Heterosite Effects in Novel Heteronuclear Clusters $[Os_2Ru(CO)_{11}(PPh_3)]$ and $[Os_2Ru(CO)_{10}$(2-acetylpyridine-*N*-isopropylimine)]

Frank W. Vergeer,[a,e] Martin Lutz,[b] Anthony L. Spek,[b] Maria J. Calhorda,[c,d] Derk J. Stufkens,[†][a] and František Hartl*[a]

Keywords: Cluster compounds / Density functional calculations / Time-resolved spectroscopy / Photochemistry / Spectroelectrochemistry

A new synthetic route towards the mixed-metal cluster $[Os_2Ru(CO)_{12}]$ is described together with the syntheses of its PPh_3 and *i*Pr-AcPy (*i*Pr-AcPy = 2-acetylpyridine-*N*-isopropylimine) derivatives. The molecular structures of the novel clusters $[Os_2Ru(CO)_{11}(PPh_3)]$ and $[Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] were determined on the basis of crystalline solid solutions of the Os_2Ru and corresponding Os_3 species. The structures reveal that coordination of the Lewis bases occurs exclusively at the ruthenium site of $[Os_2Ru(CO)_{12}]$, which is in agreement with density functional theory (DFT) calculations on several structural isomers of these compounds. According to the time-dependent DFT results, the lowest optically accessible excited state of $[Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] has a prevailing σ(Ru–Os2)-π*(*i*Pr-AcPy) character, with a partial σσ*(Ru–Os2) contribution. In weakly coordinating 2-chlorobutane, the excited state has a lifetime τ = 10.4 ± 1.2 ps and produces biradicals considerably faster than observed for $[Os_3(CO)_{10}$(*i*Pr-AcPy) (τ = 25.3 ± 0.7 ps). In coordinating acetonitrile, the excited state of $[Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] decays mono-exponentially with a lifetime τ = 2.1 ± 0.2 ps. In contrast to $[Os_3(CO)_{10}$(*i*Pr-AcPy)] that forms biradicals as the main primary photoproduct even in strongly coordinating solvents, zwitterion formation from the solvated lowest excited state is observed for the heterometallic cluster. This is concluded from time-resolved absorption studies in the microsecond time domain. Due to the lower tendency of the coordinatively unsaturated $^{+}Ru(CO)_2$-(*i*Pr-AcPy$^{-/0}$) moiety to bind a Lewis base, the heteronuclear biradical and zwitterionic photoproducts live significantly shorter than their triosmium counterparts. The influence of the weaker Os2–Ru(*i*Pr-AcPy) bond on the redox reactivity is clearly reflected in very reactive radical anions formed upon electrochemical reduction of $[Os_2Ru(CO)_{10}$(*i*Pr-AcPy)]. The dimer $[^{-}Os(CO)_4$-$Os(CO)_4$-$Ru(CO)_2$(*i*Pr-AcPy)$]_2^{2-}$ is the only IR-detectable intermediate reduction product. The dinuclear complex $[Os_2(CO)_8]^{2-}$ and insoluble $[Ru(CO)_2$(*i*Pr-AcPy)$]_n$ are the ultimate reduction products, proving fragmentation of the Os_2Ru core.

Introduction

In the last four decades, considerable efforts have been made to develop general synthetic routes towards heteronuclear transition metal clusters.[1–4] The interest in this type of clusters where at least one metal–metal bond connects two different core metal atoms, has mainly originated from their possible application in both homogeneous and heterogeneous catalysis.[5] Apart from the general expectation that different transition metal atoms in close proximity of each other could initiate novel reactions by synergistic interactions, the different reactivity of adjacent metal centres in mixed-metal clusters may provide additional bi- or multifunctional activation pathways and increase the selectivity of substrate–cluster interactions.[6] Although catalysis by mixed-metal clusters in a number of cases indeed resulted in higher catalytic activity[7,8] or different product selectivity[9,10] than observed for their homonuclear analogues, the mechanistic insight into the role of the different metal centres in the catalytic cycle is generally limited. This problem mainly has its origin in scarcely available series of isostructural mixed-metal clusters, which precludes a systematic study of their bonding properties and reactivity.

One of the best known series of mixed-metal clusters is the family of group 8 triangular clusters $[M_3(CO)_{12}]$ (M = Fe, Ru, Os), where all possible metal combinations – except $[FeRuOs(CO)_{12}]$ – have been prepared.[3,11] Within this

series, the clusters $[Os_2Ru(CO)_{12}]$ and $[Ru_2Os(CO)_{12}]$ are of particular interest for our investigations, as the bonding properties, photochemistry and redox behaviour of the homonuclear dodecacarbonyl analogues and, in particular, their α-diimine-substituted derivatives $[M_3(CO)_{10}(\alpha\text{-diimine})]$ (M = Ru, Os), have been studied thoroughly in our groups.[12–21]

A continued systematic study of their heterometallic Ru/Os derivatives is desired in order to reveal the influence of the cluster core variation on the photochemistry and redox reactivity. However, one of the underlying reasons for the lacking studies of $[Os_2Ru(CO)_{12}]$ and $[Ru_2Os(CO)_{12}]$ is the serious difficulty to obtain these clusters in the pure form. Although several synthetic procedures have been reported, they yielded either hardly separable mixtures of $[Ru_3(CO)_{12}]$, $[Ru_2Os(CO)_{12}]$, $[Os_2Ru(CO)_{12}]$ and $[Os_3(CO)_{12}]$ in a nearly statistical 1:2:2:1 ratio[22–24] or gave the desired pure heterometallic clusters merely in very low yields ($\leq$ 5%).[25,26] Development of efficient novel synthetic routes toward these species is therefore compulsory.

Aimed at performing a comparative study of the heteronuclear cluster $[Os_2Ru(CO)_{10}(\alpha\text{-diimine})]$ and its homonuclear analogues $[M_3(CO)_{10}(\alpha\text{-diimine})]$ (M = Ru, Os), a novel route for the synthesis of $[Os_2Ru(CO)_{12}]$ (**1**) has been introduced, producing the cluster in a reasonable yield. Apart from the parent carbonyl cluster, we also report the syntheses and crystal structures of the substituted derivatives $[Os_2Ru(CO)_{11}(PPh_3)]$ (**2**) and $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ (**3**) (*i*Pr-AcPy = 2-acetylpyridine-*N*-isopropylimine), schematically depicted in Figure 1. Both derivatives were prepared in order to establish the preferential coordination site of different Lewis bases in substitution reactions with $[Os_2Ru(CO)_{12}]$. The influence of the heteronuclear cluster core on the photo- and electrochemical reactivity of $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ in comparison with the homonuclear derivatives is also described. Density functional theory (DFT) calculations provide direct insight into the bonding properties of $[Os_2Ru(CO)_{11}(PPh_3)]$ and $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ and support the discussion of the experimental results.

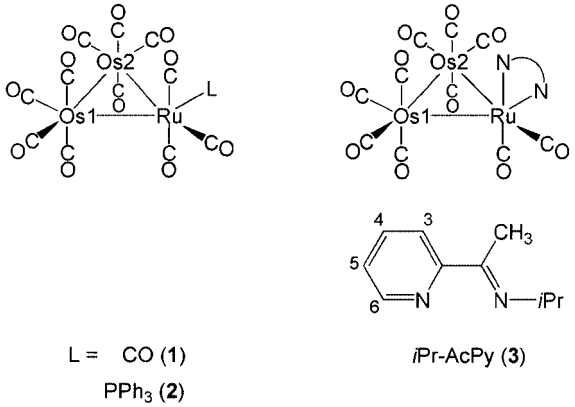

Figure 1. Schematic structures of the investigated clusters $[Os_2Ru(CO)_{11}(L)]$ [L = CO (**1**), PPh_3 (**2**)] and $[Os_2Ru(CO)_{10}(NN)]$ [NN = *i*Pr-AcPy (**3**)].

Results and Discussion

Synthesis of $[Os_2Ru(CO)_{12}]$ (1)

The heteronuclear cluster $[Os_2Ru(CO)_{12}]$ (**1**) was synthesized from its homonuclear analogues $[Os_3(CO)_{12}]$ and $[Ru_3(CO)_{12}]$ in a four-step reaction sequence (Scheme 1). Starting from $[Os_3(CO)_{12}]$, the linear cluster $[Os_3(CO)_{12}(Br)_2]$ was obtained by oxidation with Br_2 in refluxing CH_2Cl_2 [step (*i*)]. After the addition of Br_2, rapid removal of the heating bath is required in order to prevent the reaction of $[Os_3(CO)_{12}(Br)_2]$ with additional Br_2 producing at this stage undesired $[Os_2(CO)_8(Br)_2]$ that is known to transform into $[Os_2(CO)_6(Br)_2]$ at elevated temperatures.[27] Similar oxidative addition of X_2 (X = Cl, Br, I) to $[Ru_3(CO)_{12}]$ was reported[28,29] to yield the mononuclear complex *cis*-$[Ru(CO)_4(X)_2]$ as the initial product, which reflects the increasing stability of the metal–metal bonds towards oxidation on descending the periodic table. Unfortunately, the synthetic strategy depicted in Scheme 1 could therefore not be applied for the synthesis of the isostructural cluster $[Ru_2Os(CO)_{12}]$. The controlled formation of the dinuclear complex $[Os_2(CO)_8(Br)_2]$ was achieved by slight modification of the procedure described by Moss et al. [step (*ii*)].[30] Visible irradiation of $[Os_3(CO)_{12}(Br)_2]$ at $\lambda > 420$ nm was found to prevent excessive formation of the mononuclear complex *cis*-$[Os(CO)_4(Br)_2]$. The latter compound is not only obtained as an unavoidable side-product formed during irradiation of $[Os_3(CO)_{12}(Br)_2]$, but it can also be formed from $[Os_2(CO)_8(Br)_2]$ by UV/Vis irradiation of this complex in the presence of Br_2. In a third step, the powerful nucleophile $Na_2[Ru(CO)_4]$ was prepared from $[Ru_3(CO)_{12}]$ by reduction with sodium in liquid ammonia [step (*iii*)].[31] As $[Ru(CO)_4]^{2-}$ is extremely air- and moisture-sensitive and readily converts to $[Ru(CO)_4H]^-$, the reduction of $[Ru_3(CO)_{12}]$ was performed at reduced pressure (3×10^{-4} Pa) on a high-vacuum line. After the completion of the reaction, the product must be dried extensively, as small traces of ammonia proved to react instantaneously with $[Os_2(CO)_8(Br)_2]$, reducing the yield of $[Os_2Ru(CO)_{12}]$. In order to prevent thermal decomposition of $Na_2[Ru(CO)_4]$ during the drying process, the temperature was carefully kept below 273 K. Finally, $Na_2[Ru(CO)_4]$ was extracted in thoroughly dried THF and added to $[Os_2(CO)_8(Br)_2]$ by vacuum filtration, instantaneously producing $[Os_2Ru(CO)_{12}]$ (**1**) in reasonable yields (step (*iv*)).

Unfortunately, in some cases, cluster **1** was found to contain variable amounts of $[Os_3(CO)_{12}]$ and/or $[Ru_2Os(CO)_{12}]$ impurities. The latter cluster could result from incomplete reduction of $[Ru_3(CO)_{12}]$ by less than six equivalents of sodium. Thus, although the number of impurities and their percentages are significantly reduced in comparison with the established synthetic procedures,[22–24] the purity of cluster **1** and its substitution products remains difficult to control, even when employing this novel synthetic route.

In order to establish the preferred coordination site in cluster **1** for different Lewis bases (L), substituted derivatives with monodentate PPh_3 and chelating α-diimine = *i*Pr-

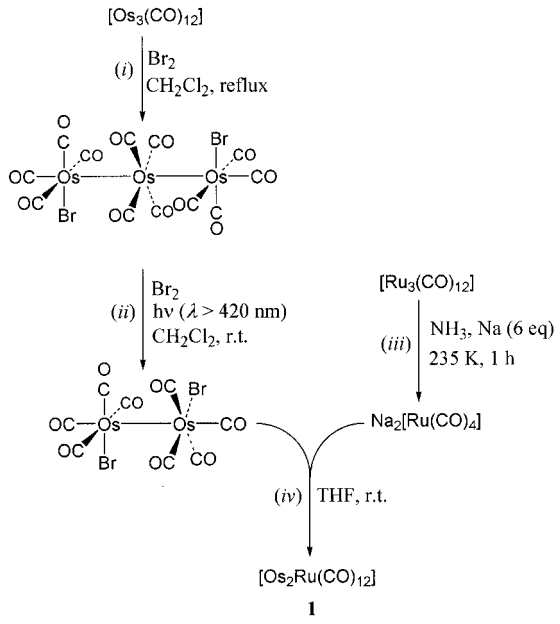

Scheme 1. Synthesis of $[Os_2Ru(CO)_{12}]$ (**1**).

AcPy ligands were prepared by a thermal reaction route involving precursor clusters $[Os_2Ru(CO)_{12-n}(MeCN)_n]$ (n = 1 for L = PPh_3; n = 2 for L = *i*Pr-AcPy). The substituted products $[Os_2Ru(CO)_{11}(PPh_3)]$ (**2**) and $[Os_2Ru(CO)_{10}(i$Pr-AcPy$)]$ (**3**) (see Figure 1) were characterised by IR and NMR spectroscopy and mass spectrometry. Their molecular structures were determined by single-crystal X-ray diffraction and compared with the optimised geometries resulting from DFT calculations.

Molecular Structure of $[Os_2Ru(CO)_{11}(PPh_3)]$ (2)

The crystal structure of cluster **2** is shown in Figure 2. This structure was determined on a mixture of $[Os_2Ru(CO)_{11}(PPh_3)]$ and $[Os_3(CO)_{11}(PPh_3)]$ in a ratio of 0.64:0.36. Selected bond lengths and angles are presented in Table 1. The structure of **2** exhibits disorder amounting to a 36% Os occupancy at the Ru atom site, being significantly distorted from the D_{3h} symmetry observed for $[M_3(CO)_{12}]$ (M = Ru, Os).[32,33] Most importantly, the crystal structure, in combination with (temperature-dependent) ^{31}P NMR spectra, reveals that the PPh_3 ligand in $[Os_2Ru(CO)_{11}(PPh_3)]$ occupies an equatorial position and is exclusively coordinated at Ru. This is in contrast with the results of Pereira et al. who obtained an 1:2 mixture of osmium- and ruthenium-substituted isomers after the reaction of PPh_3 with the tetranuclear mixed-metal cluster $[RuOs_3(\mu\text{-}H)_2(CO)_{13}]$ under similar conditions.[34]

The geometry around the phosphorus atom in cluster **2** is essentially tetrahedral, the phenyl groups being slightly bent away from the Ru atom [C–P–C angles are in the range 100.30(13)–104.64(14)°]. The average metal–metal bond length (2.894 Å) is longer than the unsubstituted homonuclear clusters $[M_3(CO)_{12}]$ [M = Ru: 2.8542 Å;[33] M = Os: 2.8771(27) Å[32]]. This is partly due to the substitution of a

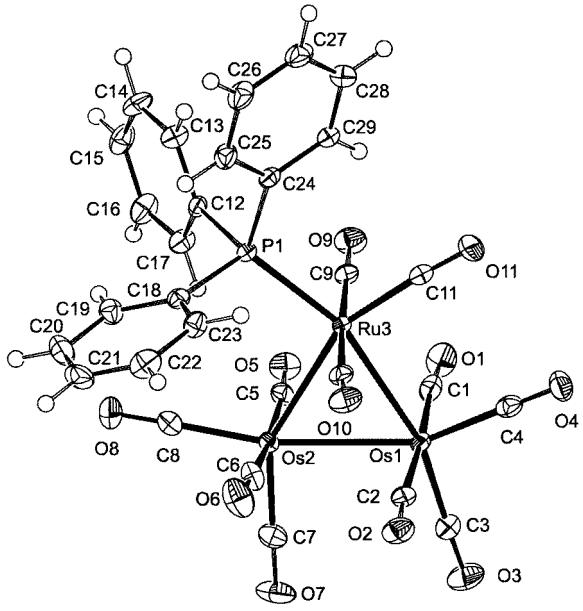

Figure 2. Molecular structure of the cluster $[Os_2Ru(CO)_{11}(PPh_3)]$ (**2**) in the crystal. Displacement ellipsoids are drawn at the 50% probability level. The site of Ru3 is occupied for 64% by Ru and for 36% by Os.

π-accepting CO ligand by the much stronger σ-donor PPh_3, increasing the electron density on the metal core and resulting in expansion. Like in the corresponding homonuclear clusters $[M_3(CO)_{11}(PPh_3)]$ (M = Os, Ru),[35,36] the length of the metal–metal bond positioned *cis* to the PPh_3 ligand [Ru–Os2: 2.9147(2) Å] is increased to a larger extent than the other metal–metal bond lengths [Ru–Os1: 2.8839(2) Å; Os1–Os2: 2.8827(2) Å]. This difference has been attributed to steric interactions between the PPh_3 ligand and the *cis*-CO group on the adjacent metal atom.[35,36] The steric and electronic effects are also reflected in the marked shortening of the M–CO_{eq} bond *cis* to the PPh_3 ligand [Ru–C11 = 1.887(3) Å] compared to the average length of these bonds in, for example, $[Ru_3(CO)_{12}]$ [average Ru–CO_{eq}: 1.921(5) Å]. This shortening is ascribed to increased π-back-bonding to the CO ligand, resulting from the presence of the σ-donating phosphorus ligand attached to the same metal and to the sterically induced lengthening of the Ru–Os2 bond *trans* to this CO group.[35]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The Ru–Os bond lenghts [2.9147(2) and 2.8839(2) Å] nicely fit within the values reported for the corresponding metal–metal bond lengths in the homonuclear analogues [$M_3(CO)_{11}(PPh_3)$] [M = Os: 2.918(1) and 2.891(1) Å, M = Ru: 2.907(3) and 2.876(3) Å]. This comparison is possible even though the reported Os–Ru distances do not correspond to "pure" [$Os_2Ru(CO)_{11}(PPh_3)$], but to a blend of Os_2Ru and Os_3 in solid solution (vide supra). The distortion from the D_{3h} symmetry, manifested by the twisting of the $Os(CO)_4$ units, is reflected in the C_{ax}–Os1–Os2–C_{ax} dihedral angles.[35] Just like for the metal–metal bond lengths, the values for C1–Os1–Os2–C5 (3.5°) and C2–Os1–Os2–C6 (12.8°) closely resemble those reported for the homonuclear analogues: 5.4° and 14.4° for Ru and 4.4° and 12.3° for Os, respectively.

The presence of [$Os_3(CO)_{11}(PPh_3)$], which was refined with a substitutional disorder model for the Ru/Os3 atom site, has most likely its origin in the formation of [$Os_3(CO)_{12}$] as a side-product during the preparation of **1** (vide supra). This is also reflected in the mass spectra of some of the [$Os_2Ru(CO)_{12}$] samples where a peak at *m*/*z* 908 is ascribed to the molecular ion of [$Os_3(CO)_{12}$]. The presence of ca. 35% [$Os_3(CO)_{11}(PPh_3)$] is also reflected in the $^{31}P\{H\}$ NMR and FD mass spectra of **2**, indicating that the observed ratio between the Os_3 and Os_2Ru phosphane-substituted clusters in the crystal structure is similar in the gas phase and in solution.

Density Functional Study of [$Os_2Ru(CO)_{11}(PPh_3)$] (2)

The density functional theory (DFT, ADF programme[37–43]) study of cluster **2** was performed with the aim to learn, whether the theory indeed predicts [$Os_2Ru(CO)_{11}(PPh_3)$] to be most stable with the PPh_3 ligand coordinated at the ruthenium centre at an equatorial site. The cluster [$Os_2Ru(CO)_{11}(PH_3)$] (**2a**) served as a model for **2**. Some features of the optimised geometry of **2a** slightly deviate from those of the crystal structure of **2** (Table 2, Figure 3). First of all, the calculated metal–metal bond lengths are slightly longer than the experimental ones (up to 0.05 Å), similar to the situation for [$Os_3(CO)_{12}$].[19,20] The Ru–Os bond *cis* to the PPh_3 ligand is calculated to be significantly longer than the other two metal–metal bonds, in agreement with the crystal structure. This trend points to the role of electronic effects apart from the expected steric influence. For, the differences in the metal–metal bond lengths should be smaller in the model **2a**, as the steric interactions of the PH_3 ligand with the *cis*-CO group on the adjacent metal atom are much less pronounced compared to the bulky PPh_3 ligand. Apart from this feature, the twisting of the $Os(CO)_4$ units in **2a** is much smaller than in the experimental structure. This is reflected in the orientation of the Os–CO_{ax} bonds in **2a**, which are almost perpendicular to the Os_2Ru plane (dihedral angles C1–Os1–Os2–C5 = 0.3° and C2–Os1–Os2–C6 = 0.5°). The larger distortion in the experimental structure has its origin presumably in the phenyl groups of the PPh_3 ligand. In the solid state, these phenyl rings interact with the phenyl rings of the two neighbouring clusters by four edge-to-face interactions to give a one-dimensional chain. Similar interactions, for example, have been reported for the cluster [$Os_3(CO)_{11}\{P(p\text{-}C_6H_4F)_3\}$].[44] Besides the crystal packing effects, not incorporated in the geometry optimisation of **2a**, the twist of the $M(CO)_4$ units also depends on the selected computational basis set.[19]

In addition to the optimised model **2a**, the relative energies of several structural isomers **2b**–**e** have also been calculated (Figure 3). The isomers **2a** and **2b** have in common that the PH_3 ligand is coordinated to ruthenium, but they differ in the coordination of the ligand relative to the Os_2Ru plane (equatorial and axial, respectively). In isomers **2c**–**e**, the PH_3 ligand is coordinated at one of the osmium atoms, **2e** being the only model with the PH_3 ligand coordinated in an axial position. Isomers **2c** and **2d** have the PH_3 ligand coordinated in an equatorial position, but they differ in the orientation of the PH_3 ligand relative to the ruthenium centre. Importantly, isomer **2a** appeared to be more stable by 11.4 kJ·mol^{-1} than isomer **2d**, which proves the preferable coordination of the PH_3 ligand at ruthenium. Isomer **2c**, with the PH_3 ligand perpendicular to the Os1–Os2 bond, is in turn slightly more stable than isomer **2d**, where the position of the PH_3 ligand presents almost a continuation of the Os1–Os2 bond. The isomers **2b** and **2e**, with the PH_3 ligand occupying an axial site at Ru and Os, respectively, are highest in energy.

Although the difference in relative energy between the model structures **2a** and **2c** is relatively small, no experimental evidence has been obtained for $[Os_2Ru(CO)_{11}(PPh_3)]$ clusters with the phosphane ligand coordinated to osmium. However, as the relative energies calculated by DFT refer to isolated gas-phase molecules at zero Kelvin temperature, with PH_3 as the model for the PPh_3 ligand, the obtained values merely reflect a trend in the thermodynamic stability of the different isomers in solution at 293 K.

In order to investigate whether a chelating α-diimine ligand also prefers coordination at the ruthenium site of **1**, we synthesized the cluster $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ (**3**) and determined its molecular geometry. Apart from its structure, the major interest in cluster **3** stems from our aim to reveal the influence of the heteronuclear cluster core on the photo- and redox reactivity of this compound. For a proper evaluation of this effect, the homonuclear clusters $[Os_3(CO)_{10}(\alpha\text{-diimine})]$ were used as a reference.

Molecular Structure of $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ (3)

The molecular structure of cluster **3**, determined by single-crystal X-ray diffraction, is shown in Figure 4. Selected bond lengths and angles are collected in Table 3. As in compound **2**, the corresponding Os_3 compound, viz. $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$, was also present in the crystal structure as a solid solution (occupancy 0.89:0.11 for Os_2Ru:Os_3). Importantly, the crystal structure reveals that the *i*Pr-AcPy ligand in $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ is again bound at the ruthenium atom. Similar to 2,2′-bipyridine (bpy) and *N*,*N*′-diisopropyl-1,4-diaza-1,3-butadiene (*i*Pr-DAB) in the closely related $[Os_3(CO)_{10}(\alpha\text{-diimine})]$ clusters,[45,46] the asymmetric *i*Pr-AcPy ligand is coordinated to a single metal centre in a chelating fashion. The nitrogen atom of the pyridine ring and the imine nitrogen occupy axial and equatorial positions, respectively.

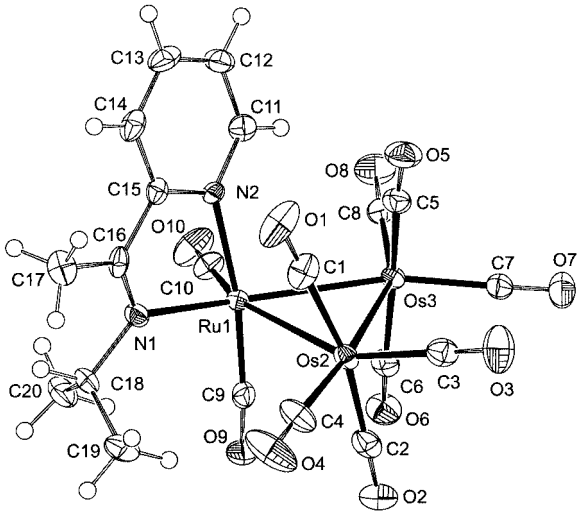

Figure 4. Molecular structure of the cluster $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ (**3**) in the crystal. Displacement ellipsoids are drawn at the 50% probability level. The site of Ru1 is occupied for 89% by Ru and for 11% by Os.

Just as for cluster **2**, the observed substitutional disorder due to a small amount of the triosmium analogue most likely has its origin in the formation of $[Os_3(CO)_{12}]$ as a side-product during the preparation of **1**. Apart from the crystal structure, the presence of a small amount of $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ is also reflected in the FAB$^+$ mass spectrum of **3** where peaks at *m*/*z* 986.9 and 957.9 can be ascribed to $[M^+ - nCO]$ (M = $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$; n = 1, 2). Moreover, the ^{1}H NMR spectrum of **3** in $CDCl_3$ displays small signals at δ = 9.50 (d, 1 H), 8.02 (d, 1 H), 7.86 (dd, 1 H), 7.11 (dd, 1 H) and 4.44 (m, 1 H) ppm, pointing to the presence of ca. 10–15% $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ (estimated from signal integrals). This proves that the ratio between $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ and $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ in solution is very close to that in the solid state.

Density Functional Study of $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ (3)

DFT calculations (ADF programme[37–43]) were performed in order to obtain more insight into the bonding

properties of **3** and the influence of the Ru atom on the character of the frontier orbitals. The cluster $[Os_2Ru(CO)_{10}(H\text{-}PyCa)]$ (H-PyCa = pyridine-2-carbaldehyde-imine) (**3′**) was taken as a model, with the isopropyl and imine methyl groups of the *i*Pr-AcPy ligand replaced by hydrogen atoms. In order to determine whether the theoretical calculations indeed predict the coordination of *i*Pr-AcPy at the ruthenium centre instead of the osmium sites, the relative energies of the structural isomers **3′** and **3′′** were calculated, with **3′** having the α-diimine coordinated at ruthenium and **3′′** at osmium (Figure 5). In both model systems, H-PyCa is coordinated with the pyridine ring in the axial position. A recent DFT study of the related cluster $[Os_3(CO)_{10}(H\text{-}PyCa)]$[18] has shown that this geometric isomer is more stable than those with the pyridine ring equatorially bound or with both nitrogen atoms coordinated in the equatorial plane.

Geometry optimisation of both isomers with DFT revealed that **3′** is more stable than **3′′** by 22 kJ·mol^{-1}. This is in agreement with the experimental structure, showing that also the *i*Pr-AcPy ligand prefers coordination at the ruthenium site of $[Os_2Ru(CO)_{12}]$. The geometry of model **3′** is in good agreement with the experimental structure of **3** (Table 4, Figure 5).

The relatively large difference between the lengths of the two Ru–N bonds in **3′** (2.05 vs. 2.17 Å) indicates that the α-diimine ligand is coordinated in a more asymmetric fashion than in the experimental structure. The probable reason is the replacement of the isopropyl group by a hydrogen atom, shortening the Ru–N1 bond as a result of different steric and electronic effects.

From the ground-state DFT calculations, the composition of the molecular orbitals of **3′** has been obtained. The

contribution of the relevant atomic wavefunctions to the frontier orbitals is given in Table 5, with the HOMO (H) and LUMO (L) being in boldface. Three-dimensional plots of the three highest occupied molecular orbitals (HOMO, HOMO-1 and HOMO-2) and of the lowest unoccupied molecular orbital (LUMO), are depicted in Figure 6. Notice that the cluster has a different orientation in Figure 6a–d. The HOMO of **3′** has large contributions from both the Ru and Os2 centres, while Os1 is almost not involved. Accordingly, the HOMO has a σ-bonding character with respect to the Ru–Os2 bond [σ(Ru–Os2)]. All three metal centres participate in the HOMO-1 that is mainly σ-bonding with regard to the Os1 and Os2 centres and will be denoted as σ(Os1–Os2). The Os2 centre is almost not involved in the HOMO-2 that receives large contributions from Ru, Os1 and the carbonyl ligands, being best described as a σ(Ru–Os1) bonding orbital.

The LUMO of **3′** mainly consists of the lowest π*(H-PyCa) orbital, while the LUMO+1 is delocalised over the cluster carbonyl core. Based on the contribution of the atomic wavefunctions to the frontier orbitals, the HOMO–LUMO transition has predominant σ(Ru–Os2)-to-π*(α-diimine) character. A comparison of the frontier orbitals with those of $[Os_3(CO)_{10}(H\text{-}PyCa)]$[18] shows that the HOMOs of both clusters are very similar, with only one specific metal–metal(α-diimine) bond involved in the bonding interactions. Notably, the ruthenium centre in **3′** contributes slightly more (25%) to the HOMO than the corresponding osmium centre in $[Os_3(CO)_{10}(H\text{-}PyCa)]$ (18%). The contributions of the π*(H-PyCa) orbital to the HOMO and the LUMO of both compounds are nearly identical. The excitation energies and the oscillator strengths of the low-lying electronic transitions of **3′** were calculated using TD-DFT and are presented in Table 6.

Electronic Absorption Spectra

The electronic absorption spectra of cluster **3** are characterised by a dominant lowest-energy band showing negative solvatochromism (Table 7) typical for charge transfer (CT) from transition metals to α-diimine ligands.

Table 7. Near-UV and visible absorptions of $[Os_2Ru(CO)_{10}(i\text{Pr-}AcPy)]$ (**3**) in different solvents.

Solvent	λ [nm]
hexane	323 (sh), 434 (sh), 520 (sh), 581
2-chlorobutane	322 (sh), 453 (sh), 562
tetrahydrofuran	323 (sh), 456, 535
acetonitrile	322 (sh), 457, 522

In order to evaluate the solvatochromism of the lowest-energy absorption band, we have plotted the experimentally determined transition energies against the empirical solvent parameter E^*_{MLCT} of Manuta et al. (Figure 7), which is based on the solvatochromism of the lowest MLCT band of $[W(CO)_4(bpy)]$.[47] The plot could be well fitted by linear regression. Its slope reflects the degree of solvatochromism, while the intercept at $E^*_{MLCT} = 0$ corresponds to the experimental transition energy (205.3 kJ·mol^{-1}, 582 nm) extrapolated to nonpolar isooctane interacting similarly weakly with both ground and excited states. The obtained extrapolated value is in good agreement with the calculated maximum of the lowest-energy transition (594 nm, Table 6) and the observed maximum of the lowest-energy absorption band of cluster **3** in hexane (581 nm, Table 7).

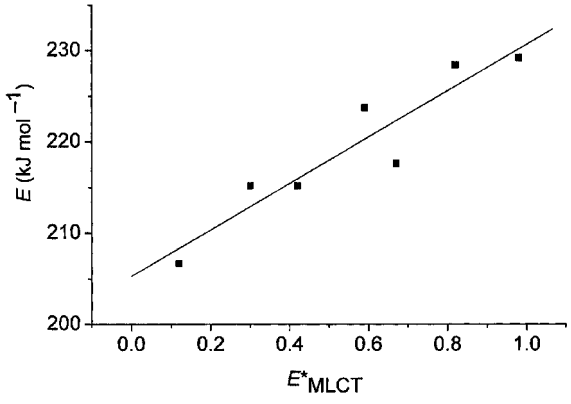

Figure 7. Solvatochromic behaviour of the lowest-energy absorption band of $[Os_2Ru(CO)_{10}(i\text{Pr-}AcPy)]$, based on the empirical solvent scale E^*_{MLCT} according to Manuta et al.[47] The solvents (with E^*_{MLCT} in parentheses) are CCl_4 (0.12), toluene (0.30), $CHCl_3$ (0.42), THF (0.59), CH_2Cl_2 (0.67), acetone (0.82) and acetonitrile (0.98).

The experimental UV/Vis spectrum of cluster **3** in hexane and the corresponding spectrum simulated with SWizard[48] are shown in Figure 8. A comparison between the theoretical and experimental data (Table 6, Table 7 and Figure 8) shows that, besides the lowest-energy absorption band, there is also a good agreement between the calculated maxima of the higher-lying transitions (Table 6), the simulated SWizard spectrum, and the higher-lying band maxima of cluster **3** in hexane (Figure 8). As the absorption features in the visible region are generally broad and poorly resolved, the lowest-energy absorption band of **3** most likely consists of several allowed transitions of a prevailing charge transfer character, which is in line with its solvatochromism. A similar solvent dependence is observed for the higher-lying shoulder at 520 nm that corresponds with the calculated charge-transfer transition 4 (Table 6). The weak shoulder on the low-energy side of the intense near-UV absorption (434 nm in hexane) most likely consists of two differently composed transitions that mainly originate in the cluster core and are directed to the LUMO+1 (transitions 7 and 8, Table 6). Although the calculated excitation energies of the three different groups of electronic transitions (cluster model **3′**) slightly deviate from the experimental values (cluster **3**), the calculated oscillator strengths compare reasonably well with the observed band intensities and clearly predict that the lowest-energy, predominantly HOMO–LUMO transition, is the most intense one in the visible region. Due to their relatively small oscillator strengths and overlap, transitions 5 and 6 (Table 6) do not appear as distinct bands in the UV/Vis spectrum of **3**.

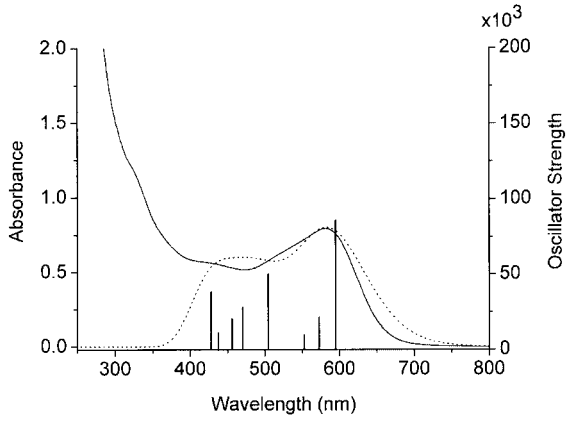

Figure 8. Electronic absorption spectrum of $[Os_2Ru(CO)_{10}(i$Pr-AcPy) in hexane at 293 K (−) together with the simulated SWizard spectrum (···) and the major electronic transitions of cluster **3′**, as calculated with the ADF programme (see Table 6).

Although the experimental results do not reveal whether the lowest-energy charge transfer transition originates from a molecular orbital with a predominant d_π(Ru) character or a delocalised σ(Ru–Os2) character, the TD-DFT results are clearly in favour of the latter assignment. The lowest-energy transition therefore belongs to a σπ* or sigma-bond-to-ligand charge transfer (SBLCT) transition, causing significant weakening of the Ru–Os2 bond in the excited state. Visible excitation of **3** is therefore expected to result efficiently in open-triangle photoproducts such as biradicals and zwitterions.

Time-Resolved Absorption Spectroscopy of Cluster 3 in Noncoordinating Solvents

Picosecond transient absorption (TA) spectra of cluster **3** were recorded in 2-chlorobutane (2-ClBu). Spectral changes following the 505 nm excitation were monitored in the region 510–710 nm. The spectra measured at 1–40 ps after the 130 fs laser pulse are depicted in Figure 9. Kinetic traces were obtained by plotting against time the ΔA values averaged over a small nanometer range. Due to the poor quality of the spectra, reliable lifetimes could only be obtained from the decay in the region 565–580 nm.

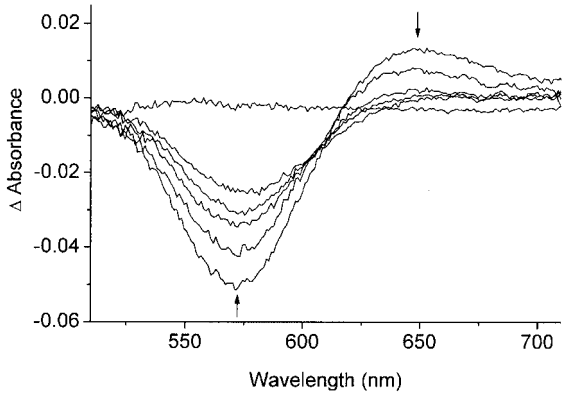

Figure 9. Transient difference absorption spectra of cluster **3** in 2-ClBu, recorded at time delays of –4 (baseline), 1, 3.5, 8.5, 16 and 31 ps, after 505 nm excitation (130 fs FWHM).

The TA spectrum at t_d = 1 ps (Figure 9) shows a bleach at about 570 nm, very close to the maximum of the ground-state absorption of the cluster in this solvent (562 nm), and an absorption with a maximum at 645 nm. The bleach partly disappears with a lifetime of 10.4 ± 1.2 ps. The remaining TA spectrum obtained at t_d = 31 ps, shows a bleach at 580 nm, which is approximately 47% of the initial signal and does not change significantly in the ps time domain. Thus, at least part of the transient species does not regenerate the parent cluster but instead converts into a second species. This is also evidenced by the long-wavelength absorption that transforms on the same time scale as the decay of the bleach into a much broader absorption without a distinct maximum. The ps TA spectra strongly resemble those of $[Os_3(CO)_{10}(i$Pr-AcPy)] in 2-ClBu.[16] This observation also implies that the 11% impurity of the latter cluster in the studied sample of **3** (vide supra) can hardly be distinguished by the TA method in this solvent.

In agreement with the results of the TD-DFT study, the initially observed broad transient absorption above 600 nm is assigned to an excited state having a predominant σπ* character. In this state, one electron has been transferred from the σ(Ru–Os2) bonding orbital (vide supra) to the lowest π* orbital of the *i*Pr-AcPy ligand. Such absorptions are characteristic for complexes in metal-to-α-diimine excited states[49–52] and for α-diimine radical anions contain-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing at least one aromatic group.[49,53,54] The remaining transient absorption in 2-ClBu is very similar to that observed in the ns TA spectra of **3** (vide infra) and is assigned to the biradical [˙Os(CO)$_4$–Os(CO)$_4$–$^+$Ru(CO)$_2$(α-diimine$^{\cdot-}$)], in accordance with the results for [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)].[16] This assignment has also been verified by recording the ps TA spectra at 250, 500 and 750 ps delays after the laser pulse. These spectra do not differ from that obtained at t_d = 31 ps, thereby proving that the biradicals formed directly from the σπ* excited state do not disappear on the picosecond time scale. Although the TA spectra of **3** in 2-ClBu are very similar to those of the corresponding triosmium cluster, the excited-state lifetime of the former complex is significantly shorter (Os$_3$: τ = 25.3 ps vs. Os$_2$Ru: τ = 10.4 ps). This may be due to the fact that the Os2–Ru(α-diimine) bond is weaker and, thus, the energetic barrier for the biradical formation is lower. Assuming similar molar absorbance for the homo- and heteronuclear biradicals, the higher intensity of the remaining transient signal after the decay of the excited state (Os$_3$: 30% vs. Os$_2$Ru: 47%) also points to a more facile formation of the open-structure photoproducts in the case of cluster **3**.

The fate of the biradicals was studied in several weakly coordinating solvents (2-ClBu, THF, acetone) by nanosecond transient absorption (ns TA) spectroscopy. Spectra of **3** in acetone were obtained by excitation at 532 nm and the spectral changes were monitored in the 350–800 nm region. The difference absorption spectra, measured 0–900 ns after the laser pulse, are depicted in Figure 10. Kinetic traces were recorded after excitation at 532 nm and probed at 560 nm (bleach). The resulting lifetimes are collected in Table 8, together with the values for the corresponding homonuclear cluster [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)].

The ns TA spectra of **3** in acetone reveal a strong bleaching between 440 and 600 nm due to the disappearance of **3**, and transient absorption below 440 nm and in the long-wavelength region. As stated above, the transient absorption is characteristic for α-diimine radical anions[49–52] and for α-diimine complexes in their metal-to-α-diimine excited state, provided the α-diimine ligand bears at least one heteroaromatic group.[49,53,54] As the ns TA spectra closely resemble those of [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)] in acetone,[15] the transient absorption is again assigned to the open-structure biradical [˙Os(CO)$_4$–Os(CO)$_4$–$^+$Ru(Sv)(CO)$_2$(*i*Pr-AcPy$^{\cdot-}$)] (Sv = acetone). In addition, the ns TA spectrum at t_d = 5 ns in acetone is very similar to the TA spectrum of **3** at t_d = 31 ps in 2-ClBu. This confirms that the biradicals formed directly from the excited state, are present in both the ps and ns time domain. The decay of the nanosecond transient species in acetone almost completely regenerated the parent cluster with a lifetime of 228 ns. On changing the solvent to THF and 2-ClBu, the lifetime decreased to 95 and 27 ns, respectively. This result demonstrates that the lifetime of the biradical follows the coordinating ability of the solvent, increasing in the order 2-chlorobutane < THF < acetone. A further increase in the lifetime was found when **3** was irradiated in 2-ClBu in the presence of 1.0 M MeCN. The kinetic trace of this solution shows a decrease of the bleach on the μs time scale (τ = 6.8 μs), but not its complete disappearance. This means that the MeCN-stabilised biradicals did not convert back to the parent cluster but transformed into the corresponding MeCN-stabilised zwitterions, just as observed for [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)].[16] In the case of the triosmium cluster, this process typically occurs for strong Lewis bases (MeCN, pyridine) and firmly coordinating olefins (styrene, octene).[15]

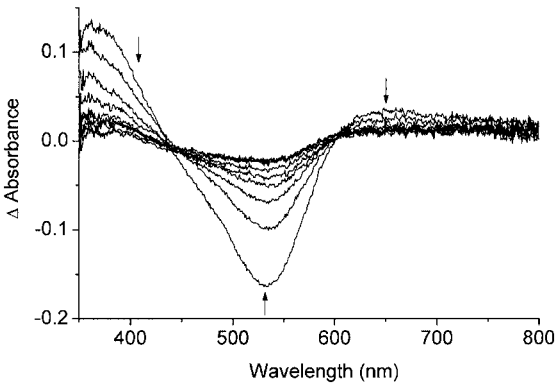

Figure 10. Nanosecond transient difference absorption spectra of cluster **3** in acetone, recorded in the time interval t = 0–900 ns after the 532 nm laser pulse; the time delay between the spectra is 100 ns.

Time-Resolved Spectroscopy in Strongly Coordinating Solvents

In addition to the experiments in 2-ClBu, ps TA spectra of cluster **3** were also recorded in strongly coordinating MeCN. The spectra measured at 1–5 ps after the 130 fs/505 nm laser pulse are depicted in Figure 11. Kinetic traces were extracted by plotting against time the ΔA values averaged in the range 605–615 nm.

Table 8. Lifetimes [ns] of the solvent-stabilised biradical photoproducts of cluster **3** and the reference compound [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)], obtained from their kinetic profiles probed at 560 nm. Standard deviations are given in parentheses.

Solvent	[Os$_2$Ru(CO)$_{10}$(*i*Pr-AcPy)]	[Os$_3$(CO)$_{10}$(*i*Pr-AcPy)]
2-chlorobutane	27(4)	22(3)
THF	95(4)	104(7)
Acetone	228(8)	677(2)
2-chlorobutane/MeCN (1.0 M)	6.8 (0.1)[a]	13.5 (0.2)[a]

[a] Lifetime in μs.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

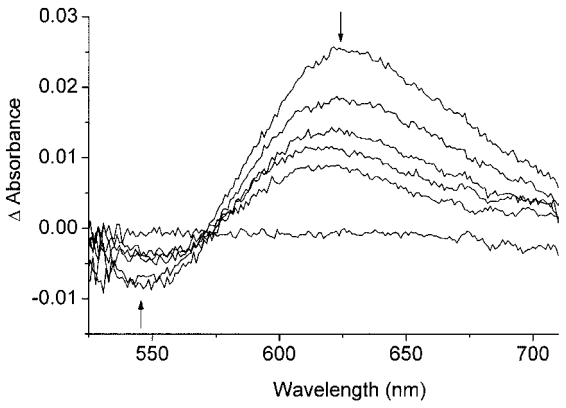

Figure 11. Transient difference absorption spectra of cluster **3** in MeCN, recorded at time delays of –1 (baseline), 1, 1.5, 2.5, 3.5 and 4.5 ps, respectively, after 505 nm excitation (130 fs FWHM).

The first TA spectra (Figure 11) are similar to those in 2-ClBu although the maxima of the bleach (550 nm) and the transient absorption (630 nm) are somewhat shifted. Although the TA spectra of **3** in MeCN resemble those obtained for $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ in this solvent,[16] the excited states of both clusters behave differently. For $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ the decay of the excited state in coordinating MeCN is bi-exponential. The slower process (τ = 21.4 ps) has been ascribed to biradical formation, having a lifetime similar to that observed in 2-ClBu.[16] The faster process (τ = 2.9 ps) has been assigned to the heterolytic cleavage of an Os–Os(α-diimine) bond from an MeCN-coordinated excited state with concomitant zwitterion formation; zwitterions were indeed observed in the ps TRIR spectra of $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$.[55] The excited state of cluster **3** decays mono-exponentially in MeCN and its lifetime (τ = 2.1 ps) closely corresponds to the shorter 2.9 ps component of the bi-exponential decay of the excited state of $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$. This points to the same process for both clusters and suggests that irradiation of **3** in neat MeCN gives rise to very fast formation of zwitterions as the only photoproduct. As will be shown hereinafter, TA studies in the nano- and microsecond time domain and rapid scan FTIR spectroscopic measurements confirm this presumption.

As described above, the kinetic trace of **3** in 2-ClBu in the presence of 1.0 M MeCN showed a decrease of the bleach on the μs time scale (τ = 6.8 μs) that, in accordance with the results for $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$,[16] was assigned to the conversion of MeCN-stabilised biradicals into the corresponding MeCN-zwitterions. The MeCN-stabilised biradicals result in this case from the substitution of weakly coordinating 2-ClBu by MeCN within the lifetime of the solvent-stabilised biradicals $[^{\cdot}Os(CO)_4–Os(CO)_4–Ru^+(Sv)(CO)_2(i\text{Pr-AcPy}^{\cdot-})]$ (Sv = 2-ClBu). In neat MeCN, however, the kinetic trace of **3** does not show any change in signal intensity on the nano- and microsecond time scale (Figure 12), indicating that the pathway for zwitterion formation via the biradicals, similar to that observed for the triosmium analogue, does not exist. Thus, contrary to $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$, cluster **3** affords a single photoproduct that does not convert into another species in the time domains studied. Based on our previous ns-μs TA studies of biradical and zwitterion photoproducts of $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ in MeCN,[12,15,16] the presence of 11% impurity of the latter cluster in the investigated sample of **3** should result in ΔA ca. 0.002 in Figure 12, which is difficult to resolve in the spectral noise.

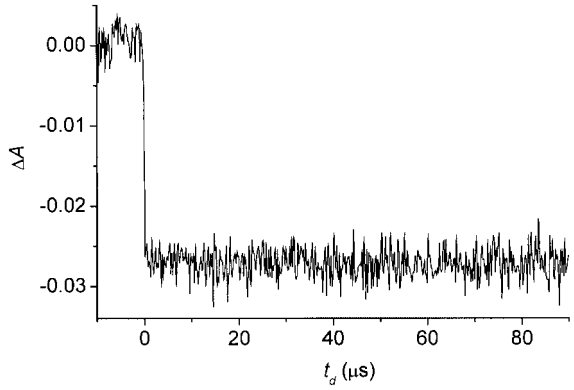

Figure 12. Transient kinetics at 560 nm measured for cluster **3** in MeCN, following irradiation at 532 nm with a Nd:YAG laser (7 ns FWHM, average of 10 shots at 10 s intervals, 2 mJ·pulse^{-1}).

In order to confirm that the single photoproduct is the zwitterion $[^{-}Os(CO)_4–Os(CO)_4–Ru^+(MeCN)(CO)_2(i\text{Pr-AcPy})]$, the photoreaction of **3** in MeCN was followed with rapid-scan IR spectroscopy in the (sub)second time domain. In addition, also pyridine was used as the solvent. Cluster **3** was irradiated for 2 s with an argon-ion laser (514.5 nm, 150 mW) and the IR spectral changes in the CO-stretching region were monitored in both solvents on the time scale of seconds to minutes. The difference IR spectra of **3** in pyridine, measured 0–93 s after the laser pulse, are depicted in Figure 13. Unfortunately, irradiation of **3** in MeCN at 293 K only resulted in the formation of very weak transient bands at 1997 (vw), 1970 (s) and 1874 (s, br) cm^{-1}, that decayed with a lifetime similar to that of the zwitterions formed upon irradiation of $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ (τ = 38 ± 1 s).[12] Based on the intensity of the transient signals and the observed lifetime, this transient species is assigned as the homonuclear zwitterion $[^{-}Os(CO)_4–Os(CO)_4–{}^{+}Os(MeCN)(CO)_2(i\text{Pr-AcPy})]$, originating from the 11% $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ impurity in the sample (vide supra). Repeating the experiment at 273 K resulted in similar, more intense product bands, whose decay was clearly bi-exponential. Both the transient absorptions and the parent bleaches rapidly decay within 5 s to approximately 15% of their initial intensity. In a second, slower process, the remaining transient fully regenerates the parent cluster with a lifetime of 54.6 ± 1.2 s, being very close to the lifetime of the zwitterions formed upon irradiation of pure $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ under these conditions. As the amplitudes of both processes nicely correspond with the observed ratio between $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ and $[Os_3(CO)_{10}(i\text{Pr-AcPy})]$ in the ^{1}H NMR spectrum and crystal structure of **3**, the faster process is assigned to the decay of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the heteronuclear zwitterions [$^{-}$Os(CO)$_4$–Os(CO)$_4$–$^{+}$Ru(MeCN)(CO)$_2$(*i*Pr-AcPy)]. In agreement with the lifetime, the slower process is then attributed to the decay of the homonuclear zwitterions originating from the [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)] impurity.

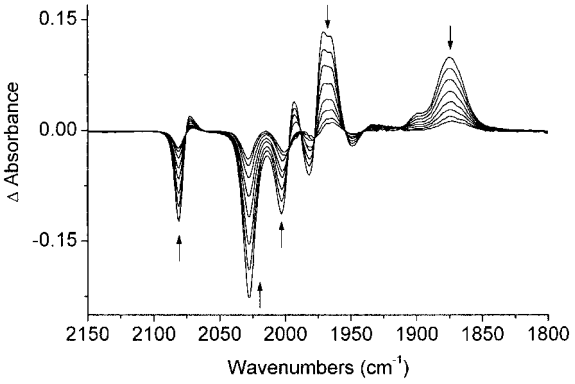

Figure 13. Difference rapid-scan IR spectra of cluster **3** in pyridine measured at time delays of 1.8, 6.6, 11.4, 18.6, 28.2, 40.2, 59.4 and 93.0 s after the 514.5 nm laser pulse.

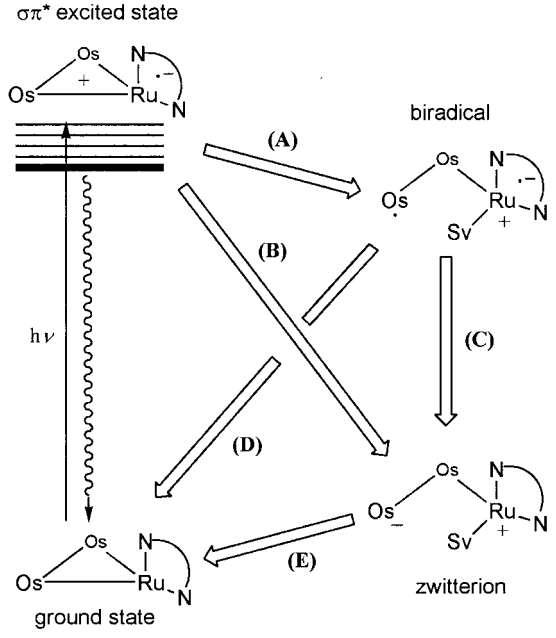
Irradiation of **3** in strongly coordinating pyridine at room temperature resulted in similar spectral changes as observed in MeCN at 273 K (Figure 13). After excitation, the first spectra display instantaneous bleaching of the parent ν(CO) bands, together with transient absorption bands at 2073 (vw), 1994 (w), 1971 (s), 1965 (sh), 1898 (sh) and 1875 (s, br) cm^{-1}. Both the transient bands and parent bleaches decay again bi-exponentially. The lifetime of the heteronuclear zwitterion increased from a few seconds in MeCN to 23.0 ± 0.3 s in pyridine, which is consistent with the stronger coordination of the latter solvent. At the same time, the difference in the lifetimes of the heteronuclear and triosmium zwitterions has also increased significantly, the latter one living in pyridine for more than 30 minutes. The rapid-scan FTIR experiments thus clearly demonstrate that the irradiation of [Os$_2$Ru(CO)$_{10}$(*i*Pr-AcPy)] in strongly coordinating solvents like MeCN and pyridine results in the formation of solvent-stabilised zwitterions, with lifetimes much shorter than those of the corresponding triosmium zwitterions. The results of the combined time-resolved studies of cluster **3** are summarised in Scheme 2.



Scheme 2. Schematic representation of the photoreaction pathways established for the cluster [Os$_2$Ru(CO)$_{10}$(*i*Pr-AcPy)] (**3**). The separate reaction steps (**A**)–(**E**) depend on the solvent (Sv) used: (*i*) (**A**) + (**D**) in 2-ClBu, THF, acetone (293 K); (*ii*) (**B**) + (**E**) in MeCN; (*iii*) (**A**) + (**C**) + (**E**) in 2-ClBu + 1.0 M MeCN.

Stability of the Photoproducts

The observed photochemical reactivity of **3** differs significantly from that of the homonuclear clusters [Ru$_3$(CO)$_8$(μ-CO)$_2$(α-diimine)].[17] Although visible excitation of the latter clusters also resulted in the formation of open-structure photoproducts like biradicals and zwitterions, the efficiency of these processes is significantly lower due to the persistent presence of bridging carbonyl ligands in the excited state. Secondly, the triruthenium photoproducts could only be stabilised at low temperatures or in the presence of strongly coordinating Lewis bases or radical scavengers. Regarding the formation of open-structure photoproducts, the photoreactivity of **3** resembles more closely that of its triosmium analogue [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)], for which fairly stable solvent-stabilised biradicals and zwitterions were observed upon excitation into its lowest-energy electronic transition.[12,15,16,55] The latter cluster therefore serves as a reference compound in order to evaluate the influence of the heteronuclear cluster core in **3** on the photoreactivity.

Interestingly, the solvent-stabilised biradicals of parent cluster **3** are significantly shorter-lived than their triosmium counterparts (Table 8). This difference in the biradical lifetime is most striking in acetone, where the lifetime of the heteronuclear biradical (τ = 228 ns) is merely 30% of the value found for [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)] (τ = 677 ns). A much smaller difference is observed in THF (Os$_2$Ru: τ = 95 ns vs. Os$_3$: τ = 104 ns) while in weakly coordinating 2-ClBu the biradical lifetimes of both clusters are almost identical. These results clearly document that the difference in the biradical lifetime increases with the coordinating ability of the solvent. A similar trend applies for the lifetimes of the solvent-stabilised zwitterions. Whereas the lifetime of the heteronuclear zwitterion increases only slightly from a few seconds in MeCN to 23 s in pyridine, the lifetime of the triosmium zwitterion in pyridine amounts to more than 30 minutes compared to 38 s in MeCN. The shorter lifetimes of the heteronuclear photoproducts in better coordinating solvents indicate that the stabilisation of these products by solvent coordination is significantly reduced compared to the corresponding triosmium species. This is attributed to the higher tendency of the coordinatively unsaturated $^{+}$Os(CO)$_2$(*i*Pr-AcPy$^{\cdot-/0}$) moieties in the photoproducts to bind a Lewis base. A similar difference in Lewis base coordination on descending a transition metal group in the peri-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

odic table is observed, for example, for the coordinatively unsaturated radicals $[M(CO)_3(\alpha\text{-diimine})]\cdot$ (M = Mn, Re; α-diimine is, e.g., bpy, *i*Pr-PyCa, *i*Pr-DAB). Thus, while the unsaturated radicals $[Re(CO)_3(\alpha\text{-diimine})]\cdot$ form at room temperature fairly stable 18e paramagnetic species $[Re(CO)_3(\alpha\text{-diimine})(Sv)]\cdot$ (Sv = MeCN, PrCN),[56–58] analogous radicals were not observed for $[Mn(CO)_3(\alpha\text{-diimine})]\cdot$.[59]

Redox Behaviour of $[Os_2Ru(CO)_{10}(i\text{Pr-AcPy})]$ (3)

A combined cyclic voltammetric and IR spectroelectrochemical study of cluster **3** was performed in order to investigate the influence of the heteronuclear cluster core on the reduction pathway and stability of the reduction products. The redox potentials are presented in Table 9.

Table 9. Redox potentials of cluster **3** and its reduction products.

Cluster[a][b]	$E_{p,c}$ [V][c]	$E_{p,a}$ [V][c]
3	–1.87 (irr)	+0.27 (irr)
3[d]	–1.93 (irr)	+0.37 (irr)
$\mathbf{3b}^{2-}$ [d]		–1.50 (irr)
$[\mathbf{3b\text{-}3b}]^{2-}$		–1.17 (irr)
$[\mathbf{3b\text{-}3b}]^{2-}$ [d]		–0.85 (irr)

[a] Conditions and definitions: 10^{-3} mol·dm^{-3} solutions in THF (containing 10^{-1} M Bu_4NPF_6) at 293 K, unless stated otherwise; Pt disk microelectrode (0.42 mm^2); v = 100 mV s^{-1}; redox potentials vs. $E_{1/2}$ (Fc/Fc$^+$); $E_{p,c}$, cathodic peak potential for reduction of parent cluster; $E_{p,a}$, anodic peak potential for oxidation of parent cluster or its reduction products. [b] Assignments given in the main text. [c] Chemical irreversibility denoted by (irr). [d] T = 200 K.

The cyclic voltammogram of **3** in THF at room temperature (v = 100 mV·s^{-1}) showed a chemically irreversible two-electron reduction at $E_{p,c}$ = –1.87 V (cathodic peak R_1, see Figure 14a), most likely producing the open-core dianion $[^{-}Os(CO)_4\text{–}Os(CO)_4\text{–}Ru^{-}(CO)_2(i\text{Pr-AcPy})]^{2-}$ ($\mathbf{3b}^{2-}$). Similar dianions are formed upon reduction of the homonuclear clusters $[M_3(CO)_{10}(\alpha\text{-diimine})]$ (M = Ru, Os).[17,53] At room temperature, the dianion $\mathbf{3b}^{2-}$ was, however, not detectable on the reverse scan (vide infra). Instead, scan reversal behind R_1 resulted in the appearance of an anodic peak at –1.17 V (O_2') assigned, in accordance with the results for $[Os_3(CO)_{10}(i\text{Pr-PyCa})]$,[53] to the oxidation of the cluster dimer $[^{-}Os(CO)_4\text{–}Os(CO)_4\text{–}Ru(CO)_2(i\text{Pr-AcPy})]_2^{2-}$ ($[\mathbf{3b\text{-}3b}]^{2-}$) containing an (*i*Pr-AcPy)Ru–Ru(*i*Pr-AcPy) bond. Additional proof for this assignment was obtained from IR spectroelectrochemical experiments (vide infra), where the reduction of **3** resulted in the appearance of a ν(CO) band pattern closely resembling that of the photogenerated zwitterions with an open cluster core. On lowering the temperature to 200 K, the reduction of **3** remained chemically irreversible (Figure 14b). However, in contrast to the room-temperature scan, the anodic sweep showed an additional anodic peak at –1.50 V (O_2) assigned[53] to the oxidation of $\mathbf{3b}^{2-}$, the latter species being sufficiently stable at low temperatures. The minor anodic process denoted with the asterisk (Figure 14b) corresponds to the oxidation of unassigned species.

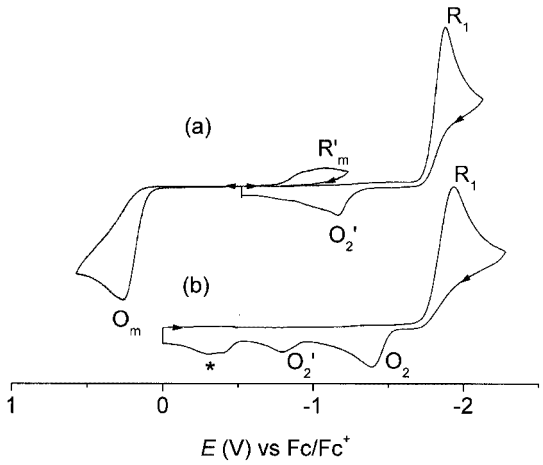


Figure 14. Cyclic voltammogram of cluster **3** at T = 293 K (a) and T = 200 K (b). Conditions: 10^{-3} M cluster in THF/10^{-1} M Bu_4NPF_6, Pt disk microelectrode (0.42 mm^2 apparent surface area), v = 100 mV s^{-1}.

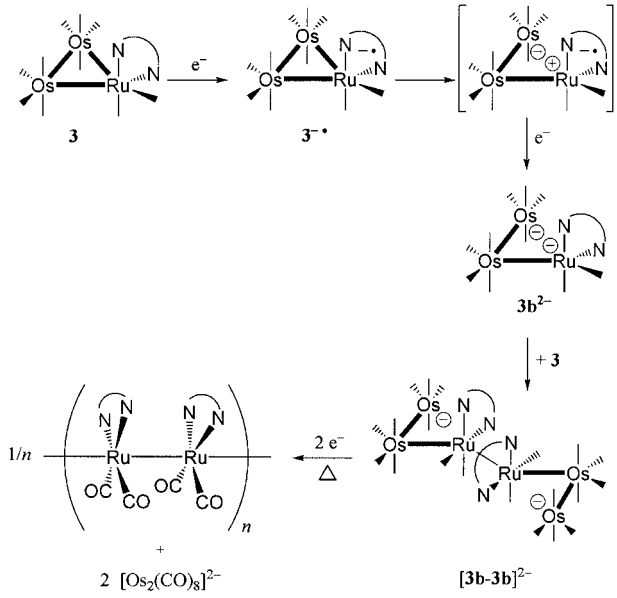
Cyclic voltammetry thus documents that the closed-triangle radical anion of **3** cannot be stabilised even at 200 K and readily transforms into the open-structure dianion $\mathbf{3b}^{2-}$ (see Scheme 3). The latter dianion is also unstable and could only be produced in detectable amounts at low temperatures. This is in contrast with the results of $[Os_3(CO)_{10}(i\text{Pr-PyCa})]$, where the oxidation of the open-structure dianion is already clearly visible at 293 K.[53] Formation of dimer $[\mathbf{3b\text{-}3b}]^{2-}$, whose oxidation is observed at 200 K at $E_{p,a}$ = –0.85 V (O_2'), is known to take place by a rapid nucleophilic attack of dianion $\mathbf{3b}^{2-}$ at the yet nonreduced parent cluster **3**. A similar ECEC reduction path, for example, has been reported for the homonuclear clusters $[Os_3(CO)_{10}(\alpha\text{-diimine})]$.[53] Both $\mathbf{3b}^{2-}$ and $[\mathbf{3b\text{-}3b}]^{2-}$ are structurally related to the solvent-stabilised zwitterions



Scheme 3. Reduction path of cluster **3**.

[$^{-}$Os(CO)$_4$–Os(CO)$_4$–$^{+}$Ru(Sv)(CO)$_2$(*i*Pr-AcPy)], the photoproduct of **3** in coordinating solvents (Sv) (vide supra).

For completeness, the oxidation of cluster **3** at the potential $E(O_m)$ is chemically irreversible, resulting in a secondary product reducible on the reverse cathodic scan at the potential $E(R'_m)$. These processes were not studied in detail.

In the course of corresponding IR spectroelectrochemical experiments, the reduction of **3** in THF at 250 K resulted in the appearance of transient ν(CO) bands at 2049 (m), 2009 (m), 1991 (m), 1965 (s), 1942 (sh) and 1864 (m) cm^{-1}, similarly to the IR ν(CO) spectrum reported for the open-core dimers [$^{-}$Ru(CO)$_4$–Ru(CO)$_4$–Ru(CO)$_2$(α-diimine)]$_2^{2-}$ (α-diimine = 2,2′-bipyridine, 2,2′-bipyrimidine).[17] Accordingly, these bands are assigned to the heteronuclear analogue [$^{-}$Os(CO)$_4$–Os(CO)$_4$–Ru(CO)$_2$(*i*Pr-AcPy)]$_2^{2-}$ ([**3b-3b**]$^{2-}$, Scheme 3). No IR bands attributable to the open-structure dianion **3b**$^{2-}$ were observed in the course of the reduction. This means that **3b**$^{2-}$ is unstable on the spectroelectrochemical time scale at 250 K and readily reacts with the parent cluster **3** to form the dimer [**3b-3b**]$^{2-}$. Actually, the latter species was also unstable and converted into another carbonyl product absorbing at 1938 (s) and 1863 (s, br) cm^{-1}. In agreement with the literature[31] and the results for [Os$_3$(CO)$_{10}$(α-diimine)],[60] this product is proposed to be the dinuclear complex [Os$_2$(CO)$_8$]$^{2-}$. As the highest-frequency ν(CO) band of the corresponding [Ru$_2$(CO)$_8$]$^{2-}$ complex is found at significantly lower wavenumber (Ru: 1930 cm^{-1} vs. Os: 1940 cm^{-1}),[31] the observation of [Os$_2$(CO)$_8$]$^{2-}$ provides another evidence that the α-diimine ligand in **3** is coordinated at ruthenium. Parallel to [Os$_2$(CO)$_8$]$^{2-}$, reduction of [**3b-3b**]$^{2-}$ most likely results in the formation of the polymeric chain [Ru(CO)$_2$(*i*Pr-AcPy)]$_n$, as indicated by the formation of a blue film at the working electrode and in its vicinity. Similar species are also formed as the ultimate reduction products of the clusters [M$_3$(CO)$_{10}$(α-diimine)] (M = Ru, Os), closely resembling [M(CO)$_2$(bpy)]$_n$, generated by electrochemical reduction of mononuclear complexes *trans*(Cl)-[M(CO)$_2$(bpy)(Cl)$_2$].[61–64]

The interest in these open-chain polymers [M(CO)$_2$(α-diimine)]$_n$ (M = Ru, Os) mainly derives from their electrocatalytic activity towards reduction of carbon dioxide.[63,65–67]

From the DFT results (Table 5, Figure 6) it is clear that the LUMO of cluster **3** is for about 65% the lowest π*(*i*Pr-AcPy) orbital. Further, the LUMO has also got a nonnegligible σ*(Ru–Os2) character. Single occupation of this orbital is therefore expected to result in largely α-diimine-localised radical anion **3**$^{\cdot-}$ with a weakened Ru–Os2 bond. This bond becomes readily cleaved, similar to the photoreactivity of cluster **3** (vide supra). While the photochemical cleavage is promoted by the partial σσ* character of the excited state, the driving force behind the electrochemical cleavage is probably the pronounced donor nature of the singly reduced *i*Pr-AcPy ligand in **3**$^{\cdot-}$ causing strong polarisation of the Ru–Os2 bond nearly perpendicular to the *i*Pr-AcPy plane. Unlike the corresponding homonuclear clusters [Os$_3$(CO)$_{10}$(*i*Pr-PyCa)][53] and [Ru$_3$(CO)$_8$(μ-CO)$_2$(α-diimine)][17] [α-diimine = 2,2′-bipyridine (bpy), 4,4′-dimethyl-2,2′-bipyridine (dmb), 2,2′-bipyrimidine (bpym)] forming fairly stable radical anions at moderately low temperatures, the reduction of **3** remains chemically irreversible even at 200 K. A comparison of the reduction potentials of the homonuclear [M$_3$(CO)$_{10}$(α-diimine)] clusters (M = Os,[68] Ru[17]) with that of **3** (–1.87 V) reveals that the π-acceptor capacity of the *i*Pr-AcPy ligand in **3** is similar to that of bpy (–1.85 V, M = Os, Ru) and dmb (–1.91 V, M = Ru). This implies that the higher reactivity of radical anions **3**$^{\cdot-}$ is not due to a limited donor power of the reduced *i*Pr-AcPy ligand but, probably, has its origin in the weak heterometallic Os2–Ru(*i*Pr-AcPy) bond.

Just as for the corresponding [Os$_3$(CO)$_{10}$(*i*Pr-PyCa)] cluster,[53] no open-structure dianions were detected by IR spectroscopy on the spectroelectrochemical time scale of minutes at 250 K, the dimer [**3b-3b**]$^{2-}$ being the initially observed reduction product. The triangular open-structure units in dimer [**3b-3b**]$^{2-}$ undergo fragmentation and linear chains [Ru(CO)$_2$(*i*Pr-AcPy)]$_n$ are ultimately formed, together with the dinuclear complex [Os$_2$(CO)$_8$]$^{2-}$.

Conclusions

Crystal structures of the novel clusters [Os$_2$Ru(CO)$_{11}$(PPh$_3$)] (**2**) and [Os$_2$Ru(CO)$_{10}$(*i*Pr-AcPy)] (**3**) clearly reveal, in agreement with DFT calculations on several structural isomers, that both PPh$_3$ and *i*Pr-AcPy prefer coordination at the ruthenium site of [Os$_2$Ru(CO)$_{12}$] (**1**). The Os2–Ru(*i*Pr-AcPy) bond in cluster **3** is weaker than the corresponding metal–metal(α-diimine) bonds in the homonuclear [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)] and doubly CO-bridged triruthenium analogues. This factor contributes to the observed differences in the photo- and electrochemical reactivity of cluster **3** compared to the homonuclear cores; although, the general course of the photo- and redox reactions remains unchanged.

Regarding the photochemical formation of biradical and zwitterionic photoproducts, cluster **3** closely resembles its homonuclear analogue [Os$_3$(CO)$_{10}$(*i*Pr-AcPy)]. In weakly coordinating 2-ClBu, the lowest σπ* excited state decays with a lifetime of approximately 10 ps, resulting in the formation of solvent-stabilised biradicals. In contrast to its triosmium analogue, irradiation of **3** in coordinating solvents exclusively results in heterolytic splitting of the Os2–Ru(*i*Pr-AcPy) bond, producing solvent-stabilised zwitterions. Interestingly, the lifetimes of the biradical- and zwitterionic photoproducts of cluster **3** are significantly shorter than their triosmium counterparts. This difference results most likely from a lower tendency of the coordinatively unsaturated $^{+}$Ru(CO)$_2$(*i*Pr-AcPy$^{\cdot-/0}$) moieties in the photoproducts to bind a Lewis base. Electrochemically, the influence of the weak Os2–Ru(α-diimine) bond is clearly reflected in the low stability of the radical anions initially formed by one-electron reduction of **3**.

In general, the combination of experimental photo- and electrochemical techniques together with the theoretical support from DFT calculations have provided a good in-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sight into the bonding properties of $[Os_2Ru(CO)_{10}(i$PrAcPy)]. Although the incorporation of a Ru centre into the cluster core does not induce drastic changes in the photo- and electrochemical reactivity pattern in comparison with the triosmium derivative, more pronounced heterosite effects may, for example, be expected for mixed-metal clusters combining transition metal centres from different groups of the periodic Table (e.g., Os_2Pt, Os_2Rh).

Experimental Section

Materials and Preparations: Solvents of analytical grade [Acros: acetone, acetonitrile (MeCN), dichloromethane (CH_2Cl_2), hexane, tetrahydrofuran (THF); Aldrich: 2-Chlorobutane (2-ClBu); Merck: pyridine] were dried with sodium wire (hexane), sodium/benzophenone (THF), $CaSO_4$ (acetone) and CaH_2 (MeCN, CH_2Cl_2, 2-ClBu, pyridine) and freshly distilled under nitrogen prior to use. $[Ru_3(CO)_{12}]$, $[Os_3(CO)_{12}]$ (Strem Chemicals), PPh_3, Br_2 (Aldrich), ferrocene (BDH) and NH_3 (Praxair) were used as received. Trimethylamine *N*-oxide, $Me_3NO{\cdot}2H_2O$ (Janssen), was dehydrated before use by vacuum sublimation. The supporting electrolyte Bu_4NPF_6 (Aldrich) was recrystallised twice from ethanol and dried in vacuo at 350 K overnight. Neutral aluminium oxide 90 (70–230 mesh, Merck) and silica 60 (70–230 mesh, Merck) for column chromatography were activated by heating in vacuo at 450 K overnight and stored under N_2. Preparative TLC was performed on Silica Gel G plates (20×20 cm, 1 μm, Analtech).

Synthetic Procedures: All syntheses were performed under dry nitrogen, using standard Schlenk techniques. The preparation of $Na_2[Ru(CO)_4]$ and the consecutive coupling with $[Os_2(CO)_8(Br)_2]$ were performed on a high-vacuum line at reduced pressure ($\approx 10^{-4}$ Pa). $[Os_3(CO)_{12}(Br)_2]$,[69] $[Os_2(CO)_8(Br)_2]$[30] and $Na_2[Ru(CO)_4]$[31] were prepared by modified literature procedures. $[Os_2Ru(CO)_{11}(MeCN)]$ and $[Os_2Ru(CO)_{10}(MeCN)_2]$ were prepared by similar procedures as used by Foulds et al. for the syntheses of $[Ru_3(CO)_{12-n}(MeCN)_n]$ (n = 1, 2).[70] Both clusters were prepared in situ and only characterised by IR spectroscopy (vide infra).

Synthesis of $[Os_3(CO)_{12}(Br)_2]$: In a typical experiment, a solution of $[Os_3(CO)_{12}]$ (500 mg, 0.55 mmol) in CH_2Cl_2 (350 mL) was heated to reflux for 20 min. After addition of Br_2 (40 μL, 0.78 mmol) the solvent was immediately removed in vacuo. The pale yellow residue was dissolved in CH_2Cl_2/hexane, 1:4 (400 mL) and precipitated at 190 K. The product was obtained as a pale yellow powder (412 mg, 70%) and used in the synthesis of $[Os_2(CO)_8(Br)_2]$ without further purification. IR (CH_2Cl_2): $\tilde{\nu}$ [ν(CO)] = 2149 (vw), 2119 (s), 2062 (vs, br), 2030 (s), 2002 (w) cm^{-1}.

Synthesis of $[Os_2(CO)_8(Br)_2]$: A solution of $[Os_3(CO)_{12}(Br)_2]$ (350 mg, 0.33 mmol) in CH_2Cl_2 (60 mL) was heated at 323 K to dissolve all starting material. After cooling to room temperature, Br_2 (14.5 μL, 0.28 mmol) was added and the solution was irradiated with a 125 W high-pressure Hg lamp using a $\lambda > 420$ nm cut-off filter. The reaction was monitored by IR spectroscopy and irradiation was stopped when no further increase of the product ν(CO) bands was observed (ca. 85% conversion). After removal of the solvent in vacuo, the crude yellow product was extracted with hexane (5×10 mL). The combined fractions were filtered and the solvents evaporated to dryness. The remaining solid was redissolved in hexane containing a few drops of CH_2Cl_2 and precipitated at 270 K. The product was obtained as a pale yellow powder (86 mg, 40%). IR (hexane): $\tilde{\nu}$ [ν(CO)] = 2118 (s), 2079 (vs), 2067 (s), 2063 (vs), 2052 (s), 2031 (s) cm^{-1}.

Synthesis of $Na_2[Ru(CO)_4]$ and $[Os_2Ru(CO)_{12}]$ (1): Two reaction vessels, equipped with Rotaflo® stopcocks and connected by a glass frit, were placed on a standard high-vacuum line. Under a continuous N_2 flow, $[Os_2(CO)_8(Br)_2]$ (200 mg, 0.26 mmol) was placed in one of the vessels while the other one contained $[Ru_3(CO)_{12}]$ (55.8 mg, 0.087 mmol) and metallic sodium (12 mg, 0.52 mmol). Anhydrous NH_3 (ca. 25 mL) was condensed in a separate vessel onto metallic sodium and frozen, using a liquid nitrogen bath. After closing the vessel containing $[Os_2(CO)_8(Br)_2]$, NH_3 was distilled under vacuum onto the sodium/$[Ru_3(CO)_{12}]$ mixture. Using an acetone/dry ice bath, the solution was slowly warmed to 235 K and stirred vigorously until the characteristic blue Na/NH_3 solution transformed into a yellow solution containing a white precipitate. This usually required about 30 minutes of reaction time. The mixture was stirred for another 30 minutes and remaining sodium, which splashed on the walls of the flask, was washed down by cold spotting with glass wool drenched with liquid nitrogen. After 1 h, NH_3 was evaporated by further warming to 260 K and the remaining cream-coloured solid was dried under high-vacuum conditions for another 3.5 h at this temperature. $Na_2[Ru(CO)_4]$ was then dissolved on the vacuum line in THF that had been pre-dried with sodium/benzophenone and thoroughly degassed in four consecutive freeze-pump-thaw cycles. The pale yellow solution was degassed once more to remove the last traces of ammonia. Finally, the THF solution was warmed to 273 K and added to $[Os_2(CO)_8(Br)_2]$ by filtration through the frit connecting the reaction vessels. Upon mixing, the solution turned red and gas was evolving. The solution was stirred overnight at 293 K, followed by evaporation of the solvent. Purification of the crude product was established by column chromatography (activated neutral alumina, hexane/CH_2Cl_2 gradient elution). After precipitation from THF at 190 K, the product was obtained as a yellow powder in yields varying between 86 and 135 mg (40–63% based on $[Os_2(CO)_8(Br)_2]$), depending on the quality of $Na_2[Ru(CO)_4]$ (vide supra). IR (hexane): $\tilde{\nu}$ [ν(CO)] = 2068(s), 2036 (s), 2015 (m), 2004 (m) cm^{-1}. UV/Vis (CH_2Cl_2): λ = 280 (sh), 329, 382 (sh) nm. MS (FD): m/z = 817 $[M]^+$ (calcd. 817.8). MS (EI): $m/z = [M^+ - n\text{CO}]$ (n = 0–12).

Synthesis of $[Os_2Ru(CO)_{11}(PPh_3)]$ (2): Me_3NO (5.5 mg, 0.07 mmol) in MeCN (2 mL) was added to a solution of $[Os_2Ru(CO)_{12}]$ (30 mg, 0.04 mmol) in THF (25 mL) at 200 K. After stirring the mixture for approximately 30 minutes, IR spectra revealed almost complete conversion to $[Os_2Ru(CO)_{11}(MeCN)]$. After addition of PPh_3 (10.6 mg, 0.04 mmol), the solution was warmed to room temperature. As IR spectra showed hardly any conversion after 60 minutes, additional PPh_3 was added (5.2 mg, 0.02 mmol) and the solution was stirred for two days in the dark. After removal of the solvent in vacuo, the residue was loaded on a silica 60 column packed in hexane. Gradient elution with hexane/THF resulted in the clean separation of three (yellow, orange and red) mobile bands. The yellow fraction was further purified by preparative TLC to remove free PPh_3. Recrystallisation of the yellow residue from petroleum ether 40–60 at 250 K yielded orange crystals of cluster **2** (15 mg, 40%). On the basis of their IR spectra, the orange and red fractions likely contained higher substituted compounds, but no detailed characterization of the mixtures was attempted.

$[Os_2Ru(CO)_{11}(MeCN)]$: IR (CH_2Cl_2): $\tilde{\nu}$ [ν(CO)] = 2104 (w), 2050 (vs), 2040 (vs), 2019 (s, sh), 2008 (vs), 1984 (m) cm^{-1}.

$[Os_2Ru(CO)_{11}(PPh_3)]$ (2): IR (CH_2Cl_2): $\tilde{\nu}$ [ν(CO)] = 2107 (m), 2054 (s), 2033 (s), 2017 (vs), 1999 (m), 1988 (m), 1977 (m), 1957 (w) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 7.35 (m, 15

H) ppm. $^{31}P\{H\}$ NMR (300 MHz, $CDCl_3$, 293 K): δ = 29.6 ([$Os_2Ru(CO)_{11}(PPh_3)$]), –0.8 ([$Os_3(CO)_{11}(PPh_3)$]) ppm (ratio ca. 2:1). MS (FD): m/z = 1142 $[M]^+$ (M = [$Os_3(CO)_{11}(PPh_3)$]) (calcd. 1141.9), 1054 $[M]^+$ (M = [$Os_2Ru(CO)_{11}(PPh_3)$]) (calcd. 1053.9) (ratio ca.1:2).

Synthesis of [$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] (3): To a solution of [$Os_2Ru(CO)_{11}$(MeCN)] at 270 K, freshly prepared from [$Os_2Ru(CO)_{12}$] (100 mg, 0.12 mmol) and Me_3NO (18.6 mg, 0.25 mmol), a solution of Me_3NO (13.5 mg, 0.18 mmol) in CH_2Cl_2 was added dropwise. After stirring for 45 minutes IR spectra revealed [$Os_2Ru(CO)_{10}$(MeCN)$_2$] as the main product. After addition of *i*Pr-AcPy (200 mg, 1.2 mmol) the solution was stirred overnight while warming to room temperature. Purification of the crude product over silica using 2:3 hexane/THF as eluent gave [$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] as a purple powder (34 mg, 30%). Crystals were grown by slow diffusion of hexane into a saturated solution of [$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] in THF.

[$Os_2Ru(CO)_{10}$(MeCN)$_2$]: IR (CH_2Cl_2): $\tilde{\nu}$ [ν(CO)] = 2079 (w), 2019 (vs), 1984 (s), 1958 (m) cm^{-1}.

[$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] (3): IR (THF): $\tilde{\nu}$ [ν(CO)] = 2082 (m), 2028 (vs), 2002 (vs), 1990 (s), 1979 (s), 1962 (m), 1956 (sh), 1907 (w) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 293 K) {for numbering scheme see Figure 1; asterisks denote signals due to [$Os_3(CO)_{10}$(*i*Pr-AcPy)] (ca.10–15%)}: δ = 9.50* (d, 1 H), 9.23 (d, $^3J_{H,H}$ = 4.5 Hz, 1 H, H^6), 8.04 (d, $^3J_{H,H}$ = 8.1 Hz, 1 H, H^3), 8.02* (d, 1 H), 7.91 (dd, $^3J_{H,H}$ = 8.1, $^3J_{H,H}$ = 7.5 Hz, 1 H, H^4), 7.86* (dd, 1 H), 7.25 (dd, $^3J_{H,H}$ = 7.5, $^3J_{H,H}$ = 5 Hz, 1 H, H^5), 7.11* (dd, 1 H), 4.44* (m, 1 H), 3.73 (m, 1 H, C*H*(CH_3)$_2$), 2.66 (s, 3 H, N=C–C*H*$_3$), 1.40 [d, $^3J_{H,H}$ = 4.8 Hz, 6 H, CH(C*H*$_3$)$_2$] ppm. MS (FAB^+): m/z = 986.9 $[M + H]^+$–CO (M = [$Os_3(CO)_{10}$(*i*Pr-AcPy)]), 957.9 $[M + H]^+$ – 2CO (M = [$Os_3(CO)_{10}$(*i*Pr-AcPy)]), 925.91 $[M + H]^+$ (M = [$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)]) (calcd. 925.89), $[M + H]^+$–*n*CO (n = 1–10) (M = [$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)]).

X-ray Crystal Structure Determinations of Clusters 2 and 3: Intensities were measured with a Nonius KappaCCD diffractometer with rotating anode (Mo-K_α, λ = 0.71073 Å) at a temperature of 150(2) K up to a resolution of ($\sin\theta/\lambda$) = 0.65 $Å^{-1}$. The structures were solved with Patterson methods (DIRDIF-97)[71] and refined with the programme SHELXL-97[72] against F^2 of all reflections. Non-hydrogen atoms were refined freely with anisotropic displacement parameters, and hydrogen atoms as rigid groups. The drawings, structure calculations, and checking for higher symmetry were performed with the programme PLATON.[73] The ruthenium sites in both structures were partially occupied by osmium atoms. The ruthenium and the corresponding osmium atoms were constrained to the same coordinates and the same anisotropic displacement parameters. Then the partial occupancies were refined with the criterion that the total occupancy remains 1.0.

[$Os_2Ru(CO)_{11}(PPh_3)$] (2): $C_{29}H_{15}O_{11}Os_{2.36}PRu_{0.64}$; Fw = 1083.94; yellow plates, 0.36 × 0.21 × 0.12 mm^3; monoclinic, space group $C2/c$ (no. 15); cell parameters: a = 21.9824(1), b = 16.0859(1) Å, c = 17.2605(1) Å; β = 103.7064(3)°; V = 5929.62(6) $Å^3$; Z = 8; ρ = 2.428 g cm^{-3}; F(000) = 3996; 55381 reflections were measured, 6811 reflections were unique (R_{int} = 0.0519). An analytical absorption correction was applied (μ = 10.526 mm^{-1}, 0.08–0.39 transmission). 398 Refined parameters, no restraints. R (obsd. refl.): R_1 = 0.0196, wR_2 = 0.0425. Residual electron density between –0.92 and 0.75 e/$Å^3$.

[$Os_2Ru(CO)_{10}$(*i*Pr-AcPy)] (3): $C_{20}H_{14}N_2O_{10}Os_{2.11}Ru_{0.89}$; Fw = 933.61; red needles, 0.39 × 0.03 × 0.03 mm^3; monoclinic, space group $P2_1/c$ (no. 14); cell parameters: a = 9.1117(1), b = 13.9915(1) Å, c = 20.7504(2) Å; β = 113.6862(4)°; V = 2422.54(4) $Å^3$; Z = 4; ρ = 2.560 g cm^{-3}; F(000) = 1710. 43532 reflections were measured, 5551 reflections were unique (R_{int} = 0.0740). An analytical absorption correction was applied (μ = 11.644 mm^{-1}, 0.20–0.78 transmission). 320 refined parameters, no restraints. R (obsd. refl.): R_1 = 0.0277, wR_2 = 0.0419. R (all data): R_1 = 0.0510, wR_2 = 0.0460. Weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0147P)^2]$, where $P = (F_o^2 + 2F_c^2)/3$. GoF = 0.996. Residual electron density between –0.95 and 1.01 e/$Å^3$.

CCDC-258240 (for **2**) and -258241 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Spectroscopic Measurements: Electronic absorption spectra were recorded with a Hewlett–Packard 8453 diode-array spectrophotometer and FT-IR spectra with a Bio-Rad FTS-7 (16 scans at 2 cm^{-1} resolution) spectrometer. Rapid-scan FT-IR spectra were measured with a Bio-Rad FTS-60A spectrometer (equipped with a dual-source rapid-scan 896 interferometer and a liquid-nitrogen cooled MCT detector) after excitation of the sample by the 514.5 nm line of a Spectra Physics Model 2016 argon-ion laser. ^1H and $^{31}P\{H\}$ NMR spectra were recorded with a Bruker AMX 300 spectrometer. Field Desorption (FD), Fast Atom Bombardment (FAB) and Electron Impact (EI) mass spectra were collected with a JEOL JMS SX/SX102A four-sector mass spectrometer. For synthetic purposes, a Philips HPK 125-W high-pressure Hg lamp, equipped with appropriate cut-off filters to select the desired wavelength region, served as a light source.

Photochemistry: All photochemical samples were prepared under nitrogen, using standard inert-gas techniques, and cluster concentrations typically between 10^{-3}–10^{-4} mol·dm^{-3}. Nanosecond transient absorption (ns TA) spectra were obtained by irradiating the samples with 2 ns pulses of the 532 nm line (typically 5 mJ $pulse^{-1}$) of a tunable (420–710 nm) Coherent Infinity XPO laser and using a high-power EG&G FX-504 Xe lamp as probe light.[17] Nanosecond flash photolysis transient kinetics were measured by irradiating the sample with 7 ns (FWHM) pulses of a Spectra Physics GCR-3 Nd:YAG laser (10 Hz repetition rate) and using a pulsed Xe lamp perpendicular to the laser beam as probe light. The excitation wavelength in this case (532 nm) was obtained by frequency doubling. The 450-W Xe lamp was equipped with a Müller Electronik MSP05 pulsing unit, giving pulses of 0.5 ms. A shutter, placed between the lamp and the sample, was opened for 10 ms to prevent photomultiplier fatigue. Suitable pre- and post-cut-off filters and band-pass filters were used to minimize both the probe light and scattered light from the laser. The sampling rate was kept at a relatively long time (10 s intervals) to prevent accumulation of possible photo-induced intermediates. The light was collected in an Oriel monochromator, detected by a P28 PMT (Hamamatsu), and recorded with a Tektronix TDS3052 (500 MHz) oscilloscope. The laser oscillator, Q-switch, lamp, shutter and trigger were externally controlled with a home made digital logic circuit, which allowed for synchronous timing. The absorption transient were plotted as $\Delta A = \log(I_t/I_0)$ vs. time, where I_0 is the monitoring light intensity prior to the laser pulse and I_t is the observed signal at delay time t.

Picosecond transient absorption (ps TA) spectra were recorded using the set-up installed at the University of Amsterdam.[16] Part of the 800 nm output of a Ti-sapphire regenerative amplifier (1 kHz, 130 fs, 1 mJ) was focussed into a H_2O flow-through cell (10 mm; Hellma) to generate white light. The residual part of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

800 nm fundamental was used to provide 505 nm (fourth harmonic of the 2020 OPA idler beam) excitation pulses with a general output of 5 μJ pulse^{-1}. After passing through the sample, the probe beam was coupled into a 400 μm optical fibre and detected by a CCD spectrometer (Ocean Optics, PC2000). The chopper (Rofin Ltd., f = 10–20 Hz), placed in the excitation beam, provided I and I_0, depending on the status of the chopper (open or closed). The excited state spectra were obtained by $\Delta A = \log(I/I_0)$. Typically two thousand excitation pulses were averaged to obtain the transient at a particular time delay.

Electrochemistry: Cyclic voltammograms (CV) of approximately 10^{-3} M parent cluster in 10^{-1} M Bu_4NPF_6 electrolyte solution were recorded in a gas-tight, single-compartment, three-electrode cell equipped with platinum microdisc (apparent surface 0.42 mm^2) working, coiled platinum wire auxillary and silver wire pseudo-reference electrodes. The cell was connected to a computer-controlled PAR Model 283 potentiostat. All redox potentials are reported against the ferrocene-ferrocenium (Fc/Fc^+) redox couple.[74,75] IR spectroelectrochemical measurements at variable temperatures were performed with previously described optically transparent thin-layer electrochemical (OTTLE) cells[76,77] equipped with a platinum minigrid working electrode (32 wires/cm) and CaF_2 windows. The potential during these measurements was controlled by a PA4 potentiostat (EKOM, Czech Republic). In the spectroelectrochemical experiments, cluster concentrations of 5×10^{-3} mol·dm^{-3} were used.

Computational Details: All density functional theory (DFT) calculations[78] were carried out with the Amsterdam Density Functional (ADF2000) programme.[37–43] Vosko, Wilk and Nusair's local exchange correlation potential was used.[79] Gradient-corrected geometry optimizations[80,81] were performed, using the Generalized Gradient Approximation (Becke's exchange[82] and Perdew's correlation[83,84] functionals). Relativistic effects were treated by the ZORA method[85] The core orbitals were frozen for Ru ([1–4]s, [2–4]p, 3d), Os ([1–4]s, [2–4]p, [3–4]d), P ([1–2]s, 2p), and C, N, O (1s). Triple ζ Slater-type orbitals (STO) were used to describe the valence shells of H (1s), C and O (2s and 2p), P (3s and 3p), Ru (4d, 5s and 5p) and Os (4f, 5d, 6s). A set of polarization functions was added: H (single ζ, 2p, 3d), C, N, O (single ζ, 3d, 4f), P(single ζ, 3d, 4f), Ru (single ζ, 5p, 4f) and Os (single ζ, 6p, 5f). Full geometry optimizations were performed without any symmetry constraints on models based on the available crystal structures. The UV/Vis spectrum was calculated using the SWizard programme,[48] revision 3.7. The half-band widths, $\Delta_{1/2,I}$, were taken to be equal to 3000 cm^{-1}, the default value of the programme. Three-dimensional representations of the orbitals were obtained with Molekel.[86]

Time-dependent DFT (TD-DFT)[87–89] calculations in the ADF implementation were used to determine the excitation energies. In all cases the ten lowest singlet-singlet excitation energies were calculated using the optimized geometries.

Acknowledgments

A. Hearley (University of Cambridge, UK) is gratefully acknowledged for valuable discussions regarding the synthesis of [$Os_2Ru(CO)_{12}$]. This work was undertaken as part of the European collaborative COST project (D14/0001/99). Financial support was received by F. W. V. and F. H. from the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO, project No. 348–032).

Preparation and Characterization of Co^{II}, Ni^{II}, and Zn^{II} Complexes of Sterically Demanding Hexaazamacrocyclic Dithiophenolates

Mathias Gressenbuch,[a] Vasile Lozan,[a] Gunther Steinfeld,[b] and Berthold Kersting*[a]

Keywords: Binding pockets / Macrocyclic ligands / Cobalt / Nickel / Zinc

N-Alkylated variants of a Robson-type 24-membered hexaazamacrocyclic dinucleating dithiophenolate ligand bearing ethyl and propyl groups have been prepared and their ligating properties towards the 3d elements Ni, Co and Zn have been examined. The new ligands support the formation of dinuclear complexes of the type $[(L^R)M^{II}_2(L')]^+$, i.e. $[(L^{Et})Ni_2(Cl)]^+$ (**7**), $[(L^{Pr})Ni_2(Cl)]^+$ (**8**), $[(L^{Et})Ni_2(OAc)]^+$ (**9**), $[(L^{Pr})Ni_2(OAc)]^+$ (**10**), $[(L^{Et})Ni_2(O_2COMe)]^+$ (**11**), $[(L^{Et})Ni_2(O_2COEt)]^+$ (**12**), $[(L^{Et})Zn_2(OAc)]^+$ (**14**), $[(L^{Et})Co_2(Cl)]^+$ (**17**), and $[(L^{Et})Co_2(OAc)]^+$ (**18**), the overall structures of which are very similar to the corresponding complexes of the parent permethylated ligand system. The use of the longer alkyl chains expands the binding pocket of the complexes to a more conical, "calixarene"-like cavity and has allowed for the isolation of the trication $[(HL^{Et})Ni_2]^{3+}$ (**13**), which is an intermediate in the substitution reactions of **7**. Complex **13** reveals a new coordination mode of the supporting ligand with adjacent four- and five-coordinate nickel atoms. Its higher stability is presumably a consequence of the increased steric crowding imposed by the longer alkyl chains of $(L^{Et})^{2-}$. These results have thus demonstrated that these highly functionalized ligand systems allow for the stabilization of reactive intermediates. This information can now be used as a guide to further modulate the chemical reactivity of these compounds.

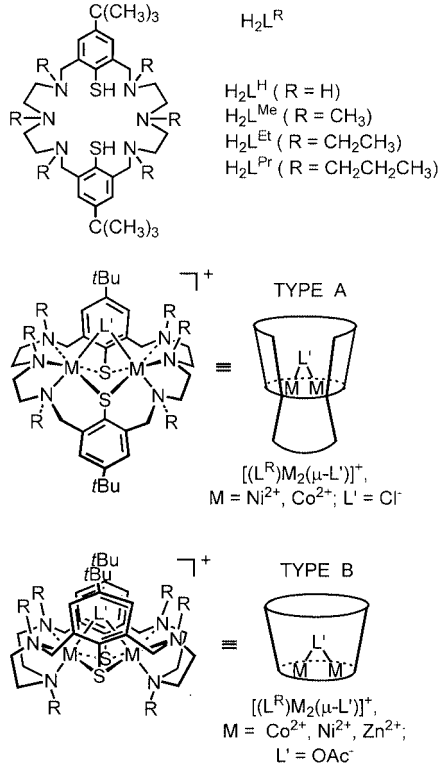
Introduction

Much effort is currently been invested in the design and development of supporting ligands for the construction of metal complexes with deep binding pockets.[1] Several suitable ligand systems have already been reported, as for instance the calixarenes,[2,3] the cyclodextrines[4,5] and some highly functionalized chelate ligands.[6,7] Recently, we reported that the Robson-type[8] macrocycles H_2L^H and its permethylated derivative H_2L^{Me} (see Scheme 1) can also be employed for this purpose.[9] Both ligands support the formation of $[(L^R)M_2(\mu\text{-}L')]^+$ complexes, whose ligand conformations are reminiscent of the "partial cone" and "cone" conformations of the calixarenes.

It has been observed that the binding pocket influences the coordination chemistry of the $[(L^R)M_2(\mu\text{-}L')]^+$ complexes significantly. For example, the substitution rates of the bridging coligands (L′) are drastically increased.[10] Likewise, it allows for the activation of small molecules such as carbon dioxide,[11] and it can mediate the course of substrate transformations as seen in the highly diastereoselective *cis*-bromination of α,β-unsaturated carboxylate coligands.[12]



Scheme 1. Structure of the ligands (H_2L^R) and schematic representation of the structures of their corresponding metal complexes $[(L^R)M_2(\mu\text{-}L')]^+$. The cavity representation of the ligands $(L^R)^{2-}$ should not be confused with the one used for cyclodextrins.

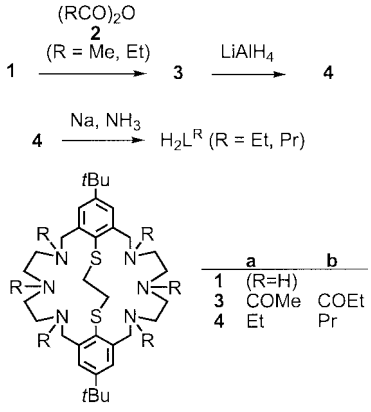
These results prompted us to expand the binding pocket of this versatile ligand system by using alkyl groups larger than methyl and to investigate the effect of this modification on the ligating properties. In this paper, we describe the synthesis and characterization of *N*-alkylated variants of H_2L^{Me} bearing ethyl and propyl groups in place of the methyl functions and report on their ligating properties towards the 3d elements Ni, Co and Zn (see Scheme 1 for abbreviations).

Results and Discussion

Ligand Synthesis

Two new derivatives of the parent hexaazamacrocyclic dithiophenolate H_2L^H with ethyl and propyl substituents were prepared in order to probe the influence of ligand structural variations on metal ion complexation and metal complex structures. For the bulkier ethyl and propyl derivatives a reaction sequence similar to that used for the alkylation of triazacyclononane[13] and cyclam[14] was used. The syntheses began with the acylation of known amine **1**,[15] with the anhydrides **2** (Scheme 2). The resulting amides **3** were then reduced with lithium aluminium hydride in refluxing THF solution to give the corresponding amines **4**. The thioether functions of the latter compounds were deprotected in the usual way[16] with sodium in liquid ammonia to afford the desired ligands which could be readily isolated as hydrochloride salts H_2L^R·6HCl (R = Et, Pr). All new compounds were characterized by elemental analysis, IR, ^1H and ^{13}C NMR spectroscopy. The hydrochloride salts of the ligands could not be obtained in analytically pure form. However, they were of sufficient purity for metal complex syntheses.



Scheme 2. Preparation of the ligands H_2L^{Et} and H_2L^{Pr}.

Synthesis of Complexes

The synthesized compounds and their labels are collected in Table 1. Of these, the compounds $[(L^{Me})Ni^{II}_2(\mu\text{-Cl})]ClO_4$ (**5**·ClO_4) and $[(L^{Me})Ni^{II}_2(\mu\text{-OAc})]ClO_4$ (**6**·ClO_4) were reported previously.[10,11] According to these procedures, the macrocycles H_2L^{Et} and H_2L^{Pr} were allowed to react with $NiCl_2$·$6H_2O$ and triethylamine in 1:2:8 molar ratios in methanolic solution according to Equation (1). In the case of the ethylated derivative H_2L^{Et}, the complexation reaction was complete after stirring at ambient temperature for 3 d. Upon addition of $LiClO_4$ to the bright yellow solution, yellow microcrystals of $[(L^{Et})Ni^{II}_2(\mu\text{-Cl})]ClO_4$ (**7**·ClO_4) could be obtained in 82% yield. The propylated ligand H_2L^{Pr} reacted similarly, generating the yellow species $[(L^{Pr})Ni^{II}_2(\mu\text{-Cl})]ClO_4$ (**8**·ClO_4), but stirring for 1 week was necessary to obtain it in comparable yields. In this respect, the two new ligands contrast the sterically less bulky ones which form dinuclear species more quickly. Characterization by elemental analysis, IR and UV/Vis spectroscopy {previously reported for $[(L^{Me})Ni^{II}_2(\mu\text{-Cl})]ClO_4$ (**5**·ClO_4)} are indicative of analogous bioctahedral structures of type A for these chloro-bridged compounds.

15	$[(L^{Me})Co^{II}_2(\mu\text{-Cl})]^+$	A [3.180]	[9b]
16	$[(L^{Me})Co^{II}_2(\mu\text{-OAc})]^+$	B [3.448]	[9b]
17	$[(L^{Et})Co^{II}_2(\mu\text{-Cl})]^+$	A[b]	this work
18	$[(L^{Et})Co^{II}_2(\mu\text{-OAc})]^+$	B [3.482]	this work

[a] The complexes were isolated as ClO_4^- or BPh_4^- salts. [b] The experimentally determined structures of **5** and **15** suggest that complexes **7**, **8** and **17** adopt the form A. [c] The experimentally determined structures of **10** and **12** suggest that complexes **9** and **11** adopt the form B.

The bridging halide ions in complexes **7** and **8** proved quite labile. Thus, the reactions of the respective $[(L)Ni_2(\mu\text{-Cl})]^+$ cations with sodium acetate proceeded smoothly and yielded green solutions, from which green crystals of $[(L^{Et})Ni_2(\mu\text{-OAc})]ClO_4$ (**9**·ClO_4) and $[(L^{Pr})Ni_2(\mu\text{-OAc})]ClO_4$ (**10**·ClO_4) were obtained in good yields [Equation (2)]. Later studies revealed that the same compounds can also be directly synthesized from the respective ligands and $Ni(OAc)_2$·$6H_2O$.

$$[(L^{Et})Ni_2(\mu\text{-}Cl)]^+ \xrightarrow[MeOH]{NaOAc} [(L^{Et})Ni_2(\mu\text{-}OAc)]^+$$
7 **9**

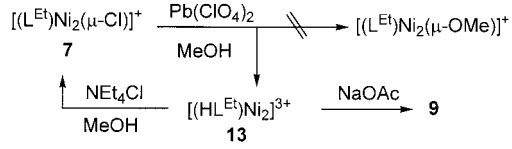
$$[(L^{Pr})Ni_2(\mu\text{-}Cl)]^+ \xrightarrow[MeOH]{NaOAc} [(L^{Pr})Ni_2(\mu\text{-}OAc)]^+$$
8 **10** (2)

The methyl carbonate species **11** and its corresponding ethyl carbonate derivative **12** represent two further examples of nickel complexes of the ethylated macrocycle. Compound **11** was obtained by a carbonation reaction of the green μ-hydroxo species $[(L^{Et})Ni^{II}_2(\mu\text{-}OH)]^+$ (prepared in situ from **7** and sodium hydroxide; Equation (3)] and isolated as the pale-green perchlorate salt **11**·ClO_4 in 88% yield. The conversion of the methyl carbonate complex **11** into the ethyl carbonate species **12** was accomplished by a transesterification reaction with neat ethanol [Equation (4)]. Similar transformations were previously observed for the nickel complex **5** of the permethylated macrocycle. Thus, the rate of the substitution reactions and the ability to fix small molecules is not drastically altered by the longer alkyl chains.

$$[(L^{Et})Ni_2(\mu\text{-}Cl)]^+ \xrightarrow[\text{2. Air } (CO_2),\ MeOH\ \text{r.t., 24h, > 95\%}]{\text{1. NaOH}} [(L^{Et})Ni_2(\mu\text{-}O_2COMe)]^+$$
7 **11** (3)

$$[(L^{Et})Ni_2(\mu\text{-}O_2COMe)]^+ \xrightarrow[\text{r.t., 12h, > 95\%}]{EtOH} [(L^{Et})Ni_2(\mu\text{-}O_2COEt)]^+$$
11 **12** (4)

The compound $[(HL^{Et})Ni^{II}_2]^{3+}$ (**13**) formed rather unexpectedly during attempts to prepare a methanolato-bridged complex $[(L^{Et})Ni^{II}_2(\mu\text{-}OMe)]^+$ (Scheme 3). Instead of the anticipated compound the dark-green trication **13** was obtained. It could be isolated as the triperchlorate salt **13**·$(ClO_4)_3$ but only in low yield. This compound differs from the ones above in several respects. It bears no coligands, reveals a central $N_2Ni(\mu\text{-}S)_2NiN_3$ core structure with adjacent four- and five-coordinate Ni^{II} ions and shows one protonated (non-coordinating) amine function (see below). It reacts readily with Et_4NCl to regenerate the parent complex **7**, and produces the acetato-bridged compound **9** upon addition of sodium acetate (Scheme 3). Recall that **7** is a type A species whereas **9** is of the kind B. The reaction in Equation (2) therefore involves a conformational change of the macrocycle from A to B. It can be shown that this requires an inversion of the configurations of the tertiary nitrogen donor atoms; however, this can only proceed by dissociation of the metal–nitrogen bonds. The crystal structure of **13** reveals such non-coordinating nitrogen donor atoms. Thus, **13** is presumably an intermediate in the above substitution reactions [e.g. Equation (2)]. All attempts to isolate the analogous compound of the permethylated macrocylce have failed.[17] Therefore, the isolation of **13** can be traced back to the sterically more demanding ethyl functions. As we will show below, the use of H_2L^{Et} in place of H_2L^{Me} results in restricted access to the two metal ions which are buried inside a sterically more encumbered cavity. This clearly shows that these highly functionalized macrocycles allow for the stabilization of reactive intermediates.



Scheme 3. Preparation and reactions of **13**.

To obtain some preliminary information on the solution structures, the synthesis of diamagnetic zinc complexes was devised next. The acetato-bridged dizinc complex **14** was obtained by the direct reaction of H_2L^{Et}·6HCl with $Zn(OAc)_2$·$2H_2O$ and triethylamine in methanol [Equation (5)]. Attempts to prepare a chloro-bridged complex such as $[(L^{Et})Zn^{II}_2(\mu\text{-}Cl)]^+$ were unsuccessful.

$$H_2L^{Et}\cdot 6HCl \xrightarrow[8\ NEt_3,\ MeOH]{2\ Zn(OAc)_2\cdot 2H_2O} [(L^{Et})Zn_2(\mu\text{-}OAc)]^+$$
14 (5)

The two Co^{II} complexes **17** and **18** represent the last two compounds of this study. These were prepared according to Equations (6) and (7). Both cations were isolated as their perchlorate salts in 83% and 74% yield, respectively. The structures of complexes $[(L^{Me})Co^{II}_2(\mu\text{-}Cl)]^+$ (**15**) and $[(L^{Me})Co^{II}_2(\mu\text{-}OAc)]^+$ (**16**) have previously been shown to be of type A and B, respectively.[18] On the basis of spectroscopic similarities (vide infra), analogous structures are likely for the complexes supported by H_2L^{Et}. This is confirmed by an X-ray crystal structure determination of $[(L^{Et})Co^{II}_2(\mu\text{-}OAc)]BPh_4$ (**18**·BPh_4, see below).

$$H_2L^{Et}\cdot 6HCl \xrightarrow[8\ NEt_3,\ MeOH]{2\ CoCl_2\cdot 6H_2O} [(L^{Et})Co_2(\mu\text{-}Cl)]^+$$
17 (6)

$$[(L^{Et})Co_2(\mu\text{-}Cl)]^+ \xrightarrow[MeOH]{NaOAc} [(L^{Et})Co_2(\mu\text{-}OAc)]^+$$
17 **18** (7)

All new complexes are stable in air both in solution and in the solid state. The perchlorate salts are very soluble in a range of common polar organic solvents (CH_3CN, EtOH, MeOH). The complexes with the longer alkyl chains also exhibit some solubility in apolar solvents such as cyclohexane or toluene. The new compounds gave satisfactory elemental analyses and were characterized by spectroscopic methods (IR, UV/Vis, ^1H and ^{13}C NMR spectroscopy) and compounds **10**·ClO_4, **12**·BPh_4, **13**·$(ClO_4)_3$, **14**·ClO_4, and **18**·BPh_4 also by X-ray structure analysis.

Spectroscopic Characterization

Infrared Spectroscopy

The infrared spectra of all compounds display the bands expected for the macrocyclic ligands, counterions, carboxylate or alkyl carbonate coligands.[19] Selected Infrared data are listed in Table 2. The ClO_4^- ion gives rise to a broad band at 1100 cm^{-1} which is normal for this counterion. The IR spectra of the acetato-bridged complexes **6**, **9**, **10**, **14**, **16**, and **18** are very similar. Each spectrum displays two strong bands around 1590 and 1430 cm^{-1}. These bands are associated with the asymmetric [$\nu_{asym}(OAc^-)$] and symmetric stretching modes [$\nu_{sym}(OAc^-)$] of the carboxylate coligands.[20] The similarities to the IR spectrum of the dinickel complex **6** are indicative of $\mu_{1,3}$-bridging acetate groups. The IR spectra of complexes **7**, **8**, **15**, and **17** lack these two bands, which is in good agreement with the formulation of the chloro-bridged $[(L^{Me})M_2(\mu\text{-}Cl)]^+$ cations. As can be seen in Table 2, the asymmetric and symmetric stretching modes of the alkyl carbonate complexes **11** and **12** are shifted to higher and lower frequencies, respectively, when compared with the corresponding values for the acetato-bridged compounds. This trend has also been observed for the carboxylate and alkyl carbonate complexes of the permethylated macrocycle.[11] We finally note that the methyl and ethyl carbonate complexes can be easily distinguished by their IR spectra [e.g. by the frequency of the $\nu_{sym}(O_2CR)$ stretching mode].

UV/Vis Spectroscopy

All new complexes were further characterized by UV/Vis spectroscopy. The electronic absorption spectra of the complexes were recorded in the 300–1600 nm range in acetonitrile solution. Selected spectroscopic data are reported in Table 2. The data for complexes **5**, **6**, **15**, and **16** have been reported previously and are included for comparative purposes.

The spectra of the nickel complexes are similar but not identical. Each compound displays two weak absorption bands. One appears in the 620–670 nm range, the other one is observed between 1000 and 1180 nm. These absorptions can be attributed to the d-d transitions ν_2 [$^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$] and ν_1 [$^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$], respectively, of an octahedral nickel(II) (d^8) ion. For the chloro-bridged compounds the ν_1 absorption is split presumably due to lower symmetry. The higher energy features below 400 nm (not listed in Table 2) result from π-π* transitions within the $(L^R)^{2-}$ ligands. The slight differences in the position of the d-d transitions indicate that each complex retains its integrity in solution. This is also supported by the NMR spectroscopic data described below for the zinc complex **14**.

As expected, the UV/Vis spectrum of the $[(HL^{Et})Ni^{II}_2]^{3+}$ trication **13** is different from the bioctahedral complexes above. The spectrum is dominated by an intense absorption band at 574 nm, which can be tentatively assigned to a d-d transition of the planar four-coordinate NiN_2S_2 chromophore. It is a typical value for complexes containing planar NiN_2S_2 units.[21] This intense absorption presumably obscures the weaker d-d transition bands of the five-coordinate NiN_3S_2 fragment.[22]

The electronic absorption spectra of the four cobalt(II) complexes are again very similar. Each compound reveals a weak band at ca. 1260 nm which can be readily assigned to the $^4T_{1g}(F) \rightarrow {}^4T_{2g}$ transition of an octahedral high-spin cobalt(II) ion.[23] Further absorption bands are observed in the 500–600 nm range. These bands are attributable to components of the parent octahedral ligand field transitions, $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ and $^4T_{1g}(F) \rightarrow {}^4A_{2g}$, split by lower symmetry. The more intense band at ca. 450 nm most probably arises from a thiolate-to-cobalt(II) charge transfer (LMCT) transition and the feature at ca. 350 nm from a π-π* transition within the $(L^R)^{2-}$ ligand. Again, these spectroscopic findings clearly show that the coligands remain attached to the cobalt ions in the solution state.

NMR Spectroscopy

The ^1H NMR spectrum of the acetato-bridged zinc complex **14** displays only one set of signals, indicative of a single isomer. The four aromatic protons (C^{Ar}) and the *tert*-butyl protons [$C(CH_3)_3$] appear as singlets, implying C_{2v} sym-

metry for the $[(L^{Et})Zn_2(\mu\text{-OAc})]^+$ cation (i.e. structure type B). This is further supported by the fact that the $[(L^{Et})Zn_2]^{2+}$ fragment gives rise to only 13 ^{13}C signals (9 for the aliphatic and 4 for the aromatic carbon atoms). The appearance of the ^1H NMR signals for the methyl protons of the bridging acetato coligand at δ = 0.85 ppm is also worth mentioning. This signal is shifted to high field when compared with free sodium acetate (δ = 1.83 ppm). This can be understood in terms of the ring current. As can be seen from Figure 3, the methyl protons of the acetate groups are positioned in the binding cavity of the $[(L^{Et})Zn_2]^{2+}$ fragment slightly above the center of the two phenyl rings in the shielding region. Similar findings have been observed for the $[(L^{Me})Zn^{II}(\mu\text{-OAc})]^+$ cation.[24] In summary, the spectroscopic data have clearly established that all complexes exist as discrete and stable species with similar "cone"- and "partial-cone"-like conformations of the macrocycles. Thus, with the exception of complex **13**, the ligating properties of the new ligands are not very different from the parent $(L^{Me})^{2-}$ and $(L^{H})^{2-}$ ligands.

X-ray Crystallography

The formulations of the new compounds were further confirmed by X-ray diffraction studies. Single crystals of X-ray quality were obtained for the perchlorate salts of **10**, **13**, and **14** and for the tetraphenylborate salts of **12** and **18**. Selected crystallographic data are listed in Table 4. The molecular structures of the complexes are displayed in Figures 1, 2, 3, 4 and 5, and selected bond lengths and angles are given in Table 3.

Description of the Structures of the Bioctahedral $[(L^R)M_2(\mu\text{-}O_2CR)]^+$ Complexes

The structures of the bioctahedral species **10**, **12**, **14**, and **18** will be discussed first. A common labeling scheme for the $[(L^{Me})M_2]^{2+}$ fragments has been used to facilitate structural comparisons. The structure of the cation $[(L^{Me})Ni_2^{II}(\mu\text{-OAc})]^+$ (**6**) has been reported previously, and its metrical parameters are also given for comparison.

Structure of the $[(L^R)M_2]^{2+}$ Fragment

It is appropriate to describe the structures of the $[(L^R)M_2]^{2+}$ fragments first. The macrocycles adopt the conformation of type B, previously reported for the acetato-bridged complex **6** (Scheme 1).[11] In each case, the two metal ions are coordinated in a square-pyramidal fashion by the two *fac*-$N_3(\mu\text{-}S)_2$ donor sets of the doubly deprotonated macrocycles. The coordination of the exogenous coligands generates distorted octahedral environments for the metal ions. The metrical parameters of the central $N_3M(\mu\text{-}S)_2(\mu\text{-}O_2CR)MN_3$ cores are very similar (see Table 3). The diethylenetriamine units are *fac*-coordinated with one larger and two smaller N–M–N bond angles, which is most commonly observed in complexes with this tridentate unit.[25] Likewise, the M–N bonds involving the four benzylic nitrogen donors are invariably longer (by ca. 0.1 Å) than the ones comprising the central nitrogen atoms of the linking diethylenetri-

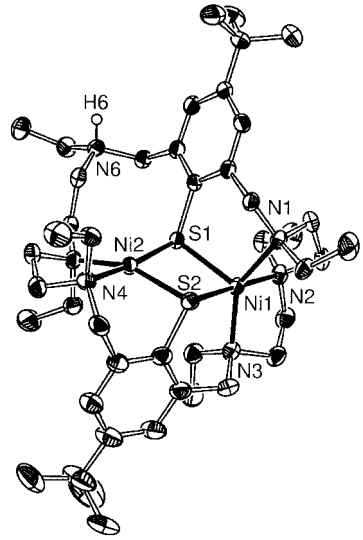

Figure 5. Structure of the dinickel complex **13** with thermal ellipsoids drawn at the 30% probability level. Only one orientation of the disordered *tert*-butyl and the *N*-propyl group is displayed. Selected bond lengths [Å] and angles [°]: Ni(1)···Ni(2) 3.319; Ni(1)–N(1) 2.051(3), Ni(1)–N(2) 2.138(3), Ni(1)–N(3) 2.060(3), Ni(1)–S(1) 2.2911(11), Ni(1)–S(2) 2.4065(13), Ni(2)–N(4) 1.991(3), Ni(2)–N(5) 1.997(3), Ni(2)–S(1) 2.2140(13), Ni(2)–S(2) 2.2129(12); N(5)–Ni(2)–S(2) 157.83(10), N(4)–Ni(2)–S(1) 171.76(10), N(2)–Ni(1)–S(2) 176.86(9), N(1)–Ni(1)–S(1) 100.57(9), N(3)–Ni(1)–S(1) 113.77(10), N(1)–Ni(1)–N(3) 145.55(12).

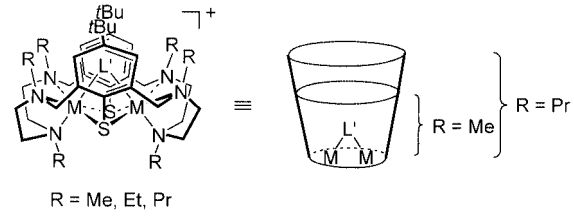

Scheme 4. Schematic representation of the expansion of the binding pocket of the $[(L^R)M_2(L')]^+$ complexes upoing going from the methylated (R = Me) to the propylated ligand system (R = Pr).

amine units. This is also normal for carboxylato-bridged structures of this ligand system {e.g. $[(L^{Me})M_2(\mu\text{-OAc})]^+$, M = Co^{II}, Ni^{II}, and Zn^{II}}. Hence, the differences in the metal–nitrogen bond lengths are due to steric constraints of the macrocycles.

Cavity Dimensions

As can be seen from Scheme 4, the four alkyl residues on the four benzylic nitrogen atoms align with the two phenyl rings. Thus, upon going from the methylated derivative to the *N*-propylated macrocycle the binding pocket of the $[(L^R)M_2]^{2+}$ fragment expands to a sterically more encumbered, conical, calixarene-like cavity as schematically illustrated in Scheme 4.

The dimensions of the binding cavities of the $[(L^{Me})M_2]^{2+}$ fragments can be described by the intramolecular distances between the two opposing aryl ring carbon atoms bearing the *tert*-butyl groups [e.g. the diameter of the pocket entrance, see for example, C(4)···C(26) in **10**]. The values range from 9.265 to 9.891 Å (Table 3). Two trends are apparent. Firstly, the diameter increases with increasing length of the *N*-alkyl residues (e.g. compare **6** with **10**). Secondly, the distances increase with increasing steric bulk of the coligand with this latter trend being the more important one (e.g. compare **10** with **12**). This is indicative of intramolecular steric repulsions between the residues of the bowl-shaped hosts and their guests.

Binding Mode of the Coligands

As expected, the acetate and ethyl carbonate coligands bind to the $[(L^{Me})M_2]^{2+}$ fragment as bidentate $\mu_{1,3}$-bridges. Consequently, the M···M separations are almost equidistant in these three compounds [average value is 3.491(1) Å]. The average metal–ligand bond lengths show no unusual features and compare well with those in **6**.

Description of the Crystal Structure of [(HL^{Et})Ni$_2$](ClO$_4$)$_3$·3MeOH·H$_2$O [13·(ClO$_4$)$_3$·3MeOH·H$_2$O]

This salt crystallizes in the triclinic space group $P\bar{1}$. The structure revealed the presence of discrete dinuclear $[(HL^{Et})Ni_2]^{3+}$ trications, perchlorate anions, and methanol and water molecules of solvent of crystallization. As can be seen in Figure 5, this complex bears no coligands and features two differently coordinated nickel atoms. One nickel atom is coordinated in a distorted planar fashion by two *cis*-oriented nitrogen atoms and two bridging thiophenolate sulfur atoms. The other nickel ion is five-coordinate. The protonated amine donor N(6) is out of range of bonding interactions with the metal atoms and points away from them.

The coordination geometry of the four-coordinate nickel ion is significantly distorted from square-planar towards tetrahedral, as indicated by an N–Ni–N/S–Ni–S dihedral angle of 23.80(2)° (mean deviation from plane 0.238 Å). This is a rather large distortion from planarity. Other nickel complexes with N_2S_2 coordination environments are more rigorously square-planar, the tetrahedral twists from the NiN_2S_2 planes not exceeding 15°.[26,27]

The coordination environment around the five-coordinate nickel atom is distorted trigonal-bipyramidal with S(1), N(1) and N(3) occupying the equatorial and S(2) and N(2) the axial positions. The angles in the equatorial plane deviate by as much as 25.6° [N(1)–Ni(1)–N(3)] from the ideal values of a perfect trigonal bipyramid. The average Ni–N and Ni–S distances of 2.083 and 2.349 Å are shorter than in the above bioctahedral species but compare well with those reported for [Ni^{II}(terpy)(S-2,4,6-(*i*Pr)$_3$C$_6$H$_2$)$_2$] (terpy = 2,2′,2″-terpyridine; Ni–N 2.057 Å, Ni–S 2.303 Å)[28] and other trigonal-bipyramidal $Ni^{II}N_3S_2$ complexes.[29] The metal–ligand bonds involving the equatorial donor atoms are shorter than the ones comprising the axial ones; an exactly analogous situation is found in the terpy complexes. As a consequence of the shorter metal–ligand bonds, the metal···metal separation is smaller at 3.319 Å. Finally, it should be noted that the two nickel(II) ions are almost completely surrounded by the apolar *N*-ethyl substituents from the macrocycle. This steric crowding about the coordinatively unsaturated dinickel site might explain its higher stability {relative to the very unstable $[(HL^{Me})Ni_2]^{3+}$ trication of the permethylated macrocycle}.

Summary and Conclusion

The following are the main findings of this investigation. a) *N*-Alkylated variants of H_2L^{Me} bearing ethyl and propyl groups in place of the methyl functions can be readily prepared by acylation of the parent hexaamine–dithioether compound **1** followed by reduction of the amide and thioether functions. b) The new ligands support the formation of dinuclear complexes of the type $[(L^R)M_2(\mu\text{-}L')]$ with a bowl-shaped structure. c) The binding pocket of the complexes expands to a more conical, "calixarene"-like cavity upon going from the permethylated to the perpropylated ligand system. d) The rate of the substitution reactions and the ability to fix small molecules is not drastically altered by the longer alkyl chains. e) Finally, it has been demonstrated that these highly functionalized ligand systems allow

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for the stabilization of reactive intermediates. These findings can now be used as a guide to further modulate the chemical reactivity of these compounds.

