[Ni(ema)] (0.273 g, 5.22×10^{-4} mol) and additional MeCN (5 mL). The resultant black solution was stirred at room temp. for 30 min, then diethyl ether (5 mL) was added dropwise. A brown solid (0.25 g, 63%) was collected by filtration. $C_{32}H_{32}N_2NiO_2P_2PdS_2$ (767.80): calcd. C 50.1, H 4.2, N 3.7; found C 50.0, H 4.2, N 3.7. IR (KBr): $\tilde{\nu}_{max}$ = (CO) 1567 . ^{31}P NMR (162 MHz. CD_3OD; ref. H_3PO_4): δ = 62.64 (s) ppm, ([D_6]DMSO): δ = 61.96 (s) ppm. MS: *m*/*z* = 769 (100) [$M^+ + H^+$]. Recrystallisation from a methanol/diethyl ether mixture gave blue-black crystals of **4**·1½MeOH (0.22 g, 52%).

[Ni(ema)(μ-*S*,*S*′)Pt(dppp)] (5): To a white slurry of [$PtCl_2$(dppp)] (0.330 g, 4.87×10^{-4} mol) in MeCN (20 mL) was added a solution of [NEt_4]$_2$[Ni(ema)] (0.255 g, 4.87×10^{-4} mol) in MeCN (10 mL). The solution was stirred for a further 10 min before the volume was decreased in vacuo to 15 mL. Diethyl ether was layered onto the solution and a red product precipitated overnight which was collected by filtration (0.29 g, 68%). $C_{33}H_{34}N_2NiO_2P_2PtS_2$ (870.48): calcd. C 45.5, H 3.9, N 3.2; found C 46.0, H 4.4, N 3.2. IR (KBr): $\tilde{\nu}_{max}$ = (CO) 1578 cm^{-1}. ^{31}P NMR (162 MHz. CD_3OD; ref. H_3PO_4): δ = –3.70 (s) ppm; ([D_6]DMSO): δ = –2.87 (s) ppm. MS: *m*/*z* =871 (100) [$M^+ + H^+$]. Recrystallisation from dichloromethane gave crystals of **5**·2CH_2Cl_2.

[Ni(ema)(μ-*S*,*S*′)Pt(dppe)] (6): Compound **6** was prepared similarly to **5** in 69% yield from [$PtCl_2$(dppe)]. $C_{32}H_{32}N_2NiO_2P_2PtS_2$ (856.46): calcd. C 44.9, H 3.8, N 3.3; found C 43.9, H 4.0, N 3.3. IR (KBr): $\tilde{\nu}_{max}$ = (CO) 1566 cm^{-1}. ^{31}P NMR (162 MHz. CD_3OD; ref. H_3PO_4): δ = 49.01 (s) ppm; ([D_6]DMSO): δ = 48.92 (s) ppm. MS: *m*/*z* =857 (100) [$M^+ + H^+$].

Crystal Data

Mononuclear and Polynuclear Chain Complexes of a Series of Multinucleating N/S Donor Ligands

Tanya K. Ronson,[a] Harry Adams,[a] and Michael D. Ward*[a]

Keywords: Chelates / Coordination chemistry / Copper / Silver / Helical structures

We have prepared a series of five ligands with potentially N,S-bidentate chelating arms derived from 3-[2-(methylsulfanyl)phenyl]pyrazole linked to central aromatic spacers by methylene units. Complexes with a variety of architectures have been obtained, including simple mononuclear complexes and polynuclear chain complexes. The *p*-xylyl-spaced ligand L^1 forms one-dimensional helical coordination polymers with copper(I) and silver(I) ions. These polymers display interligand aromatic stacking interactions within each helical chain. The *m*-xylyl-spaced ligand L^2 forms a coordination polymer with copper(I) but a mononuclear complex with the larger silver(I) ion in which the central phenyl ring is involved in an η^1 π-type Ag···C interaction with the Ag^I. The 3,3′-biphenyl-spaced ligand L^3 also forms one-dimensional polymers with silver(I) and copper(I) ions, but in this case the sequence of bridging ligands between one metal centre and the next follows a zig-zag path rather than being helical. The 1,8-naphthyl-spaced ligand L^4 only forms mononuclear complexes with copper(I) and silver(I) ions showing that this spacer is not large enough to enforce a bridging coordination mode. The three-armed ligand L^5, prepared from 2,4,6-tris-(bromomethyl)mesitylene, also forms a mononuclear complex with silver(I) ions, where one of the three arms is pendant. However, when excess silver(I) ions are present two of these mononuclear complexes can be assembled into the trinuclear complex $[Ag_3(L^5)_2](ClO_4)_3$.

Introduction

Metal-directed self assembly of elaborate polynuclear complexes relies in part on a good match between the stereoelectronic properties of the metal ion and the arrangement and type of donor sites on the bridging ligand.[1] With respect to the ligands, a minimum condition is that the binding sites must be arranged so that they bridge two or more metal centres, otherwise simple mononuclear complexes will result. If a bridging ligand is conformationally flexible, the competition between bridging and chelating coordination modes is an important factor in determining the course of a self-assembly reaction. To this end we have been investigating the coordination chemistry of ligands in which two N,N-bidentate, chelating pyrazolylpyridine groups are connected by a range of different spacer groups, which results in different separations between the two metal-ion binding sites. Depending on the nature of the spacer (a phenyl group, a biphenyl group, 1,8-naphthyl, and so on) and the coordination preferences of the metal ion, complexes have been isolated ranging in complexity from simple mononuclear species to dodecanuclear truncated-tetrahedral cages.[2]

In this paper we describe the synthesis and coordination behaviour of a related series of ligands based on N,S-donor chelating (pyrazolyl/thioether) fragments, the structures of whose complexes depend on the nature of the spacer separating the two chelating components. Potentially bridging N,S-donor ligands of this general type have been of some interest recently with respect to coordination with soft metal ions such as Cu^I and Ag^I; the combination of flexible bridging ligands with metal ions, which are tolerant of a wide range of coordination geometries has led to a remarkable collection of oligomeric and polymeric structures.[3] The complexes described in this paper illustrate in particular the propensity of the N,S-donor bridging ligands to afford one-dimensional helical coordination polymers, in contrast to the discrete M_2L_2 dinuclear double helicates which tend to form with the analogous N,O-donor ligands containing pyrazolylphenolate donor sites that we described recently.[4]

Results and Discussion

Syntheses and Structures of the Ligands

The ligands are shown in Scheme 1. 3-[2(Methylsulfanyl)-phenyl]pyrazole was prepared as described earlier,[5] and was treated with an appropriate bromomethylated aromatic compound under phase-transfer conditions[2] to give the new ligands L^1–L^5. The ligands L^1, L^2, L^3 and L^4 contain two potentially bidentate N,S-chelating units, with pyrazolyl and thioether donors, but differ in length due to variation in the length of the spacer unit. In contrast ligand L^5 is a

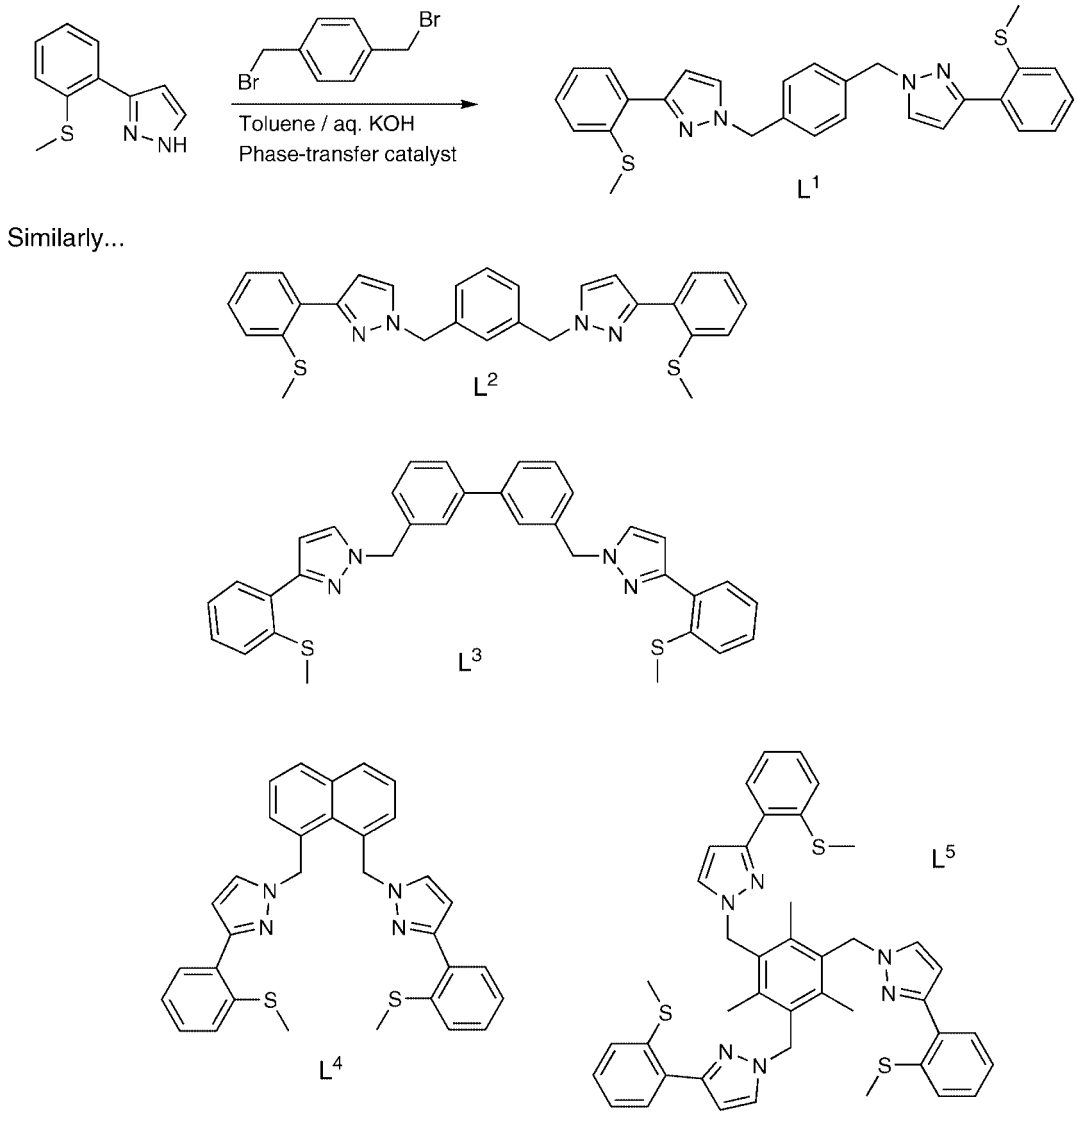

Scheme 1.

potentially hexadentate tripodal ligand with three bidentate arms linked to a central aromatic unit though methylene groups. The ligands were characterised by ^{1}H NMR and ^{13}C NMR spectroscopy, mass spectrometry and elemental analyses. Ligands L^1, L^4 and L^5 were also characterised by X-ray crystallography and their structures are shown in Figure 1, Figure 2, and Figure 3.

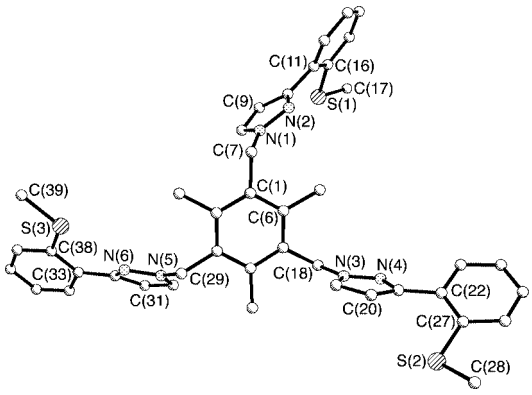

Figure 3. Molecular structure of L^5.

For L^1 the molecule lies astride a twofold axis of symmetry through the centre of the phenyl spacer, such that the two halves are crystallographically equivalent. The (methylsulfanylphenyl)pyrazole units adopt a *cisoid* configuration with the methyl group pointing away from the lone pairs of the pyrazole nitrogen atoms. The chelating units show a significant deviation from planarity with an angle of 26.6° between the methylsulfanylphenyl and pyrazole rings. The *cisoid* arrangement of the rings is, on the face of it, surprising because it brings the lone pairs of electrons on N(2) and S(1) into proximity; in polypyridyl ligands such as 2,2′-bipyridine, and the higher oligomers by contrast, adjacent pyridyl rings are always *transoid* so that the nitrogen lone pairs can avoid each other.[6] In fact the non-bonded N(2)···S(1) distance of 2.863(2) Å is in agreement with the known propensity of divalent S (and Se) atoms to become involved in relatively short contacts with nucleophilic atoms.[7] The nucleophile [here, pyrazolyl N(2)] tends to approach the S atom of an S–X bond in a direction corresponding to elongation of that bond, because of the involvement of the S–X σ* orbital in the interaction; in consequence the N···S–C angle should be nearly linear, consistent with other steric constraints, and in fact the angle N(2)–S(1)–C(14) is almost perfectly linear at 177.9(1)°.

L^4 also lies astride a twofold axis of symmetry which lies through the centre of the naphthyl spacer. The (methylsulfanylphenyl)pyrazole units this time adopt a *transoid* configuration, unlike the *cisoid* configuration observed in L^1; the chelating units show a significant deviation from planarity with an angle of 34.7° between the methylsulfanylphenyl and pyrazole rings. The two chelating arms are arranged on opposite sides of the plane of the central naphthyl spacer, and rotation of the methylsulfanylphenyl rings would be required in order for both arms to chelate to a single metal ion. It is clear from these structures that in L^1 the bidentate units are too far apart from one another to coordinate to a single metal ion, and L^1 must necessarily act as a bridging ligand. However, this is not the case for L^4 where a tetradentate chelating mode is also possible. There is no evidence for any inter- or intramolecular N···S interactions of the type seen for L^1.

Molecules of L^5 have no internal symmetry in the crystal. The chelating units show a significant deviation from planarity with angles of 39.5, 38.5 and 23.9° between the methylsulfanylphenyl and pyrazole rings. One of the (methylsulfanylphenyl)pyrazole units [involving atoms S(3) and N(6)] adopts a *cisoid* conformation, resulting again (as in L^1, above) in a relatively short N(6)···S(3) separation of 2.832 Å, and a near-linear N(6)···S(3)–C(39) angle of 175.7°, both consistent with an intermolecular donor-acceptor interaction involving the lone pair of N(3) and the S–C σ* orbital.[7] The torsion angle between these pyrazolyl and sulfanylphenyl rings is 23.9°. The other two methylsulfanylphenyl-pyrazole units, which have approximately *transoid* conformations, have a greater degree of twist between the aromatic rings (39.5 and 38.5°) because there is no N···S interaction which tends to keep the rings concerned more coplanar. Sulfur atoms S(1) and S(2) are not involved in any intermolecular N···S contacts comparable to that seen for S(3).

Complexes with L^1

The reaction of L^1 with one equivalent of $[Cu(CH_3CN)_4]PF_6$ in dry acetonitrile under nitrogen resulted in a pale yellow solution. Diethyl ether diffusion into the reaction mixture gave pale yellow crystals whose elemental analysis indicates the stochiometry $[CuL^1][PF_6]$, i.e. a 1:1 metal/ligand ratio as expected for a complex between a tetradentate ligand and a metal ion with preference for tetrahedral geometry. The presence of the PF_6^- anion was confirmed by the presence of peaks at 839 and 558 cm^{-1} in the IR spectrum,[8] and the electrospray mass spectrum showed a molecular ion peak at m/z = 545 for $\{CuL^1\}^+$.

The X-ray crystal structure (Figure 4) shows that the crystalline material is an infinite one-dimensional helical coordination polymer $\{[CuL^1](PF_6)\}_\infty$; helical chains have become well known recently with examples based on N,S-chelating[4] and other[9] bridging ligands. The Cu^I ion and the phosphorus atom of the PF_6^- are at special positions such that the asymmetric unit contains half a Cu^I ion, half a ligand and half a PF_6^- ion. Each Cu^I ion is in a four-coordinate environment, coordinated by an N,S-chelating arm from each of two separate ligands. Each ligand therefore bridges two metal ions. The Cu···Cu separation between metals linked by the same bridging ligand is 9.85 Å. The geometry around the Cu^I ion is distorted tetrahedral with an angle of 75.5° between the two Cu(NS) planes (Figure 4, a); the twist angle within each bidentate (methylsulfanylphenyl)pyrazole unit is 28.7°. The ligands are arranged around the Cu^I ions such that each polymeric chain is helical with equal amounts of each enantiomer in the crystal. There are interligand aromatic stacking interactions within each helical strand, which is a common feature of helical complexes.[10] Each central phenyl spacer is stacked to a (methylsulfanyl)phenyl ring from a ligand on each side of it, with the stacked rings inclined at 6.7° to each other. The distance between these stacked rings (distance of atoms in one from the mean plane of the other) is in the range 3.2–3.7 Å. The angle between the planes of alternating central

phenyl rings is 73.6°, hence stacking can be seen in two almost perpendicular directions (Figure 4, b) (Table 1).

Symmetry transformations used to generate equivalent atoms: $-x$, y, $-z + 1/2$.

Reaction of L^1 in methanol with a solution of one equivalent of $AgNO_3$ in H_2O gave a white powder after filtration, whose elemental analysis indicated the composition $\{[AgL^1](NO_3)\}_\infty$. The IR spectrum confirmed the presence of the NO_3^- counterion with a broad band centred around 1339 cm^{-1}, and the FAB mass spectrum (see Experimental Section) showed peaks arising from 1:1, 2:1 and 2:1 Ag/L^1 fragments.

X-ray quality crystals were grown from slow evaporation of the filtrate; the structure of the complex (Figure 5) shows it to be an infinite helical polymer $\{[AgL^1](NO_3)\cdot MeOH\}_\infty$, with a similar structure to $\{[CuL^1](PF_6)\}_\infty$. Each Ag^I ion is in a four-coordinate N_2S_2 environment, coordinated by a N,S-chelating arm from two separate ligands. The nitrate counterions are non-coordinating. The Ag···Ag separation is 7.62 Å, significantly shorter than the inter-metal separation in $\{[CuL^1](PF_6)\}_\infty$. The geometry around the Ag^I ion is almost tetrahedral with an angle of 80.2° between the two Ag(NS) planes. The bidentate (methylsulfanylphenyl)-pyrazole unit show large deviations from planarity with twist angles between the two rings of 43.5 and 47.8°. The central phenyl spacers of successive ligands in the chain are oriented at 72.5° to each other. Unlike in $\{[CuL^1](PF_6)\}_\infty$, only every second phenyl spacer is involved in interligand stacking interactions, being sandwiched between pyrazolyl rings on either side of it to which it is near-parallel (6.9° between planes); the distance between the stacked rings is 3.1–3.5 Å (Table 2).

Complexes with L^2

The reaction of L^2 with one equivalent of $[Cu(CH_3CN)_4]BF_4$ in dry acetonitrile under nitrogen resulted in a colourless solution. Diethyl ether diffusion into the reaction mixture gave almost colourless crystals whose elemental analysis indicates a 1:1 metal/ligand ratio. The IR spectrum confirms the presence of the BF_4^- counterion at 1056 cm^{-1}. The electrospray mass spectrum shows a peak at m/z = 545 for the mononuclear species $\{CuL^2\}^+$. The X-ray crystal structure (Figure 6) shows that the crystalline material is an infinite one-dimensional coordination polymer $\{[CuL^2](BF_4)\}_\infty$. However, unlike the structure of $\{[CuL^1](PF_6)\}_\infty$ the chains are not helical. Each ligand is folded back on itself with the two coordinating arms almost overlapping but pointing in opposite directions, coordinating to separate Cu^I ions.

The Cu^I ion and the boron atom of the BF_4^- are at special positions such that the asymmetric unit contains half a Cu^I ion, half a ligand and half of an anion, as well as fractions of two acetonitrile and a diethyl ether molecule which are also at special positions. Each Cu^I ion is in a four-coordinate environment, coordinated by an N,S-chelating arm from each of two separate ligands. The Cu···Cu separation between metals linked by the same bridging ligand is 6.17 Å, significantly shorter than that found in $\{[CuL^1](PF_6)\}_\infty$ (9.85 Å). The geometry around the Cu^I ion is distorted tetrahedral with an angle of 77.2° between the two Cu(NS) planes (Figure 6, a); the twist angle within each bidentate (methylsulfanylphenyl)pyrazole unit is 28.6°. There are no close π-π stacking interactions within each chain (Table 3).

The reaction of L^2 with one equivalent of $[Ag(CH_3CN)_4]BF_4$ in dry acetonitrile under nitrogen resulted in a colourless solution. Diethyl ether diffusion into the reaction mixture gave almost colourless crystals whose elemental analysis was consistent with the formulation $[Ag(L^2)](BF_4)$. The IR spectrum showed the presence of the BF_4^- counterion with a broad band at 1050 cm^{-1}. The electrospray mass spectrum showed a molecular ion peak at m/z = 589 for $\{AgL^2\}^+$ with no peaks for higher oligomers. The X-ray structure of the complex shows it to be the mononuclear complex $[Ag(L^2)](BF_4)$, in contrast to the infinite chain that was observed with Cu^I. There are two unique molecules in the asymmetric unit, which are associated into a dimer by face-to-face π-stacking between the phenyl rings of the aromatic spacers with an average distance of 3.60 Å between the overlapping rings.

The two complex molecules in the asymmetric unit display similar geometries. If only the N,S-donors are considered, both Ag^I ions are in a flattened tetrahedral environment [angles of 80.8° and 80.6° between the Ag(NS) planes], coordinated by an L^2 ligand acting as a tetradentate chelate. One of the bidentate arms shows a larger dihedral twist [44.9° and 49.3° for the molecules containing Ag(1) and Ag(2), respectively] between the two rings than the

other [17.7° and 22.7° for the molecules containing Ag(1) and Ag(2), respectively]. The average Ag–N bond length is 2.39 Å and the average Ag–S bond length is 2.64 Å (Table 4). However, the near-linearity of the N–Ag–N angles [169° at each metal centre] results in a large gap in the Ag^I coordination sphere, which is filled by an interaction of each Ag^I ion with the "capping" phenyl ring. The Ag^I ions do not sit centrally above the phenyl rings but are slightly offset, such that they interact with just one C atom (dotted line in Figure 7). The Ag(1)···C(1) separation is 2.76 Å, and the corresponding Ag(2)···C(101) separation in the independent molecule is 2.74 Å. This type of η^1 interaction of an Ag^I ion with a phenyl ring, although less common than the η^2 π-type interaction in which the metal ion interacts with one edge of a phenyl ring,[11] is still well known[12] with many dozens of examples in the Cambridge Structural Database. It is characterised by a contact in the range 2.4–2.8 Å between the Ag^I ion and one C atom such that the Ag–C vector is near-perpendicular to the aromatic ring, as we see for $[Ag(L^2)](BF_4)$, where these angles are 77°

for Ag(1) and 83° for Ag(2). In this case, this results in a coordination geometry about the metal ions that is best described as trigonal bipyramidal, with the C and two S donors forming the trigonal plane and the two N donors being axial. The τ parameter for this complex is 0.67 [0.64 for the independent complex molecular containing Ag(2)],

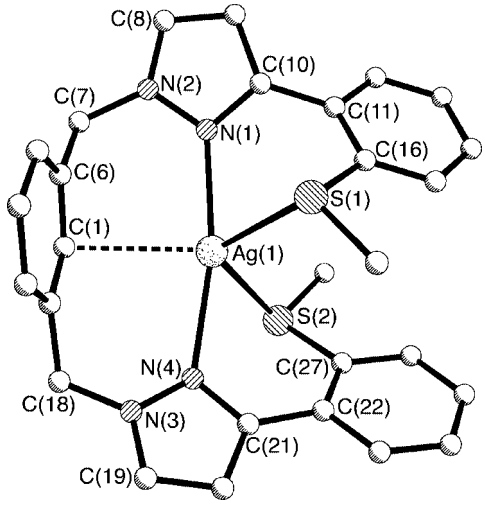

Figure 7. Structure of the metal complex unit of $[AgL^2](BF_4)$. The Ag···C interaction to the phenyl ring is shown with a dashed line.

where 1.0 denotes a perfect trigonal bipyramid and 0.0 denotes a perfect square pyramid.[13]

The presence of this metal–carbon interaction with Ag^I, but not Cu^I, is likely to be an important factor in explaining why $\{[CuL^2](BF_4)\}_\infty$ forms an infinite chain whereas $[Ag(L^2)](BF_4)$ is mononuclear; the binding mode in $[Ag(L^2)](BF_4)$ in which both bidentate arms of L^2 coordinate to the same metal ion necessarily brings the phenyl spacer into close contact with the metal ion. In addition, this mononucleating, tetradentate coordination mode would be harder to achieve with the smaller Cu^I ions in any case.

Complexes with L^3

The reaction of L^3 with one equivalent of $[Cu(CH_3CN)_4]$-BF_4 in ethanol resulted in a suspension from which an off-white solid was isolated after filtration. The infrared spectrum showed a broad band centred around 1083 cm^{-1} for the BF_4^- counterions and the FAB mass spectrum showed peaks consistent with 1:1, 1:2 and 2:2 Cu/L^3 fragments; the elemental analysis was consistent with a 1:1 metal/ligand ratio.

X-ray quality crystals were grown by diffusion of diethyl ether vapour into a solution of the complex in MeCN. The

structure of the complex (Figure 8) shows it to be the one-dimensional coordination polymer $\{[CuL^3](BF_4)\}_\infty$ with one Cu^I ion and one complete ligand in the asymmetric unit. Unlike the complexes of L^1, the structure of $\{[CuL^3](BF_4)\}_\infty$ is not helical. Rather, the sequence of bridging ligands between one ligand and the next follows a zig-zag path. The Cu^I ions are in a four-coordinate N_2S_2 environment with an almost tetrahedral geometry [angle of 87.2° between the Cu(NS) planes]. The Cu···Cu separation between metal atoms which are linked by the same bridging ligand is 10.645 Å, and the separation between alternate Cu^I centres is almost identical at 10.649 Å. The twist angle within the biphenyl spacer is 40.6° and the twist angles within each bidentate (methylsulfanylphenyl)pyrazole units are 34.7 and 36.7°. Unlike the structure of L^1 there is no face-to-face π-stacking within the polymer chains (Table 5).

The reaction of L^3 with one equivalent of $[Ag(CH_3CN)_4]BF_4$ in dry acetonitrile under nitrogen resulted in a colourless solution. Diethyl ether diffusion into the reaction mixture gave almost colourless crystals whose elemental analysis indicates a 1:1 metal/ligand ratio. The IR spectrum confirms the presence of the BF_4^- counterion at 1061 cm^{-1}. The FAB mass spectrum shows peaks arising from 1:1, 1:2 and 2:2 Ag/L^3 fragments. The X-ray crystal structure (Figure 9) shows that the crystalline material is another infinite one-dimensional coordination polymer $\{[AgL^3](BF_4)\}_\infty$. One of the coordinating arms [containing S(4) and N(7)] is disordered and has been modelled over two sites; unless otherwise stated only the major component of this disorder will be discussed. Each metal/ligand chain shows a clear zig-zag (non-helical) structure, similar to that of $\{[CuL^3](BF_4)\}_\infty$. The Ag···Ag separations between metal atoms which are linked by the same bridging ligand are 8.95 and 9.05 Å, less than the equivalent distances in $\{[CuL^3](BF_4)\}_\infty$. The separations between alternate Ag^I centres are however greater at 11.97 Å.

The Ag^I ions in each chain alternate between being four-coordinate [Ag(1)] and three-coordinate [Ag(2)]. Ag(1) is in an almost tetrahedral N_2S_2 environment [angle of 87.2° between the Ag(NS) planes], coordinated by two bidentate arms from separate ligands. Ag(2) is in an N_2S environment approximating a T-shape, with the silver atom sitting ca. 0.1 Å above the plane of the donor atoms [N(4), N(5) and S(2)]. The remaining donor atom [S(3)] is too far from the

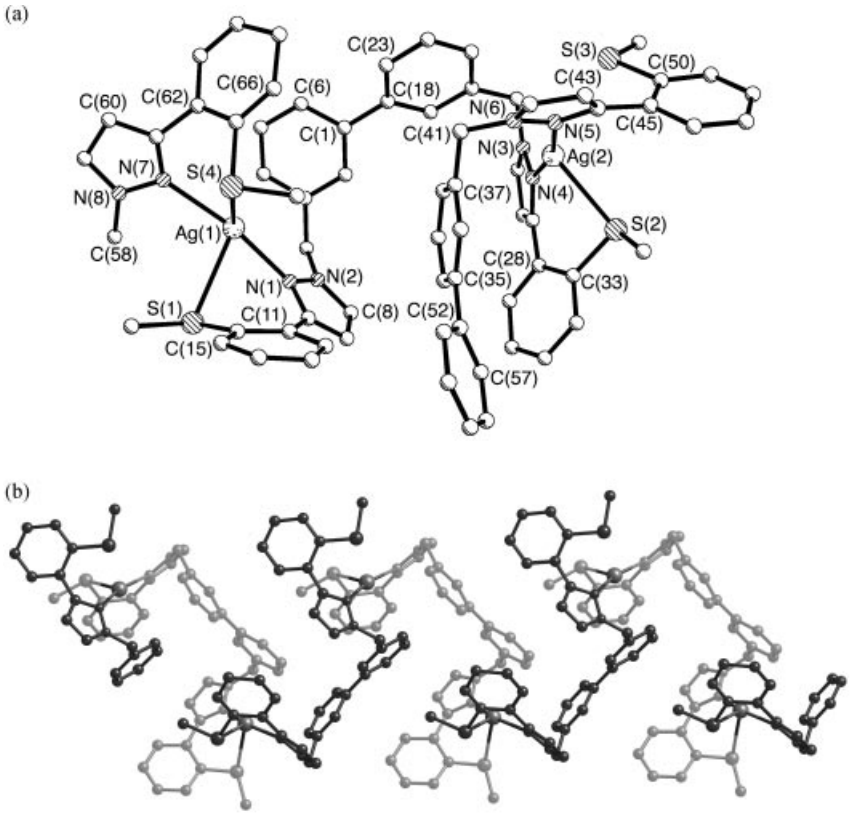

Figure 9. (a) Structure of the metal complex unit of $\{[AgL^3](BF_4)\}_\infty$ showing the asymmetric unit and the coordination geometry around the Ag^I centres. metal to be considered as forming a normal coordinate bond [Ag(2)···S(3), 3.02 Å compared to 2.6934(12) Å for Ag(2)–S(2), Table 6] but may interact weakly with Ag(2). The bonds to the N-donors are slightly shorter than those to Ag(1) [Ag(2)–N(4) 2.213(3) Å, Ag(2)–N(5) 2.191(3) Å] as a consequence of the lower coordination number. Despite the low coordination numer there is no evidence for additional Ag···C contacts of the type described above for $[Ag(L^2)](BF_4)$. The twist angles within the biphenyl spacers are 35.4 and 34.2° and the twist angles within each bidentate (methylsulfanyl)phenyl-pyrazole units are in the range 37.7–47.4°. There is no face-to-face π-stacking within the polymer chains. However there is a CH-π interaction between one of the rings of the biphenyl spacer and the CH in the 4-position of the next biphenyl spacer (separation of 2.78 Å between the H^4 of the biphenyl unit and the centroid of the relevant phenyl ring).

Complexes with L^4

Reaction of L^4 with one equivalent of $[Cu(CH_3CN)_4]PF_6$ in dry acetonitrile under nitrogen resulted in a colourless solution. Diethyl ether diffusion into the reaction mixture gave colourless crystals whose elemental analysis was consistent with a 1:1 metal/ligand ratio. The IR spectrum showed peaks at 841 and 557 cm^{-1} for the PF_6^- counterions. The FAB mass spectrum showed a molecular ion peak at *m/z* = 595 for $\{CuL^4\}^+$ but no peaks for higher oligomers. A subsequent X-ray crystal structure determination (Figure 10) showed that the crystalline material is the mononuclear complex $[Cu(L^4)](PF_6)$, in obvious contrast to the polymeric structures obtained with L^1, L^2 and L^3. The Cu^I ion is in a distorted tetrahedral N_2S_2 environment [angle of 85.6° between the Cu(NS) planes] with L^4 acting as a tetradentate chelate. The bond lengths to the Cu^I ion are

The reaction of L^4 with one equivalent of $[Ag(CH_3CN)_4]BF_4$ in ethanol resulted in a suspension from which an off-white solid was isolated after filtration. The elemental analysis of the powder is consistent with the formulation $[AgL^4](BF_4)$. The IR spectrum showed the presence of the BF_4^- counterion with a broad band at 1071 cm^{-1}. The FAB mass spectrum showed a molecular ion peak at *m/z* = 641 for $\{AgL^4\}^+$ with no peaks for higher oligomers. The crystal structure of the complex shows it to be the mononuclear complex $[Ag(L^4)](BF_4)$ (Figure 11). There are two unique complex molecules in the unit cell which are associated into a dimer by weak, long-range Ag···N interactions (> 3 Å) between the Ag^I ion of one complex and the pyrazolyl N atoms of another. The two silver ions are 4.20 Å apart, which precludes any Ag···Ag interaction between them, and the two naphthalene spacers are at opposite sides of the dimer.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

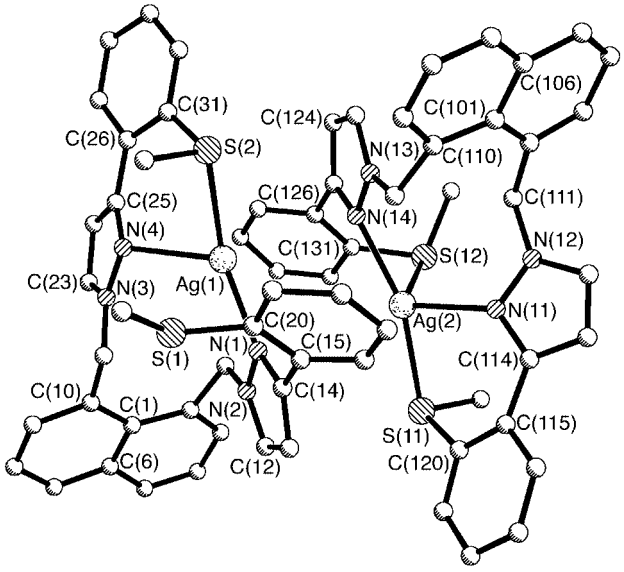

Figure 11. Molecular structure of the metal complex unit of $[AgL^4](BF_4)$ showing the stacking of two independent molecules in the unit cell.

One Ag^I ion [Ag(2)] is in a flattened tetrahedral environment [angle of 75.6° between the Ag(NS) planes] coordinated by an L^4 ligand acting as a tetradentate chelate. The Ag–N bonds are 2.246(10) and 2.367(9) Å and the Ag–S bonds are longer at 2.468(3) and 2.785(4) Å and are typical of the silver complexes in this series. One of the bidentate arms shows a larger dihedral twist between the two rings than the other [59.0° for the arm containing N(11) and S(11), and 22.8° for the arm containing N(14) and S(12)]. The other Ag^I ion is in a three-coordinate N_2S environment with all donor atoms coming from a single L^4 molecule. Here the remaining sulfur atom is too far from the metal to be considered as forming a normal coordinate bond [Ag(1)–S(1) = 3.02 Å compared to 2.445(3) Å for Ag(1)–S(2), Table 8]. The coordination environment is almost planar with the Ag(1) sitting ca. 0.1 Å above the plane of the donor atoms. The bond to one of the N-donors is significantly longer than that to the other N-donor [Ag(1)–N(1), 2.146(9) Å; Ag(1)–N(4), 2.446(9) Å]. The bidentate arm where the sulfur atom is not coordinated to the metal shows a greater dihedral angle between the pyrazole and methylsulfanylphenyl rings (58.0°) than the arm where both donor atoms are coordinated (21.5°).

The NMR spectra of $[CuL^4](PF_6)$ and $[AgL^4](BF_4)$ show that the complexes have twofold symmetry in solution.

Complexes with L^5

The reaction of L^5 with 1.5 equivalents of $Ag(ClO_4)_4 \cdot H_2O$ in dry acetonitrile under nitrogen resulted in a colourless solution. Diethyl ether diffusion into the reaction mixture gave colourless crystals whose elemental analysis indicates the stochiometry $[AgL^5](ClO_4)$, i.e. a 1:1 metal/ligand ratio rather than the 3:2 ratio expected for a complex between a hexadentate ligand and a metal ion with preference for tetrahedral geometry. The IR spectrum showed the presence of the ClO_4^- counterions at 1091 and 623 cm^{-1}, and the FAB mass spectrum showed a molecular ion peak at m/z = 835 for the fragment $\{AgL^5\}^+$ all indicating formation of a 1:1 complex.

X-ray crystallography confirmed (Figure 12) that the complex is mononuclear, with some obvious structural similarities to $[AgL^2](BF_4)$ as a consequence of the *meta* substitution pattern of the central phenyl spacer. The Ag^I ion is bound by two of the bidentate N,S-donor arms of L^5 with the third arm pendant. As we saw with $[AgL^2](BF_4)$, the orientation of the two chelating bidentate arms to the same face of the phenyl spacer necessarily results in a close contact between the metal ion and the phenyl ring, resulting in an η^1 π-type interaction with C(2) of the phenyl ring [Ag(1)···C(2), 2.70 Å (dotted line in Figure 12; Table 9), with the angle between the Ag–C vector and the phenyl plane being 89°]. The Ag^I centre is therefore five coordinate; the τ parameter of 0.12 indicates that the geometry is best described as square-based pyramidal, with S(2) being the "axial" donor. Although the third pendant arm is directed

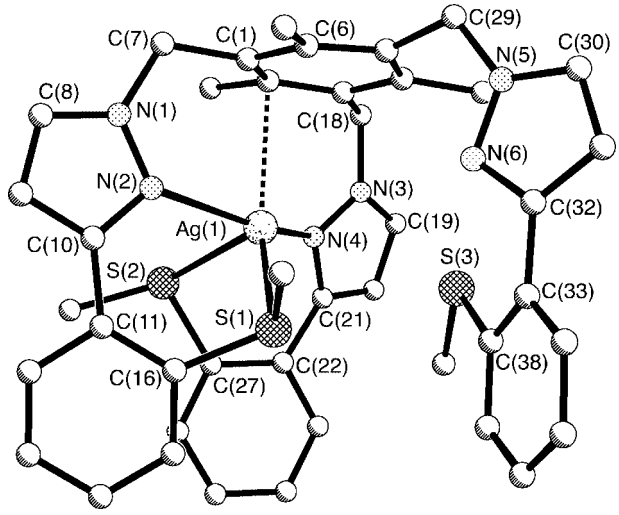

Figure 12. Molecular structure of the metal complex unit of $[AgL^5](ClO_4)$. The Ag···C interaction to the phenyl ring is shown with a dashed line.

towards the same face of the aromatic spacer as the two other arms, the remaining donor atoms are not interacting with the Ag^{I} centre [Ag(1)–N(6), 4.69 Å; Ag(1)–S(3), 3.71 Å]. All three bidentate arms show substantial deviations from planarity (twist angles of 17.7 and 33.5° between the pyrazolyl and methylsulfanylphenyl rings for the coordinated arms and 34.6° for the non-coordinated arm).

Despite the asymmetry of the complex in the solid state, the ^{1}H NMR spectrum of $[AgL^5](ClO_4)$ showed that all three arms of the ligand are equivalent in solution, indicating that the silver(I) ion is coordinated by all three arms or, more likely, that the structure is fluxional in solution.

The structure of $[Ag(L^5)](ClO_4)$ suggested that the pendant arm would be able to coordinate a second metal ion, but only after the conformation of L^5 alters such that the pendant arm is rotated away from the metal ion. Reaction of L^5 with a 10 fold excess of $AgClO_4{\cdot}H_2O$ in dry acetonitrile under nitrogen resulted in a colourless solution. Diethyl ether vapour diffusion into this solution gave crystals of unreacted $[Ag(CH_3CN)_4]ClO_4$ in addition to crystals of the trinuclear complex $[Ag_3(L^5)_2](ClO_4)_3$. The FAB mass spectrum of these latter crystals shows a peak at m/z = 835 for $\{Ag(L^5)\}^+$ and additional peaks at m/z = 1041 for $\{Ag_2(L^5)(ClO_4)\}^+$ and 1768 for $\{Ag_2(L^5)_2(ClO_4)\}^+$. No peaks were observed for intact trinuclear $\{Ag_3(L^5)_2(ClO_4)_x\}$ species. The ^{1}H NMR spectrum showed a symmetrical structure in solution with identical chemical shifts to that of $[AgL^5](ClO_4)$, suggesting that $[Ag_3(L^5)_2]^{3+}$ only exists in the solid state. Attempts to isolate pure $[Ag_3(L^5)_2](ClO_4)_3$ by using a smaller excess of $Ag(ClO_4)_4{\cdot}H_2O$ were unsuccessful resulting in a mixture of $[Ag_3(L^5)_2](ClO_4)_3$ and $[Ag(L^5)_2](ClO_4)$.

In the crystal structure of $[Ag_3(L^5)_2](ClO_4)_3$ (Figure 13), the pendant arms of two mononuclear $\{Ag(L^5)\}^+$ units are coordinated to another Ag^{I} ion, linking two such units together via a third Ag^{I} centre. The two terminal Ag^{I} ions [Ag(1), Ag(3)] are in the familiar five-coordinate environments from two bidentate N,S-chelating ligand arms and an η^1 π-type interaction with the capping phenyl ring [Ag(1)···C(2), 2.79 Å; Ag(3)···C(102), 2.83 Å, Table 10; angles between Ag–C vectors and phenyl mean planes, 82° and 83° respectively; τ parameters 0.72 and 0.61 at Ag(1) and Ag(3) respectively]. The central Ag^{I} ion [Ag(2)] is in a five coordinate N_2SO_2 environment arising from an N,S bidentate arm from one ligand, just the pyrazolyl N-donor from the other ligand, and two oxygen atoms from one of the perchlorate anions [Ag–O distances, 2.85 and 2.87 Å]. The remaining non-coordinated S atom, S(103), is 3.82 Å away from Ag(2).

The two ligands are arranged such that the silver ions form a rough triangle. The inter-metallic distances between silver ions linked by the same ligand are 8.72 Å [Ag(1)···Ag(2)] and 7.47 Å [Ag(2)···Ag(3)]; the Ag(1)···Ag(3) separation is 9.58 Å. The bidentate arms show twist angles of 11.2–49.3° between pyrazolyl and methylsulfanylphenyl rings, whereas the arm where only the pyrazolyl donor is coordinated shows a larger twist angle of 78.2° in order to avoid unfavourable steric interactions between the thioether group and the nearby bidentate arm from the other ligand.

The reaction of L^5 with $[Cu(CH_3CN)_4]BF_4$ in a 2:3 ratio in dry ethanol resulted in an off-white precipitate which was isolated by filtration. The elemental analysis of the powder

was consistent with a 1:1 metal/ligand ratio suggesting that the product is a mononuclear complex similar in structure to $[AgL^5](ClO_4)$. The IR spectrum is consistent with the presence of the BF_4^- anion with a broad band centred around 1064 cm^{-1}. The FAB mass spectrum shows a main peak at 789 for $\{CuL^5\}^+$ but also very weak peaks for 1006 ($\{Cu_2(L^5) + NOBA\}^+$), 1515 ($\{Cu(L^5)_2\}^+$) and 1669 ($\{Cu(L^5)_2 + NOBA\}^+$) suggesting that a complex of higher nuclearity could have formed. The poor solubility of this complex did not permit study by NMR spectroscopy. All attempts to crystallise this complex have been unsuccessful.

Conclusions

Reaction of the bidentate N,S-donor fragment 3-[2-(methylsulfanyl)phenyl]pyrazole with a range of aromatic groups having two or three bromomethyl substituents allows two or three N,S-donor units to be linked to a central aromatic spacer. Depending on the separation between the N,S-donor units they can either each bind to a separate metal ion, giving one-dimensional (helical or zig-zag) chains with Ag^I and Cu^I, or can chelate to a single metal centre giving smaller mononuclear (metal/ligand, 1:1) or trinuclear (metal/ligand, 3:2) complexes. Whereas the Cu^I centres in these complexes are all four coordinate from two N,S-donor units, the Ag^I centres are sometimes three-coordinate due to incomplete coordination of the N,S-donor units. An additional factor responsible for the differences between Cu^I and Ag^I complexes with the same ligand is the presence of η^1 π-type Ag···C(phenyl) interactions which do not occur with Cu^I.

Experimental Section

General Details: 2′-(Methylthio)acetophenone,[14] 3,3′-bis(bromomethyl)biphenyl[15] and $[Cu(CH_3CN)_4]X$ (X = PF_6, BF_4)[16] were prepared according to literature methods. All other organic reagents and metal salts were purchased from Aldrich or Avocado and used as received. ^1H NMR spectra were recorded with a Bruker AC 250 or Bruker AMX2 400 spectrometer, and all mass spectra (FAB and EI) with a VG AutoSpec magnetic sector instrument. IR spectra were recorded with a Perkin–Elmer Spectrum One instrument. Samples for elemental analysis were vacuum-dried.

Preparation of 1,8-Bis(bromomethyl)naphthalene: This is a slight variant of a literature method.[17] PBr_3 (6.0 cm^3, 0.064 mol) was added to a suspension of 1,8-bis(hydroxymethyl)naphthalene (3.93 g, 0.0209 mol) in dry dichloromethane (50 cm^3) under nitrogen. The resulting clear solution was stirred at room temperature for 5 h. After this period water was carefully added dropwise until the evolution of gas ceased. The organic layer was separated, washed with water and dried ($MgSO_4$). Removal of the solvent afforded the crude product as an off-white solid. Recrystallisation from dichloromethane/hexane gave 5.29 g of off-white crystals (81%). All analytical data match those previously published.[17]

Preparation of 3-[(2-Methylthio)phenyl]pyrazole: This is a slight variant of the method published earlier.[5] A solution of 2′-(methylthio)acetophenone (4.28 g, 0.0257 mol) in dimethylformamide–dimethylacetal (10 cm^3, a large molar excess) was refluxed for 3 days under nitrogen to yield a dark brown solution. Removal of excess dimethylformamide-dimethylacetal in vacuo gave crude 3-(dimethylamino)-1-[2-(methylthio)phenyl]-2-propen-1-one as an orange/brown oil. To this was added ethanol (60 cm^3) and hydrazine hydrate (10 cm^3, a large molar excess), and the mixture refluxed in air for 2 h. The pale yellow solution was cooled and added to ice/water (300 cm^3) resulting in a pale yellow precipitate. The mixture was refrigerated overnight to complete the precipitation of the product. The solid was filtered off, washed with cold water (50 cm^3) and hexane (50 cm^3) and dried in vacuo. Subsequent recrystallisation from dichloromethane/hexane afforded 3-[(2-methylthio)phenyl]pyrazole as pale yellow needle crystals (4.35 g, 89%). EI MS: m/z = 190 [M^+]. ^1H NMR (250 MHz): $CDCl_3$: δ (ppm) = 7.63 (d, 1 H, pyrazolyl H^5), 7.50 (m, 1 H, phenyl H^3), 7.31–7.36 (m, 2 H, phenyl H^5, phenyl H^6), 7.21 (m, 1 H, phenyl H^4), 6.62 (d, 1 H, pyrazolyl H^4), 2.41 (s, 3 H, SCH_3). $C_{10}H_{10}N_2S$ (190.27): calcd. C 63.1, H 5.3, N, 14.7; found C 62.7, H 5.2, N 14.7.

Preparation of L^1: A two-phase mixture of 3-[(2-methylthio)phenyl]-pyrazole (1.26 g, 6.60 mmol), α,α′-dibromo-*p*-xylene (0.711 g, 2.70 mmol), toluene (90 cm^3), nBu_4NOH (0.10 cm^3) and aqueous 10 M NaOH (15 cm^3) was heated to 75 °C and stirred vigorously at this temperature for 24 h. After cooling the mixture was diluted with water (100 cm^3) and the aqueous layer extracted with toluene (2 × 100 cm^3). The combined organic layers were washed with water and dried ($MgSO_4$). The solvent was removed in vacuo and the crude product was purified by column chromatography (alumina, dichloromethane) to give 0.767 g of pale yellow solid (59%). FAB MS: m/z = 483 [MH^+]. ^1H NMR (250 MHz, $CDCl_3$): δ (ppm) = 7.55 (dd, 2 H, methylthiophenyl H^3), 7.38 (d, 2 H, pyrazolyl H^5), 7.23–7.35 (m, 8 H, phenyl, methylthiophenyl H^5, H^6), 7.17 (dd, 2 H, methylthiophenyl H^4), 6.63 (d, 2 H, pyrazolyl H^4), 5.36 (s, 4 H, CH_2), 2.42 (s, 6 H, SCH_3) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ =

Preparation of L^2: A two-phase mixture of 3-[(2-methylthio)phenyl]-pyrazole (1.00 g, 5.26 mmol), α,α′-dibromo-*m*-xylene (0.630 g, 2.39 mmol), toluene (100 cm^3), *n*Bu_4NOH (0.10 cm^3) and aqueous 10 M NaOH (15 cm^3) was heated to 65 °C and stirred vigorously at this temperature for 24 h. After cooling the mixture was diluted with water (100 cm^3) and the aqueous layer extracted with toluene (2 × 100 cm^3). The combined organic layers were washed with water and dried ($MgSO_4$). The solvent was removed in vacuo and the crude product was purified by column chromatography (alumina, dichloromethane) to give 0.691 g of colourless oil (60%). EI MS: *m*/*z* = 483 [MH^+]. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.54 (dd, 2 H, methylthiophenyl H^3), 7.39 (d, 2 H, pyrazolyl H^5), 7.25–7.34 (m, 5 H, phenyl H^5, methylthiophenyl H^5, H^6), 7.15–7.22 (m, 5 H, phenyl H^2, H^4, methylthiophenyl H^4), 6.62 (d, 2 H, pyrazolyl H^4), 5.36 (s, 4 H, CH_2), 2.42 (s, 6 H, SCH_3) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 150.5, 137.4, 137.2, 132.3, 129.8 (two closely spaced signals), 129.2, 128.2, 127.3, 126.9, 125.2, 124.6, 106.9, 55.8, 16.0 ppm. IR (neat): $\tilde{\nu}$ = 3111 cm^{-1} (w), 3052 (w), 2979 (w), 2920 (m), 2854 (w), 1610 (w), 1591 (w), 1563 (w), 1516 (m), 1490 (s), 1453 (s), 1436 (s), 1400 (s), 1335 (s), 1259 (s), 1221 (s), 1164 (w), 1106 (w), 1064 (m), 1052 (s), 1002 (w), 967 (w), 947 (w), 753 (s), 710 (m), 654 (w) cm^{-1}. $C_{28}H_{26}N_4S_2$ (482.67): calcd. C 69.7, H 5.4, N 11.6; found C 69.4, H 5.8, N 11.4.

Preparation of L^3: A two-phase mixture of 3-[(2-methylthio)phenyl]-pyrazole (1.23 g, 6.46 mmol), 3,3′-bis(bromomethyl)biphenyl (1.00 g, 2.94 mmol), toluene (55 cm^3), *n*Bu_4NOH (0.03 cm^3) and aqueous 10 M NaOH (12 cm^3) was heated to 70 °C and stirred vigorously at this temperature for 24 h. After cooling the mixture was diluted with water (100 cm^3) and the aqueous layer extracted with toluene (2 × 100 cm^3). The combined organic layers were washed with water and dried ($MgSO_4$). The solvent was removed in vacuo and the crude product was purified by column chromatography (alumina, 20% hexane in dichloromethane) to give 0.701 g of white foam (43%). EI MS: *m*/*z* = 558 [M^+]. ^{1}H NMR (250 MHz, $CDCl_3$): δ (ppm) 7.50–7.59 (m, 6 H), 7.43 (d, 2 H, pyrazolyl H^5), 7.23–7.42 (m, 8 H), 7.17 (ddd, 2 H, methylthiophenyl H^4), 6.62 (d, 2 H, pyrazolyl H^4), 5.43 (s, 4 H, CH_2), 2.39 (s, 6 H, SCH_3) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 150.6, 141.2, 137.4, 137.2, 132.4, 129.8 (two closely spaced signals), 129.2, 128.2, 126.8 (two closely spaced signals), 126.6, 125.2, 124.6, 106.9, 56.0, 16.0 ppm. IR (KBr disk): $\tilde{\nu}$ 3050 (w), 2917 (m), 2853 (w), 1603 (w), 1588 (w), 1515 (w), 1488 (m), 1453 (m), 1434 (s), 1399 (m), 1334 (m), 1257 (m), 1220 (m), 1105 (w), 1063 (m), 1050 (m), 1000 (w), 946 (w), 751 (s), 732 (m), 695 (m), 654 (w) cm^{-1}. $C_{34}H_{30}N_4S_2$ (558.77): calcd. C 73.1, H 5.4, N 10.0; found C 72.8, H 5.6, N 9.6.

Preparation of L^4: A two-phase mixture of 3-[(2-methylthio)phenyl]-pyrazole (2.50 g, 13.1 mmol), 1,8-bis(bromomethyl)naphthalene (1.99 g, 6.34 mmol), toluene (120 cm^3), *n*Bu_4NOH (0.20 cm^3) and aqueous 10 M NaOH (26 cm^3) was heated to 65 °C and stirred vigorously at this temperature for 24 h. After cooling the mixture was diluted with water (100 cm^3) and the aqueous layer extracted with toluene (2 × 100 cm^3). The combined organic layers were washed with water and dried ($MgSO_4$). The solvent was removed in vacuo and the crude product was recrystallised twice from dichloromethane/hexane to give 0.86 g of off-white needle crystals. A second crop of 1.17 g of off-white powder was obtained from the recrystallisation filtrates by column chromatography (alumina, 20% hexane in dichloromethane). Total yield: 2.03 g (60%). FAB MS: *m*/*z* = 533 [MH^+]. ^{1}H NMR (500 MHz, $CDCl_3$): δ (ppm) = 7.89 (dd, 2 H, napthyl H^4), 7.57 (ddd, 2 H, methylthiophenyl H^3), 7.45 (dd, 2 H, napthyl H^3), 7.24–7.32 (m, 4 H, methylthiophenyl H^5, H^6), 7.23 (dd, 2 H, naphthyl H^2), 7.20 (d, 2 H, pyrazolyl H^5), 7.16 (ddd, 2 H, methylthiophenyl H^4), 6.59 (d, 2 H, pyrazolyl H^4), 5.93 (s, 4 H, CH_2), 2.39 (s, 6 H, SCH_3) ppm. ^{13}C NMR (100 MHz, $CDCl_4$): δ (ppm) = 150.9, 137.4, 135.8, 132.4, 131.8, 130.8, 130.5, 130.4, 130.1, 129.7, 128.2, 125.5, 125.3, 124.5, 106.7, 56.7, 16.1. IR (KBr disk): $\tilde{\nu}$ 3117 (w), 2918 (w), 1586 (w), 1562 (w), 1509 (m), 1489 (m), 1454 (s), 1440 (m), 1399 (w), 1331 (m), 1258 (m), 1213 (m), 1170 (w), 1107 (w), 1052 (s), 976 (w), 960 (w), 944 (w), 844 (w), 782 (s), 769 (m), 753 (s), 737 (m), 676 (m), 622 (w) cm^{-1}. $C_{32}H_{28}N_4S_2$ (532.73): calcd. C 72.1, H 5.3, N 10.5; found C 72.0, H 5.3, N 10.5. X-ray quality crystals were grown from diethyl ether diffusion into an NMR sample of L^4 in $CDCl_3$.

Preparation of L^5: A two-phase mixture of 3-[(2-methylthio)phenyl]-pyrazole (1.54 g, 8.09 mmol), 2,4,6-tris(bromomethyl)mesitylene (0.981 g, 2.46 mmol), toluene (70 cm^3), *n*Bu_4NOH (0.10 cm^3) and aqueous 10 M NaOH (25 cm^3) was heated to 70 °C and stirred vigorously at this temperature for 24 h. After cooling the mixture was diluted with water (100 cm^3) and the aqueous layer extracted with toluene (2 × 100 cm^3). The combined organic layers were washed with water and dried ($MgSO_4$). The solvent was removed in vacuo and the crude product was purified by column chromatography (alumina, 1% methanol in dichloromethane) to give 0.551 g of off-white foam (31%). EI MS: *m*/*z* = 726 [M^+], 536 {M^+-[3-(2-methylthiophenyl)pyrazole]}, 347 {M^+ – 2[3-(2-methylthiophenyl)pyrazole]}. ^{1}H NMR (250 MHz, $CDCl_3$): δ (ppm) = 7.56 (dd, 3 H, methylthiophenyl H^3), 7.23–7.35 (m, 6 H, methylthiophenyl H^5, H^6), 7.17 (ddd, 3 H, methylthiophenyl H^4), 7.09 (d, 3 H, pyrazolyl H^5), 6.56 (d, 3 H, pyrazolyl H^4), 5.54 (s, 6 H, CH_2), 2.47 (s, 9 H, CH_3), 2.42 (s, 9 H, SCH_3) ppm. ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) = 150.4, 139.7, 137.3, 132.2, 131.3, 129.6, 128.4, 128.2, 125.2, 124.6, 106.2, 50.9, 16.5, 16.1. IR (KBr disk): $\tilde{\nu}$ 3050 (w), 2977 (w), 2916 (m), 1589 (w), 1562 (w), 1514 (w), 1488 (m), 1453 (s), 1436 (s), 1398 (m), 1323 (m), 1256 (m), 1215 (s), 1106 (w), 1063 (m), 1051 (s), 998 (w), 944 (m), 752 (s), 732 (s), 654 (w), 618 (w) cm^{-1}. $C_{42}H_{42}N_6S_3$ (727.03): calcd. C 69.4, H 5.8, N 11.6; found C 69.2, H 5.9, N 11.5. X-ray quality crystals were grown from the diffusion of pentane vapour into an acetonitrile solution of L^5.

Preparation of $\{[CuL^1](PF_6)\}_\infty$: A solution of $[Cu(CH_3CN)_4]PF_6$ (62 mg, 0.17 mmol) in MeCN (5 cm^3) was added to a solution of L^1 (80 mg, 0.17 mmol) in MeCN (20 cm^3). The colourless solution was stirred for 4 h and the volume reduced to ca. 10 cm^3. Diethyl ether diffusion into the solution gave off-white crystals of $\{[CuL^1](PF_6)\}_\infty$ which were suitable for X-ray crystallography. Yield: 86 mg, 75%. ES MS: *m*/*z* = 545 [$CuL^1]^+$. ^{1}H NMR (250 MHz, $CDCl_3$): δ (ppm) = 7.69 (d, 2 H, pyrazolyl H^5), 7.48 (m, 2 H, methylthiophenyl H^3), 7.30-7.75 (m, 4 H, methylthiophenyl H^5, H^6), 7.18–7.25 (m, 2 H, methylthiophenyl H^4), 7.12 (s, 4 H, phenyl), 6.62 (d, 2 H, pyrazolyl H^4), 5.27 (s, 4 H, CH_2), 2.32 (s, 6 H, SMe). ^{13}C NMR (100 MHz, CD_3CN): δ (ppm) = 151.4, 137.8, 136.2, 132.8, 132.5, 131.1 129.7, 128.6, 127.8, 126.7, 107.6, 55.9, 17.3 ppm. IR (KBr disk): $\tilde{\nu}$ 3156 (w), 3138 (w), 3052 (w), 2997 (w), 2925 (w), 1631 (w), 1589 (w), 1564 (w), 1518 (s), 1501 (s), 1462 (w), 1425 (s), 1401 (w), 1357 (s), 1325 (s), 1277 (w), 1225 (m), 1075 (s), 1020 (w), 971 (m), 954 (m), 879 (m), 839 (s), 786 (s), 760 (s), 729 (m), 649 (w), 619 (w), 558 (s) cm^{-1}. $C_{28}H_{26}CuF_6N_4PS_2$ (691.18): calcd. C 48.7, H 3.8, N 8.1; found C 48.8, H 3.7, N 8.0.

Preparation of $\{[AgL^1](NO_3)\}_\infty$: A solution of $AgNO_3$ (29 mg, 0.17 mmol) in H_2O (3 cm^3) was added to a solution of L^1 (81 mg, 0.17 mmol) in hot MeOH (10 cm^3). The colourless solution was stirred for 4 h and the volume reduced to ca. 5 cm^3. The mixture was filtered to give $\{[AgL^1](NO_3)\}_\infty$ as a white powder. Yield: 71 mg, 65%. X-ray quality crystals were obtained from slow evaporation of the filtrate. FAB MS: *m*/*z* = 591 $[AgL^1]$, 651 $[Ag(L^1)(NO_3)]$, 697 $[Ag_2(L^1)]$, 760 $[Ag_2(L^1)(NO_3)]$, 850 $[Ag_2(L^1)$ + NOBA], 1179 $[Ag_2(L^1)_2]$, 1242 $[Ag_2(L^1)_2(NO_3)]$, 1333 $[Ag_2(L^1)_2$ + NOBA]. ^1H NMR (250 MHz, CD_3CN): δ (ppm) = 7.69 (d, 2 H, pyrazolyl H^5), 7.42 (dd, 2 H, methylthiophenyl H^3), 7.33 (ddd, 2 H, methylthiophenyl H^5), 7.25 (dd, 2 H, methylthiophenyl H^6), 7.19 (td, 2 H, methylthiophenyl H^4), 7.10 (s, 4 H, phenyl), 6.56 (d, 2 H, pyrazolyl H^4), 5.22 (s, 4 H, CH_2), 2.28 (s, 6 H, SMe); (500 MHz, CD_3NO_2): δ (ppm) = 7.80 (d, 2 H, pyrazolyl H^5), 7.37–7.42 (m, 4 H, methylthiophenyl H^3, H^5), 7.29 (td, 2 H, methylthiophenyl H^4), 7.28 (d, 2 H, methylthiophenyl H^6), 6.86 (s, 4 H, phenyl), 6.61 (d, 2 H, pyrazolyl H^4), 5.17 (s, 4 H, CH_2), 2.24 (s, 6 H, SMe). IR (KBr disk): $\tilde{\nu}$ 3108 (w), 2920 (w), 1624 (w), 1590 (w), 1519 (m), 1495 (m), 1430 (s), 1384 (s), 1339 (s), 1321 (s), 1259 (m), 1226 (m), 1065 (m), 1038 (w), 963 (m), 948 (m), 758 (s), 734 (m), 705 (w) cm^{-1}. $C_{28}H_{26}AgN_5O_3S_2$ (652.54): calcd. C 51.5, H 4.2, N 10.7; found C 51.4, H 4.1, N 10.6.

Preparation of $\{[CuL^2](BF_4)\}_\infty$: $[Cu(CH_3CN)_4]BF_4$ (61 mg, 0.19 mmol) was added to a solution of L^2 (94 mg, 0.19 mmol) in dry MeCN (20 cm^3). The colourless solution was stirred overnight under nitrogen and the volume reduced to ca. 10 cm^3. Diethyl ether diffusion into the solution gave off-white crystals of $[CuL^2](BF_4)$ which were suitable for X-ray crystallography. Yield: 70 mg, 56%. ES MS: *m*/*z* = 545 $[CuL^2]^+$. ^1H NMR (500 MHz, CD_3CN): δ = 7.68 (br. s, 2 H, pyrazolyl H^5), 7.47 (d, 2 H), 7.29–7.36 (m, 5 H), 7.11–7.23 (m, 4 H), 7.07 (s, 1 H), 6.61 (br. s, 2 H, pyrazolyl H^4), 5.32 (s, 4 H, CH_2), 2.34 (br. s, 6 H, SMe) ppm. IR (KBr disk): $\tilde{\nu}$ = 3135 (w), 3057 (w), 2975 (w), 2924 (w), 1610 (w), 1590 (w), 1567 (w), 1518 (m), 1500 (m), 1433 (s), 1406 (m), 1385 (w), 1356 (m), 1327 (w), 1280 (w), 1223 (w), 1169 (w), 1056 (s), 951 (w), 877 (w), 757 (s), 729 (m), 709 (w), 651 (w), 631 (w), 520 (w) cm^{-1}. $C_{28}H_{26}BCuF_4N_4S_2$ (633.02): calcd. C 53.1, H 4.1, N 8.9; found C 52.7, H 4.3, N 8.7.

Preparation of $[AgL^2](BF_4)$: $[Ag(CH_3CN)_4]BF_4$ (71 mg, 0.20 mmol) was added to a solution of L^2 (96 mg, 0.20 mmol) in dry MeCN (20 cm^3). The colourless solution was stirred overnight protected from light and the volume reduced to ca. 10 cm^3. Diethyl ether diffusion into the solution gave off-white crystals of $[AgL^2](BF_4)$ which were suitable for X-ray crystallography. Yield: 98 mg, 73%. ES MS: *m*/*z* = 589 $[AgL^2]^+$. ^1H NMR (500 MHz, CD_3CN): δ = 7.88 (d, 2 H, pyrazolyl H^5), 7.70 (s, 1 H, phenyl H^2), 7.45–7.49 (m, 4 H), 7.34–7.39 (m, 4 H), 7.28 (td, 2 H), 6.95 (dd, 2 H), 6.53 (d, 2 H, pyrazolyl H^4), 5.38 (s, 4 H, CH_2), 1.89 (s, 6 H, SMe) ppm. IR (KBr disk): $\tilde{\nu}$ = 3140 (w), 3127 (w), 3054 (w), 3007 (w), 2926 (w), 1590 (w), 1566 (w), 1516 (m), 1497 (s), 1456 (m), 1431 (s), 1410 (m), 1366 (w), 1351 (m), 1296 (w), 1273 (w), 1260 (w), 1217 (s), 1050 (s), 949 (m), 896 (m), 777 (m), 760 (s), 740 (s), 707 (m), 650 (w), 620 (w), 521 (s) cm^{-1}. $C_{28}H_{26}AgBF_4N_4S_2$ (677.34): calcd. C 49.7, H 3.9, N 8.3; found C 49.6, H 3.6, N 8.2.

Preparation of $\{[CuL^3](BF_4)\}_\infty$: $[Cu(CH_3CN)_4]BF_4$ (50 mg, 0.16 mmol) was added to a suspension of L^3 (89 mg, 0.16 mmol) in dry MeOH (20 cm^3). The resulting suspension was sonicated for 10 min then stirred overnight under nitrogen. Filtration gave $\{[CuL^3](BF_4)\}_\infty$ as an off-white solid which was dried in vacuo. Yield: 86 mg, 76%. FAB MS: *m*/*z* = 621 $[CuL^3]$, 1179 $[Cu(L^3)_2]$, 1331 $[Cu_2(L^3)_2(BF_4)$ and/or $Cu(L^3)_2$ + NOBA]. ^1H NMR (500 MHz, CD_3CN): δ (ppm) = 7.71 (br. s, 2 H, pyrazolyl H^5), 7.46–7.55 (m, 6 H), 7.41 (t, 2 H), 7.27–7.35 (m, 4 H), 7.25 (d, 2 H), 7.21 (m, 1 H), 6.58 (d, 2 H, pyrazolyl H^4), 5.40 (s, 4 H, CH_2), 2.28 (s, 6 H, SCH_3) ppm. IR (KBr disk): $\tilde{\nu}$ = 3143 (w), 2925 (w), 1602 (w), 1519 (w), 1502 (m), 1435 (m), 1412 (m), 1360 (w), 1329 (w), 1232 (m), 1083 (s, br), 1060 (s), 785 (m), 771 (m), 756 (s), 732 (w), 699 (m), 623 (w), 520 (w) cm^{-1}. $C_{34}H_{30}BCuF_4N_4S_2$ (709.12): calcd. C 57.6, H 4.3, N 7.9; found C 57.3, H 4.2, N 7.9. X-ray quality crystals were grown from diethyl ether diffusion into an acetonitrile solution of the complex.

Preparation of $\{[AgL^3](BF_4)\}_\infty$: $[Ag(CH_3CN)_4]BF_4$ (61 mg, 0.17 mmol) was added to a suspension of L^3 (95 mg, 0.17 mmol) in dry MeCN (20 cm^3). The colourless solution was protected from light and stirred overnight. The volume was then reduced to ca. 10 cm^3 in vacuo. Diethyl ether diffusion into the resulting solution gave off-white crystals of $\{[AgL^3](BF_4)\}_\infty$ which were suitable for X-ray crystallography. Yield: 114 mg, 89%. FAB MS: *m*/*z* = 667 $[Ag(L^3)]$, 1225 $[Ag(L^3)_2]$, 1332 $[Ag_2(L^3)_2]$, 1378 $[Ag(L^3)_2$ + NOBA], 1419 $[Ag_2(L^3)_2(BF_4)]$, 1485 $[Ag_2(L^3)_2$ + NOBA]. ^1H NMR (500 MHz, CD_3CN): δ (ppm) = 7.78 (d, 2 H, pyrazolyl H^5), 7.43–7.47 (m, 4 H), 7.40 (ddd, 2 H), 7.37 (td, 2 H), 7.30 (ddd, 2 H), 7.22 (td, 2 H), 7.18 (ddd, 2 H), 7.09 (dd, 2 H), 6.51 (d, 2 H, pyrazolyl H^4), 5.30 (s, 4 H, CH_2), 2.04 (s, 6 H, SMe). IR (KBr disk): $\tilde{\nu}$ = 3139 (w), 2924(w), 1604 (w), 1589 (w), 1519 (w), 1497 (m), 1432 (m), 1410 (m), 1356 (m), 1324 (w), 1262 (w), 1220 (m), 1061 (s, br), 786 (m), 757 (s), 728 (m), 703 (w), 520 (w) cm^{-1}. $C_{34}H_{30}AgBF_4N_4S_2$ (753.43): calcd. C 54.2, H 4.0, N 7.4; found C 54.1, H 3.9, N 7.4.

Preparation of $[CuL^4](PF_6)$: $[Cu(CH_3CN)_4]PF_6$ (57 mg, 0.15 mmol) was added to a suspension of L^4 (82 mg, 0.15 mmol) in dry MeCN (20 cm^3) and the colourless solution was stirred overnight. The volume was then reduced to ca. 10 cm^3 in vacuo and the solution filtered to remove a small amount of solid. Diethyl ether diffusion into the resulting solution gave off-white crystals of $[CuL^4](PF_6)$ which were suitable for X-ray crystallography. Yield: 57 mg, 50%. FAB MS: *m*/*z* = 595 $[Cu(L^4)]$. ^1H NMR (500 MHz, CD_3CN): δ (ppm) = 8.17 (dd, 2 H), 7.75 (dd, 2 H), 7.60–7.70 (m, 6 H), 7.42–7.49 (m, 6 H), 6.72 (d, 2 H, pyrazolyl H^4), 5.64 (s, 4 H, CH_2), 2.42 (s, 6 H, SMe). IR (KBr disk): $\tilde{\nu}$ = 2923 (w), 1624 (w), 1515 (w), 1499 (w), 1487 (w), 1431 (m), 1371 (m), 1325 (m), 1211 (m), 1065 (m), 841 (s), 781 (m), 760 (s), 685 (w), 557 (s) cm^{-1}. $C_{32}H_{28}CuF_6N_4PS_2$ (741.24): calcd. C 51.9, H 3.8, N, 7.6; found C 51.5, H 3.8, N, 7.7.

Preparation of $[AgL^4](BF_4)$: $[Ag(CH_3CN)_4]BF_4$ (137 mg, 0.38 mmol) was added to a suspension of L^4 (204 mg, 0.38 mmol) in EtOH (20 cm^3) protected from light and the mixture was stirred overnight. The off-white solid was collected by filtration and dried in vacuo. Yield: 247 mg, 89%. FAB MS: *m*/*z* = 641 $[Ag(L^4)]$. ^1H NMR (400 MHz, CD_3CN): δ (ppm) = 8.15 (dd, 2 H), 7.69 (dd, 2 H), 7.63 (dd, 2 H), 7.49 (m, 2 H), 7.41–7.45 (m, 4 H), 7.31 (m, 2 H), 7.16 (d, 2 H, pyrazolyl H^5), 6.47 (d, 2 H, pyrazolyl H^4), 5.78 (s, 4 H, CH_2), 2.50 (s, 6 H, SMe). ^{13}C NMR (100 MHz, CD_3CN): δ (ppm) = 152.6, 137.6, 135.7, 135.4, 133.3, 132.1, 131.7 (2 closely spaced signals), 131.1, 130.3, 129.8, 127.0 (2 closely spaced signals), 126.7, 107.9, 57.7, 16.9. IR (KBr disk): $\tilde{\nu}$ = 3144 (w), 2924 (w), 1590 (w), 1515 (w), 1496 (w), 1485 (w), 1429 (m), 1362 (w), 1324 (m), 1212 (m), 1103 (m), 1070 (s, br), 1048 (s), 849 (w), 825 (w), 779 (m), 765 (s), 684 (w), 520 (w) cm^{-1}. $C_{32}H_{28}AgBF_4N_4S_2$ (727.40): calcd. C 52.8, H 3.9, N 7.7; found C 52.3, H 3.8, N 7.6. X-ray quality crystals were obtained from slow evaporation of the filtrate when the reaction was carried out in methanol.

Preparation of $[CuL^5](BF_4)$: $[Cu(CH_3CN)_4]BF_4$ (54 mg, 0.17 mmol) was added to a suspension of L^5 (84 mg, 0.12 mmol) in dry and

degassed EtOH (20 cm^3) and the suspension was stirred overnight under nitrogen. The volume was then reduced to ca. 10 cm^3 in vacuo and the off-white powder filtered off. Yield: 90 mg, 89%. FAB MS: *m*/*z* = 789 [Cu(L^5)], 1006 [$Cu_2(L^5)$ + NOBA], 1515 [$Cu(L^5)_2$], 1669 [$Cu(L^5)_2$ + NOBA]. IR (KBr disk): $\tilde{\nu}$ =3134 (w), 2978 (w), 2918 (w), 1630 (w), 1588 (w), 1563 (w), 1486 (m), 1454 (m), 1433 (s), 1399 (m), 1326 (m), 1256 (w), 1216 (m), 1083 (s), 1064 (s), 1048 (s), 945 (w), 753 (s), 733 (m), 652 (w), 617 (w) cm^{-1}. $C_{42}H_{42}BCuF_4N_6S_3$ (877.38): calcd. C 57.5, H 4.8, N 9.6; found C 57.2, H 5.0, N 9.4.

Preparation of [AgL^5](ClO_4): ***Caution: Perchlorate salts are potentially explosive and should only be prepared in small quantities and handled with care!*** $AgClO_4 \cdot H_2O$ (38 mg, 0.18 mmol) was added to a suspension of L^5 (90 mg, 0.12 mmol) in dry MeCN (20 cm^3) and the colourless solution was stirred overnight while protected from light. The volume was then reduced to ca. 10 cm^3 in vacuo. Diethyl ether diffusion into the resulting solution gave colourless crystals of [AgL^5](ClO_4) which were suitable for X-ray crystallography. Yield: 93 mg, 80%. FAB MS: *m*/*z* = 835 {Ag(L^5)}. ^{1}H NMR (250 MHz, CD_3CN): δ (ppm) 7.79 (d, 3 H, pyrazolyl H^5), 7.44 (dd, 3 H, meth-

X-ray Crystallography: X-ray crystallographic data are summarised in Table 11, Table 12, Table 13 and Table 14. For each compound a suitable crystal was coated with hydrocarbon oil and attached to the tip of a glass fibre and transferred to Bruker-SMART diffractometer under a stream of cold N_2. Data were collected using a Siemens SMART CCD area diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å) with an Oxford Cryosystems low temperature system. The data were corrected for Lorentz and polarisation effects and for absorption by semi-empirical methods (SADABS)[18] based on symmetry-equivalent and repeated reflections. The structures were solved by direct methods or heavy atom Patterson methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model and with U_{iso} constrained to be 1.2 (1.5 for methyl groups) times U_{eq} of the carrier atom. Structures were solved and refined using the SHELX suite of programs.[19] Selected

Hexaazamacrocycle Containing Pyridine and Its Dicopper Complex as Receptors for Dicarboxylate Anions

Feng Li,[a] Rita Delgado,*[a,b] and Vítor Félix[c]

Keywords: Hexaazamacrocycle / Dicarboxylate anion recognition / Cascade dicopper complexes / Molecular dynamics / Receptors

The host–guest binding interactions of the hexaazamacrocycle [26]py_2N_4, in its tetraprotonated form H_4[26]$py_2N_4^{4+}$ as well as in its dicopper(II) complex $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$, with dicarboxylate anions of different stereoelectronic requirements, such as oxalate (ox^{2-}), malonate (mal^{2-}), succinate (suc^{2-}), fumarate (fu^{2-}) and maleate (ma^{2-}), were evaluated. The association constants were determined using potentiometric methods in aqueous solution, at 298.0 K and 0.10 mol·dm^{-3} KCl. These values for the tetraprotonated ditopic receptor with the dicarboxylate anions revealed that the main species in solution corresponds to the formation of $\{H_4[26]py_2N_4(A)\}^{2+}$ (pH ≈ 4–9), A being the substrate anion. The values determined are not especially high, but the receptor exhibits selectivity for the malonate anion. The study of the cascade complexes revealed several species in solution, involving mononuclear and dinuclear complexes, mainly protonated and hydrolysed species, as well as the expected complexes $[Cu_2([26]py_2N_4)(A)(H_2O)_x]^{2+}$ or $[Cu_2([26]py_2N_4)(A)_2(H_2O)_y]$. Ox^{2-} and mal^{2-} form cascade complexes with only one anion, which will necessarily bridge the two copper atoms because of the symmetrical arrangement of the dinuclear complex. The two other studied anions, suc^{2-} and ma^{2-}, form species involving two substrate anions, although species with only one suc^{2-} anion were also found. UV/Vis and EPR spectroscopy have shown that the dicopper complex can operate as a sensor to detect and quantitatively determine oxalate spectrophotometrically because of the red shift of the maximum of the visible band observed by addition of ox^{2-} to an aqueous solution of the dinuclear copper complex. However the selectivity of $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ as a receptor for ox^{2-} in the studied series is not sufficiently high to detect ox^{2-} spectrophotometrically in the presence of the other anions. Molecular dynamics simulations indicated that the $H_4[26]py_2N_4^{4+}$ receptor provides a large and flexible cavity to accommodate the studied anions. Molecular recognition is based in electrostatic interactions rather than in multiple hydrogen-bonding interactions acting cooperatively. By contrast, the $[Cu_2([26]py_2N_4)]^{4+}$ receptor has a well-shaped cavity with adequate size to uptake these anions as bridging ligands with formation of four Cu–O bonds. The ox^{2-} anion is encapsulated within the cascade complex while the remaining anions are located above the N_6 macrocyclic plane, suggesting a selective coordination behaviour of this receptor. In spite of our molecular simulation being carried out in gas phase, the modelling results are consistent with the solution studies.

Introduction

Anion recognition is an active area of supramolecular chemistry, stimulated by the chemical and biological importance of anions.[1–4] The design and synthesis of unusual receptors are also a challenge for researchers. Up to now various types of synthetic receptors for the binding of anions have been developed, although receptors for the selective binding of nonspherical anions are scarce.[1–6] Therefore there is a great need for novel anion receptors in order to better characterise anion association patterns and to obtain novel binding features.

Carboxylate anions play an important role in organic, environmental and biological processes. The carboxylate functions of enzymes and antibodies contribute to their specific biochemical behaviour and they are critical components of numerous metabolic processes.[5]

The binding of anionic substrates by a specific receptor results essentially from electrostatic interactions and hydrogen-bonding formation. Additional π–π stacking, van der Waals interactions or hydrophobic effects strongly contribute to the selective recognition process. Protonated polyazamacrocycles and cryptands can bind anions by electrostatic interactions, and simultaneously by hydrogen-bonding interactions between protonated nitrogen of the receptor and an acceptor atom from the substrate. These receptors are particularly interesting in the recognition of anions when they are completely charged in neutral or slightly acidic

aqueous solutions. Therefore, among the various types of synthetic receptors for the recognition of anions, polyamines have an important place, especially in aqueous environments.[1–6] The binding of anions by one or more metal centres forming cascade complexes is also a rich field of research. Metal complexes as receptors covalently bind anions, and then the interactions are in general stronger than those observed when only electrostatic or hydrogen-bonding interactions exist.[7,8]

In the present work the hexaazamacrocycle, 3,10,18,25,31,32-hexaazatricyclo[25.3.1.1^{12,16}]dotriaconta-1(31),12,14,16(32),27,29-hexaene ([26]py$_2$N$_4$),[9] was used directly as a ditopic receptor in the form of tetraammonium hydrochloride salt (H$_4$[26]py$_2$N$_4$·4Cl) for the study of anion-binding properties (see Scheme 1). The dicopper(II) complex of [26]py$_2$N$_4$ was also used as a receptor in cascade associations with the same anions. These receptors allowed a systematic evaluation of the main features involved in host–guest binding interactions with dicarboxylate anions with different sizes and flexibilities, such as ox^{2-}, mal^{2-}, suc^{2-}, fu^{2-} and ma^{2-} (see Scheme 2). The association constants were determined using potentiometric methods. Additional UV/Vis and EPR spectroscopic techniques were performed for the study of the cascade dicopper complexes. In order to give further insight into the solution results, molecular modelling studies comprising molecular mechanics and dynamics simulations were undertaken in gas phase.

Results and Discussion

Anionic Associations with the Receptor H$_4$[26]py$_2$N$_4^{4+}$

The association constants of H$_4$[26]py$_2$N$_4^{4+}$ with ox^{2-}, mal^{2-}, suc^{2-}, fu^{2-} and ma^{2-} were determined in aqueous solutions at 298.0 K and 0.10 mol·dm^{-3} KCl, using the HYPERQUAD programme.[10] The guests are dicarboxylate anions that differ in shape, size and rigidity. The values obtained were collected in Table 1.

As the final results strongly depend on the protonation constants of the guest anions and the reported values are spread out,[11] we redetermined them in our experimental conditions and the values obtained are compiled in Table 2. The protonation constants of [26]py$_2$N$_4$ were also determined in the same experimental conditions. The values found were within the usual standard deviations for those determined before in KNO$_3$, therefore the values already published have been adopted[9] (see Table 3).

Only three constants, corresponding to the following equilibria, were found:

$$H_4[26]py_2N_4^{4+} + HA^- \rightleftharpoons \{H_5[26]py_2N_4(A)\}^{3+} \text{ (species 511)} \qquad K_1$$

$$H_4[26]py_2N_4^{4+} + A^{2-} \rightleftharpoons \{H_4[26]py_2N_4(A)\}^{2+} \text{ (species 411)} \qquad K_2$$

$$H_3[26]py_2N_4^{3+} + A^{2-} \rightleftharpoons \{H_3[26]py_2N_4(A)\}^{+} \text{ (species 311)} \qquad K_3$$

The main species corresponds to the formation of $\{H_4[26]py_2N_4(A)\}^{2+}$, which exists in solution from about 4 to 9 pH. The $\{H_5[26]py_2N_4(A)\}^{3+}$ and $\{H_3[26]py_2N_4(A)\}^{+}$ species exist in smaller percentages, the former at lower pH and the latter at higher pH values. A typical species distribution diagram is represented in Figure 1 for the case of malonate anion, using the HYSS programme.[12]

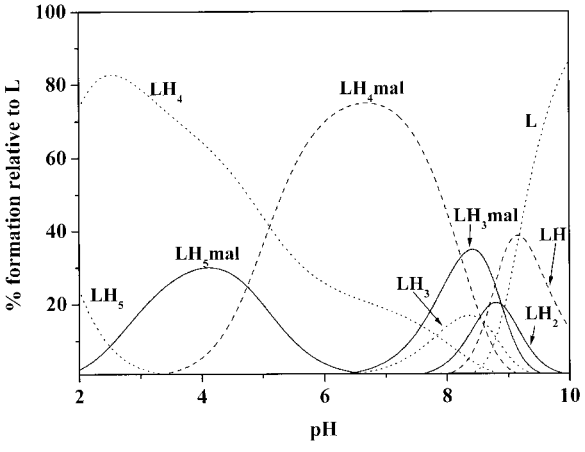

Figure 1. Species distribution curves calculated for the H_4[26]-$py_2N_4^{4+}$/mal^{2-} association in 1:1 ratio, C_L = C_{mal} = 2.00×10^{-3} mol·dm^{-3}, L being the macrocyclic ligand.

The values determined are not especially high, but the receptor is selective for malonate anion (see Figure 2). As can be observed, the K_2 values increase from oxalate to malonate and then successively decrease for the other anions, indicating that the size of the anion is the most important feature for the best association to the receptor. The overall basicity and the rigidity of the anions seem not to be very important factors for the interaction.

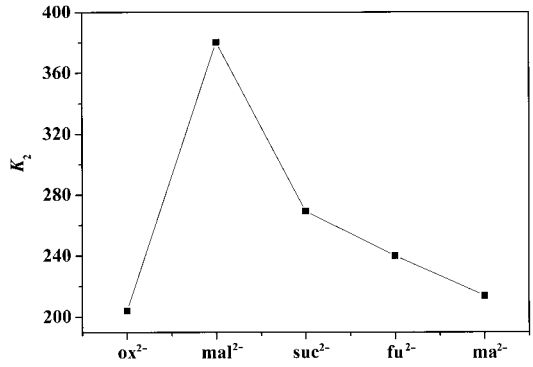

Figure 2. Plot of K_2 in function of the studied anions with different sizes and rigidities.

Cascade Dicopper Complexes

Potentiometric Measurements

The stability constants of [26]py_2N_4 with Cu^{2+} ion determined in aqueous solution at 298.0 K and 0.10 mol·dm^{-3} in KCl are also collected in Table 3.[9] For the Cu^{2+}/[26]py_2N_4 2:1 stoichiometry only dinuclear species are formed, {$[Cu_2L(H_2O)_4]^{4+}$, $[Cu_2(HL)(H_2O)_4]^{5+}$ and $[Cu_2L(H_2O)_{4-i}(OH)_i]^{4-i}$ (i = 1–4 and L = [26]py_2N_4 after pH = 4).[9] Free Cu^{2+} ions almost disappear from the solution at pH values of about 5 to yield $[Cu_2L(H_2O)_4]^{4+}$, which is the main species from pH 5 to about 8, followed by the successive hydrolysis of the four H_2O molecules directly bound to the two copper centres, $[Cu_2L(OH)_i]^{4-i}$ (i = 1–4) (see also Table 3). The X-ray single-crystal structure of the dicopper complex with a related ligand [20]py_2N_4, having propyl spacers between the pyridine heads (see Scheme 1), showed that two water molecules are directly coordinated to each copper centre,[9] and the same species was confirmed in aqueous solution.[13] Each copper centre is located at each head of the macrocycle, displaying a distorted square-pyramidal coordination environment with the basal plane defined by three consecutive nitrogen donors and one water molecule and the apical position fulfilled with the other water molecule at a longer distance than the equatorial one.[9] Therefore the presence of $[Cu_2L(H_2O)_4]^{4+}$ confirmed in our solution results led us to assume that an iden-

tical structure is adopted by the complex studied in the present work.

The predisposition of $[26]py_2N_4$ to form dinuclear complexes with copper centres, also confirmed by EPR studies,[9] led us to take advantage of this specific feature for the study of cascade complexes with dicarboxylate anions to investigate whether these guests bridge the two metal centres or, in contrast, two guests coordinate to each copper centre.

The association constants of the cascade complexes formed by addition of the anions to aqueous solutions of $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ at 298.0 K were determined using potentiometric measurements. The studied anions are ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-} (see Scheme 2). The results are summarised in Table 4, and were obtained using the protonation constants of $[26]py_2N_4$ and of the anions and their stability constants with copper determined in our experimental conditions compiled in Table 2 and Table 3.

Several species were found in solution involving mononuclear and dinuclear complexes, mainly protonated and hydrolysed species as well as the expected complexes $[Cu_2([26]py_2N_4)(A)(H_2O)_x]^{2+}$ or $[Cu_2([26]py_2N_4)(A)_2(H_2O)_y]$, A being the guest anion, as can be seen in Table 4.

The first conclusion derived from the data of Table 4 is the distinct behaviour exhibited by oxalate and malonate substrates when compared with maleate, the succinate displaying intermediate features. Oxalate and malonate form cascade complexes with $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ involving only one anion, which necessarily will bridge the two copper atoms because of the symmetrical arrangement of the dinuclear complex. The two other studied anions, succinate and maleate, form species containing two anionic substrates, although species with only one suc^{2-} anion were also found. When two substrates are involved, each one can be directly coordinated to each copper, forming a dinuclear complex of independent centres, or both anions bridge the two metal centres. The adopted structure will be the result of a delicate balance of strain energies. Indeed the folded structure adopted by the dinuclear complex will rearrange for the encapsulation of the bridging anion(s), and the expended energy for the rearrangement should only be compensated by stronger interactions of the anion to the copper centres; this means anions can be better accommodated into the topology offered by the cavity formed between both copper centres.

The main species formed in the 5–9 pH range is $[Cu_2([26]py_2N_4)(A)(H_2O)_x]^{2+}$ for A = ox^{2-} or mal^{2-}, while for A = suc^{2-} this species and $[Cu_2([26]py_2N_4)(A)_2(H_2O)_x]$ overlap (and also with $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ when the amount of substrate is increased, such as for 2:1:2 Cu/$[26]py_2N_4$/suc^{2-} stoichiometries). For A = ma^{2-}, $[Cu_2([26]py_2N_4)(A)_2(H_2O)_y]$ is the major species, at least for the 2:1:2 ratio, although for lower substrate proportions the significance of $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ increases for slightly lower pH values. By potentiometric measurements, the number of water molecules in the complexes, *x* and *y*, was not possible to be determined, because in all cases the best models with coordination chemistry sense, accepted by the HYPERQUAD programme,[10] only contain species with one water molecule for which the corresponding hydrolysis constant was determined (see Table 4). For pH values lower than 5, mononuclear and dinuclear protonated complexes, involving the anion or not, are formed, and for pH values higher than 8 the water molecule of the cascade complexes starts to be hydrolysed.

However, in all cases the hydrolysed complexes $[Cu_2([26]py_2N_4)(H_2O)_{4-x}(OH)_x]^{4-x}$ replace the cascade dinuclear species containing the dicarboxylate, at high pH (>8), al-

[a] See Experimental, Calculation of Stability Constants, for definitions. [b] Values in parenthesis are standard deviations in the last significant figures. [c] Values in brackets are determined with large standard deviations; because the species exist in solution in small amounts (<10%), the final model was refined without these species.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

though, depending on A, small amounts of mononuclear species, $\{Cu([26]py_2N_4)A\}$ or $\{Cu([26]py_2N_4)A_2\}^{2-}$, were also found. This indicates that the dicarboxylate anions, whether bridging the two copper centres or not, are replaced by OH^- groups at high pH values, or in other words, the cascade complexes dissociate, yielding successively the species $[Cu_2([26]py_2N_4)(H_2O)_{4-x}(OH)_x]^{4-x}$ with an increase of pH.

These and other features of the behaviour of these complexes in aqueous solutions as a function of the pH can be observed in Figure 3 and Figure 4 for mal^{2-} and suc^{2-} anions, respectively. The comparison of the species distribution diagrams for suc^{2-} and ma^{2-} anions (see the diagram for ma^{2-} in the Supporting Information) emphasises the intermediate behaviour of the succinate anions, as already mentioned. Indeed between pH 5 and 9 both species, $[Cu_2([26]py_2N_4)(suc)(H_2O)_x]^{2+}$ and $[Cu_2([26]py_2N_4)(suc)_2(H_2O)_x]$, exist in solution in percentages depending on the suc^{2-} ratio, while only the $[Cu_2([26]py_2N_4)(ma)_2(H_2O)_x]$ complex is formed in the same pH range (for lower anion ratios the percentage of $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ increases in both cases).

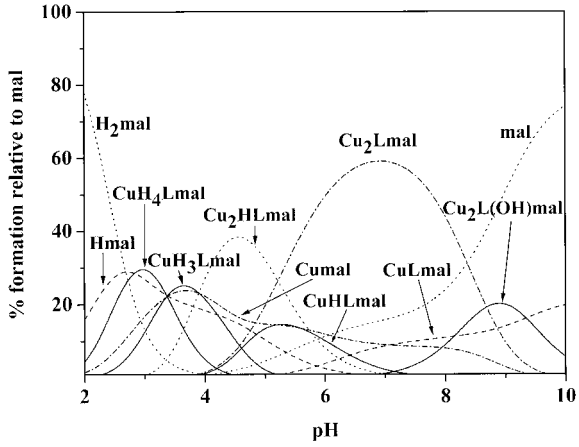

Figure 3. Species distribution curves calculated for the system $[Cu_2([26]py_2N_4)(H_2O)_x]^{4+}/mal^{2-}$ for 1:1 ratio, $C_{complex} = C_{mal} = 2.00 \times 10^{-3}$ mol·dm^{-3}, "complex" being the dicopper complex, L the $[26]py_2N_4$ and mal^{2-} the malonate anion guest.

The copper–substrate interaction, measured by the magnitude of the association constant corresponding to the equilibrium $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+} + A^{2-} \rightleftharpoons [Cu_2([26]py_2N_4)(A)(H_2O)_x]^{2+}$ (Table 4 and Table 5) is stronger for A = ox^{2-}, followed by mal^{2-} and then suc^{2-}, the values being 4.97, 3.93 and 3.58 log units, respectively (see Table 5, where the stepwise constants and the corresponding equilibrium reactions are summarised). On the other hand, the corresponding constant for the equilibrium $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+} + 2\ A^{2-} \rightleftharpoons [Cu_2([26]py_2N_4)(A)_2(H_2O)_x]$ is higher for ma^{2-} anions, being 7.39 for this anion and 6.87 for suc^{2-}, in log units. Then the strength of the Cu···A···Cu interaction decreases with the increase of the length of the spacer between the two carboxylate sites, being stronger for oxalate and weaker for succinate anions. This trend is opposite to the overall basicity of the anions, which follows the order succinate > malonate >> oxalate (see Table 2). The same happens with the species involving two carboxylate anions, suggesting that the size of the anion and its rigidity are the most important factors for the verified order of association constants.

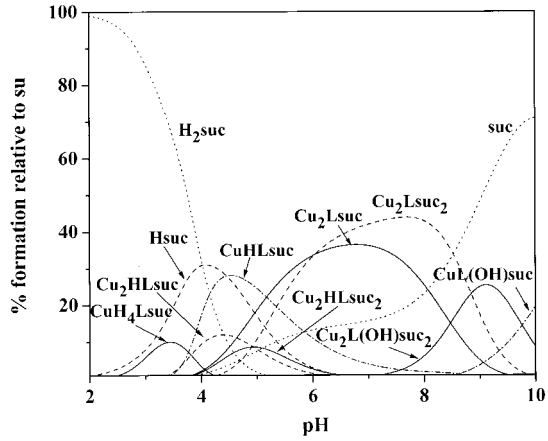

Figure 4. Species distribution curves calculated for the system $[Cu_2([26]py_2N_4)(H_2O)_x]^{4+}/suc^{2-}$ for 1:1 ratio, $C_{complex} = C_{suc} = 2.00 \times 10^{-3}$ mol·dm^{-3}, "complex" being the dicopper complex and suc^{2-} the guest succinate anion.

Spectroscopic Measurements

The UV/Vis spectrum of aqueous $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ solution was recorded at pH ≈ 6. The complex exhibits a broad d-d band at 660 nm and three main bands in the UV region at 288, 262 and 206 nm (see Table 6). The intense band at 262 nm was attributed to ligand-to-metal charge transfer absorption (LMCT). The addition of increasing amounts of the studied anion guests led to a hypochromism (a decrease in the molar absorptivity) and to a shift in wavelength of the visible band in all cases, the shifts being smaller in the UV region (see Table 6). However, while the shift of the visible band is to the red in the presence of ox^{2-}, a blue shift is observed for the other three anions, although very small for mal^{2-}.

$[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ + ma^{2-}	7.72	202 (38592.3); 208 (sh., 33418.6); 250 (sh., 16517.4); 258 (18446.1); 266 (sh., 15511.9); 282 (6663.6); 650 (336.4)

The red shift of the visible band observed when the substrate is ox^{2-} assigns the presence of this anion, but also reveals a change of the structure adopted by the copper centres in this complex because of the bridging anion,[14–17] while the blue shifts resulting from the presence of the other dicarboxylates should be a consequence of the stronger equatorial field derived from the replacement of a water molecule by the oxygen atom of the carboxylate group of the anion.

The X-band EPR spectrum of a frozen water/DMSO (1:1 v/v) solution of $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ is typical of a coupled dinuclear copper triplet-state centre with a $S = 1$ state and zero-field splitting, having two types of signals in the $\Delta M_s = 1$ and $\Delta M_s = 2$ regions[9,18,19] (see Figure 5). The $\Delta M_s = 2$ transition signal reveals a spin-exchange interaction between the two copper atoms, but the signal is very small and the seven hyperfine lines resulting from the coupling of each unpaired electron with the two copper nuclei cannot be observed.

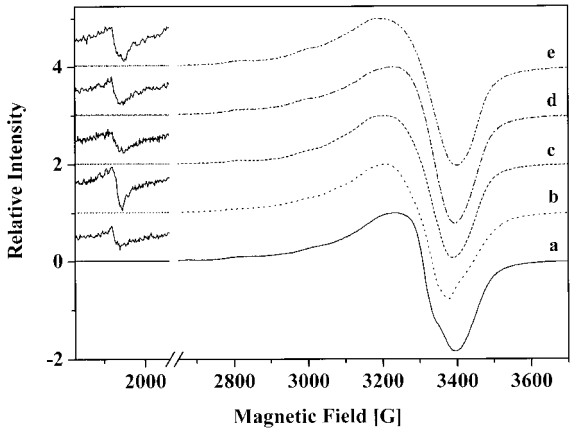

Figure 5. EPR X-band spectra of $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ (bottom) at 6.4 K and of $[Cu_2([26]py_2N_4)(A)(H_2O)_x]^{2+}$, A being successively ox^{2-} (at 11.4 K), mal^{2-} (at 11.4 K), suc^{2-} (at 6.4 K) and ma^{2-} (at 6.4 K). The signal at low field for each complex was amplified and placed above the axis. All the complexes were prepared at 2.0×10^{-3} mol·dm^{-3} in DMSO/H_2O (1:1). The spectra were recorded at the microwave power of 2.4 mW, modulation amplitude of 1.0 mT and at the frequency (ν) 9.646 GHz.

When oxalate anion is added to the solution of the dinuclear copper complex, a new signal at ≈3500 G appears, and in the $\Delta M_s = 2$ region the hyperfine structure is now perceptible, revealing a shorter distance between both copper centres because of the presence of the bridging anion. Indeed for $\Delta M_s = 1$ transitions, two groups of peaks spaced on either side of $g \approx 2$ emerge, showing an overall width as a function of r (the distance between the two copper centres).[20] Considering D, the zero-field splitting within the triplet state, built up from a dipolar contribution D_{dip}, and an exchange contribution, D_{ex}: $D = D_{ex} + D_{dip}$, and if we consider $D_{ex} \approx 0$ (valid for $-J \leq 30$ cm^{-1}), the r distance can be evaluated directly from D.[21] It was possible to estimate the D value from the spectrum only for the case of $[Cu_2([26]py_2N_4)ox]^{2+}$. The spectra of the cascade complexes for the other anions are too broad to allow the determination of the D value (see Figure 5). However for $[Cu_2([26]py_2N_4)ox]^{2+}$ the $2D$ value was calculated by the difference between the Hz_2 and Hz_1 transitions, yielding to 0.0128 cm^{-1}. Even in this case it was difficult to observe all the lines of the two expected septets, however from the more intense lines (third to fifth) it was possible to obtain a satisfactorily accurate value of the zero-field splitting constant. Taking $g_{\|} = 2.237$ and $g_{\perp} = 2.10$, obtained directly from the spectrum, the value of 6.3 ± 0.2 Å was determined for the copper–copper distance in the $[Cu_2([26]py_2N_4)ox]^{2+}$ complex.

Molecular Modelling

In order to give a further insight in our solution studies, the binding ability of $[26]py_2N_4$ to accommodate ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-} anions in its tetraprotonated form or, alternatively, as bridging ligands in its copper dinuclear complex was evaluated in gas phase through molecular mechanics (MM) and molecular dynamics (MD) simulations using the Universal Force Field[22] within the Cerius2 software package.[23]

The molecular modelling studies started with the conformational analysis of the $H_4[26]py_2N_4^{4+}$ following quenching dynamics methods over 2 ns. 10000 conformations were generated and subsequently minimised by MM as described in the experimental section. The final structures have energies in a wide range of 667.43–716.94 kcal·mol^{-1}. In spite of the presence of the two pyridine heads in the macrocyclic framework, between these two limits, the energy changes almost continuously. This result is expected due to the large

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

number of single bonds with corresponding endocyclic torsion angles determining a geometric arrangement between a *gauche* and a *trans* configuration. The two pyridine rings oscillate continuously, with the dihedral angle between them ranging from 0.1° to 134.3°. Furthermore, the intermolecular distance between the pyridine nitrogen donors, ranging from 7.591 to 11.261 Å, indicates that the receptor can adopt conformational shapes with different cavity sizes. The interactions between this receptor and ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-} were further investigated, docking each one of these four anions to the lowest energy conformation of $H_4[26]py_2N_4^{4+}$, also using a MD quenching methodology. The lowest energy structures found, presented in Figure 6, show that the $H_4[26]py_2N_4^{4+}$ receptor adopts different conformational shapes providing a suitable cavity to encapsulate all four of these dicarboxylate anions. The electrostatic bonding interactions dictate the molecular recognition between the receptor and each anion in gas phase. Indeed the binding energy determined from the difference between the energy of the inclusion compound and the sum of the individual energies of the $H_4[26]py_2N_4^{4+}$ receptor (lowest energy conformation) and the anion, listed in Table 7, indicates that in all cases the inclusion process is highly favourable, the electrostatic term being the largest contributor. Further, the dynamic behaviour of each inclusion compound was evaluated by MD at 300 K over 1 ns. In Table 8 the most significant short N–H···O hydrogen contacts found during the simulations using a cut-off of 2.5 Å for H···O distances are listed. The number of hydrogen-bonding interactions increases with the size of the anion following the order ox^{2-}, ma^{2-}, mal^{2-} and suc^{2-}. The ox^{2-} anion establishes with the $H_4[26]py_2N_4^{4+}$ receptor only one N–H···O hydrogen bond during about 170 ps of simulation with a Φ frequency of only 3.2 s^{-1}, while the oxygen atoms of the two carboxylate groups of ma^{2-} are involved in two hydrogen bonds with two N–H binding sites for almost the entire duration of the simulation. However, these contacts have low frequencies of 2.7 and 3.1 ps^{-1}, occurring separately for almost the whole time. The mal^{2-} and suc^{2-} form through two oxygen atoms, respectively, four and five N–H···O hydrogen bonds with the $H_4[26]py_2N_4^{4+}$ receptor. Again in both cases all these intermolecular contacts show low frequencies and only occasionally (without statistical significance) act cooperatively for the molecular recognition phenomena. These results show that the $H_4[26]py_2N_4^{4+}$ receptor has high flexibility and a too large cavity that is inappropriate for molecular recognition of the anions.

	421.4–650.7	1.33	N_1–H_b···O_1
	0.1–408.3	0.52	N_2–H_a···O_1
	5.9–642.5	0.48	N_3–H_a···O_3
	364.1–792.9	1.06	N_4–H_a···O_3
ma^{2-}	0.1–999.8	2.72	N_1–H_a···O_1
	0.3–999.6	1.20	N_3–H_a···O_3

[a] Φ is given by the ratio between the number of times and the period of simulation in which a short contact is observed. For each anion, the N–H-binding groups are labelled in a clockwise manner. [b] The oxygen donor atoms of the anions are labelled using the following atomic notation scheme: O_1 and O_2 for the first carboxylate group and O_3 and O_4 for the second one.

coordinated to $[26]py_2N_4$, the relative positions of the N–H groups, below (–) and above (+) the N_6 macrocyclic plane determine five independent conformations: + + + +, + + – –, + + + –, – + – + and + – – +. All these arrangements have to be considered in a complete analysis of the structural preferences of the coordinated macrocycle, which was undertaken following an identical MD methodology to that described for the $H_4[26]py_2N_4^{4+}$ receptor. For each $[Cu_2([26]py_2N_4)]^{4+}$ conformation a short MD simulation of 100 ps was carried out. The lowest energy conformations found are shown in Figure 7, while their corresponding energies are given in Table 9 together with the Cu···Cu distance and the dihedral angle between the two pyridine rings (called the α angle here). The energies range only between 452.0 and 464.7 kcal·mol^{-1} for + + + + and – + – + conformations, respectively. The + + – – conformation has an energy only 0.9 kcal·mol^{-1} higher than the lowest one. The electrostatic energy term is again the largest contributor for the total energy. The + + + + conformation adopts a cleft topology with an α angle of 59.5° while in the + + – – conformation the two pyridine rings are in antiperiplanar arrangement with an α angle of 164.4°. The remaining three conformations adopt an almost planar shape with the α angle ranging from 151.9° for + – – + to 173.2° for + + + –. The Cu···Cu distance is in a wide range of values between 7.790 and 8.768 Å, so it is not possible to establish any straight relationship between the separation of the two copper centres and the shape or conformation adopted. The first + + + + conformation having an almost planar shape appears at 464.3 kcal·mol^{-1} with an α angle of 160.2° and a Cu···Cu distance of 7.857 Å.

Table 9. Lowest energy conformations for the $[Cu_2([26]py_2N_4)]^{4+}$ receptor.

Conformation	Energy/kcal·mol^{-1}	Cu···Cu/Å	α/°[a]
+ + + +	452.0	8.768	59.5
+ + – –	452.9	8.814	164.4
+ + + –	457.6	8.225	173.2
+ – – +	462.1	7.750	151.9
– + – +	464.7	7.790	163.7

[a] α angle definition is given in the text.

The 3D scatter plot of the α dihedral angle versus steric energy and the Cu···Cu distance found for the conformational analysis of $[Cu_2([26]py_2N_4)]^{4+}$ in the + + + + conformation is presented in Figure 8. This plot shows that most of the conformations have a cleft shape, with the Cu···Cu distance in a narrow range from 8.9 to 9.0 Å. By contrast, the few conformations with almost planar or antiparallel arrangements accommodate a wide range of distances between 8.1 and 9.0 Å.

Alternatively, the distance between the two copper centres tolerated by the macrocyclic cavity can be ascertained from the energy profile for $[Cu_2([26]py_2N_4)]^{4+}$, calculated using our published method.[24] Here, the Cu···Cu dis-

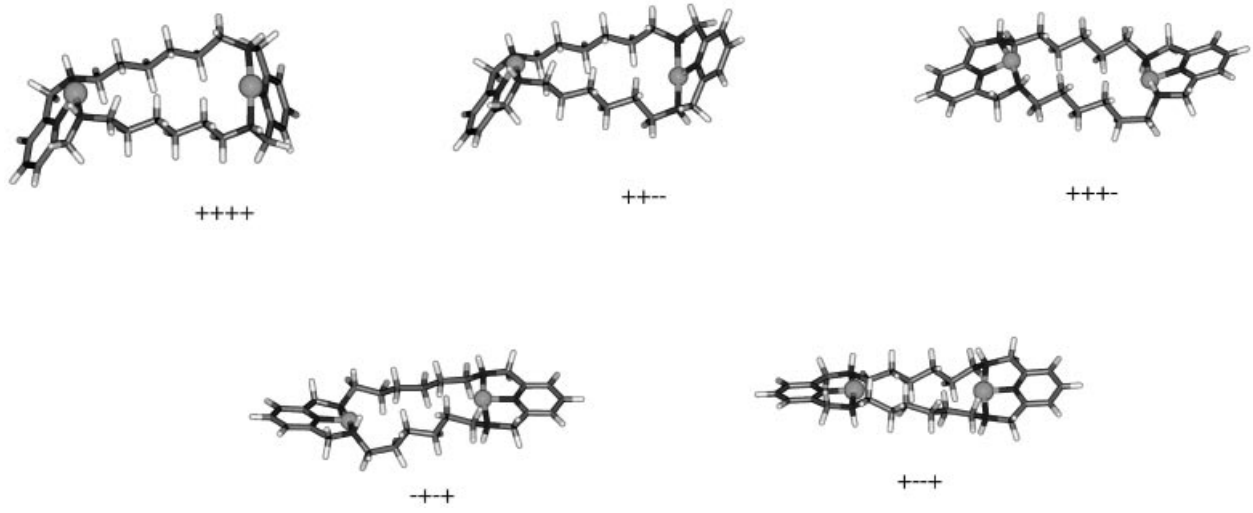

Figure 7. Lowest energy conformations for $[Cu_2([26]py_2N_4)]^{4+}$ receptor.

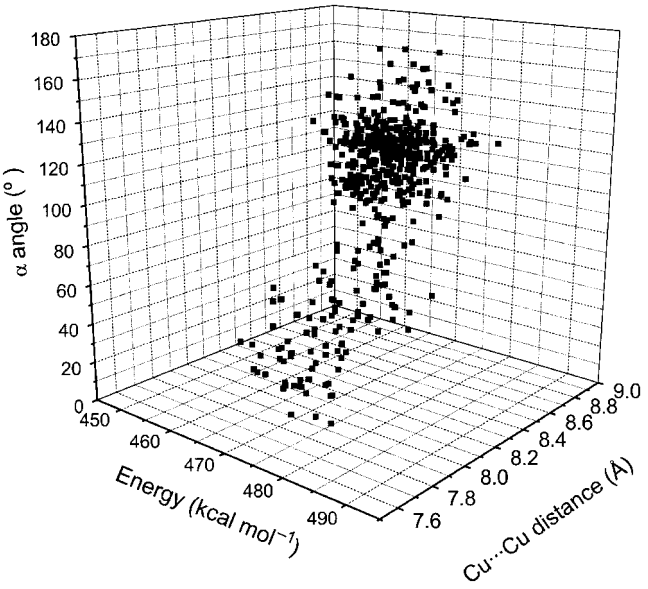

Figure 8. 3D scatter plot of the α angle against steric energy and Cu···Cu distance for $[Cu_2([26]py_2N_4)]^{4+}$ receptor.

tance was varied at 0.1 Å intervals between the limits 7.2–10.0 Å. At each distance the macrocyclic energy is minimised by MM and the resulting energies found for the + + + + cleft conformation (see Table 9), shown in Figure 9, represent the steric strain in the macrocycle caused by a specific Cu···Cu distance. The plot of Figure 9 (bottom) shows an almost deep energy profile with a minimum at 8.75 Å. When this calculation was repeated without charges (Figure 9, top), the energy profile is broad, with the macrocyclic cavity having a better tolerance for short Cu···Cu distances. This result is expected, given that the main repulsive electrostatic interaction derived from the presence of the two Cu^{2+} centres was eliminated. However, the centre of the broad minimum was only shifted 0.25 Å for shorter distances. This result suggests that the macrocycle must adopt a different conformational shape in order to accommodate bridging anions requiring shorter Cu···Cu distances, typically below 8.0 Å.

Having evaluated the steric requirements of the $[Cu_2([26]py_2N_4)]^{4+}$ complex, the interaction between this receptor (+ + + + conformation) and the ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-} anions was investigated through the MD quenching technique for 100 ps. No bonds between the oxygen donors and the two copper centres were included and consequently the host–guest interactions are purely electrostatic. In Figure 10 the lowest energy arrangements found for the four cascade complexes are shown. The sum of MM energies found for isolated anions and $[Cu_2([26]py_2N_4)]^{4+}$ (lowest energy conformation) largely exceed the energy of the corresponding cascade complex, which indicates that in gas phase its formation is highly favourable in all four cases. This binding energy takes the values of –784.4, –755.6, –747.1 and –732.4 kcal·mol^{-1} for ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-}, respectively. The dicarboxylate anions bridge the two copper centres through all four oxygen donors, with Cu–O

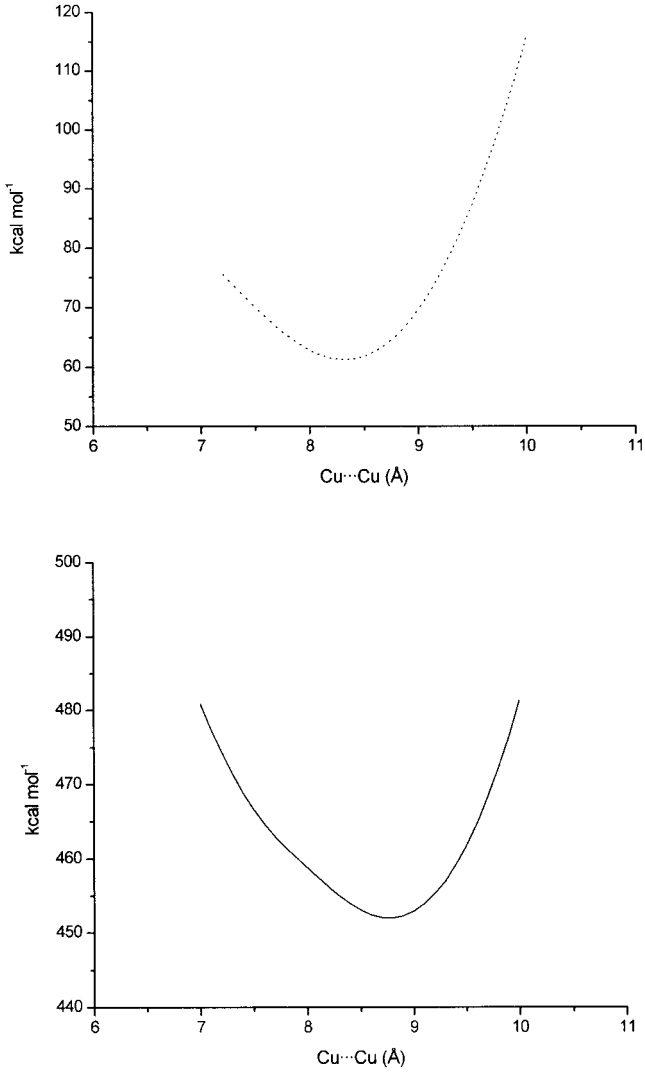

Figure 9. Plot of steric energy profile against Cu···Cu distance for $[Cu_2([26]py_2N_4)]^{4+}$ receptor with charges (solid line) and without charges (dotted line).

distances taking normal values for this type of bond, typically about 2.0 Å. However, the smaller anion ox^{2-} is inside the macrocyclic cavity, while the remaining three anions are located above the plane determined by the six nitrogen donors of the receptor. The pyridine rings are almost in a planar arrangement, making a dihedral angle of 16.3, 33.2 and 9.7° for ox^{2-}, mal^{2-} and suc^{2-}, respectively; while for ma^{2-} these rings are twisted, giving an angle of 128.1°.

Subsequently the cascade complexes were submitted to MD runs of 1 ns at room temperature. The average distances from the copper to oxygen atoms of the anions together with their small standard deviations, listed in Table 10, clearly indicate that each bridged anion remains coordinated by all four Cu–O bonds for the entire period of the simulation. In addition, the Cu···Cu distances are largely dependent on the size and the steric requirements of the bridge. Indeed the Cu···Cu distance of the lowest energy conformation of 8.768 Å was substantially shortened to 6.44(6) Å when the smallest ox^{2-} anion was included, while

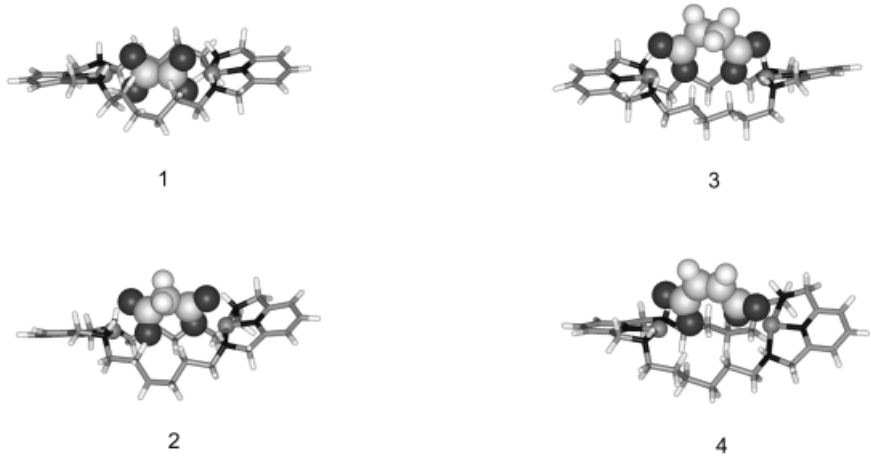

Figure 10. Lowest energy structures found for $[Cu_2([26]py_2N_4)(A)]^{2+}$ cascade complexes, with A equal to ox^{2-} (1), mal^{2-} (2), suc^{2-} (3) and ma^{2-} (4).

the ma^{2-} anion having a *cis* double bond between the two carboxylate groups kept the two metal centres at a longer distance of 6.88(15) Å. The distances between the copper centres supported by mal^{2-} and suc^{2-} bridges are 6.58(10) and 6.62(14) Å, respectively. These values are shorter than the average Cu···Cu distances for $[Cu_2([26]py_2N_4)]^{4+}$ in + + + + cleft [8.73(14) Å] and roughly planar [8.64(18) Å] topologies found from two MD simulations carried out at 300 K over 1 ns.

Table 10. Cu–O and Cu···Cu distances [Å] found for $[Cu_2([26]py_2N_4)(A)]^{2+}$ cascade complexes from MD at 300 K (A = ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-}).

	ox^{2-}	mal^{2-}	suc^{2-}	ma^{2-}
Cu–O	2.045(43)	2.094(51)	2.106(54)	2.067(47)
	2.061(46)	2.082(50)	2.046(44)	2.074(48)
	2.045(43)	2.084(50)	2.058(45)	2.073(48)
	2.062(46)	2.096(51)	2.083(50)	2.067(47)
Cu···Cu	6.44(6)	6.58(10)	6.62(14)	6.88(15)

Certainly other binding scenarios between the receptor and the substrates are possible, for instance the docking of the anions from the opposite side of the N–H groups of the macrocycle. However the evaluation of all of them would be a huge task. On the other hand, the presence of other ligands leading to five- or six-coordination geometries to the copper centres were not taken into account in our calculations. In spite of these modelling studies being carried out in the gas phase, neglecting important solution effects, they show that the selective binding of ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-} to the $[Cu_2([26]py_2N_4)]^{4+}$ receptor occurs. In other words, in contrast to the $H_4([26]py_2N_4)^{4+}$ receptor, in the dinuclear copper complex the macrocycle has a preorganised cavity with the two copper centres located at apparent flexible positions able to promote the uptake of these anions.

Conclusions

The macrocycle $[26]py_2N_4$ has been used as a receptor, in its tetraprotonated form or as a dicopper complex, for the recognition of dicarboxylate anions. Our solution studies revealed that the tetraprotonated form, $H_4[26]py_2N_4^{4+}$, is a weak receptor for the studied anions when compared with others,[25–30] although it is more selective for malonate. On the other hand, the dicopper complex of $[26]py_2N_4$ forms cascade complexes with oxalate and malonate with strong association constants,[31–34] the association with the bridging anion being stronger for oxalate. Additionally, the $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ complex can act as an optical sensor to detect and quantitatively measure oxalate spectrophotometrically by the red shift of the maximum of the visible band observed by addition of oxalate to an aqueous solution of the dinuclear copper complex. However the selectivity for oxalate is not sufficiently high for the selective detection of this anion in the presence of malonate.

Molecular mechanics and dynamics simulations were carried out in gas phase, ignoring the solvent effects. However, in spite of this limitation, our modelling studies support entirely the experimental results, showing that the cavity of $H_4[26]py_2N_4^{4+}$ is too large and too flexible for the selective binding of the studied anions. By contrast, in the $[Cu_2([26]py_2N_4)]^{4+}$ receptor the two copper centres define a well-shaped cavity suitable for the selective encapsulation of the small dicarboxylate anion, ox^{2-}. Larger dicarboxylate anions such as mal^{2-}, suc^{2-} and ma^{2-} also bridge the two copper centres, but they are located above the N_6 macrocyclic plane. Of course the receptor can interact with the oxygen donor atoms from the anions in a different way, leading to cascade complexes with R/S ratios other than 1:1. Other possible binding modes are: two bridging anions between the copper centres of the receptor or two anions axially coordinated to each copper centre. Alternatively, two $[Cu_2([26]py_2N_4)]^{4+}$ complexes are eventually linked by two anion bridges leading to the formation of dimeric or

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

polymeric species. However the evaluation of all binding modes even by molecular mechanics calculations is a huge task and is beyond the aims of these preliminary modelling studies.

Experimental Section

Potentiometric Measurements

Reagents and Solutions: All the chemicals were of reagent grade and used as supplied without further purification. The receptor $[26]py_2N_4$ and its tetraprotonated salt, $H_4[26]py_2N_4{\cdot}4Cl$, were prepared and characterised as reported.[9] Dicarboxylate anion solutions were prepared at about 5.00×10^{-2} mol·dm^{-3} to 2.00×10^{-3} mol·dm^{-3} from the corresponding dicarboxylic acids (analytical grade purchased to Merck) and the concentrations were checked by titration with standard 0.100 mol·dm^{-3} KOH solutions, except for fumarate, for which the disodium salt from Aldrich was used. Solutions of $Cu(NO_3)_2$ were prepared at about 0.025 mol·dm^{-3} (analytical grade) and the exact concentration checked by titration with K_2H_2edta following standard methods.[35] All the solutions were prepared using demineralised water (obtained by a Millipore/Milli-Q system). Carbonate-free solutions of the KOH titrant were obtained and maintained as described,[9] and they were discarded when the percentage of carbonate was about 0.5% of the total amount of base.

Equipment and Work Conditions: The equipment used has been described previously.[9] The temperature was kept at 298.0 ± 0.1 K; atmospheric CO_2 was excluded from the cell during the titration by passing purified nitrogen across the top of the solution in the reaction cell. The ionic strength was kept at 0.10 mol·dm^{-3} with KCl.

Measurements: The $[H^+]$ of the solutions was determined by the measurement of the electromotive force of the cell, $E = E'° + Q{\cdot}\log[H^+] + E_j$. $E'°$, Q, E_j and $K_w = ([H^+][OH])$ were obtained as described previously.[9] The term pH is defined as $-\log[H^+]$. The value of K_w was found to be equal to $10^{-13.80}$ mol^2·dm^{-6}.

The potentiometric equilibrium measurements were carried out using 25.00 cm^3 of about 2.00×10^{-3} mol·dm^{-3} $[26]py_2N_4$ solutions diluted to a final volume of 30.00 cm^3, in the absence of dicarboxylate anions and of copper(II) salt, then in the presence of each anion at 1:1 and 2:1 C_L/C_A ratios, and finally in the simultaneous presence of copper(II) and each anion at 2:1:1 and 2:1:2 $C_{Cu}/C_L/C_A$ stoichiometries. A minimum of two replicate measurements were performed. All the anions were also independently titrated alone and in the presence of copper(II) ion in the conditions described above, at 1:1 and 1:2 C_{Cu}/C_A ratios.

Calculation of Equilibrium Constants: Overall protonation constants, β_i^H, were calculated by fitting the potentiometric data obtained for all the performed titrations with the HYPERQUAD programme.[10] The protonation constants of $[26]py_2N_4$ and its stability constants with the Cu^{2+} ion had been determined before in 0.10 mol·dm^{-3} KNO_3[9] and redetermined in the present work in 0.10 mol·dm^{-3} KCl. The protonation constants of the dicarboxylic acids (oxalic, malonic, succinic, fumaric and maleic acids) and their stability constants with Cu^{2+} ion were also determined from the experimental data in the same experimental conditions, also using the HYPERQUAD programme. All these constants were taken as fixed values to obtain the equilibrium constants of the new species from the experimental data corresponding to all the titrations in different Cu/L/A or L/A stoichiometries, also using the HYPERQUAD programme. The initial computations were obtained in the form of overall stability constants, $\beta_{Cu_mH_hL_lA_a}$ or $\beta_{H_hL_lA_a}$ values, $\beta_{Cu_mH_hL_lA_a} = [Cu_mH_hL_lA_a]/([Cu]^m\times[H]^h\times[L]^l\times[A]^a)$ or $\beta_{H_hL_lA_a} = [H_hL_lA_a]/([H]^h\times[L]^l\times[A]^a)$. Cascade mononuclear species CuLA, CuH_iLA (i = 1–4), $CuLH_{-1}A$, $CuLA_2$, CuH_iLA_2 (i = 1–4), and also dinuclear species Cu_2LA, Cu_2H_iLA (i = 1–2), $Cu_2LH_{-1}A$, Cu_2LA_2, Cu_2HLA_2 and $Cu_2LH_{-1}A_2$ were found [$\beta_{CuLH_{-1}A} = \beta_{CuL(OH)A}\times K_w$, $\beta_{Cu_2LH_{-1}A} = \beta_{Cu_2L(OH)A}\times K_w$ and $\beta_{Cu_2LH_{-1}A_2} = \beta_{Cu_2L(OH)A_2}\times K_w$]. The species considered in a particular model were those that could be justified by the principles of coordination and supramolecular chemistry. The errors quoted are the standard deviations of the overall stability constants given directly by the programme for the input data, which include all the experimental points of all titration curves.

The stability constants for the cascade species between Cu^{2+}, $[26]py_2N_4$ and the different anions were determined from a minimum of 192 (for ox^{2-}) to 253 (for suc^{2-}) experimental points, while the association constants for the equilibrium between each anion and protonated $[26]py_2N_4$ were determined from a minimum of 135 (for fu^{2-}) to 175 (for suc^{2-}) experimental points and a minimum of two titration curves.

UV/Vis and EPR Spectrophotometric Measurements

Electronic spectra were recorded with a UNICAM model UV-4 spectrophotometer for UV/Vis, using aqueous solutions of the complexes prepared by the addition of different dicarboxylate anions (in the form of sodium or potassium salts) to the dicopper complex of $[26]py_2N_4$ at the appropriate pH value. All the solutions were prepared in the range 1.0×10^{-4} to 5×10^{-4} mol·dm^{-3}. EPR spectroscopic measurements of the $[Cu_2([26]py_2N_4)(H_2O)_4]^{4+}$ and of its cascade complexes with the different anions were recorded with a Bruker ESP 380 spectrometer equipped with continuous-flow cryostat for liquid helium, operating at X-band. The solutions were prepared at 2.0×10^{-3} mol·dm^{-3} in water/DMSO (1:1), at 6.4–11.4 K.

Molecular Modelling

The MM and MD calculations were carried out using the Universal Force Field[22] within the Cerius2[23] package software. The atomic charges were calculated with the Qeq equilibration method implemented within Cerius2. The conformational analyses of $H_4[26]py_2N_4^{4+}$ and $[Cu_2([26]py_2N_4)]^{4+}$ complexes, as well as the docking of these receptors to the anions, were undertaken thorough the quenched dynamics at 3000 K. The dynamic behaviour of the host–guest complexes was investigated by MD simulations at 300 K.

The molecular modelling studies started with conformational analysis on the $H_4[26]py_2N_4^{4+}$ receptor. The starting model was obtained from the manipulation of the X-ray atomic coordinates of a related compound. The structure was subsequently minimised and the charges recalculated, then this process was repeated successively until the steric energy remained constant. Finally, the minimised structure was heated at 3000 K over 2 ns and the snapshots were saved every 0.2 ps leading to a total of 10000 conformations, which were concomitantly minimised by MM. Subsequently the lowest energy conformation found for $H_4[26]py_2N_4^{4+}$ was docked with the anions ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-} by a quench dynamics run of 500 ps. The structures of the anions were also previously minimised by MM and their charges were calculated by the Qeq equilibration method with the total charge adjusted to –2. The dynamic behaviour of each of the lowest energy arrangements found for the inclusion compounds was subsequently evaluated by MD at room temperature over 1 ns.

The starting models of $[Cu_2([26]py_2N_4)]^{4+}$ in five different conformations were obtained from manipulation of the atomic coordi-

nates retrieved from the X-ray structure of a related compound. Charges of +2 were given to the two Cu^{2+} ions and the charges on the atoms of the macrocycle were calculated independently of the metal centres by the Qeq equilibration method assuming a neutral ligand. The structures were subsequently minimised and the charges recalculated, then this process was repeated successively until the steric energy remained constant. The Cu–N bonds were retained in the calculation, being described through a theta harmonic function with ideal distances of 2.00 and 1.93 Å for Cu–Nsp^3 and Cu–Nsp^2 bonds respectively. The bending N–Cu–N angles were restrained to the ideal angles of 90 and 180° using a cosine harmonic function. Then all minimised structures were subjected to a quenching dynamics runs of 100 ps.

The study of host–guest interactions with $[Cu_2([26]py_2N_4)]^{4+}$ receptor also started with docking of its lowest + + + + conformation found on conformational analyses and the bridging anions (ox^{2-}, mal^{2-}, suc^{2-} and ma^{2-}) positioned above the macrocyclic cavity and on the same side of the N–H groups. No bonds between the donor atoms of the bridging ligands and the copper centres were considered and therefore the host–guest bonding interactions were purely electrostatic. Each starting model was subject to a MD quenching simulation of 100 ps. The dynamic behaviour of the lowest energy structures found for each cascade complex was subsequently investigated by MD simulations over 1 ns. All simulations were carried out using a constant NVE thermostat with default parameters and a time step of 1.0 fs. The events were saved at intervals of 0.1 ps, except on the conformational analysis of $[Cu_2([26]py_2N_4)]^{4+}$ where the frames were saved every 0.2 ps as stated above.

Trinuclear Cu^{II} Complexes Containing Peripheral Ketonic Oxygen Bridges and a μ_3-OH Core: Syntheses, Crystal Structures, Spectroscopic and Magnetic Properties

Mau Sinha Ray,[a] Shouvik Chattopadhyay,[a] Michael G. B. Drew,[b] Albert Figuerola,[c] Joan Ribas,[c] Carmen Diaz,*[c] and Ashutosh Ghosh*[a]

Keywords: Copper trimers / Schiff bases / X-ray structures / Magnetic properties

Four new trinuclear copper(II) complexes, $[(CuL^1)_3(\mu_3\text{-}OH)](ClO_4)_2\cdot H_2O$ (**1**), $[(CuL^2)_3(\mu_3\text{-}OH)](ClO_4)_2$ (**2**), $[(CuL^3)_3(\mu_3\text{-}OH)](ClO_4)_2\cdot H_2O$ (**3**), and $[(CuL^4)_3(\mu_3\text{-}OH)](ClO_4)_2\cdot H_2O$ (**4**), where HL^1 = 8-amino-4,7,7-trimethyl-5-azaoct-3-en-2-one, HL^2 = 7-amino-4-methyl-5-azaoct-3-en-2-one, HL^3 = 7-(ethylamino)-4-methyl-5-azahept-3-en-2-one, and HL^4 = 4-methyl-7-(methylamino)-5-azahept-3-en-2-one, have been derived from the four tridentate Schiff bases (HL^1, HL^2, HL^3, and HL^4) and structurally characterized by X-ray crystallography. For all compounds, the cationic part is trinuclear with a Cu_3OH core held by three carbonyl oxygen bridges between each pair of copper(II) atoms. The copper atoms are five-coordinate with a distorted square-pyramidal geometry; the equatorial plane consists of the bridging oxygen atom of the central OH group together with three atoms (N, N, O) from one ligand whereas an oxygen atom of a second ligand occupies the axial position. Magnetic measurements have been performed in the 2–300 K temperature range. The experimental data could be satisfactorily reproduced by using an isotropic exchange model, $H = -J(S_1S_2+S_2S_3+S_1S_3)$ yielding as best-fit parameters: J = –66.7 and g = 2.19 for **1**, J = –36.6 and g = 2.20 for **2**, J = –24.5 and g = 2.20 for **3**, and J = –14.9 and g = 2.05 for **4**. EPR spectra at low temperature show the existence of spin frustration in complexes **3** and **4**, but it has not been possible to carry out calculations of the antisymmetric exchange parameter, G, from magnetic data. In frozen methanolic solution, at 4 K, hyperfine splitting in all complexes and spin frustration in complex **4** seem to be confirmed.

Introduction

Cyclic trinuclear metal complexes[1] are of interest because these systems can be regarded as geometrically spin-frustrated and offer the opportunity to test magnetic exchange models.[2] In fact, geometrically frustrated antiferromagnetic compounds have attracted much attention over the past few years because of their propensity to adopt unusual, even exotic magnetic ground states, which remain poorly understood.[3]

μ-Hydroxo or μ-oxo ions have generally been observed as central bridging ligands in cyclic trinuclear compounds. The existence of the M_3O core held by the peripheral bridging ligands is well documented in the chemistry of iron(II/III) and chromium(III).[4] There are only a few reports with a $Cu_3O(H)$ core of which the majority contain oxime-oximate-,[5] *N*,*N*-pyrazole-[6], or *N*,*N*-triazole[7]-type peripheral ligands. Examples of cyclic trinuclear complexes with ketonic oxygen bridges are, however, very rare. To the best of our knowledge, in the literature only three such complexes containing Schiff-base ligands, for example, 7-amino-4-methyl-5-azahept-3-en-2-one (AMAH),[8] 8-amino-4-methyl-5-azaoct-3-en-2-one (AMAO),[9] and 7-(dimethylamino)-4-methyl-5-azahept-3-en-2-one (AE)[10] are known. The first complex having an AMAH ligand was isolated accidentally during the preparation of the ternary complex, having pyridine as the other ligand. All three complexes were synthesized conveniently by adding triethylamine to the respective reaction mixtures. In order to investigate if the existence of these complexes is an exception or the formation of such trinuclear Cu^{II} complexes is a general phenomenon for this type of ligand, we synthesized four very similar tridentate N,N,O donor Schiff-base ligands derived from C- or N-substituted diamines and 2,4-pentanedione (Scheme 1, HL^1–HL^4) to obtain the desired complexes. Another objective of the synthesis of these compounds is to study their magnetic properties, especially the existence of spin frustration, which has not been detected in the other three reported complexes.[8–10] This paper re-

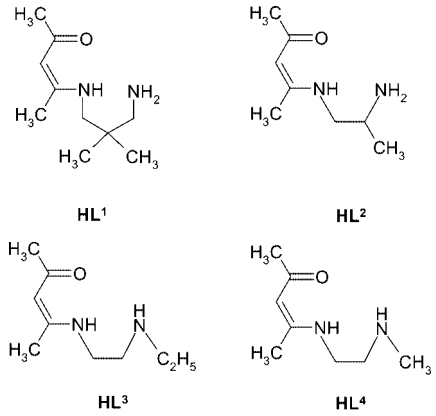
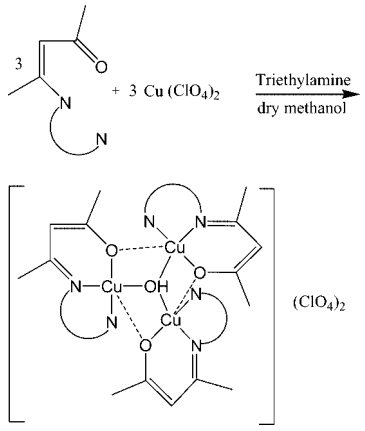
ports the synthesis, crystal structure, and magnetic properties of the four cyclic trinuclear compounds. The structural and magnetic properties of the complexes will be compared with the data of the other three similar compounds reported in the literature.



Scheme 1.

Results and Discussion

The four tridentate ligands HL^1, HL^2, HL^3, and HL^4, on treatment with a methanol solution of copper perchlorate hexahydrate and triethylamine in a 2:2:3 ratio, yielded the trinuclear complexes **1**–**4**, respectively (Scheme 2). Complexes **2** and **3** were obtained readily on mixing the constituents; no hydrolysis of the product occurred during synthesis. On the other hand, ligands HL^1 and HL^4 are rather susceptible to hydrolysis and for higher yields of **1** and **4** dry methanol was used as the reaction medium. All the complexes, however, can easily be purified by recrystallization from methanol. The formation and stability of these self-assembled cyclic trinuclear complexes may be visualized in the following way:



Scheme 2.

The chelating tridentate ligand coordinates to the Cu^{II} centers as usual to occupy the three coordination sites. In a slightly alkaline medium, the hydroxy ion, which is well known for its bridging ability, can be coordinated to the fourth coordination site to bridge two metal centers. However, coordination of the hydroxy ion to the three metal centers is not very common, as steric crowding may destabilize the resulting tetrahedral arrangement until and unless it gains some additional stability by other means. In the present systems, the three mononuclear units are assembled around the hydroxy ion in such a way that the ketonic oxygen atom of one unit is coordinated to the apical position of the Cu^{II} ion of the neighboring unit to result in a cyclic peripheral bridging that provides the required stability for the trinuclear structure (Scheme 2). As a requirement of the basal–apical bridging, the mononuclear units need to be perpendicular to each other which, fortuitously, seems to be the preferred arrangement to minimize steric contacts.

Description of the Structure of Complexes 1–4

The crystal structures of all four compounds (**1**–**4**) are built up from discrete trinuclear cations $[Cu_3L_3(\mu_3\text{-}OH)]^{2+}$ and noncoordinated perchlorate anions in a ratio of two anions per cation. In each of the complexes **1**, **3**, and **4** there is, in addition, one lattice water molecule. The trinuclear structure of **2** is shown in Figure 1 together with the common numbering scheme [complexes **1**, **3**, and **4** have very similar molecular structures, see Figures S1, S2, and S3, respectively in the Supporting Information (see also the footnote on the first page of this article)]. Selected bond lengths and bond angles are summarized in Tables 1 and 2, respectively.

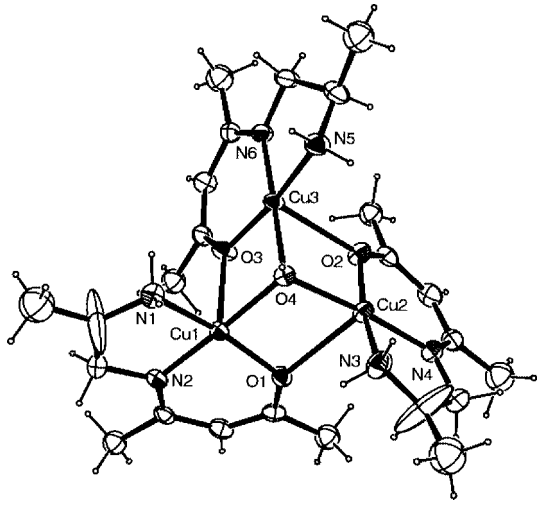


Figure 1. ORTEP-3 view of the $[(CuL^2)_3(OH)]^{2+}$ cation of complex **2** (30% thermal ellipsoids) including the atom numbering scheme.

The trinuclear cationic part is comprised of three CuL subunits in which each copper(II) ion is coordinated to a deprotonated tridentate monoanionic ligand L. The subunits are held together by two distinct bridging systems: (i) the oxygen atom (O4) of a single, triply bridging hydroxo group, which is coordinated to each of the three copper centers, and (ii) the three bridging carbonyl oxygen atoms, each of them from a different ligand molecule. The resulting trinuclear species do not contain any threefold symmetry

axis. In all four compounds no specific chirality for the propeller arrangements around the hydroxide ion is found. The three copper(II) ions and the bridging hydroxo group form a flattened trigonal pyramid, with the copper atoms falling at the corners of approximately equilateral sides and angles: 3.329(4), 3.241(4), 3.303(3) Å and 60.3(1), 61.2(1), 58.5(1)° for complex **1**; 3.238(2), 3.211(4), 3.165(3) Å and 58.8(1), 61.0(1), 60.2(1)° for complex **2**; 3.172(4), 3.165(3), 3.205(3) Å and 60.8(4), 59.7(4), 59.5(4)° for complex **3**; and 3.182(3), 3.164(4), 3.173(3) Å and 60.0(5), 60.3(5), 59.7(5)° for complex **4**. The face-capping oxygen atom (O4) is located at 0.728(5), 0.797(4), 0.836(6), and 0.861(6) Å above the plane defined by the Cu_3 triangle for complexes **1**–**4**, respectively. The presence of Cu_3OH is confirmed by (a) the location of the hydrogen atom at the expected position in the final difference Fourier map, (b) the electroneutrality of the crystal, and (c) the refined Cu–O(H) distances and Cu–O(H)–Cu′ angles, which, on the basis of the trends observed in similar structures,[6c,7b,8–10] agree well with a roughly tetrahedral or pseudotetrahedral sphere of Cu, Cu, Cu, H ligands around the oxygen atom.

As for the copper environment, in all four structures the three copper atoms of the trinuclear entity are five-coordinate, with a (4+1) square-pyramidal (NNOO and O) geometry. The four coordinating atoms making up the basal plane are the carbonyl oxygen atom, one imine nitrogen atom, and one amino nitrogen atom from the tridentate Schiff-base ligand (L), and the hydroxo group OH^-, while the apical site is occupied by one oxygen atom of another tridentate Schiff-base ligand, which, in turn, is basal to a second copper atom. As expected, the axial Cu–O bond is much longer than the equatorial one. It may be emphasized that the oxygen atom involved in this basal–apical bridge pertains to a carbonyl function, which is generally considered as a nonbridging group. Within each mononuclear unit the copper atom does not lie in the basal plane. As usual, each copper ion is displaced from the least-squares plane through the basal atoms towards the apical oxygen atom by 0.071(1), 0.085(1), 0.112(1), and 0.137(2) Å for Cu(1); 0.031(1), 0.023(1), 0.105(2), and 0.118(2) Å for Cu(2); and 0.159(1), 0.079(1), 0.099(1), and 0.130(2) Å for Cu(3) in complexes **1**–**4** respectively. The lengths of the bonds between the copper atoms and the donor sites (O, N, N) of the tridentate ligand are within the range of values normally found for such bonds.[8–11] They show only small variations in going from one unit to the other. The six-membered chelate ring formed by the acetylacetone moiety is essentially planar and the interatomic distances and angles of the ring are roughly identical in the three mononuclear units of **2** and **3**. However, in **1** and **4** the same rings deviate considerably from planarity and the deviation is different in the three subunits. The highest deviation is observed in the subunit with Cu1 for both **1** and **4** in which the six-membered ring assumes almost a boat and twist-boat conformation, respectively, with puckering parameters φ = 195(2) and 199(4)°, θ = 124.0(17) and 120.7(33)° and Q = 0.269(6) and 0.206(9) Å.[12] The trimethylene fragment in complex **1** and dimethylene fragments in the other three complexes from the starting diamines constitute the other chelate ring in the complexes. In all three subunits these six-membered chelate rings of complex **1** and five-membered chelate rings of complex **2** assume half-boat and envelope conformations, respectively. However, considerable differences have been found in the bond angles of the chelate rings among the subunits in both the complexes (7.0° for **1** and 11.7° for **2**).

[a] Deviation of the oxygen atom of the triply bridging hydroxy group above the plane of the three copper atoms. [b] Coplanarity between the least-squares planes defined by [O(H), N, N, O]; average value calculated from the Cu1/Cu2, Cu1/Cu3, Cu2/Cu3 dihedral angles. [c] The J values from the literature have been modified according to the Hamiltonian used in this paper.

Conformational analysis shows different conformations for the five-membered chelate rings in complexes **3** and **4**. In complex **3**, the ring with Cu2 is in envelope conformation on C12, whereas the rings with Cu1 and Cu3 have half-chair conformation twisted on N1···C3 and N5···C21, respectively. But for complex **4**, both the five-membered chelate rings with Cu1 and Cu2 assume half-chair conformation twisted on N1···C3 and N3···C12, respectively, whereas the ring with Cu3 is in envelope conformation on C21. However, among the subunits in each complex a considerable difference in the bond angles of the chelate rings has been found in complex **4** only (14.1°), whereas in complex **3** the difference is negligible (2.5°).

The distortions of the coordination polyhedron from the square pyramid to the trigonal bipyramid have been calculated by the Addison parameter (τ)[13] as an index of the degree of trigonality. The value of τ is defined as the difference between the two largest donor–metal–donor angles divided by 60, a value that is 0 for the ideal square pyramid and 1 for the trigonal bipyramid. The τ values are 0.19, 0.19, 0.13, and 0.09 for Cu(1); 0.08, 0.08, 0.04, and 0.14 for Cu(2); and 0.39, 0.10, 0.17, and 0.03 for Cu(3) in complexes **1**–**4**, respectively. The values clearly indicate that in **1** the distortion towards a trigonal bipyramid is significantly different in the three mononuclear units and that in Cu(3) it is considerably high. The τ values of the other three reported complexes[8–10] are also shown in Table 3 for comparison.

The perchlorate anions in the complexes show some disorder. In **1**, one of the perchlorate ions is disordered such that the oxygen atoms are distributed over two sets of tetrahedral sites around the same chlorine atom, while the other shows the complete anion distributed over two separate sites. By contrast, the perchlorate ions in **2** and **3** are ordered. In **4** the oxygen atoms show very high thermal motion but no discernible disorder pattern could be refined successfully. In complex **3**, one perchlorate oxygen atom,

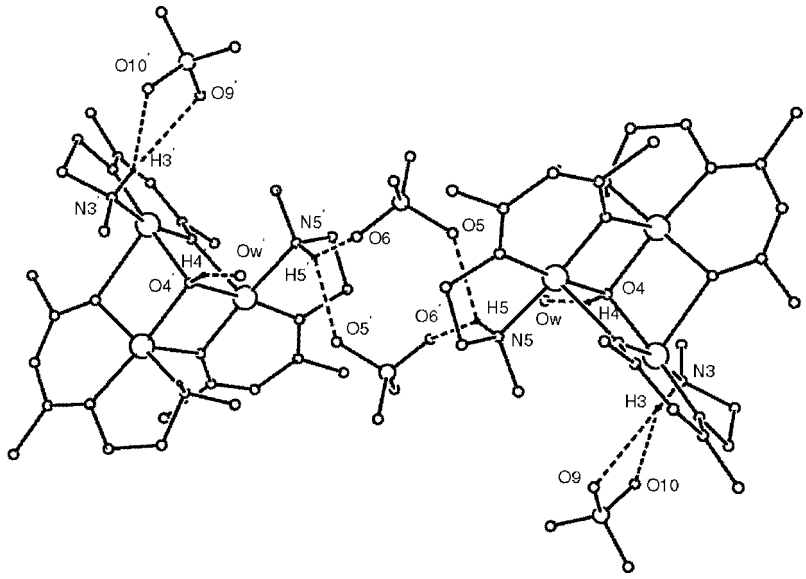

Figure 2. Illustration of the aggregation of the isolated trimeric unit by hydrogen-bonding interactions between the $[(CuL^4)_3(OH)]^{2+}$ cation and perchlorate anions in the solid state of complex **4**. Atoms marked with a prime are transformed by symmetry element $1 - x$, $1 - y$, $2 - z$.

O10, forms a weak association with the Cu2 ion at a distance of 2.961(13) Å, whereas all other Cu–O(perchlorate) distances are about 4 Å. The perchlorate ions play a significant role in the H-bonding network in all complexes.

In all four complexes hydrogen-bonding interactions are observed among the isolated trimeric units, the perchlorate anions, and the water of crystallization (Table 4). A detailed discussion of these interactions for complexes **1**–**3** along with diagrams is presented in the Supporting Information. H bonding of complex **4** is only discussed here as an example. In complex **4** two centrosymmetrically related trinuclear units are linked by an N–H···O hydrogen bond involving hydrogen atom H5(N5) and oxygen atom O6 of the two centrosymmetrically related perchlorate ions (Figure 2, Table 4). The hydrogen atom H5(N5), through which two trimers are linked, is also involved in another N–H···O contact with O5 of one of two perchlorate anions showing bifurcated hydrogen-bond formation. H3(N3) also forms strong bifurcated hydrogen bonds with two oxygen atoms, O9 and O10, of another perchlorate ion. One of the three hydrogen atoms, H1(N1), does not participate in hydrogen bonding. The water of crystallization (Ow) is stabilized, contributing to the hydrogen-bonding network, with H4 of the triply bridging hydroxo group by an O–H···O contact.

IR and Electronic Spectra

Compounds **1**, **3**, and **4** contain a noncoordinating water molecule, which makes the assignment of O–H stretching somewhat ambiguous. However, the well-defined bands at 3520, 3505, 3556, and 3550 cm^{-1} for complexes **1**–**4**, respectively, appear within the typical range for O–H stretching vibrations in monohydroxo-bridged copper complexes.[14] Therefore these bands can be attributed to ν(O–H) of the triply bridging hydroxo group. The additional broad but well-defined bands with the maximum at 3430 cm^{-1} for complex **1**, 3425, 3390 cm^{-1} for complex **3** and 3420, 3377 cm^{-1} for complex **4** are attributable to the presence of a noncoordinating water molecule with a strong hydrogen-bonding network (vide crystal structure). The remaining bands for the complexes above 3000 cm^{-1} may be assigned to ν(N–H) stretching vibrations. Concerning the ClO_4^- anions, the ν_3 mode at 1091, 1100, 1102, and 1097 cm^{-1} for **1**–**4**, respectively, is somewhat broadened, but the ν_4 band at 623, 620, 623, and 622 cm^{-1}, respectively, is devoid of any splitting and consistent with the IR-active normal modes for T_d symmetry, suggesting that these anions are not coordinated to the copper atoms as substantiated by the crystal structures.

The electronic spectra in the solid state and in methanol solution have been recorded for the four complexes. The observed ligand-field band is in agreement with the fact that the trinuclear structure is retained in methanol, as similar visible absorption bands are observed in the solid state and in methanol solution for all complexes. The reflectance electronic spectra of all four complexes display a single absorption band at 595, 593, 601, and 586 nm in the solid state and 612, 615, 587, and 595 nm in methanol. The positions of these bands are consistent with the observed square-based geometry around the copper centers.[15]

Magnetic Properties

Magnetic susceptibilities were determined for complexes **1**–**4** over the temperature range 2–300 K in an applied field of 0.1 T. The temperature dependence of $\chi_M T$ (χ_M being the magnetic susceptibility per Cu_3 entity) for complex **1** is shown in Figure 3 (complexes **2**, **3**, and **4** have very similar temperature dependences of $\chi_M T$: see Figures S7, S8, and S9, respectively, in the Supporting Information). At room

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature the $\chi_M T$ values for all four complexes are close to 1.2 $cm^3 mol^{-1} K$, as expected for the three independent Cu^{II} ions. As T is lowered, $\chi_M T$ decreases, reaching values close to 0.40 $cm^3 mol^{-1} K$ at 2 K. Complexes **1**–**3** show a plateau before reaching the final value, while **4** does not show this plateau. This value (0.4 $cm^3 mol^{-1} K$) is close to the spin-only value for a system with one unpaired electron with $g > 2.00$. This behavior indicates an antiferromagnetic interaction between the Cu^{II} ions, with an unpaired electron per Cu_3 unit in the ground state. The formation of this plateau ($S = 1/2$) is dependent upon the corresponding existence of noticeable intermolecular (intertrimer) exchange interactions. This situation has also been observed in other similar compounds.[8–10]

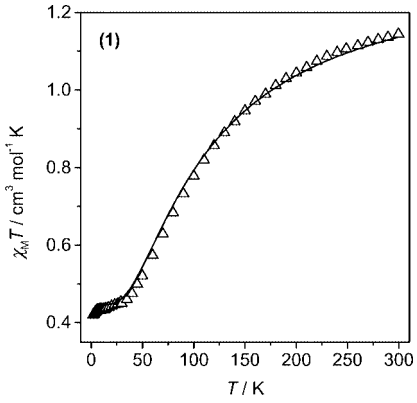

Figure 3. Plot of the $\chi_M T$ [$cm^3 mol^{-1} K$] vs T [K] in the range 2–300 K for **1**. The solid line is generated from the best-fit magnetic parameters.

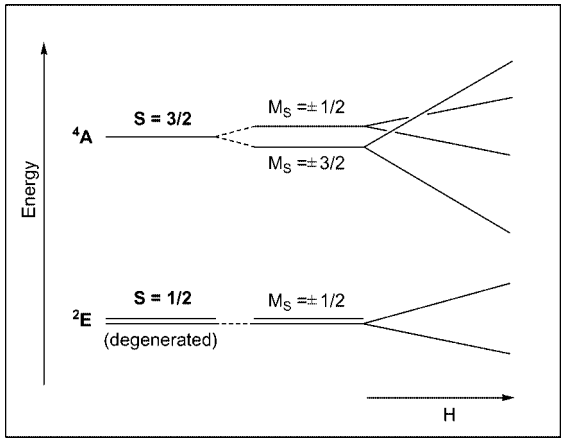
The magnetic-exchange interaction in a triangular arrangement of three $S = 1/2$ ions results in three electronic states, that is, a quartet state ($S = 3/2$; $^4A_2$) and two doublet states ($S = 1/2$; ^2E) (Scheme 3). Within the simple model of an isotropic exchange interaction for an equilateral triangle, both of the doublet states have the same energy, which differs 3J from the energy of the quartet state. From the known structures of **1**–**4**, and considering that the three copper atoms of the $Cu_3O(H)$ unit are structurally almost equivalent, and so that $J_{12} = J_{13} = J_{23} = J$, the isotropic Heisenberg–Dirac–van Vleck (HDVV) Hamiltonian formalism [Equation (1)] was used to describe the interactions of the spins.



Scheme 3.

$$H_{HDVV} = -J_{12}S_1S_2 - J_{13}S_1S_3 - J_{23}S_2S_3 \quad (1)$$

From this Hamiltonian, a solution of the magnetic susceptibility may be derived as follows [Equation (2)]:[7a,7b,16]

$$\chi_M = (N\beta^2 g^2/4kT)[1 + 5\exp(3J/2kT)]/[1 + \exp(3J/2kT)] \quad (2)$$

where N, g, β, k, and T have their usual meanings. Because of the above-mentioned experimental variation of $\chi_M T$ at low temperatures, the inclusion of an additional Weiss-like parameter θ [so that T is replaced by $T - \theta$ in Equation (2)], which would account for possible, low-temperature, intertrimer magnetic interaction mainly due to the hydrogen bonds among trinuclear entities, was deemed appropriate.

Experimental data for **1**–**4**, corrected for diamagnetic contributions and TIP (0.3×10^{-3} $cm^3 mol^{-1}$), were analyzed with the theoretical expression, which results from the modified Equation (2). Fitting was performed on $\chi_M T$. The best-fitted curves are plotted in Figure 3 and Figures S7, S8, and S9, along with the experimental data. The best-fit parameters obtained are $J = -66.7$ cm^{-1}, $g = 2.19$, and $\theta = -0.13$ with $R = 2 \times 10^{-4}$ for **1**; $J = -36.6$ cm^{-1}, $g = 2.2$, and $\theta = -0.22$ with $R = 1.9 \times 10^{-4}$ for **2**; $J = -24.5$ cm^{-1}, $g = 2.2$, and $\theta = -0.24$ with $R = 2.1 \times 10^{-4}$ for **3** and $J = -14.9$ cm^{-1}, $g = 2.05$, and $\theta = -0.13$ with $R = 2.2 \times 10^{-4}$ for **4** (where R is the agreement factor defined as $\Sigma_i[(\chi_M T)_i^{exp} - (\chi_M T)_i^{calc}]^2/\Sigma_i[(\chi_M T)_i^{exp}]^2$. The θ values are consistent with the intertrimer interactions, mainly the hydrogen bonds that link the trinuclear entities. All J values are gathered in Table 3 together with the most important structural parameters: Cu–O–Cu angles, Cu–O distances, distance from the O(H) atom to the mean Cu3 plane and the τ distortion parameter of each copper(II) ion. Considering that we have used only one J value, angles and distances given in Table 3 correspond to the average values of the triangles. However, it is clear that these values agree with those reported in the literature for similar triangular complexes.[8–10]

The most interesting feature concerning these triangular complexes is the possibility to show the spin frustration when the geometry is almost equilateral. Indeed, as indicated by Haasnoot et al.,[7a] the canonical example of spin frustration in any lattice is based on an equilateral triangular plaquette. With the typical isotropic spin Hamiltonian $-\Sigma_{ij} J_{ij} S_i S_j$, if J_{ij} is negative, which favors the antiparallel correlation, and J_{ij} is equal for all nearest neighbor pairs, then only two of the three spin constraints can be satisfied simultaneously, that is the system is geometrically frustrated. In order to interpret the magnetic properties of these frustrated systems it is necessary to go beyond the framework of the above isotropic exchange model and to introduce *antisymmetric exchange interactions*.[7a]

The spin frustration requires a highly symmetrical (equilateral) triangle. Complexes **1**–**4** are not fully equilateral,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thus spin-frustration behavior might not be expected. From magnetic data it is very difficult − mostly impossible − to calculate the antisymmetric exchange term G_{AB}. In most cases, the possibilities of intertrimeric exchange − such as in **1**–**4** because of the hydrogen bonds − preclude any exact calculation of this parameter. However, some very interesting calculations have been recently reported on singular cases:[7a] for example, Solomon et al. have reported an exhaustive study on a symmetric hydroxo-bridged trinuclear Cu^{II} complex (such as **1**–**4**) by means of nonconventional techniques, such as variable-temperature variable-field magnetic circular dichroism combined with powder/single-crystal EPR.[17] From all literature data it seems more appropriate to utilize EPR measurements for the study of the spin frustration. Obviously, in this study it is important to investigate EPR behavior at a very low temperature, when only the degenerate $S = 1/2$ states are populated. In this case, one of the signatures of spin frustration is the appearance of some g values lower than 2.00.[18]

EPR Spectra

The X-band EPR spectra of complexes **1**–**4** were recorded on powder samples varying the temperature between 4 and 295 K (Figure 4). The EPR spectra of trinuclear $S = 1/2$ compounds have been analyzed in terms of three active states (one quartet and two doublets), with temperature-dependent population.[18–22] In the light of the superexchange parameter from the magnetic measurements, at low temperatures only the doublets should be populated, whereas at room temperature signals due to the transitions inside the quartet may also be observed. This transition may show noticeable zero-field splitting (ZFS) ($S = 3/2$). Complexes **1**–**3** show a broad band (mainly complex **2**) at low fields, due undoubtedly to the presence of ZFS of the $S = 3/2$ state. Complex **4** does not show any mark of the ZFS (D parameter). Only one quasi-isotropic band is observed at this temperature. The possible spin frustration can only be observed at low temperatures. From Figure 4 it can be seen that complexes **1** and **2** do not have any signal that could be attributed to spin frustration. However, complexes **3** and **4** show unequivocally a band at high field that corresponds to $g = 1.98$, which cannot be explained as g_x, g_y, g_z for an $S = 1/2$ state without the introduction of spin frustration.[18] The antisymmetric exchange in spin-frustrated systems can give $g_\perp$ values close to 1.5.[18]

We have also carried out the EPR measurements in frozen methanol solution (Figures 5 and S10). The X-band spectra at low temperatures (60 K to 4 K) clearly show the hyperfine splitting in the $g_\parallel$ approximately of 190 Gauss for all four triangles. In $g_\perp$ there is also a significant partial splitting, mainly in complex **4** (Figure 5). In this case the splitting can be masked by the band at $g \approx 1.98$, as already shown in the solid state. Thus, the EPR data in solution seem to confirm, at least in complex **4**, the existence of the spin frustration together with the hyperfine splitting.

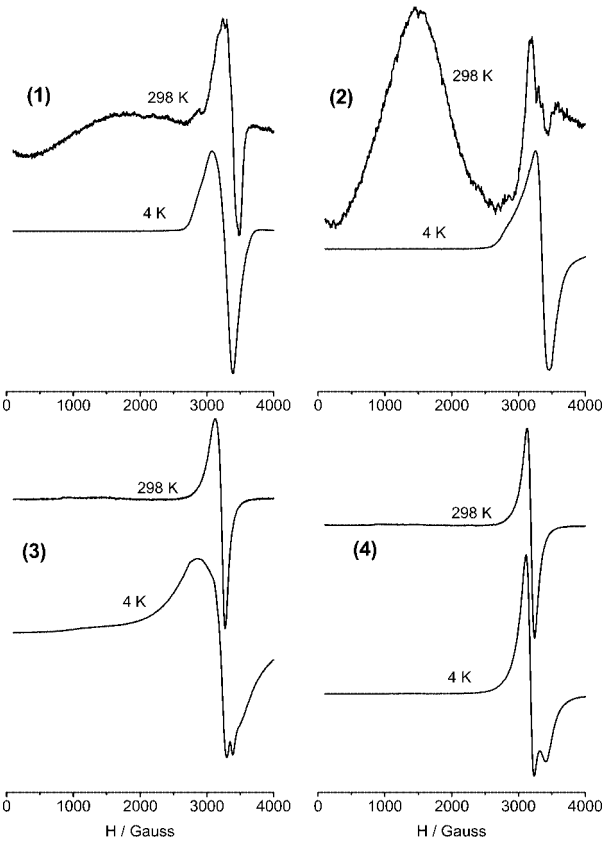


Figure 4. Polycrystalline X-band EPR spectra for complexes **1**–**4** at room temperature and 4 K.

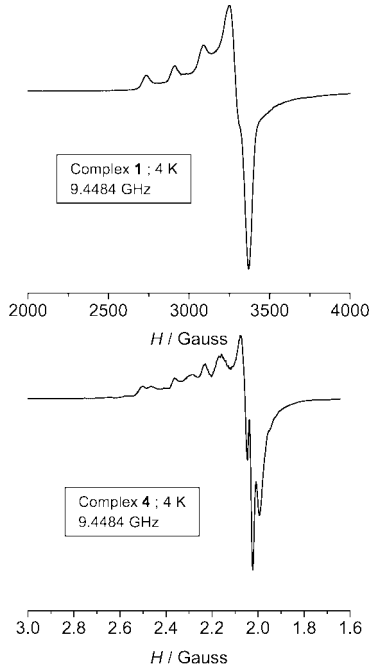

Figure 5. X-band EPR spectra for **1** and **4** in frozen methanolic solution at 4 K. For **1** the abscissa is given in Gauss to see the hyperfine splitting; for **4** the abscissa is given in g values to see the low values of $g_\perp$ attributed to the spin frustration already shown in solid state.

Discussion

Previous work has established relationships between magnetic coupling and certain structural features.[5c,6c,7a] Most of the trinuclear compounds containing a pyramidal $Cu_3O(H)$ core described in the literature can be systematized in four groups depending on the type of peripheral bridge: those with an N,O (mainly from an oxime-oximate ligand bridge),[5] those with an *N*,*N*-pyrazole bridge,[6] those with an *N*,*N*-triazole bridge,[7] and those with Schiff bases that act as tridentate N_2O ligands with only three compounds reported,[8–10] which have arisen from the condensation of the carbonyl function with only one end of the diamine. Because the electronic factors related to the nature of the ligands that afford the bridge are decisive,[7a] we were prevented from correlating the magnitude of the magnetic coupling within the above four classes of Cu_3O clusters.[8,9] From Table 3 it can be seen that the main structural differences for complexes **1**–**4** lie in the difference in the distance of the oxygen atom above the plane of the copper atoms (the maximum difference is 0.13 Å) and in the average of the Cu–O(H)–Cu′ angles (the maximum difference is 4.7°). The maximum variation in the $-J$ values is 51 cm^{-1}. These features indicate that the shortest distance of the O(H) group above the plane formed by the three copper ions in the trinuclear Cu^{II} complexes and the greatest Cu–O–Cu′ angle provide the strongest antiferromagnetic coupling.

In triangular arrangements of symmetric antiferromagnetically coupled metal ions, the magnetic properties at low temperatures can become complicated by the possible presence of spin-frustration effects, because of the presence of the antisymmetric exchange interaction (ASE) term.[7a,7b] The experimental EPR data for **3** and **4** indicate that this term is non-zero and the phenomenon of spin frustration occurs. For **1** and **2** all data seem to indicate that there is no spin frustration.

Concluding Remarks

The carbonyl functional group is generally considered as a nonbridging group but the facile synthesis of the four new trinuclear complexes **1**–**4** and the other three reported complexes suggests that the monocondensation products of various diamines and acetylacetone are a group of tridentate ligands that can readily be involved in *basal–apical*-type peripheral oxo bridging to result in the formation of trinuclear Cu^{II} complexes with a Cu_3OH core by self-assembly. All four complexes show antiferromagnetic coupling, as was also found in the three similar peripheral bridging complexes.[8–10] The magnetostructural correlation suggests that the greatest coplanarity of the three principal ligand planes, the shortest distance of the O(H) group above the Cu_3 plane, and the greatest Cu–O–Cu′ angles provide the strongest antiferromagnetic coupling.

Experimental Section

Materials: All the chemicals were of reagent grade and used without further purification. The four monocondensed ligands, HL^1, HL^2, HL^3, and HL^4, were synthesized in our laboratory by the methods described below. The ligand HL^1 was prepared for the first time. ***Caution!*** *Although no problems were encountered in this work, perchlorate salts containing organic ligands are potentially explosive. They should be prepared in small quantities and handled with care.*

Physical Measurements: Elemental analyses (C, H, N) were performed using a Perkin–Elmer 240C elemental analyzer and the Cu contents in all the complexes were estimated spectrophotometrically.[23] IR spectra in KBr (4500–500 cm^{-1}) were recorded using a Perkin–Elmer RXI FTIR spectrophotometer. Electronic spectra in methanol (1200–350 nm) were recorded with a Hitachi U-3501 spectrophotometer. The magnetic measurements were carried out in the "Servei de Magnetoquimica (Universitat de Barcelona)" on polycrystalline samples (20 mg) with a Quantum Design SQUID MPMSXL magnetometer in the temperature range of 2–300 K and the magnetic field was 1 T. The diamagnetic corrections were evaluated from Pascal's constants. EPR spectra were recorded on powder samples at X-band frequency with a Bruker 300E automatic spectrometer, varying the temperature between 4 and 300 K.

Preparation of 8-Amino-4,7,7-trimethyl-5-azaoct-3-en-2-one (HL^1) and 7-Amino-4-methyl-5-azaoct-3-en-2-one (HL^2): These two ligands are the single-condensation products of 2,2-dimethyl-1,3-propanediamine and 1,2-propanediamine, respectively, with 2,4-pentanedione. They were prepared by applying a method similar to that adopted for the half condensation of 1,2-ethanediamine or 1,3-propanediamine with 2,4-pentanedione as reported earlier, that is by allowing the constituents to react in chloroform under high dilution.[8,9,24–27] A solution of 2,4-pentanedione (1.1 mL, 10 mmol) in chloroform (50 mL) was added dropwise to a solution of 2,2-dimethyl-1,3-propanediamine (1.03 mL, 10 mmol) or 1,2-propanediamine (0.80 mL, 10 mmol) in chloroform (50 mL) at room temperature. After addition, the solution was stirred for an additional 3 h and the chloroform was evaporated under reduced pressure. The resultant viscous oil was collected as the ligand and dissolved in methanol (30 mL).

Preparation of 7-(Ethylamino)-4-methyl-5-azahept-3-en-2-one (HL^3) and 4-Methyl-7-(methylamino)-5-azahept-3-en-2-one (HL^4): HL^3 and HL^4 were prepared by condensation of the NH_2 group of *N*-ethyl-1,2-ethanediamine (0.90 mL, 10 mmol) and *N*-methyl-1,2-ethanediamine (0.74 mL, 10 mmol) with 2,4-pentanedione (1.1 mL, 10 mmol), respectively, in methanol (30 mL) under reflux for 3 h. The Schiff-base ligands were not isolated and the yellow methanolic solutions were used directly for complex formation.

Synthesis of $[(CuL^1)_3(\mu_3\text{-}OH)](ClO_4)_2\cdot H_2O$ (1), $[(CuL^2)_3(\mu_3\text{-}OH)](ClO_4)_2$ (2), $[(CuL^3)_3(\mu_3\text{-}OH)](ClO_4)_2\cdot H_2O$ (3), and $[(CuL^4)_3(\mu_3OH)](ClO_4)_2\cdot H_2O$ (4): A solution of $Cu(ClO_4)_2\cdot 6H_2O$ (3.7 g, 10 mmol) in methanol (20 mL) was added to a stirred solution of each of the ligands, HL^1, HL^2, HL^3, and HL^4 (10 mmol), in methanol (10 mL). Triethylamine (2.1 mL, 15 mmol) was then added dropwise to this solution with constant stirring. In the case of **1** and **4**, an immediate separation of a small amount of green hydrolyzed product occurred during the addition of triethylamine, which was filtered off. If the methanol contained water, the amount of the hydrolyzed products for these two compounds increased. Therefore, the methanol was dried before using as solvent for the synthesis of **1** and **4**. The resulting green and blue filtrates of **1** and **4**, respectively, were set aside at room temperature. Overnight, single crystals appeared, as green prisms for **1** and blue hexagons for **4**. The resulting blue and green solutions for HL^2 and HL^3, respectively, upon stirring at room temperature slowly yield the desired compounds, complex **2** as a precipitate and complex **3** as a microcrys-

talline precipitate. Stirring was continued for 1 h for both complexes. The products were collected by filtration and were recrystallized from methanol. The filtrates were left to stand overnight in a refrigerator. Single crystals suitable for X-ray diffraction analysis were obtained as blue plates for complex **2** and as hexagonally shaped green single crystals for complex **3**.

Complex 1: Yield: 2.0 g (60%). $C_{30}H_{60}Cl_2Cu_3N_6O_{13}$ (972.37): calcd. C 36.94, H 6.16, Cu 19.55, N 8.62; found C 37.02, H 6.37, Cu 19.98, N 8.49. UV/Vis (methanol): λ_{max} (ε_{max}) = 593 (249 dm^3 mol^{-1} cm^{-1}) nm. IR: $\tilde{\nu}$ = 3325, 3279, 3170 [ν(N–H)]; 1516 cm^{-1} [ν(C=N)]; 3520 [ν(O–H)] cm^{-1}.

Complex 2: Yield: 2.3 g (80%). $C_{24}H_{46}Cl_2Cu_3N_6O_{12}$ (872.22): calcd. C 33.02, H 5.27, Cu 21.84, N 9.63; found C 33.52, H 5.49, Cu 22.09, N 9.48. UV/Vis (methanol): λ_{max} (ε_{max}) = 615 (298 dm^3 mol^{-1} cm^{-1}) nm. IR: $\tilde{\nu}$ = 3330, 3266, 3158 [ν(N–H)]; 1515 [ν(C=N)]; 3505 [ν(O–H)] cm^{-1}.

Complex 3: Yield: 2.0 g (65%). $C_{27}H_{52}Cl_2Cu_3N_6O_{13}$ (930.30): calcd. C 34.83, H 5.59, Cu 20.47, N 9.03; found C 35.03, H 5.92, Cu 20.01, N 9.37. UV/Vis (methanol): λ_{max} (ε_{max}) = 587 (282 dm^3 mol^{-1} cm^{-1}) nm. IR: $\tilde{\nu}$ = 3390 3243 [ν(N–H)]; 1518 [ν(C=N)]; 3556 [ν(O–H)] cm^{-1}.

Complex 4: Yield: 1.3 g (45%). $C_{24}H_{46}Cl_2Cu_3N_6O_{13}$ (888.22): calcd. C 32.42, H 5.18, Cu 21.45, N 9.46; found C 32.83, H 5.03, Cu 20.97, N 9.98. UV/Vis (methanol): λ_{max} (ε_{max}) = 595 (249 dm^3 mol^{-1} cm^{-1}) nm. IR: $\tilde{\nu}$ = 3377, 3247 [ν(N–H)]; 1515 [ν(C=N)]; 3550 [ν(O–H)] cm^{-1}.

Crystallographic Studies: Suitable single crystals of all four complexes were positioned at 70 mm from the image plate. A total of 100 frames were measured at 2° intervals with a counting time of 2 min. 5786, 6505, 6526 and 6690 independent reflections for complexes **1**–**4**, respectively, were measured with Mo-K_α radiation using the MARresearch Image Plate System at 293 K. Data analyses were carried out with the XDS program.[28] The structures were solved by direct methods with the SHELX86 program.[29] The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon and nitrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they are attached. Empirical absorption corrections were carried out using the DIFABS program.[30] The structures were refined on F^2 using SHELXL[31] for 3318, 5056, 3482, and 2303 reflections respectively, with $I > 2\sigma(I)$. The crystal structure illustrations were generated using ORTEP-3.[32] Selected crystallographic data are summarized in Table 5. CCDC-236467 (**1**), -236468 (**2**), -259938 (**3**), and -259939 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: Discussion of H bonds of complexes **1**–**3**.

Acknowledgments

M. S. R. and S. C. are thankful to UGC, India, and CSIR, India, respectively, for research fellowships [Sanction No. UGC/750/Jr. Fellow Sc. 2000/2001 and 9/28(614)/2003-EMR-I]. We also thank EPSRC and the University of Reading for funds for the Image Plate System. A. F., J. R., and C. D. also acknowledge financial support from the Spanish Government (Grant BQU2003-00539).

Self-Assembly of Organotin(IV) Moieties with the Schiff-Base Ligands Pyruvic Acid Isonicotinyl Hydrazone and Pyruvic Acid Salicylhydrazone: Synthesis, Characterization, and Crystal Structures of Monomeric or Polymeric Complexes

Handong Yin,*[a] Min Hong,[a] Haolong Xu,[a] Zhongjun Gao,[a] Gang Li,[a] and Daqi Wang[a]

Keywords: N,O ligands / Self-assembly / Schiff bases / Tin

A series of organotin(IV) complexes of the type $[R_2SnLY]_2$ or $[R_2SnL(R_3SnOH)]_2$ [L = 4-$NC_5H_4CON_2C(CH_3)CO_2$ or 2-$HOC_6H_4CON_2C(CH_3)CO_2$, and Y = H_2O or CH_3OH] have been synthesized by the condensation reaction of R_2SnO (R = Ph **1**, nC_8H_{17} **2**) or R_3SnCl (R = *o*-ClBz **3**, *o*-FBz **4**, *p*-FBz **5**, *p*-CNBz **6**) with the Schiff-base ligand pyruvic acid isonicotinyl hydrazone in a 1:1 molar ratio or $(R_3Sn)_2O$ (R = *n*Bu **7**, Bz **8**, *p*-CNBz **9**) or R_3SnCl (R = *o*-ClBz **10**, *p*-ClBz **11**, *p*-CNBz **12**) with the Schiff-base ligand pyruvic acid salicylhydrazone in a 1:1 molar ratio. All complexes were characterized by elemental analysis and IR, ^1H, and ^{119}Sn NMR spectroscopy. The crystal structures of complexes **1**, **2**, **3**, **7**, and **10** have been determined by X-ray single crystal diffraction analyses, which show that the tin atoms of **1**, **2**, **3**, and **10** are all seven-coordinate in distorted pentagonal bipyramid geometries, of which only complex **1** exhibits an asymmetric structure containing two different types of tin atoms. The crystal structure of **7** exhibits a dimeric structure containing distannoxane units with two types of tin atoms, in which one tin atom appears to be seven-coordinate with a distorted pentagonal bipyramid geometry and the other is four-coordinate with a distorted tetrahedral geometry. A comparison of the IR spectra of the ligands with those of the corresponding complexes reveals that the ligands coordinate to tin in the enol form due to the disappearance of the bands assigned to the carbonyl group.

Introduction

Schiff bases still play an important role as ligands in metal coordination chemistry even after almost a century since their discovery.[1–4] Organotin(IV) complexes with Schiff bases have received increasing attention owing to their antitumor activities and potential applications in biotechnology.[5–11] In addition, Schiff base organotin(IV) complexes are of interest for structural reasons. The coordination chemistry of some tridentate ONO- and ONS-donor Schiff bases has been described,[12,13] and we have recently reported some organotin(IV) complexes with the potentially ONO tridentate Schiff-base ligands salicylideneamino acids and pyruvic acid isonicotinyl hydrazone.[14,15] As part of our ongoing project dealing with the study of the interaction of tin(IV) and organotin(IV) species with *O*-donor and *N*-donor ligands, we have now synthesized twelve new organotin(IV) complexes of pyruvic acid isonicotinyl hydrazone and salicylhydrazone by self-assembly of metal ions, utilizing their preference for different coordination geometry, choice of suitable ligands, and intermolecular interactions such as hydrogen bonding. The details of the structural and spectroscopic characterization of complexes **1**–**12** are reported herein. Five of the complexes have been studied by X-ray diffraction, and reveal that there exist five different types of coordinated tin atoms (shown in Scheme 1).

Complexes **2**, **3**, and **10** are coordinated in mode A, and each reveals a highly centrosymmetric dimeric structure containings a distannoxane unit. This is the more usual structure adopted by this class of complexes.[15,16] It is worthwhile to note that crystals containing an *n*-octyl group were obtained by the reaction of pyruvic acid isonicotinyl hydrazone with di-*n*-octyltin oxide and recrystallized from acetone, as structural information for complexes containing *n*-octyl groups was lacking until now. Meanwhile, to our surprise, we obtained an unusual asymmetric linear chain polymer complex **1** containing two different types of tin atom from the reaction of Schiff-base ligand pyruvic acid isonicotinyl hydrazone with diphenyltin oxide. These two types of tin atom contain ligands in mode B. One of the two types is coordinated by tridentate formation of the Schiff base, while the other is not in the same way due to

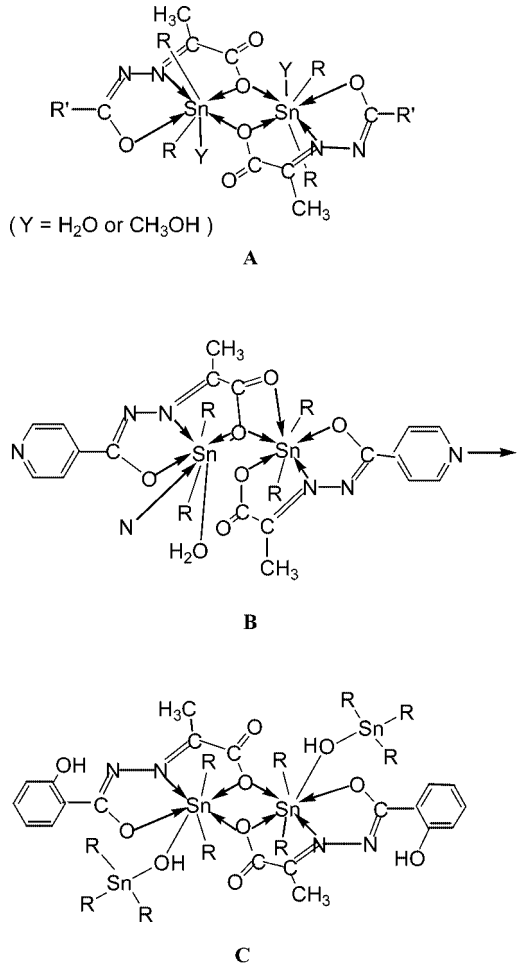

Scheme 1.

coordination between tin and two oxygen atoms derived from the carboxyl group of the adjacent ligand.

Interestingly, we also succeeded in preparing a novel tetranuclear organotin(IV) complex $[(n\text{Bu})_2\text{Sn}\{2\text{-HOC}_6\text{H}_4\text{-CON}_2\text{C(CH}_3)\text{CO}_2\}\{(n\text{Bu})_3\text{SnOH}\}]_2$ (**7**) by treatment of $[(n\text{Bu})_3\text{Sn}]_2\text{O}$ with the Schiff-base ligand pyruvic acid salicylhydrazone in a 1:1 molar ratio, which exhibits a dimeric structure containing distannoxane units with two types of tin atoms, of which one tin atom appears to be seven-coordinate with a distorted pentagonal bipyramid geometry and the other is four-coordinate with a distorted tetrahedral geometry (mode C).

Results

IR Spectra

A remarkable difference between the IR spectra of the ligands and those of the corresponding complexes is that the stretching vibration bands of the carbonyl group disappear from the spectra of all the complexes. The absence of the bands assigned to the carbonyls unambiguously confirms that the ligands coordinated to the tin are in their enol form. The characteristic absorptions at 1622–1640 and 1595–1608 cm^{-1} in the spectra of these complexes indicate the presence of C=N and C=N–N=C groups.[17] The stretching frequencies of interest are those associated with the acid COO and the Sn–O and Sn–N groups. The spectra of all complexes have some common features. The explicit feature in the infrared spectra of all complexes is the strong absorption at about 700 cm^{-1} in the spectra of the complexes, which is absent in the free ligands, which is assigned to the Sn–O stretching mode of vibration. The weak- or medium-intensity band in the region 476–486 cm^{-1} can be assigned to the Sn–N stretching vibration. All these values are consistent with those detected in a number of organotin(IV) derivatives.[18,19]

The IR spectra of organotin carboxylate complexes can provide useful information concerning the coordination behavior of the carboxyl groups. The IR spectrum of complex **1** shows that the ν_{as} and ν_{as} bands are assigned to the regions 1603, 1505 cm^{-1} and 1366, 1312 cm^{-1}, respectively. The magnitude of $\Delta\nu$ [ν_{as}(COO) – ν_s(COO)] is 237 and 193 cm^{-1}, and therefore indicates the presence of mono- and didentate carboxyl groups.[20] Moreover, the magnitude of $\Delta\nu$ (231–285 cm^{-1}) for complexes **2**–**12** indicates that the carboxylate ligand functions as a monodentate ligand in these complexes.[20] These conclusions are supported by the results of X-ray diffraction studies.

NMR Spectra

In ^{1}H NMR spectra of the free ligands, the single resonance for the proton of the -NHN= group is observed at either δ = 3.75 or 3.89 ppm, and is absent in the spectra of the complexes, thus indicating deprotonation of the -NHN= group and confirming that the ligand coordinate to the tin in the enol form. For complexes **1**–**6**, the spectra show that the chemical shifts of the protons on the pyridine ring exhibit two sets of signal in the ranges δ = 7.57–8.89 ppm, as a doublet, and δ = 7.22–8.13 ppm, also as a doublet. The coupling constant is equal to 4.80–8.40 Hz. The Ar-OH resonance appears in the region δ = 10.87–11.43 ppm, as a singlet, for the complexes **7**–**12**, which strongly suggests that the phenolic oxygen atoms do not participate in coordination to the tin atoms; this is quite different to the four complexes we have reported previously.[14]

The ^{119}Sn NMR resonance at around δ = –450 ppm is characteristic[21] of the seven-coordinate tin atom observed in the crystalline state for all the complexes. As reported in the literature,[22–24] values of $\delta_{^{119}\text{Sn}}$ in the ranges δ = –210 to –400, –90 to –190, and 200 to –60 ppm have been associated with six-, five-, and four-coordinate tin centers, respectively. On this basis we can conclude that the $\delta_{^{119}\text{Sn}}$ value for the other type of tin atom in **1** is δ = –226.9 ppm in solution, which suggests that the intermolecular Sn–N interaction probably does not survive in solution and that a six-coordinate species is formed. Therefore, it can reasonably be assumed that the structure of complex **1** in solution is different from that observed in the solid state. For com-

plexes **7**–**9**, the ^{119}Sn chemical shifts (δ = 102.3–111.7 ppm) in $CDCl_3$ indicate that there is also a type of four-coordinate tetrahedral tin atom in these complexes.

Description of the Structures

Crystal Structure of {$Ph_2Sn[4\text{-}NC_5H_4CON_2C(CH_3)CO_2](H_2O)\}_2$ (1)

The molecular structure of complex **1** is shown in Figure 1. Figure 2 shows a particular one-dimensional linear chain polymeric structure. Selected bond lengths and angles are listed in Table 1. The crystal structure of complex **1** reveals a dinuclear complex containing two types of tin atom (mode B), where a one-dimensional chain polymeric structure forms through an interaction between the N atoms of the pyridine ring and the tin atoms of an adjacent molecule. Both of the tin atoms Sn1 and Sn2 have a seven-coordinate geometry in a distorted pentagonal bipyramidal arrangement.

The Sn1 atom is rendered seven-coordinate by coordination of the nitrogen atom N6#1 of the 4-pyridinecarbonyl group from an adjacent molecule. The tin atom is surrounded by one water molecule, one tridentate pyruvic acid isonicotinyl hydrazone ligand, two *trans* phenyl groups, and nitrogen atom N6#1 (x – 1/2, $-y$ + 3/2, z). Thus, the atoms O1, N1, O3, N6#1, and O7 are coplanar within ±0.0263 Å,

and form the equatorial plane. While two *trans* phenyl carbon atoms occupy the axial sites, the angle of the axial C25–Sn1–C19 is 176.8(6)°, which deviates from the linear angle of 180°. These data indicate that the Sn1 atom is in a distorted pentagonal bipyramid geometry. The intermolecular Sn1–N6#1 distance of 2.394(9) Å is longer than the sum of the covalent radii of Sn and N (2.15 Å), but considerably less than the sum of the van der Waals radii (3.75 Å),[25] therefore it should be considered as a bonding interaction. In this connection it is relevant to note the Sn–N bond lengths found in other crystal structures of organotin complexes containing a pyridinecarboxylate ligand.[20,26] For instance, in the dicarboxylate tetraorganostannoxane $\{[(n\text{Bu})_2\text{Sn}(2\text{-pic})]_2\text{O}\}_2$ the two Sn–N bond lengths are 2.550(5) Å and 3.150(5) Å,[26] and in the linear polymer $[(\text{PhCH}_2)_3\text{Sn}(\text{OO}_2\text{CC}_5\text{H}_4\text{N-4})]$ the Sn–N distance is 2.563 Å.[20]

The Sn2 atom is bonded to the carboxyl oxygens O1 and O2, with Sn2–O1 and Sn2–O2 bond lengths of 2.594(8) and 2.388(10) Å, respectively. Thus, the Sn2 atom is surrounded by C31 and C37 of the two *trans* phenyl groups along the axial direction while O1, O2, O6, N4, and O4 form the equatorial plane. The pentagonal bipyramid geometry of Sn2 is distorted, as indicated by the bonding angles of 169.9(6)°, 93.1(5)°, 90.1(5)°, 142.5(4)°, 95.4(5)°, 83.8(6)°, 157.4(3)° and 86.4(4)° for C31–Sn2–C37, C31–Sn2–O4, C37–Sn2–O6, O4–Sn2–O6, C31–Sn2–N4, C31–Sn2–O2, N4–Sn2–O2, and C37–Sn2–O1, respectively.

Crystal Structure of $[(nC_8H_{17})_2Sn\{4\text{-}NC_5H_4CON_2C(CH_3)CO_2\}(H_2O)]_2$ *(2)*

The molecular structure of compolex **2** is shown in Figure 3. Figure S2 shows the packing of the molecule in the unit cell as seen in projection on the plane. Selected bond lengths and angles are listed in Table 2. In this complex, the Sn atom exists in a seven-coordinate environment in which one water molecule, two tridentate pyruvic acid isonicotinyl hydrazone ligands, and two *trans n*-octyl groups coordinate to each Sn center (mode A). The atoms O1, O5, O4, O3, and N1 are coplanar within ±0.0244 Å, and form the equatorial plane. Furthermore, the angle of the axial C18–Sn1–C10 is 164.4(10)°, which deviates from the linear angle of 180°. These data indicate that the tin atom of this complex is in a distorted pentagonal bipyramid geometry. The O1 atom of the carboxylate residue also binds the other tin atom, Sn2, generating an Sn_2O_2 four-membered ring. The Sn2–O1#2 (x, y + 1, z) distance [2.745(10) Å] is longer than that of Sn1–O1 [2.340(10) Å], but is comparable with those found in related seven-coordinate diorganotin systems.[20,23] The structure of this complex can therefore be described as a *trans*-C_2SnO_4N pentagonal bipyramid with the two *n*-octyl groups occupying *trans* positions [C18–Sn1–C10 = 164.4(10)° and C35–Sn2–C43 = 165.1(8)°]. It also has intradimer hydrogen bonds [O4···O6 = 2.642 Å and O8···O2 = 2.661 Å] and interdimer hydrogen bonds [O4···N6#3 (x – 1/2, –y + 1/2, z) = 2.718 Å and O8···N3#4 (x – 1/2, –y + 3/2, z) = 2.756 Å]. Neighboring molecules are held together by hydrogen bonds (O4···N6#3 and O8···N3#4). These hydrogen bonds contribute to the crystal stability and compactness and result in a one-dimensional chain arrangement. It is worthwhile to note that, for organotin(IV) complexes containing straight-chain alkyl groups, there are plenty of *n*-butyl group complexes, while complexes with *n*-octyl groups are lacking until now. This

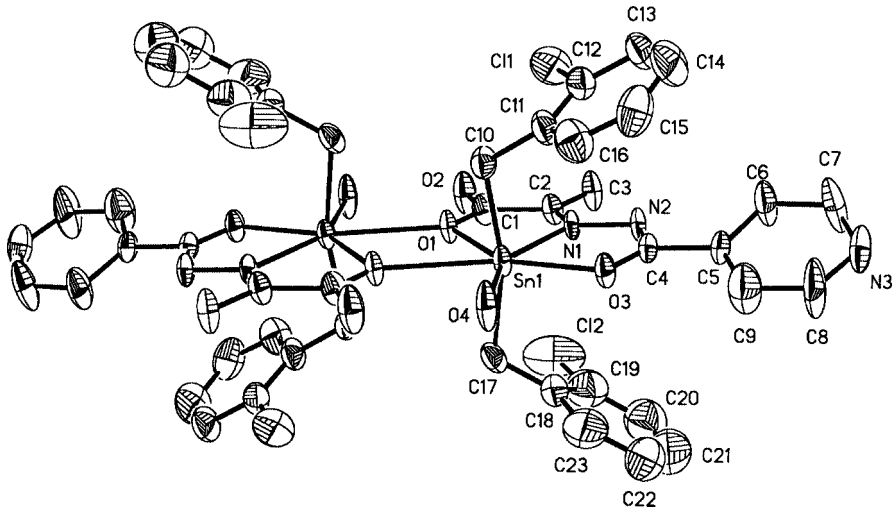

Figure 4. Molecular structure of complex **3**; ellipsoids shown at the 30% probability level.

is possibly because the *n*-octyl group chain is so long that crystals with it are not easy to form.

Although we abtained complex $[(o\text{ClBz})_2\text{Sn}\{4\text{-NC}_5\text{H}_4\text{CON}_2\text{C(CH}_3)\text{CO}_2\}(\text{H}_2\text{O})]_2$ (**3**) by a different method, the structure of **3** (Figure 4) is very similar to complex **2** (mode A), and complex **3** also contains a one-dimensional chain polymer (Figure S2) due to intermolecular hydrogen bonds (O–H···N).

Crystal Structure of $[(n\text{Bu})_2\text{Sn}\{2\text{-HOC}_6\text{H}_4\text{CON}_2\text{C(CH}_3)\text{CO}_2\}\{(n\text{Bu})_3\text{SnOH}\}]_2$ (7)

The molecular structure is illustrated in Figure 5 and selected bond lengths and angles are listed in Table 3. The molecular possesses a dimeric structure containing distannoxane units with two types of tin atoms (mode C).

The Sn1 atom lies in a distorted pentagonal bipyramidal coordination environment [Sn1–C11 = 2.087(12) Å, Sn1–C15 = 2.095(12) Å, Sn1–O3 = 2.188(8) Å, Sn1–O5 = 2.259(9) Å, Sn1–N1 = 2.324(11) Å, Sn1–O1 = 2.419(8) Å, Sn1–O1#1 = 2.585(7) Å] in which one tridentate pyruvic acid isonicotinyl hydrazone ligand, two *trans* *n*-butyl groups, and the O5 atom coordinate to each Sn center. The sum of the angles subtended at the tin atom in the pentagonal plane is 378.16°, so O3, O5, N(1), O1, and O1#1 ($-x + 2, -y + 2, -z$) lie almost in the same plane, with the Sn atom only 0.0062 Å away from the equatorial plane, while the two

trans n-butyl carbon atoms take up the axial sites around the Sn1 atom; the angle of the axial C11–Sn1–C15 is 167.5(5)°. The O1 atom of the carboxylate residue also binds the other tin atom, Sn1#1, generating an Sn_2O_2 four-membered ring, therefore the structure of this complex can be described as a dimer.

The coordination at the tin atom Sn2 is distorted tetrahedral, as indicated by bonding angles of 101.6(6)°, 107.8(5)°, 113.9(7)°, 98.9(6)°, 116.7(8)°, and 115.2(8)° for O5–Sn2–C19, O5–Sn2–C23, C19–Sn2–C23, O5–Sn2–C27, C19–Sn2–C27, and C23–Sn2–C27, respectively. In this complex, two different types of tin atom are connected through the bridging O atom, and intramolecular hydrogen bonds O5–H5···O2#1 [2.565(11) Å] and O4–H4···N2 [2.535(15) Å] are also found. The phenolate oxygen atoms do not participate in coordination to the tin atom.

Crystal Structure of [(oClBz)$_2$Sn{2-HOC$_6$H$_4$CON$_2$C(CH$_3$)CO$_2$}(CH$_3$OH)]$_2$ (10)

The crystal structure of complex **10** is shown in Figure 6. All hydrogen atoms have been omitted for the purpose of clarity. Table 4 lists selected bond lengths and angles.

Table 4. Selected bond lengths [Å] and bond angles [°] for complex **10**.

Sn1–O3	2.138(7)	N1–C2	1.266(15)
Sn1–N1	2.270(9)	N1–N2	1.377(12)

Sn1–O5	2.394(7)	O1–C1	1.297(12)
Sn1–O1#1	2.647(7)	O3–C4	1.252(12)
C11–Sn1–C18	163.8(4)	C11–Sn1–O5	82.6(4)
C11–Sn1–O3	92.9(4)	N1–Sn1–O5	148.0(3)
O3–Sn1–N1	70.7(3)	O1–Sn1–O5	142.1(3)
C11–Sn1–N1	95.5(4)	O3–Sn1–O1#1	153.8(2)
O3–Sn1–O1	140.4(3)	C11–Sn1–O1#1	85.3(3)
C18–Sn1–O1	90.2(4)	N1–Sn1–O1#1	135.5(3)
N1–Sn1–O1	69.8(3)	O1–Sn1–O1#1	65.7(3)
O3–Sn1–O5	77.5(3)	O5–Sn1–O1#1	76.4(2)

The crystal structure of **10** is also very similar to that of complex **2**. In this complex, the Sn atom exists in a distorted pentagonal bipyramidal coordination environment in which one methanol molecule, two tridentate pyruvic acid salicylhydrazone ligands, and two *trans o*-chlorobenzyl groups coordinate to each Sn center. The atoms O1, O1#1, O5, O3, and N1 are coplanar within ±0.0334 Å, and form the equatorial plane. Furthermore, the angles of the axial C18–Sn1–C11 is 163.8(4)°, which deviates from the linear angle of 180°. The O1 atom of the carboxylate residue also binds the other tin atom Sn1#1 (–x + 2, –y + 1, z), generating an Sn_2O_2 four-membered ring. Thereby the molecular structure of this compound can be described as a dimer, and the coordination geometry of tin can be also described as a *trans*-C_2SnO_4N pentagonal bipyramid, with the two *o*-chlorobenzyl groups occupying *trans* positions. From these data we can see that the crystal structure of complex **10** is very similar to those of **2** and **3**. Obviously, the nature of the alkyl group bonding to the Sn center does not exert a great influence on the overall structural motif. The Sn1–O5 bond length is 2.394(7) Å, which is longer than those in analogous complexes[20,27] due to the formation of intradimeric hydrogen bonds (O2···O5#1 = 2.583 Å). There are also strong intramolecular O–H···N hydrogen bonds (O4···N2 = 2.537 Å) involving atom N2 and the phenolic hydroxyl oxygen atom O4, which does not coordinate to the Sn center. Undoubtedly, these hydrogen bonds contribute to the compactness of the dimer.

Discussion

The complexes $[R_2SnLY]_2$ and $[R_2SnL(R_3SnOH)]_2$ (mode A, B, or C) are produced by the reaction between pyruvic acid isonicotinyl hydrazone and dialkyltin oxide or triaryltin chloride and pyruvic acid salicylhydrazone and triaryltin chloride or bis(trialkyltin) oxide, in a 1:1 molar ratio. It is clear that the presence of the enolic proton of the ligands leads to the dealkylation of the trialkyltin carboxylates $[R_3Sn\{4\text{-}NC_5H_4C(O)NHN{=}C(CH_3)CO_2\}]$ and $[R_3Sn\{2\text{-}HOC_6H_4C(O)NHN{=}C(CH_3)CO_2\}]$, which are the

major products of the reaction of R_3SnCl or $(R_3Sn)_2O$ with Schiff-base ligands. Seven-coordinate dimers are formed as a result of steric or solvent effects in the recrystallization. The crystal-structure determinations show that the structures of complexes **1**–**3** are one-dimensional infinite chain polymers due to intermolecular hydrogen-bond interactions between the coordinated water molecule and the pyridine nitrogen atom of the adjacent unit. Complexes **7** and **10**, which contain pyruvic acid salicylhydrazone, are monomers. Their possible reaction mechanisms are shown in Schemes 2, 3, and 4.

Conclusions

The pyruvic acid hydrazone ligands have been shown to be able to form monomeric or polymeric complexes. The nuclearity and stereochemistry are found to be dependent on the nature of the starting acceptor and the reaction conditions. The ligand chelates to tin atoms, bonding through the oxygen of the carboxyl or enolic hydroxy group and the nitrogen atoms. In the polymeric complex, the dimers are connected through intermolecular hydrogen bonds or interactions between the nitrogen atoms of the pyridine ring and the tin atoms of an adjacent molecule. The monomeric complexes possess a highly centrosymmetric dimeric structure containing a distannoxane unit. The reaction of $[(n\mathrm{Bu})_3Sn]_2O$ with pyruvic acid salicylhydrazone gives a novel tetranuclear organotin complex, which exhibits a dimeric structure containing a distannoxane unit with two types of tin atoms that are seven- or four-coordinate.

Experimental Section

Diphenyltin oxide, di-*n*-octyltin oxide and bis(tri-*n*-butyltin) oxide are commercially available, and were used without further purification. The ligands, bis(triaryltin) oxide and triaryltin chloride were prepared by the methods reported in the literature.[28–30] The melting points were obtained with a Kolfer micro melting point apparatus and are uncorrected. IR spectra were recorded with a Nicolet-460 spectrophotometer, as KBr discs. ^1H and ^{119}Sn NMR spectra were recorded with a Mercury Plus-400 NMR spectrometer in $CDCl_3$. The spectra were acquired at room temperature (298 K) unless otherwise specified. The chemical shifts are reported in ppm with respect to the references and are stated relative to external tetramethylsilane (TMS) for ^1H, and to neat tetramethyltin for ^{119}Sn NMR spectroscopy. Elemental analyses were performed with a PE-2400II elemental analyzer.

Pyruvic Acid Isonicotinyl Hydrazone: This Schiff base was prepared from isonicotinic acid hydrazide and pyruvic acid in ethanol according to the literature.[28] A white powder was obtained. Yield: 95% (864.2 mg). M.p. 222–223 °C. $C_9H_9N_3O_3$ (207.19): calcd. C 48.14, H 5.00, N 18.38; found C 48.00, H 4.89, N 18.67.

Pyruvic Acid Salicylhydrazone: This Schiff base was prepared from salicylhydrazide and pyruvic acid in ethanol according to the literature.[29] White, needle-shaped crystals were obtained. Yield: 80% (931.6 mg). M.p. 216 °C. $C_{10}H_{10}N_2O_4$ (222.19): calcd. C 54.92, H 4.54, N 12.61; found C 54.72, H 4.68, N 12.85.

$[Ph_2Sn\{4\text{-}NC_5H_4CON_2C(CH_3)CO_2\}(H_2O)]_2$ (1): Pyruvic acid isonicotinyl hydrazone (2.0 mmol) was added to a benzene/ethanol (3:1, v/v) solution (50 mL) of Ph_2SnO (2.0 mmol). The mixture was heated under reflux with stirring for 6 h. The clear solution thus obtained was evaporated under vacuum to form a brown solid and recrystallized from dichloromethane/hexane to give red crystals. Yield: 78% (113.2 mg). M.p. 165–167 °C. $C_{42}H_{38}N_6O_8Sn_2$ (992.16): calcd. C 50.81, H 3.73, N 8.47; found C 50.73, H 3.69, N 8.52. ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.66 (s, 6 H, CH_3), 5.31 (s, 4 H, H_2O), 7.44–7.79 (m, 20 H, Ph-H), 8.13 (d, J = 6.00 Hz, 4 H, 3,5-pyridine-H), 8.84 (d, J = 5.20 Hz, 4 H, 2,6-pyridine-H) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –226.9, –451.0 ppm.

$[(n\mathrm{C_8H_{17}})_2Sn\{4\text{-}NC_5H_4CON_2C(CH_3)CO_2\}(H_2O)]_2$ (2): Complex **2** was prepared in the same way as complex **1** by adding di-*n*-octyltin oxide (2.0 mmol) to pyruvic acid isonicotinyl hydrazone (2.0 mmol). Unlike the analogous reaction mixtures with di-*n*-butyl-[15] or diphenyltin(IV) oxide, crystallization from dichloromethane/hexane failed to generate the desired crystals of **2**, which is the di-*n*-octyltin analog of the di-*n*-butyltin complex.[15] However, when acetone was used as crystallization solvent colorless crystals of **3** were obtained. Yield: 88% (121.0 mg). M.p. 77 °C. $C_{25}H_{43}N_3O_4Sn$ (568.31): calcd. C 52.73, H 7.57, N, 7.39; found C 52.81, H 7.42, N 7.35. IR (KBr): $\tilde{\nu}$ = 2924 cm^{-1}, 2854 (s, C–H), 1640 (s, C=N), 1606 (s, C=N–N=C), 1619, 1334 (s, CO_2), 1207 (s, C–O), 694 (s, Sn–O), 541 (w, Sn–C), 476 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 0.85 (t, J = 10.0 Hz, 6 H, CH_3), 1.22–1.31 [m, 8 H, $Sn(CH_2)_2$ (α,β)], 1.64–1.75 [m, 20 H, CH_2 (ω)], 2.65 (s, 3 H, CH_3), 7.99 (d, J = 5.60 Hz, 2 H, 3,5-pyridine-H), 8.77 (d, J = 5.20 Hz, 2 H, 2,6-pyridine-H) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –460.6 ppm.

$[(o\mathrm{ClBz})_2Sn\{4\text{-}NC_5H_4CON_2C(CH_3)CO_2\}(H_2O)]_2$ (3): Pyruvic acid isonicotinyl hydrazone (2.0 mmol) and tri-*o*-chlorobenzyltin chloride (2.0 mmol) were added to a solution of absolute toluene (30 mL) and heated under reflux with stirring for 1 h. After the addition of triethylamine (2.0 mmol) to the reactor, the reaction mixture was refluxed for 1 h more. The clear solution thus obtained was evaporated under vacuum to form a white solid and recrystallized from methanol to give colorless crystals. Yield: 81% (104.8 mg). M.p. 151 °C. $C_{46}H_{42}Cl_4N_6O_8Sn_2$ (1186.0): calcd. C 46.54, H 3.54, N, 7.08; found C 46.66, H 3.51, N 7.05. ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.46 (s, 6 H, CH_3), 3.19 (s, 8 H, $ArCH_2Sn$), 7.05–7.54 (m, 16 H, Ar-H), 7.72 (d, J = 6.60 Hz, 4 H, 3,5-pyridine-H), 8.70 (d, J = 4.80 Hz, 4 H, 2,6-pyridine-H) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –457.2 ppm.

$[(o\mathrm{FBz})_2Sn\{4\text{-}NC_5H_4CON_2C(CH_3)CO_2\}]_2$ (4): Complex **4** was prepared in the same way as **3** by adding tri-*o*-fluorobenzyltin chloride (2.0 mmol) to pyruvic acid isonicotinyl hydrazone (2.0 mmol). The solid was then obtained from methanol. Yield: 80% (90.6 mg). M.p. 145 °C. $C_{46}H_{38}F_4N_6O_6Sn_2$ (1084.24): calcd. C 50.96, H 3.53, N 7.75; found C 50.84, H 3.48, N 7.88. IR (KBr): $\tilde{\nu}$ = 3007 cm^{-1} (m, Ar–H), 2937, 2738 (s, C–H), 1622 (s, C=N), 1608 (s, C=N–N=C), 1618, 1334 (s, CO_2), 1229 (s, C–O), 694 (s, Sn–O), 480 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.20 (s, 6 H, CH_3), 3.15 (s, 8 H, $ArCH_2Sn$), 6.60–7.27 (m, 16 H, Ph-H), 7.78 (d, J = 5.60 Hz, 4 H, 3,5-pyridine-H), 8.74 (d, J = 5.80 Hz, 4 H, 2,6-pyridine-H) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –456.3 ppm.

$[(p\mathrm{FBz})_2Sn\{4\text{-}NC_5H_4CON_2C(CH_3)CO_2\}]_2$ (5): Complex **5** was prepared in the same way as **3** by adding tri-*p*-fluorobenzyltin chloride (2.0 mmol) to pyruvic acid isonicotinyl hydrazone (2.0 mmol). The solid was then obtained from methanol. Yield: 86% (98.4 mg). M.p. 138 °C. $C_{46}H_{38}F_4N_6O_6Sn_2$ (1084.24): calcd. C 50.96, H 3.53, N 7.75; found C 50.91, H 3.61, N 7.61. IR (KBr): $\tilde{\nu}$ = 3021 cm^{-1} (s, Ar–H), 2944 (s, C–H), 1620 (s, C=N), 1605 (m, C=N–N=C), 1617, 1341 (s, CO_2), 1233 (s, C–O), 688 (m, Sn–O), 491 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.25 (s, 6 H, CH_3), 3.23 (s, 8 H,

$ArCH_2Sn$), 6.63–7.39 (m, 16 H, Ph-H), 7.78 (d, J = 4.80 Hz, 4 H, 3,5-pyridine-H), 8.89 (d, J = 6.40 Hz, 4 H, 2,6-pyridine-H) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –449.8 ppm.

[(*p*CNBz)$_2$Sn{4-NC$_5$H$_4$CON$_2$C(CH$_3$)CO$_2$}]$_2$ (6): Complex **6** was prepared in the same way as **3** by adding tri-*p*-cyanobenzyltin chloride (2.0 mmol) to pyruvic acid isonicotinyl hydrazone (2.0 mmol). The solid was then obtained from methanol. Yield: 91% (115.8 mg). M.p. 210 °C. $C_{50}H_{38}N_{10}O_6Sn_2$ (1112.3): calcd. C 53.98, H 3.42, N 12.60; found C 53.62, H 3.41, N 12.77. IR (KBr): $\tilde{\nu}$ = 3007 cm^{-1} (m, Ar–H), 2922, 2852 (s, C–H), 1630 (m, C=N), 1619, 1385 (m, CO_2), 1602 (m, C=N–N=C), 1200 (m, C–O), 692 (m, Sn–O), 540 (w, Sn–C), 478 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.42 (s, 6 H, CH_3), 3.08 (s, $ArCH_2Sn$), 7.21–7.35 (m, 16 H, Ph-H), 7.22 (d, J = 8.00 Hz, 4 H, 3,5-pyridine-H), 7.57 (d, J = 8.40 Hz, 4 H, 2,6-pyridine-H) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –453.9 ppm.

[(*n*Bu)$_2$Sn{2-HOC$_6$H$_4$CON$_2$C(CH$_3$)CO$_2$}{(*n*Bu)$_3$SnOH}]$_2$ (7): Pyruvic acid salicylhydrazone (1.0 mmol) was added to a benzene suspension (30 mL) of bis(tri-*n*-butyltin) oxide (1.0 mmol), then the mixture was stirred and heated at reflux for 6 h. The clear solution obtained after fliteration was evaporated in vacuo to give a solid, which was then recrystallized from dichloromethane/hexane to give colorless crystals. Yield: 83% (71.5 mg). M.p. 101 °C. $C_{30}H_{54}N_2O_5Sn_2$ (759.12): calcd. C 47.40, H 7.16, N 3.68; found C 47.32, H 7.15, N 3.77. IR (KBr): $\tilde{\nu}$ = 3423 cm^{-1} (m, OH), 2955 (s, Ar–H), 2922, 2853 (s, C–H), 1627 (m, C=N), 1608, 1334 (s, CO_2), 1583 (m, C=N–N=C), 1205 (s, C–O), 672 (m, Sn–O), 560 (w, Sn–C), 502 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 0.83 (t, J = 6.40 Hz, 15 H, CH_3), 1.19–1.61 (m, 30 H, $SnCH_2CH_2CH_2$), 2.38 (s, 3 H, CH_3), 6.88–7.35 (m, 4 H, Ph-H), 11.22 (s, 1 H, Ar-OH) ppm. ^{119}Sn NMR ($CDCl_3$): δ = 102.3, –453.9 ppm.

[Bz$_2$Sn{2-HOC$_6$H$_4$CON$_2$C(CH$_3$)CO$_2$}{Bz$_3$SnOH}]$_2$ (8): Complex **8** was prepared in the same way as **7** by adding bis(tribenzyltin) oxide (1.0 mmol) to pyruvic acid salicylhydrazone (1.0 mmol). The solid was then obtained from dichloromethane/hexane. Yield: 91% (82.2 mg). M.p. 215 °C. $C_{45}H_{43}N_2O_5Sn_2$ (929.25): calcd. C 58.10, H 4.77, N 3.01; found C 58.25, H 4.53, N 3.11. IR (KBr): $\tilde{\nu}$ = 3411 cm^{-1} (m, OH), 3035 (s, Ph–H), 2952, 2859 (s, C–H), 1630 (s, C=N), 1596, 1347 (s, CO_2), 1579 (m, C=N–N=C), 1202 (s, C–O), 679 (m, Sn–O), 555 (m, Sn–C), 477 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.65 (d, J = 5.60 Hz, 3 H, CH_3), 2.81 (t, $J_{Sn,H}$ = 68.88 Hz, 6 H, $ArCH_2Sn$), 3.16 (s, 4 H, $ArCH_2Sn$), 6.93–7.28 (m, 29 H, Ar-H and Ph-H), 11.43 (s, 1 H, Ar-OH) ppm. ^{119}Sn NMR ($CDCl_3$): δ = 111.7, –449.5 ppm.

[(*p*CNBz)$_2$Sn{2-HOC$_6$H$_4$CON$_2$C(CH$_3$)CO$_2$}{(*p*CNBz)$_3$SnOH}]$_2$ (9): Complex **9** was prepared in the same way as **7** by adding bis(tri-*p*-cyanobenzyltin) oxide (1.0 mmol) to pyruvic acid salicylhydrazone (1.0 mmol). The solid was then obtained from dichloromethane/hexane. Yield: 93% (99.7 mg). M.p. 218 °C. $C_{50}H_{38}N_7O_5Sn_2$ (1054.30): calcd. C 56.91, H 3.72, N 9.29; found C 57.15, H 3.55, N 9.21. [(*p*CNBz)$_2$Sn{2-HOC$_6$H$_4$CON$_2$C(CH$_3$)CO$_2$}]$_2$ (12): Complex **12** was prepared in the same way as **10** by adding tri-*p*-cyanobenzyltin chloride (2.0 mmol) to pyruvic acid salicylhydrazone (2.0 mmol). The solid was then obtained from methanol. Yield: 72% (92.1 mg). M.p. 215 °C. $C_{52}H_{40}N_8O_8Sn_2$ (1142.3): calcd. C 54.67, H 3.53, N 9.81; found C 54.81, H 3.44, N 9.72. IR (KBr): $\tilde{\nu}$ = 3411 cm^{-1} (m, OH), 3102 (m, Ar–H), 2922 (m, C–H), 1612 (m, C=N), 1600 (m, C=N–N=C), 1588, 1352 (s, CO_2), 1206 (m, C–O), 677 (w, Sn–O), 523 (m, Sn–C), 459 (w, Sn–N). ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.52 (s, 6 H, CH_3), 3.35 (s, 8 H, $ArCH_2Sn$), 6.35–7.61 (m, 24 H, Ar-H and Ph-H), 10.87 (s, 2 H, Ar-OH) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –452.8 ppm.

X-ray Crystallographic Study: All measurements were made on a Bruker Smart 1000 CCD diffractometer at 298(2) K with graphite-monochromated Mo-K_α (λ = 0.71073 Å). Semi-empirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and difference Fourier maps using SHELXL-97,[31] and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were included in the model at their calculated positions.

CCDC-250084 (**1**), -255498 (**2**), -255497 (**3**), -269987 (**7**), and -269988 (**10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see footnote on the first page of this article): Figures S1, S2, S3, and S4 show the unit cell of complexes **2**, **3**, **7**, and **10**, respectively Crystal data and details of the structure determinations are listed in Tables S1 and S2.

Anchoring of Vanadyl Acetylacetonate onto Amine-Functionalised Activated Carbons: Catalytic Activity in the Epoxidation of an Allylic Alcohol

Bruno Jarrais,[a] Ana Rosa Silva,[a] and Cristina Freire*[a]

Keywords: Activated carbon / Anchoring / Epoxidation / EPR spectroscopy / Vanadium

Vanadyl(IV) acetylacetonate was anchored onto two different amine-functionalised activated carbons. The starting activated carbon supports were air (A2) and nitric acid oxidised (B1) carbons; the phenol surface groups of carbon A2 were subsequently treated with (3-aminopropyl)triethoxysilane (A3) and afterwards the free amine groups were used for Schiff condensation with $[VO(acac)_2]$ (A4). Carbon B1, which possesses carboxylic surface groups, was treated with thionyl chloride to give surface acyl chloride groups (B2), which were then reacted with the amine groups of bis(3-aminopropyl)amine (B3); subsequent attachment of $[VO(acac)_2]$ was also achieved by Schiff condensation between the free amine groups of the functionalised carbon and the ligand oxygen atoms (B4). All the materials were characterised by XPS, and the $[VO(acac)_2]$-based materials were also characterised by vanadium elemental analysis and EPR spectroscopy. A combination of all the data provides evidence for the covalent attachment of the vanadium complex onto the modified activated carbons. The catalytic activity of the $[VO(acac)_2]$-based materials in the epoxidation of 3-buten-2-ol using *tert*-butyl hydroperoxide as oxygen source was assessed and compared to that of the homogeneous phase reaction. The alkene conversion in the heterogeneous phase is similar to that observed in the homogeneous phase, although the rate of oxidation is less than half that of the homogeneous system. Material A4 exhibits higher catalytic efficiency than B4; upon reuse, both materials show no significant decrease in their catalytic properties.

Introduction

Vanadyl(IV) acetylacetonate has been found to be a useful homogeneous catalyst in several oxidation reactions, such as the oxidation of alcohols,[1] oxidation of sulfides to sufoxides,[1,2] oxidation of thiols to disulfides[3] and in the epoxidation of allylic alcohols.[1,2] Moreover, the catalytic activity of vanadyl(IV) acetylacetonate is not only restricted to oxidation reactions; it has also been employed in ring-cleavage reactions[4] and in oxidative polymerisation reactions[5] and polymerisation of diphenyl disulfides,[6] thus making it a versatile and readily available catalyst.

Epoxides are extremely useful building blocks in the synthesis of organic compounds as they act as excellent intermediates that can yield a great variety of products.[7] The homogeneous epoxidation of allylic alcohols by vanadyl(IV) acetylacetonate under mild conditions and using *tert*-butyl hydroperoxide as the oxygen source has been widely studied and exhibits high activity, selectivity and regioselectivity.[1,2,8,9] The catalytically active oxo-peroxo intermediate is formed in situ by oxidation of V^{IV} to V^{V} with an excess of *tert*-butyl hydroperoxide, yielding a *tert*-butyl hydroperoxovanadium(V) complex. A good example of the high regioselectivity of this complex is the epoxidation of geraniol, an allylic alcohol containing an isolated double bond, which is catalysed by a $[VO(acac)_2]$–*tert*-butyl hydroperoxide system, where the allylic double bond is selectively oxidised, whereas peracids preferentially epoxidise the isolated double bond.[1]

The heterogenisation of these transition metal complexes on solid supports allows the combination of their homogeneous catalytic properties with those of heterogeneous catalysts, such as the ease of separation from reaction media, shape selectivity and reuseability.[10–13] Early approaches to heterogenisation consisted of ion exchanging or simple adsorption of the metal complexes onto the supports, but these procedures did not prevent active-phase leaching.[12,13] This problem was recently overcome by the development of several grafting and tethering methodologies, which allow the covalent attachment of transition metal complexes to organic polymers, silica, zeolites and other micro- and mesoporous inorganic materials.[10–13]

Activated carbons and other carbon-based materials are widely used as catalysts and as supports for metals in their reduced state,[14,15] and a few reports have appeared on the heterogenisation of metal complexes, mainly of noble metals with simple ligands, to be used in hydrogenation and hydroformylation reactions.[16–18] We have been developing several anchoring procedures to immobilise Schiff-base transition metal complexes onto activated carbons and

other supports.[19–23] In one of these works, copper(II) acetylacetonate was irreversibly anchored onto a chemically oxidised activated carbon functionalised with bis(3-aminopropyl)amine (trien) by Schiff-base condensation between the free amine groups of trien covalently attached to the activated carbon surface and the oxygen atoms of acetylacetonate coordinated to copper(II).[23] In the present work, we report an extension of this latter procedure to vanadyl(IV) acetylacetonate and a new route for complex immobilisation, in which an oxygen-oxidised activated carbon, previously functionalised with (3-aminopropyl)triethoxysilane (APTES), is used to anchor vanadyl(IV) acetylacetonate by Schiff-base condensation between the free amine groups of APTES and the ligand oxygen atoms. The functionalisation steps were followed by X-ray photoelectron spectroscopy (XPS), and the $[VO(acac)_2]$-based materials were characterised by vanadium ICP-AES analysis and by EPR spectroscopy. The catalytic activity of these two novel carbon-based vanadyl(IV) acetylacetonate heterogeneous catalysts was tested at 0 °C in the epoxidation of an allylic alcohol (3-buten-2-ol) in dichloromethane using *tert*-butyl hydroperoxide (*t*BuOOH) as the oxygen source. Their reusability was also tested.

Results and Discussion

Vanadyl(IV) acetylacetonate was anchored onto two different amine-functionalised activated carbons using the methods summarised in Scheme 1. In method A, an air-oxidised activated carbon (A2) with a high amount of surface phenol groups was treated with (3-aminopropyl)triethoxysilane (APTES), resulting in a surface with free amine groups (A3). In method B, the starting material was a nitric acid oxidised activated carbon (B1), which possesses a high concentration of carboxylic acid groups. These were converted into more reactive acyl chloride functionalities by treatment with thionyl chloride (B2), and then reacted with the amine groups of bis(3-aminopropyl)amine (trien, B3). The free amine groups in both carbons A3 and B3 were used for Schiff-base condensation with $[VO(acac)_2]$ to give A4 and B4, respectively. All the materials were characterised by XPS, and the $[VO(acac)_2]$-based materials were also characterised by vanadium ICP-AES analysis and EPR spectroscopy. The XPS data of materials A1, A2, B1, B2 and B3 have already been described in previous papers[22,23] and thus here we will focus on the characterisation of the new materials, only recalling relevant aspects of the previous ones.

Characterisation of the Heterogeneous Catalysts

X-ray Photoelectron Spectroscopy and Elemental Analysis

Table 1 contains the XPS atomic percentages of all the carbon-based materials and Figure 1 shows the XPS high-resolution spectra in the O 1s region (for the series of carbons A) and in the V 2p region (for carbons with anchored vanadyl complexes, A4 and B4).

Table 1. XPS atomic percentages for carbon-based materials.

Sample	Atom %						Ref.
	O	N	Cl	C	Si	V	
A1	7.66	0.58	0.86	90.41	–	–	this work
A2	12.58	0.70	0.30	86.15	–	–	this work

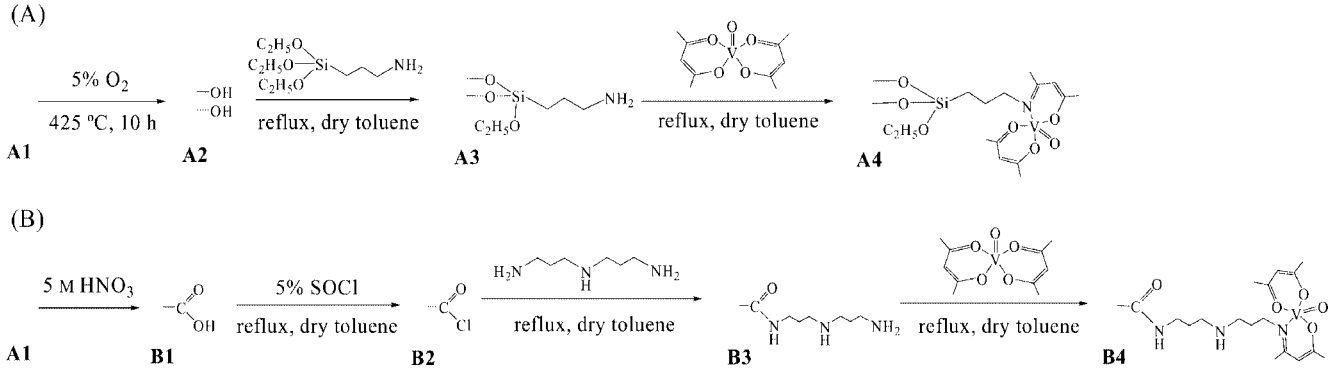
[a] Not analysed. [b] Silica impurity on carbon matrix.

There is a significant increase in the oxygen content when the parent carbon A1 is submitted to the two different oxidation procedures (Table 1), thus indicating the formation of new oxygen functionalities at the surface of the activated carbon.[19–24]

In the O 1s region (Figure 1, a), sample A1 exhibits a symmetrical broad peak centred at 532.3 eV, whereas sample A2 shows a more-intense and asymmetric peak centred at 533.6 eV with a shoulder at 532.0 eV. The air oxidation of A1 increases the number of phenol and carbonyl groups,[24] which exhibit O 1s peaks in the region 532–533 eV,[25–27] therefore the shoulder in A2 is assigned to these basic groups. After reaction with APTES (A3), there is an increase in the area under the bands in the N 1s, O 1s and Si 2p regions, as can be seen in Table 1, thus confirming



Scheme 1. Proposed structures for the anchored $[VO(acac)_2]$ on functionalised activated carbons prepared by methods A and B.

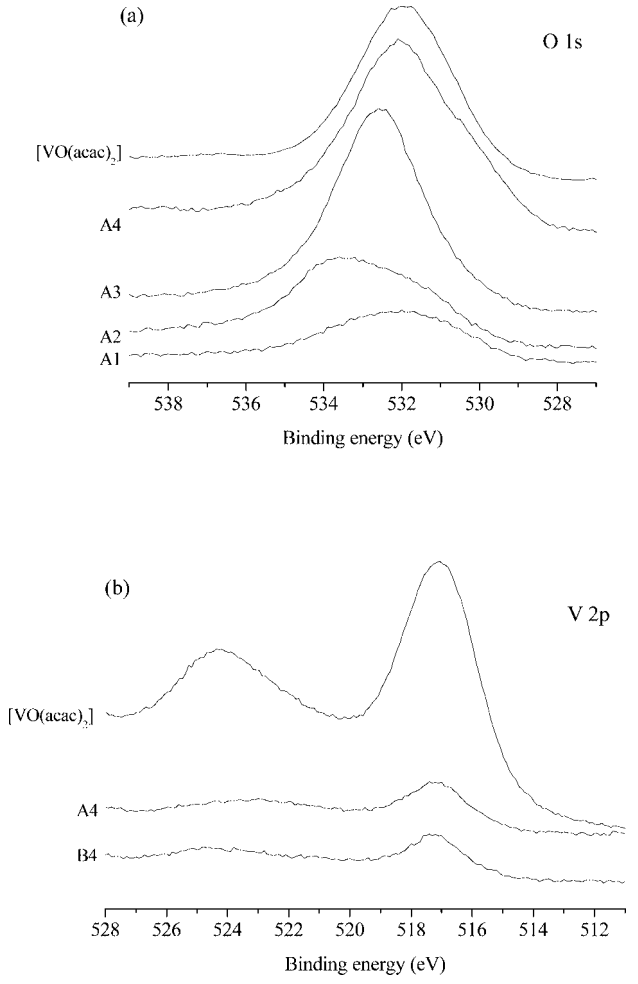

Figure 1. High-resolution XPS spectra of carbon-based materials in the O 1s (a) and V 2p (b) regions.

that APTES has been successfully anchored onto the air-oxidised carbon. The spectra of A3 in the O 1s region (Figure 1, a) is quite different from carbon A2 and shows a very intense and symmetric peak at 532.6 eV; this peak may be assigned not only to ether-type oxygen atoms, which result from the reaction between the APTES ethoxy functionalities and carbon surface phenol groups, but also to unreacted ethoxy groups from the aminoalkylsilane.[25,28] Upon complex anchoring on carbon A3, a new peak at 531.6 eV is observed in the O 1s region, which may be assigned to oxygen atoms from $[VO(acac)_2]$ (BE = 531.7 eV; Figure 1, a);[19–23] an increase in intensity in the high binding energies of the N 1s peak is also detected, suggesting the presence of nitrogen atoms in a new and different chemical environment.

Upon reaction of carbon B1 with thionyl chloride there is an increase in the chlorine content accompanied by a decrease in the oxygen content, thus indicating the formation of acyl chloride groups.[21,23] With the introduction of trien in B2, there is a significant increase in the nitrogen content, accompanied by a decrease in the chlorine surface quantity. This indicates that reaction between the amine groups of trien and the carbon acyl chloride functionalities has occurred, with formation of new amide groups and loss of hydrogen chloride. A loss of the surface oxygen is also observed, which can be explained by the parallel reaction of trien with other carbon surface groups, such as carbonyl groups, thus increasing the effectiveness of the trien anchoring.[23] Similarly, after reaction of B3 with $[VO(acac)_2]$, an increase in the peak at 532.0 eV in the O 1s region is observed (assigned to the oxygen atoms of the complex) and an increase in the broadness of the N 1s peak is also detected as a consequence of the presence of new nitrogen atoms in different chemical environments.

The observation of peaks in the V $2p_{3/2}$ region of the high-resolution spectra of A4 and B4 (Figure 1, b) confirms the presence of the metal complexes in both modified activated carbons. The areas under these bands allow the calculation of the surface amount of vanadium per weight of material, which are 697 and 554 $\mu mol\,g^{-1}$, respectively (Table 2). The similarity between the V 2p band profiles of the free and the anchored complexes (A4 and B4) suggests that the complex has kept its integrity upon immobilisation on the activated carbons. Furthermore, a comparison of the V $2p_{3/2}$ peak of free $[VO(acac)_2]$ (BE = 516.8 eV) with those of anchored complexes in A4 and B4 (BE = 517.0 and 517.2 eV, respectively; Figure 1, b) gives additional information on the V metal centre: the observed shift to higher binding energies suggests the presence of a more deshielded V centre. This observation, combined with the results referred to above, suggest complex anchoring through Schiff-base condensation between the carbon amine groups and ligand oxygen atoms, with the formation of a V–N in-plane bond, which induces a higher degree of in-plane covalence. Nonetheless, on the basis of the XPS data alone, we cannot exclude some direct axial coordination of the complex (available sixth position) onto the carbon oxygen surface

Table 2. Vanadium and silicon bulk contents obtained by ICP-AES.

groups, as a similar effect on the vanadium binding energy would be expected. The other hypothesis for complex anchoring via vanadium axial coordination through the free NH_2 groups of trien or APTES can be excluded, as it would induce an increase in V electronic density (NH_2 groups behave as electron donors), thus leading to a more shielded V atom, which would give rise to a decrease in the binding energy.

The vanadium bulk content of carbons A4 and B4 was determined by ICP-AES and from this it was possible to calculate the complex loading (mass of vanadium/mass of carbon × 100) and the immobilisation efficiency (amount of adsorbed complex/amount in original solution × 100), which are summarised in Table 2. In the case of material A4, the silicon bulk content was also obtained, allowing the calculation of APTES loading and its anchoring efficiency on carbon A4 (1.10 μmol g^{-1} and 77%, respectively). The complex is anchored more efficiently onto the trien-functionalised carbon (86%) than onto the APTES-functionalised carbon (65%).

The vanadium bulk contents for A4 and B4 are 128 and 170 μmol g^{-1}, respectively, and are therefore lower than the surface content obtained by XPS (697 and 554 μmol g^{-1}, respectively). This suggests that both vanadyl(IV) acetylacetonate complexes are mainly anchored at the outer pores of the carbon matrix (although this is more evident for material A4), probably as a consequence of size constraints imposed by the size of the innermost pores of the activated carbon. Similarly, the Si surface content in A3 is higher than that obtained by bulk analysis (3.76 and 1.10 mmol g^{-1}, respectively); this constitutes indirect evidence that the complex has been anchored preferentially onto the APTES sites within the activated carbon.

Electron Paramagnetic Resonance

The EPR spectra of A4 and B4 (Figure 2) are very similar and show a typical signal of V^{IV} $3d^1$ centres with eight-line hyperfine patterns due to the interaction of the unpaired electron with the ^{51}V nucleus (I = 7/2); the spectra are typical of magnetically diluted monomeric vanadyl ($V{=}O^{2+}$) species with g values and vanadium hyperfine coupling constants characteristic of a square-pyramidal structure with approximate axial geometry;[29–31] this indicates that there is no significant magnetic interactions between vicinal V centres and that the carbon matrix acts as a diamagnetic host.

The similarity between the EPR spectra of A4 and B4 with those observed for the free VO complexes[29–31] allows the same orientation scheme to be used for the tensor axes: $g_1 = g_2 = g_\perp$, $g_3 = g_\parallel$ (or $g_1 = g_x$, $g_2 = g_y$, $g_3 = g_z$), where g_1 and g_3 refer to the lowest and highest magnetic-field g values (obviously, $A_1 = A_2 = A_\perp$, $A_3 = A_\parallel$ or $A_1 = A_x$, $A_2 = A_y$, and $A_3 = A_z$); in this context, as $g_x = g_y > g_z$ the ground state is d^1_{xy}. The EPR spectra of A4 and B4 are presented in Figure 2, and the spin-Hamiltonian parameters for free $[VO(acac)_2]$ magnetically diluted in KBr and the carbon-anchored complexes are summarised in Table 3.

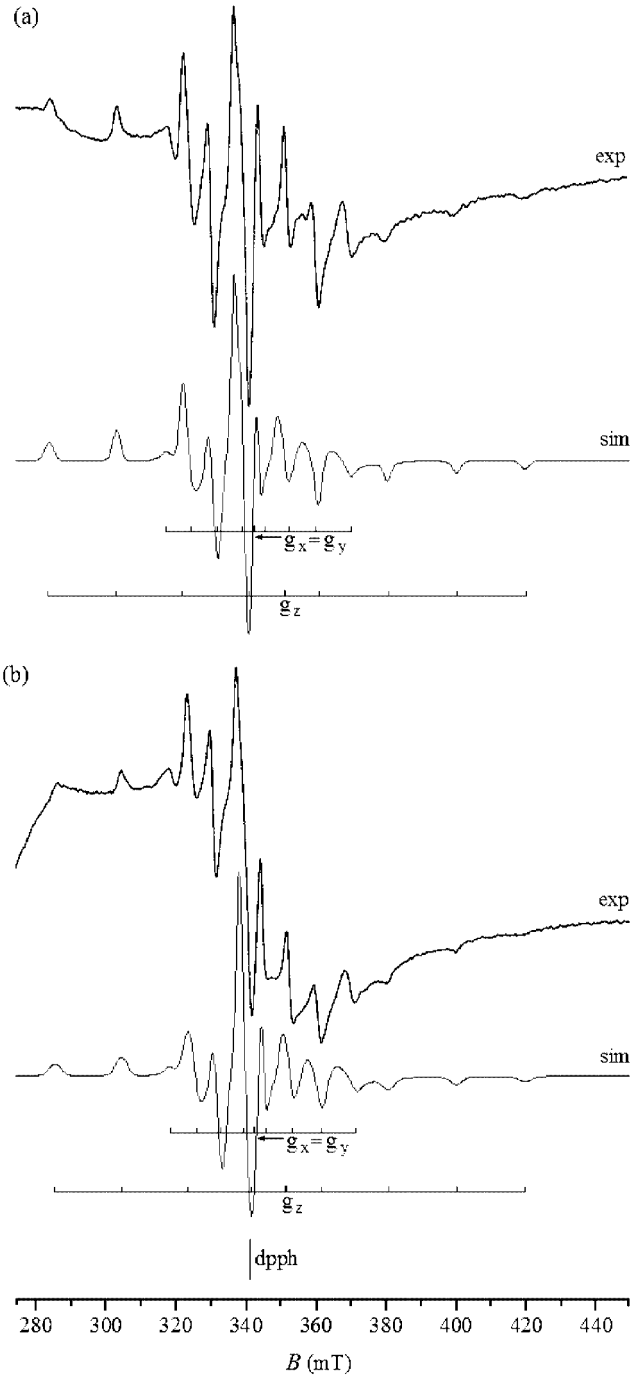

Figure 2. EPR spectra (ν = 9.57 GHz) for carbon B4 at 125 K (a) and carbon A4 at 165 K (b) (exp = measured, sim = simulated).

Table 3. Spin-Hamiltonian parameters for the free and supported $[VO(acac)_2]$ complex.

The EPR band profile of both materials indicates that there is only one major VO EPR active species within the carbon matrix (small bandwidth and no additional peaks besides those that are predicted for one species) and corroborates the V 2p XPS data. Both materials, when compared to the free complex, show a decrease in $A_{\parallel}$, although this is quite small for B4, suggesting a decrease in the unpaired spin density at the V centre upon carbon anchoring. This excludes the axial coordination of APTES or trien through the NH_2 functionalities, as this would increase the $A_{\parallel}$ values. In the light of the model developed by Wuthrich and refined later by Chasteen,[29,30,32] this result can be interpreted as an increase in the in-plane covalency: in our context, complex anchoring through the Schiff-base condensation between amine functionalities from trien or APTES and the acetylacetone ligand would lead to a new in-plane V–N bond, which would increase the delocalisation of the electron density towards the equatorial ligand, thus inducing a decrease in $A_{\parallel}$. Although new equatorial V–N bonds would give rise to the appearance of superhyperfine splittings due to the interaction of the vanadium unpaired spin with the equatorial nitrogen atom ($I = 1$; d_{xy} ground state), no splitting due to the presence of N atoms could be detected in the EPR spectra, probably due to the relatively big bandwidth that is associated with solid-state spectra.

Parallel with the decrease in $A_{\parallel}$, an increase in $g_{\parallel}$ (towards the g_e value) is usually observed as a consequence of the increase in the equatorial bonding covalence.[30–32] However, our data do not follow this trend, since no variation in the g values is observed for B4 and a decrease in g values is detected for A4 when compared to free $[VO(acac)_2]$. Nonetheless, these results do not contradict the above explanations as strong distortions of the anchored complexes within the matrix are expected to occur and, under this circumstances, the g values can show dissimilar changes upon complex distortion:[30] the g_z values are usually insensitive to the degree of the distortion of complex structure, whereas g_x and g_y exhibit a greater variation, although in an unpredicted random manner.

No characterisation of the material is possible by FTIR and UV/Vis spectroscopy in order to get further information on complex distortion induced by the anchoring procedure, as the strongly absorbing carbon matrix prevents the observation of the typical complex responses. Although EPR spectra could not give straightforward evidence for the molecular structure of the anchored complexes, a combination of all the data allowed us to propose the anchoring of $[VO(acac)_2]$ onto the amine-functionalised carbons via Schiff-base condensation with the acetylacteonate ligand, as summarised in Scheme 1.

Further indirect information on the complex anchoring can be gained by the assessment of the heterogeneous catalytic activity of the new materials in a typical reaction where the homogeneous $[VO(acac)_2]$ complex shows high catalytic performance. In fact, the catalytic activity of a homogeneous catalyst (reaction conversion and products yields) is only kept upon its heterogenisation when no significant changes occur in the coordination sphere of the active centre, namely coordination atoms and available coordination sites for the substrate. In this context, we studied the catalytic activity of $[VO(acac)_2]$ towards the epoxidation of an allylic alcohol after immobilisation on the functionalised activated carbon.

Epoxidation of 3-Buten-2-ol Catalysed by Heterogeneous [VO(Acac)$_2$] Catalysts

The results obtained in the epoxidation of 3-buten-2-ol at 0 °C using vanadyl(IV) acetylacetonate based materials as heterogeneous catalysts and *tert*-butyl hydroperoxide as the oxygen source, in dichloromethane, are summarised in Table 4 and in Figure 3; data from the homogeneous phase and a blank experiment run under identical conditions are also included.

Table 4. Epoxidation of 3-buten-2-ol at 0 °C catalysed by $[VO(acac)_2]$ in homogeneous and heterogeneous phase.[a]

	48	1st	9	5	0.1
	72	1st	20	11	0.2
	192	1st	100	53	0.3
	192	2nd	94	48	0.2

[a] Typical reaction conditions used: 0.850 mmol of 3-buten-2-ol, 0.425 mmol of chlorobenzene (internal standard), 0.017 mmol of $[VO(acac)_2]$ or 0.100 g of heterogeneous catalyst (2% of catalyst relative to 3-buten-2-ol), 1.70 mmol of *t*BuOOH. [b] Based on 3-buten-2-ol consumption. [c] TON = mmol of converted 3-buten-2-ol/mmol of vanadium. [d] TOF = TON/reaction time.

The 3-buten-2-ol conversion was approximately 100% in both heterogeneous-phase reactions, with total TONs slightly higher than the homogeneous-phase reaction, thus indicating that the catalyst conversion performances did not decrease upon heterogenisation of $[VO(acac)_2]$. The high catalytic activity of the new vanadium-based materials clearly supports the proposed structure for complexes being anchored by the ligand and not through axial coordination (spacers or carbon surface oxygen groups), which would result in a six-coordinate species without an available coordination site for the oxidant. Therefore, the axial coordination would hinder the formation of the active intermediate V species (peroxovanadium intermediate),[8] leading to inactive anchored V complexes.

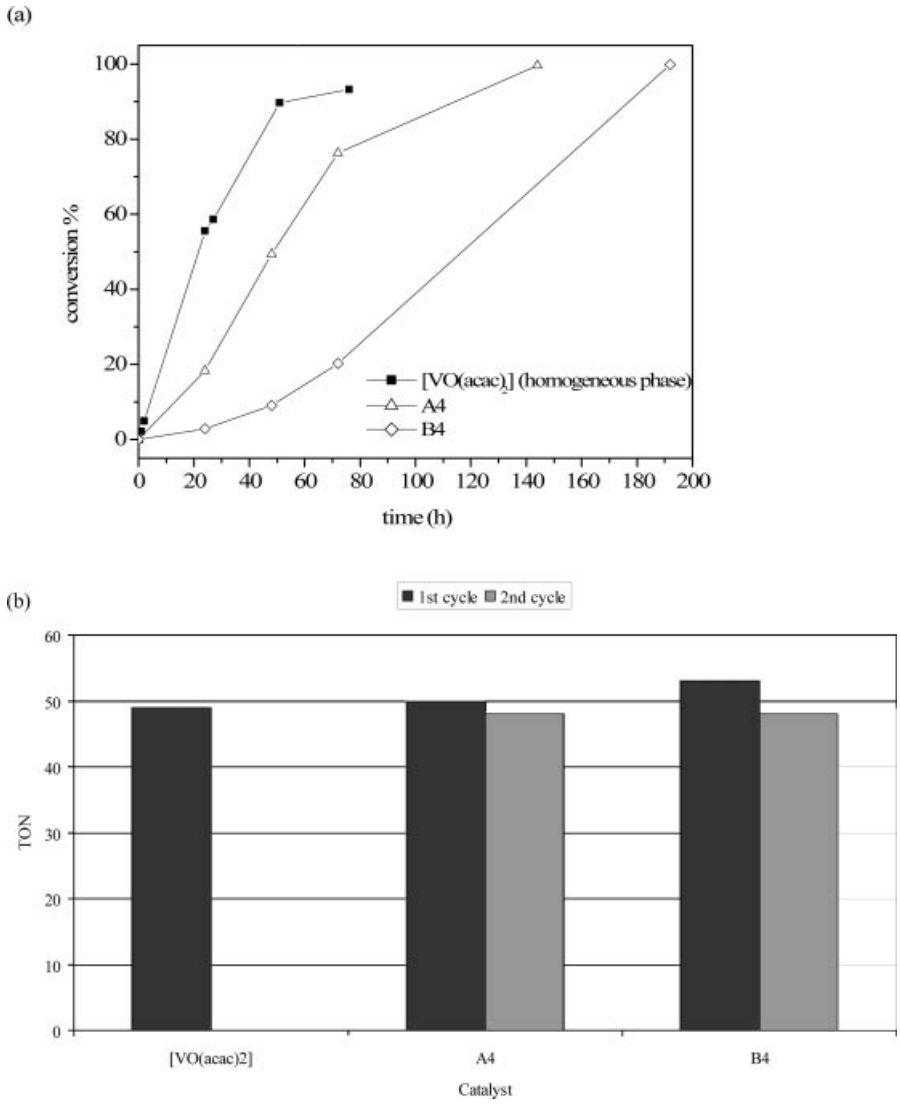

Figure 3. Epoxidation of 3-buten-2-ol catalysed by the $[VO(acac)_2]$ complex in the homogeneous phase and heterogenised onto two different functionalised activated carbons (A4 and B4): (a) conversion vs. time and (b) TON vs. catalyst.

However, on going from the homogeneous to the heterogeneous phase, an increase in the reaction time is observed in both heterogeneous catalyst runs under identical reaction conditions. This is a general effect that arises upon immobilisation of metal complexes in porous matrices, and has been attributed to diffusion constraints imposed on substrates and reactants by the porous network of the matrices.[20] As the catalytic conversions of the immobilised complexes are similar to that of free $[VO(acac)_2]$, we propose the same justification for the observed increase in the reaction time.

Comparing the two epoxidation reactions using A4 and B4 as heterogeneous catalysts, it can be observed that the former proceeds more rapidly in the initial 72 hours, a result that can be directly associated with the more external location of the metal complex in material A4, which lessens diffusion constraint effects.

Reutilisation is one of the greatest advantages of heterogeneous catalysts, and can also provide useful information about the anchoring process and catalyst stability along the catalytic cycle. As can be seen in Table 4 and in Figure 3, it is clear that neither A4 nor B4 lose their catalytic efficiency significantly after two catalytic cycles. This is an important result for heterogeneous vanadium-based catalysis and indicates that the two anchoring procedures are very effective at preventing complex deactivation and leaching, at least up to two cycles.

Concluding Remarks

New heterogeneous catalysts were prepared by heterogenisation of $[VO(acac)_2]$ onto amine-functionalised activated carbons prepared by two different methodologies: (a) using an air-oxidised carbon functionalised with APTES and (b) using an acid-oxidised carbon functionalised with trien. The combination of XPS and EPR data showed that complex anchoring was achieved by Schiff-base condensa-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion between the free amine groups of the functionalised carbon and the oxygen ligand atoms. These new vanadium-based materials show high catalytic activity in the epoxidation of 3-buten-2-ol and are not very different from $[VO(acac)_2]$ (conversion and TON), which corroborates the proposed anchoring methodologies. Material A4 proved to be a more efficient catalyst, as can be seen by its greater values of TON in the first 72 hours. Both materials were used two times with no significant loss in the alkene conversion and TON, thus indicating that the complexes have been anchored irreversibly to the carbon surface, which prevents leaching of the active phase and its deactivation.

Experimental Section

Materials and Solvents: The starting carbon material was a NORIT ROX 0.8 activated carbon (rodlike pellets with 0.8 mm diameter and 5 mm length). This material has a pore volume of 0.695 $cm^3 g^{-1}$, as determined by porosimetry (corresponding to meso- and macropores), a micropore volume of 0.359 $cm^3 g^{-1}$ and a mesopore area of 122 $m^2 g^{-1}$, as determined by N_2 adsorption at 77 K (*t*-method),[19–23] an ash content of 2.6% (w/w), an iodine number of 1000 and mercury and helium densities of 0.666 and 2.11 $g cm^{-3}$, respectively. The activated carbon was purified by Soxhlet extraction with 2 M HCl for 6 h, washed with deionised water until pH 6–7 and then dried in an oven at 150 °C for 13 h under vacuum (A1).

(3-Aminopropyl)triethoxysilane, bis(3-aminopropyl)amine, vanadyl(IV) acetylacetonate, a *tert*-butyl hydroperoxide solution in decane (5 M), chlorobenzene and 3-buten-2-ol were obtained from Aldrich and were used as received. All the reagents and solvents used in the modification of the activated carbon and in the anchoring procedure were also obtained from Aldrich, except for ethanol, toluene and thionyl chloride, which were purchased from Merck (pro analysi). The reagents and solvents used in the catalytic experiments were obtained from Aldrich, except for dichloromethane, which was purchased from Romil (HPLC grade).

$[VO(acac)_2]$: XPS (eV): C 1s 285.0 and 287.1; O 1s 531.7; V $2p_{3/2}$ 516.8.

Preparation of the Heterogeneous Catalysts: The immobilisation of the vanadium complex was performed by two different methods, A and B, that are described below and summarised in Scheme 1.

Support Oxidation: The activated carbon (A1) was oxidised by two methods:[22,23] (a) with a mixture of N_2 and air (5% O_2) at 698 K for 10 h (A2; burn-off = 11%), (b) refluxed with a 5 M nitric acid solution for 6 h (1 g/30 mL), washed with deionised water until pH 6–7 and then dried in an oven at 110 °C for 13 h under vacuum (B1). Carbon A2 was used as the support for the complex anchoring by method A whereas carbon B1 was used as support for method B.

Method A. Functionalisation of A2 with (3-Aminopropyl)triethoxysilane (APTES): Carbon A2 (3.0 g) was refluxed with a solution containing 4.3 mmol of (3-aminopropyl)triethoxysilane in 100 mL of dry toluene for 24 h, then filtered and washed extensively with dry toluene. The material was Soxhlet extracted for 8 h with toluene and 8 h with ethanol and was then dried in an oven at 120 °C for 13 h under vacuum (carbon A3).

Anchoring of $[VO(Acac)_2]$ onto the A3 Carbon: The activated carbon functionalised with (3-aminopropyl)triethoxysilane (A3, 0.60 g) was added to 100 mL of a solution of $[VO(acac)_2]$ in dry toluene (118 μmol), and the mixture was refluxed for 9 h; during the reflux a progressive disappearance of the green colour of the solution was observed. The resulting material was extensively washed with toluene and then purified by Soxhlet extraction with toluene for 8 h, and dried in an oven at 120 °C for 13 h under vacuum (carbon A4).

Method B. Reaction of B1 with Thionyl Chloride ($SOCl_2$): Carbon B1 (12.0 g) was refluxed with 40 mL of a 5% (v/v) solution of thionyl chloride in toluene for 5 h, extensively washed with toluene, and then purified by Soxhlet extraction with toluene for 2 h, and finally dried in an oven at 150 °C for 13 h under vacuum (carbon B2).[23]

Functionalisation of B2 with Bis(3-aminopropyl)amine (Trien): Carbon B2 (3.0 g) was refluxed with a solution containing 390 μmol of bis(3-aminopropyl)amine (trien) in 40 mL of dry toluene for 4 h, then filtered and extensively washed with toluene. The material was also Soxhlet extracted for 2 h with toluene and dried in an oven at 150 °C for 13 h under vacuum (carbon B3).[23]

Anchoring of $[VO(Acac)_2]$ onto the B3 Carbon: The activated carbon functionalised with trien (B3, 0.60 g) was added to 100 mL of a solution of $[VO(acac)_2]$ in dry toluene (119 μmol), and the mixture was refluxed for 9 h; during the reflux a progressive disappearance of the green colour of the solution was observed. The resulting material was extensively washed with toluene and then purified by Soxhlet extraction with toluene for 7 h, and dried in an oven at 150 °C for 13 h under vacuum (carbon B4).

Physical Measurements: Vanadium and silicon bulk contents were obtained by inductively coupled plasma emission spectrometry (ICP-AES) at "Laboratório de Análises", IST, Lisboa (Portugal). X-ray photoelectron spectroscopy (XPS) was performed at "Centro de Materiais da Universidade do Porto" (Portugal), with a VG Scientific ESCALAB 200A spectrometer using non-monochromated Mg-K_α radiation (1253.6 eV). In order to correct for possible deviations caused by the electric charge of the samples, the graphitic C 1s band at 284.6 eV was taken as internal standard.[33,34] EPR spectra were obtained with an X-band Bruker ESP 300E spectrometer. The powdered samples were diluted in KBr (5%), the microwave frequency was calibrated with diphenylpicrylhydrazyl (dpph; g = 2.0037) and the magnetic field was calibrated against Mn^{II} in MgO. Experimental conditions: modulation frequency: 100 kHz; modulation amplitude: 9 G; microwave power: 1 mV. The EPR parameters were obtained by simulation using the program WINEPR SimFonia (Bruker) by assuming axial spin-Hamiltonians. The line widths used in the simulations were 15–30 G. Gas chromatography experiments (GC) were performed with a Varian CP-3380 chromatograph equipped with an FID detector and using helium as carrier gas and a fused silica Varian Chrompack capillary column CP-Sil 8 CB Low Bleed/MS (30 m × 0.25 mm i.d.; 0.25 μm film thickness). The chromatographic conditions were: 40 °C (3 min), 5 °C min^{-1} to 170 °C (2 min), 20 °C min^{-1} to 200 °C (10 min); injector temperature: 200 °C; detector temperature: 300 °C. Aliquots of 0.1 mL were withdrawn from the reaction mixture with a hypodermic syringe, filtered through PTFE 0.22-μm syringe filters and injected directly into the injector using a 1-μL Hamilton syringe.

Catalysis Experiments: The reactions were carried out in CH_2Cl_2, at 0 °C, with constant stirring. The composition of the reaction medium was 0.85 mmol of 3-buten-2-ol, 0.425 mmol of chlorobenzene (internal standard), 0.10 g of heterogeneous catalyst (A4 or B4) in 5.00 mL of solvent. The oxidant, *tert*-butyl hydroperoxide (1.70 mmol), was progressively added to the reaction medium using a Bioblock Scientific Syringe Pump at a rate of 0.5 mL h^{-1}. For

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

each complex the reaction time for maximum conversion percentage was determined by withdrawing 0.1-mL aliquots periodically from the reaction mixture, and this time was used to monitor the efficiency of the catalyst. The composition of the reaction media was determined by GC with 3-buten-2-ol, *tert*-butyl hydroperoxide, *tert*-butanol and decane being quantified by the internal standard method (chlorobenzene). The catalysts were then washed sequentially by Soxhlet extraction with 100 mL of toluene and 100 mL of ethanol for 1–2 hours, and dried at an oven at 120 °C for 13 h, under vacuum. The catalysts were then reused using the same experimental conditions. Control experiments using the initial carbon A1 and the homogeneous reaction with vanadyl(IV) acetylacetonate in identical reaction conditions were also performed.

Acknowledgments

The authors are indebted to Dr. Carlos Sá (CEMUP) for assistance with XPS analysis and to NORIT N.V., Amersfoort, Netherlands, for providing the activated carbon. This work was partially funded by the Fundação para a Ciência e a Tecnologia (FCT, Portugal) and FEDER through project ref. POCTI/EQU/57369/2004. Inversely Polarized Phosphaalkenes as Phosphinidene- and Carbene-Transfer Reagents

Lothar Weber,*[a] Ulrich Lassahn,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]

Keywords: Carbenes / Ketenes / Phosphaalkenes / Phosphinidenes

The reaction of the inversely polarized phosphaalkenes $RP=C(NMe_2)_2$ [R = *t*Bu (**1a**), Cy (**1b**), 1-Ad (**1c**), Ph (**1d**), Mes (**1e**)] with an excess of diphenyl ketene in *n*-pentane affords the zwitterionic adduct $(Me_2N)_2C–C(O)=CPh_2$ (**2**) and the 3,5-dibenzhydrylidene-1,4,2-dioxaphospholanes **4a**–**e**. The reaction of **1a** with $Ph_2C=C=O$ in concentrated acetonitrile solution gives **4a** and 5-benzhydrylidene-2-*tert*-butyl-4,4-diphenyl-1,2-oxaphospholan-3-one (**6a**) as a by-product. In contrast, treatment of $Me_3SiP=C(NMe_2)_2$ (**1i**) with the ketene leads to the formation of 2-phospha-1,3-butadiene (**5**). The thermolabile phosphaalkene **8** decomposes into an imidazolylidene and (*t*BuP), the latter species spontaneously oligomerizes to $(tBuP)_n$ (n = 3, 4). Obviously, compounds **1a**–**e** serve as a convenient source of phosphinidenes and the carbene $C(NMe_2)_2$. A Wanzlick-type equilibrium between these species, however, must be excluded according to exchange and cross-coupling experiments. The molecular structures of **2**, **4e** and **6a** were determined by X-ray structure analyses.

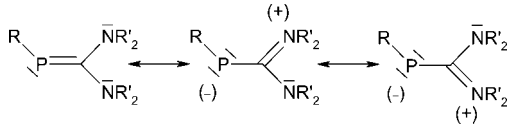
Introduction

The phosphorus atom of inversely polarized phosphaalkenes such as $R–P=C(NR'_2)_2$ (R = H, alkyl, aryl, $SiMe_3$, R′ = Me, Et) is highly nucleophilic, which is rationalized by an effective π-electron delocalization of the lone pairs at the trigonal-planar amino substituents into the P–C multiple bond (Scheme 1).[1]



Scheme 1. Limiting formulae of amino-substituted phosphaalkenes.

Protonation,[2] alkylation,[2,3] silylation,[3] and coordination to metal centers occur at the P atom with increase of the coordination number.[2,4,5] Treatment of $tBuP=C(NMe_2)_2$ with [$(Ph_3P)AuCl$], for example, leads to the cleavage of the P–C bond of some of the phosphaalkene units to yield phosphanediide units [$tBuP^{2-}$], which are incorporated as ligands in the decanuclear cluster cation $[Au_8(AuCl)_2(\mu^3\text{-}PtBu)_2\{tBuP=C(NMe_2)_2\}_6]^{4+}$. The carbodiimmonium dication $[Me_2N=C=NMe_2]^{2+}$ formed as a by-product has been trapped by chloride to afford the spectroscopically detected chloroformamidinium ion $[(Me_2N)_2CCl]^+$.[6] This transformation is formally related to the synthetic pathway to carbene complexes of transition metals via the C=C bond cleavage of bis(imidazol-2-ylidenes) in the coordination sphere of a metal atom.[7]

The conceivable dissociation of tetraamino-substituted alkenes into carbenes was already postulated by Wanzlick in the 1960s.[8] However, the ^1H NMR spectroscopic proof of Wanzlick's ideas was only provided by Hahn some 40 years later.[9]

In line with the diagonal relationship in the periodic table between the elements carbon and phosphorus, the quest for a Wanzlick-type reaction of the electron-abundant bis(amino)phosphaalkenes seems intriguing as, in addition to a relatively stable bis(amino)carbene,[10] the homolytic cleavage of the phosphaalkene would furnish reactive phosphin-

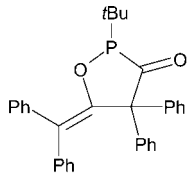
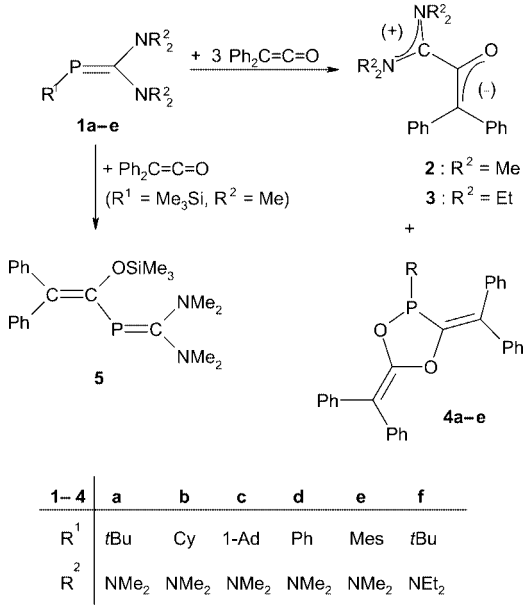
idene fragments under relatively mild conditions. For our work, the reaction of 1,1′,3,3′-tetraphenyl-2,2′-bis(imidazolidinylidene) with diphenyl ketene by Regitz et al. serves as a model reaction for the trapping of a carbene produced in agreement with Wanzlick's postulate[11] (Scheme 2).