Experimental Section

Materials and Methods: Compound **1** was prepared as described in the literature.[9] All syntheses were carried out under argon. Melting points were determined in open glass capillaries and are uncorrected. NMR spectra were recorded with a Bruker AVANCE DPX-200 spectrometer at 300 K. Chemical shifts refer to solvent signals. Infrared spectra were recorded with a Bruker VECTOR 22 FT-IR spectrometer and electronic absorption spectra with a Jasco V-570 UV/VIS/NIR spectrometer. Elemental analyses were carried out with a VARIO EL elemental analyzer. ***CAUTION:*** *Perchlorate salts are potentially explosive and should therefore be prepared only in small quantities and handled with appropriate care!*

Compound 3a: A solution of **1** (9.44 g, 15.4 mmol) in acetic anhydride (90 mL) was stirred at 50 °C for 6 h. After the solvent was distilled off at reduced pressure, the residue was taken up in aqueous potassium hydroxide solution (3 M, 100 mL) and dichloromethane (100 mL). The layers were separated and the aqueous phase was extracted with dichloromethane (3 × 50 mL). The combined organic layers were washed with water (50 mL) and dried with anhydrous sodium sulfate. Evaporation of the solvent gave **3a** as a white solid (13.1 g, 98%). M.p. 236 °C. This material was used in the next step without further purification. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.06–1.26 [m, 18 H, ArC(CH_3)$_3$], 1.94–2.23 (m, 18 H, NCOCH_3), 2.82–3.35 (m, 20 H, NCH_2CH_2 and SCH_2), 4.47–4.74 (m, 8 H, ArCH_2), 6.91–7.10 (m, 4 H, Ar*H*) ppm. IR (KBr): $\tilde{\nu}$ = 3456 m, 2963 s, 2871 w, 1652 vs, ν(CO), 1559 vw, 1474 m, 1418 s, 1363 m, 1313 vw, 1238 w, 1195 w, 1131 vw, 1094 vw, 1062 vw, 1035 vw, 988 vw, 950 vw, 878 vw, 603 w cm^{-1}. $C_{46}H_{68}N_6O_6S_2$·CH_3CO_2H (865.19 + 60.05): calcd. C 62.31, H 7.99, N 9.52, S 7.26; found C 62.33, H 8.79, N 9.23, S 6.66.

Compound 4a: A solution of **3a** (8.65 g, 10.0 mmol) in tetrahydrofuran (50 mL) was added dropwise to a suspension of lithium aluminium hydride (4.55 g, 120 mmol) in tetrahydrofuran (200 mL). The reaction mixture was refluxed for 12 h. To the hot reaction mixture was added water (10 mL) in small portions followed by 3 M aqueous potassium hydroxide solution (30 mL). Care should be taken during this step because of the violent reaction. The reaction mixture was refluxed for an additional hour to ensure complete hydrolysation of the aluminum salts. After cooling to room temperature, the organic layer was decanted from a white residue. This residue was extracted with boiling tetrahydrofuran (3 × 100 mL). The combined organic layers were dried with anhydrous sodium sulfate. Evaporation of the solvent gave the title compound as a yellowish oil which was used in the next step without further purification (6.80 g, 87%). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 0.85–1.00 (m, 18 H, NCH$_2$CH_3), 1.23 [s, 18 H, ArC(CH_3)$_3$], 2.29–2.55 (m, 28 H, NCH_2CH$_3$ and NCH_2CH_2N), 2.70 (s, 4 H, SCH_2), 3.62 (s, 8 H, ArCH_2N), 7.41 (s, 4 H, Ar*H*) ppm. ^{13}C{^{1}H}NMR (50 MHz, $CDCl_3$): δ = 13.6, 13.8 (CH_3), 32.5 [ArC(*C*H$_3$)$_3$], 35.8 [Ar*C*(CH$_3$)$_3$], 37.0 (ArS*C*H$_2$), 49.0 (CH_2), 51.0 (CH_2), 52.3 (CH_2), 53.0 (CH_2), 58.7 (CH_2), 125.8 (CH), 129.1 (C^{Ar}), 145.0 (C^{Ar}), 152.1 (C^{Ar}) ppm. IR (Nujol): $\tilde{\nu}$ = 3417 m, 2964 vs, 2869 s, 2809 s, 2354 vw, 2327 vw, 1730 vw, 1713 vw, 1691 vw, 1659 vw, 1642 vw, 1631 vw, 1600 w, 1555 vw, 1513 vw, 1463 m, 1383 m, 1363 m, 1292 w, 1262 s, 1223 w, 1173 w, 1096 s, 1073 s, 865 vw, 802 s, 710 vw, 663 vw cm^{-1}.

Compound H_2L^{Et}·6HCl: To a solution of sodium (3.45 g, 150.0 mmol) in liquid ammonia (150 cm^3) was added a solution of compound **4a** (3.91 g, 5.00 mmol) in tetrahydrofuran (50 cm^3) dropwise at –78 °C. The resulting blue reaction mixture was stirred at –78 °C for one additional hour to ensure complete deprotection of the macrocycle. Solid ammonium chloride was added in small portions at –78 °C to destroy excess reducing agent. The resulting colourless suspension was allowed to warm to room temperature. After 12 h, the remaining solvent was distilled off at reduced pressure. The residue was taken up in water (50 mL) and the pH of the suspension adjusted to ca. 1 to give a pale-yellow solution of H_2L^{Et} as the hexahydrochloride salt. To remove the inorganic salts, the solution was concentrated in vacuo to a volume of about 20 mL. Methanol (ca. 60 mL) was then added and the resulting solution was filtered from NaCl and NH_4Cl. The latter two steps were repeated several times in this order, until no more salts precipitated upon addition of MeOH. A 100-mL portion of ethanol was then added. Upon standing for 1–2 h, the product precipiated as a pale-yellow solid (2.82 g, 58%). ^{1}H NMR (200 MHz, D_2O): δ = 1.29 [s, 18 H, ArC(CH_3)$_3$], 1.39 (m, 18 H, CH$_2$CH_3), 3.33 (m, 12 H, CH_2CH$_3$), 3.75–3.90 [m, 16 H, N(CH_2CH_2)$_2$], 4.59 (s br, 8 H, ArCH_2N), 7.56 (s, 4 H, Ar*H*) ppm. ^{13}C{^{1}H} NMR (50 MHz, D_2O): δ = 9.09 (CH_3), 9.21 (CH_3), 31.49 [ArC(*C*H$_3$)$_3$], 34.90 [Ar*C*(CH$_3$)$_3$], 47.41 (CH_2), 48.73 (CH_2), 50.19 (CH_2), 50.39 (CH_2), 59.44 (CH_2), 131.74 (CH), 132.00 (C^{Ar}), 147.00 (C^{Ar}), 149.00 (C^{Ar}) ppm. This compound was pure enough for the preparation of the metal complexes. IR (KBr:) $\tilde{\nu}$ = 3407 vs, 2962 vs, 2624 vs, 1690 s, 1630 m, 1451 vs, 1400 vs, 1231 m, 1161 s, 1031 s, 898 vs, 801 vs, 565 vs cm^{-1}.

Compound 3b: The preparation of this compound was analogous to that of **3a**, except that propionic anhydride was used instead of acetic anhydride. **3b** was obtained as a white solid (8.92 g, 94%). M.p. 170–176 °C. This product was used in the next step without further purification. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.17 (m, 18 H, NCOCH$_2$CH_3), 1.25–1.36 [m, 18 H, ArC(CH_3)$_3$], 2.70 (m, 12 H, NCOCH_2CH$_3$), 3.06–3.68 [m, 20 H, N(CH_2CH_2N)$_2$ + ArSCH_2], 4.90 (s, 8 H, ArCH_2N), 7.00–7.06 (m, 4 H, Ar*H*) ppm. IR (KBr): $\tilde{\nu}$ = 3441 w, 2967 m, 2939 m, 2876 w, 1724 vw, 1648 vs, 1563 vw, 1468 s, 1421 s, 1378 w, 1364 w, 1198 m, 1184 m, 1120 vw, 1079 w, 1052 w, 970 vw, 879 vw, 815 vw, 726 vw, 683 vw, 573 vw, 535 vw cm^{-1}. $C_{52}H_{80}N_6O_6S_2$ (949.36): calcd. C 65.79, H 8.49, N 8.85, S 6.76; found C 65.02, H 8.52, N 8.28, S 6.16.

Compound 4b: The preparation of this compound was analogous to **3b**. Compound **4b** was obtained as a yellowish oil which crystallized on standing. Recrystallization from ethanol gave 5.02 g (58%) of analytically pure material. M.p. 128 °C. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 0.77 (t, ^3J = 7.2 Hz, 18 H, NCH$_2$CH$_2$CH$_3$), 1.23 [s, 18 H, ArC(CH$_3$)$_3$], 1.14–1.40 (m, 12 H, NCH$_2$CH$_2$CH$_3$), 2.26 (t, ^3J = 7.2 Hz, 12 H, NCH$_2$CH$_2$CH$_3$), 2.48 (s, 16 H, NCH$_2$CH$_2$N), 2.63 (s, 4 H, ArSCH$_2$), 3.60 (s, 8 H, ArCH$_2$N), 7.45 (s, 4 H, ArH) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 75 MHz): δ = 12.3 (NCH$_2$CH$_2$CH$_3$), 21.2(NCH$_2$CH$_2$CH$_3$), 21.6 (NCH$_2$CH$_2$CH$_3$), 31.8 [ArC(CH$_3$)$_3$], 35.2 [Ar*C*(CH$_3$)$_3$], 35.7 (ArSCH$_2$), 51.5 (CH_2), 52.4 (CH_2), 56.1 (CH_2), 58.2 (CH_2), 59.2 (CH_2), 124.7 (CH), 127.7 (C^{Ar}), 144.2 (C^{Ar}), 151.4 (C^{Ar}) ppm. IR (KBr): $\tilde{\nu}$ = 2958 s, 2933 s, 2870 m, 2817 m, 1460 m, 1404 w, 1380 w, 1361 w, 1079 m, 893 w, 647 w cm^{-1}. $C_{52}H_{92}N_6S_2$ (865.46): C 72.16, H 10.71, N 9.71, S 7.41; found C 71.92, H 10.86, N 9.60, S 7.30.

Compound H_2L^{Pr}·6HCl: The preparation of this compound was analogous to H_2L^{Et}·6HCl, except that **4b** (4.32 g, 5.00 mmol) was used as the starting material. The hydrochloride was obtained as a pale-yellow solid (3.33 g, 63%). ^{1}H NMR (200 MHz, D_2O): δ =

0.71 (t, ^3J = 7.2 Hz, 18 H, $NCH_2CH_2CH_3$), 1.04 [s, 18 H, $C(CH_3)_3$], 1.60–1.35 (m, 12 H, $NCH_2CH_2CH_3$), 2.87 (m, 12 H, $NCH_2CH_2CH_3$), 3.44 (m, 16 H, NCH_2CH_2N), 4.30 (s, 8 H, $ArCH_2N$), 7.25 (s, 4 H, ArH) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, D_2O): δ = 10.4 (CH_3), 17.2 (CH_2), 17.4 (CH_2), 30.7 [$ArC(CH_3)_3$], 34.8 [$ArC(CH_3)_3$], 35.5 (CH_2), 47.3 (CH_2), 48.7 (CH_2), 56.0 (CH_2), 59.6 (CH_2), 61.9 (CH_2), 131.1 (CH), 134.3 (C^{Ar}), 147.9 (C^{Ar}), 158.4 (C^{Ar}) ppm. IR (KBr): $\tilde{\nu}$ = 3427 w, 2967 vw, 2878 w ν(CH), 2465 w, 1629 s ν(CO), 1471 w, 1384 m, 1364 m, 1300 s, 1200 m, 1150 m, 1051 s, 996 s, 967 s, 806 vs, 755 vs, 601 vs cm^{-1}. This compound was pure enough for the preparation of the metal complexes.

$[(L^{Et})Ni_2(Cl)]ClO_4$ (7·ClO_4): To a suspension of H_2L^{Et}·6HCl (974 mg, 1.00 mmol) in methanol (40 mL) was added a solution of $NiCl_2$·$6H_2O$ (475 mg, 2.00 mmol) in methanol (2 mL). A solution of Et_3N (810 mg, 8.00 mmol) in methanol (2 mL) was then added to give a dark red solution. After stirring at room temperature for 3 d, the product was precipitated by the addition of solid $LiClO_4$·$3H_2O$ (2.50 g, 15.6 mmol). The yellow microcrystalline solid was isolated by filtration, washed with 5 mL of cold ethanol and 5 mL of ether, and dried in vacuo. This material was recrystallized once from a few milliliters of acetonitrile. Yield: 824 mg (82%). M.p. 305 °C (decomp.). IR (KBr) $\tilde{\nu}$ = 3445 m, 2961 m, 2894 w, 2361 vw, 1631 w, 1460 m, 1381 w, 1100 vs $\nu(ClO_4^-)$, 912 w, 884 w, 778 w, 733 w, 627 m cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 384 (2070), 480 sh (430), 659 (30), 930 (53), 1026 nm (76 M^{-1} cm^{-1}). $C_{44}H_{76}Cl_2N_6Ni_2O_4S_2$ (1005.53): calcd. C 52.56, H 7.62, N 8.36, S 6.38; found C 52.40, H 7.47, N 8.42, S 6.49.

$[(L^{Pr})Ni_2(Cl)]ClO_4$ (8·ClO_4): The preparation of this compound was similar to that of **7**·ClO_4, except that the reaction mixture was stirred for 1 week. The compound was obtained as yellow microcrystals and purified by recrystallization from acetonitrile. Yield: 37%. M.p. 274 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3435 vs, 2964 vs, 2874 s, 2741 vw, 2665 vw, 2381 vw, 2179 vw, 2061 s, 1732 vw, 1630 s, 1607 s, 1464 s, 1365 m, 1328 vw, 1261 w, 1233 w, 1108 vs, 926 w, 912 w, 882 w, 805 m, 751 w, 629 s, 559 m cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 674 (26), 931 (54), 1023 nm (74 M^{-1} cm^{-1}). $C_{50}H_{88}Cl_2N_6Ni_2O_4S_2$·$CH_3CN$·$3H_2O$ (1089.69 + 41.05 + 54.06): calcd. C 52.71, H 8.25, N 8.28; found C 52.90, H 8.35, N 8.17.

$[(L^{Et})Ni_2(OAc)]ClO_4$ (9·ClO_4): To a solution of **7**·ClO_4 (97.4 mg, 0.100 mmol) in methanol (25 mL) was added a solution of sodium acetate (16.4 mg, 0.200 mmol) in methanol (10 mL). After stirring for 2 h, solid $LiClO_4$·$3H_2O$ (160 mg, 1.00 mmol) was added. The resulting pale-green precipitate was isolated by filtration, washed with methanol and dried in air. This material was recrystallized once from a mixed acetonitrile/ethanol solvent system. Yield: 73.5 mg (66%). M.p. 332 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3446 m, 2964 vs, 2900 s, 2359 vw, 1714 vw, 1589 s $\nu_{asym}(OAc^-)$, 1426 s $\nu_{sym}(OAc^-)$, 1383 s, 1326 w, 1313 w, 1248 w, 1231 m, 1202 vw, 1187 vw, 1151 m, 1101 vs $\nu(ClO_4^-)$, 987 w, 949 w, 928 vw, 907 w, 878 w, 783 m, 756 vw, 664 w, 623 s, 581 vw, 558 vw cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 345 (1596), 660 (29), 1180 nm (79 M^{-1} cm^{-1}). $C_{46}H_{79}ClN_6Ni_2O_6S_2$ (1029.13): calcd. C 53.69, H 7.74, N 8.17, S 6.23; found C 53.34, H 7.72, N 8.10, S 6.08.

$[(L^{Pr})Ni_2(\mu\text{-}O_2CCH_3)]ClO_4$ (10·ClO_4): This compound was prepared by the method detailed above for **9**·ClO_4. Yield: 75.7 mg (68%). M.p. 319 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3445 m, 2963 vs, 2872 m, 1589 s $\nu_{asym}(OAc^-)$, 1457 m, 1428 m $\nu_{sym}(OAc^-)$, 1365 w, 1312 w, 1332 w, 1151 m, 1092 vs $\nu_s(ClO_4^-)$, 1061 vs, 937 w, 911 w, 876 w, 813 w, 755 w, 663 w, 626 m, 529 w cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 662 (29), 1183 nm (77 M^{-1} cm^{-1}). $C_{52}H_{91}ClNi_2N_6O_6S_2$ (1113.29): calcd. C 56.10, H 8.24, N 7.55, S 5.76; found C 56.49, H 8.42, N 7.17, S 5.48.

$[(L^{Et})Ni_2(\mu\text{-}O_2COMe)]ClO_4$ (11·ClO_4): To a solution of **7**·ClO_4 (201 mg, 0.200 mmol) in a mixture of MeOH/H_2O (40 mL/ 5 mL) was added finely ground NaOH (20 mg, 0.50 mmol). The color of the reaction mixture turned from yellow to green. The reaction mixture was exposed to air and stirred at room temperature for 24 h. A solution of $LiClO_4$·$3H_2O$ (1.00 g, 6.25 mmol) in methanol (2 mL) was then added. The green microcrystalline solid was isolated by filtration, washed with methanol and dried in vacuo. The yield was 182 mg (87%). M.p. 284–285 °C (decomp.). UV/Vis (CH_3CN): λ_{max} (ε) = 670 (20), 1138 nm (49 M^{-1} cm^{-1}). IR (KBr): $\tilde{\nu}$ = 3446 m, 2964 vs, 2901 m, 2357 vs, 1716 vw, 1638 vs $\nu_{asym}(CH_3OCO_2^-)$, 1450 vs, 1384 m, 1331 vs $\nu_{sym}(CH_3OCO_2^-)$, 1261 w, 1232 w, 1101 vs, $\nu(ClO_4^-)$, 987 vw, 950 vw, 908 vw, 979 vw, 785 s, 625 m, 581 vw, 560 vw cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 350 (2384), 668 (22), 1136 nm (84 M^{-1} cm^{-1}). $C_{46}H_{79}ClN_6Ni_2O_7S_2$ (1045.13): calcd. C 52.86, H 7.62, N 8.04, S 6.14; found C 52.26, H 7.67, N 7.90, S 5.71.

$[(L^{Et})Ni_2(\mu\text{-}O_2COEt)]ClO_4$ (12·ClO_4): The complex **11**·ClO_4 (105 mg, 0.100 mmol) was dissolved in acetonitrile (20 mL). To the green solution was added ethanol (20 mL) and the reaction mixture was stirred at room temperature for 24 h. The solution was concentrated in vacuo to about 5 mL whereupon a pale-green precipitate formed. The precipitate was filtered, washed with a few milliliters of cold ethanol and dried in air. Yield: 75 mg (71%). M.p. 295 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3453 m, 2965 vs ν(CH), 2900 s, 1638 vs $\nu_{asym}(CH_3CH_2OCO_2^-)$, 1449 vs, 1384 m, 1330 vw, 1316 vs $\nu_{sym}(CH_3CH_2OCO_2^-)$, 1248 w, 1231 m, 1187 w, 1151 m, 1101 vs $\nu(ClO_4^-)$, 1056 s, 987 vw, 949 vw, 908 vw, 878 vw, 806 w, 785 m, 756 w, 628 m, 582 vs, 560 vs cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 350 (2550), 668 (28), 1140 nm (79 M^{-1} cm^{-1}). $C_{47}H_{81}ClN_6Ni_2O_7S_2$ (1059.15): calcd. C 53.30, H 7.71, N 7.93, S 6.05; found C 52.48, H 7.65, N 7.76, S 5.85. The tetraphenylborate salt, $[(L^{Et})Ni_2(\mu\text{-}O_2COEt)]BPh_4$ (**12**·BPh_4), was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of $[(L^{Et})Ni_2(\mu\text{-}O_2COEt)]ClO_4$ (106 mg, 0.100 mmol) in methanol (40 mL). The pale-green microcrystalline solid was isolated by filtration, washed with ethanol and dried in air. Yield: 116 mg (91%). M.p. 293–294 °C (decomp). IR (KBr): $\tilde{\nu}$ = 3442 s ν(OH), 3056 s ν(ArH), 2968 vs ν(CH), 2903 s ν(CH), 1634 vs $\nu_{asym}(CH_3CH_2OCO_2^-)$, 1579 m, 1478 s, 1463 s, 1427 m, 1397 m, 1373 m, 1316 vs $\nu_{sym}(CH_3CH_2OCO_2^-)$, 1261 w, 1231 w, 1185 m, 1154 m, 1102 s, 1056 s, 948 vw, 909 vw, 879 vw, 854 vw, 803 w, 744 vs $\nu(BPh_4^-)$, 715 vs $\nu(BPh_4^-)$, 628 w, 612 w, 560 w cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 668 (27), 1140 nm (70 M^{-1} cm^{-1}). The tetraphenylborate salt was additionally characterized by X-ray crystal structure analysis.

$[(HL^{Et})Ni_2](ClO_4)_3$ (13·$(ClO_4)_3$): To a solution of **7**·ClO_4 (101 mg, 0.100 mmol) in MeOH (30 mL) was added $Pb(ClO_4)_2$ (40.6 mg, 0.100 mmol). The resulting dark green solution was stored at room temperature for 12 h during which a few crystals of the title compound precipitated as dark green crystals. Yield: 16 mg (13%). The ^1H NMR spectra obtained for the trication are broad with chemical shifts ranging from δ = +200 to –50 ppm and almost completely collapse into the base line, indicative of a paramagnetic species. UV/Vis (CH_3CN): λ_{max} (ε) = 574 (850), 1016 nm (50 M^{-1} cm^{-1}). This compound was additionally characterized by X-ray crystal structure analysis.

$[(L^{Et})Zn_2(OAc)]ClO_4$ (14·ClO_4): To a suspension of H_2L^{Et}·6HCl (974 mg, 1.00 mmol) in methanol (50 mL) was added a solution of $Zn(OAc)_2$·$2H_2O$ (439 mg, 2.00 mmol) in methanol (5 mL). A solution of triethylamine (810 mg, 8.00 mmol) in methanol (1 mL) was added and the resulting clear solution was stirred at room temperaturefor 12 h. Solid $LiClO_4$·$3H_2O$ (1.60 g, 10.0 mmol) was then

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

added. The resulting colorless precipitate was isolated by filtration, washed with methanol and dried in air. Yield: 830 mg (80%). M.p. 282–284 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3442 m, 2964 vs, 2899 s, 1585 s $\nu_{asym}(OAc^-)$, 1464 s, 1442 vw $\nu_{sym}(OAc^-)$, 1385 m, 1329 w, 1252 w, 1230 w, 1149 m, 1100 vs $\nu(ClO_4^-)$, 1056 vs, 947 vw, 906 w, 884 w, 782 w, 656 vw, 625 s, 578 vw, 553 vw cm^{-1}. ^1H NMR (300 MHz, CD_3CN, 25 °C, TMS): δ = 7.13 (s, 4 H, Ar*H*), 4.12 (d, ^2J = 12.0 Hz, 4 H, $ArCH_2$), 3.21 (d, ^2J = 12.0 Hz, 4 H, $ArCH_2$), 3.60–2.60 (m, 28 H, NCH_2CH_2 + NCH_2), 1.25 (t, ^3J = 7.0 Hz, 6 H, NCH_2CH_3), 1.23 [s, 18 H, $C(CH_3)_3$], 1.16, (t, ^3J = 7.0 Hz, 12 H, NCH_2CH_3), 0.83 (s, 3 H, CO_2CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, CD_3CN, 25 °C, TMS): δ = 174.74 (C=O), 145.96 (C), 143.85 (C), 135.65 (C), 128.30 (CH), 54.96, 54.17, 53.47, 53.16, 47.53 (all CH_2), 34.53 [$C(CH_3)_3$], 31.55 [$C(CH_3)$], 23.12 ($COCH_3$), 6.87 ($ArCH_2NCH_2CH_3$), 4.58 (NCH_2CH_3). The tetraphenylborate salt, $[(L^{Et})Zn_2(OAc)]BPh_4$ (**14**·BPh_4), was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of $[(L^{Et})Zn_2(OAc)]ClO_4$ (104 mg, 0.100 mmol) in methanol (50 mL). The colorless, microcrystalline solid was isolated by filtration, washed with methanol and dried in air. Yield: 115 mg (91%). M.p. 246–248 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1582 s $\nu_{asym}(OAc^-)$, 1440 s $\nu_{sym}(OAc^-)$, 703, 732 $\nu(BPh_4^-)$ cm^{-1}. $C_{70}H_{99}BN_6O_2S_2Zn_2$ (1262.30): calcd. C 66.60, H 7.91, N 6.66, S 5.08; found C 66.89, H 7.85, N 6.45, S 4.84. Compound **14**·ClO_4 was also characterized by X-ray crystal structure analysis.

$[(L^{Et})Co_2(\mu\text{-}Cl)]ClO_4$ (17·ClO_4): To a suspension of H_2L^{Et}·6HCl (974 mg, 1.00 mmol) in methanol (40 mL) was added a solution of $CoCl_2$·$6H_2O$ (476 mg, 2.00 mmol) in methanol (2 mL). A solution of Et_3N (810 mg, 8.00 mmol) in methanol (2 mL) was then added to give a dark red solution. After stirring at room temperature for 3 d, the product was precipitated by the addition of solid $LiClO_4$·$3H_2O$ (2.50 g, 15.6 mmol). The red microcrystalline solid was isolated by filtration, washed with 5 mL of cold ethanol and 5 mL of ether, and dried in vacuo. This material was recrystallized once from a few milliliters of acetonitrile. Yield: 765 mg (76%). M.p. 313 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3443 s, 2963 vs, 2867 s, 2354 vw, 1730 vw, 1696 vw, 1634 w, 1556 vw, 1540 vw, 1518 vw, 1478 s, 1463 s, 1382 m, 1327 w, 1278 vw, 1251 w, 1231 w, 1202 vw, 1159 m, 1099 vs $\nu(ClO_4^-)$, 987 vw, 956 vw, 913 vw, 884 w, 803 vw, 776 m, 732 vw, 674 vw, 624 m cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 342 (2401), 470 (602), 548 sh (174), 578 (161), 1280 nm (28 M^{-1} cm^{-1}). $C_{44}H_{76}Cl_2Co_2N_6O_4S_2$·$H_2O$ (1006.01 + 18.02): calcd. C 51.61, H 7.68, N 8.21, S 6.26; found C 51.20, H 7.39, N 8.37, S 6.25.

$[(L^{Et})Co_2(OAc)]ClO_4$ (18·ClO_4): A solution of sodium acetate (41 mg, 0.50 mmol) in methanol (5 mL) was added to a solution of $[(L^{Et})Co_2(\mu\text{-}Cl)]ClO_4$ (202 mg, 0.200 mmol) in methanol (40 mL). The mixture was stirred for 1 h, during which the color of the solution turned to light brown. A solution of $LiClO_4$·$3H_2O$ (320 mg, 2.00 mmol) in methanol (2 mL) was added. The resulting light brown solid was isolated by filtration, washed with cold methanol and dried in air. This compound was recrystallized once from a mixed acetonitrile/ethanol (1:1) solvent system. Yield: 152 mg (74%). M.p. 337–338 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3442 m, 2964 vs, 2898 s, 1588 vs $\nu_{asym}(OAc^-)$, 1440 vs $\nu_{sym}(OAc^-)$, 1384 s, 1361 m, 1326 w, 1314 w, 1249 w, 1230 s, 1187 vw, 1152 m, 1100 vs $\nu(ClO_4^-)$, 1055 s, 986 w, 948 w, 928 w, 906 w, 880 w, 783 m, 755 vw, 653 w, 626 s cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 338 (2203), 440 (610), 528 (204), 1288 nm (44 M^{-1} cm^{-1}). CV (CH_3CN, 295 K, 0.1 M nBu_4NPF_6, ν = 100 mV/s; E (vs. SCE): $E^1_{1/2}$ = +0.27 V (ΔE_p = 0.126 V), $E^2_{1/2}$ = +0.64 V (ΔE_p = 0.131 V). The tetraphenylborate salt, $[(L^{Et})Co_2(OAc)]$ BPh_4 (**18**·BPh_4), was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of $[(L^{Et})Co_2(\mu\text{-}O_2CCH_3)]$ ClO_4 (103 mg, 0.100 mmol) in methanol (50 mL). The light brown microcrystalline solid was isolated by filtration, washed with methanol and dried in air. Yield: 113 mg (90%). M.p. 318–319 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3437 m, 3055 s ν(Ar), 2968 vs, 2866 s, 1582 vs $\nu_{asym}(OAc^-)$, 1440 vs $\nu_{sym}(OAc^-)$, 1383 m, 1326 w, 1310 w, 1248 w, 1231 w, 1185 vw, 1154 w, 1100 m, 1057 vs, 1033 w, 987 vw, 951 vw, 909 w, 882 w, 844 vw, 780 m, 732 s $\nu(BPh_4^-)$, 704 vs $\nu(BPh_4^-)$, 653 vw, 626 w, 612 m, 579 vw, 557 vw cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 442 (597), 528 (196), 1294 nm (43 M^{-1} cm^{-1}). $C_{70}H_{99}BCo_2N_6O_2S_2$ (1249.38): calcd. (**14**·ClO_4·MeOH) were taken directly from the reaction mixtures. Crystals of [(L^{Et})Ni_2(O_2COEt)]BPh_4·MeCN·EtOH (**12**·BPh_4·MeCN·EtOH) and [(L^{Et})Co_2(OAc)]BPh_4·EtOH (**18**·BPh_4·EtOH) were grown by recrystallization from an acetonitrile/ethanol (1:1) mixed solvent system. The crystals were mounted on glass fibers using perfluoropolyether oil. Intensity data were collected at 210(2) K, using a Bruker SMART CCD diffractometer. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. Crystallographic data of the compounds are listed in Table 4. The data were processed with SAINT[30] and corrected for absorption using SADABS[31] [transmission factors: 1.00–0.92 (**10**, **13**), 1.00–0.89 (**12**, **18**), 1.00–0.87 (**14**)]. The structures were solved by using the program SHELXS-86.[32] Refinements were carried out with the program SHELXL-97.[33] PLATON was used to search for higher symmetry.[34] ORTEP-3 was used for the artwork of the structures.[35] Where appropriate, all non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned to idealized positions and given isotropic thermal parameters 1.2 times (1.5 times for CH_3 groups) the thermal parameter of the atoms to which they were attached. In the crystal structure of **10**·ClO_4·MeOH a propyl group, a *tert*-butyl group and a ClO_4^- ion were found to be disordered over two positions. The site occupancies of the respective positions were refined as follows: C(18a)–C(20A)/C(18b)–C(20b) 0.50(2)/0.50(2); C(48a)–C(50a)/C(48b)–C(50b): 0.55(2)/0.45(2); O(3a)–O(6a)/O(3b)–O(6b) 0.70(1)/0.30(1). The C and O atoms of the disordered groups and the solvate molecules were refined isotropically. In the crystal structure of **12**·BPh_4·MeCN·EtOH the C, N, and O atoms of the solvate molecules were refined isotropically. In the crystal structure of **13**·3ClO_4·3MeOH·H_2O one *tert*-butyl group and two methanol molecules of solvent of crystallization were found to be disordered over two positions [C(42a)–C(44a)/C(42b)–C(44b) 0.53(2)/0.47(2); O(14)–C(45a)/O(14)–C(45b) 0.57(2)/0.43(2), and O(15a)–C(46a)/O(15b)–C(46b) 0.47(2)/0.53(2)]. In the crystal structure of **14**·ClO_4·MeOH a *tert*-butyl group and the counteranion were found to be disordered over two positions [C(20a)–C(22a)/C(20b)–C(22b) 0.47(2)/0.53(2); O(2a),O(3a)/(O2b),O(3b) 0.71(2)/0.29(2)]. In the crystal structure of **18**·BPh_4·EtOH one *tert*-butyl group was found to be disordered over two positions at site occupancies of 0.53(2) [C(42a)-C(44a)] and of 0.47(2) [C(42b)-C(44b)]. The C and O atoms of the solvate molecule and the disordered groups were refined isotropically. CCDC-259281 (**10**), -259282 (**12**), -259283 (**13**), -259284 (**14**) and -259285 (**18**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We are particularly grateful to Prof. Dr. H. Vahrenkamp for providing facilities for NMR and X-ray crystallographic measurements. Financial support of this work from the Deutsche Forschungsgemeinschaft (Priority programme "Sekundäre Wechselwirkungen", KE 585/3-1,2) is gratefully acknowledged.

Crystallographic and Electrochemical Characteristics of $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) Hydrogen Storage Alloys

Xin-Bo Zhang,[a] Dan-Zi Sun,[b] Wen-Ya Yin,[a] Yu-Jun Chai,[a] and Min-Shou Zhao,*[a]

Keywords: High-rate dischargeability / Low-temperature dischargeability / Exchange current density / Hydrogen diffusion coefficient / Alloys / X-ray diffraction

The structure, hydrogen storage property, and electrochemical characteristics of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0, 0.2, 0.4, 0.6, 0.8) hydrogen storage alloys have been investigated systematically. The X-ray powder diffraction and Rietveld analysis results reveal that all the alloys mainly consist of the La(La, Mg)$_2$Ni$_9$ phase and the $LaNi_5$ phase. The electrochemical measurements show that the maximum discharge capacity increases first from 246.3 (x = 0) to 345.4 mAh/g (x = 0.6) and then decreases to 317.6 mAh/g (x = 0.8), which is consistent with the variation of the hydrogen storage capacity indicated by the P-C isotherms. For the discharge current density of 1200 mA/g, the high-rate dischargeability of the alloy electrodes increases linearly from 47.2 % (x = 0) to 73.8 % (x = 0.8). Moreover, according to the linear polarization curves, the exchange current density of the alloy electrodes also increases monotonously with increasing x. The hydrogen diffusion coefficient increases with increasing Al and Mo content, and thus increases the low-temperature dischargeability of the alloy electrodes.

Introduction

Hydrogen storage alloys have attracted considerable attention in view of their potential as a new energy storage material. Recently, the nickel-metal hydride battery (Ni-MH), in which a hydrogen storage alloy is employed as a negative electrode material, has become the focus of interest as a candidate consumer-used battery by virtue of its several advantages: high reversible energy storage density, high resistance to overcharging and overdischarging, good charge/discharge kinetics, environmental compatibility, and interchangeability with the nickel-cadmium battery.[1–6] To date, almost all commercial Ni-MH batteries are employing AB_5-type alloys as negative electrode materials because of their good overall electrode properties.[7] However, the electrochemical capacity of the AB_5-type alloys is limited by the single $CaCu_5$-type hexagonal structure;[8] the energy densities of the Ni-MH batteries cannot compete favorably with some other advanced secondary batteries. Therefore, new types of alloys with higher energy densities, faster activation, better rate dischargeabilities, and lower cost are urgently needed to replace the conventional rare-earth-based AB_5-type alloys.[9]

Recently, Kadir et al.[10–12] have reported the discovery of a new type of ternary alloys with the general formula RMg_2Ni_9 (R: rare earth, Ca, Y) with $PuNi_3$-type structure. It is found that some of the R–Mg–Ni-based ternary alloys can absorb–desorb 1.8–1.87 wt.-% H_2, which is much more than the $LaNi_5$ alloys (which can only absorb 1.4 wt.-% H_2), and are thus regarded as promising candidates for reversible gaseous hydrogen storage.[13,14] As for their electrochemical hydrogen storage, Chen et al.[6] have studied the electrochemical characteristics of LaCaMg(Ni, M)$_9$ [M = Al, Mn] alloys, and almost at the same time, Kohno et al.[3] have reported that the discharge capacity of the $La_{0.7}Mg_{0.3}Ni_{2.8}Co_{0.5}$ alloy reached 410 mAh/g. However, up to now, the La–Mg–Ni–Co-system hydrogen storage electrode alloys could not be used as the negative material of the Ni-MH secondary batteries due to their serious corrosion in KOH electrolyte,[15] and hence their cycling stability had to be upgraded for practical applications. In commercial AB_5-type alloys, the presence of 10 wt.-% Co has indeed improved the cycling life of Ni-MH batteries. However, it negatively influences the discharge capacity as well as initial activation, and it constitutes about 40% of the material cost.[16] Much effort has been devoted to search for a more cost-effective substitute element with high reliability of improving the cycling life of Ni-MH batteries. It is believed that Al is one of the best candidates for cobalt substitution.[17] However, the addition of Al is detrimental to the diffusion of hydrogen from the electrode surface to the alloy bulk, and thus inevitably decreases the high-rate dischargeability of the alloy electrode.[2] It is reported that the

[b] State Key Laboratory of Electro-analytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Graduate School of Chinese Academy of Sciences, Changchun 130022, P. R. China

addition of Mo can remarkably increase the kinetic property[18] as well as the electrochemical capacity of the alloy electrode.[19] Therefore, it can be expected that the overall electrochemical properties of the La–Mg–Ni-type hydrogen storage alloys could be improved by substitution of Al and Mo for Ni in the alloys.

In this work, on the basis of our previous studies and the belief that the Al and Mo addition may result in some noticeable modifications, the structure and electrochemical characteristics of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) hydrogen storage alloys has been investigated systematically.

Results and Discussion

Alloy Composition and Structure Characteristics

It is well known that the low-melting Mg metal will inevitably be lost during the sample preparation by arc melting. We have tried many ways to overcome this problem, for example, by using an Mg–Ni master alloy as an Mg additive, by decreasing the melting current, by adding a slight excess of Mg over sample composition, and so on. Among all these methods, we found that the latter is the most effective way to compensate evaporative loss of Mg. Several attempts were made until the optimum preparative conditions were found. In this paper, the weight lost during sample preparation is almost the same as excess Mg added. The results of the ICP-AES analysis for all compounds are given in Table 1. It can be seen that the final composition of all the alloys is identical to the original composition.

Table 1. Composition of the $La_{0.7}Mg_{0.3}Ni_{4.0-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloys.

[a] Atomic ratio.

The crystal structures have been identified and refined by means of X-ray powder diffraction data. Figure 1 shows the Rietveld refinement pattern of the XRD profiles for the $La_{0.7}Mg_{0.3}Ni_{4.3}(Al_{0.5}Mo_{0.5})_{0.2}$ hydrogen storage alloy as a representative example of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0, 0.2, 0.4, 0.6, 0.8) hydrogen storage alloys. The results show that, besides an impurity Ni phase, the $La_{0.7}Mg_{0.3}Ni_{4.3}(Al_{0.5}Mo_{0.5})_{0.2}$ alloy mainly consists of two phases: a La_2MgNi_9 phase with a $PuNi_3$-type rhombohedral structure and a $LaNi_5$ phase with a $CaCu_5$-type hexagonal structure. The final Rietveld structure parameters of the La_2MgNi_9 phase are tabulated in Table 2. It can be easily found that the La atoms in La_2MgNi_9 are located not only at the 3a site (the Pu1 atom position of the $PuNi_3$ structure), but also at the 6c sites (the Pu2 atom position of the $PuNi_3$ structure), while the Mg atoms in the alloy exhibit a strong preference for the 6c site, which indicates that the alloy is an ordered compound with the same structure as the previously reported RMg_2Ni_9 (R = La, Ca, Y) alloys. Hence, the final formula of the La_2MgNi_9 phase can be designated as $La(La, Mg)_2Ni_9$. The characteristics of the alloy phases in the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloys are listed in Table 3. We find that all the alloys consist of an impurity Ni phase and two other main crystallographic phases, namely, the $La(La, Mg)_2Ni_9$ phase and the $LaNi_5$ phase. In addition, variations of the cell parameters and volume of the two main phases as a function of x in $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ alloys is shown in Figure 2. It can be seen that the parameters a and c of both the $La(La, Mg)_2Ni_9$ phase and the $LaNi_5$ phase in the alloys increase linearly with an increase in x, which is mainly ascribed to the fact that the atomic radius of Al (1.432 Å) and Mo (1.363 Å) is larger than that of Ni (1.246 Å). Figure 3 shows the abundance of the $La(La, Mg)_2Ni_9$ phase and the $LaNi_5$ phase as a function of x in the alloys. As can be seen in Figure 3 and Table 3, it can be seen that the $La(La, Mg)_2Ni_9$ phase abundance decreases from 39.21% to 29.79% with increasing x, while the $LaNi_5$ phase abundance increases from 60.34% to 70.07%. These results may influence the hydrogen storage and electrochemical characteristics of the alloys studied.

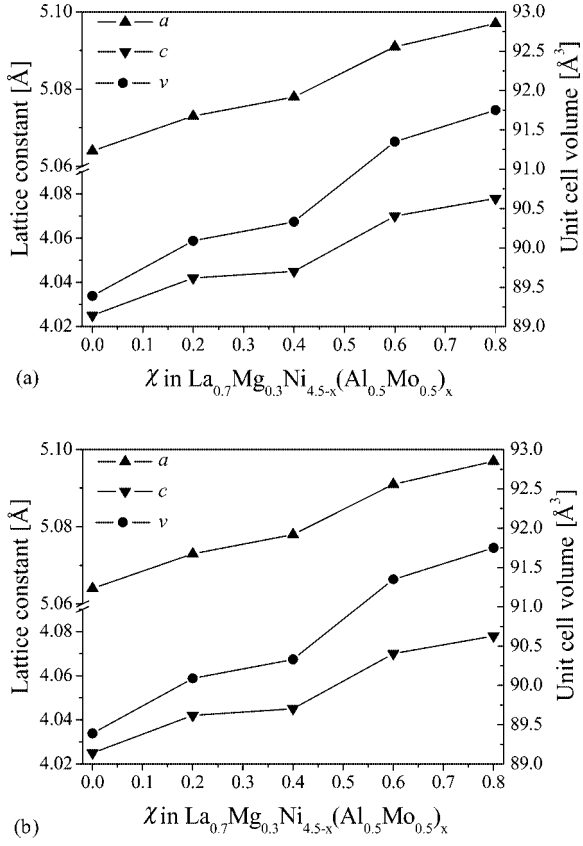

Figure 2. Variations of the cell parameters and volumes as a function of x in $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ alloys (x = 0–0.8) (a) $La(La, Mg)_2Ni_9$ phase; (b) $LaNi_5$ phase.

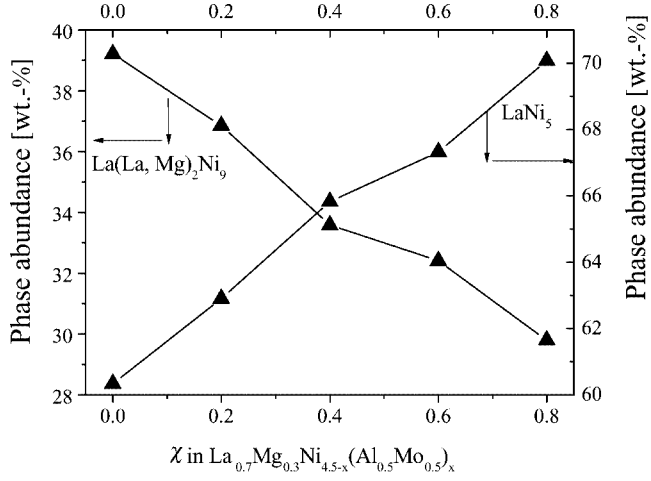

Figure 3. Phase abundance of the $La(La, Mg)_2Ni_9$ phase and the $LaNi_5$ phase existing in the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})x$ (x = 0–0.8) alloys.

P-C Isotherms

The electrochemical pressure-composition isotherm method is very useful for examining the charging and discharging levels of hydrogen in an anode, although the calculated pressures pertain to a quasi-equilibrium state.[17] Figure 4 shows the electrochemical P-C isotherms for $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes at 298 K. It can be seen that desorption pressure decreases continually as the addition of Al and Mo increases, which indicates that the stability of the hydrides of the alloys increases with the increasing Al and Mo content. The phenomenon observed here is consistent with those reported previously for AB_3 alloys[14] and most AB_5 alloys.[20] Moreover, it can be seen that there is only one plateau in each P-C curve as shown in Figure 4. Since the unit cell of the AB_3 compounds contains one-third of the AB_5 structure and two-thirds of the AB_2 structure,[6] it is perhaps concluded that the plateau pressure of the $La(La, Mg)_2Ni_9$ phase is similar to that of the $LaNi_5$ phase or that the difference between their plateau pressures of the AB_3 and AB_5 compounds is too small to be observed. With regard to the hydrogen storage capacity, it increases from 0.616 to 0.868 wt.-% as x increases from 0 to 0.6. This is mainly attributed to the enhancement of the intrinsic hydrogen storage capacity of the alloy, which results from the decrease in plateau pressure. However, as x increases further, the hydrogen storage capacity decreases to 0.799 wt.-% when x reaches 0.8. This is mainly attributed to the reasons

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as follows: it is known that the hydrogen storage capacity of the $LaNi_3$ phase (1.8–1.87 wt.-% H_2) is larger than that of the $LaNi_5$ phase (1.4 wt.-% H_2).[13–14] However, as shown in Figure 3 and Table 3, the La(La, $Mg)_2Ni_9$ phase abundance decreases while the $LaNi_5$ phase abundance increases with increasing x in the alloys.

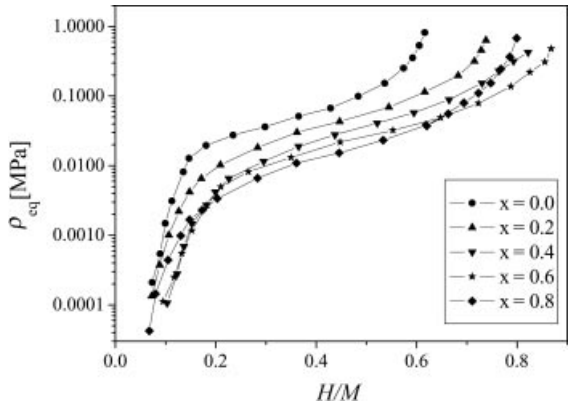

Figure 4. Electrochemical desorption P-C curves for the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0, 0.2, 0.4, 0.6, 0.8) alloys at 298 K.

Discharge Capacity and Discharge Potential

The activation and maximum discharge capacity of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes are listed in Table 4. It can be seen that all these alloys can be easily activated to reach the maximum capacity within five cycles. The maximum discharge capacity C_{max} improves first and reaches a maximum at x = 0.6, and then decreases as x increases further. The variation of the maximum discharge capacity of the alloys is basically consistent with the variation of the H/M with the Al and Mo content in the alloys.

Table 4. Electrode performance of $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes.

Sample	H/M	C_{max} [mAh/g]	N_a[a]	HRD_{1200}[b] [%]	S_{70} [%]
x = 0.0	0.616	246.3	5	47.2	54.1
x = 0.2	0.738	294.8	4	50.6	54.7
x = 0.4	0.822	327.6	3	55.8	58.9
x = 0.6	0.868	345.4	2	64.7	62.3
x = 0.8	0.799	317.6	2	73.8	68.9

[a] The cycle numbers needed to activate the electrodes. [b] The high-rate dischargeability at a discharge current density of 1200 mA/g.

Figure 5 shows the discharge curves (fifth cycle) of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes at 60 mA/g and 298 K. Obviously, each curve has a wide discharge potential plateau based on the oxidation of desorbed hydrogen from the hydride. Besides, the discharge plateau shifts towards a more positive potential as Al and Mo addition increases in the alloys. As shown in Figure 5, the mid-discharge potential (potential at 50% depth of discharge) decreases from –0.8710 to –0.8194 V when x increases from 0 to 0.8, which is in good agreement with the reduction of the desorption plateau pressure with increasing Al and Mo content in the alloys.

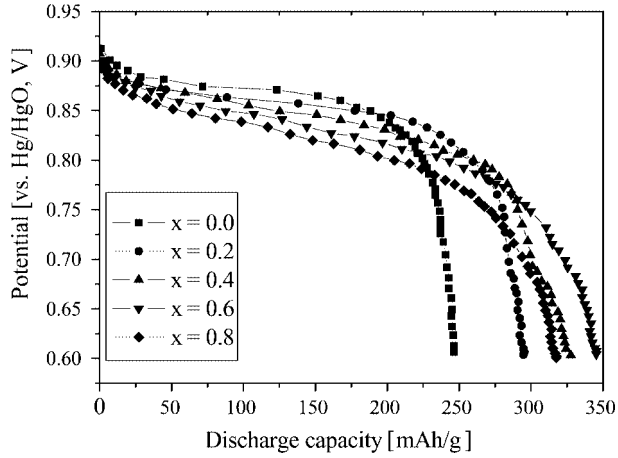

Figure 5. Discharge curves for the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes at the discharge current density of 60 mA/g and 298 K.

Cyclic Stability

The cycling capacity retention rate, expressed as S_{70} (%) = C_{70}/C_{max} × 100 (where C_{max} is the maximum discharge capacity, C_{70} is the discharge capacity at the 70th cycle), after 70 cycles at 60 mA/g is also listed in Table 4. It can be seen that the capacity retention rate (S_{70}) increases noticeably from 54.1% to 68.9% as x increases from 0 to 0.8, which indicates that the cyclic stability of the La–Mg–Ni–Al–Mo-system alloys is improved markedly with the increase in Al and Mo content in the alloys. It is known that the capacity degradation of the La–Mg–Ni-type alloy electrode results primarily from two factors: the corrosion of Mg and La and the pulverization of the alloy particles.[20] The Al substitution results in the formation of a protective oxide (hydroxide) of Al on the alloy surface and a subsequent strong protection to the alloy from further corrosion of La and Mg. Moreover, the pulverization of the alloy particles can be improved effectively by substitution of Ni by Mo. In conclusion, the combined effect of the addition of Al and Mo results in the notable increase in the stability of the alloy electrodes. Further investigations in this aspect are going on in our research group.

High-Rate Dischargeability (HRD) and Electrochemical Kinetics

As an important kinetics property of the hydride electrode in batteries, it is very important to restrain the decrease in the discharge capacity even at high discharge cur-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rent density. Figure 6 shows the relationship between the HRD and the discharge current density of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes. It can be seen that HRD of the alloy electrodes increases monotonously with increasing x. The HRD of the alloy electrodes at a discharge current density of 1200 mA/g are also listed in Table 4. It can be seen that as x increases, the HRD of the alloy electrodes increases from 47.2% (x = 0) to 73.8% (x = 0.8). It is well known that the HRD of metal hydride electrodes is influenced mainly by the electrochemical reaction kinetics on the alloy powder surface and the diffusion rate of hydrogen in the bulk of the alloy.[22] To examine the effect of the partial substitution of Ni by Al and Mo on the discharge kinetics, linear polarization was preformed on these alloy electrodes. Based on the measured linear polarization curves, values of the exchange current density I_0 and polarization resistance R_p were evaluated for the alloy electrodes and are summarized in Table 5. Figure 7 shows HRD and R_p as a function of I_0 for the hydrogen evolution reaction at the alloy electrodes. It can be seen that the HRD is a linear function of I_0. Moreover, we can find that the hydrogen diffusion coefficient (D) remains almost unchanged (13.1–13.6 × 10^{-10} cm^2/s). Iwakura et al.[23] have pointed out that, if the electrochemical reaction on the surface is the rate-determining factor, a linear dependence of the high-rate dischargeability on the exchange current density should be observed. In contrast, if the diffusion of hydrogen in the bulk is the rate-determining factor, the high-rate dischargeability should be constant, irrespective of exchange density. Therefore, in the present study, the HRD is essentially controlled by the charge-transfer reaction of hydrogen on the surface at a discharge current density of 1200 mAh/g. As the same time, from Figure 7, it can be seen that R_p decreases with increasing exchange current density, while HRD shows the reverse trend, which implies that the R_p value is closely related to HRD.

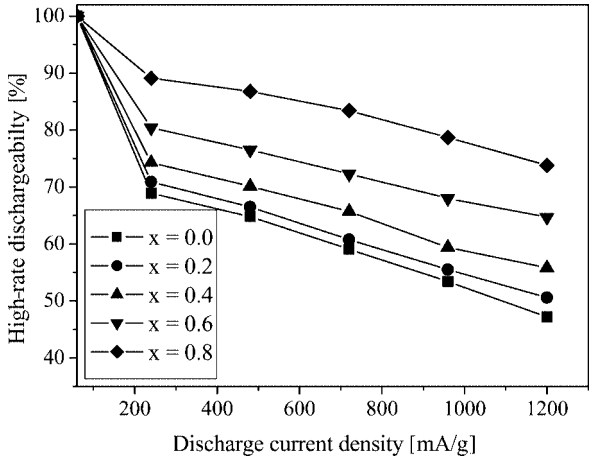

Figure 6. High-rate dischargeability of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0,0.2, 0.4, 0.6, 0.8) alloy electrodes at 298 K.

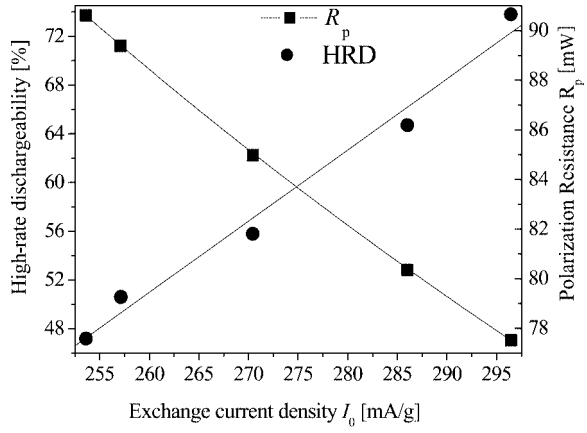

Figure 7. High-rate dischargeability and polarization resistance as a function of exchange current density for hydrogen evolution at $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo0.5)_x$ (x = 0–0.8) alloy electrodes.

Low-Temperature Dischargeability (LTD)

It has been reported that the discharge capacity of the negative electrode in nickel-metal hydrides decreases drastically with decreasing temperature.[24] Sakai et al.[2] pointed out that the dischargeability of the negative electrodes at relatively low temperatures depended on hydrogen diffusion and/or the charge-transfer process occurring at the metal electrolyte interface. The value of D in the bulk is evaluated using the method described by Iwakura et al.[18] The LTD is expressed as LTD_{233} (%) = $C_{233}/C_{298} \times 100$ (where C_{233} and C_{298} are the discharge capacities at 233 K and 298 K, respectively). The values of D and I_0 for the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes at 233 K are also listed in Table 5. It can be found that both I_0 and D are smaller than that at 298 K. Moreover, we find that I_0 remains almost unchanged (80.35–82.17 mA/g), whereas D increases remarkably with increasing x, which implies that hydrogen diffusion in the alloy probably be-

Table 5. Electrochemical kinetic parameters for the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0–0.8) alloy electrodes.

Sample	Polarization resistance, R_p [mΩ]		Exchange current density, I_0 [mA/g]		Hydrogen diffusion coefficient, D [×10^{-10} cm^2/s]	
	298 K	233 K	298 K	233 K	298 K	233 K
x = 0.0	90.61	249.56	253.62	80.35	13.1	1.6
x = 0.2	89.38	248.20	257.12	80.79	13.1	3.0
x = 0.4	84.98	246.93	270.43	81.21	13.3	3.7
x = 0.6	80.36	245.62	286	81.64	13.5	4.8
x = 0.8	77.52	244.04	296.45	82.17	13.6	6.2

comes the rate-determining factor for low-temperature dischargeability at 233 K. Figure 8 shows the LTD as a function of D in the alloy electrodes. It can be easily seen that D increases with an increase in x, which can be attributed to cell-volume expansion. The larger the value of D, the greater the LTD of the alloy electrodes.

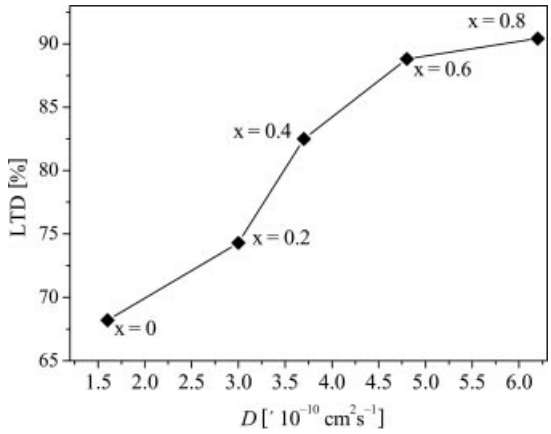

Figure 8. The low-temperautre dischargeability (LTD) as a function of hydrogen diffusion coefficient (D) of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}$-$(Al_{0.5}Mo0.5)_x$ (x = 0, 0.2, 0.4, 0.6, 0.8) alloy electrodes at 233 K.

Conclusions

The structure, hydrogen storage characteristics, and electrochemical properties of the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ (x = 0, 0.2, 0.4, 0.6, 0.8) hydrogen storage alloys have been investigated systematically. It is found that, by X-ray powder diffraction and Rietveld analysis, all the $La_{0.7}Mg_{0.3}Ni_{4.5-x}(Al_{0.5}Mo_{0.5})_x$ alloys consist of an impurity Ni phase and two main crystallographic phases, namely, the La(La, $Mg)_2Ni_9$ phase and the $LaNi_5$ phase. Moreover, the lattice parameters and cell volumes of both the La(La, $Mg)_2Ni_9$ and the $LaNi_5$ phases increase with increasing Al and Mo content in the alloys. The P-C isotherm curves indicate that the hydrogen storage capacity first increases and then decreases with increasing x, while the desorption pressure always decreases with an increase in x. The electrochemical measurements show that the maximum discharge capacity increases from 246.3 (x = 0) to 345.4 mAh/g (x = 0.6), and then decreases to 317.6 mAh/g (x = 0.8). For a discharge current density of 1200 mA/g, the HRD of the alloy electrodes increases linearly from 47.2% (x = 0) to 73.8% (x = 0.4). Moreover, according to the linear polarization curves, the exchange current density of the alloy electrodes also increases monotonously with increasing x. The value of D increases with increasing Al and Mo content, and thus increases the LTD of the alloy electrodes.

Experimental Section

Alloy Preparation and X-ray Diffraction Analysis: All alloy samples were prepared by carefully arc-melting the constituent elements on a water-cooled copper hearth under argon, followed by annealing in vacuo for 100h at 770 °C. The purity of the metals, i.e. La, Mg, Ni, Al, and Mo is higher than 99.9 mass-%, respectively. The samples were all inverted and remelted 5 times to ensure good homogeneity. A slight excess of Mg over sample composition was needed in order to compensate for evaporative loss of Mg under the preparation conditions. Several attempts were performed to find the optimum preparative conditions. The final compounds were carefully checked by Inductively Coupled Plasma-Atomic Emission Spectrometry (ICP-AES) with a TJA Poems-type instrument. Thereafter, these alloy samples were crushed in a mortar into fine powders of 200–300 mesh.

Crystallographic characteristics of the hydrogen storage alloys were investigated by X-ray diffraction on a Rigaku D/Max 2500PC X-ray diffractometer (Cu-K_α radiation, Bragg–Brentano geometry, 2θ range 10–100°, step size 0.02°, backscattered rear graphite monochromator) by using JADE5 software.[25] The lattice constants and cell volume were calculated by the RIETICA program after internal θ calibration by using silicon as standard reference material.

Electrochemical Measurement: The alloy powder and carbonyl nickel powder were mixed well in a weight ratio of 1:5 and pressed into tablets as metal hydride electrodes, which had a diameter of 13 mm and a thickness of 1.5 mm; the weight of each electrode was about 0.9 g.

The electrochemical properties were then measured in a standard three-electrode cell consisting of a working electrode (metal hydride electrode), a counter electrode ($NiOOH/Ni(OH)_2$ electrode), and a reference electrode (Hg/HgO electrode). The electrolyte in the cell was a 6 M KOH aqueous solution. Charge and discharge tests were carried out on an automatic galvanostatic system (DC-5). The emphasis of these charge/discharge tests was on the electrochemical capacity and stability of the negative electrode, thus the capacity of the positive electrode plate was designed to be much higher than that of the negative electrode. At 298 K, these experimental cells were first charged at current of 60 mA/g for 7 h followed by a rest for 30 min, and were discharged at the same discharge current density to the cut-off voltage of –0.60 V vs. Hg/HgO.

Pressure-composition isotherm (P-C) curves were electrochemically obtained by converting the equilibrium potential of the metal hydride electrode into the equilibrium pressure of hydrogen on the basis of the Nernst equation by using electrochemical data[26] as reported in reference.[27] The equilibrium potential curves were obtained by alternating the following two processes: (1) a pulse discharge of (25 mA/g × 0.25 h), and (2) a rest period until the potential became almost constant. The equilibrium potential change of approximately 30 mV corresponds to the equilibrium pressure change by one order of magnitude. Since the measured potentials have an error of 1–2 mV, the calculated pressure values are accurate to within 10%.[27]

The high-rate dischargeability (HRD) was defined by the following formula:

$$HRD\ (\%) = C_n \times 100/(C_n + C_{60})$$

where C_n is the discharge capacities of the alloy electrode at a discharge current of n mA/g (n = 60, 240, 480, 720, 960, 1200); C_{60} is the additional discharge capacity measured subsequently at 60 mA/g after Cn was measured.

For investigating the electrocatalytic activity of the hydrogen electrode reaction, the linear polarization curves of the electrode were plotted on a EG&G PARC's Model 273 Potentiostat/Galvanostat station by scanning the electrode potential at the rate of 0.1mV/s

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

from –5 to 5 mV (vs. open circuit potential) at 50% depth of discharge at 298 K and 233 K. The polarization resistance R_p can be obtained from the slope of the linear polarization curves. Moreover, the exchange current density (I_0), which is a measure of the catalytic activity of the electrode, was calculated from the slopes of the polarization curves by the following Equation (1),[17]

$$I_0 = \frac{RT}{FR_p} \quad (1)$$

where R is the gas constant; T is the absolute temperature; F is the Faraday constant; and R_p is the polarization resistance. The potentiostatic discharge technique was used to evaluate the coefficient of diffusion within the bulk of the alloy electrodes. After being fully charged followed by a 30 min open-circuit lay-aside, the test electrodes were discharged with a +500-mV potential-step for 500 s on a EG&G PARC's Model 273 Potentiostat/Galvanostat station, by using the M352 CorrWare electrochemical/corrosion software.

Electrochemical Synthesis and Structural Characterisation of Cadmium and Mercury Complexes Containing Pyrimidine-2-thionate Ligands

Antonio Rodríguez,[a] Antonio Sousa-Pedrares,[a] José A. García-Vázquez,[a] Jaime Romero,[a] and Antonio Sousa*[a]

Dedicated to Professor V. I. Minkin on the occasion of his 70th birthday

Keywords: Cadmium / Electrochemistry / Heterocycles / Mercury / S ligands

The electrochemical oxidation of anodic metal (cadmium or mercury) in a cell containing an acetonitrile solution of the appropriate pyrimidine-2-thione (RpymSH) affords complexes [M(RpymS)$_2$] (M = Cd, Hg; R = 4-CF$_3$, 4,6-CF$_3$,Me and 4,6-CF$_3$,Ph). When 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen) was added to the electrolytic cell, adducts of cadmium and compounds with these coligands were obtained. All the compounds have been characterised by microanalysis, IR spectroscopy and, in the case of the compounds that were sufficiently soluble, by ^{1}H, ^{13}C and ^{199}Hg NMR spectroscopy. The compounds [Cd(4-CF$_3$pymS)$_2$] (**1**), [Cd(4,6-CF$_3$MepymS)$_2$(bipy)] (**4**), [Cd(4,6-CF$_3$PhpymS)$_2$-(phen)] (**6**) and [Hg(4,6-CF$_3$MepymS)$_2$] (**8**) were also characterised by X-ray diffraction. Compound **1** presents a polymeric structure with the polymer chains interconnected by intermolecular C–H···N interactions. Compounds **4** and **6** adopt mononuclear structures, with weak inter- and intramolecular C–H···π interactions, as well as π–π stacking interactions for compound **6**. Compound **8** also presents a mononuclear structure with intermolecular π–π interactions between the pyrimidine rings and additional weak Hg···Hg contacts (3.484 Å).

Introduction

The chemistry of metal–sulfur complexes has attracted much interest over the past decade because of the potential relevance of such compounds to active sites in metalloenzymes and also for their ability to adopt geometries of variable nuclearity and great structural complexity.[1–7] These latter features are the result of the tendency of thiolate ligands to bridge metal centres to yield oligomeric or polymeric species, a situation that makes it difficult to obtain and isolate crystals suitable for X-ray diffraction studies. It has been shown[8–10] that the degree of association depends intimately on both the reaction conditions and the nature of the thiolate ligands. Moreover, these association phenomena may be limited by incorporating steric constraints by appropriate ligand design or introducing coligands to block a number of coordination sites around the metal. Recently, a great deal of effort has been made[11–17] to modify the thiolate ligand by introducing a solubilizing group or a bulky substituent that might modify the aggregation process.

However, in comparison with the coordination chemistry of transition metals, the chemistry of the main-group metals with sulfur ligands remains much less developed.[18–22] In many cases, the interaction of toxic metals with biological systems involves bonding of the metal to the sulfydryl groups present in enzymes. Hence, an insight into the chemistry of main-group thiolate compounds is important in terms of understanding the aforementioned interaction and for the design of detoxifying agents.[23,24] The generally poor solubility of group 12 metal thiolate compounds makes it difficult to structurally characterise these systems.

As part of our continuing interest in the chemistry of sterically hindered thiolates,[25] we report here the electrochemical synthesis and characterisation of Cd and Hg complexes with a number of substituted pyrimidine-2-thiones (Scheme 1). This type of ligand, besides having solubilising and bulky groups that might modify the degree of aggregation as a result of steric constraints, is one of the most versatile sulfur ligands. These ligands can act as follows: (a) a neutral monodentate ligand coordinated through the sulfur atom,[26] through one of the nitrogen atoms,[27] and as a bridging ligand through sulfur[28] or as an N,S-chelating ligand,[29,30] and (b) as an anionic ligand, in which case it can be monodentate through the sulfur atom,[31] as an N,S-chelating ligand,[32] as a binuclear bridging ligand through

[a] Departamento de Química Inorgánica, Universidad de Santiago de Compostela,

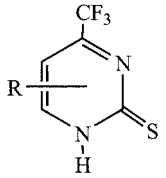
 DOI: 10.1002/ejic.200400848

nitrogen and sulfur,[33] or sulfur only,[34] as a binuclear triply bridging ligand through sulfur and one of the nitrogens[35] or the two nitrogen and sulfur atoms,[36,37] and as a trinuclear triply bridging system.[38]



R = 4-CF_3, 4,6-CF_3, Me, 4,6-CF_3, Ph

Scheme 1.

In addition, and in order to reduce the nuclearity of the homoleptic cadmium(II) complexes, didentate N,N′-donor coligands, such as 2,2′-bipyridine or 1,10-phenanthroline, were added to the electrochemical cell. This modification results in the preparation of monomeric mixed cadmium(II) complexes in one step.

Results and Discussion

Cadmium and mercury complexes of general formula $[M(RpymS)_2]$ (M = Cd and Hg; R = 4-CF_3, 4,6-CF_3,Me and 4,6-CF_3,Ph) were easily prepared in reasonable yields by a simple, one-step electrochemical method. Mixed complexes of cadmium with 2,2′-bipyridine or 1,10-phenanthroline were also obtained by addition of the corresponding coligand to the cell. The compounds are air-stable and moderately soluble in organic non-polar solvents, but soluble in dimethyl sulfoxide or *N*,*N*′-dimethylformamide.

The values of the electrochemical efficiency, defined as the amount of metal dissolved per unit of charge, were close to 0.5 mol F^{-1} regardless of the presence or absence of additional ligand. This observation, along with the evolution of hydrogen at the cathode, is compatible with the following mechanism:

Cathode: 2 RpymSH + 2 $e^- \rightarrow$ 2 $RpymS^-$ + H_2

Anode: M + 2 $RpymS^- \rightarrow [M(RpymS)_2]$ + 2 e^-

(M = Cd, Hg)

or

M + 2 $RpymS^-$ + L $\rightarrow [M(RpymS)_2L]$ + 2 e^-

(M = Cd; L = bipy, phen)

Crystallographic Studies

Crystal and Molecular Structure of [Cd(4-CF_3pymS)$_2$] (1)

[a] Symmetry codes: #1 = $-x + 2, -y, -z + 1$; #2 = $-x + 1, -y, -z + 1$.

The compound consists of polymeric chains along the *a* axis with the cadmium atom hexacoordinated by two nitrogen atoms from two different thionate ligands and four bridging sulfur atoms. Each ligand chelates one cadmium metal and bridges an adjacent cadmium atom through the exocyclic sulfur. A second ligand is almost perpendicular to the first one and also chelates this cadmium atom and bridges to the next cadmium atom in the chain. Each thionate ligand acts as a binuclear triply bridging μ_2-S,N(η^2-S;η^1-N) five-electron-donor ligand: each atom of cadmium is in a highly distorted [CdN_2S_4] octahedral environment with the nitrogen atoms in *cis* positions. The bond angles between the metal and the donor atoms that are in a *trans* disposition are in the range 151.6(3)–167.1(3)°, far from the ideal value of 180°. The values for the angles described by the donors in the *cis* positions are much lower than those expected for a regular octahedron, with values for the S–Cd–N angles of 61.1(3)° and 61.3(3)°.

Three of the four Cd–S bond lengths are very similar and are in the range 2.6347(12)–2.6777(12) Å. The other Cd–S distance is longer at 2.8011(11) Å. These values are within the range observed for other complexes containing CdN_2S_4 units with μ_2-S,N(η^2-S;η^1-N) bridging ligands; for example 2.638(6)–2.761(8) Å in the hexanuclear complex [{Cd(4,6-Me_2pymS)$_2$}$_6$][35] and 2.647–2.777 Å in other hexacoordinate thionate complexes.[39,40] However, the range for these distances in the complex [Cd(pyS)$_2$],[41] which has a similar chain structure, is much wider [2.543(5)–3.038(4) Å].

The Cd–N bond lengths of 2.336(4) and 2.457(4) Å are also close to the values found in other octahedral complexes of cadmium containing heterocyclic thionates as ligands; for example 2.42(2) and 2.53(2) Å in [Cd(pymS)$_2$(phen)],[42] [Cd(4,6-CF_3MepymS)$_2$(bipy)] and [Cd(4,6-CF_3PhpymS)$_2$-(phen)] (see below).

The S–C bond lengths of 1.755(5) and 1.745(4) Å are intermediate between the value found in free 4,6-dimethylpyrimidine-2-thione[30] [1.686(4) Å] and 1-phenyl-4,6-dimethylpyrimidine-2-thione[29] [1.676(2) Å], which exist in the thione form in the solid state, and the values of 1.781(2) Å and 1.782(3) Å found in bis(2-pyrimidyl) disulfide[43] and bis(4,6-dimethyl-2-pyrimidyl) disulfide,[44] both of which possess a simple C–S bond. This observation suggests that the ligand is coordinated in a way that is closer to the thionato form than to the thione form of the free ligand.

The packing structure of **1** (Figure 2) shows that every polymeric chain interacts with two parallel chains in the *b* direction through non-classical C–H···N hydrogen bonds. These interactions link the polymeric chains through weak C(8)–H···N(2) hydrogen bonds. The hydrogen bonds involve the uncoordinated pyrimidine nitrogen atoms, N(2), on alternate ligands in one chain that are parallel to one another and also parallel to the chain with the pyrimidyl protons bond at C(8) atom on ligands in the adjacent chains, which are again parallel between themselves but almost perpendicular to the first ones. The bond lengths and angles in this system are as follows: C···N = 3.422(7) Å, N···H = 2.58 Å and C–H···N = 150.3°.

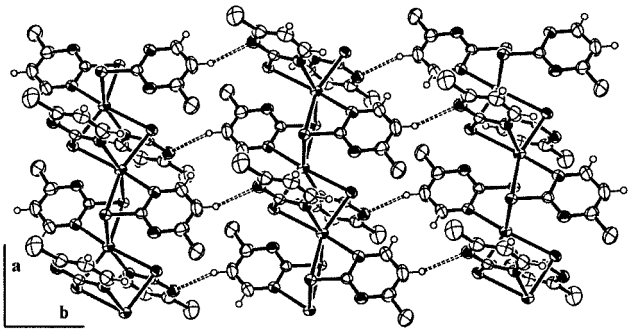

Figure 2. The crystal packing of **1** viewed along the *c* axis. Dashed lines show the C–H···N interactions.

These interactions result in the formation of layers parallel to the crystallographic *ab* plane that stack along the *c* axis.

A comparison of the structures of cadmium complexes with different pyridine and pyrimidine-2-thiones clearly demonstrates that the degree of aggregation depends to a large extent on the steric effects created by the ligand substituents. Thus, while the complex with pyridine-2-thione consists of [Cd(pyS)$_2$]$_x$,[41] a polymeric chain structure, the increased steric constraints introduced by the methyl groups in the case of 4,6-dimethylpyrimidine-2-thione reduce the tendency for polymerisation and the complex obtained is hexanuclear [Cd(4,6-Me_2pymS)$_2$]$_6$.[35] The metal atom in the latter complex is hexacoordinate as in [Cd(pyS)$_2$]$_x$.[41] A higher degree of steric hindrance, such as in 3-trimethylsilylpyridine-2-thione, produces a dimer [Cd(3-Me_3Sipyt)$_2$]$_2$,[45] with each cadmium atom in a five-coordinate environment. In the case of 4-trifluoromethylpyrimidine-2-thione, the presence of a CF_3 group in the 4-position produces greater steric hindrance than in pyridine-2-thione, but less hindrance than in 4,6-dimethylpyrimidine-2-thione. However, the steric hindrance introduced by the CF_3 group is not sufficient to reduce the aggregation level and the complex is also polymeric as in [Cd(pyS)$_2$]$_x$.[41] Naturally, other factors such as reaction conditions, kinetic factors, nature of the solvent, etc., can also play a role in the aggregation process.[25,45]

Molecular Structures of [Cd(4,6-CF_3MepymS)$_2$(bipy)] (4) and [Cd(4,6-CF_3PhpymS)$_2$(phen)] (6)

Figure 3 and Figure 4 show perspective views of compounds **4** and **6**, respectively, together with the atomic labelling schemes used. A selection of bond lengths and angles (with estimated standard deviations) are given in Table 2 and Table 3, respectively.

The cadmium atoms in both **4** and **6** are located on a twofold rotation axis; accordingly, their asymmetric units contain one half of the bipyridine (**4**) or phenanthroline (**6**) ligand, one pyrimidine-2-thionate ligand and one half of the cadmium atom.

[a] Symmetry code: #1 = $-x + 2$, y, $-z + 1/2$.

In both cases the molecular structure consists of discrete molecular species, which shows that the presence of an additional didentate coligand inhibits the polymerisation of the complexes. In both compounds the cadmium atom is hexacoordinated by the chelating nitrogen donors of the coligand (bipy or phen) and two anionic pyrimidine-2-thionate ligands, which also act in a didentate chelating (S,N) manner.

The cadmium atom in compound **4** is in a distorted [CdS_2N_4] octahedral environment. The disposition of the ligands in **4** is such that the sulfur atoms occupy *cis* positions. The equatorial plane of the molecule can be considered as being formed by the two nitrogen atoms from the 2,2′-bipyridine molecule and two sulfur atoms from pyrimidine-2-thionato ligands; these four atoms are not exactly coplanar. In terms of the best plane that includes these four donor atoms and the cadmium centre, the atoms N(3) and S, which occupy *trans* positions, are both below this plane (by –0.514 and –0.318 Å respectively), while the atoms N(3#1) and S(#1) are located above this plane (by +0.514 and +0.318 Å respectively). The cadmium atom, however, is in the plane defined above.

These deviations produce N(3)–Cd–S and N(3#1)–Cd–S(#1) bond angles of 150.9(7)°, which differ from the ideal value of 180°. In addition, the small angles of the chelate rings, together with the elongation in the axial direction, cause the S–Cd–S′ and S–Cd–N(3#1) angles to deviate significantly from 90° [109.4(6) and 94.2(8)°, respectively].

In complex **6** the disposition of the 4-trifluoromethyl-6-phenylpyrimidine-2-thionate ligands differs from that found in [Cd(4,6-CF_3MepymS)$_2$(bipy)] (**4**). As in compound (**4**), the cadmium atom in **6** is also in a [CdS_2N_4] environment, although in this case the geometry is best described as distorted trigonal prismatic. This can clearly be seen by inspection of the twist angle between the two parallel faces of the coordination polyhedron, as shown in Figure 5. These values are 14.2° for N(3) and N(3#1), 10.5° for N(1) and S(1) and 10.5° for N(1#1) and S(1#1). The expected values are 0° for a regular trigonal-prismatic geometry and 60° for an octahedral one.

In the structure, the three didentate ligands (two pyrimidine-2-thionates and one phenanthroline) link the two triangular faces of the trigonal prism. The higher value of 14.2° for the twist angle involving the phenanthroline ligand

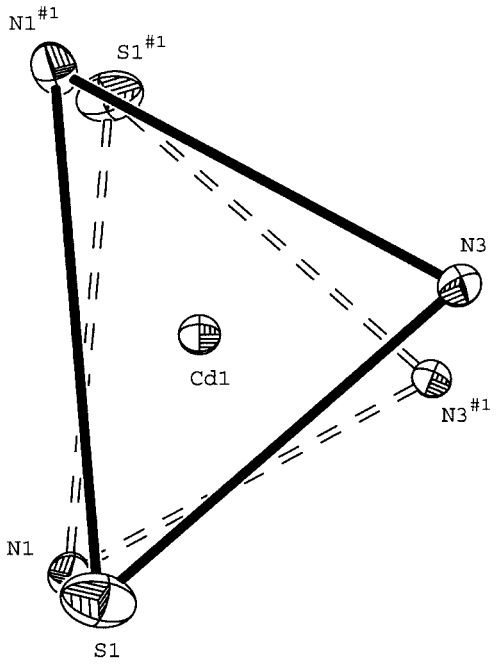

Figure 5. Distorted trigonal-prismatic environment for [Cd(4,6-CF_3PhpymS)$_2$(phen)] (**6**).

[N(3) and N(3#1)] can be explained by the formation of a rigid five-membered chelating ring, while the pyrimidine-2-thionate ligands form four-membered rings.

The Cd–S bond lengths [2.523(10) for **4** and 2.4578(17) Å for **6**] are similar to those found in other octahedral compounds of cadmium(II) with heterocyclic thionate ligands [2.588–2.5331 Å].[42,46] The Cd–N_{pymS} bond lengths [2.56(2) Å and 2.570(4) Å for **4** and **6**, respectively] are clearly longer than those involving the metal and the nitrogen atoms of the bipyridine in **4** or phenanthroline in **6** [Cd–N_{bipy} = 2.38(3) Å and Cd–N_{phen} = 2.378(4) Å]. This situation is probably due to the fact that the chelate coordination of the thionate ligand gives rise to a four-membered ring, which causes an elongation of the C–N bond as the interaction with sulfur is more favourable and the thionate ligand is rigid. However, these Cd–N_{bipy} and Cd–N_{phen} bond lengths [2.38(3) Å] do not differ significantly from those found in other octahedral cadmium(II) 2,2′-bipyridine and 1,10-phenanthroline complexes.[42,46]

The thionate ring is nearly planar and the exocyclic sulfur atom is also in the same plane. Other structural characteristics of the thionate ligand and the 2,2′-bipyridine or 1,10-phenanthroline unit are as one would expect and do not warrant further discussion.

Compound **6** shows a wide variety of intra- and intermolecular interactions that involve the π clouds of the aromatic rings.

A view of the crystal packing of this compound is shown in Figure 6. Each molecule in the crystal lattice interacts with four neighbouring molecules: two through the phenanthroline groups and two through the pyrimidine rings. Only the interactions between the phenanthroline rings are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

shown in the figure (upper part of Figure 6). The crystal packing is such that the phenanthroline rings are opposite one another and π–π stacking occurs between the outer rings of each phenanthroline unit (distance between centroids = 3.597 Å). The rings of the phenanthroline groups involved in the π interactions are arranged in such a way that the six atoms of the ring do not completely eclipse those of the other ring, meaning that the interaction is not "perfect face alignment" but "offset or slipped stacking" (distances between the corresponding atoms of the two rings of 3.587, 3.588 and 3.616 Å). Figure 7 shows a view perpendicular to the planes of the phenanthroline groups.

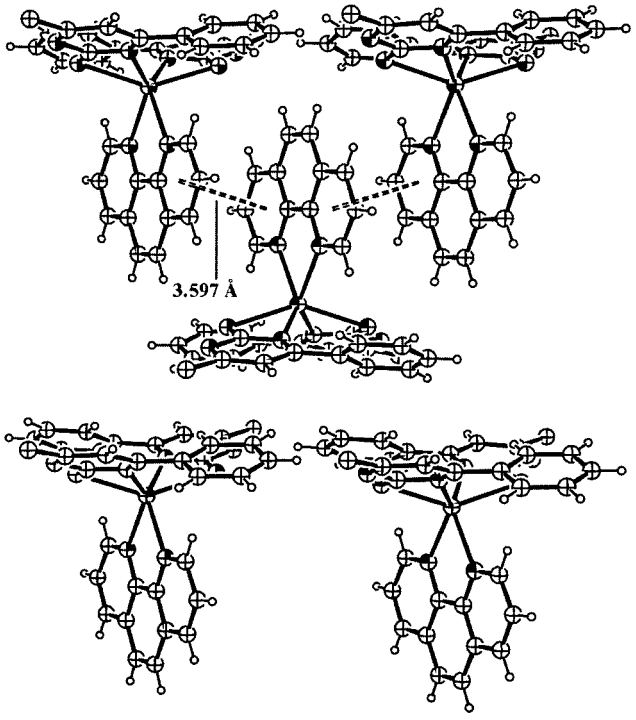

Figure 6. Crystal packing diagram of **6**; intermolecular π–π stacking interactions between phenanthroline rings are represented by dashed lines.

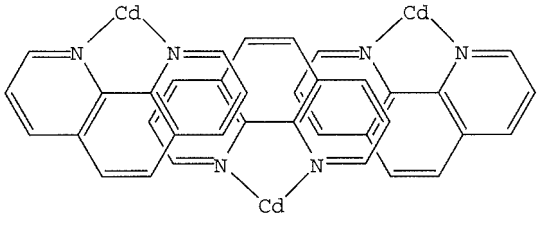

Figure 7. Overlapping between phenanthroline rings of three neighbouring molecules in **6**.

A view of the interactions between one molecule in the crystal lattice and neighbouring molecules through the pyrimidine rings is shown in Figure 8 (see also lower part of Figure 6).

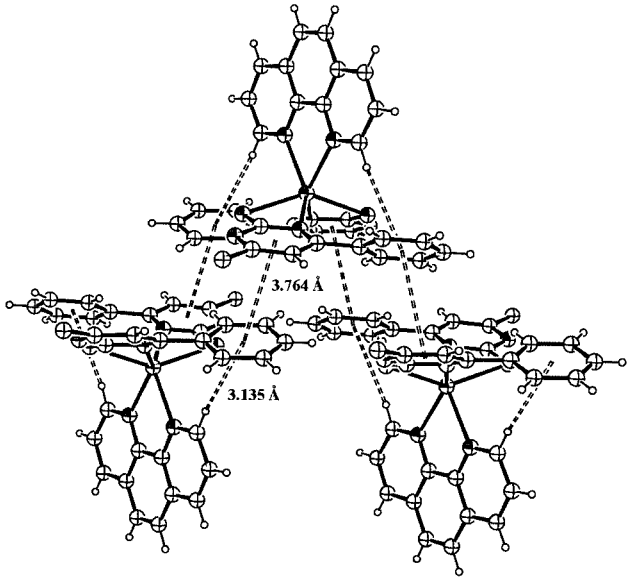

Figure 8. A view of complex **6** showing intramolecular C–H···π bonds and intermolecular π–π interactions between phenyl rings.

It can be seen from Figure 8 that, besides the π–π stacking interactions discussed above, each molecule in the crystal lattice is involved in two other interactions through the π clouds of the aromatic rings of the heterocyclic thione: one of these interactions is intramolecular and the other is intermolecular. The intramolecular interaction is of the C–H···π type and occurs between the protons *ortho* to the phenanthroline nitrogen (the most acidic protons in this unit) and the phenyl groups in the 6-position of the pyrimidine rings (H–centroid distance = 3.135 Å; C–centroid distance = 4.060 Å; C–H–centroid angle = 173.70°). It is interesting to note the high level of directionality of this interaction. In this situation each molecule is involved in two identical interactions of this type due to the presence of two pyrimidine units in each molecule.

As far as the intermolecular interaction is concerned, each pyrimidine ring takes part in a π–π stacking interaction with a phenyl ring in the 6-position of a pyrimidine ring in a neighbouring molecule. This π–π stacking interaction is of the most common offset or slipped-stacking type. This type of interaction is characterised by a distance between the centroids of the rings in question of about 3.8 Å. In the case under discussion here the distance between the centroids is 3.764 Å (the distances between the corresponding atoms ranges between 3.637 and 3.899 Å).

The compounds [Cd(4,6-CF_3MepymS)$_2$(bipy)] (**4**) and [Cd(4,6-CF_3PhpymS)$_2$(phen)] (**6**) (Figure 9) have different groups in the 6-position of the pyrimidine rings and, consequently, the disposition of the pyrimidine ligands in the two complexes is very different. These differences are clear when one considers the dihedral angles R–C–C′–R′, where R or R′ is the group in the 6-position (Me or Ph) and C or C′ is the carbon atom in the 6-position of the ring to which the substituent is attached. These angles have values of 110.0° when R = Me and 175.8° when R = Ph.

[a] Symmetry codes: #1 = $-x + 1, -y + 1, -z + 1$; #2 = $-x + 1, y, -z + 1/2$; #3 = $-x + 1, y, -z + 3/2$.

In compound **8** the whole molecule, except F(2), lies on a mirror plane (symmetry code #4) and the mercury atom is located on a centre of symmetry (symmetry code #1); accordingly, the asymmetric unit contains one pyrimidine-2-thionate ligand (apart from one of the fluorine atoms of the CF_3 group) and one half of the mercury atom. In the molecule, the mercury atom is bonded to two sulfur atoms in a linear disposition. The Hg–S bond length [2.330(2) Å] is very similar to those found in other thionatomercury complexes with a linear geometry.[11,47–49]

In the complex the two ligands are on different sides of the line defined by the S–Hg–S bonds, and the pyrimidine rings are in a staggered conformation. The ligands are oriented in such a way that the N(1) atom is close to the mercury atom (distance of 2.773 Å). This value is larger than those observed in other mercury complexes containing heterocyclic donor nitrogen ligands, such as [Hg(pyS)(OAc)][50] (2.210 Å) or [HgMepy](NO_3)[51] [2.12(2) Å], but shorter than the sum of the van der Waals radii (3.23 Å),[52] and comparable to the distances in other mercury thiolate complexes characterised by weak intramolecular Hg···N interactions (2.798–2.980 Å).[46,53–55]

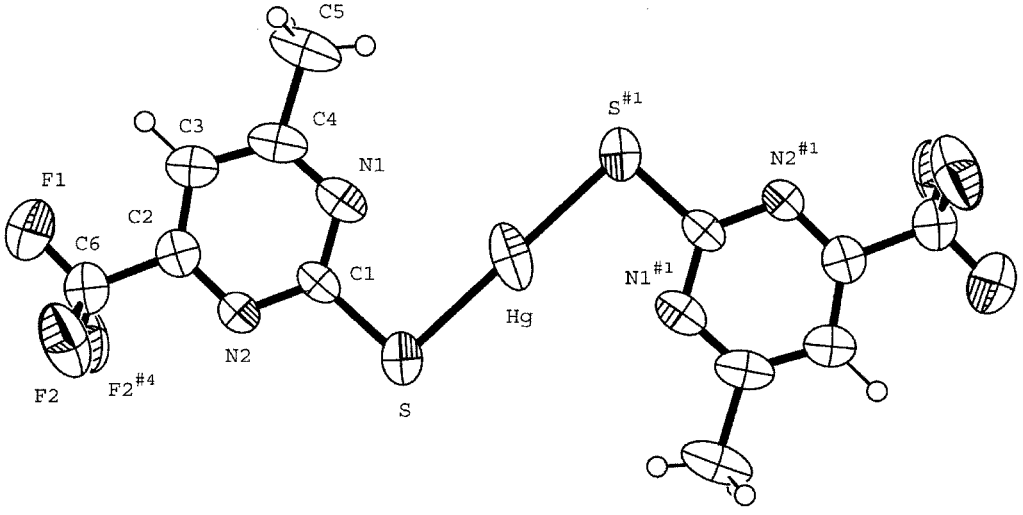

Figure 10. ORTEP diagram of the molecular structure of [Hg(4,6-CF_3MepymS)$_2$] (**8**), with 50% thermal ellipsoid probability. Symmetry codes: #1 = $-x + 1, -y + 1, -z + 1$; #4 = $x, y, -z + 1$.

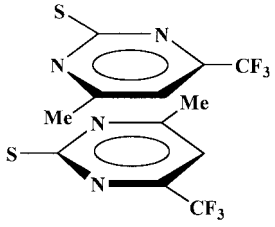
The Hg···Hg distance [3.4845(5) Å] is much longer than those found in elemental mercury[56] (3.02 Å), in mercury clusters with mercury in an oxidation state of zero or in dinuclear mercury(I) complexes (Hg_2^{2+}, 2.5 Å).[57] However, the distance is close to or shorter than the sum of the van der Waals radii (1.7–2.0 Å)[58] and even shorter than that observed in most other mercury(II) complexes (3.848–3.578 Å).[59–63] It is also similar to the shortest Hg···Hg distance found in the case of tris(1,3-dimethyluracil-5-yl)mercurioxonium salt, which dimerises in two different ways through weak Hg···Hg contacts [Hg···Hg distances in the range 3.4552(6) to 3.5974(5) Å].[64]

The pyrimidine rings are planar and the sulfur atoms are located in the same plane as the corresponding ring and the Hg atom. The S–C bond length (1.752 Å) is close to those found in many other complexes containing thionate ligands.

Each [Hg(4,6-CF_3MepymS)$_2$] unit is essentially planar given that the pyrimidine ring is planar and both rings in each unit are related by an inversion centre located on the mercury atom. The pyrimidine rings of each unit are parallel to the crystallographic *ab* plane. In the crystal packing of the complex these units are arranged parallel to one another (Figure 11). The units are not superimposable but are related through a rotation of 180° around an axis that passes through the Hg centres and is parallel to the *b* axis, followed by a translation about the *c* axis (1 – *x*, *y*, *z* + 0.5). In this arrangement the molecules are stacked in the direction of the crystallographic *c* axis. Two types of intermolecular interaction are responsible for the packing arrangement. On the one hand, an Hg–Hg interaction exists between two units and this results in the Hg atoms being in a linear arrangement parallel to the *c* axis (Hg–Hg distance = 3.484 Å). On the other hand, a π–π stacking interaction exists between the pyrimidine rings of the contiguous [Hg(4,6-CF_3MepymS)$_2$] units (distance between the centroids = 3.512 Å). In this case the π–π stacking interaction gives rise to "perfect facial alignment", as shown by the angle formed by the centroids of the three consecutive rings (165.56°). This angle is very close to the 180° that one would expect for a complete interaction. It should also be noted that, for each interaction of this type, each ring is rotated with respect to the adjacent ring, meaning that the groups present on one ring do not eclipse those on other rings. This situation can clearly be seen in the diagram below (Scheme 2), which shows a view perpendicular to the plane of the pyrimidine rings (along the crystallographic *c* axis).



Scheme 2.

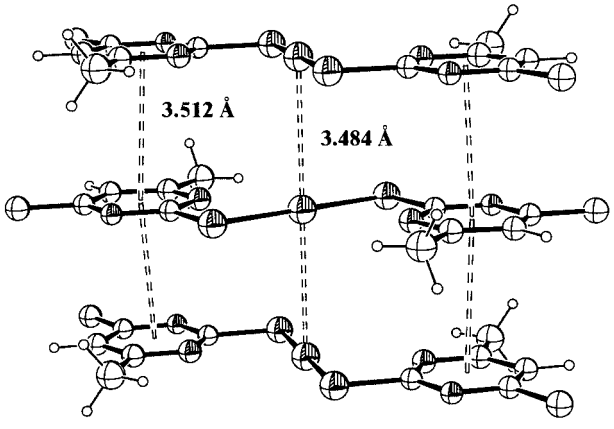


Figure 11. Partial packing diagram of **8** showing intermolecular π–π interactions and weak Hg···Hg contacts.

Spectroscopic Data

IR Spectra

The IR spectra of the complexes do not show bands due to ν(N–H), which in the free ligands appear between 3200 and 3050 cm^{-1}. This shows that deprotonation of the NH group has occurred during the synthesis and, therefore, that the ligand is coordinated in the thionato form. This conclusion is supported by the shift to smaller wavenumbers of the strong bands for ν(C=C) and ν(C=N), which appear at 1600–1550 and 1570–1525 cm^{-1}, respectively, in the free ligands, on going from the free ligands to the complexes. In addition, bands attributable to the ring breathing vibration at ca. 1000 and 630 cm^{-1} are observed. These shifts provide evidence that the nitrogen atom is bound to the metal atom.[65,66] In addition, the mixed complexes show bands typical for coordinated 2,2′-bypyridine[67] (770 and 730 cm^{-1}) and 1,10-phenanthroline[67,68] (1530–1505, 840 and 720 cm^{-1}).

NMR Spectra

The ^{1}H NMR spectra of the complexes do not contain a signal for the NH proton of the free ligand, which shows that the ligands are deprotonated in the complexes. The signals of all the protons of the pyrimidine ring and phenyl or methyl groups in the complexes are slightly shifted with respect to those of the free ligands. The NMR spectra of mixed complexes show additional signals for 2,2′-bipyridine and 1,10-phenanthroline at around δ = 7.6–9.2 ppm. These signals are slightly shifted to lower field in comparison to the corresponding signals in the free ligands. These changes again provide evidence of coordination of the ligands to the metal atom through the nitrogen atoms.[69–71] The ^{13}C NMR spectra of the free ligands 4,6-CF_3MepymSH and 4,6-CF_3PhpymSH show double the expected number of signals for C(2), C(6), CF_3 and CH_3, as the free ligands exist in two tautomeric forms. This doubling in the number of signals is not observed in the ^{13}C NMR spectra of the metal complexes. This situation provides evidence that, in solu-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion, the ligand is coordinated to the metal in the thionate form only.

The mercury complexes have $\delta(^{199}Hg)$ values in the δ = –1180 to –1213 ppm range. These values are similar to those found in other mercury(II) thionates in which a weak interaction between the metal atom and the heterocyclic nitrogen is observed.[11,49]

Mass Spectra

The cadmium and mercury complexes were also characterised by mass spectrometry using the positive-ion FAB technique in 3-nitrobenzyl alcohol (NBA) as matrix. The FAB spectra of $[Cd(RpymS)_2(bipy)]$ and $[Cd(RpymS)_2(phen)]$ show the molecular ion with the appropriate isotope distribution, as well as peaks due to the fragments produced by the loss of one and two thionate ligands. In the case of $[Cd(4,6\text{-}CF_3MepymS)_2(phen)]$ the peak due to the loss of the 1,10-phenanthroline is also observed at m/z = 294.

The FAB mass spectra of both of the mercury compounds, $[Hg(RpymS)_2]$, show the molecular ion peak at m/z = 561 (R = CF_3) and 589 (R = 4,6-CF_3,Me) along with peaks at m/z = 381 and 386, respectively, which are associated with [Hg(RpymS)] formed by loss of one thionate ligand.

Conclusions

In this report we have described the electrochemical synthesis of a series of homoleptic and heteroleptic neutral cadmium(II) complexes and homoleptic mercury complexes with pyrimidine-2-thione derivatives. The ligands differ in the nature, position and number of substituents in the heterocyclic ring.

In the case of $[Cd(4\text{-}CF_3pymS)_2]$ (**1**), the presence of the trifluoromethyl substituent is not sufficient to prevent the association process and, as a consequence, the compound is a polymer, with the metal atom in an $[S_4N_2]$ octahedral environment. However, the presence of coligands, such as 1,10-phenanthroline and 2,2′-bipyridine, in the coordination sphere of cadmium modifies the aggregation process and the complexes $[Cd(4,6\text{-}CF_3MepymS)_2bipy]$ (**4**) and $[Cd(4,6\text{-}CF_3PhpymS)_2bipy]$ (**6**) are monomers with the metal atom in a different $[S_2N_4]$ hexacoordinate environment for both compounds − distorted octahedral for **4** and distorted trigonal prismatic for **6**. The crystal packing of compound **6** shows the presence of C–H···π and π–π stacking interactions. The groups involved in the C–H···π interactions are in the 6-position of the pyrimidine rings.

Experimental Section

General Considerations: 4-Trifluoromethylpyrimidine-2-thione, 1,1,1-trifluoroacetone, 1,1,1-trifluoro-2,4-pentanedione, thiourea, benzaldehyde, 1,10-phenanthroline and 2,2′-bipyridine are all commercial products and were used as supplied. Cadmium (Aldrich) was used as 2 × 2 cm plates. Mercury metal, a commercial product, was washed with nitric acid and water prior to use.

Elemental analysis was performed with a Carlo–Erba EA microanalyser. IR spectra were recorded as KBr mulls on a Bruker IFS-66V spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker AMX 300 MHz instrument with $CDCl_3$ or $[D_6]$DMSO as solvent. Chemical shifts are given relative to TMS as the internal standard. ^{119}Hg NMR spectra were recorded on a Bruker AMX500 spectrometer with $CDCl_3$ as solvent. The mass spectra (FAB) were recorded on a Micromass Autospec spectrometer, with 3-nitrobenzyl alcohol as the matrix material.

[4,6-CF_3MepymSH]: This compound was obtained by direct reaction between thiourea (2.428 g, 32 mmol) and 1,1,1-trifluoro-2,4-pentanedione (5 g, 32 mmol) in ethanol in the presence of concentrated hydrochloric acid (1 mL) as a catalyst. The mixture was heated under reflux for 2 h and the resulting dusty yellow solid was filtered off. $C_6H_5F_3N_2S$ (194.17): calcd. C 37.11, H 2.60, N 14.43, S 16.51; found C 36.89, H 2.60, N 14.26, S 16.08. IR (KBr): $\tilde{\nu}$ = 3100–3200 (m, br), 1615 (vs), 1590 (vs), 1440 (m), 1350 (vs), 1320 (w), 1200(s, br), 1130 (m), 1100 (m), 1030 (w), 970 (s), 920 (m), 860 (w), 850 (m), 705 (w), 660 (w), 595 (w), 570 (w), 530 (m), 510 (w), 470 (m), 450 (m), 370 (w) cm^{-1}. ^1H NMR (300 MHz, $[D_6]$DMSO, 25°): δ = 14.40 (s, 1 H, NH), 7.19 (s, 1 H, H^5), 2.39 (s, 3 H, CH_3) ppm. ^{13}C NMR (300 MHz, $[D_6]$DMSO): δ = 181.00 and 172.13 (s, C^2), 155.86 and 153.72 (q $^2J_{^{13}C\text{-}^{19}F}$ = 35 Hz, C^4), 104.89 (s, C^5), 163.61 (s, C^6), 119.27 and 119.67 (q, $^1J_{^{13}C\text{-}^{19}F}$ = 275 Hz, CF_3), 23.45 and 18.46 (s, CH_3) ppm. MS (FAB): m/z = 194 (4,6-CF_3MepymSH).

[4,6-CF_3PhpymSH]: The precursor 1,1,1-trifluoro-4-phenyl-3-buten-2-one was prepared previously. Benzaldehyde (5.22 g, 49 mmol) and 1,1,1-trifluoroacetone (5.21 g, 49 mmol) were added to a solution of NaOH (9.93 g, 0.25 mol) in cold water (200 mL). The mixture was allowed to reach room temperature, stirred for 6 h and finally heated to 65 °C for 12 h. The organic compounds were extracted with CH_2Cl_2, dried ($MgSO_4$) and the solvent removed by vacuum distillation to give a colourless liquid. (yield: 3.81 g, 39%). ^1H NMR (300 MHz, $CDCl_3$): δ = 6.8 (d, olefinic protons), 6.9 (d, olefinic protons), 7.3 (m, Ph) ppm. ^{13}C NMR (300 MHz, $[D_6]$-DMSO): δ = 180.53 (q, CF_3), 150.44 (CO), 115–130 (C, phenyl ring), 34.42 and 38.42 (C, olefinic) ppm.

Dry ethanol (40 mL) was placed in a flame-dried round-bottomed flask purged with argon, and sodium (0.45 g, 19.9 mmol) was added at 0 °C. When effervescence had ceased, a solution of thiourea (0.38 g, 4.99 mmol) in dry ethanol (30 mL) was added by cannula and the mixture was stirred for 15 min at room temperature. A solution of the previously prepared 1,1,1-trifluoro-4-phenyl-3-buten-2-one (1 g, 5 mmol) in dry ethanol was added to the reaction mixture by cannula. The mixture was heated under reflux under argon for 24 h. When the reaction was complete, the solvent was removed and the resultant solid was added to water (50 mL). The suspension was filtered and the alkaline solution was acidified to pH 6 with AcOH. The resulting dusty yellow solid was filtered off and washed with water until the washings were neutral. The solid was dried under vacuum to give 1.1 g of a dusty orange solid. The product was recrystallized from ethanol to give an orange solid. Yield: 0.652 g (51%). $C_{11}H_7F_3N_2S$ (256.25): calcd. C 51.50, H 2.75, N 10.93, S 12.51; found C 51.40, H 2.81, N 11.02, S 12.39. IR (KBr): $\tilde{\nu}$ = 3100–3200 (m, br), 1645 (m), 1610 (s), 1570 (s), 1550 (m), 1530 (m), 1490 (m), 1460 (m), 1450 (w), 1390 (vs), 1350 (m), 1330 (m), 1310 (w), 1260 (s), 1190 (vs), 1140 (m), 1110 (m), 1000 (s), 970 (w), 900 (m), 870 (w), 830 (s), 720 (m), 710 (w), 690 (s), 630 (m), 580 (m), 470 (w), 410 (w) cm^{-1}. ^1H NMR (300 MHz, $[D_6]$-DMSO): δ = 13.0 (s, 1 H, NH), 7.8 (s, 1 H, H^5), 7.6 (m, Ph) ppm. ^{13}C NMR (300 MHz, $[D_6]$DMSO): δ = 169.30 (s, C^2), 167.31 (q,

C^4), 110.42 (s, C^5), 163.85 (s, C^6), 118.54 (q, CF_3), 122.98–135.32 (phenyl ring) ppm. MS: m/z = 257.2 [M^+], 511 [M_2^+].

Electrochemical Synthesis: All complexes were obtained by an electrochemical procedure.[25] The cell was a 100-mL, tall-form beaker fitted with a rubber bung. An acetonitrile solution of the thione containing tetraethylammonium perchlorate (10 mg) was electrolysed using a platinum wire as the cathode and a cadmium plate as a sacrificial anode suspended from another platinum wire. For the synthesis of mercury compounds, the anode, which was in the bottom of the vessel, was also connected through a platinum wire. For the synthesis of mixed complexes, the corresponding co-ligand was added to the solution phase. In all cases, hydrogen was evolved at the cathode. The cells can be summarised as $M_{(+)}/CH_3CN$ + RpymSH + L′/$Pt_{(-)}$. During the electrolysis the yellow colour of the solution faded and, at the end of the reaction, the solids were isolated by filtration.

[Cd(4-CF_3pymS)$_2$] (1): Electrochemical oxidation of a cadmium anode in a solution of 4-(trifluoromethyl)pyrimidine-2-thione (4-CF_3pymSH; 0.150 g, 0.83 mmol) in acetonitrile (50 mL) at 14 V and 10 mA for 1.5 h caused 36 mg of cadmium to be dissolved (E_f = 0.52 mol F^{-1}). During the electrolysis hydrogen was evolved at the cathode and at the end of the experiment a crystalline solid, suitable for X-ray studies, had formed at the bottom of the vessel. The yellow solid was filtered off, washed with acetonitrile and diethyl ether and dried under vacuum. Yield: 0.102 g (52%). $C_{10}H_4CdF_6N_4S_2$ (470.69): calcd. C 25.5, H 0.9, N 11.9, S 13.6; found C 25.5, H 0.8, N 12.0, S 13.6. IR (KBr): $\tilde{\nu}$ = 1570 (s), 1550 (vs), 1420 (m), 1345 (s), 1325 (vs), 1200 (s), 1175 (m), 1145 (m), 1110 (s), 830 (vs), 780 (m), 730 (s), 670 (s), 470 (m), 440 (m) cm^{-1}. ^1H NMR (300 MHz, [D_6]DMSO): δ = 7.37 (d, 1 H, H^5), 8.53 (d, 1 H, H^6) ppm. ^{13}C NMR (300 MHz, [D_6]DMSO): δ = 183.34 (C^2), 168.68 (C^6), 154.17 (q, C^4), 114.95 (C^5), 120 (q, CF_3) ppm.

[Cd(4-CF_3pymS)$_2$(bipy)] (2): Electrolysis of an acetonitrile solution containing 4-CF_3pymSH (0.150 g, 0.83 mmol), 2,2′-bipyridine (0.065 g, 0.42 mmol) and a small amount of tetraethylammonium perchlorate (ca. 10 mg) at 10 mA and 16 V for 1.5 h dissolved 26 mg of cadmium (E_f = 0.44). At the end of the experiment the white solid was filtered off, washed with acetonitrile and dried in vacuo. The compound was characterised as [Cd(4-CF_3pymS)$_2$(bipy)] (**2**). Yield: 0.142 g (55%) $C_{20}H_{12}CdF_6N_6S_2$ (626.88): calcd. C 38.3, H 1.9, N 13.4, S 10.2; found C 38.0, H 1.9, N 13.5, S 10.2. IR (KBr): $\tilde{\nu}$ = 1585 (m), 1550 (vs), 1475 (w), 1460 (w), 1430 (m), 1415 (s), 1335 (vs), 1240 (w), 1200 (vs), 1165 (w), 1150 (w), 1130 (m), 1110 (m), 1010 (m), 970 (m), 830 (m), 820 (m), 760 (s), 730 (m), 670 (s), 645 (w), 620 (w) cm^{-1}. ^1H NMR (300 MHz, [D_6]DMSO): δ = 7.21 (d, 2 H, H^5), 8.51 (d, 2 H, H^6); bipy: 9.10 (d, 2 H, $H^6/H^{6'}$), 7.60 (dd, 2 H, $H^5/H^{5'}$), 8.10 (dd, 2 H, $H^4/H^{4'}$), 8.80 (d, 2 H, $H^3/H^{3'}$) ppm. ^{13}C NMR (300 MHz, [D_6]DMSO): δ = 168.67 (C^2), 162.10 (C^6), 154.45 (q, C^4), 121 (q, CF_3), 114.9 (C^5), 149.12 (bipy, $C^2/C^{2'}$); 139.16 (bipy, $C^5/C^{5'}$), 125.38 (bipy, $C^3/C^{3'}$), 118.55 (bipy, $C^4/C^{4'}$) ppm. MS (FAB): m/z = 448 [Cd(4-CF_3pymS)(bipy)], 627 [Cd(4-CF_3pymS)$_2$(bipy)].

[Cd(4-CF_3pymS)$_2$(phen)] (3): A similar experiment to that described above (12 V, 10 mA, 1.5 h) with 4-CF_3pymSH (0.150 g, 0.83 mmol) and phenanthroline (0.084 g, 0.467 mmol) in acetonitrile (50 mL) dissolved 27 mg of cadmium (E_f = 0.46). The solid was filtered off, washed with cold acetonitrile and diethyl ether, and dried under vacuum. Yield: 0.122 g (45%). $C_{22}H_{12}CdF_6N_6S_2$ (650.90): calcd. C 40.6, H 1.9, N 12.9, S 9.8; found C 40.6, H 1.8, N 12.9, S 9.9. IR (KBr): $\tilde{\nu}$ = 1610 (m), 1580 (m), 1550 (vs), 1525 (w), 1510 (w), 1500 (s), 1480 (m), 1415 (vs), 1335 (vs), 1320 (m), 1190 (s), 1160 (m), 1130 (w), 1110 (w), 1095 (w), 1070 (w), 1010 (m), 985 (m), 970 (w), 860 (m), 840 (s), 830 (s), 815 (s), 770 (m), 720 (vs), 665 (s), 635 (m), 460 (w), 430 (w), 415 (w), 350 (w), 310 (w) cm^{-1}. ^1H NMR (300 MHz, [D_6]DMSO): δ = 7.60 (d, 2 H, H^5), 8.60 (d, 2 H, H^6); phen: 8.87 (d, 2 H, H^2/H^9), 7.80 (dd, 2 H, H^3/H^8), 8.80 (d, 2 H, H^7/H^4), 8.00 (s, 2 H, H^6/H^5) ppm. ^{13}C NMR (300 MHz, [D_6]DMSO): δ = 170.12 (C^2), 162.11 (C^6), 154.21 (C^4), 114.96 (C^5), 127 (q, CF_3), 149.62 (phen, C^9/C^2), 139.80 (phen, C^{4b}/C^{6b}), 139.33 (C^4/C^7), 128.74 (phen, C^{4a}/C^{6a}), 127.05 (phen, C^5/C^6), 125.13 (phen, C^3/C^8) ppm. MS (FAB): m/z = 471 [Cd(4-CF_3pymS)(phen)], 650 [Cd(4-CF_3pymS)$_2$(phen)].

[Cd(4,6-CF_3MepymS)$_2$(bipy)] (4): Electrolysis of an acetonitrile solution containing 4,6-CF_3MepymSH (0.200 g, 1.03 mmol) and bipyridine (0.080 g, 0.51 mmol) at 10 mA and 32 V for 2.75 h dissolved 73 mg of cadmium (E_f = 0.56). At the end of the experiment the yellow solid was filtered off, washed with acetonitrile and diethyl ether, and dried in vacuo. The compound was characterised as [Cd(4,6-CF_3MepymS)$_2$(bipy)]. Yield: 0.128 g (38%). $C_{22}H_{16}CdF_6N_6S_2$ (654.93): calcd. C 40.3, H 2.5, N 12.8, S 9.8; found C 40.7, H 2.3, N 12.9, S 9.6. IR (KBr): $\tilde{\nu}$ = 1590 (m), 1565 (vs), 1540 (vs), 1465 (m), 1435 (s), 1380 (vs), 1360 (m), 1310 (m), 1270 (vs), 1255 (s), 1220 (m), 1190 (m), 1135 (s), 1100 (m), 1010 (m), 1000 (m), 970 (m), 910 (m), 845 (s), 760 (s), 730 (m), 705 (s), 645 (w), 540 (m), 460 (w), 405 (w) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.53 (s, 6 H, CH_3), 6.87 (s, 2 H, H^5); bipy: 8.91 (d, 2 H, $H^6/H^{6'}$), 7.82 (dd, 2 H, $H^5/H^{5'}$), 8.05 (dd, 2 H, $H^4/H^{4'}$), 8.23 (d, 2 H, $H^3/H^{3'}$) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 184.07 (C^2), 169.13 (C^6), 155.17 (q, C^4), 109.57 (s, C^5), 24.33 (s, CH_3), 122.49 (q, CF_3), 150.62 (bipy, $C^2/C^{2'}$), 150.03 (bipy, $C^6/C^{6'}$), 140.17 (bipy; $C^5/C^{5'}$), 126.4 (bipy, $C^3/C^{3'}$), 112.8 (bipy, $C^4/C^{4'}$) ppm. MS (FAB): m/z = 463 [Cd(4,6-CF_3MepymS)(bipy)], 499 [Cd(4,6-CF_3MepymS)$_2$], 655 [Cd(4,6-CF_3MepymS)$_2$(bipy)].

Crystals of [Cd(4,6-CF_3MepymS)$_2$(bipy)] (**4**) suitable for X-ray studies were obtained by recrystallisation of the initial product from *i*PrOH.

[Cd(4,6-CF_3MepymS)$_2$(phen)] (5): An acetonitrile solution of 4,6-CF_3MepymSH (0.200 g, 1.03 mmol) and phenanthroline (0.100 g, 0.55 mmol) was electrolysed at 10 mA during 2.75 h and 68 mg of cadmium was dissolved from the anode (E_f = 0.53). At the end of the electrolysis the solution was concentrated and the resulting green solid was filtered off, washed with cold acetonitrile and diethyl ether, dried under vacuum and identified as [Cd(4,6-CF_3MepymS)$_2$(phen)]. Yield: 0.269 g (79%). $C_{24}H_{16}CdF_6N_6S_2$ (678.95): calcd. C 42.3, H 2.4, N 12.4, S 9.4; found C 42.0, H 2.4, N 12.6, S 9.0. IR (KBr): $\tilde{\nu}$ = 1570 (s), 1540 (vs), 1525 (w), 1505 (m), 1420 (m), 1385 (vs), 1360 (s), 1300 (m), 1270 (vs), 1255 (vs), 1220 (m), 1175 (s), 1160 (m), 1005 (w), 970 (w), 915 (m), 840 (s), 770 (w), 725 (s), 705 (vs), 630 (w), 545 (m), 460 (m) cm^{-1}. ^1H NMR (300 MHz, [D_6]DMSO): δ = 7.09 (s, 2 H, H^5), 2.06 (s, 6 H, CH_3); phen: 9.22 (dd, 2 H, H^2/H^9), 8.80 (d, 2 H, H^4/H^7), 8.01 (dd, 2 H, H^8/H^3), 8.2 (s, 2 H, H^5/H^6) ppm. ^{13}C NMR (300 MHz, [D_6]DMSO): δ = 184.07 (C^2), 169.13(C^6), 155.42 (q, C^4), 122.50 (q, CF_3), 109.34 (C^5), 24.40 (CH_3), 150.15 (phen, C^9/C^2), 141.82 (phen, C^{4b}/C^{6b}), 139.29 (phen, C^4/C^7), 129.62 (phen, C^{4a}/C^{6a}), 127.50 (phen, C^5/C^6), 125.39(phen, C^3/C^8) ppm. MS (FAB): m/z = 180 [phen], 294 [Cdphen], 487 [Cd(4,6-CF_3MepymS)(phen)], 499 [Cd(4,6-CF_3MepymS)$_2$], 679 [Cd(4,6-CF_3MepymS)$_2$(phen)].

[Cd(4,6-CF_3PhpymS)$_2$(phen)] (6): A similar experiment (6 V, 10 mA, 1 h) with 4,6-CF_3PhpymSH (0.100 g, 0.55 mmol) and phen (0.035 g, 0.19 mmol) in acetonitrile (50 mL) dissolved 18 mg of cadmium (E_f = 0.48). Crystals suitable for X-ray studies were obtained directly from the cell. The solid was filtered off, washed with cool acetonitrile and diethyl ether, and dried under vacuum. Yield:

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.119 g (36%). $C_{34}H_{20}CdF_6N_6S_2$ (803.08): calcd. C 50.8, H 2.5, N 10.4, S 8.0; found C 50.4, H 2.3, N 10.4, S 7.9. IR (KBr): $\tilde{\nu}$ = 1615 (s), 1559 (m), 1540 (w), 1515 (w), 1500 (m), 1430 (w), 1400 (w), 1380 (vs), 1318 (s), 1300 (m), 1241 (m), 1180 (s), 1150 (s), 1135 (s), 1000 (s), 840 (m), 810 (w), 780 (s), 720 (w), 730 (m), 715 (w), 700 (m), 650 (w), 640 (m) cm^{-1}. ^1H NMR (300 MHz, [D$_6$]DMSO): δ = 8.41 (s, 2 H, H^5); phen: 9.07 (dd, 2 H, H^2/H^9), 8.79 (d, 2 H, H^4/H^7), 8.00 (dd, 2 H, H^3/H^8), 8.20 (s, 2 H, H^5/H^6) ppm; signals at δ = 7.39–7.84 ppm were assigned to the phenyl group.

[Hg(4-CF$_3$pymS)$_2$] (7): A solution of acetonitrile (50 mL) containing 4-CF$_3$pymSH (0.150 g, 0.83 mmol) was electrolysed at 10 mA during 2 h. No precipitation occurred initially, but within several hours a white solid had formed and this was filtered off, washed with acetonitrile, dried and identified by elemental analysis. Yield: 0.096 g (41%). $C_{10}H_4F_6HgN_4S_2$ (558.87): calcd. C 21.5, H 0.7, N 10.0, S 11.5; found C 22.0, H 0.6, N 10.3, S 11.2. IR (KBr): $\tilde{\nu}$ = 1550 (vs), 1420 (s), 1350 (vs), 1330 (vs), 1280 (w), 1200 (s), 1175 (w), 1110 (s), 1005 (w), 975 (s), 845 (m), 830 (m), 750 (w), 730 (m), 670 (s), 630 (w), 455 (w), 365 (w) cm^{-1}. ^1H NMR (300 MHz, [D$_6$]DMSO): δ = 7.43 (d, 2 H, H^5), 8.61 (d, 2 H, H^6) ppm. ^{13}C NMR (300 MHz, [D$_6$]DMSO): δ = 176.95 (C^2), 160.45 (C^6), 153.85 (q, C^4), 111.98 (C^5), 121.49 (q, CF_3) ppm. ^{119}Hg NMR (500 MHz $CDCl_3$): δ = –1213 ppm. MS (FAB): m/z = 560 [Hg(4-CF$_3$pymS)$_2$], 381 [Hg(4-CF$_3$pymS)].

[Hg(4,6-CF$_3$MepymS)$_2$] (8): A similar procedure was used to that described for [Hg(4-CF$_3$pymS)$_2$]. 4,6-CF$_3$MepymSH (0.200 g, 1.03 mmol) was electrolysed at 10 mA during 2 h. At the end of the experiment a microcrystalline white solid had formed and this was filtered off, washed with acetonitrile, dried and identified by elemental analysis. Yield: 0.114 g (38%). $C_{12}H_8F_6HgN_4S_2$ (587.94): calcd. C 24.6, H 1.4, N 9.6, S 11.0; found C 24.6, H 1.2, N 9.5, S 11.1. IR (KBr): $\tilde{\nu}$ = 1580 (vs), 1535 (s), 1385 (vs), 1310 (w), 1270 (s), 1255 (m), 1220 (m), 1170 (m), 1140 (m), 1110 (m), 1025 (w), 975 (m), 920 (w), 865 (s), 845 (s), 780 (w), 750 (w), 710 (vs), 680 (w), 635 (w), 565 (w), 550 (m), 485 (w), 450 (w), 370 (w) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.18 (s, 2 H, H^5), 2.47 (s, 6 H, CH_3) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 177.13 (s, C^2), 170.80 (s, C^6), 155.60 (q, C^4), 118.70 (CF_3), 112.58 (s, C^5), 24.40 (s, CH_3) ppm. ^{119}Hg NMR (500 MHz, $CDCl_3$): δ = –1207 ppm. MS (FAB): m/z = 386 [Hg(4,6-CF$_3$MepymS)], 588 [Hg(4,6-CF$_3$MepymS)$_2$], 386 [Hg(4,6-CF$_3$MepymS)].

Crystallisation from ethanol/acetone gave monocrystals suitable for X-ray studies.

X-ray Crystal Structure Determinations: X-ray data were collected on a Bruker Smart CCD 1000 diffractometer for **1** and **6**, and on an Enraf–Nonius CAD4 diffractometer in the cases of **4** and **8**, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The data were collected at 293 K for all structures. The ω-scan technique was employed to measure intensities for all crystals. Decomposition of the crystals did not occur during data collection. Absorption effects in compounds **1** and **6** were corrected with SADABS.[72] Absorption in **4** and **8** was corrected by semi-empirical Ψ scans. All the structures were solved by direct methods and refined[73] by full-matrix least-squares based on F^2. For all the complexes, hydrogen atoms were also included in idealised positions and refined with isotropic displacement parameters. All non-hydrogen atoms in the structures were refined anisotropically with the exception of compound **4**, in which only the heavy atoms (mercury and sulfur) were refined anisotropically due to the poor quality of the high-angle data. The CF_3 groups of compounds **1** and **6** are disordered over two positions with occupancies 51:49 and 57:43 for the groups on C(5) and C(10) in compound **1** and 63:37 for the CF_3 group in compound **6**. Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from the International Tables for X-ray Crystallography.[74] The crystal data and summary of data collection and structure refinement for these compounds are given in Table 5. The structures were visualised with ORTEP3.[75]

CCDC-240151–240154 (for **1**, **4**, **6** and **8**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Trigonal-Prismatic vs. Octahedral Geometry for Mn^{II} Complexes with Innocent Didentate Ligands: A Subtle Difference as Shown by XRD and DFT on $[Mn(acac)_2(bpy)]$

Remy van Gorkum,[a] Francesco Buda,[a] Huub Kooijman,[b] Anthony L. Spek,[b] Elisabeth Bouwman,*[a] and Jan Reedijk[a]

Keywords: Trigonal prism / Distorted octahedron / Density Functional Theory (DFT) / Manganese(II) / Packing effects

In this paper the first example of a mixed-ligand Mn^{II} complex, having a trigonal-prismatic coordination geometry with simple, innocent, didentate ligands is presented. The solution and solid-state structures of $[Mn(acac)_2(bpy)]$ as studied by EPR spectroscopy, magnetic susceptibility measurements and XRD are presented: single crystals are hexagonal, space group $P6_1$ with unit cell dimensions a = 8.0482(9) Å, c = 51.602(10) Å, V = 2894.6(7) Å^3 and Z = 6. The complex has the trigonal-prismatic geometry only in the solid state. Density functional theory (DFT) calculations were performed to address the question of the preference for a specific coordination geometry in the related Mn^{II} complexes $[Mn(acac)_2(bpy)]$ (trigonal prismatic) and $[Mn(acac)_2(phen)]$ (distorted octahedral). Based on the very small energy differences for the calculated trigonal-prismatic and octahedral structures it has been concluded that crystal packing effects must contribute largely in determining the trigonal-prismatic structure for $[Mn(acac)_2(bpy)]$.

Introduction

Even though the first observed example of a trigonal-prismatic complex, $[Re(1,2\text{-}S_2C_2Ph_2)_3]$, dates back from 1965,[1] mixed ligand trigonal-prismatic complexes with simple didentate ligands are still rare. Since 1965 several tris(dithiolene) complexes with trigonal-prismatic or distorted octahedral geometry have been reported.[2] In addition a limited, but growing number of examples of non-dithiolene $[M(didentate)_3]$ trigonal-prismatic compounds is known, for instance with buta-1,3-diene, methyl vinyl ketone or acetylacetonate as ligands.[3–6] A few mixed ligand trigonal-prismatic complexes of the form $[M(didentate1)_2(didentate2)]$ are known, for example the complexes with a diimine and two (substituted) catechol semiquinonates as ligands,[7–9] but they are definitely not as common as homoleptic tris(didentate) complexes. Most compounds mentioned above have either noninnocent ligands, or ligands that can easily participate in π-(back) bonding. Therefore, it is not unexpected that for these complexes the majority of arguments for favoring trigonal-prismatic over octahedral geometry are electronic in nature, as for example: The overall charge of the complex, ligand-field stabilization energy, matching of ligand and metal orbital energies, bonding between the ligand donor-atoms and π-bonding.[10,11] Even some examples of six-coordinate trigonal-prismatic complexes with monodentate ligands have been reported.[12,13] These complexes all contain d^0 metal ions and in these cases the preference for the trigonal-prismatic geometry has been ascribed to the absence of steric or π-bonding effects.

A well-known strategy for obtaining trigonal-prismatic complexes is using rigid, penta- or hexadentate ligands that force the trigonal-prismatic geometry upon a complex by means of steric constraints.[14–16] This successful strategy has resulted in many examples of trigonal-prismatic complexes.

While searching for novel manganese-based catalysts for the oxidative drying of alkyd paints,[17] the X-ray structure of the well-known compound $[Mn(acac)_2(bpy)]$ was determined. Although this complex has been claimed to have an octahedral coordination geometry,[18] it appears to be the first example of a mixed-ligand complex with innocent didentate ligands that possesses the trigonal-prismatic coordination geometry. Herein, we describe the crystal structure details and EPR spectra of the complex. DFT calculations have been performed to address the question of the preference for trigonal-prismatic vs. octahedral geometry, comparing this complex with the related octahedral phenanthroline complex, $[Mn(acac)_2(phen)]$.

Results

Synthesis and Characterization: The synthesis of [Mn(acac)$_2$(bpy)] is best carried out under argon until the product is isolated and dried, since the complex is very sensitive to air-oxidation when moist or in solution. The dried complex is stable in air. The yield (67%) is satisfactory, as was the elemental analysis.

Spectroscopic Features: The infrared spectrum of [Mn(acac)$_2$(bpy)] is in agreement with literature,[18] with important IR peaks being ν(C–O) 1604, 1578 cm^{-1}, ν(C–C) 1516 cm^{-1}, ν(M–O) 647, 536, 415 cm^{-1} and ν(M–N) 403, 228 cm^{-1}. The electronic spectrum of the solid compound shows an MLCT band at 365 nm (27.4×10^3 cm^{-1}).