6a

Results and Discussion

Reaction of the phosphaalkenes R–P=C(NMe_2)$_2$ [**1a**–**e**; R = *t*Bu (**1a**),Cy = *c*C_6H_{11} (**1b**), 1-Ad (**1c**), Ph (**1d**), Mes (**1e**)] with an excess of diphenyl ketene in pentane at 0–20 °C for 16 h led to the precipitation of the light-yellow zwitterionic compound **2** in about 85% yield. The product was purified by chromatography on a silica column. After removal of **2**, the mother liquor was treated with an excess of powdered NaOH to destroy the excess of ketene. Filtration and concentration of the filtrate to dryness gave 3,5-dibenzhydrylidene-1,4,2-dioxaphospholanes **4a**–**e** as colorless waxy solids in 45–53% yield. Purification of these products was accompanied by decomposition (Scheme 3).



1–4	a	b	c	d	e	f
R^1	*t*Bu	Cy	1-Ad	Ph	Mes	*t*Bu
R^2	NMe_2	NMe_2	NMe_2	NMe_2	NMe_2	NEt_2

Scheme 3. Formation of compounds **2**, **3**, **4a**–**e**, and **5**.

The reactions between **1a**–**e** and diphenyl ketene were also performed in acetonitrile. Treatment of concentrated solutions of the phosphaalkene in acetonitrile (ca. 20% v/v) with neat Ph_2C=C=O gave rise to the instantaneous formation of dark-violet emulsions and generation of heat. From NMR evidence it was clear that the same products **2** and **4a**–**e** were generated as previously in pentane solution. Workup, however, did not afford pure compounds. In the case of *t*BuP=C(NMe_2)$_2$ a few crystals of 5-benzhydrylidene-2-*tert*-butyl-4,4-diphenyl-1,2-oxaphospholan-3-one (**6a**) were isolated as a by-product. This species is isomeric to **4a** and has also to be considered as the formal result of the cyclization of 2 equiv. of ketene with *tert*-butyl-phosphinidene.

Analogously to the behavior of **1a**, *t*BuP=C(NEt_2)$_2$ (**1f**) and an excess of diphenyl ketene in pentane underwent reaction to yield yellow solid **3** (73%) in addition to **4a** (Scheme 3).

The reactions under discussion are the first examples where phosphaalkenes serve as convenient sources of carbenes as well as phosphinidenes. The use of this synthetic principle, however, is limited. Thus, treatment of phosphaalkene HP=C(NMe_2)$_2$ (**1g**) with diphenyl ketene under comparable conditions led to complete decomposition of the reagents, and no reaction occurred between the ketene and the sterically encumbered compound Mes*P=C(NMe_2)$_2$ (**1h**). The behavior of Me_3SiP=C(NMe_2)$_2$ (**1i**) towards diphenyl ketene is different from that of **1a**–**f**. Here, the carbonyl group of the ketene is inserted into the P–Si bond of **1h** with the formation of the 2-phospha-1,3-butadiene **5**. This thermolabile product was identified by spectroscopy without prior purification (Scheme 3).

This process parallels the reaction of **1i** with Me_3SiCH=C=O, where 1,1-bis(dimethylamino)-3-trimethylsiloxy-4-trimethylsilyl-2-phosphabutadiene ($\delta_{^{31}P}$ = 30.0 ppm) was obtained. Obviously, the reactivity of the P–Si bond in **1i** precludes the cleavage of the P=C bond of the phosphaalkene.[12]

The ^{1}H NMR spectrum of **2** shows two singlets at δ = 2.74 and 3.21 ppm of equal intensity, which are assigned to the protons of chemically and magnetically different dimethylamino groups. Resonances in the $^{13}C\{^1H\}$ NMR spectra at δ = 42.3 and 42.6 ppm also correspond to these groups. The singlets at δ = 141.6 and 175.4 ppm are caused by the carbon atom of the carbenium unit and by that of the carbonyl group. Two intense bands at $\tilde{\nu}$ = 1713 and 1613 cm^{-1} in the IR spectrum of the adduct can be assigned to the coupled CO and C=C stretching modes.

The $^{31}P\{^1H\}$ NMR spectra of the 1,4,2-dioxaphospholanes **4a**–**e** show singlets at δ = 90.6–122.3 ppm, in the region typical for (alkyl/aryl)(alkoxy)phosphanes. The resonances in the precursors **1a**–**e** are encountered at considerably higher field (δ = 9–91 ppm). The phosphorus atom in 2-phosphabutadiene (**5**) gives rise to a singlet at δ = 17.3 ppm in the $^{31}P\{^1H\}$ NMR spectrum.

X-ray Structural Analysis of 2

To confirm the spectroscopic evidence for the adduct formation between carbene [$(Me_2N)_2$C] and diphenyl ketene, an X-ray structural analysis of **2** was performed (Figure 1, Table 1).

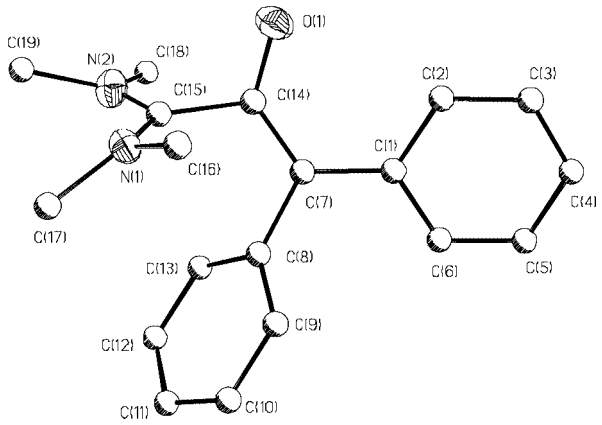

Figure 1. Molecular structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: N(1)–C(15) 1.336(10), N(1)–C(16) 1.480(10), N(1)–C(17) 1.463(10), N(2)–C(15) 1.325(10), N(2)–C(18) 1.471(10), N(2)–C(19) 1.480(10), C(14)–C(15) 1.516(11), O(1)–C(14) 1.295(9), C(7)–C(14) 1.372(11), C(7)–C(8) 1.502(11), C(1)–C(7) 1.461(11); C(16)–N(1)–C(17) 113.5(6), C(15)–N(1)–C(16) 121.3(6), C(15)–N(1)–C(17) 123.5(7), C(15)–N(2)–C(18) 121.3(7), C(15)–N(2)–C(19) 123.9(7), C(18)–N(2)–C(19) 114.6(7), N(1)–C(15)–C(14) 118.1(8), N(2)–C(15)–C(14) 119.5(7), N(1)–C(15)–N(2) 122.1(7), C(7)–C(14)–C(15) 117.6(8), O(1)–C(14)–C(15) 113.0(7), O(1)–C(14)–C(7) 129.3(7), C(14)–C(7)–C(8) 116.6(7), C(1)–C(7)–C(8) 118.9(7), C(1)–C(7)–C(14) 124.5(8).

Single crystals of **2** were grown from a CH_2Cl_2 solution at +4 °C. The analysis confirms the presence of a planar carbenium center, the positive charge of which is stabilized by π-conjugation with the two planar amino group [sum of angles at N(1) = 358.3°; N(2) = 359.8°]. In keeping with this, relatively short N(1)–C(15) [1.336(10) Å] and N(2)–C(15) [1.325(10) Å] bonds are also observed. The single bonds between the N atom and the methyl groups − N(1)–C(16) and N(1)–C(19) − are markedly longer [1.463(10)–1.480(10) Å]. The trigonal-planar configured atom C(15) (sum of angles 359.7°) is connected to the ketene part of the adduct by a C–C single bond of 1.516(11) Å. The C(14)–O(1) bond length of 1.295(9) Å clearly exceeds that of a localized carbonyl group (ca. 1.23 Å). This points to π-delocalization within the enolate part of the molecule, which means that the atoms C(14) (sum of angles 359.9°) and C(7) (sum of angles 360.0°) are trigonal-planar. The aryl ring C(1) to C(6) and the plane defined by the atoms O(1), C(14), C815), and C(7) form a dihedral angle of 22.2°. This plane forms an angle of 65.2° with the plane of the carbenium part defined by the atoms N(1), N(2), and C(15). The second aryl ring at C(7) is also twisted by 57.7° out of the plane of the atoms O(1), C(14), and C(7).

X-ray Structural Analysis of 4e

The constitution and configuration of the 3,5-dibenzhydrylidene-1,4,2-dioxaphospholanes **4a**–**c** and **4e** were also confirmed by X-ray structural analyses. Single crystals of **4a**–**c** and **4e** were grown from CH_2Cl_2 at +4 °C. As no significant differences were observed between the five-membered heterocycle of these compounds, only the structure of **4e** (R = Mes) is discussed here (Figure 2, Table 1).

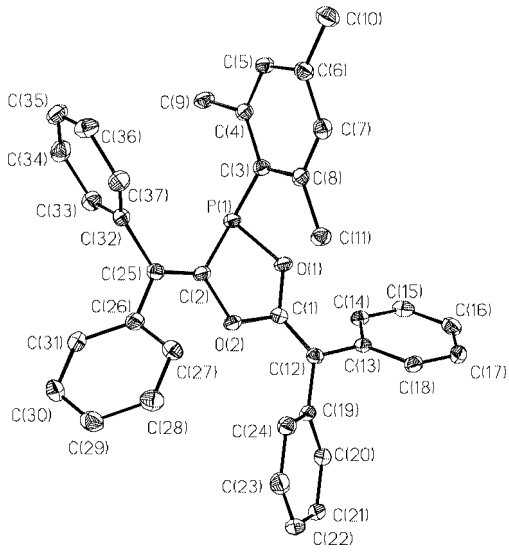

Figure 2. Molecular structure of **4e** in the crystal. Selected bond lengths [Å] and angles [°]: P(1)–C(2) 1.833(1), P(1)–C(3) 1.835(1), P(1)–O(1) 1.696(1), O(1)–C(1) 1.370(2), O(2)–C(1) 1.370(2), O(2)–C(2) 1.394(2), C(2)–C(25) 1.333(2), C(25)–C(26) 1.490(2), C(25)–C(32) 1.495(2), C(1)–C(12) 1.343(2), C(12)–C(13) 1.492(2), C(12)–C(19) 1.495(2); C(2)–P(1)–C(3) 104.22(6), O(1)–P(1)–C(3) 105.22(5), O(1)–P(1)–C(2) 88.08(5), P(1)–O(1)–C(1) 115.73(8), O(1)–C(1)–O(2) 112.59(1), C(1)–O(2)–C(2) 113.55(19), P(1)–C(2)–O(2) 109.40(10), P(1)–C(2)–C(25) 120.69(11), P(1)–C(2)–C(25) 129.86(10), O(1)–C(1)–C(12) 124.67(11), O(2)–C(1)–C(12) 122.73(11).

The key structural feature is the almost planar five-membered heterocycle (the largest deviation from the best plane is 0.0423 Å). The sum of the endocyclic angles is 539.35°, which is close to the theoretical value of 540°. The P(1)–O(1) bond [1.696(1) Å] is slightly shorter than the sum of the covalent radii of P (1.10 Å) and O (O.66 Å).[13] The endocyclic P(1)–C(2) bond [1.833(1) Å] is equally long as the exocyclic distance P(1)–C(3) [1.835(1) Å] to the mesityl substituent. The same is true for the endocyclic bond lengths C(1)–O(2) [1.370(2) Å] and C(2)–O(2) [1.394(2) Å]. All of them have a bond order of one. The exocyclic bonds C(1)–C(12) [1.343(2) Å] and C(2)–C(25) [1.333(2) Å] are double bonds. The phosphorus atom has a trigonal-pyramidal configuration (sum of angles = 297.52°). The P(1)–C(3) vector and the best plane of the heterocycle enclose an angle of 114.2°.

X-ray Structural Analysis of 6a

Yellow single crystals of **6a**, which is an isomer of **4a**, were grown from a saturated acetonitrile solution at ambient temperature (Figure 3, Table 1). The X-ray analysis revealed the molecule as a puckered 1,2-oxaphospholan-3-one (sum of angles = 530.53°). The trigonal-pyramidal phosphorus atom P(1) (sum of angles = 294.29°) forms P(1)–C(1) [1.869(2) Å], P(1)–O(1) [1.664(1) Å], and P(1)–C(5) [1.861(1) Å] single bonds to the neighboring atoms. The trigonal-planar C(5) atom is part of a carbonyl group [C(5)–O(2) = 1.206(2) Å]. The endocyclic bond O(1)–C(19)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of 1.406(2) Å is comparable to the C–O bonds in **4e** [1.394(2) and 1.370(2) Å]. The endocyclic C–C bond of the quaternary carbon atom C(6) to the carbonyl atom C(5) of 1.568(2) Å is markedly longer than the C(6)–C(19) distance of 1.522(2) Å, which is presumably due to steric interactions between the phenyl rings and the CO function. The exocyclic C(19)–C(20) bond of 1.340(2) Å matches well with the C=C double bonds of **4e**.

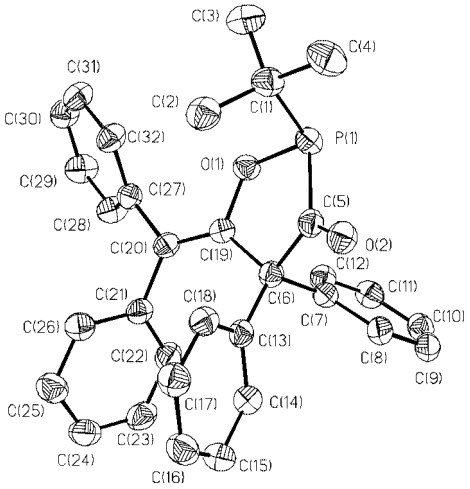

Figure 3. Molecular structure of **6a** in the crystal. Selected bond lengths [Å] and angles [°]: P(1)–C(1) 1.869(2), P(1)–O(1) 1.664(1), O(1)–C(19) 1.406(2), C(6)–C(19) 1.522(2), C(5)–C(6) 1.568(2), P(1)–C(5) 1.861(1), O(2)–C(5) 1.206(2), C(19)–C(20) 1.340(2); O(1)–P(1)–C(1) 103.45(6), C(1)–P(1)–C(5) 100.18(7), O(1)–P(1)–C(5) 90.66(5), P(1)–C(5)–C(6) 107.54(9), C(5)–C(6)–C(19) 103.42(10), O(1)–C(19)–C(6) 110.94(11), P(1)–O(1)–C(19) 117.97(8), P(1)–C(5)–O(2) 127.12(11), O(2)–C(5)–C(6) 125.24(12), O(1)–C(19)–C(20) 118.07(2), C(6)–C(19)–C(20) 130.81(12), C(19)–C(20)–C(21) 123.47(12), C(19)–C(20)–C(27) 121.50(12), C(21)–C(20)–C(27) 114.97(11).

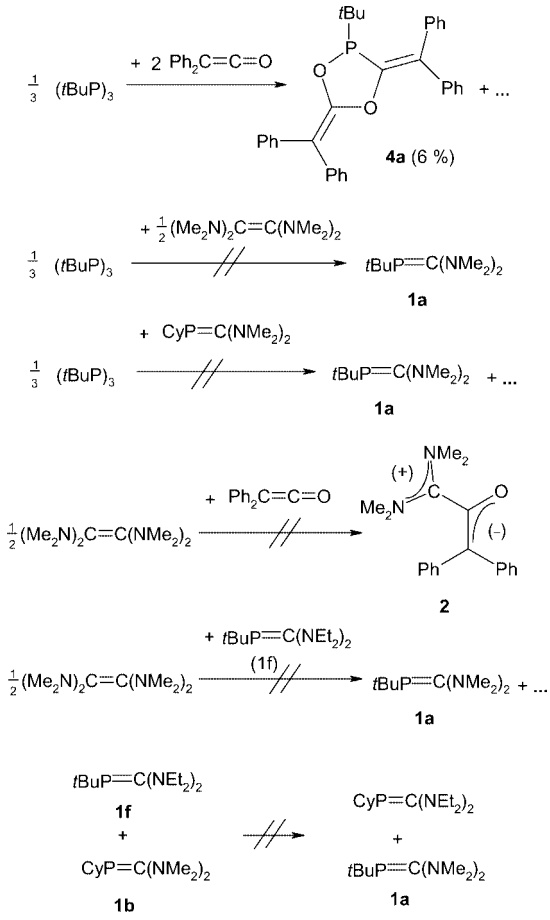
Cross-Coupling and Exchange Experiments

From a formal point of view, the phosphaalkenes employed here display a reactivity similar to tetraaminoalkenes as concerns the homolytic cleavage of the P=C double bond, as the carbene and phosphinidene fragments are efficiently trapped by $Ph_2C{=}C{=}O$. Similar to Wanzlick's observations, however, the question remained open as to whether a genuine equilibrium exists between phosphaalkenes and the electron-sextet species or whether a more complex mechanism is responsible. In order to obtain more information, a number of cross-coupling and exchange experiments were carried out (Scheme 4).

It is known that tri-*tert*-butylcyclotriphosphane serves as a source of the phosphinidene [*t*BuP]. In keeping with this, heating of a mixture of $(t\text{BuP})_3$ and $Ph_2C{=}C{=}O$ in toluene furnished heterocycle **4a** in about 6% yield.

Reaction of $(t\text{BuP})_3$ with $(Me_2N)_2C{=}C(NMe_2)_2$ did not, however, yield the expected phosphaalkene *t*BuP=$C(NMe_2)_2$ (**1a**). Similarly, the treatment of $(t\text{BuP})_3$ with CyP=$C(NMe_2)_2$ (**1b**) to give **1a** failed. Reaction of $(Me_2N)_2C{=}C(NMe_2)_2$ with $Ph_2C{=}C{=}O$ did not afford tractable products as, for example, the adduct **2**. Reaction of $(Me_2N)_2C{=}C(NMe_2)_2$ with *t*BuP=$C(NEt_2)_2$ (**6**) did not give the expected exchange product **1a**. Thus, all these experiments exclude the notable formation of free electron-sextet species. Also, the cross-coupling experiment between *t*BuP=$C(NEt_2)_2$ and CyP=$C(NMe_2)_2$ did not lead to the conceivable metathesis products *t*BuP=$C(NMe_2)_2$ and CyP=$C(NEt_2)_2$.



Scheme 4. Attempted exchange experiment.

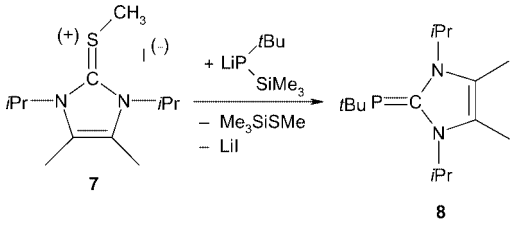
Synthesis of Labile Phosphaalkenes

According to our results, it is obvious that the phosphaalkenes studied here do show the reactivity of carbenes and phosphinidenes, although transient free electron-sextet species have to be excluded as intermediates. This is in accordance with our knowledge of Wanzlick's equilibrium of tetraaminoalkenes, where spectroscopic evidence of carbenes is restricted to only the most reactive alkenes. Quantum chemical calculations indicate that phosphaalkenes with a cyclic diaminomethylene unit should exhibit a decreased stability towards dissociation,[14] therefore it was obvious to synthesize such a thermolabile phosphaalkene and to study its decomposition.

Condensation of [LiP(*t*Bu)($SiMe_3$)] with thiouronium iodide (**7**) in THF led to a red solution, the $^{31}P\{^1H\}$ NMR spectrum of which shows a prominent singlet at $\delta = -5$ ppm

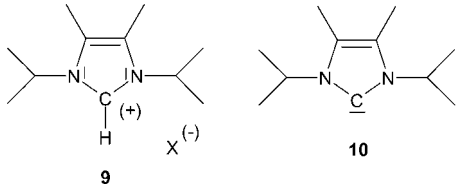
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the region known for inversely polarized phosphaalkenes and which therefore we assigned to compound **8** (Scheme 5).



Scheme 5. Synthesis of **8**.

After distillation, this resonance nearly disappeared, and new intense signals appeared in the NMR spectrum of the distillate. An AB_2 spin system at δ = –108.9 and –70.3 ppm ($J_{A,B}$ = 201 Hz) and a singlet at δ = –57.6 ppm are due to $(t\text{BuP})_3$ and $(t\text{BuP})_4$, respectively, which cover 78% of all the resonances observed. These rings presumably result from the oligomerization of *tert*-butylphosphinidene. The imidazolium cation **9** was identified in the residue of the distillation by ^{1}H and ^{13}C{^{1}H} NMR spectroscopy. This ion is most likely formed by protonation of the strong Brønsted base **10**.



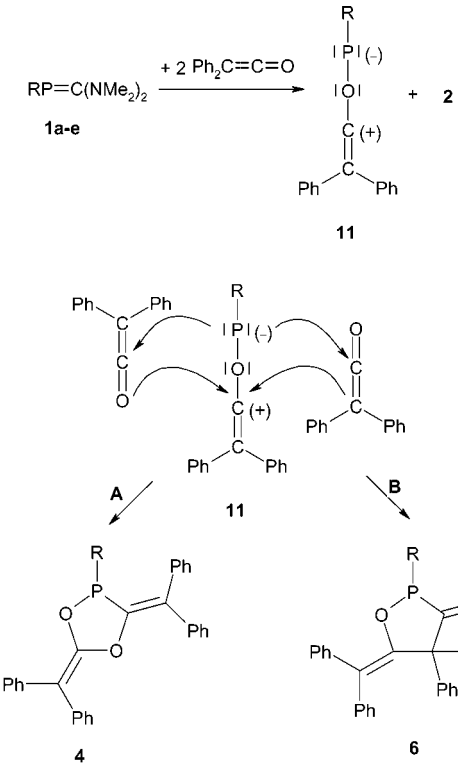
The P=C bonds have been homolytically cleaved and this process is most certainly not part of a genuine equilibrium.

Phosphaalkenes of type **8** have been synthesized previously from equivalent amounts of 1,3,4,5-tetramethylimidazol-2-ylidene and pentaphenylcyclopentaphosphane in 79% yield.[15] Similar results were obtained with 1,3-dimesitylimidazol-2-ylidene and the cyclophosphanes $(PhP)_5$ and $(CF_3P)_4$.[16]

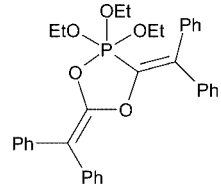
For a mechanism that rationalizes the formation of adduct **2** as well as of the heterocycles **4** and **6a**, we propose the initial cleavage of one molecule of phosphaalkene **1** by reaction with 2 equiv. of $Ph_2C{=}C{=}O$. In addition to **2**, a zwitterion **11** is formed (Scheme 6). Intermediate **11** then undergoes a 1,3-dipolar addition to the C=O bond of another ketene molecule to yield main product **4** (path A). Alternatively, the 1,3-cycloaddition to the C=C double bond of the ketene affords **6a**.

Molecules with the structural feature of a 3,5-dibenzhydrylidene-1,4,2-dioxaphospholane are rare and there are only a few examples documented with pentavalent phosphorus. For example, the reaction of triethyl phosphite with $Ph_2C{=}C{=}O$ furnishes heterocycle **12**.[17]

Similarly, cyclic trialkyl phosphites and 2 equiv. of dimethyl ketene or its dimer give rise to the formation of 2,2,2-trialkoxy-3,5-diisopropylidenephospholanes.[18] Treatment of 3,4-dimethyl-1-phenylphosphole with diphenyl ketene under high pressure (ca. 10 kbar) afforded compound



Scheme 6. Proposed mechanism for the formation of compounds **2**, **4**, and **6**.



13. A cycloreversion of the phosphole to yield a transient phenylphosphinidene has been invoked to rationalize this result.[19]

Conclusions

We have demonstrated that inversely polarized phosphaalkenes $RP{=}C(NMe_2)_2$ (**1a**–**e**) and $t\text{BuP}{=}C(NEt_2)_2$ (**1f**) serve as convenient sources for the generation of phosphinidenes [RP] and carbenes $[(Me_2N)_2C]$ and $[(Et_2N)_2C]$ under mild conditions. These carbenes are trapped by diphenyl ketene, which leads to the formation of the zwitterionic carbene/ketene adducts **2** and **3**. On the other hand, the phosphinidene fragment can also combine with 2 equiv. of ketene in a 1,3-dipolar cycloaddition between the intermediate $RP{-}O{-}C{=}CPh_2$ and $Ph_2C{=}C{=}O$ to give heterocycles **4a**–**e** and **6a**. From cross-coupling and exchange reaction it is obvious that free carbenes and/or phosphinidenes are not involved in these processes.

Experimental Section

General: All reactions were performed under dry, oxygen-free nitrogen using standard Schlenk techniques. The phosphaalkenes *t*BuP=C(NMe$_2$)$_2$ (**1a**),[20] CyP=C(NMe$_2$)$_2$ (**1b**),[21] PhP=C(NMe$_2$)$_2$ (**1d**),[22] MesP=C(NMe$_2$)$_2$ (**1e**),[20] and Me$_3$SiP=C(NMe$_2$)$_2$ (**1i**),[23] as well as Ph$_2$C=C=O,[24] AdPH$_2$,[25] *t*BuP(H)SiMe$_3$,[26] thiouronium salt **7**,[27] and (*t*BuP)$_3$[28] were prepared as described in the literature. Infrared spectra were recorded with a Bruker FT-IR IFS 66 spectrometer. NMR spectra: Bruker AM Avance DRX 500; standards: SiMe$_4$ (^{1}H, ^{13}C), external 85% H$_3$PO$_4$ (^{31}P).

1-AdP(H)SiMe$_3$: A 1.6 M *n*-hexane solution of *n*-butyllithium (59.4 mL, 95.0 mmol) was added dropwise to a solution of 1-AdPH$_2$ (16.8 g, 100.0 mmol) in THF (100 mL) at 0 °C. This slurry was added at 20 °C to a solution of Me$_3$SiCl (11.9 g, 110.0 mmol) in 30 mL of THF, and the mixture was stirred for 16 h. The volatile components were then removed in vacuo and the residue was triturated with *n*-pentane (50 mL). It was then filtered and the filter cake was washed with *n*-pentane (3 × 20 mL). The filtrate was liberated from solvents and the residue was distilled to furnish 15.0 g (69% yield) of 1-AdP(H)SiMe$_3$ as a colorless oil. ^{1}H NMR (CDCl$_3$): δ = 0.25 (d, $^3J_{P,H}$ = 5 Hz, 9 H, SiMe$_3$), 2.16 (d, $^1J_{P,H}$ = 204 Hz, 1 H, PH), 1.6–2.0 (m, 15 H, Ad) ppm. ^{31}P{^{1}H} NMR (CDCl$_3$): δ = –85.7 ppm.

1-AdP=C(NMe$_2$)$_2$ (1c): An *n*-hexane solution of *n*-butyllithium (1.6 M, 28.1 mL, 45.0 mmol) was added dropwise, at 0 °C, to a solution of 1-Ad-P(H)SiMe$_3$ (12.2 g, 50 mmol) in THF (50 mL). The resulting slurry was added dropwise to a suspension of pentamethylthiouronium iodide (13.7 g, 50 mmol) in 50 mL of THF. After 16 h of stirring at room temp., the solvent and volatile components were removed in vacuo. The residue was triturated with *n*-pentane (50 mL) and filtered. The filter cake was washed with diethyl ether (3 × 20 mL) and the filtrate was liberated from solvent in vacuo. The residue was distilled in vacuo to give 10.0 g (75%) of **1c** as an orange oil, which slowly solidified to a wax. ^{1}H NMR (C$_6$D$_6$): δ = 1.6–2.0 (m, 15 H, Ad), 2.56 (m, 12 H, NMe$_2$) ppm. ^{31}P{^{1}H} NMR (C$_6$D$_6$): δ = 89.7 ppm.

Reaction of 1a–e with Ph$_2$C=C=O (General Procedure): A sample of neat Ph$_2$C=C=O (0.27 g, 1.39 mmol) was transferred dropwise, via a cannula, into a chilled solution (0 °C) of phosphaalkene **1** (0.40 mmol) in 30 mL of *n*-pentane. The resulting slurry was stirred at ambient temp. for 18 h and then filtered. The bright-yellow filter cake was washed with *n*-pentane (3 × 10 mL) and then dried in vacuo. Purification of crude **2** was effected by column chromatography on silica. Impurities were eluted with CH$_2$Cl$_2$ before product **2** was eluted with CH$_3$OH. Removal of solvent in vacuo afforded 0.10 g (85% yield) of bright-yellow, microcrystalline **2**. ^{1}H NMR (CDCl$_3$): δ = 2.74 (s, 6 H, NMe$_2$), 3.21 (s, 6 H, NMe$_2$), 7.00–7.56 (m, 10 H, Ph) ppm. ^{13}C{^{1}H} NMR (CDCl$_3$): δ = 42.3 [s, N(CH$_3$)$_2$], 42.6 [s, N(CH$_3$)$_2$], 123–130 (s, Ph), 141.6 [s, *C*(NMe$_2$)], 143.0 (s, *C*Ph$_2$), 175.4 (s, CO) ppm. IR (KBr): $\tilde{\nu}$ = 1713 cm^{-1} (CO), 1613 (C=C). MS/ESI: *m*/*z* = 295.0 [**2** + H$^+$]. Peak matching: C$_{19}$H$_{22}$N$_2$O: calcd. 295.18049; found 295.18032. After removal of **2**, the obtained filtrate was treated with powdered NaOH (0.50 g, 12.5 mmol) and stirred at 20 °C for 18 h to destroy the excess of Ph$_2$C=C=O. It was then filtered and the colorless filtrate was concentrated to dryness to afford the heterocycles **4a–e**.

4a (R = *t*Bu): Yield: 0.10 g (53%) of an oily wax. ^{1}H NMR (CDCl$_3$): δ = 0.89 (d, $^3J_{P,H}$ = 12.6 Hz, 9 H, *t*Bu), 7.17–7.37 (m, 20 H, Ph) ppm. ^{13}C{^{1}H} NMR (CDCl$_3$): δ = 24.7 [d, $^2J_{P,C}$ = 14.9 Hz, C(*C*H$_3$)$_3$], 38.5 [d, $^1J_{P,C}$ = 33.2 Hz, *C*(CH$_3$)$_3$], 93.1 (s, Ph$_2$*C*=CO$_2$), 125.5 (d, $^2J_{P,C}$ = 6.9 Hz, Ph$_2$*C*=COP), 127–131 (20s, Ph), 150.4 (d, $^1J_{P,C}$ = 41.1 Hz, PCO), 157.4 (d, $^2J_{P,C}$ = 11.4 Hz, OCO) ppm. ^{31}P{^{1}H} NMR (CDCl$_3$): δ = 122.3 ppm (s). IR (KBr): $\tilde{\nu}$ = 1761 cm^{-1} s, 1663 m, 1599 m. MS/EI: *m*/*z* (%) = 476 (27) [**4a**]$^+$, 194 (100) [Ph$_2$C=C=O]$^+$. High resolution MS: calcd. 479.19052; found 479.1902. C$_{32}$H$_{29}$O$_2$P (476.19): calcd. C 80.65, H 6.13; found C 80.40, H 6.12.

4b (R = Cy): Yield: 0.10 g (50%) of a colorless oily wax. ^{1}H NMR (CDCl$_3$): δ = 0.90–1.77 (m, 11 H, Cy), 7.17–7.36 (m, 20 H, Ph) ppm. ^{13}C{^{1}H} NMR (CDCl$_3$): δ = 26.2 (d, $J_{P,C}$ = 5.7 Hz, Cy), 26.3 (d, $J_{P,C}$ = 6.9 Hz, Cy), 26.7 (d, $J_{P,C}$ = 11.4 Hz, Cy), 27.1 (d, $J_{P,C}$ = 12.6 Hz, Cy), 43.4 (d, $J_{P,C}$ = 34.3 Hz, Cy), 93.7 (s, Ph$_2$*C*=CO$_2$), 125.6 (d, $^2J_{P,C}$ = 28.5 Hz, Ph$_2$*C*=COP), 127–131 (20s, Ph), 137.1 (s, *i*-*C*Ph), 138.4 (s, *i*-*C*Ph), 138.6 (s, *i*-*C*Ph), 138.8 (s, *i*-*C*Ph) 150.3 (d, $^1J_{P,C}$ = 34.3 Hz, PCO), 157.5 (d, $^2J_{P,C}$ = 11.4 Hz, OCO) ppm. ^{31}P{^{1}H} NMR (CDCl$_3$): δ = 117.8 ppm (s). IR (KBr): $\tilde{\nu}$ = 1727 cm^{-1} s, 1657 m, 1597 m. MS/EI: *m*/*z* (%) = 502 (57) [**4b**]$^+$, 194.1 (100) [Ph$_2$C=C=O]$^+$. High resolution MS: calcd. for C$_{34}$H$_{31}$O$_2$P 502.20617; found 502.20571.

4c (R = Ad): Yield: 0.10 g (45%) of a colorless oily wax. ^{1}H NMR (CDCl$_3$): δ = 1.57–1.91 (m, 15 H, Ad), 7.20–7.38 (m, 20 H, Ph) ppm. ^{13}C{^{1}H} NMR (CDCl$_3$): δ = 27.8 (d, $J_{P,C}$ = 8.0 Hz, Ad), 36.0 (d, $J_{P,C}$ = 12.6 Hz, Ad), 36.5 (s, Ad), 41.9 (d, $J_{P,C}$ = 33.2 Hz, Ad), 92.5 (s, Ph$_2$*C*=CO$_2$), 125.5 (d, $^2J_{P,C}$ = 9.1 Hz, Ph$_2$*C*=COP), 127–131 (20s, Ph), 137.9 (s, *i*-*C*Ph), 138.5 (s, *i*-*C*Ph), 138.6 (s, *i*-*C*Ph), 139.6 (s, *i*-*C*Ph), 149.5 (d, $^1J_{P,C}$ = 40.0 Hz, P*C*O), 157.7 (d, $^2J_{P,C}$ = 11.4 Hz, O*C*O) ppm. ^{31}P{^{1}H} NMR (CDCl$_3$): δ = 117.1 ppm (s). IR (KBr): $\tilde{\nu}$ = 1654 cm^{-1} m, 1596 m. MS/EI: *m*/*z* (%) = 554 (53) [**4c**]$^+$, 194 (47) [Ph$_2$C=C=O]$^+$, 165 (58) [CPh$_2$]$^+$, 135 (100) [Ad]$^+$. High resolution MS: calcd. for C$_{38}$H$_{35}$O$_2$P 554.23747; found 554.23790.

5: A sample of $Ph_2C{=}C{=}O$ (0.27 g, 1.39 mmol) was combined with an *n*-pentane solution (30 mL) of phosphaalkene Me_3Si-$P{=}C(NMe_2)_2$ (**1i**; 0.05 g, 0.40 mmol) at 0 °C. The resulting solution was stirred at 20 °C for 18 h and then freed from solvent. The residue, consisting of crude **5**, was not purified further. ^{1}H NMR (C_6D_6): δ = 0.11 (s, 9 H, $SiMe_3$), 2.36 (s, 6 H, NMe_2), 2.71 (s, 6 H, NMe_2), 7.00–7.57 (m, 10 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 17.3 ppm (s). MS/EI: *m*/*z* (%) = 398 (47) [**5**]$^+$.

Reaction of $Ph_2C{=}C{=}O$ with (tBuP)$_3$: A mixture of (tBuP)$_3$ (0.10 g, 0.38 mmol) and $Ph_2C{=}C{=}O$ (0.20 g, 1.03 mmol) in 1 mL of toluene was stirred at room temp. for 18 h and then heated to 100 °C for 5 h. The $^{31}P\{^1H\}$ NMR spectrum of the resulting solution showed the resonance of **4a** at δ = 121.9 ppm (ca. 6 mol-% P), a singlet at δ = –57.8 for (tBuP)$_4$ (ca. 14 mol-% P) and the AB pattern of (tBuP)$_3$ at δ = –70.1 and –108.6 ppm.

2-*tert*-Butylphosphanylidene-1,3-diisopropyl-4,5-dimethyl-2,3-dihydro-1*H*-imidazole (8): A 1.6 M *n*-hexane solution of *n*-butyllithium (25 mL, 40.0 mmol) was added dropwise at 0 °C to a solution of tBuP(H)$SiMe_3$ (6.57 g, 40.4 mmol) in THF (35 mL). The mixture was combined with a slurry of 1,3-diisopropyl-4,5-dimethyl-2,3-dihydroimidazol-2-ylidenemethylsulfonium iodide (**7**; 14.5 g, 40.9 mmol) in THF (80 mL) at 0 °C. Stirring was continued at room temp. in the dark for 3 d to give a suspension of a colorless solid and a red solution. A $^{31}P\{^1H\}$ NMR taken from this mixture showed a singlet at δ = 5.0 ppm. The slurry was filtered, and the filtrate was concentrated to dryness. The oily red-brown residue was dissolved in *n*-pentane and filtered. The obtained filter cake was washed with 10 mL of diethyl ether and dried. An ^{1}H NMR spectrum in $CDCl_3$ showed signals at δ = 1.69 [d, $^3J_{H,H}$ = 7.0 Hz, 12 H, $NCH(CH_3)_2$], 2.28 (s, 6 H, CH_3-C=C-CH_3), 4.57 [sept, $^3J_{H,H}$ = 7.0 Hz, 2 H, $NCH(CH_3)_2$], 9.77 ppm (s, 1 H, CH), which agree with the presence of the imidazolium ion **10**. The solvent was then removed from the filtrate and the residual orange oil was distilled. The $^{31}P\{^1H\}$ NMR spectrum of the distillate shows prominent signals at $\delta_{^{31}P}$ = –108.7, –70.5 ppm (AB-spin system) due to (tBuP)$_3$ (ca. 68 mol-% P), –57.6 (tBuP)$_4$ (ca. 10 mol-% P) and 4.3 ppm (**8** ca. 5 mol-% P).

Hydrothermal Synthesis, Crystal Structures, and Properties of a Class of 2D Coordination Polymers

Xiang He,[a] Can-Zhong Lu*[a] Da-Qiang Yuan,[a] Li-Juan Chen,[a] Quan-Zheng Zhang,[a] and Chuan-De Wu[a]

Keywords: Coordination polymers / Copper / Magnetic properties / Photoluminescence / Zinc

Hydrothermal reactions between 2,6-naphthalenedicarboxylic acid (H_2NDC), 1,10-phenanthroline (1,10-phen) or 2,2′-bipyridine (2,2′-bpy), and transition metal acetates give rise to four coordination polymers, namely $[Cu_3(NDC)_3(2,2'\text{-bpy})(H_2O)_2]_n{\cdot}nH_2O$ (**1**), $[Cu(NDC)(1,10\text{-phen})]_n$ (**2**), $[Zn(NDC)(1,10\text{-phen})]_n$ (**3**), and $[Zn_4(OH)_2(NDC)_3(2,2'\text{-bpy})_2]_n$ (**4**), which show different two-dimensional layered architectures. Compound **1** consists of three kinds of polymeric chains that are interconnected to form an unusual two-dimensional layered motif, while compound **4** features a two-dimensional honeycomb network structure with a noninterpenetrating ABCDABCD packing pattern. Compounds **2** and **3** show a two-dimensional grid-type framework but have different space-filling styles. The magnetic properties for **1** and **2** and the solid-state emission spectra of **3** and **4** have also been studied.

Introduction

The construction of extended porous metal–organic frameworks (MOFs) is of current interest in the fields of supramolecular chemistry and crystal engineering, not only because of their intriguing architectures but also because of their unexpected properties for potential practical applications in a wide number of fields, such as gas storage, exploitable magnetics, photoluminescence, and molecular recognition.[1–4] The self-assembly of MOFs using suitable ligands and metal centers has been proved to be an efficient route for the formation of one- to three-dimensional networks with fascinating structural topologies. The selection of organic ligands with appropriate coordination sites is the key to the formation of MOFs with desirable physical and chemical properties. Recently, the strategy using metal ions and organic carboxylates as starting building blocks to generate extended networks has been of great interest.[5–14] For example, 1,4-benzenedicarboxylate-(BDC-)bridged metal-organic frameworks have been studied extensively.[15] Polycyclic aromatic bidentate ligands such as 2,2′-bipyridine and 1,10-phenanthroline are frequently used together with polycarboxylates, leading to many novel architectures. Most of the coordination polymers with BDC and 2,2′-bipyridine or 1,10-phenanthroline ligands are often one-dimensional structures.[16] We are currently interested in employing 2,6-naphthalenedicarboxylate (NDC) as a bridging ligand since this molecule is more rigid than BDC and might not only establish bridges between several metal centers and exhibit rich coordination modes but also be expected to form a porous framework because of its rigidity and stability. On the other hand, because the presence of conjugated aromatic rings causes its low solubility in aqueous media, quite a few examples of polymeric structures containing both NDC and other multipyridine ligands have been reported.[17]

In the present work, we have selected Cu^{II} and Zn^{II} cations as metal nodes and NDC as a rigid bridging ligand and obtained four interesting 2D polymeric compounds, namely $[Cu_3(NDC)_3(2,2'\text{-bpy})(H_2O)_2]_n{\cdot}nH_2O$ (**1**), $[Cu(NDC)(1,10\text{-phen})]_n$ (**2**), $[Zn(NDC)(1,10\text{-phen})]_n$ (**3**), and $[Zn_4(OH)_2(NDC)_3(2,2'\text{-bpy})_2]_n$ (**4**). Compound **1** consists of three different chains that are interconnected to form an unusual two-dimensional layered motif, while compound **4** features a two-dimensional honeycomb network structure with a noninterpenetrating ABCDABCD packing pattern. Compounds **2** and **3** show a two-dimensional grid-type framework but have different space-filling styles.

Results and Discussion

Synthesis

Although it is difficult to control and predict the crystal structures under hydrothermal conditions, the hydrothermal reaction is still an optimum method for the synthesis of some novel MOFs. We used Cu^{II} and Zn^{II} salts and mixed bridging ligands to obtain four 2D compounds with distinct structures under hydrothermal conditions. Subtle adjust-

ments of the conditions result in the formation of very different structures.

Crystal Structures

[Cu$_3$(NDC)$_3$(2,2′-bpy)(H$_2$O)$_2$]$_n$·nH$_2$O (1)

Compound **1** consists of three different chains that are interconnected to form an unusual two-dimensional layered motif − one is a zigzag chain and the other two are linear chains. The NDC ligands in the zigzag chain act as the junctions to link the two linear chains into a layered structure. As shown in Figure 1, the asymmetric unit contains two crystallographically unique Cu centers. Each Cu^{II} center has a quite different coordination environment: the first one has a $\{CuO_2N_2\}$ coordination sphere and is coordinated by two nitrogen atoms from one 2,2′-bpy [Cu–N = 1.984(6) Å] and two oxygen atoms from two NDC ligands [Cu–O = 1.966(5) Å] with O(N)–Cu–O(N) angles involving the neighboring atoms ranging from 82.5(2) to 97.7(2)°, showing a disordered square-planar structure, and the second one has a $\{CuO_4\}$ square-planar coordination sphere and is defined by three oxygen donors from three individual NDC ligands [Cu–O = 1.932(5)–1.996(5) Å] and one from a water molecule [Cu–O = 1.969(6) Å]. The trinuclear copper unit formed can be taken as an isosceles triangular array linked by the NDC ligands. The NDC ligands in compound **1** exhibit two different coordination modes (Scheme 1): one (NDC with O5) acts as a tetradentate ligand to link four copper(II) centers (mode I), while another (NDC with O1) acts as a bidentate ligand connecting two copper(II) centers in an *anti* fashion (mode II). As shown in Figure 2, the bidentate carboxyl groups bridge the Cu(2) atom to form linear chains running alone the *b*-axis, which are parallel to each other. The tetradentate carboxyl groups bridge the Cu(1) atom to form zigzag chains running along the *c*-axis, which also link the neighboring copper atoms in

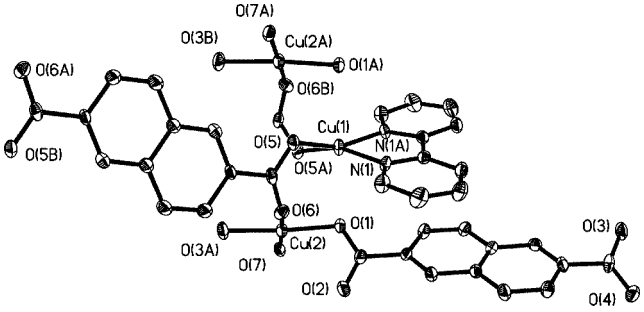

Figure 1. ORTEP representation of the symmetry-expanded structure of **1**, showing the coordination environments of the Cu^{II} atoms (30% probability thermal ellipsoids; hydrogen atoms and solvent molecules have been omitted for clarity).

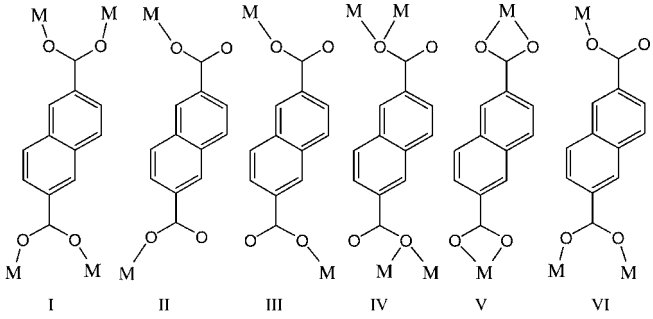

Scheme 1. Different kinds of coordination modes of the NDC ligand.

linear chains to form a thick, trilayer network. Each zigzag chain is parallel to the others, while the linear chains located behind and ahead of the zigzag chain are parallel to each other too.

The Cu···Cu distance within the zigzag chain bridged by the NDC ligand is 13.022(1) Å, while the Cu···Cu distance is 13.006(1) Å in the linear chain. The Cu···Cu distance between two neighboring linear chains is 5.638(8) Å, and the Cu···Cu distance between zigzag and linear chains is 3.395(3) Å. It is notable that the lamellar framework is made up by zigzag chains sandwiched between two adjacent linear chains. To the best of our knowledge, no documented example of such a layered structure has been reported.

[Cu(NDC)(1,10-phen)]$_n$ (2)

Compound **2** is a two-dimensional, square-grid network structure. As shown in Figure 3, the copper(II) atom exhibits a square-pyramidal configuration, coordinated by two nitrogen atoms of one 1,10-phen ligand [Cu–N = 2.029(2)–2.050(2) Å] and three oxygen atoms of the carboxyl groups from different NDC ligands [Cu–O = 1.9139(18)–2.2421(17) Å]. The O–Cu–O bond angles range from 95.89(8) to 102.41(7)° and the O–Cu–N bond angles range from 90.52(8) to 170.58(8)°. The NDC ligands in compound **2** exhibit two different coordination modes (Scheme 1): one (NDC with O3) acts as a tetradentate ligand to link four copper(II) centers (mode I), while another (NDC with O1) acts as a bidentate ligand that connects two copper(II) centers in a *trans* fashion (mode III). As shown in Figure 4a, the carboxylate groups at both ends of the NDC ligands doubly bridge the Cu dimers with a Cu···Cu separation of 4.319(3) Å to yield an infinite chain running along the *a*-axis, in which the four carboxylate oxygen atoms and two Cu atoms form an O_4Cu_2 six-membered ring. The 1D chains are stitched by the bis(monodentate) bridges along the *b*-axis to form a 2D square-grid coordination polymer with dimensions of 13.801(1) × 12.082(1) Å^2, of which the effective pore-size is partly diminished by the phen ligands. Calculations with PLATON show that the pores occupy about 47.0% of the crystal volume. Intramolecular nonclassical weak hydrogen-bonding interactions between the carbon atoms of the 1,10-phen ligand and the oxygen atoms of the carboxylate groups C(10)–H(10A)···O(4) (*–x*, *–y*, *–z*) [3.063(3) Å] exist in compound **2**. In addition, there are π–π stacking interactions between adjacent aromatic rings of phen ligands, with a plane-to-plane separation of about 3.528 Å in **2**.

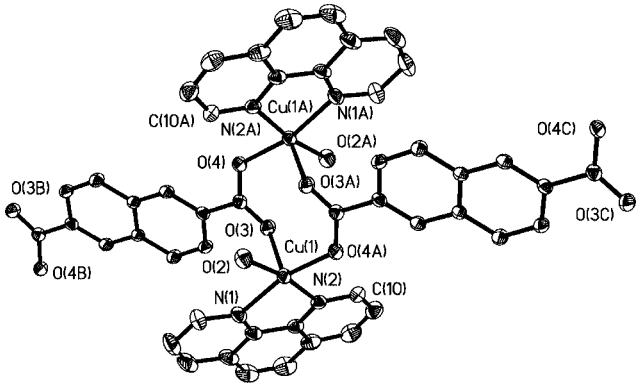

Figure 3. ORTEP representation of the symmetry-expanded structure of **2**, showing the coordination environments of the Cu^{II} atoms (30% probability thermal ellipsoids; hydrogen atoms have been omitted for clarity).

[Zn(NDC)(1,10-phen)]$_n$ (3)

The structure of **3** is also a two-dimensional square-grid network. As shown in Figure 5, the zinc(II) atom exhibits a distorted octahedral configuration, coordinated by two nitrogen atoms of a 1,10-phen ligand [Zn–N = 2.109(6)–2.173(7) Å] and four oxygen atoms of the carboxyl groups from different NDC ligands. The Zn–O distances range from 2.074(5) to 2.177(5) Å, the O–Zn–O bond angles range from 60.8(2) to 155.1(2)°, and the O–Zn–N bond angles range from 90.8(2) to 169.5(2)°. The NDC ligands in compound **3** also exhibit two different coordination modes (Scheme 1): one (NDC with O4) acts as a tetradentate ligand to link four zinc(II) atoms by two carboxylate oxygen atoms on two side (mode IV), while another (NDC with O1) bidentate NDC ligand chelates two zinc(II) centers

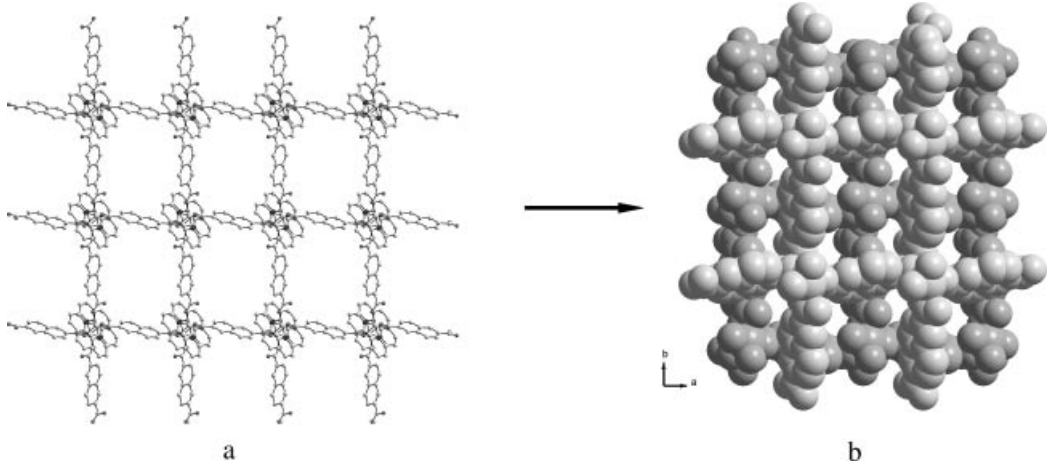

Figure 4. a) Structure of **2**, showing the 2D square grid. b) Space-filling representation of the stacking of 2D layers in **2**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(mode V). As shown in Figure 6a, the carboxylate groups at both ends of the NDC ligands doubly bridge Zn dimers with a Zn···Zn separation of 3.207(2) Å to yield an infinite chain in which the two carboxylate oxygen atoms and two Zn atoms form O_2Zn_2 four-membered rings. These chains are stitched by the bis(bidentate) bridges to give a 2D layer architecture. It is interesting to note that the adjacent layers possess large channels with approximate dimensions of $12.899(7) \times 11.147(10)$ Å^2, with the phen ligands inserted inside such grids. Calculations with PLATON show that the pores occupy about 39.2% of the crystal volume. Intramolecular nonclassical weak hydrogen-bonding interactions between the carbon atoms of the 1,10-phen ligand and the oxygen atoms of the carboxylate groups C(1)–H(1A)···O(3) ($-x + 1, -y + 1, -z + 2$) [3.281(12) Å] also exist in compound **3**. In addition, there are π–π stacking interactions between adjacent aromatic rings of the phen ligands, with a plane-to-plane separation of about 3.568 Å in **3**.

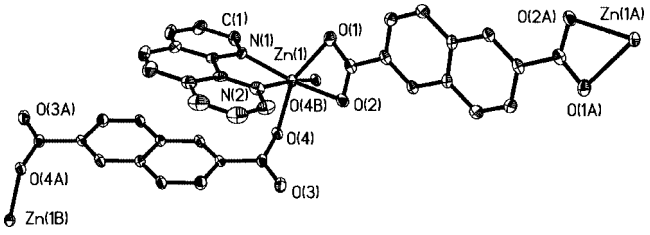

Figure 5. ORTEP representation of the symmetry-expanded structure in **3**, showing the coordination environments of the Zn^{II} atoms (30% probability thermal ellipsoids; hydrogen atoms have been omitted for clarity).

Comparing the different space-filling styles between compounds **2** and **3**, we find that the phen ligands fill the grids, resulting in the different space-filling frameworks. In compound **2**, the phen ligands align above and below one sheet and protrude into the cavities of neighboring networks. Two adjacent square grids are stacked parallel but in a staggered manner to each other along the *c*-direction. This arrangement ultimately leads to an ABAB repeat pattern of layers (Figure 4b). The phen ligands are inserted into the square grids like guest molecules in compound **3**, leading to an AA stacking pattern in the *bc* plane (Figure 6b).

[Zn$_4$(OH)$_2$(NDC)$_3$(2,2′-bpy)$_2$]$_n$ (4)

Compound **4** is a two-dimensional honeycomb network structure with a Zn_2O core as building block that is bridged by a hydroxy group. As shown in Figure 7, the Zn^{II} atoms comprise two different coordination environments: Zn(1) is coordinated by four oxygen atoms in a disordered tetrahedral geometry, with three oxygen donors from individual NDC ligands [Zn(1)–O = 1.932(2)–2.005(2) Å] and one from a hydroxy group [Zn(1)–O = 1.918(2) Å], while Zn(2) is five-coordinated by two 2,2′-bpy nitrogen atoms [Zn(2)–N = 2.078(5)–2.203(6) Å], two oxygen atoms of NDC ligands [Zn(2)–O = 2.028(2)–2.065(3) Å], and one hydroxy group [Zn(2)–O(5) = 1.918(2) Å] to furnish a square-pyramidally coordinated environment. The carboxylate groups exhibit two different coordinating modes (Scheme 1): one (NDC with O1) acts as a tridentate ligand to link three zinc(II) centers (mode VI), while another (NDC with O3)

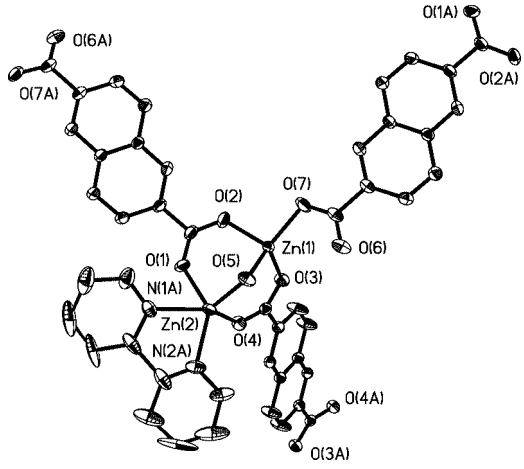

Figure 7. ORTEP representation of the symmetry-expanded structure of compound **4**, showing the coordination environments of the Zn^{II} atoms (30% probability thermal ellipsoids; hydrogen atoms and one disordered bipy have been omitted for clarity).

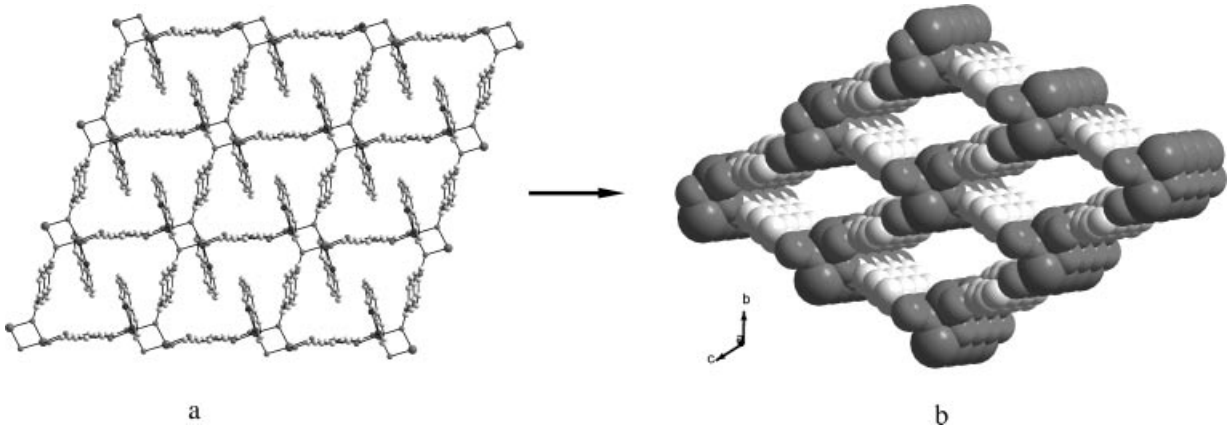

Figure 6. a) Structure of **3**, showing the 2D square grid. b) Space-filling representation of the 2D nanosized channels (2,2′-bpy ligands omitted) in **3**.

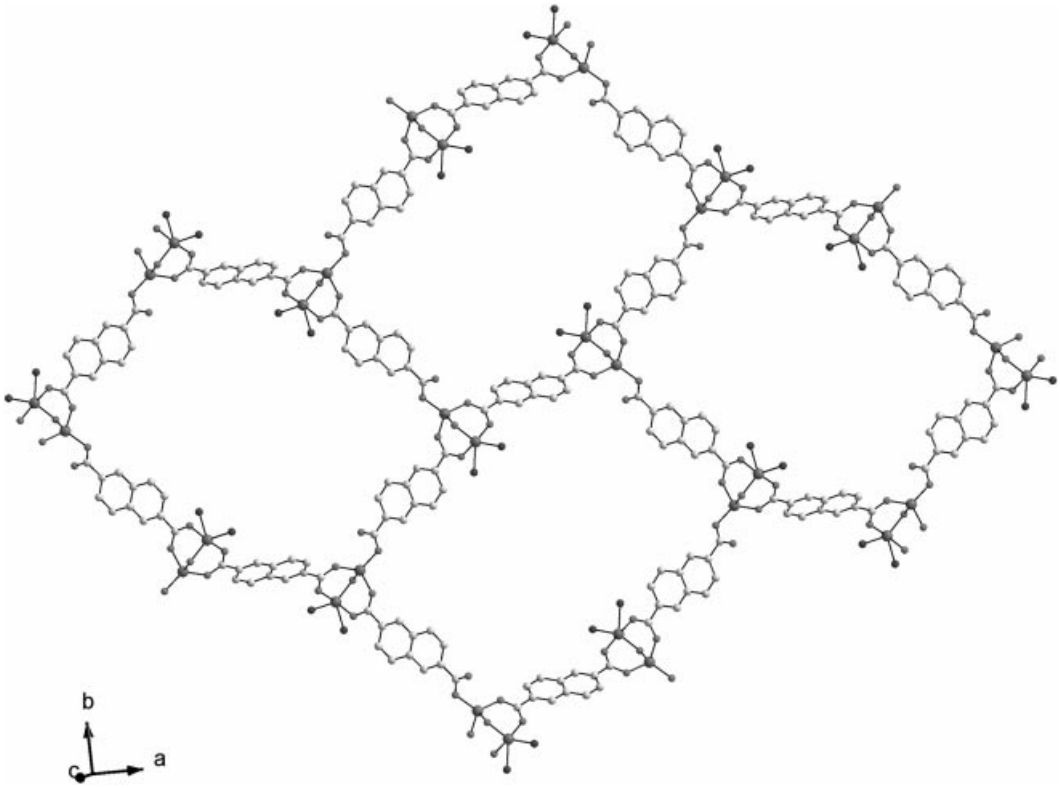

Figure 8. View of the 2D hexagonal grid (2,2′-bpy ligands omitted) of compound **4**.

acts as a tetradentate ligand to link four zinc(II) centers (mode I).

The Zn_2O building units are bridged by four tridentate and two tetradentate NDC ligands to form a hexagon with dimensions of 18.9×26.1 Å^2 (Figure 8). To the best of our knowledge, the simultaneous presence of two coordination modes of NDC ligands to form a hexagon has not been reported until now. Each hexagon shares six edges with six adjacent hexagons to form a 2D framework. It is noteworthy that the topology of compound **4** can be simplified as a (6,3) network.

Other examples of honeycomb compounds often form interpenetrated networks − one 3D fourfold interpenetrated[18] and one 2D twofold interpenetrated[19] supramolecular architectures have been reported. In contrast, compound **4** is an unusual example of a 2D noninterpenetrated honeycomb structure in which these 2D honeycomb networks are stacked together in an ABCDABCD packing mode along the *c*-axis (Figure 9), which is different to that of the other reported noninterpenetrated networks.[20,21] To the best our knowledge, compound **4** is the first example of a 2D noninterpenetrated honeycomb structure with an ABCDABCD packing pattern.

The NDC ligands possess rich coordination modes in the above four 2D structures, which results in the formation of four interesting compounds. The aromatic and rigid part of naphthalene may help the growth of high-quality crystals. Polycyclic N-heterocyclic ligands such as 2,2′-bipyridine or 1,10-phenanthroline might affect the structures due to steric factors. Finally, the different metal cations may also play important roles in the synthesis of novel multidimensional open-framework materials due to their intrinsic ability to form diverse geometric structures.

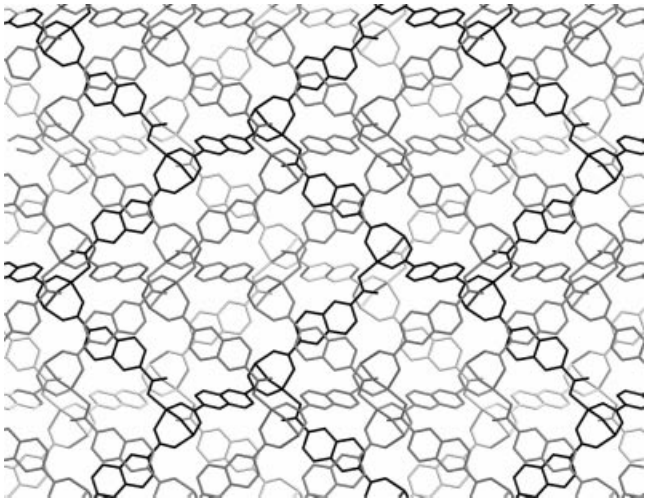

Figure 9. View of the stacking of sheets along the *c*-axis of compound **4** (different shades of gray represent distinct sheets).

Thermogravimetric Analysis

To study the thermal stabilities of these polymers, the thermogravimetric analyses (TGA) of compounds **2**–**4** were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

performed. The TGA diagram of **2** shows two main weight-loss steps. From 30 to 260 °C compound **2** is stable. In the temperature range of 260–327 °C, the observed weight loss of 39.11% is attributed to the elimination of the phen ligands (calcd. 39.35%). The second step is attributed to the further decomposition of NDC ligands. The TGA diagram of **3** is similar to that of **2**, as compound **3** is stable up to 385 °C. In the temperature range of 385–444 °C, the weight loss of 39.21% is attributed to the elimination of phen ligands (calcd. 39.20%). The next step is attributed to the further decomposition of the NDC ligands. The TGA diagram of **4** also indicates two main weight-loss steps. The observed weight loss of 25.54% (322–412 °C) is attributed to the elimination of bpy ligands (calcd. 24.98%), while the second step is attributed to the further decomposition of NDC ligands and the hydroxy group. The stabilities of **3** and **4** make them potential candidates for practical applications.

Magnetic Properties

The magnetic susceptibilities, χ_M, of compound **1** were measured between 5 and 300 K in a 5 kOe applied magnetic field and all data were corrected for diamagnetism of the ligands estimated from Pascal's constants.[22] The plots of μ_{eff} and χ_M vs. T of compound **1** are shown in Figure 10. The μ_{eff} value is 3.28 μ_B at room temperature, which slightly exceeds the value expected for three independent copper(II) ions (3.00 μ_B). The value of μ_{eff} decreases upon cooling, reaching a value of 2.07 μ_B at 5 K. A number of trinuclear copper compounds have been reported and classified from a structural point of view as linear,[23] isosceles triangle,[24] equilateral triangle,[25] and angular trinuclear.[26] The trinuclear copper center in compound **1** can be taken as an isosceles triangle array, therefore an equation that uses two different J values was tried. In this case, the exchange Hamiltonian takes on the form $H = -2J_1(S_1S_2 + S_1S_3) - 2J_2S_2S_3$. As can be seen from the crystal structure of **1**, there is no magnetic exchange interaction between atoms Cu2 and Cu2A, and therefore we can ignore this interaction ($J_2 = 0$) (Scheme 2). The corresponding molar magnetic susceptibility is expressed by Equation (1), in which a Weiss-like parameter was considered. The symbols in that equation have their usual meaning. It is assumed that the g values for all three copper atoms are equal.

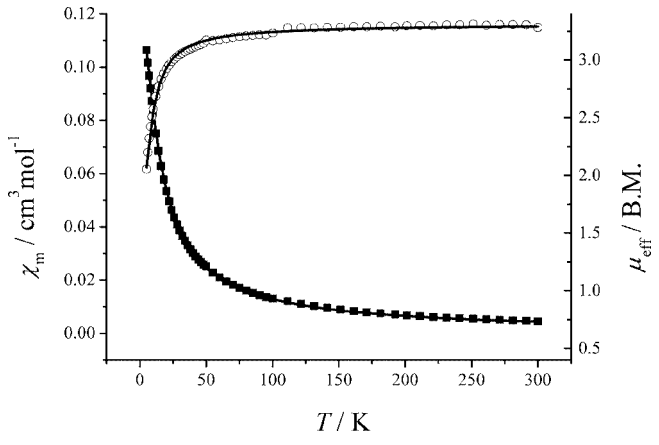

Figure 10. Temperature-dependent experimental molar susceptibility (χ_M) and effective magnetic moment (μ_{eff}) of compound **1**. The solid lines represent the calculated values.

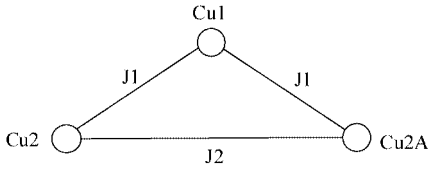
$$\chi_M = \frac{Ng^2\beta^2[15\exp(J_1/KT) + 3/2\exp(-2J_1/KT) + 3/2]}{3k(T-\theta)[4\exp(J_1/kT) + 2\exp(-2J_1/KT) + 2]} \quad (1)$$



Scheme 2. Different J values for compound **1**.

A satisfactory least-squares fitting of the observed data at 5–300 K leads to $g = 2.20$, $J_1 = -4.36$ cm^{-1}, $J_2 = 0$, and $\theta = 0.04$ K with the agreement factor $R = \Sigma(\chi_{M_{obs}} - \chi_{M_{calcd.}})^2/\Sigma(\chi_{M_{obs}})^2 = 8.37 \times 10^{-7}$. The value of J_1 indicates that an antiferromagnetic Cu1···Cu2 exchange interaction occurs through the bridging carboxylate groups of the NDC ligand, while the θ value indicates very weak ferromagnetic interactions between the trinuclear units through the tetradentate bridging carboxylate groups of the NDC ligand.

From the plots of μ_{eff} and χ_M vs. T of **2** (Figure 11), it can be seen that the μ_{eff} value at room temperature is 1.64 μ_B, which is close to the spin-only value of 1.73 μ_B for the Cu^{II} center ($S = 1/2$). To quantitatively interpret the magnetic behavior of the compound, its magnetic data were analyzed by the theoretical expression by using the HDDV model ($H = -2J_1S_1S_2$). The corresponding molar magnetic susceptibility is expressed by Equation (2), in which a Weiss-like parameter was considered. The symbols in this equation have their usual meaning.

$$\chi_M = \frac{Ng^2\beta^2}{k(T-\theta)[3 + \exp(-2J/kT)]} \quad (2)$$

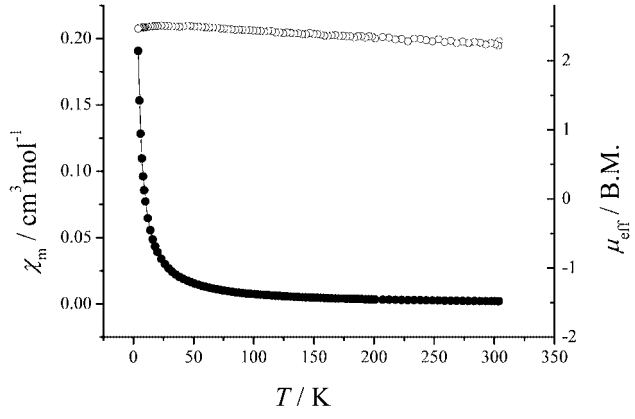


Figure 11. Temperature-dependent experimental molar susceptibility (χ_M) and effective magnetic moment (μ_{eff}) of compound **2**. The solid lines represent the calculated values.

A satisfactory least-squares fitting of the observed data at 5–300 K leads to $g = 2.02$, $J = -2.04$, and $\theta = 1.21$ with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the agreement factor $R = \Sigma(\chi_{M_{obs}} - \chi_{M_{calcd.}})^2/\Sigma(\chi_{M_{obs}})^2 = 3.50\times10^{-7}$. The J value indicates that an antiferromagnetic Cu···Cu exchange interaction occurs through the bidentate bridging carboxylate groups of the NDC ligand, while the θ value indicates that the dinuclear unit presents ferromagnetic interactions through the bis(monodentate) bridging carboxylate groups of the NDC ligand.

Photoluminescent Properties

We also investigated the photoluminescent properties of compounds **3** and **4**. The emission spectra of compounds **3** and **4** in the solid state at room temperature are shown in Figure 12. It can be seen that compound **3** exhibits an intense blue photoluminescence upon photoexcitation at 386 nm. The emission peak is located at 488 nm for **3**, which means that it is bathochromically shifted by about 20 nm relative to that of the free NDC ligand, probably due to ligand-to-metal charge transfer (LMCT). The blue fluorescent emission of **3** suggests that it might be used as a new blue-light-emitting material. Compound **4** exhibits intense green photoluminescence upon photoexcitation at 380 nm. The emission peak is located at 549 nm for **4**, and compared with the NDC ligand a clearly bathochromic shift occurs in **4**, which might also be attributed to LMCT.[27–29]

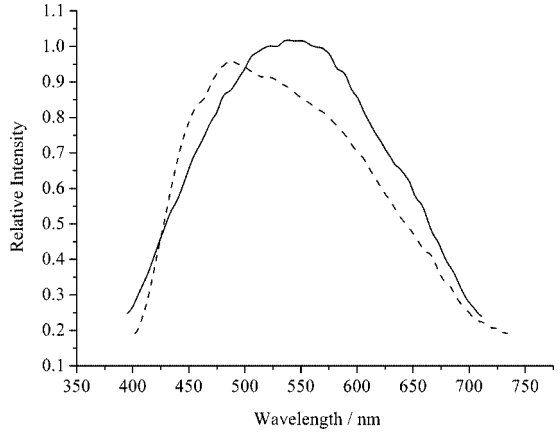

Figure 12. Emission spectra of **3** (broken line) and **4** measured in the solid state at room temperature.

Conclusions

Despite the extensive use of organic carboxylate ligands in the construction of new MOFs, combining both 2,6-naphthalenedicarboxylic acid and some other N-heteroaromatic ligands is a fairly small subset of MOFs. Four two-dimensional layer coordination compounds bridged by 2,6-naphthalenedicarboxylate and N-heteroaromatic ligands have been prepared and characterized. Substitution of metal cations or N-heteroaromatic ligands results in significant different frameworks. Compound **1** consists of three different chains that are interconnected to form an unusual two-dimensional layered motif, while compound **4** features a two-dimensional honeycomb network structure with a noninterpenetrated ABCDABCD packing pattern. Compounds **2** and **3** show a two-dimensional grid-type framework but with different space-filling styles. The magnetic studies indicate antiferromagnetic interactions transferred by the carboxylate groups of the NDC ligand in compounds **1** and **2**. Compounds **3** and **4** display strong fluorescence emission at different wavelengths.

Experimental Section

General Remarks: The syntheses were performed in Teflon-lined stainless steel autoclaves under autogenous pressure. Reagents were purchased commercially and were used without further purification. Elemental analyses of C and H were performed with an EA1110 CHNS-0 CE elemental analyzer. The IR (KBr pellet) spectra were recorded with a Nicolet Magna 750FT-IR spectrometer. TGA analyses were carried out under nitrogen at a heating rate of 10 °C min^{-1} with an STA449C integration thermal analyzer. Variable-temperature (5–300 K) magnetic susceptibility measurements were carried out with a Quantum Design MPMS-7 SQUID magnetometer at a magnetic field of 5 T using the SQUID method. The fluorescent data were collected with an Edinburgh FL-FS920 TCSPC system.

$[Cu_3(NDC)_3(2,2'\text{-bpy})(H_2O)_2]_n\cdot nH_2O$ (1): A mixture of $Cu(CH_3COO)_2\cdot H_2O$ (0.20 g, 1 mmol), NDC (0.26 g, 1 mmol), 2,2′-bpy (0.16 g, 1 mmol), and triethylamine (0.28 mL, 2 mmol) in H_2O (18 mL) was heated at 170 °C for 5 d in a sealed 30-mL Teflon-lined stainless steel vessel under autogenous pressure. Slow cooling of the reaction mixture to room temperature gave green crystals (yield: 0.19 g, 56% based on Cu). $C_{46}H_{32}Cu_3N_2O_{15}$ (1043.4): calcd. C 52.95, H 3.09, N 2.68; found C 53.13, H 2.95, N 2.54. IR (solid KBr pellet): $\tilde{\nu}$ = 3649 m, 3076 m, 1606 s, 1545 s, 1498 m, 1477 m, 1404 s, 1350 s, 1194 m, 931 w, 910 w, 843 w, 791 s, 775 s, 727 m, 650 w, 582 w, 513 w, 480 m, 447 w cm^{-1}.

$[Cu(NDC)(1,10\text{-phen})]_n$ (2): A mixture of $Cu(CH_3COO)_2\cdot H_2O$ (0.30 g, 1.5 mmol), NDC (0.13 g, 0.5 mmol), 1,10-phen (0.20 g, 1 mmol), and triethylamine (0.28 mL, 2 mmol) in H_2O (18 mL) was heated at 160 °C for 3 d in a sealed 30-mL Teflon-lined stainless steel vessel under autogenous pressure. Slow cooling of the reaction mixture to room temperature gave blue crystals (yield: 0.28 g, 62% based on Cu). $C_{24}H_{14}CuN_2O_4$ (457.93): calcd. C 62.95, H 3.08, N 6.12; found C 62.73, H 3.14, N 6.26. IR (solid KBr pellet): $\tilde{\nu}$ = 1633 s, 1616 s, 1587 s, 1518 m, 1493 m, 1425 m, 1390 s, 1350 sh, 1298 m, 1196 m, 1178 m, 1136 w, 1105 w, 937 w, 872 w, 852 s, 791 sh, 739 m, 723 s, 648 m, 577 m, 494 w, 430 w cm^{-1}.

$[Zn(NDC)(1,10\text{-phen})]_n$ (3): Compound **3** was synthesized in an analogous manner to **2** except that $Zn(CH_3COO)_2\cdot 2H_2O$ (0.22 g, 1 mmol) was used instead of $Cu(CH_3COO)_2\cdot H_2O$. The reaction mixture was cooled, which led to the formation of yellow crystals of **3** (yield: 0.24 g, 52% based on Zn). $C_{24}H_{14}N_2O_4Zn$ (459.77): calcd. C 62.70, H 3.07, N 6.09; found C 62.65, H 3.02, N 6.46. IR (solid KBr pellet): $\tilde{\nu}$ = 1628 s, 1603 m, 1556 s, 1520 m, 1495 m, 1435 s, 1421 s, 1331 s, 1296 s, 1178 m, 1132 m, 1105 w, 1047 w, 924 w, 843 m, 795 s, 768 m, 725 s, 642 w, 557 m, 540 w, 488 w, 424 w cm^{-1}.

$[Zn_4(OH)_2(NDC)_3(2,2'\text{-bpy})_2]_n$ (4): Compound **4** was synthesized in a similar manner to **3** except that 2,2′-bpy (0.16 g, 1 mmol) was used instead of 1,10-phen. The reaction mixture was cooled, which led to the formation of light yellow crystals of **4** (yield: 0.12 g, 40%

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

based on Zn). $C_{56}H_{36}N_4O_{14}Zn_4$ (1250.4): calcd. C 53.79, H 2.90, N 4.48; found C 53.36, H 2.68, N 4.23. IR (solid KBr pellet): $\tilde{\nu}$ = 3521 m, 3088 w, 1616 s, 1581 s, 1493 m, 1471 m, 1444 m, 1400 s, 1360 s, 1192 m, 1155 m, 1097 w, 1024 w, 924 w, 839 w, 785 s, 735 w, 667 m, 652 w, 580 w, 486 w cm^{-1}.

X-ray Crystallographic Study: Suitable single crystals with dimensions of 0.56×0.24×0.14 mm (**1**), 0.50×0.35×0.20 mm (**2**), 0.36×0.32×0.16 mm (**3**), and 0.35×0.25×0.20 mm (**4**) were glued to thin glass fibers with epoxy resin. Crystal structure measurements for compounds **1**–**4** were performed with a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature. A total of 3394, 4479, 3271, and 5639 unique reflections were collected by the $\omega/2\theta$ scan mode for **1**–**4**, respectively. The structures were solved by direct methods and refined on F^2 with the SHELXL-97 program.[30] All non-hydrogen atoms were refined with anisotropic displacement parameters, and the hydrogen atoms were treated as riding atoms

using the SHELX-97 default parameters. For **1**, the hydrogen atoms of the water molecules were neither found nor calculated. For **4**, the 2,2′-bpy ring was found to be disordered and was modeled in two positions with occupancies of 51.2 and 48.8%. The crystal data and details of refinements for the compounds are summarized in Table 1, while their selected bond lengths and angles are listed in Table 2. CCDC-271318 (**1**), -255855 (**2**), -271317 (**3**), and -271319 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis of Phosphido-Bridged Phosphinito Platinum(I) Complexes by Reaction of *cis*-$PtCl_2(PHCy_2)_2$ with Oxygenated Bases – Crystal Structure of $[(PCy_2OMe)Pt(\mu\text{-}PCy_2)]_2$(*Pt–Pt*)

Keywords: Platinum / Bridging ligands / Phosphinites / Oxygenated bases

Reaction of *cis*-$PtCl_2(PHCy_2)_2$ (**1**) with oxygenated bases leads to phosphido-bridged dinuclear complexes. The product obtained using sodium hydroxide is the asymmetric Pt^I complex $[(Cy_2PH)Pt(\mu\text{-}PCy_2)(\kappa^2P,O\text{-}\mu\text{-}Cy_2PO)Pt(Cy_2PH)]$(*Pt–Pt*) (**2**), which represents a rare example of a complex containing a Pt–Pt–P–O cycle. The reaction products between **1** and NaOR (R = Me, Et) depend on experimental conditions: lack of base results in the formation of *trans*-$[Pt(PHCy_2)Cl(\mu\text{-}PCy_2)]_2$ (**3**) as the main product. Using an excess of base at 50 °C allowed the isolation of the symmetric Pt^I dimers $[(PCy_2OR)Pt(\mu\text{-}PCy_2)]_2$(*Pt–Pt*) (**5**, R = Me; **7**, R = Et) containing two alkyl dicyclohexylphosphinito ligands. The asymmetric compounds $[(PCy_2H)Pt(\mu\text{-}PCy_2)_2Pt(PCy_2OR)]$(*Pt–Pt*) (**4**, R = Me; **8**, R = Et) form after work-up of the reaction of **1** with excess NaOR (8 equiv.) in toluene/methanol at room temperature. Investigations on the mechanism of formation of phosphinito Pt^I complexes (carried out also employing Na-O*t*Bu and NaOPh as oxygenated bases) show that the first two steps of the overall reaction are the metathesis leading to *cis*-$Pt(OR)_2(PHCy_2)_2$ and the subsequent formation of terminal phosphido complexes through ROH elimination. Single crystal X-ray diffraction showed that molecules of **5** are located on crystallographic inversion centres; hence their necessarily planar Pt_2P_2 core contains a Pt–Pt bond.

Introduction

Secondary phosphanes are attractive as ligands for transition metals because they add some peculiar characteristics to the typical σ basicity and π acidity of the trivalent phosphorus compounds because of the presence of the reactive P–H bond: (i) the capability to form polynuclear complexes in which the metal atoms are linked by phosphido bridges; (ii) the possibility to give rise to a metal–hydrogen bond by intramolecular oxidative addition.

Pursuing our studies on platinum complexes with bulky secondary phosphanes such as di-*tert*-butylphosphane[1,2] and dicyclohexylphosphane,[3] we recently became interested in the reactivity of *cis*-$PtCl_2(PHCy_2)_2$ (**1**) with NaOR (R = H, Me, Et, Ph, *t*Bu). The latter compounds, in fact, can act either as nucleophiles and/or as bases, triggering different reaction pathways depending on both the nature of R and the experimental conditions.

The reaction of alkaline alkoxides with phosphanyl Pt^{II} complexes has been used for the preparation of alkoxo complexes, starting from the corresponding chloro species.[4–8] In some cases the alkoxo complexes are not stable and give rise to redox processes leading to decomposition products,[9] to hydride complexes of platinum(II)[10] or to zerovalent platinum compounds.[11] The reducing ability of alkaline alkoxides towards halide metal complexes has been demonstrated also for Ni[12] and Pd[13] compounds.

Herein we describe the reactivity of *cis*-$PtCl_2(PHCy_2)_2$ (**1**) with sodium hydroxide, alkoxides and phenoxide, which led to phosphido-bridged binuclear platinum compounds, the nature of which depended on both the base and the reaction conditions (Scheme 1).

Results and Discussion

Contrary to *trans*-$PtCl_2(PHtBu_2)_2$, whose reaction with oxygenated bases such as NaOMe,[2] NaOEt[14] or NaOH[15] was ineffective, the reaction of **1** with NaOH in a biphasic CH_2Cl_2/H_2O system proceeded smoothly to form a new dinuclear Pt^I complex whose spectroscopic features and ESI-MS analysis indicate as $[(Cy_2PH)Pt(\mu\text{-}PCy_2)(\kappa^2P,O\text{-}\mu\text{-}$

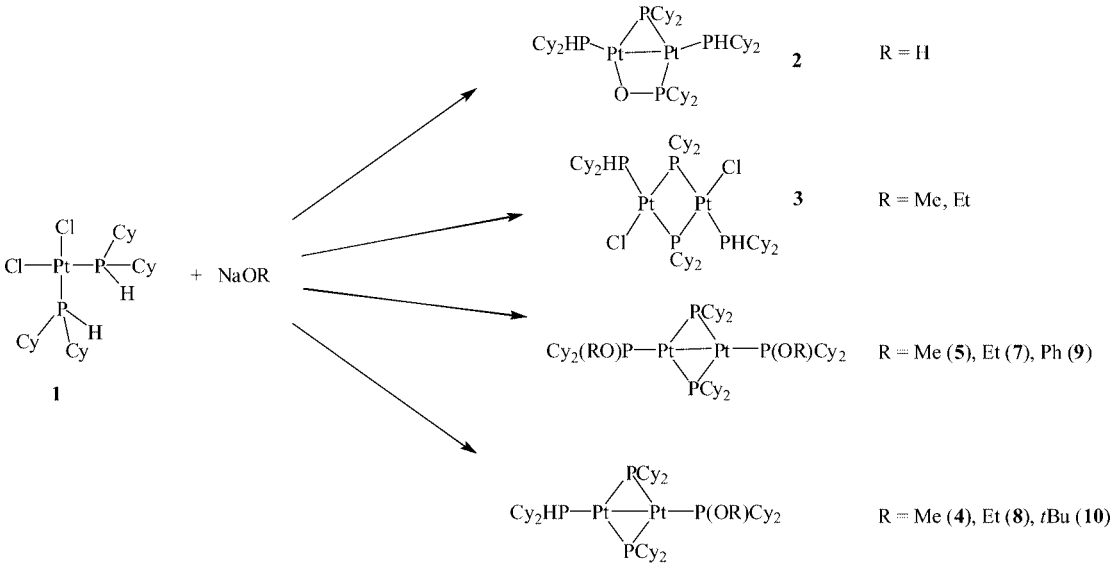

Scheme 1.

$Cy_2PO)Pt(Cy_2PH)](Pt–Pt)$ (**2**). The $^{31}P\{^1H\}$ NMR spectrum of **2** (Figure 1) showed 4 mutually coupled doublets of doublets of doublets flanked by ^{195}Pt satellites centred at δ = 134.4, δ = 94.6, δ = 18.5 and δ = 15.9 ppm.

Of these, the latter two can be ascribed to coordinated PCy_2H (comparison with proton-coupled spectrum gave $^1J_{P,H}$ of 310 Hz and 323 Hz respectively) while that at δ = 94.6 is ascribable to a deshielded P–O ligand. The remaining low field signal at δ = 134.4 is flanked by three different sets of satellites and can be attributed to a phosphide involved in a three-membered Pt_2P ring[16,17] bridging two inequivalent Pt atoms. The ^1H NMR spectrum showed, beside cyclohexyl protons, two signals attributable to the hydrogens directly bound to P in coordinated PCy_2H, which were attributed to the proper PCy_2H ligand on the basis of $^1H–^{31}P$ HMQC experiments (Supporting Information, ESI 1). The $^{195}Pt\{^1H\}$ NMR spectrum consisted of two dddd centred at δ = –4798 (Pt^1) and δ = –5205 (Pt^2) (Figure 2).

The characterisation of **2** was completed by IR, elemental and ESI-MS analysis. In particular, the IR spectrum showed two weak bands in the region of P–H stretching (2279 and 2252 cm^{-1}) and bands at 816 and 1024 cm^{-1} ascribable to the P–O stretchings. Eventually, the ESI-MS spectrum showed the signals corresponding to $[M + H]^+$ with an isotope pattern identical to that calculated on the basis of the natural abundances (Figure 3).

Complex **2** is a rare example of an asymmetric monophosphido-bridged Pt^I complex. The spectroscopic data summarised above are consistent either with structure **A**, in which the $P(O)Cy_2$ ligand acts as monodentate (κ-*P* bound to Pt^2), or with structure **B**, in which the $P(O)Cy_2$ acts as bidentate (κ^2-*P,O*) bridging the two Pt atoms (Figure 4).

An equilibrium between the two structures might also be conceived. NMR features can help in discriminating between the two structures. We have previously noticed that binuclear monobridged dicyclohexylphosphane complexes of Pd and Pt such as $[(Cy_2PH)(Cl)Pt(\mu\text{-}PCy_2)Pt(Cy_2PH)_2]$-

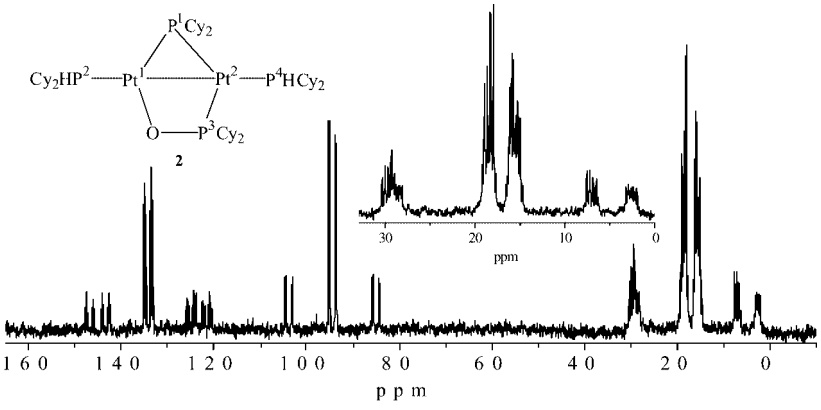

Figure 1. $^{31}P\{^1H\}$ NMR spectrum of **2** (161 MHz, 295 K, C_6D_6).

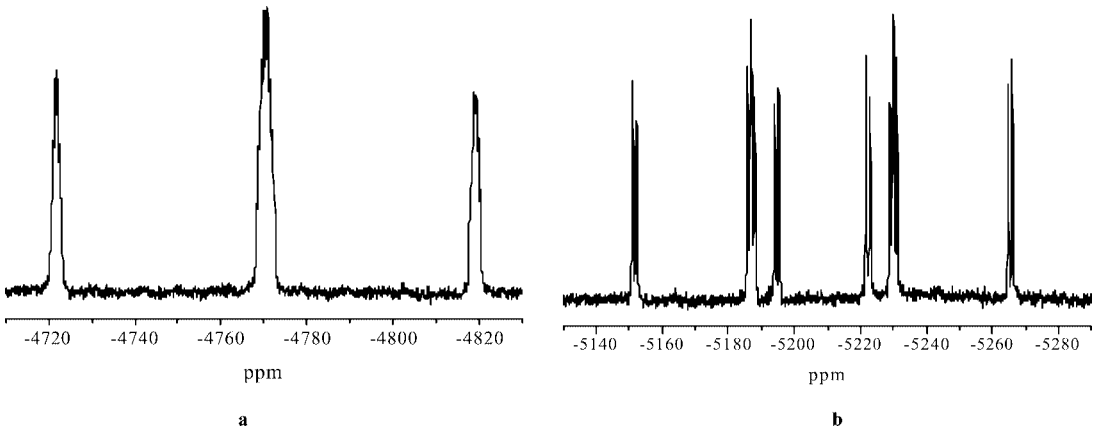

Figure 2. $^{195}Pt\{^1H\}$ NMR spectrum of **2** (295 K, C_6D_6). a: Pt^1; b: Pt^2.

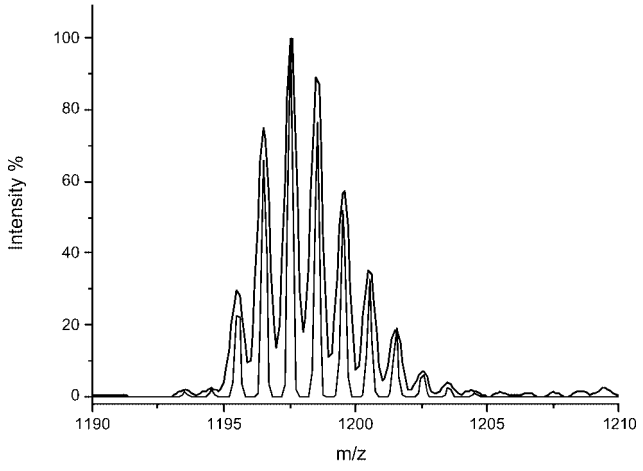

Figure 3. ESI-MS spectrum of **2** (bottom trace: calculated).

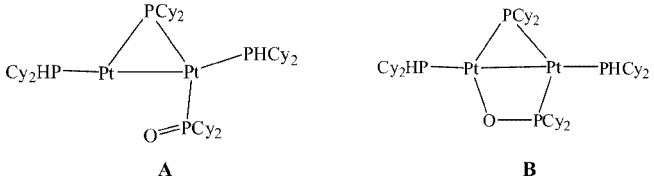

Figure 4. Possible structures of **2**.

(*Pt–Pt*)[3] or $[(Cy_2PH)(Cl)Pd(\mu\text{-}PCy_2)Pd(Cy_2PH)_2]$-(*Pd–Pd*)[18] (Supporting Information, ESI 2) are characterised by broad $^{31}P\{^1H\}$ NMR signals for all ligands except the bridging PCy_2, a feature that was ascribed to hindered rotation of the $PHCy_2$ ligands about the metal–P bond. The sharp signals found in the $^{31}P\{^1H\}$ NMR of **2** (Figure 1) favour structure **B**, in which both $PHCy_2$ (in particular that bound to Pt^2) have more room to freely rotate around the Pt–P bonds.

The presence of a Pt–P–O–Pt ring in **2** is corroborated by the literature. In fact, XRD analysis of the related Pt^I complex $[Pt(\kappa^2P,O\text{-}\mu\text{-}OPPh_2)(PMePh_2)]_2$ showed that each platinum atom is involved in a four-membered Pt–P–O–Pt ring.[19]

Finally, equilibrium between structures **A** and **B** seems unlikely because the signals found in the $^{195}Pt\{^1H\}$ NMR spectrum recorded at 195 K did not differ significantly from those found at 295 K.

The reaction of **1** with solid sodium methoxide (2 equiv.) in toluene at room temperature gave the symmetric dimer *trans*-$[Pt(PHCy_2)Cl(\mu\text{-}PCy_2)]_2$ (**3**) as the main product (82% yield).[20] Complex **3** was characterised by multinuclear NMR, IR, ESI-MS and elemental analysis. The appearance of an AA′XX′ spin system in the $^{31}P\{^1H\}$ NMR spectrum for the isotopomer not containing ^{195}Pt substantiates the *trans* geometry of the complex. Computer simulation of the spectrum, using as starting chemical shifts and coupling constants those extractable directly from the experimental spectrum,[21] gave the spectroscopic features reported in Table 1 (Supporting Information, ESI 3–4). The values found for $^3J_{P^{A'},Pt^1} = {}^3J_{P^A,Pt^2}$, for $^2J_{P^X,P^{X'}}$ and for $^3J_{P^A,P^X} = {}^3J_{P^{A'},P^{X'}}$ are consistent with a planar geometry of the Pt_2P_2 core.[22]

Table 1. Spectroscopic features for **3** ($CDCl_3$, 295 K).

	P^A	$P^{A'}$	P^X	$P^{X'}$	Pt^1	Pt^2
P^A	15.1	4.2	357.3	9.2	1948	79
$P^{A'}$	4.2	15.1	9.2	357.3	79	1948
P^X	357.3	9.2	–137.9	–150.8	2048	2399
$P^{X'}$	9.2	357.3	–150.8	–137.9	2399	2048
Pt^1	1948	79	2048	2399	–4014	
Pt^2	79	1948	2399	2048		–4014

The analogous palladium(II) complex *trans*-$[Pd(PHCy_2)$-$Cl(\mu\text{-}PCy_2)]_2$ is the reaction product between *cis*-$PdCl_2(PHCy_2)_2$ and 1 equiv. NaOPh and reacts at 50 °C with 1 more equiv. NaOPh to afford the bis(dicyclohexyl)-phenylphosphinito palladium(I) complex $[(PhOPCy_2)Pd(\mu\text{-}PCy_2)]_2$.[23] This reaction is not transferable to our system because **3** was recovered unaltered after 24 h stirring with 2 equiv. NaOMe in toluene at 50 °C (Scheme 2). A possible

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

explanation for the different reactivity of *trans*-[Pd(PHCy$_2$)Cl(μ-PCy$_2$)]$_2$ and **3** might reside in a different strength of the metal–Cl bond. IR stretching of the Pd–Cl bond (275 cm^{-1}) is in fact 14 cm^{-1} red-shifted with respect to that of the Pt–Cl in **3** (289 cm^{-1}).

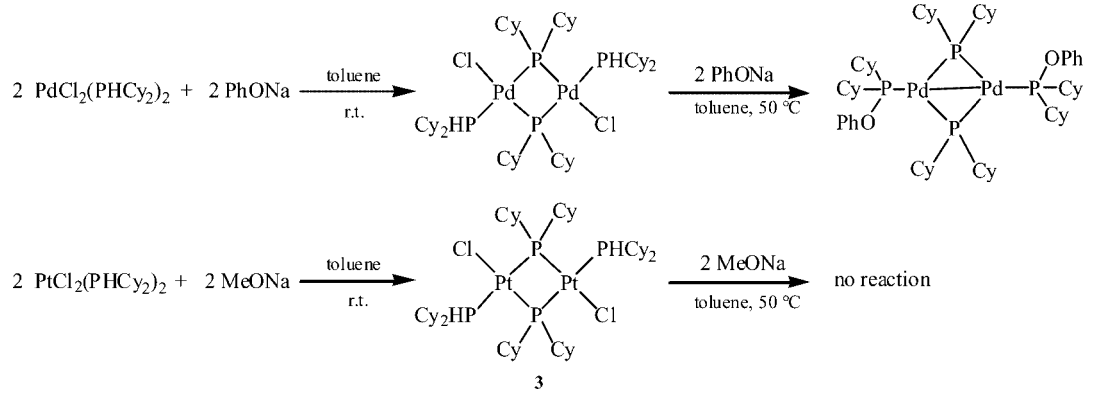
The reaction of **1** with excess NaOMe (5 equiv.) in toluene/methanol at room temperature for 1 day afforded, after work-up, a mixture of products made up of the asymmetric Pt^{I} complex [(PCy$_2$H)Pt(μ-PCy$_2$)$_2$Pt(PCy$_2$OMe)](*Pt–Pt*) (**4**, 60%), the symmetric Pt^{I} dimer [(PCy$_2$OMe)Pt(μ-PCy$_2$)]$_2$-(*Pt–Pt*) (**5**, 35%) and traces of **3** (Scheme 3).

Complex **4** showed in the ^{31}P{^{1}H} NMR spectrum two low field signals and one signal in the region of coordinated PHCy$_2$ (each flanked by ^{195}Pt satellites due to isotopomers containing one or two NMR active Pt atoms). The low field signals are a doublet of doublets centred at δ = 245.7 and a doublet of triplets centred at δ = 173.6. Both signals are due to phosphorus atoms not directly bound to hydrogens (comparison with proton coupled spectra) and are easily assigned, the first to a dicyclohexylphosphido group involved in three-membered rings, and the second, according to ^{1}H NMR and ESI-MS data, to a coordinated PCy$_2$OMe. The remaining signal is a doublet of triplets (further split in the proton-coupled spectrum due to the 318 Hz $^{1}J_{P,H}$) centred at δ = 19.1 ascribed to a coordinated PHCy$_2$. The ^{1}H NMR spectrum showed, beside resonances due to cyclohexyl protons, a doublet at δ = 3.94 [3 H, $^{3}J_{P,H}$ = 13 Hz] ascribable to the methyl group of the coordinated PCy$_2$-OMe and a doublet of multiplets due to the hydrogen directly bound to the phosphorus of the coordinated PCy$_2$H [δ = 6.36, $^{1}J_{P,H}$ = 318 Hz]. The two ^{195}Pt{^{1}H} NMR signals of the atoms directly bound to PHCy$_2$ and PCy$_2$OMe were mutually coupled [$^{1}J_{Pt,Pt}$ = 337 Hz)] and were centred at δ = –5530 and δ = –5570 respectively.

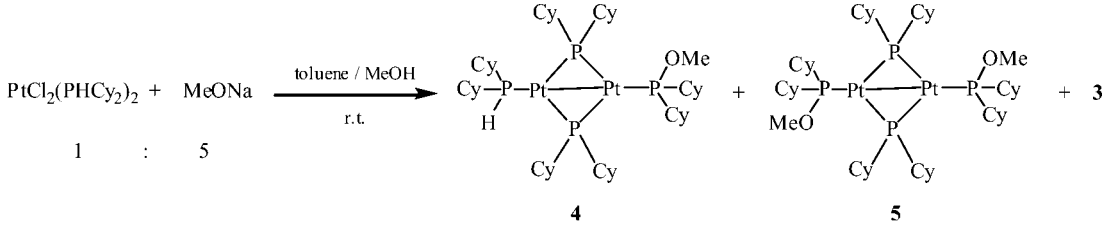
The symmetric dimer **5** showed in the ^{31}P{^{1}H} NMR spectrum the signal of the bridging phosphide at δ = 245.3 and that of the terminal methyl dicyclohexylphosphinite at δ = 171.2. The ^{195}Pt{^{1}H} NMR spectrum consisted of a doublet of triplets centred at δ = –5570 ppm.

Prolonging to 7 days the stirring time of the reaction between **1** and excess NaOMe described above resulted in the synthesis of the dimer **5** as the main product, devoid of the asymmetric complex **4**. This result prompted us to monitor the reaction by ^{31}P{^{1}H} NMR in order to ascertain whether **4** is the precursor of **5**, so as to shed some light on the reaction mechanism. The spectrum recorded after 30 min reaction showed the transformation of **1** into *cis*-Pt(PHCy$_2$)$_2$(OMe)$_2$ (**6**) and traces of **3**. Prolonging the reaction time resulted in the progressive decrease of signals due to **6** with contemporary appearance of signals due to **5**, which became predominant after 2 days.

Complex **6** gave a singlet with ^{195}Pt satellites in the ^{31}P{^{1}H} NMR spectrum [δ = 7.2, $^{1}J_{P,Pt}$ = 3267 Hz], which split into a doublet in the proton-coupled spectrum [$^{1}J_{P,H}$ = 341 Hz)]. The corresponding ^{195}Pt{^{1}H} NMR spectrum consisted in a triplet centred at δ = –4233 [$^{1}J_{P,Pt}$ = 3267 Hz]. Experiments carried out in deuterated solvent allowed assignation of the ^{1}H NMR resonance of the coordinated Cy$_2$P*H* [δ = 3.6, $^{1}J_{H,P}$ = 341 Hz] and OC*H*$_3$ [δ = 3.5, $^{4}J_{H,P}$ = 3.9 Hz; $^{3}J_{H,Pt}$ = 25 Hz]. Complex **6**, which is very soluble in the reaction mixture so as to prevent its precipitation at low temperature, could not be isolated in a pure state because of its fast and irreversible transformation into **4** during solvent removal either by reduced pressure or by bub-



Scheme 2.



Scheme 3.

bling of inert gas. This explains our experimental results: the starting complex **1** reacts with excess methoxide to give **6** (and traces of **3**, which does not further react), which slowly transforms into **5**. If the reaction is stopped when **6** is still present (e.g. 1 day), work-up of the crude results in the formation of a mixture containing **4** (formed mainly during solvent removal) and **5**. Complex **4** could be obtained in a pure state after work-up of the reaction of **1** with excess NaOMe (8 equiv.) in toluene/methanol at room temperature, and **5** could be obtained in 67% yield after 6 h by reacting **1** with excess NaOMe (8 equiv.) in toluene/methanol at 50 °C. Longer reaction times resulted in lower isolated yields because of decomposition of **5** into unidentified products.

Slow evaporation of a toluene solution of **5** deposited yellow-orange crystals suitable for single-crystal X-ray diffraction. The structure of a molecule in the crystal is shown in Figure 5. Significant bond lengths and angles are given in Table 2. The complex crystallises in the monoclinic space group $P2_1/c$. The molecule contains an inversion centre, and therefore the Pt_2P_2 quadrilater with angles of 110.30(4)° and 69.70(4)° is planar for reasons of symmetry; the OCH_3 oxygen atoms also lie in this plane within experimental error. The presence of a Pt–Pt bond is evidenced by an intermetal distance of 2.6307(5) Å, which is comparable with the 2.6127(6) Å and 2.604(1) Å Pt–Pt distances of $[(Pt^tBu_2H)Pt(\mu\text{-}P^tBu_2)_2Pt(CO)]$(*Pt–Pt*)[24] and $[(PPh_3)Pt(\mu\text{-}PPh_2)_2Pt(PPh_3)]$(*Pt–Pt*)[25] respectively. The average Pt–Pt bond length for 66 error-free observations in the CSD[26] amounts to 2.633 Å.

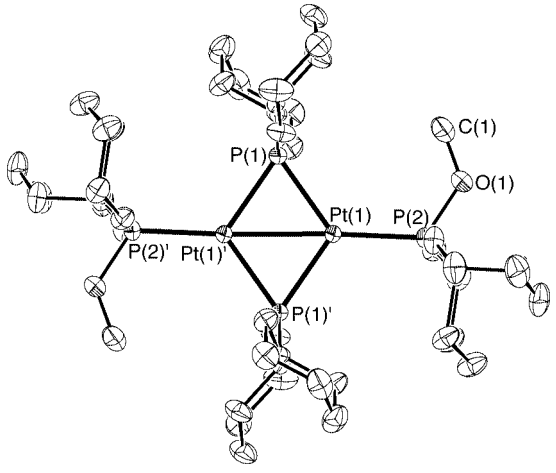


Figure 5. Displacement ellipsoid plot of **5**;[27] ellipsoids are scaled to 30% probability, H atoms have been omitted for clarity.

The Pt–P_μ distances (2.30 Å) are longer than Pt–P_t [2.2150(14) Å]. The external angle P(1)′–Pt(1)–P(2) [122.17(5)°] is smaller than P(1)–Pt(1)–P(2) [127.53(5)°] because of a rather short (2.01 Å) and repulsive H···H contact between a methoxy hydrogen and a H atom of a cyclohexyl substituent bonded to P(1).

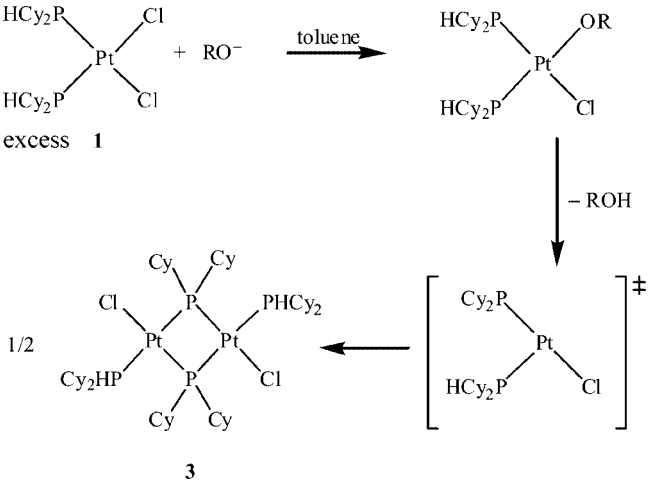
The reactivity shown by **1** towards NaOEt parallels that found for NaOMe: the reaction of **1** with 8 equiv. EtONa at 50 °C in a toluene/ethanol mixture afforded $[(PCy_2OEt)Pt(\mu\text{-}PCy_2)]_2$(*Pt–Pt*) (**7**) in 55% yield after only 2 h. However, because of the higher reactivity shown by EtONa, in this case it was not possible to isolate the asymmetric complex $[(PCy_2H)Pt(\mu\text{-}PCy_2)_2Pt(PCy_2OEt)]$(*Pt–Pt*) (**8**) in a pure state. It was observed in mixture with **7** and characterised in solution by multinuclear NMR spectroscopy.

Table 2. Selected bond lengths [Å] and angles [°] for **5**.

Pt(1)–P(2)	2.2150(14)
Pt(1)–P(1)′	2.2982(15)
Pt(1)–P(1)	2.3058(14)
Pt(1)–Pt(1)′	2.6307(5)
P(2)–O(1)	1.626(4)
C(1)–O(1)	1.365(7)
P(1)–Pt(1)–P(2)	127.53(5)
P(1)′–Pt(1)–P(2)	122.17(5)
Pt(1)′–Pt(1)–P(1)	55.01(4)
Pt(1)′–Pt(1)–P(1)′	55.29(4)
Pt(1)′–Pt(1)–P(2)	177.45(4)

The experimental data presented so far allow some mechanistic considerations to be put forward.

A possible explanation for the selectivity towards **3** of the reaction between **1** and NaOMe (2 equiv.) in toluene could be the accumulation, in these conditions, of the monosubstituted methoxo complex *cis*-$PtCl(OMe)(PHCy_2)_2$, which can dimerise to **3** by loss of methanol (Scheme 4). Such accumulation could derive from the constant lack of methoxide present in the reaction medium, because of its scarce solubility in toluene. Complex *cis*-$PtCl(OMe)(PHCy_2)_2$ could be detected by recording $^{31}P\{^1H\}$ NMR spectra of CD_2Cl_2 solutions of **1**, to which an equimolar amount of NaOMe was added. The solution showed, along with the singlets of residual **1** and **6**, two mutually coupled [$^2J_{P,P}$ = 15 Hz] doublets centred at δ = 17.3 [$^1J_{P,Pt}$ = 3814 Hz] and δ = 8.7 [$^1J_{P,Pt}$ = 2942 Hz] attributable to the P *trans* to Cl and P *trans* to OMe respectively. Analogous results were obtained by using NaOEt instead of NaOMe as limiting reagent. In this case the spectroscopic features of *cis*-$PtCl(OEt)(PHCy_2)_2$ are δ = 16.6 [$^1J_{P,Pt}$ = 3734 Hz, P *trans* to Cl] and δ = 7.4 [$^1J_{P,Pt}$ = 2966 Hz, P *trans* to OEt] [$^2J_{P,P}$ = 18 Hz].



Scheme 4. Proposed mechanism for the formation of **3**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

As to the formation of the alkylphosphinito Pt^{I} dimers observed when the reaction was carried out in the presence of excess NaOR (R = H, Me, Et), a possible mechanism is depicted in Scheme 5.

The initially formed metathesis product *cis*-$Pt(PHCy_2)_2(OR)_2$ can formally lose ROH, giving the terminal phosphido species **a**. The latter can give rise to an intramolecular process involving the metal, the coordinated RO group and the coordinated terminal phosphide, resulting in the phosphinito intermediates **b**. When R is an alkyl group, intramolecular oxidative addition of the P–H bond to Pt followed by hydrogen elimination and dimerisation (path 1) would account for the observed formation of the symmetric dimers $[(PCy_2OR)Pt(\mu\text{-}PCy_2)]_2$(*Pt–Pt*). The sequence of reactions leading from **b** to $[(PCy_2OR)Pt(\mu\text{-}PCy_2)]_2$(*Pt–Pt*) has already been proposed for the synthesis of several analogous systems.[3,18,28]

When R is H, the intramolecular oxidative addition of the P–H bond to Pt is disfavoured by the co-presence in the hypothetically formed $Pt(PCy_2)(H)(PCy_2OH)$ of a strongly basic centre (the terminal phosphide) and an acidic proton ($Cy_2PO\mathit{H}$). Reaction of **a** with **b** (R = H, path 2) can give intermediate **c**, which evolves into the final product **2** after loss of water and ring closure.

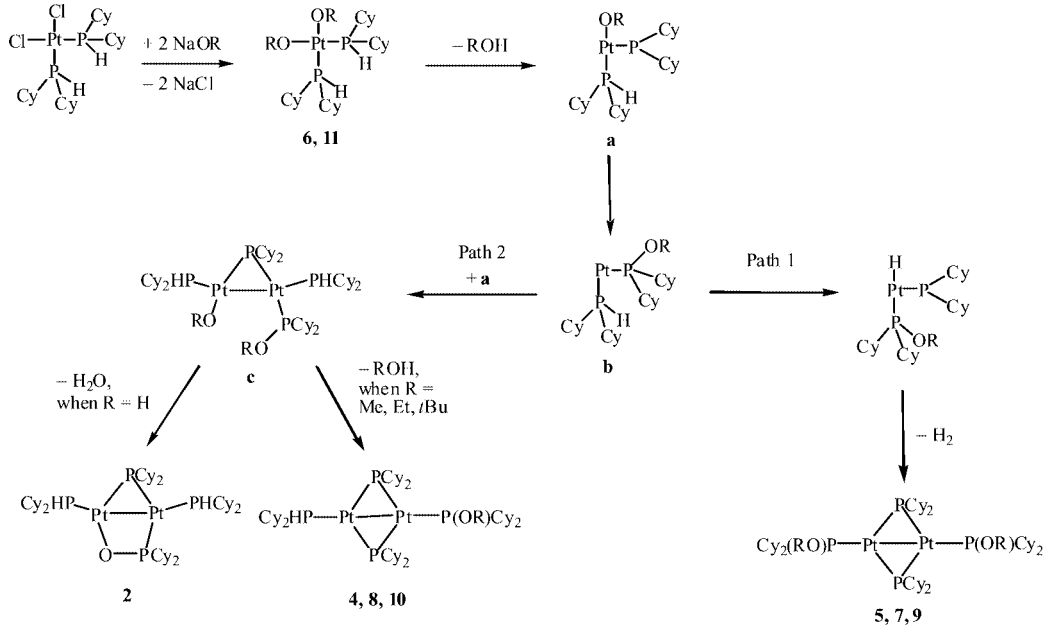
The central point of the suggested mechanism is the metal assisted formation of the P–O bond that leads to the dicyclohexylphosphinito ligands. In the literature, few examples can be found of such a transformation. In particular, the following have been reported: (*i*) $PhOPCy_2$ from $PHCy_2$ and phenoxide ion coordinated to palladium;[23] (*ii*) $MeOPPh_2$ from PPh_2Im (Im = 1-methylimidazole) and methoxide coordinated to ruthenium;[29] (*iii*) 1-phenyl-3*H*-2,1-benzoxaphosphole from *o*-(diphenylphosphanyl)benzyl alkoxide coordinated to platinum;[30] (*iv*) (4-methylphenyl)-dimethylphosphinite from PMe_3 and 4-methylphenoxide coordinated to ruthenium;[31] (*v*) MeOP(Ph)R (R = H, Ph, OMe) from $PPhR^-$ coordinated to osmium and methoxide.[32] In all cases the formation of the P–O bond is explained in terms of intramolecular [intermolecular in case *v*] attack of RO^- on a coordinated phosphide (or phosphane), substantially identical to our proposal for the transformation of **a** into **b**.

Path 2 of Scheme 5 could also explain the formation of the asymmetric complexes $[(PCy_2H)Pt(\mu\text{-}PCy_2)_2Pt(PCy_2OR)]$(*Pt–Pt*), which could be derived from intermediate **c** (R = Me, Et) after loss of alcohol and ring closure. The circumstance that the asymmetric compounds formed only when reaction mixtures containing significant amounts of complexes *cis*-$Pt(PHCy_2)_2(OR)_2$ were evaporated can be explained by the fact that, under reaction conditions, the transformation from **a** to **b** is fast, so that **a** never accumulates in the reaction medium. Putting mixtures containing *cis*-$Pt(PHCy_2)_2(OR)_2$ under vacuum would progressively enhance the amount of **a** in solution, rendering the formation of **c** competitive with Path 1.

The transformation of *cis*-$Pt(PHCy_2)_2(OR)_2$ into **a** when R is Me or Et deserves comment. It is known that mononuclear dimethoxo Pt^{II} complexes are unstable and give aldehyde, alcohol and traces of CO.[9] In our case, intermediate **a** could form either by alcohol elimination or a dehydrogenative pathway consisting in the formation of Pt hydride with loss of aldehyde and subsequent loss of H_2 (Scheme 6).

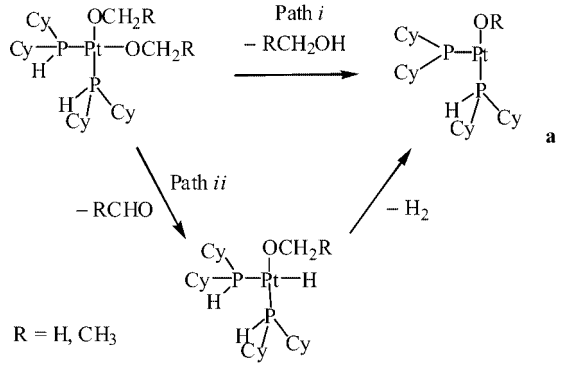
In order to ascertain which of the above-mentioned pathways is operative in our system, we have carried out reactions between **1** and phenoxide or *tert*-butoxide, two bases incapable of forming the aldehyde contemplated by path *ii*.

The reaction of **1** with NaOPh (8 equiv.) in toluene at 50 °C for 1 day afforded the symmetrical Pt^{I} dimer $[(PCy_2OPh)Pt(\mu\text{-}PCy_2)]_2$(*Pt–Pt*) (**9**), whereas the asymmetric Pt^{I} complex $[(PCy_2H)Pt(\mu\text{-}PCy_2)_2Pt(PCy_2O\mathit{t}Bu)]$(*Pt–Pt*) (**10**)



Scheme 5. Proposed mechanism for reactions carried out with excess NaOR.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 6.

was the main product of the reaction of **1** with NaO*t*Bu (8 equiv.) in toluene at 50 °C.

Although the dehydrogenative pathway *ii* of Scheme 6 cannot be conclusively ruled out when NaOMe or NaOEt were the bases, these findings indicate that the loss of alcohol (path *i*) can be responsible (as in the cases of NaOPh or NaO*t*Bu) for the transformation of *cis*-Pt($PHCy_2$)$_2$-$(OR)_2$ into the intermediate Pt($PHCy_2$)(PCy_2)(OR) (**a**).

The diverse behaviour observed passing from NaOPh to NaO*t*Bu can be explained on the basis of the high difference in basicity exhibited by the two oxygenated bases and further supports the mechanism proposed. In fact, according to Scheme 5, the formation of asymmetric monophosphinito dimers is related to the contemporary presence in solution of significant amounts of intermediates **a** and **b**. In the case of NaOPh the formation of **a** is disfavoured because of the low basicity of phenoxide[33] and it is presumable that as soon as it forms it gives **b**, which evolves into **9**. On the contrary, with the very strong base NaO*t*Bu, the loss of *t*BuOH leading to **a** is very fast, so that path 2 of Scheme 5 becomes predominant.

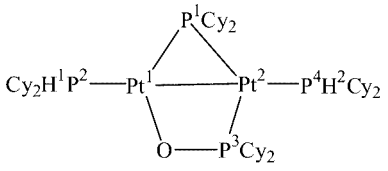
In conclusion, the presence of the relatively weak P–H bonds determines a rich reactivity of **1** with oxygenated bases. Depending on the base and on the experimental conditions it is possible to address the reaction towards the phosphido-bridged Pt^{II} complex **3**, the asymmetric alkyl dicyclohexylphosphinito complexes **4**, **8**, **10** or the bis dicyclohexylphosphinito complexes **5**, **7**, **9**. Using NaOH resulted in the smooth formation of a Pt^{I} complex, showing a rare example of a Pt–P–O–Pt ring.

Experimental Section

General Remarks: All manipulations were carried out under pure dinitrogen, using freshly distilled, thoroughly dehydrated and oxygen-free solvents. All aromatic deuterated solvents were carefully dehydrated (molecular sieves) and deoxygenated (freeze and pump). *cis*-Dichlorobis(dicyclohexylphosphane)platinum(II) (**1**) was prepared as described in ref.[3].

C, H elemental analyses were carried out on a Eurovector CHNS-O Elemental Analyser. Cl elemental analysis was performed by potentiometric titration using a Metrohm DMS Titrino. Melting points were measured with a Gallenkamp apparatus and are uncorrected. Infrared spectra were recorded with a Bruker Vector 22 spectrometer. THF (CH_2Cl_2 in the case of **3**) solutions of the complexes were infused with a Cole-Parmer syringe pump. All the ESI-MS spectra were recorded with an Agilent LC/MS SL series instrument adopting the following general conditions: electrospray, positive ions, flow rate 0.200 mL min^{-1}, drying gas flow 4.0 l min^{-1}, nebuliser pressure 25 psi, drying gas temperature 300 °C, capillary voltage 4000 V, mass range 400–1400 *m*/*z*. The isotopic pattern was calculated by the Isotope Pattern Viewer software, downloadable free of charge from the www.surfacespectra.com website. NMR spectra were recorded with a BRUKER Avance 400 spectrometer; frequencies are referenced to Me_4Si (^1H and ^{13}C), 85% H_3PO_4 (^{31}P) and H_2PtCl_6 (^{195}Pt). NMR simulation was performed using the program WINDAISY.

[(Cy_2PH)Pt(μ-PCy_2)(κ^2*P*,*O*-μ-Cy_2PO)Pt(Cy_2PH)](*Pt*–*Pt*) (2): An aqueous solution of NaOH (0.7 mL, 0.90 M) was added to a vigorously stirred colourless CH_2Cl_2 solution (10 mL) of *cis*-[Pt($PHCy_2$)$_2$-Cl_2] (0.203 g, 0.306 mmol) at room temperature. After 3 days the yellow organic phase was separated, washed twice with water and dried on Na_2SO_4. After filtration the solvent was evaporated to dryness under reduced pressure, affording 152 mg of pure **2** as a yellow powder (83%). The complex was air sensitive in solution, very soluble in dichloromethane, toluene and *n*-hexane and scarcely soluble in acetone. $C_{48}H_{90}OP_4Pt_2$ (1197.28): calcd. C 48.15, H 7.58; found C 48.25, H 7.60. LC-MS: exact mass calcd. for $C_{48}H_{90}OP_4Pt_2$: 1196.52 amu; found: 1197.5 [M + H]$^+$. M.p. 135 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 2279 (w, P–H), 2252 (w, P–H), 1024 (s, P=O) cm^{-1}. ^1H NMR (400 MHz, C_6D_6, 295 K): δ = 5.68 [m, $^1J_{H(2),P(4)}$ = 310, $^2J_{H(2),Pt(2)}$ = 53 Hz, H(2)], 4.85 [m, $^1J_{H(1),P(2)}$ = 323, $^2J_{H(1),Pt(1)}$ = 112 Hz, H(1)] ppm. $^{31}P\{^1H\}$ NMR (161 MHz, C_6D_6, 295 K): δ = 134.4 [sharp ddd, $^2J_{P(1),P(2)}$ = 48, $^2J_{P(1),P(3)}$ = 229, $^2J_{P(1),P(4)}$ = 54, $^1J_{P(1),Pt(1)}$ = 4091, $^1J_{P(1),Pt(2)}$ = 2985 Hz, P(1)], 94.6 [sharp ddd, $^2J_{P(3),P(1)}$ = 229, $^3J_{P(3),P(2)}$ = 29, $^2J_{P(3),P(4)}$ = 5, $^1J_{P(3),Pt(2)}$ = 3061, $^2J_{P(3),Pt(1)}$ = 42 Hz, P(3)], 18.5 [broad ddd, $^2J_{P(4),P(1)}$ = 54, $^3J_{P(4),P(2)}$ = 112, $^2J_{P(4),P(3)}$ = 5, $^1J_{P(4),Pt(2)}$ = 3682, $^2J_{P(4),Pt(1)}$ = 83 Hz, P(4)], 15.9 [broad ddd, $^2J_{P(2),P(1)}$ = 48, $^3J_{P(2),P(3)}$ = 29, $^3J_{P(2),P(4)}$ = 112, $^1J_{P(2),Pt(1)}$ = 4230, $^2J_{P(2),Pt(2)}$ = 107 Hz, P(2)] ppm. $^{195}Pt\{^1H\}$ NMR (86 MHz, C_6D_6, 295 K): δ = –4798 [dddd, $^1J_{Pt(1),P(1)}$ = 4091, $^1J_{Pt(1),P(2)}$ = 4230, $^2J_{Pt(1),P(3)}$ = 42, $^2J_{Pt(1),P(4)}$ = 83 Hz, Pt(1)], –5205 [dddd, $^1J_{Pt(2),P(1)}$ = 2985, $^2J_{Pt(2),P(2)}$ = 107, $^1J_{Pt(2),P(3)}$ = 3061, $^1J_{Pt(2),P(4)}$ = 3682 Hz, Pt(2)] ppm.



***trans*-Dichlorodi-μ-cyclohexylphosphidobis(dicyclohexylphosphane)-platinum(II) (3):** A suspension of *cis*-[Pt($PHCy_2$)$_2$$Cl_2$] (0.564 g, 0.85 mmol), CH_3ONa (0.092 g, 1.70 mmol) in toluene (20 mL) was vigorously stirred at room temperature (21 °C) for 3 days. The resulting pale yellow suspension was evaporated under reduced pressure. The residue was washed twice with *n*-hexane and the product was extracted with 10 mL CH_2Cl_2. Evaporation of the solvent afforded *trans*-[Pt($PHCy_2$)(PCy_2)Cl]$_2$ as a white powder (0.439 g, 82%). The complex was air stable, very soluble in dichloromethane and chloroform, scarcely soluble in toluene and insoluble in *n*-hexane. $C_{48}H_{90}Cl_2P_4Pt_2$ (1252.18): calcd. C 46.04, H 7.24, Cl 5.66; found C 46.15, H 7.25, Cl 5.68. LC-MS: exact mass calcd. for $C_{48}H_{90}Cl_2P_4Pt_2$: 1250.5 amu; found: 1251.5 [M + H]$^+$. M.p. >300 °C. IR (nujol mull): $\tilde{\nu}_{max}$ = 2337 (m, P–H), 289 (m, Pt–Cl) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$, 295 K): δ = 3.9 (m, $^1J_{H,P}$ = 322,

X-ray Data Collection, Structure Solution and Refinement of 5:[34] Crystal data, parameters for intensity data collection and convergence results are compiled in Table 3. A yellow platelet of approximate dimensions 0.20 × 0.11 × 0.04 mm was studied at room temperature with a BRUKER-AXS SMART APEX diffractometer. An empirical absorption correction[35] was applied before averaging symmetry-related reflections. The structure was solved by direct methods[36] and refined on F^2.[37]

Synthesis, Structure and Magnetic Properties of a Novel Linear Cu^{II}-Trimer Complex

Vladimir Pashchenko,*[a] Bernhard Brendel,[a] Bernd Wolf,[a] Michael Lang,[a] Konstantin Lyssenko,[b] Olga Shchegolikhina,[b] Yulia Molodtsova,[b] Larisa Zherlitsyna,[c] Norbert Auner,*[c] Florian Schütz,[d] Marcus Kollar,[d][‡] Peter Kopietz,[d] and Neil Harrison[e]

Keywords: Copper / Cluster compounds / Sandwich complexes / Magnetic properties

A new hexanuclear copper(II) sandwich complex based on two 10-membered macrocyclic phenylsiloxanolate ligands, $\{Cu_6[(C_6H_5SiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(DMF)\cdot 3(H_2O)$ (**1**), was synthesized and characterized by single-crystal X-ray diffraction and measurements of the magnetic susceptibility and isothermal magnetization. The cluster compound crystallizes in the triclinic system, space group $P\bar{1}$ (No. 2), with a = 14.925(3) Å, b = 16.745(2) Å, c = 23.053(3) Å, α = 83.079(9)°, β = 84.836(13)°, γ = 65.019(17)°, and Z = 2. The unit cell contains two identical molecules, each consisting of six interacting Cu^{2+} (S = 1/2) ions. Within the molecule, the six Cu^{2+} ions are arranged in two almost linear, parallel trimers. While pairs of oxygen atoms link the Cu^{2+} ions within the trimers, single oxygen atoms residing at the ends of the trimers provide the strongest intertrimer bonds. Magnetic measurements reveal an antiferromagnetic *intra*trimer exchange interaction, J/k_B = 85 K, as the dominant magnetic coupling of the complex. By introducing a weak antiferromagnetic *inter*trimer coupling, J'/k_B = 3.5 K, a satisfactory description of the magnetic behavior over a wide range of temperature and magnetic field is obtained. The departure of the model curves from the data at the lowest available temperature indicates the presence of additional, weak *intra*- and/or *inter*molecular interactions.

Introduction

The synthesis of new magnetic clusters with unprecedented spin topologies is a central topic in the field of molecular magnetism. Among different strategies that have been developed, serendipitous assembly[1] and rational design[2] represent opposite limiting approaches. Following on from the latter route, the rational construction of heptanuclear clusters with high-spin ground states has been reported very recently, starting from hexacyanometalates $[M(CN)_6]^{3-}$ (M = Cr, Fe) and mononuclear complexes bearing a capping ligand.[2]

Moreover, a decanuclear copper(II) cluster, $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot[Cu(tmpa)CN]_4\}\cdot(PF_6)_4$ (**2**) [tmpa = tris(2-pyridilmethyl)amine], was designed and synthesized by a self-assembly between a hexacopper(II) siloxanolate cage and the monomeric complex $[Cu(tmpa)CN]\cdot(PF_6)$.[3] This cluster compound exhibits interesting magnetic properties with a low-lying S = 5 state arising from a unique spin arrangement.

In the past decade, a widespread series of copper-containing siloxanolate complexes was synthesized and structurally characterized,[4] basically showing two different types of structural features: a sandwich-like molecular structure was found for $\{K_4[\{(RSiO_2)_6\}_2Cu_4]\}\cdot 4(n\text{BuOH})$ [R = Et (**3**),[4a] Ph[4b]] and $\{Cu_6[(PhSiO_2)_6]_2\}\cdot 6(L)$ [L = EtOH (**4**),[4c] L = DMF (**5**)[4d]]. These clusters are composed of two 12-membered (6 Si + 6 O) stereoregular organosiloxanolate fragments, *cis*-$[RSi(O)O^-]_6$, linked together through four or six copper atoms. In contrast, compounds such as $\{Na_4[(PhSiO_2)_{12}Cu_4]\}\cdot 8(n\text{BuOH})$ (**6**),[4e,4f] $\{M_4[(ViSiO_2)_{12}Cu_4]\}\cdot m(n\text{BuOH})$ [M = K, Vi = vinyl, m = 6 (**7**);[4e] M = Na, m = 4 (**8**)[4f]] and $\{Na_4[(EtSiO_2)_{12}Cu_4]\}\cdot 4(n\text{BuOH})$[4g] are based on a 24-membered stereoregular organosiloxanolate fragment $[RSi(O)O^-]_{12}$ (R = Et, Vi, Ph) of tris-*cis*-tris-*trans* configuration and fixed in the "horse saddle" conformation

by four Cu and four alkaline metal atoms. Investigations of the magnetic properties of the globular tetranuclear complex $\{Na_4[(PhSiO_2)_{12}Cu_4]\}\cdot 8(n\text{BuOH})$ (**6**) and the sandwich-like tetranuclear complex $\{K_4[\{(EtSiO_2)_6\}_2Cu_4]\}\cdot 4(n\text{BuOH})$ (**3**), as well as the hexanuclear sandwich complex $\{Cu_6[(PhSiO_2)_6]_2\}\cdot 6(\text{EtOH})$ (**4**), revealed that the six copper ions in **4** are ferromagnetically coupled with a total spin $S = 3$, whereas strong antiferromagnetic Cu–Cu interactions with an $S = 0$ ground state were detected in the tetranuclear complexes **3** and **6**. These experimental findings prompted us to recrystallize complex **6** with additional ligands that would assemble the molecular unit into a supramolecular structure with new physical properties. Thus, recrystallization of **6**, which contains four sodium ions along with four copper ions, in DMF as solvent and in the presence of 2,2′-bipyridine (bipy), was performed. Unexpectedly, a completely new hexanuclear Cu complex with a sandwich-like structure not containing any alkaline metal ions was obtained.

Here we report the synthesis, structural and magnetic properties of a novel hexacopper(II) siloxanolate cluster compound $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(\text{DMF})\cdot 3(H_2O)$, which is unique in that the six Cu^{2+} ions are arranged in two parallel 3-site strings, that is, coupled $S = 1/2$ trimers. A preliminary account of the work has been published in ref.[5]

Results and Discussion

According to Scheme 1, the hexanuclear Cu sandwich complex **1**, which is based on 10-membered *cis*-pentaphenylcyclopentasiloxanolate ligands, was obtained by recrystallization of a tetranuclear Cu complex **6**, which is based on a 24-membered dodecaphenylcyclododecasiloxanolate ligand of tris-*cis*-tris-*trans* configuration possessing the globule-like structure $\{Na_4[(PhSiO_2)_{12}Cu_4]\}\cdot 8(n\text{BuOH})$,[4e,4f] in DMF and in the presence of 2,2′-bipyridine (bipy) at about 30 °C.

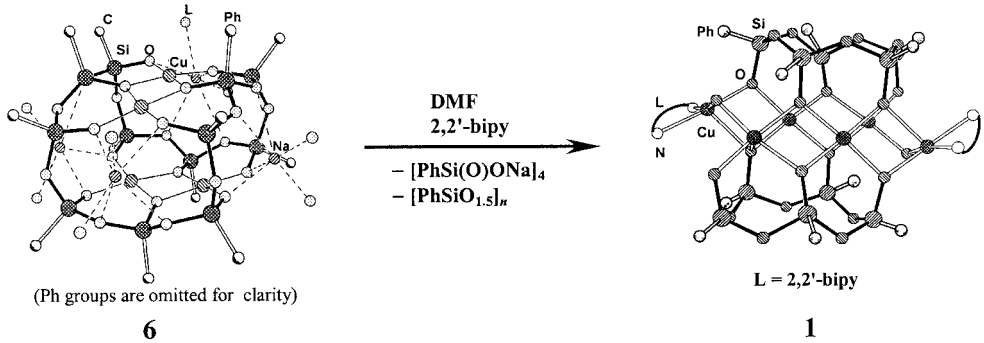
Under these experimental conditions, the initial complex **6** underwent a dramatic rebuilding with a formation of complex **1**, no longer containing alkaline ions in yields up to 92%. Crystals of sodium phenylsiloxanolate and of polyhedral phenylsilsesquioxane can easily be separated from the blue crystals of **1** (crystal size ca. 1 mm) and were detected as by-products of the complex formation.

The surprising transformation of complex **6** into **1** is reproducible, but strongly depends on the reaction conditions. The amount of 2,2′-bipyridine is of great importance on product formation. While from the stoichiometric ratio of 1 × complex **6**/4 × bipy in DMF, $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(\text{DMF})\cdot 3(H_2O)$ (**1**) is obtained, mixtures of 1 × **6**/2 × bipy in DMF and toluene gave $\{Cu_6[(PhSiO_2)_6]_2\}\cdot 6(\text{DMF})$, and without toluene the complex $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 3(\text{DMF})$ was isolated. Reaction of **6** with bipy in DMF in a molar ration of 1:1 gave $\{Cu_6[(PhSiO_2)_6]_2\}\cdot 6(\text{DMF})$. DMF was not especially dried prior to use. Performing the two months' recrystallization in an open system, even the moisture from air might influence the product formation, resulting in the introduction of different amounts of hydroxy ligands and water into the crystals. All the compounds formed have been fully characterized by single-crystal X-ray analysis and will be published elsewhere.[6] These very complex reaction pathways are currently being investigated in detail in our laboratories.

Crystal Structure of $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(\text{DMF})\cdot 3(H_2O)$ (1)

Complex **1** exhibits a sandwich-like structure (Figure 1) and consists of two pentaphenylcyclopentasiloxanolate ligands connected by six Cu^{II} atoms arranged in a $Cu_6O_{10}(OH)_2$ moiety (Figure 2). Notably, this is the first example of a metallasiloxane with an odd number of Si–O units in the siloxanolate rings, which seem to predominantly determine the structural and physical features of the complex.

The two 10-membered siloxanolate $(Si–O)_5$ rings are coaxial and shifted in respect to each other and to the central $Cu_6O_{10}(OH)_2$ segment (Figure 1). The siloxanolate cycles are characterized by an envelope conformation with the deviation of Si(2) or Si(9) atoms from the plane of the remaining silicon atoms by 0.52 and 0.60 Å, respectively. The Ph groups exhibit an all-*cis* arrangement. The Si–O bond lengths vary in the range of 1.591(2)–1.652(2) Å, which is usual for this class of compounds.[7] The $Cu_6O_{10}(OH)_2$ segment is built up of two almost parallel Cu–O_2–Cu–O_2–Cu–



Scheme 1.

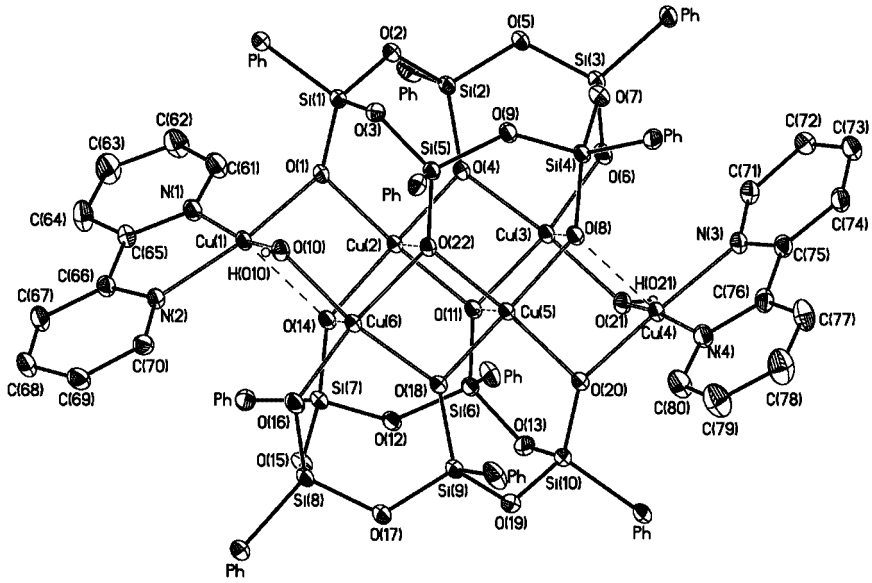


Figure 1. General view of complex **1** (50% probability ellipsoids). Ph groups are omitted for clarity. The dashed lines indicate the apical coordination of copper atoms.

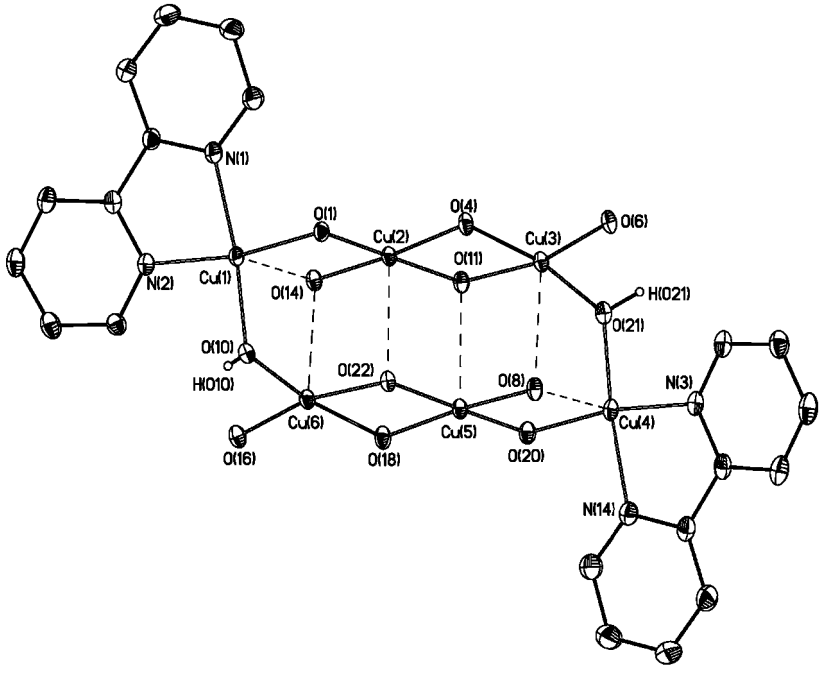

Figure 2. The $Cu_6O_{10}(OH)_2 \cdot bipy_2$ moiety in **1**.

(O,OH) layers. The three copper atoms within the layer form a nearly linear trimer with a Cu–Cu–Cu angle of 173.5(1)° (Figure 2). The nonbonded Cu···Cu distances in the trimer are within the range of 2.9931(6)–3.0310(6) Å, which is significantly longer than corresponding distances described earlier in the sandwich-like copperphenylsiloxanes $\{Cu_6[(PhSiO_2)_6]_2\} \cdot 6(EtOH)$ (**4**),[4c] $\{Cu_6[(PhSiO_2)_6]_2\} \cdot 6(DMF)$ (**5**),[4d] and $\{[Cu_6\{(PhSiO_2)_6\}_2] \cdot [Cu(tmpa)CN]_4\} \cdot (PF_6)_4$ (**2**),[3a] yielding an average value of about 2.82 ± 0.03 Å.

The coordination surrounding of the copper atoms in the layers is different and consists of solely siloxanolate oxygen atoms [for Cu(2), Cu(5)], siloxanolate and hydroxyl oxygen atoms [Cu(3), Cu(6)], or, finally, siloxanolate as well as hydroxyl oxygen atoms and bipyridyl nitrogen atoms [Cu(1), Cu(4)].

Despite the differences in the coordination environment of the copper atoms, all of them exhibit a slightly distorted square-pyramidal (SP) configuration. An analogous configuration of Cu^{II} atoms was found earlier for sandwich-

like (phenylsiloxane)copper compounds **2**, **4**, and **5**. For globular-type copper-containing organosiloxanolates $\{Na_4[(PhSiO_2)_{12}Cu_4]\}\cdot 8(n\text{BuOH})$ (**6**), $\{K_4[(ViSiO_2)_{12}Cu_4]\}\cdot 6(n\text{BuOH})$ (**7**), and $\{Na_4[(ViSiO_2)_{12}Cu_4]\}\cdot 4(n\text{BuOH})$ (**8**), a square-planar configuration was determined.[4e,4f] It should be noted that in compounds **2**, **4**, or **5** the copper–oxygen moieties are organized in cyclic forms and the SP configuration arises from the apical bonding with solvent (**4**, **5**) or organometallic cluster (**2**) molecules. In contrast, for complex **1** the apical positions are occupied by oxygen atoms of the $Cu_6O_{10}(OH)_2$ segment.

The equatorial Cu–O bonds in **1** vary in the range of 1.907(2)–2.013(2) Å (average value 1.95 Å) (Table 1), which is close to the expected values for copper atoms with an SP coordination environment. In the recently reported sandwich-type complex **2**, it was demonstrated that the Cu–O bond lengths in the basal plane for SP [1.909(5)–2.005(4), av. 1.96 Å] and square-planar coordination [1.876(5)–1.922(5), av. 1.90 Å] are different.[3a] The Cu–N bonds in **1** are 1.999(2)–2.015(2) Å long.

Table 1. Selected bond lengths and angles in the $Cu_6O_{10}(OH)_2$ segment of **1**.

Bond lengths [Å]

Cu(3)–O(11)–Cu(5)	88.66(6)	Cu(6)–O(22)–Cu(2)	87.21(6)

The apical positions of all copper polyhedra in **1** are occupied by siloxanolate oxygen atoms and the bonds are always significantly longer than the equatorial ones. Regarding the Cu(1) and Cu(4) atoms, the apical positions [O(14) and O(8), respectively] are occupied by siloxanolate oxygen atoms of the same layer with the Cu–O bonds being 2.242(2) and 2.182(2) Å long, while for all other copper atoms the apical oxygen atom belongs to the adjacent layer. The apical Cu–O bonds between layers vary in the range of 2.413(2)–2.593(2) Å, the shortest one being the Cu(6)–O(14) bond.

Interestingly, such an architecture of a copper–oxide moiety with Cu–O interlayer interactions is rather rare. Thus, in the series of globular-like copper-containing organosiloxanes **6**, **7**, and **8**, the corresponding interlayer Cu···O distances are in the range of 3.371(5)–3.899(3) Å, which fully excludes any interlayer bonding.

The Cu–O–Cu angles, which mainly determine the magnetochemical behavior of polynuclear clusters, differ within a Cu–O_2–Cu–O_2–Cu–(O,OH) layer and between the layers significantly. For a single layer, these angles are close to 100°, with the exception of one angle, the Cu(1)–O(14)–Cu(2) angle, for example, for the top layer, which is equal to 93.13(6)° (Table 1). In contrast, the Cu–O–Cu angles formed by copper atoms of different layers are closer to 90°, with the exception of two angles at the hydroxy oxygen atoms O(10) and O(21) [108.59(8)° and 110.94(9)°, respectively]. It is interesting that the range of Cu–O–Cu angles of **1** contains all of the corresponding angles typical for other copper-containing organosiloxanes. Thus, Cu–O–Cu angles for sandwich-like (phenylsiloxane)copper compounds **4** and **5** are close to 100°, while in globular-type **6**, **7**, and **8** they are approximately equal to 90°.

The analysis of the crystal packing in **1** revealed that the stacking of the bipyridyl cycles is the only direct intercomplex interaction. Because of the overlap of the π-systems, neighboring complexes are arranged into stacking-bonded chains parallel to the [011] direction (Figure 3). It should be noted that the interplanar distances (3.43 and 3.22 Å) between the bipyridyl ligands are rather short[8] and a significant π-orbital overlap between adjacent complexes can be expected.

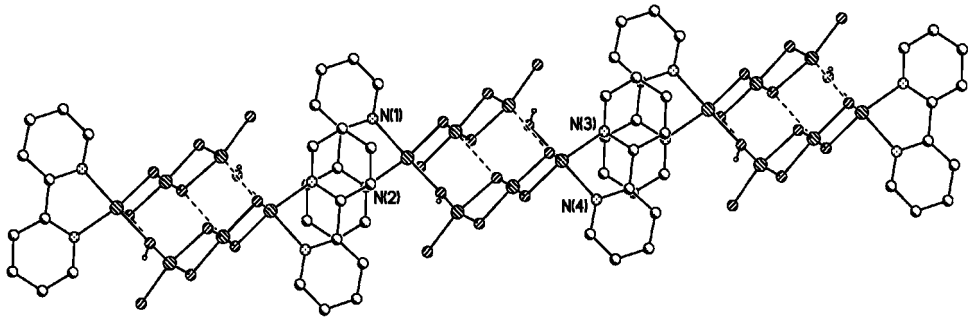

Figure 3. Illustration of the stacking-bonded chains in **1**.

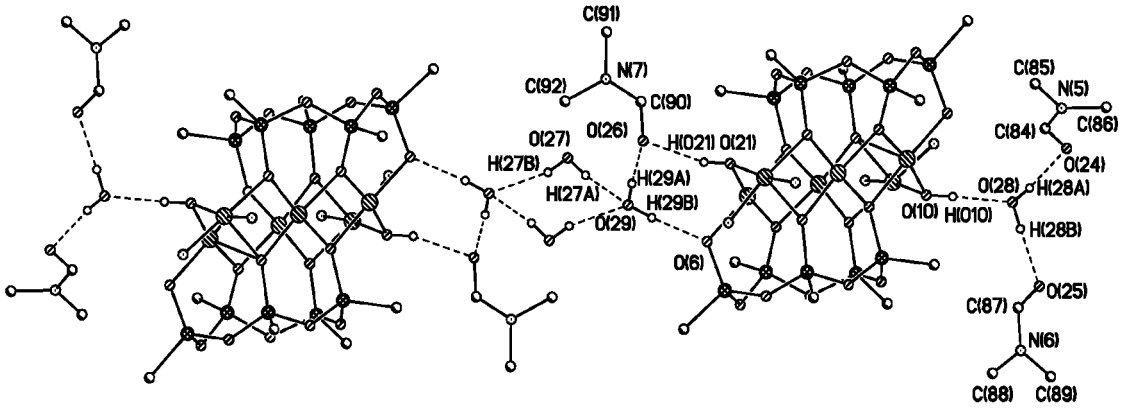

Figure 4. The O–H···O mediated bridging of adjacent complexes in crystals of **1**.

Additionally, the complexes in **1** are connected by intermolecular O–H···O bonds [O···O 2.717(3)–2.894(3) Å] of solvate water molecules (Figure 4). The combination of H-bonding and stacking interactions results in a layered supramolecular arrangement in the crystal.

Magnetic Properties

Magnetic susceptibility and magnetization measurements were performed on polycrystalline samples of $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(DMF)\cdot 3(H_2O)$ (**1**). The data were corrected for the contribution of the sample holder and for the diamagnetic core contribution. Notably, the temperature-independent diamagnetic contribution of $\chi_{dia} = -2\times10^{-3}$ cm^3/mol, determined by analyzing the high-temperature magnetic behavior, is in reasonable agreement with the core contribution of $\chi_{core} = -1.7\times10^{-3}$ cm^3/mol calculated by using tabulated values for Pascal's constants.[9]

Figure 5 shows the susceptibility $\chi(T) = M(T)/B$ of complex **1** in a representation $\chi^{-1}(T)$ versus T, where M denotes the magnetic moment of the sample (see also ref.[5]). The data were found to be reversible upon cooling and heating, with no indications of hysteretic behavior. Moreover, no sign of long-range magnetic ordering was observed in the temperature range under investigation.

Figure 5 discloses, to a good approximation, two linear regimes of $\chi^{-1}(T)$ that are separated by a broad crossover range. In an attempt to set up a simple model, capable of describing the main feature of the magnetic susceptibility, these linear sections can be assigned to Curie–Weiss-like temperature dependencies $\chi(T) = C_i\times(T + \theta_i)^{-1}$, with different Curie constants C_i and Weiss temperatures θ_i for the low- (i = LT) and high- (i = HT) -temperature range. At high temperatures of 100–300 K, the best fit reveals C_{HT} = 5.25 cm^3 K/mol and θ_{HT} = 47 K. This Curie constant is consistent with the presence of six Cu^{2+} ions per molecule (two molecules per unit cell) yielding a spin-only value of C_{HT} = 4.96 cm^3 K/mol. The latter number is based on an average spectroscopic g value of 2.09 ± 0.05, as determined by our ESR measurements operated at X- and Q-band frequencies. The positive Weiss constant indicates a dominant antiferromagnetic spin–spin interaction in the high-temperature regime.

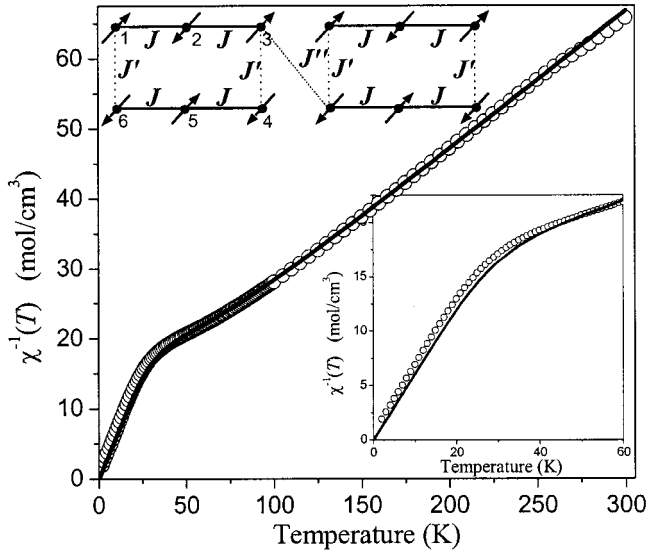

Figure 5. Temperature dependence of the inverse magnetic susceptibility of complex **1** for temperatures 2–300 K. The data have been taken at a magnetic field of 0.05 T. The solid line corresponds to the best fit for the model of isolated, linear S = 1/2 trimers with an antiferromagnetic intratrimer exchange coupling constant J/k_B = 85 K, i.e. $J' = J'' = 0$ in the scheme for the exchange coupling interactions of two adjacent molecules indicated in the upper left of the figure. The inset shows the low-temperature part on expanded scales.

From the linear behavior of $\chi^{-1}(T)$ versus T at low temperatures, that is, in the range 2–15 K, a Curie constant of C_{LT} = 1.61 cm^3 K/mol and an antiferromagnetic Weiss temperature as small as θ_{LT} = 1.05 K were found. A reduction of the Curie constant by a factor close to 3 indicates that the low-temperature magnetic system behaves essentially like an effective "2-spin" S = 1/2 configuration per molecule. In fact, in this case, a Curie constant of 1.65 cm^3 K/mol (for g = 2.09) is expected, which is very close to the C_{LT} value derived from the experiment.

Thus, the magnetic susceptibility of the present hexanuclear complex **1** is reminiscent of that observed in a variety

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of systems containing largely isolated trimers.[10,11] This suggests that the dominant magnetic coupling is provided by an *intra*trimer Cu–Cu exchange interaction J within the 3-site Cu strings (cf. the coupling scheme given in the inset of Figure 5).

In a first approach, which has been discussed also in ref.[5], we therefore consider isolated trimers with a uniform isotropic Heisenberg *intra*trimer exchange coupling constant J and an isotropic g factor described by the spin Hamiltonian given in Equation (1).

$$\hat{H}_3 = J(\hat{\boldsymbol{S}}_1\cdot\hat{\boldsymbol{S}}_2 + \hat{\boldsymbol{S}}_2\cdot\hat{\boldsymbol{S}}_3) - g\mu_B\boldsymbol{B}\cdot(\hat{\boldsymbol{S}}_1 + \hat{\boldsymbol{S}}_2 + \hat{\boldsymbol{S}}_3) \quad (1)$$

The energy spectrum of Equation (1) consists of a doublet ground state separated from an excited doublet and quartet by an energy gap $\Delta = J$ and $3J/2$, respectively (see Figure 6). In Figure 6 the spin states of the isolated trimer are labeled according to the eigenvalues of the square of the total spin operator $\hat{\boldsymbol{S}}_{123} = \hat{\boldsymbol{S}}_1 + \hat{\boldsymbol{S}}_2 + \hat{\boldsymbol{S}}_3$, $\hat{\boldsymbol{S}}_{456} = \hat{\boldsymbol{S}}_4 + \hat{\boldsymbol{S}}_5 + \hat{\boldsymbol{S}}_6$ (the coupling scheme of Figure 5) and an intermediate coupling quantum number, S_{13} and S_{46}, defined through the relations $\hat{\boldsymbol{S}}_{13} = \hat{\boldsymbol{S}}_1 + \hat{\boldsymbol{S}}_3$ and $\hat{\boldsymbol{S}}_{46} = \hat{\boldsymbol{S}}_4 + \hat{\boldsymbol{S}}_6$, respectively.

From the partition function the magnetic susceptibility can be derived in a straightforward way yielding Equation (2), where $x = \exp(-J/2k_BT)$.

$$\chi(T) = \frac{N\mu_B^2g^2}{k_B}\cdot\frac{1}{4T}\cdot\frac{1 + x^2 + 10x^3}{1 + x^2 + 2x^3} \quad (2)$$

The result for the magnetization of the isolated linear trimer can be written as Equation (3), where $h = g(\mu_B/k_B)B$.

$$M(T,h) = N\mu_Bg\cdot\frac{1}{2}\cdot\frac{(1 + x^2 + x^3)s_1 + 3x^3s_3}{(1 + x^2 + x^3)c_1 + x^3c_3} \quad (3)$$

We have used the following shorthand notations: $c_1 = \cosh(h/2T)$, $c_3 = \cosh(3h/2T)$, $s_1 = \sinh(h/2T)$, and $s_3 = \sinh(3h/2T)$. In the limit $J\rightarrow\infty$ or $T << J/k_B$, that is, $x\rightarrow 0$, the trimer is locked into a spin-1/2 state and $M(T,h)$ reduces to the spin-1/2 Brillouin function $B_{1/2}(T,h) = (1/2)\tanh(h/2T)$. On the contrary, for vanishing exchange coupling J or $T >> J/k_B$, that is, for $x\rightarrow 1$, the spins of the trimer are independent and $M(T,h)$ can easily be shown to be equivalent to $3B_{1/2}(T,h)$.

Fitting Equation (2) to the susceptibility data in Figure 5 for temperatures between 300 and 25 K, we find a good overall agreement (solid line in Figure 5) for an antiferromagnetic *intra*trimer exchange coupling constant of $J/k_B = 85\pm1$ K (see also ref.[5]). Figure 5 demonstrates that the simple trimer model according to Equation (1) covers the main features of the susceptibility, in particular the increase of the slope of $\chi^{-1}(T)$ by a factor of 3, that is, a reduction of the Curie constant by 2/3, upon cooling. However, a closer look at the low-temperature behavior in Figure 5 (cf. inset) discloses deviations of the model curve from the data, indicating the presence of additional, weaker interactions such as the intertrimer (J') and/or intermolecular couplings (J'') indicated in Figure 5.

A finite trimer–trimer interaction can, indeed, be expected because of the presence of the hydroxy oxygen atoms O(10) and O(21), which may provide an exchange path between the terminal Cu^{II} atoms of adjacent trimers (see Figure 2). Likewise, weak trimer–trimer interactions can arise through the apical oxygen atoms O(14), O(22), O(11), and O(8). Because the latter exchange paths involve rather long Cu–O bonds ranging from 2.413 to 2.593 Å, we expect their coupling strength to be much weaker than those of the above Cu(1)–O(10)–Cu(6) and Cu(3)–O(21)–Cu(4) bonds (cf. Table 1). In a second step we thus model the trimer–trimer interactions by introducing the coupling constant J' that links the ends of the linear trimers within the molecule (cf. the coupling scheme indicated in the upper left of Figure 5).

The resulting Hamiltonian of such an isolated 6-spin $S = 1/2$ assembly, that is, two coupled trimers, then reads as Equation (4).

$$\hat{H}_6 = J(\hat{\boldsymbol{S}}_1\cdot\hat{\boldsymbol{S}}_2 + \hat{\boldsymbol{S}}_2\cdot\hat{\boldsymbol{S}}_3 + \hat{\boldsymbol{S}}_4\cdot\hat{\boldsymbol{S}}_5 + \hat{\boldsymbol{S}}_5\cdot\hat{\boldsymbol{S}}_6) + J'(\hat{\boldsymbol{S}}_1\cdot\hat{\boldsymbol{S}}_6 + \hat{\boldsymbol{S}}_3\cdot\hat{\boldsymbol{S}}_4) - g\mu_B\boldsymbol{B}\cdot(\hat{\boldsymbol{S}}_1 + \hat{\boldsymbol{S}}_2 + \hat{\boldsymbol{S}}_3 + \hat{\boldsymbol{S}}_4 + \hat{\boldsymbol{S}}_5 + \hat{\boldsymbol{S}}_6) \quad (4)$$

As a consequence of the finite trimer–trimer coupling, the degeneracy of the $S = 1/2$ ground state doublets for the isolated trimers within the molecule is lifted and a singlet ($S = 0$) ground state (for an antiferromagnetic coupling $J' > 0$) is formed, which is separated from the first excited triplet ($S = 1$; $M = 1, 0, -1$) state by a zero-field gap of $(8/9)|J'|$, up to higher order corrections in J'/J (see Figure 6). In case of a ferromagnetic coupling $J' < 0$, the order of the low-lying singlet and triplet states is reversed.

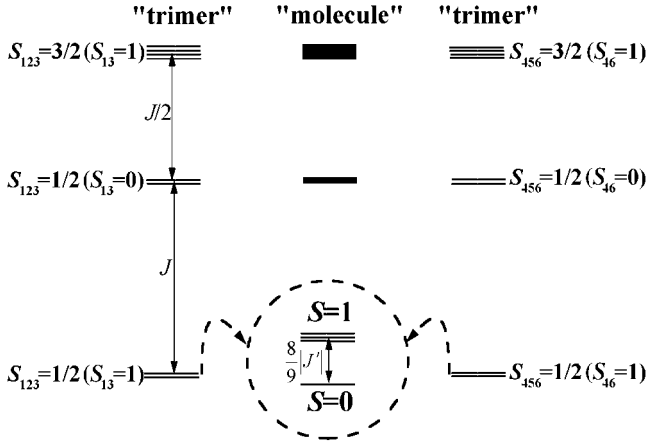

Figure 6. Ground-state splitting of two trimers within the molecule because of antiferromagnetic intertrimer coupling. The spin states of the isolated trimers are labeled as $S(S^*)$. S is the total spin and $S^* = S_1 + S_3$ or $S_4 + S_6$, respectively.

For the magnetic susceptibility, a perturbative approach for $|J'| << |J|$ yields Equation (5), where $x = \exp(-J/2k_BT)$ and $y = \exp(-2J'/9k_BT)$.

$$\chi(T) = \frac{N\mu_B^2g^2}{k_B}\cdot\frac{1}{2T}\cdot\frac{(1 + x^2 + 2x^3)(1 + x^2 + 10x^3) + y - 1}{(1 + x^2 + 2x^3)^2 + (y^{-3} + 3y)/4 - 1} \quad (5)$$

The magnetization is given by Equation (6), where the same shorthands as in Equation (3) are used.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$M(T,h) = N\mu_B g \cdot \frac{[(1 + x^2 + x^3)c_1 + x^3c_3][(1 + x^2 + x^3)s_1 + 3x^3s_3] + (y - 1)c_1s_1}{[(1 + x^2 + x^3)c_1 + x^3c_3]^2 + c_1^2(y - 1) + (y^{-3} - y)/4} \quad (6)$$

Equations (5) and (6) can be checked by comparison with numerical diagonalization for the full model. At least up to $|J'/J| \leq 0.1$, we obtain excellent agreement with the exact result. For $J' = 0$, Equations (5) and (6) result in twice the susceptibility and the magnetization of an isolated trimer given in Equations (2) and (3), respectively, as expected. Note that the influence of J' on susceptibility is rather small and deviations from the pure trimer model become visible only at low temperatures. To visualize the effect of a weak intertrimer coupling on the susceptibility more clearly, the data together with the model curves for the isolated and coupled trimers are plotted in Figure 7 in a representation χT versus T.

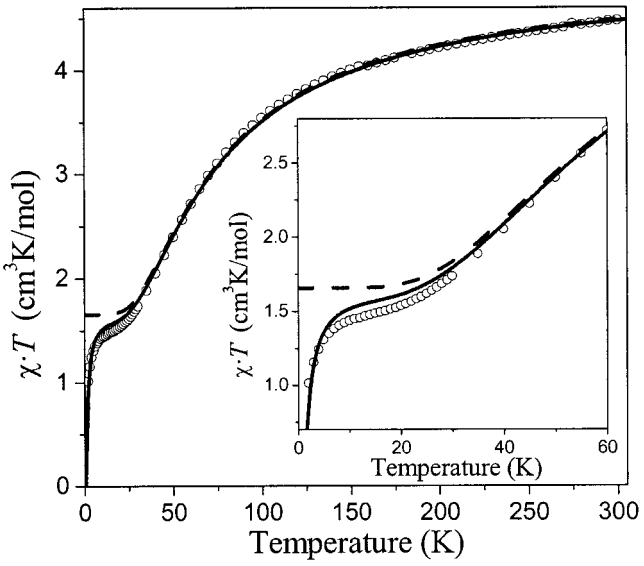

Figure 7. Magnetic susceptibility data of complex **1** taken at a field of 0.05 T plotted as χT versus T. The inset shows the low-temperature behavior on expanded scales. The dashed lines correspond to the best fit for the isolated linear trimer model with $J/k_B = 85$ K; the solid lines are the result of the model for antiferromagnetically coupled trimers with $J/k_B = 85$ K and $J'/k_B = 3.5$ K.

Figure 7 shows the best fit for weakly coupled trimers with an *intra*trimer coupling $J/k_B = 85$ K and a weak antiferromagnetic *inter*trimer coupling $J'/k_B = 3.5$ K, while the dashed line indicates the results for the isolated trimer model with $J/k_B = 85$ K. Figure 7 clearly demonstrates that the incorporation of a finite intertrimer coupling J' improves the fit considerably at low temperatures, although small deviations of the model curve from the data are still visible below 30 K. This is most likely due to the presence of additional, weaker interaction pathways between the copper atoms of adjacent trimers such as the coupling through the apical oxygen atoms mentioned above. As has been discussed by Zaspel et al.,[12] who carried out a high-temperature series expansion for the Heisenberg model with the intertrimer coupling constants as expansion parameters, the low-temperature behavior of such a generalized coupled-trimer model depends on the sign combinations and magnitudes of the intertrimer coupling constants. As the above coupled-trimer model covers the main properties of the susceptibility of complex **1** in the temperature range under investigation, we refrain from introducing additional coupling constants at the present stage. This also includes the introduction of a finite intermolecular coupling J'', which does not significantly improve the quality of the fit. Thus, we conclude that the temperature dependence of the magnetic susceptibility of complex **1** can be satisfactorily described by coupled trimers with an average antiferromagnetic trimer–trimer interaction $J'/k_B = 3.5$ K.[13]

Further support for this assignment can be gained from the results of isothermal magnetization measurements (see Figure 8). The figure also shows the calculated magnetization curves for the above-discussed models of isolated [dashed lines, Equation (3)] and antiferromagnetically coupled [solid lines, Equation (6)] trimers. Figure 8 clearly demonstrates that, for temperatures below 20 K, the isolated-trimer model progressively departs from the experimental data. On the other hand, a very good description of the magnetization curves, except the data taken at the lowest temperature of 2 K, is achieved by the model of antiferromagnetically coupled trimers, with the best fit obtained for the parameters $J/k_B = 85$ K and $J'/k_B = 3.4 \pm 0.5$ K. This model also explains the high-field data taken at $T = 4.2$ K, showing a saturation of the magnetization at a value close to $2\mu_B$ per molecule, as expected for two weakly coupled $S = 1/2$ (trimer) states. However, deviations of the above model from the experimental data become visible at the lowest temperature of 2 K for fields $B \geq 2$ T. This indicates the presence of additional weak *intra*- and/or *inter*molecular interactions giving rise to a more complicated low-energy spectrum of this cluster compound. We note that for

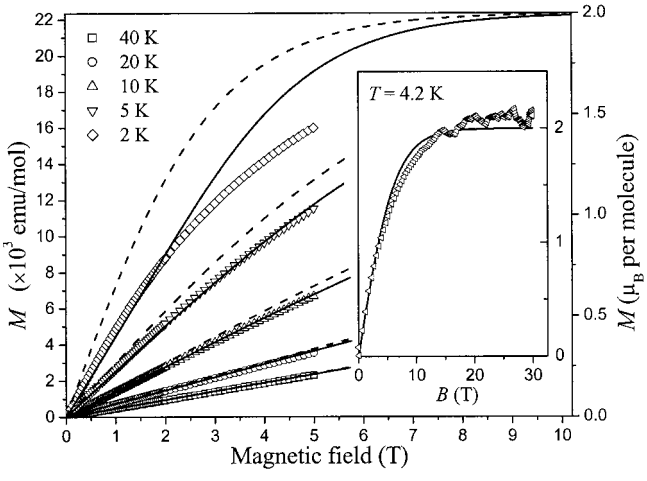

Figure 8. Isothermal magnetization measurements in dc fields from 0 to 5 T (main panel) and pulsed fields from 0 to 30 T (inset) at varying temperatures as indicated in the figure. The right scales of the main panel and inset are given in units of μ_B per molecule. The dashed and solid lines correspond to the model curves for isolated and antiferromagnetically coupled trimers, respectively, with the coupling parameters given in the text.

a ferromagnetic coupling $J' < 0$, as suggested in ref.[5], the initial slope of the corresponding magnetization curves even exceeds that for the isolated trimers (broken lines), which would make the fit worse.

Conclusions

This paper reports on the synthesis, X-ray crystal structure, and magnetic properties of a new hexanuclear copper(II) siloxanolate cluster compound **1**, $\{Cu_6[(C_6H_5SiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(DMF)\cdot 3(H_2O)$. This molecular complex differs from the known hexacopper(II) cluster compounds in its unique $S = 1/2$ trimer arrangement: each molecule contains two linear oxygen-bridged three-site Cu^{II} strings that are parallel to each other.

According to magnetic measurements, an antiferromagnetic *intra*trimer coupling constant marks the dominant magnetic coupling in this complex. Indeed, an $S = 1/2$ Heisenberg trimer model with an isotropic antiferromagnetic exchange coupling $J/k_B = 85$ K covers the main features of the magnetic susceptibility, namely the formation of an effective $S = 1/2$ low-temperature trimer state. This model, however, fails to describe adequately the magnetic behavior at low temperatures. The model can be improved significantly by introducing a weak antiferromagnetic *inter*trimer interaction $J'/k_B = 3.5$ K, giving rise to a singlet ($S = 0$) ground state and a nearby [with energy gap $\Delta = (8/9)|J'|$] excited triplet ($S = 1$) state for the molecules. The small deviations of the model curves from the experimental data at low temperatures indicate the action of additional, weaker magnetic interaction pathways such as additional couplings between the copper atoms of adjacent trimers within a single molecule or a finite *inter*molecular coupling. The latter might originate in the overlap of π-orbitals from the bipyridine groups of adjacent molecules.

Experimental Section

Synthesis of the Hexanuclear Copper Complex $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(DMF)\cdot 3(H_2O)$ (1): A solution of complex **6** (0.5 g, 0.25 mmol), which was prepared as described in ref.[4f], was made up of DMF (25 mL) and 2,2′-bipyridine (0.156 g, 1 mmol) in DMF (25 mL). Within two months, blue crystals precipitated. They were isolated and dried under vacuum (1 Torr, 50 °C). Yield: 0.33 g (91.7%). Anal.: Calcd. for $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot(DMF)$, $[C_{83}H_{75}Si_{10}Cu_6N_5O_{23}]$, %: C 45.88, H 3.49, Si 12.93, Cu 17.55, N 3.22; found, %: C 46.14, H 4.28, Si 12.38, Cu 17.34, N 2.39. Notably, metallasiloxane compounds always contained some amount of solvate molecules. During the separation of the crystals from the mother liquor and during the drying process in vacuo, some of the solvate molecules evaporated. Consequently, the molecular formula determined by X-ray analysis of a single crystal differed from the molecular formula obtained by an elemental analysis including solvate ligands. The composition of the hexanuclear complex **1** was determined by single-crystal X-ray analysis as $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(DMF)\cdot 3(H_2O)$ and by elemental analysis as $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot(DMF)$. Magnetic measurements were performed with crystals directly isolated from the mother liquor and thus corresponding to the formula determined by X-ray analysis.

X-ray Crystallography: The crystallographic data for complex **1**, $\{Cu_6[(PhSiO_2)_5]_2(OH)_2(C_{10}H_8N_2)_2\}\cdot 4(DMF)\cdot 3(H_2O)$, are listed in Table 2. The X-ray diffraction measurements were performed employing a Smart CCD diffractometer (Mo-K_α radiation, graphite-monochromator, ω-scan technique). A numerical absorption correction was carried out based on six indexed crystal faces. The transmission factor ranges from 0.609 to 0.784. The structure was solved by direct methods and refined by full-matrix least squares against F^2 in the anisotropic (H-atoms isotropic) approximation, using the SHELXTL-97 package.[14] The H positions of the Ph groups were calculated from a geometrical point of view, while the methyl and hydroxyl groups and the hydrogen atoms of water molecules were located in the Fourier electron-density synthesis. CCDC-269903 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Magnetic Susceptibility and Magnetization Measurements: Variable-temperature magnetic susceptibility measurements in the temperature range 2–300 K and magnetic fields up to 5 T were carried out using a Quantum Design SQUID magnetometer MPMS-XL. These measurements were complemented by isothermal magnetization runs at temperatures between 2 and 40 K for fields up to 5 T. In addition, pulsed-field magnetization measurements up to 35 T were performed at the NHMFL, Los Alamos, using a wire-wound extraction magnetometer.

[13] In ref.[5], a weak ferromagnetic trimer–trimer coupling $J'/k_B = -7$ K has been claimed from the temperature evolution of the absorption signal in a preliminary ESR study. For such a ferromagnetic coupling $J' < 0$, the order of the low-lying singlet–triplet states in the energy spectrum in Figure 6 is just reversed, resulting in an $S = 1$ ground state. In the presence of additional weak anisotropies in the exchange couplings, which can be expected for the present system, the selection rule is no longer valid, enabling transitions between the singlet and triplet states to be observed by ESR measurements. As a result, the ESR studies are not very sensitive to the difference between a ferromagnetic and an antiferromagnetic coupling, unless the data are available for covering the low-temperature range of the order of $(1/2)J'/k_B$.

A Convenient Synthetic Route for the Preparation of Nonsymmetric Metallo-salphen Complexes

Arjan W. Kleij,*[a] Duncan M. Tooke,[b] Anthony L. Spek,[b] and Joost N. H. Reek*[a]

Keywords: N,O ligands / Nonsymmetric / Salen / Templated synthesis / Zinc

New nonsymmetric metallo(II)-salphen complexes **1**–**6** [salphen = *N*,*N*′-bis(salicylidene)-1,2-diaminobenzene, M = Zn, Ni] have been prepared in high yield by a templated, one-pot two-step procedure starting from substituted *ortho*-phenylenediamines, salicylaldehydes and metal acetates in MeOH under mild conditions. The procedure allows the introduction of functional groups in the bridging phenyl fragment, whereas the use of the substituted monoimine intermediates **7**–**10** results in complexes with two structurally different phenyl side groups with various functionalities (complexes **11**–**21**) upon reaction with a second, different, salicylaldehyde reagent. A range of analytical tools confirmed the structures of these nonsymmetric salphen derivatives and the X-ray molecular structure of one of these nonsymmetric Zn^{II}-salphen complexes (i.e., **4**) is also reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Salen ligands[1] are interesting tetradentate ligands with a rich coordination chemistry. Since the discovery of the effective use of salen-type ligands in the epoxidation of olefins,[2] asymmetric homogeneous catalysis with these systems has been subject of widespread investigations.[3] In order to achieve a constructive transformation of chiral information to a substrate molecule, an effective use of the steric and electronic information of the applied ligand is needed. However, such a desired variation of an asymmetrical ligand is often troublesome and synthetic methods in most cases give rise to a limited number of ligands. Our interest in the salen ligand was recently aroused as the salphen structure [salphen = *N*,*N*′-(phenylene)salicylidene] proved to be a highly useful building block for the construction of supramolecular architectures such as molecular boxes.[4] In these Zn^{II}-salphen complexes the metal ion is located in a nearly planar, rigid N_2O_2 coordination geometry with a vacant axial coordination site. We, and others, have used these planar structures in supramolecular synthesis, where the axial coordination site provides a binding site for suitable N donor systems that allows the construction of multicomponent tailored materials.[5] Beside their use in supramolecular technology, Zn^{II}-salen complexes have also recently gained renewed interest as a result of their scope in a number of catalytic conversions.[6] The blend of these two complementing aspects could launch new opportunities for the construction of catalytically active, functional assemblies.[7] Here, we disclose new, attractive templated methods for nonsymmetrical M^{II}-salphen building blocks, that circumvent the isolation of the salphen ligand prior to metalation.[8] The variation of the steric and electronic features using these flexible procedures will be demonstrated by the introduction of different (functional) groups that ultimately can be used to fine-tune the (donor) properties of the nonsymmetric ligand backbone.

Results and Discussion

The synthetic approach towards nonsymmetric Zn^{II}-salphen complexes **1**–**6** is outlined in Scheme 1. Commercially available, mono-substituted *ortho*-phenylene diamines or diamino-pyridines were used as starting materials.[4] Generally, the aldehyde and phenylene diamine precursors combined with a metal precursor $M(OAc)_2 \cdot nH_2O$ (M = Zn: $n = 2$; M = Ni: $n = 4$) were mixed in the appropriate stoichiometry to afford in a one-pot two step protocol complexes **1**–**6**. In most cases, the product could be simply isolated by one filtration step and isolation of the ligands prior to metalation is thus not necessary. This procedure therefore allows the introduction of functional groups in the phenyl bridge of the salphen structure and also different metal ions can be incorporated concomitantly (cf. complex **6**).

The molecular structure for Zn^{II}-salphen complex **4** was determined by X-ray crystallography (Figure 1). Interestingly, complex **4** is, unlike **1**–**3**, only moderately soluble in

toluene and CH_2Cl_2 and re-crystallization was achieved from hot toluene. X-ray quality crystals were, however, only obtained from a mixture of hot acetone/pyridine.[9] As expected from our previous studies using the Zn^{II}-salphen structure as a supramolecular building block through axial pyridine ligation,[4,5] complex **4** was analysed as its pyridine adduct under these conditions. Obviously, the presence of an internal pyridine donor in both **4** and **5** could provoke intermolecular association through supramolecular Zn–N_{pyr} interactions, which could account for their low solubility in the common organic solvents. In the presence of an excess of an external pyridine donor the intermolecular association is broken and monomeric **4**·pyridine was obtained exclusively this way. The LC-MS analysis for **5** also revealed the presence of an intensive peak for the dimeric species $[2M^+ + H]$, whereas for other Zn^{II}-salphen species in this work with small 3- and/or 3′-substituents present in the salphen backbone these species were not observed or with very low intensity. These dimeric species observed under the mass spectrometric conditions are generally associated to a dimerization process involving the O atoms of the individual monomers.[10] Obviously, this dimerization process is not only dependent on the size of the salphen substituents, but will also be influenced by the presence of nitrogen donor atoms such as in pyridines (vide supra, Figure 1) and the presence of donor solvents such as acetonitrile (cf. LC-MS studies, Exp. Sect.). The lower solubility features found for **4** and **5** are thus accountable for the presence of larger, associated species. It should be noted that their respective NMR spectra were recorded in the presence of solvent(s) combinations able to compete with this association behav-

iour (for, **4**: [D_5]pyridine and for **5**: [D_6]dmso) leading to the predominant observation of monomeric Zn^{II}-salphen complexes.[11]

The coordination geometry around the central zinc atom (Figure 1) is best described as distorted square pyramidal. Interestingly, the distances Zn(1)–N(2) and Zn(1)–N(4) are identical within experimental limits [2.1168(11) Å vs. 2.1164(12) Å], while the remaining Zn(1)–N(1) bond length is significantly shorter [2.0620(11) Å]. This leads to a non-symmetrical positioning of the Zn^{II} center above the N_2O_2 plane since both the Zn–O distances are rather similar [1.9755(9) and 1.9617(10) Å]. The bond length of the axial Zn–N interaction corresponds well with earlier reports on similar Zn^{II}salphen–pyridine interactions in the solid state (Zn–N distance in the range 2.10–2.14 Å),[4,12a] but is somewhat longer than communicated for Zn–pyridine interactions based on cyclohexyl-bridging salen ligands [Zn–N = 2.089(3) Å].[12b]

The introduction of functional entities in the aromatic bridge of the salphen structure was achieved by using a step-wise approach starting with the pre-isolation of the monoimine reagents **7**–**10**.[13] The monoimines **8**–**10** were isolated as mixture of regioisomers.[14] Particularly important in the selective isolation of monoimine products is the choice for an excess of the phenylene diamine reagent, and mono Schiff bases **7**–**10** were isolated as yellow to orange crystalline materials in moderate to good yield (26–84%, Scheme 2).[15]

Synthesis of complexes **11**–**15** was carried out with monoimine precursors **7**–**10** and a second aldehyde reagent in the presence of $Zn(OAc)_2{\cdot}2H_2O$ and NEt_3 (see Scheme 3). Complexes **11**–**14** were isolated in high yield (60–94%) while the yield of **15** was low (25%). Interestingly,

the use of dihydroxybenzaldehydes allows the easy introduction of synthetically powerful phenol groups (cf. complexes **13**–**14**). We have previously shown that *meso*-phenol-substituted Zn^{II}porphyrins can be readily converted into their respective tri-phosphite derivatives by treatment with PCl_3 and applied in homogeneously catalysed hydroformylation.[16] One important drawback in these cases, however, is the synthetic accessibility of these Zn^{II}porphyrin complexes and the labour-intensive purification procedures. Thus, Zn^{II}-salphen complexes **13**–**14** represent excellent alternatives and their phenol positions could be used for the preparation of new phosphite/phosphinite ligands and their subsequent application in homogeneous catalysis.

We were also interested in the introduction of larger aromatic groups than phenyl in the salphen structure. Obviously, like in conjugated systems such as porphyrin rings, this could lead to interesting photophysical phenomena.[17] Therefore, we first prepared symmetrical Zn^{II}-salphen complex **16** and **17** as model derivatives and these were isolated in high yield (84% and 96%, respectively) (Scheme 4. The use of monoimine reagents **7** and **9** allows the presence of both phenyl as well as naphthyl groups in the final product (cf. complexes **18**, **19** and **21**) and therefore the photochemical properties can be fine-tuned by simple variation of the polyaromatic reagents and/or monoimine precursor.

Please note that complex **21** represents an interesting chiral Zn^{II}-salphen building block with the chiral information located in (only) one of the aromatic side groups. In principle, this procedure can be extended using different chiral aldehyde/ketone reagents and enables simple variation in the salphen structure. This could open up possibilities for the construction of a new combinatorial libraries of chiral (Zn^{II})salphen-based catalysts, a field which has attracted much recent interest.[6] Additionally, such chiral building blocks could also be used for the construction of optically active, multi-component supramolecular assemblies.[4,5]

In summary, this contribution shows that the salphen structure is a versatile building unit that can be functionalised both at the bridging phenyl unit as well as the aromatic side groups with relative ease. Such new complexes will find their way in further synthesis (e. g. cross-coupling procedures and preparation of phosphite ligands) or can be simply used to fine-tune the electronic/steric properties of the salphen building block. This makes the salphen structure extremely useful for the creation of supramolecular materials and salphen-based homogeneous catalysts.[18] Studies along these lines are currently in progress in our laboratory.

Experimental Section

General: All reactions were carried out in air using commercial solvents, and reagent grade starting materials were purchased and used without purification. Compounds **20**,[19] 5-bromo-3-(*tert*-bu-

tyl)salicylaldehyde[20] and complexes **1** and **2**[4] were prepared according to literature procedures. All NMR spectra were recorded at ambient temperature with a Mercury/Inova (Varian) 300 or 500 MHz spectrometer; chemical shift values (δ) are given in ppm. Elemental analyses were carried out by Dornis und Kolbe, Mikroanalytisches Laboratorium, Mülheim a. d. Ruhr, Germany. MS measurements were carried out in CH_3CN with a Shimadzu LCMS 2010-A spectrometer using atmospheric pressure chemical ionization.

Zn^{II}-salphen Complex 3: A mixture of 4-methoxy-*o*-phenylenediamine (0.51 g, 2.42 mmol), 3,5-bis(*tert*-butyl)salicylaldehyde (1.22 g, 5.21 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (0.56 g, 2.55 mmol) and neat NEt_3 (2 mL) in MeOH (40 mL) was stirred at room temp. for 24 h. Then the product was isolated as reported for complexes **1** and **2** to furnish, after trituration with pentane, a yellow-orange solid (1.17 g, 76%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.31 [s, 18 H, $C(CH_3)_3$], 1.53 [s, 18 H, $C(CH_3)_3$], 3.90 (s, 3 H, OCH_3), 6.93 [d, ^3J(H,H) = 8.9, $^3J_{H,H}$ = 2.7 Hz, 1 H, ArH], 7.21 (d, $^4J_{H,H}$ = 2.1 Hz, 1 H, ArH), 7.23 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.40 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.43 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.47 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.86 (d, $^3J_{H,H}$ = 9.0 Hz, 1 H, ArH), 9.01 [s, 1 H, C(H)=N], 9.10 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone): δ = 31.86, 31.93, 34.42, 36.29, 55.96, 101.43, 113.97, 117.59, 119.29, 119.41, 124.03, 124.37, 124.71, 129.32, 130.16, 130.44, 134.37, 134.56, 136.97, 137.26, 142.13, 142.39, 149.44, 149.82, 150.19, 159.91, 162.11, 171.56, 172.35 ppm. UV/Vis (toluene, c = 0.844 mg/50 mL): λ_{max} (ε) = 428 nm (22400 $mol^{-1}\,dm^3\,cm^{-1}$). MS (LC-MS, direct inlet, CH_3CN, APCI): m/z = 632 [M^+ + H], 674 [M^+ + H + CH_3CN]. $C_{37}H_{48}N_2O_3Zn$ (632.30): calcd. C 70.07, H 7.63, N 4.42; found C 69.92, H 7.74, N 4.32.

Zn^{II}-salphen Complex 4: A mixture of 2,3-diaminopyridine (0.47 g, 4.31 mmol), 3,5-bis(*tert*-butyl)salicylaldehyde (2.09 g, 8.92 mmol) and $Zn(OAc)_2{\cdot}2H_2O$ (1.13 g, 5.15 mmol) in MeOH (40 mL) was stirred at room temp. for 18 h. Then the product was collected by filtration to furnish a deep orange solid (2.19 g, 84%). ^{1}H NMR (300 MHz, [D$_6$]acetone/5% [D$_5$]pyridine): δ = 1.31 [s, 9 H, $C(CH_3)_3$], 1.33 [s, 9 H, $C(CH_3)_3$], 1.55 [s, 9 H, $C(CH_3)_3$], 1.56 [s, 9 H, $C(CH_3)_3$], 7.24 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.26 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.31 (dd, $^3J_{H,H}$ = 4.8 Hz, 1 H, pyr-H), 7.49 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.51 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 8.27 (d, $^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 1.4 Hz, 1 H, pyr-H), 8.33 (d, $^3J_{H,H}$ = 4.7, $^4J_{H,H}$ = 1.4 Hz, 1 H, pyr-H), 9.15 [s, 1 H, C(H)=N], 9.61 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_2$]dichloromethane/5% [D$_5$]pyridine): δ = 29.90, 31.63, 31.66, 34.30, 36.16, 118.72, 118.64, 122.23, 123.23, 129.57, 130.43, 130.71, 131.00, 135.01, 135.09, 135.51, 142.81, 142.85, 146.03, 151.54, 163.71, 164.56, 172.20, 173.33 ppm. UV/Vis (DMF, c = 0.928 mg/50 mL): λ_{max} (ε) = 433 nm (25900 $mol^{-1}\,dm^3\,cm^{-1}$). MS (LC-MS, direct inlet, CH_3CN, APCI): m/z = 603 [M^+ + H], 644 [M^+ + H + CH_3CN], 683 [M^+ + H + 2CH_3CN]. $C_{35}H_{45}N_3O_2Zn$ (603.28): calcd. C 69.47, H 7.50, N 6.94; found C 69.27, H 7.40, N 7.06.

Zn^{II}-salphen Complex 5: A yellow solution of 3,4-diaminopyridine (0.42 g, 3.85 mmol), salicylaldehyde (0.98 g, 8.02 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (0.84 g, 3.83 mmol) and NEt_3 (1 mL) in MeOH (40 mL) was stirred at room temp. for 18 h. In due course, an orange suspension was obtained, which was filtered to furnish the product as an orange solid. Yield: 1.32 g (90%). ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 6.52–6.56 (m, 2 H, ArH), 6.73 (d, $^3J_{H,H}$ = 8.5 Hz, 2 H, ArH), 7.25–7.32 (m, 2 H, ArH), 7.42 (dd, $^3J_{H,H}$ = 8.5 Hz, 2 H, ArH), 7.86 (d, $^3J_{H,H}$ = 5.0 Hz, 1 H, pyr-H$_{meta}$), 8.49 (d, $^3J_{H,H}$ = 5.3, $^4J_{H,H}$ = 1.5 Hz, 1 H, pyr-H$_{ortho}$), 9.12, 9.14, 9.16 [3×s, 3 H, 2×C(H)=N and other pyr-H$_{ortho}$] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]DMSO): δ = 110.88, 113.43, 113.68, 119.34, 119.56, 123.43, 123.74, 135.00, 135.34, 135.87, 136.50, 137.00, 139.19, 145.74, 147.48, 163.89, 165.91, 172.69, 173.79 ppm. UV/Vis (DMF, c = 1.648 mg/50 mL): λ_{max} (ε) = 410 nm (21600 $mol^{-1}\,dm^3\,cm^{-1}$). MS (LC-MS, direct inlet, CH_3CN, APCI): m/z = 377 [M^+ + H], 418 [M^+ + H + CH_3CN], 457 [M^+ + H + 2CH_3CN], 763 [2M^+ + H]. $C_{28}H_{30}N_2O_3Zn$ (379.03): calcd. C 59.94, H 3.44, N 11.04; found C 60.08, H 3.51, N 10.84.

Ni^{II}-salphen Complex 6: To a solution of salicylaldehyde (1.22 g, 10.0 mmol) and 4-trifluoromethyl-*o*-phenylenediamine (0.76 g, 4.31 mmol) in MeOH (50 mL) was added a solution of $Ni(OAc)_2{\cdot}4H_2O$ (1.07 g, 4.30 mmol) in MeOH (15 mL). Slowly a red solid started to precipitate that was collected after 3 h in different fractions. All fractions were combined and dried in vacuo to yield 1.62 g (85%) of **6**. ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 6.67 (dt, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.0 Hz, 2 H, ArH), 6.95 (d, $^3J_{H,H}$ = 8.7 Hz, 2 H, ArH), 7.32–7.39 (m, 2 H, ArH), 7.58 (dt, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.8 Hz, 2 H, ArH), 7.65 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, ArH), 8.31 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, ArH), 8.46 (s, 1 H, ArH), 8.90 [s, 1 H, C(H)=N], 8.99 [s, 1 H, C(H)=N] ppm. ^{19}F NMR (282 MHz, [D$_6$]-acetone): δ = –57.1 ppm. The product was too insoluble for a proper ^{13}C{^{1}H} NMR analysis. UV/Vis (DMF, c = 1.193 mg/50 mL): λ_{max} (ε) = 382 nm (26300 $mol^{-1}\,dm^3\,cm^{-1}$), 485 nm (8750 $mol^{-1}\,dm^3\,cm^{-1}$). MS (LC-MS, direct inlet, CH_3CN, APCI): m/z = 441 [M^+ + H]. $C_{21}H_{13}F_3N_2NiO_2$ (440.03): calcd. C 57.19, H 2.97, N 6.35; found C 56.93, H 3.08, N 6.22.

Monoimine 8: A mixture of 4-chloro-*o*-phenylenediamine (4.31 g, 30.23 mmol) and 3,5-di(*tert*-butyl)salicylaldehyde (2.02 g, 8.62 mmol) in MeOH (100 mL) was stirred at room temp. for 16 h. Then the solution was slowly concentrated upon which the title compound separated as a yellow solid. The product was collected by filtration and dried. Yield: 0.79 g (26%). ^{1}H NMR (300 MHz, [D$_6$]acetone, major isomer): δ = 1.33 [s, 9 H, $C(CH_3)_3$], 1.45 [s, 9 H, $C(CH_3)_3$], 5.05 (br. s, 2 H, NH_2), 6.67 (d, $^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 2.1 Hz, 1 H, ArH), 6.90 (d, $^4J_{H,H}$ = 2.4 Hz, 1 H, ArH), 7.17 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, ArH), 7.47–7.50 (m, 2 H, ArH), 8.84 [s, 1 H, C(H)=N], 13.44 (s, 1 H, OH) ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$] acetone, major isomer): δ = 31.70, 34.79, 35.64, 115.42, 117.75, 119.83, 120.57, 128.32, 128.51, 133.29, 134.60, 137.11, 141.53, 144.47, 158.67, 164.87 ppm. UV/Vis (toluene, c = 1.163 mg/50 mL): λ_{max} (ε) = 382 nm (11200 $mol^{-1}\,dm^3\,cm^{-1}$). MS (LC-MS, direct inlet, CH_3CN, APCI): m/z = 359 [M^+ + H]. $C_{21}H_{27}ClN_2O$ (358.18): calcd. C 70.28, H 7.58, N 7.81; found C 70.21, H 7.64, N 7.73.

Monoimine 9: A mixture of 2,3-diaminonaphthalene (0.78 g, 4.93 mmol) and 3,5-di(*tert*-butyl)salicylaldehyde (1.10 g, 4.69 mmol) in MeOH (40 mL) was stirred at room temp. for 3 d. Then the mixture was filtered and the product collected by filtration and dried. Yield: 0.78 g (44%). ^{1}H NMR (300 MHz, [D$_6$]-acetone): δ = 1.36 [s, 9 H, $C(CH_3)_3$], 1.48 [s, 9 H, $C(CH_3)_3$], 5.00 (br. s, 2 H, NH_2), 7.14–7.20 (m, 2 H, ArH), 7.30 (t, $^3J_{H,H}$ = 7.7, $^4J_{H,H}$ = 1.5 Hz, 1 H, ArH), 7.53–7.60 (m, 4 H, ArH), 7.73 (d, $^3J_{H,H}$ = 8.1 Hz, 1 H, ArH), 8.97 [s, 1 H, C(H)=N], 13.52 (s, 1 H, OH) ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone): δ = 29.87, 31.85, 34.92, 35.76, 109.21, 116.93, 119.99, 123.08, 126.12, 126.62, 128.61, 128.67, 128.80, 128.85, 135.26, 137.22, 139.80, 141.81, 142.10, 158.60, 166.35 ppm. UV/Vis (toluene, c = 0.945 mg/50 mL): λ_{max} (ε) = 366 nm (12500 $mol^{-1}\,dm^3\,cm^{-1}$). MS (LC-MS, direct inlet, CH_3CN, APCI): m/z = 375 [M^+ + H]. $C_{25}H_{30}N_2O$ (374.24): calcd. C 80.17, H 8.07, N 7.48; found C 79.97, H 8.10, N 7.36.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Monoimine 10: A mixture of 3,4-diaminopyridine (2.48 g, 22.73 mmol) and 3,5-di(*tert*-butyl)salicylaldehyde (1.84 g, 7.85 mmol) in MeOH (40 mL) was stirred at room temp. for 24 h. Then the mixture was filtered and the product collected by filtration and dried. Concentration of the mother liquor yielded a second fraction of a yellow solid. Total yield: 1.73 g (68%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.34 [s, 9 H, C(CH$_3$)$_3$], 1.46 [s, 9 H, C(CH$_3$)$_3$], 5.60 (br. s, 2 H, NH$_2$), 6.75 (d, $^3J_{H,H}$ = 5.7 Hz, 1 H, pyr-H), 7.51 (pseudo s, 2 H, ArH), 8.01 (d, $^3J_{H,H}$ = 5.4 Hz, 1 H, pyr-H), 8.11 (s, 1 H, pyr-H), 8.86 [s, 1 H, C(H)=N], 13.30 (s, 1 H, OH) ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone): δ = 29.84, 31.81, 34.84, 35.68, 110.12, 119.83, 128.50, 128.71, 132.99, 137.15, 140.24, 141.60, 148.76, 148.94, 158.73, 165.85 ppm. UV/Vis (toluene, *c* = 1.753 mg/50 mL): λ_{max} (ε) = 365 nm (9400 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): *m*/*z* = 322 [M$^+$ + H]. C$_{20}$H$_{27}$N$_3$O (325.22): calcd. C 73.65, H 8.42, N 12.78; found C 73.81, H 8.36, N 12.91.

Zn^{II}-salphen Complex 11: A mixture of monoimine **1** (0.44 g, 1.36 mmol), 5-bromo-3-(*tert*-butyl)salicylaldehyde[20] (0.35 g, 1.36 mmol), Zn(OAc)$_2$·2H$_2$O (0.33 g, 1.50 mmol) and neat NEt$_3$ (2 mL) in MeOH (40 mL) was stirred at room temp. for 68 h. Then two volumes of H$_2$O were added and the product collected by filtration, dried and triturated with pentane to furnish an orange-yellow solid. Yield: 0.50 g (60%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.31 [s, 9 H, C(CH$_3$)$_3$], 1.51 [s, 9 H, C(CH$_3$)$_3$], 1.53 [s, 9 H, C(CH$_3$)$_3$], 7.26 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.29 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.37–7.40 (m, 2 H, ArH), 7.45 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.93–7.96 (m, 2 H, ArH), 9.05 [s, 1 H, C(H)=N], 9.12 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone): δ = 30.00, 30.15, 34.40, 36.23, 103.74, 116.53, 116.70, 119.25, 121.89, 127.38, 128.11, 129.94, 130.35, 133.67, 134.79, 136.09, 140.23, 141.04, 142.25, 145.86, 162.13, 163.65, 171.92, 172.08 ppm. UV/Vis (toluene, *c* = 0.814 mg/50 mL): λ_{max} (ε) = 427 nm (17000 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): *m*/*z* = 627 [M$^+$ + H], 668 [M$^+$ + H + CH$_3$CN], 707 [M$^+$ + H + 2CH$_3$CN]. C$_{32}$H$_{37}$BrN$_2$O$_2$Zn (624.13): calcd. C 61.30, H 5.95, N 4.47; found C 61.39, H 6.05, N 4.55.

Zn^{II}-salphen Complex 12: A mixture of monoimine **2** (0.65 g, 1.81 mmol), 3-(*tert*-butyl)salicylaldehyde (0.33 g, 1.85 mmol), Zn(OAc)$_2$·2H$_2$O (0.42 g, 1.91 mmol) and neat NEt$_3$ (1 mL) in MeOH (40 mL) was stirred at room temp. for 41 h. Then the product was collected by filtration and dried to furnish a yellow solid. Yield: 0.99 g (94%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.31 [s, 9 H, C(CH$_3$)$_3$], 1.51 [s, 9 H, C(CH$_3$)$_3$], 1.53 [s, 9 H, C(CH$_3$)$_3$], 6.49 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, ArH), 7.24 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.29–7.33 (m, 2 H, ArH), 7.36 (d, $^4J_{H,H}$ = 2.1 Hz, 1 H, ArH), 7.45 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.93 (d, $^3J_{H,H}$ = 5.7 Hz, 1 H, ArH), 7.95 (s, 1 H, ArH), 9.10 [s, 1 H, C(H)=N], 9.11 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_2$]dichloromethane/5% [D$_5$]pyridine): δ = 29.80, 29.90, 31.65, 34.30, 35.87, 36.11, 113.41, 116.50, 117.35, 118.56, 119.80, 127.02, 129.72, 130.42, 131.90, 132.47, 134.80, 135.04, 139.57, 141.58, 142.64, 143.42, 163.24, 163.38, 172.02, 173.90 ppm. UV/Vis (toluene, *c* = 0.728 mg/50 mL): λ_{max} (ε) = 429 nm (20700 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): *m*/*z* = 583 [M$^+$ + H], 622 [M$^+$ + H + CH$_3$CN], 661 [M$^+$ + H + 2CH$_3$CN]. C$_{32}$H$_{37}$ClN$_2$O$_2$Zn·H$_2$O (580.18 for complex without H$_2$O): calcd. C 64.00, H 6.55, N 4.66; found C 63.85, H 6.78, N 4.51.

Zn^{II}-salphen Complex 13: A green suspension of 2,3-dihydroxybenzaldehyde (0.30 g, 2.17 mmol), monoimine **1** (0.71 g, 2.19 mmol) and Zn(OAc)$_2$·2H$_2$O (0.48 g, 2.19 mmol) in MeOH (40 mL) was stirred at room temp. for 24 h. In due course, a yellow-ish suspension was obtained, which was filtered to furnish the product as a yellow-orange solid. Yield: 0.89 g (81%). ^{1}H NMR (300 MHz, [D$_6$]acetone/5% [D$_5$]pyridine): δ = 1.30 [s, 9 H, C(CH$_3$)$_3$], 1.53 [s, 9 H, C(CH$_3$)$_3$], 6.45 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, ArH), 6.82 (d, $^3J_{H,H}$ = 8.4 Hz, 1 H, ArH), 6.94 (d, $^3J_{H,H}$ = 7.8 Hz, 1 H, Ar-H), 7.23 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.36 (t, $^3J_{H,H}$ = 6.3, $^4J_{H,H}$ = 2.1 Hz, 2 H, ArH), 7.44 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, pyr-H), 7.46 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.84 (t, $^3J_{H,H}$ = 8.7 Hz, 1 H, pyr-H), 9.00 [s, 1 H, C(H)=N], 9.05 [s, 1 H, C(H)=N] ppm. The OH proton was in exchange with residual water in the solvent. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]DMSO/5% [D$_5$]pyridine): δ = 29.40, 31.29, 33.53, 35.18, 113.16, 113.47, 116.75, 117.28, 118.21, 125.27, 126.81, 127.73, 128.80, 129.74, 133.61, 139.19, 140.16, 140.71, 148.88, 159.24, 163.13, 164.11, 170.53 ppm. UV/Vis (DMF, *c* = 1.746 mg/50 mL): λ_{max} (ε) = 414 nm (15500 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): *m*/*z* = 507 [M$^+$ + H], 548 [M$^+$ + H + CH$_3$CN], 1017 [2M$^+$ + H]. C$_{28}$H$_{30}$N$_2$O$_3$Zn (506.15): calcd. C 66.21, H 5.95, N 5.52; found C 66.07, H 6.10, N 5.38.

Zn^{II}-salphen Complex 14: A yellow suspension of 2,4-dihydroxybenzaldehyde (0.22 g, 1.59 mmol), monoimine **1** (0.47 g, 1.45 mmol) and Zn(OAc)$_2$·2H$_2$O (0.35 g, 1.59 mmol) in MeOH (40 mL) was stirred at room temp. for 18 h. Hereafter, water was added to precipitate the product, which was washed with pentane and isolated by filtration. Drying in vacuo afforded a yellow solid. Yield: 0.51 g (69%). ^{1}H NMR (300 MHz, [D$_6$]acetone/5% [D$_5$]pyridine): δ = 1.30 [s, 9 H, C(CH$_3$)$_3$], 1.49 [s, 9 H, C(CH$_3$)$_3$], 6.13 (d, $^3J_{H,H}$ = 8.7, $^4J_{H,H}$ = 8.7 Hz, 1 H, ArH), 6.26 (d, $^4J_{H,H}$ = 2.4 Hz, 1 H, ArH), 7.21–7.30 (m, 4 H, Ar-H), 7.42 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.72–7.76 (m, 2 H, ArH), 8.85 [s, 1 H, C(H)=N], 8.96 [s, 1 H, C(H)=N] ppm. The OH proton was in exchange with residual water in the solvent which appeared as a broad signal at δ = 3.01 ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]DMSO/10% [D$_5$]pyridine): δ = 29.63, 30.69, 31.41, 33.61, 35.29, 105.12, 107.06, 113.89, 115.92, 116.39, 118.37, 123.48, 123.80, 124.13, 126.25, 126.80, 128.49, 129.66, 133.34, 136.58, 138.20, 139.74, 140.01, 140.76, 148.44, 148.81, 149.15, 161.15, 164.11, 170.50, 174.77 ppm. UV/Vis (toluene, *c* = 1.888 mg/50 mL): λ_{max} (ε) = 398 nm (15800 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): *m*/*z* = 505 [M$^+$ + H], 546 [M$^+$ + H + CH$_3$CN], 1017 [2M$^+$ + H]. C$_{28}$H$_{30}$N$_2$O$_3$Zn·3.5H$_2$O (506.15 for complex without H$_2$O): calcd. C 58.90, H 6.53, N 4.91; found C 58.73, H 6.51, N 4.83.

Zn^{II}-salphen Complex 15: A mixture of monoimine **4** (0.42 g, 1.29 mmol), 3-(*tert*-butyl)salicylaldehyde (0.24 g, 1.35 mmol) and Zn(OAc)$_2$·2H$_2$O (0.33 g, 1.50 mmol) in MeOH (40 mL) was stirred at room temp. for 3 d. Then the product was collected by filtration to furnish an orange-red solid (178.6 mg, 25%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.33 [s, 9 H, C(CH$_3$)$_3$], 1.53 [s, 9 H, C(CH$_3$)$_3$], 1.58 [s, 9 H, C(CH$_3$)$_3$], 6.53 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, ArH), 7.31–7.37 (m, 3 H, ArH), 7.52 (d, $^4J_{H,H}$ = 2.7 Hz, 1 H, ArH), 7.75 (d, $^3J_{H,H}$ = 6.0 Hz, 1 H, pyr-H$_{meta}$), 8.46 (d, $^3J_{H,H}$ = 5.7 Hz, 1 H, pyr-H$_{ortho}$), 8.61 (s, 1 H, pyr-H$_{ortho}$), 9.16 [s, 1 H, C(H)=N], 9.28 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_2$]dichloromethane/30% [D$_5$]pyridine): δ = 29.72, 29.85, 31.52, 34.12, 35.74, 36.01, 109.84, 113.67, 118.69, 119.66, 129.74, 130.40, 132.52, 135.06, 139.10, 142.55, 143.52, 146.19, 147.69, 163.71, 164.89, 172.08, 174.90 ppm. UV/Vis (DMF, *c* = 1.294 mg/50 mL): λ_{max} (ε) = 426 nm (20900 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): *m*/*z* = 547 [M$^+$ + H], 588 [M$^+$ + H + CH$_3$CN], 626 [M$^+$ + H + 2CH$_3$CN]. C$_{31}$H$_{37}$N$_3$O$_2$Zn (547.22): calcd. C 67.82, H 6.79, N 7.65; found C 68.64, H 6.66, N 7.72.

Zn^{II}-salphen Complex 16: A mixture of 2,3-diaminonaphthalene (0.42 g, 2.65 mmol), 3-(*tert*-butyl)salicylaldehyde (1.10 g,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

6.17 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (0.66 g, 3.01 mmol) and neat NEt_3 (2 mL) in MeOH (65 mL) was stirred at room temp. for 17 h. Then the product was collected by filtration and dried to furnish an orange solid (1.21 g, 84%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.55 [s, 18 H, C(CH$_3$)$_3$], 6.50 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, ArH), 7.31 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, ArH), 7.47–7.50 (m, 2 H, ArH), 7.92–7.95 (m, 2 H, ArH), 8.32 (s, 2 H, ArH), 9.22 [s, 2 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone/5% [D$_5$]pyridine): δ = 30.18, 36.03, 113.57, 114.27, 120.72, 126.89, 128.69, 131.89, 133.25, 135.47, 140.56, 143.02, 165.18, 174.13 ppm. UV/Vis (toluene, c = 0.751 mg/50 mL): λ_{max} (ε) = 431 nm (25400 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): m/z = 539 [M$^+$ + H], 581 [M$^+$ + H + CH$_3$CN]. $C_{32}H_{32}N_2O_2Zn{\cdot}H_2O$ (540.18 for complex without H_2O): calcd. C 68.63, H 6.12, N 5.00; found C 68.24, H 6.65, N 4.59.

Zn^{II}-salphen Complex 17: A mixture of 2,3-diaminonaphthalene (0.37 g, 2.34 mmol), 3,5-di(*tert*-butyl)salicylaldehyde (1.24 g, 5.29 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (0.54 g, 2.46 mmol) and neat NEt_3 (2 mL) in MeOH (40 mL) was stirred at room temp. for 17 h. Then the product was collected by filtration and dried to furnish an orange solid (1.47 g, 96%). ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 1.34 [s, 18 H, C(CH$_3$)$_3$], 1.55 [s, 18 H, C(CH$_3$)$_3$], 7.25 (d, $^4J_{H,H}$ = 3.0 Hz, 2 H, ArH), 7.44 (d, $^4J_{H,H}$ = 2.7 Hz, 2 H, ArH), 7.45–7.48 (m, 2 H, ArH), 7.92–7.95 (m, 2 H, ArH), 8.30 (s, 2 H, ArH), 9.21 [s, 2 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone/5% [D$_5$]pyridine): δ = 30.30, 31.86, 34.48, 36.33, 113.63, 114.01, 114.35, 119.55, 126.76, 128.64, 130.47, 133.30, 134.76, 140.95, 142.47, 165.47, 172.61 ppm. UV/Vis (toluene, c = 1.013 mg/50 mL): λ_{max} (ε) = 443 nm (25800 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): m/z = 652 [M$^+$ + H], 694 [M$^+$ + H + CH$_3$CN]. $C_{40}H_{48}N_2O_2Zn$ (652.30): calcd. C 73.44, H 7.40, N 4.28; found C 73.24, H 7.29, N 4.18.

Zn^{II}-salphen Complex 18: A mixture of monoimine **1** (0.66 g, 2.03 mmol), 2-hydroxy-1-naphthalenecarbaldehyde (0.35 g, 2.03 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (0.52 g, 2.37 mmol) and neat NEt_3 (2 mL) in MeOH (40 mL) was stirred at room temp. for 16 h. Then the product was collected by filtration and dried to furnish an orange/brown solid (0.60 g, 55%). Analytically pure **18** was obtained by crystallization from hot CH$_3$CN. ^{1}H NMR (300 MHz, [D$_6$]acetone/10% [D$_5$]pyridine): δ = 1.32 [s, 9 H, C(CH$_3$)$_3$], 1.56 [s, 9 H, C(CH$_3$)$_3$], 7.00 (d, $^3J_{H,H}$ = 9.0 Hz, 1 H, ArH), 7.17–7.47 (m, 6 H, ArH), 7.66–7.82 (m, 3 H, ArH), 8.01 (d, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.8 Hz, 1 H ArH), 8.38 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, ArH), 9.02 [s, 1 H, C(H)=N], 9.91 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone/10% [D$_5$]pyridine): δ = 31.85, 34.44, 36.26, 110.17, 116.96, 117.55, 119.44, 120.04, 122.41, 127.04, 127.36, 127.77, 128.24, 128.61, 129.74, 129.95, 130.49, 134.74, 136.57, 141.06, 142.23, 142.44, 157.66, 164.34, 172.15, 175.50 ppm. UV/Vis (toluene, c = 0.734 mg/50 mL): λ_{max} (ε) = 423 nm (23000 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): m/z = 539 [M$^+$ + H], 581 [M$^+$ + H + CH$_3$CN], 1088 [2M$^+$ + H]. $C_{32}H_{32}N_2O_2Zn$ (540.18): calcd. C 70.91, H 5.95, N 5.17; found C 70.81, H 6.04, N 5.35.

Zn^{II}-salphen Complex 19: A mixture of monoimine **3** (0.50 g, 1.34 mmol), 2-hydroxy-1-naphthalenecarbaldehyde (0.26 g, 1.51 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (0.37 g, 1.69 mmol) and neat NEt_3 (2 mL) in MeOH/acetone (40:20 mL) was stirred at room temp. for 18 h. Then, extra MeOH (40 mL) was added and the precipitated product was collected by filtration and dried to furnish an orange solid (0.52 g, 66%). Analytically pure **19** was obtained by crystallization from hot CH_3CN/CH_2Cl_2. ^{1}H NMR (300 MHz, [D$_6$]acetone/10% [D$_5$]pyridine): δ = 1.36 [s, 9 H, C(CH$_3$)$_3$], 1.62 [s, 9 H, C(CH$_3$)$_3$], 7.07 (d, $^3J_{H,H}$ = 9.0 Hz, 1 H, ArH), 7.24 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, ArH), 7.33 (s, 1 H, ArH), 7.44–7.55 (m, 4 H, ArH), 7.69–7.79 (m, 2 H, ArH), 7.93 (m, 1 H, ArH), 8.00 (m, 1 H, ArH), 8.47 (m, 2 H, ArH), 9.18 [s, 1 H, C(H)=N], 10.09 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_2$]dichloromethane/10% [D$_5$]pyridine): δ = 29.90, 31.68, 34.27, 36.06, 109.94, 113.62, 113.87, 119.01, 119.29, 122.26, 126.42, 126.70, 127.90, 128.20, 129.51, 129.88, 130.25, 132.63, 132.91, 135.04, 136.55, 140.62, 142.00, 142.24, 158.19, 164.55, 171.99, 175.38 ppm. UV/Vis (toluene, c = 1.188 mg/50 mL): λ_{max} (ε) = 434 nm (28200 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): m/z = 590 [M$^+$ + H], 631 [M$^+$ + H + CH$_3$CN]. $C_{36}H_{34}N_2O_2Zn{\cdot}1/3CH_2Cl_2{\cdot}1/3CH_3CN$. (590.19 for complex without solvent): calcd. C 70.09, H 5.67, N 5.15; found C 70.29, H 5.24, N 5.30.

Zn^{II}-salphen Complex 21: A mixture of **1** (166.0 mg, 0.512 mmol), (*S*)-2-hydroxy-2′-methoxy-1,1′-binaphthalene-3-carboxaldehyde (168.1 mg, 0.512 mmol), $Zn(OAc)_2{\cdot}2H_2O$ (115.3 mg, 0.525 mmol) and neat NEt_3 (0.5 mL) in hot MeOH (50 mL). The initial dark-red colored solution gradually turned into a suspension, which was filtered after 17 h to give, after drying, an orange to red solid (180.4 mg, 0.258 mmol, 50%). Analytically pure **21** was obtained by crystallization from CH_3CN/CH_2Cl_2. ^{1}H NMR ([D$_6$]acetone): δ = 1.06 [s, 9 H, C(CH$_3$)$_3$], 1.24 [s, 9 H, C(CH$_3$)$_3$], 3.74 (s, 3 H, OCH$_3$), 6.83 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, ArH), 7.29–6.97 (m, 7 H, ArH), 7.48–7.41 (m, 2 H, ArH), 7.53 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, ArH), 7.77 (d, $^3J_{H,H}$ = 7.2 Hz, 1 H, ArH), 7.87 (t, $^3J_{H,H}$ = 8.7 Hz, 2 H, ArH), 7.98 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, ArH), 8.20 (s, 1 H, ArH), 8.94 [s, 1 H, C(H)=N], 9.36 [s, 1 H, C(H)=N] ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2/d$_5$-pyridine, 95:5): δ = 29.41, 31.55, 34.17, 35.51, 114.90, 116.42, 116.49, 118.20, 120.65, 121.15, 122.99, 123.25, 123.36, 124.17, 124.90, 125.87, 126.06, 126.94, 128.41, 128.46, 128.72, 128.86, 129.36, 129.62, 130.08, 130.21, 134.51, 135.01, 138.03, 138.24, 139.68, 142.00, 142.52, 155.73, 162.91, 163.75, 165.82, 172.00 ppm. UV/Vis (toluene, c = 1.087 mg/50 mL): λ_{max} (ε) = 357, 453 nm (27200, 12800 mol^{-1} dm^3 cm^{-1}). MS (LC-MS, direct inlet, CH$_3$CN, APCI): m/z = 697 [M$^+$ + H]. $C_{44}H_{42}N_2O_3Zn$ (696.23): calcd. C 74.20, H 5.71, N 3.93; found: C 74.05, H 5.94, N 4.01.

Crystal Structure Determination of Zn^{II}-salphen Complex 4: $C_{40}H_{50}N_4O_2Zn$, Fw = 684.21, orange block, 0.34×0.26×0.23 mm. Monoclinic crystal system, space group $P2_1/c$. Cell parameters: a = 12.8185(14) Å, b = 15.3860(12) Å, c = 18.6414(15) Å, β = 91.442(9)°, V = 3675.4(6) Å^3, Z = 4, $D_{calcd.}$ = 1.237 gcm^{-3}. 110831 reflections were measured on a Nonius KappaCCD diffractometer with rotating anode and Mo-K_α radiation (graphite monochromator, λ = 0.71073 Å) at a temperature of 150(2) K, using Collect,[21] DIRAX[22] and EvalCCD.[23] A multi-scan absorption correction was applied using SADABS[24] (μ = 0.707 mm^{-1}, 0.74–0.85 transmission). 8401 unique reflections (R_{int} = 0.0306), of which 7376 were observed [$I > 2\sigma(I)$]. The structure was solved with the program DIRDIF,[25] and refined using the program SHELXL-97[26] against F^2 of all reflections up to a resolution of sinθ/λ = 0.65. Non-hydrogen atoms were freely refined with anisotropic displacement parameters. H atoms were placed in geometrically idealized positions [d(C–H) = 0.98 for methyl H atoms and 0.95 for other H atoms] and constrained to ride on their parent atoms, with U_{iso}(H) = 1.5U_{eq}(C) for methyl H atoms and U_{iso}(H) = 1.2U_{eq}(C) for all other H atoms. 436 refined parameters, 0 restraints. R(obsd. refl.): R_1 = 0.0269, wR_2 = 0.0681. R (all data): R_1 = 0.0342, wR_2 = 0.0722. Weighting Scheme $w = 1/[\sigma^2(F_o^2) + (0.0367P)^2 + 1.1877P]$, where $P = (F_o^2 + 2F_c^2)/3$. GoF = 1.056. Residual electron density between –0.307 and 0.384 e/Å^3. The drawings, structure calculations, and checking for additional symmetry were performed with the program PLATON.[27]

Dalton, M. F. Renehan, D. G. Gilheany, *Tetrahedron Lett.* **1999**, *40*, 3617–3620; d) D. M. Boghaei, S. Mohebi, *Tetrahedron* **2002**, *58*, 5357–5366; e) D. A. Annis, E. N. Jacobsen, *J. Am. Chem. Soc.* **1999**, *121*, 4147–4154. Please note that the majority of these reported methods make use of a step-wise synthetic protocol involving trapping of the monoimine intermediate using protection/deprotection sequences. Ref. 8d describes an interesting templated approach using Co^{II}-acetate but here only two examples were reported. In order to use the nonsymmetric ligands for further synthesis, the authors had to demetalate the Co^{II}-salen complexes with dimethyl glyoxime and reengage in new metalation procedures. In strong contrast, our approach directly affords the desired metallated salphen complexes and any desired suitable metal precursor can be chosen in advance to afford different metallo-salphen systems.

[9] CCDC-278364 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[11] Please note that the presence of [D_5]pyridine as co-solvent for those species lacking a large 3- and/or 3′-substituent or comprising internal pyridine-N atoms in the salphen backbone (i.e., compounds **5**, **13**–**15** and **18**–**19**) greatly increased their solubility as a result of the formation of [D_5]pyridine adducts; see also references 4 and 5.

[12] a) A. L. Singer, D. A. Atwood, *Inorg. Chim. Acta* **1998**, *277*, 157–162; b) G. A. Morris, H. Zhou, C. L. Stern, S. T. Nguyen, *Inorg. Chem.* **2001**, *40*, 3222–3227.

[13] The synthesis of monoimine **7** was reported previously: M.-A. Muñoz-Hernández, T. S. Keizer, S. Parkin, B. Patrick, D. A. Atwood, *Organometallics* **2000**, *19*, 4416–4421.

[14] Please note that for compounds **8**–**10** two regio–isomers can be formed. For mono–imine **10** one of these isomers was isolated exclusively, while for **8** and **9** mixtures of both species were obtained. The isomer ratios were determined by signal integration (93:7 for **8** and ca. 60:40 for **9**). For simplicity, for **8**–**10** only the major species are presented in the main text and their structures were corroborated by NMR spectroscopy.

[15] Note that the nonsymmetric monoimine products **8**–**10** were rather soluble in MeOH and significant concentration of the mixture was needed to isolate pure materials.

Copper(II) Complexes of Schiff-Base and Reduced Schiff-Base Ligands: Influence of Weakly Coordinating Sulfonate Groups on the Structure and Oxidation of 3,5-DTBC

Bellam Sreenivasulu,[a] Muthalagu Vetrichelvan,[a] Fei Zhao,[b] Song Gao,*[b] and Jagadese J. Vittal*[a]

Keywords: Biomimetic studies / Copper / Schiff-base complexes / Organosulfonate ligands / Catecholase activity / Magnetic properties

The copper(II) complexes of the Schiff-base ligands H_2Sams and H_2Saes and the reduced Schiff-base ligands H_2Sam and H_2Sae formed between salicylaldehyde and aminomethanesulfonic acid or 2-aminoethanesulfonic acid (taurine) have been synthesized in moderate yields. The solid-state structures of the five dinuclear complexes, $[Cu_2(Sams)_2(H_2O)_2]$ (**1**), $[Cu_2(Sam)_2(H_2O)_2]\cdot H_2O$ (**2**), $[Cu_2(Saes)_2(H_2O)_2]\cdot 2H_2O$ (**3**), $[Cu_2(Sae)_2]\cdot 2H_2O$ (**4**), and $[Cu_2(Sae)_2(DMF)_2]\cdot 2DMF$ (**5**), have been determined by X-ray crystallography, showing that the Cu^{II} centers have distorted square-pyramidal geometry. The Schiff-base copper complexes **1** and **3** have hydrogen-bonded 2D sheet structures while the reduced Schiff-base complexes **4** and **5** display a 2D coordination network and a hydrogen-bonded 2D structure respectively. All these complexes have been investigated for their catecholase activity and activity measurements have been compared with those of dinuclear copper(II) complexes of similar ligands obtained with carboxylate analogues of the corresponding sulfonic acids; these studies show that **4** has significantly higher activity. Further, a strong antiferromagnetic interaction between Cu^{II} ions in dimeric complexes **1** [$J = -9.04(2)$ cm^{-1}], **3** [$J = -272(4)$ cm^{-1}), and **4** [$J = -237(4)$ cm^{-1}] has been observed.

Introduction

In the past decades, significant progress has been made in understanding the coordination chemistry of copper(II) complexes of various Schiff-base ligands.[1] Most of the model studies of the metal complexes of Schiff-base ligands containing salicylaldehyde and amino acids have focused upon the binding mode of these ligands.[2] X-ray crystal structures of complexes thus obtained demonstrated that the Schiff-base ligand acts as a tridentate moiety, coordinating through the phenolato oxygen, imine nitrogen, and carboxylate oxygen.

Our research group is interested in tridentate reduced Schiff-base ligands, specifically *N*-(2-hydroxybenzyl)amino acids, as they are more flexible because of the reduction of the C=N bond of the Schiff base, and help to overcome the ligand instability. Further, in addition to their potential hydrogen-bond donor–acceptor functionalities, these ligands can form conformationally flexible five- and six-membered rings upon complexation. Several copper complexes of reduced Schiff-base ligands formed between salicylaldehyde and amino acids were explored to serve as models for the intermediate species in biological racemization and transamination reactions.[3] Making use of these advantages, we employed such reduced Schiff-base ligands to synthesize dinuclear Cu^{II} and Zn^{II} complexes that exhibit interesting structural transformations in the solid state.[4] Further, in our recent report, we showed that incorporation of an additional carboxylate group in the side arm of the ligand *N*-(2-hydroxybenzyl)-L-glutamic acid formed between salicylaldehyde and L-glutamic acid resulted in a novel structural display of a spiral staircase conformation.[5] Copper(II) complexes of the reduced Schiff-base ligand derived from salicylaldehyde and histidine have been found to self-assemble to form a capsule incorporating four pyridine molecules.[6]

Various dicopper active sites found in copper-containing metalloenzymes have similar structural aspects with three histidine donors for each of the two Cu centers, which are separated by a distance of about 3.5 Å, and catechol oxidase as one of the prominent members of the type III copper proteins that catalyze the two-electron oxidation of *ortho*-diphenols to the corresponding quinones.[7] Conse-

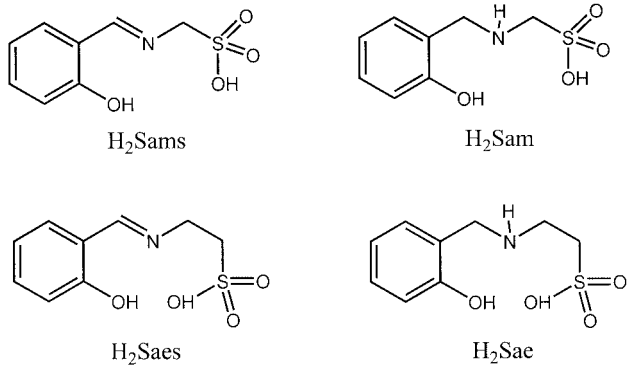
quently, quite a number of dinuclear copper complexes have been investigated as biomimetic catalysts for catechol oxidation by employing the most common and convenient model substrate, 3,5-di-*tert*-butylcatechol (3,5-DTBC), which can be oxidized to 3,5-di-*tert*-butylquinone (3,5-DTBQ).[8] With regard to this, we have recently reported a series of dinuclear copper(II) complexes of the tridentate and binucleating reduced Schiff-base ligands and their functional relationship with catecholase activity.[9] Apart from the reduced Schiff-base ligands with carboxylate donor group, their sulfonic acid analogues are expected not only to improve solubility in aqueous media but also form interesting supramolecular architectures by modifying the connectivity at the metal centers as well as the hydrogen-bonding pattern.[10] However, the coordination chemistry of transition metals with a similar ligand system containing organosulfonate species is not well documented.[11] Despite the available literature showing the organosulfonate anions as good hydrogen-bonding acceptors to form strongly hydrogen-bonded networks,[12] there are few metal-based supramolecular arrays in the literature.[13]

Encouraged by our previous results, we were prompted to synthesize such tridentate *N*-(2-hydroxybenzyl)aminomethane/ethanesulfonic acids (Scheme 1), and their corresponding dinuclear copper(II) complexes of both Schiff-base and reduced Schiff-base ligands. In order to evaluate these complexes for the effect of the sulfonate donor group, compared to the corresponding carboxylate analogues, on the crystal structures and the consequent influence on the catecholase activity, herein we report and highlight different structural features between Schiff-base and reduced Schiff-base dicopper(II) complexes, and their catecholase activity. Variable temperature magnetic studies have also been discussed for the Cu^{II} complexes containing *syn-syn* O–S–O-bridged **1** and **3** and phenoxo-bridged **4**, which can mediate magnetic interaction effectively within the dimeric Cu unit.



Scheme 1. Ligands employed for complexation.

Results and Discussion

Copper complexes **1** and **3** were prepared by treating copper(II) nitrate trihydrate solution with the Schiff bases formed in situ between salicylaldehyde and aminomethanesulfonic acid and/or aminoethanesulfonic acid. The reduced Schiff-base complex $[Cu_2(Sam)_2(H_2O)_2]\cdot H_2O$ (**2**) was obtained by treating a copper(II) nitrate trihydrate solution with H_2Sam generated in situ. On the other hand, reduced Schiff-base H_2Sae was synthesized first and then complexed with copper(II) acetate monohydrate to obtain $[Cu_2(Sae)_2]\cdot 2H_2O$ (**4**). The complex $[Cu_2(Sae)_2(DMF)_2]\cdot 2DMF$ (**5**) resulted when **4** was recrystallized from the DMF/acetone solvent mixture. We were unable to isolate *N*-(2-hydroxybenzyl)aminopropanesulfonic acid or prepare its Cu^{II} complex in situ as in the case of the H_2Sam ligand. Complexes **1**–**4** show absorption bands at 3400, 3443, and 3410 cm^{-1} corresponding to the presence of water molecules. The C=N stretching frequencies are observed at 1629 cm^{-1} in **1** and 1617 cm^{-1} in **3**. As the C=N bond is reduced in **2**, **4**, and **5**, the N–H stretching frequencies appeared in the range of 2920–2935 cm^{-1}. The frequencies characteristic of the S–O stretching modes are observed in the range 1000–1380 cm^{-1}.[14]

The electronic spectra of **1** and **3** in water display weak bands at 678 and 688 nm followed by intense bands at 367 and 322 nm respectively. The high intensity can be attributed to the delocalization of charge in the conjugated Schiff base. Copper(II) complexes of Schiff bases and related ligands exhibit weak bands in the range 620–680 nm which are due to d-d transitions.[15] For an octahedral geometry, the expected ^2E_g to $^2T_{2g}$ transition takes place at around 800 nm. This band will undergo a significant blue shift when octahedral geometry distorts to square pyramidal and square planar structure.[16] For the reduced Schiff-base copper(II) complexes with square pyramidal geometry, the d-d transitions and charge transfer transitions generally occur in the ranges 650–720 and 360–450 nm respectively.[9,17] In the case of **2**, **4**, and **5** the absorption bands at 717–736 nm correspond to d-d transitions and a strong band at 405–420 nm is due to ligand-to-metal charge transfer.

TG analysis of **1** showed a weight loss of 6.8% (calculated 6.1%) for the loss of two aqua ligands in the temperature range 159–192 °C. In **2**, the loss of three water molecules, including two aqua ligands and a lattice water, was indicated by a weight loss of 8.1% (calculated 8.4%) in the temperature range 148–183 °C. Similarly, a weight loss of 11.7% (calculated 11.0%) corresponding to two aqua ligands and two lattice water molecules has been found to occur at 30–155 °C in **3**. TG weight loss of 5.7% (calculated 5.8%) agrees well with the loss of two lattice water molecules in **4**.

Description of X-ray Crystal Structures

Selected crystallographic data and refinement details are displayed in Table 1.

Crystal Structure of $[Cu_2(Sams)_2(H_2O)_2]$ (1)

Dark green prismatic single crystals of **1** suitable for single-crystal X-ray crystallographic studies were obtained from the filtrate of the reaction mixture on slow evaporation. Compound **1** is a centrosymmetric dimer with copper centers assuming square pyramidal geometry ($\tau = 0.16$).[18]

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

At each copper center, the basal plane of the square pyramid is occupied by three oxygen atoms, one each from the phenolate group [Cu1–O1, 1.898(2) Å], the sulfonate group [Cu1–O2, 2.019(2) Å], and the aqua ligand [Cu1–O5, 1.932(2) Å]; and nitrogen [Cu1–N1, 1.936(3) Å] from the imine group. The apical sites of the Cu^{II} centers have *anti* configuration and are occupied by the oxygen atoms [Cu1–O3A, 2.393(3) Å; Cu1A–O3, 2.393(3) Å] of the sulfonate group from the neighboring molecule as shown in Figure 1. Selected bond lengths and bond angles are given in Table 2.

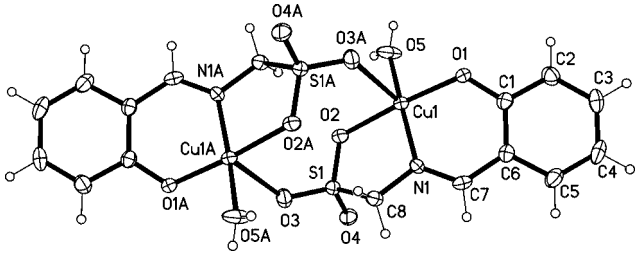

Figure 1. An ORTEP diagram of **1**.

Unlike the complexes obtained with reduced Schiff bases displaying the phenoxo-bridged dinuclear Cu^{II} centers with the usual Cu···Cu distance of about 3 Å, H_2Sams gave rise to the dinuclear copper core with Cu···Cu separation of 5.12 Å without bridging phenolate moiety. Instead, the centrosymmetric dinuclear core forms an interesting eight-membered ring consisting of Cu1, O2, S1, O3, Cu1A, O2A, S1A, and O3A (Figure 1). Further, compared with the phenolato-bridged structures formed by the reduced Schiff-base Cu^{II} compounds, formation of an entirely different structure of **1** may be attributed to kinetic factors, as several phenolato-bridged dinuclear complexes have been reported in the literature.[19–21]

The dimers are packed in the solid state to give a hydrogen-bonded 2D structure in the *ac* plane (Figure 2). Two types of complementary hydrogen bonds are present: the first one is between the phenoxo oxygen and one of the hydrogen atoms of the aqua ligand from the adjacent dimer along the *c*-direction; the next one is between the free oxygen atom of the sulfonate group with another hydrogen atom of the aqua ligand, normal to (100) plane. In addition, these 2D sheets are also supported by C–H···O hydrogen-bonding interactions, C(3)–H(3)···O(4), 2.53 Å; C(7)–H(7)···O(4), 2.52 Å, which are considered medium strong when compared with the shorter and stronger C–H···O interac-

tions of about 2.0 Å available in the literature.[22] Hydrogen bond parameters in **1** are tabulated in Table 3.

Crystal Structure of [Cu$_2$(Saes)$_2$(H$_2$O)$_2$]·2H$_2$O (3)

Compound **3** is also a binuclear complex of formula [Cu$_2$(Saes)$_2$(H$_2$O)$_2$]·2H$_2$O with a crystallographic center of inversion as in **1**. An ORTEP diagram of **3** with numbering scheme is shown in Figure 3. Selected bond lengths and bond angles are given in Table 2. Each Cu^{II} center has square pyramidal geometry.

The ligand connectivity in **3** is very similar to that found in **1** except that this Saes dianion forms two six-membered rings. The ring expansion is due to an additional methylene group in the H$_2$Saes ligand, which reduces the ring strain

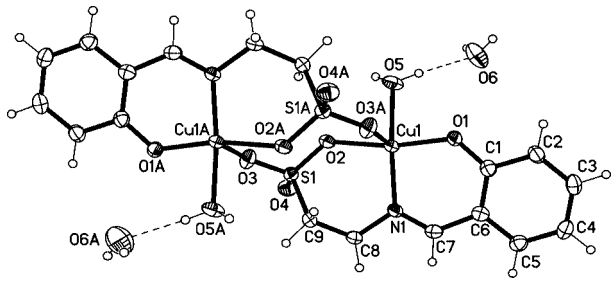

Figure 3. An ORTEP diagram of **3**.

and thus lowers the τ-value to 0.03. As observed in **1**, the dinuclear core in **3** also shows the axial coordination mode by sulfonato oxygen atoms in the centrosymmetric dimer. The introduction of a –CH$_2$ group in the H$_2$Saes ligand changed a five-membered ring to a six-membered ring and hence increased the Cu···S distances (3.01 Å in **1** vs 3.15 Å in **3**). This is also reflected in the widening of the Cu(1)–O(2)–S(1) angle from 117.7° in **1** to 131.3° in **3** and an increase in the Cu···Cu separation to 5.33 Å.

Compound **3** also forms hydrogen-bonded sheets similar to **1** (Figure 4). However, a water molecule is strongly hydrogen bonded between the phenoxo oxygen atom and the aqua ligand. The second hydrogen atom of the lattice water is disordered and found to be hydrogen bonded to another lattice water molecule as well as to other oxygen atoms of the sulfonate group. Table 3 shows the hydrogen bond parameters.

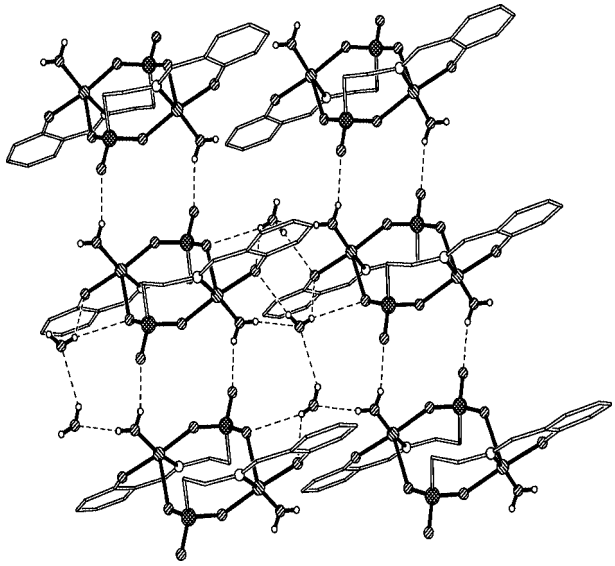

Figure 4. Hydrogen-bonded 2D sheets in **3**.

Crystal Structure of [Cu$_2$(Sae)$_2$]·2H$_2$O (4)

When the C=N double bond is reduced, the complexation behavior of the Sae dianion is completely different from that of the Saes dianion. The Sae ligand with flexible backbone behaves like other reduced Schiff-base ligands in terms of forming a phenolato-bridged Cu^{II} dimer having the expected connectivity of the donor atoms.[4,9] A perspective view of **4** exhibiting the coordination environments

[a] The hydrogen atoms were placed in calculated positions.

around the Cu^{II} atoms is shown in Figure 5. Selected bond lengths and bond angles in **4** are shown in Table 2. The phenolato oxygen atoms, a nitrogen atom from the imine group, and an oxygen atom of the sulfonate group form the basal square. The apical site in each Cu^{II} center is occupied by another oxygen atom of the sulfonate group from the neighboring dimer. This interdimer connectivity leads to the formation of a 2D (4, 4) network structure as shown in Figure 6. The two axial oxygen atoms have *trans* geometry due to the crystallographic center of inversion present at the center of the Cu_2O_2 ring. Such geometry has also been observed in several Cu^{II} dimers having nonchiral reduced Schiff-base ligands.[9] Interestingly the infinite 2D network structure with (4, 4) net formed in **4** is the first of its kind observed in the Cu^{II} and Zn^{II} complexes containing reduced Schiff-base ligands although these nets are ubiquitous in the literature.[23]

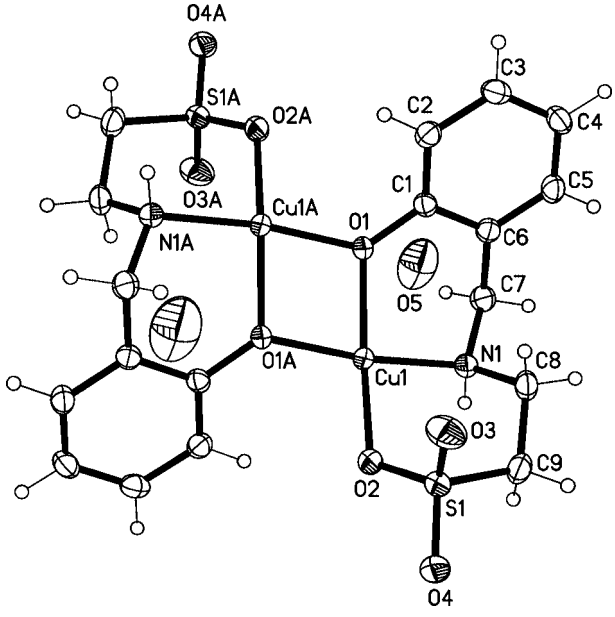

Figure 5. An ORTEP diagram of **4**.

The N–H proton is weakly hydrogen bonded to one of the sulfonate oxygen atoms (N1–H1···O2, 2.324 Å). The

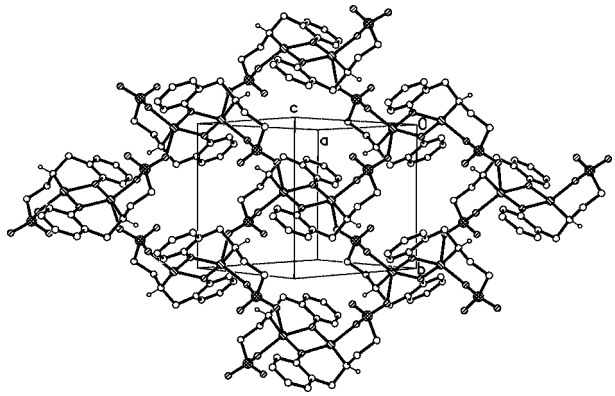

Figure 6. A portion of the 2D structure in **4**.

intermolecular N–H···O hydrogen bond between the NH_2 and sulfonate groups in the solid state and in solution has been utilized as a crystal engineering tool.[12] The properties and the functions of the N–H···O hydrogen bonds involving coordinated $-SO_3^-$ groups in a dinuclear calcium complex have been reported.[24] As in **1**, medium strong C–H···O hydrogen bonds have also been observed in the solid state.

Crystal Structure of [Cu₂(Sae)₂(DMF)₂]·2DMF (5)

Complex **5** is formed upon recrystallization of **4** from strongly coordinating solvent DMF. The axial sulfonate groups in **4** are replaced by DMF molecules in **5** and hence discrete dinuclear compounds are formed. Two more DMF molecules were found in the crystal lattice. The crystal packing of **5** generated 2D hydrogen-bonded polymeric structures parallel to the $(10\bar{1})$ planes. The solid-state structure exhibits N–H···O hydrogen bonding between one of the sulfonate oxygen and NH hydrogen atoms (Table 3).

Magnetic Properties of 1, 3, and 4

The temperature dependences of χ_m and $\chi_m T$ for crystalline samples of **1**, **3**, and **4** are presented in Figure 7. For compound **1**, χ_m increases upon cooling and reaches a maximum at 16 K; the data above 30 K can be well fitted with the Curie–Weiss law [$\chi_m = C/(T-\theta)$], giving C =

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.802 $cm^3 mol^{-1} K$, and θ = –12.7(5) K. The maximum and negative Weiss constant suggests an antiferromagnetic coupling between Cu^{II} ions. The susceptibility data in the 2–330 K range were fitted with a Cu_2 dimer model ($H = -2JS_1S_2$), giving the intradimer coupling J = –9.04(2) cm^{-1}, and g = 2.002(3) with $R = 2.3\times10^{-4}$ ($R = \Sigma[(\chi_m)_{obs} - (\chi_m)_{calc}]^2/\Sigma[(\chi_m)_{obs}]^2$).

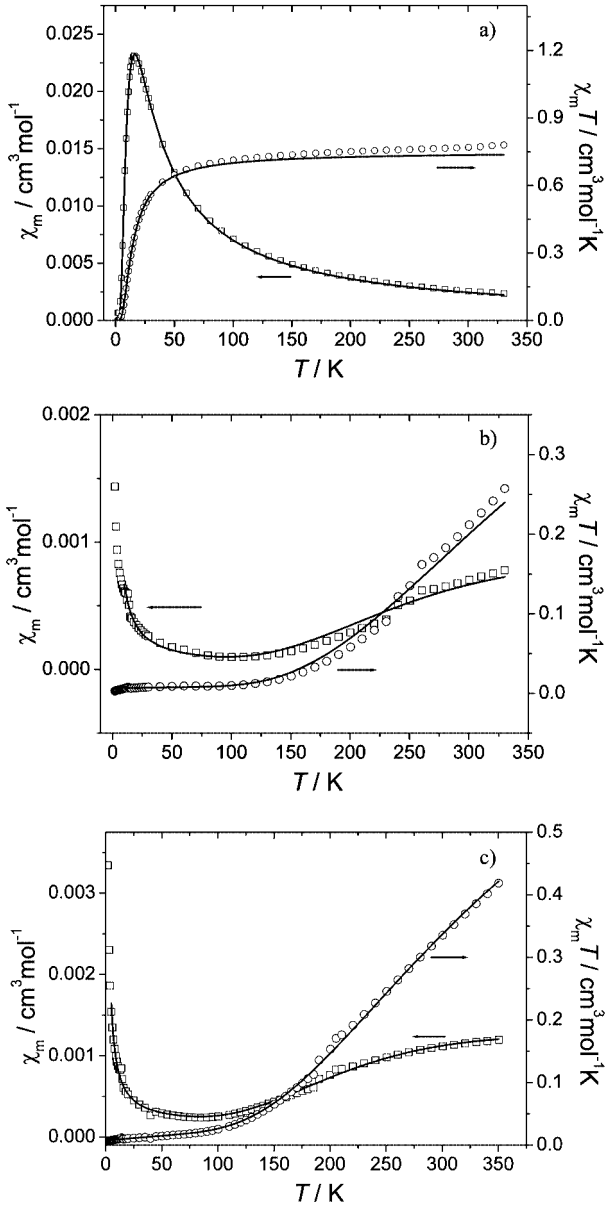

Figure 7. The temperature dependences of χ_m and $\chi_m T$ in the range of 2–350 K for a) **1**, b) **3**, and c) **4**. The solid lines are fits using a Cu_2 dimer model.

Compounds **3** and **4** show similar behavior; on lowering the temperature, χ_m decreases gradually, and there is an increase below about 100 K while the $\chi_m T$ value even at 330 or 350 K is quite small compared with the expected value of 0.75 $cm^3 mol^{-1} K$ for two noninteracting Cu^{II} ions. Upon cooling it decreases rapidly to a value close to zero at 2 K. The increase of χ_m at low temperature is probably due to trace paramagnetic impurity (ρ). Overall, the data suggest a strong antiferromagnetic coupling between the adjacent Cu^{II} ions in **3** and **4**. Based on the structure of **3**, two Cu^{II} ions are bridged by two sulfonate O–S–O bridges in *syn-syn* mode with Cu···Cu separation at 5.32 Å. Although the distance is quite large compared to the phenoxo-bridged Cu_2 in **4** with a distance of 3.03 Å, the basal planes of the two Cu^{II} ions are almost parallel, which might favor the overlap of $d_{x^2-y^2}$ orbitals of Cu^{II} ions within the dimer. On the other hand, the coupling between the dinuclear moiety in the 2D layer of **4** is negligible, as expected, because of both the *anti–syn* sulfonate bridging mode and the orthogonal relationship of the planes of the neighboring Cu_2O_2.[4d] Therefore, the magnetic data of **3** and **4** can be analyzed by fitting the susceptibilities to an equation calculated using an $H = -2JS_1S_2$ Hamiltonian for a dimer plus impurity of monomer model. The parameters have their usual meanings. As shown in Figure 7b and 7c, quite good fits were obtained for **3**: J = –272(4) cm^{-1}, g = 2.05(5), ρ = 0.0164; Na = 22×10^{-6} with $R = 7.4\times10^{-3}$; and for **4**: J = –237(4) cm^{-1}, g = 2.21(3), ρ = 0.0163; Na = 149×10^{-6} with $R = 2.4\times10^{-3}$.

Catecholase Activity

Many copper-containing metalloenzymes, characterized by the dinuclear active site with two copper atoms operating within their convenient intermetallic distance, are involved in distinct processes in living systems among which the type III copper protein catechol oxidase catalyzes the oxidation of a wide range of *ortho*-di-phenols to *ortho*-di-quinones.[7,8] Hence, dinuclear copper complexes with two metal atoms in close proximity have received a great deal of attention, particularly in relation to their potential uses as bimetallic catalysts, mimicking the activity of enzymes.[8,25–27] Such di-copper(II) complexes exhibiting the catecholase activity are probably crucial for a better understanding of the oxygenation reactions mediated by catechol oxidase.[28–32] The Cu^{II} complexes of Schiff-base and reduced Schiff-base ligands studied here have structurally distinct features. Hence we have evaluated their ability to oxidize catechols to quinones by employing 3,5-DTBC, a common and convenient model substrate. Figure 8 shows the course of oxidation of 3,5-DTBC with time in the presence of **4**. The results are shown in Table 4.

A linear relationship between the initial rates and the concentration of the complexes has been obtained for **2**–**4**, which shows a first-order dependence on the catalyst concentration for these systems. An example of the Lineweaver–Burk plot[29f] is given in Figure 9 for **4**. The data obtained from the Lineweaver–Burk plot model is employed for a comparison of catalytic activity.

It is obvious that catalytic ability towards the oxidation of 3,5-DTBC has been found to follow the order: **4** > **2** > **3**. The least activity observed in the case of Schiff-base complex **3** can be attributed to the inefficient binding of the substrate to the catalyst caused by the formation of the

eight-membered ring with largely separated Cu^{II} ions. Thus, the larger Cu···Cu distance of 5.33 Å in **3** is highly unfavorable for the efficient binding of the substrate. Furthermore, very distinct structural differences between **3** and **4** account for the difference in their activity.

The catecholase activity of copper(II) compounds with different structural parameters has been investigated and compared to some extent by varying the properties of chelating ligands with respect to their conformation, and the number as well as the nature of the donor atoms.[8] In our earlier report,[9] the reduced Schiff-base complexes $[Cu_2(Sab4)_2(H_2O)_2]$ and $[Cu_2(Sbal)_2(H_2O)_2]$, containing 4-aminobutanoic acid and 3-aminopropanoic acid (β-alanine) respectively, were found to exhibit higher activity, which has been attributed to the larger ring size due to a longer alkyl chain in the side arm of the corresponding ligands. It has been proposed that the formation of seven-membered rings in $[Cu_2(Sab4)_2(H_2O)_2]$ and six-membered rings in $[Cu_2(Sbal)_2(H_2O)_2]$ resulted in higher activity, with K_{cat} values of 3800 and 1280 h^{-1} respectively. The lower activity (K_{cat} = 563 h^{-1}) in $[Cu_2(Sgly)_2(H_2O)]$ due to the shorter glycine side-chain forming five-membered rings appears to support this view. In the present set of complexes, **2** contains aminomethanesulfonate, which is the sulfonic acid analogue of glycine, and **4** has aminoethanesulfonate, which is the sulfonic acid analogue of β-alanine. Based on the connectivity observed in the structures of Cu^{II} complexes containing Schiff bases, as well as chemical, spectroscopic, and catalytic data, the structure of **2** is expected to be similar to that of $[Cu_2(Sgly)_2(H_2O)]$. As a consequence, these five-membered rings formed by the side arm of the ligand in **2** would account for the lower catalytic activity as compared to **4**.

It is important to emphasize here that the K_{cat} value of 4612 h^{-1} observed in **4**, under similar experimental conditions, is much higher than that observed for **2** and **3** and is significantly greater than even the highest activity (K_{cat} = 3800 h^{-1}) reported for $[Cu_2(Sab4)_2(H_2O)_2]$.[9] Quite remarkably, complex **4** has also considerably superior catalytic activity compared to its carboxylate analogue $[Cu_2(Sbal)_2(H_2O)_2]$ (K_{cat} = 1287 h^{-1}).[9] It should be noted that for the five-coordinate dicopper(II) complexes to act as active catalysts, dissociation of the axial bonds should easily occur so that a free coordination site will be readily available for the binding of the substrate in a bridging mode.[31,32] A conformationally flexible ligand backbone can easily assist the conformational changes in the dinuclear core and hence the effective binding of the substrate. Compared to the strongly coordinating carboxylate oxygen atoms as in $[Cu_2(Sab4)_2(H_2O)_2]$ or $[Cu_2(Sbal)_2(H_2O)_2]$, the sulfonate groups are weakly coordinating and can be readily dissociated in solution to accommodate the substrate.[11,13] The combined effect of the sufficiently longer alkyl side arm and the weakly coordinating sulfonate donor group facilitate easy binding of the substrate, especially in **4**, and hence enhance its catalytic activity. Further, the presence of a weakly coordinating sulfonate donor group in **2** makes it a more efficient catalyst (K_{cat} = 1140 h^{-1}) than its carboxylate analogue $[Cu_2(Sgly)_2(H_2O)]$ (K_{cat} = 563 h^{-1}).

Our attempts to evaluate the catecholase activity of **2**, **3**, and **4** in pure water have been unsuccessful because of the insolubility of the product 3,5-DTBQ in water. Hence we tried to employ various ratios of MeOH/H_2O in order to investigate the solvent influence on the activity. Nonethe-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

less, reliable data could only be collected in 95:5 of MeOH/H_2O for **4**. From this result, it has been found that the activity of **4** increased by about 10% in the presence of water.

Summary

Several Cu^{II} complexes of the Schiff-base and reduced Schiff-base ligands formed between salicylaldehyde and aminomethane/ethanesulfonic acid have been synthesized and characterized by spectroscopic methods, and the solid-state structures have been determined by X-ray crystallography.

The salient structural features displayed by the Schiff-base copper complexes **1** and **3** provided an opportunity to perform comparative studies with those of the reduced Schiff-base complexes **2** and **4**. Copper centers in **1** and **3** assumed square pyramidal geometry with the apical position preferably occupied by the sulfonate oxygen atoms. While the reduced Schiff-base complexes **4** and **5** form a phenoxo-bridged dinuclear Cu_2O_2 core with intermetallic distances of 3.03 and 3.06 Å, the Schiff-base complexes **1** and **3** resulted in the formation of eight-membered rings with Cu···Cu distances of 5.12 and 5.33 Å, respectively. Apart from the expected dinuclear copper complexes with a Cu_2O_2 core, there are also reports of mononuclear copper complexes formed preferentially from Schiff bases containing amino acid residues.[33] But strikingly, because of the rigid C=N double bonds, H_2Sams and H_2Saes with sulfonic group offered the formation of eight-membered sulfonato-bridged dinuclear copper centers. Furthermore, **1** and **3** generated a hydrogen-bonded 2D structure unlike the 2D (4, 4) coordination polymeric network containing channels in **4**. Recrystallization of **4** in DMF/acetone mixture gave rise to **5** with the solvent DMF coordinated Cu^{II} centers. DMF, being a strong coordinating solvent, is able to displace the axial oxygen atoms of sulfonate groups in **4** and convert a (4, 4) net to a 2D hydrogen-bonded structure in **5**.

The crystal structures of **4** and **5** exhibit N–H···O hydrogen bonds from the metal-coordinated imine N–H and the sulfonate O while **1** and **3** illustrate a 2D hydrogen-bonding pattern involving the O(w)–H and sulfonate O atoms. These results will further enhance the structural insight into the transition-metal coordination chemistry of organosulfonates and their derivatives.[11–13,24] Variable temperature magnetic studies show that the *syn–syn* sulfonate O–S–O bridges in **3** can mediate antiferromagnetic interaction between Cu^{II} ions quite effectively, as well as the expected strong antiferromagnetic coupling through phenoxo bridges in **4**.

While investigating complexes **2**–**4** as synthetic functional models for the catechol oxidase, **4** has been found to show significantly higher activity than **2** and **3**. Comparative structural studies made between the Schiff-base complexes and the corresponding reduced Schiff-base complexes have provided more insight into the understanding of their catalytic activity. The trend observed in this study using different types of functional groups in the side arm of the ligand complements our earlier observation that the ring size of the side arm in these Cu^{II} complexes has profound influence on the kinetics of the oxidation of 3,5-DTBC. Further, the complexes described here with a weakly coordinating sulfonate group in the ligands have exhibited higher catecholase activity than that of the corresponding carboxylate analogues with strongly coordinating carboxylate groups. These findings are in agreement with the available data in the literature.[28–32]

Experimental Section

Materials: All reagents were purchased from commercial sources and used as received without any further purification.

Physical Measurements: The ^{1}H NMR spectra were recorded with a Bruker ACF300 FT-NMR instrument using TMS as an internal reference by using appropriate deuterated solvents and the IR spectra were recorded using an FTS165 Bio-Rad FTIR spectrometer in the range 4000–450 cm^{-1}. The absorption spectra were recorded with a Shimadzu UV-2501/PC UV/Vis spectrophotometer in aqueous solution. ESI-MS spectra were recorded with a Finnigan MAT LCQ mass spectrometer. The elemental analyses were performed in the Microanalytical Laboratory, Department of Chemistry National University of Singapore. Water present in the compounds was determined by an SDT 2960 TGA thermal analyzer with a heating rate of 10 °C min^{-1} under nitrogen using a sample size of about 10 mg per run. Variable temperature magnetic studies were made using a Quantum Design MPMS-XL5 SQUID magnetometer operating in an applied field of 5 kOe. The experimental susceptibilities were corrected for the diamagnetism (Pascal's tables).

Ligand

***N*-(2-Hydroxybenzyl)aminoethanesulfonic Acid (H_2Sae):** Salicylaldehyde (0.29 g, 2.50 mmol) in MeOH (5 mL) was added to a solution of aminoethanesulfonic acid (0.31 g, 2.50 mmol) in MeOH (10 mL) containing NaOH (0.11 g, 2.50 mmol). The yellow solution was stirred for about 45 min at room temperature prior to cooling in an ice bath. The intermediate Schiff base that formed was reduced with an excess of $NaBH_4$ (0.10 g, 2.65 mmol). The yellow color slowly discharged, and after half an hour the solution was acidified with acetic acid to pH 3–5. Then the solvent was reduced to half and Et_2O was added to get the product, which was filtered off, washed with Et_2O, dried, and stored in a desiccator, as H_2Sae is very hygroscopic. Because of its highly hygroscopic nature, elemental analysis results of H_2Sae were not consistent and hence are not provided. Yield: 0.35 g (60%). MS (EI): *m*/*z* (%) = 257.0 [(L^{2-} + Na)]. ^{1}H NMR ([D_6]DMSO): δ = 7.31 and 6.92 ppm (m, 4 H, aromatic), 4.21 (s, 2 H, benzylic –CH_2), 3.32 (t, 2 H, –CH_2), 3.21 (t, 2 H, –CH_2), 2.01 (s, –SO_3H). ^{13}C NMR: δ = 157.1 (=C_{ar}–O), 115.5 ($C2_{ar}$), 128.2 ($C3_{ar}$), 120.8 ($C4_{ar}$), 129.5 ($C5_{ar}$), 124.4 ($C6_{ar}$), 49.4 (–CH_2SO_3H), 48.9 (benzylic –CH_2), 44.0 (–CH_2CH_2). IR (KBr): $\tilde{\nu}$ = 3365 (OH), 2942 (NH), 1401 and 1115 (SOO^-), 1030 (SO), 1267 (phenolic CO) cm^{-1}.