EPR: The room temperature powder spectrum of [Mn(acac)$_2$(bpy)] shows a strong, nonisotropic resonance signal at g = 3.25 and a very weak signal at high field, at g = 0.74, see Figure 1. The powder spectrum of [Mn(acac)$_2$(phen)] shows a single broad signal at g = 2 (see the inset in Figure 1).[19]

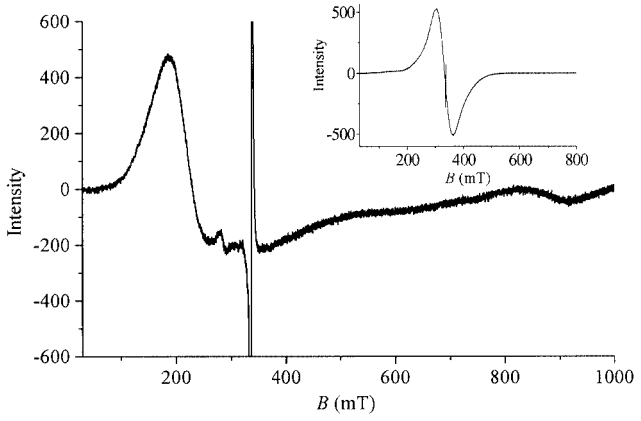

Figure 1. Room temperature powder EPR spectra of [Mn(acac)$_2$(bpy)] and [Mn(acac)$_2$(phen)] (inset). Important EPR parameters for both spectra: frequency 9.434 GHz, power 4 mW. The dpph reference can be seen as a sharp radical signal at 336 mT. The small signal at 280 mT is due to an impurity in the cavity.

The frozen-solution spectra (77 K, 0.001 M in CH_2Cl_2/toluene) of [Mn(acac)$_2$(bpy)] and [Mn(acac)$_2$(phen)] are nearly identical, showing a broad peak at g = 2.7 and a very broad signal (260–410 mT) centered around g = 2 (see supporting information for the frozen-solution EPR spectra of both compounds; for supporting information see also the footnote on the first page of this article). Overlapping the signal at g = 2 a six-line signal typical for octahedral manganese(II) is present, showing ^{55}Mn hyperfine structure and additional lines due to zero-field splitting.

Magnetic Susceptibility: A χT vs. T plot for [Mn(acac)$_2$(bpy)] shows a straight line which declines at low temperatures, most likely due to the zero-field splitting of the Mn^{II} ion.[20] Plotting χ^{-1} vs. T also results in a straight line and thus the compound obeys the Curie–Weiss law. Fitting the data, the Curie and Weiss constants are obtained, being C = 4.137 cm^{-3} K·mol^{-1} and θ = –1.35 K, respectively. The Curie constant allows for calculating the total molecular spin of the compound, and a value of S = 2.42 (ca. 5/2) is obtained. For [Mn(acac)$_2$(phen)] a value of μ_{eff} = 6.2 μ_b is given in the literature, which also confirms an S = 5/2 spin state.[21]

Description of the Crystal and Molecular Structure: The filtered reaction mixture was left stand overnight at –20 °C to yield single crystals of [Mn(acac)$_2$(bpy)] . The geometry of the complex and the atom labeling scheme are shown in Figure 2. Selected bond lengths and angles are collected in Table 1.

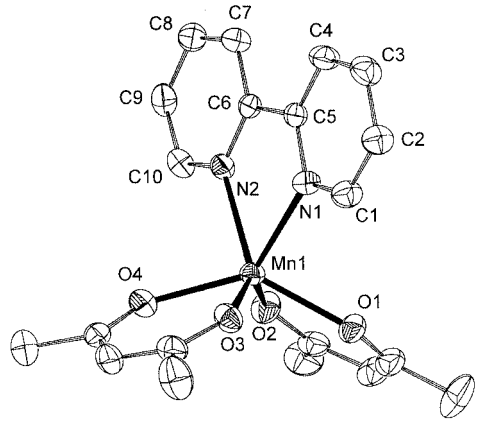

Figure 2. ORTEP plot of [Mn(acac)$_2$(bpy)], ellipsoids are shown at 50% probability. Hydrogen atoms are omitted for clarity.

Table 1. Selected bond lengths [Å] and angles [°] experimentally obtained with XRD compared to values obtained by DFT calculations.

gands is for each Mn–O bond almost the same, and lie in the range 2.1480(16)–2.1580(18) Å. The bite angles for each of the acetylacetonate ligands are also nearly identical, being 81.69(6)° (O1–Mn1–O2) and 81.92(6)° (O3–Mn1–O4). Since the bite angles are rather small and the Mn–O distance rather large, the Mn–O–C angles are also large, in the range 130.39(17)–131.78(16)°. The bipyridine ligand has a bite angle (N1–Mn1–N2) of 70.41°. The two acetylacetonate ligands are nearly planar, but the angle between the least-squares planes through the rings of the bipyridine ligand amounts to 3.79(12)°, and this ligand is thus not planar. For all three ligands, the atoms comprising the chelate rings deviate little from their least-squares mean plane. The obtuse angles between the least-squares mean planes of the chelate rings lie in the range 117.67(7)–121.30(6)°, in accordance with the trigonal-prismatic coordination geometry.

The two trigonal-faces of the prism constitute one oxygen atom of each of the acetylacetonate ligands and one nitrogen atom, thus forming O1–O3–N1 and O2–O4–N2. Figure 3 shows the trigonal-prismatic coordination geometry around manganese in more detail, and the dimensions and angles of the prism are tabulated in Table 2. The lengths of the triangular sides are in the range 2.901(2)–3.030(3) Å for the triangle O1–O3–N1 and 2.846(2)–3.007(3) Å for the triangle O2–O4–N2, all angles are in the range 56.88(7)–62.25(7)°. The four acetylacetonate oxygen atoms as make up an almost exact square, the sides of which are in the range 2.816(2)–2.901(2) Å. The remaining two faces of the prism are trapezoids consisting of two oxygen atoms of one acetylacetonate ligand and are joined by the two nitrogen atoms of bipyridine. Both faces have an O–O distance of 2.826(2) and 2.816(2) Å, an N–O distance in the range 2.968(3)–3.030(3) Å and a markedly shorter distance of 2.635(3) Å for the N1–N2 side. Since the N1–N2 side is shorter than the O–O sides of the trapezoid faces of the prism, the two triangular faces are not parallel. The planes defined by O1–N1–O3 and O2–N2–O4 make an angle of 4.04(10)°. The torsion angles about the centroids of the triangular faces and each of the corners [for example Ct1–N1–N2–Ct2 are –2.1(3)°, –1.9(3)° and –2.5(3)°] are faces exactly overlapping.. A perfect trigonal prism would have angles of 0°, the triangular faces exactly overlapping.

The crystal structure has a hexagonal unit cell and space group $P6_1$. Figure 4 and Figure 5 show the packing in the *a*, *b* and *c* directions. The structure is composed of right-handed helices along the *c*-axis and therefore is chiral. A single helix consists of six molecules of $[Mn(acac)_2(bpy)]$ per unit cell, due to the inherent hexagonal symmetry. The helices are tightly packed together in such a way that each molecule in the helix is part of a layer that extends in the *a* and *b* direction. Within such a layer, one can observe rows of $[Mn(acac)_2(bpy)]$ molecules with aligned bipyridine ligands, each bipyridine pointing in-between the acetylace-

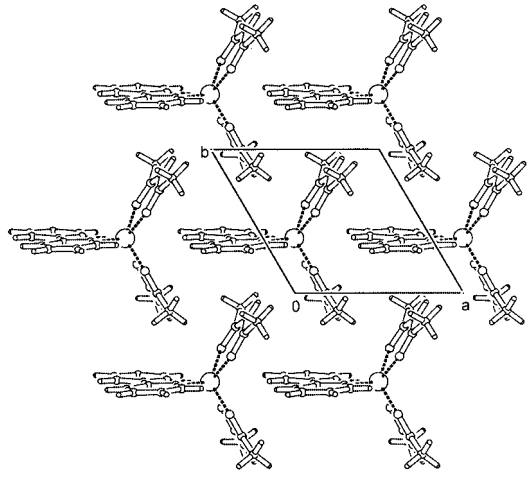

Figure 4. Crystal packing of $[Mn(acac)_2(bpy)]$ in the *a*,*b* plane. The acac methyl groups are packed together in rows along *a*.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

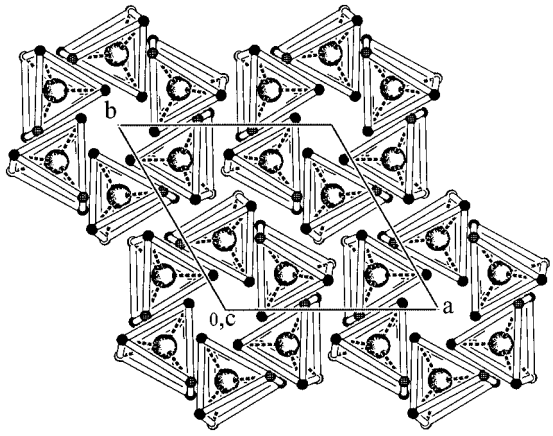

Figure 5. Projection of the crystal lattice of [Mn(acac)$_2$(bpy)] down the *c*-axis. The lattice is composed of right-handed helices in the *c* direction. Each complex in the helix is part of a layer in the *a*,*b* plane. Only the trigonal-prismatic polyhedra are shown for clarity.

tonate ligands of the following molecule in the row. Due to this orientation, all acetylacetonate methyl groups are also packed together in rows.

DFT Calculations: The DFT-B3LYP geometry optimization shows that the complex [Mn(acac)$_2$(bpy)] is stable in the trigonal-prismatic structure in vacuo and that the high-spin (S = 5/2) electronic state is the lowest energy configuration. Some of the theoretically predicted bond lengths and angles for this complex (in the vacuum) are reported in Table 2. The comparison between computed and experimental data in the crystal structure shows a good agreement. In particular the theory predicts that the bipyridine ligand is not planar, showing a small torsion angle of about 4° between its pyridine rings. The high-spin electronic configuration (S = 5/2) is important for the stability of the trigonal-prismatic geometry. Indeed, the optimized structure for S = 3/2 is found to be about 34 kcal/mol higher in energy than the S = 5/2 spin state. In the low-spin state S = 1/2, the trigonal-prismatic geometry is unstable and during the optimization the complex changes spontaneously towards an octahedral geometry.

To study the relative stability we have also optimized the complex [Mn(acac)$_2$(bpy)] in an octahedral coordination geometry in the vacuum. To obtain a relevant starting configuration the X-ray coordinates of the known octahedral compound [Mn(acac)$_2$(phen)] have been used,[22] removing C11 and C12 from the phen ligand in the coordinate file, thereby generating a bpy ligand. The final octahedral structure has an energy which is only a few tenths of a kcal/mol different from the energy of the trigonal-prismatic geometry. Given the typical accuracy of these calculations, the two structures can be considered energetically equivalent. The high-spin state is the lowest in energy also for the octahedral coordination geometry.

Subsequently the relative energy difference for the similar compound [Mn(acac)$_2$(phen)] was computed in a distorted-octahedral environment and in a trigonal-prismatic geometry for comparison. It turned out that for this compound the octahedral geometry is favoured by 1.5 kcal/mol over the trigonal-prismatic one, both again favoring the S = 5/2 spin state.

Discussion

Structural Features: The manganese to bipyridine distances 2.288(3) and 2.283(2) Å are not extraordinary and comparable to the Mn–N distances reported for the similar compound [Mn(acac)$_2$(phen)], which are 2.307 Å.[22] The bipyridine ligand has a bite angle N1–Mn1–N2 of 70.41°, which is quite small and can be related to the large ionic radius of Mn^{II}. Unsubstituted bipyridine ligands in manganese complexes commonly have bite angles varying between 72–80°.[23] Simple donor-atom to donor-atom repulsion energy considerations predict small bite angles for trigonal-prismatic complexes,[3] and indeed the average bite angle for the acetylacetonate ligands (81.81°) is among the lowest found for 2,4-pentanedionate coordinated to manganese(II).[23] The only other case found in literature where the 2,4-pentanedionato ligand coordinated to Mn^{II} has a bite angle smaller than 82°, is in the structure [Mn^{II}(Mn^{II}(acac)$_3$)$_2$], in which the two peripheral Mn^{II} ions also have a trigonal-prismatic coordination geometry.[24]

Trigonal Prism vs. Octahedron: Why does [Mn(acac)$_2$(bpy)] adopt a trigonal-prismatic coordination geometry in the solid phase, and why does the complex [Mn(acac)$_2$(phen)] not do so? The high-spin d^5 Mn^{II} ion has no ligand field stabilization and no large degree of π-bonding is present, since the magnetic data shows both complexes having a spin state of S = 5/2. This value would be lower if π-bonding would take place to the extent of that found in rhenium dithiolene complexes for example.[25]

The solid-state EPR spectra for the two complexes are quite different, reflecting the different coordination symmetries and thus the difference in the zero-field splitting parameters. The symmetry of the trigonal-prismatic complex is rhombic, which is the cause of the large EPR signal at g = 3.25. Although the exact magnitudes of the zero-field splitting parameters D, E and λ (= E/D) have not been calculated, it is clear from literature that D is likely to be significant ($0.05 < D < 0.15$ cm^{-1}) and λ will approach its limiting value of 1/3.[26] The complex [Mn(acac)$_2$(phen)] has a fairly regular octahedral coordination environment, which gives very small zero-field splitting values (D in the order of 10^{-2} cm^{-1}, λ approximately 0) and thus a resonance signal near the free electron value of g = 2 is observed.[26]

The similar solution-EPR spectra that are obtained demonstrate that in solution, the geometry around the Mn^{II} ion is comparable for both complexes.

The DFT calculations in vacuo show a slight (1.5 kcal/mol) preference for the octahedral geometry for [Mn(acac)$_2$(phen)], although this "octahedral" geometry is significantly trigonally distorted. The complex [Mn(acac)$_2$(bpy)] does not show a preference for either prism or octahedron, but there is some barrier for going from one to the other, since it does not adopt the trigonal-prismatic geometry when starting from the octahedral geometry. The calcu-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lated octahedral complexes for both bpy and phen show a significant trigonal distortion of 37° (the average torsion angle between the centroids of the faces N1–O1–O3 and O2–N2–O4, see Table 1). This is even more than that for the starting configuration (the X-ray geometry of [Mn(acac)$_2$(phen)], see Figure 6) which has a trigonal distortion of 41.37° (for a regular octahedron this angle is 60°). Apparently, for both complexes there does seem to exist some driving force towards the trigonal-prismatic geometry. The calculations also show that the prismatic geometry is only stable for the high-spin complexes, the complex [Mn(acac)$_2$(bpy)] spontaneously adopts an octahedral geometry when the calculation is performed with $S = 1/2$. This behaviour is to be expected, since for the low-spin Mn^{II} ion ligand field stabilization energy does play a role and the octahedral geometry is now significantly lower in energy compared to the trigonal-prismatic conformation.[15]

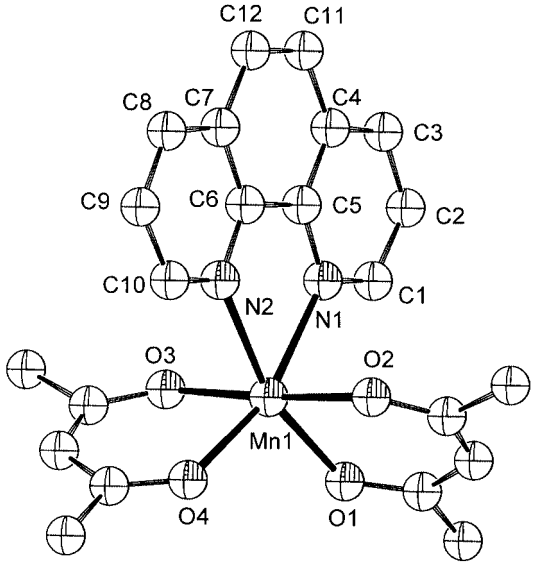

Figure 6. Molecular structure of [Mn(acac)$_2$(phen)]; hydrogen atoms are omitted for clarity; coordinates taken from the Cambridge structural database.

Contrary to expectation, the difference in rigidity between the bpy and phen ligand does not seem to have a large influence on the coordination geometry. Comparing the torsion angles for the calculated prismatic complexes in Table 2, it can be seen that the phen ligand can be regarded as more rigid than the bpy ligand, judging by the torsion angle N1–C5–C6–N2, which is 0.61° for phen vs. 4.42° for bpy. The same values are found for the calculated octahedral complexes. The deviation from a perfect prism is slightly larger for the phen complex, however, whereas for the calculated octahedral complexes the average trigonal distortion is identical. Furthermore, in the crystal structures the bpy and phen N1–C5–C6–N2 torsion angles are nearly identical, yet the coordination geometry is certainly different.

It thus seems that an important factor for determining the preference for octahedral vs. trigonal-prismatic geometry for the complexes [Mn(acac)$_2$(bpy)] and [Mn(acac)$_2$(phen)] is the crystal structure packing. In the *a*,*b* layer of the lattice of [Mn(acac)$_2$(bpy)], the bpy ligand fits precisely in-between the two acac ligands of the next molecule in the row (see Figure 4). The phenanthroline complex has a comparable *a*,*b* layer structure where the phenanthroline ligands of the complexes in the layer are aligned in rows and point towards, but do not fit in-between, the acac ligands of the next complex in the row.[22] The tighter packing that results for [Mn(acac)$_2$(bpy)] is likely stabilising the trigonal-prismatic geometry.

Conclusions

The trigonal-prismatic and octahedral environments in the compounds [Mn(acac)$_2$(bpy)] and [Mn(acac)$_2$(phen)] are both stable and very similar in energy for the high spin state. However, in the solid state [Mn(acac)$_2$(phen)] favours a (distorted) octahedral geometry whereas [Mn(acac)$_2$(bpy)] adopts a nearly perfect trigonal-prismatic geometry. Since the rigidity of the dinitrogen diimine ligand does not seem to play a role and the energy difference between different ligand environments for the complexes in the vacuum is quite small, packing effects in the crystal lattice must play an important role in determining the final solid-state structure.

Experimental Section

Materials: 2,2′-Bipyridine (bpy) and acetylacetone (Hacac) were purchased from Acros and used as received. [Mn^{II}(acac)$_2$(H$_2$O)$_2$] was prepared according to a literature procedure.[27] Methanol was distilled from CaH_2 and stored with 3-Å molecular sieves under argon prior to use.

Synthesis of [Mn(acac)$_2$(bpy)]: The title compound was synthesized using a slightly modified procedure from that published.[21] The reaction was performed under argon using standard Schlenk techniques. To a stirred, dark orange solution of [Mn(acac)$_2$(H$_2$O)$_2$] (1 g, 3.46 mmol) in 20 mL of methanol was added a solution of bpy (1.08 g, 6.92 mmol) in 10 mL of methanol. After 1 minute of stirring, [Mn(acac)$_2$(bpy)] precipitated as a bright yellow microcrystalline material. Stirring was continued for an additional 15 minutes and then the product was filtered under argon and dried for 24 hours at room temperature under reduced pressure. Yield: 0.95 g (67%). $C_{20}H_{22}MnN_2O_4$ (409.3): calcd. C 58.68, H 5.42, N 6.84; found C 58.51, H 5.26, N 7.08. The filtrate was stored overnight at –20 °C. Yellow, prismatic-shaped single crystals precipitated. One of these crystals was used to determine the crystal structure.

Physical Measurements: Elemental analyses on C, H and N was performed with a Perkin–Elmer series II CHNS/O Analyzer 2400. The IR spectrum was recorded with a Perkin–Elmer FT-IR Paragon 1000 spectrophotometer, using a CsI pellet (4000–200 cm^{-1}, resolution 1 cm^{-1}). Ligand field spectra were obtained with a Perkin–Elmer Lambda 900 spectrophotometer. The diffuse-reflectance technique was used with MgO as a reference for the solid compound. Electron paramagnetic resonance measurements were performed with a JEOL JES-RE2X ESR Spectrometer with a JEOL X-band microwave, a JEOL electromagnet and a JEOL ESPRIT 330 ESR Datasystem unit. A special quartz Dewar flask was used for measurements at liquid nitrogen temperature (77 K). Magnetic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

susceptibility measurements (5–300 K) were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer (measurements carried out at 1000 Gauss). Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

DFT Calculations: Density functional theory (DFT) calculations were performed to address the question of the preference for a specific coordination geometry in the Mn^{II} complex [$Mn(acac)_2$(bpy)]. The relative energy of the trigonal-prismatic vs. the octahedral coordination geometry was calculated for the complex [$Mn(acac)_2$-(bpy)] in the vacuum. For comparison the same relative energy difference was calculated for the related phenanthroline compound [$Mn(acac)_2$(phen)], which is known to have a distorted octahedral environment about the Mn atom in the solid state.[22]

The hybrid B3LYP exchange and correlation functional was used.[28] All self-consistent field (SCF) calculations were done using the 6-31G(d,p) gaussian basis set and were performed with the Gaussian 98 package.[29] The geometries of the various complexes were fully optimised without imposing any symmetry constraint. All calculations were spin unrestricted and the relative stability of the different spin states were checked.

X-ray Crystallographic Study: A crystal of dimensions $0.10 \times 0.15 \times 0.35$ mm was selected from a batch of yellow prisms, obtained from the filtrate of the reaction mixture overnight at –20 °C. Crystal data and details on data collection are listed in Table 3.

Table 3. Crystallographic data for [$Mn(acac)_2$(bpy)].

Formula	$C_{20}H_{22}MnN_2O_4$
Fw	409.34
Crystal system	hexagonal
Space group	$P6_1$
a [Å]	8.0482(9)
c [Å]	51.602(10)
V [Å^3]	2894.6(7)
Z	6
λ [Mo-K_α]	0.71073
T [K]	150
$\delta_{calcd.}$ [g cm^{-3}]	1.4089(3)
μ [mm^{-1}]	0.712
R [$I > 2\sigma(I)$][a]	0.0291
wR_2[b]	0.0584
GoF	1.035

[a] $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

Data were collected with an Enraf–Nonius KappaCCD area detector on a rotating anode. 30196 Reflections were measured ($1.0° < \theta < 25.37°$), 3375 of which were independent ($R_{int} = 0.0528$). The structure was solved by Patterson methods (DIRDIF[30]) and refined on F^2 by using SHELXL-97-2.[31] Hydrogen atoms were included in the refinement on calculated positions, riding on their carrier atoms. Methyl hydrogen atoms were refined as a rigid group, allowing for rotation around the C–C bond. Non-hydrogen atoms were refined with anisotropic displacement parameters Hydrogen atoms were refined with a fixed isotropic displacement parameter linked to the value of the equivalent isotropic displacement parameter of their carrier atoms. A total of 248 parameters were refined. All peaks in the final difference Fourier map were in the range $-0.19 < \Delta\rho < 0.18$ e·Å^{-3}. The Flack *x* parameter,[32] derived during the final structure-factor calculation, amounts to –0.012(14), indicating a correctly assigned absolute structure. Refinement of the inverse absolute structure resulted in an *x* parameter of 0.97(2) (value derived during the final structure-factor calculation). Figures of merit for this inverted structure are $R_1 = 0.0428$, $wR_2 = 0.1067$ and $S = 1.040$. CCDC-257462 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also footnote on the first page of this article): The frozen-solution EPR spectra of [Mn(acac)2(bpy)] and [Mn(acac)2(phen)] are available as supporting information.

Complex Formation of ICL670 and Related Ligands with Fe^{III} and Fe^{II}

Stefan Steinhauser,[a] Uwe Heinz,[a] Mark Bartholomä,[a] Thomas Weyhermüller,[b] Hanspeter Nick,[c] Kaspar Hegetschweiler*[a]

Keywords: Iron / Ligand design / Chelates / N,O ligands / Redox chemistry

The pFe values of the two ligands H_3L^x and H_3L^y in section 2.3 on page 4183 of the original article[1] are incorrect; the corresponding sentence with the correct values should read as follows:

In general, the iron binding properties of H_3L^x and H_3L^y are indeed closely related: the pFe values[30] for H_3L^x and H_3L^y (total [L] = 10 μM, total [Fe] = 1 μM, pH = 7.4, H_2O, I = 0.1 M) are 23.5 and 22.6, respectively.

COVER PICTURE

The cover picture shows how the isophthalate-bridged structures are tuned by various polydentate ligands from tetradentate ligand tpa to tridentate ligand tpm to bidentate ligand bpm, which results in one dinuclear and two one-dimensional complexes, $[Cu_2(tpa)_2(m\text{-bda})](ClO_4)_2$ (**1**), $\{[Cu_2(tpm)_2(m\text{-bda})_2]\cdot 2CH_3OH\cdot 4H_2O\}_n$ (**2**) and $\{[Cu_2(bpm)_2(m\text{-bda})_2(H_2O)]\cdot CH_3CN\cdot H_2O\}_n$ (**3**). The variable-temperature magnetic behavior reveals the existence of ferromagnetic interactions in them. Details of synthesis and characterization of these complexes are given in the article by P. Cheng et al. on p. 2297ff.

Group II Intron Ribozymes and Metal Ions – A Delicate Relationship

Roland K. O. Sigel*[a]

Keywords: Bioinorganic chemistry / Ribozymes / RNA structures / Metal ions / Calcium

Group II introns are naturally occurring ribozymes in plants, fungi, bacteria, and lower eukaryotes that undergo a fascinating array of reactions. These large molecular machines with a size ranging between 600 and 2500 nucleotides are self-splicing introns also capable of reinserting themselves into RNA or DNA, thus making them mobile genetic elements. The structural information available on group II intron ribozymes is very scarce. So far, only one crystal structure and one NMR solution structure of two domains located in the catalytic core are available. For proper folding and function, each intron requires specific concentrations of monovalent and divalent metal ions. Although most of these metal ions are used for charge screening, some are bound to distinct sites as has been shown by hydrolytic cleavage experiments. These specifically bound ions are crucial for tertiary contact formation and catalysis. This review will discuss the different metal-ion requirements of self-splicing group II introns, the available structural data and information on the binding location and affinity of metal ions, as well as the methods applied to investigate the metal-ion binding properties of these large RNAs. Due to the size of these introns, the richness of local structures, the catalytic versatility and the involvement of metal ions in all of the above-mentioned aspects, group II introns are an ideal target to be studied by combined means from the fields of Biochemistry, Molecular Biology, Analytical, and (Bio)Inorganic Chemistry.

1. Introduction

In contrast to the typical misconception that RNA is a stringy, single-stranded molecule without defined architecture, most functional RNA molecules are compact, stable, and tightly folded into a unique conformation.[1–4] Even mRNAs, which are normally thought of as linear "tapes" encoding for protein sequences, contain highly structured regions at their termini that serve as signals for regulating gene expression.[5,6] In the early 1980s, the research in RNA biochemistry "exploded" after the exciting discovery by Altman, Cech, and Pace that RNA is able to catalyze various reactions in living cells without the aid of amino acids.[7,8] Thus, the old dogma of only proteins being enzymes was overthrown and ribozymes were "born".

In the past twenty years, many more catalytic and noncatalytic functions of RNA in Nature have been and are still being discovered.[9] To name just a few: Aside from its diverse roles in protein synthesis (e.g., tRNA, rRNA), RNA is also involved in protein transport (signal recognition par-

Roland K. O. Sigel, born 1971 in Basel, Switzerland, graduated from the University of Basel with a Diploma in Chemistry in 1995. He carried out his Ph.D. thesis in the group of Professor Bernhard Lippert at the University of Dortmund, Germany, working on the effect of platinum(II) coordination on the acid-base and hydrogen-bonding properties of nucleobases and received his doctoral degree summa cum laude in 1999. During 2000–2002, he spent nearly three years as a postdoctoral fellow at Columbia University, New York, working with Professor Anna Marie Pyle (now Yale University) on ribozymes. During the six years abroad he received several fellowships, including a European TMR Fellowship covered by the Swiss National Science Foundation and the Swiss Federal Office for Education & Science as well as a fellowship from the Swiss Academy of Natural Sciences and the Swiss National Science Foundation. In early 2003, he returned to Switzerland and in April of this year he became an Assistant Professor of Inorganic Chemistry at the University of Zürich, endowed with a Förderungsprofessur of the Swiss National Science Foundation. His research interests are in Bioinorganic Chemistry and focus on the interrelations between metal ions and ribozymes, especially group II introns; his research group evaluates structural and catalytic impacts of metal ions by applying a broad combination of tools, including biochemical syntheses, stability-constant measurements, kinetic methods and 3-dimensional NMR spectroscopy. Since Volume 43 Roland K. O. Sigel is also an editor of the Metal Ions in Biological Systems series.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ticle, SRP).[10] Furthermore, in the last couple of years, small RNAs composed of about 21–23 nucleotides in lengths were discovered to occur in periodic cycles within the cell. Such small interfering RNAs (siRNAs) play a key role in cell development (RNA interference, RNAi).[11,12] Only very recently, so-called coRNAs (coregulatory RNA) or riboswitches[13–19] were found to be important for gene regulation. Last, but not least, RNA molecules also fulfil diverse functions regarding RNA editing as well as RNA processing, i.e., they carry out post-transcriptional modifications. Catalytic RNAs are found among several of these groups; they are involved in protein synthesis, gene regulation, RNA editing, as well as RNA processing.[9] In all of these RNAs, catalytic or noncatalytic, metal ions play an essential role in their architectural assemblies and modes of action that are central to RNA biology.

Today, three different families of naturally occurring ribozymes are known: (i) The large phosphoryl transfer ribozymes (group I and group II introns, ribonuclease P), (ii) the small phosphoryl transfer ribozymes [hammerhead, hairpin, hepatitis delta, and Varkud satellite (VS) ribozyme], and (iii) the aminoacylesterase ribozymes (ribosome).[20] All these ribozymes either catalyze the cleavage and/or joining of RNA and DNA molecules through reactions at phosphate centers[20] or catalyze peptidyl transfers during protein synthesis, which involve the transfer of an activated ester at a carbon center.[21]

Very recently two new ribozymes have been discovered. First, the *glms* ribozyme, which belongs to the small phosphoryl transfer ribozymes [family (ii) mentioned above].[18] This ribozyme consists of a RNA motif found within a mRNA that self-cleaves upon binding to the reaction product of its encoded protein, therefore providing self-regulation in gene expression. Second, the co-transcriptional cleavage (CoTC) RNA motif that occurs in the 3′-flanking regions of primate β-globin genes and promotes transcription termination.[22] There is also strong evidence that another large ribonucleoprotein complex within the cell is a ribozyme – the so-called spliceosome.[23,24] This molecular machine, composed of five different snRNA molecules (small nuclear RNA) and numerous proteins, is found in all higher eukaryotes and is responsible for the correct splicing of freshly transcribed RNAs (thus belonging to the first mentioned family).[25,26]

As indicated in the above paragraphs, natural ribozymes encompass a surprisingly large chemical and functional repertoire in living organisms. The structures and reaction mechanisms of some of these ribozymes, like the Hammerhead, the Hairpin, or group I introns have been resolved to some detail in the past few years.[27–33] This short review focuses on group II introns, their occurrence, the reactions they catalyze, their structure, as well as on what is known about their delicate and complicated interaction with metal ions. For example, the Mg^{2+} requirements of different group II introns originating from the same gene within one organism can differ by a factor of more than ten. In addition, these large RNAs have one very remarkable quality: A group II intron broken into individual domains will reassemble into the catalytically active ribozyme! It is this modular behavior of the components, together with the anticipated richness of structural motifs and the strict requirement of metal ions for folding and catalysis that makes group II introns excellent systems to be studied by a combination of biochemical, analytical, and (bio)inorganic methods.

2. What are Group II Intron Ribozymes?

Group II introns are a very interesting class of naturally occurring ribozymes. These large molecular machines consist of about 600 to 2500 nucleotides and are second in size only to ribosomal RNAs. More than 750 gene locations of group II introns are known.[34] They are found primarily in organellar genes of plants, fungi, and lower eukaryotes, but also in many bacteria.[35] These RNAs are best known for their ability to undergo self-splicing, but they also perform a variety of other reactions including RNA and DNA hydrolysis as well as intron mobility into RNA and DNA substrates.[35,36]

RNA splicing is defined as follows: Most genes are transcribed into mRNA precursors that are not ready to undergo translation into proteins. Before translation, these mRNAs (as well as most tRNAs, rRNAs, and snRNAs) must undergo the process of splicing, in which noncoding introns (*in*tervening sequences) are removed from the coding exons (*ex*pressed regions). RNA splicing can be achieved by either autocatalytic introns (group I and group II introns), the eukaryotic spliceosome, or proteins (tRNA splicing).[37] The spliceosome releases the excised introns from the mRNA precursor as branched lariat molecules. This formation of lariat RNA resembles very much the splicing pathway of group II introns, with the only difference that the catalytic components responsible for splicing reside within the intron itself (Figure 1).[38–40]

In group II introns, the first step of the splicing reaction consists of a nucleophilic attack of the 2′-OH of a highly conserved adenosine located in a bulge within domain 6 (D6) (see below). In the second step, the 5′ and 3′ exons are ligated and the lariat intron is simultaneously released (Figure 1). Both steps of this branching reaction are highly reversible, explaining the fact that free lariat group II introns can catalytically insert themselves into RNA and DNA.[41–43] This ability makes group II introns infectious genetic elements that are capable of migrating into new hosts or new positions within a host genome.[44–50] Unlike other systems of genetic transposition, in group II introns, this process depends on the reactivity of the intron itself, which catalyzes its own reverse splicing into new genomic locations. Studies of intron mobility have shown that group II introns can be designed to target and insert themselves at any desired location, thereby either knocking out or transforming a gene.[45,48,51]

The transesterification reaction in group II intron splicing is in constant competition with an alternative hydrolytic pathway: A water molecule can readily react as nucleophile

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

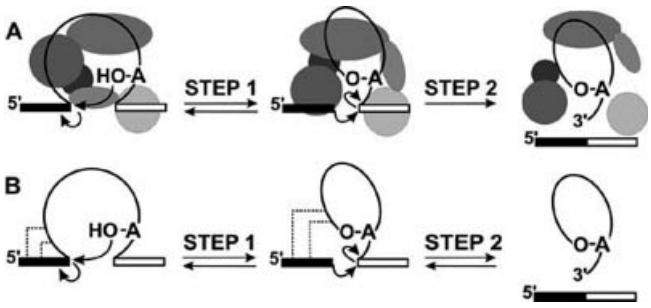

Figure 1. Comparison of the similar splicing pathways of the spliceosome and group II introns. **(A)** In higher eukaryotes the spliceosome removes introns and joins exons together. Five RNAs and several proteins assemble around the splice site and remove the intron as a lariat. An intronic 2′-OH of an adenosine serves as the nucleophile. After removal of the intron and joining of the exons, the RNAs and the proteins disassemble and then reassemble at the next splice site. **(B)** Group II introns fold into the active structure around the splice site. Correct cleavage site recognition by the EBS-IBS base pairings is indicated by dashed lines. In a first step, an internal 2′-OH of a conserved adenosine attacks the 5′-splice site to form a lariat. In a second step, the two exon pieces are joined and the intron removed as a lariat. Both steps are reversible, enabling group II introns to reinsert themselves into RNA or DNA.

during the first step of splicing (both in vitro and in vivo) making the two steps irreversible.[52–54] Although autocatalytic in vivo, group II introns often employ proteins to stabilize the intron structure or to enhance their functionality (e.g., reverse transcriptase activity during intron mobility).[36,55–57] Many group II introns have the innate capability to function in vitro, but only a few have been characterized in more detail. Among those best studied regarding folding, tertiary structure, and catalytic activity is ai5γ, which is located in the cytochrome oxidase 1 gene of mitochondria in baker's yeast *Saccharomyces cerevisiae*.[36,58]

Despite a relative lack of sequence conservation among group II introns they all possess a conserved set of six domains that contain well-defined secondary structural elements (Figure 2).[36,58] Each domain has a specific function: Domain 1 (D1) is an independent folding unit and a molecular scaffold for docking of the other domains.[59] In addition, this domain recognizes the 5′-exon through two EBS-IBS (exon/intron binding site) base pairing interactions, which are not conserved but always co-vary.[60] D1 contains components important for catalysis, including motifs involved in the λ[61] and ε[62] tertiary interactions, and forms together with domain 5 (D5) the minimal structure capable of supporting catalytic activity.[63,64] D2 lacks phylogenetic conservation but may aid to stabilize the tertiary structure of the folded intron.[64,65] D3 is a catalytic effector that increases the rate of catalysis by D1 and D5.[66–68] D4 does not contribute to self-splicing activity but often contains an open reading frame (ORF) encoding a maturase protein that aids in splicing and intron mobility in vivo.[69,70] Unlike the other domains of the intron, D5 is highly conserved and represents the most critical active-site component. It forms a very stable hairpin and binds through the ζ-ζ′[71] and the κ-κ′[72] tertiary interactions to the central region of D1 (Figure 2). Combination with the λ-λ′[61] (and ε-ε′)[62] interaction places the 5′ splice site right next to the "chemical face" of D5, i.e., to functional groups which have been identified to play a direct role in catalysis.[73,74] D6 contains the conserved bulged adenosine branch-point that serves as the nucleophile during the first step of branching.[38] The branch-point region of D6 contains conserved functionalities that position the bulged adenosine relative to the active-site components in D1 and D5.[72,75]

Group II introns have the interesting ability that their domains are independent folding units.[59] Thus the individual domains can be added together *in trans* (i.e. not covalently linked) and they will reassemble (at the proper metal-ion concentration) to the active three dimensional fold.[61,68,76] It should be added that the individual domains or combinations thereof can be easily synthesized by in vitro transcription from double-stranded DNA (dsDNA) templates, e.g. linearized plasmids or synthetic dsDNA, and purified by polyacrylamide gel electrophoresis (PAGE).[77,78] All these points make group II introns ideal targets to study with respect to either structure-function and/or metal-ion binding-function relationship.

3. The Need of Metal Ions in RNA Folding and Catalysis

Due to the polyanionic nature of the phosphate-sugar backbone metal ions are inextricably involved in the process of RNA folding and function. A simplified two-step folding pathway of large RNAs starts with the transition from a random coil to the secondary structure followed by the second step of compaction to the tertiary structure, in which specific long-range interactions orient all the structural elements in space (Figure 3).[79,80] Monovalent ions tend to play an important role in charge-screening, thereby allowing the secondary structure to form (Figure 3). Only recently one has begun to decipher the repertoire of tertiary interaction motifs that stabilize folded RNA molecules.[71,81] Tertiary structural elements are stabilized by interactions with divalent metal ions, preferably Mg^{2+}, but also the monovalent potassium appears to have an additional role in binding to high affinity sites.[82] The stabilization of nucleobase quartets by alkaline metal ions,[83,84] e.g. in telomeres,[85,86] is just one prominent example. In general, the formation of RNA tertiary structure is dependent on four parameters: (i) RNA sequence, (ii) metal-ion identity, (iii) metal-ion concentration, and (iv) the presence of RNA binding proteins and polyamines.[20] However, in addition to employing metal ions within structural elements, ribozymes also use them directly for catalysis.

One of the major differences between nucleic acids and proteins is that in DNA or RNA, due to the existence of only four nucleobase moieties (compared to 21 amino acids) a much smaller diversity of functional groups is present, none of which having a pK_a value near the physiological pH. This lack in diversity can be overcome by several factors: Stabilization of a protonated spezies by hydrogen

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

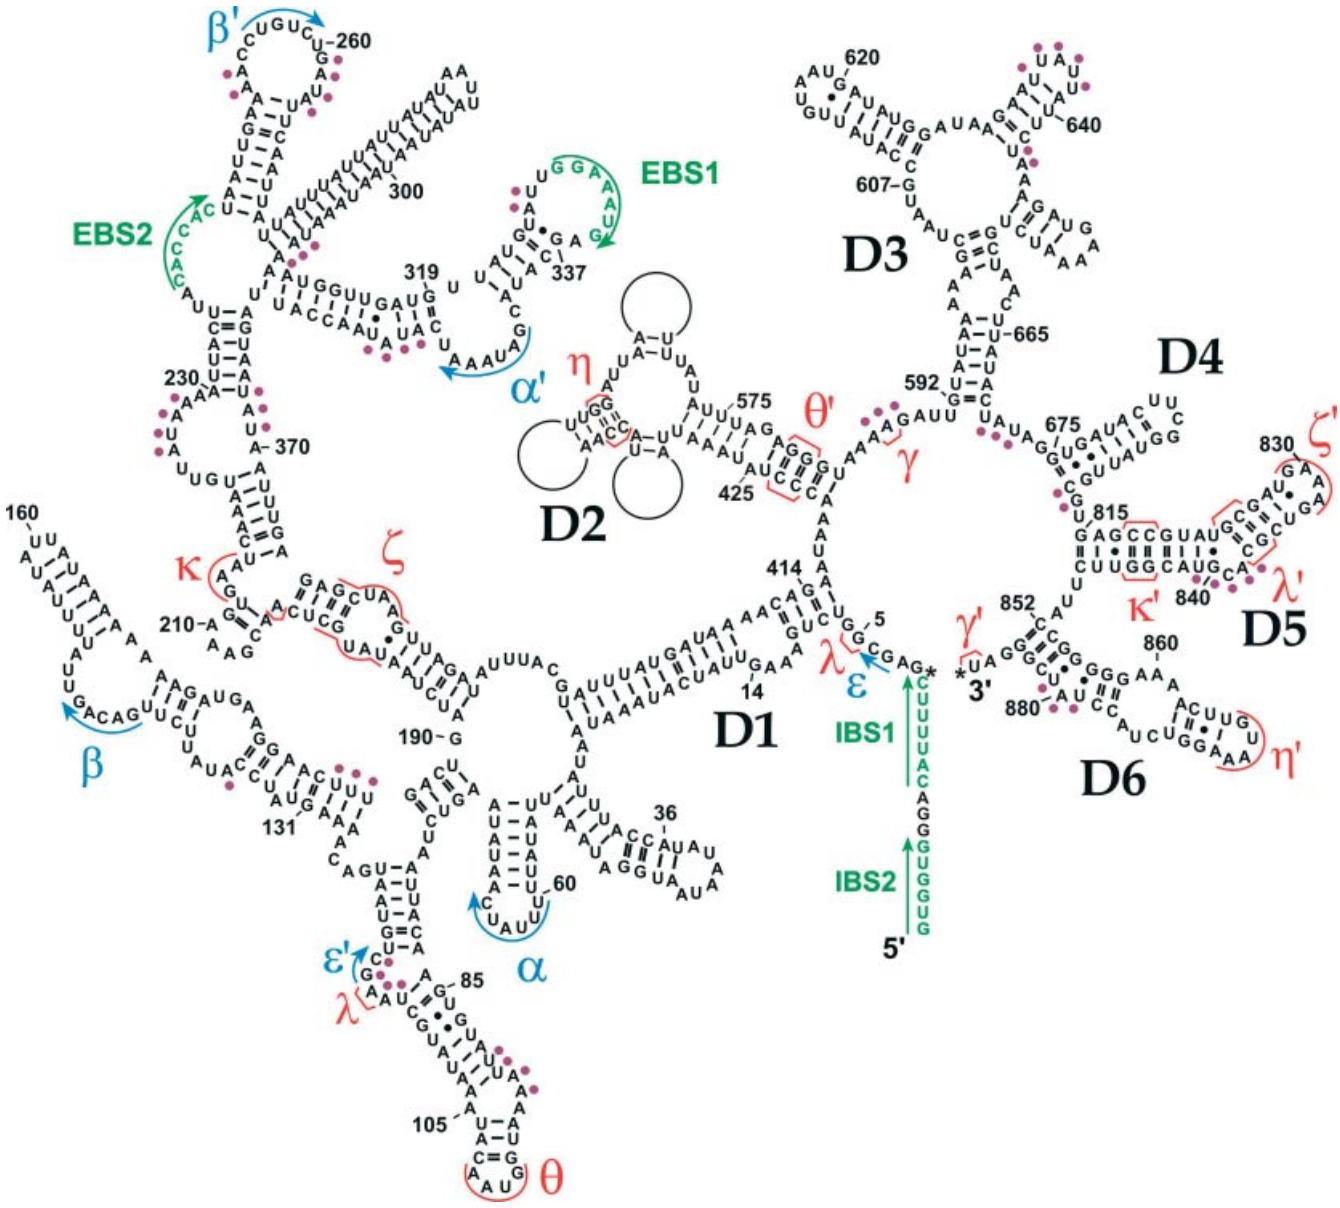

Figure 2. Secondary structure of a ribozyme derived from the group II intron ai5γ from *S. cerevisiae*. Domain 2 (D2) is only partly drawn; further regions making no known contacts to the other intronic domains are indicated as circles. Domain 4 (D4), which in some introns contains an open reading frame (ORF) is truncated and reduced to a hairpin, although the numbering of the nucleotides corresponds to that of the full lengths intron. The last sixteen nucleotides of the 5′ exon are also shown and separated from the intronic nucleotides by the splice site. Both, the 5′ and the 3′ splice sites are indicated by asterisks. Long-range tertiary contacts are labeled with pairs of Greek letters: Of the latter ones, intra-domain contacts are colored in blue, whereas inter-domain contacts are shown in red. Intron-exon interactions (IBS1-EBS1 & IBS2-EBS2) are shown in green. Sites of intense Tb^{3+} cleavage are marked by filled circles in magenta (see also ref.[78]).

bonding like in A·C$^+$ base pairs,[23] formation of a special fold with distinct electrostatic properties, and/or by the aid of metal ions.[87–89] Coordination of a metal ion to a nucleobase can lead to large pK_a shifts at amino and/or imino groups.[90–95] As a consequence, hydrogen bonding might be strengthened,[92,94,96,97] and/or rare tautomers stabilized[98] leading to new base pairing patterns.[96] In addition, such acidified protons could now participate directly in catalysis at a pH close to neutral. In fact, in most ribozymes structurally and/or biochemically investigated today, divalent metal ions are found within the catalytic core. There they are used, e.g., to activate the attacking nucleophile for phospho-diester cleavage, to stabilize the transition state, or the leaving group.[20,99,100] It follows that in nucleic acids not only kinetically inert metal ions, e.g. Pt^{2+},[101,102] but also labile metal ions[103] can coordinate in close neighborhood to each other,[104–106] sometimes even to the same nucleobase.[107] In a few cases, divalent metal ions can be replaced by high, i.e. molar, concentrations of monovalent ions, suggesting a mechanism where metal ions "only" have an electrostatic role and are thus probably not coordinated at the active site. However, it is unclear if under such conditions

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

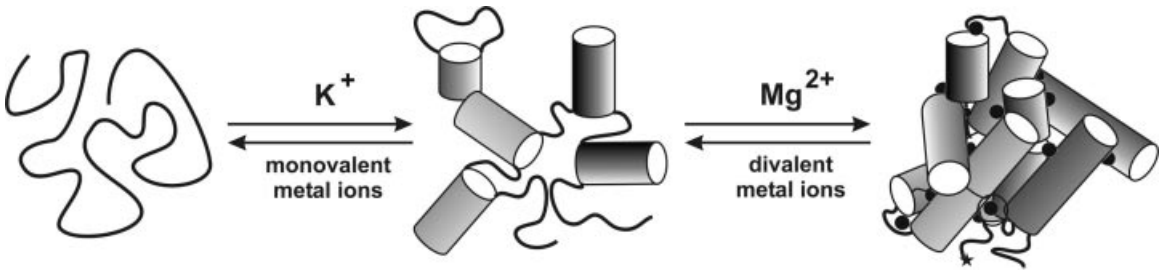

Figure 3. Schematic view of group II intron folding. Monovalent metal ions are needed for charge-screening and enable formation of the secondary structure. Tertiary structure formation to the catalytically active architecture only takes place in the presence of divalent metal ions like Mg^{2+}. Several Mg^{2+} ions (in some instances also K^+ ions) occupy specific binding sites stabilizing local structural motifs (adapted from ref.[79,80]).

of nonnatural high concentrations of M^+ ions, the mechanism of catalysis corresponds to the one in the presence of divalent ions.

To summarize, both Mg^{2+} and K^+ play an indispensable role in the world of RNA metabolism (see Figure 3), but in limited cases, also Na^+ and Li^+ (and NH_4^+) can contribute to correct folding of certain RNAs. Ca^{2+}, Mn^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} can sometimes substitute for Mg^{2+}, but they are rarely the natural cofactors.[108,109]

4. Metal Ions and Group II Introns

Large ribozymes like group II introns are particularly dependent on metal ions for function and are therefore ideal "targets" for study by bioinorganic chemists. It is interesting to note, although so far not understood, that different group II introns have rather different requirements for divalent and monovalent ions in vitro (see Table 1).[110–112] This specificity does not only relate to ribozymes from different organisms, but also to those originating from within one gene.[110] Considering the highly conserved secondary structure of these molecules, the range of Mg^{2+} concentrations varying between 0.1 and 100 mM is astonishing – even more so because there seems to be no correlation with the GC content of the nucleic acid sequence. Today, only one catalytic Mg^{2+} ion is known, which binds to the 3′-oxygen of the scissile phospho diester bond in both steps of splicing thereby stabilizing the 3′-oxoanion leaving group.[24] This Mg^{2+} coordination is observed in group II introns and the spliceosome, thus extending the parallels between these two splicing machineries.[24,113]

Binding studies of metal ions to folded RNA molecules are hampered because Mg^{2+} and K^+ are spectroscopically silent and are further complicated by the fact that these ions serve multiple roles (structural and catalytical) within the same molecule; hence, it is difficult to focus on one particular binding site. In addition, high Mg^{2+} concentrations are often required as Mg^{2+} binding is predominantly weak. Therefore, in experimental studies Mg^{2+} is often partly replaced by other metal ions. Besides d-transition metal ions, as well as Zn^{2+}, Cd^{2+}, and Pb^{2+}, lanthanides have lately become important mimics of Mg^{2+} to probe RNA structures and functions.[114,115] Like Mg^{2+}, lanthanide ions are mostly redox inactive and coordinate preferably to hard ligands such as phosphate oxygen atoms. Their +3 charge enables them to interact stronger with RNA than Mg^{2+}, but also leads to lower pK_a values for coordinated water molecules compared to the situation encountered with Mg^{2+}. The lanthanide hydroxide species can either directly attack the phospho diester bond, or alternatively depro-

Table 1. Concentrations of K^+ (or NH_4^+) and Mg^{2+} needed for achieving the best splicing activity in vitro with group II introns from different organisms. In column 1, the organism is given, in which the group II intron (column 2) belonging to one of the two subgroups (column 3) is found. The gene location is given in column 4. Optimal concentrations of K^+/NH_4^+ (column 5) and Mg^{2+} (column 6) are listed together with the tested concentration range, in which the ribozyme is active.

tonate a 2′-hydroxy group, which itself can then act as a nucleophile to break the scissile phospho diester linkage. This reaction mechanism has two consequences: (i) only those metal-ion binding sites are detected, where the Ln^{III} ion is in close neighborhood to either the phospho diester or the 2′-OH, and (ii) under physiological conditions Ln^{3+} ions cleave RNA more efficiently at their coordination site than Mg^{2+}.[77,116,117]

Taking advantage of the above-mentioned properties of Ln^{3+} ions, we have applied them to locate the metal-ion binding sites in domains 1, 3, 5 and 6 of the group II intron ai5γ (Figure 4).[77] The ribozyme was labeled at either the 5′ or the 3′ end with ^{32}P and subsequently incubated with sufficient K^+ and Mg^{2+} at pH 7 to achieve the correct three-dimensional fold. Micromolar amounts of Tb^{3+} (or other lanthanides) were then added and the reaction mixture put on ice to protect the ribozyme from additional unspecific cleavage. As the natural Mg^{2+} ions are bound kinetically labile at their coordination sites, these ions are now in equilibrium with the higher charged Ln^{3+} ions. Binding of the lanthanide ions within the binding pocket subsequently leads to cleavage of the phospho diester backbone close to their binding site. The resulting RNA pieces of different length can then be separated by denaturing polyacrylamide gel electrophoresis (PAGE) and thus the multiple metal-ion binding sites within the RNA can be located.

Analysis of the PAGE gels shows that some sites are cleaved with high specificity whereas other regions are completely protected from hydrolysis.[77] When plotting the determined metal-ion binding sites onto the secondary structure of the RNA, it is striking to see that the metals are spread out all over the intron and are located mostly at single-stranded regions, suggesting unspecific cleavage (Figure 2). However, comparison with biochemical data from footprinting experiments[118] shows that almost all binding sites are located in the inner core of the active three dimensional architecture. Furthermore, the cleaved nucleotides are mostly known to be either crucial for long-range or tertiary contact formation via diverse hydrogen bonding patterns, or to take part in catalysis itself. Additional evidence that Ln^{3+} ions bind to the same sites as Mg^{2+} ions in the active structure is given by the fact that only the corresponding hydrolytic cleavage experiments with Mg^{2+} yield the same sites, though the cleavage intensities are much lower than with, e.g., Tb^{3+} and the gels therefore more difficult to interpret.[77] Hence, it is reasonable to assume that indeed $Ln^{3+}$and Mg^{2+} ions bind to the same sites in group II introns and RNA in general.

Divalent d-transition metal ions, as well as Zn^{2+} and Pb^{2+}, have also been applied in metal-mediated cleavage reactions of the RNA backbone.[119–122] These metal ions usually have a well defined coordination geometry but often prefer the softer nitrogen donor atoms instead of the harder oxygen atoms of the phosphate and carbonyl groups, which are the predominant binding partners of Mg^{2+}. In contrast, Ln^{3+} ions have the distinct advantage of preferentially binding to oxygen atoms as well. Although their preferred coordination geometry does not fit the one of Mg^{2+}, it is very

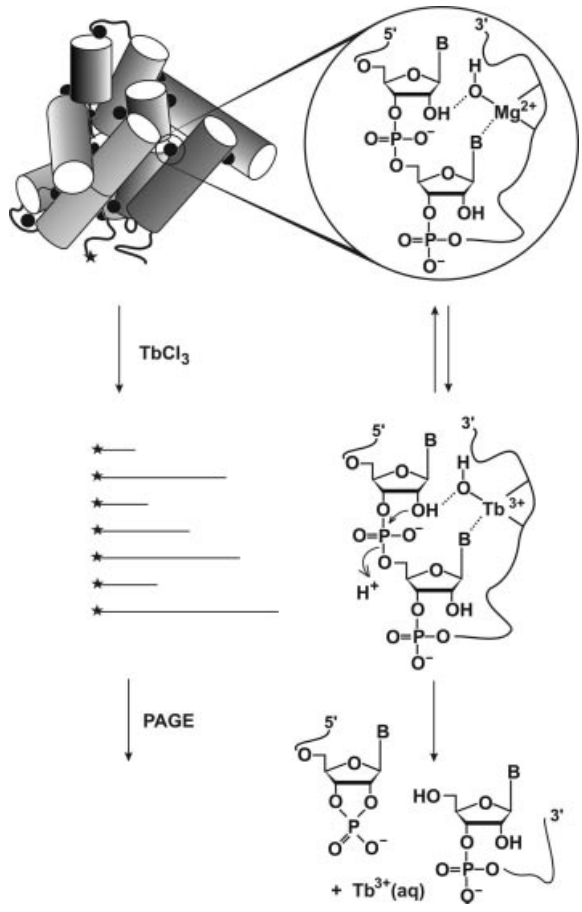

Figure 4. Lanthanide(III)-mediated cleavage of the phosphate-sugar backbone of large RNA molecules. The ribozyme, which is labeled with ^{32}P either at its 5′ or 3′ end (indicated by an asterisk), is folded to its active three-dimensional structure in the presence of K^+ and Mg^{2+}. Subsequently added Tb^{3+} competes with Mg^{2+} at its binding sites and cleaves the phosphate-sugar backbone by hydrolysis (B indicates the nucleobase moiety). The resulting RNA fragments of different lengths are separated by denaturing polyacrylamide gel electrophoresis (PAGE) and visualized with a phosphoimager. The cleavage sites, and thus coordination sites, of the Tb^{3+} ions appear as dark bands and these can be correlated with their position in the intron by a nuclease T1 digest run in parallel.[77]

flexible and can thus adopt easily to different environments. Thus, lanthanide ions seem to preserve the prefolded tertiary structure and not to disturb the local geometry within the binding pocket. The relative rigidity of the coordination sphere of Pb^{2+} is reflected by the fact that in case of the group II intron ai5γ, backbone cleavage induced by this metal ion leads to fewer detectable sites but these being identical with those induced by Tb^{3+} or Mg^{2+}.[77]

With another group II intron, bI1 from the cob gene in yeast, Mn^{2+} and Zn^{2+} were used to test for metal-ion binding sites.[122] In this case not the primary cleavage pattern was investigated, but a primer extension analysis was chosen. Although primer extension is not as sensitive as the direct observation, this method has the advantage that it can be applied to very large RNAs.[116,122] In the case of bI1, Mn^{2+} and Zn^{2+} induced cleavage revealed the same sites. However, some sites detected with Tb^{3+} did not show

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

up, like the one in the bulge of domain 5, which is part of the catalytic center (see also below).[77]

Tb^{3+} has another striking feature: When applied at millimolar concentrations, Tb^{3+} nonspecifically cleaved also intronic regions with a high AU content. Most of these regions are not crucial for catalysis; they are believed to lie on the surface of the ribozyme and are therefore likely to be dynamic or disordered in secondary structure. Under such conditions of high concentration, Tb^{3+} coordinates unspecifically to the surface nucleotides of the intron, leading to an enhanced hydrolysis of the phospho diester bridges at these positions. Thus, depending on the concentration applied, Tb^{3+} can also be readily used as a probe for unstructured regions within a large folded RNA.

In addition to their use to determine metal-ion binding sites in large RNA molecules like group II introns, hydrolytic cleavage experiments with Ln^{3+} ions also yield information about the affinity of these ions to the RNA at each specific site.[114] Variation of the Tb^{3+} concentration shows that at some sites cleavage already occurs at low micromolar concentrations, whereas at other sites high micromolar or even millimolar amounts of this lanthanide(III) ion are needed to cleave the backbone.[114] Assuming a 1:1 binding behavior, the dependence of cleavage intensity on the Tb^{3+} concentration can be fitted with a nonlinear least-squares fit and affinity constants for each site determined. It is interesting to see that the intensity of the cleavage does not coincide with the affinities of Tb^{3+} at the single sites. This simply means that at some sites the Tb^{3+} ion is geometrically ideally positioned to promote cleavage but that this positioning is independent from its affinity at the site.[114] To conclude, in such experiments it is always important to perform Tb^{3+} titrations over a large concentration range, as the cleavage picture/intensity at just a single concentration can easily be misleading regarding the affinity of the metal ion to a given site.

5. Structure and Metal Ion-Binding Properties of the Catalytic Domain 5

5.1. The Role of Magnesium Ions

Domain 5 (D5) (see Section 2 and Figure 2) is the phylogenetically most conserved region of group II introns and is an essential active-site component for any reaction catalyzed by these ribozymes. D5 forms a hairpin-loop structure with usually about 34 nucleotides in length.[36,75] This hairpin always consists of two helical stems separated by a two-nucleotide bulge and is closed on one side by a GNRA tetraloop (N = any nucleotide, R = purine). Almost every nucleotide within D5 has at least one functional group, which is important for either catalysis itself or for binding of D5 to other intronic domains. Close to the 5′ end of D5, the so-called AGC, or catalytic, triad is located. These three nucleotides are almost invariable and their major groove functional groups have been shown to be crucial for the catalytic step.[74] D5 has a nanomolar affinity for the other intronic components,[123] of which advantage is taken in so-called *trans*-splicing experiments, where D5 acts as the "enzyme" in Michaelis–Menten-type kinetics.[76] The major interaction between D5 and the central region within D1 is a tetraloop-tetraloop receptor interaction, which is highly dependent on the presence of divalent metal ions.[124] In addition, further contacts between these two domains are known.[61,72] There are no phylogenetic covariations of Watson–Crick base pairing between nucleotides in D5 and other intronic or exonic regions, thus, these interactions are made through conserved hydrogen bonding patterns, which can be rather stable,[102] involving nucleobase and sugar moieties thus building higher order structures like base triples.[61,62,71,72]

Only few of these inter domain contacts are structurally characterized, mainly based on nucleotide analog interference mapping studies (NAIM).[72] Indeed, any structural information on group II introns is very scarce.[78,125] Regarding D5, phylogenetic alignment clearly shows a two-helix structure. However, the secondary structure around the bulge is still a matter of debate (Figure 5). On the one hand a GU wobble pair leaving the adjacent A and C unpaired, and on the other hand an AU Watson–Crick pair with flipped out C and G nucleobases is proposed. In favor of the first base pairing scheme with the GU wobble is a crystal structure of a permuted D5D6 construct.[125] The first helix is closed by the wobble pair between U823 and G840 and the second helix is stacked on top thus forming one straight long helix with two flipped out nucleotides A and C in the middle. The two flipped out nucleotides form crystal lattice contacts with neighboring molecules, possibly mimicking similar contacts within the whole ribozyme (Figure 5B).[125] In the NMR solution structure of D5 in the presence of Mg^{2+} the bulge adopts a hitherto unknown structure.[78] The two bulged AC nucleotides are stacked within the hairpin and the downstream G840 does not form a wobble pair but instead is in a *syn* conformation and thus flipped down into the major groove of stem 1 (Figure 5C). As a consequence, the two helixes are slightly twisted against each other, exposing the AU base pair below to the solvent providing a possible platform for stacking interactions with incoming nucleotides of the above λ-λ′ contact. In support of the flipped down *syn*-G840 is the biochemical observation that the NH_2 group of G840 is known to be crucial for catalysis.[72,126] In the NMR structure the exocyclic amino group is very close to the AGC triad[78] and thus, to the reaction center.[61] In addition, Tb^{3+} cleavage experiments of D5 alone and in the presence of D1 both revealed a metal-ion binding site in the bulge, suggesting that D5 adopts a similar structure in solution as in the ribozyme.[77]

Several metal-ion binding sites have been detected in D5. Thio rescue experiments revealed a Mg^{2+} coordinated to the S_p-oxygen atom of the A816 phosphate group within the AGC triad, thus being important for binding of D5 to the other domains.[127] Titration studies of D5 with $MgCl_2$ by NMR revealed further binding sites of Mg^{2+} within D5.[78,128] In fact, such sites may closely neighbor each other.[107] The recording of 2D $^1H,^1H$-NOESY spectra al-

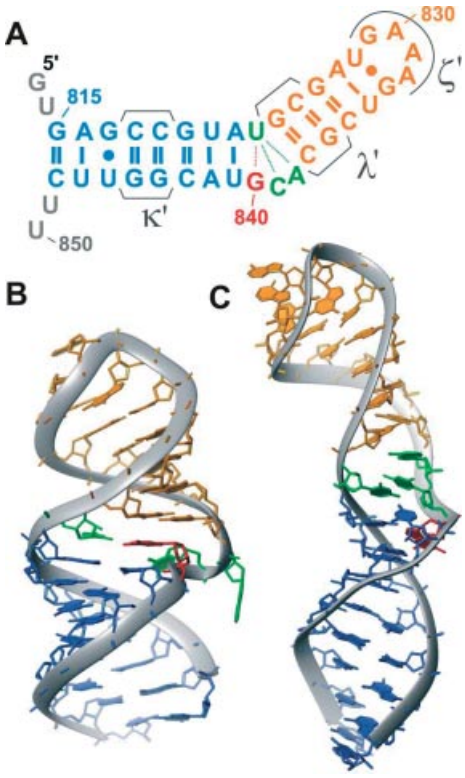

Figure 5. Solution and crystal structures of D5 together with its secondary structure. (**A**) Secondary structure of D5 from ai5γ together with its numbering scheme and tertiary contacts with other domains indicated by Greek letters (see also Figure 2). Helix one is colored in blue, helix two in orange, G840 in red, and the other bulge nucleotides in green. Nucleotides shown in grey, flanking D5, are not included in the two structures. (**B**) In the crystal structure (pdb entry 1KXK),[125] D5 adopts a straight helix with the two bulge nucleotides A838 and C839 flipped out making lattice contacts with neighboring molecules. (**C**) The NMR structure (pdb entry 1R2P)[78] reveals a more flexible structure with the two helices slightly kinked as all bulge-nucleotides are found within the helix. The syn-G840 is flipped down into the major groove. Both structures were drawn with the program MOLMOL,[147] based on the pdb entries given above.

lowed us to follow the chemical shift changes of the aromatic nucleobase, as well as the aliphatic sugar protons and yielded therefore a very detailed picture not only about the location, but also about the strength of the binding.[78,128] Almost all protons in D5 are affected by the addition of Mg^{2+} implying that in general Mg^{2+} binds unspecifically to the phosphate groups of this oligonucleotide. However, some chemical shifts show a much larger dependence on Mg^{2+} concentration, e.g., resonances belonging to nucleotides around the bulge, the tetraloop and the tandem GC pairs in helix 1. In line with the above-mentioned results from the Tb^{3+} cleavage experiments[77] and the structural orientation of the bulge, is the strong metal-ion binding in this region (log $K = 2.52 \pm 0.12$ M^{-1})[77] for Mg^{2+}, K being the stability constant), which is high compared to e.g., $Mg(pUpU)^-$ (log $K = 1.84 \pm 0.04$ M^{-1}).[129] Indeed, several carbonyl oxygen atoms are positioned in the minor groove of the bulge, providing possible multiple coordination sites for the hard Mg^{2+} ion. The large chemical shift changes of about 0.3 ppm may be indicative of a structural change in the bulge upon Mg^{2+} binding, although the NOESY pattern did not change up to 7.5 mM $MgCl_2$ added. Metal-ion coordination within the bulge region together with a hydrophobic stacking interaction of incoming nucleotides with the below lying AU platform, might facilitate the formation of the λ-λ′ tertiary contact by providing charge compensation for the anionic backbone.

5.2. The Effect of Other Metal Ions on Group II Intron Reactivity

Monovalent cations are primarily used for charge screening, but in a few cases also very specific binding sites for, e.g., K^+ ions, are known.[130] In living cells, the concentration of Na^+ and K^+ is (depending on the organism and kind of cell) usually between 2 and 150 mM. In addition, polyamines and RNA binding proteins are abundant in the cell to stabilize large three dimensional RNA structures such as group II introns. For in vitro splicing, much higher salt concentrations are needed; usually between 500 and 1500 mM (see Table 1 and refs. therein). However, also for in vitro splicing, usually 100 mM Mg^{2+} (Table 1) can be partly replaced (e.g. 10 mM $MgCl_2$ total) by either polyamines like spermidine (2 mM)[38] or protamine (5 nM),[53] or RNA binding proteins: Experiments with the Ll.ltrB intron have shown that the self-encoded maturase protein LtrA binds to intronic sequences in D4 and enables splicing also under reduced salt conditions (450 mM NaCl, 5 mM $MgCl_2$).[131]

KCl can be replaced in most instances by ammonium salts like NH_4Cl or $(NH_4)_2SO_4$ without much loss of overall activity, but having an effect on the chosen splicing pathway: Ammonium sulfate favors transesterification (branching), KCl the hydrolytic pathway, whereas NH_4Cl yields the products of both pathways in similar amounts.[53,132–134] Thus, for many biochemical experiments, like NAIM (nucleotide analog interference mapping), NAIS (nucleotide analog interference suppression), as well as for reverse-splicing reactions ammonium salts are preferred.[72,131] In intron insertion reactions into DNA, i.e. in the presence of a self-encoded maturase protein, Na^+ is readily used (at low Mg^{2+} concentrations). However, there are only few examples of in vitro splicing reactions where Na^+ is used instead of K^+ (or NH_4^+),[131] as the presence of high amounts of Na^+ can lead to a loss in activity.[110] Li^+ can promote folding of some RNAs,[135] but it is only rarely employed. However, one should be aware that, although not specifically reported, sodium (and lithium) ions are almost always present to some extent: Many lithium and sodium salts of nucleotide triphosphates and of buffers are used during transcription and purification of the RNA as well as in the splicing reaction itself (MOPS, Edta, to name just two).

All group II introns investigated up to now need Mg^{2+} to perform splicing or branching. However, other divalent metal ions are often added in low millimolar amounts, e.g., in thio-rescue, hydrolytic cleavage experiments, and NAIS/

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NAIM studies. In thio-rescue experiments, mainly $CdCl_2$ and $MnCl_2$ are used in concentrations between 2 and 10 mM in the presence of 100 mM Mg^{2+}.[72,127,136] Under such conditions, both branching and splicing still take place. It should be added here that it is a common misconception that Mn^{2+} is significantly more thiophilic than Mg^{2+}. Mn^{2+} does not show an increased affinity towards thiophosphate groups compared to phosphate groups.[137] However, due to its position in the Irving–Williams series, its affinity to (thio)phosphate groups is slightly higher than that of Mg^{2+}, explaining the few observed "rescue" effects (related results are given in refs.[137–140]).

5.3. The Special Effects of Calcium Ions

Above, the need of group II introns for K^+/NH_4^+ and Mg^{2+} as well as the use and effect of various mimicking metal ions has been summarized. But what about other alkaline earth metal ions? For example, Ca^{2+} is abundant in Nature, although in living cells the free calcium concentration is normally kept low. Ca^{2+} is slightly larger than Mg^{2+}, but it also prefers oxygen donors as ligands and therefore effectively binds carbonyl groups.[141] Complexes of Ca^{2+} with monophosphate groups[142] are known to be weaker by a factor of about 0.75 compared to those with Mg^{2+}. For the simultaneous coordination to several phosphate groups like in a nucleoside triphosphate, the factor between Mg^{2+} and Ca^{2+} is further reduced to about 0.4.[143] One would therefore assume that small amounts of Ca^{2+} have only little effect on the reactivity of group II introns. Surprisingly, the opposite is observed. We have performed *trans* cleavage assays, in which the 5′-exon is cleaved from the intronic domains 1, 2, and 3 upon addition of D5 (Figure 6).[144,145] Such a setup has been shown to be an excellent mimic for the first step of splicing obeying Michaelis–Menten kinetics, when D5 is added in excess.[76]

Under saturating conditions of D5 (500 mM KCl, 100 mM $MgCl_2$) the observed rate constant $k_{obsd.}$ equals 0.044 ± 0.002 min^{-1}.[76,144,145] In the presence of only 1 mM Ca^{2+} (and, 99 mM Mg^{2+}), the rate of the reaction decreases significantly (Figure 6).[144,145] The slightly decreased concentration of Mg^{2+} cannot be the reason for reduced catalysis, especially as at concentrations down to 50 mM Mg^{2+} the ribozyme still remains folded and active.[112] The mode of inhibition by Ca^{2+} is unclear. The displacement of Mg^{2+} from the active site is a first possibility, although a less likely one. Nevertheless, it is evident that, despite having normally a lower affinity towards the constituents of nucleic acids, Ca^{2+} must somehow alter the three dimensional fold of a local metal-ion binding motif or even of the whole ribozyme, for example by binding to (additional) carbonyl groups due to its larger size and higher coordination number. This observation proves that group II intron ribozymes indeed are a very delicate molecular machinery being extremely sensitive to small changes in its environment, and despite its size show a high specificity for certain metal ions.

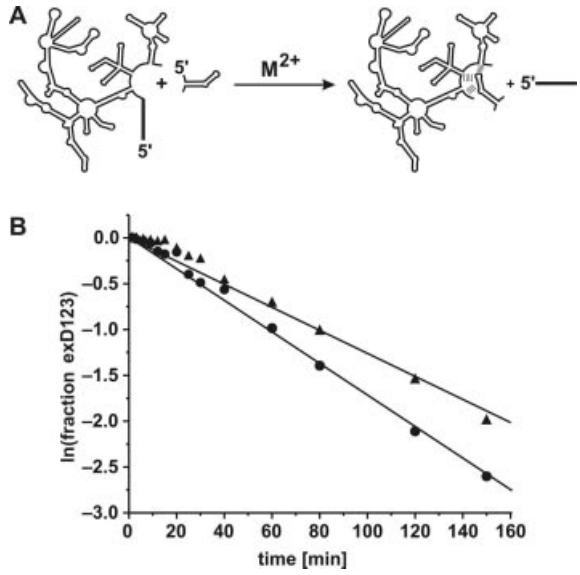

Figure 6. Effect of Ca^{2+} on the splicing reaction of the group II intron ai5γ. (**A**) Reaction scheme of the *trans* splicing reaction of exD123 upon addition of D5 in the presence of divalent metal ions. (**B**) Comparison of the observed rate of the above reaction in the presence of only Mg^{2+} (100 mM, ●) and a ratio of Ca^{2+}:Mg^{2+} = 1 mM:99 mM (▲). The fraction of precursor is drawn vs. time. The reaction is clearly slower in the presence of Ca^{2+}.[144,145]

6. Conclusions and Outlook

In this review, I have tried to show why group II introns are fascinating molecules and worthwhile targets for studies by Bioinorganic Chemists. After a short summary of the diverse array of reactions catalyzed by group II intron ribozymes, the role of metal ions in folding and activity of these catalytic RNAs was discussed. In living cells only concentrations in the lower millimolar range of monovalent and divalent metal ions are needed, as polyamines and RNA binding proteins support the folding of these large RNAs to the active three dimensional structure. Such stabilizing effects by biomolecules other than RNA are usually replaced in vitro by high concentrations of metal ions, also supporting catalysis. However, it is reasonable to assume that both in vivo and in vitro, metal ions are occupying the same key sites within the catalytic core or regions of tertiary interactions.

In the light of the highly conserved secondary structure of group II introns it is not understood why introns from different organisms and gene loci exhibit such a diverse need regarding the concentration of Mg^{2+}. A set of minor groove binding sites for metal ions has been determined by hydrolytic cleavage experiments for the ai5γ and bI1 introns from yeast.[77,122] Not all binding sites appear to correspond to each other. However, as different metal ions have been used for the promoted backbone hydrolysis as well as different methods to visualize the cleavage sites, a thorough interpretation is difficult.

It will be interesting to see if group II introns from different organisms have high affinity binding sites for metal ions at different locations within the intronic domains. One

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

can speculate if group II introns do not manifest one particular fold and reaction pathway, but rather that there might be subtle differences in the structure depending on the subgroup and the origin of a particular group II intron. Such a scenario is quite well possible, as two existing models of the catalytic centers of ai5γ and Pl.lsu/2 cannot be superimposed.[118,146] The two structures of single domains of the group II intron ai5γ solved so far,[78,125] together with the two models of the catalytic core,[118,146] are first important steps in the direction of building a structural basis for these molecular machines. Indeed, more structural information is highly needed for the interpretation of metal-ion binding necessary for folding and catalysis. It is evident that much work needs to be done because at present hardly any exact binding site is known; for example, if a divalent metal ion binds to a G unit, where is the metal ion exactly located? At N1, O6, N7 or even at N3? Is the phosphate group also involved? Only if we are able to answer these questions down to the atomic level we shall be able to characterize and understand the reaction processes in detail.

Acknowledgments

I thank Dr. Eva Freisinger, as well as the members of my enthusiastic group Michèle Erat, Maya Furler, Sofia Gallo, Dr. Bernd Knobloch, Daniela Kruschel, and Miriam Steiner for helpful comments and discussions regarding this manuscript. Financial support by the Swiss National Science Foundation (SNF-Förderungsprofessur PP002–68733/1) is gratefully acknowledged.

Facile Catalytic Decomposition at Low Temperature of Energetic Ionic Liquid as Hydrazine Substitute

Laurence Courthéoux,[a] Dan Amariei,[a] Sylvie Rossignol*[a] and Charles Kappenstein[a]

Keywords: Platinum-based catalyst / Sol-gel synthesis / Ionic liquids / Alumina-silica / Catalyst activity

Platinum supported on doped alumina catalysts were prepared and evaluated for the decomposition of NH_3OHNO_3/water energetic liquid. Powdered and shaped catalysts remain active after 23 injections at 45 °C.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Energetic liquid compounds known as monopropellants are used for propulsion and gas generator purposes. For example, the orbit and attitude control of satellites is obtained through small thruster engines using the catalytic decomposition of hydrazine, N_2H_4, on supported iridium catalysts. The high toxicity of hydrazine induces high costs and its replacement by a less toxic propellant is of current interest.[1,2] The most currently proposed and studied hydrazine substitutes are energetic aqueous ionic liquids and a representative mixture contains hydroxylammonium nitrate (or $NH_3OH^+NO_3^-$, HAN) as oxidizer, water and a fuel.[3–5] Nevertheless, the use of such mixtures involves more drastic conditions than for hydrazine, due to the high temperature reached during the decomposition (up to 1400 °C) and the need of frequent restarts that involve a preheating of the catalyst (300–400 °C). Therefore, a high catalytic activity at low temperature (20–200 °C) associated with a high thermal stability of shape formed catalysts remain critical parameters for the future development of new engines.

Previous studies performed by our group have revealed that platinum supported on thermally stable Si-doped alumina displays a good activity at low temperatures[6,7] The powder or shaped Si-doped alumina (xerogel) are obtained by sol-gel procedure and were demonstrated to be stable at high temperature (1200 °C, 5 h);[8] the metallic phase (10 wt.-% Pt) is added by the wet impregnation procedure. These catalysts have been evaluated for the decomposition of HAN/water solutions in a lab-made constant volume batch reactor,[9] and lead to decomposition at very low temperatures, less than 60 °C,[10] whereas the thermal decomposition temperature is in the range 115–120 °C.[4] Another key point concerns the long-term stability of the catalysts, particularly in the presence of a large amount of propellant. In this paper, we present the activity of powdered and shaped (spheres) catalysts for successive HAN/water injections. These successive injections were carried out to simulate the pulse mode of the satellite thrusters. The catalysts (160 mg) are preheated at 45 °C during 1 h, then 100 μL (150 mg) of a binary 79 wt.-% HAN/water mixture (i.e. 1.23 mmol) was injected manually 23 times, using a syringe, in the constant volume reactor (167 cm^3). Each injection is made after the thermal re-equilibration (approximately 4 min); the number of injections is limited by the pressure gauge and by the size of the sample holder.

The evolution of pressure and temperature (catalyst and gas phase) as a function of time during the successive injections using the sphere-shaped catalyst are represented in part a of Figure 1. Each peak corresponds to the decomposition following the injection, with an ignition delay of about 0.5 s; the catalysts are still active after all the injections. The decomposition reaction can form the thermodynamic products N_2, O_2 and H_2O [Equation (1)] or give additional kinetic products, in the form of nitrogen oxides [i.e. Equation (2)]. The calculated values of pressure increase (gas phase temperature: 25 °C) using the perfect gas formula are 365 mbar and 91 mbar, respectively, for a reaction giving thermodynamic [Equation (1)] and kinetic [Equation (2)] products.[11]

$$NH_2OHNO_3(aq) \rightarrow N_2(g) + O_2(g) + 2\ H_2O(l) \quad (1)$$

$$NH_3OHNO_3(aq) \rightarrow NO_2(g \text{ or } aq) + 0.5\ N_2(g) + 2\ H_2O(l) \quad (2)$$

Moreover, in both cases, the reaction produces water, which stay for the main part in the sample holder. An enlargement of a catalytic decomposition peak is given in Figure 1b; for each peak, the pressure increase (ΔP) due to the formation of gaseous products[10] and the rate of the decomposition (slope: $\Delta P/\Delta t$ in mbar·s^{-1}) between the points 1 and 2 are determined. The catalyst temperature-

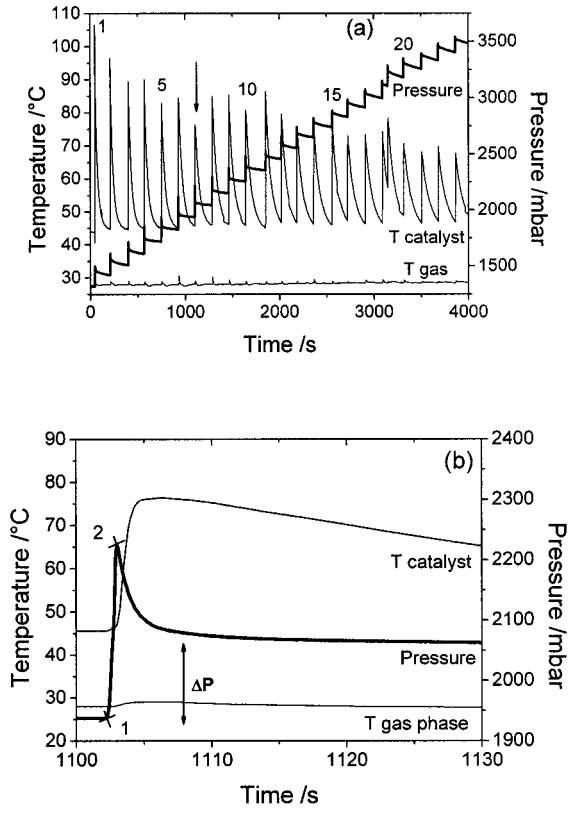

Figure 1. (a) Catalytic decomposition of 79 wt.-% HAN/H_2O at 45 °C with the sphere-shaped sample (23 injections) and (b) enlargement of one decomposition peak (see arrow, part a): Determination of pressure increase and the slope between points 1 and 2.

decrease is due to the heat transfer to the reactor; the progressive reduction of the temperature maxima (106 to 70 °C; Figure 1a) is related to the increasing amount of water in the sample holder. The pressure increase (ΔP) variations of the two catalysts are similar, as shown in Figure 2. The values gradually decrease from 140 mbar at the beginning, to 110 mbar at the end of the 23 injections, corresponding to 0.94 and 0.74 mmol of gaseous product formed during the decomposition reaction. This decrease can be explained by a small deactivation of the catalyst related to the increasing amount of water in the sample holder. The pressure-increase values for both samples are close to the kinetic value (91 mbar), indicating the formation of nitrogen oxides. Other experiments carried out in a dynamic reactor with on-line MS analysis are in progress in order to determine the gas phase composition during the decomposition reaction. The first results show the formation of kinetics products, such as NO, NO_2 and lower amounts of N_2O.[12]

The evolution of the decomposition rate (measured by the $\Delta P/\Delta t$ slope) during the 23 successive injections on both catalysts is given in Figure 3. Whatever the catalyst, an increase of the reaction rate is evidenced until the seventh injection to reach 434 mbar·s^{-1} for the sphere-shaped sample and 323 mbar·s^{-1} for the powder, indicating a fast reaction rate. Then, the slope values oscillate between 200 and

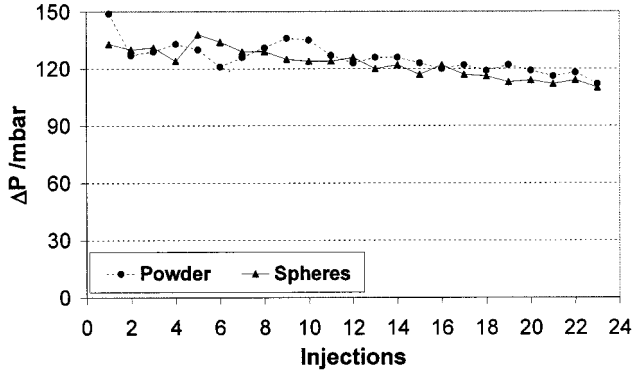

Figure 2. Evolution of pressure increase (ΔP) values during the 23 successive injections of 79 wt.-% HAN/H_2O at 45 °C on both catalysts.

400 mbar·s^{-1}. The nonreproducible oscillations are due to the manual injection procedure. An automatic injection system using a microburette failed for this pulse injection mode. These results show the very good efficiency of both catalysts and the noninhibiting effect of the shaping. Nevertheless, mechanical breaking of the spheres has been observed during the reaction probably due to the strong exothermic decomposition of the HAN/H_2O solution. This mechanical breaking could be avoided by a preheating at 100 °C.

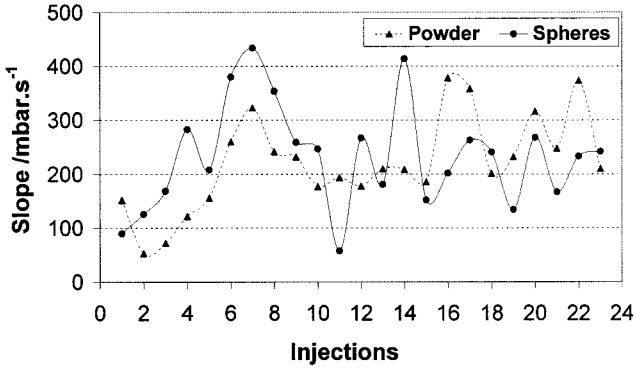

Figure 3. Evolution of $\Delta P/\Delta t$ slopes during the successive injections of HAN/H_2O at 45 °C on the powder and sphere-shaped catalysts.

All these experiments display the very good activity and stability of our catalysts. Indeed they allowed the efficient decomposition of the HAN/water solution at low temperature (45 °C) even in presence of a large amount of solution. Moreover, these materials remain active, showing a high reaction rate and an important pressure increase, after 23 monopropellant injections which remains a challenge for the development of new satellites thrusters. Nevertheless, the breaking of the sphere implies to find a more mechanically stable shaped catalyst support.

A Structural and Magnetic Investigation of Ferromagnetically Coupled Copper(II) Isophthalates

Wei-Zheng Shen,[a] Xiao-Yan Chen,[a] Peng Cheng,*[a] Shi-Ping Yan,[a] Bin Zhai,[a] Dai-Zheng Liao,[a] and Zong-Hui Jiang [a]

Keywords: Copper / Magnetic properties / N ligands / Organic-inorganic hybrid composites

Dinuclear and one-dimensional copper complexes $[Cu_2(tpa)_2(m\text{-bda})](ClO_4)_2$ (**1**), $[\{Cu_2(tpm)_2(m\text{-bda})_2\}\cdot 2CH_3OH\cdot 4H_2O]_n$ (**2**), and $[\{Cu_2(bpm)_2(m\text{-bda})_2(H_2O)\}\cdot CH_3CN\cdot H_2O]_n$ (**3**) [tpa: tris(2-pyridylmethyl)amine; tpm: tris(pyrazolyl)methane; bpm: bis(pyrazolyl)methane; *m*-bda: isophthalate dianion] have been prepared from various polydentate terminal ligands. Complex **1** crystallizes in the monoclinic $P2_1/c$ space group with a = 14.003(6), b = 17.201(7), c = 20.654(9) Å, Z = 4, R_1 = 0.0678, wR_2 = 0.1751. Complex **2** crystallizes in the triclinic $P\bar{1}$ space group with a = 10.250(7), b = 15.078(10), c = 15.190(10) Å, Z = 2, R_1 = 0.0571, wR_2 = 0.1288. Complex **3** crystallizes in the orthorhombic *Pnma* space group with a = 17.956(6), b = 17.615(5), c = 10.776(4) Å, Z = 4, R_1 = 0.0554, wR_2 = 0.0845. In these complexes the isophthalate anion acts as a bis(monodentate) ligand bridging copper(II) centers. The variable temperature magnetic behavior reveals the existence of ferromagnetic interactions in **1**–**3**. The best fittings to the experimental magnetic susceptibilities give J = 1.02 cm^{-1} (**1**), 2.58 cm^{-1} (**2**), and 35.5 cm^{-1} (**3**). In light of the structural data it can be concluded that the magnetic coupling via the isophthalate bridging ligand is negligibly small, and the abnormally large ferromagnetic interaction in complex **3** may be due to the hydrogen bonding between copper centers via carboxylic groups through a spin-polarization mechanism.

Introduction

The study of superexchange interactions between paramagnetic ions in a variety of magnetic systems has been a vital field in inorganic chemistry in the last decades driven by the need to understand the fundamental science associated with magnetic interactions between metal centers and develop structure-function relationships that enable the rational design of new magnetic materials.[1] Owing to its fundamental importance, the study of long-range magnetic interactions has also been an active field of research,[2] in which phenyldicarboxylate ligands have been extensively studied.[3–6] Alhough magnetic interactions transmitted through phenyldicarboxylate bridges are usually weak,[2,6–8] the magnitude and nature of the coupling interactions can be influenced by a series of factors, such as the separation of the metal centers, bridging modes, degree of coplanarity between the coordination basal planes and the ligand, the dihedral angles between the carboxylato planes and the phenyl ring, and the angle between the planes of the two carboxylato groups of each phthalato bridge.[9–12]

In copper phthalates, magnetic systems with terephthalate as bridges are the most abundant, whereas those with isophthalate have been less widely reported.[5,6,13,14] In fact, compounds of phenyldicarboxylates are mostly dinuclear and oligonuclear, while those with polymeric structures and transition metal varieties are still relatively limited, especially for isophthalic acid. In a previous report,[14] we systematically investigated the influence of various isomers of phthalic acids on magnetic properties, and found that the structural differences caused by the bridging ligands lead to unexpected magnetic behavior, including changes from ferromagnetic to antiferromagnetic couplings. As a continuation of this magneto-structural relationship study, we initiated a systematic experimental approach in an attempt to design μ-isophthalato-Cu^{II} magnetic systems to investigate the factors that influence the isophthalate-bridged complexes. Three ferromagnetically coupled complexes $[Cu_2(tpa)_2(m\text{-bda})](ClO_4)_2$ (**1**), $[\{Cu_2(tpm)_2(m\text{-bda})_2\}\cdot 2CH_3OH\cdot 4H_2O]_n$ (**2**), and $[\{Cu_2(bpm)_2(m\text{-bda})_2(H_2O)\}\cdot CH_3CN\cdot H_2O]_n$ (**3**) [tpa: tris(2-pyridylmethyl)amine; tpm: tris(pyrazolyl)methane; bpm: bis(pyrazolyl)methane; *m*-bda: isophthalate dianion] were prepared. The coordination geometries of the Cu^{II} centers are tuned by the various polydentate terminal ligands, which ultimately leads to the different crystal structures and magnetic properties.

Results and Discussion

Complexes **1**–**3** were prepared with the same bridging ligand, the isophthalate dianion, and three different terminal

E-mail: pcheng@nankai.edu.cn

ligands, tris(pyrazolyl)methane, tris(2-pyridylmethyl)amine and bis(pyrazolyl)methane. Since tris(pyrazolyl)methane is a tridentate ligand, it reacts very easily with 0.5 equiv. of the metal ion to form the sandwich complex $M(tpm)_2$. On the other hand, the isophthalate dianion is not an active bridging ligand in neutral environments. In this paper, we successfully obtained a half-sandwich structure by making the pH basic. This solution also works when we change the terminal ligand into tris(2-pyridylmethyl)amine or bis(pyrazolyl)methane.

The X-ray crystal structure analyses reveal a dinuclear unit for **1** and one-dimensional zigzag chain motifs for **2** and **3**. The copper(II) ions in **1** and **2** are all five-coordinate, whereas there are two types of crystallographically different copper atoms − four-coordinate and five-coordinate − in **3**.

Crystal Structure of $[Cu_2(tpa)_2(m\text{-bda})](ClO_4)_2$ (1)

The structure of **1** contains a $[Cu_2(tpa)_2(m\text{-bda})]^{2+}$ cation and a ClO_4^- anion. The $[Cu_2(tpa)_2(m\text{-bda})]^{2+}$ unit is shown in Figure 1. The tpa ligand acts as a quadridentate terminal ligand with four nitrogen atoms ligated at the copper center. The *m*-bda group acts as a bis(monodentate) ligand, and bridges copper(II) ions to form a dinuclear complex. The coordination geometry around the copper atom is distorted trigonal-bipyramidal. The apical sites of the trigonal bipyramid are occupied by the N4 and O1 atoms [Cu1–N4 = 2.033(6) Å; Cu1–O1 = 1.901(5) Å]. The best equatorial plane is defined by atoms N1, N2, and N3, with an average Cu–N bond length and N–Cu–N bond angle of 2.085(7) Å and 117.3(3)°, respectively. The Cu1 atom is 0.091(6) Å out of this plane. The distance between two copper(II) ions is 10.557(5) Å.

$[\{Cu2(tpm)2(m\text{-bda})2\}\cdot 2CH_3OH\cdot 4H_2O]_n$ (2)

In the structure of **2**, tpm is a tridentate terminal ligand. The isoelectronic tris(pyrazolyl)methane ligand is formally derived from tris(pyrazolyl)borate ligands by replacing the central boron anion with a carbon atom, and has received considerably less attention.[15–17] Surprisingly, 1D or multidimensional polymers with tpm as terminal ligand have seldom been reported so far, which is probably due to the fact that tpm is such a strong tridentate, chelating, six-electron donor that it can effectively prevent building blocks from constructing infinite aggregates. In principle, the half-sandwich complexes containing tpm can be extended into infinite structures through appropriate bridging ligands. Here, the *m*-bda anion, as a bis(monodentate) ligand, bridges copper(II) ions to form a one-dimensional zigzag chain-like structure, as shown in Figure 2. The coordination geometry around the copper atom is distorted square pyramidal. The apical site of the square pyramid around the Cu1 atom is occupied by N3 [Cu1–N3 = 2.414(5) Å]. Other Cu–N bond lengths vary slightly, from 1.984(5) to 1.991(4) Å. The Cu–O bond lengths [Cu1–O1 = 1.899(4) Å, Cu1–O5 = 1.905(14) Å] are somewhat shorter than in other *m*-bda-bridged complexes,[5,6,13] which may be due to the distorted square pyramid geometry caused by the rigid tridentate tpm ligand. The best equatorial plane is defined by N1, N5, O1, and O5. The largest deviation from the mean plane is 0.2261 Å for O5, and the Cu1 atom is 0.0023 Å out of this plane. The distance between copper(II) ions along the chain is 10.403 Å, which is much longer than the shortest interchain distance (6.644 Å) between copper ions.

$[\{Cu_2(bpm)_2(m\text{-bda})_2(H_2O)\}\cdot CH_3CN\cdot H_2O]_n$ (3)

The polymeric $[Cu_2(bpm)_2(m\text{-bda})_2(H_2O)\}$ unit of **3** is shown in Figure 3. The bpm ligand acts as a bidentate terminal ligand. There are two kinds of crystallographically different Cu^{II} ions in **3**: Cu1 (five-coordinate) and Cu2 (four-coordinate). The coordination geometry around Cu1 is perfectly square pyramidal, with two nitrogen atoms from bpm [Cu1–N1(N1A) = 2.081(3) Å] and two oxygen atoms from *m*-bda [Cu1–O1(O1A) = 1.937(3) Å] composing the equatorial plane. The Cu1 atom is 0.0541(4) Å out of this plane. The apical site of this square pyramid is occupied by the oxygen atom from the coordinated water molecule [Cu1–O5 = 2.394(4) Å]. The coordination geometry around Cu2 is a distorted square plane with two nitrogen atoms from bpm [Cu2–N3(N3B) = 2.009(3) Å] and two oxygen

atoms from *m*-bda [Cu2–O3(O3B) = 1.939(9) Å]. The Cu2 atom is 0.1514 Å out of the plane. The *m*-bda group acts as a bis(monodentate) ligand and bridges two crystallographically different copper(II) ions alternately to form a one-dimensional zigzag chain (Figure 3). The distance between copper(II) ions along the chain is 10.643 Å, which is much longer than the shortest interchain distance [4.936(4) Å] between copper ions.

There are two kinds of weak interactions between neighboring copper chains: (i) Cu–O···Cu weak coordination bonds, where the oxygen atom from the coordinated water molecule of the five-coordinate Cu atom forms a weak coordination bond with the four-coordinate Cu atom of the neighboring chain [Cu···O 2.552(7) Å, bold dashed line in Figure 4]. The Cu···Cu distance is 4.936(4) Å, and the Cu–O···Cu angle is 172.7(8)°; (ii) hydrogen bonds, with a distance of 2.692(3) Å between the oxygen atom of the H_2O coordinated to one Cu and the nonbonded carboxylate oxygen atoms of the adjacent Cu center. Such a distance strongly suggests the occurrence of H-bonding between these units (thin dashed line in Figure 4).

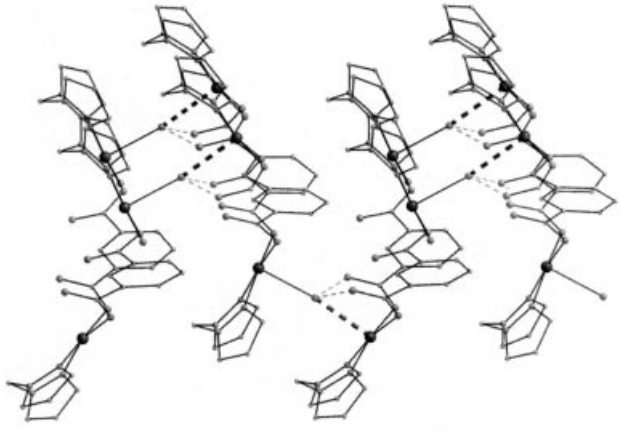

Figure 4. Packing arrangement of **3** along the *ac* plane.

The terminal ligands play an important role during the structure formation. For **1**, the terminal ligand is tetradentate tpa, and the large steric hindrance prevents the formation of infinite chainlike polymer; a dinuclear complex **1** is therefore obtained. For complex **2**, tpm is a tridentate ligand, and the steric hindrance is smaller than tpa. The copper centers are five-coordinate, with two oxygen atoms from an *m*-bda ligand which bridges copper centers into a 1D chain. We have previously published a series of phthalic acid bridged complexes − $[\{Cu_4(tacn)_4(o\text{-bda})_2\}(ClO_4)_4(H_2O)_2]_n$, $[\{Cu(tacn)(m\text{-bda})\}(CH_3OH)_{0.5}(H_2O)_{0.5}]_n$, and $[\{Cu_2(tacn)_2(p\text{-bda})\}(ClO_4)_2]_n$ (tacn = 1,4,7-triazacyclononane, bda = benzenedicarboxylic acid)[14] − in which the terminal ligand tacn is also a tridentate ligand and leads to the formation of one-dimensional chains. For complex **3**, bpm is a bidentate ligand, and the steric hindrance is the smallest, which allows a water molecule to coordinate to Cu1 while Cu2 is square planar. In general, tetradentate tpa ligands create a binuclear complex, whereas tridentate tpm and tacn ligands favor the formation of 1D chains, and the bidentate bpm ligand permits the formation of a 2D layer composed of weak interactions.

Magnetic Properties

The molar magnetic susceptibilities, χ_M, were measured in a field of 5000 G for **2** and 10000 G for **1** and **3**; plots of χ_M and μ_{eff} vs. T are shown below.

For **1**, the μ_{eff} is 2.55 μ_B at room temperature, which is similar to the spin-only value of 2.45 μ_B for two uncoupled copper(II) ions (Figure 5). It increases slightly on cooling to 18 K, and then decreases to 2.45 μ_B at 6 K. Intermolecular antiferromagnetic coupling results in the decrease of μ_{eff} be-

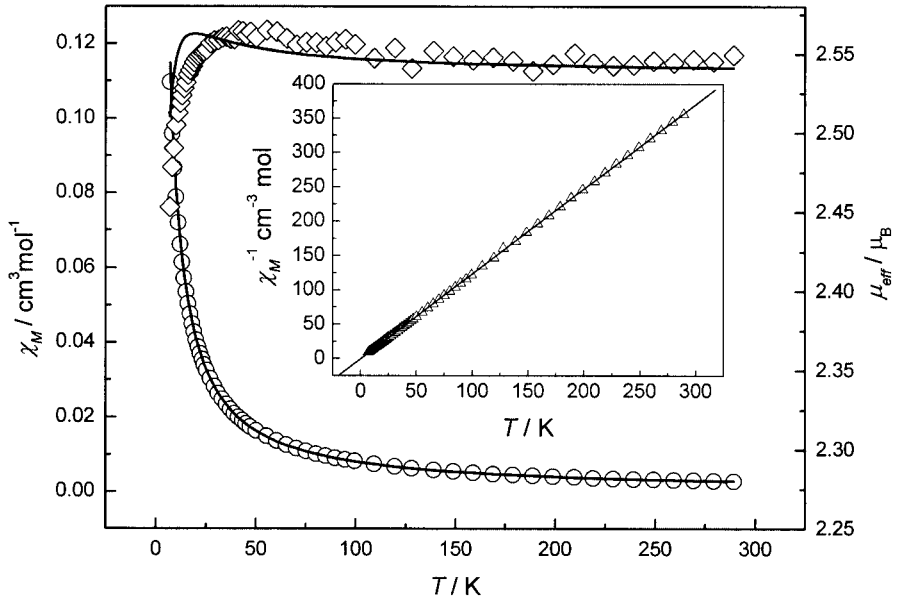

Figure 5. Plots of χ_M (O) and μ_{eff} (◊) vs. T and χ_M^{-1} vs. T (Δ) (inset) for **1**. The solid line represents the theoretical curve with the best-fit parameters.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

low 18 K. The χ^{-1} data for **1** obey the Curie–Weiss law with a Curie–Weiss temperature, θ, of 0.2 K and a Curie constant, C, of 0.81 emu K mol^{-1} (see inset of Figure 5). The Curie constant is larger than the expected value for two uncoupled Cu^{2+} spins (C_{theor} = 0.75 emu K mol^{-1}). The positive sign of the Weiss constant suggests the presence of ferromagnetic interactions between two copper centers. The magnetic parameters were estimated from a least-squares fitting of the susceptibility data by the equation for dinuclear Cu^{II} complexes [Equation (1)],[18] considering the decrease of μ_{eff} below 18 K, a temperature independent susceptibility term ($N\alpha$) was applied and set as 1.2×10^{-4} cm^3 mol^{-1}. A molecular field approximation [Equation (2)] was also used. The best fit was obtained for J = 1.02 cm^{-1}, zJ' = –0.05 cm^{-1}, g = 2.08, and $R = 3.6\times10^{-3}$ [agreement factor, defined as $\Sigma(\chi_M^{obs} - \chi_M^{calc})^2/\Sigma(\chi_M^{obs})^2$].

$$\chi_M = \frac{2Ng^2\beta^2}{kT}\left[3+\exp(-2J/kT)\right]^{-1} + N\alpha \quad (1)$$

$$\chi_M = \chi_{chain}/(1 - zJ'\chi_{chain}/NG^2\beta^2)$$
$$H = -2JS_1S_2 \quad (2)$$

For **2**, the effective magnetic moment is 1.83 μ_B at room temperature, which is close to that of an isolated Cu^{II} ion (1.73 μ_B). As the temperature is lowered, μ_{eff} of **2** smoothly increases to the maximum value of 1.91 μ_B at 24 K, and then decreases to 1.84 μ_B at 5.2 K (Figure 6). The increase of μ_{eff} is due to intrachain ferromagnetic coupling, while the interchain antiferromagnetic coupling results in the decrease of μ_{eff} below 24 K. The χ^{-1} data above 24 K for **2** obey the Curie–Weiss law, with a Curie–Weiss temperature of 1.4 K and a Curie constant of 0.42 emu K mol^{-1} (see inset of Figure 6). The Curie constant is larger than the expected value for one uncoupled Cu^{2+} spin (S = 1/2, C_{theor} = 0.375 emu K mol^{-1}), and the positive sign of the Weiss constant suggests ferromagnetic interactions between copper centers.

The magnetic susceptibility data of **2** were fitted approximately by the equation for a ferromagnetic chain [Equation (3)] with S = 1/2 and a molecular field correction equation [Equation (4)][19] in which A = 5.7979916, B = 16.902653, C = 29.376885, D = 29.832959, E = 14.036918, A' = 2.7979916, B' = 7.0086780, C' = 8.6538644, D' = 4.5743114, and $x = 2|J|/KT$. A temperature-independent susceptibility term ($N\alpha$) was also included and set as 60×10^{-6} cm^3 mol^{-1}. The other symbols have their usual meanings.

$$\chi_{chain} = \frac{Ng^2\beta^2}{4KT}\left[\frac{1+Ax+Bx^2+Cx^3+Dx^4+Ex^5}{1+A'x+B'x^2+C'x^3+D'x^4}\right]^{2/3} + N\alpha \quad (3)$$

$$\chi_M = \chi_{chain}/(1 - zJ'\chi_{chain}/NG^2\beta^2) \quad (4)$$

The best fit to the magnetic susceptibility data yielded J = 2.58 cm^{-1}, zJ' = –0.9 cm^{-1}, g = 2.13, and $R = 9.8\times10^{-4}$. These results confirmed the weak ferromagnetic coupling between adjacent copper(II) ions through the bridging isophthalate ligand, while $zJ' < 0$ indicates the weaker antiferromagnetic interaction between the chains.

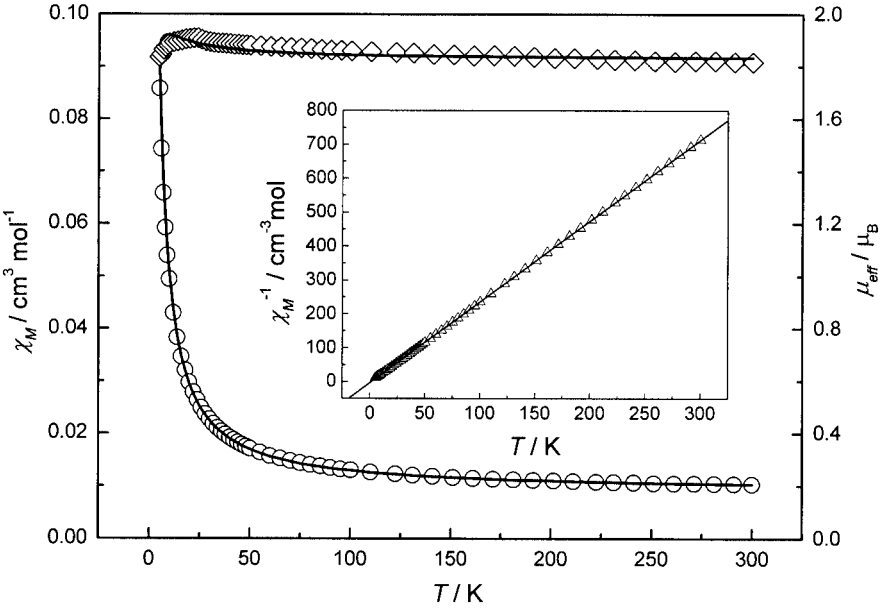

Figure 6. Plots of χ_M (O) and μ_{eff} (◊) vs. T and χ_M^{-1} vs. T (Δ) (inset) for **2**. The solid line represents the theoretical curve with the best-fit parameters.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

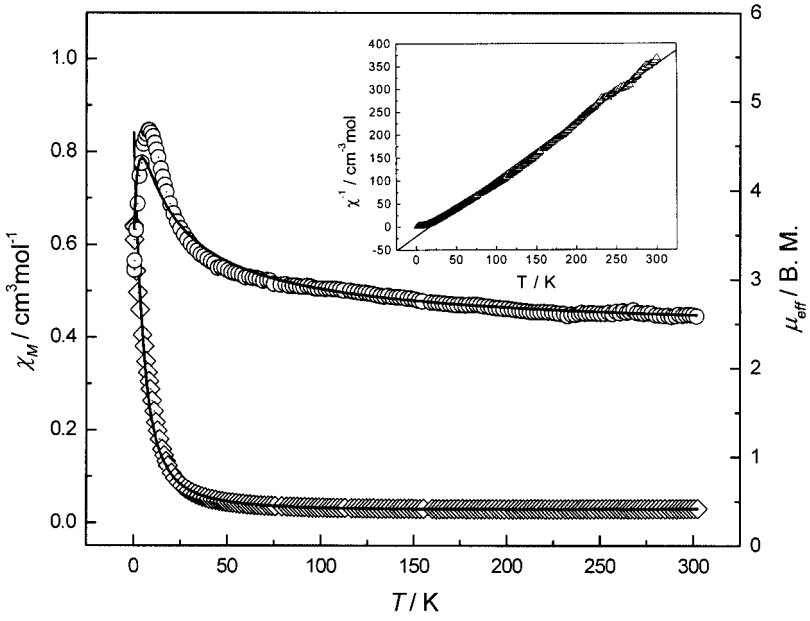

Figure 7. Plots of χ_M (O) and μ_{eff} (◊) vs. T and χ_M^{-1} vs. T (Δ) (inset) for **3** from Equation (1). The solid line represents the theoretical curve with the best-fit parameters.

The effective magnetic moment of **3** is 2.56 μ_B at room temperature, which is close to the value of two isolated Cu^{II} ions (2.45 μ_B). As the temperature is lowered, μ_{eff} of **3** increases to a maximum value of 4.79 μ_B at 9.5 K, and then decreases to 3.15 μ_B at 2 K (Figure 7). The increase of μ_{eff} indicates a ferromagnetic coupling between the copper centers. The χ^{-1} data obey the Curie–Weiss law, with a Curie–Weiss temperature of 16.2 K and a Curie constant of 0.42 emu K mol^{-1}. The positive sign of the Weiss constant also suggests the presence of ferromagnetic interactions between copper centers. Although the one-dimensional zigzag chain structure of **3** is similar to that of **2**, and the neighboring Cu···Cu distances are almost equal, the magnetic behavior is significantly different from that of **2**. First, we attempted to analyze the susceptibilities by the same equation as for complex **2** with the best-fit parameters of J = 33.9 cm^{-1}, zJ' = –2.73 cm^{-1}, g = 2.00, and $R = 9.38 \times 10^{-3}$. In our previous published results, we obtained an *m*-bda-bridged complex [{Cu(tacn)(*m*-bda)}$(CH_3OH)_{0.5}(H_2O)_{0.5}]_n$ (**4**) (tacn = 1,4,7-triazacyclononane).[14] Like tpm, tacn is a tridentate ligand, and the crystal structure of complex **4** is similar to that of **2**. Consequently, J was found to be 1.2 cm^{-1}, which is also close to that of **2**. The selected magnetostructural data of **1**–**4** are listed in Table 1; τ_1, τ_2, and δ are defined in Scheme 1. Comparing the terminal ligands, we can see that although the steric hindrance of the tetradentate ligand tpa prevents the formation of infinite aggregates for **1**, a long bridge through the benzene ring exists at the same time for **1**–**4**, which leads to a similar intramolecular metal–metal separation; in **1**, **2**, and **4** it is the only exchange pathway.

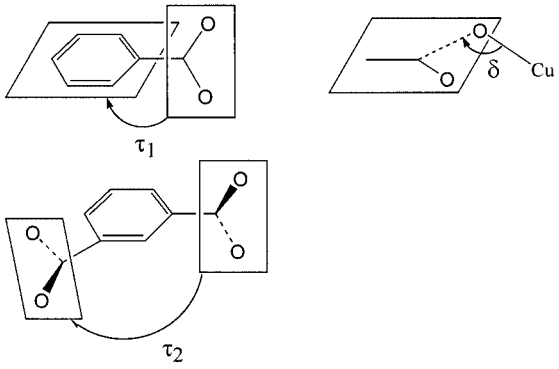

Scheme 1.

Despite the anomalously different τ_1, τ_2, and δ angles, the J values of **1**, **2** and **4** are similar. This implies that the coordination geometry of the metal centers and *m*-bda bridging configuration has no effect on the magnitude of the exchange coupling via the *m*-bda ligand. Accordingly, isophthalic acid is not an efficient bridging ligand for the transmission of electronic effects. The presence of weak ferromagnetic interactions in **1**, **2**, and **4** could be the result of the accidental orthogonality of the magnetic orbitals, while the unusually strong ferromagnetic interaction observed for complex **3** is not possible for the simple exchange pathway through the *m*-bda bridge. A similar condition has been observed by Bakalbassis et al.[20] By calculating the energies of the frontier MOs of $[Cu_2(\mu\text{-TPHA})(bpy)_2(OH_2)_2](ClO_4)_2$ (TPHA = terephthalato and bpy = 2,2′-bipyridine) on the basis of the EHMO method, they ascribed the unexpectedly strong antiferromagnetic interaction ($2J = -51.8\ cm^{-1}$) to the orbital interactions located on the intermolecular Cu–O···Cu moieties and came to the conclusion that the terephthalato bridging unit has an unfavorable character to transmit electronic effects over long distances owing to the very low electron density delocalization on the bridging unit of each magnetic orbital. As for our complex **3**, in the Cu–O···Cu weak coordination bonds the bridging oxygen atom occupies an axial coordination site on both Cu^{II} ions, but the magnetic orbital for Cu^{II} is not located along the z axis, and therefore only a very weak exchange interaction can be expected. The contribution of intrachian interactions via the *m*-bda bridge is insignificant to the overall magnetic behavior of **3**. Thus, the hydrogen bonding between copper centers via carboxylic groups may account for the ferromagnetic interactions through a spin-polarization mechanism. Accordingly, the magnetic data of **3** were fitted again by the same equation as for complex **1** for dinuclear Cu^{II} complexes.[18] Considering the decrease of μ_{eff} in the low-temperature region, a molecular field correction was applied. A fit of the data gave $J = 35.5\ cm^{-1}$, $zJ' = -2.0\ cm^{-1}$, $g = 2.08$, and $R = 3.0 \times 10^{-3}$.

Cano et al. have also proposed that the relatively strong antiferromagnetic coupling observed for terephthalate-bridged Cu^{II} complexes is due to the carboxylate-assisted loss of the coordinated water molecule and subsequent carboxylate dimerization.[8] In light of the peculiar coordination geometry of Cu^{II} in **3** (four- and five-coordinate), the presence of hydrogen bonds between copper centers via carboxylic groups through a spin-polarization mechanism is feasible.

Conclusions

In summary, three copper isophthalates have been prepared and characterized by variable-temperature susceptibility measurements. The above discussion shows that isophthalic acid can be used as an appropriate bridging unit to design magnetic systems with a separation of about 11 Å between the two paramagnetic centers. However the magnetic interactions are, as with the terephthalate-bridged systems, negligibly small. The small steric hindrance of the terminal ligand bpm leads to hydrogen bonding between Cu^{II} centers, which accounts for the abnormally large ferromagnetic coupling of complex **3**.

Experimental Section

General Remarks: Copper(II) perchlorate hexahydrate, tpm, bpm, and tpa were obtained by literature methods.[21–24] These ligands were analyzed by elemental analysis and NMR spectroscopy. Isophthalic acid and other reagents were obtained from commercial sources and used without further purification. Analyses for C, H, and N were carried out on a Perkin–Elmer analyzer at the Institute of Elemento-Organic Chemistry, Nankai University. Variable-temperature magnetic susceptibilities were measured on a Quantum Design MPMS-7 SQUID magnetometer. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms.

Synthesis of $[Cu_2(tpa)_2(m\text{-bda})](ClO_4)_2$ (1): Tpa·3 $HClO_4$ (0.059 g, 0.1 mmol) was dissolved in 10 mL of methanol and triethylamine (1.572 g, 1.55 mmol) was added. $Cu(ClO_4)_2 \cdot 6H_2O$ (0.0371 g, 0.1 mmol) and dipotassium isophthalate (0.0105 g, 0.05 mmol) were added to the resulting solution. The mixture was stirred for 30 min and then filtered. After several weeks, green crystals suitable for X-ray analysis were obtained. Yield: 0.012 g (32% based on Cu). IR (KBr): $\tilde{\nu}$ = 1603 (s) cm^{-1}, 1560 (m), 1475 (w), 1435 (m), 1356 (s), 1315 (w), 1280 (w), 1085 (s), 1010 (m), 815 (w), 760 (s). $C_{44}H_{40}Cl_2Cu_2N_8O_{12}$ (1070.8): calcd. C 49.35, H 3.74, N 10.46; found C49.10, H 3.71, N 10.48.

Synthesis of $[\{Cu_2(tpm)_2(m\text{-bda})_2\} \cdot 2CH_3OH \cdot 4H_2O]_n$ (2): An aqueous solution of $CuCl_2 \cdot 2H_2O$ (0.171 g, 1.0 mmol) was added to NaOH (0.040 g, 2.0 mmol) in H_2O (5 mL), then isophthalic acid (0.166 g, 1.0 mmol) was added. After stirring for 2 h at room temperature, tpm (0.214 g, 1.0 mmol) in MeOH (15 mL) was added dropwise and stirred for 1 h. The mixture was then filtered. Blue crystals suitable for X-ray structure analysis were obtained by slow evaporation of the filtrate. Yield: 0.066 g (39% based on Cu). IR (KBr): $\tilde{\nu}$ = 1600 (s) cm^{-1}, 1568 (m), 1440 (w), 1400 (s), 1360 (w), 1290 (s), 1240 (w), 1080 (m), 850 (s). $C_{37}H_{40}Cu_2N_{12}O_{13}$ (987.89): calcd. C 44.94, H 4.05, N 17.65; found C 44.48, H 4.04, N 17.50.

Synthesis of $[\{Cu_2(bpm)_2(H_2O)(m\text{-bda})_2\} \cdot CH_3CN \cdot H_2O]_n$ (3): A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.0742 g, 0.2 mmol) in CH_3CN (5 mL) was added to bpm (0.214 g, 1.0 mmol) in CH_3CN (5 mL), then an aqueous solution of isophthalic acid (0.166 g, 1.0 mmol) was added. After stirring for 15 min, NaOH (0.1 M) was added to adjust the pH value to 7. The mixture was stirred for 2 h at room

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature and the precipitates were filtered off. Blue crystals suitable for X-ray structure analysis were obtained by slow evaporation of the filtrate. Yield: 0.030g (40% based on Cu). IR (KBr): $\tilde{\nu}$ = 1620 (s) cm^{-1}, 1572 (m), 1460 (w), 1410 (s), 1350 (w), 1300 (s), 1250 (w), 1100 (m), 850 (s). $C_{32}H_{31}Cu_2N_9O_{10}$ (828.74): calcd. C 44.34, H 3.74, N 15.20; found C 44.56, H 3.35, N 15.32.

Crystallographic Studies: Crystals of complexes **1**, **2**, and **3** were mounted on a Bruker Smart 1000 diffractometer equipped with a CCD camera. The determination of unit-cell parameters and data collection were performed with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved primarily by direct methods and secondly by Fourier difference techniques and refined by the full-ma-

trix least-squares method. The computations were performed with the SHELXL-97 program.[25,26] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were set in calculated positions and refined as riding atoms with a common fixed isotropic thermal parameter. The crystal parameters and details of the data collections and refinement for the complexes are listed in Table 2. Selected bond lengths are listed in Table 3.

New Copper Chalcogenide Clusters with a Selenide Core and a Sulfide Shell

Olaf Fuhr,*[a] Lucia Fernandez-Recio,[a] and Dieter Fenske[a,b]

Keywords: Cluster compounds / Chalcogens / Copper / S ligands

The reaction of copper(I) acetate with mixtures of $PhSSiMe_3$ and $Se(SiMe_3)_2$ in the presence of PPh_3 leads to a series of new cluster compounds consisting of a copper selenide core surrounded by a sulfide shell: $[Cu_{17}Se(SPh)_{15}(PPh_3)_4]$, $[Cu_{20}Se(SPh)_{12}(OAc)_6(PPh_3)_4]$, $[Cu_{28}Se_6(SPh)_{16}(PPh_3)_8]$, $[Cu_{36}Se_8(SPh)_{20}(PPh_3)_8]$, $[Cu_{54}Se_8(SPh)_{30}(OAc)_8(PPh_3)_6]$, and $[Cu_{72}Se_{14}(SPh)_{36}(OAc)_8(PPh_3)_6]$. They have been structurally characterized by single-crystal X-ray analysis. The two smallest clusters have a ball-like structure with one selenium atom in the center totally enclosed by sulfur atoms. In the other clusters the inner copper–selenium core is surrounded by an incomplete sulfur shell varying between 53 and 87 % coverage.

Introduction

Within the last few years there has been a lot of interest in the synthesis and properties of nanoparticles consisting of binary compounds that are known to be semiconductors as bulk substances.[1–3] Investigations of their optical properties show that the quantum yield of their fluorescence can be improved enormously by surrounding them with a thin shell (one or two monolayers) of a compound that has a larger bandgap than the core material.[4–6]

In the corresponding field of binary-ligand-protected cluster compounds a large number of species have been synthesized and structurally characterized by single-crystal X-ray analysis.[7,8] In these systems the size regime of the larger clusters overlaps with the size regime of the smaller nanoparticles (having diameters of 1–3 nm). An investigation of a series of different sized cadmium selenide clusters has shown that their absorption properties are mainly dominated by the metal chalcogenide core, whereas the very weak fluorescence is due to processes in the organic ligand shell.[9–11] Further studies of clusters with the composition $[Cd_{10}E_4(E'Ph)_{12}(PEt_3)_4]$ (E, E′ = S, Se, Te) have found that the absorption is dependent upon the inner Cd_6E_4 core; the surrounding shell with its E′Ph groups has only a small influence on the absorption.[12]

In this paper we describe the synthesis and structure of six copper chalcogen clusters having a copper selenide core surrounded by a copper sulfide shell.

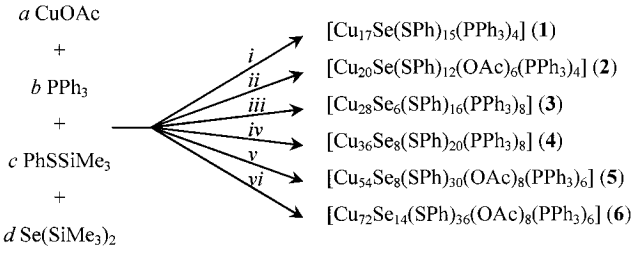
Results and Discussion

The reactions of copper(I) acetate with a mixture of the disilylated selenium compound $Se(SiMe_3)_2$ and the monosilylated sulfur species $PhSSiMe_3$ lead to the formation of several new copper chalcogenide clusters. As usual in the chemistry of cluster formation these reactions are highly dependent on the stoichiometry used. Scheme 1 summarizes the reactions leading to compounds **1**–**6**.



Scheme 1. Reactions leading to compounds **1**–**6**; ratios of the coefficients a:b:c:d i) 20:10:15:1, ii) 24:8:12:1, iii) 30:25:16:5, iv) 10:10:5:2, v) 60:15:30:5. iv) 40:10:18:7.

All compounds were crystallized and their structure determined by single-crystal X-ray analysis. Due to the different number of $SiMe_3$ groups in the chalcogen sources used, the selenium compound $Se(SiMe_3)_2$ reacts to give Se^{2-} ions whereas the sulfur species $PhSSiMe_3$ keeps its phenyl ring to form SPh^- groups. Therefore, all of the new compounds consist of an inner copper(I) selenide core surrounded by a sulfide shell. The phenyl groups of the SPh units and the PPh_3 ligands form an organic layer around the inorganic copper chalcogenide part. In some cases (**2**, **5**, **6**) there are additional acetate groups integrated into the ligand shell.

The cluster $[Cu_{17}Se(SPh)_{15}(PPh_3)_4]$ (**1**) crystallizes as yellow bars in the trigonal space group $R\bar{3}$ with six formula units per elemental cell. Figure 1 shows the molecular structure of the heavy atom framework and in the upper right corner the chalcogenide substructure.

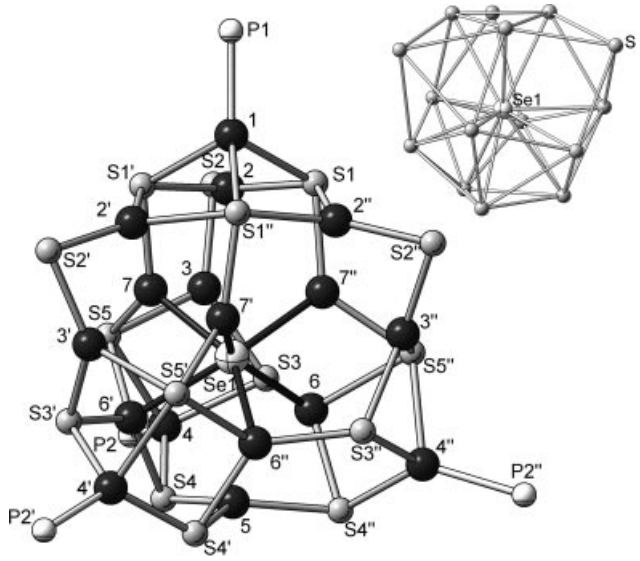

Figure 1. The molecular structure of the core of compound **1** (C and H atoms omitted for clarity); upper right: the chalcogenide substructure of **1** (same line of vision). Bond lengths [pm] in **1**: Cu–Se 239.8(3) (Cu7–Se1) and 262.8(3) (Cu6–Se1); Cu–S 221.2(7) (Cu3–S2) to 234.7(3) (Cu2–S1′); average Cu–P: 219.5.