Complexes

[Cu_2(Sams)$_2$(H_2O)$_2$] (1): Salicylaldehyde (0.1 mL, 0.94 mmol) was added to the clear solution containing aminomethanesulfonic acid (0.10 g, 0.94 mmol) and NaOH (0.04 g, 0.94 mmol) in aqueous MeOH (20 mL, 1:1, v/v) to obtain the yellow Schiff base. After stirring for 30 min, copper nitrate trihydrate in MeOH (0.23 g, 0.94 mmol) was directly added in portions and the resulting green product was further stirred for 30 min and filtered, washed with

water, MeOH, Et_2O and dried under vacuum. Dark green prismatic single crystals suitable for X-ray diffraction were obtained from the filtrate after one day. Yield: 0.2 g (67%). IR (KBr): $\tilde{\nu}$ = 3400 (OH), 1629 (C=N), 1305 and 1128 (SOO^-), 1247 (phenolic CO) cm^{-1}. UV/Vis (H_2O): λ_{max} (ε, $M^{-1}cm^{-1}$): 678 nm (200), 367 nm (13135). MS (ESI): *m/z* (%) = 276.7 $[CuL]^+$, 553.5 $[Cu_2L_2]$. $C_{16}H_{14}Cu_2N_2S_2O_8(H_2O)_2$ (589.5): calcd. C 32.6, H 3.1, N 4.7, S 10.9, H_2O 6.1; found C 32.5, H 3.0, N 4.4, S 10.8, H_2O 6.8 (from TG weight loss).

$[Cu_2(Sam)_2(H_2O)_2]\cdot H_2O$ (2): Salicylaldehyde (0.1 mL, 0.94 mmol) in MeCN (10 mL) was added to a clear solution of aminomethanesulfonic acid (0.10 g, 0.94 mmol) and NaOH (0.08 g, 1.88 mmol) in MeOH (10 mL) and the resulting yellow Schiff base solution was stirred for 30 min. The mixture was then cooled in an ice bath followed by the addition of $NaBH_4$ (0.02 g, 0.47 mmol). The yellow color of the Schiff base slowly discharged after 20 min and the clear solution was maintained at a pH of 4–6 by adding a few drops of CH_3COOH. Copper nitrate trihydrate (0.23 g, 0.94 mmol) was added to this acidic solution to facilitate in situ complexation. The dark green product obtained after stirring for 1 h was filtered off, washed with MeOH (2 mL), Et_2O (5 mL), and then dried under vacuum. Yield: 0.22 g (66%). IR (KBr): $\tilde{\nu}$ = 3450 (OH), 2920 (NH), 1380 and 1147 (SOO^-), 1037 (SO), 1279 (phenolic CO) cm^{-1}. MS (ESI): *m/z* (%) = 278.7 $[CuL]^+$, 557.8 $[Cu_2L_2]$, 580.7 $[Cu_2L_2Na]^+$. UV/Vis (MeOH) λ_{max} (ε, $M^{-1}cm^{-1}$): 717 nm (190), 405 nm (870). $C_{16}H_{18}Cu_2N_2S_2O_8(H_2O)_3$ (611.6): calcd. C 31.4, H 4.0, N 4.7, S 10.5, H_2O 8.4; found C 31.7, H 4.1, N 4.6, S 10.8, H_2O 8.0 (from TG weight loss).

$[Cu_2(Saes)_2(H_2O)_2]\cdot 2H_2O$ (3): Compound **3** was prepared by a method similar to that described for **1** by using 2-aminoethanesulfonic acid. Yield: 0.2 g (71%). IR (KBr): $\tilde{\nu}$ = 3443 (OH), 1617 (C=N), 1287 and 1173 (SOO^-), 1244 (phenolic CO) cm^{-1}. UV/Vis (H_2O): λ_{max} (ε, $M^{-1}cm^{-1}$): 688 nm (160), 322 nm (5000). $C_{18}H_{18}Cu_2N_2S_2O_8(H_2O)_4$ (653.6): calcd. C 33.1, H 4.0, N 4.3, S 10.0, H_2O, 11.1; found C 33.3, H 4.1, N 4.4, S 10.1, H_2O 11.9 (from TG weight loss).

$[Cu_2(Sae)_2]\cdot 2H_2O$ (4): Copper acetate (0.08 g, 0.40 mmol) in MeOH (10 mL) was added to a solution of the ligand H_2Sae (0.09 g, 0.40 mmol) in MeOH (20 mL) and the resultant solution stirred for about 6 h. The green precipitate formed was filtered, washed with MeOH and Et_2O, and dried under vacuum. Slow evaporation of the dark green clear aqueous solution of **4** furnished dark green single crystals after 4–5 d. Yield: 0.06 g (55%). IR (KBr): $\tilde{\nu}$ = 3410 (OH), 2935 (NH), 1312 and 1181 (SOO^-), 1020 (SO), 1255 (phenolic CO) cm^{-1}. UV/Vis (H_2O): λ_{max} (ε, $M^{-1}cm^{-1}$): 736 nm (190), 420 nm (855). MS (ESI): *m/z* (%) = 291.0 $[(CuL)^-]$, 522.0 $[(CuL_2)^-]$, 584.2 $[(Cu_2L_2)^-]$, 875.0 $[(Cu_3L_3)^-]$, 1106.0 $[(Cu_3L_4)^-]$, 1397.7 $[(Cu_4L_5)^-]$, 1689.6 $[(Cu_5L_6)^-]$. $C_{18}H_{22}Cu_2N_2S_2O_8$ (H_2O) (602.18): calcd. C 34.7, H 4.2, N 4.5, S 10.3, H_2O 5.8; found C 34.3, H 4.2, N 4.6, S 10.3, H_2O 5.9 (from TG weight loss).

$[Cu_2(Sae)_2(DMF)_2]\cdot 2DMF$ (5): The filtered and clear dark green solution of **4** (0.04 g) in DMF (4 mL) was slowly diffused into acetone (10 mL) in a small beaker. Dark green crystals suitable for the single-crystal X-ray diffraction studies were obtained after a week. Yield: 0.02 g (50%). IR (KBr): $\tilde{\nu}$ = 2928 (NH), 1387 and 1150 (SOO^-), 1023 (SO), 1260 (phenolic CO) cm^{-1}. UV/Vis (MeOH) λ_{max} (ε, $M^{-1}cm^{-1}$): 731 nm (195), 412 nm (660). MS (ESI): *m/z* (%) = 292.2 $[(CuL)^-]$, 522.3 $[(CuL_2)^-]$, 584.2 $[(Cu_2L_2)^-]$, 875.0 $[(Cu_3L_3)^-]$. $C_{30}H_{46}Cu_2N_6S_2O_{12}$ (873.9): calcd. C 41.2, H 5.3, N 9.6, S 7.0; found C 41.8, H 5.1, N 9.2, S 7.2.

Catalytic Activity for the Oxidation of 3,5-DTBC and Kinetic Measurements: Catecholase activity of complexes for the oxidation of 3,5-DTBC by complexes **2**–**4** was measured by recording their electronic spectra at 25 °C by time-dependent UV/Vis spectroscopy. For this purpose, 10^{-4} M solutions of complexes **1**–**4** were treated with 50 equiv. of 3,5-DTBC under aerobic conditions. The UV/Vis spectra of the original solution directly after the addition and after 10, 20, and 30 min were recorded and corrected for volume changes up to 2 h.

The kinetics of oxidation of 3,5-DTBC were measured at 25 °C by the method of initial rates by monitoring the growth of the absorption band at 390 nm of the product 3,5-DTBQ. The complex (2 mg) was added to the 3,5-DTBC solution (25 mL) of concentrations 1.0×10^{-3}–1.5×10^{-2} M so that the concentration of the complex was maintained at 10^{-4} M. During the first 10 min of the reaction, the development of the absorption band at 390 nm was monitored. In order to determine the kinetic parameters, the Michaelis–Menten approach was applied.[8,34]

The reactivity studies were performed in methanol solution because of the good solubility of the substrate, 3,5-DTBC, and of its product 3,5-DTBQ. Also, because of the considerable solubility of **4** in water, investigations have also been attempted in a MeOH/H_2O mixture for comparison. Attempts to record the activity of **2** and **3** in MeOH/H_2O were unsuccessful because of the solubility problem producing unreliable data. Preliminary qualitative studies on the activity of **1** have also been unsuccessful owing to its insolubility in common solvents.

X-ray Crystallography: The diffraction experiments were carried out on a Bruker AXS SMART CCD diffractometer. The program SMART[35a] was used for collecting frames of data, indexing reflection and determination of lattice parameter, SAINT[35a] for integration of the intensity of reflections and scaling, SADABS[35b] for absorption correction, and SHELXTL[35c] for space group and structure determination, least-squares refinements on F_2. Positional and thermal parameters of the non-hydrogen atoms were refined in the least-squares cycles. The hydrogen atom positions and individual *U*'s were refined for the water molecules in **1**. One of the hydrogen atoms of the lattice water in **3** was found to be disordered. The option DFIX was used in the model to idealize the geometry. No hydrogen atoms could be located for the lattice water in **4**. The methyl carbon atom of the lattice DMF was found to be disordered (0.65/0.35) in **5**. Only isotropic thermal parameters were refined for the minor component of the disorder.

CCDC-266070 (for **1**), CCDC-266071 (for **3**), CCDC-266072 (for **4**), and CCDC-266073 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also the footnote on the first page of this article): Molecular and packing diagrams of **5**, thermogravimetry of **1**–**5**, UV/Vis plots and Lineweaver–Burk plots for **2**–**4** (total number of pages: 7).

Mn^{II}/Co^{II}-Terephthalate Frameworks Containing Dipyridine Coligands: Syntheses, Crystal Structures, Magnetic Behaviors, and Thermal Studies

Subal Chandra Manna,[a] Sanjit Konar,[a] Ennio Zangrando,[b] Ken-ichi Okamoto,[c] Joan Ribas,*[d] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Manganese(II) / Cobalt(II) / Crystal structure / Magnetic behavior / Supramolecular chemistry

Three new metal–organic hybrid polymeric networks of Co^{II} and Mn^{II} with the molecular formulae $[Co(bpp)(tp)(H_2O)_2]$ (**1**), $[Mn(bpds)(tp)(H_2O)_2]\cdot(bpds)$ (**2**), and $[Mn(4,4'\text{-bipy})(H_2O)_4]\cdot(tp)$ (**3**) (bpp = 4,4′-trimethylenedipyridine; bpds = 4,4′-bipyridyl disulfide; 4,4′-bipy = 4,4′-dipyridyl; tp = terephthalate) have been synthesized and characterized by single-crystal X-ray diffraction studies, low temperature (300–2 K) magnetic measurements, and thermal behaviors. The structure determination of complexes **1** and **2** reveals a parallel interpenetrated structure of 2D layers with (4,4) topology, with metal ions at the nodes connected through tp and *N*,*N*-donor coligands. The octahedral N_2O_4 chromophore surrounding the metal ion results from *trans* located tp oxygens, two water molecules, and two nitrogen donors of the co-ligands in the *cis* position. The presence of uncoordinated bpds between the interpenetrated layers leads to the formation of a wafer-like structure for **2**. In complex **3**, however, manganese(II) ions bridged by 4,4′-bipy and coordinated by four water molecules give rise to a 1D polymeric chain. The adjoining chains encapsulate terephthalate anions (tp) to give a 3D structure through H-bonding. Low-temperature magnetic data indicate weak antiferromagnetic coupling in complexes **1** and **2**.

Introduction

The construction of one- to three-dimensional functional metal-organic hybrid materials of paramagnetic metal ions is of great interest as their intriguing network topologies lead to potential applications,[1] for example in electrical, conductivity, magnetism, host–guest chemistry, ion exchange, catalysis, nanotechnology, fluorescence, nonlinear optics, etc. Research in this field has been carried out by a number of eminent groups, in particular those of Rao,[2] Yaghi,[3] Fujita,[4] Zaworotko,[5] etc. The availability of new polyfunctional ligands, as well as the discovery of alternative synthetic procedures, has led to the syntheses of unique and novel metal–organic frameworks (MOFs) that suggest routes for chemists and physicists to pursue in search of such materials. A literature survey shows that the most commonly used strategies for the synthesis of MOFs are the use of (a) anionic bridging ligands, which, in addition, can partially or fully counterbalance the charge of the metal centers, (b) anionic as well as neutral spacers to increase the possibility of enhancing the dimension of molecular materials, and (c) only neutral spacers, where charges of the metal centers are counterbalanced by noncoordinating anions.

Recently, we have reported the synthesis of some structurally and magnetically interesting MOFs using strategy (a), such as $[Ni_3(fum)_2(\mu_3\text{-}OH)_2(H_2O)_4]_n\cdot 2nH_2O$,[6] $[Cu(\mu\text{-}fum)(NH_3)_2]_n\cdot 2nH_2O$,[7] $[Mn(mal)(H_2O)_2]_n$,[8] and $[Co(H_2O)_4(fum)]_n\cdot nH_2O$,[9] where fumarate (fum) and malonate (mal) dicarboxylates act as anionic bridging ligands only. We have also reported MOFs obtained through strategies (b), where dicarboxylates are used in combination with neutral spacers, such as $[\{Cu_3(mal)_2(bpe)_3(H_2O)_2\}(NO_3)_2(H_2O)_2]_n$,[10] $[Cu_2(fum)_2(4,4'\text{-bipy})]_n\cdot 0.5nH_2O$,[11] $[Mn_2(mal)_2(4,4'\text{-bipy})(H_2O)_2]_n$,[8] $[Cu_4(mal)_4(urotropin)]\cdot 7H_2O$ and $[Co_2(mal)_2(urotropin)]\cdot 2H_2O$,[12] and $[Ni_3(maleate)_2(bpe)_4(H_2O)_4](NO_3)_2\cdot H_2O$, [Mn(adipate)(bpe)],[13] [Ni(fum)(bpe)], and [Ni(fum)(bpp)(H_2O)][14] [bpe = 1,2-(bispyridine)ethane, bpp = 1,3-bis(4-pyridyl)propane], and (c), where noncoordinated dicarboxylates counterbalance the charge of the metal ions, as in $[Co(H_2O)_4(4,4'\text{-bipy})]_n(fum)_n\cdot 4nH_2O$[9] and $[\{Mn(bpe)(H_2O)_4\}(C_4O_4)\cdot 4.5H_2O]$ ($C_4O_4^{2-}$ = acetylene dicarboxylate).[15] Thus, depending on the metal ion and dicarboxylate or dicarboxylate/neutral bipyridine spacer, several MOFs with novel structural diversity and interesting

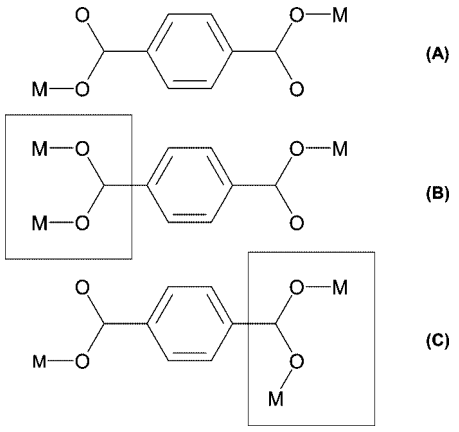
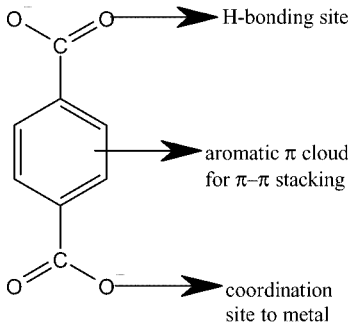
magnetic properties have been reported. This has prompted us to synthesize new MOFs using a well-known but less-documented dicarboxylate anion − terephthalate − in combination with other neutral bipyridines. The choice of terephthalate arises as it possesses versatile coordination modes (Scheme 1) and has the ability to form large and tightly bound metal cluster aggregates with specific and directional hydrogen bonds in building the molecular architecture,[16] as well as to undergo π–π stacking due to the presence of aryl rings (Scheme 2).



Scheme 1.



Scheme 2.

Herein we report the syntheses, crystal structures, low-temperature magnetic studies, and thermal behaviors of three novel Mn^{II}/Co^{II}-terephthalate frameworks containing dipyridyl coligands, namely $[Co(bpp)(tp)(H_2O)_2]$ (**1**), $[Mn(bpds)(tp)(H_2O)_2]\cdot(bpds)$ (**2**), and $[Mn(4,4'\text{-bipy})(H_2O)_4]\cdot(tp)$ (**3**) (tp = terephthalate; bpp = 4,4′-trimethylenedipyridine; bpds = 4,4′-bipyridyl disulfide; 4,4′-bipy = 4,4′-dipyridyl). Complexes **1** and **2** show unexpected 2D parallel interpenetrated structural motifs, whereas in complex **3** the use of linear 4,4′-bipy spacers gives rise to 1D coordination polymers with encapsulated tp anions. The low-temperature magnetic data of complexes **1** and **2** show weak antiferromagnetic coupling. Complex **1** exhibits thermally induced reversible octahedral (pink) ⇌ tetrahedral (blue) thermochromism upon dehydration/rehydration.

Results and Discussion

Description of the Structures

Complex 1

The crystal structure of complex **1** consists of 2D corrugated layers of square meshes of composition $[Co(tp)(bpp)(H_2O)_2]_n$, as depicted in Figure 1. The cobalt ions, with octahedral coordination geometry, occupy the 4-connecting nodes while bridging tp and bpp ligands give rise to a square grid of equal sides (11.486 × 11.486 Å). Intranet hydrogen bonds reinforce the overall structure [O(1w)–O(4) = 2.66; O(2w)–O(6) = 2.64 Å]. The N_2O_4 chromophore about the cobalt(II) center involves *trans* located tp oxygens and two water molecules, with two bpp nitrogen donors in the *cis* positions. The coordination bond lengths cover the range 2.106(2) Å [Co–O(1w)] to 2.140(2) Å [Co–N(2)] (Table 1). The bpp ligand exhibits a *TG* conformation[17] with torsion angles of –174.5(3)° and 73.4(4)° about the propyl chain. A careful analysis of the crystal structure shows parallel interpenetrated layers,[18,19] as illustrated in Figure 2, where weak π–π tp ring interactions are evident (distance between centroids = 3.807 Å). The spacing between the mean planes through the cobalt atoms of each sheet is 2.381 Å. Both the layers involved in interpenetration (A and B are structurally equal) are linked to the adjacent sheet to form a concatenated -AB-BA-AB- structure, where hyphens indicate H-bonds involving the water molecule O(1w) and the tp oxygen O(6) (O···O = 2.76 Å). As shown in Figure 3, these interactions contribute to the enhancement of molecular dimensionality. It is worthwhile to note that the aqua ligand O(1w) forms intra- and interlayer H-bonds and presents a shorter coordination distance in comparison to Co–O(2w) [2.106(2) vs. 2.132(2) Å]. The tp carboxylates are rather tilted from a coplanar conformation and form dihedral angles of 26.0(2)° and 37.6(2)° with the aromatic ring as a subtle balance to favor the intranet

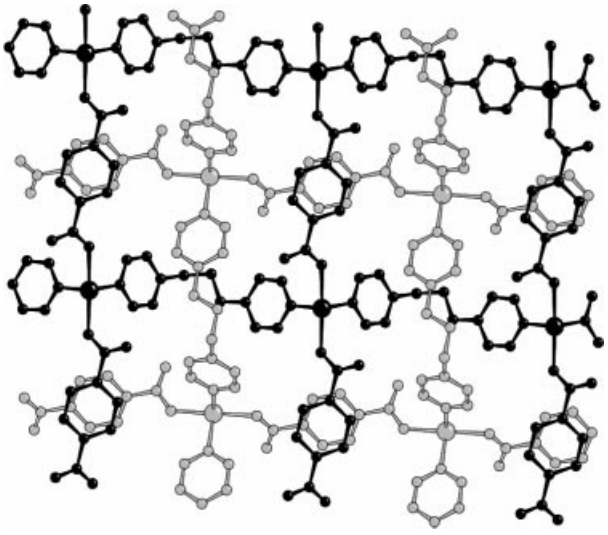

Figure 2. Parallel interpenetration of 2D sheets in complex **1** (coordinated water oxygens not shown for sake of clarity).

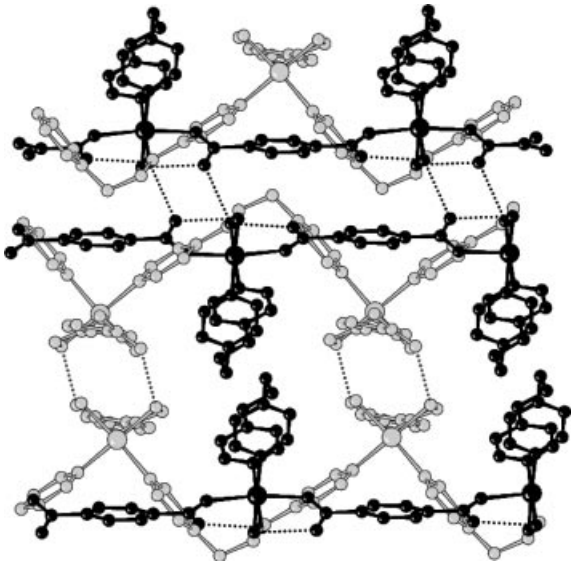

Figure 3. Interpenetrated sheets (each pair indicated in black and gray) concatenated by H-bonds (dotted lines) in complex **1**.

Complex 2

Complex **2** contains a 2D undulating $[Mn(tp)(bpds)(H_2O)_2]_n$ sheet (Figure 4), extending in the *ab* plane, where octahedral manganese ions occupy the 4-connecting nodes of the square grid, which has equal sides of 11.425 Å. The square grid is strengthened by hydrogen bonds involving the aqua ligand and the adjacent carboxylate oxygen [O(1w)–O(3′) = 2.71 Å]. The manganese(II) ion is positioned on a twofold axis with *trans* located tp oxygens, with the coordination geometry being completed by two water molecules and two bpds N donors in the *cis* position. The Mn–O(2), Mn–O(1w), and Mn–N(1) bond lengths are 2.131(2), 2.204(3), and 2.309(3) Å, respectively (Table 1). The 2D layers reveal a parallel interpenetration with a topology closely comparable to that observed in complex **1** (Figure 5). The entangled layers in the present arrangement seem more tightly connected, with the mean planes through the metals being separated by 2.228 Å and the π-stacking of tp rings being more efficient (centroid-to-centroid distance = 3.568 Å). The conformation assumed by the tp is also very similar to that found in the cobalt complex, with angles between the carboxylate groups and aromatic ring of 26.3(3)°. However, compared with complex **1**, the main difference emerges from the presence of uncoordinated bpds between the interpenetrated layers. This peculiar feature leads to the formation of a wafer-like structure, where the bidentate bpds ligands are linked to water molecules through hydrogen bonds (N···O = 2.840 Å;L N···HO = 158.9°). A view of the crystal packing is given in Figure 6.

An estimation of the torsion angles around the disulfide bonds in a series of coordination polymers indicates rigidity in the bpds ligands [C–S–S–C angles between 83.8(6)° and 95.5(8)°],[20] regardless of the different coordination environment. The present value for the coordinated bpds ligand falls in the range reported (92.5°), while it is 102.7° in free bpds. Correspondingly, the N···N distance is longer in the

latter (8.494 vs. 8.029 Å), a conformation that appears to assist the N–OH_2 hydrogen bond.

As a comparison, in the 1D polymer [Mn(bpds)(F_6-acac)$_2$],[21] (F_6-acac = hexafluoroacetylacetonate), which represents the only known example of manganese(II) ions bridged by a bpds ligand, longer Mn–N distances of 2.282 Å are found, with the metals separated by 11.785 Å.

Complex 3

The $Mn(H_2O)_4$ units in complex **3** are bridged by 4,4′-bipy ligands to give a 1D coordination polymeric array along the crystallographic *b* direction, with metals located on twofold axes. A drawing of the packing with the atom labeling scheme is shown in Figure 7; a selection of bond

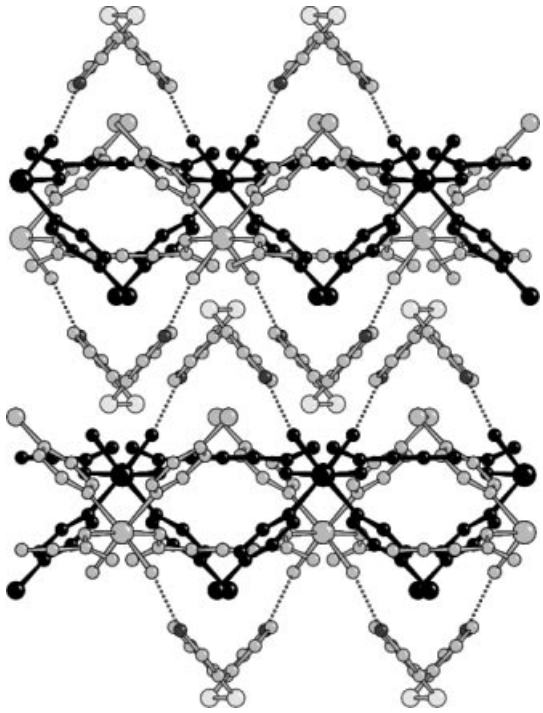

Figure 6. Crystal packing (view along axis *b*) of complex **2** with uncoordinated bpds ligands sandwitched between the parallel interpenetrated layers and connected through H-bonds (dotted lines) to coordinated water molecules. The larger circles indicate Mn ions.

lengths and bond angles is given in Table 1. The MnN_2O_4 chromophore presents a slightly distorted octahedral coordination geometry, with the equatorial oxygens showing a tetrahedral distortion (±0.18 Å). The Mn–O(1w) and Mn–O(2w) distances are 2.208(2) and 2.188(2) Å, respectively; the nitrogen bipy donors N(1) and N(2) occupy the *trans* axial positions with Mn–N(1) and Mn–N(2) distances of 2.210(2), 2.269(3) Å, respectively. The rings of the 4,4′-bipy ligand are not coplanar, but are tilted by about 20°. The terephthalate dianions are also located on twofold axes and are sandwiched by 4,4′-bipy ligands of contiguous polymeric chains to give rise to a three-dimensional structure through a H-bonding scheme with the water molecules. In fact, O2w is involved in H-bonding with the sandwiched tp anions (O3 and O4 at 2.74 Å, mean value), while O1w is connected to O4 at a longer distance (2.90 Å) and also a symmetry-related O3 of a side-located tp at 2.71 Å (not shown in Figure 7).

The 4,4′-bipy ligand spans the metal ions at a distance correspondening to the length of the crystallographic *b* axis, namely 11.565 Å (Figure 7), while the shortest interchain Mn···Mn separation in the 3D architecture is 6.562 Å. The orientations (dihedral angles) taken up by carboxylate groups with respect to the phenyl ring are 4.86(5)° and 22.03(6)°, which is assumed to favor the H-bonding.

The overall structure presents structural features comparable to those observed in the analogous Mn polymeric derivative with croconate $(C_5O_5)^{2-}$ dianions.[22] However, accounting for the smaller dimensions of $(C_5O_5)^{2-}$ (with re-

spect to tp) in the latter, an additional water molecule was detected in the lattice in order to favor the H-bonding interactions.

Magnetic Properties

Although the crystal nets consist of a two-dimensional structure with terephthalate and bpp or bpds as bridging ligands in complexes **1** and **2**, respectively, we assumed the possible couplings between the long amines bpp and bpds to be zero. With this hypothesis, the magnetic data can be interpreted as being derived from a pseudo-one-dimensional structure formed by cobalt(II) and manganese(II) ions (for **1** and **2**, respectively) linked by terephthalate at a long distance. For complex **3**, the terephthalate dianion remains encapsulated and the manganese ions are bridged by long 4,4′-bipy ligands (Mn···Mn = 11.565 Å). Such a type of bridging ligand usually gives negligible antiferromagnetic interactions,[23] therefore we did not study the magnetic behavior.

Complex 1

Considering the spin-orbit coupling due to the $^4T_{1g}$ ground state for octahedral Co^{II} complexes,[24] precise calculations to derive the *J* parameter from experimental data in all the temperature range are not possible except for dinuclear[25] or small polynuclear complexes.[26] One-dimensional systems of Co^{II} are frequently associated with anisotropic Ising systems, and they can be fitted in the low-temperature zone by assuming again an effective spin, *S*′, of ½.[27] More recently, Rueff et al.[28] have proposed a phenomenological approach for some low-dimensional Co^{II} systems that allows an estimation of the strength of the antiferromagnetic exchange interactions. They postulated the phenomenological equation:

$$A\chi_M T = A \exp(-E_1/kT) + B \exp(-E_2/kT)$$

where $A + B$ is the Curie constant [approx. 2.8–3.4 $cm^3 mol^{-1} K$ for octahedral cobalt(II) ions], and E_1 and E_2 represent the "activation energies" corresponding to the spin-orbit coupling and the antiferromagnetic exchange interaction, respectively. E_1/k, the effect of spin-orbit coupling and site distortion, is of the order of +100 K.[28,29] Excellent results have been reported in one- and two-dimensional cobalt(II) complexes.[28]

The $\chi_M T$ vs. *T* plot for **1** (χ_M is the molar magnetic susceptibility for one Co^{II} ion) is shown in Figure 8. A $\chi_M T$ value of 3.27 $cm^3 mol^{-1} K$ at 300 K is a typical value for the Co^{II} system.[30,31] Upon decreasing the temperature, the $\chi_M T$ values decrease continuously to 1.91 $cm^3 mol^{-1} K$ at 2 K. To calculate an estimated *J* value we used the Rueff expression, which suitable for any temperature greater than the possible T_c.[28] The fit values obtained with this procedure are: A + B = 3.5 $cm^3 mol^{-1} K$, in agreement with those given in the literature.[28] The E_1/k value of 69.09 K is of the same magnitude as those reported by Rueff et al. for several one- and two-dimensional cobalt(II) complexes.[30b] As for the value found for the antiferromagnetic exchange interaction, it is very weak (E_2/k = 0.21 K), corresponding to $J = -0.42$ K (ca. -0.3 cm^{-1}), according to the Ising chain approximation, $\chi_M T = \exp(J/2kT)$ (Figure 8). The reduced magnetization curve, $M/N\beta$, at 2 K tends to 2.35 $N\beta$ at 5 T, a typical value for isolated or quasi-isolated cobalt(II) ions (Figure 8 inset).

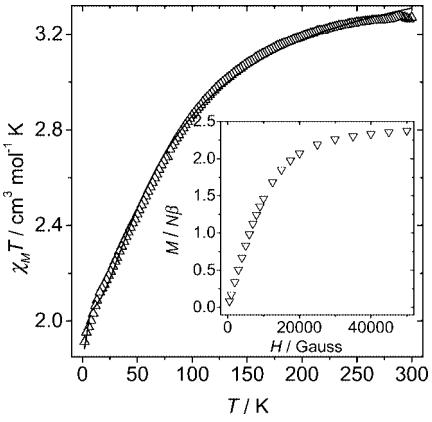

Figure 8. Plot of $\chi_M T$ vs. *T* for complex **1** (solid line represents the best fit using the Rueff formula). Inset: plot of the reduced magnetization ($M/N\beta$) vs. *H* at 2 K for complex **1**.

Complex 2

The $\chi_M T$ vs. *T* plot is given in Figure 9 for one manganese(II) ion. The $\chi_M T$ values start at 4.35 $cm^3 mol^{-1} K$, corresponding to the value for one isolated manganese(II) ion (with $g \approx 2.00$). This value decreases smoothly to close to 4.0 $cm^3 mol^{-1} K$ at 2 K. Such behavior is typical for a very weak antiferromagnetic coupling between manganese(II) ions in the chain. The magnetism of this kind of one-dimensional Mn^{II} system has been studied theoretically mainly by Fisher by assuming an infinite number of classical spins (S = 5/2).[32] The best-fit parameters were: $J = -0.045 \pm 0.01$, $g = 2.00 \pm 0.004$, and $R = 4.1 \times 10^{-3}$ (R is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2/\Sigma_i[(\chi_M T)_{obs}]$).[33] The g value agrees perfectly with that expected for a manganese(II) ion (S = 5/2, g = 2.00). The reduced magnetization (Figure 9, inset) is also indicative of a very weak antiferromag-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

netic coupling. The experimental values tend to 4.8 $N\beta$ and practically follow the Brillouin formula at 2 K for $S = 5/2$ and $g = 2.0$.

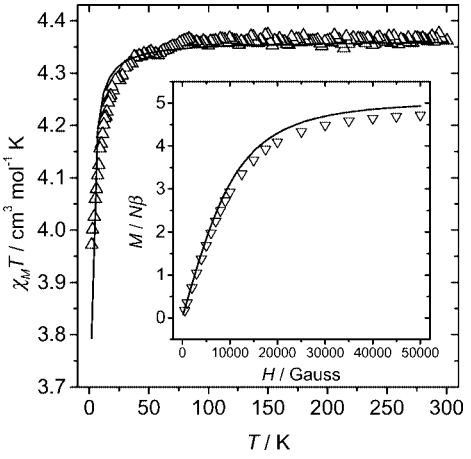

Figure 9. Plot of $\chi_M T$ vs. T for complex **2** (solid line represents the best fit). Inset: plot of the reduced magnetization, $M/N\beta$ (solid line indicates the Brillouin formula for $S = 5/2$ and $g = 2.0$).

The small antiferromagnetic J values for **1** and **2** may be interpreted as being due to the terephthalate bridging ligand. When the coordination mode is that shown in Scheme 1A (complexes **1** and **2**), the terephthalate bridging ligand shows a very small antiferromagnetic coupling for M = Mn^{II}, Co^{II}, Ni^{II}, and Cu^{II}.[33] To the best of our knowledge, only two Mn complexes with this kind of coordination have been reported to date – $[\{Mn(dca)(terpy)(MeOH)\}_2(\mu\text{-ta})]$[34] and $[Mn_2(phen)_4(H_2O)_2(\mu\text{-ta})](ClO_4)_2$.[35] The calculated J values of –0.06 cm^{-1} and –0.065 cm^{-1}, respectively, are in good agreement with that found in complex **2**. All these very weak J values are in accordance with the MO calculations made by Cano et al.,[35] which show that a terephthalate bridge is not a suitable bridging unit to mediate significant exchange coupling.

Thermal Studies

The pink complex **1** starts to lose its coordinated water molecules, upon heating, at around 125 °C and becomes dehydrated at 190 °C, yielding the species [Co(bpp)(tp)] (**1a**, blue), which reverts to **1** in a humid atmosphere (relative humidity of ca. 60%) at ambient temperature. This dehydration-rehydration process involves an octahedral ⇌ tetrahedral transformation of Co^{II} that shows thermochromism, as evidenced from the solid state electronic spectra [(19455, ca. 16666, and 8510 cm^{-1} for **1**) and (19300, 17985, 14000–15500, and 8802 cm^{-1} for **1a**; Figure S1)] and room temperature magnetic measurements [μ_{eff} for **1** (see magnetic properties) and for **1a** 4.82 μ_B (at 300 K)].

Complex **2** starts to lose water molecules, upon heating, at 110 °C and shows continuous decomposition with concomitant formation of an intermediate species. The initial temperature of dehydration suggests the presence of coordinated water molecules as well as their involvement in H-bonding. It should be noted that after dehydration the network in **2** collapses as the terephthalate carboxylate fails to function here as a chelate to attain octahedral geometry, which is a requirement for the existence of Mn^{II} in the polymeric networks according to the crystal structure (Figure 4).

Complex **3** is thermally stable up to 100 °C, a lower temperature than that of **2**. It undergoes dehydration in two steps that overlap each other and is fully dehydrated at 150 °C. The dehydrated species collapses immediately upon further heating as the manganese centers fail to attain the required geometry after removal of their water molecules.

Conclusions

We have reported the syntheses, crystal structures, low-temperature magnetic studies, and thermal behaviors of three metal–organic hybrid polymeric networks. The tp and bipyridine ligands in complexes **1** and **2**, respectively, take part in formation of a covalently bonded 2D parallel interpenetrated polymeric architecture, whereas in complex **3** the tp anions are encapsulated by 1D Mn(4,4′-bipy) chains. The presence of uncoordinated bpds ligands in **2** between the interpenetrated layers leads to formation of a wafer-like structure where bpds is anchored to coordinated water molecules through H-bonds. All these crystal structures contain extensive H-bonding between the water molecules and the tp oxygens, which increases the dimensionality of the architectures to 3D. As a consequence, in order to favor H-bonding connections the tp carboxylate groups show different conformations, as indicated by the dihedral angles of the carboxylates with respect to the phenyl ring. These are about 30° in complexes **1** and **2**, and quite different in **3** (about 5° and 22°). The variable-temperature magnetic data reveal weak antiferromagnetic coupling for **1** and **2**.

Experimental Section

Materials: High purity 4,4′-trimethylenedipyridine (98%), 4,4′-bipyridyl disulfide (Aldrithiol-4; 98%), 4,4′-dipyridyl (98%), disodium terephthalate (96%), and manganese(II) chloride tetrahydrate (98%) were purchased from the Aldrich Chemical Co. Inc. and were used. All other chemicals were of AR grade.

Physical Measurements: Elemental analyses (carbon, hydrogen, and nitrogen) were performed with a Perkin–Elmer 240C elemental analyzer. IR spectra were measured as KBr pellets on a Nicolet 520 FTIR spectrometer. Magnetic measurements were carried out with polycrystalline samples (20–30 mg) by the Servei de Magnetoquímica, Universitat de Barcelona, with a Quantum Design MPMS SQUID magnetometer operating at a magnetic field of 0.1 T, in the temperature range 2–300 K. The diamagnetic corrections were evaluated from Pascal's constants. Thermogravimetric analyses were carried out with a Mettler Toledo Star system. The UV/Vis reflectance spectra were recorded between 300–1400 nm with a Hitachi U-3501 spectrophotometer at room temperature in the solid state.

Crystallographic Data Collection and Refinement: Crystal data and details of data collections and refinements for the structures re-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ported are summarized in Table 2. Diffraction data for all complexes were carried out on a Rigaku Mercury CCD area detector using graphite-monochromated Mo-K_α radiation. Cell refinement, indexing, and scaling of the data sets were carried out using the Crystal package.[36] All the structures were solved with SIR97[37] and subsequent Fourier analyses[38] and refined by the full-matrix least-squares method based on F^2 with all observed reflections.[38] Most of the water hydrogens detected in the difference Fourier map were restrained with a fixed O–H bond length (0.85 Å). All the calculations were performed using the WinGX System, Ver 1.64.05.[39]

CCDC-262151 to -262153 (for **1**–**3**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

[Co(bpp)(tp)(H$_2$O)$_2$] (1): A methanolic solution (5 mL) of bpp (1 mmol, 0.198 g) was added dropwise to a methanolic solution (5 mL) of $Co(NO_3)_2{\cdot}6H_2O$ (1 mmol, 0.291 g) with constant stirring. An aqueous solution (10 mL) of disodium terephthalate (1 mmol, 0.210 g) was added to the resulting light-pink reaction mixture and stirred for 1 h. A deep-pink complex separated out. Single crystals suitable for X-ray analysis were obtained by diffusing a methanolic solution (10 mL) of bpp into an aqueous (10 mL) layer containing $Co(NO_3)_2{\cdot}6H_2O$ and disodium terephthalate (1:1) in a tube. The deep-pink crystals deposited at the junction of the two layers after a few days. Yield: 0.320 g (70%). $C_{21}H_{22}CoN_2O_6$ (457.35): calcd. C 55.10, H 4.81, N 6.12; found C 55.18, H 4.80, N 6.16. IR: $\tilde{\nu}$ = 3604 (vs), 3256 (s), 3071 (w), 2943 (s), 2872 (vw), 1615 (vs), 1546 (vs), 1501 (w), 1380 (s) 1018 (w), 795 (s), 757 (s), 510 (w) cm^{-1}.

[Mn(bpds)(tp)(H$_2$O)$_2$]·(bpds) (2): A methanolic solution (10 mL) of manganese(II) chloride tetrahydrate (1 mmol, 0.197 g) was allowed to react with an aqueous solution (10 mL) of disodium terephthalate (1 mmol, 0.210 g) and stirred for 20 min. Then, a methanolic solution (5 mL) of bpds (1 mmol, 0.220 g) was poured slowly into it and the resulting mixture was refluxed for 4 h. It was then allowed to cool and filtered. The filtrate was kept in a $CaCl_2$ desiccator and shiny, yellowish single crystals suitable for X-ray determination were obtained after a few days. Yield: 0.500 g (72%). $C_{28}H_{24}MnN_4O_6S_4$ (695.70): calcd. C 48.30, H 3.45, N 8.05; found C 48.29, H 3.45, N 8.04. IR: $\tilde{\nu}$ = 3500–3090 (s), 3008 (w), 2904 (w), 1579 (vs), 1566 (vs), 1379 (s), 1319 (w), 1222 (vw), 815 (w), 758 (w), 704 (w) cm^{-1}.

[Mn(4,4′-bipy)(H$_2$O)$_4$]·(tp) (3): This complex was synthesized following the procedure adopted for complex **2** using 4,4′-bipy (1 mmol, 0.156 g) instead of bpds. Colorless crystals of **3** suitable for X-ray diffraction were obtained from the $CaCl_2$ desiccator after a few days. Yield: 0.313 g (70%). $C_{18}H_{20}MnN_2O_8$ (447.30): calcd. C 48.29, H 4.47, N 6.26; found C 48.28, H 4.48, N 6.27. IR: $\tilde{\nu}$ = 3500–3020 (s, v br.), 1656 (vw), 1610 (s), 1559 (vs), 1419 (vw), 1368 (vs), 1067 (vw), 807 (w), 752 (w), 632 (vw) cm^{-1}.

Supporting Information: A table containing H-bonding parameters, the thermogravimetric curves of complexes **1**, **2**, and **3**, and the solid-state electronic spectra for complexes **1** and **1a**, see also footnote on the first page of this article.

Steady-State and Time-Resolved Photophysical Studies on a Series of Gallium Phthalocyanine Monomers and Dimers

Yu Chen,*[a,b] Yasuyuki Araki,[b] Michael Hanack,[c] Mamoru Fujitsuka,[b] and Osamu Ito*[b]

Keywords: Optical properties / Photophysics / Gallium / Phthalocyanines

Intramolecular interaction between coplanar-stacked phthalocyanine (Pc) and porphyrin molecules plays an important role in the energy- and electron-transfer process. A series of results from different photophysical experiments on gallium phthalocyanine compounds are initially described. The PcGa dimer with a direct gallium–gallium bond, i.e. [tBu$_4$PcGa]$_2$·2dioxane, may exist in two different conformations: one in which the two phthalocyanines are poorly interacting and the other in which they are very close and strongly interacting. In the former, the emission lifetime is quite close to that of the monomer model compounds; in the latter, it is much shorter probably due to different radiative and nonradiative deactivation constants from those of the monomers. Because no significant difference between the absorption spectra of the monomer and dimer was observed in the photophysical experiments, implying that no ground-state interaction can be assessed, the results regarding triplet excited state lifetimes of [tBu$_4$PcGa]$_2$·2dioxane can be attributed to strong intramolecular interactions existing only in the excited state.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Phthalocyanines (Pcs) offer a high structural flexibility, which facilitates the tailoring of their physical, optoelectronic and chemical parameters over a very broad range. The exploitation of the chemical reactivity of the M–Cl (M = Ga, In) bond allows the preparation of a series of highly soluble, axially substituted and bridged phthalocyanine complexes.[1] Very recently, we have prepared a new dimeric gallium phthalocyanine complex with a direct gallium–gallium bond, i.e. [tBu$_4$PcGa]$_2$·2dioxane.[2] The Extended X-ray Absorption Fine Structure (EXAFS)-determined gallium–gallium bond length of this compound was found to be 2.46 Å, which is in good agreement with the reported values in the literature.[3–6] The gallium center is located 0.45 Å out of the plane, which is quite close to the reported out-of-plane value of 0.439 Å in crystalline PcGaCl.[7] Z-scan experiments show that dimerization of tBu$_4$PcGaCl is clearly a viable method of tuning saturation energy density (F_{Sat}) of the material. As a result, [tBu$_4$PcGa]$_2$·2dioxane exhibits a significantly lower F_{Sat} than that of tBu$_4$PcGaCl,[8] by approximately a factor of 3. This reduction in F_{Sat} is coupled with a slight increase in the non-linear absorption coefficient (β_I) at low incident intensity and with approximately equivalent β_Is at higher intensities. The ratio of the excited- and ground-state absorption cross sections (κ) is reduced by approximately 22% after dimerization of tBu$_4$PcGaCl to [tBu$_4$PcGa]$_2$·2dioxane. However, this can probably be mostly attributed to the increase in the linear absorption coefficient (α_0) by approximately 18% over the same molecular modification.[2]

It has long been recognized that the intramolecular interaction between coplanar-stacked phthalocyanine and porphyrin molecules plays an important role in the energy- and electron-transfer process.[9] Studies on the facial interaction between the phthalocyanine macrocycles are thus very interesting. In the case of the μ-oxo-bridged silicon phthalocyanine dimer (PcSi–O–SiPc), strong intramolecular interaction between PcSi macrocycles was observed by us previously.[10] In contrast to this complex, μ-oxo-bridged gallium and indium phthalocyanine dimers ([tBu$_4$PcGa]$_2$O and [tBu$_4$PcIn]$_2$O)[11] exhibit no apparent intramolecular interaction. The inter-Pc distances in [tBu$_4$PcGa]$_2$O and [tBu$_4$PcIn]$_2$O are 3.72 and 4.32 Å, respectively.[1d] In this contribution, we report on the steady-state and time-resolved photophysical properties of [tBu$_4$PcGa]$_2$·2dioxane (**5**). The photophysical data of the other four gallium phthalocyanine compounds, tBu$_4$PcGaCl (**1**);[8] tBu$_4$PcGa(p-CPO) (**2**, p-CPO = p-chlorophenoxy);[12] {[tBu$_4$Pc Ga]$_2$·SDPO}(**3**, SDPO = 4,4′-sulfonyl-diphenoxy)[12] and [tBu$_4$PcGa]$_2$O (**4**),[11] are also given in this paper for comparison. Figure 1

shows the molecular structures of these five phthalocyanine compounds.

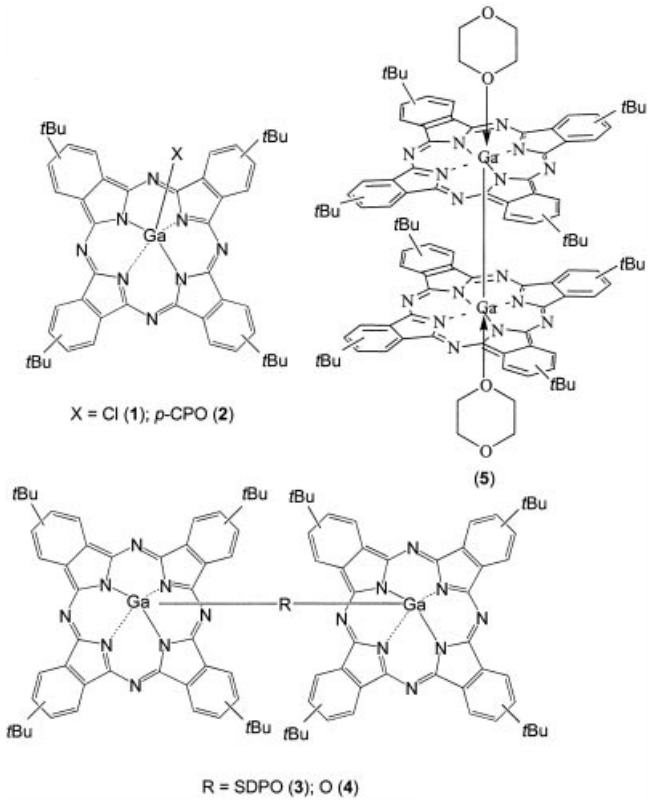

Figure 1. Molecular structures of **1**–**5**.

Results and Discussion

Axial substitution in Pc complexes favorably influences non-linear optical absorption towards the presence of a dipole moment perpendicular to the macrocycle in the axially substituted phthalocyanines, but does not generally affect the linear optical properties of phthalocyanines; the Q- and B-bands in the UV/Vis absorption spectra are shifted only slightly by a few nanometers on exchanging the axial ligands on the metal.[1] Likewise, dimerization of tBu$_4$PcGaCl does not considerably affect the spectral profile, as shown in Figure 2. The Q-band maxima of **1** and **5** are located at 695 and 693 nm, respectively. The extent of electronic conjugation in both compounds **1** and **5** is virtually identical, since compound **5** has a gallium–gallium single bond of σ-type lacking delocalized electrons. As expected, the main differences between the spectral features of these two complexes are related to the change in the extinction coefficient value because of the different number of absorbing Pc rings per molecular unit in the monomer relative to the gallium–gallium bridged dimer. Upon excitation with a laser light of 355 nm, both compounds display a Stokes shift of the emission peak with respect to the location of the Q-band absorption. Although dimerization affects both the UV/Visible and emission spectra differently, it influences the emission energy more strongly, since the extent of the Stokes shift is larger for the monomer than for the [tBu$_4$PcGa]$_2$·2dioxane dimer. Maximum emission peaks for **1** and **5** are found at 713 and 700 nm, respectively. Such a difference could be assigned to the more rigid structure of the dimer than of the monomer. This means that the dimer relaxes radiatively from the electronic excited state π* in a higher vibrational level.[13–15] Similarly, the photoluminescence spectra of **2**–**4** also show the mirror images of the corresponding UV/Vis absorption spectra with small Stokes shift, suggesting that the structural change between the ground state and excited singlet state is small.

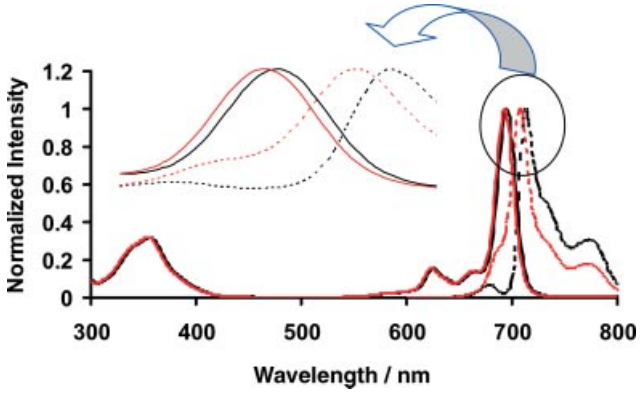

Figure 2. UV/Vis absorption spectra (solid line) and photoluminescence spectra (dashed line, λ_{ex} = 355 nm) of **1** (black line) and **5** (red line) in dilute chloroform solutions.

The fluorescence-decay time profiles of **1**–**4** display a single exponential decay yielding long fluorescence lifetimes (τ_{fluo}) in the range of 2570–3570 ps (see Table 1). On the contrary, the fluorescence-decay time profile of **5** was curve-fitted with two exponential functions, as shown in Figure 3, giving two fluorescence lifetimes [τ_{f1} = 180 ps (42%) and τ_{f2} = 2480 ps (58%)]. The τ_{f1} value is much shorter than those of **1**–**4**, while the τ_{f2} value is slightly smaller than those of the gallium phthalocyanine compounds mentioned above. This experimental finding suggests that the dimer may exist in two different conformations: one in which the two phthalocyanines are poorly interacting and the other in which they are very close and strongly interacting. In the former, the emission lifetime is quite close to that of the monomer model compounds; in the latter, it is much shorter probably due to different radiative and nonradiative deactivation constants from those of the monomer compounds.

Figure 4 shows that the nanosecond transient absorption spectra (λ_{ex} = 355 nm) obtained in argon-saturated anhydrous toluene for all gallium phthalocyanine compounds studied here are very similar. After the laser pulse irradiation, the transient absorption band appeared at 520 nm, accompanying the depletion at about 700 nm due to the transient consumption of ground state of **5**. On addition of O_2, the decay of the 520 nm band, which is attributed to the triplet-triplet (T-T) absorption of the Pc compounds[11,12] was accelerated, indicating that quenching by O_2 takes place from the triplet excited state of **5** to O_2, probably yielding $^1O_2$. The decay of the 520 nm band in the presence

4	1.60	186	520	3570	357	2.0×10^9
5	1.30	144	520	180 (42%) 2480 (58%)	2.1 (39%) 71 (61%)	2.3×10^9

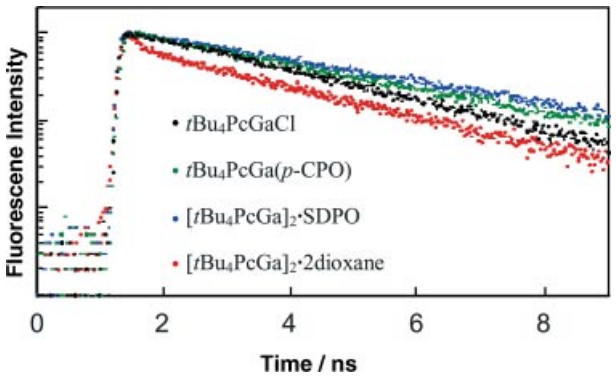

Figure 3. Time profiles of fluorescence intensities at 700–705 nm of **1**, **2**, **3** and **5** in deoxygenated anhydrous toluene by the excitation at 410 nm.

of O_2 obeys first-order kinetics, giving $k_{first\text{-}order}$, which increases with the concentration of added O_2; from the pseudo-first-order relation, the second-order rate constants for the reaction with O_2 (k_{O2}) were evaluated as listed in Table 1. Dimers and monomers have almost the same k_{O2} values, but they are all less than the diffusion controlled limit ($k_{diff} = 1.1\times10^{10}$ $mol^{-1}dm^3s^{-1}$ in toluene).

In the absence of O_2, the decay rates depend on the laser power. Fast decay observed at high laser power is attributed to the T-T annihilation because of the collision between the highly concentrated triplet excited states. The time profile at 520 nm observed for ^{3}(*t*Bu$_4$PcGa–X)* (X = Cl; *p*-CPO; O–*t*Bu$_4$PcGa; SDPO–*t*Bu$_4$PcGa) under the irradiation of low laser power reveals a single exponential decay giving the triplet excited state lifetimes (τ_T) in the range of 257–667 μs. In contrast, two exponential-decay processes were observed for ^{3}([*t*Bu$_4$PcGa]$_2$·2dioxane)* as shown in Figure 5. From the initial fast decay process, the triplet excited state lifetime (τ_{T1}) of ^{3}([*t*Bu$_4$PcGa]$_2$·2dioxane)* was evaluated to be 2.1 μs (39%), much shorter than the τ_T values of **1**–**4**. From the slow decay process of **5**, the second lifetime (τ_{T2}) was found to be 71 μs (61%), which is still shorter than those of the other four gallium phthalocyanine compounds. It should be noted that in the photophysical characterization, no significant difference between the absorption spectra of the monomer and dimer was observed, suggesting that no ground-state interaction can be assessed. The results regarding triplet excited state lifetimes can thus be attributed to strong intramolecular interactions existing only in the excited state.

Experimental Section

Materials: *t*Bu$_4$PcGaCl was obtained by the reaction of 4-*tert*-butylphthalonitrile with anhydrous $GaCl_3$ in doubly distilled, deoxygenated quinoline at 180 °C in the presence of catalytic amounts

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the non-nucleophilic base 1,8-diazabicyclo-[5.4.0]-undec-7-ene (DBU).[8] tBu$_4$PcGa(p-CPO) was prepared by the reaction of tBu$_4$PcGaCl with p-chlorophenol in anhydrous DMSO at 110 °C in the presence of K_2CO_3.[12] The [tBu$_4$PcGa]$_2$O dimer was synthesized by the reaction of tBu$_4$PcGaCl with excess concentrated H_2SO_4 at –20 °C.[11] The 4,4′-sulfonyldiphenoxy (SDPO)-axially bridged gallium phthalocyanine dimer {[tBu$_4$PcGa]$_2$.SDPO} was synthesized by the reaction of tBu$_4$PcGaCl with bis(4-hydroxyphenyl)sulfone in anhydrous DMSO at 110 °C in the presence of K_2CO_3.[12] [tBu$_4$PcGa]$_2$.2dioxane was obtained in 83% yield by the reaction of soluble tBu$_4$PcGaCl with activated magnesium in freshly dried THF, in the presence of 1,4-dioxane.[2]

Photophysical Measurements: UV/Vis absorption spectra were recorded on a JASCO V-530 spectrophotometer. Fluorescence spectra and lifetimes were measured by a single-photon counting method using an argon ion laser, a pumped Ti:sapphire laser (Spectra-Physics, Tsunami 3960, fwhm 150 fs) with a pulse selector (Spectra-Physics, 3980), a second harmonic generator (Spectra-Physics, GWU-23PS), and a streakscope (Hamamatsu Photonics, C4334–01). Each sample was excited in deoxygenated anhydrous toluene with 410 nm laser light. Nanosecond-transient absorption measurements were carried out using third harmonic generation (THG, 355 nm) of an Nd:YAG laser (Spectra-Physics, Quanta-Ray GCR-130, 6 ns FWHM) as an excitation source. For transient absorption spectra in the near-IR region (600–1400 nm), monitoring light from a pulsed Xe-lamp was detected with a Ge-avalanche photodiode (Hamamatsu Photonics, B2834). For the visible region (400–1000 nm), a Si–PIN photodiode (Hamamatsu Phonics, S1722–02) was employed as a detector.

New Polymeric Manganese Azide Derivatives with Quinazoline

Morsy A. M. Abu-Youssef,*[a] Albert Escuer,[b] and Vratislav Langer[c]

Keywords: Azides / Coordination polymers / Magnetic properties / Manganese

Two new polymeric derivatives of the (azido)Mn^{II} system with formula $[Mn(H_2O)(\mu\text{-}N_3)(N_3)(quinaz)_2]_n$ (**1**) and $[Mn(\mu\text{-}N_3)_2(quinaz)_2]_n$ (**2**) (quinaz = quinazoline) have been structurally and magnetically characterised. Compound **1** crystallises in the triclinic system, space group $P\bar{1}$, and consists of 1D chains with single end-to-end azido bridges. These chains give a two-dimensional supramolecular arrangement by means of H-bond interactions. Compound **2** crystallises in the monoclinic system, space group $C2/c$, and contains a square alternating 2D network bridged by azido ligands in the end-to-end coordination mode. Compound **2** exhibits some unusual features, such as the unprecedented linear coordination of the azido bridge. Magnetic analysis reveals moderate antiferromagnetic coupling, with J values in good agreement with the expected range, as a function of the Mn–N–N bond angles.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The azido ligand is currently one of the most interesting bridging ligands in the attempt to build polynuclear or *n*-dimensional architectures, which combine its interest as a ligand in coordination chemistry with a large variety of magnetic responses.[1] The versatility of this ligand is a direct consequence of its ability to act as a bridge in a large variety of coordination modes. For example, it is able to link two cations [in either end-to-end (EE)[2–4] or end-on (EO)[3,5] modes], three cations in the more exotic $\mu_{1,1,1}$ or $\mu_{1,1,3}$ modes,[4] or act as a bridge between four metallic centres in the rare examples of $\mu_{1,1,1,1}$ and $\mu_{1,1,3,3}$ modes.[5] The simultaneous presence of more than one of these coordination modes in the same compound is not rare, and this increases the number of possible topologies.[6,7] The interest of magnetochemists in this ligand lies in the well-established relationship between its coordination mode and the resulting magnetic properties, which cover a wide range of ferro-, ferri- and antiferromagnetic responses,[1] although it should be pointed out that the topology of the resulting systems is far from being controllable. The large structural variations of azide derivatives reported in the last few years provides experimental proof of the effects of minor changes in the synthetic conditions or in the co-ligands bridged to the metallic centre. One of the most complete series of compounds, with general formula $[Mn(N_3)_2(R\text{-}py)_2]_n$, (R-py = substituted pyridyl ligands) is a paradigmatic example of how minor differences in R can change the dimensionality or the coordination mode of the azido bridges, which are generally related to weak supramolecular π–π stacking interactions or to the packing forces in the solid, drastically.

In this paper, we present the synthesis and X-ray and magnetic characterisation of two new polymeric manganese azide derivatives with formula $[Mn(H_2O)(\mu\text{-}N_3)(N_3)(quinaz)_2]_n$ (**1**) and $[Mn(\mu\text{-}N_3)_2(quinaz)_2]_n$ (**2**). The co-ligand quinazoline (quinaz) was chosen in order to combine the versatility of the azido ligand with the possibility of a second bridging ligand closely related to previously reported systems such as pyrimidine,[8] but introducing structural differences in the ligand in order to generate new topologies. The resulting compounds show that quinaz, in contrast to pyrimidine, coordinates through only one of its donor N-atoms in a similar way to classical pyridine ligands. Compound **1** is a 1D alternating system with single EE bridges in a *cis* arrangement, giving an uncommon 1D zigzag topology. Extended H-bonds between terminal azide and water molecules coordinated to the manganese atom generate a supramolecular 2D network. Compound **2** is an alternating square 2D layer of manganese EE azido bridges with *trans*-quinaz coordinated ligands. The magnetic behaviour agrees with the antiferromagnetic coupling expected for this kind of bridge.

Results and Discussion

Synthesis

Slow concentration of water/methanol solutions of manganese nitrate tetrahydrate, the quinazoline ligand and sodium azide gave single crystals of **1** (cold solutions) and **2** (room temperature crystallization).

Structure of $[Mn(H_2O)(\mu\text{-}N_3)(N_3)(quinaz)_2]_n$ (1)

A labelled ORTEP plot of the structure is shown in Figure 1. Selected distances and angles are listed in Table 1. The structure of this compound can be described as zigzag chains of manganese atoms linked by single azido bridges coordinated in the EE mode.

The manganese atoms are placed in an octahedral environment and are linked to two quinazoline ligands in a *trans* position, two azide N atoms corresponding to the bridging end-to-end ligands, one terminal azido and one water molecule. Larger bond lengths are found to the N(quinazoline) atoms (2.318 Å), intermediate distances (around 2.2 Å) to the N(azide) atoms and a shorter distance (2.179 Å) to the O atom. The azido bridges along the chain are not equivalent and show similar, but not identical, Mn–N–N bond angles [142.6° for Mn(1)–N(11)–N(12) and 137.3° for Mn(1)–N(31)–N(32)]. The terminal azido ligand shows a larger Mn(1)–N(21)–N(22) bond angle of 150.4°. The torsion angle for the two non-equivalent Mn–N–N–N–Mn units is 180°. The water molecule and the N(23) atom

from the terminal azido ligand are related by means of H-bonds through H(11) and H(12) giving a 2D supramolecular arrangement (Figure 2). The Mn···Mn intrachain distances are 6.426(1) Å [bridge N(11)–N(12)–N(11)′] and 6.360(1) Å [bridge N(31)–N(32)–N(33)]. The minimum interchain Mn···Mn distance is 7.214(1) Å.

Structure of $[Mn(\mu\text{-}N_3)_2(quinaz)_2]_n$ (2)

A labelled ORTEP plot of the structure is shown in Figure 3. Selected distances and angles are listed in Table 2. The structure consists of a 2D square network of Mn^{II} cations bridged by EE azido bridges (Figure 4).

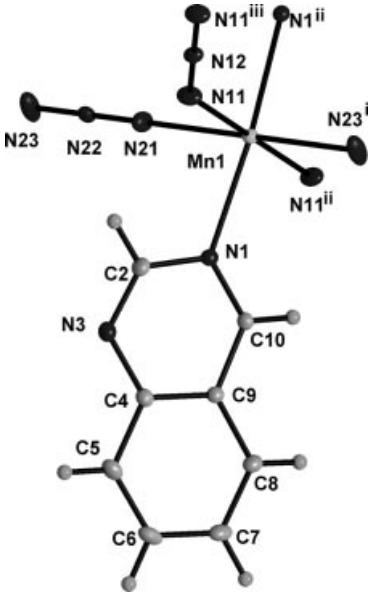

Figure 3. Labelled ORTEP plot of the basic unit of $[Mn(\mu\text{-}N_3)_2(quinaz)_2]_n$ (**2**) with thermal ellipsoids at 50% probability.

Each manganese atom is surrounded by two quinazoline ligands in a *trans* position and four N(azide) atoms, which act as a bridge to the four neighbouring manganese atoms. As observed in **1**, the Mn–N(quinazoline) bonds (ca. 2.285 Å) are longer than those found for the Mn–N(azide) bonds (2.217–2.254 Å). The Mn–N–N bond angles show large differences: Mn(1)–N(11)–N(12) is 144.3(1)°, which lies in the normal range for this ligand, whereas the two bond angles Mn(1)–N(21)–N(22) and Mn(1)iv–N(23)–N(22) have a value of 180°, which means that this Mn–NNN–Mn subunit is fully linear. The torsion angle for the Mn–N(11)–N(12)–N(13)–Mn units is 180°. The Mn···Mn intraplane distances are 6.8045(1) Å [bridge N(21)–N(22)–N(23)] and 6.4921(1) Å [bridge N(11)–N(12)–N(11)′], and the minimum interplane Mn···Mn distance is 9.845(1) Å.

The most singular detail of this structure is the linear coordination of one of the azide bridges. Some unusually large Mn–N–N bond angles have previously been found in the 2D system $[Mn(DENA)_2(N_3)_2]$ (DENA = diethylnicotinamide),[9] for which one of the bridges exhibits a pair of Mn–N–N bond angles of 148.4° and 171.7°. Large bond angles have also been found in one dinuclear (cryptand)

Mn^{II} compound,[10] but in all cases the coordination of the bridge is far from linear.

Magnetic Measurements and Coupling Constant Calculations

The magnetic measurements were performed on powdered crystalline samples in the 2–300 K temperature range. The overall interaction is moderately antiferromagnetic for the two compounds.

The plot of the susceptibility vs. temperature for compound **1** shows a regular increase on cooling up to a maximum value at 20 K (Figure 5). The $\chi_M T$ value at room temperature is 3.93 $cm^3 K mol^{-1}$ for the manganese atom, which is lower than the expected value for an isolated Mn^{II} ion (4.375 $cm^3 K mol^{-1}$), and decreases continuously, tending to zero at low temperature. Based on the structural data, compound **1** is strictly an alternating one-dimensional system which shows similar bond lengths, identical torsion angles and quite similar Mn–N–N bond angles in the bridging region. Two alternative and complementary fits were performed on the χ_M data in order to determine coherent values for the coupling constants. The first fit was made assuming that the differences in the bond parameters are a minor effect, and the fit of the experimental data was performed as a system with only one average J coupling constant by applying the analytical expression for a regular chain derived from the Hamiltonian $H = -JS_i \cdot S_{i+1}$ for local $S = 5/2$.[11] The best-fit parameters were $J = -4.4(1)$ cm^{-1} and $g = 2.00(1)$ (paramagnetic impurities: 1.3%). As would be expected from the similar bond parameters, attempts to differentiate two J coupling constants in a second fit on the basis of the Hamiltonian $H = J_1 \Sigma S_{2i} \cdot S_{2i+1} - J_2 \Sigma S_{2i+1} \cdot S_{2i+2}$, as proposed by Drillon et al.,[12] did not improve the results obtained in the fit as a homogeneous chain, giving similar J_1 and J_2 values around the –4.35 cm^{-1} average value.

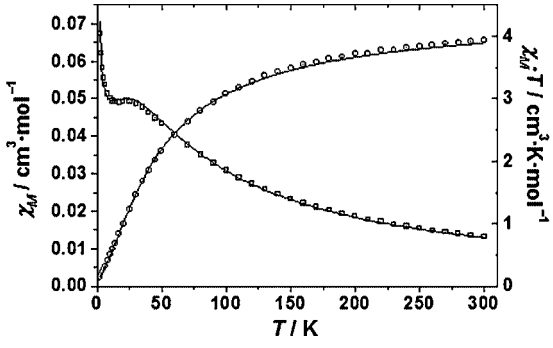

Figure 5. Plot of χ_M (open squares) and $\chi_M T$ product (open circles) for compound **1**. Solid lines correspond to the best fit (see text).

Compound **2** shows a similar shape for the susceptibility plot, with a maximum at 32 K and a $\chi_M T$ value of 4.04 at room temperature (Figure 6). In this case, the structural data indicate a 2D system with two clearly different J coupling constants, as would be expected from the very different Mn–N–N bond angles found in the network. Analytical expressions for the calculation of the coupling constants for systems of this kind are not available, so only an approximation can be made for **2**. The fit as a simplified 2D quadratic layer by means of the high-temperature expansion series derived from the Hamiltonian $H = \Sigma_{nn} - JS_iS_j$, (where Σ_{nn} runs over all pairs of nearest spins i and j),[13] gives a relatively poor fit [dotted line in Figure 6, $J = -2.5$ cm^{-1}, $g = 2.00(1)$], thus indicating that the magnetic behaviour of this system is far from a homogeneous 2D response. Not surprisingly, a better fit of the experimental data was obtained by treating the system as a homogeneous 1D system [solid line in Figure 6, $J = -4.9(1)$ cm^{-1}, $g = 2.03(1)$].

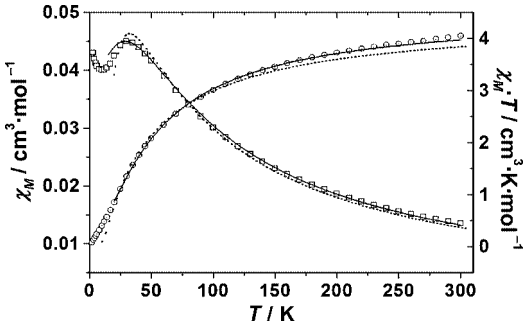

Figure 6. Plot of χ_M (open squares) and $\chi_M T$ product (open circles) for compound **2**. The dotted line shows the best fit as a homogeneous 2D system. The solid line shows the best fit as a one-dimensional system (see text).

Magnetostructural Correlations

As was calculated previously,[14] the superexchange interaction for a d^5 ion should be antiferromagnetic in nature and mediated by two kind of pathways. The main interaction goes via σ-interactions involving one of the non-bonding π-MOs of the azide and the atomic e_g-orbitals of the metallic ions. As shown in Figure 7,[14] this interaction pathway is very effective at small Mn–N–N bond angles and is practically negligible for large bond angles. The contribution of this pathway to the antiferromagnetic component of the interaction is therefore very sensitive to the experimental Mn–N–N bond angle. This fact has been checked experimentally for Cu^{II} and Ni^{II} cryptand systems with M–N–N bond angles close to 165°,[10] for which the antiferromagnetic component is close to zero and the global coupling is ferromagnetic. The second interaction pathway, which is active in our case, corresponds to pπ–dπ interactions between the non-bonding π-MOs of the azido and two of the atomic t_{2g}-orbitals of the metallic ion (Scheme 1). This second interaction mechanism is much less effective than the σ-pathway due to the worse overlap at any Mn–N–N angle value.[10]

Compound **1** is an alternating system with similar Mn–N–N bond angles. From Figure 7, is easy to justify the reason for the failure of the fit as an alternating system: the antiferromagnetic components for the two kinds of bridges should be very similar and therefore the two J values cannot be differentiated. The calculated J value as a homogeneous chain can be assumed as a good mean value with poor

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

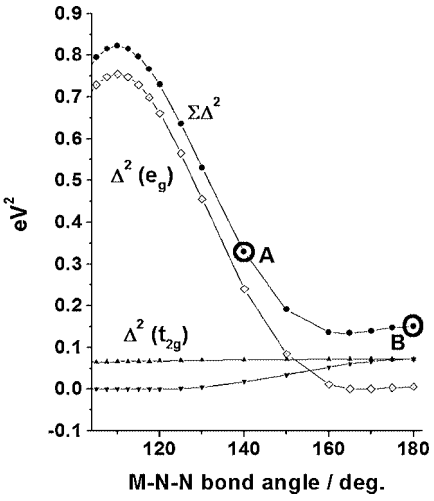

Figure 7. Walsh diagram of the Δ^2 gaps. Filled triangles correspond to the t_{2g}-components, open diamonds show the e_g-component and the filled circles show the global contribution to the antiferromagnetic interaction for a d^5-ion like Mn^{II}. Points A and B correspond to the antiferromagnetic contribution for 145° and 180° Mn–N–N bond angles, respectively.

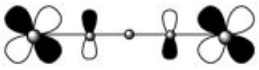

Scheme 1. One of the pπ–dπ superexchange pathways that are active for d^5-ions bridged by a linear azido bridge.

deviation for these bond parameters. Comparison with other 1D azido systems with similar bond parameters is reasonable.[1]

Compound **2** shows two very different bond angles, one of which (144.1°) is slightly larger than the mean values of compound **1**, and 180° for the second Mn–N–N bond angle. Therefore a moderate antiferromagnetic coupling should be expected for the bridge with normal bond angles for compound **2** (A in Figure 7), in contrast to the much lower antiferromagnetic coupling for the linear bridge (B in Figure 7) and agreeing with the poor fit as a 2D system with only one mean *J* value. It is obviously erroneous to assume that the interaction mediated by the linear Mn^{II}–azido units is negligible, and it is not surprising that the susceptibility plot shows better fit as a 1D system and with a calculated *J* value close to compound **1**. It is not possible to evaluate the correct *J* values from analytical fits, but the above result is indicative of the low antiferromagnetic contribution of the 180° azido bridge, as expected from theoretical predictions.[14]

Conclusions

The reported results are new examples of the importance of synthetic conditions and weak supramolecular interactions in the resulting topologies of high-dimensional manganese azide systems. Compound **2** shows an unprecedented linear coordination between two metallic centres, which has not been obtained even with previously studied cryptand systems. This kind of coordination can be assumed to be a special case of the EE coordination mode. Magnetic measurements afford the first experimental confirmation of the low antiferromagnetic coupling for such large Mn–N–N bond angles, as was predicted previously.

Experimental Section

General Remarks: Magnetic susceptibility measurements were carried out on polycrystalline samples with a Quantum Design susceptometer working in the 2–300 K range in a magnetic field of 0.3 T and remeasured in a field of 0.03 T in the 20–2 K range. Diamagnetic corrections were estimated from Pascal's tables. Infrared spectra (4000–200 cm^{-1}) were recorded from KBr pellets with a Bruker IFS-125 FT-IR spectrophotometer.

$[Mn(N_3)_2(H_2O)(quinaz)_2]_n$ (1): A solution of quinazoline (0.52 g, 4 mmol) in methanol (15 mL) was added to a methanolic solution (15 mL) of manganese nitrate tetrahydrate (0.5 g, 2 mmol). Then, a concentrated aqueous solution of sodium azide (0.65 g, 10 mmol) was added dropwise with continuous stirring. The resulting clear solution was allowed to stand for several days in a refrigerator. Yellow crystals suitable for X-ray measurements were collected and dried in air. Yield: 0.58 g (70%). $C_{16}H_{14}MnN_{10}O$ (417.31): calcd. C 46.04, H 3.35, Mn 13.16, N 33.57; found C 45.98, H 3.11, Mn 12.89, N 34.14. IR (KBr): $\tilde{\nu}$ = 3347 vs, 3233 vs, 3043 ms, 2122 vs, 2089 vs, 1619 vs, 1573 vs, 1554 w, 1519 w, 1489 vs, 1465 m, 1428 m, 1408 m, 1381 vs, 1306 s, 1277 m, 1257 m, 1239 m, 1212 vs, 1154 w, 1139 s, 1065 s, 1013 m, 987 m, 955 vs, 930 vs, 874 s, 832 s, 794 vs, 762 vs, 633 vs, 593 vs, 521 s, 473 vs, 409 wm, 387 m, 368 m, 343 m, 316 m, 293 m, 269 vs cm^{-1}.

$[Mn(N_3)_2(quinaz)_2]_n$ (2): An aqueous solution (10.0 mL) of manganese nitrate tetrahydrate (0.25 g, 1.0 mmol) was mixed with a methanolic solution (10 mL) of quinazoline (0.26 g, 2.0 mmol) and the mixture was stirred for about 5 min. A solution of sodium azide (0.32 g, 5 mmol) in water (5 mL) was then added dropwise with vigorous stirring. The resulting clear solution was allowed to stand at room temperature for several weeks. Brown-yellowish crystals suitable for X-ray measurements were collected and dried in air. Yield: 0.26 g (65%). $C_{16}H_{12}MnN_{10}$ (399.30): calcd. C 48.12, H 3.00, Mn 13.76, N 35.08; found C 47.98, H 3.11, Mn 13.89, N 35.24. IR (KBr): $\tilde{\nu}$ = 3439 w, 3046 w, 2096 vs, 1618 s, 1573 s, 1489 s, 1458 m, 1409 m, 1379 s, 1308 m, 1269 m, 1239 m, 1210 ms, 1139 ms, 1103 wm, 1066 ms, 1012 wm, 983 wm, 955 ms, 926 m, 881 m, 832 m, 795 s, 762 s, 636 s, 617 m, 598 m, 588 m, 524 wm, 479 m, 451 vw, 409 vw, 387 vw, 367 vw, 343 vw, 317 vw, 294 vw, 269 m, 235 s cm^{-1}.

It should be pointed out that the two compounds were obtained with the same stoichiometric ratio of reagents. The factors that control the final compound are difficult to evaluate and the solubility of the products, the temperature and the reaction time play an important role. In this case, the coordination of a second azido ligand in **2** in comparison with **1** is probably related to the higher temperature of the reaction mixture that favours the replacement of the coordinated water molecule.

X-ray Crystallographic Study: All diffraction data were collected with a Siemens SMART CCD diffractometer with Mo-K_α radiation (λ = 0.71073 Å, graphite monochromator). The crystals were cooled to 173(2) K by a flow of nitrogen gas using an LT-2A device. Full spheres of reciprocal lattices were scanned by 0.3° steps in ω with a crystal-to-detector distance of 3.97 cm. Preliminary orientation matrices were obtained from the first frames using SMART.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The collected frames were integrated using the preliminary orientation matrices, which were updated every 100 frames. Final cell parameters were obtained by refinement on the positions of reflections with $I > 10\sigma(I)$ after integration of all the frames with SAINT.[15] The data were empirically corrected for absorption and other effects with SADABS.[16] The structures were solved by direct methods and refined by full-matrix least squares on all F^2 data with SHELXTL.[17] The non-H atoms were refined anisotropically, while hydrogen atoms were refined isotropically with the use of geometrical restraints. Selected crystallographic and refinement data are summarised in Table 3. Molecular graphics were prepared with Diamond.[18] CCDC-264957 (**1**) and -264958 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

We are grateful to Professor Ulrich Müller, of Philipps-Universität Marburg, for drawing the attention of ourselves and the referees to a prior structure report for $(NMe_4)_3[Fe(NCS)_6]$.[1] The 1977 and 2005[2] reports differ only in the choice of unit cell origin. The conclusions from the structure–spectra relationships discussed in the 2005 paper remain the same.

COVER PICTURE

The cover picture shows the properties of the antiferromagnetic molecular spin-ladder built by combining the $5NAP^+$ diamagnetic cations and the $CuBr_4^{2-}$ radical anions. The upper left box shows the structure of the two ions, the middle box its magnetic topology (the weakly interacting two-leg ladders are clearly marked), while the lower box shows the experimental and computed magnetic susceptibility curves. Details are discussed in the article by M. Deumal, J. J. Novoa et al. on p. 4697ff.

Adventures in Vanadocene Chemistry

Robert Choukroun,*[a] and Christian Lorber[a]

Keywords: Alkynes / Ceramics / Colloids / Metallocenes / Nitriles / Vanadium

This review surveys some aspects of the chemistry of $[VCp_2]$. The high potential of vanadocene $[VCp_2]$ (and $[V(CO)Cp_2]$) in organometallic chemistry is illustrated by new organometallic architectures. The rich redox chemistry of $[VCp_2]$ is shown by incorporation of this fragment into various C≡C and C≡N bonds. This molecular approach allows the connection of two (or more) paramagnetic centers through an organic linker in order to build magnetic nanoscopic organometallic wires. $[VCp_2]$ has also been studied in the field of materials such as vanadium carbide (VC) ceramics and in its role as a reducing agent toward elements of groups 8–10 to prepare Fe, Rh, and Pd colloids.

Introduction

Vanadocene, which is the only stable and easily accessible metallocene of the early transition metals, is an electronically and coordinatively unsaturated molecule. Other metallocenes of the early transition metals, such as titanocene and zirconocene, do not exist in their original sandwich structure and need another ligand (alkyne, butadiene) to stabilize the metallocene fragment.[1] The reactivity of vanadocene $[VCp_2]$, in spite of its accessibility,[2] has scarcely been studied, probably due to the formation of various paramagnetic V^{III} and V^{IV} compounds that prevent further spectroscopic analysis. This paramagnetism excludes classical NMR techniques, and the literature on the reactivity of vanadocene is often dominated by EPR and IR spectroscopic characterization, chemical derivatization, or by analogy with its diamagnetic titanium analogue.[3,4]

Robert Choukroun was born in Alger (in the former French department of Algeria) on June 24, 1944, and arrived in France in 1962. He received all of his degrees from the Université Paul Sabatier, in Toulouse, where he joined the CNRS in 1968 (Doctorat d'Etat, in 1975, under the Supervision of Professor Danièle Gervais). After a postdoctoral stay in 1975–1976 at the Unit of Nitrogen Fixation, University of Sussex (Brighton, U.K.) under the direction of Professor Chatt, he joined the Laboratoire de Chimie de Coordination de Toulouse, where he has remained to this day, becoming Directeur de Recherche in 1996. His current research interests are concerned with organometallic chemistry of the early transition metals of groups 4 and 5 and their development and use as catalysts for homogeneous catalysis and molecular precursors to ceramic materials and colloids.

Christian Lorber did his undergraduate studies at Louis Pasteur University in Strasbourg (France; 1985–1989). In 1989 he joined the group of Professor John A. Osborn at the Chemistry Department of Louis Pasteur University, where he studied homogeneous catalysis with oxo complexes of transition metals (oxidation and isomerization reactions). He obtained his PhD in 1995 and spent three years as a Postdoctoral Fellow, first at the Inorganic Chemistry Department of Lund University (Sweden) with Dr. Ebbe Nordlander (1996), and then in the group of Professor Richard H. Holm at the Chemistry and Chemical Biology Department of Harvard University (Cambridge, USA; 1997–1998) where he participated in the synthesis and studies of new models of Mo- and W-oxotransferase enzymes. In fall 1998 he obtained a research position at the Centre National de la Recherche Scientifique (CNRS) and moved to the Laboratoire de Chimie de Coordination in Toulouse (France). His interests include the inorganic and organometallic chemistry of high-oxidation-state early transition metal complexes, especially those that contain an amido, imido, diamido, alkyl, or alkoxy group, and related cationic species, catalytic reactions and mechanisms of reactions involving these complexes, especially in olefin-polymerization reactions, the controlled synthesis of polymers prepared using well-defined organometallic initiators, and hydroamination of alkynes. He is also involved in the synthesis of nanoparticles and their use in various catalytic transformations.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

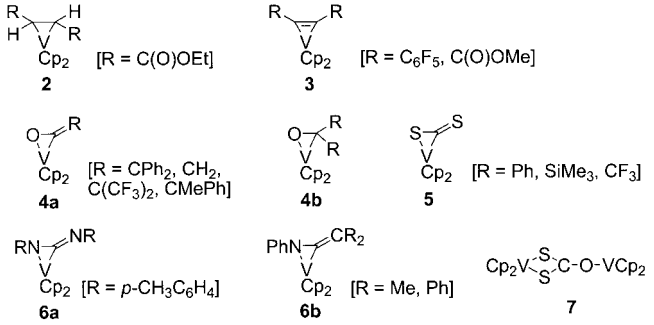
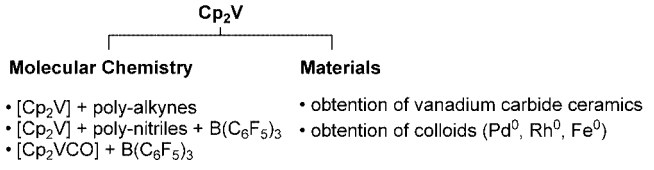
Ideally, X-ray structure analysis is a highly recommended tool to determine the real chemical environment around the metal center.

The starting point of our research was, in part, the recent development of the so-called "carbon-rich chemistry", which allows access to different kinds of polyalkynes,[5] and also the pioneering work of Floriani and others[6] on the addition of an activated alkyne to $[VCp_2]$ (**1**). The synthesis of olefin and acetylene derivatives of vanadocene is readily achieved by treating **1** with the appropriate substrates. The reaction can be formally described as the addition of the metal carbene to the C–C multiple bond to afford a metallacyclopropane $[Cp_2V(\eta^2\text{-}EtO_2CCHCHCO_2Et)]$ (**2**) and metallacyclopropene $[Cp_2V(\eta^2\text{-}C_2R_2)]$ (**3**; Scheme 1). It behaves as a carbene-like unit and adds to many organic functional groups (ketene, thioketene, ketene imine, ...; Scheme 1).[7–9] The interest in this η^2-C,X (X = C, O, S, N) bonding was originally as model compounds for studying molecular activation promoted by transition metals and associated to the problem of CO_2 activation. All these complexes can be related both structurally and chemically to some intermediates believed to be formed in the reaction between a metal center and carbon dioxide. As an example, carbonylsulfide (COS), when it reacts with vanadocene, undergoes a disproportionation reaction to form COS_2^- and CO, resulting in the formation of divalent $[Cp_2V(CO)]$ and $[(Cp_2V)_2(COS_2)]$ (**7**) in which the COS_2^- ligand is chelated to one metal center through both sulfur atoms and to the second metal center through the O atom.[10]



Scheme 1.

This review covers mostly our work aimed at the reactivity of vanadocene (or the carbonyl vanadium complex $[Cp_2VCO]$, another form of the d^2 vanadocene) with polyalkynes, polynitriles, and tris(perfluorophenyl)borane. Materials are also emerging from the chemistry of $[VCp_2]$ that illustrate the diversity of its potential applications (Scheme 2). Only the literature dealing with $[VCp_2]$ is reviewed.

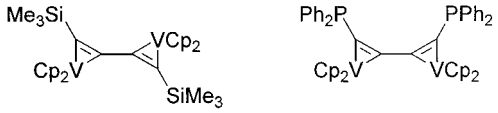


Scheme 2.

Reactivity of $[VCp_2]$ with Polyalkynes

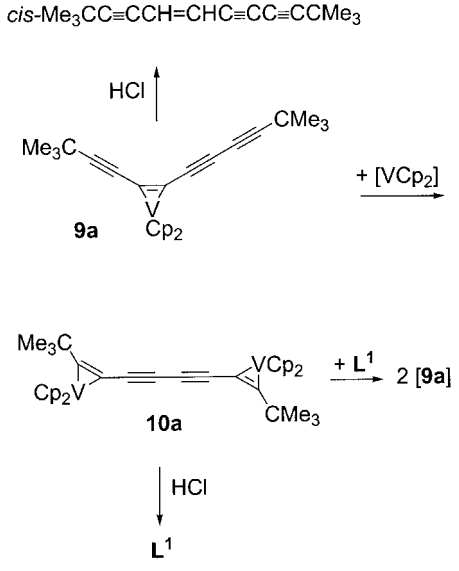
From the reactivity of vanadocene toward C=C and C≡C described above, it appeared to us that we could use the same strategy to prepare new vanadocene systems using polyalkynes $R–(C{\equiv}C)_n–R'$ (n = 2–4; R, R′ = Me, *t*Bu, PPh_2, $SiMe_3$). One might expect that two identical species possessing one unpaired electron connected by an acetylenic carbon chain could produce different structural and magnetic situations. Synthetic work is facilitated by the solubility of $[VCp_2]$ (**1**) and many yne ligands in pentane, a solvent in which crystalline compounds are usually formed.

Treatment of **1** with the diyne R–C≡C–C≡C–R (R = $SiMe_3$, PPh_2) resulted in the oxidative addition of **1** to both alkyne bonds and the formation of homobimetallic vanadium complexes $[(Cp_2V)_2(1,2\text{-}\eta\text{:}3,4\text{-}\eta\text{-}R–C{=}C–C{=}C–R)]$ (**8a**: R = $SiMe_3$; **8b**: R = PPh_2) whatever the stoichiometry of the reaction.[11]



8a **8b**

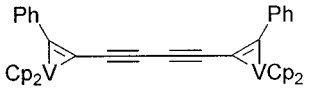
This result encouraged us to pursue the reactivity of **1** with tri- and tetraynes. The reaction of the octatetrayne ligand RC≡C–C≡C–C≡C–C≡CR (**L¹**: R = *t*Bu; **L²**: R = Ph) is dependent on the substituent R attached to the tetrayne and on the stoichiometry of the reaction (Scheme 3).[12] First, the reaction performed with one equivalent of **1** and **L¹** in pentane gives the organometallic complex $[Cp_2V(3,4\text{-}\eta\text{-}t\text{BuC}{\equiv}C–C_2–C{\equiv}C–C{\equiv}Ct\text{Bu})]$ (**9a**) in which the $[VCp_2]$ unit is located at the internal position of the C8 carbon chain, whereas the reaction of two equivalents of **1** with one equivalent of **L¹** in pentane leads to the homodimetallic complex $[(Cp_2V)_2(1,2\text{-}\eta\text{:}7,8\text{-}\eta\text{-}t\text{BuC}_2–C{\equiv}C–C{\equiv}C–C_2t\text{Bu})]$ (**10a**). The Cp_2V units are nearly *trans* and are located at both extremities of the C8 carbon chain.



Scheme 3.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

On the other hand, the reaction of one or two equivalents of **1** with $\mathbf{L^2}$ in toluene gives exclusively the homodimetallic complex $[(Cp_2V)_2(1,2\text{-}\eta\text{:}7,8\text{-}\eta\text{-}PhC_2\text{–}C{\equiv}C\text{–}C{\equiv}C\text{–}C_2Ph)]$ (**10b**).



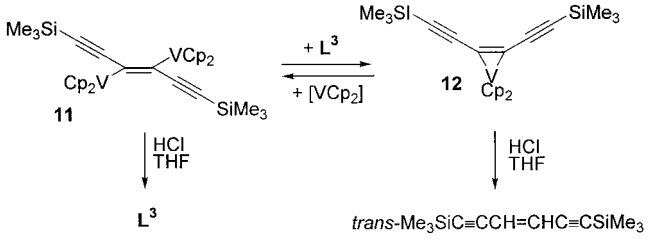
10b

These results offer synthetically attractive but puzzling features as the $[VCp_2]$ unit could migrate reversibly by sliding from an internal 3,4-η position to an external 1,2-η position on the carbon chain of the tetrayne ligand. The shift of the vanadocene unit could be dependent on a dissociation process between $[VCp_2]$ and the ligand in solution or on the existence of an η^4 complex $[Cp_2V(\eta^4\text{-}t\text{Bu}C_4\text{–}C{\equiv}C\text{–}C{\equiv}Ct\text{Bu})]$.[13]

The bond lengths and angles associated with the vanadium–acetylene interaction in **8**–**10** indicate that the acetylene molecule is symmetrically attached to the vanadium atom by two σ-type V–C bonds. This produces a metallacyclopropene structure for the central VC_2 moiety. The different orientation of the Cp_2VC_2 unit could be due to the steric effects of the substituent R ($SiMe_3$, PPh_2, *t*Bu, Ph) on the polyynes. Another difference in the structural aspects is the carbon skeleton of the ligand, which is distorted for **8a** and **10b** whereas all the carbon atoms are nearly coplanar in **8b** and **10a**.

As a result of such a situation, paramagnetic vanadium centers of d^1 electronic configuration could produce different magnetic behavior.[14] The antiferromagnetic interaction was calculated and found to be J = –10.5 and –59.8 cm^{-1} for **8a** and **8b** respectively, and J = –12.5 and –4.1 cm^{-1} for **10a** and **10b**, respectively. The antiferromagnetic interaction for **8b** and **10a** is greater than that for **8a** and **10b**, whereas the vanadium–vanadium distances show an opposite relation. In fact, the interaction is propagated by the carbon chain, and a consideration of the bonding situation in the complex seems necessary. The orientation of the Cp_2VC_2 unit in the molecule suggests a favorable "in-plane π-type" interaction for the complexes **8b** and **10a**. This can be described as a linear combination of mainly p-orbital character of the carbon of the diyne with the main contribution of the d_{z^2} orbital of the HOMO in a d^1-type system.[6b,6c] This is disfavored in **8a** and **10b**, where the Cp_2VC_2 unit and its magnetic orbital contributions can be considered to be orthogonal.

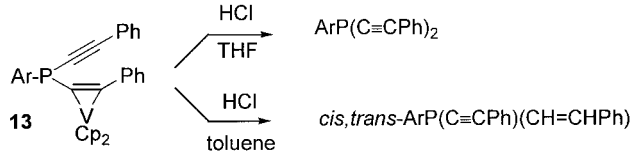
Particular attention was given to the reactivity of **1** with the triyne $Me_3SiC{\equiv}C\text{–}C{\equiv}C\text{–}C{\equiv}CSiMe_3$ ($\mathbf{L^3}$), which gives a crystalline black solid of a homodimetallic d^2-d^2 complex $[(Cp_2V)_2(3,4\text{-}\eta\text{-}Me_3SiC{\equiv}C\text{–}C{=}C\text{–}C{\equiv}CSiMe_3)]$ (**11**; Scheme 4). The main feature of **11** is the bonding mode of the two vanadocene moieties, which are attached to both the internal carbon atoms of the triyne by a single σ-type V–C bond of 2.165 Å. This brings the vanadium oxidation state from +2 to +3 instead of the expected classical V^{IV} that has been observed in all other cases. This unexpected reactivity seems to be due to the odd number of C≡C bonds in $\mathbf{L^3}$. The central C≡C bond of $\mathbf{L^3}$, which is more electron-rich than the other C≡C bonds, may favor the reaction at the central core of the ligand.[15] Variable-temperature magnetic susceptibility measurements have been carried out to confirm the V^{III} homobimetallic d^2-d^2 nature of **11**. The effective moment (μ_{eff} = 4.01 μ_B at 300 K) is consistent with two noninteracting vanadium(III) units, and a weak antiferromagnetism (J = –3.7 cm^{-1}) is observed.



Scheme 4.

When one equivalent of **1** was treated with only one equivalent of $\mathbf{L^3}$, in pentane, small, brown needles of the vanadium(IV) complex $[Cp_2V(3,4\text{-}\eta^2\text{-}Me_3SiC{\equiv}C\text{–}C{=}C\text{–}C{\equiv}CSiMe_3)]$ (**12**) were obtained (μ_{eff} = 1.9 μ_B). A vanadocene cyclopropene structure could be suggested on the basis of its hydrolysis with HCl (*trans*-$Me_3SiC{\equiv}C\text{–}CH{=}CH\text{–}C{\equiv}CSiMe_3$ was obtained; $\mathbf{L^3}$ is liberated upon hydrolysis of **11** with HCl). Treatment of **12** in C_6D_6 with another equivalent of **1** leads to **11**. A comproportionation reaction between V^{IV} (**12**) and V^{II} (**1**) to give two V^{III} centers (**11**) is probably operative, but a full mechanistic description must await further experimental evidence.

The reaction of the phosphane $ArP(C{\equiv}CPh)_2$ (Ar = 2,4,6-$t\text{Bu}_3C_6H_2$) with one equivalent of **1** in pentane, at room temperature, leads to the formation of the V^{IV} complex $[Cp_2V(\eta^2\text{-}PhC{=}C)P(C{\equiv}CPh)Ar]$ (**13**) as a crystalline product.[16] The reactivity of **13** towards HCl was examined (Scheme 5). Reaction of **13** in THF with HCl gives, selectively, the starting phosphane as the main product, along with a green precipitate of $[Cp_2VCl_2]$. The same reaction performed in toluene leads to the alkenyl-alkynylphosphane (1:1 ratio of *cis* and *trans* isomers), isolated as its sulfur derivative, and $[Cp_2VCl_2]$. The solvents (THF, toluene) could account for the reactivity of **13**. However, the IR and EPR spectra of **13** in these solvents do not show any detectable difference; similar data are observed for both solvents. This observation supports the view that the facile protonation of **13** could occur equally in toluene or in THF, in contrast to the release of the phosphane observed in THF.

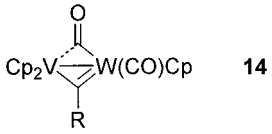


Scheme 5.

Another interesting reactivity is the reaction of $[VCp_2]$ with carbyne complexes. A typical example for the forma-

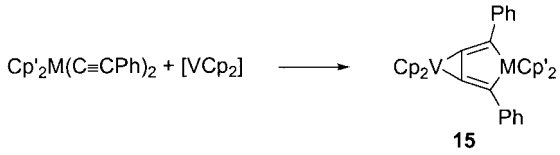
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion of a dimetallic compound containing **1** has been realized with [W(≡CR)(CO)$_2$Cp] (R = 4 Me-C$_6$H$_4$), since this complex and alkynes have similar reactivity patterns.[17] The reaction of **1** with the tungsten complex afforded black crystals of [Cp$_2$V(μ-CR)W(CO)$_2$Cp] (**14**). A weak attachment between **1** and the tungsten complex is observed from the structure, as exemplified by the dissociation of the heterodimetallic complex in solution.



14

Oxidative addition of a diyne of a ligand-stabilized metallocene of a group 4 element, or reaction of an alkyne compound of a group 4 element with a Lewis metal complex, have been reported to give dimetallic complexes.[18] These results showed the way towards heterodimetallic [Ti,V] or [Zr,V] complexes involving the reaction of acetylenic titanium or zirconium compounds with **1**. Reaction of [(C$_5$H$_4$R)$_2$M(C≡CPh)$_2$] (M = Ti, R = H; M = Zr, R = H, Me, *t*Bu, SiMe$_3$) with **1** yields the heterobimetallic complex [Cp$_2$V(μ-η^2:η^4-butadiyne)M(C$_5$H$_4$R)$_2$] (Scheme 6).[19,20] The measured magnetic moments show that the formal oxidation state of vanadium has increased from II to IV.

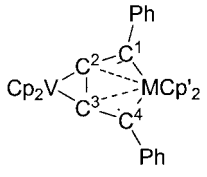


15

15a: M = Ti, Cp' = C$_5$H$_5$
15b: M = Zr, Cp' = C$_5$H$_5$
15c: M = Zr, Cp' = C$_5$H$_4$Me
15d: M = Zr, Cp' = C$_5$H$_4$CMe$_3$
15e: M = Zr, Cp' = C$_5$H$_4$SiMe$_3$

Scheme 6.

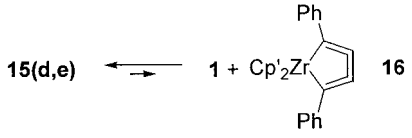
The ease of solving the crystal structure of the series of compounds **15** seems to be very much dependent on the nature and size of the different substituents on the cyclopentadienyl groups of the metal–alkyne compound. Nevertheless, an overall arrangement similar to that observed in the fully resolved structures of **15d** and **15e**, in which the two metal centers are strongly differentiated by the substituents on their respective cyclopentadienyl groups, was found. The vanadium atom adopts a metallacyclopropane environment. The interatomic distances between C^2 and C^3 and their four neighboring atoms (Zr, V, C^1, and C^3 and Zr, V, C^2, and C^4, respectively), and the 360° value for the sum of the angles around C^2 and C^3, indicate that these carbon atoms are planar tetracoordinate carbons (ptC). Most of the ptC-containing transition metal complexes reported to date, mainly by Erker et al., are group 4 homo- and groups 4 and 10 or 13 heterodimetallic complexes.[21]



15d,e

ELF analysis[22] reveals the existence of three multicenter bonds involving the Zr atom and the four carbon atoms of the butadiyne fragment. The existence of electron-sharing interactions between each of the two central carbon atoms of the butadiyne fragment and four neighbors (for example, C^2 interacts with Zr, V, C^1, and C^3) has been established.[20] Both these central carbon atoms are involved in three bonds, two of which are three-center bonds. Therefore, these central carbon atoms may be considered as planar tetracoordinate.

The mechanism of formation of these complexes has been elucidated. Analogous complexes obtained by reaction of [Ni(PPh$_3$)(η^2-PhC≡C–C≡CPh)] and "Cp$_2$Ti" or "Cp$_2$Zr" to give heterodimetallic [Cp$_2$M(μ-η^2:η^4-PhC≡C–C≡CPh)Ni(PPh$_3$)$_2$][23] show the same skeletal (μ-η^2:η^4-PhC≡C–C≡CPh) arrangement as that observed in compounds **15**, and the formation of an intermediate zirconacyclocumulene species [Cp$_2$Zr(η^4:1,2,3,4-PhC=C=C=CPh)] was therefore suggested.[23] Some partial dissociation of **15** in solution (estimated by EPR spectroscopy to be ca. 10–20%; Scheme 7) shows the presence of the zirconacyclocumulene species **16**.



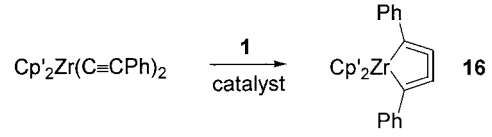
16

Scheme 7.

Interestingly, the formation and the reactivity of **16** is governed by the nature of the substituents attached to the alkyne.[18e,24,25] In contrast, attempts to prepare a similar heterodimetallic complex from **1** and [Cp$_2$Zr(C≡CSiMe$_3$)$_2$] failed.[26] On the other hand, the use of different electron-donating R groups on the Cp ring of the dialkyne zirconocene (H in **15b**, Me in **15c**, *t*Bu in **15d**, and SiMe$_3$ in **15e**) does not change the nature of the resulting heterodimetallic [Zr,V] complex.

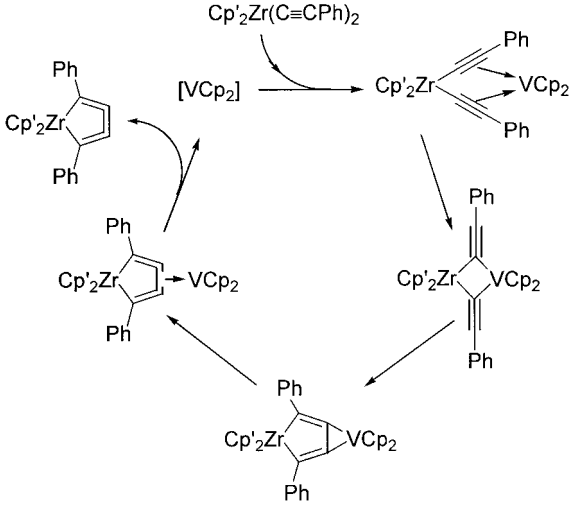
The transformation of the dialkynylzirconocene precursors [(C$_5$H$_4$R)$_2$Zr(C≡CPh)$_2$] (R = H, Me, *t*Bu, SiMe$_3$) into the corresponding zirconacyclocumulene species **16** in daylight is complete in around four days. Zirconacyclocumulene complexes **16** can also be generated by treating the corresponding dialkynylzirconocene with a catalytic amount of **1** (ratio 10:1) for about two days (this is a shorter time than the same reaction in daylight), which implies the involvement of **1** in forming the zirconacyclocumulene (Scheme 8). Finally, complexes **15d** and **15e** can be generated from the corresponding zirconacumulene by treatment with a stoichiometric amount of **1**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



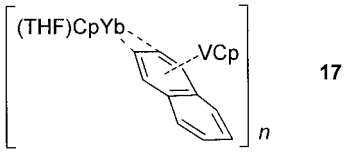
Scheme 8.

The observed reaction between the bis(phenylethynyl-metallocene and -vanadocene and the formation of the heterodimetallic [M,V] compounds can be understood as resulting from the partial transfer of the phenylethynyl group from M to vanadium. Thus, both pathways, i.e. irradiation and/or Cp_2V catalysis, lead to the same zirconacyclocumulene species, and their relative importance in our reactions is difficult to assess. Nevertheless, our results clearly show that, the two C≡CPh alkynyl moieties of [Cp′$_2$Zr-(C≡CPh)$_2$] undergo a C–C coupling, vanadocene being actually involved in the mechanism of formation of compounds **8** through a transfer of the C≡CPh moiety from Zr to V, and that a zirconacyclocumulene species is a key intermediate in this mechanism. The formation of the zirconacyclocumulene species may proceed through the catalytic cycle proposed in Scheme 9.



Scheme 9.

Other dimetallic complexes containing a vanadium atom have been prepared from **1**. Reduction of **1** with naphthalenylpotassium leads to a suitable source of the CpV fragment from isolated [CpV($C_{10}H_8$)].[27] Reduction of **1** to vanadium(0) by naphthalenylytterbium [($C_{10}H_8$)Yb(THF)$_2$] in THF generates the polymeric, two-dimensional, multidecker complex [CpV(μ-η^6:η^2-$C_{10}H_8$)Yb(THF)Cp]$_n$ (**17**),[28] the molecular structure of which consists of infinite zig-zag chains formed by CpYb moieties with one CpV(η^6-$C_{10}H_8$) unit η^2-coordinated through the naphthalene to each Yb atom.

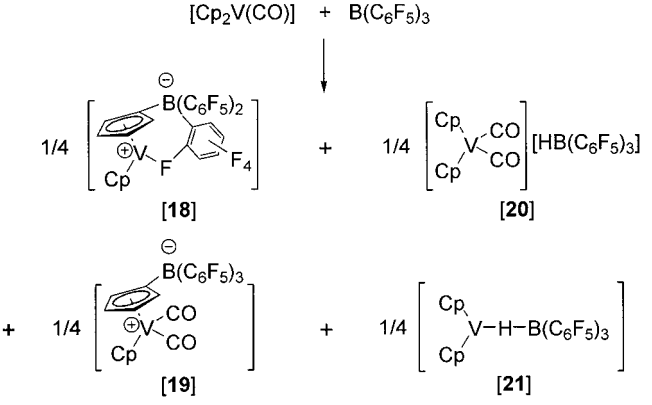


The reactivity of **1** towards the cobalt complex [Co_2-($CO)_8$] was also re-examined and the salt [$Cp_2V(CO)_2$]-[$Co(CO)_4$] was isolated.[29]

Reactivity of [Cp_2VCO] − Another Source of Vanadocene

Turning now to another source of vanadocene, carbonylbis(cyclopentadienyl)vanadium(II) [Cp_2VCO] is easily obtained by treatment of **1** with CO.[30] A few reactivity studies have been conducted with olefins[31] and dinitrogen oxides[32] in which, in the absence of X-ray analysis, IR spectroscopy plays an important role in the characterization of the resulting compounds.

In light of the tremendous amount of work on the reactivity of tris(perfluorophenyl)borane [$B(C_6F_5)_3$] with organometallic complexes and as an activator in olefin polymerization,[1a,33] we explored the reactivity of $B(C_6F_5)_3$ towards our vanadium compounds.[34] In this context, the reactivity of [Cp_2VCO] and $B(C_6F_5)_3$ was studied as an extension of our previous report showing that a related dicarbonyltitanocene gives the acylborane complex [$Cp_2Ti(CO)$-{η^2-$OCB(C_6F_5)_3$}] by attack of the Lewis acid at the carbonyl carbon atom.[35] Although the reaction with [Cp_2VCO] resulted in the formation of four complexes, all of them were fully characterized by X-ray structure elucidation after careful separation by hand.[36] Particularly interesting and intriguing is the formation of the zwitterionic, ring-borylated vanadium(III) complex [(Cp){C_5H_4B-($C_6F_5)_3$}V] (**18**) and [(Cp){$C_5H_4B(C_6F_5)_3$}$V(CO)_2$] (**19**), and of the salt [$Cp_2V(CO)_2$][$HB(C_6F_5)_3$] (**20**) and the hydride [Cp_2V(μ-H)$B(C_6F_5)_3$] (**21**).[37] In **18**, the borane is linked to one of the cyclopentadienyl rings, and an *ortho*-fluorine atom of one perfluorophenyl group of the borane is coordinated to the vanadium center. Complex **21** can be described as a vanadocene hydride stabilized by the borane. Formation of the vanadium(IV) hydride [(Cp){C_5H_4B-(C_6F_5)}$_3$VH(CO)] by the electrophilic addition of the borane at the Cp ring, followed by redox and disproportiona-



Scheme 10.

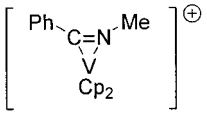
tion reactions, is thought to account for these results (Scheme 10).

Reactivity of [VCp_2] with Nitrile Ligands

The literature reveals that the reaction between vanadocene and the nitrilium salt [RC≡NMe][BF_4] (R = Me, Ph) produces iminoacyl vanadocene; the ionic complex [$Cp_2V\{\eta^2$-(Ph)C=$NCH_3\}$][BF_4] (**22**) was characterized by an X-ray structure determination.[38] On the other hand, adducts of nitriles RC≡N with a Lewis acid have been known for a long time and have been widely studied.[39] From the large increase in the ν(C≡N) stretching frequency induced by complexation with a strong Lewis acid, it was found that the polarity of the nitrile group is increased in the complex.[40] Considering that the Lewis acid could modify the reactivity of the C≡N bond, the RCN·Lewis acid adduct can be considered as a ligand containing an "activated" C≡N bond.



22

Addition of various BR_3 Lewis acids to acetonitrile and trifluoro-*p*-tolunitrile (R′C≡N) in toluene to form the expected RC≡N·BR_3 adduct in situ, followed by the addition of **1** in toluene, gives, after two to three days, the crystalline borane adduct of the vanadaazirine complexes [$Cp_2V\{\eta^2$-(R′C=N·BR_3)}] (**23** and **24**; Scheme 11).

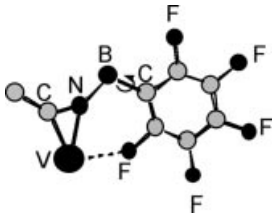
R	C_6F_5	C_6F_5	2,6-$F_2C_6H_3$	3,4,5-$F_3C_6H_2$	Ph	Cl

Scheme 11.

These complexes are paramagnetic due to the presence of one unpaired electron, in agreement with the spin value for a formally vanadium(IV) (d^1) system. The main feature of the X-ray structures is that the nitrile group attached to the vanadium atom by two σ-type V–C and V–N bonds of 2.04 Å (av.) and 2.08 Å (av.). This produces a metallacycloimine structure. Changing $B(C_6F_5)_3$ to $B(C_6H_5)_3$ or BCl_3 in the vanadaazirine(IV) complex adduct produces slight differences in the VNC cycle, in which a C=N double bond is now formed. In contrast, the B–N distances are modified according to the expected Lewis acidity of the boranes [$BCl_3 > B(C_6F_5)_3 > BPh_3$] and in agreement with the $\nu_{C=N}$ frequencies observed for these complexes.

X- and Q-band EPR studies were carried out in THF solution. An expected eight-line pattern was observed for **24c**–**e** [average: g = 1.998; $A(^{51}V)$ = 41 G]. For **23** and **24a**,**b**, the formation of a doublet of octets was observed. An additional hyperfine coupling of the unpaired electron of the vanadium atom with a fluorine atom of the borane $B(C_6F_5)_3$ is responsible for the second coupling constant [average: g = 1.997, $A(^{51}V)$ = 42 G; $a(^{19}F)$ = 15 G]. This fact can be explained by the absence of any fluorine atom in the *ortho* position of the boranes in **24c**,**d**. The presence of two fluorine atoms in the *ortho* position of the phenyl rings in **23** and **24a**,**b** contributes to the C–F···V interaction and a subsequent $a(^{19}F)$ hyperfine coupling is observed. A careful investigation of the X-ray structures of **23** and **24a**,**b** does not indicate such an interaction in the solid state. However, a dynamic process involving the rotation of B–C and N–B allows the fluorine atom to approach the vanadium center in solution. A model can be drawn to take into account this flexibility, and the best situation for a C–F···V interaction is a plane containing the V–C(1)–N–B–$C_{ipso}(C_6F_5)$ atoms where one *ortho* fluorine atom of the fluorophenyl ligand could approach the vanadium center by the formation of a six-membered ring (Scheme 12). Moreover, the presence of a doublet signal indicates the retention of only one V···F coordinative bond in solution. These results support the view that the *ortho* fluorine atom of the phenylborane interacts with the vanadium.



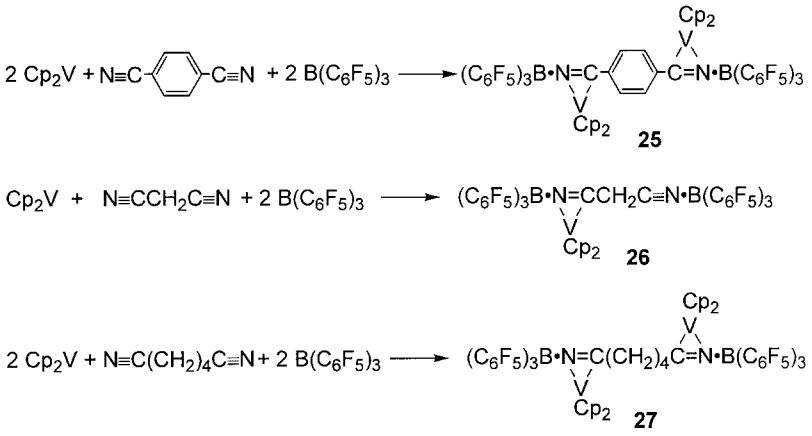
Scheme 12.

It is remarkable that the nitrile RC≡N can react with the borane BPh_3 in the presence of **1**. In the absence of **1**, the IR spectra of a mixture of the nitrile $F_3CC_6H_4C$≡N and BPh_3 (1:1 or 1:5 ratio) in toluene do not show any change in the position of the ν_{CN} absorption due to an eventual formation of the borane–Lewis acid adduct. Nevertheless, it is clear that an undetectably small amount of the adduct is formed, which allows the formation of **24d**.

In attempts to synthesize a bimetallic vanadium d^1-d^1 complex with a potential magnetic interaction between the two metal centers,[41] the first ligands of choice were 1,4-benzene dicarbonitrile N≡C–(C_6H_4)–C≡N, malononitrile N≡CCH_2C≡N, and adiponitrile N≡$C(CH_2)_4$C≡N. Microcrystalline, blue-violet solids of [$(VCp_2)_2\{\eta^2$:*C*,*N*-($C_6F_5)_3$B·N=$C(C_6H_4)$C=N·$B(C_6F_5)_3\}$] (**25**), [$VCp_2\{\eta^2$:*C*,*N*-($C_6F_5)_3$B·N=C–CH_2C≡N·$B(C_6F_5)_3\}$] (**26**), and [$(VCp_2)_2\{\eta^2$:*C*,*N*-($C_6F_5)_3$B·N=$C(CH_2)_4$C=N·$B(C_6F_5)_3\}$] (**27**), respectively, were isolated (Scheme 13).

The X-band EPR spectra of **25**–**27** in THF were recorded and the formation of a doublet of octets was observed. Coupling of the unpaired electron of the vanadium atom with the ^{51}V (I = 7/2) nucleus and the *ortho*-fluorine atoms of the borane $B(C_6F_5)_3$, via a C–F···V interaction, give rise to these spectra [average: g = 1.996, $a(^{51}V)$ = 43 G, $a(^{19}F)$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 13.

= 17 G]. Complexes **25** and **27** were also studied by variable-temperature magnetic susceptibility measurements resulting from homobimetallic d^1-d^1 situations. Unfortunately, these paramagnetic d^1-d^1 systems do not present any antiferromagnetic interaction due to the presence of a long sp^3 alkyl chain when adiponitrile is used (in **27**) and to a suggested disfavored orientation of the VCp_2CN units within the $NC(C_6H_4)CN$ ligand (in **25**). This latter situation has already been observed in the case of **8b** and **10b**, where the dihedral angle between both Cp_2VC_2 units is nearly 110–120° and thus prevents a favorable "in-plane π-type" geometry in the molecule.[11]

[VCp_2] as a Source for VC-Containing Ceramics

Transition metal nitrides or carbides, like other ceramic materials, show outstanding physical and chemical properties. They are usually prepared by reaction of the corresponding metal halides with nitrogen and ammonia, and sometimes in the presence of hydrogen. These reactions have to be carried out at high temperature, usually above 1000 °C. Such drastic conditions restrict applications such as the protective coating of materials whose mechanical properties are sensitive to high temperature, i. e. steel or materials for electronics. The use of coordination compounds as organometallic precursors allows the preparation of thin-film ceramic materials by the so-called organometallic chemical vapor deposition (OMCVD), which is a process that involves much lower temperatures.[42] Compound **1** is a suitable precursor for CVD of vanadium carbide (VC). The precursor sublimes at 60 °C/20 Pa and has a sufficient vapor pressure under these conditions. Films containing crystalline vanadium carbide (VC) have also been deposited from **1** by plasma-assisted CVD (PACVD).[43]

Compound **1** was also selected for the preparation of the quaternary ceramic system vanadium-titanium carbonitride,[44] which is a solid solution though to exhibit better mechanical properties than those of the binary ones TiN, TiC, VN, and VC, by OMCVD.[45] To reach this goal, appropriate molecular organometallic precursors are needed. The most elegant approach, but maybe not the most efficient, could be the use of a single precursor containing all the desired elements. However, to date, such molecules are not known.

An introduction to this type of molecule was provided by the dimetallic [Ti,V], complex described above by reaction of $[Cp_2Ti(C{\equiv}CPh)_2]$ with **1**. However, this molecule is not suitable for OMCVD due to its poor volatility.[46] Therefore, the use of pairs of independent precursors was investigated, each precursor being the source of the desired elements, for example TiN and VC or TiC and VN. Moreover, as the pairs of precursors are introduced simultaneously into the CVD reactor, they should exhibit compatible thermal behaviors. Given the applied aspects of this work, the selection of the precursors should rest on criteria based on industrial and economic grounds. Among the several VC precursors studied for this purpose, **1** (under H_2, at 700 °C in a cold wall reactor) yields 13-μm-thick, crystallized, vanadium carbide films which were characterized by XRD (X-ray diffraction) and EPMA/WDS (electron probe microanalysis with wavelength-dispersive spectroscopy).[47] The influence of deposition rate and grain size on the composition of the deposits was investigated by varying three factors: the substrate temperature, the hydrogen carrier flow rate, and the distance between the substrate and the precursor handling crucible. The residence time of the gaseous species in the reactor was found to be an important factor, leading to a maximum of the deposition rate. Even when drastic conditions are applied (high purity hydrogen carrier gas) the use of a low temperature is not thermodynamically in favor of the formation of carbides over that of oxides, and the high C-to-metal ratio in the precursor molecule often leads to contamination of the films by graphitic carbon. Therefore, it is worth noting that *tert*-butyl-substituted vanadocene $[V(C_5H_4\text{-}t\text{Bu})_2]$ was shown to be an excellent precursor for the preparation of crystalline VC thin films not contaminated by graphitic carbon or oxygen.[48] These films were fully characterized by XRD, scanning electron microscopy, X-ray photoelectron spectroscopy, and EPMA/WDS. Within the "pairs of precursors" approach it

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

should be noted that another vanadium derivative, namely $[Cp_2VMe_2]$, and $[CpTiCl_2(NSiMe_3)_2]$ afford (Ti, V, C, N)-containing films.[49]

$[VCp_2]$: A Reducing Agent for Chloride Organometallic Precursors to Colloids

The use of **1** as a reducing agent in the fabulous area of nanoparticles must be cited. The past decade has demonstrated the importance of the role of colloids in various catalytic reactions, primarily for hydrogenation of arenes. Different synthetic pathways are presently studied to obtain various types of colloids displaying a controlled size and chemical environment.[50] The most popular method for the preparation of noble metal particles involves reduction of chloride precursors by various reducing agents, for example refluxing alcoholic solutions in the presence of a polymer. The role of vanadocene $[VCp_2]$ as an organometallic reducing agent to prepare metal colloids embedded in a PVP polymer matrix [PVP: poly(vinylpyrrolidone)] has been successfully demonstrated in the case of $FeCl_2$, $[Rh(C_2H_4)_2Cl]_2$, and $[Pd(\eta^3\text{-allyl})_2Cl]_2$ to give Fe, Rh, and Pd nanoparticles, respectively.[51–53] This unusual synthetic organometallic route allows the preparation of colloids from organometallic complexes containing chloride group(s) (Scheme 14).

$$2\,[VCp_2] + FeCl_2 \xrightarrow{PVP} [Fe^0(PVP)] + 2\,(Cp_2VCl)$$

$$[VCp_2] + MCl(L)_x \xrightarrow{PVP} [M^0(PVP)] + (Cp_2VCl) + L_x$$

$$MCl(L)_x = [Rh(\mu\text{-}Cl)(C_2H_4)_2]_2,\ [Pd(\mu\text{-}Cl)(\eta^3\text{-}C_3H_5)_2]_2$$

Scheme 14.

The reaction of a THF solution of $[Rh(C_2H_4)_2Cl]_2$, $[Pd(\eta^3\text{-allyl})_2Cl]_2$, or a solid suspension of $FeCl_2$ with a stoichiometric amount of $[VCp_2]$ per chloride atom in the presence of poly(vinylpyrrolidone) (K30-PVP; average molecular weight: 40000) as protecting polymer, at room temperature, leads to metal colloids dispersed in PVP and isolated as the black solid [M-PVP]. A low-magnification TEM micrograph registered for each solid shows that the particles are well dispersed. The HREM micrograph evidences fringes in the particles. The regular periodicity of the fringes allows the determination of the fcc structure of the particles. From $FeCl_2$, big agglomerates of Fe particles with diameters ranging from 50 to 200 nm are present in which individual nearly 8-nm-diameter nanoparticles are observed. All these individual grains have a common orientation inside one large Fe grain, as observed by HRTEM experiments.[51] A relatively narrow size distribution is observed for Rh particles, with a mean diameter of about 1.3 nm. Structural characterization of the metal colloids by wide-angle X-ray scattering (WAXS) was performed in the solid state on the same batch that was used for the TEM experiments, using procedures previously validated for colloids in PVP. This technique, in which the radial distribution function (RDF) gives the M–M distances, confirms the fcc structure of the particles. Structural characterization of the rhodium colloids by WAXS was consistent in size and structure with a proposed model, a small 55-atom cuboctahedron.[52] The size of the Pd particles shows a mean diameter of about 1.8 nm with a relatively large size distribution. The coherence length can be evaluated to be 2 nm, in agreement with TEM measurements.[53] The same RDF was observed when solids [Rh-PVP] and [Pd-PVP] were treated with O_2 or CO (20 bar, 4 d). With O_2, the RDF gives direct evidence of the absence of significant oxidation of the solid sample, at least in the core of the nanoparticles. The concentration of metal embedded in the polymer can be modulated as a function of the different amounts of PVP added (2% to 13% in M weight).

The catalytic potential of the [Rh-PVP] and [Pd-PVP] nanoparticles, which are soluble in alcoholic solvents as well as in water, has been explored in heterogeneous and biphasic conditions, as well as ionic liquids, for the hydrogenation of different types of substrates (benzene, quinoline, adiponitrile, aromatic nitro compounds, ...).[54]

The main advantage of this $[VCp_2]$ method for reducing chloride-containing organometallic precursors to nanoparticles is the availability of the organometallic complexes $M^I(L)_x$ of groups 8–10. Large-scale synthesis of nanoparticles embedded with PVP can be performed and their use in different catalytic processes from the same batch is possible, thus allowing kinetic measurements under various experimental conditions.

Concluding Remarks

Throughout this review we have mainly reported the isolation and characterization of various vanadocene complexes. Importantly, all pathways have been confirmed by a structural elucidation of the molecules present in the reaction. We have to point, again, this necessity to ensure the chemical nature of the different species when paramagnetism, disproportionation, and redox reactions are possible due to the nature of the vanadium center. Indeed, starting from divalent vanadocene different redox reactions are observed with formation of V^{III} and V^{IV} species. Vanadocene has been shown to react with various poly-ynes, and some similarities were observed with related titanocene or zirconocene chemistry. Their intrinsic reactivity towards small organic molecules has not yet been explored but we can predict a high chemical potential for all these compounds. On the other hand, the incorporation of two paramagnetic centers along a chain constitutes a challenge in the realization of new homodimetallic systems that are able to convey magnetic coupling. The reactivity with nitriles and polynitriles could constitute a new approach to the fascinating area of molecular magnets developed by Miller from TCNE and TCNQ with $[V(CO)_6]$ or $[V(C_6H_6)_2]$.[55] Indeed, some

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

research on TCNE with **1** in the presence of a borane is in progress in our group.

The role of vanadocene as a source of vanadium carbide (VC) or as a reducing agent for the formation of metal nanoparticles seems an efficient starting point for expending the number of new applications in the ever-growing field of advanced materials chemistry.

Acknowledgments

We are indebted to all the people in our research group and collaborators cited in references for their partnership. Particularly, we are very grateful to B. Donnadieu and L. Vendier for their kind and helpful technical contributions to the X-ray analysis of the vanadium compounds described in this review. Low-Temperature Flux Synthesis, Crystal Structure and Ce-Doped Luminescence of the First Lutetium Diphosphate $NH_4LuP_2O_7$

Man-Rong Li,[a,b] Wei Liu,[a] Hao-Hong Chen,[a] Xin-Xin Yang,[a] Zan-Bin Wei,[c] Dun-Hua Cao,[d] Mu Gu,[d] and Jing-Tai Zhao*[a]

Keywords: Low-temperature self-flux synthesis / Structure / Diphosphate / Luminescence

The first lutetium diphosphate $NH_4LuP_2O_7$ has been prepared by a two-step, low-temperature self-flux synthesis in the presence of the F^- anion, functioning as a mineralizer, which played a significant role in the synthetic process. The crystal structure has been characterized by single-crystal X-ray diffraction. The title compound crystallizes in a monoclinic system of the space group $P2_1/c$ (No. 14), a = 7.651(2) Å, b = 10.789(2) Å, c = 8.577(2) Å, β = 105.75(3)°, V = 681.4(2) Å^3, Z = 4. The three-dimensional framework of $NH_4LuP_2O_7$, composed of $Lu_2P_4O_{14}$ building units formed by vertex-linking LuO_6 and P_2O_7 goups, is isostructural with compounds of the type $KAlP_2O_7$ in the ternary diphosphate($A^IM^{III}P_2O_7$) system. X-ray-excited luminescence measurements of Ce-activated samples show insteresting scintillation properties with a short decay time of 16 ns at room temperature.

Introduction

Recently, investigation of the synthesis and characterization of wide-bandgap rare-earth (RE) phosphate materials has gained much more attention, for their potential applications in diverse areas such as X- and gamma-radiation detectors, lighting, display phosphors, light-emitting diodes, scintillators, and solid state lasers, and because they are highly transparent, easily shaped, and cost-effective.[1–4] In contrast to the well-known ternary rare-earth phosphates, the diphosphates, which should have had potentially attractive applications on the basis of their analogous structure with the phosphates, are still to be explored, except for the compounds already reported, partly because it is difficult to synthesize them in the crystalline and pure phase requested for considerable applications. $MLaP_2O_7$ (M = Li, Na, K),[5] $NaCeP_2O_7{\cdot}4.5H_2O$,[6] and $NaGdP_2O_7{\cdot}4.5H_2O$,[7] obtained from reaction in solution, have been reported, but only some complex X-ray powder diffraction patterns have been given without further indexing for the lattice parameters, and no single-crystal X-ray structural determinations have been reported to support the lattice parameters until now. In addition, the function of the pH value is rather subtle in the solution method. Jansen et al.[8] prepared $CsYbP_2O_7$ by rigorous solid-state reaction (under argon at 1173 K) and characterized the crystal structure without further investigation. Most often it is not so easy to obtain the pure phase and carry out further purification by high-temperature solid reactions, as reported in the preparations of $NaGdP_2O_7$,[7] AYP_2O_7 (A = Na,[9] K,[10] Cs[11]), and $NaEuP_2O_7$[12] in the presence of an auxiliary solvent.

The above compounds have been mostly prepared by reaction in solution and by the high-temperature flux method. In addition, other relevant characterization data and optical properties of this type of compounds have been seldom reported. Along this line of research, we present here the novel two-step, low-temperature self-flux synthesis, crystal structure, and Ce-activated luminescence of $NH_4LuP_2O_7$.

Results and Discussion

F^--Optimized Procedure

The preparation procedure is outlined in reaction (1) and reaction (2). As shown in reaction (1), sodium lutetium tetrafluoride, $NaLuF_4$, was obtained under mild water-free flux of abundant H_3BO_3, with a low melting point of 458 K, instead of the traditional synthetic method for this type of compounds.[13] Excess H_3BO_3 and a stoichiometric quantity of NaF were essential in the first reaction.

$$Lu_2O_3 + 8\ NaF + 2\ H_3BO_3 \xrightarrow{523\ K} 2\ NaLuF_4 + 2\ Na_3BO_3 + 3\ H_2O\uparrow \quad (1)$$

$$NaLuF_4 + 3\ NH_4H_2PO_4 + 2\ NaF \xrightarrow{553\ K} NH_4LuP_2O_7 + Na_3PO_4 + 2\ NH_3\uparrow + HF\uparrow + H_2O\uparrow \quad (2)$$

In reaction (2), the mixture of prepared $NaLuF_4$, excess $NH_4H_2PO_4$, and the correct quantity of NaF was heated in a Teflon-lined stainless steel autoclave at 553 K. Here the excess $NH_4H_2PO_4$ (melting point: 453 K) was used as the self-flux, and the quantity of NaF played a very important role. Lots of $LuPO_4$ powder and a few crystals of $NH_4LuP_2O_7$ were produced in the absence of NaF. The yield of $NH_4LuP_2O_7$ increased by adding NaF, and the pure phase of the target compound could only be obtained when the molar ratio of F/Lu was larger than two. This observation indicates that reaction (2) tends to yield $NH_4LuP_2O_7$ instead of $LuPO_4$ in the presence of a large quantity of F^-.

Related investigations were carried out for systems with RE (RE = Y, La, Nd, Gd, Er, Yb) instead of Lu. $NH_4YP_2O_7$ and $NH_4YbP_2O_7$ were obtained with the same structure type, while $REPO_4$ was produced in systems containing La, Nd, and Gd. The Er system yielded a mixture of $ErPO_4$ and $NaErF_4$. Obviously, the size of the ion plays a very important role in the synthetic procedure.

Crystal Structures of $NH_4LuP_2O_7$

The many structural investigations devoted to the $A^IM^{III}P_2O_7$-type diphosphates in the past two decades have shown the existence of eight structural types.

The compounds of type I exhibit the $KAlP_2O_7$[14] structure, whereas those of type II are isotypic with $NaFeP_2O_7$.[15] The lithium-containing compounds constitute the third family and adopt the $LiFeP_2O_7$ structure.[16] The fourth type is only represented by α-$NaTiP_2O_7$.[17] A fifth type occurs for the $NaYP_2O_7$ structure,[9] and KYP_2O_7 belongs to structural type VI.[10] The structural investigation of $NaEuP_2O_7$[12] and $NaGaP_2O_7$[7] reveals new structural arrangements of type VII and type VIII, respectively.

The crystal structure of the title compound $NH_4LuP_2O_7$ was determined by single-crystal X-ray diffraction. It is isotypic with type I compounds and possesses a three-dimensional framework consisting of $Lu_2P_4O_{14}$ building units as shown in Figure 1. The NH_4^+ cations occupy the one-dimensional six-membered ring tunnels (about 3.83 × 3.83 Å, evaluated from the O···O distances) and participate in moderate hydrogen bonding with the framework oxygen atoms (N–H···O hydrogen bonds with distances of 2.884–3.344 Å). The tunnels running along [001] result from the stacking of rings formed by the edges of three LuO_6 octahedra and four PO_4 tetrahedra. Adjacent layers are generated by the *c*-glide plane, and these layers form a three-dimensional network with tunnels running along the *c*-axis.

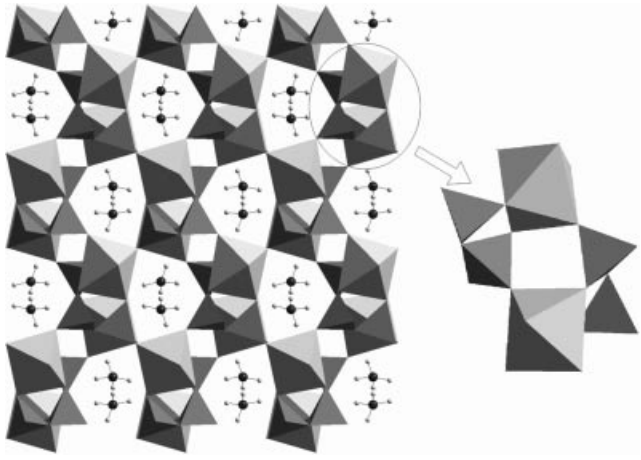

Figure 1. (a) 3D polyview structure along the [001] direction (b) $Lu_2P_4O_{14}$ structural building unit in the crystal structure of $NH_4LuP_2O_7$ (LuO_6, light-gray octahedra; PO_4, dark-gray tetrahedra; N atoms black spheres; H atoms, light gray spheres).

Lu atoms have a hexagonal close-packed arrangement. Each LuO_6 group is connected, through Lu–O–P bonds, to five P_2O_7 groups: two corners of the LuO_6 octahedron are linked to one P_2O_7 group, and the other four corners are connected with four distinct P_2O_7 groups. The LuO_6 octahedra are also distorted [the bond valence sum (BVS) of Lu is 3.19], as shown by the Lu–O distances ranging from 2.143(12) to 2.223(11) Å and O–Lu–O bond angles ranging from 82.8(4) to 178.9(5)°. The P_2O_7 group presents a staggered configuration with one long P–O bond and three much shorter P–O bonds (Figure 2), which is very common in the $A^IM^{III}P_2O_7$ family except for the semi-staggered configuration in several compounds ($NaInP_2O_7$,[18] $NH_4VP_2O_7$,[19] and $NaYP_2O_7$[9]) and the eclipsed configuration in type II, III, VI, VII, and VIII compounds. The P–$O_{terminal}$ bonds (average: 1.511 Å) are shorter than the P–$O_{bridging}$ bonds (average: 1.597 Å), and the P–O–P bond angle is 128.9(8)°, which falls into the generally observed range of 122–141° for ternary diphosphate compounds. The O–P–O angles show distortion from the ideal tetrahedral geometry [105.1(6) to 113.9(8)°], and the BVSs of the two P atoms are 4.93 and 4.90. The calculated BVSs are very close to the chemical valences; this confirms the reliability of the determined structure.[20,21]

Luminescence Properties

The Ce-doped crystals were grown under the same conditions by adding CeF_3 in reaction (1). X-ray-excited lumines-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cence (XEL) measurements showed that $NH_4LuP_2O_7$ activated with 0.5 at.-% Ce^{3+} exhibited the strongest band emission when the concentration of Ce^{3+} was in the range 0.1–3 at.-% (stoichiometric amounts of lutetium oxide). The XEL spectrum of $NH_4LuP_2O_7$:Ce^{3+} (0.5 at.-%) shows a band emission with a maximum at 375 nm (Figure 3), which can be explained by transitions occurring between the lowest level of the excited 5d (2D) sate and the ground $^2F_{5/2}$ and $^2F_{7/2}$ levels of 4f(^{2}F) in the Ce^{3+} ion. Compared with the reported Ce^{3+}-activated spectrum of lutetium phosphate,[22] the emission band in Figure 3 is less well-resolved because of increased overlap. A Gaussian fit reveals that the emission band consists of two sub-bands centered at about 364 and 395 nm. An energy discrepancy of about 2156 cm^{-1}, which is a typical value for the spin-orbit-split ground level of the Ce^{3+} ion ($^2F_{5/2}$ and $^2F_{7/2}$), confirms the Ce^{3+} d-f origin of this emission.

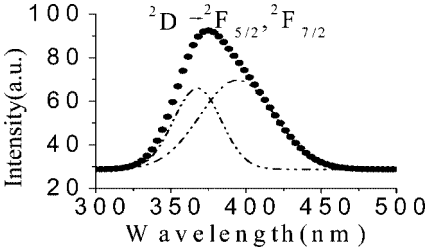

Figure 3. The X-ray-excited luminescence spectra of 0.5 at.-% Ce-activated $NH_4LuP_2O_7$ measured at room temperature.

The scintillation pulse shape for the 0.5 at.-% Ce-activated sample is shown in Figure 4, which exhibits a decay time of about 16 ns. The large contribution and very short decay time of this compound produces an excellent zero-time (initial) scintillation amplitude. This is very advantageous, since for the majority of (and especially for timing) applications, it is the zero-time scintillation amplitude that is the most important factor.[23]

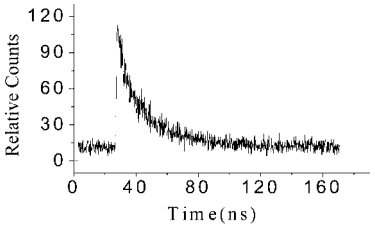

Figure 4. Scintillation decay curve of 0.5 at.-% Ce-activated $NH_4LuP_2O_7$ measured after pulsed X-ray excitation.

The luminescence properties of Ce^{3+} in different phosphate hosts are interesting because of their influence on the crystal field.[24] $LuPO_4$:Ce^{3+} (0.1 at.-%)[25] has the strongest band emission (360 nm) with a decay time of 24 ns, while $K_3Lu(PO_4)_2$:Ce^{3+} (0.5 at.-%)[22,26] and $Rb_3Lu(PO_4)_2$:Ce^{3+} (1 at.-%)[26] show strong band emissions (410 nm) with decay times of 37 and 34 ns respectively.

Conclusions

The first lutetium diphosphate $NH_4LuP_2O_7$ was synthesized under novel two-step, mild reaction conditions. The F^- optimized synthetic procedure is very significant. The open-framework crystal structure is isotypic with $KAlP_2O_7$ type compounds. The P_2O_7 group is staggered. The Ce-doped sample shows interesting luminescence and scintillation properties with a very fast decay time of 16 ns. Ternary diphosphates of other representative rare-earth systems are being investigated by this new method of synthesis for their analogous properties, and further researche will be carried out on the relation between activator concentration and activator type and luminescence and scintillation properties.

Experimental Section

Materials and Measurements: All chemicals were obtained from commercial sources and used as received. The products were examined by powder X-ray diffraction (Rigaku D/max 2550 V diffractometer, Cu-K_α) in order to confirm their phase identity and purity. Single-crystal X-ray diffraction data were collected with a Nonius Kappa CCD with graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å). The XEL and decay time measurements were carried out at room temperature with a FluoMain X-ray-excited luminescence spectrometer and a pulsed X-ray-excited decay measuring equipment designed at Tongji University. IR spectra were recorded with a Nicolet-NEXUS spectrophotometer using KBr discs. Elemental analysis was performed with an EPMA-8705H_2 (Lu, P) and a PE-2004II (N) apparatus.

Reaction (1): Lu_2O_3 (1.592 g), H_3BO_3 (1.855 g), and NaF (0.67 g) were mixed in the molar ratio 2:15:8. The mixture was sealed in a 40-mL Teflon-lined stainless steel autoclave after grinding fully and heated under autogenous pressure at 523 K for 120 h. It was cooled to 443 K at a rate of 1 K h^{-1} and then left to cool to room temperature. The product was washed with hot deionized water for purification (2.081 g, 95% based on Lu_2O_3). X-ray powder diffraction indicated that $NaLuF_4$ was obtained (J.C.P.D.S No. 27–726).

Reaction (2): $NaLuF_4$ (2.08 g), $NH_4H_2PO_4$ (3.68 g), and NaF (0.67 g) were mixed in the molar ratio 1:4:2 and heated in a Teflon-lined stainless steel autoclave at 553 K for 120 h. It was cooled to 453 K at a rate of 1 K h^{-1} and then left to cool to room temperature. The product was washed with hot deionized water for purification, and colorless, octahedral bipyramidal crystals of $NH_4LuP_2O_7$ were obtained (2.120 g, 76% based on $NaLuF_4$). $NH_4LuP_2O_7$(366.949): calcd. N 3.81, P 16.88, Lu 47.68; found N 3.48, P 17.46, Lu 48.26. IR(KBr): υ_3(N–H) (3286 cm^{-1}), υ_1(N–H) (3035 cm^{-1}), $2\upsilon_4$(N–H) (2850 cm^{-1}), υ_4(N–H) (1434 cm^{-1}), $\upsilon_s(PO_3)$ (1203 cm^{-1}, 1110 cm^{-1}), υ_{as}(POP) (941 cm^{-1}), υ_s(POP) (748 cm^{-1}), $\delta(PO_2$ terminal bending) (624, 574, 470, 420 cm^{-1}).

X-ray Crystallographic Study: Monoclinic, space group $P2_1/c$ (No. 14), a = 7.6507(15) Å, b = 10.789(2) Å, c = 8.577(2) Å, β = 105.75(3)°, V = 681.4(2) $Å^3$, Z = 4, D = 3.577 g cm^{-3}, crystal dimensions [mm], 0.07 × 0.03 × 0.02; μ = 14.951 cm^{-1}, F(000) = 672, T = 293(2) K; 1588 unique reflections (R_{int} = 0.0874) and 101 parameters were used for the full-matrix, least-squares refinement of F^2 using the direct method in the program package SHELXL-97/2,[27] R_1 = 0.0690 [$I > 2\sigma(I)$], R_1 = 0.0842 (all data); wR_2 = 0.1211 [$I > 2\sigma(I)$], wR_2 = 0.1271 (all data). The Mechanism of Magnetic Interaction in Spin-Ladder Molecular Magnets: A First-Principles, Bottom-Up, Theoretical Study of the Magnetism in the Two-Legged Spin-Ladder Bis(2-amino-5-nitropyridinium) Tetrabromocuprate Monohydrate

Mercè Deumal,*[a] Giacomo Giorgi,[b] Michael A. Robb,[c] Mark M. Turnbull,[d] Christopher P. Landee,[e] and Juan J. Novoa*[a][‡]

Keywords: Copper / Density functional calculations / Magnetic properties / Spin-ladders / Structure-activity relationships

The magnetic properties of the isotropic ($J_{rail} \approx J_{rung}$), two-legged spin-ladder bis(2-amino-5-nitropyridinium) tetrabromocuprate monohydrate, $[(5NAP)_2CuBr_4 \cdot H_2O]$, have been studied using a first-principles, bottom-up approach, which allows computation of macroscopic magnetic properties (for instance, the magnetic susceptibility) of a crystal from only a knowledge of its crystal packing. Evaluation of the J_{AB} parameters, using the 163 K X-ray structure of $[(5NAP)_2CuBr_4 \cdot H_2O]$, indicates that the magnetic topology of this crystal is a two-legged antiferromagnetic spin-ladder, with values of J_{rail} and J_{rung} of $-22.2\ cm^{-1}$ and $-19.7\ cm^{-1}$, respectively. These values are very close to those that best fit the experimental magnetic susceptibility curve, which are $-13.59\ cm^{-1}$ and $-14.16\ cm^{-1}$, respectively. Very weak diagonal interactions within each ladder [$J(d3) = -0.9\ cm^{-1}$] and between nearby ladders [$J(d4) = -0.3\ cm^{-1}$] are also found. The computed magnetic susceptibility curve obtained using the two-legged spin-ladder properly reproduces the experimental magnetic curve (a quantitative agreement is obtained by applying a linear scaling factor of about 0.75 to the energies). The singlet–triplet spin-gap of this spin-ladder was computed to be 17 K, in close agreement with the experimental result (11 K). The change of the spin-gap/J_{rail} with the size (2xL) of the magnetic spin-ladder model space was found to converge towards 0.5, while that for a single-legged (1xL) spin-ladder converges towards zero, both in good agreement with the known trends for these systems.

Introduction

Current research in molecular magnetism (understood here as all forms of molecule-based magnetism) aims to rationally design and synthesize molecular materials with tailor-made magnetic properties that, in some cases, will coexist with other technological properties of interest, such as conductivity or superconductivity. As a result of the combined work of many experimental and theoretical groups, progress in the field during recent years has been spectacular.[1] A rational design of molecular magnets requires the existence of: (i) properly based magneto-structural correlations, which would allow us to correlate the nature of the magnetic interaction with the relative orientations of the radical units, (ii) a rigorous form for correlating the microscopic magnetic interactions with the macroscopic magnetic properties, (iii) a reliable methodology to predict the most likely polymorphs of a crystal, and (iv) methodologies to control the growth of the desired polymorph of a crystal. Progress along these lines has been achieved, however more is required before a rational design of molecular magnets can be achieved.

One form of improving our knowledge on magneto-structural correlations is by having a better (and properly based) knowledge of the mechanism of the magnetic interaction for materials that present properties of special interest. Such studies should be performed using a rigorous first-principles methodology that avoids approximations or over-simplifications and, thus, does not reach averaged results or misleading conclusions. These studies should allow us to generate a database of first-principles information regard-

ing the keys governing the magnetic interaction in molecular materials.

Spin-ladders[2] are one of these materials of special interest. They result from assembling a given number (n) of chains (L) and connecting them magnetically (nxL). In the literature, the connected chains are referred to as either the legs or rails of the spin-ladder. The connections between the chains are referred to as rungs. Within this field, antiferromagnetic spin-ladders have attracted much interest for two main reasons: (i) their connection with high-temperature superconductors, which are lightly-doped 2D antiferromagnets, and (ii) the special properties that are present depending on the number of legs (ladders with an even number of legs present a finite spin-gap between singlet ground state, E_0, and lowest energy triplet state, E_1, energies, while ladders with an odd number of legs behave as single chains and show no spin-gap; such results have been verified both theoretically and experimentally[2]).

Up to now, the study of the magnetic properties of spin-ladders has been based on finding a good empirical model to fit the experimental magnetic susceptibility, and then rationalizing the experimental properties using the available solutions for that model, usually found in the literature as a function of the J_{rung}/J_{rail} ratio.[2] In this work we will carry out for the first time, to the best of our knowledge, a first-principles, bottom-up, theoretical analysis of the mechanism of magnetic interactions in a two-legged antiferromagnetic spin-ladder. We have selected for study the bis(2-amino-5-nitropyridinium) tetrabromocuprate monohydrate spin-ladder [see Figure 1 (a)], herein identified as [$(5NAP)_2CuBr_4{\cdot}H_2O$], whose crystal structure has been determined by X-ray diffraction at 163 K. This is an antiferromagnetic, two-legged spin-ladder[3] with the added interest of having similar values for the experimental J_{rail} and J_{rung} values (–13.59 and –14.16 cm^{-1}, respectively, obtained from fitting the magnetic susceptibility as a function of temperature). The isotropic exchange ($J_{rail} \approx J_{rung}$) case is where the effect of the quantum fluctuations is most pronounced; the physics is the most complex and cannot be properly treated by perturbation theory. We will apply to [$(5NAP)_2CuBr_4{\cdot}H_2O$] our recently proposed, first-principles, bottom-up, theoretical procedure[4] to find the mechanism of the magnetic interaction within this system and properly justify the available experimental magnetic data.

Our first-principles, bottom-up, theoretical analysis of molecular magnetic materials[4] is a tool that connects the microscopic and macroscopic magnetic properties using a rigorous numerical procedure. It could thus become a practical tool for the rational design of molecular magnets, once good magneto-structural correlations are found[5] and a better control of the crystal packing prediction and growth is also achieved. The first-principles, bottom-up, theoretical analysis starts by computing the strength of all unique radical–radical magnetic interactions (the J_{AB} constants of the Heisenberg Hamiltonian). There are no prior assumptions of the relative importance of J_{AB}, so the procedure is fully nonbiased. The values of the J_{AB} magnetic interactions are then used to define the magnetic topology of the crystal,[6]

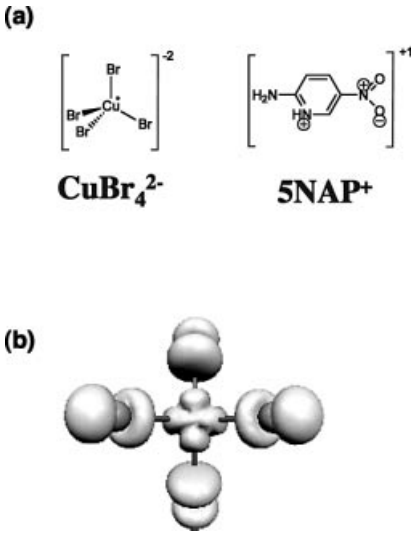

Figure 1. (a) Structure of the ions present in [$(5NAP)_2CuBr_4{\cdot}H_2O$]. (b) Spin distribution in the $CuBr_4^{2-}$ anion (isodensity surface of 0.002 au).

a property that allows the selection of a finite model space representative of the magnetic interactions in the full-sized crystal. The matrix representation of the Heisenberg Hamiltonian is then computed in the space of all the spin functions of the finite model space, and the energy of all possible magnetic states is calculated by diagonalization of that matrix. This allows the connection of the microscopic and macroscopic [e.g. magnetic susceptibility $\chi(T)$ and heat capacity $C_p(T)$] magnetic properties using the appropriate expressions from statistical mechanics.[4] The magnetic topology also allows identification of the magnetic pathways along which the magnetic interactions propagate over the whole crystal. We should mention that this first-principles, bottom-up, theoretical approach has already been successfully applied to the study of the magnetic properties of a variety of prototype systems.[4,7]

Results and Discussion

Here we will briefly describe the main steps and underlying physics behind the first principles, bottom-up procedure that we will then apply to the study of [$(5NAP)_2CuBr_4{\cdot}H_2O$]. For the interested reader, a detailed mathematical and physical account of the procedure and its basis is available in the literature.[4]

We have found that the following four steps allow us to carry out the proposed first principles, bottom-up procedure in a nonbiased form:

1) The first step consists of performing a detailed analysis of the crystal packing to identify all unique A-B radical–radical pairs whose interpair distance is smaller than a given threshold value (above which the magnetic interaction between radicals is expected to be negligible). This threshold is deliberately chosen to select more pairs than the first nearest neighbors (the usual candidates in the literature).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Such a selection procedure of radical–radical pairs is completely nonbiased.

2) Secondly, for all A-B radical–radical pairs selected in the previous step, we evaluate the value of the corresponding J_{AB} magnetic interactions using quantum chemical methods.

3) Using the computed J_{AB} parameter values, we then determine the magnetic topology of the crystal in terms of how non-negligible J_{AB} interactions propagate along the crystal axes. Two neighboring A-B radical sites are connected whenever its magnetic interaction presents a $|J_{AB}|$ value larger than a given threshold, which in previous calculations was estimated to be $|0.05|$ cm^{-1}. Then, we search for the smallest (finite-sized) minimal magnetic model space that describes the magnetic interactions of the whole crystal in a balanced way. The repetition of such a minimal model along the (*a*,*b*,*c*) crystallographic directions should regenerate the magnetic topology of the whole crystal. The radical centers constituting the minimal magnetic model define a spin-space that is used to compute the matrix representation of the corresponding Heisenberg Hamiltonian (see Computational Data section). Note that the only parameters required to compute that matrix representation of the Heisenberg Hamiltonian are the J_{AB} parameters computed in step 2.

4) In the fourth and final step, the Heisenberg Hamiltonian matrix is diagonalized to obtain the energy for all possible spin-states. These energies are then used to compute the magnetic susceptibility $\chi(T)$ and/or heat capacity $C_p(T)$ using the appropriate expressions obtained from a statistical mechanical treatment.[4]

The magnetic properties of $[X_2CuBr_4]$ compounds have been reported for a large variety of systems.[8] The packing of these crystals can be modified by changing the size and shape of the X^+ organic cation, which, in turn, induces modifications in the observed magnetic properties. Some of these $[X_2CuBr_4]$ crystals are low-dimensional 1D and 2D magnetic systems.

The structure of the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ ionic crystal was determined by X-ray diffraction at 163 K.[3] It crystallizes in the $P\bar{1}$ space group, with cell parameters a = 7.566, b = 9.359, c = 14.909 Å, α = 77.073°, β = 75.912°, γ = 76.393°, and Z = 2. The packing can be rationalized as a stack of double-decked planes [see Figure 2 (a) for a general view and Figure 2 (b) for a view of a single double-decked plane]. Each individual plane constituting the double-decked planes [Figure 2 (c)] presents a structure where the $5NAP^+$ cations surround the $CuBr_4^{2-}$ anions in a T-shaped disposition (this allows the formation of short C–H···O contacts between the cations, with distances within the 2.46–2.56 Å range, in addition to the C–H···Br contacts between anions and cations, in the 3.0–3.2 Å range). The disposition of the spin-containing units (the $CuBr_4^{2-}$ anions) in the crystal is shown in Figure 3. The topology of a two-legged ladder along the crystal *a*-axis, previously proposed to explain the magnetism of this crystal,[3] is clearly observed when looking at the shortest intermolecular Cu···Cu distances [6.34 and 7.57 Å; Figure 3 (b)].

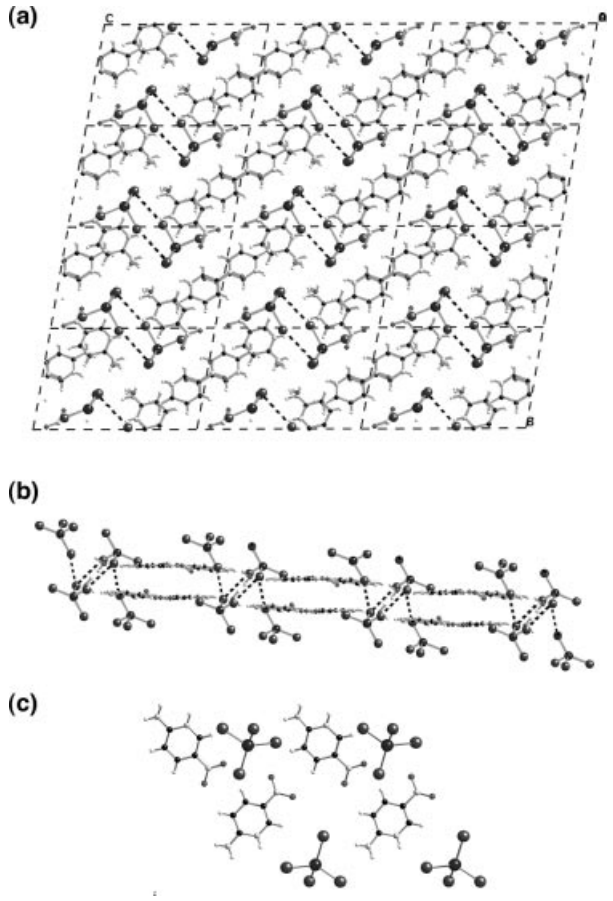

Figure 2. (a) *bc*-view of the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ ionic crystal, where double-decked planes run along the *a*-axis (Br···Br contacts in the 3.9–4.1 Å range are indicated). (b) View along the *a*-axis of a double-decked plane. (c) *bc*-view of one of the two planes forming the double-decked planes, where the $5NAP^+$ cations surround the $CuBr_4^{2-}$ anions in a T-shaped disposition.

The only available experimental data on the magnetic properties of this crystal are magnetic susceptibility measurements.[3] The experimental $\chi(T)$ data were fitted to a two-legged spin-ladder model based on two facts: (i) the magnetic pathways between $CuBr_4^{2-}$ radicals were expected to be through-space (by means of short Br···Br contacts), and (ii) the shortest Cu···Cu (and Br···Br) contacts showed the topology of a two-legged spin-ladder [see Figure 3 (b)]. The expression used for fitting the experimental $\chi(T)$ data for the spin-ladder was derived by extensive Monte Carlo calculations using a Heisenberg Hamiltonian that included both J_{rung} and J_{rail} at an arbitrary ratio of the two interactions.[3c] Johnston et al.[3c] have obtained two different expressions for the spin-ladder susceptibility, depending on the ratio J_{rung}/J_{rail}. Both expressions were applied to fit the experimental data without knowing in advance the ratio of the exchange parameters. The dominant rung expression ($|J_{rung}| > |J_{rail}|$) gave an excellent description of our data with the reported J_{rung} = –14.16 cm^{-1} and J_{rail} = –13.59 cm^{-1};[3a] the dominant rail expression ($|J_{rung}| < |J_{rail}|$) would not converge, yielding a susceptibility curve of entirely the wrong shape, for any combination of parameters.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

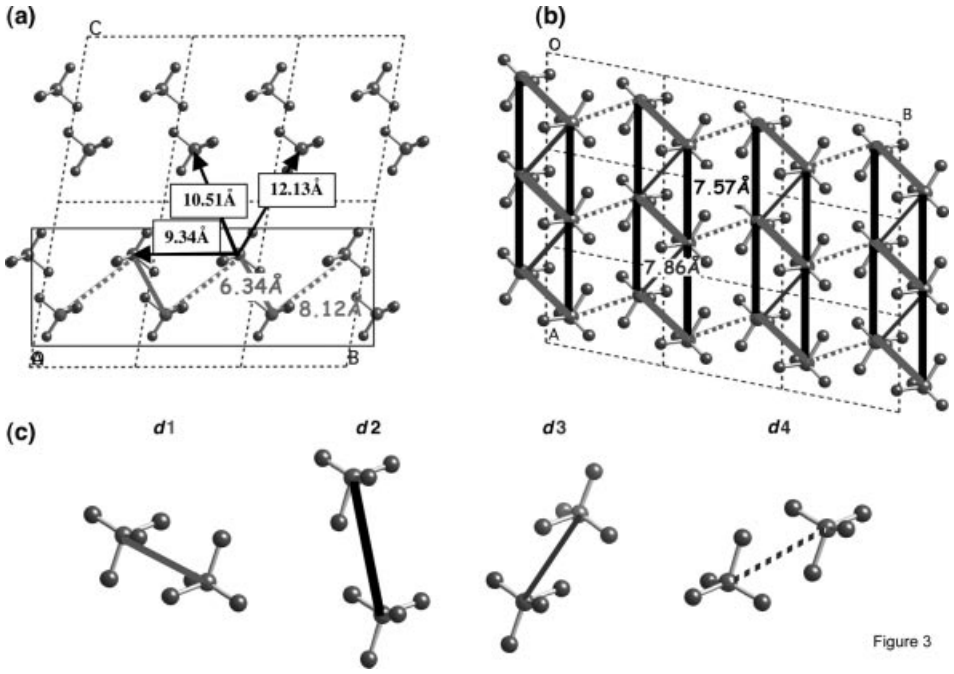

Figure 3. Views of the $CuBr_4^{2-}$ anion within the structure of the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ crystal along (a) the *bc* and (b) the *ab* crystallographic axes. Note that the Cu···Cu distances for all *di* radical pairs are given. The topology of a two-legged ladder is clearly envisaged. (c) Selected *di* radical pairs verifying a spin-carrier interradical distance cutoff of 8.5 Å (see Table 1 for details on main distances).

At this point, it is essential to stress that, although a ladder model was explicitly used to fit the experimental available $\chi(T)$ data by means of J_{rung} and J_{rail}, it could not get the origin of these *J*'s. As we will show shortly, we can contribute to explicitly get the origin of J_{rung} and J_{rail} by identifying the radical pairs that are responsible for such microscopic magnetic interactions.

Keeping in mind the packing described above for the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ crystal, we can now start the first-principles, bottom-up study of the magnetism of this crystal. On the basis of calculations that show that the $CuBr_4^{2-}{\cdots}CuBr_4^{2-}$ magnetic interaction becomes negligible at Cu···Cu distances above 8.5 Å, in step (1) we selected all $CuBr_4^{2-}{\cdots}CuBr_4^{2-}$ pairs with Cu···Cu distances shorter than 8.5 Å [see Figure 3 (a) and (b)]. This resulted in the four $CuBr_4^{2-}{\cdots}CuBr_4^{2-}$ pairs depicted in Figure 3 (c) whose Cu···Cu distances are 6.34, 7.57, 7.86, and 8.12 Å [the next three pairs of radicals have Cu···Cu pair distances of 9.34, 10.51, and 12.13 Å, see Figure 3 (a)]. Each radical–radical pair is identified as *d*1–*d*4, according to an increasing ordering of the Cu···Cu distance (Table 1 contains the values of the main intermolecular parameters).

We can now proceed to step (2) and compute the value of J_{AB} for all *di* radical–radical pairs selected in step (1). As mentioned above, these parameters are obtained by subtracting the total energy of the singlet and triplet states for each *di* radical–radical pair at its crystal geometry. One could think of doing such a calculation using an $(anion)_2$ cluster, but numerical tests (see Table 1 and discussion below) indicated that the $(anion)_2$ cluster does not properly reproduce the electronic structure of the radical anions within the crystal and that one has to include in the calculation at least the first-neighboring cations of the radical-anion pairs of interest. Therefore, the calculation must be done on an $(anion)_2(cation)_x$ cluster. As the crystal is neutral, we selected four cations to build a neutral $(anion)_2(cation)_4$ cluster (note that, in this case, the anions have a –2 charge and the cations have +1 charge). The inclusion of the cations also has an extra advantage as it automatically takes into account the possible participation of the diamagnetic cations in the through-space radical–radical magnetic interaction.

Table 1. Values of the Cu···Cu and shortest Br···Br distances for the four $CuBr_4^{2-}{\cdots}CuBr_4^{2-}$ radical–radical pairs of the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ crystal having a Cu···Cu distance smaller than 8.5 Å [see Supporting Information Figure S1 for the actual geometry of the *d*1–*d*4 $(anion)_2(cation)_4$ clusters used to compute *J*(*di*)]. Also included are the values of the *J*(*di*) parameters for each pair.

di	Cu···Cu [Å]	Br···Br [Å]	Model	*J*(*di*) [cm^{-1}]
*d*1	6.34	4.07(2) – 4.25 – 5.98(2)	$(anion)_2$	–43.54
			$(anion)_2(cation)_4$	–19.73
*d*2	7.57	3.93 – 6.00 – 6.32	$(anion)_2$	–28.38
			$(anion)_2(cation)_4$	–22.17
*d*3	7.86	4.68 – 4.94(2) – 7.26	$(anion)_2$	+0.18
			$(anion)_2(cation)_4$	–0.85
*d*4	8.12	5.24(2) – 6.13 – 6.62	$(anion)_2$	–0.79
			$(anion)_2(cation)_4$	–0.31

There is more than one form of selecting four cations for each di radical–radical pair [see Figure 3 (c) for *d*1–*d*4]. Therefore, we have to evaluate the effect that such selection has on the computed J_{AB} values [hereafter *J*(*di*)]. We did this evaluation for all four pairs, but we only report the results for *d*1, as the trends are similar in all cases. The test was done using the three $(anion)_2(cation)_4$ clusters shown in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

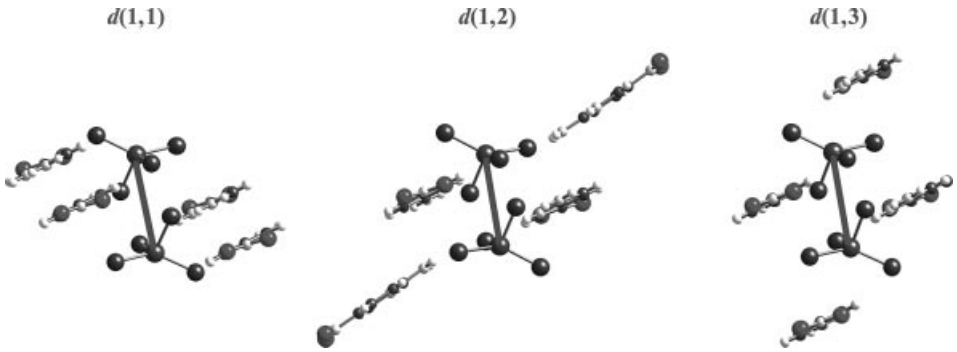

Figure 4. Geometry of the various $(anion)_2(cation)_4$ clusters used to evaluate the effect of the selected cations on the computed $J(d1)$ value.

Figure 4, identified as $d(1,1)$, $d(1,2)$, and $d(1,3)$. The results collected in Table 2 show a change smaller than 3 cm^{-1} in the computed $J(d1)$ value. We also tested the effect that the Madelung field[9] generated by the rest of the crystal has on the computed $J(d1)$ value. For the specific case of the $d(1,2)$ cluster (see Figure 4), the computed $J(d1)$ value accounting for the Madelung field is –19.84 cm^{-1}, while without this field it is –19.73 cm^{-1}. Due to the small impact of the inclusion of the Madelung field, we did not evaluate its effect on the other di radical–radical pairs. Finally, we can discuss the origin of the difference between the $J(d1)$ results obtained using either an $(anion)_2(cation)_4$ model [e.g. the $d(1,2)$ cluster] or an only an $(anion)_2$ cluster (J_{AB} values of –19.73 and –43.54 cm^{-1}, respectively). To test if this difference is due to the lack of electrostatic confinement induced by the cations in the anion wavefunction, we did further calculations to mimic such electrostatic effects by using point atomic charges (fitted to reproduce the electrostatic potential of the nuclei of the isolated cations) instead of the atoms themselves. The computed J_{AB} value was –26.60 cm^{-1}, which differs by 6.87 cm^{-1}, in absolute terms, from the computed J_{AB} using the $d(1,2)$ $(anion)_2(cation)_4$ cluster. Such small difference can be attributed to two factors: (a) the use of point charges does not reproduce the Pauli repulsion (due to the Pauli Exclusion Principle) induced by the electrons of the cations on the electrons of the anions, and (b) the presence of a cation-mediated through-space interaction, where the cation orbitals are used to magnetically connect the anions (a sort of superexchange through-space mechanism). It is difficult to evaluate the relative importance of each factor accurately, but in any case our results indicate that it is safer to use $(anion)_2(cation)_4$ clusters to include both a proper description of the anions' environment and any possible cation-mediated exchange.

Table 2. Dependence of the computed $J(d1)$ value on the selected cations included in the $(anion)_2(cation)_4$ cluster. The values are for the $d(1,1)$, $d(1,2)$, and $d(1,3)$ $(anion)_2(cation)_4$ clusters shown in Figure 4.

d(1,*j*)	$J(d1,j)$ [cm^{-1}]	Model
$d(1,1)$	–19.05	$(anion)_2(cation)_4$
$d(1,2)$	–19.73	$(anion)_2(cation)_4$
	–19.84	$(anion)_2cation_4$ + Madelung (ref.[16])
$d(1,3)$	–16.18	$(anion)_2(cation)_4$

Table 1 shows the all computed $J(di)$ values using appropriate $(anion)_2(cation)_4$ clusters. All four $J(di)$ magnetic interactions are antiferromagnetic, with $J(d1)$ and $J(d2)$ almost identical and much larger than the values of $J(d3)$ and $J(d4)$. These results show that there is no direct correspondence between the Cu···Cu and Br···Br distances and the size of the $J(di)$ parameter. The value and connectivity of the $J(di)$ magnetic interactions define the magnetic topology of the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ crystal (see Figure 5). The main magnetic motif consists of two-legged spin-ladders along the crystallographic *a*-axis, where $J_{rail} = J(d2) =$ –22.17 cm^{-1} and $J_{rung} = J(d1) =$ –19.73 cm^{-1}. Within any individual two-legged spin-ladder there is a small diagonal magnetic interaction, $J(d3) =$ –0.85 cm^{-1}, and adjacent two-legged spin-ladders interact very weakly along the *b*-axis through $J(d4) =$ –0.31 cm^{-1}. Therefore, the magnetic topology of $[(5NAP)_2CuBr_4{\cdot}H_2O]$ seems to be better described as consisting of isolated two-legged spin-ladders (a 1D topology), but could also be described as a set of noninteracting *ab*-planes, each formed by weakly interacting, two-legged spin-ladder motifs (a 2D topology). Below, we will show the results of numerical simulations that indicate that the 1D topology gives a proper description of the magnetism for $[(5NAP)_2CuBr_4{\cdot}H_2O]$.

To perform steps (3) and (4) of the bottom-up procedure, we have to select a minimal magnetic model space. For an isolated two-legged spin-ladder, based on previous work,[7] we expect that a four-sites (4s) model [Figure 6 (a)] should be an appropriate minimal magnetic model space. For $[(5NAP)_2CuBr_4{\cdot}H_2O]$, we will validate this model by studying the convergence of the macroscopic magnetic susceptibility $\chi(T)$ values when the minimal 4s model is replicated along the three crystallographic axes. Thus, the 4s model is propagated along (i) the *a*-axis, obtaining the 6s, 8s, ..., up to 14s models [Figure 6 (a)], and (ii) the *b*-axis by selecting the 4s4s and 4s4s4s models [Figure 6 (b)]. No replication is required along the *c*-axis, as there are no J_{AB} magnetic interactions along this direction, therefore the propagated model gives exactly the same results as the 4s model. As a further test, we also propagated the 4s4s model along the *a*-axis to generate the 6s6s and 8s8s models. The matrix

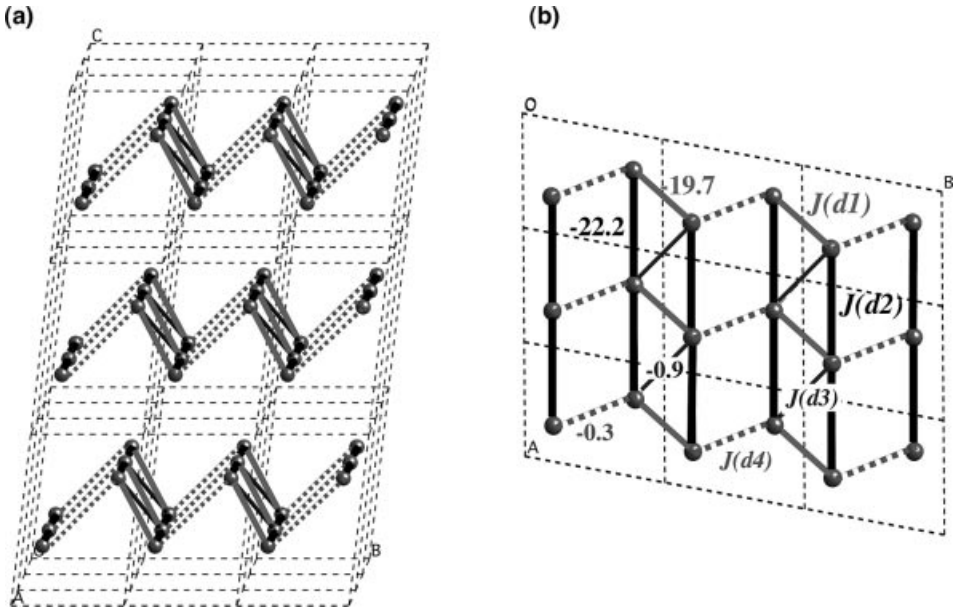

Figure 5. Magnetic topology of the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ crystal: (a) magnetically noninteracting *ab*-layers; (b) magnification of any given *ab*-layer, which consists of two-legged spin-ladder motifs with $J(d2) = -22.2\ cm^{-1}$ as rail and $J(d1) = -19.7\ cm^{-1}$ as rung magnetic interactions. Within any individual two-legged spin-ladder there is a small diagonal magnetic interaction, $J(d3) = -0.9\ cm^{-1}$, and adjacent two-legged spin-ladders interact very weakly along the *b*-axis through $J(d4) = -0.3\ cm^{-1}$.

representation of the Heisenberg Hamiltonian was built[11] and diagonalized for all these model spaces. The resulting energy levels and corresponding spin quantum numbers were then used to calculate the magnetic susceptibility $\chi(T)$ (see Figure 6).

The simulated $\chi(T)$ data shown in Figure 6 allow us to conclude: (i) all the $\chi(T)$ curves show a shape similar to the experimental curve; (ii) there is a good convergence on $\chi(T)$ as the size of the model increases by propagating the minimal 4s model along both the *a*-axis [Figure 6 (a)], and the

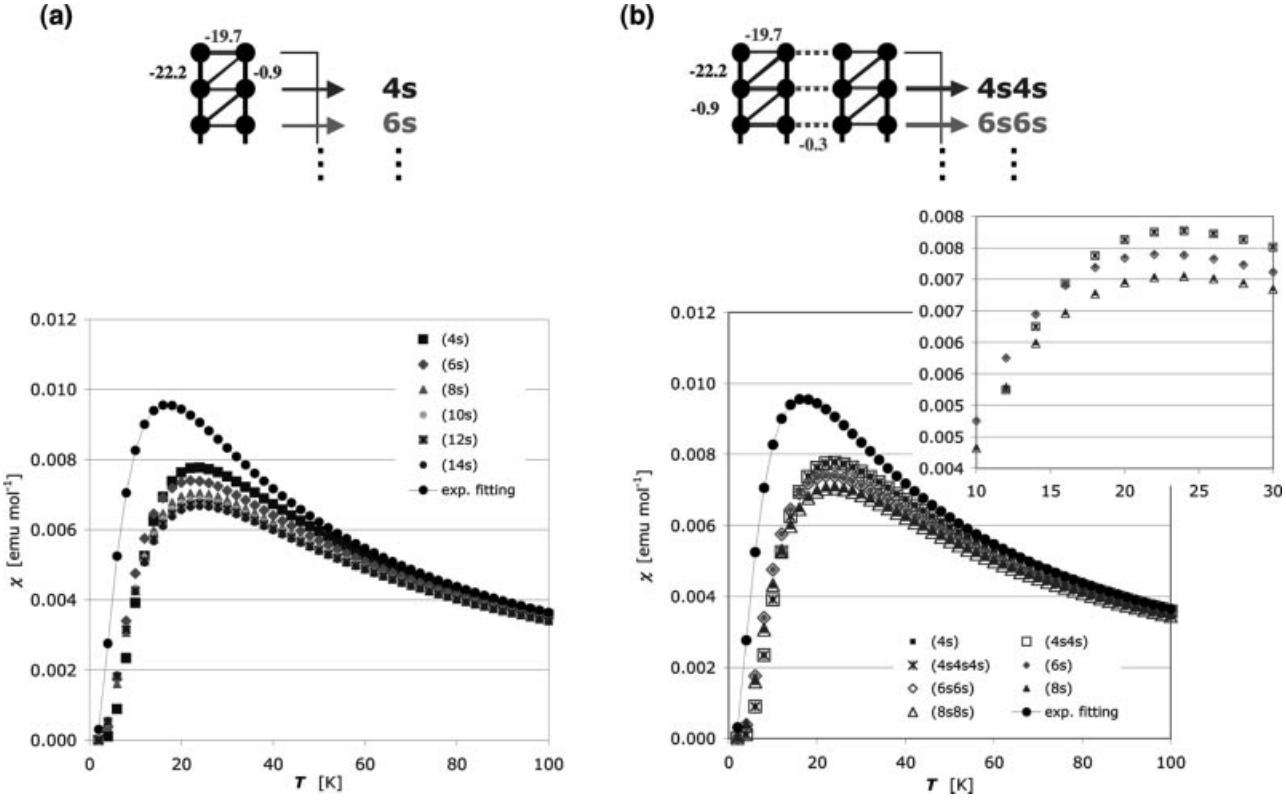

Figure 6. Magnetic susceptibility $\chi(T)$ numerically calculated values extending the minimal 4s magnetic model along the (a) *a*-axis (intra spin-ladder 6s–14s models) and (b) *b*-axis (inter spin-ladder 4s4s, 4s4s4s, 6s6s and 8s8s models).

b-axis [Figure 6 (b)]; and (iii) the $\chi(T)$ values obtained with the inter-ladder *nsn*s models reproduce the $\chi(T)$ values obtained using the intra-ladder *ns* models perfectly [Figure 6 (b)], thus suggesting that there is no need to account for $J(d4)$ in the minimal magnetic model space. The latter conclusion is the final indication that our magnetic topology consists of basically noninteracting spin-ladders, i.e. it is a 1D topology.

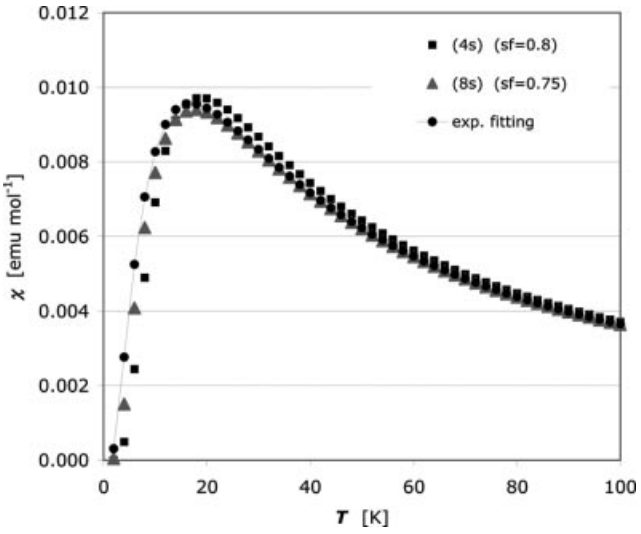

Figure 7. Required scaling factor (sf) to quantitatively reproduce the experimental magnetic susceptibility $\chi(T)$ data using both a 4s and an 8s model.

Although in all cases the shape of the computed magnetic susceptibility curves closely resembles the experimental curve, the agreement is not perfect. Previous studies[7] have suggested that such a difference can be attributed to various factors: (i) the use of high-temperature crystal structures, (ii) errors due to the use of a nonexact DFT functional and the broken-symmetry approach, and (iii) the use of a cluster approximation to compute the values of the $J(di)$ parameters, which neglects possible collective effects. In the case of $[(5NAP)_2CuBr_4{\cdot}H_2O]$, the crystal structure used throughout this study was determined at 163 K, which is a low enough temperature as to expect only small distortions due to temperature factors. We have also found[7] that it is possible to account for the difference between computed and experimental magnetic susceptibility curves by applying a constant linear scaling factor to all energy levels. For $[(5NAP)_2CuBr_4{\cdot}H_2O]$, when we apply a factor of 0.8 to all energy levels of the 4s minimal model we can quantitatively reproduce the experimental $\chi(T)$ curve (Figure 7). However, an even better agreement is found by applying a linear scaling factor of 0.75 to the 8s model (Figure 7).

A final test of the quality of the first-principles, bottom-up procedure in describing the properties of two-legged spin-ladder systems consists of computing the value of the singlet–triplet spin-gap (experimental data[3,12] indicate that

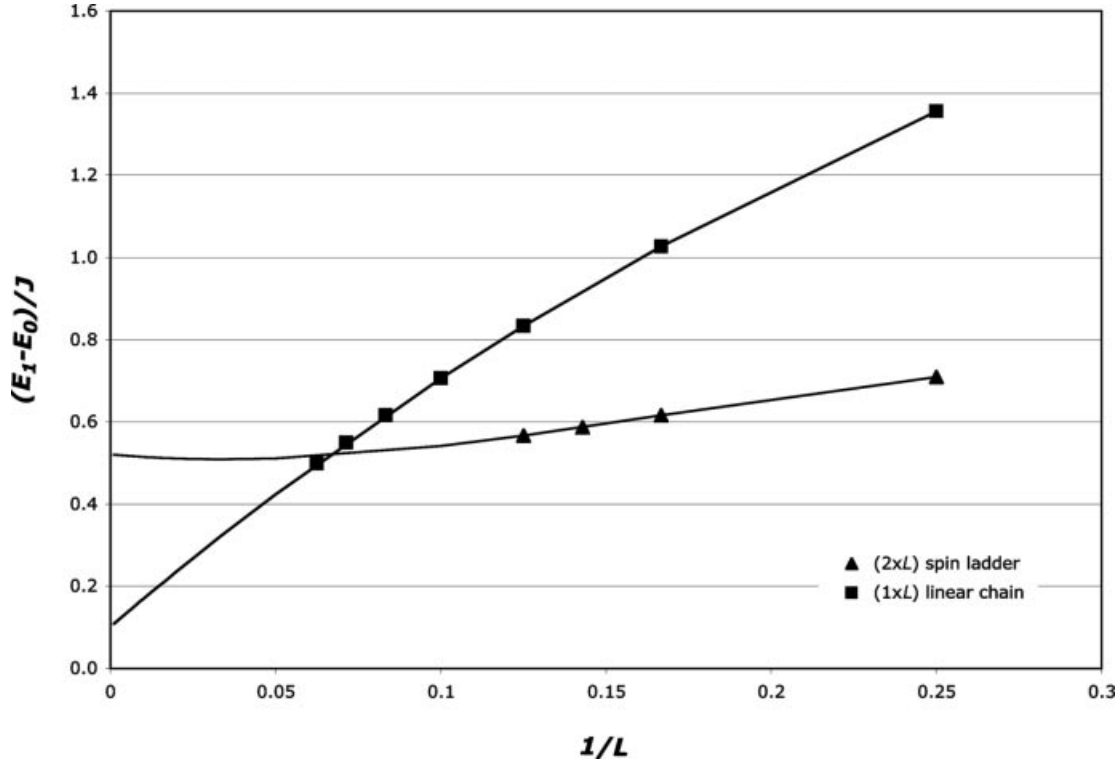

Figure 8. Values of $\Delta = (E_1 - E_0)/J$ as a function of the length of both a two-legged (2xL, with L = 4–8) and a single-legged (1xL, with L = 4–16) spin-ladder. In both cases the Δ values vary as $1/L$. In the limiting case of an infinite, two-legged spin-ladder the extrapolated Δ value is 0.5211. For an antiferromagnetic single-legged spin-ladder (i.e. a linear chain), the extrapolated result of Δ for the infinite chain (i.e. $1/L = 0$) is 0.1015, which is slightly larger than the expected zero value.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

it should be 11 K) and its changes with the size of the model space. For a two-legged spin-ladder, previous studies indicate that there is a finite spin-gap[2] whose value decreases as the size of the model space increases.[2] Using the 4s magnetic model space with a linear scaling factor of 0.8, the computed value of the singlet–triplet spin gap ($E_1 - E_0$) is 24.24 K, about twice the experimental value. However, it decreases to 17.0 K when using the 8s model with a linear scaling factor of 0.75. Furthermore, as shown in Figure 8, the value of the expression $\Delta = (E_1 - E_0)/J$ decreases with the ladder length (2xL, with L = 4–8) as 1/L, as reported in the literature.[2] Extrapolating our fitted results to an infinite two-legged spin-ladder we found a Δ value of 0.5211 (see Figure 8), which agrees well with the best estimates (0.504) of this property.[2] As a further test, we also computed the value of $\Delta = (E_1 - E_0)/J$ for an antiferromagnetic single-legged spin-ladder (that is, a linear chain) for lengths L = 4–16. For an infinite linear chain, Δ is expected to be zero.[2] The results, also shown in Figure 8, follow a similar trend with respect to 1/L to those reported in the literature:[2] as L increases, the value of Δ approaches zero. However, our extrapolated result of Δ for the infinite chain (i.e., 1/L = 0) is 0.1015, which is slightly larger than zero. This small deviation is due to the fact that it may be necessary to look at a chain as long as 100 spins to actually see the gap vanish,[2] and this is obviously out of the reach of our current code. However, we have successfully described the main trends known for the spin-gap of the two main classes of spin-ladders. Consequently, we can conclude that our first-principles, bottom-up procedure properly describes the experimentally known properties of spin-ladder magnets.

Conclusions

Using the X-ray crystal structure determined at 163 K, we have computed the magnetic interactions in the [$(5NAP)_2CuBr_4 \cdot H_2O$] crystal. There are two dominant antiferromagnetic interactions, whose magnetic topology is found to consist of noninteracting, two-legged spin-ladders, with similar values for the rail $J(d2)$ (–22.2 cm^{-1}) and rung $J(d1)$ (–19.7 cm^{-1}) magnetic interactions. It is essential to stress that our contribution has been to explicitly get the origin of J_{rung} and J_{rail} by identifying the $(anion)_2(cation)_4$ clusters that are responsible for such microscopic magnetic interactions. The magnetic topology is in agreement with the experimentally proposed magnetic pathways, which were based only on the crystal packing of the $CuBr_4^{2-}$ radical-anions within the [$(5NAP)_2CuBr_4 \cdot H_2O$] crystal. However, we believe that the exchange interaction between Cu^{2+} ions does not only result from Br···Br direct contacts, but also from $5NAP^+ \cdots CuBr_4^{2-}$ contacts, since the organic ligands play the role of spin couplers.

The simulated $\chi(T)$ data reproduce the shape of the experimental $\chi(T)$ curve, although a linear scaling factor of about 0.75 is required to quantitatively reproduce the experimental values. Such a factor compensates for the use of a high-temperature (163 K) X-ray crystal structure and errors associated with the quantum chemical methods employed to compute the $J(di)$ parameters.

We have computed the singlet–triplet spin-gap ($E_1 - E_0$) for [$(5NAP)_2CuBr_4 \cdot H_2O$] two-legged spin-ladder and found it to be in the range of the experimental results (11 K). Furthermore, the values of $\Delta = (E_1 - E_0)/J$ show the same dependence on 1/L (L being the length of the spin-ladder) as reported in the literature: for a two-legged spin-ladder Δ decreases towards 0.5211 as 1/L tends to zero, while for a single-legged spin-ladder Δ approaches a value near zero (we believe that the small differences with the tabulated results[2] are due to the fact that it may be necessary to look at a chain as long as 100 spins to actually see the gap vanish, which is out of the reach of our current code).

Computational Data

The basic idea behind our first principles, bottom-up procedure[4] is to find a finite model space that properly describes the properties of the magnetic topology of the crystal. Within this space we then compute the matrix representation of the Heisenberg Hamiltonian (1)

$$\hat{H} = -\sum_{A,B}^{N} J_{AB}(2\hat{S}_A \cdot \hat{S}_B + \tfrac{1}{2}\hat{I}_{AB}) \quad (1)$$

where $\hat{S}_A$ is the spin operator associated with radical A, and $\hat{I}_{AB}$ the identity operator. Note that the only variables in this Hamiltonian are the microscopic J_{AB} parameters, which define the nature and size of the radical–radical magnetic interactions present in our model space. These microscopic J_{AB} parameters depend on the relative orientation of the radicals A and B, and can be computed using the appropriate quantum chemical methods. Once the matrix representation of the Heisenberg Hamiltonian is known, we can compute the energy spectrum of all spin states, and then apply the corresponding statistical mechanics expressions to compute the macroscopic magnetic properties of interest [$\chi(T)$, $C_p(T)$, ...]. Note that the individual energy values obtained by diagonalizing expression (1) are equivalent to those obtained using the more familiar $\hat{H} = -2\Sigma J_{AB}\hat{S}_A \cdot \hat{S}_B$ Heisenberg Hamiltonian, except for a shift in all energy values. Therefore, the corresponding energy differences will be the same. As the statistical mechanics expressions used to compute $\chi(T)$ and $C_p(T)$ use energy differences, both Hamiltonians give the same macroscopic results.

The entire procedure depends only on the microscopic radical–radical magnetic interactions (J_{AB}). The values of the J_{AB} parameters are also used to define the magnetic topology in terms of the connectivity that the J_{AB} parameters establish between the radicals that form the crystal. The magnetic topology provides a very useful pictorial representation of the magnetism within the crystal.

The minimal magnetic model space must be small enough to keep the Heisenberg Hamiltonian matrix at a reasonable size (in our current implementation $N \leq 16$ spin radical sites), but it must also be large enough to contain all significant magnetic pathways detected within the crystal. From our experience, the most important step in the above procedure is the selection of a proper minimal magnetic model space. In order to legitimate the selected minimal magnetic model space, we check the convergence of macroscopic properties [e.g. $\chi(T)$] as the model space is replicated along the three crystallographic directions by applying a regionally reduced density matrix approach: if the minimal magnetic model space is properly

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chosen, the computed $\chi(T)$ values using such extended models should rapidly converge to the values obtained with the non-replicated minimal model space. All sets of results should also numerically reproduce the experimental $\chi(T)$ data.

As indicated above, the values of the microscopic J_{AB} pair interactions are computed using quantum chemical methods. In the $[(5NAP)_2CuBr_4{\cdot}H_2O]$ crystal, the $CuBr_4^{2-}$ anions are the only spin-carrier units; the $5NAP^+$ cations are closed-shell molecules with no spin whose primary function in the crystal is to act as spacers of the $CuBr_4^{2-}$ spin-carrier units. The ground electronic state of $CuBr_4^{2-}$ anions is a doublet, with the spin partially distributed over the bromine and Cu^{II} atoms (Figure 1, b). As the radicals are doublets, the value of J_{AB} is obtained by subtracting the energy of the most stable open-shell singlet (E^S_{BS}) and triplet (E^T) states, both computed at the geometry of the radical–radical pair found in the crystal, according to Equation (2).

$$J_{AB} = E^S_{BS} - E^T \quad (2)$$

The broken-symmetry approximation[13,14] is used to compute the energy of the open-shell singlet state. The E^S_{BS} and E^T energy values have been computed using the UB3LYP functional[15] (a 10^{-8} convergence criterion on the total energy and 10^{-10} on the integrals was used to ensure enough accuracy in the computation of the J_{AB} parameters). All DFT calculations performed in this study were carried out using the Gaussian-03 package.[16] We used in our calculations an Ahlrichs all-electron basis set[17] for Cu, and a 6-31+G basis set[18] for C, H, N, and O. For Br^-, we used the 6-31+G(d) basis set.[19]

Supporting Information: Table S1 shows the charges computed according to a Merz–Singht–Kollman scheme and employed to account for the Madelung field created by the nearest-neighboring $CuBr_4^{2-}$ anions and $5NAP^+$ cations to the *d*(1,*2*) $(anion)_2(cation)_4$ cluster. Figure S1 shows the final geometry of *d*1–*d4* of the $(anion)_2(cation)_4$ clusters used to compute *J*(*di*).

[11] The Heisenberg Hamiltonian (1) is used for diagonalization purposes in order to obtain all the energy eigenvalues required in the statistical mechanics expression of $\chi(T)$. For a numerical calculation of the energy eigenvalues, we use *J*(*di*)/2 values (–11.085, –9.865, –0.425, and –0.155 cm^{-1}) rather than *J*(*di*) values (–22.17, –19.73, –0.85, and –0.31 cm^{-1}) in Hamiltonian (1) in order to be consistent with the definition of *J*(*di*).

[12] The 11 K value for the singlet–triplet gap was determined experimentally using the equation: $(E_1 - E_0) = g{\cdot}\mu_B{\cdot}H_{C1}$, where *g* is the gyromagnetic factor ($g = 2.15$, for a polycrystalline sample), μ_B is the Bohr magneton, and H_{C1} is the critical field. The lower critical field was determined to be 7.6 T from the magnetization data collected at 0.65 K.

Keywords: Nickel / Palladium / Platinum / Terdentate hybrid ligands / Heck reaction

Ni^{II}, Pd^{II} and Pt^{II} cationic complexes of the general formula [MCl(PNN)]PF_6, where PNN is the terdentate ligand *N*-[2-(diphenylphosphanyl)benzylidene][2-(2-pyridyl)ethyl]amine, have been synthesised and fully characterised in solution by NMR spectroscopy. The diamagnetic Ni^{II} complex **1** shows fluxionality, which can be attributed to a conformational rearrangement of the two six-membered chelate rings. On the contrary, the Pd^{II} **2** and Pt^{II} **3** derivatives are stereochemically rigid on the NMR timescale. The crystal structures of **1** and **2** are reported, which show a planar geometry for both complexes. Complex **2** has been investigated as a precatalyst in the Heck coupling between styrene and bromobenzene. Interestingly, the nature of the solvent has a critical role in determining the yield of the reaction product.

Introduction

In recent years, transition-metal complexes bearing multidentate ligands that contain significantly different types of hard (N- or O-) and soft (P-) donor functions have been extensively studied because of their potential application in homogeneous catalysis.[1] These ligands possess weakly coordinating groups that can be reversibly released during the catalytic cycle providing unsaturation at the metal centre. Thus, the less strongly bound moiety of this type of ligand, called hemilabile, can be seen as an intramolecular solvent molecule that is capable of temporarily holding a coordination site on the metal. There are several hemilabile ligands containing a substitutionally inert phosphorus function and a labile oxygen or nitrogen donor. Among the various kinds of P,N hybrid ligands, those showing pyridyl or imine arms have been widely used to prepare complexes of different transition metals,[1b,1c,1e,1f] some of which have been successfully employed in catalytic reactions. Thus, for example, Ni^{II} complexes have been tested in olefin polymerisation, while Pd^{II} complexes have been found to be very active in asymmetric allylic alkylation and cross-coupling reactions. Also, our group has worked in this field with particular interest in complexes with phosphane–pyridyl bidentate ligands.[2]

By contrast, few terdentate P,N,N-type ligands showing mixed functionalities such as phosphane-, imine- and pyridyl-donating groups have been reported so far.[3] The presence of two different sp^2 N-donors affects the way the ligand binds to the metal, with effects on both reactivity and catalytic activity of the resulting complexes. Effectively, some of these complexes have shown valuable efficiency in different catalysed reactions, such as enantioselective conjugate addition of diethylzinc to enones,[3e] olefin hydrogenation,[3f] asymmetric allylic alkylation[3h] and asymmetric olefin cyclopropanation.[3j]

Vrieze and co-workers have described the potentially terdentate P,N,N ligand *N*-[2-(diphenylphosphanyl)benzylidene][2-(2-pyridyl)ethyl]amine[4] (PNN) (Figure 1), which shows the P-sp^3, N-sp^2 (imine), N-sp^2 (pyridyl) donors sequence. Several different transition-metal complexes bearing PNN have been reported, in particular with group 10 metals,[4] the ligand acting as both terdentate[4–6] or bidentate with a dangling pyridyl arm.[4–6] Among these species, the Pd^{II} η^1-allyl cationic complex has shown good catalytic activity in allylic alkylation[4b] and 1,3-butadiene telomerisation with methanol.[7]

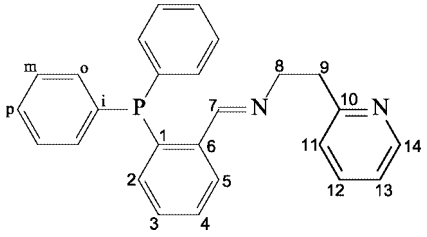

Figure 1. The ligand PNN along with the numbering scheme.

For our part, we decided to investigate the coordination chemistry of PNN towards group 10 metal halides, as the

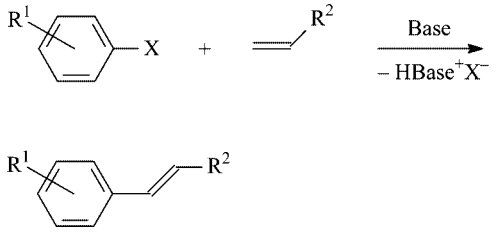
first step of a more detailed study on the catalytic properties of PNN-containing late transition-metal complexes. In this paper we present the preparation and characterisation of the cationic complexes [MCl(PNN)]PF_6 [M = Ni (**1**), Pd (**2**), Pt (**3**)], also describing preliminary results on the catalytic activity of **2** in the Heck C–C coupling[8] using aryl bromides as starting material (Scheme 1). The choice for this reaction was stimulated by the fact that PNN is able to stabilise Pd^0 species without the need of additional stabilising ligands[4b] and that the couple Pd^0/Pd^{II} is thought to be involved in the Pd-catalysed Heck reaction.[8]



Scheme 1.

Complexes **1**–**3** have been fully characterised by spectroscopic and analytical methods. In addition, as the NMR investigation has evidenced that, unlike complexes **2** and **3**, the Ni^{II} derivative **1** is fluxional in the whole temperature range 293–183 K, the crystal structure determination of **1** and **2** has been performed to establish whether the different behaviour in solution of the two species could be related to structural modifications due to the nature of the metal ion.

Results and Discussion

The compound PNN was prepared as described in the literature[4b] and obtained as a cream-coloured powder after double recrystallisation from *n*-hexane. In the original publication,[4b] besides ^{31}P and ^{15}N NMR spectroscopic data, only selected ^1H and ^{13}C values were reported for PNN. Also two later papers dealt with selected ^1H NMR values only.[5,6] Therefore, we decided by means of $^1H\{^{31}P\}$, ^1H–^1H COSY, ^1H–^{13}C HETCOR, ^{13}C DEPT and ^{13}C PENDANT experiments to assess all ^1H (confirmed by computer simulation) and ^{13}C parameters. The ^1H and ^{13}C NMR spectroscopic data have been collected in Table 1 and Table 2, respectively, to allow a direct comparison with the data of complexes **1**–**3**. The numbering scheme of carbon and hydrogen atoms of PNN is reported in Figure 1.

Solution Structure of Complexes 1–3

Complexes [PdCl(PNN)]PF_6 (**2**) and [PtCl(PNN)]PF_6 (**3**) have been prepared by the room-temperature reaction between the appropriate [$MCl_2(RCN)_2$] precursor (M = Pd, R = CH_3; M = Pt, R = C_6H_5) and the ligand PNN in a 1:1 molar ratio in CH_2Cl_2 solution, followed by addition of an excess of NH_4PF_6 in propan-2-ol and vacuum elimination of CH_2Cl_2. The complexes were obtained pure as pale yellow crystals by recrystallisation from CH_2Cl_2/propan-2-ol. For both **2** and **3**, the best fit of the elemental analysis data is obtained for the formula [MCl(PNN)]$PF_6 \cdot 0.5CH_2Cl_2$. The presence of dichloromethane within the crystals has

been confirmed by ^{1}H NMR analysis and crystal structure determination of complex **2** (see below).

The ^{1}H NMR spectra of **2** and **3**, which are very similar, indicate that the structures of the cations are static on the NMR timescale. Meaningful shifts of some resonances can be observed upon coordination of the ligand to the metal centre (Table 1). For example, the signal of the H^9 proton, which is at δ = 2.98 in the free ligand, is shifted to lower fields in complexes **2** (δ = 3.47) and **3** (δ = 3.50), while that of the H^8 proton does not show an appreciable shift. Furthermore, both methylene signals of the –CH_2CH_2– chain appear as unsymmetric multiplets whose lines have about the same intensity. This spectral feature is diagnostic of the presence of diastereotopic pairs of protons within each methylene group, arising from the rigidity of the chelate N,N ring. The H^7 resonance, which is at δ = 8.85 in the free ligand, is shifted to higher fields in complexes **2** (δ = 8.51) and **3** (δ = 8.75). On the contrary, the H^{14} resonance, which is at δ = 8.48 in the free ligand, is markedly shifted to lower fields (**1**, δ = 8.83; **2**, δ = 8.81 ppm).

In the free ligand, H^2, H^3, H^5 and H^7 protons are coupled to the ^{31}P nucleus. In complexes **2** and **3** the ^{1}H–^{31}P coupling constants are not lost but considerably modified. In particular, the $^4J(^1H–^{31}P)$ value on H^7, which is 4.7 Hz in free PNN, is reduced to 1.7 Hz in **2** and 0.5 Hz in **3**. This observation contrasts with the lack of coupling between H^7 and ^{31}P nuclei found in previously reported Pd^{II} and Pt^{II} complexes bearing PNN.[4b] It is worth noting that also H^{14} shows a coupling with phosphorus both in **2** [$^4J(^1H–^{31}P)$ = 3.3 Hz] and **3** [$^4J(^1H–^{31}P)$ = 2.9 Hz]. This feature again confirms that the pyridyne nitrogen of the ligand is coordinated to the metal centre.

Interestingly, the H^7, H^8 and H^{14} resonances in the spectrum of **3** show the presence of satellites due to ^{1}H–^{195}Pt coupling. While H^8 and H^{14} show similar low ^3J values (28 and 26 Hz, respectively), the coupling constant on H^7 is 115 Hz. As can be seen in Figure 2, these hydrogen atoms are the closest to the metal centre, all others being separated from it by four or more bonds. The ^{1}H–^{195}Pt coupling value found for H^7 is much higher than that reported by Puddephatt and co-workers for the imine proton in other Pt^{II} four-coordinate complexes.[9]

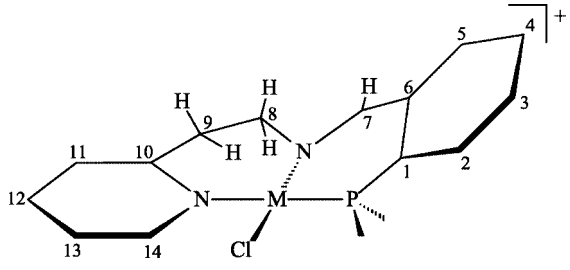

Figure 2. Structure of the cationic complexes (the two phenyl rings bound to phosphorus have been omitted for clarity).

The orange cationic diamagnetic complex [NiCl(PNN)]-PF_6 (**1**) was prepared by reacting equimolar amounts of $NiCl_2·6H_2O$ and PNN in methanol, followed by addition of an excess of NH_4PF_6 dissolved in propan-2-ol and concentration of the solution. The ^{31}P{^{1}H} NMR spectrum of **1** recorded at 293 K in CD_2Cl_2 solution shows a broad singlet at δ = 22.4 ($\Delta\nu_{1/2} \approx$ 340 Hz) along with the regular sharp septet at δ = –143.9 [$^1J(^{19}F–^{31}P)$ = 711 Hz], which is typical of the PF_6^- ion. On lowering the temperature, the width of the broad signal progressively sharpens and at 183 K, the lowest available temperature, $\Delta\nu_{1/2}$ is reduced to 4 Hz (δ = 24.7). The process is completely reversible and also the room-temperature ^{1}H and ^{13}C{^{1}H} spectra of complex **1** exhibit broad signals and no ^{31}P–^{13}C coupling constant is shown.

We have examined the possibility that the broadening of the signals may arise from the presence of a paramagnetic Ni^{II} species. In this regard, it should be noted that complexes [NiX_2(P-N)], where P-N is a phosphane-pyridyl[10] or a phosphane-imine[10d,11] ligand, are tetrahedral, with magnetic moments in the range 1.82–2.62 μ_B. Furthermore, for a Ni^{II} derivative with a PNNX donor set the possibility for a temperature-dependent equilibrium between diamagnetic square-planar and high-spin tetrahedral structures should be considered.[12] However, determinations of the magnetic moment in dichloromethane (183–293 K) and 1,2-dichloroethane (293–343 K) solutions show that complex **1** is diamagnetic in agreement with a square-planar structure. This finding fits well with the observation that there is no colour change of the solutions in the whole temperature range 183–343 K. Another Ni^{II} complex with a X(P–N–N) donor set has been found to be diamagnetic.[13]

In the ^{13}C{^{1}H} spectrum of **1** recorded at 183 K almost all signals are rather sharp and ^{31}P–^{13}C couplings are shown by C^7 and several carbon atoms of both phenyl and phenylene rings. Unfortunately, the slow-exchange limit spectrum is not reached and the resonances of C^8 and C^9 appear as still broad signals. However, the comparison between the ^{13}C{^{1}H} spectra of **1** (at 183 K) and **2** (at 293 K) allows us to conclude that, as chemical shifts and coupling constants do not exhibit remarkable differences (see Table 2), the "frozen" structure of **1** is analogous to that of **2**. Most probably, the dynamic process observed for complex **1** in solution is due to a conformational flexibility of the chelate ring, which allows both chair and boat conformations. In this regard, several different transition-metal complexes bearing bidentate ligands that form a six-membered chelate ring,[14] including square-planar species of the type [Ni(P-P)X_2],[14b] exhibit a fluxional behaviour due to δ-twist-boat−λ-twist-boat rearrangement through a higher-energy chair conformation. It is likely that the dynamic process shown by complex **1** involves a rearrangement of both rings; that formed by the nitrogen donors being more flexible, as suggested by the observation that the most significant modifications of the spectral pattern mainly involve the resonances of the –CH_2CH_2– bridge of the PNN ligand. It should be noted that the other chelate ring exhibits a chain of four sp^2-hybridised atoms (–C–C–C–N–), which reduces the conformational flexibility of the cycle. At very low temperatures, the rate of the rearrangement processes is strongly slowed down and the two rings most probably adopt the conformation characteristic of the solid-state

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure of the complex (see below). Another interpretation of the fluxional behaviour of **1** invoking the rupture of the metal–nitrogen bond *trans* to the P atom is less precedented.

Crystal Structure Determination of Complexes 1 and 2

Structural analysis of complexes **1** and **2** in the solid state was undertaken in order to understand the different dynamic behaviour of the two species observed in solution. Orange-red needles of **1**, as well as pale yellow needles of **2**, suitable for X-ray analysis were obtained by slow diffusion of propan-2-ol into a dichloromethane solution of the complex. The molecular structures of **1** and **2** are presented in Figure 3 and Figure 4, respectively. The metal in both the complexes exhibits the expected square-planar geometry with coordination distances that are slightly shorter in **1** because of the smaller radius of the Ni^{II} ion. The bond lengths and angles are reported in Table 3, and data of the Pd derivative have values similar to those measured in similar complexes.[4] In both complexes, the ring formed by the N,N donor set shows a nearly ideal boat conformation, while the other one can be seen as a slightly twisted half-chair (Figure 3). It should be noted that the former is considered to be an unconventional form.[14c] These conformations cause a twist of the ligand around the metal centre. However, the overall configuration of **1** and **2** is closely comparable and there are no significant geometrical differences. The slight differences in the orientation of pyridine and of the imine moiety C(7)–N(2)–C(8)–C(9) with respect to the coordination plane likely originate in the crystal packing. On the other hand, a detailed examination of the coordination environment shows a slight tetrahedral distor-

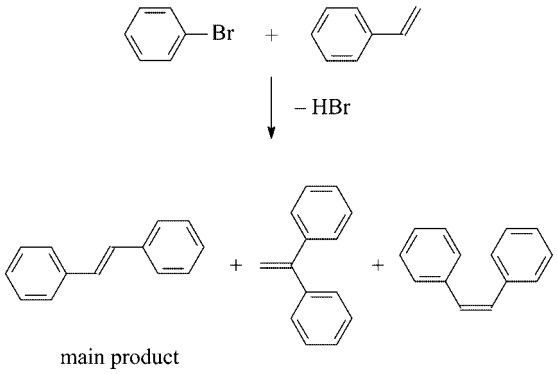
tion in the square-planar geometry of the Ni derivative [±0.112(1) Å] in contrast to the more coplanar donors, ±0.066(2) Å in the case of Pd. The packing in compound **1** shows a PF_6^- anion located close to the nickel ion with a Ni–F distance of 3.335 Å. This is a feature often encountered in square-planar complexes containing this anion.[15]

Catalytic Properties of Complexes 1 and 2 in the Heck Reaction

To evaluate the catalytic activity of complex **2** in the Heck reaction, the process of formation of *trans*-stilbene from bromobenzene and styrene has been chosen as a model (Scheme 2). The results of the investigation are collected in Table 4. For all trials, samples of the reaction mixture have been extracted and then analysed by GC after 4, 8 and 20 h. First, we have examined how the nature of the solvent influences yield and selectivity. Thus, the reaction between C_6H_5Br and styrene was performed under argon at 120 °C, using Cs_2CO_3 as the base, in the following solvents: *N*-methylpyrrolidinone (NMP), dimethyl sulfoxide (DMSO), dimethylformamide (DMF), ethylene glycol monomethyl ether (EGME) and 2,2′-thiodiethanol (TDE). NMP, DMF and DMSO are commonly used solvents for the Heck reaction, while the same is not true for the protic solvents EGME and TDE, which have been chosen mainly to ensure a complete dissolution of both the cationic complex and the base. The high final yield (89%) of *trans*-stilbene obtained using EGME (entry 5) with respect to the other solvents (entries 1–4) is rather surprising. Conversely, both regio- and stereoselectivity are rather low, as 9% of a mixture of 1,1-diphenylethene (main byproduct) and *cis*-stilbene is formed. The use of DMF resulted in the immediate formation of an insoluble brown material and only very small amounts of products were detected. The almost negligible activity of complex **2** in DMSO is most probably due to the strong coordinating ability of this solvent, which does not allow substrate activation on the metal centre. Notably, using EGME the yield is very high within a short time (83% after 4 h), despite the formation of palladium black after only a few minutes. We have found that the catalytic activity of complex **2** drastically decreases after the addition of a second batch of reagents. Thus, the *trans*-stilbene yield drops from 83 to 49% after 4 h in the second run. Such a finding agrees with the observed increasing formation of palladium black in the reaction vessel. In this regard, several authors have reported that palladium black is not an active Heck catalyst.[16] Apparently, the effective catalyst is longer lived, but slightly less active, in TDE, the final yield being good nevertheless (85%). The best base to use in combination with EGME is Cs_2CO_3, as with dimethylcyclohexylamine, K_2CO_3 and $CsOH·H_2O$ lower yields have been obtained (entries 6–8). In the case of cesium hydroxide the conversion of C_6H_5Br into products is almost complete, but a dramatic lowering of the selectivity is observed. To reduce palladium black formation, the reaction has been performed at lower temperature (80 °C), but in this case the reaction rate is too low to obtain an acceptable yield (entry 9). Surprisingly, the use of C_6H_5I instead of C_6H_5Br does not correspond to the expected neat increase of the reaction rate[8g] (entry 10). The mechanism of the reaction is currently under investigation, but some preliminary results can be briefly discussed. ^{31}P NMR measurements indicate that complex **2** is stable at 120 °C in EGME alone and even in the presence of both C_6H_5Br and styrene, but immediately after the introduction of Cs_2CO_3 the pale yellow colour of the solution turns dark orange. The $^{31}P\{^1H\}$ NMR spectrum of this solution shows that a singlet at δ = 33.0 has completely replaced the signal at δ = 31.1 because of complex **2**, while no other resonance is detectable. Thus, the starting complex is no longer present in solution under catalytic conditions but is transformed into a new species, most probably the effective catalyst. Attempts to isolate this derivative were unsuccessful. A prolonged warming of the dark orange solution at 120 °C results in the formation of increasing amounts of palladium black.



Scheme 2.

Finally, the Ni^{II} derivative **1** does not show any catalytic property in the reaction between C_6H_5Br and styrene, or in the presence of an excess of zinc dust (entry 11). It is well known that Ni^{II} compounds are less active than Pd^{II} compounds, but the beneficial role of a reductant such as zinc has been demonstrated in several cases.[17] The complete lack of catalytic activity of **1** is most probably due to the more difficult β-elimination and HBr removal steps for Ni^{II} with respect to Pd^{II}.[18]

It should be noted that α,β-unsaturated esters, used as starting material in combination with bromobenzene in EGME, undergo a transesterification process, promoted by Cs_2CO_3, giving the corresponding 2-methoxyethyl ester, which then undergoes the Heck reaction. Thus, for example, a mixture of *cis*- and *trans*-2-methoxyethyl-2-methyl-3-phenylpropenoate (major product) has been obtained from ethyl methacrylate.

In conclusion, complex **2** shows a good catalytic performance in the Heck reaction starting from aryl bromides, and the use of EGME as solvent is crucial to achieve good yields.

[a] Experimental conditions: aryl halide (1.0 equiv.), alkene (1.2 equiv.), base (1.2 equiv.). [b] NMP = 1-methyl-2-pyrrolidinone, DMSO = dimethyl sulfoxide, TDE = 2,2′-thiodiethanol, EGME = ethylene glycol monomethyl ether. [c] DMCA = dimethylcyclohexylamine. [d] GC yield. Aryl halide conversion after 20 h is reported in parenthesis. [e] With 10% Zn (dust) added.

Experimental Section

General Remarks: All reagents were purchased from Aldrich and used without further purification. Commercial solvents were dried according to standard methods[19] and freshly distilled under argon before use. All syntheses and manipulations were carried out under argon using standard Schlenk techniques. The ligand *N*-[2-(diphenylphosphanyl)benzylidene][2-(2-pyridyl)ethyl]amine (PNN) was prepared as described in the literature[4b] and was obtained very pure as a cream-coloured powder after double recrystallisation from *n*-hexane.

Instrumentation and Analyses: The ^1H, ^{13}C and ^{31}P NMR spectra (at 200.13, 50.32 and 81.02 MHz, respectively) were recorded with a Bruker AC 200 F QNP spectrometer equipped with a variable-temperature probe. The ^1H and ^{13}C chemical shifts were referenced to $SiMe_4$, while positive ^{31}P chemical shifts were downfield from 85% H_3PO_4 as external standard. The temperature in the range 273–183 K was calibrated with methanol. The simulation of the 293 K ^1H spectrum of PNN was performed with an Aspect 2000 computer using the programme PANIC (Bruker Spectrospin AG). The GC-MS analyses, run to control the identity of the compounds obtained in the catalytic trials, were carried out with a Fisons TRIO 2000 gas chromatograph-mass spectrometer working in the positive ion 70 eV electron impact mode. Injector temperature was kept at 250 °C and the column (Supelco® SE-54, 30 m long, 0.25 mm i.d., coated with a 0.5 μm phenyl methyl silicone film) temperature was programmed from 50 °C to 310 °C with a gradient of 10 °C/min. The GC analyses were run on a Fisons GC 8000 Series gas chromatograph equipped with a Supelco® PTA-5 column [30 m long, 0.53 mm i.d., coated with a 3.0 μm poly(5% diphenyl/95% dimethylsiloxane) film]. Injector and column temperatures were as indicated above. The elemental analyses (C, H, N) were carried out in the Microanalytical Laboratory of our department.

Synthesis of [NiCl(PNN)]PF_6 (1): A methanol solution (10 mL) of PNN (158 mg, 0.40 mmol) was added to 15 mL of a methanol solution of $NiCl_2·6H_2O$ (90 mg, 0.38 mmol). The red solution was stirred for 10 min and then NH_4PF_6 (196 mg, 1.2 mmol) dissolved in propan-2-ol (20 mL) was added. An orange powder immediately formed, which was filtered off, washed with methanol and dried. The product was then recrystallised from dichloromethane/propan-2-ol. Needle-shaped red crystals were obtained by slow diffusion of propan-2-ol into a dichloromethane solution of the complex. Yield: 195 mg, 81%. $C_{26}H_{23}ClF_6N_2NiP_2$ (633.57): calcd. C 49.29, H 3.66, N 4.42; found C 48.93, H 3.62, N 4.37. ^{31}P NMR (CD_2Cl_2, 183 K): δ = 24.7 ppm. ^1H and ^{13}C NMR spectroscopic data are reported in Table 1 and Table 2, respectively.

Synthesis of [PdCl(PNN)]PF_6 (2): A mixture of [$PdCl_2(CH_3CN)_2$] (156 mg, 0.60 mmol) and PNN (245 mg, 0.62 mmol) in dichloromethane (20 mL) was stirred for 30 min. NH_4PF_6 (294 mg, 1.8 mmol) dissolved in propan-2-ol (25 mL) was then added to the yellow solution and the dichloromethane was pumped off. The pale yellow precipitate, which was filtered off, washed with propan-2-ol and vacuum dried, was then recrystallised from dichloromethane/propan-2-ol. Needle-shaped pale yellow crystals were obtained by slow diffusion of propan-2-ol into a dichloromethane solution of the complex. The crystals contain half mol of CH_2Cl_2 per mol of complex. Yield: 379 mg, 87%. $C_{26}H_{23}ClF_6N_2P_2Pd·0.5CH_2Cl_2$ (723.76): calcd. C 43.98, H 3.34, N 3.87; found C 43.72, H 3.37, N 3.81. ^{31}P NMR (CD_2Cl_2, 293 K): δ = 31.0 ppm. ^1H and ^{13}C NMR spectroscopic data are reported in Table 1 and Table 2, respectively.

Synthesis of [PtCl(PNN)]PF_6 (3): A mixture of [$PtCl_2(C_6H_5CN)_2$] (118 mg, 0.25 mmol) and PNN (103 mg, 0.26 mmol) in dichloromethane (20 mL) was stirred for 30 min. After the addition of NH_4PF_6 (130 mg, 0.8 mmol) dissolved in propan-2-ol (20 mL), the dichloromethane was eliminated in vacuo affording a pale yellow product, which was filtered off, washed with propan-2-ol and vacuum dried. The crude product was recrystallised from dichloromethane/propan-2-ol. Needle-shaped pale yellow crystals were obtained by slow diffusion of propan-2-ol into a dichloromethane solution of the complex. The crystals contain half mol of CH_2Cl_2

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

per mol of complex. Yield: 186 mg, 91%. $C_{26}H_{23}ClF_6N_2P_2Pt\cdot 0.5CH_2Cl_2$ (812.42): calcd. C 39.18, H 2.98, N 3.45; found C 38.94, H 3.03, N 3.40. ^{31}P NMR (CD_2Cl_2, 293 K): δ = 1.4; $^1J(^{31}P–^{195}Pt)$ = 3459 Hz. ^1H and ^{13}C NMR spectroscopic data are reported in Table 1 and Table 2, respectively.

Magnetic Moment Measurements on Complex 1 in Solution: Measurements were run on CH_2Cl_2 and $ClCH_2–CH_2Cl$ solutions of the complex, at temperatures below and above 293 K, respectively. The method described by Evans[20] was adopted using a 5-mm NMR tube with a 2-mm coaxial capillary inside containing the pure solvent. The solutions (5×10^{-2} M) were prepared by dissolving 15.8 mg (25 μmol) of **1** into 0.5 mL of the appropriate solvent. Spectra were recorded at 183, 193, 213, 233, 253, 273, 293, 313, 333 and 343 K.

General Procedure for the Heck Reaction: Under argon, a 10-mL Schlenk flask containing a magnetic stir bar was charged with the catalyst (2.0 mg for each single experiment, 1 mol-%) and appropriate amounts of aryl halide (1.0 equiv.), alkene (1.2 equiv.) and base (1.2 equiv.). After addition of the solvent (2 mL), the flask was capped with a silicon stopper and heated at 120 °C in an oil bath. The reaction mixture was extracted from the flask by syringe after 4, 8 and 20 h. The samples were treated with water, extracted with ethyl ether, dried with Na_2SO_4 and then analysed by GC.

Crystallographic Structure Determination: Diffraction data of the structures reported were carried out on a rotating anode Nonius FR591 (Cu-K_α radiation λ = 1.54178 Å) equipped with a Kappa CCD imaging plate. Cell refinement, indexing and scaling of the data sets were carried out using Denzo[21] and Scalepack.[21] Both the structures were solved by Patterson and Fourier analyses[22] and refined by the full-matrix least-squares method based on F^2 with all observed reflections.[22] A ΔF map of **2** revealed, besides the PF_6^- anion, a disordered molecule of CH_2Cl_2 (occupancy factor 0.5, based on the electron density peaks). The hydrogen atoms were located at geometrically calculated positions. All the calculations were performed using the WinGX System, version 1.70.00.[23] Crystallographic data and details of structure refinements are reported in Table 5.

Keywords: Boron / Cyclic voltammetry / Ferrocene / Methylcymantrene

Reaction of (dibromoboryl)ferrocene (**1**) with 1 equiv. of the diazabutadiene *t*BuN=CH–CH=N*t*Bu, and subsequent reduction of the obtained borolium salt **2** with sodium amalgam, affords the first ferrocenyl-functionalized 1,3,2-diazaborole (**3**). Similarly, 1,1′-bis(dibromoboryl)ferrocene (**4**) can be transformed into compound **6**, which contains two diazaborolyl substituents at the ferrocene core. Treatment of precursors **1** and **4** with 1,2-bis(*tert*-butylamino)ethane in the presence of Et_3N gives rise to the formation of the diazaborolidine derivatives **13** and **14**. 1-Dibromoboryl-3-methylcymantrene (**7**) was also treated with *t*BuN=CH–CH=N*t*Bu to give the borolium salt **8**, which was subsequently reduced to the 2-cymantrenyl-diazaborole **9**. Treatment of **7** with *t*BuN(H)-CH_2CH_2N(H)*t*Bu in the presence of Et_3N furnished the corresponding 2-cymantrenyl-diazaborolidine **15**. The novel compounds were characterized by elemental analyses and various spectroscopic techniques (IR; ^{1}H, ^{13}C, and ^{11}B NMR; MS). The molecular structures of **3**, **6**, and **15** were elucidated by X-ray diffraction analyses. Cyclovoltammetric studies of the ferrocene derivatives at high scan rates show features of a quasireversible oxidation at the iron center. The heterocyclic groups serve as electron donors, considerably lowering the oxidation potential of the central iron atoms when compared to the parent compound ferrocene.

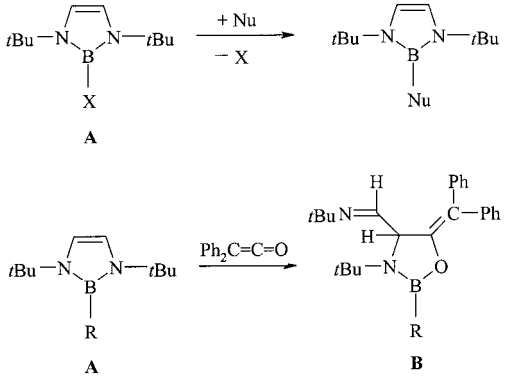
Introduction

Boryl- and borate-functionalized metallocenes are of great current interest. Two recent reviews have described their applications in homogeneous catalysis, anion sensing, and organometallic polymer chemistry.[1,2] Another point of interest is related to the influence of the boryl substituent on the electronic and structural properties of the metallocene moiety. The boron systems that concern us are 2,3-dihydro-1*H*-1,3,2-diazaboroles **A**, for which we have recently developed high-yield syntheses.[3] With this, the door was opened to an exceedingly rich chemistry of these heterocycles, including reactions where the structural integrity of the ring system is retained (e.g. nucleophilic displacements at the boron atom)[4] as well as processes where the ring is reorganized (e.g. in the reaction with diphenylketene to afford 1,3,2-oxazaborolidenes **B**;[5] Scheme 1).

At this point, it was of particular interest to combine such inorganic heterocycles with metallocene fragments. It is conceivable that the 6π-electron-containing heterocycle communicates electronically with the metallocene by (pp)π-interactions and/or σ-bonding, thus altering the electronic properties of the organometallic moiety.

In this paper we report on the synthesis and molecular structures of ferrocenyl- and cymantrenyl-functionalized 1,3,2-diazaboroles as well as their saturated counterparts, the respective 1,3,2-diazaborolidines. Moreover, electrochemical studies should provide information on the influence of the boron heterocycles on the redox-active center of the organometallic fragment.



Scheme 1. Reactivity of 1,3,2-diazaboroles **A**.

Results and Discussion

Several synthetic pathways for the construction of the 2,3-dihydro-1*H*-1,3,2-diazaborole system are currently available:

a) the catalytic dehydrogenation of the corresponding saturated 1,3,2-diazaborolidines;[6]

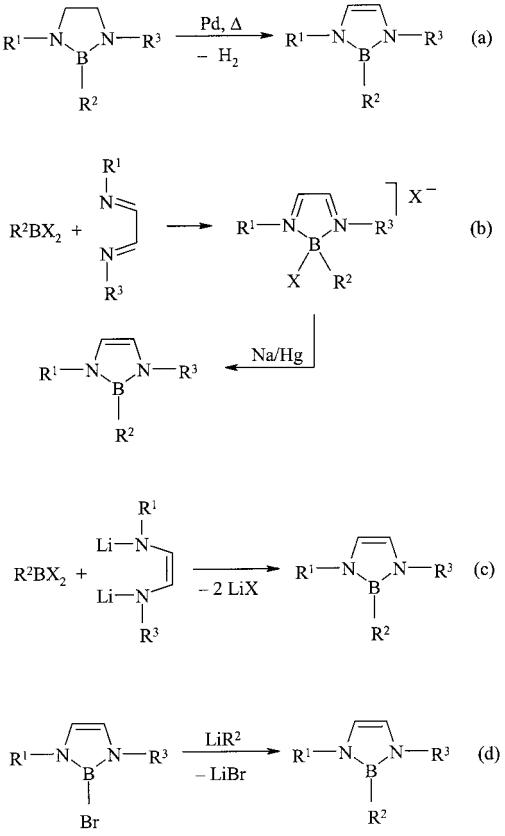
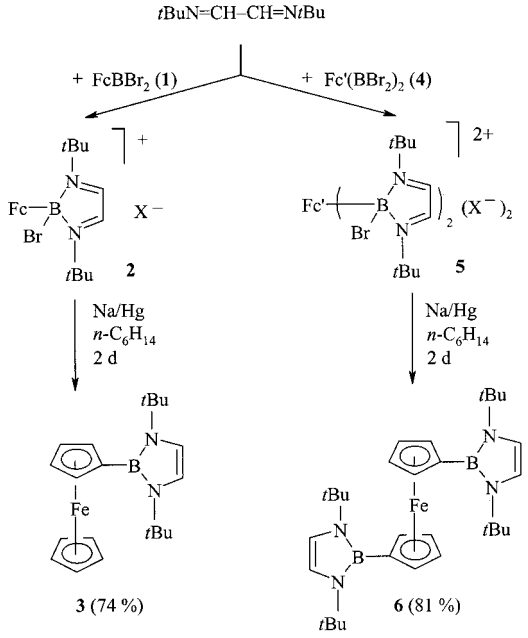
b) the reaction of di- or trihaloboranes with 1,4-diazabutadienes to afford borolium salts and the reduction of the latter species with sodium amalgam;[4,7]
c) the cyclocondensation of di- and trihaloboranes with dilithiated diazabutadienes;[4] and
d) nucleophilic substitution processes at the boron atom of preformed 2-halo-1,3,2-diazaboroles[4] (Scheme 2).



Scheme 2. Synthethic pathways to 1,3,2-diazaboroles.

Path (b) seems promising for the synthesis of 2-ferrocenyl- and 2-(methylcymantrenyl)-functionalized diazaboroles as the required precursors (dibromoboryl)ferrocene (**1**), 1,1′-bis(dibromoboryl)ferrocene (**4**), and 1-dibromoboryl-3-methylcymantrene (**7**) are readily available from ferrocene and methylcymantrene by Friedel–Crafts-type reactions with BBr_3 (Scheme 3).[8]

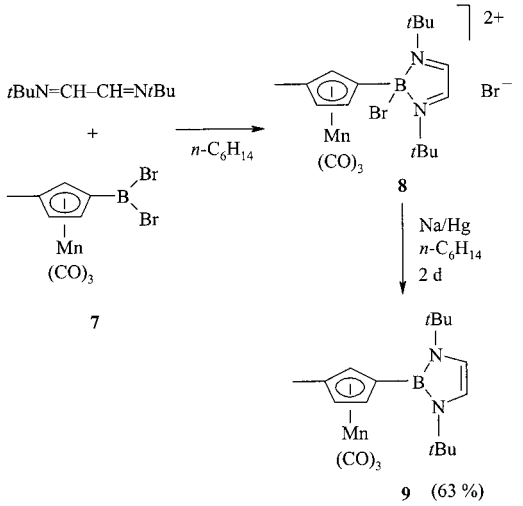
Reaction of **1** with the diazabutadiene (tBuN=CH)$_2$[9] in n-hexane gave an olive-green precipitate of borolium salt **2**, which shows resonances in the $^{11}B\{^1H\}$ NMR spectrum in the region of tetracoordinate boron [δ = 3.8, 7.1 ppm (CD_3CN)]. The two different signals are presumably due to different counterions in the salts. This phenomenon has frequently been encountered during the synthesis of borolium salts from diazabutadienes and boron halides.[4c,10] The obtained slurry was reduced in situ with an excess of sodium amalgam for2 d in the absence of light. Red crystals of product **3** were isolated in 74% yield from the resulting dark-red n-hexane phase. Similarly, the treatment of 1,1′-bis(dibromoboryl)ferrocene with2 equiv. of diazabutadiene gave borolium salt **5** [$\delta_{^{11}B}$ = 3.8, 7.1 ppm (CD_3CN)], which



Scheme 3. Syntheses of **3** and **6** {Fc = [(C_5H_5)(C_5H_4)Fe]; Fc′ = [(C_5H_4)$_2$Fe]; X = Br}.

was subsequently reduced to bis(borolyl)ferrocene **6**. The product was isolated as cherry-red crystals in 81% yield (Scheme 3).

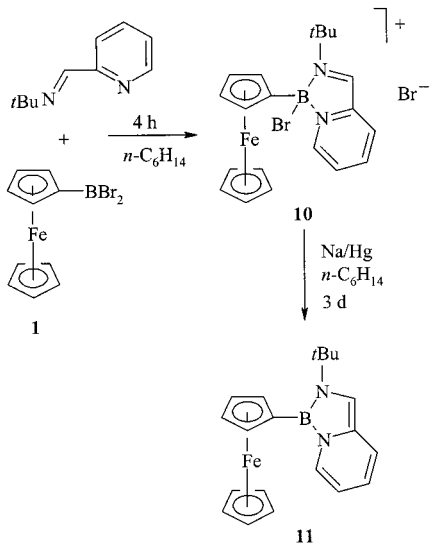
Yellow, crystalline methylcymantrenyl-1,3,2-diazaborole (**9**) was synthesized in 63% yield by the reaction of complex **7** with the diazabutadiene in n-hexane and the usual reduction of the borolium salt [$\delta_{^{11}B}$ = 5.0 ppm (CD_3CN)] with sodium amalgam (Scheme 4).



Scheme 4. Synthesis of **9**.

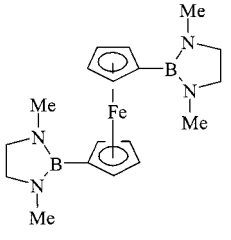
Thermolabile 2-ferrocenyl[1,3,2]diazaborolo[1,5-*a*]pyridine (**11**) was accessible by treatment of **1** with *N*-(2-pyridylmethylene)-*tert*-butylamine[11] and the subsequent reduction of borolium salt **10** ($\delta_{^{11}B}$ = 6.3, 7.8 ppm) to produce the orange solid product (Scheme 5).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

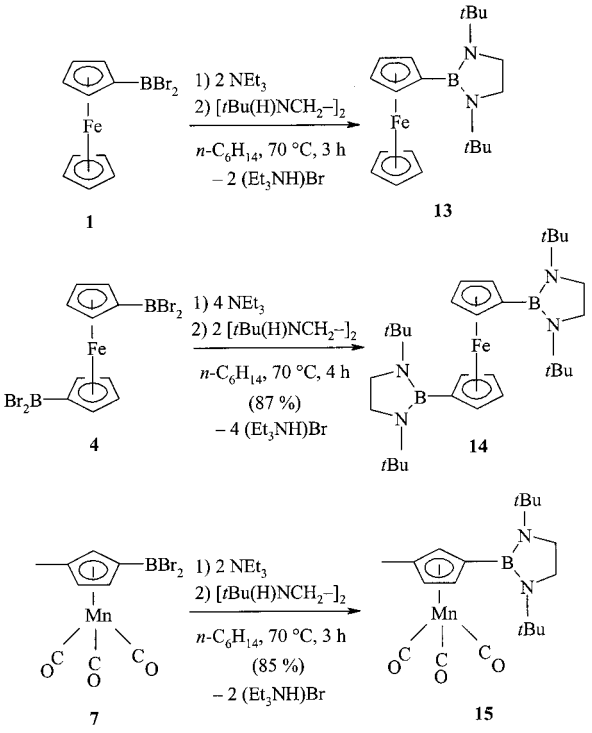


Scheme 5. Synthesis of **11**.

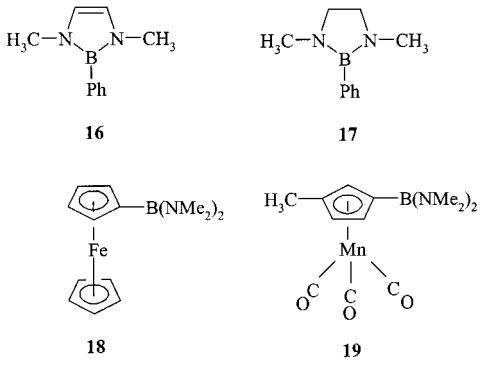
For comparison, the saturated analogs of the organometallic diazaboroles **3**, **6**, and **9** − the respective 1,3,2-diazaborolidenes − were also studied. One complex of this type, compound **12**, has previously been synthesized by the reaction of 1,1′-dilithioferrocene with 2-chloro-1,3-dimethyl-1,3,2-diazaborolidine.[12]



In this study, the aminolysis of the B–Br bonds in **1**, **4**, and **7** by *N*,*N*′-di-*tert*-butylethane-1,2-diamine in the presence of triethylamine was preferred as a synthetic approach (Scheme 6).



Scheme 6. Synthesis of diazaborolidines **13**–**15**.



The reactions were performed in boiling *n*-hexane for 3–4 h to afford red, oily **13**, dark-red, crystalline **14**, and colorless, crystalline **15** in good yields (85–87%). All the novel organometallic diazaboroles and diazaborolidines are sensitive to air and moisture. Moreover, the thermolability of compound **11** precluded reliable elemental analyses.

The $^{11}B\{^1H\}$ NMR spectra of the ferrocenyl-diazaboroles **3** and **6** display resonances at δ = 25.3 ppm, which are comparable with the ^{11}B NMR signal of 2-phenyl-1,3,2-diazaborole (**16**; δ = 25.6 ppm).[6] Generally, the shielding of the ^{11}B nuclei in 1,3-dialkyl-1,3,2-diazaboroles is mainly governed by the substituents at the boron atom.

This resonance is shifted by 6.5 ppm to δ = 31.8 ppm on going to the saturated systems **13** and **14**. Again, these resonances compare well with the ^{11}B NMR signal of 1,3-dimethyl-2-phenyl-1,3,2-diazaborolidine (**17**; δ = 32.2 ppm).[6] The ^{11}B NMR signal in the acyclic (diaminoboryl)ferrocene **18** appears at δ = 33.3 ppm,[8b] thus indicating that the ferrocenyl and the phenyl group at the boron atom contribute similarly to the shielding of the boron center. The situation is similar in the ^{11}B NMR spectra of the methylcymantrenyl derivatives. In the methylcymantrenyl-substituted diazaborole **9**, for example, the ^{11}B NMR resonance is observed at δ = 23.2 ppm. The ^{11}B atom of diazaborolidine **15** is more deshielded (δ = 29.6 ppm) as in the corresponding 6π-electron heterocycle. The ^{11}B NMR signal of the acyclic bis(aminoboryl) derivative **19** appears at δ = 30.1 ppm.[8b]

The chemical shifts of the ^1H and ^{13}C nuclei of the C_5H_5 ring in monoborylated ferrocenes in comparison to the parent compound is thought to reflect the donor/acceptor properties of the boryl substituent. Thus, on going from $[FeCp_2]$ ($\delta_{^{13}C}$ = 68.2 ppm) to the dibromoboryl derivative **1** ($\delta_{^{13}C}$ = 71.7 ppm) this resonance is shifted by 3.5 ppm. In comparison, the 1,3,2-diazaborolyl- and 1,3,2-diazaborolidinyl substituents in **3** and **13** (δ = 69.6 ppm) give rise to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the considerably smaller low-field shift of only 1.4 ppm. In ferrocene **18**, which contains the $B(NMe_2)_2$ group as a substituent, a singlet is observed at $\delta_{^{13}C}$ = 68.6 ppm. The signals of the α- and the β-C atoms of the C_5H_4B unit in **1** are found at $\delta_{^{13}C}$ = 77.4 and 78.4 ppm, respectively, whereas the corresponding signals in the bis(dibromoboryl)ferrocene **4** appear at δ = 79.0 and 80.3 ppm. In the monoborolyl- and monoborolidinyl ferrocenes **3** and **13** the nuclei $^{13}C_\alpha$ and $^{13}C_\beta$ resonate at δ = 76.2, 68.6 (**3**) and 76.2, 68.3 (**13**) ppm. For comparison, the corresponding signals in **18** appear at $\delta_{^{13}C}$ = 76.0 and 70.1 ppm.[12] The resonances for the $^{13}C_\alpha$- and $^{13}C_\beta$ atoms of the diborylated species **6** and **14** are found at $\delta_{^{13}C}$ = 79.3 (**6**) and 79.0 (**14**), and 68.6 (**6**) and 68.3 (**14**) ppm. The pronounced difference in the resonances of C_α and C_β in **3**, **6**, **13**, **14**, and **18** agrees with a significant transfer of negative charge from the heterocycles to the organometallic unit via the B–C σ-bond. Singlets at δ = 112.7 or 112.9 ppm in the ^{13}C NMR spectra of **3** and **6**, respectively, were assigned to the C=C groups of the diazaborole.

The ^1H NMR spectra of complexes **1**, **3**, **13**, and **18** show singlets in the narrow range of δ = 4.06–4.12 ppm for the C_5H_5 groups. The electron-withdrawing effect of one or two Br_2B units in **1** and **4** is reflected by the separation of the multiplets for H_α and H_β of the substituted rings by $\Delta\delta$ = 0.35 and 0.20 ppm, respectively, with δ_{H_β} at lower field. No such separation is observable in the monoborylated complexes **3**, **14**, and **18**, and in the diborylated ferrocenes **6** and **14** a separation of signals of only $\Delta\delta$ = 0.11–0.14 ppm is found. Singlets in the ^1H NMR spectrum of **9** at δ = 1.34 (18 H), 1.56 (3 H), 4.04 (1 H), 4.57 (1 H), 4.65 (1 H), and 6.34 (2 H) ppm are attributed to the protons of the *tert*-butyl groups, the ring methyl group, the protons H(4), H(2), and H(5) of the methylcyclopentadienyl ligand, and to the CH=CH unit, respectively. The corresponding resonances in the borolidinyl derivative **15** are found at δ = 1.30 (18 H), 1.68 (3 H), 4.14 (1 H), 4.64 (1 H), and 4.68 (1 H) ppm, whereas the protons of the CH_2–CH_2 fragment are observed as a singlet at δ = 3.11 ppm (4 H). The ^{13}C NMR spectra of **9** and **15** show singlets for the CO ligands at δ = 226.2 and 226.0 ppm, respectively, which are close to the resonance in methylcymantrene [δ(CO) = 225.7 ppm]. The ^{13}C NMR signals of the η^5-ligand in **9** and **15** are similar to those of **7**, where the Br_2B group is clearly electron-withdrawing. Here, singlets for C(3), C(5), C(2), and C(4) are found at δ = 107.2, 96.6, 95.8, and 90.0 ppm. In **9**, the respective resonances appear at δ = 99.8, 95.2, 94.8, and 90.0 ppm, which points to a higher electron density in the ring than in **7**. This tendency is even more pronounced in **15**, where singlets are observed at δ = 98.8, 94.1, 93.5, and 81.7 ppm. This is also mirrored in the ν(CO) region of the IR spectra of **7**, **9**, **15**, and $[(CH_3C_5H_4)Mn(CO)_3]$ (Table 1).

Two strong ν(CO) bands are observed at $\tilde{\nu}$ = 2025 and 1944 cm^{-1} due to the local C_{3v} symmetry of the $Mn(CO)_3$ group in the starting material. Strong absorptions at $\tilde{\nu}$ = 2020 and 1938 cm^{-1} in the spectra of **9** and **15**, respectively, show the transfer of electron density from the heterocyclic substituents to the carbonyl groups. In comparison to that, ν(CO) bands are found at higher wavenumbers for the dibromoboryl precursor **7** ($\tilde{\nu}$ = 2033, 1949 cm^{-1}) than for methylcymantrene.

Table 1. IR data of the methylcymantrene derivatives in *n*-hexane solutions.

Compound	$[(CH_3C_5H_4)Mn(CO)_3]$	**7**	**9**	**15**
$\tilde{\nu}$ [cm^{-1}]	2025, 1944	2033, 1949	2020, 1938	2020, 1938

X-ray Structural Analysis of 3, 6, and 15

X-ray analyses of compounds **3**, **6**, and **15** were carried out to determine the mutual orientation of the 1,3,2-diazaborolyl substituent and the η^5-C_5H_4 ring ligand, and for an evaluation of a possible π-conjugation between these cycles in the solid state (Table 3).

X-ray Structural Analysis of 3

An ORTEP drawing of **3** is shown in Figure 1; selected bond lengths and angles are given in the caption.

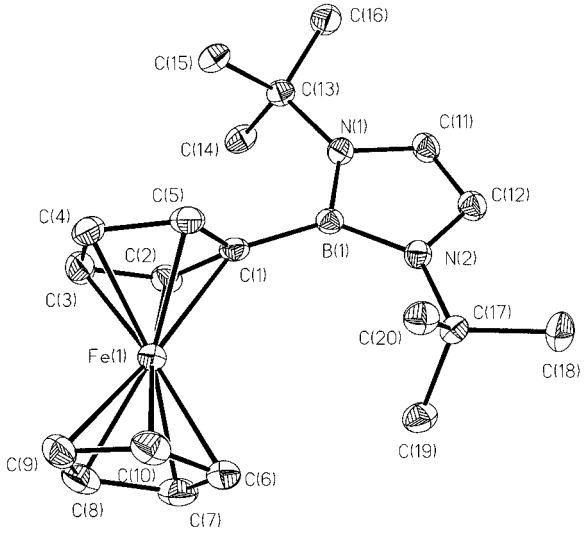


Figure 1. Molecular structure of **3** in the crystal. Selected bond lengths [Å] and angles [°]: B(1)–C(1) 1.588(2), B(1)–N(1) 1.455(2), B(1)–N(2) 1.444(2), N(1)–C(11) 1.400(2), N(2)–C(12) 1.396(2), N(1)–C(13) 1.497(2), N(2)–C(17) 1.488(2), C(11)–C(12) 1.342(2), Fe(1)–C(1) 2.132(2), Fe(1)–C(2) 2.053(2), Fe(1)–C(3) 2.031(2), Fe(1)–C(4) 2.038(2), Fe(1)–C(5) 2.066(2), Fe(1)–C(6,-10) 2.048(2)–2.070(2), C(1)–C(2) 1.434(2), C(2)–C(3) 1.421(2), C(3)–C(4) 1.424(3), C(4)–C(5) 1.426(2), C(1)–C(5) 1.437(2); N(1)–B(1)–N(2) 104.84(13), B(1)–N(1)–C(11) 107.21(13), N(1)–C(11)–C(12) 110.16(14), C(11)–C(12)–N(2) 109.75(14), B(1)–N(2)–C(12) 107.99(13), C(1)–B(1)–N(2) 133.04(15), C(1)–B(1)–N(1) 122.12(13), B(1)–N(2)–C(17) 130.51(13), B(1)–N(1)–C(13) 132.59(13), C(13)–N(1)–C(11) 120.19(13), C(12)–N(2)–C(17) 121.49(12), B(1)–C(1)–C(2) 124.81(14), B(1)–C(1)–C(5) 126.58(14), C(2)–C(1)–C(5) 105.24(14).

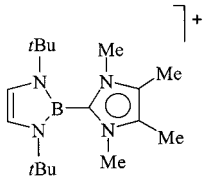
The molecular structure of **3** features a planar 1,3,2-diazaborole ring with a ferrocenyl substituent that is linked to the boron atom by a B–C single bond of 1.588(2) Å. This

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

value compares well with the B–C bond in the borolylimidazolium ion **20** [1.580(11) Å].[4d]



20

The atomic distances and valence angles are in good agreement with the equivalent data for cation **20**. The B–N bond lengths in **3** [1.444(2), 1.455(2) Å] indicate multiple-bond character. The B–N bond lengths in a series of diazaboroles range from 1.407(3) to 1.450(2) Å. The atomic distance C(11)–C(12) [1.342(2) Å] and the N–C(sp^2) bond lengths [1.396(2) and 1.400(2) Å] also indicate multiple bonding. Bond lengths of 1.497(2) and 1.488(2) Å are found for the N(sp^2)–C(sp^3) single bonds N(1)–C(13) and N(2)–C(17), respectively. The endocyclic angles in **3** [N(1)–B(1)–N(2) = 104.84(13)°, B(1)–N(1)–C(11) = 107.21(13)°, B(1)–N(2)–C(12) = 107.99(13)°, N(1)–C(11)–C(12) = 110.16(14)°, and N(2)–C(12)–C(11) = 109.75(14)°] resemble those in **20** [107.1(6), 105.9(4), and 110.5(3)°]. The exocyclic angle C(1)–B(1)–N(2) is much wider [133.04(15)°] than the C(1)–B(1)–N(1) angle of only 122.12(13)°, presumably due to severe steric interaction between the *tert*-butyl group at N(2) and the ferrocenyl unit. In the ferrocenyl part of the molecule it is obvious that the Fe(1)–C(1) bond of 2.132(2) Å significantly exceeds the distances between the metal atom and the remaining ring carbon atoms [2.031(2)–2.066(2) Å]. The Fe–C distances to the C_5H_5 ligand range from 2.048(2) to 2.070(2) Å, and the planes of the two Cp rings form an angle of 9.8°. The boron atom is not coplanar with ring C(1) to C(5), but is located 0.49 Å above this plane. The vector B(1)–C(1) and the ring plane enclose an angle of 17.6°. The diazaborole ring and the ring C(1) to C(5) form an angle of 73.1°, thus excluding significant π-communication between the two units.

X-ray Structural Analysis of 6

The molecular structure of **6** (Figure 2, Table 3) features a ferrocene scaffold, with each ring substituted by a planar 1,3,2-diazaborolyl group by single bonds [B(1)–C(11) = 1.596(3) Å; B(2)–C(16) = 1.584(4) Å].

The two cyclopentadienyl rings are not parallel but are bent by an angle of 12.9°. The heterocycle defined by the atoms B(1), N(1), N(2), C(1), and C(2) and the ring C(11)–C(15) show an interplanar angle of 46.6°. The plane of the second diazaborolyl substituent and the plane defined by the atoms C(16) to C(20) feature an interplanar angle of 103.1°. The boron atoms B(1) and B(2) are located 0.31 and 0.51 Å above their respective cyclopentadienyl ligands, which means that the vectors B(1)–C(11) and B(2)–C(16) form angles of 10.7° and 18.1° with the respective C_5H_4 planes. The vectors B(1)–C(11) and B(2)–C(16) form an angle of 75.7°, which mirrors a *gauche* conformation of both substituents. As already observed with complex **3**, the

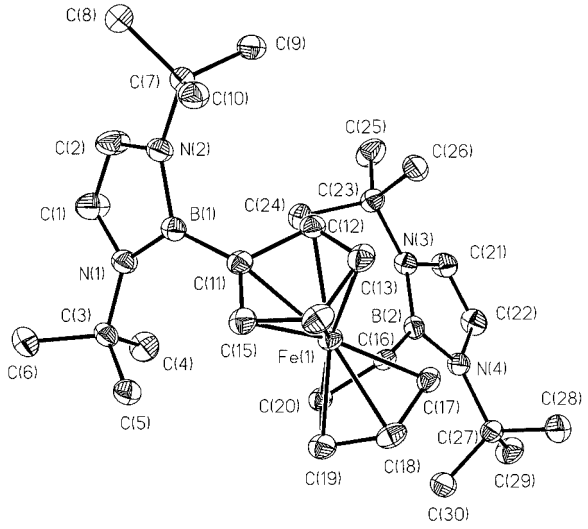


Figure 2. Molecular structure of **6** in the crystal. Selected bond lengths [Å] and angles [°]: B(1)–C(11) 1.596(3), B(1)–N(1) 1.450(3), B(1)–N(2) 1.464(3), N(1)–C(1) 1.396(3), N(1)–C(3) 1.485(3), N(2)–C(2) 1.379(3), N(2)–C(7) 1.499(3), C(1)–C(2) 1.343(3), B(2)–C(16) 1.584(4), B(2)–N(3) 1.447(3), B(2)–N(4) 1.462(3), N(3)–C(21) 1.404(3), N(3)–C(23) 1.483(3), N(4)–C(22) 1.397(3), N(4)–C(27) 1.497(3), Fe(1)–C(11) 2.136(2), Fe(1)–C(12) 2.051(2), Fe(1)–C(13) 2.044(2), Fe(1)–C(14) 2.042(2), Fe(1)–C(15) 2.072(2), Fe(1)–C(16) 2.155(2), Fe(1)–C(17) 2.059(2), Fe(1)–C(18) 2.026(2), Fe(1)–C(19) 2.035(2), Fe(1)–C(20) 2.079(2), C–C(Cp) 1.407(3)–1.436(3); B(1)–N(1)–C(1) 106.9(2), N(1)–C(1)–C(2) 110.4(2), N(2)–C(2)–C(1) 110.3(2), B(1)–N(2)–C(2) 107.3(2), N(1)–B(1)–N(2) 104.8(2), N(1)–B(1)–C(11) 132.8(2), N(2)–B(1)–C(11) 122.2(2), B(1)–N(1)–C(3) 135.7(2), C(1)–N(1)–C(3) 117.3(2), C(2)–N(2)–C(7) 118.0(2), B(1)–N(2)–C(7) 134.6(2), B(1)–C(11)–C(15) 132.5(2), B(1)–C(11)–C(12) 121.7(2), C(12)–C(11)–C(15) 104.7(2), B(2)–N(3)–C(21) 107.6(2), N(3)–C(21)–C(22) 110.2(2), N(4)–C(22)–C(21) 110.1(2), B(2)–N(4)–C(22) 107.5(2), N(3)–B(2)–N(4) 104.6(2), C(16)–B(2)–N(3) 132.6(2), B(2)–N(3)–C(23) 130.4(2), C(21)–N(3)–C(23) 121.2(2), C(16)–B(2)–N(4) 122.7(2), B(2)–C(16)–C(17) 124.4(2), B(2)–C(16)–C(20) 127.2(2), C(17)–C(16)–C(20) 104.8(2).

Fe(1)–C(11) [2.136(2) Å] and Fe(1)–C(16) [2.155(2) Å] contacts are much longer than the remaining Fe–[C(12)–C(15)] [2.042(2)–2.072(2) Å] or Fe–[C(17)–C(20)] [2.026(2)–2.079(2) Å] bonds, although the bond lengths and angles within the heterocycles are similar to those in **3**. As is also the case in **3**, the exocyclic angles N(1)–B(1)–C(11) [132.8(2)°] and N(3)–B(2)–C(16) [132.6(2)°] are more obtuse than the angles N(2)–B(1)–C(11) [122.2(2)°] and N(4)–B(2)–C(16) [122.7(2)°], which reflects the steric requirements of the ferrocene unit.

X-ray Structural Analysis of 15

The molecule of **15** (Figure 3, Table 3) adopts the structure of a three-legged piano-stool with three essentially linear carbonyl ligands. The C–Mn–C angles range from 89.9(2) to 93.6(2)°. The most interesting feature of **15** is the methylcyclopentadienyl ligand, which is linked to a 1,3,2-diazaborolidinyl substituent by a B–C single bond of 1.594(5) Å. The heterocycle is slightly puckered (sum of angles: 532.8°; mean deviation from the best plane: 0.1037 Å), and features a dihedral angle with the cyclopentadienyl ring of 39.6°. The boron atom is located 0.20 Å

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

above the carbocycle and C(11) is situated 0.44 Å underneath the plane of the heterocycle. The vector B(1)–C(11) forms angles of 7.1° and 13.3° with the carbocycle and the borolidine, respectively.

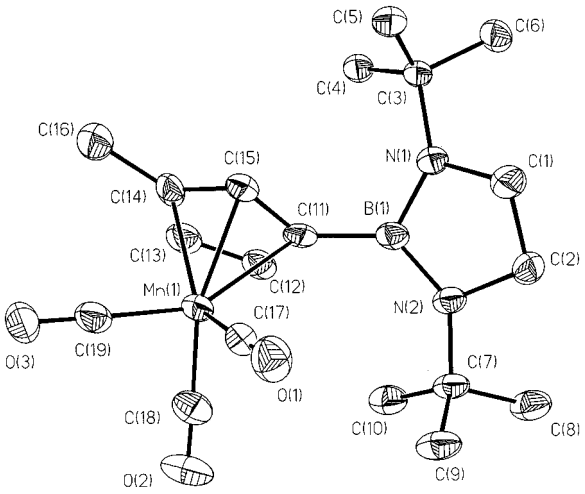

Figure 3. Molecular structure of **15** in the crystal. Selected bond lengths [Å] and angles [°]: B(1)–N(1) 1.445(5), B(1)–N(2) 1.431(5), N(1)–C(1) 1.470(4), N(2)–C(2) 1.469(4), C(1)–C(2) 1.502(5), N(1)–C(3) 1.481(4), N(2)–C(7) 1.489(4), B(1)–C(11) 1.594(5), Mn(1)–C(11) 2.187(3), Mn(1)–C(12) 2.172(4), Mn(1)–C(13) 2.163(4), Mn(1)–C(14) 2.138(4), Mn(1)–C(15) 2.109(3), Mn(1)–C(17) 1.787(4), Mn(1)–C(18) 1.794(4), Mn(1)–C(19) 1.793(4), C–O 1.152(5)–1.156(5); B(1)–N(1)–C(1) 106.8(3), B(1)–N(1)–C(3) 135.4(3), N(1)–C(1)–C(2) 104.1(3), C(1)–N(1)–C(3) 117.8(3), N(2)–C(2)–C(1) 105.5(3), B(1)–N(2)–C(2) 108.2(3), N(1)–B(1)–N(2) 108.2(3), N(1)–B(1)–C(11) 119.7(3), N(2)–B(1)–C(11) 131.7(3), B(1)–C(11)–C(15) 121.4(3), B(1)–C(11)–C(12) 133.9(3), C(12)–C(11)–C(15) 104.1(3), C(17)–Mn(1)–C(18) 93.6(2), C(17)–Mn(1)–C(19) 90.8(2), C(18)–Mn(1)–C(19) 89.9(2), Mn(1)–C–O 177.5(3)–178.9(3).

The manganese atom is unsymmetrically attached to the carbocycle with Mn–C bond lengths ranging from 2.109(3) Å [Mn(1)–C(15)] to 2.187(3) Å [Mn(1)–C(11)]. The B–N distances 1.431(5) and 1.445(5) Å indicate multiple bonding. The remaining endocyclic distances N(1)–C(1) [1.470(4) Å], N(2)–C(2) [1.469(4) Å], and C(1)–C(2) [1.502(5) Å] are single bonds and differ markedly from those in **3** and **6**. The exocyclic angle N(2)–B(1)–C(11) [131.7(3)°] is similar to those of the previously discussed molecules **3** and **6**, and it is wider than the angle N(1)–B(1)–C(11) [119.7(3) Å]. As a consequence of steric hindrance, the exocyclic angles B(1)–N(1)–C(3) [135.4(3)°] and B(1)–N(2)–C(7) [136.7(3)°] clearly exceed the angles C(1)–N(1)–C(3) [117.8(3)°] and C(2)–N(2)–C(7) [115.1(3)°].

Electrochemistry

All the ferrocenyl- and methylcymantrenyl-functionalized diazaboroles and diazaborolidines described here were also investigated by cyclic voltammetry. With the ferrocene derivatives **3**, **6**, **11**, **13**, and **14** a quasi-reversible Fe^{2+}/Fe^{3+} oxidation was observed (Table 2). At low scan rates ($5\ mV\ s^{-1}$) the cyclovoltammograms feature an irreversible wave, which changes to a quasi-reversible one on going to higher rates. The oxidation potentials, $E^{0\prime}$, have been taken from square-wave voltammograms with reference to the redox pair Fc/Fc^+. From these data it is obvious that the diazaborole and the diazaborolidine group transfer electron density onto the redox-active center of the ferrocene unit. The diborolylated ferrocene **6** is more easily oxidized ($E^{0\prime}$ = –0.34 V) than the monoborolylated analog **3** ($E^{0\prime}$ = –0.18 V), and the same trend is observed with compounds **13** ($E^{0\prime}$ = –0.11 V) and **14** ($E^{0\prime}$ = –0.20 V), where one or two diazaborolidinyl substituents are present. Moreover, it is evident that the oxidation of the ferrocenyl-diazaboroles **3** and **6** is easier than the saturated congeners **13** and **14**; no decomposition of the ferrocene derivatives was observed during these experiments. This is not the case with the methylcymantrenyl systems **9** ($E^{0\prime}$ = +0.21 V) and **15** ($E^{0\prime}$ = +0.49 V), where an irreversible oxidation process with the formation of free methylcymantrene ($E^{0\prime}$ = +0.84 V) was observed. Wagner et al. have previously reported that boryl-substituted ferrocenes also suffer from degradation to ferrocene during their cyclovoltammetric studies.[13]

Table 2. Voltammetric data ($E^{0\prime}$) of ferrocenyl- and methylcymantrenyl-functionalized diazaboroles and diazaborolidines vs. Fc/Fc^+ standard.