There is a threefold axis running through the atoms Cu1, Cu5, Se1, and P1. A selenium atom (Se1) is present at the center of the cluster, and is surrounded by six copper atoms to form a skewed trigonal prism. The trigonal faces of this prism (formed by Cu6, Cu6′, Cu6′′ and Cu7, Cu7′, Cu7′′) are twisted by 17.1° against each other. The Se–Cu distances are 239.8(3) pm (Se1–Cu7) and 262.8(3) pm (Se1–Cu6). This inner (Cu_6Se) core is surrounded by a shell of the composition $[Cu_{11}(SPh)_{15}]$; four of the outer copper atoms (Cu1, Cu4, Cu4′, Cu4′′) have additional phosphane ligands. In compound **1** the metal atoms either have a nearly trigonal planar (Cu2, Cu3, Cu5, Cu6) or a skewed tetrahedral coordination sphere (Cu1, Cu4, Cu7). The sulfur atoms within the shell bond to either two (S2), three (S3, S4), or four (S1, S5) copper atoms in addition to a phenyl group.

Compound **2** crystallizes as yellow octahedra with eight molecules per unit cell in the cubic space group *Pa*3, with a C_3 axis running through the atoms Cu1, Cu7, Se1, and P1. Figure 2 illustrates the molecular structure of **2** and the arrangement of the chalcogen atoms.

Compound **2** has a shell-like construction with the central selenium atom Se1 surrounded by copper atoms Cu6, Cu6′, Cu6′′, and Cu7 that form a slightly distorted tetrahedron with bond lengths of 237.5(3) pm (Cu7–Se1) and 239.1(1) pm (Cu6–Se1). Around this polyhedron the twelve sulfur atoms of the SPh groups form a cube octahedron, whereby the four inner copper atoms are located beneath trigonal faces of the sulfur polyhedron. The distances between the sulfur atoms and the inner metal atoms vary from 236.0(3) pm (Cu6–S2) to 246.1(3) pm (Cu6–S1). The core can also be viewed as a section of a cubic closest packing of chalcogen atoms with half of the tetrahedral holes filled with copper atoms. The outer shell of the heavy atom framework of **2** is again formed by copper atoms. The four copper atoms (Cu1, Cu8, Cu8′, Cu8′′) that are additionally bonded to phosphane ligands cap the trigonal faces of the sulfur cube octahedron that are not bridged by the inner metal atoms (average Cu–S distance: 255.7 pm). The remaining twelve copper atoms are bound by acetate ligands to form six (Cu_2OAc) units, which cap the six tetragonal faces of the sulfur polyhedron. The average Cu–Cu distance in these units is about 279 pm, which is significantly longer than the corresponding distance in copper(I) acetate (255.6 pm);[13,14] the bonds between these copper atoms and the sulfur shell are about 224.8 pm long.

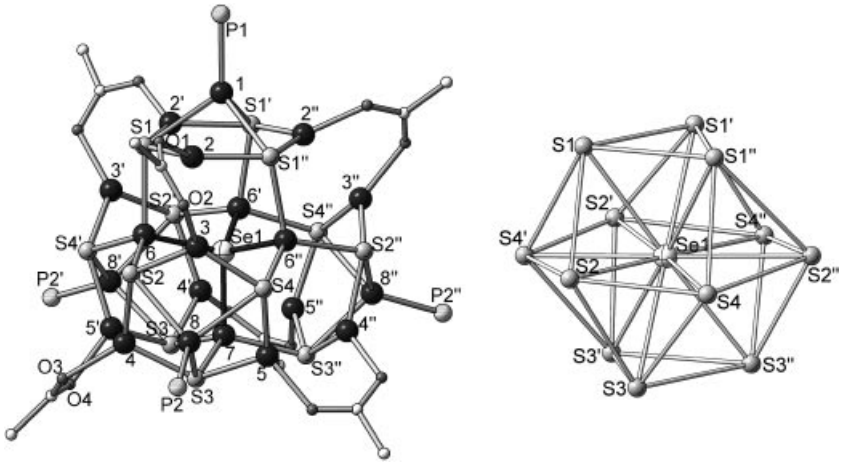

Figure 2. Left: The molecular structure of compound **2** (phenyl groups omitted for clarity); right: the chalcogenide substructure of **2** (same line of vision). Bond lengths [pm] in **2**: Cu–Se 237.5(3) (Cu7–Se1) and 2.391(2) (Cu6–Se1); Cu–S 219.5(3) (Cu2–S1′′) to 258.3(3) (Cu1–S1); average Cu–P: 222.5; average Cu–O: 195.8.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

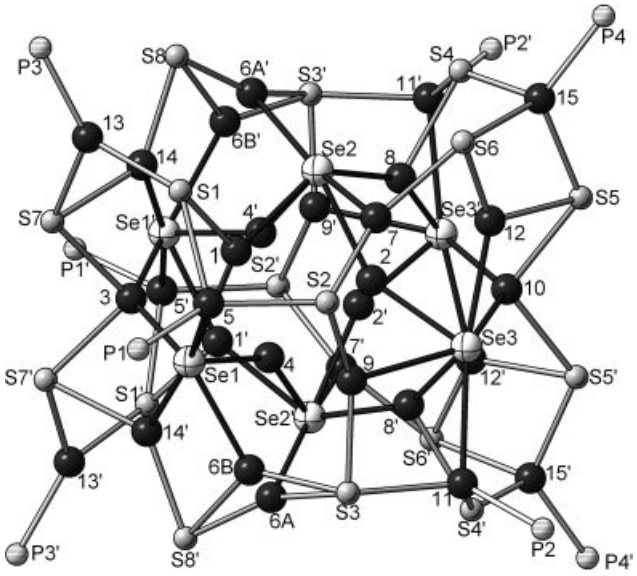

Figure 3. The molecular structure of the core of compound **3** (C and H atoms omitted for clarity). Bond lengths [pm] in **3**: Cu–Se 233.1(2) (Cu4–Se1) to 289.9(3) (Cu6A′–Se2); Cu–S 212.7(6) (Cu6A–S8′) to 2.469(9) (Cu6B–S8′); average Cu–P: 223.1.

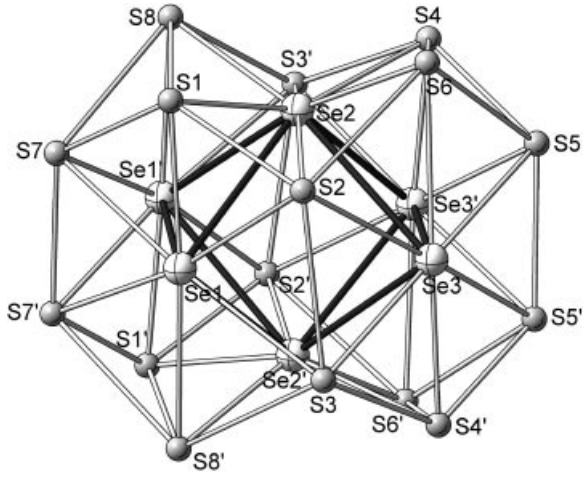

Figure 4. The chalcogenide substructure of **3**.

Recently, a copper–selenium structure with a similar composition and structure has been published: $[Cu_{20}Se(SePh)_{12}(OAc)_6(Ph_2PC_6H_4SMe)_2]$.[15]

Cluster **3** contains 28 copper atoms and crystallizes in the orthorhombic space group *Pnn*2 as red blocks with two formula units per elemental cell. A crystallographic C_2 axis runs through the atoms Cu3 and Cu10. Figure 3 shows the heavy atom framework and Figure 4 the arrangement of the selenium and sulfur atoms in **3**.

The selenium substructure formed by six atoms can be described as two-edge sharing tetrahedra. Except for the shared one, all edges are μ_2-bridged by copper atoms. The four atoms Cu2, Cu2′, Cu4 and Cu4′ are located inside the selenium polyhedron and do not have any further associations. The other copper atoms of this $Cu_{10}Se_6$ core are either coordinated by one additional sulfur atom in a trigonal planar way (Cu1, Cu1′, Cu8, Cu8′) or by two extra sulfur atoms (Cu3, Cu10) to form a tetrahedral sphere.

The sulfide shell in **3** consists of 16 sulfur atoms that form a polyhedron made out of four trigonal and six hexagonal faces (see Figure 4). Four of the hexagonal faces are nearly planar, whereas the other two are highly folded. In the center of each of these six-membered rings there is a selenium atom of the core structure. Therefore in **3**, in contrast to compounds **1** and **2**, the sulfide shell surrounding the selenium core is incomplete. Four (Cu13, Cu13′, Cu15, Cu15′) of the eight copper atoms coordinated to phosphane

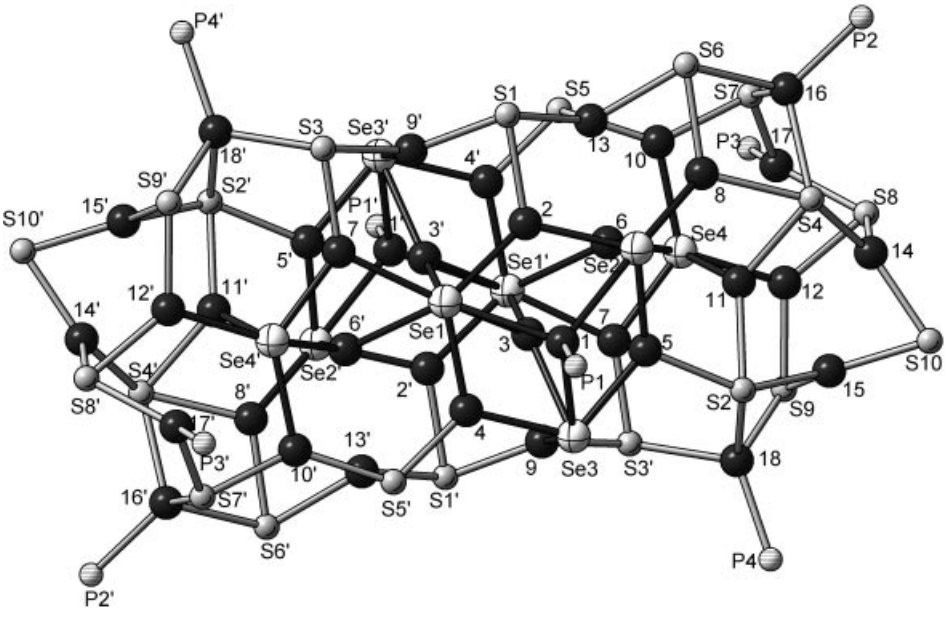

Figure 5. The molecular structure of compound **4** (C and H omitted for clarity). Bond lengths [pm] in **4**: Cu–Se 235.9(2) (Cu3–Se1′) to 281.8(2) (Cu3–Se1); Cu–S 220.6(3) (Cu4–S5′) to 246.0(3) (Cu18–S2); average Cu–P: 223.4.

ligands are located above the trigonal faces of the sulfur polyhedron. Whereas for Cu15 and Cu15′ one finds two short (about 232 pm) and one long (271 pm) Cu–S distance, for Cu13 and Cu13′ one can only speak of bonding towards two sulfur atoms (230 pm); the distance to the third sulfur atom (S8) is too long (334 pm) to be considered as a real bond. The other four copper atoms having phosphane ligands (Cu5, Cu5′, Cu11, Cu11′) are each acting as μ_3-bridges between two sulfur and one selenium atom. All other copper atoms are located inside the chalcogenide polyhedron and have (except for the already mentioned twofold and fourfold coordinated atoms) a trigonal planar sphere formed either by two sulfur and one selenium atom or by one sulfur and two selenium atoms. One copper atom (Cu6) is disordered over two positions and has been refined with an occupation of Cu6A:Cu6B of 2:1. The same phenomenon has been observed in repeated X-ray measurements of different crystals. Therefore it can be said that this disorder is a principle characteristic of compound **3** and not simply a defect of a single individual crystal.

Compound **4** crystallizes in the monoclinic space group $P2_1/n$ with two cluster molecules per unit cell. There are also noncoordinating solvent molecules (DME) in the crystal lattice which are disordered over four crystallographic positions. A symmetry center is located in the middle of the cluster (Figure 5).

The chalcogenide substructure, which is shown in two different projections in Figure 6, can be described as a stack of two skewed hexagonal layers that are shifted against each other like inside a closest packing. The eight selenium atoms are located in the middle of the chalcogenide substructure and, similar to **3**, six of them (Se1, Se2, Se3 and their symmetry equivalents) form two edge-sharing tetrahedra. The remaining two (Se4, Se4′) are found above the edges formed by Se1 and Se2, and Se1′ and Se2′, respectively. As in **3** the sulfide shell surrounding the selenide core is incomplete.

All copper atoms that do not have phosphane ligands are coordinated to three chalcogen atoms in all different combinations ranging from three selenium through to three sulfur atoms. The Cu–Se distances are found to be between 239.2(2) and 281.9(2) pm, and the Cu–S distances are between 220.7(3) and 245.9(4) pm. The copper atoms Cu17 and Cu17′ also form a trigonal planar sphere by acting as a μ_2-bridge over one S–S edge of the chalcogenide frame [Cu17–S7 229.1(3) pm, Cu17–S8 228.4(4) pm]; they also have an additional bond to a phosphane ligand. Only the copper atoms Cu1, Cu16, and Cu18, and their symmetry equivalents, show a skewed tetrahedral coordination sphere: Cu1 binds to Se1, Se2, Se3 and the phosphorus atom P1, whereas Cu16 and Cu18 bind to three sulfur and one phosphorus atom each. The copper–chalcogen distances of these atoms are, on average, about 16 (Cu–Se) and 9 pm (Cu–S) longer than those of the triply coordinated copper atoms. The remaining electron density found in the refinement (largest peak 2.095 e Å^{-3}) is located in the area between the cluster molecules, thus indicating that the additional DME molecule might be disordered over more than the refined positions.

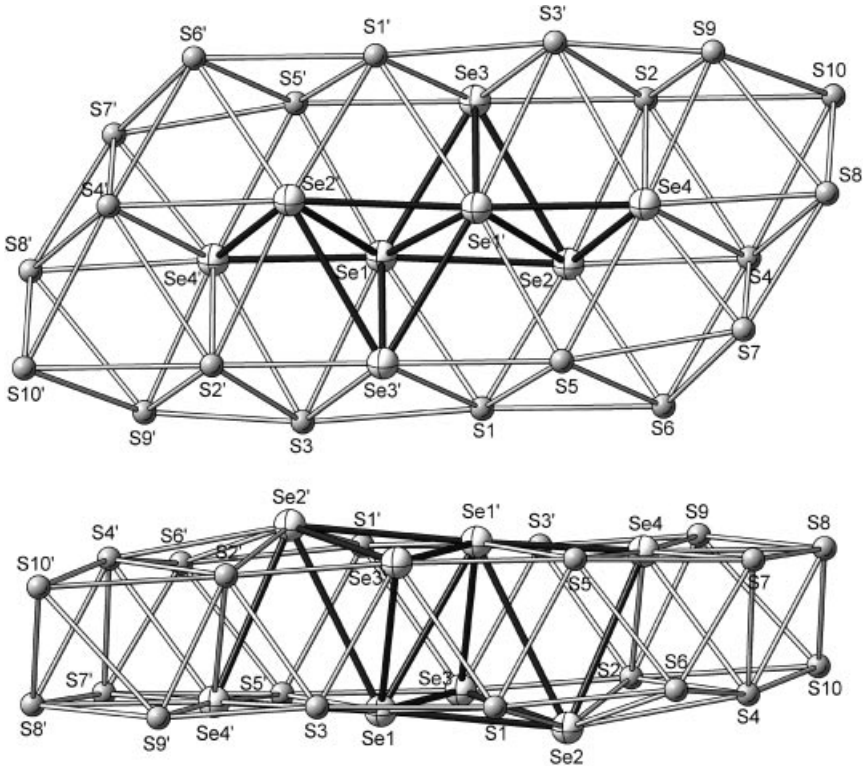

Figure 6. Two different views of the chalcogenide layer structure of **4**.

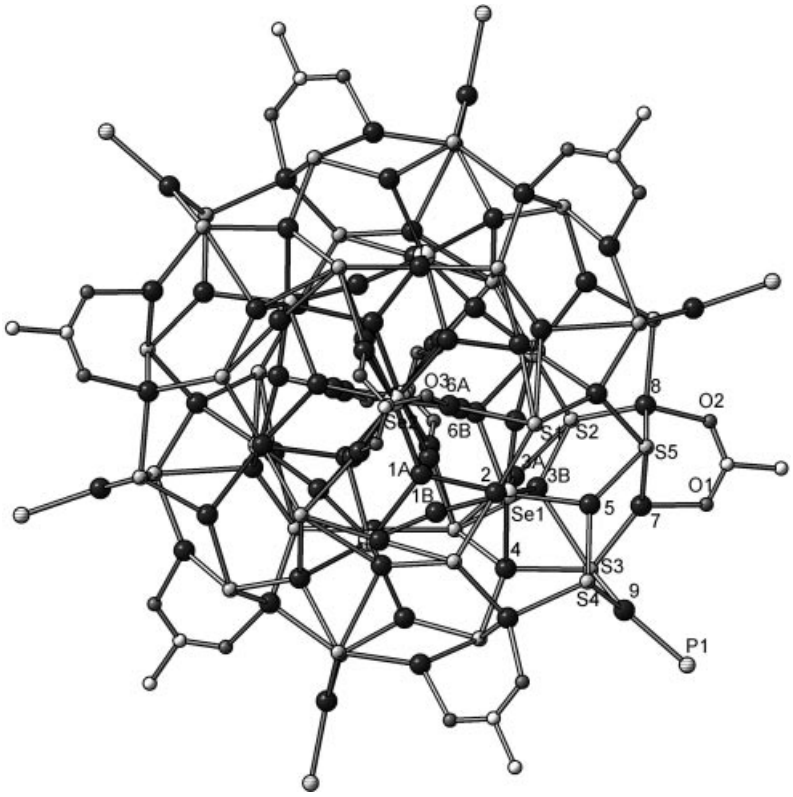

Figure 7. The molecular structure of compound **5** (phenyl groups omitted for clarity; only the atoms of the asymmetric unit are labeled). Bond lengths [pm] in **5**: Cu–Se 195.4(6) (Cu1B–Se1′) to 248.4(2) (Cu3A–Se1); Cu–S 213.3(8) (Cu6B–S1) to 266.8(8) (Cu3B–S1′); Cu–P 223.5(3); average Cu–O: 196.1.

The dark-red compound **5** crystallizes with three formula units per elemental cell in the trigonal space group $R\bar{3}$. The crystallographic $\bar{3}$ axis runs through the atoms Se2, Se2′, C3, C3′, C4, and C4′. The heavy-atom framework of **5** is shown in Figure 7 and the chalcogenide substructure in Figure 8.

Compound **5** appears to be discus-like in shape with the copper chalcogenide core having a diameter of 1.6 nm and a height of 0.7 nm. In the middle of the cluster eight selenium atoms form a highly compressed hexagonal bipyramid in which six copper atoms are embedded. These are disordered and were refined over two positions where they are either occupying a face of the bipyramid (pos. A), where they are coordinated by three selenium atoms, or an edge, with two neighboring selenium atoms (pos. B). The inner Cu_6Se_8 core is surrounded by a copper–sulfur shell consisting of 30 copper atoms and the 30 sulfur atoms from the SPh groups. In this shell the coordination spheres of the copper atoms vary. The tetrahedral copper atoms are bonded to three sulfur and one selenium atom (Cu–Se: av. 242.2 pm; Cu–S: av. 245.3 pm), whilst the trigonal copper atoms are bonded to one selenium and two sulfur atoms (Cu–Se: av. 245.1 pm; Cu–S: av. 225.4 pm). The remaining copper atoms are either bonded to one phosphane ligand and two sulfur atoms or form Cu_2OAc groups, as in compound **2**. At the top and bottom of the discus-like copper chalcogenide core are two acetate units whose two oxygen atoms are disordered over three positions, consistent with

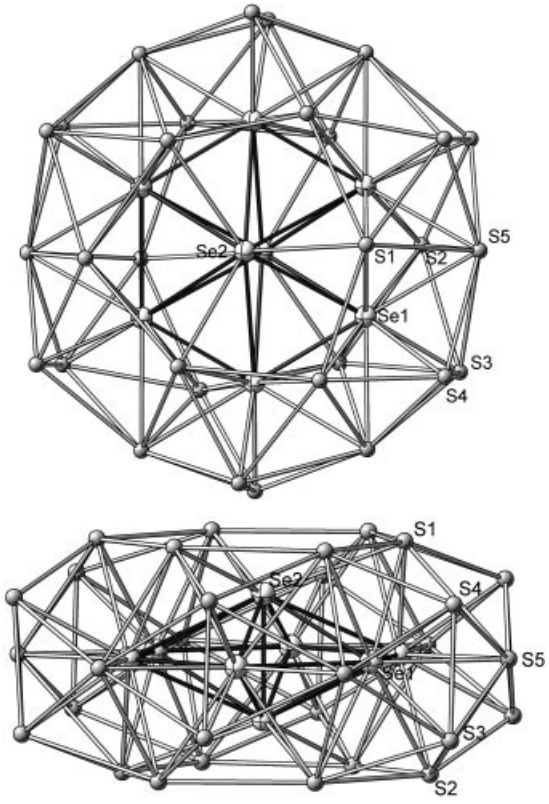

Figure 8. Two different views of the chalcogenide substructure of **5**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the threefold symmetry of the cluster. The copper atoms binding to these ligands are also disordered and occupy one position (Cu6A), with coordination to a sulfur, a selenium, and an oxygen atom, or are coordinated linearly (Cu6B) to only the two chalcogen atoms. Due to all of these disordering phenomena, all of which were observed in several crystals, the structure solution ends up with poor quality factors and additional electron density near to the disordered copper atoms [distance between largest peak (2.329 e Å^{-3}) and Cu3B: 0.75 Å].

Compound **6**, which contains 72 copper atoms, crystallizes in the monoclinic space group $P2_1/n$ with four formula units per elemental cell as large black blocks. Figure 9 shows the heavy-atom framework.

The whole cluster has pseudo-C_3 symmetry with a (pseudo) axis running through the atoms Cu54, Cu56, Cu72, Se13, and Se14. The selenide core in **6** has the shape of a hexagonal antiprism (hexagonal faces formed by Se1–Se6 and Se7–Se12) with one additional selenium atom at the center of each hexagonal face (Se13 and Se14, respectively). Thus, the mantle as well as the top and the bottom faces of the selenium polyhedron consist of nearly equilateral triangles. At the center of the selenide core there is a linearly coordinated copper atom (Cu72); further doubly coordinated copper atoms are located on the edges of the mantle faces of the selenium prism (Cu39 between Se2 and Se8; Cu43 between Se4 and Se10; Cu47 between Se6 and Se12). Another twelve copper atoms (Cu60–Cu71) are located inside the selenium polyhedra, with each being coordinated by three selenium atoms. These copper atoms form an icosahedron which is highly compressed in the direction of the (pseudo)-C_3 axis. The $Cu_{16}Se_{14}$ core described above is shown in Figure 10, and the chalcogenide substructure is shown in Figure 11.

The first copper shell surrounding the selenium core consists of eight atoms (Cu13, Cu15, Cu17, Cu19, Cu21, and Cu23) which each bonded to one sulfur and two selenium atoms. Furthermore, there are 44 copper atoms bonded to only one selenium atom. Three different coordination

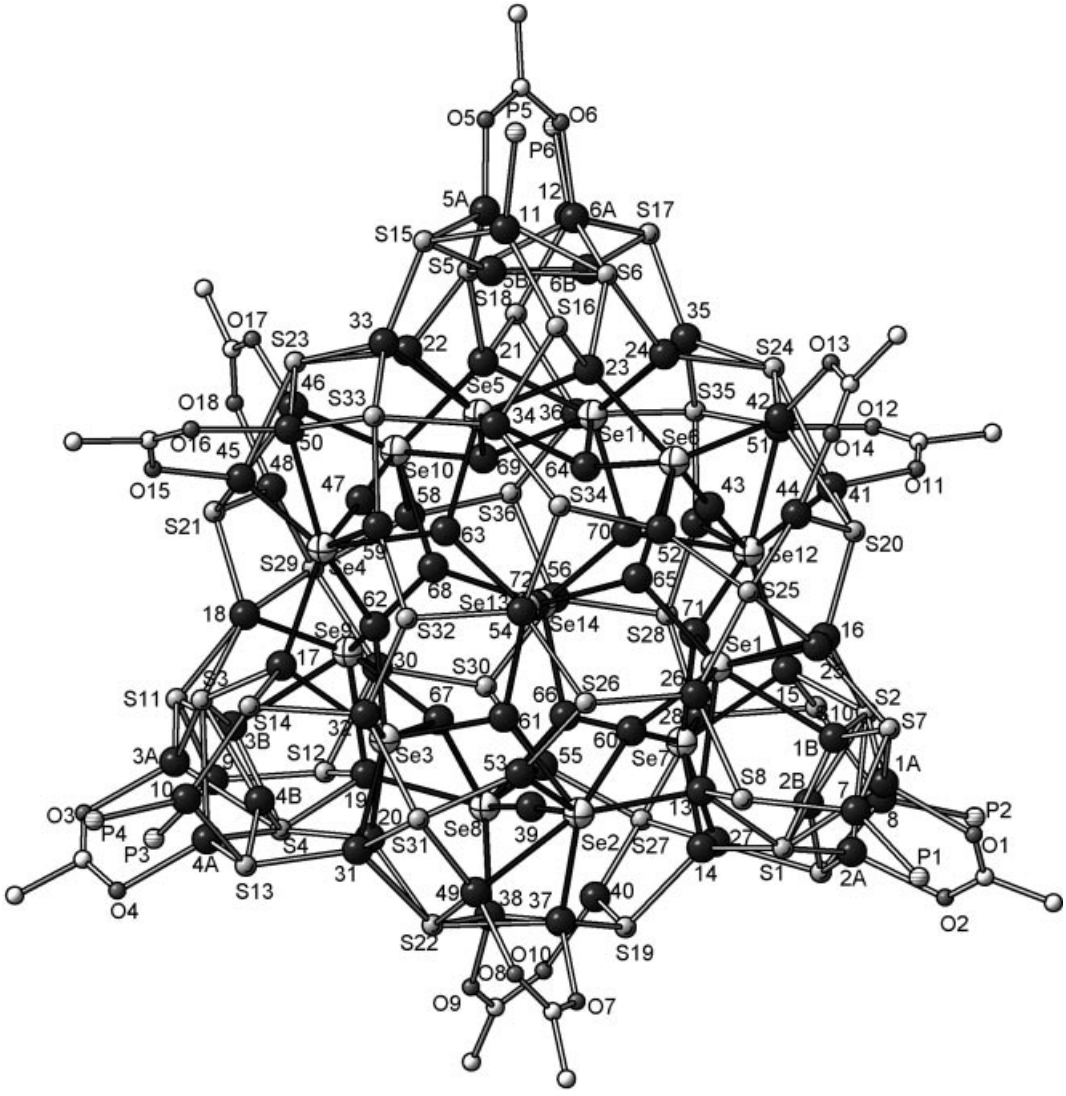

Figure 9. The molecular structure of compound **6** (phenyl groups omitted for clarity). Bond lengths (pm) in **6**: Cu–Se 232.7(4) (Cu72–Se13) to 291.4(7) (Cu44–Se6); Cu–S 192(3) (Cu1B–S7) to 276(1) (Cu2A–S2); average Cu–P 220; average: Cu–O 201.

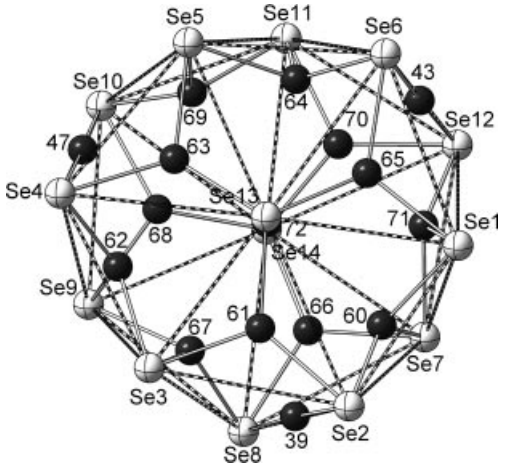

Figure 10. The inner $Cu_{16}Se_{14}$ core of **6**.

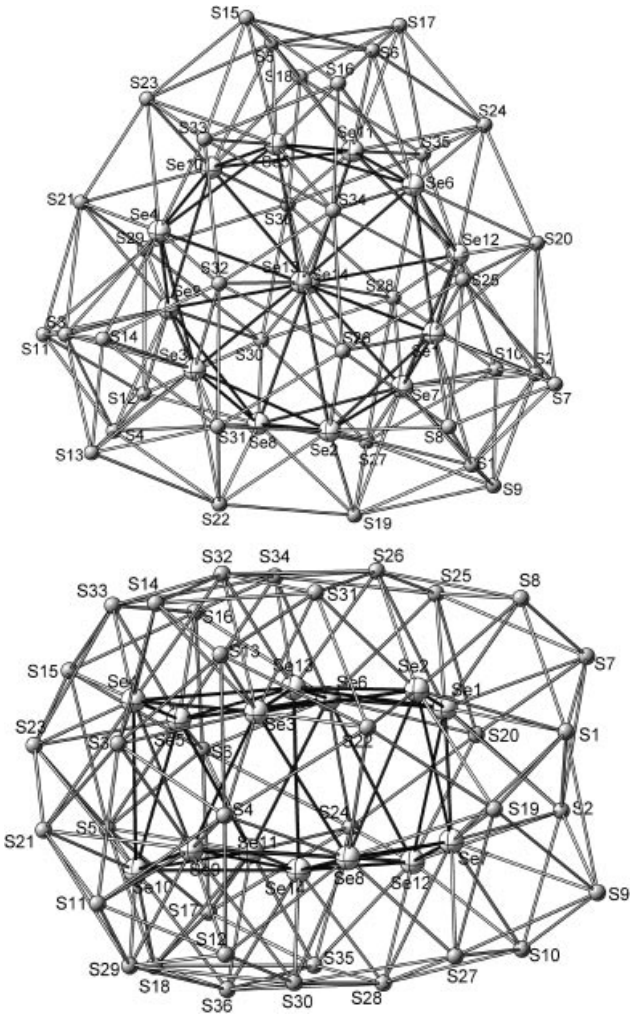

Figure 11. Two different views of the chalcogenide substructure of **6**.

spheres are observed within this group. The first contains trigonal-planar copper atoms coordinated by two additional sulfur atoms, whilst in the second the copper atoms have a tetrahedral geometry, binding to three more sulfur atoms. The remaining twelve copper atoms form six Cu_2OAc units with coordination spheres comprising one selenium, two sulfur, and one oxygen atom each. Not all of the copper atoms in the sulfide shell bond to the core selenium atoms. On the one hand Cu7–Cu12 are coordinated by two sulfur atoms and one phosphorus atom, while on the other hand Cu1A–Cu6A bond to two sulfur atoms and one oxygen atom of an acetate group. As in clusters **3** and **5** it is found that some of the copper atoms present in **6** are disordered. In this case, it is the atoms Cu1–Cu6, which have been refined using occupations between 0.1 and 0.9 for positions A and B. Position A has already been described above. Those copper atoms in position B are located further inside the cluster and again interact with two sulfur atoms along with a core selenium atom. Assuming that the corresponding positions A and B have a total occupancy of one copper atom, the total number of copper atoms for the whole cluster is 72. Considering **6** to be electrically neutral there must be eight acetate units; six of these were refined with satisfying vibration factors. The remaining two acetate groups are split over three possible positions, with bonds to the partially occupied copper positions A.

Due to disordering the refinement has poor R values (R_1 = 0.141, wR_2 = 0.393), with additional electron density near to the areas of disordered copper atoms [distance between largest peak (3.772 e Å^{-3}) and Cu2A: 0.78 Å]. Similar results were obtained with crystals from other reactions.

Conclusions

We have described six new cluster compounds. All of them have a selenide core consisting of 1 to 14 selenium atoms. In compound **2** the one selenium atom in the center is surrounded by twelve sulfur atoms to form a cube octahedron. Compared with the corresponding fcc lattice, this means that there is one complete shell formed around the central atom. In **1** there are 15 sulfur atoms in more than one layer. In the other compounds the covering of the interior selenide core is less than one layer of sulfur atoms. The approximate completeness of the covering in all compounds is summarized in Table 1.

Table 1. Comparison of the completeness of the sulfide shell covering the selenide core in **1**–**6**.

Compound	Se in core	S in shell	Coverage [%]
1	1	15	>100
2	1	12	100
3	6	16	53
4	8	20	53
5	8	30	83
6	14	36	67

The colors of the compounds vary from yellow (**1**, **2**) to different shades of red (**3**–**5**), and black (**6**). Investigations into the optical properties of these compounds are an area of current work.

Experimental Section

Due to the high oxygen and moisture sensitivity of the compounds used, all reactions were performed under a dry, oxygen-free nitro-

gen using standard Schlenk techniques. Solvents were dried with sodium/benzophenone and freshly distilled. Copper(I) acetate (CuOAc),[16] $Se(SiMe_3)_2$,[17]and $PhSSiMe_3$[18] were synthesized according to literature procedures. All reactions described below are very sensitive to small variations of the starting material ratio such that in some cases mixtures of different compounds were obtained.

Synthesis of $[Cu_{17}Se(SPh)_{15}(PPh_3)_4]$ (1): At room temperature, copper(I) acetate (0.365 g, 2.98 mmol) and PPh_3 (0.39 g, 1.49 mmol) were suspended in DME (100 mL). $PhSSiMe_3$ (0.42 mL, 2.23 mmol) and $Se(SiMe_3)_2$ (0.034 mL, 0.15 mmol) were then added. The bright yellow solution was stirred for 24 h and then its volume was reduced. After some hours **1** crystallized as yellow rods. Yield: 0.23 g (40%). $C_{162}H_{135}Cu_{17}P_4S_{15}Se$ (3845.6): calcd. C 50.59, H 3.54, S 12.51; found C 51.32, H 3.78, S 12.59.

Synthesis of $[Cu_{20}Se(SPh)_{12}(OAc)_6(PPh_3)_4]$ (2): $PhSSiMe_3$ (0.54 mL, 2.87 mmol) and $Se(SiMe_3)_2$ (0.057 mL, 0.24 mmol) were dissolved in DME (10 mL) and added to a suspension of CuOAc (0.703 g, 5.73 mmol) and PPh_3 (0.50 g, 1.91 mmol) in DME (100 mL) at –30 °C. After stirring for five minutes the mixture was filtered and allowed to warm up to 4 °C. Within several hours **2** crystallized as small, yellow octahedra. Yield: 0.35 g (36%). found C 46.87, H 3.98, S 9.14; $C_{156}H_{138}Cu_{20}O_{12}P_4S_{12}Se$ (4063.2): calcd. C 46.11, H 3.42, S 9.47%).

Synthesis of $[Cu_{28}Se_6(SPh)_{16}(PPh_3)_8]$ (3): CuOAc (0.329 g, 2.68 mmol) and PPh_3 (0.59 g, 2.22 mmol) were suspended in DME (50 mL). After adding $PhSSiMe_3$ (0.27 mL, 1.43 mmol) and $Se(SiMe_3)_2$ (0.11 mL, 0.45 mmol) all solids were dissolved resulting a dark red solution. Within several days one got **3** as red coffin shaped crystals. Yield: 0.19 g (41%). $C_{244}H_{208}Cu_{28}O_2P_8S_{16}Se_6$ (**3**·DME) (6185.7): calcd. C 47.37, H 3.39, S 8.29; found C 46.61, H 3.50, S 8.42.

Synthesis of $[Cu_{36}Se_8(SPh)_{20}(PPh_3)_8]$ (4): CuOAc (0.342 g, 2.79 mmol) and PPh_3 (0.73 g, 2.79 mmol) were dissolved in DME (100 mL). Addition of $PhSSiMe_3$ (0.26 mL, 1.39 mmol) led to a yellow solution, which turned dark red after addition of $Se(SiMe_3)_2$ (0.13 mL, 0,56 mmol). Within some days **4** crystallized directly from the reaction mixture as red plates. Yield: 0.15 g (30%). $C_{268}H_{230}Cu_{36}O_2P_8S_{20}Se_8$ (**4**·DME) (7290.6): calcd. C 44.15, H 3.18, S 8.80; found C 44.43, H 3.25, S 8.79.

Synthesis of $[Cu_{54}Se_8(SPh)_{30}(OAc)_8(PPh_3)_6]$ (5): CuOAc (0.55 g, 4.49 mmol) and PPh_3 (0.29 g, 1.12 mmol) were suspended in DME (75 mL) and stirred for two hours. $PhSSiMe_3$ (0.42 mL, 2.24 mmol) and $Se(SiMe_3)_2$ (0.089 mL, 0.37 mmol) were added within two minutes resulting a dark-red solution with no solids left. Within a few minutes a yellow precipitate had formed. After five hours the mixture was filtered and within one day square, red plates of **5** crystallized. Yield: 0.11 g (25%). $C_{304}H_{264}Cu_{54}O_{16}P_6S_{30}Se_8$ (9383.6): calcd. C 38.91, H 2.84, S 10.25; found C 38.43, H 2.81, S 10.49).

Synthesis of $[Cu_{72}Se_{14}(SPh)_{36}(OAc)_8(PPh_3)_6]$ (6): $PhSSiMe_3$ (0.24 mL, 1.28 mmol) and $Se(SiMe_3)_2$ (0.12 mL, 0.50 mmol) were dissolved in DME (10 mL) and added to a suspension of CuOAc (0.347 g, 2.83 mmol) and PPh_3 (0.19 g, 0.71 mmol) in DME (50 mL) at 0 °C. After one hour the resulting dark solution was allowed to warm up to room temperature. Within some days **6** crystallized as big black blocks. Yield: 0.11 g (26%). $C_{344}H_{304}Cu_{72}O_{18}P_6S_{36}Se_{14}$ (**6**·DME) (11747.1): calcd. C 35.17, H 2.61, S 9.83; found C 35.19, H 2.67, S 9.69.

X-ray Structure Determination: Crystals were removed from the reaction flask under a stream of N_2 gas and immediately covered with a layer of perfluoropolyether oil (Riedel-de Haën). A suitable crystal was selected, attached to a glass fiber, and immediately placed in the low-temperature nitrogen stream. The data were collected with a STOE IPDS II diffractometer using Mo-K_α (λ = 0.71073 Å) radiation, either from a common X-ray tube at 2 kW (compounds **1**–**3**, **5**) or a rotating anode run at 4.8 kW (**4**, **6**). Structure solution and refinement against F^2 were carried out using shelxs and shelxl software.[19] Molecular drawings were prepared with Diamond 2.1[20] and PaintShopPro 7AE;[21] in the figures cop-

Cationic Iridium Complexes with Chiral Dithioether Ligands: Synthesis, Characterisation and Reactivity under Hydrogenation Conditions

Leticia Flores-Santos,[a] Erika Martin,*[a] Ali Aghmiz,[b] Montserrat Diéguez,[b] Carmen Claver,[b] Anna M. Masdeu-Bultó,*[b] and Miguel Ángel Muñoz-Hernández[c]

Keywords: Chiral auxiliaries / S ligands / Iridium / Hydrides / Asymmetric catalysis

A series of cationic Ir^I complexes containing chiral dithioether ligands have been prepared in order to study the influence of the sulfur substituents and the metallacycle size on the acetamidoacrylate hydrogenation reaction. In the case of complexes **6**, **7** and **10**, a mixture of diastereomers is observed in solution due to the sulfur inversion processes. In contrast, this fluxional behaviour is efficiently controlled by using bicyclic ligands which inhibit the S-inversion in complexes **8** and **9**. The solid-state structure of complex **10b** shows only one diastereomer with the sulfur substituents in a relative *anti* disposition and in an overall configuration of $S_CS_CS_SS_S$ at the coordinated dithioether ligand. Iridium complexes containing seven- and six-membered metallacycles (**6b**–**d**, **7b**,c, **10a**,**b**) react with the substrate through S-ligand substitution, and the rate of this substitution is related to the position of the fluorine atom on the aromatic ring. On the contrary, complexes containing a *bis*metallacycle (**8** and **9**) are not displaced by the substrate. The catalytic hydrogenation activity of complexes **8** and **9** is analysed in terms of the high stability of the corresponding dihydride complexes (**13** and **14**). In both cases, only two of the four possible diastereomeric dihydride species are formed in solution.

Introduction

The study of chiral sulfur transition-metal complexes as asymmetric catalysts has notably increased during the last decades.[1,2] In particular, complexes containing thioether mixed-donor ligands such as the P,S-,[3–8] N,S-[9–17] and O,S-[18–22] donors have been successfully applied in asymmetric hydrogenation,[5,6,23] allylic substitutions[7–10,18] and enantioselective hydrosilylation of ketones.[4,23] In contrast, catalysts with chiral bidentate thioether ligands have been scarcely investigated,[24–32] although some have shown promising catalytic properties. In fact, we have recently shown that metal complexes with chiral dithioether ligands afford up to 81% *ee* in palladium-catalysed asymmetric allylic substitutions[24] and 68% *ee* in iridium-catalysed asymmetric hydrogenation reactions.[25,26]

Upon coordination to a metal, thioether ligands generate a stereogenic centre at the sulfur atom, whose close proximity to the metal coordination sphere may be advantageous for enantioinduction; however, these centres are not configurationally stable, since sulfur inversion has a low energy barrier. In the case of chiral dithioether complexes, the presence of two stereogenic centres at sulfur atoms, in addition to the carbon stereogenic centres at the ligand backbone, can lead to mixtures of diastereomers. The presence of mixtures of diasteromeric species and the difficulty to control their interconversion in solution have been regarded as a problem for asymmetric induction in catalytic reactions. In spite of this behaviour, enantioinductions have been improved when the configuration at the sulfur atom is controlled by steric effects.[24,31,32] Unfortunately, having few examples of S,S-homodonor ligands, which also differ considerably in their skeleton size and rigidity, makes it difficult to elucidate the structure-performance relationship.

In order to understand the influence of structural and electronic factors on the reactivity of chiral dithioether-containing catalysts, in the present work we prepared a series of cationic iridium complexes with chiral dithioether ligands **1**–**5** (Figure 1) derived from L-(+)-diethyltartrate[33] and (2*R*,4*R*)-2,4-pentanediol.[34] These ligands were selected in order to study electronic and ring size effects and sulfur inversion control, by the following strategies: (i) introduction of fluorine atoms at *ortho*- *meta*- or *para*- positions of a thioether aromatic ring in order to change the donor/acceptor electronic properties of sulfur atoms (ligands **1a–c** and **2a**–**c**); (ii) evaluation of two ring sizes to tune the rigidity of the molecular backbone (ligands **1a**–**d** and **2a**–**c** vs.

5); (iii) effective stereocontrol at sulfur atoms in metal intermediates by using cyclic chiral thioether ligands which eliminate pyramidal inversion and also allow a backbone rigidity modulation (ligands **3** and **4**).

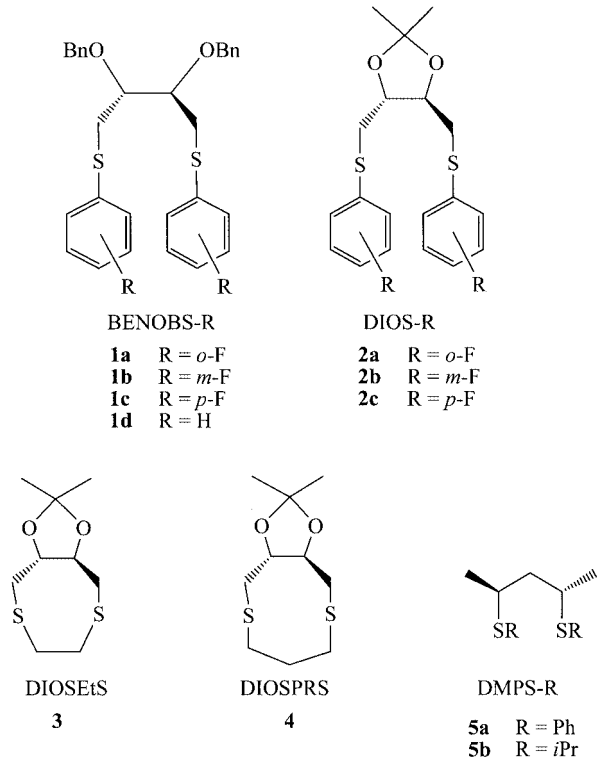

Figure 1. Dithioether ligands **1–5**.

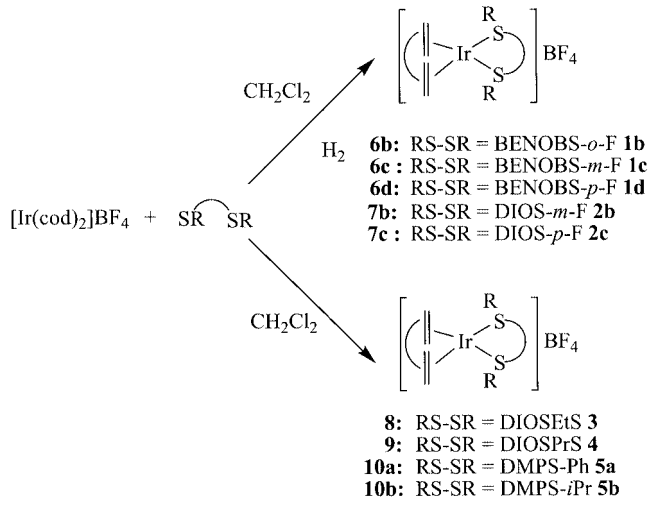
The reactivity of the synthesised complexes [Ir(dithioether)(cod)]BF_4 towards acrylic acid derivatives and dihydrogen is discussed in relation to the activity and selectivity observed under catalytic hydrogenation conditions.

Results and Discussion

Iridium Complexes [Ir(cod)(dithioether)]BF_4

Ligands **3**, **4** and **5a**,**b** reacted with dichloromethane solutions of [Ir(cod)$_2$]BF_4 to form the corresponding [Ir(cod)(dithioether)]BF_4 complexes **8**, **9** and **10a**,**b** by cod substitution (Scheme 1). The complexes were isolated as relatively air-stable, yellow or orange solids by addition of hexane or diethyl ether with yields ranging from 50 to 99%. In contrast, ligands **1a–d** and **2a–c** did not react with dichloromethane solutions of [Ir(cod)$_2$]BF_4 unless hydrogen was bubbled through the solution to reduce cod and promote its substitution. These results can be rationalised according to the lower stability of the seven-membered metallacycle formed in the case of ligands **1** and **2**. A similar behaviour was observed for the non-fluorinated derivative of ligands **2**.[25] In the case of ligands **3** and **4**, the generation of [7,5]- and [7,6]-membered rings, respectively, increases the chelate stability. Dithioethers **1a** and **2a** did not form the iridium complexes, probably because of steric hindrance in addition to the electron-withdrawing effect of the *ortho*-fluoro substitution.



Scheme 1. Syntheses of complexes **6–10**.

FAB mass spectra confirmed the formation of the mononuclear species in all cases. Complexes were characterised in solution by ^1H and ^{13}C NMR spectroscopy. ^{19}F NMR spectroscopy was also used for complexes **6b**,**c** and **7b**,**c**. The full assignment of ^1H and ^{13}C NMR parameters was performed by using homo- and heteronuclear two-dimensional spectroscopy techniques (^1H,^1H-COSY, HETCOR and NOESY).

The coordination of the dithioether ligands to the metal generates a stereogenic centre at each sulfur atom. Therefore, a mixture of diastereomers with different spatial arrangements of the sulfur substituents and conformations of the chelate ring could exist in solution (Figure 2). Taking into account that ligands **1** and **2** have absolute *RR*-configuration at their asymmetric carbon centres and two possible configurations at the sulfur atoms, three diastereomers could be formed: $R_CR_CR_SR_S$ and $R_CR_CS_SS_S$ (both attributed to the *anti* isomers) and $R_CR_CR_SS_S$ or $R_CR_CS_SR_S$ (corresponding to the *syn* isomer). This analysis applies also for complexes with ligands **5**, which have absolute *SS* configuration at their asymmetric carbon centres, therefore three possible diastereomers, $S_CS_CR_SR_S$ and $S_CS_CS_SS_S$ (*anti* isomers), and $S_CS_CR_SS_S$ or $S_CS_CS_SR_S$ (*syn* isomer) can be formed. In contrast, for complexes containing ligands **3** and **4**, there is only one possible *syn* isomer with $R_CR_CR_SS_S$ or $R_CR_CS_SR_S$ configuration, since the inversion at both sulfur atoms is inhibited.

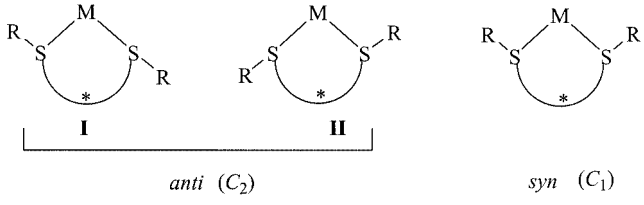


Figure 2. Possible diastereomers for metal complexes with ligands **1–5**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In fact, variable temperature NMR studies (down to –80 °C) performed on complexes **8** and **9** are in accordance with the presence of only one diastereomer in solution, which corresponds to a C_1-symmetry molecule with $R_CR_CR_SS_S$ configuration. Full assignment of ^{1}H and ^{13}C spectra was achieved by homo- and heteronuclear 2D NMR techniques and the conformation of both rings was determined by using NOE experiments (Figure 3). The seven-membered ring has a twisted chair conformation in both complexes. The second ring is either a five-membered chelate ring with an envelope conformation in **8** (NOE contact between H^4 with H^1 and H^2) or a six-membered ring with a chair conformation in **9** (NOE contact between H^1 and H^7).

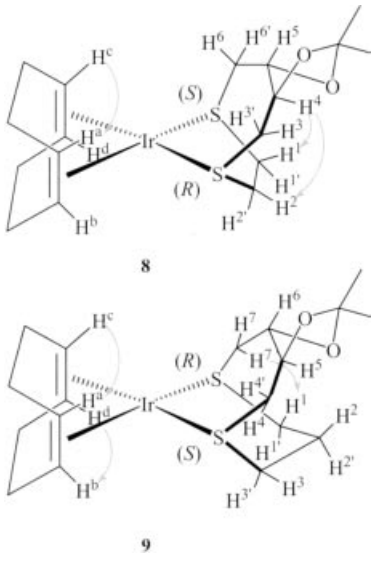

Figure 3. Structures proposed for complexes **8** and **9** showing the NOE contacts.

For complexes **10a**,**b** containing a six-membered metallacycle, variable temperature ^{1}H NMR spectra (–40 to +25 °C) exhibited patterns corresponding to the presence of only one species with C_2 symmetry, which may be attributed to one of the two possible *anti* diastereomers $S_SS_CS_CS_CS_S$ or $R_SS_CS_CR_S$ with equatorial–equatorial or axial–axial conformations, or to the chair equatorial–axial conformers interchanging fast in solution. VT NMR spectra of **10b** in CD_2Cl_2 were invariant in the temperature range studied. NOE experiments suggested that an equatorial–equatorial species was likely to be present in solution; nevertheless, the possibility of rapid equilibration with other species could not be discarded. Moreover, the structure in the solid state of **10b**, determined by X-ray diffraction (see following section), confirmed that the sulfur substituents were *anti* with an equatorial–axial disposition.

The ^{1}H and ^{19}F NMR spectra of complexes **6b**,**c** and **7b**,**c** show in all cases broad signals at room temperature. It is interesting to note that the chemical shifts of the cod methynic protons are not sensitive to the position of the fluoro substituent on the dithioether ligands. Nevertheless, the reactivity towards acrylic acid derivatives depends on the position of the fluorine atom in the aromatic ring.

The ^{13}C NMR spectra for complexes **6b–d** showed only two signals for cod methylenic carbons and two signals for cod methynic carbons, which can be attributed to the presence of only one *anti* diastereomer or a fast exchange between both *anti* diastereomers. However, the ^{19}F NMR experiments in the temperature range of +30 °C to –60 °C show two different signals for complexes **6b** and **6c** in the ratios 10:6 and 10:9.1, respectively, proving the presence of two *anti* diastereomers in solution (**I** and **II**). The rate of isomer interconversion for complex **6b** was very low and invariant in the temperature range studied ($k = 1.10^{-3}$ s^{-1}) [35], and for complex **6c** the rate could not be calculated, since no significant change in the shape of the spectra was observed in the same range of temperatures. Although no splitting of signals in ^{1}H and ^{13}C NMR spectra was observed for complex **6d**, by analogy with **6c**,**d**, two diastereomers could also be present in solution.

In the case of complexes **7b** and **7c**, two isomers, **I** and **II**, were also detected at low temperature. The exchange rates ranged from 5.26×10^2 s^{-1} (at –60 °C) to 1.22×10^4 s^{-1} (at 30 °C) for **7b** and from 8.22×10^2 s^{-1} (–60 °C) to 5×10^4 s^{-1} (30 °C) for **7c**. The values of the Gibbs activation energy ($\Delta G^{\neq}$, evaluated by the Eyring equation) are 50.4 ± 1.0 kJ mol^{-1} for **7b** and 48.1 ± 1.3 kJ mol^{-1} for **7c**, and are in the range reported for sulfur inversion in thioether complexes.[36,37] Therefore, the dynamic behaviour in solution of **7b** and **7c** is independent of the position of the fluorine atom in the aromatic ring.

Crystal Structure of [Ir(cod)(5b)]BF$_4$ (10b)

Single crystals of **10b** suitable for X-ray diffraction were obtained by slow diffusion of *n*-hexane into an ethyl acetate solution of the complex. The cationic structure is shown in Figure 4, and selected bond lengths and angles are listed in Table 1. The iridium atom shows a slightly distorted square-planar environment. The sulfur atoms are in a *cis* configuration and the cyclooctadiene ligand occupies the other two coordination sites. For the latter ligand, using the centroids of the C12–C13 and C16–C17 double bonds, X1a and X1b, respectively, a twist of 4.8° of the dihedral planes S1–Ir1–S2 and X1a–Ir1–X1b is found. A similar situation was observed for the Ir complex [Ir(cod){C[P(S)(Ph)$_2$]$_3$}],[38] which showed a twist of 9.0°. The distortion is also evident from the deviation from 90° observed in the following bond angles: X1a–Ir1–S1 86.8°, X1b–Ir1–S2 99.6° and X1a–Ir1–X1b 85.6°, which is more pronounced than in [Ir(cod)-{[P(S)(Ph)$_2$]$_3$C}] (89.5, 88.3 and 87.5°, respectively)[38] and the Rh complex [Rh(cod){CH[P(S)(Ph)$_2$]$_2$}] (86.4, 88.3 and 86.7°, respectively).[39] The Ir–S and Ir–C average bond lengths [2.3537(19) and 2.131(9) Å, respectively] are in the range reported for related Ir^{I} complexes.[38,40,41] Furthermore, similar Ir–S distances were reported for Ir^{I} cyclooctadiene complexes with thiolate bridging ligands.[42,43] The average angle C–S–Ir [110.0(3)°] is close to the tetrahedral angle, indicating sp^3 hybridization at the sulfur atom.

Table 1. Selected bond lengths [Å] and angles [°] for complex **10b**.

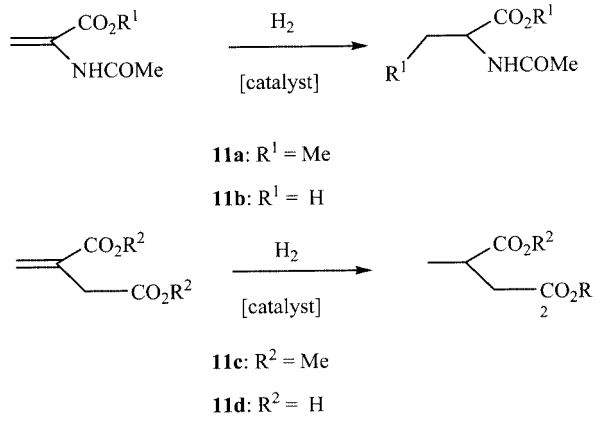
Bond lengths	[Å]	Bond angles	[°]
Ir(1)–C(16)	2.116(11)	C(16)–Ir(1)–C(12)	95.5(4)
Ir(1)–C(12)	2.126(8)	C(17)–Ir(1)–C(13)	88.4(4)
Ir(1)–C(17)	2.141(9)	C(16)–Ir(1)–S(2)	98.6(3)
Ir(1)–C(13)	2.141(8)	C(17)–Ir(1)–S(2)	99.6(3)
Ir(1)–S(2)	2.344(2)	C(12)–Ir(1)–S(1)	85.9(2)
Ir(1)–S(1)	2.3633(18)	C(13)–Ir(1)–S(1)	87.9(2)
		S(2)–Ir(1)–S(1)	88.18(8)
		C(1)–S(1)–C(4)	105.0(4)
		C(1)–S(1)–Ir(1)	108.3(3)
		C(4)–S(1)–Ir(1)	111.3(3)
		C(3)–S(2)–C(9)	105.4(4)
		C(3)–S(2)–Ir(1)	104.4(3)
		C(9)–S(2)–Ir(1)	116.1(3)

The solid structure shows only one diastereomer with the sulfur substituents in a relative *anti* disposition. The metallacycle adopts a chair conformation with an overall configuration $S_C S_C S_S S_S$.

Catalytic Experiments and Reactivity of the Iridium Complexes

The catalytic activity of iridium complexes **6b**–**d**, **7b**,**c**, **8**, **9**, **10a**,**b** in the hydrogenation of acrylic acid derivative **11a** at 25 °C and 1 atm of hydrogen pressure was examined (Scheme 2).

All catalyst precursors show low conversions even at 12 h of reaction (Figure 5). Regarding the influence of the fluoro-substitution on the aromatic ring, the *meta*-fluoro derivatives **6b** and **7b** showed higher conversion than their analogous *para*-fluoro derivatives **6c** and **7c**, in the same reaction time. The complex **6d** without the fluoro-substituted ligand showed higher conversion than the *meta*- and *para*-fluoro complexes **6b** and **6c**.



Scheme 2. Hydrogenation of acrylic acid derivatives **11a**–**d**.

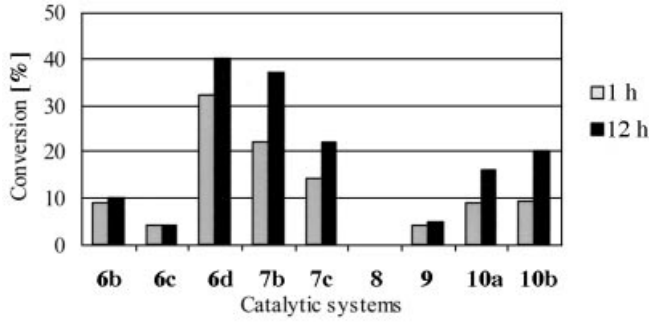


Figure 5. Catalytic hydrogenation of methyl acetamidoacrylate (**11a**) by using dithioether iridium complexes. Conditions: [{Ir(cod)L}BF_4] = 4.3 mM, [Substrate] = 175 mM, T = 25 °C and $p(H_2)$ = 1 atm.

The activity is also modified by the dithioether skeleton; complexes **7b**,**c** provided higher conversion than **6b**,**c** and complex **10a**, with a smaller six-membered metallacycle, showed lower conversion than the seven-membered chelate complex **6d**. Finally, complexes **8** and **9**, which contain metallabicycles, provided less active catalytic systems. In all cases, the enantioinduction was practically nonexistent.

These catalytic results can be explained in terms of the stability of the complexes. Catalytic systems **6**, **7** and **10** decomposed gradually during the catalytic reaction to form Ir^0 with the consequent loss of the chiral ligand. This was confirmed for the fluorinated precursors (**6b**,**c** and **7b**,**c**) by analysis of the catalytic mixture at the end of the hydrogenation reactions through ^{19}F NMR spectroscopy, which showed the presence of the free ligand as a distinct species. The decoordination of the dithioether ligands is promoted by substrate coordination, since the addition of **11a** to dichloromethane solutions of complexes **6**, **7** and **10** under nitrogen generates free dithioether ligands and [Ir(**11a**)(cod)]$^+$, detected by ^{19}F NMR spectroscopy or by ^1H and ^{13}C NMR.

In an attempt to recoordinate the dithioether ligand by forcing cod reduction, H_2 was bubbled into a solution containing **6b** and **11a**, but the signal of the free dithioether

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

remained unaltered, and the formation of metallic iridium was observed.

For purposes of comparison, the catalytic activity of complex $[Ir(cod)_2]^+$ (**12**) was studied under the same catalytic conditions and was found to be the highest (45% conversion at 1 h). Since the conversion obtained with **12** is higher than that found with the dithioether complexes and it has been demonstrated that these dithioether ligands are replaced by the substrate to yield $[Ir(\mathbf{11a})(cod)]^+$, the increasing conversion can be related to a higher rate of dithioether substitution. Thus, the less active systems are those in which the rate of substitution is lower, suggesting that the dithioether ligand is more strongly coordinated to the metal. Consequently, in the case of seven-membered complexes, catalytic precursors **6** lead to more active systems probably because of the formation of weaker M–S bonds. The same situation is observed when the more stable six-membered complex **10a** is compared with the seven-membered complex **6b**. Concerning the electronic factors, the lower activity of the fluorinated systems may be related to a stronger M–S interaction due to an enhancement of the π-acceptor ability of these ligands.

In contrast to the above-mentioned behaviour, bicyclic systems **8** and **9** do not decompose to Ir^0 under catalytic conditions, and the dithioether ligands are not replaced by substrate **11a**. Therefore, the catalytic hydrogenation of **11b**–**d** was studied by using **8** and **9**. For these substrates, the conversions ranged from modest to low and only for the acid substrates **11b** and **11d**, the *ee* reached up to 15% (*R*), with **8** as catalyst precursor. In order to understand the catalytic performance of these *bis*metallacycles, we studied the species formed in the presence of hydrogen.

Reactivity of Complexes 8 and 9 with Hydrogen

Complexes **8** and **9** reacted with H_2 at –70 °C to form the corresponding dihydride species $[Ir(H)_2(\mathbf{8})(cod)]BF_4$ (**13**) and $[Ir(H)_2(\mathbf{9})(cod)]BF_4$ (**14**) (Scheme 3). Similar reactivity was reported for other dithioether iridium complexes.[25,26]

$$[Ir(COD)(L)]BF_4 + H_2 \longrightarrow [Ir(H)_2(COD)(L)]BF_4$$

8: L = DIOSEtS **3** — **13**: L = DIOSEtS **3**
9: L = DIOSPrS **4** — **14**: L = DIOSPrS **4**

Scheme 3. Reaction of complexes **8** and **9** with H_2.

Taking into account the two different faces of the coordination plane (named seven-membered- and five-membered ring faces) four diastereomers can be formed (Figure 6).

The hydride region of the ^1H NMR spectra of complex **13** showed four signals at –70 °C which were attributed to the presence of two different isomers: a major isomer (δ = –11.37 and –13.83 ppm) and a minor one (δ = –11.56 and –13.78 ppm) in a 5:3 ratio. The measurement of relaxation times, T_1 (see Experimental Section), confirmed the formation of "classical hydride ligands".[44–48] Moreover, signals at δ = –11.37 and –11.56 ppm showed similar T_1 values (0.31 s) and the same was observed for T_1 values (0.2 s) of

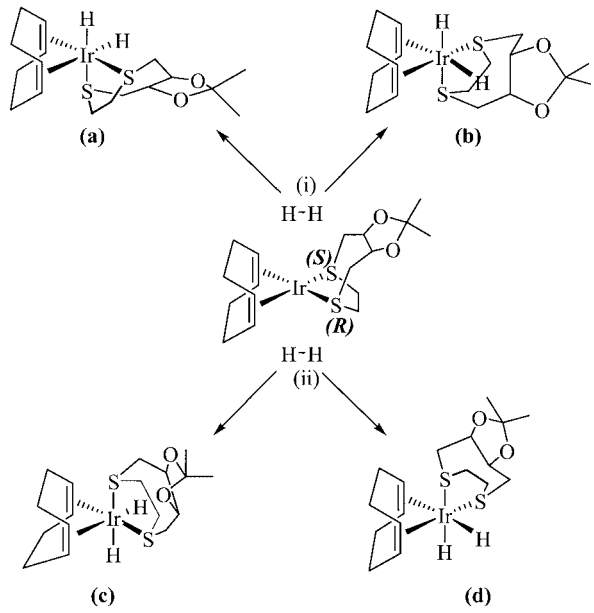

Figure 6. Attack of H_2 (i) through the "upper" seven-membered ring face with displacement of the (a) S_S (**13-I**) and (b) S_R atoms (**13-II**); (ii) through the "lower" five-membered ring face with displacement of the (c) S_S (**13-III**) and (d) S_R (**13-IV**) atoms.

signals at δ = –13.83 and –13.78 ppm, suggesting similar chemical environments for each couple sharing equal T_1 values.

NOE experiments allowed identification of the major isomer as **13-I**, formed by the attack of H_2 through the seven-membered ring face with displacement of the sulfur with absolute *S* configuration (Figure 7). In particular, NOE contacts between the methynic proton H^5 with $H^{3'}$ and the hydride ligand H^f, indicated the proximity of the seven-membered ring face to the hydride ligand. The methynic proton H^4 showed contacts with the ethyl protons $H^1$and H^2. The minor isomer corresponds to isomer **13-II**, formed also by the attack of H_2 through the seven-membered ring face but with displacement of the sulfur with absolute *R* configuration. The NOE contacts H^f–H^5, H^2–H^4–H^1 and H^b-$H^{3'}$ allowed determination of the minor isomer structure.

The dihydride complexes **13-I** and **13-II** were very stable; the hydride signals remained in the ^1H NMR spectra up to 25 °C after 24 h. The high stability of these complexes may account for the very low activity of **8** in the hydrogenation of acrylic acid derivatives. Although the oxidative addition takes place readily at –70 °C, the 1,2-insertion of the hydride ligands in the M-alkene (cod) bond to hydrogenate the cod ligand is very slow.

Similar results were obtained in the reactivity study of complex **9** with H_2 to form the dihydride complex **14**. The ^1H NMR in the hydride region also showed four signals corresponding to two isomers in a 5:3 ratio. In this case, the NOE contacts suggested that hydrogen attack also takes place through the seven-membered ring face for both isomers. The structure assignment of the major and minor isomers was not possible because the hydride NOE signals

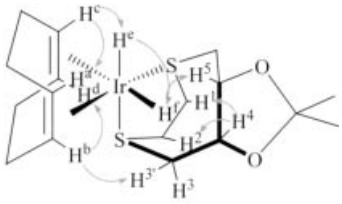
13-I



13-II

Figure 7. Representation of complexes of **13-I** and **13-II**, showing the NOE contacts.

were superimposed. Upon increasing the temperature up to 0 °C, the hydride signals disappeared, and both signals of cyclooctane and complex **9** were observed. This corresponds to two parallel reactions, the hydrogenation of cod and the reversible reductive elimination of H_2.

As has been shown, the approach of dihydrogen to complexes **8** and **9** takes place through the seven-membered ring face, which is presumably the more hindered. Nevertheless, upon formation of the dihydride complex, the reorganization of the dithioether cyclic ligand leads to a less hindered structure than when the approach is through the five- (for complex **8**) or six- (for complex **9**) -membered ring face. In this latter case, the bicyclic moiety of the resulting structure would be bent towards the cod coordinated ligand while in the other case, this fragment is launched outside the coordination sphere (Figure 6), which may favour the formation of the observed isomers. The low enantioselectivity obtained with both systems is probably related to the formation of different dihydrido complexes in solution.

Conclusion

Cationic iridium(I) complexes containing chiral dithioether ligands were prepared and their fluxional behaviour in solution was efficiently controlled by using bicyclic ligands, which form configurationally stable sulfur stereocentres upon coordination to the metal. The systematic study of the reactivity of these complexes allowed to establish that: (i) seven-membered chelating ligands are displaced in all cases by methyl acetoamidoacrylate to form the species $[Ir(substrate)(cod)]^+$, which is responsible for the catalytic activity in the hydrogenation of this substrate; (ii) the position of the fluorine atoms in the aromatic rings affects the substitution rate of the dithioether, thus modifying the catalytic activity directly; (iii) the dithioether substitution does not occur in the more rigid complexes containing cyclic dithioligands; however, these systems show poor activities and enantioselectivities; (iv) the low activity of the *bis*-metallacycles is directly related to the high stability of the corresponding dihydride species; (v) only two diastereomeric dihydride species (5:3) are formed in both cases; (vi) in the *bis*metallacycle systems the enantioinduction is slightly improved using the more rigid [7,5]- in comparison to the [7,6]-*bis*metallacycle.

Experimental Section

General Remarks: All iridium complexes were prepared by standard Schlenk techniques under nitrogen. The complex $[Ir(cod)_2]BF_4$ was prepared by methods described in the literature.[49] The syntheses of ligands **1a–d**, **2a–c**, **3** and **4** were reported previously.[33] The syntheses of ligands **5a** and **5b** will be described elsewhere.[34] Solvents were dried over standard drying agents and were freshly distilled and deoxygenated prior to use. All other reagents were used as commercially supplied. ^1H, ^{13}C, and ^{19}F NMR spectra were measured with Varian 300 or 400 MHz spectrometers operating at 300 or 400 MHz (^1H), 75 or 100 MHz (^{13}C), 282 or 376 MHz (^{19}F). Chemical shifts are relative to TMS δ = 0 ppm (^1H), CD_2Cl_2 δ = 55 ppm (^{13}C) and $CFCl_3$ δ = 0 ppm (^{19}F). All species were studied in deuterated dichloromethane unless otherwise indicated. Infrared spectra were measured with a Nicolet AVATAR 320 FT-IR spectrometer. Electronic Impact and FAB^+ mass spectra were recorded with a Jeol SX102A inverse geometry spectrometer and VG Autospect using a 3-nitrobenzyl alcohol matrix. Elemental analyses were performed with an AE FISONS CHNS-0 equipment or a Carlo–Erba EA-1108 microanalyser. Gas chromatography analyses were performed with a Hewlett–Packard 5890A instrument. Enantiomeric excesses (*ee*) were determined with a fused silica capillary column Permabond L-Chirasil-Val (25 m × 0.25 mm) for substrates **11a**,**b**, and Chiraldex-G-TA (30 m × 0.25 mm) for substrates **11c**,**d**.

Synthesis of Complexes [Ir(cod)(dithioether)]BF_4 (dithioether = 1b–d, 2b,c, 3–5)

Procedure A: A solution of the corresponding ligand (**1b–d, 2b**,**c**, 0.08 mmol) in dichloromethane (3 mL) was added to a solution of $[Ir(cod)_2]BF_4$ (40 mg, 0.08 mmol) in dichloromethane (5 mL) under nitrogen. The solution was stirred for 30 min, and then hydrogen was bubbled into the solution for 15 s in order to hydrogenate the 1,5-cyclooctadiene ligand and coordinate the dithioether to iridium. The solution was filtered to remove Ir^0, and the solvent was evaporated. The residue was thoroughly washed with hexane and recrystallised from dichloromethane/hexane to yield the products as yellow microcrystalline solids.

[Ir(cod)(1b)]BF_4 (6b): Colour: yellow; yield: 33.5 mg, 46%. Synthesis of [Ir(H)$_2$(cod)(dithioether)]BF_4 (dithioether = 3, 4)

General Procedure: Hydrogen was bubbled into an NMR tube containing a solution of [Ir(cod)(dithioether)]BF_4 (ditihioether = **3**, **4**)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(0.066 mmol) in deuterated dichloromethane at –72 °C for 20 min, obtaining yellow solutions in both cases. The tube was introduced into the NMR equipment at –80 °C and spectra were acquired. The relaxation time, T_1, was determined at –70 °C, and then the temperature was increased by 10 °C intervals, recording spectra at each successive temperature, until 25 °C was reached. 2D NMR spectra were acquired at 25 °C for complex $[Ir(H)_2(cod)(\mathbf{3})]BF_4$ and at 0 °C for complex $[Ir(H)_2(cod)(\mathbf{4})]BF_4$.

$[Ir(H)_2(cod)(3)]BF_4$ (13): ^{1}H NMR (300 MHz, –70 °C, refer to Figure 3 and Figure 7 for assignments): δ = 4.85 (m, 1 H, CH_a cod), 4.64 (m, 1 H, CH_d cod), 4.50 (m, 1, CH *5*), 4.41 (m, 1 H, CH_b cod) 4.41 (m, 1 H, CH_c cod), 4.13 (m, 1 H, CH *4*), 3.77 (m, 1 H, CH_2 *3*), 3.59 (m, 1 H, CH_2 *6*), 3.28 (m, 3 H, CH_2 *6′,1, 2′*), 3.07 (m, 1 H, CH_2 *2*), 2.80 (m, 1 H, CH_2 *1′*), 2.59 (m, 1 H, CH_2 *3′*) 2.06 (m, 4 H, CH_2 cod), 1.91 (m, 4 H, CH_2 cod), 1.34 (s, 3 H, CH_3), 1.33 (s, 3 H, CH_3), –11.37 [s, 1 H, complex **13-I**, H*f*, T_1 = 0.3112 s (err = 0.008368)], –11.56 [s, 1 H, complex **13-II**, H*f*, T_1 = 0.3112 s (err = 0.009975)], –13.78 [s, 1 H, complex **13-II**, H*e*, T_1 = 0.222 s (err = 0.006233)], –13.83 [s, 1 H, complex **13-I**, H*e*, T_1 = 0.2087 s (err = 0.003677)] ppm; **13-I/13-II** = 5:3. ^{1}H NMR (CD_2Cl_2, 300 MHz, 20 °C): δ = 4.93 (m, 1 H, CH_a cod), 4.76 (m, 1 H, CH_d cod), 4.66 (m, 1, CH *5*), 4.60 (m, 1 H, CH_b cod) 4.43 (m, 1 H, CH_c cod), 4.17 (m, 1 H, CH *4*), 3.81 (m, 1 H, CH_2 *3*), 3.34 (m, 1 H, CH_2 *6*), 3.316 (m, 3 H, CH_2 *6′,1, 2′*), 3.15 (m, 1 H, CH_2 *2*), 2.91 (m, 1 H, CH_2 *1′*), 2.61 (m, 1 H, CH_2 *3′*) 2.24 (m, 4 H, CH_2 cod), 2.06 (m, 4 H, CH_2 cod), 1.39 (s, 6 H, CH_3), –11.39 (s, 1 H, complex **1**, H*f*), –11.59 (s, 1 H, complex **2**, H*f*), –13.87 (s, 1 H, complex **2**, H*e*), –13.85 (s, 1 H, complex **1**, H*e*) ppm.

Catalysis: A standard hydrogenation experiment was performed in the following manner.[25] A solution in dichloromethane (6 mL) containing the complex $[Ir(cod)L]BF_4$ (L = dithioether or cod, 0.026 mmol) and the substrate (1.05 mmol) was introduced into the evacuated hydrogenation system which was filled up to atmospheric pressure with hydrogen. The mixture was vigorously stirred using a wrist-shaker and it was analysed directly by GC in the case of substrates **11a** and **11c**. The final mixtures resulting from the hydrogenation of acid substrates **11b** and **11d** were transformed into the esters by the following procedure: trimethylsilyldiazomethane (0.3 mL, 2 M in hexane) and MeOH (0.1 mL) were added to the final catalytic solution (0.5 mL). This mixture was stirred for 30 min at room temperature, filtered through silica and analysed by GC.

Crystal Data for Complex 10b: Suitable crystals of complexes **10b** were grown by slow diffusion of *n*-hexane into a solution of the complex in ethyl acetate and mounted on a glass fiber. The X-ray data were collected at 293.5 K with a Bruker APEX instrument (Mo-K_α radiation, λ = 0.71073 Å). The SHELXTL v. 6.1 program package was used for structure solution and refinement. An absorption correction was applied using SADABS. The structure was solved by direct methods and refined by full-matrix least-squares procedures. All non-hydrogen atoms were refined anisotropically. $C_{19}H_{36}BF_4IrS_2$, M = 607.61, Monoclinic space group $P2_1$, a = 9.2855(12), b = 12.5844(17), c = 10.0187(13) Å, β = 97.892(2)°, V = 1159.6(3) Å^3, Z = 2, D_c = 1.740 Mg/m^3, 11295 reflections measured, 4057 unique (R_{int} = 0.0492) which were used in all calculations; the final R value was 0.0331 [$F > 4\sigma(F)$] and 0.0501 (all data). The ORTEP diagram was generated using ORTEP-3.[50]

CCDC-239321 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Orbital Splitting and Pairing Energy in Open-Shell Organometallics: A Study of Two Families of 16-Electron Complexes [Cp_2M] (M = Cr, Mo, W) and [$CpM(PH_3)$] (M = Co, Rh, Ir)

Rinaldo Poli*[a] and Ivo Cacelli[b]

Keywords: Density functional calculations / Metallocenes / Open-shell organometallics / Pairing energy / Singlet–triplet gap

The singlet–triplet gap for two families of 16-electron organometallic complexes has been examined in detail by DFT calculations at the B3LYP level with polarized basis sets on both metal and ligands. For the first family, the group 6 metallocenes (Cp_2M with Cp = η^5-C_5H_5 and M = Cr, Mo, W), the singlet–triplet gap ($E_S - E_T$) is always positive and decreases continuously on going from Cr to Mo to W. For the family of group 9 $CpM(PH_3)$, on the other hand, there is a decrease on going from Co to Rh, followed by a slight increase on going further to Ir. These trends have been analyzed in qualitative monoelectronic terms as a function of the competition between the pairing energy and the orbital gap. While the pairing energy decreases as expected in the order 3d >> 4d > 5d, the orbital gap varies in a different way for the two families and, though quantitatively less important, is responsible for the different trends. It is argued that changes in orbital gap are system-dependent for open-shell organometallic systems, thus it is not possible to establish a universal trend of singlet–triplet gaps for a homologous series of complexes with a group of transition metals.

Introduction

Reaction selectivities and catalytic activities can be tuned by the relative stabilization of the reaction intermediates and transition states. The most typical situation encountered in organometallic chemistry involves reaction intermediates that are less electronically saturated than the reagents and products; for instance a saturated, 18-electron compound may generate a 16-electron intermediate by a ligand dissociation, or reductive elimination, or migratory insertion, etc. Although most organometallic reactions involve reagents, products and intermediates having a diamagnetic ground state, it is now well appreciated that compounds with fewer than 18-electrons and a paramagnetic ground state are also involved in all sorts of stoichiometric and catalytic transformations.[1,2] Even when the reagents and the products are saturated, diamagnetic systems, it is possible that a reaction takes place via more than one potential energy surface, through open-shell intermediates in a different spin state.[3–7]

Three distinct factors are recognized to play a role in the energetic stabilization of open-shell compounds, relative to more saturated ones. Steric pressure, enforced by encumbering ligands, destabilizes higher coordination numbers and therefore stabilizes less saturated intermediates in a relative sense. Ligands possessing inactive electron pairs for the saturated systems (e.g. π-symmetry lone pairs), may stabilize the less saturated intermediates by becoming engaged in bonding with the metal orbital associated with the open coordination site. Finally, a third factor is present when the system undergoes a changes of spin state on going from the reagent to the intermediate. The binding energy lost during the formation of the open coordination site can be partially recovered by unpairing two electrons. In the qualitative, single-electron framework, the promotion of one electron to a higher-energy orbital may be more than compensated by the lower electron–electron coulombic repulsion (J) and by a gain in exchange energy (K). The combination of these factors is known by the general term "pairing energy".

The concept of pairing energy has a solid place in the chemistry of Werner-type coordination compounds to understand the preference of a low- vs. high-spin configuration for octahedral or tetrahedral complexes, as a function of the orbital splitting between the t_{2g} and e_g orbitals (Δ_O) or between the e and t_2 orbitals (Δ_T), respectively. In particular, it is widely appreciated that, whereas this separation increases down a series of transition metals (e.g. $3d \leqslant 4d \leqslant 5d$ for elements within the same group), the pairing energy correspondingly decreases.[8] Therefore, both factors concur for the stabilization of the low-spin state relative to the high-spin one on going from the lighter to the heavier element.

However, the same trend does not appear to be valid in general for open-shell organometallic compounds. Few families of ML_n complexes within the same group of transition metals have been studied in terms of high spin–low spin energy gap at the same level of theory. The trend of the Werner complexes seems reproduced for the organometallic group 8 $M(CO)_4$ systems, the energy difference ($E_S - E_T$, in kcal mol^{-1}) being 1.7 for Fe, –13.1 for Ru, and –16.2 for Os at a nonlocal DFT level.[9] On the other hand, a nonmonotonous variation of the same quantity results for the group 9 CpM(CO) series at various computational levels, for instance 11.2 for Co, –5.9 for Rh, and 0.3 for Ir using a CI calculation combined with a couple pair functional to correct the lack of size consistency.[10] It is generally known that the pairing energy decreases on going from the lighter to the heavier element, because of the cloud expansion (nephelauxetic) effect on going from lower (e.g. 3d) to higher (e.g. 5d) valence shells. It is also known that this effect is particularly strong on going from the 3d to the 4d element.[8] This trend is common to the Werner-type octahedral and tetrahedral complexes mentioned above. On the other hand, it is not clear how the orbital splitting should change along a homologous series of open-shell organometallic compounds.

There is an important difference between Werner-type complexes and open-shell organometallic compounds. For the Werner-type systems, the higher-energy orbitals whose occupation increases in the higher spin state have metal-ligand antibonding character (strong for the octahedral e_g orbitals, weaker for the tetrahedral t_2 orbitals), while those losing electrons in the same process are nonbonding (or π-bonding in the presence of π-acceptor ligands). Thus, the well-known increase of metal–ligand binding energy on going from the lighter to the heavier metal[11,12] results in an energy increase for the higher-energy orbitals and possibly in an energy decrease for the lower-energy ones, both effects contributing to raise the orbital gap. On the other hand, both the high energy and the low energy orbitals involved in the spin transition for open-shell organometallic compounds generally have similar characteristics with respect to metal-ligand bonding (essentially σ nonbonding; possibly π bonding), thus the variation of this orbital gap along a group of transition metals cannot be easily predicted a priori.

For this reason, we set out to study two representative families of homologous 16-electron complexes, the group 6 metallocenes Cp_2M (M = Cr; Mo, W) and the Group 9 "one-legged piano stools" $CpM(PH_3)$ (M = Co, Rh, Ir), that are models of the more widely studied PMe_3 complexes. A variety of calculations at different levels of theory[13–19] have already shown that these complexes, or at least some of them, adopt a spin-triplet ground state configuration. In this contribution, we examine for the first time the details of how orbital gap and pairing energy vary along the two homologous series, and compare these findings with the computed singlet–triplet gaps. It will be shown that the trends of the singlet–triplet energy difference are qualitatively reproduced by the approximate one-electron formula, which expresses the energy difference as a combination of orbital energy gap and a pairing energy term. Thus, the qualitative thinking that is often applied to Werner-type coordination compounds can be successfully extended to open-shell organometallics. However, although the pairing energies trends are as expected, the trends of orbital gaps are found to be family-dependent. Therefore, a universal trend for the singlet–triplet gap upon descending a group of transition metals cannot be established.

Results and Discussion

DFT Calculations: Electronic and Molecular Structures

Our investigation makes use of the DFT approach, using the B3LYP functional and polarized basis sets, which has proven effective for the computation of several other cases of spin-state dichotomy in coordination and organometallic chemistry.[7,10,20,21] The optimized geometries for all systems are shown in Figure 1 for the group 6 metallocenes and Figure 2 for the group 9 $CpM(PH_3)$ systems.

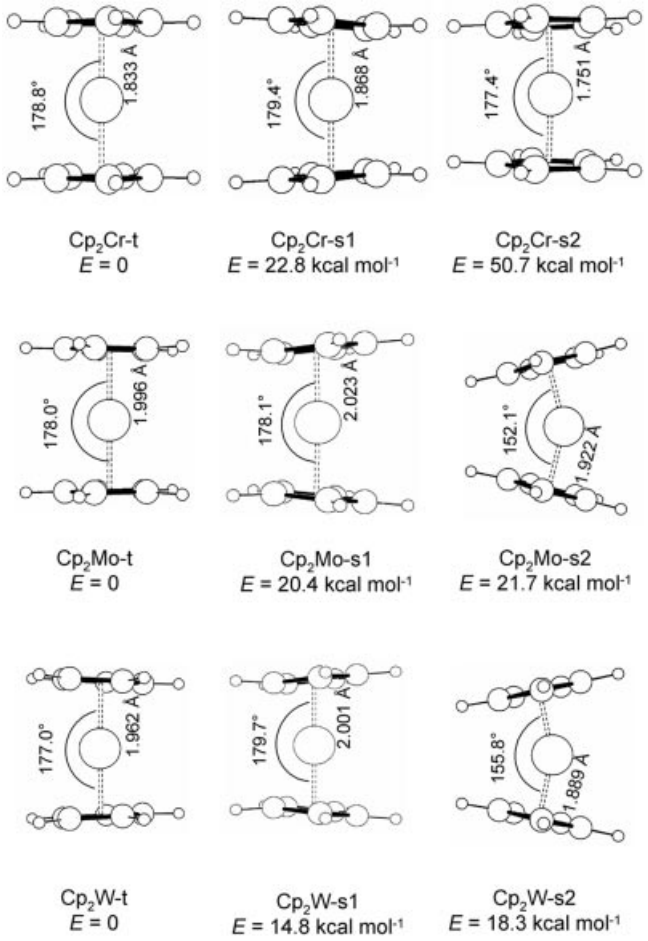

Figure 1. Views of the optimized geometries, relative energies, and selected bonding parameters for the Cp_2M systems (M = Cr, Mo, W; s = singlet, t = triplet). The distance of the metal from the Cp ring is calculated from the ring centroid (CNT).

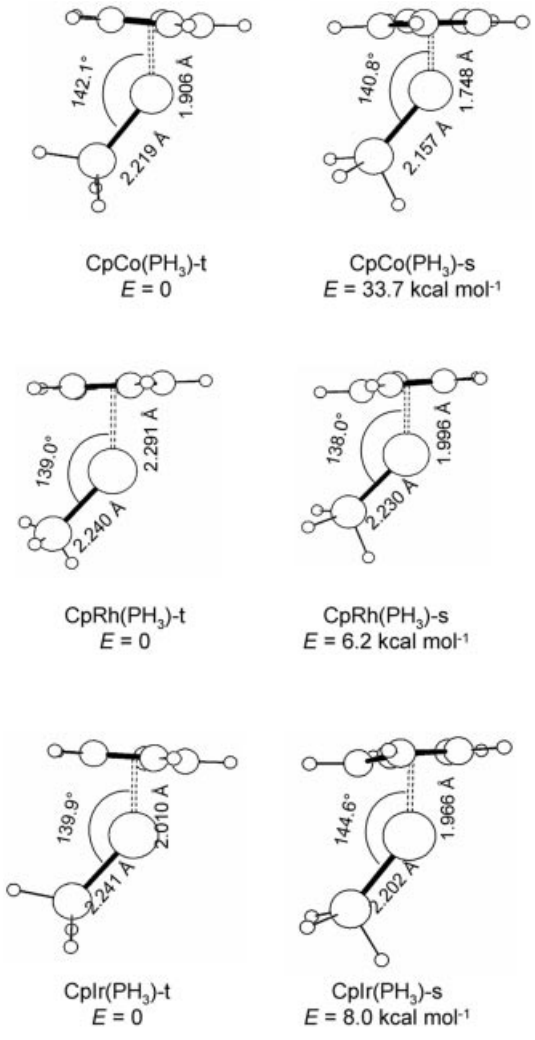

Figure 2. Views of the optimized geometries, relative energies, and selected bonding parameters for the $CpM(PH_3)$ systems (M = Co, Rh, Ir; s = singlet, t = triplet). The distance of the metal from the Cp ring is calculated from the ring centroid (CNT).

The energies obtained at the chosen level of theory favor a triplet ground state for all systems. From the experimental point of view, chromocene is a stable triplet compound[22] whereas molybdenocene and tungstenocene cannot be isolated. However, a magnetic circular dichroism study demonstrates their triplet ground state.[23,24] The calculated Cr–Cp (center) distance of 1.833 Å for triplet Cp_2Cr is in relatively good agreement with the experimentally determined one of 1.791(4) Å.[25] There is no experimental information on any 16-electron $CpM(PR_3)$ system, to the best of our knowledge.

All metallocene molecules yielded two different stable minima (termed s1 and s2 in Figure 1) that differ by their orbital occupation, as shown in Figure 3. It is noteworthy that, with only one exception for chromocene,[21] all previously published computational studies on the group 6 metallocenes report only one energy minimum for both the singlet and the triplet state.[15,26] The recent report by Reiher et al.,[21] which probed the effect of the exact exchange admixture parameter c_3 on the singlet–triplet gap for various first row metallocenes, mentions the location of a second singlet minimum for chromocene at low c_3 values. However, neither the energy difference between these two minima, nor the optimized geometry of either minimum, were reported.

It is curious that the two chromocene minima s1 and s2 were obtained starting with the same input geometry and guess orbitals, at the same computational level, and using the closely related Gaussian98 and Gaussian03 programs, respectively. With particular care in the choice of alternative input geometries, or by artificially altering the list of filled and empty guess orbitals, both energy minima were eventually obtained with both program packages. The molybdenocene and tungstenocene molecules only yielded the s2 minima initially. They provided the lower-energy s1 minima only by artificially altering the list of filled and empty guess orbitals, and, in particular, by substituting the LUMO for the HOMO in the guess density of the self-consistent procedure. This example serves to illustrate that one has to be very careful about checking all considered states in close-to-degeneracy situations.

The origin of the double-singlet minimum can be related to the observed geometrical distortions as follows. In an ideal symmetric top geometry (D_{5x} with $x = h$ or d or nothing, depending on the dihedral angle), the metallocene electronic structure is well known.[27] The metal frontier orbitals (z^2, xy and $x^2 - y^2$) are partitioned into a singly degenerate (z^2, a_1-type) orbital and a doubly degenerate (xy, $x^2 - y^2$, e-type) set, their complete symmetry label depending on the point group (e.g. a_1' or a_{1g} for z^2 in D_{5h} and D_{5d}, respectively). However, a molecular distortion that lowers the symmetry to C_{2v} splits the e-set into an a_1 and a b_2 orbital.[28] This symmetry lowering allows orbital mixing with a consequent energy lowering, a phenomenon known as the pseudo-Jahn–Teller effect (or second-order Jahn–Teller effect).[29] Different levels of mixing lead to different orbital energies and consequently to different geometries and orbital occupations. The s1 minimum corresponds to the configuration $(x^2 - y^2)^2(z^2)^2$, whereas the s2 minimum has the configuration $(x^2 - y^2)^2(xy)^2$ (we maintain the same orientation of the principal axes as in the higher-symmetry molecule). The same double-minimum phenomenon has been described previously for several other 16-electron organometallic complexes such as a variety of d^6 ML_5 complexes,[30,31] $[(arene)Nb(CO)_3]^+$,[32] and $[CpMo(L)_2X]$ (L = CO, PH_3; X = H, CH_3, Cl, Br, I, etc.).[33,34] For the latter two systems in particular, Hasanayn was able to show that the second-order Jahn–Teller distortion generates two different symmetry states for both the singlet and the triplet electronic configurations. In principle, more than one triplet minimum could also exist for the metallocenes. However, only a single minimum with the same relative orbital ordering as the s1 singlet could be located, yielding the $(x^2 - y^2)^2(z^2)^1(xy)^1$ configuration ($^3B_2$). Numerous attempts, starting with differently populated guess geometries, either linear or bent, led to the same optimized minimum.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

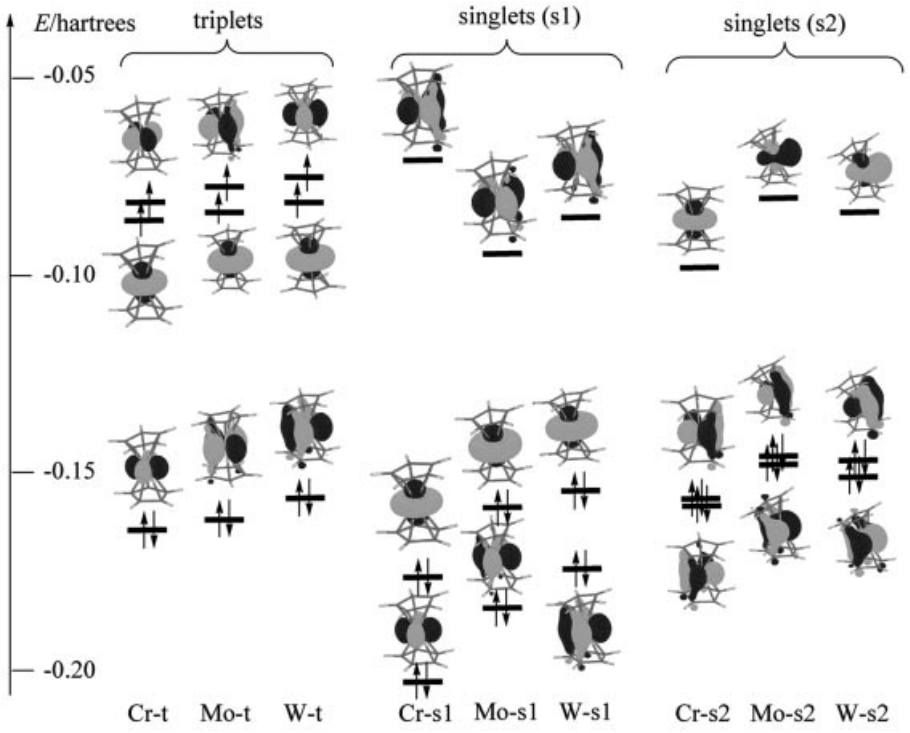

Figure 3. Electronic structure (frontier orbital region) of the singlet and triplet metallocenes. The orbital energies shown for the triplet states were obtained at the ROB3LYP level.

The metal orbital mixing, resulting from the geometrical distortion, is only very slight for all triplets and also for the s1 singlets. The Mo and W metallocenes of s2 type show a significant participation of the p orbital that points along the symmetry C_2 axis (a_1 type) in the LUMO (see Figure 3). There is no significant mixing of this kind, on the other hand, for the chromocene s2 minimum. This orbital mixing is reflected in the molecular geometry, which is severely bent (CNT-M-CNT << 180°) for the molybdenocene and tungstenocene s2 minima (see Figure 1).

On the other hand, all triplets and s1 singlets, as well as the chromocene s2 minimum, are very close to linear. The different orbital occupancy reflects very strongly on the Cp–M distance: the double occupation of the z^2 orbital, which has a slight Cp-M σ* character, considerably lengthens the M–CNT distance in Cp_2M-s1 relative to Cp_2M-s2. This distance is, in fact, even longer in Cp_2M-s1 than in Cp_2M-t.

A second interesting effect is that the Cp rings are differently tilted from the ideal arrangement, with equivalent M–C distances, in which the metal lies on the C_5 symmetry axis of the Cp moiety. The s2 singlets do not display any significant tilting, the angle between the M–CNT vector and the Cp least-squares plane being 90.0° for all three metals. On the other hand, the distortion is significant for the triplets (85.4°, 85.9°, and 85.9° for Cr, Mo, and W, respectively) and even more so for the s1 singlets (76.4°, 84.3°, and 81.1° for Cr, Mo, and W, respectively). This effect can be attributed to δ-type M–Cp back-bonding interactions, as previously highlighted by Hoffmann et al.[35] These interactions can be established by the $x^2 - y^2$ and xy orbitals. When both orbitals are filled, as in the s2 singlets, the δ back-bonding has cylindrical symmetry and no major distortion occurs. This cylindrical symmetry is broken by the molecular distortion to C_{2v} symmetry for the molybdenocene and tungstenocene, resulting in a slight ring tilting, but both back-bonding interactions are still present, as can be appreciated from Figure 3. The triplets and the s1 singlets, on the other hand, have a reduced population of the xy orbitals, thus the prevalence of the back-bonding interaction from the $x^2 - y^2$ orbital causes the ring tilting. It is noteworthy that neither Cp_2Cr-s1 nor Cp_2Cr-s2 correspond to the optimized geometry obtained by the previous calculation reported by Green and Jardine,[26] which is bent like those of the Mo and W analogs, with an inter-ring angle of 26.8°. Our s1 and s2 minima have inter-ring angles of 10.1° and 2.7°, respectively.

It should be noted that the higher-energy s2 singlets for molybdenocene and tungstenocene are better pre-organized than the corresponding s1 singlets for the interaction with molecules of L or X–Y type, leading to L addition or X–Y oxidative addition to generate saturated $Cp_2M(L)$ or $Cp_2M(X)(Y)$ products. The metallocene is bent as in the final products and the LUMO is geometrically well disposed to receive electron density from the L or X–Y donating orbital. Thus, a reaction coordinate leading from the free Cp_2M triplet molecule to the above singlet products should involve crossing of the reagent triplet surface with the higher-energy s2 singlet surface, rather than with the lower-energy one. A similar situation has been described for the addition of CO and N_2 to triplet $[CpMo(PH_3)_2Cl]$,[33] which is isoelectronic with the metallocenes studied here.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The energy of the frontier orbitals for the Cp_2M triplet systems increases regularly on going from the 3d to the 5d metal (see Figure 3), following the analogous trend of the atomic orbitals which contribute almost totally to their composition. On the other hand, the orbital energies for the singlet systems show a different and more complex trend, which is probably related to the different degree of orbital mixing and geometrical distortions discussed above. The chromocene s1 system is anomalous for having a higher-energy LUMO than the heavier congeners. Within the s2 series, on the other hand, tungstenocene unexpectedly shows lower energies for all frontier orbitals relative to molybdenocene.

For each member of the group 9 $CpM(PH_3)$ series, we located only one singlet and one triplet minimum. We did not exhaustively explore the possibility of other minima in any of the two spin-states. Since the geometry of these molecules is much farther from a pseudo-symmetry situation than for the metallocenes, less complications of this kind are anticipated. The optimized geometries (Figure 2) are very close to those obtained for the same systems at other levels of theory. All metal–ligand bonds shorten slightly on going from the triplet to the singlet, as expected.

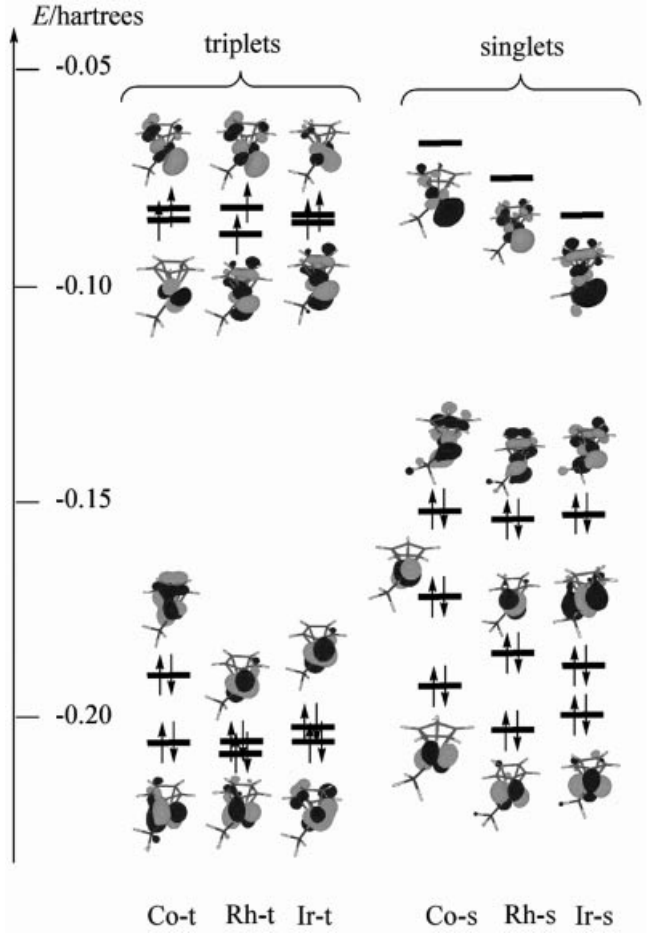

Figure 4. Electronic structure (frontier orbital region) of the singlet and triplet $CpM(PH_3)$ systems (M = Co, Rh, Ir). The orbital energies shown for the triplet states were obtained at the ROB3LYP level.

The main structural changes observed upon changing spin state have been amply discussed previously.[16] The electronic and molecular structures of the $CpM(PH_3)$ systems do not deserve any further discussion. The orbital energies, shapes, and occupations in both spin states are shown in Figure 4. The electronic structure remains unchanged along the series for both triplets and singlets. The orbital analysis agrees with that already reported by Ziegler et al.[16] for $CpRh(PH_3)$, although in this paper we find a somewhat larger mixing between the metal and the Cp orbitals. Notice, however, that in that work a reverse order was found for the singlet–triplet energy gap: the singlet was found to be the most stable state. The rationalization of the orbital energies is found in the interaction of the metal orbitals with different types of Cp orbitals, with minor effects of the σ- and σ*-orbitals of PH_3. For instance, the HOMO in the singlet state shows a small antibonding metal-Cp character, indicating a destabilization due to the interaction with the occupied π-orbitals of Cp. On the contrary, metal-Cp bonding character, due to interaction with the empty π*-orbitals, is observed for the low-lying, metal-based molecular orbitals. The most notable change in the series is the stabilization of the LUMO for the singlet system on going from Co to Ir, whereas the HOMO remains approximately at the same energy. Consequently, the HOMO–LUMO gap decreases.

DFT Calculations: Singlet–Triplet Gaps

As far as we are aware, experimental determinations of the singlet–triplet gap are unavailable for any of the compounds examined here. As anticipated in the introduction, there is no clear monotonous trend of singlet–triplet gap on going from the 3d through the 4d to the 5d system within each family. The gap is larger for the 3d system, relative to the heavier congeners, within each family of complexes. On going from the 4d to the 5d system, on the other hand, the calculations predict a slight decrease for the metallocene series and a slight increase for the $CpM(PH_3)$ series. In previous computational work on the same systems, the singlet state was found to be higher than the triplet for all Cp_2M systems (M = Cr, 34.8; Mo, 16.4; W, 17.9 kcal mol^{-1}).[26] Our own previous calculations on Cp_2M (M = Mo, W) gave a lower-energy triplet by 24.1 and 19.1 kcal mol^{-1} at the B3LYP/LANL2DZ level, or by 23.0 and 19.6 kcal mol^{-1} at the same level used here, except that polarization functions on the metal atoms were not used (those calculations dealt only with the singlet structure that corresponds to the s2 minimum reported herein).[15] For the $CpM(PH_3)$ series, the Co system was found as a ground-state triplet, 33.0 kcal mol^{-1} more stable than the singlet at the B3LYP/LANL2DZ level.[13] For the Rh and Ir systems, the triplet was reported to be more stable by 8.17 and 20.1 kcal mol^{-1} at the MP2/LANL1DZ level,[18] and by 13.2 and 16.9 kcal mol^{-1} at the B3LYP/LANL2DZ level,[19] respectively. However, another report on the Ir system gives a relative stability for the triplet of 6.4 or 8.4 kcal mol^{-1} by using B3LYP and the LANL2DZ or TZV basis sets.[14] In all re-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ported cases, except one,[26] the stability of the triplet state relative to the singlet on going from the 4d to the 5d metal *decreases* for the Cp_2M system and *increases* for the $CpM(PH_3)$ system.

Analysis of the Orbital Gaps and Pairing-Energy Factors

Using the qualitative concepts of orbital splitting and pairing energy, the singlet–triplet gap for the neutral system can be approximately expressed as in Equation (1), where the relevant orbital energies, ε, and the two-electron coulombic (J) and exchange (K) integrals appear.

$$\Delta E_{ST} = E_S - E_T = (J_{11} - J_{12} + K_{12}) - (\varepsilon_2 - \varepsilon_1) \quad (1)$$

In this simple expression the pairing energy ($J_{11} - J_{12} + K_{12}$) is defined as the change of electrostatic energy in going from a $\varphi_1\alpha\varphi_2\alpha$ (triplet) to a $\varphi_1\alpha\varphi_1\beta$ (singlet) configuration irrespective of the one-electron potential arising from the nuclei and from the other electrons (core electrons). The latter is accounted for by the orbital energy gap ($\varepsilon_1 - \varepsilon_2$), which includes also the kinetic energy of the orbitals entering Equation (1). This equation is, of course, a rather drastic approximation because both the orbital relaxation and the electronic correlation between the two active electrons, which may be of crucial importance for low singlet–triplet energy gaps, are completely neglected. In addition, the core electrons are considered frozen, i.e. their distribution is assumed to be independent of the configuration of the two active electrons. Nevertheless, this simple picture has a great appeal, and in several cases can furnish a fashioned model to rationalize a number of results, the best known application in coordination chemistry being the rationalization and prediction of high-spin vs. low-spin magnetic properties for octahedral complexes of d^4–d^7 metal ions.[8] Assuming $\varepsilon_1 < \varepsilon_2$, it is apparent that high orbital energy gaps favor the singlet state, i.e. the one-electron terms stabilize the singlet state. Conversely, the pairing energy expression contains the $J_{11} - J_{12}$ term, which is generally positive and accounts for the larger electron–electron repulsion energy of the singlet, as well as the K_{12} exchange term, which further stabilizes the triplet state; greater values for J and K integrals therefore lead to a stronger preference for the higher spin state.

Once the model has been well characterized, a second important problem arises. How can the active orbitals to be used in Equation (1) be determined? One possibility was originally suggested and implemented by Hall et al.[36] in order to analyze nephelauxetic effects in the series of compounds $[Ti(dmpe)_2X_2]$ (X = Cl, OPh),[36] and later applied by us to a family of [CpCr(NO)XY] compounds (X, Y = Cl, alkyl, amido).[37] In this approach, the active orbitals are the LUMO and LUMO+1 of a simple HF calculation with $n - 2$ electrons (dication in our case). As pointed out by the authors,[36] this choice provides an unbiased determination of the active orbitals, which proved to predict qualitatively correct singlet–triplet splittings. One other possibility that we suggest here is based on the DFT approach which, in the Kohn–Sham (KS) scheme, furnishes a set of orbitals and a set of orbital energies which can be recognized to have a physical meaning. For instance, in Slater's transition state method,[38] the basic Equation (2) shows that the change in the total energy, E, due to an infinitesimal increase of charge in the KS orbital φ_i, corresponds to its eigenvalue ε_i. This equation gives a real physical meaning to the KS orbitals and recognizes the orbital energies of the occupied orbitals as true ionization potentials.[39–41] The extension to unoccupied orbitals is trivial and HOMO and LUMO KS orbital energies are currently used to estimate a number of molecular properties. Therefore, the B3LYP KS eigenvalues and the corresponding orbitals obtained for the dication can be inserted in Equation (1) in order to look for some rationale for the energy splittings. This choice, while preserving the simplicity of such an expression, has the clear advantage, with respect to the previous choice based on HF results, of using orbitals that represent a more accurate density function and are thus expected to give more reliable estimates of the quantities entering Equation (1). As a matter of fact, we found that the KS orbitals are generally a bit more contracted than the HF ones and lead to slightly higher values of the Coulomb and exchange integrals. This finding can be rationalized as the effect of the electronic correlation, which optimizes the inter-electronic repulsion energy and allows the density to better accumulate in the wells of the nuclear potential.

$$\frac{\delta E}{\delta n_i} = \varepsilon_i \quad (2)$$

In view of the approximations contained in Equation (1), only general and clear trends may be physically meaningful; conversely, some caution must be used in order to draw conclusions based on strongly method-dependent quantities. For instance, the comparison between the results for the different systems can be meaningful only if the active orbitals in the dication systems (LUMO and LUMO+1) have the same nature, i.e. show similar lobes along each series. In addition, these orbitals should be pure metal orbitals, in order for the resulting J and K values to have a stronger significance. The only cases where we found this set of conditions to be satisfied, for the Cp_2M systems, are for the B3LYP calculations of the dication using either the s1 optimized structures or the optimized triplet structures of the neutral complexes. This is probably because the three geometries follow a regular trend in these cases. The orbital order found in the dications is the same as that observed for the neutral triplets and s1 singlets (Figure 3), with z^2 below xy. For the $CpMPH_3$ systems, the best trend was observed for the singlet optimized geometries and these were then used for the dication calculations. The results are shown in Table 1. The results obtained with the triplet geometries for the metallocene series (not reported) are nearly identical to those obtained with the s1 geometries.

Despite the approximations just described, it is possible to analyze trends of orbital gap and pairing energy along both series of isoelectronic complexes and draw some reasonable conclusions. As stated in the introduction, conventional wisdom tells us that the J values should decrease on

Table 1. Orbital energies and relevant J and K integrals (in kcal mol^{-1}) for the Cp_2M (M = Cr, Mo, W) and $CpM(PH_3)$ complexes. The reported quantities arise from B3LYP calculation of the 2+ ion at the geometries of the neutral complex.

	Cp_2M[a]			$CpM(PH_3)$[b]		
M	Cr	Mo	W	Co	Rh	Ir
ε_2	–318.5	–328.3	–321.2	–316.3	–303.7	–299.0
ε_1	–330.6	–329.9	–326.1	–333.1	–330.6	–323.7
J_{11}	435.5	289.7	264.1	275.4	208.3	194.2
J_{12}	383.3	271.1	252.9	249.9	188.6	176.8
K_{12}	16.8	17.1	18.8	9.6	9.2	10.0
$(\varepsilon_2 - \varepsilon_1)$	12.1	1.5	4.9	16.7	26.9	24.7
PE[c]	69.0	35.7	30.0	35.1	29.0	27.5
ΔE_{ST}[d]	56.9	34.2	25.1	18.4	2.1	2.8

[a] Using the singlet (s1) optimized geometries. [b] Using the singlet optimized geometries. [c] PE = Pairing energy = $J_{11} - J_{12} + K_{12}$. [d] Estimated singlet–triplet energy gap from Equation (1).

going from the 3d to the 4d element, and then again (though by a smaller extent) on going from the 4d to the 5d element. This is indeed what our calculations reveal (see Table 1). It can also be seen that, as expected, J_{11} is greater than J_{12} for all systems and that the J values are much greater than the K values.

It is apparent from the data of Table 1 that the simple Equation (1) is able to reproduce the correct energy trends for both systems: the triplet is always the most stable state (see Figures 1 and 2). For the metallocene systems, the ΔE_{ST} values from Table 1 must be compared with the gap between the triplet state and the s1 state, because that is the state having the same orbital ordering as the triplet state, used for the ΔE_{ST} calculation by Equation (1).

For the Cp_2M series, ΔE_{ST} is dominated by the pairing energy whose decrease is mainly due to the difference between J_{11} and J_{12}, since K_{12} is almost constant. Notice that the orbital gap is of the same order as those of the RO-B3LYP triplet calculations on the neutral molecule (3–4 kcal mol^{-1}) and is much smaller than the HOMO–LUMO gap of the singlet s1, which involves the same orbitals. This can be expected because the two involved orbitals have the same occupancy in the triplet and in the dication (1 and 0, respectively). Thus, unlike the neutral singlets, their near degeneracy is preserved.

For the $CpM(PH_3)$ systems, the PE decreases whereas the orbital energy gap increases on going from 3d to 4d and changes little from 4d to 5d. It is somewhat surprising that the trend of this gap is in contrast with the HOMO–LUMO gap of the neutral singlet calculation, which shows a monotonic decrease. However, the different meaning of the orbital energies in the dication (empty orbitals include interactions with $n - 2$ core orbitals only) and of the neutral singlet system (empty and occupied orbitals feel the effect of n and $n - 1$ electrons, respectively, for Self Interaction free methods) do not allow a significant comparison. Differently from the Cp_2M systems, the orbital energy gaps are greater than the (HOMO – 1)–HOMO gaps of the neutral triplet state: this is possibly related to the geometry used for the dication (neutral singlet) which can remove the near degeneracy. Calculations of the dications at the neutral triplet geometry indeed show generally lower energy gaps. All in all we do not see any systematic trend in the orbitals leading to a rationale for the variation of the energy splitting along the $CpM(PH_3)$ series.

The different trend of the PE and orbital energy gap for $CpM(PH_3)$ generates a nonmonotonic behavior of ΔE_{ST} along the series. Whereas for Co the PE dominates and favors the triplet state, for Rh and Ir complexes the two terms practically cancel each other out, leading to near degenerate triplet and single states. This feature agrees with the DFT calculations of the neutral systems, whose relative energies are reported in Figure 2: 33.7, 6.2, and 8.0 kcal mol^{-1} for Co, Rh, and Ir, respectively.

Conclusions

This contribution reports the first analysis of the electronic structure of families of open-shell organometallic complexes in terms of the variations of the pairing energy and the orbital gap. On one side, there is always a monotonous decrease of the pairing energy on going from the 3d to the 4d and further to the 5d orbitals, the biggest change occurring between 3d and 4d. On the other side, the variations of the orbital gap are smaller upon descending the group and may occur, in principle, in either direction (increase or decrease). As a result, a very different trend of the low-spin–high-spin energy gap, relative to the Werner-type octahedral and tetrahedral complexes, may result on going from the 3d to the 5d element within a group of transition metals. In some cases, like the group 9 $CpM(PH_3)$ complexes examined here, a nonmonotonous change may result. While the pairing-energy effect seems to dominate the situation on going from the 3d to the 4d complex, such that the lighter complex seems to always favor the higher-spin ground state to a greater extent, the low-spin–high-spin energy gap may decrease or increase on going from the 4d to the 5d metal, depending on the system under consideration. A universal model allowing us to predict this trend for any structure is not available at the moment, thus one must examine this problem on a case-by-case basis.

Computational Details

All geometry optimizations were performed using the B3LYP three-parameter hybrid density functional method of Becke,[42] as implemented in the Gaussian03 suite of programs.[43] However, many calculations were also carried out with the previous version (Gaussian98) of the program. With one exception (see Results section), both programs gave the same optimized geometry and energy, within insignificant fractions of 1 kcal mol^{-1}. All calculations were performed with no symmetry restrictions and all optimized geometries were characterized as local minima of the potential energy surface (PES) by verifying that all second derivatives of the energy were positive. The unrestricted formulation was used for the triplet states, whereas singlet states were obtained within the restricted formulation. For the purpose of computing and visualizing the shape of the Kohn–Sham orbitals, the calculations for all triplet states were also carried out by the Restricted Open (RO)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

method at the fixed unrestricted optimized geometry (these energies were generally 1–2 kcal mol^{-1} higher than the unrestricted ones). All reported relative energies are relative to the unrestricted computations. Numerical integrations were performed using the "ultrafine" grid of Gaussian98 and Gaussian03, consisting of 99 radial shells and 590 angular points per shell, and the default values were chosen both for the self consistency and for the geometry optimization convergence criteria. The basis sets used for the geometry optimizations are the standard 6-31G** for C, H, and P atoms, and the standard LANL2DZ basis set, which includes the Hay and Wadt effective core potentials (ECP),[44] for the metal atoms. To the latter, however, was added a single *f*-type polarization function (α = 0.8) in order to obtain a balanced basis set and to improve the angular flexibility of the metal functions. In the model calculations for the study of the trends in the metal series a newly coded program (SPINETTA) was used to read the results of the DFT calculations, to sort the relevant orbitals, and to compute the one- and two-electron necessary integrals.

Addition of Enolisable Ketones to (dpp-bian)Mg(THF)$_3$ [dpp-bian = 1,2-Bis{(2,6-diisopropylphenyl)imino}acenaphthene]

Igor L. Fedushkin,*[a] Alexandra A. Skatova,[a] Georgii K. Fukin,[a] Markus Hummert,[b] and Herbert Schumann*[b]

Dedicated to Prof. Dr. Alexei N. Egorochkin on the occasion of his 70th birthday

Keywords: Enolisation / Ketones / Magnesium / N ligands

The enolates [(dpp-bian)(H)]Mg[OC(=CHPh)CH$_2$Ph](THF)$_2$ (**6**), [(dpp-bian)(H)]Mg[OC(=CPh$_2$)CH$_3$](THF)$_2$ (**7**) and [(dpp-bian)(H)]Mg(camphor)(py)$_2$ (**8**) were prepared by treating (dpp-bian)Mg(THF)$_3$ (**1**) with equimolar amounts of dibenzyl ketone, 1,1-diphenylacetone and camphor, respectively. Single-crystal X-ray structure analyses showed these enolates to be five-coordinate, trigonal bipyramidal magnesium complexes with terminal, nonbridging enolate ligands. In solutions of **6** and **7** the proton, which in the solid-state is attached to only one of the two nitrogen atoms of the dpp-bian ligand, is delocalised between both nitrogen atoms.

Introduction

Besides fundamental chemical knowledge, the chemistry of metal complexes prepares the way for applied material science, bioinorganic and synthetic organic chemistry. Traditionally, metal complexes have been widely used in organic synthesis[1] and, so far, this area of research has not lost its topical interest. Nowadays, it is difficult to find a complex organic molecule, the synthesis of which does not involve transition metal mediated key steps.[2] The electronic differences between transition and non-transition metal atoms cause the differences in the reactivity of their corresponding organic complexes. In general, the main group metals hold quite distinct oxidation states in their complexes, thus preventing oxidative addition and reductive elimination processes which play a very important role in transition metal chemistry. The application of organometallic compounds of the alkali, alkaline earth and group 13 metals in organic synthesis is primarily based on their ability to transfer organic groups, whereas transition metal complexes are mainly used in transformation reactions of various organic molecules including catalytic processes.

A short time ago, we became interested in the preparation of main group metal complexes which would be able to compete with the reactivity modes of transition metal complexes. The idea was to design a complex in which the central main group metal atom with all its advantages such as Lewis acidity, vacant coordination sites and ability to form thermodynamically stable but reactive metal-to-carbon bonds, is coordinated by a ligand which would adopt certain features of transition metals especially their oxidative and reductive power and their ability to add protons, Lewis acids and Lewis bases. Ligands which meet these requirements to a high degree are the 1,2-bis(arylimino)-acenaphthenes. These ligands possess (a) a conformationally rigid, chelating diimine fragment, (b) lone pairs of electrons at the nitrogen atoms capable of coordinating to metals or capturing protons, and (c) a conjugated π system acting as an electron tank.

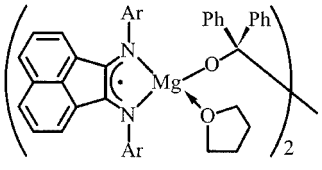
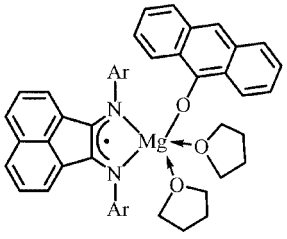
During the last decade, 1,2-bis(arylimino)acenaphthens have been used in transition metal chemistry as ancillary ligands. The corresponding nickel and palladium complexes show high catalytic activity in a number of important organic reactions including the polymerisation of olefins.[3] Very recently, we reported several alkali,[4a,4b] alkaline earth[4c–4e] and germanium(II) complexes[4f,4g] with different charged 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene (dpp-bian) anions as ligands. Following our initial idea that dpp-bian complexes of the main group metals might show unique reactivity, we began to study the reactions of (dpp-bian)Mg(THF)$_3$ (**1**), a complex which is easy to prepare from activated magnesium and dpp-bian in THF[4c] with organic substrates. We were able to demonstrate that **1** reduces diphenyl ketone with simultaneous oxidation of the dianionic dpp-bian ligand to a radical-anionic ligand, thus affording the pinacolate complex [(dpp-bian)$^{\bullet-}$Mg(THF)]$_2$-[μ-$O_2C_2Ph_4$] (**2**).[5a] On the other hand, the reaction of **1** with 9(10*H*)-anthracenone causes deprotonation of the respective phenolic tautomer yielding the 9-anthracenolato complex [(dpp-bian)$^{\bullet-}$Mg($OC_{14}H_9$)$(THF)_2$] (**3**).[5a]

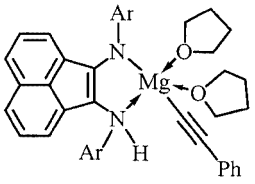


2

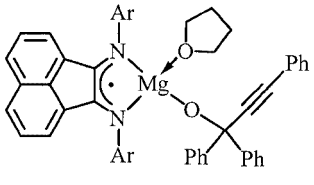


3

Owing to the Lewis basicity of **1**, it also adds phenylacetylene to give the phenylethynyl derivative [dpp-bian(H)]-Mg(C≡CPh)$(THF)_2$ (**4**) which in turn reacts with diphenyl ketone with insertion into the magnesium carbon bond, elimination of the *N*-bonded hydrogen and oxidation of the dianionic dpp-bian ligand to the radical anion affording the carbonilate (dpp-bian)$^{\bullet-}$Mg[OC(Ph_2)CCPh](THF) (**5**).[5b]



4

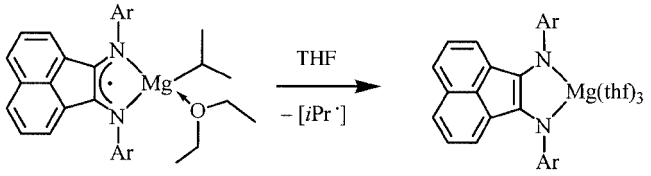


5

Recently we observed the unprecedented elimination of isopropyl radicals from (dpp-bian)$^{\bullet-}$(MgPr-*i*)(Et_2O) accompanied by the reduction of the radical anionic dpp-bian ligand to the dianion.[5c]

From the short survey of the reactivity of **1** given above the following two important conclusions can be drawn: (1) in all the reactions the dpp-bian ligand remains coordinated to the metal and (2) the reactions occur not only at the metal but also at the ligand.

Continuing our studies on the reactivity of **1** towards organic substrates, we report in this paper the reactions of **1** with aliphatic ketones containing C–H bonds in α-position to the carbonyl group.



1

Results and Discussion

Reactions of Enolisable Ketones with (dpp-bian)Mg(THF)$_3$ (1)

Complex **1**, prepared by treating activated magnesium metal with dpp-bian in THF,[4c] was used in situ for the reactions with ketones. Addition of one equiv. of acetone, butan-2-one, or pentan-3-one to THF solutions of **1** caused a quick colour change from deep green to deep blue. Unfortunately, we did not succeed in isolating these products since they are highly soluble in THF and aromatic solvents and too little soluble in Et_2O and hexane. Attempts to isolate the products from THF/hexane or THF/Et_2O resulted in their decomposition into dpp-bian$(H)_2$ and colourless, insoluble solids. However, since a similar change in colour from green to blue was observed in the reaction of **1** with phenylacetylene yielding **4**, it can be suggested that the reactions proceed in a comparable way by protonation of one of the two nitrogen atoms of the dpp-bian ligand and attachment of the respective enolate anion to magnesium. Fortunately, the reactions of **1** with equimolar amounts of dibenzyl ketone, 1,1-diphenylacetone and camphor in THF allowed the successful isolation of the enolates [(dpp-bian)-(H)]Mg[OC(=CHPh)CH_2Ph]$(THF)_2$ (**6**), [(dpp-bian)(H)]-Mg[OC(=CPh_2)CH_3]$(THF)_2$ (**7**) and [(dpp-bian)(H)]-Mg(camphor)$(py)_2$ (**8**), respectively (Scheme 1). In the case of the reaction of **1** with dibenzyl ketone and 1,1-diphenylacetone, the colour of the reaction mixture immediately changed from green to deep blue, whereas in the reaction with camphor the respective change in colour was not to observed until the mixture was heated to 60 °C for some minutes. Using two equiv. of the ketone caused a violet colour which might indicate double protonation of the ligand forming the diimine (dpp-bian)H_2.