Compound	**3**	**6**	**9**	**11**	**13**	**14**	**15**
$E^{0\prime}$ [V]	–0.18	–0.34	+0.21	–0.32	–0.11	–0.20	+0.49

Conclusions

We have extended methodologies for the synthesis of 1,3,2-diazaboroles to the construction of ferrocenyl- and cymantrenyl-functionalized diazaboroles. X-ray structure analyses show that the heterocycle is twisted out of the plane of the adjacent cyclopentadienyl ligand in the crystal, thus preventing significant electronic communication by π-electron delocalization. According to the cyclic voltammetric studies, borole and borolidine substituents serve as electron donors and cause cathodic shifts of the oxidation potentials of the iron center relative to the parent system Fc/Fc^+.

Experimental Section

General: All reactions were performed under dry, oxygen-free nitrogen using standard Schlenk techniques. The dibromoboryl derivatives $[(\eta^5\text{-Cp})(\eta^5\text{-}C_5H_4BBr_2)Fe]$ (**1**), $[(\eta^5\text{-}C_5H_4BBr_2)_2Fe]$ (**4**), and $[\{\eta^5\text{-}(3\text{-}CH_3)(1\text{-}Br_2B)C_5H_3\}Mn(CO)_3]$ (**9**), as well as the imines *t*BuN=CH–CH=N*t*Bu[9] and *N*-(2-pyridylmethylene)-*tert*-butylamine,[11] were synthesized as described in the literature. *N*,*N*′-Di-*tert*-butylethane-1,2-diamine and triethylamine were purchased commercially. Infrared spectra were recorded with a Bruker FT-IR IFS 66 spectrometer. NMR spectra: Bruker AM Avance DRX 500. Standards: $SiMe_4$ (^1H, ^{13}C), $BF_3{\cdot}OEt_2$ (^{11}B). Mass spectra were recorded with a VG Autospec sector field mass spectrometer (Micromass). The electrochemical experiments were performed

with a PAR Model 270 A and the relevant software (Model 270). A system of microelectrodes with a three-electrode array was used, with a platinum wire as working electrode (1.5 cm length, 0.5 mm diameter), which was wound as a helix around the counter electrode and a silver wire (1.5 cm length, 1 mm diameter) as pseudo-reference electrode. All experiments were conducted in a glass device, which was flame-dried prior to use and filled with dry nitrogen. The determinations were performed in a 0.1 M solution of tetrabutylammonium hexafluorophosphate (TBAPF) in dichloromethane with concentrations of the analyte of ca. 1×10^{-4} M. The cyclovoltammograms were recorded with scan rates of 5–700 mV s^{-1}. All published potentials were determined by means of square-wave voltammetry (frequency: 5 Hz). Ferrocene and octamethylferrocene were used for calibration. All the potentials with octamethylferrocene were converted into the ferrocene standard.

[(η^5-C_5H_5){η^5-$C_5H_4BN^a$(*t*Bu)CH=CHN^b(*t*Bu)}Fe](*B*–*N*^{b}) (3): Solutions of (dibromoboryl)ferrocene (**1**; 3.10 g, 8.7 mmol) and *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene (1.46 g, 8.7 mmol), each in *n*-hexane (70 mL), were simultaneously added dropwise to *n*-hexane (50 mL). An olive-green precipitate of borolium salt **2** [^{11}B NMR (CD_3CN): δ = 3.8 and 7.1 ppm] separated. A sample of freshly prepared sodium amalgam (obtained from 1.30 g of Na and 120 g of Hg) was added to the slurry, which was subsequently vigorously stirred in the dark for 2 d. A dark-red solution was decanted and concentrated in vacuo until the solution became cloudy. Storing at –80 °C for 10 d furnished 2.35 g of **3** as red crystals (yield 74%). ^{1}H NMR (C_6D_6): δ = 1.40 (s, 18 H, *t*Bu), 4.10 (s, 5 H, C_5H_5), 4.23 (s, 4 H, C_5H_4B), 6.42 (s, 2 H, NCH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 32.7 [s, C(*C*H$_3$)$_3$], 53.2 [s, *C*(CH$_3$)$_3$], 68.6 (s, BC$_2{}^a$*C*$_2{}^b$H$_4$), 69.6 (s, C_5H_5), 76.2 (s, BC$_2{}^a$C$_2{}^b$H$_4$), 112.7 (s, NCH) ppm. ^{11}B{^{1}H} NMR (C_6D_6): δ = 25.3 ppm. MS-EI: *m*/*z* (%) = 364 (100) [M$^+$]. $C_{20}H_{29}BFeN_2$ (364.12): calcd. C 65.97, H 8.03, N 7.69; found C 64.78, H. 7.67, N 7.22. Repeated attempts to obtain better analyses were unsuccessful. $E^{0\prime}$ = –0.18 V (vs. Fc/Fc$^+$).

[{η^5-$C_5H_4BN^a$(*t*Bu)CH=CHN^b(*t*Bu)}]Fe(*B*–*N*^{b}) (6): Solutions of 1,1′-Bis(dibromoboryl)ferrocene (**4**; 2.20 g, 6.2 mmol) and *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene (2.09 g, 12.4 mmol), each in *n*-hexane (70 mL), were simultaneously added dropwise to *n*-hexane (25 mL), whereby the olive-green borolium salt **5** (^{11}B{^{1}H} NMR: δ = 3.8, 7.1 ppm) separated. Freshly prepared sodium amalgam (obtained from 1.30 g of Na and 120 g of Hg) was added, and the slurry was vigorously stirred in the dark for 2 d. A dark-red solution was decanted from the mercury phase and concentrated in vacuo until the solution turned cloudy. Storing of the solution at –80 °C for 12 d and then at –10 °C for 2 d gave 2.72 g (81% yield) of compound **6** as cherry-red crystals. ^{1}H NMR (C_6D_6): δ = 1.42 (s, 36 H, *t*Bu), 4.23 (s, 4 H, Cp), 4.36 (s, 4 H, Cp), 6.39 (s, 4 H, NCH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 32.8 [s, C(*C*H$_3$)$_3$], 53.2 [s, *C*(CH$_3$)$_3$], 69.2 (s, CH-Cp), 79.3 (s, CH-Cp), 112.9 (s, NCH) ppm. ^{11}B{^{1}H} NMR (C_6D_6): δ = 25.3 ppm. MS-EI: *m*/*z* (%) = 542 (100) [M$^+$]. $C_{30}H_{48}BFeN_2$ (542.21): calcd. C 66.46, H 8.92, N 10.33; found C 66.53, H 9.12, N 9.90. $E^{0\prime}$ = –0.34 V (vs. Fc/Fc$^+$).

[{(3-Me)[1-BN^a(*t*Bu)CH=CHN^b(*t*Bu)]C_5H_3}Mn(CO)$_3$](*B*–*N*^{b}) (9): Solutions of 1-dibromoboryl-3-methylcymantrene (**7**; 4.00 g, 10.3 mmol) and *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene (1.74 g, 10.3 mmol), each in *n*-hexane (100 mL), were slowly added (one drop per second!) to *n*-hexane (50 mL). The dark-yellow borolium salt **8** [^{11}B{^{1}H} NMR (CD_3CN): δ = 5.0 ppm] separated. It was filtered and washed with *n*-hexane (3 × 40 mL). The salt was suspended in *n*-hexane (100 mL), sodium amalgam (from 1.60 g of Na and 165 g of Hg) was added, and the resulting slurry was vigorously stirred in the dark for 2 d. Storing at –30 °C for 4 d gave yellow crystals of thermolabile **9** (2.58 g, 63%). Decomposition at room temp. was complete after 24 h. ^{1}H NMR (C_6D_6): δ = 1.34 (s, 18 H, *t*Bu), 1.56 (s, 3 H, CH_3), 4.04 (s, 1 H, C_5H_3), 4.57 (s, 1 H, C_5H_3), 4.65 (s, 1 H, C_5H_3), 6.34 (s, 2 H, NCH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 12.8 (s, CH_3), 32.9 [s, C(*C*H$_3$)$_3$], 53.6 [s, *C*(CH$_3$)$_3$], 82.1 (s, C4), 94.4; 95.2 (2s, C2, C5), 99.8 (s, C3), 113.7 (s, NCH), 226.2 (s, CO) ppm. ^{11}B{^{1}H} NMR (C_6D_6): δ = 23.2 (s) ppm. MS-EI: *m*/*z* (%) = 396 (21) [M$^+$], 312 (63) [M$^+$ – 3CO], 296 (100) [M$^+$ – 3CO – CH_4]. $C_{19}H_{26}BMnN_2O_3$ (396.18): calcd. C 57.60, H 6.61, N 7.07; found C 57.09, H 6.87, N 7.08. $E^{0\prime}$ = +0.21 V (vs. Fc/Fc$^+$).

[*t*BuN^aC^{b}H=C^{c}C^{d}H=C^{e}HC^{f}H=C^{g}HN^hBC_5H_4](C_5H_5)Fe(*N*^{a}–*B*,*N*^{h}–*C*^{e}) (11): Solutions of (dibromoboryl)ferrocene (**1**; 1.70 g, 4.78 mmol) and *N*-(2-pyridylmethylene)-*tert*-butylamine (0.70 g, 4.78 mmol), each in *n*-hexane (20 mL), were simultaneously added dropwise to *n*-hexane (50 mL). Stirring for 4 h led to the precipitation of borolium salt **10** as an olive-green solid [^{11}B{^{1}H} NMR (CD_3CN): δ = 6.3, 7.8 ppm]. Sodium amalgam (obtained from 0.23 g of Na and 213 g of Hg) was added and the suspension was stirred in the dark for 3 d. The *n*-hexane phase was decanted and concentrated until the beginning of cloudiness. Storing at –80 °C for 2 d gave 1.16 g (68% yield) of **11** as an orange solid. ^{1}H NMR (C_6D_6): δ = 1.35 (s, 9 H, *t*Bu), 4.00 (s, 5 H, C_5H_5), 4.21 (s, 2 H, C_5H_4), 4.31 (s, 2 H, C_5H_4), 5.78 (m, 1 H, CH), 6.16 (m, 1 H, CH), 6.47 (s, 1 H, *t*BuNC*H*), 6.78 (m, 1 H, CH), 8.33 (s, 1 H, CH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 32.6 [s, C(*C*H$_3$)$_3$], 53.7 [s, *C*(CH$_3$)$_3$], 68.0 (s, C_5H_4), 68.7 (s, C_5H_5), 69.7 (s, C_5H_4), 74.4(s, C_5H_4), 105.1 (s, *t*BuN*C*H), 105.7 (s, CH), 117.7 (s, CH), 119.0 (s, CH), 126.6 (s, *t*BuNCH=*C*), 130.9 (s, CH) ppm. ^{11}B{^{1}H} NMR (C_6D_6): δ = 23.9 ppm. MS-EI: *m*/*z* (%)= 318 (9) [M$^+$ – 2 CH_3]. $C_{20}H_{23}BFeN_2$ (358.09): calcd. C 67.08, H 6.47, N 7.82; because of the thermolability of **11** no reliable elemental analyses could be obtained. $E^{0\prime}$ = –0.32 V (vs. Fc/Fc$^+$).

[{η^5-$C_5H_4BN^a$(*t*Bu)$CH_2CH_2N^b$(*t*Bu)}(η^5-C_5H_5)Fe](*B*–*N*^{b}) (13): A solution of **1** (2.80 g, 7.8 mmol) in *n*-hexane (10 mL) was added to a chilled (0 °C) solution of NEt_3 (1.60 g, 15.6 mmol) in *n*-hexane (50 mL). It was warmed to room temp., 1.40 g (8.00 mmol) of neat *N*,*N*′-di-*tert*-butylethane-1,2-diamine was added dropwise, and the mixture was heated under reflux for 3 h. It was then filtered and the filtrate was concentrated to dryness. Distillation of the residue at 250 °C and 10^{-6} bar afforded 2.46 g (86%) of product **13** as a red oil (b.p. 210 °C, 10^{-6} bar). ^{1}H NMR (C_6D_6): δ = 1.26 (s, 18 H, *t*Bu), 3.11 (s, 4 H, NCH_2), 4.08 (s, 5 H, C_5H_5), 4.18 (s, 2 H) and 4.19 (s, 2 H, C_5H_4B) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 31.3 [s, C(*C*H$_3$)$_3$], 45.5 (s, NCH_2), 51.7 [s, *C*(CH$_3$)$_3$], 68.3 (s) and 76.2 (s, C_5H_4B), 69.6 (s, C_5H_5) ppm. ^{11}B{^{1}H} NMR (C_6D_6): δ = 31.8 ppm. MS-EI: *m*/*z* (%) = 366 (63) [M$^+$], 351 (20) [M$^+$ – CH_3], 294 (31) [M$^+$ – *t*Bu – H$^+$]. $C_{20}H_{31}BFeN_2$ (366.64): calcd. C 65.46, H 8.51, N 7.63; found C 64.82, H 8.69, N 7.40. $E^{0\prime}$ = –0.11 V (vs. Fc/Fc$^+$).

[{$C_5H_4BN^a$(*t*Bu)$CH_2CH_2N^b$(*t*Bu)}$_2$Fe](*B*–*N*$_b$) (14): A solution of **4** (4.00 g, 7.6 mmol) in *n*-hexane (40 mL) was added dropwise to a chilled (0 °C) solution of Et_3N (3.08 g, 30.4 mmol) in *n*-hexane (100 mL). The mixture was then warmed to room temp., combined with neat *N*,*N*′-di-*tert*-butylethane-1,2-diamine (2.63 g, 15.2 mmol), and heated under reflux for 4 h. It was then filtered and the filtrate concentrated to dryness. The deep-red solid residue was dissolved in *n*-hexane (20 mL), and the solution was stored at –80 °C for 7 d to give 3.62 g (87% yield) of red solid **14**. ^{1}H NMR (C_6D_6): δ = 1.43 (s, 18 H, *t*Bu), 3.23 (s, 8 H, NCH_2), 4.30 and 4.44 (m, 8 H, C_5H_4B) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 31.4 [C(*C*H$_3$)$_3$], 45.5 (s, NCH_2), 51.8 [s, *C*(CH$_3$)$_3$], 68.9 [s, C(3),(4)], 79.0 [s, C(2),(5)] ppm. ^{11}B{^{1}H} NMR (C_6D_6): δ = 31.8 ppm. Asymmetric [2+2] Cycloaddition of (*E*)-2-(Diphenylphosphanyl)styrene Promoted by a Chiral Metal Template

Wee-Chuan Yeo,[a] Geok-Kheng Tan,[a] Lip Lin Koh,[a] and Pak-Hing Leung*[b]

Keywords: Asymmetric synthesis / Cycloaddition / Platinum / Phosphane ligands / Template synthesis

An organoplatinum complex containing the (*S*)-form of orthometalated [1-(dimethylamino)ethyl]naphthalene as the chiral auxiliary promotes the asymmetric [2+2] dimerization of (*E*)-2-(diphenylphosphanyl)styrene to generate two isomeric chelating diphosphanyl-substituted cyclobutane platinum template complexes in the ratio of 6:1. The four substituents on the cyclobutane rings adopt the pseudo-equatorial positions with an *all-trans* arrangement. The naphthylamine auxiliary can be removed chemoselectively from the template products by treatment with concentrated hydrochloric acid to form the corresponding dichloroplatinum(II) complexes, which, upon subsequent ligand displacement with aqueous cyanide, liberate the enantiomerically enriched free diphosphane ligand in high yields. Recomplexation of the liberated diphosphane to the (*R*)-form of the platinum template, followed by fractional crystallization, allows separation of the optically pure platinum template complex containing the diphosphane ligand (1*R*,2*R*,3*R*,4*R*)-1,2-bis(diphenylphosphanyl)-3,4-diphenylcyclobutane, from which the free diphosphane can be subsequently liberated efficiently.

Introduction

The [2+2] cycloaddition reaction is an important method for the synthesis of cyclobutane derivatives.[1] According to the Woodward–Hoffmann rules, concerted thermal $[_{\pi}2_{s}+_{\pi}2_{s}]$ cycloadditions are symmetry-forbidden, but reactions involving $[_{\pi}2_{s}+_{\pi}2_{a}]$ cycloaddition, stepwise addition involving biradical or zwitterionic intermediates, and photocycloaddition are possible.[2] Lewis acids[3] and transition metal complexes[4] have been shown to be useful for the activation of the [2+2] cycloaddition reaction. Recently, it has been reported that the intramolecular [2+2] photochemical dimerization of *trans*-1,2-bis(diphenylphosphanyl)-ethene can be promoted efficiently by platinum and palladium ions.[5] The resultant tetradentate phosphane and other phosphane ligands with the cyclobutane backbone have been successfully applied to many metal-catalyzed reactions.[6]

Over the years, chiral cyclometalated-amine complexes have contributed significantly in many aspects of synthetic chemistry. These organometallic compounds have been used as resolving agents for chiral ligands,[7] clear and reliable references for the NMR assignment of unknown absolute configurations,[7g,8] chiral derivatizing agents (CDAs) for enantiomeric purity determination of chiral compounds,[9] efficient chiral catalysts for asymmetric Claisen rearrangements,[10] reaction promoters for the oxidative coupling between vinylphosphanes and imines,[11] chiral templates for asymmetric Diels–Alder reactions,[12] asymmetric hydroamination,[13] and hydrophosphanylation[14] reactions. In pursing our interest in the application of chiral cyclometalated-amine complexes in asymmetric transformations, we present here the organoplatinum-promoted asymmetric [2+2] dimerization of (*E*)-2-(diphenylphosphanyl)styrene.

Results and Discussion

In the absence of a metal ion, no dimerization of (*E*)-2-(diphenylphosphanyl)styrene is observed upon heating. In principle, the use of the chiral metal promoter (*S*)-**1** for this reaction could be beneficial in several aspects as it could: (a) provide electronic activation, (b) enable the *cis* coordinated vinylphosphane ligands to approach each other closely for the intramolecular cycloaddition reaction, and (c) provide stereochemical induction. Indeed, upon removal of the chloro ligands with silver tetrafluoroborate,[12b,12c,15] the chiral metal template (*S*)-**1** promotes the targeted asymmetric [2+2] cycloaddition reaction of (*E*)-2-(diphenylphosphanyl)styrene (Scheme 1). The reaction is complete after refluxing the mixture in toluene for four days. Prior to purification, the ^{31}P NMR spectrum of the crude reaction mixture in $CDCl_3$ indicated that two major products, together with (*E*)-diphenylstyrylphosphane oxide and trace amounts of other, as-yet unidentified compounds, had formed. The two desired major products − the diastereomeric cycloadducts (*S*)-**2** and (*S*)-**3** − exhibit two pairs of doublet phos-

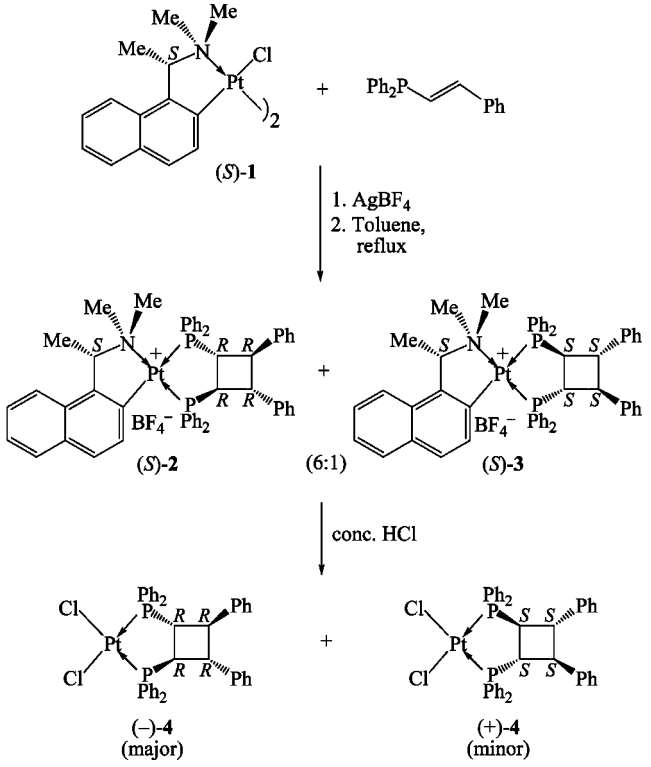
phorus resonance signals at δ = 30.3 ($J_{P,P}$ = 15.3, $J_{Pt,P}$ = 3719 Hz) and 35.2 ppm ($J_{P,P}$ = 15.3, $J_{Pt,P}$ = 1793 Hz) and δ = 29.4 ($J_{P,P}$ = 15.3, $J_{Pt,P}$ = 3780 Hz) and 35.9 ppm ($J_{P,P}$ = 15.3, $J_{Pt,P}$ = 1789 Hz)], respectively, with an intensity ratio of 6:1. It is important to note that this reaction is sensitive to the counterion present. With the tetrafluoroborate or hexafluorophosphate anion, the two desired products, (*S*)-**2** and (*S*)-**3** were formed predominantly. Between the tetrafluoroborate and hexafluorophosphate anions, the use of the former is somewhat more efficient as slightly fewer side-products are formed. However, when perchlorate was used as the counterion, the amount of (*E*)-diphenylstyrylphosphane oxide formed increased significantly, and only trace amounts of the desired cycloadducts were formed (<10%), under identical conditions. The use of a lower reaction temperature also resulted in lower yields of cycloaddition products.



Scheme 1.

The two cycloadducts generated could not, however, be purified by fractional crystallization or column chromatography, hence the naphthylamine auxiliary was removed by treatment with concentrated hydrochloric acid to generate the corresponding dichloro complexes (Scheme 1). After purification by column chromatography and fractional crystallization, an enantiomerically enriched mixture of dichloro complexes **4** [enriched in (–)-**4**] was obtained as colorless crystals. Despite repeated recrystallization, dichloro complex (–)-**4** could not be isolated in its enantiomerically pure state [the optical purity was checked by liberation of the free diphosphane ligand and recoordination to the chiral dimeric complexes (*S*)-**1** and (*R*)-**1** separately, see below]. The X-ray crystallographic analysis of a single crystal from the enantiomeric mixture of dichloro complexes **4** indeed showed that both enantiomers were present in the unit cell. The structure of one of the enantiomers is shown in Figure 1, and selected bond lengths and angles are given in Table 1. The structural analysis confirmed that the tetrasubstituted cyclobutane adducts were formed as depicted in Scheme 1. The cyclobutane ring in **4** is folded with an angle of 142.4° between the C(9)–C(1)–C(2) and C(9)–C(10)–C(2) planes. All the diphenylphosphanyl and phenyl substituents on the cyclobutane ring adopt the pseudo-equatorial positions with an *all-trans* arrangement. The two phosphorus atoms are equivalent as the molecule is C_2-symmetrical, and indeed the ^{31}P NMR spectrum of **4** in $CDCl_3$ exhibits only a singlet at δ = 26.8 ppm ($J_{Pt,P}$ = 3727 Hz).

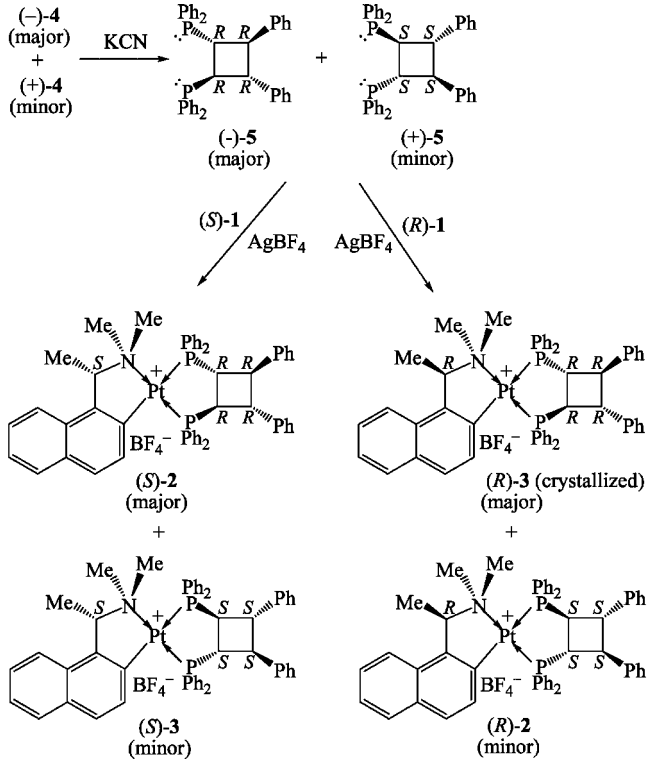
in (–)-**5**] in quantitative yield (Scheme 2). The ^{31}P NMR spectrum of **5** in $CDCl_3$ shows a singlet resonance signal at $\delta = -0.5$ ppm. Recomplexation of the liberated C_2-symmetrical diphosphane ligands **5** to the optically pure dimeric complex (*R*)-**1**, followed by replacement of the chloride counterion with a tetrafluoroborate ion, gave two diastereomeric products, (*R*)-**3** and (*R*)-**2**, in a ratio of 5:1 (Scheme 2), which indicated the presence of both enantiomeric forms of **5** in the liberated diphosphane mixture. Importantly, these two recomplexation products exhibit identical ^{31}P NMR spectra to those recorded for the two cycloadducts generated directly from the asymmetric [2+2] cycloaddition reaction. Eventually, the major recomplexation product, with phosphorus resonance signals at $\delta = 29.4$ ($J_{P,P} = 15.3$, $J_{Pt,P} = 3780$ Hz) and 35.9 ppm ($J_{P,P} = 15.3$, $J_{Pt,P} = 1789$ Hz), could be isolated in a diastereomerically pure form by fractional crystallization from dichloromethane/diethyl ether as colorless crystals in 66% yield {$[\alpha]_D = +148$ (CH_2Cl_2)}. Due to the unique *trans*-electronic influences which originate from the organoplatinum unit, the larger platinum–phosphorus coupling constant observed for the doublet signal at $\delta = 29.4$ ppm is diagnostic of the PPh_2 group coordinated *trans* to the σ-donating nitrogen atom.[12b,12c,15] On the other hand, the doublet at $\delta = 35.9$ ppm, which shows the smaller platinum–phosphorus coupling constant, is unambiguously assigned to the PPh_2 group that is coordinated *trans* to the strong π-accepting orthometalated carbon atom. This crystalline product was confirmed by X-ray crystallography to be complex (*R*)-**3**, as shown in Scheme 2 and Figure 2. Selected bond lengths and angles are given in Table 2. The cyclobutane ring in complex (*R*)-**3** is folded with an angle of 141.9° between the C(16)–C(15)–C(18) and C(16)–C(17)–C(18) planes. The absolute configurations at C(11), C(15), C(16), C(17), and C(18) are established to be *R*, *R*, *R*, *R*, and *R*, respectively, with the diphenylphosphanyl and phenyl substituents on the cyclobutane ring adopting the pseudo-equatorial positions in an *all-trans* arrangement. The minor recomplexation product was assigned to complex (*R*)-**2**, which differs from (*R*)-**3** only in the absolute configurations of the C_2-symmetrical diphosphane chelate. It is noteworthy that complexes (*R*)-**3** and (*R*)-**2** are the enantiomeric forms of (*S*)-**3** and (*S*)-**2**, respectively. In the absence of any chiral NMR solvent, the NMR spectra of (*R*)-**3** and (*R*)-**2** would show identical resonance signals to those recorded for their enantiomeric counterparts. Hence from the ^{31}P NMR spectroscopic data it could be established that complex (*S*)-**3** is



Scheme 2.

the minor component of the diastereomeric mixture generated directly from the asymmetric dimerization reaction, while complex (*S*)-**2** is the major cycloaddition product formed.

Recomplexation of the liberated enantiomerically enriched diphosphane ligands **5** to (*S*)-**1**, followed by treatment with silver tetrafluoroborate, gave the two diastereomeric complexes (*S*)-**2** and (*S*)-**3** in a ratio of 5:1 (Scheme 2). This is in agreement with the earlier assignments of the respective complexes and the presence of both enantiomers of **5** in the liberated diphosphane mixture.

Enantiomerically pure diphosphane ligand (–)-**5** {$[\alpha]_D$ = –108 ($CHCl_3$)}, was obtained in 87% yield by similar treatment of the diastereomerically pure complex (*R*)-**3** with concentrated hydrochloric acid, followed by ligand displacement with aqueous cyanide. Recomplexation of (–)-**5** to (*S*)-**1**, followed by replacement of the chloride counterion with a tetrafluoroborate ion, gave complex (*S*)-**2** as the sole product. This confirmed the optical purity of the diphosphane ligand (–)-**5** and reaffirmed the earlier assignments of the cycloadducts and recomplexation products.

From these recoordination experiments and spectroscopic and crystallographic studies, the two cycloadducts generated by [2+2] cycloaddition reaction of (*E*)-2-(diphenylphosphanyl)styrene promoted by the chiral metal complex [(*S*)-**1**] were established to be complexes (*S*)-**2** and (*S*)-**3** in the ratio of 6:1, respectively. This dimerization reaction proceeds with high stereoselectivity and the substituents on the cyclobutane ring of the cycloadducts generated adopt the pseudo-equatorial positions with an *all-trans* arrangement, while the diastereoselectivity of the reaction is moderately high [(*S*)-**2**:(*S*)-**3** = 6:1]. Similarly, the enantiomeric products (*R*)-**2** and (*R*)-**3** can be obtained in the same ratio of 6:1 when the equally accessible complex (*R*)-**1** is used as the chiral metal promoter for the cycloaddition reaction. As related transition-metal-assisted thermal or photodimerizations of vinylphosphanes and phospholes have been reported to proceed via a stepwise biradical mechanism,[5,16] it is possible that the present chiral organoplatinum-template-promoted dimerization of (*E*)-2-(diphenylphosphanyl)styrene also follows such a biradical pathway. However, a stepwise addition involving zwitterionic intermediates and a concerted pathway cannot be ruled out.

Experimental Section

Reactions involving air-sensitive compounds were performed under a positive pressure of purified nitrogen. NMR spectra were recorded at 25 °C on Bruker ACF 300 and AMX500 spectrometers. The spectral assignments in the ^{1}H NMR spectra are based on selective decoupling of the two types of ^{31}P nucleus, and NOE data from the 2D-ROESY spectrum.[8b] The phase-sensitive ROESY NMR experiments were acquired into a 1024 × 512 matrix with a 250-ms spin-locking time and a spin-lock field strength such that $\gamma B_1/2\pi$ = 5000 Hz and then transformed into 1024 × 1024 points using a sine bell weighting function in both dimensions. Optical rotations were measured on the specified solution in a 0.1-dm cell at 25 °C with a Perkin–Elmer Model 341 polarimeter. Melting points were determined on a Büchi melting point B-540. Elemental analyses were performed by the Elemental Analysis Laboratory of the Department of Chemistry at the National University of Singapore.

(*E*)-2-(diphenylphosphanyl)styrene[17] and dimeric platinum complexes (*S*)- and (*R*)-**1**[12b] were prepared according to literature methods.

Asymmetric Dimerization of (*E*)-2-(Diphenylphosphanyl)styrene and Removal of the Chiral Naphthylamine Auxiliary: An aqueous solution of silver tetrafluoroborate (0.35 g, 1.80 mmol) was added to a solution of (*S*)-**1** (0.546 g, 0.579 mmol) and (*E*)-2-(diphenylphosphanyl)styrene (0.770 g, 2.40 mmol, 90% pure) in dichloromethane (80 mL). The mixture was stirred vigorously at room temperature for 2 h, then filtered through Celite, washed with water (3 × 80 mL), and dried ($MgSO_4$). After removal of dichloromethane from the mixture, it was redissolved in toluene (350 mL) and refluxed for 4 d. After that the toluene was removed under reduced pressure and the reaction mixture was redissolved in dichloromethane (90 mL). The naphthylamine auxiliary was removed by vigorous stirring of the crude reaction mixture with concentrated hydrochloric acid (25 mL) for 14 h. The mixture was washed with water (4 × 100 mL) and dried ($MgSO_4$). The crude product was chromatographed on a silica column with dichloromethane/acetone (20:1) as eluent. Subsequent fractional crystallization from dichloromethane/petroleum ether gave an enantiomerically enriched mixture of dichloro complexes (–)-**4** and (+)-**4** as colorless crystals: 0.273 g (28% yield). $C_{40}H_{34}Cl_2P_2Pt$ (842.7): calcd. C 57.0, H 4.1; found C 57.0, H 4.1. ^{1}H NMR ($CDCl_3$): δ = 2.69–2.79 (m, 2 H, PC*H*), 3.26–3.34 (m, 2 H, PhC*H*), 6.79–8.19 (m, 30 H, aromatics) ppm. ^{31}P NMR ($CDCl_3$): δ = 26.8 (s, $J_{Pt,P}$ = 3727 Hz, 2 P, P^1, P^2) ppm.

Synthesis and Isolation of [{(*R*)-1-[1-(Dimethylamino)ethyl]naphthyl-*C*^{2},*N*}{(1*R*,2*R*,3*R*,4*R*)-1,2-bis(diphenylphosphanyl)-3,4-diphenylcyclobutane-*P*^{1},*P*^{2}}]platinum(II) Tetrafluoroborate [(*R*)-3]: Enantiomerically enriched dichloro complexes **4** (0.129 g, 0.153 mmol) dissolved in dichloromethane (30 mL) were stirred vigorously with a saturated aqueous solution of potassium cyanide (2 g) for 2 h. The organic portion was separated, washed with water (3 × 25 mL), and dried ($MgSO_4$). After that it was added to a solution of (*R*)-**1** (0.068 g, 0.072 mmol) in dichloromethane (10 mL), followed by the addition of aqueous $AgBF_4$ (0.050 g, 0.26 mmol). The mixture was stirred vigorously for 2 h, then filtered through Celite, washed with water (3 × 40 mL), and dried ($MgSO_4$). Recrystallization of the crude product from dichloromethane/diethyl ether gave complex (*R*)-**3** as colorless crystals: m.p. 278–279 °C (decomp.). $[\alpha]_D$ = +148 (*c* = 0.7, CH_2Cl_2); 0.106 g (66% yield). $C_{54}H_{50}BF_4NP_2Pt$ (1056.8): calcd. C 61.4, H 4.8, N 1.3; found C 61.0, H 4.8, N 1.4. ^{1}H NMR ($CDCl_3$): δ = 1.67 (d, $^3J_{H,H}$ = 6.0 Hz, 3 H, CH*Me*), 2.37–2.52 (m, 1 H, H_1), 2.58–2.73 (m, 1 H, H_2), 2.82 (dd, $^4J_{P,H}$ = 4.3, $^4J_{P,H}$ = 2.7 Hz, 3 H, NMe_{eq}), 3.05–3.17 (m, 1 H, H_3), 3.17 (d, $^4J_{P,H}$ =

1.9 Hz, 3 H, NMe_{ax}), 3.26–3.38 (m, 1 H, H_4), 4.92 (quin, $^3J_{H,H}$ = $^4J_{P,H}$ = 6.0 Hz, 1 H, C*H*Me), 6.57–8.14 (m, 36 H, aromatics), ppm. ^{31}P NMR ($CDCl_3$): δ = 29.4 (d, $J_{P,P}$ = 15.3, $J_{Pt,P}$ = 3780 Hz, 1 P, P^1), 35.9 (d, $J_{P,P}$ = 15.3, $J_{Pt,P}$ = 1789 Hz, 1 P, P^2) ppm.

Liberation of (1*R*,2*R*,3*R*,4*R*)-1,2-Bis(diphenylphosphanyl)-3,4-diphenylcyclobutane [(–)-5]: The naphthylamine auxiliary in complex (*R*)-**3** was first removed chemoselectively by stirring a solution of the complex (0.036 g, 0.034 mmol) vigorously in dichloromethane (12 mL) with concentrated hydrochloric acid (4 mL) at room temperature for 7 h. After that more dichloromethane (15 mL) was added and the mixture was washed with water (4 × 20 mL) and dried ($MgSO_4$). The resultant dichloro complex (–)-**4** solution was stirred vigorously with a saturated aqueous solution of KCN (2 g) for 2 h. The organic portion was separated, washed with water (3 × 30 mL), and dried ($MgSO_4$). A white solid was obtained after removal of the solvent: $[\alpha]_D$ = –108 (*c* = 0.6, $CHCl_3$); 0.017 g (87% yield). $C_{40}H_{34}P_2$ (576.7): calcd. C 83.3, H 5.9; found C 82.9, H 6.1. ^{1}H NMR ($CDCl_3$): δ = 3.20–3.37 (m, 4 H, PC*H*, PhC*H*), 6.65–7.44 (m, 30 H, aromatics) ppm. ^{31}P NMR ($CDCl_3$): δ = –0.5 (s, 2 P, P^1, P^2), ppm.

Crystal Structure Determination of Complexes 4 and (*R*)-3: X-ray crystallographic data for complexes **4** and (*R*)-**3** are given in Table 3. The structures were analyzed at the National University of Singapore using a Siemens SMART CCD diffractometer with graphic monochromated Mo-K_α radiation. SADABS absorption corrections were applied for both complexes. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced at a fixed distance from carbon atoms and were assigned fixed thermal parameters. The absolute configurations of complex (*R*)-**3** was determined unambiguously using the Flack parameter.[18]

Experimental and Theoretical Study of the Encapsulation of a Linear Oligo(ferrocenylsilane) Trimer with β-Cyclodextrin

José A. Fernandes,[a] Sérgio Lima,[a] Susana S. Braga,[a] Martyn Pillinger,[a] José E. Rodríguez-Borges,[b] Paulo Ribeiro-Claro,*[a] José J. C. Teixeira-Dias,[a] and Isabel S. Gonçalves*[a]

Keywords: Cyclodextrins / Ferrocene / Inclusion compounds / Oligo(ferrocenes) / Ab initio calculations

An inclusion compound comprising β-cyclodextrin (β-CD) and the trimetallic oligo(ferrocenylsilane) $FcSiMe_2[(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_4SiMe_2)]Fc$ [Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$] has been prepared and characterised in the solid state by elemental analysis, powder X-ray diffraction, thermogravimetric analysis and magic angle spinning NMR spectroscopy (^{13}C, ^{29}Si). The results are consistent with the formation of a 2:1 (host-to-guest) inclusion complex. Ab initio calculations were carried out in order to investigate the possible inclusion geometries. The best host–guest fit was obtained for a tilted geometry of the ferrocene fragment relative to the β-CD axis (φ = 29°) with a 140-pm inclusion of the corresponding Fe centre below the plane of the rim. The structure of the organometallic trimer allows its inclusion interaction with a second β-CD host, leading to the 2:1 stoichiometry.

Introduction

Ferrocene has captured the interest of chemists, leading to the formation of countless derivatives with applications in areas as diverse as catalysis,[1] nonlinear optics,[2] electrochemistry,[3] medicine and biology.[4] Recently, macromolecular derivatives with luminescent properties have been created, with promising applications in biosciences.[5] Polymers containing ferrocene units either in the side chain or in the main chain have also attracted increasing attention as they may feature new electrical, optical or even magnetic properties.[6] Research into main chain polymers began to really expand with the development of new polymerisation techniques, in particular the discovery of the ring-opening polymerisation (ROP) of strained [1]ferrocenophanes.[7] ROP of silicon-bridged [1]ferrocenophanes gives poly(ferrocenylsilanes), which have been shown to yield magnetic composite ceramics at 500–1000 °C.[8] Poly(ferrocenylsilanes) are thermoplastic materials that become liquid above 150 °C and can be shaped into films, tablets or nanometric fibres.[9] Their thermoplastic properties are a result of the molecular flexibility and of the helix-shaped molecular packing. In order to gain insight into the conformation and packing of these polymers in the solid state, linear oligo(ferrocenes) have been prepared and studied by single-crystal X-ray diffraction and computer modelling.[10,11] The structure observed for the pentamer, $FcSiMe_2[(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_4SiMe_2)]_nFc$ [Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$, n = 3], appears to be a good model for the corresponding prototypical high polymer, poly(ferrocenyldimethylsilane).[10a,10b]

The oligo(ferrocenyldimethylsilanes) with n = 0–7 can be prepared by the anionic ring-opening oligomerisation of (1,1′-ferrocenediyl)dimethylsilane (**1**). The [1]ferrocenophane **1** is also the precursor used to prepare the corresponding high polymers (by ROP). We recently reported on the modification of β-cyclodextrin (β-CD) with ferrocenyl groups by ring-opening of encapsulated molecules of **1**.[12] This work has led us to study the interaction of cyclodextrins with oligo(ferrocenyldimethylsilanes).[13] CDs are cyclic oligosaccharides capable of binding hydrophobic molecules, called guests, noncovalently in the ring cavity. Inclusion of ferrocene in α-, β- and γ-CDs was first described in 1984.[14] Since then, the binding of a broad variety of ferrocene derivatives with CDs has been reported.[15] However, to the best of our knowledge, the only ferrocene–cyclodextrin adduct to be successfully characterised by single-crystal X-ray diffraction is the 2:1 (host-to-guest) α-CD–ferrocene complex.[16] This makes theoretical calculations a very important tool to evaluate the structures of CD–organometallic inclusion compounds. Two possible inclusion geometries of ferrocene derivatives in cyclodextrins were proposed by Harada and Takahashi,[14] namely axial and equatorial inclusion. Molecular mechanics studies in 1988 confirmed Harada's conclusions.[17] In the present work, we describe an experimental and theoretical study of the interaction of the trimer $FcSiMe_2[(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_4SiMe_2)]Fc$ (**2**) with β-CD. We anticipated that these

studies would yield information about the flexibility and conformation of the oligo(ferrocenes), as well as providing a new family of potentially interesting organometallic-cyclodextrin inclusion compounds.

Results and Discussion

Synthesis and Characterisation

A solution of the trimer $FcSiMe_2[(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_4SiMe_2)]Fc$ (**2**) in CH_2Cl_2 was added to an aqueous solution of β-CD at 50 °C, in a 2:1 (β-CD:**2**) stoichiometry. A pale orange solid precipitated slowly at the interface between the two solutions. After stirring the mixture for 4 days, the product was isolated by decantation and rinsed with water. Elemental analysis indicated the formation of a 2:1 (host-to-guest) inclusion compound, designated as $(\beta\text{-CD})_2\cdot\mathbf{2}$. The yield was 36%. Figure 1 shows the powder XRD patterns for pristine β-CD hydrate, the trimer **2** and the product $(\beta\text{-CD})_2\cdot\mathbf{2}$. The pattern for $(\beta\text{-CD})_2\cdot\mathbf{2}$ indicates that the solid is microcrystalline and does not contain measurable amounts of either pure β-CD or compound **2**. The formation of a new phase is a good indication for the presence of a true inclusion compound.[18] Elemental analysis and thermogravimetry (TG, not shown) showed that the encapsulation of the trimetallic guest was accompanied by a slight decrease in the overall crystal water contents, from 14.4% for β-CD (10–11 water molecules per β-CD molecule) to 8.5% for $(\beta\text{-CD})_2\cdot\mathbf{2}$ (about 8 water molecules per β-CD molecule). This is usual for CD inclusion complexes, as a certain fraction of the water molecules initially present in the cyclodextrin cavity must be expelled upon encapsulation of the guest molecule. TG of $(\beta\text{-CD})_2\cdot\mathbf{2}$ showed a second mass loss of about 60% between 250 and 315 °C, because of simultaneous decomposition of the guest and the host. The fact that the two components decompose in the same range is another indication for the formation of an inclusion complex.

Figure 2 shows the solid-state ^{13}C CP MAS NMR spectra of β-CD hydrate, the trimer **2** and the inclusion compound $(\beta\text{-CD})_2\cdot\mathbf{2}$. The spectrum of β-CD hydrate is similar to that reported previously and exhibits multiple resonances for each type of carbon atom.[19,20] This has been mainly correlated with different torsion angles about the (1→4) linkages for C-1 and C-4,[19] and with torsion angles describing the orientation of the hydroxy groups.[20] The different carbon resonances are assigned to C-1 (101–104 ppm), C-4 (78–84 ppm), C-2,3,5 (71–76 ppm) and C-6 (57–65 ppm). The spectrum of the trimer **2** shows single sharp peaks for the Cp ($\eta^5\text{-}C_5H_5$) and methyl groups at 68.5 and 0 ppm, respectively. Several overlapping signals in the range 71–73 ppm are assigned to the carbon atoms of substituted cyclopentadienyl rings. In the spectrum of $(\beta\text{-CD})_2\cdot\mathbf{2}$, a single sharp peak is observed at δ = 68.6 ppm for the guest Cp group, and the methyl groups give rise to one main peak at 0.5 ppm. The multiplicities in the resonances for the β-CD carbon atoms are reduced in the spectrum of the inclusion compound, giving broad signals with very little structure. This is a common result for CD inclusion compounds containing either organic or organometallic guests, and can be attributed to an increase in the symmetry of the

β-CD macrocycle upon inclusion complexation.[21] In other words, encapsulation of the guest molecule induces the ring to adopt a more symmetrical conformation, with each glucose unit in a similar environment. ^{29}Si CP MAS NMR spectra were also recorded for the trimer **2** and (β-CD)$_2$·**2** (Figure 3). Crystalline **2** exhibits one fairly broad peak for the bridging dimethylsilyl group at δ = –8.0 ppm. After inclusion in β-CD, four resolved signals are found at –6.7, –6.9, –7.6 and –8.0 ppm. At the time of writing, attempts to prepare single crystals of the inclusion compound suitable for X-ray diffraction have been unsuccessful. Therefore, we cannot be certain about the reasons for having nonequivalent silicon nuclei in the complex. It may simply be due to crystal packing effects, subtle conformational changes of the guest molecule, variations in the host–guest interaction (even within a single β-CD/trimer complex) and/or the effect of inclusion complexation, which results in "isolation" of the trimetallic guest. It is interesting to note that the ^{29}Si NMR resonances for solutions of oligo(ferrocenyldimethylsilanes), FcSiMe$_2$[(η^5-C$_5$H$_4$)Fe(η^5-C$_5$H$_4$SiMe$_2$)]$_n$Fc (n = 0–7), are all found at –6.6 ± 0.1 ppm.[10a,10b]

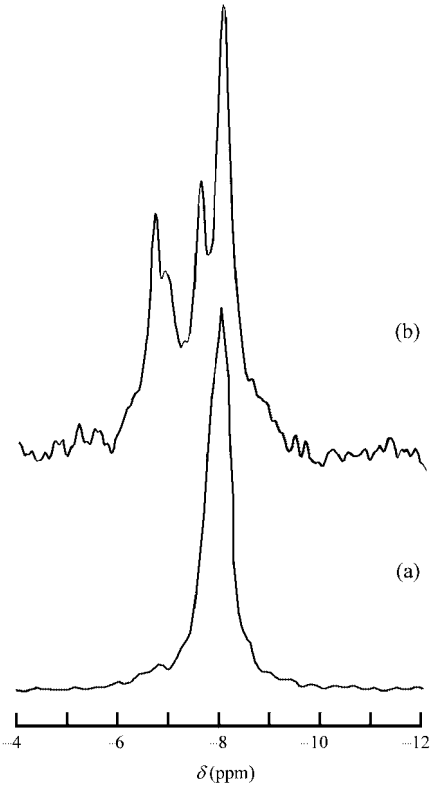

Figure 3. Solid-state ^{29}Si CP MAS NMR spectra of the trimer **2** (a) and the inclusion compound (β-CD)$_2$·**2** (b).

Ab Initio Calculations

Ab initio calculations were used in order to obtain information concerning the possible inclusion geometries, with particular attention being given to the plausibility of the host–guest fit. Figure 4 presents three conformers found for 1,1′-bis(ferrocenyldimethylsilyl)ferrocene (**2**). These conformers were obtained from a set of different starting geometries (generated by the combination of *trans* and *gauche* Fe–C$_{(ring)}$–Si–C$_{(ring)}$ dihedral angles) and are thought to be representative of the minimum energy configurations for the trimer. The most stable form, **2a**, has a helical-type structure, with Fe–C$_{(ring)}$–Si–C$_{(ring)}$ dihedral angles of about 103°, 156° and 66°, 69°. Conformers **2b** and **2c** lie above **2a** by about 4.7 and 5.9 kJ·mol^{-1}, respectively. Conformer **2b** mimics the extended structure found in the crystal and conformer **2c** has a ladder-type structure. The relative orientations of the cyclopentadienyl rings in the ferrocene units of **2b** are staggered for the central ferrocene and eclipsed for the terminal ones, as found in the crystal.[10d] The preference for the staggered configuration in the central ferrocene fragment in **2b** is probably due to repulsion between the substituent groups. In fact, for ferrocene itself, calculations at the same level predict the eclipsed D_{5h} form to be about 3.1 kJ·mol^{-1} more stable than the staggered D_{5d} form.

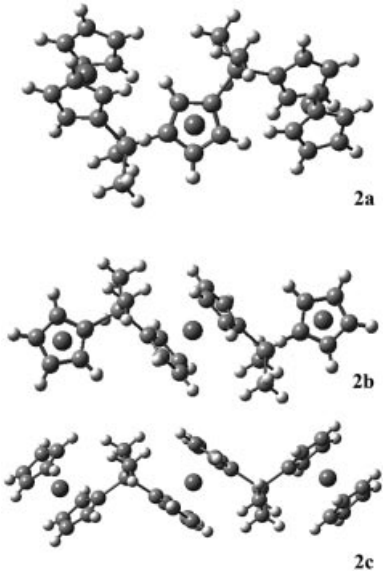

Figure 4. The three conformers found for the trimer **2**.

Figure 5 shows the definition of the coordinates used in the geometry scanning procedure to locate the best inclusion geometry of ferrocene units in β-CD. In a first step, the inclusion geometry of the complex containing ferrocene itself was determined in order to assess the reliability of the method used and to provide a starting point for the search of optimum β-CD·**2** inclusion geometries. Three different structures were found for the β-CD·ferrocene adduct (Figure 6). The lowest energy structure is achieved with axial orientation of the ferrocene guest, with ΔE = –102 kJ·mol^{-1} and z_{Fe} = –380 pm (Figure 6, b). This is a less-common structure, with the ferrocene guest protruding from the lower rim of the β-CD. The equatorial orientation shown in Figure 6 (a) has an inclusion energy of –28 kJ·mol^{-1} and z_{Fe} = –30 pm. The possible occurrence of a tilted inclusion geometry, as found for the (α-CD)$_2$·ferrocene complex,[16] was tested. A stable geometry was found at (r_{Fe}, z_{Fe}) = (100, –40) pm and φ = 18°, with an inclusion energy of –70 kJ·mol^{-1}. As expected, a and θ values present sevenfold

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and fivefold periodicity, with barriers between minima of about 8 and 23 kJ·mol^{-1}, respectively. This structure, represented in part c of Figure 6, was considered to be the most reasonable starting point for the calculations of the β-CD·**2** inclusion geometry.

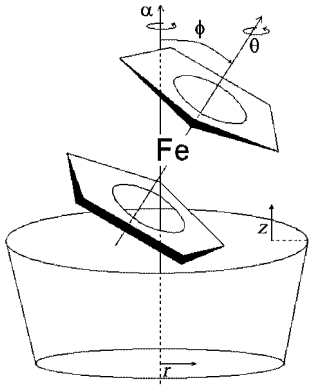

Figure 5. Definition of the variables used in the single-point scanning calculations.

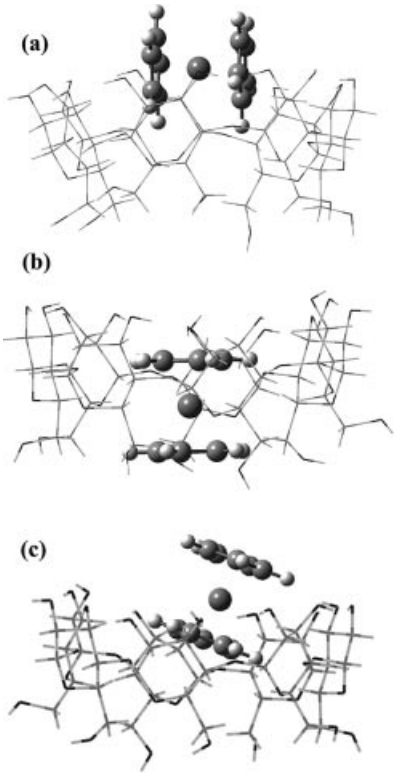

Figure 6. Inclusion geometries found for the β-CD·ferrocene adduct: (a) equatorial, (b) axial and (c) tilted.

Figure 7 shows the minimum energy structure found for the complex β-CD·**2b**. Structure **2b** was selected for the guest because it provides a better host–guest fit than either **2a** or **2c**. The corresponding optimised values are (r_{Fe}, z_{Fe}) = (110, –140) pm and φ = 29°. This structure presents some short contact interactions between the oxygen atoms of β-CD and the cyclopentadienyl hydrogen atoms of terminal and central ferrocenes. These C–H···O interactions, which lie within the 208–244 pm range, are likely to contribute to the stability of the complex.[22]

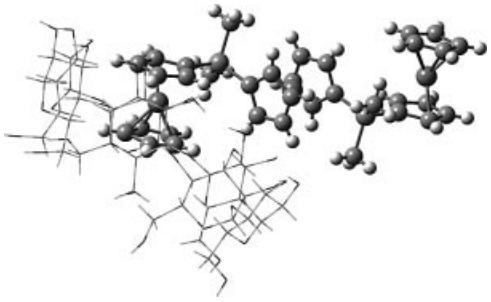

Figure 7. Best geometry obtained for a 1:1 inclusion compound comprising β-CD and **2b**.

The reliability of the inclusion geometries obtained at different computational levels has recently been assessed by Casadesús et al.,[23] based on the occurrence of unrealistic H···H host–guest contacts. In the present structure, there are only three H···H contacts which fall below the 220-pm limit (at 184, 209 and 212 pm). As noted in ref.[23], a small number of short contacts is acceptable and even values below 200 pm are not necessarily unphysical. Thus we may assume that the calculated structure is plausible, despite the well-known limitations of the present approach.

The 2:1 inclusion complex (β-CD)$_2$·**2b** was built from the previous 1:1 structure using the symmetry properties of the inversion centre located at the central iron atom of the guest molecule (Figure 8). This operation assumes that the two CD host molecules do not interact with one another, which is a reasonable approximation for the structure shown, because the distance between the two CDs is about 7 Å. The inclusion energy found for the 2:1 adduct (–302 kJ·mol^{-1}) is roughly double that for the 1:1 adduct (–157 kJ·mol^{-1}), as would be expected. Both values are quite large compared with the corresponding value of –70 kJ·mol^{-1} for the β-CD·ferrocene complex. This increase can be explained by the additional interaction provided by the central ferrocenyl moiety with the CD hosts. Nevertheless, a word of caution is required concerning the magnitude of these values, as they are not corrected for basis set superposition error (BSSE), expected to be important when small basis sets are used, or for zero point vibrational energy (the BSSE correc-

tion is not available for ONIOM calculations and frequency calculations only apply to fully-optimised structures).

Conclusions

The encapsulation of a trimetallic oligo(ferrocenyldimethylsilane) by β-cyclodextrin has been achieved and supported by a combination of experimental and theoretical methods. This compound and the corresponding adduct containing diferrocenyldimethylsilane are a potentially interesting family of organic–organometallic inclusion compounds. Future work in our laboratories will be directed towards investigating the effect of CD inclusion on certain properties of the guest molecules, for example, their electrochemical behaviour. We are also studying the interaction of the oligo(ferrocenes) with other CDs, such as α- and γ-CD.

Experimental Section

General Methods and Procedures: All air-sensitive reactions and manipulations were performed using standard Schlenk techniques under oxygen-free and water-free argon. Solvents were dried by standard procedures (*n*-hexane, THF and Et_2O over Na/benzophenone ketyl; CH_2Cl_2 and NCMe over CaH_2), distilled under argon and kept over 4-Å molecular sieves. β-CD (Fluka) and ferrocene (Aldrich) were obtained from commercial sources and used as received. Monolithioferrocene[24] and (1,1′-ferrocenediyl)dimethylsilane (**1**)[13] were prepared using published procedures.

Microanalyses for CHN were performed at the ITQB, Oeiras, Portugal (by C. Almeida), and Fe was determined by ICP-AES at the Central Laboratory for Analysis, University of Aveiro (by E. Soares). Powder XRD data were collected with a Philips X′pert diffractometer using Cu-K_α radiation filtered by Ni (λ = 1.5418 Å). TGA studies were performed using a Mettler TA3000 system at a heating rate of 5 K·min^{-1} under static air. Infrared spectra were recorded with a Unican Mattson Mod 7000 FTIR spectrophotometer using KBr pellets. Solid state ^{13}C and ^{29}Si CP MAS NMR spectra were recorded at 100.62 and 79.49 MHz respectively, on a (9.4-T) Bruker Avance MSL 400P spectrometer. ^{13}C CP MAS NMR spectra were recorded with 4.5 μs ^1H 90° pulses, 1.0 ms contact time, a spinning rate of 5.0 kHz and 4-s recycle delays. ^{29}Si CP MAS NMR spectra were recorded with 5 μs ^1H 40° pulses, 5.0 ms contact time, a spinning rate of 5.0 kHz and 5-s recycle delays. Chemical shifts are quoted in parts per million from TMS.

1,1′-Bis(ferrocenyldimethylsilyl)ferrocene (2): Following the literature method,[10a,10b] a mixture of ferrocenylsilane oligomers was obtained from the reaction of (1,1′-ferrocenediyl)dimethylsilane (**1**) (15.4 g, 64 mmol) with monolithioferrocene (29.6 mg, 108 mmol). The mixture was fractionated using an alumina chromatographic column (90 active, acidic [Activity I] Merck 0.063–0.200 mm, 70–230 mesh ASTM) and a 9:1 hexane/dichloromethane mixture as the mobile phase. Fractions of 250 mL were collected, of which the first six contained pure ferrocene. Fractions 7–39, containing a mixture of ferrocene, diferrocenyldimethylsilane and 1,1′-bis(ferrocenyldimethylsilyl)ferrocene (**2**), were submitted to a second chromatography using neutral alumina (Typ. 507C Brockmann I, STD grade, Approx. 150 Mesh, 58 Å) and the same mobile phase to yield 0.9 g of pure **2**. Fractions 40–65, containing a mixture of **2**, traces of diferrocenyldimethylsilane and larger oligomers, were also submitted to another chromatography using neutral alumina and 0.15 g of **2** was isolated. The total amount of compound **2** obtained was therefore 1.05 g. ^1H and ^{13}C solution NMR spectroscopic data for **2** were in agreement with those reported.[10a,10b] IR (KBr): $\tilde{\nu}$ = 3096 (m), 3089 (m), 3072 (m), 2958 (m), 2924 (m), 2904 (m), 1419 (m), 1409 (m), 1383 (m), 1367 (m), 1245 (vs), 1164 (vs), 1104 (s), 1036 (vs), 1027 (s), 1000 (m), 895 (m), 886 (m), 863 (m), 820 (vs), 798 (vs), 775 (vs), 666 (m), 486 (s), 434 (s) cm^{-1}. ^{13}C CP MAS NMR: δ = 72.5, 72.1, 71.2 (η^5-C_5H_4), 68.5 (η^5-C_5H_5), 0.0 ($SiMe_2$). ^{29}Si CP MAS NMR: δ = –8.0 ppm ($SiMe_2$).

Reaction of β-CD with 1,1′-Bis(ferrocenyldimethylsilyl)ferrocene [(β-CD)$_2$·2]: β-CD (157 mg, 0.12 mmol) was dissolved in water (10 mL) at 50 °C. This solution was treated with **2** (40 mg, 0.06 mmol) dissolved in CH_2Cl_2 (8 mL). The mixture was stirred for 4 days at room temperature, during which time a homogeneous solid product formed at the water–dichloromethane interface. The mixture was left to settle and the product isolated by centrifugation, washed twice with 2 mL-aliquots of water, and dried under air in a desiccator. Yield: 70 mg (36%). $(C_{42}H_{70}O_{35})_2$·$(C_{34}H_{38}Fe_3Si_2)$·$15H_2O$ (3210.6): calcd. C 44.14, H 6.53, Fe 5.22; found C 43.77, H 6.06, Fe 5.28. IR (KBr): $\tilde{\nu}$ = 3373 (vs), 2925 (m), 1638 (m), 1419 (m), 1383 (m), 1368 (m), 1333 (m), 1299 (m), 1245 (m), 1158 (s), 1105 (s), 1081 (s), 1053 (sh), 1029 (vs), 1002 (s), 938 (m), 861 (m), 819 (m), 797 (m), 775 (m), 756 (m), 703 (m), 665 (m), 606 (m), 576 (m), 530 (m), 502 (m), 482 (m), 444 (m) cm^{-1}. ^{13}C CP MAS NMR: δ = 103.9 (β-CD, C-1), 81.8 (β-CD, C-4), 73.1 (β-CD, C-2,3,5), 68.6 (guest, Cp), 60.8 (β-CD, C-6), 0.5 (guest, $SiMe_2$). ^{29}Si CP MAS NMR: δ = –6.7, –6.9, –7.6, –8.0 ppm (guest, $SiMe_2$).

Computational Details: Ab initio calculations were carried out using the Gaussian 03W programme package, running on a personal computer.[25] Compound **2** and ferrocene were fully optimised at the B3LYP/LanL2DZ level. The internal rotation of Cp rings about the C_5 axis in ferrocene allows the existence of eclipsed (D_{5h}) and staggered (D_{5d}) conformations. For compound **2**, the additional degrees of freedom due to the rotation about the $C_{(ring)}$–Si bonds lead to the existence of several conformers. Some attempts to characterise these conformers using computational methods have been reported in the literature.[10d,11,26] In ferrocene, the eclipsed form was found to be more stable than the staggered form by 2.78 kJ·mol^{-1}.[26] Molecular mechanics studies of **2** yield somewhat conflicting results. While Pannell et al. point to large energy differences between conformers,[10d] Barlow et al. found at least 10 noncentrosymmetrical conformers within an interval of 8.8 kJ·mol^{-1}, with the centrosymmetrical conformers lying 12 kJ·mol^{-1} above the absolute minimum.[11]

The models of the inclusion compound were performed by single-point calculations scanning, using the two-layer approximation of Morokuma et al.,[27] with the organometallic guests treated at high layer (B3LYP/LanL2DZ), and cyclodextrins set as low layer (HF/CEP-4G). The crystal structures of β-cyclodextrin hydrate[28] and the trimer **2**[10c,10d] were used to generate the model for the host and the initial model (structure **2b**) for the guest. The optimisation through single-point calculations was used because of the failure of the built-in optimisation procedures to converge to a stable geometry under the ONIOM conditions. The scanning was performed on a 20 pm/4° grid for the r, z, φ, θ and α coordinates (see Figure 5 for the definition of these coordinates). The minimum energy structure was determined from quadratic interpolation, using the lowest energy points in the grid.

Mixed-Ligand Copper Complexes with 8-Methylthioquinoline and Triphenylphosphane or the *o*-Semiquinone/Catecholate Redox System

Shengfa Ye,[a] Biprajit Sarkar,[a] Mark Niemeyer,[a] and Wolfgang Kaim*[a]

Keywords: Copper / Crystal structure / EPR spectroscopy / Heterocycles / Thioether ligands

The complex $[Cu(MTQ)(PPh_3)_2](BF_4)$, MTQ = 8-methylthioquinoline, exhibits distorted tetrahedral coordination at the copper(I) center. One of two crystallographically independent molecules found in the unit cell exhibits a more pronounced inclination towards a (3+1) coordination arrangement. In comparison to the analogous complex with the related imine/thioether chelate ligand 1-methyl-2-(methylthiomethyl)-*1H*-benzimidazole, the cation $[Cu(MTQ)(PPh_3)_2]^+$ shows stronger bonding of Cu^I to S and weaker interaction with N. With 3,5-di-*tert*-butyl-*o*-semiquinone as co-ligand instead of two PPh_3 ligands a valence-tautomer equilibrium situation involving the copper(II)-catecholate state can be observed by EPR spectroscopy, showing an unusually large isotropic $^{63,65}Cu$ hyperfine coupling of 2.1 mT and an untypically small isotropic *g* value of 1.975.

Introduction

Imino and thioether donor atoms have different characteristics for metal ions, especially for copper in its two biorelevant oxidation states +1 and +2.[1,2] While a "soft" thioether S (such as in methionine) prefers copper(I), the imino function (as in the imidazole ring of histidine) tolerates both the Cu^I and Cu^{II} states.[1,2] In an attempt to mimic the biochemically relevant[3] valence tautomerism [Equation (1)] between the copper(I)-*o*-semiquinone and copper(II)-catecholate combinations, we have used a corresponding mixed-donor ligand system in the form of 1-methyl-2-(methylthiomethyl)-*1H*-benzimidazole (mmb) to observe such a temperature-dependent valence-tautomer equilibrium outside biological material.[4]

Valence-tautomer (or redox isomer) equilibria are not only of interest for the enzymatic mechanism of copper-dependent amine oxidases;[3] (1) has also been implicated in catechol-enhanced Fenton processes for wood decay.[5] In general, valence-tautomer equilibria[6] involving cobalt,[7] manganese, copper,[4,8] nickel,[9] and iron[10] have been discussed with respect to potential applications in molecular electronics ("switching").[6–11]

While thioether (methionine) coordination to biological copper(I/II) is observed for electron transfer proteins[1,2a] and enzymes,[12] there has also been a recent report describing N–S five-membered ring chelate binding of copper in methanobactin.[13]

Extending our previous approach[4] to other N–S chelate ligands we have focused on 8-methylthioquinoline (MTQ),[14–16] which contains an azine (pyridyl) nitrogen donor instead of the more basic but less π-accepting azole (imidazole) N in mmb. Also, mmb contains a flexible dialkylthioether substituent, whereas MTQ offers an arylalkythioether sulfur in a more rigid chelate setting. Accordingly, a comparison between mmb and MTQ compounds with d^6-configured metal complex fragments has revealed considerable differences in the metal–donor bond lengths within the five-membered chelate ring.[15] A homoleptic complex of MTQ with copper(I), $[Cu(MTQ)_2](ClO_4)$, was also reported recently,[16] showing relatively short bonds from the metal to N (2.0165 Å) and S (2.3242 Å).

Results and Discussion

The chelate ligand MTQ forms a stable complex with $[Cu(PPh_3)_2]^+$ [Equation (2)]. The results of the structural analysis as shown in Figure 1 and summarized in Table 1

[a] Calculation for $[Cu(MTQ)(PH_3)_2]^+$.

for the two crystallographically independent molecules reveal a slight asymmetry in the binding of the two triphenylphosphane ligands as is typical for many such copper(I) compounds.[17]

$$MTQ + [Cu(CH_3CN)_2(PPh_3)_2](BF_4) \longrightarrow [Cu(MTQ)(PPh_3)_2](BF_4) + 2\ CH_3CN \quad (2)$$

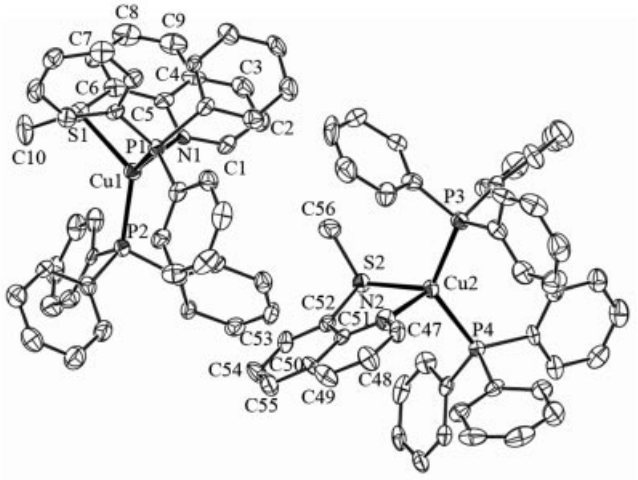

Figure 1. Molecular structures of two independent complex ions in the crystal of $[Cu(MTQ)(PPh_3)_2](BF_4)$.

The tendency of the $3d^{10}$ system for (3+1) instead of 4 coordination may be further enhanced by π–π interactions between different coordinated ligands.[17]

In comparison to the homoleptic $[Cu(MTQ)_2]^+$ ion[16] the Cu–N and Cu–S distances in $[Cu(MTQ)(PPh_3)_2]^+$ are significantly lengthened from about 2.02 to 2.09 Å and from about 2.32 to 2.37 Å, respectively. The Cu–N and Cu–S bond length data represent the average bond lengths of the two crystallographically independent molecules. Relative to several reported d^6 metal complexes[15] of MTQ, the copper(I) compound described here exhibits a balanced binding of the metal to N and S. In contrast, Ru^{II} prefers to bind to N and Pt^{IV} exhibits strong bonding to S.[15] In comparison with $[Cu(mmb)(PPh_3)_2]^+$,[18] the $[Cu(MTQ)(PPh_3)_2]^+$ ion is distinguished by longer Cu–N and shorter Cu–S bonds; the difference Δ_{NS} [d(Cu–S) – d(Cu–N)] is 0.394 Å for $[Cu(mmb)(PPh_3)_2]^+$[18] but only about 0.28 Å for the two molecules of $[Cu(MTQ)(PPh_3)_2]^+$. Apparently, the higher degree of rigidity conferred by the aromatic chelate ligand MTQ enforces a more balanced coordination by the two donor atoms, whereas mmb, which has a higher flexibility due to the CH_2 group in the chelate ring, allows for a more disparate binding of N and S to the metal.

The optimized geometry of $[Cu(MTQ)(PH_3)_2]^+$ is in reasonable agreement with the experimental results. Some deviations (Table 1) result from the approximation of PPh_3 by PH_3. The highest occupied molecular orbital (HOMO) of this complex is mainly formed by a combination between d orbitals of Cu (42%) and p orbitals of S (18%). The next lower lying orbital consists of 45% d orbitals from the Cu center and 12% p orbitals on the two P atoms. The lowest unoccupied molecular orbital (LUMO) comprises π* orbitals of the ligand with about 2% contribution from Cu orbitals. The contribution of d orbitals of Cu to the LUMO can be viewed as metal-to-ligand π-back-bonding. HOMO and LUMO diagrams of $[Cu(MTQ)(PH_3)_2]^+$ are depicted in Figure 2.

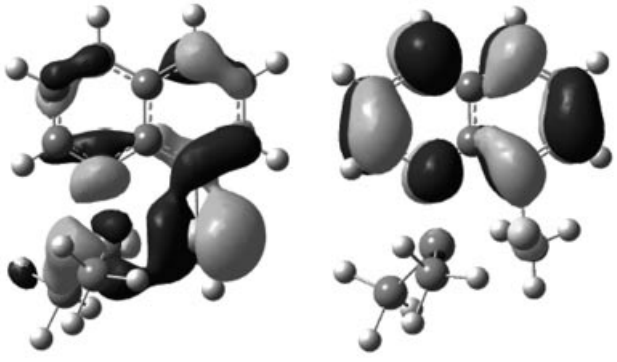

Figure 2. Composition of the HOMO (left) and LUMO (right) of $[Cu(MTQ)(PH_3)_2]^+$.

The successful use[4] of the mmb ligand in combination with the Cu^{n+}/Q_x^{n-} valence-tautomer system (n = 1 or 2; Q_x = 3,5-di-*tert*-butyl-*o*-benzoquinone) has prompted us to employ MTQ in a similar set of EPR experiments. The EPR results from mixing equimolar amounts of MTQ and

Q_x with excess activated copper[4] [Equation (3)] are shown in Figure 3.

$$MTQ + Q_x + Cu \longrightarrow [Cu^{n+}(MTQ)(Q_x)^{n-}] \quad n = 1 \text{ or } 2 \qquad (3)$$

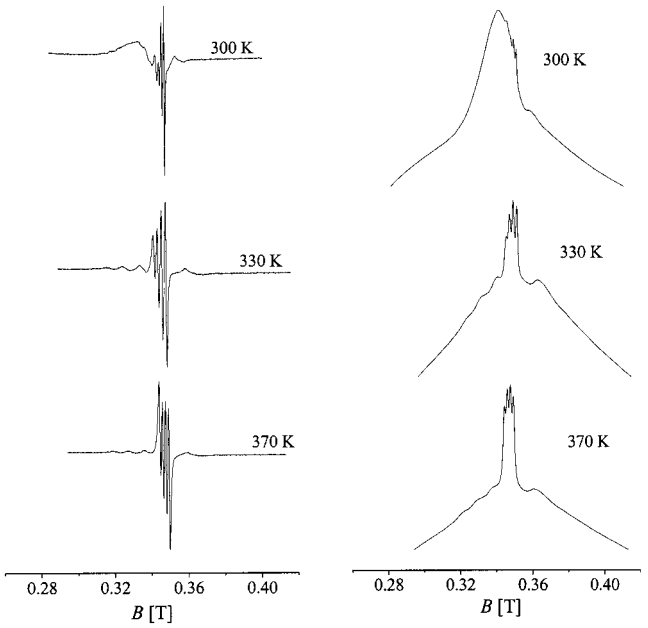

Figure 3. Temperature-dependent EPR spectra of the solution obtained by treating MTQ and 3,5-di-*tert*-butyl-*o*-semiquinone (1:1) with excess copper in toluene: derivative spectra (left) and integrated (nonderivative) spectra (right).

Although a uniform product could not be isolated from this reaction, an EPR pattern corresponding to a temperature-dependent solution equilibrium [Equation (1)] was observed with a major catecholato-copper(II) component characterized by broad signals with the typical Cu^{II} features of $a_{iso}(^{63,65}Cu) = 8.5$ mT and $g_{iso} = 2.077$ ($A_{\parallel} = 19.0$ mT, $g_{\parallel} = 2.16$, $A_{\perp} = 3.0$ mT, $g_{\perp} = 2.036$ at 110 K; ^{63}Cu: 69.2%, $I = 3/2$; ^{65}Cu: 30.8%, $I = 3/2$). The minor component, emerging to an appreciable extent at $T > 270$ K, can be expected to exhibit semiquinone/copper(I) features [$a_{iso}(^{63,65}Cu) < 1.2$ mT, $g_{iso} \approx 2.005$],[19] as for [Cu^{I}(mmb)($Q_x^{\cdot-}$)],[4] however, the parameters observed here are very unusual: The resolved quartet from the $^{63,65}Cu$ hyperfine coupling shows a large spacing of 2.1 mT which lies between typical values of 0.5–1.2 mT for semiquinone/copper(I) species[19] and 8 mT for copper(II) systems.[20] A semiquinone–H (H^4) hyperfine coupling is not observed here because of the relatively broad lines (peak-to-peak distance ca. 2.0 mT). Even more unusual is the isotropic *g* factor at 1.975 for this quartet signal which has no precedent in either copper(II) or semiquinone/copper(I) EPR spectroscopy.[19,20] The unusually low value indicates[21] the presence of a low-energy excited state, possibly involving the π* orbital of MTQ, lying close to the doublet ground state. At this point we can only speculate that the rigidity of the unsaturated MTQ chelate ligand enforces a strictly four-coordinate copper(I) arrangement with significant contribution from the thioether S center of MTQ, whereas more flexible chelate ligands such as mmb [see Equation (2)] with partially saturated chelate ring centers allow for a 3+1 coordination. This interpretation is supported by the shorter Cu–S bond observed in [Cu(MTQ)(PPh_3)$_2$](BF_4) relative to the mmb analogue. The electronic effect alone would favor the Cu^{I}-semiquinone alternative because MTQ is a better π acceptor than mmb.[15,16]

Experimental Section

Instrumentation: EPR spectra were recorded in the X band with a Bruker System ESP 300 equipped with a Bruker ER035M gaussmeter and a HP 5350B microwave counter. ^1H NMR spectra were recorded with a Bruker AC 250 spectrometer.

Synthesis: A solution containing 130 mg (0.172 mmol) [Cu(CH_3CN)$_2$(PPh_3)$_2$]BF_4 and 30.5 mg (0.172 mmol) MTQ[15,16] was heated to reflux in 20 mL of dry CH_2Cl_2 for 4 h. After evaporating half of the solvent volume, the precipitate was collected by filtration and washed with cold diethyl ether to yield 117 mg (80%) of light yellow microcrystals. Single crystals were obtained from a CH_2Cl_2 solution layered with diethyl ether at –10 °C. $C_{46}H_{39}BCuF_4NP_2S$: calcd. C 64.99, H 4.62, N 1.65; found C 64.65, H 4.65, N 1.63. ^1H NMR (250 MHz, 300 K, $CDCl_3$): $\delta = 8.70$ (dd, $^3J = 4.6$ Hz, $^4J = 1.6$ Hz, 1 H, H2), 8.62(dd, $^3J = 8.4$ Hz, $^4J = 1.6$ Hz, 1 H, H4), 8.11 (d, $^3J = 8.0$ Hz, 1 H, H7), 8.06 (d, $^3J = 8.0$ Hz, 1 H, H5), 7.77 (t, $^3J = 8.0$ Hz, 8.0 Hz, 1 H, H6), 7.65 (dd, $^3J = 8.4$ Hz, 4.6 Hz, 1 H, H3), 7.38–7.04 (m, 15 H, aromatic), 2.15 (s, 3 H, SCH_3) ppm.

Crystallography: Data for [Cu(MTQ)(PPh_3)$_2$](BF_4) were collected at 173 K with a Siemens P3 four-circle diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Formula $C_{46}H_{39}BCuF_4NP_2S$; formula weight = 850.13 g·mol^{-1}; monoclinic space group *Pc*; $a = 21.520(4)$, $b = 10.607(2)$, $c = 19.993(4)$ Å; $\beta = 116.61(3)°$; $V = 4080.3(14)$ Å^3; $Z = 4$ (2 independent molecules); $F(000) = 1752$; $\rho_{calcd.} = 1.384$ g·cm^{-3}; $\mu = 0.717$ mm^{-1}, $T = 173(2)$ K; θ range 1.92 – 25.02°; number of unique reflections 7376 ($R_{int} = 0.064$), number of parameters 1011; Flack parameter = –0.009(18); $R_1 = 0.0566$, $wR2 = 0.0988$ [for, 5436 reflections with $I > 2\sigma(I)$]; $R_1 = 0.0955$, $wR_2 = 0.1145$ (all data); $GOF = 1.073$. The structure was solved by direct methods and refined by full-matrix least-squares against F_2 of all data using the SHELXTL software package.[22] Anisotropic thermal factors were assigned to the non-hydrogen atoms. The hydrogen atoms were included in calculated positions (riding model) and refined with fixed $U_{iso} = 1.2\ U_{iso}$ of the carbon atoms to which they are bonded.

CCDC-275097 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Computational Details: Ground-state electronic structure calculations on [Cu(MTQ)(PH_3)$_2$]$^+$ have been done by density functional theory (DFT) methods, using the Gaussian 03 program package.[23] Within the Gaussian program, the quasirelativistic effect core potential basis sets[24] were employed for the Cu atom; for other atoms Dunning's DZP basis sets[25] were used. The geometry optimization was performed by using the pure density BP86 functional[26] at the spin-restricted level; the single point energy was calculated using the hybrid density B3LYP functional[27] with optimized geometry.

Intense Near-Infrared Luminescence of a Mesomorphic Ionic Liquid Doped with Lanthanide β-Diketonate Ternary Complexes

Lada N. Puntus,[a,c] Kurt J. Schenk,[b] and Jean-Claude G. Bünzli*[c]

Keywords: Ionic liquids / Liquid crystals / Lanthanides / Near infrared luminescence / Quantum yield / Small-angle X-ray diffraction

The ionic liquid 1-dodecyl-3-methylimidazole chloride ([C_{12}-mim]Cl) is doped with 1 mol-% of the lanthanide ternary complexes [Ln(tta)$_3$(phen)] (tta = thenoyltrifluoroacetonate, phen = 1,10-phenanthroline, Ln = Nd, Eu, Er, Yb), resulting in luminescent mesogenic phases at room temperature. According to DSC and SAXS measurements, the temperature of the crystal → liquid crystal transition is below 10 °C. Analysis of vibrational and luminescence data points to the inner co-ordination sphere of the Eu^{III} ion being very similar in both the mesomorphic sample and the parent β-diketonate complex. The mesomorphic samples containing Nd^{III}, Er^{III}, or Yb^{III} display relatively intense near-infrared luminescence. This emission is enhanced in the liquid crystalline phases with respect to the initial compounds, as demonstrated for instance by the quantum yield of the [Yb(tta)$_3$(phen)]-containing mesogenic sample which amounts to 2.1 %, as compared to 1.6 and 1.1 % for the powdered ternary complex and its solution in toluene, respectively.

Introduction

The development of smaller, more penetrable probes for biological imaging using near-infrared (NIR) light,[1,2] as well as of luminescent polymers for optical amplifiers[3] and light-emitting diodes working in the telecommunication window (1–1.6 μm)[4] have attracted a lot of attention recently. In this context, near-infrared lanthanide-based emitters are presenting considerable interest in view of their peculiar spectroscopic properties, namely narrow and easily recognizable emission lines and relatively long lifetimes of their excited states, compared with organic chromophores, which allows the use of time-resolved spectroscopy in analytical procedures, thus enhancing considerably the signal-to-noise ratio. In recent papers, we have demonstrated how Yb($^2F_{5/2}$) can be populated through energy transfer from Cr^{III} in a heterobimetallic d-f helicate, leading to an apparent lengthening of the Yb^{III} lifetime in the ms range,[5,6] and we have proposed an octadentate podand yielding highly stable and luminescent complexes in water.[7]

Liquid crystalline phases provide anisotropic media which are used in displays (LCD) and succeeding in producing emissive LCD by rendering the liquid crystalline phase luminescent would be a definitive advantage.[8] In addition, NIR-emitting mesomorphic materials could be useful in optical telecommunications since they would act as switchable light-converting devices. One strategy for producing lanthanide-containing mesophases is the doping of existing liquid crystalline phases with luminescent lanthanide salts and complexes.[9–16] For instance, we have recently shown how the emission color of a room temperature ionic liquid (RTIL) presenting a liquid crystalline phase at room temperature, 1-dodecyl-3-methylimidazolium chloride ([C_{12}-mim]Cl) can be tuned by the introduction of various Eu^{III} salts and by varying the excitation wavelength.[10] Ionic liquids present definitive advantages over classical solvents,[17–19] and some of them have been used for generating lanthanide-containing solutions emitting in the NIR range.[20,21] In this paper, we report the thermal, structural, and photophysical properties of solutions of lanthanide tris(thenoyltrifluoroacetylacetonate)[22] with *o*-phenanthroline in [C_{12}-mim]Cl and demonstrate an exaltation of their NIR-emitting properties with respect to solutions of these complexes in toluene and in the solid state.

Results and Discussion

Characterization of the Mesophases

Imidazolium chlorides with long alkyl chains form lamellar arrays in the crystalline phase and an enantiomeric

smectic liquid crystalline phase (SmA_2) at higher temperature.[23] The temperature of the crystal→smectic A_2 transition of [C_{12}-mim]Cl heavily depends on hydration (44.5 °C for the monohydrate and –2.8 °C for an anhydrous salt) owing to the significant structural stabilization induced by hydrogen bonds with water molecules. The H-bond array is destroyed at elevated temperature and under vacuum, which allowed Guillet et al.[10] to obtain 10 mol-% solutions of Eu salts (chloride, nitrate, perchlorate, and triflate) in [C_{12}-mim]Cl without disturbing the mesomorphic properties of this RTIL. In our case, the [Ln(tta)$_3$(phen)] complexes are too sensitive to thermal decomposition and since they have low solubility in anhydrous [C_{12}-mim]Cl, we have settled for a partially dehydrated ionic liquid (<1 water molecule per molecule of ionic liquid, probably around 0.25), in which 1 mol-% solutions of ternary complexes could be prepared. In the following description, we use **Ln1** to designate the samples prepared in this way. DSC data indicate the formation of a SmA_2 phase starting between 6 and 10 °C and ending by isotropization between 99 and 102 °C for all the Ln-containing materials obtained (Figure 1).

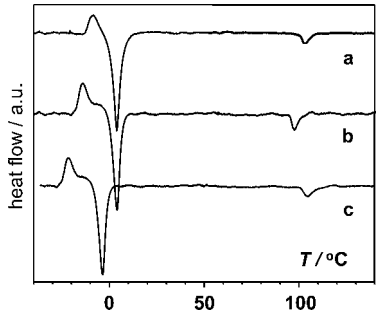

Figure 1. DSC traces (first heating-cooling cycle) of (a) **Nd1**, (b) partially dehydrated [C_{12}-mim]Cl and (c) anhydrous [C_{12}-mim]Cl.

We have resorted to small-angle X-ray scattering (SAXS) experiments to get more insight into a correlation between the structural and liquid crystalline properties of the doped mesophases. Data were collected both for the monohydrated imidazolium salt and the **Eu1** sample as a function of temperature and typical SAXS patterns are shown on Figure 2. At room temperature the most intense peak in the low-angle region (2θ = 1.89°) is assigned to the (001) layer repeat unit in the [C_{12}-mim]Cl·H_2O structure with d spacing of 46.6 Å (Figure 2c, Table 1). This d value corresponds to the double/extended bilayer spacing and is reported for the first time for [C_{12}-mim]Cl·H_2O. Similar values of layer spacing have been determined for [C_n-mim]Cl·H_2O with longer alkyl chains (n = 14, 16, 18).[23] Another, less intense peak at 2θ = 3.80° corresponds to a layer spacing of 23.3 Å and is assigned to the (002) regular repeat unit. In addition, a very weak peak at 2θ = 2.79° reveals the presence of a small amount of anhydrous [C_{12}-mim]Cl under its liquid crystalline SmA_2 phase (d = 31.8 Å). At 90 °C only one intense peak is observed at 2θ = 3.08°, corresponding to a layer spacing of 28.7 Å, and is characteristic of the SmA_2 phase. The latter value of the d spacing, as well as the one found for the crystalline phase (d = 23.3 Å) are slightly different from the ones reported by Bradley et al. for fully anhydrous [C_{12}-mim]Cl (22.5 Å in the crystalline phase and 31.7 Å in the SmA_2 phase determined on cooling the isotropic phase[23]). On the other hand, Guillet et al. have extracted a d value of 22.8 Å from the crystal structure of [C_{12}-mim]-Cl·H_2O.[10] These small differences may originate from the hydration state and thermal history of the sample (whether partial or full dehydration was performed) and from the SAXS experimental conditions (during heating or cooling cycles and from which phase SAXS data were collected).[23,24] Depending on these factors different phases such as the extended bilayer and/or double bilayer structures can form both in the initial crystalline phase and in the subsequent re-crystallization process after isotropization. The SAXS pattern for **Eu1** prepared from the previously partially dehydrated imidazolium salt, which feature a single peak at 2θ = 2.79° (Figure 2, a), is totally consistent with the presence of the SmA_2 phase at 26 °C (d = 31.8 Å) similar to that found for pure [C_{12}-mim]Cl (Figure 2, b). Thus, both DSC and SAXS data point to **Ln1** having a structural behavior close to the one of anhydrous [C_{12}-mim]-Cl and therefore, the experimental procedure proposed for preparing the **Ln1** samples successfully produces Ln-containing phases with mesomorphic SmA_2 properties at room temperature.

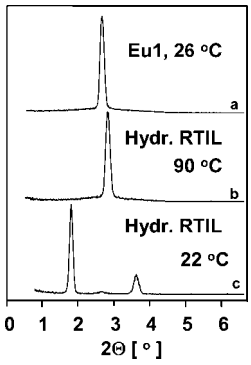

Figure 2. SAXS patterns for **Eu1** at 26 °C (a) and for [C_{12}-mim]-Cl·H_2O at 90 °C (b) and 22 °C (c) obtained during the heating.

Table 1. Layer spacing determined for the crystalline and SmA_2 phases from the position of the lowest-angle diffraction peak.

Sample	T [°C]	Layer spacing (d) [Å]	Phase[a]
[C_{12}-mim]Cl·H_2O	22	23.3 (46.6[b])	Cr
	90	28.7	LC
Eu1	26	31.8	SmA_2

Photophysical Properties

The Eu-containing samples have been used to probe changes in the local structure of the lanthanide ions upon the transition from both the crystalline to the liquid crystalline phase and from the solid state to the solution. The crys-

tal-field splitting of the $^5D_0$–^7F_J transitions (J = 1–4), which is very sensitive to differences in the nearest environment of Eu^{III} are alike for all samples, except for some broadening which masks finer details in the luminescence spectra of **Eu1** and of [Eu(tta)$_3$(phen)] in toluene (Figure 3). In the luminescence spectra of powdered [Eu(tta)$_3$(phen)] and **Eu1**, emission from the $^5D_1$ level is also detected, pointing to a not so fast nonradiative relaxation from $^5D_1$ to $^5D_0$ (Figure 4). The luminescence spectra of all the Eu^{III}-containing compounds reveal maximum (2J +1) splitting of the ^7F_J electronic levels, consistent with a low symmetry (at most C_{2v}) of the immediate Eu^{III} surroundings. Judging from the qualitative criterion of the integrated intensity of the $^5D_0 \rightarrow {}^7F_0$ transition relative to the magnetic dipole $^5D_0 \rightarrow {}^7F_1$ transition, the symmetry around the metal ion seems to be lower in the mesophase compared to the powdered sample (0.14 and 0.17, respectively).

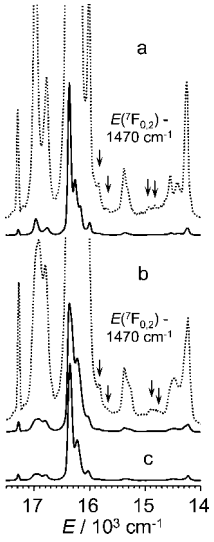

Figure 3. Luminescence spectra at 295 K of (a) [Eu(tta)$_3$(phen)] (solid state), (b) **Eu1**, and (c) [Eu(tta)$_3$(phen)] 10^{-3} M in toluene with inserts showing the vibronic satellites associated to $^5D_0 \rightarrow {}^7F_0$ and $^5D_0 \rightarrow {}^7F_2$ transitions; the excitation wavelength is 385 nm.

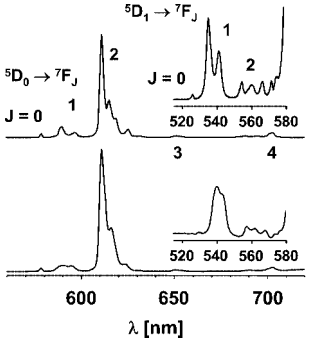

Figure 4. Luminescence spectra of [Eu(tta)$_3$(phen)] (top) and **Eu1** (bottom) at 295 K obtained under ligand excitation at 385 nm.

Both broad structured bands of the ligands and narrow lines of f-f transitions are observed in all the excitation spectra of **Ln1** (Figure 5). These spectra are similar and their coincidence with the absorption spectra indicates a sizeable energy transfer from the ligands onto the lanthanide ion. A broad shoulder with a low-frequency edge at 19665 cm^{-1} and a maximum around 22200 cm^{-1} is most remarkable in the spectrum of [Eu(tta)$_3$(phen)]. Its absence in the excitation spectrum of **Nd1** allows one to assign it to a ligand→metal charge transfer (LMCT) transition. The mean optical electronegativity[25] is equal to χ_{opt} = 2.73, a value obtained by using the optical electronegativity of Eu^{III} reported by Demirbilek et al.[26] This value can then be used to estimate the energy of the LMCT states in the complexes with the other lanthanide ions (Table 2). According to these calculated energies, influence of the LMCT state on the energy migration within the ternary complex should be much smaller in the cases of NIR-emitting ions compared to Eu^{III}.

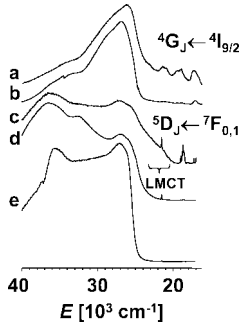

Figure 5. Luminescence excitation spectra of (a) [Nd(tta)$_3$(phen)] (solid state), (b) **Nd1**, (c) [Eu(tta)$_3$(phen)] (solid state), (d) **Eu1**, and (e) [Eu(tta)$_3$(phen)] 10^{-3} M in toluene; λ_{an} are 614 (Eu) and 1060 nm (Nd).

Table 2. Lifetimes of the Ln excited state at room temperature and energy of $^1\pi\pi^*$, $^3\pi\pi^*$, and LMCT states for powdered [Ln(tta)$_3$(phen)] and **Ln1** samples.

Compound	τ_{obs} [μs]	$E(^1\pi\pi^*)$ [cm^{-1}][a]	$E(^3\pi\pi^*)$ [cm^{-1}][b]	E(LMCT) [cm^{-1}][c]
[Nd(tta)$_3$(phen)]	1.29 ± 0.03	24690	20400	40200
Nd1	1.52 ± 0.01	24845		–

Yb1	12.4 ± 0.03	24235		–

[a] From fluorescence spectra at 295 K. [b] From phosphorescence spectra at 77 K. [c] Calculated values, see text.

To help characterize the liquid crystalline phases, we have resorted to vibronic satellites appearing in the emission spectra of the Eu-containing samples. They are similar for powdered and mesomorphic samples and the most intense ones are assigned to the symmetric vibration of the β-diketonate chelating ring with a large contribution of the C···O bond stretching with a frequency of 1470 cm^{-1} (Figure 3, cf. the bands marked by arrows in the 15900–15600 and 15110–14800 cm^{-1} spectral ranges). A comparison with the IR spectra of [C_{12}-mim]Cl·H_2O, [Yb(tta)$_3$(phen)], and **Yb1** reveals a homogeneous mixture of both components in the doped liquid crystalline sample (Figure S1, Supporting Information): vibrations of both the ionic liquid and the β-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

diketonate complex (although very weak) are indeed seen in the IR spectrum.

On the other hand, the lifetime of the Eu($^5D_0$) state hints at some differences between **Eu1** and the powdered sample. Both luminescence decays are single exponential, but lifetimes amount to 0.64 ± 0.02 and 0.97 ± 0.03 ms for **Eu1** and [Eu(tta)$_3$(phen)], respectively. The shorter lifetime in the former could be explained as follows. In a fluent system, energy transfer quenching involves collisions between complexes during diffusion.[27] The critical distance for nonradiative energy transfer, as calculated from known theory for energy transfer via electric dipole-dipole interaction[28,29] is larger than the collision distance, which leads to energy transfer via cross-relaxation and excitation migration. Moreover, collisional deactivation with [C_{12}-mim]$^+$ cations should also be taken into account. In summary, the luminescence analysis of **Eu1** confirms that dissolution of [Eu(tta)$_3$(phen)] in the RTIL does not modify substantially the inner co-ordination sphere of the europium ion, although it reveals an influence of the ionic liquid on the deactivation processes.

NIR Luminescence

The luminescence excitation spectra of NIR-emitting lanthanide complexes as well as the corresponding **Ln1** (Ln = Nd, Er, Yb) samples are similar (Figure S2, Supporting Information). Comparison of the normalized excitation spectra of powdered and mesophase samples reveals a much lower excitation efficiency of the lanthanide ions through ligand levels in the powdered samples. This reduced luminescence efficiency at high concentration is known as concentration quenching. In spite of the low concentration of the doped ternary complex (1 mol-%), relatively intense luminescence is obtained for all the **Ln1** samples, as ascertained by the intensity ratios found between the total integrated emission intensity of the pure complexes and that of the **Ln1** samples: 6, 3, and 5 for Nd, Er, and Yb, respectively. The near-infrared luminescence spectra of mesomorphic **Ln1** samples at room temperature are presented in Figure 6 and relevant photophysical data are given in Table 2. The observed f-f emission bands correspond to the typical electronic transitions of the NIR-emitting lanthanide ions: $^4F_{3/2}\rightarrow{}^4I_J$ (J = 9/2, 11/2, 13/2) for Nd, $^4I_{13/2}\rightarrow{}^4I_{15/2}$ for Er, and $^2F_{5/2}\rightarrow{}^2F_{7/2}$ for Yb. We have determined the quantum yields of the Yb-centered luminescence taking [Yb(tta)$_3$(H$_2$O)$_2$] as standard. Upon excitation at 390 nm, the quantum yield of **Yb1** amounts to 2.1 ± 0.3%, compared with 1.1 ± 0.1% for a solution of [Yb(tta)$_3$(phen)] in toluene and 1.6 ± 0.2% for a solid-state sample of [Yb(tta)$_3$(phen)] (Figure 6). Thus, the quantum efficiency increases in the order **Yb1** > [Yb(tta)$_3$(phen)] powdered > [Yb(tta)$_3$(phen)] solution, which agrees well with the corresponding lengthening of the emission lifetime. This correlation means that nonradiative relaxation processes are minimized in the ionic liquid used. The improvement in the photophysical properties of the **Ln1** samples is further substantiated by the lifetimes of the metal-centered excited states, which are slightly longer compared with those of the pure ternary complexes (Table 2).

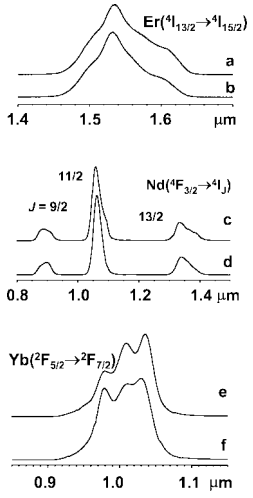

Figure 6. Near-infrared photoluminescence of (a) [Er(tta)$_3$(phen)], (b) **Er1**, (c) [Nd(tta)$_3$(phen)], (d) **Nd1**, (e) [Yb(tta)$_3$(phen)], and (f) **Yb1** at 295 K. The excitation wavelength is 385 nm.

At room temperature, [C_{12}-mim]Cl displays a bright-blue fluorescence with a maximum at 410 nm upon excitation between 225 and 280 nm.[10] Therefore, both a sensitization of the lanthanide-centered NIR luminescence and fluorescence from the RTIL are obtained upon UV excitation. Moreover, owing to the energy transfer from the ionic liquid, lanthanide-centered luminescence can be observed with excitation wavelengths as large as 410 nm (cf. Figures 5, 7, and S2), which is interesting because getting near-infrared emission upon excitation by visible light is an attractive aim for various industrial and analytical applications.

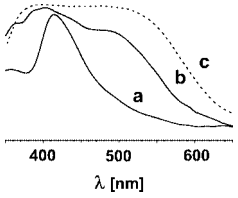

Figure 7. Luminescence spectra of (a) [Nd(tta)$_3$Phen] (solid state), (b) **Nd1** and (c) [C_{12}-mim]Cl at 295 K. The excitation wavelength is 385 nm.

Conclusions

In summary, a method for obtaining [C_{12}-mim]Cl mesophases doped by 1 mol-% [Ln(tta)$_3$(phen)] complexes at room temperature has been developed. The layer spacing in the liquid crystalline phases is independent of the presence of 1 mol-% of [Ln(tta)$_3$(phen)] complexes and identical with the one measured for the anhydrous ionic liquid.[23] The prepared **Ln1** samples have an enantiomeric smectic liquid crystalline phase in the temperature range 10–102 °C. The inner co-ordination sphere of the lanthanide ion remains

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

essentially unchanged, while the photoluminescence properties are enhanced. The studied liquid crystalline phases display relatively intense near-infrared photoluminescence, thus opening up interesting perspectives for the design of NIR-emitting materials since emission lines from 0.9 to 1.6 μm are easily obtained at the expense of a small amount of β-diketonate complexes (1 mol-%) and since sensitization of this luminescence can be obtained with visible light.

Experimental Section

All reagents and solvents were used as received (Acros); monohydrate of 1-dodecyl-3-methylimidazolium chloride ([C_{12}-mim]Cl·H_2O, Scheme 1)[23] as well as the lanthanide ternary complexes [Ln(tta)$_3$(phen)][30] where Ln = Nd, Eu, Er, Yb were synthesized according to literature procedures and characterized by elemental analyses, IR, and NMR spectroscopy. Thermogravimetric analyses (TGA) under normal atmospheric pressure showed the monohydrated imidazolium salt losing one water molecule per formula weight between 120 and 150 °C and no degradation occurring until 320 °C but decomposition started at 330 °C. In order to obtain a mesophase material at room temperature and to avoid thermal decomposition, the ionic liquid was dehydrated before the introduction of the lanthanide compounds, although complete dehydration was avoided because [Ln(tta)$_3$(phen)] complexes have very low solubility in anhydrous [C_{12}-mim]Cl. All preparations were performed under N_2 using Schlenk techniques and further handling of the samples was performed in a glove-box. Monohydrated [C_{12}-mim]Cl·H_2O was heated from room temperature to 230 °C at a speed of 10 °C/min and under reduced pressure (6.5×10^{-1} Torr), left 5 min at this temperature and then cooled to room temp. The resulting partially dehydrated RTIL showed a crystal → liquid crystal (Cr-LC) transition at 6 °C and isotropization (LC-I transition) at 99 °C. Determination of the transition temperature was performed by means of differential scanning calorimetry (DSC) experiments during the first heating from –90 to 160 °C (Table 3). A DSC experiment was carried out every time before addition of the lanthanide ternary complex for confirmation of the partial dehydration of ionic liquid. Then the lanthanide complexes (1 mol-%) were added to the molten ionic liquid and the mixtures were stirred for 30 min at 130 °C under vacuum. The thermal properties of the Ln-containing samples were tested by DSC again and temperatures of the phase transitions for prepared samples are reported in Table 1. The following notation is used for the samples: **Nd1**, **Eu1**, **Er1**, **Yb1**. Heating the mixtures at higher temperature and during a longer span of time allows the doping of larger quantities of ternary complexes in [C_{12}-mim]Cl but we observed some thermal decomposition. The mesomorphic samples were transferred into 0.1-cm quartz Suprasil® cells under controlled atmosphere and the cells were sealed with paraffin.

[a] Partially dehydrated.

Elemental analyses were performed by the Ilse Beetz Laboratory (96301 Kronach, Germany). IR spectra were obtained with a Perkin–Elmer Spectrum One FT-IR spectrometer equipped with a Universal ATR sampling accessory. DSC thermograms were recorded with a Setaram DSC 131 instrument equipped with a liquid nitrogen cooler under nitrogen with cooling-heating cycles between –90 and 160 °C at a rate of 10 °C/min. Thermogravimetric traces were obtained with a Pyris 6 thermogravimetric analyzer from Perkin–Elmer. UV/Visible spectra were measured at 295 K with a Perkin–Elmer Lambda 900 spectrometer. Luminescence measurements (spectra and lifetimes) were recorded with a Fluorolog FL3-22 spectrometer from Jobin–Yvon at 295 and 77 K. Lifetimes for NIR-emitting lanthanides were determined with a high resolution instrumental set-up equipped with a Hamamatsu H9170-75 photomultiplier as described previously.[5] The quantum yields of **Yb1** and of the solution of [Yb(tta)$_3$(phen)] in toluene were determined upon ligand excitation and taking [Yb(tta)$_3$-(H_2O)$_2$] as standard (0.35% in toluene at room temp.).[31] Refractive indices were 1.4964 for the toluene solutions and 1.5059 for **Yb1**.[10] The quantum yield of a powdered sample of [Yb(tta)$_3$-(phen)] was measured by means of an integration sphere from Spex-Jobin Yvon-Horiba 99FL-PLQY, using a described procedure.[32] SAXS patterns were recorded, on samples in 1-mm borosilicate capillaries from Hilgenberg sealed with Araldite®, with a SAXS system from Molecular Metrology equipped with a Cu-K_α Bede micro source configured with confocal Max-Flux™ optics, a variable-temperature universal sample chamber, and a two-dimensional multi-wire gas detector; analysis was performed with the open-source analysis software from Molecular Metrology. The diffraction patterns of pure [C_{12}-mim]Cl were isotropic, whereas those for **Eu1** were somewhat anisotropic. The traces reported in Figure 2 are azimuthally averaged. The Electronic Supporting Information contains IR spectra and excitation luminescence spectra of pure and doped ionic liquids.

Pd^{II} Complexes of Tridentate PCP N-Heterocyclic Carbene Ligands: Structural Aspects and Application in Asymmetric Hydroamination of Cyano Olefins

Sebastian Gischig[a] and Antonio Togni*[a]

Keywords: N-heterocyclic carbene ligands / Ferrocenes / Palladium complexes / Asymmetric catalysis / Hydroamination / Aminonitriles

The synthesis of the ligand precursor 1,3-bis{(*R*)-1-[(*S*)-2-(diphenylphosphanyl)ferrocenyl]ethyl}imidazolium iodide ([PCPH]I, **1**) was extended to the electronically and sterically modified ligand precursors 1,3-bis{(*R*)-1-[(*S*)-2-{[3,5-bis(trifluoromethyl)phenyl]phosphanyl}ferrocenyl]ethyl}imidazolium iodide ([3,5-CF_3-PCPH]I, **6**), and 1,3-bis[(*R*)-1-{(*S*)-2-[bis(3,5-dimethylphenyl)phosphanyl]ferrocenyl}ethyl]imidazolium iodide ([3,5-Me-PCPH]I, **7**). Palladium complexes were prepared starting from $[Pd(OAc)_2]_3$ in THF to afford [PdI(PCP)]OAc (**8**), [Pd(OAc)(3,5-CF_3-PCP)]I (**9**), and [PdI(3,5-Me-PCP)]OAc (**10**), in excellent yields. The crystal structures of the ligand precursor [3,5-CF_3-PCPH]I (**6**), the complex [PdI(3,5-CF_3-PCP)]PF_6 (**14**), as well as the dicationic complex [Pd($NCCH_3$)(PCP)]$(PF_6)_2$ (**11**), were determined by X-ray diffraction. Complex **11** and its derivative [Pd($NCCH_3$)-(3,5-Me-PCP)]$(PF_6)_2$ (**13**) have been tested as catalysts in the asymmetric addition of, for example, thiomorpholine to methacrylonitrile giving selectivities up to 63 and 75% *ee*, respectively, at –80 °C.

Introduction

N-Heterocyclic carbenes (NHCs), their corresponding metal complexes, and their applications in catalysis have become a well-established area of research in organometallic chemistry.[1–5] An important step in the development of carbene ligands is their chiral modification and many chiral NHCs acting as monodentate[6–10] as well as bidentate ligands[11–15] in asymmetric reactions have been reported.[5]

Our interest in tridentate ligands based on the ferrocene scaffold derives from the successful application of the triphosphane Pigiphos (see Scheme 1)[16] in, for instance, Ni-catalyzed hydroamination and hydrophosphanation of cyano olefins.[17,18] The replacement of the central PCy unit of Pigiphos by an NHC fragment generates a C_2-symmetric ligand. We speculated that this should lead, in the case of square-planar complexes, to a chiral environment that is better defined than in Pigiphos. We previously reported the synthesis of the PCP ligand precursor **1** as well as its complexation with ruthenium and palladium.[19] In this work we address the modification of the ligand, the complexation with palladium, and the formation of dicationic complexes. The X-ray crystal structures of the activated palladium complex **11**, the CF_3-modified ligand precursor **6** and the palladium complex of this ligand (**14**) are presented, along with the application of these NHC complexes in the catalytic hydroamination reaction of cyano olefins.

Results and Discussion

Ligand Synthesis

The introduction of substituents at the 3- and 5-positions of the phenyl groups in diphenylphosphanyl derivatives is a common approach in view of modifying both the steric and electronic properties of such ligands. Modifications of this kind, as applied to carbene precursor **1** ([PCPH]I), should lead to altered catalytic properties of the corresponding Pd complexes. The synthesis of the ligand precursors—via the amines **2** and **3**, as well as the acetates **4** and **5**, i.e. the (diarylphosphanyl)ferrocene derivatives bearing either a dimethylamino group or an acetate at the stereogenic center—containing methyl and trifluoromethyl substituents,

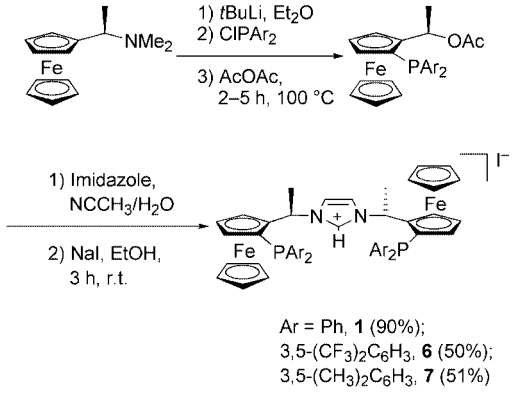
respectively, has been accomplished analogously to the one of the unsubstituted derivative **1**. The preparation of [3,5-CF_3-PCPH]I (**6**) and [3,5-Me-PCPH]I (**7**) from the corresponding acetate derivatives **4** and **5**, respectively, and imidazole was carried out in a mixture of acetonitrile and water in a ratio of 4:1 for **6** and 2:1 for **7**. However, for reactions at room temperature as described for **1**, no substitution of the acetate by imidazole was observed. Heating of the reaction mixture at 60 °C followed by ion exchange with NaI in ethanol yielded **6** in 50% yield after 24 h and **7** in 51% yield after 32 h, respectively (Scheme 2). The yields are lower than the one obtained for **1** and could not be improved by longer reaction times or by using different reaction conditions (temperature, acetonitrile/water mixture).



Scheme 2. Synthesis of the ligand precursors **1**, **6**, and **7**.

Treatment of **1**, **6**, and **7** with NaO*t*Bu in THF resulted in the deprotonation of the imidazolium salts. However, the attempted isolation of the free carbenes was not successful. For ^{13}C NMR spectroscopic reasons, these imidazolium salts were also prepared in the form containing a ^{13}C label at position 2 of the imidazole.[20] The deprotonation of the labeled **1**, **6**, and **7** using an excess of NaO*t*Bu in THF allowed us to observe broad ^{13}C NMR signals of the free carbenes at room temperature (Table 1). While the NMR spectroscopic data of the free carbenes confirm the clean generation of these reactive species, the significant line widths account for the difficulties in observing the same signals for the nonlabeled compounds. Furthermore, solutions of these species in C_6D_6 showed the formation of the imidazolium ion within minutes, indicating that the acidic sites of the NMR tube glass are sufficient to protonate the carbenes. The C(2)–H coupling constants (J_{CH}) of the imidazolium salts of 218.7, 222.6, and 218.8 Hz for **1**, **6**, and **7**, respectively, could be estimated with the help of 2D one-bond HMQC experiments. Interestingly, the coupling constant for the more electron-deficient compound **6**, containing the CF_3 substituents, is larger than for **1** and **7**.

Table 1. ^{13}C NMR chemical shifts of the free carbenes derived from **1**, **6**, and **7**.

Free carbene of	δ [ppm]	Line width [Hz]	J_{CP} [Hz]
1	209.0	36	–
6	209.8	–	13.3 (t)
7	209.5	25	–

Synthesis of Palladium Complexes

As already shown for the ligand precursor **1**, the method of choice for the complexation of these carbene ligands to Pd^{II} is to start from $[Pd(OAc)_2]_3$ {see the synthesis of [PdI(PCP)]OAc (**8**), giving 98% yield}.[19] Analogously, the reaction of (3,5-CF_3-PCPH)I (**6**) and (3,5-Me-PCPH)I (**7**) with $[Pd(OAc)_2]_3$ generates the complexes [Pd(OAc)(3,5-CF_3-PCP)]I (**9**) and [PdI(3,5-Me-PCP)]OAc (**10**) in 91% and 95% yield, respectively (Scheme 3).

In order to isolate the complexes containing iodide as a ligand and acetate as the counterion, an ionic ligand exchange reaction is necessary. This ion exchange was studied by NMR on samples of the ^{13}C-labeled complexes (Table 2). It is reasonable to expect that iodide and acetate will exert a different influence on the chemical shift of the carbene carbon atom in the *trans* position. Addition of NaI to a dichloromethane solution of the palladium complexes **8**, **9**, and **10** shifts the ion exchange equilibrium towards the iodo complex (Table 2, Entries 1, 3, and 5). Abstraction of the counterion and the fourth ligand with Et_3OPF_6 (vide infra), followed by the addition of Bu_4NOAc leads to the formation of the complexes having acetate as a ligand (Table 2, Entries 2, 4, and 6). These experiments show a slight downfield shift of the ^{13}C carbene signal in going from coordinated acetate to coordinated iodide, this effect being more pronounced for [Pd(OAc)(3,5-CF_3-PCP)]I (**9**). We also observed a larger coupling constant J_{CP} between the carbene carbon atom and the P atoms for the iodo complexes. Comparing the chemical shifts and the coupling constants observed for compounds **8**, **9**, and **10** we concluded that there is an ion exchange for [PdI(PCP)]OAc (**8**)

Table 2. ^{13}C NMR spectroscopic data for labeled carbene derivatives.

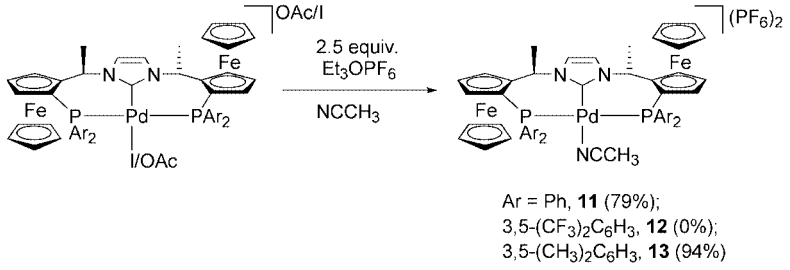
Entry	Complex	Ligand	δ [ppm] (by ion exchange)	J_{CP} [Hz]	δ [ppm] (by synthesis)	J_{CP} [Hz]
1	[PdI(PCP)]OAc (**8**)	I^-	152.3 (t)	12.0	151.4 (t)	13.2
2	[Pd(OAc)(PCP)]PF_6	^-OAc	149.8 (t)	14.6		
3	[PdI(3,5-CF_3-PCP)]OAc	I^-	151.5 (br)	–		
4	[Pd(OAc)(3,5-CF_3-PCP)]I (**9**)	^-OAc	145.7 (t)	13.5	146.8 (t)	13.3
5	[PdI(3,5-Me-PCP)]OAc (**10**)	I^-	152.5 (t)	12.4	151.8 (t)	12.4
6	[Pd(OAc)(3,5-Me-PCP)]PF_6	^-OAc	149.9 (t)	13.6		

and [PdI(3,5-Me-PCP)]OAc (**10**), resulting in products with iodide as the ligand, instead of acetate. This exchange is quite slow and takes approximately 1 d to reach completeness in dichloromethane. Therefore, for further synthesis the equilibrium mixture was used. However, the clean product [PdI(3,5-Me-PCP)]OAc (**10**) could only be obtained by flash chromatography (silica, dichloromethane + 4% methanol). For the electron-poorer complex [Pd(OAc)(3,5-CF_3-PCP)]I (**9**), ion exchange seems to be absent, resulting in a complex with acetate as the fourth ligand. Only the addition of an excess of NaI to **9** allowed us to observe the iodo complex characterized by a rather broad ^{13}C NMR signal (Table 2, Entry 3).

In order to obtain catalytically active species acting as chiral Lewis acids, complexes **8** and **10** were converted into the dicationic derivatives [Pd($NCCH_3$)(PCP)]$(PF_6)_2$ (**11**) and [Pd($NCCH_3$)(3,5-Me-PCP)]$(PF_6)_2$ (**13**) in 79% and 94% yield, respectively, using Et_3OPF_6 in acetonitrile (Scheme 4). The acetonitrile complexes **11** and **13** are characterized by higher ^{31}P chemical shifts and significantly lower ^{13}C carbene chemical shifts with respect to their corresponding precursors, as summarized in Table 3. Somewhat surprisingly, the activation of **9** with Et_3OPF_6 was not selective and led to product mixtures from which the dicationic species could not be identified. It is important to note that all complexes described in this section give NMR spectra consistent with C_2-symmetric structures in solution.

Crystal Structures

Crystals of imidazolium salt **6** suitable for X-ray analysis could be obtained from a dichloromethane solution overlayered with hexane. An ORTEP representation of the structure is shown in Figure 1 and selected bond lengths and angles are listed in Table 4. The overall structure is only approximately C_2-symmetric, i.e., the two ferrocenyl units are not symmetry-related. Three CF_3 groups with the atoms C(6), C(12), and C(15) are disordered over two positions, a phenomenon which can be observed very often for crystal structures containing CF_3 substituents. Iodide was also found to be disordered over two positions with an occupational ratio of 93:7. One of the most specific structural features of this compound is that the molecule backbone, i.e., the chain joining the two phosphorus atoms, displays helical chirality with (*P*) configuration. This chain approximately describes a full screw turn in going from one P atom to the other. The distance between the two P atoms is 7.353 Å and can be viewed as the screw pitch, the backbone being the screw thread. The three donor atoms are already positioned in such a way that the coordination to a metal center only requires a relatively minor conformational change that can be best viewed as a compression of the screw pitch of the ligand backbone (vide infra). Two of the aryl groups, one of each of the phosphane units, are placed on each side of the imidazole plane indicating a possible



Scheme 4. Synthesis of the dicationic complexes **11** and **13**.

Table 3. ^{31}P and ^{13}C NMR chemical shifts of **8**, **10**, and the dicationic complexes **11** and **13**.

weak π-stacking interaction of the aryl groups and the imidazole ring (the average distance between the aromatic rings is 4.02 Å and the interplanar angles are 23.7 and 31.4°). The orientation of the ferrocenyl moieties can be described as pseudo-equatorial with respect to the imidazole plane.

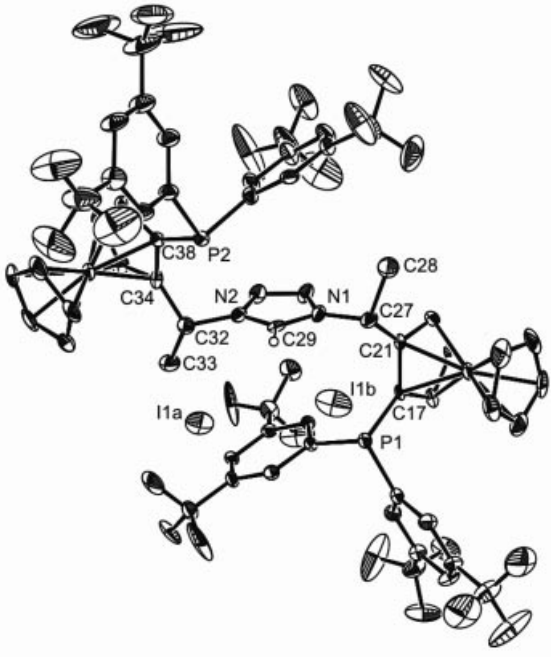

Figure 1. ORTEP representation of (3,5-CF_3-PCPH)I (**6**). Hydrogen atoms and the CF_3 disorder are omitted for clarity. Thermal ellipsoids are set to 30% probability.

The N(1)–C(29)–N(2) angle is with 109.3(5)° at the upper limit of the range found for derivatives of this kind (usually 107.6–109.7°[21–24]). It is also larger than the values measured in the complexes [PdCl(PCP)]PF_6 [106.2(7)°], [Pd($NCCH_3$)(PCP)]$(PF_6)_2$ [106.2(7)]°, [PdI(3,5-CF_3-PCP)]-PF_6 [108.4(10)°], and [RuClI(PCP)] [103.7(19), 104(2)°].

Although it was not possible to isolate the complex [PdI(3,5-CF_3-PCP)]PF_6 (**14**) on a preparative scale, we obtained crystals suitable for X-ray analysis from a chloroform solution of the mixture obtained from the activation of [Pd(OAc)(3,5-CF_3-PCP)]I (**9**) with Et_3OPF_6. The structure is represented in Figure 2 and selected bond lengths and angles are listed in Table 4.

The geometry around the Pd atom is almost square-planar with a slight tetrahedral distortion, as indicated for instance by the C(29)–Pd(1)–I(1) angle of 165.7(4)°. The Pd(1)–C(29) bond of 2.040(12) Å is longer than the reported Pd^{II}–carbene distances with iodide *trans* to a carbene C atom [1.984(4),[25] 1.990(3),[26] 1.990(9),[27] 2.004(3),[27] 1.991(5) Å,[28] 1.994(5),[28] 1.962(8) Å[19] are examples of previously reported distances]. The P(1)–Pd(1)–C(29) and P(2)–Pd(1)–C(29) bite angles are 83.0(4) and 86.3(4)°, which is less than the ideal value of 90°. Contrary to what is found for many (carbene)Pd^{II} complexes, the imidazole plane is not orthogonal to the coordination plane, as illustrated by the torsion angle P(2)–Pd(1)–C(29)–N(2) of –68.2(12)° and the angle between the least-squares planes

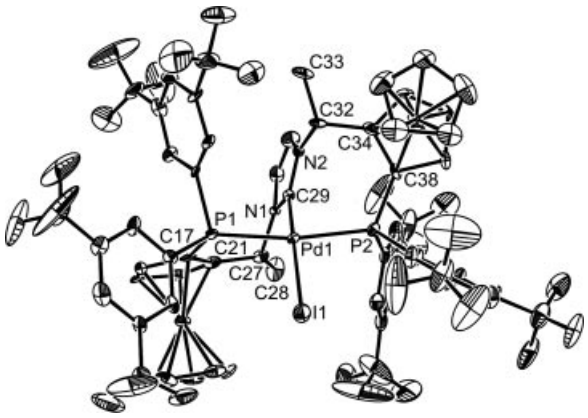

Figure 2. ORTEP representation of the cation in [PdI(3,5-CF_3-PCP)]PF_6 (**14**). Hydrogen atoms are omitted for clarity. Thermal ellipsoids are set to 30% probability.

containing C(29), N(1), C(30), C(31), N(2) and Pd(1), I(1), P(1), P(2), C(29), respectively, which is 70.8°. This deviation from the perpendicular situation of the two planes is inherently due to the helical conformation of the ligand backbone. It has also been found in the previously reported structure of the complex [PdCl(PCP)]PF_6 (**15**), with the corresponding torsion angle of –75.6(7)° and the angle between the coordination plane and the imidazole plane of 72.9°. As opposed to the case of [PdCl(PCP)]PF_6 (**15**), the solid-state structure of **14** is almost, but not perfectly C_2-symmetric. Therefore, the aryl groups on each side of the ligand have very similar orientations. One aryl group at each phosphorus atom is lying roughly in the coordination plane defined by Pd(1), P(1), P(2) and C(29) pushing the iodo ligand out of this plane by 0.7468 Å. The other two aryl groups assume a pseudo-axial orientation.

As was the case for the precursor **6**, the ligand backbone of **14** displays helical chirality with (*P*) configuration. From a topological point of view, the essential difference between the two compounds is the compression of the screw pitch on going from **6** to **14**. In fact, the distance between the two P atoms decreases from 7.353 Å to 4.601 Å, as a consequence of a conformational change. There are only two pairs of equivalent single bonds potentially susceptible to significant conformational changes, i.e., the linkages joining the stereogenic centers to the respective Cp and N atom. An inspection of the torsion angles provided in Table 4 reveals that a counterclockwise rotation around the two N–C bonds by ca. 35 and 47°, respectively, mainly accounts for the observed change of conformation. Indeed, rotation around the crucial pair of single C–C bonds occurs in a clockwise manner, but only to an extent of ca. 19 and 3°, respectively, in going from **6** to **14**.

It was also possible to obtain X-ray quality crystals of the moisture-sensitive complex [Pd($NCCH_3$)(PCP)]$(PF_6)_2$ (**11**) by slow diffusion of diethyl ether into an acetonitrile solution at –20 °C. The structure is represented in Figure 3 and selected bond lengths and angles are collected in Table 4. This complex shows in the solid state an almost square-planar geometry. The overall structure is approxi-

mately C_2-symmetric with one pair of phenyl rings located very close to the coordination plane and the second pair, together with the ferrocenyl units, in a pseudo-axial position. The C(25)–Pd(1)–N(3) angle of 177.9(4)° is much closer to the ideal value of 180° than the corresponding angles of the previously discussed complexes [PdI(3,5-CF_3-PCP)]PF_6 (**14**), with 165.7(4)°, and [PdCl(PCP)]PF_6 (**15**), containing the unsubstituted PCP ligand, with 164.3(3)°.[19] The Pd(1)–C(25) bond length for **11** is 1.993(9) Å which is longer than that observed in [PdCl(PCP)]PF_6 (**15**), with a value of 1.962(8) Å. Lee recently reported crystal structures of a cationic $[PdCl(PCP)]^+$ complex, as well as of the corresponding dicationic counterpart $[Pd(NCCH_3)(PCP)]^{2+}$, containing the tridentate NHC ligand PCP = PPh_2–$(CH_2)_2$–NHC–$(CH_2)_2$–PPh_2, i.e., compounds structurally related to ours.[29] However, in contrast to our results, Lee found that the Pd–C distance is longer in the chloro complex than in the dicationic acetonitrile derivative [1.983(7) vs. 1.961(4) Å]. The bite angles P(1)–Pd(1)–C(25) of 87.3(2)° and P(2)–Pd(1)–C(25) of 83.7(2)° are slightly larger than the corresponding values for [PdCl(PCP)]PF_6 (**15**) [86.6(3)

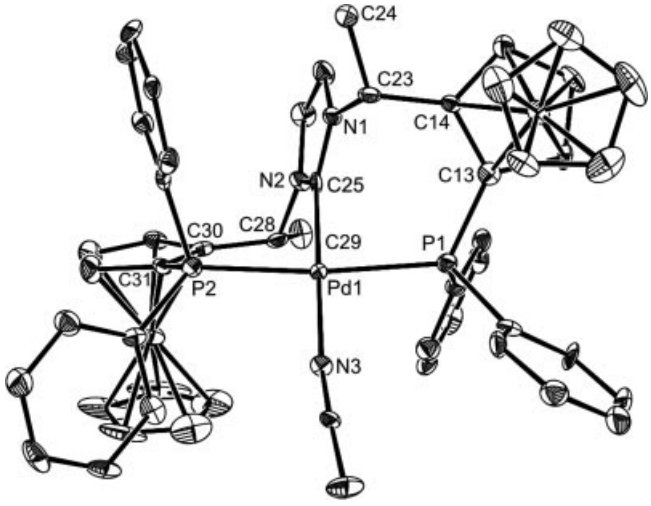

Figure 3. ORTEP representation of the dication in [Pd($NCCH_3$)(PCP)]$(PF_6)_2$ (**11**). Hydrogen atoms are omitted for clarity. Thermal ellipsoids are set to 30% probability.

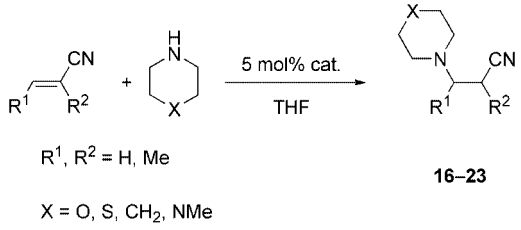
and 82.2(3)°]. The imidazole plane is again tilted away from the orientation perpendicular to the coordination plane. The torsion angle P(1)–Pd(1)–C(25)–N(1) has a value of –71.7(7)° and the angle between the least-squares planes containing C(25), N(1), C(26), C(27), N(2) and Pd(1), P(1), P(2), N(3), C(25), respectively, is 70.9°. The N(3)–C(52) bond length in the acetonitrile ligand is 1.126(10) Å which lies within the range of N–C distances found for palladium complexes containing phosphanes (1.114–1.144 Å),[30–34] or pincer-type carbene ligands (1.124–1.135 Å)[35–38] *trans* to the acetonitrile.

Catalysis

The acetonitrile ligand in the complexes $[Pd(NCCH_3)(PCP)](PF_6)_2$ (**11**) and $[Pd(NCCH_3)(3,5\text{-Me-PCP})](PF_6)_2$ (**13**) can be readily replaced by a substrate containing a functional group. This allows an activation of such substrates with the complex acting as a Lewis acid. Encouraged by the results achieved in our group[17,18] with $[Ni(PPP)(THF)](ClO_4)_2$ (PPP = Pigiphos, Scheme 1) as a Lewis acidic catalyst, we also tested our complexes in the asymmetric hydroamination of cyano olefins (Scheme 5).



Scheme 5. Hydroamination of cyano olefines.

In most experiments we used 5 mol-% of catalyst and the typical reaction time was 24 h at room temperature. The amines tested for this reaction were morpholine, thiomorpholine, piperidine, *N*-methylpiperazine, and aniline affording always the isolated product of the *anti*-Markovnikoff addition. The first experiments were carried out with the complex $[Pd(NCCH_3)(PCP)](PF_6)_2$ (**11**) using methyl methacrylate as the activated olefin; however, no activity was found. The test runs with crotonitrile as the amine acceptor afforded good to excellent yields (76–98%) but low enantioselectivities (up to 6% *ee*) in the case of aliphatic amines, whereas aniline showed no activity at all. We reasoned that aniline is poisoning the catalyst by coordination to the active site, but we never succeeded in isolating an aniline complex. The first promising results could be obtained with methacrylonitrile, having the methyl group in the α-position with respect to the electron-withdrawing group. The results involving methacrylonitrile as the substrate are summarized in Table 5. While aniline still showed no activity, the products derived from the aliphatic olefins were isolated in good to excellent yields, but the enantioselectivities were still low (up to 36% *ee* for *N*-methylpiperazine). No improvement was found by using acetone (no activity), or 1,2-dichloroethane as solvents. In this latter solvent, thiomorpholine could be added to methacrylonitrile affording 78% yield and 27% *ee*. Lowering of the reaction temperature from room temperature to –20 °C resulted, as expected, in lower isolated yields after a reaction time of 24 h (Table 5, Entries 5–8). The enantioselectivity could be somewhat improved for morpholine (38% *ee*) and thiomorpholine (44% *ee*). Surprisingly, for piperidine (23% *ee*) and *N*-methylpiperazine (33% *ee*) the enantioselectivity was reproducibly lower at –20 °C than at room temperature. Lowering of the temperature to –80 °C while using longer reaction times (3 d) in order to reach complete conversion, resulted in an improvement of the selectivity (except for piperidine) up to 63% *ee* (Table 5, Entries 9–12).

In view of a possible improvement of the enantioselectivity, the ligands bearing 3,5-disubstituted phenyl rings were tested. As mentioned earlier, the activation of the complex [Pd(OAc)(3,5-CF_3-PCP)]I (**9**) with Et_3OPF_6 re-

sulted in a mixture from which the active species could not be identified. Using this mixture as the catalyst did not result in any activity even after heating the reaction mixture at 60 °C. Therefore, the less electron-deficient complex $[Pd(NCCH_3)(3,5\text{-Me-PCP})](PF_6)_2$ (**13**) was tested for the methacrylonitrile system. The activity at room temperature (Table 5, Entries 13–16) as well as at –80 °C (Table 5, Entries 17–20) was found to be in the same range as when using the unsubstituted ligand. The enantioselectivities, however, were improved up to 61% *ee* (thiomorpholine) at room temperature and finally up to 75% *ee* (thiomorpholine) at –80 °C. Interestingly, the lowering of the reaction temperature again had no significant influence on the selectivity for piperidine. This indicates that in this system the additional heteroatom (O, S, NMe) has an influence on the stereodifferentiating step during the catalysis.

Conclusions

The three-step synthesis of the ligand precursor [PCPH]-I (**1**) was extended to the synthesis of the electronically and sterically modified ligand precursors (3,5-CF_3-PCPH)I (**6**) and (3,5-Me-PCPH)I (**7**), bearing substituents at the 3- and 5-positions of the aryl groups. The reaction of the imidazolium salts **1**, **6**, and **7** with $[Pd(OAc)_2]_3$ in THF is the most efficient route to Pd^{II} complexes of the corresponding carbene ligands affording [PdI(PCP)]OAc (**8**), [Pd(OAc)(3,5-CF_3-PCP)]I (**9**), and [PdI(3,5-Me-PCP)]OAc (**10**) in excellent yields. These complexes displayed a different behavior concerning the exchange of the anions acetate and iodide as addressed by NMR studies. Reaction of these complexes with Et_3OPF_6 in acetonitrile afforded the dicationic species $[Pd(NCCH_3)(PCP)](PF_6)_2$ (**11**) and $[Pd(NCCH_3)(3,5\text{-Me-PCP})](PF_6)_2$ (**13**) in good to excellent yields. However, a similar activation of [Pd(OAc)(3,5-CF_3-PCP)]I (**9**) failed and resulted in a product mixture that was catalytically not active.

The solid-state structures of the ligand precursor (3,5-CF_3-PCPH)I (**6**) and its corresponding complex [PdI(3,5-CF_3-PCP)]PF_6 (**14**) show that their common molecule backbone assumes a helical conformation and that the most relevant conformational difference between the two compounds is accounted for mainly by a different torsion around the two N–C single bonds.

The dicationic complexes $[Pd(NCCH_3)(PCP)](PF_6)_2$ (**11**) and $[Pd(NCCH_3)(3,5\text{-Me-PCP})](PF_6)_2$ (**13**) are active catalysts for the addition of cyclic aliphatic secondary amines to cyano olefins. The additions to methacrylonitrile catalyzed by $[Pd(NCCH_3)(PCP)](PF_6)_2$ (**11**) showed moderate enantioselectivities which increased at low temperatures. The sterically modified complex $[Pd(NCCH_3)(3,5\text{-Me-PCP})](PF_6)_2$ (**13**) showed higher enantioselectivities at room temperature (up to 61% *ee*) as well as at –80 °C (up to 75% *ee*). Comparing Pd(PCP) and Ni(Pigiphos) catalysts having the same absolute configuration of the ferrocenyl units, it is interesting to note that products of opposite absolute configuration are obtained. Somewhat surprisingly and disappointingly, it appears that the C_2-symmetric PCP ligands described here do not offer any significant advantage when compared to the asymmetric ligand Pigiphos in the Ni/Pd-catalyzed addition of amines to methacrylonitrile.

Experimental Section

General Methods: (*R*)-*N*,*N*-Dimethyl-1-ferrocenylethylamine was generously provided by Solvias AG (Basel) and was recrystallized as tartrate salt according to the reported procedure.[39] The chlorophosphanes $[3,5\text{-}(CF_3)_2C_6H_3]_2PCl$ and $[3,5\text{-}(CH_3)_2C_6H_3]_2PCl$ were prepared as described.[40] Derivatives **2**–**5** have been prepared before in our laboratory.[41] All reactions were performed under an inert gas and air-sensitive substances were handled in a glove box. NMR: The routine ^1H, ^{13}C, and ^{31}P NMR spectra were measured in the given solvent with either a Bruker DPX250 or Bruker DPX300 instrument. The 2D experiments were generally carried out with a Bruker DPX500 instrument. EI-MS, FAB-MS, MALDI-MS: Measurements were performed by the MS service of the "Laboratorium für Organische Chemie der ETHZ". The signals are given as *m*/*z*. Elemental analyses were performed by the micro elemental analysis service of the "Laboratorium für Organische Chemie der ETHZ". Crystallography: X-ray structural measurements were carried out with a Bruker CCD diffractometer (Bruker SMART PLATFORM, with a CCD detector, graphite monochromator, and Mo-K_α radiation). The program SMART served for data collection. Integration was performed with SAINT. The structure solution (direct methods) and refinement on F^2 were accomplished with SHELXTL-97. Model plots were made with ORTEP32. For the structures of **6**, **14** (with exceptions), and **11** all non-hydrogen atoms were refined freely with anisotropic refinement parameters. For **6** a CH_2Cl_2 molecule was found to be disordered over two sites. The C–Cl bond lengths were restrained to standard values. Iodide and some of the CF_3 groups are disordered over two sites. The C–F distances were restrained by the use of a variable and the F···F distances were equalized with the SADI instruction. In the structure of **14** there are three $CHCl_3$ molecules present. The carbon atom in one of the $CHCl_3$ molecules is disordered over two positions. The C–Cl bond lengths were restrained to standard values. For the disordered CF_3 groups of C(6) and C(45) the same procedure was adopted as for **6**. Due to the low data-to-parameter ratio, the atoms C(1), C(10), C(62), C(29), and N(2) were refined anisotropically in combination with the ISOR instruction. In the structure of **11** one ethanol and one diethyl ether molecule are present. C(55) of the ether molecule and C(58) of ethanol is disordered over two positions. Hydrogen atoms were refined at calculated positions riding on their carrier atoms. Weights were optimized in the final refinement cycles. Crystallographic data are given in Table 6. CCDC-240665 (**6**), -240662 (**14**), and -240664 (**11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

1,3-Bis{(*R*)-1-[(*S*)-2-{[3,5-bis(trifluoromethyl)phenyl]phosphanyl}-ferrocenyl]ethyl}imidazolium Iodide (6): A suspension of **4** (1.51 g, 2.07 mmol) and imidazole (77.5 mg, 1.14 mmol, 0.55 equiv.) in a mixture of acetonitrile (14 mL) and water (3.5 mL) was heated at 60 °C for 24 h. After addition of benzene (9 mL), the organic phase was separated and concentrated in vacuo. The residue was dissolved together with NaI (683 mg, 4.55 mmol, 2 equiv.) in ethanol (15 mL) and stirred for 3 h. After evaporation of the solvent in vacuo, the crude product was filtered through silica (CH_2Cl_2, then

General Procedure for the Pd-Catalyzed Hydroamination of Cyano Olefins: A solution of palladium complex (0.025 mmol; 5 mol-%) and olefin (1 mmol; 2 equiv.) in THF (3 mL) was stirred at room temperature for 5 min. The amine (0.5 mmol) was then added and the reaction mixture was stirred at the required temperature for the corresponding time. The reaction was stopped by the addition of hexane. Filtration and evaporation of the solvent yielded the hydroamination product. If necessary, the product was purified by chromatography (silica, hexane/ethyl acetate, 1:1 + 5% NEt_3). Enantioselectivities were determined by GC or HPLC analysis.

3-(Morpholino)butanenitrile (16): TLC (hexane/ethyl acetate, 1:1 + 5% NEt_3): R_f = 0.47. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.20 (d, J = 6.8 Hz, 3 H, CHC*H*$_3$), 2.38 (dd, J = 7.3 Hz, J = 16.8 Hz, 1 H, C*H*H′CN), 2.52 (t, J = 4.8 Hz, 4 H, C*H*$_2$N), 2.52 (dd, J = 6.5 Hz, J = 16.8 Hz, 1 H, CH*H*′CN), 2.94 (m, J = 6.0 Hz, 1 H, NC*H*CH$_3$), 3.70 (t, J = 4.6 Hz, 4 H, C*H*$_2$O) ppm. ^{13}C(DEPT) NMR (250 MHz, $CDCl_3$): δ = 15.2 (CH*C*H$_3$), 21.3 (*C*HH′CN), 48.8 (*C*H$_2$N), 56.3 (N*C*HCH$_3$), 67.1 (*C*H$_2$O) ppm. GC (β-dex, 90 °C iso): t_r = 267.50, 267.64 min.

Influence of Solvent on Ligand-Substitution Reactions of Pt^{II} Complexes as Function of the π-Acceptor Properties of the Spectator Chelate

Christian F. Weber[a] and Rudi van Eldik*[a]

Keywords: Solvent effects / Kinetics / Platinum(II) chemistry / Ligand effects / UV/Vis spectroscopy

A detailed kinetic study of the substitution reactions of $[Pt^{II}(L^3)Cl]^+$ complexes, where L^3 represents a tridentate N-donor chelate which contains different numbers of π-acceptor pyridine units, with thiourea as a function of nucleophile concentration, temperature and pressure was undertaken in a series of solvents of different polarity, viz. 1-pentanol, 1-propanol, ethanol, methanol and water. The substitution behaviour of [Pt(diethylenetriamine)Cl]$^+$ (**aaa**), [Pt{2,6-bis(aminomethyl)pyridine}Cl]$^+$ (**apa**), [Pt{bis(2-pyridylmethyl)amine}Cl]$^+$ (**pap**) and [Pt(terpy)Cl]$^+$ (**ppp**) was studied in the selected solvents. In the case of alcoholic solutions, an increase in the substitution rate with increasing length of the carbon chain was observed, which is ascribed to the possible role of van der Waals forces in stabilizing the transition state. In the case of methanol and water as solvent, the second-order rate constants correlate with the polarity of the solvent. The activation parameters for the substitution of the **aaa**, **apa**, **pap**, and **ppp** complexes in methanol and water were determined, from which evidence for an associative mechanism was obtained. The introduction of π-acceptor ligands leads to a higher electrophilicity of the platinum(II) centre and consequently a higher lability of the complex. The reactivity of the complexes is controlled by a combination of solvent and π-acceptor effects.

Introduction

We are interested in the effect of solvent on ligand-substitution reactions of Pt^{II} complexes because of the high activity of some Pt complexes against certain tumour cells.[1] For this reason ligand-substitution reactions of square-planar (low-spin d^8) Pt^{II} complexes are among the best investigated dynamic processes in chemistry.[2] Up to now the kinetic and thermodynamic data show that in nearly all cases the substitution mechanism has an associative character,[2,3] according to which the entering ligand forms a bond with the metal centre prior to bond cleavage with the leaving group, which involves an increase in the coordination number of the Pt centre from four (square-planar) to five (trigonal-bipyramidal) in the transition state. In some rare cases ligand-substitution reactions on Pt^{II} complexes follow a dissociative reaction mechanism.[4–6]

The rate constants for such ligand-substitution reactions vary considerably and depend on the nature of the solvent, entering nucleophile, spectator ligand, leaving group, charge on the complex and pH. For a series of (aqua)Pt^{II} complexes with a varying number of π-acceptor ligands (viz. pyridine ligands), it was shown that the π-acceptor effect controls the substitution rate since it causes a decrease in the electron density and an increase in electrophilicity of the Pt^{II} centre.[7] Kotowski et al. determined rate and activation parameters for the reaction of *trans*-$[Pt(py)_2(NO_2)Cl]$ with pyridine in nitromethane, methanol, ethanol and dichloromethane.[8,9] The solvent dependence of the activation volume, $\Delta V^{\neq}$, could be used to separate intrinsic and solvational volume contributions which result from changes in bond lengths and angles, and changes in polarity, dipole interactions and electrostriction during formation of the transition state of the reaction, respectively. Such information is crucial for a full understanding of the intimate nature of the substitution mechanism.[8,9]

In this paper we report the effect of solvent on ligand-substitution reactions of Pt^{II} complexes as a function of the π-acceptor properties of the spectator chelate. The investigated reaction is given in Equation (1).

$$[Pt(L^3)Cl]^+ + TU \xrightarrow{k_2} [Pt(L^3)TU]^{2+} + Cl^- \quad (1)$$

Thiourea (TU) was used as a neutral entering ligand such that the overall reaction is accompanied by charge creation on which basis a characteristic solvent dependence is to be expected. In addition, formation of the five-coordinate transition state may involve changes in dipole moment which will affect the activation parameters, especially the entropy and volume of activation. The selected Pt^{II} complexes are [Pt(diethylenetriamine)Cl]$^+$ (**aaa**), [Pt{2,6-bis(aminomethyl)pyridine}Cl]$^+$ (**apa**), [Pt{bis(2-pyridylmethyl)amine}Cl]$^+$ (**pap**) and [Pt(2,2′:6′,2′′-terpyridine)Cl]$^+$ (**ppp**), where **a** and **p** represent amine and pyridine, respectively. The structures of the complexes[7] and adopted abbrevi-

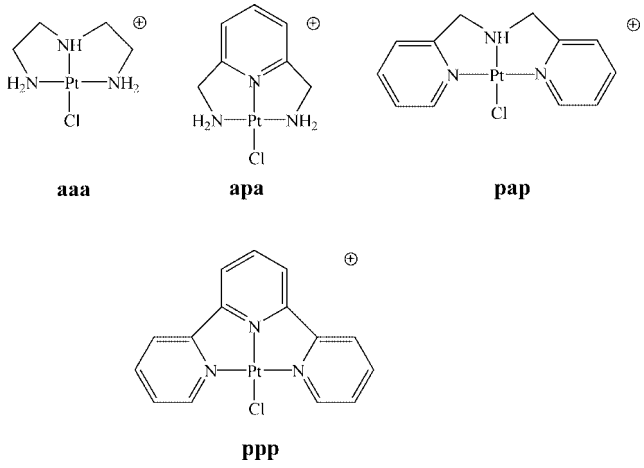
ations are summarized in Scheme 1. A series of solvents of different polarity were selected and are summarized in Table 1.[10] We report the effect of the solvent on the π-acceptor properties, activation parameters and polar nature of the transition state for the studied reaction.



Scheme 1.

Results and Discussion

In order to investigate the solvent dependence of ligand-substitution reactions on Pt^{II} complexes as a function of the π-acceptor property of the spectator chelate, a total of four (chloro)Pt^{II} complexes were synthesized and characterized. More information on the crystal structure of the complexes is available from the literature.[7] Solutions of the complexes were prepared by dissolving known amounts of the chloro complexes in the selected solvents in the presence of 0.002 M LiCl in order to prevent spontaneous solvolysis reactions. The solubility of the complexes differed significantly and UV/Vis spectra were recorded to monitor the solvolysis reactions.

The ligand-substitution reactions were studied as a function of the thiourea (TU) concentration, temperature and pressure for the series of solvents. An example of the UV/Vis spectral changes and a representative kinetic trace are shown in Figures 1 and 2, respectively. The wavelengths used to monitor the reactions are listed in Table 2. All kinetic traces showed excellent fits to a single exponential function. We studied the effect of the concentration of trifluoromethanesulfonic acid on the observed rate constants for the substitution reactions of the **apa** complex in water and methanol. In water as solvent, following $k_{obsd.}$ values were obtained at 25 °C (concentration of trifluoromethanesulfonic acid is given in parentheses): 0.0497 s^{-1} (0.001 M), 0.0439 s^{-1} (0.01 M), and 0.0466 s^{-1} (0.02 M) for [TU] = 0.0274 M. From these results it is clear that no significant protonation of thiourea occurs in water in the acidity range employed in this study. For the same reaction in methanol the following values were found: 0.0151 s^{-1} (0.001 M), 0.0141 s^{-1} (0.01 M), and 0.0125 s^{-1} (0.02 M) for [TU] = 0.0367 M. The observed trend is ascribed to partial protonation of thiourea at higher acid concentrations. Apparently, there is quite some confusion in the literature concerning the protonation constant of thiourea. We have therefore performed a reinvestigation (experimental and theoretical) of the protonation constant of thiourea in different solvents and will report the results separately.[11] Furthermore, the influence of low concentrations of water on the rate constants for the reactions in methanol and propanol was also studied. In methanol as solvent the following $k_{obsd.}$ values were obtained at 25 °C (vol.% of water is given in parentheses): 0.0141 s^{-1} (as received), 0.01503 s^{-1} (1 vol.%), 0.01514 s^{-1} (2 vol.%), 0.01403 s^{-1} (3 vol.%), 0.01438 s^{-1} (4 vol.%) and 0.01460 s^{-1} (5 vol.%) for [TU] = 0.0367 M. In propanol as solvent the following values were obtained: 0.0212 s^{-1} (as received), 0.0215 s^{-1} (1 vol.%), 0.0205 s^{-1} (2 vol.%), 0.0199 s^{-1} (3 vol.%), 0.0197 s^{-1} (4 vol.%) and 0.0194 s^{-1} (5 vol.%) for [TU] = 0.0265 M. It follows that low concentrations of water have no significant effect on the observed rate constant.

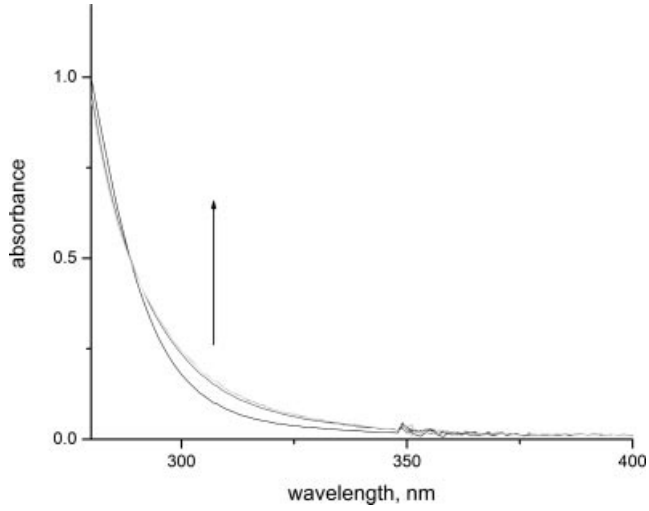


Figure 1. UV/Vis spectral changes recorded for the reaction between the **apa** complex and thiourea in water at 25 °C. The concentrations of **apa** and thiourea are 1.9×10^{-4} M and 0.0106 M, respectively.

The observed pseudo-first-order rate constants, $k_{obsd.}$, were plotted against the thiourea concentration, and for all studied reactions a linear dependence with a negligible in-

1–Propanol	–	300	300	336
Ethanol	–	300	300	333
Methanol	–	300	300	333
Water	300	305	285	336

tercept was observed. Two typical plots are shown in Figures 3 and 4, respectively, from which it follows that $k_{obsd.}$ can be expressed by Equation (2), where k_2 is the second-order rate constant for the overall reaction in Equation (1). The corresponding plots for all other studied reactions are reported as Supporting Information (see also the footnote on the first page of this article).

$$k_{obsd.} = k_2 [TU] \quad (2)$$

The values of k_2 for the substitution of chloride by thiourea on complexes of the type $[Pt^{II}(L^3)Cl]^+$ are summarized in Table 3 for the selected solvents. Formamide (FMA) was in general unsuitable as solvent due to the rapid displacement of chloride by the solvent and formation of $[Pt(L^3)\text{-}FMA]^{2+}$. Also the substitution reactions of **aaa** in methanol and **pap** in 1-pentanol could not be studied due to the formation of insoluble products. The higher charge on the product led to a decrease in solubility in relative nonpolar solvents. The k_2 values show that the substitution reactions in water and methanol depend on polarity, viz. the k_2 values decrease with decreasing polarity. Changing the solvent from water to methanol causes a fourfold deceleration in the case of **apa**, a sixfold deceleration in the case of **pap** and a twofold deceleration in the case of **ppp**. This can be related to the creation of charge during the overall displacement of the chloride anion by neutral thiourea, viz. leading to a partial increase in polarity in the transition state of the process. According to the Hughes–Ingold rules a decrease in solvent polarity results in a decrease in the rates of those reactions in which the charge density is larger in the activated complex than in the initial reactants. The change to a less polar solvent will decrease the reaction rate when the activated complex is more polar than the initial reactants.[12] In the case of water as solvent the polar transition state is even more stabilized.

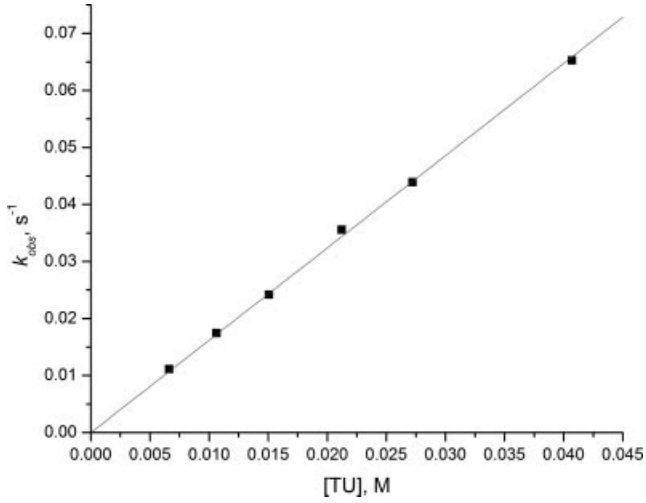

Figure 3. Plot of $k_{obsd.}$ vs. thiourea concentration for the **apa** complex in water. Experimental conditions: [**apa**] = 1.9×10^{-4} M. 25 °C, 0.002 M LiCl, pH = 2 (0.01 M trifluoromethanesulfonic acid).

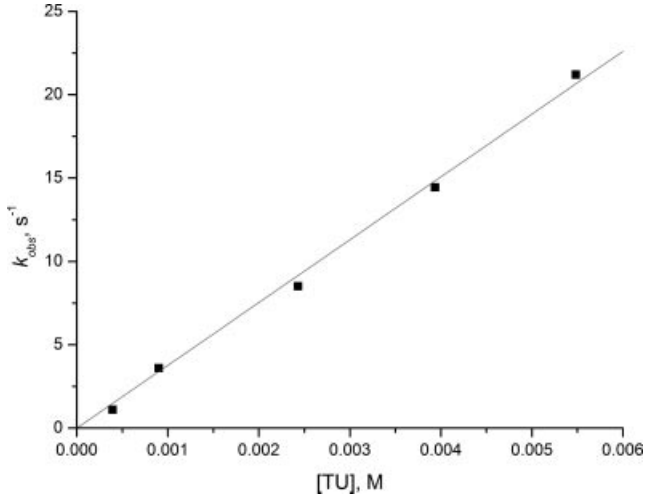

Figure 4. Plot of $k_{obsd.}$ vs. thiourea concentration for the **ppp** complex in 1-propanol. Experimental conditions: [**ppp**] = 1.16×10^{-4} M. 25 °C, 0.002 M LiCl, 0.01 M trifluoromethanesulfonic acid.

On changing the solvent to methanol, ethanol, 1-propanol and 1-pentanol, an acceleration of all substitution reactions for the complexes **apa**, **pap** and **ppp** was observed. This tendency was also observed by Kotowski et al.[9] for substitution reactions on related Pt^{II} complexes. Various attempts were undertaken to correlate the reported second-order rate constants with physical parameters that describe

[a] Formation of colloid particles.

the solvent properties. No direct correlation could be found for solvent polarity or the possible influence of hydrogen bonding. Furthermore, no correlation was found between the second-order rate constant and the Kamlet and Taft solvatochromic parameters that measure the solvent hydrogen-bond donor acidity (α), solvent hydrogen-bond acceptor basicity (β) and solvent dipolarity/polarizability (π^*).[13] The only apparently meaningful correlation that could be found is based on the observation that an increase in the van der Waals forces with increasing carbon-chain length of the alcohols seemed to play an important role. With increasing carbon-chain length the van der Waals forces, as indicated by the boiling points of the solvents, increase to the point that they become stronger than the hydrogen bonding network.[14] The boiling points of the employed alcohols are listed in Table 1. A similar trend is observed in the second-order rate constants. A comparison of both trends is shown in Figure 5, from which it is concluded that van der Waals forces apparently contribute significantly to the stabilization of the transition state. A referee suggested that the longer-chain alcohols could behave as nano-micelles with the alcohol portions directed toward the evolving charge centre. In this way the reaction in the higher alcohols could occur inside a polar sphere, not in contact with the non-polar alcohol tails.

It is well known that the rate of associative substitution reactions strongly depend on the nucleophilicity of the entering nucleophile, viz. the stronger the nucleophile, the faster the rate of the substitution reaction. The four complexes **aaa**, **apa**, **pap** and **ppp** show different k_2 values in the same solvent. In water as solvent we obtained a second-order rate constant of 0.54 M^{-1} s^{-1} for the reaction between **aaa** and TU at 25 °C, 1.62 M^{-1} s^{-1} for **apa**, 3.67 M^{-1} s^{-1} for **pap** and 2797 M^{-1} s^{-1} for **ppp** as reactant. In methanol as solvent we found 0.39 M^{-1} s^{-1} for **apa**, 0.59 M^{-1} s^{-1} for **pap** and 1344 M^{-1} s^{-1} for **ppp** as reactant. This shows that the second-order rate constants increase with increasing number of π-acceptor ligands on the spectator chelate. π-Acceptor ligands have the ability to withdraw electron density from the Pt^{II} centre, thus making it more electrophilic for a nucleophilic attack and enabling stabilization of the electron-rich, five-coordinate transition state. This results in a reduction of the activation barrier and an acceleration of the reaction. The π-acceptor effect is also used to account for the unusually high lability of the **ppp** complex. This effect was investigated in more detail for Pt^{II} complexes in which the number of pyridine ligands was varied systematically.[7] The **ppp** complex shows the highest reactivity relative to the corresponding **aaa** complex due to π-back-bonding from the Pt^{II} centre to the empty π*-orbitals of the pyridine moieties of the terpy ligand.

The activation parameters ($\Delta H^{\neq}$, $\Delta S^{\neq}$ and $\Delta V^{\neq}$) were determined for the substitution reaction of the **aaa** complex in water and of the **apa**, **pap** and **ppp** complexes in methanol and water, respectively, and are listed in Table 4. Two representative plots showing typical temperature and pressure

pap	water	3.67 ± 0.02	46 ± 1	–81 ± 2	–7.0 ± 0.3
ppp	methanol	1344 ± 21	35 ± 1	–67 ± 3	–2.6 ± 0.1
ppp	water	2797 ± 42	29 ± 1	–82 ± 2	–[b]

[a] Not possible to measure. [b] Not possible due to low solubility of **ppp** in water.

dependences are reported in Figures 6 and 7, respectively. The corresponding plots for all other studied reactions are reported as Supporting Information. The acceleration of the substitution reactions by pressure is indicative of an associative substitution mechanism, which is supported by the negative $\Delta S^{\neq}$ values. The decrease in entropy is associated with a highly structured transition state which is accompanied by a decrease in volume due to the compact nature of the transition state as a result of bond formation and an increase in solvation due to an increase in polarity of the transition state.[15]

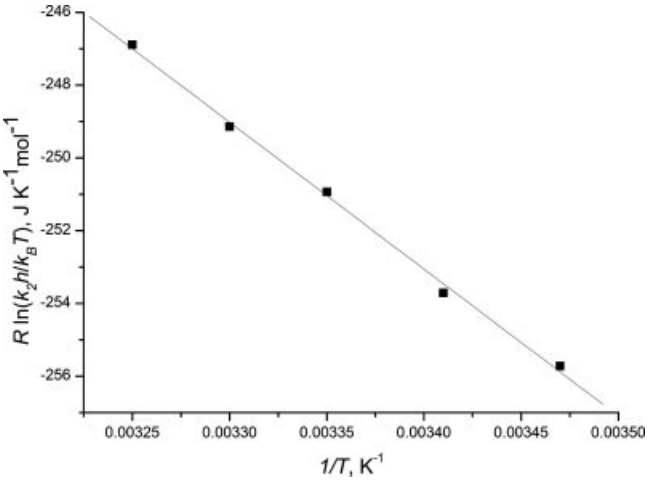

Figure 6. Temperature dependence of the reaction of the **aaa** complex with thiourea in water. Experimental conditions: [**aaa**] = 3.36×10^{-4} M, [TU] = 0.271 M, 0.002 M LiCl, pH = 2 (0.01 M trifluoromethanesulfonic acid).

For all investigated reactions, changing the solvent from methanol to water leads to more negative entropies of activation and in the case of **apa** the volume of activation changes from –6.6 to –10.4 cm^3 mol^{-1}, which corresponds to the tendency shown by the entropies of activation. $\Delta S^{\neq}$ decreases from –42 to –77 J K^{-1} mol^{-1} in the case of **apa**, from –65 to –81 J K^{-1} mol^{-1} for **pap** and from –67 to –82 J K^{-1} mol^{-1} **ppp** on changing the solvent from methanol to water. This can be ascribed to a larger number of highly structured water molecules as compared to the number of structured methanol molecules in the second coordination sphere of the transition state, in which hydrogen bonding plays a major role. Activation volumes were found to be –5.9 cm^3 mol^{-1} for the reaction of **aaa** with TU in water, –7.0 cm^3 mol^{-1} for **pap** in water and –2.6 cm^3 mol^{-1} for **ppp**

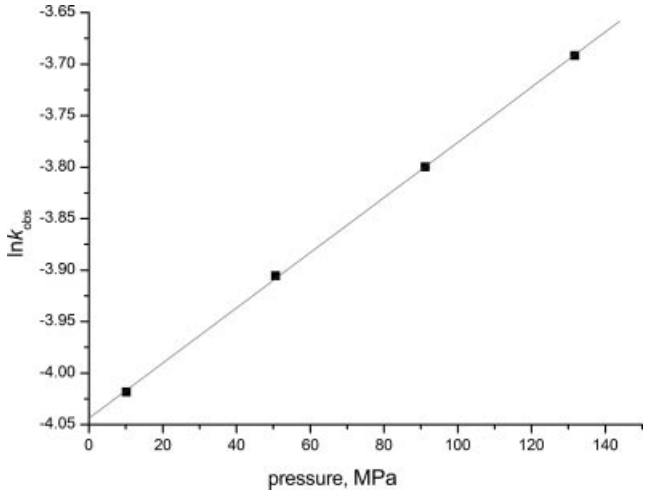

Figure 7. Pressure dependence of the reaction of the **apa** complex with thiourea in methanol. Experimental conditions: [**apa**] = 4.75×10^{-4} M, [TU] = 0.059 M, 25 °C, 0.002 M LiCl, 0.01 M trifluoromethanesulfonic acid.

in methanol. These values parallel the trends in the activation entropies and can be interpreted in a similar way.

As mentioned above, changing the solvent from methanol to water causes an acceleration of all studied reactions. Thus, in general an increase in solvent polarity leads to higher rate constants and lower $\Delta H^{\neq}$ values. We observed a change in $\Delta H^{\neq}$ from 63 to 49 kJ mol^{-1} for the reaction of **apa** with thiourea, from 55 to 46 kJ mol^{-1} for **pap** and from 35 to 29 kJ mol^{-1} for **ppp** on changing the solvent from methanol to water. In the case of **apa**, the decrease in $\Delta H^{\neq}$ is more significant than for **pap** and **ppp** for the two solvents. This must be related to the increase in the number of pyridine ligands which causes an increase in the electrophilicity of the Pt^{II} centre and apparently makes $\Delta H^{\neq}$ less sensitive to the polarity of the solvent.

Conclusions

The effect of solvent on ligand-substitution reactions of Pt^{II} complexes as a function of the π-acceptor property of the spectator chelate was studied systematically. Four mono(chloro)Pt^{II} complexes were synthesized and characterized. A series of solvents were selected as a function of polarity, viz. 1-pentanol, 1-propanol, ethanol, methanol, water, and formamide. The ligand-substitution reactions

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were studied as a function of the nucleophile (thiourea) concentration, temperature and pressure. Formamide as solvent was ruled out due to the formation of solvento complexes.

In the case of alcohols as solvent, we observed a systematic increase in the second-order rate constant with increasing length of the carbon chain of the alcohol and ascribed it to a possible role of van der Waals forces in stabilizing the transition state of the substitution process. An increase in rate constant was observed in going from methanol to water, which is in line with the expected trend in terms of the polarity of the solvent, viz. a more polar solvent will stabilize the polar transition state formed through the associative attack of the neutral nucleophile. The negative $\Delta S^{\neq}$ and $\Delta V^{\neq}$ values are indicative of an associative substitution mechanism. The magnitude of $\Delta V^{\neq}$ favours the operation of an associative interchange (I_a) mechanism and can be interpreted in terms of an intrinsic volume collapse due to bond formation with the entering nucleophile, accompanied by solvational changes resulting from changes in the polarity of the five-coordinate transition state. In all investigated reactions, a change in polarity from a relative nonpolar to a polar solvent resulted in more negative entropies and volumes of activation. Furthermore, the results suggest that in the case of water as solvent a larger number of structured water molecules are present in the second coordination sphere of the transition state, as compared to the number of structured methanol molecules in the case of methanol as solvent.

The four complexes **aaa**, **apa**, **pap**, and **ppp** showed in the same solvent a steady increase in rate constant with increasing electrophilicity of the platinum centre. The π-acceptor pyridine ligands have the ability to withdraw electron density from the Pt^{II} centre to make it more electrophilic which is accompanied by an increase in rate constant for nucleophilic attack. In the case of the **ppp** complex the rate constant is much less solvent dependent than in the case of the **apa** and **pap** complexes, indicating that a highly electrophilic metal centre will lead to a less polar transition state making the substitution reaction less solvent dependent.

Experimental Section

General: All chemicals used were of analytical reagent grade and of the highest purity commercially available. The ligands diethylenetriamine, bis(2-pyridylmethyl)amine and 2,2′:6′,2′′-terpyridine were purchased from Aldrich. K_2PtCl_4 was obtained from Strem. K_2PtCl_4 was separated from metallic Pt and K_2PtCl_6 by dissolution in water and filtering.[16] All chemicals were used without further purification. Ultra pure water was used for the spectroscopic as well as kinetic measurements. The organic solvents used were of analytical reagent grade (see Results and Discussion).

Synthesis of Complexes

[Pt(diethylenetriamine·HCl)Cl_2]: The complex was prepared in a similar way as described by Mahal and van Eldik.[17] K_2PtCl_4 (0.5 g, 1.2 mmol) was dissolved in water (8 mL), filtered and diethylenetriamine (0.240 mL, 0.23 g, 2.27 mmol) was added. The pH of the solution was adjusted to ca. 3 by the addition of HCl, followed by heating to reflux for 3 d. The yellow solution was filtered, concentrated to ca. 2.5 mL and cooled with ice. A yellow product precipitated, which was recrystallized from 1 M HCl (0.315 g, 65%). $C_4H_{14}Cl_3N_3Pt$ (405.6): calcd. C 11.9, H 3.5, N 10.4; found C 11.64, H 3.51, N 10.15.

[Pt(diethylenetriamine)Cl]Cl:[17] The above prepared compound was dissolved in water and the pH adjusted to 10 with LiOH. After that, the solution was heated at 80 °C for 30 min during which the pH was kept at 10 with LiOH. The colourless solution was cooled, the pH adjusted to 4 with HCl, concentrated and cooled. White crystals precipitated, which were washed with ethanol and ether (0.182 g, 63%). $C_4H_{13}Cl_2N_3Pt$ (369.2): calcd. C 13.0, H 3.5, N 11.4; found C 12.72, H 3.53, N 11.14.

[Pt(diethylenetriamine)Cl]CF_3SO_3 (aaa):[18] Concentrated solutions of [Pt(diethylenetriamine)Cl]Cl (0.161 g, 0.4 mmol) and $Ag(CF_3SO_3)$ (0.112 g, 0.4 mmol) were prepared in warm water. The $Ag(CF_3SO_3)$ solution was added dropwise and AgCl precipitated immediately. After repeated filtration, the solvent was removed and the product was dried (0.149 g, 77%). $C_5H_{13}ClF_3N_3O_3PtS$ (482.8): calcd. C 12.44, H 2.71, N 8.70, S 6.64; found C 12.62, H 2.66, N 8.46, S 6.52.

[Pt{2,6-bis(aminomethyl)pyridine}Cl]Cl·H_2O (apa): The ligand 2,6-bis(aminomethyl)pyridine was prepared according to a method used to synthesize 6-(aminomethyl)-2,2′-bipyridine[19] by using 2,6-bis(bromomethyl)pyridine[20] as starting material.[7] The corresponding platinum complex was prepared as described in the literature[7] and was obtained in the same quality (0.260 g, 38%). $C_7H_{13}Cl_2N_3OPt$ (421.2): calcd. C 19.95, H 3.09, N 9.98 ;found C 19.76, H 3.19, N 9.76. ^{1}H NMR (300 MHz, D_2O): δ = 7.7 (t, 1 H, 1 CH, *para*), 7.25 (d, 2 H, 2 CH, *meta*), 4.25 (s, 4 H, 2 CH_2) ppm.

[Pt{bis(2-pyridylmethyl)amine}Cl]CF_3SO_3 (pap): K_2PtCl_4 (0.2 g, 0.48 mmol) was dissolved in 0.005 M HCl (200 mL) and then 97% bis(2-pyridylmethyl)amine (0.1 mL) was added. The solution was stirred under reflux for 3 d and then cooled to room temperature. The colourless solution was filtered and concentrated to about 10 mL. Addition of saturated CF_3SO_3Na solution (2–3 mL) produced the precipitate of the desired complex. This was collected by filtration, washed with small amounts of water, ethanol and ether, and dried under vacuum. $C_{13}H_{13}ClF_3N_3O_3PtS$ (578.9): calcd. C 26.97, H 2.26, N 7.26, S 5.54; found C 26.49, H 2.16, N 7.05, S 5.57. ^{1}H NMR (400 MHz, D_2O): δ = 8.70 (d, 2 H, 2 CH, *ortho*), 8.05 (td, 2 H, 2 CH, *para*), 7.52 (d, 2 H, 2 CH, *meta*), 7.41 (dd, 2 H, 2 CH, *meta*) ppm.

[Pt(2,2′:6′,2′′-terpyridine)Cl]CF_3SO_3 (ppp): A mixture of K_2PtCl_4 (0.5 g, 1.2 mmol) and 2,2′:6′,2′′-terpyridine (terpy) (0.33 g, 1.4 mmol) in water (25 mL) was stirred under reflux until a clear red solution had formed, which took about 75 h. The solution was filtered and concentrated to about 3 mL. The red trihydrate salt of [Pt(2,2′:6′,2′′-terpyridine)Cl]Cl precipitated upon cooling. This was collected by vacuum filtration, washed with dilute 0.1 M HCl and acetone, and the product [Pt(2,2′:6′,2′′-terpyridine)Cl]Cl·$3H_2O$ was dried under vacuum (0.181 g, 28%).[21] Concentrated solutions of [Pt(2,2′:6′,2′′-terpyridine)Cl]Cl·$3H_2O$ (0.161 g, 0.3 mmol) and $Ag(CF_3SO_3)$ (0.075 g, 0.3 mmol) were prepared in warm water. The $Ag(CF_3SO_3)$ solution was added dropwise and AgCl precipitated immediately. An additional red precipitate was observed. The solution was stirred at room temperature for 1 h, diluted to 250 mL and stirred at 60 °C overnight. After repeated filtration, the solvent was removed and the product was dried (0.108 g, 61%). $C_{16}H_{11}ClF_3N_3O_3PtS$ (612.9): calcd. C 31.36, H 1.81, N 6.86, S 5.23; found C 30.81, H 1.83, N 6.65, S 5.18.

Instrumentation and Measurements: A Carlo Erba Elemental Analyser 1106 and 1108, and NMR spectroscopy (Bruker Avance DPX 300 and DRX 400) were used for chemical analysis and compound characterization. UV/Vis spectra for the study of slow reactions were recorded with a Varian Cary 1G spectrophotometer, equipped with a thermostatted cell holder. The chloro complexes all show absorbance maxima between 280 and 340 nm. Addition of an excess of thiourea causes a large increase in absorbance below 350 nm. Appropriate wavelengths (see Table 2) were selected to monitor the substitution of chloride by thiourea. Kinetic measurements for fast reactions were studied with an Applied Photophysics SX 18MV stopped-flow instrument. For experiments at elevated pressure (1–130 MPa), a laboratory-made high-pressure stopped-flow instrument was used.[22] The temperature of the instruments was controlled with an accuracy of ±0.1 °C. Thiourea (TU) was selected as entering ligand since its high nucleophilicity prevents the back reaction. LiCl solutions (0.002 M) were used to avoid spontaneous solvolysis of the chloro complexes. In the case of alcohol as solvent, trifluoromethanesulfonic acid (0.01 M) was used to avoid formation of alcoholate species that can compete as nucleophiles (see Results and Discussion). The ligand-substitution reactions were studied under pseudo-first-order conditions by using at least a ten-fold excess of TU. All listed rate constants represent an average value of at least five kinetic runs under each experimental condition.

Supporting Information (see also footnote on the first page of this article): Plots showing the concentration, temperature, and pressure dependence of the reactions between the Pt^{II} complexes and thiourea.

The Synthesis and Characterisation of Bis(phosphane)-Linked (η^6-*p*-Cymene)-ruthenium(II)–Borane Compounds

Adrian B. Chaplin,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]

Keywords: Ruthenium / P ligands / Bridging ligands / Coordination modes / Boranes

The reaction of $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$ with some bis(phosphane) ligands (dppm, dppe, dppv, dppa, dpp14b, dppf) has been investigated. In general mixtures of products were obtained, although the pendant phosphane complexes $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-dppv})]$ and $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-dppa})]$ were isolated and characterized in the solid state by X-ray diffraction. The later complex was obtained in lower yield and undergoes an equilibration reaction resulting in the formation of a dimeric species, where the dppa bridges two ruthenium centres, and uncoordinated phosphane; the bridging species was also structurally characterised in the solid state. In contrast, the reaction of $[(\eta^6\text{-}p\text{-cymene})RuCl_2(PPh_3)]$ with dppa in the presence of $[NH_4]PF_6$ results in the formation of $[(\eta^6\text{-}p\text{-cymene})RuCl(PPh_3)(\eta^1\text{-dppa})]PF_6$, which is stable in solution. A series of linked ruthenium–borane complexes, viz. $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-phosphane-}BH_3)]$ (phosphane = dppm, dppe, dppv, dppa, dpp14b, dppf) and $[(\eta^6\text{-}p\text{-cymene})RuCl(PPh_3)(\eta^1\text{-dppa-}BH_3)]PF_6$ have been prepared from isolated pendant phosphane complexes, those generated in situ, or from a preformed phosphane–borane adduct. The solid-state structures of $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-dppm-}BH_3)]$, $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-dppe-}BH_3)]$ and $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-dppv-}BH_3)]$ have been determined by X-ray diffraction analysis.

Introduction

The use of chelating phosphane ligands is prevalent in the coordination chemistry of the transition metals,[1] with complexes incorporating chelating phosphane ligands finding many applications in catalysis, where the versatility of this ligand class has allowed the rational design of highly active and selective compounds.[2] Bis(phosphane) ligands can also be found to bridge metal centers and coordinate selectively through one phosphorus centre, leading the other end free.[3–5] Such pendant coordination provides a way to link a variety of fragments, including simple metal complexes, metal cluster compounds, and main group fragments.[3c–g,4,6]

Ruthenium(II) complexes have well documented catalytic utility in organic chemistry,[2d] among which half sandwich (η^6-arene)ruthenium(II) complexes constitute an important class. As part of our continuing investigation of these complexes for catalytic hydrogenation reactions,[7] we have embarked on developing methodologies for the preparation of compounds in which the catalytically active ruthenium fragment is linked to other metal and non-metal moieties. These include functionalisation of the coordinated arene with imidazolium groups or crown ether moieties,[8] and formation of a heterometallic carbene complex.[9] In this paper we describe the preparation of model-linked (η^6-*p*-cymene)-ruthenium(II) systems using bis(phosphane) ligands.

For these linked systems the borane moiety, BH_3, was selected as a model-linked species as phosphane–borane adducts are formed rapidly and tend to be thermally stable.[10] Furthermore, coordination of a phosphane to BH_3 is a common method for protecting valuable (usually chiral) phosphanes from oxidation, either during storage or during synthetic transformations.[10] Phosphane–borane adducts have also been used as bidentate ligands, coordinating through a P centre and agostic B–H interactions (**a**,[11] **b**,[12] **c**–**e**[13] in Figure 1). In addition, as models for metalloborane ruthenium clusters, Barton and co-workers have previously prepared $[(\eta^6\text{-}p\text{-cymene})RuCl_2PPh_2CH_2C_6H_4\text{-}CH_2PPh_2BH_3]$ (**f**) and $[(\eta^6\text{-}p\text{-cymene})RuCl_2PPh_2(CH_2)_6\text{-}PPh_2BH_3]$ (**g**) from the reaction of either isolated or in-situ generated (η^6-*p*-cymene)ruthenium pendant phosphane complexes with BH_3·THF.[4]

Results and Discussion

The direct reaction between $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$ and bis(phosphane) ligands in a 1:2 ratio generally results in the formation of the desired pendant phosphane complexes, viz. $[(\eta^6\text{-}p\text{-cymene})RuCl_2(\eta^1\text{-phosphane})]$, together with other ruthenium-containing species. In the case of potentially chelating phosphane ligands, formation of the η^2-coordinated complex, presumably following initial η^1-coordination followed by intramolecular chloride substitution,

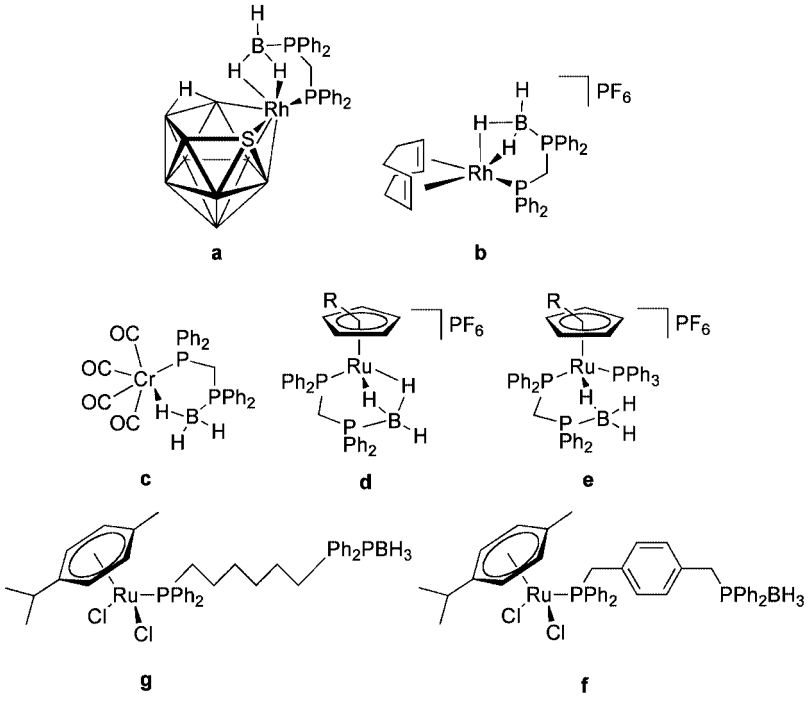

Figure 1. Examples of metal-containing phosphane–borane adducts.

can be suppressed by avoiding polar solvents, such as methanol and ethanol, which promote chloride loss. In such a way the previously reported complex [(η^6-*p*-cymene)-$RuCl_2$(η^1-dppm)] (**1**) has been prepared in high yield (76%) [7a] using benzene as a solvent.[5,7a] However, reaction of the phosphane ligands investigated in this report, see Figure 2, even in large excess, with [(η^6-*p*-cymene)$RuCl_2$]$_2$ in dichloromethane generally resulted in the formation of mixtures composed of the η^1-coordinated phosphane complex and a linked ruthenium–ruthenium complex where the phosphane ligand bridges the two metal centres. The *cis*-bis(1,2-diphenylphosphanyl)ethylene (dppv) ligand was, however, a notable exception to this generalisation, forming only the desired pendant phosphane complex [(η^6-*p*-cymene)-$RuCl_2$(η^1-dppv)] (**2**) in 89% yield using a stoichiometric phosphane to ruthenium ratio. The η^1-coordination mode is clearly evidenced by the presence of two doublets at δ = 15.1 and –30.6 ppm ($^3J_{PP}$ = 9.1 Hz) in the ^{31}P NMR spectrum, with the high-frequency resonance corresponding to the coordinated P centre. Selected NMR spectroscopic data for **2** and the other compounds described herein are listed in Table 1.

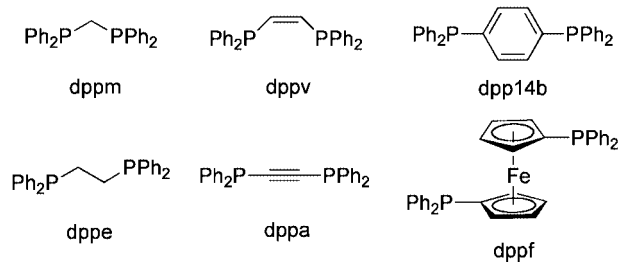

Figure 2. Bis(phosphane)s used in this study with their abbreviations.

To provide a possible explanation for the selective formation of these pendant phosphane complexes the solid-state structures of **2** and the oxide derivative of **1**, [(η^6-*p*-cymene)-$RuCl_2$(η^1-dppmO)] (**3**), obtained by slow oxidation of **1** in solution over a period of months,[16] were determined by X-

ray diffraction analysis (see Figure 3 and Figure 4). The solid-state structure of **3** is much the same as that of **1**,[5b,5c] and the related pendant oxide complex [(η^6-*p*-cymene)-$RuCl_2\{\eta^1$-$PPh_2PCH(CH_3)P(O)Ph_2\}$] (**4**).[17] Each adopt the expected "piano-stool" geometries, with the phosphane chelate angle directed away from the chloride ligands. The Ru–P bond length in **3** is similar to that in **1** [2.355(7) vs. 2.368(7)[5b] Å], and the P–O bond in **3** is comparable with that in **4** [1.49(1) vs. 1.484(3) Å]. The structure of **2** bears close resemblance to **1** and **3** in many respects including the conformation of phosphane with respect to the ruthenium arene moiety and the Ru–P bond length [2.362(2) Å]. Of particular relevance to the reactivity of the pendant phosphane is the close proximity of the P centres in both **2** and **3** (and **1**). In the case of **2**, with a P···P distance of 3.481(3) Å, the close approach originates from the *cis* conformation of the alkene backbone, whereas in **3** the close approach [3.173(6) Å – averaged over the asymmetric cell, cf. **1**, 3.138(2) Å][5b] is a consequence of the small chelate angle [120.6(7)°]. These constraints provide a satisfactory explanation for the selective formation of the pendant phosphane complexes for dppm and dppv, as the steric bulk from the coordinated phosphane moieties, notably from the phenyl groups, can act to hinder further coordination.

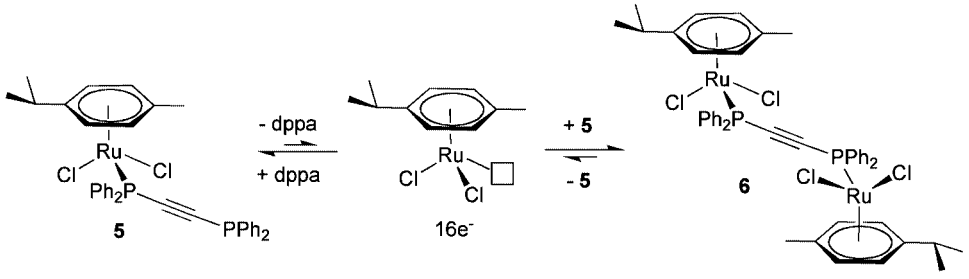
The competing formation of the bridged diruthenium species, by coordination of the pendant P centre to another ruthenium unit, encumbers the isolation of the desired pendant phosphane complexes. For example, the pendant phosphane complex, [(η^6-*p*-cymene)$RuCl_2$(η^1-dppa)] (**5**) was separated from the corresponding bridged species [(η^6-*p*-cymene)$RuCl_2$(μ-dppa)$RuCl_2$(η^6-*p*-cymene)] (**6**), in ca. 17% yield, following successive recystallisations from dichloromethane/pentane at –20 °C. Compound **5** is, however, unstable at room temperature and undergoes an equilibration reaction, liberating free phosphane and generating the bridged species **6**, as depicted in Scheme 1. After ca. 1 day in $CDCl_3$ an equilibrium composition is reached, corresponding to an equilibrium constant of $K = 0.42$ (Figure 5). Likewise, this equilibration can also be effected starting from **6** and dppa (≈ 1:1) on a similar timescale (ca. 1 day at room temperature in $CDCl_3$). Both these reactions follow first-order reaction kinetics, consistent with a mechanism involving dissociation of dppa and formation of the coordinately unsaturated arene ruthenium species "[(η^6-*p*-cymene)-$RuCl_2$]", as depicted in Scheme 1. An alternative proposal in which chloride dissociation leads to the intermediate species [(η^6-*p*-cymene)$RuCl_2$(η^1-dppa){(μ-dppa)$RuCl_2$(η^6-*p*-cymene)}]$^+$, moderately stable in solution,[18] can be dismissed because it was not detected by NMR spectroscopy during the equilibration process.

Using toluene as the solvent instead of dichloromethane for the reaction between [(η^6-*p*-cymene)$RuCl_2$]$_2$ and dppa (1.1 equiv. per Ru, room temperature), **6** selectively precipitates on formation, driving the equilibrium to the right hand side, resulting in a **5**/**6** product distribution of ca. 2 compared to the equilibrium ratio of 0.63.[19] The reaction was also carried out in dichloromethane at –78 °C with an excess of phosphane (2.3 equiv. per Ru). The resultant ratio of **5**/**6** was ca. 0.2, as determined by ^{31}P NMR spectroscopy, much lower than that of the equilibrium composition. Below –50 °C the rate of formation of **6** is slow enough to allow NMR characterisation of **5**. The ^{31}P NMR spectrum (as for complex **2**) displays the characteristic pair of doublets, with the coordinated phosphane resonance at $\delta = 0.4$ and the pendant P centre at $\delta = -34.2$, although the coupling constant, $^3J_{PP}$, is reduced in comparison to **2** [9.1 vs. 3.6 Hz]. The solid-state structures of **5** and **6** have been determined by X-ray diffraction analysis, and are depicted in Figure 6 and Figure 7, respectively. Each have "pianostool" geometries about the Ru centres, although as sug-



Scheme 1. Proposed mechanism for the equilibration of [(η^6-*p*-cymene)$RuCl_2$(η^1-dppa)] (**5**) with [(η^6-*p*-cymene)$RuCl_2$(μ-dppa)$RuCl_2$(η^6-*p*-cymene)] (**6**).

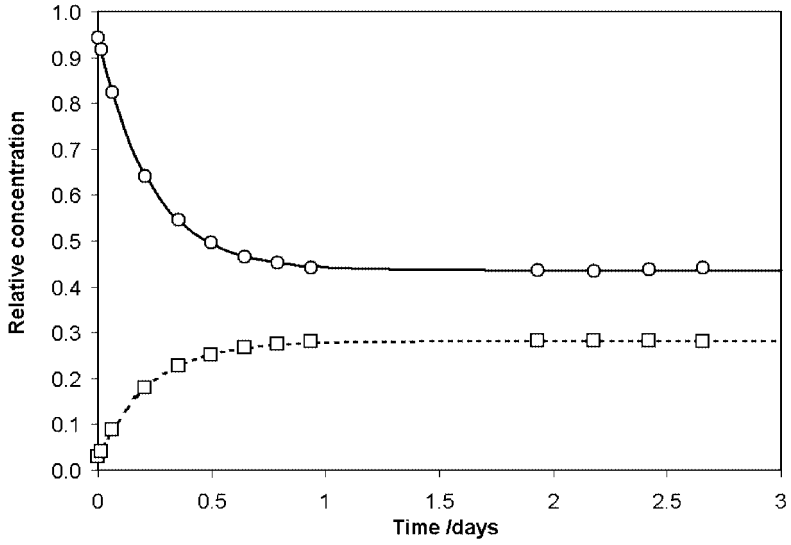


Figure 5. Equilibrium between complexes **5** and **6** at room temperature in $CDCl_3$. Relative concentrations of **5** (circles) and **6** (squares) were determined by integration of ^{1}H NMR spectroscopic data. Note, the concentration of dppa is not shown as it is identical to that of **6**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gested by the difference in the coordinated phosphane resonances [**5**, δ = 0.4; **6**,[15] δ = 10.1] there are slight differences in the coordination sphere geometries. In particular the Ru–P bond in **5**, is elongated in comparison to **6** [2.336(1) vs. 2.319(1) Å] together with increased Cl–Ru–P angles [87.18(8) vs. 85.1(7)°] and a reduced Cl–Ru–Cl angle [86.08(4) vs. 88.10(4)°]. These differences are likely to originate from the steric constraints present in **6** owing to the rigid backbone of the dppa ligand, which deviates from linearity slightly more in **6**.

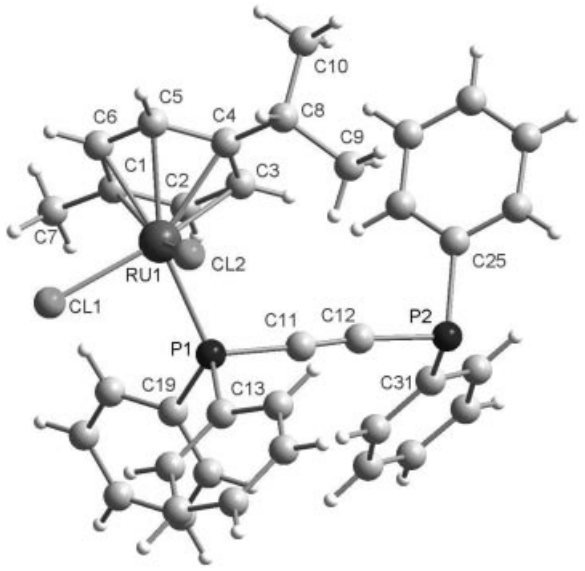

Figure 6. Ball-and-stick depiction of **5** in the solid state. Key bond lengths [Å] and angles [°]: Ru1–Cl1, 2.418(1); Ru1–Cl2, 2.402(1); Ru1–P1, 2.336(1): Cl1–Ru1–Cl2, 86.08(4); Cl1–Ru1–P1, 87.12(5); Cl2–Ru1–P1, 87.24(5); Ru1–C_{avg}, 2.21(2); Ru1–centroid, 1.7006(5); P1–C11, 1.782(5); P2–C12, 1.765(6); C11–C12, 1.202(7); P1–C11–C12, 175.1(5); P2–C12–C11, 174.0(5).

To further investigate the coordination chemistry of dppa it was reacted with the monosubstituted triphenylphosphane derivative [(η^6-*p*-cymene)$RuCl_2(PPh_3)$] together with one equivalent of $[NH_4]PF_6$ in methanol, resulting in the selective formation of the cationic pendant phosphane complex [(η^6-*p*-cymene)$RuCl(PPh_3)$(η^1-dppa)]PF_6 (**7**). The proposed structure was unambiguously identified by NMR spectroscopy, ES-MS and elemental analysis. The ^{31}P NMR spectrum shows three distinct phosphane resonances; a high-frequency doublet at δ = 24.2 ppm (Ru–*P*Ph_3, $^2J_{PP}$ = 55.1 Hz), a doublet of doublets at δ = 1.0 (Ru–*P*Ph_2CCPPh_2, $^2J_{PP}$ = 55.1, $^3J_{PP}$ = 3.2 Hz), and low frequency doublet at δ = –31.7 ppm corresponding to the pendant P centre ($^3J_{PP}$ = 4.9 Hz), in accordance with the proposed structure. In contrast to **5**, the cationic complex **7** is stable in solution over long periods of time, as evidenced by no discernible changes in its ^{31}P NMR spectrum after ca. 3.5 days in $CDCl_3$ solution. In **7** the signal of the quaternary carbon of the isopropyl group at the *p*-cymene ring (C^4 in Figure 8) is located at δ = 129.7 ppm by ^{1}H,^{13}C long-range correlation NMR spectroscopy, ca. 20 ppm to higher frequency than in **5** and **6** (and also to the other ruthenium complexes). This is indicative of weaker coordination to the metal centre, presumably from the increased steric bulk in the ruthenium coordination sphere. The ES-MS spectrum recorded in MeOH exhibits a strong molecular ion peak at *m*/*z* +927 with the expected isotope pattern. Structural information was obtained by selective fragmentation[20] of the parent peak resulting primary in loss of the PPh_3 ligand.

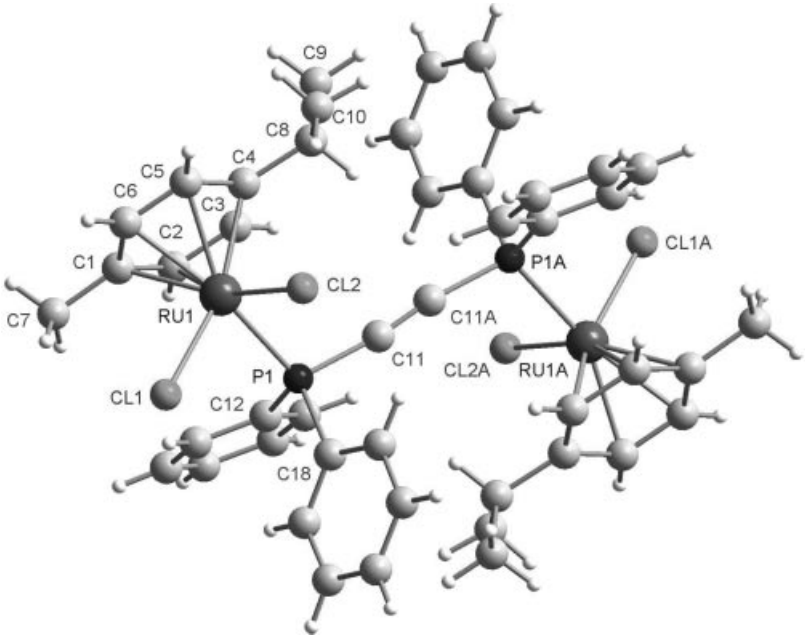

Figure 7. Ball-and-stick depiction of **6** in the solid state. Symmetry equivalent atoms, labeled with an A, are obtained by the symmetry operation –*x*, –*y*, 2 – *z*. Key bond lengths [Å] and angles [°]: Ru1–Cl1, 2.403(1); Ru1–Cl2, 2.204(1); Ru1–P1, 2.319(1): Cl1–Ru1–Cl2, 88.10(4); Cl1–Ru1–P1, 84.56(4); Cl2–Ru1–P1, 85.56(4); Ru1–C_{avg}, 2.22(3); Ru1–centroid, 1.7045(3); P1–C11, 1.762(4); C11–C11#, 1.207(8); P1–C11–C11#, 172.4(5).

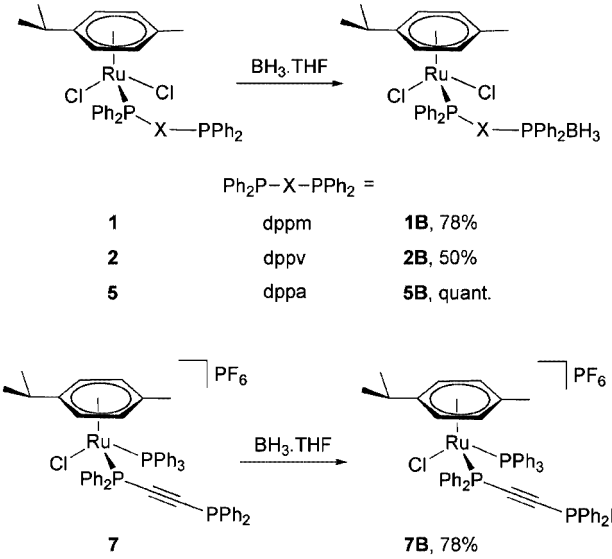
Synthesis and Characterisation of Ruthenium–Borane Adducts

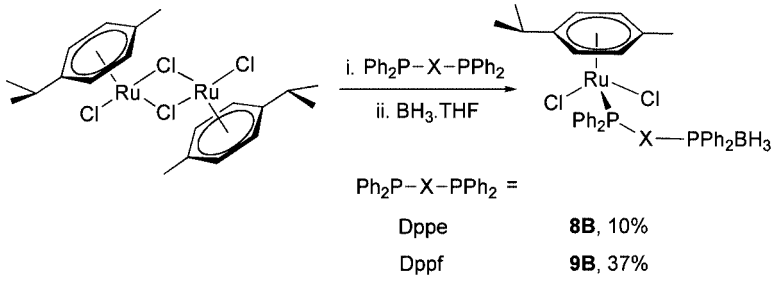
The isolated pendant phosphane complexes, **1**, **2**, **5** and **7**, react readily with BH_3·THF to give the corresponding ruthenium–borane adducts, **1B**, **2B**, **5B** and **7B**, in good yield as depicted in Scheme 2. For complexes **5** and **7**, it was necessary to carry out the reaction at –78 °C to prevent hydroboration of the alkyne moiety. Similarly, complexes **8B** (dppe) and **9B** (dppf) can be prepared by reaction of BH_3·THF with the corresponding pendant phosphane complexes formed, instead, in situ (Scheme 3). Partial separation from the corresponding bridging species, formed in parallel to the pendant phosphane complexes, can be achieved by extraction of the solid residue with toluene and recyrstallisation from dichloromethane/pentane, although chromatography is necessary for complete separation.



Scheme 2. Preparation of **1B**, **2B**, **5B** and **7B**.

A high-yielding method for the preparation of the ruthenium–borane species linked with the 1,4-bis(diphenylphosphanyl)benzene ligand (dpp14b) has been devised. The route, depicted in Scheme 4, involves the reaction of a preformed phosphane–borane, prepared in good yield (61%, 2 steps) from 1,4-bromo(diphenylphosphane)benzene, directly with $[(\eta^6$-*p*-cymene)$RuCl_2]_2$ (82% yield).

Large shifts of ca. δ = 35 ppm (see Table 1) and characteristic line broadening of the pendant P-centre resonances are observed in the ^{31}P NMR spectra for the ruthenium–borane complexes, although the frequencies of the coordinated P-centre resonances remain similar. Distinctive resonances at ca. δ = –38 ppm in the ^{11}B NMR spectra (see Table 1) are in agreement with related, previously reported, phosphane–borane adducts.[4] ^1H and ^{13}C NMR spectroscopic data for complexes **1B**, **2B**, **5B**, and **7B** are comparable with those of the isolated pendant phosphane complexes. In particular, the signal of the isopropyl quaternary carbon of the *p*-cymene ring in **7B** is similarly located at high frequency (δ = 131 ppm) as observed for **7**. The ES-MS spectrum of **7B** in MeOH exhibits a peak at *m*/*z* +927 resulting from loss of BH_3. If dichloromethane is used instead, the molecular ion peak at *m*/*z* +941 is observed to-



Scheme 3. Preparation of **8B** and **9B**.

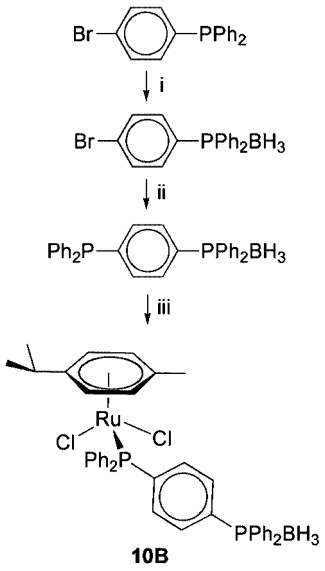

Scheme 4. Stepwise preparation of **10B**. Reagents and conditions: i. BH_3·THF, 0 °C; ii. BuLi, –78 °C, followed by $ClPPh_2$; iii. $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$, room temp.; overall yield: 50%.

gether with a weaker peak at *m/z* +927. MS/MS of the parent peak correspondingly results in loss of BH_3, further selective fragmentation of this peak results resulting primary in loss of the PPh_3 ligand as for **7**.

Spectroscopic data for complexes **8B**, **9B** and **10B** corroborate the structure of the complexes well. Using NOESY it was possible to unambiguously determine the conformation of the dppf ligand in solution in **9B**, as depicted in Figure 9. In this conformation, the ferrocenyl rings adopt the expected antiperiplanar configuration, with both the borane moiety and ruthenium centre directed away from the ligand.

The solid-state structures of the complexes **1B**, **2B** and **8B** have been determined by X-ray diffraction analysis and are depicted in Figure 10, Figure 11 and Figure 12. Complexes **1B** and **2B** retain similar conformations as their parent pendant phosphane complexes **1**[5b] (also **3**, Figure 4) and **2** (Figure 3), although in both cases Ru–P bond lengths are slightly contracted in the borane adducts [2.351(2) vs. 2.368(7) Å for dppm; 2.3424(8) vs. 2.362(2) Å for dppv]. The structure of complex **8B** exhibits similar bonding parameters around the ruthenium centre to those observed in the related bridging species $[(\eta^6\text{-}p\text{-cymene})Ru(S_2C_2\{B_{10}H_{10}\})(\mu\text{-dppe})Ru(S_2C_2\{B_{10}H_{10}\})(\eta^6\text{-}p\text{-cymene})]$.[21] The P–B bond lengths range from 1.91–1.93 Å and are comparable to other phosphane–BH_3 adducts.[4,12,13]

In conclusion, a series of neutral bis(phosphane)-linked ruthenium–borane complexes have been prepared using a variety of phosphane ligands. While the use of isolated pendant phosphane complexes is more desirable and higher yielding, the formation of these complexes is usually accompanied by the formation of dimeric ruthenium–ruthenium species. In the case of the reaction between bis(diphenylphosphanyl)acetylene (dppa) and $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$, equilibration between these two species occurs in

solution. In contrast, the reaction between *cis*-bis(1,2-diphenylphosphanyl)ethylene (dppv) and $[(\eta^6\text{-}p\text{-cymene})\text{-}RuCl_2]_2$ results in the selective formation of the pendant phosphane complex akin to dppm. These observations were rationalised by inspection of their solid-state structures (and related oxide and borane adducts), which show a close proximity between the P centres. In contrast for dppe and dppf the solid-state structure and solution conformation determined by NOESY, respectively, of the linked ruthenium–borane complexes are suggestive (vide infra) of little steric hindrance to further coordination. Correspondingly, the linked ruthenium–borane systems using these ligands are prepared in lower yield and require chromatographic purification. As an alternative methodology, a preformed phosphane–borane ligand was prepared preventing contamination from the corresponding bridging species.

Experimental Section

All organometallic manipulations were carried out under nitrogen using standard Schlenk techniques. CH_2Cl_2, diethyl ether, hexane, THF and toluene were dried using a solvent purification system,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

manufactured by innovative technology inc., in which nitrogen-saturated solvents are passed through a series of alumina columns or, for the hydrocarbons, through one column of alumina then another containing a copper catalyst under a positive pressure of nitrogen. All other solvents were p. a. quality and saturated with nitrogen prior to use. Chromatographic separations were carried out in air using 1.0×20×20 mm silica gel 60 F_{254} plates (Merck). [(η^6-*p*-cymene)$RuCl_2$]$_2$,[22] [(η^6-*p*-cymene)$_2Ru_2(\mu$-Cl)$_3$]PF_6,[23] [(η^6-*p*-cymene)-$RuCl_2(PPh_3)$],[23] [(η^6-*p*-cymene)$RuCl_2(\eta^1$-dppm)],[7a] dpp14b,[24] and 1,4-bromo(diphenylphosphane)benzene,[24] were prepared as described elsewhere. All other chemicals are commercial products and were used as received. Spectra were recorded with a Bruker Avance 400 spectrometer at room temperature, unless otherwise stated. Chemical shifts are given in ppm and coupling constants (*J*) in Hz. ES mass spectra were recorded with a Thermo Finnigan LCQ DECA XPPlus and microanalyses performed at the EPFL. Numerical analysis for the equilibration of **5** – (**6** + dppa) was carried out using Origin 7.5 (OriginLab).

Preparation of [(η^6-*p*-Cymene)$RuCl_2(\eta^1$-*cis*-$PPh_2CHCHPPh_2$)] (2): A solution of [(η^6-*p*-cymene)$RuCl_2$]$_2$ (0.160 g, 0.26 mmol) and dppv (0.207 g, 0.26 mmol) in CH_2Cl_2 (50 mL) was stirred at room temperature for 1 h. The product was obtained as an orange solid following concentration and precipitation with diethyl ether. Yield 0.32 g (89%). Crystals suitable for X-ray crystallography were obtained by recrystallisation from CH_2Cl_2/diethyl ether at 4 °C. ^{1}H NMR ($CDCl_3$): δ = 8.1–8.2 [m, 4 H, RuP(*o*-C_6H_5)$_2$ {^{31}P@δ = 15.1} δ = 8.15, d, $^3J_{HH}$ = 7.2], 7.54 (ddd, $^3J_{HH}$ = 13.5, $^2J_{PH}$ = 28.5, $^3J_{PH}$ = 31.0 Hz, 1 H, $RuPPh_2CHCH$), 7.38–7.44 [m, 2 H, RuP(*p*-C_6H_5)$_2$], 7.30–7.38 [m, 4 H, RuP(*m*-C_6H_5)$_2$], 7.18–7.24 [m, 2 H, pend-P(*p*-C_6H_5)$_2$], 7.12–7.18 [m, 4 H, pend-P(*m*-C_6H_5)$_2$], 7.06 (ddd, $^3J_{PH}$= 13.5, $^2J_{HH}$ = 4.0, $^3J_{PH}$ = 38.1 Hz, 1 H, $CHCHPPh_2$), 6.85–6.95 [m, 4 H, pend-P(*o*-C_6H_5)$_2$ {^{31}P@δ = –30.6} δ = 6.91 dd, $^4J_{HH}$ = 1.2, $^3J_{HH}$ = 8.2 Hz], 5.26 (d, $^3J_{HH}$ = 5.1, 2 H, *o*-$CH_3C_6H_4$), 5.15 (d, $^3J_{HH}$ = 6.0, 2 H, *m*-$CH_3C_6H_4$), 2.55 [sept, $^3J_{HH}$ = 6.9 Hz, 1 H, $CH(CH_3)_2$], 1.84 (s, 3 H, CH_3–C_6H_4), 0.85 [d, $^3J_{HH}$ = 6.9 Hz, 6 H, $CH(CH_3)_2$] ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 145.2 (dd, $^1J_{PC}$ = 7.6, $^2J_{PC}$ = 17.4 Hz, $CHCHPPh_2$), 140.3 (dd, $^1J_{PC}$ = 21.5, $^2J_{PC}$ = 44.4 Hz, $RuPPh_2CHCH$), 137.6 [d, $^1J_{PC}$ = 10.6, pend-P(*i*-C_6H_5)$_2$], 134.2 [d, $^1J_{PC}$ = 45.6, RuP(*i*-C_6H_5)$_2$], 133.5 [dd, $^4J_{PC}$ = 4.5, $^2J_{PC}$ = 9.7, RuP(*o*-C_6H_5)$_2$], 132.5 [d, $^2J_{PC}$ = 18.4, pend-P(*o*-C_6H_5)$_2$], 130.4 [d, $^4J_{PC}$ = 2.4, RuP(*p*-C_6H_5)$_2$], 128.2–128.4 [obscured, pend-P(*p*-C_6H_5)$_2$], 128.3 [d, $^3J_{PC}$ = 10.9, P(*m*-C_6H_5)$_2$], 128.2 [d, $^3J_{PC}$ = 10.0, P(*m*-C_6H_5)$_2$], 108.6 [s, $CCH(CH_3)_2$], 93.7 (s, CH_3–*C*), 90.3 (d, $^2J_{PC}$ = 4.2, *o*-$CH_3C_6H_4$), 85.2 (d, $^2J_{PC}$ = 6.0, *m*-$CH_3C_6H_4$), 30.1 [s, $CH(CH_3)_2$], 21.4 [s, $CH(CH_3)_2$], 17.4 (s, CH_3–C_6H_4) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 15.1 (d, $^3J_{PP}$ = 9.1 Hz, 1 P, Ru–*P*), –30.6 (d, $^3J_{PP}$ = 9.1 Hz, 1 P, pend-*P*) ppm. $C_{36}H_{36}Cl_2P_2Ru$ (702.60): calcd. C 61.54, H 5.16; found C 60.98, H 5.25.

Preparation of [(η^6-*p*-Cymene)$RuCl_2(\eta^1$-*cis*-$PPh_2CHCHPPh_2BH_3$)] (2B): To a solution of **2** (0.100 g, 0.14 mmol) in CH_2Cl_2 (15 mL, 0 °C) a solution of BH_3·THF in THF (0.12 mL of ca. 1.2 M, 0.14 mmol) was added dropwise. The solution was then warmed to room temperature and stirred for 1 h. The solvent was then removed in vacuo, and the solid washed with diethyl ether (25 mL) and then recrystallised from CH_2Cl_2/pentane at –20 °C to give red crystals suitable for X-ray diffraction. Yield: 0.05 g (50%) ^{1}H NMR ($CDCl_3$, –50 °C): δ = 7.9–8.1 [m, 4 H, RuP(*o*-C_6H_5)$_2$ {^{31}P@δ = 18.4} δ = 7.97, d, $^3J_{HH}$ = 7.3], 7.69 (ddd, $^3J_{HH}$ = 16.2, J_{PH} = 21.2, J_{PH} = 39.7, 1 H, PPh_2CH), 7.2–7.5 [m, 16 H, P(*o*-C_6H_5)$_2BH_3$ and P(*m*,*p*-C_6H_5)$_2$], 6.86 (ddd, J_{PH} = 4.7, $^3J_{HH}$ = 16.2, J_{PH} = 36.9, 1 H, PPh_2CH), 5.17 (d, $^3J_{HH}$ = 5.8, 2 H, *m*-$CH_3C_6H_4$), 5.11 (d, $^3J_{HH}$ = 5.9, 2 H, *o*-$CH_3C_6H_4$), 2.62 [sept, $^3J_{HH}$ = 6.6, 1 H, $CH(CH_3)_2$], 1.75 (s, 3 H, CH_3–C_6H_4), 0.83 [d, $^3J_{HH}$ = 6.7, 6 H, $CH(CH_3)_2$], 0.1–0.7 [br., 3 H, BH_3; {^{11}B@δ = –37.3} δ = 0.42, d, $^2J_{PH}$ = 16.3]. ^{13}C{^{1}H} NMR ($CDCl_3$, –50 °C): δ = 145.6 (d, $^1J_{PC}$ = 39.0, PPh_2CH), 133.8 [d, $^2J_{PC}$ = 10.0, RuP(*o*-C_6H_5)$_2$], 133.3–133.9 (obscured, PPh_2CH), 132.1 [d, $^2J_{PC}$ = 9.5, P(*o*-C_6H_5)$_2BH_3$], 131.4 [br., RuP(*p*-C_6H_5)$_2$], 131.2 [br., P(*p*-C_6H_5)$_2BH_3$], 130.7 [d, $^1J_{PC}$ = 47.5, P(*i*-C_6H_5)$_2$], 130.4 [d, $^1J_{PC}$ = 60.3, P(*i*-C_6H_5)$_2$], 128.9 [d, $^3J_{PC}$ = 10.2, P(*m*-C_6H_5)$_2$], 128.5 [d, $^3J_{PC}$ = 10.6, P(*m*-C_6H_5)$_2$], 109.7 [d, $^2J_{PC}$ = 1.8, $CCH(CH_3)_2$], 94 (m, CH_3–*C*), 89.7 (d, $^2J_{PC}$ = 2.8, *o*-$CH_3C_6H_4$), 85.9 (d, $^2J_{PC}$ = 5.4 *m*-$CH_3C_6H_4$), 30.4 [s, $CH(CH_3)_2$], 21.4 [s, $CH(CH_3)_2$], 17.8 (s, CH_3–C_6H_4). ^{31}P{^{1}H} NMR ($CDCl_3$, –50 °C): δ = 18.4 (d, $^3J_{PP}$ = 12.9, 1 P, Ru–*P*), 9.3–10.1 (m, 1P, *P*–BH_3). ^{11}B{^{1}H} NMR ($CDCl_3$, –50 °C): δ = –37.3 (br). IR (nujol, cm^{-1}): $\tilde{\nu}_{v(BH)}$ = 2448 (br), 2380 (sh). $C_{36}H_{39}BCl_2P_2Ru{\cdot}CH_2Cl_2$ (801.37): calcd. C 55.46, H 5.16; found C 55.65, H 5.33.

Oxidation of [(η^6-*p*-Cymene)$RuCl_2(\eta^1$-$PPh_2CH_2PPh_2$)]: Orange crystals of [(η^6-*p*-cymene)$RuCl_2(\eta^1$-dppmO)] (**3**) suitable for X-ray diffraction were obtained by recrystallisation of a reaction mixture containing [(η^6-*p*-cymene)$RuCl_2(\eta^1$-dppm)] over several months from chloroform/pentane at 4 °C. Alternatively, [(η^6-*p*-cymene)-$RuCl_2(\eta^1$-dppm)] can be quantitatively converted to **2** by treatment with H_2O_2 in THF. ^{1}H and ^{31}P NMR spectroscopic data were in agreement with the literature data.[17]

Preparation of [(η^6-*p*-Cymene)$RuCl_2(\eta^1$-PPh_2CCPPh_2)] (5): To a vigorously stirred solution of dppa (0.17 g, 0.43 mmol) in CH_2Cl_2 (15 mL, –78 °C) a solution of [(η^6-*p*-cymene)$RuCl_2$]$_2$ (0.10 g, 0.16 mmol) in CH_2Cl_2 (15 mL) was added rapidly. Following an additional 5 min stirring, the solvent was removed in vacuo at room temperature. The resultant orange solid material was an ca. 0.4:1.0:0.7 mixture of **6**/**5**/dppa as determined by ^{31}P NMR spectroscopy. Successive recrystallisation from CH_2Cl_2/pentane at –20 °C gave orange crystals of **5** in ca. 0.04 g (17%) yield. Crystals of **6** suitable for X-ray analysis were obtained by slow diffusion of pentane into a CH_2Cl_2 solution of the reaction mixture at room temperature, whereas those of **5** were obtained after successive recrystallisation of the reaction mixture from CH_2Cl_2/pentane at –20 °C. ^{1}H NMR ($CDCl_3$, –50 °C): δ = 7.97 [dd, $^3J_{HH}$ = 7.2, $^3J_{PH}$ = 11.5, 4 H, RuP(*o*-C_6H_5)$_2$], 7.6–7.9 [m, 4 H, pend-P(*o*-C_6H_5)$_2$], 7.3–7.6 [m, 12 H, P(*m*,*p*-C_6H_5)$_2$], 5.31 (d, $^3J_{HH}$ = 5.9, 2 H, *m*-$CH_3C_6H_4$), 5.22 (d, $^3J_{HH}$ = 5.6, 2 H, *o*-$CH_3C_6H_4$), 2.80 [sept, $^3J_{HH}$ = 6.5, 1 H, $CH(CH_3)_2$], 1.85 (s, 3 H, CH_3–C_6H_4), 1.04 [d, $^3J_{HH}$ = 6.6, 6 H, $CH(CH_3)_2$]. ^{13}C{^{1}H} NMR ($CDCl_3$, –50 °C): δ = 133.7 [m, P(*i*-C_6H_5)$_2$], 133.0–133.5 [m, P(*o*-C_6H_5)$_2$], 131.0 [s, RuP(*p*-C_6H_5)$_2$], 130.2 [s, pend-P(*p*-C_6H_5)$_2$], 129.3 [d, $^3J_{PC}$ = 8.0, P(*m*-C_6H_5)$_2$], 128.4 [d, $^3J_{PC}$ = 10.9, P(*m*-C_6H_5)$_2$], 109.6 [s, $CCH(CH_3)_2$], 96.1 (s, CH_3–*C*), 89.9 (d, $^2J_{PC}$ = 3.5, *o*-$CH_3C_6H_4$), 87.3 (d, $^2J_{PC}$ = 5.2, *m*-$CH_3C_6H_4$), 30.5 [s, $CH(CH_3)_2$], 22.0 [s, $CH(CH_3)_2$], 17.9 (s, CH_3–C_6H_4), the signals of $RuPPh_2CCPPPh_2$ were not unambiguously located. ^{31}P{^{1}H} NMR ($CDCl_3$, –50 °C): δ = 0.4 (s, 1 P, Ru–*P*), –34.2 (d, $^3J_{PP}$ = 3.6, 1 P, pend-*P*). IR (nujol, cm^{-1}): $\tilde{\nu}_{v(CC)}$ = 2110 (w).

Preparation of [(η^6-*p*-Cymene)$RuCl_2(\eta^1$-$PPh_2CCPPh_2BH_3$)] (5B): To a solution of **5** (0.007 g, 0.01 mmol) in THF (2 mL, –78 °C) a solution of BH_3·THF in THF (0.01 mL of ca. 1.2 M, 0.012 mmol) was added dropwise. The solution was then stirred for 1 h, and the solvent was removed in vacuo as the solution warmed to room temperature. Yield: quantitative (by ^{1}H NMR). ^{1}H NMR ($CDCl_3$, –50 °C): δ = 7.8–7.95 [m, 8 H, {^{31}P@δ = 3.2} δ = 7.90, d, RuP(*o*-C_6H_5)$_2$, $^3J_{HH}$ = 7.2; {^{31}P@δ = 5.8} δ = 7.88, d, P(*o*-C_6H_5)$_2$-BH_3, $^3J_{HH}$ = 7.3], 7.3–7.65 [m, 12 H, P(*m*,*p*-C_6H_5)$_2$], 5.36 (d, $^3J_{HH}$ = 6.0, 2 H, *m*-$CH_3C_6H_4$), 5.28 (d, $^3J_{HH}$ = 5.7, 2 H, *o*-$CH_3C_6H_4$), 2.75 [sept, $^3J_{HH}$ = 6.7, 1 H, $CH(CH_3)_2$], 1.86 (s, 3 H, CH_3–C_6H_4), 1.02 [d, $^3J_{HH}$ = 6.8, 6 H, $CH(CH_3)_2$], 1.0–1.6 [br., 3 H, BH_3;

{^{11}B@δ = –37.3} δ = 1.30, d, $^2J_{PH}$ = 17.0]. ^{13}C{^{1}H} NMR ($CDCl_3$, –50 °C): δ = 133.3 [d, $^2J_{PC}$ = 10.6, RuP(*p*-C_6H_5)$_2$], 132.7 [s, P(*p*-C_6H_5)$_2$$BH_3$], 132.4 [d, $^2J_{PC}$ = 11.6, P(*p*-C_6H_5)$_2$$BH_3$], 131.4 [s, RuP(*p*-$C_6H_5$)$_2$], 130 [d, $^1J_{PC}$ ca. 60, P(*i*-C_6H_5)$_2$], 129.6 [d, $^3J_{PC}$ = 11.3, P(*m*-C_6H_5)$_2$$BH_3$], 128.7 [d, $^3J_{PC}$ = 11.0, RuP(*m*-C_6H_5)$_2$], 126.7 [d, $^1J_{PC}$ = 64.6, P(*i*-C_6H_5)$_2$], 110.4 [s, *C*CH(CH_3)$_2$], 104.5 [dd, $^1J_{PC}$ = 65.7, $^2J_{PC}$ = 7.5, PC*C*P], 99.2 (dd, $^1J_{PC}$ = 89.4, $^2J_{PC}$ < 2, P*C*CP), 96.9 (s, CH_3–*C*), 90.0 (d, $^2J_{PC}$ = 3.5, *o*-$CH_3C_6H_4$), 87.4 (d, $^2J_{PC}$ = 5.6, *m*-$CH_3C_6H_4$), 30.5 [s, *C*H(CH_3)$_2$], 21.9 [s, CH(*C*H_3)$_2$], 17.9 (s, *C*H_3–C_6H_4). ^{31}P{^{1}H} NMR ($CDCl_3$, –50 °C): δ = 5.8 (br., 1 P, *P*BH_3), 3.2 (s, 1 P, Ru*P*). ^{11}B{^{1}H} NMR ($CDCl_3$): δ = –37.3 (br).

Preparation of [(η^6-*p*-Cymene)RuCl(PPh_3)(η^1-PPh_2CCPPh_2)]PF_6 (7): A suspension of [(η^6-*p*-cymene)$RuCl_2$(PPh_3)] (0.70 g, 1.23 mmol), $[NH_4]PF_6$ (0.20 g, 1.23) and dppa (0.49 g, 1.23 mmol) in MeOH (150 mL) was heated at 35 °C for 3 h. The solvent was removed in vacuo, and the residue taken up in a minimal amount of CH_2Cl_2. A small amount of (unidentified) solid material was removed by the addition of hexane and filtration. Removal of the solvent gave an orange oil that solidified under high vacuum. Yield: 0.74 g (56%). ^{1}H NMR ($CDCl_3$): δ = 7.97 [dd, $^3J_{HH}$ = 7.2, $^3J_{PH}$ = 12.3, 2 H, RuP(*o*-C_6H_5)$_2$CCPPh_2], 7.60–7.75 [m, 4 H, pend-P(*o*-C_6H_5)$_2$ and pend-P(*o*-C_6H_5')$_2$], 7.30–7.60 (m, 20 H, P*Ph*), 7.10–7.25 [m, 7 H, RuP(*m*-C_6H_5)$_3$ and RuP(*p*-C_6H_5')$_2$], 6.92 [td, $^4J_{PH}$ = 2.9, $^3J_{HH}$ = 7.7, 2 H, RuP(*m*-C_6H_5')$_2$CCPPh_2], 5.66 (d, $^3J_{HH}$ = 6.2, 1 H, *m*-$CH_3C_6H_4$), 5.42–5.48 [m, 1 H, *o*-$CH_3C_6H_4'$ {^{31}P@δ = 1.0} δ = 5.45, d, $^3J_{HH}$ = 6.3], 5.30–5.35 [m, 1 H, *o*-$CH_3C_6H_4$ {^{31}P@δ = 24.1} δ = 5.33, d, $^3J_{HH}$ = 6.4], 4.99 (d, $^3J_{HH}$ = 6.1, 1 H, *m*-$CH_3C_6H_4'$), 2.79 [sept, $^3J_{HH}$ = 6.9, 1 H, C*H*(CH_3)$_2$], 1.28 (s, 3 H, C*H*$_3$–C_6H_4), 1.23 [d, $^3J_{HH}$ = 6.4, 3 H, CH(C*H*$_3$)$_2$], 1.21 [d, $^3J_{HH}$ = 6.4, 3 H, CH(C*H*$_3'$)$_2$]. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 134.0 [d, $^2J_{PC}$ = 9.6, RuP(*o*-C_6H_5)$_3$], 133.6 [d, $^2J_{PC}$ = 21.8, pend-P(*o*-C_6H_5)$_2$ or pend-P(*o*-$C_6'H_5$)$_2$], 133.0 [d, $^2J_{PC}$ = 21.0, pend-P(*o*-$C_6'H_5$)$_2$ or pend-P(*o*-C_6H_5)$_2$], 132.5 [d, $^1J_{PC}$ = 47.9, P(*i*-C_6H_5)$_2$], 132.4 [d, $^2J_{PC}$ = 9.9, RuP(*o*-$C_6'H_5$)$_2$], 131.7 [d, $^4J_{PC}$ = 2.3, P(*p*-C_6H_5)$_2$], 131.3 [d, $^2J_{PC}$ = 10.8, RuP(*o*-C_6H_5)$_2$], 130.9 [d, $^4J_{PC}$ = 2.3, P(*p*-C_6H_5)$_3$], 130.5 [d, $^1J_{PC}$ = 47.4, P(*i*-C_6H_5)$_3$], 130.2 [d, $^4J_{PC}$ = 2.9, P(*p*-C_6H_5)$_2$], 129.7 [s, *C*CH(CH_3)$_2$], 129.4 [d, $^3J_{PC}$ = 11.3, pend-P(*m*-C_6H_5)$_2$ or pend-P(*m*-$C_6'H_5$)$_2$], 128.4 [d, $^3J_{PC}$ = 10.5, pend-P(*m*-$C_6'H_5$)$_2$ or pend-P(*m*-C_6H_5)$_2$], 129.1 [d, $^3J_{PC}$ = 11.2, RuP(*m*-C_6H_5)$_2$], 128.4 [d, $^3J_{PC}$ = 10.5, RuP(*m*-C_6H_5)$_3$], 128.3 [d, $^3J_{PC}$ = 11.9, RuP(*m*-$C_6'H_5$)$_2$], 114.8 (m, RuPPh_2*CC*PPh_2), 100.3 (s, CH_3–*C*), 99.0 (s, *o*-$CH_3C_6H_4$ and *o*-$CH_3C'_6H_4$), 91.0 (d, $^2J_{PC}$ = 9.6, *m*-$CH_3C_6H_4$), 90.4 (d, $^2J_{PC}$ = 9.4, *m*-$CH_3C_6'H_4$), 31.3 [s, *C*H(CH_3)$_2$], 21.6 [s, CH(*C*H_3)$_2$ or CH(*C*′H_3)$_2$], 21.1 [s, CH(*C*′H_3)$_2$ or CH(*C*H_3)$_2$], 15.5 (s, *C*H_3–C_6H_4). ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 24.2 (d, $^2J_{PP}$ = 55.1, 1 P, Ru–*P*Ph_3), 1.0 (dd, $^3J_{PP}$ = 3.2, $^2J_{PP}$ = 55.1, 1 P, Ru–*P*Ph_2), –31.7 (d, $^3J_{PP}$ = 4.9, 1 P, pend-*P*Ph_2), –144.4 (sept, $^1J_{PF}$ = 712.7, 1 P, *P*F_6). Preparation of [(η^6-*p*-Cymene)$RuCl_2$(η^1-$PPh_2C_5H_4FeC_5H_4PPh_2$-BH_3)] (9B): To a solution of dppf (0.145 g, 0.26 mmol) in CH_2Cl_2 (10 mL, 0 °C ice slurry) a solution of [(η^6-*p*-cymene)$RuCl_2$]$_2$ (0.100 g, 0.16 mmol) in CH_2Cl_2 (5 mL) followed, ca. 1 min later, by a solution of BH_3·THF in THF (0.16 mL of ca. 1.2 M, 0.19 mmol) were added. The solution was then warmed to room temperature and stirred for 1 h, and the solvent was removed in vacuo. Extraction of the solid with toluene (40 mL) followed by recrystallisation of this extract from CH_2Cl_2/pentane at –20 °C gave the product as a orange solid. Yield: 0.11 g (61% /BH_3, 37% /Ru). Further purification is achieved by preparative TLC (acetone/CH_2Cl_2, 1:10), extracting the first orange band with acetone. ^{1}H NMR ($CDCl_3$): δ = 7.7–7.8 [m, 4 H, RuP(*o*-C_6H_5)$_2$; {^{31}P@δ = 18.5} δ = 7.77, dd, $^4J_{HH}$ = 1.4, $^3J_{HH}$ = 7.7], 7.3–7.5 [m, 16 H, P(*o*-C_6H_5)$_2$$BH_3$ and P(*m*,*p*-C_6H_5)$_2$], 5.17 (d, $^3J_{HH}$ = 5.8, 2 H, *o*-$CH_3C_6H_4$), 5.10 (d, $^3J_{HH}$ = 6.1, 2 H, *m*-$CH_3C_6H_4$), 4.45–4.50 [m, 2 H, (*m*-C_5H_4)PPh_2BH_3], 4.32–4.37 [m, 2 H, (*o*-C_5H_4)PPh_2BH_3], 4.10–4.15 [m, 2 H, RuP-Ph_2(*o*-C_5H_4)], 4.80–4.86 [m, 2 H, $RuPPh_2$(*m*-C_5H_4)], 2.53 [sept, $^3J_{HH}$ = 6.9, 1 H, *C*$H(CH_3)_2$], 1.78 (s, 3 H, CH_3–C_6H_4), 0.94 [d, $^3J_{HH}$ = 7.0, 6 H, $CH(CH_3)_2$], 0.7–1.5 [br., 3 H, BH_3; {^{11}B@δ = –38.5} δ = 1.13, d, $^2J_{PH}$ = 16.4]. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 136.8 [d, $^1J_{PC}$ = 47.1, RuP(*i*-C_6H_5)$_2$], 133.8 [d, $^2J_{PC}$ = 9.5, RuP(*o*-C_6H_5)$_2$], 132.5 [d, $^2J_{PC}$ = 9.7, P(*o*-C_6H_5)$_2$$BH_3$], 131.0 [d, $^1J_{PC}$ = 59.2, P(*i*-C_6H_5)$_2$$BH_3$], 130.9 [d, $^4J_{PC}$ = 2.3, RuP(*p*-C_6H_5)$_2$], 130.2 [d, $^3J_{PC}$ = 2.1, P(*p*-C_6H_5)$_2$], 128.4 [d, $^3J_{PC}$ = 10.2, P(*m*-C_6H_5)$_2$], 127.7 [d, $^3J_{PC}$ = 9.7, P(*m*-C_6H_5)$_2$], 109.7 [s, *C*$CH(CH_3)_2$], 95.1 (s, CH_3–*C*), 90.4 (d, $^2J_{PC}$ = 4.2, *o*-$CH_3C_6H_4$), 85.9 (d, $^2J_{PC}$ = 6.0, *m*-$CH_3C_6H_4$), 76.53 [d, $^3J_{PC}$ = 7.4, (*m*-C_5H_4)PPh_2BH_3], 76.49 [d, $^2J_{PC}$ = 10.0, $RuPPh_2$(*o*-C_5H_4)], 73.3 [d, $^3J_{PC}$ = 9.8, $RuPPh_2$(*m*-C_5H_4)], 72.5 [d, $^2J_{PC}$ = 7.5, (*o*-C_5H_4)PPh_2BH_3], 69.0 [d, $^1J_{PC}$ = 67.4, $RuPPh_2$(*i*-C_5H_4)], 29.9 [s, *C*$H(CH_3)_2$], 21.7 [s, $CH(CH_3)_2$], 17.0 (s, *C*H_3–C_6H_4); the signal of (*i*-C_5H_4)PPh_2BH_3 was not unambiguously located. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 18.5 (s, 1 P, Ru–*P*), 15.8 (br., 1 P, *P*–BH_3). ^{11}B{^{1}H} NMR ($CDCl_3$): δ = –38.5 (br). IR (nujol, cm^{-1}): $\tilde{\nu}_{v(BH)}$ = 2373 (br).

Preparation of 1,4-$BrC_6H_4PPh_2BH_3$: To a solution of 1,4-$BrC_6H_4PPh_2$ (1.50 g, 4.40 mmol) in THF (50 mL, 0 °C) a solution of BH_3·THF in THF (3.7 mL, ca. 1.2 M, 4.40 mmol) was added dropwise. The solution was warmed to room temperature after 15 minutes and then concentrated to approximately 30 mL. The product was then precipitated by the addition of hexane, filtered, washed with hexane (ca. 20 mL) and dried in vacuo. Yield 1.30 g (83%). ^{1}H NMR ($CDCl_3$): δ = 7.4–7.7 [m, 14 H, BH_3PPh_2(C_6H_4Br)], 0.8–1.8 [br., 3 H, BH_3 {^{11}B@δ = –38.0} δ = 1.27, d, $^2J_{PH}$ = 16.3]. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 20.8 (d, $^1J_{PB} \approx$ 55). ^{11}B{^{1}H} NMR ($CDCl_3$): δ = –38.0 (d, $^1J_{PB} \approx$ 55). IR (nujol, cm^{-1}): $\tilde{\nu}_{v(BH)}$ = 2385 (br).

Preparation of 1,4-$PPh_2C_6H_4PPh_2BH_3$: To a solution of 1,4-$BrC_6H_4PPh_2BH_3$ (0.60 g, 1.69 mmol) in THF (30 mL, –78 °C) a solution of BuLi in hexane (1.1 mL, ≈ 1.6 M, 1.7 mmol) followed by $ClPPh_2$ (0.32 mL, 1.78 mmol) were added dropwise. The solution was stirred for a further 20 minutes and then warmed to room temperature. The product was precipitated as a white solid by concentration and then collected by filtration, washed with methanol (2 × 10 mL) and dried in vacuo. Yield 0.61 g (73%). ^{1}H NMR ($CDCl_3$): δ = 7.4–7.7 [m, 14 H, BH_3PPh_2(C_6H_4Br)], 0.8–1.8 [br., 3 H, BH_3 {^{11}B@δ = –38.0} δ = 1.27, d, $^2J_{PH}$ = 16.3]. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 20.8 (br., 1 P, PPh_2BH_3), –4.9 (s, 1 P, pend-PPh_2). ^{11}B{^{1}H} NMR ($CDCl_3$): δ = –38.0 (br). IR (nujol, cm^{-1}): $\tilde{\nu}_{v(BH)}$ = 2398 (br).

Preparation of [(η^6-*p*-Cymene)$RuCl_2$(η^1-1,4-$PPh_2C_6H_4PPh_2BH_3$)] (10): A solution of [(η^6-*p*-cymene)$RuCl_2$]$_2$ (0.20 g, 0.33 mmol) and 1,4-$PPh_2C_6H_4PPh_2BH_3$ (0.30 g, 0.65 mmol) in CH_2Cl_2 was stirred at room temperature for 1 h. After concentration to ca. 25 mL the product was precipitated with hexane. The orange solid was collected by filtration, washed with hexane (3 × 10 mL) and dried in vacuo. Yield: 0.41 g (82%). ^{1}H NMR ($CDCl_3$): δ = 7.79–7.93 [m, 6 H, $RuPPh_2$(*o*-$C_6H_4PPh_2BH_3$) and RuP(*o*-C_6H_5)$_2$; {^{31}P@δ = 24.9} δ = 7.89, dd, 2 H, $RuPPh_2$(*o*-$C_6H_4PPh_2BH_3$), $^3J_{PH}$ = 1.2, $^3J_{HH}$ = 8.3 Hz; δ = 7.85, dd, 4 H, RuP(*o*-C_6H_5)$_2$, $^4J_{HH}$ = 1.5, $^3J_{HH}$ = 7.9], 7.52–7.6 [m, 4 H, P(*o*-C_6H_5)$_2$$BH_3$; {^{31}P@$\delta$ = 20.5} δ = 7.56, dd, $^4J_{HH}$ = 1.4, $^3J_{HH}$ = 8.3], 7.3–7.52 [m, 14 H, $RuPPh_2$(*m*-$C_6H_4PPh_2BH_3$) and P(*m*,*p*-C_6H_5)$_2$], 5.22 (d, $^3J_{HH}$ = 6.1, 2 H, *m*-$CH_3C_6H_4$), 5.02 (d, $^3J_{HH}$ = 5.6, 2 H, *o*-$CH_3C_6H_4$), 2.85 [sept, $^3J_{HH}$ = 6.9, 1 H, *C*$H(CH_3)_2$], 1.88 (s, 3 H, CH_3–C_6H_4), 1.11 [d, $^3J_{HH}$ = 6.9, 6 H, $CH(CH_3)_2$], 0.6–1.76 [br., 3 H, BH_3; {^{11}B@δ = –38.1} δ = 1.23, d, $^2J_{PH}$ = 16.3]. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 137.1 [dd, $RuPPh_2$(*i*-$C_6H_4PPh_2BH_3$), $^4J_{PC}$ = 2.3, $^1J_{PC}$ = 44.1], 134.4 [m, RuP-Ph_2(*o*-$C_6H_4PPh_2BH_3$)], 134.3 [d, $^2J_{PC}$ = 9.7, RuP(*o*-C_6H_5)$_2$], 133.4 [d, $^1J_{PC}$ = 45.0, P(*i*-C_6H_5)$_2$], 132.1 [m, $RuPPh_2$(*m*-$C_6H_4PPh_2BH_3$)], 131.2 [dd, $^4J_{PC}$ = 2.2, $^1J_{PC}$ = 56.2, $RuPPh_2$(*p*-$C_6H_4PPh_2BH_3$)], 131.4 [d, $^4J_{PC}$ = 2.3, P(*p*-C_6H_5)$_2$$BH_3$], 130.7 [d, $^4J_{PC}$ = 2.2, RuP(*p*-C_6H_5)$_2$], 128.8 [d, $^3J_{PC}$ = 10.3, P(*m*-C_6H_5)$_2$], 128.4 [d, $^1J_{PC}$ = 58.2, P(*i*-C_6H_5)$_2$], 128.3 [d, $^3J_{PC}$ = 9.9, P(*m*-C_6H_5)$_2$], 111.4 [d, $^2J_{PC}$ = 3.4, *C*$CH(CH_3)_2$], 96.2 (s, CH_3–*C*), 89.0 (d, $^2J_{PC}$ = 3.0, *o*-$CH_3C_6H_4$), 87.3 (d, $^2J_{PC}$ = 5.5, *m*-$CH_3C_6H_4$), 30.3 [s, *C*$H(CH_3)_2$], 21.8 [s, $CH(CH_3)_2$], 17.8 (s, *C*H_3–C_6H_4). ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 24.9 (s, 1 P, Ru–*P*), 20.5 (br., 1 P, *P*–BH_3). ^{11}B{^{1}H} NMR ($CDCl_3$): δ = –38.1 (br). IR (nujol, cm^{-1}): $\tilde{\nu}_{v(BH)}$ = 2372 (br). $C_{40}H_{41}BCl_2PRu \cdot {}^1/_3CH_2Cl_2$ (794.81): calcd. C 60.95, H 5.28; found C 60.78, H 5.19.

X-ray Crystallography: Relevant details about the structure refinements are given in Table 2 and Table 3. Selected geometrical parameters are included in the captions of Figure 3, Figure 4, Figure 6, Figure 7, Figure 10, Figure 11 and Figure 12. Data collection for the X-ray structure determinations for compounds **2**, **3**, **5**, **2B** and **8B** were performed with a four-circle Kappa goniometer equipped with an Oxford Diffraction KM4 Sapphire CCD at 140(2) K. For compounds **6** and **1B** diffraction data were collected with a mar345 IPDS instrument at 140(2) K. Data reduction was performed using CrysAlis RED.[25] Structure solutions were solved by direct methods using SIR92 (**8B**),[26] SIR97 (**2**, **6**, **1B**),[27] or

SHELXTL[28] (**3**, **5**), or by Patterson interpretation using SHELXTL (**2B**).[28] Structure refinements were performed using the SHELXTL software package for all compounds. An empirical absorption correction (DELABS)[29] was applied to all data sets except for that of **3**. The structures of all compounds were refined using full-matrix least-squares on F^2 with the exception of **3**, which was refined using full-matrix-block least-squares on F^2. All non-hydrogen atoms were refined anisotropically, with hydrogen atoms placed in calculated positions using the riding model with the exception of the BH hydrogen atoms, which were located on the Fou-

rier difference map and then constrained to equal BH bond lengths and H–B–H angles. Disorder in the *p*-cymene ring in complex **1B** was satisfactorily modeled by splitting the isopropyl moiety (with constrained geometries) over two sites, constraining the ring and restraining the atomic displacement parameters of the ring using SIMU and ISOR commands. Some of the solvent molecules in **3**, **5** and **6** were constrained or split over multiple sites. It was also necessary to restrain the atomic displacement parameters of some atoms in the structures of **3**, **5**, and **8B**. Graphical representations of the structures were made with Diamond.[30] CCDC-280165–280171 contain the supplementary crystallographic data for this paper (see Table 2 and Table 3). These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Formation of 3D Dandelions and 2D Nanowalls of Copper Phosphate Dihydrate on a Copper Surface and Their Conversion into a Nanoporous CuO Film

Xufeng Wu,[a] Gaoquan Shi,*[a] Shibin Wang,[a] and Peiyi Wu[b]

Keywords: Copper / Materials science / Nanostructures / Oxides / Phosphates

3D dandelion-like porous nanostructures and 2D nanowalls of copper phosphate dihydrate built up of thin nanosheets have been synthesized simply by corrosion of a copper foil with aqueous phosphoric acid under mild conditions. The composition of the nanostructures has been confirmed by XRD, ICP-AES, and Raman spectroscopy. Controlling the initial concentration of the acid and the conditions of drop drying allows control of the morphology of the nanostructures. The phosphate nanostructures can be converted into nanoporous CuO films by pyrolysis.

Introduction

Over the past ten years, metal-based nanomaterials have attracted extensive interest due to their promising applications in catalysis, energy storage or conversion, and data storage and memory devices.[1,2] To date, many interesting zero-dimensional (0D) and one-dimensional (1D) nanomaterials have been synthesized.[3–5] However, the fabrication of well-controlled two-dimensional (2D) or three-dimensional (3D) nanostructures is usually difficult because control of the nucleation and growth of nanomaterials is still a challenge:[6–9] simply mixing two incompatible solutions of metal salts will lead to the formation of a polycrystalline deposit with an irregular structure. It is known that a double-jet technique can be used to provide supersaturation conditions by continuously replenishing nutrients. However, the impurity of the counterions often leads to an unpredictable change in the crystal morphology.[6] Thus, it is important to develop innovative and convenient techniques for fabricating metal-based nanomaterials with 2D or 3D structures under mild conditions and at low cost.

On the other hand, copper phosphates are catalysts for the oxidation of aromatic compounds.[10–12] Nanostructures of these salts provide high specific surface areas that enhance their catalytic activity and selectivity. Cupric oxide (CuO) and basic Cu^{II} salts with layered structures have also been studied extensively in the past few years.[13–18] CuO is a p-type semiconductor with a narrow bandgap and its nanostructures have potential applications in catalysis, superconductors, and the fabrication of sensors and solar cells.[19–22] Orthorhombic [$Cu_2(OH)_3Cl$] was the first copper-based biomineral found in living organisms. It exists as polycrystalline nanofibers arranged along the outer contour of the tooth tip, leading to an extraordinary resistance to abrasion.[23] Galvanic cell corrosion is a general phenomenon in everyday life and it may provide a continuous low concentration of metal ions for controlling the formation of characteristic micro- or nanostructures.[18] In this paper, we report a 3D dandelion-like nanostructure and a 2D nanowall of copper phosphate dihydrate by simple corrosion of a copper foil with aqueous phosphoric acid. Furthermore, a nanoporous CuO film is also produced by pyrolysis of these phosphate nanostructures.

Results and Discussion

Drying of a drop of aqueous phosphorus acid solution on a copper foil leads to the formation of many pale-blue particles on its surface. Figure 1 shows the typical SEM images of the particles. As shown in Figure 1 (A) nearly all the particles are round with a size in the range of 40 to 50 μm. When two or more particles merge together a peanut-like 3D architecture is formed. When a single particle as shown in part A of Figure 1 was further magnified, a crystalline dandelion-like structure was revealed. This dandelion-like structure is made up of uniform nanosheets and its surface is porous, with pore sizes ranging from several hundreds of nanometers to one micrometer (Figure 1, B). Figure 1 (C) indicates that the dandelion grows at almost the same rate from the core in all directions above the copper surface. A magnified view of the top of the dandelion reveals that the nanosheets are about 35 nm thick (Figure 1,

D). Figure 1, part E, is the bottom view of a single dandelion. It reveals that there is an obvious core at the center of the dandelion and that the nanosheets grow with their thin face perpendicular to the bottom plane. Figure 1 (F) is a magnified view of the core, the formation mechanism of which is not very clear yet.

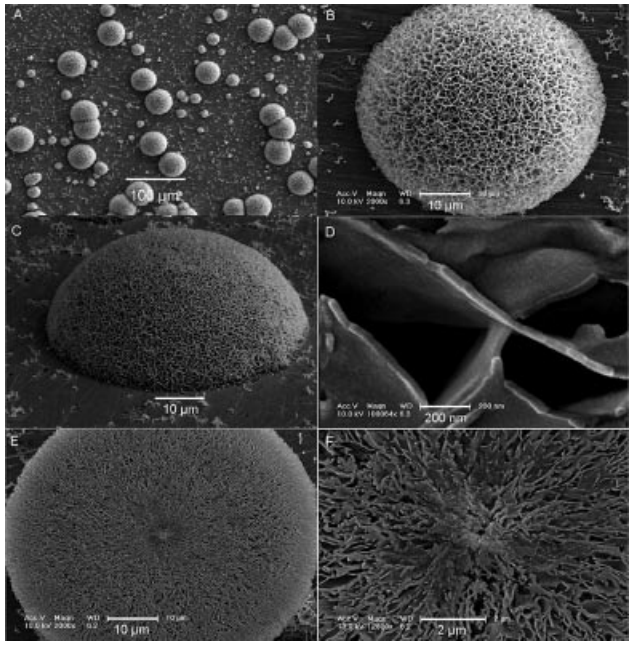

Figure 1. Typical SEM images of $Cu_3(PO_4)_2{\cdot}2H_2O$ dandelion-like nanostructures formed by drop-drying of 100 μL of 5 mM phosphorus acid on a copper foil surface. A) Overview SEM image of the copper surface. B) A dandelion-like 3D nanostructure. C) Side view of a dandelion. D) Magnified view of a dandelion. E) Bottom view of a dandelion. F) Magnified view of the dandelion bottom.

In order to study the composition of the dandelion-like nanostructures, the blue product was collected and washed repeatedly with deionized water, then dissolved in aqueous HNO_3 solution. The ion concentrations of copper and phosphorus in the solution were determined by ICP-AES and the results confirmed a strict stoichiometric Cu/P ratio of 1.5:1.0. Furthermore, the chemical weight of the blue product was calculated to be 416.60, thus indicating its chemical formula to be $[Cu_3(PO_4)_2{\cdot}2H_2O]$ (416.67). The formation of crystalline copper phosphate dihydrate $[Cu_3(PO_4)_2{\cdot}2H_2O]$ was further confirmed by the use of wide-angle X-ray diffraction. Figure 2 shows the XRD pattern of an as-prepared $[Cu_3(PO_4)_2{\cdot}2H_2O]$ powder sample. The diffraction lines are in agreement with those reported in the literature.[24] The X-ray photoelectron spectrum (XPS) of a dandelion exhibits peaks at 935.4, 531.5, and 133.4 eV, which are attributed to Cu $2p_{3/2}$, O 1s, and P $2p_{1/2}$ of $[Cu_3(PO_4)_2{\cdot}2H_2O]$,[25] respectively.

The chemical structure of the as-prepared $[Cu_3(PO_4)_2{\cdot}2H_2O]$ dandelion-like nanostructures was also confirmed by Raman spectroscopy. Figure 3 is the 633-nm-excited Raman spectrum of a dandelion and the inset is its optical microscope image. The band at 994 cm^{-1} is assigned to the PO_3 symmetric stretching vibration, the two bands at 646 and 553 cm^{-1} belong to the PO_3 out-of-plane bending vibrations, and the band at 450 cm^{-1} is attributed to the PO_3 symmetric bending vibration.[26,27]

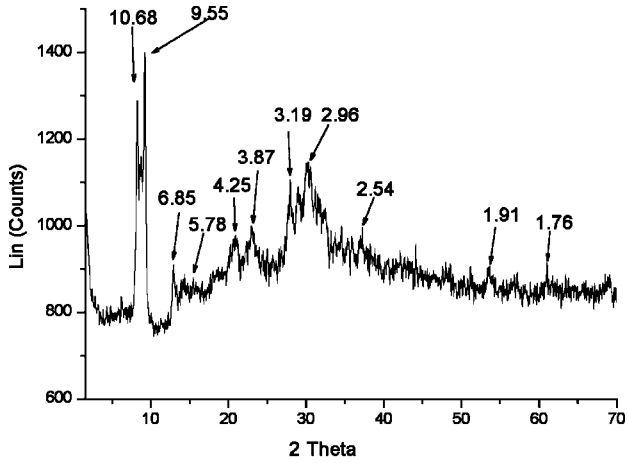

Figure 2. An XRD pattern of an as-prepared $[Cu_3(PO_4)_2{\cdot}2H_2O]$ powder sample formed by drop drying of a 50 mM H_3PO_4 solution on a copper foil at 15 °C and 49% humidity.

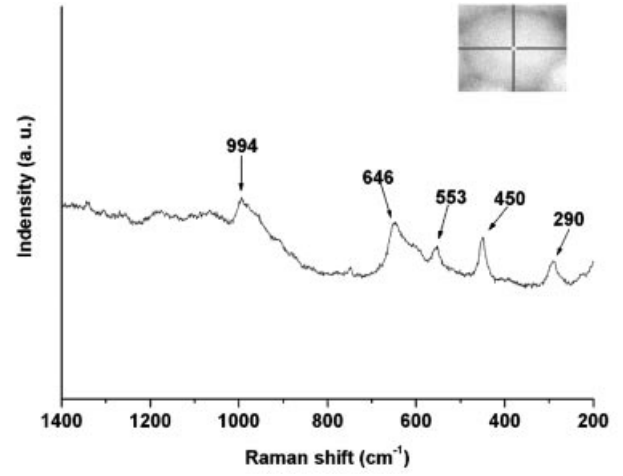

Figure 3. 633-nm-excited Raman spectra of as-prepared $[Cu_3(PO_4)_2{\cdot}2H_2O]$ dandelion (typically sample) recorded in the region of 200–1400 cm^{-1}; the inset image is the optical image of the dandelion.

The growth process of the dandelion has been carefully investigated. Figure 4 shows the SEM images of the copper surface recorded at different drying times after removing the residual solutions with a capillary tube. As shown in part A of Figure 4, the heterogeneous nucleation process is very slow, and sheet-like nuclei grow on the copper surface in the initial 60 minutes. When the drying time is increased from 60 to 120 minutes, the sheet-like nuclei form branches on the surface and gradually grow upward into small cores with a size of around 4 μm (Figure 4, B). This small core grows at nearly the same rate in all directions above the surface of the substrate to form a 3D dandelion (ca. 24 μm) as the drying time is increased further to 240 minutes (Figure 4, C). Finally, a dandelion with a diameter of about 45 μm is generated after 420 minutes (Figure 4, D).

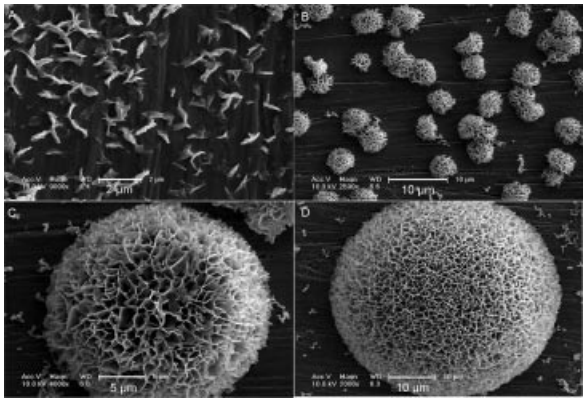

Figure 4. Typical SEM images of the copper surface recorded after drop drying 100 μL of 5 mM phosphorus acid for different times and removal of the residual solutions with a capillary tube: (A) 60 min; (B) 120 min; (C) 240 min; (D) 420 min.

It is known that copper can be corroded easily in a moist atmosphere. Under our experimental conditions, the corrosion mechanism can be simply illustrated by the two half electrochemical reactions

Anode: $Cu - 2\ e^- \rightarrow Cu^{2+}$

Cathode: $O_2 + 4\ H^+ + 4\ e^- \rightarrow 2\ H_2O$

There are a lot of microelectrodes on the corroding copper surface. During the process of corrosion, more and more copper atoms are changed into ions and enter into solution, which results in a high copper(I) ion concentration in anodic domains. Simultaneously, the pH of the solutions in the cathodic domains becomes higher than that of the host solution. The diffusion of copper ions causes the slow crystallization of $[Cu_3(PO_4)_2{\cdot}2H_2O]$ and leads to the formation of the dandelions. As can be seen from Figures 1 (F), 4 (A), and 5, a core is formed in the initial stage of generation of the dandelion-like nanostructure, and because the cathodic domain is uniformly distributed in the solution, the dandelion grows at almost the same rate in all directions from the core.

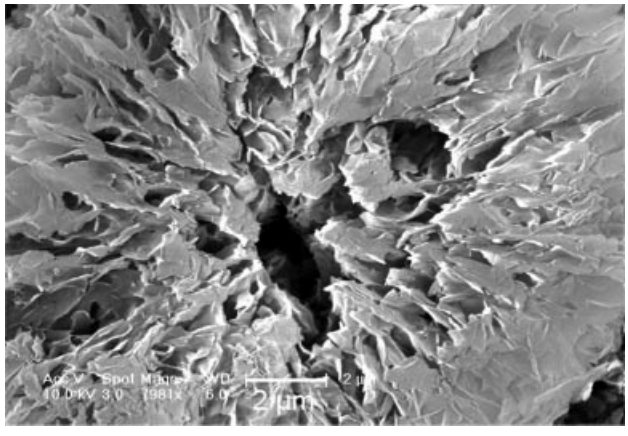

Figure 5. SEM image of a crushed dandelion bottom.

We found that the concentration of phosphorus acid ($C_{p.a.}$) can strongly affect the morphology of the dandelions. As is shown in Figure 6 (A), when $C_{p.a.}$ = 0.5 mM, small particles with sizes of 5–8 μm are formed that cover the copper surface sparsely. The shapes of the particles are irregular and an obvious number density gradient is observed. This is mainly due to the fact that the dioxygen concentration in the edge region is higher than that in the central region of the droplet. As $C_{p.a}$ was increased to 2 mM, the structures of dandelions became more regular and their sizes also increased to about 25 μm (Figure 6, B). As described above, the formation of the dandelions depends mainly on the concentration of the phosphate ions. Increasing the phosphorus acid concentration will therefore result in the formation of more and larger dandelions. When $C_{p.a}$ is higher than 10 mM, the sizes of the resulting dandelions no longer increase. In this case a large number of "nuclei" are generated and two neighboring dandelions expand and intermesh with each other to form an interconnected porous structure of nanosheets in their boundary region (Figure 6, C).[6,28,29] A further increase of $C_{p.a}$ makes the dandelions cover the whole copper surface compactly to form a lotus-like micro-nanostructure (Figure 6, D).

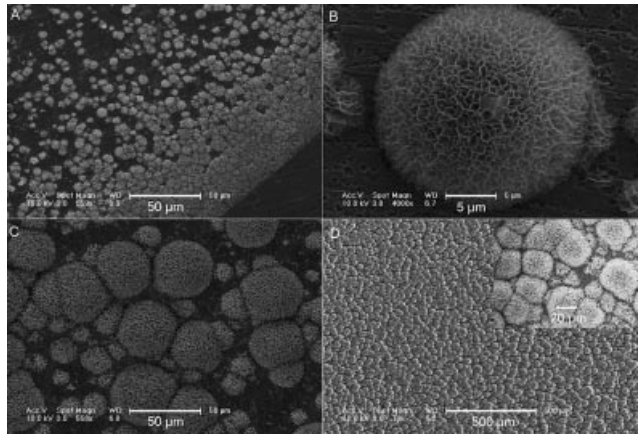

Figure 6. SEM images of the copper surface after drying of different phosphorus acid concentrations: A) 0.5 mM; B) 2 mM; C) 10 mM; D) 20 mM (droplet: 100 μL).

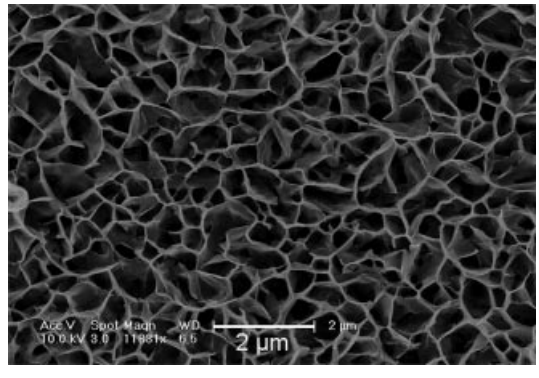

Figure 7. SEM images of the nanowalls. (100 μL of 2 mM aqueous phosphorus acid solution was dropped onto the surface of a piece of copper foil in a sealed box filled with oxygen gas at a temperature of 15–17 °C and humidity of 100% for 48 h. The foil was dried at 15 °C with a humidity of 30%).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

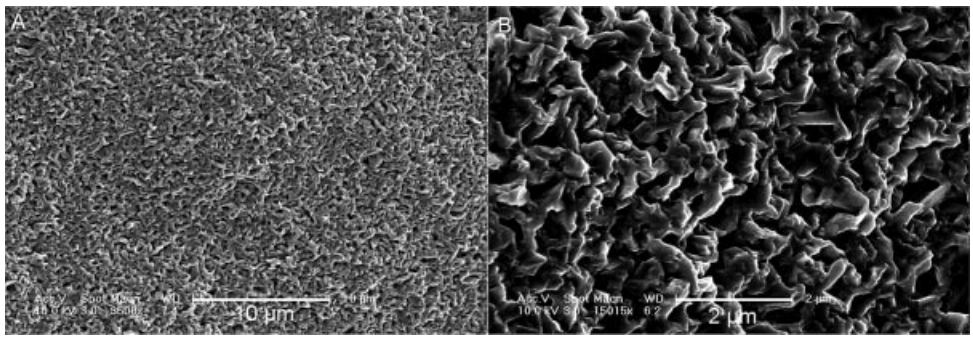

Figure 8. SEM images of the copper foil prepared from 50 mM H_3PO_4 heated at 650 °C for 6 h under nitrogen: A) overall view; B) magnified view.