Compounds **6** and **7** were crystallised from diethyl ether and isolated in yields of 72 and 79%, respectively, as deep blue, almost black crystals. The crude camphor derivative was treated first with pyridine and then crystallised from benzene affording **8** in 43% yield. In the solid-state as well as in solution **6**–**8** are extremely sensitive towards moisture and air but thermally quite stable. They decompose (**6**) or melt (**7**, **8**) above 115 °C and are stable in THF at reflux for several minutes. The single-crystal X-ray structure determinations indicated the formation of magnesium enolates each supported by a dpp-bian amido/amino ligand. The ^1H

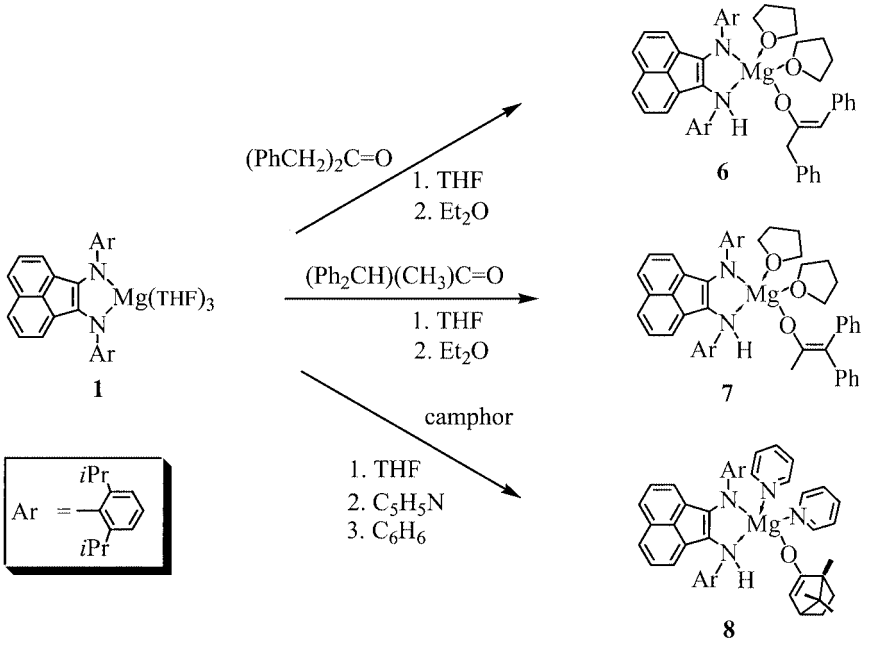

Scheme 1.

NMR spectra of **6** and **7** discussed below indicate delocalisation of the amino hydrogen in solution between both nitrogen atoms.

Henderson and co-workers reported the formation of magnesium enolates by amine elimination from enolisable ketones and magnesium amides such as iPr$_2$NMgBr, (iPr$_2$N)$_2$Mg, and [(Me$_3$Si)$_2$N]$_2$Mg.[6] Since both nitrogen atoms of the dpp-bian ligand in **1** and **6**–**8** are part of a conformationally rigid chelating system, an amine elimination cannot take place. Despite the protonation of one of the nitrogen atoms of the dpp-bian system in **6**, **7** and **8**, the system still acts as a chelating ligand.

Molecular Structures of 6, 7 and 8

The molecular structures of **6**, **7** and **8** are depicted in Figures 1, 2 and 3, respectively. The crystallographic, collection and structure refinement data are listed in Table 1, selected bond lengths and bond angles are collected in Table 2.

The magnesium atoms in the molecules of the complexes **6**, **7** and **8** are five-coordinate with slightly distorted trigonal bipyramidal geometries. In **6** and **7** the axial positions of the bipyramids are occupied by the atoms N(2) and O(3) and in **8** by the atoms N(2) and N(4). The angles between the axially positioned atoms are 177.32(13)° in **6**, 176.09(7)° in **7**, and 172.22(8)° in **8**. The significant differences in the lengths of the two Mg–N bonds in **6**, **7** and **8** [**6**: Mg–N(1), 2.066(3) Å, Mg–N(2), 2.369(4) Å; **7**: Mg–N(1), 2.051(2) Å, Mg–N(2), 2.410(2) Å; **8**: Mg–N(1), 2.055(2) Å, Mg–N(2), 2.436(2) Å] reflect the different strengths of the metal coordination to the amido [N(1)] and the amino functions [N(2)]. The long Mg–N(2)(amino) bonds are always to the N atoms in the axial positions. The differences between the

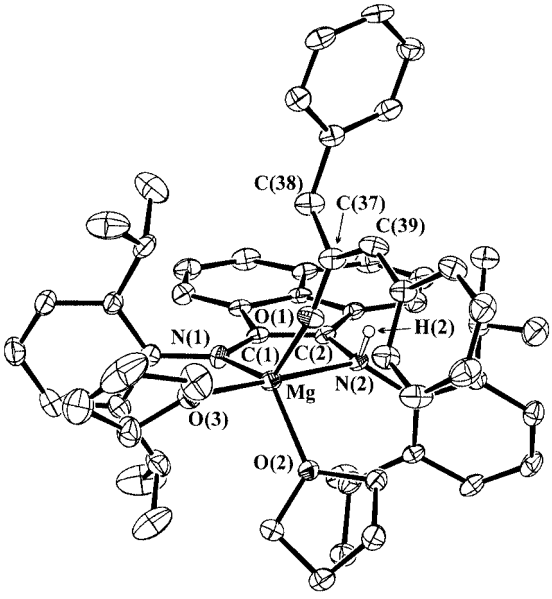

Figure 1. ORTEP drawing of **6** with thermal ellipsoids drawn at the 30% probability level. Hydrogen atoms with the exception of H(2) are omitted for clarity.

N(amido)–metal and the N(amino)–metal distances correspond well with those found for **4** (2.355 and 2.045 Å), obtained by addition of phenylacetylene to **1**.[5b] The short amido Mg–N(1) bonds in **6**, **7** and **8** are close to the Mg–N bond lengths in the starting complex **1** (2.045 and 2.105 Å).[4c] In **6** as well as in **7**, the Mg–O(2) bond of the equatorially positioned THF molecule is shorter than the Mg–O(3) bond to the THF molecule situated in the axial position [**6**: Mg–O(2) 2.075(3), Mg–O(3) 2.114(3) Å; **7**: Mg–O(2) 2.042(2), Mg–O(3) 2.137(2) Å]. The difference in the lengths of the Mg–N coordination bonds of the two equato-

rially and axially positioned pyridine molecules in **8** is far less pronounced [Mg–N(3) 2.151(2) and Mg–N(4) 2.195(2) Å]. In **6**, **7** and **8** the enolate ligand and the amine hydrogens H(2) are located on the same side of the plane formed by the metallacycle Mg–N(1)–C(1)–C(2)–N(2). The torsion angles H(2)–N(2)–Mg–O(1) are 7.0° (**6**), 17.2° (**7**) and 8.1° (**8**), respectively. Whereas the enolate group in the four magnesium enolates studied crystallographically up to now – [{*t*Bu(CH$_2$)CO}MgBr{(Me$_2$N)$_3$PO}]$_2$,[6a] [Mes(CH$_2$)CO]$_8$Mg$_4${OC(Mes)(Me)}$_2$,[6c] [{*t*Bu(CH$_3$CH)CO}MgBr(Et$_2$O)]$_2$[7a] and [{CH(CMeN-C$_6$H$_3$-2,6-*i*Pr$_2$)$_2$}Mg(μ-OC$_6$H$_9$)]$_2$[7b] – is acting as a μ$_2$-bridging ligand, the enolate group in **6**, **7** and **8** is a terminal group. This is clearly due to steric crowding imposed by the 2,6-diisopropylphenyl substituents on the nitrogen atoms of the ligand. The terminal Mg–O(1) bonds are 1.902(3), 1.921(2) and 1.890(2) Å for **6**, **7**, and **8**, respectively, and are somewhat shorter than the Mg–O(μ$_2$-enolate) bonds in two of the above mentioned magnesium enolates [{*t*Bu(CH$_2$)CO}MgBr{(Me$_2$N)$_3$PO}]$_2$ [1.956(4) and 1.981(4) Å][6a] and [{CH(CMeNC$_6$H$_3$-2,6-*i*Pr$_2$)$_2$}Mg(μ-OC$_6$H$_9$)]$_2$ [1.970(2) and 1.994(2) Å].[7b] The carbon-carbon double bonds formed as a consequence of the enolisation of the ketones are longer in **6** and **7** [C(37)–C(39): 1.368(6) (**6**), 1.373(3) Å (**7**)] than in **8** [C(47)–C(48) 1.333(4) Å] probably due to π conjugation of those double bonds in **6** and **7** with the phenyl rings of the dpp-bian unit. The conjugation is evident from the small dihedral angle of only 0.6° between the plane formed by the phenyl ring attached to C(39) and the plane formed by O(1)–C(37)–C(39).

^{1}H NMR Spectroscopic Studies on Solutions of 6 and 7

As indicated by the X-ray structural analyses, the molecules of **6**, **7** and **8** exhibit asymmetric amido/amino structures in the solid-state. Proceeding on the assumption that this general molecular structure will be maintained in solution, the ^{1}H NMR spectra of the compounds should reveal nonequivalence for all aromatic ring protons as well as for the four methine protons and the eight CH$_3$ groups of the isopropyl substituents at the phenyl groups of the dpp-bian ligand. It was expected, however, that in analogy to the ^{1}H NMR spectroscopic results obtained for the closely related compound [(dpp-bian)(H)]Mg(C≡CPh)(THF)$_2$ (**4**), the complexes **6** and **7** would adopt more symmetric structures in solution with the amino hydrogen not being fixed at one dpp-bian nitrogen atom but being delocalised between both nitrogen atoms of the ligand. Such a fast proton transfer (on the NMR time scale) between both nitrogen atoms results in a general structure with a plane of symmetry bisecting the N–Mg–N angle thus dividing the dpp-bian ligand into two equal parts. The ^{1}H NMR spectra of **6** and **7** are depicted in the supporting information.

According to our expectations, the ^{1}H NMR spectrum of **6** in [D$_8$]toluene revealed two septets for the methine protons centred at δ = 3.97 and 3.32 ppm. The low field signal overlaps with the THF signal at δ = 3.39 ppm but can be clearly assigned by means of the ^{1}H ^{1}H COSY spectrum. Each septet has cross peaks with two pairs of doublets in the range of δ = 1.4 to 1.0 ppm which can be assigned to the methyl protons and appear together with signals of THF and Et$_2$O. The signal of the delocalised N–H proton appears as a singlet at δ = 6.10 ppm and overlaps partially with a doublet signal of the aromatic protons at δ = 6.15 ppm. The protons of the CH and CH$_2$ groups of the enolate ligand give rise to singlets at δ = 5.31 and 3.53 ppm, respectively.

In agreement with the spectroscopic results obtained for **6**, the ^{1}H NMR spectrum of **7** in [D$_8$]THF shows two septets for the isopropyl methine protons at δ = 3.79 and 3.67 ppm, four doublets for the protons of the isopropyl methyl groups at δ = 1.30, 1.22, 0.98 and 0.92 ppm, a singlet

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for the protons of the CH_3 group of the enolate ligand at δ = 1.99 ppm and a singlet separated from other resonances for the delocalised NH proton at δ = 6.42 ppm. The ^1H NMR spectra of **6** and **7** indicate the presence of small amounts of (dpp-bian)H_2 probably due to partial hydrolysis of the compounds during sample preparation.

Conclusions

We have been able to demonstrate that the recently prepared magnesium complex (dpp-bian)Mg(THF)$_3$ containing the dianionic 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene ligand can serve as an enolising reagent towards aliphatic ketones such as dibenzyl ketone, 1,1-diphenylacetone or camphor. In contrast to the reactions of magnesium amides with enolisable ketones which proceed with amine elimination,[6] the above reactions proceed by addition of the enols with formation of magnesium enolate bonds and simultaneous protonation of one of the acenaphthene nitrogen atoms of the stabilising ligand. These reactions are the first examples of such a reaction pathway in transition as well as non-transition metal chemistry. The magnesium enolates [dpp-bian(H)]MgOR formed from dibenzyl ketone and 1,1-diphenylacetone are labile in solution. The proton attached only to one nitrogen atom of the dpp-bian ligand in the solid-state is delocalised between the two nitrogen atoms of the ligand in solution. We intend to investigate the potential of the compounds reported here as reagents for aldol reactions.

Experimental Section

General Remarks: All manipulations were carried out under vacuum using Schlenk ampoules. The solvents THF and diethyl ether were dried by distillation from sodium benzophenone. The deuterated solvents [D_8]THF (Aldrich) and [D_8]toluene (Aldrich) used for the NMR measurements were dried with sodium benzophenone at ambient temperature and, just prior to use, condensed under vacuum into the NMR tubes already containing the respective compound, the spectrum of which could then be recorded. Melting points were measured in sealed capillaries. 1,2-Bis[(2,6-diisopropylphenyl)imino]acenaphthene was prepared according to the published procedure.[8] The IR spectra were recorded on a Specord M80 spectrometer and the ^1H NMR spectra on a Bruker DPX-200 NMR spectrometer.

(dpp-bian)Mg(THF)$_3$ (1): Magnesium shavings (2.4 g, 100 mmol) and CH_2I_2 (0.8 g, 2.98 mmol) were placed in a Schlenk-like ampoule (ca. 100 mL volume) equipped with a Teflon stopcock. After evacuation of the ampoule (at 10^{-1} Torr for ca. 1 min), THF (40 mL) was added by condensation and the mixture was stirred for 2 h. The $MgI_2(THF)_n$ formed was decanted together with the

solvent and the residual metal was washed three times with THF (40 mL). A suspension of dpp-bian (0.5 g, 1.0 mmol) in THF (30 mL) was then added to the activated magnesium metal and the mixture was heated to reflux. Over the course of about 30 min, the reaction mixture turned deep green due to the formation of **1**. The solution was then cooled to ambient temperature, decanted from the excess magnesium and used in situ for the reactions with ketones.

[(dpp-bian)(H)]Mg[OC(=CHPh)CH$_2$Ph](THF)$_2$ (6): To a THF solution of **1** [prepared from 0.5 g (1.0 mmol) of dpp-bian in 30 mL THF] was added dibenzyl ketone (0.21 g, 1.0 mmol) with stirring. The solution immediately turned deep blue. Evaporation of the solvent and crystallisation of the crude product from diethyl ether (40 mL) at room temperature yielded 0.66 g (72%) of **6**(Et$_2$O)$_{0.5}$ as deep blue crystals. M.p. >115 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1580 (s), 1510 (s), 1405 (m), 1315 (m), 1290 (w), 1240 (m), 1180 (s), 1110 (w), 1080 (w), 1040 (w), 1012 (m), 935 (w), 920 (w), 905 (m), 895 (m), 870 (s), 825 (m), 805 (w), 770 (s), 745 (s), 695 (s), 660 (w), 620 (w), 565 (w), 515 (m), 465 (m), 420 (w) cm^{-1}. ^{1}H NMR (200 MHz, [D$_8$]toluene, 20 °C): δ = 7.56 (d, J = 6.8 Hz, 2 H, C–H Ar.), 7.33–6.76 (m, 18 H, C–H Ar.), 6.38 (d, J = 7.0 Hz, 1 H, C–H Ar.), 6.15 (d, J = 6.5 Hz, 1 H, C–H Ar.), 6.10 (s, 1 H, N–H), 5.31 (s, 1 H, C*H*Ph), 3.97 [sept, J = 6.8 Hz, 2 H, C*H*(CH$_3$)$_2$], 3.53 (s, 2 H, C*H*$_2$ Ph), 3.39 (m, 8 H, α-THF), 3.32 [sept, 2 H, C*H*(CH$_3$)$_2$], 3.23 (q, 4 H, Et$_2$O), 1.32 [d, J = 6.8 Hz, 6 H,CH(C*H*$_3$)$_2$], 1.24–1.09 (m, 8 H, β-THF; 12 H, CH(C*H*$_3$)$_2$; 6 H, Et$_2$O), 1.03 (d, J = 6.8 Hz, 6 H, CH(C*H*$_3$)$_2$). C$_{59}$H$_{70}$MgN$_2$O$_3$·(C$_4$H$_{10}$O)$_{0.5}$ (916.58): calcd. C 79.94, H 8.25; found C 80.03, H 8.14.

[(dpp-bian)(H)]Mg[OC(=CPh$_2$)CH$_3$](THF)$_2$ (7): Diphenylacetone (0.21 g, 1.0 mmol) was added with stirring to a THF solution of **1** (prepared in situ from 0.5 g (1.0 mmol) of dpp-bian in 40 mL THF). The solution instantly turned deep blue. The residue remaining after removal of the solvent in vacuo was crystallised from diethyl ether (40 mL) affording 0.72 g (79%) of **7**(Et$_2$O) as deep blue crystals. M.p. 142–144 °C. IR (Nujol): $\tilde{\nu}$ = 1560 (s), 1515 (s), 1330 (m), 1290 (m), 1275 (m), 1240 (m), 1185 (s), 1170 (m), 1105 (s), 1080 (w), 1045 (w), 1030 (m), 1010 (s), 970 (m), 935 (w), 915 (w), 865 (s), 835 (m), 815 (w), 800 (w), 760 (s), 700 (vs), 660 (w), 615 (m), 570 (w), 525 (m), 500 (m), 485 (m) cm^{-1}. ^{1}H NMR (200 MHz, [D$_8$]THF, 20 °C): δ = 7.37–6.67 (m, 20 H, C–H Ar.), 6.42 (s, 1 H, N–H), 5.96 (d, J = 7.0 Hz, 1 H, C–H Ar.), 5.75 (d, J = 6.3 Hz, 1 H, C–H Ar.), 3.79 [sept, J = 6.8 Hz, 2 H, C*H*(CH$_3$)$_2$], 3.67 [sept, J = 6.8 Hz, 2 H, C*H*(CH$_3$)$_2$] 3.39 [q, J = 7.0 Hz, 4 H, (CH$_3$C*H*$_2$)$_2$O], 1.99 (s, 3 H, C*H*$_3$), 1.30 [d, J = 6.8 Hz, 6 H, CH(C*H*$_3$)$_2$], 1.22 [d, J = 6.8 Hz, 6 H, CH(C*H*$_3$)$_2$], 1.10 [t, J = 7.0 Hz, 6 H, (C*H*$_3$CH$_2$)$_2$O], 0.98 [d, J = 6.8 Hz, 6 H, CH(C*H*$_3$)$_2$], 0.92 [d, J = 6.8 Hz, 6 H, CH(C*H*$_3$)$_2$]. C$_{59}$H$_{70}$MgN$_2$O$_3$·(C$_4$H$_{10}$O) (953.60): calcd. C 79.35, H 8.46; found C 79.72, H 8.61.

[(dpp-bian)(H)]Mg(camphor)(py)$_2$ (8): Camphor (0.15 g, 1.0 mmol) was added with stirring to a THF solution of **1** [prepared in situ from 0.5 g (1.0 mmol) of dpp-bian in 40 mL THF]. The solution was heated to 60 °C for 1 h. During heating, the solution turned deep blue. The solvent was then removed in vacuo and the residue was dissolved in pyridine (10 mL). After removal of pyridine and all other volatiles in vacuo, a waxy residue remained which was dried in vacuo at room temperature for 1 h. Subsequently the solid was dissolved in benzene (20 mL). The resultant solution was concentrated to 10 mL in vacuo at 50 °C. Crystallisation at room temperature afforded 0.37 g (43%) of **8**(C$_6$H$_6$)$_{0.5}$ as deep blue crystals. M.p. 172–174 °C. C$_{56}$H$_{66}$MgN$_4$O·0.5(C$_6$H$_6$) (874.40): calcd. C 81.03, H 7.95; found C 81.38, H 8.09. IR (Nujol): $\tilde{\nu}$ = 1595 (vs), 1510 (s), 1325 (m), 1305 (w), 1240 (m), 1190 (s), 1135 (w), 1100 (m), 1060 (m), 1035 (m), 1005 (w), 970 (w), 930 (w), 905 (m), 880 (m), 860 (w), 830 (w), 815 (w), 800 (w), 770 (s), 745 (s), 700 (s), 675 (s), 455 (m) cm^{-1}.

Single Crystal X-ray Structure Determinations of 6, 7 and 8: The crystal data and details of data collection are given in Table 1, selected bond lengths and bond angles are collected in Table 2. The data for **6** were collected on a Siemens SMART CCD diffractometer (graphite-monochromated Mo-K_α radiation, ω-scan technique, λ = 0.71073 Å) at 173 K. The data for **7** and **8** were collected on a Bruker SMART APEX diffractometer (graphite-monochromated Mo-K_α radiation, ω- and Φ-scan technique, λ = 0.71073 Å) at 100 K. The structures were solved by direct methods using SHELXS-97[9] and were refined on F^2 using SHELXL-97.[10] All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 Å^2. SADABS[11] was used to perform area detector scaling and absorption corrections. The geometrical aspects of the structures were analysed by using the PLATON program.[12] CCDC-259974 (for **6**), -259975 (for **7**) and -259976 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information Available: ^{1}H NMR spectra of **6** and **7**.

Coordination Assembly of TTF Derivatives through CuI Bridges

Wen Lu,[a] Zhe-Min Yan,[a] Jie Dai,*[a–c] Yong Zhang,[a] Qin-Yu Zhu,[a] Ding-Xian Jia,[a] and Wen-Juan Guo[a]

Keywords: Tetrathiafulvalene / Copper(I) complexes / Crystal structures / Molecular assembly

The sulfur-rich ligand $C_{12}H_{12}O_4S_6$ (**1**) and complexes $[(C_{12}H_{12}O_4S_6)CuI]_2$ (**2**) and $[(C_7H_6O_4S_3)CuI]_\infty$ (**3**) have been synthesized and characterized crystallographically. Molecules of compound **1,** a tetrathiafulvalene (TTF) derivative, have a boat-shaped configuration and are packed discretely within the crystal. Compound **1** coordinates to a rhomboid CuI center forming a dimeric TTF derivative **2**. In complex **2** the boat-shaped configuration of **1** is flattened. Molecules of **2** are packed regularly and compactly in the crystal and are arranged side by side with short S···S contacts, which assemble the molecules into a 1D ribbon structure. This provides evidence that metal coordination or assembly is a useful stratagem for changing the molecular configuration and packing that further influence the intermolecular interactions. Complex **3** has a step-like polymeric structure formed by copper-iodine bridges and copper-sulfur bridges (coordinated thiocarbonyl).

Introduction

Although tetrathiafulvalene (TTF) and its derivatives have been intensively investigated for several decades, these unique functional molecules continue to attract great attention. So far, much research on the design and preparation of dimeric and oligomeric TTFs has been reported by organic chemists. The reported dimeric TTFs can be roughly divided into two types: one is linked through conjugated π systems and the other through nonconjugated σ chains.[1–4] Recently, a new kind of dimeric TTF has been reported, in which two TTF units are connected by metal coordination. Great efforts in synthesis and characterization have revealed the wide application of TTF derivatives with additional groups having coordinating properties. The incorporation of TTF units into dithiolate ligands is one of the successful examples (see a in Scheme 1) and a series of metal coordinated bis-TTF complexes was reported by Kobayashi et al.[5–9] The metal coordination extends and enhances the π conjugation of the sulfur-rich system, and hence provides the complexes with novel conductive and magnetic properties. Furthermore, the coordination of TTF derivatives to metal ions is expected to give new bis-TTF or polymolecular systems with improved inter- or intra- molecular interactions. The synthesis of a number of metal complexes of TTF derivatives with coordinating groups of alkylthiole,[10–13] phenylphosphite,[14,15] pyridine[16–18] or alkylsilyl[19] (see b in Scheme 1) has provided insight into the role of metal ions in molecular assembly.

Scheme 1.

The synthesis and coordination properties of TTF derivatives attracted our interest.[20–22] Here, structures of dimethyl 2-[4,5-bis(methylthio)-1,3-dithiol-2-ylidene]-1,3-dithiole-4,5-dicarboxylate (**1**) and its derivatives are studied. Detailed discussions about the roles of metal coordination in the molecular assembly are presented.

Results and Discussion

Synthesis and Characterization

Some methods for synthesizing the asymmetric compound **1** have been reported.[23,24] However, the detailed procedures have only recently been reported by Hudhomme et al. and McCullough et al.[25,26] Followed these latter methods, the compound was synthesized successfully in our laboratory. The details can be found in the experimental section. Single crystals of **1** were obtained and its molecular structure was reported for the first time (see next section).

Scheme 2 exhibits the synthetic routes for compounds **1**, **2** and **3**. Compound **2** (D-σ-D type) was synthesized by refluxing a mixture of **1** and CuI in acetonitrile under argon. The inorganic-organic hybrid compound **2** was stable under ambient conditions. The cyclic voltammetry of **2** was studied in acetonitrile containing 0.1 mol dm^{-3} Et_4NClO_4. Two reversible redox peaks were detected and the results are listed in Table 1 together with the data of the free ligand **1**. The potential shift of **1** for the methylthio group coordinated with the Cu^I ion was not observed, which was different from the electrochemical behavior of the dithiolate complexes.[27] This might be a result of the complex dissociating to free ligand **1** and solvated CuI in a dilute solution of acetonitrile at a concentration of ca. 10^{-3} mol dm^{-3}. This indicates that the coordination of the methylthiol group to copper(I) is not as strong as that of thiolate. It should be also pointed out that the oxidation of Cu^I was not observed from cyclic voltammetry. In the IR spectra of **2**, the stretching band of C=C was observed at 1431 cm^{-1} with a slightly red shift compared to that of **1** at 1439 cm^{-1}. It is well known that the central C=C stretching of TTF undergoes a large down-shift in frequency on oxidation (normally more than 50–100 cm^{-1}).[28,29] Therefore, the ligand in the CuI complex is in neutral state, which is in agreement with the molecular composition deduced from microanalysis. A slightly blue shift was observed for the C=O stretching bands of the carboxyl group. The complex **3** was synthesized by a similar method to that of **2** in acetonitrile, the reaction proceeded readily at room temperature due to the strong tendency of the C=S group to coordinate to Cu^I ions. The C=S vibrational mode of complex **3** appears at 1065 cm^{-1} which is shifted to a lower frequency in comparison with that of the free ligand at 1088 cm^{-1}.

Table 1. Data from cyclic voltammetry of compound **1** and **2** in acetonitrile (V, vs. SCE).

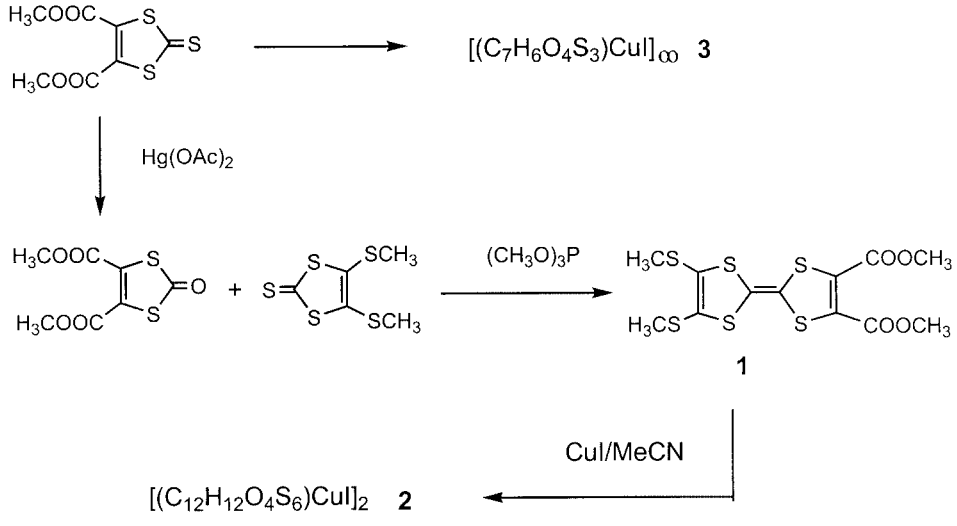
Description of Structures

$C_{12}H_{12}O_4S_6$ (1): The ORTEP view of **1** and atom labeling scheme are shown in Figure 1. Atom pair O(3)/O(3′) is presented with occupancies of 0.60 and 0.40, respectively, due to the C=O bond disorders over two orientations. The distances of the C=C double bonds are 1.344(4), 1.337(4) and 1.341(4) Å for C(1)–C(2), C(3)–C(4) and C(5)–C(6), respectively (Table 2). The central C=C bond is slightly shorter than the others. The TTF moiety takes on a boat-shaped configuration formed by three planes defined as plane 1: S(3), S(4) C(3), C(4), S(5), S(6) (central plane), plane 2: S(1), S(2) C(1), C(2), S(3), S(4) and plane 3: S(5), S(6), C(5), C(6), C(9), C(11). Their mean deviations are 0.0107, 0.0395 and 0.0389 Å, respectively. The planes 1 and 2 share a common line along S(3)–S(4) with a dihedral angle of 19.15(3)° and the planes 1 and 3 share a common line along S(5)–S(6) with a dihedral angle of 11.39(7)° (Figure 2, top). The contributions of the TTF fragment to the boat shaped configuration, are the envelope configurations, on C(3) or C(4), of both of the five-membered dithiol rings. In the crystal structure, four molecules are contained in a unit cell with different orientations, being a direct consequence of the symmetrical operation of a $P2_1/c$ (no.14) space group.



Scheme 2.

				S(1)···I(1)	3.707
		Cu(1)···Cu(1^{ii})	2.6469(15)		
		S(2)···S(6^{iii})	3.586(2)		
		S(4)···S(6^{iii})	3.599(2)		

^{i} x, 1 + y, z; ^{ii} 1 – x, 1 – y, –z; ^{iii} 1 – x, 1 – y, 1 – z; ^{iv} x – 1/2, –y + 1/2, 1 – z; ^{v} x + 1/2, –y + 1/2, 1 – z; ^{vi} x – 1/2, 3/2 – y, 1 – z

The shortest S···S distance between two molecules is 4.072 Å, significantly longer than the van der Waals radius sum (3.7 Å). Thus, the S···S interaction within this crystal is negligible.

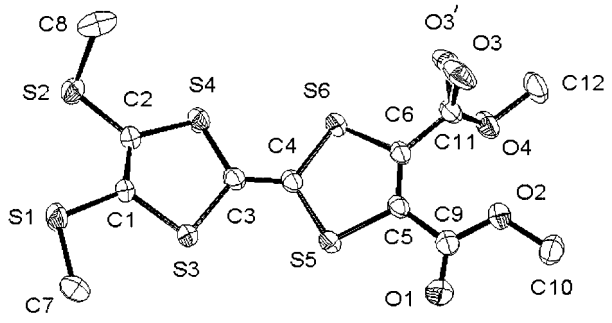

Figure 1. An ORTEP view of **1** showing the atom labeling scheme. Non-H atoms are shown as 50% probability displacement ellipsoids. H-atoms have been omitted for clarity.

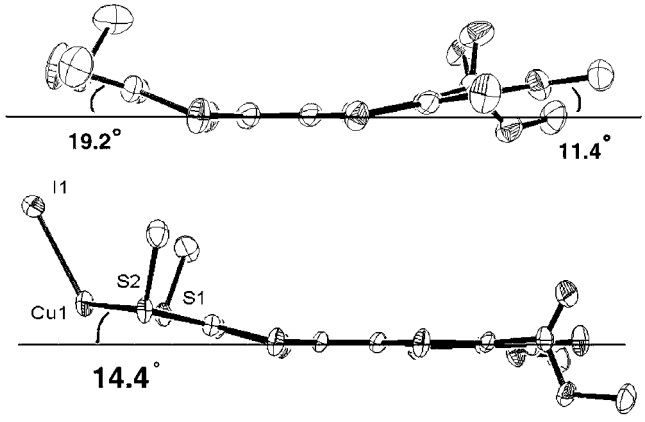

Figure 2. Side views of **1** (top) and **1**·CuI (**2**) (bottom) showing the change in the dihedral angles of the ligand.

[($C_{12}H_{12}O_4S_6$)CuI]$_2$ (2): An ORTEP view of complex **2** with atom labeling is shown in Figure 3. The methylthiol groups of ligand **1** are coordinated to the coppers of rhomboid Cu_2I_2 to produce a dimeric structure. The geometry around the copper atom is a distorted tetrahedron with an I–Cu–I angle of 118.42(3)° and S–Cu–S angle of 91.36(5)°. The Cu–I and Cu–S distances are in agreement with those of the corresponding compounds.[3,12]

Some changes are found by comparing the structures of complex **2** and the ligand **1**. When the coordination bonds are formed, the S(1)–C(1) and S(2)–C(2) distances of **1** [1.745(3) and 1.741(3) Å] are elongated to 1.763(5) and 1.760(5) Å, respectively. Correspondingly the angles of S(1)–C(1)–C(2) and S(2)–C(2)–C(1) [122.6(2) and 123.9(2)°] are enlarged to 125.6(4) and 125.1(4)°, respectively (Table 2). The boat configuration of **1** is flattened in complex **2**. The dihedral angle changes from 19.15(3)° to 14.44(5)° at the methylthio-side and on the carboxyl ester side plane 3 is completely coplanar with plane 1 (b in Figure 2). The mean deviation of the new plane, C(3)–C(6), S(3)–S(6), C(9), C(11), is 0.0269 Å. These changes enhance the delocalization of the conjugated π electrons of the TTF derivative.

The boat-shaped configuration might be one of the important reasons for the discrete packing of **1** (no S···S contacts). However, the molecular packing of **2** is very regular and compact. The bis-TTF compound approximately resembles a planar ruler and twelve sulfur atoms lie on the sides. The molecules are further arranged side by side and S···S contacts are shown between S(2), S(6^{iii}) (3.586(2) Å, iii: 1 – x, 1 – y, 1 – z) and S(4), S(6^{iii}) [3.599(2) Å], which assembles the molecules into a 1D ribbon structure along the [001] direction (Figure 4). Sulfur atoms from two neighboring molecules are alternately contacted as an occluded slide fastener. Between these ribbons, only weak C–H···O and C–H···I interactions are found.

A similar compound was reported by Delhaès,[30] who studied the crystal structure and properties of the radical salt, but unfortunately the chemical composition of those radical salts were not characterized. However, the crystal structure of the neutral complex can be compared with that

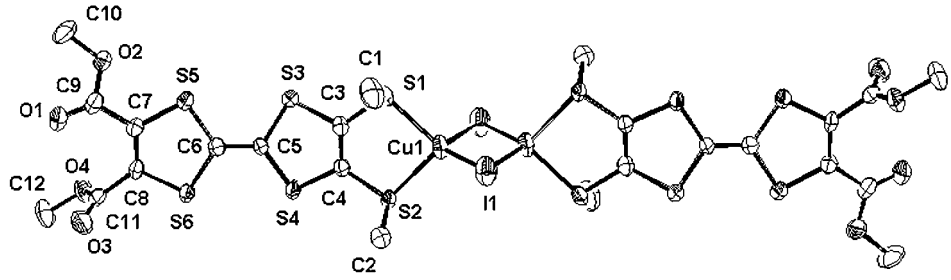

Figure 3. An ORTEP view of **2** showing the atom labeling scheme. Non-H atoms are shown as 50% probability displacement ellipsoids. H-atoms have been omitted for clarity.

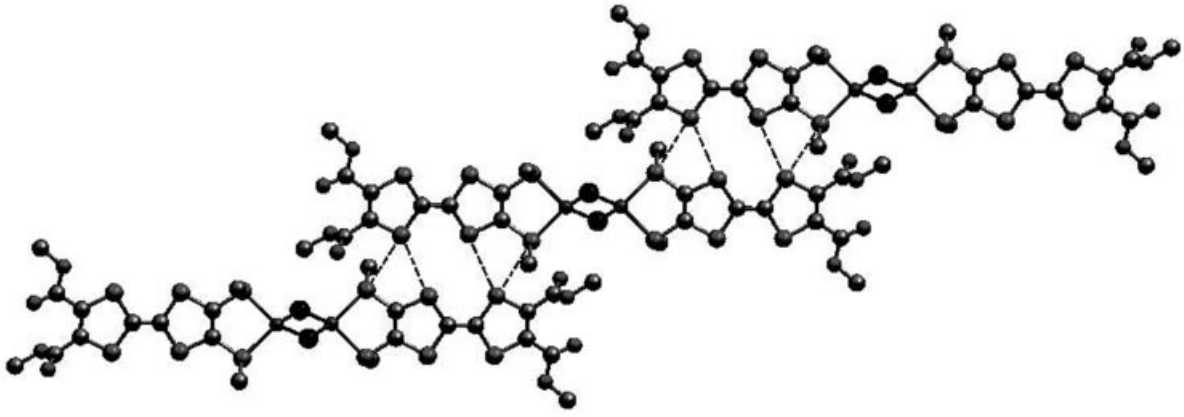

Figure 4. Part of an intermolecular contacts assembled ribbon. Dashed lines are used to represent short S···S contacts.

of **2**. Although the difference between these two molecules is only at the terminal substituted groups, ethylenedithiol group instead of di(methyl carboxylate) of **2**, the crystal systems and molecular packing of them are completely different from each other.

$[(C_7H_6O_4S_3)CuI]_\infty$ (3): Figure 5 gives the ORTEP view of the unit of complex **3** with selected atom labeling. The geometry around the copper atom is a distorted tetrahedron with three iodide ions and a thiocarbonyl sulfur atom from the ligand. Through iodine bridges, the $C_7H_6O_4S_3CuI$ units form a step-like polymeric structure (or chain) propagated in the direction of the *a* axis (Figure 6). The Cu(1)–I(1) distance, 2.6223(7) Å, for **3** is somewhat shorter than those for $[(C_5H_4S_5)CuI]$[31] and $[(C_5H_6S_5)CuI]$,[32] sulfur-rich complexes with ligands of 4,5-bisalkylthiol-1,3-dithiole-2-thione. The Cu–S (thiocarbonyl sulfur) distance of 2.2806(11) Å and the S(1)=C(1) distance of 1.653(4) Å are within the expected values for these kinds of CuI complexes.[13,14]

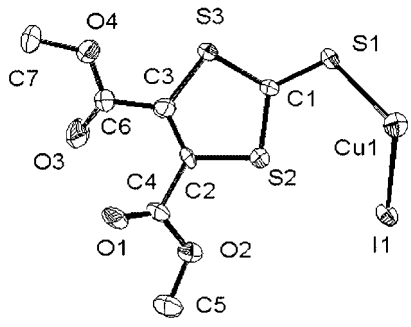

Figure 5. An ORTEP view of **3** showing the atom labeling scheme. Non-H atoms are shown as 50% probability displacement ellipsoids. H-atoms have been omitted for clarity.

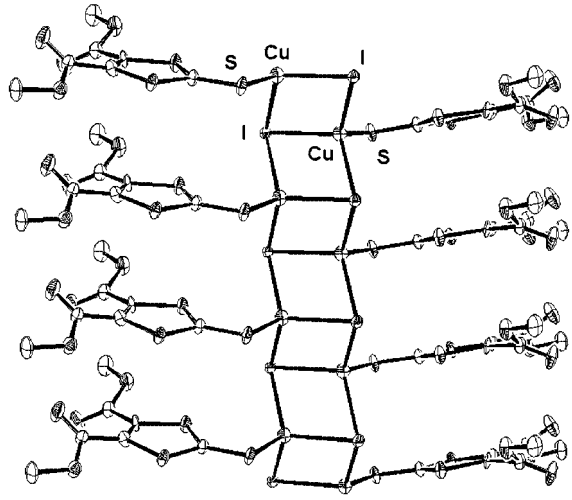

Figure 6. The $C_7H_6O_4S_3CuI$ units of **3** form a step-like chain structure propagated in the direction of the *a* axis.

Unlike $[(C_5H_6S_5)CuI]$, no significant S···S contacts exist between the ligands within the chains, however short interchains, S···S contacts, occur between S(1) and S(3^{vi}), 3.591(3) Å (vi: $x - 1/2, 3/2 - y, 1 - z$). With these contacts,

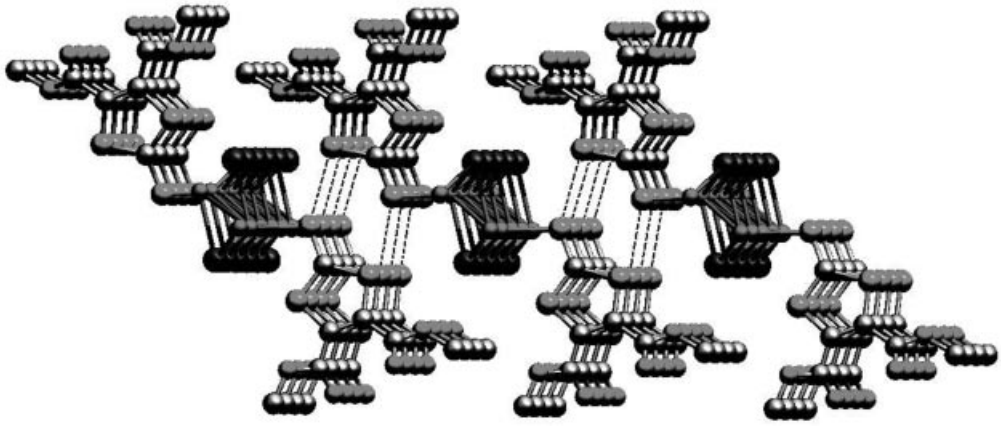

Figure 7. The representation shows the short S···S contacts (dashed lines) between the 1D chains, viewed along the direction of the chains.

a novel two-dimensional network is formed. Figure 7 shows the molecular packing and the intermolecular S···S contacts, when looking along the *a* axis.

Conclusions

Although the copper halogen frameworks are dramatically changed due to the coordination of different halogen ions and other ligands, only two types of CuI coordination centers, rhomboid and step-like structures, have been reported for sulfur-rich compounds (TTF derivatives).[3,31,32] The thiocarbonyl sulfur coordination usually produces step-like structures, whereas the chelate coordination of *ortho*-bis(alkylthiol) groups prefer a rhomboid structure. The Cu–S (thiocarbonyl) coordination bond is stronger than the Cu–S (methylthio) bond. In the case where both groups exist, the thiocarbonyl group predominantly coordinates to Cu^{I}, giving a step-like polymeric structure.[32] Both the change in the substituted groups, and also metal coordination are useful stratagems for rearranging the molecular packing, which further influences the intermolecular interactions of the TTF derivatives. Besides the molecular packing, the configuration of the TTF moiety is also affected by these stratagems. The room temperature conductivity (σ_{RT}) of I_2 doped **2** (1.0×10^{-3} S cm^{-1}) is one order of magnitude greater than that of the I_2 doped ligand **1** (2.0×10^{-4} S cm^{-1}), under the same conditions. The results also illustrate the effects of metal coordination on the molecular arrangement and the intermolecular interactions in crystals.

Experimental Section

General Remarks: The reagents, 4,5-bis(methylthio)-1,3-dithiole-2-thione ($C_5H_6S_5$), dimethyl 2-thioxo-1,3-dithiole-4,5-dicarboxylate ($C_7H_6O_4S_3$) and dimethyl 2-oxo-1,3-dithiole-4,5-dicarboxylate ($C_7H_6O_5S_2$), were prepared according to the literature.[33–35] Acetonitrile was dried by a standard method and distilled before use. Elemental analyses of C, H and N were performed with an MOD 1106 elemental analyzer. The IR spectra were recorded as KBr discs on a Nicolet Magma 550 FT-IR spectrometer. ^{1}H NMR spectra were recorded with an INOVA-400 spectrophotometer. Cyclic voltammetry (CV) was performed with a model CHI600 electrochemistry workstation, with a cell containing a Pt plate as the working electrode, a Pt wire as the counter electrode and saturated calomel electrode (SCE) as a reference electrode. The electrical conductivity was measured with a conventional two-probe method at room temperature with compressed discs.

Synthesis of Compounds

$C_{12}H_{12}O_4S_6$ (1): The compound was synthesized by a coupling reaction from 4,5-bis(methylthio)-1,3-dithiole-2-thione ($C_5H_6S_5$) and dimethyl 2-oxo-1,3-dithiole-4,5-dicarboxylate ($C_7H_6O_5S$), using a similar method to that reported.[25,26] A mixture of the reactants (1 mmol, respectively) was refluxed for 2 h in trimethyl phosphite (10 mL) and toluene (10 mL) under argon. The dark purple solution was then evaporated and the residue was purified by chromatography on a silica gel column (CH_2Cl_2). $C_{12}H_{12}O_4S_6$ (412.58) dark-red crystals, (yield: 145 mg, 35%). ^{1}H NMR: δ = 3.43 (s, CH_3S–), 3.85 (s, CH_3O–) ppm. IR: 1726 (s, C=O), 1708 (s, C=O), 1272 (s, COOC), 1438 (m, C=C) cm^{-1}; m.p. 86–87 °C; calcd. C 34.93, H 2.93; found C 34.85, H 3.06%.

$[(C_{12}H_{12}O_4S_6)CuI]_2$ (2): Ligand **1** (41.2 mg, 0.1 mmol) in acetonitrile (5.0 mL) was added to an acetonitrile solution (5.0 mL) of CuI (19.3 mg, 0.1 mmol). The mixture was stirred for 2 h while refluxing under argon. The red filtrate was evaporated slowly under ambient conditions. Orange crystals suitable for X-ray crystal determination were obtained after two days, which were filtered and washed with acetonitrile, and finally dried in vacuo (yield: 48 mg, 40%). IR: 1743 (s, C=O), 1725 (s, C=O), 1251 (s, COOC), 1431 (m, C=C) cm^{-1}. $C_{24}H_{24}O_8S_{12}Cu_2I_2$ (1206.07): calcd. C 23.90, H 2.01; found C 23.67, H 2.26%.

$[(C_7H_6O_4S_3)CuI]_\infty$ (3): A solution of the ligand $C_7H_6O_4S_3$ (25 mg, 0.1 mmol) in acetonitrile (5.0 mL) was added to an acetonitrile solution (5.0 mL) of CuI (19.1 mg, 0.1 mmol). The mixture was stirred for 30 min at room temperature under argon. The red filtrate was evaporated slowly under ambient conditions. Red crystals suitable for X-ray crystal determination were obtained after several days, which were filtered and washed with acetonitrile, and finally dried in vacuo (yield: 27 mg, 60%). IR: 1759 (s, C=O), 1728 (s, C=O), 1258 (s, COOC), 1065 (m, C=S) cm^{-1}. $C_7H_6O_4S_3CuI$ (440.75): calcd. C 19.10, H 1.38; found C 19.05, H 1.36%.

X-ray Crystallographic Study: All measurements were carried out with a Rigaku Mercury CCD diffractometer at 193 K with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. X-ray crystallographic data for compounds **1**–**3** were collected and processed

using CrystalClear (Rigaku).[36] The structures were solved by direct methods using SHELXS-97[37] and the refinements against all reflections of the compounds were performed using SHELXL-97.[38] The non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined using the theoretical riding model. A summary of the experimental details and selected results for compounds **1**–**3** is given in Table 3. The selected bond lengths and angles are listed in Table 2.

CCDC No. 256152–256154 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Measurements of Conductivity: To confirm the effect of coordination assembly, compounds **1** and **2**, as precursors, were doped by iodine using the gaseous diffusion method at 50 °C. The dark-red color of compound **2** turned gradually into black after a week. The conductivity (σ_{RT}) of the I_2 doped compound **2** was 1.0×10^{-3} S cm^{-1} which was measured by a conventional two-probe method for compacted pellets at room temperature. The conductivity of the I_2 doped ligand **1** was 2.0×10^{-4} S cm^{-1}, doped and measured under the same experimental conditions.

Bridging β-Lactam Coordination at Dinuclear Zinc Sites

Franc Meyer,*[a] and Hans Pritzkow[b]

Dedicated to Professor Heinrich Vahrenkamp on the occasion of his 65th birthday

Keywords: Dinuclear complexes / Metalloenzymes / N ligands / Pyrazolate ligands / Zinc

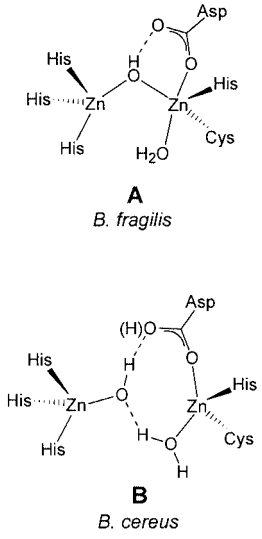
Two highly preorganized dizinc scaffolds based on compartmental pyrazolate ligands are found to incorporate 2-azetidinone in its deprotonated β-lactamide form as an N,O-bridging ligand within the dimetallic pocket. Both dizinc β-lactamide complexes **3**·$(ClO_4)_2$ and **4**·$(ClO_4)_2$ have been characterized structurally and spectroscopically, revealing a strengthening of the β-lactamide C–N bond and a weakening of the C=O bond relative to free 2-azetidinone. These findings contrast the reverse geometrical changes observed recently by Brombacher and Vahrenkamp for β-lactamide *N*-bound to only a single zinc ion, thus underlining the particular dimetallic effect that is achieved by the cooperativity of two adjacent metal ions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

β-Lactamases are a class of enzymes that efficiently catalyze the hydrolytic opening of β-lactam rings.[1,2] Since the β-lactam motif is a crucial subunit of the largest group of therapeutically useful antibiotics comprising the penicillin, cephalosporin, and carbapenem families, bacteria express β-lactamases in order to escape the action of those important drugs. Nowadays, increasing resistance against β-lactam antibiotics poses a serious clinical problem.[3–5] Unfortunately, most clinically useful inhibitors are inactive towards a particular class of β-lactamases, which depend on one or two zinc(II) ions within their active site.[6–8] These so-called metallo-β-lactamases hydrolyze a wide range of substrates, and insight into the binding and transformation of β-lactam compounds by such zinc active sites is considered not only of fundamental interest, but may also contribute to the development of efficient mechanism-based inhibitors.

Detailed information about the active-site structure of several metallo-β-lactamases has been gained from X-ray crystallography and other methods, in particular for the enzymes from *Bacillus cereus* and *Bacteroides fragilis*.[8,9] The majority of these sites have similar unsymmetrical dizinc binding motifs and a shared water/hydroxide ligand in a typical bridging position (**A**),[10–15] but structural evidence has also been reported for a nonbridged form with a loose ligand arrangement and a larger Zn···Zn distance of 4.4 Å.[14] The latter configuration has been reproduced in theoretical models by an O_2H_3 unit between the two zinc ions (**B**; Scheme 1),[16] and such an O_2H_3 moiety has indeed been proposed as a possible functional motif in oligozinc hydrolases.[17–19]



Scheme 1.

Although the dizinc form of the metallo-β-lactamases from *B. fragilis* and *B. cereus* is usually considered as the biologically active form, the role of the second Zn^{2+} re-

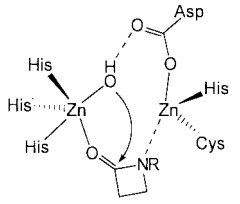
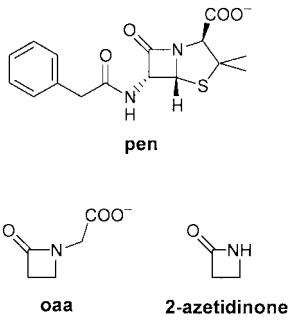
mains controversial,[20,21] and distinct mechanisms may be relevant for the mono- and dimetallic forms.[9,21–23] Details of the catalysis by dizinc metallo-β-lactamases are still a subject of debate, although it is generally postulated that interaction of the β-lactam carbonyl group with a zinc ion polarizes the C–O bond and allows nucleophilic attack by a metal-bound hydroxide ion with fission of the C–N bond. Subsequent protonation of the β-lactam N atom and dissociation of the acyl group would liberate the ring-opened product (Scheme 2).[22] A ring-opened form of the substrate has been detected as an intermediate in the hydrolysis of nitrocefin by the *B. fragilis* enzyme;[24] its identity as a zinc(II)-bound *N*-deprotonated species formed by C–N bond cleavage was corroborated by model studies.[25]



Scheme 2. Proposed β-lactam cleavage step of dizinc metallo-β-lactamase.

The pH profiles of the *B. cereus* reaction indicate that the second zinc(II) center is not required for nucleophile activation, but its role in orienting the attacking nucleophile and in stabilizing reaction intermediates has been proposed.[22,26–28] While several groups have dealt with the hydrolysis or methanolysis of β-lactams by simple transition-metal salts, including Zn^{2+} salts,[29,30] very few studies have employed preorganized dinuclear zinc(II) complexes as functional mimics of metallo-β-lactamases.[25,31–33] Such models might provide valuable insights into, inter alia, the mechanistic role of the second Zn^{2+} ion, cooperative effects of the adjacent metal ions, and possible binding modes of the substrate. Lippard et al. recently reported an in-depth study of nitrocefin hydrolysis mediated by some phenol- and naphthyridine-based dizinc complexes.[31,32] Preferential metal ion coordination of typical β-lactam substrates through a monodentate carboxylate group was inferred from ^{13}C NMR and IR spectroscopy.[31,32]

Structure–activity correlations have been deduced for the hydrolytic cleavage of penicillin G (pen; Scheme 3) mediated by a series of pyrazolate-based dizinc(II) complexes with tunable Zn···Zn distances.[33] The drastic differences in activity for the various systems were explained on the basis of the necessity of suitably oriented, accessible coordination sites that are required to bind and activate both the nucleophile and the substrate. The molecular structures of several adducts of such pyrazolate-based dizinc scaffolds with the small substrate analog oxazetidinyl acetate (oaa) confirmed that binding of the zinc ion to the carboxylate group is favored over binding to the β-lactam amide group. However, additional zinc coordination by the β-lactam amide O atom may still be induced under suitable circumstances, and was observed crystallographically for the first time in the tetranuclear complex **C** (Scheme 4), which reveals significant



Scheme 3. β-Lactams used in this and previous work with dizinc complexes **1** and **2**.

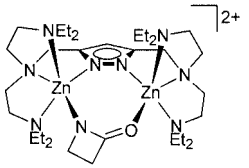
changes of the internal geometry of the β-lactam moiety that are likely to facilitate subsequent hydrolytic ring cleavage.[33]

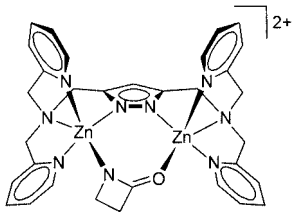
In this contribution we report the synthesis and crystallographic characterization of adducts between the most simple β-lactam, 2-azetidinone, and two highly preorganized dizinc complexes **1** and **2** (Scheme 5)[34,35] that mimic the loosely bridged type **B** form (Scheme 1) of the active site of the *B. cereus* β-lactamase.

Results and Discussion

Complexes **1** and **2** were prepared in situ from the respective ligand HL, 2 equiv. of base (KO*t*Bu), and 2 equiv. of $Zn(ClO_4)_2 \cdot 6H_2O$; 1 equiv. of 2-azetidinone was then added to the reaction mixture, and colorless single crystals of **3**·$(ClO_4)_2$·MeOH and **4**·$(ClO_4)_2$·acetone could be obtained upon recrystallization of the resulting complexes from methanol or acetone solutions, respectively (Scheme 6). The FAB mass spectra of solid samples show prominent peaks at *m*/*z* = 818 (**3**) and 786 (**4**) with an isotopic distribution pattern characteristic for the ions $[L^1Zn_2(C_3H_4NO)(ClO_4)]^+$ and $[L^2Zn_2(C_3H_4NO)(ClO_4)]^+$, respectively, suggesting the formation of 1:1 adducts between the dizinc complexes and deprotonated 2-azetidinone. The IR spectrum of **3**·$(ClO_4)_2$ reveals a strong absorption at 1606 cm^{-1} for the β-lactam $\nu(C{=}O_{amide})$ stretch, which is significantly shifted to lower frequency compared to free 2-azetidinone (IR: $\tilde{\nu}$ = 1723 cm^{-1}; Raman: $\tilde{\nu}$ = 1697 cm^{-1}).[36,37] This shift indicates Zn coordination by the lactam O atom. In the case of **4**·$(ClO_4)_2$, the $\nu(C{=}O_{amide})$ vibration cannot be identified unambiguously, since several strong bands of the pyridyl groups also appear in that region (1629, 1606, 1589, 1565 cm^{-1}). The molecular structures of **3** and **4** were elucidated by X-ray crystallography and are depicted in Figures 1 and 2, respectively.



3
d(Zn···Zn) = 4.28 Å



4
d(Zn···Zn) = 4.02 Å

Scheme 6. Complexes **3** and **4** prepared in this work.

In both cases the $\{LZn_2\}$ entities of the starting complexes **1** and **2** are fully conserved. The 2-azetidonone is

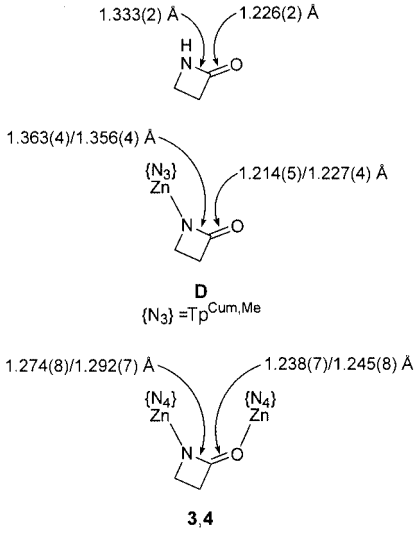
Selected interatomic distances [Å] and angles [°]: Zn1–N1 1.984(4), Zn1–N3 2.281(5), Zn1–N4 2.062(5), Zn1–N5 2.056(5), Zn1–O1 1.973(4), Zn2–N2 1.993(5), Zn2–N6 2.303(5), Zn2–N7 2.074(5), Zn2–N8 2.081(5), Zn2–N9 1.980(6), C30–O1 1.245(8), C30–N9 1.274(8); N9–C30–O1 130.9(6).

incorporated in its *N*-deprotonated lactamide form within the dimetallic pocket and bridges the two zinc ions in an N,O-fashion at a Zn···Zn distance of 4.277(1) Å (**3**) and 4.015(1) Å (**4**). A similar Zn···Zn distance of 4.180 Å was observed in a carbonato-bridged complex of a related pyrazolate ligand.[18] All zinc ions in **3** and **4** are found in a slightly distorted trigonal-bipyramidal coordination environment (**3**: τ = 0.88 for Zn1 and 0.94 for Zn2; **4**: τ = 0.90 for Zn1 and 0.87 for Zn2).[38] The bond lengths between the zinc ions and the N-donor atoms of the dinucleating ligand scaffolds L are in the normal range, with bonds between Zn and the pyrazolate N atom being the shortest [1.984(4)–2.051(3) Å] and bonds between Zn and the backbone N3/N6 atoms being the longest [2.238(4)–2.303(5) Å]. In the latter case, the Zn–N bonds *trans* to the lactamide N

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

atom are somewhat longer than those *trans* to the lactamide O atom.

The most interesting metric parameters are those of the bound β-lactamide, which can be compared to those of free 2-azetidinone[39] and to the β-lactamide subunit of a $Tp^{Cum,Me}$Zn(β-lactamide) complex **D** reported recently by Brombacher and Vahrenkamp [Scheme 7; $Tp^{Cum,Me}$ = tris(3-cumyl-5-methylpyrazolyl)borate].[40] It should be noted that no other structurally characterized zinc β-lactamide complex has been reported in the literature, and complexes featuring a bridging β-lactamide between other metal ions are very scarce.[41] In **D** the β-lactamide is bound through its N atom to a single zinc ion, while the lactamide O atom remains uncoordinated. This reduces conjugation within the amide moiety and hence leads to lengthening of the C–N bond [1.363(4)/1.356(4) Å in **D** vs. 1.333(2) Å in free 2-azetidinone] and a shortening of the C=O bond [1.214(5)/1.227(4) Å in **D** vs. 1.226(2) Å in free 2-azetidinone]. Binding of a second zinc ion to the β-lactamide O atom, as observed in complexes **3** and **4**, reverses this trend: the C–N bond is shortened [1.274(8)/1.292(7) Å] and the C=O bond is clearly elongated [1.238(7)/1.245(8) Å]. At the same time the N–C–O bond angle of 131.5(5)° (**3**) or 130.9(6)° (**4**) remains unchanged [131.7(4)/131.1(3)° in **D**]. A CSD search reveals that many organic molecules containing a β-lactam subunit have been characterized crystallographically, and both the C=O and C–N bond lengths are found to vary considerably, with most C=O bonds in the range 1.15–1.27 Å (mean value 1.207 Å) and most C–N bonds in the range 1.30–1.45 Å (mean value 1.370 Å). Overall, the lactamide ligand within the dimetallic clamp of **3** and **4** features a relatively long C=O bond and a short C–N bond that is close to the lower limit of the above range.



Scheme 7. C–N and C=O bond lengths of 2-azetidinone,[39] complex **D**,[40] and complexes **3** and **4**.

In line with these structural findings, the β-lactam ν(C=O) stretch in **D** (1709 cm^{-1}) is barely shifted from those of free 2-azetidinone, while the ν(C=O) vibrations of **3** and **4** appear at much lower frequency, as mentioned above. Apparently, changes in the β-lactam unit (and possible activation towards subsequent reactions, such as hydrolysis) differ dramatically depending on whether the β-lactamide is bound to a single or two adjacent zinc ions. Although initial experiments with **3** and **4** did not reveal any activation of the β-lactam ring towards hydrolytic cleavage (as expected due to the anionic character of the *N*-deprotonated species), the present findings once more underline the particular ability of highly preorganized dinuclear scaffolds to accommodate and polarize small substrate molecules within their dimetallic binding pocket, which is distinct from activation at a single metal ion.

Experimental Section

General Remarks: Manipulations were carried out under dry nitrogen by employing standard Schlenk techniques. Solvents were dried according to established procedures. Complexes **1** and **2** were prepared in situ starting from HL^1 and HL^2;[42,43] all other chemicals were used as purchased. Microanalyses: Mikroanalytische Laboratorien des Organisch-Chemischen Instituts der Universität Heidelberg. IR spectra: Perkin–Elmer 983G; recorded as KBr pellets. UV/Vis spectra: Perkin–Elmer Lambda 19. FAB mass spectra: Finnigan MAT 8230.

Caution! Although no problems were encountered in this work, perchlorate salts are potentially explosive and should be handled with proper precautions.

Synthesis of $[L^1Zn_2(C_3H_4NO)](ClO_4)_2$·MeOH (3): A solution of HL^1 (260 mg, 0.50 mmol) in MeOH (30 mL) was treated with 2 equiv. of KO*t*Bu (112 mg, 1.00 mmol) and 2 equiv. of $Zn(ClO_4)_2$·$6H_2O$ (372 mg, 1.00 mmol). After stirring the mixture at room temperature for 30 min, 1 equiv. of 2-azetidinone (36 mg, 1.01 mmol) was added, and stirring continued for 2 h. The reaction mixture was then concentrated to dryness and the residue was taken up in methanol (20 mL) and filtered. Layering of the resulting clear solution with diethyl ether afforded colorless crystals of the product **3**·MeOH at room temperature over a period of several days (320 mg, 67%). MS (FAB+): *m*/*z* (%) = 818 (100) $[L^1Zn_2(C_3H_4NO)(ClO_4)]^+$. IR (KBr): $\tilde{\nu}$ = 3523 (w, CH_{MeOH}), 2973 (m), 2938 (m), 2877 (m), 1606 (s, C=O), 1516 (w), 1468 (m), 1384 (m), 1348 (w), 1331 (w), 1283 (w), 1263 (w), 1225 (w), 1181 (w), 1091 (vs, ClO_4), 970 (m), 909 (m), 818 (m), 795 (m), 778 (m), 734 (m), 622 (s), 546 (w) cm^{-1}. $C_{32}H_{65}Cl_2N_9O_9Zn_2$·MeOH (953.6): calcd. C 41.56, H 7.29, N 13.22; found C 41.10, H 7.13, N 13.43.

Synthesis of $[L^2Zn_2(C_3H_4NO)](ClO_4)_2$·acetone (4): A solution of HL^2 (245 mg, 0.50 mmol) in MeOH (30 mL) was treated with 2 equiv. of KO*t*Bu (112 mg, 1.00 mmol) and 2 equiv. of $Zn(ClO_4)_2$·$6H_2O$ (372 mg, 1.00 mmol). After stirring the mixture at room temperature for 30 min, 1 equiv. of 2-azetidinone (36 mg, 1.01 mmol) was added, and stirring continued for 2 h. The reaction mixture was then concentrated to dryness and the residue was taken up in acetone (20 mL) and filtered. Layering of the resulting clear solution with light petroleum afforded colorless crystals of the product **4**·acetone at room temperature over a period of several days (180 mg, 38%). MS (FAB+): *m*/*z* (%) = 786 (10) $[L^2Zn_2(C_3H_4NO)(ClO_4)]^+$, 307 (100). IR (KBr): $\tilde{\nu}$ = 3108 (w), 3069 (w), 2957 (w), 2904 (w), 2857 (w), 1704 (m, $C{=}O_{acetone}$), 1629 (s), 1606 (s), 1589 (s), 1565 (m), 1504 (w), 1479 (m), 1438 (m), 1378 (w), 1314 (w), 1259 (m), 1218 (w), 1159 (w), 1090 (vs, ClO_4), 1024 (m), 974 (w), 954 (w), 899 (w), 880 (w), 811 (w), 768 (m), 650 (m), 622 (s), 527

X-ray Crystallographic Study: Data collection was carried out with a Bruker AXS CCD diffractometer at 173 K using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares techniques based on F^2 (SHELXL-97).[44] Atomic coordinates and thermal parameters of the non-hydrogen atoms were refined in fully anisotropic models. Hydrogen atoms were included using the riding model. Some of the ethyl groups in **3** are disordered. Crystal data and refinement details are listed in Table 1. CCDC-258281 (**3**) and -258282 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[37] The noncoincidence of the IR and Raman frequencies of the C=O stretch of 2-azetidinone has been explained by the presence of cyclic H-bonded dimers with a center of symmetry. The C=O vibration that is symmetric with respect to the center of symmetry is then observed at 1697 cm^{-1} in the Raman spectrum, while the asymmetric mode is observed at 1723 cm^{-1} in the IR spectrum.[36]
[38] The angular structural parameter, τ, is defined as $\tau = (\beta - \alpha)/60$, where α and β represent two basal angles with $\beta > \alpha$. It is a measure of the degree of trigonality: a perfect TB-5 structure is associated with $\tau = 1$, while $\tau = 0$ is expected for an idealized SPY-5 geometry: A. W. Addision, T. N. Rao, J. Freestanding, Highly Flexible, Large Area, Nanoporous Alumina Membranes with Complete Through-Hole Pore Morphology

Jörg J. Schneider,*[a] Jörg Engstler,[a] Karl P. Budna,[a,b] Christian Teichert,[c] and Steffen Franzka[d]

Keywords: Alumina / Electrochemistry / Porous template / Oxidation

Electrochemical anodic oxidation of aluminium metal sheets leads to the formation of compact and dense, but highly porous alumina surfaces on top of the anode. The alumina surfaces obtained by anodic oxidation can be detached from the bare metal by using a voltage detachment procedure, without employing chemical etching techniques. This procedure leads to large area porous alumina membranes with closed backsides. Prestructuring of the aluminium base metal leads to ordered pore regions at anodisation voltages of 25, 40 and 50 V, resulting in porous alumina membranes with pore diameters of 33, 40 and 72 nm. The careful opening of the backside alumina membranes can be realised by acid treatment leading to highly flexible large area porous alumina membranes with complete through-hole pore morphology. The backside pore-opening process realised by chemical etching is strongly dependent on time and acid concentration and is best monitored routinely by microscopy techniques in order to gain control over the process.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Over the last few years mesoporous alumina has attracted much scientific interest in materials chemistry because of its compact and highly ordered porous structure.[1] These features, in combination with the possibility to vary the pore size of the individual alumina pores between 10 and 300 nm, as well as its high temperature and chemical resistance, makes this material attractive as a template material for the synthesis of one-dimensional ordered nanoscaled functional materials such as wires, tubes, fibres and particles.[2] The thickness of the porous alumina membrane which determines the pore length as well as the pore diameter is controlled by the electrochemical synthesis conditions of the anodic oxidation process. Aside from the electrochemical parameters, a dependence of its properties on temperature, pH, time of the process, as well as the aluminium metal surface conditions is observed. It is highly desirable to have as much experimental control as possible over the complex alumina formation process, because the alumina pore morphology controls the morphology of the templated guest materials incorporated within the pores. Therefore it is necessary to control the synthetic anodisation process as well as the detachment and pore conditioning process in its crucial parameters: (a) pore size, (b) membrane thickness, (c) regular arrangement of the pores, (d) detachment of the *p*orous *a*lumina *ox*ide (PAOX) membrane from the aluminium base metal and (e) generation of a complete through-hole pore morphology of the PAOX membrane. Point (e) is especially important for employing PAOX membranes in controlled gas phase processes, for example in a chemical vapour deposition nanoreactor in which gaseous species are transported through or reacted within the PAOX membrane. Examples in this area are the formation of carbon nanotubes[3] or polymer fibres derived from [2.2] paracyclophane[4] as well as catalytic gas phase hydrogenation and CO oxidation reaction.[5]

Herein we present our investigations on the synthesis of alumina membranes with regular hexagonal pore order. These membranes are produced at 25, 40 and 50 V anodisation voltage giving rise to 33, 40 and 72 nm diameter pores. To the best of our knowledge and despite the intensive use of the unique pore system of PAOX membranes in synthetic materials chemistry, no detailed studies dealing with backside pore opening of PAOX membranes has been reported. One goal is to establish reliable experimental protocols for PAOX alumina backside pore opening. This is necessary in order to employ PAOX membranes on a broader basis, for example as a nanoporous template platform in synthetic as well as catalytic gas phase processes. A qualitative model of the stepwise pore opening is developed herein which offers for the first time an experimental verifi-

cation of the dissolution processes of the different dense alumina compositions which constitute the PAOX pore walls. This procedure allows the experimental realisation of freestanding, large area PAOX membranes with enhanced mechanical flexibility (area size of several 10 cm^2) and complete through-hole pore morphology.

General Features of Porous Anodic Alumina

Figure 1 represents a schematic top view on the surface of the open pore side of a PAOX membrane. The membrane is constructed of individual alumina cells with hexagonal cell shape. In the centre of these hexagonal cells are uniform uniaxially rounded pores. The diameter of the PAOX cells as well as the diameter of the PAOX pores is directly proportional to the applied anodisation voltage.[6] The pore walls consist of two different types of alumina.[7] On the one hand is a relatively pure anion-free dense alumina which makes up the hexagonal body of the cell. This material is not in direct contact with the pore itself. On the other hand, in the inner cell region is an electrolyte-contaminated less dense alumina, which forms the pore wall. Figure 1 (part a) shows a cross-section of the PAOX membrane with the unidirectional pore arrangement. At the bottom the pores are separated from the aluminium metal base by the barrier layer, which seals the PAOX membrane on one side. To obtain a total through-hole pore morphology (i) the PAOX membrane has to be detached from the aluminium metal base and (ii) a pore opening process has to be employed which dissolves the barrier layer and forms a uniform pore diameter *without* destroying the overall porous backside structure. Steps (i) and (ii) have to be applied consecutively in two independent processes.

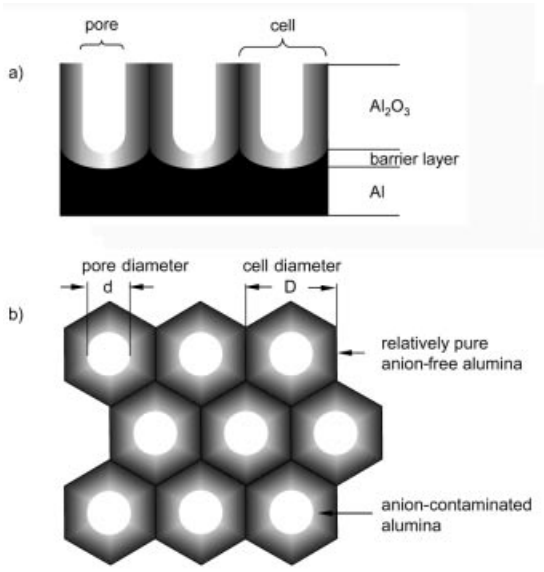

Figure 1. Schematic view of the characteristics of an idealised PAOX membrane pore geometry. (a) Schematic of the cross section of the unidirectional pore arrangement of a PAOX membrane. The pores are sealed on one side by the convex shaped barrier layer, which forms the connection of the PAOX membrane to the aluminium metal base. (b) Top view of the surface showing the hexagonal cells with the central through-hole pores. The alumina consists of two different types: (i) relatively pure dense alumina which constitutes the outer cell region cell and (ii) anion-contaminated, less dense alumina, which forms the surrounding through-hole pore material which is in direct contact with the inner pore. This different material composition is schematically shown by the greyish colour graduation.

Results and Discussion

Our first experimental step in the synthesis of alumina membranes is the high temperature annealing of commercial aluminium sheets at 400 °C. This procedure relaxes the surface of the aluminium base metal from defects.[8] Figure 2 (part a) shows an SEM picture of as-received aluminium (99.93%, PURALUX®). The general roughness of the surface as measured by AFM is 47 nm. Part b of Figure 2 shows an SEM picture of the same aluminium sheet after heat treatment under air (400 °C) for 1 h. Its roughness has increased. The general roughness of the heat-treated aluminium is about 100 nm as compared to 47 nm before this treatment. This difference can be explained by a thermal expansion of the aluminium sheet during the heat treatment followed by subsequent contraction of the metal surface while cooling down to room temperature.[9] This relaxes stresses within the surface, but on the other hand results in a folding of the surface which increases the overall roughness in comparison to the untreated material.

To remove this surface roughness the heat-treated metal specimen is electropolished in a solution of perchloric acid in ethanol.[10] Electropolishing is used in deburr processes

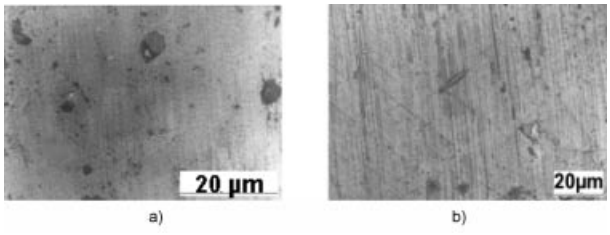

Figure 2. SEM pictures of (a) aluminium PURALUX® as received, (b) PURALUX® surface after heat treatment of 450 °C for 1 h. The roughness of the surface has increased.

of metals, where cutting edges of metals are flattened. This treatment removes the induced roughness of the Al metal sheet surface by chemical etching. The roughness of the aluminium surface after electropolishing is about 29 nm as detected by AFM (part a in Figure 3). However, what is most important here for the alumina surface is that the electropolishing procedure pretextures the metallic surface on a nanoscale [Figure 3, parts a (AFM) and b (SEM)]. This pretexturing is dependent on the applied voltage. The diameter of the concave spots on the electropolished aluminium surface (SEM, Figure 3, part b) is about 55 nm at 40 V. A direct connection exists between the electropolishing conditions employed and the formation of the PAOX membranes by the follow-up anodic oxidation process (see below and upcoming section on PAOX membrane formation).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Nevertheless, other recent reports on the formation of PAOX membranes claim no significant effect of electropolishing on the prestructuring of the aluminium metal surface.[11]

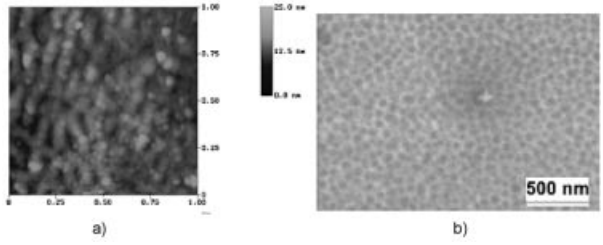

Figure 3. (a) AFM picture of an electropolished aluminium surface (1×1 μm^2 scan, height bar 0–25 nm). The roughness of the surface is 30 nm. (b) Concave structures (diameter 60 nm) on the top of the surface are visible by SEM. The diameter of the concave part is in the range of 60 nm.

Figure 4 shows an SEM of an aluminium surface which was first electropolished (see Exp. Section) followed by long-term anodic oxidation for 24 h, followed by detachment of the thus formed alumina membrane from the aluminium metal base by reversing the initially applied anodisation voltage (see Exp. Section).[12] This procedure leaves the aluminium metal base with a characteristic starting pore geometry on top (Figure 4). The diameter of the concave hollows on the metal surface is 80 nm, which is in fair agreement with the theory of voltage versus cell/pore size relationship of PAOX films. For an anodic oxidation voltage of 40 V, as in the present experiments, values of 51.6 nm for the pore diameter and 110.8 nm for the overall cell diameter are expected.[6] The mean diameter of the experimentally observed concave hollow structures (80 nm) on the aluminium surface is between these two values.

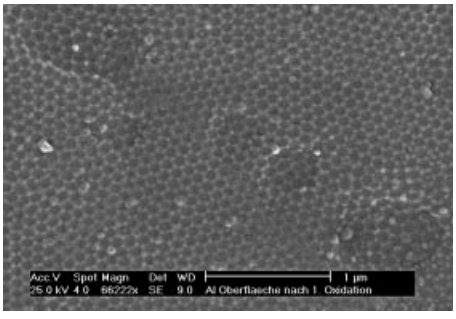

Figure 4. SEM picture of an aluminium surface after first anodisation and detachment of the resulting alumina membrane.

These results show that the different steps of pretreatment of the aluminium base metal have an enormous effect on the structure of the surface. It is interesting to note that the concave oxidic hollows on the underlying aluminium metal base generated by detachment of the PAOX membrane may serve as future template structures for depositing ordered nanodots of equivalent dot size.

Preparation of Freestanding PAOX Membranes with Through-Hole Morphology

After having studied the initial steps of porous oxide formation, we investigated the formation of PAOX membranes with hexagonally ordered pores at anodisation voltages of 25, 40 and 50 V in more detail. For pretexturing the electropolished aluminium surface we carried out the above-described process involving electropolishing followed by an anodic anodisation for 24 h, followed by detachment of the resulting membrane from the aluminium backside by reverse voltage technique (see Exp. Section). This procedure results in aluminium metal sheets with hexagonal textured structures on top (Figure 4). To obtain PAOX membranes from such prestructured metal surfaces we then performed a final anodisation step under the same electrolysis conditions as before with such a prestructured aluminium surface. The complete procedure was carried out for PAOX membranes under anodisation conditions of 40, 50 and finally 20 V.

40-V PAOX Membranes from Prestructured Aluminium Surfaces

Prestructured aluminium metal sheets (see above) were finally anodised for 20 h/10 °C/40 V anodisation voltage (see experimental). The resulting PAOX membrane was then detached from the aluminium base by reversing the voltage (Figure 5). We have optimised this technique and found that membrane detachment by the voltage reversal has significant advantages over chemical detachment methods using $HgCl_2$ or $CuBr_2$ often employed to obtain freestanding PAOX membranes. Detachment by careful voltage reversal allows production of up to several square centimetres of sized flexible PAOX membranes which may find use in future large area template applications (Figure 6).

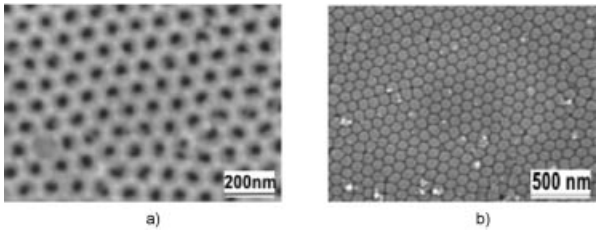

Figure 5. SEM pictures of a detached PAOX membrane prepared in a second anodisation step at 40 V. (a) Front side with hexagonally ordered open pores, (b) rear side with closed hexagonally ordered pores.

In Figure 5 the hexagonally ordered open pores of the PAOX membrane can be seen. The uniform diameter of the pores is 36 nm (±2 nm) and the cell diameter is 105 nm (±4 nm). It is known that the pore walls of PAOX membranes contain varying amounts of electrolyte.[7,13,14] The contrast-rich region of the SEM picture, next to the middle of the neighbouring pores, represents electrolyte-free dense alumina (see Figure 1). The less contrast-rich part of the inner pore region corresponds to the electrolyte-containing

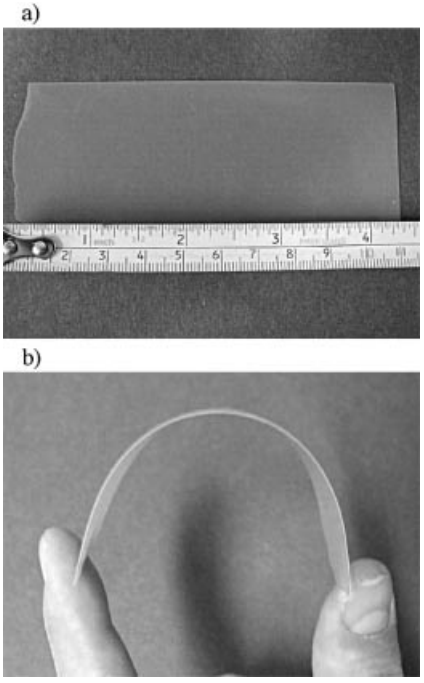

Figure 6. (a) Photo of a freestanding PAOX membrane (size about 40 cm^2). (b) Same sized PAOX membrane under manual mechanical torsion.

part of alumina. Their distinction in the SEM is due to the scattering behaviour of the electron beam for different dense materials. Figure 5b shows the rear side of a detached PAOX membrane. The hexagonally arranged pores are closed because of the presence of the barrier layer. Figure 7 (pos. 1, pos. 2) shows regions in which highly ordered domains are separated from unordered domains by different unordered boundary pore arrangements, for example, a flowerlike arrangement (Figure 7, pos. 1) and a linear arrangement of pores (Figure 7, pos. 2). We have observed such morphologies separating well ordered, hexagonally arranged pore regions from each by lower ordered regions throughout the whole PAOX membrane structure over cm^2 large areas in several independent experiments. The pore formation process in PAOX membranes has been studied theoretically by applying the mathematical theory of Voronoi.[14,15] Similar disordered pore structures are expected

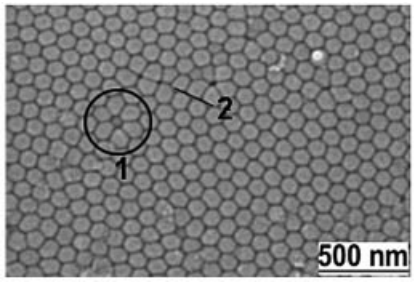

Figure 7. SEM of a backside of a detached PAOX membrane showing different ordered domains. Several kinds of disorder can be observed at the boundaries of the domains. Defects labelled with 1 have a flowerlike structure, and those labelled 2 display a linear structure.

by the theoretical model reported therein, and are also found experimentally by others.[15] This inherent and characteristic domain disorder of PAOX membranes can be overcome to a significant extent by using a prestructured alumina metal base which is available, for example, by embossing techniques using mechanically hard master stamps (produced e.g. by e-beam lithography), as has been shown by Masuda et al. for the first time.[16]

Figure 8 shows a cross-section of a typical PAOX membrane generated at 40 V exhibiting an all through parallel pore morphology. The nearly perfect parallel pore structure running orthogonal to the PAOX membrane surface is evident.

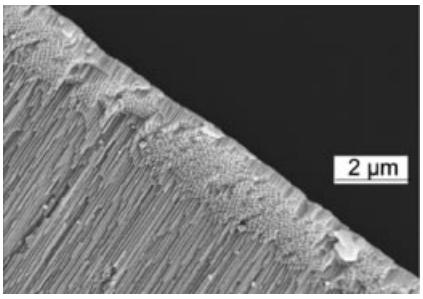

Figure 8. SEM of a cross-section of a detached PAOX membrane generated at 40 V. The pore channels are nearly perfectly parallel and orthogonally aligned to the surface which is seen partly in the foreground of the image. The channels are running from the top to the bottom of the image.

50-V PAOX Membrane from Prestructured Aluminium Surfaces

Figure 9 (parts a, b) show the front side of such a membrane. A hexagonal order of pores in μm^2-sized domains can be seen. The pore diameter is 57 nm (±4 nm) and the cell diameter is 114 nm (±4 nm), both corresponding to the values expected theoretically, which are 64.5 nm for the pore diameter and 138.5 nm for the cell diameter.[6] Part c of Figure 9 depicts the closed backside of a PAOX membrane detached from the aluminium metal base by the voltage reversal technique. The hexagonal ordering of the pores is again nearly perfect. Figure 9 (part d) shows the massive parallel pore arrangement of such a PAOX channel system.

We also routinely generated hexagonally ordered alumina membranes at 25-V anodisation voltage with the same morphological characteristics as discussed for the 40- and 50-V membranes (SEM, AFM topological characterisation not shown). Their pore diameter is 36 nm (±3 nm) and the cell diameter 64 nm (±2 nm), both in good agreement with the theoretical values of 32 and 69 nm for the cell and pore diameters, respectively.

Controlled Dissolution Studies of the Barrier Layer from Freestanding PAOX Membranes

For detachment of the alumina membrane after their synthesis we generally use the reversing voltage technique

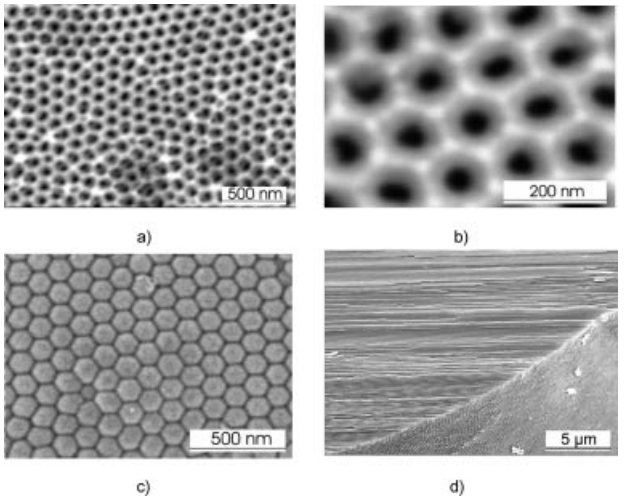

Figure 9. SEM of hexagonally ordered pores of a detached PAOX membrane generated at 50 V with complete through-hole morphology. (a) Front side of a PAOX membrane generated at 50 V with hexagonally ordered open pores; (b) as (a), but higher magnification; (c) back side of a PAOX membrane (50 V) with closed barrier layer; (d) cross-section of the same membrane with parallel pore arrangement.

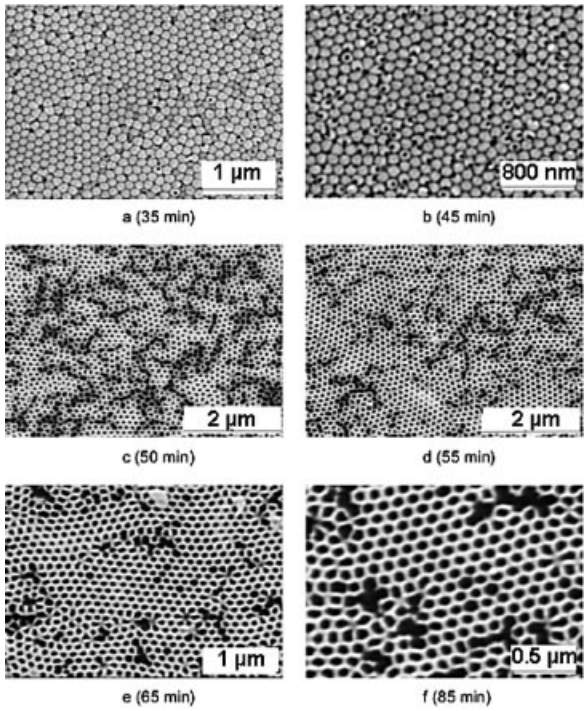

Figure 10. SEM images of the barrier layer of a PAOX membrane (50 V) at different intervals of backside pore opening (5% H_3PO_4). After 45 min of acid treatment (9a and 10b) the majority of the pores are still closed. After 50 min (c) pores are fully opened and pore widening of the inner pores starts to take place. (d) Further etching leads to an increased pore widening and subsequent destruction of the opened alumina membrane backside. This occurs predominantly in areas of hexagonal disorder [e and f (scale bar 200 nm)].

(see before). This results in the formation of a freestanding PAOX membrane with a *single* open pore side. The open pore side represents the initial oxidation front of the electrochemical anodisation process and reflects in its cell size and overall surface structure the unsteady electrolysis conditions present during the beginning of the aluminium oxidation when equilibrium conditions for pore cell formation have not been reached. The closed side of the PAOX membrane, the barrier side, represents the front of the ongoing oxidation process directly attached to the aluminium metal substrate. Therefore the backside typically shows well-arranged pore cells, because electrolysis conditions reach an equilibrium state during the ongoing anodisation.

Time-Dependent Acid Etch of the Barrier Layer

In numerous experiments we have found that the process of pore opening of the backside of PAOX membranes is experimentally the most difficult procedure in obtaining PAOX membranes with a complete through-hole morphology.[16] It depends crucially on the acid strength, and time and type of contact in order to open the closed backside in a controlled and reproducible way. Control over this process by straightforward chemical etching techniques is desirable in order to have access to through-hole open pore geometries with different pore diameters.

To obtain PAOX membranes with a continuous through-hole pore morphology we studied dissolution of the barrier layer over different time intervals. In our experiments we studied hexagonally arranged PAOX membranes that were generated at 50 V and the barrier layer was dissolved with 5% H_3PO_4 (aq.) over time. Figure 10 (parts a–f) show SEM micrographs at different time intervals representing different stages of barrier layer dissolution.

35 min of Acid Treatment

The initial dissolution process starts by producing hole structures in the convex domes of the barrier layer (Figure 10, part a). The location of the holes in the individual pores appear as black dots distributed inhomogeneously over the membrane surface, for example holes can be observed in the centre of one pore, as well at the edges of individual pores. The majority of the backside pore domes, however, are still unaffected after that time interval.

45–55 min of Acid Treatment

After 45 min the number of partially opened backside pore domes has increased significantly (Figure 10, part b). Interestingly the dimensions of the already opened pore domes from the first etch period (35 min) are nearly unaffected. After 50 and 55 min of dissolution (Figure 10, parts c and d) the barrier layer is completely removed and all pores are opened. However different stages of pore opening are detectable after these times. Some pores are opened to such an extent that connecting neighbouring pores are already affected. This effect is observed to a significantly large extent in domain areas where cell disorder is found. Ordered domain areas show a more even pore dissolution characteristic. This effect is even more pronounced after

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

65 min (Figure 10, part e) and after 85 min (Figure 10, part f) of pore dome dissolution. With ongoing acid treatment, not only are the disordered parts of the membrane dissolved, but the structure of the inner pore walls of the ordered regions also becomes larger. This is due to an ongoing dissolution of alumina from the already opened pores. This process is generally known as pore widening and is caused by the dissolution of the electrolyte-rich inner alumina phase. In Figure 10f the inner alumina phase is nearly completely dissolved, leaving the electrolyte-free outer alumina portion of the pore cell structure, which is not prone to dissolution under these conditions, unaffected.

Based on the results of these dissolution experiments we have developed a scheme illustrating the acid dissolution process of the PAOX membrane backside over time (Figure 11).

The first step of the dissolution process is a slow thinning of the outer electrolyte-free alumina, which represents the top of the barrier layer of the convex dome structures as shown in (a) on the left-hand side of Figure 11. Until dissol-

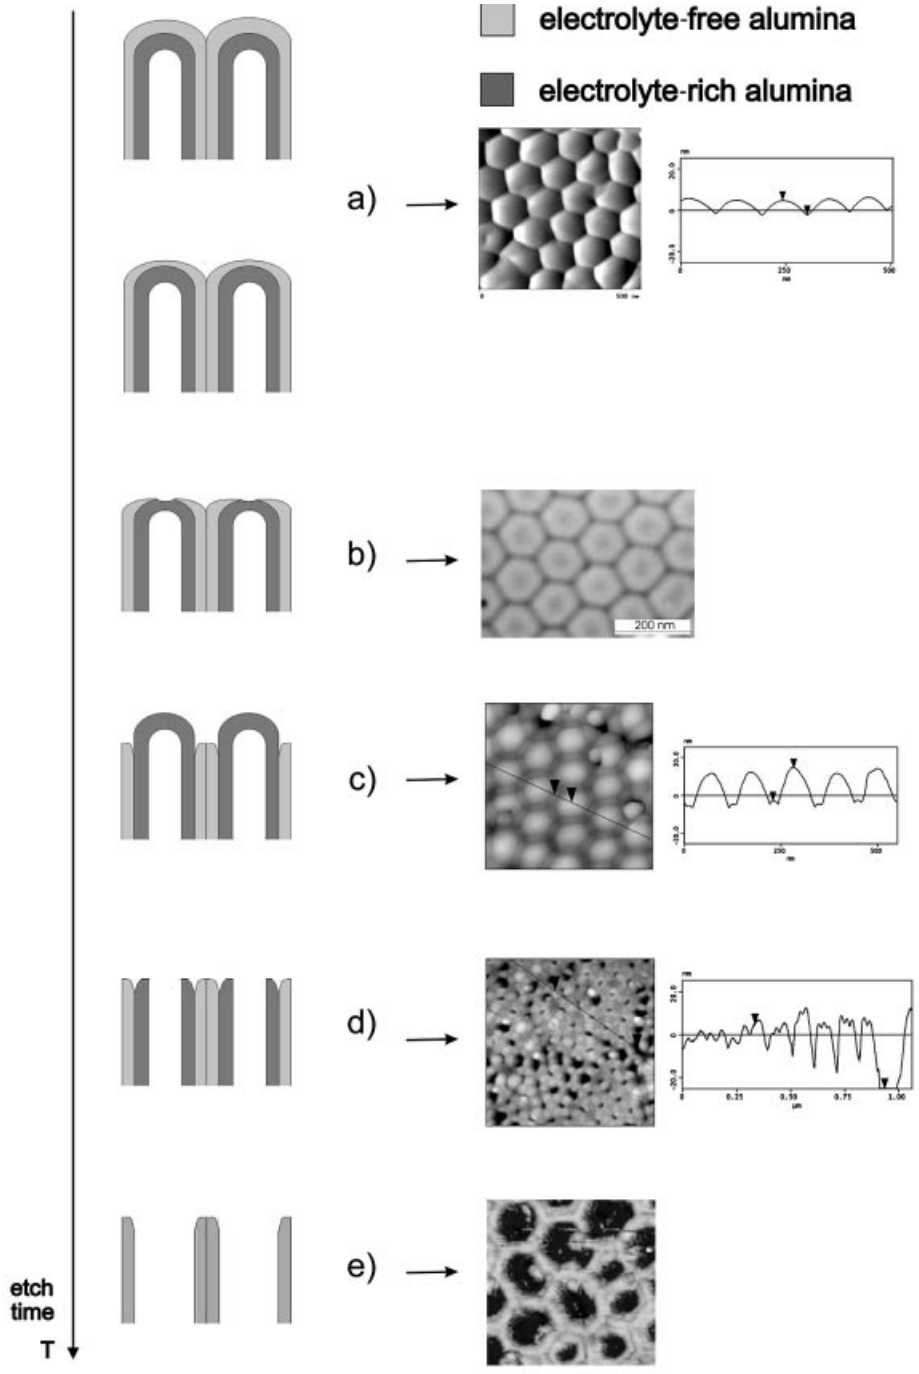

Figure 11. Scheme of the dissolution process leading to a pore opening by acid treatment (see text for details). (a) Line scan 0–500 nm, height bar 0–20 nm; (b) scale bar SEM 200 nm; (c) line scan 0–500 nm, height bar 0–20 nm; (d) line scan 0–1 μm, height bar 0–20 nm.

ution of the alumina dome caps of the backside has progressed significantly, we are not able to detect any significant change in morphology using AFM. After increasing reaction time the dome caps are dissolved to a significant extent, which can be visualised by SEM (Figure 11b). The initial process of dome cap opening needs a significantly longer time compared to the next steps of the overall dissolution process finally leading to the complete opening of the PAOX membrane backside. A rationale for this can be found in the different compositions of the outer and inner alumina compositions of the PAOX cell structure (see Figure 1). The dome caps of the alumina cells are composed of electrolyte-free (Figure 11, light grey region) and electrolyte-contaminated alumina (Figure 11, dark grey region). The former is more resistant towards acidic dissolution than the inner pore walls of the cells. Once the outlying, more dense, electrolyte-free alumina part of the dome caps has been completely dissolved, the overall backside dissolution process leading to complete pore opening proceeds very quickly.

Part c of Figure 11 shows the situation of a strongly dissolved, electrolyte-free alumina dome cap structure. The pore walls are already strongly dissolved in comparison to the still closed underlying dome cap of the electrolyte-containing alumina (see AFM cross-section analysis, Figure 11, part c, right side). The interface region separates two neighbouring, still closed pores in which the electrolyte-free alumina is completely dissolved.

The next step in the dissolution process is the beginning of the complete pore opening which produces the desired through-hole morphology of the PAOX membrane (AFM, Figure 11, part d; right side). Ongoing dissolution opens the pores to a further significant extent (Figure 11, part e). This last dissolution step is the so-called pore-widening step because it enlarges the entrance part of the opened pores over their regular sized dimensions (the 'pore size', see Figure 1) by dissolving interior material from the alumina pores. Obviously the pore-opening model developed here is in good agreement with the dissolution process as it is verified experimentally in Figure 10.

The required times for total pore opening and widening (Figure 11, part e) for 25-, 40- and 50-V PAOX membranes are summarised in Table 1. With increasing pore diameter and barrier-layer thickness, the time for pore opening increases. However, no linear correlation between dissolution time, anodisation voltage and thickness of the barrier layer was found. To obtain reproducible PAOX membrane properties we check the PAOX morphology by routine interval SEM studies to watch the ongoing dissolution process in a stepwise manner. These checks allow simple but efficient control of the pore-opening process and give the possibility of varying pore entrance diameters at will just by stopping the chemical etching process at a certain time. To the best of our knowledge such control over pore entrance diameters in PAOX membranes has only been reported by using grazing angle Ar ion milling[17] of a closed PAOX membrane backside. This technique is able to produce certain degrees of pore openings. However, this is a technique that is not applicable over several cm^2-large PAOX membrane areas as we have reported herein with the time-controlled etching method.

Table 1. Typical time intervals for generation of a PAOX membrane with complete through-hole pore morphology generated from a detached PAOX membrane with closed backside at different anodisation voltages viz. different pore and cell diameters.

Anodisation voltage [V]	Time of acid treatment [min]
25	23
40	75
50	85

Another point of importance for the pore-opening procedure is the occurrence of domain boundaries between ordered pore regions. They represent areas of local disorder in which alumina surrounding these areas is dissolved more quickly than alumina in higher ordered areas. This effect is demonstrated in Figure 12 in which the initial start period of a PAOX backside dissolution process is shown. Dissolution is predominant in areas where disordered structures are present (boundary regions), denoted by dark circles.

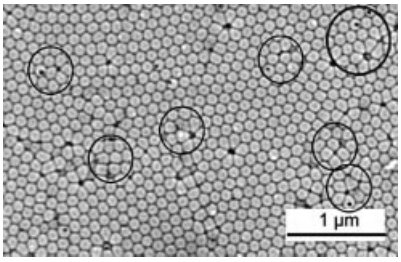

Figure 12. SEM picture of alumina membrane barrier layer at an early stage of backside pore opening. The circles mark positions where pore opening is observed preferentially. This is dominantly α or β to a location of pore disorder.

Conclusion

We have synthesised freestanding, large area sized PAOX membranes with an all through pore arrangement by electrochemical anodic oxidation of aluminium followed by detachment and selective pore opening. We have shown that hexagonally ordered pores over several square µm regions can be obtained at anodisation voltages of 25, 40 and 50 V, resulting in PAOX membranes with pore diameters of 33, 40 and 72 nm.

It has also been shown by AFM and SEM investigations that pretreatment (annealing and electropolishing) of the aluminium metal substrate, especially the applied voltage in the electropolishing step, has a significant influence on the quality and order of the pores of the PAOX membrane. By using the reversing voltage technique for detachment of the prepared alumina membrane, samples with an open pore side and a closed barrier side are obtained. We investigated a time resolved dissolution of the barrier layer with AFM and SEM. Based on these results we have proposed a mechanism for the successive dissolution of the closed pores

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with H_3PO_4. This allows access to flexible, freestanding, large area PAOX membranes with ordered pore geometries and completes through-hole pore morphology on a routine experimental basis by straightforward chemical techniques.

Experimental Section

General Information: Aluminium (99.93%, PURALUX Quality) was from AMAG, Ranshofen, Austria. For SEM characterisation the PAOX membranes were sputter coated with gold using a Cressington 108a sputter coater. SEM was carried out with a Zeiss Gemini DSM 982 and AFM was done with a DI Nanoscope IIIa in the tapping mode. Pore and cell diameter measurements of PAOX membranes were made on a statistical basis determining up to 20 structures in different domain areas of the membrane.

Electropolishing of the Aluminium Base Metal: This was performed in a mixture of ethanol and perchloric acid (4:1, vol.-%) at 0 °C. The distance of the aluminium electrodes was fixed at 9 cm. The best results for polishing were obtained with current densities between 0.25 and 0.40 A cm^{-2}. The polishing voltage was the same as for the following anodisation step. After 3 min of polishing the anode was removed while voltage was still on and was rapidly rinsed with water and acetone.

PAOX Sample Preparation (General Preparation Procedure): $10 \times 3 \times 0.13$ cm aluminium base metal sheets were first degreased with acetone and subsequently annealed at 400 °C for one hour. Following the electropolishing of the sample (current density between 7 and 30 mA cm^{-2}) a first anodisation was carried out for 24 h followed by voltage reversal at the same voltage to detach the membrane from the alumina base. Time for detachment varies between 12 and 24 h, depending on the degree of pore opening. The final anodisation of the prestructured aluminium metal base under identical conditions (see Table 2) was followed again by detachment of the formed membrane from the aluminium metal base through the voltage reversal technique.

Table 2. Experimental conditions for aluminium anodisation leading to PAOX membranes with hexagonal pore geometry.

Electrolyte	Concentration [wt.-%]	Anodisation voltage [V]; time	Temperature [°C]
H_2SO_4	10	(25)[a]; 15–30	(5); 10–25
$H_2C_2O_4$	4	(40, 50); 30–60	(5); 0–25

[a] Number in parentheses: this work; others: possible temperature window which can be also used to form PAOX membranes under otherwise same conditions.

Dissolution of the Barrier Layer: To open the backside of the PAOX membrane the barrier layer was treated with a 5% phosphoric acid solution at 30 °C. Therefore the membrane was placed with the barrier layer face down on the phosphoric acid solution (see Table 1 for time intervals). After the time necessary for dissolution of the backside PAOX membrane it was carefully lifted off the acid bath, rinsed with distilled water for 30 min and thereafter washed with acetone.

Acknowledgments

We thank AMAG, Ranshofen, Austria for donation of the PURALUX aluminium metal sheets. Use of the SEM facility in the Dep. of Geology (Prof. Piller), Karl-Franzens-University Graz, Austria, is also acknowledged with gratitude.

Exploring the Reactivity towards Acidic Protic Ligands of the Di-μ-hydroxo Complex $[NBu_4]_2[Pd_2\{C_4(COOMe)_4\}_2(\mu\text{-}OH)_2]$: A Convenient Precursor in the Preparation of New Palladacyclopentadiene Complexes

Gregorio Sánchez,*[a] Jorge Vives,[a] Gregorio López,[a] José Luis Serrano,[b] Luis García,[b] and José Pérez[b]

Keywords: Palladacyclopentadiene complexes / Hydroxo complexes / Metallacycles / Cycloaddition

The dinuclear hydroxo complex $[NBu_4]_2[Pd_2\{C_4(COOMe)_4\}_2(\mu\text{-}OH)_2]$ (**I**) reacts in a 1:2 molar ratio with a wide variety of protic electrophiles H(L) bearing different sets of donor atoms (L = O^O, N^S or O^N) to give the mononuclear anionic palladium(II) derivatives with the general formula $[Pd\{C_4(COOMe)_4\}(L)]^-$ [O^O = salycilaldehydate (sal) (**1**), acetohydroxamate (ahx) (**2**) and benzohydroxamate (bhx) (**3**); N^S = 2-pyridinthiolate (spy) (**4**), 2-pyrimidinthiolate (spym) (**5**), 3-methyl-2-imidazolin-thiolate (meimt) (**6**) and 2-aminothiophenolate (2-atp) (**7**); O^N = *N*-phenylsalycilaldiminate (*N*-phsal) (**8**), *N*-*p*-chlorophenylsalycilaldiminate (*N*-clsal) (**9**), *N*-*p*-tolylsalycilaldiminate (*N*-tolsal) (**10**), 2-aminophenolate (2-atp) (**11**), 2-pyrrole-carboxaldeydate (2-pcal) (**12**), 8-hydroxiquinolinate (oxin) (**13**), picolinate (2-pic) (**14**)]. Structural characterisation by X-ray diffraction of complexes **5**, **8** and **13** confirmed the proposed formula. Dinuclear complexes $[NBu_4]_2$ $[Pd\{C_4(COOMe)_4\}(\mu\text{-az})]_2$ (az = pyrazolate (pz) (**15**), triazolate (tz) (**16**) and 3,5-dimethylpyrazolate (3,5-Me_2pz) (**17**) were obtained when treating **I** with azoles in the same molar ratio, and also treating the hydroxo complex with chloranilic acid (chl) (**18**) and squarate (sq) (**19**) in 1:1 proportion to yield compounds $[NBu_4]_2[Pd\{C_4(COOMe)_4\}\{(\mu\text{-O–O})\}]$ with the ligands acting as *bis*-bidentate ones. A related process takes place when (**I**) reacts with ammonium *O*,*O*′-dialkyldithiophosphates in acetone under mild conditions and complexes $[NBu_4][Pd\{C_4(COOMe)_4\}\{S(S)P(OR)_2\}]$ (R = Me (**20**), Et (**21**), *i*Pr (**22**)) are obtained. Deprotonation of secondary amines Et_2NH, Pr_2NH, piperidine or morpholine by (**I**) in the presence of carbon disulfide leads to the corresponding dithiocarbamate complexes $[Pd\{C_4(COOMe)_4\}(S_2CNR_2)]$ **23**–**26**. (**I**) also promotes the nucleophilic addition of water to pyridine-2-carbonitrile and a mononuclear complex **27** containing the pyridine-2-carboxamidate ligand is formed. Its structure has been determined by a single-crystal diffraction study. The new complexes were fully characterised by analytical and spectroscopic techniques (FAB-MS, IR; ^1H, ^{13}C and ^{31}P-NMR).

Introduction

The chemistry of metallacycles has received growing interest during the last few years, as a result of their involvement in catalytic processes and their applications in organic synthesis.[1] The cycloaddition of two unsaturated fragments to a metal unit is one of the most useful methods of metallacycle synthesis, since it gives access to relatively complex structures starting from small unsaturated molecules.[1a] In particular, the oxidative cycloaddition of acetylenic esters such as dimethylacetylenedicarboxylate (dmad) to Ni, Pd and Pt has received attention in the past,[2,3] in part because of its involvement in different oligomerization and co-oligomerization catalytic reactions,[4] and also because of the interesting behaviour as precursors in organometallic chemistry of the compounds formed. Specifically, the polymeric palladacyclopentadiene complex [1,2,3,4-tetrakis(methoxycarbonyl)-1,3-butadiene-1,4-diyl]palladium(II) (TCPC) $[Pd(C_4(COOMe)_4)]_n$, obtained in the reaction of dmad with $Pd(dba)_2$ (dba = dibenzylidenacetone) reacts with a wide range of donor ligands to give soluble discrete molecules,[2,3,5,6] although to date, just a few crystal structures of such palladacyclopentadiene compounds are known.[7,8] Other interesting features recently studied are their use as catalysts in several types of reactions. Thus, intramolecular carbametalation and [2 + 2 + 2] cycloaddition,[9] enyne metathesis accompanied by skeletal rearrangement,[10,11] co-cyclotrimerization of various alkynes[5], and hydrostannation of cyclopropenes,[12] have employed TCPC amongst other derivatives as the catalyst. In this sense, in the frame of our collaboration with Fairlamb and co-workers, we have reported the first application of mononuclear palladacyclopentadiene complexes containing

imidato ligands as catalysts in standard Stille cross-coupling reactions,[13]stating that yields and reaction times are dependent on the presence and type of these ligands. The exceptional catalytic properties of related dinuclear derivatives are currently under investigation, and suggest potential applications of compounds presented here.

On the other hand, in addition to their interest related to applied fields such antitumour activity of Pt^{II} complexes or catalytic processes,[14] the synthetic value of palladium(II) and platinum(II) di-μ-hydroxo complexes is a subject of growing study. For example, Sharp[15,16] and later others[17] have employed several such complexes as precursors in the preparation of scarce oxo and imido derivatives that are also relevant to C–O and C–N bond forming reactions in catalytic processes.[14] The reactivity towards protic substrates of dinuclear compounds $[Pd(\mu\text{-}OH)L^n]_2$ (L^n = orthometallated imine-based ligands) provides a general route to obtain dinuclear complexes with double and mixed bridges that have shown liquid crystal behaviour.[18] In this sense, during the last few years we have also been developing the usefulness of binuclear hydroxo complexes of palladium in the preparation of an extensive selection of new compounds, by means of a simple acid-base reaction.[19] Our more recent contribution to the area has been the synthesis of the dinuclear complex $[Pd_2\{C_4(COOMe)_4\}_2(\mu\text{-}OH)_2][NBu_4]_2$ and its use in the preparation of new palladacyclopentadiene derivatives that, as mentioned above, have shown interesting catalytic properties.[13] We expand in this paper on the reactivity of this complex towards several protic electrophiles and describe other related reactions, like that against amines in the presence of carbon disulfide or the addition of water experienced by pyridine-2-carbonitrile when $[Pd_2\{C_4(COOMe)_4\}_2(\mu\text{-}OH)_2][NBu_4]_2$ is present in the reaction.

Results and Discussion

The palladacyclopentadiene complex $[Pd_2\{C_4(COOMe)_4\}_2(\mu\text{-}OH)_2]^{2-}$ (**I**) was conveniently prepared by reaction of the polymeric complex $[Pd\{C_4(COOMe)_4\}]_n$ with NBu_4OH in water.[13] Its reactivity was easily followed by the disappearance of both an IR stretching vibration at 3600 cm^{-1} and a high-field shielded ^1H NMR resonance at δ = –0.85 ppm. The reactions explored in this paper are displayed in Scheme 1 and specific conditions followed for each of them are collected in the experimental section.

The hydroxo complex reacts with weak protic acids H(L) to give mono- or binuclear species depending on whether the deprotonated acid $(L)^-$ is *exo*- or *endo*-bidentate. These reactions can be viewed as an initial proton abstraction by (**I**) that provides $(L)^-$ and the metal substrate, subsequently trapped by the anion to form the new complexes. The protonation at the nucleophilic oxygen atom of the bridging OH should give an initial *aqua* complex that experiences H_2O replacement by the *endo*- or *exo*-bidentated $(L)^-$ leading to the formation of $[Pd\{C_4(COOMe)_4\}(L)]^-$ (**1**–**14**) or $[Pd\{C_4(COOMe)_4\}(\mu\text{-}L)]_2^{2-}$ (**15**–**17**) respectively. Similarly, the use of ligands able to coordinate in a *bis*-bidentate mode reacting with the precursor (**I**) in a 1:1 molar ratio allows the obtention of complexes **18** and **19**. The considerable nucleophilicity of the bridging OH groups of **I** makes it also

reactive towards ammonium *O,O′*-dialkyldithiophosphates, yielding complexes **20**–**22** with the concomitant release of NH_3 and H_2O. The preparation of the dithiocarbamate complexes **23**–**26** should involve a first step of amine deprotonation, followed by nucleophilic attack of R_2N^- to carbon disulfide to form the dithiocarbamate anion. On the other hand, the activation of nitriles with respect to attack by nucleophiles in the coordination sphere of metal ions has attracted considerable interest.[20] We have described the attack of OH^- and MeO^- on benzonitrile coordinated to Pt^{II}[21] and the use of the hydroxo complex $[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ in the formation of complexes containing amidate ligands,[22] and now we employ a similar reaction between **I** and pyridine-2-carbonitrile in acetone/water to prepare complex **27**.

The new palladium complexes are air-stable and their IR spectra show two very strong bands [ν(CO)] around 1700 cm^{-1} characteristic of the carboxylate groups,[2] in some cases partly overlapped by those absorptions attributed to the incoming deprotonated ligands (see Exp. Section). The ^{1}H-NMR spectra show the corresponding signals of these ligands, and as a common feature the characteristic chemical shifts of the methoxycarbonyl groups, which act as a preliminary probe for the compounds geometry, i.e., symmetric complexes show two signals and asymmetric show four resonances, in accordance with previous results.[7,8]

The proposed nuclearity of the new complexes is also confirmed by FAB mass spectrometry and the negative FAB-MS data of the complexes with the *m/z* values for the observed fragments are collected in the experimental section. The abundance of the signals around the parent ion are consistent in all cases with the natural isotopic abundances. This technique has special relevance conferring the mononuclearity of complexes with heterocyclic-2 thiolate ligands **4**–**7**, as NMR spectroscopic data would be compatible with either mononuclear complexes with the ligands acting in a chelating mode or dinuclear complexes with bridging ligands. This extent has been further proved by X-ray diffraction analysis of compound **5** whose structure and selected bond lengths and angles are shown in Figure 1 and Table 1. The Pd–N and Pd–S distances are slightly longer than the ones found for related Pd^{II} complexes with this ligand[23] and the N(1)–Pd–S(1) angle is considerably smaller than 90°, in agreement with previously reported data for four-membered N,S-chelate rings.[24,25]

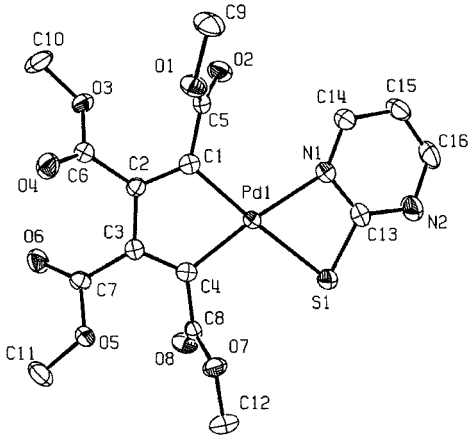

Figure 1. ORTEP diagram of anion complex **5** with the atom numbering Scheme; thermal spheres are drawn at the 50% probability level.

The mononuclear nature of complexes **8** and **13** that contain chelating ON donor ligands has also been confirmed by single-crystal X-ray analysis. The ORTEP diagrams of the two anions are shown in Figure 2 and Figure 3, while the relevant bond lengths and angles are reported in

all similar with values of ca. 2 Å, with independence of the donor atom placed in *trans*- to the metallacyclic carbon. However, the distance Pd(1)–C(4) in complex **27** *trans*- to the pyridinic nitrogen is comparatively shorter. In this structure (Figure 5) is also found a short Pd(1)–N(1) distance if compared with the analogous one in complex **5** with the 2-pyrimidinthiolate ligand described above.

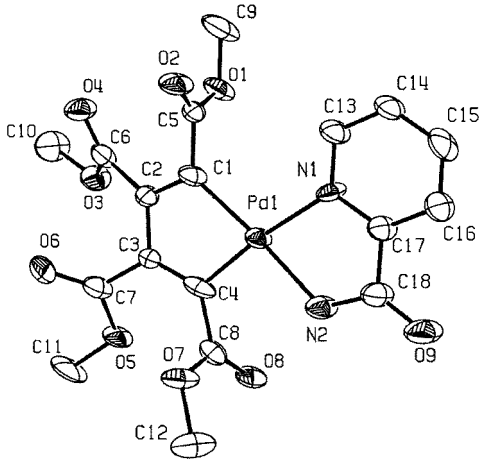

Figure 5. Structure of the $[Pd\{C_4(COOMe)_4\}(2\text{-}HNCOpy)]^-$ anion in the single crystal structure of **27**. All hydrogen atoms have been omitted for clarity.

The five new structures may be described as nearly planar, and their deviation from the planar coordination has been quantified by the $N_1{*}C_1C_4Pd_1$ and $E{**}C_4C_1Pd_1$ improper torsion angles (see Table 2).[28]

Experimental Section

General Remarks for Synthesis: C,H,N,S analyses were carried out with a Carlo–Erba model 1108 microanalyser. IR spectra were recorded with a Perkin–Elmer spectrophotometer 16F PC FT-IR, using Nujol mulls between polyethylene sheets. NMR spectroscopic data were recorded on Bruker Avance 200, 300 and 400 spectrometers. Mass spectrometric analyses were performed with a Fisons VG Autospec double-focusing spectrometer, operated in the negative mode. Ions were produced by fast atom bombardment (FAB) with a beam of 25-keV Cs atoms. The mass spectrometer was operated with an accelerating voltage of 8 kV and a resolution of at least 1000. The hydroxo complex precursor $[NBu_4]_2[Pd_2\{C_4(COOMe)_4\}_2(\mu\text{-}OH)_2]$ was prepared by a published method.[13] Reagents were purchased from commercial sources and used directly unless otherwise stated in the text.

Preparations

Complexes $[NBu_4][Pd[C_4(COOMe)_4\}(O–O)]$ [O–O: Salycilaldehydate (sal) (1), Acetohydroxamate (ahx) (2) and Benzohydroxamate (bhx) (3)]: These mononuclear complexes were obtained according

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to the following general method. To an acetone solution (10 mL) of hydroxo complex (0.07 g, 0.054 mmol) the stoichiometric amount of H(O–O) (molar ratio 1:2) was added. The solution was stirred at room temperature for 30 min and the solvent was partly evaporated under reduced pressure. The addition of diethyl ether caused the formation of yellow-orange solids, which were filtered off, washed with diethyl ether and air-dried. The compounds were recrystallised from dichloromethane/diethyl ether.

[NBu$_4$][Pd(C$_4${COOMe}$_4$)(sal)] (1): Yield 0.072 g (88%), m.p. 153 °C (dec.). $C_{35}H_{53}NO_{10}Pd$ (754.2): calcd. C 55.7, H 7.1, N 1.9; found C 55.5, H 7.0, N 2.0. IR (Nujol) $\tilde{\nu}$ = 1692 (vs), 1612 (vs), 1596 (vs), 1556 (vs) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 3.60 (s, 6 H, COOMe), 3.75 (s, 3 H, COOMe), 3.80 (s, 3 H, COOMe), 6.39 (m, 1 H, aromatic), 6.64 (d, 1 H, aromatic, J = 8.8 Hz), 7.17–7.27 (m, 2 H, aromatics), 9.06 (s, 1 H, CH=O) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 50.9 (COO*Me*), 51.0 (COO*Me*), 51.2 (COO*Me*) ppm. FAB-MS (negative mode): *m*/*z* (%) = 512 [Pd{C_4(COOMe)$_4$}(sal)]$^-$ + 1.

[NBu$_4$][Pd(C$_4${COOMe}$_4$)(ahx)] (2): Yield 0.068 g (89%), m.p. 180 °C (dec.). $C_{30}H_{52}N_2O_{10}Pd$ (707.2): calcd. C 50.9, H 7.4, N 4.0; found C 50.6, H 7.3, N 4.0. X-ray Structure Analysis: Suitable crystals of **5**, **8**, **13**, **20** and **27** were grown from dichloromethane/ether liquid diffusion. The crystals were mounted onto the tip of a glass fibre, and the data collection was performed with a Siemens P4 diffractometer for **5**, **8**, **20** and **27**, the scan mode was θ-2θ. Data collection for **13** was performed with a Bruker Smart CCD diffractometer with a nominal crystal to detector distance of 4.5 cm. Diffraction data were collected with a ω scan run. A total of 1371 frames were collected at 0.3° intervals and 10°s per frame. The diffraction frames were integrated using the SAINT package[29] and corrected for absorption with SADABS.[30] The structures were solved by direct methods SHELXS-97[31] and refined by full-matrix least-squares SHELXL-97[31] (Table 3). Hydrogen atoms were included using a riding model. CCDC-258720 (for **5**) -258721 (for **8**), -258722 (for **13**), -258723 (for **20**) and -258724 (for **27**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Thermodynamic Study of the Binding of Methyltrioxorhenium with Pyridine and Its Derivatives in Benzene Solution

S. Masoud Nabavizadeh,*[a] Alireza Akbari,[a] and Mehdi Rashidi[a]

Keywords: N ligands / Rhenium / Thermodynamics

A spectrophotometric study of the interaction of methyltrioxorhenium (MTO) with pyridine and its derivatives in benzene solution has been carried out at various temperatures. The stability constants of the resulting 1:1 complexes were determined by analysis of spectrophotometric data and found to vary in the order 3,4-Me_2Py > 4-*t*BuPy > 4-MePy > 3-MePy > 4-BenzylPy > Py > 3-PhPy > 3-C(O)OMePy > 3-ClPy. The enthalpy and entropy of adduct formation were determined from the temperature dependence of the stability constants. All complexes formed were enthalpy stabilized but entropy destabilized.

Introduction

Methyltrioxorhenium (MTO) has found numerous applications in various catalytic processes, especially the oxidation of olefins,[1,2] alcohols,[3,4] arenes[5] and carbonylmetal compounds.[6,7] Epoxidations with MTO/H_2O_2 has several advantages. For instance, MTO is easily available and is active at low concentrations of both MTO and H_2O_2. It works within a broad temperature range (–40 to +90 °C) and is stable in aqueous acidic solution as well as in basic media in special cases. Furthermore, the MTO/H_2O_2 system works in a broad variety of solvents, ranging from highly polar solvents (e.g. nitromethane, water) to solvents with low polarity (e.g., toluene). A major advantage of MTO, however, is that it does not decompose hydrogen peroxide. The most important drawback of the MTO-catalyzed process is the concomitant formation of diols instead of the desired epoxides, especially in the case of more sensitive substrates.[8] It has been reported that the use of Lewis base adducts of MTO significantly decreases the formation of diols due to the reduced Lewis acidity of the catalyst system. It has also been found that addition of a significant excess of pyridine as Lewis base not only hampers the formation of diols but also increases the reaction velocity in comparison to MTO as catalyst precursor.[9,10] In addition, it has been shown that 3-cyanopyridine, and especially pyrazole, as Lewis bases are even more effective and less problematic than pyridine itself, while pyridine *N*-oxides are less efficient.[11–14] The Brønsted basicity of pyridines lowers the activity of hydronium ions, thus reducing the rate of opening of the epoxide ring.[15] MTO forms trigonal-bipyramidal adducts with monodentate N-bases and (distorted) octahedral adducts with bidentate Lewis bases.[16–19] MTO and its monodentate Lewis base adducts react with H_2O_2 to form mono- and bisperoxo complexes. The activity of the bisperoxo complexes (with coordinated Lewis base) in olefin epoxidation depends on the nature, concentration, and redox stability of the Lewis bases. High selectivity (epoxide vs. diol) can be attained by temperature control, trapping of water, or the use of certain additives, such as aromatic Lewis-base ligands, which additionally accelerate the epoxidation reactions.[20] The pK_a of the Lewis base used is important in achieving ligand-accelerated catalysis since the extent of interaction between rhenium and the Lewis base can be correlated to the latter's pK_a: more basic Lewis bases tend to deactivate the MTO.[21] In this regard, we have recently presented a convincing correlation between log *K* of the binding constant, *K*, of the ligand L to MTO and the pK_a of L.[19] Considering the important applications of the pyridine–MTO complexes in catalytic processes, and the effect of temperature on olefin epoxidation, in the present work we have obtained the stability constants of adduct formation of MTO with pyridine derivatives at different temperatures and studied their thermodynamics.