It was interesting to find that control of the evaporation conditions can also change the morphology of the copper surface from 3D dandelions to 2D nanowalls. Figure 7 shows a typical image of copper phosphate dihydrates nanowalls formed by drop-drying 5 mM phosphoric acid on a copper foil surface in an environment with a humidity of 100% and at a temperature of15–17 °C. As can be seen from this figure, the nanosheets grow with their surfaces perpendicular to the copper surface and have a thickness of about 35 nm. The nanosheets intermesh with each other to form a porous film with a pore size ranging from 100 to 400 nm. In this case, the drying time is much longer than those described above and more nuclei are generated to form nanowalls.

When the film prepared from 50 mM H_3PO_4 was heated at 650 °C for 6 h under nitrogen and then cooled naturally to room temperature a nanoporous CuO film was produced. Figure 8 shows the SEM images of the as-prepared CuO film. Rod-like CuO particles intermesh with each other to form a porous film. It is clear from this figure that the original walls of the $[Cu_3(PO_4)_2{\cdot}2H_2O]$ nanostructures have collapsed. This is mainly due to the decomposition of copper phosphate dihydrate in the reaction that can be simply expressed as follow: $[Cu_3(PO_4)_2{\cdot}2H_2O] \rightarrow 3CuO + 2H_2O\uparrow + P_2O_5\uparrow$. The release of water and phosphorus pentoxide at temperatures higher than 400 °C destroys the framework of the copper phosphate dihydrate and results in the formation of a porous CuO film. The composition of the CuO film was confirmed by its EDS spectrum (Cu/O = 1:1; no phosphorus peak was observed). The composition of the film was also supported by its Raman spectrum (Figure 9): the bands at 301, 348, and 630 cm^{-1} correspond to the Ag, $Bg^{(1)}$, and $Bg^{(2)}$ modes of CuO crystals.[30]

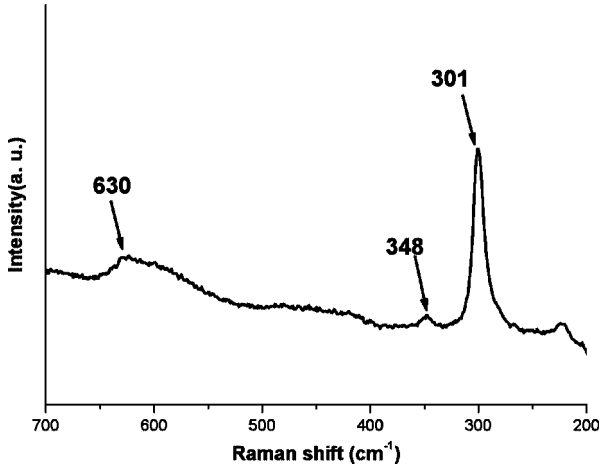

Figure 9. Raman spectrum of the as-prepared CuO film excited at 785 nm.

Conclusions

In summary, 3D dandelion-like porous nanostructures and 2D nanowalls of copper phosphate dihydrate built up of thin nanosheets can be fabricated by automatic drop-drying an aqueous solution of phosphoric acid on the surface of a copper foil under mild conditions. Controlling the initial concentration of the acid and the conditions of drop-drying can modulate the morphology of the nanostructures. The complex structure reported here brings new insights into understanding the mineralization mechanisms of nanostructured natural minerals. This work develops a simple, template-free method for fabricating high surface-to-volume ratio complex 3D nanostructures of metal-based materials. We believe this technique could be extended to fabricate 3D nanostructures of other materials by changing the solute or the substrate.

Experimental Section

Materials: Copper foil (99.9%, Shanghai Chemical Reagent Co. Ltd., Shanghai, China) with a thickness of 0.1 mm was polished with abrasive paper (1200 mesh), then cleaned with deionized water repeatedly and dried before each experiment. Phosphorous acid (analytical grade, Beijing Chemical Co. Ltd., Beijing, China) was used as received.

Preparation of $[Cu_3(PO_4)_2{\cdot}2H_2O]$ 3D Dandelions: Typically, in a sealed box (the bottom of the box was covered with allochroic silica gel) filled with dioxygen gas, 100 μL of aqueous phosphorus acid solution was dropped onto the surface of a piece of copper foil and dried automatically at a temperature of 15–17 °C. After the reaction, the copper foil was washed with deionized water and dried under vacuum at 40 °C overnight before characterization.

Preparation of $[Cu_3(PO_4)_2{\cdot}2H_2O]$ 2D Nanowall Films and CuO Nanoporous Films: Typically, a $[Cu_3(PO_4)_2{\cdot}2H_2O]$ 2D nanowall film

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was synthesized by putting a copper foil in an sealed box filled with dioxygen gas at a humidity of 100% and then dropping 100 μL of 2 mM aqueous phosphorus acid solution onto the foil surface and drying at a temperature of 15–17 °C for 48 h. Finally, the foil with the nanostructures was dried at 15 °C in an environment with a humidity of 30%. The CuO nanoporous film was produced by putting the copper foil covered with $[Cu_3(PO_4)_2{\cdot}2H_2O]$ nanostructures (fabricated from 50 mM H_3PO_4) into a furnace, heating to 650 °C for 6 h under nitrogen, and cooling naturally to room temperature.

Characterizations: Scanning electron micrographs (SEM) were taken with a FEI Sirion 200 or a S530 (Hitachi) scanning electron microscope. Ion concentrations were measured by using an inductively coupled plasma-atomic emission spectrometer (ICP-AES) model Vista-MP (Varian). X-ray diffraction (XRD) patterns were obtained with a D8 Advance (Bruker) X-ray diffractometer. X-ray photoelectron spectra (XPS) were recorded with an AEM PHI5300 (PE) photoelectron spectrometer. Raman spectra were recorded with a RM 2000 microscopic confocal Raman spectrometer (Renishaw PLC., England) employing a 633- or 785-nm laser beam and a CCD detector with 4 cm^{-1} resolution. The spectra were obtained by focusing a 10-μm laser spot on the sample using a 20 objective and accumulated three times for 30 s each. The powers were always kept very low (≈ 0.05 mW) to avoid destruction of the samples.

Cyclometalated Ruthenium Compounds Containing 2-(2′-Pyridyl)-4-methylphenyl and Benzo[*h*]quinolyl Ligands

Qian-Feng Zhang,[a] Ka-Man Cheung,[a] Ian D. Williams,[a] and Wa-Hung Leung*[a]

Keywords: Ruthenium / Cyclometalated ligands / Organometallic compounds / Transition metals

Transmetalation of $Hg(ptpy)_2$ [Hptpy = 2-(4-tolylpyridine) with $Cp^*Ru(NO)Cl_2$ ($Cp^* = \eta^5$-C_5Me_5)] gave $[Cp^*Ru(NO)(ptpy)]_2[Hg_2Cl_6]$ ($[\mathbf{1}]_2{\cdot}Hg_2Cl_6$) whereas that with $[Cp^*RuCl_2]_x$ gave the dinuclear Ru^{II}–Ru^{IV} compound $[Cp^*Ru(\mu\text{-}\eta^6{:}\eta^2\text{-}ptpy)RuCl_2Cp^*][Hg_2Cl_6]$ (**2**). Treatment of Ru(3-phenylindenylid-1-ene)$Cl_2(PPh_3)_2$ with $Hg(ptpy)_2$ resulted in coupling of ptpy with the 3-phenylidenylid-1-ene ligand, and the formation of Ru(Ph-ind-ptpy)$(PPh_3)Cl$ {Ph-ind-tpy = 3-phenyl-1-[2-(4-toyl)pyridyl]indenyl} (**3**), in which the chelated [Ph-ind-tpy]$^-$ ligand binds to Ru through the η^5-indenyl ring and the pendant pyridyl group. Treatment of $[Ru(CO)_2Cl_2]_n$ with $[Hg(ptpy)Cl]_2$ afforded $[Ru(ptpy)(CO)_2]_2(\mu\text{-}Cl)_2$ (**8**). Irradiation of *cis*-$[Ru(bzq)_2(CO)_2]$ (Hbzq = benzo[*h*]quinoline) with UV light in MeCN afforded *cis*-$[Ru(bzq)_2(CO)(MeCN)]$ (**9**). Photolysis of *cis*-$[Ru(bzq)_2(CO)_2]$ in THF in the presence of PPh_3 and pyridine (py) afforded *cis*-$[Ru(bzq)_2(CO)(L)]$ [L = PPh_3 (**10**), py (**11**)]. The crystal structures of complexes **1**–**3**, **8**, and **10** have been determined.

Introduction

Transition-metal complexes containing cyclometalated N^C ligands, notably 2-phenylpyridine (ppy), have attracted much attention because of their interesting photoluminescent properties[1] and their potential applications in organic synthesis[2] and bioinorganic chemistry.[3,4] Of note are cyclometalated Ir^{III} complexes, which have been used as phosphorescent dopants for organic light-emitting diodes,[5] chemical sensors,[6] and luminescent labels for biomolecules.[7] While the coordination chemistry of cyclometalated Ir^{III} compounds of the types $[Ir(ppy)_3]$ and $[Ir(ppy)_2(L)(X)]$[1,8–10] is well developed, the isoelectronic Ru^{II} analogues have received less attention.[9,10] This is in sharp contrast with cationic Ru^{II} complexes with 2,2′-bipyridyl (bpy) and polypyridyl ligands that exhibit rich redox- and photochemistry.[11] Owing to the anionic nature of ppy$^-$, it is anticipated that high-valence Ru–ppy complexes are more easily accessible than the bpy analogues. Recently, electron-rich Ru^{II} cyclometalated complexes have been used as mediators for electron transfer with horseradish peroxidase and glucose oxidase.[3]

To date, the most extensively explored Ru–ppy complexes are those supported by polypyridyl ligands.[12] Cyclometalated Ru^{II} N^C complexes containing η^6-arene[13] and phosphane[14,15] co-ligands have also been synthesized. These complexes were generally prepared by either transmetalation with organomercurials or direct cycloruthenation of N^CH ligands. In contrast to $[M(ppy)_2]^+$ (M = Rh, Ir), Ru^{II} bis-cyclometalated complexes are rather rare, the only structurally characterized example being *cis*-$[Ru(bzq)_2(CO)_2]$ (Hbzq = benzo[*h*]quinoline).[16] As part of our continuing effort to explore the organometallic chemistry of high-valence Ru complexes, we set out to investigate the transmetalation between $Hg(ptpy)_2$ [Hptpy = 2-(4-tolyl)-pyridine] and a variety of organoruthenium chloride compounds. Herein, we report on the syntheses and crystal structures of some cyclometalated ruthenium compounds containing the ptpy ligand. Furthermore, in order to prepare new Ru bis-cyclometalated complexes, photosubstitution of *cis*-$[Ru(bzq)_2(CO)_2]$ with two-electron ligands has been studied.

Results and Discussion

Cyclometalated Ru Cp* Complexes

Treatment of $Cp^*Ru(NO)Cl_2$ with $Hg(ptpy)_2$ in refluxing THF gave $[Cp^*Ru(ptpy)(NO)]_2[Hg_2Cl_6]$ ($[\mathbf{1}]_2{\cdot}[Hg_2Cl_6]$). Anion metathesis of $[\mathbf{1}]_2{\cdot}[Hg_2Cl_6]$ with $NaPF_6$ in acetone afforded Hg-free $[Cp^*Ru(ptpy)(NO)][PF_6]$ ($\mathbf{1}[PF_6]$) (Scheme 1). The formation of the chloromercurate anion $[Hg_2Cl_6]^{2-}$ from $HgCl_2$ and chloride salts is well documented.[13c,17,18] It may be noted that Djukic et al. previously reported that treatment of $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$ with Hg(ppy)Cl afforded $[(\eta^6\text{-}p\text{-cymene})Ru(ppy)Cl]{\cdot}HgCl_2$.[13c] The IR spectrum of $[\mathbf{1}]_2{\cdot}[Hg_2Cl_6]$ shows the N–O band at about 1780 cm^{-1}, which is higher than that for $[Cp^*Ru(NO)Ph_2]$ (1755 cm^{-1}).[19] The structure of $[\mathbf{1}]_2{\cdot}[Hg_2Cl_6]$ has been established by an X-ray diffraction study. The $[Hg_2Cl_6]^{2-}$

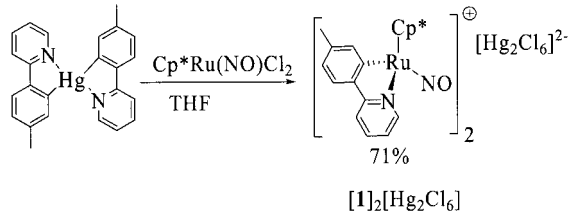
anion lies on a twofold rotation axis between two $[Cp^*Ru(ptpy)(NO)]^+$ cations. The molecular structure of the cation $[\mathbf{1}]^+$ is shown in Figure 1. The Ru–C(ptpy) [2.080(4) Å] and Ru–N [2.097(4) Å] distances and C(21)–Ru(1)–N(10) angle [77.95(17)°] in $\mathbf{1}^+$ are similar to those in $[(\eta^6\text{-}p\text{-cymene})Ru(ppy)Cl]\cdot HgCl_2$.[13c] The Ru–NO distance of 1.751(4) Å is shorter than that in $[Ru(ppy)(tpy)(NO)][PF_6]$ (tpy = 2,2′:6′,6′′-terpyridine) [1.826(4) Å],[12d] indicating the strong Ru–to-NO π-backbonding in $\mathbf{1}^+$. The N–O distance of 1.146(5) Å and the Ru–N–O angle of 174.4(4)° are normal by comparison with other linear nitrosyl compounds.[20]



Scheme 1. Synthesis of $[\mathbf{1}]_2\cdot[Hg_2Cl_6]$.

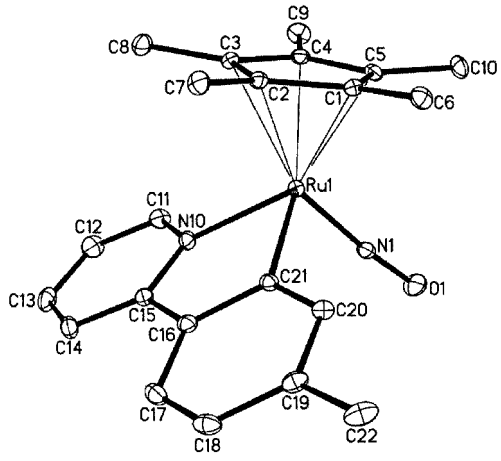


Figure 1. Perspective view of the cation $[Cp^*Ru(ptpy)(NO)]^+$ (displacement ellipsoids drawn at the 50% probability level). Selected bond lengths [Å] and angles [°]: Ru–Cp*(centroid) 1.898(3), Ru(1)–N(1) 1.751(4), Ru(1)–N(10) 2.097(4), Ru(1)–C(21) 2.080(4), N(1)–O(1) 1.146(5); N(10)–Ru(1)–C(21) 78.0(2), N(1)–Ru(1)–N(10) 99.9(2), N(1)–Ru(1)–C(21) 94.5(2), Ru(1)–N(1)–O(1) 174.4(4).

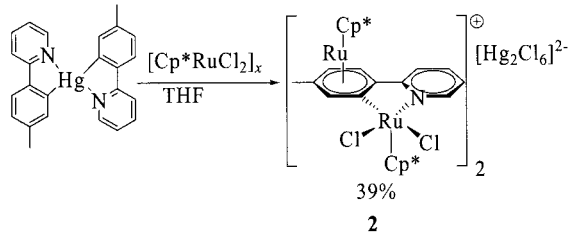
Treatment of $[Cp^*RuCl_2]_x$ with $[Hg(ptpy)_2]$ afforded a dark green material from which air-stable dark crystals characterized as $[Cp^*Ru(\mu\text{-}ptpy)RuCp^*Cl_2]_2[Hg_2Cl_6]$ (**2**) were isolated (Scheme 2). The ^1H NMR spectrum shows two Cp* signals at δ = 1.87 and 1.99 ppm, consistent with the solid-state structure. Upon binding to the Cp^*Ru^{II} fragment the resonant signals for the tolyl ring of the ptpy ligand are shifted to the upfield region (δ = 4.86–5.36 ppm; cf. δ = 7.40–7.72 ppm for $\mathbf{1}^+$). The identity of **2** has been established by a single-crystal X-ray diffraction study (Figure 2). The molecular structure of the cation $[Cp^*Ru(\mu\text{-}ptpy)RuCp^*Cl_2]^+$ in **2** consists of a $[Cp^*Cl_2Ru^{IV}(ptpy)]^+$ moiety, the 4-tolyl ring of which binds to the Cp^*Ru^{II} fragment in an η^6 fashion. It may be noted that a related bimetallic complex, $[(CO)_3Cr(\mu\text{-}ppy)Ru(\eta^6\text{-}p\text{-cymene})Cl]$, which contains a $\mu\text{-}\eta^2\text{:}\eta^6$-ppy ligand, has been synthesized recently.[13c] The geometry around Ru^{IV} in **2** is four-legged piano-stool whereas the Ru^{II}-containing moiety has a sandwich structure. The 4-tolyl and pyridine rings of the ptpy ligand are not coplanar, with a dihedral angle of about 12.3°. Cyclometalated Ru^{IV} complexes are rare. To the best of our knowledge, the only structurally characterized Ru^{IV} ppy complex is the mixed-valence Ru^{III}–Ru^{IV} compound $[\{Ru(ppy)(phen)Cl\}_2(\mu\text{-}O)][PF_6]$ (phen = 1,10-phenanthroline).[12e] The Ru^{IV}–Cp*(centroid) distance in **2** of 1.912(3) Å is comparable to reported Cp^*Ru^{IV} compounds (e.g. 1.916(4) Å for $[Cp^*Ru(\eta^2\text{-}Se_2P\mathit{i}Pr_2)(\eta^2\text{-}SeP\mathit{i}Pr_2)][PF_6]$),[21] but is obviously longer than the Ru^{II}–Cp*(centroid) distance [1.717(2) Å]. The Ru^{IV}–N and Ru^{IV}–C(ptpy) distances [2.132(7) and 2.081(8) Å, respectively] in **2** are similar to those in $\mathbf{1}^+$. The average Ru^{IV}–Cl distance of 2.417(2) Å is slightly longer than that of $[Cp^*Ru^{IV}Cl_2]_2[\mu\text{-}O]$ [2.356(8) Å].[22]



Scheme 2. Synthesis of **2**.

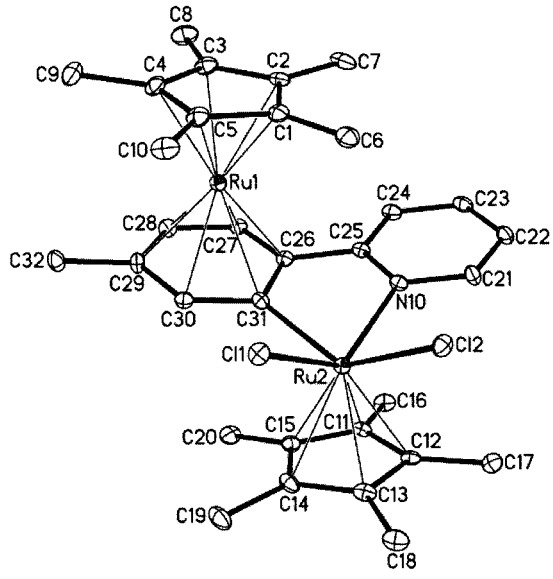


Figure 2. Perspective view of the cation $[Cp^*Ru(\mu\text{-}ptpy)RuCp^*Cl_2]^+$ (displacement ellipsoids drawn at the 50% probability level). Selected bond lengths [Å] and angles [°]: Ru(1)–Cp*(centroid) 1.717(2), Ru(1)–tolyl(centroid) 1.810(2), Ru(2)–N(10) 2.132(7), Ru(2)–C(31) 2.291(8), Ru(2)–Cl(1) 2.429(2), Ru(2)–Cl(2) 2.405(2), Ru(2)–Cp*(centroid) 1.912(3); N(10)–Ru(2)–C(31) 75.7(3), N(10)–Ru(2)–Cl(1) 129.1(2), N(10)–Ru(2)–Cl(2) 84.5(2), C(31)–Ru(2)–Cl(1) 82.1(2), C(31)–Ru(2)–Cl(2) 134.4(2), Cl(1)–Ru(2)–Cl(2) 79.40(7).

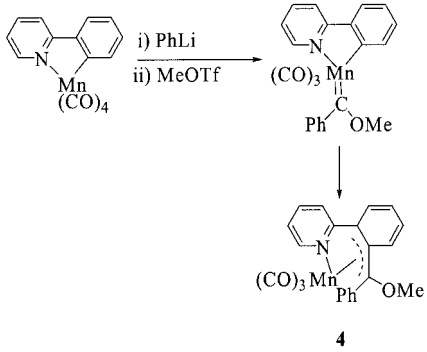
Transmetalation of [Hg(ptpy)$_2$] with Ru Carbene

Attempts to synthesize cyclometalated Ru complexes containing metal–carbon multiple bonds starting from Ru carbene and vinylidene species such as Ru(=CHPh)(PCy_3)$_2$Cl$_2$ and Ru(=C=CHPh)(PCy_3)$_2$Cl$_2$ were unsuccessful. In most cases, dark intractable materials were obtained. However, treatment of Ru(3-phenylindenylid-1-ene)(PPh_3)$_2$Cl$_2$ with Hg(ptpy)$_2$ afforded an air-stable crystalline product that has been characterized as Ru(Ph-ptpy-ind)(PPh_3)Cl (**3**) (Ph-ptpy-ind = η^5:κ*N*-3-phenyl-1-[2-(2-pyridyl)-4-tolyl]indenyl). It seems likely that **3** was formed by insertion of the indenylid-1-ene group into the Ru–C(ptpy) σ-bond. The insertion of carbene group into the M–C(N^C) bonds in M(N^C)(CO)$_4$ (M = Mn, Re) has been studied in detail by Djukic, Dötz, and Pfeffer and their co-workers.[23,24] It was found that treatment of Mn(CO)$_4$(ppy) with PhLi followed by addition of MeOTf led to insertion of the carbene ligand C(Ph)(OMe) into the Mn–C(ppy) bond and the formation of a η^3-benzyltricarbonyl Mn^I complex **4** (Scheme 3).[23a] On the other hand, thermolysis of Mn(CO)$_4$(Me-ppy) in the presence of 7-diazofluorene resulted in the insertion of the *exo*-alkylidene group into the Mn–C(ppy) bond. Subsequent cleavage of the Mn–N bond coupled with a series of haptotropic ring slippages afforded the Mn^I η^5-fluorenyl complex **5** (Scheme 4).[23e] On the basis of these results, we propose that the transmetalation of Ru(3-phenylindenylid-1-ene)(PPh_3)$_2$Cl$_2$ with Hg(ppy)$_2$ initially afforded a Ru^{II} indenylid-1-ene intermediate **6** (Scheme 5). Insertion of the indenylid-1-ene ligand into the Ru–C bond in **6** followed by haptotropic ring shifts, possibly via an η^3-allyl intermediate **7**, afforded **3**. Unlike the Mn(CO)$_4$(N^C) system, in which arenes tethered with cymantranes were formed,[23e] insertion of indenylidene into the Ru–C(ppy) bond led to formation of a chelated η^5-indenyl-ppy ligand, presumably because the PPh_3 ligand in **3** can be dissociated more easily than the carbonyl in the Mn counterparts.



4

Scheme 3. Insertion of carbene into the Mn–C(ppy) bond.[23a]

The $^{31}P\{^1H\}$ NMR spectrum of **3** shows a singlet at δ = 33.1 ppm due to the PPh_3 ligand. The solid-state structure of **3** is shown in Figure 3. Similar to other Ru^{II} indenyl complexes, the Ru–C distances involving the bridging carbon atoms C(25) and C(29) [2.354(3) and 2.307(3) Å] are longer than those for C(26), C(27), and C(28) [2.105(3)–2.196(3) Å]. The Ru–P distance [2.2690(8) Å] is similar to

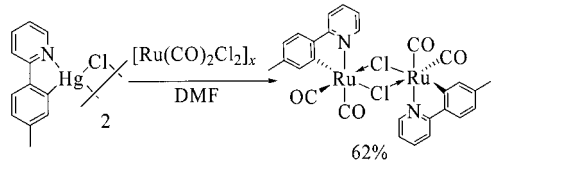
that in $[Ru(CO)(PPh_3)_2(\eta^5\text{-}C_9H_7)][ClO_4]$ [2.273(3) Å].[25] The pendant ptpy substituent of the indenyl group is significantly twisted and nonplanar with a dihedral angle between the 4-tolyl and pyridyl rings of about 36.8°.

Cyclometalated Ru Carbonyl Complexes

Treatment of $[Ru(CO)_2Cl_2]_x$ with $Hg(ptpy)_2$ afforded a yellow compound characterized as *cis*-$[Ru(ptpy)(CO)_2]_2(\mu\text{-}Cl)_2$ (**8**) in 18% yield. A higher yield (62%) of **8** was obtained when $[Hg(ptpy)(\mu\text{-}Cl)]_2$ was employed as the transmetalating agent (Scheme 6). The cyclometalated azobenzene analogue, $[Ru(N\text{^}C)(CO)_2Cl]_2$ (N^CH = azobenzene), has been previously prepared by Bruce et al.[26] The IR spectrum of **6** shows $\nu(C{\equiv}O)$ at 2039 and 2104 cm^{-1}, indicative of the *cis* geometry of the carbonyl ligands. The molecular structure of **8** consisting of two symmetry-related $Ru(ptpy)(CO)_2Cl$ fragments is shown in Figure 4. The geometry around Ru is pseudo-octahedral, with the *cis*-disposed CO ligands opposite the pyridyl ring and chloride. The Ru–C(ptpy) distance [2.048(6) Å] in **8** is shorter than that in *cis*-$[Ru(bzq)_2(CO)_2]$ [2.161(5) Å],[16] in which both the Ru–C(bzq) bonds are *trans* to CO. The Ru–CO distances [1.888(7) and 1.830(7) Å] in **8** are comparable to those in *cis*-$[Ru(bzq)_2(CO)_2]$ [1.87(1) and 1.81(1) Å].[16b] The Ru–Cl(*trans* to 4-tolyl) [2.542(2) Å] is longer than Ru–Cl(*trans* to CO) [2.465(2) Å], suggesting that the σ 4-tolyl group has a stronger *trans* influence than carbonyl.



Scheme 6. Synthesis of **8**.

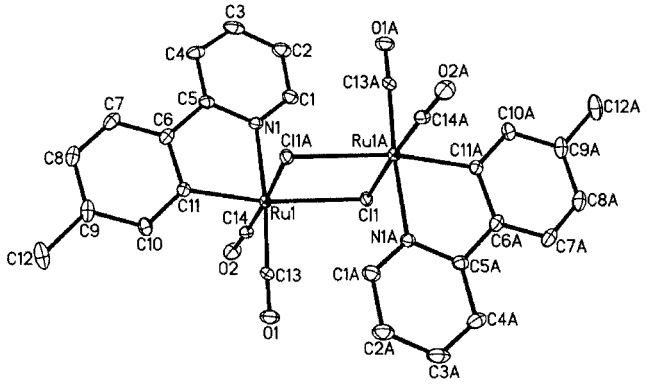


Figure 4. Perspective view of *cis*-$[Ru(ptpy)(CO)_2]_2(\mu\text{-}Cl)_2$ (**8**) (displacement ellipsoids drawn at the 50% probability level). Selected bond lengths [Å] and angles [°]: Ru(1)–C(11) 2.048(6), Ru(1)–N(1) 2.139(5), Ru(1)–C(13) 1.888(7), Ru(1)–C(14) 1.830(7), Ru(1)–Cl(1) 2.542(2), Ru(1)–Cl(1A) 2.465(2); C(14)–Ru(1)–C(13) 88.0(3), C(14)–Ru(1)–C(11) 87.7(3), C(13)–Ru(1)–C(11) 94.5(3), C(14)–Ru(1)–N(1) 92.7(2), C(13)–Ru(1)–N(1) 174.5(2), C(11)–Ru(1)–N(1) 80.1(2), C(14)–Ru(1)–Cl(1A) 175.8(2), C(13)–Ru(1)–Cl(1A) 91.1(2), C(11)–Ru(1)–Cl(1A) 88.3(2), N(1)–Ru(1)–Cl(1A) 88.0(1), C(14)–Ru(1)–Cl(1) 101.1(2), C(13)–Ru(1)–Cl(1) 92.3(2), C(11)–Ru(1)–Cl(1) 169.1(2), N(1)–Ru(1)–Cl(1) 93.0(2), Cl(1A)–Ru(1)–Cl(1) 83.00(5), Ru(1A)–Cl(1)–Ru(1) 97.00(5) (symmetry code: $-x + 1, -y, -z + 1$).

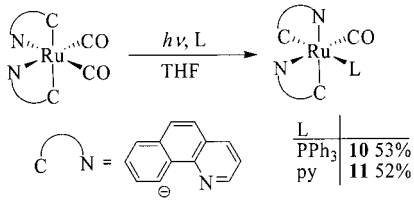
Photosubstitution of *cis*-$[Ru(bzq)_2(CO)_2]$

Attempts to prepare Ru^{II} bis-cyclometalated complexes by treatment of $[Ru(CO)_2Cl_2]_x$ with excess $[Hg(ptpy)(\mu\text{-}Cl)]_2$ were unsuccessful. We then turned our attention to substitution of the reported compound *cis*-$Ru(bzq)_2(CO)_2$ with Lewis bases. Prolonged reaction of *cis*-$[Ru(bzq)_2(CO)_2]$ with excess PPh_3 in refluxing DMF afforded the mono carbonyl compound *cis*-$[Ru(bzq)_2(CO)(PPh_3)]$ in low yield (about 7%). The substitution of *cis*-$[Ru(bzq)_2(CO)_2]$ was found to be accelerated by UV light. Photolysis of *cis*-$[Ru(bzq)_2(CO)_2]$ in THF at room temperature afforded a highly air-sensitive, yellow species, presumably $Ru(bzq)_2(CO)(THF)$, which exhibited a C–O band at 2000 cm^{-1} in the IR spectrum. The MeCN adduct *cis*-$[Ru(bzq)_2(CO)(MeCN)]$ (**9**) was prepared similarly by photolysis of *cis*-$[Ru(bzq)_2(CO)_2]$ in MeCN and isolated as an air-sensitive red solid. Photosubstitution of *cis*-$[Ru(bzq)_2(CO)_2]$ with PPh_3 in THF afforded *cis*-$[Ru(bzq)_2(CO)(PPh_3)]$ (**10**) (Scheme 7). Compound **10** could also be prepared in good yield from **9** and PPh_3. An X-ray diffraction study revealed that the photosubstitution of *cis*-$[Ru(bzq)_2(CO)_2]$ led to a change in the stereochemistry of the complex. The two Ru–C(bzq) σ-bonds that are *trans* to each other in *cis*-$[Ru(bzq)_2(CO)_2]$ become mutually *cis* in **10** (vide infra). Similarly, the pyridine (py) adduct $Ru(bzq)_2(CO)(py)$ (**11**) was prepared by photosubstitution of *cis*-$[Ru(bzq)_2(CO)_2]$ with pyridine in THF. An attempt to prepare the bis-pyridine complex $Ru(bzq)_2(py)_2$ by photolysis of *cis*-$[Ru(bzq)_2(CO)_2]$ in neat pyridine was unsuccessful. Unlike **9** and **11**, **10** is air stable in both solutions and the solid state. The solid-state structure of **10** is shown in Figure 5. In contrast to *cis*-$[Ru(bzq)_2(CO)_2]$, both the Ru–N and Ru–C bonds for the bzq ligands adopt the *cis* arrangement. The Ru–C(bzq) [2.088(9) and 2.033(8) Å], Ru–N [2.157(7) and 2.194(7) Å], and Ru–CO [1.84(1) Å] distances in **10** are similar to those in *cis*-$[Ru(bzq)_2(CO)_2]$ [Ru–C(bzq) 2.13(1) and 2.12(1) Å, Ru–N 2.148(8) and 2.161(9) Å, Ru–CO 1.81(1) and 1.87(1) Å].[16b]



Scheme 7. Photosubstitution of *cis*-$[Ru(bzq)_2(CO)_2]$.

Attempts to prepare bis-cyclometalated Ru carbene species by reactions of **9** with alkynes and alkynols were unsuccessful. Treatment of **9** in THF with ethyl diazoacetate (EDA) resulted in a brown solution, which possibly contained a Ru carbene species given its ability in carbene

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

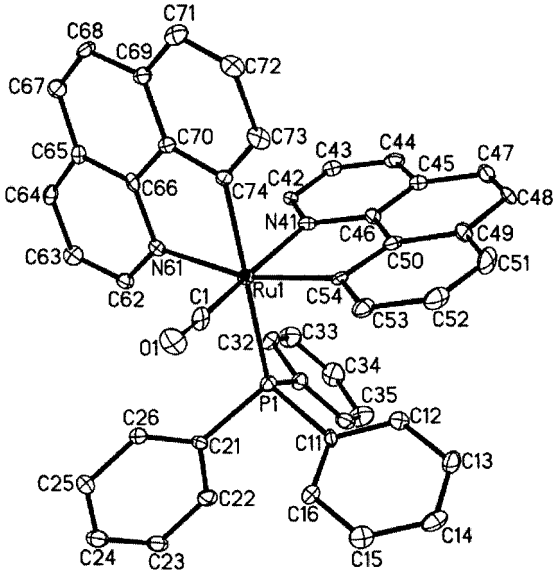


Figure 5. Perspective view of *cis*-[Ru(bzq)$_2$(CO)(PPh$_3$)] (**10**) (displacement ellipsoids drawn at the 50% probability level). Selected bond lengths [Å] and angles [°]: Ru(1)–C(1) 1.84(1), Ru(1)–C(54) 2.033(8), Ru(1)–C(74) 2.088(9), Ru(1)–N(41) 2.157(7), Ru(1)–N(61) 2.194(7), Ru(1)–P(1) 2.385(3), C(1)–O(1) 1.14(1); C(1)–Ru(1)–C(54) 90.3(4), C(1)–Ru(1)–C(74) 87.9(4), C(54)–Ru(1)–C(74) 89.0(3), C(1)–Ru(1)–N(41) 168.7(3), C(54)–Ru(1)–N(41) 80.0(3), C(74)–Ru(1)–N(41) 86.2(3), C(1)–Ru(1)–N(61) 98.7(3), C(54)–Ru(1)–N(61) 165.0(3), C(74)–Ru(1)–N(61) 79.4(3), N(41)–Ru(1)–N(61) 89.7(3), C(1)–Ru(1)–P(1) 92.2(3), C(54)–Ru(1)–P(1) 91.6(3), C(74)–Ru(1)–P(1) 179.4(3), N(41)–Ru(1)–P(1) 93.8(2), N(61)–Ru(1)–P(1) 100.1(2), O(1)–C(1)–Ru(1) 173.8(9).

transfer (vide infra). Unfortunately, no crystalline products were isolated from the brown reaction mixture. A preliminary result showed that **9** is an active catalyst for cyclopropanation of styrene. For example, treatment of styrene with EDA in the presence of 5 mol-% of **9** afforded 2-phenylcyclopropane carboxylate in 76% yield along with a small amount of the homo-coupling product $C_2H_2(CO_2Et)_2$ (<5%). At present, efforts are being made to isolate the reactive cyclometalated Ru carbene species.

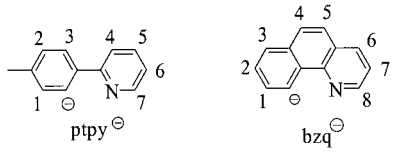
Conclusions

In summary, we have studied the transmetalation of [Hg(ptpy)$_2$] with a variety of organoruthenium compounds. Treatment of [Hg(ptpy)$_2$] with [Cp*RuCl$_2$]$_x$ afforded a mixed-valence Ru^{II}–Ru^{IV} complex that contains a μ-η^6:η^2 ptpy ligand. Transmetalation of [Hg(ptpy)$_2$] with [Ru(3-phenylindenylid-1-ene)(PPh$_3$)$_2$Cl$_2$] resulted in coupling of the carbene and the ptpy ligand and the formation of a Ru^{II} complex with a η^5:κ*N*-Ph-ind-ptpy ligand. The bis-cyclometalated Ru monocarbonyl complexes *cis*-[Ru(bzq)$_2$(CO)L] were prepared by photosubstitution of *cis*-[Ru(bzq)$_2$(CO)$_2$] with L (MeCN, PPh$_3$, and py).

Experimental Section

General: All manipulations were carried out under nitrogen by standard Schlenk techniques. Solvents were purified, distilled, and degassed prior to use. NMR spectra were recorded with a Bruker ALX 300 spectrometer operating at 300 and 121.5 MHz for ^{1}H and ^{31}P, respectively. Chemical shifts (δ, ppm) were reported with reference to SiMe$_4$ (^{1}H) and H$_3$PO$_4$ (^{31}P). Infrared spectra were recorded with a Perkin–Elmer 16 PC FT-IR spectrophotometer, and mass spectra with a Finnigan TSQ 7000 spectrometer. Elemental analyses were performed by Medac Ltd., Surrey, UK.

The compounds [Cp*RuCl$_2$]$_x$,[27] [Cp*Ru(NO)Cl$_2$][28] (Cp* = η^5-C$_5$Me$_5$), [Ru(3-phenylindenylid-1-ene)(PPh$_3$)$_2$Cl$_2$],[29] *cis*-[Ru(bzq)$_2$(CO)$_2$],[16a] [Hg(ptpy)$_2$], and [Hg(ptpy)(μ-Cl)]$_2$[30] were synthesized according to literature methods. Hydrogen atom labeling schemes for cyclometalated ptpy$^-$ and bzq$^-$ ligands are shown below.



[Cp*Ru(ptpy)(NO)]$_2$[Hg$_2$Cl$_6$] ([1]$_2$·[Hg$_2$Cl$_6$]): A mixture of Cp*Ru(NO)Cl$_2$ (80 mg, 0.237 mmol) and Hg(ptpy)$_2$ (65 mg, 0.120 mmol) in THF (25 mL) was heated at reflux for 4 h, during which time the reaction color changed from green to orange. The solvent was pumped off, and the residue was washed with Et$_2$O and then extracted into CH$_2$Cl$_2$. Recrystallization from CH$_2$Cl$_2$/Et$_2$O gave orange crystals. Yield: 125 mg (71%). $C_{44}H_{50}Cl_6Hg_2N_4O_2Ru_2$·1/2THF (1520.0): calcd. C 36.5, H 3.65, N 3.69; found C 36.3, H 3.32, N 3.75. ^{1}H NMR ([D$_6$]acetone): δ = 2.04 (s, 30 H, Cp*), 2.61 (s, 6 H, CH$_3$), 7.40 (m, 4 H, H^1 and H^2), 7.72 (d, *J* = 6.7 Hz, 2 H, H^3), 8.13 (m, 4 H, H^5 and H^6), 8.45 (d, *J* = 7.2 Hz, 2 H, H^4), 8.94 (d, *J* = 6.2 Hz, 2 H, H^7) ppm. IR (KBr): $\tilde{\nu}$ = 1783 (s) [*ν*(NO)]. MS (FAB): *m*/*z* (%) = 435 ([Cp*Ru(ptpy)(NO)]$^+$), 406 ([Cp*Ru(ptpy)]$^+$ + 1).

[Cp*Ru(ptpy)(NO)][PF$_6$] (1[PF$_6$]): Na[PF$_6$] (1 equiv., 14 mg, 0.081 mmol) was added to a solution of [**1**]$_2$·[Hg$_2$Cl$_6$] (60 mg, 0.081 mmol) in acetone (20 mL) and the mixture was stirred at room temperature for 2 h and filtered through a Celite pad. The filtrate was evaporated to dryness and the residue recrystallized from acetone/Et$_2$O to give an orange crystalline solid. Yield: 48 mg (79%). $C_{22}H_{25}F_6N_2OPRu$ (579.48): calcd. C 45.5, H 4.3, N 4.83; found C 46.1, H 4.26, N 4.77. ^{1}H NMR ([D$_6$]acetone): δ = 2.01 (s, 15 H, Cp*), 2.64 (s, 3 H, CH$_3$), 7.42 (m, 2 H, H^1 and H^2), 7.70 (d, *J* = 6.7 Hz, 1 H, H^1), 8.12 (m, 2 H, H^5 and H^6), 8.47 (d, *J* = 7.2 Hz, 1 H, H^4), 8.98 (d, *J* = 6.2 Hz, 1 H, H^7) ppm. ^{31}P{^{1}H} NMR ([D$_6$]-acetone): δ = 76.8 ppm. IR (KBr): $\tilde{\nu}$ = 1779 cm^{-1} [*ν*(NO)]. MS (FAB): *m*/*z* (%) = 435 (M$^+$ – PF$_6$), 405 (M$^+$ – PF$_6$ – NO).

[Cp*Ru(μ-ptpy)RuCl$_2$Cp*]$_2$[Hg$_2$Cl$_6$] (2): A mixture of [Cp*RuCl$_2$]$_x$ (85 mg, 0.138 mmol) and [Hg(ptpy)$_2$] (94 mg, 0.135 mmol) in THF (30 mL) was stirred at room temperature overnight and filtered. The filtrate was evaporated to dryness and the residue was recrystallized from CH$_2$Cl$_2$/Et$_2$O to give dark red crystals, which were suitable for X-ray diffraction analysis. Yield: 54 mg (39%). [$C_{32}H_{40}Cl_5HgNRu_2$]$_2$·HgCl$_2$ (1136.65): calcd. C 33.8, H 3.52, N 1.23; found C 34.1, H 3.64, N 1.21. ^{1}H NMR ([D$_6$]acetone): δ = 1.87 (s, 30 H, Cp*), 1.99 (s, 30 H, Cp*), 2.46 (s, 6 H, CH$_3$), 4.86–5.03 (m, 4 H, H^1 and H^2), 5.36 (d, *J* = 6.2 Hz, 2 H, H^3), 7.86–7.94 (m, 4 H, H^5 and H^6), 8.63 (d, *J* = 7.1 Hz, 2 H, H^6), 9.08 (d, 2 H, *J* = 6.8 Hz, H^7) ppm. MS (FAB): *m*/*z* (%) 712 ([Cp*Ru(ptpy)RuCp*Cl$_2$]$^+$).

[Ru(Ph-ind-ptpy)(PPh$_3$)Cl] (3): Hg(ptpy)$_2$ (94 mg, 0.175 mmol) was added to a solution of Ru(3-phenylindenylid-1-ene)(PPh$_3$)$_2$Cl$_2$ (100 mg, 0.113 mmol) in THF (20 mL) and the mixture was stirred

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at room temperature overnight and filtered. The solvent was pumped off and the residue was washed with hexane/Et_2O and extracted with CH_2Cl_2. Recrystallization from CH_2Cl_2/hexane gave red crystals. Yield: 37 mg (43%). $C_{45}H_{35}ClNPRu\cdot 1/2H_2O$ (766.29): calcd. C 70.5, H 4.74, N 1.83; found C 70.0, H 4.55, N 1.84. ^1H NMR ($CDCl_3$): δ = 2.17 (s, 3 H, CH_3), 5.30 (s, 1 H, CH), 6.88–7.49 (m, 27 H, Ph), 7.68 (d, J = 5.8 Hz, 1 H, H^4), 7.81 (m, 2 H, H^5 and H^6), 8.61 (d, J = 7.2 Hz, 1 H, H^7) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 33.1 ppm. MS (FAB): m/z (%) = 758 ($M^+ + 1$), 722 ($M^+ - Cl$).

[Ru(ptpy)(CO)$_2$]$_2$(μ-Cl)$_2$ (8): A mixture of $[Ru(CO)_2Cl_2]_x$ (80 mg, 0.35 mmol) and [Hg(ptpy)(μ-Cl)]$_2$ (285 mg, 0.35 mmol) in DMF (15 mL) was heated at reflux overnight. The solvent was removed in vacuo and the residue was extracted with CH_2Cl_2. The extract was concentrated to about 10 mL and excess Et_2O was added until a yellow solid was formed. The product was purified by column chromatography (silica) using CH_2Cl_2/acetone (9:1) as eluent. Recrystallization from CH_2Cl_2/Et_2O afforded pale yellowish green crystals. Yield: 68 mg (62%). $C_{28}H_{20}Cl_2N_2O_4Ru_2$ (721.50): calcd. C 46.6, H 2.77, N 3.88; found C 47.3, H 2.71, N 3.79. ^1H NMR ($CDCl_3$): δ = 2.21 (s, 6 H, CH_3), 6.92–7.03 (m, 4 H, H^1 and H^2), 7.14 (d, J = 6.2 Hz, 2 H, H^3), 7.76–7.96 (m, 4 H, H^5 and H^6), 8.49 (d, J = 7.4 Hz, 2 H, H^6), 9.17 (d, J = 7.0 Hz, 2 H, H^7) ppm. IR (KBr): $\tilde{\nu}$ = 2039, 2104 cm^{-1} [ν(C≡O)]. MS (FAB): m/z = 360 ([1/2M]$^+$).

***cis*-[Ru(bzq)$_2$(CO)(MeCN)] (9):** A solution of *cis*-[Ru(bzq)$_2$(CO)$_2$] (30 mg, 0.058 mmol) in MeCN (25 mL) was irradiated with a mercury lamp under N_2 for 1 h, during which time the color changed from pale yellow to dark red. The solvent was pumped off, and the residue was washed with Et_2O and then extracted with MeCN. Recrystallization from MeCN–CH_2Cl_2–Et_2O gave an air-sensitive dark red crystalline solid. Yield: 23 mg (76%). $C_{29}H_{19}N_3ORu\cdot CH_2Cl_2\cdot 1/2CHCl_3$ (671.19): calcd. C 54.6, H 3.23, N 6.26; found C 54.7, H 3.27, N 6.21. ^1H NMR (CD_3CN): δ = 6.69 (d, J = 7.5 Hz, 1 H, H^1), 6.87 (t, J = 7.5 Hz, 1 H, H^2), 6.98–7.03 (m, 1 H, H^1), 7.10–7.25 (m, 2 H, H^2 and H^3), 7.48–7.58 (m, 2 H, H^3 and H^7), 7.55 (t, J = 7.5 Hz, 1 H, H^7), 7.75 (s, 2 H, H^4), 7.82–7.87 (m, 2 H, H^5), 8.09 (d, J = 8.0 Hz, 1 H, H^6), 8.45 (d, J = 7.0 Hz, 1 H, H^8), 8.55 (d, J = 7.8 Hz, 1 H, H^6), 9.40 (d, J = 4.8 Hz, 1 H, H^8) ppm. IR (KBr): $\tilde{\nu}$ = 1890 [ν(C≡O)], 2014 [ν(C≡N)] cm^{-1}.

***cis*-[Ru(bzq)$_2$(CO)(PPh$_3$)] (10):** A mixture of *cis*-[Ru(bzq)$_2$(CO)$_2$] (50 mg, 0.097 mmol) and PPh_3 (51 mg, 0.195 mmol) in THF (25 mL) was irradiated with UV light under N_2 for 1 h, during which time the reaction color changed from pale yellow to dark yellow. The solvent was pumped off, and the residue was washed with Et_2O and extracted with CH_2Cl_2. Recrystallization from CH_2Cl_2/Et_2O/hexane gave yellow crystals that were suitable for X-ray diffraction. Yield: 38 mg (53%). $C_{45}H_{31}N_2OPRu\cdot 1/2H_2O$ (756.81): calcd. C 71.4, H 4.26, N 3.70; found C 71.3, H 4.29, N 3.68. ^1H NMR ($CDCl_3$): δ = 6.47–6.52 (m, 1 H, H^1), 6.66 (d, J = 5.0 Hz, 1 H, H^2), 6.92–7.00 (m, 2 H, H^1 and H^2), 7.02–7.18 (m, 15 H, PPh_3), 7.27–7.35 (m, 4 H, H^4 and H^5), 7.55–7.58 (m, 1 H, H^6), 7.67–7.99 (m, 4 H, H^3 and H^7), 8.12–8.15 (m, 1 H, H^8), 8.27 (d, J = 7.8 Hz, 1 H, H^6), 8.88 (d, J = 4.8 Hz, 1 H, H^8) ppm. IR (KBr): $\tilde{\nu}$ = 1912 cm^{-1} [ν(C≡O)].

[Ru(bzq)$_2$(CO)(py)] (py = pyridine) (11): A mixture of *cis*-[Ru(bzq)$_2$(CO)$_2$] (30 mg, 0.058 mmol) and pyridine (10 μL, 0.116 mmol) in THF (25 mL) was irradiated with UV light under N_2 for 1 h, during which time the color changed from pale yellow to orange red. The solvent was filtered and pumped off, and the residue was washed with Et_2O and then extracted with THF. Recrystallization from THF/Et_2O gave an air-sensitive, orange crystalline solid. Yield: 17 mg (52%). Despite several attempts, we have not been able to obtain satisfactory analytical data for the compound. ^1H NMR ([D$_6$]benzene): δ = 6.02–6.08 (m, 2 H, H^1), 6.85–6.89 (m, 2 H, H^2), 7.00 (m, 4 H, H^3 and H^7), 7.27–7.36 (m, 2 H, py), 7.56 (t, J = 7.4 Hz, 2 H, py), 7.62–7.69 (m, 4 H, H^4 and H^5), 7.76 (t, J = 8.6 Hz, 1 H, py), 8.37 (d, J = 4.8 Hz, 2 H, H^6), 9.31 (d, J = 7.4 Hz, 2 H, H^8) ppm. IR (KBr): $\tilde{\nu}$ = 1898 cm^{-1} [ν(C≡O)].

X-ray Crystallographic Study: A summary of crystallographic data and experimental details for complexes $[\mathbf{1}]_2 \cdot [Hg_2Cl_6]$, $\mathbf{2} \cdot HgCl_2$, $\mathbf{3} \cdot C_4H_8O$, **8**, and $\mathbf{10} \cdot C_6H_{14} \cdot Et_2O$ are listed in Table 1. All intensity data were collected with a Bruker SMART-APEX diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.70173 Å). The data were integrated and sorted using SAINT v6.26A software[31] and were corrected for absorption by empirical methods. The structures were solved by direct methods and refined by full-matrix least-squares analyses on F^2. Calculations were performed using the SHELXTL[32] crystallographic software package. All non-hydrogen atoms were refined anisotropically with suitable restraints. Hydrogen atoms were generated geometrically (C–H = 0.95 Å) and allowed to ride on their respective parent carbon or nitrogen atoms before the final cycle of least-squares refinement.

CCDC-269638 to -269642 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Keywords: Nickel / Nanostructures / Chemical reduction / Crystal growth

A novel chemical reduction route was designed for the synthesis of nickel nanocrystals with distinct flowery shapes by using a mixture of two complexes of $Ni(N_2H_4)_3^{2+}$ and $Ni(dmg)_2$ (nickel dimethylglyoximate) as the nickel source. Formation of these flowers, comprising spherical centers and swordlike petals, was related to the varying stability and structural properties of the two precursors as well as the reaction conditions. Investigations of the time-dependent shape-evolution process indicated that spherical particles were formed first as flower centers, and then swordlike petals grew radially from the particle surfaces. A rational mechanism of formation was proposed on the basis of a range of contrasting experiments. Compared with bulk nickel, these nanoflowers exhibited an enhanced coercivity (H_c) and a decreased saturation magnetization (M_s); this fact is attributed to their peculiar morphology.

Introduction

For many years, control of the morphology of nanomaterials has been of great interest for their shape-dependent properties and potential applications in nanoelectronics, photonics, magnetics, catalysis, and so forth.[1] Exploration of various shape-controlling synthetic methods and studies on their unusual properties will inevitably drive the progress in nanotechnology. Templates such as macroporous membranes, carbon nanotubes, aluminum anode oxides (AAO), block copolymers, microemulsions, polymers, and complexing agents are often utilized during synthesis to control the shape of nanomaterials.[2] Among these templates, utilizing coordination complexes as precursors has attracted particular attention for its simplicity and convenience. A range of novel-shaped nanocrystals have been fabricated by this method, for example Cu_2O nanowires, cubic FeS_2 crystallites, and several different shaped ZnO nanostructures including hollow spheres, ringlike nanosheets standing on spindlelike rods, nanoparticles nanoribbons, flowerlike cupped-end microrod bundles, branched spindles, and prismatic whiskers.[3] In this technique, the morphology of the target product was closely associated with the structure and shape of the complex precursors. Upon removal of the ligand molecules in a rational and controllable manner, inorganic nanomaterials with the desired size and shape could be synthesized.[3e]

In addition to the effect of templates, modification of the reaction steps also has great influence on the crystal configuration. Generally, the formation processes of crystals include nucleation and growth, which is practically a continuous process. However, in the two-step, seed-mediated synthesis technique, the nucleation and growth are purposely separated for adjusting the crystal morphology. In the first step, the seed nanocrystals, whose characteristic symmetry and structure are critical for directing the final crystal shape, are synthesized and added to the synthetic system. Then, precursors to the desired structures are chemically reduced in the presence of capping molecules and seed nanocrystals that serve as nucleation sites.[4] Following this methodology, a series of different shaped nanocrystals were fabricated. For example, uniform Au and Ag nanorods, dumbbell-shaped Au–Ag core-shell nanocrystals were all created from the seed-mediated growth in solution.[5a–5c] Oriented arrays of ZnO nanorods were produced from citrate solution in the presence of nanosized ZnO seeds.[5d] Likewise, using Ag nanoparticles as seeds, a peculiar netlike Ag skeleton could be synthesized by reduction of silver ions with Raney nickel.[5e] These results indicate this synthetic approach has great potential for the anisotropic growth of inorganic nanocrystals, but the interface issues between the seed and growing materials have not been well resolved, and further research is required for their general applicability and extension to the synthesis of complex nanostructures.[4b]

Nanosized particles of nickel have diverse applications in the fields of catalysis, magnet recording, medical diagnosis, and conduction.[6] In the past decade, nickel nanocrystals with the following shapes have been fabricated: nanotubes,

hollow spheres, nanobelts, nanorods, nanoprisms, and hexagonal flakes. However, the creation of nickel nanoflowers has seldom been reported.[7] In this paper, we have designed a new reaction route which combines coordination control with the step modulation technique and yields nickel nanocrystals with a novel flower shape. This strategy involves the monitoring of crystal nucleation and growth through chemical reactions. In contrast to previous methods using a single-source precursor, two complexes, $Ni(N_2H_4)_3^{2+}$ and $Ni(dmg)_2$, comprise the nickel source. The reaction process involves two steps: firstly, $Ni(N_2H_4)_3^{2+}$ is reduced, and the resulting spherical nanocrystals serve as the flower centers. Then, $Ni(dmg)_2$ yields swordlike nanocrystals which grow radially on the existing spherical centers as petals. A series of experiments were conducted to investigate the possible formation process.

Results and Discussion

The phase and purity of the as-prepared product was determined by X-ray diffraction (XRD), as shown in Figure 1. All the diffraction peaks could be indexed as face-centered cubic (fcc) nickel (JCPDS 01–1260). No characteristic peaks due to the impurities of nickel oxides or hydroxides were detected, indicating that pure crystalline nickel was fabricated under such conditions.

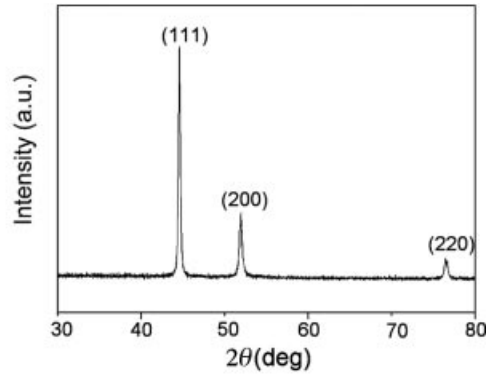

Figure 1. XRD pattern of as-prepared flowerlike nickel crystals.

The morphology of the sample was investigated by field emission scanning electron microscopy (FE-SEM) and transmission electron microscopy (TEM). A low-magnification image, shown in Figure 2a, demonstrates that the product exhibits novel flowerlike shapes. A magnified image of an individual crystallite indicated that the flower comprised dozens of swordlike petals radiating from the center, which can be seen in Figure 2b. The petals with sharp ends and protruding surface ridges have sizes in the range of 30–80 nm in diameter, 20–50 nm in thickness, and 0.5–2.0 μm in length. Sonication for 10 min did not break this nanostructure into discrete particles, indicating that the nanoflowers were actually integrated, and were not only aggregations of spherical and swordlike particles. TEM images of the nanoflowers with petals assembled at the center, agreeing well with the FE-SEM observations, can be seen in Figure 2c. Besides the flowerlike nanostructures, it was noted that a small fraction of hexagonal flakes (about 1%, as arrowed in Figure 2a) emerged in the final product. Shown in Figure 2d is a TEM image of two overlapping flakes with a side length of about 100 nm. The corresponding selected area electron diffraction (SAED) pattern indicated that they are also due to fcc nickel.

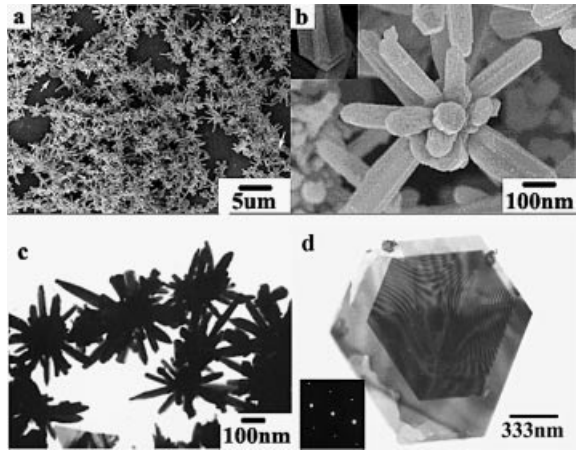

Figure 2. SEM images of as-prepared samples: (a) a low-magnification SEM image; (b) a high-magnification SEM image of an individual flower (the inset is a typical petal); TEM images of the sample: (c) several typical nickel flowers; (d) two overlapping hexagonal flakes of fcc Ni.

More details of the flowerlike structure were investigated by high resolution transmission electron microscopy (HRTEM) and SAED. A typical sharp-ended petal (Figure 3a) with a diameter of about 20 nm was chosen as the object of investigation. The HRTEM image in Figure 3b shows three sets of lattice spacings of ≈ 0.20, 0.18, and 0.12 nm that are in accordance with the separation between the (111), (200), and (220) planes of fcc Ni, respectively. From the HRTEM image, the growth direction of the petal could be indexed as along [01$\bar{1}$]. The corresponding ED pattern in Figure 3c was recorded with the electron beam along the [011] zone axis, revealing the single crystalline nature of the petal. It was noted that in the SAED pattern additional diffraction spots along the directions of [111] and [200] appeared, which implied the presence of five superlattices in both directions.

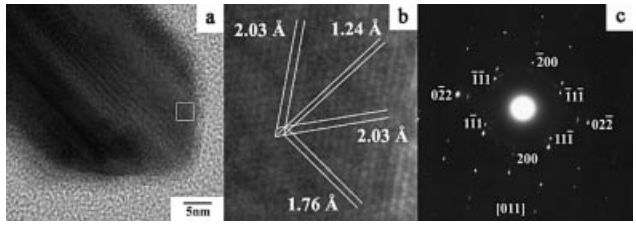

Figure 3. (a) TEM image of the tip of a typical petal. (b) HRTEM image taken from the petal. (c) The corresponding SAED pattern, taken from the [011] zone axis. The additional diffraction spots along [111] and [200] implied the presence of five superlattices of nickel in these two directions.

To probe into the growth process of the nanoflowers, we studied the shape evolution of the product over time by FE-SEM. Figure 4 shows the images of three samples hydrothermally treated for 3 h, 7 h, and 11 h, respectively (Figure 4a, b, and c). It was shown that spherical nickel particles with diameters of about 100 nm emerged as the initial product after the mixture was heated at 120 °C for 3 h. With time, short rods grew out on these spherical particles, and some particles developed into flowery crystals. After 11 h, most of the product had evolved into flower-shaped crystallites with swordlike petals.

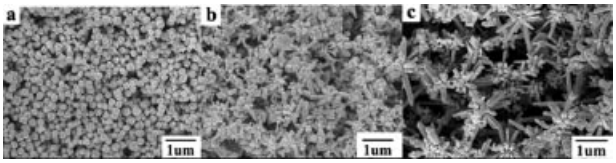

Figure 4. SEM images of the samples obtained at different reaction stages. (a) 3 h, (b) 7 h, (c) 11 h.

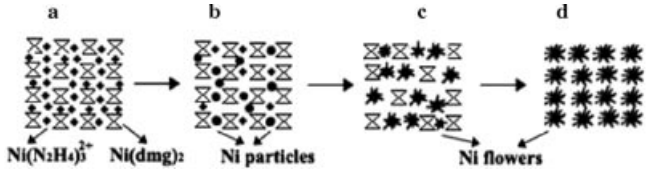
On the basis of previous studies of nickel nanocrystals from different complexes and the evolution of nickel flowers described above, the possible mechanism of formation of the nickel nanoflowers was detailed. It is known that Ni^{2+} ions can react with dimethylglyoxime (dmgH) and hydrazine (N_2H_4) in aqueous solution to form the complexes of $Ni(dmg)_2$ and $Ni(N_2H_4)_3^{2+}$, respectively. In basic solution, the $Ni(N_2H_4)_3^{2+}$ (with an instability constant of 4.5×10^{-8}) can react with OH^- in the following manner:

$$2\ Ni(N_2H_4)_3^{2+} + 4\ OH^- \rightarrow 2\ Ni + N_2 + 4\ H_2O + 5\ N_2H_4$$

When the pH of the solution was above 12 and the temperature was higher than 85 °C, the reaction proceeded very fast and produced spherical particles.[8] Because of its higher stability (with an instability constant of 4×10^{-24}) and special planar square structure, $Ni(dmg)_2$ reacted with hydrazine at a relatively slow rate and yielded nickel nanocrystals with a hexagonal flakelike shape.[9,7f] In our system, about 60 mol-% Ni^{2+} ions were coordinated by dmgH and the rest yielded $Ni(N_2H_4)_3^{2+}$. These two complexes coexisted in one system and comprised the nickel source. However, because of their different stability and structure, they were reduced at different reaction stages and resulted in differently shaped particles. $Ni(N_2H_4)_3^{2+}$ was reduced first and yielded spherical particles, which were dispersed in the system. As the reaction proceeded, $Ni(dmg)_2$ was attacked, and the newly formed nickel atoms tended to spontaneously transfer onto the surfaces of the existing particles which served as seed sites for further growth. Because of the higher stability of $Ni(dmg)_2$, the reaction rate at this stage slowed down, and the concentration of nickel atoms was not enough for the former spherical particles to grow from the circumference. This would lead to undersaturation around the existing particles, and the continuous addition of nickel atoms to the as-formed particle surface would preferentially occur at the active sites of the circumferential edges which had relatively higher free energies than other sites on the surface. As a result, a flowerlike structure was formed because of the lack of mass transport of nickel atoms to the seed particles for their further growth.[10] The reduced particles grew around each seed particle until all the $Ni(dmg)_2$ was reduced, eventually resulting in radially oriented petals on the surfaces. It is worth noting that the growth of nickel nanocrystals from $Ni(dmg)_2$ proceeded in a different manner relative to that from $Ni(N_2H_4)_3^{2+}$. As a special planar complex, $Ni(dmg)_2$ imposes obvious confinement on the growth of the resultant particles, orienting them along a certain direction.[7f] Therefore, anisotropic petals with swordlike shapes were produced. A schematic pattern of the formation process is shown in Scheme 1. However, it is interesting that the petals did not grow into hexagonal flakes as before, but mainly into swordlike rods, which may be attributed to the effect of the spherical nanocrystals formed at the initial stage. Since the seed particles greatly affected the shape of the crystals, the nickel nanocrystals grown in the presence of spherical particles may develop into a different shape.[11] In fact, if the spherical nanoparticles were prepared first and then dispersed into the system with $Ni(dmg)_2$ and hydrazine, a similar flowerlike nanostructure (as seen in Figure 5c) could also be pro-



Scheme 1. Schematic illustration of the formation process of the nickel nanoflowers. (a) mixture of $Ni(dmg)_2$ and $Ni(N_2H_4)_3^{2+}$ complexes in the system. (b) spherical nickel nanoparticles were formed which came from the reduction of $Ni(N_2H_4)_3^{2+}$ (c) part of the spherical nickel particles had evolved into small flowers with the reduction of $Ni(dmg)_2$. (d) nickel nanoflowers emerged as the final product.

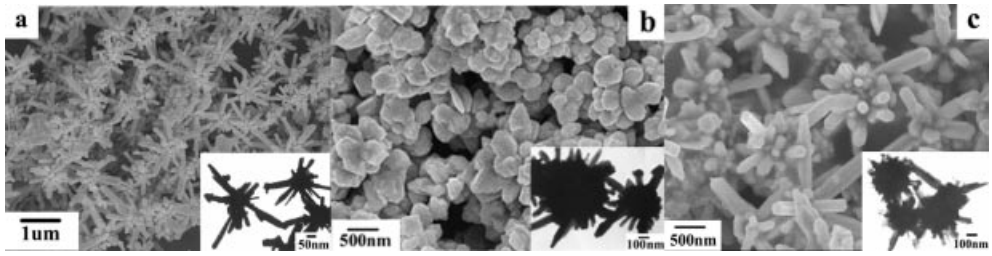


Figure 5. SEM and TEM images of the samples from the system with different molar ratios (ω) of $Ni(N_2H_4)_3^{2+}$ to $Ni(dmg)_2$ (a) ω = 20:80 (b) ω = 80:20, (c) TEM image of the sample in which the spherical particles were added externally to the system.

duced, which supported the two-step formation process proposed above.

Following the formation of the nickel flowers, it was rationally proposed that the size of the flower centers and petals could be adjusted by changing the molar ratio (ω) of $Ni(N_2H_4)_3^{2+}$ to $Ni(dmg)_2$, considering their different contribution to the flowerlike structure. This supposition was validated by the FE-SEM images of two samples obtained at different ω values while the other reaction conditions were kept the same. Figure 5a and b shows the images of two samples from the systems with ω values of 20:80 and 80:20, respectively. It is clear that increasing the proportion of $Ni(dmg)_2$ obviously promoted the size of petals, while a higher proportion of $Ni(N_2H_4)_3^{2+}$ led to flowers with bigger centers.

In all the samples, a small quantity of hexagonal nickel flakes appeared regardless of the reaction time and the ratio of the two Ni sources, as shown in Figure 2, Figure 4, and Figure 5. It was believed that they originated solely from the precursor of $Ni(dmg)_2$, and not through the two-step process observed above for the flowers. When $Ni(dmg)_2$ is the only source of nickel, hexagonal flakelike nickel crystals can be produced exclusively. The current system, however, became inhomogeneous because of flocculent $Ni(dmg)_2$ suspended in the solution, which caused differences in the local concentrations of the reactants. In places where the concentration of hydrazine was relatively high, part of $Ni(dmg)_2$ would be reduced simultaneously with $Ni(N_2H_4)_3^{2+}$ and directly developed into flakes. Careful observations indicated that small hexagonal flakes appeared even when the mixture was only heated for 3 h (shown in Figure 4a), which well validated our supposition.

The present synthetic route monitored crystal nucleation and growth through two matching chemical reactions in one system. For the two complexes, their different stability resulted in reduction reactions at different stages, and the different structures resulted in particles with different shapes. Cooperation of the two precursors was responsible for the formation of the unique flowerlike nanostructure. Controlled experiments show that, keeping the rest of the conditions the same, substitution of the two complexes with other pairs of Ni sources such as $Ni(NH_3)_6^{2+}$-$Ni(dmg)_2$, $Ni(N_2H_4)_3^{2+}$-$Ni(C_4H_2O_6)^{2-}$ (tartrate), $Ni(N_2H_4)_3^{2+}$-$Ni(C_9NOH_7)_2$ (nickel 8-hydroxyquinoline), or $Ni(NH_3)_6^{2+}$-$Ni(en)_3^{2+}$ (ethylenediamine) did not all result in nanoflower formation (as seen in Figure 6). This lack of nanoflower formation is possibly due to a mismatch of the stability or structure of the two starting materials, which idd not meet the conditions required for the formation of the flowers. The role of the temperature was also studied, and it was found that the flowers could be reproducibly prepared over an optimized temperature range of 100–150 °C. Temperatures above 150 °C led to spherical particles due to a faster reducing rate, while at temperatures below 100 °C, $Ni(dmg)_2$ was not completely reduced.

It is known that the magnetic properties of nanomaterials are closely related to the sample size, shape, crystallinity etc. The M–H hysteresis loop of the flowers obtained was

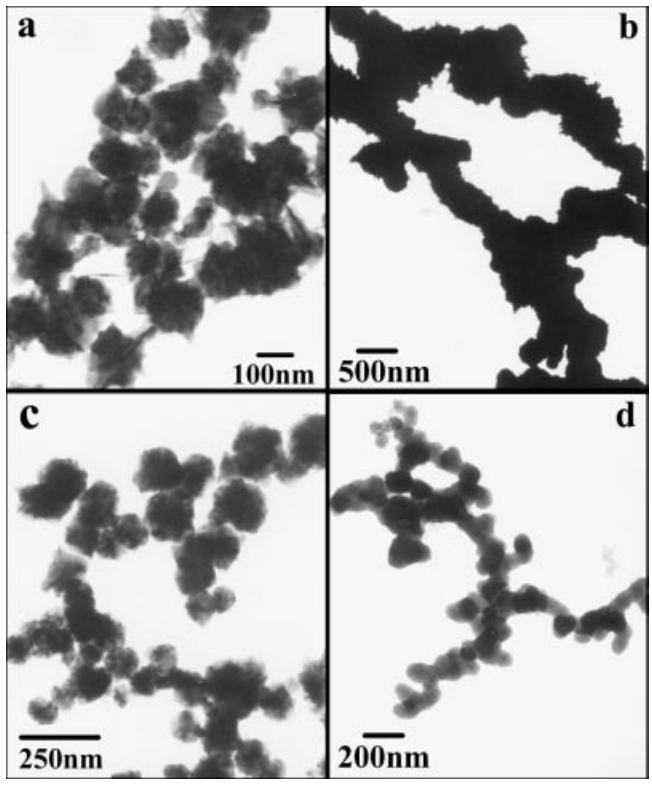

Figure 6. TEM images of the samples prepared from the other mixed nickel sources. (a) $Ni(NH_3)_6^{2+}$-$Ni(dmg)_2$; (b) $Ni(N_2H_4)_3^{2+}$-$Ni(C_4H_2O_6)^{2-}$ (tartrate); (c) $Ni(N_2H_4)_3^{2+}$- $Ni(C_9H_7NO)_2$ (nickel 8-hydroxyquinoline); (d) $Ni(NH_3)_6^{2+}$-$Ni(en)_3^{2+}$ (ethylenediamine).

measured at room temperature (Figure 7), showing coercivity (H_c), saturation magnetization (M_s), and remanent magnetization (M_r) values of approximately 173.2 Oe, 30.8 emu g^{-1}, and 9.9 emu g^{-1}, respectively. Compared with that of the bulk nickel (100 Oe, 55 emu g^{-1}, 2.7 emu g^{-1}), the H_c value was much enhanced. As ultrafine ferromagnetic particles often exhibit enhanced coercivity relative to the corresponding bulk material, the small size and shape anisotropy of the flowers may be responsible for the increased H_c value.[12] However, it was noted that this value was much lower than that of the 1D nanorods (332 Oe) or nanobelts (640 Oe), which was possibly attributed to the special 3D

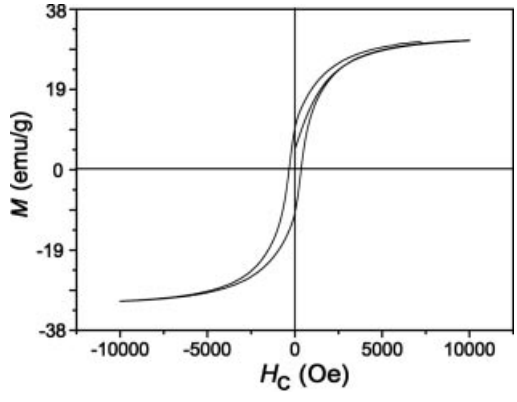

Figure 7. Magnetic hysteresis loop of as-prepared nickel nanoflowers measured at room temperature.

flowerlike structure. Because of the radial orientation of the petals, it was difficult for all of them to be aligned simultaneously along the direction of the external magnetic field compared with the 1D nanomaterials. Therefore, a relatively low H_c value was observed.[13,7e] As for the decrease in M_s, it might likewise be due to the decrease in particle size accompanied by an increased surface area, together with the magnetic interaction between the petals, which reduced the total magnetic moment at a given field.[14]

Conclusions

Flower-shaped nickel nanocrystals were successfully prepared by reduction of the mixed complexes of $Ni(N_2H_4)_3^{2+}$ and $Ni(dmg)_2$ in alkaline solution with hydrazine hydrate. Spherical nickel nanocrystals formed first from $Ni(N_2H_4)_3^{2+}$ and served as the nucleation sites for the growth of the swordlike petals, which originated from the reduction of $Ni(dmg)_2$. The different stability and structure of the two complexes played an important role in the formation of the distinct nickel nanoflowers. The size of the flower centers and petals could be adjusted by changing the molar ratio of the two complexes. Due to their unique flowery shapes, these crystals exhibited an enhanced coercivity and a decreased M_s value as compared with that of bulk nickel. The present work realized the control of the crystal shape through rationally matching different chemical reactions to adjust the crystal nucleation and growth processes. Such a novel and facile strategy is being further explored for the preparation of other materials under controlled conditions.

Experimental Section

X-ray diffraction (XRD) patterns of the samples were recorded with a Philips X′pert diffractometer with Cu-K_α radiation (λ = 0.15418 nm). Field emission scanning electron microscopy (FE-SEM) images were recorded with a JEOL JSM-6300F SEM. Transmission electron microscopy (TEM) images were collected with a Hitachi, H-800 electron microscope with an accelerating voltage of 200 kV. High-resolution transmission electron microscopy (HRTEM) images and the selected area electron diffraction (SAED) patterns were recorded with a JEOL-2010 TEM at an acceleration voltage of 200 kV. M–H hysteresis loops were recorded with a vibrating sample magnetometer (BHV-55) at an applied field of 10^4 Oe and a magnetization scale of 2.5 emu on a 0.0352-g sample sealed in a 6.6×10^{-2} mL vessel.

Nickel chloride ($NiCl_2 \cdot 6H_2O$), dimethylglyoxime (dmgH), sodium hydroxide (NaOH) were all of analytical purity. In a typical experiment, $NiCl_2 \cdot 6H_2O$ (0.166 g) was dissolved in distilled water (25 mL) to give a green transparent solution. Then an ethanol solution (13 mL) containing 1 wt.-% dmgH was added dropwise into the solution. Red flocculates emerged, indicating the formation of $Ni(dmg)_2$. Subsequently, $N_2H_4 \cdot H_2O$ (2.0 mL, 80 wt.-%) was added under continuous stirring. The solution pH was adjusted to above 12 using sodium alkali. The mixture was stirred for 30 min and transferred into a Teflon-lined autoclave with a capacity of 50 mL. The autoclave was sealed, heated at 110 °C for 12 h, and then cooled naturally to room temperature. The resulting black powders were collected and washed, and finally dried in vacuum at 60 °C for 4 h.

Synthesis, Characterization, and Reactivity of Neutral and Cationic Pd–C,N,N Pincer Complexes

Claudio Bianchini,[a] Géraldine Lenoble,[a] Werner Oberhauser,*[a] Sébastien Parisel,[a] and Fabrizio Zanobini[a]

Keywords: Pd pincer / NMR spectroscopy / IR spectroscopy / Secondary phosphanes / Suzuki reaction

The *ortho*-palladation of the iminophosphane ligand 6-phenyl-2-[(2,6-diisopropylphenyl)imino]pyridine (**HL**) with $Pd(OAc)_2$ and $PdCl_2(PhCN)_2$ in benzene yields the neutral Pd–C,N,N pincer complexes $Pd(OAc)(\kappa^3$-C,N,N-L) (**1**) and $PdCl(\kappa^3$-C,N,N-L) (**2**), respectively. In the presence of Na-BAr'_4 [Ar′ = 3,5-$(CF_3)_2C_6H_3$], **2** reacts in CH_2Cl_2 with MeCN, PPh_3, or PH[*o*-$MeO(C_6H_4)$]$_2$ to give the cationic palladium(II) pincer complexes $[Pd(CH_3CN)(\kappa^3$-C,N,N-L)]BAr'_4 (**3**), $[Pd(PPh_3)(\kappa^3$-C,N,N-L)]BAr'_4 (**4**) and {Pd[PH(*o*-$MeOC_6H_4)_2$]-(κ^3-C,N,N-L)}BAr'_4 (**5**), respectively. Complexes **1**–**5** have been characterized by multinuclear NMR and IR spectroscopy. The solid-state structures of **1** and **2** have been determined by single-crystal X-ray diffraction techniques. Both the neutral compounds **1** and **2** and the cationic derivatives **3**, **4**, and **5** were tested as catalyst precursors for the Suzuki cross-coupling of 4-bromo- and 4-chloroacetophenone with phenylboronic acid.

Introduction

Palladacycles constitute a numerous and thoroughly investigated class of organometallics commonly stabilized by four-electron (bidentate) or six-electron (tridentate) donor ligands.[1] The synthesis of palladacycles is relatively facile and the modulation of their electronic and steric properties can be achieved by varying (i) the size of the metallacyclic ring, (ii) the nature of the metallated carbon atom (aliphatic, aromatic, vinylic), (iii) the type of donor atoms (N, P, S, O) in the supporting ligand, and (iv) the nature of the co-ligands. Proper combinations of these factors determine whether dinuclear, mononuclear, neutral, or cationic compounds are formed.

Herrmann's discovery in 1995 that palladacycles can be effective catalysts for Heck coupling reactions of aryl halides has stimulated much research aimed at using these organometallics in C–C bond-forming processes.[2] The most important applications reported so far include Heck coupling, Suzuki and Stille cross-couplings, and Sonogashira reactions.[1a] Some of the most active palladacycle catalysts for Suzuki coupling reactions are reported in Scheme 1.

The C,N-palladacycles **g** and **h** reported by Milstein[3a] and Nájera,[3b] respectively, are the only really efficient phosphane-free catalysts for the Suzuki reaction of bromoarenes and chloroarenes, while the C,N- and C,O-palladacycles **b**–**f** in conjunction with either secondary bulky phosphanes[4] or N-heterocyclic carbenes[5] are very active catalytic systems for the Suzuki reaction of chloroarenes. The phosphinite P,C,P pincer complex **i** described by Bedford exhibits a good activity for bromoarenes and constitutes a successful example of the application of a terdentate palladium(II) pincer complex in a Suzuki reaction.[6] Terdentate Pd–C,N,N pincer complexes have also been used to catalyze Heck and Heck-type reactions.[7]

The ligands that have been employed so far for the synthesis of Pd–C,N,N pincer complexes are shown in Scheme 2.[8] A common structural motif to most ligands is a planar assembly of nitrogen donor atoms from either pyridine rings or imine groups, yet the combination of both moieties in the same molecule has never been tested in palladium *ortho*-metallation.

Aimed at filling this gap, we decided to study the coordination chemistry of the (imino)pyridine ligand 6-phenyl-2-[(2,6-diisopropylphenyl)imino]pyridine (**HL**) (Scheme 3) that has been successfully employed to oligomerize ethylene in conjunction with $CoCl_2$ and MAO.[9] As a result, both neutral and cationic Pd^{II}–C,N,N pincer complexes have been obtained and fully characterized. A preliminary study of the performance of these complexes in Suzuki cross-coupling reactions of 4-bromo- and 4-chloroacetophenone with phenylboronic acid has been carried out and is herein reported.

Results and Discussion

The reaction of **HL** with $Pd(OAc)_2$ and $PdCl_2(PhCN)_2$ in refluxing benzene yields the yellow, air-stable, neutral terdentate Pd–C,N,N pincer complexes Pd(OAc)L (**1**) and PdClL (**2**) in fairly good yields (57 and 81%), respectively. Complex **2** was transformed into the monocationic Pd–C,N,N pincer compounds **3**, **4**, and **5** by scavenging the chloride ion with $NaBAr'_4$ in the presence of MeCN, PPh_3, or $PH(o\text{-}MeOC_6H_4)_2$. The synthesis of the latter compounds was readily achieved by dissolving **2** in oxygen-free dichloromethane and adding acetonitrile, PPh_3, or the new secondary monophosphane $PH(o\text{-}MeOC_6H_4)_2$ (Scheme 3).

The cationic complexes were isolated in good yields, from 60–70%, as yellow, air- and moisture-stable solids. All our attempts to isolate **3**, **4**, and **5** with chloride as the counterion were unsuccessful.

The solid-state structures of **1** and **2** have been determined by a single-crystal X-ray diffraction analysis. Crystallographic data as well as selected bond lengths and angles of both compounds are reported in Tables 1 and 2, respectively, while ORTEP illustrations are presented in Figure 1.

The asymmetric unit of **1** contains one molecule of the neutral pincer complex, while that of **2** contains one molecule of **2** together with one molecule of CH_2Cl_2 and half a molecule of toluene located on an inversion center. Both complexes exhibit a distorted square-planar coordination geometry. The metal center in **1** deviates by 0.004(6) Å in the direction of C(20) from the plane defined by the atoms C(1), N(1), and N(2). From the analogous plane, **2** deviates by 0.016(6) Å in the direction of C(23). In both structures, the Pd atom is coordinated by nitrogen atoms from pyridine and imine groups and by one carbon atom, C(1), from the 6-phenyl ring. The square-planar geometry is completed by an oxygen atom, O(1) from an acetate ligand in **1**, and by a chloride atom in **2**. The slightly longer Pd(1)–N(2) bond in **1** as compared to **2** is probably due to a significant steric interaction between the acetate unit and an isopropyl group of the ligand [shortest O···H contact distance of 2.844 Å between O(2) and H(21B)]. A longer $Pd–N_{imine}$ distance in **1** was also inferred from the IR spectrum which shows a less pronounced red shift of the C=N band in **1** (21 cm^{-1})

Table 2. Selected bond lengths [Å] and angles [°] for compounds **1** and **2**·CH_2Cl_2·0.5 C_7H_8.

	1	**2**·CH_2Cl_2·0.5 C_7H_8
Pd(1)–N(1)	1.954(6)	1.955(5)
Pd(1)–N(2)	2.184(6)	2.156(6)
Pd(1)–C(1)	1.957(8)	1.970(7)
Pd(1)–O(1)	2.051(6)	
Pd(1)–Cl(1)		2.295(2)
N(2)–C(12)	1.262(10)	1.286(9)
N(1)–Pd(1)–N(2)	77.7(3)	77.4(2)
N(1)–Pd(1)–C(1)	81.8(3)	81.6(3)
C(1)–Pd(1)–O(1)	98.7(3)	
N(1)–Pd(1)–O(1)	171.5(3)	
C(1)–Pd(1)–Cl(1)		97.6(2)
N(1)–Pd(1)–Cl(1)		177.9(2)

as compared to **2** (30 cm^{-1}). The Pd(1)–C(1) bond lengths of either structure [1.957(8) Å in **1** and 1.970(7) Å in **2**] match well the values reported for other pincer Pd^{II} systems.[8a,8c,8d,8f,8h,8i] The two bite angles [N(1)–Pd(1)–C(1): 81.8(3)° in **1**; 81.6(3)° in **2**; N(1)–Pd(1)–N(2): 77.7(3)° in **1**; 77.4(2)° in **2**] are comparable in either structure, while the coordination angle N(1)–Pd(1)–O(1) of 171.5(3)° in **1** and the coordination angle N(1)–Pd(1)–Cl(1) of 177.9(2)° in **2** are significantly different. Indeed, **1** shows a deviation of the bonded oxygen atom O(1) by 0.292(17) Å from the plane defined by C(1), N(1), and N(2) in the direction of C(23), while **2** exhibits a deviation of Cl(1) by 0.111(16) Å from the analogous plane in the direction of C(23). In both crystal structures, the 2,6-(diisopropyl)phenyl moiety is, as

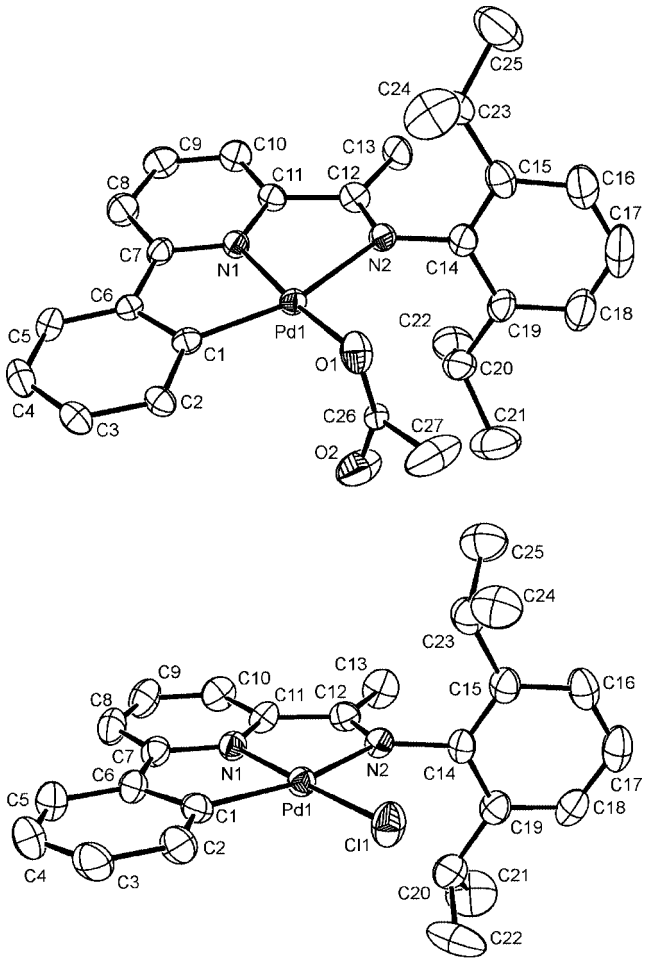

Figure 1. ORTEP representation (30% probability displacement ellipsoids) of compounds **1** (top) and **2** (bottom). Hydrogen atoms as well as solvent molecules are omitted for clarity.

expected, tilted with respect to the coordination plane, showing a dihedral angle of 76.1(5)° and 85.8(4)° in **1** and **2**, respectively, due to the pronounced steric repulsion between the coordinating acetate and an isopropyl group from the ligand.

Compounds **1**–**5** have been characterized in solution by multinuclear 1D and homo- and heteronuclear correlated 2D NMR spectroscopy.[10a] $^{13}C\{^1H\}$ NMR spectroscopy has proved to be a useful technique to elucidate the solution structure of all compounds, especially to assess the presence of a Pd–C bond involving the phenyl ring attached at the 6-position of the pyridine unit.[10b–10e] Significant ^{13}C NMR chemical shifts, namely those pertaining to the C-1, C-2,

and C-4 carbon atoms from the phenyl ring and to the imine carbon atom C-12 are reported in Table 3, which also provides ^{13}C NMR spectroscopic data for the free ligand. In line with the literature, the signals of C-1 and C-2 are shifted down-field as compared to the free ligand, while the signal of C-4 is shifted up-field.[10e] The ^2J(C,P) coupling constants of 4.9 Hz in **4** and 5.4 Hz in **5** provide further evidence for *ortho*-palladation involving the 6-phenyl ring. The coordination of the imine nitrogen atom to the Pd^{II} center can be safely assessed on the basis of the down-field shift of the imine carbon signal of C-12.

The ^{1}H NMR spectra of **1**–**5** are fully consistent with *ortho*-palladation of the 6-phenyl ring (Table 4).

Of particular relevance to confirm the occurrence of *ortho*-metallation are the multiplicities of the resonances of the 6-phenyl ring. Indeed, the signals of 2-H and 5-H appear as a doublet of doublet and 3-H and 4-H show a triplet of doublet, while the free ligand exhibits a doublet for the *ortho* protons 1-H and 5-H, triplets for 2-H and 4-H and a triplet of triplet for the *para* proton 3-H. The small $^4J_{P,H}$ coupling constant of 5.3 Hz observed for 2-H in the ^{1}H NMR spectra of compounds **4** and **5** is consistent with the coordination of PPh_3 and HP[*o*-MeO(C_6H_4)]$_2$. The coordination of the imine nitrogen atom to the palladium atom is confirmed by an up-field shift of the methylimine resonance (13-H), as compared to the free ligand.

Compounds **1**–**5** have been tested as catalyst precursors for the Suzuki cross-coupling reaction of 4-bromo- and 4-chloroacetophenone with phenylboronic acid in the presence of Cs_2CO_3 as the basic co-reagent in 1,4-dioxane at 100 °C (Scheme 4). This catalytic protocol is rather common for Suzuki reactions leading to selective production of the unsymmetrically substituted biaryl.[1a,1b] Selected results are given in Table 5.

X: Br, Cl

Scheme 4.

All catalytic coupling reactions were carried out under an inert gas in freshly distilled 1,4-dioxane in order to avoid the risk of imine hydrolysis, which may be responsible for the low catalytic activity observed in a water/dioxane mixture (Entry 6). Examination of withdrawn samples showed the formation of the biaryl product after only 5 min. Unlike the reaction catalyzed by $Pd(OAc)_2$, no Pd metal precipitation was observed using **1**–**5** as the catalyst precursors. In situ NMR experiments showed the absence of free phosphane ligands during the reaction catalyzed by **4** and **5**.

In line with the results reported in the literature, 4-bromoacetophenone is much more reactive than the analogous chloro derivative, due to the lower bond strength of Ar–Br as compared to Ar–Cl.[11] The coupling of 4-bromoacetophenone with phenylboronic acid is catalyzed by both the phosphane-free precursors **1**, **2**, and **3** and the phosphane-modified precursors **4** and **5**. However, the latter form much

more active catalysts, which has been previously observed and attributed to the formation of coordinatively unsaturated (phosphane)Pd^0 catalysts.[1b] As a general trend, the cationic precursors originate more efficient catalysts.

In the Suzuki cross-coupling of 4-chloroacetophenone only the monophosphane-modified precursors **4** and **5** have shown a significant activity.[12] Interestingly, the catalyst modified with the secondary phosphane $PH(o\text{-}MeOC_6H_4)_2$ is the most active with both 4-bromo- and 4-chloroacetophenone, which is consistent with Indolese's finding that bulky secondary monophosphanes in conjunction with Pd–C,N or Pd–C,O palladacycles provide powerful systems for Suzuki and Heck reactions.[4] Indeed, most of the really efficient catalytic systems for Suzuki cross-coupling contain bulky monophosphanes,[12] hemilable P–O[13] and P–N ligands,[14] and 1,3-disubstituted imidazol-2-ylidenes.[15]

In the case of **5**, an in situ NMR study under catalytic conditions has shown the occurrence of phosphane deprotonation to give various unidentified phosphido–palladium species, which might be responsible for the high catalytic activity.

Conclusions

New Pd^{II}–C,N,N pincer complexes have been synthesized and fully characterized in both the solid state and solution. As a probe reaction to test their potential in homogeneous catalysis, these complexes have been employed as catalyst precursors for cross-coupling reactions of 4-bromo- and 4-chloroacetophenone with phenylboronic acid to give 4-acetylbiphenyl. Only the phosphane-modified complexes have shown significant activity. This activity, however, is far lower than the most active catalysts reported in the literature.

Experimental Section

General: All manipulations were carried out under nitrogen using Schlenk-type techniques. All the solid compounds were collected on sintered-glass frits and washed with appropriate solvents before being dried in a stream of nitrogen. $PdCl_2(C_6H_5CN)_2$[16] and $NaB[C_6H_3(CF_3)_2]_4$ ($NaBAr'_4$)[17] were prepared according to literature methods. The ligands (2,6-diisopropylphenyl)[1-(6-phenylpyridin-2-yl)ethylidene]amine (**HL**) and 1-(6-phenylpyridin-2-yl)ethanone were prepared as reported in the literature.[9] The solvents were distilled under nitrogen from Na (*n*-pentane, diethyl ether, benzene) or CaH_2 (CH_2Cl_2). All the other reagents and solvents were used as purchased from commercial suppliers. Deuterated solvents for NMR measurements were dried with molecular sieves. Elemental analyses were performed with a Carlo Erba Model 1106 elemental analyzer. Infrared spectra were recorded with an FT-IR Spectrum GX instrument. ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded at 200.13, 50.32, and 81.01 MHz, respectively, with a Bruker ACP-200 spectrometer or at 400.13, 100.62, and 161.98 MHz, respectively, with a Bruker Avance DRX-400 spectrometer. Chemical shifts are reported in ppm (δ) with reference to either TMS as an internal standard [^1H and $^{13}C\{^1H\}$ NMR spectra] or 85% H_3PO_4 as an external standard [$^{31}P\{^1H\}$ NMR spectra]. The assignment of ^1H and ^{13}C signals was based on 1D and 2D NMR experiments, such as ^1H COSY, ^1H NOESY, and ^1H-^{13}C correlations using degassed nonspinning samples. All the 2D NMR spectra were recorded with a Bruker Avance DRX-400 instrument using pulse sequences suitable for phase-sensitive representations using TPPI. The ^1H-^{13}C correlations were recorded using an HMQC sequence with decoupling during acquisition. GC analyses were performed with a Shimadzu GC-14A gas chromatograph equipped with a flame ionization detector and a 30 m (0.25 mm i.d., 0.25 μm film thickness) SPB-1 Supelco fused silica capillary column. GC-MS analyses were performed with a Shimadzu QP 5000 apparatus equipped with a column identical to that used for GC analysis.

Catalytic Reactions: 1,4-Dioxane (15 mL) was degassed in a round-bottomed flask by means of vacuum/nitrogen cycles. To this solvent were added 4-bromoacetophenone or 4-chloroacetophenone (2×10^{-4} mol), phenylboronic acid (36 mg, 3×10^{-4} mol), $CsCO_3$ (115 mg, 6×10^{-4} mol) and the appropriate precatalyst (2×10^{-6} mol) at room temperature under nitrogen. The resulting suspension was heated under nitrogen to 100 °C with stirring to give a clear solution. Heating was continued for the desired time. Then, the solution was cooled to room temperature and ethyl acetate (15 mL) was added. The solid products were removed from the solution by filtration and the organic layer was washed with water (three 30 mL portions) to remove $CsCO_3$. The aqueous layer was extracted three times with ethyl acetate. The combined organic layers were washed with brine, dried with $MgSO_4$ and concentrated to yield a pale yellow solid. The yield of the product was determined by ^1H NMR in $CDCl_3$.

Syntheses

$PH(o\text{-}CH_3OC_6H_4)_2$: The bis(*o*-methoxyphenyl)phosphane oxide $HPO(o\text{-}CH_3OC_6H_4)_2$ was synthesized as described in the literature.[18] The subsequent reduction of the phosphane oxide was performed applying a protocol similar to that published by Vineyard.[19] $HSiCl_3$ (12.1 mL, 120.0 mmol) was added to a solution of bis(*o*-methoxyphenyl)phosphane oxide (10.48 g, 40.0 mmol) and triethylamine (16.7 mL, 120.0 mmol) in acetonitrile (250 mL) at room temperature. The reaction mixture was refluxed for 8 h. Afterwards, the solution was cooled to 0 °C and a solution of KOH (40 g) in water (150 mL) was slowly added to the reaction mixture. An off-white solid precipitated that was, however, dissolved at the end of the addition to form a clear two-phase system. The organic phase was separated and the solvent was removed under reduced pressure. The crude product was washed with degassed ethanol (30 mL) and the product was filtered off and dried in a stream of nitrogen. Yield: 7.19 g (73%). $C_{14}H_{14}O_2P$ (245.1): calcd. C 68.60, H 5.71; found C 68.20; H 5.60. ^1H NMR (200.13 MHz, $CDCl_3$, 294 K): δ = 3.78 (s, 6 H, OCH_3), 5.23 (d, $^1J_{H,P}$ = 229 Hz, 1 H, PH), 6.80–7.40 (m, 8 H, C_6H_4) ppm. $^{31}P\{^1H\}$ NMR (81.01 MHz, $CDCl_3$, 294 K): δ = –71.70 (s) ppm.

[6-C_6H_4-py-2-C(Me)=N(2,6-iPr$_2C_6H_3$)]PdOAc (1): The ligand **HL** (300 mg, 0.84 mmol) and $Pd(OAc)_2$ (190 mg, 0.84 mmol) were dissolved in degassed benzene (30 mL). The resultant red solution was heated at 60 °C for 16 h. Afterwards, this solution was filtered through Celite and concentrated to 2 mL. To this solution diethyl ether (15 mL) was added to precipitate a yellow-green compound, which was filtered off and dried in a stream of nitrogen. Yield: 250 mg (57%). $C_{27}H_{30}N_2O_2Pd$ (520.69): calcd. C 62.28, H 5.76, N 5.38; found C 62.10, H 5.55, N 5.10. ^1H NMR (400.13 MHz, $CDCl_3$, 294 K): δ = 1.15 [d, $^3J_{H,H}$ = 6.8 Hz, 6 H, $CH(CH_3)_2$], 1.40 [d, $^3J_{H,H}$ = 6.8 Hz, 6 H, $CH(CH_3)_2$], 1.75 [s, 3 H, CH_3CO_2], 2.19 [s, 3 H, 13-H], 3.17 [sept, $^3J_{H,H}$ = 6.8 Hz, 2 H, $CH(CH_3)_2$], 7.02 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1.4 Hz, 1 H, 4-H), 7.08 (td, $^3J_{H,H}$ = 7.4,

X-ray Crystallographic Analysis of 1 and 2: Single crystals of both compounds were obtained by slow diffusion of toluene at room temperature into a saturated CH_2Cl_2 solution of **1** and **2**, respectively. Diffraction data were collected at room temperature with an Enraf Nonius CAD4 automatic diffractometer with Mo-K_α radiation (graphite monochromator). Unit cell parameters of both structures were determined from a least-squares refinement of the setting angles of 25 carefully centered reflections. Crystal data and data collection details are given in Table 1. Lorentz polarization and absorption corrections were applied.[20a] Atomic scattering factors were taken from ref.[20b] and an anomalous dispersion correction, with a real and imaginary part, was applied.[20c] The structures were solved by direct methods and refined by full-matrix F^2 refinement. While in **1** anisotropic thermal parameters were assigned to all non-hydrogen atoms, in **2** only the disordered toluene molecule was treated isotropically. In both structures, the hydrogen atoms were introduced in their calculated positions, with thermal parameters 20% larger than those of the respective carbon atoms. All the calculations were performed with a PC using the WINGX package[20d] with SIR-97,[20e] SHELX-97,[20f] and ORTEP-3 programs.[20g] CCDC-271410 (**1**), and -271409 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis, Characterization, and Catalytic Properties of SiPW-X Mesoporous Silica with Heteropolyacid Encapsulated into Their Framework

Chunfeng Shi,[a,b] Runwei Wang,[a] Guangshan Zhu,[a] Shilun Qiu,*[a] and Jun Long*[b]

Keywords: Heteropolyacids / Mesoporous materials / Encapsulation / Cracking / Esterification / Bulky molecule reactions

A series of SiPW-X mesoporous silica with Keggin-type heteropolyacids (HPAs) encapsulated into their framework have been synthesized under strong acidic conditions. During hydrolysis of tetraethyl orthosilicate (TEOS), Na_2HPO_4 (P source) and Na_2WO_4 (W Source) are added into the initial sol-gel system to form Keggin type HPAs. The final products have been intensively characterized by various techniques, such as XRD, TEM, N_2 adsorption isotherm analysis, and by IR, UV/Visible, and ^{31}P Magic Angle Spinning (MAS) NMR spectroscopy. Characterization results suggest that samples with an HPA weight percent of 13.3–20.7 % show very ordered hexagonal mesostructures. In addition, HPAs incorporated in the mesosilica are insoluble during catalysis. Results of catalytic tests show that SiPW-X materials have catalytic activities that are comparable to bulk HPA in catalytic tests implementing chemical reactions of both small (cumene cracking and esterification of ethanol with acetic acid) and bulky (1,3,5-triisopropylbenzene cracking and esterification of benzoic acid with *tert*-butanol) molecules. It can be readily separated from the reaction system for reuse, which suggests the potential industrial application.

Introduction

The discovery of mesoporous materials (such as M41S, MSU and the SBA series) in the last decade has attracted much attention because of their potential uses as catalysts or catalyst supports in industrial applications. .[1–5] Incorporation of heteroatoms into mesoporous silica frameworks to form active sites in catalysis has been widely reported. For example, Al species have been introduced into the mesostructure and used as acidic catalysts in many catalytic reactions.[6–13] In addition, mesoporous silica has often been used as a solid support in catalysis because of its high surface area and relatively large pore size. Some mesoporous materials with strong acidic sites on the surface have shown relatively high activities in many catalytic reactions.[14–49]

It is well known that heteropolyacids (HPAs) with Keggin structures, especially 12-tungstophosphoric acid (HPW), have been widely applied in catalysis due to its strong acidity, facile preparation, and acceptable stability.[32–49] However, the catalytic activities of HPAs are greatly limited because of their very low specific surface areas.[16] Therefore, some researchers have carried on the investigation of HPAs supported on mesoporous materials.[14–31] For example, Corma et al. and Xia et al. have used HPAs supported on MCM-41 carriers, and these materials show high activity in isobutene alkylation and in the synthesis of MTBE.[16,17] Nevertheless, their success and widespread use is limited for two reasons. First, HPA clusters block some pores causing the surface area of the modified mesoporous materials to be reduced significantly. Second, HPAs, from modified samples, leach into polar solvents leading to a decrease in catalytic activity and making it impossible to recycle in liquid-phase reactions.[36] Some new synthetic routes and techniques for supporting HPAs on the porous materials have been reported that avoid these two problems.[37–41] Hu et al. have prepared silica-supported Keggin-type HPAs by encapsulating HPAs into a silica matrix by a sol-gel technique involving the hydrolysis of tetraethoxysilane (TEOS).[40] Recently, Nowińska et al. have reported the incorporation of HPAs into mesoporous materials by introducing the HPA into the sol-gel during the hydrolysis of TEOS in the preparation of SBA-3.[41] However, after heating to reflux in methanol, HPA is extracted and the mesostructure collapsed. The relatively low stability of the materials can be attributed to their relatively thin wall thickness.

It has been widely reported that mesoporous silica of SBA-15 has been extensively used as support and host because of its larger pore size, thicker wall and higher hydrothermal stability than MCM-41 (SBA-3).[4,5] We have introduced Na_2HPO_4 (P source) and Na_2WO_4 (W Source) into the initial sol-gel during preparation of SBA-15 and suc-

cessfully synthesized new mesoporous silica encapsulated with Keggin-type HPA. Here, we report the synthesis, characterization, and catalytic properties of SiPW-X mesosilica with Keggin-type 12-tungstophosphoric acid (HPW) encapsulated into their framework.

Results and Discussions

Spectroscopy

X-ray Diffraction

Figure 1 shows small-angle powder XRD patterns of SiPW-X samples with various HPW content. Obviously, the mesostructure ordering of the samples gradually decreases with increasing HPW content. The samples of SiPW-16 and SiPW-8 (Figure 1b and c, and Table 1) exhibit three well-resolved peaks indexed as (100), (110), and (200), which can be associated with *p6mm* hexagonal symmetry that is similar to that of pure silica SBA-15 (Figure 1a).[4,5] In fact, the ordering of the samples with high HPW content is very small. For example, sample SiPW-4 only gives one broad peak (Figure 1d) and sample SiPW-2 gives no obvious diffraction pattern (Figure 1e). These results indicate that the content of HPW in mesosilica with a highly ordered structure is 13.3–20.7 wt.-%. Additionally, the only difference in the XRD patterns of pure silica SBA-15, SiPW-8, and SiPW-16 is the intensity of the three observed diffraction peaks (Figure 1), and this suggests that the formation of HPW by the addition of Na_2HPO_4 and Na_2WO_4 into the sol-gel during the hydrolysis of TEOS does not disturb the formation of the mesoporous structure. Moreover, wide-angle powder XRD patterns recorded for modified samples (not given) do not show any obvious characteristic signals for HPW, indicating very high HPW dispersion in the mesosilica matrix.[30]

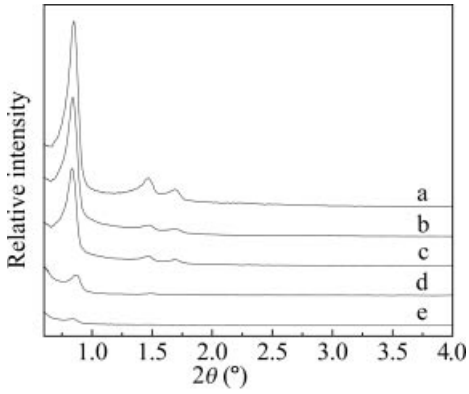

Figure 1. Small-angle XRD patterns of various samples: (a) SBA-15, (b) SiPW-16, (c) SiPW-8, (d) SiPW-4, and (e) SiPW-2.

Table 1. HPW content and parameters for the pore structure of SiPW-X, SBA-15, HPW, and HPW/SBA.

Samples	HPW content		*d* (nm)	*a* (nm)	Pore size (nm)	Wall thickness (nm)[a]	BET surface area (m^2/g)	Pore volume (cm^3/g)
	sol-gel (wt.%)	Product (wt.%)						
SiPW -4	50.0	23.2	10.2	11.8	6.8	5.0	570	0.77
SiPW -8	33.2	20.7	10.6	12.2	7.5	4.7	805	0.94
SiPW -16	20.0	13.3	10.5	12.1	7.6	4.5	828	1.03
SBA-15	0.0	0.0	10.3	11.9	7.9	4.0	860	1.15
HPW/SBA	20.0	20.0	10.2	11.8	7.8	4.0	366	0.65
HPW	100	100	-	-	-	-	7	-

[a] Pore size distributions were determined from N_2 adsorption isotherms, and the wall thickness was calculated as: thickness = *a* – pore size ($a = 2d_{(100)}/3^{1/2}$).

Transmission Electron Microscopy

TEM images of mesoporous samples with varied HPW content are shown in Figure 2. Obviously, the pores of all the samples are hexagonal analogous to those of pure silica SBA-15.[4,5] Compared with Figure 2c–f, the images shown in Figure 2a and b suggest that the ordering of the SiPW-4 sample is less than that of the SiPW-8 and SiPW-16 samples, which is in agreement with the results of XRD. Moreover, it can also be observed that there are many out-of-order components deposited in the mesoporous channels of

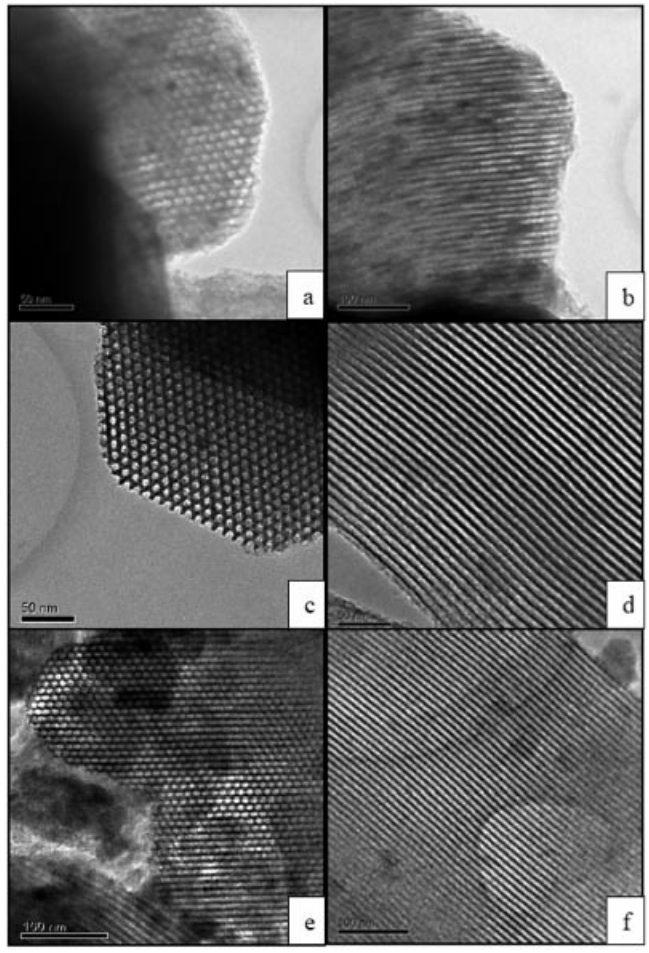

Figure 2. TEM images of various samples: (a) SiPW-4 in [100] direction, (b) SiPW-4 in [110] direction, (c) SiPW-8 in [100] direction, (d) SiPW-8 in [110] direction, (e) SiPW-16 in [100] direction, and (f) SiPW-16 in [110] direction.

the SiPW-4 sample (Figure 2a and b). The weight content of HPW in the SiPW-4 sample is a little higher (23.2%) than those of the other samples. Therefore, some HPW species cannot be incorporated into the wall of the mesoporous silica but rather be deposited in the mesoporous channels as small, silica-HPW domains.

N_2 Adsorption Isotherms

Figure 3 shows the N_2 adsorption isotherms of the SiPW-X samples with varied HPW content. The porous parameters are listed in Table 1. Obviously, SiPW-8 and SiPW-16 show a typical adsorption curve of type IV with an obvious hysteresis loop at a relative pressure of $0.6<P/P_0<0.9$ (Figure 3c and d), which is very similar to that of pure silica SBA-15.[4,5] However, increasing the content of HPW leads to a decrease in surface area and pore volume. For example, the Brunauer, Emmett and Teller (BET) surface area and pore volume of SiPW-16 were found to be 828 m^2/g and 1.03 cm^3/g, the corresponding values of SiPW-8 and SiPW-4 were 805 m^2/g and 0.94 cm^3/g, and 570 m^2/g and 0.77 cm^3/g, respectively. Additionally, there is no obvious difference in the porous parameters of pure silica SBA-15 and of the SiPW-8 and SiPW-16 samples, indicating the formation and presence of HPW in the initial gel does not disturb the formation of the mesostructure, which is in agreement with the XRD results.

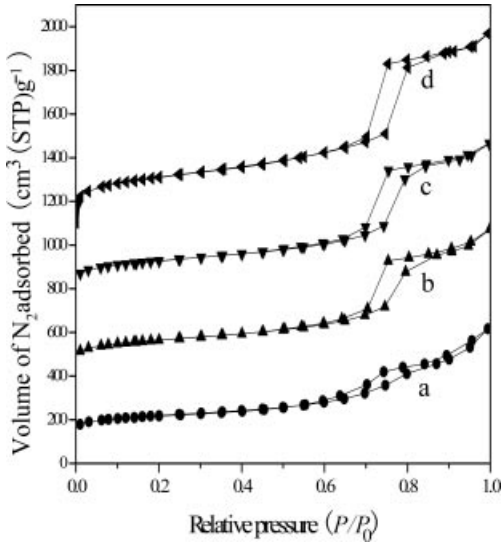

Figure 3. N_2 adsorption/desorption isotherms of various samples at STP: (a) SiPW-4, (b) SiPW-8, (c) SiPW-16, and (d) SBA-15.

IR Spectra

Infrared spectra of various samples are shown in Figure 4. It has been widely reported that HPWs with Keggin structures give several strong, typical IR bands at ca. 1080 cm^{-1} (stretching frequency of P–O in the central PO_4 tetrahedron), 983 cm^{-1} (terminal bands for W=O in the exterior WO_6 octahedron), 889 and 803 cm^{-1} (bands for the $W–O_b–W$ and $W–O_c–W$ bridge, respectively)[21,22,24] [Figure 4a]. It is well known that pure mesoporous SBA-15 silica shows framework bands at 805 cm^{-1} (symmetric stretching frequency of Si–O–Si), 960 cm^{-1} (stretching frequency of Si–O–H), 1060–1100 cm^{-1} (*anti*-symmetric stretching of Si–O–Si) [Figure 4d]. In our case, the SiPW-8 and SiPW-16 samples give bands at 1080, 963, 890, 803 cm^{-1} and one shoulder band at 982 cm^{-1} in the 600–1400 cm^{-1} region (Figure 4b and c). The band at 890 cm^{-1} and the weak shoulder band at 982 cm^{-1} can be attributed to the characteristic Keggin type HPW $W–O_b–W$ bridge and the terminal W=O, respectively,[21] the broadened bands at 1080 and 800 cm^{-1} are the characteristic bands of HPW, which overlap with the bands of mesoporous SBA-15.[22,43] These results confirm the presence of HPW encapsulated into the mesoporous silica framework.

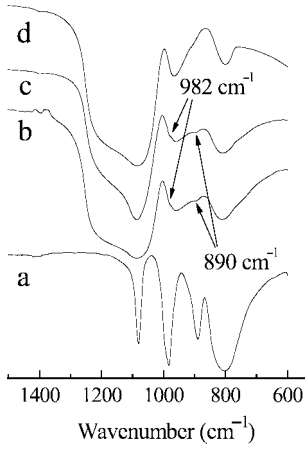

Figure 4. IR spectra of various samples: (a) HPW, (b) SiPW-8, (c) SiPW-16, and (d) SBA-15.

UV/Visible Diffuse Reflectance Spectra

Some evidence of the presence of HPW in the mesoporous silica framework is also provided by UV/Visible spectroscopy. The UV/Visible spectra of mesoporous samples with varied HPW content are shown in Figure 5. Bulk HPW shows a maximum UV absorption peak at 265 nm, which is attributed to the oxygen–tungsten charge-transfer absorption band for Keggin anions[40] (Figure 5a). Pure SBA-15 silica shows no UV absorption (Figure 5d). In our case, both SiPW-8 (Figure 5b) and SiPW-16 (Figure 5c) samples have a broad UV absorption in the range of 200–300 nm – a characteristic UV absorption peak is centered at 263–266 nm, which is similar to that of the $PW_{12}O_{40}^{3-}$ species. These results indicate that the primary Keggin structure has been introduced into the mesostructure framework and is very stable even after the surfactants are extracted and washed by deionized water; this is in agreement with the IR results.

^{31}P MAS NMR Spectra

Figure 6 shows the ^{31}P MAS NMR spectra of SiPW-8 and HPW. The spectrum for bulk HPW, consisting of a single peak at –15.3 ppm, agrees well with the literature data.[16,46] The spectrum for SiPW-8 is practically the same as that of bulk HPW with one signal at –15.3 ppm, which is attributed to homogeneously dispersed HPW clusters that

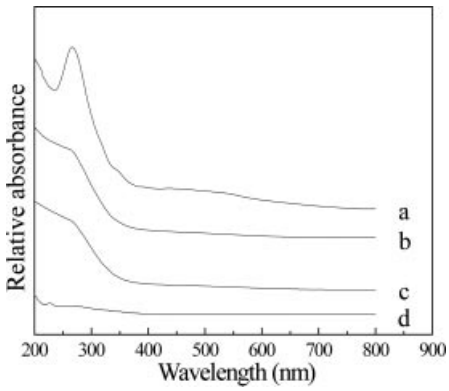

Figure 5. UV/Visible spectra of various samples: (a) HPW, (b) SiPW-8, (c) SiPW-16, and (d) SBA-15.

retain the Keggin structure; however, there is another resonance of lower intensity at –14.1 ppm. This new signal at –14.1 ppm may be induced by chemical interactions of HPW with the framework of the mesoporous material, which is constituted of a network of SiO_2.[46]

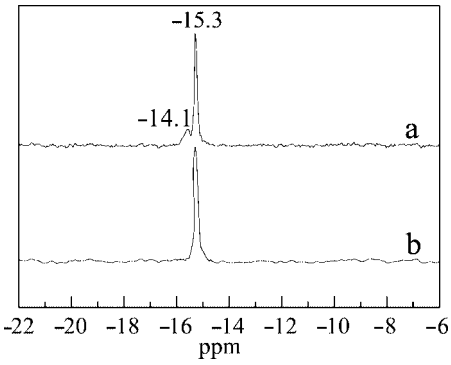

Figure 6. ^{31}P MAS NMR spectra of: (a) SiPW-8 and (b) HPW.

Catalytic Results

Cumene Cracking

The cumene cracking reaction is used to evaluate the acidity of the samples. As shown in Table 2, mesoporous pure silica (SBA-15) shows a very low catalytic activity (conversion at 1.2%) in this reaction. All SiPW-X samples show relatively high catalytic activities. The conversion of cumene is 13.7% for the reaction with the SiPW-16 sample, while a higher catalytic activity, with a conversion of 28.6%, is observed for the reaction with SiPW-8. It has been reported that HPW supported on the surface of SBA-15 by the impregnation method give cumene cracking conversions of 46.1 and 5.7%, with the weight content of HPW at 40 and 20%, respectively.[43] In our case, HPW supported on the surface of SBA-15 prepared by the same method gives 9.1% conversion with a weight content of HPW at 20%, and SiPW-8 shows much higher conversion (28.6%) with a similar HPW weight content. These results indicate that HPWs have been well encapsulated in the mesoporous framework and show good catalytic activities.

TIPB Cracking

In TIPB cracking, as shown in Table 2, pure SBA-15 silica shows low catalytic activity (3.8%) and, according to previous reports, HPW supported on the surface of MCM-41 by impregnation methods gives a conversion of 55%, with an HPW weight content of 23%.[30] In our case, SiPW-8 (20.7 wt.-%) and SiPW-16 (13.3 wt.-%) show high catalytic activities and give conversions of 70.2 and 58.5%, respectively, which are higher than those of previous reports.[30] The results suggest the potential use of these compounds as catalysts for bulky molecule catalysis.

Esterification of Acetic Acid with Ethanol and of Benzoic Acid with tert-Butanol

In the esterification of acetic acid with ethanol, the SiPW-16 and SiPW-8 samples give conversions of 17.2 and 31.5%, respectively. HPW/SBA prepared by the impregnation method shows a similar catalytic activity (32.3%). Moreover, after the catalysts were reused five times (Table 2), the SiPW-8 and SiPW-16 samples still showed catalytic activities similar to those of the fresh catalysts, while that of HPW/SBA prepared by the impregnation method decreases remarkably, which is attributed to the leaching of HPW supported on the surface of SBA-15.[36]

Table 2. Catalytic activity of SiPW-X, SBA-15, HPW, and HPW/SBA, and the element analysis of spent catalysts and liquid solution for P- and W content.

Samples	Conversion of cumene (wt. %)	Conversion of TIPB (wt. %)	Conversion 1[a] (wt. %)		Conversion 2[b] wt. %)		P content		W content	
			fresh	used[c]	fresh	used[c]	sc[d]	ls[e]	sc[d]	ls[e]
SiPW-8	28.6	70.2	31.5	30.9	10.3	10.1	0.223	≈ 0	15.9	≈ 0
SiPW-16	13.7	58.5	17.2	17.0	7.5	7.2	0.143	≈ 0	10.2	≈ 0
HPW/SBA	9.1	19.7	32.3	3.4	3.8	0.7	0.009	0.04	0.64	0.51
HPW	35.8	53.5	50.8	–	8.0	–	–	–	–	–
SBA-15	1.2	3.8	1.5	1.0	0	0	–	–	–	–

[d] Spent catalysts (sc) in esterification reactions of benzoic acid with *tert*-butanol after being used five times, the units for P- and W content are wt.-%. [e] Liquid solution (ls) in esterification reactions of benzoic acid with *tert*-butanol after separation of the catalysts after being used five times, the units for P- and W content are $\times 10^{-3}$ mmol/ml.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Similar phenomena have also been observed in the esterification of benzoic acid with *tert*-butanol. The SiPW-16 and SiPW-8 samples give conversions of 7.2 and 10.1%, respectively, even after being reused five times, while the HPW/SBA samples only show a conversion of 0.7% after five uses. The above results suggest that the SiPW-X samples are very stable in liquid reactions even when reused many times, and leaching of HPW in these samples is hardly observed relative to that in the samples prepared by the impregnation method.

In order to help the reader better understand the difference between SiPW-X and HPW/SBA prepared by the impregnation method, we give a simple schematic model of SiPW-X (bottom part of Figure 7). We also give a schematic model of the interactions of silicon species with heteropolyanions under strong acidic conditions during preparation of SiPW-X (top part of Figure 7) and of terminal silicon hydroxyl groups of SBA-15 with heteropolyanions during preparation of conventional SBA-15 supported HPW (Figure 8). From Figure 7 and 8, we can see that the interaction of the silicon species with the heteropolyanions under strong acidic conditions is much stronger than that of the terminal silicon hydroxyl groups of SBA-15 with the heteropolyanions. Therefore, the stability of the composite materials (SiPW-X) comes from the fact that HPW is dispersed in the silica wall.

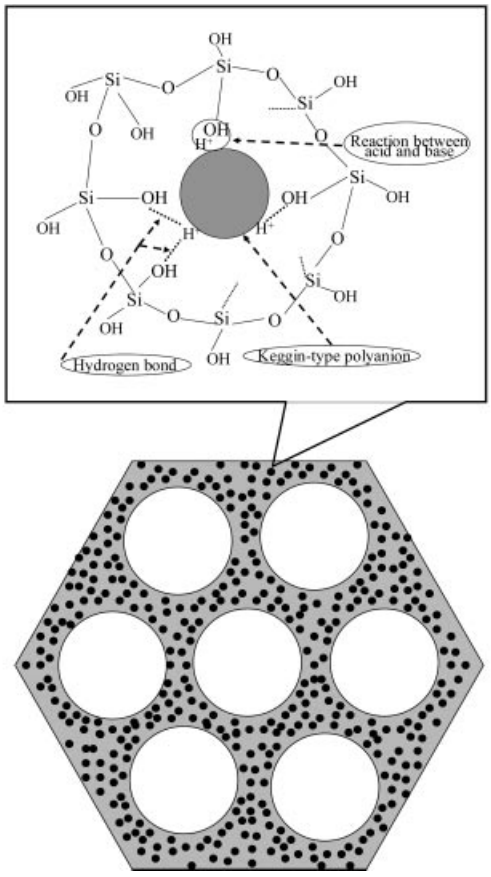

Figure 7. Simple schematic model of the interaction of the silicon species with heteropolyanions under strong acidic conditions during preparation of SiPW-X.

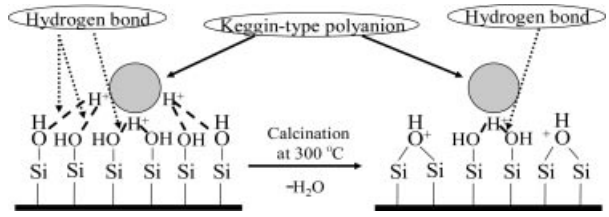

Figure 8. Simple schematic model of the interaction of terminal silicon hydroxyl groups of SBA-15 with heteropolyanions during preparation of conventional SBA-15 supported HPW.

In summary, the SiPW-X mesosilica materials with Keggin-type heteropolyacids encapsulated into their framework are excellent acidic catalysts for both small and bulky molecules. Additionally, other properties, such as easy separation, reusability etc., ensure the potential use in industrial applications.

Conclusion

Mesoporous silica with Keggin-type heteropolyacids encapsulated into their framework has been synthesized by addition of Na_2HPO_4 and Na_2WO_4 into the initial sol-gel system during hydrolysis of TEOS under strong acidic conditions. Characterization results suggest that samples with HPA contents of 13.3–20.7 wt.-% show very ordered hexagonal mesostructures. The HPA incorporated in the mesosilica is insoluble during catalysis. Catalytic cracking results suggest that these samples are very active in both small molecule (cumene) and bulky molecule (1,3,5-triisopropylbenzene) reactions. Additionally, esterification results in liquid reactions (polar solvent) after recycling indicate that these materials are can be easily separated and recycled.

Experimental Section

Materials: Tetraethyl orthosilicate (TEOS), hydrochloric acid (HCl), cumene, benzoic acid, tertiary butanol, ethanol, and acetic acid were of analytical grade and purchased from Tianjin Chemical Co. (China). Sodium tungstate (Na_2WO_4) and sodium monohydrogen phosphate (Na_2HPO_4) were of analytical grade and supplied by Beijing Chemical Co. (China). $EO_{20}PO_{70}EO_{20}$ (Pluronic P123) and 1,3,5-triisopropylbenzene (TIPB) were from Aldrich.

Synthesis: The typical synthesis process was as follows: (1) Pluronic P123 (4.0 g) was dissolved in a solution of deionized water (100 mL) containing hydrochloric acid (20 mL, 36 wt.-%), followed by addition of TEOS (10 mL). The mixture was stirred at 40 °C for 3 h. (2) A requisite amount of Na_2WO_4 and Na_2HPO_4 was added simultaneously to the above mixture to form a white precipitate. (3) The mixture was further stirred at 40 °C for 20 h and then transferred to a stainless steel autoclave for crystallization at 100 °C for 48 h.

The obtained products were collected and dried in vacuo ($<10^{-2}$ Pa) at 150 °C for 6 h and washed with an ethanol solution containing HCl and distilled water three times, and finally dried in vacuo ($< 10^{-2}$ Pa) at 300 °C for 5 h. The final products were desig-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nated as SiPW-X, where X stands for the Si/W molar ratio in the initial gel.

For comparison, pure silica SBA-15 and HPW were synthesized according to the literature procedures;[5,42] conventional SBA-15 supported HPW was made by immersing SBA-15 powder into an HPW solution for 3 h followed by drying at 100 °C for 24 h, and then calcining at 300 °C for 5 h; this is denoted as HPW/SBA.

Characterization: Powder X-ray diffraction (XRD) data were recorded on a Siemens D5005 (30 kV, 30 mA) using nickel-filtered Cu-K_α radiation with a wavelength of $\lambda = 0.15418$ nm, diffraction patterns were collected under ambient conditions in the 2θ range of 0.6–4° at a scanning rate of 0.6°/min and in the 2θ range of 4–70° at a scanning rate of 6°/min. Transmission electron microscopy (TEM) experiments were performed on a JEM-3010F electron microscope (JEOL, Japan) with an acceleration voltage of 300 kV. The nitrogen isotherms at the temperature of liquid nitrogen were measured using a Micromeritics ASAP 2010M system. The samples were outgassed for 10 h at 300 °C before the measurements. Infrared (IR) spectroscopy was performed on a Bruker IFS 66v/S infrared spectrometer in the range 400–4000 cm^{-1} using KBr pellets in vacuo (<0.4 Pa) at ambient temperature. The diffuse reflectance UV/Visible spectra for powder samples were obtained on a Perkin–Elmer Lambda 20 UV/Visible spectrometer equipped with an integrating sphere, with $BaSO_4$ as an internal standard. Solid-state ^{31}P NMR experiments were performed with magic angle spinning (MAS) on an Infinity Plus-400 spectrometer operating at a frequency of 104.26 MHz, chemical shifts were referenced to 85% H_3PO_4 as an external standard. The HPW content in solid samples were determined by the results of inductively-coupled plasma analysis (ICP, Perkin–Elmer 3300DV).

Catalytic Test

Catalytic Cracking of Cumene and 1,3,5-Triisopropylbenzene (TIPB): Catalytic cracking of cumene and 1,3,5-triisopropylbenzene were carried out using the pulse technique in a micro-reactor, and the analyses of the catalytic products were performed by gas chromatography (GC-17A, Shimadzu Co.) equipped with a flame ionization detector (FID). The catalytic cracking was performed according to the following standard conditions: the reaction temperature was 300 °C (no thermal cracking); the reaction pressure was atmospheric pressure; the mass of the catalyst was 0.050 g; 0.2 μL of cumene or 1,3,5-triisopropylbenzene was injected for each test; nitrogen was used as the carrier gas at a flow rate of 45 mL/min.

Esterification of Acetic Acid with Ethanol and of Benzoic Acid with *tert*-Butanol: The esterification of acetic acid with ethanol was performed under nitrogen at 40 °C in a flask (50 mL) containing suspended catalyst powder (60 mesh pass), acetic acid (0.15 mol), and ethanol (0.15 mol), and with vigorous agitation for 4 h. The amount of catalyst used was 0.10 g. The product esters were analyzed by gas chromatography (6890N, Agilent Co.) equipped with a flame ionization detector (FID) with an HP-5 flexible quartz capillary column (30 m in length).

The esterification of benzoic acid with *tert*-butanol was performed under nitrogen at 80 °C in a flask (50 mL) containing suspended catalyst powder (60 mesh pass), benzoic acid (5 mmol), and *tert*-butanol (10 mmol), and with vigorous agitation for 5 h. The amount of catalyst used was 0.10 g. The product esters were analyzed by gas chromatography (6890N, Agilent Co.) equipped with a flame ionization detector (FID) with an HP-5 flexible quartz capillary column (30 m in length).

Synthesis, Structure and Characterisation of a New Trinuclear Di-μ-phenolato-μ-carboxylato $Mn^{III}Mn^{II}Mn^{III}$ Complex with a Bulky Pentadentate Ligand: Chemical Access to Mononuclear Mn^{IV}–OH Entities

Christelle Hureau,*[a,b] Elodie Anxolabéhère-Mallart,*[a] Geneviève Blondin,[a] Eric Rivière,[a] and Martine Nierlich[c]

Keywords: EPR spectroscopy / Manganese / Mass spectrometry / N,O ligands / Oxidation

A new trinuclear $Mn^{III}Mn^{II}Mn^{III}$ complex has been isolated and X-ray characterised, namely $[(py\text{-}salpn)Mn^{III}(\mu\text{-}OAc)Mn^{II}(\mu\text{-}OAc)Mn^{III}(py\text{-}salpn)]^{2+}$ (**1**), where H_2py-salpn is the new bulky $[N_3O_2]$ ligand derived from the H_2salpn Schiff base by the addition of one pyridine arm and the reduction of the imine function. The crystal structure reveals that the complex has a strictly 180° $Mn^{III}\cdots Mn^{II}\cdots Mn^{III}$ angle, the Mn^{II} ion being located at an inversion centre. The complex is valence-trapped, with the terminal Mn^{III} ions showing a Jahn–Teller elongation along the pyridine–Mn^{III}–acetate axis. The $Mn^{II}\cdots Mn^{III}$ separation is 3.1224(13) Å. The EPR spectra recorded on solid and frozen solutions are consistent with an $Mn^{III}Mn^{II}Mn^{III}$ species. The electrochemical response of complex **1** in acetonitrile solution exhibits two, one-electron reduction waves at $E_{1/2}$ = 0.140 and –0.075 V vs. SCE. Phenolato and acetato→Mn^{III} ligand-to-metal charge-transfer transitions are detected by UV/Visible spectroscopy at 359 and 587 nm, respectively. Chemical oxidation of an acetonitrile solution with *tert*-butyl hydroperoxide leads to mononuclear Mn^{IV}–hydroxo species, as evidenced by UV/Visible and EPR spectroscopy as well as ESI mass spectrometry.

Introduction

The development of bioinorganic manganese chemistry has been stimulated by the involvement of manganese ions in many biological systems,[1,2] such as superoxide dismutase,[3] catalase[4] and photosystem II of green plants.[5–8] In this last intricate machinery, an oxomanganese entity is the key element of the oxygen evolving complex (OEC), which performs the light-induced oxidation of water into dioxygen. This reaction requires the photogeneration of four oxidative equivalents and their storage by the OEC. These two processes are accomplished during the first four steps of the Kok cycle,[9,10] ($S_0\rightarrow S_1$, $S_1\rightarrow S_2$, $S_2\rightarrow S_3$ and $S_3\rightarrow S_4$) where S_i (i = 0–4) denote the five oxidation states of the OEC, dioxygen being released during the last step ($S_4\rightarrow S_0$). High-valent oxidation states are thus reached by the manganese ions in the S_4 state. Recently, two X-ray structures obtained for the photosystem II (PSII) of the cyanobacterium *Thermosynechococcus elongatus* have appeared in the literature, one at 3.5 Å[11] and the other at 3.2 Å resolution.[12] The structure of the Mn cluster, however, is still a matter of debate. Nevertheless, the resolution level allows the authors to propose two models of the OEC that agree in terms of having two moieties: a small one containing one cation and a larger one containing three or more cations. Zouni et al. describe the OEC cluster as containing only four metal ions, whereas Ferreira et al. describe the oxomanganese entity as a "3+1" tetranuclear manganese complex. More precisely, in the latter case three manganese ions together with one calcium ion are arranged in a tetrahedral geometry at four corners of a distorted cube, the other four corners being occupied by bridging oxo ions. The fourth manganese ion is linked to the Mn–Ca–oxo cube by a unique oxo bridge. Two amino acid residues are involved in the coordination of the fourth manganese ion, namely Asp170 and Glu333, and Asp61 is coordinated through a water molecule. Lastly, one exogenous labile hydrogencarbonate ligand is proposed to interact with the fourth manganese and the calcium ions. Due to its peculiar location and to the presence in its surroundings of labile positions along with the tightly bound Ca^{2+}, this fourth manganese ion is anticipated to ensure a special role in the water oxidation process. In particular, the present structure supports recent hypotheses in which one of the four manganese ions binds a water molecule, thus producing a highly reactive intermediate. This electrophilic species is then predisposed

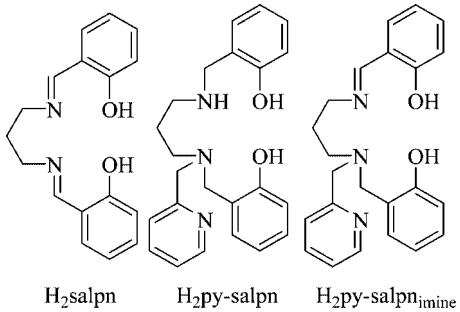
to be attacked by the second water molecule bound to the calcium ion to form the O–O bond.[13]

The water oxidation mechanisms proposed by Siegbahn et al.[14–16] and Brudvig et al.[17] all rely on a tightly bound Ca^{2+} ion located close to a manganese ion. Indeed, it is proposed that during the Kok cycle only one of the Mn ions binds a water substrate molecule and, before dioxygen formation, produces either a highly reactive electrophilic intermediate or an Mn^{IV}–oxyl radical. A Mn^{V} centre has also been advocated by Pecoraro et al.[18] In these assumptions, the reactive manganese ion would be the fourth manganese ion of the "3+1" tetranuclear complex.

The large number of papers found in the literature attests that high-valent manganese compounds have been developed as selective organic oxidation catalysts,[19–25] and tested in bleaching processes.[26–28] Consequently, generating high-valent and/or Mn–oxo complexes is a relevant challenge for inorganic chemists, both for OEC modelling and for the development of oxidation catalysts.

Among the numerous manganese compounds synthesised, complexes containing Schiff-base ligands, like H_2salen or H_2salpn,[29] or their derivatives, have been intensively studied as much for their biological relevance[30–33] as for their catalytic activity.[25,28,34–38] Indeed, these complexes possess the ability to form high-valent Mn–oxo species,[39,40] the sixth position being occupied by various ligands.[41,42] In particular, the use of pyridine as the sixth ligand has been proposed to assist the formation of Mn^{V}–oxo species from the $[(salen)Mn^{III}]^+$ complex, using *tert*-butyl hydroperoxide as the oxidant.[25]

Taking into account these different elements, we designed a new bulky pentadentate ligand, derived from reduced H_2salpn by the addition of one pyridine arm and denoted H_2py-salpn (see Scheme 1). In the present work, we describe the synthesis and the crystal structure of the new trinuclear manganese complex $[(py\text{-}salpn)Mn^{III}(\mu\text{-}OAc)Mn^{II}(\mu\text{-}OAc)Mn^{III}(py\text{-}salpn)](BPh_4)_2$ [**1**$(BPh_4)_2$]. The magnetic and EPR properties of **1**$(BPh_4)_2$ have been investigated on crystalline product. Characterisations of complex **1**$(BPh_4)_2$ upon dissolution in acetonitrile have been performed by EPR and UV/Visible spectroscopy, as well as cyclic voltammetry and mass spectrometry. We also describe the reactivity of **1** upon addition of *tert*-butyl hydroperoxide, where EPR spectroscopy suggests the formation of mononuclear Mn^{IV} species that are identified as Mn^{IV}–OH complexes by mass spectrometry measurements.



Scheme 1. H_2salpn, H_2py-salpn and H_2py-salpn$_{imine}$.

Results and Discussion

The reaction of H_2py-salpn with $Mn^{III}(OAc)_3{\cdot}2H_2O$ in ethanol solution leads to the formation of the cation $[(py\text{-}salpn)Mn^{III}(\mu\text{-}OAc)Mn^{II}(\mu\text{-}OAc)Mn^{III}(py\text{-}salpn)]^{2+}$ (**1**), which was precipitated by addition of two equivalents of sodium tetraphenylborate. It is worth noting that the presence of Mn^{II} in the complex is not unexpected considering that the $Mn^{III}(OAc)_3{\cdot}2H_2O$ starting material contains Mn^{II} species, even after recrystallisation.

Crystal Structure of $[(py\text{-}salpn)Mn^{III}(\mu\text{-}OAc)Mn^{II}(\mu\text{-}OAc)Mn^{III}(py\text{-}salpn)]^{2+}$ (1)

The structure of complex **1** is presented in Figure 1 and principal bond lengths and angles are listed in Table 1. The cation consists of three manganese ions, two $(py\text{-}salpn)^{2-}$

ligands and two bridging acetate ions. The Mn1 ion is located at the inversion centre of the cation in a quasi-regular octahedral geometry. The Mn1 and Mn2 (or Mn2′) ions are held together by two bridging phenolato arms from one $(py\text{-}salpn)^{2-}$ ligand and by one bridging acetate ion. Mn1 is coordinated by the four phenolic bridging oxygen atoms from the two $(py\text{-}salpn)^{2-}$ ligands that indeed form a plane and, quasi-perpendicularly to it, by two oxygen atoms from the two acetate bridging ligands. Mn2 and Mn2′ are coordinated by the three nitrogen atoms and the two bridging phenolato arms of the $(py\text{-}salpn)^{2-}$ ligand and by one oxygen atom from the acetate bridging ligand. The phenolato arms are in a *cis* position, as are two amine nitrogen atoms, whereas the pyridine nitrogen atom and the oxygen atom of the acetate ion are in a *trans* position. The metal–ligand distances reported in Table 1 reveal that **1** is a valence-trapped $Mn^{III}Mn^{II}Mn^{III}$ complex, with the terminal Mn^{III} ions exhibiting a Jahn–Teller elongation along the acetate–Mn–pyridine (O4–Mn2–N3) direction. The bridging acetate ions are in the usual *syn-syn* coordination mode, as reported for analogous trinuclear manganese complexes.[43] The distance between the Mn^{II} and the Mn^{III} ions in **1** is 3.1224(13) Å, which is slightly shorter than that reported in similar core units (3.137–3.173 Å).[44] It is, however, significantly shorter than in μ-alkoxo-bis-μ-carboxylato-bridged $Mn^{III}Mn^{II}Mn^{III}$ trinuclear complexes (3.419–3.551 Å).[45–49] The presence of two phenolato bridges in **1** is the origin of this shortening of the distance. Crystal data also reveal that the secondary amine function is not oxidised during the metallation [N1–C7 = 1.501(7) Å], as could be anticipated from reported syntheses of similar complexes.[50]

IR, Magnetic and EPR Properties of $1(BPh_4)_2$

The IR spectrum of $\mathbf{1}(BPh_4)_2$ presents significant absorption bands at 1602, 1559, 1424, 760, 734 and 708 cm^{-1}. The three bands detected below 800 cm^{-1} are assigned to the tetraphenylborate counterions, whereas the two broad bands detected at 1559 and 1424 cm^{-1} are attributed to the bridging acetate ions.[51,52] The difference of 135 cm^{-1} calculated between the symmetrical and the unsymmetrical C=O vibration bands is in agreement with the *syn-syn* bridging coordination mode of the acetate ions.[51] The C=N vibration band of the pyridine function is detected at 1602 cm^{-1}. Lastly, the absence of a broad absorption band near 1630 cm^{-1} confirms the absence of the imine function in **1**.[53]

The product of the molar magnetic susceptibility, χ_M, and the temperature, T, recorded on a powder sample of $\mathbf{1}(BPh_4)_2{\cdot}3CH_3CN$ is approximately constant between 50 and 300 K. The $\chi_M T$ product lies between 10.31 and 10.37 $cm^3 mol^{-1} K$. This is close to the theoretical value of 10.375 $cm^3 mol^{-1} K$ expected for two $S_{Mn^{III}} = 2$ and one $S_{Mn^{II}} = 5/2$ uncoupled spins with g-factor values fixed to 2. The observed temperature dependence indicates that the manganese ions are very weakly coupled. This contrasts with the μ-alkoxo-bis-μ-carboxylato-$Mn^{II}Mn^{III}$ core complexes that are usually found to be weakly antiferromagnetically coupled, with $J_{Mn^{II}Mn^{III}}$ lying between –8 and –14.2 cm^{-1}, using the expression $-JS_{Mn^{II}}{\cdot}S_{Mn^{III}}$ for the exchange Hamiltonian within a pair.[47–49] A weak exchange interaction, either antiferromagnetic or ferromagnetic, has been observed in analogous $Mn^{III}Mn^{II}Mn^{III}$ trinuclear systems where the Mn^{III} and the Mn^{II} ions are connected by one phenolato, one alkoxo and one carboxylato bridge.[44] The magnitude of the exchange interaction is indeed controlled by the presence of two alkoxo or phenoxo bridges. Such doubly bridged $Mn^{II}Mn^{III}$ core units present J values ranging from –3.4 to 13.2 cm^{-1}.[31,54–56]

The X-band EPR spectrum was recorded at 10 K using the conventional perpendicular mode on a powder sample of complex $\mathbf{1}(BPh_4)_2{\cdot}3CH_3CN$ and is presented in Figure S1 (trace a). An intense and broad line is observed at 335 mT ($g_{eff} = 2$). Two weaker lines are also detected at 145 and 558 mT, which are strongly indicative of weak interactions between the Mn ions within complex **1**. In the absence of an interaction between the metal ions, the EPR signal would originate solely from the Mn^{II} site as the Jahn–Teller-elongated Mn^{III} centres exhibit a strong zero-field splitting effect that prevents the detection of any EPR signal at 9 GHz. In addition, the regular environment of the Mn^{II} ion should induce a small zero-field splitting effect. Consequently, a broad line at $g_{eff} = 2$ is expected. The dipolar and isotropic exchange interactions between the central Mn^{II} site and the two terminal Mn^{III} ions split this signal quasi-symmetrically and new lines appear at both lower and higher fields. This was checked by calculating powder X-band EPR spectra for a fictitious system containing two terminal $S = 1$ and one central $S = 1/2$ sites. The profile is, however, strongly dependent on the relative orientation of the terminal zero-field splitting tensors towards that of the dipolar tensors and on the nature − ferro- or antiferromagnetic − of the exchange interaction (see Figure S2 in the Supporting Information). Due to the important spin values of the manganese ions and to the number of parameters, no simulation was attempted on the real system.

Characterisation of $1(BPh_4)_2$ upon Dissolution in Acetonitrile

The X-band EPR spectra of millimolar dichloromethane and acetonitrile solutions of complex **1** at 10 K are presented in Figure S1 (see Supporting Information; traces b and c, respectively). The EPR signatures of complex **1** upon dissolution are close to that recorded for a powder sample. In acetonitrile solvent, however, an additional six-line signal is detected at $g_{eff} = 2$, which is attributed to solvated Mn^{II}. This contribution has been quantified (See Experimental Section for details) and accounts for less than 5% of the total Mn-based species. This experiment shows that the trinuclear structure of complex **1** is essentially maintained upon dissolution in acetonitrile.

The UV/Visible spectrum of complex **1** in acetonitrile is reproduced in Figure 2 (dashed line-left scale). Two major

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bands are detected at 587 and 359 nm, with extinction coefficient values (ε) of 3.1 and 8.9×10^3 $M^{-1}cm^{-1}$, respectively, with a shoulder at 450 nm ($\varepsilon = 4.0\times10^3$ $M^{-1}cm^{-1}$). The band at 587 nm is attributed to a phenolato→Mn^{III} ligand-to-metal charge transfer (LMCT) transition,[50,53,57,58] whereas the other two transitions may originate from either phenolato→Mn^{III} or acetato→Mn^{III} LMCT transitions.[59] The large ε values of the LMCT transitions prevent the observation of the Mn^{III} d–d transitions, which are theoretically expected with lower ε values.[60,61]

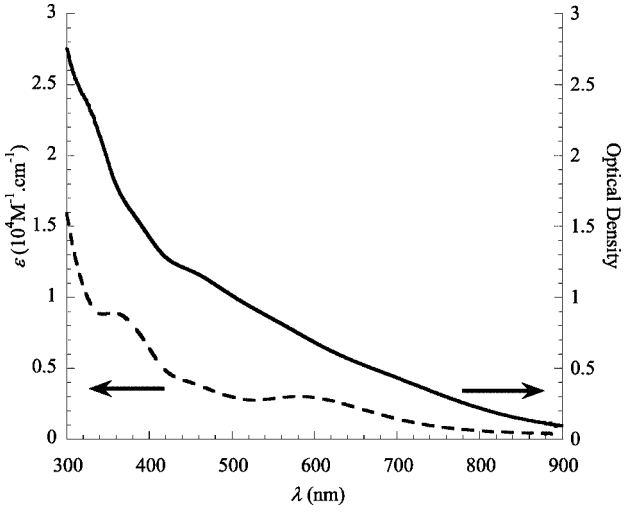

Figure 2. UV/Visible spectra of complex $\mathbf{1}(BPh_4)_2$ (10^{-3} M in acetonitrile, dashed line) and immediately after the addition of 20 equivalents of *t*BuOOH (solid line). T = 20 °C, l = 1 mm.

The cyclic voltammogram recorded under argon on a millimolar solution of complex **1** in acetonitrile in the presence of 0.1 M tetrabutylammonium perchlorate is presented in Figure 3. Two quasi-reversible waves of equal intensity are detected when scanning towards cathodic potentials at $E_{1/2}$ = 0.140 (ΔE^P = 80 mV) and –0.075 V vs. SCE (ΔE^P = 80 mV), respectively.[62] When scanning towards anodic potentials, an intense irreversible wave is observed at E^P = 0.88 V vs. SCE that remains irreversible when reversing the scan at 1.0 V vs. SCE. A second, weaker-intensity, irreversible wave is detected at E^P = 1.16 V vs. SCE. The two reduction waves are attributed to two successive one-electron reductions of complex **1**, leading firstly to [(py-salpn)-Mn^{III}(μ-OAc)Mn^{II}(μ-OAc)Mn^{II}(py-salpn)]$^+$ and then to [(py-salpn)Mn^{II}(μ-OAc)Mn^{II}(μ-OAc)Mn^{II}(py-salpn)]. The Mn^{III}/Mn^{II} reduction process presents low potential values, as it is to be expected considering the anionic environment of the Mn^{III} centre. These values are close to those reported for other diphenolato-coordinated Mn^{III} complexes.[63] The detection of two single-electron Mn^{III}/Mn^{II} processes presenting $E_{1/2}$ potentials that differs by 225 mV ($\Delta E_{1/2}$) is indicative of a weak electrostatic interaction between the two Mn^{III} ions. The low $\Delta E_{1/2}$ value is related to the long distance between the two Mn^{III} ions (6.24 Å).[64] The first anodic process detected is attributed to the oxidation of the tetraphenylborate counterion of complex **1**,[65] and the second irreversible anodic process may be attributed to the oxidation of complex **1**, leading to the formation of [(py-salpn)-Mn(μ-OAc)Mn(μ-OAc)Mn(py-salpn)]$^{3+}$, which further evolves chemically. Unfortunately, the interaction of the oxidised tetraphenylborate ion generated at the electrode surface with complex **1** and/or with the [(py-salpn)Mn(μ-OAc)Mn(μ-OAc)Mn(py-salpn)]$^{3+}$ species renders the process difficult to analyse.

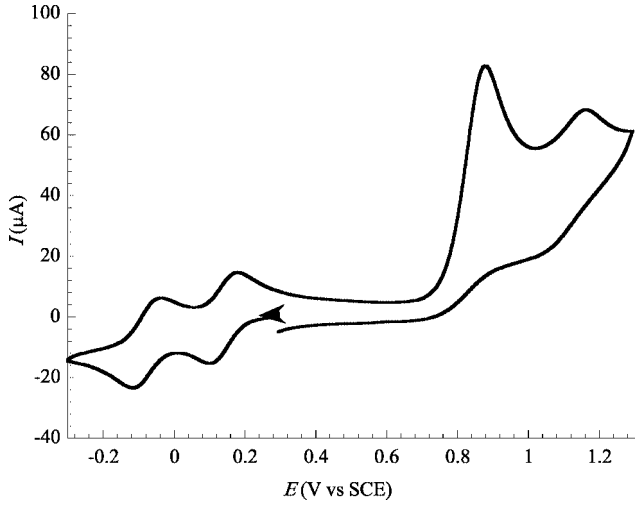

Figure 3. Cyclic voltammograms of $\mathbf{1}(BPh_4)_2$ (10^{-3} M in acetonitrile with 0.1 M of tetrabutylammonium perchlorate). T = 20 °C and scan rate = 100 $mV\,s^{-1}$.

Chemical Oxidation

The chemical oxidation of complex **1** was performed on a millimolar acetonitrile solution with *tert*-butyl hydroperoxide (*t*BuOOH) as the oxidant. The oxidant was added in large excess (20 equivalents). Upon addition, the solution turned from dark green to black. We will show in the next

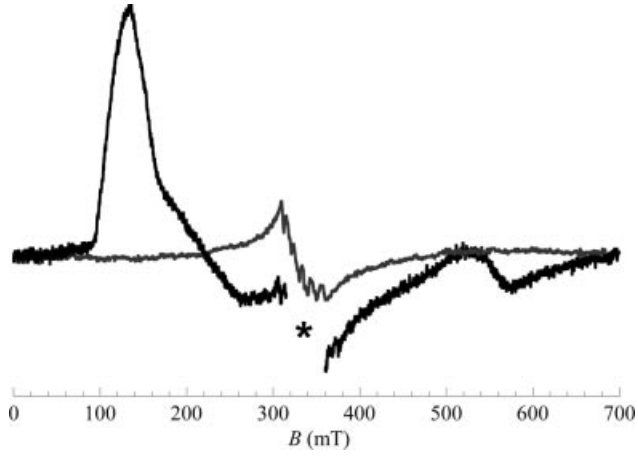

Figure 4. EPR spectra of complex $\mathbf{1}(BPh_4)_2$ (10^{-3} M in acetonitrile, grey line) and immediately after the addition of 20 equivalents of *t*BuOOH (black line). Recording conditions: 0.5 mT modulation amplitude, 100 kHz modulation frequency, T = 100 K, 2.0 mW microwave power, ν = 9.39 GHz. The $tBuO^{\cdot-}$ radical signal has been removed off the black trace.

section that the chemical oxidation of complex **1** leads to the formation of high-valent Mn species (**1ox**). The **1ox** species were characterised by UV/Visible and EPR spectroscopy and ESI mass spectrometry.

The UV/Visible spectrum of **1ox**, shown in Figure 2 (solid line, right scale), is mainly featureless in the visible region and presents a strong absorbance in the UV domain. Shoulders are observed at 463 and 685 nm. These observations are reminiscent of previous observations for hydroxyl-rich[66] or for carboxylato[67] mononuclear Mn^{IV} Schiff-base complexes. The intense absorption band in the UV region may therefore be attributed to a phenolato→Mn^{IV} or to a

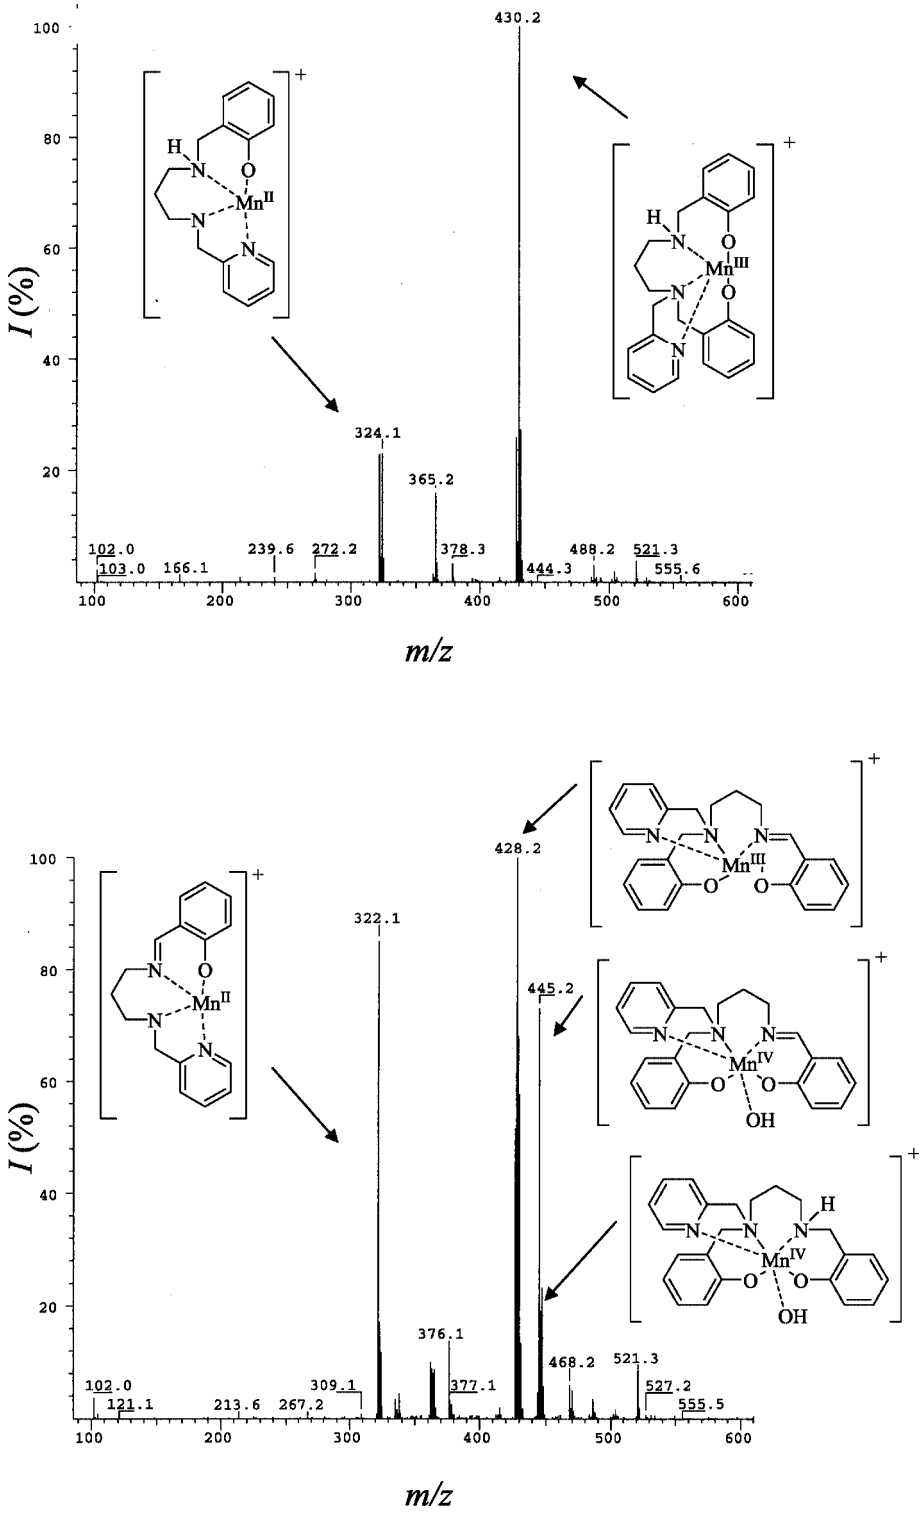

Figure 5. Electrospray mass spectrum of complex **1** (10^{-4} M in acetonitrile) recorded for the starting solution (top) and after addition of 20 equivalents of *t*BuOOH (bottom).

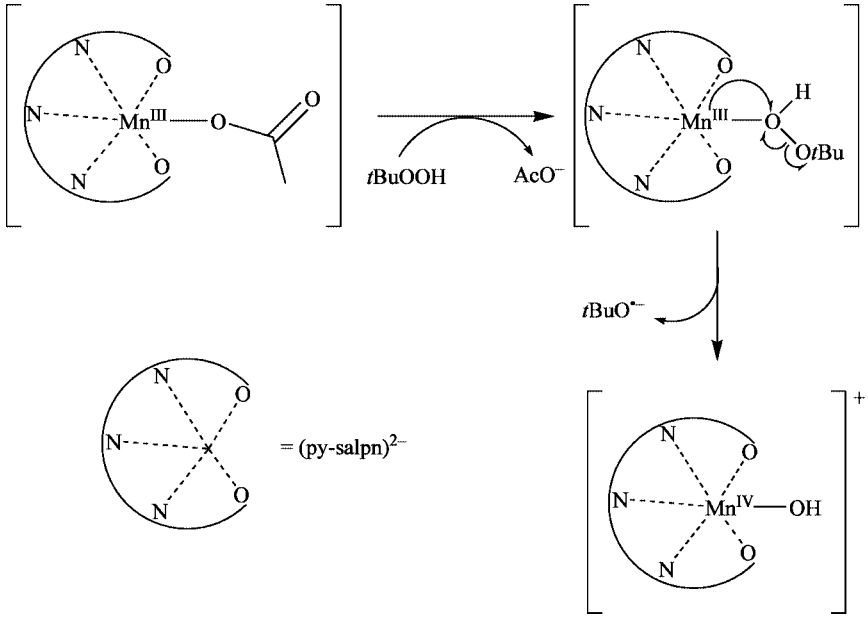
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydroxo→Mn^{IV} LMCT transition. The shoulders observed in the visible region can be attributed to a poorly resolved phenolato→Mn^{IV} MLCT[50,53,57] or to Mn^{IV} d–d transitions, the strong intensity of which originates from the tail of the absorption in the UV region.

The X-band EPR spectrum of **1ox** at 100 K, recorded in the perpendicular detection mode, is presented in Figure 4 (black line). An intense $g = 2$ signal corresponding to an organic radical has been removed for clarity. The EPR signature of complex **1** recorded under the same conditions is also reproduced (grey line in Figure 4). The signal of complex **1** differs slightly from trace c of Figure S2, with the low-field transitions being undetectable at this recording temperature. Four new transitions appear at $g_{eff} = 4.9$, 3.0, 1.5 and 1.17 after the addition of the oxidant.[68] These resonances are broad and show no evidence for ^{55}Mn hyperfine coupling. The EPR signature of **1ox** is indicative of an $S = 3/2$ Mn^{IV} ion. The complexity of the EPR spectrum of a d^3 species depends on the magnitude of the zero-field splitting (ZFS) compared to the applied microwave frequency. In axial symmetry ($E/D = 0$), two limiting cases can be discussed depending on the relative magnitude of $|2D|$ vs. $h\nu$, where D is the axial ZFS parameter. At X-band ($h\nu = 0.3\ cm^{-1}$), and when $|2D| >> h\nu$, the ZFS effect dominates the Zeeman effect, and a strong transition is expected at low field ($g_{eff} \approx 4$) with a weak component at around $g_{eff} = 2$. This behaviour has been observed for numerous Mn^{IV} centres with anionic chelating ligands, such as hydroxo, phenolato, carboxylato or anilido.[57,66,67,69–74] When $|2D| << h\nu$, the Zeeman effect dominates the ZFS effect and the signal is centred at $g_{eff} \approx 2$, with weaker lines at both the low- and high-field edges. This behaviour has been reported for rare Mn^{IV}–tetraphenolato,[72] Mn^{IV}–thiohydroxamato,[75] and Mn^{IV}–thiocarbamato[76] complexes. The strong absorption detected at $g_{eff} = 4.9$ and the weaker one near $g_{eff} = 1.5$ suggest that the present Mn^{IV} species exhibits a strong ZFS effect. The divergence from a g_{eff} value of around 4 originates from the rhombicity of the ZFS. According to the diagram showing the evolution of the g_{eff} values for the two Kramer doublets as a function of E/D,[77] one can see that the line positions at $g_{eff} = 4.9$, 3.0, 1.5 and 1.17 can be well reproduced with $E/D = 0.17$. These first two characterisations suggest that **1ox** is a mononuclear Mn^{IV} species.

In order to identify the Mn^{IV} species formed, ESI/MS experiments were performed. The mass spectra of complexes **1** and **1ox** are presented in Figure 5. The mass spectrum of complex **1** exhibits a major molecular peak at m/z = 430 amu and three other peaks at m/z = 322, 324 and 365 amu.[78] The first peak is attributed to the mononuclear Mn^{III} entity $\{[(py\text{-}salpn)Mn]\}^+$, and the peaks at 322 and 324 amu correspond to Mn^{II} species, namely $\{[(L^1_{imine})\text{-}Mn]\}^+$ and $\{[(L^1)Mn]\}^+$, where L^1 stands for the $(py\text{-}salpn)^{2-}$ ligand after the loss of one phenolato arm and L^1_{imine} for L^1 with a reduced secondary amine function (see Figure 5). The peak at m/z = 365 amu can be attributed to the adduct $\{[(L^1)Mn]CH_3CN\}^+$, even though such solvated species are rarely detected under the present recording conditions. After addition of *t*BuOOH, the peak at m/z = 430 amu disappears and the peak at 322 amu increases in intensity together with the apparition of three new peaks at m/z = 428, 445 and 447 amu. The peak at 428 amu corresponds to the Mn^{III} species $\{[(py\text{-}salpn_{imine})Mn]\}^+$, where subscript imine means that the secondary amine function has been oxidised to an imine (Scheme 1). The peaks at 445 and 447 are attributed to the mononuclear hydroxo Mn^{IV} entities $\{[(py\text{-}salpn_{imine})Mn(OH)]\}^+$ and $\{[(py\text{-}salpn)\text{-}Mn(OH)]\}^+$, respectively. It is worth noting that the formation of the imine function may be due to the use of the oxidant *t*BuOOH. Species **1ox** is subsequently attributed to



Scheme 2. Proposed mechanism for the formation of the Mn^{IV}–OH species.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the mixture of the two Mn^{IV} monocations $\{[(py\text{-}salpn_{imine})Mn(OH)]\}^+$ and $\{[(py\text{-}salpn)Mn(OH)]\}^+$.

Lastly, according to the EPR spectra, we can propose that the central Mn^{II} ion is oxidised into an EPR-silent Mn^{III} species, the UV/Visible signature of which may be masked by the tail of the UV absorbance of complexes **1ox**.

Formation of the Mn^{IV}–hydroxo Entities

A mechanism for the formation of the Mn^{IV}–hydroxo species **1ox** is tentatively proposed in Scheme 2. For clarity, only the terminal Mn^{III} ions of complex **1** are considered. We propose that after the coordination of the *t*BuOOH oxidant to the Mn^{III} centre, the homolytic breakage of the O–O bond[79] would lead to the release of the radical *t*BuO$^{\cdot}$– and to the formation of the Mn^{IV}–OH complex.

We should mention that it is also plausible that the acetate ion, which is a particularly strong base in acetonitrile (pK_a = 22)[80] would be able to deprotonate the hydroxo ion coordinated to the Mn^{IV} ion, thus forming a Mn^{IV}–oxo species. The EPR and UV/Visible spectra do not allow us to discriminate an oxo from a hydroxo Mn^{IV} species. The detection in of peaks at 445 and 447 amu in the ESI mass spectrum may then be explained by the formation of a proton adduct of the neutral Mn^{IV}–oxo entities, leading to $\{[(py\text{-}salpn_{imine})Mn(O)]H\}^+$ and $\{[(py\text{-}salpn)Mn(O)]H\}^+$. It is also worth noting that the presence of the oxidised ligand may be due to the formation of Mn^{IV} species or to the *t*BuOOH itself.

Concluding Remarks

A new trinuclear $Mn^{III}Mn^{II}Mn^{III}$ complex **1** containing a bulky $[N_3O_2]$ ligand derived from the H_2salpn Schiff-base ligand by the addition of one pyridine arm has been isolated and X-ray characterised. This complex has been fully characterised by magnetic studies, UV/Visible, IR and EPR spectroscopy, cyclic voltammetry and ESI mass spectrometry. The chemical oxidation of the trinuclear complex **1** by *t*BuOOH leads to the formation of Mn^{IV} entities, which are UV/Visible and EPR characterised and identified by mass spectrometry as mononuclear Mn^{IV}–OH species.

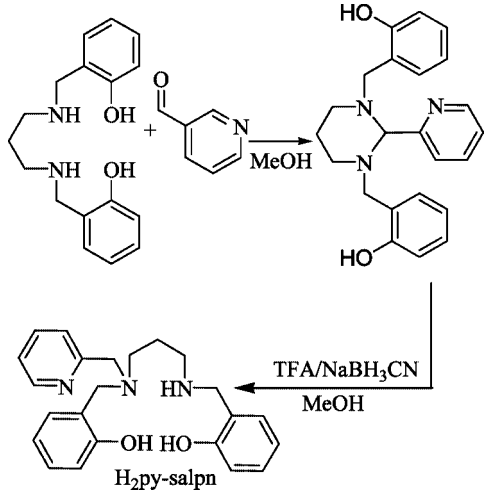
From the recent crystallographic data obtained for the *Synechococcus elongatus* PSII, a "3+1" structure has been proposed for the OEC. Some water oxidation mechanisms consistent with this recent structure favour the role of a unique highly reactive Mn ion. In this context, the synthesis and the complete characterisation of trinuclear species as well as high-valence mononuclear Mn entities remains highly relevant for the spectroscopic OEC modelling. In the near future, it will be interesting to substitute the central Mn^{II} ion in complex **1** by a calcium ion as such a putative complex should present some OEC relevant Mn–Ca–carboxylate interactions.

Experimental Section

General Remarks: Reagents and solvents were purchased commercially and used as received. Elemental Analysis was performed by the Service de Microanalyse of the CNRS (Gif sur Yvette, France) for carbon, nitrogen and hydrogen and by the Service Central d'Analyse of CNRS (Vernaison, France) for manganese and chloride. Infrared spectra were recorded as KBr pellets in the range of 4000 to 200 cm^{-1} with a Perkin–Elmer Spectrum 1000 spectrophotometer. ^1H NMR spectra were recorded withg a Bruker AM-250 (250 MHz) spectrometer. Electrospray ionisation mass spectra were recorded with a Finnigan Mat95S in a BE configuration at low resolution on millimolar acetonitrile solutions.

Caution: *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small quantities of these compounds should be prepared and they should be handled behind suitable protective shields.*

Synthesis of H_2py-salpn: The two-step synthesis of the ligand H_2py-salpn from the reduced H_2salpn is shown in Scheme 3. The reduced H_2salpn ligand 2.86 g, (10 mmol), prepared according to a previously reported synthesis,[57] was dissolved in 100 mL of methanol and 2-pyridinecarboxaldehyde (1 mL, 10 mmol) was added with stirring. The white precipitate that appeared was filtered and washed with methanol, and then redissolved in methanol by addition of two equivalents of trifluoroacetic acid. Two equivalents of sodium cyanoborohydride were added and the solution and was stirred for 12 h. Methanol was eliminated and 150 mL of water was added. The aqueous solution was extracted three times with 50 mL of dichloromethane. After removal of the solvent, H_2py-salpn was obtained as a yellow oil. Yield: 62% (2.3 g). ^1H NMR (250 MHz, $CDCl_3$): δ = 8.29 (d, J = 4.6 Hz, 1 H, *H*-Py), 7.62–7.55 (m, 2 H, *H*-Ar), 7.18–7.05 (m, 3 H, *H*-Ar), 7.00–6.93 (m, 2 H, *H*-Ar), 6.86 (d, 1 H, *H*-PhOH), 6.79 (d, 1 H, *H*-PhOH), 6.72–6.65 (m, 2 H, *H*-Ar), 3.91 (s, 2 H, RN-CH_2-PhOH), 3.77 (s, 2 H, RN-CH_2-Py), 3.54 (s, 2 H, HN-CH_2-PhOH), 2.65 (t, J = 5.8 Hz, 2 H, HN-CH_2-CH_2), 2.55 (t, J = 5.8 Hz, 2 H, RN-CH_2-CH_2), 1.78 (q, J = 5.8 Hz, 2 H, CH_2-CH_2-CH_2) ppm. ^{13}C NMR (62.9 MHz, $CDCl_3$) 157.5, 157.3, 156.6, 148.7, 137.3, 130.5, 129.8, 129.5, 129.3, 123.4, 122.9, 122.5, 120.0, 119.2, 119.1, 116.6, 58.2, 56.7, 52.2, 51.0, 47.6, 24.4 ppm. IR: $\tilde{\nu}$ = 1674 cm^{-1} (s), 1613 (m), 1595 (s), 1489 (m), 1460 (s), 1436 (m), 1383 (m), 1265 (s), 1201 (m), 1134 (m), 1104 (w), 737 (s). ESI-MS: *m*/*z* (%) = 378.2 (45) $[M + H]^+$, 272.2 (100) $[M - CH_2PhOH + H]^+$, 166.1 (60) $[M - 2CH_2PhOH + H]^+$.



Scheme 3. Synthetic route from reduced H_2salpn to H_2py-salpn.

Synthesis of $[(py\text{-}salpn)Mn^{III}(\mu\text{-}OAc)Mn^{II}(\mu\text{-}OAc)Mn^{III}(py\text{-}salpn)](BPh_4)_2{\cdot}2CH_3CN{\cdot}0.5H_2O$ [$1(BPh_4)_2{\cdot}2CH_3CN{\cdot}0.5H_2O$]: $Mn(OAc)_3{\cdot}2H_2O$ (268 mg, 1.0 mmol) was added to a 5 mL ethanol solution

of H_2py-salpn (377 mg, 1.0 mmol). The solution turned from purple to dark green. Addition of an excess (1.5 mmol) of sodium tetraphenylborate led to the precipitation of a dark green powder, which was collected by filtration and washed carefully with ethanol. Yield: 68% (239 mg). $C_{102}H_{103}B_2N_8O_{8.5}Mn_3$ [**1**$(BPh_4)_2$·$2CH_3CN$·$0.5H_2O$] (1761): calcd. C 69.5, H 5.9, N 6.3, B 1.2, Mn 9.3; found C 69.3, H 5.7, B 1.2, Mn 9.4, N 6.2. IR: $\tilde{\nu}$ = 3439 cm^{-1} (m), 3176 (m), 3054 (m), 1602 (m), 1558 (s), 1483 (s), 1458 (m), 1444 (m), 1425 (s), 1345 (w), 1249 (s), 1204 (w), 1113 (w), 1006 (w), 791 (w), 760 (m), 734 (m), 708 (m), 655 (w), 612 (m), 573 (w). The powder was then redissolved in acetonitrile and the solution was filtered and placed in an atmosphere of diethyl ether. Crystals of **1**$(BPh_4)_2$·$3CH_3CN$ suitable for X-ray crystallographic study were obtained, collected by filtration, washed with diethyl ether and dried in air.

Crystallographic Data Collection and Refinement of the Structure of 1$(BPh_4)_2$·$3CH_3CN$: The crystal data of **1**$(BPh_4)_2$·$3CH_3CN$ and the parameters of data collection are summarised in Table 2. Crystal data for **1**$(BPh_4)_2$·$3CH_3CN$ were collected on a Nonius Kappa-CCD area detector diffractometer using graphite-monochromated Mo-K_α radiation. The lattice parameters were determined from ten images recorded with 2° φ-scans and later refined on all data. The data were recorded at 123 K. A 180° φ-range was scanned with 2° steps with a crystal-to-detector distance fixed at 30 mm. Data were corrected for Lorentz polarisation. The structures were solved by direct methods with SHELXS-86[81] and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters for all non-H atoms with SHELXTL-93.[82] H atoms (unless H of CH_3CN solvent molecule) were introduced at calculated positions as riding atoms with an isotropic displacement parameter equal to 1.2 (CH, and CH_2) or 1.5 (CH_3) times that of the parent atom. The CH_3CN solvent molecules were found disordered over two positions with 0.5 occupancy factors. The molecular plots were drawn with SHELXTL.[83] All calculations were performed on a Silicon Graphics R10000 workstation.

Table 2. Details of structure determination, refinement and experimental parameters for **1**$(BPh_4)_2$·$3CH_3CN$.

Empirical formula	$C_{104}H_{103}B_2Mn_3N_9O_8$
Formula mass [g mol^{-1}]	1793.39
Temperature [K]	123(2)
Wavelength [Å]	0.71073
Crystal system	triclinic
Space group	$P\bar{1}$
a [Å]	11.573(2)
b [Å]	14.073(3)
c [Å]	15.889(3)
α [°]	71.26(3)
β [°]	85.08(3)
γ [°]	72.05(3)
Volume [Å^3]	2331.0(9)
Z	1
Density (calculated) [g cm^{-3}]	1.278
Absorption coefficient [mm^{-1}]	0.462
Crystal size [mm]	0.15 × 0.10 × 0.10
θ range for data collection [°]	2.47 to 24.70
Index ranges	$0 \le h \le 13$, $-15 \le k \le 16$, $-18 \le l \le 18$
Reflections collected	14334
Independent reflections/R(int)	7285 [R(int) = 0.0530]
Data	4705
Parameters	601
Goodness-of-fit on F^2	0.913
Final R indices [$I > 2\sigma(I)$]	R_1 = 0.0704, wR_2 = 0.1893
R indices (all data)	R_1 = 0.1131, wR_2 = 0.2265
Largest diff. peak/hole [e Å^{-3}]	0.631/–0.433

CCDC-233590 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Magnetic Susceptibility Measurements: Magnetic susceptibility data were recorded on a MPMS5 magnetometer (Quantum Design Inc.). The calibration was made at 298 K using a palladium reference sample furnished by Quantum Design Inc. The data were collected over a temperature range of 50–300 K at a magnetic field of 5000 Oe and were corrected for diamagnetism.

EPR Spectroscopy: EPR spectra were recorded with a Bruker ELEXSYS 500 spectrometer at X-band. For low-temperature studies, an Oxford Instruments continuous flow liquid helium cryostat and a temperature control system were used. The quantity of free Mn^{II} was estimated by comparison with spectra of $Mn(ClO_4)_2$·$6H_2O$ dissolved in acetonitrile to various concentrations.

Cyclic Voltammetry: Cyclic voltammetry measurements were recorded with an EGG PAR potentiostat (M273 model). The counter electrode was an Au wire, the working electrode a glassy carbon disk, which was carefully polished before each voltammogram with a 1-μm diamond paste, sonicated in an ethanol bath and then washed carefully with ethanol. The reference electrode was an Ag/$AgClO_4$ electrode (0.530 V vs. NHE electrode), isolated in a fritted bridge. The solvent used was distilled acetonitrile and tetrabutylammonium perchlorate was added to obtain a 0.1 M supporting electrolyte.

UV/Visible Spectroscopy: UV/Visible spectra were recorded with a Cary 300 Bio spectrophotometer at 20 °C with 0.1-cm quartz cuvettes.

Supporting Information (see footnote on the first page of this article): The X-band 10 K EPR spectra of millimolar dichloromethane and acetonitrile solutions of complex **1** are presented in Figure S1 (traces b and c, respectively). Theoretical powder X-band EPR spectra calculated for a trinuclear system with two terminal S_{t1} = S_{t2} = 1 and one central S_c = 1/2 spins (ν = 9.39 GHz, T = 10 K) is given in Figure S2.

Acknowledgments

We are grateful to Félix Perez for mass spectrometry measurements, to Guillaume Blain for EPR technical assistance, and to Dr. Alain Boussac (Service de Bioénergétique, URA CNRS 2096, CEA Saclay, Gif-sur-Yvette, France) for EPR facilities. Laurent Sabater is acknowledged for NMR technical assistance. We thank Prof. Jean-Jacques Girerd and Prof. Vincent L. Pecoraro for stimulating discussions. The Conseil Régional de l'Ile de France is acknowledged for its contribution to the acquisition of the Bruker ELEXSYS X-band EPR spectrometer. The COST D21 European action and the LRC-CEA project are acknowledged for their financial support.

A Terephthalato-Bridged Ni^{II} Complex Capped with a Nonchelating Ligand Displays a Three-Dimensional Supramolecular Network Constructed by Coordination and Multi-Intermolecular Forces

Chang Seop Hong,*[a] Jung Hee Yoon,[a] Jeong Hak Lim,[a] and Hyun Hee Ko[a]

Keywords: Magnetic properties / Nickel / Noncovalent interactions / O ligands / Supramolecular chemistry

A new tp-bridged complex $[Ni(pyrazole)_4(tp)]_n$ (**1**; tp = terephthalate) coordinated with a nonchelating pyrazole ligand has been synthesized and characterized using X-ray structure determination and magnetic studies. The crystal structure reveals that the capping ligand functions as a source of hydrogen bonding and intermolecular contacts, such as π–π and CH–π interactions, that result in a three-dimensional supramolecular assembly. Weak antiferromagnetic couplings are transmitted between Ni^{II} centers through the tp linkage.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Coordination polymers have been one of the active research areas applicable to molecular magnets and functional metal–organic frameworks for storage, exchange, and separations.[1,2] The tp ligand is frequently employed in the construction of such complexes due to its diverse binding modes as a linker which allow it to form a variety of structures from discrete molecules to one- (1D), two- (2D), or three-dimensional (3D) networks.[3–7] Interestingly, the molecular dimensionality of coordination polymers bridged by tp can be raised by hydrogen bonding and other intermolecular contacts, such as face-to-face π–π and edge-to-face CH–π interactions.[8,9] The former are realized when lattice water molecules that act as hydrogen donors and acceptors are present in the crystal structures.[10] The use of aromatic bidentate moieties such as 2,2′-bypridine and 1,10-phenanthroline, which fill up coordination spaces around the metal ions, as capping ligands promotes the supramolecular contacts between the aromatic pyridyl groups, which in turn leads to increased dimensionality.[8] It is highly desirable to fabricate dehydrated supramolecular self-assemblies with all these intermolecular interactions (hydrogen bonding, π–π, and CH–π interactions) at the same time as lattice water molecules, which are sources of hydrogen bonds, are easily removed and the crystal lattice could consequently collapse. In this respect, we have selected pyrazole as a capping ligand as it possesses an N–H group for hydrogen bonding and a planar aromatic ring for the other intermolecular interactions.

Here we present the synthesis and detailed structural and magnetic characterization of a new tp-linked dehydrated Ni^{II} compound $[Ni(pyrazole)_4(tp)]_n$ (**1**), which, to the best of our knowledge, is the first example capped by a nonchelating pyrazole ligand among coordinative 1D Ni^{II} systems bridged by tp. The capping ligand plays a crucial role in the formation of the unique 3D supramolecular framework of **1** as it is connected by the combined forces of coordination as well as noncovalent hydrogen bonds and face-to-face π–π and edge-to-face CH–π interactions. Weak antiferromagnetic interactions are operative between the magnetic centers through the long tp bridge.

Results and Discussion

The reaction of Ni^{2+}, pyrazole and dipotassium terephthalate in a ratio of 1:4:1 in water led to the formation of **1**. The strong bands in the IR spectrum centered at 3370 and 3350 cm^{-1} are assigned to the characteristic N–H stretching vibrations of pyrazole, and the presence of the broad bands in the range 2900–2400 cm^{-1} are indicative of hydrogen bonds between the N–H groups of pyrazole and the carboxylate oxygens of tp. The differences (Δ) between the antisymmetric $\nu_a(CO_2^-)$ and symmetric $\nu_s(CO_2^-)$ stretching frequencies in the IR spectrum of **1** are 178 and 203 cm^{-1}. The calculated Δ values, when compared with the reference value (170 cm^{-1}) of dipotassium terephthalate, suggest that the binding mode of tp appears to be monodentate,[11] which was confirmed by X-ray analysis.

A perspective view of **1** together with the atom-labeling scheme is presented in Figure 1. Selected distances and angles are tabulated in Table 1. The specific feature is that two crystallographically different chains exist in the unit cell. Each nickel atom lies on an inversion center and exhib-

its a distorted octahedral geometry consisting of four equatorial nitrogen atoms of pyrazole ligands, with an average Ni–N distance of 2.097(7) Å, and two axial oxygen atoms of the tp bridge, with an average Ni–O distance of 2.109(1) Å. For a chain including Ni1 atoms (Ni1 chain), the dihedral angle (a) between the carboxylate group and the benzene ring of the tp ligand is 21.41(28)°, whereas the other chain with Ni2 atoms (Ni2 chain) has a dihedral angle of 10.25(32)°. The benzene rings of the two chains are tilted with a dihedral angle of 77.20(13)°, and the shortest intrachain Ni···Ni distance is 11.446(2) Å for both chains.

The chains form an extended 3D network structure in which, interestingly, three types of noncovalent forces, namely hydrogen bonds, face-to-face π–π interactions, and edge-to-face CH–π interactions, are involved. As displayed in Figure 2 (a), the 3D molecular view in the *ac* plane can be described as a combination of two sheets that are slanted with respect to each other. Sheet A comprises Ni1 chains and Ni2 chains, with a shortest interchain Ni1···Ni2 distance of 8.060(1) Å (Figure 2, b). There is intrachain hydrogen bonding between unbound carboxylate oxygens and N–H groups of pyrazole in an Ni2 chain. Simultaneously, the free carboxylate oxygen atoms participate in interchain hydrogen bonds to N–H groups in other Ni1 chains, eventually generating a 3D network structure. It is worthwhile to note that interchain edge-to-face CH–π interactions become established between C14–H14 from the pyrazoles and C6-containing benzene rings (2.826 Å), as well as between C3–H3 from the benzene rings and the N5-containing pyrazole rings (3.019 Å). In sheet B, shown in Figure 2 (c), symmetry-related free carboxylate oxygen atoms in an Ni2 chain undergo intrachain and interchain hydrogen bonding to the N–H groups of the pyrazole rings in the same chain and adjacent Ni1 chains, respectively. In comparison with sheet A, sheet B consists of CH–π interactions between pyrazole rings: interchain contacts between C17–H17 from N5-containing pyrazoles and N1-containing pyrazoles (3.007 Å). The C9–H9 moiety from the N1-containing pyrazoles undergoes intrachain contacts with N3-containing pyrazole planes (2.852 Å). For sheets A and B, the distances of the hydrogen bonds are d(D···A) = 2.931(2) Å and ∠(D–H···A) = 134° for N2–H2···O4, d(D···A) = 2.711(2) Å and ∠(D–H···A) = 158° for N6–H6···O4a (–x – 1, –y + 3, –z + 1), d(D···A) = 2.720(2) Å and ∠(D–H···A) = 168° for

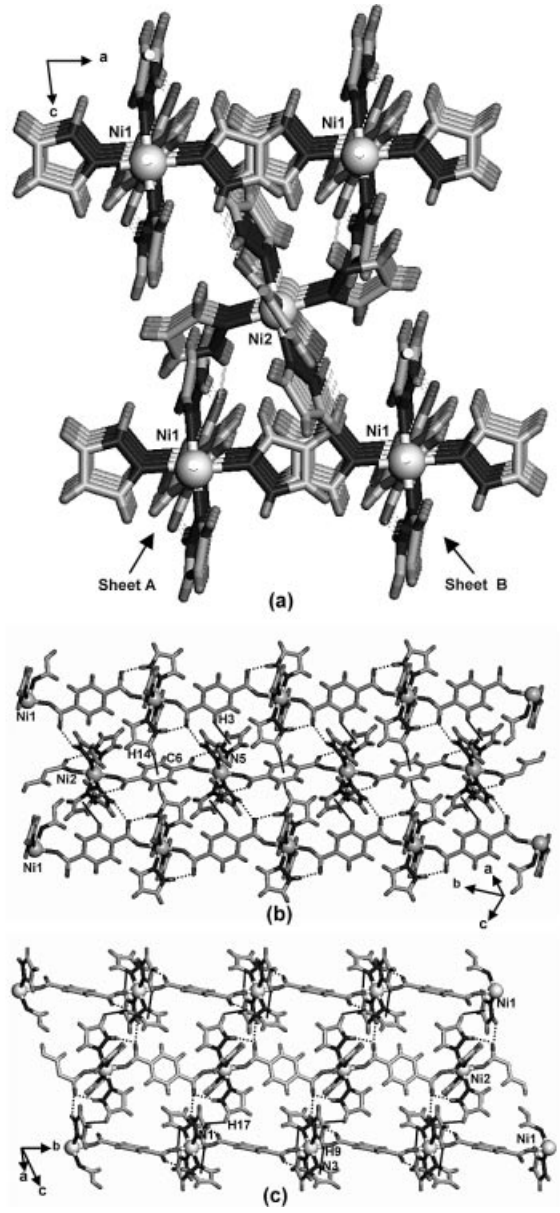

Figure 2. Extended view of **1** showing (a) a 3D network in the *ac* plane, (b) sheet A, and (c) sheet B. Progressively darker shades of grey represent Ni, C, H, N, and O, respectively. The dotted lines indicate hydrogen bonds and the solid lines denote CH–π interactions.

N4–H4A···O2, and d(D···A) = 2.976(2) Å and ∠(D–H···A) = 137° for N8–H8A···O2b (x – 1, y, z). As seen in Figure 3, additional noncovalent interactions correspond to face-to-face π–π stacking between aromatic pyrazole rings residing on the same type of nearest neighbor chains residing in sheets A and B, respectively, where the shortest interchain distance of Ni1(Ni2)···Ni1(Ni2) is equal to 8.467(1) Å. The pyrazole groups associated with π–π interactions are separated by 3.410–3.507 Å, which is consistent with those between 2,2′-bipyridine or 1,10-phenanthroline ligands in tp-bridged Ni^{II} chain compounds.[8] Thus, it should be noted that the capping pyrazole ligand plays a key role in the construction of the 3D supramolecular network structure by allowing multi-intermolecular interactions concurrently.

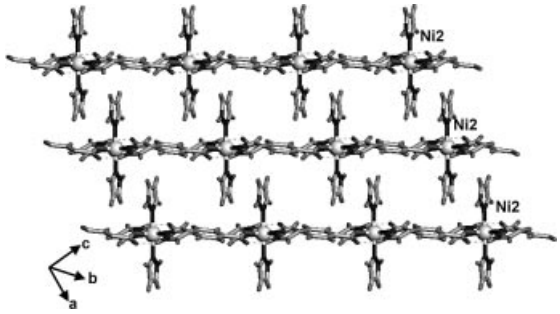

Figure 3. Extended molecular view exhibiting π–π stacking. Progressively darker shades of grey represent Ni, C, H, N, and O, respectively.

The magnetic behavior of **1** is shown in Figure 4 in the form of the temperature dependence of χ_m and $\chi_m T$ at 2000 G in the temperature range 1.8–300 K. At 300 K, the $\chi_m T$ value is 1.24 $cm^3 K mol^{-1}$, which is in the usual range for a noninteracting Ni^{II} ion. The $\chi_m T$ value decreases slowly upon cooling, then drops abruptly below 20 K, finally reaching a value of 0.45 $cm^3 K mol^{-1}$ at 1.8 K, thus indicating the existence of an antiferromagnetic interaction between the magnetic centers. The inverse magnetic susceptibility data obey the Curie–Weiss equation [$\chi_m = C/(T - \theta)$] in the linear region, giving C = 1.24 $cm^3 K mol^{-1}$ and θ = –0.46 K. This definitely demonstrates that adjacent magnetic spins are coupled antiferromagnetically.

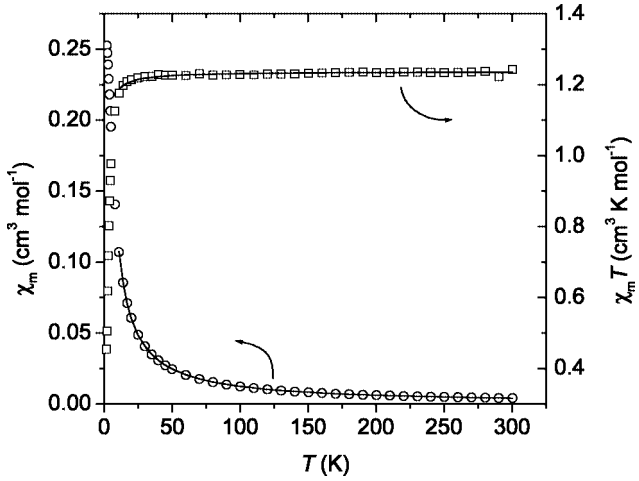

Figure 4. Plots of χ_m and $\chi_m T$ vs. T for **1**. The solid lines show the best theoretical fits.

The magnetic data were fitted to the analytical expression derived by Weng on the basis of the spin Hamiltonian $H = -J \cdot \sum_i S_i \cdot S_{i+1}$, where the local anisotropy is neglected [Equation (1)].[12]

$$\chi_m = \{Ng^2\beta^2/kT\}[2.0 + 0.0194x + 0.777x^2]/ [3.0 + 4.346x + 3.232x^2 + 5.834x^3] \quad (1)$$

in which $x = |J|/kT$. Because this equation does not take into account the zero-field splitting or the Haldane gap, fitting was performed above 10 K. With consideration of a molecular field approximation (zJ'), the magnetic fitting given by the solid line in Figure 4 yields parameters of g = 2.224(1), J = –0.22(1) cm^{-1}, and $zJ' \approx 0$. The use of the infinite chain model derived by Fisher[13] produces similar results of g = 2.224(1), J = –0.24(1) cm^{-1}, and $zJ' \approx 0$ in the same temperature range. Thus, it is evident that a weak antiferromagnetic interaction is operative between the Ni^{II} centers. It is reasonable to assume that the antiferromagnetic behavior occurs via the long tp bridge because, with the given distances, intrachain interactions through covalent linkages are stronger than interchain couplings via the intermolecular contacts, which is consistent with the results reported previously for tp-linked Ni^{II} systems.[3,10,14,15] In comparison with the 1D Ni^{II} macrocyclic complex (J = –1.37 cm^{-1}), where the intrachain Ni–Ni separation is virtually the same (11.5 Å) and a is significantly smaller (5.6°), the weaker antiferromagnetic interaction ($J \approx$ –0.2 cm^{-1}) in **1** arises from the sizeable difference in a (21.41° and 10.25° for **1**).[14]

In summary, we have prepared a tp-bridged Ni^{II} compound with a 3D network structure built by covalent and noncovalent bonds. In particular, the nonchelating capping pyrazole ligand, which contains an N–H group and a planar aromatic ring, behaves as a unique and efficient synthon for noncovalent contacts of hydrogen bonding, face-to-face π–π interactions, and edge-to-face CH–π interactions, thus opening-up an opportunity to create a new class of supramolecular assemblies.

Experimental Section

Physical Measurements: Elemental analyses for C, H, and N were performed at the Elemental Analysis Service Center of Sogang University. Infrared spectra were obtained from KBr pellets with a Bomen MB-104 spectrometer. Magnetic susceptibilities for **1** were carried out using a Quantum Design MPMS-7 SQUID susceptometer. Diamagnetic corrections of **1** were estimated from Pascal's tables.

[Ni(pyrazole)$_4$(tp)]$_n$ (1): Pyrazole (2.0 mmol), dissolved in 5 mL of water, was added, with stirring, to a 10 mL aqueous solution of nickel(II) nitrate hexahydrate (0.50 mmol). The resultant pale-green

Crystal Structures, EPR Spectra, and Magnetic Properties of a Series of Ionic Multi-Component Complexes $[(TBPDA)_2{\cdot}(C_{60}^{\cdot-}){\cdot}(D^+)]$ (D = Cp^*_2Cr, Cp^*_2Co, TDAE)

Dmitri V. Konarev,*[a,b] Andrey Yu. Kovalevsky,[c] Salavat S. Khasanov,[a,d] Gunzi Saito,*[a] Akihiro Otsuka,[a,e] and Rimma N. Lyubovskaya[b]

Keywords: Crystal engineering / EPR spectroscopy / Fullerenes / IR spectroscopy / Magnetic properties / Metallocenes

New ionic multi-component complexes $[(TBPDA)_2{\cdot}(C_{60}^{\cdot-}){\cdot}(D^+)]$ [TBPDA = *N*,*N*,*N*′,*N*′-tetrabenzyl-*p*-phenylenediamine; D = decamethylchromocene (Cp^*_2Cr, **1**) and decamethylcobaltocene (Cp^*_2Co, **2**)] were obtained additionally to previously characterized $[(TBPDA)_2{\cdot}(C_{60}^{\cdot-}){\cdot}(TDAE^{\cdot+})]$ [TDAE = tetrakis(dimethylamino)ethylene, **3**]. The presence of D^+, $C_{60}^{\cdot-}$, and neutral TBPDA in **1**–**3** was proved by the IR and UV/Visible/NIR spectra. D^+ and $C_{60}^{\cdot-}$ form loose layers in **1** and **3** and are spatially separated by bulky TBPDA molecules. The $C_{60}^{\cdot-}$ radical anions alternate in the layer with the phenylene groups of TBPDA to form π-π stacking, whereas disordered $Cp^*_2Cr^+$ cations are isolated in the voids formed by eight benzyl groups of TBPDA. The EPR spectra of the complexes show single Lorentzian lines with g = 2.2526 and ΔH = 215 mT (**1**), g = 1.9999 and ΔH = 6.7 mT (**2**), and g = 2.0009 and ΔH = 2.93 mT (**3**) at room temperature. The EPR signal of **2** was attributed to $C_{60}^{\cdot-}$ ($Cp^*_2Co^+$ is diamagnetic) and those in **1** and **3** to resonating signals between $C_{60}^{\cdot-}$ (g = 1.9996–2.0000) and $Cp^*_2Cr^+$ [an asymmetric EPR signal with $g_\perp$ = 4.02(1) and $g_\parallel$ = 2.001(1)] (**1**) or $TDAE^{\cdot+}$ (g = 2.0035; **3**) due to indirect coupling. The EPR signals from **2** and **3** are split into two components below 50 and 60 K, respectively, which shift in the opposite directions (to lower and higher fields) with decreasing temperature. The magnetic moments of **1**–**3** decrease below 50–100 K. Both effects are associated with the formation of field-induced short-range antiferromagnetically ordered clusters. It is shown that the D^+ cations do not noticeably affect this interaction. Most probably, it is realized mainly between $C_{60}^{\cdot-}$ spins within the layer and is mediated by the phenylene groups of TBPDA.

Introduction

Fullerenes, as acceptors, form molecular and ionic complexes with different donor molecules.[1–3] Ionic complexes are interesting due to their magnetic properties,[4] the reversible formation of diamagnetic single-bonded $(C_{60}^-)_2$ dimers,[5–8] and other types of negatively charged σ-bonded structures.[9] However, only a limited number of organic and organometallic donors can ionize fullerenes in the solid state. These include metallocenes [decamethylnickelocene, Cp^*_2Ni;[10] decamethylchromocene, Cp^*_2Cr;[6,7] decamethylcobaltocene, Cp^*_2Co;[11,12] cobaltocene, Cp_2Co;[7,13] bis(benzene)chromium, $Cr(C_6H_6)_2$,[7,14] and its substituted analogs;[8,15,16] $Fe^ICp(C_6Me_6)$[17]], unsaturated amines [tetrakis(dimethylamino)ethylene, TDAE, and related compounds[4,18]], and some metalloporphyrins.[19,20] We have developed a multi-component approach to modify ionic complexes of fullerenes, in which a neutral D_1 molecule is introduced into an ionic complex to produce a new compound with two donor counterparts: $(D_1){\cdot}(D_2^{\cdot+}){\cdot}(\text{fullerene}^{\cdot-})$.[21–24] In such a complex, D_1 forms a supramolecular packing pattern, whereas D_2 is a strong donor of a small size relative to D_1 that is potentially able to ionize the fullerene moiety. D_1 defines not only the complex structure but in some cases affects the electronic state of the fullerenes. In the series of complexes $[Co^{II}TPP{\cdot}(D_2^+){\cdot}(C_{60}^-){\cdot}\text{solvent}]$ [$Co^{II}TPP$ = cobalt(II) tetraphenylporphyrin; D_2 = $Cr(C_6H_6)_2$[21] or TDAE[22]] $Co^{II}TPP$ forms unusual diamagnetic σ-bonded ($Co^{II}TPP{\cdot}\text{fullerene}^-$) anions, whereas in $[CTV{\cdot}(Cs^+)_2{\cdot}(C_{60(70)}^-)_2{\cdot}(DMF)_x]$ (CTV = cyclotriveratrylene; DMF = *N*,*N*′-dimethylformamide; x = 5–7) we observed the formation of single-bonded $(C_{60}^-)_2$ and $(C_{70}^-)_2$

dimers[23,24] and in [(TBPDA)$_2$·($C_{60}^{\cdot-}$)·($TDAE^{\cdot+}$)] (Figure 1) a short-range antiferromagnetic interaction of the spins was found.[22] In the present work we have studied the incorporation of cations other than $TDAE^{\cdot+}$ into the (TBPDA)$_2$·C_{60} framework. We used two strong donors − Cp^*_2Cr and Cp^*_2Co (Figure 1) − that ionize C_{60} in the solid state[6,7,11,12] and whose cations are comparable in size to the $TDAE^{\cdot+}$ ones but have different spin states ($Cp^*_2Cr^+$: S = 3/2; $Cp^*_2Co^+$: S = 0) relative to that of $TDAE^{\cdot+}$ (S = 1/2). Thus, we can study how cations with different spin states and shapes ($Cp^*_2Cr^+$, $Cp^*_2Co^+$, and $TDAE^{\cdot+}$) can affect the EPR spectra and the magnetic and structural properties of a series of multi-component complexes [(TBPDA)$_2$·($C_{60}^{\cdot-}$)·(D^+)].

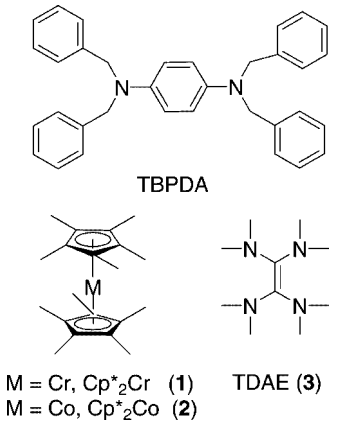

Figure 1. Molecular structures of the components used to prepare **1**–**3**.

The crystal structure of [(TBPDA)$_2$·($C_{60}^{\cdot-}$)·(Cp^*Cr^+)] (**1**) is studied for the first time; the IR and UV/Visible/NIR spectra and the EPR and magnetic susceptibility data down to liquid helium temperatures are presented for **1** and [(TBPDA)$_2$·($C_{60}^{\cdot-}$)·(Cp^*Co^+)] (**2**). These data are compared with those for previously described [(TBPDA)$_2$·($C_{60}^{\cdot-}$)·($TDAE^+$)] (**3**).[22]

Results and Discussion

Synthesis

Complexes **1** and **2** were obtained by a diffusion method in which C_{60}, Cp^*_2M, and an excess of TBPDA dissolved in a mixture of C_6H_6 and C_6H_5CN were precipitated with hexane. Previously, [(TBPDA)$_2$·C_{60}·TDAE] (**3**) was synthesized by the same procedure.[22] The use of smaller Cp_2Co or $Cr(C_6H_6)_2$ molecules under similar conditions did not afford multi-component complexes. Therefore, the size of the D_2 component is important for the stabilization of the [(TBPDA)$_2$·($C_{60}^{\cdot-}$)·(D_2^+)] complexes.

IR and UV/Visible/NIR Spectra

The IR spectra of **1** and **2** in a KBr matrix are a superposition of the spectra of C_{60}, Cp^*_2M, and TBPDA (see Supporting Information). Neutral C_{60} has absorption bands at 527, 577, 1182, and 1429 cm^{-1} [F_{1u}(1–4) modes, respectively]. The F_{1u}(1) and -(2) modes retain their positions (at 526–527 and 575 cm^{-1}), whereas the F_{1u}(4) mode, which is the most sensitive to charge transfer to the C_{60} molecule,[25] is shifted to 1388 cm^{-1} in the spectra of **1** and **2**. The integral intensity of the F_{1u}(2) mode also essentially increases relative to that of the F_{1u}(1) mode. Such changes are characteristic of $C_{60}^{\cdot-}$.[25] The formation of $C_{60}^{\cdot-}$ is justified by the appearance of additional bands in the UV/Visible/NIR spectra of **1** and **2** at 10.75–10.77 × 10^3 and 9.20 × 10^3 cm^{-1}.

Cp^*_2Cr has one band in the IR spectrum that is sensitive to charge transfer and is shifted from 418 to 437 cm^{-1} due to the transition from a neutral to a cationic form in **1** as well as in ($Cp^*_2Cr^+$)·(PF_6^-)[26] and ($Cp^*_2Cr^+$)·($C_{60}^{\cdot-}$)·($C_6H_4Cl_2$)$_2$.[6,7] Similarly, the band of Cp^*_2Co in the IR spectrum is shifted from 429 to 442, 448, and 445 cm^{-1} in **2**, ($Cp^*_2Co^+$)·(PF_6^-),[26] and [($Cp^*_2Co^+$)$_2$·(C_{60}^{2-})·($C_6H_4Cl_2$, C_6H_5CN)$_2$],[12] respectively. The absorption bands of TBPDA in the IR spectrum are shifted by up to 10 cm^{-1} in **1** and **2** relative to those in the spectrum of neutral TBPDA·(C_{60})$_2$.[27] This is probably associated with the different geometry of TBPDA in **1**, **2**, and TBPDA·(C_{60})$_2$. The absence of additional absorption bands in the IR and UV/Visible/NIR spectra of **1** and **2**, which must accompany the dimerization or polymerization of $C_{60}^{\cdot-}$,[28] indicates their monomeric nature at room temperature (room temp.). Complex **3**[22] has IR and UV/Visible/NIR spectra similar to those of **1** and **2**.

Crystal Structures

Complex **1** crystallizes in a tetragonal system in the $I\bar{4}$ space group and has a structure similar to that of [(TBPDA)$_2$·C_{60}·TDAE] (**3**)[22] (see Figures 2 and 3). $C_{60}^{\cdot-}$ and $Cp^*_2Cr^+$ (**1**) or $TDAE^{\cdot+}$ (**3**) occupy positions with $\bar{4}$ or 4/m symmetry and are statistically disordered in both structures as they lie on a symmetry position higher than their own symmetry. Complex **1** has a more complicated disorder pattern than **3**. A fourfold inversion axis passes through the midpoints of oppositely located 6-6 bonds of $C_{60}^{\cdot-}$ and the central C=C bond of $TDAE^{\cdot+}$ in **3** and coincides with the twofold symmetry axes of these ions. The rotation of both ions by 90° about a fourfold axis generates two orientations with equal occupancies.[22] In contrast to **3**, the fourfold inversion axis in **1** passes through the midpoints of oppositely located 6–5 bonds of C_{60} and the Cr atom of $Cp^*_2Cr^+$ to form an angle of about 85° with a fivefold symmetry axis of $Cp^*_2Cr^+$ (as shown in Figure 4). In this case, the symmetry operation generates four orientations of the $C_{60}^{\cdot-}$ and $Cp^*_2Cr^+$ ions with equal occupancies. The ordered TBPDA molecules occupy positions with 2/m symmetry.

The unit-cell parameters a and b (see Experimental Section) are larger by 0.35 Å in **1** than in **3**, whereas the parameter c is smaller by 0.32 Å. The unit-cell volume of **1** is increased by about 180 Å^3 relative to that of **3**, thus indicat-

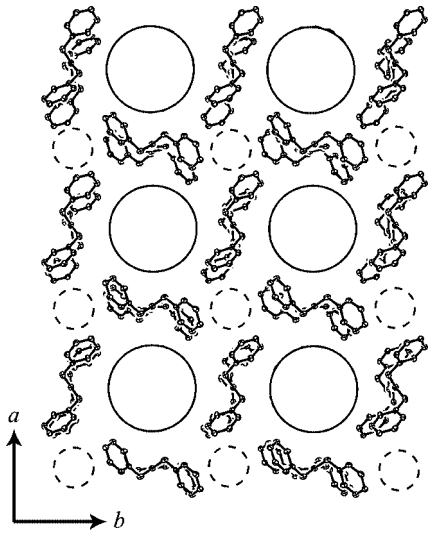

Figure 2. General view of the crystal structures of **1** and **3** on the *ab* plane. The positions of disordered $C_{60}^{\cdot-}$ radical anions are shown by large circles and those of the cations ($Cp^*_2Cr^+$ and $TDAE^{\cdot+}$) are shown by smaller dashed circles.

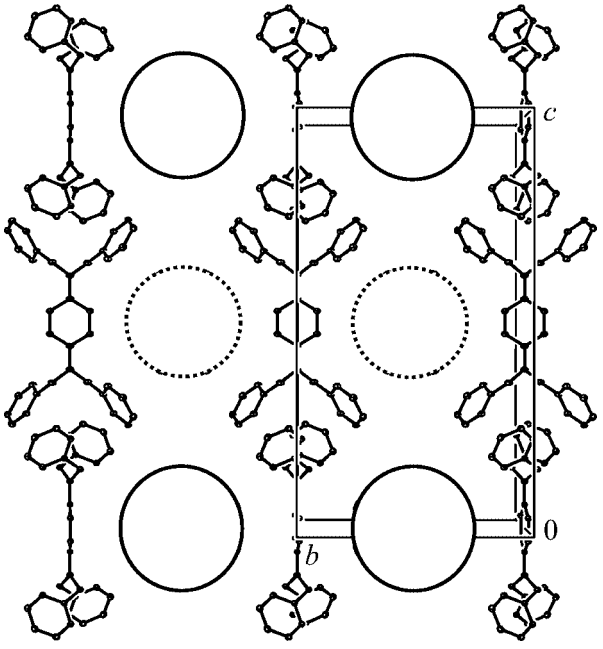

Figure 3. General view of the crystal structures of **1** and **3** on the *bc* plane. The positions of disordered $C_{60}^{\cdot-}$ radical anions are shown by large circles and those of the cations ($Cp^*_2Cr^+$ and $TDAE^{\cdot+}$) are shown by smaller dashed circles.

ing that $Cp^*_2Cr^+$ is slightly larger than $TDAE^{\cdot+}$. $C_{60}^{\cdot-}$, $Cp^*_2Cr^+$ ($TDAE^{\cdot+}$), and TBPDA form square loose layers in **1** and **3** parallel to the *ab* plane (Figure 2). The $C_{60}^{\cdot-}$ radical anions are separated from each other [the shortest center-to-center distance between adjacent fullerenes in the layer is 13.973(2) Å in **1** and 13.626(2) in **3**] and alternate with the central phenylene (-C_6H_4-) groups of TBPDA along the *a* and *b* directions (Figure 2). Consequently, each $C_{60}^{\cdot-}$ forms van der Waals contacts with four phenylene groups of the adjacent TBPDA molecules. The hexagons of

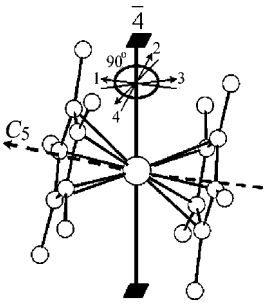

Figure 4. Disorder of the $Cp^*_2Cr^+$ cations. A fourfold inversion axis (solid line) and a fivefold symmetry axis of $Cp^*_2Cr^+$ (dashed line) are shown. Both axes form an angle of ca. 85°. Four positions of $Cp^*_2Cr^+$ with equal occupancies obtained by its rotation by 90° about a fourfold axis are marked by the numbers from 1 to 4.

$C_{60}^{\cdot-}$ and the phenylene groups of TBPDA are nearly parallel in **3** (the corresponding dihedral angle is only 5°), thus indicating the presence of π-π interactions. The C(TBPDA)···$C(C_{60}^{\cdot-})$ contacts lie in the range 3.43–3.68 Å (the sum of the van der Waals radii of two sp^2 carbon atoms is 3.42 Å[29]). Large disorder in **1** does not allow the estimation of the C···C contacts and angles. Nevertheless, the C···C contacts should be slightly larger than those in **3** due to the larger unit-cell parameters *a* and *b*.

Each $Cp^*_2Cr^+$ moiety is located within the layer in the cavities formed by eight benzyl groups of TBPDA (Figure 2). All C(TBPDA)···C($Cp^*_2Cr^+$ or $TDAE^{\cdot+}$) contacts are large (>3.70 Å) to prevent π-π interactions between the Cp* rings and TBPDA fragments. Therefore, the $Cp^*_2Cr^+$ cations are separated from each other. The interlayer space is filled with the benzyl groups of TBPDA (Figure 3). The ordered TBPDA molecules retain pristine geometry, thus showing their neutral state in the complex. Only the torsion angles of the benzyl groups of the TBPDA molecule in **1** are smaller (73°) than those in neutral TBPDA (85–87°).[30] Such changes are probably caused by packing forces.

A schematic view of the crystal structures of **1** and **3** along the *a* direction is shown in Figure 3. The chains of alternating $C_{60}^{\cdot-}$ and D^+ ions can be seen along the *c* direction. These chains are separated from the neighboring ones by bulky TBPDA molecules. The distances between the $C_{60}^{\cdot-}$ and D^+ ions in the chains are rather large [all intermolecular C(C_{60})···C(D^+) contacts are longer than 5 Å]. Thus, **1** and **3** are dilute systems in which the $C_{60}^{\cdot-}$ and D^+ ions are separated in three directions by the TBPDA molecules. Nevertheless, the $C_{60}^{\cdot-}$ radical anions alternate and form π-π interactions with the phenylene groups of TBPDA, which can mediate magnetic coupling between $C_{60}^{\cdot-}$ spins within the layer. The TBPDA molecules can probably also mediate weak coupling between spins localized on $C_{60}^{\cdot-}$ and D^+.

Magnetic Properties

The magnetic properties of polycrystalline **1**, **2**, and **3**[33] sealed in quartz tubes under 10^{-5} Torr vacuum were studied by EPR (Table 1, Figures 5 and 6) and SQUID (Figure 7)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

techniques from room temp. down to liquid helium temperatures.

Table 1. EPR parameters of **1**–**3**.

Complex	290 K		4 K	
	g factor	ΔH [mT]	*g* factor	ΔH [mT]
$[(TBPDA)_2{\cdot}C_{60}{\cdot}Cp^*_2Cr]$ (**1**)	1.9999	6.7	1.9985	0.42
			1.9950	0.51
$[(TBPDA)_2{\cdot}C_{60}{\cdot}Cp^*_2Co]$ (**2**)	2.2526	215	2.7563	168
$[(TBPDA)_2{\cdot}C_{60}{\cdot}TDAE]$ (**3**)[22]	2.0009	2.93	2.0063	0.76
			1.9966	0.21

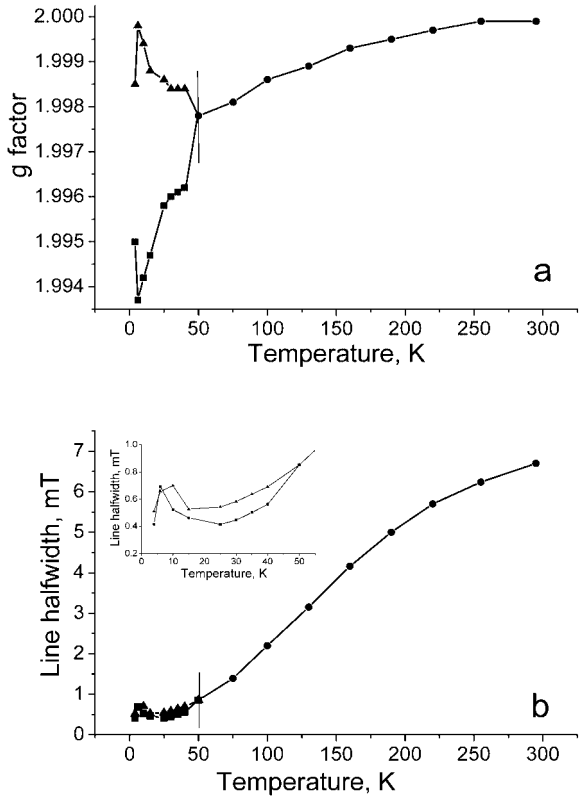

Figure 5. Temperature dependence of the *g*-factor (a) and line halfwidth (b) for $[(TBPDA)_2{\cdot}C_{60}{\cdot}Cp^*_2Co]$ (**2**) in the 4–295 K range.

Complex **2** shows a broad Lorentzian line with g = 1.9999 and line halfwidth (ΔH) of 6.7 mT (Figure 5). This signal is characteristic of $C_{60}^{\cdot-}$, which has a *g*-factor in the range 1.9996–2.0000 and ΔH of 3–5 mT at room temp.[2,3] Diamagnetic and EPR silent $Cp^*_2Co^+$ makes no contribution to the EPR spectrum of **2**.

The EPR signal of **3** has a larger *g*-factor of 2.0009 and a narrower line (ΔH = 2.93 mT).[22] $TDAE{\cdot}C_{60}$ has a similar EPR signal (g = 2.0003 and ΔH = 2.2 mT at room temp.[31]). Both signals can be attributed to resonating ones between $C_{60}^{\cdot-}$ and $TDAE^{\cdot+}$ ion-radicals due to an intermediate *g*-factor value ($C_{60}^{\cdot-}$ has a *g*-factor of 1.9996–2.0000 and $TDAE^{\cdot+}$ of 2.0035[32]). The resonating signal is characteristic of exchange coupling between $TDAE^{\cdot+}$ and $C_{60}^{\cdot-}$ ion-radicals. This coupling in $TDAE{\cdot}C_{60}$ can be realized directly between both ion-radicals due to short C···C contacts (3.401–3.482 Å[33]) and the overlapping of their π-orbitals.

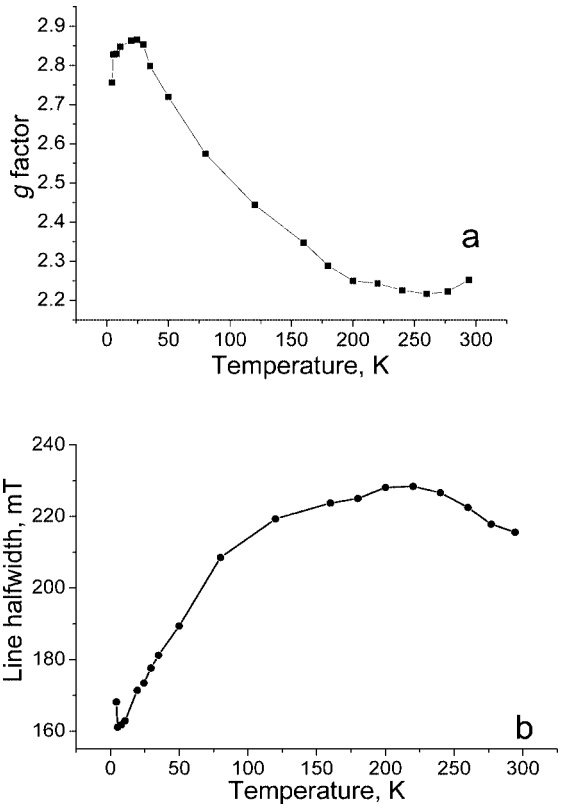

Figure 6. Temperature dependence of the *g*-factor (a) and line halfwidth (b) for $[(TBPDA)_2{\cdot}C_{60}{\cdot}Cp^*_2Cr]$ (**1**) in the 4–295 K range.

The distances between ion-radicals in **3** are large and in this case we can suppose only indirect coupling (for example, through the TBPDA molecules). Indirect coupling through nonmagnetic ligands has previously been observed even in clusters.[34]

The EPR spectrum of **1** contains a single Lorentzian line with g = 2.2526 and ΔH = 215.6 mT at room temp. (Figure 6). A similar EPR signal has been observed for a high-temperature monomeric phase of $[Cp^*_2Cr{\cdot}C_{60}{\cdot}(C_6H_4Cl_2)_2]$ (g = 2.2210 and $\Delta H \approx$ 100 mT at 320 K[24]). The observed *g*-factors are intermediate between those of $C_{60}^{\cdot-}$ and Cp^*_2Cr {an asymmetric EPR signal with $g_\perp$ = 4.02(1) and $g_\parallel$ = 2.001(1)[26]}, thus implying a resonating signal between these ions. Exchange coupling between the $Cp^*_2Cr^+$ and $C_{60}^{\cdot-}$ ions can be realized directly in $[Cp^*_2Cr{\cdot}C_{60}{\cdot}(C_6H_4Cl_2)_2]$ as the shortest C···C distance is 3.049(6) Å[6] and only indirectly in **1** due to the large distances between the ions, similar to **3**.

The EPR signal of **2** essentially narrows with decreasing temperature and the *g*-factor shifts monotonically to 1.9978 at 50 K (Figure 5). A similar behavior of ΔH has been observed for **3** and other solid ionic complexes of C_{60}.[2] The EPR signal becomes asymmetric below 50 K and splits into two components (see Supporting Information). These components shift in the opposite directions (to higher and lower magnetic fields) with decreasing temperature (g = 1.9985 and 1.9950 at 4 K, Figure 5a). The shifts are accompanied by a small broadening of both components (Figure 5b). The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

magnetic moment of **2** (μ_{eff} = 1.65 μ_B at 300 K) is nearly temperature independent down to around 100 K and begins to decrease below this temperature (Figure 7b). Both effects in SQUID and EPR originate from the antiferromagnetic interaction of spins. Such a behavior can be attributed to the formation of a field-induced short-range antiferromagnetically ordered cluster.[35,36] The behavior of **3** is very similar. The temperatures of the splitting of the EPR signal and the decrease of the magnetic moment are 60 and about 80 K, respectively (Figure 7c).[22]

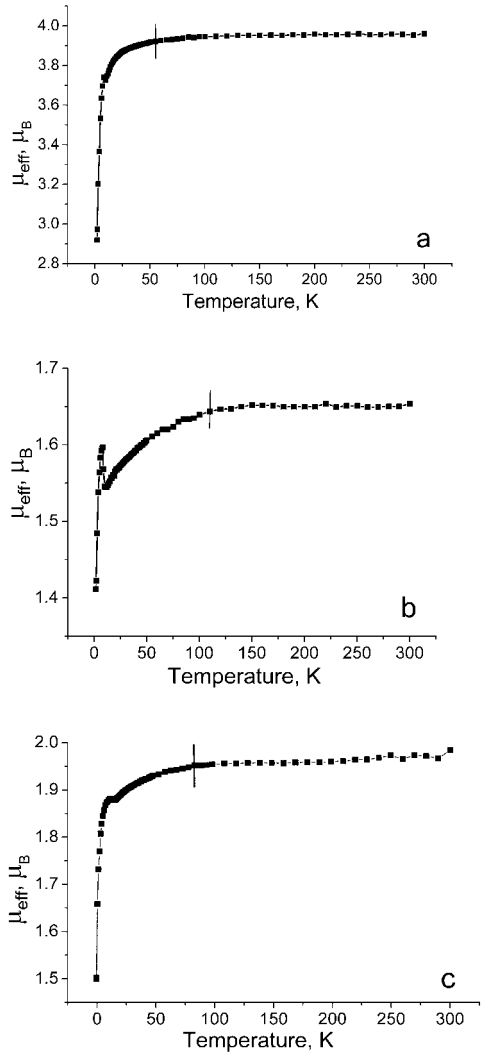

Figure 7. Temperature dependence of the magnetic moments of **1** (a), **2** (b), and **3** (c) in the 1.9–300 K range. Vertical bars show the temperature for a decrease of the magnetic moment.

The EPR signal of **1** shifts to larger *g*-factors with decreasing temperature (g = 2.7563 at 4 K, Figure 6a), whereas ΔH remains very broad in the whole temperature range (approx. 160–230 mT; Figure 6, b). The magnetic moment of **1** (μ_{eff} = 3.96 μ_B at 300 K) indicates a contribution from $Cp^*_2Cr^+$ (S = 3/2) and $C_{60}^{\cdot-}$ (S = 1/2) (μ_{eff} = 4.27 μ_B for a system of noninteracting S = 3/2 and 1/2 spins). Ionic $[Cp^*_2Cr{\cdot}C_{60}{\cdot}(C_6H_4Cl_2)_2]$[7] and $[Cr^{III}TPP{\cdot}C_{60}{\cdot}(THF)_3]$ [Cr^{III}TPP = tetraphenylporphyrinatochromium(III)][20] have similar magnetic moments equal to 4.20 μ_B. The magnetic moment of **1** is temperature independent down to around 50 K and decreases below this temperature due to the antiferromagnetic interaction of spins (Figure 7, a). However, the EPR signal of **1** is unsplit down to 4 K, probably due to a very large ΔH value.

An antiferromagnetic character of interaction of spins in **1**–**3** was justified by SQUID measurements. The complexes show small negative Weiss constants of –0.7 K for **1**, –1.8 K for **2**, and –2.3 K for **3**.

Conclusion

Two new ionic multi-component complexes $[(TBPDA)_2{\cdot}(C_{60}^{\cdot-}){\cdot}(D^+)]$ containing decamethylchromocene (Cp^*_2Cr, **1**) and decamethylcobaltocene (Cp^*_2Co, **2**) have been obtained. Together with previously characterized $[(TBPDA)_2{\cdot}(C_{60}^{\cdot-}){\cdot}(TDAE^{\cdot+})]$ (**3**), they form a series of multi-component complexes with cations of different shape and spin state. The optical absorption spectra of **1**–**3** in the IR and UV/Visible/NIR ranges prove the presence of D^+, $C_{60}^{\cdot-}$, and neutral TBPDA. The D^+ and $C_{60}^{\cdot-}$ ions in the crystal structures of **1** and **3** form loose layers that are spatially separated by the bulky TBPDA molecules. As this takes place, the $C_{60}^{\cdot-}$ radical anions alternate with the phenylene groups of TBPDA to form π-π stacking interactions with them, whereas the D^+ cations are spatially and magnetically isolated in the voids formed by eight benzyl groups of TBPDA. The complexes show single Lorentzian EPR lines with g = 1.9999 and ΔH = 6.7 mT (**2**), g = 2.0009 and ΔH = 2.93 mT (**3**), and g = 2.2526 and ΔH = 215 mT (**1**) at room temp. Two-component ionic complexes of C_{60}, namely $TDAE{\cdot}C_{60}$[31] and $[Cp^*_2Cr{\cdot}C_{60}{\cdot}(C_6H_4Cl_2)_2]$[24] have EPR signals similar to those of **3** and **1**. The EPR signal in **2** was attributed to $C_{60}^{\cdot-}$ as $Cp^*_2Co^+$ is diamagnetic and therefore EPR silent. The EPR signals in **1** and **3** and in corresponding two-component complexes were assigned to resonating signals between $C_{60}^{\cdot-}$ and D^+ ($Cp^*_2Cr^+$ or $TDAE^{\cdot+}$). In two-component complexes this is a result of direct exchange coupling between $C_{60}^{\cdot-}$ and D^+, which is possible due to short intermolecular contacts between them and the overlapping of their π-orbitals. Complexes **1** and **3** are dilute systems with large spatial separation between the $C_{60}^{\cdot-}$ and D^+ ions. In this case only indirect coupling can be supposed through the TBPDA molecules. Below 60 K (**3**) and 50 K (**2**), the EPR signals are split into two components that shift in opposite directions to lower and higher fields. The magnetic moments of **1**–**3** also decrease below 50–100 K. These phenomena can be explained by the formation of field-induced short-range antiferromagnetically ordered clusters. The substitution of paramagnetic $Cp^*_2Cr^+$ and $TDAE^{\cdot+}$ by diamagnetic $Cp^*_2Co^+$ does not noticeably affect the antiferromagnetic interaction of the spins in **1**–**3**. In accordance with X-ray diffraction data, this interaction is realized mainly between $C_{60}^{\cdot-}$ spins within the layer through the phenylene groups of TBPDA as the D^+ cations are surrounded by benzyl groups of TBPDA and are not involved in this interaction. Nevertheless, the TBPDA mole-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cules probably mediate weak exchange coupling between the $C_{60}^{\cdot-}$ and D^+ spins seen by EPR. The large distances between $C_{60}^{\cdot-}$ and D^+ in **1**–**3** and the mediation of magnetic coupling through the diamagnetic TBPDA molecules are reasons for the relatively weak magnetic interaction of spins with Weiss constants from –0.7 to –2.3 K.

Experimental Section

General: Decamethylchromocene (Cp^*_2Cr) and decamethylcobaltocene (Cp^*_2Co) were purchased from Strem Chemicals, *N*,*N*,*N*′,*N*′-Tetrabenzyl-*p*-phenylenediamine (TBPDA) was purchased from Lancaster and C_{60} of 99.98% purity from MTR Ltd. Solvents were purified under argon. Benzonitrile (C_6H_5CN) was distilled from Na under reduced pressure; benzene and hexane were distilled from Na/benzophenone. The solvents were degassed and stored in a glove box. Synthesis of the complexes was carried out in an MBraun 150B-G glove box with controlled atmosphere (content of H_2O and O_2 less than 1 ppm). The crystals were stored in the glove box and were sealed in 2 mm quartz tubes for EPR and SQUID measurements at 10^{-5} Torr. KBr pellets for IR and UV/Visible/NIR measurements were prepared in the glove box.

UV/Visible/NIR spectra were measured on a Shimadzu-3100 spectrometer in the 240–2600 nm range. FT-IR spectra were measured as KBr pellets with a Perkin–Elmer 1000 Series spectrometer (400–7800 cm^{-1}). A Quantum Design MPMS-XL SQUID magnetometer was used to measure static susceptibilities of **1** and **2** between 300 and 1.9 K in a 0.1 T static magnetic field. A sample holder contribution and core temperature independent diamagnetic susceptibility (χ_0) were subtracted from the experimental values. The values of Θ and χ_0 were calculated from the high-temperature range using the formula $\chi_M = C/(T - \Theta) + \chi_0$. EPR spectra were recorded from room temp. down to 4 K with a JEOL JES-TE 200 X-band ESR spectrometer equipped with a JEOL ES-CT470 cryostat.

Synthesis: Crystals of [(TBPDA)$_2$·C_{60}·Cp^*_2Cr] (**1**) and [(TBPDA)$_2$·C_{60}·Cp^*_2Co] (**2**) were obtained by slow diffusion of hexane (20 mL) into 20 mL of a C_6H_6/C_6H_5CN mixture (4:1) containing C_{60} (25 mg, 0.035 mmol), Cp^*_2M (0.037 mmol), and TBPDA (120 mg, 0.255 mmol). The starting solution was prepared by dissolving C_{60} and Cp^*_2M in 4 mL of C_6H_5CN by stirring at 60 °C for 4 h. After this 16 mL of benzene was added and TBPDA was dissolved by stirring overnight at 60 °C. The obtained solution was cooled down to room temperature and filtered. Diffusion was carried out in a glass tube of 1.8 cm diameter and 50 mL volume with a ground glass plug during one month. The solvent was decanted and the crystals were washed with hexane and dried to yield black square thick plates of complexes **1** and **2** in 60–80% yield.

[(TBPDA)$_2$·C_{60}·Cp^*_2Cr] (1980.3): calcd. C 89.80, H 4.75, Cr 2.62, N 2.83; found C 89.41, H 4.86, N 2.69.

[(TBPDA)$_2$·C_{60}·Cp^*_2Co] (1987.2): calcd. C 89.48, H 4.73; Co 2.97, N 2.82; found C 89.00, H 4.65, N 2.64.

The composition of **1** and **2** was determined from the elemental analysis, and was justified for **1** by X-ray diffraction on a single crystal. The synthesis of crystals of **3** has been described elsewhere.[22]

X-ray Crystallographic Study of 1: $C_{148}H_{94}CrN_4$, M_r = 1980.27, black square plates, tetragonal, space group $I\bar{4}$. Unit cell parameters $a = b$ = 13.9732(3), c = 24.3682(11) Å, V = 4757.9(3) Å^3, Z = 2, D_c = 1.382 g cm^{-3}, μ = 0.186 mm^{-1}, and $F(000)$ = 2068. X-ray diffraction data for **1** were collected at 90(1) K using a Bruker SMART1000 CCD diffractometer installed at a rotating anode source (Mo-K_α radiation, λ = 0.71073 Å), and equipped with an Oxford Cryosystems nitrogen gas-flow apparatus. The data were collected by the rotation method with a 0.3° frame-width (ω scan) and 10 s exposure time per frame. Four sets of data (600 frames in each set) were collected, nominally covering half of the reciprocal space. The data were integrated, scaled, sorted, and averaged using the SMART software package.[37] In total, 42648 reflections were measured up to $2\Theta_{max}$ = 59.98°, 6879 of which were independent. The structure was solved by direct methods using SHELXTL NT Version 5.10.[38] The structure was refined by full-matrix least-squares against F^2. Non-hydrogen atoms were refined in the anisotropic approximation. Positions of hydrogen atoms were calculated geometrically. Subsequently, the positions of H atoms were refined by the "riding" model with U_{iso} = 1.2 U_{eq} of the connected non-hydrogen atom or as ideal CH_3 groups with U_{iso} = 1.5 U_{eq}. The least-squares refinement on F^2 was done to $R_1[I > 2\sigma(F)]$ = 0.0885 for 5626 observed reflections with $F > 2\sigma(F)$, wR_2 = 0.2358 and R_1 = 0.1053 for all 6879 observed reflections with 482 parameters and 7956 restraints; final GoF = 1.078.

CCDC-275769 contains the supplementary crystallographic data for compound **1**. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (for details see the footnote on the first page of this article): IR, UV/Visible/NIR, and EPR spectroscopic data of complexes **1**–**3** (Tables S1 and S2 and Figures S1–S4).

Kinetic Inertness and Electrochemical Behavior of Copper(II) Tetraazamacrocyclic Complexes: Possible Implications for in Vivo Stability

Katrina S. Woodin,[a] Katie J. Heroux,[a] C. Andrew Boswell,[b] Edward H. Wong,*[a] Gary R. Weisman,*[a] Weijun Niu,[a] Sterling A. Tomellini,[a] Carolyn J. Anderson,[b] Lev N. Zakharov,[c] and Arnold L. Rheingold[c]

Keywords: Macrocyclic ligands / N ligands / Copper

The kinetic inertness of copper(II) complexes of several carboxymethyl-armed cyclams and cyclens in 5 M HCl have been determined confirming that the complex derived from cross-bridged cyclam (Cu-CB-TE2A) is by far the most resistant to acid decomplexation. FT-IR studies in D_2O solution revealed its unique resistance to full carboxylate protonation and its retention of coordination by both pendant arms even in 1 M DCl. The X-ray structure of its monoprotonated form, [Cu-CB-TE2AH]$^+$, also established full coordination by both COO^- and COOH pendant arms in the solid state. Cyclic voltammograms of four carboxymethyl pendant-armed cyclam and cyclen complexes in aqueous solution were obtained with only Cu-CB-TE2A displaying a quasi-reversible Cu^{II}/Cu^{I} reduction wave. These indicators correlate with the superior in vivo behavior of this complex and its bifunctional conjugate.

Introduction

Carboxymethyl pendant-armed derivatives of tetraazamacrocycles are promising chelators for copper(II)-based radiopharmaceuticals.[1,2] The 14-membered macrocycle (cyclam) derivative TETA (Figure 1) has been evaluated as a ^{64}Cu-carrier by in vivo studies.[1] Despite its high in vitro thermodynamic stability, significant in vivo loss of radio-metal from both ^{64}Cu-TETA and its bifunctional conjugates was observed.[2] In addition to Cu^{II} dissociation from the chelator, its reduction and subsequent complex destabilization prior to Cu^{I} loss may also be a pathway for loss of radio-copper. The latter demetallation mode has been implicated in the selective trapping of ^{64}Cu from its bis(thiosemicarbazone) complexes in hypoxic cells.[3,4] We therefore hypothesize that *both* kinetic inertness to Cu^{II} dissociation in aqueous solution as well as resistance towards Cu^{II}/Cu^{I} reduction and subsequent Cu^{I} loss are useful indicators of desirable in vivo performance of a potential copper-based radiopharmaceutical.

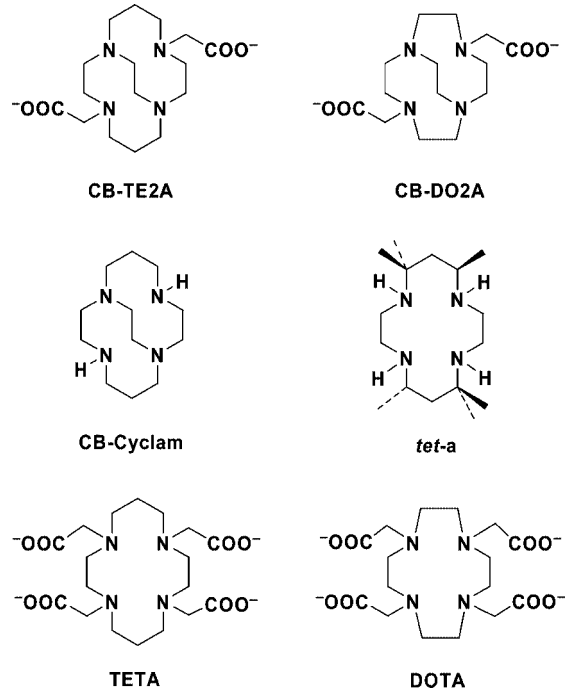

Figure 1. The cross-bridged ligands CB-TE2A, CB-DO2A, and CB-Cyclam with TETA, DOTA, and *tet*-a.

Recently we reported the superior in vivo behavior of a ^{64}Cu-labeled chelator CB-TE2A (Figure 1) and a bioconjugate compared to TETA, DOTA, as well as CB-DO2A analogues.[5–7] Briefly, the respective ligands were labeled

 © 2005 Wiley-VCH Verlag GmbH & Co. KgaA, Weinheim

with ^{64}Cu and injected into rats, the animals were sacrificed at appropriate time points, and the biodistribution and metabolism of the labeled complexes assayed out to 20 h post-injection. It was found that ^{64}Cu-CB-TE2A and its bioconjugate showed a marked improvement in both clearance and resistance to demetallation. Presence in the chelator of both a cross-bridged cyclam backbone and at least one carboxymethyl pendant arm appears to be essential for this enhanced performance. To gain insight into these observations and to develop convenient indicators for bio-stability, we have initiated kinetic inertness as well as electrochemical studies of this and related copper complexes in aqueous media. We report herein the extraordinary kinetic inertness of Cu-CB-TE2A to acid decomplexation as well as its unique electrochemical behavior compared to Cu-TETA and their related cyclen analogues, Cu-CB-DO2A and Cu-DOTA (Figure 1).

Table 1. Half-lives of copper(II) complexes.

Complex	Half-life
5 M HCl, 90 °C	
Cu-CB-TE2A	154(6) h
Cu-TETA	4.5(5) min
Cu-DOTA	< 1 min
Cu-CB-cyclam	11.8(2) min
Cu-*tet*-a	1.1(1) h
5 M HCl, 50 °C	
Cu-TETA	3.2(1) h
Cu-*tet*-a	83.7(6) h
5 M HCl, 30 °C	
Cu-TETA	3.5(2) days
Cu-CB-cyclam	18.5(7) days
Cu-CB-DO2A	< 2 min
Cu-cyclam	2.7(1) days
1 M HCl, 30 °C	
Cu-CB-DO2A	4.0(1) h

Results and Discussion

The primary aim of this work is to develop a convenient and practical, albeit qualitative, assay of in vitro inertness for predicting the suitability of each new copper chelator in follow-up biological studies. Since aqueous acid-assisted decomplexation of polyazamacrocyclic copper complexes is a convenient and useful indicator of their kinetic inertness,[8,9] we chose to compare the decomplexation half-lives of Cu-CB-TE2A and analogues under pseudo first-order conditions in 5 M HCl (Table 1). As the detailed decomplexation mechanisms have not yet been elucidated, the data must be interpreted with caution. Nonetheless, we can readily conclude that Cu-CB-TE2A is by far the most kinetically inert amongst the carboxymethyl pendant-armed tetraazamacrocyclic complexes studied, with the relative order: Cu-CB-TE2A >> Cu-DOTA ≈ Cu-TETA > Cu-CB-DO2A. It is noteworthy that even the extremely robust red isomer of Cu-*tet*-a (Figure 1) decomposed more rapidly under these strongly acidic conditions.[8,10] Neither Cu-CB-Cyclam nor Cu-CB-DO2A showed comparable inertness to Cu-CB-TE2A, suggesting that both the carboxymethyl pendant arms and the bicyclo[6.6.2] cross-bridged cyclam backbone are essential for Cu-CB-TE2A's exceptional robustness. Sargeson and co-workers have reported encapsulated Cu^{II} complexes of hexaaza cage ligands which are also extremely inert to acid decomplexation,[11,12] although direct comparisons with Cu-CB-TE2A have not yet been made.

To gain insight into the speciation of these complexes in acidic aqueous media, FT-IR spectra of Cu-CB-TE2A, Cu-CB-DO2A, Cu-TETA, and Cu-DOTA in DCl/D_2O solutions were examined in the 1550–1800 cm^{-1} region. In 0.1 M DCl, all complexes revealed prominent ν_{asym}(COO) bands due to coordinated carboxylate (1598–1620 cm^{-1}) as well as protonated carboxylic acid (1688–1724 cm^{-1}) bands (Figure 2, a and Figure 3). While Cu-CB-DO2A decomposed in 1.0 M DCl within hours, both the Cu-TETA and Cu-DOTA spectra showed carboxylic acid bands (1685–1727 cm^{-1}) as the only major features (Figure 3). The splitting of these carboxylic acid bands is due to the presence of both coordinated as well as uncoordinated pendant arms. By contrast, the Cu-CB-TE2A complex exhibited both carboxylate (1611 cm^{-1}) and carboxylic acid (1702 cm^{-1}) bands (Figure 2, b). Since the free ligand CB-TE2A displayed distinct carboxylate (at pD 12, not shown) and carboxylic acid (1.0 M DCl, Figure 2, b) bands at 1574 and 1718 cm^{-1}, respectively, we can infer retention of *both* carboxylate and carboxylic acid pendant arm coordination at the copper center of Cu-CB-TE2A.

tonated complex $[Cu\text{-}CB\text{-}TE2AH]ClO_4$. Its X-ray structure (Figure 4) confirmed the weak coordination of the carboxylic acid pendant arm with a Jahn–Teller elongated Cu(1)–O(3) bond length of 2.525(2) Å as well as strong coordination of the remaining carboxylate arm with a much shorter Cu(1)–O(1) bond at 1.966(2) Å. The C(16)–O(3) distance of 1.219(3) Å relative to C(16)–O(4) of 1.306(3) Å confirmed carbonyl coordination of the COOH group. For comparison, the parent Cu-CB-TE2A complex has less pronounced Jahn–Teller elongated copper-carboxylate bond lengths of 2.30–2.33 Å and undistorted bonds of 2.00–2.01 Å.[13] In both structures, the metal cation fits snugly inside the cross-bridged cyclam ligand's cleft as indicated by nearly linear *trans*-N–Cu–N angles (173–182°). Additional structural data for the $[Cu\text{-}CB\text{-}TE2AH]^+$ cationic complex are listed in Table 2.

The solid-state IR spectrum of the monoprotonated complex displayed both coordinated carboxylate and carboxylic acid COO stretches at 1616 and 1694 cm^{-1}, respectively, reasonably close to the 1.0 M DCl solution values of 1611 and 1702 cm^{-1}. This further supports retention of both carboxylate and carboxylic acid pendant arm coordination of Cu-CB-TE2A in DCl solution. As acid-assisted decomplexation of carboxylate and phosphonate pendant-armed cyclam and cyclen metal complexes typically involves *O*-protonation pre-equilibria,[8,9,14–18] dissociation of protonated arms likely precedes rupture of Cu–N bonds. The 10-membered rings of the ligand adopt [2233] conformations rather than the distorted diamond-lattice [2323] conformation found in the unprotonated analogue. We propose that for protonated Cu-CB-TE2A, at least one coordinated carboxylic acid arm must dissociate from the metal before any Cu–N bond cleavage can occur. Even then, such bond breaking is discouraged by the cross-bridged cyclam's low-energy [2233] or [2323] solution conformation. Indeed, such a ruptured Cu–N bond is predisposed to reform the original complex. Consistent with this rationale, Cu-CB-Cyclam is almost an order of magnitude more kinetically inert than Cu-Cyclam (Table 1).

Since Cu^I has significantly different coordination preferences than Cu^{II}, in vivo reduction of stable Cu^{II} complexes to form Cu^I products can lead to demetallation or disproportionation in an alternative decomplexation pathway. We carried out cyclic voltammetry experiments on Cu-CB-TE2A, Cu-TETA, Cu-DOTA, and Cu-CB-DO2A in 0.1 M aqueous sodium acetate solution adjusted to pH 7 (Figure 5).

Both Cu-TETA and Cu-CB-DO2A yielded irreversible reduction voltammograms. Cu-DOTA gave both a broad reduction peak at –1.00 V (vs. Ag/AgCl) and an attenuated oxidation wave at –0.39 V in the return scan. By contrast, a quasi-reversible reduction was observed for Cu-CB-TE2A at –1.08 V with a peak separation of 120 mV. This voltammogram was reproducible upon repeated cycling between

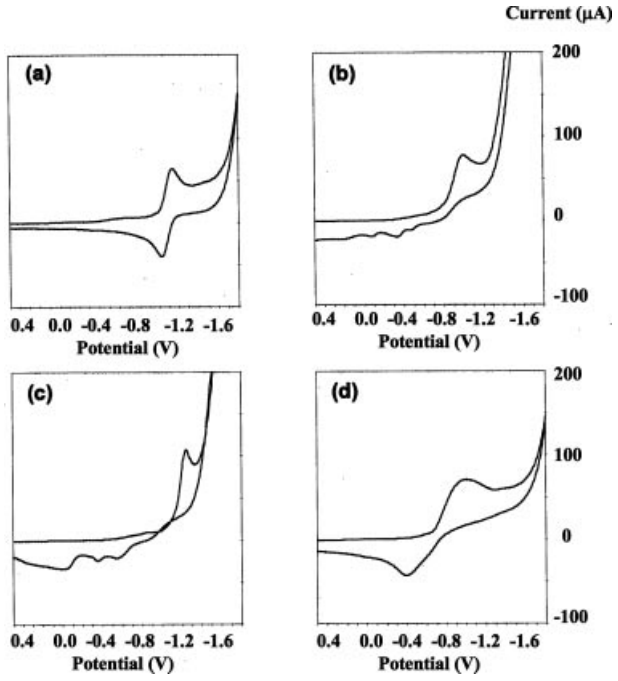

Figure 5. Cyclic voltammograms of (a) Cu-CB-TE2A, (b) Cu-CB-DO2A, (c) Cu-TETA, and (d) Cu-DOTA in 0.1 M sodium acetate, pH 7.0.

+0.8 V and –1.4 V. An increase of the scan rate (ν) resulted in an increased peak separation. A differential pulse voltammogram (0.0 V to –1.4 V at v = 20 mV/s) further confirmed a well-defined reduction peak at –1.06 V. We were also able to observe a similar quasi-reversible reduction of this complex in DMSO ($E_{1/2}$ = –1.23 V, ΔE = 162 mV). The higher chemical reversibility ($i_{pa}/i_{pc} \approx 0.8$) of this redox couple suggests that the reduction product, Cu^{I}-CB-TE2A, must be longer-lived compared to its analogues. Thus none of the related ligands DOTA, TETA, or CB-DO2A appear to be able to adapt to the coordination requirements of Cu^{I} and stabilize it. In contrast, the ability of a dibenzyl derivative of cross-bridged cyclam to accommodate the disparate coordination preferences of both a cuprous as well as a cupric cation has already been demonstrated.[19] Efforts to isolate and characterize the Cu^{I} complex of CB-TE2A are in progress.

Conclusions

Taken together, the relative kinetic inertness, FT-IR and electrochemical data single out the unique properties of Cu-CB-TE2A compared to its closely-related Cu-TETA, Cu-DOTA, and Cu-CB-DO2A analogues. This particular combination of a cross-bridged cyclam backbone together with carboxymethyl pendant arms stabilizes the complex towards *both* acid-assisted and reductive decomplexation and correlate well with the improved in vivo performance of ^{64}Cu-CB-TE2A. Further investigations to confirm these correlations in parallel with biological studies to gain insight into the in vivo mechanism of metal dissociation from ^{64}Cu-labeled tetraazamacrocyclic complexes are underway.

Experimental Section

Caution! Although we encountered no problems, perchlorate salts of organic ligands are potentially explosive and should be handled with care and only in small quantities. All copper(II) complexes of carboxymethyl pendant-armed tetraazamacrocyclic ligands were prepared according to published literature procedures: Cu-TETA,[20] Cu-DOTA,[20] Cu-CB-TE2A,[13] and Cu-CB-DO2A.[6]

Acid-Decomplexation Studies: Sample concentrations of copper complexes studied were between 1–3 mM. Each complex's visible electronic spectrum in 5.0 M HCl at 90 °C was recorded at specific time points using a Cary 50 Bio UV/Vis spectrophotometer. In each case, isosbestic spectra were obtained indicative of a single decomplexation product. The decreasing absorbance at the λ_{max} of each spectrum (Cu-CB-TE2A 529 nm, Cu-CB-DO2A 606 nm, Cu-TETA 615 nm, Cu-DOTA 725 nm, Cu-*tet-a* 516 nm, Cu-cyclam 510 nm, and Cu-CB-cyclam 587 nm) was used to monitor the progress of the decomplexation reaction. Half-lives were calculated from the slopes of the linear *ln*(absorbance) vs. time plots.

Solution FT-IR Spectra: FT-IR absorbance spectra in D_2O solutions were obtained in a barium fluoride cell (0.01 cm pathlength) with a Nicolet 520 FT-IR spectrophotometer. Absorbance spectra were produced by ratioing the single beam spectra of the samples to the corresponding solvents. All spectra were acquired at a nominal 2 cm^{-1} resolution (using a liquid nitrogen-cooled MCT detector).

Synthesis of [Cu-CB-TE2AH]ClO_4: A sample of Cu-CB-TE2A was dissolved in 0.1 M $HClO_4$ and the solvent was evaporated from a beaker to yield dark-blue crystals suitable for X-ray studies. Analytical data for [Cu-CB-HTE2A]ClO_4 $C_{16}H_{29}ClCuN_4O_8(H_2O)_{0.5}$ (513.44): calcd. C 37.43, H 5.89, N 10.91, Cl 6.91; found C 37.47, H 5.78, N 10.82, Cl 6.69. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3500, 3000–2800,

X-ray Structural Determination of [Cu-CB-TE2AH]ClO_4: A blue block crystal was found to produce the crystal and refinement data listed in Table 3. All non-hydrogen atoms were refined anisotropically and all hydrogen atoms were treated as idealized contributions. All software used is contained in libraries maintained by Bruker-AXS (Madison, WI).

CCDC-262407 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Electrochemical Studies: Cyclic voltammograms were obtained with an EG&G PAR Model 263A scanning potentiostat with PowerCV data collection and analysis software. A three-electrode cell under argon was used with a glassy carbon disk working electrode, platinum auxiliary electrode, and silver/silver chloride reference electrode. Samples (1 mM) were run in 0.1 M aqueous sodium acetate adjusted to pH 7.0 with glacial acetic acid at scan rates of v = 100 mV/s. Samples in DMSO solution were run using 0.1 M tetra-*n*-butylammonium hexafluorophosphate electrolyte. Differential pulse voltammograms were run with a BAS Model 100B electrochemical system equipped with a PC utilizing BAS software. A similar three-electrode system was used and the scan rate was 20 mV/s.

A Fluxional $Cu^{I}N_2O_2$ Core: Binding of a Keto Oxygen Atom to Cu^{I} and Ag^{I}

Michael G. B. Drew,[a] Jnan P. Naskar,[b] Shubhamoy Chowdhury,[b] and Dipankar Datta*[b]

Keywords: Copper / Fluxional compounds / N ligands / O ligands / Silver

$[Cu(2\text{-acetylpyridine})_2]ClO_4$ (**1**), characterised here, has a novel $Cu^{I}N_2O_2$ core in the solid state. Variable-temperature ^1H NMR studies show that the two chelate rings open up in solution at room temperature and the keto oxygen atoms dangle freely. As the temperature is lowered, the O atoms tend to bind to the metal atom. The corresponding silver(I) complex, $[Ag(2\text{-acetylpyridine})_2]ClO_4$ (**4**), characterised by single-crystal X-ray crystallography, has an $Ag^{I}N_2$ core in the solid state as well as in solution. Thus, while **1** is fluxional, **4** is not. In cyclic voltammetry, complex **1** displays a quasireversible $Cu^{II/I}$ couple with a half-wave potential of 0.40 V vs. SCE. Complex **1** is easily oxidised by air and H_2O_2 in methanol to give rise to a dinuclear copper(II) complex where the ligand framework is not simple acetylpyridine.

Introduction

The bonding between copper(I) and an aldehyde/ketone oxygen atom has received little attention. While simple Cu^+ ion disproportionates into Cu^{2+} and metallic copper in most O-donor solvents like water, methanol etc., it is considerably more stable towards disproportionation in acetone.[1] Consequently, a copper(I)–keto oxygen bond may not be thermodynamically unfeasible. However, to date, there is only one example of a copper(I) complex where the metal atom has a discrete bond with a keto oxygen atom; the oxygen atom belongs to an acetone molecule.[2] This copper(I) complex was not synthesised deliberately. There is a report by Lin et al.,[3] where the authors have claimed to observe bonds between Cu^{I} and the keto oxygen atoms in bis(triphenylphosphane)bis(phenalenone)copper tetrafluoroborate. In reality, however, they have observed bonds between Cu^{I} and the O^- ends of the zwitterionic phenalenone fragments. However, in the oxidation of benzyl alcohol catalysed by a copper(II) complex, a copper(I) species having a bond between the metal atom and the O atom of benzaldehyde was proposed by Kitajima et al. as a possible intermediate.[4] On the other hand, several structurally characterised examples of copper(II) complexes containing bonds between Cu^{II} and the carbonyl O atom of some aldehydes/ketones are known.[5–8] For example, in azurin − a blue copper-containing protein − there is a peptide carbonyl O atom in close proximity to the metal ion [mean Cu^{I}–O distance = 3.22 Å; mean Cu^{II}–O distance = 3.13 Å],[9] although it is doubtful whether this O atom is bonded to the copper atom in azurin.[10] Thus, the possibility of a copper(I)–keto oxygen bond is of biological relevance as well. Recently, we have undertaken a project to study the chemistry of this bond, and here we make the first report of our efforts by describing some properties of a homoleptic copper(I) complex of 2-acetylpyridine (ACPY) containing copper(I)–keto oxygen bonds. For comparison, we have also studied the homoleptic silver(I) complex of ACPY.

Results and Discussion

Reaction of ACPY with $[Cu(CH_3CN)_4]ClO_4$ in anhydrous methanol under N_2 in a 2:1 molar ratio yields reddish brown $[Cu(ACPY)_2]ClO_4$ (**1**). This complex is stable in air for more than a week in the solid state, although in solution it is not at all stable towards aerial oxidation: the reddish colour of the solution first changes to green and then to pink.

Luo et al.[8] have reported the synthesis and X-ray crystal structure of a mixed-ligand copper(II) complex containing ACPY as one of the ligands. Prior to them, El-Hilaly and El-Zaby reported that reaction of 2-pyridinecarboxaldehyde (PYCA) with hydrated $Cu(NO_3)_2$ in aqueous medium at pH = 8.0 yielded a pink complex which analysed as Cu(pyridin-2-ylmethanediolate monoanion)$_2$, thus indicating aquation of PYCA.[11] However, when we followed the procedure of El-Hilaly and El-Zaby with ACPY, metallic copper was precipitated. Further, reaction of $Cu(ClO_4)_2{\cdot}6H_2O$ with ACPY in methanol in a 1:2 molar proportion yields a blue copper(II) complex which seems to contain pyridin-2-ylmethanediolate monoanion as one of the ligands. Thus, we have not yet been able to characterise any pure homoleptic copper(II) complex of ACPY.

That the keto oxygen atoms of the two ACPY moieties in **1** are bonded to copper(I) is unequivocally revealed in

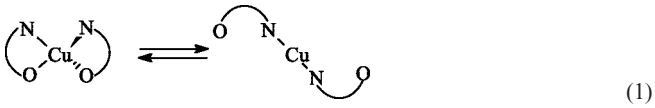
the FTIR spectra. The ν(C=O) absorption of the free ligand appears at 1697 cm^{-1} as a very strong band, whereas in the complex two ν(C=O) bands are observed at 1689 and 1672 cm^{-1} as moderately strong with unequal intensities. The lowering of the ν(C=O) absorption in the complexes compared to that of free ACPY suggests that π back-bonding between copper(I) and the keto fragments is possible. Since two C=O stretching frequencies are observed in the complex, we can say that there are two types of keto groups in the complex which may be due to the difference in the two Cu^I–O bond lengths [a shorter Cu^I–O bond being associated with the ν(C=O) of 1672 cm^{-1}]. The ν(C=N) absorption of pyridine in ACPY (1583 cm^{-1}) moves to higher energy (1591 cm^{-1}) upon binding to copper(I), therefore it is reasonable to assume that there is a distorted tetrahedral $Cu^IN_2O_2$ chromophore in **1**.

A variable-temperature ^1H NMR study of **1** in CD_2Cl_2 (Figure 1) shows that **1** undergoes a dynamic equilibrium according to Equation (1) in solution leading to broadening of the proton signals at room temperature.



(1)

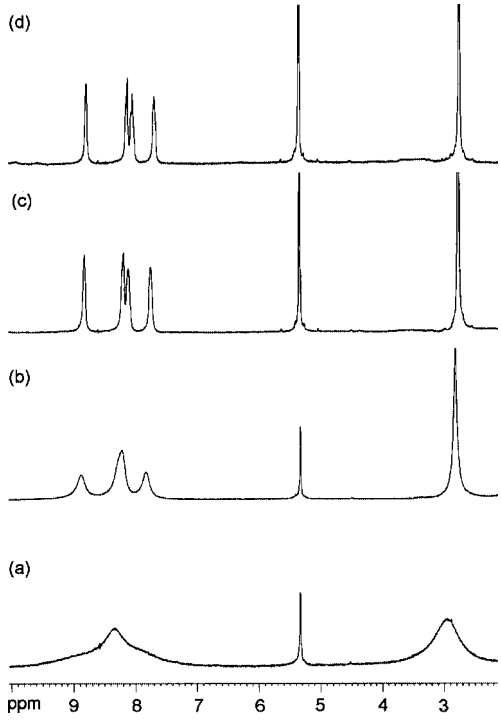


Figure 1. Variable-temperature 300 MHz ^1H NMR spectra of [Cu(ACPY)$_2$]ClO_4 (**1**) in CD_2Cl_2: (a) 298, (b) 253, (c) 213 and (d) 193 K. Assignments: δ [ppm] = 2.2–3.7 (methyl protons), 5.3 (residual protons of the solvent), 7–10 (pyridyl protons).