Results and Discussion

Adduct Formation with Electron Donors

(η^1-Organo)rhenium(VII) trioxides are Lewis acids with two free coordination sites. Reaction with Lewis bases leads to electronic and steric saturation of the Re center. Ligands, especially those with oxygen or nitrogen donor atoms, form Lewis acid–base adducts with MTO.[22–25] Although both sites of bidentate ligands, such as 2,2′-bipyridine, can bind

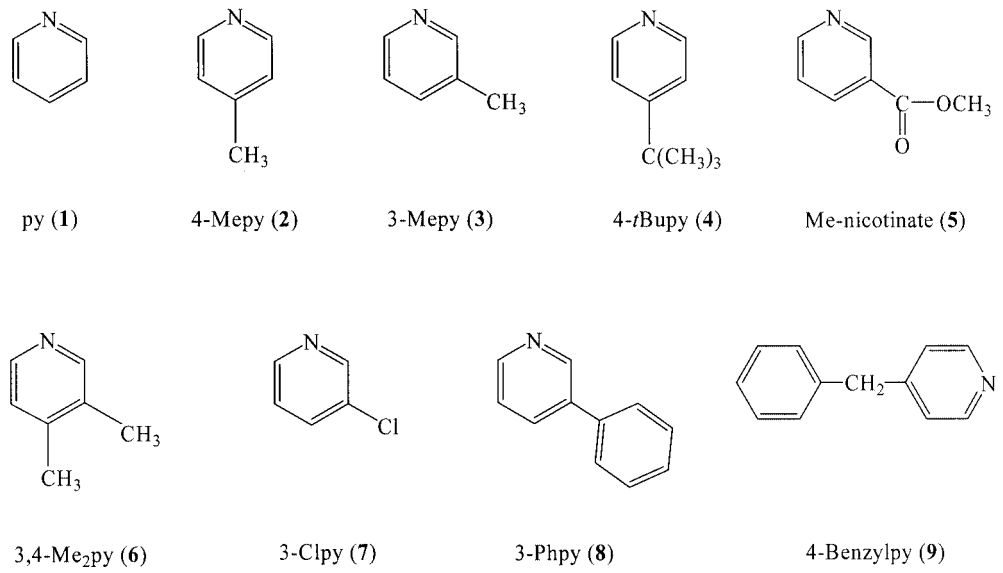
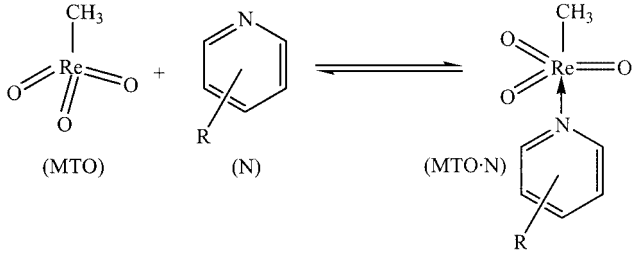


Scheme 1. Structural formulae of pyridine and its derivatives.

to the rhenium center to form a distorted octahedral complex,[26] usually only a single monodentate ligand coordinates to the rhenium atom when a monodentate ligand is used. The lack of formation of MTO·L_2 (L = monodentate ligands) is probably caused by steric factors. Adducts of the composition MTO·L_2 are only known for very small Lewis bases, for example NH_3.[24,25] Special attention has been paid to these adducts because they have proven to be highly selective oxidation catalysts.[23] The reaction of MTO with various pyridine derivatives in benzene affords 1:1 adducts of the composition [CH_3ReO_3]·N [N = pyridine (**1**), 4-picoline (**2**), 3-picoline (**3**), 4-*tert*-butylpyridine (**4**), methyl nicotinate (**5**), 3,4-dimethylpyridine (**6**), 3-chloropyridine (**7**), 3-phenylpyridine (**8**), and 4-benzylpyridine (**9**); see Scheme 1].

The interaction between MTO and several pyridines at different temperatures was studied by UV/Vis spectroscopy. The reaction between MTO and pyridines produces the indicated adduct; the crystal structure for the 4-*tert*-butyl analog has been reported previously.[16] In solution, however, these reactions do not proceed to completion. With UV/Vis detection, an increase in N-donor concentration caused more adduct to form. A series of experiments was carried out with various pyridine derivatives containing substitution in the 3- or 4-position. The values of the stability constants at different temperatures were evaluated for the reaction represented in Scheme 2.



Scheme 2.

The corresponding stability constant, K_{eq}, is given by Equation (1).

$$K_{eq.} = \frac{[MTO{\cdot}N]}{[MTO][N]} \quad (1)$$

where [MTO·N], [MTO], and [N] represent the equilibrium molar concentrations of adduct (CH_3ReO_3·N), free MTO, and free (uncomplexed) pyridine or other ligand, respectively. The absorbance changes in the UV/Vis spectra were analyzed by a nonlinear least-squares fitting according to Equation (2):[19]

$$Abs_{eq} = \frac{\varepsilon_{MTO}([MTO]+[MTO{\cdot}N]) + \varepsilon_{MTO{\cdot}N} K_{eq}[N]([MTO]+[MTO{\cdot}N])}{1+K_{eq}[N]} \quad (2)$$

where Abs_{eq} is the absorbance of a solution at equilibrium, and ε_{MTO} and $\varepsilon_{MTO{\cdot}N}$, are molar absorptivities for the MTO and MTO·N species at the corresponding wavelength. The data for pyridine fit well to Equation (2), affording these values for the parameters: K_{eq} = 677.6 ± 9.7 L mol^{-1} and $\varepsilon_{MTO{\cdot}py}$ = 964.4 ± 2.7 L mol^{-1} cm^{-1} in benzene at 20 °C. Figure 1 shows the fit to Equation (2) of the absorbance values at corresponding wavelength for pyridine at different temperatures.

Derivatives of pyridine [4-Me, 3-Me, 4-C(CH_3)$_3$, 3-C(O)OMe, 3,4-Me_2, 3-Cl, 3-Ph and 4-CH_2Ph] also interact with MTO to a greater or lesser extent. These data were also treated by the same procedure used for pyridine. The resulting parameters are indicated in Table 1.

As shown before,[19] stability constants are sensitive to both steric and electronic effects. For N-donor ligands, a linear relationship between log K_{eq} and pK_a at given temperature is expected, as expressed by Equation (3).

$$\log K_{eq} = m(pK_a) + b \quad (3)$$

[a] Experimental values are given in bold; the others are redundant values calculated from them at a given temperature according to Equation (3). [b] K_a applies to the reaction $HL^+ \rightleftharpoons H^+ + L$ in aqueous solution. Data are from ref.[27,28]. [c] The σ_m parameter was used for substitution at C(3), and the σ_p parameter was used for substitution at C(4). [d] These substituent parameters were obtained by adding the individual σ_m or σ_p values for both substituents. [e] Not defined. [f] Values of K_{eq} for these N-donor ligands were calculated with the Hammett equation [log $(K/K_0) = \rho\sigma$]. [g] Not known.

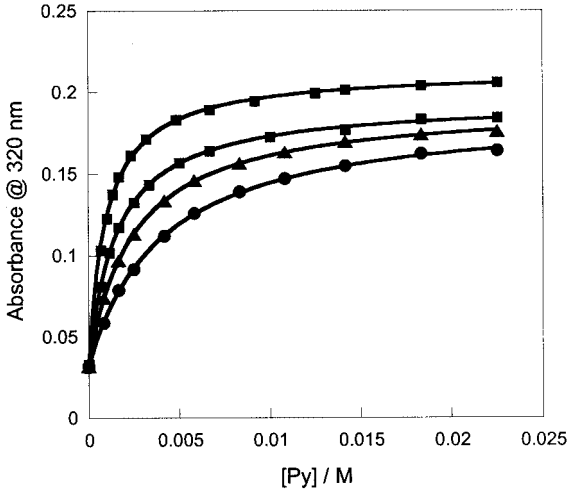

Figure 1. Change in absorbance at 320 nm on addition of pyridine (**1**) to MTO in benzene at T = 10, 20, 30, and 40 °C (temperature increases reading downward); the solid lines show the fit of the spectrophotometric data to Equation (2).

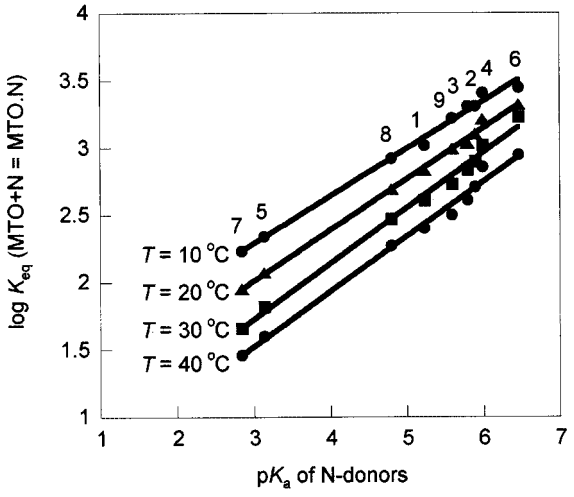

Figure 2. Plot showing a correlation between the stability constants (on the logarithmic scale) for adduct formation of MTO with different N-donors in benzene and pK_a of the same ligands.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In Figure 2, the values from Table 1 for log K_{eq} are plotted against pK_a at various temperatures. It is evident that the data for MTO·N fit on a straight line. The experimental results listed in Table 1 were used to calculate the straight-line equations summarized in Table 2 by least-squares procedures. These equations allow calculation of the expected stability constant for an adduct of any monodentate N-donor ligand from its pK_a. In Table 1, 36 values of K_{eq} at different temperatures are derived from experiments and the remaining 88 values of K_{eq} are redundant and were calculated directly from these 36 experimental values; of course, the calculated ones will have higher error limits owing to the propagation of errors.

Table 2. Straight-line correlations for stability constants of MTO with monodentate N-donors and ligand basicities[a] at different temperatures in benzene.

Temp. [°C]	m	b	R[b]
10	0.35 ± 0.01	1.23 ± 0.06	0.992
20	0.38 ± 0.01	0.87 ± 0.04	0.997
30	0.41 ± 0.02	0.49 ± 0.07	0.992
40	0.41 ± 0.02	0.30 ± 0.09	0.989

[a] The slopes (m) and intercepts (b) for the straight reference lines from plots of log K_{eq} vs. pK_a were calculated by the least-squares procedure from the data listed in Table 1. [b] Correlation coefficient.

From Table 1, it is obvious that the MTO–ligand interaction is considerably weakened at higher temperatures. The pyridine adducts of MTO are considerably less stable towards moisture and temperature than MTO itself. This enhanced sensitivity has also been observed for other N-donor adducts of MTO.[29]

Linear Free-Energy Relationship (LFER)

An attempted linear free-energy relationship (LFER) correlation according to the Hammett equation at 20 °C is displayed in Figure 3. The slopes of the line of log (K/K_0) vs. σ (substituent constant) are –2.04 ± 0.14 (R = 0.985), –2.22 ± 0.09 (R = 0.986), –2.42 ± 0.11 (R = 0.987) and –2.41 ± 0.07 (R = 0.992) at T = 10, 20, 30, and 40 °C, respectively, which are the reaction constants (ρ). The ρ values for these plots have an absolute magnitude greater than 1, thus indicating that the equilibrium is more sensitive to electronic effects than ionization of benzoic acid. The negative reaction constant for the pyridines' equilibrium indicates that a positive charge develops on the pyridine nitrogen in the adduct as compared with the free molecule. As expected, the Re^{VII} center acts as an electron acceptor, attracting electrons upon coordination. MTO is believed to be a hard Lewis acid on the basis of its strong interactions with N- and O-donor ligands and its weak interaction with S-donor ligands.[15] Therefore, the affinity for the hard N-atom in the N-donor ligands investigated here is expected to be quite high.

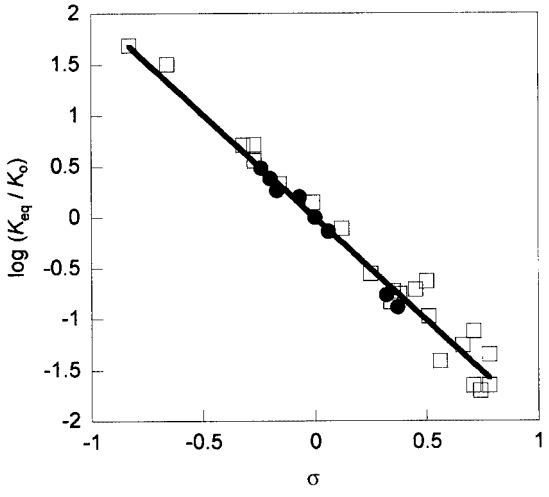

Figure 3. Hammett plot based on the stability constants (●: experimental values; □: calculated values) for the binding of substituted pyridines to MTO in benzene at 20 °C. The reaction constant (for ligands **1**–**9**) is –2.22 ± 0.09.

Effect of Donor

In this work, we have nine donors with different electron-donating capabilities due to different substitution on pyridine. We chose to examine only adducts with pyridines substituted in the *p*- and *m*- positions in order to minimize the steric influence of the Lewis base on the adducts. It is believed that the interaction between MTO and these donors is governed by the electron density on the nitrogen atom of the pyridine ring. On the basis of this description, the following sequence was confirmed from ΔG (20 °C, from Table 3) and K_{eq} (20 °C) values for the interaction of MTO with monodentate N-donors.

	MTO+(**5**)	MTO+(**1**)	MTO+(**4**)
K_{eq} (20 °C) /L mol^{-1}	117.3	677.6	1637.9
ΔG (20 °C) /kJ mol^{-1}	–11.6	–15.9	–18.1

Thermodynamic Parameters

In order to have a better understanding of the thermodynamics of adduct-formation reactions of monodentate N-donors with MTO, it is useful to consider the enthalpic and entropic contributions to these reactions. The ΔH and ΔS values for the adduct formation reactions were evaluated from the corresponding temperature data by applying a linear ln K_{eq} least-squares analysis according to the van't Hoff equation [Equation (4)].

$$\ln K_{eq} = \frac{-\Delta H}{RT} + \frac{\Delta S}{R} \quad (4)$$

Plots of ln K_{eq} vs. 1/T for different MTO·N systems were linear for all cases studied (Figure 4). The enthalpies and entropies of adduct formation were determined in the usual manner from the slopes and intercepts of the plots and the

results are summarized in Table 3. The values of ΔH and ΔS for ligands **1**–**9** were calculated directly from experimental values of K_{eq} and for ligands **10**–**31** they were derived from calculated K_{eq} values at different temperatures. These data allow calculation of the enthalpy and entropy changes for an adduct of any N-donor ligand from its K_{eq} and pK_a. From the data given in Table 3, it is readily obvious that the MTO·N adducts formed in benzene solution are enthalpy stabilized but entropy destabilized. It should be noted that, to the best of our knowledge, no published values of ΔH and ΔS for the adduct formation of MTO are available for comparison with the results obtained here. The ΔG values, calculated from $\Delta G = -RT \ln K_{eq}$ at 20 °C, are included in Table 3.

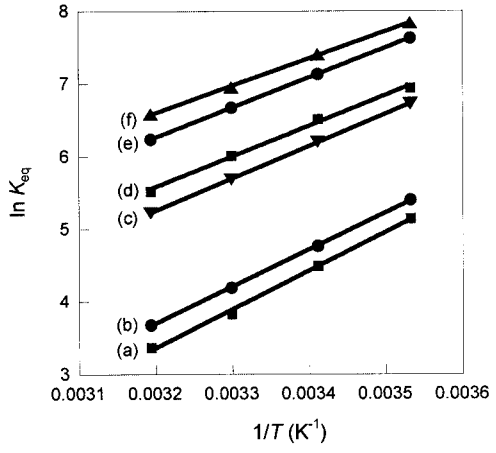

Figure 4. van't Hoff plots for adduct formation of MTO with pyridine derivatives [(a) 3-chloropyridine; (b) methylnicotinate; (c) 3-phenylpyridine; (d) pyridine; (e) 4-methylpyridine; (f) 4-*tert*-butylpyridine] in benzene.

Thermodynamic Analysis of the Adduct-Formation Reaction

Solvation Energy

An Onsager's reaction field model[33–35] was introduced to estimate the solvation energy. The reaction field model expresses solvation energy by

$$\Delta E_{solv} = \frac{2\mu^2}{r^3}\left(\frac{\varepsilon_r - 1}{\varepsilon_r + 2} - \frac{n^2 - 1}{n^2 + 2}\right) \quad (5)$$

where ε_r and n are the dielectric constant and refractive index, respectively, of the solvent and μ and r represent the dipole moment and the diameter, respectively, of the solute. Since the solvent (benzene) is the same for all the systems (MTO + N ⇌ MTO·N), the parentheses term of Equation (5) becomes constant. Thus, solvation energy is assumed to depend only on the μ^2/r^3 term. Since the radii will change only slightly, one can approximate $r_{MTO\cdot N} = r_{MTO}$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

+ r_N, and the solvation energy can therefore be expressed as a linear function of μ (see Table 4).

Table 4. Dipole moments of some pyridine derivatives.

Ligand	$\mu_{calcd.}$ [D][a]	$\mu_{exp.}$ [D][b]

3,4-Dimethylpyridine	3.05	
3-Chloropyridine	2.16	2.02
3-Phenylpyridine	2.48	
4-Benzylpyridine	2.64	

[a] The μ values for N-donors were obtained from B3LYP/6-311++G** calculations with the Gaussian 98 program package.[30] [b] Available experimental data are from refs.[31,32]

For reactions of the type considered in this work $\Delta G = \Delta G^i - \Delta G^s$, where ΔG^i is the Gibbs free energy change of the adduct formation reaction without solvation and ΔG^s is the additional term due to the effect of solvation. We performed a trial plot of ΔG against μ according to Equation (5) for nine different N-donors (**1**–**9**), shown in Figure 5, to determine if there exists any correlation between ΔG (or ΔG^s) and μ. The plot shows a good linear relationship. Therefore, we concluded that ΔG, and hence ΔG^s, are controlled by μ of the N-donor after the reaction field model.

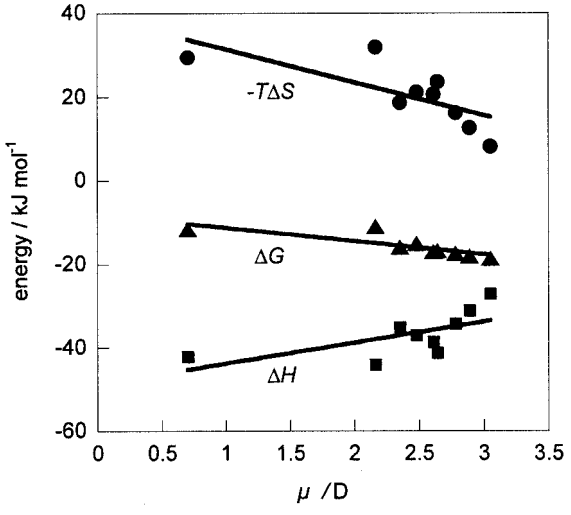

Figure 5. Correlation between ΔH, ΔG, or $T\Delta S$ and dipole moment. Data were taken from Tables 3 and 4 (for ligands **1**–**9**) at 20 °C and fitted to a linear relation.

Enthalpy and Entropy Contributions

The stabilization model by solvation seems to explain the μ-dependence of ΔG in the MTO·N-donor adduct formation. Since the Gibbs free energy consists of enthalpy and entropy terms ($\Delta G = \Delta H - T\Delta S$), we discuss the solvation effect by considering the two terms separately and try to understand how these thermodynamic terms (ΔH and ΔS) of the reaction depend on the dipole moment of the N-donors.

For a given reaction, the enthalpy and entropy changes can be considered to be composed of intrinsic (ΔH^i and ΔS^i) and solvation (ΔH^s and ΔS^s) terms:

$$\Delta H = \Delta H^i + \Delta H^s$$

$$\Delta S = \Delta S^i + \Delta S^s$$

In the enthalpy term, the second term is for the solvation energy and is possibly proportional to μ. We plot the ΔH values against μ in Figure 5 to find some correlation between ΔH and μ. Figure 5 shows a reasonable linear dependence of ΔH upon μ. Therefore, we concluded that ΔH is controlled by μ of the N-donors, and the reaction field model seems valid in the adduct formation MTO + N-donor → Adduct. Since the slope in the plot of ΔH vs. μ is positive, the solvation energy of the reactants is larger than that of the adduct. We discuss this result according to Equation (5). Since the refractive index, n, and the dielectric constant, ε_r, of the solvent are constant, we consider only the μ^2/r^3 term. This formula means that the solvation energy depends on the dipole moment and the volume. We discuss these factors separately. The volumes of MTO and the N-donor are smaller than the adduct, although one can assume that this factor, compare to the dipole moment, is not very important, because $r_{MTO\cdot N} \approx r_{MTO} + r_N$. Thus, the solvation energy for the reactants is larger than that of the adduct. The dipole moment plays an important role in the solvation. The dipole moment of the adduct is probably smaller than the reactants due to the structure of the adduct. The dipoles of MTO and N-donors may be antiparallel and cancel each other out in the adduct. Also, the ΔH value for the adduct MTO·3,4-dimethylpyridine is less negative (–27.1 kJ mol^{-1}) than the others (i.e. MTO·3-ClPy: ΔH = –44.1 kJ mol^{-1}), although the formation constant is the highest (2082.5 L mol^{-1} at 20 °C). It seems that this donor is better solvated, due to its larger dipole moment, and this reduces the overall enthalpy.

The ΔS values, which are negative in the present association reaction, apparently depend on μ and change from –104.1 to –29.0 (J K^{-1} mol^{-1}) as μ increases from 0.7 to 3.05 D, for ligands **5** and **6** respectively. We qualitatively discuss the relation between enthalpy change (ΔH^s) and entropy change (ΔS^s) by solvation. The ΔH values are plotted against ΔS in Figure 6. The absolute value of ΔH (or exothermicity of the reaction) increases as the entropy change decreases, which indicates that solvation controls not only ΔH but also ΔS. When the N-donor has negligibly small μ, the enthalpy changes of solvation ΔH^s for the reactants and the adduct are negligible, and the solvent molecules are loosely bound to the reactants and the adduct. Thus, the solvent molecules are not well aligned with the reactants or with the adduct (negligible ΔS^s). This is the case of the "small μ limit" as shown in the energy diagrams in Figure 7. On the other hand, for the N-donor having large μ, the solvation energy becomes much larger, according to Onsager's reaction field model (negative and larger ΔH^s), and the solvent molecules are tightly trapped by the reactants and the adduct. Thus, the solvent molecules are well aligned

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with the reactants and with the adduct (negative and large ΔS^s). This is the case of the "large μ limit" in Figure 7. As a result, the absolute magnitudes of ΔH and ΔS values decrease when μ changes from the small μ limit to the large μ limit. It might be worthy to note that: (1) both ΔH and $T\Delta S$ contribute similarly to ΔG, and that (2) these contributions cancel out each other, resulting in a rather constant ΔG value against μ. This feature is visualized in Figure 5, where ΔG, ΔH, or $-T\Delta S$ are plotted against μ values; the ΔH and $T\Delta S$ contributions vary, but ΔG does not vary greatly for various N-donors with different μ. All these phenomena can be reasonably explained in the thermodynamical terms described above.

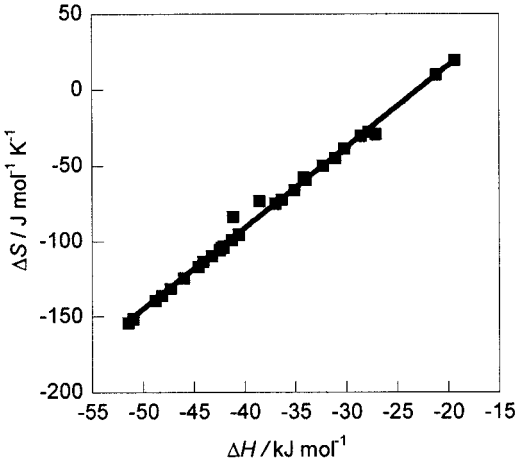

Figure 6. Correlation between ΔH and ΔS (enthalpy–entropy compensation) for adduct formation of MTO with pyridine derivatives. The data are listed in Table 3.

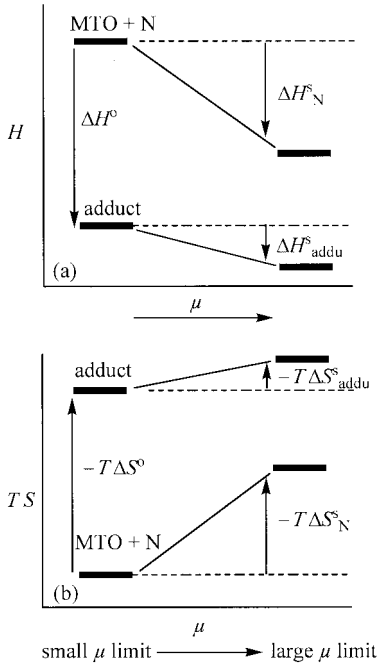

Figure 7. Energy diagrams of the reactants and the adduct: (a) enthalpy changes upon adduct formation; (b) entropy changes upon adduct formation. Both ΔH and $T\Delta S$ are small for N-donors with large μ.

The enthalpy–entropy compensation plot of adduct formation of MTO with pyridine derivatives, which is shown in Figure 6, gives a good straight line. This may be taken as evidence for the operation of a common structure–activity relationship in this series of complexes.[36,37]

Conclusions

Lewis-base adducts of MTO are known to be more rigid at lower temperatures and less strongly coordinated at higher temperatures. The stability of the adducts formed by pyridine and its derivatives with MTO is entirely due to a negative ΔH, while ΔS counteracts the adduct formation investigated here. ΔH and ΔS are controlled by the dipole moments of pyridine derivatives. Both ΔH and ΔS are small for N-donors with large μ.

Experimental Section

The compound methyltrioxorhenium ($MeReO_3$ or MTO) was synthesized according to a literature procedure.[22] The pyridine derivatives were purchased from commercial sources (Merck or Fluka) and were used as received. Benzene (Merck, quality: for spectroscopy) was used as solvent throughout this study and the data were obtained at different temperatures (10, 20, 30, and 40 °C). A Perkin–Elmer Lambda 25 spectrophotometer with temperature control using an EYELA NCB-3100 constant temperature bath was used to record UV/Vis spectra. Typically, a 2×10^{-4} M solution of the MTO in benzene contained in a quartz cuvette with a 1-cm path length was treated with successive aliquots of a solution of the N-donor ligand, of known concentration, in the same solvent. The values of stability constants and the extinction coefficient of adducts at different wavelengths were determined by fitting the equilibrium absorbance to Equation (2) by the method of nonlinear least-squares.

Acknowledgments

We thank the Shiraz University Research Council, Iran (Grant No. 82-SC-1664-C259) for financial support. We also thank Dr. Ghatee for his key help in purchasing the UV/Vis spectrometer.

Dinuclear Complexes of M^{II} Thiocyanate (M = Ni and Cu) Containing a Tridentate Schiff-Base Ligand: Synthesis, Structural Diversity and Magnetic Properties

Suparna Banerjee,[a] Michael G. B. Drew,[b] Can-Zhong Lu,[c] Javier Tercero,[d] Carmen Diaz,*[d] and Ashutosh Ghosh*[a]

Keywords: Copper / Nickel / N,N,O ligands / Schiff-base ligands / Magnetic properties / Crystal structures

A dinuclear Ni^{II} complex, $[Ni_2(\mathbf{L})_2(H_2O)(NCS)_2]\cdot 3H_2O$ (**1**) in which the metal atoms are bridged by one water molecule and two μ_2-phenolate ions, and a thiocyanato-bridged dimeric Cu^{II} complex, $[Cu(\mathbf{L})NCS]_2$ (**2**) [**L** = tridentate Schiff-base ligand, *N*-(3-aminopropyl)salicylaldimine, derived from 1:1 condensation of salicylaldehyde and 1,3-diaminopropane], have been synthesized and characterized by IR and UV/Vis spectroscopy, cyclic voltammetry and single-crystal X-ray diffraction studies. The structure of **1** consists of dinuclear units with crystallographic C_2 symmetry in which each Ni^{II} atom is in a distorted octahedral environment. The Ni–O distance and the Ni–O–Ni angle, through the bridged water molecule, are 2.240(11) Å and 82.5(5)°, respectively. The structure of **2** consists of dinuclear units bridged asymmetrically by di-$\mu_{1,3}$-NCS ions; each Cu^{II} ion is in a square-pyramidal environment with τ = 0.25. Variable-temperature magnetic susceptibility studies indicate the presence of dominant ferromagnetic exchange coupling in complex **1** with J = 3.1 cm^{-1}, whereas complex **2** exhibits weak antiferromagnetic coupling between the Cu^{II} centers with J = –1.7 cm^{-1}.

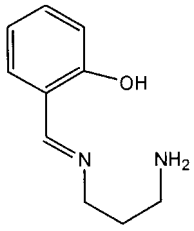
Introduction

Dinuclear metal complexes and ligands facilitating their formation have been extensively investigated due to their potential applications in many field of chemistry.[1–10] The essential requirements for the formation of these dimeric complexes are an unsaturated coordination environment of the single-coordinated metal ion and the presence of bridging atoms or groups. The bridging abilities of the phenolate oxygen atom[11] and polyatomic moieties[12–15] (e.g. N_3, NCO, NCS, NCSe) have been exploited extensively for the synthesis of dinuclear species. However, it is very difficult to predetermine the structure of the self-assembled species when both types of bridging groups are present. Parameters that should be considered to achieve the desired species in such cases include the nature of the metal ions and their coordination requirement. In order to have an insight into the controlling parameters we have synthesized complexes of Ni^{II} and Cu^{II} with thiocyanate and the tridentate Schiff-base ligand **L** (Scheme 1), prepared by 1:1 condensation of salicylaldehyde and 1,3-propanediamine. We have found that Ni^{II} forms a phenolate-bridged dinuclear complex with thiocyanate acting as terminal ligand, whereas Cu^{II} yields an end-to-end thiocyanato-bridged dinuclear species having phenoxo as the terminal ligand.



Scheme 1. Ligand **L**.

The structural and magnetic properties of dinuclear nickel(II) complexes with bridging ligands have received considerable attention over the past two decades. Magneto-structural correlations have been made and interesting trends have emerged. Among these compounds, the azide group has been predominant due to its versatility as a ligand. When the N_3^- anion acts as bridging ligand, normally the end-to-end 1,3-coordination mode gives antiferromagnetic coupling, while the end-on 1,1-mode gives ferromagnetic coupling, but for very large M–$\mu_{1,3}$-N_3–M bond angles the magnetic coupling may be reversed.[16–19] For the SCN^- anion the bridging mode usually involves a 1,3-coordination mode with both nitrogen and sulfur atom bound to the metal ions. From crystal structures it has been shown

experimentally that in Ni^{2+} dinuclear complexes, all dinuclear $[Ni_2(\mu\text{-}NCS)_2]$ cores have approximately the same angles and distances, and they generally show low ferromagnetic behavior, which was explained by Ginsberg et al.[19d] and Duggan et al.[19e] Ferromagnetic interactions have been found, generally, in octahedrally coordinated dimeric nickel(II) complexes with 1,3-thiocyanate[16a,17] and -selenocyanate bridges.[18]

When the phenolate acts as a bridging ligand through the oxygen atom in dinuclear nickel(II) complexes, generally antiferromagnetic behaviour was found;[20–23] only three complexes showing ferromagnetic coupling have been described in the literature.[24] Complex **1**, is, to the best of our knowledge, the first dinuclear complex in which the octahedral Ni^{2+} ions share a face, and it is therefore of considerable interest that its magnetic behavior is ferromagnetic.

The study of polynuclear complexes of Cu^{II} with pseudohalogen bridges has received considerable attention in recent years.[25–29] Again, there are many examples of such complexes in which the azide group acts as a bridge. By contrast the literature available for magneto-structural studies on Cu^{II} complexes containing the bridging thiocyanate groups is scarce, as this ligand is less versatile and also less efficient as a transmitter of magnetic interactions than the azide.[26,27] Most of the previously reported asymmetric end-to-end 1,3-thiocyanate-bridged Cu^{II} compounds have octahedral geometry and exhibit very low values of *J* or paramagnetic behavior.[26a,28,29] There are only a few examples of double bridged end-to-end thiocyanato dimers in which the Cu^{II} atoms are five-coordinate.[28,30] The design of molecule-based magnets relies on the presence of both intra- and intermolecular coupling. Therefore, the identification of structural features that can be correlated with the strength and sign of this interaction clearly constitutes a necessary step in such design.

Results and Discussion

Synthesis

The monocondensed ligand *N*-(3-aminopropyl)salicylaldimine (**L**) was prepared as $[NiL_2]$ by the reaction of Ni^{II} nitrate, salicylaldehyde and 1,3-propanediamine (see Exp. Sect.). $[NiL_2]$ reacted readily with $Ni(SCN)_2$ in a 1:1 molar ratio in methanolic solution to produce the μ_2-phenolato- and aqua-bridged complex $[Ni_2(L)_2(H_2O)(NCS)_2]\cdot 3H_2O$ (**1**). The free ligand (**L**) which was isolated by removing nickel as bis(dimethylglyoximato)nickel(II) from $[NiL_2]$, on reaction with the methanolic solution of copper acetate followed by ammonium thiocyanate yielded the thiocyanato-bridged dinuclear complex $[Cu(L)NCS]_2$ (**2**).

IR Spectra

In the IR spectrum of complex **1**, a strong band at 2091 cm^{-1} is due to ν(CN) of the *N*-bonded thiocyanate and a band at 1626 cm^{-1} is due to ν(CO) of the phenolato-bridged ligand. The broad band in the range 3391–3340 cm^{-1} is assigned to the O–H stretching vibrations of uncoordinated and bridged water molecules.

In complex **2**, only one ν(CN) vibration at 2094 cm^{-1} is observed, due to the presence of bridging thiocyanato ligands and the ν(CS) is assigned at 782 cm^{-1}. The C=N stretch of the phenolate ligand is observed near 1630 cm^{-1} in both complexes. The two primary NH_2 stretching modes are clearly seen in **2** near 3310 and 3185 cm^{-1} for the asymmetric and symmetric vibrations respectively.

Description of Structure 1

The molecular structure of **1** is shown in Figure 1. Selected bond lengths and angles are summarized in Table 1. The dimeric structure shows a crystallographic two-fold

axis through the bridging water molecule O100. The dinuclear unit is formed by two Ni^{II} atoms labeled Ni1 and Ni1A, bridged by this water molecule and by the two μ_2-phenolato oxygen atoms O11 and O11A of the Schiff-base ligands. The two equivalent nickel atoms have distorted octahedral environments. The basal plane $Ni_2N_2O_2$ is formed by the two nitrogen atoms N18 and N22 and the two oxygen atoms O11 and O11A of the bridging phenoxo ligands. The N1 atom of the thiocyanato terminal ligand and the O100 atom of the bridging aqua ligand occupy the axial positions. The two Ni atoms are separated by 2.953(4) Å with two Ni–O11–Ni bridge angles of 91.5(4)° and one Ni–O100–Ni bridge angle of 82.5(5)°. The basal bond lengths around the Ni atom are in the range of 1.990(10)–2.131(9) Å. The apical bond lengths are Ni1–N1 2.039(12) Å and Ni1–O100 2.240(11) Å, the bond angle being O100–Ni1–N1 170.5(4)°. The Ni–NCS distance, 2.039(12) Å, is as expected. However, the Ni–OH_2 distance, 2.240(11) Å, although comparable to those found in some aqua-bridged dinuclear Ni^{II} complexes,[31] is much longer than the range 2.09–2.16 Å reported for few other known examples of water bridges in Ni^{II} structures.[32] Some of this bond lengthening can be accounted for by the involvement of the bridging water molecule in hydrogen bonds to another water molecule O101. Another water molecule O102 is also hydrogen-bonded to the nitrogen atom of the thiocyanato ligand (Figure 2). The *cis* angles in the nickel polyhedra are all within 15° of 90° (Table 1). These distortions can be rationalized as resulting from the ligand constraints in the molecule, particularly in the bridging system.

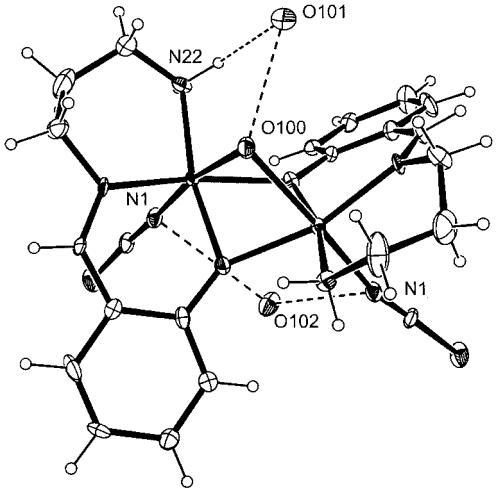

Figure 2. Hydrogen bonding in complex **1** involving uncoordinated water molecules (30% thermal probability ellipsoids, water molecules uninvolved in hydrogen bonding are omitted for clarity).

Description of Structure 2

Figure 3 shows an NCS-bridged copper dimer $[Cu_2(\mathbf{L})_2(\mu\text{-NCS})_2]$, in which the asymmetric units are related by a centre of inversion. Selected bond lengths and angles are summarized in Table 2. The intradimer Cu–Cu distance is 5.863 Å. The copper atoms are located in a distorted square-pyramidal environment as revealed by the trigonal index, $\tau = 0.25$. The value of τ is defined as the difference between the two largest donor–metal–donor angles divided by 60, a value which is 0 for the ideal square pyramid and 1 for the trigonal bipyramid[33] In the present case τ is calculated as (176.8 – 161.4)/60 = 0.25. The elongated square-pyramidal (4 + 1) geometry of the copper(II) centers is constructed from a basal plane containing three ligating atoms, O, N2, N3 of the tridentate Schiff-base ligand and a nitrogen atom, N1 from the thiocyanate group. In addition, the elongated apical position is occupied by the weakly bonded sulfur donor atom S′ from the other centrosymmetrically related thiocyanato bridge at a distance of 2.952(1) Å (symmetry operation: $^1/_2 - x$, $^1/_2 - y$, $1 - z$); the bond angle at the axially coordinated Cu–S′–C1′ being 102.6(1)°. The metal–nitrogen and metal–oxygen distances involving the equatorial plane ($CuON_3$) agree well with those generally found in five-coordinate Cu^{II} complexes.[26a,30] The metal atom is 0.064 Å above the basal plane in the direction of the apex, which is usual for square-pyramidal geometry. The dimeric units are related by translation along the *y* axis to form extended chains by strong interdimer hydrogen bonding between the amine nitrogen atom of one dimeric unit and the phenolate oxygen atom of the adjacent dimeric unit (N2A···O = 2.938 Å, H2A···O = 2.067 Å, ∠N2–H2A···O′ = 162.67°) (Figure 4). The shortest interdinuclear Cu^{II}–Cu^{II} distance between the two H-bonded units is

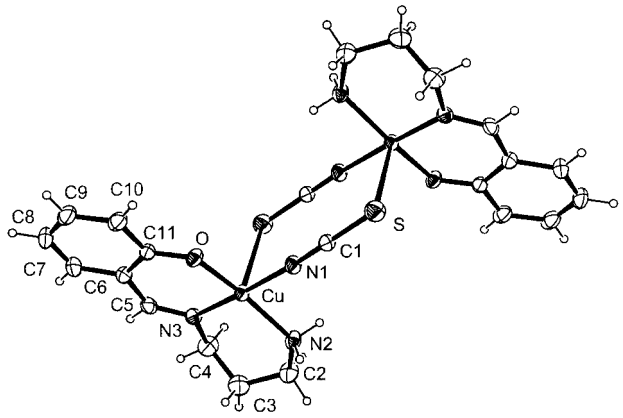

Figure 3. Perspective view of complex **2** (30% thermal probability ellipsoids).

3.571 Å. Numerous (thiocyanato)Cu^{II} complexes have been described in the literature; however, it is worth noting that most of them are made up of dinucluear entities and have octahedral coordination around Cu^{II} containing di-$\mu_{1,3}$-NCS bridges[17] whereas in the present complex end-to-end thiocyanato-bridged dimer the Cu^{II} atoms are five-coordinate.

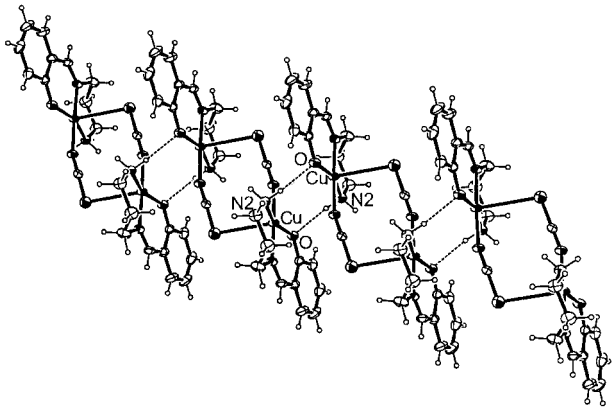

Figure 4. Molecular packing view of **2** along the *y* direction; the intermolecular hydrogen bonds are shown as dashed lines.

Electronic Spectra

The peaks in the electronic spectrum, taken in the solid state (Nujol mull) and in acetonitrile solution are similar in the two complexes.

The dinickel complex **1** exhibits two distinct bands at 610 and 874 nm and a weaker band near 773 nm. The first two bands can be assigned to the spin-allowed d-d transition $^3T_2 \leftarrow {}^3A_{2g}$ and $^3T_{1g} \leftarrow {}^3A_{2g}$, respectively, and the weaker band to the spin-forbidden transition $^1E_g \leftarrow {}^3A_{2g}$. These values are in agreement with the literature values for octahedral Ni^{II} compounds.[34]

The dicopper complex **2** shows a d-d transition around 612 nm. The UV absorption band observed at 358 nm can be assigned to the charge transfer transition. Strong absorption bands in the region 280 nm are clearly also due to charge transfer.

Electrochemical Study

The cyclovoltammogram of complex **1** in acetonitrile solution (Pt electrode) under nitrogen displays a electrochemically irreversible (ΔE_p = 120 mV) oxidative response attributed to the Ni^{II}/Ni^{III} couple at +0.70 V vs. SCE.

The cyclovoltammogram of the copper complex **2** recorded in dry acetonitrile solution (vs. SCE) at ambient temperature exhibits a reversible signal at +1.1 V (ΔE_p = 80 mV). The redox process is assigned to Cu^{2+}/Cu^{3+} oxidation. No reductive response of either Cu^{2+}/Cu^{1+} or Cu^{2+}/Cu was observed in the cathode sweep.

To ascertain the stoichiometry of the redox couple of the Cu^{II} complex **2** we performed constant potential exhaustive electrolysis at +1.25 V under ambient conditions. The coulomb count of the experiment revealed one electron oxidative transfer from Cu^{2+} resulting in the formation of Cu^{III} analogs. The oxidized Cu^{III} compound, however, is not isolable at room temperature but stable enough for EPR study at 77 K (toluene/acetonitrile mixture) to determine the metal valence. The oxidized compound is EPR-inactive under frozen glass conditions (77 K), thereby confirming the formation of a diamagnetic Cu^{III} species.

The other possibility of ligand oxidation has been far outweighed from this experimental observation, which otherwise would have resulted in an odd electron paramagnetic species (s = 1/2), sensitive towards EPR measurement. Therefore, it is justified to conclude the oxidative response at +1.1 V to be associated with a Cu^{II}/Cu^{III} oxidation instead of an energetically unfavourable phenolate moiety based ligand oxidation event.

Magnetic Properties

The variable-temperature magnetic properties $\chi_M T$ vs. T of **1** and **2** are illustrated in Figures 5 and 6, respectively.

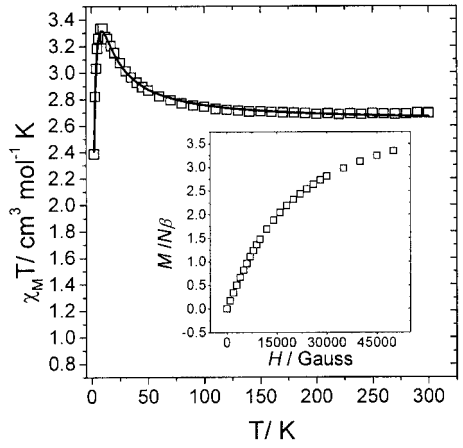

Figure 5. Plot of $\chi_M T$ [cm^3 mol^{-1} K] vs. T [K] in the range 2–300 K for **1**. The solid line is generated from the best-fit magnetic parameters. Inset: Plot of $M/N\beta$ vs. H for complex **1**.

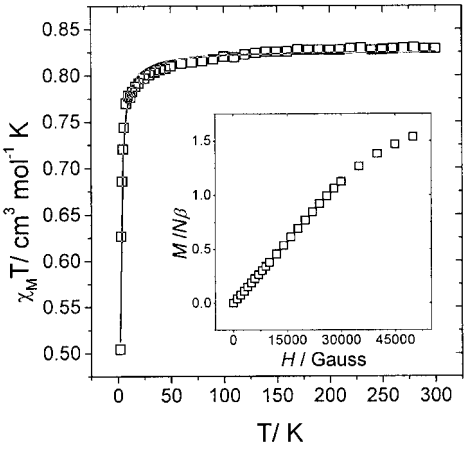

Figure 6. Plot of $\chi_M T$ [cm^3 mol^{-1} K] vs. T [K] in the range 2–300 K for **2**. The solid line is generated from the best-fit magnetic parameters. Inset: plot of $M/N\beta$ vs. H for complex **2**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In complex **1** the $\chi_M T$ values (χ_M is the molar susceptibility for two Ni^{II} ions) show a gradual increase from a room-temperature value of 2.70 $cm^{-1} mol^{-1} K$ to 3.25$cm^{-1} mol^{-1} K$ at 6 K, followed by a drop at lower temperature. This behavior is typical of a system exhibiting dominant intramolecular ferromagnetic exchange coupling. The $\chi_M T$ vs. temperature curve for **1** was least-squares-fitted {by minimizing the function $R = \Sigma[(\chi_M T)_{exp.} - (\chi_M T)_{calcd.}]^2/\Sigma(\chi_M T)_{exp.}^2\}$ to the theoretical expression of magnetic susceptibility of Ginsberg et al.,[35] from the Hamiltonian

$$H = -2JS_1S_2 - D(S_{1Z}^2 + S_{2Z}^2) - g\beta H(S_1 + S_2) - Z'J'S\langle S\rangle$$

in which J is the intradimer exchange parameter, D the single-ion zero-field splitting, and $Z'J'$ the parameter for effective interdimer exchange; it is assumed that $g_x = g_y = g_z = g$. The resulting χ_M expression is:

$$\chi_M = 2Ng^2\beta^2/3k[F_1/(T - 4Z'J'F_1) + 2F'/(1 - 4Z'J'F')$$

F_1 and F' being complicated functions of temperature, zero-field splitting, and the intradimer exchange parameter J.

The best-fitting parameters obtained are $J = 3.1(1)$ cm^{-1}, $g = 2.29(1)$, $D = 1.8(1)$ cm^{-1}, $Z'J' = -0.2(1)$ cm^{-1} with $R = 1.8 \times 10^{-5}$. These values should be considered with caution because, although the Ginsberg expression gives accurate values of J and g, the parameters D and $Z'J'$ are not well determined from magnetic susceptibility data.[35b,35c] The value of the reduced molar magnetization is 3.55 $N\beta$ when the field is 5 T (inset, Figure 5). This small value can be explained by the presence of either parameter D or antiferromagnetic interdimer interactions or by a combination of the two.

For complex **2** the value of $\chi_M T$ at 300 K is 0.83, which is expected for two magnetically quasi-isolated spin doublets ($g > 2.00$). This value remains practically constant upon cooling and then decreases sharply in the low-temperature region attaining a value of 0.50 at 2 K; no maximum of the magnetic susceptibility (χ_M vs. T) is observed. These observed features are characteristic of very weak antiferromagnetic interactions between copper(II) ions. We have analyzed the magnetic data through a simple Bleaney–Bowers expression for a copper(II) dimer,[36] derived through the isotropic Hamiltonian $H = -JS_1S_2$, where J is the exchange coupling parameter and $S_1 = S_2 = 1/2$ (interacting local spins). Least-squares fitting leads to the following parameters: $J = -1.71(1)$ cm^{-1}, $g = 2.10(1)$, and $R = 3 \times 10^{-5}$ {R is the agreement factor defined as: $R = \Sigma[(\chi_M T)_{exp.} - (\chi_M T)_{calcd.}]^2/\Sigma(\chi_M T)_{exp.}^2\}$. Considering that in complex **2** the dinuclear entities are linked by structurally strong hydrogen bonds, the fit of the magnetic data has been carried out, too, by the Bleaney–Bowers expression taking into account the J' intermolecular parameter. The best-fit parameter obtained was $J = -1.8$ cm^{-1}, $J' = 0.10$ cm^{-1}, $g = 2.10$ and the same R value. The small positive J' value indicates that the hydrogen intermolecular interactions could be ferromagnetic. The value of the reduced molar magnetization is 1.55 $N\beta$ when the field is 5 T (inset in Figure 6). The shape of the curve formed by the experimental points does not follow the Brillouin formula. This feature is also indicative of the small antiferromagnetic coupling.

Discussion

Complex 1

The demonstration of a linear dependence of the exchange coupling constant (J) with the Cu–O–Cu bridge angle in planar dihydroxy-bridged dicopper(II) complexes has turned out to be one of the most useful and best known magneto-structural correlations.[37] Unlike hydroxo- and alkoxo-bridged Cu^{II} dinuclear complexes[38] structural modeling and magneto-structural correlations are scarce in nickel(II) complexes, due to fewer number of known complexes and to the large number of structural parameters that affect the superexchange mechanism in these systems. Dinuclear nickel(II) complexes in which one or two phenolate groups act as bridges are generally found to be antiferromagnetic.[20–23] Ferromagnetic behavior has been found in only three complexes[24] of which one has not been structurally characterized,[24a] while the other two have one of the nickel ions in a five-coordinate, trigonal-bipyramidal coordination environment. Correlations of the superexchange coupling in centrosymmetric Ni–O–Ni dinuclear nickel(II) complexes made by Nanda et al.,[21] and a quantumchemical ab initio study by Wang el al.,[39] show that the value of the exchange coupling constants is directly proportional to the Ni–O–Ni bridge angles or Ni···Ni distance. The results (at least qualitatively) are in very good agreement with nearly all measurements on such complexes: Thus, for Ni–O–Ni angles in the region of 90° the coupling is ferromagnetic with J values in the order of 10 cm^{-1}. The magnetic properties of **1**, which contain a distorted octahedral geometry around the Ni^{2+} ions and with a noncentrosymmetric structure, are interpreted in terms of two different bridges, the phenolate and the H_2O. The Ni–O–Ni′ bridge angle through the phenolato ligand is 91.5(4)° and the Ni···Ni distance is 2.953(4) Å. The Ni–O100–Ni′ bridge angle through the oxygen atom of the water molecule is 82.2(4)° and the Ni–O100 distance is 2.240(11) Å. Taking into account the small Ni···Ni distance and the small angles in the bridges, it is reasonable to assume a ferromagnetic exchange through the two kinds of bridges.

Complex 2

A weak but significant interaction between the copper(II) centers is observed through the end-to-end thiocyanato intrametallic bridges. Complex **2** shows the following features: (a) the copper(II) centers are bridged by two thiocyanate ions in an asymmetric end-to-end fashion, (b) the copper(II) ions are five-coordinated, (c) the nitrogen atom of the SCN bridge ligand lies in the equatorial plane and the sulfur li-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gand occupies the axial position. Few complexes with these characteristics are reported in the literature.[30]

The majority of the complexes described in the literature with NCS^--bridged ligand(s) with an N(basal)–S(apical) disposition, exhibit either very low values of J or paramagnetic behavior.[26a,28,29] This behaviour is characteristic of all complexes and does not seem to depend on either the topology of the copper(II) centers (usually octahedral) or the existence of single or double μ-NCS bridges.

EPR Measurements

The X-band EPR spectra of complexes **1** and **2** were recorded on microcrystalline powders at temperatures from 280 to 4 K.

It is of interest to note that in complex **1** the spectrum, recorded at low temperature, shows only one absorption at very low field (Figure 7a). For an axial integer $S = 2$ spin system, the zero-field interaction (D parameter) splits the m_s levels into two doublets $m_s = |\pm2\rangle$ and $|\pm1\rangle$ and one $m_s = 0$ state. Transitions between these Kramer doublets are not possible due to the D value expected for the nickel(II) ion. For a rhombic distortion, the E parameter splits the $m_s = |\pm2\rangle$ and $m_s = |\pm1\rangle$ Kramer doublets giving a Δ_2 and Δ_1 gap at zero field. The value of Δ_1 is strongly dependent on E and is usually much greater than the $g\beta H$ energy of an X-band measurement. In contrast, the Δ_2 increases as a function of E^2/D and the ±2 transition usually lies in the low-field region of the spectra.[40] This type of EPR spectrum is similar to that previously reported for manganese(III), iron(IV), and tetranuclear cobalt(II) spectra.[24b,41]

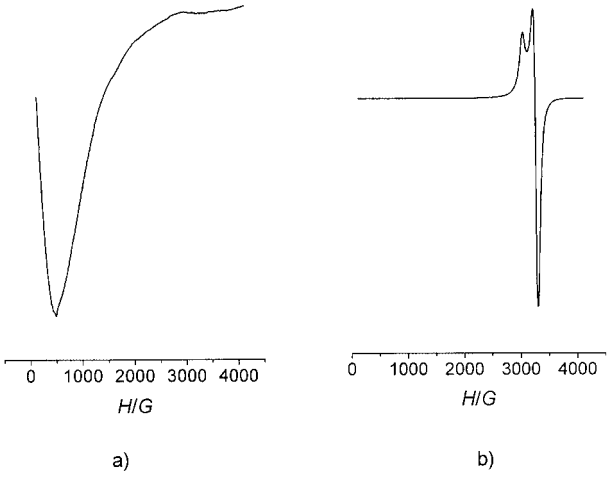

Figure 7. EPR spectra of polycrystalline complexes **1** (a) and **2** (b) at 4 K.

The X-band EPR spectra of complex **2** shown in Figure 7b shows absorption features of axial symmetry with $g_{\|} = 2.22$ and $g_{\perp} = 2.08$. The observed g inequality ($g_{\|} > g_{\perp}$) is consistent with the square-pyramidal geometry of complex **2** with the unpaired electron residing in the $3d_{x^2-y^2}$ orbital thereby making $^2B_{1g}$ the ground state.

Conclusions

Two new complexes of Ni^{II} and Cu^{II} thiocyanate have been synthesized using an N,N,O-donor Schiff-base ligand. The tridentate ligand is chelated and the thiocyanate ion is coordinated to metal centers through the nitrogen atom in both complexes, as expected. However, the construction of the dinuclear entities occurs in very different ways. In complex **1** two Ni ions are bridged through the phenolate oxygen atom, and a water molecule acts as an additional bridge to complete the hexacoordination around the nickel ion. On the other hand, the sulfur atom of the *N*-bonded thiocyanato ligand coordinates axially to bridge the two copper atoms in complex **2**. The weak axial coordination and consequently the square-pyramidal geometry around Cu^{II} is probably dictated by the active Jahn–Teller effect of the d^9 system. Thus, the nature of the metal ion plays a very important role in the self-assembly of the mononuclear units into the dinuclear complex. From the magnetic point of view complex **1** is the first example where dinucluear Ni^{II}, simultaneously bridged by phenolato and aqua ligands, exhibits ferromagnetic behaviour.

Experimental Section

Starting Materials: Salicylaldehyde, 1,3-diaminopropane, $Cu(OAc)_2{\cdot}H_2O$, ammonium thiocyanate and Ni^{II} salts were purchased from commercial sources and used as received. HPLC grade acetonitrile, was used for electrochemical and UV/Vis measurements and all other solvents were of reagent grade and were used without further purification.

Physical Measurements: Spectral measurements were carried out using the following equipments: UV/Vis (both in acetonitrile solution and solid), Hitachi-U 3501 Spectrophotometer. IR (KBr disc), Perkin–Elmer RXI FT-IR spectrometer and Nicolet Magna IR 750 Series II. A Perkin–Elmer 240C elemental analyzer was used for microanalysis (C, H, N). The magnetic measurements were carried out in the "Servei de Magnetoquimica (Universitat de Barcelona)" on polycrystalline samples (20 mg) with a Quantum Design SQUID MPMSXL susceptometer in the temperature range of 2–300 K and the magnetic field was 1 T. Magnetization measurements were carried out in the same instrument at 2 K. EPR spectra were recorded on powder samples at X-band frequency with a Bruker 300E automatic spectrometer, varying the temperature between 4 and 300 K. Electrochemical measurements were performed under nitrogen using a PAR model Versastat-2 electrochemical analyzer, with a platinum working electrode under dry nitrogen. The supporting electrolyte was tetraethylammonium perchlorate (TEAP), and the potentials are referenced to the saturated calomel electrode (SCE) without junction correction.

***N*-(3-Aminopropyl)salicylaldimine (L):** The complex bis(3-aminopropylsalicylideneiminato)nickel(II) ($C_{20}H_{26}N_4Ni$) was prepared by the method of Elder.[42] A solution of the ligand (10 mmol) was obtained by refluxing the Ni^{II} complex (2.06 g, 5 mmol) with 2 equiv. of DMG (1.16 g, 10 mmol) in methanol (20 mL) for 2 h and filtering the precipitated bis(dimethylglyoximato)nickel(II) according to the procedure of Burke and McMillin.[43]

$[Ni_2(L)_2(H_2O)(NCS)_2]{\cdot}3H_2O$ (1): $Ni(SCN)_2$ (0.351 g, 1.5 mmol), dissolved in 10 mL of hot methanol, was added to a methanolic solution (10 mL) of bis(3-aminopropylsalicylideneiminato)nickel(II)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(0.619 g, 1.5 mmol) and stirred for 10 min. The colour of the solution turned to light green. The resulting solution, on keeping at room temperature for several hours, yielded a dark green crystalline solid. It was filtered and dissolved in a minimum volume of acetonitrile and kept in a refrigerator. Upon slow evaporation of the solvent, dark green crystals of complex **1,** suitable for X-ray analysis appeared after 2 d. Yield: 0.529 g (86%). $C_{22}H_{34}N_6Ni_2O_6S_2$ (660.06): calcd. C 40.03, H 5.19, N 12.73; found C 39.90, H 5.14, N 12.72.

[Cu(L)NCS]$_2$ (2): To a solution of **L** (0.534 g, 3 mmol) in methanol (10 mL), $Cu(OAc)_2 \cdot H_2O$ (0.598 g, 3 mmol), dissolved in a minimum volume of hot methanol, was added and stirred for 30 min. To the resulting solution, a methanolic solution of NH_4SCN (456 mg, 6 mmol) was added. The blue solution yielded needle-shaped crystals on keeping at room temperature for 24 h. Yield: 0.824 g (92%). $C_{11}H_{13}CuN_3OS$ (298.02): calcd. C 44.21, H 4.38, N 14.06; found C 44.15, H 4.30, N 14.51.

X-ray Crystallography: Data for both crystals were measured with Mo-K_α radiation (λ = 0.71073 Å) using a MARresearch Image Plate System for **1** and a Siemens SMART CCD diffractometer for **2**. For **1** the crystals were positioned at 70 mm from the image plate. 100 frames were measured at 2° intervals with a counting time of 2 min. Data analysis for **1** was carried out with the XDS program[44] and for **2** with the SHELXAL™ V.5.03 program.[45] The structures were solved by direct methods (SHELX-86 program for **1**[46] and SHELXTL for **2**). Absorption corrections were carried out using DIFABS[47] for **1** and SADABS for **2**[48] The structures were then refined to convergence on F^2 using SHELXL for **1**[49] and SHELXTL for **2**. The non-hydrogen atoms were refined with anisotropic thermal parameters in all cases. For **1** the hydrogen atoms bonded to carbon atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atoms to which they are attached. All calculations were carried out using SHELX-86, SHELXL-93, PLATON-99 for **1** and Siemens SHELXTL, Bruker SHELXTL for **2**. Selected bond lengths and bond angles of the crystals are presented in Tables 1 and 2. while selected crystallographic data for the two complexes are summarized in Table 3. Repeated recrystallization from acetonitrile failed to produce good-quality crystals of **1**. The poor quality of the crystals of **1** gave rise to misshapen large spots in the diffraction pattern which in turn led to high *R* values. CCDC-256766 (**1**) and -256767 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Amphiphile Structures in the Solid State: Complex Cations with Lipophilic Substituents

Jack M. Harrowfield,*[a,b] George A. Koutsantonis,[a] Gareth L. Nealon,[a] Brian W. Skelton,[a] and Allan H. White[a]

Keywords: Cage complexes / Lipophilicity / Solid state structures

Structural characterisation of hexamine cage complexes, two containing diamagnetic Co^{III} and one containing paramagnetic Cu^{II}, to which both rather short (C_4) and relatively long (C_{13}) alkyl substituents have been attached, shows that while the longer "tail" introduces an anticipated bilayer form to the crystalline solid, even the shorter tail can be associated with a form of aggregation of lipophilic entities in the crystal. The short tail at least may also be involved in interactions with anions of a complex type. As surfactants, functionalised cage complexes contain a head group, which is a multi-site hydrogen-bonding entity, and which can thus provide a mechanism for further aggregation concomitant with that of any apolar functionality.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

As potential head groups for surfactant molecules, complex cations and anions offer the chance to introduce entities, often chiral, of unusually high charge, of variable spectroscopic and magnetic properties, and with structures that may facilitate specific forms of association of counterions with those head groups.[1] The same virtues apply, of course, in the design of metallomesogens.[2] The kinetic inertness and ease of functionality of cage amine complexes[3] render them particularly appealing for use as head groups, and it has been shown that surfactants derived from Co^{III} cage complexes can have unusual physical and biological properties.[4] In seeking to expand this field of chemistry, we have investigated alternative syntheses of amphiphiles and what might be termed "reverse" bola-amphiphiles[5,6] based on cage amine complexes of various metals and have sought to characterise these materials in detail, in the solid state, through X-ray crystallography. This report is specifically concerned with some structural results, which have uncovered both expected and unexpected properties concerning the cage amines **1**–**3**

The broad basis of the present work was an effort to develop methods for the synthesis of functionalised cage amines, which continued to exploit the advantages associated with the selective protection of nucleophilic centres by metal ion coordination,[3,4] while avoiding the commonly encountered difficulty[3f,7] of the need for extreme conditions in order to remove the new ligands from the metal centre on which they are formed. In the case of reductive alkylation reactions of amine centres as presently described, the use of a metal (Mg^{II}) easily removed[7] from the cage as an agent to protect endocyclic amine centres introduces problems in that even the mildly acidic conditions normally applied in $RCHO/NaBH_3CN$ reactions[8] cause its loss from the reactant cage. However, the value of the syntheses described herein is that they demonstrate that Mg^{II}, under weakly basic conditions, can be used to selectively protect multiple N-donor sites, while efficient reductive alkylation still occurs at unprotected centres.

$CH_3(CH_2)_2CHO/NaBH_3CN$ in large excess results in quite efficient monoalkylation. As in simple alkylation reactions,[3f] this monofunctionalisation appears to occur predominantly on a secondary and not a primary amine centre of the reactant, generating the ligand **1**. The reaction was studied in order to establish a model procedure for alkylations involving long-chain aldehydes, although it in fact did not prove particularly useful for this purpose. As expected for a ligand-containing tertiary nitrogen donor centres,[3c,3f,9] significant distortions of the coordination sphere of a bound metal result, this being reflected in the beautiful crimson (not yellow) colour (λ_{max} 502 nm) of the Co^{III} complex, $[Co(\mathbf{1})]^{3+}$. Given the presence of a lipophilic (albeit short) substituent on **1**, the high water-solubility of all simple salts of $[Co(\mathbf{1})]^{3+}$ was surprising and thus the crystal structure of $[Co(\mathbf{1})][Sm(dipic)_3]\cdot 15\,H_2O$ was studied in order both to characterise the Co^{III} coordination sphere and to determine what interactions with the butyl chain might be involved. The high degree of hydration of this material is typical of compounds containing $[Ln(dipic)_3]^{3-}$ species,[10,11] though it was not immediately clear that this should be the only consideration here. The discovery that $[Sm(dipic)_3]^{3-}$ in particular could be used to obtain a crystalline solid from $[Co(\mathbf{1})]^{3+}$ was purely a matter of good fortune, resulting from the availability of hydrated $Na_3[Sm(dipic)_3]$ in the laboratory, and was not a consequence of any logic other than "charge matching" of the anion and cation (Table 1).

The complex, a racemate in a non-centrosymmetric space group, crystallises with one formula unit, devoid of crystallographic symmetry, comprising the asymmetric unit of the structure. Projections of the cation, the anion, and the unit cell, viewed variously, are presented in Figure 1, with hydrogen bonding summarised in Table 2. The cation presented in part (a) of Figure 1 is very similar to that found in the complex of 3-carboxymethyl-1,8-diaminosarcophagine (**4**), in $[Co(\mathbf{4})]Cl(S_2O_6)\cdot 4.5\,H_2O$.[3f] The bond to the tertiary donor [Co–N(3b), 2.063(4) Å] is elongated compared to those to the secondary donors [1.974–2.000(4), <> 1.986(11) Å], though in the present case by only ca. 0.07 Å rather than ca. 0.09 Å. The cation again has the lel_3 configuration, with two NH units (3a,3b′) H bonding to one water molecule [O(6) ($^1/_2 - x$, $\bar{y}$, $z - {}^1/_2$)], two others (3c,3a′) H bonding to separate water molecules H-bonded to one another [O(1,4)], and the remaining NH (3c′) interacting with an uncoordinated carboxylate-*O* [O(14)] of an adjacent complex anion. Bridging of NH units by H-bond acceptors appears to be a significant feature concomitant with adoption of the lel_3 form.[3f] The primary amino groups are also involved in H bonding to both water and carboxylate groups, as part of the extended H bonding array in the heavily hydrated crystal, which resembles overall that found in other $[Ln(dipic)_3]^{3-}$ derivatives. The *N*-butyl substituent is extended and remote from water molecules, projecting towards a neighbouring complex anion, the terminal methyl group appearing to contact at least one pyridine ring, with C···ring centroid 3.76 Å (CH···π interaction?), and the adjacent methylene carbon atom [C(33b)] being 3.361(7) Å from a coordinated carboxylate-*O* [O(13)] (CH···O bonding?). The anion geometry is similar to those reported for related $[Ln(dipic)_3]^{3-}$ species,[10,11] with Sm–N 2.551–2.556(3), <> 2.554(3) Å; Sm–O 2.420–2.478(4), <> 2.45(2) Å.

When viewed down *a* and *b* [part (b) of Figure 1], the lattice of $[Co(\mathbf{1})][Sm(dipic)_3]\cdot 15\,H_2O$ appears to contain separate columns of the two metals, Co and Sm, running parallel to *a*. Two Sm columns nearly superimpose and may be considered as one column gently undulating about *a*. Along *c*, these columns are separated by double columns of Co atoms which can also be considered as in a markedly zig-zagged array of a single column down *a*. The alternations in both these "columns" are associated with the fact

that the metals are the centres of chiral entities (cationic for Co, anionic for Sm), such that the undulation/zig-zag can be described as ···Δ–Λ–Δ–Λ–Δ–Λ–Δ–Λ··· in both cases. Columnar arrays, more often homochiral {as in the closely-related $[Co(sar)][Eu(dipic)_3]\cdot 13\,H_2O$;[10] and see below} than heterochiral as here, are very commonly seen in structures of $[Ln(dipic)_3]^{3-}$ derivatives,[10,11] interactions (stacking and edge-to-face[12]) of the heteroaromatic ligands, as seen in many similar helical complexes,[13] possibly being one factor favouring their presence. Given its persistence, it is perhaps appropriate to regard this array as a kind of "molecular register" which, in the present case, determines the associated array of chiral cations. Along *c*, the necessarily polar cation array is such that the butyl substituents of both Δ and Λ species are oriented to the one side of each zig-zag column, creating two different "sides" to the undulating Sm complex columns (perpendicular to the undulation plane). For a given Sm centre, its nearest Co neighbour [at 7.027(1) Å] to one side is from a complex unit of the same chirality for which the butyl substituent approaches the dipicolinate ligand atoms on the Sm. To the other side, a slightly more remote Co [at 7.392(1) Å] is the centre of a complex cation of the opposite chirality. Interactions here occur through a pair of H-bonded water molecules which is H-bonded to a cation NH and an uncoordinated carboxylate-*O* of the anion.

A possibly simpler analysis of the lattice is provided in the view down *b*, from which it appears that the two metals can also be considered to form true columns parallel to *b*. The complexes in these columns are all of the same chirality, species contacts within the columns all seemingly the result of H bonding involving lattice water, so that the (homochiral) Sm···Sm distance, *b* [10.439(2) Å], is longer than the (heterochiral) separation, *a*/2 [= 18.890(2)/2 Å], associated with aromatic/aromatic interactions in the undulating column parallel to *a*. Homo- and hetero-chiral Co···Co separations, *b* and 10.235(2) Å, respectively, differ much less, perhaps reflecting the fact that H bonding (via water) is the common cause of contact.

A feature lacking in the lattice of $[Co(\mathbf{1})][Sm(dipic)_3]\cdot 15\,H_2O$ is any sign of close contact between the butyl substituents of the cations. This is consistent with the lack of any evidence for surfactant properties of $[Co(\mathbf{1})]^{3+}$ or the related dibutylated complex $[Co(\mathbf{2})]^{3+}$ in aqueous solution, and with the expectation that a butyl chain would be too short to induce such properties in a cage complex.[4] Though the difficulty of obtaining adequate crystals means that relatively limited structural data are available for true

surfactant complexes,[1,14] these do show prominent aggregation of the lipophilic moieties in the lattice. It is somewhat surprising, therefore, that the crystal structure of [Co(**2**H_2)]Cl_5·6H_2O does provide evidence for association of the butyl substituents. In this complex, one half of the formula unit comprises the asymmetric unit of the structure. The cation present in this compound [part (a) of Figure 2], disposed with the central Co on a crystallographic *2*-axis, adopts the relatively uncommon but still quite familiar *ob*$_3$ conformation,[3b–3f] but has properties otherwise completely unexceptional for a Co^{III} complex of a cage amine. The *ob*$_3$ conformation, as in other cases, appears to result from the abundance of H-bond acceptors within the lattice, this leading in particular to the absence of any bridging interactions involving the secondary NH entities of a given complex unit. Such bridging "chelation" of chloride anions by *lel*$_3$ cations formally results, in several instances,[3] in the presence of D_3-symmetric {Co(L)Cl_3} ion quartets, but here the coordinated NH centres of the cation separately hydrogen-bond to chloride ions [N,H(3a)···Cl(1) 3.149(2), 2.3; N,H(3b)···Cl(1) (${}^1/_2 + x$, ${}^1/_2 - y$, z) 3.202(1), 2.3$_5$; N,H(3c)···Cl(2) 3.144(1), 2.3 Å], while the terminal ammonio groups contact both Cl [N(0),H(0a)···Cl(3) 3.058(2), 2.2 Å] and water molecule oxygen [N(0),H(0b)···O(01) 2.791(2), 1.9 Å], displacement amplitudes of all non-hydrogen atoms in this cation/anion/solvent system being small ($U_{eq} \leq 0.031$ Å^2), the cation "tail" excepted. Amplitudes in the latter increase markedly towards its periphery [parts (b) and (c) in Figures 2] and are high, as are those of the remaining anion, Cl(4), (which, located on a "special position" of the lattice, may be susceptible to unresolved disorder) and the remaining water molecules, many of these modelled as disordered fragments and forming a much less well-defined segment of the array. Cl(1–3), in fact, all have bridging functions, Cl(1) bridging a pair of cations as indicated above, while Cl(2,3), both located on symmetry elements – a mirror plane and a *2*-axis, respectively – link the symmetry images, via NH···Cl interactions. Other close contacts to the chlorides are sparse (Table 3), involving for Cl(1,3) a further pair of water molecules (or fragments), symmetry-related for Cl(3).

The lattice of [Co(**2**H_2)]Cl_5·6H_2O can be regarded as built up from alternating sheets parallel to the [–2,0,1] plane, one sheet containing complex cations and some chloride anions, the other water molecules and chloride ions. Viewed down *b*, the sheets are seen edge-on, with the cations extended in the *ac* plane. Within the cation sheets, there are regions where all polar entities, including chloride, are excluded and the butyl chains aggregate. These "greasespot" regions (Figure 3) are defined by laterally compressed hexagonal clusters of essentially coplanar cation units, which alternate in chirality Δ–Λ–Δ–Λ–Δ–Λ around the hexagon. The arrays in adjacent cation planes are displaced such that each greasespot contacts carbon atoms of ethylene links of the complex cations, two sets thereof in each plane above and below, creating thus a "greaseball". Closest C···C contacts within this greaseball range from 3.7–4.3 Å, very similar to analogous contacts in structures of true surfactants,[1] with the shortest present contact being 3.743(4) Å between the 3-carbon atoms of adjacent butyl chains. Though the greaseball structure may be a conse-

based on the use of Mg^{II} to protect the secondary amino group nitrogen atoms of the reactant, illustrates a problem presumably due to association in the preparative medium. Thus, dialkylation predominates even in media where the reactant ratio is 1:1, a result which may be explicable if initially-formed mono-alkylated complex associates with unreacted aldehyde and so favours its attack on the other primary amino group of the same complex entity. (Note that the dialkylated product is the symmetrical 1,8 isomer.) The complex as crystallised, modelled as $[Cu(\mathbf{3}H)][Cu(\mathbf{3}H_2)](ClO_4)_7{\cdot}6H_2O$, contains formally a 1:1 mixture of diprotonated and monoprotonated cations [part (a) of Figure 4], a circumstance encountered in various unfunctionalised cage complexes[15] and, presumably, another indication of the important influence of H bonding on the form of the lattices, since the "additional" proton is taken to be shared between pairs of monoprotonated complex cations. The lattice, as viewed down *c*, for example, [part (b) in Figure 4] shows multiple layering, one aspect of which is the double layer of cage units formed by the (amino) head-to-head H-bonded array of complex cations. Consistent with related known structures[3c,3f,15,16] and the susceptibility of Cu^{II} to Jahn–Teller distortions, the CuN_6 environment (Table 4) in the cage is not only irregular, but disordered with the chiral, *lel*$_3$ complex cations distributed equally as Δ and Λ species over the available sites. The cores of the cations are disposed about copper atoms lying at (approximately) $z = {}^1/_3, {}^2/_3$, forming layers encompassing perchlorates 1,3 which lie close and equidistant to either side [*z*(Cl(1,3)) 0.27, 0.40], the "inwardly" directed oxygen atoms O(11–13;31–33) interacting directly with the cation or a translation image within the layer by way of hydrogen bonds with the core NH centres, and in such a way that the interaction is with one or other of the disordered components. Thus, O(11) contacts H(3a,3cB), O(12) contacts H(3b,3aB) ($x - 1$, $y - 1$, z) and O(13) contacts H(3c,2bB) (where "B" atoms belong to the Λ form of the cation, otherwise Δ) among the unprimed $(NH)_{3(2/2)}$ triad, while O(31) contacts H(3a′,3b′B) ($x - 1$, $y - 1$, z), O(32) H(3b′,3c′B) ($x - 1$, $y - 1$, z), and O(33) H(3c′,3a′B) among the primed, all at distances of 2.1–2.4 Å. No disorder is resolvable in these two perchlorates, U_{eq} among the hydrogen-bonded oxygens all ≤ 0.08 Å^2, excepting O(31) (0.13). Displacement amplitudes on perchlorate 2 are also ≤ 0.1 Å^2, presumably in consequence of its proximity to water molecules 1,2 [O(21)···O(02); O(23)···O(01) both 2.96(1) Å, hydrogen atoms not located] but anion **4** is modelled with half-occupancy, presumed disordered in concert with O(03,04) (water) about $z = 0.5$, this plane also imaging the $NH_2{\cdots}H{\cdots}H_2N$ cation components.

Between the polar layers just described, the tridecyl chains aggregate to form a lipophilic layer about 13 Å thick, the extended, *transoid* chains being bent away from the *pseudo-C$_3$* axis of the head group complexes so as to lie, with their neighbours down *a*, in sheets which confront similar, parallel sheets arising from the next layer of complex units. As in some[14,17] but not all[1] related complex structures, there is no interdigitation of the chains, and closest

Table 4. Selected bond lengths and bond angles for [Cu(**3**H)][Cu(**3**H_2)]$(ClO_4)_7$·6H_2O.

Atoms	Bond lengths [Å]	Atoms	Bond angles [°]
Cu–N(3a)	2.17(1)	N(3a)–Cu–N(3a′)	79.4(5)
Cu–N(3aB)	2.16(1)	N(3aB)–Cu–N(3a′B)	80.8(5)
Cu–N(3a′)	2.24(2)	N(3b)–Cu–N(3b′)	83.2(4)
Cu–N(3a′B)	2.27(1)	N(3bB)–Cu–N(3b′B)	82.3(4)
Cu–N(3b)	2.16(1)	N(3c)–Cu–N(3c′)	82.9(4)
Cu–N(3bB)	2.15(1)	N(3cB)–Cu–N(3c′B)	80.7(5)
Cu–N(3b′)	2.15(1)		
Cu–N(3b′B)	2.151(9)		
Cu–N(3c)	2.21(1)		
Cu–N(3cB)	2.10(1)		
Cu–N(3c′)	2.07(1)		
Cu–N(3c′B)	2.18(1)		

C···C within and between chain layers lie in the range ca. 4.1–4.3 Å, presumably indicative of extensive but rather weak dispersion interactions (as found in other systems, interdigitated or not). For a given H-bonded pair of complex cations bridging a layer the tails are oppositely oriented, so as to make a centrosymmetric entity.

Conclusions

The high aqueous solution solubility of simple salts of [Co(**1**)]$^{3+}$ is presumably indicative of a low lattice energy for the solids, since substitution of N(butyl) for NH in the cation would, again presumably, not enhance its hydration energy. A low lattice energy could result from the particular regioisomeric form being such as to inhibit association between butyl entities and other components present (e.g. water, chloride) not being capable of significant interactions with butyl, so that the apparent CH_3-π and CH···O interactions of the butyl group observed in [Co(**1**)][Sm(dipic)$_3$]·15H_2O may be important determinants of its insolubility. Although yet to be quantified, such effects are of potential interest for the systematic construction of crystalline solids, in particular for the use of a "molecular register" defined by columnar arrays of $\{[Ln(dipic)_3]^{3-}\}_n$.[18] The structure of [Co(**2**H_2)]Cl_5·6H_2O shows that a butyl substituent upon a cage complex is not too short to be involved in lipophilic aggregation processes and indicates that there may be novel ways for such "reverse bola-amphiphile" complexes to aggregate in solution, possibly more readily exploited in systems with alkyl-functionalised chelate arms. Association of relatively water-soluble cage complexes in solution may be a more useful means of creating a multi-electron redox catalyst than that of linking cage units through kinetically inert scaffolds.[19] The structure of the true surfactant species [Cu(**3**H)][Cu(**3**H_2)]$(ClO_4)_7$·6H_2O shows both that introduction of a sufficiently long alkyl-chain substituent gives rise to solid state aggregation of a familiar form, and that, when considered with the other structures presently described, a cage complex head group is not a simple cationic centre and may be involved in a variety of interactions which could provide mechanisms for the control of solution aggregation processes.

Experimental Section

Instrumentation and Procedures: ^1H and ^{13}C NMR spectra were recorded with a Bruker ARX 500 instrument (^1H at 500.13 MHz, ^{13}C at 75.5 MHz) using solvent resonances [CH_3OH (^1H: 3.34 ppm, ^{13}C: 49.50 ppm); $(CH_3)_2CO$ (^1H: 2.22 ppm, ^{13}C: 215.94, 30.89)] as internal references. Tridecanal was freed of contaminant acid by washing its dichloromethane solution with aqueous $NaHCO_3$. Cation exchange chromatography was conducted under gravity flow in glass columns using either Na^+-form SP Sephadex C25 or H^+-form Dowex 50Wx2 resins.

Synthesis: 1,8-Diamino-3-butylsarcophagine (**1**), and its Co^{III} Complex, [Co(1)][Sm(dipic)$_3$]·15H_2O (dipic = pyridine-2,6-dicarboxylate, dipicolinate). $(NH_2)_2$sar[7] (0.53 g) and large excesses of butanal (3.0 mL) and $NaBH_3CN$ (0.25 g) were dissolved in absolute ethanol (50 mL) and the mixture heated at reflux under Ar for 24 h. The solvent was then removed under reduced pressure and the oily brown residue acidified with concentrated HCl. The resulting mixture of a clear brown solution and a small amount of brown oil was again taken to dryness and *cis*-[$CoCl_2(OH_2)_4$]·2H_2O (0.44 g) in water (20 mL) added, followed by sufficient ethanol to give a homogeneous solution. After aerating and heating (steam bath) the mixture for 30 min, the deep pink-red supernatant solution was decanted from some residual brown oil, diluted with water (500 mL) and passed through a column of Na^+ form SP Sephadex C25 cation exchange resin. The absorbed complexes were then eluted with 0.1 mol L^{-1} Na_2HPO_4. A small amount of Co^{II} was rapidly eluted first, followed by a trace amount of a pink species which was not further characterised beyond recording its ^1H NMR spectrum, which indicated that it did contain (probably mono-) alkylated cage ligand. The bulk of the product was in the third eluted fraction, from which the complex was recovered as its chloride by H^+ form Dowex 50Wx2/HCl chromatography. This material proved to be extremely soluble in water and no efficient way of precipitating the cation from solution was found other than to crystallise it as its $[Sm(dipic)_3]^{3-}$ derivative. Thus, the residue obtained by evaporating a 3 mol L^{-1} HCl solution of the complex to dryness was dissolved in water and an excess of $Na_3[Sm(dipic)_3]$[10] added. The precipitate which formed immediately (due to acid decomposition of the Sm complex), was dissolved by the dropwise addition of aqueous NH_3 (2 mol L^{-1}) and the deep pink solution formed was allowed stand overnight as small, pink tablet-like crystals, as used for the X-ray work, deposited. Sample drying prior to analysis appeared to cause some loss of water relative to the composition found from the crystal structure determination: [Co(1)][Sm(dipic)$_3$]·8H_2O = $C_{39}H_{67}CoN_{11}O_{20}Sm$ (1219.3): calcd. C 38.42, H 5.54, N 12.64; found C 38.3, H 5.4, N 12.4. NMR spectra were recorded on the residue obtained by evaporating a solution of the chloride salt after it had been re-evaporated (twice) from D_2O. ^1H NMR (D_2O): δ = 0.96 (t, 3 H), 1.42 (m, 2 H), 1.75–2.00 (m, 2 H), 2.85–3.70 (m, 26 H) ppm. $^{13}C\{^1H\}$ NMR (D_2O): δ = 13.66, 20.37, 24.82, 51.22, 51.51, 52.46, 53.02, 53.29, 53.83, 54.09 (br. s, possibly two unresolved resonances), 54.93, 55.07, 55.68, 56.60, 60.27, 61.22, 61.38 ppm.

1,8-Di(butylamino)sarcophagine (2) and its Co^{III} Complex [Co(2H_2)]Cl_5·*n*H_2O: [Co{$(NH_2)_2$sar}]$(OAc)_3$·6.5H_2O[3b] (626 mg), a large excess of butanal (20 mL) and an excess of $NaBH_3CN$ (170 mg) were dissolved in absolute EtOH (50 mL) and the reaction mixture heated at reflux under Ar for 24 h. The mixture was dried, treated with concentrated HCl (ca. 50 mL), and then dried again before adding water (ca. 100 mL). The brown mixture was then extracted with CH_2Cl_2 (4 × 150 mL), and after discarding the organic extracts, the aqueous layer was applied to a column of Na^+ SP

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Sephadex cation exchange resin. Elution with 0.1 M Na_2HPO_4 solution removed a very broad orange band, in which dialkylated product appeared to lead monalkylated but with imperfect separation, so that the leading third of the band was taken to obtain an eluate of predominantly the dialkylated species. Purification by absorption on H^+ Dowex 50Wx2 resin, elution with 5 M HCl, evaporation to dryness and crystallisation (twice) from the minimum quantity of hot water by addition of EtOH, gave a fine yellow powder of $[Co(\mathbf{2}H_2)]Cl_5{\cdot}nH_2O$ (50 mg; the total yield of mixed species was 270 mg) in a form which, after vacuum desiccation, appeared to be a trihydrate of the fully protonated complex. $C_{22}H_{52}Cl_5CoN_8{\cdot}3H_2O$ (719.0): calcd. C 36.75, H 8.13, N 15.59; found C 37.1 , H 7.1, N 15.5. ^{1}H NMR (D_2O): δ = 0.87 (t, 6 H), 1.35 (m, 2 H), 1.53 (m, 2 H), 2.85–3.20 (m, 16 H), 3.40–3.75 (m, 16 H) ppm. $^{13}C\{^1H\}$ NMR (D_2O): δ = 15.04 (CH_3), 21.43 (CH_2), 30.46 (CH_2), 45.05 (CH_2), 52.18 (CH_2), 55.52 (CH_2), 62.65 (4 C) ppm. Crystals for the structure determination were obtained by vapour diffusion of ethanol into a concentrated solution of the complex in 1 mol L^{-1} HCl, the structure solution being consistent with the tentative formulation of the crystalline material as an ethanol sesquisolvate trihydrate, $[Co(\mathbf{2}H_2)]Cl_5{\cdot}3H_2O{\cdot}1.5CH_3CH_2OH$. An inadvertent discovery appreciated only after completion of further structural work was that it would appear possible to separate the mono- and dialkylated complexes by fractional crystallisation of their chlorides. Thus, in an attempt to obtain crystals of the monoalkylated complex, vapour diffusion of ethanol into an aqueous solution of the residue from the trailing third of the SP Sephadex/Na_2HPO_4 chromatography band (indicated by ^{1}H NMR to be at least 90% monoalkylated complex) gave crystals subsequently shown, by means of the structure recorded herein, to be essentially those of the dialkylated species as its pentachloride hexahydrate.

Tridecylation of Diaminosarcophagine to give 1-Alkylated and 1,8-Dialkylated Derivatives 3 and 4, respectively: $(NH_2)_2$sar (1.02 g), $Mg(OAc)_2$ (1.89 g), tridecanal (0.990 mL) and $NaBH_3CN$ (215 mg) were dissolved in absolute EtOH (50 mL) and the reaction mixture heated at reflux for 24 h under argon. The white precipitate of magnesium acetate hydroxide was filtered off, the solution dried, and the oily white residue treated with concentrated HCl (ca. 10 mL). The mixture was again dried, and the white solid extracted with $CHCl_3$ (3 × 50 mL; discarded) and 1 mol L^{-1} HCl (3 × 10 mL), leaving a residue of dialkylated ligand hydrochloride. This was recrystallised from boiling methanol to give a white, waxy solid (762 mg). $(C_{13}H_{27}NH)_2$sar·4 HCl·3 H_2O = $[\mathbf{4}H_4]Cl_4{\cdot}3H_2O$ = $C_{40}H_{96}Cl_4N_8O_3$ (879.1): calcd. C54.65, H 11.01, Cl 16.13, N12.75; found 54.7, H 9.3, Cl 16.1, N 12.7. ^{1}H NMR (CD_3OD): δ = 0.90 (t, 6 H), 1.29 (m, br., 36 H), 1.39 (m, 4 H), 1.66 (m, 4 H), 2.75–3.50 (m, 28 H), 4.50 (m., br., NH) ppm. $^{13}C\{^1H\}$ NMR (CD_3OD): δ = 14.44, 23.73, 27.55, 28.00, 30.20, 30.47, 30.50, 30.62, 30.74, 30.77, 33.06, 42.88, 49.88, 53.19, 58.2 ppm. To isolate the pure monoalkylated ligand (as its Cu^{II} complex), the 1 mol L^{-1} HCl extracts of the bulk product were dried, the residue dissolved in water (ca. 30 mL) and excess $Cu(OAc)_2$ added. Concentrated ammonia (ca. 1 mL) was added and the blue solution was heated to boiling, producing a green precipitate of copper acetate hydroxide. After filtration, concentrated $HClO_4$ (ca. 1 mL) was added to the filtrate, producing a blue precipitate of the monoalkylated ligand complex. Yield: 144 mg. [Cu{(1-tridecylammonio)(8-ammonio)sar}][Cu{(1-tridecylammonio)(8-amino)sar}]$(ClO_4)_7{\cdot}6H_2O$ = $[Cu(\mathbf{3}H)][Cu(\mathbf{3}H_2)](ClO_4)_7{\cdot}6H_2O$ = $C_{54}H_{135}Cl_7Cu_2N_{16}O_{34}$ (1928.0): calcd. 33.64, H 7.06, Cl 12.87, N 11.62; found C 34.1, H 6.9, Cl, 13.7, N 11.6. ESMS: *m*/*z* (658.7) = $[Cu(\mathbf{3})(ClO_4)]^+$; *m*/*z* (320.8) = $[Cu(\mathbf{3})(CH_3CN)_2]^{2+}$; *m*/*z* (300.4) = $[Cu(\mathbf{3})(CH_3CN)]^{2+}$. The filtrate from the bulk of the rather insoluble Cu^{II} complex was allowed to evaporate slowly, producing blue crystals as used for the X-ray work. In order to obtain NMR spectra for the (coordinated) ligand, the complex was dissolved in hot water and converted into the zinc complex by addition of Zn powder. After heating and stirring the mixture for 15 minutes on the steam bath, the solid was filtered off and the clear filtrate was dried. The white solid obtained was only slightly soluble in D_2O, so the solution was acidified with a few drops of concentrated DCl, causing the solid to dissolve rapidly. ^{1}H NMR (D_2O/DCl): δ = 0.82 (t, 3 H), 1.25 (br. 20 H), 1.67 (br., 2 H), 2.50–3.70 (m, br. 26 H), 4.28 (br., ≈ 5 H, NH) ppm. $^{13}C\{^1H\}$ NMR (D_2O): 14.36, 23.11, 26.90, 27.12, 29.70, 29.99, 30.04, 30.30, 30.32, 30.37, 30.43, 32.44, 42.55, 49.20, 51.70, 53.12, 54.81, 56.49 ppm. It again appears that two methylene-C signals may superimpose but the important aspect of this $^{13}C\{^1H\}$ NMR spectrum is the appearance of two distinct quaternary carbons at δ = 51.70 and 56.49.

Structure Determinations: Full spheres of "low"-temperature CCD area-detector diffractometer data were recorded (Bruker AXS instrument, ω-scans; monochromatic Mo-K_α radiation, λ = 0.7107$_3$ Å; *T* ca. 153 K) yielding $N_{t(otal)}$ reflections, merging to *N* unique (R_{int} cited) after "empirical"/multiscan absorption correction (proprietary software), N_o with $F > 4\sigma(F)$ considered "observed" and used in the full-matrix least-squares refinements, refining anisotropic displacement parameter forms for the non-hydrogen atoms, $(x, y, z, U_{iso})_H$ (where defined) constrained at estimates. Conventional residuals *R*, R_w on |*F*| are cited at convergence {weights: $[\sigma^2(F_o) + 10^{-3}n_w F_o^2]^{-1}$}. Neutral atom complex scattering factors were employed within the Xtal 3.7 program system.[20] Pertinent results are given below and in the Tables and Figures, the latter showing 50% probability amplitude displacement envelopes, hydrogen atoms having arbitrary radii of 0.1 Å. Individual diversities in procedure are noted below (variata).

Variata: $[Co(\mathbf{1})][Sm(dipic)_3]{\cdot}15H_2O$. The residue assigned as water molecule oxygen 15 was modelled as disordered over a pair of sites of equal occupancy separated by 2.17(2) Å, associated hydrogen atoms not being located. Hydrogen atoms were located in association with all other water molecule oxygen atoms. "Friedel" data being retained distinct, x_{abs} refined to 0.062(8).

Variata: $[Co(\mathbf{2}H_2)]Cl_5{\cdot}6H_2O$ (crystallised from a solution containing largely the monoalkylated complex). Difference map residues were refined as (disordered) water molecule oxygen atom fragments. The O(01) site was fully occupied, with associated hydrogen atoms resolvable; for the remainder, no credible hydrogen atom complement could be resolved, occupancies being set at 0.5 [O(02–05)] or 0.25 [O(06–07)], after trial refinement. The possibility that the lattice contained both mono- and dialkylated species was a cause of some concern, the site occupancies of the "tail" components having little impact on the refinement for a range between 85 and 100%, though being finally set at the latter. As noted above, material more confidently assigned as fully dialkylated was also studied, being formulated in the refinement as an ("isomorphous") mixed ethanol/water solvate. Displacement parameters on the solvent component were very high, however, and the overall precision of the determination appreciably lower, so that the "hexahydrate" determination was ultimately preferred and presented, there being otherwise no non-trivial differences in cation model and geometries.

Variata: $[Cu(\mathbf{3}H)][Cu(\mathbf{3}H_2)](ClO_4)_7{\cdot}6H_2O$. The coordinated nitrogen atoms were modelled as disordered over pairs of sites, occupancies set at 0.5 after trial refinement. Perchlorate **4** was modelled over two sets of sites, occupancies set at 0.5, as also for water molecule oxygen residues O(03,04). Hydrogen atoms were not located in association with water molecule oxygen atoms; the stoichiometry

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the compound is rationalised in terms of the proximity of the amine cap N(0′) lying in the vicinity of an inversion image, distance 2.86(1) Å, postulating the array as $–NH_2\cdots H\cdots H_2N–$ or derivative.

For the latter two compounds, attempted refinement in lower symmetry was (inherently) unfruitful, the bulk of the structure (including the major species) being generally well-behaved in refinement except as detailed.

CCDC-194249, -194250 and -261886 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Multi-Channel Receptors and Their Relation to Guest Chemosensing and Reconfigurable Molecular Logic Gates

Diego Jiménez,[a] Ramón Martínez-Máñez,*[a] Félix Sancenón,*[a] José V. Ros-Lis,[a] Juan Soto,[a] Ángel Benito,[a] and Eduardo García-Breijo[b]

Keywords: Cations / Chemosensing / Chromophores / Electrochemistry / Molecular logic gates

The synthesis and characterisation of a family of multi-channel receptors containing crown-cation binding sites anchored to a 1-aminophenyl-1,2,2-tricyanoethylene group is reported. The ligands L^1–L^6 bear a 1-aminophenyl-1,2,2-tricyanoethylene scaffolding which is simultaneously a redox-active group (showing reduction processes at moderately modest potentials) and an acceptor moiety in the 1-aminophenyl-1,2,2-tricyanoethylene chromophore. Additionally, dyes L^1–L^6 also show fluorescence emission. The colour variation of L^1–L^6 in acetonitrile in the presence of the metal cations Ag^+, Cd^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Pb^{2+} and Zn^{2+} has been studied. Selective hypsochromic shifts were found for the systems L^4-Pb^{2+}, L^5-Hg^{2+} and L^6-Hg^{2+}. For Hg^{2+} with L^5 and L^6 and Pb^{2+} with L^4, emission fluorescence enhancements most likely associated with metal coordination to the anilinium nitrogen were observed. The electrochemical behaviour of receptors L^1–L^6 was studied in acetonitrile with platinum as working electrode and $[Bu_4N][BF_4]$ as supporting electrolyte. This family of receptors shows a one-electron reversible reduction process at around –0.70 V vs. SCE, attributed to the reduction of the tricyanovinyl group. Additionally, all the receptors also show the oxidation of the anilinium moiety at about 1.2–1.4 V vs. SCE. Significant anodic shifts of both reduction and oxidation waves were found in the presence of certain metal cations. The relationship of these multiple-channel signalling receptors with guest chemosensing and reconfigurable molecular-based logic gates is discussed.

Introduction

One of the most interesting and expanding fields in supramolecular chemistry is related to the management of input/output signals and their relationship with molecular information. This double "signal-information" concept has, for instance, been applied to different research fields, such as those of molecular logic gates[1] and chemosensing.[2] In the former, chemical species are used as inputs and the output is usually a light signal (emission or colour variation). In chemosensing protocols, light (emission or colour variation) or an electrochemical signal can be considered as input events which are related to the presence of certain chemical species (output information). In many cases these molecular input/output transducers have in common the presence of "binding sites" and "signalling" units.

In the development of chemosensors, the binding site is specifically designed to achieve a high degree of complementarity with target ions, whereas the signalling unit is capable of transducing the (usually selective) binding event into a signal.[3] Following this approach, a number of examples have been described in recent years on the synthesis of cation[4] and anion chemosensors.[5] A large number of coordination sites have been designed that are dependent on the nature of the guest. Three groups of reporters have been mainly used as signalling units: fluorescent groups[6] (the signal is an emission fluorescence change), dyes (the signal is a colour variation) and redox-active groups[7] (the signal upon guest coordination is a shift in the redox potential of the redox-active groups). Advances in this area have been described as important for the selective and sensitive development of target molecular probes.

However and despite the development of individual chromogenic, fluorogenic and electrochemical molecular sensors, there are few examples of receptors capable of displaying two or more output signals upon guest binding. Towards the development of multi-signalling receptors, we have recently reported chemosensors containing both anthracene (as fluorescent) and ferrocene (as electroactive) subunits.[8] Some other recent examples of multi-signalling include the work of Delavaux-Nicot et al., who have developed cation chemosensors containing ferrocene and *N*,*N*-diethylbenzene fluorescent groups.[9] A similar approximation has been used by Beer et al. by synthesising redox-

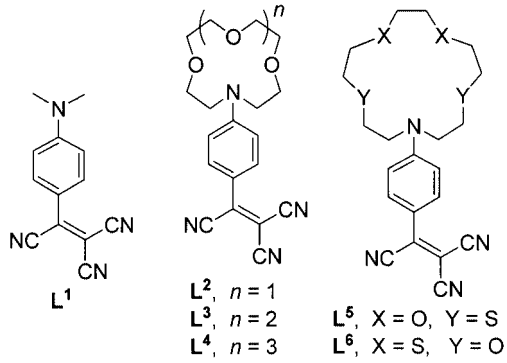
active and photoactive ruthenium(II) and osmium(II) bipyridylferrocene and -cobaltocene-containing macrocycles capable of sensing anionic guests by electrochemical and fluorescence techniques.[10] Also remarkable are the papers published by Shimidzu and Lehn.[11] Chemosensors functionalised with only one subunit capable of displaying two or more observable events (usually two-channel fluorescence – colour changes) upon addition of a certain guest are commonly observed in the so-called intrinsic sensors, in which at least one coordination atom from the binding site is also part of the signalling subunit (usually a dye scaffolding). For example, Fabbrizzi et al. recently reported the synthesis of a chemodosimeter for copper(II), composed of a cyclam unit functionalised with 7-nitrobenzo[1,2,5]oxadiazol-4-ylamine chromophore, which operates through two different channels − colour change and fluorescence quenching of the chromophore.[12] A pH sensor operating through both absorption and emission and based on 1,3-diaryl-5-pyridyl-4,5-dihydropyrazole has been reported by de Silva.[13] However, as far we know, chemosensors operating through three different channels (colour, fluorescence and redox) are very rare and are not common in the literature.[14] We report here the synthesis and characterisation of a family of multichannel receptors containing different crown cation binding sites anchored to a 1-aminophenyl-1,2,2-tricyanoethylene group, which is simultaneously a redox-active group (showing reduction processes at moderately modest potentials) and an acceptor moiety in the 1-aminophenyl-1,2,2-tricyanoethylene chromophore. Additionally, the synthesised receptors also show fluorescence emission. An advance report of the results shown here has recently been published.[14] These multi-signalling systems are not only of interest in sensing protocols but could also be of importance for the development of "reconfigurable" molecular-based logic gates.

Results and Discussion

Receptors L^2–L^6 are built of macrocyclic binding sites (of different sizes, also containing different heteroatoms; nitrogen, oxygen and sulfur) and an (aminophenyl)tricyanovinyl signalling reporter (Scheme 1). Ligands L^1 and L^3 have previously been synthesised by Charles[15a] and Beer,[15b] respectively. Receptor L^1 has an *N*,*N*-dimethylamino moiety and was selected as a model compound in order to study the selectivity towards metal cations imposed by the nature of the binding rings. The Richman–Atkins procedure was used to synthesise the phenyl-functionalised macrocyclic subunits.[16] Aza-oxa macrocycles were synthesised in high dilution procedures by deprotonation of *N*,*N*-phenyldiethanolamine (**3**) with sodium hydride followed by reaction with the methylsulfonyl ester derived from the corresponding polyethylene glycol (**2a**–**2c**; see Scheme 2). The macrocycles used to obtain receptors L^3 and L^4 were previously synthesised in 1978 by Vögtle.[17] The macrocycles used to obtain receptors L^5 and L^6, which contain sulfur atoms in their structures, were synthesised by a modified procedure in which 3,6-dioxaoctane-1,8-dithiol (**6a**) and 3,6-dithiaoctane-1,8-diol (**6b**) were deprotonated with potassium carbonate and sodium hydride, respectively, followed by treatment with the methylsulfonyl ester of *N*,*N*-phenyldiethanolamine (**5**) to give the sulfur-containing macrocycles **7a** and **7b**. *N*,*N*-Dimethylaniline and the synthesised phenyl-containing macrocycles were treated with tetracyanoethylene in warm DMF (60 °C) to give the corresponding receptors L^1–L^6, which were isolated as dark-reddish solids.



Scheme 1.

The ^{1}H NMR spectra of receptors L^2–L^6 show macrocyclic protons in the range of δ = 2.6 to 3.8 ppm, with two clearly defined zones − the methylene protons adjacent to the sulfur atoms at δ = 2.6–2.9 ppm and the methylene protons adjacent to nitrogen and oxygen atoms in the range δ = 3.5–3.8 ppm. Two doublets at δ = 6.70 and 8.00 ppm indicate the presence of a 1,4-disubstituted aromatic benzene ring. In the ^{13}C NMR spectrum the methylenes adjacent to the sulfur atoms appear in the range δ = 30–35 ppm, whereas the methylenes adjacent to nitrogen and oxygen show signals in the δ = 51–73 ppm range. The aromatic and cyanide carbons appear in the δ = 113–155 ppm range. The most significant signals are the three cyanide carbons centred at δ = 113.7, 114.0 and 114.5 ppm and the signals at δ = 117.8 and 137.3 ppm attributed to the quaternary carbons of the tetrasubstituted double bond.

Despite their easy synthesis and extensive application in different fields, such as optical recording materials or in electrophotography,[18] tricyanovinyl dyes have scarcely been used for sensing purposes. Phenyltricyanoethylene dyes coupled with a phenylboronic acid have previously been used as chromogenic reagents for carbohydrate sensing.[19] Additionally, receptors L^1 and L^3 have previously been used for electrochemical studies in the presence of Na^+, K^+ and Mg^{2+} cations.[15b]

The crystal structure of receptor L^5 was solved by single-crystal X-ray procedures. Suitable crystals for X-ray diffraction were obtained by slow diffusion of diethyl ether into dichloromethane solutions of the receptor L^5. The compound crystallises in the space group $P\bar{1}$ with two molecules of L^5 per asymmetric unit. Figure 1 shows a view of one of the two molecules. The aromatic ring, the double bond and the three cyanide moieties that form the chromogenic subunit are planar within the experimental error. This chromo-

genic subunit is linked to the macrocycle by a nitrogen atom.

Chromogenic Signaling

The visible spectrum of the chemosensors L^1–L^6 in acetonitrile solutions (5.0×10^{-5} M) is characterised by a band centred at about 520 nm which can tentatively be assigned to a charge-transfer band from the donor anilinium group to the acceptor tricyanovinyl moiety.[20] This visible band is responsible for the red-pink colour shown by the receptors in acetonitrile solution.

Addition of equimolar quantities of alkali (Li^+, Na^+, K^+) or alkaline-earth (Ca^{2+}, Ba^{2+}, Mg^{2+}) cations to acetonitrile solutions of receptors L^1–L^6 produced negligible changes in this band. The visible behaviour was also studied in the presence of the metal cations Cd^{2+}, Cu^{2+}, Hg^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+} and Ag^+. The model compound L^1, without a macrocyclic cavity in its structure, shows three different behaviours (see Figure 2 and Table 1); namely no changes with Ag^+ and Cd^{2+}, a slight hyperchromic effect (intensity enhancement of the visible band centred at 516 nm) in the presence of Zn^{2+}, Pb^{2+} and Hg^{2+}, and the apparition of a shoulder at 468 nm in the presence of Fe^{3+} and Cu^{2+} (see Figure 2) attributed to metal coordination with the donor nitrogen atom of the aniline group.[6] Upon titration of a

solution of receptor L^1 with Cu^{2+} cation, clear isosbestic points were obtained. The presence of these isosbestic points is indicative of the formation of only one complex, with a 1:2 stoichiometry (cation:receptor). Monitoring the changes at 468 nm upon Cu^{2+} addition, a logarithm of the stability constant of 4.53 ± 0.03 for the formation of the $[Cu(L^1)_2]^{2+}$ complex was obtained.[21] Studies with Fe^{3+} gave no clear isosbestic points, most likely due to the simultaneous formation of complexes with different stoichiometries.

[a] The downward pointing arrows indicate a significant hypochromic change in the visible band with respect to that of the free ligand.

On changing from the receptor L^1 to those containing macrocycles, important changes in the selectivity trends were found. Thus, addition of equimolar quantities of Cd^{2+}, Cu^{2+}, Hg^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+} or Ag^+ to acetonitrile solutions of L^2 produced negligible changes in the UV/Vis spectrum, whereas the presence of equimolar quantities of Fe^{3+} resulted in a remarkable hypochromic change (diminution of the visible band intensity of 60% for Fe^{3+}). A concomitant unremarkable hypsochromic shift of the band centred at 523 nm to 519 nm was also observed for Fe^{3+}. Studies on the variation of the intensity at 523 nm upon addition of increasing amounts of this cation suggested the formation of well-defined 1:1 complexes. A $\log K$ value of 4.69 ± 0.09 was determined for the formation of the $[Fe(L^2)]^{3+}$ complex (see Table 2).[21] These results for L^2, which has a relatively small coordination ring, are somehow related to the characteristics of the Fe^{3+} metal cation, which is, of all the metal cations studied, that with the smallest ionic radius (0.64 Å). The perfect fitting of the Fe^{3+} cation within the macrocyclic subunit of L^2 probably induces Fe–N interactions that could be the responsible for the hypsochromic shift observed. The lack of response in the presence of Cu^{2+} shown by L^2 (when compared to L^1) could be due to the poorer tendency of the Cu^{2+} cation to fit within the macrocyclic cavity (Cu^{2+} ionic radius = 0.69 Å), although steric constraints could make the Cu–N interaction less effective.

For L^3 − the macrocycle in L^3 contains one oxygen atom and one methylene unit more than the macrocycle in L^2 − only Fe^{3+} is able to induce a hypochromic change in the visible band at 518 nm similar to that observed for L^2 (no hypsochromic shifts were found). A $\log K$ of 4.63 ± 0.15 for the formation of the $[Fe(L^3)]^{3+}$ complex was obtained from the intensity changes of the 518 nm band (see Figure 3). The addition of equimolar quantities of the other metal cations tested induced negligible changes.

A more selective and remarkable behaviour was found for chemosensor L^4, which contains the largest macrocyclic cavity of all the receptors studied. A selective colour variation from red-pink to yellow-orange (hypsochromic shift from 520 to 475 nm) was observed upon addition of the heavy metal cation Pb^{2+} (see Figure 4).[22] This result is in agreement with the larger radius of Pb^{2+}, which apparently fits well into the large binding cavity of L^4. The correct combination of ring and cation size would result in a suitable coordination to the nitrogen atom of the macrocyclic subunit, thus inducing the hypsochromic shift of the charge-transfer band.[6] UV/Vis titration experiments for the system Pb^{2+}-L^4 showed clear isosbestic points indicative of the formation of 1:1 ligand-to-metal species. The $\log K$ for the formation of the $[Pb(L^4)]^{2+}$ complex, obtained by nonlinear least-squares treatment of the titration profile, is 6.42 ± 0.03 (see Figure 5).[21] The presence of Fe^{3+} results in

a hypochromic effect and an unremarkable hypsochromic shift of less than 10 nm. Monitoring the intensity changes at 520 nm upon addition of Fe^{3+} gave moderate log K values (4.97 ± 0.10). Addition of other metals such as Ag^+, Cu^{2+}, Cd^{2+}, Hg^{2+}, Ni^{2+} and Zn^{2+} to acetonitrile solutions of L^4 gave no change in the colour of the solutions.

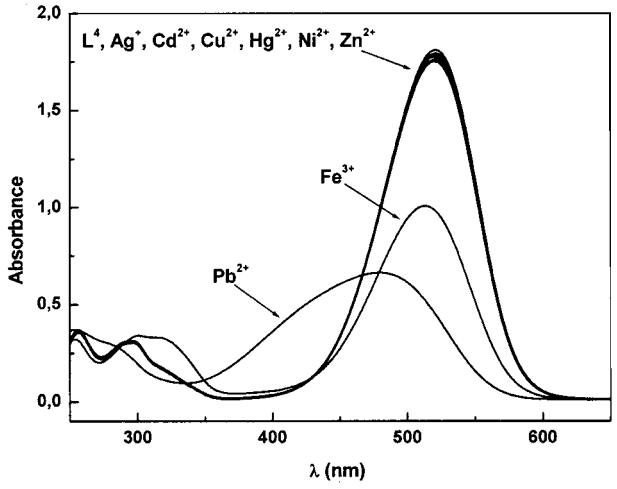

Figure 4. Changes in the UV/Vis spectra of receptor L^4 upon addition of equimolar amounts of metal cations in acetonitrile (5.0×10^{-5} M).

The receptors L^5 and L^6, which bear oxathiaaza crowns, were synthesised in an attempt to colourimetrically recognise additional thiophilic cations such as Hg^{2+}.[23] Thus, red-pink acetonitrile solutions of L^5 changed to yellow upon addition of Hg^{2+} due to a hypsochromic shift of the visible band upon cation binding (see Figure 6). Other metal cations (Li^+, Na^+, K^+, Ca^{2+}, Ba^{2+}, Mg^{2+},Cd^{2+}, Pb^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Ag^+ and Fe^{3+}) induced no significant changes.[24] The behaviour of acetonitrile solutions of receptor L^6 in the presence of equimolar quantities of metal cations was very similar to that found for L^5: only Hg^{2+} induced a significant hypsochromic shift of the band centred at 518 nm to 504 nm associated with a change in colour from pink to orange. This lesser hypsochromic shift shown by L^6 when compared to L^5 can be ascribed to the position of the sulfur atoms in the macrocyclic subunit. Hypsochromic shifts of a charge-transfer band are observed upon a suitable interaction (for instance coordination) with the donor group. In receptor L^5, the sulfur atoms are placed in the vicinity of the anilinium nitrogen that is part of the chromogenic unit. This spatial proximity might favour the interaction (orbital overlap) of the nitrogen with the Hg^{2+} cation. In receptor L^6, however, the sulfur atoms are separated from the anilinium nitrogen by oxygen atoms and the corresponding methylene subunits. In this case, a preferential coordination of the highly thiophilic Hg^{2+} cation with these sulfur atoms would result in a weaker interaction with the anilinium nitrogen, with concomitant smaller changes in the UV/Vis spectra. As in the above cases, the hypsoch-

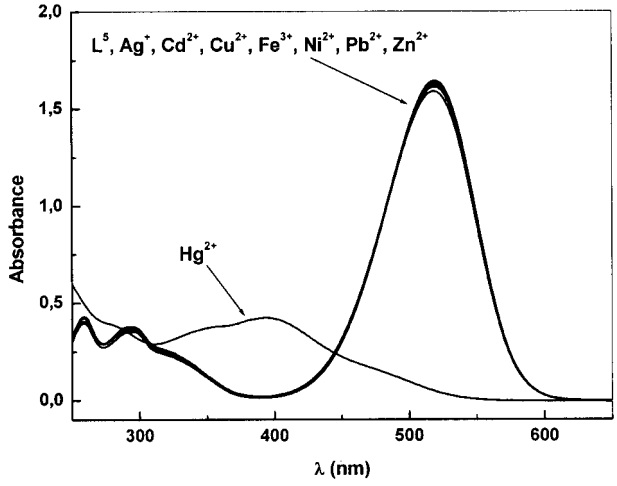

Figure 6. Changes in the UV/Vis spectra of receptor L^5 upon addition of equimolar amounts of metal cations in acetonitrile (5.0×10^{-5} M).

romic shift of the visible band upon Hg^{2+} coordination is consistent with a decrease in the donor strength of the donor group.[6] UV/Vis titrations showed clear isosbestic points, indicating the formation of 1:1 L^5-to-Hg^{2+} complexes. A log K of 7.57 ± 0.02 was calculated for the formation of the $[Hg(L^5)]^{2+}$ complex (see Figure 7); 1:1 complexes were also formed between L^6 and Hg^{2+}. In this case, log K for the formation of the $[Hg(L^6)]^{2+}$ complex, calculated by nonlinear least-squares treatment of the titration profiles, was 5.60 ± 0.05.

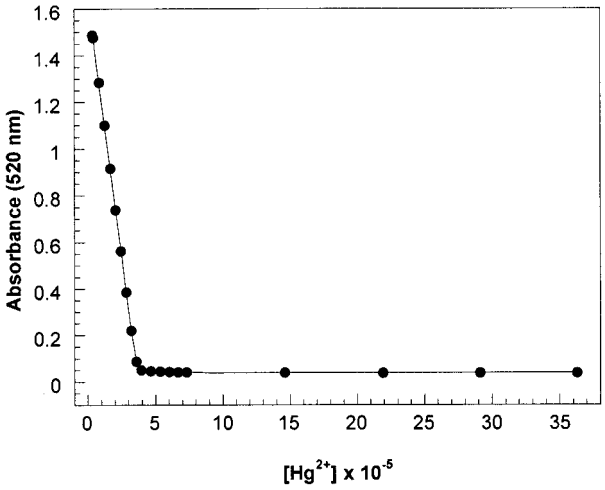

Figure 7. Variation of the intensity at 518 nm for receptor L^5 upon addition of increasing amounts of Hg^{2+} cation in acetonitrile (5.0×10^{-5} M).

Fluorogenic Signalling

The 1-aminophenyl-1,2,2-tricyanoethylene chromophore also shows fluorescence emission upon excitation at the visible absorption band. Fluorescence studies were carried out with acetonitrile solutions (ca. 3.0×10^{-5}M) of the receptors by addition of equimolar quantities of the corresponding metal cation. L^1 shows dual emission features in acetonitrile upon excitation at 517 nm, with a broad, unstructured emission band centred at 610 nm and another more-intense, red-shifted band centred at 690 nm. This red-shifted emission can tentatively be ascribed to formation of an excimer by interaction of an excited state fluorophore with a fluorophore in the ground state.[25] Addition of Ag^+, Pb^{2+}, Zn^{2+}, Ni^{2+} or Cd^{2+} resulted in no significant variation in the emission intensity profiles, whereas the presence of Fe^{3+}, Hg^{2+} or Cu^{2+} inhibited the formation of the excimer and caused an almost complete quenching of the red-shifted band centred at 690 nm.

The emission behaviour of receptors functionalised with macrocyclic subunits (L^2–L^6) is somewhat different to that of L^1 and, upon excitation, only an emission band centred at 600 nm was found; the red-shifted emission found in L^1 was not observed. This could be related to steric factors due to the presence of the bulky macrocyclic moieties, which might prevent excimer formation in the L^2–L^6 receptors. The emission behaviour of acetonitrile solutions of L^2 and L^3 (excitation at 518 and 515 nm for L^2 and L^3, respectively) upon addition of metal cations was unexciting, with only minor changes in the emission intensity (centred at 610 nm) upon addition of the Fe^{3+} cation (see Table 3).

Table 3. Fluorescence emission intensity variation (as % of that of the receptor) obtained for L^1–L^6 upon addition of metal cations in acetonitrile solutions.

	$L^{1[a]}$	$L^{2[a]}$	$L^{3[a]}$	$L^{4[a]}$	$L^{5[a]}$	$L^{6[a]}$
Ag^+	<5	<5	<5	<5	<5	<5

[a] Excitation wavelengths of 517, 518, 515, 467, 450 and 470 nm for L^1, L^2, L^3, L^4, L^5 and L^6, respectively. [b] The upward and downward pointing arrows indicate increase and quenching, respectively, of the emission intensity (690 nm for L^1 and 610 nm for L^2–L^6).

A more significant and selective behaviour was observed with receptors L^4 and L^5. The isosbestic points obtained in the UV/Vis titrations of L^4 with Pb^{2+} (467 nm) and L^5 with Hg^{2+} (450 nm) were chosen as excitation wavelengths. Upon excitation unstructured emission bands centred at 610 and 605 nm were observed for L^4 and L^5, respectively. The results obtained upon addition of one equivalent of the corresponding metal cations are shown in Table 3. The most remarkable effect was the selective enhancement of the emission intensity (90%), coupled with a moderate 10-nm hypsochromic shift of the emission band (from 605 to 595 nm) observed upon addition of Hg^{2+} to solutions of L^5 (Figure 8). Other metal cations tested (Ag^+, Cd^{2+}, Cu^{2+}, Fe^{3+}, Pb^{2+} and Zn^{2+}) induced negligible variations (less than 5%) in the fluorescence emission of this receptor. The excitation spectra (λ_{exc} = 610 nm) measured upon addition of one equivalent of Hg^{2+} cation to an acetonitrile solution of receptor L^5 show the apparition of a band centred at 380 nm, indicating that the $[Hg(L^5)]^{2+}$ complex is the emissive species that induces the apparition of the emission band centred at 605 nm. With L^4, the addition of equimolar quantities of Pb^{2+} or Zn^{2+} induced enhancement in the emission intensity (45% with Pb^{2+} and 10% with Zn^{2+}) with a very low hypsochromic shifts in the emission band (2 nm for Pb^{2+} and negligible with Zn^{2+}), whereas the presence of Cu^{2+} or Fe^{3+} induced moderate quenching and hypsochromic shifts (5 and 10 nm for Cu^{2+} and Fe^{3+} respectively). The fluorescent behaviour of receptor L^6 in the presence of metal cations is very similar to that found for L^5. Upon excitation at the isosbestic point obtained from UV/Vis titrations of L^6 with the mercuric cation (470 nm), a broad emission band centred at 614 nm developed. Of all the metal cations tested, only Hg^{2+} induces a 20% enhancement of the emission intensity, with a hypsochromic shift of the emission band to 604 nm.

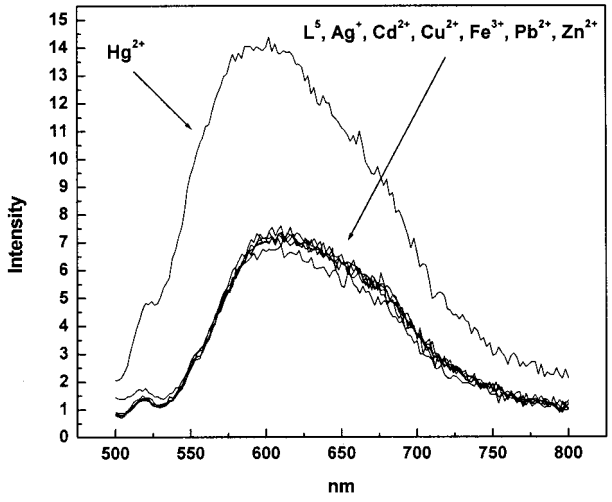

Figure 8. Emission spectra of receptor L^5 (λ_{ex} = 450 nm) upon addition of equimolar amounts of metal cations in acetonitrile (3.0×10^{-5} M).

Table 3 shows that only Hg^{2+}, Pb^{2+} and Zn^{2+} display fluorescence enhancement effects. This is in agreement with their d^{10} electronic configuration, for which electron-transfer or energy-transfer processes usually do not occur.[26] For Hg^{2+} with L^5 and L^6, and Pb^{2+} with L^4, the emission fluorescence enhancement is remarkable and is most likely associated with a strong metal coordination to the anilinium nitrogen (this is also supported by the UV/Vis studies, see above). On the other hand, quenching was observed with the redox-active metal cations Fe^{3+} and Cu^{2+}, for which electron-transfer processes involving the d-orbitals of the metals and the excited state of the fluorophore can occur.[26]

Electrochemical Signalling

The electrochemical behaviour of the tricyanovinyl receptors was studied in acetonitrile with platinum as working electrode and $[Bu_4N][BF_4]$ as supporting electrolyte. This family of receptors shows a one-electron reversible reduction process at about –0.70 V vs. SCE attributed to the reduction of the tricyanovinyl group.[15b] They also show a reversible oxidation process at 1.2–1.4 V vs. SCE due to the oxidation of the anilinium moiety.[27] This electrochemical interpretation is in agreement with molecular modelling and orbital calculations performed on L^1 at the PM3 level.

A detailed electrochemical study in the presence of the metal cations Ag^+, Cd^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Pb^{2+} and Zn^{2+} was carried out with ligands L^4, L^5 and L^6, which are those that show a more remarkable optical behaviour (see above). A summary of the electrochemical responses is shown in Table 4. For ligand L^5, three different cation-induced electrochemical behaviours were observed. The first type of behaviour was found in the presence of Hg^{2+}, with a remarkable anodic shift (340 mV) of the reduction wave of L^5 along with a significant drop in the reduction wave intensity. Additionally, in the presence of this metal cation the oxidation peak of L^5 "disappears" (the wave is shifted anodically out of the solvent redox window). As is well-known, cation coordination with redox-active molecules results in significant electrochemical anodic shifts of either oxidation or reduction processes.[28] A simple explanation of this effect is related to the idea that it is easier to reduce and more difficult to oxidize the positively charged $[Hg(L^5)]^{2+}$ complex than the corresponding neutral ligand. Therefore, coordination of Hg^{2+} to the oxathiaaza ring would give rise to both an anodic shift in the oxidation wave of the aniline (the shift is so large that the new wave is not observed) and an anodic shift of the reduction process (340 mV). This strong Hg^{2+}–N interaction in L^5, suggested by the electrochemical results, is in agreement with the selective chromogenic results found for this cation (see above).

Table 4. Anodic shifts of the reduction wave (ΔE in mV) obtained for L^4, L^5 and L^6 in the presence of metal cations in acetonitrile solutions.

	$\Delta E(L^4)$[a]	$\Delta E(L^5)$[a]	$\Delta E(L^6)$[a]
Ag^+	10	17	<10
Cd^{2+}	170	120	80
Cu^{2+}	40	25	20
Fe^{3+}	340	240	<10
Hg^{2+}	370	340	200
Pb^{2+}	360	330	160
Zn^{2+}	160	140	20

[a] $\Delta E(L^n) = E(L^n + M^{n+}) - E(L^n)$.

A second sort of electrochemical behaviour was observed for L^5 upon addition of cations such as Pb^{2+}, Zn^{2+}, Fe^{3+} and Cd^{2+}. In this case, there is also a significant anodic shift of the reduction wave, but there is no significant shift of the oxidation peak of L^5. A drop of the peak intensity was found for both the oxidation and reduction waves. This intensity drop (attributed to the formation of species with a lower diffusion coefficient), along with the anodic shift of the reduction wave suggests that there must be some kind of interaction between these metal cations and L^5. Additionally, the absence of changes in the oxidation wave suggests that this interaction is not with the anilinium nitrogen. Tentatively, this interaction can be assigned to a weak coordination of the metal cations with either remote donor atoms from the ring, such as S or O, or due to some interaction with the electron-rich cyano groups. The absence of significant shifts observed in the oxidation wave is often indicative of CE (chemical electrochemical) processes (decoordination and oxidation of the free ligand) favoured by a weak metal–ligand interaction in these cases. Finally, for cations such as Ag^+, Al^{3+} and Cu^{2+} no remarkable changes were observed in either the oxidation or reduction peaks of L^5.

Ligand L^6 shows a somehow similar behaviour to L^5, although in this case, in general, smaller anodic shifts of the reduction wave are observed. The most remarkable are the anodic shifts of 200 and 160 mV of the reduction wave observed for L^5 in the presence of Hg^{2+} and Pb^{2+} cations, respectively.

L^4 shows a notably large anodic shift of the reduction wave of 370 mV with the metal cations Hg^{2+}, Pb^{2+} and

Fe^{3+}. Addition of Cd^{2+} and Zn^{2+} cations induced a less-important redox shift (170 and 160 mV for Cd^{2+} and Zn^{2+}, respectively). Of all these metal cations, Pb^{2+} is the only one capable of inducing a significant anodic shift of the oxidation peak (140 mV), strongly suggesting coordination of the Pb^{2+} cation with the anilinium nitrogen, in agreement with the chromogenic results. Ag^{+} and Cu^{2+} cations gave unremarkable variations of the electrochemical behaviour of L^4.

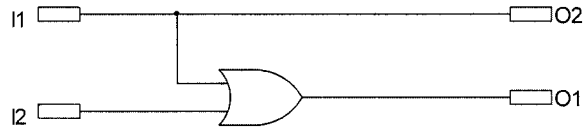
Triple Signalling

A very remarkable aspect is that, in their molecular interaction with metal cations, the receptors gave a somewhat different response depending on the transduction channel studied (electrochemical, chromogenic or fluorogenic). In order to explain this effect, it has to be taken into account that the specific response observed in each case strongly depends on the particularities of each coordination-transduction process. Thus, for instance, chromogenic transduction (hypsochromic shift) would be expected when there is a strong enough interaction of a certain metal cation with the anilinium nitrogen (the donor group involved in the anilinotricyanoethylene chromophore). On the other hand, the electrochemical transduction is related to a coulombic-type interaction between the reduced form of the redox-active group (the tricyanovinyl moiety in this case) and the metal cation. This means that the interaction of a certain metal cation with "remote" binding sites, such as the oxygen and sulfur atoms or the cyano groups, might result in an electrochemical response, but in a poor optical variation. Also remarkable is that, in certain cases, the response obtained by fluorescence is also somehow different to that found chromogenically. Thus, for L^4 the coordination of d^{10} cations such as Pb^{2+} induces emission enhancement, whereas redox-active cations such as Fe^{3+} induce significant quenching, probably by interaction with the photo-excited L^4 receptor through energy or photoelectron transfer processes.

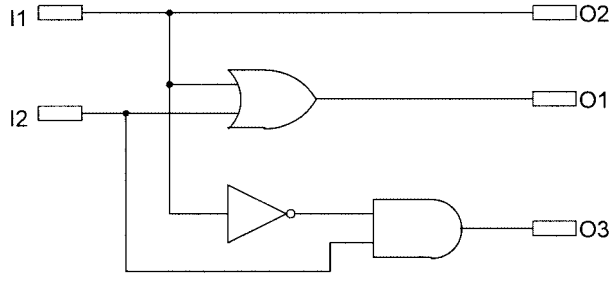
As we have commented above, there is a recent interest in the development of molecules with intrinsic logic capabilities. This concept has become widespread since it was realized that the interaction of a receptor molecule with certain species (input) and the observed response (output) can follow Boolean logic rules.[29] Since then a number of examples have been described, most of them using two inputs (usually the presence of protons and a certain metal cation) that cooperatively control the output observed (usually an optical signal). It is also common to many described molecular logic systems to be related to just one Boolean function, whereas it is less common to observe different logical expressions from one unique molecular entity. However the development of "reconfigurable" molecular logic gates could be of interest.[30] In this context, some of the multichannel signalling chemosensors described above might lead to the expression of different logical truth tables by selecting different types of output. This is, for instance, observed in Table 5, which shows the changes in receptor L^4 upon addition, as inputs, of the metal cations Pb^{2+} and Hg^{2+}. A two-input OR logic gate is observed when the output is electrochemical, whereas a TRANSFER gate is found for colour variation outputs. Table 5 also shows changes in L^4 upon addition of Pb^{2+} and Fe^{3+} input cations. An OR, TRANSFER and INHIBIT logic gate is obtained when the electrochemical, colour and emission quenching outputs are selected, respectively. These multi-channel systems can be seen as reconfigurable versatile logic systems. More-complex, three-input reconfigurable molecular logic systems can also be obtained, as shown in Table 6, where the logic gates OR, TRANSFER and INHIBIT are found for just one molecular entity (receptor L^4) by selecting the output channel.

Table 5. Two-input logical truth tables associated with electrochemical, colour and emission quenching measurements using receptor L^4 and different metal cations as input signals.

Input 1	Input 2	$\Delta E > 300$ mV	Colour variation
Pb^{2+}	Hg^{2+}	O1	O2
0	0	0	0
1	0	1	1
0	1	1	0
1	1	1	1



Input 1	Input 2	$\Delta E > 300$ mV	Colour variation	Emission quenching
Pb^{2+}	Fe^{2+}	O1	O2	O3
0	0	0	0	0
1	0	1	1	0
0	1	1	0	1
1	1	1	1	0



A related aspect is that multi-channel signalling receptors such as L^4 and L^5 can give multiple signalling expressions (combination of different signals) that can be used for sensing purposes. This is also depicted in Table 6, where the equivalence between the output observed and the sensing information one can obtain can be seen. Thus a 1/1/0 output pattern (ΔE larger than 300 mV/colour variation/emission quenching) would only be observed in the presence of Pb^{2+}. In the absence of lead (no colour variation), 1/0/0 and 1/0/1 patterns would be indicative of the presence of Hg^{2+} and Fe^{3+}, respectively. Some other combinations (not shown in Table 6) are possible; for instance, and despite the

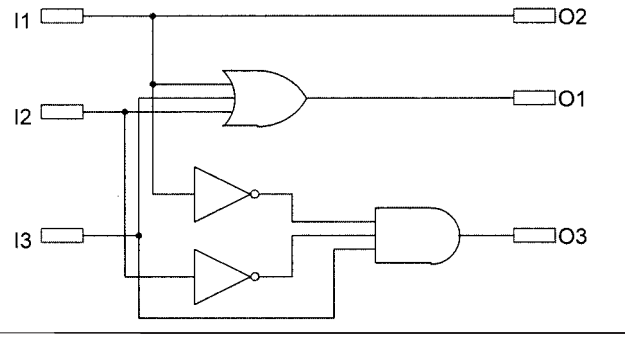
0	1	1	1	0	0
1	1	1	1	1	0



low quenching found for copper, a 0/0/1 combination would be observed with Cu^{2+}; a 0/0/0 pattern, but with variations of ΔE of about 100 mV. can indicate the presence of Cd^{2+} or Zn^{2+} cations. L^4 therefore acts as a prototype of molecular chemosensors capable of sensing several single guests by multiple signalling combinations. Similar observations can be made with other receptors and a suitable combination of input signals.

Table 6 shows how reconfigurable logic gates or multichannel signalling receptors are both intimately related concepts. This is indicated by using tricyanoethylene receptors, which are rare electro-optical signalling systems capable of reporting molecular interaction by a triple-channel transduction. These studies suggest that the development of receptors containing a number of reporter groups might open new perspectives in the design of a new generation of multichannel signalling molecules capable of being used as either prototypes of "reconfigurable" molecular logic gates or as multi-channel guest reporting systems by the use of different output signals from just one molecular entity.

Conclusions

A family of receptors based on functionalised tricyanoethylene moieties has been synthesised and characterised and their interaction with metal cations monitored by optical (colour and fluorescence) and electrochemical changes. A selective chromogenic response was found for the L^4-Pb^{2+}, L^5-Hg^{2+} and L^6-Hg^{2+} systems in acetonitrile, whereas fluorescence and electrochemical responses were usually less selective. A final discussion suggests that receptors containing several reporter channels (multi-channel signalling molecules) can be used for studying the intimately related concepts of multi-channel signalling and reconfigurable logic gates.

Experimental Section

General Remarks: All commercially available reagents were used without further purification. Air/water-sensitive reactions were performed in flame-dried glassware under argon. Acetonitrile was dried with CaH_2 and distilled prior to use.

Physical Measurements: Metal cations (Ag^+, Cd^{2+}, Fe^{3+}, Ni^{2+}, Pb^{2+} as perchlorate salts and Cu^{2+}, Hg^{2+}, Zn^{2+} as triflate salts) were used to obtain approximately 1.0×10^{-3} M acetonitrile solutions. UV/Vis studies were carried out with a Perkin–Elmer Lambda 35 spectrometer. The concentration of ligands used in the measurements was about 5.0×10^{-5} M in acetonitrile. UV/Vis spectra were recorded in the presence of equimolar quantities of the corresponding ligand and metal cation or anion. The fluorescence behaviour was studied with an FS900CDT Steady State T-Geometry Fluorimeter from Edinburgh Analytical Instruments. All solutions for photophysical studies were previously degassed. The concentration of ligands was about 3.0×10^{-5} M in acetonitrile. Fluorescence emission spectra were recorded in the presence of equimolar quantities of ligand and the corresponding metal cation. Electrochemical data were recorded fors previously degassed dry acetonitrile solution, with a programmable function generator Tacussel IMT-1, connected to a Tacussel PJT 120–1 potentiostat. The concentration of ligands and metal ions was about 1.0×10^{-3} M in acetonitrile (the metal ions were perchlorate or triflate salts of Ag^+, Cd^{2+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, Pb^{2+} and Zn^{2+}). Electrochemical studies were carried out in the presence of equimolar quantities of ligand and the corresponding metal cation. The working electrode was platinum connected to a saturated calomel reference electrode separated from the test solution by a salt bridge containing the solvent and the supporting electrolyte (0.25 M $[Bu_4N][BF_4]$). The auxiliary electrode was a platinum wire.

The ^1H and ^{13}C NMR spectra were recorded with a Varian Gemini spectrometer. Chemical shifts are reported in ppm downfield from TMS signal. Spectra recorded in $CDCl_3$ were referenced to residual $CHCl_3$.

Synthetic Procedures: The syntheses of 2-(2-methylsulfonyloxyethoxy)ethyl methanesulfonate (**2a**),[31] 2-[(2-methylsulfonyloxyethyl)phenylamino]ethyl methanesulfonate (**5**),[31] 13-phenyl-1,4,7,10-tetraoxa-13-azacyclopentadecane (**4b**)[17] and 16-phenyl-1,4,7,10,13-pentaoxa-16-azacycloheptadecane (**4c**)[17] have been previously published. Compound **3** is commercially available.

Synthesis of 10-Phenyl-1,4,7-trioxa-10-azacyclododecane (4a): *N*,*N*-phenyldiethanolamine (**3**; 10 g, 0.05 mol) was dissolved in dry acetonitrile (400 mL) and then sodium hydride (3.3 g, 0.137 mol) was slowly added over 60 min with vigorous stirring at room temperature. The mixture formed was heated to reflux and then, over 4 h, 2-(2-methylsulfonyloxyethoxy)ethyl methanesulfonate (**2a**; 14.4 g, 0.055 mol) dissolved in dry acetonitrile was added. The crude reaction mixture was refluxed overnight. The mixture was then filtered and the filtrate concentrated in vacuo to dryness to give an orange sticky oil that was purified by column chromatography on aluminium oxide with dichloromethane and dichloromethane/ethanol (50:1 v/v) as eluents to give 10-phenyl-1,4,7-trioxa-10-azacyclododecane (3.8 g, 0.015 mol) as a yellowish oil. Yield: 30%. ^1H NMR (300 MHz, $CDCl_3$): δ = 3.55 (t, J = 7.5 Hz, 4 H, O-CH_2-CH$_2$-N), 3.64 (m, J = 7.5 Hz, 8 H, O-CH_2-CH_2-O-CH_2-CH_2-O), 3.83 (t, J = 7.5 Hz, 4 H, O-CH$_2$-CH_2-N), 6.68 (t, J = 6 Hz, 2 H, C_6H_5), 6.70

(d, J = 6 Hz, 1 H, C_6H_5), 7.18 (t, J = 6 Hz, 2 H, C_6H_5) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 52.35 (CH_2-N), 69.55 (CH_2-O), 69.77 (CH_2-O), 71.46 (CH_2-O), 112.24 (C_6H_5), 116.03 (C_6H_5), 128.98 (C_6H_5), 148.44 (C_6H_5) ppm. MS: m/z = 251 [M^+], 220, 176, 162, 150, 132, 120, 105, 91 [C_6H_5N], 77 [C_6H_5]. $C_{14}H_{21}NO_3$ (251): calcd. C 66.91, H 8.42, N 5.57; found C 66.62, H 8.37, N 5.60.

Synthesis of 10-Phenyl-1,4-dioxa-7,13-dithia-10-azacyclopentadecane (7a): 3,6-Dioxaoctane-1,8-dithiol (**6a**; 3.6 g, 0.022 mol) and anhydrous potassium carbonate (12.2 g, 0.088 mol) were dissolved in dry acetonitrile (400 mL) and heated to reflux. Then, 2-[(2-methylsulfonyloxyethyl)phenylamino]ethyl methanesulfonate (**5**; 7.4 g, 0.022 mol) was added over 4 h. The crude reaction mixture was refluxed overnight. The resultant mixture was then filtered and the filtrate concentrated in vacuo to dryness to give a yellow sticky oil that was purified by column chromatography on silica with dichloromethane as eluent to give 10-phenyl-1,4-dioxa-7,13-dithia-10-azacyclopentadecane (2.9 g, 0.009 mol) as a white solid. Yield: 40%. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.73 (t, J = 7 Hz, 4 H, O-CH_2-CH_2-S), 2.88 (t, J = 7 Hz, 4 H, N-CH_2-CH_2-S), 3.62 (s, 4 H, O-CH_2-CH_2-O), 3.64 (t, J = 7 Hz, 4 H, O-CH_2-CH_2-S), 3.79 (t, J = 7 Hz, 4 H, N-CH_2-CH_2-S), 6.63 (m, 3 H, C_6H_5), 7.20 (d, J = 6 Hz, 2 H, C_6H_5) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 29.29 (CH_2-S), 30.95 (CH_2-S), 51.63 (CH_2-N), 70.56 (CH_2-O), 74.11 (CH_2-O), 111.57 (C_6H_5), 115.98 (C_6H_5), 129.29 (C_6H_5), 146.46 (C_6H_5) ppm. MS: m/z = 327 [M^+], 204, 192, 179, 164, 149, 132, 119, 105, 91 [C_6H_5N], 77 [C_6H_5]. $C_{16}H_{25}NO_2S_2$ (327): calcd. C 58.68, H 7.69, N 4.28; found C 58.60, H 7.61, N 4.23.

Synthesis of 4-Phenyl-1,7-dioxa-10,13-dithia-4-azacyclopentadecane (7b): 3,6-Dithiaoctane-1,8-diol (**6b**; 3.6 g, 0.022 mol) was dissolved in dry acetonitrile (400 mL) and then sodium hydride (1.6 g, 0.066 mol) was slowly added over 1 h with vigorous stirring at room temperature. The mixture formed was heated to reflux and then, over 4 h methanesulfonic acid 2-[(2-methylsulfonyloxy-ethyl)phenylamino]ethyl methanesulfonate (**5**; 7.4 g, 0.022 mol) dissolved in dry acetonitrile was added. The crude reaction mixture was refluxed overnight, filtered, and the filtrate concentrated in vacuo to dryness to give a yellow sticky oil that was purified by column chromatography on silica with dichloromethane as eluent to give 4-phenyl-1,7-dioxa-10,13-dithia-4-azacyclopentadecane (1.8 g, 0.0055 mol) as a yellowish oil. Yield: 25%. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.72 (t, J = 7 Hz, 4 H, O-CH_2-CH_2-S), 2.88 (s, 4 H, S-CH_2-CH_2-S), 3.60–3.82 (m, 12 H, N-CH_2-CH_2-O), 6.63 (m, 3 H, C_6H_5), 7.20 (d, J = 6 Hz, 2 H, C_6H_5) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 31.50 (CH_2-S), 32.72 (CH_2-S), 51.06 (CH_2-N), 69.73 (CH_2-O), 72.02 (CH_2-O), 112.02 (C_6H_5), 116.33 (C_6H_5), 129.18 (C_6H_5), 148.02 (C_6H_5) ppm. MS: m/z = 327 [M^+], 204, 192, 179, 164, 149, 132, 119, 105, 91 [C_6H_5N], 77 [C_6H_5]. $C_{16}H_{25}NO_2S_2$ (327): calcd. C 58.68, H 7.69, N 4.28; found C 58.55, H 7.73, N 4.31.

General Procedure for the Synthesis of Tricyanovinyl Dyes: *N*,*N*-Dimethylaniline or the corresponding phenyl macrocycle (1.0 mmol) and tetracyanoethylene (192 mg, 1.5 mmol) were dissolved in dry DMF (12 mL) and heated at 60 °C for 90 min. The crude reaction mixture was concentrated in vacuo to dryness and purified by column chromatography as indicated below. Receptors L^1 and L^3 were previously synthesised by Beer et al. in 1990. ***CAUTION:*** *Synthesis of L^2 to L^6 occurs with elimination of HCN.*

Receptor L^2: Flash chromatography (dichloromethane/acetonitrile, 9:1 v/v) on silica gel gave a dark reddish solid. Yield: 65%. ^1H NMR (300 MHz, $CDCl_3$): δ = 3.58 (m, 8 H, O-CH_2-CH_2-O), 3.73 (t, J = 4.9 Hz, 4 H, O-CH_2-CH_2-N), 3.92 (t, J = 4.9 Hz, 4 H, O-CH_2-CH_2-N), 6.86 (d, J = 9.4 Hz, 2 H, C_6H_4), 8.01 (d, J = 9.4 Hz, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 53.19 (CH_2-N), 69.08 (CH_2-O), 69.81 (CH_2-O), 71.24 (CH_2-O), 113.41 (C_6H_4), 113.76 (CN), 114.03 (CN), 114.48 (CN), 117.79 (C=C), 132.70 (C_6H_4), 137.30 (C=C), 154.91 (C_6H_4) ppm. MS (FAB$^+$): m/z (%) = 353 (100) [M^+ + 1]. HRMS: calcd. for $C_{19}H_{20}N_4O_3$ 353.1614; found 353.1608.

Receptor L^4: Flash chromatography (dichloromethane/acetonitrile, 8:2 v/v) on silica gel gave a dark reddish oil. Yield: 68%. ^1H NMR (300 MHz, $CDCl_3$): δ = 3.53–3.64 (m, 16 H, O-CH_2-CH_2-O), 3.73 (t, J = 4.7 Hz, 4 H, O-CH_2-CH_2-N), 3.80 (t, J = 4.7 Hz, 4 H, O-CH_2-CH_2-N), 6.80 (d, J = 9.4 Hz, 2 H, C_6H_4), 8.00 (d, J = 9.4 Hz, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 51.80 (CH_2-N), 68.40 (CH_2-O), 70.61 (CH_2-O), 70.72 (CH_2-O), 70.76 (CH_2-O), 70.92 (CH_2-O), 112.74 (C_6H_4), 113.84 (CN), 114.08 (CN), 114.47 (CN), 117.54 (C=C), 132.92 (C_6H_4), 137.10 (C=C), 154.31 (C_6H_4) ppm. MS (FAB$^+$): m/z (%) = 440 (100) [M^+ + 1]. HRMS: calcd. for $C_{23}H_{28}N_4O_5$ 440.2060; found 440.2057.

Receptor L^5: Flash chromatography (dichloromethane) on silica gel gave a dark reddish solid. Yield: 58%. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.75 (t, J = 4.8 Hz, 4 H, O-CH_2-CH_2-S), 2.89 (t, J = 7.9 Hz, 4 H, N-CH_2-CH_2-S), 3.62 (s, 4 H, O-CH_2-CH_2-O), 3.76–3.83 (m, 8 H, O-CH_2-CH_2-S and N-CH_2-CH_2-S), 6.70 (d, J = 9.4 Hz, 2 H, C_6H_4), 8.04 (d, J = 9.4 Hz, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 29.65 (CH_2-S), 31.88 (CH_2-S), 52.40 (CH_2-N), 70.64 (CH_2-O), 74.30 (CH_2-O), 112.54 (C_6H_4), 113.58 (CN), 113.84 (CN), 114.36 (CN), 117.76 (C=C), 133.14 (C_6H_4), 137.51 (C=C), 153.03 (C_6H_4) ppm. MS (FAB$^+$): m/z (%) = 429 (100) [M^+ + 1]. HRMS: calcd. for $C_{21}H_{24}N_4O_2S_2$ 429.1419; found 429.1426.

Receptor L^6: Flash chromatography (dichloromethane) on silica gel gave a dark reddish solid. Yield: 61%. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.72 (t, J = 5.7 Hz, 4 H, O-CH_2-CH_2-S), 2.81 (s, 4 H, N-CH_2-CH_2-S), 3.70 (t, J = 5.7 Hz, 4 H, O-CH_2-CH_2-O), 3.77 (t, J = 4.7 Hz, 4 H, O-CH_2-CH_2-S), 3.85 (t, J = 4.7 Hz, 4 H, N-CH_2-CH_2-S), 6.78 (d, J = 9.4 Hz, 2 H, C_6H_4), 8.03 (d, J = 9.4 Hz, 2 H, C_6H_4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 31.93 (CH_2-S), 32.96 (CH_2-S), 51.73 (CH_2-N), 69.23 (CH_2-O), 72.16 (CH_2-O), 112.65 (C_6H_4), 113.50 (CN), 113.78 (CN), 114.35 (CN), 117.80 (C=C), 132.93 (C_6H_4), 137.52 (C=C), 154.26 (C_6H_4) ppm. MS (FAB$^+$): m/z (%) = 429 (100) [M^+ + 1]. HRMS: calcd. for $C_{21}H_{24}N_4O_2S_2$ 429.1419; found 429.1413.

Structure Determination of L^5: $C_{21}H_{24}N_4O_2S_2$, M = 428.56, triclinic space group $P\bar{1}$, a = 9.654(4), b = 13.643(6), c = 17.196(5) Å, α = 96.68(3)°, β = 102.98(3)°, γ = 97.72(3)°, Z = 4, V = 2161.7(14) Å^3, $D_{calcd.}$ = 1.317 g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, T = 293(2) K, μ(Mo-K_α) = 0.271 mm^{-1}. Measurements were carried out with a Siemens P4 diffractometer with graphite-monochromated Mo-K_α radiation on a crystal of dimensions 0.17 × 0.17 × 0.15 mm^3. A total of 5963 reflections was collected of which 5558 were independent (R_{int} = 0.0468). Lorentz, polarisation and absorption (ψ-scan, max. and min. transmission 0.295 and 0.210) corrections were applied. The structure was solved by direct methods (SHELXTL) and refined by full-matrix least-squares analysis on F^2 (SHELXTL).[32] The refinement converged at R_1 = 0.090 [$F > 4\sigma(F)$] and wR_2 = 0.2494 (all data). Largest peak and hole in the final difference map +0.58 and –0.37 e Å^3.

CCDC-252155 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[27] We have found (unpublished results) oxidation values for products **4a**, **4b**, **4c**, **7a** and **7b** of +0.8–0.9 V in acetonitrile. However, in the electrochemical studies carried out with L^1–L^6 there was no oxidation peak in this anodic region − the first anodic peak was found at +1.2–1.4 V and attributed to the oxidation of the anilinium moiety. The different nature of the ligands and the existence of CE (chemical electrochemical) mechanisms (the anilinium oxidation peak is not reversible) might account for this difference between the oxidation peaks of the anilinum crowns **4a**, **4b**, **4c**, **7a**, **7b** and those of L^1–L^6.

The Hexakis(thiocyanato)ferrate(III) Ion: a Coordination Chemistry Classic Reveals an Interesting Geometry Pattern for the Thiocyanate Ligands

Anthony W. Addison,*[a] Raymond J. Butcher,[b] Zoltán Homonnay,[c] Vitaly V. Pavlishchuk,*[d] Michael J. Prushan,[e] and Laurence K. Thompson[f]

Keywords: Iron / Thiocyanate / X-ray diffraction / Magnetic properties / IR spectroscopy / Moessbauer spectroscopy / Coordination modes / Isomers

$(NMe_4)_3[Fe(NCS)_6]$ crystallizes from ethanol in the monoclinic space group *C*2/*c*. Two different types of complex ions are contained in the unit cell, though both possess exclusively *N*-coordination of the thiocyanate ligands. In one ion, the thiocyanate ligands are all essentially linearly bound, with an Fe–N–C angle of 174 ± 4°, while in the other, there are two *cis*-thiocyanate ligands with a notably small Fe–N–C angle of 146.5°. The EPR and Mössbauer results show that all the iron(III) centers maintain the high-spin state down to 80 K, while the magnetic susceptibility confirms this to 2 K. Infrared and Mössbauer spectra provide evidence for an unusually "soft" lattice. Traditional criteria for interpretation of the infrared frequencies are not strictly applicable for this compound.

Introduction

Given that the $[Fe(NCS)_6]^{3-}$ ["iron(III) rhodanide"] ion is a classical Werner complex of fundamental significance, there has hardly been an overwhelming number of studies of it since Krüsz and Moraht[1] first described its isolation as (the apparently double) salt $Na_3[Fe(NCS)_6]\cdot 6NaNCS\cdot 4H_2O$ over a century ago. Other cations' $[Fe(NCS)_6]^{3-}$ salts were subsequently prepared by Rosenheim and Cohen,[2] while spectrophotometric studies, originated in 1931,[3] moved forward to define the d-d (940 nm, 570 nm) and LMCT (480, 320, 250 nm) bands.[4–9] Forster and Goodgame[6] also demonstrated the high-spin nature of $(NMe_4)_3[Fe(NCS)_6]$ at ambient temperature (μ = 5.92 μ_B). From the LMCT spectroscopy of the $Fe(NCS)_6^{3-}$ ion doped into the analogous lanthanide lattices $(R_4E)_3[Ln(NCS)_6]$, Walker and McCarthy[10] noted a photosensitivity which they ascribed to NCS^- dissociation, yielding $[Fe(NCS)_5]^{2-}$. In hyperbaric studies of $[Me_4N]_3[Fe(NCS)_6]$[11] and $K_3[Fe(NCS)_6]$[12] by infrared and Mössbauer spectroscopy, respectively, Hellner et al.[11] and Fung and Drickamer[12] detected responses which they attributed to an intramolecular redox process (presumably corresponding to hyperbaric stabilisation of the LMCT excited state Fe^{II}–NCS·–; cf. ref.[10]) and also to the linkage isomerisation Fe–NCS ⇌ Fe–SCN. The assignment of this remarkable isomerisation was based on the shifting of ν_{Fe-NCS} and ν_{C-N}[6,11] to frequencies traditionally associated with M–*S*CN rather than M–*N*CS bonding.[13]

Thiocyanatometallates are capable of acting as ligands (i.e., thiocyanato-bridged Fe–M systems), in this regard bearing an analogy to hexacyanoferrates, which have been used extensively in supramolecular lattice construction.[14] In connection with our interest in the potential of $[Fe(NCS)_6]^{3-}$ as a building block for supramolecular lattices, we present here the results of a crystallographic characterisation of a salt of this anion.

Questions which we anticipated might thus be addressed included: (1) is any *S*-thiocyanato coordination present under ambient conditions, or is coordination exclusively via the nitrogen atoms? and (2) if the latter is the case, does spin-crossover occur for $[Fe(NCS)_6]^{3-}$ at sub-ambient temperatures?

As we considered it important to avoid coordinative interactions between $[Fe(NCS)_6]^{3-}$ and any metal countercation, we sought tetraalkylammonium salts of $[Fe(NCS)_6]^{3-}$, of which the tetramethylammonium one, $(Me_4N)_3[Fe(NCS)_6]$, indeed proved amenable to crystallography.

Results and Discussion

$(Me_4N)_3[Fe(NCS)_6]$ crystallises from ethanol as unsol vated monoclinic crystals belonging to the space group *C*2/*c*

[a] The *trans*-N–Fe–N angles are obligatorily 180°.

The most notable feature of the Fe coordination is that there are two types of anions present in the unit cell. In one set of anions (*B*, Fe[1]; Figure 1, Table 2), the thiocyanate ligands are all essentially "linearly" coordinated to iron(III), with Fe–N–C angles ranging from 170 to 179°.

In the other half of the $[Fe(NCS)_6]^{3-}$ population (anions *A*, possessing C_2 symmetry), a mutually *cis* pair of the NCS^- ligands are in a "bent" mode, with the Fe–N–C angle at 146.5(4)°. Such structural diversity within the unit cell is reminiscent of previously reported instances, such as $[Cu(Dipica)_2](BF_4)_2$,[15] and $[Ni(CN)_5]^{2-}$.[16] M–N–C angles of 160–175° are common in the literature,[17,18] including cases[19] where different thiocyanate ligands in the same complex display significantly different angles. On the other hand, M–N–C angles of 130–150° are encountered less frequently (almost exclusively for M = Cd),[20] and a difference of 30° in M–N–C angles within the same molecule, as observed in the present case, is unusual, if not unique.

Sulfur coordination is not seen in either complex anion, any ligand N/S-orientation ambiguity in this regard being mitigated by the clear differentiation between N–C and C–S bonds in the lattice (1.14 ± 0.01 Å vs. 1.62 ± 0.01 Å, respectively) The thiocyanate ligands (particularly the sulfur atoms) show some librational mobility, principally in one of the local (coordination octahedron) Cartesian directions. For the bent thiocyanate ligands, this occurs at right-angles to the Fe–N–C angle, so is not connected with any intrinsic variation in the Fe–N–C angle. Even in the more

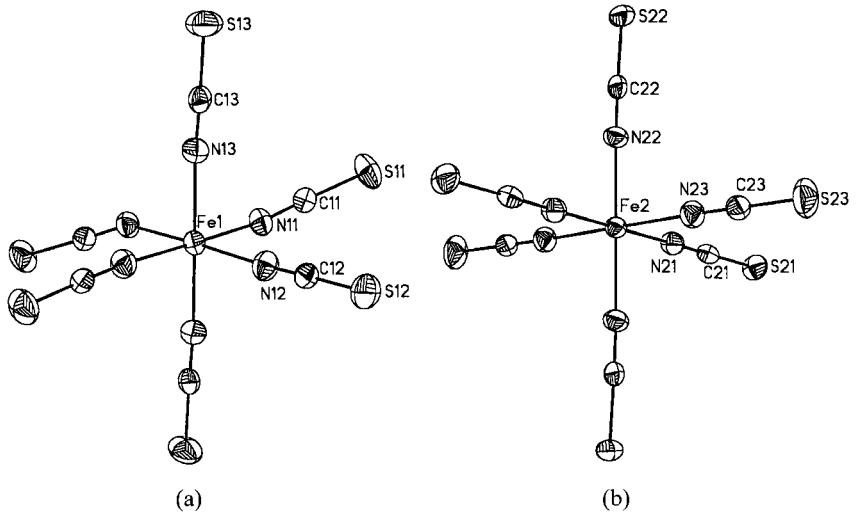

Figure 1. ORTEP diagrams of (a) the "*A*" anion in $(Me_4N)_3[Fe(NCS)_6]$, displaying the four "linear" and the two "bent" *cis*-Fe–*N*–CS linkages, and (b) the "*B*" anion, displaying the six linear Fe–*N*–CS linkages. In each ion, there is a unique facial set of NCS^- ligands with the opposite set symmetry-related to them. The ellipsoids are displayed at the 20% level.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

symmetric *B* anions, the FeN_6 moiety is not homometric, the thiocyanate ligands being arranged (via their local inversion symmetry) as *trans* pairs, with the intermediate Fe–N distance (2.052 Å) being the mean of the shorter (2.045 Å) and longer (2.059 Å) values. Although static Jahn–Teller distortion is not expected (depending on the spin state, vide infra), the possibility of lattice dynamism should not be ruled out, and may be a factor relevant to the various spectroscopic results.[11,12] We do not consider the difference (0.004 Å) between the average Fe–N distances in the *A* anions vs. the *B* anions to be chemically significant. Perhaps unexpectedly, the mutually *trans*-linear Fe–NCS in the *A* anion display the shortest (2.040 Å) Fe–N linkages, the Fe–N (bent) distances (2.046 Å) being hardly unique, but close to the average (2.050 ± 0.007 Å) of the six discrete Fe–N values in the unit cell. All the thiocyanate ligands are linear within 2° (N–C–S).

Magnetic susceptometry of $(Me_4N)_3[Fe(NCS)_6]$ yielded a susceptibility ($\chi_{m,c} = 14.5 \times 10^{-3}$ cm^3·mol^{-1}) at ambient temperature, corresponding closely to the high-spin moment reported previously.[6] The variable-temperature results are shown in Figure 2; the value of χT (4.37 cm^3·K·mol^{-1}) is essentially constant from ambient temperature down to 15 K, and may be compared with the value (4.375 cm^3·K·mol^{-1}) expected for a $g = 2.0$, $S = 5/2$ ion.

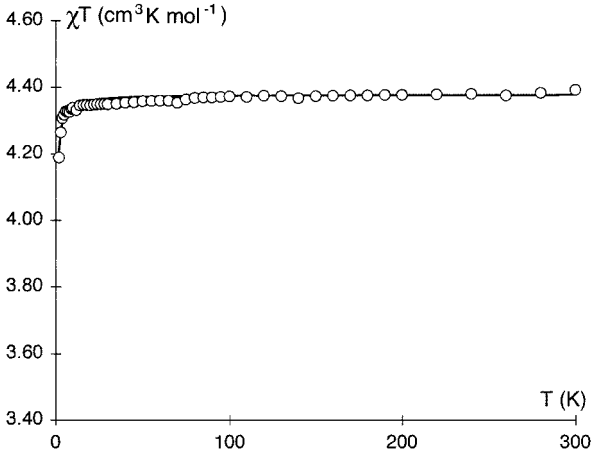

Figure 2. Plot of χT vs. T for $(Me_4N)_3[Fe(NCS)_6]$. The solid line is the fit computed with $g = 2.00(5)$, the circles being the experimental data. The goodness-of-fit index used was R^2 (on χT) = $\Sigma(\chi T_{obsd.} - \chi T_{calcd.})^2/\Sigma(\chi T_{obsd.})^2 = 4 \times 10^{-6}$.

Below 15 K, χT decreases noticeably, reaching 4.19 cm^3·K·mol^{-1} at 2 K. The data accede to a Curie–Weiss law, with $C = 4.375$ and $\theta = +0.07$ K. The downturn in χT at very low temperature could be attributed to the onset of weak intermolecular antiferromagnetic ordering (cf. θ value). However, we advocate a more informative interpretation, in which the departure from simple paramagnetism is due to zero-field splitting of the $S = 5/2$ state:[21]

$$\chi_m = \frac{Ng^2\beta^2}{12kT} \cdot \frac{75e^{-10D/3kT} + 27e^{2D/3kT} + 3e^{8D/3kT}}{e^{-10D/3kT} + e^{2D/3kT} + e^{8D/3kT}}$$

Polycrystalline $(Me_4N)_3[Fe(NCS)_6]$ at 77 K yielded a powder ESR spectrum with broad resonances (ΔH_{p-p} of 25–70 mT) typical of iron(III). An intense bisignate resonance at $g = 2.08$ is assigned to the (M_s) –1/2→+1/2 transition of $S = 5/2$ Fe^{III}, for which the ZFS parameter D is expected to be small ($D < h\nu$) when the ion is close to O_h symmetry.[22] A band at $g = 5.68$ and shoulder near $g = 3.2$ are indicative of a non-O_h component, the g values for Fe^{III} being highly sensitive to D.[23] If the D value for the *A* anions, for instance, dominates that from the more symmetric *B* anions, then attribution of the low-T downturn in the χT value to the ZFS of the *A* anions yields $D = +0.051(2)$ cm^{-1}. A first-order estimate of the resonance fields (Table 3) reveals that the observed EPR spectrum is in turn consistent with this interpretation, when the more anisotropic component has $D \approx 0.05$ cm^{-1}. (There is no unique solution yielding values for both D_A and D_B; the solution yields only that $D_A + D_B \approx 0.05$ cm^{-1}.)

Table 3. Resonance fields with $D > 0$.

Transition	Energy	$g_{app./calcd.}$[a]	$g_{obsd.}$
–1/2 → +1/2	gβH	2.08	2.08
–1/2 ↔ –3/2	±(2D – gβH)	3.05	3.17
–3/2 ↔ –5/2	±(4D – gβH)	5.69	5.68
+3/2 ↔ +5/2	4D + $g\beta H$	1.27	[b]

[a] Using $g = 2.08$, $D = 0.0485$ cm^{-1} at $\nu = 9.15$ GHz. [b] Not observed.

The data thus confirm a high-spin state for iron(III) at all temperatures, so that it is clear that there is no spin-crossover. The results also militate against any static Jahn–Teller distortion, which would require an inhomogeneous spin population in the e_g or t_{2g} subshell ($S = 1/2$, t_{2g}^5).

The Mössbauer spectroscopic results for $(Me_4N)_3[Fe(NCS)_6]$ displayed in Table 4 and Figure 3 are in consonance with the bulk magnetochemical results. Data were obtained at both 300 K and 80 K, and the isomer shift is characteristic of iron(III).

Table 4. Mössbauer results.

Temp.	Isomer shift [mm·s^{-1}]	Line width [mm·s^{-1}]	Relative mössbauer effect (area/baseline)
300 K	+0.46	1.54	0.6%
80 K	+0.57	1.66	3.4%

Although the ambient-temperature data could be fitted with a non-zero quadrupole splitting (0.45 mm·s^{-1}), its difference from zero was not of great statistical significance, and the quadrupole splitting actually diminished to essentially zero for the 80 K spectrum. Thus, the electronic field symmetry of the iron center is close to spherical, which matches its homoleptic, high-spin d^5 situation. However, the linewidths are unusually large, and there is a notable difference in sensitivity (amplitude response) between 80 K (higher) and 300 K (lower). This indicates a very low Debye temperature and the presence of numerous low-energy lattice phonon modes which serve as relaxation pathways for the γ-absorption recoil energy. This is especially so at room

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

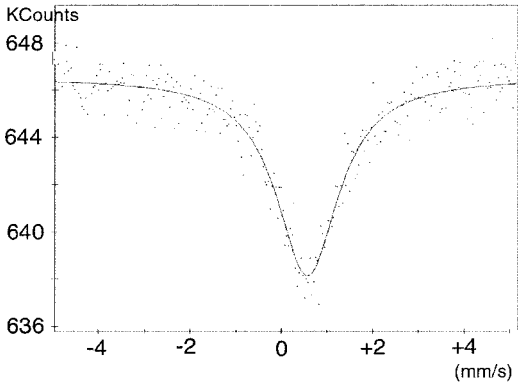

Figure 3. Mössbauer spectrum of $(Me_4N)_3[Fe(NCS)_6]$ at 80 K. The abscissa is the isomer shift, relative to α-Fe.

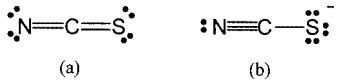
temperature, though the large linewidth would also require that the consequent polarisability be transmitted to the metal ion itself. This observation is consistent with the hypothesis of lattice dynamism (vide supra) – and the previously observed effects of applied pressure – i.e., the lattice is mechanically "soft".

Similarly to prior reports for $[Fe(NCS)_6]^{3-}$ salts,[6,11,24] the infrared spectrum of $(Me_4N)_3[Fe(NCS)_6]$ displayed very strong absorption in the ν_{CN} region, consisting of a band at 2060 cm^{-1}, along with a well-defined but lesser intensity absorption at 2012 cm^{-1}. Frequencies near 2050 cm^{-1} are traditionally considered typical of *N*-coordinated thiocyanate, while S-coordination shifts the frequency to near 2100 cm^{-1}, the ν_{CN} pattern in any case being much more dependent on the NCS^- binding mode than on molecular symmetry considerations.[13] From an orbital hybridisation viewpoint (as implied by the resonance structures in Scheme 1), the higher C–N bond order can be associated with the more intense band assigned to the majority of the thiocyanate ligands coordinated in the linear mode [Scheme 1(b)], which, by requiring sp hybridisation at the nitrogen atom, elevates the C–N bond order. Thus, the two ν_{CN} bands' frequencies and relative intensities are actually quite consistent with the difference in ligand electronic structure between linear and bent NCS^- coordination. A similar correlation, between spin state and ν_{CN} (with ν_{CN} = 2110 cm^{-1}), was seen for some (triaryltriazole)iron(II) *N*-thiocyanates.[18] Inasmuch as the molar volume of an $[M(NCS)_6]^{n-}$ anion should decrease when ligands transform from the linear to the bent coordination mode, such a transformation may well contribute to any hyperbaric reorganisation pathway. However, the facts that (a) these frequencies are slightly different from those reported previously for the tetra*ethyl*ammonium salt,[24] and (b) the previous Mössbauer study[12] was performed on the *potassium* salt brings forward the likelihood that the precise coordination geometry in $[Fe(NCS)_6]^{3-}$ is actually countercation-dependent, opening the way for validation of further studies on a variety of $[Fe(NCS)_6]^{3-}$ salts.



Scheme 1.

In acetonitrile solution at the 1 mM level, a quasireversible Fe^{III}/Fe^{II} redox couple was observed at +0.11 V vs. the nonaqueous Ag^+/Ag electrode (+0.41 V vs. SCE[26]).

Conclusions

In $(Me_4N)_3[Fe(NCS)_6]$, two different types of complex ions are contained in the unit cell, though both possess exclusively *N*-coordination of the thiocyanate ligands. In one ion, the thiocyanate ligands are all essentially linearly bound, with an Fe–N–C angle of 174 ± 4°, while in the other, two of the thiocyanate ligands are *cis*, with an Fe–N–C angle of 146.5°. The EPR, magnetic susceptibility and Mössbauer results show that all the iron(III) centers maintain the high-spin state down to 2 K. Infrared and Mössbauer spectra provide evidence for a lattice of unusual mechanical softness. Traditional criteria for interpretation of the infrared frequencies are not strictly applicable for this compound.

Experimental Section

$(NMe_4)_3[Fe(NCS)_6]$ was prepared according to Forster and Goodgame,[6] using tetramethylammonium thiocyanate obtained by metathesis between KNCS and Me_4NCl in ethanol. The product was recrystallised from ethanol, yielding crystals which indeed in reflected light appear olive-green, with a metallic lustre. Infrared spectra were obtained from powdered crystals and nujol oil mulls (to minimise pressurization) with a Thermo Nicolet Avatar 360 FT-IR equipped also with a Nicolet Smart MIRacle ATR diamond crystal accessory. Magnetic susceptibilities were measured with a Pd-standard-calibrated Quantum Design MPMS5S SQUID magnetometer, at a field of 0.1 T. EPR spectra were obtained with a Varian E-12 X-band instrument, calibrated with diphenylpicrylhydrazyl radical and chloropentaamminechromium(III) chloride. Mössbauer spectra were obtained in the transmission mode with a constant-acceleration-type spectrometer (Wissel), a liquid nitrogen cooled, bath-type cryostat being used for low-temperature spectra. An 800 MBq $^{57}Co(Rh)$ sample was used as the γ-ray source, while isomer shifts are referred to α-iron at room temperature. The sample was measured in the form of a fine powder in order to avoid texture effects in the spectra. Spectra were deconvoluted using the MossWin 3.0 code,[25] applying Lorentzian lineshape. Cyclic voltammetry was performed at 25 °C in deoxygenated CH_3CN solution with 0.1–0.2 M Et_4NClO_4 as supporting electrolyte using a Bioanalytical Systems BAS 100A electrochemical analyzer. The three-electrode assembly comprised a Pt-wire working electrode, an Ag^+ (0.01 M, 0.1 M Et_4NClO_4, CH_3CN)/Ag reference electrode ("APE")[26] and a Pt auxiliary electrode. For X-ray diffraction, a suitable crystal was mounted on a glass fiber with epoxy cement and attached to a goniometer head of a Siemens P4S diffractometer utilising a CCD area detector and graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Cell constants and orientation matrices were obtained by least-squares procedures using φ and ω scans, the data collection and reduction being controlled by Bruker SMART software. Absorption corrections (μ = 0.865 mm^{-1}) were obtained with SHELXA.[27] A total of 28471 reflections were collected (–29

$\leq h \leq 29$, $-10 \leq k \leq 10$, $-33 \leq l \leq 33$) in the θ range 1.45–24.71°. Solution, refinement and outputting were performed using the SHELX suite of programmes.[27] The structure was refined with direct methods using full-matrix least-squares procedures, on F^2 against 5576 independent reflections with $F^2 > 2\sigma(F^2)$. H atoms were initially emplaced geometrically and then included in subsequent cycles of refinement.

[1+1] Asymmetric Compartmental Macrocycles Bearing a Pendant Arm and Related *s,f*-Heterodinuclear Complexes Containing Lanthanide(III) and Sodium Ions

Sergio Tamburini,*[a] Umberto Casellato,[a] Laura Bertolo,[a] and Pietro Alessandro Vigato[a]

Keywords: Compartmental macrocycles / Lanthanides / Schiff bases / NMR of paramagnetic systems / Shift reagents / ^{23}Na NMR

[1+1] Asymmetric compartmental macrocycles and/or related mononuclear, homodinuclear and sodium(I)-lanthanide(III) heterodinuclear complexes are reported and their properties investigated by SEM-EDS microscopy and ^{1}H, ^{13}C and ^{23}Na NMR spectroscopy. These ligands bear a pendant arm, represented by a -CH_2COOH (H_3L_A), -$CH_2C_5H_4N$ (H_2L_B) or -$CH_2C_6H_4OH$ (H_3L_C) group bonded to the aminic nitrogen, and contain an O_2O_3 crown-ether-like chamber and an N_3XO_2 (where X = O, N) Schiff-base chamber. It was found that the lanthanide(III) ion resides in the N_3XO_2 chamber while the sodium(I) ion fills the O_2O_3 crown-ether-like chamber, as ascertained for the complex [DyNa(L_C)(PrOH)(Cl)] by a single-crystal X-ray structural investigation. The complex is monoclinic, space group $P2_1/c$, with a = 9.601(2), b = 12.927(2), c = 26.638(4) Å, β = 99.55(3)°. The dysprosium ion is seven-coordinate in the N_3O_2 site, showing a pentagonal-bipyramid-coordination polyhedron and bonded, in the axial positions, to a chlorine ion and to the oxygen of the pendant phenolic group of the ligand. The sodium ion is six-coordinate in the O_3O_2 site and bonded to the propyl alcohol oxygen. Furthermore, the potential use of these complexes as molecular probes for the selective recognition of specific metal ions has been tested. In particular, their ability to act as shift reagents towards Na^+ was investigated by ^{23}Na NMR spectroscopy. The relationship between the structure of these complexes in the solid state and in solution is reported.

Introduction

Macrocyclic compounds have attracted an increasing interest owing to their role in the understanding of the molecular processes that occur in different scientific fields, ranging from chemistry to biochemistry and medicine, from material science to hydrometallurgy.[1–9]

In the past, dinucleating macrocyclic systems attracted great interest. In particular, the physico-chemical properties arising from the proximity of two metal ions closely coordinated within an appropriate organic moiety were investigated. This molecular aggregation can mediate certain chemical reactions better (or in a different manner) than those in isolated centres. Moreover, it significantly contributes to the knowledge of cooperative effects in the activation, transport and separation of specific molecules with different complexity, in the selective recognition of neutral and charged species, in the design of probes and devices capable of operating at molecular level.[10–17]

Furthermore, dinucleating macrocyclic ligands have been used for the synthesis of compounds with specific spectroscopic and magnetic properties. It was demonstrated that complexes containing dinuclear (or polynuclear) magnetic entities at appropriate distances and/or with well-defined stereochemistry exhibit peculiar magnetic properties, arising from the nature and magnitude of the interactions between the metal ions within the molecular unit.[10,12]

In this field, a particular role was played by compartmental macrocyclic ligands, that is, systems with two adjacent coordination chambers capable of coordinating two metal ions, interacting through the appropriate bridging donor atoms of these ligands. This interaction can be tuned by changing the donor atoms of the two chambers, the flexibility of the ligands, the metal ions, the distance between the two chambers and/or the metal ions themselves.[10,12]

These compartmental ligands can be symmetric or asymmetric in nature, depending on the difference in the donor set and/or in the aliphatic or aromatic chains of the two adjacent coordination chambers; the symmetric ligating systems give rise almost exclusively to homo-dinuclear complexes. Only under specific, experimental conditions can they form mononuclear complexes, which, however, easily turn into the homo-dinuclear analogues.

Unsymmetrical modifications of these symmetric systems were designed in order to achieve a different recognition process at the two adjacent chambers and consequently to favour the formation of hetero-dinuclear complexes. The type and the extent of dissymmetry introduced in the coor-

E-mail: sergio.tamburini@icis.cnr.it

dination moiety can influence and modify considerably the coordination selectivity of the two sites, allowing the formation of pure hetero-dinuclear species, not otherwise accessible.[11,12,18]

Recently we have started a project aimed at the preparation of molecular probes for selective recognition of alkali or alkaline metal ions. In particular, we have prepared the [1+1] asymmetric cyclic ligands H_2L_D and H_2L_E by reaction of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldheyde) or 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldheyde) with 1,5-diamino-3-azamethylpentane. They contain an N_3O_2 Schiff-base chamber and an O_2O_n (where n = 3, 4) crown-ether-like chamber and react with $LnCl_3{\cdot}nH_2O$ in alcoholic solution, giving rise to the related mononuclear complexes $[Ln(H_2L_D)(Cl)_3(H_2O)_4]$ or $[Ln(H_2L_E)(Cl)_3(H_2O)_4]$, where the lanthanide(III) ion invariantly occupies the O_2O_n crown-ether-like chamber, as ascertained also by X-ray diffractometric investigations.[19,20] However, when this chamber is already occupied by a suitable metal ion [i.e. sodium(I) or calcium(II) ion] the lanthanide(III) ion is forced into the N_3O_2 Schiff-base chamber with the consequent formation of the hetero-dinuclear complexes $[Ln^{III}Na^{I}(L_D)(Cl)_2(CH_3OH)]$ or $[Ln^{III}Ca^{II}(L_D)(Cl)_3]$.[16,17]

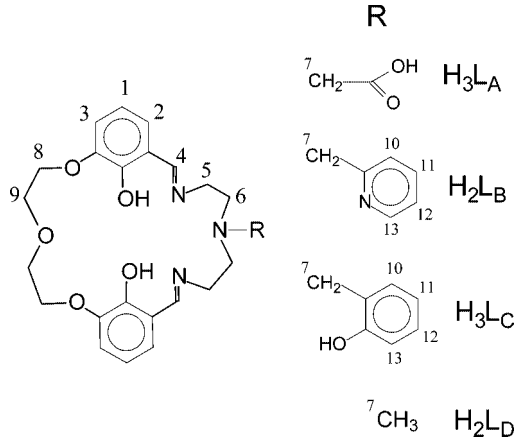
The alkali metal cations Na^+ and K^+ and the alkaline metal cations Mg^{2+} and Ca^{2+} are ubiquitous in living systems. The role of sodium and potassium stems essentially in their unequal distributions in the intra- and extracellular compartments and related transmembrane transport processes. The divalent magnesium and calcium cations possess a more marked binding ability towards macromolecules, polyelectrolytes and biological surfaces and thus their role is more differentiated. Under the form of aqua complexes, Mg^{2+} is concentrated in the cells, whereas Ca^{2+} is excluded. The distribution of alkaline and alkaline-earth ions in the inner- and outer-cell compartments is crucial to the viability of any organism. Thus, their qualitative and quantitative determination is essential, and NMR spectroscopy offers unique tools to reach this goal. The separation of the NMR signals from the two compartments is possible when their magnetic environments are made different by the presence of a paramagnetic agent, which selectively distributes in one compartment only. A successful separation of in- and out-signals is strongly dependent upon the interaction that the cation of interest is able to set up with the paramagnetic agent. In this context, compartmental ligands can be very useful. In fact, one may design systems containing a suitable lanthanide(III) ion endowed with a high magnetic moment and a non-*S* electronic configuration in one chamber, whereas the second chamber is available for coordination of an alkaline or alkaline-earth ion, possibly involved in an exchange process with the "bulk".

By this procedure quite interesting and powerful shift reagents (LIS reagents) have been proposed, in particular for Na^+.[21–23] The lanthanide(III) ions offer the unique possibility of progressively modifying their physical properties (and hence their ability to act as shift reagents), while maintaining the same chemical properties.

Most of the work was carried out on heterodinuclear lanthanide(III) complexes containing sodium(I).[24,25] More recently, some very encouraging results have been obtained with analogous complexes containing lithium(I), potassium(I) or calcium(II) ions instead of sodium(I).[26]

Unfortunately, these systems are sparingly soluble and not very stable in water. Consequently, in order to overcome these problems, we have functionalized the macrocyclic ligand by inserting pendant arms, which also bear additional donor groups. An additional, not negligible result of these functionalizations is that they further diversify the two coordination chambers, thus introducing more precise and selective recognition properties at the two chambers.

This paper deals with the design, synthesis and characterization of hetero-dinuclear sodium(I)-lanthanide(III) complexes with the ligands H_3L_A, H_2L_B,[27] H_3L_C, containing an O_2O_3 crown-ether-like chamber and an N_3XO_2 (X = O, N) Schiff-base chamber, where the pendant arm is represented by $-CH_2COOH$, $-CH_2C_5H_5N$, $-CH_2C_6H_4OH$, respectively, directly bound to the central aminic nitrogen as described in Scheme 1. The ligand H_2L_D and related complexes have been already studied and are here included for comparison purposes only.



Scheme 1. The prepared ligands with the numbering scheme used to assign the peaks of the NMR spectra.

Results and Discussion

H_3L_A, H_2L_B, H_3L_C and/or Related Sodium(I) Derivatives

While the macrocyclic ligand H_3L_A was not obtained in acceptable quantities by condensation of the appropriate diformyl and polyamine precursors, the related trisodium derivative Na_3L_A was synthesised in a considerable amount by treating the disodium diformyl precursor Na_2L' with the functionalized polyamine *i*-DTMA·3 HCl in the presence of NaOH. The crude product can be purified by crystallization from *i*PrOH. Its IR spectrum shows a strong band at 1623 cm^{-1} ($\upsilon_{C=N}$) and two intense bands at 1594 cm^{-1} (υ_{asymm} COO) and at 1396 cm^{-1} (υ_{symm} COO); two additional strong bands at 1213 and 1096 cm^{-1} are due to the υ_{C-O} of the crown-ether groups. The ^1H NMR spectroscopic data

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in CD_3OD show a peak at δ = 8.41 ppm due to the formation of the CH=N group; the contemporary absence of the CH=O resonance at δ = 10 ppm proves that the condensation process is complete. As for the macrocycle Na_3L_A, the NMR spectroscopic data indicate that the Na^+ ion is not strongly coordinated to the etheric chamber and is bound only to phenolato groups. In fact, the molecules are very flexible in solution (fast exchange on the NMR timescale) and there is no evidence of geminal multiplets in the aliphatic region, due to the characteristic stereochemical rigidity of Na^+ when it is fully coordinated in the etheric site. The ESI-MS spectrum in MeOH shows a peak at *m*/*z* (%) = 473 (5) due to the free ligand $[H_4L_A]^+$, an intense peak at *m*/*z* (%) = 495 (100) due to the species $[NaH_2L_A]$ and two additional peaks at *m*/*z* (%) = 517 (20) $[Na_2HL_A]$ and *m*/*z* (%) = 538 (20) $[Na_3L_A]$.

Attempts to isolate the ligand H_2L_B or its sodium derivative Na_2L_B by self-condensation of the precursors, using different experimental conditions, failed. The ligand can only be obtained under template conditions, as mononuclear or dinuclear lanthanide(III) complexes as a result of the experimental conditions used, as reported in the subsequent paragraph.

The phenol-containing ligand H_3L_C was obtained as the sodium derivatives $[Na_2(HL_C)]$ or $[Na(H_2L_C)]$ by treating the appropriate precursors in the presence of NaOH in two different synthetic ways: $[Na_2(HL_C)]$ was prepared by condensation of Na_2L' and Moden·3HCl in methanol, whereas for $[Na(H_2L_C)]$, H_2L', Moden·3HCl and NaOH were dissolved in a minimum amount of methanol, but the condensation reaction was conducted in diethyl ether. Once more, the completion of the condensation reaction is proved by the presence of the infrared $\upsilon_{C=N}$ band at 1624 cm^{-1} for $[Na_2(HL_C)]$ and at 1639 cm^{-1} for $[Na(H_2L_C)]$, which indicates, for the latter, that the Na^+ is not bound to the iminic nitrogen and quite probably resides in the crown-ether site. The ESI-MS spectrum of $[Na(H_2L_C)]$ in MeOH shows the parent peak at *m*/*z* (%) = 542 (55) due to $[Na(H_3L_c)]^+$. The ^1H NMR spectrum in CD_3OD of both sodium derivatives, together with the bidimensional experiments COSY, NOESY and HMQC, allow us to correctly assign the observed proton and carbon peaks. The CH=N resonance at δ = 8.26 ppm proves that the condensation process has occurred, while 2D data demonstrate that the phenol pendant arm resonances at δ = 7.15 (10-H), 6.93 (12-H), 6.68 (11-H) and 6.30 (13-H) ppm are connected via the methylenic (7-H) resonance at δ = 3.81 ppm to the other methylenic groups of the Schiff base moiety at δ = 2.98 (6-H) and 3.88 (5-H) ppm and via the iminic resonance at δ = 8.26 (4-H) ppm to the phenolic protons.

Mononuclear or Homodinuclear Lanthanide(III) Complexes

Complexes with $[L_A]^{3-}$

Owing to the availability of Na_3L_A and the difficulty in obtaining a suitable amount of H_3L_A, the complexation reactions were carried out using the tris-sodium derivative. Na_3L_A reacts with the appropriate $LnCl_3{\cdot}nH_2O$ in methanol in a 1:1 molar ratio to yield, after a 2 h reflux, $[LnNa(NaL_A)(Cl)_2]{\cdot}nH_2O{\cdot}x$ NaCl (where NaL_A indicates the diphenolate macrocycle with a sodium acetate group and Ln = Y, Lu, Yb) and, after a 12 h reflux, $[Ln_2(L_A)(Cl)_3]{\cdot}nH_2O{\cdot}x$ NaCl (where Ln = Y, Lu, Yb, Nd) (see Scheme 2). Attempts to isolate the LnNa heterodinuclear complexes by template synthesis failed. Furthermore, attempts to crystallize homo- and hetero-dinuclear complexes under a variety of experimental procedures failed. However, careful SEM-EDS investigations prove an Ln/Cl = 1:2 ratio together with well-detectable NaCl grains for the heterodinuclear LnNa and an Ln/Cl = 2:3 ratio for the homodinuclear LnLn complexes.

The properties of the Ln-Na complexes will be discussed in detail in the appropriate paragraph.

In the homodinuclear lanthanide(III) complexes, the $\upsilon_{C=N}$ is found at 1624–1654 cm^{-1} and the stretchings of the etheric groups occur at 1230–1223 cm^{-1} and at 1094–1090 cm^{-1}. Surprisingly, the $\upsilon_{C=N}$ of the homodinuclear complexes lies at higher wavelength in relation to the heterodinuclear Ln-Na analogues, where the same bands lie at 1625–1637 cm^{-1}. The long refluxing time required for the preparation of the homodinuclear complexes resulted in the loss of the sodium ion from the complex and consequent formation of NaCl, as shown by SEM and elemental analyses.

The carboxylate group quite probably participates in the coordination to the lanthanide ion as a monodentate group. The $\upsilon_{asymm}(COO)$ is found at1601–1618 cm^{-1} whereas the $\upsilon_{symm}(COO)$ is at 1415–1459 and 1460–1500 cm^{-1}.

It may be suggested that, in the formation of the homodinuclear species, the first event to take place is the formation of the heterodinuclear LnNa complex with the lanthanide ion probably lying in the mean equatorial plane of the N_3O_2 donor set of the Schiff base, as already found for similar lanthanide complexes.[25] This is followed, as a consequence of the prolonged reflux and subsequent release of the Na^+ ion, by the coordination of a second lanthanide in the free O_3O_2 site, which is the favourite site of the lanthanide(III) ion, as already ascertained.[27] The macrocycle does not have the correct coordination shape to encapsulate both metal ions firmly into the mean equatorial plane. Consequently, the lanthanide ion coordinated to the Schiff-base site, owing to the steric hindrance caused by the incoming second lanthanide ion, is pushed away from the N_3O_2 mean plane toward the acetate group. This causes a coordination lowering of the iminic nitrogen to the central metal ion with the consequent shift of the $\upsilon_{C=N}$ toward higher wavelengths. The NMR spectroscopic data of $[Lu_2(L_A)(Cl)_3]{\cdot}0.3$ PrOH in $MeOD_4$ show that the compound is not stable in solution. The complexity of the aromatic and iminic region proves the presence of several species deriving from the demetalation reaction, with the formation of mononuclear complexes with different coordination sets. Another proof of this instability comes from the ESI-MS spectra of these complexes where no peak attributable to the homodinuclear specie was found.[28]

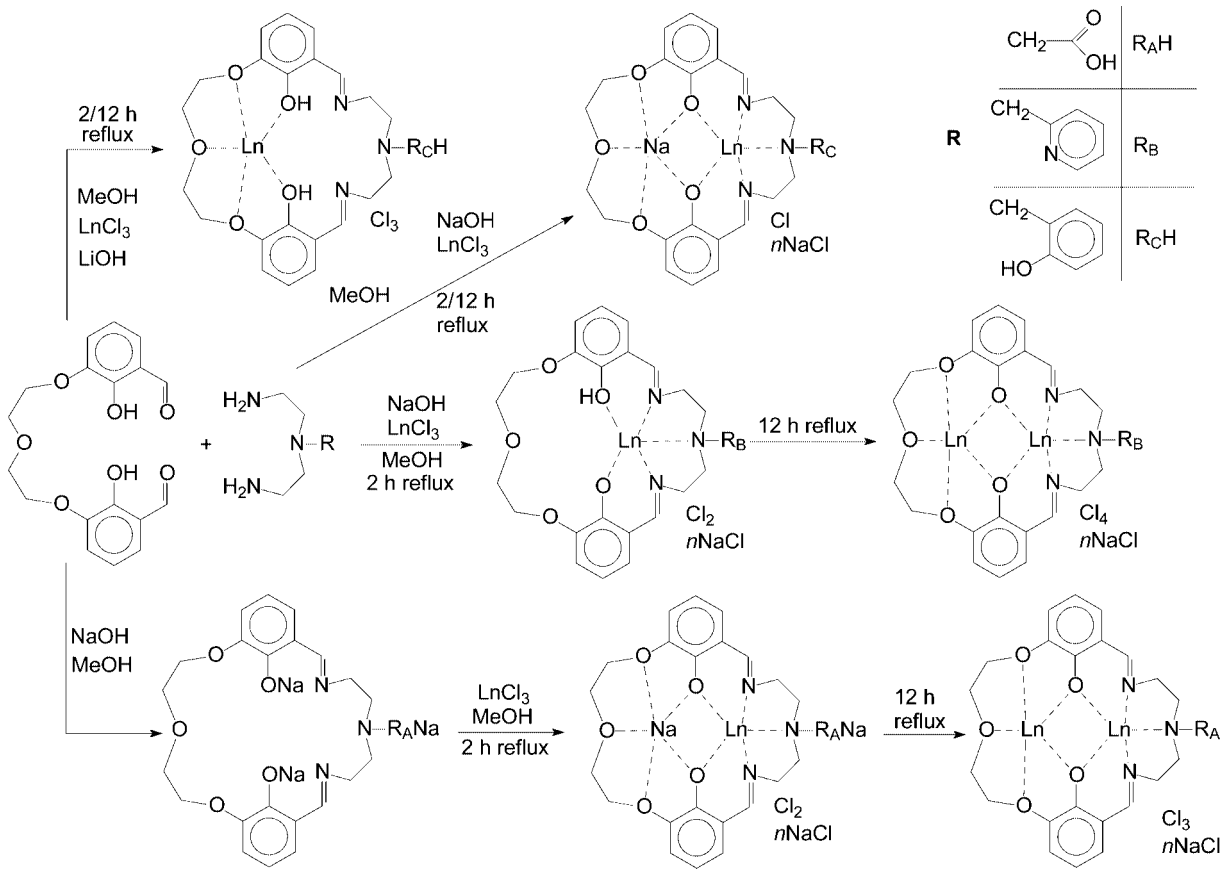

Scheme 2. Preparation of mononuclear and homo- or hetero-dinuclear complexes.

Complexes with $[L_B]^{2-}$

As H_2L_B or Na_2L_B are not available, the pyridine-containing macrocycle was prepared by a template synthesis in the presence of the desired lanthanide(III) chloride hydrate in alcoholic solution. It was found that when the diformyl and amine precursor are condensed in the presence of NaOH and $LnCl_3 \cdot n H_2O$ in methanol (molar ratio 1:1:3:1), and the reaction mixture is allowed to reflux for 1–2 h, the mononuclear complexes $[Ln(HL_B)(Cl)_2] \cdot n NaCl \cdot m H_2O$ are obtained (Ln = Y, Yb, Lu, Tm, Tb, La, Ce); on the contrary, when the reflux is continued for 12 h, the homodinuclear complexes $[Ln_2(L_B)Cl_4] \cdot n NaCl \cdot m H_2O$ are collected (Ln = Y, Lu, Tb, La; see Scheme 2). Again, careful SEM-EDS investigations prove an Ln/Cl = 1:1 ratio for both complexes together with well-detectable NaCl grains.

The IR spectra of these mononuclear and dinuclear complexes are comparable to those obtained for the similar complexes with Na_3L_A. In particular, the mononuclear complexes show a strong $\upsilon_{C=N}$ absorption at 1617–1655 cm^{-1}. This band is generally higher in the dinuclear analogue; it lies for instance at 1625 cm^{-1} in $[La(HL_B)(Cl)_2] \cdot 2.5 H_2O$ and at 1647 cm^{-1} in $[La_2(L_B)(Cl)_4] \cdot 3.9 H_2O$.

The close proximity of the two metal ions in the dinuclear complexes, and the consequent steric hindrance, push a lanthanide ion partially out of its N_4O_2 coordination plane, causing a wavelength increase of the $\upsilon_{C=N}$ stretching band. A similar trend is observed in the related ^1H NMR spectrum in [D4]MeOH: the peak at δ = 8.15 ppm due to the iminic groups of the mononuclear complexes is shifted to δ = 8.60 ppm in the homodinuclear analogue.

The NMR experiments in the diamagnetic La, Y and Lu complexes also show that the impurities present in the mononuclear complexes are mainly the homodinuclear analogues. The NMR spectra of these dinuclear species, in fact, match perfectly those of the impurities present in the mononuclear complexes. The main differences in these spectra are localized in the Schiff-base protons. This confirms the above assumption that the Schiff-base site is only partially involved in the coordination. The solution instability of the dinuclear species represents a severe limitation to an exhaustive description of the behaviour of these complexes in solution.

In the mononuclear complexes, no evidence of Na^+ coordinated in the crown-ether moiety was found, probably because it may be more easily released than in the complexes with Na_3L_A, facilitating the formation of mononuclear lanthanide complexes. The lability of Na^+ in the crown-ether moiety, also verified by ^{23}Na NMR spectroscopy, is quite important in the determination of interesting LIS properties as reported above.

A study of the ^1H, $^{13}C\{^1H\}$ and 2D COSY, NOESY, HMQC NMR spectra in [D4]MeOH allows a complete assignment and interpretation of the peaks occurring in the mononuclear $[Ln(HL_B)(Cl_2)]$ and dinuclear diamagnetic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and paramagnetic $[Ln_2(L_B)(Cl)_4]$ complexes (see Exp. Sect.).

The study of the weak paramagnetic complex $[Ce(HL_B)(Cl)_2]\cdot 7H_2O$ is particularly indicative of the lanthanide coordination. On the basis of 2D NOESY, acquired at several mixing times and HMQC experiments, it was possible to fully assign 13 resonances in the ^1H NMR spectrum. The very low-field 21.30 ppm shift of protons 4-H and the severe shift (δ = 8.01 and –11.46 ppm) and broadening of methylenic protons of the Schiff-base moiety strongly support the thesis of lanthanide coordination in the Schiff-base site, also confirmed by the usual position of 8-H and 9-H resonances (δ = 3.66 and 4.77 ppm) of the O_3O_2 site. Furthermore, the downfield shift of pyridinic protons 13-H, 12-H, 11-H and 10-H (δ = 11.50, 8.62, 9.27, and 9.10 ppm) suggests that the pendant arm is involved in such coordination.

ESI-MS spectra of these samples show the presence of signals related to the sodium or lanthanide mononuclear complexes; this proves the real occurrence of the mononuclear lanthanide(III) complexes. Moreover, in a few cases the mononuclear lanthanide complexes encapsulate a methanol or chloride and/or water molecule.[28] As for the L_A^{3-} ligand, no evidence of homodinuclear species was found.

Complexes with $[L_C]^{3-}$

The mononuclear complexes $[Ln(H_3L_C)(Cl)_3]$ (where Ln = Lu, Eu, Tb, Y, La) were synthesised by [1+1] condensation of the triamine precursor (Moden·3HCl), neutralized with LiOH, with the diformyl precursor (H_2L') in the presence of $LnCl_3\cdot n H_2O$. SEM-EDS data confirm the Ln/Cl = 1: 3 ratio (see Scheme 2). The key of this synthesis is the use of LiOH as a neutralizing agent of the aminic precursor instead of NaOH; Li^+ is not a suitable competitor of the lanthanide(III) ion for the hard site and hence it allows the coordination of the lanthanide ion to the crown-ether site. On the contrary, Na^+ strongly competes with the lanthanide(III) ion and makes the coordination of the 4f ion very problematic or impossible.

Long refluxing times do not yield homodinuclear species, as for the previous ligands H_3L_A or H_2L_B. The complexes recovered after a 12 h reflux always produce the mononuclear or the heterodinuclear Ln-Na complexes when LiOH or NaOH, respectively, are used.

Quite interestingly, when a higher LiOH/ligand ratio is used, the coordination site of the lanthanide ion can be chosen. More precisely, under basic conditions (LiOH/Moden·3HCl/H_2L'/$LnCl_3$ = 6:1:1:1), complexes have been invariantly obtained where the NMR (iminic proton at higher field shifts and appearance of geminal peaks in the Schiff base methylenic region) and IR ($\upsilon_{C=N}$ at 1620–1625 cm^{-1}) spectra clearly indicate that the lanthanide ion resides in the Schiff-base site. Unfortunately, the compounds prepared always contain a low amount of mononuclear species with the lanthanide coordinated in the crown-ether moiety.

Less basic conditions (LiOH/Moden·3HCl/H_2L'/$LnCl_3$ = 3:1:1:1) always lead to pure mononuclear complexes in which the crown ether site is occupied by the lanthanide(III) ion. IR data corroborate the coordination in the O_3O_2 site: in fact, the $\upsilon_{C=N}$ IR band in these complexes lies between 1647 and 1653 cm^{-1}, which is higher than the analogue LnNa derivatives ($\upsilon_{C=N}$ at 1619–1626 cm^{-1}), where the lanthanide was found to reside in the Schiff-base site.

This hypothesis is in agreement with the study of the ^1H NMR spectrum of the paramagnetic $[Eu(H_3L_C)(Cl)_3]$ in $[D_4]$MeOH. In fact, the coordination of the Eu^{III} ion in the crown ether moiety shifts and widens the peak at δ = 11.83 ppm related to aliphatic protons (8-H) and (9-H). On the other hand, protons of the pendant arm do not seem to be involved in the coordination of europium since they do not undergo any change in bandwidth or chemical shift [they are found at δ = 7.42 (10-H), 7.06 (12-H), 6.67 (11-H, 13-H) ppm; (see part a of Figure 1).

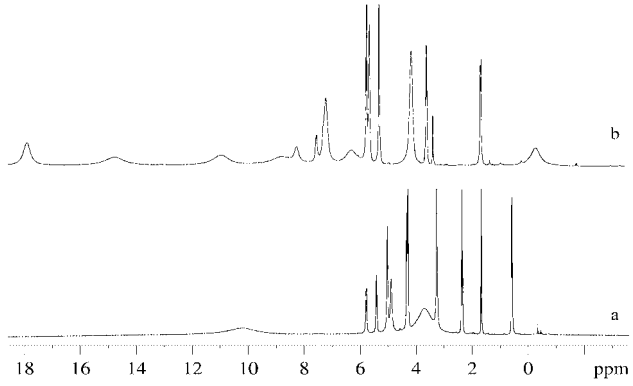

Figure 1. ^1H NMR spectra of $[Eu(H_3L_C)(Cl)_3]$ in CD_3OD at 293 K (a) and 253 K (b).

The europium(III) coordination was further clarified by the NMR spectrum acquired at 253 K. The broad peak centered at δ = 11.83 ppm generated four peaks at 17.75, 14.53, 10.84 and –0.34 ppm assigned, on the basis of 2D NOESY acquired at several mixing times and HMQC experiments, to the geminal axial and equatorial 8-H and 9-H methylenic protons of the O_3O_2 site. At that temperature, the other broad resonance at δ = 5.33 ppm, assigned to the 5-H and 6-H methylenic protons of the N_3O_3 site, is shifted to 6.22 and 4.08 ppm but still unresolved (see part b of Figure 1).

Heterodinuclear Lanthanide(III)–Sodium(I) Derivatives

Complexes with $[L_A]^{2-}$

As reported above, the reaction of Na_3L_A with the appropriate $LnCl_3\cdot n H_2O$ in methanol and in a 1:1 molar ratio, under a 2 h reflux, yields $[LnNa(NaL_A)(Cl)_2]\cdot n H_2O$, where it is likely that one sodium ion resides in the crown-ether chamber and the other is linked to the carboxylate group (see Scheme 2). These complexes always contain variable amounts of NaCl, clearly detected as grains by SEM-EDS microscopy. These measurements also prove that the complexes possess the right Na/Ln/Cl = 2:1:2 metal ratio (excluding NaCl crystals present in the sample).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The IR spectra of the LnNa complexes show a strong $\upsilon_{C=N}$ absorption at 1631–1619 cm^{-1}, supporting a complexation of the lanthanide(III) ion inside the Schiff-base site. The broadening of this band also suggests that the $\upsilon_{symm}(COO)$ occurs at these wavenumbers. Furthermore, strong bands at 1221–1217 cm^{-1} and at 1093–1090 cm^{-1}, due to the stretching of the crown-ether C–O groups, have been observed, together with $\upsilon_{symm}(COO)$ absorption at 1410–1417 cm^{-1}.

NMR 2D data in CD_3OD of the diamagnetic LuNa complex resemble those obtained for the Na_3L_A precursor, allowing a complete assignment and interpretation of the peaks (see Exp. Sect.). Furthermore, the NMR spectroscopic data of the EuNa complex give a good indication of the site occupancy of the metal ions. In particular, the remarkable upfield shift of the iminic proton (δ = 28.28 ppm) and the presence of geminal methylenic protons between δ = –6.96 and –20.12 ppm indicate that the europium ion is coordinated to the Schiff-base site. Furthermore, geminal methylenic protons in the range δ = 2.33 to –0.36 ppm suggest that the etheric region of the macrocycle is rigidly coordinated to the sodium(I) ion. The peak at δ = 28.99 ppm of the remaining methylenic protons of the acetate pendant arm is very interesting and the considerable shift indicates that the acetate group is probably involved in the coordination of the paramagnetic ion. Moreover, the absence of methylenic geminal protons in the diamagnetic lutetium and lanthanum complexes suggests that the coordination proposed for the europium ion could be unrealistic for other LnNa complexes. The parent peaks at 644 and 666 *m*/*z* in the ESI-MS spectra of the europium and lutetium complexes, respectively, confirm the occurrence of a heterodinuclear $[(LnNaL_A)]^+$ species.

Surprisingly, the ^{23}Na NMR spectra in methanol of the paramagnetic complexes $[LnNa(Na_xL_A)(Cl)_{1+x}]$ (where Ln = Yb, Tm, Tb; x = 0, 1) do not show any ^{23}Na shift, thus proving that no interaction between the two metal ions occurs. The reason for this failure is not easily explainable. Certainly it is due to a wrong Ln···Na alignment. It could also be due to the fact that the coordination observed in the NMR spectroscopic data of the europium complex is not maintained in other complexes and the acetate group is competing with the O_3O_2 site in coordinating the sodium ion, thus determining an incorrect stereochemistry for obtaining a relevant ^{23}Na shift. Alternatively, even if the lanthanide(III) ion were in the Schiff-base site, its displacement from the equatorial plane toward the carboxylate group would give rise to an incorrect alignment.

Complexes with $[L_B]^{2-}$

Heterodinuclear Ln-Na complexes were not obtained with L_B^{2-}, but SEM-EDS measurements clearly prove the presence of NaCl in $[Yb(HL_B)(Cl)_2]\cdot 7\,NaCl\cdot 0.1\,H_2O\cdot 1.6\,EtOH$ and $[Tm(HL_B)(Cl)_2]\cdot 7.6\,NaCl\cdot EtOH$. As reported above, we have proved, by 2D NMR measurements on these paramagnetic complexes, that the lanthanide(III) ion, probably owing to the presence of a pyridinic pendant arm, prefers the Schiff-base site rather than the etheric one. Consequently, in methanolic solution, the sodium ion related to NaCl is partially coordinated to the Ln complex and this coordination causes a high isotropic ^{23}Na shift (δ = 330 ppm for the Tm complex at –20 °C). Furthermore, as expected, the ^{23}Na chemical shift linearly decreases with the increasing temperature. This behaviour is similar to that observed in the $[LnNa(L_D)(Cl)_2(MeOH)]$ complexes described in a previous paper,[25] where X-ray structural determinations show that the lanthanide(III) ion resides in the N_3O_2 Schiff-base chamber and the sodium(I) ion is in the crown-ether-like chamber. Thus we can reasonably suggest that heterodinuclear complexes are formed and that a site occupancy similar to that ascertained for $[LnNa(L_D)(Cl)_2(MeOH)]$ occurs, taking into account that the similar positional isomeric complexes with H_2L_D, where the lanthanide(III) ion resides in the O_3O_2 chamber and the sodium(I) ion in the crown-ether site, show a negligible ^{23}Na chemical shift.

The formation of an LnNa hetero-dinuclear coordination is also proved by the ESI-MS spectra in methanol of the complexes. The presence of peaks at 331.4 and 349.8 *m*/*z* (where z = 2) of the La and Yb complexes, respectively, is convincing evidence of the formation of $[LnNa(L_B)]^{2+}$ species.

The lability of Na^+, mentioned above, is an interesting and useful feature in order to obtain powerful molecular shift devices as they need a quick complexation–decomplexation process of the species to be characterized.

Complexes with $[L_C]^{3-}$

The heterodinuclear complexes $[LnNa(L_C)(Cl)]\cdot x\,NaCl$ (where Ln = Y, Yb, Lu, Tm, Tb, Dy, Eu, Er, La, Ce) were synthesised by condensation of the triamine precursor (Moden·3 HCl), with the diformyl precursor (H_2L') in the presence of NaOH and the appropriate $LnCl_3\cdot n\,H_2O$ in a 1:1:5:1 ratio (see Scheme 2) in methanolic solution.

The IR spectra of the LnNa complexes show a strong $\upsilon_{C=N}$ absorption at 1626–1619 cm^{-1}, supporting a complexation of the lanthanide(III) ion inside the Schiff-base site. These complexes always contain variable amounts of NaCl, detected as grains by SEM-EDS electron microscopy. The ESI-MS spectra in MeOH for each complex clearly show the parent peak due to the appropriate $[LnNaL_C]^+$ molecule, bearing in mind that additional NaCl or solvent molecules present in the sample are not directly involved in the coordination. In agreement with the related systems containing H_3L_A or H_2L_D and with the literature,[25] the presence of Na^+, which preferentially fills the O_2O_3 site, forces the lanthanide(III) ion into the Schiff-base moiety; this coordination is strengthened by the further coordination of the phenolic group, as confirmed by X-ray diffractometry structural studies in the solid state and in solution by NMR spectroscopy.

The complexes are very soluble in methanol and sparingly soluble in water. Consequently, NMR spectra were carried out in CD_3OD. Moreover, the complexes are soluble and stable for a long period of time in a CD_3OD/D_2O (1:1)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solution; the results in this solution completely parallel those obtained in CD_3OD.

In order to clarify the coordination in solution of the lanthanide ion, ^1H and ^{13}C NMR bidimensional studies were carried out on the paramagnetic complex [EuNa(L_C)(Cl)]·6.5 NaCl in CD_3OD. On the basis of COSY, HMQC and several NOESY spectra with different mixing times and starting from the two doublets at δ = 0.52 ppm (d) and 1.98 ppm (d) (with identical T_1 = 450 ms), assigned respectively to protons 2-H and 3-H, we find the triplet related to proton 1-H at δ = 4.20 ppm (m), proton 4-H at δ = –29.90 ppm (s) (dipolar correlation with 2-H; see Figure 2, line a) and geminal proton 8e-H at δ = 2.63 ppm (t) [scalar coupled with 8a-H at δ = 4.42 ppm (m)] (dipolar correlation with 3-H). Geminal protons 9e-H at 3.95 (m) and 9a-H at δ = 5.67 ppm (m) are then assigned by scalar correlation with protons 8-H. Again, 2D NOESY spectra reveal the aliphatic geminal protons 5e-H, at δ = –9.57 ppm (s) (dipolar coupling with 4-H; see Figure 2, line b) and 5a-H, at δ = 4.22 ppm (m), and 6a-H, at δ = –1.00 ppm (s), and 6e-H, at δ = 19.46 ppm [(s); see Figure 2, line e]. Then proton 7-H lies at δ = –12.87 ppm [(s) dipolar correlation with 6a-H; see Figure 2, line c], which correlates with proton 10-H at δ = 4.20 ppm [(m); see Figure 2, line d]. Protons 11-H, 12-H and 13-H are found at δ = 5.67 (m), 5.31 (t) and 11.37 ppm (d), respectively.

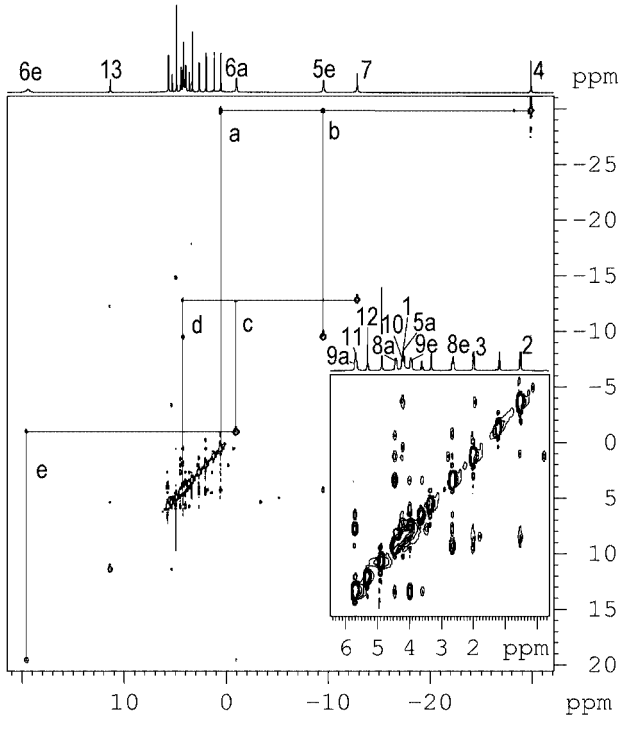

Figure 2. 2D ^1H NOESY NMR spectra of [EuNa(L_C)(Cl)] in CD_3OD at 293 K. Main window: mixing time = 60 ms; small window: mixing time = 220 ms.

NMR spectroscopy of paramagnetic Eu complexes is a powerful tool for a satisfactory understanding of the site occupancy of the lanthanide(III) ions. In contrast to [Eu(H_3L_C)($Cl)_3$], where it was clearly demonstrated that the europium ion occupies the O_3O_2 site, in [EuNa(L_C)(Cl)] the europium ion, due to the large shift of 5-H, 6-H (from δ = –9.57 to 19.46 ppm) and 4-H (δ = –29.90 ppm) resonances, lies in the N_3O_3 site. Furthermore, the pendant arm, owing to the large shift of the 10-H, 11-H, 12-H and 13-H resonances (from δ = 4.20 to 11.37 ppm), quite different from the diamagnetic one, is clearly coordinated to the europium(III) ion. Finally, the occurrence of a geminal resonance for each methylenic group proves that the complex is very rigid in solution and that both coordination sites are firmly occupied by a metal ion.

^{23}Na NMR spectra of the [LnNa(L_C)(Cl)] complexes (where Ln = Yb, Tm, Tb, Dy) show that complexes with L_C^{3-} have the same behaviour as those with L_B^{2-}. The presence of a broad resonance with a large shift from the free-ion peak arises from the coordination of Na^+ in the O_3O_2 site of the complexes, resulting in a slow exchange at room temperature on the NMR timescale.

The slow exchange is confirmed by the peak at δ = 0 ppm corresponding to the free ion, which originates from the presence of NaCl in the sample. The observed isotropic shift is very large as far as the Tm, Dy and Tb complexes are concerned, whereas it is smaller for the Yb complex; numerical values of these shifts are: [TmNa(L_C)(Cl)] +270 ppm (room temp.), +360 ppm (–20 °C); [DyNa(L_C)(Cl)] –158 ppm (room temp.), –200 ppm (–20 °C); [TbNa(L_C)(Cl)] –258 ppm (room temp.), –352 ppm (–20 °C); [YbNa(L_C)(Cl)] +50 ppm (room temp.), +61 ppm (–20 °C; see Figure 3).

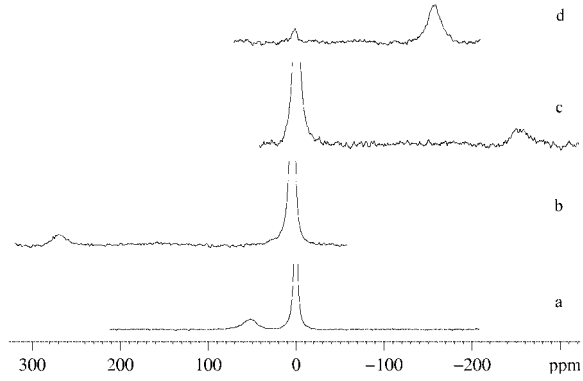

Figure 3. ^{23}Na NMR spectra at 293 K of [YbNa(L_C)(Cl)] (a), [TmNa(L_C)(Cl)] (b), [TbNa(L_C)(Cl)] (c), [DyNa(L_C)(Cl)] (d).

The ^{23}Na NMR spectroscopic data in CD_3OD/D_2O (1:1) containing NaCl are comparable with those in CD_3OD reported above; the most remarkable difference is a considerable broadening of the signal of the bound sodium ion due to the high Na_{bound}/Na_{free} exchange.

Crystal Structure

Crystals of [DyNa(L_C)(PrOH)(Cl)] were obtained from slow evaporation of 1-propanol solutions. The ORTEP representation of the crystal-structure complex and coordination geometries are shown in Figure 4.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

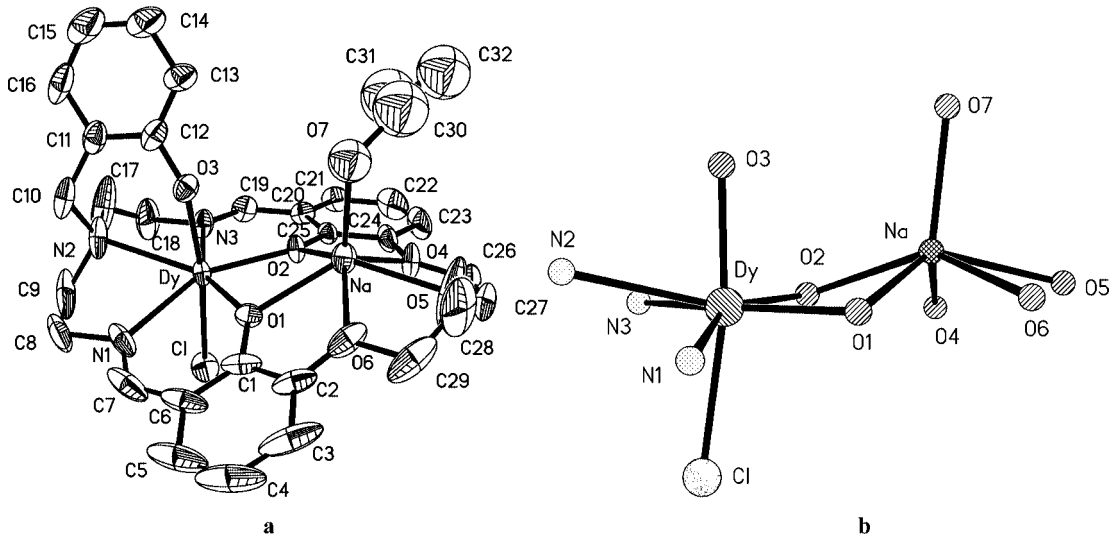

Figure 4. ORTEP representation of the (a) crystal structure of the complex [DyNa(L_C)(PrOH)(Cl)] and (b) coordination geometries.

The sodium ion is located in the O_2O_3 crown-like site of the macrocyclic ligand and reaches the coordination number of six by bonding to five oxygen atoms from the ligand and one oxygen atom from the 1-propanol molecule. The oxygen atoms O(4), O(5) and O(6), are etheric, whereas O(1) and O(2) are phenolic. The coordination geometry around the sodium ion can be described as a distorted pentagonal pyramid with the 1-propanol oxygen atom as apex; the sodium atom is displaced by 0.765 Å from the basal mean plane. The seven-coordination of the dysprosium ion is achieved by three nitrogen atoms, two phenolic oxygens [O(1) and O(2)] that act as a bridge, the pendant phenolic oxygen of the ligand and one chlorine ion. The coordination polyhedron around the dysprosium ion is better depicted as a distorted pentagonal bipyramid with the chlorine ion and the phenolic pendant oxygen, O(3), as apices. The total four positive charges of the two metal ions are neutralized by the three, negatively charged phenyl oxygens and by the chlorine ion.

As for other similar complexes,[25] the molecule adopts a butterfly shape with the two benzene rings as wings that form a dihedral angle of 34.6°. The pendant system, beginning from N(2) and coordinated to Dy by the O(3) atom is placed on the convex part of the molecule and influences the conformation of the torsion angles involving the nitrogen atoms of the Schiff-base chamber.

The mean plane formed by the five, donor atoms [O(1), O(2), N(1), N(2), N(3)] bonded to the dysprosium atom includes this ion (displacement –0.0083 Å) while the displacements of the five atoms range between +0.416 and –0.456 Å. The mean plane formed by the five oxygen atoms bonded to the sodium ion [O(1), O(2), O(4), O(5), O(6)] is more planar; the displacements vary between +0.197 and –0.169 Å. The sodium ion is –0.7651 Å far from the plane.

The Dy–O distances are similar in the atoms involved in the bridge [O(1) 2.236(5) Å and O(2) 2.226(4) Å], while the Dy–O(3) bond is shorter, 2.185(6) Å [the O(3) atom is negatively charged and non-bridging]. Minor differences are present in the Dy–N distances; in fact the Dy–N(iminic) bonds are similar [Dy–N(1) 2.474(8) Å and Dy–N(3) 2.494(7) Å], while the Dy–N(2) (aminic) is 2.556(7) Å.

The Na–O(etheric) distances vary between 2.376(8) and 2.410(7) Å.

Owing to the interesting LIS data found for these complexes, structural data of the [DyNa(L_C)(PrOH)(Cl] complex have been compared with the similar [LnNa(L_D)-($Cl)_2$(MeOH)] (where Ln = Nd, Eu, Gd, Yb) complexes[25] that present a comparable ^{23}Na NMR shift. All the complexes have shown that the sodium environment is always preserved with very similar coordination distances and angles, while some differences, as foreseen, are detected about the bond lengths around the lanthanide ions. These, in fact, follow the constant decreasing of the ionic radii along the lanthanide series with a decrease of the coordination bond lengths in going from Nd to Yb complexes. In the [LnNa(L_D)($Cl)_2$(MeOH)] complexes, the conformation of the torsion angles N(1)–C(8)–C(9)–N(2) and N(2)–C(17)–C(18)–N(3) are g^- and g^+, respectively, while they are g^- (–47.6°) and g^- (–42.6°) in [DyNa(L_C)(PrOH)(Cl]. Other differences with the structure described here are present in the bond angles of coordinated atoms and are mainly due to the geometrical constrains of the pendant phenolate group. The contact distance Ln···Na of L_D complexes has a mean value 3.55 Å compared to the 3.496(3) Å of Dy···Na found in the [DyNa(L_C)(PrOH)(Cl] crystal.

Conclusion

A series of heterodinuclear sodium-lanthanide complexes, together with the related mononuclear and/or homodinuclear lanthanide complexes with three different [1+1] asymmetric macrocyclic ligands, containing two adjacent cavities, an O_3O_2 crown-ether site and an N_3XO_2 Schiff-base site, where X is N or O of a pendant arm (-CH_2COOH for H_3L_A, -$CH_2C_5H_4$N for H_2L_B and -$CH_2C_6H_4$OH for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

H_3L_C) bonded to the aminic nitrogen, were synthesised by different routes, that is, self-condensation of the precursors followed by the reaction of the cyclic Schiff base with the appropriate lanthanide(III) ion or template synthesis [the lanthanide(III) ion used as templating agent]; both methods lead to the same products.

Remarkably, the use of NaOH as a base also introduces an Na^+ ion into the crown-ether cavity for both L_A^{3-} and L_C^{3-}, but not for L_B^{2-} (which generates only mononuclear and homodinuclear lanthanide complexes). Mononuclear lanthanide(III) complexes with L_C^{3-} were synthesised only when NaOH was substituted by LiOH, as the Li^+ ion is not as tightly coordinated as Na^+ to the crown-ether moiety, thus it forces the lanthanide(III) ion to reside in the Schiff-base site, as confirmed by the X-ray structure of [DyNa-$(L_C)(Cl)(CH_3OH)$].

The refluxing time appears to be very important in determining the reaction pathway for complexes with L_A^{3-} and L_B^{2}. Thus, when the appropriate reactants were refluxed for 2 h, the heterodinuclear LnNa (for L_A^{3-}) or the mononuclear Ln (for L_B^{2-}) complexes were obtained, whereas a prolonged reflux (12 h) led to the homodinuclear Ln_2 complexes of both ligands. Neither heterodinuclear LnNa complexes with L_B^{2-}, nor mononuclear Ln complexes with L_A^{3-} were obtained. Under similar conditions, no homo-dinuclear lanthanide complexes were obtained with L_C; the hetero dinuclear NaLn or the mononuclear Ln complexes were invariantly obtained.

In all complexes, the presence of the lanthanide ion in the Schiff-base site is favoured only when the ligand is fully deprotonated. The formation of strong hydrogen bonds between phenolic hydrogen and iminic nitrogen or imine protonation probably prevent the coordination of the lanthanide in the N_3O_2 site.

There is not a clear explanation of the impossibility of obtaining the heterodinuclear LnNa complexes with L_B^{2-}. It must be stressed that this ligand, under particular conditions (i.e. a prolonged reflux in methanol), forms exclusively the dinuclear lanthanide(III) complexes. The partial occupancy of the crown-ether site by a lanthanide(III) ion may prevent a stable sodium encapsulation in the crown-ether moiety. The presence of a basic pendant arm may favour partial deprotonation of the phenolic oxygen and hence an easier formation of homodinuclear species, instead of heterodinuclear LnNa analogues. In any case, the coordination of sodium to the crown-ether moiety, whether it occurs, appears weak.

The introduction of a pendant arm containing a coordinating group in the macrocyclic system improves the solubility in relation to the complexes $[LnNa(L_D)(Cl)_2(MeOH)]$. Complexes with L_C^{3-} show the best solubility in alcohol, but the heterodinuclear LnNa complexes are still insoluble in water (whereas mononuclear Ln complexes are slightly water-soluble). The solubility in H_2O/MeOH (1:1), however, is very good and the complexes are stable for many days. The stability of the LnNa complexes with the phenol pendant arm seems to increase significantly as well, though this is not a general trend with pendant arms.

The behaviour of $[LnNa(L_C)(Cl)]$ in solution was carefully studied especially by ^1H and ^{13}C NMR spectra. It was pointed out that in $[LnNa(L_C)(Cl)]$, the phenol pendant arm is tightly coordinated to the lanthanide ion. Evidence of a rigid system also comes from the quite simple ^1H NMR spectral pattern which denotes the presence of a symmetry plane perpendicular to the molecule and passing through the Ln-Na axis. These data show that the behaviour of these complexes in solution parallels that observed in the solid state.

While the ^{23}Na NMR spectra of the paramagnetic $[LnNa(L_A)(Cl)]$ (where Ln = Yb, Tm, Tb) do not show any ^{23}Na shift, probably for an incorrect alignment of Ln^{3+} and Na, as already described, those of $[Ln(HL_B)(Cl)_2]\cdot n$NaCl (Ln = Yb, Tm) prove that the NaCl present in these complexes is partially coordinated to the crown-ether moiety, thereby causing a high isotropic ^{23}Na shift.

We have already observed that the mononuclear complexes $[Ln(HL_D)(Cl)_2(MeOH)]$,[25] where the lanthanide(III) resides in the O_3O_2 crown-ether chamber, do not strongly coordinate Na^+ in the N_3O_2 Schiff-base site (or in a correct way). In fact, only a negligible ^{23}Na shift was detected in these complexes. Thus, the mononuclear complexes with L_B^{2-}, on prolonged reflux, may prefer to coordinate a second lanthanide instead of an Na^+ ion. Moreover, Na^+ is not able to transmetallate the Ln^{3+} from the crown-ether moiety. Nevertheless, the mononuclear complexes, once formed, when reacted with Na^+ in $[D_4]$MeOH, give rise to a significant ^{23}Na shift, which proves that a correct geometry is reached at least in solution with the Na^+ ion in the crown-ether moiety.

The coordination lability of Na^+, together with its relevant ^{23}Na shift, testifies that it could be an excellent molecular device for sodium detection in solution.

In the paramagnetic complexes $[LnNa(L_C)(Cl)]$ (where Ln = Yb, Tm, Tb, Dy), the ^{23}Na NMR resonance of the bound cation is markedly shifted from that of the free ion, and the shift itself is greater than that observed for L_B^{2-} and for L_D^{2-} complexes.

The formation of solution-stable LaNa complexes with H_3L_C testifies also that the $N–CH_2–C_6H_4O^-$ arm, which forms a six-membered ring with the lanthanide(III) ion, is quite suitable to suppress molecular movements of the metal ions, assuring a correct stereochemistry that favours the interaction between the Ln^{3+} ion and Na^+ that makes the paramagnetic complexes $[LnNa(L_C)(Cl)]$ the best ^{23}Na shift reagents prepared so far.

The ^{23}Na paramagnetic shift depends on the geometrical position of the sodium ion in relation to the magnetic symmetry axis of the complex and on the Ln–Na distance. Under the simplified hypothesis that the lanthanide complex is characterized by an effective axial symmetry (often a good approximation),[29] the magnitude of the shift is proportional to a term of the type $D_1(3\cos^2\theta - 1)/r^3$, where θ is the angle between the Ln–Na vector and the principal magnetic axis of the complex and r is the Ln–Na distance. In the heterodinuclear $[LnNa(L_C)(Cl)]$ complexes, the distance r is only 3.496(3) Å, shorter than that found in similar

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[LnNa(L_D)(Cl)_2(MeOH)]$ (Ln = Nd, Eu, Gd, Yb) complexes[25] (ca. 3.55 Å) and much shorter than that estimated for the corresponding polyaminopolycarboxylic (ca. 3.9 Å) and polyoxa tetraaza macrocyclic complexes (5.3 Å).[30] Furthermore, the negative sign of the hyperfine ^{23}Na shifts for the Tb and Dy complexes ($D_1 > 0$) and the positive sign of the Tm complex ($D_1 < 0$) suggests that the angle θ is close to 90° and thus that the principal magnetic susceptibility axis of the complex is orthogonal to the molecular plane. For the Yb complex ($D_1 > 0$) the sign of the ^{23}Na shift is positive (in contrast with the negative sign found in $[YbNa(L_D)(Cl)_2(MeOH)]$). In this case the principal magnetic susceptibility axis is parallel to the molecular plane (probably due to the fact that Yb has the smallest ionic radius) and this is supported by the ^1H NMR spectrum of the Yb complex (for which the dipolar contribution to the paramagnetic shift has the largest contribution), where the resonances have positive chemical shift values.

In conclusion, the introduction of suitable, coordinating pendant arms at the periphery of the coordination moiety of the [1+1] asymmetric compartmental macrocycles containing one N_3O_2 and one O_3O_2 adjacent coordination sites, increases the solubility and, for the complexes with H_2L_B and H_3L_C, the ^{23}Na shift. Unfortunately, the three pendant arms do not confer enough solubility to the LnNa complexes to allow NMR spectroscopy experiments in water. The quite stimulating, preliminary results obtained in CD_3OD/H_2O (1:1), however, force us to shift our efforts toward a deeper investigation of the complexes with H_3L_C in water-containing solvents.

Experimental Section

Materials: The solvents, the inorganic and organic compounds and the lanthanide chloride hydrates were commercial products, supplied by Aldrich, Riedel-de Haën, Carlo–Erba or Fluka. They were used as received, without further purification. Dimethyl sulfoxide, used in the preparation of the diformyl precursors, was purified according to the literature.[31]

Physico-Chemical Measurements: Elemental analyses were carried out using a Fison 1108 analyzer. IR spectra were recorded as KBr pellets on a Mattson FTIR spectrometer. All NMR spectra (^1H, ^{13}C, ^{23}Na) were recorded on a Bruker AMX300 spectrometer equipped with direct and inverse broad-band multinuclear probes and variable-temperature unit, with lanthanide(III) complexes dissolved in CD_3OD, used also as internal reference. The T1 longitudinal relaxation times and the mixing times of NOESY experiments of paramagnetic europium and cerium complexes were measured using the standard inversion recovery pulse sequence. All ESI-MS mass spectrometric measurements were performed using an LCQ mass spectrometry (Finnigam) and methanolic solutions of the samples (10^{-5} M). The morphology, homogeneity and the Ln/Cl or Ln/Na/Cl ratio of the complexes were investigated using a Philips XL40 model scanning electron microscope equipped with an EDAXDXPRIME energy dispersive spectrometer.

Diformyl and Amine Precursors: The diformyl precursor 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldheyde) (H_2L') and its disodium derivative Na_2L' were prepared according to the literature.[13,17] The diformyl precursor was purified by chromatography on silica gel using $CHCl_3$ as eluent. The amine precursors: 4-diethylenetriaminoacetic acid·3 HCl (i-DTMA·3 HCl), 1,7-bis-(aminoethyl)-2-(aminomethyl)pyridine·3 HCl (DETPY·3 HCl),*N*,*N*-bis(2-aminoethyl)-2-hydroxybenzylamine·3 HCl (Moden·3HCl) were prepared according to the literature.[32] Elemental analysis, ESI-MS, IR and NMR spectroscopic data agree with the proposed formulation.

Macrocyclic Ligands

Preparation of H_3L_A: *i*-DTMA·3 HCl (0.10×10^{-2} mol) and NaOH (0.30×10^{-2} mol) were added to a methanolic solution of the diformyl precursor H_2L' (0.10×10^{-2} mol) and the solution was refluxed for 3 h. The solvent was then evaporated to dryness and the resulting solid was dissolved in CH_2Cl_2. The solution was clarified by filtration and the solvents evaporated to dryness. The yellow solid obtained was collected by filtration, dried in vacuo and recrystallised from a methanol/diethyl ether solution. Owing to the difficult purification, the ligand was obtained in very low yield (<5%). IR $\tilde{\nu}$ = 1646 (C=N) cm^{-1}. $C_{25}H_{36}N_3O_{9.5}$: calcd. C 56.60, H 6.84, N 7.92; found C 56.82, H 6.97, N 8.34. ^1H NMR (CD_3OD): δ = 8.42 (s, 2 H, 4-H), 6.96 (d, 2 H,3-H), 6.91 (d, 2 H, 2-H), 6.56 (t, 2 H, 1-H), 4.21 (m, 4 H, 8-H), 4.00 (m, 4 H, 9-H), 3.85 (m, 4 H, 5-H), 3.56 (s, 2 H, 6-H), 3.35 (m, 4 H, 7-H) ppm.

Preparation of Na_3L_A: *i*-DTMA·3 HCl (0.10×10^{-2} mol) was dissolved in methanol (30 mL) at a pH adjusted to ≈ 7 by NaOH. Then it was added to a methanolic solution of Na_2L' (0.30×10^{-2} mol) and the resulting solution was refluxed for 2 h. The solvent was evaporated to dryness and the yellow solid obtained was dissolved in CH_2Cl_2. The solution, clarified by filtration, was evaporated to dryness. 2-Propanol was added to the residue and the mixture heated until a clear solution was obtained. The yellow product, crystallised by cooling the solution, was filtered and dried in vacuo. IR $\tilde{\nu}$ = 1623 (C=N) cm^{-1}. $C_{24.9}H_{31.2}N_3O_{8.7}Na_3 \cdot 1.4\,H_2O \cdot 0.3\,PrOH$: calcd. C 51.51, H 5.42, N 7.24; found C 51.44, H 5.07, N 6.47. ^1H NMR (CD_3OD): δ = 8.41 (s, 2 H, 4-H), 6.95 (d, 2 H, 3-H), 6.91 (d, 2 H, 2-H), 6.57 (t, 2 H, 1-H), 4.19 (m, 4 H, 8-H), 3.99 (m, 4 H, 9-H), 3.84 (m, 4 H, 5-H), 3.56 (s, 4 H, 6-H), 3.29 (m, 2 H, 7-H) ppm. ^{13}C NMR (CD_3OD): δ = 166.34 (C-4), 176.24 (C-13), 114.18 (C-2), 114.39 (1), 124.83 (3), 115.97 (C-10), 149.46 (C-11), 163.29 (C-12), 68.70 (C-8), 63.33 (C-9), 56.24 (C-5), 52.37 (C-6), 57.66 (C-7) ppm.

Preparation of Na_2HL_C: Methanolic solutions of NaOH (0.90×10^{-3} mol) and Na_2L' (0.30×10^{-3} mol) were added in succession to a methanolic solution of Moden·3 HCl (0.30×10^{-3} mol). The resulting yellow solution was refluxed for 3 h, then reduced in volume. The subsequent addition of 3 mL of ethanol formed a precipitate that was filtered off. The solution was evaporated to dryness and the residue treated with 1-propanol. The solution, clarified by filtration, was evaporated to dryness; the yellow solid obtained was filtered, washed twice with 1-propanol and dried in vacuo. IR $\tilde{\nu}$ = 1624 (C=N) cm^{-1}. $C_{37.5}H_{55}N_3O_{9.5}Na_{2.5}Cl_{0.5}$: calcd. C 58.12, H 7.15, N 5.42; found C 58.05, H 7.14, N 6.60. ^1H NMR (CD_3OD): δ = 8.26 (s, 2 H, 4-H), 7.19 (d, 1 H, 10-H), 7.01 (d, 2 H, 3-H), 6.90 (m, 1 H, 12-H), 6.86 (d, 2 H, 2-H), 6.66 (t, 1 H, 1-H), 6.65 (t, 1 H, 11-H), 6.34 (d, 1 H, 13-H), 4.24 (m, 4 H, 8-H), 4.03 (m, 4 H, 9-H), 3.90 (m, 4 H, 5-H), 3.81 (s, 2 H, 7-H), 2.97 (m, 4 H, 6-H) ppm.

Preparation of NaH_2L_C: Methanolic solutions of Moden·3 HCl (0.30×10^{-3} mol) neutralized with NaOH (0.90×10^{-3} mol) and H_2L' (0.30×10^{-3} mol) were added dropwise to a flask containing Et_2O. The suspension was stirred for 2 h at room temp. The white precipitate was filtered, dried in vacuo and then dissolved in $CHCl_3$. The resulting solution was clarified by filtration and re-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

duced in volume, then petroleum ether was added and the yellow solid obtained was filtered and dried in vacuo. IR $\tilde{\nu}$ = 1639 (C=N) cm^{-1}. $C_{29}H_{32}N_3O_6Na_{12.5}Cl_{11.5}$: calcd. C 28.70, H 2.66, N 3.46; found 28.91, H 2.63, N 3.04. MS: *m*/*z* (%) = 542 (55) $[Na(H_3L_C)]^+$. ^1H NMR (CD_3OD): δ = 8.27 (s, 2 H, 4-H), 7.15 (d, 1 H, 10-H), 7.03 (d, 2 H, 3-H), 6.93 (m, 1 H, 12-H), 6.87 (d, 2 H, 2-H), 6.72 (t, 1 H, 1-H), 6.68 (t, 1 H, 11-H), 6.30 (d, 1 H, 13-H), 4.24 (m, 4 H, 8-H), 3.99 (m, 4 H, 9-H), 3.88 (m, 4 H, 5-H), 3.81 (s, 2 H, 7-H), 2.98 (m, 4 H, 6-H) ppm. ^{13}C NMR (CD_3OD): δ = 166.85 (C-4), 128.62 (C-10), 128.10 (C-12), 124.16 (C-2), 119.42 (C-11), 115.85 (C-1), 115.29 (C-13), 113.83 (C-3), 68.31 (C-9), 66.58 (C-8), 55.94 (C-6), 55.15 (C-7), 52.11 (C-5) ppm.

Complexes

Preparation of $[LnNa(Na_xL_A)(Cl)_{1+x}]\cdot nH_2O$ (x = 0, 1): $LnCl_3\cdot 6H_2O$ (0.20×10^{-3} mol) (where Ln = Y, Lu, Yb, Tm, Tb, Eu) in methanol (20 mL) was added to a methanolic solution (20 mL) of Na_3L_A (0.20×10^{-3} mol). The solution obtained was refluxed for 2 h, then evaporated to dryness and the resulting residue was treated twice with 1-propanol. The yellow precipitate was filtered, washed with diethyl ether and dried in vacuo. The reported stoichiometry and the Na/Ln/Cl ratio were ascertained by SEM-EDS together with elemental analysis.

$[YNa(NaLA)(Cl)_2]\cdot 3NaCl\cdot 2H_2O$: IR $\tilde{\nu}$ = 1636 (C=N) cm^{-1}. $C_{24}H_{30}N_3O_9Na_5Cl_5Y$: calcd. C 32.55, H 3.41, N 4.74; found C 32.00, H 3.34, N 4.63. ^1H NMR (CD_3OD): δ = 8.34 (s, 2 H, 4), 7.13 (d, 2 H, 2), 7.00 (d, 2 H, 3), 6.67 (t, 2 H, 1), 4.27 (m, 4 H, 8), 4.04 (m, 4 H, 9), 3.96 (m, 4 H, 5), 3.79 (s, 2 H, 7), 2.75 (m, 4 H, 6) ppm.

$[LuNa(NaL_A)(Cl)_2]\cdot 4.5NaCl\cdot PrOH$: IR $\tilde{\nu}$ = 1625 (C=N) cm^{-1}. $C_{27}H_{34}N_3O_8Na_{6.5}Cl_{6.5}Lu$: calcd. C 29.93, H 3.16, N 3.88; found C 29.41, H 2.76, N 3.60.

$[YbNa(NaL_A)(Cl)_2]\cdot 1.3NaCl\cdot 3.2H_2O$: IR $\tilde{\nu}$ = 1637 (C=N) cm^{-1}. $C_{24}H_{32.4}N_3O_{10.2}Na_{3.3}Cl_{3.3}Yb$: calcd. C 34.34, H 3.89, N 5.01; found: C 34.60, H 3.68, N 4.95.

$[TmNa(L_A)(Cl)]\cdot 5.5NaCl\cdot 2.5H_2O$: IR $\tilde{\nu}$ = 1625 (C=N) cm^{-1}. $C_{24}H_{31}N_3O_{9.5}Na_{6.5}Cl_{6.5}Tm$: calcd. C 27.14, H 2.94, N 3.96; found C 27.10, H 2.95, N 3.05.

$[TbNa(L_A)(Cl)]\cdot 0.6NaCl\cdot 0.3H_2O$: IR $\tilde{\nu}$ = 1625 (C=N) cm^{-1}. $C_{24}H_{26.6}N_3O_{7.3}Na_{1.6}Cl_{1.6}Tb$: calcd. C 39.69, H 3.69, N 5.79; found: C 39.54, H 3.68, N 4.21.

$[EuNa(L_A)(Cl)]$: IR $\tilde{\nu}$ = 1619 (C=N) cm^{-1}. $C_{24}H_{26}N_3O_7NaClEu$: calcd. C 42.46, H 3.86, N 6.19; found: C 43.10, H 3.66, N 4.50. ^1H NMR (CD_3OD): δ = 28.99 (s, 2 H, 7-H), 3.46 (t, 2 H, 1-H), 2.33 (t, 2 H, 8-H), 1.23 (d, 2 H, 9-H), 1.09 (d, 2 H, 9-H), 0.97 (d, 2 H, 3-H), 0.25 (t, 2 H, 2-H), –0.36 (t, 2 H, 8-H), –6.96 (s, 2 H, 6-H), –8.68 (s, 2 H, 5-H), –19.93 (s, 2 H, 6-H), –20.12 (s, 2 H, 5-H), –28.28 (s, 2 H, 4-H) ppm.

Preparation of $[Ln_2(L_A)(Cl)_3]\cdot nH_2O\cdot m$PrOH: The same synthetic procedure used for $[LnNa(NaL_A)(Cl)]\cdot nH_2O$, but a 12 h reflux (when Ln = Y, Lu, Yb, Nd) leads to the homodinuclear complexes $[Y_2(L_A)(Cl)_3]\cdot 1NaCl\cdot 7.7H_2O$; $[Lu_2(L_A)(Cl)_3]\cdot 4.8NaCl\cdot 0.3$PrOH; $[Yb_2(L_A)(Cl)_3]\cdot 4NaCl\cdot 1.3H_2O$; $[Nd_2(L_A)(Cl)_3]\cdot 1.2NaCl\cdot 1.2$PrOH.

$[Y_2(L_A)(Cl)_3]\cdot NaCl\cdot 7.7H_2O$: IR $\tilde{\nu}$ = 1655 cm^{-1} (C=N) cm^{-1}. $C_{24}H_{41.4}N_3O_{14.7}NaCl_4Y_2$: calcd. calcd.C 30.35, H 4.39, N 4.42; found C 30.26, H 4.39, N 5.08.

$[Lu_2(L_A)(Cl)_3]\cdot 4.8NaCl\cdot 0.3$PrOH: IR $\tilde{\nu}$ = 1639 (C=N) cm^{-1}. $C_{24.9}H_{28.4}N_3O_{7.3}Na_{4.8}Cl_{7.8}Lu_2$: calcd. C 24.45, H 2.34, N 3.43; found C 24.37, H 2.27, N 2.92.

$[Yb_2(L_A)(Cl)_3]\cdot 4NaCl\cdot 1.3H_2O$: IR $\tilde{\nu}$ = 1624 cm^{-1} (C=N) cm^{-1}. $C_{24}H_{28.6}N_3O_{8.3}Na_4Cl_7Yb_2$: calcd. C 24.47, H 2.45, N 3.57; found C 24.58, H 2.45, N 2.98.

$[Nd_2(L_A)(Cl)_3]\cdot 1.2NaCl\cdot 1.2$PrOH: IR $\tilde{\nu}$ = 1654 (C=N) cm^{-1}. $C_{27.6}H_{35.6}N_3O_{8.2}Na_{1.2}Cl_{4.2}Nd_2$: calcd. C 32.97, H 3.57, N 4.18; found C 32.88, H 3.59, N 4.05.

Preparation of $[Ln(HL_B)(Cl)_2]\cdot xNaCl\cdot yH_2O$: NaOH in methanol (20 mL) was added to a methanolic solution (20 mL) of DETPY·3 HCl (0.10×10^{-2} mol) until pH = 7–8. The appropriate lanthanide chloride hydrate $LnCl_3\cdot nH_2O$ (0.10×10^{-2} mol) (where Ln = Y, Yb, Lu, Tm, Tb with n = 6 and Ln = La, Ce with n = 7), and the diformyl derivative H_2L' (0.10×10^{-2} mol) were added in succession and the resulting solution refluxed for 2 h. The solution was clarified by filtration, then evaporated to dryness. The solid obtained was washed twice with ethanol. The yellow precipitate was filtered, washed with diethyl ether and dried in vacuo. The reported stoichiometry and the Ln/Cl ratio were ascertained by SEM-EDS together with elemental analysis.

$[Y(HL_B)(Cl)_2]\cdot 2.9NaCl\cdot 0.6H_2O$: IR $\tilde{\nu}$ = 1647 (C=N) cm^{-1}. $C_{27}H_{32.2}N_4O_{5.6}Na_{2.9}Cl_{4.9}Y$: calcd. C 39.00, H 3.90, N 6.74; found C 39.86, H 3.80, N 4.76. ^1H NMR (CD_3OD): δ = 8.66 (s, 2 H, 4-H), 8.45 (d, 1 H, 13-H), 7.93 (t, 1 H, 11-H), 7.58 (d, 1 H, 10-H), 7.37 (m, 1 H, 12-H), 7.33 (d, 2 H, 3-H) 7.15 (2-H), 6.78 (t, 2 H, 1-H), 4.55 (m, 8 H, 8-H + 9-H), 4.08 (s, 2 H, 7-H), 4.00 (m, 4 H, 5-H), 3.04 (m, 4 H, 6-H) ppm. ^{13}C NMR (CD_3OD): δ = 171.97 (4), 151.79 (16), 135.31 (14), 128.80 (13), 127.45 (15), 130.29 (3), 120.08 (2), 118.41 (1), 73.78 (8), 68.75 (9), 57.03 (6), 52.29 (5), 61.86 (7) ppm. Similar results were obtained for the diamagnetic complexes $[La(HL_B)(Cl)_2]\cdot 10NaCl\cdot 2.5H_2O$, and for the paramagnetic $[Ce(HL_B)(Cl)_2]\cdot 6.4NaCl\cdot 7H_2O$, $[Yb(HL_B)(Cl)_2]\cdot 7NaCl\cdot 0.1H_2O\cdot 1.6$EtOH, $[Tb(HL_B)(Cl)_2]\cdot 7.7NaCl\cdot 5.3H_2O$, $[Tm(HL_B)(Cl)_2]\cdot 7.6NaCl\cdot$EtOH. IR $\tilde{\nu}$ = 1617 (C=N, Tm complex)–1652 (C=N, Tb complex) cm^{-1}.

$[La(HL_B)(Cl)_2]\cdot 10NaCl\cdot 2.5H_2O$: IR $\tilde{\nu}$ = 1625 (C=N) cm^{-1}. $C_{27}H_{36}N_4O_{7.5}Na_{10}Cl_{12}La$: calcd. C 24.37, H 2.73, N 4.21; found C 25.02, H 2.72, N 3.84.

$[Ce(HL_B)(Cl)_2]\cdot 6.4NaCl\cdot 7H_2O$: IR $\tilde{\nu}$ = 1638 (C=N) cm^{-1}. $C_{27}H_{45}N_4O_{12}Na_{6.4}Cl_{8.4}Ce$: calcd. C 29.96, H 3.77, N 4.66; found C 27.71, H 3.73, N 6.39. ^1H NMR (CD_3OD): δ = 21.30 (s, 2 H, 4-H), 11.50 (d, 1 H, 13-H), 11.36 (d, 2 H, 2-H), 9.27 (t, 1 H, 11-H), 9.10 (d, 1 H, 10-H), 9.04 (d, 2 H, 3-H), 8.62 (m, 3 H, 12-H + 1-H), 4.77 (m, 4 H, 9-H), 5.01 (s, 2 H, 7-H), 3.66 (m, 4 H, 8-H), 8.01 (broad, 4 H, aliph.), –11.46 (broad, 4 H, aliph.) ppm.

$[Yb(HL_B)(Cl)_2]\cdot 7NaCl\cdot 0.1H_2O\cdot 1.6$EtOH: IR $\tilde{\nu}$ = 1624 (C=N) cm^{-1}. $C_{31.8}H_{40.8}N_4O_{6.7}Na_7Cl_9Yb$: calcd. C 29.79, H 3.37, N 4.59; found C 29.73, H 3.37, N 3.63.

$[Tb(HL_B)(Cl)_2]\cdot 7.7NaCl\cdot 5.3H_2O$: IR $\tilde{\nu}$ = 1652 (C=N) cm^{-1}. $C_{27}H_{41.6}N_4O_{10.3}Na_{7.7}Cl_{9.7}Tb$: calcd. C 25.60, H 3.31, N 4.42; found C 25.63, H 3.32, N 4.72.

$[Tm(HL_B)(Cl)_2]\cdot 7.6NaCl\cdot$EtOH: IR $\tilde{\nu}$ = 1617 (C=N) cm^{-1}. $C_{29}H_{37.4}N_4O_{6.2}Na_{10.5}Cl_{10.5}Tm$: calcd. C 28.51, H 3.05, N 4.59; found C 28.58, H 2.95, N 3.23.

Preparation of $[Ln_2(L_B)(Cl)_4]\cdot xNaCl\cdot yH_2O$: The same procedure was used as for $[Ln(HL_B)(Cl)_2]$, but a 12 h reflux of the appropriate solution (when Ln = Y, Lu, Dy with n = 6 and Ln = La with n = 7) leads to the homodinuclear complexes $[La_2(L_B)(Cl)_4]\cdot 8NaCl\cdot 3.9H_2O$, $[Y_2(L_B)(Cl)_4]\cdot 0.6NaCl\cdot 7.5H_2O\cdot 3$MeOH, $[Lu_2(L_B)(Cl)_4]\cdot 2.7NaCl\cdot 6.6H_2O$, $[Dy_2(L_B)(Cl)_4]\cdot 4.5\ NaCl\cdot 9H_2O\cdot$MeOH.

$[La_2(L_B)(Cl)_4]\cdot 8NaCl\cdot 3.9H_2O$: IR $\tilde{\nu}$ = 1647 (C=N) cm^{-1}. $C_{27}H_{37.8}N_4O_{8.9}Na_8Cl_{12}La_2$: calcd. C 22.40, H 2.63, N 3.87; found

C 22.71, H 2.63, N 3.78. ^{1}H NMR (CD_3OD): δ = 8.53 (s, 2 H, 4-H), 8.46 (d, 1 H, 13-H), 7.91 (d, 1 H, 11-H), 7.61 (d, 1 H, 10-H), 7.39 (t, 1 H, 12-H), 7.27 (d, 2 H, 3-H), 7.09 (d, 2 H, 2-H), 6.71 (t, 2 H, 1-H), 4.51 (m, 8 H, 8-H + 9-H), 4.09 (s, 2 H, 7-H), 4.02 (m, 4 H, 5-H), 3.09 (m, 4 H, 6-H) ppm.

$[Y_2(L_B)(Cl)_4]\cdot 0.6\,NaCl\cdot 7.5\,H_2O\cdot 3\,MeOH$: IR ṽ = 1654 (C=N) cm^{-1}. $C_{30}H_{57}N_4O_{15.5}Na_{0.6}Cl_{4.6}Y_2$: calcd. C 33.48, H 5.34, N 5.20; found C 33.65, H 5.34, N 5.12.

$[Lu_2(L_B)(Cl)_4]\cdot 2.7\,NaCl\cdot 6.6\,H_2O$: IR ṽ = 1658 (C=N) cm^{-1}. $C_{27}H_{43.2}N_4O_{11.6}Na_{2.7}Cl_{6.7}Lu_2$: calcd. C 25.76, H 3.46, N 4.45; found C 25.65, H 3.45, N 4.65.

$[Dy_2(L_B)(Cl)_4]\cdot 4.5\,NaCl\cdot 9\,H_2O\cdot MeOH$: IR ṽ = 1655 (C=N) cm^{-1}. $C_{28}H_{52}N_4O_{15}Na_{4.5}Cl_{8.5}Dy_2$: calcd. C 23.78, H 3.71, N 3.96; found C 23.69, H 3.67, N 4.34.

Preparation of $[LnNa(L_C)(Cl)]\cdot x\,NaCl\cdot y\,H_2O$: $LnCl_3\cdot nH_2O$ (5×10^{-2} mol) (where Ln = Y, Yb, Lu, Tm, Tb, Dy, Eu, Er with n = 6 and Ln = La, Ce with n = 7) dissolved in methanol was added to a methanolic solution of Na_2HL_C (5×10^{-2} mol). The solution was refluxed for 3 h, then evaporated to dryness. The crude product was treated with 1-propanol and the yellow solid obtained was filtered, washed with 2-propanol and dried in vacuo. The reported stoichiometry and the Na/Ln/Cl ratio were ascertained by SEM-EDS together with elemental analysis.