Since only one type of methyl signal is observed in the temperature range 298–193 K, equilibrium processes involving dissociated and undissociated ligands can be ruled out. We can therefore speculate that **1** is two-coordinate in solution at room temperature, with the ligands bound to the metal atom through the pyridine nitrogen atoms, and at low temperature it is four-coordinate with the keto oxygen atoms also participating in the bonding. This implies that Cu^I–keto oxygen bonds are very weak. Equilibrium (1) indicates that our copper(I) complex **1** is stereochemically nonrigid in solution, i.e. fluxional. Incidentally, the methyl protons in the free ligand ACPY resonate as a singlet at δ = 2.72 ppm and the pyridyl protons at δ = 7.35–7.70 (m), 7.80–8.10 (m) and 8.65–8.72 (d) ppm in $CDCl_3$.[12]

In an attempt to grow single crystals of **1**, we allowed direct diffusion of diethyl ether into its dilute methanolic solution (reddish). After two weeks, there was deposition of shiny, dark-green single crystals of **2**. This green compound is paramagnetic. X-ray crystallography revealed that it is a diperchlorate salt of a dinuclear copper(II) complex where the original ligand, ACPY, has been chemically changed to a monoanionic form of **3**. The formulation of compound **2** is [Cu_2(**3**-H^+)$_2$]$(ClO_4)_2$ (Figure 2). It has a crystallographic centre of symmetry with a Cu···Cu distance of 3.002(3) Å. It is an alkoxo-bridged dinuclear copper(II) complex where each copper atom is five-coordinate; the bridging angle is 101.6(2)°. The coordination sphere of each metal ion is an approximate square pyramid with the alcoholic oxygen atom O(30) in an axial site at a distance of 2.249(6) Å. The atoms in the equatorial plane form shorter bonds [Cu–O(1) = 1.956(5), Cu–O(1) (2 – *x*, –*y*, 2 – *z*) = 1.918(5), Cu(1)–N(11) = 1.982(6) and Cu(1)–N(24) = 1.999(6) Å]. While reports of coordination of an alcoholic oxygen atom to copper(II) are rare,[13,14] many examples of alkoxo-bridged dinuclear copper(II) complexes are known.[15,16]

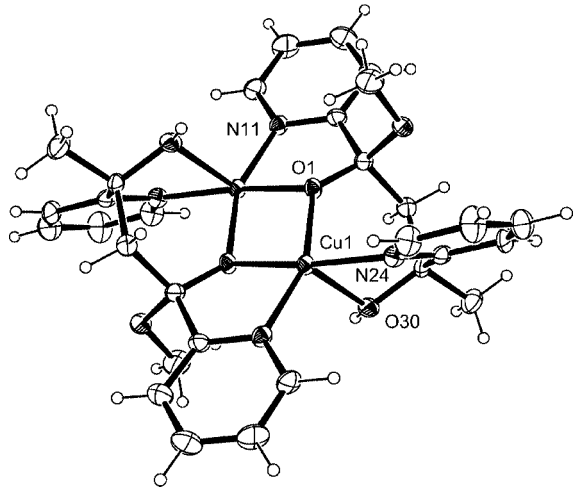

Figure 2. Centrosymmetric structure of the cation in **2** with ellipsoids at 25% probability. Selected bond lengths [Å] and angles [°]: Cu1–O1 1.956(5), Cu1–O30 2.249(6), Cu1–N11 1.983(6), Cu1–N24 2.000(7); O1–Cu1–O30 86.1(2), O1–Cu1–N24 93.6(2), O30–Cu1–N24 76.0(2).

Oxidation of copper(I) to copper(II) is a prerequisite for the conversion of **1** into **2**. In our above experiment, aerial oxygen brings about the required oxidation; the conversion **1** → **2** does not occur under N_2. Later, we found that [Cu_2(**3**-H^+)$_2$]$(ClO_4)_2$ can be easily generated by oxidising **1**

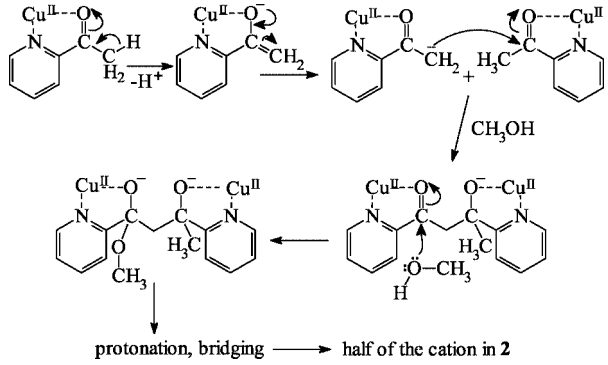
3

with dilute H_2O_2 in methanolic medium. However, our attempts to isolate the free ligand **3** from $[Cu_2(\mathbf{3}\text{-}H^+)_2](ClO_4)_2$ always led to the isolation of ACPY only. A tentative mechanism for the conversion of **1** into **2** is proposed in Scheme 1. The mechanism is shown explicitly for one half of **2**; it is the same for the other half. Oxidation of the metal atom from copper(I) to copper(II) facilitates the enolisation and subsequent formation of the carbanion in Scheme 1.



Scheme 1. Proposed mechanism for the conversion of complex **1** into **2** in methanol followed by oxidation of the metal centre from copper(I) to copper(II).

Having failed to obtain single crystals of **1**, we decided to synthesise its silver(I) analogue, as the structure of the Ag^I complex is found to be similar[17] to that of the Cu^I variety for many ligands. Stirring of $AgClO_4{\cdot}xH_2O$ with ACPY in tetrahydrofuran (THF) in the required proportion yielded $[Ag(ACPY)_2]ClO_4$ (**4**). Its X-ray crystal structure is given in Figure 3. There are two pyridyl nitrogen atoms and two keto oxygen atoms in close proximity to the silver atom. The Ag^I–N distances are 2.213(6) and 2.214(5) Å and the Ag^I–O distances 2.544(6) and 2.554(6) Å. The two pyridine rings intersect at 71.2(1)°.

The Ag^I–O bonds in **4** are rather long. In order to find out whether the two keto O atoms are at all bonded to the silver atom, we decided to use the bond valence sum (BVS) model,[18,19] which relates the bond lengths around a metal ion with its oxidation state. Our BVS calculations with a bond valence parameter, r_0, for the Ag^I–N bond of 1.859 Å[20] show that the valency of the silver(I) atom in **4** is well satisfied by the two N atoms; inclusion of the two keto oxygen atoms in the coordination sphere of the silver atom in **4** is unnecessary. This conclusion is also supported by the FTIR spectrum of **4**, where ν(C=O) appears at 1700 cm^{-1}, thus indicating no bonding between the metal atom and the keto oxygen atoms. No silver(I) complex with an Ag^I–keto oxygen bond is known in the literature. In 1997, Lin et al.[21] reported the crystal structure of bis(triphenylphosphane)bis(diphenylcyclopropenone)silver(I) tetrafluoroborate, where there is a bond between Ag^I and the O atom of the diphenylcyclopropenone moiety. However, because of the possible resonance structures of this complex, the O atom behaves more as O^- of the zwitterionic diphenylcyclopropenone fragment. In our case, since the keto oxygen atoms do not bind Ag^I in **4**, no fluxional behaviour is observed in its variable-temperature ^1H NMR spectra in CD_2Cl_2 (Figure 4), in contrast to the copper(I) complex **1**.

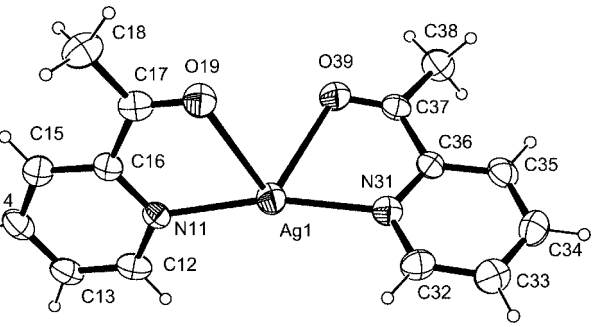


Figure 3. Structure of the cation in **4** with ellipsoids at 25% probability. Selected bond lengths [Å] and angles [°]: Ag1–N11 2.214(5), Ag1–N31 2.213(6), Ag1–O19 2.554(6), Ag1–O39 2.544(6); N31–Ag1–N11 165.8(2), O39–Ag1–O19 84.0(2), N31–Ag1–O39 69.6(2), N11–Ag1–O19 68.83(19).

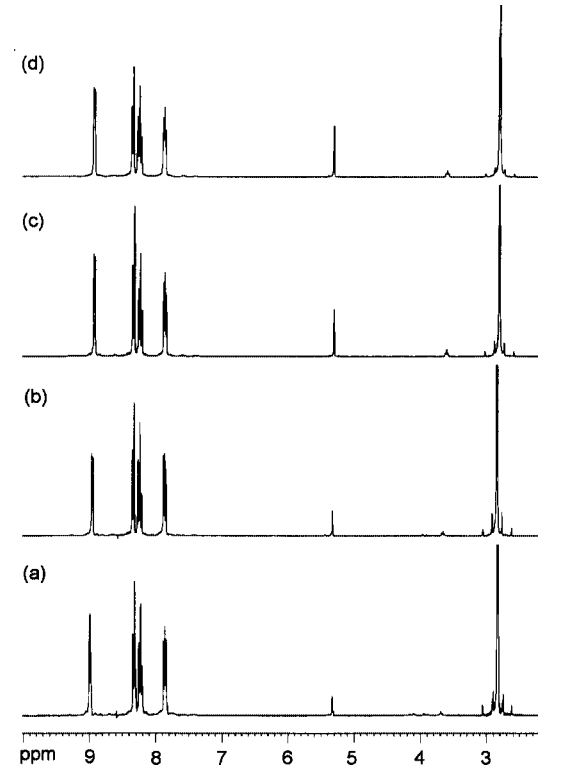

Figure 4. Variable-temperature 300 MHz ^1H NMR spectra of $[Ag(ACPY)_2]ClO_4$ (**4**) in CD_2Cl_2: (a) 298, (b) 253, (c) 213 and (d) 193 K. Assignments: δ [ppm] = 2.83 (methyl protons), 5.3 (residual protons of the solvent), 7.75–9.25 (pyridyl protons).

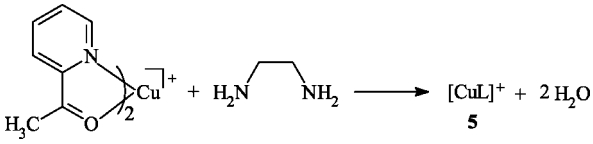
The keto groups in **1** are capable of forming Schiff bases. This is evidenced by the fact that reaction of ethylenediamine (en) with **1** in an equimolar proportion in anhydrous

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

methanol results in $[CuL]^+$ (**5**), where L is the 2:1 condensate of ACPY and en [Equation (2)]. Previously, we have shown by means of X-ray crystallography that the 2:1 condensate of PYCA and en yields a homotopic dicopper(I) cationic double helicate when treated with $[Cu(CH_3CN)_4]ClO_4$ in a 1:1 molar proportion.[22] We believe that **5** has a similar structure.



(2)

We have examined the electrochemical behaviour of **1** by cyclic voltammetry and coulometry in purified dichloromethane under dry N_2. At a glassy carbon electrode in cyclic voltammetry, it displays a quasi-reversible oxidative electrode process (Figure 5) with an average half-wave potential, $E_{1/2}$, of 0.40 V vs. SCE (saturated calomel electrode). The involvement of one electron in the electrode process was confirmed by coulometry at a platinum wire gauge electrode (4.35 mg of **1** was electrolysed at 0.65 V vs. SCE in CH_2Cl_2; 1.069 coulomb was collected, against the theoretical count of 1.036. The oxidised solution was almost colourless.). Thus, the couple observed in Figure 5 is a $Cu^{II/I}$ one.

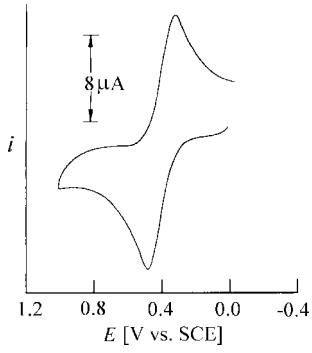


Figure 5. Cyclic voltammogram of $[Cu(ACPY)_2]ClO_4$ (**1**) in dichloromethane (concentration 1.20 mM) containing 0.1 M tetrabutylammonium perchlorate at a glassy carbon electrode at a scan rate of 50 mV s^{-1}. Under the same experimental conditions, the ferrocene–ferrocenium couple appears at 0.47 V vs. SCE with a peak-to-peak separation of 80 mV.

As revealed by the ^1H NMR spectra, our copper(I) complex is two-coordinate in solution at room temperature. The metallophore in **1** in solution can be represented as $[Cu^IN_2]$-O_2, thus indicating that the O atoms of the two ACPY fragments are not bound to the metal atom. The oxidative electrode process observed for **1** can then be described by Equation (3), where the corresponding Cu^{II} species is four-coordinate with the two keto oxygen atoms ligated to the metal atom.

$$Cu^{II}N_2O_2 + e^- \rightleftharpoons [Cu^IN_2]O_2 \quad (3)$$

Since the coordination number of the metal ion changes so much with the change in the oxidation state, the peak-to-peak separation in Figure 5 is quite large (0.17 V). The reasons for assuming that the Cu^{II} species in Equation (3) is four-coordinate are as follows:

(i) While a number of structurally characterised copper(I) complexes having a Cu^IN_2 core are known,[10] no one has ever observed a quasi-reversible cyclic voltammogram for such a core (an irreversible voltammogram with possible characteristics of adsorption is expected for a Cu^IN_2 core).

(ii) No example of a two-coordinate copper(II) complex is known in the literature; hence, the copper(II) species in Equation (3) cannot have a $Cu^{II}N_2$ core.

(iii) The keto oxygen atom of ACPY is known to bind Cu^{II}.[8]

The $Cu^{II/I}$ potential indicates that complex **1** can be oxidised by aerial oxygen, as the potential of the couple according to Equation (4) at pH = 7 is 0.57 V vs. SCE.[23a]

$$\tfrac{1}{2}O_2 + 2H^+ + 2e^- \rightleftharpoons H_2O \quad (4)$$

Concluding Remarks

We have characterised a copper(I) complex, $[Cu(ACPY)_2]$-ClO_4 (**1**), with a novel $Cu^IN_2O_2$ core and having two Cu^I–keto oxygen bonds. These Cu^I–keto oxygen bonds exist in the solid state, where complex **1** provides the first example of a $Cu^IN_2O_2$ core. However, the Cu^I–keto oxygen bonds in **1** are so weak that, even in a non-coordinating solvent like dichloromethane, the two chelate rings open up and the keto ends dangle freely in solution. However, with the lowering of temperature, the keto oxygen atoms tend to bind the metal atom. Thus, the $Cu^IN_2O_2$ core is stereochemically non-rigid in solution. Accordingly, our copper(I) complex **1** is "fluxional". We wish to point out that, so far, to the best of our knowledge, no other fluxional copper(I) complex is known in inorganic chemistry. We have also demonstrated that the silver(I) counterpart of **1** is not fluxional. This is because the keto oxygen atoms do not bind Ag^I even in the solid state. Incidentally, Ag^I shows a pronounced tendency to exhibit linear twofold coordination.[23b] In **4**, the N–Ag–N angle is 165.8(2)°.

Complex **1** has a low-potential $Cu^{II/I}$ couple and is easily oxidised by air in solution. Oxidation by air or H_2O_2 in methanol results in a dinuclear copper(II) complex, although the organic moiety in this dinuclear compound no longer remains as simple ACPY: it undergoes a chemical transformation, which is facilitated by the oxidation of the metal centre, to yield a novel dinucleating ligand.

Experimental Section

General: $[Cu(CH_3CN)_4]ClO_4$ was prepared by a reported procedure.[24] Copper was estimated gravimetrically as CuSCN. Microanalyses were performed with a Perkin–Elmer 2400II elemental analyser. FTIR spectra (KBr disc) were recorded with a Nicolet Magna-IR spectrophotometer (Series II), UV/Vis spectra with a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Shimadzu UV-160A spectrophotometer and NMR spectra (in CD_2Cl_2) with a Bruker DPX300 spectrometer. Cyclic voltammetry and coulometry were performed using an EG&G PARC electrochemical analysis system (model 250/5/0) in purified dichloromethane, under dry nitrogen, in a conventional three-electrode configuration. A planar EG&G PARC G0229 glassy carbon milli electrode was used as the working electrode in cyclic voltammetry and a platinum wire gauge electrode in coulometry. Magnetic susceptibility was determined at room temperature with a PAR 155 vibrating sample magnetometer. The magnetometer was calibrated with [Hg{Co(SCN)$_4$}] and the susceptibility data were corrected for diamagnetism using Pascal's constants.

Synthesis of [Cu(ACPY)$_2$]ClO$_4$ (1): ACPY (0.6 mL, 5.36 mmol) was dissolved in anhydrous, degassed methanol (15 mL) to which freshly prepared [Cu(CH$_3$CN)$_4$]ClO$_4$ (0.88 g, 2.68 mmol) was added under dry N_2 and stirred for 30 min. The reddish-brown compound precipitated was filtered, washed thoroughly with diethyl ether (50 mL) and stored in vacuo over fused $CaCl_2$. Yield: 0.65 g (60%). $C_{14}H_{14}ClCuN_2O_6$ (405.2): calcd. C 41.46, H 3.48, Cu 15.68, N 6.91; found C 41.43, H 3.60, Cu 15.61, N 7.08. FTIR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1689 (s), 1672 (s) [ν(C=O)], 1591 (m) [ν(C=N)], 1568 (m) [ν(C=C)], 1088 (vs), 625 (s) [ν(ClO$_4$)]. UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε_{max} [M^{-1}cm^{-1}]) = 233 (1.5×10^4), 267 (1.0×10^4), 321 (2.1×10^3); (nujol mull): 260, 350, 465 sh.

Synthesis of [Cu$_2$(3-H$^+$)$_2$](ClO$_4$)$_2$ (2): Solid **1** (0.405 g, 1 mmol) was suspended in 10 mL of methanol to obtain a reddish-brown suspension. 30% (w/v) hydrogen peroxide solution (0.11 mL, 1 mmol) was then added with stirring. A green colour appeared immediately and, after 5 min of stirring, a green solution was obtained from which a dark-green compound started to separate. The reaction mixture was left in the air undisturbed for another 30 min. The precipitated green compound was then filtered, washed thoroughly with 15 mL of methanol cautiously and dried in vacuo over fused $CaCl_2$. Yield: 0.156 g (36%). $C_{30}H_{34}Cl_2Cu_2N_4O_{14}$ (872.61): calcd. C 41.27, H 3.93, Cu 14.57, N 6.42; found C 40.79, H 4.20, Cu 14.55, N 5.98. FTIR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3383 (vs) [ν(OH)], 1609 (sh) [ν(C=N)], 1570 (m) [ν(C=C)], 1146–1053 (vs), 625 (s) [ν(ClO$_4$)]. μ [μ_B] = 1.05 (per Cu; at 298 K). UV/Vis (DMF): λ_{max} [nm] (ε_{max} [M^{-1}cm^{-1}]) = 268 (1.5×10^4), 324 (2.5×10^3), 674 (9.9×10); (nujol mull): 267, 311, 677 sh. Single crystals were grown by direct diffusion of diethyl ether into a methanol solution of the complex.

Attempted Isolation of 3 from [Cu$_2$(3-H$^+$)$_2$](ClO$_4$)$_2$: 30 mL of 25% ammonia was added to a suspension of [Cu$_2$(**3**-H$^+$)$_2$](ClO$_4$)$_2$ (3.2 g, 3.67 mmol) in 75 mL of chloroform with stirring. The stirring was continued for 3 h. The aqueous layer was then discarded and the organic layer was washed thoroughly with 2×25 mL of water and then dried with anhydrous Na_2SO_4. The brown ligand solution thus obtained was concentrated in a rotary evaporator to obtain a dense liquid. The FTIR spectrum of the isolated ligand matched that of ACPY.

Synthesis of [Ag(ACPY)$_2$]ClO$_4$ (4): Solid $AgClO_4{\cdot}xH_2O$ (1.04 g) was added to ACPY (1.12 mL, 10 mmol) in THF (15 mL) and stirred for 30 min. The white compound precipitated was filtered, washed with diethyl ether (10 mL) and dried in vacuo over fused $CaCl_2$. Yield: 1.48 g (66%). $C_{14}H_{14}AgClN_2O_6$ (449.6): calcd. C 37.38, H 3.14, N 6.23; found C 37.49, H 3.05, N 6.20. FTIR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1700 (vs) [ν(C=O)], 1583 (m) [ν(C=N)], 1099 (vs), 630 (s) [ν(ClO$_4$)]. UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε_{max} [M^{-1}cm^{-1}]) = 232 (1.2×10^4), 270 (1.0×10^4). Single crystals suitable for X-ray crystallography were grown by direct diffusion of *n*-hexane into a dilute CH_2Cl_2 solution of **4**.

Reaction 2: Freshly distilled en (0.06 mL, 0.89 mmol) was added to **1** (0.36 g, 0.89 mmol), dissolved in anhydrous methanol (20 mL). The resulting red solution was refluxed for 4 h and then kept in the refrigerator overnight. The red compound, [**5**]ClO$_4{\cdot}0.5H_2O$, precipitated was filtered, washed with diethyl ether (5 mL) and stored in vacuo over fused $CaCl_2$. Yield: 0.30 g (67%). $C_{16}H_{19}ClCuO_{4.5}N_2$ (410.2): calcd. C 43.82, H 4.37, Cu 14.50, N 12.78; found C 43.85, H 4.42, Cu 14.45, N 12.70. FTIR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1589 (s) [ν(C=N)], 1088 (vs), 627 (s) [ν(ClO$_4$)]. UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε_{max} [M^{-1}cm^{-1}]) = 229 (1.9×10^4), 258 (2.2×10^4), 277 (1.3×10^4), 382 (3.5×10^3), 471 (8.3×10^3). ^{1}H NMR (300 MHz, CD_2Cl_2, TMS): δ [ppm] = 3.41–3.82 (alkyl protons), 7.67–8.58 (pyridyl protons).

Caution! *Although we have not met with any incident during our studies, care should be taken in handling these compounds as perchlorate salts are potentially explosive. They should not be prepared and stored in large amounts.*

X-ray Crystallography: Data were measured with Mo-K_α radiation with an MARresearch Image Plate System at 293(2) K. The crystals were positioned at 70 mm from the image plate; 100 frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program[25] to provide 3352 independent reflections for **2** and 2951 for **4**. The structures were solved by direct methods with the Shelx86 program.[26] Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon atoms were included in geometric positions and given thermal parameters equivalent to 1.2-times those of the atom to which they are attached. The hydrogen atom on O30 in **2** was located in the difference Fourier map and refined with a distance constraint. The perchlorate anion in **4** was disordered with two sets of oxygen tetrahedra being refined with half occupancy. An empirical absorption correction was applied using DIFABS.[27] The structures were refined on F^2 using Shelxl.[28] Selected crystallographic data for complexes **2** and **4** are given in

Table 1. Crystallographic data for complexes **2** and **4**.

(η^5-Pentamethylcyclopentadienyl)iridium(III) Complexes with η^2-N,O and η^2-P,S Ligands

Michael Gorol,[a] Herbert W. Roesky,*[a] Mathias Noltemeyer,[a] and Hans-Georg Schmidt[a]

Keywords: Cyclopentadienyl ligands / Iridium / N,O ligands / P,S ligands

Chloro(η^5-pentamethylcyclopentadienyl)(η^2-pyridine-2-carboxylato)iridium(III) [Ir(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl] (**2**) and chloro(η^5-pentamethylcyclopentadienyl)[η^2-2-(diphenylphosphanyl)thiophenolato]iridium(III) [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Cl] (**3**) were prepared and their structures determined by single-crystal X-ray diffraction analysis. Complex **2** crystallizes in the orthorhombic space group *Pbca*. The number of molecules per unit cell is eight, whereas **3** crystallizes in the orthorhombic space group $Pna2_1$ and the number of molecules per unit cell is four. The coordination of the η^2-bound ligands in **2** and **3** leads to chelate bite angles N–Ir–O(2) and P–Ir–S of 77.0(2)° and 82.42(7)°, respectively. The iridium atoms in **2** and **3** are chiral and both enantiomers are present in the unit cell. The substitution of the chloro ligand in **3** affords hydrido(η^5-pentamethylcyclopentadienyl)-[η^2-2-(diphenylphosphanyl)thiophenolato]iridium(III) [Ir($\eta^5$$C_5Me_5$)($\eta^2$-2-$Ph_2PC_6H_4S$)H] (**4**) and methyl($\eta^5$-pentamethylcyclopentadienyl)[η^2-2-(diphenylphosphanyl)thiophenolato]iridium(III) [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Me] (**5**), respectively, in good yields. The $^{31}P\{^1H\}$ NMR resonances of **4** (δ = 33.9 ppm) and **5** (δ = 35.8 ppm) prove unambiguously that the 2-(diphenylphosphanyl)thiophenolato ligand still remains η^2-coordinated.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The chemistry of (η^5-pentamethylcyclopentadienyl)iridium(III) complexes has been extensively investigated during the last few decades.[1] However, there are only a few compounds that contain anionic η^2-coordinated ligands (η^2-A,B), of which α-amino acid complexes are the best-known examples.[2,3] The main aspect of research in this field is focused on the chiral-at-metal behavior of the isolated complexes. However, in general, the diastereoselectivity is low and, due to the configurational instability at the metal center, epimerization reactions occur in solution.[4] Pyridine-2-carboxylic acid is an analog to amino acids and is commercially available. Examples of η^2-coordinated pyridine-2-carboxylato ligands (η^2-N,O) applied in organoiridium chemistry are [Ir(η^5-C_5Me_5)(η^2-N,O)(OH_2)]$^+$ and [Ir(η^5-C_5Me_5)(η^2-N,O)]$_3$(ClO_4)$_3$, although they were structurally not characterized.[5]

Stable thiolato complexes have for some time also been of special interest. Dimeric iridium(I) complexes with bridging thiolato ligands, for example, have been intensely examined for their catalytic activity in hydroformylation reactions.[6] However, the elimination of the free thiol by reaction with dihydrogen has proved problematic. Chelating phosphanyl-thiolate ligands, like the 2-(diphenylphosphanyl)thiophenolato ligand (η^2-P,S), have been introduced to ensure retention of the thiolate. Accordingly, the two compounds [Ir(η^2-P,S)$(Cl)_2$($PMePh_2$)$_2$] and [Ir(η^2-P,S)$_3$]·0.75CH_2Cl_2 have been observed.[7] In addition, an increased stability due to the chelate effect has been observed for the iridium(I) complex [Ir(η^2-P,S)(CO)(PPh_3)].[8]

A particular objective of our research in organoiridium chemistry is the synthesis of stable monomeric complexes with a defined reaction center that allows further reactions. Thus, these compounds are useful as starting materials in the search for new applications in preparative chemistry as well as in catalysis. We present here the syntheses, characterizations, and crystal-structure analyses of the thus far unknown chloro(η^5-pentamethylcyclopentadienyl)iridium(III) complexes [Ir(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl] (**2**) and [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Cl] (**3**), which contain η^2-coordinated pyridine-2-carboxylato (η^2-N,O) and 2-(diphenylphosphanyl)thiophenolato (η^2-P,S) ligands, respectively. The substitution of the chloro ligand in **3** by a hydride ion and a methyl group are described too, and the analytical data are given.

Results and Discussion

The reaction of di-μ-chlorobis[chloro(η^5-pentamethylcyclopentadienyl)iridium(III)] [Ir_2(η^5-C_5Me_5)$_2$(μ-Cl)$_2$$Cl_2$] (**1**) with sodium pyridine-2-carboxylate in methanol or sodium 2-(diphenylphosphanyl)thiophenolate in tetrahydrofuran gives the orange crystalline compounds chloro(η^5-pentamethylcyclopentadienyl)(η^2-pyridine-2-carboxylato)iri-

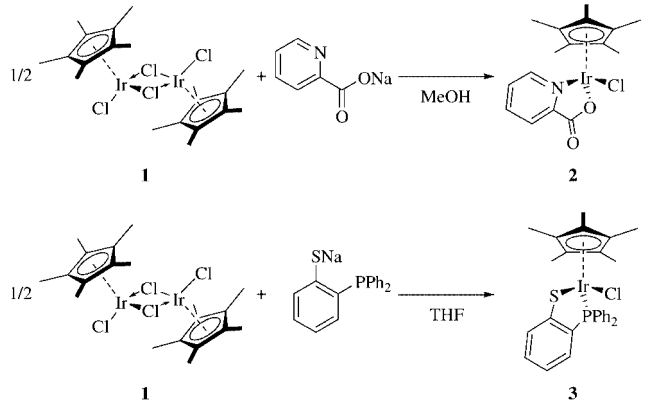
dium(III) [Ir(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl] (**2**) in 89% yield and chloro(η^5-pentamethylcyclopentadienyl)[η^2-2-(diphenylphosphanyl)thiophenolato]iridium(III) [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Cl] (**3**) in 72% yield, respectively (Scheme 1).



Scheme 1.

The resonances of the protons of the η^5-C_5Me_5 groups appear in the ^{1}H NMR spectrum of **2** as a singlet (δ = 1.63 ppm, 15 H) and that of **3** as a doublet (δ = 1.56 ppm, $J_{H,P}$ = 2.2 Hz, 15 H). In the ^{13}C NMR spectrum of **2**, the resonances of the η^5-C_5Me_5 ring carbon atoms are found at δ = 84.9 ppm and those of the methyl groups at δ = 8.3 ppm. The corresponding resonances of compound **3** are observed at δ = 92.9 ppm (d, $J_{C,P}$ = 3 Hz) and δ = 8.2 ppm (d, $J_{C,P}$ = 1 Hz). The ^{31}P{^{1}H} NMR spectrum of **3** shows a resonance at δ = 30.4 ppm, which is strongly shifted downfield ($\Delta\delta$ = 43.5 ppm) in comparison to the free phosphane (δ = –13.1 ppm).[9]. This is in agreement with the coordination shift typical for the ^{31}P NMR resonances of five-membered rings.[10]

The bands at $\tilde{\nu}$ = 253 and 267 cm^{-1} in the IR spectra of **2** and **3** can be assigned to the absorptions of the Ir–Cl stretching modes.

Single crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of diethyl ether into a saturated solution of **2** in dichloromethane. Compound **2** crystallizes in the orthorhombic space group *Pbca*. Figure 1 shows the molecular structure of [Ir(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl] (**2**) together with selected bond lengths and angles. The Ir–Cl [239.97(15) pm] and Ir–N [208.8(7) pm] bonds are shorter than in the L-prolinato complex [Ir(η^5-C_5Me_5)(L-ProO)Cl] [Ir(1)–Cl(1) = 241.7(2), Ir(2)–Cl(2) = 240.6(3), Ir(1)–N(1) = 212.8(7), and Ir(2)–N(2) = 213.1(7) pm],[2] which is probably due to the π-acceptor properties of the pyridine ring in **2**. The coordination of the η^2-bound pyridine-2-carboxylate leads to an N–Ir–O(2) bond angle of 77.0(2)°, which is similar to that of 77.7(1)° in the corre-

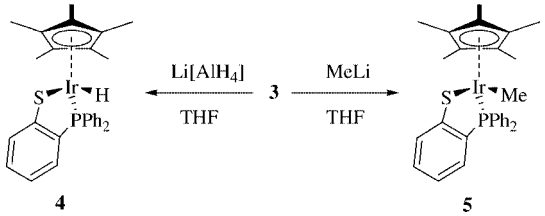
Figure 1. sponding rhodium(III) complex [Rh(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl].[11]

Slow cooling of a hot solution of **3** in toluene gave single crystals suitable for X-ray diffraction analysis. Compound **3** crystallizes in the orthorhombic space group *Pna*2_1. Figure 2 shows the molecular structure of [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Cl] (**3**) together with selected bond lengths and angles. In comparison with [Ir(Cl)$_2$(η^2-2-$Ph_2PC_6H_4S$)(PMePh_2)$_2$] [Ir–P(1) = 236.1(1), Ir–S = 240.1(1), Ir–Cl(1) = 238.42(9), Ir–Cl(2) = 237.36(9) pm; P–Ir–S = 81.06(3)°][7] the Ir–P [227.32(18) pm] and Ir–S [238.0(2) pm] bonds are shorter and the Ir–Cl bond [241.93(18) pm] is longer. The deviation from 90°, with a P–Ir–S bond angle of 82.42(7)°, is of the same order of magnitude and is not as clear as that in **2**. The geometry in both **2** and **3** can be described as pseudo-octahedral coordination of the iridium atom in which the η^5-C_5Me_5 group occupies three *fac* coordination sides. The metal coordination sphere is completed by an η^2-coordinated ligand and a chlorine atom (the bond angles at the iridium atom are listed in the captions of Figures 1 and 2). In each case, the iridium atom is chiral and both enantiomers are present in the unit cell.

Substitution Reactions

Substitution of the chloro ligand by a hydride ion or a methyl group was achieved successfully only for **3**. Thus, the reaction of [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Cl] (**3**) with $LiAlH_4$ or MeLi in tetrahydrofuran results, after removal of the solvent and subsequent extraction with hexane, in the corresponding hydrido complex hydrido(η^5-pentamethylcyclopentadienyl)[η^2-2-(diphenylphosphanyl)thiophenolato]iridium(III) [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)H] (**4**) in 91% yield and the methyl compound methyl(η^5-pentamethylcyclopentadienyl)[η^2-2-(diphenylphosphanyl)-thiophenolato]iridium(III) [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)-Me] (**5**) in 87% yield, respectively (Scheme 2).



4 5

Scheme 2.

The resonances of the protons of the η^5-C_5Me_5 groups in the ^{1}H NMR spectrum of **4** appear, due to the coupling to the iridium-bound hydrido ligand, as a doublet of doublets (δ = 1.62 ppm, $^4J_{H,P}$ = 2.0, $^4J_{H,H}$ = 0.8 Hz, 15 H) and those of **5** as a doublet (δ = 1.57 ppm, $^4J_{H,P}$ = 1.9 Hz, 15 H). The resonances of the hydrido ligand in **4** and of the methyl group in **5** are observed as doublets at high field at δ = –15.37 (d, $^2J_{H,P}$ = 36.0 Hz, 1 H) and –0.22 ppm (d, $^3J_{H,P}$ = 6.1 Hz, 3 H), respectively. In the ^{13}C NMR spectrum of **4**, the resonance of the η^5-C_5Me_5 ring carbon atoms is found at δ = 93.2 ppm (d, $J_{C,P}$ = 3.1 Hz) and that of the methyl groups at δ = 9.1 ppm (d, $J_{C,P}$ = 0.8 Hz). The corresponding resonances of compound **5** appear at δ = 92.8 (d, $J_{C,P}$ = 3.3 Hz) and 8.20 ppm (d, $J_{C,P}$ = 1.0 Hz). The resonance of the methyl group bound to the iridium atom is observed at δ = –17.4 ppm (d, $J_{C,P}$ = 8.4 Hz). The ^{31}P{^{1}H} NMR spectrum of **4** shows a resonance at δ = 33.9 ppm whereas that of **5** appears at δ = 35.8 ppm. In comparison to the free ligand (δ = –13.1 ppm),[9] this strong downfield shift is good evidence that the 2-(diphenylphosphanyl)thiophenolato ligand still remains η^2-coordinated.

In the IR spectrum of **4**, the band at $\tilde{\nu}$ = 2102 cm^{-1} is characteristic of absorptions of the Ir–H stretching modes.[12]

Conclusions

The cleavage of the chloro bridges in [Ir$_2$(η^5-C_5Me_5)$_2$(μ-Cl)$_2$Cl$_2$] (**1**) by η^2-A,B ligands affords stable monomeric chelate complexes. Thus, the reactions of **1** with pyridine-2-carboxylate and 2-(diphenylphosphanyl)thiophenolate yield [Ir(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl] (**2**) and [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Cl] (**3**), respectively. The X-ray diffraction analyses show that the geometry of both complexes can be described as pseudo-octahedral coordination of the iridium atom in which the η^5-C_5Me_5 group occupies three *fac* coordination sides. In each case the complex is chiral at the iridium atom and both enantiomers are present in the unit cell. The complexes [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)H] (**4**) and [Ir(η^5-C_5Me_5)(η^2-2-$Ph_2PC_6H_4S$)Me] (**5**) are easily accessible by substitution of the chloro ligand in **3**. According to the ^{31}P NMR spectra, the 2-(diphenylphosphanyl)thiophenolato ligand remains η^2-coordinated in both compounds. The hydrido complex **4** and the methyl compound **5** are useful derivatives for further investigations.

Experimental Section

General Remarks: Solvents were dried and distilled under nitrogen prior to use. All reactions were carried out under dry nitrogen, using standard Schlenk techniques. NMR spectra were recorded using a Bruker Avance 200, a Bruker MSL 400, or a Bruker Avance 500 spectrometer and referenced to the resonances of the residual protons in [D_6]DMSO, $CDCl_3$, or C_6D_6. ^{1}H NMR: external standard TMS. ^{13}C NMR: external standard TMS. ^{31}P NMR: external standard 85% H_3PO_4. Infrared spectra were recorded with a BIO-RAD Digilab FTS 7 spectrometer. [Ir$_2$(η^5-C_5Me_5)$_2$(μ-Cl)$_2$Cl$_2$] (**1**) [13] and 2-$Ph_2PC_6H_4SH$[9] were prepared by literature methods. All other materials used in the syntheses were reagent grade chemicals and used without further purification.

[Ir(η^5-C_5Me_5)(η^2-C_5H_4N-2-CO_2)Cl] (2): A mixture of **1** (0.80 g, 1.00 mmol), C_5H_4N-2-CO_2H (0.26 g, 2.12 mmol), and NaOEt (0.12 g, 2.22 mmol) in methanol (70 mL) was heated under reflux for 3 h and finally filtered hot through Celite. The solution was concentrated under reduced pressure to 20 mL. The resulting orange crystalline solid was filtered off, washed with diethyl ether (2 × 10 mL), and dried in vacuo (0.85 g, 89%). M.p. 270 °C (decomp.). $C_{16}H_{19}ClIrNO_2$ (485.00): calcd. C 39.62, H 3.95, Cl 7.31, N 2.89; found C 39.59, H 4.01, Cl 7.39, N 2.96. IR (CsI): $\tilde{\nu}$ = 253

X-ray Crystallographic Study: The single crystals were mounted on a glass fiber in a frozen drop of paraffin. Diffraction data were collected with a STOE AED2 four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 71.073 pm). The crystal structures were solved by direct methods using SHELXS-97[15] and refined with SHELXL-97[16] against F^2 on all data by full-matrix least squares. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the model at fixed positions (Table 1). CCDC-272324 (**2**) and -272325 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

COVER PICTURE

The cover picture shows three heterobimetallic sodium-bismuth-oxo silanolates: $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]$ (**2**), $[Bi_{15}\text{-}Na_3O_{18}(OSiMe_3)_{12}]$ (**3**) and $[Bi_{14}Na_8O_{18}(OSiMe_3)_{14}(thf)_4]$ (**4**). These novel polynuclear metal-oxo clusters were obtained in addition to the hexanuclear oxygen-centred complex $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**), which represents a well-known structural motif found in several heterometallic group 15/group 1 compounds. As result of the similar ionic radii of sodium and bismuth and the flexible coordination chemistry of these main group metals, the formation of a large variety of heterobimetallic molecular structures is conceivable. Structural relationships between the metal-oxo silanolates are described and a comparison with other polynuclear bismuth-oxo compounds is given in order to identify basic building blocks. The approach is envisaged to develop rational design strategies towards molecular bismuth-containing precursors for heterometallic materials. Details are discussed in the article by M. Mehring et al. on p. 4891ff.

Variable-Valent Rhenium Chemistry of Conjugated Nitrogenous Ligands: Structure and Reactivity

Animesh Chakravorty*[a,b]

Keywords: Rhenium / Variable valence / Conjugated nitrogen ligands / Oxygen atom transfer / Isomer specificity / Twin isomerization

The valence states of particular concern in this review are VI–I and the ligand types are diimine, azoimine, imineamide and azooxime all bidentate and *N*,*N*-coordinating. Metal reduction potentials and stability of oxidation states are subject to control via variation of the nature and extent of *N*,*N*-chelation and coligation. Back-bonding plays a major role in determining stability and isomer specificity, particularly in the valence domain III–I. Three types of mediated oxygen atom transfer processes have been scrutinized and modeled: from $Re^{V}O$ to tertiary phosphanes and variable-spacer diphosphanes, from water to diimine and from oxime to metal/coligand. Other reactivity topics include isomerizations associated with ligand substitution, stable azo anion radical generation and azo cleavage.

1. Introduction

Named after the river Rhine, rhenium ($6s^25d^5$) occurs in very low abundance (0.7 ppb) in earth's crust. It was indeed the last of the naturally occurring chemical elements to be discovered (1925).[1] Progress in the chemistry of rhenium which spans the oxidation states –1 to +7 has been comprehensively reviewed from time to time.[2–4] But for a short earlier involvement,[5] our sustained activity in rhenium chemistry dates from the early nineties when we were attracted by the prevalence of the $Re^{V}O$ motif[2,3] and its documented ability to transfer oxygen atoms.[6–9] Since then the chemistry of $Re^{V}O$-promoted transfer reactions has been enriched in several laboratories[4,10–16] including ours (vide infra).

Conjugated nitrogen donor organic molecules constitute a large family of chelating ligands that have been widely used for binding transition metal ions. However, reactive $Re^{V}O$ species incorporating such ligands have been relatively rare[2,3] and this provided the initial lead for us. Our endeavour in this area would eventually lead us to a rich arena of variable-valent rhenium chemistry encompassing interesting reactions, structures and bonding situations. The salient features of this chemistry will be outlined in this article.

2. Ligands, Coligands and Coordination Types

Three bidentate chelating moieties widely used in our work and generally represented as (NN) are diimine, **1**, azo-

Animesh Chakravorty was born in Mymensingh, Bangladesh, in 1935. He received his PhD degree from Calcutta University and did postdoctoral work at M.I.T. and Harvard University. He was Professor and Head of the Department of Chemistry at I.I.T. Kanpur and subsequently of the Department of Inorganic Chemistry at Indian Association for the Cultivation of Science, Kolkata, where he is now an Emeritus Professor. He is also a Chair Professor of the Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore. His research interest lies in design and structure of reactive d-block complexes and organometallics, variable valence phenomena and redox transformations. Recent highlights include carbohydrate ligation, crystalline anion radical complexes, metal promoted oxygen atom transfer and insertion into small metallacycles. He has authored 300 papers with his students, sixty of whom have graduated. He has been on the Editoriall Advisory Boards of Inorganic Chemistry, Dalton Transactions, Inorganica Chimica Acta, Comprehensive Coordination Chemistry II and Indian Journal of Chemistry. He is the current President of the Chemical Research Society of India and had been a Golden Jubilee Research Professor of the Indian National Science Academy.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

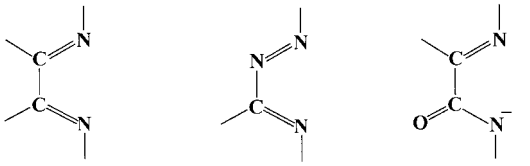
imine, **2** and anionic imineamide, **3** which is derived from **1**. All of these are excellent σ-donors (nitrogen lone pairs); **1** and **2** are also potentially good π-acceptors, **2** being superior in this respect [low-lying π*(azo) orbital].[17,18]



diimine **1** azoimine **2** imineamide **3**

By regulating this duality of bonding with the help of coligands multiple oxidation states of rhenium have been realized. The majority of ligand systems of types **1**–**3** used by us are listed in Table 1 along with abbreviations. Other ligands such as azooximes will be considered in due course.

The majority of coordination types encountered are set out in Table 2. These are uniformly hexacoordinate and generally belong to the (NN)-monochelated [ReQ(NN)] class [chloride ligand(s) omitted] wherein the coligand Q is a good handle for modulation of metal reduction potential and valence. Thus O^{2-} and NAr^{2-} (strong σ-and π-donor)

Table 2. Coordination types.

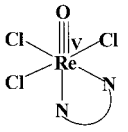
are suited for Re^{VI}/Re^{V}; OP (σ-donor) and P (σ-donor and π-acceptor) for Re^{IV}/Re^{III}; $(CO)_3$ (strong σ-donor and π-acceptor) for Re^{I} and azo anion radicals. Bis- and tris-chelation of azoimines (strong σ-donor and π-acceptor) respectively support Re^{II} and Re^{I} without assistance from any special coligand. These can also be formally looked upon as [ReQ(NN)] species where Q stands for (NN) and $(NN)_2$ in bis- and tris-chelates, respectively.

3. The Parent $Re^{V}O$ Systems and $Re^{V}(NAr)$ and $Re^{III}(OPPh_3)$ Derivatives

3.1 Synthetic Methods

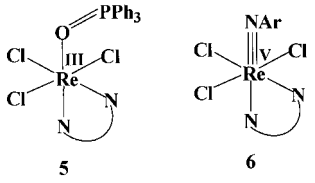
The diimine ligands Rpyal, pyox and pyth react with $[Re^{V}OCl_3(PPh_3)_2]$ in nonpolar solvents under mild conditions (to avoid phosphane oxide formation) furnishing oxo species of type **4**.[19,20] In the case of Rdabd phosphane oxide formation is fast even under mild conditions and $[Re^{V}OCl_3(AsPh_3)_2]$ is the convenient (weaker oxygen affinity of $AsPh_3$) starting material.[21]



4

On the other hand azoimine ligands react with $KReO_4$ in hot concentrated hydrochloric acid (reducing agent and source of chloride ligand) furnishing **4**.[22–24] Spontaneous aryl chlorination may, however, occur[22,23] as in the formation of $[Re^{V}OCl_3(Clazpy)]$ from Hazpy and $KReO_4$.[22]

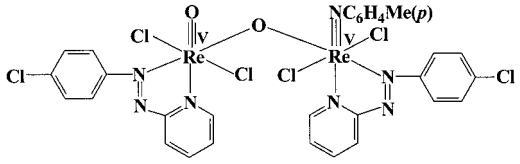
The phosphane oxide system **5** can be generally prepared by the reaction of **4** with PPh_3 (other tertiary phosphanes behave similarly) or of the (NN) ligand with $[Re^{V}OCl_3(PPh_3)_2]$ in a polar solvent.[19–27] The imido system **6** is formed via oxide (water) elimination from **4** in presence of $ArNH_2$ which also reacts with **5** in air to furnish **6**.[20–24,29–31]



5 **6**

Two observations, both relating to Razpy are noteworthy. First, is the otherwise rare[32] metal-promoted splitting of the azo function, see Equation (1), leading to an imido complex, where the PhN fragment of Hazpy binds to the metal and the pyridyl fragment dimerizes to 2,2′-azobispyridine(azbp).[22] Second, is the synthesis of the first binuclear oxo-imido dimer **7** by the reaction of $[Re^{V}OCl_3(Clazpy)]$ with *p*-toluidine.[22,33]

$$[Re^{III}(OPPh_3)Cl_3(Hazpy)] + Hazpy \rightarrow [Re^{V}(NPh)Cl_3(Hazpy)] + azbp + OPPh_3 \quad (1)$$



7

3.2 Structural Features

The structures (for a selection see Table 3 and Table 4) of a number of systems of type **4**,[19–24] **5**[22–25,28] and **6**[5,20–24,29–31] are known. All of these have meridional geometry. It is convenient to discuss **4** and **6** together (Table 3). Here the metal atom is systematically shifted from the equatorial plane (Cl_3N) towards the oxo oxygen atom by 0.30–0.35 Å in **4** and towards the imido nitrogen by 0.27–030 Å in **6**. In **4** the Re–O distances generally lie in the range 1.65–1.67 Å representing approximate triple bonding. Idealized $Re^{V}{\equiv}O$, $Re^{V}{=}O$ and Re^{V}–O distances

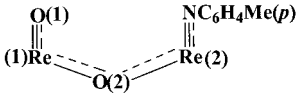
[a] Heterocyclic N *trans* to O. [b] Azo/imine N *cis* to O. [c] Average value. [d] Re···Re distance is 8.222(1) Å.

have been estimated to be 1.60, 1.76 and 2.05 Å respectively.[22,34,35] In **6** the Re–N(imido) distance, 1.68–1.72 Å, again corresponds to triple bonding (estimated Re≡NAr, Re=NAr and Re–NAr lengths are 1.69, 1.84 and 2.14 Å respectively).[5,22,36,37] The Re–N bond lying *trans* to Re≡O or Re≡NAr is uniformly longer by 0.1–0.2 Å compared to the other Re–N bond.

In the unique oxo-imido dimer **7**[22] the Re–N(imido) [1.735(10) Å] and Re–O(oxo) [1.685(8) Å] distances are slightly longer than those in **6** and **4**. The oxygen bridge, highlighted in **8**, is unsymmetrical: Re(1)–O(2), 1.849(7) Å and Re(2)–O(2), 1.945(7) Å. Thus the Re(1)–O(2) bond has a large double bond character and this diminishes the bond order of Re(1)–O(1), as depicted by dotted lines in **8**.



8

The same applies to the O(2)Re(2)N fragment but to a smaller degree. In simple terms, **7** can be described as a complex in which the rare *cis*-$Re^{V}O_2$ moiety acts as a monodentate oxygen donor ligand forming a coordinate bond with the Re^{V}(NAr) moiety.

In the $[Re^{III}(OPPh_3)Cl_3(NN)]$ species, (Table 4) Re–O (2.02–2.08 Å) is a single bond and the metal is no longer shifted towards the oxygen atom. Significant Re(NN) back-bonding is present particularly in the azoimine system. The Re–N(azo) bond is generally shorter than the Re–N(heterocyclic) bond (Table 4) implying involvement of π*(azo) orbitals. Indeed, the N–N(azo) distance in the complexes span the range 1.32–1.35 Å[22–24,27,43] as compared to 1.25 Å in free azo ligands. In the $Re^{V}O$ and Re^{V}(NAr) complexes of azoimines back-bonding is expected to be unimportant but the N–N(azo) distance (1.25–1.31 Å) is still somewhat long possibly due to azo←Re←NAr type interactions.[5,22–24,31]

3.3 Metal Redox

The Re^{VI}/Re^{V} reduction potentials in $[Re^{V}OCl_3(NN)]$[19–24] and $[Re^{V}(NAr)Cl_3(NN)]$[5,20–24,29–31] span the ranges 1.5–2.2 and 0.8–1.5 V, respectively. The Re^{IV}/Re^{III} couple in $[Re^{III}(OPPh_3)Cl_3(NN)]$[19–25] occur in the domain 0.2–1.2 V. Representative data are collected in Table 5. The azo group is electron-withdrawing and in general azoimine complexes have higher $E_{1/2}$ values than diimine complexes. For a given (NN) ligand the Re^{VI}/Re^{V} reduction potential of an Re^{V}(NAr) complex is 0.6–0.8 V lower than that in the $Re^{V}O$ congener reflecting the superior donor ability of NAr^{2-}. Although the $Re^{VI}O$ species are too unstable for chemical/electrochemical generation in solution in bulk quantities, it has been possible to obtain certain Re^{VI}(NAr) species such as $[Re^{VI}\{NC_6H_4Me(p)\}Cl_3(Meazpy)]^{+}$ in solution. It displays a six-line EPR spectrum (see Section 5.3) with g = 1.96 and A = 540 G.[5]

3.4 Bond Lengths Trends in a $Re^{III}(OPPh_3)/Re^{IV}(OPPh_3)$ Pair

The $[Re^{IV}(OPPh_3)Cl_3(NN)]^{+}$ system **9** can be generated by coulometric or dilute nitric acid oxidation of **5**.

Table 5. Reduction potential data [V vs. SCE] for $[Re^{V}OCl_3(NN)]$, $[Re^{V}(NAr)Cl_3(NN)]$, $[Re^{III}(OPPh_3)Cl_3(NN)]$, and $[Re^{III}(PPh_3)Cl_3(NN)]$ in acetonitrile solution at 298 [K].

9

The complex $[Re^{IV}(OPPh_3)Cl_3(pyth)]^+$ has been isolated and characterized as the nitrate salt.[28] Its metal–ligand distances are compared with those of $[Re(OPMe_2Ph)Cl_3(pyth)]$ in Table 6. The lengths of the Re–O and Re–Cl bonds decrease by 0.06 Å due to radial contraction upon metal oxidation. On the other hand oxidation increases the average Re–N distance by 0.06 Å, reflecting considerable weakening of back-bonding in the $Re^{IV}(OPPh_3)$ system.

Table 6. Bond lengths [Å] in a pair of rhenium(IV)-rhenium(III) phosphane oxide complexes.[28]

	$[Re^{IV}(OPPh_3)Cl_3(pyth)]^{+}$[a]	$[Re^{III}(OPMe_2Ph)Cl_3(pyth)]$

[a] The asymmetric unit consists of two molecules and the lengths are average values. [b] Average value.

4. Oxygen Atom Transfer from $Re^{V}O$ to Tertiary Phosphanes

4.1 Monophosphanes: Reactivity Trends and Reaction Model

Oxygen atom transfer reactions involving iron, molybdenum and tungsten sites are important in the chemistry of life.[38,39] Rhenium is not a biometal, but as an element in an adjacent periodic group transfer processes of $Re^{V}O$ are of potential interest as reaction models. The reaction of interest here is stated in Equation (2). In dichloromethane solution the reaction follows second-order kinetics.

$$Re^{V}{\equiv}O + PPh_3 \rightarrow Re^{III}{-}O{=}PPh_3 \quad (2)$$

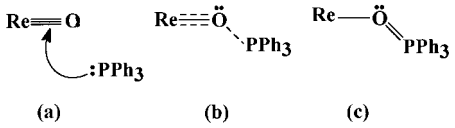
Selected rate data[19,20] are set out in Table 7. An increase in phosphane basicity makes the transfer reaction more facile, and PPh_2Me reacts nearly six times faster than PPh_3. Electron withdrawal from the $Re^{V}O$ moiety via ligand modification hastens the transfer process. Thus, for $[ReOCl_3(Rpyal)]$ log k increases linearly with the Hammett constant of R (Me<H<Cl).[19] Finally, the $[ReOCl_3(pyox)]$ complex reacts nearly twice as fast as $[ReOCl_3(pyth)]$ which is qualitatively consistent with the heteroatom electronegetivity order O>S.[20]

Table 7. Rates of reactions of $[Re^{V}OCl_3(NN)]$ with phosphanes in dichloromethane solution.

(NN) Ligand	Phosphane	T [K]	$10^3\ k$ [$M^{-1}s^{-1}$][a]	Ref.
Mepyal	PPh_3	299	7.96	[19]
Hpyal	PPh_3	299	12.26	[19]
Clpyal	PPh_3	299	24.02	[19]
Pyox	PPh_3	302	4.18	[20]
Pyth	PPh_3	302	2.00	[20]
Mepyal	PPh_2Me	295	47.00	[19]
Pyox	PPh_2Me	302	24.80	[20]
Pyth	PPh_2Me	302	10.65	[20]
Pyox	$Ph_2P(CH_2)_4PPh_2$	308	30.67	[28]
Pyth	$Ph_2P(CH_2)_4PPh_2$	308	14.17	[28]

[a] Estimated standard deviation lie in the range 0.02–0.06.

For the ligands Mepyal, pyox and pyth the activation enthalpies (kcal mol^{-1}) are 8.91, 13.49 and 14.31 respectively while the activation entropies (cal K^{-1} mole^{-1}) are –38.69, –24.15 and –23.32 respectively.[19,20] The large and negative $\Delta S^{\neq}$ values imply close association of $[Re^{V}OCl_3(NN)]$ and PPh_3 in the transition state. A model[20] of this association and subsequent events are stylized in **10** which has common features with oxygen atom transfer reactions of $Mo^{VI}O_2$ and $W^{VI}O_2$.[40–42]



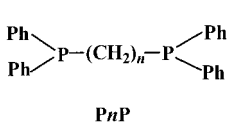
(a) (b) (c)

10

In **10** the full and broken lines, respectively, represent coordinate covalent bonds and weak links. In structurally characterized $[Re^{III}(OPPh_3)Cl_3(NN)]$ complexes the phosphorus atom uniformly lie within 2.8 Å from the centroids of one or both of the triangular OCl_2 faces (see **5**) whereas the distances from the two OClN centroids is greater than 3 Å. It is believed that phosphane attack occurs from the side away from the (NN) chelate ring.

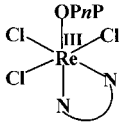
4.2 Diphosphanes: Single and Double Oxygen Atom Transfer

The diphosphanes used are of type **11** abbreviated as P*n*P (n = 1–4). The reaction of $[Re^{V}OCl_3(NN)]$ with excess P*n*P follows second-order kinetics[28] (Table 7) affording **12** which has a dangling phosphane function. The (NN) ligands examined include Mepyal,[27] pyox,[28] pyth,[28] Clazpy[27] and Clazim.[43] Spontaneous solution isomerization is an interesting feature of **12**, vide infra.



P*n*P

11

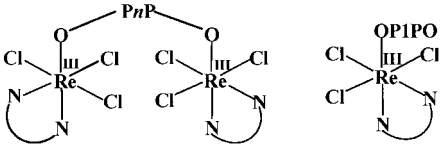


12

The reaction of excess $[Re^{V}OCl_3(NN)]$ with P*n*P leads to successive oxygen atom transfer furnishing binuclear **13**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

when $n > 1$.[27,43] In the case of P1P two atom transfer furnishes only mononuclear $[Re^{III}(OP1PO)Cl_3(NN)]$ (**14**). The dangling phosphane oxide function strongly implicates transient binucleation on the reaction pathway.



13 **14**

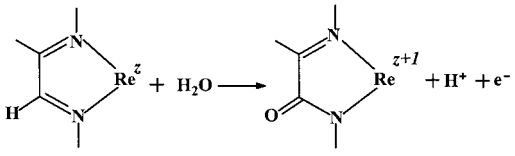
The instability of the binuclear intermediate leading to dissociation of one of the $ReCl_3(NN)$ fragment is due to the excessive steric crowding imposed by the short spacer ($n = 1$).[27]

Metal–ligand bond lengths in the species of type **12**–**14** are very similar to those in $[Re^{III}(OPPh_3)Cl_3(NN)]$ (Table 4). This close similarity extends to other properties including Re^{IV}/Re^{III} reduction potentials.[27,28,43]

5. Oxygen Atom Transfer from Water: Imine→Amide Oxidation

5.1 Re^{IV}(imineamide) Species: Synthesis and Reaction Model

The general reaction is stated in Equation (3) where the imineamide ligand in the product complex is monoanionic (Table 1). This reaction was first encountered in the case of $[Re^{III}(OPPh_3)Cl_3(Rpyal)]$ which afforded $[Re^{IV}(OPPh_3)Cl_3(Rpiam)]$.[19,25,26] The required oxidation equivalents could be provided electrochemically and/or chemically.[19]

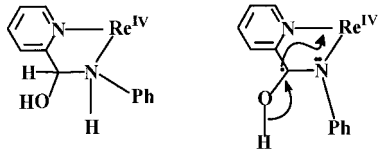


(3)

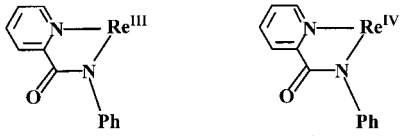
The quasireversible Re^{IV}/Re^{III} couple in $[Re^{III}(OPPh_3)Cl_3(Rpyal)]$ lie near 0.3 V (Table 5). The rhenium(IV) cation $[Re^{IV}(OPPh_3)Cl_3(Rpyal)]^+$, the actual reactive intermediate, is quantitatively afforded upon coulometry (0.5 V in dry MeCN). Upon regulated addition of H_2O to be the oxidized solution (after completion of coulometry) the spontaneous imine→amide reaction [Equation (3)] occurred and the final solution is found to contain $[Re^{III}(OPPh_3)Cl_3(Rpyal)]$ and $[Re^{IV}(OPPh_3)Cl_3(Rpiam)]$ in the mol ratio 2:1. Of the three electrons of Equation (3), one is accounted by the cathodic process corresponding to the anodic $Re^{III}\rightarrow Re^{IV}$ oxidation. The remaining two electrons are consumed by $[Re^{IV}(OPPh_3)Cl_3(Rpyal)]^+$ regenerating two mol of the precursor.

The imineamide complexes were isolated in excellent yields by oxidizing $[Re^{III}(OPPh_3)Cl_3(Rpyal)]$ with excess of chemical oxidants such as Ce^{IV} or H_2O_2 in wet solutions.[19] Here the aldimine→amide conversion proceed quantitatively since it is no longer necessary for $[Re^{IV}(OPPh_3)Cl_3(Rpyal)]^+$ to act as oxidant. Imineamide complexes of type $[Re^{IV}(OPPh_3)Cl_3(Riaam)]$ have been similarly prepared by oxidising the corresponding $[Re^{III}(OPPh_3)Cl_3(Rdabd)]$ precursors with H_2O_2.[21]

In the case of $[Re^{III}(OPPh_3)Cl_3(Hpyal)]$ the reaction rate was found to be first-order with respect to both $[Re^{IV}(OPPh_3)Cl_3(Hpyal)]^+$ and H_2O.[19] The $\Delta H^{\neq}$ and $\Delta S^{\neq}$ parameters are 13.4 kcal mol^{-1} and –27.3 cal K^{-1} mol^{-1}, respectively.[19] Water attack is believed to occur on the aldimine π*-orbital furnishing the α-hydroxy amine intermediate **15** (Cl^- and $OPPh_3$ ligands not shown).



15 **16**



17 **18**

Instances of aqua adduct formation by aldimines have been documented.[44,45] The adduct **15** is however unstable and can undergo rapid transformation via induced transfer of two electrons.[46] The rational steps are: **15**→**16** (oxidative radical formation and proton dissociation), **16**→**17** (internal redox and proton dissociation), and **17**→**18** (metal oxidation). The net result is the imineamide complex **18**.[19]

The crucial requirement for realizing the imine→amide oxidation is the facile accessibility of two oxidation states (here Re^{III} and Re^{IV}) such that the higher state is able to affect sufficient electron withdrawal from the aldimine function to promote nucleophilic water attack. Aldimine→amide oxidation has earlier been documented in ruthenium[47] and iron[48,49] chemistry.

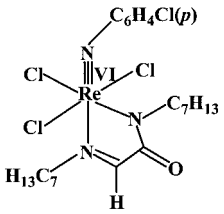
5.2 Re^{VI}(imineamide) Complexes: Regiospecificity and Steric Blockade

The reaction of Equation (3) has provided an elegant way for stabilizing the otherwise rare $Re^{VI}(NAr)$ moiety in the form of $[Re^{VI}(NAr)Cl_3(Rpiam)]$[29,30,50] and $[Re^{VI}(NAr)Cl_3(Riaam)]$[21] which have been isolated via chemical oxidation of $[Re^{V}(NAr)Cl_3(Rpyal)]$ and $[Re^{V}(NAr)Cl_3(Rdabd)]$ in wet solvents.

In the oxidation of the Rdabd complex there are two imine functions to choose from but structure determination of $[Re^{VI}(NC_6H_4Cl)Cl_3(C_7H_{13}iaam)]$ has revealed that the amide nitrogen lie exclusively *trans* to a chloride ligand as in **19** and not to the NAr ligand.[21] This is consistent with the reaction model considered in the previous section of this article. We recall that in $Re^{V}(NAr)$ complexes (see Section 5.1) the Re–N bond lying *trans* to the NAr group is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

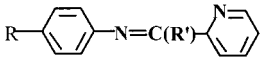
elongated (*trans* influence) compared to the other Re–N bond.



19

The imine function supporting the shorter Re–N bond will thus be more polarized and subject to more facile nucleophilic attack by water. It is indeed this function that is selectively oxidized to amide.

The ketimine analogues, **20**, of Rpyal affords [Re^{V}(NAr)Cl_3(NN)] type systems.[29] The R′ = Me complex was readily converted into the same amide chelate [Re^{VI}(NAr)Cl_3(Rpiam)] obtained from [Re^{V}(NAr)Cl_3(Rpyal)]. But the R′ = Ph system failed to afford any amide complex. Space-filling structural models have revealed that the C=N function in the R′ = Ph system is greatly hindered due to aryl crowding making it inaccessible to nucleophilic water attack. In contrast the function is well exposed in the R′ = H/Me complexes.[29]



R′ = Me, Ph

20

5.3 Structure and Properties

The structures of one $Re^{IV}(OPPh_3)$ and a few Re^{VI}(NAr) imineamide complexes are known (Table 8). These have meridional geometry as in their precursors and the amide group, C–C(=O)–N is uniformly planar. In going from [$Re^{III}(OPPh_3)Cl_3$(Mepyal)] (Table 4) to [$Re^{IV}(OPPh_3)Cl_3$(Mepiam)] (Table 8) the Re–O and Re–Cl distances decrease while the Re–N distances increase very significantly, reflecting decrease of both radius and extent of back-bonding upon metal oxidation (see also Section 3.3).

In the Re^{VI}(NAr) species[21,30] the metal atom is shifted from the Cl_3N plane towards the imido nitrogen by ca. 0.3 Å and the Re–N bond *trans* to the imide function is lengthened by 0.15 to 0.20 Å (Table 8). The radial changes between rhenium(V) and rhenium(VI) species are relatively small. The Re^{VI}–N(imide) length (1.70–1.72 Å) imply triple bonding as in Re^{V}–N(imide) (see Section 3.2). Outside our work structures of very few Re^{VI}N(imide) complexes are known.[29,51]

In [Re^{V}(NAr)Cl_3(diimine)] species the Re^{VI}/Re^{V} couple occur near 1.0 V (Table 5). In the corresponding imineamide complexes two one-electron couples (Re^{VI}/Re^{V} and Re^{VII}/Re^{VI}) occur near 0.2 and 1.5 V (Table 9).[21,19] The Re^{VI}/Re^{V} reduction potential is thus dramatically lowered upon imine oxidation reflecting stabilization of the hexavalent state by the amide function. A similar relationship applies to the Re^{IV}/Re^{III} and Re^{V}/Re^{IV} couples among diimine and imineamide complexes of Re($OPPh_3$)Cl_3 (Table 5 and Table 9).[19]

Table 9. Reduction potentials [V vs. SCE] of Re(imineamide) species in MeCN at 298 [K].

[a] $z = 3$. [b] $z = 5$. [c] Cathodic peak potential.

The Re^{VI}(NAr) complexes (t_2g^1) display six-line EPR spectra in fluid solution[21,29,30] corresponding to the I = 5/2 nuclei ^{185}Re and ^{187}Re which have nearly equal nuclear moments. The centre-field g value and average hyperfine splitting lie near 1.91 and 440 G, respectively.

6. Oxygen Atom Transfer from Azooximes: Oxime→Imine Reduction

In this third type of transfer reaction a preoxidized imine i.e., an oxime function gives up the oxygen atom either to a metal site or to an oxophilic substrate.[52] The concerned oxime ligands are of type **21**, RazoxH (the terminal H is the dissociable oxime proton). Treatment of [Re^{III}(MeCN)$Cl_3(PPh_3)_2$] with the silver salt of **21** in cold affords the azoimine complex **22** isolated as the PF_6^- salt. On the other hand the reaction of [Re^{V}(NPh)$Cl_3(PPh_3)_2$] with **21** furnished the deprotonated azoimine chelated complex **23**. In contrast to **21** the oxime of 2-acetylpyridine reacts with [Re^{V}(NAr)$Cl_3(PPh_3)_2$] without oxygen atom transfer affording stable oximato complexes such as **24**. Bond parameters of **22**–**24** are listed in Table 3.

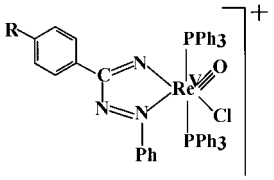
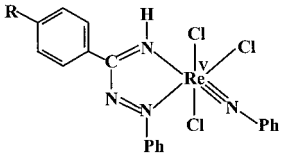
21

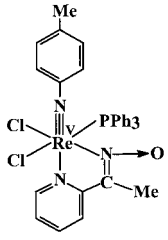


22

The azoimine ligand in **22** and **23** are not known in the free state. There is a report on the chelation of such ligands to bivalent palladium achieved via azooximates reduction.[53] The formation of **22** involves oxidative addition of the oxime function. Instances of such addition are in general rare,[54,55] particularly in rhenium chemistry.[56] Oxime→imine reduction by PPh_3 as in the formation of **23** has been documented in salicylaldoxime chemistry.[57,58] Outside certain dioximates,[59] **24** appears to be the only other structurally characterized oximato complex of rhenium.

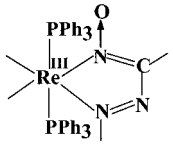


23

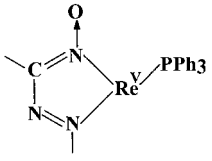


24

The system **25** involving the usual[60] azooxime chelation has been proposed as a possible intermediate in the formation of **22**. The crucial event is activation of oximato oxygen by the electron-withdrawing azo group leading to oxygen atom transfer to the metal site with concomitant displacement of a chloride ligand in *cis* position.[52]



25



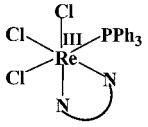
26

In analogy with **24**, the moiety **26** has been proposed to be the possible intermediate in the formation of **23**. Here, rhenium(V) acts as a Lewis acid activator[7] promoting oxygen atom transfer to PPh_3 followed by displacement of $OPPh_3$ by chloride. The relatively weak electron withdrawal by the imine function ensures stability of **24**.

7. Reaction of $[Re^{III}(OPPh_3)Cl_3(NN)]$ with PPh_3

7.1 Geometrical Isomerization

Meridional $[Re^{III}(OPPh_3)Cl_3(NN)]$ (**5**) undergoes facile displacement of coordinated $OPPh_3$ by PPh_3 furnishing facial $[Re^{III}(PPh_3)Cl_3(NN)]$ (**27**).[24,27,28,61] Metal–ligand bond parameters in selected species are listed in Table 10.



27

Table 10. Bond lengths in Re^{III}(phosphane) complexes.

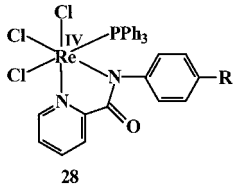
[a] Pyridine/imidazole N. [b] Imine/azo N. [c] Average value.

In **27** two π-acceptor ligands [PPh_3 and (NN)] are present and the net back-bonding is maximized in the facial geometry which ensures minimum competition between the acceptor sites for the same metal orbital. On the other hand in **5** the (NN) ligand can occupy any two *cis* positions and the net geometry is controlled by steric and electrostatic factors. Thus logical stable geometries of **5** and **27** are respectively meridional and facial as observed. Interestingly, the average Re–N distance in a phosphane complex is longer (by upto 0.06 Å) than that in the corresponding $OPPh_3$ complex (see Table 4 and Table 10) where (NN) alone does all the back-bonding. The geometrical selectively is strong and exclusive and in no case isomers have been observed. We recall that $[Re^{V}OCl_3(NN)]$ and $[Re^{V}(NAr)Cl_3(NN)]$ are meridional as expected.

7.2 Metal Redox, Imine→Amide Oxidation and Facial Re^{IV}(imineamide) Species

The Re^{IV}/Re^{III} reduction potential in **27** lie near 0.6 and 1.0 V for diimine and azoimine ligands respectively. These values are higher than those of the corresponding $OPPh_3$ complexes by 0.2–0.3 V (Table 5) reflecting the superior net back-bonding in the PPh_3 complexes.

The complex $[Re^{IV}(PPh_3)Cl_3(Rpyal)]^+$, electrogenerated in solution reacts spontaneously with water affording the corresponding facial imineamide system $[Re^{IV}(PPh_3)Cl_3$-(Rpiam)], **28**. In **28** (R = Cl) the Re–N(py), Re–N(amide), Re–P and Re–Cl(av) distances are 2.123, 2.061, 2.549 and 2.325 Å respectively.[61]



28

The average Re–Cl distance is thus shorter by 0.05 Å and the Re–P distance is longer by 0.1 Å than those in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

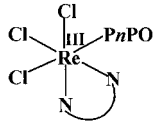
$[Re^{III}(PPh_3)Cl_3(Hpyal)]$ (Table 10) consistent with decrease of metal radius and the degree of back-bonding upon oxidation. The Re^{IV}/Re^{III} reduction potential in $[Re^{IV}(PPh_3)Cl_3(Mepiam)]$ is –0.15 V (Table 9)[61] again signifying the dramatic stabilizing influence of imineamide chelation as opposed to diimine chelation on higher oxidation states (see Section 5.3).

8. Twin Isomerization of $[Re^{III}(OPnP)Cl_3(NN)]$

8.1 The Reaction and Its Pathway

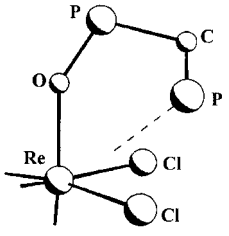
The meridional $[Re^{III}(OPnP)Cl_3(NN)]$ species, **12** undergo spontaneous intramolecular twin isomerization (linkage and geometrical), Equation (4), in solution furnishing facial $[Re^{III}(PnPO)Cl_3(NN)]$, **29**.[27,28,43] The metal–ligand bond lengths in type **29** complexes are very similar to those in **27** (Table 10), also **27** and **29** have very similar Re^{IV}/Re^{III} reduction potentials.[27,28,43]

$$[Re^{III}(OPnP)Cl_3(NN)] \rightarrow [Re^{III}(PnPO)Cl_3(NN)] \quad (4)$$



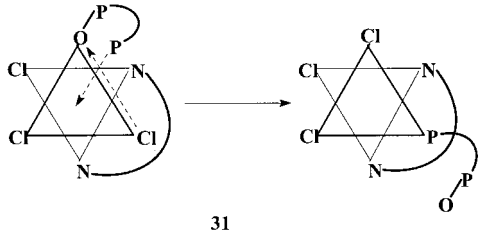
29

The reaction of Equation (4) follows first-order kinetics and is characterized by strongly negative entropy of activation (–20 to –40 cal K^{-1} mol^{-1}). A model for the association of the dangling phosphane function in the transition state (n = 1) is stylized in **30**.



30

Subsequent attack by the P atom on the triangular face with concomitant edge displacement of a chloride ligand and Re–OP bond cleavage affords the facial complex as depicted in **31**.[27]



31

8.2 Effect of Spacer Length and Metal Oxidation State

For the $[Re^{III}(OPnP)Cl_3(pyox)]$ and $[Re^{III}(OPnP)Cl_3(pyth)]$ complexes the rate of the twin isomerization reaction has been determined over the domain n = 1–4[28] (Table 11). The rate decreases approximately exponentially as n increases. The number of possible conformations of the dangling $(CH_2)_nPPh_2$ fragment is indeed expected to increase exponentially with increase of n,[62] but only a few of the conformations will be spatially suited (proximal metal and phosphane site) for the reaction to occur.

Table 11. Rate constants for the twin isomerization of $[Re^{III}(OPnP)Cl_3(pyox/pyth)]$ in CH_2Cl_2 at 308 [K].[28]

N	10^5 k $[s^{-1}]$[a]	
	Pyox	pyth
1	8.42	3.62
2	4.07	1.80
3	1.58	0.72
4	0.67	0.25

[a] Estimated standard deviation lie in the range 0.02–0.05.

In the system $[Re^{IV}(OP1P)Cl_3(pyox/pyth)]^+NO_3^-$ prepared by treating the trivalent congener with dilute nitric acid (see also Section 3.4) the isomerization process is completely arrested even though it is n = 1 case which corresponds to maximum reactivity before oxidation. This is consistent with the kinetic inertness of rhenium(IV) ($5d^3$). Other factors also work in the same direction. Thus rhenium(IV) is a harder acceptor than rhenium(III) and oxygen is a harder donor than phosphorus. This as well as the weaker back-bonding ability of rhenium(IV) is expected to disfavor the attack of the metal by the dangling phosphane function.[28]

9. Bis and Tris Chelation: Rhenium(II) and Rhenium(I)

9.1 Ligand Choice, Synthesis, Magnetism and Metal Redox

Metal π-basicity would increase progressively upon reduction: $Re^{III}<Re^{II}<Re^{I}$. In designing (NN)-chelated complexes of the latter two oxidation states it is imperative that good π-acids are chosen. Azoheterocycles are excellent π-acceptors with low-lying π*(azo) orbitals.[17,18,63,64] These have indeed afforded bis and tris chelates of coordination types $[Re^{II}Cl_2(NN)_2]$, **32** and $[Re^{I}(NN)_3]^+$, **33** for the first time in rhenium chemistry.[31,65] In **32** and **33** N^a and N^h are azo and heterocyclic nitrogen atoms respectively. A remarkable feature is the exclusive occurrence of the geometrical forms depicted in **32** and **33**. For synthesis, $[Re^{V}OCl_3(PPh_3)_2]$ and/or $[Re^{V}O(OEt)Cl_2(PPh_3)_2]$ were used as starting materials. For assembling bis and tris chelates the Re:(NN) ratio used was 1:2.5 and 1:6 respectively.[31,65] In most cases the tris chelates were isolated as ReO_4^- salts.

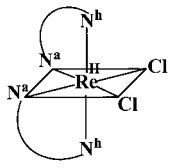
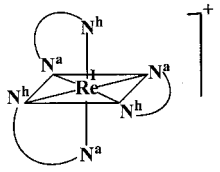
[a] Average values in bis and tris chelates. [b] Azo N. [c] Heterocyclic N. [d] $z = 2$. [e] $z = 1$.



32



33

The bis-chelates are paramagnetic (t_{2g}^5) and in fluid solution these display well-resolved EPR spectra with six hyperfine lines. The centre-field *g* value and the average hyperfine splitting lie near 2.10 and 280 G, respectively[31,65] [compare with the Re^{VI}(NAr) case, see Section 5.3]. The tris chelates are diamagnetic (t_{2g}^6) and their ^{1}H NMR spectra reveal that the three chelate rings are magnetically equivalent consistent with the facial geometry. The bis and tris chelates display well defined Re^{III}/Re^{II} and Re^{II}/Re^{I} couples respectively (Table 12).

9.2 Structure, Back-Bonding and Isomer Specificity

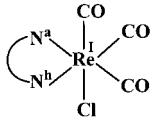
Selected average bond lengths[31,65] are listed in Table 12. The Re–N^a length is uniformly shorter than Re–N^h length by 0.05–0.1 Å and the average N–N distance is longer by 0.1 Å than that in uncoordinated azo ligands (1.25 Å). Clearly strong d(Re)-π*(azo) back-bonding is present [compare with rhenium(III) species, Section 3.2].

The observed geometrical disposition of the ClCl–N^hN^h–N^aN^a donor sites in $[ReCl_2(NN)_2]$ is uniformly *cis*-*trans*-*cis*, see **32**. Four other isomers are possible but none of these have been observed.[65] Similarly the tris-chelates were isolated exclusively in the facial form (no meridional isomer observed). The *cis* (as opposed to *trans*) disposition of two N^a donor sites as in **32** ensures maximum back-bonding. Further, **32** is sterically more favorable than other possible isomers. In facial **33** the three N^a atoms represent a model situation for back-bonding which more than offsets the steric disadvantage of the facial geometry.

Two comparisons are relevant. First, $[Os(N^aN^h)_3]^{2+}$ which is isoelectronic with $[Re(N^aN^h)_3]^+$ occur in isomeric forms, primarily meridional,[64] reflecting the π-basicity order $Re^{I}>>Os^{II}$. Second, tris chelation of 2,2′-bipyridine stabilizes the rhenium(II)[66] as opposed to rhenium(I) showing that azoheterocycles are superior π-acceptors than bipy.

10. Monochelation of $Re^{I}(CO)_3$ by (NN) and ($NN^{\bullet-}$)

The $[Re^{I}(CO)_3Cl(NN)]$ system, **34**, results from the reaction of $[Re(CO)_5Cl]$ with azoimines.



34

The Re–N^a and Re–N^h distances (2.15 ± 0.02 Å) are nearly equal and the azo N–N distance lie close to 1.27 Å (Table 12).[67–70] Thus carbon monoxide does most of the back-bonding and the t_{2g} shell is greatly stabilized as reflected in the high Re^{II}/Re^{I} reduction potential (Table 12). A second one-electron couple (–0.6 to –0.1 V) assignable to azo reduction is also observed and the $[Re^{I}(CO)_3Cl(NN^{\bullet-})]$ species so generated have been spectrally characterized in solution.[71]

The chloride ligand in $[Re^{I}(CO)_3Cl(NN^{\bullet-})]$ is labile furnishing $[Re^{I}(CO)_3(MeCN)(NN^{\bullet-})]$ in acetonitrile solution. These anion radical complexes, as well as $[Re^{I}(CO)_3(PPh_3)(NN^{\bullet-})]$ and $[Re^{I}(CO)_3(imidazole)(NN^{\bullet-})]$ derived from them have been isolated. These are EPR-active in solution with g values lying near 2.003. Six hyperfine lines representing a small metal contribution to the spin-bearing orbital are observed. Thus in $[Re^{I}(CO)_3(D)(Clazim^{\bullet-})]$ coupling constants are 27.25, 28.75 and 39.1 G for D = MeCN, imidazole and PPh_3, respectively.[70]

11. Conclusion

New families of rhenium complexes incorporating chelation of conjugated (NN)-donors have been assembled in a rational manner. Systematic structural and electrochemical studies have revealed interesting trends of bond lengths and reduction potentials. Three types of oxygen atom transfer reactions have been encountered and their pathways scrutinized using rate and structural data. Unusual redox induced oxygen atom transfers from water and from the oximato function have respectively provided access to rare tetra-/hexa-valent imineamide and pentavalent azoimine systems. π-Basicity and back-bonding is a dominant feature of the lower oxidation states ($Re^{III}<Re^{II}<Re^{I}$) as reflected in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bond parameters. This gets expressed in spontaneous isomerization upon substitution of phosphane oxide by phosphane, in the isomer specificity of bis/tris chelates of di-/mono-valent rhenium and in the stabilization of anion radical species. A concern of ongoing studies is the search for active complexes of new (NN) ligands and unusual atom transfer reactions.

Acknowledgments

No amount of thanking will be sufficient to express my gratitude to the many students who did the work reported and whose names appear in the references cited. Generous funding received from the Department of Science and Technology, New Delhi, and to a certain extent from the Council of Scientific and Industrial Research, New Delhi, is gratefully acknowledged. I am very thankful to S. Sengupta, and S. Das for helping with the preparation of this review.

A New Coordination Polymer Architecture with (10,3)-a Network Containing Chiral Hydrophilic 3-D Channels

Aksana Zharkouskaya,[a] Axel Buchholz,[a] and Winfried Plass*[a]

Keywords: Coordination polymer / Copper / Magnetic properties / N,O ligands

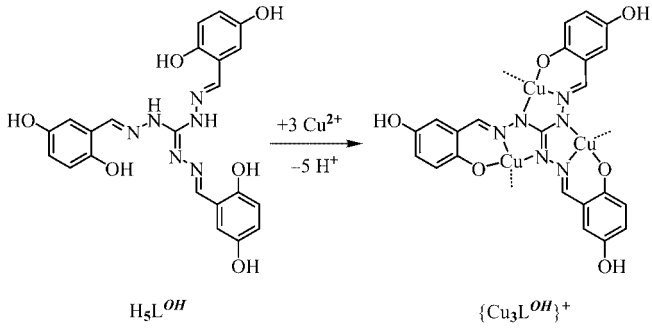
The triaminoguanidine-based Schiff-base ligand H_5L^{OH} reacts with copper(II) ions to afford a three-dimensional coordination polymer with (10,3)-a topology which is solely assembled by a single trigonal molecular building block $\{Cu_3L^{OH}\}^+$. The unusual bridging mode of the phenolate oxygen atoms between the trigonal building blocks leads to a dihedral angle between the interlinked $\{Cu_3L^{OH}\}^+$ units of 71°. The (10,3)-a topology of the singular network results in a rather large void space of about 56 % that is established by interpenetrated chiral channels with a diameter limited by pseudo-tetrahedral cavities defined by non-coordinating phenolate hydroxy groups of the ligand. Additional information to establish the composition is derived from elemental analysis and TGA measurements. For the coordination polymer an overall antiferromagnetic behavior is observed. The spin-frustrated trinuclear building blocks $\{Cu_3L^{OH}\}^+$ are antiferromagnetically coupled via the bis(phenoxide)-bridged dinuclear copper(II) moieties for which a dihedral angle of 132° is observed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Over the last decade the design of porous coordination polymers has become one of the most rapidly developing areas because of their potential applications as rationally designed functional solids with interesting optical, electrical and magnetic properties.[1,2] Of great interest is the architecture and the topological variety of frameworks.[3] Particularly challenging is the design of crystalline material combining different properties like porosity and chirality.[4] Because of specific pore size, type and function of cavities such materials can be applied in ion exchange, catalysis, enantioselective sorption, and gas separation.[1,5] Coordination polymers with (10,3)-a topology are particularly interesting, since they are known to form homochiral porous frameworks which at the same time can show considerable structural stability towards the exchange of guest molecules. These properties make such materials important subjects of research for the development of enantioselective sorption and chiral catalysis.[6]

The interaction of transition metal ions with multifunctional ligands by self-assembly processes is a basic strategy to afford a broad variety of coordination polymers.[1] In particular, the assembly of (10,3)-a nets is generally based on trigonal molecular building blocks that are linked by additional connecting units; both can be either appropriate ligands or metal fragments.[3] Triaminoguanidine-based ligand systems have recently been employed by Robson and Müller et al. in the synthesis of a variety of interesting discrete cage molecules with different topologies.[7]

Here, we report a novel three-dimensional coordination polymer with (10,3)-a topology assembled from a single trigonal molecular building block leading to a homochiral three-dimensional channel system. The utilized trigonal building block is derived from tris[(2,5-dihydroxybenzylidene)amino]guanidine (H_5L^{OH}) chelating copper(II) ions as depicted in Scheme 1. Dark brown cube-shaped single crystals of $[Cu_6(L^{OH})_2(HCOO)_2(H_2O)_{0.5}(DMF)_{0.5}]\cdot xH_2O\cdot y$DMF (**1**) were obtained by slow diffusion of a solution of Bu_4NOH in methanol into a DMF solution containing $(H_6L^{OH})Cl$ and $Cu(BF_4)_2\cdot 6H_2O$ in a 1:3 molar ratio at room temperature.



Scheme 1.

Single-crystal X-ray diffraction reveals a three-dimensional porous framework that is composed of trigonal $\{Cu_3L^{OH}\}^+$ units which are interlocked by the formation of bis(phenoxide)-bridged dinuclear copper(II) moieties as

depicted in Figure 1. In contrast to the generally observed planar coordination motif for the bis(phenoxide)-bridged dinuclear copper(II) moieties a dihedral angle of 132° is observed for compound **1**. The typically observed symmetric planar bridging mode is prevented by the steric requirements of the given ligand. As a consequence, an asymmetric bridging moiety is obtained, with the bridging oxygen atoms O11 and O21 in an equatorial position at Cu1, whereas for Cu2 they occupy axial and equatorial positions, respectively. As a result, the copper ions of the two crystallographically distinct $\{Cu_3L^{OH}\}^+$ units exhibit different coordination environments, which are tetracoordinate square-planar for Cu1 and pentacoordinate square-pyramidal for Cu2. In the latter case the bridging oxygen atom O11 is in the apical position at a distance of 232.5 pm and the fourth equatorial position, not occupied by the ligand L^{OH}, is filled by an oxygen atom from the formate counterion or a solvent molecule (see Exp. Sect.). This leads to distinct conformational variations of the two crystallographically independent $\{Cu_3L^{OH}\}^+$ units as depicted in Figure 2. Within the two trinuclear units the distance between the copper ions is about 475 pm, whereas a distance of 290 pm is found along the bridging dinuclear moiety. The resulting dihedral angle between the interlinked $\{Cu_3L^{OH}\}^+$ units is about 71°.

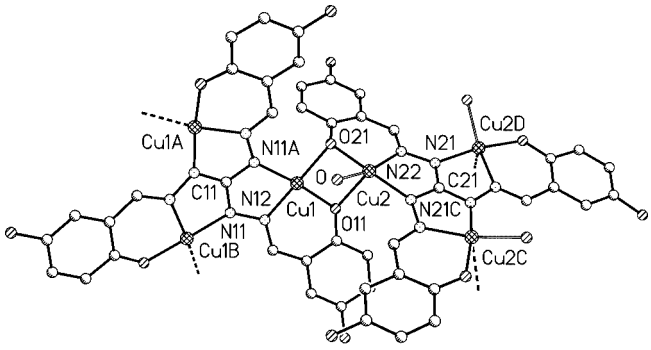

Figure 1. Molecular structure of the $\{Cu_6(L^{OH})_2\}$ building unit of the 3-D coordination polymer **1**. Hydrogen atoms are omitted for clarity; formate anion and solvent molecules are represented by the coordinating oxygen atom; symmetry-equivalent atoms are denoted by A–D. Selected bond lengths [pm] and angles [°]: Cu1–O11 188.9(6), Cu1–O21 200.6(5), Cu1–N12 192.9(6), Cu1–N11A 194.8(6), N11–N12 138.4(9), Cu2–O11 232.5(6), Cu2–O21 195.1(5), Cu2–N22 194.8(6), Cu2–N21C 1.952(6), N21–N22 139.3(9); O11–Cu1–O21 82.9(2), N12–Cu1–N11A 80.5(3), O21–Cu2–O11 73.6(2), N22–Cu2–N21C 80.7(3), Cu1–O11–Cu2 86.4(2), Cu2–O21–Cu1 94.3(2).

The three-dimensional coordination polymer **1** possesses a (10,3)-a network as shown using a simplified view in Figure 3. The fact that two different $\{Cu_3L^{OH}\}^+$ trigonal building blocks assemble the framework leads to a considerable distortion of the archetype (10,3)-a network. The distortion arises from the intercentroid vectors no longer being coplanar, with the angles between the vectors centered at the trigonal building blocks $\{Cu1_3L^{OH}\}^+$ and $\{Cu2_3L^{OH}\}^+$ changing from 120° in an ideal (10,3)-a net to 114.9 and 118.7°, respectively. The chirality of the present (10,3)-a network arises form the [100] pseudo-fourfold and [111] pseudo-

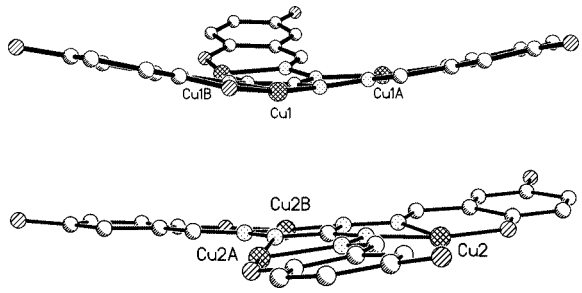

Figure 2. Molecular conformations of the trinuclear building units of **1**: Bowl-shaped $\{Cu1_3L^{OH}\}^+$ (top) and propeller-shaped $\{Cu2_3L^{OH}\}^+$ (bottom).

threefold coordination helices running along the crystallographic 2_1 and 3_2 axes which are of the same handedness propagating in all crystallographic equivalent directions. The packing diagram of compound **1** depicted in Figure 4 shows pseudotetragonal channels along the [100] direction. The size-limiting feature of these channels are the pseudotetrahedral cavities centered at 0,0,1/4 which are defined by the noncoordinating phenol hydroxy groups of the ligand with a diameter of 800 pm for an inscribed sphere. Along the [111] direction this leads to pseudohexagonal zigzag channels passing through these cavities (see Figure 4). The noncoordinating hydroxy groups lead to a hydrophilic character of the solvent-accessible free volume of compound **1**. As a consequence, the resulting void space of **1** is occupied by disordered DMF and H_2O guest molecules.[8] The effective free volume of **1** was calculated with PLATON[9] as 56.4% of the crystal volume (6327 nm^3 out of the 11220 nm^3 unit cell volume). A representation of the void space of **1**, based on the pseudotetragonal channels, is given in Figure 5.

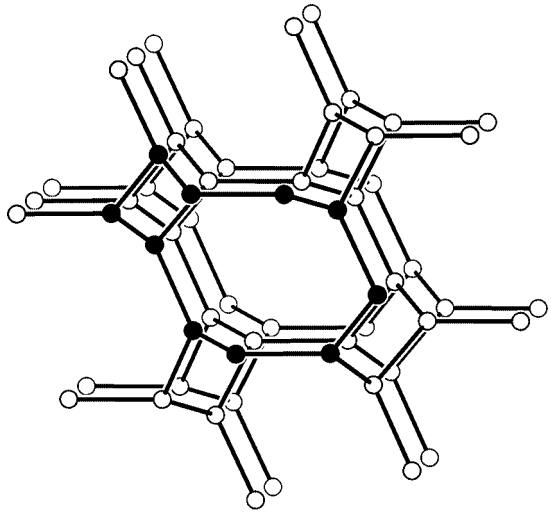

Figure 3. Topology of the 3-D porous framework of **1** shown along [010] with one of the 10-membered rings of the (10,3)-a network highlighted; the nodes represent the central carbon atoms C11 and C21 of the building units.

The thermal behavior of **1** was studied in the range 298–573 K under a flow of nitrogen. The TGA analysis indicates, that the guest molecules can be removed over the tem-

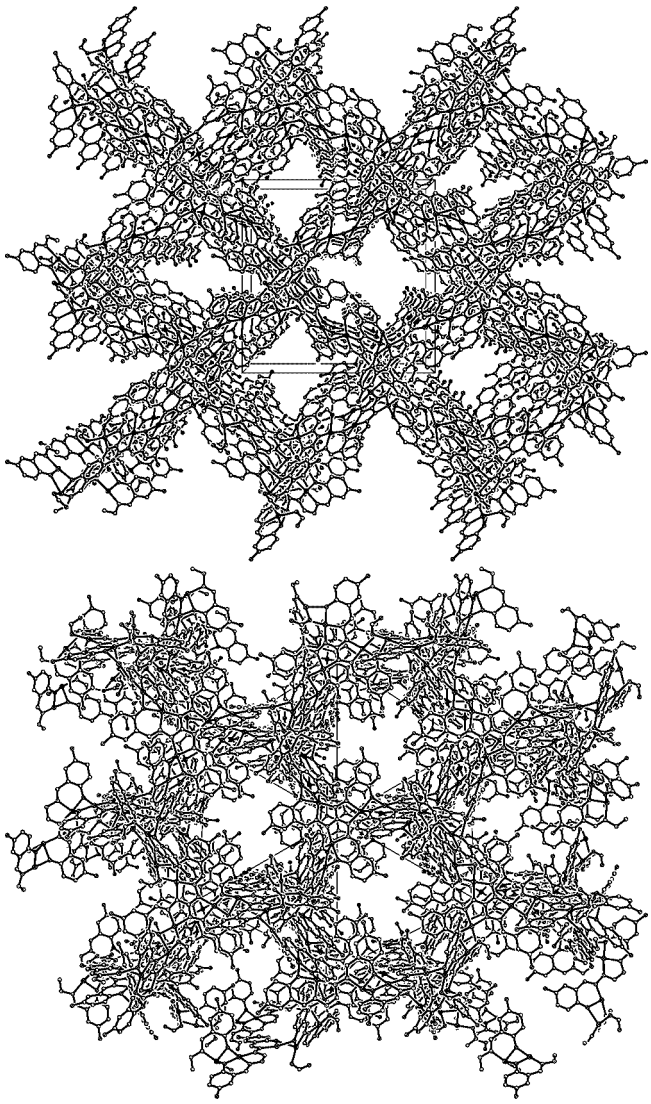

Figure 4. Representation of the network structure of **1** showing the channels along [100] (top) and [111] (bottom).

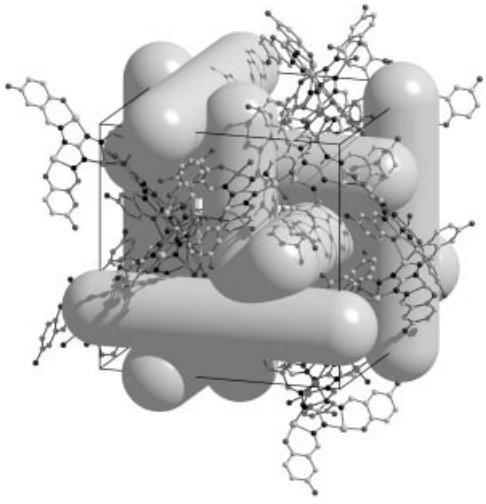

Figure 5. Unit cell of **1** with the pseudo-tetragonal channels represented by cylinders with a diameter of 0.8 nm; all building units originating within the cell are generated.

perature range 313–453 K with an observed weight loss of about 25%. Together with the data from the elemental analyses for samples after prolonged storage under ambient conditions (temperature and atmosphere) this gives a number of three DMF and six H_2O guest molecules per formula unit of **1** filled in the void space.[10] X-ray powder diffraction studies of samples heated to 453 K indicate that the long-range order of the framework structure of **1** is retained upon removal of the guest molecules. If samples of **1** are evacuated at room temperature, a weight loss of about 9% is observed within the first 5.5 h. After 36 h in vacuo, the final weight was constant with an observed loss of about 12%.

The magnetic susceptibility of **1** was measured with a SQUID susceptometer for polycrystalline samples in the temperature range of 2–300 K at a field of 1000 Oe. The temperature dependence of the susceptibility χ and the product χT is shown in Figure 6. For practical reasons the mass susceptibility χ_g was used here, as the actual solvent content can vary considerably.[10] Within the measured range the high-temperature limit expected for a spin-only value of independent copper(II) centers is not reached. In fact, the room-temperature value of χT, based on a molecular mass as derived form TGA and elemental analysis, corresponds to less than 80% of the expected spin-only value. Together with the observed decrease of χT upon cooling, this is indicative for rather strong antiferromagnetic interactions within the system. Nevertheless, within the low-temperature limit of the measurement at 2 K the χT product does not vanish completely with a value that corresponds approximately to the spin-only value of one copper(II) center. The X-band ESR spectrum of **1** recorded on a powdered sample at 77 K exhibits one unstructured broad band at g = 2.072 with a peak-to-peak separation of 29 mT.

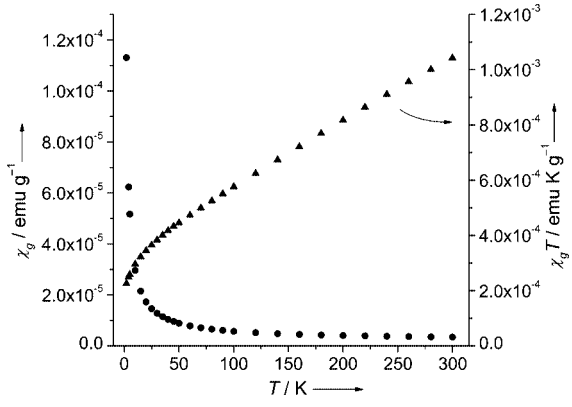

Figure 6. Temperature dependence of χ_g (•) and $\chi_g T$ (▲) for **1**.

Given the structural topology, two basic exchange pathways between the copper(II) centers are possible. One across the trinuclear $\{Cu_3L^{OH}\}^+$ units and the other within the bis(phenoxide)-bridged dinuclear copper(II) moieties. Consequently, two simplified exchange models could be anticipated if either of the two coupling constants prevails the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

overall system. Attempts to fit the experimental data with either isotropic spin Hamiltonian model did not yield satisfactory results, suggesting that both exchange pathways are important. For the interaction of the two bis(phenoxide)-bridged dinuclear copper(II) centers Thompson's linear relationship between the Cu–O(Ph)–Cu angle and the coupling constant J (J = 2462 – 31.95a)[11] gives an estimate of about –400 cm^{-1}, based on an average angle of 90°. Nevertheless, this value probably overestimates the actual exchange coupling constant, since for compound **1** with a dihedral angle of 71° a considerable distortion from the coplanarity of the two square planes is observed (cf. Figure 1). On the other hand for isolated trinuclear $\{Cu_3L^{OH}\}^+$ units as part of complexes with appropriate capping ligands at the copper(II) centers a spin-frustrated system with antiferromagnetic coupling parameters in the order of –320 cm^{-1} is observed.[12] The fact that no plateau in the χT diagram corresponding to the spin-frustrated triangular units is evident, indicates the equal importance of the exchange coupling along the dinuclear copper(II) interlocking moieties.

In summary, a novel magnetic 3-D coordination polymer with distorted (10,3)-a network has been synthesized. The size limit and character of the void space of the polymer is defined by the *para* substituent on the coordinating phenolate moiety of the ligand. Both the variation of the ligand substitution and the metal ion are expected to yield materials with interesting new properties.

Experimental Section

General: $Cu(BF_4)_2{\cdot}6H_2O$ and Bu_4NOH were purchased from commercial sources and used as received. (H_6L^{OH})Cl was prepared analogous to procedures reported in the literature.[13] Yield: 79%. (H_6L^{OH})Cl·3H$_2$O ($C_{22}H_{27}ClN_6O_9$, 554.9): calcd. C 47.62, H 4.90, N 15.14; found C 48.01, H 4.79, N 15.38. ^{1}H NMR (200 MHz, CD_3OD, 298 K): δ = 8.80 (s, 3 H, N=CH), 7.39 (d, J = 2.72 Hz, 3 H, C6-H), 6.73–6.85 (m, 6 H, aromatic CH) ppm. ^{13}C NMR (50 MHz, CD_3OD, 298 K): δ = 114.0, 118.0, 120.9, 121.4, 150.2, 150.5, 151.4, 152.2 ppm.

[$Cu_6(L^{OH})_2(HCOO)_2(H_2O)_{0.5}(DMF)_{0.5}$]·$xH_2$O·$y$DMF (1): A solution of ($H_6L^{OH}$)Cl·3H$_2$O (278 mg, 0.5 mmol) in DMF (5 mL) was added to a solution of $Cu(BF_4)_2{\cdot}6H_2O$ (518 mg, 1.5 mmol) in DMF (5 mL). The resulting dark green-brown solution was carefully layered in a glass tube with DMF (3 mL) and with a 1 M methanolic solution of Bu_4NOH (2.5 mL). The glass tube was sealed and left at room temperature. Slow diffusion afforded dark brown crystals of **1** within 3 weeks. The crystals were isolated, washed with MeOH and dried in air. Yield: 30 mg. **1** with x = 6 and y = 3 (prolonged storage at room temperature, $C_{56.5}H_{69.5}Cu_6N_{15.5}O_{26}$, 1763.0): calcd. C 38.49, H 3.97, N 12.31; found C 38.56, H 3.77, N 12.66. Elemental analyses for freshly prepared samples shown higher C and H values due to a higher content of disordered solvent molecules.

Crystal Data for 1: $C_{47.5}H_{36.5}Cu_6N_{12.5}O_{17}$·guests, M = 1435.7, 0.03 × 0.03 × 0.02 mm, cubic, space group $P2_13$, a = 2238.69(5) pm, V = 11.2197(4) nm^3, Z = 4, $\rho_{calcd.}$ = 0.917 g cm^{-3}, T = 183 K, λ = 71.073 pm, μ(Mo-K_α) = 1.164 mm^{-1}, Θ range 3.28–27.46°, 7530 measured and 5231 independent reflections (R_{int} = 0.0415), 285 parameters with no restraints, R_1 = 0.0746, wR_2 = 0.1799 for 5231 reflections with $I > 2\sigma(I)$, GOF = 1.089, Flack parameter = –0.02(4). The data were collected with a Nonius KappaCCD diffractometer. The structure was solved by direct methods (SHELXS) and subsequent full-matrix least-squares refinement against F^2 (SHELXL). The fourth equatorial position at Cu2 (not occupied by the ligand L^{OH}) is occupied by an oxygen atom from either a formate counterion or a solvent molecule of DMF or H_2O, leading to a partial occupation of the corresponding positions in the ratio of 2:3, 1:6 and 1:6, respectively. CCDC-268709 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Infinite Chains of Quasi-Planar Hexameric Water Clusters Stabilized in a Metal-Organic Framework Built from Co^{II} and Pyrazine-2,3,5,6-tetracarboxylic Acid

Sujit K. Ghosh[a] and Parimal K. Bharadwaj*[a]

Keywords: Water cluster / Supramolecular chemistry / Self assembly / Organic-inorganic hybrid composite

Pyrazine-2,3,5,6-tetracarboxylic acid ($ptcH_4$) reacts with $Co(NO_3)_2 \cdot 6H_2O$ in 1:2 molar ratio in aqueous pyridine (py) at room temperature to form a coordination polymer with the empirical formula, $\{[Co_2(ptc)\cdot(py)_2\cdot 4H_2O]\cdot 4H_2O\}_n$, (**1**). The structure consists of 2D sheets of metal-organic frameworks and infinite chains of cyclic water hexamers that join these sheets to form an overall 3D structure. Thermogravimetry, X-ray powder diffraction and X-ray structural analysis have been used in addition to infrared spectroscopy and elemental analysis to characterize **1**. Crystal data for **1**: monoclinic space group $P2_1$, a = 7.153(4), b = 17.003(2), c = 11.060(5) Å, β = 107.207(5)°, V = 1284.9(11) Å^3, Z = 2, $R1$ = 0.0340, $wR2$ = 0.0875, S = 1.028. This structure demonstrates a new mode of association of water molecules.

Introduction

Identification of small water clusters[1a–1g] in diverse environments continue to be a subject of considerable interest as it provides the key to test and calibrate theoretical studies to understand this liquid. In spite of characterization of a number of clusters of different nuclearity coupled with advances in computational capabilities, some of the properties of liquid water still cannot be accurately described over a significant range of conditions.[2] The advantage of water clusters/networks having different structures is the possibility to correctly describe the many-body interactions among a group of molecules. It also affords to simply vary the size and to investigate the development of properties of the condensed phase in a step-by-step manner.

Supramolecular association of water molecules in the form of chains constitute an important form of water that is poorly understood.[3] However, water chains are generally accepted to play important roles in several biological processes. In membrane-spanning protein gramicidine *A*, the conduction of protons is believed[4] to take place through a chain of hydrogen-bonded water molecules embedded in the protein. Water chains appear to be important[4] in the control of proton fluxes in a variety of biomolecules such as cytochrome b6f, mitochondral ATPase, carbonic anhydrase II, cytochrome c oxidase, bacteriorhodopsin, etc. The highly dynamic water molecules present in membrane channel protein aquaporin I adopt a chain structure for efficient and selective permeation of water across membranes.[5] Although identification of water chains in crystal hydrates is growing, the structural constraints of the host lattice required to stabilize chain structure or the influence of the chain on the host structure remain incomplete.

Water chains can be built either from zig-zag connections of water molecules or through connections of one or more types of cyclic rings. Of particular interest here is the water chains made from hexameric rings. The hexamer has been subjected to a number of experimental[6] and theoretical[7] studies as it is the building block of ice and also exhibits some of the properties of bulk water.[8] Clusters up to pentamers generally have cyclic and quasi-planar structures and the larger clusters have 3D structures. The hexamer behaves as the transitional point from 2D to 3D structures.[9] Theoretical calculations[7] on the $(H_2O)_6$ cluster show five minima in the potential energy surface that correspond to five almost iso-energetic conformers – "cage", "prism", "book", "boat" and "cyclic". The "cage" conformer is the most stable at low temperature and has been observed[10] by vibration-rotation tunneling spectroscopy while a quasi-planar cyclic hexamer was detected[11] in a helium droplet. The lattice of a crystal host offers an environment where a higher energy conformer can be stabilized and this way, chair,[6b,6c,6f] boat[6a,6d] and planar[6e] forms have been characterized in inorganic as well as in organic crystal hosts.

We report here, the X-ray structure of infinite chains of hexameric quasi-planar water molecules present in a metal-organic framework (MOF) built from Co^{II}, pyridine and pyrazine-2,3,5,6-tetracarboxylic acid.[12] Our recent efforts[1d,e,6a,c,13] are directed towards the synthesis of MOFs with voids of different shapes and sizes that can include

water clusters of different nuclearity. The degree of structuring of water clusters that can be imposed by its environment and vice versa are important in the design of new MOF structures with the ultimate aim(s) of having materials with potentially useful applications.

Results and Discussion

Compound **1** crystallizes in a non-centrosymmetric space group presumably due to unsymmetrical distribution of lattice water molecules. The structure consists of two types of hexacoordinate Co^{II} ions that are bonded to the ligands as shown in Scheme 1. For the ligand, ptc^{4-}, only the carboxylate group at the 2-position is not bonded to a metal. Here, Co2 is equatorially bonded to two pyrazine tetracarboxylate ligands through ring N and one carboxylate O atoms (N_2O_2 donor) and the axial positions on the metal are occupied by a pyridine and a water molecules. Thus, Co2 and ptc^{4-} ligands form a linear coordination polymer extending along the crystallographic *a* axis. The Co1 ion is axially bonded to two carboxylate O atoms belonging to two different polymeric chains thus connecting them to form a 2D coordination polymer in the crystallographic *ac* plane (Figure 1). The equatorial sites of Co1 are occupied by three H_2O and one pyridine molecules. The bond lengths and bond angles involving each Co^{II} center are comparable[13b] with reported values for octahedral Co^{II} complexes. Atoms Ow1 bound to Co1 and Ow4 bound to Co2 are hydrogen-bonded to four other water molecules forming a cyclic hexameric water cluster. The atoms Ow7 and Ow8 are not connected to the cluster. These clusters further assemble the 2D networks along the crystallographic *b* axis into an overall 3D MOF (Figure 2 and Figure 3).

Atom Ow3 of the hexamer is H-bonded to Ow5′′ belonging to another hexamer forming a chain of cyclic hexamers parallel to the *ab* plane and extending along the crystallographic *a* axis (Figure 4). Due to a long distance (3.955 Å) between Ow2′ and Ow6, they are not considered as H-bonded even though one of the H atoms of Ow2 is pointed toward Ow6′. However, the less number of H-bonding interactions among the water molecules are compensated by H-bonding interactions these molecules have with the surroundings (Table 1). Chains of hexameric water clusters with different modes of connectivity present in different crystal hosts are collected[17] in two recent articles. Interconnected hexameric boat conformers are present[18] in hexagonal ice (I_h) and also identified[6g] between the layers of an inorganic polymer constructed from $CdNi(CN)_4$ units. Water molecules forming a hexameric chair conformation and self-assembly of these units into a 1D tape had been found[6f] in an organic host constructed from 5-amino-2,4-dimethylbenzo[*b*]-1,8-naphthyridine. Very recently, 1D chains consisting of cyclic hexameric chair conformers connected by Zn^{II} or Co^{II} have been found[6b] in the complexes, $[M(H_2biim)_2(OH_2)_2](ina)_2{\cdot}4H_2O$ [M = Zn^{II} or Co^{II}, H_2biim = 2,2′-biimidazole, *ina* = isoniconate]. Following the nomenclature suggested by Infantes and Motherwell,[17] the water chain in **1** may be designated as T6(0)A0. Although a structure with the same designation is reported[17] by these authors, the chain is propagated through Ow1 and Ow4 atoms whereas in this case, it is through Ow3′ and Ow5 atoms (Figure 4).

While theoretical calculations[7a] predicts the "cage", "prism", "book", "boat" and "cyclic" conformations that are almost isoenergetic, the lattice of a crystal host may offer an environment for stabilizing a higher energy conformer. In the present structure, the six O atoms of the

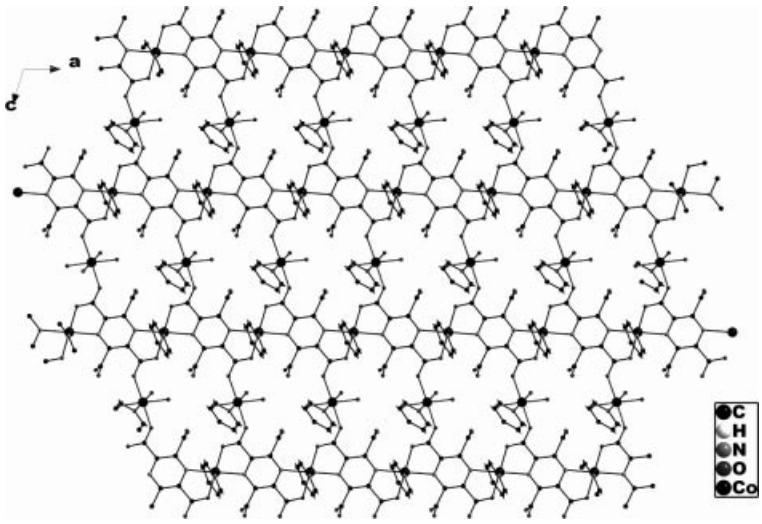

Figure 1. A perspective view of the planar sheet structure of **1** viewed down the *b* axis. Hydrogen atoms are omitted for clarity.

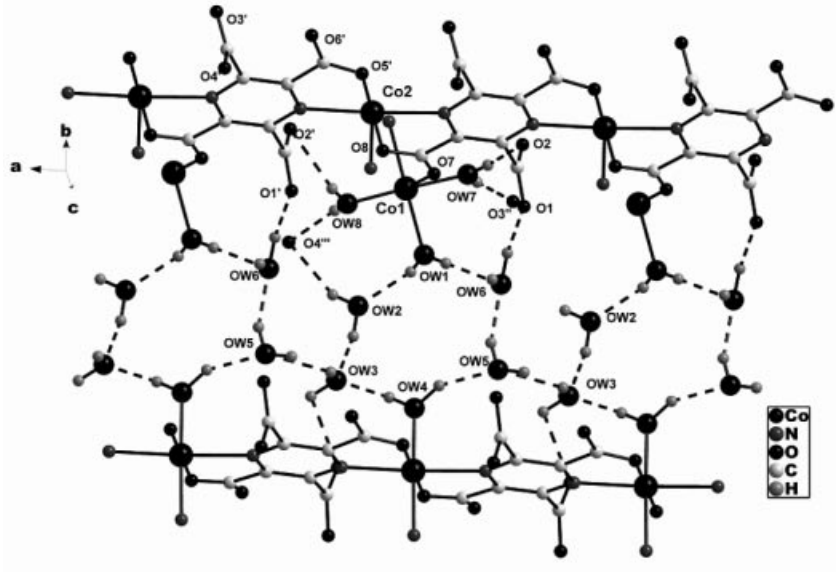

Figure 2. A view showing how water molecules are bound to the MOF. The lone blue spheres are pyridine N atoms. The entire pyridine molecule is not shown for clarity.

hexameric unit assume a slightly puckered conformation and this mode of association results from two factors: (1) the Ow atoms are H-bonded to the carboxylate O atoms which are fixed as almost coplanar in space and (2) the metal-bound pyridine molecules (Figure 3) would obstruct if the conformation is deviated significantly from planarity. Cyclic planar water hexamer is the basic structural motif found[19] in ice II structure under high pressure. This is also a prominent structural unit present[20] in liquid water based on computer simulation while Nauta and Miller detected the "quasi-planar" hexamer within a helium droplet.[11]

The nonbonding Ow···Ow distances (Table 1) show a wide variation commensurate with the MOF structure. The average O···O distance of 2.795 Å is smaller than that of liquid water which shows a value of 2.85 Å from the X-ray diffraction radial distribution curve while for the gas phase, this value is ca. 0.1 Å longer.[18] The water molecules present in clefts of biological/abiological molecules are very different from the gas phase or bulk liquid water. Here, the principle of maximizing H-bonding interactions is followed where the environment plays a major role. Consistent with this principle, the O···O distances in the cluster vary widely for optimized interactions between the water molecules and between a water molecule and its surrounding. For a discrete quasi-planar hexamer[6e] trapped in an organic supramolecular complex with bimesityl dicarboxylic acid, the average O···O distance (2.775 Å) is shorter while in case of a dodecameric[21] water cluster built around a planar cyclic hexamer in a supramolecular complex of a cryptand, the O···O distance (2.801 Å) is similar to the present structure. The nonbonding O···O···O angles (Table 1) in **1** span a wide range [104.8 (3)–132.7(2)°] deviating considerably from an ideal benzene-like structure. In the chain, Ow1 and Ow4 act as double donors, Ow6 as double acceptors while the rest

[a] One H atom in each of Ow4 and Ow5 could not be located in the difference Fourier maps. Their positions were calculated (H2W4 and H2W5) and added to the atom list. Atoms Ow3′ and Ow5′′ are related by 2 – *x*, 1/2 + *y*, 2 – *z* and 2 – *x*, –1/2 + *y*, 2 – *z* respectively.

act both as donors and acceptors of H-bonding. So, every O atom in the unit does not show four coordination. Such hydrogen-bond deficient water molecules are present[22] at the surface of ice while recent X-ray absorption spectroscopy and Raman scattering studies of liquid water also point to the fact that significant number of O atoms show less than tetracoordination in liquid water.[23]

Thermal analysis of the compound shows that onset of water loss starts at ca. 30 °C and complete loss of water takes place within 100 °C without showing any plateau in the thermogram.[24] The FTIR spectrum[24] of **1** shows a broad band centered around 3415 cm^{-1} attributable to the O–H stretching frequency of the water cluster. This broad band vanishes on heating the compound under vacuum (0.1 mm) at 140 °C for 2 h suggesting escape of the water molecules from the lattice. The IR spectrum of ice[18a] shows the O–H stretching at 3220 cm^{-1} while this stretching vibration in liquid water[18a] appears at 3490 and 3280 cm^{-1}. This suggests that the water cluster in **1** shows O–H stretching vibration similar to that of liquid water. Deliberate ex-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

posure to water vapor for 3 days does not lead to re-absorption of water into the lattice as monitored by FTIR spectroscopy. The spectrum below 2000 cm^{-1} does not change appreciably on heating **1** at 140 °C for 2 h that suggests coordination of ptc^{4-} to Co^{II} is still maintained. However, powder X-ray diffraction[24] patterns of **1** before and after water expulsion show major changes with respect to peak positions and intensities suggesting breakdown of the host lattice once the water molecules are expelled.

Conclusion

In conclusion, we have identified infinite chains of quasi-planar hexameric water clusters in an MOF built from Co^{II} and pyrazine-2,3,5,6-tetracarboxylic acid. Each chain assembles two planar 2D coordination polymeric networks where the structure of the water chain is commensurate with the MOF.

Experimental Section

Materials: The metal salt and phenazene were acquired from Aldrich and used as received.

Physical Measurements: Spectroscopic data were collected as follows: IR (KBr disk, 400–4000 cm^{-1}) Perkin–Elmer Model 1320; X-ray powder pattern (Cu-K_α radiation at a scan rate of 3°/min, 293 K) Siefert ISODEBYEFLEX-2002 X-ray generator; thermogravimetric analysis (heating rate of 5 °C/min) Mettler Toledo Star System. Microanalysis data for the compound were obtained from CDRI, Lucknow.

Synthesis of $\{[Co_2(ptc)\cdot(py)_2\cdot 4H_2O]\cdot 4H_2O\}_n$ (1): $Co(NO_3)_2\cdot 6H_2O$ (0.64 g; 2 mmol) was added to a solution of pyrazine-2,3,5,6-tetracarboxylic acid ($ptcH_4$) (0.26 g; 1 mmol) in 25 mL of aqueous pyridine (1:1, v/v). A dark reddish solution was obtained. After filtering the solution, the solvent was allowed to evaporate slowly at room temperature whereupon (after 10 days) red rectangular parallelopiped crystals of **1** appeared (0.302 g, 45% yield). $C_{18}H_{26}Co_2N_4O_{16}$ (672.29): C 32.16, H 3.89, N 8.33; found C 32.67, H 4.02, N 8.14.

X-ray Structural Studies: Single-crystal X-ray data on **1** were collected at 100 K on a Bruker SMART APEX CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). The linear absorption coefficients, scattering factors for the atoms, and the anomalous dispersion corrections were taken from International Tables for X-ray Crystallography. The data integration and reduction were processed with SAINT[14] software. The structure was solved by the direct method using SHELXTL[15] and was refined on F^2 by full-matrix least-squares technique using the SHELXL-97[16] program package. All non-hydrogen atoms present were anisotropically refined. All hydrogen atoms except two could be easily located in successive difference Fourier maps and they were treated as riding atoms using SHELXL default parameters. The remaining two H atoms were calculated theoretically and added to the list. Crystal data of **1**: M = 672.29 g mol^{-1}, monoclinic, space group $P2_1$, a = 7.153(5), b = 17.003(5), c = 11.060(5) Å, β = 107.207(5)°, U = 1284.9(11) $Å^3$, Z = 2, $R1$ = 0.0340, $wR2$ = 0.0875, S = 1.028. T = 100 K, D_c = 1.738 g cm^{-3}, μ = 1.376 mm^{-1}, $F(000)$ = 688, crystal size = 0.17 × 0.14 × 0.10 mm^3. A total of 8112 reflections up to θ = 28.30 were collected of which 4482 unique reflections were used.

CCDC-236954 contains the supplementary crystallographic data for this paper. These data can be obtained from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Octameric Water Clusters of Staircase Structure Present in a Metal-Organic Framework Built from Helical Lanthanide Coordination Polymers

Sujit K. Ghosh[a] and Parimal K. Bharadwaj*[a]

Keywords: Water chemistry / Supramolecular chemistry / Self assembly / Metal-organic framework / Helical structure

Two lanthanide-carboxylate polymeric complexes containing nine-coordinate lanthanide metal centers, {[Pr(*ptc*$^{-3}$)·2H_2O]·2H_2O} (**1**), {[Nd(*ptc*$^{-3}$)·2H_2O]·2H_2O} (**2**) have been prepared by hydrothermal synthesis of $Pr(NO_3)_3$·6H_2O or $Nd(NO_3)_3$·6H_2O with pyridine-2,4,6-tricarboxylic acid (*ptc*H_3). These network structures are characterized by X-ray crystallography, powder X-ray diffraction, infrared and thermal gravimetric analyses. Both **1** and **2** form infinite single helical chains with large widths and pitches containing six metal ions per turn. The overall structure consists of two helices connected via discrete octameric water clusters.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Water clusters of different nuclearity and structure in both inorganic and organic hydrates continue to attract a lot of attention because such studies facilitate our understanding of the liquid by allowing better description of the many-body interactions in a step by step manner.[1] Of particular interest here is the structure of the $(H_2O)_8$ cluster. Theory predicts[2] two closely related iso-energetic cubane structures with S_4 and D_{2d} symmetries where O atoms occupy the corners and hydrogen bonds along the edges which are supported by experimental proofs in the molecular beam[3] and in gas-phase $C_6H_6(H_2O)_8$ clusters.[4] In crystal hosts, cubane,[5] opened-cubane,[6] cyclic octamer[7] resembling ice I_h and cyclic octamer consisting of a hexamer and two dangling water molecules[8] have been identified. We present here a discrete octamer whose structure is very different from any of these.

The water clusters are present in the voids of 3D metal-organic frameworks built by connecting single helical coordination polymers through carboxylate bridging. Helicate chemistry is not only important in the development and understanding of self-assembly processes, but also to search for new supramolecular architectures endowed with functional properties. The accepted model for helication requires a long multidentate ligand as a molecular thread containing a number of discrete metal-binding sites separated by spacer units. Such a molecular thread can twist around several metal ions controlled by their coordination behavior. Synthesis of only discrete helicates of both transition metals[9] and lanthanides[10] can be achieved following this strategy. We report here formation of open framework structures by connecting infinite single-strand helices[11] made from pyridine-2,4,6-tricarboxylic acid (*ptc*H_3) and either Nd^{III} or Pr^{III} ions.

Results and Discussion

Compounds {[Pr(*ptc*$^{3-}$)·2H_2O]·2H_2O} (**1**) and {[Nd(*ptc*$^{3-}$)·2H_2O]·2H_2O} (**2**) were synthesized hydrothermally in ca. 55% yield, by treating the ligand pyridine-2,4,6-tricarboxylic acid[12] (*ptc*H_3) with $Pr(NO_3)_3$·6H_2O or $Nd(NO_3)_3$·6H_2O, respectively. As both **1** and **2** have an identical structure, only the structure of **1** is discussed.

The asymmetric unit of **1** consists of one *ptc*$^{3-}$ unit, one Pr^{III}, two metal-bound water and two free water molecules. Each metal ion exhibits 9-coordination (Scheme 1) with bonding from six carboxylates of five different ligand units, one ring N atom of one the ligands and two water molecules. All carboxylate groups are bridged to complete the 3D structure. The Pr^{III} ions are arranged in infinite single helices extending along the crystallographic *b* axis (Figure 1) with intervening *ptc*$^{3-}$ ligands. The helical structure is a result of metal–ligand interactions coupled with stereoelectronic characteristics of the ligand and the conditions prevailing during the synthesis. The width of the helix is calculated to be 16.70 Å and the pitch is 11.95 Å and there are six Pr^{III} ions present per turn. Both the width and the pitch are large as a result of the topology of the *ptc*$^{3-}$ ligand and the electrostatic repulsive interactions among the metal ions. The stability of the final helical structure relies on the coordinate bonds that each metal makes with the ligand. Known structures of lanthanide helicates[10] are double- or triple-stranded with long polydentate ligands which are able

to wrap around lanthanide ions forming compact helical structures with lower pitch and narrower width. The helices in **1** are further organized into metal-organic framework structures through inter-helix bridging of the carboxylates (Figure 2) with voids occupied by water molecules. Four metal-bound water molecules catch hold of four other water molecules forming an overall discrete octamer. The cluster takes the shape of a staircase-like structure (Figure 3) where only Ow3 and centrosymmetrically related Ow3′ show tetra-coordination while all other water O atoms are tri-coordinated. Such hydrogen-bond deficient water molecules are present[3] at the surface of ice as well as in liquid water.[13] An important feature of this cluster is a very short distance between Ow3 and Ow4′ (2.231 Å). In **2**, this distance is only 1.977 Å although H atoms belong to the water oxygens could not be located in the difference map. Locating these hydrogens by neutron diffraction and probing the nature of Ow···Ow distances in **2** will be another study. Generally, short H bonds are encountered with charged H

bond donors (O^+–H···O) or acceptors (O–H···O^-) such as the Speakman salts[14] with RCOOH···$^-$OOCR hydrogen bonding. In the present case, the metal organic framework pushes the Ow3 and Ow4 atoms closer together. Values of other Ow···Ow distances (range: 2.668–2.903 Å) and O···H–O angles (range: 140.35–175.38°) (Table 1) suggest strong H-bonding interactions among the water molecules. In comparison, bulk water exhibits a short-range O···O order of 2.85 Å in the X-ray diffraction radial distribution curve while for the gas phase, this value is ca. 0.1 Å longer.[15] Hydrogen atoms of Ow2, Ow2′, Ow3 and Ow3′ are also bonded to the nearby carboxylate O atoms cementing the structure further with the MOF and the ultimate symmetry of the octamer results from interactions between the water molecules and between the water molecules and the MOF.

Ow2···Ow3···Ow4′	109.15
Ow3···Ow4···Ow3′	121.47
Ow4···Ow3···Ow4′	58.53

Thermal gravimetric analyses[16] further corroborate the strong water–MOF interactions. For **1**, with 23.39 mg sample in air shows the loss of first 3 water molecules occur at 145 °C beginning at ca. 100 °C and the loss of all of the water is achieved only above 250 °C and the compound decomposes soon after. Compound **2** shows an almost identical thermogram. The FTIR spectra[16] of **1** and **2** exhibit a broad band centered around 3405 cm^{-1} attributable to the O–H stretching frequency pertaining to the water cluster. All water could be removed by heating either compound at 200 °C for 2 h under 10 mm pressure. However, water expulsion leads to complete breakdown of the 3D lattice as the powder X-ray diffraction patterns[16] of the compounds before and after water expulsion are completely different.

Conclusions

In conclusion, we describe here two open-framework structures formed via carboxylate bridging of infinite single helical coordination polymeric chains. The driving force for helication is the metal–ligand interaction coupled with stereoelectronic characteristics of the ligand and the reaction conditions. Discrete octameric water clusters of hitherto unknown staircase structure occupy the voids in the MOFs.

Experimental Section

Materials and Measurements: The metal salts and 2,4,6-trimethylpyridine were acquired from Aldrich and used as received. Spectroscopic data were collected as follows: IR (KBr disk, 400–4000 cm^{-1}) Perkin–Elmer Model 1320; X-ray powder pattern (Cu-K_α radiation at a scan rate of 3°/min, 293 K) Siefert ISODEBYEFLEX-2002 X-ray generator; thermogravimetric analysis (heating rate of 5 °C/min) Perkin–Elmer Pyris 6. Microanalyses for the compounds were obtained from the Central Drug Research Institute, Lucknow, India. Synthesis of pyridine-2,4,6-tricarboxylic acid (*ptc*H_3): This compound was synthesized in 50% yield by oxidation of 2,4,6-trimethylpyridine with aqueous $KMnO_4$ following a literature method.[12]

Synthesis of {[Pr(*ptc*$^{3-}$)2H_2O]2H_2O}$_n$ (1): This compound is synthesized by mixing 1 mmol of $Pr(NO_3)_3{\cdot}6H_2O$ and 1 mmol of pyridine-2,4,6-tricarboxylic acid (*ptc*H_3) in 5 mL of water in a Teflon-lined autoclave. The autoclave is heated under autogenous pressure to 180 °C for 2 days and then kept at 90 °C for a further 12 h period. Upon cooling to room temp. the desired product appeared as long pale green rectangular parallelopipeds in ca. 55% yield. $C_8H_{10}NO_{10}Pr$ (421.08): calcd. C 22.82, H 2.39, N 3.32; found C 22.16, H 2.47, N 3.21.

Synthesis of [Nd(*ptc*$^{3-}$)2H_2O]2H_2O (2): This was prepared in ca. 54% yield as light purple rectangular parallelopipeds crystals on hydrothermal reaction of 1 mmol of $Nd(NO_3)_3{\cdot}6H_2O$ with 1 mmol of the ligand in 5 mL H_2O and under identical experimental conditions as above. $C_8H_{10}NO_{10}Nd$ (424.41): calcd. C 22.64, H 2.37, N 3.30; found C 22.31, H 2.46, N 3.23.

X-ray Crystallography. Crystal Data for 1: $C_8H_{10}NO_{10}Pr$, M = 421.08, rectangular parallelopiped, light green crystals, 0.17 × 0.14 × 0.11 mm, monoclinic, space group $P2_1c$, a = 6.754(5) Å, b = 11.937(2) Å, c = 13.456(5) Å, β = 100.381(5)°, U = 1067.1(10) $Å^3$, T = 100 K, Z = 4. μ(Mo-K_α) = 4.627 mm^{-1}, 6998 reflections measured, 2454 [$I \geq 2\sigma(I)$] unique reflections were used in all calculations. The final R_1 = 0.0312, wR_2 = 0.0773, S = 1.066. **Crystal Data for 2:** $C_8H_{10}NO_{10}Nd$, M = 424.41, rectangular parallelopiped, light purple crystals, 0.18 × 0.14 × 0.11 mm, monoclinic,

Structural Relationships in High-Nuclearity Heterobimetallic Bismuth-Oxo Clusters

Michael Mehring,*[a] Sanna Paalasmaa,[a] and Markus Schürmann[a]

Keywords: Bismuth / Sodium / Silanolate / Metal-oxo cluster / Structure elucidation

The novel heterobimetallic sodium-bismuth-oxo clusters $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**), $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]\cdot 1.5C_7H_8$ (**2**·1.5C_7H_8), $[Bi_{15}Na_3O_{18}(OSiMe_3)_{12}]\cdot C_7H_8$ (**3**·C_7H_8) and $[Bi_{14}Na_8O_{18}(OSiMe_3)_{14}(THF)_4]\cdot C_6H_6$ (**4**·C_6H_6) were prepared starting from $BiCl_3$ and $NaOSiMe_3$. Compound **1** crystallises in the trigonal space group $R\bar{3}c$ with the lattice constants a = 12.8844(3) Å and c = 54.6565(3) Å, compound **2**·1.5C_7H_8 crystallises in the triclinic space group $P\bar{1}$ with the lattice constants a = 15.0377(2) Å, b = 16.0373(2) Å, c = 27.8967(5) Å, α = 87.1321(6)°, β = 86.6530(7)° and γ = 63.6617(6)°, compound **3**·C_7H_8 crystallises in the monoclinic space group $C2/c$ with the lattice constants a = 54.311(11), b = 19.846(4), c = 22.885(5) Å and β = 112.32(3)°, and compound **4**·C_6H_6 crystallises in the trigonal space group $R\bar{3}$ with the lattice constants a = 15.9786(4) Å and c = 46.8329(17) Å. The formation of M–O–M bonds results from both partial hydrolysis followed by condensation as well as from elimination of $Me_3SiOSiMe_3$ from M–$OSiMe_3$ groups. The hexanuclear metal-oxo silanolate **1** is more conveniently synthesised by the addition of $NaOSiMe_3$ to a toluene solution of in situ-prepared $[Bi(OSiMe_3)_3]$. The metal-oxo(hydroxo) silanolates differ significantly in composition, but show similar building units. Thermal decomposition of the metal-oxo silanolates in the solid state gave heterogeneous decomposition products containing bismuth silicates.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Bismuth alkoxides are valuable precursors for the synthesis of bismuth oxide-based materials prepared via chemical vapour deposition[1] or via the sol-gel process.[2,3] Their potential application for the synthesis of materials such as high-temperature superconductors or non-volatile random-access memories has prompted several research groups to investigate the reactivity and the structural chemistry of homo- and heterometallic bismuth alkoxides in order to control composition and morphology of the final material on a molecular level.[3–6] Alternatively, bismuth silanolates might serve as molecular precursors to bismuth-containing materials. However, the chemistry of bismuth silanolates was only scarcely explored so far.[7–11] In contrast to bismuth, metallasiloxanes of the heavier group 14 metals tin and lead have received considerable interest.[7,8,12,13] It was noticed that homoleptic heavy metal silanolates of the type $[M(OSiR_3)_2]$ (M = Sn, Pb) readily decompose at moderate temperatures with elimination of $R_3SiOSiR_3$ to give the parent metal oxide or metal-oxo clusters.[7,13] It is promising to exploit this non-hydrolytic strategy for the synthesis of tailor-made bismuth-oxo clusters and bismuth oxide-based nanoparticles. Recently, the potential of metal silanolates as molecular precursors for a variety of mixed metal oxide materials[8,14] as well as for nanoparticles of zinc oxide[15] and zinc silicate[16] was demonstrated.

Among the homoleptic bismuth silanolates the trimethylsilyl derivative $[Bi(OSiMe_3)_3]$ is one of the most promising candidates with respect to materials synthesis. The reaction of $BiCl_3$ with $NaOSiMe_3$ was previously reported to give $[Bi(OSiMe_3)_3]$,[7] but the material obtained gave analytical data which disagreed with the expected values. We have revisited this reaction and report here our findings including the molecular structures of $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**), $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]\cdot 1.5C_7H_8$ (**2**·1.5C_7H_8), $[Bi_{15}Na_3O_{18}(OSiMe_3)_{12}]\cdot C_7H_8$ (**3**·C_7H_8), and $[Bi_{14}Na_8O_{18}(OSiMe_3)_{14}(THF)_4]\cdot C_6H_6$ (**4**·C_6H_6).

Results and Discussion

Reaction of $NaOSiMe_3$ with $BiCl_3$ in a 3:1 stoichiometry using THF as solvent gave a solid material the EDX analysis of which accounted for the presence of both bismuth and sodium. Crystallisation from hot toluene gave single crystals of the heterometallic bismuth-oxo silanolate $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**). The low yield was only slightly improved to approximately 10% when the reaction was carried out in toluene and the stoichiometry was modified to a bismuth-to-sodium ratio of 1:5 (Scheme 1).

Oxygen incorporation into compound **1** does not result from hydrolysis, but from the reaction of M–$OSiMe_3$ groups to give $Me_3SiOSiMe_3$ and the corresponding metal-

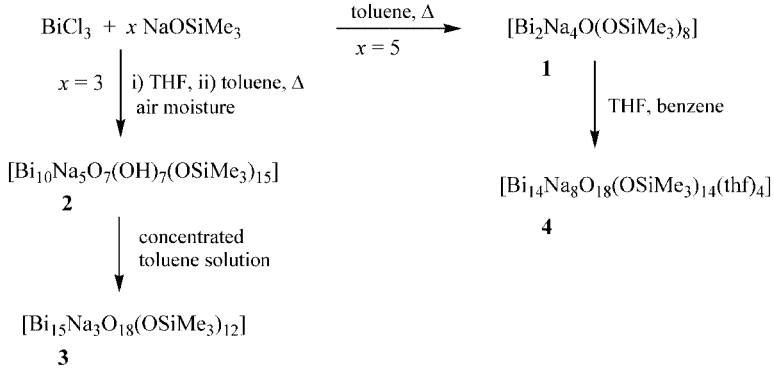
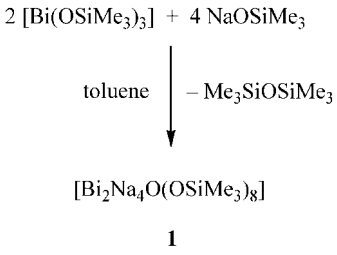


Scheme 1.

oxo fragment. The ^{29}Si NMR spectrum of a crude reaction mixture according to Scheme 1 (x = 5) showed a signal at δ = 7.2 ppm assigned to $Me_3SiOSiMe_3$ and a broad signal at δ = –2.9 ppm assigned to unreacted $NaOSiMe_3$. Due to its poor solubility, no ^{29}Si NMR signal was observed for [$Bi_2Na_4O(OSiMe_3)_8$] (**1**). Compound **1** was obtained with a significantly higher yield when in situ-prepared [$Bi(OSiMe_3)_3$] (^{29}Si NMR δ = 10.9 ppm) and $NaOSiMe_3$ were used as starting materials [Equation (1)]. The synthesis and molecular structure of [$Bi(OSiMe_3)_3$] was reported recently.[11b]



(1)

The molecular structure of compound **1** is best described to be composed of an octahedron with two bismuth atoms and four sodium atoms occupying the corners and a μ_6-oxygen atom being enclosed within the octahedron (Figure 1). Eight silanolate groups cap the trigonal faces. The compound crystallises in the space group $R\bar{3}c$ and only one crystallographic independent position for the metal atoms is found. Each position is occupied by both sodium and bismuth atoms with occupancies of 2/3 and 1/3, respectively. The analogous problem of disorder was reported for the closely related molecular structures of [$Sb_2Na_4O(OSiMe_3)_8$],[17] [$Bi_2Na_4O(O\mathit{t}Bu)_8$],[18] [$Sb_2M_4O(O\mathit{t}Bu)_8(thf)_n$] (M = Na, n = 0; M = K, n = 0, 4),[18] and [$Bi_2Na_4O(OC_6F_5)_8(thf)_4$].[19] For these compounds it was shown by means of solid state NMR, variable-temperature NMR in solution and crystallography that both in the solid state and in solution the group 15 atoms are located in *cis*-position of the octahedron. We have carried out a theoretical study of *cis*- and *trans*-[$Bi_2Na_4O(OSiMe_3)_8$] (**1**) at the RHF/LANL2DZ level of theory which confirms that a *cis*-arrangement is favoured ($\Delta E_{cis/trans}$ = 3.92 kcal mol^{-1}). At room temperature only one ^{1}H NMR signal is observed for the methyl protons, which is indicative of a fast exchange process involving the trimethylsilanolate groups. Further NMR studies in solution, such as variable temperature NMR, were hampered by the low solubility of compound **1**.

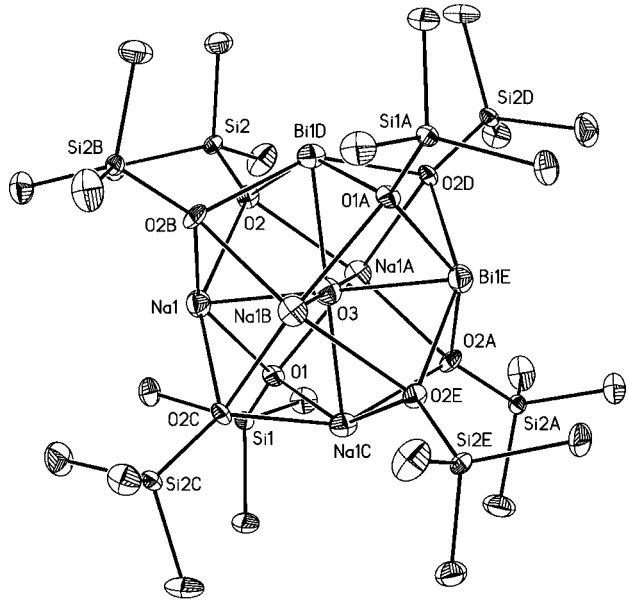


Figure 1. ORTEP diagram of [$Bi_2Na_4O(OSiMe_3)_8$] (**1**) showing 30% displacement ellipsoids and the atom numbering scheme. Hydrogen atoms are omitted. The positions of the metal atoms are occupied by both sodium and bismuth atoms with occupancies of 2/3 and 1/3, respectively. Selected bond lengths [Å] and bond angles [°] (M = Na, Bi): M(1)–O(3) 2.289(1), M(1)–O(2) 2.361(2), M(1)–O(2B) 2.422(2), M(1)–O(2C) 2.405(2), M(1)–O(1) 2.361(2); M(1)–O(3)–M(1E) 180.00(1), M(1)–O(3)–M(1B) 89.55(1), M(1)–O(3)–M(1C) 90.45(1), M(1)–O(2)–M(1A) 84.88(5), M(1)–O(2B)–M(1D) 84.61(5), M(1)–O(1)–M(1C) 86.11(8), O(1)–M(1)–O(2) 86.39(4), O(1)–M(1)–O(3) 73.56(5), O(2)–M(1)–O(3) 74.51(4), O(2)–M(1)–O(2B) 86.09(4), O(2)–M(1)–O(2C) 147.06(7). Symmetry operations used to generate equivalent atoms: A = –y, x – y, z; B = y, –x + y, –z; C = –x + y, –x, z; D = x – y, x, –z; E = –x, –y, –z.

The reaction of $BiCl_3$ with $NaOSiMe_3$ in 1:3 stoichiometry according to Scheme 1 gave a solid material containing sodium, bismuth and silicon as was shown by EDX analysis. The ^{29}Si NMR spectrum of the supernatant solution showed only one signal assigned to $Me_3SiOSiMe_3$. Crystallisation from toluene gave a crop of single crystals of the novel heterobimetallic compound of the formula [Bi_{10}-

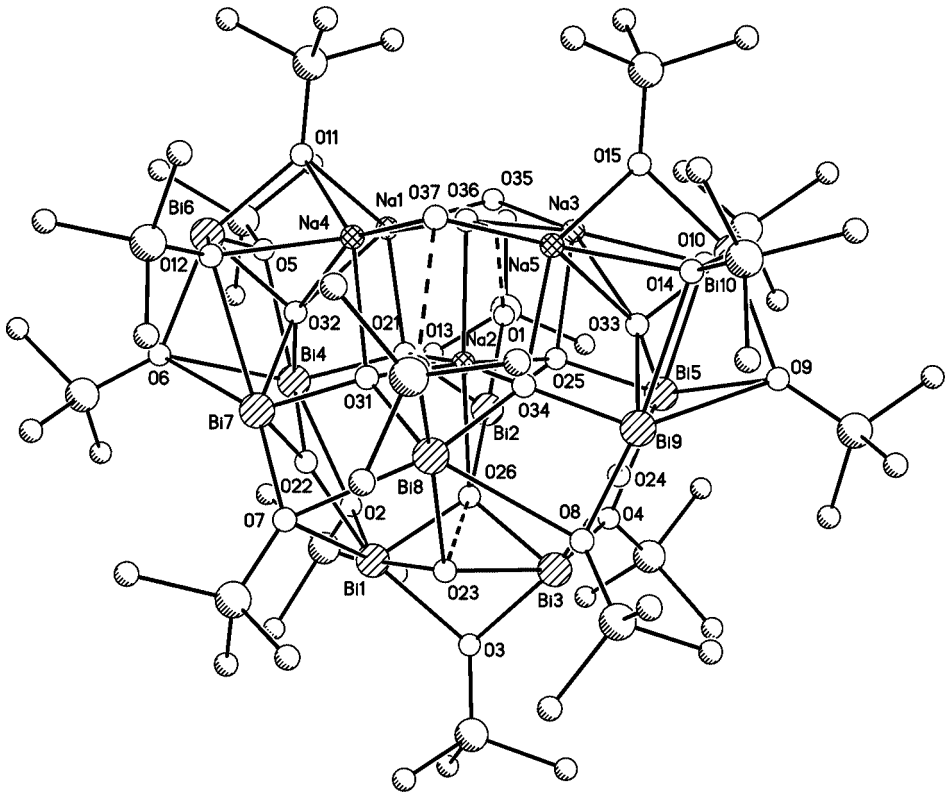

Figure 2. Molecular structure of $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]$ (**2**); hydrogen atoms are omitted; typical bond lengths [Å] and bond angles [°] are found in the ranges: Bi–O 2.056(4)–2.728(5), Na–O 2.369(4)–2.710(5); O–Bi–O 64.5(2)–98.8(2) and 128.0(2)–166.5(2), O–Na–O 62.0(2)–99.2(2) and 122.1(2)–156.7(2), O–Na(2)–O 65.4(2)–106.3(2) and 112.6(2)–175.9(2), Bi–O–Bi 84.9(2)–137.1(2), Bi–O–Na 79.4(2)–158.7(2), Na–O–Na 79.9(2)–168.3(2). Additionally, weak secondary bonds between bismuth and oxygen with distances of 3.0 Å are observed for Bi(7) and Bi(9).

$Na_5O_7(OH)_6(OSiMe_3)_{15}]\cdot 1.5C_7H_8$ (**2**·$1.5C_7H_8$) (Figure 2). Apparently, partial hydrolysis of initially formed compounds took place as a result of contact with air moisture. Noteworthy, formation of single crystals of the metal oxo cluster **2** were also observed when a C_6D_6 solution of "$[Bi(OSiMe_3)_3]$", prepared from $NaOSiMe_3$ and $BiCl_3$, was kept for approximately two weeks under atmospheric conditions. We recently noticed, that reaction of $BiCl_3$ with $NaOSiMe_3$ (ratio 1:3) at room temperature under rigorous exclusion of air moisture again produced compound **1** as major product, but additionally single crystals of the bismuth-oxo silanolates $[Bi_{18}Na_4O_{20}(OSiMe_3)_{18}]$ and $[Bi_{33}NaO_{38}(OSiMe_3)_{24}]$ were obtained from toluene/benzene. A detailed comparison of the molecular structures of these bismuth-rich compounds with polynuclear homometallic bismuth-oxo silanolates is reported elsewhere.[11c] In conclusion, $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**) is always obtained as the major product by the metathesis route and subtle changes regarding temperature, moisture and choice of the solvent lead to various heterobimetallic oxo(hydroxy)silanolates as byproducts.

The molecular structure of $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]$ (**2**) is shown in Figure 2 and selected bond lengths and bond angles are given in the Figure caption. Compound **2** is composed of a metal-oxo core comprising 15 metal atoms and 15 trimethylsilyl groups. The metal-oxo core is best described to be composed of the different subunits **A**, **A′** and **B**, which are connected via Na(2) placed in the centre of the metal-oxo core (Figure 3). At the periphery of the molecule a total of fifteen μ_2- and μ_3-silanolate groups is found.

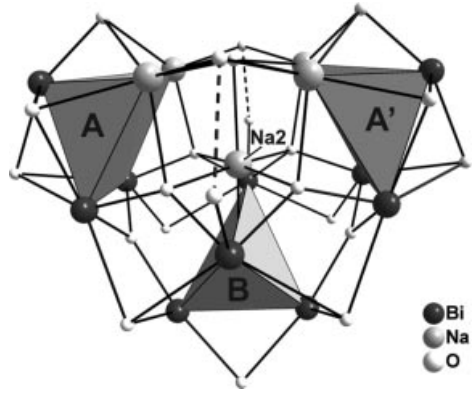

Figure 3. View of the $[Bi_{10}Na_5O_{28}]$ core structure of compound **2** (Me_3Si groups and H atoms are omitted; six oxygen atoms are covered by polyhedra). The sodium atom Na(2) connects the fragments **A**, **A′** and **B**.

Both pentanuclear fragments **A** and **A′** are composed of three bismuth atoms, two sodium atoms and thirteen oxygen atoms. The five metal atoms occupy the corners of a square pyramid with four μ_3-silanolate groups capping each

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trigonal face (Figure 4). A μ_5-oxygen atom occupies approximately the centre of the basal plane. In addition, four oxygen atoms are coordinated terminal to the metal atoms of the basal plane of **A** and four oxo ligands are bidentate bridging. The subunits **A** and **A′** are not related by symmetry, but show similar bond lengths and bond angles. The basic structural motif of the $[Bi_3Na_2O_{13}]$ fragment **A** is closely related to the metal-oxo core of $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**) as is shown in Figure 4. Other examples with related molecular structures were reported among pentanuclear metal μ_5-oxo alkoxides,[20,21] several hexanuclear compounds with μ_6-oxo ligands[17–19,21,22] and hexanuclear bismuth-oxo-hydroxo cations with a $[Bi_6O_8]$ fragment (Figure 4).[23]

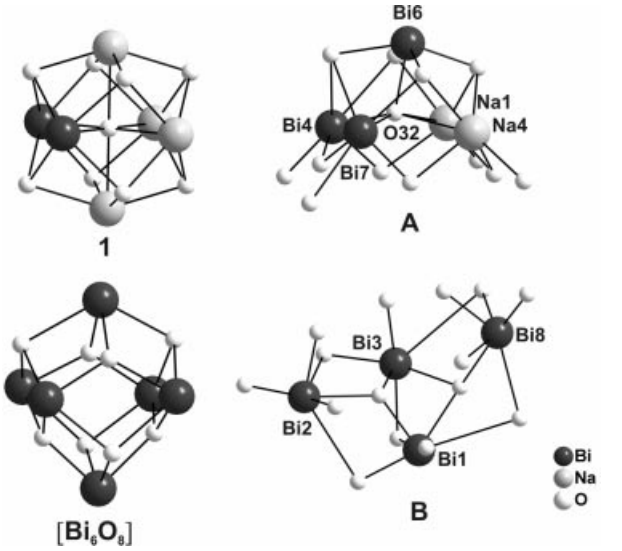

Figure 4. View of the structural fragments, which constitute the metal-oxo clusters **1**, **2** (**A** and **B**) and the $[Bi_6O_8]$ fragment of previously described hexanuclear bismuth-oxo-hydroxo cations.[23]

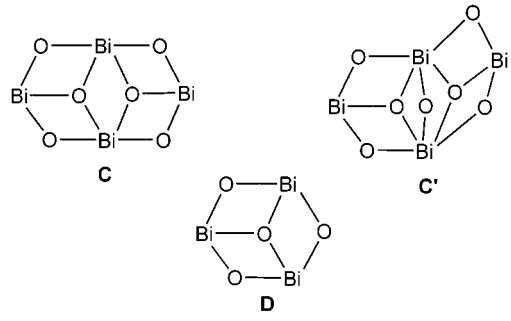
In compound **1** the oxygen atom is located in the centre of the cluster and thus all M–O (M = Na, Bi) bond lengths equally amount to 2.289(1) Å. This is a result of the disorder model suggested for the symmetric cluster **1**. In contrast, fragment **A** shows two short Bi–μ_5-O distances [Bi(4)–O(32) 2.192(4) Å, Bi(6)–O(32) 2.086(4) Å], a longer Bi–μ_5-O bond length [Bi(7)–O(32) 2.425(4) Å] and two similar Na–μ_5-O distances [Na(1)–O(32) 2.559(5) Å, Na(4)–O(32) 2.588(5) Å]. However, the average M–μ_5-O distance in **A** (av. M–O 2.365 Å) is close to the M–O distance in compound **1**. Comparison of the metal-oxo core structure of **1** with that of **A** sheds some light on the disorder problem reported above for compound **1**. The higher oxophilicity of the bismuth atom compared with the sodium atom should favour the formation of short Bi–O distances to give a *cis*-arrangement in compound **1** as it was observed for subunit **A**. This result is in agreement with our theoretical model. A *cis*-arrangement gives a structure of lower symmetry. Thus, we suggest the disorder observed in compound **1** to be a result of disordered molecules in the crystal lattice rather than disordered metal atoms. Noteworthy, another example, namely $[(Cp^*Zr)_6(\mu_4\text{-}O)(\mu_2\text{-}O)_4(\mu_2\text{-}OH)_8]$, was reported recently, in which an asymmetric structure with an μ_4-oxo ligand in the centre of an octahedron is favoured over the more symmetric structure which requires an ideal μ_6-oxo ligand.[24]

The structural fragment **B** consists of four bismuth atoms and fifteen oxygen atoms (Figure 4). The $[Bi_4O_{15}]$ fragment resembles the Bi_4O_6-ladder-type arrangement (**C**) which was described as a central structural motif in other bismuth-oxo compounds.[6,25] However, in contrast to the ladder-type arrangement **C** fragment **B** is strongly distorted and an additional μ_2-oxo ligand connects the two central bismuth atoms to give an structural arrangement, which is better assigned to type **C′**. Molecular structures based on this motif have been reported for the bismuth-oxo alkoxides $[Bi_6O_3(OR)_{12}]$ (R = C_6F_5,[6] 2,6-$C_6H_3Cl_2$[26]). Both structural arrangements **C** and **C′** can formally be reduced to the trinuclear fragment **D**, which might be expected to be the most stable building unit of bismuth-oxo clusters. However, so far discrete trinuclear units similar to type **D** were solely observed for hydrolysis products of bismuth trifluoroacetate, such as $[Bi_3(OH)(OOCCF_3)_8]$.[23k,27]



The more symmetric ladder-type arrangement **C** is observed for the central metal-oxo core composed of Bi(7)–Bi(9) and Na(2) (Figure 5). Each bismuth atom belongs to a different subunit [Bi(7) in **A**, Bi(9) in **A′** and Bi(8) in **B**; see Figure 3 and Figure 4] which are connected by Na(2).

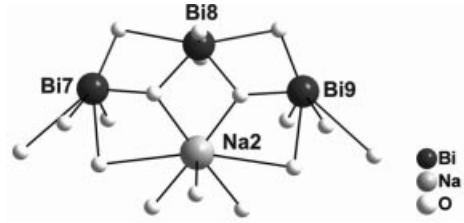


Figure 5. View of the central metal-oxo core of compound **2**, which connects the three subunits **A**, **A′** and **C**.

The heavy metal bismuth in $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]\cdot 1.5C_7H_8$ (**2**·$1.5C_7H_8$) does not unambiguously allow the location of OH hydrogen atoms. However, different O···O distances make an assignment of hydroxy groups possible. Thus, O(35) [O(35)···O(1) 2.618(7) Å], O(37) [O(37)···O(13) 2.680(7) Å], O(23) [O(23)···O(26) 2.564(6) Å], O(22) [O(22)···O(2) 2.766(7) Å], and O(24) [O(24)···O(4) 2.783(7) Å] are assigned to hydroxo ligands. In addition, we suggest O(36), which is located at the periphery of the metal-oxo silanolate, to be a hydroxo ligand.

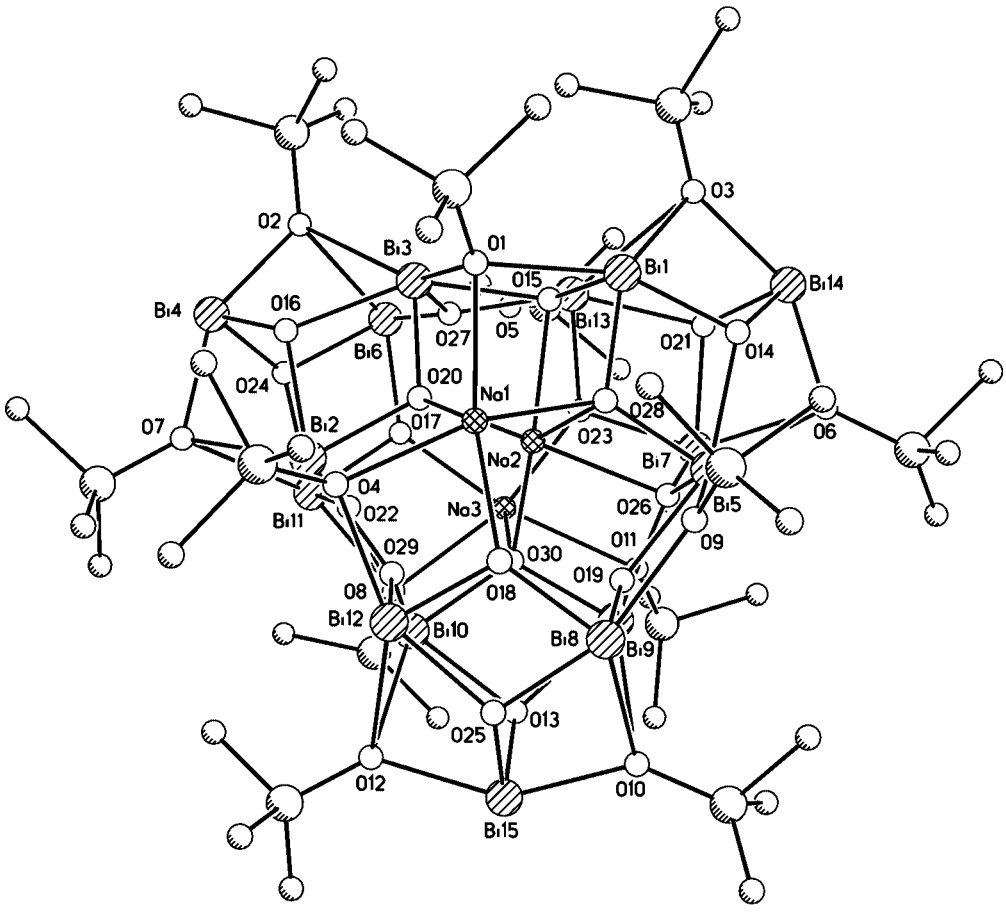

Figure 6. Molecular structure of $[Bi_{15}Na_3O_{18}(OSiMe_3)_{12}]$ (**3**); hydrogen atoms are omitted; typical bond lengths [Å] and bond angles [°] are found in the following ranges: Bi–O 2.033(9)–2.737(9), Na–O 2.264(10)–2.606(12); O–Bi–O 64.9(3)–160.1(3), O–Na–O 70.1(3)–165.1(4), Bi–O–Bi 93.9(3)–134.3(4), Bi–O–Na 84.6(3)–138.0(4). Additionally, weak secondary bonds between bismuth and oxygen with distances in the range of 3.2–3.5 Å are observed for Bi(2), Bi(5), Bi(9) and Bi(11)–Bi(13).

After the batch of single crystals of **2**·1.5C_7H_8 had been separated by filtration, a second crystal fraction, hereafter referred to as **3**·C_7H_8 (Figure 6), was obtained. The molecular structure of $[Bi_{15}Na_3O_{18}(OSiMe_3)_{12}]$·$C_7H_8$ (**3**·C_7H_8) is closely related to that of compound **2** although both compounds differ significantly in composition. The metal-oxo core of compound **3** is best described to be composed of three $[Bi_5O_{12}]$ subunits of type **E**, which are connected via three sodium atoms (Figure 7). Each subunit **E**, **E**′ and **E**′′ shares four oxygen atoms with a neighbouring subunit. The $[Bi_5O_{12}]$ subunits **E**, **E**′ and **E**′′ show similar structural parameters and thus only **E** is discussed in more detail (Figure 8).

The $[Bi_5O_{12}]$ subunit **E** is composed of five bismuth atoms, which occupy the corners of a square pyramid (Figure 8). Two μ_3-silanolate groups and two μ_3-oxygen atoms cap the trigonal faces. Each bismuth atom of the basal plane is connected to two bismuth atoms of the same plane by two oxo ligands. These oxo ligands further link each subunit to another subunit and/or a sodium atom to give six μ_3- and six μ_4-oxo ligands. In addition, six silanolate groups bridge adjacent corners of two subunits. Four of these ligands additionally coordinate to a sodium atom, which results in four μ_3- and two μ_2-$OSiMe_3$ ligands. Noteworthy,

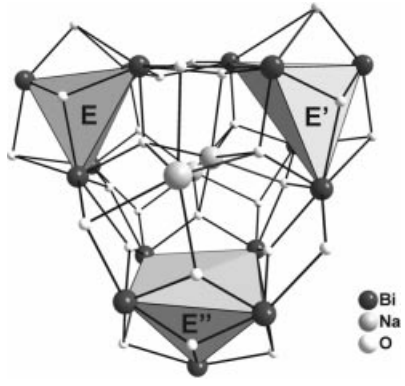

Figure 7. View of the $[Bi_{15}Na_3O_{30}]$ core structure of **3** (Me_3Si groups are omitted). Three sodium atoms connect the subunits **E**, **E**′ and **E**′′.

the molecular structures of the recently reported nonanuclear bismuth-oxo cations $[Bi_9(\mu_3\text{-}O)_8(\mu_3\text{-}OR)_6]^{5+}$ (R = H, Et)[25d] show a remarkable structural relationship with compound **3**. The cations might be described to be composed of a $[Bi_5O_6(OR)_6]$ subunit of type **E** and two edge-sharing trigonal $[Bi_3(\mu_3\text{-}O)]$ subunits.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

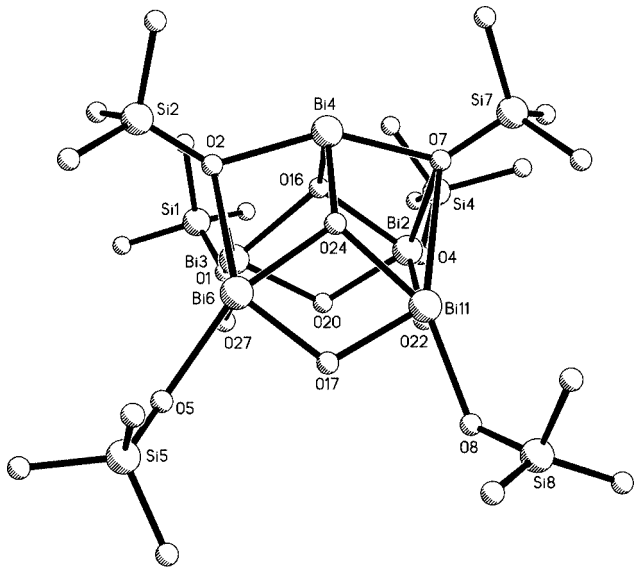

Figure 8. View of the $[Bi_5O_{12}]$ subunit **E** including Me_3Si groups. Two additional Bi–O bonds of Bi(2) and Bi(3) to O(29) and O(15), which are part of **E**′ and **E**′′, are omitted. Selected bond lengths [Å] and angles [°]: Bi(3)–O(1) 2.532(11), Bi(3)–O(2) 3.196(11), Bi(3)–O(16) 2.310(9), Bi(3)–O(20) 2.066(9), Bi(3)–O(27) 2.254(10), Bi(4)–O(2) 2.260(9), Bi(4)–O(7) 2.243(9), Bi(4)–O(16) 2.033(9), Bi(4)–O(24) 2.079(9), Bi(6)–O(2) 2.737(9), Bi(6)–O(5) 2.378(9), Bi(6)–O(17) 2.084(10), Bi(6)–O(24) 2.214(9), Bi(6)–O(27) 2.115(8); Bi(4)–O(2)–Bi(3) 89.7(3), Bi(4)–O(2)–Bi(6) 96.0(3), Bi(3)–O(2)–Bi(6) 83.7(3), Bi(3)–O(16)–Bi(4) 127.8(4), Bi(3)–O(27)–Bi(6) 130.6(4), Bi(4)–O(24)–Bi(6) 120.5(4), O(2)–Bi(6)–O(5) 128.8(3), O(2)–Bi(6)–O(17) 135.6(3), O(2)–Bi(6)–O(24) 65.7(3), O(2)–Bi(6)–O(27) 76.7(3), O(5)–Bi(6)–O(17) 87.3(3), O(5)–Bi(6)–O(24) 158.4(4), O(5)–Bi(6)–O(27) 74.6(3), O(17)–Bi(6)–O(24) 73.2(4), O(17)–Bi(6)–O(27) 93.0(4), O(24)–Bi(6)–O(27) 96.8(4).

In addition, the metal-oxo core of the $[Bi_5O_{12}]$ subunit **E** shows some structural relationship to the $[Bi_3Na_2O_{13}]$ subunit **A** (Figure 4). The basic structural motif of both **A** and **E** is a square pyramid with the metal atoms occupying the corners (Figure 8). An additional oxygen atom in **A** occupies a position within the oxo cage. However, both subunits **E** and **A** can be deduced from the metal-oxo core of bismuth-oxo-hydroxo complexes[23] of the type $[Bi_6O_{4+x}(OH)_{4-x}]^{[6-x]+}$ by removal of one bismuth atom (Figure 4). It might be assumed that only in octahedral structures of the type $[Bi_xNa_yO_z]$ ($x + y = 6$) and $[Bi_xNa_y\square O_z]$ ($x + y = 5$, $\square$ = metal vacancy) with at least two sodium atoms the octahedral void might be occupied by an oxygen atom. Noteworthy, the additional oxygen atom in **A** results in a smaller instead of the expected larger volume of subunit **A** compared with that of **E**. This is best demonstrated by the metal–metal distances along the edges of the pyramid. In structure fragment **A** these distances are in the range 3.290(2)–3.460(2) Å whereas those in fragment **E** are in the range 3.430(1)–3.958(1) Å. In subunit **E** the Bi–O distances are in a large range between 2.033(9) Å and 3.196(12) Å, which is attributed to the combination of strong primary bonds and weak secondary interactions. As a result large distortions of the coordination polyhedra are observed. For example, Bi(6) shows four Bi–O bond lengths in the range 2.084(10)–2.378(9) Å, a significantly longer Bi–O bond length of 2.737(9) Å and O–Bi(6)–O angles in the range 65.7(3)–158.4(4)° (Figure 8). The coordination geometry in the first-coordination shell might be described as distorted *pseudo*-trigonal bipyramid (BiO_4X) built from O(5), O(17), O(24), O(27) and a stereochemically active lone pair. An additional secondary Bi–O bond to O(2) completes the coordination sphere to give a [4+1] coordination. Similarly, all bismuth atoms in compound **3** show irregular coordination geometries which are best described as 4-, [4+1] and [4+2] coordination, respectively.

The metal-oxo silanolate $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**) can be recrystallised from benzene or toluene, but attempts to recrystallise it from THF failed. Instead, the novel heterobimetallic compound $[Bi_{14}Na_8O_{18}(OSiMe_3)_{14}(thf)_4]\cdot C_6H_6$ (**4**·C_6H_6) was obtained. Its molecular structure is shown in Figure 9.

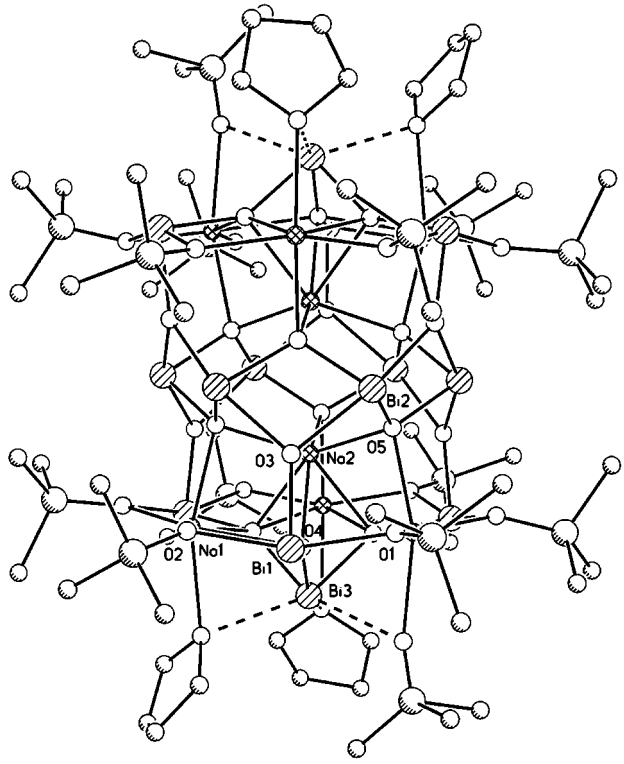

Figure 9. Molecular structure of $[Bi_{14}Na_8O_{18}(OSiMe_3)_{14}(thf)_4]$ (**4**); hydrogen atoms are omitted.

The molecular structure of compound **4** is best described to be composed of a symmetric $[(BiO_2)_6]^{6-}$ unit [Bi(2), O(3) and O(5)] which is sandwiched between two $[Bi_4Na_4O_3(OSiMe_3)_7(thf)_2]^{3+}$ subunits (Figure 10). The $[(BiO_2)_6]^{6-}$ unit resembles a small cylinder which is closed from both sides by Na(2) and Na(2D), respectively [Na(2)–Na(2D) 3.515(5) Å, Bi(2)–Bi(2A) 5.965(1) Å, Bi(2)–Bi(2D) 6.888(1) Å]. The bismuth atoms within the $[(BiO_2)_6]^{6-}$ ring show a *pseudo*-trigonal bipyramidal coordination geometry with Bi(2)–O distances of 2.103(3) Å and 2.268(3) Å. The *cis*-O–Bi–O angles amount to 74.70(9)° and 97.13(5)°, and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the *trans*-O–Bi–O angle is 156.39(12)°. A similar cyclic structural arrangement of eight such $[BiO_2]$ moieties was recently reported for the ethanol solvate of $[Bi(OEt)_3]_8$.[28] The subunit $[Bi_4Na_4O_3(OSiMe_3)_7(thf)_2]^{3+}$ is composed of a symmetric layer, which consists of three bismuth and three sodium atoms [Bi(1) and Na(1)], three μ_5-oxygen atoms [O(4)] and six μ_2-$OSiMe_3$ ligands [O(1) and O(2)]. The sodium atom Na(2) is placed above the layer and the bismuth atom Bi(3), two thf ligands as well as a silanolate ligand are placed below the layer. Within the layer the bond lengths between the metal atoms and the oxygen atoms of the silanolate ligands are found to be similar for sodium and bismuth with values in the range 2.270(3)–2.319(3) Å. In contrast Bi(1)–O(4) amounts to 2.057(3) Å and Na(1)–O(4) to 2.583(3) Å. The μ_5-oxygen atom O(4) is further coordinated to Na(1A), Na(2) [Na(2)–O(4) 2.540(3) Å] and Bi(3) [Bi(3)–O(4) 2.138(3) Å]. The coordination geometry of Bi(3) is best described as trigonal pyramidal [O(4)–Bi(3)–O(4A) 83.69(5)°]. Additionally, secondary bonds of Bi(3) to the three oxygen-donor ligands thf and $OSiMe_3$ are observed [Bi(3)–O(6) 2.776(5) Å]. A similar coordination of the bismuth atom was reported for $[Bi(OSiPh_3)_3(thf)_3]$,[9] but in contrast to the terminal coordination of the thf ligands in the bismuth triphenylsilanolate those in compound **4** are bridging between Bi(3) and Na(1) [Na(1)–O(6) 2.513(4) Å].

The two subunits $[(BiO_2)_6]^{6-}$ and $[Bi_4Na_4O_3(OSiMe_3)_7(thf)_2]^{3+}$ are linked via O(3), O(5) and their symmetry related counterparts. Thus, μ_4-O(5) is connected to Na(1A), Na(2), Bi(2) and Bi(2B), and μ_3-O(3) to Bi(1), Bi(2) and Bi(2C) [O(5)–Na(1A)/Na(2)/Bi(2)/Bi(2B) 2.388(5)/2.446(3)/2.103(2)/2.103(2) Å; O(3)–Bi(1)/Bi(2)/Bi(2C) 2.045(3)/2.268(3)/2.268(3) Å]. The coordination geometry of Bi(1) is best described as *pseudo*-trigonal bipyramidal assigned to BiO_4X (X = lone pair). The *cis*-O–Bi–O angles are in the range 80.91(11)–91.66(10)° and the *trans*-O–Bi–O angle amounts to 161.65(11)°. Two short bonds between the bismuth atom and the *cis*-positioned oxygen atoms O(3) and O(4) [Bi(1)–O(3) 2.045(3) Å, Bi(1)–O(4) 2.057(3) Å] as well as two elongated bonds to the *trans*-located oxygen atoms O(1) and O(2) [Bi(1)–O(1) 2.319(3) Å, Bi(1)–O(2) 2.295(3) Å] are observed. Noteworthy, the sodium-rich bismuth-oxo cluster **4** is neither composed of the above-mentioned $[M_5O_{12}]$ subunits nor of ladder type arrangements of type **C**. The structural relationship is restricted to the formation of trinuclear $[Bi_3O]$ subunits, planar four-membered $[Bi_2O_2]$ and $[NaBiO_2]$ rings and strongly distorted bismuth-oxygen polyhedra.

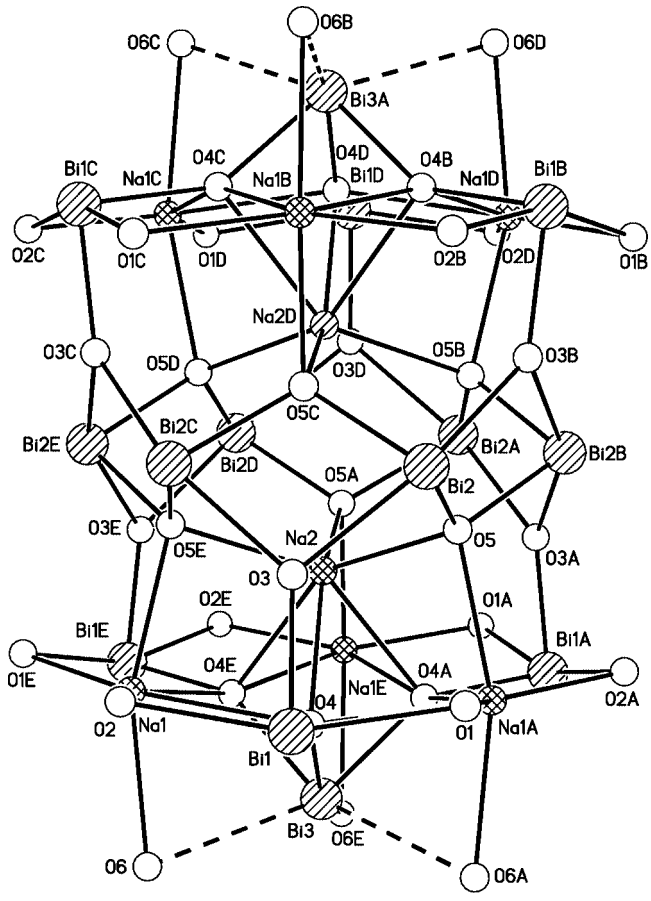

Figure 10. View of the metal-oxo core structure of **4** (Me_3Si groups, C and H atoms are omitted) showing the atom numbering scheme. Selected bond lengths [Å] and angles [°]: Bi(1)–O(1) 2.319(3), Bi(1)–O(2) 2.295(3), Bi(1)–O(3) 2.045(3), Bi(1)–O(4) 2.057(3), Bi(2)–O(3) 2.268(3), Bi(2)–O(3B) 2.263(3), Bi(2)–O(5) 2.103(2), Bi(2)–O(5C) 2.097(3), Bi(3)–O(4) 2.138(3), Bi(3)–O(6) 2.776(5), Na(1)–O(2) 2.270(3), Na(1)–O(1E) 2.277(3), Na(1)–O(5E) 2.388(3), Na(1)–O(6) 2.513(4), Na(1)–O(4) 2.583(3), Na(1)–O(4E) 2.535(3), Na(2)–O(5) 2.446(3), Na(2)–O(4) 2.540(3); O(1)–Bi(1)–O(2) 161.7(1), O(1)–Bi(1)–O(3) 81.0(1), O(1)–Bi(1)–O(4) 91.7(1), O(2)–Bi(1)–O(3) 80.9(1), O(2)–Bi(1)–O(4) 91.6(1), O(3)–Bi(1)–O(4) 90.6(1), O(5C)–Bi(2)–O(5) 94.3(1), O(5C)–Bi(2)–O(3B) 89.5(1), O(5)–Bi(2)–O(3B) 74.7(1), O(5C)–Bi(2)–O(3) 74.7(1), O(3)–Bi(2)–O(5) 88.9(1), O(3)–Bi(2)–O(3B) 156.4(1), O–Na(1)–O 67.6(1)–160.1(1), O–Na(2)–O 68.2(1)–148.2(1), Bi(1)–O(3)–Bi(2) 129.1(1), Bi(2)–O(5)–Bi(2B) 110.2(1), Bi(2)–O(3)–Bi(2C) 99.0(1). Symmetry operations used to generate equivalent atoms: A = $-x + y + 1$, $-x$, z; B = $y + 2/3$, $-x + y + 1/3$, $-z + 1/3$; C = $x - y - 1/3$, $x - 2/3$; $-z + 1/3$; D = $-x + 2/3$; $-y - 2/3$; $-z + 1/3$; E = $x - y - 1$; $x - 1$, $-z$.

Studies on the thermal behaviour of compounds **1**–**3** were carried out. The thermal stability of the clusters **2** and **3** is rather low as was shown by DTA-TG measurements. The onset of decomposition starts below 120 °C and is attributed to the loss of solvate molecules. The major weight loss for compounds **1**–**3** is observed between 150 °C and 250 °C. The observed weight loss (**1** 39.8%; **2** 27.6%; **3** 18.8%) is lower than calculated for the formation of pure Na/Bi/O phases and indicates formation of silicates. The observed values correspond to mixtures with general formulas such as $Bi_2Na_4Si_{2.5}O_{10}$ (calcd. 40.3%, **1b**), $Bi_{10}Na_5Si_{2.5}O_{10}$ (calcd. 26.6%, **2b**) and $Bi_{15}Na_4Si_3O_{30}$ (calcd. 19.0%, **3b**). It should be noted that the sillenite-type bismuth silicate $Bi_{12}SiO_{20}$ was observed upon thermal decomposition of $[Bi_{22}O_{16}(OSiMe_2tBu)_{22}]$.[10] Similarly, the powder X-ray data of the decomposition products **2b** and **3b** were also indicative of $Bi_{12}SiO_{20}$ (JCPDS No. 76–726) as major crystalline material. In case of compound **2** Na_2SiO_3 (JCPDS No. 82–0604) was observed as an additional minor product. The latter was the only crystalline material in the mainly amorphous decomposition product **1b**.

Conclusions

Both partial hydrolysis and elimination of $Me_3SiOSiMe_3$ from $[Bi(OSiMe_3)_3]$ contribute to the formation of heterobimetallic bismuth-oxo silanolates. We assume that $[Bi(OSiMe_3)_3]$ is formed in situ by reaction of $BiCl_3$ with $NaOSiMe_3$, but the reaction of the bismuth silanolate with additional $NaOSiMe_3$ to give $Me_3SiOSiMe_3$ is faster than the metathesis reaction. The favoured product is $[Bi_2Na_4O(OSiMe_3)_8]$ (**1**). Several different heterobimetallic byproducts are observed, the amounts of which depend on subtle changes in the reaction conditions. The use of THF as solvent favours the elimination of $Me_3SiOSiMe_3$, but its formation is also observed in non-polar solvents. It is noteworthy that in contrast to $[Bi(OSiMe_3)_3]$, the corresponding alkoxide $[Bi(OtBu)_3]$ is accessible via salt elimination. Despite of the ready M–O–M bond formation by elimination of $Me_3SiOSiMe_3$, thermolysis of heterometallic bismuth-oxo silanolates in the solid state results in silicate materials instead of heterobimetallic oxides. The $Bi–OSiMe_3$ moiety is very sensitive towards hydrolysis, and trace amounts of water induce hydrolysis/condensation processes to take place until the reactivity of the metal-oxo silanolate is significantly reduced. The resulting heterobimetallic compounds are covered by Me_3SiO ligands which are still moisture-sensitive but prevent further aggregation.

The peculiarity of sodium and bismuth to assemble into diverse heterobimetallic complexes is explained by their similar ionic radii, and their rich and variable coordination chemistry. As a consequence, heterobimetallic metal-oxo subunits such as the ladder-type $[Bi_{3-x}Na_xO_y]$ and square pyramidal $[Bi_{5-x}Na_xO_y]$ fragments constitute basic building blocks. Thermolysis of bismuth-oxo silanolates gives compounds of the Sillenite-type family, which are extensively studied because of their interesting optical properties such as photorefractivity and photoconductivity.[29] It might be anticipated that novel heterometallic bismuth compounds are accessible starting from heterobimetallic bismuth-oxo silanolate derivatives. Such bismuth-rich metal-oxo silanolates might serve as molecular precursors for doped materials of the Sillenite-type family.

Experimental Section

General Remarks: All manipulations were performed with exclusion of oxygen and moisture by using Schlenk-type techniques and argon atmosphere. Solvents were distilled from appropriate drying agents prior to use. Elemental analyses were performed on a LECO-CHNS-932 analyser. No satisfactory elemental analyses were obtained for compound **1** which is assigned to partial substitution of $OSiMe_3$ by $OtBu$ – isostructural $[Bi_2Na_4O(OtBu)_8]$ was reported previously[18] – and for compound **2** which is assigned to its high moisture sensitivity. The DTA-TG measurements were performed at a heating rate of 6 °C min^{-1} to a maximum temperature of 700 °C in an atmosphere of flowing argon using Al_2O_3 as reference material. The residues were examined by powder X-ray diffraction using a Phillips PW1050/25 diffractometer. ^1H and ^{29}Si NMR spectra were recorded at 400.13 MHz and 59.6 MHz, respectively. Chemical shifts (δ values given in ppm) were referenced against Me_4Si. The IR spectra were run as Nujol mulls and absorption bands assigned to the compounds in the range 400–1400 cm^{-1} are listed. Celite® (FLUKA) and sodium silanolate (Aldrich) were dried in vacuo at 120 °C prior to use. Bismuth trichloride (Lancaster) was heated at reflux in thionyl chloride, washed with pentane and dried in vacuo. $[Bi(OtBu)_3]$[5] and Me_3SiOH[30] were prepared according to literature procedures.

Synthesis of $[Bi_2Na_4O(OSiMe_3)_8]$ (1) (Method a): To a solution of $NaOSiMe_3$ (12.70 g, 113.2 mmol) in toluene (100 mL) was added anhydrous $BiCl_3$ (7.00 g, 22.2 mmol) in small portions at room temperature. The beige suspension was stirred at room temperature for one hour and heated at reflux for two hours. The solid material was filtered off through Celite® and the clear solution was concentrated to approximately 50 mL. Crystallisation at 4 °C gave colourless crystals of compound **1**. The first crop of crystals isolated was not analytically pure and an EDX analysis revealed the presence of chloride in addition to bismuth, sodium and silicon. The second crop of crystals (1.20 g, 9%) was analytically pure **1**, which decomposes upon heating above 150 °C. A small quantity of compound **1** was suspended in THF/benzene and after stirring overnight a clear yellow solution was obtained. From this solution moisture-sensitive single crystals of $[Bi_{14}Na_8O_{18}(OSiMe_3)_{14}(thf)_4]\cdot C_6H_6$ (**4**·C_6H_6) were obtained and dried in vacuo.

Synthesis of 1 (Method b): A solution of Me_3SiOH (1.64 g, 18.2 mmol) in toluene (10 mL) was added dropwise to a solution of $[Bi(OtBu)_3]$ (2.61 g, 6.1 mmol) in toluene. All volatile components were removed in vacuo and the residue was dissolved in toluene. To this solution $NaOSiMe_3$ (1.36 g, 12.1 mmol) was added portionwise and the resulting suspension was heated at reflux for 1.5 h. The solid material was isolated by filtration and dried in vacuo to give compound **1** (2.86 g, 76%).

1: $C_{24}H_{72}Bi_2Na_4O_9Si_8$ (1239.4): C 23.3, H 5.9; found C 24.0, H 6.4. IR (Nujol) $\tilde{\nu}$ = 1298 w, 1258 m, 1246 m, 1021 m, 996 w, 980 w, 967 w, 925 m, 894 s, 829 s, 742 m, 724 sh, 675 w, 660 w, 620 vw, 584 w, 537 w, 462 w, 414 cm^{-1} w.

4: $C_{42}H_{126}Bi_{14}Na_8O_{32}Si_{14}$ (4646.3): C 10.9, H 2.7; found C 11.4, H 2.9. IR (Nujol) $\tilde{\nu}$ = 1257 m, 1241 m, 1051 w, 941 m, 910 m, 826 m, 740 m, 725 m, 668 w, 593 cm^{-1} m.

Synthesis of $[Bi_{10}Na_5O_7(OH)_6(OSiMe_3)_{15}]$ (2) and $[Bi_{15}Na_3O_{18}(OSiMe_3)_{12}]$ (3): To a solution of $BiCl_3$ (11.88 g, 37.4 mmol) in THF (180 mL) was added $NaOSiMe_3$ (12.70 g, 113.2 mmol) in small portions at room temperature to give a beige suspension. The solvent was evaporated, the residue extracted with hot toluene (150 mL) and the solid material filtered through Celite®. Evaporation of the solvent gave a solid containing Na, Bi and Si according to an EDX analysis. The residue was dissolved in toluene and the solution stored at 4 °C for several weeks. Single crystals of **2** were isolated by filtration and dried in vacuo to give 410 mg **2**. The filtrate was collected, the amount of the solvent was reduced to approximately 20 mL, and the solution was kept at 4 °C for several months to give single crystals of **3**. The colourless crystals were isolated by filtration and the solvent was removed from the crystals in vacuo to give 550 mg of **3**. Both compounds show a poor solubility, are moisture sensitive and decompose upon heating above 120 °C.

2: $C_{45}H_{141}Bi_{10}Na_5O_{28}Si_{15}$ (3756.6): C 14.4, H 3.8; found: C 13.4, H 3.0. IR (Nujol) $\tilde{\nu}$ = 3450 br, 1257 m, 1244 m, 1021 w, 925 s, 830 s, 741 m, 669 w, 632 w, 584 w, 536 w, 501 w, 410 cm^{-1} br.

3: $C_{43}H_{116}Bi_{15}Na_3O_{30}Si_{12}$ (4654.1): C 11.1, H 2.5; found: C 10.9, H 2.5. IR (Nujol) $\tilde{\nu}$ = 1258 m, 1244 m, 934 s, 921 s, 907 s, 828 s, 742 m, 674 w, 652 w, 632 m, 600 s, 543 w, 496 m, 442 w, 414 cm^{-1} w.

Structure Determination: See Table 1. Intensity data for the colourless crystals were collected on a Nonius KappaCCD diffractometer with graphite-monochromated Mo-$K\alpha$ radiation at 173 K. The data collection covered almost the whole sphere of reciprocal space with two (**1**), four (**2**·1.5C_7H_8) and seven sets (**3**·C_7H_8, **4**·C_6H_6) at different κ-angles and 202 (**1**), 510 (**2**·1.5C_7H_8), 652 (**3**·C_7H_8) and 592 (**4**·C_6H_6) frames via ω-rotation (Δ/ω = 1°) at two times 30 s (**1**), 60 s (**2**·1.5C_7H_8), 157 s (**3**·C_7H_8) and 60 s (**4**·C_6H_6) per frame. The crystal–detector distance was 3.4 cm (**1**, **4**·C_6H_6), 4.4 cm (**2**) and 3.8 cm (**3**·C_7H_8). Crystal decay was monitored by repeating the initial frames at the end of data collection. Analysing the duplicate reflections there was no indication for any decay. The structures were solved by direct methods SHELXS97[31] and successive difference Fourier syntheses. Refinement applied full-matrix least-squares methods SHELXL97.[32] The H atoms were placed in geometrically calculated positions using a riding model with U_{iso} constrained at 1.2 times U_{eq} of the carrier C atom for non-methyl and 1.5 times U_{eq} of the carrier C atom for methyl groups. Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from the *International Tables for X-ray Crystallography*. Absorption correction was carried out with multi-scan using SCALEPACK[33] [T_{min} = 0.310, T_{max} = 0.543 (**1**); T_{min} = 0.245, T_{max} = 0.525 (**2**·1.5C_7H_8); T_{min} = 0.085, T_{max} = 0.543 (**3**·C_7H_8); T_{min} = 0.119, T_{max} = 0.467 (**4**·C_6H_6)]. In **1** disorder of the metal atoms was found. Bi1 and Na1 were refined with equal position and occupancies of 0.33 and 0.66, respectively. In **2**·1.5C_7H_8 disorder over two positions was found for C6C, C6C′, C8A, C8A′, C8B, C8B′ with occupancies of 0.5. All solvent molecules toluene (C51–C57, C61–C67) and disordered atoms were refined isotropically. One solvent molecule toluene (C61–C67) was refined with occupancies of 0.5. In **3**·C_7H_8 disorder over two positions was found for C5A–C5′, C6A–C6′, C8A, C8′, C8B, C8′′, C9A–C9′, C10A–C10′, C11A–C11′ with occupancies of 0.5, for C12A, C12B with occupancies of 0.7 and for C12′, C12′′ with occupancies of 0.3. All solvent molecules toluene (C21–C27, C31–C37) and disordered atoms were refined isotropically. The solvent molecules toluene were refined with occupancies of 0.5. In **4**·C_6H_6 a trimethylsilanolate ligand and a solvent molecule THF share the oxygen atom O6. The $SiMe_3$ group (Si3, C11–C13) was refined with occupancies of 0.33 and the C atoms of the solvent molecule THF (C7–C10) were refined with occupancies of 0.66. Si3, C7–C10 were refined anisotropically and C11–C13 were refined isotropically. The figures were created by SHELXTL[34] and DIAMOND (release 2.1e, 2001).

CCDC-276495 (for **1**), -276497 (for **2**·1.5C_7H_8), -276496 (for **3**·C_7H_8) and -276498 (for **4**·C_6H_6) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We acknowledge the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Fachbereich Chemie of Dortmund University (support of young scientists) and Professor Dr. K. Jurkschat for support of this work. S. P. is grateful to the department of chemistry at the University of Joensuu (Finland) and the foundation of Heikki and Hilma Honkanen for financial support as well as for receipt of an ERASMUS grant.

Synthesis and Investigations of the Crystal Structure of a Dinuclear Diazadiene Molybdenum Oxo-Imido Complex with a Unique $N_3Mo(\mu\text{-}O)_2MoN_3$ Core

Alexei Merkoulov,[a] Klaus Harms,[a] and Jörg Sundermeyer*[a]

Keywords: Molybdenum / Oxo ligands / Imido ligands / Metathesis / Crystal structure

Ligand metathesis of the diimido and dioxo precursor complexes $[Mo(X)_2Cl_2(DME)]$ (X = O, N*t*Bu) leads to the mixed oxo-imido derivative $[Mo(N\textit{t}Bu)(O)Cl_2(DME)]$ (**1**). By treatment with Li_2DAD (DAD = 1,4-di-*tert*-butyl-1,4-diazabuta-1,3-diene), **1** is converted into the complex $[Mo(N\textit{t}Bu)(O)(DAD)]_2$ (**2**). The crystal structure determination on a non-merohedral twin of **2** reveals a dinuclear molecular structure with nearly symmetrical bridging oxygen atoms. The smaller oxo ligand tends to be a better bridging functionality than the imido ligand; the unprecedented $N_3Mo(\mu\text{-}O)_2MoN_3$ configuration is favored over a $ON_2Mo(\mu\text{-}N)_2MoN_2O$ core. Compared to other known molybdenum DAD complexes, **2** reveals some degree of pyramidalization at the nitrogen atoms of the DAD ligand. In accord with the Mo–N, N–C, and C–C bond lengths, complex **2** is best described as an ene-diamido complex of formally six-valent molybdenum.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Complexes based on the 1,4-diazabuta-1,3-diene DAD ligand backbone have been the focus of attention for many years. Due to several possible coordination modes and their redox activity, DAD ligands can stabilize metals with a wide range of formal oxidation states.[1] While DAD is a strong π-acceptor ligand that stabilizes low-valent metal centers, the two-electron-reduced DAD ligand, which is best described as an ene-diamido functionality, can be envisaged as a strong π-donor ligand that stabilizes high-valent metal centers. The diversity of substituents at the nitrogen and carbon atoms offers a perfect handle for the fine-tuning of electronic and steric ligand features that may be relevant in catalytic applications. For example, complexes of the late transition metals and diazadiene ligands with bulky electron-withdrawing aryl substituents at the nitrogen atom are extensively used in olefin oligomerization and polymerization.[2]

Following our previous investigations[3] on high-valent N-organoimido complexes of group 6 metals with other strong π-donor ligands, such as cyclopentadienyl, oxo, alkylidene or metallated phosphorus ylide ligands, we set out to explore the unknown chemistry of ene-diamido ligands with imido and oxo complexes. We now report the synthesis of a key oxo-imido complex, $[Mo(N\textit{t}Bu)(O)Cl_2(DME)]$ (**1**), and the conversion into its DAD derivative $[Mo(N\textit{t}Bu)(O)(DAD)]_2$ (**2**) (DAD = 1,4-di-*tert*-butyl-1,4-diazabuta-1,3-diene). Complexes with the functional and structural building block $[CpM(DAD)L_n]$ have been investigated for many years. This is the first report of a group 6 complex with a related σ,2π-donor and π-acceptor ligand regime $[(RN)M(DAD)L_n]$.

Results and Discussion

The oxo-imido complex **1** is formed in good yield by ligand metathesis between the known dioxo $[Mo(O)_2Cl_2(DME)]$[4] and diimido $[Mo(N\textit{t}Bu)_2Cl_2(DME)]$[5a] complexes in DME (Scheme 1). In agreement with the spectroscopic data and with related structurally characterized d^0 oxo-imido complexes,[5b] **1** probably has an octahedral structure with *trans* chloro ligands and the strong π-donor ligands O^{2-} and NR^{2-} in *cis* configuration. Reduction of DAD by lithium in THF affords the ene-diamide Li_2DAD.[6] The latter reacts with **1** to form the ene-diamido title complex **2** in a fair yield of 59%. Complex **2** is a hexane-soluble, dark purple, diamagnetic compound. ^1H and ^{13}C NMR spectra reveal equivalent *tert*-butyl groups at the DAD and imido N atoms, as well as equivalent methine protons at the C_2 bridge of DAD. These data are consistent with either a mononuclear tetrahedral structure or a binuclear species with either a mirror plane or a center of inversion. The EI mass spectra show mononuclear molecular ions $[Mo(N\textit{t}Bu)(O)(DAD)]$ as the highest peaks. To gain further insight into the nature of the title complex, single crystals for X-ray crystal structure determination were grown from a hexane solution.

Data Collection and Structure Refinement

A crystal with the dimensions $0.35 \times 0.15 \times 0.15$ mm was mounted on a glass fiber by using the "oil drop method". Data were collected at $T = 193$ K with a STOE IPDS area detector system using graphite monochromated Mo-K_α radiation. The crystal is orthorhombic with $a = 19.913(2)$, $b = 18.437(2)$, $c = 9.547(2)$ Å and happens to be a nonmerohedral twin with only minor overlap of the reflections. Only one orientation matrix was used during the integration of the intensities. Overlapping reflections were ignored. This procedure led to 13576 integrated intensities, with 2877 independent ($R_{int} = 12.26\%$) and the completeness was 90% for $\Theta_{max} = 25°$. No absorption correction was applied ($C_{28}H_{58}Mo_2N_6O_2$: $M = 702.68$, $\mu = 7.46$ cm^{-1} for $Z = 4$). Structure solution (direct methods) and refinement in the space group *Pnma* were performed by using the SHELX-97 programs,[7] with all non-hydrogen atoms anisotropic, and hydrogen atoms with fixed isotropic temperature factors determined with a riding model. In the final stage of the refinement, two residual peaks in the difference Fourier map (distance 3.09 Å) were interpreted as disorder positions of atoms Mo(1) and Mo(2) (noncrystallographic transformation close to x, y, $5 - z$). The ratio of the occupancies [all atoms of the main part versus atoms Mo(3) and Mo(4)] were refined to 0.907:0.093. No disordered positions of the light atoms were located, final residuals: $wR_2 = 11.28\%$ (for all unique reflections), conventional $R_1 = 4.86\%$ [for 1346 reflections with $I > 2\sigma(I)$], and 205 refined parameters.

Molecular Structure of 2

The molecular structure of **2** in the crystal is shown by Figure 1, with selected bond lengths and angles in Table 1. Figure 2 displays the disorder and inner coordination spheres. The title complex **2** is binuclear in the solid state. Both molybdenum atoms are tetragonal pyramidal and coordinated by five atoms: an axial imido nitrogen atom, two basal nitrogen atoms of the DAD ligand, and two oxygen atoms of the central planar $Mo_2(\mu\text{-}O)_2$ core. All six basal atoms $N_2O_2N_2$ lie in the same plane. Both imido ligands adopt an *anti* collinear orientation. There is a crystallographic mirror plane defined by the two metal centers and the two Mo–N(imido) vectors. Although there is no inversion symmetry unit, the $Mo_2(\mu\text{-}O)_2$ core can be considered to be symmetrical on the basis of the bond lengths and their standard deviations; the Mo–O bond lengths are 1.959(5) and 1.952(5) Å. These bond lengths correlate with the value for Mo–O single bonds, e.g. in **A**,[8] they are approximately 1.95 Å (Scheme 2).

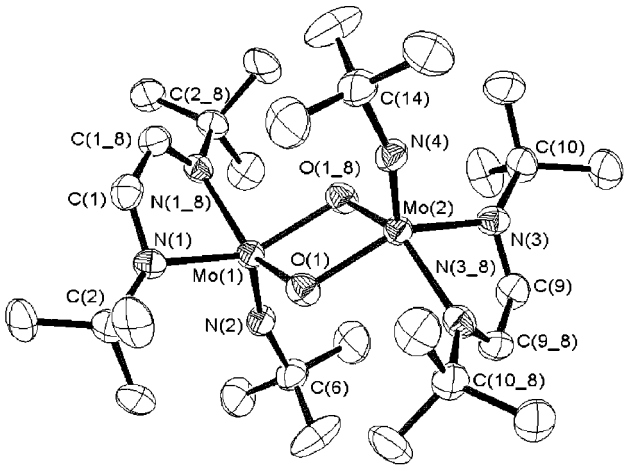

Figure 1. Molecular structure of **2**.

To date, no other structurally characterized example of an $N_3Mo(\mu\text{-}O)_2MoN_3$ coordination polyhedron is known, therefore a direct comparison cannot be made (CCSD search, September 2005). However, a similar framework has been found in a dinuclear thiolato(oxo) complex of the type $S_2(O)Mo(\mu\text{-}O)_2Mo(O)S_2$ (**A**). In contrast to **2**, the two square pyramids with their apical Mo–O vectors are in a *syn* configuration to each other in **A**.

Several molybdenum DAD complexes have been described in the literature, with examples given by **B**–**E**.[9–12] Type **B**[9] represents a four-electron Lewis base adduct of the diazadiene ligand that is coordinated to a formally six-valent molybdenum center, which is characterized by perfectly planar N atoms and long Mo–N distances of ca. 2.40 Å, short N–C distances of ca. 1.27 Å, and long C–C distances of ca. 1.48 Å. It is anticipated, for a metal of d^0 electron configuration that there is no M→L back-bonding in **B**. This is demonstrated by negligible differences between the discussed bond lengths in free DAD[13] and those in **B** (Table 2). However, due to its low-lying π* orbitals, neutral DAD can easily be reduced by more electron-rich metal centers to form the coordinated radical anion $[DAD]^{-}$[14] and the ene-diamido $[DAD]^{2-}$ ligands.[1,6,10,11,15,16] Examples of molybdenum complexes with a fully reduced DAD moiety are **C**[10] and **D**.[11] The structural parameters of their MN_2C_2 units are similar to that of the phenylene-1,2-diamido system **E**[12] (Table 2). Typically, flat[15] and folded[16] ene-diamido units (MN_2C_2) are known. In folded conformations, the metal is located out of the N_2C_2 plane (E^{NCCN}), as indicated by the distance $d(M\text{–}E^{NCCN})$, which

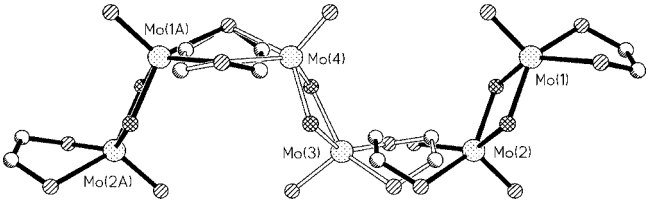

Figure 2. Coordination polyhedra and disorder in the crystal structure of **2**. Open bonds: minor part of disorder, positions of light atoms calculated.

is listed in Table 2. In almost flat conformations, as found in **C** and **D**, the Mo atom is only ca. 0.3 Å out of the plane. Perfectly flat conformations are present in DAD adducts such as **B**. Similarly to those in **B**, the nitrogen atoms of **C** and **D** are close to planar (the sum of angles at the N atoms Σ°N ca. 360°). By comparing the M–N, N–C, and C–C bond lengths, complex **2** is best described as an ene-diamide of d^0-Mo^{VI} and not as a neutral diazadiene adduct of d^2-Mo^{IV}. In contrast to those of **C** and **D**, the Mo atom of **2**

is located 0.951(1) Å out of the N_2C_2 plane, and the sum of angles at the nitrogen atoms, Σ°N = 355.5° and 357.2°, respectively, indicates a trend for pyramidalization, which is analogous to that of phenylene-diamido complexes of type **E**. Table 2 shows that the shortening of the Mo–N and C–C bonds is accompanied by a lengthening of the N–C bonds and a higher degree of pyramidalization at the N atoms. Currently we are investigating the scope of this statement by exploring other diazadiene imido complexes of the early transition metals. Preliminary results reveal that the liaison of both DAD and NR ligands at one metal offers access to a growing new class of covalent functional compounds.

Experimental Section

General: All reactions and manipulations were carried out under argon using standard Schlenk techniques. Solvents were refluxed in the presence of an appropriate drying agent and distilled: C_6D_6 and hexane (Na/K alloy), THF and DME (Na/benzophenone), and toluene (Na). Literature methods were employed for the synthesis of starting materials $[Mo(O)_2Cl_2(DME)]$,[4] $[Mo(N\textit{t}Bu)_2Cl_2(DME)]$,[5] 1,4-di-*tert*-butyl-1,4-diazabuta-1,3-diene (DAD),[17] and Li_2DAD.[6] Melting points (uncorrected) were measured with a Büchi MP B-540 apparatus. C, H, and N analyses were carried out with a Heraeus CHN-Rapid analyzer. Mass spectra were recorded with a Varian MAT CH-7a (EI, 70 eV) instrument. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded with Bruker AMX300 and DRX500 spectrometers; chemical shifts were referenced to the ^1H (δ = 7.15 ppm) and ^{13}C (δ = 128.0 ppm) residual signals of C_6D_6. Infrared spectra were recorded with a Bruker IFS 88 FT instrument, and samples were Nujol mulls between KBr plates.

Preparation of [Mo(N*t*Bu)(O)Cl$_2$(DME)] (1): Under argon, $[Mo(N\textit{t}Bu)_2Cl_2(DME)]$ (400 mg, 1.00 mmol) and $[Mo(O)_2Cl_2(DME)]$ (290 mg, 1.00 mmol) were dissolved in DME (10 mL) and heated to reflux for 3 days. The volatiles were removed in vacuo, and the yellow-green product was extracted into toluene (30 mL) and crystallized at –40 °C. Yield 500 mg (73%). M.p. 71 °C. $C_8H_{19}NCl_2O_3Mo$ (M = 344.09 g mol^{-1}): calcd. C 27.93, H 5.57, N 4.07; found C 27.49, H 5.44, N 3.97. ^1H NMR (C_6D_6, 300 MHz, 300 K): δ = 3.41 (s, 6 H, Me), 3.02 (s, 4 H, CH_2), 1.41 (s, 9 H, N*t*Bu) ppm. $^{13}C\{^1H\}$NMR (C_6D_6, 75 MHz, 300 K): δ = 70.6 (s, CH_2), 63.2 (br s, Me), 27.8 (s, N*t*Bu) ppm. IR (KBr): 3160 (m, vbr), 1587 (m), 1405 (w), 1362 (s), 1276 (w), 1259 (w), 1228 (s, br), 1188 (w), 1162 (w), 1137 (w), 1108 (w), 1086 (s), 1044 (s, b), 1005 (vw), 961 (m), 910 (s), 861 (s), 826 (m), 799 (m), 725 (w), 627 (w), 592 (w), 572 (m), 515 (w) cm^{-1}.

Preparation of [Mo(N*t*Bu)(DAD)(μ-O)]$_2$ (2): A solution of Li_2DAD (265 mg, 1.45 mmol) in THF (20 mL) was added dropwise to a solution of **1** (500 mg, 1.45 mmol) in THF (20 mL) at –80 °C. After 10 min at –80 °C, the reaction mixture reached room temperature within 30 min. After 8 h at room temperature, THF was removed at reduced pressure, and the product was extracted with two portions of hexane (30 mL). The analytically pure dark violet compound was obtained by crystallization from hexane at –80 °C. Yield: 300 mg (59%). M.p. 190 °C (dec.). $C_{28}H_{58}N_6O_2Mo_2$ (M = 702.69 g mol^{-1}): calcd. C 47.86, H 8.32, N 11.96; found C 47.44, H 8.02, N 11.55. EI-MS: *m*/*z* (%) = 353 (1) [M/2$^+$], 338 (2) [M/2$^+$ – Me], 57 (100). ^1H NMR (C_6D_6, 500 MHz, 300 K): δ = 6.75 (s, 2 H, CH–DAD), 1.51 (s, 18 H, *t*Bu-DAD), 1.38 (s, 9 H, N*t*Bu) ppm. $^{13}C\{^1H\}$NMR (C_6D_6, 125 MHz, 300 K): δ = 119.9 (CH–DAD), 69.9 ($NCMe_3$), 57.6 (CMe_3–DAD), 30.5 (DAD–CMe_3), 30.4 ($NCMe_3$) ppm. IR (KBr): 3038 (w), 1605 (w), 1420 (w), 1358 (m), 1262 (s), 1235 (s), 1219 (s), 1148 (w), 1098 (m, br), 1022 (m, br), 936 (w), 864 (w), 804 (s), 766 (m), 723 (w), 644 (m, br), 567 (m), 525 (w), 492 (w) cm^{-1}.

Synthesis of Main Group Polycations in Molten and Pseudo-Molten $GaBr_3$ Media

Alexei N. Kuznetsov,[a] Boris A. Popovkin,[a] Kenny Ståhl,[b] Martin Lindsjö,[c] and Lars Kloo*[c]

Keywords: Antimony / Bismuth / Tellurium / Cluster compounds

The prospects of synthesizing polycationic species using $GaBr_3$ in benzene solution at room temperature have been investigated. The salts $Bi_8[GaBr_4]_2$, $Sb_8[GaBr_4]_2$ and $Te_4[Ga_2Br_7]_2$ have been isolated and characterized. The first two compounds are isotypic with $Sb_8[GaCl_4]_2$, crystallize in the space group $Pna2_1$, and feature square *anti*-prismatic E_8^{2+} polycations (E = Sb, Bi). Unit-cell parameters for $Bi_8[GaBr_4]_2$ are a = 18.3014(10) Å, b = 10.3391(6) Å and c = 13.5763(7) Å, and for $Sb_8[GaBr_4]_2$; a = 18.096(2) Å, b = 10.1572(9) Å and c = 13.2168(10) Å. $Te_4[Ga_2Br_7]_2$ crystallizes in the space group $P2_1/c$ with a = 10.1600(9) Å, b = 10.8314(9) Å, c = 13.8922(10) Å and β = 99.182(7)°, and features a square-planar Te_4^{2+} polycation. The compound $Bi_5[GaBr_4]_3$ has been synthesized from molten $GaBr_3$ and characterized by using powder diffractometry in space group Fm-3c; a = 17.6263(8) Å. The structure model for this compound suggests the included Bi_5^{3+} cations to be practically freely oriented within its cavities in the solid phase.

Introduction

Homopolyatomic ions of the main-group elements have for a long time been an area of many studies and discussions, resulting in a large number of publications.[1] Species such as Cd_2^{2+}, Bi_8^{2+}, Bi_9^{5+}, Se_8^{2+}, Te_4^{2+}, I_3^+ etc. have been synthesized employing several different routes, for instance using molten salts or superacidic media.[2] Recently, in a series of papers we have illustrated the possibility to obtain polycations from $GaCl_3$–benzene solutions.[3–6] This method is based on the extraordinarily high solubility of $GaCl_3$ in benzene, which renders a pseudo-melt behavior to the saturated solution.[7] Thus, it has been possible to repeat, at room temperature, several of the reactions previously performed in molten $AlCl_3$. The major advantage of performing reactions at low temperatures is that it allows easier study of reactants and products in solution, using for instance spectroscopy. The method also offers some possibility to influence processes like crystal growth, as recently demonstrated by the successful isolation of the previously unknown $Sb_8[GaCl_4]_2$.[5]

Unfortunately, there are only very few other Lewis acids known with a propensity comparable to $GaCl_3$ for dissolution in benzene or other non-polar solvents. However, there is one obvious alternative – $GaBr_3$. The properties of $GaBr_3$ are similar to those of $GaCl_3$; the same structure in the solid phase and also a very high solubility in arenes, albeit not as high as its chloride congener. It can be noted that only very few *bromo*-aluminate/gallate/indate salts containing main-group polycations have been reported in literature – $Te_4[AlBr_4]_2$[8] and $Bi_8[InBr_4]_2$.[9] It is not known to us if the brevity of this list, in comparison to the record of chloroaluminate structures, is due to unforeseen complications in their syntheses or if it just reflects the small number of synthetic attempts made. The main goal of this investigation is to extend the knowledge on main-group polycation chemistry, employing a $GaBr_3$–benzene system as reaction medium because; (i) it is chemically closely related to the $GaCl_3$–benzene system, known to be successful; (ii) only a few reports have been made about the isolation of crystalline compounds from ternary M–Al/Ga/In–Br systems, and; (iii) it allows the possibility to affect polycation chemistry and thereby a possibility to isolate new polycations in the liquid or solid state.

The following sections describe observations made regarding the synthesis of a selection of main-group polycations in $GaBr_3$–benzene media. Some experiments have also been performed in molten Bi–$BiBr_3$–$GaBr_3$ systems.

Results and Discussion

The syntheses performed in this work followed the general procedures developed for the analogous $GaCl_3$–benzene system, which have been well described in earlier papers.[3–6] The solubility of gallium tribromide in benzene at ambient

conditions is somewhat lower than that of gallium trichloride, estimated within this work to be ca. 8–9 mol%. In order to confirm the nature of $GaBr_3$ when dissolved in benzene, Raman spectra were recorded, see Figure 1, and compared with known spectra of Ga_2Br_6.[10] This evaluation verifies that gallium tribromide predominantly exists as dimeric units in benzene solution.

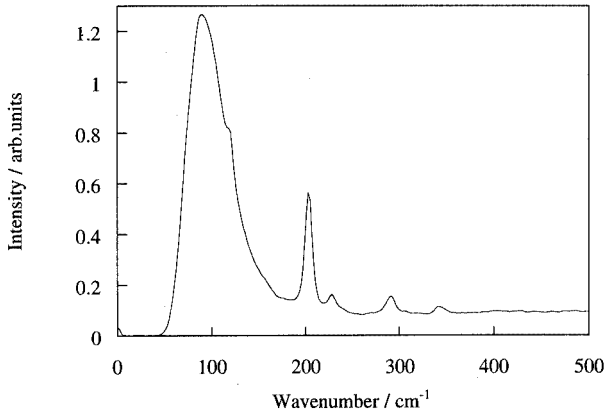

Figure 1. The Raman spectrum of $GaBr_3$ in benzene solution.

Bi–$GaBr_3$–Benzene Systems

Most of our work considering $GaBr_3$–benzene systems has been devoted to attempts to isolate bismuth polycations. First, the oxidation of bismuth metal by $GaBr_3$ in benzene solution was analyzed. In contrast to the reaction between bismuth and $GaCl_3$ in benzene, for which a red color can be noticed after a few hours, no coloration or other visible changes are observed in the Bi–$GaBr_3$–benzene case. However, after a few days it was noticed that the bismuth metal surface had lost it luster due to the formation of a black substance. By repeatedly exposing the crude product to fresh $GaBr_3$-benzene solutions, a sufficient amount of this black phase was obtained.

The final product was characterized by using powder X-ray diffraction. Although bismuth metal constituted a major impurity, it was possible to obtain the unit cell parameters for the black phase from the indexed reflections. The compound crystallizes in space group $Pna2_1$, a = 18.3014(10), b = 10.3391(6), c = 13.5763 Å. It was noted that this cell is very similar to the cells of $Sb_8[GaCl_4]_2$ and $Sb_8[GaBr_4]_2$ (see below), and the black phase was assumed to be $Bi_8[GaBr_4]_2$ (**1**). The coordinates of $Sb_8[GaBr_4]_2$ were used as starting coordinates in the Rietveld refinement of **1**. From the difference pattern it was concluded that the sample contained a third phase, the positions of the unassigned reflections matched known positions of $GaBr_3$, and this phase was added to the refinement.

The structure of **1** features a distorted square-antiprismatic Bi_8^{2+} cation and two tetrahedral $GaBr_4^-$ anions. The distortion of the cation is illustrated by the fact that the two Bi_4 squares are not parallel, see Figure 2. As a consequence, the variation in Bi–Bi distances is large, 2.88(2)–3.23(3) Å, see Table 1. In the discussion on $Sb_8[GaCl_4]_2$,[5] it was observed that for the antimony cluster the inter-square Sb–Sb distances are 3.3% longer than the intra-square distances, while the inter-square metal–metal distances in the case of $Bi_8[GaCl_4]_2$ are only 0.4% longer than the intra-square ones. The mean values for inter-square and intra-square Bi–Bi distances in **1** are 3.07(9) and 3.00(6) Å, respectively, giving a ratio of 1.023. This ratio is close to the one found for the Sb_8^{2+} cation, however, the distortion of the cation in **1** invites to some care in the interpretation.

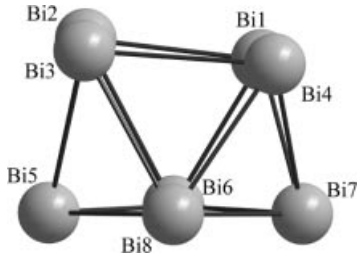

Figure 2. The Bi_8^{2+} cation of **1**. The two Bi_4 squares are not parallel to each other, consequently a large variation in Bi–Bi distances is observed.

Table 1. Bond lengths of **1**. Bismuth atom labels are given in Figure 2.

In our studies, it has been generally observed that the recording of Raman spectra is problematic for solid compounds containing bismuth polycations, probably due to heavy absorption. Therefore, no reliable Raman spectrum for **1** has been obtained.

If instead the reduction of $BiBr_3$ by Ga metal in $GaBr_3$–benzene is considered, the outcome is likewise problematic and different from the analogous reaction in the chloride system. The mixing of a solution containing $BiBr_3$ with one containing Ga^+ ions causes an immediate formation of a black precipitate, while the solution remains colorless. No subvalent bismuth species can be registered in the liquid phase by use of Raman spectroscopy. The black substance can be inspected by means of X-ray powder diffraction and has been found to be amorphous, most likely due to the instantaneous precipitation.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Obviously, the speed of precipitation has to be reduced in order to obtain proper crystals. By using a special set-up, allowing for a very slow speed of mixing, a small amount of tiny, black, bar-shaped crystals could be isolated. A unit cell determination for one of these crystals shows that they belong to the orthorhombic system with the unit cell parameters: a = 23.854(6) Å, b = 15.634(5) Å, c = 9.128(5) Å; hence in very good agreement with the unit cell parameters of Bi_6Br_7.[11] This is quite remarkable, as it is the first salt, isolated from this synthetic method, that not includes halidogallate anions. Furthermore, this implies that Bi_9^{5+} cations are likely to be present in the solution at very low concentrations, undetectable by spectroscopy. The reasons why bromogallate(III) anions are not incorporated into the crystallization product are not yet clear. One possible explanation may lie in the expected thermodynamic stability of Bi_6Br_7 in combination with weaker Lewis acidity of $GaBr_3$ with respect to $GaCl_3$.

The main conclusion drawn from the synthesis of bismuth polycations in $GaBr_3$–benzene media is that compounds containing polycations form; $Bi_8[GaBr_4]_2$ and Bi_6Br_7 have been isolated. However, although the reaction principles work, the solubility of the formed polycations in media containing bromogallates ions is very low, and the crystal growth is severely hampered with reduced crystal size as consequence.

Molten Bi–$GaBr_3$ and Bi–$GaBr_3$–$BiBr_3$ Systems

In order to obtain crystals of **1** of better quality, an attempt on the direct high-temperature oxidation of bismuth by gallium tribromide was made. However, no interaction between the components was observed even after a week of annealing at 350 °C. This clearly demonstrates the vital role of benzene in coordinating Ga^+ cations formed on the reduction of Ga^{III} in $GaBr_3$–benzene media.

Instead, symproportionation was employed; from a solid state synthesis, the starting materials having the ratio 4Bi:$BiBr_3$:4$GaBr_3$, a red-brown microcrystalline material could be obtained. The recorded powder X-ray diffractogram of this product shows strong similarities to that of the previously characterized cubic modification of $Bi_5[GaCl_4]_3$.[3] In analogy to that structure, the diffraction pattern was indexed as F-centered cubic with a = 17.6263(8) Å. The atomic coordinates for the chloride structure were taken as the initial model for full-profile Rietveld refinement. The atomic coordinates for this phase, cubic $Bi_5[GaBr_4]_3$ (**2**), are given in Table 2.

Both **2** and cubic $Bi_5[GaCl_4]_3$ are related to the rhombohedral form of $Bi_5[GaCl_4]_3$.[6,12] All these three compounds contain trigonal bipyramidal Bi_5^{3+} polycations and tetrahedral GaX_4^- anions as the structural units (see Figure 3). However, the difference for the cubic phases is that their description within the given crystal system implies a substantial degree of disorder. Eight Bi_5^{3+} units, occupying centers of octants in the cubic cell, may in the cubic $Bi_5[GaCl_4]_3$ have 4 different orientations parallel to the body diagonals of the cube. In **2**, the positions of Bi(2) are slightly off the body diagonals, resulting in 8 possible positions. In practice, it is hardly meaningful to discuss the polycations in terms of atomic positions, the number of possible positions, together with the relatively large displacement parameter, suggest that the Bi_5^{3+} polycations can be assumed to rotate freely in all direction within its cavities, defined by the positions of the tetrabromogallate anions. Therefore, it has also not been relevant to analyze any Bi–Bi distances of this cation. In contrast, the anions are found to be almost ordered, although a second bromine site, occupied by 6% of the bromine atoms, has been refined. The Ga–Br(1) distance is found to be 2.338(4) Å, in good agreement with the reported distance of the tetrabromogallate anion.

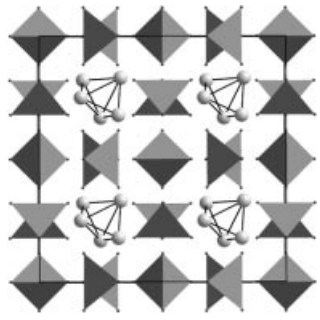

Figure 3. An idealized two-dimensional projection of the unit cell content of **2**. The Bi_5^{3+} polycations are displayed in one of all possible orientations and the Br(2) atoms have been omitted.

In the case of cubic $Bi_5[GaCl_4]_3$ it has already been concluded that no further information is added to the structure solution through the generation of single crystals.[6] One possible explanation may be that the cubic phase is a microtwinned modification of the rhombohedral one (still to be isolated in the case of $Bi_5[GaBr_4]_3$).

It can be noted that all the attempts to produce more bismuth-rich compounds from molten Bi–$BiBr_3$–$GaBr_3$ (e.g. $Bi_8[GaBr_4]_2$) resulted in the formation of **2** and some unreacted bismuth metal in the reaction container, i.e. no

Table 2. Refined fractional coordinates, isotropic temperature coefficients and occupancy factors for **2**.

other ternary cluster compound was obtained in this system through the molten salt route of synthesis.

Synthesis and Crystal Structure of $Sb_8[GaBr_4]_2$

Also the reactions of antimony in $GaBr_3$–benzene have been studied. In the case of antimony it has previously been noted that elemental antimony is not oxidized in $GaCl_3$–benzene, probably due to low solubility.[5,13] It is assumed that the same is true for the bromide case, hence only the reduction of $SbBr_3$ by Ga metal has been empolyed. From this route, a large amount of a black amorphous phase together with a few small orange crystals have been isolated. Single-crystal X-ray diffraction and Raman spectroscopy experiments have confirmed the orange crystals to be $Sb_8[GaBr_4]_2$ (**3**).

The structure of **3** is isotypic to the structure of **1**, described above, as well as the chloride analogue, $Sb_8[GaCl_4]_2$,[5] with an increase in unit cell volume of 8.6%. The structure features a Sb_8^{2+} polycation, the geometry being very close to square-antiprismatic (although the true molecular symmetry is C_1), and two crystallographically independent tetrabromogallate tetrahedra, see Figure 4. The Sb–Sb distances vary between 2.854(2) and 2.890(2) Å [mean: 2.871(11) Å] within the squares, while the inter-square distances vary between 2.940(2) and 2.987(2) Å [mean: 2.97(2) Å], see Table 3. Thus, the inter-square/intra-square distance ratio is found to be 1.035 (see discussion on the structure of **1**). This is in very good agreement with the distances of the cation found in the tetrachlorogallate structure. The Ga–Br distances are in the interval 2.299(3)–2.327(3) Å. Just as in the case of the chloride structure, there are some rather short cation–anion distances, the shortest being 3.552(2) Å.

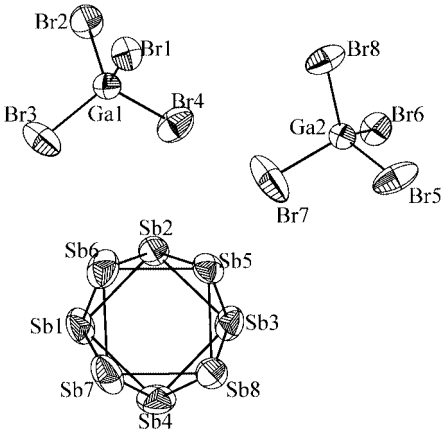

Figure 4. The atoms of the asymmetric unit of **3**. Thermal ellipsoids are drawn at the 70% probability level.

Raman spectroscopy on selected single crystals of **3** reveals signals at $\tilde{\nu}$ = 177 (s) and 209 (m) cm^{-1}. The first one corresponds to the strongest Raman peak of the Sb_8^{2+} polycation, shifted a few wavenumbers down with respect to the chloride structure, while the latter peak corresponds to the strong symmetrical stretch vibration mode of the $[GaBr_4]^-$ ion.[14]

Table 3. Bond lengths of **3**. Atom labels are given in Figure 4.

Ga(1)–Br(4)	2.320(3)	Ga(2)–Br(8)	2.310(2)

Neither X-ray diffractometry nor Raman spectroscopy proved to be useful in the characterization of the black precipitate, which is the major product of the reaction above. Energy-dispersive X-ray analysis (EDX) was performed on this compound in order to obtain some information of its contents. Unfortunately, the results of these measurments are ambiguous. The observed Ga:Br ratio (1:2) is unexpectedly low; not an uncomon result of elemental analyses in gallate systems. On the other hand, the observed Sb content tend to match the expected theoretical values. Based on the assumption that the Sb content is in good agreement also for this black product obtained from the reduction of $SbBr_3$, it can be conluded that the phase contains an antimony polycation and that it is likely to be a another polycation than Sb_8^{2+} (theoretical Sb content; 44%). Plausible compounds, based on the antimony content (ca. 24%), include $Sb_5[GaBr_4]_3$ (25%), $Sb_6[GaBr_4]_4$ (23%), $Sb_7[GaBr_4]_5$ (22%) and $Sb_8[GaBr_4]_4$ (29%).

Te–$GaBr_3$–Benzene

It has also proved feasible to synthesize polycations of elements from other groups than group 15 by using the benzene route. Recently, $Te_4[Ga_2Cl_7]_2$ was isolated from $GaCl_3$–benzene media,[15] and other ions may be attainable in the analogous bromide system. Therefore, a series of experiments were pursued, attempting to oxidize different elements to polycations in $GaBr_3$–benzene solution.

No reaction was detected in the case of cadmium, arsenic or selenium. However, in the case of tellurium, the solution becomes slightly green in color within a couple of hours after the addition of elemental tellurium. After a few days this color disappears, and instead small, black, block-shaped crystals are formed. Unfortunately, the crystals are too small to allow for even a unit cell determination and the Raman spectrum is ambiguous, showing only one band at 210 cm^{-1}, which could be attributed to different expected ions such as Te_4^{2+} or $GaBr_4^-$.[14,16]

Instead, reduction of $TeBr_4$ with Ga metal in $GaBr_3$–benzene is successful, and violet, plate-shaped crystals were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

obtained. Single-crystal diffraction confirms these crystals to contain $Te_4[Ga_2Br_7]_2$ (**4**), the formula analogue of the compound previously found in the chlorogallate case.[15] **4** is found to crystallize in the space group $P2_1/c$, just like the previously reported chlorogallate structure, however the unit cell parameters are different, with a much larger β-angle [99.182(7)°] in the case of **4**.

The structure of **4** features a square-planar Te_4^{2+} cation and staggered $[Ga_2Br_7]^-$ anions, see Figure 5. Selected bond lengths for **4** are given in Table 4. The Te–Te distances are 2.6702(14)–2.6720(14) Å, which compares well with other structures containing this cation.[1c] The distances between the gallium atoms and the terminal bromine atoms, 2.266(2)–2.331(2) Å, are in the normal range for Ga–Br bonds. Just as in $Te_4[Ga_2Cl_7]_2$ and $Te_4[Al_2Cl_7]_2$,[17] there are some rather short Te–X distances (X = Cl, Br), of which the shortest are found for bromides positioned in the plane of the cation, capping the edges of the square-planar cation. In this particular structure, the shortest Te–Br distance is 3.412(2) Å.

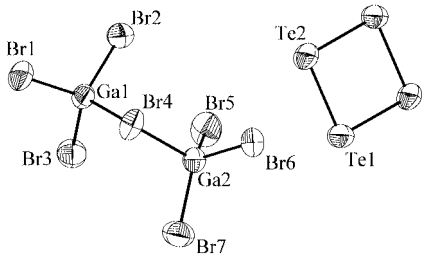

Figure 5. The atoms of the asymmetric unit of **4**. Thermal ellipsoids are drawn at the 70% probability level. Unlabelled Te atoms are related to Te(1) and Te(2) by the inversion operator $(1 - x, 1 - y, -z)$.

Table 4. Bond lengths of **4**. Atom labels are given in Figure 5.

Atoms	Distance [Å]
Te(1)–Te(2)	2.6702(14)
Te(2)–Te(1)^i	2.6720(14)
Ga(1)–Br(1)	2.290(2)
Ga(1)–Br(2)	2.311(2)
Ga(1)–Br(3)	2.275(2)
Ga(1)–Br(4)	2.432(2)
Ga(2)–Br(4)	2.445(2)
Ga(2)–Br(5)	2.274(2)
Ga(2)–Br(6)	2.331(2)
Ga(2)–Br(7)	2.266(2)

In the Raman spectrum recorded from a single crystal of **4**, bands are observed at 419 (*m*), 314 (w), 250 (br) and 210 (s) cm^{-1}. The lowest band is attributable to the cation,[16] and the bands at 250 and 314 cm^{-1} to the anion.[18] The origin of the peak at 419 cm^{-1} is unknown, but a similar band was observed for $Te_4[Ga_2Cl_7]_2$, which in the report of that compound, was suggested to be attributed to the chlorogallate anion.[15] However, this may possibly be a common band of both structures, originating either from the cation or an impurity.

It can be concluded that the Te_4^{2+} cation has the highest solubility of the polycations formed in $GaBr_3$–benzene; a colored solution is retained at least for a couple of minutes when reducing $TeBr_4$ with Ga metal, instead of immediate precipitation as in the cases of $BiBr_3$/$SbBr_3$. Furthermore, a slight coloration of the solution can be observed also when elemental tellurium is put in $GaBr_3$–benzene, and small crystallites are formed spatially separated from the solid reactants, hence, transport via solution must occur.

Conclusions

Experimental attempts to synthesize polycations of different elements in $GaBr_3$–benzene solutions have been performed. For all experiments in such media, the problem of low solubility of the products formed represents a serious complication, lowering the quality of the crystalline materials obtained. Nevertheless, the compounds $Bi_8[GaBr_4]_2$, $Sb_8[GaBr_4]_2$ and $Te_4[Ga_2Br_7]_2$ have been isolated and their structures characterized, illustrating the similarity in chemistry between $GaCl_3$ and $GaBr_3$ in benzene media. Additionally, $Bi_5[GaBr_4]_3$ has been isolated from molten $GaBr_3$ and its structure has been partly characterized.

Experimental Section

Chemicals: Commercial Bi (Aldrich, 99.999%), Ga and In metals (both ALFA Chemicals, 99.9999%), bromine, $BiBr_3$ (Aldrich, 99.9%), $SbBr_3$ (Aldrich, 99.99%), $TeBr_4$ (Aldrich, anhydrous, 99.995%) and $GaBr_3$ (Aldrich, anhydrous, 99.999%) were used as purchased. For certain experiments $GaBr_3$ was synthesized from the elements according to a literature procedure.[19] Benzene (Merck, pro analysi grade) was distilled and stored over molecular sieves in a glovebox under a dry nitrogen atmosphere. Because of the high moisture sensitivity of the anhydrous metal halides used in this work, all operations were performed in a glovebox under dry nitrogen with less than 0.5 ppm H_2O.

Synthesis of 1: Bi metal powder (0.2 g, 1 mmol) was added to 0.7 g of a saturated $GaBr_3$/benzene solution in a standard NMR tube. No obvious signs of reaction, such as change of solution color, were observed, but after a few days it could be noticed that a black substance had formed on the surface of the metal. From X-ray powder diffraction the crude product was found to a mixture of bismuth metal and an unknown compound. In order to improve the purity of the unknown phase, the product was washed with pure benzene, dried, re-ground and added to a fresh $GaBr_3$/benzene solution. These steps were repeated several times until a satisfactory purity of the product was obtained.

Synthesis of Bi_6Br_7: Two solutions, In–$GaBr_3$–benzene and $BiBr_3$–$GaBr_3$–benzene, were prepared and added to two vessels connected by a bridge, an overturned U-shaped tube, filled with pure benzene.[20] The reactor was then sealed to prevent solvent evaporation. After a month, some crystallization was observed in the form of black bars at the bend of the bridge.

Synthesis of 2: A mixture with the ratio of $4Bi:BiBr_3:4GaBr_3$ was heated to 350 °C in a evacuated and sealed standard 5 mm NMR tube for several days and then slowly cooled to room temperature. The excess of gallium tribromide was removed by sublimation at 150 °C under dynamic vacuum. The obtained product is a dark brown microcrystalline mass, brick red when powdered.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of 3: $GaBr_3$ (0.30 g, 1.0 mmol) was dissolved in benzene (1.0 mL) and the solution was separated into two parts. $SbBr_3$ (0.035 g, 0.1 mmol) was added to one of the solutions and Ga metal (0.02 g, 0.3 mmol) to the other. After 24 hours, the two solutions were mixed. A black precipitate formed immediately while the solution remained colorless. When the product was studied under microscope, it was noticed that small crystals of **3** had formed as orange cylinders together with the amorphous, black, main product.

Synthesis of 4: $GaBr_3$ (0.30 g, 1.0 mmol) was dissolved in benzene (1.0 mL) and the solution was separated in two parts. $TeBr_4$ (0.05 g, 0.1 mmol) was added to one solution and Ga metal (0.02 g, 0.3 mmol) to the other. After 24 hours, the two solutions were mixed, and a very darkly green solution formed. After a few minutes a dark precipitate formed and the solution became clear. Crystals of **4** were found as violet plates.

Raman Spectroscopy: Raman spectra from solutions were recorded using Bruker IFS-66/FRA-106 and Bio-Rad FT-Raman spectrometers equipped with a low power Nd:YAG laser (1064 nm) and solid state Ge detector cooled by liquid nitrogen. A resolution of 4 cm^{-1} was used in all measurements. Spectra from single crystals, mounted in standard melting point tubes, were recorded using a Renishaw System 1000 spectrometer, equipped with a DMLM Leica microscope and a 25-mW He-Ne laser (633 nm).

Elemental Analysis: Energy dispersive X-ray Analysis was performed on the amorphous black product formed contemporarily with the formation of **3**, using a JEOL JSM-820 scanning electron microscope. Totally 16 points at three different areas of a sample of the amorphous compound was measured. The observed average contents were (standard deviation in parenthesis): Sb, 24 (3) atom-%; Ga, 26 (3) atom-%; Br, 50 (1) atom-%.

Powder X-ray Diffraction: The powder diffraction data were collected using an INEL powder diffractometer, equipped with CPS-120 position-sensitive detector. The detector was calibrated with a $Pb[NO_3]_2$ standard and the diffraction pattern re-calculated into an equal-step pattern using a cubic-spline function. Standard 0.3 or 0.5 mm Lindemann capillaries were used as sample containers. The samples were kept spinning during the data collection. The Rietveld analyses of the powder diffraction data of **1** and **2** were performed using a local version of the LHPM1 program,[21] and employed pseudo-Voight profile functions, limited to 18 half-widths, with five-peak asymmetry correction, a Lorentzian component $\gamma = \gamma_1 + \gamma_2 (2\theta)$ and FWHM defined as $(U\tan^2\theta + V\tan\theta + W)^{1/2}$. The refinements also included 2θ zero-point correction and Chebyshev background parameters.

1 ($Bi_8[GaBr_4]_2$): An orthorhombic unit cell was indicated from the indexing of the reflections. Certain peaks could be attributed to bismuth metal impurities. On the basis of the similarities in the unit cell parameters of **1** with those of **3**, the compound was believed to be $Bi_8[GaBr_4]_2$. The Rietveld refinement was started with the structural parameters of **3**, including bismuth metal as a second phase. From the difference pattern it was observed that a third phase was present in the sample. The positions of the peaks for this phase matched the known positions of $GaBr_3$, which was included as a third phase in the refinement.[22] The final results suggested the ratio of the different phases in the sample to be Bi metal, 11.3(2)%; $GaBr_3$, 15.9(6)%; $Bi_8[GaBr_4]_2$, 72.8(1.1)%. The structural model of $Bi_8[GaBr_4]_2$ was refined using free coordinates for Bi_8 and restrained for $GaBr_4$ [Ga–Br = 2.35(1) Å]. Individiual isotropic thermal parameters were refined for Bi8 and one each for $GaBr_4$.

Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD-415130.

2 ($Bi_5[GaBr_4]_3$): The powder diffraction pattern was collected by using the MAXII synchrotron radiation source at Lund University (beamline I711, λ = 1.3700 Å), also equipped with an INEL CPS-120 detector. The wavelength was calibrated with a Si standard. The Rietveld refinement was started with parameters from cubic $Bi_5[GaCl_4]_3$. A different disorder pattern was found for the Bi_5^{3+} polycation, and the Bi positions were refined in general positions. The structural model was refined using free coordinates, coupled occupancies for Br sites, free for Bi. The thermal parameters were coupled for the Bi and Br sites respectively, and free for Ga (Table 5).

Single-Crystal X-ray Diffraction: The crystal structure determinations of **3** and **4** were performed on a Bruker-Nonius KappaCCD diffractometer. Unit cell parameters and crystal data for **3** and **4**, respectively, are found in Table 6. **3** ($Sb_8[GaBr_4]_2$) crystallizes in the orthorhombic system, Laue group *mmm*. The systematic abscences led to the possible space groups *Pna*2$_1$ or *Pnma*, of which the former, non-centrosymmetric, space group was confirmed during the structure determination. **4** ($Te_4[Ga_2Br_7]_2$) crystallizes in the monoclinic system, Laue group 2/*m*. The space group $P2_1/c$ was indicated by the systematic absences. Because of the very weak intensities observed for reflections at high angles, the scan range was limited to $2\theta = 50°$ for the data collection in the case of **4**.

All atoms were refined using anisotropic temperature parameters for both structures. Numerical absorption corrections were applied.[23] Both structures were solved and refined using direct methods and difference Fourier techniques using the SHELXS97/SHELXL97.[24,25]

Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository numbers CSD-415089 (for $Sb_8[GaBr_4]_2$) and CSD-415090 (for $Te_4[Ga_2Br_7]_2$), respectively.

Catechol Oxidation with Dinuclear Copper Complexes of Aliphatic Tripodal Amino Alcohols

Christoph Jocher,[a] Tania Pape,[a] Wolfram W. Seidel,[a] Patrick Gamez,[b] Jan Reedijk,[b] and F. Ekkehardt Hahn*[a]

Keywords: Tripodal ligands / Amino alcohols / Copper / Catechol oxidase

A set of unsymmetrical tripodal (aminoalkyl)bis(hydoxyalkyl)-amine ligands H_4-**2** to H_4-**6** with either ethyl or propyl ligand arms has been prepared and characterized. These ligands react with copper hydroxide and ammonium hexafluorophosphate, copper(II) bromide or tris(triphenylphosphane)copper(I) bromide to give di- and polynuclear complexes. The dinuclear copper complexes **9a–f** catalyze the oxidation of 3,5-di-*tert*-butylcatechol (DTBC). The coordination geometry at the copper center is influenced by the length of the side arms resulting in a different reactivity of complexes **9a–f** in the DTBC oxidation. Alternative preparation procedures lead in selected cases to the formation of coordination polymers **10a** and **10b**. The reversible formation of the poly(dinuclear) cations in **10a** illustrates that the apical alcohol groups are labile. The solid-state structures are neither necessarily identical with solution structure nor do they represent the catalytically active species. Electronic spectra, however, agree with a dinuclear structures in solution as indicated by the characteristics of the oxygen–copper-CT. The observation of comparable catalytic activities for complexes **9a–9d** renders the bridging coordination of the catechol by both copper ions of a dinuclear complex moiety unlikely.

Introduction

The diverse applications of tripodal tetraamine ligands in coordination chemistry have been reviewed recently.[1] Several transition metal complexes of triethanolamine illustrate the application of aliphatic tripodal ligands in supramolecular chemistry.[2] Furthermore, unsymmetrical tripodal ligands are used in modeling active metal sites in enzymes. For example, a variety of aromatic tripodal NN_2O and NNO_2 ligands have been prepared to model the metal site in the copper enzyme galactose oxidase.[3] The field of aliphatic tripodal ligands with unsymmetrical donor functions developed more recently. Some complexes of the unsymmetrical aliphatic tripodal ligands NN_2O-222 (H_5-**A**),[4] NN_2O-332 (H_5-**1**), NN_2O-333 (H_5-**B**),[5] NNO_2-222 (H_4-**2**),[4c] NNO_2-233 (H_4-**4**),[3i] NNO_2-223 (H_4-**3**),[6] and NNO_2-322 (H_4-**5**)[7] have been prepared (Figure 1). Complexes of sulfur containing unsymmetrical tripodal ligands have also been reported.[8]

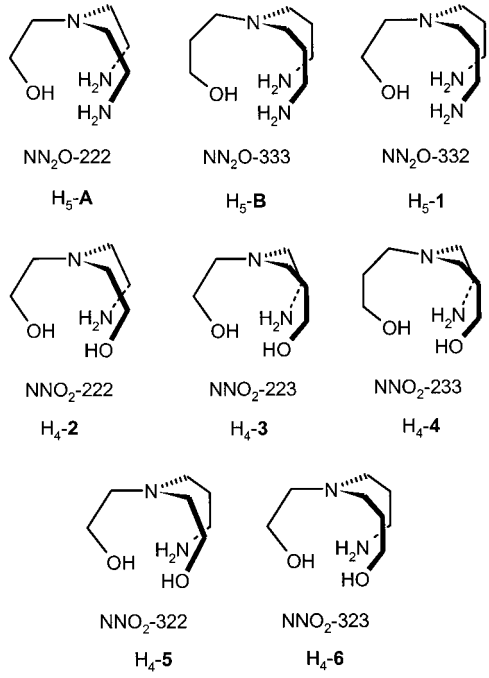

Figure 1. Aliphatic tripodal amino alcohols.

Others and we have studied the correlation between the topology of tripodal ligands and the reactivity of their complexes. A remarkable example for the influence of ligand topology on complex reactivity is the phosphate ester cleavage promoted by tris(3-aminopropyl)amine (trpn) com-

plexes of cobalt while the tris(2-aminoethyl)amine (tren) complexes are 300 times less active.[9] Other studies found interrelations between the ligand topology and complex properties for copper(II)[10] and nickel(II)[11] complexes of the tetraamine ligands tren, (3-aminopropyl)bis(2-aminoethyl)amine (baep), (2-aminoethyl)bis(3-aminopropyl)amine (abap), and trpn.

In this contribution, we present a study on copper complexes of a set of NNO_2 ligands and extend the relation between ligand shape and complex properties to catalysis. To allow for a fine-tuning of the geometric strain the flexible aliphatic ligands H_4-**2** to H_4-**6** (Figure 1) and their copper(II) complexes were studied. The copper complexes of ligands H_5-**1** to H_4-**6** (**9a**–**f**) may serve as models of the metal site in type 3 copper proteins. One member of this group is the ubiquitous plant enzyme catechol oxidase (CO, E.C.1.10.3.1) that converts catechols under consumption of molecular oxygen into *o*-quinones, which auto-polymerize to protect the plant from damage.[12] Many models for the active center in CO have been prepared,[13] but so far conversion rates of the model compounds are lower by four orders of magnitude compared to the enzyme.[14] In our study 3,5-di-*tert*-butylcatechol (DTBC) was chosen as model substrate (Figure 2). To date different mechanisms for the oxidation of this substrate are discussed controversially based on measurements on model compounds.[15]

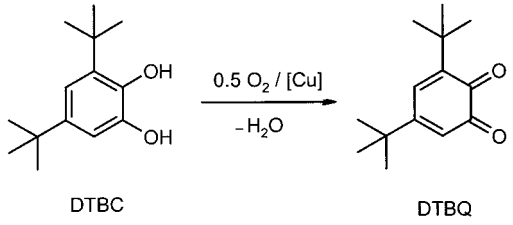

Figure 2. Oxidation of DTBC to 3,5-di-*tert*-butylquinone (DTBQ).

Results and Discussion

Ligand Synthesis

Ethanolamine, propanolamine and diethanolamine, respectively are employed as starting materials for the synthesis of ligands H_5-**1** to H_4-**6**. A Strecker synthesis[16] or Michael addition of acrylic acid derivatives[17] is applied to assemble the tripodal backbone. The ester or nitrile functions of the protected ligands are reduced with aluminum hydride prepared in situ.[18] Alternative synthetic procedures described for the preparation of ligands NNO_2-222 (H_4-**2**),[19] NN_2O-222 (H_5-**A**),[20] NN_2O-332 (H_5-**1**)[21] were found to be less efficient in our hands.

The preparation of the diamino-dihydroxy ligand NNO_2-323 (H_4-**6**) (Scheme 1) starts with the Michael addition of one equivalent ethyl acrylate to ethanolamine.[8a] A small amount of methanol and excess acrylonitrile were added to the wax-like solid **7**. The mixture was heated to 60 °C for 24 h. After removal of volatiles compound **8** was isolated and the ester and nitrile group were reduced with aluminum hydride at temperatures increasing from 0 °C to ambient temperature. The reaction mixture was carefully hydrolyzed after eight hours and H_4-**6** was obtained by Soxhlet extraction with methanol for 24 h. The extract was dried with sodium sulfate, filtered through celite® and volatiles were removed. Bulb to bulb distillation affords ligand NNO_2-323 (H_4-**6**) as colorless viscous oil.

Solid State Structure of Dinuclear Copper Complexes

Copper complexes of the tripodal amino alcohols were prepared as described for complex $[Cu(H_3\text{-}\mathbf{4})]_2(PF_6)_2 \cdot 2MeOH$ **9c**·2MeOH.[2e,3i] For the preparation of the copper complexes, one equivalent of ligand was added to an equimolar suspension of copper(II) hydroxide in deionized water. After stirring for one hour two equivalents NH_4PF_6 were added. The solutions were concentrated to approximately 1 mol/L by warming to 40 °C. Blue solids precipitated upon cooling of these solutions to 5 °C. Diffusion of diethyl ether into an ethanol (**9a**), acetonitrile (**9b**, **9e**, **9f**), or methanol (**9d**) solutions of these residues gave crystals of $[Cu(H_3\text{-}\mathbf{2})_2]_2(PF_6)_4 \cdot 0.5EtOH \cdot 0.5H_2O$ (**9a**·0.5EtOH·0.5H_2O), $[Cu(H_3\text{-}\mathbf{3})]_2(PF_6)_2 \cdot 2H_2O$ (**9b**·2H_2O), $[Cu(H_3\text{-}\mathbf{5})]_2(PF_6)_2 \cdot CH_3OH$ (**9d**·CH_3OH), $[Cu(H_3\text{-}\mathbf{6})]_2(PF_6)_2$ (**9e**), and $[Cu(H_4\text{-}\mathbf{1})]_2(PF_6)_2$ (**9f**). The molecular structures of these complexes were determined by X-ray diffraction (Figure 2 and Figure 3). The dinuclear complexes of type **9** were the dominant species under the reaction conditions selected. All attempts to isolate and characterize mononuclear complexes by adding more NH_4PF_6 or $NaPF_6$ failed.

The structure determinations on **9a**, **9b**, **9d**, **9e**, and **9f** in the solid state show dinuclear dicationic complexes $[Cu_2L_2]^{2+}$ as were previously observed for **9c**, in which one deprotonated alcohol group of each ligand serves as bridging donor to the second copper ion in a μ^3-fashion (Figure 3 and Figure 4). The second hydroxyl arm of each ligand remains protonated as indicated by much longer copper–oxygen distances relative to the bridging alkoxide (com-

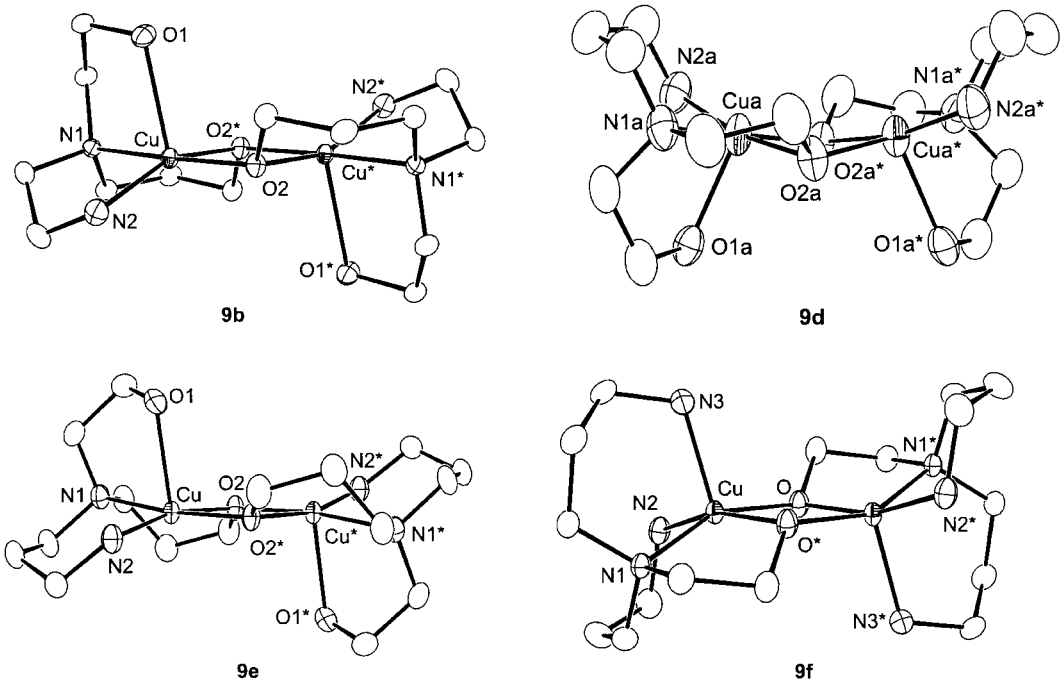

Figure 3. Molecular structures of the dinuclear cations of **9b** and **9d**–**f**.

pare Cu–O1 and Cu–O2 in Table 1). Comparison of the various structures reveals that propylalkoxide ligand arms, if available, preferably act as bridging donors. Complexes **9b**, **9e**, and **9f** form centrosymmetric complex ions with a planar $[Cu_2(OR)_2]^{2+}$ moiety and with *trans*-arrangement of the apical alcohol functions.

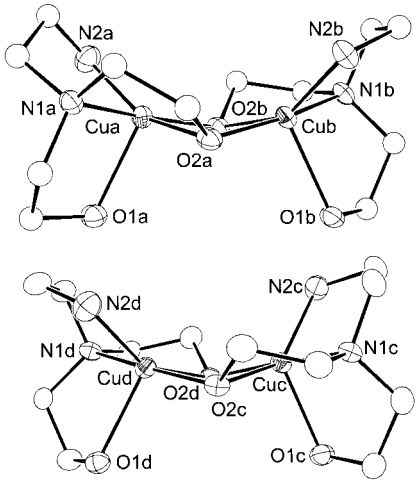

Figure 4. Molecular structure of the two dinuclear isomeric dications in **9a**.

Complexes **9a** and **9d** with ligands H_4-**2** and H_4-**5**, respectively, adopt a rather bowl-shaped geometry with a butterfly-like distorted $[Cu_2(OR)_2]^{2+}$ core and *cis*-constitution of the coordinated alcohol groups. The short ligand arms of the ethyl alcohol lead to geometric strain and a distortion of the angles at the copper atom (Table 1). Hence, metal ions with a different coordination environment are found in the crystal structures of **9a** and **9d**. The unit cell of **9d** contains two not related halves of the dinuclear complex ion $[\mathbf{9d}]^{2+}$. Complex **9a** crystallizes in a polar space group ($P2_1$) and the unit cell contains four different copper atoms of two dinuclear complex dications $[\mathbf{9a}]^{2+}$. The observation of the polar space group $P2_1$ for **9a** can be rationalized by the helicity of the dinuclear units and by the fact that the diamino chelate rings adopt different configurations in the two dinuclear complexes (λλ and λδ, respectively) (Figure 4).

Bond lengths and angles differ between the two dinuclear units in crystals of **9a**. Consequently, four different τ-values[22] (0.21, 0.32, 0.51, 0.36) were observed for the four copper atoms in the asymmetric unit, indicating a distorted tetragonal-pyramidal coordination environment for the metal ions. The Cu–O distances range from 2.177(4) Å to 2.265 Å for the alcohol functions in the apical position. Within the $Cu(\mu\text{-}O)_2Cu$ core the Cu–O2 distances in *trans*-position to the tertiary nitrogen donor are distinctively shorter [1.939(3) Å to 1.956(4) Å] than the Cu–O2 bond lengths *trans* to the primary nitrogen donor [1.998(4) Å to 2.075(4) Å, Table 1].

While **9d** exhibits an almost ideal tetragonal-pyramidal copper environment (τ = 0.03), **9e** and **9f** are also close to such a coordination geometry (τ = 0.10 and τ = 0.12, respectively). The highest τ-value is observed for **9a** and **9b** (τ = 0.3) which can be attributed to the shorter ethyl ligand arms leading to a distortion towards a trigonal-bipyramidal coordination geometry.

An interesting structural feature of these dinuclear complexes is the angle at the bridging oxygen atoms. Often, the magnetic coupling between two paramagnetic Cu^{II} centers is antiferromagnetic for angles larger than 96° while a ferromagnetic interaction is observed for smaller angles.[23a,23b]

[a] The asymmetric unit contains for copper atoms in two dinuclear complexes **9a**. [b] Published data.[3i] [c] Atoms labeled with an asterisk denote atoms from different ligands not necessarily related by a symmetry element.

The bridging alkoxide groups lead to angles below this value for complex **9a**, while the Cu–O–Cu angles fall in the range 98° and 102° (Table 1) for the other complexes. However, temperature dependent measurements of the magnetic susceptibility for **9b**–**f** indicate that the coupling between the copper centers is antiferromagnetic in all cases.

Electronic Spectra

The electronic spectra of the dinuclear copper complexes **9a**–**f** show three transitions (Table 2, Figure 5 for **9f**). The most intense absorption is observed between 36 500 cm^{-1} (**9a**) and 39 400 (**9e**) cm^{-1} with extinction coefficients between 4900 L/mol·cm (**9c**) to 15700 L/mol·cm (**9f**). This absorption is assigned to a nitrogen-centered ligand-to-metal charge transfer (LMCT) by comparison with a variety of copper amine complexes.[23c] Hence, a distinct difference in intensity appears between the complex with the triamine NN_2O ligand (**9f**) and the complexes with the diamine NNO_2 ligands (**9a**–**9e**).

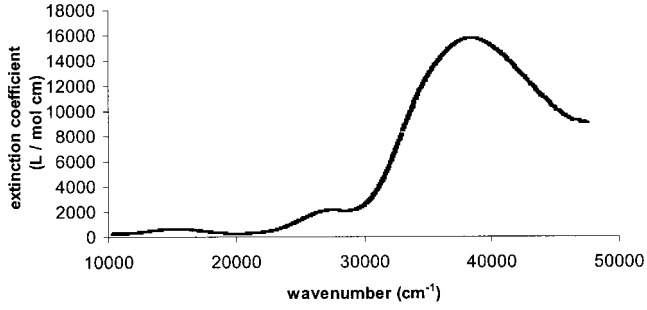

Figure 5. Electronic spectrum of **9f** in acetonitrile solution.

The second absorption is observed between 27300 cm^{-1} (**9c**, **9e**, **9f**) and 27800 cm^{-1} (**9a**) with extinction coefficients around 2000 L/mol·cm (Table 2). As the intensity of this band is similar in all complexes and as the common feature of complexes of type **9** is the dialkoxy bridge, this band is associated with a charge transfer from the alkoxy oxygen atoms to the copper centers.[24] This assignment is sup-

ported by the intensity decrease observed for complexes **9a** and **9d**. Within these two complexes the $Cu(\mu\text{-}O)_2Cu$ rings are distorted, because five-membered chelate rings are involved in the formation of the bridging four-membered ring (Figure 4). Apparently, the planarity of this four-membered ring is responsible for an optimum absorption. The observed difference of the extinction coefficient for the band around 27000 cm^{-1} between the *cis* structures **9a** and **9d** and the *trans* structures **9b**, **9c**, and **9e** support retention of the dinuclear structures in solution.

The absorptions with the lowest intensity and energy result from d→d transitions. They fall in the range between 15150 cm^{-1} (**9f**) and 17090 (**9c**) cm^{-1} with extinction coefficients from 120 L/mol·cm (**9c**) to 580 L/mol·cm (**9f**). The increased extinction coefficient in **9f** is most likely associated with the extra nitrogen atom present which causes a stronger mixing of ligand orbitals and metal d-orbitals in **9f**.

The energy of the d→d bands is consistent with either a trigonal-bipyramidal or a square-pyramidal geometry around the copper atoms. The coordination geometry at the copper center has been derived from the energy of the d→d absorption band for CuN_4,[10b] CuN_5 and CuN_6 complex fragments or complexes.[25] However, with compounds **9a**–**9e** no significant correlation was observed between τ-value and energy of the low energy transition. A comparison of different methods to determine the distortion of the trigonal-bipyramidal towards the tetragonal-pyramidal geometry showed the τ-value to be a sufficient criteria to distinguish between the two geometries for CuN_5 chromophores.[26] In general, the d→d transitions of complexes of type **9** shift hypsochromic with an increasing number of six-membered chelate rings as well as for a change in the donor set from NNO_2 to NN_2O ligands (Table 2).

Cyclic Voltammetry

Cyclic voltammetry experiments show one irreversible reduction and one irreversible oxidation peak for the copper complexes **9b**–**9e** in acetonitrile solution (Table 2). The CV′s of complex **9e** are shown as an example in Figure 6. The presence of four reduction peaks for **9a** can be attributed to four different copper centers displaying different τ-values as found in the solid-state structure. For the oxidation process two peaks are observed for compounds **9a** (1.15 V and 1.27 V) and **9f** (0.87 V and 1.50 V). In general, reduction of complexes of type **9** occurs between –1.78 V and –1.07 V while oxidations are observed between 0.87 and 1.50 V vs. Fc/Fc^+.

Compound **9f** with an NN_2O ligand exhibits the strongest ligand field, which is reflected by the lowest reduction potential (–1.78 V) in the series of complexes of type **9**. The precipitation of copper metal during this reduction suggests that Cu^{II} is reduced to Cu^{I}, whose complexes are unstable. The irreversibility of the reduction process with complexes of type **9** is thus explained with the instability of Cu^{I} within a strong ligand field generated by the alkoxide and amine

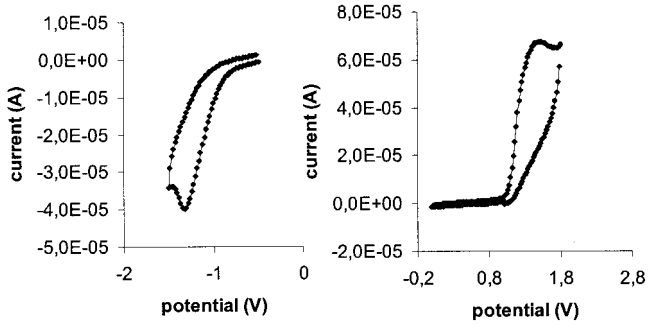

Figure 6. Irreversible reduction and oxidation peaks for **9e**. CV data were recorded in a 0.1 M solution of Bu_4NPF_6 in acetonitrile against Fc/Fc^+.

functions. A sharp reoxidation peak is observed around –0.4 V resulting from the oxidation of metallic copper to Cu^{II} in the presence of ligand. A limited number of stable Cu^{I}–OR species is known.[27] While the Cu^{I} alkoxide can be stabilized in the absence of air or water either sterically or by conjugated π–systems in phenolates or enolates, Cu^{I}–OMe species decomposes vigorously into copper metal, formaldehyde and methanol.

The irreversible nature of the oxidation process suggests that hypothetical Cu^{III} species are highly reactive and might lead to ligand degradation. Within the functional groups present, the bridging alkoxide functions are most susceptible for oxidation, which can produce aldehydes, carboxylic acid derivatives or CC coupled products.

DTBC Oxidation

Acetonitrile solutions of complexes of type **9** and DTBC (30 equiv.) were mixed in a shaking device under an oxygen atmosphere. The amount of oxygen consumed was monitored by an experimental set up described by one of us previously for similar experiments.[28] Typically, green solutions were obtained upon mixing of the catalyst and the DTBC solution. The addition of one equivalent sodium methoxide initiated oxygen consumption, otherwise complexes of type **9** were found catalytically inactive. The order of mixing of the solutions influenced the yield of the oxidation product DTBQ. For example, mixing of **9b** and DTBC followed by addition of base gave lower yields (25%–30%) than mixing **9b** and base followed by DTBC addition (83% yield, Table 2). In general, complexes **9a**–**f** show a variation in catalytic activity giving yields from 15 to 99% with a TON from 90 to 500 h^{-1} (Table 2). A plot of the oxygen consumption during the oxidation of DTBC with complex **9f** as the catalyst is depicted in Figure 7. The experimental data confirm our assumption that a nitrogen (amine) rich coordination environment improves the catalytic activity of the copper center for the DTBC oxidation. Unfortunately, compound **9f** is less stable than **9a**–**e** under the required basic conditions. The coordination geometry described by the τ-value and catalytic activity do not correlate. Reaction rates and yields are best in the presence of six-membered chelate

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rings for the alcohol functions and five-membered chelate rings for the terminal amine functions.

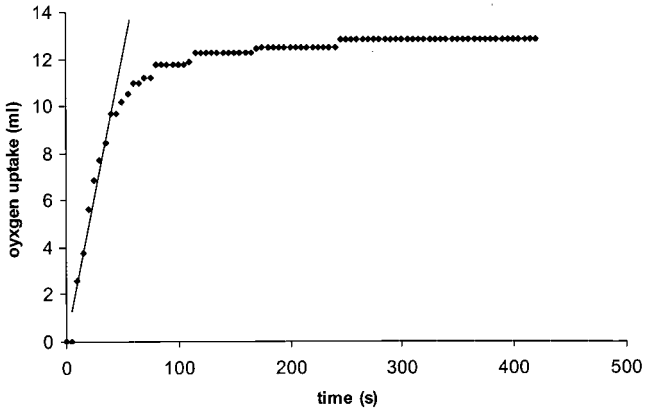

Figure 7. Consumption of O_2 (mL) vs. time (s) for the catalytic oxidation of DTBC (3 mmol) with **9f** in acetonitrile (maximum oxygen uptake: 33.6 mL).

Additional Copper Complexes

The stability of the copper(II) complexes of type **9** was corroborated by the formation of a purple Cu^{II} species upon reaction of $[Cu^{I}(PPh_3)_3Br]$ with ligand NNO_2-233 (H_4-**4**). Equimolar amounts of the copper(I) compound and the ligand were mixed at air in a dichloromethane solution. The initially colorless solution turned blue rapidly and a purple solid **10a** precipitated. The elemental analysis suggested a ratio of Cu/Br/ligand of 1:1:1. The purple color of **10a** differs from the blue color of the dinuclear hexafluorophosphate salts **9a**–**9e**. Compound **10a** can be obtained directly by reaction of anhydrous copper(II) bromide and H_4-**4** in methanol. The X-ray structure analysis revealed that a polymer chain consisting of dinuclear dicationic units, which are bridged by alkoxy functions of the singly deprotonated ligand had formed (Figure 8). The remaining alcohol function of the ligand binds to a copper atom of an adjacent dinuclear unit in the apical position. The coordination geometry around the copper atoms is square-pyramidal with $\tau = 0$ (Table 1).

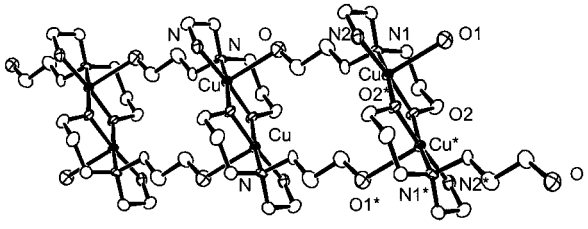

Figure 8. Fraction of the poly(dinuclear) coordination polymer built from $[Cu_2(H_3\text{-}\mathbf{4})_2]^{2+}$ cations of complex **10a**.

In an attempt to exchange the apical protonated alcohol function in the dinuclear complex $[Cu(H_3\text{-}\mathbf{4})]_2(PF_6)_2$ (**9c**) against 2,4,6-trimethylphenol (TMP), purple $[Cu(H_3\text{-}\mathbf{4})(TMP)]_2(PF_6)_2$ (**10b**) precipitated from a green solution. We assume that the TMP ligand substituted the protonated (apical) alcohol function at the copper center. Apparently, this apical alcohol function is the most labile in the complex and can be substituted for other ligands. Furthermore, **10b** can be reconverted to **9c** in the absence of competing ligands such as methanol or TMP. Dissolving the purple complex $[Cu(H_3\text{-}\mathbf{4})(TMP)]_2(PF_6)_2$ (**10b**) in acetonitrile gives a blue solution. Addition of diethyl ether to this solution leads to precipitation of the dark blue dinuclear complex **9c**.

In conclusion, the energy difference between the two solid-state structures of type **9** and type **10** is small enough to allow interconversion. Apparently, the apical alcohol ligands in the dinuclear copper complexes of type **9** are labile and can be substituted for the catechol substrate without breaking up the dinuclear units immediately. The Cu–Cu distances in complexes of type **9** fall in the range between 2.89 Å (**9a**) and 3.01 Å (**9e**). However, the observation of comparable catalytic activity for both the *cis* complexes **9a** and **9d** and the *trans* complexes **9b** and **9c** renders the bridging coordination of the catechol by both copper ions of a dinuclear complex moiety unlikely. We therefore assume that during the catalytic cycle catechol substitutes one of the apical alcohol groups in the dinuclear copper complexes and eventually η^1-coordinated catechol replaces one of the bridging alkoxide arms with the second oxygen donor atom.[29] This process is aided by addition of a base which deprotonates the catechol ligand thereby enhancing its basicity. The addition of bases to the dinuclear complexes of type **9** in the absence of catechol leads to decomposition of the dinuclear complexes to a brown insoluble substance.

Conclusions

The rates of catalytic DTBC oxidation by the model compounds **9a**–**f** are far from modeling the enzyme catechol oxidase. However, **9f** shows an activity which is comparable to some other model compounds.[13b,13d] The aim of this study was to probe the relation between the particular ligand design of basically similar ligands and the catalytic activity of its Cu^{II} complexes. Complexes **9a** to **9e** show indeed a different catalytic activity manifested in a variation of the yield in DTBC oxidation (15% to 99%) and different TON (94 to 227 h^{-1}). Since complexes **9a** to **9e** contain identical donor sets all differences in the activity can be attributed to different arm length at the tripodal ligands. However, the derivation of linear correlations between structural factors and catalytic activity turns out to be difficult.

Experimental Section

Materials and Methods: All manipulations were carried out in air unless noted otherwise. Solvents were purified by standard methods and freshly distilled prior use. Infrared spectra were recorded in KBr (pellets or thin films) with a Bruker Vector 22 FT spectrometer. ^1H and ^{13}C NMR spectra were recorded on Bruker AC 200 or Bruker ARX 300 spectrometers. Elemantal analyses (C,H,N) were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

performed with a Vario EL III Elemental Analyzer at the Institut für Anorganische und Analytische Chemie, University of Münster. MALDI, ESI and EI mass spectra were measured with Bruker Reflex IV, Micromass Quattro LC and Varian MAT 212 instruments, respectively. UV/Vis spectra were recorded in acetonitrile with a Varian Cary 50 spectrophotometer. Cyclic voltammetry experiments were carried out with a Eco-Chemie PGSTAT 30 potentiostat using a three-electrode cell configuration (working electrode: glassy carbon, auxiliary electrode: platinum, reference electrode: Ag/AgCl/3 M KCl). The experiments were performed in 0.1 M acetonitrile solutions of Bu_4NPF_6 as supporting electrolyte with scan rates of 100 mV/s. A computer-controlled apparatus[28] was used for oxygen uptake measurements in oxidation experiments with DTBC (Aldrich). Solutions of DTBC were freshly prepared. 30 equivalents of DTBC were mixed with one equivalent catalyst and one equivalent sodium methoxide in acetonitrile at 25 °C.

Ligand Syntheses: Ligands NNO_2-222 (H_4-**2**),[4c] NNO_2-223 (H_4-**3**),[6b] NNO_2-233 (H_4-**4**),[3i] NNO_2-322 (H_4-**5**),[7] and NN_2O-332 (H_5-**1**)[5] were prepared according to previously published procedures.

Ethyl 3-[(2-Cyanoethyl)(2-hydroxyethyl)amino]propanoate (8): 2.0 equivalents of acrylonitrile (5.46 g, 0.10 mol) were added to a solution of ethyl 3-[(2-hydroxyethyl)amino]propanoate (**7**)[8a] (8.29 g, 0.0514 mol) in methanol (5 mL). The reaction mixture was heated to 60 °C for 48 h. Excess acrylonitrile and methanol were removed under reduced pressure and **8** remained as a colorless liquid. Yield: 10.6 g (0.049 mol, 96%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 4.07 (q, 2 H, OCH_2CH_3), 3.52 (t, 2 H, CH_3CH_2OH), 2.85–2.70 (m, 4 H, NCH_2), 2.59 (t, 2 H, NCH_2CH_2OH), 2.47–2.33 (m, 4 H, NCH_2CH_2), 1.18 (t, 3 H, OCH_2CH_3). ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 172.4 [*C*(O)OEt], 118.7 (CN), 60.6 (CH_2O), 59.4 (CH_2O), 55.6 (NCH_2CH_2OH), 49.6 (NCH_2), 48.8 (NCH_2), 32.7 ($NCH_2CH_2CO_2Et$), 16.6 (NCH_2CH_2CN), 13.9 (OCH_2CH_3).

N*-(2-Hydroxyethyl)-*N*-(3-hydroxypropyl)propylene-1,3-diamine NNO_2-323 (H_4-6):** Dry lithium aluminum hydride (8.36 g, 0.209 mol) was suspended in THF (200 mL). After stirring for 60 minutes and cooling to –5 °C concentrated sulfuric acid (4.80 g, 0.047 mol) was added carefully dropwise (Caution:*** this reaction is extremely exothermic, hydrogen is evolved). The suspension was stirred for 60 min and ethyl 3-[(2-cyanoethyl)(2-hydroxyethyl) amino]propanoate (**8**) (15.0 g, 0.020 mol) dissolved in THF (30 mL) was slowly added. The reaction mixture should not be allowed to boil during the addition of **8**. The suspension was stirred at room temperature for 8 h and then quenched by slow addition of degassed water (15.1 g, 0.84 mol) at 0 °C. The reaction mixture was filtered under an argon atmosphere. The filtrate contained H_4-**6** and side products, but most of the ligand was found in the solid residue. It was isolated by continuous extraction with methanol for one day. An immediate work-up after hydrolysis increased the yield of ligand H_4-**6** because otherwise aluminum complexes form. The extract and the filtrate were united and dried with sodium sulfate. Removal of the solvent gave a colorless to yellow residue, which was suspended in dichloromethane (200 mL) and dried with sodium sulfate. The drying agent and precipitated lithium salts were separated by filtration through Celite®. Distillation under reduced pressure (180 °C, 0.05 mbar) afforded H_4-**6** as colorless oil. Yield: 3.37 g (19.1 mmol, 27%). $C_8H_{20}N_2O_2$ (176.26): calcd. C 54.52, H 11.44, N 15.89; found C 53.32, H 11.43, N 15.12. ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 3.62 (t, 2 H, $NCH_2CH_2CH_2OH$), 3.54 (t, 2 H, NCH_2CH_2OH), 3.29 (s br, 4 H, OH + NH_2), 2.68 (t, 2 H, $NCH_2CH_2CH_2NH_2$), 2.54 (t, 2 H, $NCH_2CH_2CH_2OH$), 2.48 (t, 2 H, NCH_2CH_2OH), 2.46 (t, 2 H, $NCH_2CH_2CH_2NH_2$), 1.63 (qi, 2 H, $NCH_2CH_2CH_2OH$), 1.55 (qi, 2 H, $NCH_2CH_2CH_2NH_2$). ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 62.2 ($NCH_2CH_2CH_2OH$), 59.4 (NCH_2CH_2OH), 55.6 (NCH_2CH_2OH), 53.3 ($NCH_2CH_2CH_2OH$), 51.8 ($NCH_2CH_2CH_2NH_2$), 39.8 ($NCH_2CH_2CH_2NH_2$), 29.6 ($NCH_2CH_2CH_2NH_2$), 28.7 ($NCH_2CH_2CH_2OH$). IR (KBr film): ν = 3358 (s, NH), 3285 (s, NH), 2949 (s, CH), 2871 (s, CH), 2829 (s, CH), 1662 (w), 1602 (w, NH), 1464 (m, CH), 1375 (w, CH), 1299 (w), 1060 (s, CO), 910 (m), 870 (w), 750 (w). Synthesis of Copper Complexes. General Procedure: Copper hydroxide was prepared from copper chloride and sodium hydroxide in the presence of a small amount of polyethylene glycol ether at 0 °C. The turquoise solid can be stored at –30 °C for several months without darkening. The preparation of copper complexes of type **9** was carried out according to a published procedure described for the preparation of complex **9c**.[3i] Copper hydroxide was suspended in deionized water (10–20 mL) and the ligand dissolved in water (10 to 20 mL) was added. The reaction mixture was stirred at 40 °C for 2 h. Solid NH_4PF_6 was added and the volume of the solutions was reduced to reach a concentration of approximately 1 M. Crystalline material precipitated upon storage at 5 °C. For further purification, the raw material was recrystallized from ethanol (**9a**·0.5EtOH·0.5H_2O), methanol (**9d**·MeOH), acetonitrile (**9b**·2H_2O, **9e**, **9f**) or dichloromethane (**10a**). Yields and selected analytical data for complexes **9a**·0.5EtOH·0.5H_2O, **9b**·2H_2O, **9d**·MeOH, **9e**, **9f** and **10a** are given below.

$[Cu_2(H_3\text{-}2)_2](PF_6)_4$·0.5EtOH·0.5$H_2O$ (9a·0.5EtOH·0.5H_2O): $Cu(OH)_2$ (425 mg), 4.36 mmol, ligand H_4-**2** (647 mg, 4.36 mmol) and NH_4PF_6 (711 mg, 4.36 mmol) were used in the procedure described for the preparation of **9c**.[3i] Yield: 340 mg (0.457 mmol, 21%). IR (KBr): $\tilde{\nu}$ = 3364 cm^{-1} (s), 3312 (s), 3208 (s, br), 2990 (s), 2927 (s), 2870 (s), 1597 (m), 1473 (m), 1371 (w), 1269 (w), 1134 (m). MALDI-MS (337.0 nm, 3 ns) *m*/*z*: 482 (45, $[Cu_3(H_3\text{-}2)_2]^+$), 416 (75, $[Cu_2(H_3\text{-}2)_2(CH_3CN)]^+$), 419 (100, $[Cu_2(H_3\text{-}2)_2]^+$).

$[Cu_2(H_3\text{-}3)_2](PF_6)_2$·2$H_2O$ (9b·2H_2O): $Cu(OH)_2$ (195 mg, 2.00 mmol), ligand H_4-**3** (330 mg, 2.00 mmol) and NH_4PF_6 (530 mg, 4.00 mmol) were used. Yield: 308 mg (0.397 mmol, 40%). **9b**·2H_2O $C_{14}H_{38}N_4Cu_2F_{12}O_6P_2$ (775.52): calcd. C 21.68, H 4.94, N 7.22; found C 21.59, H 4.35, N 6.91. ^{19}F NMR (188.3 MHz, CD_3CN): δ = –66.8 ($^1J_{FP}$ = 710 Hz). IR (KBr): $\tilde{\nu}$ = 3627 cm^{-1} (m), 3327 (s), 3128 (m), 2919 (m), 2861 (m), 2821 (m), 1594 (m), 1472 (m), 1320 (m), 1120 (s), 1084 (s), 1062 (s), 830 (s, PF_6). MALDI-MS (337.0 nm, 3 ns) *m*/*z*: 447 (100, $[Cu_2(H_3\text{-}3)_2]^+$), 592.9 (30, $[\{Cu_2(H_3\text{-}3)_2\}PF_6]^+$).

$[Cu_2(H_3\text{-}5)_2](PF_6)_2$·$CH_3OH$ (9d·CH_3OH): $Cu(OH)_2$ (292 mg, 3.00 mmol), ligand H_4-**5** (487 mg, 3.00 mmol) and NH_4PF_6 (980 mg, 6.00 mmol) were used. Yield: 550 mg (0.713 mmol, 48%). IR (KBr): $\tilde{\nu}$ = 3666 cm^{-1} (s), 3448 (s), 3343 (s), 3297 (s), 3131 (s), 2951 (m), 2921 (m), 2880 (m), 2765 (m), 1604 (s), 1463 (m), 1333 (m), 1286 (m), 1265 (m), 1161 (s), 1072 (s), 1044 (s), 1015 (s), 833 (s, PF_6).

$[Cu_2(H_3\text{-}6)_2](PF_6)_2$ (9e): $Cu(OH)_2$ (211 mg, 2.18 mmol), ligand H_4-**6** (383 mg, 2.18 mmol) and NH_4PF_6 (711 mg, 4.36 mmol) were used. Yield: 350 mg (0.456 mmol, 42%). IR (KBr): $\tilde{\nu}$ = 3591 cm^{-1} (s), 3358 (s), 3305 (s), 2951 (m), 2871 (m), 2803 (w), 2712 (w), 1602 (m), 1463 (m), 1311 (w), 1089 (s), 1048 (s), 839 (s, PF_6). MALDI-MS (337.0 nm, 3 ns) *m*/*z*: 475 (100, $[Cu_2(H_3\text{-}6)_2]^+$), 659 (10, $[\{Cu_2(H_3\text{-}6)_2\}PF_6\ CH_3CN]^+$), negative ions *m*/*z*: 910 ($[\{Cu_2(H_3\text{-}6)_2\}(PF_6)_3]^-$).

$[Cu_2(H_4\text{-}1)_2](PF_6)_2$ (9f): $Cu(OH)_2$ (390 mg, 4.00 mmol), ligand H_5-**1** (701 mg, 4.00 mmol) and NH_4PF_6 (1.30 g, 8.00 mmol) were used.

Yield: 330 mg (0.431 mmol, 22%). IR (KBr): $\tilde{\nu}$ = 3373 cm^{-1} (m), 3355 (m), 3324 (m), 3304 (m), 2974 (m), 2946 (m), 2933 (m), 2892 (m), 2857 (m), 1603 (m), 1487 (w), 1457 (w), 1244 (w), 1150 (m), 1056 (m), 1022 (m), 835 (s, PF_6). MALDI-MS (337.0 nm, 3 ns) *m*/*z*: 238 (24, $[Cu(H_5\text{-}\mathbf{1})]^+$), 422 (24, $[Cu(H_5\text{-}\mathbf{1})(PF_6)(CH_3CN)]^+$), 606 (100, $[Cu(H_5\text{-}\mathbf{1})(PF_6)_2(CH_3CN)_2]^+$).

$[Cu_2(H_3\text{-}4)_2]Br_2$ (10a): Preparation starting from Cu^I: A solution of H_4-**4** (162 mg, 1.0 mmol) in dichloromethane (10 mL) was added to a colorless solution of $[Cu^I(PPh_3)_3Br]$ (930 mg, 1.0 mmol) in dichloromethane (20 mL). Within several minutes the solution turned blue upon stirring under air. Purple crystals precipitated, which were suitable for X-ray diffraction analysis. Yield: 65 mg (0.10 mmol, 20%). $[Cu_2(H_3\text{-}4)_2]Br_2$ **10a** $C_7H_{18}BrCuN_2O_2$ (318.66): calcd. C 30.15, H 6.01, N 8.79; found C 30.78, H 6.04, N 8.90%.

Preparation Starting from Cu^{II}: A solution of H_4-**4** (353 mg, 2.0 mmol) in methanol (10 mL) was added to a brown solution of copper bromide (447 mg, 2.0 mmol) in methanol (10 mL). Immediately upon mixing the color of the solution changed to blue. Purple crystals formed upon standing in air. More crystals were precipitated by diffusion of diethyl ether into this solution. Yield: 227 mg (0.356 mmol, 36%). $C_7H_{18}Br_2CuN_2O_2$ (318.66): calcd. C 30.15, H 6.01, N 8.79; found C 30.19, H 6.01, N 8.72%.

Crystal Structure Analyses: Blue crystals of **9a**·0.5EtOH·0.5H_2O, **9b**·2H_2O, **9d**·MeOH, **9e** and **9f** and purple crystals of **10a** were obtained by recrystallization from ethanol (**9a**·0.5EtOH·0.5H_2O), methanol (**9d**·MeOH), acetonitrile (**9b**·2H_2O, **9e**, **9f**) or dichloromethane (**10a**) at 5 °C. Diffraction data were measured at low temperature (Table 3 and Table 4) on a Bruker APEX diffractometer

equipped with a rotating molybdenum anode (λ = 0.71073 Å) and a CCD area detector. Empirical absorption corrections were applied to all data sets. The structures were solved and refined by standard Patterson- and Fourier-techniques.[30] All non-hydrogen atoms were refined with anisotropic displacement parameters, and hydrogen atoms were added to the structure model on calculated positions. Selected crystal, data collection and refinement details are listed in Table 3 and Table 4.

Supplementary Material: CCDC-276044 (for **9a**·0.5EtOH·0.5H_2O), -276045 (for **9b**·2H_2O), -276046 (for **9d**·MeOH), -276047 (for **9e**), -276048 (for **9f**), and -276049 (for **10a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Enantiopure Ruthenocenes Cp*Ru(1,2-$C_5H_3R^1R^2$) with a Planar Chiral Cyclopentadienyl Ligand and a Pentamethylcyclopentadienyl Spectator Ligand[‡]

Gerhard E. Herberich,*[a] Ulli Englert,[a] and Tobias Wirth[a][‡‡]

Keywords: Ruthenium / Ruthenocene / Sandwich complexes / Planar chirality / (*S*)-2-(methoxymethyl)pyrrolidine

Kreutzberger's synthesis was used to produce 6-(morpholino)-fulvene (**7a**) from 1,3,5-triazine, cyclopentadiene and morpholine (94 %). Likewise with (*S*)-2-(methoxymethyl)pyrrolidine (HSMP) the 6-[(*S*)-2-(methoxymethyl)pyrrolidino] analogue **7b** was obtained (62 %). Hydride addition from $NaBHEt_3$ in toluene afforded the cyclopentadienides $Na[C_5H_4CH_2–N(C_2H_4)_2O]$ (**8a**) (83 %) and $Na(C_5H_4CH_2–SMP)$ (**8b**) (90 %). Cp*Ru($C_5H_4CH_2$–SMP) (**5**) was synthesized from $[Cp^*RuCl]_4$ and **8b** (84 % yield). The related methyleneiminium salt $[Cp^*Ru(C_5H_4CH{=}SMP)]PF_6$ (**9**) was made from $[Cp^*Ru(MeCN)_3]PF_6$ and **7b** and could be transformed into **5** by hydride addition from $LiAlH_4$ in THF. Diastereoselective lithiation of **5** with Li*s*Bu in Et_2O/cyclohexane and subsequent quenching with electrophiles E–X gave enantiomerically pure (*de* > 98 %), 1,2-disubstituted complexes Cp*Ru(E–$C_5H_3CH_2$–SMP) **10a–i** with E = F, Cl, Br, I, Me, CD_3, $SiMe_3$, PPh_2, $Au(PPh_3)$ as oils. The chiral auxiliary was removed from **10a**, **b**, and **f** by quaternization with MeI and subsequent reductive cleavage with $LiAlH_4$ in THF to afford the exclusively planar chiral complexes Cp*Ru(1-E-2-MeC_5H_3) **14a** (E = F), **14b** (E = Cl), and **14f** (E = CD_3). The complexes **14a**,**b**,**f** no longer possess central chirality. The crystal structure of **12**, a LiI adduct of **10f**, gave the absolute configuration via internal reference to the (*S*)-stereochemistry of the SMP group. The absolute configuration of the planar chiral complex **14b** was determined from the anomalous X-ray dispersion of the crystals of **14b**.

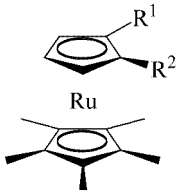
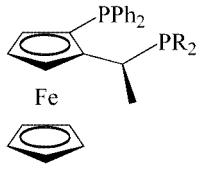
Introduction

In this paper we describe a synthetic route to ruthenocenes Cp*Ru(1,2-$C_5H_3R^1R^2$) (**1**) that have a planar chiral cyclopentadienyl ligand and a pentamethylcyclopentadienyl (Cp*) spectator ligand, but do not possess any further element of chirality in the substituents R^1 and R^2.



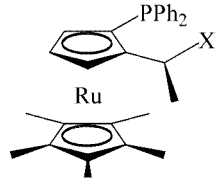
1

Planar chiral ferrocenes[2,3] have found application as excellent chiral ligands in homogeneous asymmetric catalysis. For instance, the industrial production of (+)-biotine makes use of the chiral ferrocene-based ligand **2**,[4,5] and the herbicide (*S*)-metolachlor® is produced with the help of the closely related ligand **3**.[5,6] The quest for chiral ligands which are optimized for specific catalytic processes has led to the development of a large family of chiral pentamethylferrocenes[5b] and a group of similar chiral pentamethylruthenocenes;[7] the complexes Cp*Ru[1,2-C_5H_3(PPh_2)-(CHXMe)] (**4**) (X = e.g. NMe_2, PCy_2) may serve as examples.[7b] All these complexes are deceptively similar to ruthenocenes of type **1**; however, they possess a center of chirality in one of the sidechains as the distinguishing feature.



2, R = *t*Bu

3, R = 3,5-$Me_2C_6H_3$



4, X = NMe_2, PCy_2

Although the chemistry of the ruthenocenes is much less developed than that of the ferrocenes a number of planar chiral and enantiopure ruthenocenes are known. There are essentially three methods to produce such complexes. i) The first planar chiral, more or less enantiopure ruthenocenes

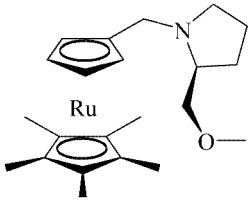
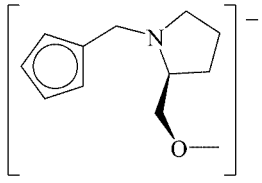
were made by the group of K. Schlögl using the classical method of resolution of racemates.[8] Chiral HPLC has also been used as a modern and efficient resolution method.[9] ii) The second method is the diastereoselective *ortho*-metalation, discovered by I. Ugi et al. as highly stereoselective derivatization reactions of the two [(1-dimethylamino)ethyl]-ferrocene – or (1-ferrocenylethyl)dimethylamine – enantiomers.[10] In this way T. Hayashi et al. synthesized the ruthenocene derivatives $Ru(C_5H_4PPh_2)[C_5H_4(PPh_2)\{CHR(NMe_2)\}]$ (R = Me, Et),[11] and A. Togni et al. synthesized the pentamethylruthenocenes **4**.[7b] iii) Finally, as U. Koelle et al. demonstrated more recently, enantioselective reaction of planar chiral cyclopentadienides with suitable chiral sources of the Cp^*Ru^+ fragment may also give chiral, enantiomerically enriched pentamethylruthenocene derivatives.[12]

We now return to the goal of this work, the development of a synthetic route to complexes of type **1**. We decided to use the method of diastereoselective *ortho*-metalation with the (*S*)-2-(methoxymethyl)pyrrolidino (≡ SMP) group as *ortho*-directing chiral auxiliary. Ruthenium was preferred to iron because ruthenocenes are more robust than ferrocenes. Thus, the synthesis of complex **5** assumes a central role in this work. It seemed reasonable and most promising, to introduce the Cp*Ru group as late as possible, for instance by treating $[Cp^*RuCl]_4$[13] with a salt of the (as yet unknown) chiral cyclopentadienide $\mathbf{6}^-$. Once complex **5** was available, we studied the *ortho*-metalation of **5** and the subsequent quenching with electrophiles, and finally the removal of the chiral auxiliary.



5

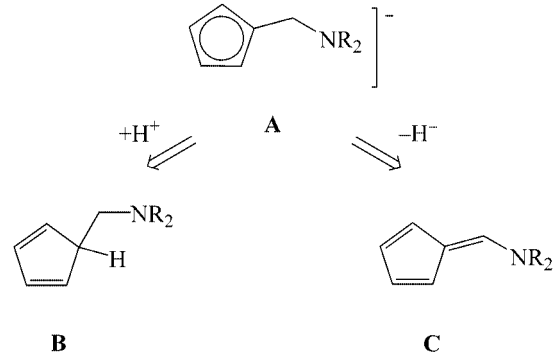


$\mathbf{6}^-$

Results and Discussion

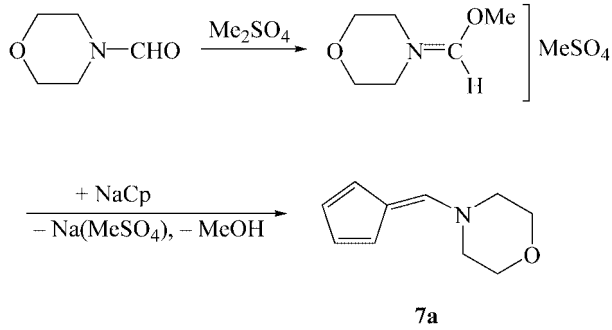
Ligand Precursors

From a retrosynthetic point of view [(dialkylamino)-methyl]cyclopentadienides **A** (such as $\mathbf{6}^-$) are related to [(dialkylamino)methyl]cyclopentadienes **B** (via formal proton addition) and alternatively to 6-(dialkylamino)fulvenes **C** (via formal hydride abstraction)[14] (Scheme 1). The constitution of the cyclopentadienes **B** is reminiscent of products of Mannich condensation reactions. Experimentally, Mannich condensations with cyclopentadienes are stricken with low chemoselectivity. In favorable situations fulvenes are obtained,[15] and under some more special conditions Diels–Alder products are formed.[16] The alternative to use 6-(dialkylamino)fulvenes **C** seemed more promising. Especially the 6-(dimethylamino) derivative $C_5H_4{=}CH(NMe_2)$ is a well known compound which may undergo hydride addition from $LiAlH_4$ to form the corresponding cyclopentadienide.[17]



Scheme 1.

We first consider the syntheses of 6-(dialkylamino)fulvenes **C**. The 6-morpholino compound **7a** served as a testing ground. There are essentially three fulvene syntheses: the historical Thiele synthesis,[18] Hafner's synthesis of 6-(dimethylamino)fulvene,[19] and Kreutzberger's synthesis.[20] An attempt to apply Thiele's synthesis, i.e. the direct base-catalyzed condensation of cyclopentadiene with a carbonyl compound,[18a] to formylmorpholide, using an improved procedure,[18b] failed altogether; the dominating process was the dimerization of cyclopentadiene. Hafner's more forcing synthesis (Scheme 2) produced the desired 6-(morpholino) derivative **7a**, but the yield dropped from the 74% obtained for the 6-(dimethylamino)fulvene[19] to unsatisfactory 16% for **7a**. Kreutzberger's method[20] (Scheme 3) uses 1,3,5-triazine[21] as a synthon for formamide and presumably produces 6-aminofulvene as the primary product; this then undergoes nucleophilic substitution[22] of the amino group with morpholine and gave 6-(morpholino)fulvene **7a** as golden-brownish, analytically pure microcrystals in near quantitative isolated yield (94%). Compound **7a** has been mentioned in the literature, but has not been described in any detail.[23]

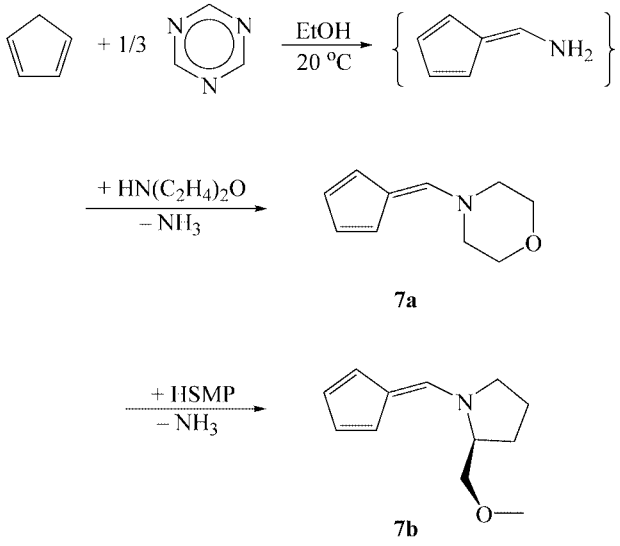


7a

Scheme 2.

Our observations suggest that Kreutzberger's synthesis should be the best option for the preparation of the (*S*)-2-(methoxymethyl)pyrrolidino analogue **7b**. When it was applied to (*S*)-2-(methoxymethyl)pyrrolidine (HSMP),[24] **7b**

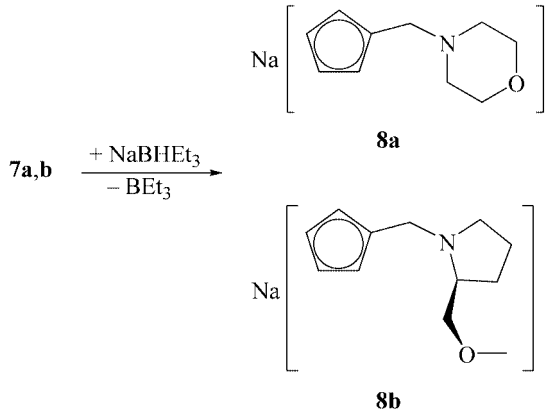
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3.

was obtained as a yellow to red, analytically pure oil in good yield (62%).

The second task was the hydride addition to the 6-aminofulvenes **7a**,**b** which turned out to be more difficult than in the case of 6-(dimethylamino)fulvene.[17] The reaction of **7b** with $LiAlH_4$ in THF mainly produced LiC_5H_4Me, indicating an undesired substitution of the amide group with a hydride. We found, however, that the milder reagent $NaBHEt_3$ in toluene effected a smooth addition of hydride (Scheme 4). In the case of **7a** the reaction was fast at 0 °C and markedly exothermic. The triethylborane also formed was in part bonded to the nitrogen of the morpholine ring; it was removed by washing the raw product with diethyl ether to give the salt $Na[C_5H_4CH_2–N(C_2H_4)_2O]$ (**8a**) in high yield (83%), but still contaminated with small amounts of BEt_3 (^1H and ^{11}B NMR). The analogous reaction in the SMP series gave $Na(C_5H_4CH_2–SMP)$ (**8b**), again in high yield (90%), but at a much lower rate at ambient temperature. Both salts are highly air-sensitive.



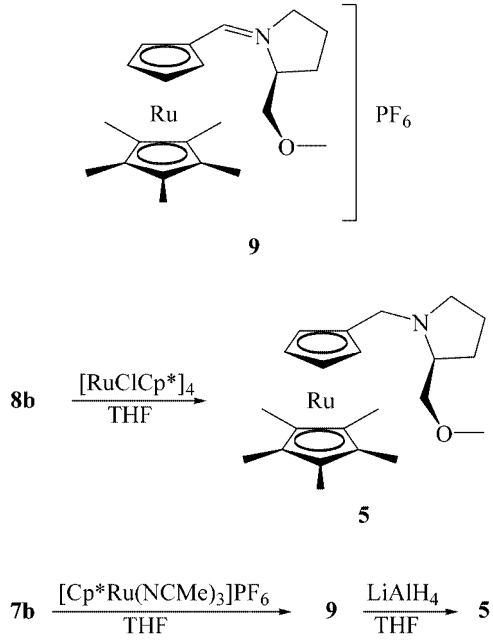
Scheme 4.

The cyclopentadienides **8a**,**b** show surprisingly low solubilities, and only strong donor solvents such as DMF and DMSO give moderately concentrated solutions which tend to decompose at ambient temperature within hours to days. Only solutions in liquid ammonia did not show decomposition, even after several days. Functionalized cyclopentadienides with N- and/or O-donor centers often have the structure of a coordination polymer.[25] This could well be the cause of the observed low solubilities of **8a**,**b**.

Pentamethylruthenocenes with a SMP-Methyl Side Chain

The Starting Material 5

Complex **5** was synthesized from $[Cp^*RuCl]_4$[13] and the sodium cyclopentadienide **8b** in THF (Scheme 5). It is a golden yellow, chemically and thermally robust oil which could not be crystallized. Complex **5** can also be made by a two-step procedure. In the first step a slight excess of the fulvene **7b** is treated with $[Cp^*Ru(MeCN)_3]PF_6$[26] to produce the (ruthenocenylmethylene)iminium salt **9** (Scheme 5). An excess of **7b** can be removed by recrystallization of the material **9** from acetone/ether or from THF/ether. In the second step hydride addition from $LiAlH_4$ in THF smoothly transforms complex **9** into the desired complex **5**. This alternative has not been optimized.



Scheme 5.

Lithiation and Derivatization of 5

We now turn to the diastereoselective lithiation of **5**. Lithiations of ruthenocenes are known to be faster and less selective than those of ferrocenes and may give rise to homo- and heteroannular di- and even trilithiations.[8a,27] In the case of **5** the presence of the Cp* ligand greatly reduces the resulting problems.

All lithiation reactions were conducted under standardized conditions. Complex **5** was used as 0.1 M solution in diethyl ether at –78 °C and the lithiations were performed with titrated[28] ca. 1.5 M Li*s*Bu solutions in cyclohexane

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at –78 °C, usually in a 1:1.7 ratio. After mixing the reagents the reaction mixture was stirred at –78 °C for 3.5 h. A quenching reagent E–X was then added at –78 °C and the mixture was warmed to ambient temperature (Scheme 6). All products Cp*Ru[1-E-2-(SMP–CH_2)C_5H_3] **10a**–**i** are very pale yellow, almost colorless oils. They were analyzed mainly with the help of ^{1}H NMR spectroscopy (500 MHz). In no case could we detect a second diastereomer; hence the diastereomeric excess should be better than 98%. In all cases an admixture of starting material was present as impurity; for more details see below and Experimental Section.

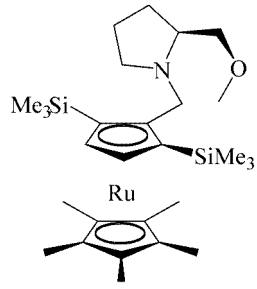
Scheme 6.

The stereochemistry of complexes **1** may be specified in one of two ways:[29] either by specifying the *planar* chirality of the $C_5H_3R^1R^2$ ring as originally proposed by Schlögl,[30] or by specifying the *central* chirality of the ring carbon bearing the highest ranking substituent with the help of the CIP rules.[31] As we shall prove below, the SMP–CH_2 group of the complexes **10a**–**i** has the role of R^1 in the illustration of complex **1**, and E occupies the position of R^2. For most substituents E we have therefore (S_P)-stereochemistry for the planar chirality;[32] only the low-ranking groups Me and CD_3 of **10e**,**f** leave the higher priority to the SMP–CH_2 group thus implying (R_P)-stereochemistry.

A few details concerning specific cases should be mentioned here. The fluororuthenocene **10a** was obtained by electrophilic fluorination[33] with *N*-fluoro-*N*,*N*-bis(benzenesulfonyl)imide.[34] The higher homologues **10b**, **10c**, and **10d** were obtained with C_2Cl_6, 1,2-$C_2H_4Br_2$, and 1,2-$C_2H_4I_2$, respectively, as source of the halogen. The iodo compound **10d** seems to form an adduct with LiI (cf. below compound **12**), but an aqueous workup step smoothly removed the coordinated LiI. Iodomethane was used to synthesize **10e** and likewise CD_3I gave **10f**, using again an aqueous workup procedure. In the case of **10b** the metalation conditions were varied with the aim to find out the optimum procedure. It was found that temperatures below –78 °C (without change of other parameters) resulted in incomplete lithiation and a higher admixture of starting material **5** in the product. On the other hand, when the lithiation mixture was warmed up to 40 °C and then was cooled again to –78 °C before the addition of the quenching reagent, the admixture of **5** in the product was no longer seen.

The remaining examples are more complex. Quenching with $SiClMe_3$ under the usual conditions gave **10g** and in addition a doubly silylated product **11** in a 3:1 ratio. This by-product could largely be suppressed if the temperature of the quenching mixture was increased more slowly (for instance in 14 h vs. the usual 1.5 h) from –78 °C to ambient temperature. This observation suggests that a transmetalation step is coming into play in this system. In the cases **10h**,**i** byproducts (inter alia P*s*BuPh$_2$[35] in the case of **10h** and *s*BuAu(PPh$_3$)[36] in the case of **10i**) formed from the excess of Li*s*Bu, which were difficult to remove; their formation can be suppressed if the lithiation reagent is used in near equivalent quantity, but then the metalation remains incomplete and the product becomes contaminated by larger admixtures (up to 25%) of starting material **5**. These difficulties were aggravated by the fact that none of the products **10a**–**i** could be crystallized.



11

First Proof of the Product Stereochemistry: the Structure of the LiI Adduct [10f(LiI)]$_2$

Quite serendipitously we obtained crystals of a lithium iodide adduct [**10f**(LiI)]$_2$ (≡ **12**), when we intended to synthesize **10f** and used a non-aqueous workup procedure. This

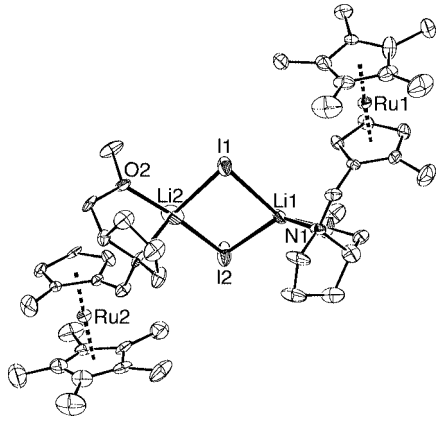


Figure 1. Molecular structure of the LiI adduct **12** (PLATON plot[38] at the 30% probability level). Selected distances [Å]: Ru1–Cp 2.147(13), Ru2–Cp 2.167(12), Ru1–Cp* 2.157(14), Ru2–Cp* 2.138(15).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

allowed us to determine the stereochemistry of the directed *ortho*-lithiation of **5** via *internal reference* to the (*S*)-stereochemistry of the chiral auxiliary group SMP. Compound **12** crystallizes in the monoclinic, noncentrosymmetric space group $P2_1$. The crystal consists of dinuclear molecules. Inspection of Figure 1 shows that the planar chiral cyclopentadienyl rings in **12** are coordinated to the Ru atom with (R_P)-stereochemistry.[37]

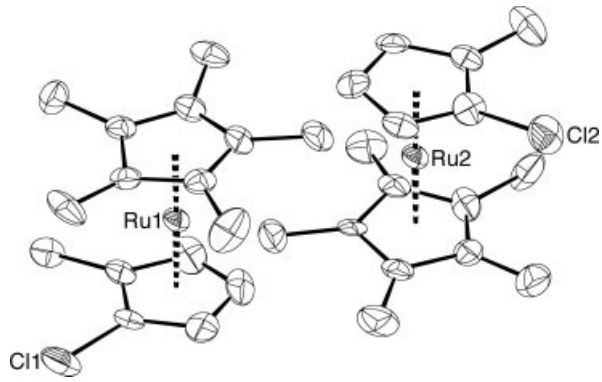

Figure 2. Structure of (S_P)-Cp*Ru(1-Cl-2-MeC_5H_3) (**14b**) (PLATON plot[38] at the 50% probability level). Selected distances [Å]: Ru1–Cp 2.184(12), Ru2–Cp 2.174(12), Ru1–Cp* 2.180(11), Ru2–Cp* 2.165(11), Cl1–C11 1.767(12), Cl2–C31 1.748(11).

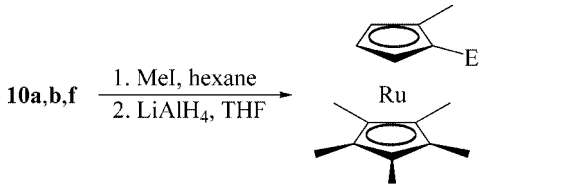
Planar Chiral Pentamethylruthenocenes

The removal of the chiral auxiliary group SMP is the next step in our strategy. We give three examples, the replacement of the SMP group in **10a**, **b** and **f** with hydride (Scheme 7). This replacement is achieved in a two-step reaction sequence. In the first step iodomethane was added to give ammonium iodides **13a**,**b**,**f** which were mixtures of diastereomers. As these compounds are of no interest by themselves we give only a minimal description in the Experimental Section. Early in ferrocene chemistry it was found that the NMe_3 group of [CpFe($C_5H_4CH_2NMe_3$)]I is readily amenable to nucleophilic substitution reactions, for instance with CN^- ion.[39] In this vein the tertiary amine moiety *N*-Me–SMP in **13a**,**b**,**f** could readily be substituted with hydride from $LiAlH_4$ in THF. Thus we obtained the planar chiral ruthenocenes Cp*Ru(1-E-2-MeC_5H_3) **14a** (E = F), **14b** (E = Cl), and **14f** (E = CD_3) as enantiomerically pure, crystalline compounds in high yields. It should be emphasized that these complexes possess the planar chirality of the 1,2-disubstituted cyclopentadienyl ring as the sole element of chirality.



14a, E = F; **14b**, E = Cl; **14f**, E = CD_3

Scheme 7.

Second Proof of the Product Stereochemistry: the Structure of the 1-Cl-2-Me Derivative 14b

The structure of **14b** was determined with the aim to confirm the assigned absolute configuration of the planar chiral ruthenocenes **14a**,**b**,**f** by measuring the anomalous dispersion of the X-ray radiation. Complex **14b** crystallizes in the triclinic space group *P*1 with two independent molecules in the unit cell.[37] The pseudocentrosymmetric arrangement of these molecules (Figure 2) is understandable in view of the roughly similar space filling requirements for a Cl atom and Me substituents.[40] The absolute configuration was found to be the (S_P)-configuration in agreement with the result from the structure determination for **12**.

It could be argued that picking a single crystal from a crystalline sample is unsafe: a crystal of the nonrepresentative stereoisomer might unfortunately be chosen. In the present work this is a most unlikely scenario. In the case of the complexes **10a**–**i** we have never observed any indication for the presence of the alternative stereoisomer. As we have two independent determinations of the configuration the unlikely unfortunate choice would have to have occurred twice. And last not least, in the case of **14b** it would be required that the two enantiomers do form a conglomerate. The very nature of the pseudocentrosymmetric structure of **14b** renders the possibility of conglomerate formation for **14b**/***ent*-14b** unlikely. We would rather expect the formation of racemic crystals or of a solid solution.

Concluding Remarks

In this paper we have established a synthetic route to enantiomerically pure ruthenocenes with a pentamethylcyclopentadienyl spectator ligand and with exclusively planar chirality. The absolute configuration of the metalation product has been determined by two independent methods. As may be seen from the experimental details the choice of the SMP group as a chiral auxiliary was not a very fortunate one, as all complexes **10a**–**i** were oils which did not show any tendency to crystallize. This was a severe disadvantage practically, and might be due to the fact that the SMP group is a five-membered saturated ring. Rings of this type are mechanically soft, and the pending methoxymethyl group adds further conformational flexibility. A six-membered ring as chiral auxiliary might be more recommendable.

It should be noted that complex **5** could also be used to synthesize bidentate chiral ligands which would potentially be useful as chiral ligands in homogeneous catalysis. The first coordinating sidearm could be introduced as in the synthesis of the phosphanyl derivative **10h** which in itself is already a potentially useful, bidentate *N*,*P* ligand. Furthermore, the SMP group can not only be replaced with hydride (as in this work), but also with other nucleophiles such as

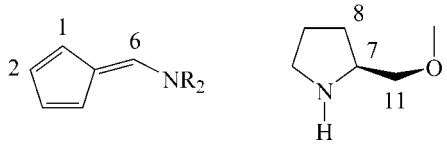
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

amino or phosphanyl functionalities which would again provide a second coordinating site.

In earlier work we had used achiral (pentamethylcyclopentadienyl)ruthenium sandwich complexes to show that certain ring-ligand transfer reactions take place via triple-decker intermediates.[41] If enantiomerically pure, planar chiral pentamethylruthenocenes were used in such studies, they would give additional, specific and stringent insights into the mechanism and the stereochemistry of ring-ligand transfer reactions. We do, however, not have the means to elaborate these ideas any further.

Experimental Section

General Remarks: All manipulations were carried out under nitrogen or argon using standard Schlenk techniques. 'Vacuum' corresponds to ca. 10^{-6} bar, unless stated otherwise. Solvents were dried by conventional methods,[42] freed from oxygen and stored under nitrogen. Alumina (ICN Alumina N, activity 1), kieselguhr (Merck), silica gel (Merck, Kieselgel 60, 0.063–0.200 mm), molecular sieves (Merck, 4 Å), and seasand were freed from oxygen and water by heating in a vacuum (10^{-6} bar) to 300 °C for 24 h and then stored under nitrogen. Alumina was deactivated before use by controlled addition of water (5%, degassed). IR spectra were recorded on a Nicolet Avatar 360 FT IR spectrometer using NaCl cuvettes with PTFE stoppers. Mass spectra were recorded on a Finnigan MAT 95 (EI, CI, SIMS) or on a Nermag R10/10 spectrometer (DCI). NMR spectra were measured on a Varian VXR 500 Unity (^{1}H, 500.0 MHz; ^{7}Li, 194.2 MHz; ^{11}B, 160.3 MHz; ^{13}C, 125.6 MHz; ^{19}F, 470.1 MHz; ^{29}Si, 99.3 MHz; ^{31}P, 202.3 MHz) in most cases. Chemical shifts are given in ppm; they were referenced to TMS for ^{1}H and ^{13}C. ^{2}H NMR spectra were measured using the deuterated solvent as internal reference; since $\delta(^1H)$ of the natural solvent is equal to $\delta(^2H)$ of the deuterated solvent,[43] the chemical shift of the natural solvent could be taken as reference value. Assignments were based on APT spectra, 2D experiments (COSY, HETCOR, HMQC, HMBC), and on ^{1}H{^{1}H} NOE difference spectra. In the documentation of the NMR spectra the numbering follows the chemical numbering Scheme in most instances; for fulvenes the traditional numbering is used and for the pyrrolidine ring of SMP arbitrary numbers are defined as shown below.



Synthesis of 6-Morpholinofulvene (7a) – Method A: a) (Methoxy)-morpholinocarbenium methyl sulfate: *N*-Formylmorpholide (11.35 g, 98.6 mmol) was placed in a 50 mL three-necked flask equipped with a dropping funnel and a reflux condenser. Dimethyl sulfate (12.44 g, 98.6 mmol) was added dropwise with stirring at 55 °C. Stirring was continued at 75 °C for 2 h, and the reaction mixture turned dark brown and became rather viscous. b) **7a**: A 100-mL three-necked flask equipped with a dropping funnel and a reflux condenser was charged with NaCp (98.6 mmol) in THF (70 mL) and cooled to –10 °C. The carbenium methyl sulfate was then added with stirring at such a rate that the temperature did not rise above –5 °C. The mixture was then warmed up to ambient temperature overnight. Pentane (40 mL) was added. The solid material was filtered off and washed with CH_2Cl_2 and pentane until the filtrate was nearly colorless. The volatiles were removed from the collected filtrates in a vacuum, and the resulting dark residue was crystallized from EtOH/H_2O (1:1) or from hexane to afford **7a** (2.59 g, 16%) as air-stable, orange-yellow platelets; m.p. 75 °C; highly soluble in polar organic solvents, soluble in toluene, moderately soluble in cold hexane, insoluble in water. $C_{10}H_{13}NO$ (163.2): calcd. C 73.59, H 8.03, N 8.58; found C 73.77, H 8.03, N 8.44. MS (EI): *m*/*z* (%) = 163 (100) [M^+, $C_{10}H_{13}NO^+$], 79 (44) [$C_6H_7^+$], 58 (97) [$C_2H_4NO^+$]. ^{1}H NMR (500 MHz, [D$_6$]DMSO, 25 °C): δ = 3.37 (br., $\nu_{1/2}$ = 14 Hz, 2 CH_2N, gives rise to a multiplet at 90 °C), 3.69 (m, 2 CH_2O), 6.03 (m, 2-H), 6.24 (m, 1-H), 6.28 (m, 3-H), 6.44 (dt, 4-H), 7.28 (br. s, 6-H), coupling constants from simulation: $^3J_{12}$ = 4.50, $^4J_{13}$ = 1.88, $^4J_{14}$ = 2.15, $^4J_{16}$ = 0.15, $^3J_{23}$ = 2.51, $^4J_{24}$ = 1.39, $^5J_{26}$ = 0.25, $^3J_{34}$ = 4.77, $^5J_{36}$ = 0.88, $^4J_{46}$ = 0.42 Hz; the line-broadening of the signals for 6-H, CH_2N and CH_2O is caused by hindered rotation around the bond N–C-6. ^{13}C{^{1}H} NMR (125.6 MHz, [D$_6$]DMSO, 25 °C): δ = 147.94 (C-6), 125.40 (C-1), 124.47 (C-3), 118.13 (C-2), 115.50 (C-5), 113.65 (C-4), 65.76 (CH_2O, $\nu_{1/2}$ = 17 Hz; $\nu_{1/2}$ = 0.8 Hz at 90 °C), 49.64 (CH_2N, $\nu_{1/2}$ = 215 Hz; $\nu_{1/2}$ = 4.9 Hz at 90 °C). For NMR spectroscopic data in C_6D_6 and CD_2Cl_2 see ref.[1].

Synthesis of 6-Morpholinofulvene (7a) – Method B: A Schlenk flask equipped with a gas outlet was charged with freshly distilled cyclopentadiene (6.61 g, 100 mmol), morpholine (17.4 g, 200 mmol), and ethanol (absolute, 10 mL). Solid 1,3,5-triazine[21] (3.24 g, 40.0 mmol) was then added with efficient stirring at 0 °C, and stirring was continued at ambient temperature for 24 h. A yellow, glistening suspension formed. Water was added to complete the precipitation of the product. The solid was collected on a frit, washed several times with water (a total of 300 mL), and dried in a high vacuum for 12 h, to give **7a** (15.3 g, 94%) as a golden-brownish, analytically pure [elemental analysis (CHN), NMR] microcrystalline powder; m.p. 77 °C, other data as above.

6-[(*S*)-2-(Methoxymethyl)pyrrolidino]fulvene (7b): As described above for **7a** the reaction of cyclopentadiene (4.29 g, 64.9 mmol), HSMP[24] (14.95 g, 129.8 mmol), ethanol (absolute, 13 mL), and 1,3,5-triazine[21] (2.10 g, 26.0 mmol) produced a dark red oil. Ethanol (5 mL) was added and thereafter water (60 mL). The mixture was vigorously shaken and then kept standing until the phases had separated. The upper turbid, yellow phase was removed with the help of a syringe and the lower, oily, dark red organic phase was washed twice with water. The organic phase was then kept in a high vacuum with occasional shaking to remove the more volatile components. After about 60 h a film of the oil no longer gave off bubbles, and the residue was pure (NMR) **7b** (7.73 g, 62%); could not be crystallized; highly soluble in the common soft and/or polar organic solvents, soluble in Et_2O, moderately soluble in hot hexane. Chromatography on alumina (5% H_2O) with pentane/ether (1:4) gave particularly pure samples, but also resulted in high losses of material. $C_{12}H_{17}NO$ (191.3): calcd. C 75.35, H 8.96, N 7.32; found C 75.49, H 9.01, N 7.19. MS (EI): *m*/*z* (%) = 191 (20) [M^+], 146 (36) [M^+ – CH_2OMe], 70 (100) [$C_4H_8N^+$]. ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.81 (br., $\nu_{1/2}$ = 22.0 Hz, 1 H, 8-H), 2.07 (m, 8-H + 2 9-H), 3.36 (s, OMe), 3.44 (m, CH_2O), 3.65 (m, CH_2N), 3.96 (br., $\nu_{1/2}$ = 18.0 Hz, 7-H), 6.22 (m, 2-H), 6.37 (m, 1-H), 6.43 (m, 3-H), 6.48 (m, 4-H), 7.50 (br., $\nu_{1/2}$ = 7.5 Hz, 6-H). ^{13}C{^{1}H} NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 24.60 (C-9), 27.86 (C-8), 50.54 (C-10), 59.27 (OMe), 63.94 (C-7), 75.45 (CH_2O), 114.71 (C-4), 118.14 (C-5), 119.46 (C-2), 124.00 (C-1), 124.53 (C-3), 144.92 (C-6).

Sodium (Morpholinomethyl)cyclopentadienide Na[$C_5H_4CH_2$–$N(C_2H_4)_2O$] (8a): A Schlenk tube was charged with toluene

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(30 mL) and **7a** (0.918 g, 5.63 mmol), and cooled to 0 °C. A solution of $NaBHEt_3$ in toluene (1 M, 6.19 mL, 6.19 mmol) was added dropwise with vigorous stirring. The cooling bath was then removed, and stirring was continued at ambient temperature for 20 h. The volatiles were then removed in a vacuum and the solid residue was kept in a high vacuum for 24 h. This raw product contained (inter alia) triethylborane (0.32 equiv.) coordinated to morpholino groups [$\delta(^{11}B)$ = 4 and –2 ppm, two conformers] and borates [$NaBHEt_3$: $\delta(^{11}B)$ = –13 ppm; $NaBEt_4$: $\delta(^{11}B)$ = –16 ppm; in [D_7]-DMF or [D_6]DMSO].[44] The triethylborane could not be removed in a high vacuum at 80 °C. The residue was dispersed in diethyl ether (10 mL) with the help of an ultrasonic bath; when the solid had settled again, the supernatant liquid was removed with a syringe. This procedure was repeated twice with ether and three time with pentane. Drying the solid in a high vacuum overnight left **8a** (0.87 g, 83%, with 0.04 eq BEt_3) as a light brown to ochre colored, extremely air-sensitive solid; soluble in DMF, DMSO and liquid ammonia, and moderately soluble in MeCN, slowly decomposing in solution. ^1H NMR (500 MHz, [D_7]DMF, 25 °C): δ = 2.34 (br., $\nu_{1/2}$ = 21.8 Hz, 2 CH_2N), 3.35 (s, $C_5H_4CH_2$), 3.52 ("t", br, "J" = 4.58 Hz, 2 CH_2O), AA′BB′ system: 5.54 ("t", 3-/4-H), 5.56 ("t", 2-/5-H), $N = J_{12} + J_{13}$ = 2.44 Hz; protons of residual BEt_3: –0.04 (q, BCH_2Me), 0.71 (t, BCH_2), ^3J = 7.94 Hz. $^{13}C\{^1H\}$ NMR (125.6 MHz, [D_7]DMF, 25 °C): δ = 54.38 (NCH_2), 61.65 ($C_5H_4CH_2$), 67.51 (CH_2O), 102.91 (C-3,4), 105.41 (C-2,5), 114.19 (C-1). $^{11}B\{^1H\}$NMR (160.3 MHz, [D_7]DMF, 25 °C, ext. $BF_3{\cdot}OEt_2$): δ = 4.1, –2.0.

Sodium {[(*S*)-2-(Methoxymethyl)pyrrolidino]methyl}cyclopentadienide, Na($C_5H_4CH_2$–SMP) (8b): A Schlenk tube was charged with toluene (3 mL) and **7b** (0.676 g, 3.53 mmol). A solution of $NaBHEt_3$ in toluene (1 M, 3.89 mL, 3.89 mmol) was added dropwise with vigorous stirring, and stirring was continued for 20 h. Further workup as described for **8a** (but with 5 mL volumes of solvent) afforded **8b** (0.684 g, 90%, with 0.018 eq BEt_3) as a light brown to ochre colored, extremely air-sensitive solid; soluble in liquid ammonia, slightly soluble in MeCN and THF, slowly decomposing in solution. There is no improved solubility in DME, TMEDA or in the presence of 15-crown-5. Prolonged washing of **8b** with ether removed the residual triethylborane completely, but also drastically reduced the yield. ^1H NMR (500 MHz, [D_8]THF, 25 °C): δ = 1.47 (m, 1 H, 8-H), 1.56 (m, 2 H, 9-H), 1.78 (m, 1 H, 8-H), 2.37 (m, 1 H, 10-H), 2.74 (m, 7-H), 2.96 (m, 1 H, 10-H), 3.11 (dd, ^2J = 9.46, $^3J_{7,11}$ = 6.10 Hz, 1 H, 11-H), 3.19 (d, ^2J = 9.46 Hz, 1 H, 11-H), 3.25 (s, OMe), AB system $C_5H_4CH_2$: 3.44 (d) and 3.66 (d), ^2J = 12.51 Hz; 5.60 (s, C_5H_4). $^{13}C\{^1H\}$ NMR (125.6 MHz, [D_8]THF, 25 °C): δ = 23.46 (C-9), 28.88 (C-8), 55.19 (C-10), 56.43 ($C_5H_4CH_2$), 58.72 (OMe), 62.62 (C-7), 76.47 (CH_2O), 103.26 (C-3,4), 104.36 (C-2,5), 116.45 (C-1).

Cp*Ru($C_5H_4CH_2$–SMP) (5): A suspension of **8b** (1.615 g, 7.50 mmol) in THF (10 mL) was cooled to –78 °C and [Cp*RuCl]$_4$[13] (2.039 g, 1.876 mmol), also suspended in THF (10 mL), was added. The mixture was stirred and was warmed up to ambient temperature within 4 h and stirring was continued for 2 h. Then the volatiles were removed in a vacuum. The red-brown oily residue was extracted with pentane (15 mL), the solution was separated from solid material by filtration through kieselguhr, which was then washed and extracted with several portions of pentane (a total of 35 mL). Removal of the pentane in a vacuum left a raw product which was contaminated with BEt_3, which had come into the system as a contaminant of **8b**. It was dissolved in diethyl ether (15 mL) and a saturated aqueous solution of NaF (5 mL) was added. After vigorous shaking the two phases were separated, the aqueous phase was extracted several times with diethyl ether (a total of 25 mL); the combined ethereal solutions were dried with Na_2SO_4, filtered and the solvents evaporated to dryness. The yellow-brownish, oily residue was heated in a high vacuum ($5{\cdot}10^{-7}$ bar); above 160 °C a yellow oil was condensed over a short (!) bridge into a small flask. The product **5** (2.70 g. 84%) is a viscous yellow oil, highly soluble in all common organic solvents (except MeOH), insoluble in perfluoropentane and water. $C_{22}H_{33}NORu$ (428.6): calcd. C 61.65, H 7.76, N 3.27; found C 61.79, H 7.95, N 3.34. MS (EI): m/z (%) = 429 (15) [M^+], 315 (100) [M^+ – SMP]. ^1H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.49–1.55 (m, 1 H, 8-H), 1.59–1.66 (m, 2 9-H), 1.77–1.85 (m, 1 H, 8-H), 1.89 (s, Cp*), 2.22 (m, 1 H, 10-H), 2.60 (m, 1 H, 7-H), 2.89 (m, 1 H, 10-H), 2.95 (d, ^2J = 12.97 Hz, 1 H, 6-H), 3.17 (dd, ^2J = 9.33, $^3J_{7,11}$ = 6.52 Hz, 1 H, 11-H), 3.31 (s, OMe), 3.34 (dd, ^2J = 9.33, $^3J_{7,11'}$ = 4.94 Hz, 1 H, 11-H′), 3.36 (d, ^2J = 12.97 Hz, 1 H, 6-H), 4.08 (m, 2-/5-H), 4.10 (m, 3-/4-H). $^{13}C\{^1H\}$ NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 12.07 (C_5Me_5), 23.11 (C-9), 29.09 (C-8), 53.43 ($C_5H_4CH_2$), 54.36 (C-10), 59.06 (OMe), 61.96 (C-7), 73.12 and 72.97 (C-3,4), 74.65 and 74.45 (C-2,5), 77.02 (CH_2O), 85.12 (C_5Me_5), 85.48 (C-1).

[Cp*Ru(C_5H_4CH=SMP)]PF_6 (9): To a Schlenk tube charged with [Cp*Ru(MeCN)$_3$]PF_6[26] (0.581 g, 1.151 mmol) was added a solution of **7b** (0.227 g, 1.186 mmol) in THF (15 mL). The resulting reaction mixture was heated to reflux temperature for 24 h. The volatiles were removed in a vacuum. The residue was powdered at liquid nitrogen temperature and was warmed to ambient temperature in a high vacuum. This procedure was repeated several times and left **9** (0.660 g, 100%) as dark red-brown powder; m.p. 155 °C, rather soluble in CH_2Cl_2, THF and acetone, sparingly soluble in ether, decomposes in MeOH. The product may be crystallized as dark yellow needles by layering of acetone solutions with ether. $C_{22}H_{32}F_6NOPRu$ (572.54): calcd. C 46.15, H 5.63, N 2.45; found C 46.19, H 5.62, N 2.56. MS (DCI, NH_3) m/z (%) = 428 (85) [M^+], 116 (100) [H_2SMP^+]. ^1H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.91 (s, Cp*), 1.92–2.00 (m, 1 H, 8-H), 2.19–2. 34 (m, 3 H, 8-H′ + 2 9-H), 3.40 (s, OMe), 3.36–3.48 (m, CH_2N), 3.55 (dd, ^2J = 10.68, $^3J_{7,11}$ = 7.63 Hz, 1 H, 11-H), 3.68 (dd, ^2J = 10.68, $^3J_{7,11}$ = 3.36 Hz, 1 H, 11-H′), 4.26 (m, 7-H), C_5H_4: 4.78 (ddd, 1-H), 4.86 (ddd, 4-H), 4.93 (ddd, 2-H), 4.95 (ddd, 3-H), simulated with $^3J_{12}$ = $^3J_{34}$ = 2.75, $^3J_{23}$ = 2.67, $^4J_{13}$ = $^4J_{14}$ = $^4J_{24}$ = 1.14 Hz; 8.28 (br., $\nu_{1/2}$ = 4.2 Hz, 6-H). $^{13}C\{^1H\}$ NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.86 (C_5Me_5), 24.52 (C-9), 27.53 (C-8), 53.01 (CH_2N), 59.34 (OMe), 68.08 (C-7), 73.64 (CH_2O), 75.01 (C-5), 76.34 and 76.70 (br., C-1,4), 82.87 and 82.92 (C-2,3), 90.32 (C_5Me_5), 162.95 (C-6).

Synthesis of 5 by Hydride Addition to Complex 9: A solution of **9** in THF (20 mL) was prepared as described above from [Cp*Ru(MeCN)$_3$]PF_6[26] (0.550 g, 1.090 mmol) and **7b** (0.210 g, 1.099 mmol). A solution of $LiAlH_4$ in THF (1 M, 1.090 mL) was added dropwise at –78 °C. The mixture was then warmed to ambient temperature and stirred at that temperature for 7 d. Water (2 mL) was added, then the mixture was evaporated to dryness. The residue was extracted with several portions of pentane (a total 50 mL). The combined, lemon yellow extracts were filtered through kieselguhr. Removal of the pentane left a very pure (NMR) sample of **5** (0.24 g, 50%, yield not optimized).

Lithiation of 5: Complex **5** was used as 0.1 M solution in diethyl ether at –78 °C. A titrated solution of Li*s*Bu in cyclohexane[28] (ca. 1.5 M) was added at –78 °C within 30 s. The ratio **5**/Li*s*Bu was usually 1:1.7 The reaction mixture was kept stirring at –78 °C for 3.5 h. Then the quenching reagent E–X was added, still at –78 °C, and the mixture was warmed to ambient temperature. Stoichiometric quantities are specified below.

(S_P)-Cp*Ru[1-F-2-(SMP–CH_2)C_5H_3] (10a): A solution of **5** in diethyl ether (0.298 g, 0.695 mmol, 1.39 mL) was cooled to –78 °C

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and a solution of Li*s*Bu in cyclohexane (1.58 M, 0.748 mL, 1.181 mmol) (ratio 1:1.70) was added at –78 °C within 20–30 s. The mixture was stirred at –78 °C for 3.5 h. Then a suspension of *N*-fluoro-*N*,*N*-bis(benzenesulfonyl)imide [$(PhSO_2)_2NF$] (0.3835 g, 1.216 mmol) in diethyl ether (a total of 10 mL) was added. The reaction mixture was warmed to ambient temperature within 2.5 h and stirring was then continued for 12 h. The volatiles were removed in a high vacuum and the residue was extracted with several portions of pentane (a total of 25 mL). The combined solutions were passed through kieselguhr and carefully freed of all volatiles to leave **10a** (0.233 g, 75%) as pale yellow oil, de > 98%, 8% admixture of **5** (only the ring protons 1-H – 4-H of **5** are not hidden by signals of **10a**). MS (EI): *m*/*z* (%) = 447 (9) [M^+], 333 (100) [M^+ – SMP]. Further comment: $(PhSO_2)_2NF$ should be colorless. The commercial product (Aldrich) was dissolved in CH_2Cl_2; the solution was passed through kiesel gel (Kieselgel 60, Merck), freed from solvent and carefully dried in a high vacuum. ^1H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.90 (s, Cp*), 3.01 (d, 1 H, 2-CH_2), 3.66 (d, 1 H, 2-CH_2), ^2J(2-CH_2) = 13.42 Hz; 3.846 (dddd, 4-H), 3.897 (dd, 3-H), 4.338 (dddd, 5-H), $^3J(^{19}F,5\text{-H})$ = 3.74, $^3J_{34}$ = 2.52, $^3J_{45}$ = 2.51, $^4J(^{19}F,4\text{-H})$ = 0.61, $^4J(^{19}F,3\text{-H})$ = 0.50, $^4J_{35}$ = 1.29, ^4J(3-H,2-CH_2) = 0.25, ^5J(4-H,2-CH_2) = 0.53, ^5J(5-H,2-CH_2) = 0.57 Hz; SMP fragment: 1.50–1.57 (m, 1 H, 8-H), 1.61–1.68 (m, 2 H, 9-H,H′), 1.78–1.86 (m, 1 H, 8-H′), 2.25 (ddd, br, 1 H, 10-H), 2.67 (br. m, 7-H), 2.95 (ddd, br, 1 H, 10-H′), 3.20 (dd, ^2J = 9.46, $^3J_{7,11}$ = 6.41 Hz, 1 H, 11-H), 3.31 (s, OMe), 3.36 (dd, ^2J = 9.46, $^3J_{7,11'}$ = 5.19 Hz, 1 H, 11-H′). $^{13}C\{^1H\}$ NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.69 (C_5Me_5), 23.15 (C-9), 29.04 (C-8), 49.42 (d, $^3J_{FC}$ = 3.9 Hz, C-6), 54.31 (C-10), 59.05 (OMe), 61.76 (C-7), 62.32 (d, $^2J_{FC}$ = 15.9 Hz, C-5), 66.26 (d, $^3J_{FC}$ = 3.9 Hz, C-4), 69.68 (d, $^3J_{FC}$ = 2.7 Hz, C-3), 73.72 (small, d, $^2J_{FC}$ = 14.3 Hz, C-2), 77.02 (C-11), 86.29 (C_5Me_5), 133.81 (d, $^1J_{FC}$ = 267.9 Hz, C-1). ^{19}F NMR (470.1 MHz, CD_2Cl_2, 25 °C): δ = –196.8 vs. ext. $CFCl_3$; when measured at 188.1 MHz a doublet was seen with $^3J(^{19}F,5\text{-H})$ = 3.5 Hz.

(S_P)-Cp*Ru[1-Cl-2-(SMP–CH_2)C_5H_3] (10b): The reaction of **5** (59.5 mg, 138.8 μmol), Li*s*Bu (1.65 M, 143 μL, 236 μmol), and C_2Cl_6 (82.2 mg, 347 μmol) gave **10b** (64.0 mg, 100%) as pale yellow oil; de > 98%, ca. 2% admixture of **5** (the signal at δ = 1.893 ppm of the Cp* ligand of **5** was the only impurity signal seen). MS (EI): *m*/*z* (%) = 463 (7) [M^+], 349 (100) [M^+ – SMP], 316 (17) [$RuC_{16}H_{22}^+$]. ^1H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.85 (s, Cp*), 2.91 (d, 1 H, 2-CH_2), 3.59 (d, 1 H, 2-CH_2), ^2J(2-CH_2) = 13.18 Hz; 4.09 (ddd, 4-H), 4.15 (dd, 3-H), 4.34 (ddd, 5-H), $^3J_{34}$ = 2.47, $^3J_{45}$ = 2.38, $^4J_{35}$ = 1.29, ^4J(3-H,2-CH_2) = 0.25, ^5J(4-H,2-CH_2) = 0.40, ^5J(5-H,2-CH_2) = 0.55 Hz; SMP fragment: 1.51–1.57 (m, 1 H, 8-H), 1.60–1.70 (m, 2 H, 9-H,H′), 1.80 –1.90 (m, 1 H, 8-H′), 2.20 (ddd, ^2J = 9.06, $^3J_{9,10} \approx 9.3$ $^3J_{9',10} \approx$Hz, 1 H, 10-H), 2.66 (m, 7-H), 2.99 (ddd, ^2J = 9.06, $^3J_{9,10'}$ = 6.68, $^3J_{9',10'}$ = 2.38 Hz, 1 H, 10-H′), 3.21 (dd, ^2J = 9.33, $^3J_{7,11}$ = 6.40 Hz, 1 H, 11-H), 3.32 (s, OMe), 3.42 (dd, ^2J = 9.33, $^3J_{7,11'}$ = 4.90 Hz, 1 H, 11-H′). $^{13}C\{^1H\}$ NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.29 (C_5Me_5), 23.12 (C-9), 29.06 (C-8), 50.71 ($C_5H_4CH_2$), 54.57 (C-10), 59.06 (OMe), 62.32 (C-7), 70.98 (C-4), 73.59 (C-3), 73.79 (C-5), 77.15 (CH_2O), 83.57 (C-2), 86.39 (C_5Me_5), 92.11 (C-1).

(S_P)-Cp*Ru[1-Br-2-(SMP–CH_2)C_5H_3] (10c): The reaction of **5** (70.5 mg, 164.5 μmol), Li*s*Bu (1.65 M, 170 μL, 280 μmol), and 1,2-$C_2H_4Br_2$ (54.1 mg, 288 μmol) gave **10c** (83.3 mg, 100%) as pale yellow oil; de > 98%, ca. 5% admixture of **5** (NMR). MS (EI): *m*/*z* (%) = 507/509 (5) [M^+], 393/395 (100) [M^+ – SMP], 315 (22) [$RuC_{16}H_{21}^+$]. ^1H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.84 (s, Cp*), 3.55 (d, 1 H, 2-CH_2), 2.95 (d, 1 H, 2-CH_2), ^2J(2-CH_2) = 13.26 Hz; 4.132 (ddd, 4-H), 4.170 (dd, 3-H), 4.358 (ddd, 5-H), $^3J_{34}$ = 2.29, $^3J_{45}$ = 2.38, $^4J_{35} \approx 1.2$, ^5J(4-H,2-CH_2) = 0.40, ^5J(5-H,2-CH_2) = 0.55 Hz; SMP fragment: 1.554–1.716 (m, 3 H, 8-/9-H,H′), 1.80–1.89 (m, 1 H, 8-H′), 2.22 (ddd, $^2J \approx 9.35$, $^3J_{9,10} \approx 9.40$, $^3J_{9',10} \approx 7.46$ Hz, 1 H, 10-H), 2.68 (m, 7-H), 3.02 (ddd, $^2J \approx 9.2$, $^3J_{9,10'} \approx 7.2$, $^3J_{9',10'} \approx 2.0$ Hz, 1 H, 10-H′), 3.25 (dd, ^2J =.38, $^3J_{7,11}$ = 6.18 Hz, 1 H, 11-H), 3.34 (s, OMe), 3.45 (dd, ^2J = 9.38, $^3J_{7,11'}$ = 4.72 Hz, 1 H, 11-H′). $^{13}C\{^1H\}$ NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.21 (C_5Me_5), 23.05 (C-9), 28.93 (C-8), 51.49 ($C_5H_4CH_2$), 54.55 (C-10), 59.12 (OMe), 62.31 (C-7), 72.33 (C-4), 73.97 (C-3), 75.99 (C-5), 76.76 (CH_2O), 79.17 (C-1), 84.53 (C-2), 86.54 (C_5Me_5).

(S_P)-Cp*Ru[1-I-2-(SMP–CH_2)C_5H_3] (10d): The reagents were **5** (141.8 mg, 331 μmol), Li*s*Bu (1.65 M, 211 μL, 347 μmol), and 1,2-$C_2H_4I_2$ (93.3 mg, 331 μmol). The reaction mixture was kept at ambient temperature for 50 h. Then the volatiles were removed in a vacuum. the residue was treated with diethyl ether (5 mL) and then with water (5 mL) and vigorously shaken. The aqueous phase was extracted with two portions of ether (5 mL each). The combined ethereal phases were dried with $MgSO_4$ and carefully freed from all volatiles to leave **10d** (99.4 mg, 54%) as a brown oil; de > 98%, ca. 2% admixture of **5** (^1H NMR: δ = 1.893 ppm, Cp* ligand of **5**). (S_P)-Cp*Ru[1-(Ph_2P)-2-(SMP–CH_2)C_5H_3] (10h): The reagents were **5** (0.272 g, 0.635 mmol), Li*s*Bu (1.41 M, 653 μL, 0.921 mmol), and $PClPh_2$ (0.8974 *M* in hexane, 1.097 mL, 0.984 mmol). After warming the reaction mixture to ambient temperature within 1.5 h, the volatiles were removed in a high vacuum. The yellow oily residue was extracted with several portions of ether. The combined extracts were filtered through kieselguhr and carefully freed of solvent. The residue was heated in a high vacuum (oil diffusion pump, ca. 10^{-9} bar) for several hours; above 80 °C P*s*BuPh_2 was condensed over a short (!) bridge into a small flask. This procedure finally left **10h** (0.327 g, 84%) as a dark yellow, extremely viscous oil; soluble in CH_2Cl_2, THF, and ether, only moderately soluble in pentane; de > 98, ca. 15% admixture of **5** (^{1}H NMR); the P-containing compounds were **10h** (90%), residual P*s*BuPh_2 (ca. 4%), and phosphane oxides (ca. 6%) (^{31}P NMR). MS (EI) *m*/*z* (%): 613 (1) [M$^+$], 499 (3) [M$^+$ – SMP], 429 (15) [**5**$^+$], 315 (100) [$C_{16}H_{21}Ru^+$]. ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.80 (s, Cp*), 2.64 (d, 1 H, 2-CH_2), 3.87 [dd, $^4J(^{31}P,2\text{-CH})$ = 2.44 Hz, 1 H, 2-CH_2], ^2J(2-CH_2) = ^2J = 12.21 Hz; 4.01 (ddd, 5-H), 4.217 (dddd, 4-H), 4.235 (ddd, 3-H), $^3J(^{31}P,5\text{-H})$ = 0.54, $^3J_{34}$ = 2.29, $^3J_{45}$ = 2.36, $^4J(^{31}P,3\text{-H})$ = 1.15, $^4J(^{31}P,4\text{-H})$ = 0.68, $^4J_{35}$ = 1.22, ^5J(4-H,2-CH_2) = 0.38 Hz; PPh2 group: 7.17–7.19 (m, 3 H), 7.22 –7.26 (m, 2 H), 7.29–7.31 (m, 3 H), 7.56 –7.59 (m, 2 H); SMP fragment: 0.97–1.16 (m, 2 H, 8-/9-H), 1.34–1.404 (m, 1 H, 9-H′), 1.59–1.67 (m, 1 H, 8-H′), 1.83–1.91 (m, partially overlapped by Cp* signal of **5**, 1 H, 10-H), 2.38 (m, 7-H), 2.61 (dd, ^2J = 9.16, $^3J_{7,11}$ = 7.63 Hz, 1 H, 11-H), 2.69 ("t"m, 1 H, 10-H′′), 3.25 (s, OMe), 3.80 (dd, ^2J = 9.16, $^3J_{7,11'}$ = 4.58 Hz, 1 H, 11-H′). ^{13}C{^{1}H} NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.85 (C_5Me_5), 22.67 (C-9), 29.32 (C-8), 52.86 (d, $^3J_{PC}$ = 7.1 Hz, $C_5H_4CH_2$), 53.92 (C-10), 58.85 (OMe), 63.06 (C-7), 74.55 (s, C-4), 75.77 (d, $^2J_{PC}$ = 4.9 Hz, C-5), 76.81(d,$^6J_{PC}$= 2.2 Hz, CH_2O), 78.86(d,$^3J_{PC}$ = 3.3 Hz,C-3),78.91 (d,small,$^2J_{PC}$ = 9.3 Hz,C-2), 85.71 (C_5Me_5), 90.74 (d, small, $^1J_{PC}$ = 26.8 Hz, C-1), 8 signals of PPh_2 group 127.4–142.4. ^{31}P{^{1}H} NMR (202.3 MHz, CD_2Cl_2, 25 °C): δ = –24.03 vs. ext. H_3PO_4 (85%).

(S_P)-Cp*Ru[1-{(Ph_3P)Au}-2-(SMP–CH_2)C_5H_3] (10i): The reagents were **5** (72.3 mg, 169 μmol), Li*s*Bu (1.65 M, 107 μL, 177 μmol; only 1.05 equiv. !), and AuCl(PPh_3) (83.5 mg, 169 μmol). The metalation solution was kept at –78 °C for 12 h, was then warmed to ambient temperature within 13 h, and was cooled again to –78 °C. The gold reagent was added as a fine powder. The reaction mixture was warmed to ambient temperature and kept at that temperature for 3 h. Further workup as described for **10a** gave **10i** (0.115 g, 77%) as a yellow oil; de > 98%, ca. 25% admixture of **5** (NMR). MS (EI): *m*/*z* (%) = 887 (0.03) [M$^+$], 429 (8) [**5**$^+$], 315 (49) [$C_{16}H_{21}Ru^+$], 262 (100) [PPh_3^+]. ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.92 (s, Cp*), 2.995 (d, overlapping with 10-/11-H, 1 H, 2-CH_2), 3.57 (d, 1 H, 2-CH_2), ^2J(2-CH_2) = 12.51 Hz; 3.97 (m, 5-H), 4.16 (m, 4-H), 4.22 (m, 3-H); PPh3: 7.47–7.541–(m, 9 H), 7.60–7.64 (m, 6 H); SMP fragment: 1.49–1.57 (m, 1 H, 8-H), 1.59–1.67 (m, 2 H, 9-H,H′), 1.74–1.80 (m, 1 H, 8-H′), 2.37 (ddd, 1 H, 10-H), 2.80 (m, 7-H), 2.97 (d, OMe), 2.995 (dd, overlapping with signals of 2-CH_2 and 10-H′, ^2J = 9.16, $^3J_{7,11} \approx 1.2$ Hz, 1 H, 11-H), 3.006 (m, overlapping with signals of 2-CH_2 and 11-H, 1 H, 10-H′), 3.41 (dd, ^2J = 9.15, $^3J_{7,11'}$ = 3.96 Hz, 1 H, 11-H′). ^{13}C{^{1}H} NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 12.95 (C_5Me_5), 23.35 (C-9), 29.51 (C-8), 54.92 (C-10), 57.28 (s, $C_5H_4CH_2$), 58.82 (OMe), 61.85 (C-7), 74.23 (d, $^4J_{PC}$ = 6.5 Hz, C-4), 75.26 (d, $^4J_{PC}$ = 6.1 Hz, C-3), 77.14 (CH_2O), 80.96 (d, $^3J_{PC}$ = 5.5 Hz, C-5), 84.55 (C_5Me_5), 92.41 (d, small, $^3J_{PC}$ = 6.1 Hz, C-2), 111.24 (d, small, $^2J_{PC}$ = 121.8 Hz, C-1), 4 signals of PPh_3 group 129.4–134.7. ^{31}P{^{1}H} NMR (202.3 MHz, CD_2Cl_2, 25 °C): δ = 47.46 vs. ext. The Dimer [(R_P)-Cp*Ru{1-(LiI·SMP–CH_2)-2-$CD_3C_5H_3$}]$_2$ (12): Reagents and reaction as described for **10f**. After warming up to ambient temperature the reaction mixture was kept at that temperature for 0.5 h. The volatiles were then removed in a high vacuum. The foamy residue was extracted with 5–10 portions of hexane (5 mL each). The combined solutions were filtered through kieselguhr. Crystallization set in spontaneously and was completed by cooling to –26 °C for 15 h. The mother liquor was removed and the crystals were dried in a vacuum maintaining low temperature during the whole procedure. This gave **12** (0.54–0.60 g, 90–100%)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as yellowish, almost colorless, rather hygroscopic needles; m.p. 165 °C (dec.); only slightly soluble in hexane. NMR spectra similar to those of **10f**.

(S_P)-Cp*Ru(1-F-2-MeC$_5$H$_3$) (14a): a) A solution of **10a** (0.233 g, 0.522 mmol) and excess MeI (0.50 mL, 8.0 mmol) in hexane (10 mL) was kept at ambient temperature for 10 d. The precipitate was collected, washed with hexane (2 × 3 mL), and dried in a high vacuum to give **13a** (0.251 g, 82%) as ochre-colored powder. The minor stereomer was best seen in the ^{19}F NMR (376.3 MHz, [D$_6$]-DMSO) spectrum which displayed two signals at $\delta(^{19}F)$ = –194.2 and –196.6 ppm vs. ext. $CFCl_3$ in a 8:1 ratio. b) A Schlenk tube was charged with **13a** (0.251 g, 0.427 mmol) and THF (16 mL). A solution of $LiAlH_4$ in THF (1 M, 0.64 mL, 0.64 mmol) was added at ambient temperature, and the mixture was heated to reflux temperature for 50 h. Then the reaction mixture was hydrolyzed with water (2.5 mL) and dried in a vacuum. The residue was extracted with several portions of pentane (a total of 40 mL). The combined extracts were filtered through kieselguhr and dried with $MgSO_4$. The concentrated solution was chromatographed on a column (7 cm long, 1 cm diameter) of alumina (5% H_2O) and eluted with pentane (a total of 20 mL). Careful removal of the solvent left **14a** (80 mg, 56%) as white crystals containing 2% (NMR) of Cp*Ru(C$_5$H$_4$Me);[45] m.p. 43 °C. $C_{16}H_{21}FRu$ (333.4): calcd. C 57.64, H 6.35; found C 57.53, H 6.48. MS (EI): *m/z* (%) = 334(100) [M$^+$],319(47) [M$^+$–Me],316(28) [$C_{16}H_{22}Ru^+$]. ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.82 (s, 2-Me), 1.90 (s, Cp*), 3.78 (ddd, $^4J_{FH}$ = 0.76 Hz, 4-H), 3.81 (m, 3-H), 4.28 (ddd, $^3J_{FH}$ = 3.82 Hz, 5-H), $^3J_{34}$ = $^3J_{45}$ = 2.52, $^4J_{35}$ = 1.22 Hz. ^{13}C{^{1}H} NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 9.56 (d, $^3J_{FH}$ = 2.8 Hz, 2-Me), 11.58 (C$_5$*Me*$_5$), 61.48 (d, $^2J_{FC}$ = 16.4 Hz, C-5), 65.43 (d, $^3J_{FC}$ = 4.4 Hz, C-4), 69.16 (d, $^3J_{FC}$ = 2.7 Hz, C-3), 73.42 (d, $^2J_{FC}$ = 14.2 Hz, C-2), 85.98 (*C*$_5$Me$_5$), 134.02 (d, $^1J_{FC}$ = 266.5 Hz, C-1). ^{19}F NMR (470.1 MHz, CD_2Cl_2, 25 °C): δ = –198.05 [d, $^3J(^{19}F,5\text{-H})$ = 3.7 Hz] vs. ext. $CFCl_3$.

(S_P)-Cp*Ru(1-Cl-2-MeC$_5$H$_3$) (14b): a) A solution of **10b** (1.890 g, 4.082 mmol) in pentane (60 mL) was treated with excess MeI (2.50 mL, 41 mmol). Workup after 13 d and as described for **13a** gave **13b** (2.47 g; 100%) as colorless solid. In the NMR spectra a second set of signals with ca. 2% relative intensity was seen indicating the presence of a second stereomer in 50:1 ratio. b) A Schlenk tube charged with **13b** (2.47 g, 4.08 mmol), THF (150 mL), and a solution of $LiAlH_4$ in THF (1 M, 6.12 mL, 6.12 mmol) was heated to reflux temperature for 50 h. After hydrolysis with water (20 mL, dropwise addition) all volatiles were removed in a vacuum. The residue was extracted with several portions of Et_2O (a total of 100 mL). The combined ethereal solutions were filtered through kieselguhr and dried with $MgSO_4$. The drying agent was filtered off and washed with diethyl ether (2 × 10 mL). Removal of the solvent left **14b** (1.14 g, 80%) as an off-white solid, contains 4% (NMR) of Cp*Ru(C$_5$H$_4$Me);[45] may be sublimed at 120 °C/10^{-6} bar, m.p. 103 °C. The compound may be recrystallized as needles by cooling pentane solutions to –30 °C. $C_{16}H_{21}ClRu$ (349.9): calcd. C 54.93, H 6.05, Cl 10.13; found C 54.73, H 6.16, Cl 9.98. MS (EI): *m/z* (%) = 350 (77) [M$^+$], 315 (100) [M$^+$ – Cl]. ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.78 (s, 2-Me), 1.84 (s, Cp*), 4.02 (dd, 4-H), 4.05 (ddq, 3-H), 4.29 (dd, 5-H), $^3J_{34}$ = 2.47, $^3J_{45}$ = 2.38, $^4J_{35}$ = 1.28, ^4J(3-H,2-Me) = 0.46 Hz. ^{13}C{^{1}H} NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.04 (2-Me), 11.15 (C$_5$*Me*$_5$), 70.16 (C-5), 72.73 (C-4), 73.01 (C-3), 83.36 (C-2), 86.03 (*C*$_5$Me$_5$), 92.33 (C-1).

(S_P)-Cp*Ru(1-CD$_3$–2-MeC$_5$H$_3$) (14f): a) A solution of **10f** (412 mg, 0.925 mmol) in hexane (10 mL) was treated with MeI (0.30 mL, 4.8 mmol). Workup as described for **13a** gave **13f** (0.503 g, 93%) as a colorless powder. In the NMR spectra a second set of signals with ca. 2% relative intensity was present. This was best seen for the *N*-Me group [$\delta(^1H)$ = 2.78 and 2.99 ppm, $\delta(^{13}C)$ = 41.64 and 48.83 ppm, with the low-field signals assigned to the minor stereomer]. b) The reaction of **10f** (0.503 g, 0.856 mmol) in THF (32 mL) with $LiAlH_4$ in THF (1 M, 1.28 mL, 1.28 mmol) gave, after workup as described for **14b**, the product **14f** (0.231 g, 81%) as a white solid; m.p. 95 °C. The compound may be recrystallized from very concentrated pentane solutions by cooling to –30 °C. $C_{17}H_{21}D_3Ru$ (332.5): calcd. C 61.42, H(D) 7.28 (for, 24 "H" atoms; after combustion D is detected with the same weight as H); found C 61.45, H 7.40. MS (EI): *m/z* (%) = 333 (100) [M$^+$], 318 (40) [M$^+$ – Me]. ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): δ = 1.71 (s, 2-Me), 1.83 (s, Cp*), 3.946 (t, 4-H), 3.974 (d, 3-/5-H), $^3J_{34}$ = $^3J_{45}$ = 2.45 Hz. ^{2}H{^{1}H} NMR (61.4 MHz, CD_2Cl_2, 25 °C): δ = 1.69 (CD_3) vs. $\delta(CD_2Cl_2)$ = 5.330. ^{13}C{^{1}H} NMR (125.6 MHz, CD_2Cl_2, 25 °C): δ = 11.49 (2-Me), 11.54 (C$_5$*Me*$_5$), 70.74 (C-4), 74.36 (C-3,5), 84.36 (*C*$_5$Me$_5$), 84.53 (small, C-2), C-1 not observed; in a ^{13}C NMR spectrum (i.e. without proton decoupling) the 1-CD_3 group can be seen as a septet: δ = 10.53 [sept, $^1J(^{13}C,^2H)$ = 19.7 Hz].

Crystal Structure Determinations of 12 and of 14b: Geometry and intensity data were collected with an ENRAF-Nonius CAD4 diffractometer (Mo-*K*α radiation, 0.71073 Å, graphite monochromator). A summary of crystal data, data collection parameters and convergence results is compiled in Table 1. A numerical absorption correction[46] was applied to the intensity data of **12**, and an empirical correction based on azimuthal scans[47] to those of **14b**. The structures were solved by direct methods[48] and subsequent Fourier difference syntheses, and were refined on intensities.[49] Non-hydro-

gen atoms were assigned anisotropic displacement parameters and hydrogen atoms were included as riding in standard geometry. The structure of **14b** contains two symmetrically independent molecules of the same planar chirality; pseudo inversion relates the chloro substituent on one molecule to the methyl group of the other moiety and vice versa; all remaining atoms closely match a non-crystallographic inversion. It is therefore no surprise that during refinement of this structure high correlations were encountered, and that similarity and rigid bond restraints were required to ensure physically reasonable molecular geometries and displacement parameters. We note that, despite a clearly acentric intensity distribution in the diffraction pattern, refinement in the centrosymmetric super group $P\bar{1}$ initially proceeds smoothly, but converges at unsatisfactory agreement factors (wR_2 ca. 0.28), and results in apparently disordered substituents in the chloro methyl ring ligand. CCDC-272905 (for **12**) and CCDC-272906 (for **14b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Syntheses, Structure and Intercalation Properties of Low-Dimensional Phenylphosphonates, $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ (A = Alkali Metal, NH_4 and Tl)

Koya Prabhakara Rao[a] and Kanamaluru Vidyasagar*[a]

Keywords: Phenylphosphonates / Organic-inorganic hybrid composites / X-ray diffraction / Layered compounds / Intercalation

Seven new low-dimensional phenylphosphonates, $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), NH_4 (**6**) and Tl (**7**)], have been synthesized and characterized by X-ray diffraction, spectroscopic and thermal studies. They crystallize in triclinic unit cells with two formula units and have approximately planar arrangement of A^+ ions, coordinated to oxygen atoms of phenylphosphonates, on both sides. Compounds **1** and **6** are one-dimensional, whereas others are two-dimensional. All of them undergo room-temperature intercalation reactions with primary *n*-alkylamines and ammonia. Single crystal X-ray structures of compounds **1**, **2** and **6** have been determined.

Introduction

Metal organophosphonates are a class of organic-inorganic hybrid materials, in which the organophosphonate groups are covalently bonded to the metal inorganic backbone. In the recent past, there has been a renewed interest and activity in the research arena of metal organophosphonates,[1–6] mainly due to their varied compositions, structural diversity and potential applications[7–11] like sorbents, ion-exchangers, sensors, and catalysts. The expansion[1–6,12,13] of metal organophosphonate chemistry includes phosphonates and diphosphonates of *s*-, *p*-, *d*- and *f*-block metals. The structures reported for these compounds could be broadly classified into two categories, namely, zero-dimensional types[14] such as mononuclear and complex molecular clusters and extended framework types[15] of one-, two- and three-dimensional networks. Mostly low-dimensional, namely chain and layered, structures are observed for the compounds of second type, due to the segregation of hydrophobic regions of organic moieties from the rest of the framework.

The solid-state chemistry of phenylphosphonates constitutes a significant portion of this research area. Reported are many investigations about the synthesis, structures and properties of di-, tri-, tetra-, penta-, and hexavalent metal phenylphosphonates[16–21] with extended frameworks, such as $Ca(HO_3PPh)_2$, $Ca(HO_3PPh)_2{\cdot}2H_2O$, $Pb(HO_3PPh)_2$, $Zn(O_3PPh){\cdot}H_2O$, α- and β- forms of $Al(HO_3PPh)(O_3PPh){\cdot}H_2O$, $Al(HO_3PPh)_3{\cdot}H_2O$, $Al_2(O_3PPh)_3{\cdot}2H_2O$, $Mn(HO_3PPh)(O_3PPh)$, $Fe(HO_3PPh)(O_3PPh){\cdot}H_2O$, $HFe(HO_3PPh)_4$, $La(HO_3PPh)(O_3PPh)$, $Zr(O_3PPh)_2$, $Th(O_3PPh)_2$, $[VO(O_3PPh)]{\cdot}2H_2O$, $[MoO_2(O_3PPh)]{\cdot}H_2O$, $[UO_2(O_3PPh)]{\cdot}0.7H_2O$, $[UO_2(HO_3PPh)_2(H_2O)]_2{\cdot}8H_2O$, $[(UO_2)_3(HO_3PPh)_2(O_3PPh)_2]{\cdot}H_2O$. These examples illustrate the structural diversity and the compositional variations with different ratios of metal to phenylphosphonates, mono- and di-anionic forms of phenylphosphonic acid and inclusion of O^{2-} and/or H_2O in the coordination sphere of metals. One noteworthy feature of all reported phenylphosphonates is their insolubility in water that enabled their isolation as precipitates from aqueous solutions. Most of these compounds, especially those with 1:1 and 1:2 ratios of metal to phenylphosphonic acid content, are lamellar phases. They contain layers of metal atoms coordinated to oxygen atoms of phosphonate groups and, in a few cases, additionally to O^{2-} and/or H_2O as well. The hydrophobic phenyl groups of phosphonates protrude into the interlayer region, on both sides of the inorganic metal layer.

Intercalation of metal phenylphosphonates is well studied[16b,17b–17f] and important from the point of view of sensors.[9] For example, the lamellar 1:1 divalent metal phenylphosphonates, such as $Zn(O_3PPh){\cdot}H_2O$, are known to intercalate ammonia and amines, which occupy the interlayer region and coordinate to the metal. This intercalation involves Lewis acid–base reaction that brings a change in the coordination sphere of the metal. The dependence of interlayer distance of intercalates on the chain length of the intercalated *n*-alkyl primary amine, structural elucidation of intercalates and stereo selectivity towards primary amines for intercalation have been reported.[17b–17f]

All 1:2 tri- and divalent metal phenylphosphonates, such as $La(HO_3PPh)(O_3PPh)$[18c] and $Ca(HO_3PPh)_2{\cdot}2H_2O$,[16b] have similar lamellar structure of $Zr(O_3PPh)_2$,[19b] with different coordinations for metals. Lewis acid-base intercalation of primary amines has been reported for only one compound, $Ca(HO_3PPh)_2{\cdot}2H_2O$. These compounds contain mono $(HO_3PPh)^-$ anions and are, therefore, potential solid Brönsted acids. The acid-strength would be higher for lower-valent metal phases, and the potentiality of these compounds as Brönsted-acid hosts, for intercalation of bases such as ammonia and amines, has not been investigated so far. This Brönsted acidity is distinctly different from the one reported[22] as due to functional SO_3H group of the phenyl moiety.

It is in this context that 1:2 phenylphosphonates of monovalent metals, $A(HO_3PPh)(H_2O_3PPh)$ are envisaged to be strong solid Brönsted acids that can undergo intercalation with bases. It is surprising that no structurally characterized monovalent metal phenylphosphonate has been reported so far. $Na_2(O_3PPh)$ and $Na(HO_3PPh)$ are the only two compounds of this family realized by Corbridge and Tromans,[23] who reported the powder X-ray data without any crystallographic information. In view of these observations, we undertook a study of 1:2 phenylphosphonates of alkali and thallium metals and ammonium. We report here the successful synthesis, characterization and intercalation chemistry of seven new phenylphosphonates, $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), NH_4 (**6**) and Tl (**7**)].

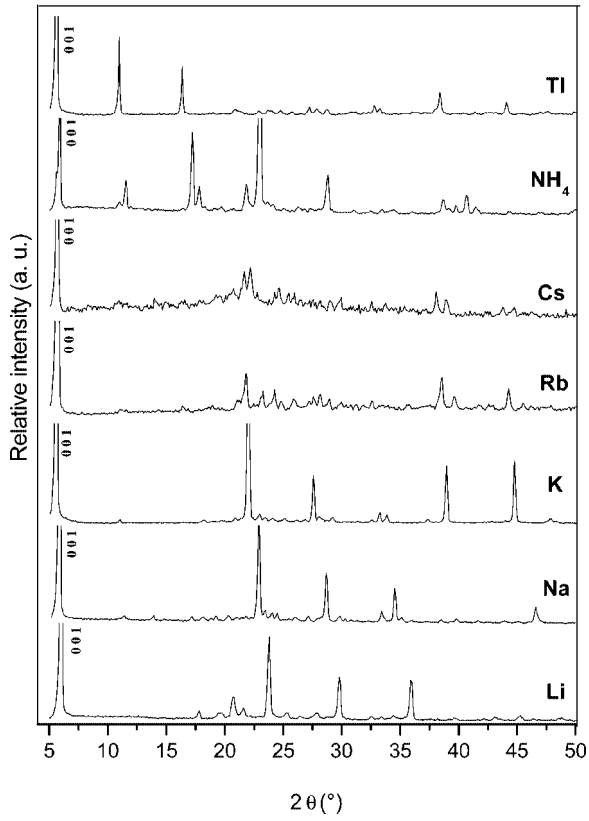

Figure 1. Powder X-ray diffraction patterns of $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), NH_4 (**6**) and Tl (**7**)] compounds.

Results and Discussion

X-Ray Diffraction and Crystal Structures: The powder X-ray diffraction (XRD) patterns (Figure 1) of all the seven $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ compounds are, in general, similar to one another, corroborating the similarity of the values of their triclinic unit cell parameters. The 001 reflection, with the 2θ value of about 5°, is the most intense and the observed main reflections arise from a family of $\{00l\}$ planes. The values of unit cell volumes of **2**–**7** vary in accordance with the relative sizes of A ions and lithium compound **1**, however, has slightly bigger unit cell volume than sodium compound **2**. For the four structurally characterized compounds **1**, **2**, **5** and **6**, the observed powder XRD patterns agree with those simulated, using the LAZY-PULVERIX program,[24] on the basis of single-crystal X-ray structures. However, the observed relative intensities of some of the $00l$ reflections are more than those calculated, due to the preferential orientation of the crystallites. The XRD powder pattern of **2** is different from those of $Na_2(O_3PPh)$ and $Na(HO_3PPh)$.[23]

The values of the triclinic unit cell parameters of compounds **1**–**7**, though similar, show that they have five types of structures. The single-crystal X-ray data sets of compounds **1**, **2**, **5** and **6** have enabled the identification of the four types, whereas the fifth type, namely the structure of the thallium compound (**7**), could not be ascertained. Compounds **3** and **4** have the structure type of **5**. The structural and crystallographic similarities, as deduced from XRD study, of the seven phosphonates, **1**–**7** are as follows: Two formula units are present in their centrosymmetric triclinic unit cells. A^+ ions are confined approximately to *ab* plane and coordinated to oxygen atoms of phosphonates on both sides. The phenyl groups are oriented, without *interdigitation* and π-π stacking, in approximately perpendicular fashion to the *ab* planes. Thus hydrophobic regions of phenyl groups separate the *inorganic ab* planes. The observed values of bond lengths and angles of these phosphonates compare well with those reported[16–21] in the literature. The labeling Scheme followed is such that P(1) is bonded to O(1)–O(3) oxygen atoms and C(1) carbon atom of phenyl ring C(1)–C(6), whereas P(2) is similarly bonded to O(4)–O(6) and C(7) of phenyl ring C(7)–C(12).

Lithium compound (**1**) is, as shown in Figure 2, one-dimensional in nature. O(3) and O(6) form short P–O bonds of ca. 1.49 Å length. Lithium is tetrahedrally bonded to these two oxygen atoms of four [two $P(1)O_4$ and two $P(2)O_4$] phosphonate moieties. Each LiO_4 tetrahedron is connected to two such tetrahedra, through O(3)–O(6) edges, and also to phosphonate moieties, to form one dimensional chains of $Li(HO_3PC_6H_5)(H_2O_3PC_6H_5)$, along *a*-axis. These chains are apart by 8.50 Å within the *ab* plane and 14.99 Å between such planes. The other four oxygen atoms form longer P–O bonds of 1.53–1.56 Å length and have acidic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydrogen atoms.[18d] The hydrogen bonding between these four oxygen atoms hold the chains along *b*-axis.

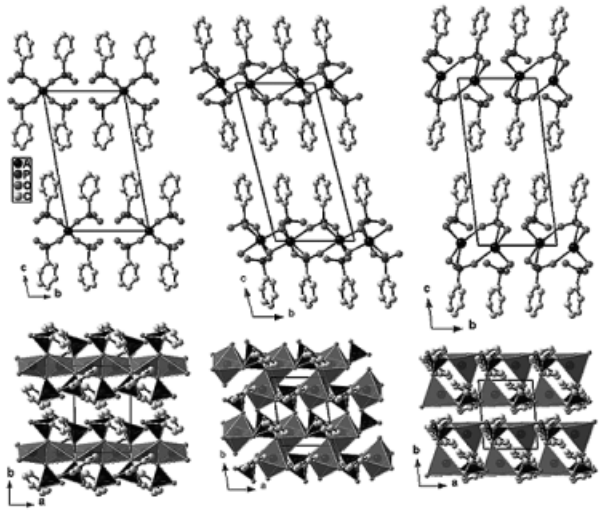

Figure 2. Unit cell of $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ [A = Li (**1**) (left), Na (**2**) (middle) and NH_4 (**6**) (right)], viewed along the *a* axis (top: ball-stick representation) and the *c* axis (bottom: polyhedral representation).

Sodium compound (**2**) is a two-dimensional phosphonate (Figure 2). The layered framework could be conceived as being built from centrosymmetric $Na_2O_6(O_3P–C_6H_5)_4$ blocks, each of which consists of an edge-shared bioctahedral Na_2O_{10} unit, corner-connected to four phosphonates. Only five of the crystallographically distinct oxygen atoms, O(1)–O(5), are involved in octahedral coordination of sodium. Two NaO_6 octahedra share an edge, O(5)–O(5)′ to form a Na_2O_{10} unit, which links, at the O(5) and O(3) atoms, to four phosphonate moieties. These building blocks are linked to one another such that the phosphonates of one block are corner-connected to Na_2O_{10} units of another, resulting in the layered framework. Sodium atom is coordinated to oxygen atoms of six phosphonate groups, whereas the phosphonates of P(1) and P(2) are coordinated to three and two sodium atoms respectively. These $Na(HO_3PC_6H_5)$-$(H_2O_3PC_6H_5)$ layers are stacked along *c*-axis, with an interlayer distance of 15.59 Å. The three oxygen atoms, O(1), O(2) and O(4), form longer P–O bonds of 1.54–1.58 Å length and have acidic hydrogen atoms. The hydrogen bonding exists between these oxygen atoms as well as O(6).

$NH_4(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ (**6**) is one-dimensional compound (Figure 2). With the cut-off distance of 3.0 Å for bonding, the nitrogen atom is found to be hydrogen-bonded, in an irregular tetrahedral fashion, to four oxygen atoms, O(1), O(2), O(3) and O(5), of four phenylphosphonate moieties. This arrangement leads to ladder-like chains, parallel to *a*-axis. The layered framework is not feasible, because the nitrogen atoms are not hydrogen-bonded to oxygen atoms of neighbouring chain in the *ab* plane, even with the higher cut-off value of 3.6 Å for bonding. These chains are apart by 7.66 Å within the plane and 16.34 Å between the planes. O(3) and O(6) form longer P–O bonds of ca. 1.56 Å length and have two acidic hydrogen atoms, H(13) and H(14), that are hydrogen-bonded to O(5) and O(2), respectively. Furthermore, O(4)–H(15) is strongly hydrogen-bonded to O(1).

The positional parameters of cesium (**5**) and ammonium (**6**) compounds are similar. However, cesium compound is two-dimensional and cesium is nine-coordinate, with the maximum value of Cs–O bond length being 3.52(2) Å. The layered framework of **5** is due to higher coordination number of cesium, which bonds additionally to oxygen atoms of those corresponding neighbouring chains in one-dimensional **6**. Compounds **3** and **4** are isostructural with the layered **5**, and potassium and rubidium are computed to be eight-coordinate. It could only be inferred that the structure type of thallium compound **7** has a similar arrangement of phosphonate moieties, which bond differently to thallium atoms in the *inorganic ab* plane. Thus the differences between the above five structure types stem from the different types of coordination of A^+ ions.

The reported 1:2 tetra-, tri- and divalent metal phenylphosphonates, with no additional O^{2-}/H_2O, have similar structural features of compounds **1**–**7**. $Zr(O_3PPh)_2$,[19b] $La(HO_3PPh)(O_3PPh)$,[18d] $Mn(HO_3PPh)(O_3PPh)$,[18b] $A(HO_3PPh)_2$ (A = Ca, Sr, Ba, Pb)[16a–16e] and the compounds **1**–**7** are the only 1:2 metal phenylphosphonates, for which the unit cell parameters have been determined from either single-crystal X-ray data or structural elucidation. Similar unit cell lengths of (5.36–6.16) Å × (7.65–10.215) Å are due to analogous planar arrangement of A atoms. The different types of coordination of A atoms and stacking of planes of A atoms are responsible for the variations in the third axis length and unit cell angles.

Spectroscopic and Thermogravimetric Data: Infrared spectra of compounds **2** and **6** are presented in Figure 3. The C–H stretching vibrations of the phenyl ring in the region 3090–3000 cm^{-1}, the aromatic C=C stretching vibrations at 1438 cm^{-1}, the peaks at 692 and 745 cm^{-1} representing the out-of-plane bending of the mono substituted phenyl ring, the peak at 2376 cm^{-1}, characteristic of $PhPO_3H$ group, the peak at 1594 cm^{-1} due to phenyl group stretching, the P–O stretching vibrations in the region 1200–1000 cm^{-1} and the O–P–O bending vibrations in the region 540–410 cm^{-1}, are the common features[18a,21a] observed in the infrared spectra of the seven compounds, **1**–**7**. The infrared spectrum of ammonium compound (**6**), shows two additional peaks at 3240 and 1401 cm^{-1} corresponding to the stretching and bending vibrations of the ammonium ion.[25] All these compounds, as illustrated in the solid-state ^{13}C and ^{31}P spectra (Figure 4) of **2**, show four ^{13}C signals[16b] between 140.0–120.0 ppm, corroborating the presence of aromatic carbon atoms and three ^{31}P signals[18a] between –1.2 and 7.8 ppm. Thermogravimetric analysis revealed, as illustrated with the case of **2** in the Figure 5, that all compounds **1**–**7** are stable up to about 200 °C and then undergo weight losses of 51.5%, 48.5%, 46.0%, 42.0%, 37.0%, 71.1% and 32.50%, respectively, in the temperature range 200–700 °C in four or five steps. These values agree with those calculated for $AP_2O_{5.5}$ as the products of decom-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

position for alkali and thallium metal compounds. All of them undergo further decomposition above 700 °C.

Intercalation Reactions: These seven phosphonates, **1**–**7** are solid Brönsted acids with a porous region between the *inorganic ab* planes. Therefore, they have been investigated from the point of view of Brönsted acid–base intercalation

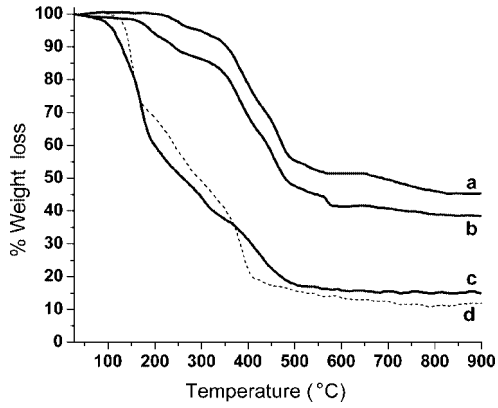

Figure 5. Thermogravimetric curves of (a) sodium (**2**) compound and its intercalates, (b) **2**·$(NH_3)_{1.2}$, (c) **2**·$(C_8H_{17}NH_2)_{1.5}$ and (d) **2**·$(C_8H_{17}NH_2)_{4.1}$.

reactions with ammonia and primary *n*-alkylamines, $CH_3(CH_2)_{n-1}NH_2$ (n = 4–9, 12, 16, 18). These reactions, as determined from chemical analysis and powder XRD, spectroscopic and thermal studies, turned out to be successful.

The optimum conditions, given in experimental section, for the first method of intercalation processes have been realized from the results of several trials, under different conditions, of intercalation reaction of sodium compound with *n*-octylamine. A variation of molar ratio of *n*-octylamine and sodium phosphonate **2**, from 2:1 to 3:1 to 4:1, led to intercalates, **2**·$(C_8H_{17}NH_2)_x$ with the corresponding x values of 0.9, 1.5 and 1.5, showing that the maximum intercalation at room temperature could be achieved with the reactant molar ratio of 4:1. There was no significant increase in the values of x, when similar reactions were carried out under reflux conditions at 70–80 °C. Similar attempts under solvothermal conditions, by heating reactant mixtures with 4 mL of *n*-hexane solvent, at 170 °C over a period of 2 days, resulted in only polycrystalline intercalates without any increase in the values of x. The second method involving neat liquid amines at room temperature is confined to $CH_3(CH_2)_{n-1}NH_2$ (n = 4–9,12) only.

The relevant data of the intercalates, **2**·$[CH_3(CH_2)_{n-1}NH_2]_x$ and **1**–**7**·$(C_8H_{17}NH_2)_x$ obtained by the first method, are presented in Table 1. The values of x range from 0.5 to 4.0 and do not seem to show any systematic trend with either n or A. The powder XRD patterns of **2**·$[CH_3(CH_2)_{n-1}NH_2]_x$ intercalates, as shown for a few selected cases in Figure 6, contain moderate to prominent reflections at low 2θ values of 2–5° and no significant reflections with 2θ of >40°. The first reflection is found to be doubled in a few cases such as **2**·$[CH_3(CH_2)_{11}NH_2]_x$. It is noteworthy that the powder XRD patterns of these intercalates, do not undergo any change, even when the samples were heated in open air at 40–50 °C for 12 h. The d value of the first reflection is considered to be associated with the distance between the *ab* planes. This is found to be higher than that observed for the parent phase **2**, due to incorporation of the amine in the porous region, perpendicularly to the inorganic *ab* planes, with the alkyl chains aligned out of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

perpendicular. These intercalates, unlike the parent **2**, do not show higher order 00*l* reflections prominently. The *d* value increases with *n* except in the case of nonylamine intercalate. The values of *d* do not show any systematic increase with *n*, probably due to the presence of *gauche* and *trans* conformations of the alkyl chains of the amines in different proportions. In general, these powder XRD patterns confirm the crystalline nature of intercalates and the topotactic intercalation of the amines. The powder XRD patterns of **1**–**7**·$(C_8H_{17}NH_2)_x$ intercalates also contain moderate to prominent reflections at low 2θ values of 2–5° and the values of *d* are higher than those in the parent phases. However, the increase in the *d* values is not systematic with respect to both A and *x*. Structural elucidation of these intercalates would reveal the placement of the intercalated amines and probably explain this lack of systematic variation of *d* with *n*, *x* and A. There are no structurally characterized Brönsted acid–base intercalates of this type reported, for a comparison. However, structurally characterized Lewis acid–base intercalates, $Zn(O_3PPh)(RNH_2)$ (R = C_3H_9, C_4H_{11}, C_5H_{13}), were reported[17b] to exhibit similar nonsystematic behavior, due to coordination of the intercalated amine to the metal.

Table 1. Interplanar distance (*d*), number (*x*) of mol of amine intercalated of the **2**·$[CH_3(CH_2)_{n-1}NH_2]_x$ (top) and **1**–**7**·$(C_8H_{17}NH_2)_x$ (bottom) intercalates.

n	–	4	5	6	7	8	9	12	16	18

A	Li	Na	K	Rb	Cs	Tl	NH_4			
x	2.7	1.5	2.1	1.6	1.9	2.9	4.0			
d [Å]	18.7	21.2	21.0	21.3	18.8	19.2	19.2			

The infrared spectra (Figure 3) of intercalates contain, in addition to all the features of the infrared spectrum of parent phase **2**, peaks in the region 3100–2700 cm^{-1} attributed to N–H and C–H stretching vibrations[16b] of the amine molecules. The CH_2 bending bands observed around 1437 cm^{-1} and 1470 cm^{-1} are ascribed[26] to *gauche* and *trans* conformations of alkyl chains of amines, respectively. The relative intensities of these two bands indicate that the alkyl chains, in the intercalates containing C_4–C_8 and C_9–C_{18} amines, are predominantly in *gauche* and *trans* conformations, respectively. The shift of N–H stretching vibrations towards lower frequencies suggests that the amine molecules are protonated[25] and electrostatically bonded to oxygen atoms of phosphonate moieties. The solid-state ^{13}C NMR spectra (Figure 4) of the intercalates show signals between 140.0–125.0 ppm and also multiple signals in the region 45.0–15.0 ppm, indicating the presence of both aromatic carbon atoms of the phenyl group and the aliphatic carbon atoms of the amines, respectively. The ^{13}C signals of alkyl carbon atoms, though not fully resolved, are in order of C_1, C_2, C_3,...C_n. The ^{31}P NMR spectra consist of three signals between –0.83 and –9.37 ppm, with up-field shift

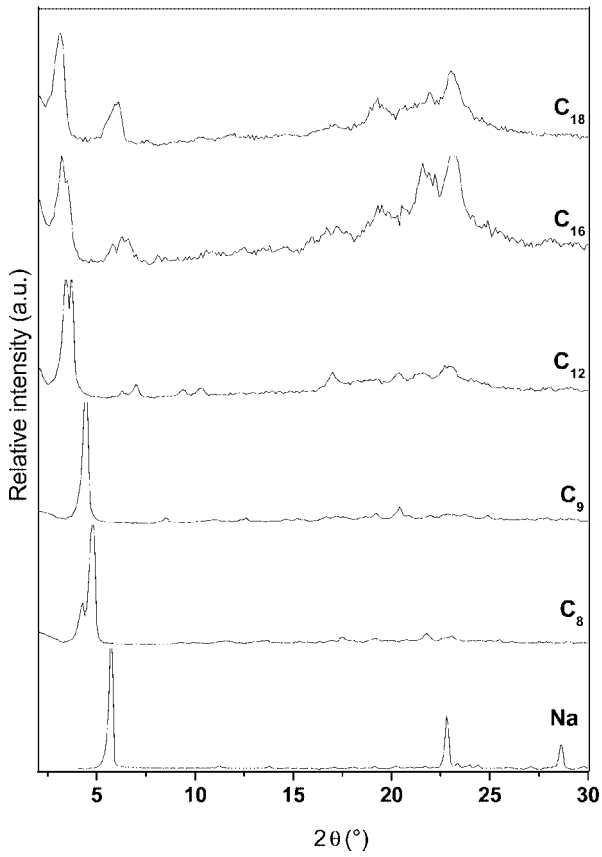

Figure 6. Powder X-ray diffraction patterns of sodium (**2**) compound and its intercalates, **2**·$[CH_3(CH_2)_{n-1}NH_2]_x$ (*n* = 8, 9, 12, 16 and 18).

compared to parent phases. Thermogravimetric analysis of a few selected intercalates revealed that they undergo more percentage of decomposition than the parent phases. For example, the total decomposition of 84% for **2**·$(C_8H_{17}NH_2)_x$ (Figure 5) starts at 70 °C and is completed by 600 °C. The first two stages of weight loss of 36% in the 70–200 °C range are attributable to the loss of intercalated amine, 1.5 mol of $C_8H_{17}NH_2$. The spectral and thermal features of other intercalates are similar to those of the sodium compound.

The second method of intercalation is compared with the first one, in terms of the compositions, the powder XRD patterns and spectral features of the corresponding intercalates. The *x* values of **2**·$[CH_3(CH_2)_{n-1}NH_2]_x$ are 1.5, 2.1, 2.0, 1.4, 4.1, 2.4, 2.5 for *n* = 4–9 and 12, respectively. Similarly the *x* values of **1**–**7**·$(C_8H_{17}NH_2)_x$ are 2.8, 4.1, 2.7, 5.0, 5.0, 3.2, 4.3, respectively. In general, the extent of intercalation, as corroborated by thermogavimetric study (Figure 5), is larger in the second method. The powder XRD patterns revealed no increase in the *d* values with increase in *x* values. There are no significant changes in their infrared and solid-state NMR spectra. The maximum amount of intercalation of primary amines reported is about two molecules per formula unit of $Ca(HO_3PPh)_2{\cdot}2H_2O$[16b] and 1:1 phenylphosphonates.[17b–17f] Contrastingly, the extent of intercalation in the present 1:2 phenylphosphonates **1**–**7** is as high

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as five molecules of amine per formula unit. This could be attributed to the Brönsted acidity of the compounds and thus intercalates with $x > 3$ and $x \leq 3$ values could be represented as $CH_3(CH_2)_{n-1}NH_3]_3[CH_3(CH_2)_{n-1}NH_2]_{x-3}$-$[A(O_3PC_6H_5)_2]$ and $[CH_3(CH_2)_{n-1}NH_3]_x[AH_{3-x}(O_3PC_6H_5)_2]$, respectively. Thus the amine upto the value of $x = 3$ is present as RNH_3^+ ions, whereas the amine in excess of $x = 3$ is present as RNH_2, held together by van der Waals forces in the lattice.

The success and extent of ammonia intercalation in the intercalates, **1**–**7**·$(NH_3)_x$ have been determined from infrared spectra and the analysis of carbon and nitrogen contents. The infrared spectra contain two peaks at 3240 and 1450 cm^{-1} corresponding to the stretching and bending vibrations of the ammonium ion.[17e] The x values of **1**–**7**·$(NH_3)_x$ are 2.0, 1.2, 1.1, 1.5, 1.7, 2.3 and 2.3, respectively, and indicate no systematic variation with A. Thus these intercalates could be represented as $[NH_4]_x[AH_{3-x}$-$(O_3PC_6H_5)_2]$. Some of the reflections in the powder XRD patterns of ammonia intercalates are more intense than those in the parent phases. **2**·$(NH_3)_{1.2}$, unlike the parent phase **2**, decomposes even below 200 °C and shows higher weight loss (Figure 5). The total decomposition of 59% occurs in the 160–700 °C range and the weight loss below 200 °C is probably due to the loss of intercalated ammonia.

The **2**·$(NH_3)_{1.2}$ intercalate undergoes deintercalation, on heating. The success of deintercalation is proved by CHN analysis and absence of vibrational frequencies of NH_4^+ in the infrared spectrum of deintercalate. Moreover, its powder pattern is the same as that of parent phenylphosphonate **2**, showing that the process of intercalation and deintercalation is reversible and topotactic. This process of deintercalation is probably true for other ammonia intercalates of this study.

$Zn(O_3PPh)$ and $[UO_2(HO_3PPh)_2(H_2O)]_2{\cdot}8H_2O$ have been reported[9,21c] to be sensors and proton conductors, due to their intercalation and Brönsted acidic properties, respectively. All the seven title compounds **1**–**7** exhibit both these properties and could be potentially useful as sensors and proton conductors. A similar study of phenylarsonate analogues has revealed interesting structural variations, which we would report elsewhere.

Concluding Remarks

A series of seven, new low-dimensional phenylphosphonates, $A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ (A = alkali metal, NH_4 and Tl) have been synthesized and characterized by X-ray diffraction and spectroscopic studies. Lithium and ammonium compounds are one-dimensional in nature, whereas others are layered compounds. These compounds are solid Brönsted acids and undergo room-temperature intercalation reactions with primary *n*-alkylamines and ammonia. The deintercalation of ammonia occurs on heating.

Experimental Section

Synthesis: The high-purity chemicals, A_2CO_3 [A = Li, Na, K, NH_4 (SD Fine, India), Rb, Cs and Tl (Aldrich)] carbonates, phenylphosphonic acid, $C_6H_5PO_3H_2$ (Fluka) and primary *n*-alkylamines, $CH_3(CH_2)_{n-1}NH_2$ (n = 4–9,12,16,18) (Fluka) were used, as purchased, for the synthesis.

$A(HO_3PC_6H_5)(H_2O_3PC_6H_5)$ [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), NH_4 (**6**) and Tl (**7**)] compounds were synthesized, on the scale of 1–2 grams, by evaporating aqueous solutions of stoichiometric reactant mixtures of phenylphosphonic acid and appropriate A_2CO_3 carbonate. Slow evaporation, at room temperature, led to the formation of compounds as colourless flaky crystals. However, evaporation on a steam bath yielded products in polycrystalline form. In all the cases, the yields were almost quantitative. These seven compounds were ascertained to be pure from the analysis of their CHN content, using elemental analyzer, Perkin–Elmer series 11 Model. $C_{12}H_{13}LiO_6P_2$ (**1**) (322.10): calcd. C 44.75, H 4.07; found C 44.29, H 4.11. $C_{12}H_{13}NaO_6P_2$ (**2**) (338.15): calcd. C 42.62, H 3.88; found C 42.75, H 4.04. $KP_2O_6C_{12}H_{13}$(**3**) (354.26): calcd. C 40.70, H 3.70; found C 40.59, H 3.77. $C_{12}H_{13}O_6P_2Rb$ (**4**) (400.63): calcd. C 36.00, H 3.27; found C 36.23, H 3.21. $C_{12}H_{13}CsO_6P_2$ (**5**) (448.06): calcd. C 32.17, H 2.90; found C 32.47, H 2.97. $C_{12}H_{17}NO_6P_2$ (**6**) (333.21): calcd. C 43.20, H 5.14, N 4.20; found C 43.70, H 4.89, N 4.50. $C_{12}H_{13}O_6P_2Tl$ (**7**) (519.56): calcd. C 27.74, H 2.52; found C 27.45, H 2.46.

Intercalation Reactions: Intercalation reactions of *n*-alkylamines with the water-soluble phosphonates, **1**–**7** were carried out under nonaqueous conditions by two methods at room temperature. In the first method, a 4:1 molar reactant mixture of *n*-alkylamine and phosphonate (**1**–**7**), along with 15 mL of *n*-hexane, was stirred for 1.5 days. The solid products were in the form of waxy material. In the second method, the phosphonate (**1**–**7**) was added to excess of liquid *n*-alkylamine ($\approx$ 1:10 molar ratio) and the solid immediately swelled, with the evolution of heat. The reaction mixture was left undisturbed for 7 days. The waxy solid products, in both methods of intercalation reactions, turned out to be dry powders after filtration, washing with *n*-hexane and then air drying. Intercalation of ammonia was achieved by passing ammonia gas for 2 h, over solid phosphonates (**1**–**7**). In summary, all these trials pertain to intercalation of nine amines, $CH_3(CH_2)_{n-1}NH_2$ (n = 4–9, 12, 16, 18), into sodium compound (**2**), intercalation of *n*-octylamine into other six phosphonates and intercalation of ammonia into all seven phosphonates. The amount of intercalated amine/ammonia was determined from the analysis of the carbon and nitrogen contents of the solid intercalates, **2**·$[CH_3(CH_2)_{n-1}NH_2]_x$, **1**–**7**·$(C_8H_{17}NH_2)_x$, and **1**–**7**·$(NH_3)_x$.

Ammonia Deintercalation: Ammonia deintercalation of sodium compound intercalate, **2**·$(NH_3)_{1.2}$ was carried out by heating the sample in air-oven at 170 °C over a period of 12 h.

X-Ray Diffraction and Crystal Structure: The powder X-ray diffraction (XRD) patterns of the compounds **1**–**7** and their intercalation products were recorded on XD-D1 X-ray diffractometer, Shimadzu, using Cu-K_α (λ = 1.5406 Å) radiation. Thin plate-like single crystals, suitable for X-ray diffraction, were selected and mounted with glue, on thin glass fibers in the case of compounds **2** and **4** and in glass capillaries along with the mother liquor, for other five compounds. The X-ray data were gathered successfully from the crystals of only four compounds, **1**, **2**, **5** and **6**, at 25 °C, on an ENRAF-NONIUS CAD4 automated four-circle diffractometer, by the standard procedures involving ω-2θ scan techniques. There was no decay of crystals during X-ray data collection. Empirical absorption corrections, based on psi-scans, were applied to the data sets of **1** and **2** only. In the case of **5** and **6**, these corrections were not applied because of abnormal shape and bigger size of the crystals employed. These data sets were reduced by routine computa-

tional procedures. The structure solution and refinements were carried out by the program[27] SHELXL-97 and the graphic program[28] DIAMOND was used to draw the structures. The structure solutions were obtained by direct method and all the non-hydrogen atoms were refined anisotropically. The non-hydrogen atom content in the asymmetric unit does not account for charge neutrality and thus indicates the presence of three acidic protons of two phenylphosphonic acid moieties. These acidic hydrogen atoms were located in the difference Fourier maps and refined with riding model restraints. The phenyl hydrogen atoms were introduced in the calculated positions and refined isotropically. The ammonium hydrogen atoms of compound **6** were similarly located in the difference Fourier map and refined with riding model restraints. The structure refinement proceeded smoothly for **1** and **2**. In the case of **6**, the final difference Fourier map showed no residual peak with electron density of > 1 e/Å^3 and the final R value was ca. 12%. Absorption correction, based on the isotropically refined model, was applied to the X-ray data using the program DIFABS[29] and R value had come down to ca. 6.2%. Similar absorption correction was applied to the X-ray data of cesium compound **5**. The ten peaks with electron density of > 1 e/Å^3 found in the final difference Fourier map, were ghosts. The final R value was ca. 8.6% and the crystal structure of **5** is, nevertheless, qualitatively correct. The pertinent crystallographic data of **1**, **2** and **6** are presented in Table 2. CCDC-276185 (for **1**), CCDC-276186 (for **2**) and CCDC-276187 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

For lithium compound **1**, an alternate triclinic unit cell, with a = 5.4561(8), b = 10.209(2), c = 15.235(3) Å, α = 98.03(2), β = 91.17(2), γ = 122.2(2) ° and V = 706.4(2) Å^3, is possible. However, our choice was based on the least deviation of unit cell angles from the value of 90°. The crystals of the remaining four compounds were good enough for only the determination of their triclinic unit cell parameters, listed below.

3: a = 5.861(3), b = 7.865(3), c = 16.45(1) Å, α = 96.77(4), β = 97.57(9), γ = 94.82(5)°, V = 742.7(8) Å^3.

4: a = 5.9183(5), b = 7.9212(9), c = 16.860(2) Å, α = 96.948(5), β = 93.352(2), γ = 94.519(9)°, V = 771.0(2) Å^3.

5: a = 6.16(1), b = 7.650(7), c = 16.96(2) Å, α = 97.38(7), β = 97.7(1), γ = 93.9(1)°, V = 775.5(6) Å^3.

7: a = 5.946(9), b = 7.999(3), c = 17.11(6) Å, α = 90.1(5), β = 107.6(2), γ = 99.9(2)°, V = 763(4) Å^3.

Spectroscopic Data: The infrared spectra in the range 400 to 4000 cm^{-1}, were measured with a Bruker IFS 66V FT-IR spectrometer. The samples were ground with dry KBr and pressed into transparent discs for infrared spectroscopic study. Solid-state nuclear magnetic resonance (NMR) experiments were performed with magic angle spinning (MAS) with Bruker DSX 300 and Avance 400 series spectrometers with the spinning frequency of 7.0 kHz and recycle delay times of 2 and 5 s for ^{31}P and ^{13}C, respectively. The first instrument operated at resonance frequencies of 121.5 and 75.5 MHz with the pulse lengths of 4.75 and 3.0 μs for ^{31}P and ^{13}C, respectively. Similarly resonance frequencies of 162 and 100.5 MHz with the pulse lengths of 5.0 and 5.0 μs for ^{31}P and ^{13}C, respectively, were employed in the second one. Chemical shifts were referenced to an external standard of 85% H_3PO_4 for ^{31}P and glycine for ^{13}C.

Thermal Analysis: Thermogravimetric analytical data were collected with a Netzsch STA 409C instrument. The samples were heated to 1000 °C at a rate of 10 °C per minute under a stream of nitrogen gas.

Acknowledgments

We gratefully acknowledge the financial support (Project No: 98/37/29/BRNS) received from the Board of Research in Nuclear Sciences, Government of India. We thank the Sophisticated Analytical Instrumentation Facility of our institute for single-crystal X-ray data and Sophisticated Instrument Facility of Indian Institute of Science, Bangalore for solid-state NMR spectroscopic data. We acknowledge the help of Mr. Y. Ram Sai in the isolation and structural characterization of $Na(HO_3PC_6H_5)(H_2O_3PC_6H_5)$.

Polymorphism Driven by π–π Stacking and van der Waals Interactions: Preparation and Characterization of Polymorphic Vanadium Crystals of $[V^{V}O(Hacshz)(OEt)]$ and $[V^{IV}(Hacshz)_2]$

Yinshi Jin[a] and Myoung Soo Lah*[a]

Keywords: Crystal engineering / Pi interactions / Polymorphism / Supramolecular chemistry / Vanadium

Polymorphic mono-oxo mono-alkoxo square-pyramidal $[V^{V}O(Hacshz)(OEt)]$ (where $Hacshz^{2-}$ is a doubly deprotonated dianionic acetylacetosalicylhydrazone; thick plate-shaped dark-greenish-brown crystals for **1a** and block-shaped dark-reddish-brown crystals for **1b**) and mononuclear trigonal-prismatic $[V^{IV}(Hacshz)_2]$ (block-shaped dark-bluish-brown crystals for **2a** and triangular-shaped dark-violet crystals for **2b**) were synthesized and characterized. The crystals were prepared by simple addition of vanadium(III) acetylacetonate to an ethanol solution of salicylhydrazide (H_3shz). Depending on the ratio of the ligand to the metal ion, the extent of exposure to molecular oxygen, and the filtration of the intermediate, various polymorphs could be obtained as both mixtures and pure forms. A common π–π stacked dimeric species was observed in both polymorphs **1a** and **1b**. The dimeric species behaves as a common repeating motif, but in different interaction modes. A second type of π–π interaction, in addition to van der Waals interactions, was observed in crystals of **1a**, while only van der Waals interactions were observed in crystal **1b**. Another type of π–π-stacked dimeric vanadium(IV) species again behaves as a repeating motif in crystals of **2a** and **2b**, but in different interaction modes. The thermal properties, such as the decomposition behavior and melting points, of the two different polymorphs of the same vanadium complexes are very similar but not identical.

Introduction

Crystal engineering and supramolecular chemistry are the planning and construction of the structure and properties of materials using relatively weak interactions such as hydrogen bonding,[1] van der Waals interactions,[2] dipole interactions,[3] π–π stacking interactions,[4] and coordination[5] by appropriate design of the molecular building units. Understanding these weak intermolecular interactions is important to comprehend the factors governing crystal engineering and supramolecular chemistry. The building units are arranged into crystalline materials or supramolecular entities as a result of the accumulation of several weak intermolecular interactions. Relatively strong and directional hydrogen-bonding interactions and partly directional π–π stacking interactions are most commonly utilized for rational design in crystal engineering and supramolecular chemistry.[6] Nondirectional van der Waals and dipole interactions are also used to orient molecules in crystals or in solution.[7] It is usually very difficult to utilize these weak intermolecular interactions in rational design because these different types of interactions act together in a concerted rather than in a separate way, so the prediction of the desired structure is often impossible.

Polymorphism − the different packing arrays of the same building units − is frequently found in crystalline materials of some organic and inorganic complexes.[8] This phenomenon is of interest because it utilizes the different intermolecular interactions of the same structural entity for the formation of different polymorphs and, therefore, understanding their role in polymorphism can be utilized for molecular and/or crystal design. There are many examples of polymorphs involving hydrogen-bonding interactions together with other weak interactions.[9] However, only a few examples are known where π–π stacking interactions without hydrogen-bonding interactions play the major role in the formation of different polymorphic crystals.[10] π–π Stacking interactions have been recognized in solid state and supramolecular design, and have been utilized in many research areas such as molecular conductors,[11] molecular machines,[12] and electronics.[13]

Recently, we reported the synthesis and characterization of the mono-oxo mono-alkoxo square-pyramidal vanadium(V) complex $[VO(Hacshz)(OEt)]$.[14] During our investigation of this complex, we identified a polymorphism phenomenon where the building unit is arranged in different packing interaction modes. In addition, we isolated $[V^{IV}(Hacshz)_2]$ as an intermediate or side product, which also appeared in two different packing modes. In both com-

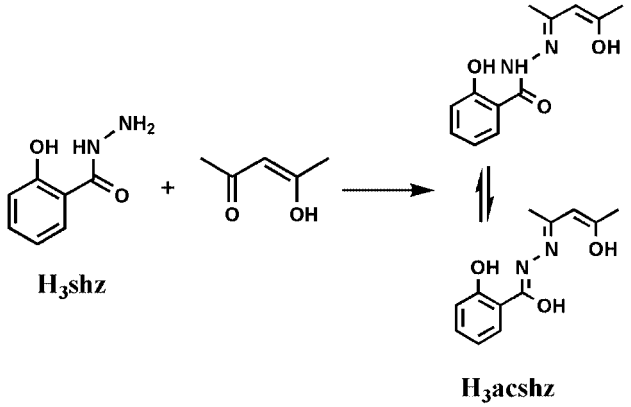
plexes, the intermolecular interactions involved are only π–π stacking and van der Waals interactions, with no hydrogen-bonding interactions. Thus, these complexes could serve as simplified model systems in which the complexity of combined interactions is reduced to only two kinds in polymorphic crystal packing. Here, we report the synthesis and characterization of the polymorphic mono-oxo monoalkoxo square-pyramidal vanadium(v) complex [VO(Hacshz)(OEt)] (**1**) and the mononuclear trigonal-prismatic vanadium(iv) complex [V(Hacshz)$_2$] (**2**). Various π–π stacking interaction modes of the same motif, acetylacetosalicylhydrazone, are presented and discussed.



Scheme 1.

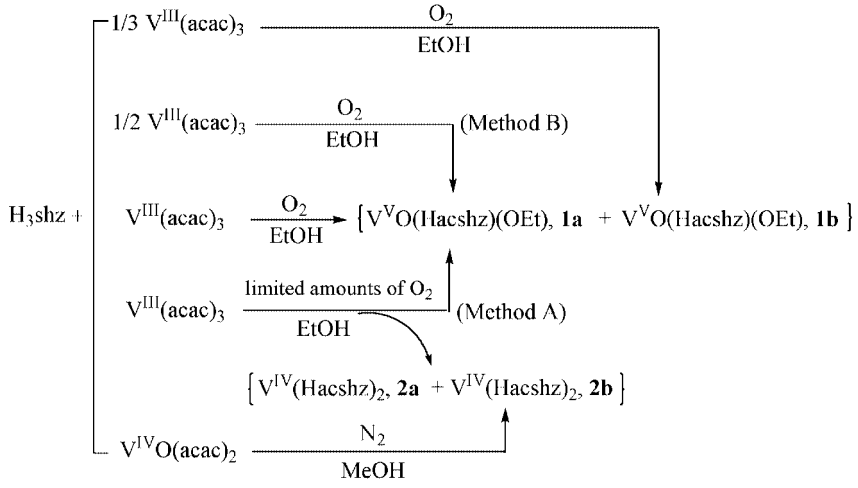
Results and Discussion

Preparation and Characterization of Polymorphic Vanadium Crystals

The vanadium(v) complex [V^{V}O(Hacshz)(OEt)] (**1**) was prepared following a reported method.[14] The complex was synthesized by simple addition of one equivalent of vanadium(iii) acetylacetonate to an ethanol solution of H_3shz in a beaker in air; Hacshz^{2-} was formed by the Schiff-base condensation reaction of H_3shz with acetylacetonate in situ (Scheme 1). In repeated experiments under exactly the same conditions, we noticed that the products were a mixture of two slightly different shaped and colored crystals, namely thick, plate-shaped, dark-greenish-brown crystals (**1a**) and block-shaped, dark-reddish-brown crystals (**1b**; Scheme 2). The IR spectrum of **1a** is very similar to that of **1b**, but not identical. The characteristic V=O stretching band is observed at 998 cm^{-1} for **1a** but at 1001 cm^{-1} for **1b**. The crystals also have different physical properties: **1a** melts in the range 115.1–116.9 °C while **1b** melts over a slightly higher temperature range (117.2–118.8 °C). Complexes **1a** and **1b** are indistinguishable in solution, as expected. The ^{1}H NMR spectrum of **1a** in chloroform is identical to that of **1b**.

When the reaction was performed under the same conditions but in a closed 30-mL vial, a crystalline precipitate of **2** formed within a day. Complex **2** was filtered off, and, on standing, the filtrate produced only crystals of **1a**. Complex **2** was confirmed to be [V^{IV}(Hacshz)$_2$], which has no oxo group and two dianionic Hacshz^{2-} ligands per vanadium(iv) ion. In the presence of limited amounts of oxygen, the vanadium(iii) ion is oxidized to the vanadium(iv) complex. Complex **1a** could also be obtained as the sole product with a 2:1 ratio of H_3shz and vanadium(iii) acetylacetonate in ethanol solution in the presence of enough oxygen. Surprisingly, **1b** was obtained as the sole product with a 3:1 ratio of H_3shz and vanadium(iii) acetylacetonate, while a mixture of **1a** and **1b** was obtained with a 1:1 ratio of H_3shz and vanadium(iii) acetylacetonate. It is not clear why different polymorphs are obtained with different amounts of metal ions.

The mononuclear vanadium(iv) complex **2** was obtained when the amount of oxygen was limited. Careful examination of the crystalline precipitate **2** revealed two types of crystalline material, namely block-shaped, dark-bluish-brown crystals (**2a**) as a major species and triangular-



Scheme 2.

shaped, dark-violet crystals (**2b**) as a very minor species. Complex **2b** is identical to the previously reported crystal structure of $[V^{IV}(Hacshz)_2,]$, which was prepared from H_3shz and vanadyl(IV) acetylacetonate in methanol under nitrogen.[16] Magnetic susceptibility measurements of **2a** (μ_{eff} = 1.80 μ_B after a diamagnetic correction with Pascal's constants) suggest that the complex contains a paramagnetic d^1 vanadium(IV) ion.

Crystal Structure of $[V^{V}O(Hacshz)(OEt)]$ (1)

The molecular structure of **1a** is very similar to that of the previously reported square-pyramidal dialkoxo-bound monooxo-vanadium(V) complex **1b** (Table 1).[14] An ORTEP drawing of **1a** is shown in Figure 1. $Hacshz^{2-}$ serves as a tridentate ligand to form five- and six-membered chelating rings. An ethoxide anion occupies the remaining basal site of the square-pyramidal oxovanadium(V) center.

Table 1. Bond lengths [Å] and bond angles [°] for **1a** and **1b**.

	1a	1b		1a	1b
V1–O1	1.589(1)	1.582(1)	V1–O4	1.863(1)	1.862(1)
V1–O3	1.930(1)	1.939(1)	V1–N2	2.073(1)	2.096(1)
V1–O5	1.766(1)	1.749(1)

O3–V1–N2	74.97(4)	74.81(5)	O5–V1–O4	99.36(5)	99.28(5)
O4–V1–N2	84.10(5)	83.39(5)	O5–V1–N2	151.30(5)	151.08(6)

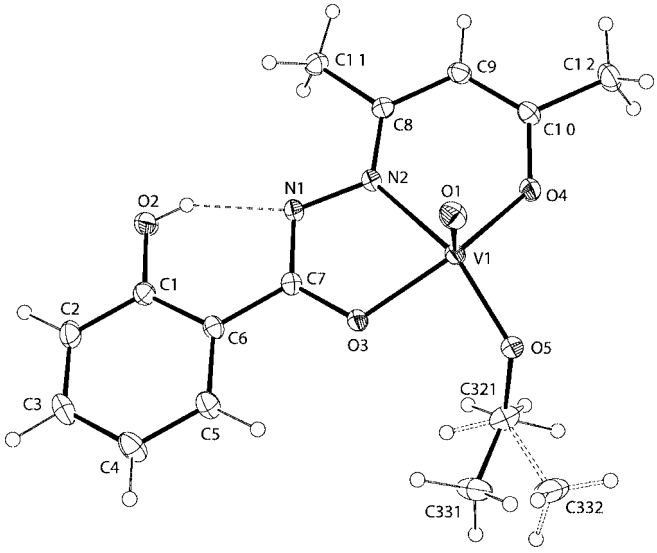

Figure 1. ORTEP drawing of complex **1a**. The minor part of the disordered ethoxide is represented by broken lines.

The packing of **1a** (Figure 2, a) is quite different from that of **1b** (Figure 3, a). In **1b**, the π–π stacked dimeric species (Figure 3, parts a and b) interact only through van der Waals interactions to form a three-dimensional crystal

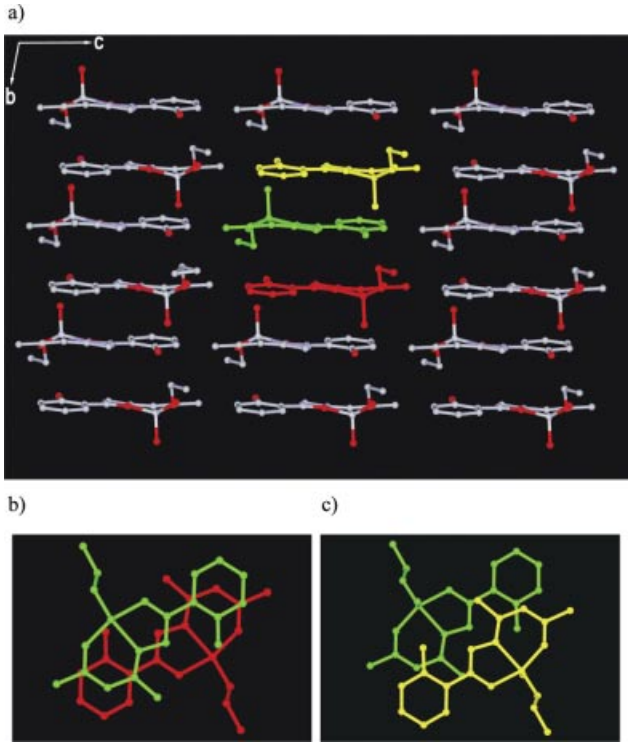

Figure 2. (a) Packing of **la**. The alternation of two types of π–π stacking interactions forms a one-dimensional chain. Only van der Waals interactions are observed between the π–π stacked one-dimensional chains. (b) Type I: the π–π stacking interaction is between the phenoxy and acetylacetohydrazone groups. (c) Type II: the π–π stacking interaction is similar to that of type I but slightly displaced.

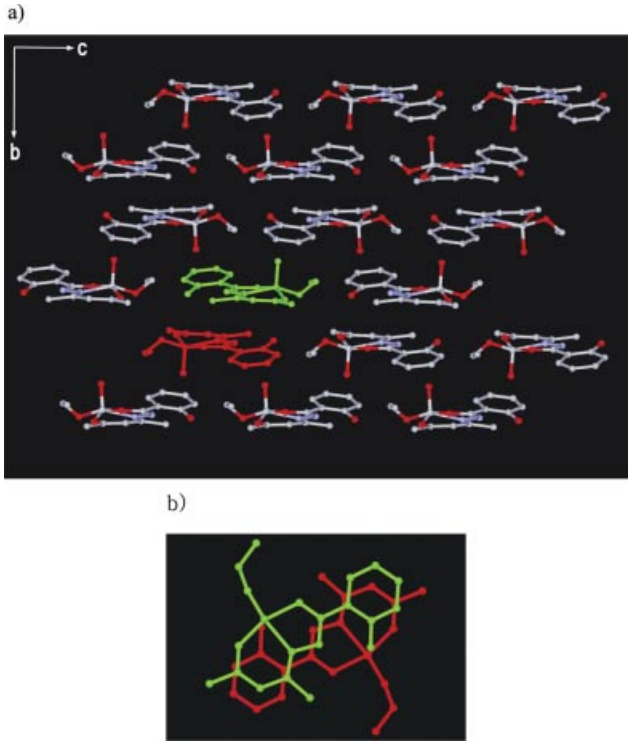

Figure 3. (a) Packing of **lb**. The three-dimensional structure is formed by van der Waals interactions between the π–π stacked dimeric species. (b) Type-I π–π stacking interaction.

structure. A π–π stacking interaction (type I) between the phenoxy group and the conjugated acetylacetohydrazones [N1···C7 = 3.300(2), C6···C10 = 3.315(3), C2···C8 = 3.350(2) Å] is observed in the dimeric species (part b in Figure 3 and Table 2). An additional close contact between the vanadium atom and the symmetry-related O2 atom [3.190(2) Å] is also observed.

In **1a**, two different types of π–π stacking interactions are seen. The first type of π–π stacking interaction (type I) is the same as that found in **1b** (parts b in Figure 2 and Figure 3, and Table 2). The only difference in both dimeric species is in the conformation of the ethoxide groups. The dimeric species in crystal **1a** interacts with two neighboring dimeric species to form a one-dimensional chain through a second type of π–π stacking interaction (type II). The type II interaction is similar to that of type I, but slightly displaced (part c in Figure 2 and Table 2). The type II stacking interaction [C1···C9 = 3.442(2), C7···C11 = 3.453(2) Å] is longer than the type I interaction. In **1a**, the one-dimensional chains connect by alternating the two types of π–π stacking interactions to form a three-dimensional crystal structure containing van der Waals interactions (Figure 2, a).

Crystal Structure of $[V^{IV}(Hacshz)_2]$ (2)

The molecular structure of **2a** is also very similar to that of **2b**. As in **2b**, **2a** has a trigonal-prismatic coordination sphere with pseudo-C_3 symmetry (Figure 4 and Table 3). The bite distances of the prismatic edges formed by the two five-membered chelating bidentate ligands are 2.417(3) Å for O3a···N2a and 2.406(3) Å for O3b···N2b; the bite angles are 75.3(1)° for O3a–V1–N2a and 74.6(1)° for O3b–V1–N2b. The length of the remaining prismatic edge formed by the two alkoxo atoms (O4a···O4b) is 2.505(2) Å, and the O4a–V1–O4b angle is 80.8(1)°. The twist angles[17] determined by the relative orientation of two opposite triangular faces are 4.3° for **2a** and 4.6° for **2b**.

Even though the molecular structure of **2a** is very similar to that of **2b**, the packing of **2a** is quite different to that of **2b**. In **2a**, two different types of π–π stacking interactions (types III & IV) are observed, as in the crystal structure of **1a**. The third type of π–π stacking interaction (type III) is seen between the salicylhydrazones [C2b···C2b = 3.511(5), C1b···C7b = 3.557(5) Å; part b in Figure 5 and Table 2]. As

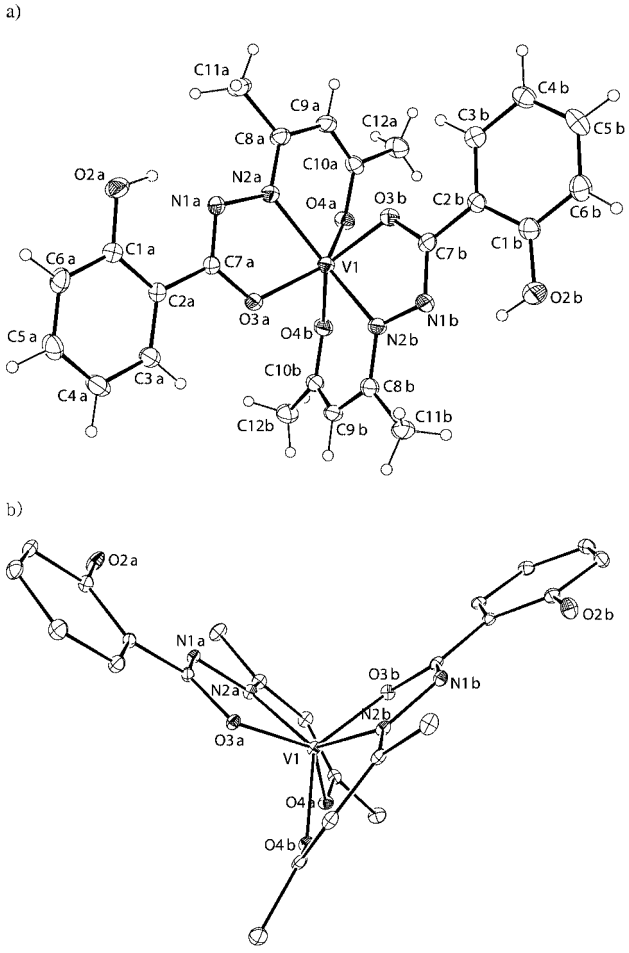

Figure 4. (a) ORTEP drawing of complex **2a** with numbering Scheme. (b) View showing the pseudo-C_3-symmetric trigonal-prismatic coordination geometry of the vanadium center.

in **1a**, the π–π stacked dimeric species formed interacts with two neighboring dimeric species to form a one-dimensional chain through the fourth type of π–π stacking interaction (type IV). The type IV interaction is again longer than the type III interaction [C2a···C7a = 3.478(5), C5a···C8a = 3.624(5) Å; Figure 5 (c) and Table 2]. The one-dimensional chains connect through two types of π–π stacking interactions to form a three-dimensional structure containing van der Waals interactions.

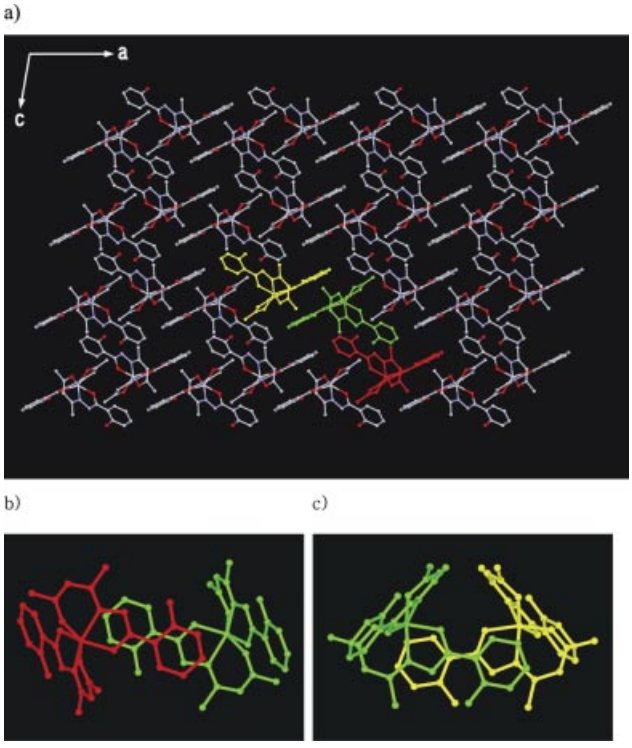

Figure 5. (a) Packing of **2a**. (b) Type-III π–π stacking interaction. (c) Type-IV π–π stacking interaction.

The same type III interaction is also observed in the packing of **2b** (Figure 6, b). However, the same π–π stacked dimeric species formed by the type III interaction is connected by a different type of π–π stacking interaction (type V) with the neighboring dimeric species to form a one-dimensional chain in **2b** (Figure 6, a and c).

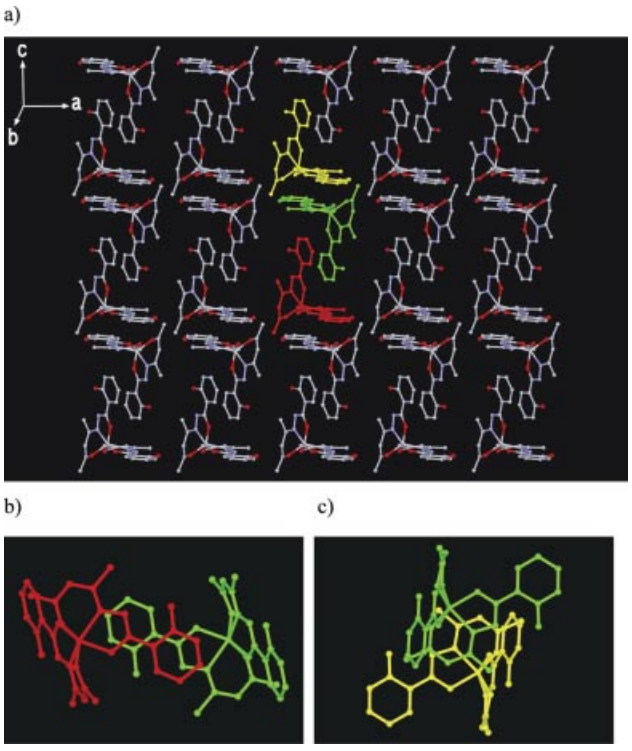

Figure 6. (a) Packing of **2b**. (b) Type-III π–π stacking interaction. (c) Type-V π–π stacking interaction.

Thermal Stability

The TGA and DSC data for polymorphic vanadium crystals **1a**, **1b**, **2a**, and **2b** were obtained in air. The data for **1a** indicate multistage weight loss with the related endotherms and exotherms (Figure 7, a). The first weight loss, related to the first endotherm near 106 °C, can be assigned as the loss of about one equivalent of water (found: 4.97%; calcd.: 4.95%). Even though no water molecules were observed in the crystal structure, water molecules in air are probably physisorbed on the surface of **1a**.[18] The second endotherm near 116 °C, with no weight loss, is assigned to the melting of **1a**. This assignment was also supported by the melting point measurement of a crystal of **1a**. Additional multistage weight loss was observed between 125 and 500 °C. At least four exotherms in the DSC could be related to weight loss in the TGA. However, the decomposition pattern of **1a** could not be followed in detail due to overlapping decomposition steps. The TGA and DSC data for **1b** also indicated multistage weight loss with related endotherms and exotherms (Figure 7, b). The first weight loss occurs near 108 °C and can also be assigned to the loss of about one equivalent of water (found: 5.03%; calcd.: 4.97%). The second endotherm near 118 °C is again assigned to the melting of crystal **1b**. Similar multi-step weight loss and related exotherms are observed to those in crystal **1a**. The thermal properties of the polymorphs are very similar to each other, but not identical. The melting point of crystal **1b** is slightly higher than that of crystal **1a**, even though only one type of π–π stacking interaction is observed in crystal **1b**, while a second type of π–π stacking interaction is also observed in crystal **1a**.

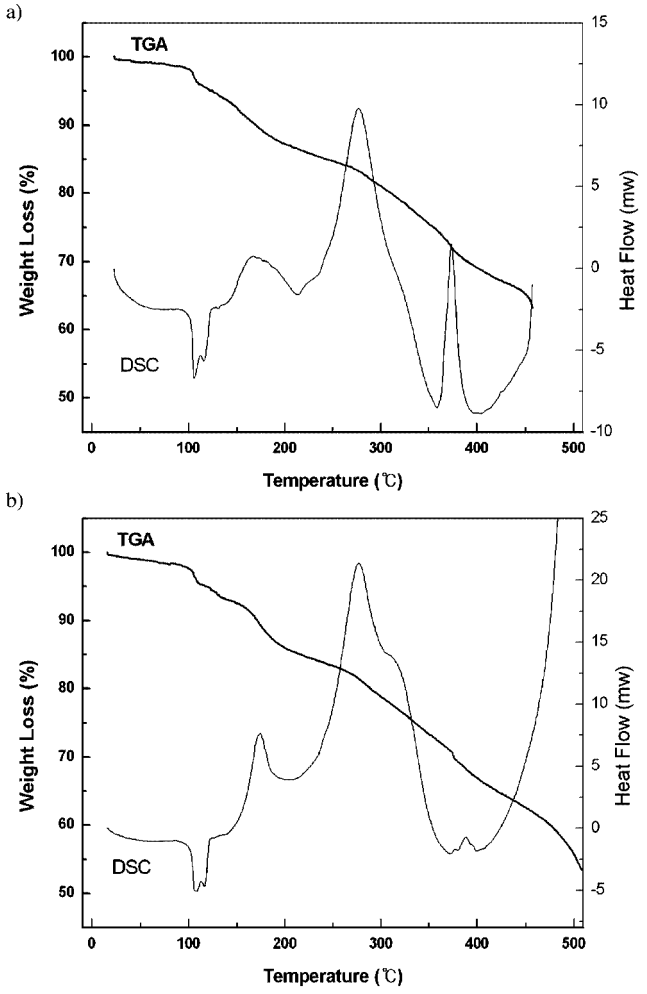

Figure 7. TGA and DSC curves for (a) crystals of **1a** and (b) crystals of **1b**.

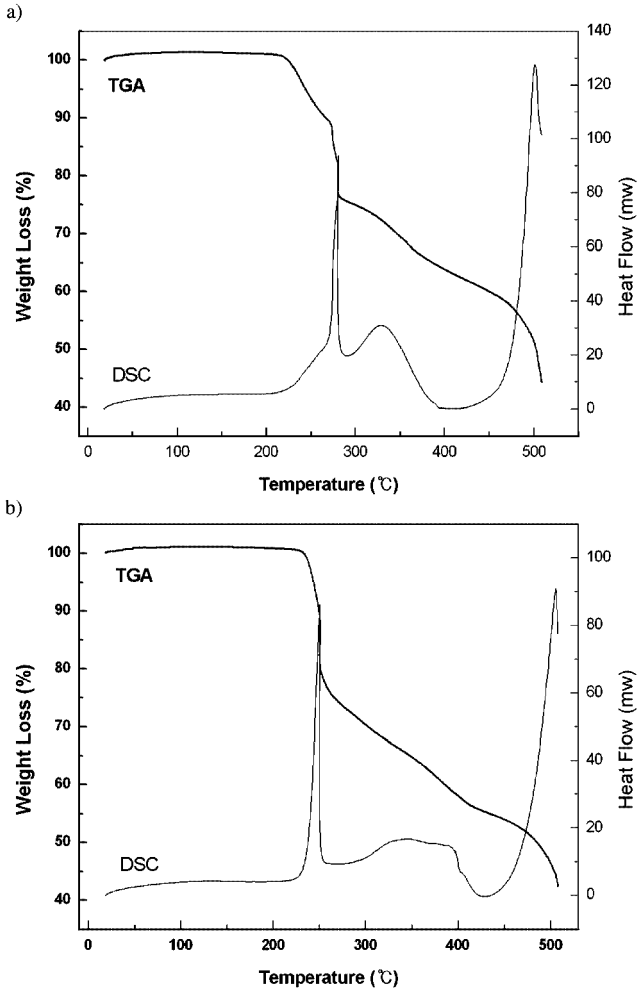

Figure 8. TGA and DSC curves for (a) crystals of **2a** and (b) crystals of **2b**.

The TGA and DSC data for **2a** and **2b** do not show any indication of weight loss or phase transition up to about 200 °C (Figure 8). Crystal **2a** starts an (at least) four-step weight loss around 220 °C (Figure 8, a). The TGA and DSC data for **2b** are also similar to those of crystal **2a**, but not identical (Figure 8, b). Crystal **2b** starts a fast weight loss around 230 °C. The TGA and DSC data for **2a** and **2b** imply that crystals of **2a** and **2b** have slightly different decomposition pathways. The decomposition pattern of crystals **2a** and **2b** could not be followed in detail due to overlapping decomposition steps.

Conclusions

We have prepared two polymorphs of vanadium(IV) and vanadium(V) complexes under slightly different conditions. Depending on the ratio of ligand to metal ion, various polymorphs can be obtained as both mixtures and pure crystal forms. We assume that the extent of exposure to oxygen also affects the formation of polymorphs. The amount of oxygen affects the amount of vanadium(IV) complex in solution, and the precipitation and filtration of the vanadium(IV) intermediate changes the composition of the related species in solution. The mononuclear mono-oxo mono-alkoxo square-pyramidal vanadium(V) complex [$V^{V}O$(Hacshz)(OEt)] (**1**), in two different polymorphs (**1a** and **1b**), was prepared by simple addition of one equivalent of vanadium(III) acetylacetonate to an ethanol solution of H_3shz. The same type of π–π stacking interaction mode (type I) is observed in both polymorphs. This interaction mode results in the very similar dimeric species observed in both polymorphs. While van der Waals interactions between the π–π stacked dimeric species result in polymorph **1b**, a combination of type II interactions and van der Waals interactions between the π–π stacked dimeric species results in polymorph **1a**.

The mononuclear vanadium(IV) complex [V^{IV}(Hacshz)$_2$] (**2**) was obtained as an intermediate or side product in the formation of complex **1** with limited amounts of oxygen, or was alternatively prepared with H_3shz and vanadyl(IV) acetylacetonate in methanol under nitrogen. As in complex **1**, the same (type III) interaction was observed in both polymorphs **2a** and **2b**. This interaction mode again results in the same dimeric species existing in both crystals. Two dif-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ferent types of π–π stacking interactions (type IV and type V) result in two polymorphs (**2a** and **2b**).

The prenucleation step involves the same dominant π–π stacking in solution, and two subsequent nearly isoenergetic packing modes may be the reason for the formation of the two polymorphs in both complexes **1** and **2**.

The thermal properties, such as the decomposition behavior and melting points, of the two different polymorphs of the same vanadium complexes are very similar, but not identical.

Experimental Section

Materials and Instrumentation: The following were used as received with no further purification: salicylhydrazide (H_3shz), vanadium(III) acetylacetonate, [D_6]dimethyl sulfoxide, and [D]chloroform from Aldrich, Inc.; ethanol (EtOH) from Carlo–Erba. The determination of C, H, and N contents was performed at the Elemental Analysis Laboratory of the Korean Institute of Basic Science, Seoul. Infrared spectra were recorded from KBr pellets in the spectral range 4000–600 cm^{-1} with a Bio-Rad FT-IR spectrophotometer. Absorption spectra were obtained with a Shimadzu UV-2401PC spectrophotometer. ^{1}H-NMR spectra were obtained with a Varian-300 spectrometer. Room-temperature magnetic susceptibilities of well-ground solid samples were measured using the Evans method.[15] Melting points of well-ground solid samples were measured with a Sanyo Gallenkamp PLC melting point apparatus. Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) data were obtained simultaneously with a SCINCO STA S-1000.

Synthesis of [V^{V}O(Hacshz)(OEt)] (1): Complex **1** was synthesized following the reported method.[14] H_3shz (0.234 g, 1.53 mmol) was dissolved in 15 mL of ethanol in a 50-mL beaker. One equivalent of vanadium(III) acetylacetonate (0.531 g, 1.52 mmol) was then added to the solution, whereupon the solution changed color to dark brown. After 20 min of stirring, the solution was filtered. Slow evaporation of the filtrate in air over three days produced dark crystals (0.270 g, 51.4%). A mixture of two different colored crystals, with dark greenish-brown crystals as the major component and dark-reddish-brown crystals as the minor component, could be noticed upon careful visual examination. IR data for the mixture: $\tilde{\nu}$ = 1622, 1597, 1543, 1502, 1489, 1432, 1376, 1328, 1305, 1286, 1255, 1158, 1085, 1033, 1000, 954, 916, 825, 791, 761, 717, 696, 662, 600 cm^{-1}.

[V^{V}O(Hacshz)(OEt)] (1a). Method A: H_3shz (0.234 g, 1.53 mmol) was dissolved in 15 mL of ethanol in a 30-mL vial fitted with a cap. One equivalent of vanadium(III) acetylacetonate (0.531 g, 1.52 mmol) was then added to the solution, whereupon the solution changed color to dark brown. The solution was filtered after stirring for 5 min. Dark-bluish-brown crystals of [V^{IV}(Hacshz)$_2$] (**2**) formed from the solution over one day and were filtered off. Allowing the the filtrate to stand for a further three days in a vial gave dark-greenish-brown crystals of **1a**.

Method B: H_3shz (0.234 g, 1.53 mmol) was dissolved in 15 mL of ethanol in a 50-mL beaker. Half an equivalent of vanadium(III) acetylacetonate (0.262 g, 0.752 mmol) was added to the solution, whereupon the solution changed color to dark brown. The solution was filtered after stirring for 5 min. Slow evaporation of the filtrate in air gave dark-greenish-brown crystals of **1a** after three days (0.126 g, 48.6%). [V^{V}O(Hacshz)(OEt)]·H_2O ($C_{14}H_{19}N_2O_6V$; M = 362.26): calcd. C 46.42, H 5.29, N 7.73, V 14.06; found C 46.51, H 5.11, N 8.12, V 14.06. Selected IR bands (KBr): $\tilde{\nu}$ = 1622, 1598, 1545, 1491, 1431, 1385, 1349, 1307, 1288, 1256, 1160, 1086, 1041, 998, 953, 919, 826, 788, 758, 713, 696, 659, 606 cm^{-1}. M.p. 115.1–116.9 °C.

[V^{V}O(Hacshz)(OEt)] (1b): H_3shz (0.234 g, 1.53 mmol) was dissolved in 15 mL of ethanol in a 50-mL beaker. One-third of an equivalent of vanadium(III) acetylacetonate (0.174 g, 0.500 mmol) was then added to the solution, whereupon the solution changed color to dark brown. The solution was filtered after stirring for 5 min. Slow evaporation of the filtrate in air gave dark-reddish-brown crystals of **1b** after four days (0.0554 g, 32.2%). [V^{V}O(Hacshz)(OEt)]·H_2O ($C_{14}H_{19}N_2O_6V$; M = 362.26): calcd. C 46.42, H 5.29, N 7.73, V 14.06; found C 46.74, H 4.98, N 8.14, V 14.50. Selected IR bands (KBr): $\tilde{\nu}$ = 1619, 1599, 1546, 1503, 1490, 1432, 1382, 1346, 1304, 1286, 1254, 1159, 1085, 1035, 1001, 954, 916, 824, 789, 760, 718, 694, 660, 599 cm^{-1}. M.p. 117.2–118.8 °C.

[V^{IV}(Hacshz)$_2$] (2): Two different shaped dark crystals were observed in the precipitate (0.254 g, 32.9%) obtained during the synthesis of **1a** using method A. Most of them were block-shaped, dark-bluish-brown crystals of **2a**, while a few crystals with a different morphology (**2b**) were also noticed. Elemental analysis and spectroscopic analysis were performed with **2a**. V^{IV}(Hacshz)$_2$ ($C_{24}H_{24}N_4O_6V$; M = 515.42): calcd. C 55.93, H 4.69, N 10.87, V 9.88; found C 55.77, H 4.66, N 10.54, V 9.93. Selected IR bands (KBr): $\tilde{\nu}$ = 1623, 1589, 1536, 1485, 1464, 1421, 1375, 1320, 1256, 1159, 1112, 1032, 960, 946, 878, 858, 826, 795, 772, 761, 752, 716, 697, 663, 599 cm^{-1}. Decomposition temperature: 212.6–214.2 °C. μ_{eff} = 1.80 μ_B.

[V^{IV}(Hacshz)$_2$] (2b): Compound **2b** was synthesized following a reported method.[16] H_3shz (0.761 g, 5.0 mmol) was dissolved in 40 mL of anhydrous methanol in a 100-mL round-bottomed flask. Half an equivalent of vanadyl(IV) acetylacetonate (0.663 g, 2.50 mmol) was then added to the solution, whereupon the solution changed color to dark brown. After 40 min of refluxing under nitrogen, the solution was cooled. The deep-purple precipitate formed was filtered off and washed with methanol and hexane (0.661 g, 51.3%). V^{IV}(Hacshz)$_2$ ($C_{24}H_{24}N_4O_6V$; M = 515.42): calcd. C 55.93, H 4.69, N 10.87, V 9.88; found C 55.77, H 4.66, N 10.54, V 11.00. Selected IR bands (KBr): $\tilde{\nu}$ = 1624, 1588, 1536, 1485, 1419, 1376, 1328, 1319, 1256, 1158, 1111, 1091, 1032, 1023, 1013, 961, 945, 878, 858, 825, 794, 772, 762, 752, 717, 705, 696, 663, 599 cm^{-1}. Decomposition temperature: 216.8–217.6 °C.

X-ray Crystallography: Crystals of complexes **1a**, **1b**, **2a**, and **2b** were mounted on a glass fiber. Preliminary examination and data collection were performed using a Bruker SMART CCD Detector single-crystal X-ray diffractometer equipped with a graphite-monochromated Mo-K_α radiation source (λ = 0.71073 Å) equipped with a sealed tube X-ray source operating at –100 °C. Preliminary unit-cell constants were determined from a set of 45 narrow frame scans (0.3° in ω). The data sets collected consisted of 1286 frames of intensity data, collected using a frame width of 0.3° in ω, and a count time of 10 seconds per frame, with a crystal-to-detector distance of 5 cm. The double pass scanning method was used to exclude any noise. The collected frames were integrated using an orientation matrix determined from the narrow frame scans. The SMART and SAINT software packages[19] were used for data collection and integration, respectively. Analysis of the integrated data did not show any decay. The final cell constants were determined using a global refinement of 8192 reflections ($\theta < 25.0°$). Collected data were corrected for absorbance using the SADABS package[20] based upon the Laue symmetry using equivalent reflections. The structural solution and refinement of the structure were carried out

using the SHELXTL v5.1 software package.[21] All non-hydrogen atoms were refined anisotropically. In **1a**, hydrogen atoms were refined isotropically, except for the hydrogen atoms of the disordered ethoxide, which were refined with assigned isotropic displacement coefficients U(H) = 1.2 U(C) or 1.5 $U(C_{methyl})$ on their respective atoms. In **1b** and **2b**, all hydrogen atoms were refined isotropically. In **2a**, hydrogen atoms were refined with assigned isotropic displacement coefficients U(H) = 1.2 U(C) or 1.5 $U(C_{methyl})$ on their respective atoms, except for two phenolic hydrogen atoms, which were refined isotropically. The crystal and intensity data are shown in Table 4.

CCDC-262588 to -262591 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Keywords: Bioinorganic chemistry / Coordination modes / EPR spectroscopy / Peptides / Vanadium

The complexation of $V^{IV}O$ ion with three tripeptides of biological importance containing L-histidine or L-cysteine (HisGlyGly, GlyGlyHis and GlyGlyCys) has been studied. This study was performed in aqueous solution by the combined application of potentiometric and spectroscopic (electronic absorption and EPR) techniques. The results indicate that these oligopeptides, if a ligand-to-metal molar ratio of 10 or 15 is used, can keep $V^{IV}O$ ion in solution until the deprotonation of the amide group with the donor set (NH_2, CO, $N_{im}{}^{ax}$) for HisGlyGly or (COO^-, CO) for GlyGlyHis and GlyGlyCys. In all the systems, at pH values around neutrality, a $VOLH_{-2}$ species is formed with an (NH_2, N^-, N^-, COO^-) donor set for HisGlyGly, (NH_2, N^-, N^-, N_{im}) for GlyGlyHis and (NH_2, N^-, N^-, S^-) for GlyGlyCys. These species, and those with one deprotonated amide group coordinated to the $V^{IV}O$ ion, can be detected by EPR spectroscopy. The N^-(amide) contribution to the hyperfine coupling constant along the z axis, A_z, depends on the total charge of the donor atoms in the equatorial plane. The participation of albumin in the transport of vanadium and insulin-mimetic $V^{IV}O$ compounds is reconsidered based on these results.

Introduction

Vanadium plays a number of roles in biological systems.[1] It is present in vanadium-dependent haloperoxidases[2] and nitrogenase enzymes,[3] and many sea squirts accumulate it in very high concentrations, although the reason for this is not completely known.[4] The most recent studies concern the insulin-mimetic activity of vanadium compounds.[5] All these observations suggest interactions between vanadium ions and proteins.

Peptides are the most closely related models for proteins, and in some cases proteins may have specific terminal metal ion binding sites, for example albumin.[6] Among the various residues, histidine and cysteine play a main role: histidine is involved in the active site of vanadium haloperoxidases[2] and in the metal ion binding to albumin,[6] and the cysteine of glutathione takes part in redox processes such as the reduction of V^V to V^{IV} inside the cell. Moreover, peptide sequences containing cysteine mimic the binding sites of thioneins.

The interaction of $V^{IV}O$ with oligopeptides needs the presence of anchoring groups. Those most effective in promoting peptide amide deprotonation and coordination are phenolate-O^- followed by alkoxide-O^- and thiolate-S^-; COO^- and NH_2 are weaker groups.[7] The first examples of amide deprotonation for vanadium involved exclusively V^V,[8] although since then examples have been characterised for $V^{IV}O$ too, both in solution and in the solid state.[9] Recent results[10] have demonstrated that a histidyl residue in the N-terminal position can act as a valid anchor because the coordination of the amino group is assisted by the imidazole nitrogen. In the absence of suitable groups in the N-terminal position, mixed complexes with the (COO^-, CO) donor set can keep vanadium in solution until amide deprotonation occurs. As a consequence, L/M molar ratios of 10 are enough to favour complexation at physiological pH values.

The speciation of $V^{IV}O$ with HisGlyGly, GlyGlyHis and GlyGlyCys is reported in this work. The ligands are displayed in Scheme 1. GlyGlyHis is a model for albumins [e.g., human serum albumin (HSA), bovine serum albumin (BSA) and rat serum albumin (RSA)], neuromedins C and K, human sperm protamine P2a and histatins.[6] This motif binds Cu^{II} and Ni^{II} specifically, although it can release the metal to appropriate ligands, by playing the role of transport site in albumins. For example, 5–10% of serum cop-

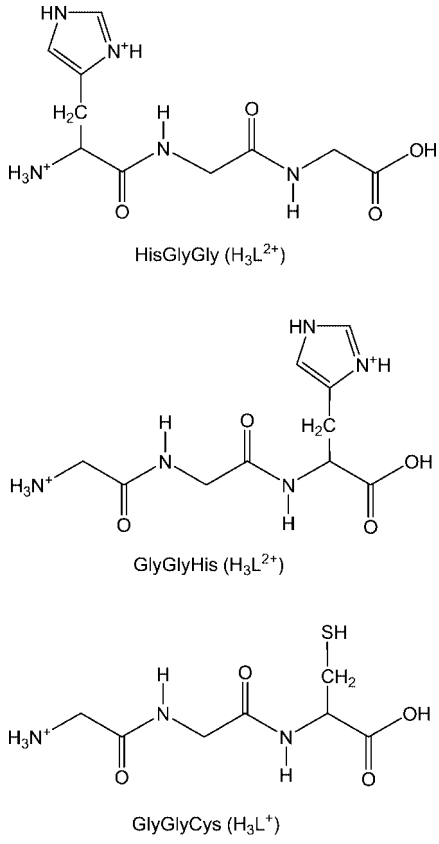
per[11] and 95% of serum nickel is bound to albumin.[12] The Cu^{II} ion can bind albumin in the form of a binary complex or ternary species with amino acids such as histidine.[13]



Scheme 1. Fully protonated forms of the ligands.

The form involved in the transport of vanadium in the human body is still unknown. However, the participation of albumin has been proposed for vanadium transport in blood.[14]

As far as $V^{IV}O$ insulin-mimetic compounds are concerned, the form that reaches target organs (bone, liver, kidney, muscles) is unknown. For many years it was suggested that it could be bound by human serum transferrin (hTF) and that the participation of albumin is negligible.[15] However the data for the $V^{IV}O$–transferrin interaction are quite uncertain, and no reliable thermodynamic data exist on the interaction with albumin. Willsky et al.[16] and Liboiron et al.[17] have reported albumin binding to a well-known insulin-mimetic compound [bis(maltolato)oxovanadium(IV)] (BMOV). The results were explained by the formation of adducts like $[VO(maltolato)_2HSA]$.[17] This suggests that adducts or ternary albumin complexes could be the pharmacologically active species or, at least, the main method of vanadium delivery to cells. However, equilibrium studies on the distribution of an insulin-mimetic complex between hTF and HSA are lacking. In particular, it is important to measure the stability constants for the interaction of albumin with $V^{IV}O$ and $V^{IV}O$ chelates to establish its participation in the transport of vanadium and insulin-mimetic vanadium compounds. GlyGlyHis represents a good model of albumin. Albumin can take part in the transport of insulin-mimetic compounds through: i) formation of binary complexes, such as those proposed for Cu^{II} and Ni^{II},[6] and studied in this work for $V^{IV}O$, and ii) formation of ternary complexes or adducts, such as [VO(maltolato)(HSA)] or $[VO(maltolato)_2(HSA)]$, as proposed by Liboiron et al.[17]

Results

L-Histidylglycylglycine (HisGlyGly)

The potentiometric titration of the ligand (H_3L^{2+}, Scheme 1 and Table 1) indicates three deprotonation steps with pK_a values of 3.10 (COOH), 5.39 ($N_{im}H^+$) and 7.34 (NH_3^+). The values are in good agreement with those reported in the literature.[18] The concentration distribution curves of the $V^{IV}O$ complexes as a function of pH are depicted in Figure 1.

Table 1. Protonation constants (log K) and $V^{IV}O$ (log β_{pqr}) stability constants for the studied ligands and complexes at 25.0 ± 0.1 °C and I = 0.1 M (KNO_3).

log K	HisGlyGly	GlyGlyHis	GlyGlyCys
COOH	3.10	3.26	2.98
$N_{im}H^+$	5.39	6.71	–
NH_3^+	7.34	7.93	7.77

anchoring group due to the binding ability of the imidazole nitrogen. $HisNH_2$, HisGly and HisHis behave as tridentate ligands by coordinating the metal ion through the amino and imidazole nitrogen atoms and the carbonyl oxygen atom.

This speciation process was substantiated by pH-potentiometric titrations (see Experimental Section). Complex formation starts with a $VOLH_2$ species which predominates at pH 3–4 (**I** in Figure 2). To evaluate the "basicity adjusted" stability constant, we assume the following reaction: $VO^{2+} + H_3L^{2+} \rightarrow VOLH_2^{3+} + H^+$. A value of –1.28 is calculated for HisGlyGly, which can be compared with those for GlyGly (–1.43), GlyGlyGly (–1.59),[19] Ala (–1.33),[20] H_2SalGly (–1.29),[9b] H_2sal-RGG (–1.56) and H_2sal-RGGG (–1.51),[9f] for which a pure carboxylate coordination has been substantiated. The EPR parameters (Table 2) support this assignment.

VOLH (**IIa** in Figure 2) is formed upon deprotonation of the amino group, with $g_z = 1.947$ and $A_z = 168 \times 10^{-4}$ cm^{-1}. We compared the EPR spectra with those obtained in the $V^{IV}O$/L-glycine methyl ester (GlyOMe) system at L/M = 500. The stepwise formation of two species was observed, with $g_z = 1.946$, $A_z = 168 \times 10^{-4}$ cm^{-1} and $g_z = 1.951$, $A_z = 163 \times 10^{-4}$ cm^{-1}, respectively.[21] They were identified as VOL and VOL_2, with (NH_2, CO) and [2 × (NH_2, CO)] coordination modes, respectively. The data are also similar to those of mono- and bis-chelated complexes of $V^{IV}O$ with L-histidine methyl ester (HisOMe),[21] $g_z = 1.946$, $A_z = 170 \times 10^{-4}$ cm^{-1} and $g_z = 1.950$, $A_z = 164 \times 10^{-4}$ cm^{-1}. The parameters reported for the mono-chelated complex formed by imidazole-4-acetic acid, with an (N_{im}, COO^-) donor set, are quite different from those observed with HisGlyGly.[22] Therefore, the spectroscopic features of VOLH are typical of an (NH_2, CO) donor set.

The deprotonation of the imidazole N takes place with $pK_a = 4.16$, and VOLH transforms into VOL (**IIb** in Fig-

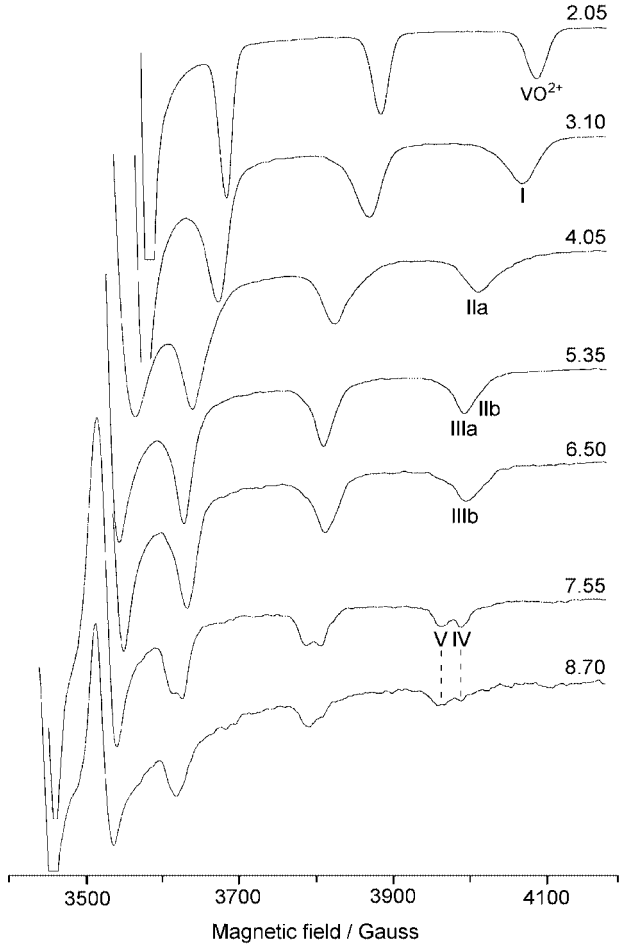

Figure 2. High-field region of the X-Band EPR spectra recorded at 140 K as a function of pH for aqueous solutions of $V^{IV}O$ and HisGlyGly at metal-to-ligand molar ratio of 1:10 and a $V^{IV}O$ concentration of 4 mM. The dotted line indicates the high-field resonance of the complexes with the deprotonated amide group.

Table 2. EPR parameters and donor sets for $V^{IV}O$ complexes.

Ligand	Complex	Symbol[a]	g_z	A_z[b]	Donor set
HisGlyGly	$VOLH_2$	**I**	1.935	177	(COO^-)
	VOLH	**IIa**	1.947	168	(NH_2, CO)
	VOL	**IIb**	1.947	168	(NH_2, CO, N_{im}^{ax})

ure 2). The pK_a value is lower, by one order of magnitude, than in the free ligand because of the coordination of the nitrogen atom. The EPR parameters are the same as VOLH and comparable with those of complexes of dipeptides with histidine in N-terminal position, such as HisGly and HisHis.[10] In a previous work,[10] we suggested a tridentate equatorial-axial-equatorial (*eq-ax-eq*) binding mode of the ligand to explain the similar behaviour of $HisNH_2$, HisGly and HisHis. The two external donor groups (NH_2 and CO) are in the equatorial positions and N_{im} is in the axial position. The "basicity adjusted" stability constant for the reaction $VO^{2+} + HL^+ \rightarrow [VOL]^{2+} + H^+$ is –1.03. This means that the involvement of an imidazole nitrogen as the third donor increases the stability of the species with an (NH_2, CO, N_{im}^{ax}) donor set significantly compared with those of (NH_2, CO) or (COO^-, CO).

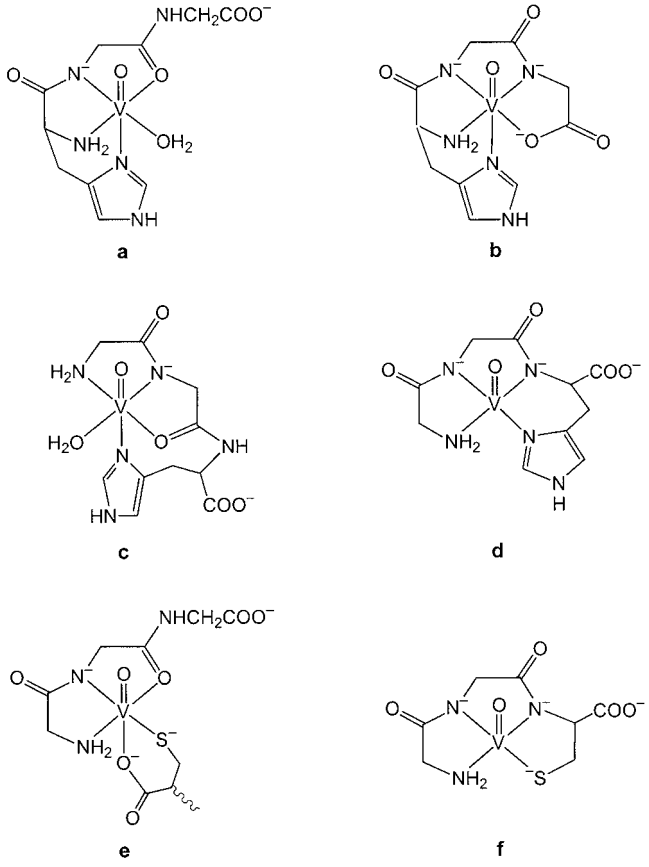
The imidazole N in the axial position of VOL does not affect the A_z value significantly according to the Chasteen "additivity rule", which assumes that only the equatorial donors contribute to the hyperfine ^{51}V constant along the *z* axis.[23]

The bis-complexes VOL_2H and VOL_2 are the major species at pH 5–7. At ligand-to-metal molar ratios as high as 10 for HisGlyGly and 15 for GlyGlyHis and GlyGlyCys, we believe that weak donor sets like (NH_2, CO) can replace monodentate water molecules in the equatorial plane of $V^{IV}O$. In VOL_2H (**IIIa** in Figure 2), only two positions of the equatorial plane are available for the second ligand, therefore the coordination mode is [(NH_2, CO, N_{im}^{ax}); (NH_2, CO)], with the imidazole nitrogen of the second ligand molecule still protonated.

The transformation of VOL_2H into VOL_2 (**IIIb** in Figure 2) takes place upon deprotonation of the $N_{im}H^+$ group. The pK_a of 5.84 is very close to that of the free ligand, suggesting that the aromatic nitrogen of the second ligand molecule does not participate in the coordination. Since the donor set is the same, the same EPR parameters are observed for VOL_2H and VOL_2 (g_z = 1.950, A_z = 164×10^{-4} cm^{-1}), comparable to those of HisGly (g_z = 1.951, A_z = 165×10^{-4} cm^{-1}) and HisHis (g_z = 1.950, A_z = 164×10^{-4} cm^{-1}).[10]

$VOLH_{-1}$ (**IV** in Figure 2 and **a** in Scheme 2) is detected both by potentiometry and EPR spectroscopy at a pH of around 7.5. Its spectral parameters are g_z = 1.950 and A_z = 161×10^{-4} cm^{-1}, and its pK_a value is 7.55. For this species we propose the deprotonation of the first amide group to give a complex with an [(NH_2, N^-, CO, N_{im}^{ax}); H_2O] coordination mode. The axial binding of an imidazole nitrogen stabilises this coordination mode differently from tripeptides lacking coordinating side-chains.

At higher pH values the formation of $VOLH_{-2}$ (**V** in Figure 2 and **b** in Scheme 2) starts. The EPR parameters (g_z = 1.951 and A_z = 159×10^{-4} cm^{-1}) suggest the deprotonation of the second amide bond and an (NH_2, N^-, N^-, COO^-) donor set with four donor atoms in the equatorial positions, analogously to the Cu^{II} ion;[24] hydrolysis processes occur at pH values above 9.



Scheme 2. Structures of $V^{IV}O$ complexes formed by HisGlyGly (a,b), GlyGlyHis (c,d) and GlyGlyCys (e,f) with deprotonated amide groups.

Glycylglycyl-L-histidine (GlyGlyHis)

GlyGlyHis (H_3L^{2+}, Table 1 and Scheme 1) shows three pK_a values in the titrable pH range, 3.26 (COOH), 6.71 ($N_{im}H^+$) and 7.93 (NH_3^+). These values are comparable with those in the literature.[25] Distribution curves are shown in Figure 3 and EPR spectra in Figure 4.

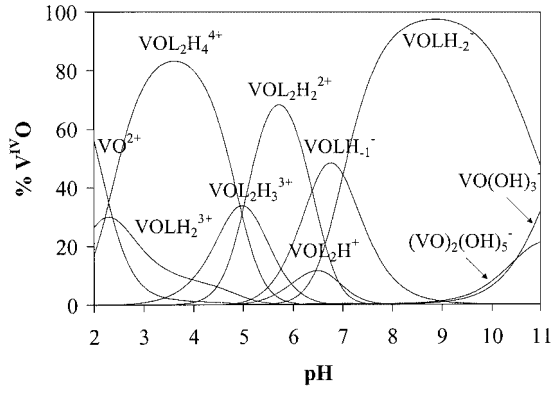


Figure 3. Species distribution for the $V^{IV}O$–GlyGlyHis system at a metal-to-ligand molar ratio of 1:15 and a $V^{IV}O$ concentration of 1 mM.

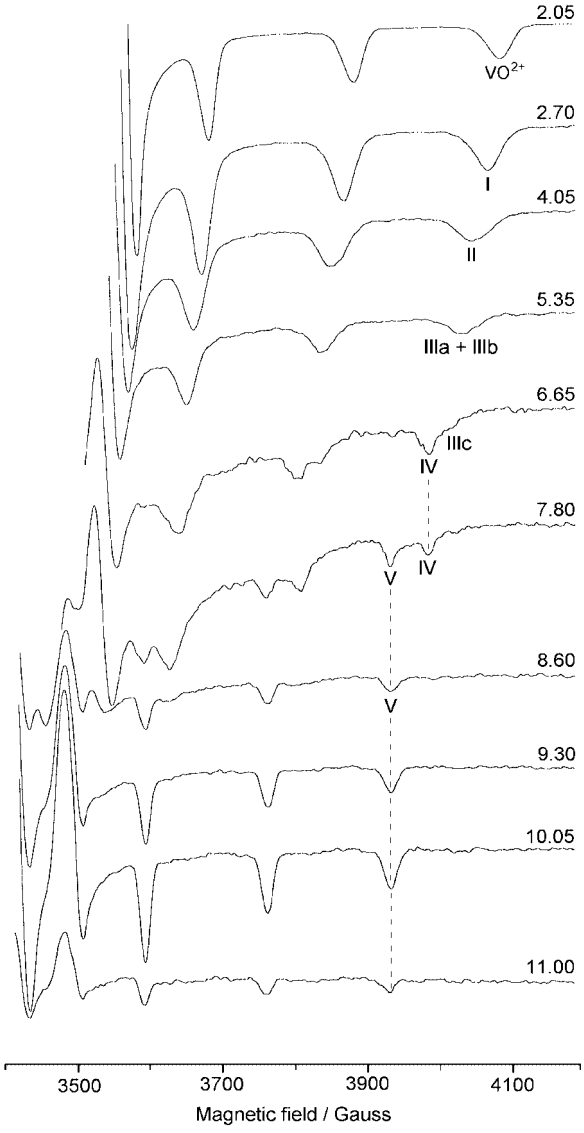

Figure 4. High-field region of the X-Band EPR spectra recorded at 140 K as a function of pH on aqueous solutions of $V^{IV}O$ and GlyGlyHis at a metal-to-ligand molar ratio of 1:15 and a $V^{IV}O$ concentration of 4 mM. The dotted line indicates the high-field resonance of the complexes with the deprotonated amide group.

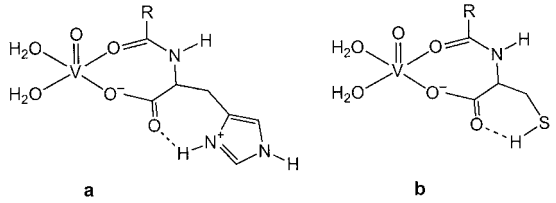
If the N-terminal residue has no coordinating chain donor, the (NH_2, CO) donor set is not a good anchoring group and the (COO^-, CO) donor set is stronger.[10] This supports the spectroscopic results of previous works.[19] In this system the complexation starts with $VOLH_2$ (**I** in Figure 4), similar to the analogous complexes of GlyHis and GlyCys.[10] The "basicity adjusted" stability constant of this complex (–0.46) is somewhat higher than expected for pure carboxylate coordination[26] and indicates extra donors, presumably the amide carbonyl, which closes a seven-membered chelate ring. The EPR parameters (Table 2) are in agreement with recent reports,[9c,9h,10,27a,27b] which attribute hyperfine coupling constants in the range 175–179×10^{-4} cm^{-1} to mono-chelated species. We believe that the formation of an intramolecular hydrogen bond between the carboxylate oxygen and the NH^+ group of imidazole provides an extra stabilisation of this structure (Scheme 3). In fact, this coordination mode is not observed with dipeptides or tripeptides with glycine in the C-terminal part, for example GlyGly,[19] HisGly,[10] GlyGlyGly[19] or HisGlyGly (this work).



Scheme 3. Structures of $VOLH_2$ complexes formed by GlyGlyHis (a) and GlyGlyCys (b).

Around pH 4 a species of composition VOL_2H_4 (**II** in Figure 4) predominates. It can be described as a bis-chelated complex of the [2×(COO^-, CO)] type (Table 2). The two ligands have their amino and imidazole nitrogens still protonated. The EPR parameters are in agreement with the literature data,[9c,9h,10,27a,27b] which report hyperfine coupling constants in the range $171–174 \times 10^{-4}$ cm^{-1} for bis-chelated species.

In VOL_2H_3 (**IIIa** in Figure 4) one of the two ligands has released a proton from the amino group, and the coordination therefore becomes [(NH_2, CO); (COO^-, CO)], with EPR parameters $g_z = 1.945$ and $A_z = 169 \times 10^{-4}$ cm^{-1}, which are intermediate between those of the [2×(COO^-, CO)] and [2×(NH_2, CO)] donor sets.[10]

VOL_2H_2 and VOL_2H (**IIIb** and **IIIc**, respectively, in Figure 4) form from VOL_2H_3 upon deprotonation of the two imidazole rings (pK_a = 5.03 and 6.02, respectively). The coordination mode can be described as [(NH_2, CO); (CO, COO^-)], since the spectral parameters don't change, although an [(NH_2, CO); (N_{im}, COO^-)] donor set cannot be excluded.

The deprotonation of the first amide group leads to $VOLH_{-1}$, which has an [(NH_2, N^-, CO, $N_{im}{}^{ax}$); H_2O] donor set (**IV** in Figure 4 and **c** in Scheme 2). The weak coordination of the imidazole nitrogen in the axial position could stabilise this species.

The deprotonation of the second amide group gives $VOLH_{-2}$ (**V** in Figure 4 and **d** in Scheme 2), with an (NH_2, N^-, N^-, N_{im}) donor set and g_z = 1.960, A_z = 153×10^{-4} cm^{-1}. The difference between this and the $VOLH_{-2}$ complex formed by HisGlyGly is the presence of an imidazole nitrogen instead of a carboxylate group in the fourth equatorial position, which lowers the hyperfine coupling constant. For an (NH_2, N^-, N^-, COO^-) coordination we expect the same parameters observed for $VOLH_{-2}$ of HisGlyGly.

A special comment must be devoted to the different behaviour of GlyGlyHis and GlyGlyGly. We studied the system with GlyGlyGly up to an L/M molar ratio of 20.[21] The complexation process stops at acid pH values with the formation of species with only COO^- coordination. The higher stability of the (COO^-, CO) donor set for GlyGlyHis is responsible for the stabilisation of the mixed species

VOL_2H_3, VOL_2H_2 and VOL_2H, which avoids hydroxide precipitation and promotes the amide deprotonation.

Glycylglycyl-L-cysteine (GlyGlyCys)

With oligopeptides containing L-cysteine the complexation of Ni^{II}, Pd^{II}, Co^{II}, Zn^{II} and Cd^{II} depends strongly on the position of the residue in the peptide and on the "hardness" of the metal ion.[28] $V^{IV}O$ follows the same trend: with CysGly a stable cysteine-like (NH_2, S^-) coordination is favoured and mono [VOA] and bis $[VOA_2]^{2-}$ complexes are formed. On the other hand, with a C-terminal cysteine dipeptide like GlyCys, $V^{IV}O$ promotes the coordination of the deprotonated amide group as with Ni^{II} and Pd^{II}.[24a,24b]

GlyGlyCys (H_3L^+, Table 1 and Scheme 1) shows three pK_a values: at 2.98 (COOH), 7.77 (NH_3^+) and 9.59 (SH), in good agreement with those in the literature.[24a] The species distribution for this system as a function of pH is displayed in Figure 5.

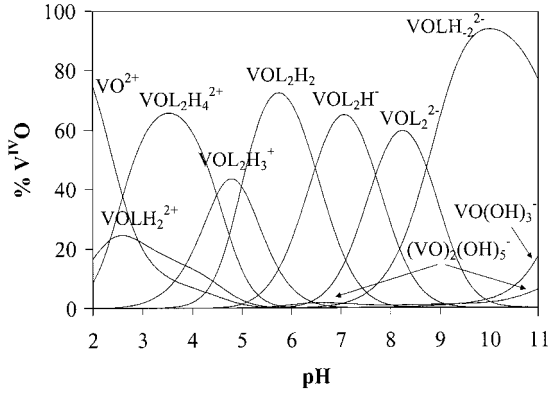

Figure 5. Species distribution for the $V^{IV}O$–GlyGlyCys system at a metal-to-ligand molar ratio of 1:15 and a $V^{IV}O$ concentration of 1 mM.

As with GlyGlyHis, the complexation scheme starts with the formation of $VOLH_2$ (**I** in Figure 6) and VOL_2H_4 (**II** in Figure 6) at pH around 3 and 4, respectively, in strongly overlapping processes. The donor sets are (COO^-, CO) and [2×(COO^-, CO)], respectively, and the EPR parameters (g_z = 1.935, A_z = 176×10^{-4} cm^{-1} and g_z = 1.940, A_z = 171×10^{-4} cm^{-1}) are in good agreement with those of the species formed by 2-mercaptopropionylglycine,[27a] GlyHis and GlyCys,[10] and GlyGlyHis (see above). In both complexes each ligand maintains protonated amino and thiol groups. As for GlyGlyHis, the (COO^-, CO) coordination is stabilised by an intramolecular hydrogen bond between the carboxylate oxygen atom and the SH group of cysteine (Scheme 3).

The consecutive deprotonation of the amino groups gives rise to VOL_2H_3 and VOL_2H_2 (**III** and **IV** in Figure 6) in the pH range 5–7. A mixed [(NH_2, CO); (COO^-, CO)] coordination can be proposed for the first complex and a [2×(NH_2, CO)] coordination for the second. The EPR parameters support this assignment (Table 2). With increasing pH the first SH group undergoes deprotonation and VOL_2H_2 is replaced by VOL_2H (**V** in Figure 6), which is

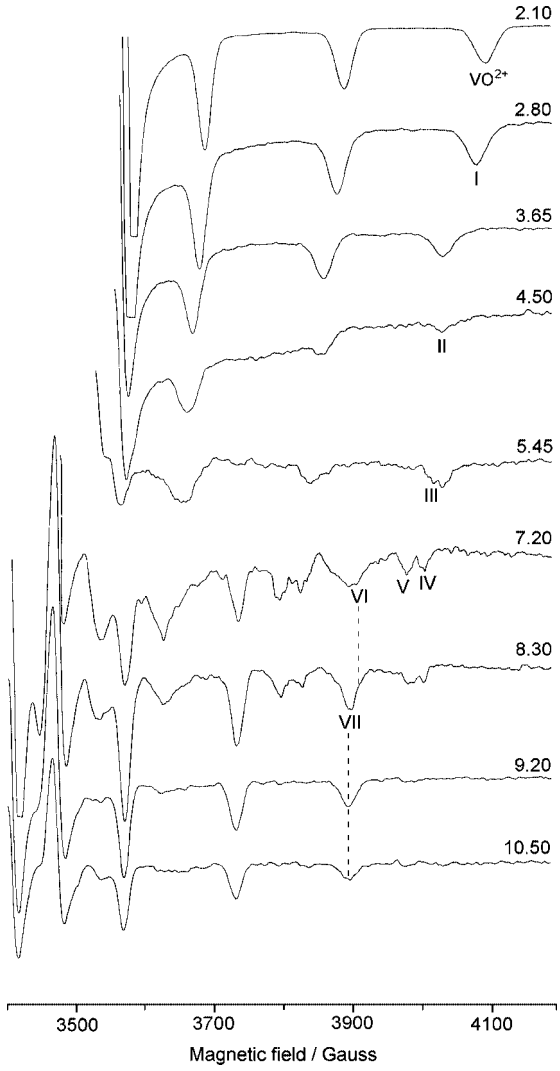

Figure 6. High-field region of the X-Band EPR spectra recorded at 140 K as a function of pH on aqueous solutions of $V^{IV}O$ and GlyGlyCys at a metal-to-ligand molar ratio of 1:15 and a $V^{IV}O$ concentration of 4 mM. The dotted line indicates the high-field resonance of the complexes with the deprotonated amide group.

presumably a complex with a mixed donor set [(S^-, COO^-); (NH_2, CO)]. This conclusion is supported by the EPR parameters (g_z = 1.950, A_z = 160×10^{-4} cm^{-1}), which are intermediate between those of [2×(NH_2, CO)] and [2×(S^-, COO^-)] and similar to those of the analogous species with GlyCys.[10]

Upon deprotonation of the first amide group the coordination of the first ligand molecule switches from (NH_2, CO) to (NH_2, N^-, CO) and VOL_2, with the donor set [(NH_2, N^-, CO); (S^-, COO^{-ax})], is formed (**VI** in Figure 6 and **e** in Scheme 2). Its spectral parameters (Table 2) are consistent with our expectations, as will be discussed later.

At pH values above 8 potentiometry suggests a $VOLH_{-2}$ species, which is explainable by the deprotonation of the second amide group and the coordination of an S^- donor (**VII** in Figure 6 and **f** in Scheme 2). The EPR parameters, g_z = 1.967, A_z = 148×10^{-4} cm^{-1}, are consistent with an

(NH_2, N^-, N^-, S^-) coordination mode, which is also observed with Ni^{II}.[28a]

Discussion

The Chasteen "additivity rule" is a powerful tool to estimate the ^{51}V hyperfine constant along the z axis of $V^{IV}O$ complexes and is based on the individual contribution to A_z from the four equatorial donors.[23] This rule provides a valid criterion for the identification of the equatorial donor atoms. Data for the contribution of amino and imidazole nitrogen atoms and for thiolate group were taken from Chasteen's publication.[23] For carboxylate, the value of 42.1×10^{-4} cm^{-1} reported by Kiss and Costa-Pessoa was chosen.[27a] The mean value for a neutral oxygen atom belonging to an amide CO group is 43.5×10^{-4} cm^{-1}.[29]

The amide contribution, A_z(amide), is in the range 29–43×10^{-4} cm^{-1},[30] and is sensitive to the charge of the coordination sphere. We have demonstrated previously that this contribution decreases with an increased donation of electron density from the ligands to the $V^{IV}O$ ion.[10] In particular, we found that if the total charge of the donor atoms in the equatorial plane (TEC) is –2, –3 or –4 (including the –1 charge of the deprotonated peptide nitrogen), the mean A_z(amide) values are 35.3, 38.6 and 40.9×10^{-4} cm^{-1}, respectively, in good agreement with those calculated by Kabanos and Deligiannakis.[9d] We were able to extrapolate the contribution of the amide group when TEC is –1 (32.7×10^{-4} cm^{-1}).[10]

Table 3 is based on these contributions to the value of A_z. If we examine the three fully deprotonated $VOLH_{-2}$ species no ambiguity exists in the coordination mode: two amide groups are deprotonated and three of the four equatorial positions are occupied by amino and two deprotonated amide groups. The fourth position is occupied by three different donors: the carboxylate group in HisGlyGly and the side-chain of the C-terminal amino acid in GlyGlyHis and GlyGlyCys (i.e. the imidazole nitrogen of histidine and the thiolate group of cysteine, respectively; Table 3). This is substantiated by the A_z values of 158.6×10^{-4} cm^{-1} for HisGlyGly, 152.9×10^{-4} cm^{-1} for GlyGlyHis and 147.9×10^{-4} cm^{-1} for GlyGlyCys. The experimental values are very close to the calculated ones, with differences of less than 1%.

A substantially good agreement is also found for the other species involving a deprotonated amide group (Table 3), according to our previous analysis.[10] The structures of the complexes formed by deprotonation of the amide groups are displayed in Scheme 2.

We used the thermodynamic data to evaluate in which form the $V^{IV}O$ ion and $V^{IV}O$ insulin-mimetic compounds are transported in the human body. Given the chemical composition of serum,[31] the two h.m.m. (high molecular mass) metal-ion binders in the serum are albumin and transferrin,[16,17] whilst among the l.m.m. (low molecular mass) constituents, oxalic acid, lactic acid, citric acid and phosphate are the most likely.[15] Detailed studies have been reported on the interaction of $V^{IV}O$ ion with transferrin and albumin.[32]

Human serum transferrin (hTF), a bilobal, single-chain protein, is the main Fe^{III} transport protein in serum. It is responsible for tight, reversible binding of two equivalents of Fe^{III} and binds a variety of other metal ions such as $V^{IV}O$.[33] It has two non-equivalent vanadium binding sites, with different binding constants.[32f,34a,34b] This requires a synergistic anion binding.[33] These sites should correspond to the usual N-lobe and C-lobe binding sites of the protein. An approximate value for the two stability constants ($\log K_1^* = 13.2$ and $\log K_2^* = 12.2$) was reported recently by some of us.[15]

Human serum albumin (HSA), bovine serum albumin (BSA) and rat serum albumin (RSA) share the same structural motif in the N-terminal part of the protein, namely two amino acids with non-coordinating or weakly coordinating side-chains in the first two positions and a histidine residue in the third position (AspAlaHis for HSA, AspThrHis for BSA and GluAlaHis for RSA). This results in an identical chemical and spectroscopic behaviour; for instance, Cu^{II} shows the same electronic[35] and EPR parameters.[36] It has been proposed that this is the site preferred by $V^{IV}O$ too, although there are four or five additional weaker binding sites in the side-chain, namely Asp and Glu carboxylates.[14,32c] The substitution in other mammalian species of the histidine residue in the third position, e.g. Tyr in dog serum albumin (DSA) and Glu in chicken serum albumin (CSA), produces a lack of specific binding to metal ions.[37]

These features, as well as the geometry of the ligand array in the native protein and the nature of the donor groups, were considered in the design of the first model of this structural motif, GlyGlyHis-*N*-methylamide. Moreover, theoretical calculations using energy minimisation show similar conformations for AspAlaHis and GlyGlyHis bound to Cu^{II}.[38] For these reasons, we propose that

Table 3. Coordination modes of $V^{IV}O$ complexes with deprotonated amide groups on the basis of the EPR data.

Ligand	Complex	g_z	A_z exp.[a]	A_z calcd.[a]	Donor atoms
HisGlyGly	$VOLH_{-1}$	1.950	161.1	161.9	[(NH_2, N^-, CO, $N_{im}{}^{ax}$); H_2O]
HisGlyGly	$VOLH_{-2}$	1.951	158.6	159.4	(NH_2, N^-, N^-, COO^-, $N_{im}{}^{ax}$)
GlyGlyHis	$VOLH_{-1}$	1.950	161.4	161.9	[(NH_2, N^-, CO, $N_{im}{}^{ax}$); H_2O]
GlyGlyHis	$VOLH_{-2}$	1.960	152.9	151.4	(NH_2, N^-, N^-, N_{im})

GlyGlyHis is also a good model for the interaction between $V^{IV}O$ and albumin. The structure of Cu^{II}-GlyGlyHis-*N*-methylamide has been solved by X-ray crystallography.[39] Cu^{II} ion is chelated by the NH_2-terminal nitrogen, the next two deprotonated amide nitrogens and a histidyl imidazole nitrogen of GlyGlyHis through an (NH_2, N^-, N^-, N_{im}) donor set in a slightly distorted square-planar arrangement similar to that which we propose for $VOLH_{-2}$ (Table 2), the most relevant form under physiological conditions.

An association constant of 2.6×10^6 M^{-1} has been measured for the N-terminal site of BSA at pH 5, although at physiological pH the corresponding value is thought to be several orders of magnitude higher.[14] No data exist for the interaction with a model system like GlyGlyHis.

Chasteen et al.[32b] have found that transferrin binds $V^{IV}O$ about six times more strongly than albumin in vitro. If we accept Chasteen's assumption that albumin is an efficient binder and apply his estimation [K(hTF)/K(alb) ≈ 6], the calculated biodistribution indicates that only the h.m.m. fraction of the serum (80% albumin and 20% transferrin) binds $V^{IV}O$.[15]

By taking into account the data for the association constants for transferrin,[15] the stability constants of the model ligand for albumin (GlyGlyHis), and the binary systems with oxalate,[40] lactate,[41] citrate[42] and phosphate,[43] the complete distribution of $V^{IV}O$ ion can be calculated for the conditions in the serum. The results are reported in Table 4.

Table 4. Species distribution [%] of the $V^{IV}O$ ion between the components of the blood serum at pH 7.4.[a]

$c_{V^{IV}O}$ [μM]	l.m.m. components	Transferrin	GlyGlyHis
1	0.1	99.7	0.2
10	0.1	99.7	0.2
100	22.0	70.8	7.2

[a] Oxalate = 9.20 μM; lactate = 1.51 mM; citrate = 99.0 μM; phosphate = 1.10 mM; transferrin = 37 μM; GlyGlyHis = 630 μM.

Table 4 reveals that at a $V^{IV}O$ concentration of 1 μM and 10 μM the $V^{IV}O$ ion is almost totally bound to transferrin, with less than 1% bound to albumin. However, at a concentration of 100 μM both albumin and l.m.m binders participate in the transport of $V^{IV}O$ ion, with approximately 7% bound to albumin and about 22% bound to l.m.m. ligands, especially citrate.

This discussion can be extended to the transport of insulin-mimetic compounds. We examined the bis-chelate compounds formed by $V^{IV}O$ ion with maltolato (ma),[44] picolinato (pic) and 6-methylpicolinato (6-Mepic),[45] 3-hydroxy-1,2-dimethyl-4(1*H*)-pyridinone (HDP),[46] 5-methoxycarbonylpicolinic acid (5-MeOpic),[47] 2-hydroxypyridine *N*-oxide (HPO) and 2-mercaptopyridine *N*-oxide (MPO).[48] For the calculations we used the association constants for transferrin;[15] the stability constants of the binary complexes with GlyGlyHis, oxalate,[40] lactate,[41] citrate,[42] and phosphate;[43] and the thermodynamic data for the $V^{IV}O$ species formed by the seven carriers[43,47,48b,49] and for the $V^{IV}O$ ternary complexes formed by the carriers and the l.m.m. binders of the serum.[43,47,48b,49b,49c] If a 10 μM level of the insulin-mimetic compounds in the serum is used, $V^{IV}O$ is totally bound to transferrin, with a minor amount bound to albumin, whereas the binding to the l.m.m. components is negligible. Only in the system with HDP, due to the high value of the stability constant of the bis chelated complex, is about 30% of $V^{IV}O$ bound to the carrier.

If the concentration of the $V^{IV}O$ complex is increased to 100 μM, albumin and l.m.m. binders also take part in the metal binding. The results of the biodistribution of insulin mimetics in serum are presented in Table 5.

Table 5. Species distribution [%] of $V^{IV}O$ insulin-mimetic compounds between the components of blood serum at pH 7.4.[a]

Complex[b]	VO^{IV} carrier	l.m.m components		h.m.m. components	
		Binary species	Ternary species	Transferrin	GlyGlyHis
$[VO(ma)_2]$	10.4	4.6	15.4	66.7	2.9
$[VO(pic)_2]$	0.3	2.7	28.8	65.7	2.5
$[VO(6\text{-}Mepic)_2]$	0.1	4.6	24.2	67.7	3.4
$[VO(HDP)_2]$	79.6	0.0	3.4	16.9	0.1
$[VO(5\text{-}MeOpic)_2]$	0.1	2.8	29.3	65.4	2.4
$[VO(HPO)_2]$	30.2	0.1	29.0	40.4	0.3
$[VO(MPO)_2]$	1.5	10.9	13.7	69.2	4.7

[a] $V^{IV}O$ = 100 μM; oxalate = 9.20 μM; lactate = 1.51 mM; citrate = 99.0 μM; phosphate = 1.10 mM; transferrin = 37 μM; GlyGlyHis = 630 μM. [b] ma = maltolato; pic = picolinato; 6-Mepic = 6-methylpicolinato; HDP = 3-hydroxy-1,2-dimethyl-4(1*H*)-pyridinone; 5-MeOpic = 5-(methoxycarbonyl)picolinic acid; HPO = 2-hydroxypyridine *N*-oxide; MPO = 2-mercaptopyridine *N*-oxide.

The amount of $V^{IV}O$ bound to transferrin and albumin depends on the strength of the $V^{IV}O$–carrier interaction. With the two stronger binders (HDP and HPO) a high fraction of $V^{IV}O$ is found in the native form of $[VO(carrier)_2]$, whereas in the other systems most of the $V^{IV}O$ (65–70%) is bound to transferrin and the rest is distributed among the binary and ternary compounds of the l.m.m. binders and the complexes with albumin. In particular, with the five weaker binders about 2–5% is associated with albumin. Of this amount, the highest part is present as $VOLH_{-2}$ and the rest as $VOLH_{-1}$. These data confirm the results of previous studies substantiating that the amount of $V^{IV}O$ bound to albumin is lower than that bound to transferrin.[15] However, it is worth noting that albumin can play a secondary role comparable to that of the l.m.m. components.

The distribution of $V^{IV}O$ between h.m.m. and l.m.m. fractions is very sensitive to the binding constants of $V^{IV}O$–hTF.[15] As a consequence of the relatively high uncertainties in the transferrin binding constants (±0.8 log units),[50] the results could change considerably if the association constants are overestimated. For example, if the values of $\log K_1^*$ and $\log K_2^*$ were 12.4 and 11.4, the amount of $V^{IV}O$ transported by albumin, at a vanadium concentration of 100 μM, rises to 9.1%. In the systems with the insulin-mimetic compounds, the fraction increases to 4.4% with ma, 4.1% with pic, 5.3% with 6-Mepic, 0.2% with HDP, 3.7% with 5-MeOPic, 0.5% with HPO and 6.3% with MPO.

However, in light of the recent results of Liboiron et al.,[17] the equilibrium data concerning the formation of ter-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nary complexes between the insulin-mimetic $V^{IV}O$ compounds and albumin could be important.

Finally, we would like to note that we have neglected the possibility of reduction and oxidation of $V^{IV}O$ species, although $V^{IV}O$ compounds in aqueous solution at varying pH, ligand-to-metal molar ratios and concentration and in the presence of biogenic ligands are subject to several processes, including redox activity.[51] However, in the conditions of transport (acid pH in the stomach and pH 7.4 in the blood serum), a complex of $V^{IV}O$ is relatively stable. Only after its translocation across the cell membrane into the intracellular medium can reducing agents such as glutathione (GSH), nicotinamide adenine dinucleotide (NADH) or ascorbate reduce $V^{IV}O$ to V^{III} [52a–52c] or potential oxidizing agents such as oxygen, peroxide, superoxide[53] or $OH^{\cdot}$ radicals[54] oxidise $V^{IV}O$ to V^{V}.

Conclusions

Simple HisGlyGly, GlyGlyHis and GlyGlyCys tripeptides coordinate the $V^{IV}O$ ion at acidic pH values and keep it in solution until the deprotonation of the amide group. Two main differences distinguish HisGlyGly, GlyGlyHis and GlyGlyCys. With HisGlyGly, only the weak coordination of carboxylate is observed at very acidic pH values, and this is easily replaced by a stronger (NH_2, CO, N_{im}^{ax}) donor set. With GlyGlyHis and GlyGlyCys an intramolecular hydrogen bond between the carboxylate oxygen and NH or SH bond of GlyGlyHis and GlyGlyCys stabilises the (COO^-, CO) donor set, so that $VOLH_2$ and VOL_2H_4 species with (COO^-, CO) and [2×(COO^-, CO)] coordination are formed. This coordination mode is indicated by a higher value of the "basicity adjusted" stability constant than expected for pure carboxylate coordination and by an accurate measurement of the A_z value, which is around 175–176×10^{-4} cm^{-1} for mono-chelated complexes and 171–172×10^{-4} cm^{-1} for bis-chelated species.

With GlyGlyHis and GlyGlyCys the final complexes (NH_2, N^-, N^-, N_{im}) and (NH_2, N^-, N^-, S^-) are more stable than (NH_2, N^-, N^-, COO^-) because the imidazole nitrogen and thiolate sulfur are more effective donors than carboxylate oxygen. Therefore, at constant L/M molar ratios (15), $VOLH_{-2}$ is the main species in solution until pH 11.6 with GlyGlyCys, pH 11.1 with GlyGlyHis and pH 10.8 with HisGlyGly.

The final species with both the amide groups deprotonated − (NH_2, N^-, N^-, COO^-), (NH_2, N^-, N^-, N_{im}) and (NH_2, N^-, N^-, S^-) − are easily detected by EPR spectroscopy. A contribution of 38.6, 35.3 and 38.6×10^{-4} cm^{-1} to the A_z value is attributed to the N^- donor according to a total charge in the equatorial plane (TEC) of –3, –2 and –3, respectively.[10]

A direct application of these results is of biological interest. In fact, the binding to GlyGlyHis can be considered a good model for the interaction of the $V^{IV}O$ ion with albumin.[6] At physiological pH, GlyGlyHis binds mainly $V^{IV}O$ with an (NH_2, N^-, N^-, N_{im}) donor set, as with Cu^{II} and Ni^{II},[6] to form a very stable $VOLH_{-2}$ species.

Albumin can also take part in the transport of vanadium and insulin-mimetic $V^{IV}O$ compounds such as those formed by maltolato, picolinato, 6-methylpicolinato, 3-hydroxy-1,2-dimethyl-4(1*H*)-pyridinone, 5-methoxycarbonylpicolinato, 2-hydroxypyridine *N*-oxide and 2-mercaptopyridine *N*-oxide. Its contribution is less important than that of transferrin, but cannot be neglected completely as proposed by previous studies.[15,47,48b,49c] Accordingly, the formation of adducts between the insulin-mimetic compounds [VO(maltolato)$_2$] and albumin has been reported.[17] Thus, the role of albumin in these processes must be re-evaluated.

Potentiometric and spectroscopic studies on the biodistribution of $V^{IV}O$ ion between GlyGlyHis and an organic carrier will be useful to establish the importance and role of the ternary complexes in the transport of the insulin-mimetic compounds in vivo.

Experimental Section

Chemicals: The ligands were Aldrich products of puriss. quality. Their purity and concentration were determined by Gran's method.[55] $V^{IV}O$ solutions were prepared following literature methods.[56] The concentration of the metal ion was determined by $KMnO_4$ titration and that of H^+ by a potentiometric titration using the appropriate Gran function. The ionic strength was adjusted to 0.1 M with KNO_3. The temperature was 25.0±0.1 °C.

Potentiometric Measurements: The stability constants of proton and $V^{IV}O$ complexes were determined by pH-potentiometric titrations on 1.2–2 mL of the samples. The ligand-to-metal molar ratio was 1:1, 5:1, 10:1 and 15:1 and $V^{IV}O$ concentration was 0.001–0.004 M. Titrations were performed from pH 2.0 until precipitation or very extensive hydrolysis by adding carbonate-free NaOH of known concentration (ca. 0.1 M NaOH). The pH was measured with a Russel CMAWL/S7 semi-micro combined electrode, calibrated for hydrogen concentration by the method of Irving et al.[57] Measurements were carried out at 25.0±0.1 °C and at a constant ionic strength of 0.1 M KNO_3 with a MOLSPIN pH-meter equipped with a digitally operated syringe (the Molspin DSI 0.250 mL) controlled by a computer. Purified argon was bubbled through the samples to ensure the absence of oxygen. The number of experimental points was 100–150 for each titration curve and the reproducibility of the points included in the evaluation was within 0.005 pH units in the whole pH range examined. As usual, the stability of the complexes is reported as the logarithm of the overall formation constant $\beta_{pqr} = [VO_pL_qH_r]/[VO]^p[L]^q[H]^r$, where L is the deprotonated form of the ligand and H is the proton, calculated with the aid of the SUPERQUAD program.[58] Standard deviations were calculated by assuming random errors. The conventional notation has been used. Negative indices for protons indicate either the dissociation of groups that do not deprotonate in the absence of $V^{IV}O$ coordination, or hydroxo ligands. Hydroxo complexes of $V^{IV}O$ were taken into account. The following species were assumed: $[VO(OH)]^+$ ($\log\beta_{10-1} = -5.94$), $[(VO)_2(OH)_2]^{2+}$ ($\log\beta_{20-2} = -6.95$), with stability constants calculated from the data of Henry et al.[59] and corrected for the different ionic strengths by use of the Davies equation,[60] $[VO(OH)_3]^-$ ($\log\beta_{10-3} = -18.0$) and $[(VO)_2(OH)_5]^-$ ($\log\beta_{20-5} = -22.0$).[61]

Spectroscopic Measurements: Anisotropic EPR spectra were recorded on aqueous solutions with an X-band (9.15 GHz) Varian E-9 spectrometer in the temperature range 120–140 K. As usual for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

low-temperature measurements, a few drops of DMSO were added to the samples to ensure good glass formation. The spectra were simulated with the computer program Bruker WinEPR SimFonia. Electronic spectra were recorded with a Perkin-Elmer Lamda 9 spectrometer. All operations were performed under a purified argon atmosphere in order to avoid oxidation of $V^{IV}O$ ion.

Supporting Information (see footnote on the first page of this article): Figures S1–S3 present the titration curves of the free ligands and of the systems with $V^{IV}O$ ion. Figures S4–S6 show the X-Band EPR spectra of $VOLH_{-2}$ complexes formed by the three ligands.

Oxo-Entity-Controlled Diastereomer Peculiarity of Rhenium(V) Complexes $ReOX_2(P{\sim}O)py$ [X = Cl, Br, I; P~O = $(OCMe_2CMe_2O)POCMe_2CMe_2O$(1–); py = pyridine]: Synthesis and Molecular and Crystal Structural Characterization

Dedicated to Professor Józef J. Ziółkowski on the occasion of his 70th birthday

Keywords: Noncovalent interactions / Crystal engineering / Rhenium complexes / P,O ligand / Density functional calculations

The stability of diastereomers of $ReOX_2(P{\sim}O)py$ complexes determined by the arrangement of the oxo-entity O=Re(–O~P) is manifested in molecular recognition and crystallization behavior [X = Cl, Br, I; P~O = $(OCMe_2CMe_2O)PO$-CMe_2CMe_2O(1–); py = pyridine]. With X = Cl and Br both chiral *cis* [*OC*-6–52] and achiral *trans* [*OC*-6–15] complexes can be obtained concomitantly, while for X = I only a *trans* complex can be afforded. Molecular structures were characterized using NMR IR and UV/Vis spectroscopic methods with the aid of DFT computational analysis and were ultimately corroborated by the single-crystal X-ray diffraction method. These analyses revealed that the most stable diastereomers involve an O=Re(–O~P) oxo arrangement in an axial disposition reinforced with a phosphorus ligating atom mutually *cis* due to extensive π-bonding both for chiral *cis* and achiral *trans* complexes, regardless of whether X = Cl, Br, or I. However, the disparate intramolecular geometry either *cis* or *trans* in the solid state results in enantiomorphic crystals related to space group $P2_12_12_1$ (X = Cl, Br) or crystals pertinent to the centrosymmetric framework $P2_1/c$ (X = Cl, Br, I), respectively. Thoughtful analysis of crystal structures reveals a supramolecular architecture due to intermolecular forces involving hydrogen bonding and electric dipole–dipole interactions (among other contact interactions). Thus, chiral *cis* complexes (X = Cl, Br) show helical crystal packing that succeeds in spontaneous resolution, while *trans* stereoisomers (X = Cl, Br, I) do not and rather exhibit a zig-zag supramolecular framework.

Introduction

The recognition that crystal structure, among other self-assembled systems (e.g. liquid crystals, molecular layers, wires etc.), is the result of a subtle balance between a multitude of supramolecular noncovalent weak forces has attracted much attention to the ability to predict crystal structures.[1] Most efforts are still devoted to searches for a correlation between intramolecular arrangements and crystal packing.[2] The great structural diversity characteristic of transition metal complexes can play a special role in this context both from a theoretical point of view and from the point of view of experimental chemistry applications in crystal engineering and material sciences.[3] The various coordination sites available on the metal center allow ligands to adopt a structural array appropriate to their steric demands and electronic properties. Still, for a given set of metal ligands several stable diastereomeric arrangements are possible showing different molecular properties with consequences for their supramolecular arrangements.[4] Occasionally, a similar potential energy for the diastereomers may result in an isomerization reaction and in the separation of the diastereomers.[5] Several interesting instances of both isomerization and the separation of diastereomers of coordination compounds have been reported recently.[6]

Metal oxo complexes, however, exhibit pronounced anisotropy that might be recognized by other ligands in the molecular stage and by molecules at the supramolecular level.[7] This anisotropy is manifested in multiple bonding within the metal oxo moiety, e.g. the total bond orders are close to three for M=O or near to four for mutually *trans* O=M–OR oxo arrangements. During the course of our studies on the chelating ability of the spirophosphorane ligand HP~O [HP~O = $HP(OCMe_2CMe_2O)_2$][8a,8b]

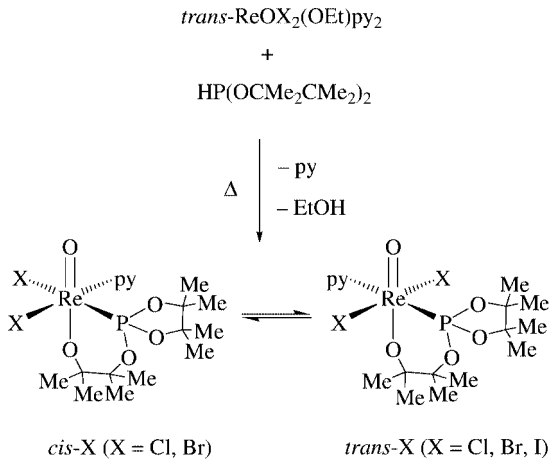
(Scheme 1) we succeeded in the chirally autocatalytic and highly efficient preparation of one enantiomer (from optically inactive precursors) owing to a subtle interplay between chiral *cis* and achiral *trans* oxo-rhenium complexes $ReOCl_2(P{\sim}O)py$ (py = pyridine).[8c] We reasoned that for a particular set of halide ligands X (X = Cl, Br, I) a specific configuration of the complex should be stabilized. Subsequently, we became interested in the more general question of to what extent one can, by selecting ligands, control the preparation of a certain diastereomer and ultimately its crystal structure including intermolecular recognition and conceivable chiral packing. Breu and co-workers have shown, using the example of trisdiimine-metal chelate complexes, that even a minor intramolecular modification related to metal center ions (Ru or Zn) can drastically alter the packing pattern and crystallization behavior proceeding from racemate to enantiomorph, essentially due to weak intermolecular forces.[9] Known oxo-rhenium complexes of the $ReOX_2(Y{\sim}Z)L$ type, containing an oxo dihalide moiety and a bidentate chelate (Y, Z = O, N, P as ligating atoms) in addition to any other monodentate ligand (L), exhibit either *cis* or *trans* geometry. Chloride complexes mostly adopt the *cis* arrangement,[10] although the *trans* geometry also exists.[11] On the other hand, iodide complexes[12] show a *cis* arrangement, while bromide complexes[13] exhibit *trans* stereochemistry. Thus, no preferential stereochemistry for halide complexes with roughly similar structural frameworks has been observed so far. Obviously, the stereochemistry of those complexes is controlled by much more complex matching of the properties of the ligands and of the metal center. These instances did not allow us to verify our reasoning and consequently gave this work a different focus, especially as we had at our disposal a closely related series of $ReOX_2(P{\sim}O)py$ complexes. In this paper we report on the results of experimental studies, aided computationally by the density functional theory (DFT), on structural characterization of the title diastereomeric complexes, including their syntheses as well as spectroscopic and X-ray single crystal determinations.[14]



Scheme 1.

Results and Discussion

Synthesis and Spectroscopic Characterization of the $ReOX_2(P{\sim}O)py$ Complexes

The reaction of dihalogeno oxo complexes *trans*-$ReO(OR)X_2py_2$ with an excess of spirophosphorane HP~O, (summarized in Scheme 1) affords corresponding *cis* and/or *trans* $ReOX_2(P{\sim}O)py$ complexes with the new oxo alkoxy entity, O=Re(–O~P), mutually in *trans* disposition. These six-coordinate complexes, besides the monodentate ligands also contain a chelating alkoxy phosphite that derives from a tautomeric deprotonated form of the spirophosphorane $(OCMe_2CMe_2O)POCMe_2CMe_2OH$.[8a,15] Both the chloro and bromo complexes might be isolated in the solid state from the reaction mixture either as the less soluble *cis* or the more soluble *trans* stereoisomer owing to feasible isomerization reactions. Furthermore, certain *cis* or *trans* stereoisomers (X = Cl, Br) can also be obtained from their congeners due to the *cis–trans* equilibration. However, the iodo complex permits only the *trans* isomer. The *cis* and *trans* solubility difference notwithstanding, these complexes are moderately soluble in dichloromethane, acetonitrile, sparingly soluble in toluene, and their solutions are stable at ambient conditions. It is apparent that for the molecular composition of these dihalide $ReOX_2(P{\sim}O)py$ (X = Cl, Br, I) complexes, five chiral *cis* configurations and two achiral *trans* are potentially implicit as depicted in Scheme 2. Configuration indices can been applied to distinguish these diastereomers.[16] Anticipating further discussion of the results, we can for now disclose that *cis*-X-[52] and *trans*-X-[15] are the only synthetically affordable diastereomers.[17]

The relatively distinctive NMR spectra of the obtained complexes are summarized in Table 1. The spectra make it only possible to distinguish between *cis* and *trans* geometry, and no further molecular configuration assignment can be predicted. It is noteworthy that *trans* complexes at room temperature exhibit a C_s ^1H NMR pattern (i.e. four signals related to four enantiotopic pairs of methyl groups) and a long-range coupling $^4J(P,H)$ between ^{31}P and ^1H at the α-position of the py ligand. For *cis* complexes, however, eight resonances related to all the eight methyl groups of the P~O ligand and the absence of a $^{31}P–^1H$ (α-py) coupling corroborate the C_1 symmetry around the metal center and do not reveal much more than this roughly estimated geometry.

IR spectroscopic measurements outlined in the Experimental Section and in the first column of Table 2 are even less distinctive for molecular structure determination. Due to considerable overlapping of the relevant absorption bands, the stretching vibrations attributed to the rhenium-ligating atom set are rather difficult to assign. However, there are exceptions for well-resolved rhenium alkoxo oxygen stretching vibrations ν(Re–O) observed at ca. 621 cm^{-1} both for *cis*-X and *trans*-X complexes. Yet careful examination of the spectral region 1000–900 cm^{-1} by means of mutual comparison of the spectra of all obtained complexes and the spectrum of the free HP~O ligand only makes it possible to tentatively assign the ν(Re=O) vibrations at ca.

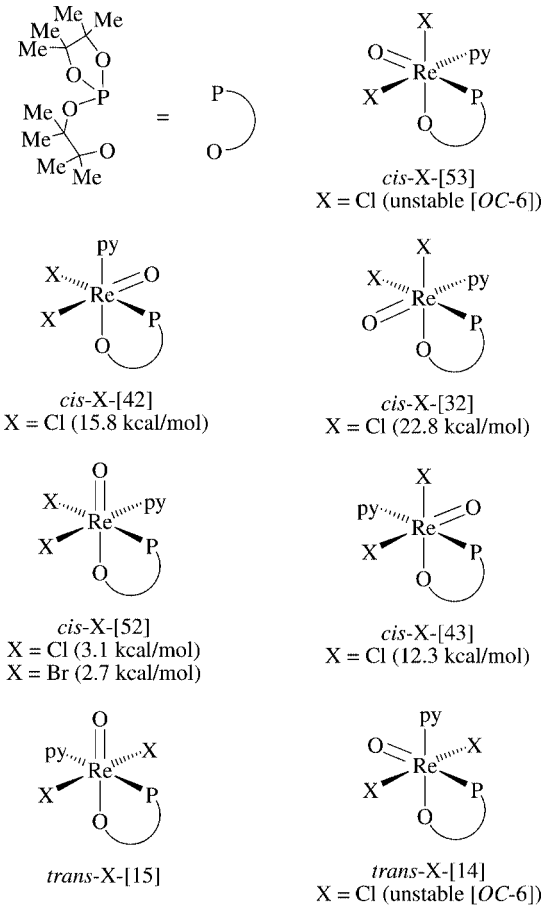

Scheme 2.

956 cm^{-1}, both for *cis* and *trans* complexes. In the low-energy range (FIR), however, ν(Re–X), ν(Re–P), and ν(Re–N) vibrations all occur in a similar region (400–100 cm^{-1}) and straightforward, unambiguous assignment is rather difficult.[18]

Another, fairly indistinctive feature of these complexes is their pink violet color visible in their UV/Vis spectra shown in Table 1. That most likely originates from d–d electronic transitions, which will be discussed later.[19]

To rationalize the above ambiguities in the molecular structure of these complexes and gain insight into their supramolecular arrangements including chirogenesis in the crystal state, more detailed studies were undertaken. The following sections describe molecular electronic structure analyses performed using density functional (DFT) calculations and crystal structure determination supported by single-crystal X-ray analyses.

DFT Computational Analysis of Molecular Structures of $ReOX_2$(P~O)py Diastereomers

This versatile method was used deliberately as it makes it possible to elucidate the experimental uncertainties described above in a reasonable manner and to strike a balance between computational effort and completeness. The primary aim of the computational study was to analyze the relative stability of the seven diastereomers implied above, mainly in the case of the most representative chloride complexes (X = Cl).[20] We expected that general conclusions obtained for the chloride congeners would be largely valid for other halide complexes too. The relative electronic energies for the series *cis*-Cl and *trans*-Cl stereoisomers are shown in Scheme 2. The lowest total electronic energy, and thus the highest stability was found for the *trans*-Cl-[15] configuration located at the bottom left in Scheme 2. Comparison of the calculated relative energy differences reproduces the experimentally observed order of stability of the complexes: achiral *trans*-Cl-[15] > chiral *cis*-Cl-[52] (3.12 kcal mol^{-1}) >> other *cis*- and *trans*-Cl diastereomers (remarkably above 10 kcal mol^{-1}). This low-energy barrier between the Cl-[15] and the Cl-[52] diastereomers supports

the above-mentioned *cis–trans* isomerization reaction and the feasible separation of *cis* and *trans* complexes.[21] Furthermore, the resulting diastereomer stability trend is in good agreement with the expected promotion and efficiency of the π-donor-acceptor bonding pattern at the metal center with the arrangement of O and P ligating atoms. Phosphorus ligating atoms with their intrinsic π-acidity show a preference to adopt a *cis* disposition with respect to the inherent *trans* O=M–OR oxo arrangement [R = (CMe_2CMe_2O)-$P(OCMe_2CMe_2O)$].[7]

Consequently, the multiply bonded *trans* oxo arrangement is stabilized to some extent due to accessible π-back-donation from rhenium to phosphorus. Other hypothetical diastereomers with mutually *cis* O=M(–OR) oxo arrangements are evidently less encouraging (Scheme 2). Besides, computational studies indicate the lowest stability for pseudo-octahedral complexes [*OC*-6] comprising mutually *cis* oxo arrangements with phosphorus in the *trans* location to the terminal oxygen atom (*trans* -Cl-[14] and *cis* -Cl-[53]), which tend rather to transform to five coordinating species loosing the phosphorus ligand.

Notably, energy differences calculated only for selected bromide and iodide congeners (*trans* -X-[15] and *cis* -X-[52]), assumed to be the most stable, are again in good agreement with the experimental observations. Thus, for bromides, a low energy difference between *trans* -Br-[15] and *cis* -Br-[52] (2.68 kcal mol^{-1}), again implies facile *cis-trans* isomerization. In the case of iodides, *trans* -I-[15] appears to be the only stable complex. To sum up, computational study at this stage dispelled the configuration ambiguity indicating not only the geometry of the most stable diastereomers, X-[15] and X-[52], but also the feasibility of the *cis-trans* isomerization reaction, excluding X = I congeners. For the sake of clarity, below we simply use the abbreviations *trans*-X and *cis*-X for the affordable complexes of X-[15] and X-[52] configurations, respectively.

Afterwards, with computed structures fully optimized using the B3LYP functional, we also tried to deal with am-

biguities in the IR spectra using the DFT method. A summary of the spectral characteristics and stretching vibrations for the *trans*-X and *cis*-X complexes in selected relevant regions are presented in Table 2. Tentative assignment of the observed absorption bands to those calculated was based on the order of their appearance and intensity, in experimental and calculated spectra. In the FIR range, the equivocal position of stretching vibrations ν(Re–P), ν(Re–N), and ν(Re–X) can be verified to some extent. Thus, weak absorption at 150–160 cm^{-1} and medium to strong absorption at 230–240 cm^{-1} can be cautiously assigned to ν(Re–P) and ν(Re–N) vibrations, respectively. Meanwhile, ν(Re–X) absorptions occur in the region of ca. 300 cm^{-1} for ν(Re–Cl), 200 cm^{-1} for ν(Re–Br), and 150 cm^{-1} for ν(Re–I) (accurate values in Table 2), usually as strong bands. Apart from these, ν(Re=O) stretching vibrations resolved using DFT appear, interestingly, at almost invariable positions, 956–957 cm^{-1} for all the attainable complexes. This suggests once more a very stable moiety comprised of ligating phosphorus in *cis* disposition to the oxo arrangement O=M–OR, powered by π-backdonation.

Similarly, the near nonpeculiarity of the electronic absorption spectra intrinsic to complexes with a *cis* or *trans* geometry and the observed complexes with different halides (Table 1) might also suggest that the oxo-metal entity has a controlling nature. With the aim of elucidating this observation in more detail, we performed time-dependent density functional (TDDFT) calculations of the spectral properties. Recently, several computational analyses have been performed for rhenium complexes,[22] which improve the rationalization of their electronic absorption spectra including the related oxo complexes *trans*-$ReO(OEt)Cl_2(L)_2$ (L = py, pyrazine, pyrimidine).[23] Computational analysis has been accomplished in the case of the pair of *trans*-Cl and *cis*-Cl complexes, which represent an exceptional term as a precursor in this series. In comparing the experimental and calculated spectra we consider only the first two bands in the visible range mainly involving the d orbitals. A third, very intensive and higher-energy band occurs in the UV region and is not needed for the purpose of this comparison. The calculated orbital excitations and the corresponding electronic transitions are summarized in Table 3. The assignment of the calculated orbital excitations to the observed absorption bands was guided by an overview of the contour plots and relative energy appropriate to the orbitals HOMO and LUMO involved in the electronic transitions depicted in Figure 1.

The lower-energy excitations are attributed to the two HOMO → LUMO and HOMO → LUMO +1 transitions either for *cis*-Cl or for *trans*-Cl complexes (set 1, Table 3). The contour plots corresponding to these MOs comprise mainly rhenium 5d atomic orbitals (Figure 1). Thus, initial HOMOs involve the rhenium d_{xy} (π*) orbital interacting with chlorine 3p (π*). Both LUMO and LUMO +1 also engage the rhenium d_{xz} (π*) orbital but interact with the π* orbitals of the oxo arrangement. Therefore, the low-energy absorption bands, observed at 650 nm (*cis*-Cl) and 670 nm (*trans*-Cl), can be assigned to d–d (π*) transitions with a certain contribution of metal-to-oxo-ligand charge transfer (MLCT). Two higher-energy excitations, however, are attributed to the two HOMO → LUMO +2 and HOMO → LUMO +4 transitions, which involve rhenium d orbitals but with slightly different contributions (for *cis*-Cl and *trans*-Cl complexes, sets 2–3 in Table 3 and Figure 1). While LUMO +2 comprise substantially pyridine molecular orbitals, easily visible in the contour plots, LUMO +4 again involves mainly rhenium atomic orbitals but with a $d_{x^2-y^2}$ (σ*) symmetry. The observed absorptions at 499 nm (*cis*-Cl) and 522 nm (*trans*-Cl) can be related to a metal-to-pyridine ligand charge transfer (MLCT) with a certain contribution of d (π*)–d (σ*) transitions. Consequently, the similar natures of the above transitions seem to be responsible for the nearly identical absorption spectra at least for *cis* and *trans* chloride complexes.

Table 3. The most important electronic transitions calculated with the TDDFT method: wavelength λ, oscillator strength *f*, and measured λ_{exp} (ε) for *cis*- and *trans*-$ReOCl_2$(P~O)py.

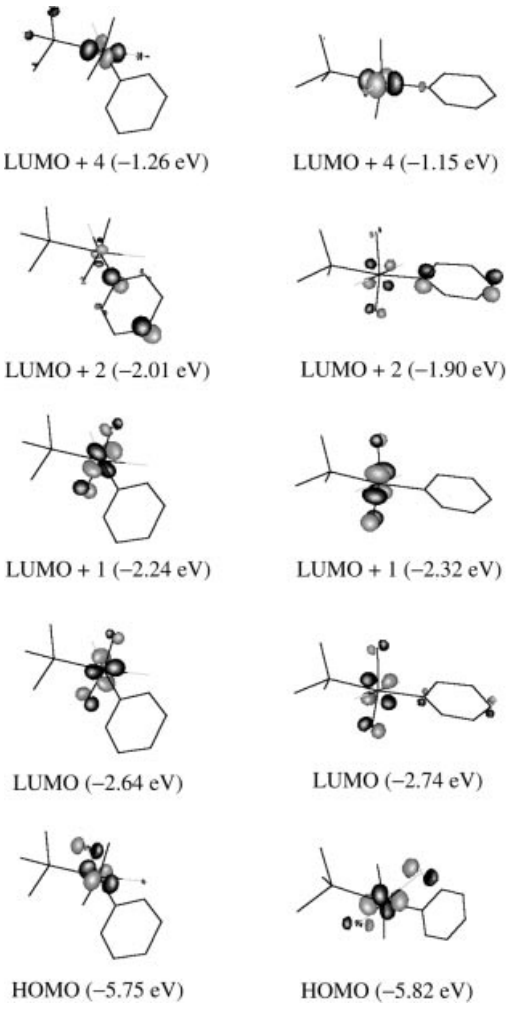

Figure 1. Contour plots relative to selected orbitals HOMO and LUMO active in the electronic transitions in *cis*- (left) and *trans*-$ReOCl_2(P{\sim}O)py$ (right). The orbitals were plotted with the contour values –0.12 (black) and 0.12 au (gray), and referred to the *z*-axis adjacent to the oxygen atoms and the *y*-axis occupied by pyridine and or chlorides. The chlorides are printed in gray.

X-ray Crystal Structure Determination

In general chiral molecules, if they are not pure enantiomers, may form either chiral (conglomerate) or achiral (racemate, racemic solution) crystal structures. Yet, the same might be true for achiral molecules.[24] The question arises what a crystal structure will be if only minor structural changes are applied to a molecule that prior to these changes formed chiral crystals (e.g. Cl^- vs. Br^- ligands or chiral *cis*- vs. achiral *trans*-arrangements) and whether the formation of enantiomorph crystals will still be possible although the molecular structure might now be achiral.

The crystallographic data of $ReOX_2(P{\sim}O)py$ complexes are summarized in Table 5. While two *cis*-X (X = Cl, Br) complexes crystallize in the orthorhombic space group $P2_12_12_1$, as enantiomorphic crystals (conglomerate), three *trans*-X (X = Cl, Br, I) isomers yield monoclinic crystals belonging to the centrosymmetric space group $P2_1/c$. The unit cell of each crystal structure consists of four molecules of $ReOX_2(P{\sim}O)py$ complexes. The packing of the achiral *trans* complexes is slightly less compact (ca. 5% ρ) than that of the chiral *cis* isomers. The Flack parameter, *x*,[25] for selected single chiral crystals of *cis*-Cl [*x* = 0.024(5)] and *cis*-Br [*x* = –0.018(12)] indicates packing with molecules of one enantiomer that accidentally appeared with the opposite absolute configuration of *C* and *A*, respectively. Figure 2 shows the ORTEP drawings with the selected atom numbering schemes for representative *cis*-X (X = Cl) and *trans*-X (X = Cl) complexes. Except for rather insignificant differences related to the coordination of pyridine, the molecular structures do not show extraordinary features in terms of bond lengths and angles. Significant coordination bond lengths and angles for these complexes are submitted in the supporting information in Table S1. All pseudo-octahedral complexes exhibit the characteristic multiply bonded *trans* oxo arrangement, O=Re–O. The rhenium bond lengths with terminal oxo at ca. 1.7 Å and the bridging alkoxo below 1.9 Å are in the usual range, which imply a total bond order of close to four.[7] Furthermore, the coplanarity of the rhenium atom with the plane traced by phosphorus and oxo-moiety donor atoms is a rather meaningful feature of all those complexes. The dihedral angles close to zero between the least-squares planes Re O(1) P and Re O(2) P for *cis*-X [Cl, 4.5(1)°, Br 4.7(2)°] and *trans*-X [Cl, 1.0(1)°, Br 0.0(1)°, I 0.4(2)°], respectively, confirm the approximately coplanar arrangements. This may suggest the remarkable stability of such a four-membered core arrangement, O=Re(–O~P–), due to a versatile π-bonding already anticipated from DFT computational analysis for all the readily affordable diastereomers.

Besides the similarity, there are also some well-pronounced disparities in the intramolecular structures of these stereoisomers between the geometry types, *cis*-X (X = Cl, Br) or *trans*-X (X = Cl, Br, I). Ring puckering analysis[26,27] shows that both fluxional (in solution) five-membered phosphorus and six-membered rhenium cycles in the crystal state adopt conformations relevant for each geometry (i.e. *cis*- or *trans*-), albeit with slight differences between them.[28] Thus, the relevant five-membered phosphorus cycle, -PO4C7C8O5-, embraces the envelope (E) tilted on the enantiotopic carbon atoms, either C7 (*cis*-X) or C8 (*trans*-X). For the relevant six-membered rhenium metallacycles, -RePO2C1C2O3-, tentative inquiries disclose either half-chair (HC) or envelope conformations on C2 for *cis*-X and *trans*-X complexes, respectively.

The molecular peculiarities and similarities discussed above, while subtle, have further consequences in the supramolecular structure and the crystal packing of these stereoisomers. Yet, this might be expected from the molecular self-recognition and self-assembly paradigm[1a,29] for the structure of supramolecular objects and crystals due to weak noncovalent intermolecular forces.[30] These intermolecular interactions might be both directional and nondirectional in nature. To minimize the void volume in 3D structures, molecules tend to pack exploiting weak specific interactions, including directional hydrogen bonds and/or minimal dipole–dipole electrostatic forces. The representative

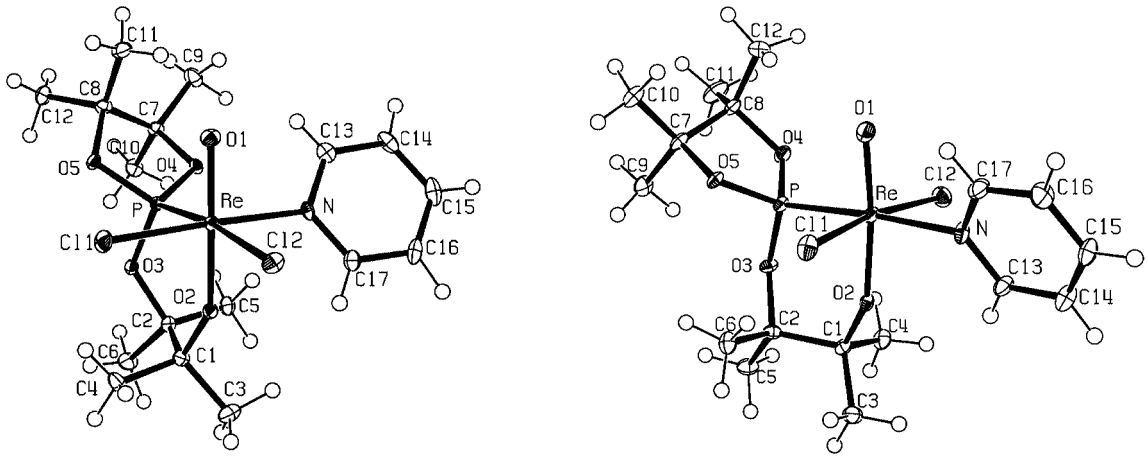

Figure 2. ORTEP molecular diagram (with 30% probability ellipsoids) showing selected atom labeling in *cis*-$ReOCl_2$(P~O)py (left) and *trans*-$ReOCl_2$(P~O)py (right) with hydrogen atoms unlabeled.

modes of crystal packing for *cis*-X (X = Cl) and *trans*-X (X = Cl) complexes are shown in Figures 3 and 4, respectively. Crystals within each stereoisomer type, *cis*-X or *trans*-X (X = Cl, Br), are isomorphous, except for the *trans*-I complex (Table 5). Both *cis*-X and *trans*-X complexes disclose columnar structures in their crystal states. *Cis*-X complexes reveal molecules arranged in cylinders running along the crystallographic axis 2_1, that is parallel to the cell *b* axis (Figure 3), and maintain molecules forming a helical pattern.[31] Meanwhile, *trans*-X complexes exhibit molecules stacked along the *c* axis with stacks mutually related by axis 2_1 parallel to the *b* axis (Figure 4), which sustain them in stacks rather than in any helical structures. The driving noncovalent interactions are obviously responsible for either a cylindrical or stacking disposition of the molecules in the crystals.

Avoiding precarious quantification of the strength of these intermolecular interactions, one can take the opportunity to only roughly classify them. Thoughtful qualitative analysis of the packing shows that molecules might be held together by hydrogen bonds, contact interactions, and dipole–dipole electrostatic interactions.[32] Interactions that are sustained almost twice as often are effected through intermolecular arrangement (11 to 13) rather then by intramolecular arrangement (6 to 7 encounters) for each compound. Notably, in spite of the rather modestly realistic (or very weak) hydrogen bonds involving alkyl hydrogen atoms (H3–H6, H9–H12), the aryl hydrogen atoms (H13–H17) may make an energetically significant contribution to H bonding. This may result in a substantial influence on the type of supramolecular arrangement. With great caution, we can only shed light on the difference in intermolecular

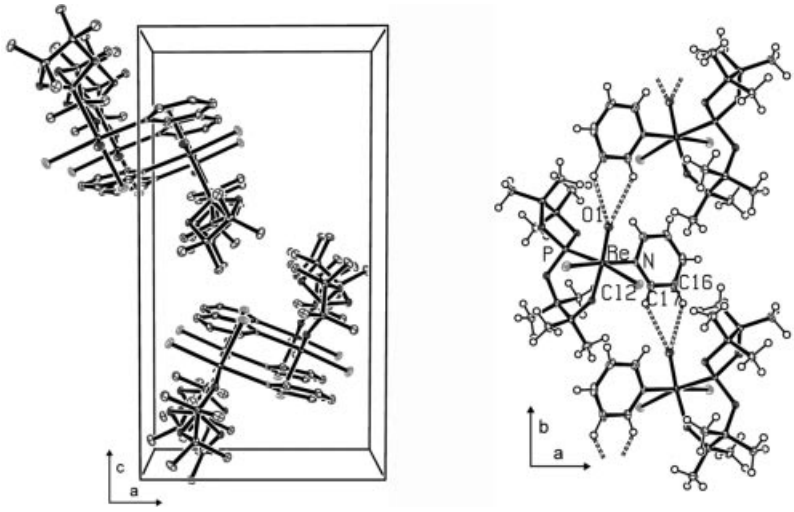

Figure 3. Crystal structure of *cis*-$ReOCl_2$(P~O)py. Perspective view along columns (left), in which molecules are connected by the intracolumn hydrogen bonds (right).

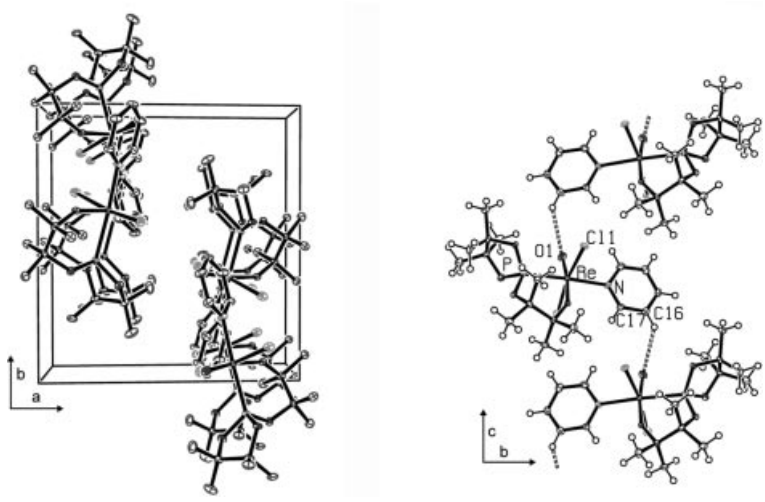

Figure 4. Crystal structure of *trans*-$ReOCl_2(P{\sim}O)py$. Perspective view along columns (left), in which molecules are connected by the intra-column hydrogen bonds (right).

hydrogen bonding acquired by terminal oxygen atoms with both α and β pyridine hydrogen atoms (H17, H16) for *cis*-X (X = Cl, Br, Figure 3, b) and only with β pyridine hydrogen atoms (H16) for *trans*-X (X = Cl, Br, I, Figure 4, b) complexes. Other implied interactions seem to be more concealed and do not allow clear-cut conclusions.[32]

However, on the other hand, the apparent difference in polarity and in the dipole moment[33] between *cis* and *trans* geometry complexes offers an additional possibility of discriminating between intermolecular dipole–dipole electrostatic interactions. In the *cis*-X molecules, a substantial dipole moment (ca. 12.7 D) is pointed out of the most polar bonds and electronegative donor atoms (X1, X2 O1 and O2), whereas in the *trans* stereoisomers a rather moderate dipole moment (ca. 3.15 D) is situated in proximity to the donor atoms, which is depicted in a simplified form in Figure 5. Thus, within each column, the *cis*-X molecules adjust the obtuse angle of the dipole–dipole arrangement, while the *trans* molecules seem not to. We can consider the obtuse angles of dipole arrangements to be a result of the subtle interplay between the tendency towards antiparallel alignment of dipoles and a variety of other weak specific intermolecular forces. This obtuse angle of dipole arrangement (for *cis*-X) allows the bulky part of the molecule to improve accommodation within the column, which manifests itself in a shorter Re–Re distance (e.g. 6.84 Å, X = Cl), as shown in Table 4. In the case of *trans* isomers, substantially smaller dipole moments of molecules are arranged in a parallel way with longer Re–Re distances (e.g. 7.20 Å, X = Cl) within each column. These distances are not too different from inter-column Re–Re distances (e.g. 8.24 Å, X = Cl).

Using this uncomplicated cooperative model, which includes hydrogen bonding and dipole–dipole electrostatic interactions, we can rationalize the supramolecular structure of the title complexes. Both of these specific directional interactions seem to be controlling in the case of *cis*-X complexes. This is manifested in the helical arrangement of the molecules, the shorter Re–Re distance within the column, and the more compact packing. Consequently, this is seen in the greater lattice energies and in the enantiomorphic

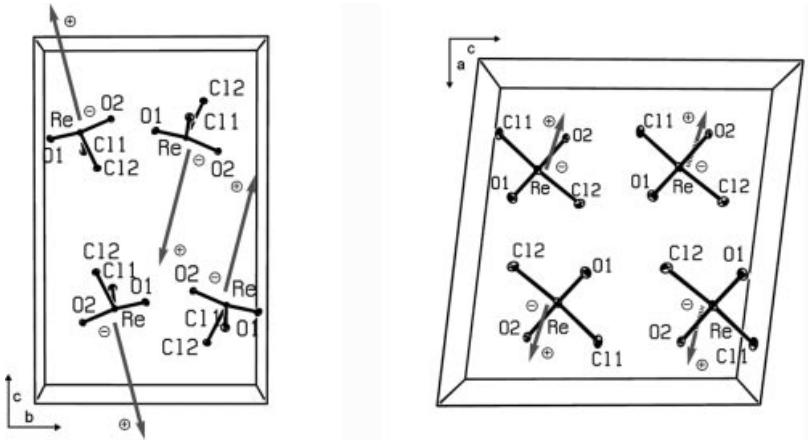

Figure 5. Supramolecular arrangement of molecular dipoles along columns for *cis*-$ReOCl_2(P{\sim}O)py$ (12.65 D, left) and *trans*-$ReOCl_2(P{\sim}O)py$ (3.18 D, right), a schematic overview of the projection of the dipole moments on respective planes.

Table 4. Adjacent intermolecular distances for $ReOX_2$(P~O)py complexes.

Complex	Re–Re distances [Å] Intra-column	Inter-column
cis-Cl	6.84	10.02
trans-Cl	7.20	8.24
cis-Br	6.87	10.20
trans-Br	7.66	8.67
trans-I	8.40	8.25

crystal structures. In contrast, in the case of *trans* geometry complexes, with no dipole–dipole disposition consequences, hydrogen bonding along with other weak interactions including dispersion forces seems to be the operating driving force. This revealed in a stacking arrangement of molecules longer Re–Re distances within the column (Table 4), and less compact packing with a definitely lower lattice energy.

Conclusions

Systematic studies of the title $ReOX_2$(P~O)py complexes definitely illustrate that the oxo entity O=M–OR inherently in *trans* disposition is a building block determining the stability of these diastereomers. Even with this fixed oxo entity, different arrangements of halide ligands are still available, either *trans* or *cis* (X = Cl, Br), implying nonrigidity of these complexes in terms of configuration and conformation. Further, we can stipulate that due to the self-recognition nature of molecules, the molecular structure of the compound may affect the supramolecular arrangement in the crystal state, the eventual spontaneous resolution (X = Cl, Br vs. I), and ultimately chirogenesis. This points to the involvement of fine-tuning in the form of specific interactions involving molecular recognition, which utilize the electronic and steric properties of the ligands and the metal center. We bear in mind the stimulating accounts of Breu and his associates,[9] which showed that for similar complexes with a rigid molecular shape (e.g. $[M(bpy)_3]^{2+}$), a small difference in molecular composition (M = Ni, Zn, Ru) may have a dramatic influence on the form of crystal packing. In fact, that observation validates one of the alternative clear-cut assumptions that crystal structure cannot be predicted.[34] In our case, however, the described structural intramolecular properties and the related intermolecular arrangements of the molecules do not seem to corroborate the above assumption. Replacements of halides do not dramatically alter the packing pattern. Both chloride and bromide complexes can crystallize in the orthorhombic ($P2_12_12_1$) and monoclinic centrosymmetric ($P2_1/c$) space groups, depending intimately on their intramolecular geometry. Consequently, these observations seem to support the alternative statement of Grepioni, Braga, and co-workers that "objects of similar shape tend to pack in a similar manner."[35] It is noteworthy that in our system, the related molecules exhibit pronounced anisotropy owing to the oxo arrangement and are not rigid. This obviously convenient case makes it possible to utilize intramolecular degrees of freedom and optimize the similar packing for the corresponding halide (X = Cl, Br, I) diastereomers.

Experimental Section

All preparations were performed under dry, oxygen-free nitrogen, using conventional Schlenk techniques. Solvents were carefully dried and deoxygenated by standard methods.[36] *trans*-$ReOX_2$(OEt)py_2 (X = Cl, Br, I),[37] *cis*-$ReOCl_2$(P~O)py[8a], and the ligand $HP(OCMe_2CMe_2O)_2$[8a] were prepared according to literature procedures.

IR and FIR measurements were performed in KBr pellets either with a Nicolet FTIR Impact 400 or in Nujol with a Bruker IFS 113V. ^1H, ^{13}C, ^{31}P NMR spectra were obtained with a Bruker AMX (300 MHz for ^1H NMR). The chemical shifts (δ) are given in ppm towards the TMS (^1H, ^{13}C) and H_3PO_4 (^{31}P) using deuterated solvents as lock and reference (^1H, ^{13}C), respectively. 2D NMR and ^1H-^{31}P COSY experiments made it possible to distinguish and unambiguously assign the chemical shifts of methyl groups attributed to both phosphorocycles and metallacycles (Table 1). UV/Vis spectra in CH_2Cl_2 solution were obtained with a Carry 500. Elemental analyses were performed with a Perkin–Elmer 2400 CHN by the Laboratory of Elemental Analyses in our Department.

***trans*-$ReOCl_2$(P~O)py (*trans*-Cl):** Finely ground crystalline *cis*-[$ReOCl_2${$OCMe_2CMe_2OP(OCMe_2CMe_2O)$}py] (0.025 g, 0.04 mmol) was added to toluene (50 mL). It was vigorously stirred and slowly distilled (over 1 h) to about 25 mL. After cooling to room temperature, the remaining solid, which appeared to be the starting *cis* complex, was filtered (0.0024 g, 9.6%). The mother liquor yielded crystals (0.018 g, 72%) of pure *trans*-[$ReOCl_2${$OCMe_2CMe_2OP(OCMe_2CMe_2O)$}py]. Single crystals suitable for X-ray analysis were obtained by re-crystallization from a dichloromethane/ethyl ether solution as a purple-violet compound. $C_{17}H_{29}Cl_2NO_5PRe$ (615.5): calcd. C 33.17, H 4.75, N 2.28; found C 33.5, H 4.65, N 2.52. IR (KBr): $\tilde{\nu}$ = 623.0 [m, ν(Re–O)], 931.8 (s), 956.3 [vs., ν(Re=O)], 1024.7 [s, ν(C–O–P)], 1608.4 [m, ν(C=N)] cm^{-1}; FIR (nujol): 154.0 (w), 237.4 (m), 247(s), 302.6 [ν(Re–P)], ν(Re–N), ν(Re–Cl) cm^{-1}. The compound was also isolated as a side product from the toluene filtrate remaining after the preparation of the isomer *cis*. The filtrate was evaporated to dryness, the residue washed several times with pentane and ethyl ether, than crystallized from toluene with ca. 8% yield. In addition, when the sample of the pure *trans*-Cl complex (0.066 g) was placed in boiling toluene (10 mL) for 1 h, it again afforded the *cis*-Cl complex (65%) as a solid, which proves the isomerization reaction.

***cis*-$ReOBr_2$(P~O)py (*cis*-Br):** A suspension of the blue complex $ReOBr_2$(OEt)py_2 (0.395 g, 0.699 mmol) and the spirophosphorane ligand $HP(OCMe_2CMe_2O)_2$ (0.341 g, 1.292 mmol) in toluene (25 mL) was stirred and boiled for 6 h until the starting rhenium compound reacted and a light-violet crystalline solid was afforded. The product was filtered, washed with Et_2O, and dried in vacuo (0.368 g, 74.8%). Single crystals suitable for X-ray analysis were obtained by crystallization from a dichloromethane/ethyl ether solution as a purple-violet compound. $C_{17}H_{29}Br_2NO_5PRe$ (704,4): calcd. C 28.99, H 4.15, N 1.99; found C 29.06, H 3.93, N 2.07. IR (KBr): $\tilde{\nu}$ = 618.6 [m, ν(Re–O)], 925.7 (vs), 955.9 [vs., ν(Re=O)], 1014.6 [s, ν(C–O–P)], 1605.3 [m, ν(C=N)] cm^{-1}; FIR (nujol) 159.7 (w), 180.7(s), 215.6(s), 235[m, ν(Re–Br)], ν(Re–N), ν(Re–P) cm^{-1}.

***trans*-$ReOBr_2$(P~O)py (*trans*-Br):** A suspension of the pink-violet compound *cis*-$ReOBr_2$(P~O)py (0,05 g, 0,071 mmol) in toluene

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(50 mL) was stirred and boiled for 1 h. After cooling to room temperature, the remaining *cis*-$ReOBr_2(P{\sim}O)py$ solid was filtered. The remaining solution was evaporated to dryness affording *trans*-$ReOBr_2(P{\sim}O)py$ (0.04 g, 80%). Single crystals suitable for X-ray analysis were obtained by crystallization from a dichloromethane/ethyl ether solution as a purple-violet compound. Besides, this complex was afforded as a side product from the remaining toluene filtrate obtained in the *cis*-Br preparation, by a method similar to that used for *trans*-Cl, with ca. 12% yield. $C_{17}H_{29}Br_2NO_5PRe$ (704.4): calcd. C 28.99, H 4.15, N 1.99; found C 29.0, H 4.09, N 2.02. IR (KBr): $\tilde{\nu}$ = 622.9 [m, ν(Re–O)], 931.9 (vs), 955.9 [vs., ν(Re=O)], 1023.3 [s, ν(C–O–P)], 1609.1 [m, ν(C=N)] cm^{-1}; FIR (nujol) 150.1 (vw), 179 (s), 205.7 (vs), 232 (s), 248 [m, ν(Re–P)], ν(Re–Br), ν(Re–N) cm^{-1}.

***trans*-$ReOI_2(P{\sim}O)py$ (*trans*-I):** A mixture of $ReOI_2(OEt)py_2$ (0.359 g, 0.545 mmol), toluene (25 mL), and the spirophosphorane ligand $HP(OCMe_2CMe_2O)_2$ (0.279 g, 1.059 mmol) was stirred and boiled for 6 h until the starting rhenium compound reacted and new a deep-orange solution appeared. The solution was concentrated in vacuo by half to obtain a red-violet precipitate of $ReOI_2(P{\sim}O)py$. The product was filtered, washed with Et_2O and dried (0.38 g, 87%). Single crystals suitable for X-ray analysis were obtained by crystallization from dichloromethane/ethyl ether solution as a red-violet compound. For $C_{17}H_{29}I_2NO_5PRe$ (798,41): calcd. C 25.57, H 3.66, N 1.75; found C 25.66, H 3.34, N 2.00. IR (KBr): $\tilde{\nu}$ = 622.6 [m, ν(Re–O)], 929.5 (vs), 957.2 [vs., ν(Re=O)], 1022.7 [m, ν(C–O–P)], 1606.6 [m, ν(C=N)] cm^{-1}; FIR (nujol) 156.4 (s), 228 (s), 239.9 (vs), ν(Re–P), ν(Re–I), ν(Re–N) cm^{-1}.

Computational Analysis: The calculations were carried out with the GAUSSIAN 2003 program.[38] All structures were optimized starting from experimental geometries (X-ray) with no symmetry restrictions, using the Kohn–Sham density functional theory (DFT) with Becke's three-parameter[39] exchange functionals and the gradient-corrected functionals of Lee, Yang, and Parr [DFT(B3LYP)] with the SDD basis set. Vibrational frequencies were calculated in order to confirm the nature of the stationary points and to achieve the zero-point energies (ZPEs). Calculations of electronic spectra were performed at the TDDFT level. Molecular structures were visualized using the program MOLDEN.[40] Molecular orbitals were drawn by the program gOpenMol.[41] The programs ORTEP[42] and GSVIEW[43] were used for graphical presentation of crystallographic results. Cartesian coordinates for optimized structures have been deposited with the Supporting Information.

Crystal Structure Determination: Crystal data for *cis*- and *trans*-$ReOX_2(P{\sim}O)py$ complexes are summarized in Table 5. The data collected with the KM4CCD diffractometer were corrected for Lorentz and polarization effects. Data reduction and analysis were carried out using the Oxford Diffraction (Poland) programs. The structure was solved by means of heavy atom methods using SHELXS-97 and refined by the full-matrix least-squares method on F^2 using SHELXL-97 procedures (G. M. Sheldrick, University of Göttingen, Germany, **1997**). Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included from the Δρ maps and refined with isotropic thermal parameters. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center (CCDC) as a supplementary publication. CCDC-167174 (for *cis*-Cl) and -271243 ... -271246 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (details see footnote on the first page of this article): A PDF file with supporting information for this article is also available from the authors. It contains tables showing the relevant bond lengths and angles (Table S1), the ring puckering analysis (Table S2), the analysis of possible hydrogen bonding and contacts (Table S3), and color versions of Figures 1, 3, and 4, which ensure better visualization of the 3D structures (Figure S1, S2, and S3, respectively).

Synthesis, Crystal Structures and Photoluminescence of Mercury(II) Complexes with Two Homologous Novel Functional Rigid Ligands

Hong-Ping Zhou,[a,b] Yu-Peng Tian,*[a,c,d] Jie-Ying Wu,[a] Ju-Zhou Zhang,[a] Dong-Mei Li,[a] Yong-Min Zhu,[a] Zhang-Jun Hu,[a] Xu-Tang Tao,[c] Min-Hua Jiang,[c] and Yi Xie*[b]

Keywords: Mercury / Functional rigid ligands / X-ray diffraction / Luminescence

Two novel functional rigid ligands, 2,2′- and 4,4′-bipyridyl-based "building blocks", 9-ethyl-3,6-bis[2-(4-pyridyl)ethenyl]carbazole ($\mathbf{L^1}$) and 9-ethyl-3,6-bis[2-(2-pyridyl)ethenyl]-carbazole ($\mathbf{L^2}$), were synthesized. Treatment of $L^{1,2}$ as "building blocks" with $Hg(SCN)_2$ or HgI_2 afforded helixes, macrocycles, and chains, which can be further self-assembled by a π–π stacking interaction, hydrogen bond, and interatomic force in the solid state to form two-dimensional networks. In complexes **1**–**4**, Hg^{II} centers all adopt four-coordination modes in different coordination environments, but they present different architectures with slightly adjusted structures of the ligands and counteranions, indicating that the nature of the ligand and anion plays an important role in the coordination networks. The luminescent properties of compounds **1**–**4** have been studied.

Introduction

In the past decade, more and more attention has been focused on the crystal design and engineering of multidimensional arrays and networks containing metal ions as nodes because of the potential application of such molecular materials in catalysis, electronics, molecular sensing, magnetic devices, and porous and nanosize materials.[1,2] The rational design and construction of metal–organic frameworks, with their fascinating structures and potential properties, continues to attract interest in current supramolecular chemistry.[3] Up to now, extensive studies have been carried out to give many novel one- (1D), two- (2D), and three-dimensional (3D) frameworks based on the assembly of metal salts with rigid *N*,*N*′- donor ligands, such as 4,4′-bipyridine or 2,2′-bipyridine and their derivatives. Bridging bis(pyridyl) ligands are often used in the construction of metal-containing macromolecules, and the geometry of the bis(pyridyl) ligand can define the primary structure of the self-assembled macromolecule through metal-coordination, hydrogen bonds and π–π stacking interactions.[4] However, some organic ligands with special functionality for supramolecular architectures and functional compounds, because of synthetic difficulties, have been reported rarely to date.

On the other hand, carbazole compounds, as is well known, exhibit good hole transporting properties and their charge transporting complexes can create free carriers in the visible region through the photocarrier generation process.[5] Recently, carbazole-containing compounds have been extensively studied for the application of an electroluminescent (EL) device and fabrication of light-emitting diodes (LED)[6] because of their sufficient hole/electron transporting and luminescent properties. However, the devices are mostly organic compounds or polymers, and the low melting points or low decomposition temperatures inhibit their applications. Functionalization of the organic molecule (addition of donor atoms, e.g. N or O) to allow incorporation into inorganic/organic coordination complexes can offer the advantages of high thermal stability and solvent resistance compared to all-organic materials. So we have tried to design and synthesize functional ligands 9-ethyl-3,6-bis[2-(4-pyridyl)ethenyl]carbazole ($\mathbf{L^1}$) and 9-ethyl-3,6-bis[2-(2-pyridyl)ethenyl]carbazole ($\mathbf{L^2}$). Interestingly, by the careful design of rigid ligands containing carbazole cores and bipyridyl, we were able to obtain complexes with functionally different structures. Furthermore, mercury(II) complexes have been extensively studied because of their structural diversities and attractive optical properties such as photoluminescence and nonlinear optical effects.[7] In this article, we present a series of mercury(II) complexes containing the new functional rigid ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ (Scheme 1). Slightly adjusting the structure of the

ligands and counteranions gives potential changes to form different architectures. Here the syntheses, structures, photoluminescence and high thermal stability properties of mercury(II) complexes are reported.

Results and Discussion

All of the compounds are stable in air and insoluble in water or in common organic solvents. High yields of the products indicate that these compounds are thermodynamically stable under the prevailing reaction conditions. IR spectra of the same counteranion compounds are similar, compounds **1** and **3** showing strong absorption bands at about 2065 and 2061 cm^{-1} respectively that are diagnostic of coordinated sulfocyan; middle absorption bands at about 419 and 420 cm^{-1} respectively that are the Hg–N stretching frequencies; and middle absorption bands at about 327 and 328 cm^{-1} respectively that are the Hg–S stretching frequencies. Compounds **2** and **4** show middle absorption bands at about 420 and 419 cm^{-1} respectively that are the Hg–N stretching frequencies and strong absorption bands at about 151 cm^{-1} that are the Hg–I stretching frequencies.

Crystal Structures

In many previous examples, the Hg^{II} cation was found to act as a tetrahedral node with a coordination angle of about 90° to generate 1-D, 2-D, and 3-D structures.[7] It has recently been reported that macrocycles, polymers, or sheets resulted from the reaction of a pyridine spacer with an angle of 120° and a metal node with an angle of 90°.[7] Thus, the reaction of $\mathbf{L^1}$ and $\mathbf{L^2}$ with $Hg(SCN)_2$ and HgI_2 was anticipated to afford 1-D, 2-D, and 3-D structures bearing metallacyclic or metallamacrocyclic analogous structures.

The reaction of equimolar amounts of the bis(pyridine) ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ (Scheme 1) and mercury(II) halide or sulfocyanate gave the corresponding complexes **1**–**4**. These compounds were isolated as analytically pure, air-stable, yellow or red solids that are very sparingly soluble in common organic solvents such as chloroform, dichloromethane, and tetrahydrofuran. Complexes **1**–**4** were characterized by X-ray structure determinations.

Crystal Structure of $[HgL^1(SCN)_2]_n$ (1)

By the slow diffusion of MeOH solution of $Hg(SCN)_2$ into a solution of $\mathbf{L^1}$ in CH_2Cl_2, red crystalline **1** was obtained. Its formulation, $[Hg(\mathbf{L^1})(SCN)_2]_n$, was confirmed by elemental analysis and the use of the single-crystal X-ray diffraction method. The X-ray structural analysis revealed the formation of single-stranded helical chain structures. Each Hg^{II} center exhibits a distorted tetrahedral coordination geometry with two pyridines from $\mathbf{L^1}$ and two sulfur atoms of $Hg(SCN)_2$ as anticipated (Figure 1, a). The bond angles around the mercury atom are in the range 98.67(14)–127.06(6)°, indicating a quite distorted tetrahedral geometry. The coordinated pyridine rings are perpendicularly twisted relative to each other, presumably to minimize the steric hindrance between them.

It is shown in part a of Figure 1 that the ligand takes on the *cis*-conformation in this structure to connect two crystallographically different Hg^{II} ions. Two pyridine rings

Figure 1. (a) Molecular structure of **1** showing different coordination environments of the two structurally independent Hg^{II} ions. (b) Space-filling plots of the right-handed chain (left), left-handed chain (right), and the ball-and-stick plot (middle) of the double helix bridged by a π–π stacking interaction in complex **1**. (c) Molecular packing of complex **1**.

are connected by Hg(1) to adopt the same orientation, while those connected by Hg(1A) take on the opposite orientation. This connectivity extends the span of the two ligands and forces a turn in the chain. Such an arrangement endows the chain structure with an intrinsic helical sense. The repeating unit in this single-stranded helix consists of a pair consisting of the $Hg(SCN)_2$ unit and the ligand. As depicted in part b of Figure 1, a fairly flattened, loose helix runs along the *b* axis with a pitch of about 7.99 Å (distance between the two mercury centers at the same phase); at the widest point the diameter of the helix equals 16.03 Å. Left-handed helicates connect through an intermolecular π–π stacking interaction between phenyl and pyridine rings with the short distance of 3.38 Å, and there is some evidence of a weak interaction between each nitrogen atom of $Hg(SCN)_2$ and the pyridyl C–H group of a molecule in an adjacent chain (C–H···N = 3.24 Å);[4] right-handed helicates also connect in this way (Figure 1, c). Unlike most double-helical complexes,[9] the adjacent left-handed and neighboring right-handed helical chains are not entangled together but interact through π–π stacking interactions with the short distance of 3.24 Å as illustrated in Figure 1 (parts b and c), which may contribute to stabilizing the formation of the helical structure. Then a two-dimensional network is formed through the C–H···N hydrogen bond interaction established between ligands and thiocyanate anions of adjacent chains and intermolecular π–π stacking interactions. Because left-handed and right-handed helical chains coexist in the crystal structure, the whole crystal is mesomeric and does not exhibit chirality.

Crystal Structure of $Hg(L^1)_2I_2$ (2)

The crystal contains individual $Hg(\mathbf{L^1})_2I_2$ neutral molecules. A perspective drawing with atom-labeling scheme is shown in Figure 2 (a). Each metal atom is tetracoordinated by two N donors from different ligands and two terminal iodine atoms of HgI_2. The Hg–N distance (Table 1) in the complex is in the range of those found in the other complexes;[7] Hg–I distances are also in the range of those found in other Hg^{II} iodine complexes with terminal Hg–I bonds.[7] The bond angles N(2A)–Hg(1)–N(2), N(2A)–Hg(1)–I(1), N(2)–Hg(1)–I(1) and I(1)–Hg(1)–I(1A) are 76.3(3), 105.10(2), 106.74(2) and 139.18(3)°, respectively. Table 1 shows that the Hg–N and Hg–I distances are almost equal; thus the strong distortion in the tetrahedral environment of the four donor atoms is explained on the basis of strong stereo interactions between the two $\mathbf{L^1}$ ligands in each complex.

However, in crystal complex **2**, the ligand with two potential coordination nitrogen atoms, only one pyridine nitrogen atom of the ligand participates, coordinating to mercury(II). It does not present helices like the reported 2,2′- and 4,4′-bipyridyl-based "building block" compounds before. It is possible that the large volume of two iodine atoms repulses the ligands to form the very small angle of N–Hg–N [76.3(3)°], which produces strong stereo interactions when Hg^{II} ions bridge ligands to form the coordination polymer. The adjacent molecules are stacked to sheets through π–π interaction along the *b* axis with the short distance of 3.44 Å, and opposite sheets interact through pairwise C–H···I contacts [C–H···I = 3.92 Å, H···I = 3.16 Å][4] along the *c* axis, which have 2D sheets propagated as depicted in Figure 2 (b). Taking the van der Waals radii of H and I to be 1.20 and 2.15 Å, respectively, any H···I contact

less than 3.35 Å and C–H···I angle >130° may therefore potentially be considered significant.[8] In complex **2**, the distance of H···I is 3.16 Å and the C–H···I angle is 152°, which indicate the formation of C–H···I hydrogen bonds. The importance of such C–H···I hydrogen bonds in supramolecular self-assembly has also been reported recently.[8] The overall structure is compact with small cavities.

Crystal Structure of $Hg_2(L^2)_2(SCN)_4$ (3)

The structure of complex **3** is shown in Figure 3 (a). The molecules of **3** exist as a centrosymmetric 30-membered macrometallacyclic ring formed by two $\mathbf{L^2}$ ligands bridging two Hg^{II} ions with pyridine nitrogen in *trans*-form. However, the macrocycle **3** is nonplanar and its cavity is large [N(2)–N(3A) = 12.713 Å, Hg(1)–Hg(1A) = 12.122 Å]; the dihedral angles between the pyridyl and carbazolyl rings, and the neighboring pyridyl ring are 31.6° and 20.2°, respectively. The opposite carbazolyl rings and pyridyl rings are parallel to each other.

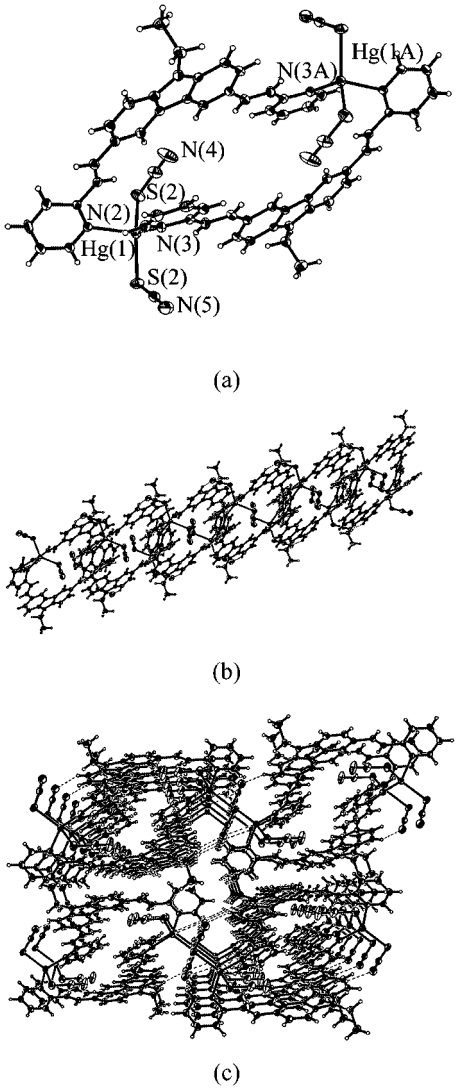

Figure 3. (a) Perspective view of the 30-membered macrometallacyclic ring of complex **3**. (b) The packing diagram of complex **3** showing π–π stacking interaction and the weak C–H···N interactions along the *b* axis. (c) The packing diagram of complex **3** between different chains showing the weak Hg···N interactions along the *c* axis.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In this complex, the $\mathbf{L^2}$ ligand has bidentate coordination, and each Hg^{II} center is coordinated by two pyridine nitrogen atoms from two different ligands and two sulfur atoms from two thiocyanate anions, showing a distorted tetrahedron geometry with a N–Hg–N bond angle of 95.77(1)°. The bond lengths of Hg–N_{av} of 2.39 Å and Hg–S_{av} of 2.455 Å fall within the expected values (Table 1). The dinuclear structures connect to each other through a π–π stacking interaction (the shortest distance of two macrocycles is 2.85 Å) and weak C–H···N interactions (C–H···N = 3.45 Å)[4] to form an infinite chain of macrocycles like a stair structure along the *b* axis (Figure 3, b). In particular, the difference chains (Figure 3, c) show some weak interaction through single, secondary Hg···N–C–S interactions (Hg···N = 3.59 Å) along the *a* axis. Together, the π–π stacking interaction and hydrogen bond form the overall two-dimensional network.

Crystal Structure of $[HgL^2I_2]_n$ (4)

Helical structures represent a longstanding synthetic target for the supramolecular chemist because of their intrinsic aesthetic appeal and potentially exploitable properties.[9] At this time, our attempts are directed toward the generation of a helical chain through the variation of the anion while maintaining the metal ion and ligand structure. The most striking feature of compound **4** is the interesting arrangement of $\mathbf{L^2}$ molecules and usual coordination of mercury atoms forming a unique helical structure. As described in Figure 4 (a), complex **4** also contains a pair of HgI_2 units and two $\mathbf{L^2}$ ligands in its asymmetric unit cell. However, these components do not connect to another to form a macrocyclic structure like complex **3**, but rather connect to form an infinite polymeric chain structure. A compact single-stranded helical chain is formed by self-assembly of $[HgL^2I_2]$ by coordination of *meta*-related peripheral pyridine-N of this unit to the neighboring Hg^{II} center running along a crystallographic 2_1 axis in the *a* direction with a long pitch of about 11.69 Å; at the widest point the diameter of the helix equals 6.13 Å.

In addition, like complex **1**,[7] the adjacent helical chains in compound **4**, one exhibiting left-handedness and the other right-handedness, are not entangled together but interact through π–π stacking interactions (the shortest distance of pyridyl and benzyl rings is 3.42 Å), which are alternatively offered by two helical chains to generate a compact double-stranded helical chain (Figure 4, b). To illustrate this clearly, the left- and right-handed helical chains are represented in Figure 4, b. Like complex **1**, these double-stranded helical chains are further extended into the two-dimensional architecture by C–H···I hydrogen bond interactions established between ligands and iodine anions of adjacent chains (C–H···I = 4.14 Å, H···I = 3.23 Å)[4] with interactions along the *b* axis in compound **4** (Figure 4, c). In complex **4**, the distance of H···I is 3.23 Å and the C–H···I angle is 142°, which indicate the formation of C–H···I hydrogen bonds. Because left-handed and right-handed helical chains coexist in the crystal structure, the whole crystal is mesomeric and does not exhibit chirality.

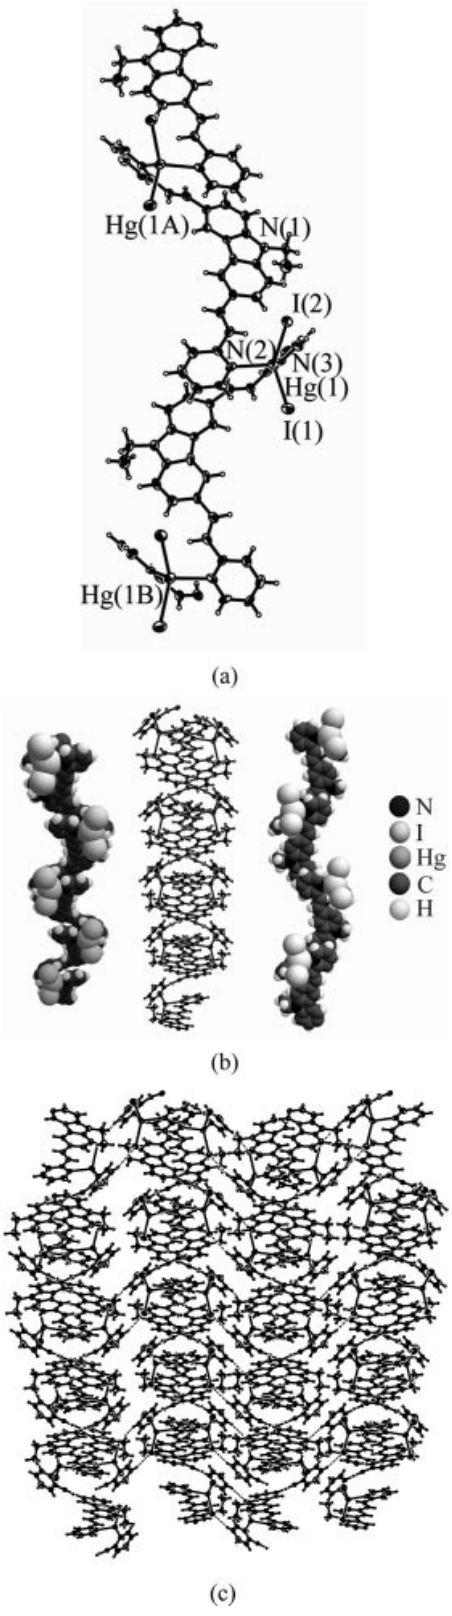

Figure 4. (a) Molecule structure of **4** showing different coordination environments of the two structurally independent Hg^{II} ions. (b) Space-filling plots of the right-handed chain (left), left-handed chain (right), and the ball-and-stick plot (middle) of the double helix bridged by a π–π stacking interaction in complex **4**. In the present work, four different Hg^{II} coordination complexes **1**–**4** with bis(pyridyl) ligands (**L**^{1}, **L**^{2}) have been prepared and structurally characterized, giving metal–organic supramolecular architectures. Although compared with rigid bridging ligands, flexible bridging ligands are able to produce some unique frameworks with aesthetics and useful properties because of their flexibility and conformational freedom,[10] we designed and synthesized two novel functional rigid ligands with long conjugated chains that also present flexibility and conformational freedom to a certain extent. In complexes **1**–**4**, Hg^{II} centers all adopt four-coordination modes in different coordination environments. By comparing the structures of the four complexes, it is clear that the conformations of ligands in the complexes are related to the position of the nitrogen atom. Although complexes **1** and **3** have the same mercury(II) cation and thiocyanate counterion, ligand **L**^{1} of 4-N atoms in complex **1** takes on the *cis*-conformation to form helical chains and ligand **L**^{2} of 2-N atoms in complex **3** takes on the *trans*-conformation to form the macrometallacyclic ring; otherwise, ligand **L**^{1} of 4-N atoms in complex **1** and ligand **L**^{2} of 2-N atoms in complex **4** all take on the *cis*-conformation to form similar helical chains with nearly uniform bond lengths and angles (Table 1). Also, it should be noted that although **L**^{1}, with two potential coordination nitrogen atoms but only one pyridine nitrogen atom of the ligand, coordinates to mercury(II) in complex **2**, it is possible that the very small angle of N–Hg–N [76.3(3)°] produces strong stereo repulsion. This indicates that the conformations of ligands in the complexes may play an important role, indicating that the nature of the ligand is a determining factor in controlling the structural topology of these metal–organic supramolecular architectures, which offers the opportunity to control the coordination networks by ligand modifications.

Characterization

Thermogravimetric Analysis

The TG-DSC measurements of complexes **1**–**4** were determined in the range of 20–800 °C under nitrogen. To study the thermal stability of compounds **1**–**4**, thermal gravimetric analyses (TGA) were performed on the single crystal samples. TG data show that **1** is stable up to 235.2 °C, loses weight from 235.2 to 474 °C corresponding to decomposition of ligand **L**^{1}, and finally loses weight from 557 to 764 °C corresponding to the losses of $Hg(SCN)_2$. The TG data of **2** show that it is also stable up to 250 °C and then keeps losing weight from 250 °C to 768 °C, corresponding to decomposition of ligand **L**^{1} and HgI_2. The TG data for **3** show that it begins to decompose at 197 °C, then there are two weight-loss stages in the ranges 197–481 °C and 530–775 °C, corresponding to decomposition of ligand **L**^{2} and the losses of $Hg(SCN)_2$, respectively. The TG data of **4** show that the weight loss from 192 to 292 °C corresponds to the losses of ligand **L**^{2}, and the weight loss from 292 to 520 °C corresponds to decomposition of HgI_2.

Luminescent Properties

Luminescent transition-metal complexes containing multichromophoric ligands with extended conjugation have been extensively studied in recent years, partly because of their potential use as sensors, probes, and photonic devices.[11] Owing to the ability to affect the emission wavelength of organic materials, syntheses of inorganic–organic coordination complexes by the judicious choice of organic spacers and transition-metal centers can be an efficient method for obtaining new types of electroluminescent materials.[12] Free ligands **L**^{1} and **L**^{2}, and their metal complexes **1**–**4** show emission in solid state at room temperature (Figure 5). The nanosecond range of lifetime in the solid state at 298 K reveals that the emission is fluorescent in nature. The solid-state fluorescent analyses show that complexes exhibit different properties. As shown in Figure 5 (a), complex **1** exhibits an intense broad emission band centered at 608 nm, which is completely invariant to the excitation over the range of 300 to 534 nm and complex **2** always displays a weak broad emission band centered at 604 nm upon excitation over the range of 300 to 543 nm. These fluorescent emissions can be tentatively assigned to the ligand-to-metal charge transfer (LMCT), as two emissions at 452 and 522 nm upon excitation over the range of 300–428 nm can be observed for the free **L**^{1}. Complex **3** exhibits a broad

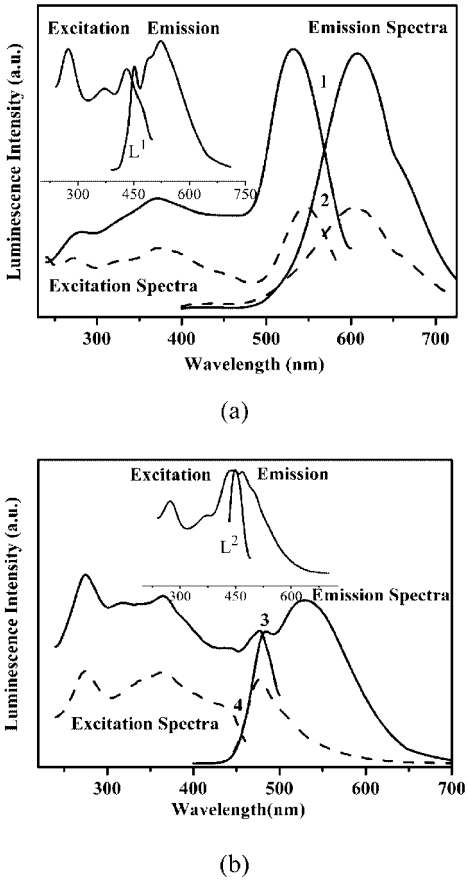

Figure 5. Solid-state emission spectra of complexes at room temperature: (a) **L**^{1}, **1**, and **2**; (b) **L**^{2}, **3** and **4**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

intense emission band at 528 nm with a shoulder at 484 nm upon excitation over the range of 365–477 nm, which can be tentatively assigned to LMCT and the intraligand fluorescent emission. However, complex **4** presents a sharp weak emission band with the maximum at 477 nm, which is completely invariant to the excitation over the range of 300–429 nm. The emission spectrum in complex **4** is largely characteristic of the intraligand fluorescent emission, as two emissions at 448 and 467 nm upon excitation over the range of 300 to 423 nm can be observed for the free $\mathbf{L^2}$. Thus the difference in the intense emission results from the different coordinated counteranions to Hg^{II} (I^- for **2**, **4** and SCN^- for **1**, **3**), which suggests that the change of counteranions has an important effect on their fluorescent property.[13]

Experimental Section

All chemicals and solvents were dried and purified by the usual methods. Elemental analyses were performed with a Perkin–Elmer 240C elemental analyzer. IR spectra were recorded with a Nicolet FTIR Nexus 870 instrument in the range 4000–400 cm^{-1} by using KBr pellets. The far-IR spectra (600–50 cm^{-1}) were recorded as Nujol mulls between polyethylene sheets. ^1H and ^{13}C NMR spectra were performed on a Bruker av600 MHz Ultrashield spectrometer and are reported as parts per million (ppm) from TMS (δ). The thermal behaviors were recorded with a Perkin–Elmer Pris-1 DMDA-V1 analyzer in N_2 at a heating rate of 5 °C min^{-1}. The luminescent spectra were measured on single crystals at room temperature using a Fluorolog-3-TAU steady-state/lifetime spectrofluorometer. The excitation slit was 2 nm, and the emission slit was 2 nm also.

X-ray Crystallography: Single-crystal X-ray diffraction measurements were carried out on a Bruker Smart 1000 CCD diffractometer equipped with a graphite crystal monochromator situated in the incident beam for data collection at room temperature. The determination of unit cell parameters and data collections were performed with Mo-K_α radiation (λ = 0.71073 Å). Unit cell dimensions were obtained with least-squares refinements, and all structures were solved by direct methods using SHELXL-97.[14] The other non-hydrogen atoms were located in successive difference Fourier syntheses. The final refinement was performed by full-matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms on F^2. The hydrogen atoms were added theoretically and riding on the concerned atoms. Crystallographic crystal data and processing parameters for compounds **1**–**4** are shown in Table 2. Selected bond lengths and bond angles are listed in Table 1.

CCDC-245193 (for **1**), -245192 (for **2**), -241585 (for **3**), and -241588 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Preparation of 9-Ethyl-3,6-diiodocarbazole: 9-Ethylcarbazole (10 g, 51 mmol) and anhydrous ethanol (150 mL) were added to a three-necked flask equipped with a magnetic stirrer, a reflux condenser, and an isobaric dropping funnel. ICl (20 g, 123 mmol)/ethanol (20 mL) was added to the mixture at 80 °C. The reaction mixture was refluxed for 2 h, cooled to room temperature and filtered. The grey needle crystals (20.52 g, 45.9 mmol) obtained (90%) were washed with ethanol. M.p. 154–155 °C. ^1H NMR (600 MHz, [D_6]-DMSO): δ = 1.27 (t, J = 6.6 Hz, 3 H), 4.41 (q, J = 6.6 Hz, 2 H), 7.50 (d, J = 8.4 Hz, 2 H), 7.74 (d, J = 8.4 Hz, 2 H), 8.61 (s, 2 H).

Preparation of 9-Ethyl-3,6-bis[2-(4-pyridyl)ethenyl]carbazole ($\mathbf{L^1}$): 9-Ethyl-3,6-diiodocarbazole (3.13 g, 7 mmol), potassium carbonate (2.42 g, 17.5 mmol), tetra-*n*-butylammonium bromide (2.26 g, 7 mmol), tri-*o*-tolylphosphane (0.21 g, 0.7 mmol), 4-vinylpyridine (4 mL, 30 mmol), palladium(II) acetate (0.047 g, 0.2 mmol) and redistilled *N*,*N*-dimethylformamide (7 mL) under nitrogen were added to a three-necked flask equipped with a magnetic stirrer, a reflux condenser and a nitrogen input tube. The reaction mixture was refluxed in an oil bath at 100 °C under nitrogen. The resulting solution was refluxed for 48 h and then cooled to room temperature. The residue was extracted with dichloromethane (600 mL), washed three times with distilled water, and dried with anhydrous magnesium sulfate. Then it was filtered and concentrated. The resulting solution was chromatographed over 200 g of silica gel. Elution with ethyl acetate and the recrystallization from ethanol produced light yellow crystals. Yield: 1.99 g (71%). M.p. 247.1–247.4 °C. ^1H NMR (600 MHz, [D_6]DMSO): δ = 1.35 (t, J = 6.9 Hz, 3 H), 4.49 (q, J = 6.9 Hz, 2 H), 7.29 (d, J = 16.3 Hz, 2 H), 7.59 (d, J = 4.8 Hz, 4 H), 7.69 (d, J = 8.4 Hz, 2 H), 7.74 (d, J = 16.3 Hz,

2 H), 7.83 (d, J = 8.4 Hz, 2 H), 8.52 (s, 2 H), 8.55 (d, J = 4.8 Hz, 4 H). ^{13}C NMR (600 MHz, [D$_6$]DMSO): δ = 150.43, 145.34, 140.83, 134.51, 128.16, 126.11, 123.63, 123.12, 121.06, 119.97, 110.32, 37.81, 14.31. IR (KBr): $\tilde{\nu}$ = 2927 (m), 2860 (w), 1729 (m), 1627 (m), 1600 (s), 1485 (m), 1413 (w), 1344 (m), 1233 (m), 1155 (w), 1126 (w), 1022 (w), 960 (m), 805 (m), 705 (m), 591 (w), 525 (w) cm^{-1}. $C_{28}H_{23}N_3$ (401.50): calcd. C 83.76, H 5.77, N 10. 47; found C 83.80, H 5.76, N 10.44.

Preparation of 9-Ethyl-3,6-bis[2-(2-pyridyl)ethenyl]carbazole (L^2): 9-Ethyl-3,6-diiodocarbazole (3.13 g, 7 mmol), potassium carbonate (2.42 g, 17.5 mmol), tetra-*n*-butylammonium bromide (2.26 g, 7 mmol), and 2-vinylpyridine (4 mL, 30 mmol) were dissolved in redistilled *N*,*N*-dimethylformamide (7 mL). Palladium(II) acetate (0.047 g, 0.2 mmol) and tri-*o*-tolylphosphane (0.21 g, 0.7 mmol) were added to it. The resulting solution was refluxed for 5 days and then cooled to room temperature. The residue was extracted with dichloromethane (600 mL), washed three times with distilled water, and dried with anhydrous magnesium sulfate. Then it was filtered and concentrated. The resulting solution was chromatographed over silica gel (200 g). Elution with ethyl acetate/petroleum ether (2:1) and the recrystallization from ethyl acetate produced light yellow crystals. Yield: 1.88 g (67%). M.p. 189.3–189.4 °C. ^{1}H NMR (600 MHz, [D$_6$]DMSO): δ = 1.35 (t, J = 7.2 Hz, 3 H), 4.48 (q, J = 7.2 Hz, 2 H), 7.24 (t, J = 6.0 Hz, 2 H), 7.36 (d, J = 16.2 Hz, 2 H), 7.57 (d, J = 7.2 Hz, 2 H), 7.66 (d, J = 7.2 Hz, 2 H), 7.80 (q, 4 H), 7.87 (d, J = 16.2 Hz, 2 H), 8.55 (s, 2 H), 8.59 (d, J = 4.2 Hz, 2 H). ^{13}C NMR (600 MHz, [D$_6$]DMSO): δ = 155.59, 149.50, 140.21, 136.81, 133.11, 127.87, 125.58, 125.44, 122.76, 121.91, 121.87, 119.53, 109.74, 37.31, 13.84. IR (KBr): $\tilde{\nu}$ = 2933 (m), 2866 (w), 1733 (m), 1626 (m), 1590 (s), 1488 (m), 1412 (w), 1385 (m), 1347 (w), 1236 (m), 1193 (w), 1160 (w), 1124 (w), 970 (m), 810 (m), 597 (w), 520 (w) cm^{-1}. $C_{28}H_{23}N_3$ (401.50): calcd. C 83.76, H 5.77, N 10.47; found C 83.72, H 5.78, N 10.50.[15]

Preparation of $[HgL^1(SCN)_2]_n$ (1): L^1 (40.01 mg, 0.1 mmol) in CH_2Cl_2 solution (5 mL) was layered onto a solution of $Hg(SCN)_2$ (31.6 mg, 0.1 mmol) in MeOH (5 mL) and stood for several days to give red single crystals of **1**. Yield 64.64 mg (90%). IR: $\tilde{\nu}$ = 2065 (vs), 419 (m), 327 (m). $C_{30}H_{23}HgN_5S_2$ (718.24): calcd. C 50.17, H 3.23, N 9.75; found C 50.14, H 3.24, N 9.77.

Preparation of $Hg(L^1)_2I_2$ (2): L^1 (40.01 mg, 0.1 mmol) in $CHCl_3$ solution (5 mL) was layered onto a solution of HgI_2 (45.4 mg, 0.1 mmol) in MeOH (10 mL) and stood for a week to give yellow single crystals of **2**. Yield 111.91 mg (89%). IR: $\tilde{\nu}$ = 420 (m), 151 (s). $C_{56}H_{46}HgI_2N_6$ (1257.38): calcd. C 53.49, H 3.69, N 6.68; found C 53.51, H 3.68, N 6.69.

Preparation of $Hg_2(L^2)_2(SCN)_4$ (3): L^2 (40.01 mg, 0.1 mmol) and $Hg(SCN)_2$ (31.6 mg, 0.1 mmol) were dissolved in MeOH (20 mL), refluxed for 2 h at 70 °C, and cooled to give a clear yellow solution. Yellow crystals suitable for X-ray diffraction were obtained after two weeks by slow evaporation of the methanol solution at room temperature. Yield 57.46 mg (80%). IR: $\tilde{\nu}$ = 2061 (vs), 420 (m), 328 (m). $C_{60}H_{46}Hg_2N_{10}S_4$ (1436.49): calcd. C 50.17, H 3.23, N 9.75; found C 50.14, H 3.24, N 9.77.

Preparation of $[HgL^2I_2]_n$ (4): L^2 (40.01 mg, 0.1 mmol) and HgI_2 (31.6 mg, 0.1 mmol) were dissolved in MeOH (20 mL), refluxed for 2 h at 70 °C, and cooled to room temperature giving a clear yellow solution. Pale yellow crystals suitable for X-ray diffraction were obtained after several days by slow evaporation of the methanol solution at room temperature. Yield 77.89 mg (91%). IR: $\tilde{\nu}$ = 419 (m), 151 (s). $C_{28}H_{23}HgI_2N_3$ (855.88): calcd. C 39.29, H 2.71, N 4.91; found C 39.28, H 2.72, N 4.92.

Acknowledgments

We thank the National Natural Science Foundation of China (50272001, 50335050, 50532030), and Person with Ability Foundation of Anhui Province 2002Z021. We also wish to thank Prof. D. Q. Wang of University of Liao Cheng for his assistance with the X-ray structure determinations.

The Mo_{36}-polyoxometalate $[Mo_{36}O_{108}(NO)_4(H_2O)_{16}]^{12-}$ reacts with Ln^{3+} to give crystalline solids with 1D, 2D, and 3D polymeric frameworks, depending on the size of Ln^{3+} and the reaction conditions. Reaction of $LaCl_3$ with $(NH_4)_{12}$-$[Mo_{36}O_{108}(NO)_4(H_2O)_{16}]$ gives $(H_3O)_2[\{La(H_2O)_5\}_2\{La(H_2O)_6\}$-$\{La(H_2O)_5Cl\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]Cl{\cdot}21H_2O$ (**1**), in whose structure the La^{3+} cations and the polyoxometalate anions are united in a 3D framework, whereas $NdCl_3$ and $SmCl_3$ give $[\{Ln(H_2O)_6\}_4\{Ln(H_2O)_4\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]$-$Cl_3{\cdot}nH_2O$ [Ln = Nd, n = 24 (**2**); Ln = Sm, n = 21 (**3**)], which have 2D frameworks. Under different conditions, large Ln^{3+} ions (La–Nd) give the one-dimensional coordination polymers $[\{Ln(H_2O)_6\}_2\{Ln(H_2O)_7\}_2\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]{\cdot}nH_2O$ [Ln = La, n = 29 (**4**); Ln = Ce, n = 41 (**5**), Ln = Pr; n = 40 (**6**), Ln = Nd, n = 36 (**7**)], whereas reaction with $Gd(NO_3)_3$ gives $[\{Gd(H_2O)_5\}_4\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]{\cdot}34H_2O$ (**8**), which has a unique 2D layered structure. Smaller Ln^{3+} ions (Tb–Lu) give isostructural 1D chain coordination polymers $(H_3O)_3$-$[\{Ln(H_2O)_6\}_2\{Ln(H_2O)_4\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]{\cdot}nH_2O$ [Ln = Tb, n = 42 (**9**); Ln = Dy, n = 43 (**10**), Ln = Ho, n = 46 (**11**), Ln = Er, n = 50 (**12**); Ln = Yb, n = 56 (**13**); Ln = Lu, n = 31 (**14**)]. The first coordination polymer based on $[Mo_{36}O_{112}$-$(H_2O)_{16}]^{8-}$, namely $(H_3O)_2[\{Nd(H_2O)_5\}_2\{Mo_{36}O_{112}(H_2O)_{16}\}]{\cdot}$ $40H_2O$ (**15**), was prepared from MoO_4^{2-}, NH_2OH, and Nd^{3+}. It has a 2D layered structure. All these compounds are obtained in moderate to high yields (35–93 %), and were characterized by elemental analysis, IR spectroscopy, and single-crystal X-ray structural analysis. Direct coordination of Ln^{3+} to the oxygen atoms of terminal *cis*-MoO_2^{2+} groups is responsible for the formation of these polymeric frameworks. The coordination numbers of Ln^{3+} change from 9 (La–Sm) to 8 (Gd–Lu).

Introduction

Giant polyoxometalates (POMs) are relatively recent but increasingly fascinating objects of study owing to their potential applications in catalysis, photochemistry, sorption, magnetism, medicine, etc.[1–5] Furthermore, they are attractive building blocks for the design of new one-, two-, and three-dimensional frameworks in new functional materials because they possess both well-defined tunable structures and properties and can act as macroligands toward heterometals.[6,7] The heterometal can bring into play its own properties, such as magnetism. The oxophilic and paramagnetic lanthanide ions are especially well suited for these purposes[8,9] as they also may serve as luminescent[10–16] and Lewis acid catalytic centers.[17] Organic linkers between the lanthanide centers can also be inserted, giving rise to new hybrid organic–inorganic polymeric frameworks.[18] Lanthanide complexes of $[SiW_{11}O_{39}]^{8-}$ and $[P_2W_{17}O_{61}]^{10-}$, for example, show antiviral activity against HIV virus,[19] and there are some examples of using Anderson[20] $\{[Al(OH)_6$-$Mo_6O_{18}]^{3-}\}$ and Keggin[21–23] $\{[XM_{12}O_{40}]^{n-}$, $[Mo_8O_{27}]^{6-}$,[24] $[Mo_9O_{30}]^{6-}$,[25] $[V_{18}O_{42}(X)]^{n-}$,[26–30] and $[Mo_{36}O_{108}(NO)_4$-$(H_2O)_{16}]^{12-}\}$ anions[31–32] as building blocks for inorganic polymers.

Herein we report a series of new compounds (**1**–**15**) with one-, two-, and three-dimensional extended structures, which were obtained by linking large Mo_{36}-polyoxometalate anionic units by lanthanide cations.

Results and Discussion

Syntheses

Orange rhombic crystals of **1**–**3** and **5**–**14** were prepared from the ammonium salt of the polyoxomolybdate $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ and the corresponding Ln^{3+} salts in a 1:4 molar ratio in moderate to high yields by the synthetic procedures described in the Experimental Section. The reactions generally occur in a straightforward manner, although only in the case of La (**1**), Ce (**5**), Pr (**6**), Nd (**7**, synthesis 2), and Gd (**8**) does the Ln/POM ratio in the product correspond to the reagent ratio. The counterion of the

Ln salts sometimes enters the final product, as in **1**–**3**, but more often does not influence the final composition: chlorides, nitrates, and sulfates were used for the preparation of isostructural compounds **9**–**14** with equal efficiency. Some of the isolated solids could actually be metastable phases and sometimes longer crystallization times led to different products (as in the case of **1** and **4**). The POM building blocks $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ or $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$ can also be generated in situ, and the compounds **4**, **7** (synthesis 1), and **15** were obtained by refluxing the mixture of $Na_2MoO_4{\cdot}2H_2O$ and $NH_2OH{\cdot}HCl$ at pH ≈ 2, followed by addition of $LaCl_3{\cdot}7H_2O$ or $NdCl_3{\cdot}6H_2O$. In the case of Nd, longer refluxing followed by slow cooling and crystallization below room temperature led to NO-free $(H_3O)_2[\{Nd(H_2O)_5\}_2\{Mo_{36}O_{112}(H_2O)_{16}\}]{\cdot}40H_2O$ (**15**). The Gd compound **8**, which was previously obtained by reaction of the ammonium salt of keplerate, $[\{(Mo^{VI})Mo^{VI}_5O_{21}(H_2O)_6\}_{12}\{Mo^{V}_2O_4(CH_3COO)\}_{30}]^{42-}$, with $Gd(NO_3)_3$,[33] was obtained from $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ and Gd^{3+} in a more straightforward manner.

The compounds were characterized by elemental analysis and FT-IR spectroscopy. Compounds **1**–**14** and the parent $(NH_4)_{12}[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]{\cdot}36H_2O$ have similar FT-IR spectra, showing only slight shifts in some band positions. All spectra show characteristic absorption bands attributable to H_2O, ν(Mo–O_{term}), ν(Mo–{μ_2-O}), and ν(Mo–{μ_3-O}) groups. The ν(NO) vibrational frequency of 1617 cm^{-1} overlaps with δ(HOH) and is typical for the linear $\{MoNO\}^{3+}$ moiety.[34] There are three types of water in compounds **1**–**15**: water of crystallization, water coordinated to Ln^{3+}, and water attached to the POM anion. Theoretically, it should be possible to follow the water loss by TGA and to discriminate between the types of water leaving the structure. However, our preliminary experiments showed only one nondifferentiated step for water loss over a wide temperature range.

Structures

The structures of compounds **1**–**15** were determined by single-crystal X-ray diffraction. The main bond lengths and angles are given as Supporting Information. The structures show remarkable diversity, being 1D, 2D, or 3D, neutral or anionic frameworks where the discrete POM fragments $\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}$ (for **1**–**14**) or $\{Mo_{36}O_{112}(H_2O)_{16}\}$ (for **15**) are united by $\{Ln(H_2O)_n\}$ units depending on the identity of Ln^{3+}. The coordination environment of the lanthanide cations in **1**–**15** is summarized in Table 1.

The polyoxomolybdate anions $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ $\{Mo_{36}(NO)_4\}$, and $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$ $\{Mo_{36}\}$,[34,35] which serve as building blocks, are built of two $\{Mo_{17}\}$ subunits that are joined together by two MoO_2^{2+} groups. There are two MoL^{n+} groups (L = NO, n = 3; or L = O, n = 4) within each subunit with pentagonal-bipyramidal coordination, surrounded by five MoO_6 octahedra: three are derived from MoO^{4+} and two from *cis*-

MoO_2^{2+}. These six Mo atoms form a five-pointed star. Two such stars are held together by two pairs of edge-sharing octahedra (*cis*-MoO_2^{2+} type), and by one "inner" Mo atom with no terminal oxygen atoms, and are also octahedrally coordinated. Only the terminal MoO_2^{2+} groups coordinate lanthanide cations, and altogether 16 terminal oxygen atoms of $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ can participate in this bonding. For the sake of simplicity we will call the two octahedra attached to the $Mo(NO)^{3+}$ unit as "coordinated" (type A), those in the dimer that hold two "stars" together in each subunit as "peripheral" (type B), those holding two $\{Mo_{17}\}$ subunits together as "closing" (type C), and the MoO_2^{2+} units in the dimer that hold two "stars" together in each subunit as "inner" (type D; Figure 1). Two neighboring A-type MoO_2^{2+} groups always behave as a bidentate ligand, while the others are monodentate.

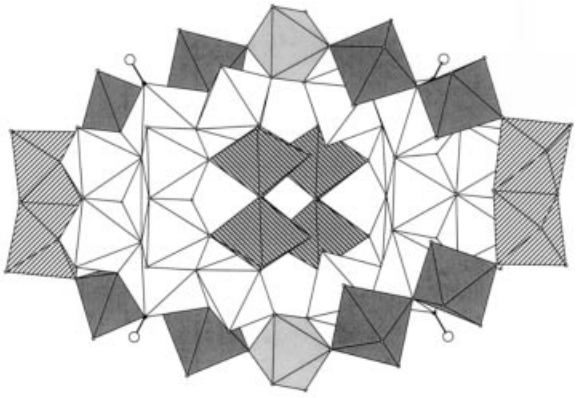

Figure 1. The structure of building block $[Mo_{36}L_4O_{108}(H_2O)_{16}]^{n-}$ (L = NO, n = 12; L = O, n = 8). Representation in polyhedra: dark-grey: type A octahedra; hatched white: type B octahedra; light-grey: type C octahedra; hatched dark-grey: type D octahedra; white: the remaining polyhedra.

The compound $(H_3O)_2[\{La(H_2O)_5\}_2\{La(H_2O)_6\}\{La(H_2O)_5Cl\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]Cl\cdot 21H_2O$ (**1**) is the only one in this series with a 3D-framework structure. Each POM anion is coordinated by 10 La^{3+} cations through 14 oxygen atoms. In turn, these 10 La^{3+} cations join each polyoxoanion with another eight POM anions. All possibilities for coordination of the POM anion to La^{3+} are realized in **1**: through oxygen atoms of A-type groups (eight atoms of four "bidentate ligands"), B-type groups (two atoms), C-type (two atoms), and D-type groups (two atoms). In fact, **1** is the only example of a $\{Mo_{36}(NO)_4\}$-based polymer compound where oxygen atoms of D-type groups take part in coordination to the lanthanide cation. There are two types of La^{3+} cations, with two of each type for every POM fragment. Cations of the first type ensure the binding together of POM building blocks along the crystallographic axes *a* and *b*. Each POM is coordinated by six La cations of this type, such that an A-MoO_2^{2+}–La^{3+}–D-MoO_2^{2+} sequence runs along the *a* axis, while in the other direction (along the *b* axis) the pattern of the sequence is C-MoO_2^{2+}–La^{3+}–D-MoO_2^{2+} and C-MoO_2^{2+}–La^{3+}–A-MoO_2^{2+} (Figure 2). Thus, one La^{3+} cation joins together three POM fragments to form pseudo-layers packed along the crystallographic *c* axis. Four oxygen atoms of type A, two of type C, and two of type D take part in this coordination for each POM fragment. Cations of the second type join together the aforementioned "layers" in a 3D framework along the diagonal between the crystallographic *a* and *c* axes in ay A-MoO_2^{2+}–La^{3+}–B-MoO_2^{2+} sequence. Each POM is coordinated by four La^{3+} cations of this type. Four oxygen atoms of an A-type group (as two "bidentate ligands") and two oxygens of two B-type groups, which are joined together in pairs by an inversion center, participate in this bonding. Every two neighboring POM fragments are bound together by two La cations of this type (Figure 3). Lanthanum cations of this type are disordered over two positions in such a way that in the first position La^{3+} additionally coordinates six water molecules and in the other position five water molecules and one Cl^- anion. There are two types of solvent water molecules in **1**. Two water molecules are clathrated in the inner cavity of the POM whereas the others lie in the voids of framework. There is an extended network of hydrogen bonds involving water molecules and oxygen atoms of the cluster.

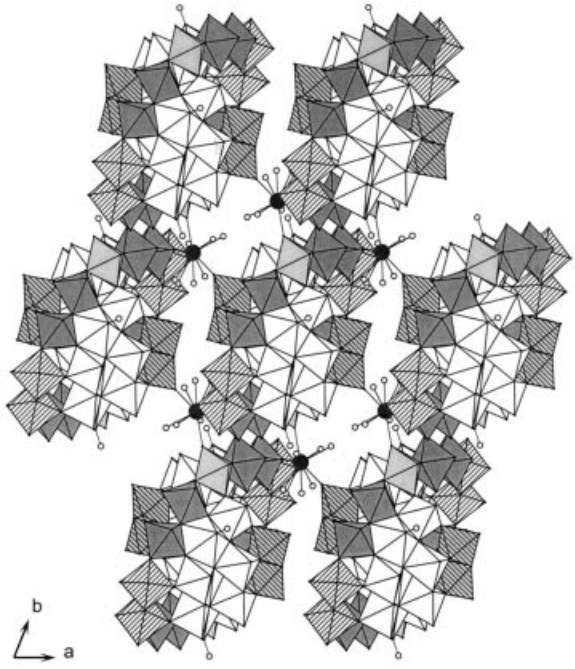

Figure 2. Connectivity pattern in the crystal structure of compound **1** in the *ab* plane. $\{La(H_2O)_5\}$ fragments in ball-and-stick representation (La: dark-grey; O: white); polyoxometalate fragments as polyhedra (for "color" legend see Figure 1).

Compounds $[Nd_5Mo_{36}(NO)_4]$ (**2**), $[Sm_5Mo_{36}(NO)_4]$ (**3**), $[Gd_4Mo_{36}(NO)_4]$ (**8**), and $[Nd_2Mo_{36}]$ (**15**) have different 2D-network structures. The networks in **2** and **3** are isostructural. Each POM anion is coordinated by ten lanthanide cations through fourteen oxygen atoms. In turn, the latter join it to another six POM anions (Figure 4). There are two types of Ln^{3+} in the structure: one is disordered

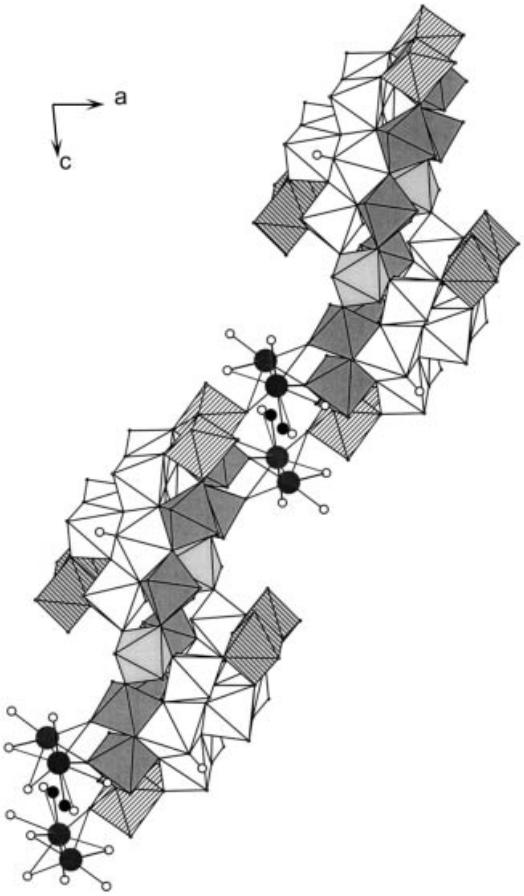

Figure 3. Connectivity pattern in the crystal structure of compound **1** along the diagonal between the crystallographic *a* and *c* axes. Lanthanum cations are disordered over two positions. $\{La(H_2O)_5Cl\}$ and $\{La(H_2O)_6\}$ fragments in ball-and-stick representation (La: dark-grey; O: white; Cl: black); polyoxometalate fragments as polyhedra (for "color" legend see Figure 1).

and coordinates oxygens of C-type groups of two adjacent $\{Mo_{36}(NO)_4\}$ units, whereas the other coordinates oxygen atoms of A-type groups of one POM unit and oxygen atoms of B-type groups of a neighboring POM. Thus, a layered structure forms with a C-MoO_2^{2+}–Ln^{3+}–C-MoO_2^{2+} sequence along the *b* axis and an A-MoO_2^{2+}–Ln^{3+}–B-MoO_2^{2+} sequence along the diagonal between the *b* and *c* axes (Ln = Nd and Sm; Figure 5).

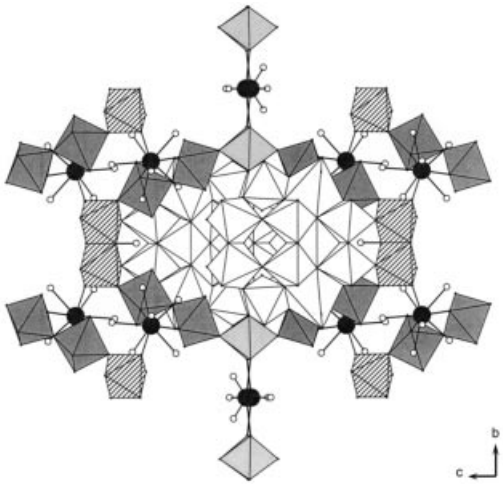

Figure 4. Connectivity pattern in the crystal structure of compounds **2** and **3**. $\{Ln(H_2O)_n\}$ fragments in ball-and-stick representation (Ln: dark-grey; O: white) and $\{Mo_{36}(NO)_4\}$ fragments as polyhedra (for "color" legend see Figure 1).

The structure of $[Gd_4Mo_{36}(NO)_4]$ (**8**) was described in detail in our previous work.[33] This compound was ob-

tained by decomposition of Keplerate polyoxoanions, $[\{(Mo^{VI})Mo^{VI}_5O_{21}(H_2O)_6\}_{12}\{Mo^{V}_2O_4(CH_3COO)\}_{30}]^{42-}$, in the presence of Gd^{3+} cations. Every POM building block in $[Gd_4Mo_{36}(NO)_4]$ is surrounded by eight Gd^{3+} cations and in that way is joined to four adjacent polyoxoanions. There are two unique gadolinium(III) atoms in the structure of **8**, each of which is octacoordinate. The Gd cations of the first type coordinate terminal oxygen atoms of two MoO_2^{2+} groups of type A and one oxygen atom of an MoO_2^{2+} group of type B, whereas the Gd cations of the second type coordinate two oxygens of neighboring A-type groups and one oxygen atom of an MoO_2^{2+} C-type group. In this way the coordination polyhedron of each Gd is filled with three POM oxygen atoms, the rest being coordinated water. Thus, we have an A-MoO_2^{2+}–Gd^{3+}–C-MoO_2^{2+} regularity along the *b* axis, while in the other direction (along the *c* axis) this pattern is A-MoO_2^{2+}–Gd^{3+}–B-MoO_2^{2+} (Figure 6).

Each POM fragment in $[Nd_2Mo_{36}O_{112}]$ (**15**) is surrounded by four Nd^{3+} cations, all of which are equivalent. Only oxygen atoms of type A take part in coordination to form infinite layers where every polyoxoanion is bonded together with four adjacent POM blocks (Figure 7). These layers are perpendicular to the crystallographic *a* axis. Only one (molecular) complex of this polyoxoanion with a lanthanide $(NH_4)_6[Gd_2Mo_{36}O_{112}(H_2O)_{22}]\cdot 50H_2O$ has been described previously.[36]

The crystal packing of **2**, **3**, **8**, and **15** consists of adjusted neutral, in the cases of **2**, **3**, and **8**, and anionic, in the case of **15**, layers stacked in an ABAB... mode (Figure 8). There are three types of solvent water molecules in these network compounds: two water molecules are clathrated in the inner cavity of the POM, and of the rest, some are placed inside the layers and the others fill the gap between adjacent layers. There is an extended network of hydrogen bonds involving water molecules and oxygen atoms of the cluster.

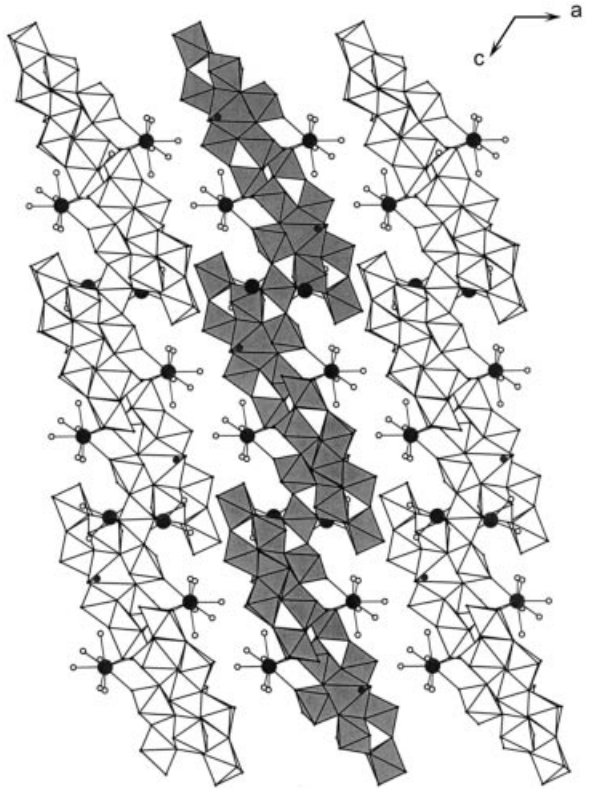

Figure 8. Three neighboring layers (view along the *b* axis) in the crystal structures of **2** and **3**. Polyoxometalate building blocks are given as polyhedra, Ln atoms in ball-and-stick representation. Polyoxometalate fragments of neighboring layers have different "colors" for clarity. Crystallization water molecules have been omitted.

The rest of the coordination polymers in this series have 1D-chain frameworks of different structure. Isostructural compounds with general formula $[\{M(H_2O)_6\}_2\{M(H_2O)_7\}_2\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]\cdot nH_2O$ were obtained for the larger lanthanides La^{3+} (**4**), Ce^{3+} (**5**), Pr^{3+} (**6**), and Nd^{3+} (**7**). There are two types of lanthanide cations in the lattice, and only one type takes part in the formation of infinite chains. It provides connection between POM fragments to give an ...A-MoO_2^{2+}–Ln^{3+}–C–MoO_2^{2+}... sequence along the *a* axis. The cations of the other type are attached to the oxygen atoms of A-type MoO_2^{2+} groups of only one POM anion. These lanthanide cations are disordered over two positions. Every polyoxoanion is coordinated to four cations through eight A-type oxygen atoms (acting as four "bidentate ligands") and to two C-type oxygen atoms (Figure 9). The chains run parallel to each other, forming *ac* pseudolayers which pack up in the ABAB... mode, as observed for **2**, **3**, **8**, and **15** (Figure 10).

We obtained six isostructural compounds with a different 1D chain structure by using the smaller Ln^{3+} ions Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Yb^{3+}, and Lu^{3+} as linkers, namely $(H_3O)_3[\{M(H_2O)_6\}_2\{M(H_2O)_4\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]\cdot nH_2O$ (M = Tb, Dy, Ho, Er, Yb and Lu; **9**–**14**) Here, oxygen atoms of all A-type groups of each polyoxoanion $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{8-}$ are coordinated to lanthanide cations. Two lanthanide cations coordinate only one POM fragment and another two Ln^{3+} ions coordinate oxygen atoms of A-type groups of two neighboring POMs (Figure 11). These compounds crystallize in the trigonal system in the space group $R\bar{3}c$. The infinite chains pack to form pseudo-layers perpendicular to the *c* axis. These pseudo-layers are stacked in such a way that chains of each layer are turned relative to the chains of two neighboring layers by 60° (Figure 12). There is an extended network of hydrogen bonds involving water molecules and oxygen atoms of the cluster.

There are two more $\{Mo_{36}(NO)_4\}$-based one-dimensional polymers $(H_3O)_{12}\{[Mo_2O_5(H_2O)_2][Mo_{36}(NO)_4O_{108}(H_2O)_{16}]\}\cdot 44H_2O$ (**16**)[31] and $[La_2(MoO)_2Mo_{36}(NO)_4O_{108}(H_2O)_{28}]\cdot 56H_2O$ (**17**).[32] These were obtained by refluxing $(H_3O)_{12}[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]$ with an excess of $NH_2OH\cdot HCl$ in water for no more than 30 min (in the presence La^{3+} salt in the case **17**). The $\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}$ units in **16** are connected by bridging $\{Mo_2O_4(\mu\text{-}O)(H_2O)_2\}$ groups coordinated to A-type MoO_2^{2+} groups only (A-MoO_2^{2+}–{Mo–O–Mo}–A-MoO_2^{2+} connectiv-

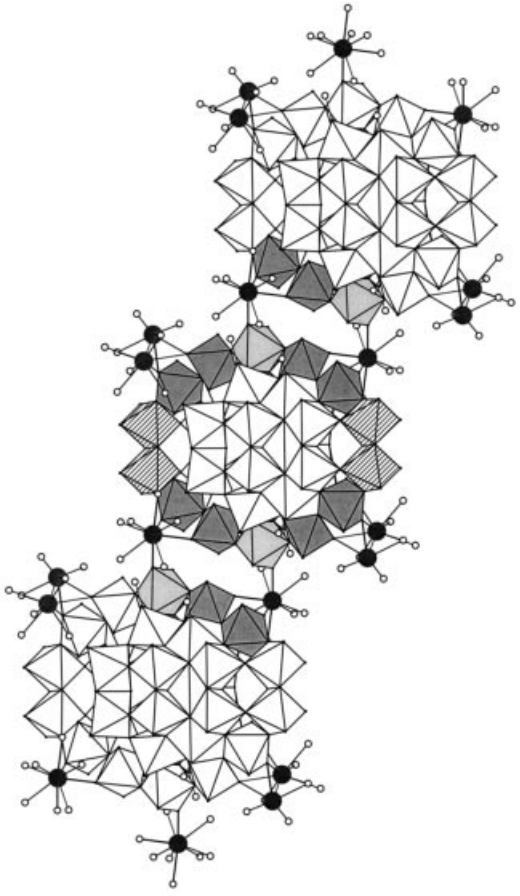

Figure 9. Connectivity pattern in the chains in compounds **4**–**7** distinguishing between the building units or constituents: $\{Ln(H_2O)_n\}$ fragments in ball-and-stick representation and $\{Mo_{36}(NO)_4\}$ fragments as polyhedra (for "color" legend see Figure 1).

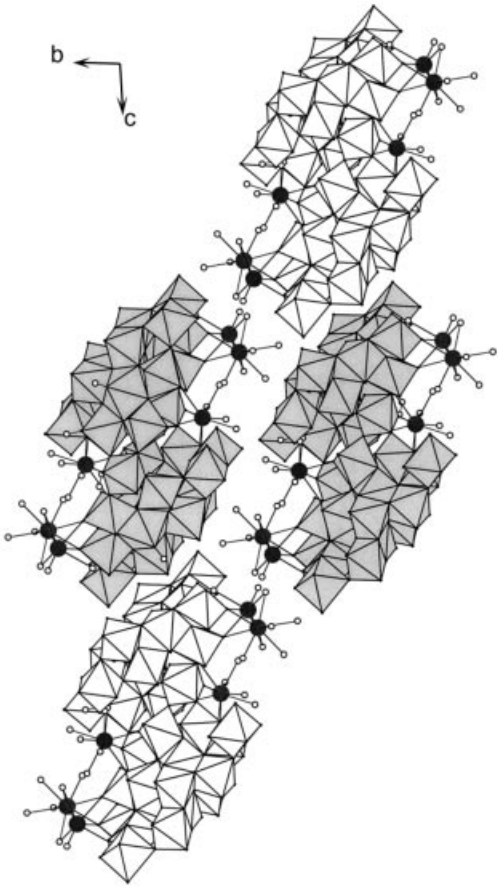

Figure 10. Packing of infinite chains in the crystal structures of **4**–**7** (view along the *a* axis). Polyoxometalate building blocks are given as polyhedra, $\{Ln(H_2O)_n\}$ fragments in ball-and-stick representation. Polyoxometalate fragments of neighboring chains have different "colors" for clarity. Crystallization water molecules have been omitted.

ity),[32] and in **17** two MoO^{3+} groups are coordinated to the A-type *cis*-MoO_2^{2+} units. Chain-building is realized through A-MoO_2^{2+}–La^{3+}–C-MoO_2^{2+} interactions.[31]

Thus, we can see that the nature of Ln^{3+} is decisive with respect to the type of framework adopted. For the same stoichiometry $\{Ln_4Mo_{36}(NO)_4\}$ and without extra ligands (except H_2O) attached to the Ln^{3+}, the larger Ln^{3+} ions (La–Nd, compounds **4**–**7**) adopt a chain structure with nine-coordinate lanthanide, in the middle of the lanthanide series another, layered arrangement appears, exemplified here by the Gd salt **8** (CN Gd^{3+} = 8), and with the smaller Ln^{3+} ions (Tb–Lu, compounds **9**–**14**) a chain-like 1D ar-

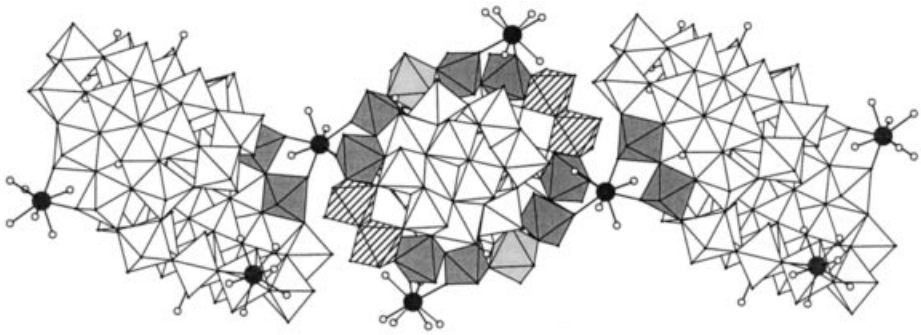

Figure 11. Connectivity pattern in chains in compounds **9**–**14** distinguishing between the building units or constituents: $\{Ln(H_2O)_n\}$ fragments in ball-and-stick representation and $\{Mo_{36}(NO)_4\}$ fragments as polyhedra (for "color" legend see Figure 1).

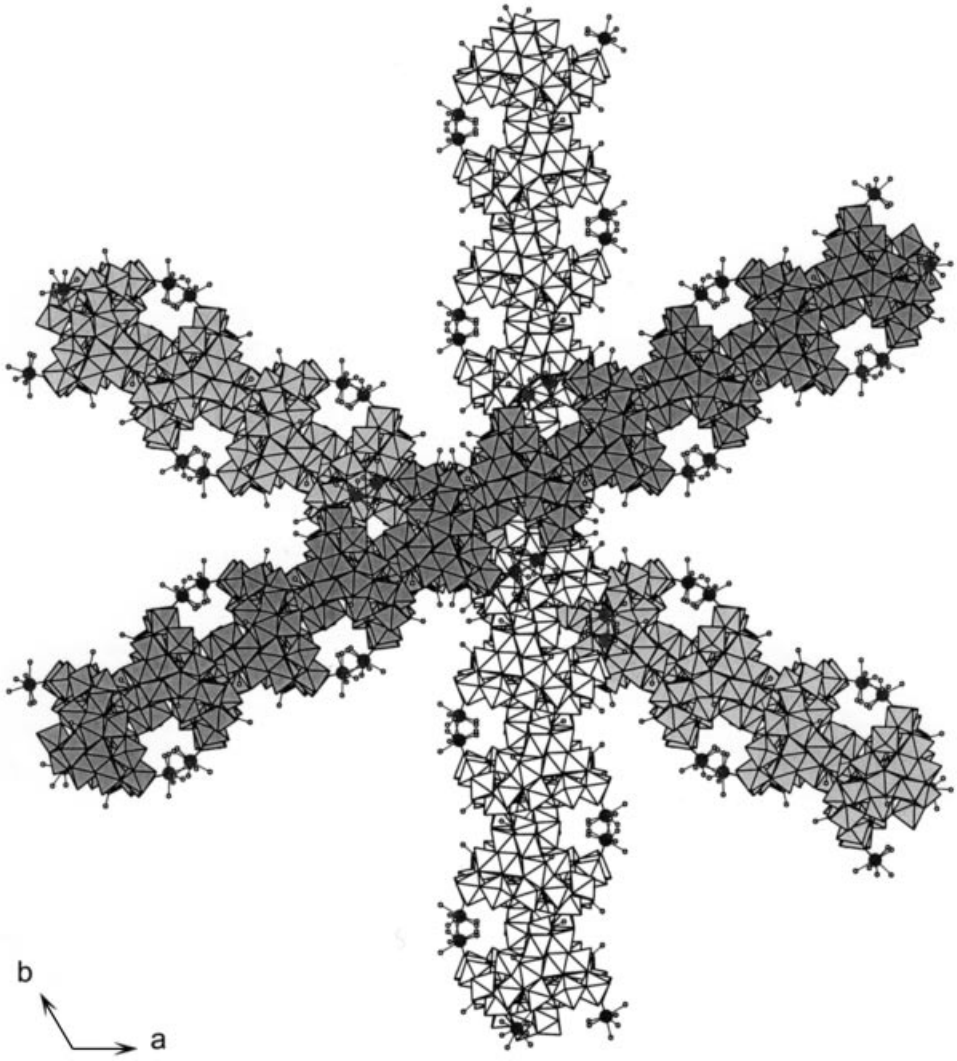

Figure 12. Packing of infinite chains in the crystal structures of **9**–**14** (view along the *c* axis). Polyoxometalate building blocks are given as polyhedra, $\{Ln(H_2O)_n\}$ fragments in ball-and-stick representation. Polyoxometalate fragments of neighboring chains have different "colors" for clarity. Crystallization water molecules have been omitted.

rangement reappears. It is, however, not identical to that found in **4**–**7** as the Ln^{3+} ions are now eight-coordinate and their coordination polyhedra correspond to a dodecahedron and a distorted square antiprism rather than the bicapped trigonal prism of **8**. A similar influence of the Ln^{3+} size can also be found for the series of 1:1 salts formed by Ln^{3+} and monovacant lacunary $[\gamma\text{-}SiW_{11}O_{39}]^{8-}$: the La and Ce salts feature a nine-coordinate lanthanide, the Eu salt is eight-coordinate, and the Yb salt is seven-coordinate. All these compounds are built from 1D chains that change from zig-zag to linear on going from La to Yb.[16]

In conclusion, we have developed a simple synthetic method that allows us to obtain polymeric compounds based on $\{Mo_{36}(NO)_4\}$ building blocks and Ln^{3+} in high yields. Only two compounds were known before our work, both of which are 1D chain polymers. We have synthesized fifteen new polymeric compounds, among which are one with a 3D framework, three with 2D networks of two different types, and eleven with 1D chains, also of two different types. We have also synthesized one 2D network, $[Nd_2Mo_{36}]$, which is the only example of a polymeric compound, based on $\{Mo_{36}O_{112}\}$ building blocks. The influence of the counterion and the reaction conditions (pH crystallization time, and temperature) on the structural type, observed in this work, allows us to expect even more complex architectures to be realized from these nanosized building blocks.

Experimental Section

Materials: $(NH_4)_{12}[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]\cdot 33H_2O$ was prepared according to the previously published procedure.[34] All other reagents were obtained commercially and used as supplied.

X-ray Data Collection and Structural Determination: Single crystals of the complexes were selected and mounted on a Stoe IPDS II

diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Absorption corrections were made with SADABS.[37] The structures were solved by direct methods and refined by the full-matrix least-squares method minimization of $[\Sigma w(F_o - F_c)^2]$ with anisotropic thermal parameters for all skeleton non-hydrogen atoms, and for practically all oxygen atoms of the lattice water molecules, using the SHELX 97 program package.[38] The crystallographic and refinement data are listed in Tables 2, 3, and 4. Selected bond lengths and angles of complexes **1**–**15** are given as Supporting Information.

$(H_3O)_2[\{La(H_2O)_5\}_2\{La(H_2O)_6\}\{La(H_2O)_5Cl\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]Cl\cdot 21H_2O$ [$La_4Mo_{36}(NO)_4$-3D, 1]: $(NH_4)_{12}[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]\cdot 33H_2O$ (0.300 g, 0.047 mmol) was dissolved in 25 mL of water whilst stirring and heating gently (50 °C). The solution was then allowed to cool down to room temperature and filtered. $LaCl_3\cdot 7H_2O$ (0.070 g, 0.188 mmol) was added to the filtrate with stirring (5 min). Small orange crystals of the product started to appear after one hour. These were filtered off and the filtrate was kept at room temperature for three days to produce a crop of single crystals, which were collected by filtration, washed twice with a minimal amount of ice-cooled water, and dried in air. Yield: 0.236 g [72% based on $\{Mo_{36}(NO)_4\}$]. $H_{122}Cl_2La_4Mo_{36}N_4O_{172}$: calcd. H 1.74, N 0.80; found H 1.96, N 0.83. IR (KBr pellet): $\tilde{\nu}$ = 3431 cm^{-1} (s, br), 1626 (s), 1399 (m), 957 (m), 875 (s), 835 (w), 776 (m), 619 (s), 566 (s), 531 (m), 369 (m).

$[\{Nd(H_2O)_6\}_4\{Nd(H_2O)_4\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]Cl_3\cdot 24H_2O$ [$Nd_5Mo_{36}(NO)_4$}, 2]: $(NH_4)_{12}[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]\cdot 33H_2O$ (0.300 g, 0.047 mmol) was dissolved in 25 mL of water whilst stirring and heating gently (50 °C). After the solution had cooled down and been filtered, $NdCl_3\cdot 6H_2O$ (0.066 g, 0.184 mmol) was added to the filtrate whilst stirring (5 min). After one hour small, orange, rhombic crystals of product started to form. After one day they were collected by filtration, washed twice with a small amount of ice-cooled water, and dried in air. X-ray quality single crystals were obtained by reagent diffusion in a U-tube. Yield: 0.250 g [73% based on $\{Mo_{36}(NO)_4\}$, 93% based on $NdCl_3\cdot 6H_2O$]. $H_{136}Cl_3Mo_{36}N_4Nd_5O_{180}$: calcd. H 1.87, N 0.77; found H 2.03, N 0.84. IR (KBr pellet): $\tilde{\nu}$ = 3442 cm^{-1} (s, br), 1622 (s), 1402 (m), 950 (m), 874 (s), 774 (m), 614 (s), 566 (s), 478 (m), 370 (m), 338 (m).

$[\{Sm(H_2O)_6\}_4\{Sm(H_2O)_4\}\{Mo_{36}(NO)_4O_{108}(H_2O)_{16}\}]Cl_3\cdot 21H_2O$ [$Sm_5Mo_{36}(NO)_4$}, 3]: Compound **3** was prepared by exactly the same protocol as **2**, but with $SmCl_3\cdot 6H_2O$ (0.066 g, 0.181 mmol). Dark-orange crystals. Yield: 0.166 g [49% based on $\{Mo_{36}(NO)_4\}$, 63% based on $SmCl_3\cdot 6H_2O$]. X-ray quality single crystals were grown by reagent diffusion in a U-tube. $H_{130}Cl_3Mo_{36}N_4O_{177}Sm_5$: calcd. H 1.79, N 0.77; found H 2.01, N 0.90. Mechanism of Isomerization of Ni(cyclam) in Aqueous Solutions

Eric Maimon,*[a,b] Israel Zilbermann,[a,b] Haim Cohen,[a,d] Daniel Kost,[a] Rudi van Eldik,[c] and Dan Meyerstein*[a,d]

Keywords: Isomerization / Cyclam / Nickel complexes / Oxidation states

Nickel complexes of cyclam and cyclam derivatives isomerize in aqueous solutions via two different mechanisms: i. deprotonation of one of the coordinated amino groups followed by inversion and ii. cleavage of the Ni–N bond followed by inversion. While the first mechanism is relevant for the di- and tri-valent nickel complexes, the second one occurs for the mono-valent complexes, and for complexes with tertiary amines as ligands.

Introduction

Qualitative studies based on molecular models first performed by Bosnich et al.[1,2] described the five possible conformational isomers (*trans-I*-*trans-V*, Figure 1, a) of planar complexes of the "classic" macrocyclic ligand system, cyclam. Of the five possible configurational isomers of [Ni(cyclam)]$^{2+}$, (NiL^1)$^{2+}$, it has long been supposed that the *trans-III* configuration is the most stable one.[1,3]

Molecular mechanics (MM) theoretical studies predicted that when four-coordinate low-spin species are involved, the *trans-I* isomer is favoured over the *trans-III* one, while if six-coordinate species are present, the stabilities are reversed.[4] Later theoretical studies applying MM techniques[5–8] and local density functional theory analysis[9] that compare the calculated data to the already published X-ray structures of *trans-III* and *trans-V*,[5,11–13] indicated that the *trans-I* and *trans-III* isomers of [Ni(cyclam)]$^{2+}$ (Figure 1, c), are energetically most stable, and that the energy difference between them is insignificant.

Solution ^{1}H-NMR studies[10a,10b] indicate that both [Ni(cyclam)]$^{2+}$ *trans-I* and *trans-III* forms coexist in aqueous solutions, the *trans-I* isomer comprising ca. 15% of the total complex at room temperature. The rate of equilibration (1) is rapid at high pH, but extremely slow at acidic pH. On the other hand, the equilibrium is shifted to produce more of the *trans-I* isomer at higher temperatures. Based on the latter and on the fact that *trans-I*-[Ni(cyclam)]$^{2+}$ has an extremely small tendency to add axial ligands, the latter complex could be isolated.[10b]

trans-I-[Ni(cyclam)]$^{2+}$ ⇄ *trans-III*-[Ni(cyclam)]$^{2+}$ (1)

Studies performed on the low-spin *N*-alkylated derivative (tmc)-(NiL^3)$^{2+}$ of [Ni(cyclam)]$^{2+}$ (tmc = *N*,*N*′,*N*′′,*N*′′′-Me$_4$-cyclam) led to the conclusion that the *trans-III* configuration is the lowest energy structure and the *trans-I* configuration is kinetically favored.[12–14] The two isomers are not interconvertable unless strong coordinating solvents are present[12] and then the *trans-I* species is favoured.

Solution ^{13}C-NMR studies[15] showed that the published methods[16] for the preparation of *trans-I*-[Ni(tmc)]$^{2+}$ also produce some amounts of the *trans-II* isomer in the crude product. If triflate is used instead of perchlorate as the precipitation agent, a markedly higher proportion of the *trans-II* isomer is obtained. Recrystallization of these products in CH_3NO_2 converts the *trans-II* isomer almost entirely to the *trans-I* isomer. A strong donor solvent such as DMF enhances the rate of isomerization from *trans-II* to *trans-I*. The authors[15] propose that the isomerization mechanism involves the inversion about a nitrogen, which probably requires the inverting nitrogen to detach from the divalent metal centre rendering the previously tetradentate tmc temporarily to become a tridentate chelate.

A very similar mechanism is proposed for the isomerization of the Ni^{II} complex with an alkylated derivative of diazacyclam,[17] L^9 [see reaction (2) and Figure 1, b].

trans-I-[Ni(L^9)]$^{2+}$ ⇄ *trans-III*-[Ni(L^9)]$^{2+}$ (2)

The authors suggest an inversion of one tertiary and one secondary nitrogen donor in the six-membered chelate ring. The coordination of a water molecule to the metal centre following the detachment of a coordinated nitrogen in the transition state is also proposed. The authors also propose

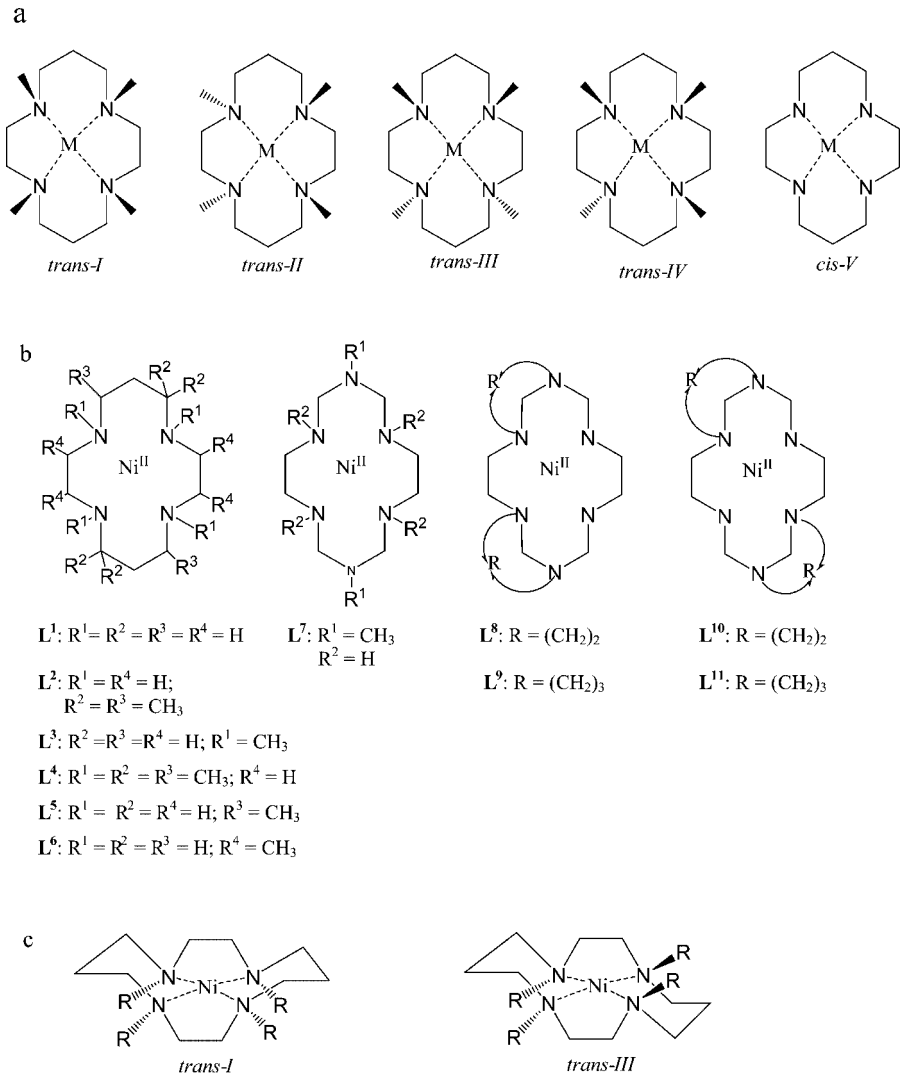

Figure 1. **a**: The five known isomers of metal complexes of cyclam. **b**: The nickel complexes of cyclam and alkylated derivatives. **c**: The most stable isomers of cyclam and derivatives (in this study R = H or CH_3).

the formation of the *trans-II* isomer as one of the intermediates in the mechanistic cycle.

The isomerization of the macrocyclic frame bound to the nickel ion both in the +1 and +3 oxidation states of the metal was also reported. Isomerization according to (3) leads to an equilibrated mixture of a ca. 1:3 ratio, respectively, has been reported to occur in aqueous solutions over a period of several hours.[18a,18b]

$$\textit{trans-I}\text{-}[Ni^{I}(tmc)]^{+} \rightleftarrows \textit{trans-III}\text{-}[Ni^{I}(tmc)]^{+} \quad (3)$$

It is of interest to note that the very fast reduction of $[Ni(cyclam)]^{2+}$ and analogous complexes by e^{-}_{aq} or by $CO_2^{\cdot-}$,[19] is followed by reactions obeying first order kinetics with rate constants in the range $(0.1–2.6)\times10^3\ s^{-1}$, which were attributed to isomerization processes.

Kelly et al.[20] showed that the fast addition of CO to $[Ni^{I}(cyclam)]^{+}$ in aqueous solutions is followed by a slower first-order reaction with a rate constant of 1.8 s^{-1}, which was tentatively attributed to the isomerization process (4).

$$\textit{trans-III}\text{-}[Ni^{I}(cyclam)CO]^{+} \rightleftarrows \textit{trans-I}\text{-}[Ni^{I}(cyclam)CO]^{+} \quad (4)$$

Such a reaction channel was not observed for $[Ni^{I}(L^{6})CO]^{+}$ perhaps due to steric constrains, but it does operate for $[Ni^{I}(L^{5})CO]^{+}$, which is less sterically restrained.[21]

Electrochemical studies[10b] demonstrated the rapid conversion (5) on a time scale of 400 ms.

$$\textit{trans-I}\text{-}[Ni^{III}(cyclam)]^{3+} \rightleftarrows \textit{trans-III}\text{-}[Ni^{III}(cyclam)]^{3+} \quad (5)$$

Isomerization processes of $[Ni^{III}(cyclam)]^{3+}$[22] or cyclam and diazacyclam derivatives were observed following the oxidation of the divalent nickel by strong single electron oxidizing agents.[23–27] Furthermore, the decomposition processes of $[Ni^{III}(cyclam)]^{3+}$ or diazacyclam $(L^{7–11})$[27–29] complexes were shown to obey first order kinetics even though the common decomposition mechanism requires second order kinetics. It was proposed that the rate-determining step in the decomposition process is presumably an isomerization reaction.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Clearly the suggestion that $[Ni^{III}(L^1)(H_2O)_2]^{3+}$ isomerizes faster than $[Ni^{II}(L^1)]^{2+}$[10b] and the effect of pH on the rate of isomerization of $[Ni^{II}(L^1)]^{2+}$[10b] do not fit a mechanism requiring the detachment of a nitrogen atom from the central nickel ion. The availibility of *trans-I*-$[Ni^{II}(L^1)]^{2+}$ and *trans-III*-$[Ni^{II}(L^1)]^{2+}$ suggested that the homogeneous isomerization of the corresponding $[Ni^{I}(L^1)]^{+}$ and $[Ni^{III}(L^1)(H_2O)_n]^{3+}$ could be studied in order to elucidate the isomerization mechanisms and the factors that affect them.

Results and Discussion

The Case of $[Ni^{III}(L^1)]$

As already mentioned, the *trans-III*-$[Ni^{II}(L^1)]^{2+}$ and *trans-I*-$[Ni^{II}(L^1)]^{2+}$ isomers were separated[10a] and their oxidatively induced interconversion was studied using electrochemical techniques.[10b] Since the time scale of the isomerization process is 400 ms, which is close to the detection limit of the electrochemical techniques used, and as it occurs near the electrode and might therefore be a heterogeneous process, it was decided to study this process in homogeneous solutions using the pulse radiolysis technique.

N_2O saturated aqueous solutions containing 5×10^{-4} M *trans-III*-$[Ni^{II}(L^1)]^{2+}$ or *trans-I*-$[Ni^{II}(L^1)]^{2+}$ at pH 3.4–4.2, were irradiated by fast 5 MeV electrons at a dose rate of 2.5–25 Gy/pulse. Under these experimental conditions over 90% of the primary radicals formed by the radiation, reaction (6), are transformed into $^{\cdot}OH$ radicals via reaction (7).

$$H_2O \xrightarrow{e^-,\,\gamma} e^-_{aq}\ (2.65);\ H^{\cdot}\ (0.60);\ {}^{\cdot}OH\ (2.65);\ H_2\ (0.45);\ H_2O_2\ (0.75);\ H^+\ (2.65) \quad (6)$$

where the values in parentheses give the relative yields of the primary products.[36a]

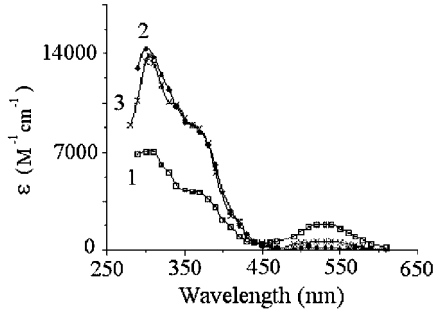
$$N_2O + e^-_{aq} + H_2O \rightarrow N_2 + {}^{\cdot}OH + OH^-$$
$$k_7 = 8.7\times10^9\ M^{-1}\,s^{-1}\ [31] \quad (7)$$

The $^{\cdot}OH$ radicals then oxidize $[Ni^{II}(L)]^{2+}$ according to equation (8), presumably with conservation of the isomeric composition.

$$^{\cdot}OH + [Ni^{II}(L)]^{2+} \rightarrow OH^- + [Ni^{III}(L)]^{3+}$$
$$k_8 > 2\times10^9\ M^{-1}s^{-1}\ [27] \quad (8)$$

The spectra of *trans-III*-$[Ni^{III}(L^1)_{aq}]^{3+}$ and *trans-I*-$[Ni^{III}(L^1)_{aq}]^{3+}$ thus formed differ considerably, Figure 2. *trans-III*-$[Ni^{III}(L^1)_{aq}]^{3+}$ is long-lived, whereas the spectrum of *trans-I*-$[Ni^{III}(L^1)_{aq}]^{3+}$ changes in a process which obeys first order kinetics, Figure 3, to form a species with a spectrum which is identical to that of *trans-III*-$[Ni^{III}(L^1)_{aq}]^{3+}$. Therefore the observed process is attributed to the isomerization reaction (5).

$$trans\text{-}I\text{-}[Ni^{III}(L^1)_{aq}]^{3+} \rightarrow trans\text{-}III\text{-}[Ni^{III}(L^1)_{aq}]^{3+}$$
$$k_5 = (3.3\pm0.7)\times10^3\ s^{-1}\ \text{at pH 3.2} \quad (5)$$



1) 14 μs after the pulse → $5\cdot10^{-4}$ M *trans-I*-($Ni^{II}L$); N_2O saturated; pH 3.2; 8 Gy/pulse

2) 40 ms after the pulse → $5\cdot10^{-4}$ M *trans-I*-($Ni^{II}L$); N_2O saturated; pH 3.2; 8 Gy/pulse

3) 40 ms after the pulse → $5\cdot10^{-4}$ M *trans-III*-($Ni^{II}L$); N_2O saturated; pH 3.2; 8 Gy/pulse

Figure 2. Spectra of the tervalent nickel complexes of the *trans-I* and *trans-III* complexes formed by the oxidation of $[Ni^{II}(L^1)]^{2+}$.

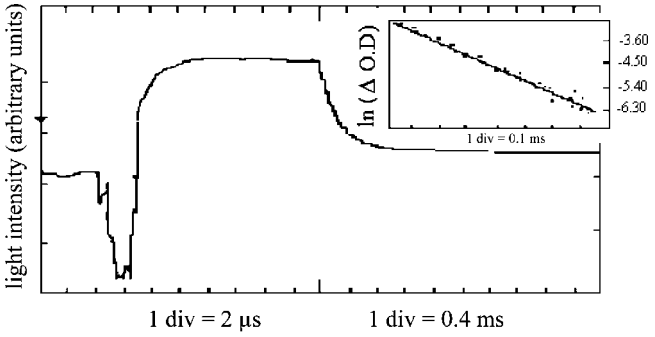


Figure 3. The formation and isomerization of *trans-I*-$[Ni^{III}(L^1)_{aq}]^{3+}$ 5×10^{-4} M *trans-III*-$[Ni^{II}(L^1)]^{2+}$, N_2O-saturated solution, pH 3.2, irradiation at λ = 550 nm, 18 Gy.

The observed rate constant, k_5, decreases by a factor of 10 when the pH of the solutions is raised from 3.2 to 4.2. The experiments could not be performed either at more alkaline pH values since *trans-I*-$[Ni^{II}(cyclam)]^{2+}$ isomerizes fast at higher pH,[10b] or at a more acidic pH since at pH < 3 the production of $^{\cdot}OH$ radicals is not quantitative.[23] The pH effect may be explained by the formation of *trans-I*-$[Ni^{III}(L^1)(OH)]^{2+}$[22] which might slow down the isomerization process by allowing a more energetically appropriate pentacoordinate geometry for the latter and by raising the pK_a of the Ni–N–H group, see below.

The product *trans-III*-$[Ni^{III}(L^1)_{aq}]^{3+}$ is stable on a time scale of hours at pH 3.2. At this point it must be mentioned that the specific rate constant for the isomerization process

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

measured here differs by three orders of magnitude from that reported by Billo et al.[10b] for the same pH. This apparent discrepancy might be explained in terms of different conditions in the electrochemical experiments i.e probably the involvement of heterogeneous factors (viz. the electrode surface) in the latter study.

The isomerization process in reaction (5) might in principle proceed via one of the following mechanisms:
a) deprotonation of one of the coordinated amino groups followed by inversion
b) cleavage of the Ni–N bond followed by inversion, though it is difficult to envisage why this should be faster for $[Ni^{III}(L^1)_{aq}]^{3+}$ than for $[Ni^{II}(L^1)_{aq}]^{2+}$.

In order to differentiate between these mechanisms, it was decided to see whether the isomerization is accompanied by proton exchange of the N–H groups with the solvent. For this purpose ^{1}H-NMR experiments were carried out in order to see whether the N–H groups are transformed into N–D groups when the oxidation reaction is carried out in D_2O. The following experiments were performed.

^{1}H-NMR measurements were performed using D_2O solutions of $(2–5)\times10^{-3}$ M of *trans-I*-$[Ni^{II}(L^1)_{aq}]^{2+}$ at pH 2.0 (Figure 4, a). The broad singlet at 3.5 ppm is attributed to N–H. The quartet at 3.1 ppm is interpreted as an overlapped double triplet and is attributed to H–C–H (Figure 4, a, $–H_C$), i.e. it is a result of the splitting of the genuine triplet by coupling to the N–*H* proton. Due to overlaps the detailed signals of H_d, H_e and H_f could not be separated. When solutions containing *trans-I*-$[Ni^{II}(L^1)_{aq}]^{2+}$ were made alkaline by the addition of NaOD, the singlet disappeared and the quartet was transformed into a triplet, indicating that the amine proton exchanged with deuterium (Figure 4, b). The same solution at pH 2.0 was reacted with an equivalent amount of $Na_2S_2O_8$ to oxidize the metal centre and then immediately reduced by an equivalent amount of $NaHSO_3$. The ^{1}H-NMR spectrum of the product was then recorded. The broad known spectrum[11a] of the paramagnetic "blue" *trans-III*-$[Ni^{II}(L^1)(H_2O)_2]^{2+}$ was shifted by raising the temperature to 75 °C, where the "yellow" diamagnetic species is the prevailing one.[10b] Under these conditions the ^{1}H-NMR spectrum could be resolved. The spectrum showed no singlet at 3.5 ppm and a triplet at 3.1 ppm (Figure 4, c), indicating that isomerization proceeds via deprotonation, i.e. via route (a) above.

As sulfate was shown to stabilize $[Ni^{III}(L^i)]^{3+}$ (i = 1, 2, 7),[22,23,27,28] it seemed of interest to investigate the difference in behaviour of the two $[Ni^{III}(cyclam)]^{3+}$ isomers. CV and square-wave experiments showed that the *trans-III*-$[Ni^{III}(cyclam)]^{3+}$ isomer as expected for the relative symmetrical octahedral environment, binds two sulfate anions (Figure 5) with $K = 2\times10^6$ M^{-2}, the CVs are reversible. While the *trans-I*-$[Ni^{III}(cyclam)]^{3+}$ isomer prefers to be pentacoordinate binding only one sulfate anion with $K = 8.2\times10^5$ M^{-1}, in this case the CVs are quasi-reversible. The latter result indicates that the rate of isomerization of *trans-I*-$[Ni^{III}L]_{aq}$ is slowed down at least by several orders of magnitude by the complexation with sulfate.

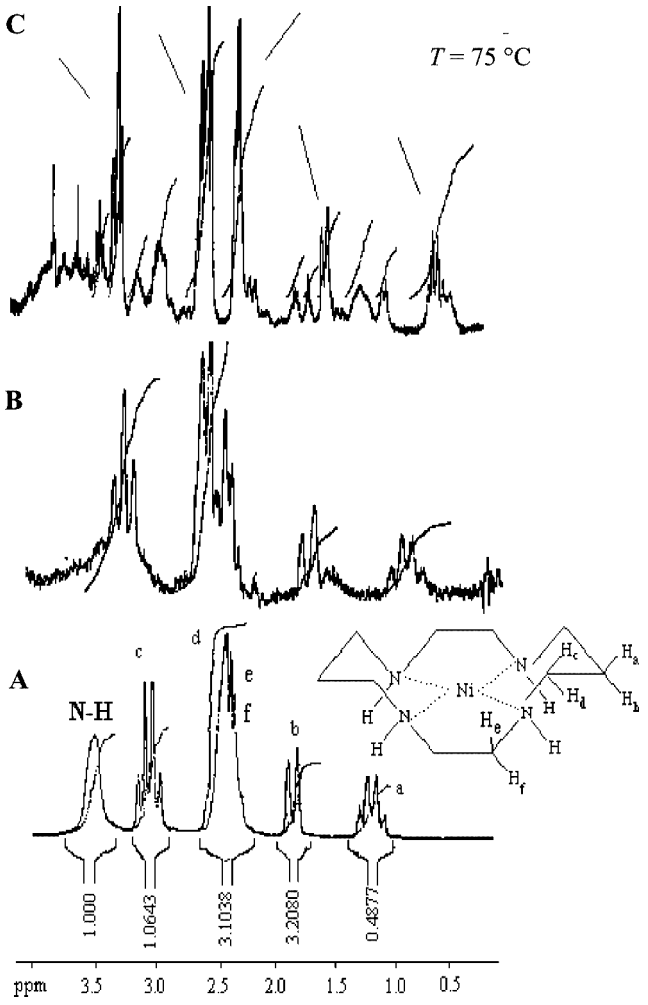

Figure 4. ^{1}H-NMR measurements performed for *trans*-I-$[Ni^{II}(L^1)]^{2+}$. **A**: *trans-I*-$[Ni^{II}(L^1)]$, pH 2.0, D_2O, room temperature. **B**: *trans*-I-$[Ni^{II}(L^1)]$, pH 8.0, D_2O, room temperature. **C**: $[Ni^{II}(L^1)]$, pH 2.0, D_2O, obtained by oxidation of the *trans-I* isomer to give the *trans-III* isomer and then reduction.

The Case of $[Ni^I(L^i)]$

Ni^{II} complexes of saturated tetraazamacrocycles undergo an one-electron reduction to produce Ni^I species, both in organic solvents[30a,30b] and in aqueous solutions.[31] The reduced species react with CO and were studied in water,[32–34] dimethylformamide[32] and in acetonitrile[21,35] as solvents.

As already mentioned, Kelly et al.[20] reported the chemistry of $[Ni^I(L^1)]^+$ in the presence of CO in aqueous solutions. When *trans-III*-$[Ni^{II}(L^1)]^{2+}$ was reduced in the presence of CO, two consecutive reactions were observed.
i. The formation of the complex *trans-III*-$[Ni^I(L^1)(CO)]^+$, in a process approaching the diffusion-controlled limit, which has an absorption band with λ_{max} = 470 nm.
ii. Followed by a unimolecular rearrangement to yield a more stable product with λ_{max} = 350 nm. The $\Delta S^{\#}$ of the latter reaction was determined to be –14.4 cal K^{-1} mol^{-1}. The observed reaction is assumed to proceed according to reaction (9).

trans-III-$[Ni^I(L^1)(CO)]^+ \rightarrow$ *trans-I*-$[Ni^I(L^1)(CO)]^+$ (9)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

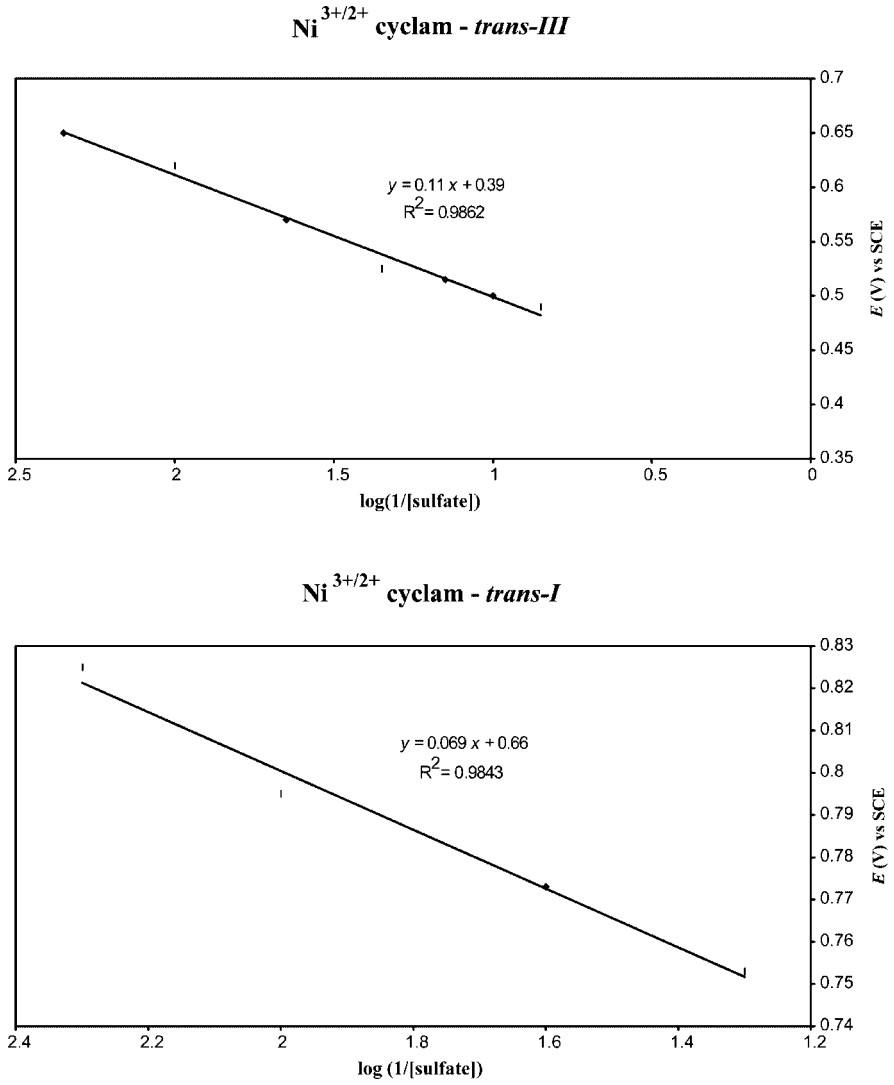

Figure 5. The dependence of $E^{1/2}$ $[Ni(L^1)]^{3+/2+}$ of the two isomers on [sulfate] 5×10^{-4} M $[Ni^{II}(L^1)]^{2+}$, 0.005–0.14 M Na_2SO_4, pH 3.2, ionic strength kept constant by addition of $NaClO_4$, working electrode: glassy carbon, 80 mV/s.

It seemed of interest to verify this assignment and to determine the source of the negative $\Delta S^{\#}$ value. For this purpose *trans-III*-$[Ni^I(L^3)]^+$ (L^3 = 1*R*,4*R*,8*S*,11*S*-1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane ≡ *trans-III*-tmc) and *trans-I*-$[Ni^I(L^3)]^+$ (L^3 = 1*R*,4*S*,8*R*,11*S*-1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane ≡ *trans-I*-tmc) were prepared in the presence of CO and their reactions with CO were studied. These experiments are of interest as it is known that the interconversion between *trans-I*- and *trans-III*-$[Ni^I(L^3)]^+$ is very slow.[18a,18b] Furthermore, we also determined $\Delta V^{\#}$ for reaction (9).

Indeed the formation of *trans-I*-$[Ni^I(L^3)]^+$ in the presence of CO is followed by a fast reaction. The rate of this process is proportional to [CO] and is attributed to reaction (13).

trans-I-$[Ni^I(L^3)]^+$ + CO ⇄ *trans-I*-$[Ni^I(L^3)(CO)]^+$
$k_{13} = 3.7 \times 10^8$ M^{-1} s^{-1}, $K_{13} = 4.3 \times 10^3$ M^{-1} (13)

The product does not isomerize and decomposes on a time scale of several minutes. The spectra of *trans-I*-$[Ni^I(L^3)]^+$ and *trans-I*-$[Ni^I(L^3)(CO)]^+$ were measured, see Figure 6. The spectrum and the kinetics of decomposition of *trans-I*-$[Ni^I(L^3)(CO)]^+$ at pH 10.5 were also measured, Figure 7, and no isomerization was observed during the decomposition process.

No complexation of *trans-III*-$[Ni^I(L^3)]^+$ by CO was observed at pH 10.5 and a slow isomerization process was observed, which has a life time of several minutes, Figure 8. The *trans-I*-$[Ni^I(L^3)]^+$ formed in the isomerization process naturally forms the *trans-I*-$[Ni^I(L^3)(CO)]^+$ complex. Neither *trans-I*-$[Ni^I(L^3)(CO)]^+$ nor *trans-III*-$[Ni^I(L^3)]^+$ isomerizes in the presence of CO, on the time scale on which $[Ni^I(L^1)(CO)]^+$ isomerizes. This finding is in agreement with expectations due to the known rigidity of complexes of the L^3 ligand. Thus our observations corroborate the sugges-

The second plot shows the spectra obtained after the solution was irradiated with 200 Gy in a 1-cm quartz cell (blank: non-irradiated solution).

tion by Kelly et al.[20] that the fast isomerization observed is described by reaction (9).

The volume of activation of reaction (9) was found to be $\Delta V^{\#} = 0\pm1$ cm^3 mol^{-1}. This result points out that the reported $\Delta S^{\#}$ is due to a transition state in which the macrocyclic ligand is less flexible which does not involve a significant volume change during the isomerization process.

Concluding Remarks

The results obtained in this study indicate that two different mechanisms are involved in the isomerization processes of nickel complexes with cyclam and cyclam derivatives as chelates.

i. Detachment of the Ni–N bond and inversion presumably via the *cis-V* isomer. This mechanism is relevant to low valent complexes and seems to occur in general for tmc complexes as was also observed for copper.[37]

ii. Deprotonation of coordinated N–H and inversion, presumably also via the *cis-V* isomer. This mechanism seems to be relevant to high oxidation state complexes. This mechanism explains the reason for a faster isomerization step in the case of nickel for the tervalent complex vs. the divalent complex. This mechanism corroborates also the

pH effect in the case of the $[Ni^{II}(L^1)]^{2+}$ complex. A similar effect was observed also for $[Cd^{II}(L^1)]^{2+}$ and $[Zn^{II}(L^1)]^{2+}$.[38a,38b]

Experimental Section

Materials: All the chemicals used were of AR grade and were used without further purification. The solutions were prepared with heat-distilled water that was then passed through a Millipore set-up, the final resistance being greater than 10 MΩ

The complexes $[Ni^{II}(cyclam)](ClO_4)_2$, *trans-III*-$[Ni^{II}(cyclam)](ClO_4)_2$, *trans-I*-$[Ni^{II}(cyclam)](ClO_4)_2$, *trans-III*-$[Ni^{II}(tmc)](ClO_4)_2$, *trans-I*-$[Ni^{II}(tmc)](ClO_4)_2$ were prepared according to literature procedures.[10a,11,39] The complexes were characterized by C,H,N elemental analysis and UV/Vis and IR spectroscopy. The results for all the complexes were in excellent agreement with the expected formula and the literature data.

NMR Measurements: ^{1}H-NMR measurements were run at 200 MHz on a Bruker-WP-200-SY spectrometer using a 5-mm broadband probe. Spectra were acquired in the double precision mode at ambient (20 °C) and at higher (75 °C) temperatures.

A typical sample consisted of 1–2 mg of complex dissolved in 1 mL of D_2O. Homonuclear decoupling experiments were carried out using the lowest decoupling power which saturated the desired resonance. Chemical shifts were referenced by computer to the TMS frequency.

Electrochemical Measurements: A three-electrode cell was used. The working electrode for the CV measurements was a Metrohm teflon-shrouded glassy carbon electrode (0.07 cm^2). The auxiliary electrode was a Pt wire and a SCE was used as the reference electrode. The auxiliary and the reference electrodes were placed in separate compartments of the cell. All potentials are reported vs. SCE CV measurements were performed using a EG&G Princeton Applied Research potentiostat/galvanostat, Model 263, operated by a Research Electrochemistry Software EG&G PARC. Potentials were determined by square wave voltammetry. Measurements were performed at 80 mv/s.

Pulse Radiolysis: The solutions were handled by the syringe technique. Deaeration was performed by bubbling He or N_2O (when oxidizing conditions were required) through the solutions. The experiments were carried out at the linear accelerator facility of the Hebrew University of Jerusalem: 0.5–1.5 μs, 5 MeV and 200-mA pulses were used. The dose per pulse was in the range of 2.5–25 Gy/pulse. The experimental set up and the techniques used for evaluating the results have been described elsewhere in detail.[40] The high-pressure experiments were performed using an instrument which has been described in detail elsewhere.[41,42]

Preparation of *trans-I*- and *trans-III*-$[Ni^IL^3]^+$ Complexes: *trans-I*-$[Ni^I(L^3)(CO)]^+$ was prepared via the reduction of the corresponding Ni^{II} complex in the presence of CO. Aqueous He-saturated solutions containing 5×10^{-4} M *trans-I*-$[Ni^{II}(L^3)]^{2+}$, 0.1 M HCOONa, and $(0.1–1)\times10^{-3}$ M CO at pH 7.4, were irradiated by a pulse of 5 MeV electrons. Under these conditions reactions (10)–(12) have to be considered.

$$HCOO^- + H^{\cdot}/{}^{\cdot}OH \rightarrow COO^{\cdot-} + H_2/H_2O$$
$$k_{10\ H/OH} = 2.1\times10^8/3.2\times10^9\ M^{-1}\ s^{-1}\text{[36b]} \quad (10)$$

$$trans\text{-}I\text{-}[Ni^{II}(L^3)]^{2+} + e^-_{aq} \rightarrow trans\text{-}I\text{-}[Ni^{I}(L^3)]^{+}$$
$$k_{11} > 1\times10^{10}\ M^{-1}\ s^{-1} \quad (11)$$

$$trans\text{-}I\text{-}[Ni^{II}(L^3)]^{2+} + COO^{\cdot-} \rightarrow trans\text{-}I\text{-}[Ni^{I}(L^3)]^{+} + CO_2$$
$$k_{12} \approx 1\times10^9\ M^{-1}s^{-1} \quad (12)$$

trans-III-$[Ni^I(L^3)]^+$ was prepared by using an analogous experimental approach.

Spectrophotometric Measurements and Slow Kinetics: The spectra and the kinetics of the relatively long lived species ($t_{1/2} \geq 20$ s) were recorded using a HP 8452 A diode-array spectrophotometer. The long lived monovalent nickel species were produced by irradiating He-saturated solutions in a 1-cm quartz spectrophotometric cell.

IR Spectra: Were recorded using KBr pellets on a NICOLET 5ZDX FT-IR spectrometer.

Elementary Analyses: Were performed at the micro-analysis laboratory at the Hebrew University in Jerusalem.

Self-Assembly of an Alkali Metal Cluster Stabilized by a New Flexidentate Metalloligand: Formation and Structure of Heterobimetallic Na–Mo and Cs–Mo 2D Networks

Snehadrinarayan Khatua,[a] Sohaham Dasgupta,[a] Kumar Biradha,*[a] and Manish Bhattacharjee*[a]

Keywords: Alkali metals / Heterometallic complexes / Metalloligands / Molybdenum / Self-assembly

A new tridentate ligand, {(3,5-di-*tert*-butyl-2-hydroxybenzyl)amino}acetic acid, has been synthesized. This ligand forms $[\{Na_4(H_2O)_4(\mu\text{-}H_2O)_2\}\subset(Mo_2O_5L_2)_2]$ (**1**), which contains an Na_4^{4+} cluster cation stabilized by $[LMoO_2(\mu\text{-}O)MoO_2L]^{2-}$, upon reaction with Na_2MoO_4 in aqueous methanol. This compound has been characterized by various spectroscopic techniques and crystallizes in the triclinic space group $P\bar{1}$. Furthermore, compound **1** undergoes smooth exchange of Na^+ for Cs^+ to give $[Cs_2(Mo_2O_5L_2)\cdot H_2O]_n$ (**2**) upon treatment with CsCl in aqueous methanol. Similarly, **2** reacts with an excess of NaCl to produce **1**. Complex **2** crystallizes in the monoclinic space group $C2/c$. The crystal structure of this compound reveals that the geometry of the $[LMoO_2(\mu\text{-}O)MoO_2L]^{2-}$ unit stays almost intact but that it stabilizes a polymeric chain of Cs^+ cations, unlike in **1**.

Introduction

The role of judiciously designed ligands in the synthesis of supramolecular assemblies containing two types of metal ions has been demonstrated.[1,2] In recent years, a large number of metalloligands have been synthesized for the assembly of bimetallic complexes.[3] The main thrust has been on the aggregation of transition metal ions using main group metals as templates.[2] However, alkali metal cluster cations have received scant attention. Molybdates and tungstates have been widely used as ligands for metal ions due to their diverse structural flexibility and their applications in fields such as catalysis, analytical and clinical chemistry, biochemistry, and medicine.[4] Although a lot of attention has been paid to the synthesis of transition metal and rare-earth metal derivatives of polyoxometalates, alkali metal complexes of polyoxometalates have received much less attention.[5–7] We were interested in the synthesis of a flexible metalloligand that can coordinate alkali metal cations, and the effect of their size on the architecture of the structure. Also, we intended to explore the transmetalation of the alkali metal cations.

Herein we report the synthesis of the ligand {(3,5-di-*tert*-butyl-2-hydroxybenzyl)amino}acetic acid, and the synthesis and structure of an unusual polyoxomolybdate, $[\{Na_4(H_2O)_4(\mu\text{-}H_2O)_2\}\subset(Mo_2O_5L_2)_2]$ (**1**), which bears an Na_4^{4+} cluster cation stabilized by the metalloligand $[LMoO_2(\mu\text{-}O)MoO_2L]^{2-}$ ($\mathbf{L^{Mo}}$), and the corresponding cesium compound, a helical 1D infinite chain of $[Cs_2(Mo_2O_5L_2)\cdot H_2O]_n$ (**2**), obtained by transmetalation of the Na^+ ions in **1**. The transmetalation behavior of the compounds has also been investigated.

Results and Discussion

Synthesis and Characterization of {(3,5-Di-*tert*-butyl-2-hydroxybenzyl)amino}acetic Acid

Our synthetic strategy was to design a tridentate, dibasic ligand (L) containing one carboxylate donor site that is expected to form the metalloligand $[LMoO_2(\mu\text{-}O)MoO_2L]^{2-}$ ($\mathbf{L^{Mo}}$). This ligand has the potential to coordinate alkali-metal cations through bridging carboxylate and self-assemble into various architectures (Scheme 1).

Accordingly, the ligand was synthesized by a one-pot Mannich reaction of glycine, 2,4-di-*tert*-butylphenol, and formaldehyde in aqueous ethanol. Glycine and formaldehyde (40%) were dissolved in water in a 1:10 ratio and an ethanolic solution of the phenol was added. The reaction solution afforded the ligand on standing for about 10 h. The ligand was characterized by elemental analysis, mass spectrometry, and IR, UV/Vis, and ^1H and ^{13}C NMR spectroscopy. The elemental analysis and mass spectral measurements agreed well with the proposed composition. The ^1H and ^{13}C NMR data were also in agreement with the proposed structure (see Experimental Section).

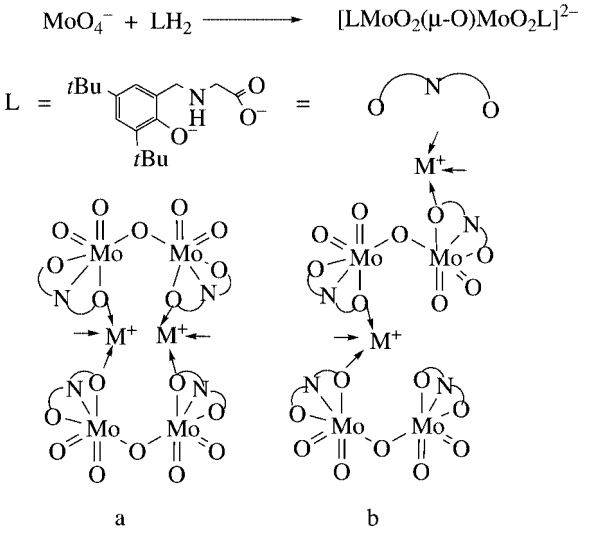

Scheme 1.

Synthesis, Characterization, and Solution Properties of the Molybdenum Complexes 1 and 2

Compound **1** was synthesized by the reaction of LH_2 with $Na_2MoO_4{\cdot}2H_2O$ in aqueous methanol and **2** was obtained by the reaction of CsCl with **1** in aqueous methanol. Compound **2** can also be prepared from an in situ reaction between an excess of CsCl and Na_2MoO_4 and the ligand. It should be noted that Cs^+ ions can be exchanged by Na^+ ions by treating **2** with an excess of NaCl. Thus, it is clear that both compounds show the ability to exchange cations and are interconvertable, which is rare in such molecules.

The elemental analyses agree well with the compositions. The compounds were further characterized by IR, UV/Vis, and ^1H, ^{13}C, ^{95}Mo, and ^{23}Na (compound **1**) NMR spectra and solution conductivity measurements. The IR spectrum of the compounds show two sharp bands at about 920 and 880 cm^{-1} due to symmetric and antisymmetric *cis*-Mo=$(O)_2$ stretches, respectively, and a band at around 780 cm^{-1} due to the Mo–O–Mo stretch; these clearly show the presence of the [MoO_2(μ-O)MoO_2] moiety. The UV/vis spectra of the compounds show strong bands due to a ligand-to-metal charge-transfer transition at about 350 nm along with internal ligand transitions.

The ^1H NMR spectra of **1** in [D_6]DMSO show signals at δ = 1.20 (br. s, 9 H) and 1.30 ppm (br. s, 9 H) due to the methyl protons of the *tert*-butyl groups. The CH_2 proton signals appear at δ = 3.36 (br. m, 2 H) and 4.25 ppm (br. m, 2 H). The signal at δ = 4.80 ppm (br. s, 1 H) can be assigned to the NH proton. We could not observe the signals due to the protons of coordinated water. This may be due to excessive broadening of the signals. The signals for the aromatic protons appear at δ = 6.85 (br. m, 1 H) and 7.10 ppm (br. m, 1 H). The ^{13}C NMR spectrum of **1** in [D_6]-DMSO shows signals at δ = 29.6, 29.9, 30.1, 31.5, 31.7, 33.7, 34.4, and 34.5 ppm due to the CH_3 and tertiary carbons of the *tert*-butyl group. The CH_2 signals appear at δ = 51.3, 51.6, 52.7, and 53.1 ppm, with the aromatic carbon signals at δ = 121.5, 121.9, 122.5, 122.7, 123.0, 124.1, 124.3, 136.7, 136.8, 137.9, 138.3, 159.8, and 159.9 ppm. The carboxylate carbon signals appear at δ = 175.2 and 175.3 ppm. The appearance of two signals for each carbon indicates that the ligands are bonded in a slightly different fashion. Thus, the ^1H and ^{13}C NMR and IR spectral studies clearly indicate the presence of an [$LMoO_2$(μ-O)MoO_2L] moiety in solution and the solid state. The ^{23}Na NMR spectrum of **1** shows a single broad signal at δ = 2.0 ppm (relative to NaCl as an external reference). This clearly shows that the coordinated nature of the sodium is maintained even in solution and that all the sodium ions are in a similar chemical environment. The observed low-field position of the ^{23}Na NMR signal, with respect to the NaCl reference, indicates the existence of an interaction between the sodium ions and between sodium and molybdenum, even in solution. The ^{95}Mo NMR spectra of the compounds show a sharp signal at δ = 0.3 ppm, which indicates that the molybdenum atoms are in a predominantly oxo environment. Similar spectral features were observed in the case of **2**. The observed molar conductance of **1** in methanol (95 $\Omega^{-1}cm^2mol^{-1}$) clearly indicates that the aggregate [{$Na_4(H_2O)_4$(μ-$H_2O)_2$}⊂($Mo_2O_5L_2)_2$] partially disintegrates in solution. The high-resolution ESI mass spectrum (methanol solution) of **1** shows a peak at *m*/*z* = 936.3138, which corresponds to $C_{34}H_{54}Mo_2N_2Na_2O_{13}$ {or [Na_2-($Mo_2O_5L_2$)($H_2O)_2$]}. Similarly, the mass spectrum of compound **2** shows a peak at *m*/*z* = 1138.2913 corresponding to $C_{34}H_{52}Cs_2Mo_2N_2O_{12}$, which can be formulated as [Cs_2($Mo_2O_5L_2$)(H_2O)]. The mass spectral studies clearly show that the coordinated nature of the alkali metals is maintained even in solution and that the clusters undergo partial disintegration in solution.

Crystal Structures of [{$Na_4(H_2O)_4$(μ-$H_2O)_2$}⊂($Mo_2O_5L_2)_2$] (1) and [$Cs_2(Mo_2O_5L_2){\cdot}H_2O]_n$ (2)

X-ray diffraction analysis revealed that the asymmetric unit of **1** contains only half of the cluster as it sits on an inversion center, with one L^{Mo} unit, two Na atoms, and three water molecules being present (Figure 1). The coordination environments of the two Mo atoms are almost similar: both have an octahedral geometry and are bonded to five oxygens and one nitrogen. The ligand L^{Mo} binds the two sodium atoms in two different ways and one of the Mo centers has an interaction with sodium [Mo1···Na2 = 3.553(5) Å]. The distinctive feature of the structure is the formation of a rectangular $(Na_4)^{4+}$ cluster cation (Figure 2, a). The distinctly shorter Na···Na distances of 3.539(5) Å (Na1–Na2) and 3.728(6) Å (Na1–Na1′) compared to that in elemental sodium (3.82 Å) show attractive Na–Na interactions in the cluster. The Na1–Na2′ distance [3.898(5) Å] is longer than that in elemental sodium. Recently, a tetrasodium dication, Na_4^{2+}, stabilized by two silyl(fluorosilyl) phosphonides, with a similar structure but with shorter Na–Na distances has been reported.[8] The $(Na_4)^{4+}$ unit binds six O atoms to form a Na_4O_6 cluster that can be described as a dicubane unit of the type M_6O_6 in which the two ex-

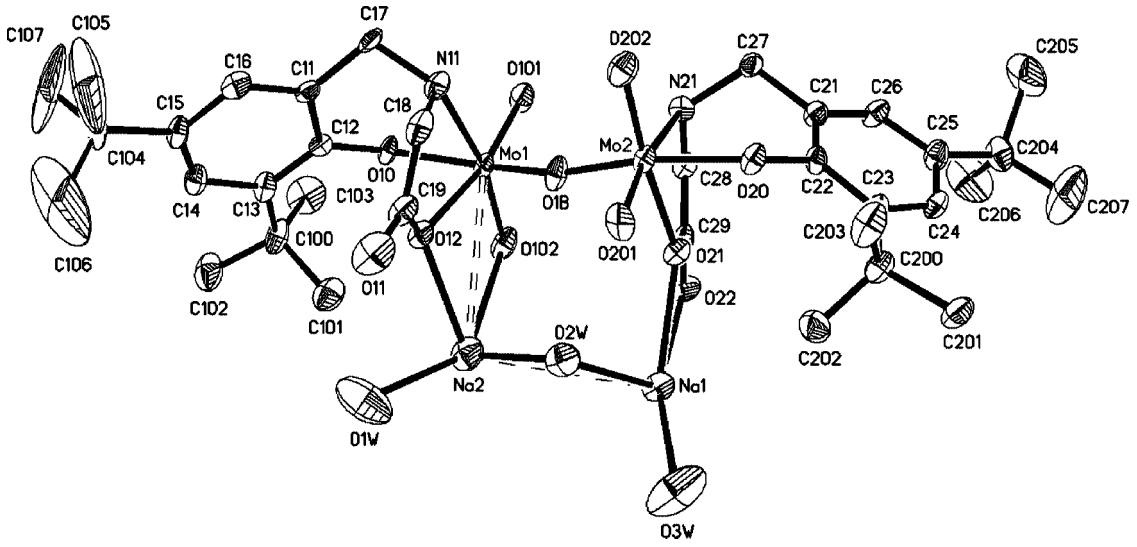

Figure 1. ORTEP drawing of the asymmetric unit of **1** (thermal ellipsoids at 50% probability).

treme and opposite corners have been removed (Figure 2, b). Two of the Na^+ ions (Na1) in the Na_4O_6 cluster are coordinated to five oxygens, and two (Na2) are hexacoordinate. Each of the four Na^+ ions is coordinated to one terminal water molecule [Na1–O3W = 2.277(9) and Na2–O1W = 2.301(11) Å] and are bridged by one water molecule [Na2–O2W = 2.366 (8) and Na1–O2W = 2.512 (7) Å; Na1–O2W–Na2 = 93.0(2)°]. In addition, Na1 and Na2 are also bridged by a Mo–O μ_3 oxygen (O102) [Na2–O102 = 2.727 (7) Å] and one carboxylate oxygen (O22) bridges three sodiums in a μ_3-fashion [Na1–O22 = 2.567(6), Na2–O22 = 2.318 (6) Å; Figure 2, b]. The compound forms a one-dimensional chain through Mo–O···H–N hydrogen bonding, and the 1D chains are joined by –COO···O and Mo–O···O hydrogen bonds to form a 2D network (Figure 3).

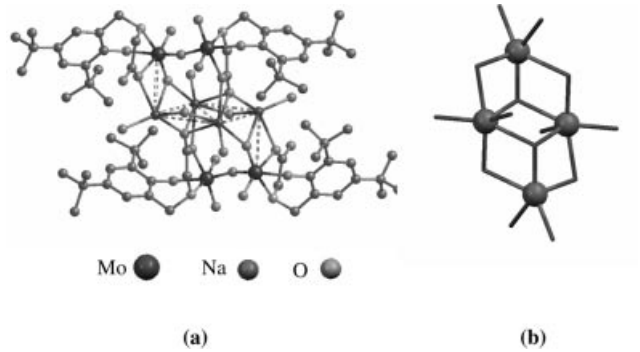

Figure 2. (a) Illustration of the tetramolybdate cluster **1**. The double dashed lines are long-distance interactions; H atoms have been omitted for the sake of clarity. (b) Illustration of the Na_4O_6 cluster with its terminal O atoms on Na; some atoms have been omitted for the sake of clarity.

The crystal structure of **2** reveals that the geometry of L^{Mo} (Figure 4) is almost the same as that of compound **1**. However, unlike in structure **1**, the asymmetric unit in **2** contains half of L^{Mo}, one Cs^+ ion, and one H_2O. The Cs^+ ions are found to form an infinite 1D-helical chain, which is stabilized by coordination of the $–COO^–$ and Mo–O

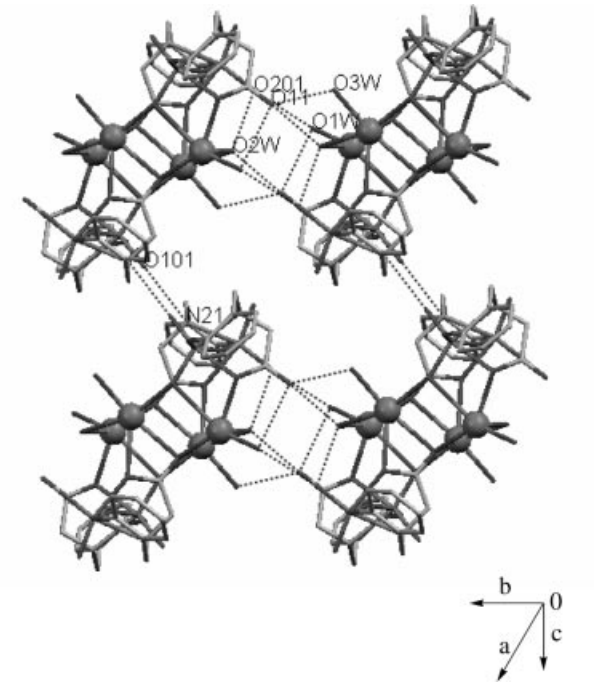

Figure 3. View of the 2D hydrogen-bonding network along the *c* axis (H bonds are shown as dotted lines; *tert*-butyl groups have been omitted for clarity).

groups of L^{Mo}, and are coordinated to six oxygens (Figure 5, a). This polymeric chain is generated by two Cs–Cs distances of 4.093(11) and 4.717(12) Å. The shorter Cs–Cs bond is bridged by two O atoms of two $–COO^–$ groups [Cs–O11 = 3.099(6) and 3.263(7) Å], whereas the longer one is not bridged by O atoms (Figure 5, b). The observed Cs···Cs distance clearly shows that there is substantial interaction between the Cs^+ ions. Similar to the structure **1**, the Mo atom interacts with Cs^+ with a distance of 4.172 Å. Interestingly, unlike **1**, the water molecules do not bind to the alkali metal ion (Cs^+) but join the one-dimensional polymeric chains of [{$(Cs)_2LO_2Mo$-O-MoO_2L}] via hydrogen

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

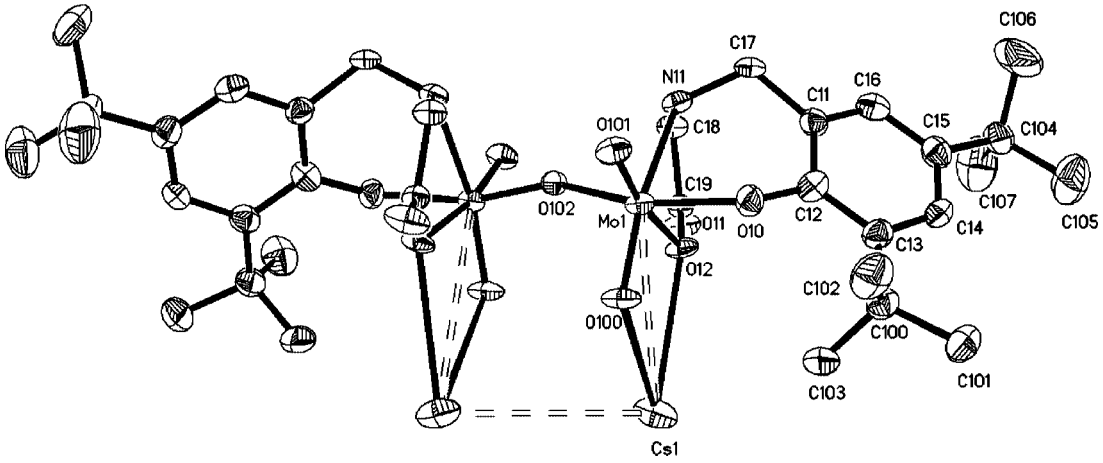

Figure 4. ORTEP drawing of the $[Cs_2(LO_2Mo\text{-}O\text{-}MoO_2L)]$ unit in the crystal structure of **2** (thermal ellipsoids at 50% probability). The double dashed lines represent long-distance interactions.

bonds [N–H···O = 3.006(8) Å (178°); O···O = 2.764(8); Figure 5, c]. In **1**, water is able to bridge two Na^+ ions, whereas, due to the larger size of the cation, water cannot bind the Cs^+ ions in a similar fashion in **2**. Similarly, in **1**, one of the O atoms of $–COO^–$ binds three Na^+ ions, whereas in **2**, due to the larger size of the Cs^+ ion, only two cations are bonded by the $–COO^–$ oxygen to form a 1D chain. Thus, both **1** and **2** form 2D networks but in **1** the network is built by hydrogen bonding only, whereas in **2** a 1D network is generated by Cs–Cs polymeric cluster chains that are joined by hydrogen bonding to form a 2D network.

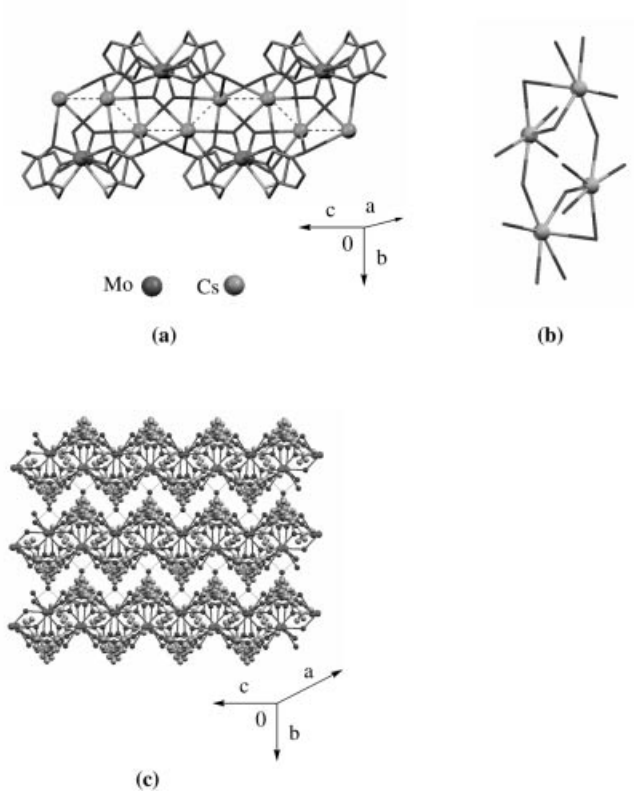

Figure 5. (a) Binding of Cs^+ ions by $[LO_2Mo\text{-}O\text{-}MoO_2L]$ units in the crystal structure of **2**. The *tert*-butyl groups have been omitted for the sake of clarity. The 1D chain is parallel to the crystallographic *c* axis. (b) Illustration of the Cs_4O_6 unit with its terminal O atoms on Cs; some atoms have been omitted for the sake of clarity. (c) 2D arrays of infinite 1D chains of **2** formed by hydrogen bonds.

Conclusions

A tridentate dibasic ligand has been designed which forms a new metalloligand, $[LMoO_2(\mu\text{-}O)MoO_2L]^{2–}$ (L^{Mo}) upon reaction with $MoO_4^{2–}$. This metalloligand binds Na^+ ions to form a heterobimetallic octanuclear compound. It has been shown that the alkali metal cations in **1** and **2** can easily undergo exchange with each other and the resulting compounds are structurally different. It should be noted that such interconvertibility in this type of molecules is rare. The structural differences between **1** and **2** can be attributed to the difference in size of the cations. Thus, L^{Mo} may be treated as a new polydentate flexible metalloligand for assembly of heterobimetallic complexes. These complexes are expected to afford mixed oxides of molybdenum on heating to high temperature, and work in this direction is already in progress. It should be mentioned that such mixed oxides have been shown to be effective catalysts for various coupling and oxidation reactions.[9] It would be interesting to explore the reactions of L^{Mo} with various transition metal ions and study their structural, magnetic, and catalytic properties.

Experimental Section

General Remarks: 2,4-Di-*tert*-butylphenol was purchased from Fluka. Glycine, formaldehyde, $Na_2MoO_4{\cdot}2H_2O$, and all solvents used were reagent-grade products. Elemental analyses were performed with a Perkin–Elmer C,H,N analyzer model 2400. Sodium was estimated by a flame photometric method. Molybdenum was estimated by gravimetric analysis [dioxobis(oxinate)molybdenum;

$MoO_2(C_9H_9ON)_2$]. ^1H, ^{13}C, ^{23}Na, and ^{95}Mo NMR spectra were recorded in $CDCl_3$, CD_3OD, or [D_6]DMSO on a Bruker AC-200 instrument. The IR spectra were recorded on a Perkin–Elmer model 883 spectrometer. UV/vis spectra were recorded in solution with a Shimadzu model UV-1601 spectrophotometer. For the mass spectral measurements a methanolic solution of the compounds was prepared and the spectra recorded on a Waters LCT mass spectrometer using the electrospray ionization (ES^+ mode) technique.

Synthesis of {(3,5-Di-*tert*-butyl-2-hydroxybenzyl)amino}acetic Acid (L): Glycine (3.00 g, 40 mmol) was dissolved in water (20 mL), a 40% aqueous formaldehyde (30 mL, 400 mmol) solution was added, and the mixture was stirred for 20 min. An ethanolic solution (30 mL) of 2,4-di-*tert*-butylphenol (2.06 g, 10 mmol) was then added dropwise and the reaction mixture was stirred for 30 min and allowed to stand overnight. The precipitated ligand was filtered, washed with water, dried, and finally recrystallized from a mixture of methanol and dichloromethane. Yield: 2.53 g (86.5%). $C_{17}H_{27}NO_3$ (293.4): calcd. C 69.59, H 9.28, N 4.77; found C 69.25, H 9.10, N 4.46. IR (KBr pellet): $\tilde{\nu}$ = 2960 cm^{-1}, 1710, 1630, 1230, 1122. UV/Vis: λ_{max} (ε) = 280 nm (2290), 220 (7470). ^1H NMR ($CDCl_3$): δ = 1.28 (s, 9 H), 1.37 (s, 9 H), 3.62 (s, 2 H), 4.10 (s, 2 H), 4.86 (s, 1 H), 6.79 (d, J = 2.3 Hz, 1 H), 7.19 (d, J = 2.4 Hz, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 29.6, 31.4, 34.2, 34.8, 52.0, 53.3, 116.8, 121.9, 122.8, 137.3, 143.5, 149.4, 172.6 ppm. MS: m/z = 293 [M^+] ($C_{17}H_{27}NO_3$).

Synthesis of [{$Na_4(H_2O)_4(\mu\text{-}H_2O)_2$}⊂$(Mo_2O_5L_2)_2$] (1): An aqueous solution (5 mL) of $Na_2MoO_4{\cdot}2H_2O$ (0.121 g, 0.5 mmol) was added to a methanolic solution (25 mL) of the ligand (0.147 g, 0.5 mmol). The solution immediately turned orange. The solution was stirred for 3 h and was then allowed to stand overnight. The precipitated crystalline compound was filtered, washed 3–4 times with water, dried in vacuo, and finally recrystallized from a mixture of methanol and acetonitrile. Yield: 0.13 g (54%). $C_{68}H_{112}Mo_4N_4Na_4O_{28}$ (1909.3): calcd. C 42.78, H 5.91, Mo 20.10, N 2.93, Na 4.82; found C 43.25, H 6.10, Mo 19.45, N 2.40, Na 4.20 (by flame photometry). IR (KBr pellet): $\tilde{\nu}$ = 3433 cm^{-1}, 2960, 1600, 1470, 1250, 1170, 920, 880, 780. UV/Vis: λ_{max} (ε) = 355 nm (11830), 270 (22950), 230 (24440). ^{95}Mo NMR ([D_6]DMSO) [reference Na_2MoO_4 (δ = 0 ppm)]: δ = 0.3 ppm. ^{23}Na NMR ([D_6]DMSO) [reference NaCl (δ = 0 ppm)]: δ = 2.0 ppm. ^1H NMR ([D_6]DMSO): δ = 1.20 (br. s, 9 H), 1.34 (br. s, 9 H), 3.36 (br. m, 2 H), 4.25 (br. m, 2 H), 4.78 (br. s, 1 H), 6.85 (br. m, 1 H), 7.10 (br. m, 1 H) ppm. ^{13}C NMR ([D_6]DMSO): δ = 29.6, 29.9, 30.1, 31.5, 31.7, 33.7, 34.4, 34.5, 51.3, 51.6, 52.7, 53.1, 121.5, 121.9, 122.5, 122.7, 123.0, 124.1, 124.3, 136.7, 136.8, 137.9, 138.3, 159.8, 159.9, 175.2, 175.3 ppm. ESI HRMS: m/z = 936.3138 [$Na_2(Mo_2O_5L_2)(H_2O)_2$].

Reaction of 1 with CsCl. Synthesis of $[Cs_2(Mo_2O_5L_2){\cdot}H_2O]_n$ (2): Compound **1** (0.048 g, 0.025 mmol) was dissolved in methanol (20 mL), an aqueous solution (5 mL) of CsCl (0.037 g, 0.2 mmol) was added, and the reaction solution was stirred for 5 h. On standing for about 20 days orange crystals of **2** were obtained in 50% yield. $C_{34}H_{52}Cs_2Mo_2N_2O_{12}$ (1138.5): calcd. C 35.87, H 4.60, Mo 16.85, N 2.46; found C 36.05, H 4.34, Mo 17.15, N 2.54. IR (KBr pellet): $\tilde{\nu}$ = 2960 cm^{-1}, 1580, 1475, 1260, 906, 870, 790. UV/Vis: λ_{max} (ε) = 356 nm (6460), 213 (27590). ESI HRMS: m/z = 1138.2913 [$Cs_2(Mo_2O_5L_2)(H_2O)$]. ^1H NMR ([D_6]DMSO): δ = 1.27 (br. s, 9 H), 1.39 (br. s, 9 H), 3.28 (br. m, 2 H), 4.64 (br. s, 1 H), 6.95 (br. m, 1 H), 7.20 (br. m, 1 H) ppm.

Independent Synthesis of $[Cs_2(Mo_2O_5L_2){\bullet}H_2O]_n$ (2): An aqueous solution (5 mL) of $Na_2MoO_4{\cdot}2H_2O$ (0.061 g, 0.25 mmol) was added to a methanolic solution (25 mL) of the ligand (0.073 g, 0.25 mmol). The solution immediately turned orange. The reaction solution was stirred for 6 h and then CsCl (0.2524 g; 1.5 mmol) was added and solution was stirred for a further hour. On standing for 10 days crystals of compound **2** were obtained in 60% yield.

X-ray Crystallographic Study: Suitable crystals of **1** and **2** were grown from dilute acetonitrile/MeOH and MeOH/water solutions, respectively, at room temperature over a period of 5 to 20 days. The single crystal data were collected on Bruker–Nonius Mach3 CAD4 X-ray diffractometer that uses graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) by the ω-scan method. No absorption correction was used. The structure was solved by direct methods and refined by least-squares methods on F^2 using SHELX-97.[10] Non-hydrogen atoms were refined anisotropically and hydrogen atoms on C atoms were fixed at calculated positions and refined using a riding model. The H atoms of the water molecules in **1** and **2** and N atoms in **1** and **2** could not be located. The details of crystal data are given in Table 1; selected bond lengths are summarized in Table 2.

CCDC-269980 (for **1**) and -269981 (for **2**) contain the supplementary crystallographic data for this paper. These data can be ob-

Palladium-Catalysed Amination Reactions Using Cobalt-Containing Bulky Phosphane Ligands

Jian-Cheng Lee,[a] Ming-Gin Wang,[a] and Fung-E. Hong*[a]

Keywords: Amination / Palladium / Cobalt complexes / Phosphane ligands / Orthometallation

Aminations of aryl bromides by morpholine have been investigated using palladium complexes as catalyst precursors modified by the cobalt-containing phosphane ligand [(μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$][μ,η-PhC≡CP(*t*Bu)$_2$] (**1**). Reactions were carried out under various conditions with satisfactory results. The components of the optimised reaction conditions consist of 1.0 mmol of aryl bromide, 1.2 equiv. of morpholine, 1.4 equiv. of NaO*t*Bu, 1 mL of toluene and 1 mol-% of a 1:1 mixture of **1** and $Pd(OAc)_2$. In contrast, related aminations using [(μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$][μ,η-pyC≡CP(*t*Bu)$_2$] (**2**), [(μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$][{μ,η-PhC≡CP(cy)$_2$}] (**3**) and [(μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$][μ,η-PhC≡CP(*i*Pr)$_2$] (**4**) as phosphane ligands do not exhibit comparable efficiency. A novel palladium complex **5**, i.e. Pd(OAc) chelated by deprotonated **1** was obtained from the reaction of **1** with $Pd(OAc)_2$. As revealed by the crystal structure, an orthometallation process occurs between the phenyl ring of **1** and the palladium ion. Presumably, the process is accompanied by release of one equivalent of acetic acid. The coordinated acetate ligand binds to the palladium ion in a bidentate chelating mode.

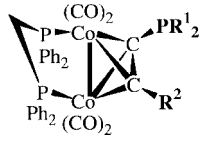
Introduction

The amination of aryl halides by a phosphane-coordinated palladium catalyst is a much more superior method for the preparation of aromatic amines than the original methods using tin amides.[1] Clearly, it is neither ecologically friendly nor practical to use stoichiometric amounts of tin amides in the amination reaction. Recently, momentous improvements have been achieved by Buchwald[2] and Hartwig[3] in the catalytic amination of aryl bromides using free amines. Based on their extensive investigations into this subject, a well accepted mechanism has now been proposed.[4] Recently, a second-generation of much more efficient catalysts for aminations was introduced by Buchwald[5] and Hartwig.[6] These are palladium complexes chelated by biphosphane ligands such as 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) or BINAP. As is known for transition-metal-complex-assisted catalytic reactions, the rate of the reductive elimination process is normally enhanced by employing a bulky ligand such as dppf. Lately, because of their bulky nature, the use of using metal-containing phosphanes in transition-metal catalysed reactions has received increasing attention.[7] In particular, we were interested in exploiting a new type of metal-containing phosphane ligand which would allow us to gain direct access to a family of phosphanes which would hopefully be electron-rich and bulky in character.[7,8] As a result, a new family of novel cobalt-containing (mono- or bidentate) phosphanes has been prepared and their catalytic efficiencies in phosphane modified, palladium-catalysed reactions have been evaluated.[9] It was also found that in most of the phosphane assisted cases, the catalytic efficiencies are higher when using monodentate rather than bidentate phosphanes. Among the monodentate phosphane ligands possible, a series of organometallic versions of tris(alkylphosphanes), [(μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$][μ,η-$R^2C{\equiv}CPR^1{}_2$] (**1**: R^1 = *t*Bu, R^2 = Ph; **2**: R^1 = *t*Bu, R^2 = py; **3**:[9a] R^1 = Cy, R^2 = Ph; **4**: R^1 = *i*Pr, R^2 = Ph), were chosen and used in palladium-catalysed amination reactions (Scheme 1). Results of a careful examination of the amination reactions catalysed by $Pd(OAc)_2$ complexes chelated with **1**, **2**, **3** or **4** are reported in this paper. Following this, the efficiencies of these ligands in the reactions are compared and discussed.



1: R^1 = *t*Bu, R^2 = Ph
2: R^1 = *t*Bu, R^2 = py

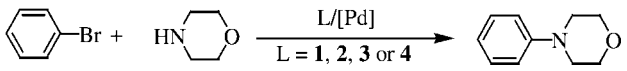
cobalt-containing phosphane ligands **1**, **2**, **3** or **4** as the catalyst precursors (Scheme 2).



Scheme 2.

The general procedure for the catalytic reactions under investigation is as follows. A suitable Schlenk tube was first charged with 1.0 mmol of bromobenzene, 1.2 equiv. of morpholine, 1.4 equiv. of NaO*t*Bu, 1 mL of toluene and 1 mol-% of **1**/$Pd(OAc)_2$. The reaction mixture was then stirred at either 40 °C or 60 °C for 2 to 24 h depending on the reaction under investigation. The results are shown below (Table 1). Excellent yields (>99%) were obtained when the reaction was carried out at 60 °C for 20 h or more (entries 2 and 3). As shown, the reactions reach a satisfactory yield after about 4 h (entry 7). An induction period is obviously needed before the reaction reaches a reasonable rate (entry 8). Similar reactions were carried out employing **2**/$Pd(OAc)_2$ as the catalyst precursor. However, a reduction in the efficiency of the catalysis was observed using this L/Pd combination.

Table 1. Amination reactions employing **1**/$Pd(OAc)_2$ or **2**/$Pd(OAc)_2$ as the catalyst at various temperatures and reaction times.

Entry	Time (h)	Temp. (°C)	Yield (%) (L = **1**)[a]	Yield (%) (L = **2**)[b]
1	24	40	67	–
2	24	60	>99	80
3	20	60	>99	–
4	16	60	93	–
5	12	60	94	82
6	8	60	95	–
7	4	60	94	72
8	2	60	52	–

[a] Reaction conditions: 1.0 equiv. of bromobenzene, 1.2 equiv. of morpholine, 1.4 equiv. of base, 1 mL of solvent and 1 mol-% **1**/$Pd(OAc)_2$. Average of two runs. Determined by gas chromatography. [b] 1 mol-% **2**/$Pd(OAc)_2$.

Compound **2** was synthesised according to the procedure shown in the Experimental Section. The identity of **2** was established by spectroscopic means as well as by X-ray diffraction methods. Two distinct chemical shifts at δ = 3.04 and 4.26 ppm were observed for the methylenic protons of **2** by ^{1}H NMR spectroscopy. Large differences in the shifts imply that the back-and-forth motion of the bridging dppm group around the dicobalt fragment is rather slow. The ^{31}P NMR spectrum displays two singlets in a ratio of 2:1 at δ = 39.03 ppm (2 P, dppm) and 42.74 ppm (1P), respectively, for three phosphorus atoms. The ORTEP diagram for **2** is depicted in Figure 1. As revealed from the structure, the pyridyl ring and the phosphanyl group of the bridged alkyne point away from the centre of the molecule to prevent severe steric hindrance. This situation is also true for the coordinated dppm ligand and the P(*t*Bu)$_2$ substituent. All four carbonyls are located at the terminal positions.

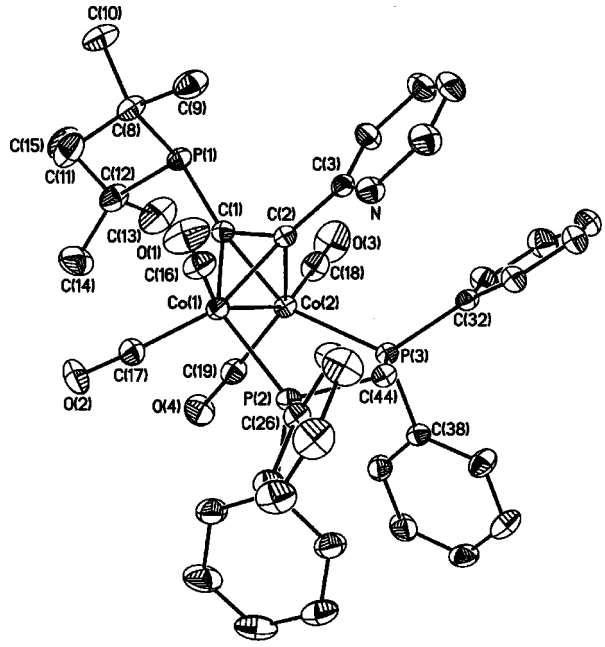


Figure 1. Diagram of **2**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and bond angles [°]: Co(1)–C(2) 1.946(2); Co(1)–C(1) 2.007(2); Co(1)–P(2) 2.2267(8); Co(1)–Co(2) 2.4876(5); Co(2)–C(2) 1.957(2); Co(2)–C(1) 1.998(3); Co(2)–P(3) 2.2415(8); P(1)–C(1) 1.809(3); P(2)–C(44) 1.828(3); P(3)–C(44) 1.828(3); N–C(3) 1.340(3); C(1)–C(2) 1.359(3); C(2)–C(3) 1.470(4); C(2)–Co(1)–C(1) 40.17(10); C(1)–Co(1)–P(2) 138.98(8); C(1)–Co(1)–Co(2) 51.43(7); C(2)–Co(2)–C(1) 40.17(10); C(1)–Co(2)–P(3) 131.70(8); C(1)–Co(2)–Co(1) 51.76(7); C(2)–C(1)–P(1) 132.4(2); Co(2)–C(1)–Co(1) 76.81(9); C(1)–C(2)–C(3) 136.5(2); Co(1)–C(2)–Co(2) 79.18(9); N–C(3)–C(2) 118.2(2); P(3)–C(44)–P(2) 109.79(15).

For comparison, similar reactions were carried out using $Pd(OAc)_2$ complexes chelated with **3** or **4** as catalyst precursors. In these cases, higher reaction temperatures of 80 °C and longer reaction times of 16 h were required for the reactions to be reasonably efficient. Generally speaking, amination reactions carried out employing **3**- or **4**/$Pd(OAc)_2$ as the catalytic systems are not as effective as those based on **1**/$Pd(OAc)_2$ (Table 2). These experimental observations are consistent with the commonly accepted idea that a phosphane ligand with bulky *t*Bu substituents is generally more efficient than that with a less bulky Cy or *i*Pr group.[8a,10]

Compound **4** was prepared and characterised by spectroscopic means. Its crystal structure was also determined by X-ray diffraction methods (see below). In the ^{1}H NMR spectrum of **4**, two distinct chemical shifts at δ = 3.27 and 3.42 ppm were observed for the methylenic protons. In addition, the ^{31}P NMR spectrum displays two singlets in the ratio of 2:1 at δ = 37.89 ppm (2 P, dppm) and 23.48 ppm (1 P) for three phosphorus atoms. The ORTEP diagram for complex **4** is depicted in Figure 2. The structural features observed in **4** were similar to those observed for **2** except that the *i*Pr groups are not as bulky.

Amination reactions were carried out with various ratios of **1**/Pd(OAc)$_2$ or **3**/Pd(OAc)$_2$ under the reaction conditions shown below (Table 3). The optimum yield was achieved when the reaction was conducted with an NaO*t*Bu / toluent solvent system and a L/Pd(OAc)$_2$ ratio of 1:1 (Table 3, entry 3). The positive role played by the phosphane ligand in the reaction can be clearly seen. No conversion was observed without the presence of phosphane (Table 3, entry 6). Again, better efficiency was obtained by employing **1**/Pd(OAc)$_2$.

Table 3. Reactions employing various ratios of Pd(OAc)$_2$/L.

Entry	L/Pd(OAc)$_2$	Yield (%) (L = **1**)[a]	Yield (%) (L = **3**)[b]
1	2:1	36	54
2	1.5:1	73	62
3	1:1	94	85
4	0.5:1	88	71
5	0.1:1	57	23
6	0:1	0	0

[a] Reaction conditions: 1.0 equiv. of bromobenzene, 1.2 equiv. of morpholine, 1.4 equiv. of NaO*t*Bu, 1 mL of toluene and **1**/Pd(OAc)$_2$ at 60 °C for 4 h. Average of two runs. Determined by gas chromatography. [b] **3**/Pd(OAc)$_2$ at 80 °C for 16 h.

As has been established, a well chosen base/solvent system is essential for the success of an efficient palladium-catalysed coupling reaction. As a consequence, amination reactions of bromobenzene by morpholine employing **1**- or **3**/Pd(OAc)$_2$ as the catalyst precursor with various base/solvent systems were carried out at 60 °C for 4 h (Table 4). As shown, the best base/solvent composition is NaO*t*Bu/toluene (entry 1). This may be partially due to the reductive capacity of NaO*t*Bu in toluene.[11]

Amination reactions of bromobenzene by morpholine employing **1** with various Pd sources in a NaO*t*Bu/toluene system were carried out at 60 °C for 4 h (Table 5). As shown, excellent yields were obtained using Pd(OAc)$_2$ or [(η^3-C$_3$H$_5$)PdCl]$_2$ as palladium sources (entries 1 and 6) and this was true using **1** or **3** as the ligand. However, while the [(η^3-C$_3$H$_5$)PdCl]$_2$ system exhibits good catalytic efficiency, the complex is not suitable for use because of its air-sensitivity. Interestingly, no product was detectable when using PdCl$_2$ as the palladium source (entry 2).

It has been commonly observed that a better conversion may be reached for an aryl halide with an electron-withdrawing rather than an electron-donating substituent in a palladium-catalysed coupling reaction.[8c] Amination reactions employing **1**/$Pd(OAc)_2$ and aryl bromides, with various electron-withdrawing/donating capacities in a NaO*t*Bu /toluene system were carried out at 60 °C for 4 h (Table 6). The best yield was obtained for aryl halides with an electron-withdrawing group which is in agreement with the common observation for palladium-catalysed coupling reactions (entry 6). Similar trends were observed when employing **3**/$Pd(OAc)_2$ or **4**/$Pd(OAc)_2$ as the catalyst precursor (Table 6). Interestingly, in our previous work using **4**/$Pd(OAc)_2$ as a catalyst precursor in Suzuki reactions, the catalytic efficiency was rather poor. Nevertheless, the efficiency was comparable with that using **1**- or **2**/$Pd(OAc)_2$ as a precursor in amination reactions.

Characterisation of a Novel Deprotonated Palladium Complex Chelated with 1

Interestingly, a novel palladium complex **5**, namely Pd(OAc) chelated by deprotonated **1**, was obtained from the reaction of **1** with $Pd(OAc)_2$ in toluene at 25 °C for 1 h (Scheme 3). Compound **5** was characterised by spectroscopic means and its crystal structure was determined by X-ray diffraction (Table 7). As revealed by its crystal structure, a process of orthometallation must have occurred which was presumably accompanied by the release of one equiv. of acetic acid (Figure 3). The acetate ligand is coordinated to the palladium through a bidentate chelating mode.[12] The palladium metal centre is in a square planar environment. Two bulky units, $P(t\text{Bu})_2$ and dppm, are in *anti* positions. There is one diethyl ether molecule in each asymmetric unit. As has been established, most acetate palladium complexes are dimeric with two acetates bridging two palladium ions. We believe that the formation of this exceptional monomeric structure of **5** is due to the unique bulkiness and bonding mode of ligand **1**. A rather downfield ^{31}P NMR shift at δ = 91.6 ppm was observed which we assigned to the corresponding palladium attached phosphorus site. A triplet signal was observed in the ^1H NMR spectrum corresponding to the two methylenic protons of the coordinated dppm. This implies that the coordinated dppm is in a rapid back-and-forth thermal motion. All these spectroscopic data are consistent with the data obtained from the solid-state structure. The crystal structure of **5** also demonstrates that only one molar equivalent of phosphane ligand is needed for effective coordination to a palladium ion. For a conventional PR_3 (R: alkyl or aryl), two or even three ligands are required to sustain a stable palladium complex.

Buchwald has proposed a phosphane ligand coordinated palladium complex **6** as an active species in one of the palladium-catalysed amination reactions.[13] However, nothing further was stated about the bonding mode of the acetate ligand in **6** probably because its crystal structure was not established. By comparing **5** and **6**, the structural similarities for these two compounds are clear (Scheme 4). The

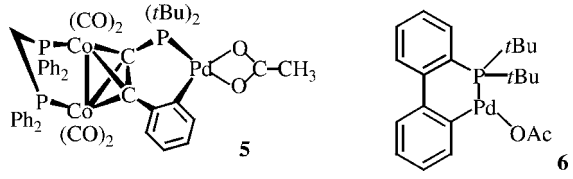
newly characterised compound **5** can be regarded as a more complicated, metal-containing version of **6**.



Scheme 4.

Complex **5** was employed as the Pd source for the aminations of bromobenzene by morpholine. Reactions were carried out in an NaO*t*Bu/toluene phase at 60 °C for 4 h (Table 7). The catalytic efficiency of the reaction employing complex **5** is clearly not as good as that carried out in situ (Table 1, entry 7 vs. Table 7, entry 2). It indicates that complex **5** is not a genuinely catalytically active species. Rather, complex **5** could be regarded as the precursor to a genuine catalytically active Pd^0 species. It still requires a reduction process to convert the Pd^{II} to the more active Pd^0 species.[14] Furthermore, the catalytic efficiency could be greatly improved by increasing the molar ratio of **5** (Table 7, entry 3).

For comparison, amination reactions of aryl bromides bearing various electron-withdrawing/electron-donating substituents, with morpholine, employing **5** in a NaO*t*Bu/toluene system, were carried out at 60 °C for 4 h (Table 8). Generally speaking, the efficiencies are lower for **5** than for **1**/$Pd(OAc)_2$ (Table 6 vs. Table 8). The best yield was found in the case of the aryl bromide with an electron-withdrawing group (entry 6).

Concluding Remarks

We have demonstrated that the amination reactions of aryl bromides by morpholine can be carried out catalytically with palladium complexes modified with a novel cobalt-containing phosphane ligand **1**. The catalytic performance is best with a **1**/$Pd(OAc)_2$ ratio of 1:1. The same reactions may also be carried out using palladium complexes modified with **2**, **3** or **4** but with reduced efficiency.

A novel palladium complex **5** was obtained from the reaction of **1** with $Pd(OAc)_2$. As revealed by the crystal structure, a process of orthometallation occurs presumably accompanied by the release of one equiv. of acetic acid. We propose that **5** could be the precursor to the true catalytically active Pd^0 species.

Experimental Section

Synthesis of (μ-$PPh_2CH_2PPh_2$)$Co_2(CO)_4$[μ,η-PyC≡CP(*t*Bu)$_2$] (2): Dicobalt octacarbonyl $Co_2(CO)_8$ (1.00 mmol, 0.34 g), dppm (1.00 mmol, 0.38 g) and toluene (10 mL) were placed in a 100 mL capacity round flask charged with a magnetic stirrer. The solution was stirred at 65 °C for 6 h and a yellow coloured compound, $Co_2(CO)_6$(μ-P,P-dppm), was produced. Without further separation, the reaction flask was then charged with one equiv. of

PyC≡CP(tBu)$_2$ (0.25 g) in toluene (5 mL). Subsequently, the solution was stirred at 80 °C for 16 h before the solvent was removed under reduced pressure. The residue was further separated by CTLC. A dark green coloured band was eluted using a mixed solvent mobile phase (CH_2Cl_2/hexane, 1:3) and was identified as **2**. The yield was 72% (0.62 g, 0.72 mmol). ^{1}H NMR ($CDCl_3$): δ = 6.90–8.50 (m, 24 H, arene), 3.04 (q, 1 H, dppm), 4.26 (q, 1 H, dppm), 1.23 ppm [d, 18 H, P(tBu)$_2$]. ^{31}P NMR ($CDCl_3$): δ = 39.03 (s, 2 P, dppm), 42.74 ppm [s, 1 P, P(tBu)$_2$]. ^{13}C NMR ($CDCl_3$): δ = 127.86–133.07 (29 C, arene), 30.43 ppm (1 C, dppm). $C_{44}H_{44}Co_2NO_4P_3$: calcd. C 60.91, H 5.11; found C 61.34, H 5.15. MS (EI): m/z = 862 [M]$^+$

Synthesis of (μ-PPh$_2$CH$_2$PPh$_2$)Co$_2$(CO)$_4$[μ,η-PyC≡CP(iPr)$_2$] 4: Dicobalt octacarbonyl, $Co_2(CO)_8$ (1.00 mmol, 0.34 g), dppm (1.00 mmol, 0.39 g) and toluene (10 mL) were placed in a 100 mL capacity round flask containing a magnetic stirrer. The solution was stirred at 65 °C for 6 h during which time a yellow coloured compound, $Co_2(CO)_6$(μ-P,P-dppm), was formed. Without further separation, the reaction flask was charged with one equiv. of PyC≡CP(iPr)$_2$ (0.22 g) in toluene (5 mL) and the solution was then stirred at 80 °C for 16 h. The solvent was removed under reduced pressure and the resultant dark red coloured residue was separated by CTLC. A dark red band was eluted out using mixed solvent mobile phase (CH_2Cl_2: hexane = 1:3) and the compound was identified as **4**. The yield was 82.0% (0.69 g, 0.82 mmol). ^{1}H NMR ($CDCl_3$): δ = 7.77–7.00 (m, 25 H, arene), 3.27–3.42 (d, 2 H, CH_2), 2.23–2.25 (m, 2 H), 1.23–1.43 ppm [m,12 H, P(iPr)$_2$]. ^{31}P NMR ($CDCl_3$): δ = 37.89 (s, 2 P, dppm), 23.48 ppm [s, 1 P, P(iPr)$_2$]. $C_{43}H_{41}Co_2O_4P_3$: calcd. C 61.95, H 4.90; found: C 62.03, H 4.96.

Synthesis of [(μ-PPh$_2$CH$_2$PPh$_2$)Co$_2$(CO)$_4${μ,η-PhC≡CP(tBu)$_2$}]-PdOAc (5): The two reactants, Pd(OAc)$_2$ (1.00 mmol, 0.22 g) and [(μ-PPh$_2$CH$_2$PPh$_2$)Co$_2$(CO)$_4${μ,η-PhC≡CP(tBu)$_2$}] **1** (1.00 mmol, 0.86 g) were placed in a 100-mL round-bottomed flask charged with a magnetic stirrer and toluene (5 mL). The solution was stirred at 25 °C for 1 h before the solvent was removed in vacuo. The crude material was further purified by CTLC. A red-brown band was eluted with CH_2Cl_2 and was identified as **5**. The yield was 80% (0.82 g, 0.80 mmol). ^{1}H NMR ($CDCl_3$): δ = 7.54–6.92 (24 H, arene), 3.30 (t, J_{PH} = 10.2 Hz, 2 H, CH_2), 1.53 ppm (d, J_{PH} = 7 Hz, 18 H, tBu). ^{13}C NMR ($CDCl_3$): δ = 137.16–124.92 (30 C, arene), 41.32 (t, 1 C, CH_2), 38.93 [d, 2 C, -C(CH$_3$)$_3$], 30.55 [d, 6 C, -C(CH$_3$)$_3$], 67.97 ppm [s, 1 C, PhC≡CP(tBu)$_2$]. ^{31}P NMR ($CDCl_3$): δ = 38.8 (s, 2 P, dppm), 91.6 ppm [s, 1 P, P(tBu)$_2$]. MS (ESI): m/z = 1024 [M]$^+$. $C_{51}H_{57}Co_2O_7P_3Pd$: calcd. C 55.07, H 4.62; found: C 53.85, H 4.63.

Amination of Aryl Bromides

Method: An oven-dried Schlenk tube was charged with **1** (8.60 mg, 0.01 mmol), Pd(OAc)$_2$ (2.24 mg, 0.01 mmol) and base (1.4 mmol). The tube was evacuated, filled with nitrogen and then the aryl bromide (1.00 mmol), toluene (1 mL) and morpholine (1.20 mmol) were added. The tube was sealed with a Teflon screw cap and the mixture was stirred at 60 °C for 4 h. After all the starting materials had been consumed, the mixture was cooled to room temperature and was then diluted with diethyl ether (40 mL). The resultant suspension was transferred to a separating funnel and washed with water (10 mL). The organic layer was separated, dried with anhydrous $MgSO_4$ and concentrated in vacuo. The crude residue was purified by CTLC with a mixture of hexane/ethyl acetate as the mobile phase.

The couplings of morpholine with bromobenzene, 4-bromotoluene, 3-bromoanisole or 3-chloronitrobenzene were examined using the method. The isolated yields of the corresponding products, *N*-phenylmorpholine, *N*-(4-methyl)phenylmorpholine, *N*-(3-methoxyphenyl)morpholine and *N*-(3-nitrophenyl)morpholine were 94% (0.153 g), 68% (0.120 g), 80% (0.155 g) and 99% (0.206 g), respectively.

***N*-Phenylmorpholine:** ^{1}H NMR ($CDCl_3$): δ = 6.88–6.93, 7.25–7.30 (m, 5 H), 3.87 (t, 4 H, J = 2.4 Hz), 3.16 ppm (t, 4 H, J = 2.6 Hz).

***N*-(4-Methylphenyl)morpholine:** ^{1}H NMR ($CDCl_3$): δ = 3.10 (t, 4 H, J = 5 Hz), 3.86 (t, 4 H, J = 4.6 Hz), 6.83 (d, 2 H, J = 8.6 Hz), 7.10 ppm (d, 2 H, J = 8.4 Hz).

X-ray Crystallographic Studies: Suitable crystals of **2**, **4** and **5** were sealed in thin-walled glass capillaries under nitrogen and mounted on a Bruker AXS SMART 1000 diffractometer. Intensity data were collected from 1350 frames with increasing ω (width of 0.3° per frame). The absorption correction was based on the symmetry equivalent reflections using the SADABS program. The space group determination was based on a check of the Laue symmetry and systematic absences and was confirmed using the structure solution. The structure was solved by direct methods using the SHELXTL package.[15] All non-hydrogen atoms were located from successive Fourier maps and the hydrogen atoms were refined using a riding model. Anisotropic thermal parameters were used for all non-hydrogen atoms and fixed isotropic parameters were used for H atoms.[16] The crystallographic data of **2**, **4** and **5** are summarised in Table 9.

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre. CCDC-261777, -261778 and -261779 for compounds **2**, **4** and **5**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

A Crystalline Phase Transition and Optical Properties in a $Co^{II}Cu^{II}$ Oxamato-Bridged Ferrimagnetic Chain

Cynthia L. M. Pereira,[a] Antonio C. Doriguetto,[b] Cibele Konzen,[c] Luiz C. Meira-Belo,[c] Ulisses A. Leitão,[d] Nelson G. Fernandes,[a] Yvonne P. Mascarenhas,[b] Javier Ellena,[b] Ana L. Brandl,[e] Marcelo Knobel,[e] and Humberto O. Stumpf*[a]

Keywords: Birefringence / Chain structures / Molecular magnetism / Phase transitions / Transition metals

The compound [CoCu(opba)$(DMSO)_3$] (**1**) [opba = *ortho*-phenylenebis(oxamato)] has been synthesized and characterized. Its crystal structure has been analyzed by X-ray diffraction techniques at 100 and 298 K. A structural phase-transition has been detected at around 150 K. An orthorhombic crystalline system is found at both temperatures, with very similar unit-cell dimensions. At room temperature **1** crystallizes in the *Pnam* space group (**α-1** phase), with a = 7.6712(2), b = 14.8003(3), c = 21.0028(5) Å, and Z = 4, whereas at low temperature it crystallizes in the $Pna2_1$ space group (**β-1** phase), with a = 7.3530(2), b = 14.5928(4), c = 21.0510(7) Å, and Z = 4. Both crystalline phases consist of linearly ordered bimetallic chains with the $[Cu(opba)]^{2-}$ units tied by Co^{II} ions to form a one-dimensional system. The DMSO molecules in **α-1**, which are coordinated to either Cu^{II} or Co^{II}, are disordered. At low temperature, a small reorganization of the Cu^{II} and Co^{II} environments is observed. The origin of this phase transition, which is completely reversible, is the modification of the crystalline packing with the temperature. Linear birefringence measurements were done on single crystals in the 100–300 K temperature range. Around 150 K, the linear birefringence curve shows an inflexion that is interpreted as being related to the conversion of **α-1** into **β-1**. Both dc and ac magnetic measurements were performed on the polycrystalline sample. The results reveal a one-dimensional ferrimagnetic behavior. Single crystal optical characterization at room temperature shows that **1** presents a very strong dichroism superposed on the linear birefringence.

Introduction

The first molecule-based magnets described were the organometallic compound $[Fe(Me_5Cp)_2][TCNE]$ (Me_5Cp = pentamethylcyclopentadienyl; TCNE = tetracyanoethylene)[1] and the chain $[MnCu(pbaOH)(H_2O)_3]$ [pbaOH = 2-hydroxy-1,3-propylenebis(oxamato)].[2] Since then, there has been a rapid development of this field of research, with special focus on the design of materials with predictable magnetic properties and potential technological applications.[3–5] In the last two decades, the chemistry of molecular magnetic materials has been widely exploited in two branches. In the first one, the key goal is to optimize the magnetic properties by increasing the Curie temperature, coercivity, spin transition, blocking temperature, or tunneling effects,[6–11] whereas in the second branch the focus is on aggregating other characteristics to the magnetic materials, such as optical properties or conductivity.[12–14] What these two branches have in common is the employment of molecular chemistry in a bottom-up strategy. Let us illustrate this using the oxamato-bridged system as an example. One of the first steps of this approach consists in synthesizing a building block like $[Cu(opba)]^{2-}$ [Figure 1; opba = *ortho*-phenylenebis(oxamato)].[15] This precursor possesses two lone pairs on either side of the peripheral oxygen atoms and therefore it may behave as a bis-bidentate ligand. The next stage is the choice of a metal ion whose characteristics must induce the production of a material with desirable properties. Supramolecular aspects can become very impor-

tant in this step. Besides the stoichiometric ratios, concentration, and counterion nature, the solvent can play a key role. Indeed, the first chain to be synthesized using this precursor was [MnCu(opba)$(DMSO)_3$], which was obtained in DMSO.[15] This compound has an unexpected zigzag chain structure with two DMSO molecules bound to the manganese atom in a *cis* fashion. [MnCu(opba)$(DMSO)_3$] is an almost perfect one-dimensional ferrimagnet where the chains are isolated by DMSO molecules in the crystalline packing. When the reaction is performed in a DMSO/H_2O mixture, the octahedral environment of the Mn^{II} is completed by two water molecules in *trans* positions and the product obtained, [MnCu(opba)$(H_2O)_2$]·DMSO, consists of linear chains.[16] In this latter compound, the chains interact weakly within the crystal lattice and the compound shows an antiferromagnetic transition with T_N = 5 K and metamagnetic behavior. By making some changes we can prepare 2D, graphite-like compounds with the general formula $[cat]_2[M_2\{Cu(opba)\}_3]$[15,17] or interlocked systems[6,18,19] where the counterion cat^+ is a nitronyl-nitroxide radical cation. Very recently, a new class of bidimensional metallacyclophane-based compounds $[Co_2Cu_2(mpba)_2(H_2O)_6]\cdot 6H_2O$ [mpba = *meta*-phenylenebis(oxamato)], which present a corrugated brick-wall structure, have been obtained.[20]

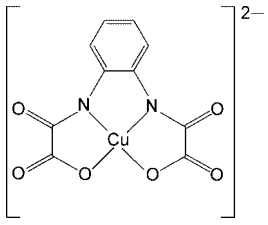

Figure 1. Building block $[Cu(opba)]^{2-}$.

The aim in preparing these 2D and 3D molecule-based systems was to increase the critical temperatures of the magnetic ordering. With the report of the [$Co(hfac)_2$NITPhOMe] nanowire, which shows slow relaxation of the magnetization and hysteretic effects, by Gatteschi et al.,[21] a renewed interest in linear systems has emerged. In this paper, we will describe the synthesis, structure, and magnetic and optical properties of the chain [CoCu(opba)$(DMSO)_3$] (**1**). Furthermore, a study of the linear birefringence measurements and single-crystal X-ray crystallography in order to confirm a temperature-induced crystalline phase-transition for **1** will be presented.

Results and Discussion

Crystal Structures of [CoCu(opba)$(DMSO)_3$] Phases

X-ray diffraction experiments were carried out at two different temperatures (298 and 100 K). The structures of **α-1** and **β-1** are shown in Figure 2. In both cases the structure consists of ordered infinite linear chains running along the *c* axis with adjacent Co^{II} and Cu^{II} ions bridged by oxamato groups. This compound does not have the zigzag structure of [MnCu(opba)$(DMSO)_3$];[15] it is more similar to the linear chain of [MnCu(opba)$(H_2O)_2$]·DMSO.[16] However, in contrast to this latter chain, the aromatic rings of **1** are alternately on one and the other side of the chain axis.

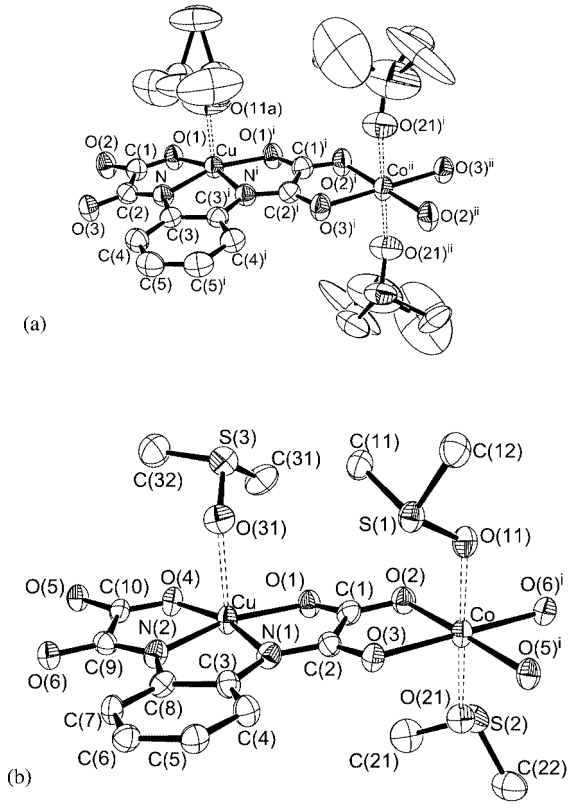

Figure 2. ORTEP3 drawing of the phases **α-1** (a) and **β-1** (b) of the chain [CoCu(opba)$(DMSO)_3$] (**1**) showing some atom designation. The thermal ellipsoids are drawn at the 50% probability level.

The main geometric parameters for phases **α-1** and **β-1** are given in Table 1. It is important to emphasize that **α-1** has half as many independent atoms as **β-1** due to its extra inversion center.

The geometry around the copper atom is approximately square pyramidal with two nitrogen atoms and two oxygen atoms from the opba group in the basal plane and one DMSO oxygen atom in the apical position. The DMSO molecules bonded to the Cu ions are disordered in **α-1**. This disorder disappears at low temperature, and a subsequent phase transition occurs to give **β-1**. In the phase **α-1**, the two N–Cu–O fragments present identical geometry due to their mirror symmetry. The $[Cu(opba)]^{2-}$ unit geometry is not analogous to those previously found for $Mn^{II}Cu^{II}$ bimetallic compounds either for **α-1** or **β-1**.[15,16]

The cobalt atom is coordinated to six oxygen atoms in a distorted octahedral surrounding. Two of these oxygen atoms, arising from the DMSO molecules, are in *trans* positions; the other four belong to oxamido groups of two different opba ligands. Similar to the Cu coordination sphere, the DMSO molecules coordinated to the Co atoms are disordered in **α-1**, whereas no disorder is observed in the **β-1** phase. In **α-1**, the Co ions are located on the inversion center. Therefore, only two of four opba oxygen atoms and one

[a] Symmetry codes: phase **α-1**: [i] *x*, *y*, –*z* + 1/2; [ii] *x*, –*y* + 1, *z* + 1/2; phase **β-1**: [i] –*x*, –*y* + 1, *z* + 1/2.

of the two DMSO oxygen atoms are independent. In spite of this, the geometric parameters of the Co octahedron do not exhibit significant differences when the two phases are compared (see Table 2).

Both phases have very similar packing in which each chain is surrounded by six others (see Figure 3).[22] The shortest metal–metal distances (approx. 5.3 Å) occur between intrachain nearest neighbor Cu^{II} and Co^{II} ions. In **α-1** there is just one independent Cu···Co intrachain separation [5.303(1) Å], whereas in **β-1** there are two symmetrically independent intrachain Cu···Co contacts with distances equal to 5.336(1) (Cu···Co) and 5.305(1) Å (Cu···Co^{ii}; *ii* = –*x*, –*y* + 1, *z* – 1/2). The separation between adjacent chains along the *a* axis is exactly equal to the length of the cell parameter in this direction. This means that interchain Co···Co^{i} and Cu···Cu^{i} (*i* = *x* + 1, *y*, *z*) distances along the *a* axis are equivalent and decrease by about 0.3 Å from **α-1** to **β-1**. The interchain metal–metal separations considering transverse adjacent chains show significant differences between the **α-1** and **β-1** phases, mainly with respect to the Co···Co distances. For **α-1** there is just one independent transversal Co···Co distance [8.335(1) Å] since the Co atom is in the special position (0, 0, 1/2). For **β-1** the Co atom is shifted from the unit-cell edges mainly for the *z* coordinate. Therefore, the Co···Co distance is split in two: [Co···Co^{vi} = 7.818(1) Å (*vi* = *x* + 1/2,–*y* + 1/2, *z*) and Co···Co^{vii} = 8.526(1) Å (*vii* = *x* + 1/2,–*y* + 3/2, *z*)]. Due to the waving of the chain along the *c* axis, the structure presents two very different interchain Cu···Cu separations among transverse adjacent chains. One of them is the shortest metal–metal interchain separation [Cu···Cu^{v} = 7.108(1) Å for **α-1** (*v* = *x* + 1/2, –*y* + 3/2, –*z* + 1/2) and Cu···Cu^{vii} = 6.965(1) Å for **β-1** (*vii* = *x* + 1/2, –*y* + 3/2, *z*)], and the other one is the longest metal–metal first-neighbor separation [Cu···Cu^{iv} = 9.614(1) Å (*iv* = *x* + 1/2, –*y* + 1/2, –*z* + 1/2) for **α-1** and Cu···Cu^{vi} = 9.424(1) Å for **β-1** (*vi* = *x* + 1/2, –*y* + 1/2, *z*)]. The Cu···Co interchain distances range

from 9.134(1) to 10.481(1) Å for **α-1** and from 8.752(1) to 10.546(1) Å for **β-1**. For both phases, the shortest contact takes place between parallel chains stacking along the *a* axis. Comparing the two phases, the biggest split due to the inversion symmetry break occurs for the Cu···Co^{i} and Cu···Co^{iii} distances, which are equal to 9.513(1) Å for **α-1** and decrease to 9.256(1) and 8.752(1) Å, respectively, for **β-1**.

Since *Pnam* (**α-1**) differs from *Pna*2$_1$ (**β-1**) only in the extra inversion symmetry in the former, there is no additional peak in the low-temperature diffraction pattern. Due to the reversibility, the phase transition involves only small changes in the atomic positions. This is true for the $[Cu(opba)]^{2-}$ unit and the Co atom. In spite of the fact that the Co ions leave the inversion center on going from phase **α-1** to phase **β-1**, the chains are very similar in both phases. On the other hand, the orientations of the DMSO molecules change significantly between the two phases. With

these results in mind, two DMSO ordering mechanisms have been proposed to explain the structural transition. Initially, it was considered that all DMSO molecules could suffer a rotation of 180° around its O–S bond, as depicted in Figure 4 (mechanism 1), where both **α-1** and **β-1** crystalline phases are superposed. However, comparing the packing of the two phases (Figure 5), it is possible to conclude that mechanism 1 should not be the most plausible due to the steric hindrance effects. The most probable is that the DMSO molecule coordinated to the Cu^{II} ion migrates from a chain to another parallel one whilst maintaining almost the same orientation (Figure 5; mechanism 2). Therefore, the DMSO molecule ordering from 298 to 100 K occurs concomitantly with the displacement of DMSO molecules bonded to the Cu ions, with the DMSO groups bonded to the Co ions remaining in almost the same place.

Optical Properties

In order to verify optical anisotropy effects, namely linear birefringence (LB) and linear dichroism (LD), the sample was placed between crossed polarizers. Upon rotating the sample relative to the polarizers, points of extinction were noticed at 90°. Both effects, LB and LD, could be responsible for the observed optical behavior. Upon removing one polarizer we noted extinction points at 180°, thus revealing the LD effect in the sample. The photographic records of these results are available as Supporting Information.

The temperature dependence of the LB is dominated by small differences in the thermal expansion coefficients of the lattice parameters, as shown in Figure 6. This gives rise to an almost linear temperature-dependence behavior, except for the anomalies in the LB. This kind of anomaly is typical of a first-order structural phase transition. A large thermal hysteresis of about 70 K was observed.

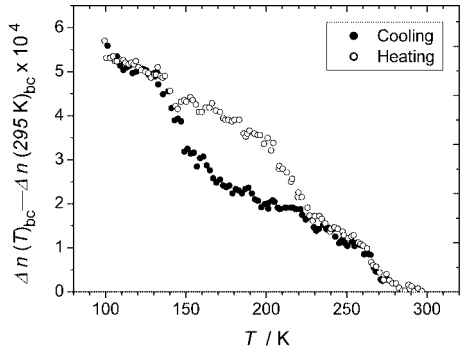

Figure 6. Cooling (solid circles) and heating (open circles) runs of the linear birefringence thermal dependence for **1**.

The optical properties assigned to the structural symmetry of transparent crystals can be described by their characteristic indicatrix, an ellipsoid on phase space of the refraction indices.[23] Orthorhombic crystals have three different values for the axes of its indicatrix, with two circular central sections characterizing a biaxial system, i.e., the crystal has two optical axes. Although both symmetry point groups for **α-1** and **β-1** are orthorhombic, their tensorial properties are different, which became evident by the changes in the birefringence curve on both runs.

The temperature dependence of the LD for **1** was obtained by using a lock-in detector technique analogous to the LB experiment, except for the removal of the analyzer polarizer.[24] The data were collected in the 20–295 K temperature range and the sample was oriented at 45° in order to maximize the LD signal. No significant variation of the lock-in amplifier signal was detected upon maintaining the LD approximately constant during the whole experiment.

Magnetic Studies

The temperature dependence of the magnetic susceptibility for **1** is shown in Figure 7 in the form of a $\chi_M T$ vs. T plot, with χ_M being the molar magnetic susceptibility and T the temperature. At 300 K, $\chi_M T$ (2.87 emu K mol^{-1}) corresponds to what is expected for uncoupled Co^{II} and Cu^{II} ions.[25] At high temperatures, a spin S, of 3/2 can be assigned for Co^{II} ions. As T is lowered, $\chi_M T$ decreases smoothly and reaches a rounded minimum around 90 K with $\chi_M T$ = 2.31 emu K mol^{-1}, and then increases as T is lowered further. Such behavior is characteristic of one-dimensional ferrimagnetism. This decrease of $\chi_M T$ could be due to the spin-orbit coupling effect of octahedral Co^{II} ion,[26] but it is strong enough to confirm the presence of antiferromagnetic coupling between near neighbors, as expected for oxamato-bridged compounds.[27] As T is lowered further below the minimum of $\chi_M T$, the correlation length within the chain increases rapidly. At very low temperatures, the Co^{II} ion behaves as an effective spin of 1/2, but the different g value with respect to the Cu^{II} centers ensures that the ground state will be magnetic.[28]

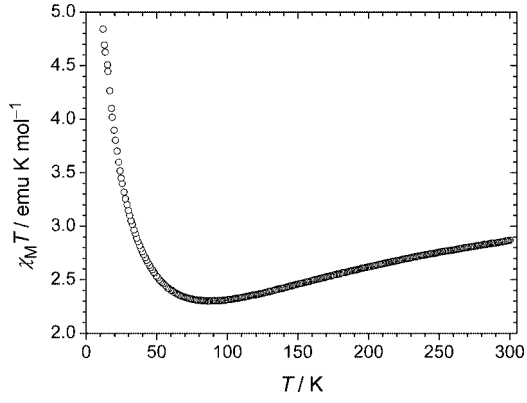

Figure 7. Temperature dependence of $\chi_M T$ for **1** at 1 kOe.

The temperature dependence of the magnetization for **1** is shown in Figure 8. The field-cooled magnetization (FCM), recorded by cooling the sample under a field of 100 Oe, shows a continuous increase, and reaches a value of 600 emu Oe mol^{-1} at 2 K. The zero-field cooled magnetization (ZFCM, not shown) was measured by cooling the sample without an applied field, then warming up under

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a 100 Oe field. ZFCM and FCM are coincident, thereby revealing the absence of remnant magnetization.

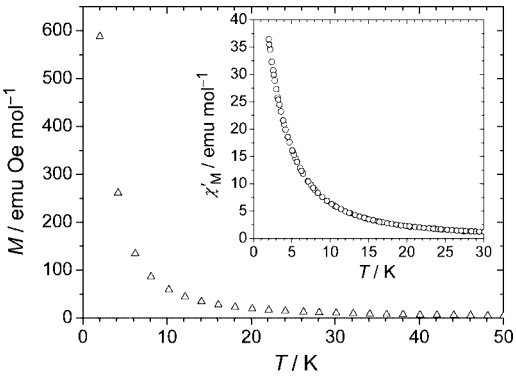

Figure 8. Field-cooled magnetization (FCM) in an applied field of 100 Oe. Inset: Real (χ_M') component of the ac magnetic susceptibility at a frequency of 1 kHz.

The thermal dependence of the in-phase (χ_M') and out-of-phase (χ_M'') components of the ac magnetic susceptibility were also investigated. The χ_M' results at an ac field of 10 Oe measured at 1 kHz and no dc field applied (inset of Figure 8) are very similar to the FCM curve with a rapid increase below 4 K. The χ_M'' curves are close to zero in the investigated temperature range.

Figure 9 shows the field dependence of the magnetization at 2 K for the chain **1**. As the applied field increases, M increases, and does not saturate even for fields as high as 65 kOe, where it reaches a value of 1.4 μ_B mol^{-1} (Nβ). The saturation magnetization is expected to be higher than 2 Nβ, a value related to all S_{Co} local spins aligned along the field direction and all the S_{Cu} local spins aligned along the opposite direction.[25,27] The difference between these values indicates that the local magnetic moments do not reach a perfect alignment with the field direction. This is probably due to the anisotropy of the spin carriers, which prevents the magnetic moments from rotating freely when applying the field. Such behavior is typical for oxamato-based magnets containing Co^{II} ions. No magnetic hysteresis is observed for this compound, even at 2 K (inset of Figure 9).

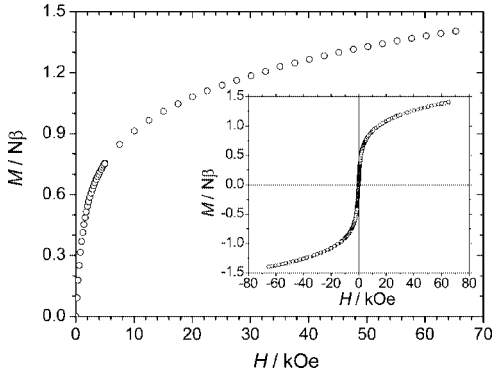

Figure 9. Molar magnetization vs. applied magnetic field for **1** at 2 K. Inset: Hysteresis loop at 2 K.

Let us now briefly discuss the relationship between structure and magnetic properties for **1**. The high-temperature behavior of the magnetic properties is widely dominated by the intrachain couplings along the c axis (J_c or J_{CoCu}). The mechanism of these M^{II}–Cu^{II} interactions (M being a transition metal ion) through the oxamato bridge is rather well understood. These interactions are due to the overlap of the $d_{x^2-y^2}$ magnetic orbitals centered on adjacent spin carriers. The strong covalent bonds and electron delocalization in molecule-based magnets with ligands like opba have, as a consequence, J_{MCu} values of about –30 cm^{-1}. This is a strong coupling and we can expect a similar value for **1**. In contrast, the interchain couplings are not very effective at high temperatures since kT is considerably larger than J_a and J_b. It is well established that a purely one-dimensional system is not able to exhibit spontaneous magnetization, except at absolute zero; a magnetic transition is generally a three-dimensional phenomenon.[28] For **1**, the structural changes in the crystalline phase transition are small and not sufficient to increase the interactions along the a or b axes to lead to a magnetic transition.

Conclusions

The ferrimagnetic chain [CoCu(opba)$(DMSO)_3$] (**1**) has been synthesized and characterized. It presents two crystalline phases – *Pnam* at room temperature and $Pna2_1$ at 100 K – whose structures consist of ordered infinite linear chains running along the c axis with adjacent Co^{II} and Cu^{II} ions bridged by oxamato groups. In the **α-1** phase, the DMSO molecules are disordered over the Co^{II} and Cu^{II} coordination sphere, whereas at low temperatures this structural disorder vanishes. The crystalline phase transition has been confirmed by a study using linear birefringence in a small single crystal with no polished surfaces. In addition, the LB results show a large thermal hysteresis associated to the structural changes in **1**, thereby revealing that the structural phase transition is a first-order process.

Magnetic studies (dc and ac) have been performed for **1** in a polycrystalline sample. At high temperatures, the stronger interactions along the c direction are responsible for the ferrimagnetic behavior. Since the changes that occur in the structural phase transitions do not affect this coupling significantly, anomalies in the magnetic data at the same temperatures observed by X-ray diffraction and LB measurements were not detected. The bimetallic chains in **1** are almost isolated from each other. The intrachain interaction between nearest neighbor ions is rather large but the interchain interactions are negligibly small. It is possible that **1** presents only a ferrimagnetic behavior, with correlation length increasing with a decrease of temperature without divergence of these values until the magnetometer temperature limit. In view of the crystalline arrangement, interactions along the packing direction (a axis) probably take place while the interactions along the b axis must be very weak. Therefore, the magnetic behavior for **1** below 2 K, where the effective spin of Co^{II} ions is 1/2, needs to be better investigated.

Compound **1** exhibits some interesting features with respect to magnetic nanowires. Indeed, good candidates to present slow relaxation of the magnetization and hysteretic effects require strong anisotropy, ferromagnetic intrachain coupling or ferrimagnetic behavior, and the chains must be rather isolated. Therefore, the control of the chemistry, including supramolecular aspects, of compound **1** and related systems gives rise to a challenge: the preparation of oxamato-based nanowires, and also 2D systems, with higher blocking temperatures. We are presently focusing ours efforts in this direction.

Experimental Section

Preparation of [CoCu(opba)(DMSO)$_3$] (1): Compound **1** was prepared by adding $Co(NO_3)_2 \cdot 6H_2O$ (15 mg, 0.05 mmol), previously dissolved in DMSO (3 mL), to a solution of $Na_2[Cu(opba)] \cdot 3H_2O$[15] (170 mg, 0.41 mmol) in DMSO (22 mL) whilst stirring. The crystals obtained after three months under controlled temperature (35 °C) were separated by filtration, washed with DMSO, and dried in a desiccator. Yield: 105 mg (29%). $C_{16}H_{22}CoCuN_2O_9S_3$ (605.01): calcd. C 31.76, H 3.64, Co 9.74, Cu 10.50, N 4.63, S 15.91; found C 30.80, H 3.46, Co 9.64, Cu 9.90, N 4.93, S 15.52. IR (KBr): $\tilde{\nu}$ = 3450 cm^{-1} (vs), 1610 (vs), 1575 (s, br), 1475 (m), 1400 (m), 1350 (m), 1025 (s), 940 (m), 750 (m), 575 (w), 550 (w), 450 (m).

X-ray Crystallographic Study: A blue prismatic crystal of dimensions $0.03 \times 0.08 \times 0.09$ mm^3 was used for data collection. The X-ray diffraction data were collected at 298 and 100 K on an Enraf–Nonius Kappa-CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) up to 50° in 2θ, with a redundancy of 4. The final unit-cell parameters were based on all reflections. The temperature was controlled with an Oxford Cryosystem low temperature device. Absorption corrections were carried out using the multi-scan method.[29] The structures were solved by direct methods with SHELXS-97.[30] The models were refined by full-matrix least-squares procedures on F^2 using SHELXL-97.[31] The H atoms of the phenyl and methyl groups were positioned stereochemically and they were refined with fixed individual displacement parameters [U_{iso}(H) = 1.2 U_{eq}(C_{phenyl}) or 1.5 U_{eq}(C_{methyl})] using the SHELXL riding model. Crystal data, data collection procedures, structure determination methods and refinement results are summarized in Table 2.

CCDC-272758 (for **α-1**) and -231896 (for **β-1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Optical Measurements: The single crystal optical characterization, namely linear birefringence (LB) and linear dichroism (LD), was done at room temperature, under incoherent light, using an Olympus model BX50 optical microscope equipped with an Olympus SC35 camera. The temperature dependence of the birefringence was investigated using a lock-in null detector technique applied for LB.[32] The equipment consists of a photoelastic modulator working at 50 kHz and a computer-controlled Soleil–Babinet compensator, with resolution of $\delta(\Delta n) \leq 3 \times 10^{-8}$, corresponding to a phase difference of about 0.01°. The system has a built-in microscope to allow the study of small samples.[33] The typical dimensions of the samples studied in this paper were a thickness of 0.1 mm and 0.25×0.50 mm^2 transverse dimensions. Due to the reduced dimensions of the crystals, no polishing procedure was possible. A pinhole inserted into the microscope allows it to choose the best regions on the surface of the sample. Measurements were made at the 488-nm line of an argon ion laser. The sample containing a drop of the mother solution where the crystal was grown was placed on a thin glass plate. Thermally conducting glue was used to connect the glass plate to the sample holder, which was inserted into an evacuated cryostat, horizontally positioned, and cooled by helium flux. When the mother solution had evaporated, the crystals were fixed to the glass plate by surface tension. The sample was oriented in the crystallographic *ac* plane. The data were collected from 295 to 20 K. The cooling and heating rates were kept to be approximately 1 K min^{-1}. The chosen orientation of 45° maximizes the birefringence.[23]

Magnetic Measurements: The dc magnetic properties of **1** were studied in a Quantum Design SQUID MPMS XL7 in the 2–300 K temperature range using polycrystalline samples. The ac magnetic properties were studied in a commercial Quantum Design PPMS system. The diamagnetic corrections were estimated from Pascal's tables.

A Novel Integrated X-ray Powder Diffraction (XRPD) and Molecular Dynamics (MD) Approach for Modelling Mixed-Metal (Zn, Al) Layered Double Hydroxides (LDHs)

Giuseppe M. Lombardo,[a] Giuseppe C. Pappalardo,*[a] Francesco Punzo,[a] Ferdinando Costantino,[b] Umberto Costantino,[b] and Michele Sisani[b]

Keywords: Layered double hydroxides / Molecular dynamics / X-ray diffraction / Structure elucidation

A combination of experimental (XRPD) and computational (MD-simulation) techniques was used for a detailed study of the structural, dynamic and hydration properties of the ZnAl layered double hydroxides (LDHs) of formula $[Zn_{0.65}Al_{0.35}(OH)_2]Cl_{0.35}\cdot yH_2O$ (**I**) and $[Zn_{0.65}Al_{0.35}(OH)_2](CO_3)_{0.175}\cdot yH_2O$ (**II**), with y = 0.35 and 0.69, respectively. Our approach was based on a direct comparison made, for the first time, between the observed XRPD diffraction pattern and the MD-simulated pattern of each model that was considered. The XRPD curve is affected (reflection angles and line shapes) by dynamic and structural factors, and the interlayer distribution of the water content. Accordingly, its reproduction through MD modelling is the most suitable means of monitoring these properties of the material. Molecular modelling was performed by MD simulations of models of **I** and **II** built up through appropriate modifications of their interlayer total water contents and related distribution. The validated models, namely those that provided the best MD-simulated pattern of **I** and **II**, were then used to determine structures and features which have not been previously determined by conventional diffraction techniques. The calculated XRPD curves were corrected to take into account the "size" broadening effect. The approach provided structural data that matched well those obtained by Rietveld analyses for the usual parameters. Furthermore, the study was original in its capability to detect and thus to discriminate between the different interatomic distances Zn–O, Al–O, Al···Al, Zn···Zn, Zn···Al in the slabs. The MD-simulated models of **I** and **II** provided the best reproduction of the XRPD curves for total water of hydration contents of y = 0.25 and y = 0.69, respectively. In the case of **II**, a domain with a homogeneous distribution of total water contents predominated. Conversely, in the case of **I**, a nonhomogeneous distribution featured by two (or multiple) shared crystalline domains having different interlayer water contents was evidenced.

Introduction

Layered double hydroxides (LDHs), also known as anionic clays or hydrotalcite-like compounds (HTlc), are solid compounds having positively charged layers and intercalated exchangeable interlayer anions to maintain charge neutrality.[1–11] Their general formula is $[M^{II}_{1-x}M^{III}_{x}(OH)_2]^{x+}(A^{n-}_{x/n})^{x-}\cdot yH_2O$ in which M^{II} = Mg, Zn, Co, Ni, Mn, etc., M^{III} = Cr, Fe, V, Co, etc., A^{n-} = an inorganic or organic anion of charge *n*.

The great technological relevance of LDHs stems from their use as precursors in catalysis.[7,10,12–16] In particular, ternary LDHs of type $[Cu_yZn_{1-x-y}Al_x(OH)_2](CO_3)_{x/2}\cdot(1–3x/2)H_2O$, after thermal decomposition and successive reduction of the copper oxide to the metal with hydrogen, attain a tight mixture of oxides with copper particles (Cu/ZnO/Al_2O_3) that is active as a catalyst for hydrogen production from oxidative steam reforming of methanol (OSRM). This is useful for developing a clean power source for vehicles.[17–19]

Understanding the structural and dynamic properties of this important class of materials is a central issue in studies focusing on the design of second-generation LDH precursors and derived catalysts with enhanced or new performances.

The arrangement of the interlayer species is not well understood and is difficult to probe experimentally. It frequently happens that anions and water molecules associate strongly with particle surfaces, and some adsorbed water molecules are indistinguishable from interlayer water in thermal analyses.

Unfortunately, these materials are obtained only as powders, often with a low degree of crystallinity, thus making structural determinations by single-crystal X-ray analysis impossible. Further, even in cases where the powdered solids initially exhibit a high degree of crystallinity, large overlapping bands from relatively poor diffraction patterns are often observed when these solids are modified by heating, ion-exchange, intercalation, pillaring or topotactic functionalisation by ligand substitution. Therefore, detailed structural information on these systems from X-ray powder diffraction (XRPD) data is difficult to obtain or otherwise inaccessible.

We have recently used molecular dynamics (MD), combined with large angle X-ray scattering (LAXS)[20–24] or XRPD experiments,[25,26] for determining structural parameters (molecular assembly, interatomic and intermolecular distances).

Application of MD for simulating these materials provides the following: (i) an ability to monitor the internal molecular fluctuations, thus revealing, by implementing high-temperature MD runs, processes leading to metal segregation and to the breakdown of the structure of the precursor; (ii) the ability to generate microscopic-level structural information that can be correlated directly with the experimentally detectable activity and selectivity of catalysts for OSRM; (iii) the capacity to refine molecular structures by using experimental data, especially from X-ray diffraction experiments for microcrystalline and amorphous solid phases.

The ability to predict macroscopic properties of HTlc on the basis of microscopic structures derived from MD simulations has a fundamental impact on the design of new materials with improved technological requisites. To accomplish this, not only should the molecular simulations be carried out on a long enough time scale to sample a significant volume of phase space, but also: (i) a suitable unit or fragment of the material should be selected to serve as the model of the real system; and (ii) the force field (FF) used by the MD program should feature a high-quality parameterisation developed ad hoc for the system that is being dealt with.

Previous computer modelling focused on interlayer distance dynamics in binary LDH systems[27–32] by using generic force fields. Quite recently, a force field (CLAYFF) designed for simulations of clay phases was optimised on the basis of known mineral structures for the Si, Al, Mg, Ca, Fe and Li species.[33] In order to model binary Zn-containing LDHs by using MD simulations for the first time, we relied on a modified version of the CLAYFF into which suitable ad hoc developed Zn parameters were inserted.

The models used for the simulations (Figure 1) of $[Zn_{0.65}Al_{0.35}(OH)_2]Cl_{0.35}\cdot 0.35H_2O$ (**I**) and $[Zn_{0.65}Al_{0.35}(OH)_2](CO_3)_{0.175}\cdot 0.69H_2O$ (**II**) were preliminarily validated on the basis of a direct agreement between the experimental XRPD patterns and those calculated from MD. The calculated XRPD patterns were obtained by averaging patterns calculated from snapshots collected along the entire evolution time of the MD simulation for each of the models considered. By this procedure, the positions of the observed diffraction lines could be reproduced by taking the thermal, dynamic and structural factors, as well as the water content of the material into account.

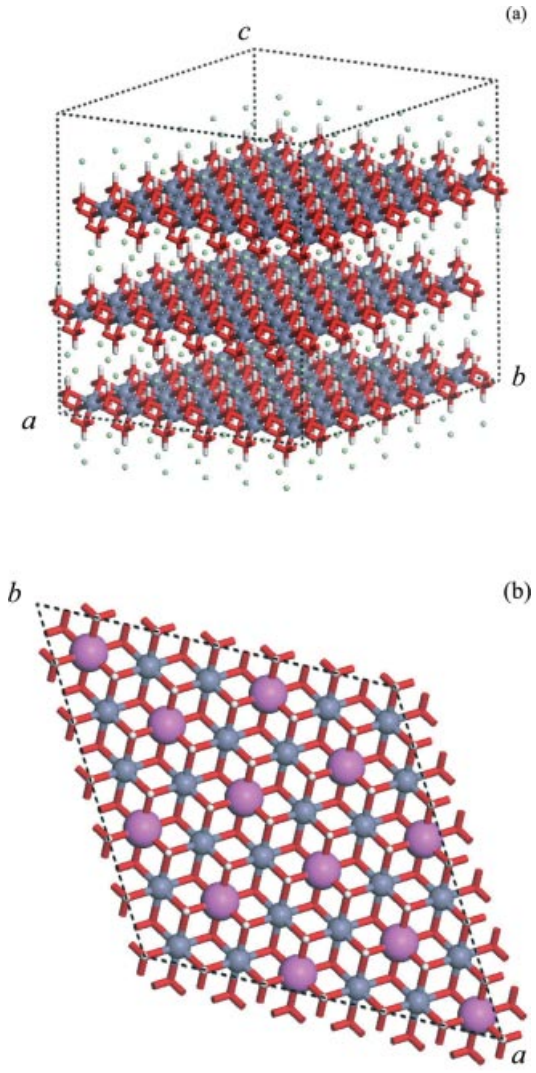

Figure 1. (a) The 3-layered model supercell with independent variables a, b, c, α, β, γ used for the MD simulations of both the LDHs **I** and **II**. The green balls represent the positions available for accommodation of interlayer water molecules with chloride (**I**) or carbonate (**II**) anions. (b) View of the preferred planar arrangement of metallic ions in the Zn/Al slab in the ratio 2:1 (element colours: Zn blue-grey; Al pink; O red, H white).

In the present study the combined approach, validated as stated above, was used for featuring the LDHs **I** and **II** in terms of structure, dynamics and arrangement of their interlayer water molecules and anionic species.

Results and Discussion

Analysis of XRPD Patterns

The Rietveld plots and crystallographic data obtained from the XRPD patterns of the well-crystallised samples of **I** and **II** are given in Figure 2 and Table 1, respectively.

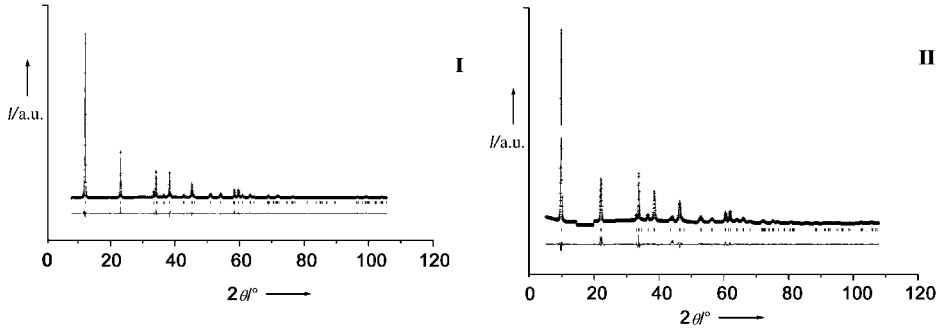

Figure 2. Rietveld plots for **I** and **II**; experimental (+), calculated (–) and difference (lower) profiles.

Table 2 contains the atomic parameters and main geometrical data of compounds **I** and **II**. These results show a good general agreement with those already known in the literature for analogous HTlc.[9,10] The relative positions of the atoms inside the unit cells, as attained by the fractional coordinates given in Table 1 and Table 2, and their relative images due to the *R*3*m* symmetry are depicted in Figure 3.

Table 1. Crystallographic data for $[Zn_{0.65}Al_{0.35}(OH)_2](Cl)_{0.35}\cdot 0.35H_2O$ (**I**) and $[Zn_{0.65}Al_{0.35}(OH)_2](CO_3)_{0.175}\cdot 0.69H_2O$ (**II**) from Rietveld analysis.

In both samples the hydroxy groups are coordinated to the metal (octahedral) pointing alternatively upwards and downwards from the layer, giving rise to three cavities in the interlayer region around each metal on both sides of the layer. The chloride anions occupy a single site in the unit cell of **I**, whereas the carbonate anions are arranged parallel to the layer and occupy three sites with the oxygen atoms in the unit cell of **II**. This determines, assuming that ionic exchange is the same, a greater number of positions available for the water of hydration in the chloride phase.

MD Simulations of XRPD Patterns

The examination of the whole series of simulations was performed in terms of comparisons between the calculated and experimental XRPD patterns. The best MD simulations of the XRPD patterns of compounds **I** and **II** were achieved for models containing 27 (y = 0.25) and 75 (y = 0.69) water molecules, respectively. Measures of similarity (R_{wp}) between experimental and MD-simulated patterns as a function of the total water contents y are quoted in Figure 4. All the experimental peak positions were located well by MD, whereas, as expected, the peak heights and line shapes did not exactly reproduce the experimental curves of either **I** or **II**. The heights of the calculated peaks are lower than the experimental ones. This is typical in the case of the occurrence of very thin microcrystals (exfoliation along the c axis) for which: (i) the intensity of the first peak (003) decreases significantly, and (ii) the normalisation with respect to this small angle peak determines the higher intensities at the large angle portion of the pattern. Further, the MD simulations of the crystal (see forthcoming section Structural Data) reveal the skidding of the c planes and the important concerted fluctuations, which affects the entire set of cell parameters. A further contribution to such a discrepancy comes from the restricted spanning of the phase space resulting from the small size of the simulated models. In fact, the interlayer species of the models cannot attain all the reticular positions made available by the Rietveld analysis in the $R3m$ symmetry (Figure 3). Figure 5 shows the XRPD patterns of **I** and **II** compared with the simulated ones after corrections have been made for crystallite size broadening (see Computational Details).

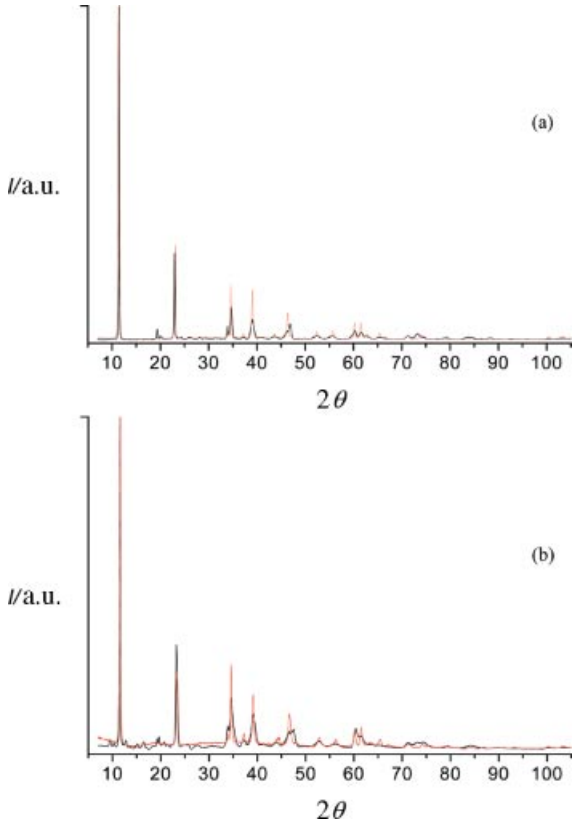

Figure 5. Comparison of experimental (red) and MD-simulated (black) XRPD patterns of **I** (a) and **II** (b).

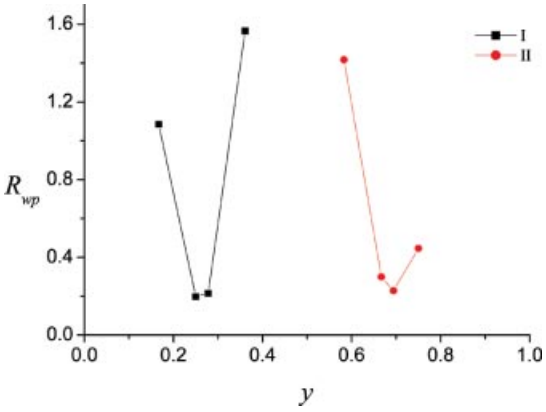

Figure 4. A measure of the similarity (R_{wp}) between experimental and MD-simulated patterns as a function of the total water content y. The minima show that the models which best reproduce the XRPD patterns of **I** and **II** have formula coefficients y = 0.25 and y = 0.69, respectively.

Hydration Properties

The MD runs showed that the simulated models of **I** and **II** having total water of hydration contents of 27 (y = 0.25) and 75 (y = 0.69), respectively, were the best at reproducing the experimental XRPD curves. In the case of the carbonate compound **II**, the MD simulation attained a value of the averaged empirical formula coefficient y = 0.69 for reproducing the experimental data of the sample as determined by using TG analysis. This corresponds to the model in which the water molecules (N_w = 75) are distributed in a homogeneous fashion, i.e. as three sets of 25 water molecules per interlayer.

In the case of the chloride compound **I** the theoretical model having a total N_w of 27 (y = 0.25) distributed as nine

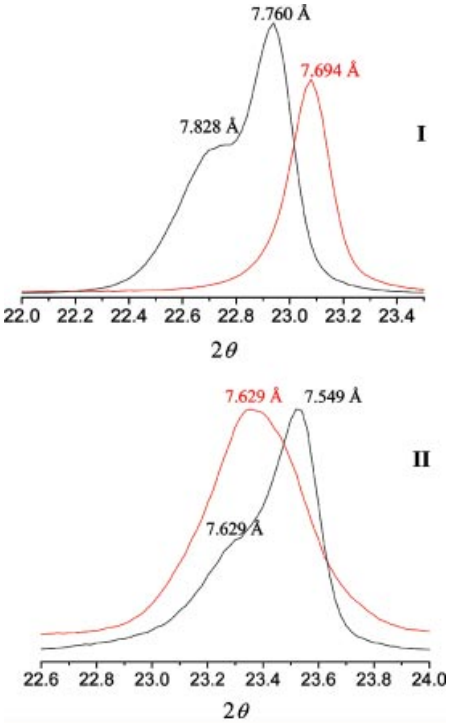

Figure 6. Detailed view of the (006) peaks of the treated (red) and nontreated (black) samples of **I** and **II**. The interlayer distances [Å] are indicated on the corresponding peaks and shoulders of the curves. This multiplicity collapsed into a well-resolved single peak shifted to a higher (2θ = 23.1°) and lower angle (2θ = 23.3°) in the case of the treated samples **I** and **II**, respectively. In **I** the treated sample gave rise to a single peak due to water loss; in **II** the treated sample took on a single peak shape due to the decreased size of the microcrystals and a shift towards increasing water content in the interlayer. In fact, the raised baseline and the broader peak denote the formation of amorphous material due to disaggregation resulting from the exfoliation process of the layers after the treatment.

water molecules per interlayer does not coincide with the average formula index value y = 0.35 measured for the synthesized sample. By keeping in mind that all the simulated models featured a regular interlayer distribution of the total number of water molecules, N_w, and that the MD simulation of the model N_w = 27 corresponds well with the experimental pattern, the observed discrepancy in the water contents between the experimental formula index value measured by TGA (y = 0.35) and the theoretical value (y = 0.25) can be accounted for in terms of a predominantly heterogeneous distribution of the water content in the interlayer of the material. Further evidence for this was provided by the (006) peaks observed in the XRPD patterns at ca. 2θ = 23.0° of the freshly prepared samples of **I** and **II**, both showing a marked shoulder (Figure 6). This multiplicity is consistent with two (or multiple) shared crystalline domains that have different water contents in the interlayer. The above findings are consistent with the results provided by the averaged total energies calculated from MD trajectories of the models of **I** and **II** at the various arrangements (Table 3; Figure 7). These results confirmed on an energy basis that: (i) the approach is sensitive to the more or less homogeneous distribution of the total water content in the interlayer; (ii) in the case of **I** the most heterogeneous interlayer water arrangement is the predominant motif; (iii) in the case of **II** the homogeneous motif predominates at the values of total water content measured by thermogravimetric techniques (y = 0.69); and (iv) in the case of both **I** and **II**, for total water contents higher than the measured ones, a more heterogeneous interlayer distribution of the water contents is predicted on the basis of the force field that was used. The theoretical relationship between interlayer distance and total water content is shown in Figure 8.

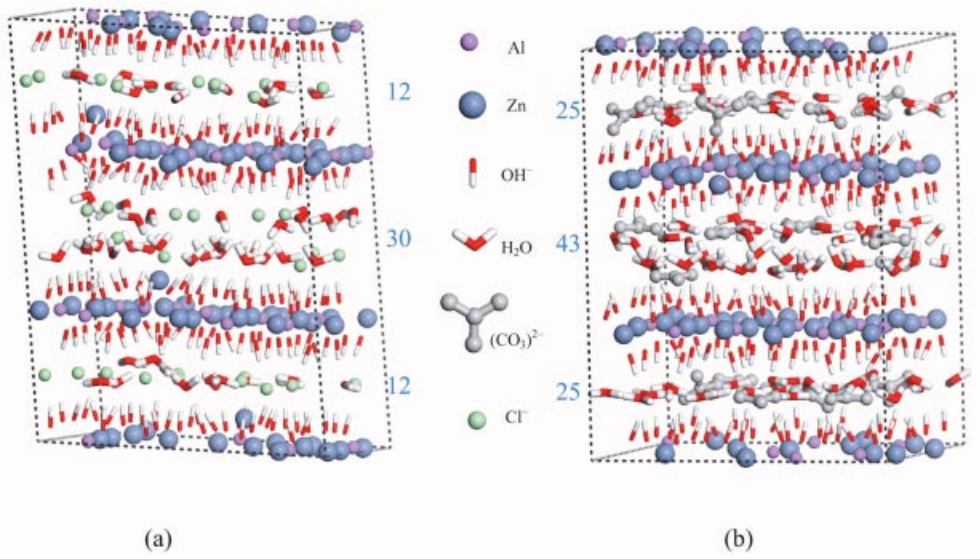

Figure 7. Example of models of **I** (a) and **II** (b) with $y = 0.500$ and $y = 0.861$, respectively (snapshot after the 200-ps simulation). The nonhomogeneous distribution of water molecules between the layers (see Table 3) is shown here by the blue numbers along the *c* axis. The notation used for atoms and interlayer species (water and anions) is given in colours.

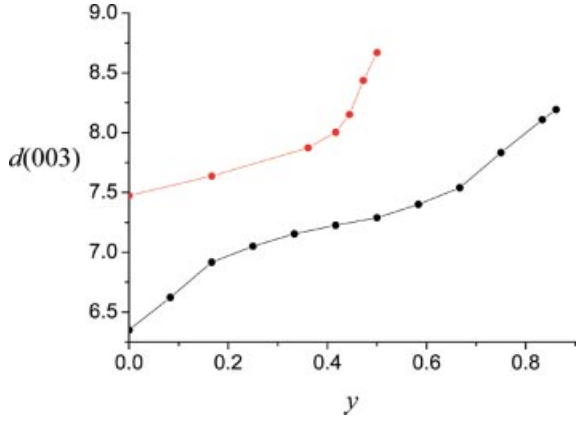

Figure 8. MD-calculated (averaged collection of 200-ps trajectories) interlayer distances [*d*(003)] in **I** (red) and **II** (black) as a function of the total interlayer water content.

Structural Data

The acceptable agreement of the interatomic distances calculated from MD with those provided by Rietveld analyses is shown in Table 4. This constitutes a further validation of the good quality of the FF used and consequently of the whole combined approach. The MD analyses of both **I** and **II** provide a complete set of layer interatomic distances (Zn–O, Zn···Zn, Zn···Al) that agree with those available from EXAFS experiments on the nitrate analogues (Table 4). Furthermore, the analysis of the trajectories of the models of **I** and **II** bearing $y = 0.25$ and $y = 0.69$ water molecules, respectively, which produced the best MD reproduction of the experimental XRPD pattern, provided (Figure 9a and b) microscopic information concerning: (i) the fluctuating orientation (from parallel to perpendicular) of the interlayer planar moieties of the CO_3^{2-} anions, (ii) the effective ten-

Table 4. MD-calculated average interatomic distances [Å] compared with those obtained from Rietveld analyses for models of **I** and **II**. EXAFS[41] data available for the analogous LDHs $(Zn_xAl_{1-x})(OH)_2(NO_3)\cdot(1-x)H_2O$ are quoted for the purpose of comparison.

dency of the Zn atoms to segregate in the samples of both compounds **I** and **II**, (iii) the interlayer H_2O molecules of **I** and **II** that fluctuate about the coplanar arrangement with respect to the layer; and (iv) the dynamics of the layer as determined by the concerted sliding of the slabs about the equilibrium position.

Conclusions

The structural features, dynamics and arrangement of the interlayer species (total water content and anions) for the ZnAl hydrotalcite-like compounds in the chloride (**I**) and carbonate (**II**) forms were studied by using experimental (XRPD, TGA) and computational (MD) techniques in a complementary fashion. To this purpose we first implemented, for the systems in which Me(II) = Zn, a set of parameters from the recent CLAYFF force field[34] that included suitable parameters for LDH species. The structural data coming from the XRPD Rietveld analyses were in agreement with the MD results, thus providing a first validation of the FF parameters that were used.

The main findings of the present work revealed: (i) the general ability of this approach to monitor microscopic-level properties such as the guest orientations, their fluctuations and the interlayer arrangement in the studied LDHs; (ii) the ability to detect and thus to discriminate between the different interatomic distances (Zn–O, Al–O, Al···Al, Zn···Zn, Zn···Al) of the slab, in a manner independent from other X-ray diffraction techniques such as EXAFS; (iii) the tendency of the zinc atoms to segregate, which occurs in both compounds **I** and **II**; (iv) the tendency of compound **I** to adopt a heterogeneous interlayer distribution of water. This heterogeneous distribution, although it includes domains having $y = 0.25$, leads to a higher average formula index value (y) in compound **I**; (v) that the crystal size of **I** remained unaffected by dehydration (even down to $y = 0$) of the material; (vi) that material **II** preferred the homogeneous distribution (25 per interlayer) of the experimental total water content ($y = 0.69$); (vii) the fact that, for the same reason as in (iv), the crystal was likely to disaggregate through exfoliation of the *c* layers, leading to water loss and consequently a smaller size of the microcrystals; and (viii) the capability of the computational approach to indicate with good accuracy the interlayer water distribution of the material.

In conclusion, the following general issues were achieved: first, a nonexpensive approach, which shows the tendency of LDHs to attain structures bearing heterogeneous or homogeneous interlayer distribution of their total water contents, and second, the symbiosis between experiment and theory that played a role in validating MD-simulated structure models of LDHs through direct matching of the experimental XRPD patterns. The direct reproduction of the diffraction pattern made possible a model that accounts for microscopic thermal, dynamic and structural factors, in addition to water-content distribution of the material being studied.

Experimental Section

Preparation of the Samples: A large batch of Zn–Al hydrotalcite-like compound, with the formula $[Zn_{0.65}Al_{0.35}(OH)_2](CO_3)_{0.175}\cdot 0.69H_2O$ (**II**), was prepared by the urea method[9] according to the following procedure: a clear solution, obtained by mixing $AlCl_3$ (100 mL, 0.50 M), $ZnCl_2$ (200 mL, 0.50 M) and urea (30 g), was maintained at reflux temperature for 3 d. The precipitate obtained was filtered, washed with deionised water and equilibrated, whilst stirring, with Na_2CO_3 (100 mL, 0.1 M) for 1 d in order to exchange the chloride ions (sometimes incorporated during the synthetic procedure) with carbonate ions. After equilibration, the solid was recovered, washed with deionised water, and finally dried and stored over P_4O_{10} in the presence of soda lime.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The Zn–Al hydrotalcite-like compound in the chloride form, $[Zn_{0.65}Al_{0.35}(OH)_2]Cl_{0.35}\cdot 0.35H_2O$ (**I**), was obtained by titrating the carbonate form, previously dispersed in NaCl (0.1 M, mass/volume ratio 1 g 50 mL^{-1}), with HCl (0.1 M) by means of a Radiometer automatic titrator operating in the pH stat mode and at pH 5. The solid was washed with CO_2-free deionized water and stored over P_4O_{10} in the presence of soda lime.

Analytical Procedures: The metal ion content of HTlc was determined by ion chromatography, after dissolution of about 100 mg of sample in concentrated HCl. The metal ion concentration in the resulting solution was measured by the following procedures: (i) Zn content: column Dionex CS5a, eluent PDCA, flow 1.0 mL min^{-1}, spectrophotometric detection after Post Column Reaction (PCR) with PAR; (ii) Al content: column Dionex CS5a, eluent HCl (0.75 M), flow 1 mL min^{-1}, spectrophotometric detection after PCR with Tiron. The chloride content was determined by ion chromatography for the solution obtained by soaking the solid samples in Na_2CO_3 (1 M) at 80 °C for 4 h. C and H elemental analysis was performed with a Carlo Erba 1106 analyser. Carbonate and water contents were also evaluated from TGA.

Characterisation: X-ray powder patterns were collected in the 7–110° and 0.02° step size (2θ range) according to the step scanning procedure using Cu-K_α radiation with a Philips X'Pert APD diffractometer, PW3020 goniometer equipped with a bent graphite monochromator on the diffracted beam. Divergence and scatter slits of 0.5° and a receiving slit of 0.1 mm were used. The LFF ceramic tube operated at 40 kV and 30 mA. To minimise preferred orientations, the sample was carefully side loaded onto an aluminium sample holder with an oriented quartz monocrystal underneath. The counting time was 20 sec step^{-1} for all the diffraction patterns. The TG/DTG/DTA analyses were performed in air with a Netzsch STA449C thermal analyser at a heating rate of 5 °C min^{-1} under an air flow.

Rietveld Refinement: Rietveld refinements for **I** and **II** were performed using the GSAS program.[34] Sample displacement, cell parameters and background were first refined. Fractional coordinates and isotropic thermal factors for all the atoms, and profile shape were also refined. The profile was modelled using a pseudo Voigt profile function (six terms) with two terms for the modelling of asymmetry at low 2θ angle. The interatomic distances and bond lengths were refined freely, except for the O–H distance that was restrained to 0.9(3) Å. Isotropic thermal factors were refined by constraining the program to apply the same shift to the metal atoms and another shift to the light atoms. The metal atom occupancies were set at fixed values (according to the stoichometry) and were not refined. At the end of the refinement the shifts on all parameters were less than their standard deviations.

Computational Details

FF Parameters: The Materials Studio package (Accelrys Inc., San Diego) was used to perform all MD simulations through the Discover module. In the present work, the recently developed CLAYFF force field[34] was included. This FF features suitable parameters for LDHs containing the Si, Al, Mg, Ca, Fe and Li species. Accordingly, to overcome the lack of parameters for systems in which Me(II) = Zn, the Zn parameters were derived by using the following minerals, for which structural data are available, as model compounds: ε-$Zn(OH)_2$[35,36] γ-$Zn(OH)_2$,[37] $Zn_5(OH)_8Cl_2\cdot H_2O$.[38] For the VDW function, the following parameters were obtained: $D_0 = 1.0\times10^{-6}$ kcal mol^{-1}, $R_0 = 5.0$ Å, charge = 1.05 *e*. The orders of magnitude of these calculated Zn nonbonding parameters were in agreement with those of the species Si, Al, Mg, Ca, Fe, Li as quoted in Table 1 of ref.[34]. The parameter values of the electrostatic terms reported in this table were readjusted as follows: hydroxy oxygen (OH) = –0.875 *e*; aqueous chloride ion (Cl^-) = –0.975 *e*, on the basis of the hydrotalcite-type structure used for modelling. This was done in order to achieve total electroneutrality through the redistribution of the charge on Al among the surrounding hydroxy groups.

Protocols: The MD simulations started from the energy-minimised structures. The periodic boundary conditions (PBC) with an NPT ensemble were used for all the runs. Transients of 200 ps and 1 ns were collected for the models at various hydration degrees and for the models selected for the validation procedure of the simulations, respectively. In both cases the integration time step was 0.001 ps, and the sampling interval was 1000 time steps. The energy-optimised structures were obtained with the smart minimiser of the Discover module, satisfying a gradient of 0.1 kJ mol^{-1}. The nonbonding (NB) settings were those provided by default in this module for VDW interaction: atom-based summation method with cutoff = 9.5 Å, spline width = 1.0, buffer width = 0.50, and long-range energy correction = 9.5. For the Coulomb interaction, an Ewald summation method was used with accuracy = 0.01, update width = 1.0, dielectric constant $\varepsilon = 1$.

Modelling: The structural models of the samples **I** and **II**, which were submitted to all the simulations, were generated on the basis of the X-ray crystal structures (unit cells and atomic fractional coordinates) provided by refinement of their XRPD data by Rietveld analysis (Table 1, Table 2). All structures were 3-layered periodic supercells built up by setting *R*3*m* symmetry conditions and the factors 6, 6 and 1 for the unit-cell parameters *a*, *b* and *c*, respectively. Each layer included 36 atoms of the two metals in the ratio Zn/Al = 2:1 (Figure 1) for 108 formula units. The supercell parameters *a*, *b*, *c*, *α*, *β*, *γ*, were independent variables in the MD simulations. The interlayer water molecules and chloride (**I**) or carbonate (**II**) anions from the Rietveld analyses (Figure 2) were regularly distributed in the lattice positions denoted by green balls in Figure 1. Preliminary molecular modelling energy calculations showed that the energy-preferred position of the metallic atoms in the slab was the most regularly ordered one, i.e., that in which six Zn atoms were the nearest neighbours of each Al atom, and three Al atoms and three Zn atoms were the nearest neighbours of each Zn atom (Figure 1b). The simulated models of **I** and **II** were obtained by determining the amount of the regularly distributed interlayer water molecules for each compound by varying the sequence of the total number of water molecules (N_w) from 54, 51, 48 down to 0, and from 93, 90, 81, 72 down to 0, respectively. This corresponded to the formula coefficients (y) which varied from $y = 0.5$, 0.47, 0.44 down to 0 for **I**, and from $y = 0.86$, 0.83, 0.75 down to 0, for **II**. In the search for the best model, the interval over which N_w was varied was adequately restricted.

Calculation of XRPD Pattern from MD Trajectory (MD-XRPD): The cell and atomic positional parameters were calculated from the MD trajectory and stored. The angles θ and Miller indices (h, k, l) for which a diffraction peak should appear were determined for each of these snapshots by using the Bragg equation, $n\lambda = 2d\times\sin\theta_{(hkl)}$.

The intensity of these diffraction peaks is $I_{hkl} = |F_{hkl}|^2$, in which $F_{hkl} = \Sigma f_n e^{2\pi i(hu_n + kv_n + lw_n)}$, where u, v, w are atomic fractional parameters and f_n X-ray scattering factors.

The intensity obtained in this way was then stored in an array of bin size $\delta(2\theta)$ at the position corresponding to $2\theta(N) = 2\theta_{(hkl)} \pm \frac{1}{2}\delta(2\theta)$. Averaging all of the snapshots of the MD simulation

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

completed the above MD-XPRD procedure. The diffraction intensity $I(2\theta)$, obtained in this way, was then scaled[39] for the Lorentz [$L = 1/(\sin\theta \times \sin 2\theta)$] and polarization [$p$] corrections (Lp).

Crystallite Size Broadening: The above procedure led to an MD-determined XRPD pattern for a perfect crystal of infinite dimension, whose atomic and cell parameters fluctuated due to thermal motions. When crystallites are less than approximately 1000 Å in size, appreciable broadening in the XRPD lines will occur. The shape of the peaks take on a predominantly Lorentzian profile[40] centred at $\theta_{(hkl)}$, with a full width at the half maximum (FWHM) that depends on the crystallite size. The relation that quantitatively describes the FWHM [$\Delta(2\theta_{hkl})$] as a function of the dimensions of the crystal and the order of the diffraction peak (hkl) is[40]

$$\Delta(2\theta_{hkl}) = \frac{\lambda}{\cos\theta_{hkl}} \frac{1}{d_{hkl}} \left[h^2 \left(\frac{L_a}{a} \right)^2 + k^2 \left(\frac{L_b}{b} \right)^2 + l^2 \left(\frac{L_c}{c} \right)^2 \right]^{\frac{1}{2}}$$

in which h, k and l are the Miller indices, and L_a, L_b, L_c are the crystallite dimensions along a, b and c, respectively. The procedure for calculating the size-broadened MD-XRPD pattern, given the dimensions L_a, L_b and L_c of the crystallite, was the same as that for a perfect crystal, whereas the values of the intensity profile of the broadened peaks were stored in the array along the bins centred around $2\theta(K) = 2\theta_{(hkl)}$ for a width of $\pm 10\,\Delta(2\theta_{hkl})$.

Modelling the XRPD Pattern: The experimental XRPD pattern (line shape and peak heights) was modelled by calculating a set of XRPD patterns from the MD trajectory that corresponded to different crystallite sizes (N patterns for N crystal sizes). Subsequently the calculated pattern was compared with the experimental XRPD curve by using the equation having the best fit for the coefficients w_i.

$$I(\theta)_{calcd} = w_1 I_1(\theta) + w_2 I_2(\theta) + \cdots + w_N I_N(\theta) = \sum_{i=1}^{N} w_i I_i(\theta)$$

Acknowledgments

This work was supported by the MIUR (Italy) within the PRIN Program (prot. 2004031878_002). Thanks also go to Prof. Kenny B. Lipkowitz for useful suggestions and discussions.

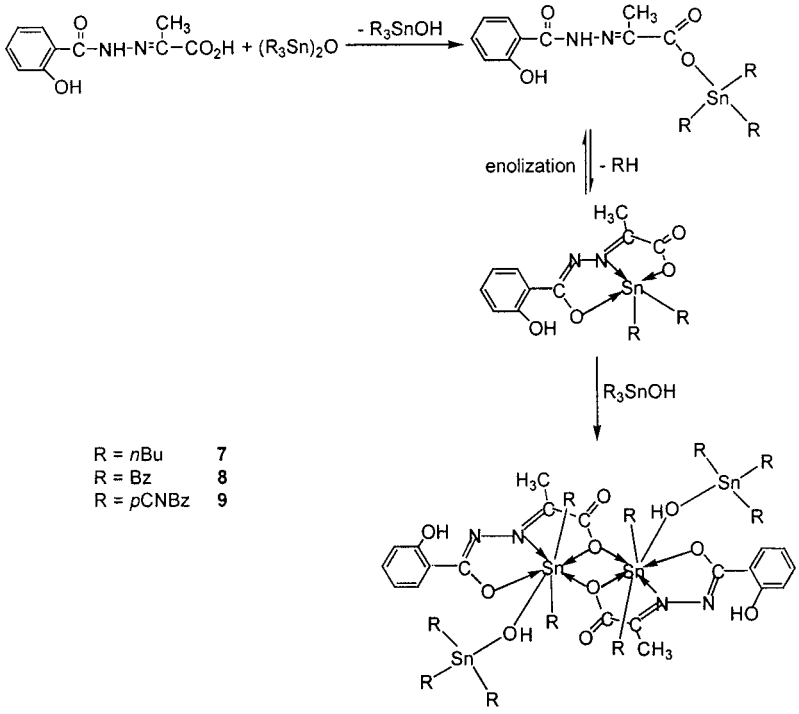
Self-Assembly of Organotin(IV) Moieties with the Schiff-Base Ligands Pyruvic Acid Isonicotinyl Hydrazone and Pyruvic Acid Salicylhydrazone: Synthesis, Characterization, and Crystal Structures of Monomeric or Polymeric Complexes

Handong Yin,*[a] Min Hong,[a] Haolong Xu,[a] Zhongjun Gao,[a] Gang Li,[a] and Daqi Wang[a]

Keywords: N,O ligands / Self-assembly / Schiff bases / Tin

Scheme 4 on page 4578 of the original article[1] inadvertently represents a copy of Scheme 3; the correct Scheme 4 is shown below.



Scheme 4.