$[LuNa(L_C)(Cl)]\cdot 4.2\,NaCl\cdot 1.7\,H_2O$: IR ṽ = 1626 (C=N) cm^{-1}. $C_{29}H_{33.4}N_3O_{7.7}Na_{5.2}Cl_{5.2}Lu$: calcd. C 33.95, H 3.28, N 4.10; found C 33.91, H 3.28, N 3.68. ^{1}H NMR (CD_3OD): δ = 8.35 (s, 2 H, 4-H), 7.13 (d, 2 H, 3-H), 7.02 (d, 1 H, 10-H), 6.96 (d, 2 H, 2-H), 6.93 (m, 1 H, 12-H), 6.62 (t, 2 H, 1-H), 6.51 (t, 1 H, 11-H), 6.34 (d, 1 H, 13-H), 4.30 (m, 4 H, 8-H), 4.13 (m, 2 H, 5-H), 4.08 (m, 4 H, 9-H), 3.85 (m, 2 H, 5-H), 3.76 (s, 2 H, 7-H), 3.23 (m, 2 H, 6-H), 2.84 (m, 2 H, 6-H) ppm. ^{13}C NMR (CD_3OD): δ = 171.71 (4), 132.05 (10), 130.89 (12), 128.80 (2), 119.37 (13), 117.34 (11), 116.45 (3), 115.52 (1), 70.21 (9), 67.07 (8), 57.97 (7), 57.05 (5), 55.04 (6) ppm. ESI-MS: m/z (%) = 715 (100) $[LuNa(L_C)]^+$.

$[YNa(L_C)(Cl)]\cdot 2.2\,NaCl\cdot 0.7\,MeOH$: IR ṽ = 1625 (C=N) cm^{-1}. $C_{29.7}H_{32.8}N_3O_{6.7}Na_{3.2}Cl_{3.2}Y$: calcd. C 43.78, H 4.06, N 5.16; found C 43.81, H 4.04, N 4.72. Similar results were obtained for the paramagnetic complexes $[YbNa(L_C)(Cl)]\cdot 4.1\,NaCl$, $[TbNa(L_C)(Cl)]\cdot 1.5\,NaCl$, $[TmNa(L_C)]Cl\cdot 4.3\,NaCl$, $[DyNa(L_C)(Cl)]\cdot 2.3\,NaCl$, $[EuNa(L_C)(Cl)]\cdot 6.5\,NaCl$. IR $\upsilon_{C=N}$ varies within the range 1620–1629 cm^{-1}.

$[EuNa(L_C)(Cl)]\cdot 6.5\,NaCl$: IR ṽ = 1623 (C=N) cm^{-1}. $C_{29}H_{30}N_3O_6Na_{7.5}Cl_{7.5}Eu$: calcd. C 31.47, H 2.73, N 3.80; found C 31.60, H 2.73, N 3.56. ^{1}H NMR (CD_3OD), paramagnetic: δ = 19.46 (s, 2 H, 6-H), 11.37 (d, 1 H, 13-H), 5.67 (m, 2+ 1 H, 9-H + 11-H), 5.31 (t, 1 H, 12-H), 4.42 (m, 2 H, 8-H), 4.22 (m, 2 H, 5-H), 4.21 (t, 2 H, 1-H), 4.19 (t, 1 H, 10-H), 3.95 (m, 2 H, 9-H), 2.63 (t, 2 H, 8-H), 1.98 (d, 2 H, 3-H), 0.52 (d, 2 H, 2-H), –1.00 (s, 2 H, 6-H), –9.57 (s, 2 H, 5-H), –12.87 (s, 2 H, 7-H), –29.90 (s, 2 H, 4-H) ppm. ^{13}C NMR (CD_3OD): δ = 152.38 (4), 134.24 (10), 131.98 (2), 124.39 (12), 119.55 (6), 113.57 (11), 110.98 (3), 106.16 (1), 92.04 (5), 77.10 (13), 76.90 (7), 70.99 (9), 66.90 (8) ppm.

$[YbNa(L_C)(Cl)]\cdot 4.1\,NaCl$: IR ṽ = 1626 (C=N) cm^{-1}. $C_{29}H_{30}N_3O_6Na_{5.1}Cl_{5.1}Yb$: calcd. C 35.27, H 3.06, N 4.25; found C 35.29, H 2.76, N 3.86. ESI-MS: m/z (%) = 713 (100) $[YbNa(L_C)]^+$.

$[TbNa(L_C)(Cl)]\cdot 1.5\,NaCl$: IR ṽ = 1623 (C=N) cm^{-1}. $C_{29}H_{30}N_3O_6Na_{2.5}Cl_{2.5}Tb$: calcd. C 42.40, H 3.68, N 5.11; found C 42.72, H 3.64, N 4.74. ESI-MS: m/z (%) = 699 (100) $[TbNa(L_C)]^+$.

$[TmNa(L_C)(Cl)]\cdot 4.3\,NaCl$: IR ṽ = 1625 (C=N) cm^{-1}. $C_{29}H_{30}N_3O_6Na_{5.3}Cl_{5.3}Tm$: calcd. C 35.00, H 3.04, N 4.22; found C 35.03, H 2.53, N 3.69. ESI-MS: m/z (%) = 708 (100) $[TmNa(L_C)]^+$.

$[DyNa(L_C)(Cl)]\cdot 2.3\,NaCl$: IR ṽ = 1623 (C=N) cm^{-1}. $C_{29}H_{30}N_3O_6Na_{3.3}Cl_{3.3}Dy$: calcd. C 39.95, H 3.47, N 4.82, found C 40.07, H 3.22, N 4.23. ESI-MS: m/z (%) = 704 (100) $[DyNa(L_C)]^+$.

Preparation of $[Ln(H_3L_C)(Cl)_3]\cdot x\,LiCl\cdot y\,EtOH$: LiOH ($0.9\times10^{-3}$ mol) dissolved in ethanol was added to an ethanolic suspension of Moden·3 HCl (0.3×10^{-3} mol) up to pH ≈ 8. $LnCl_3\cdot n\,H_2O$ (0.3×10^{-3} mol) (where Ln = Lu, Eu, Tb, Y with n = 6, Ln = La with n = 7) was added to an ethanolic solution of H_2L' (0.3×10^{-3} mol) and the two solutions were mixed and refluxed for 5 h. The yellow solution, reduced in volume under reduced pressure, separated a yellow precipitate which was filtered, washed with ethanol and dried in vacuo. The reported stoichiometry and the Ln/Cl ratio were ascertained by SEM-EDS together with elemental analysis.

$[Eu(H_3L_C)(Cl)_3]\cdot 0.6\,LiCl$: IR ṽ = 1647 (C=N) cm^{-1}. $C_{29}H_{33}N_3O_6Li_{0.6}Cl_{3.6}Eu$: calcd. C 43.36, H 4.14, N 5.23; found C 43.40, H 4.03, N 4.91. ^{1}H NMR (CD_3OD), paramagnetic: δ = 11.83 (s, broad, 8 H, aliph.), 7.42 (d, 1 H, 13-H), 7.06 (t, 1 H, 12-H), 6.67 (m, 2 H, 10-H + 11-H), 6.53 (m, 2 H, 7-H), 5.96 (d, 2 H, 2-H), 5.93 (s, 2 H, 4-H), 5.33 (s, broad, 8 H, aliph.), 4.00 (t, 2 H, 1-H), 2.22 (d, 2 H, 3-H) ppm.

$[Lu(H_3L_C)(Cl)_3]\cdot 1\,LiCl\cdot 1.4\,H_2O$: IR ṽ = 1651 (C=N) cm^{-1}. $C_{29}H_{35.8}N_3O_{7.4}LiCl_4Lu$: C 40.11, H 4.15, N 4.84; found C 40.36, H 4.15, N 4.39. ^{1}H NMR (CD_3OD): δ = 8.63 (s, 2 H, 4-H), 7.39 (d, 2 H, 3-H), 7.17 (d, 2 H, 2-H), 7.16 (d, 1 H, 10-H), 6.89 (t, 1 H, 12-H), 6.81 (t, 2 H, 1-H), 6.75 (d, 1 H, 13-H), 6.66 (t, 1 H, 11-H), 4.67 (m, 4 H, 8-H), 4.56 (m, 4 H, 9-H), 4.13 (m, 4 H, 5-H), 3.85 (s, 2 H, 7-H), 3.04 (m, 4 H, 6-H) ppm.

$[La(H_3L_C)(Cl)_3]\cdot 1.8\,LiCl\cdot 2.9\,H_2O$: IR ṽ = 1645 (C=N) cm^{-1}. $C_{29}H_{38.8}N_3O_{8.9}Li_{1.8}Cl_{4.8}La$: calcd. C 41.20, H 4.63, N 4.97; found C 41.15, H 4.61, N 5.24.

$[Tb(H_3L_C)(Cl)_3]\cdot 0.2\,LiCl\cdot EtOH$: IR ṽ = 1653 (C=N) cm^{-1}. $C_{31}H_{39}N_3O_7Li_{0.2}Cl_{3.2}Tb$: calcd. C 44.36, H 4.68, N 5.01; found C 44.48, H 4.67, N 5.00.

$[Er(H_3L_C)(Cl)_3]\cdot 2\,LiCl\cdot H_2O\cdot EtOH$: IR 1652 (C=N) cm^{-1}. $C_{31}H_{41}N_3O_8Li_2Cl_5Er$: calcd. C 39.52, H 4.39, N 4.46; found C 40.00, H 4.39, N 4.42.

X-ray Crystallographic Study: Diffraction data were collected at room temperature on a Philips PW1100 automatic four-circle diffractometer (FEBO System) using the graphite-monochromated Mo-Kα radiation and ω-2θ scan method. Lattice parameters were obtained from least-squares refinement of the setting angles of 30 reflections with $10 \le 2\theta \le 24°$. Table 1 lists a summary of the crystallographic data and structure refinement. No sign of crystal deterioration was revealed by monitoring three standard reflections after every 200 measurements but the quality of the crystals was very poor, even after several attempts with different crystals. The structure was solved by standard Patterson methods and subsequently completed by a combination of least-squares techniques and Fourier syntheses with SHELX program.[33,34] All the benzene rings were refined as rigid bodies, the hydrogen atoms were included in the idealized positions with fixed C–H distances (C–H = 0.93 Å) and isotropic temperature factors fixed to $1.2\times U$(eq) of the preceding carbon atom.

The poor quality of the crystals did not give very good data. In particular, serious disorder in the C3–C5, O5 atoms and the coordinated propanol molecule was found and high values of thermal parameters were maintained to absorb the disorder.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Listing of selected bond lengths and angles pertinent to the coordination sphere are summarized in Table 2. Additional crystallographic data, atomic coordinates, anisotropic thermal parameters, and full listings of bond lengths and angles are provided as supplementary material to CCDC. Final geometrical calculations and drawings were carried out with the PARST program[35] and the XP utility of the Siemens package[36] respectively, running on a DIGITAL ALPHA-AXP 300 computer.

CCDC-251962 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 1. Crystal and intensity data for the DyNa complex.

Empirical formula	$C_{32}H_{30}ClDyN_3NaO_7$
Formula mass	789.53
Crystal system	monoclinic
Space group	$P2_1/c$ (no. 14)
a [Å]	9.601(2)
b [Å]	12.927(2)
c [Å]	26.638(4)
β [°]	99.55(3)
V [Å^3]	3260(1)
Z	4
Calcd. density [g cm^{-3}]	1.609
μ [mm^{-1}] (Mo-$K\alpha$)	2.437
Range of rel. transm. factors[a] [%]	88–100
θ limits [°]	6.3–52
Data collected/unique	6749/6606
Data observed	6443 [$F \geq 3\sigma(F)$]
No. of parameters (obsd. per parameter)	351 (9.8)
$R(\Sigma(\|F_o\| - \|F_c\|) / \Sigma\|F_o\|)$	0.059
$R_w[\Sigma w(\|\|F_o\| - \|F_c\|)^2 / \Sigma w(F_o)^2]^{1/2}$	0.130
Highest map residual [e Å^{-3}]	1.12

[a] Corrections: Lorentz-polarization and absorption (empirical, ψ scan).

Hemilabile Thioether Ligands Based on Pyrimidine and/or Pyridine Derivatives that Interconvert between *N*,*S*- and *N*-Coordination in Congested Ruthenium(II) Complexes

Giuseppe Tresoldi,*[a] Laura Baradello,[a] Santo Lanza,[a] and Paola Cardiano[a]

Keywords: Ruthenium / Pyridine thioether / Pyrimidine thioether / *N*,*S*-Coordination / *N*-Coordination

The thioether ligands **L** [**L** = 2-pyridylmethyl 2′-pyridyl sulfide (**L_1**), 2-pyridylmethyl 2′-pyrimidyl sulfide (**L_2**) and 2-pyridylmethyl 2′-(4-methylpyrimidyl) sulfide (**L_3**)] react with *cis*-[Ru(*N*,*N*-diimine)$_2$Cl$_2$] {diimine = 2,2′-bipyridine (bipy), di-2-pyrimidyl sulfide (dprs), 2,2′-bis(5-ethylpyrimidyl) sulfide (5edprs)} to give compounds [Ru(*N*,*N*-diimine)$_2$L][PF$_6$]$_2$ {diimine = bipy, **L** =**L_1** (**1**), **L_2** (**2**), **L_3** (**3**); diimine = dprs, **L** = **L_1** (**4**); diimine = 5edprs, **L** = **L_1** (**5**); diimine = dprs, **L** = **L_2** (**6**), **L** = **L_3** (**7**); diimine = 5edprs, **L** = **L_2** (**8**), **L** = **L_3** (**9**)}. NMR investigations show that these potentially tridentate ligands act as *N*,*S*-bidentate species, to form a five-membered RuSCCN(*Ru–N*) ring, and in certain cases, as *N*-monodentate species coordinated to the ruthenium through the 2-pyridylmethyl group. The *N*,*S*-chelated species contain chiral sulfur and ruthenium atoms with (*R*) and (*S*), and Δ and Λ configurations, respectively. Two invertomers and two sets of NMR signals in the slow-exchange region are expected. However, the low-temperature ^{1}H NMR spectra show that sulfur inversion is fast. The variable-temperature ^{1}H NMR spectra allow two species to be observed (**6a** + **6b**, **7a** + **7b**, **8a** + **8b** and **9a** + **9b**), which exhibit different abundances. In the minor species (**6b**, **7b**, **8b**, and **9b**), **L_2** or **L_3** exhibits an *N*-monodentate coordination, while in the major species, the usual *N*,*S*-coordination. At low temperatures, the population ratio is about 85:15, while when the temperature increases, the abundance of the minor species grows rapidly. The one-dimensional band-shape analysis of the exchanging methylene proton signals shows that the energy-barrier for the interchange process ($\Delta G^{\#}_{298}$) for **6a** + **6b**, **7a** + **7b**, **8a** + **8b**, and **9a** + **9b** is practically the same (ca. 59.5 kJ·mol^{-1}), while the $\Delta S^{\#}$ values are negative or near to zero. The possible mechanisms for the process are discussed. The NMR spectroscopic findings strongly support the formation of an *N*,*N*-chelated labile intermediate.

Introduction

The coordination chemistry of chelated ligands containing mixed functionalities in transition-metal complexes is an active area of research. In particular, the chemistry of hemilabile ligands, which contain both inert and labile groups, has received considerable attention.[1] Since one group bonds strongly to a metal center, the substitutionally labile group, which can be displaced from the metal center, remain available for recoordination. Thus the hemilability of a chelate can be observed as a dynamic process that involves the dissociation and recoordination of weakly bound moieties. When the hemilabile ligand contains two or more weakly bonding groups, it may undergo intramolecular ligand-exchange reactions. These processes often have been referred to as "wind-screen wiper" or "tick-tock" mechanisms,[2–9] and "opening and closing" or "rotation" mechanisms.[8–10] Furthermore, hemilability through ligand-interchange reactions involving equilibria between weakly bonding groups of the ligand and coordinating counterions, small molecules, or solvent molecules has been observed.[10,11]

There are many reasons for studying hemilabile ligands. Since these ligands can furnish open coordination sites and stabilize reactive transition-metal centers throughout the course of the reaction, their complexes can be utilized in catalytic reactions. Complexes containing hemilabile ligands have been shown to be active, for example, toward hydrogenation,[12] methanol carbonylation,[13] hydroformylation,[14] dimerization of ethene,[15] isomerization of alkene,[16] allylation,[17] and epoxidation of alkenes.[18] Furthermore, the labile fragments of these ligands are often displaced easily and reversibly from the metal center by small molecules, and the corresponding complexes are useful for small molecule activation[19] and sensing.[20]

N-heterocyclic donors are often good ligands for many transition-metal centers, and ligands containing inert *N*-heterocyclic moieties, in particular, pyridine or bipyridine groups are the most common type of nitrogen-based hemilabile ligands.[21] Hybrid S/N/S ligands consisting of substitutionally inert pyridine moieties and labile sulfur moieties are known.[22–25] In these complexes, the S–S switching, in

addition to sulfur inversion, was often observed.[23–25] Although the thioether-containing aromatic nitrogen heterocycles such as di-2-pyridyl sulfide (dps) usually adopts the *N*,*N*-bidentate coordination,[26–32] it can exhibit a variety of bonding modes to a metal, for example, monodentate[29–31] and bridging modes.[30–34] However, the hemilability of dps has been addressed in a few cases, and only the pyridine moieties have been utilized as inert and labile, bound groups.[29–31] Recently we demonstrated that dps, under the proper conditions, binds the ruthenium metal in an *N*,*S*-chelate fashion, leaving one of the rings uncoordinated.[35] In such species some dynamic processes occur, as shown by the temperature dependence of the NMR spectra, but only the restricted uncoordinated ring rotation could be studied and the total dynamic stereochemistry remained unclear.[35] We have been able to obtain activation-energy data for the pyramidal inversion at the coordinated sulfur atom[36] as well as for the restricted rotation of the pendant ring[37] when the ruthenium(II) center is *N*,*S*-chelated by thioether ligands based on pyridine or pyrimidine, and benzyl or phenyl derivatives.

We have now turned our attention to metal complexes that contain unsymmetrical NSN or NSNN thioethers; we are interested in studying the hemilability of these ligands and consequently the interchange process between chemically distinct coordination species. Since the potentially polydentate ligands **L** [**L** = 2-methylpyridyl pyridyl sulfide (**L_1**), 2-methylpyridyl pyrimidyl sulfide (**L_2**) and 2-methylpyridyl 2-(4-methylpyrimidyl) sulfide (**L_3**)] may bind to the ruthenium center through nitrogen atoms[27,28,32,35–37] or nitrogen and sulfur atoms,[35–37] an NMR spectroscopic study has been carried out to identify the different coordination species obtained when **L** reacts with $Ru(bipy)_2Cl_2$, $Ru(dprs)_2Cl_2$, and $Ru(5edprs)_2Cl_2$ and to examine any dynamic process which might lead to their interconversion.

Results

Synthesis of the Compounds

The air-stable compounds **1–9** were obtained by the reactions of *cis*-[$RuCl_2$(*N*,*N*-diimine)$_2$] and **L** as depicted in Scheme 1.

The complexes are yellow or orange solids that are soluble in acetone or acetonitrile. They were characterized by elemental analysis, conductivity measurements in acetonitrile solutions with values characteristic of 1:2 electrolytes (315–350 $S cm^2 mol^{-1}$), IR spectroscopy, which shows the

bands of PF_6^- (ca. 844 and 558 cm^{-1}) and those characteristic of thioether ligands in the range (1630–1540 and 780–720 cm^{-1}). These data indicate that the ligands bipy, dprs, and 5edprs act as *N*,*N*-chelate ligands.[26–32] These findings were confirmed by subsequent ^1H and ^{13}C NMR spectroscopic studies.

Coordination of L_1 in $[Ru(bipy)_2(N,S/L_1)][PF_6]_2$ (1), $[Ru(bipy)_2(N,S/L_2)][PF_6]_2$ (2), and $[Ru(bipy)_2(N,S/L_3)][PF_6]_2$ (3).

The crystal structure of $[Ru(N,N\text{-dps})_2(N,S/L_1)][PF_6]_2$[37] has shown that $\mathbf{L_1}$ is *N*,*S*-chelated to the ruthenium atom forming the five-membered ring RuSCCN*(Ru–N)*. Further-

more, in the compounds $[Ru(diimine)_2(N,S/L')][PF_6]_2$ [diimine = dps, 4-mdps, 5-mdps, dprs and 5edprs; **L′** = 2-pyrimidylmethyl *p*-tolyl sulfide and *p*-chlorophenyl 2-pyrimidylmethyl sulfide], **L′** is *N,S*-chelated to Ru and forms a five-membered ring.[37] These data suggest that the present ligands **L** can adopt an *N,S*-coordination in the complexes $Ru(bipy)_2(N,S\text{-}L)][PF_6]_2$. However, the NMR spectra of the complexes $Ru(dprs)_2(N,S\text{-}L)][PF_6]_2$ and $Ru(5edprs)_2(N,S\text{-}L)][PF_6]_2$ (see infra) show the presence of two different coordination species. Thus, in the absence of the crystal structure data of **1**, **2** and **3**, we performed several NMR spectroscopic experiments at various temperatures to exclude the presence of different coordination species.

Identification of the coordination mode of $\mathbf{L_1}$, $\mathbf{L_2}$ and $\mathbf{L_3}$ in compounds **1**, **2** and **3**, respectively, was based preliminarily on the analysis of the ^{1}H NMR spectra. In particular: i) the H(6) and H(4) pyrimidine protons of $\mathbf{L_2}$ in **2** are equivalent in that the pyrimidine ring is uncoordinated, ii) the H(3) signal of the uncoordinated pyridine ring of $\mathbf{L_1}$ appears at an unusually low frequency δ = 6.78 ppm (in the free ligand δ = 7.28 ppm); this upfield shift is consistent with increased shielding as the proton lies above the π cloud of the bipyridine ring C or F in the two invertomers (see infra), iii) the temperature has a negligible effect on the methylene proton signals which appear, at all the temperatures, as a single AB system (for instance in **2** at 223 K, δ = 5.61 and 5.18 ppm, J = 17.3 Hz, and at 330 K, δ = 5.65 and 5.17 ppm, J = 17.2 Hz, see also Table 1). Since **1**, **2** and **3** contain a stereogenic sulfur atom [(*R*) and (*S*) configurations] of the unsymmetrical thioether *N,S*-coordinated ligands and a stereogenic tris-chelated ruthenium center (Δ and Λ configurations), two invertomers are expected as enantiomeric couples (ΔR, ΛS) and (ΔS, ΛR). They should give two set of signals in the low-temperature ^{1}H NMR spectra and, in particular, two AB systems for the methylene protons of the two slowly exchanging invertomers. However, the spectra show a single AB system. This can indicate the presence of: 1) only one invertomer, 2) two invertomers that give superimposed signals, 3) two rapidly exchanging invertomers at low temperatures. From literature precedents,[23–25,36] the presence of only one invertomer or two invertomers that have similar resonances is unlikely. Thus, a fast sulfur inversion occurs, even at low temperatures, which is in accordance with the presence of a flexible five-membered chelate ring.[37,38]

On the other hand, the splitting patterns of the methylene protons at higher temperatures (single AB system) rule out the possibility of racemization ($\Delta \rightleftharpoons \Lambda$), which should average the environments of the methylene protons.

The ^{1}H NMR spectra of **1**, **2**, and **3**, in the range 210–330 K (Table 1) show the absence of different coordination species and dynamic processes of interconversion. Furthermore, in the NOESY phase-sensitive experiments of the compounds, positive cross-peaks due to chemical exchange of magnetization are absent.

The NOESY spectrum of **1** at 223 K is shown in Figure 1. Strong NOEs include intraring *ortho* interactions (6–5, 5–4 and 4–3) in the pyridine rings as well as interactions between the methylene protons. Most significantly, it shows interactions between: 1) the H(3) proton of the uncoordinated pyridine ring (labelled B in Table 1) of $\mathbf{L_1}$ at δ = 6.78 ppm, and that of the coordinated pyridine ring (A) at δ = 8.07 ppm; 2) the last proton and the methylene protons at δ = 5.02 and 5.80 ppm, respectively, and the H(6) proton of the bipyridine ligand at δ = 8.31 ppm (ring C); 3) the H(6) bipyridine proton at δ = 9.75 ppm (ring E) and the methylene proton at δ = 5.02 ppm. Weak interactions are observed between the H(3) proton of the uncoordinated pyridine group of $\mathbf{L_1}$ at δ = 6.78 ppm and the methylene proton at δ = 5.80 ppm and the H(6) bipyridine proton at δ = 9.75 ppm (ring E). Furthermore, the NOEs between the H(3) bipyridine protons at δ = 8.32 and 8.34 ppm, and those at δ = 8.94 and 8.89 ppm were used to identify the H(3) protons in the same bipyridine ligand (rings C, D and E, F, respectively).

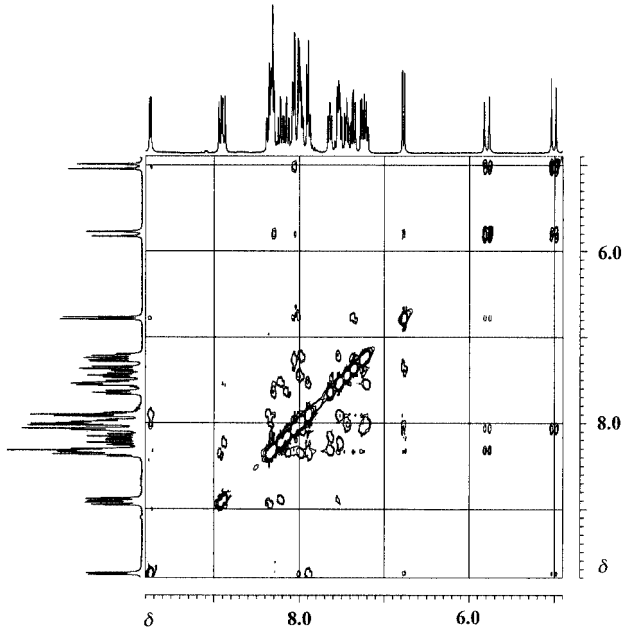

Figure 1. 2D NOESY of $[Ru(bipy)_2L_1][PF_6]_2$ (**1**) at 223 K in $[D_6]$-acetone.

On the basis of 2D phase-sensitive NOESY, 2D COSY, decoupling experiments and monodimensional ^{1}H NMR spectra at various temperatures the *N,S*-coordination of $\mathbf{L_1}$, $\mathbf{L_2}$ and $\mathbf{L_3}$ ligands resulting in the formation of the five-membered ring was assigned. In one invertomer, the uncoordinated pyridine ring B has a *cis* conformation with respect to the pyridine ring labelled C; in the other invertomer, ring B has a *cis* conformation with respect to ring F. Rings and proton positions of **1**, **2** and **3** are listed in Table 1.

Solution Structure of $[Ru(N,N\text{-dprs})_2(N,S/L_1)][PF_6]_2$ (4) and $[Ru(N,N\text{-5edprs})_2(N,S/L_1)][PF_6]_2$ (5) at Low Temperatures

The signal assignments for **4** and **5** were performed with the help of the aforementioned experiments, and the results are listed in Table 1. The portion of the NOESY spectrum of $[Ru(N,N\text{-dprs})_2\mathbf{L_1}][PF_6]_2$ (**4**), performed at 233 K in $(CD_3)_2$-

CO, shown in Figure 2, displays the proton signals of the pyridyl rings labelled A (coordinated ring) and B (uncoordinated ring), the pyrimidyl rings C and D of the same dprs (the first ring is near ring B, Figure 3), and the rings E and F of the other ligand (E is *trans* with respect to the sulfur atom, Figure 3). 6A (δ = 9.27 ppm, $\Delta\delta$ with respect to the free ligand is 0.79 ppm) displays a high-frequency shift due to coordination and short contact with the 6C proton of the pyrimidine ring at δ = 9.33 ppm. The strong NOEs include: a) intraring *ortho* interactions: 6–5, 5–4, and 4–3 in the pyridine rings, 6–5 and 5–4 in the pyrimidine rings; b) geminal interaction of the methylene protons; c) adjacent-group interaction of the methylene proton at δ = 4.55 and 3A at δ = 7.53; d) interaction between the H(6) protons of the pyrimidine rings (6A and 6C, 6F at δ = 9.69 ppm and 6E at δ = 8.84 ppm, 6C and 6D at δ = 9.06 ppm).

Solution Behaviour of 6a + 6b, 7a + 7b, 8a + 8b and 9a + 9b

Variable-temperature ^{1}H NMR spectra of the compounds were obtained in $(CD_3)_2CO$ in the range 215–330 K and in CD_3CN (220–370 K). At low temperature in $(CD_3)_2CO$ or CD_3CN, the ^{1}H NMR spectra of the complexes consist of two sets of signals; one set is much more intense than the other, and this is in agreement with the presence of two different coordination species, one of which was predominant in solution (**6a**, **7a**, **8a**, or **9a**). Identification of these pairs of species was based primarily on the analysis of the proton signals of $\mathbf{L_2}$ or $\mathbf{L_3}$. The shift at high frequencies of the pyridyl proton signals of $\mathbf{L_2}$ and $\mathbf{L_3}$ with respect to the free ligand is in agreement with the pyridyl coordination in both the species. The equivalence, of the pyrimidyl protons 4B and 6B, as well as 4B′ and 6B′ of $\mathbf{L_2}$, suggests that pyrimidyl ring is uncoordinated in both species.

The ^{1}H NMR spectrum of **6a** + **6b** at 218 K in $(CD_3)_2CO$ is shown in Figure 4. All the proton signals of **6a** and some signals of **6b** are labelled. The data are listed in Table 1. According to the presence of two species (population ratio 87:13), four doublets appear in the methylene region: two doublets of major intensity at δ = 4.89 and 3.93 ppm (J = 17.2 Hz), labelled M and N, respectively, and two doublets at δ = 5.08 and 4.18 ppm (J = 15.2 Hz), labelled M′ and N′, respectively. In the aromatic region, the multiplets of major intensity were all assigned, with the help of NOESY, COSY and decoupling experiments, to the 19 protons of **6a**: 12 nonequivalent pyrimidyl protons of *N*,*N*-chelated dprs ligands (with the coupling constants $J_{4,5} \approx 4.6$, $J_{4,6} \approx 2.1$, and $J_{5,6} \approx 6.0$ Hz) and seven protons of $\mathbf{L_2}$; of the latter protons, four are pyridyl protons at δ = 7.55 (3A), 8.03 (4A), 7.63 (5A), and 9.22 ppm (6A) and three are pyrimidyl protons (5B at δ = 7.41 ppm and the equivalent 4B and 6B at δ = 8.42 ppm). These signals are clearly associated to the coordination species containing the five-membered ring RuSCCN(*Ru–N*) and the uncoordinated pyrimidyl ring. In the same aromatic region, full assignment of the minor intensity signals was not possible due to their weakness and numerous partial or complete overlap of these signals with the more intense signals. The assignment of some significant signals was made on the basis of the cited experiments and the multiplet structures of these signals which matched those of their major counterparts. In particular, the pyridyl signals of $\mathbf{L_2}$ in **6b** are at δ = 9.37 (6A′), 8.15 (4A′), 7.90 (3A′), and 7.63 ppm (5A′) (the last masked by the signal of the corresponding proton of the major isomer) and the pyrimidyl signals at δ = 7.70 (5B′) and 8.88 ppm (4B′ and 6B′).

The 2D NOESY spectrum of **6a** + **6b** (Figure 5) was obtained at 243 K. At this temperature, some significant signals

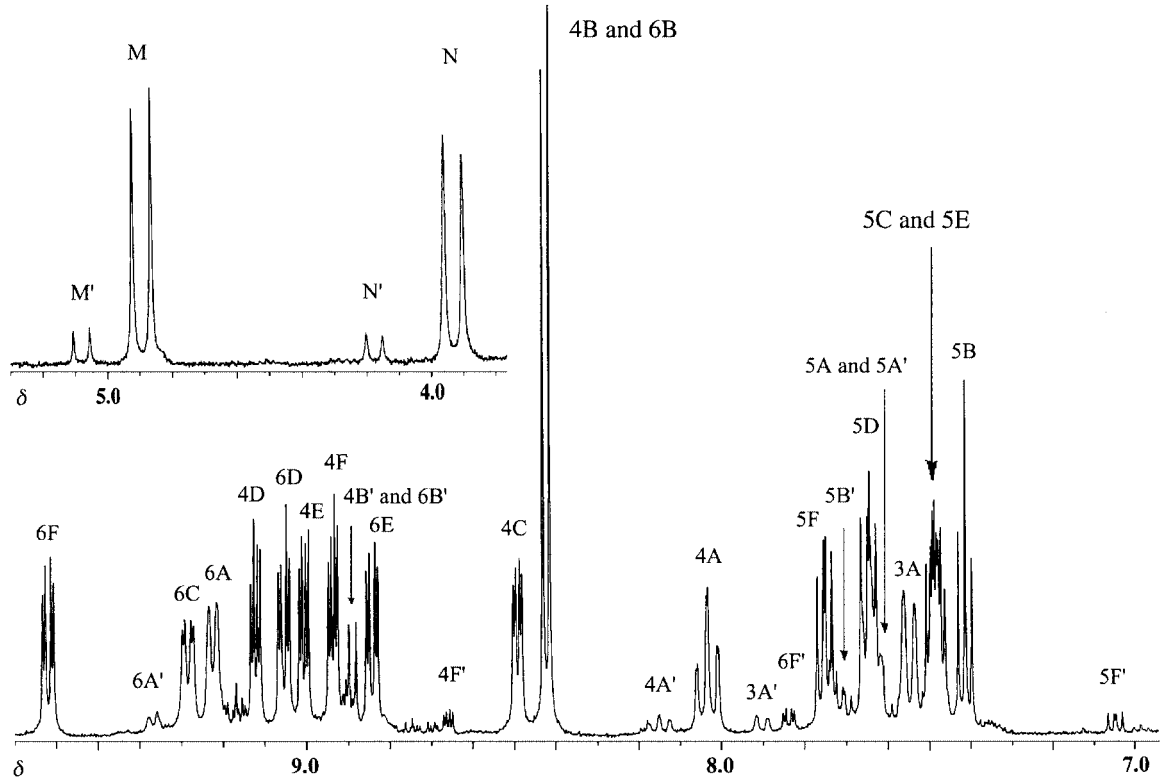

Figure 4. ^{1}H NMR spectrum of $[Ru(dprs)_2L_2][PF_6]_2$ (**6a** + **6b**) at 218 K in $[D_6]$acetone.

of the two species are well separated, and the interchange process is slow. The cross peaks, resulting from chemical exchange of magnetization (grey in Figure 5), are detected in the methylene region between the proton signals M–M′ and N–N′, whereas in the aromatic region (see Figure 4), well-resolved cross peaks are observed between the corresponding $\mathbf{L_2}$ proton signals of the two species (6A – 6A′, 4A – 4A′, 3A – 3A′, 6B and 4B – 6B′ and 4B′, 5B – 5B′) and between 6F (δ = 9.62) and 6F′ (δ = 7.84 ppm), 4F (δ = 8.94 ppm) and 4F′ (δ = 8.66 ppm) and 5F (δ = 7.75 ppm) and 5F′ (δ = 7.05 ppm).

The strong NOEs (black in Figure 5), for the major species, include interactions between the methylene protons, intraring interactions (e.g. 6–5, 5–4 and 4–3 in the pyridine ring and 6–5 and 4 –5 in the pyrimidine rings) and, most significantly, the following interactions between: methylene proton at δ = 4.89 ppm and 3A δ = 7.55 ppm, methylene proton at δ = 3.93 ppm and 6F, equivalent protons (6B and 4B at δ = 8.42 ppm) and 5B at δ = 7.41 ppm.

We assume that the sulfur inversion is fast in the major species even at the low temperatures as observed in **1**, **2**, **3**, **4**, **5**, and similar complexes.[37,38] In fact, the methylene protons of **6a** give only one AB system. On the contrary, if slow inversion occurs at low temperatures, the presence of two diasteroisomers ΔR (ΛS) and ΔS (ΛR) should produce two AB systems in the methylene region of the spectrum.[36] There is no restricted rotation of ring B at 218 K. Restricted rotation of the pyrimidine ring probably occurs below this temperature. Unfortunately, experimental difficulties and, in particular, solubility problems ruled out the possibility of performing NMR experiments below 215 K. In terms of fast inversion and rotation, 4B and 6B are equivalent.

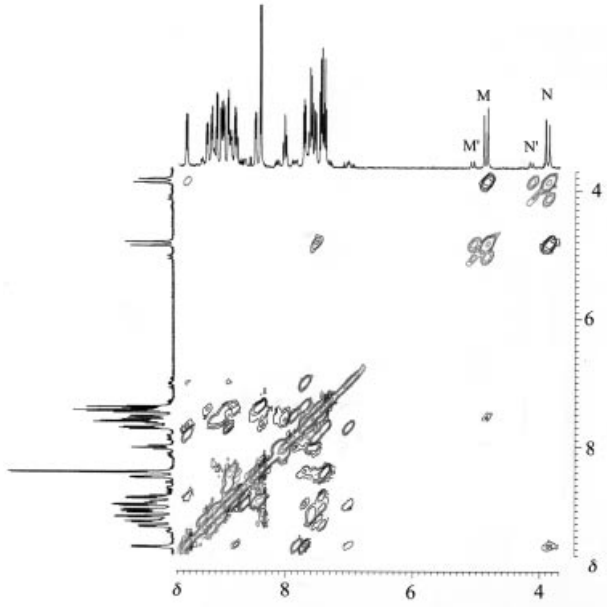

Figure 5. 2D NOESY of $[Ru(dprs)_2L_2][PF_6]_2$ (**6a** + **6b**) at 243 K in $[D_6]$acetone.

The equivalence of 4B′ and 6B′ indicates that the coordination of $\mathbf{L_2}$ does not involve the pyrimidyl group in **6b** also. Since the sulfur inversion and the pyrimidyl rotation are fast, it is unlikely that the minor species is an invertomer or rotamer of the major species. On the other hand, the minor

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species is very different from the major species. In particular, the coupling constants of the methylene protons in the two species are different (for instance, the coupling constant value in **6a** is 17.2 Hz, whereas in **6b**, 15.2 Hz). Some corresponding signals are very different (the signals of the ring A, B and F with respect to those of rings A′, B′ and F′). Thus, in the minor species, the pyrimidyl coordination as well as the *N*,*S*-coordination are unlikely. Since the complete dissociation of $\mathbf{L_2}$ or $\mathbf{L_3}$ by the minor species can be excluded because free ligand addition allows for the observation of separate signals for the free and coordinated ligands (Figure 6), the possible species to be considered are the monodentate ones with *N*-(pyridine)- or *S*-coordination. The *N*-coordination is assigned on the basis of: i) the nitrogen of the pyridyl group is a better donor atom than the sulfur atom towards these ruthenium centers;[23,27,28,35–38] ii) the ^{1}H NMR spectra show downfield shifts of the H(6) protons of isomers **6b**, **7b**, **8b**, and **9b** (see Table 1 and 6A′ in Figure 4); iii) the minor species containing the uncoordinated pyrimidine group attached to the sulfur is favored with respect to that containing the pyridine group, whereas a weakening of the Ru–S bond is expected when the pyridine group is replaced by the better electron-withdrawing pyrimidine group.

On warming the solutions, all the spectral lines in the ^{1}H NMR spectra broaden but the signal intensity of the minor species increases. The methylene signals M′ and N′ of **6b** disappear at ca 288 K.

Figure 6 shows the ^{1}H NMR spectrum of **6a** + **6b** in the presence of a small amount of free ligand ($\mathbf{L_2}$) at 330 K, the highest temperature reached. Eighteen signals in the aromatic region and two averaged doublets in the methylene region are observed. Moreover, some signals for free ligand $\mathbf{L_2}$ are observed (in particular, the methylene signal at δ = 4.55 ppm). These NMR findings are in line with the presence of an exchange between the major species containing the five-membered ring RuSCCN(*Ru–N*) and the minor containing the *N*-monodentate ring, in the range 218–330 K. Furthermore, the averaged methylene signals for $\mathbf{L_2}$ at 330 K are observed at δ = 4.99 and 4.01 ppm. These values are the weighted means of 4.89 (M) and 5.08 (M′), and 3.93 (N) and 4.18 (N′) if the population ratio, at this temperature, is 55:45 (see Table 2), whereas at 218 K the ratio is 87:13.

The rates for the process were deduced by band-shape analysis of the methylene signals. Some experimental and computer-simulated spectra of **6a** + **6b** are shown in Figure 7. In the temperature range 218–243 K, the rates are very

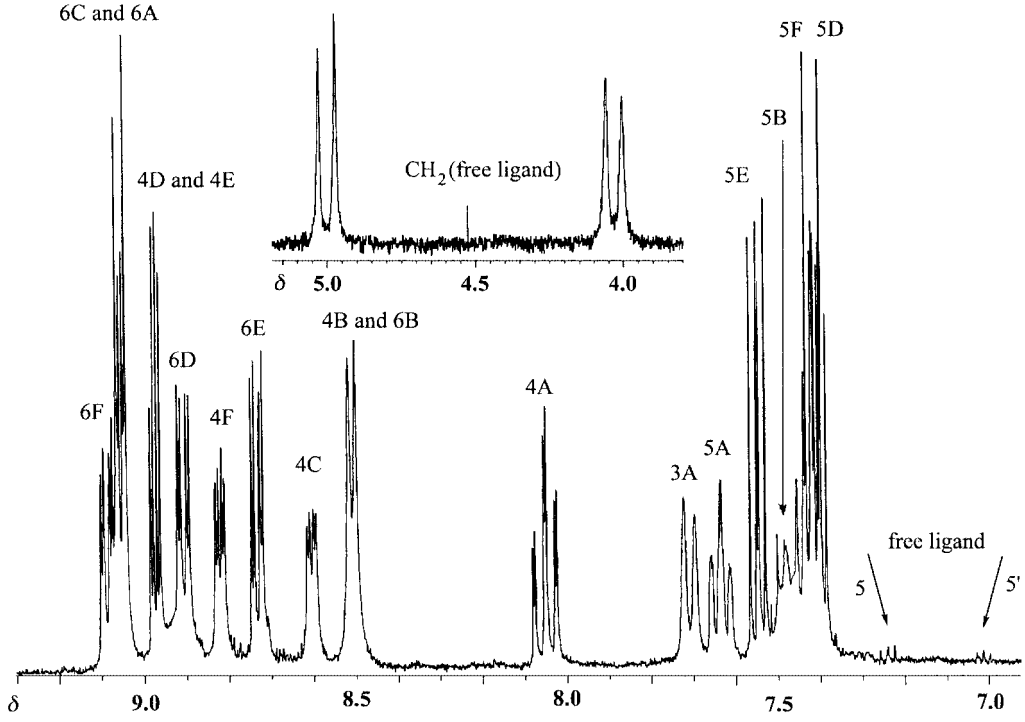

Figure 6. ^{1}H NMR spectrum of $[Ru(dprs)_2L_2][PF_6]_2$ (**6a** + **6b**) at 330 K in $[D_6]$acetone, with small amount of free $\mathbf{L_2}$.

Table 2. Activation energy data.

Species	Population (%) at 218 K	Population (%) at 330 K	$\Delta G^{\#}_{298\ K}$ (kJ·mol^{-1})	$\Delta H^{\#}$ (kJ·mol^{-1})	$\Delta S^{\#}$ (kJ mol^{-1})
6a + **6b**	87:13	55:45	59.1± 0.05	50.5± 1.1	–28.8±3.8
7a + **7b**	82:18	51:49	59.8± 0.10	51.1± 1.3	–29.1±4.8
8a + **8b**	84:16	60:40	59.3± 0.01	57.7± 0.9	–5.4±3.0
9a + **9b**	84:16	60:40	59.5± 0.02	59.0± 1.3	–1.7+4.4

low; however, the population ratio is temperature dependent. To correct for this temperature dependence, a linear interpolation was used.[39] This correction gives the ratio 55:45 at 330 K. Activation parameters were calculated from 15 independent fittings in the temperature range 218–330 K. The activation parameters for the mixtures **7a** + **7b**, **8a** + **8b**, and **9a** + **9b** were obtained in a similar manner and are collected in Table 2.

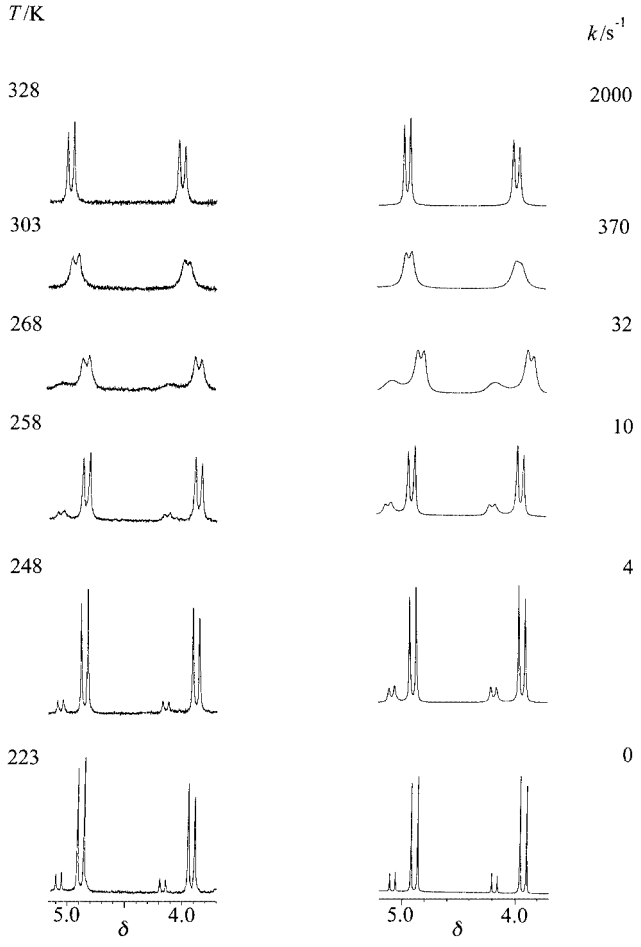

Figure 7. The methylene region of the experimental (left) and computer generated (with the gNMR program, right) ^{1}H NMR spectra of [Ru(dprs)$_2$L$_2$][PF$_6$]$_2$ (**6a** + **6b**) in [D$_6$]acetone.

The ^{13}C NMR spectra of the *N*,*S*-chelate species were interpreted easily (Table 3) by comparison of the spectra of these compounds with those of the free ligand and similar complexes containing *N*,*S*-chelate ligands.[37] Furthermore, although some carbon signals of the minor species are not observed, the ^{13}C NMR spectra show the equivalence of the H(4) and H(6) pyrimidine carbons of **L$_2$** from the presence of uncoordinated pyrimidine ring in the species **6b** and **8b**.

Discussion

We have found that in the complexes [Ru(*N*,*N*-diimine)$_2$(*N*,*S*-pySCH$_2$R)][PF$_6$]$_2$[36] (diimine = dps or dprs, py = pyridine or pyrimidine, and R = phenyl derivative), the ligand pySCH$_2$R is *N*,*S*-coordinated and forms the four-membered ring RuSCN(*Ru–N*). Furthermore, since the ruthenium and sulfur atoms are stereogenic centers, with Δ and Λ, and *R* and *S* configurations, respectively, they lead to the formation of four isomers: Δ*R*, Λ*S*, Λ*R* and Δ*S*. The NMR spectra at various temperatures showed that the pyramidal inversion at the sulfur atom produces an exchange between the diasteroisomers Δ*R* and Λ*S*, as well as between Λ*R* and Δ*S*. The low values of $\Delta G^{\#}_{298}$ (50–55 kJ·mol^{-1}) were explained in terms of the simultaneous presence of the congested Ru(*N*,*N*-dprs)$_2$ fragment and sterically demanding *N*,*S*-coordinated thioethers, which have a high-energy ground state.

In the compounds [Ru(diimine)$_2$(*N*,*S*/L)][PF$_6$]$_2$ [diimine = dps, 4-mdps, 5-mdps, dprs, and 5edprs; L = 2-pyrimidylmethyl *p*-tolyl sulfide (**a**) and *p*-chlorophenyl 2-pyrimidylmethyl sulfide (**b**)], **a** and **b** are *N*,*S*-chelated and form a five-membered ring RuSCCN(*Ru–N*). A restricted phenyl rotation, which exchanges *ortho* as well as *meta* phenyl protons, was also observed. The values of $\Delta G^{\#}_{298}$ are 49–55 kJ·mol^{-1}.

In the present compounds **1**, **2** and **3**, the ligands 2-pyridylmethyl 2′-pyridyl sulfide (**L$_1$**), 2-pyridylmethyl 2′-pyrimidyl sulfide (**L$_2$**), and 2-pyridylmethyl 2′-(4-methylpyrimidyl) sulfide (**L$_3$**) adopt only the *N*,*S*-coordination and form five-membered rings RuSCCN(*Ru–N*) as observed in the crystal structure of [Ru(dps)$_2$(2-pyridylmethyl 2′-pyridyl sulfide)][PF$_6$]$_2$.[37]

The expected invertomers Δ*R* and Λ*S*, and Δ*S* and Λ*R* give only one set of signals in the ^{1}H NMR spectra even at low temperatures as a result of fast sulfur inversion. For the complexes **4**–**9**, two fast exchanging *N*,*S*-chelated invertomers are present, as observed in similar species containing flexible five-membered *N*,*S*-chelated ring.[37]

Although the NMR spectra at low temperatures of **4** and **5** are in agreement with *N*,*S*-coordination, in the range 290–310 K, the proton signals broaden, particularly, the H(6) signal of the dprs ring F. These NMR findings are likely to be associated with the presence of the *N*-monodentate species at high temperature. It is pertinent to note at this point that a strong temperature dependence of the population ratio is normally observed in these systems (see population ratio of **6a** + **6b**, **7a** + **7b**, **8a** + **8b** and **9a** + **9b** in Table 2). Furthermore, very different resonances are observed for corresponding protons 6F and 6F′ of the two different coordination species (Table 1). In other words, at low temperature the *N*,*S*-chelated species of **4** and **5** largely predominates, the concentration of the *N*-monodentate species increases on warming; the H(6) signals of ring F are sensitive to this process.

For **4** and **5**, we cannot calculate the activation parameters of the process, as we do not know the population ratio and difference in the chemical shifts of the two species at low temperatures.

With regard to a mechanism that is consistent with the exchange of the two different coordination species (**6a** + **6b**, **7a** + **7b**, **8a** + **8b** and **9a** + **9b**), we base our suggestion preliminarily on the following observations: i) The $\Delta G^{\#}_{298}$ values for these mixtures are almost the same, approximately equal to 59,5 kJ·mol^{-1}; ii) the $\Delta S^{\#}$ values are negative for **6a** + **6b** and **7a** + **7b** and close to zero for **8a** + **8b** and **9a** + **9b**.

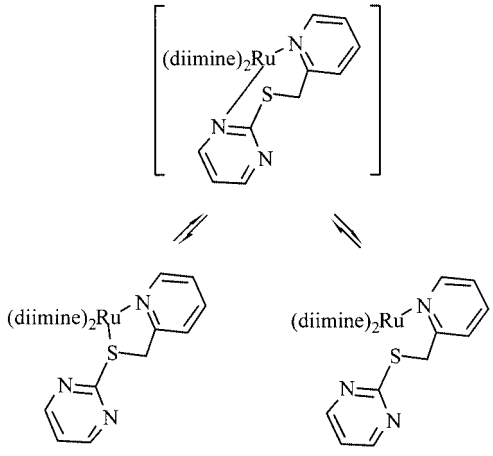
We propose that the mechanism for the interconversion involves the formation of a labile *N*,*N*-intermediate, and subsequent fast dissociation of the Ru–N(pyrimidine) bond, which gives rise to the *N*-monodentate species (Scheme 2). The hemilabile ligands $\mathbf{L_2}$ or $\mathbf{L_3}$ contain three different types of bonding groups. The pyridine group bonds strongly to a metal center, whereas the sulfur and the pyrimidine nitrogen atoms are substitutionally labile groups. In other words, the ruthenium atom undergoes a 1,3-shift between the N(pyrimidine) atom and the sulfur atom, whereas the N(pyridine) atom is always coordinated to the metal, as a result of the ligand attempting, but failing, to adopt a terdentate bonding. The labile *N*,*N*-intermediate involves a seven-coordinate metal transition-state in which S and N(pyrimidine) atom contribute to the bonding. Furthermore, as a consequence of the rotation of the pyrimidine ring in the *N*,*S*-chelate and the *N*-monodentate species, involvement of the both N(pyrimidine) atoms in the coordination is achieved. A substantially stronger Ru–N(pyridine) bond than the Ru–S and Ru–N(pyrimidine) bonds would favor this mechanism.



Scheme 2. Proposed mechanism of the interconversion between the different coordination species.

The negative or close to zero $\Delta S^{\#}$ values reflect the formation of a seven-coordinate metal transition-state, while the $\Delta G^{\#}_{298}$ values, practically unchanged by substitution of $\mathbf{L_2}$ with $\mathbf{L_3}$, are compatible with the a similar congested nature of the transition state in all the complexes.

A simple dissociative mechanism involving rupture of the Ru–S bond in the *N*,*S*-chelated species is unlikely, not only because the $\Delta S^{\#}$ values are negative or close to zero, but also because of the following NMR findings: 1) the ^{1}H NMR signals are temperature-reversible and concentration-independent; 2) the process is clearly the same in acetone and acetonitrile below 345 K (in acetonitrile above this temperature some decomposition is observed); 3) the substitution of the uncoordinated pyridine ring with the pyrimidine ring favors the dynamic process.

Although electronic effects can be invoked to explain this behavior, these effects are not observed when the H(4) pyrimidyl proton of $\mathbf{L_2}$ is substituted with the methyl group or when the H(5) pyrimidyl proton of dprs is substituted with the ethyl group.

It is important to note at this point that the process is present only in congested ruthenium cores in which the *N*,*S*-chelated ligand must contain at least three donor atoms, and is favored by the presence of two donor atoms in the uncoordinated pyrimidine ring. The pyrimidine group bonded to the sulfur atom not only weakens the Ru–S bond but also increases the statistical probability of the *N*,*N*-intermediate.

On the other hand, an associative mechanism, involving solvent, anion, or free ligand, is incompatible with the following observations: a) addition of free ligand or PF_6^- anion does not affect the rates of the process; b) separate signals for the free and coordinated ligand were observed in the range 200–330 K (Figure 6). Therefore, the mechanism, consistent with the experimental results, appears to involve the labile *N*,*N*-chelated intermediate.

Conclusions

The reactions of thioethers bearing CH_2Py and pyridine or pyrimidine groups with $Ru(dprs)_2Cl_2$ has allowed us to extend the chemistry of octahedral congested ruthenium(II) compounds containing *N*,*S*-chelated ligands with a five-membered chelate ring. The ring size of *N*,*S*-chelated ligands plays a determining role for sulfur inversion. In the five-membered chelate ring, the process is fast, in the four-membered ring, it is much slower.[36] The NMR experiments show that a minor species containing the *N*-monodentate thioether is favored by the presence of two nitrogen atoms in the uncoordinated ring, whereas it is not observed when the nitrogen atoms are absent.[37] Further experiments are in progress with the aim of studying the effect of the nature of congested $Ru(N,N\text{-dimmine})_2$ cores on the interconversion between different coordination species.

Experimental Section

General Remarks: Bis(2-pyrimidyl) sulfide,[35] 2-pyridylmethyl 2′-pyridyl sulfide ($\mathbf{L_1}$),[40] 2,2′-bis(5-ethylpyrimidyl) sulfide (5edprs),[37] $[Ru(dprs)_2Cl_2]\cdot 2H_2O$,[35] and $[Ru(5edprs)_2Cl_2]$[37] were prepared according to published methods. $Ru(bipy)_2Cl_2$ and other reagents and solvents were used as received. All the syntheses were performed under N_2, and all the complexes were dried over P_4O_{10} under vacuum. Elemental analyses were carried out by Redox Microanalytical Laboratory of Cologno Monzese (Milano). Conductivity measurements were done on a Metrohm 644 conductometer. Infrared spectra were recorded with a Perkin–Elmer RX I FT-IR spectrophotometer with samples as Nujol mulls placed between KBr plates, and the ^{1}H and ^{13}C NMR spectra were recorded with a Bruker AMX 300 spectrometer. Simulations of static and dynamic spectra were performed by the gNMR program.

Preparations

The known[40] 2-pyridylmethyl 2′-pyrimidyl sulfide ($\mathbf{L_2}$) was prepared with the following procedure: 2-sulfanylpyrimidine (5.6 g, 0.05 mol), 2-picolyl chloride hydrochloride (8.2 g, 0.05 mol), and K_2CO_3

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(9.67 g, 0.07 mol) were vigorously stirred in DMF (30 cm^3) at 100 °C for 6 h. The solvent was distilled under reduced pressure, and the residue extracted with CH_2Cl_2 (200 cm^3). This was then concentrated (ca. 5 cm^3) and added to the top of the chromatography column (diameter 2 cm) packed with aluminium oxide (35 g; Aldrich neutral, STD grade, 150 mesh). Elution with CH_2Cl_2/hexane (5:2) gave a pale yellow band, which was collected. The solvent was removed in vacuo, and the remaining yellow oil was kept at –24 °C until a solid was formed (ca. 2 d). Yield 4.57 g (45%). Selected IR data (KBr): $\tilde{\nu}$ = 1670 vs, 1590 vs, 1563 vs, 1548 vs, 1257 s, 1199 vs, 1184 vs, 1091 vs, 994 s, 799 vs, 773 vs, 749 vs, 734 s and 588 ms cm^{-1}.

2-Pyridylmethyl 2′-(4-Methylpyrimidyl) Sulfide (L_3): Prepared similarly starting from 2-mercapto-4-methylpyrimidine hydrochloride (8.13 g, 0.05 mol), 2-picolyl chloride hydrochloride (8.20 g, 0.05 mol), and K_2CO_3 (16.7 g, 0.12 mol). Yield 4.35 g (40%). Selected IR data (KBr): $\tilde{\nu}$ = 1592 vs, 1568 vs, 1541 vs, 1223 s, 1206 vs, 1091 s, 995 s, 881 s, 785 s, 771 s, 750 vs, 713 vs, 698 s, 590 s, 547 s and 406 s cm^{-1}. $C_{11}H_{11}N_3S$ (217.29), calcd. C 60.80, H 5.10, N 19.34, S 14.75; found C 60.70, H 5.20, N 19.50, S 14.70.

$[Ru(bipy)_2(L_1)][PF_6]_2$ (1): $[Ru(bipy)_2Cl_2]\cdot 2H_2O$ (0.174 g, 0.33 mmol) in degassed ethanol/water (3:2, 50 cm^3) was heated under reflux for 1 h. 2-pyridylmethyl 2′-pyridyl sulfide (0.178 g, 0.882 mmol) was then added, and the mixture was heated under reflux for a further 4 h. The hot solution was filtered, and the filtrate was added to water (50 cm^3) containing NH_4PF_6 (0.98 g, 6.0 mmol). An orange precipitate was obtained, filtered, washed with water, and dried overnight. The solid was dissolved in acetone (15 cm^3), precipitated with diethyl ether (100 cm^3), and washed with diethyl ether (70 cm^3). Yield 0.181 g (60%). Selected IR data (KBr): $\tilde{\nu}$ = 1605 s, 1575 s, 1560 ms, 1548 ms, 1515 s, 1315 s, 1243 s, 1162 s, 1125 s, 845 br, 764 vs, 740 ms, 730 s, 558 vs cm^{-1}. $C_{31}H_{26}F_{12}N_6P_2RuS$ (905.65), calcd. C 41.11, H 2.89, N 9.28, S, 3.54; found: C 40.90, H 3.00, N 9.30, S 3.60. Conductivity: Λ_M (MeCN, 2×10^{-4} mol·dm^{-3}, 20 °C) = 333 S·cm^2·mol^{-1}.

$[Ru(bipy)_2(L_2)][PF_6]_2$ (2): This compound was obtained in the same way as that described above starting from $[Ru(bipy)_2Cl_2]\cdot 2H_2O$ (0.302 g, 0.623 mmol) and 2-pyridylmethyl 2′-pyrimidyl sulfide (0.630 g, 3.100 mmol). Yield 0.339 g (60%). Selected IR data (KBr): $\tilde{\nu}$ = 1605 s, 1561 s, 1557 vs, 1315 ms, 1243 ms, 1164 s, 1108 s, 838 br, 764 vs, 731 s, 558 vs cm^{-1}. $C_{30}H_{25}F_{12}N_7P_2RuS$ (906.64), calcd. C 39.74, H 2.78, N 10.81, S, 3.53; found: C 39.70, H 2.80, N 10.85, S 3.60. Conductivity: Λ_M (MeCN, 2×10^{-4} mol·dm^{-3}, 25 °C) = 310 S·cm^2·mol^{-1}.

$[Ru(bipy)_2(L_3)][PF_6]_2$ (3): The compound was obtained in the same way as that described above starting from $[Ru(bipy)_2Cl_2]\cdot 2H_2O$ (0.200 g, 0.413 mmol) and 2-pyridylmethyl 2′-(4-methylpyrimidyl) sulfide (0.510 g, 2.34 mmol). Yield 247 (65%). Selected IR data (KBr): $\tilde{\nu}$ = 1603 ms, 1575 s, 1534 ms, 1163 ms, 844 br, 768 vs, 732 ms, 558 vs cm^{-1}. $C_{31}H_{27}F_{12}N_7P_2RuS$ (920.66), calcd. C 40.44, H 2.95, N 10.65, S, 3.48; found: C 40.40, H 2.90, N 10.65, S 3.50. Conductivity: Λ_M (MeCN, 2×10^{-4} mol·dm^{-3}, 25 °C) = 340 S·cm^2·mol^{-1}.

$[Ru(dprs)_2(L_1)][PF_6]_2$ (4): $[Ru(dprs)_2Cl_2]\cdot 2H_2O$ (0.196 g, 0.33 mmol) and 2-pyridylmethyl 2′-pyridyl sulfide (0.178 g, 0.882 mmol) in ethanol/water (3:2, 50 cm^3) were heated under reflux under N_2 for 4 h. The hot solution was filtered, and the filtrate was added to water (50 cm^3) containing NH_4PF_6 (0.65 g, 4 mmol). An orange precipitate was obtained, filtered, washed with cold water (30 cm^3), and dried overnight. The solid was then dissolved in acetone (15 cm^3), precipitated with diethyl ether (100 cm^3), washed with diethyl ether (70 cm^3), and dried over P_4O_{10} under vacuum. Yield 0.195 g (60%). Selected IR data (KBr): $\tilde{\nu}$ = 1654 br, 1575 s, 1549 s, 1168 s, 1127 s, 1085 ms, 847 br, 767 s, 753 s, 721 ms, 559 vs cm^{-1}. $C_{27}H_{22}F_{12}N_{10}P_2RuS_3$ (973.72), calcd. C 33.31, H 2.28, N 14.38, S, 9.88; found: C 33.30, H 2.30, N 14.20, S 9.80. Conductivity: Λ_M (MeCN, $2\cdot10^{-4}$ mol·dm^{-3}, 25 °C) = 320 S·cm^2·mol^{-1}.

$[Ru(5edprs)_2(L_1)][PF_6]_2$ (5): The compound was obtained in the same way as **4** starting from $[Ru(5edprs)_2Cl_2]$ (0.219 g, 0.33 mmol) and 2-pyridylmethyl 2′-pyridyl sulfide (0.178 g, 0.882 mmol). Yield 0.215 g (60%). Selected IR data (KBr): $\tilde{\nu}$ = 1653 br, 1574 s, 1548 vs, 1242 s, 1145 vs, 1061 vs, 878 vs, 845 br, 780 s, 765 s, 721 ms, 558 vs cm^{-1}. $C_{35}H_{38}F_{12}N_{10}P_2RuS_3$ (1085.93), calcd. C 38.71, H 3.53, N 12.90, S, 8.86; found: C 38.60, H 3.60, N 12.80, S 8.80. Conductivity: Λ_M (MeCN, $2\cdot10^{-4}$ mol·dm^{-3}, 25 °C) = 315 S·cm^2·mol^{-1}.

$[Ru(dprs)_2(L_2)][PF_6]_2$ (6a + 6b): The procedure used in this synthesis was similar to that described for **4** starting from $[Ru(dprs)_2Cl_2]\cdot 2H_2O$ (0.196 g, 0.33 mmol) and 2-pyridylmethyl 2′-pyrimidyl sulfide (0.178 g, 0.882 mmol.) Yield 0.195 g (60%). Selected IR data (KBr): $\tilde{\nu}$ = 1654 br, 1578 vs, 1561 s, 1549 vs, 1169 vs, 1085 s, 845 br, 769 ms, 754 s, 723 ms, 558 vs cm^{-1}. $C_{26}H_{21}F_{12}N_{11}P_2RuS_3$ (974.71), calcd. C 32.04, H 2.17, N 15.81, S 9.87; found C 32.00, H 2.20, N 15.60, S 9.80. Conductivity: Λ_M (MeCN, $2\cdot10^{-4}$ mol·dm^{-3}, 25 °C) = 318 S·cm^2·mol^{-1}.

$[Ru(dprs)_2(L_3)][PF_6]_2$ (7a + 7b): The procedure used in this synthesis was similar to that described above with an equivalent quantity of 2-pyridylmethyl 2′-(4-methylpyrimidyl) sulfide (0.192 g, 0.882 mmol) used in place of L_2. Yield 0.190 g (68%). Selected IR data (KBr): $\tilde{\nu}$ = 1575 vs, 1549 vs, 1261 s, 1167 vs, 1086 s, 846 br, 767 ms, 753 s, 721 ms, 558 vs cm^{-1}. $C_{27}H_{23}F_{12}N_{11}P_2RuS_3$ (988.74), calcd. C 32.80, H 2.34, N 15.58, S 9.73; found C 32.60, H 2.40, N 15.60, S 9.80. Conductivity: Λ_M (MeCN, $2\cdot10^{-4}$ mol·dm^{-3}, 25 °C) = 321 S·cm^2·mol^{-1}.

$[Ru(5edprs)_2(L_2)][PF_6]_2$ (8a + 8b): $[Ru(5edprs)_2Cl_2]$ (0.219 g, 0.33 mmol) and 2-pyridylmethyl 2′-pyrimidyl sulfide (0.178 g, 0.882 mmol) in ethanol/water (3:2, 50 cm^3) were heated under reflux for 2 h. $AgPF_6$ (0.167 g 0.66 mmol) was then added, and the mixture was stirred for 1 h at 50 °C in the dark. After filtration of the solution into water (50 cm^3) containing NH_4PF_6 (0.65 g, 4.0 mmol), an orange precipitate was obtained, filtered, washed with cold water (30 cm^3), and dried overnight. Aluminium oxide (0.200 g) was added to the crude product dissolved in acetone (15 cm^3), and the mixture was stirred for 15 min. The solution was then filtered, and the aluminium oxide was washed with acetone (5 cm^3). The solution and washing liquids were concentrated (5 cm^3), and diethyl ether (50 cm^3) was added. The precipitate was collected and washed with diethyl ether. Yield 0.108 g (30%). Selected IR data (KBr): $\tilde{\nu}$ = 1580 s, 1556 s, 1549 vs, 1260 vs, 1093 vs, 1061 s, 1022 vs, 845 br, 777 s, 754 s, 740 ms, 721 s, 558 vs cm^{-1}. $C_{34}H_{37}F_{12}N_{11}P_2RuS_3$ (1086.93), calcd. C 37.57, H 3.43, N 14.18, S 8.85; found C 37.60, H 3.55, N 14.10, S 8.80. Conductivity: Λ_M (MeCN, $2\cdot10^{-4}$ mol·dm^{-3}, 25 °C) = 343 S·cm^2·mol^{-1}.

$[Ru(5edprs)_2(L_3)][PF_6]_2$ (9a + 9b): The procedure used in this synthesis was similar to that described above with an equivalent quantity of 2-pyridylmethyl 2′-(4-methylpyrimidyl) sulfide (0.192 g, 0.882 mmol) used in place of L_2. Yield 0.134 g (37%). Selected IR data (KBr): $\tilde{\nu}$ = 1575 vs, 1548 vs, 1143 s, 1061 s, 841 br, 757 s, 740 ms, 721 ms, 558 vs cm^{-1}. $C_{35}H_{39}F_{12}N_{11}P_2RuS_3$ (1100.95), calcd. C 38.18, H 3.57, N 13.99, S 8.74; found C 38.20, H 3.60, N 13.90, S 8.80. Conductivity: Λ_M (MeCN, $2\cdot10^{-4}$ mol·dm^{-3}, 25 °C) = 350 S·cm^2·mol^{-1}.

Synthesis and Characterization of Radical Cations Derived from Mono- and Biferrocenyl-Substituted 2-Aza-1,3-butadienes: A Study of the Influence of an Asymmetric and Oxidizable Bridge on Intramolecular Electron Transfer

Vega Lloveras,[a] Antonio Caballero,[b] Alberto Tárraga,[b] M. Desamparados Velasco,[b] Arturo Espinosa,[b] Klaus Wurst,[c] David J. Evans,[d] José Vidal-Gancedo,[a] Concepció Rovira,[a] Pedro Molina,*[b] and Jaume Veciana*[a]

Keywords: Charge transfer / Electrochemistry / Electron transfer / Metallocenes / Optical spectroscopy

The synthesis and study of structural and electronic properties of mono-ferrocenyl π-conjugated complexes **5a**–**d**, whose electronic characteristics have been systematically varied by introducing an electron-donating or electron-withdrawing substituent either at the 1-position or at the 4-position of the 2-aza-1,3-butadiene moiety linked to the ferrocenyl unit, are presented. The structural and electronic properties of the homobimetallic complex **5f**, with two ferrocene units linked through the asymmetric and oxidizable 2-aza-1,3-butadiene bridge, is also reported. The crystal structures of complexes **5b**, **5d**, and **5f** show a large degree of conjugation in this family of compounds. Complexes **5** show a rich electrochemical behavior due both to the oxidation of ferrocenyl units and the 2-aza-1,3-butadiene bridge, as revealed by cyclic voltammetry. Radical cations $\mathbf{5}^{+\cdot}$ were prepared from **5** by coulometric oxidations following their generation by absorption spectroscopy. The electronic properties of all reported neutral and oxidized π-conjugated complexes have been investigated by means of UV/Vis–near-IR, EPR and ^{57}Fe Mössbauer spectroscopy. The detailed study of mono-oxidized species $\mathbf{5a}^{+\cdot}$–$\mathbf{5f}^{+\cdot}$ has permitted the determination of the influence of an asymmetric bridge with an electroactive character on the intramolecular electron transfer (IET) phenomenon, thus demonstrating that the 2-aza-1,3-butadiene bridge promotes the IET between the two metallic units of $\mathbf{5f}^{+\cdot}$ through two different pathways. The experimental data and conclusions are supported by DFT computations (B3LYP/3-21G*) and time-dependent DFT methods.

Introduction

Currently, there is considerable interest in the study of the properties of compounds bearing multiple redox centers separated by an organic bridge and, in particular, those that are able to produce mixed-valence species.[1] Such species are interesting not only because of their importance in producing new valuable materials, such as molecular wires and switches, that show intramolecular electron transfer (IET) phenomena, but also to understand the role of biologically relevant mixed-valence compounds.[2] One of the richer areas of metallocene chemistry is the study of general strategies for assembling two or more such electroactive metal fragments in close proximity in order to determine the type of electronic interactions between the metal fragments.[3] Among the various possibilities to bridge two cyclopentadienyl-type (Cp) ligands, emphasis has been laid on the electronic and steric properties of organic bridges because both will influence the interaction between the metal fragments bound to the Cp's and, in many cases, these factors will not be independent.

It is worth noting that IET can be monitored by the study of optical transitions occurring in mixed-valence complexes,[4] and that intervalence charge-transfer (IV-CT) bands may be observed in both σ- and π-bridged systems. In the former case, a through-space mechanism is generally believed to be responsible, such that low-energy bands at the near-IR are usually only observed in species that are sufficiently flexible to allow the two metal centers to come into close proximity. In π-bridged systems, near-IR bands are much more widely observed, even when the metals are well separated by rigid bridges, thereby suggesting that through-bond mechanisms are involved. IET in such π-bridged systems may proceed either by a superexchange and/or a hopping mechanism.[5] In the superexchange

mechanism the bridge serves solely to mediate the wavefunctions of the two electroactive centers that act as electron-donor and -acceptor groups; the electron (or hole) is never vibronically localized on the bridge. In contrast, in the hopping mechanism the electron (or hole) is located at the bridge for a short time (vibronically localized) during its journey from one redox center to the other. The former mechanism is generally the origin of many of the observed IV-CT bands in mixed-valence species, while the hopping one is much less common, probably because of the strict structural and electronic requirements that must be fulfilled by the bridge. Nowadays there is a great interest in the development of organic bridges that favor the hopping mechanism between the two electroactive centers since they could provide new molecular devices that act as electronic relays to promote IETs over large distances.

A large number of bis-metallocenes and metallocenes linked by saturated carbon bridges have been synthesized and studied with respect to metal–metal interactions. It has been demonstrated that, compared to bis-metallocenes, species linked by a single carbon bridge show substantially weaker metal–metal interactions.[6] In general, stronger electrochemical metal–metal interactions occur when two linkages are made between two metallocenes and the metals are brought into closer proximity. On the other hand, IV-CT absorptions are usually not observed in the mono-oxidized derivatives of ferrocenes with insulating hydrocarbon bridges.[7] Most bis-metallocenes linked by saturated carbon bridges belong to class I in the Robin–Day classification,[8] the only interaction detected being at the electrochemical level and which can be attributed only to electrostatic and inductive effects. In contrast, ferrocenyl groups linked by unsaturated bridges show slightly larger metal–metal interactions than those with analogous saturated bridges,[2c,9–13] and the corresponding mono-oxidized olefin-bridged species show IV-CT absorptions in the near-IR region. Thus, many such species belong to class II, in which there is a moderate coupling between the two electroactive centers mediated by the organic bridge through a superexchange mechanism. Intermetallic interactions of different magnitudes have been observed in diferrocene complexes in which the two metallocene units are linked through a symmetric spacer with two conjugated double bonds (e.g. butadiene,[14] 1,4-diaza-1,3-butadiene,[15] 2,3-diaza-1,3-butadiene,[16] and others[17]). However, no examples have been reported of metal–metal interactions between metallocene units linked by an asymmetric spacer like the 2-aza-1,3-butadiene bridge.

Here we wish to present the synthesis and study of structural and electronic properties of ferrocenyl (Fc) π-conjugated complexes **5a**–**d**, whose electronic properties have been systematically varied by introducing an electron-donating or electron-withdrawing substituent, either at the 1-position or at the 4-position of the 2-aza-1,3-butadiene moiety linked to the ferrocenyl unit. We also wish to present here a study of the homobimetallic complex **5f**, which contains two ferrocene units linked by the asymmetric 2-aza-1,3-butadiene bridge. The mono-oxidized species of this complex, $\mathbf{5f}^{+\bullet}$, has permitted the study of the influence of an asymmetric bridge with an electroactive character on the intramolecular electron transfer (IET) phenomenon, demonstrating that the 2-aza-1,3-butadiene bridge favors the IET between the two metallic centers.

Results and Discussion

Synthesis and Characterization

Compounds **5** were all prepared from the readily available diethyl aminomethylphosphonate (**1**),[18] which was condensed with the appropriate aromatic or organometallic aldehyde **2** to give the corresponding *N*-substituted diethyl aminomethylphosphonate **3** in excellent yields (85–95%). Generation of the metalloenamine by treatment with *n*BuLi at –78 °C and subsequently with one equivalent of the aldehyde **4** provided the 1,4-disubstituted 2-aza-1,3-butadienes **5** in yields ranging from 40% to 90% (Scheme 1). While two individual operations are required in the latter synthesis, it is possible to execute the entire sequence of reactions in a single flask without isolation of the intermediates **3** without affecting the yield. However, in this case, isolation of compounds **5** proved to be more difficult. Compounds **5**, recrystallized from dichloromethane/diethyl ether (1:10), were characterized by mass spectroscopy and ^{1}H and ^{13}C NMR spectroscopy, as well as by elemental analyses.

Assignment of the configuration of the double bonds present in the 1,4-disubstituted 2-aza-1,3-butadienes **5** was achieved by inspection of the ^{1}H NMR spectroscopic data. It is well established that the condensation reaction between a primary amine and an aldehyde is not stereoselective, hence both (*E*)- and (*Z*)-aldimine isomers are generally present in the reaction product. However, it must be emphasized that the condensation reaction between **1** and the appropriate aldehyde **2** takes place stereoselectively to give exclusively the (*E*)-isomer, as ascertained by ^{1}H NMR spectroscopy. Indeed, an NOE effect is observed to the methylene group on irradiation of the aldiminic proton of **3a**. On the other hand, *N*-substituted diethyl aminophosphonates **3**, after deprotonation with *n*BuLi, react smoothly in THF with the corresponding aldehyde **4** to give only the *trans* configured carbon-carbon double bond, as is expected in a Horner–Wadsworth–Emmons olefination process. This configuration was confirmed by the characteristic vicinal coupling constants (J = 14.0 Hz) in the ^{1}H NMR spectrum. In addition, NOE and two-dimensional NOESY experiments on a solution of compound **5f** in $CDCl_3$ confirmed not only the (*E*,*E*)-configuration of the double bonds present in the bridge, but also the *s-cis*-conformation in this solvent. Thus, on irradiation at δ = 7.04 ppm (H_4) an NOE effect is observed on the aldiminic H_1; no NOE effect is observed to H_1 when irradiation takes place at δ = 6.63 ppm (H_3).

X-ray Crystal Structures

Single crystals of compounds **5b**, **5d**, and **5f**, suitable for X-ray structure determination, were grown from diffusion of *n*-hexane into a solution of the compound in CH_2Cl_2. The crystal data and details of data collection and structure refinement are given as Supporting Information (Table S1). Attempts to grow good-quality single crystals of **5a** and **5c** for X-ray determination were unsuccessful.

Compound **5b** crystallizes in the triclinic space group $P\bar{1}$ with four molecules in the unit cell. Two independent molecules were found per asymmetric unit. Figure 1 (see a) shows the ORTEP drawing of the molecular structure of **5b** with the atomic numbering scheme. The molecular structure reveals that **5b** is present as the (*E*,*E*)-isomer, as is observed in solution by ^{1}H NMR spectroscopy, and has an *s-trans* configuration in the solid state. The interatomic distances and bond angles of **5b** are close to those previously observed for ferrocene[19] and other substituted ferrocene

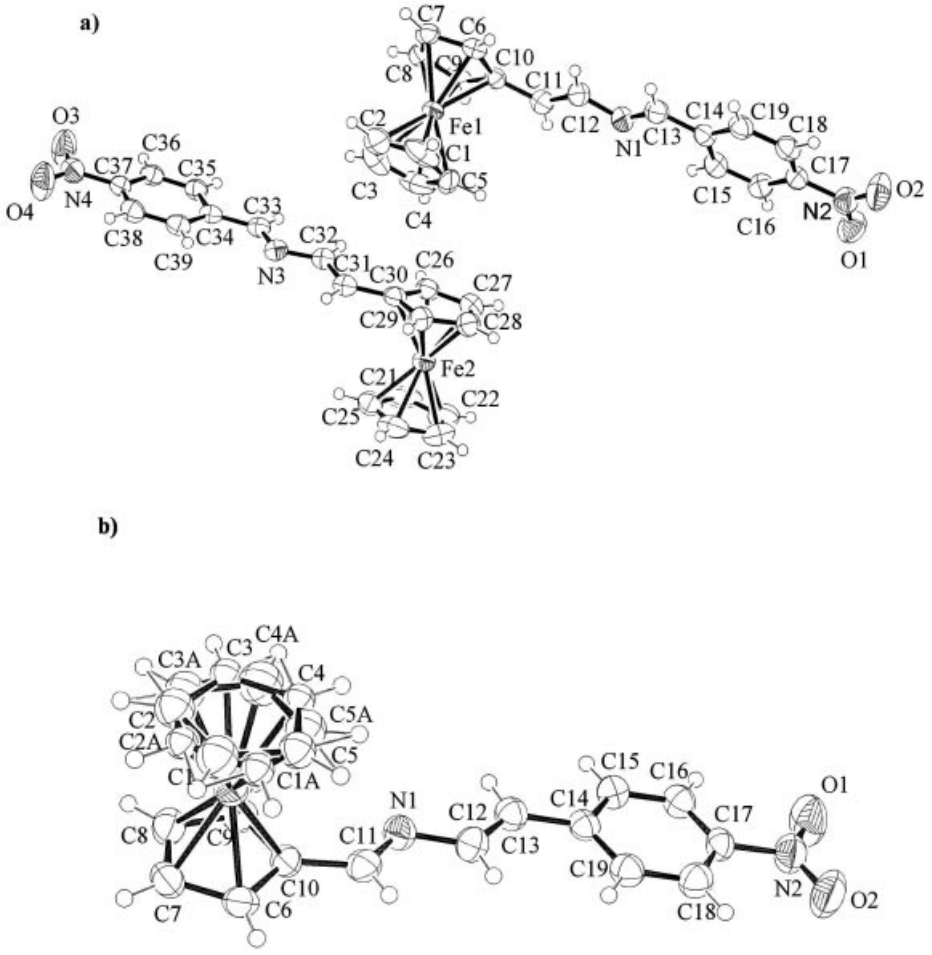

Figure 1. ORTEP views of the asymmetric unit of **5b** showing the atom numbering scheme (a) and of **5d** showing the atom numbering scheme (b). Thermal ellipsoids are drawn at the 50% probability level.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compounds.[20] The most interesting structural feature of **5b** is that all atoms of the 2-aza-1,3-butadiene bridge and the two attached rings are disposed in a planar configuration, thus indicating a large degree of π-conjugation and rigidity of this organic ligand.

Compound **5d** crystallizes in the monoclinic space group *P*21/*n* with four molecules in the unit cell. Figure 1 (see b) shows the ORTEP drawing with the atomic numbering scheme. Molecules of this compound are also present as the (*E*,*E*)-isomer, as observed in solution by ^{1}H NMR spectroscopy, and have an *s-trans* configuration in the solid state. The bond and dihedral angles reveal that all the atoms of the bridge and the two linked rings are disposed in a planar configuration, as in compound **5b**, thus indicating a large degree of conjugation in the π-system.

Compound **5f** crystallizes in the monoclinic space group *P*21/*c* with two molecules in the unit cell. Figure 2 shows the ORTEP drawing of **5f** with the atomic numbering scheme. The molecular structure of **5f** reveals a 1:1 disorder of the two atoms C12 and N1 at the same position. The crystallographic asymmetric unit is only one half of the molecule, since the other half is generated by a symmetry operation with a center of symmetry, as shown in Figure 2. Since the molecule does not really possess a symmetry center it must be disordered, therefore C12 and N1 were refined each with an occupancy of 0.5 with the same coordinates and temperature factors. Molecules of **5f** are also present as the (*E*,*E*)-isomer, as observed in solution by ^{1}H NMR spectroscopy, but in the solid state they adopt an *s-trans* conformation in contrast to the major conformation adopted in solution (vide supra). One of the two equivalent possibilities of the molecule is shown in Figure 2.

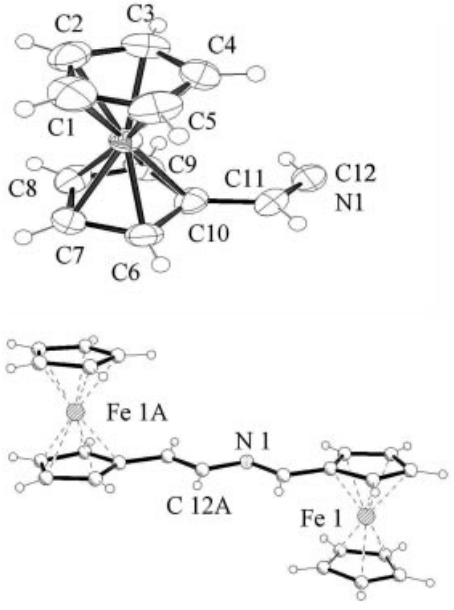

Figure 2. Top: ORTEP view of the asymmetric unit of **5f** showing the atom numbering scheme. Thermal ellipsoids are drawn at the 50% probability level. Bottom: drawing of a complete molecule of **5f**.

Theoretical Calculations

Geometry optimizations at the DFT level were carried out for neutral 2-aza-1,3-butadienes **5** as well as for the oxidized species **5**$^{\bullet+}$; the resulting geometrical parameters are gathered in Table 1. For those compounds whose X-ray structures are reported here, a high degree of coincidence is observed with the calculated values, as shown by the following critical geometrical parameters: the calculated N(bridge)···Fe distances for **5b**, **5d**, and **5f** are 5.309, 3.868, and 3.885 (Fe_1) and 5.380 Å (Fe_4), while the corresponding experimental distances are 5.242, 3.893, and 3.967 and 5.169 Å, respectively; the calculated Fe_1···Fe_4 distance in **5f** is 9.225 Å, while the experimental one is 9.107 Å. The other two calculated structures **5a** and **5c** display similar values (5.350 and 3.860 Å, respectively) for the N(bridge)···Fe distance. On the other hand, all calculated structures have a pure *s-trans* conformation (C1–N2–C3–C4 dihedral angles of 179.7°, 178.3°, 177.5°, 178.6°, and 179.2° for **5a**–**d** and **5f**, respectively), with the substituted phenyl rings almost parallel to the 2-aza-1,3-butadiene plane (angles between mean planes of 0.3°, 3.5°, 4.7°, and 1.4° for **5a**–**d**, respectively) and the bridge-attached Cp rings with small twisting angles (13.6°, 5.6°, 7.8°, 3.5°, 1.4°, and 12.1° for **5a**–**d** and Fc_1 and Fc_4 in **5f**, respectively). Where available, all experimental ring (Cp or substituted phenyl) twisting angles are systematically higher than the corresponding calculated values. From these calculations it is possible to conclude that both neutral 2-aza-1,3-butadienes **5** and oxidized species **5**$^{\bullet+}$ show planar structures exhibiting a large conjugation and a high structural rigidity (Table 1).

Electronic Spectroscopy

The UV/Visible data obtained in CH_2Cl_2 for **5a**–**d** and **5f** are collected in Table 2. These spectra are characterized by a very strong absorption with a maximum between 336 and 375 nm, which is assigned to a localized π-π* excitation mainly within the 2-aza-1,3-butadiene bridge. In addition to this band, another weaker absorption is visible between 469 and 535 nm, which is assigned to another localized excitation with a lower energy produced either by two nearly degenerate transitions, an Fe^{II} d-d transition[21] (e.g. HOMO–1 → LUMO+3 in **5a**), or by a metal-to-ligand charge transfer (MLCT) process (d_π-π*)[22] (e.g. HOMO–3 → LUMO+1 in **5a**). By comparison of the compounds with the ferrocenyl unit in the same position of the bridge it is easy to conclude that the presence of an electron-donating methoxy group (**5a** and **5c**) results in a significant decrease of the wavelength of the absorption maximum relative to the compounds with a nitro substituent (**5b** and **5d**). On the other hand, the compounds with the ferrocenyl group at the 4-position of the bridge show a shift of the absorption maxima to longer wavelengths relative to the compounds with the ferrocenyl group at the 1-position. Therefore, the calculated energy gap between HOMO and LUMO in the first position (3.6558 and 2.8194 eV for **5a** and **5b**, respectively) is slightly smaller than in the second position (3.6889 and

[a] In CH_2Cl_2.

2.9889 eV for **5c** and **5d**, respectively) and this gap is greatly increased by the presence of an electron-donating substituent at the aromatic ring. Finally, the homobimetallic complex **5f** shows an absorption spectrum that is very similar to those of complexes **5a** and **5c**, as expected from the similar electron-donor abilities of ferrocenyl and *p*-methoxyphenyl groups (calculated HOMO–LUMO gap of 3.7785 eV for **5f**).

At this point, it is useful to consider the electronic transitions in terms of the molecular orbitals involved. Analysis of the electronic transitions by time-dependent DFT methods (TDDFT) gave essentially identical results for each studied compound between experimental and calculated transitions (summarized in Table 2). The agreement between calculated optical transitions and the experimentally observed results lends credence to the used theoretical level as well as to the attained geometries and the molecular-orbital model developed to explain such optical transitions. In addition, such an agreement confirms the assignation previously made to each optical transition.

Electrochemistry

Compounds **5** are all expected to show electroactivity due both to the Fe^{II}/Fe^{III} couple and the oxidation of the 2-aza-1,3-butadiene bridge. Indeed, monoferrocenyl derivatives **5a**–**d** show two oxidation waves in the range 0–1.5 V vs. SCE; their potentials are collected in Table 3. The first oxidation wave for all compounds is reversible and occurs at potentials close to that of the Fe^{II}/Fe^{III} couple in ferrocene (0.460 V vs. SCE, or 0.530 V vs. decamethylferrocene, DMFc).[23] Therefore, this wave is assigned to the Fe^{II}/Fe^{III} redox couple. The oxidation potentials of the ferrocenyl units of these compounds show a dependence on the position of the 2-aza-1,3-butadiene bridge to which they are attached and also on the electron-donating ability of the aromatic group linked to the bridge. Thus, higher potentials are observed when the ferrocenyl is attached at the 1-position of the bridge and when the substituent of the aromatic ring is a nitro group. In contrast to the first oxidation wave, the second wave is clearly not reversible for **5a**–**c** under the conditions of our experiments, since only the anionic peak appears in the cyclic voltammogram. Taking into account that the *p*-methoxyphenyl moiety is the most "ferrocene-like" group in terms of its electron-donating capability, as demonstrated experimentally by the similarity of the UV/Vis spectra of **5a**, **5c**, and **5f** (vide supra), and also by independent non-linear optical measurements,[24] the 1,4-bis(*p*-methoxyphenyl)-2-aza-1,3-butadiene **5e** was also studied for comparison purposes. The CV of this compound shows two

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

irreversible oxidation waves at 1.084 and 1.440 V vs. DMFc that may be assigned to the oxidation of the N atom of the bridge and the *p*-methoxyphenyl group, respectively. This assignment is based on the fact that when the N atom of **5e** is protonated under acidic conditions the first oxidation peak disappears while the second remains unchanged. On the basis of these observations, the second wave observed in the CVs of compounds **5a**–**c** is also assigned to the oxidation of the 2-aza-1,3-butadiene group, the potential of which varies from 1.090 V to 1.416 V vs. DMFc and also shows a dependence on the substituents of the aromatic ring and on the relative position of the ferrocenyl and aromatic groups. Such an irreversible oxidation wave is not observed for compound **5d**, probably because it appears at a potential more positive than +1.5 V vs. DMFc due to the strong electron-withdrawing character of the nitro group.

Table 3. Cyclic voltammogram data for compounds **5a**–**f** in CH_2Cl_2.

5f	Fc	Fc	0.560 0.770	1.116

[a] $E_{1/2}$ [V] vs. decamethylferrocene.

To gain further insight into the nature of the irreversible oxidation wave, the electrochemical behavior of compounds **5a**–**d** was investigated in the presence of HBF_4. Upon protonation, the potential shift of the ferrocenyl unit present in these compounds was found to be strongly dependent on its position in the 2-aza-1,3-butadiene bridge. When it is placed at the 4-position a $\Delta E_{1/2}$ (L – LH^+) of 70 mV (**5a**) and 80 mV (**5b**) was observed, while when it is placed at the 1-position the corresponding shifts are 300 mV (**5c**) and 320 mV (**5d**). Additionally, in all these cases, the irreversible wave associated with the oxidation of the bridge disappeared upon protonation, except for **5c**, which seems to be due to the oxidation of the methoxy group present in the ring.

The species formed during the irreversible oxidation waves of **5a**–**c** are probably the radical cations centered mainly at the N atom of the 2-aza-1,3-butadiene bridge, species which must be relatively unstable under the experimental conditions used. Although no electrochemical oxidation study of the 2-aza-1,3-butadiene fragment has been reported, this description is based on the fact that the anodic oxidation of the closely related *N*-benzylidene-*p*-anisidine Schiff bases show two irreversible anodic peaks at 1.08–1.25 and 1.41–1.61 V vs. SCE. The peak potentials of the first wave, which show good linearity against the σ^+ values of the substituent in the benzylidene ring, are ascribed to the formation of a radical cation centered at the nitrogen atom, whereas the second peak is attributed to the oxidation of the substituent in the aromatic ring.[25] In this sense, the electrochemical behaviors of compound **5e** and *N*-*p*-methoxybenzylidene-*p*-anisidine are almost identical, since the CV displays two irreversible oxidation peaks at 1.08 and 1.52 V vs. SCE.

The CV of **5f**, which contains two ferrocenyl groups, was recorded in two different experiments. Firstly, the CV (see a in Figure 3) scanned from 0–1 V shows two closely spaced reversible one-electron oxidations corresponding to the oxidation of the ferrocenyl units present in the molecule. Secondly, when the CV was run from 0.0–1.6 V, after the first scan, three oxidation waves were observed: two for the ferrocenyl units and one for the oxidation of the bridge. The cathodic return wave is, in general, higher and thinner than the anodic forward wave, which can be attributed to some adsorption of the oxidized compound onto the electrode surface in the ferrocenium form. The difference between the anodic and cathodic peak potentials (ΔE_p) is lower than the 58 mV value expected for a reversible single-electron wave of an electroactive species in solution at 20 °C (the fully adsorbed redox species would ideally have a ΔE_p value of zero). However, it is important to emphasize that the results obtained in the latter experiment could only be reproduced when the electrode was cleaned before subsequent scans were run. Otherwise, the wave corresponding to the oxidation of the bridge disappears, indicating that the electrode behaves as an insulator in the region in which the azadiene moiety is oxidized. The protonation process of **5f** was also followed by cyclic voltammetry. Upon protonation, the three waves present in the neutral ligand evolve into two waves in the protonated derivative, the latter wave appearing at almost the same potential region as that corresponding to the bridge in the neutral ligand. In order to understand the nature of the unit causing that wave, Osteryoung square-wave voltammetry (OSWV) experiments were carried out by protonation of **5f** (see b in Figure 3). While the neutral ligand exhibits only two oxidation waves at 0.560 and 0.770 V vs. DMFc, stepwise addition of HBF_4 resulted in a clear evolution of the first oxidation wave from 0.560 V to 0.630 V and the disappearance of the second oxidation wave, accompanied by concomitant appearance of a new oxidation wave at 1.060 V. The peak intensity of the new oxidation wave increases with the concentration of the acid added up to until two equivalents. At this point, the original oxidation waves disappear and the new ones reach full development. The resulting two oxidation waves, with a 1:1 ratio and a separation of 0.430 V, are due to the oxidation of the two ferrocenyl moieties in the protonated complex. Again, for reproducibility, it is very important to clean the electrode after each scan.

It is worth mentioning that the difference between the first two reversible oxidation waves in compound **5f** ($\Delta E_{1/2}$ = 210 mV) is much larger than those observed for most bis-ferrocenyl compounds with four-membered π-conjugated bridges, such as 1,4-bis(ferrocenyl)butadiene (129 mV),[14] 1,4-bis(ferrocenyl)butadiyne (120 mV),[10] 1,4-bis(ferrocenyl)-1,4-diazabutadiene (60 mV),[15] and 1,4-bis(ferrocenyl)-2,3-diaza-1,4-dimethylbutadiene (90 mV).[16] The origin of this large $\Delta E_{1/2}$ value must be ascribed to the asym-

metry of the bridge linking the two ferrocenyl groups. Thus, the distinct position of the N atom with respect to the two ferrocenyl groups should perturb the two ferrocenyl moieties to a different extent.

Optically Induced Intramolecular Electron Transfer in $5a^{\cdot+}$–$d^{\cdot+}$

It has been demonstrated that in electrochemically active ferrocenylthiophene derivatives, in which the gap between the metal and the organic bridge oxidation potentials is relatively small, it is possible, upon oxidation of the ferrocenyl group, to induce optically an electron transfer from the thienyl group to the Fe^{III} center.[26] This IET has an associated low-energy ligand-to-metal charge transfer (LMCT) band in the near-IR, which is very similar to those observed in symmetrical mixed-valence complexes. Moreover, it has been reported recently that the electrochemical oxidation of Fe^{II} centers of mono- or bis(ferrocenylethynyl)oligothiophenes, in which the potential difference between the reversible oxidation of the ferrocenyl group and the irreversible oxidation of the thienyl ring varies from 0.38 V to 1.12 V, yields the corresponding radical cations, which also exhibit oligothiophene-to-Fe^{III} charge-transfer LMCT bands in the near-IR region.[27] Taking into account that in compounds **5a**–**d** the potential differences between the two successive oxidation waves are in the range of 0.3–0.7 V (Table 3), and that these values are comparable to those of oligothiophene-substituted ferrocenes, the oxidized ferrocenyl derivatives $\mathbf{5a}^{\cdot+}$–$\mathbf{d}^{\cdot+}$ were considered suitable candidates to study the optically induced IET from the 2-aza-1,3-butadiene bridge to the Fe^{III} center. In favor of such an expectation is the recently reported fact that ferrocenyl derivatives containing a $-CH_2-N(R)-CH_2-$ bridge undergo intramolecular electron transfer between the Fe^{III} center and the nitrogen atom in the electrochemically oxidized state to give an intermediate containing an Fe^{II} center and a nitrogen with a radical cation character.[28]

The generation of the oxidized species derived from **5a**–**d** was performed electrochemically and monitored by absorption spectroscopy. Stepwise coulometric titrations were performed on ca. 2×10^{-3} M solutions of complexes **5a**–**d** in CH_2Cl_2, with $[(nBu)_4N]PF_6$ (0.15 M) as supporting electrolyte, and the absorption spectra were regularly recorded for different average number ($0 \le n \le 1$) of removed electrons. The UV/Vis–near-IR spectroscopic data of $\mathbf{5a}^{\cdot+}$–$\mathbf{d}^{\cdot+}$ are collected in Table 4. The spectra of $\mathbf{5a}^{\cdot+}$–$\mathbf{d}^{\cdot+}$ show three absorption bands, one in the UV region in the range of 371–418 nm of strong intensity, another in the visible region between 518 and 685 nm, with a weaker intensity, and an even weaker additional band in the near-IR region between 973–1219 nm. The latter band is not observed for $\mathbf{5d}^{\cdot+}$. The high-energy absorptions in the UV appear at similar wavelengths and have comparable intensities to those shown by the corresponding neutral complexes **5a**–**d** and, therefore, they are assigned to localized π-π* transitions at the 2-aza-1,3-butadiene group. The absorptions appearing in the visible region are similar to the bands shown by other oxidized ferrocenyl derivatives and, consequently, are assigned to Cp → Fe^{III} ligand-to-metal charge transfer (LMCT) transitions.[21] Finally, the absorption band in the near-IR, which is not observed in the neutral complexes and is likely to take place after the creation of an electronic vacancy in the HOMO, is assigned to a 2-aza-1,3-butadiene → Fe^{III} LMCT transition. This assignment is based on the following considerations: (i) during the course of the oxidations of **5a**–**c** these low-energy bands increase continuously in intensity, achieving a maximum when the oxidation process is complete (see

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Figure 4); (ii) defined isosbestic points at 385 and 487 nm are maintained during the course of the oxidations (see Figure 4); and (iii) similar low-energy transitions have been observed in the near-IR region in other Fe^{III} and Ru^{III} complexes with conjugated oligothiophene ligands[26,27] and with a -CH_2-N(*R*)-CH_2- bridge.[28] Therefore, the absorption bands in the near-IR shown by **5a**$^{\cdot+}$–**c**$^{+}$ correspond to an optically induced electron transfer from the 2-aza-1,3-butadiene to the Fe^{III} center, as schematically shown in Figure 5 using the Marcus–Hush model.[4] We have assumed that during this optical transition one electron from the localized pair of nonbonding electrons on the N atom of the 2-aza-1,3-butadiene bridge is transferred to the Fe^{III} d_π orbital of the ferrocene moiety. This assumption is supported by the presence of a high-energy filled orbital in oxidized complexes **5a**$^{\cdot+}$–**d**$^{+}$ (e.g. HOMO–2 in **5a**$^{\cdot+}$ and HOMO–3 in **5c**$^{\cdot+}$) that is mainly localized on this N atom, as pointed out by theoretical calculations. Such calculations also show an absolute energetic minimum on the potential energy hypersurface essentially corresponding to the respective neutral top after the appropriate geometrical reorganization to redistribute the electronic density. Only a rough correlation with the experimental absorption values was claimed from time-dependent DFT calculations performed on some of these structures (see Table 4), due to the reported inaccuracy of these types of methods in particular cases.[29] Although there is only a rough correlation between the experimental and calculated values of absorption bands for oxidized complexes **5a**$^{\cdot+}$–**d**$^{\cdot+}$, the results of the time-dependent DFT calculations confirmed the assignations of optical transitions previously given for **5a**$^{\cdot+}$–**d**$^{\cdot+}$, based on experimental facts.

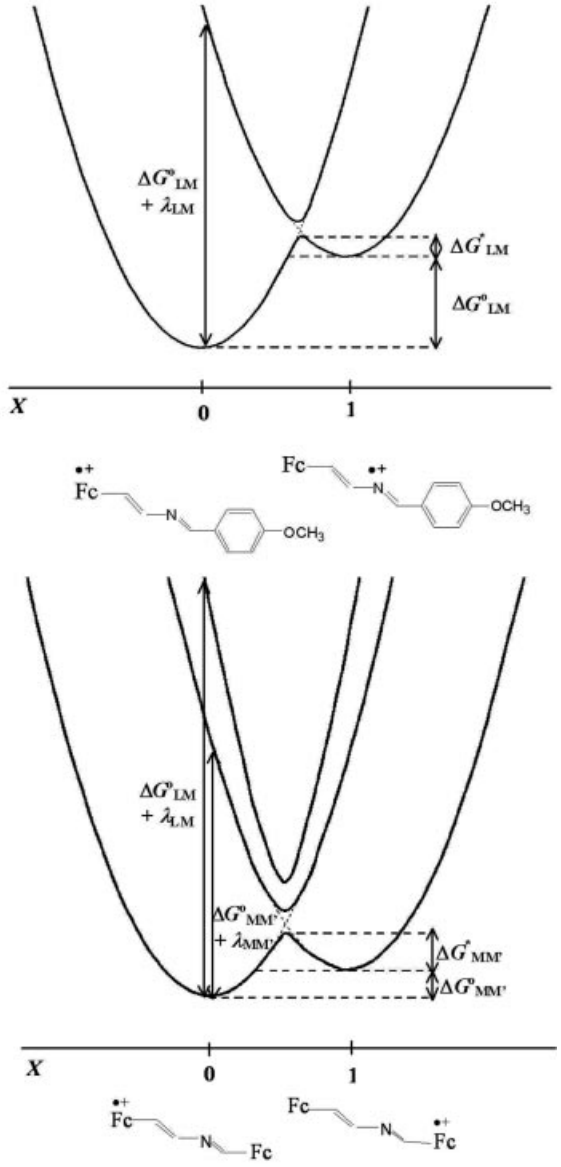

Figure 5. Marcus–Hush model used to describe IET in asymmetric oxidized complexes **5a**$^{\cdot+}$–**d**$^{\cdot+}$ (top) and in oxidized homobimetallic complex **5f**$^{\cdot+}$ (bottom).

The Marcus–Hush model can be used to describe the classical intramolecular electron-transfer process when the electron is coupled between a donor and an acceptor group via a single oscillator having the same frequency in both initial and final states.[4] Originally developed for the interpretation of intervalence charge transfer (IV-CT) bands in extended solids, the Marcus–Hush model has been extended and applied to IV-CT in mixed-valence organometallic[30,31] and organic compounds,[1g,32] as well as to LMCT and metal-to-ligand charge transfer (MLCT) processes in charge-localized asymmetric complexes.[33,34] In accordance with such precedents we have also used the Marcus–Hush model to study the IET of asymmetric complexes **5a**$^{\cdot+}$–**d**$^{\cdot+}$. As schematized in Figure 5, such species exist in two states having the charge/hole localized either on the metal (M) or a particular region of the organic ligand (L), which are separated by the relative free enthalpy $\Delta G°_{LM}$. The electronic coupling between the two electroactive centers (M and L) is measured by the V_{LM} term and the optical transition energy of the LMCT band at its maximum ($h\nu_{max}$; in cm^{-1}), corresponds to the sum of $\Delta G°_{LM}$ and the vertical reorganization energy λ_{LM} (i.e. $h\nu_{max} = \Delta G°_{LM} + \lambda_{LM}$).

The spectral data of LMCT bands of **5a**$^{\cdot+}$–**d**$^{\cdot+}$, summarized in Table 5, can be used to determine the electronic coupling parameter, V_{LM}, and the reorganization energy, λ_{LM}, for each oxidized compound. This was accomplished by deconvoluting the LMCT bands[35] using the classical procedure (see Figure S2 in the Supporting Information) assuming that the effective electron-transfer distance is the distance between the Fe and N atoms. Such distances can be determined from the crystal structures of **5b**, **5d**, and **5f** (5.2 and 3.9 Å for the complexes with the ferrocenyl groups attached to the 4- and 1-positions, respectively). The relative free enthalpies of the two vibronically localized electronic states for compounds **5a**–**c** can be estimated, in a first approximation, from the difference of electrochemical potentials corresponding to the oxidation of the 2-aza-1,3-butadiene center (L) and to the ferrocenyl center (M) of neutral complexes. Due to the experimental impossibility of measuring the L^0/L^{+1} couple of the 2-aza-1,3-butadiene when it is linked to a neutral ferrocenyl group, the corresponding oxidation potential was assumed to be 40 mV less positive than the anionic peak of compound **5e**, observed at +1.084 V, since the *p*-methoxyphenyl and ferrocenyl groups have similar electron-donor capabilities but the first group is not electrochemically active at potentials lower than +1.4 V (vide supra). An inspection of the resulting V_{LM} val-

ues for complexes **5a**–**c** (Table 5) shows that electronic couplings between the ferrocenyl and the 2-aza-1,3-butadiene ligand are moderate, such that all these complexes belong to class II.[8] In addition, the electronic coupling of complexes **5a**–**c** is influenced by the position to which the ferrocenyl is attached, as well as on the electron-donor capability of the substituent on the phenyl group. It should be noted from the spectral analysis that the charge-transfer transition oscillator strengths clearly increase for complexes **5a**–**d**. Complex **5d** apparently does not show any LMCT band. This can be ascribed to the presence of a nitro group linked to the 4-position of the bridge, which drains some electron density from the 2-aza-1,3-butadiene chain, thus lowering the effective overlap between diabatic orbitals and decreasing the probability of the transition. This effect has indeed been predicted theoretically for other electron-withdrawing groups, such as the cyano group.[36]

Intramolecular Electron Transfer in the Mixed-Valence Compound $5f^{+\cdot}$

Oxidized species derived from **5f** were generated electrochemically and their formation followed by absorption spectroscopy. Thus, a stepwise coulometric titration was performed on a 2×10^{-3} M solution of **5f** in CH_2Cl_2, with $[(n\text{Bu})_4\text{N}]PF_6$ (0.15 M) as supporting electrolyte, and absorption spectra were regularly recorded for a different average number ($0 \le n \le 2$) of removed electrons. Figure 6a shows the evolution of the spectra during the oxidation of **5f** in the $0 \le n \le 1$ range, with an increase of the Cp → Fe^{III} LMCT band appearing at 547 nm, characteristic of a ferrocenium ion, and a decrease of the band that corresponds to a localized excitation of a ferrocene group at 478 nm. Along with the changes of these bands, the appearance and maintenance of two well-defined isosbestic points at 425 and 501 nm was observed. Nevertheless, the most interesting feature is that during the oxidation of **5f** two new weak and broad bands centered at 764 nm (band A) and at 1250 nm (band B) appear, and these increase continuously in intensity until one electron has been removed (i.e. when the formation of $\mathbf{5f}^{+\cdot}$ is complete). As also shown in Figure 6, on removing more electrons ($1 \le n \le 2$) the intensity of band A continues to increase until its intensity has doubled, while band B decreases until it disappears (when the dication $\mathbf{5f}^{2+}$ is completely formed). At the same time, another new weak and broad band at 971 nm (band C) increases until the fully oxidized species $\mathbf{5f}^{2+}$ is formed. Table 4 collects all the spectroscopic data for oxidized complexes $\mathbf{5f}^{+\cdot}$ and $\mathbf{5f}^{2+}$. The deconvolution of the experimental spectra of $\mathbf{5f}^{+\cdot}$, performed on spectral intensity times wavenumber vs. wavenumber, assuming Gaussian shapes (Figure 6c), allows an accurate determination of the position, width, and intensity of bands A and B, which are gathered in Table 5.[35,37] These spectral parameters are relevant for the characterization of intramolecular electron transfer in $\mathbf{5f}^{+\cdot}$

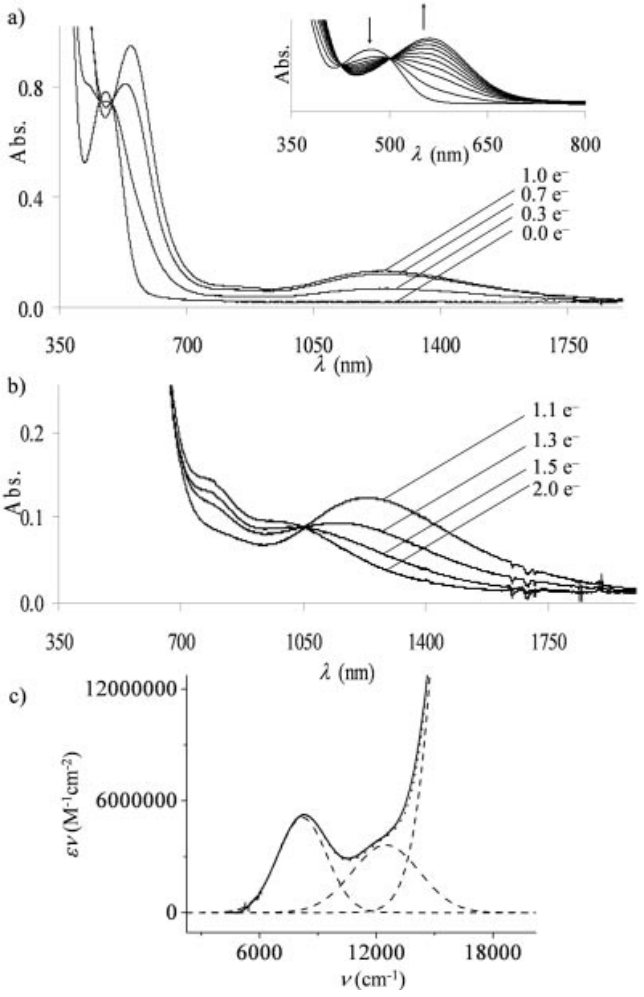

Figure 6. Evolution of Vis-near-IR spectra upon oxidation of **5f**: a) oxidation of **5f** until the maximum ($n = 1$) of the mixed-valence species $\mathbf{5f}^{+\cdot}$ is achieved. Inset: Expanded spectra of the visible region showing the two isosbestic points; b) oxidation until the maximum ($n = 2$) of the fully oxidized species $\mathbf{5f}^{2+}$ is achieved; c) deconvolution of the NIR spectrum of the $\mathbf{5f}^{+\cdot}PF_6^{-\cdot}$ salt. The experimental spectrum was deconvoluted by means of three Gaussian functions (dashed lines) using spectral intensity times wavenumber vs. wavenumber. The sum of the dashed lines (dotted line) closely matches the experimental spectrum (solid line).

The presence of several near-IR bands in the spectrum of a mixed-valence complex is not uncommon, and their occurrence is generally explained by one of three different possible causes.[38,39] One could be the presence of a strong spin-orbit coupling effect, which becomes important only for complexes containing third-row transition metals.[38] A second source could be the presence of a double-exchange mechanism,[39] a mechanism that becomes more probable as the bridge length and the level of π-orbitals increases. Finally, such multiple near-IR bands might be caused by the presence of a bridge with accessible redox state levels, as has been recently proposed to explain the rich absorption spectrum of certain mixed-valence compounds with redox-active bridges.[1g] Based on the behaviors of $\mathbf{5a}^{+\cdot}$–$\mathbf{c}^{+\cdot}$, the latter source seems to be the most probable origin for the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

two near-IR bands of **5f**$^{+\cdot}$. Accordingly, and also based on the spectral evolution observed during the oxidation of **5f**, the band A is assigned to a 2-aza-1,3-butadiene → Fe^{III} LMCT transition, which implies an electron transfer from the N atom of the 2-aza-1,3-butadiene bridge to the Fe^{III} site linked at the 4-position of the bridge, whereas band B is attributed to the bridge-mediated superexchange between the two coupled iron sites (M and M′) − an IET between the two iron sites.

In order to estimate the effectiveness of both IET pathways we used the Marcus–Hush model, as schematized in Figure 5, where the reorganization energies of both transitions, λ_{LM} and $\lambda_{MM'}$, were determined from the absorption maxima of the bands A and B. For the free-energy difference between the two electronic states of **5f**$^{+\cdot}$ having the charge localized on each Fe site we used, in a first approximation, the value of $\Delta G°_{MM'}$ (1113 cm^{-1}) obtained from the difference of the first oxidation potentials of **5c** and **5f**. For $\Delta G°_{LM}$ we used a value of 3904 cm^{-1}, which was determined by employing the same approximations as for **5a**$^{+\cdot}$–**c**$^{+\cdot}$ (vide supra). The spectral parameters of bands A and B were also used to determine the effective electronic coupling parameters V_{LM} and $V_{MM'}$, taking as effective electron-transfer distances those measured between the N and the two Fe atoms in the crystal structure of **5f**. Both effective electronic couplings are moderate, indicating that the mixed-valence **5f**$^{+\cdot}$ also belongs to class II.[8] The relative values of V_{LM} and $V_{MM'}$ indicate that the IET may proceed through the two different pathways. The IET mediated by the bridge through a superexchange is apparently less effective than that in which the electron jumps into the bridge. It is also of interest to compare the effective electronic coupling between the two iron sites of **5f**$^{+\cdot}$ with that of the mixed-valence compound derived from 1,4-diferrocenyl-1,3-butadiene, i.e., $[Fc(CH=CH)_2Fc]^{+\cdot}$.[14] The latter compound has a $V_{MM'}$ of 430 cm^{-1}, which is larger than that of **5f**$^{+\cdot}$, suggesting that the replacement of an sp^2 C atom by an N atom in the 1,3-butadiene bridge results in a decrease of the interaction between both ferrocenes, probably because of a poorer overlap between the diabatic orbitals of the two ferrocenes with the orbital of the bridge involved in the superexchange mechanism. Indeed, in both types of systems the HOMO of the neutral molecule is the bridge-centered superexchange involved MO, which can be considered as being formed by a combination of the higher energy MO of π-type at the bridge and two $3e_2'$-based MOs of both ferrocene subunits (Figure 7). At the level of theory used, the latter is 0.953 eV higher in energy than the HOMO in 1,3-butadiene, but 1.587 eV higher than HOMO–1 in the 2-aza-1,3-butadiene, the HOMO being that containing the electron lone-pair at the N atom. (See Figure S3 in the Supporting Information). This leads to a poorer, although still significant, overlap between the diabatic orbitals of the two ferrocenes with the orbital of the bridge involved in the superexchange mechanism.

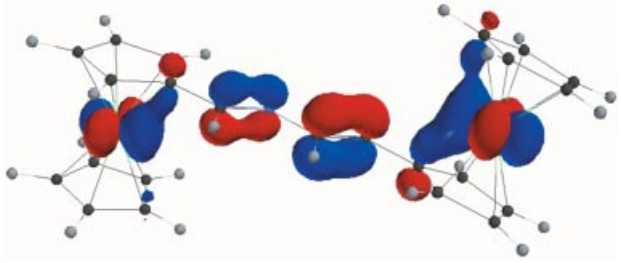

Figure 7. Superexchange-responsible MO (HOMO) in compound **5f** at a 0.050 isovalue.

For the mixed-valence **5f**$^{+\cdot}$ the free energy difference between the two electronic states having the charge localized on each Fe site is 3.2 kcal mol^{-1}. This relatively large value suggests that, at 300 K, the population of the state with the positive charge located on the iron attached to the 4-position of the 2-aza-1,3-butadiene bridge is dominant, with just a very small population (<0.1%) of the state with the charge on the other iron site. In addition, we can make a crude estimation of the thermal activation energy barrier for the interconversion of such two states, using the Marcus–Hush model.[40,41] The resulting thermal energy barrier of about 7.4 kcal mol^{-1} suggests a rate constant of about 10^8 s^{-1} at 300 K and hence any spectroscopic technique with a time scale faster than 10^9 s^{-1} should show the valence-localized mixed-valence complex **5f**$^{+\cdot}$, with the positive charge trapped on the Fe site attached at the 4-position of the bridge, at this temperature. This effect would be even more pronounced at temperatures below 100 K, so that with spectroscopic techniques such ^{57}Fe Mössbauer and EPR the valence should appear to be localized, as is indeed the case (see Supporting Information).

Conclusion and Perspectives

The presence of low-energy LMCT and IV-CT bands in the oxidized forms **5a**$^{+\cdot}$–**d**$^{+\cdot}$ and **5f**$^{+\cdot}$ of mono- and bis-ferrocenyl derivatives attached to a 2-aza-1,3-butadiene bridge indicates the existence of optically induced IETs between the metal units and the organic linkers. This important result demonstrates that the introduction of a heteroatom, like the N atom, in a conjugated organic bridge is an attractive strategy for promoting IET through an alternative pathway. This finding may have implications in the design of molecular electron-transfer materials and, in particular, in the development of new molecular devices that act as electronic relays which promote IET over large distances. Efforts in this direction are in progress in our laboratories using symmetrical compounds with two electroactive units attached to oxidizable, symmetrical, and conjugated organic bridges containing two heteroatoms.

Experimental Section

General Procedures: All reactions were carried out under N_2 and using solvents which were dried by routine procedures. All melting points were determined on a Kofler hot-plate melting point apparatus and are uncorrected. IR spectra were determined as Nujol emulsions or films on a Nicolet Impact 400 spectrophotometer. UV/Vis–near IR spectra were recorded on a Varian Cary 5 E spec-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trophotometer. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC200, 300, or 400 spectrometer (200, 300, or 400 MHz for ^{1}H). Chemical shifts are referenced to signals of tetramethylsilane in the case of ^{1}H and ^{13}C NMR spectra and to 85% aqueous phosphoric acid in the case of ^{31}P NMR spectra. The EI and FAB$^+$ mass spectra were recorded on a Fisons AUTOSPEC 500 VG spectrometer, using 3-nitrobenzylalcohol as matrix. EPR spectra were obtained with an X-Band Bruker ESP 300E spectrometer equipped with a TE_{102} microwave cavity, a Bruker variable temperature unit, a field frequency lock system Bruker ER 033 M; line positions were determined with an NMR Gaussmeter Bruker ER 035 M. The modulation amplitude was kept well below the line width, and the microwave power was well below saturation. Crystallographic measurements were made at 233(2) K on a Bruker diffractometer equipped with an area detector positioned at the window of a rotating anode generator using Mo-K_α radiation (λ = 0.71073 Å). Mössbauer spectra were recorded on an ES-Technology MS-105 spectrometer, with a 100 MBq ^{57}Co source, in a rhodium matrix. Solid samples were prepared by grinding with boron nitride. Spectra were referenced to natural iron at 298 K. Parameters were obtained by fitting the data with Lorentzian lines; errors <0.01 mm s^{-1}. Microanalyses were performed on a Perkin–Elmer 240C instrument. The cyclic voltammetric measurements were performed on a QUICELTRON potentiostat/galvanostat controlled by a personal computer and driven by dedicated software. Cyclic voltammetry was performed with a conventional three-electrode configuration consisting of platinum working and auxiliary electrodes and an SCE reference electrode. The experiments were carried out with a 10^{-3} M solution of sample in dry CH_2Cl_2 containing 0.1 M $[N(nC_4H_9)_4]ClO_4$ as supporting electrolyte. Deoxygenation of the solutions was achieved by bubbling nitrogen for at least 10 min and the working electrode was cleaned after each run. The cyclic voltammograms were recorded with a scan rate increasing from 0.05 to 1.00 V s^{-1}. The square-wave voltammograms were recorded before and after addition of sequential additions of an aliquot of 0.1 equiv. of 2.5×10^{-2} M solutions of $HBF_4 \cdot Et_2O$ in CH_3CN. ΔE_s = 4 mV, ΔE_p = 25 mV, and f = 15 Hz. Decamethylferrocene (DMFe) (–0.07 V vs. SCE) was used as an internal reference both for potential calibration and for reversibility criteria. Oxidations were performed by electrolysis in a three-electrode cell under argon using dry CH_2Cl_2 as solvent and 0.15 M $[N(n\text{-}C_4H_9)_4]ClO_4$ as supporting electrolyte. The progress of the oxidation was followed coulometrically (or chronoamperometrically) by 263A of EG&PAR potentiostat-galvanostat. The reference electrode and the counter electrode were separately immersed in the solvent containing the supporting electrolyte and isolated from the bulk solution by a glass frit. The working electrode was a platinum grid. UV/Vis–near IR absorption spectra were regularly recorded by transferring a small aliquot of the solution contained in the electrochemical cell into a UV quartz cell for a different average number of removed electrons.

Theoretical Calculations: Geometry optimizations were performed with the Spartan'02 package (Spartan'02, build 119, Wavefunction Inc., Irvine, CA). For neutral compounds **5a**–**f** a preliminary optimization was done at the semi-empirical PM3(d) level and the obtained geometries were then refined at the DFT level of theory,[42] which has proved to be remarkably successful in reproducing experimental ground-state geometries and rotational barriers for ferrocenes.[43] The B3LYP functional[44] (Becke's three-parameter hybrid functional[45] with the Lee–Yang–Parr[46] correlation functional) and the 3-21G* basis set were used. Harmonic frequency calculations verified the nature of the stationary points as minima (all real frequencies).[47] The geometry of oxidized radical-cation species **5a**$^{+\cdot}$, **5c**$^{+\cdot}$, **5d**$^{+\cdot}$, and **5f**$^{+\cdot}$ were optimized starting from the corresponding neutral minimized structures with the appropriate charge and multiplicity constraints. Structure **5b**$^{+\cdot}$ was not calculated due to systematic failures in the SCF convergence. Similarly, **5f**$^{+\cdot}$ was used as the initial geometry for the fully oxidized **5f**$^{2+}$. Time-dependent DFT methods (TDDFT), as contained within the Gaussian 98 program suite,[48] performed as an SPE calculation at the same level as the minimized structures, were employed to study the excited states and model the UV/Vis–NIR electronic transitions in both neutral and oxidized species.

General Procedure for the Preparation of Diethyl *N*-Arylidene- and [(Ferrocenylmethylidene)aminomethyl]phosphonates 3: A mixture of diethyl aminomethylphosphonate (0.78 g, 4.64 mmol), an equimolar amount of the appropriate aldehyde **2**, and *p*-toluenesulfonic acid (0.01 g, 0.058 mmol) in dry benzene (50 mL) was stirred at room temperature for 4 h. Then, the flask was fitted with a Dean–Stark trap and a reflux condenser and heated overnight, atr reflux temperature, with constant removal of water. The reaction mixture was allowed to cool to room temperature and the solvent was removed under vacuum to give the corresponding diethyl phosphonates **3** as colored oils, which were used without further purification in the next step.

Diethyl [(*p*-Methoxybenzylidene)aminomethyl]phosphonate (3a): Yield: 95%. IR (Nujol): $\tilde{\nu}$ = 1641, 1609, 1577, 1524, 1444, 1422, 1396, 1316, 1252, 1166, 1102, 969 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.34 (t, $^4J_{H,P}$ = 6.5 Hz, 6 H), 3.84 (s, 3 H), 4.07 (d, $^1J_{H,P}$ = 16.8 Hz, 2 H),4.19–4.09 (m, 4 H), 6.91 (d, J = 8.6 Hz, 2 H), 7.68 (d, J = 8.6 Hz, 2 H), 8.22 (d, $^4J_{H,P}$ = 4.7 Hz, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 16.5 (d, $^3J_{P,C}$ = 5.6 Hz, CH_3), 55.3 (CH_3O), 57.4 (d, $^1J_{P,C}$ = 152.6 Hz, NCH_2), 62.4 (d, $^2J_{P,C}$ = 6.7 Hz, OCH_2), 114.0 (CH_{Ar}), 128.7 (q), 130.0 (CH_{Ar}), 162.0 (q), 164.9 (d, $^3J_{P,C}$ = 16.0 Hz, CH=N) ppm. ^{31}P NMR ($CDCl_3$): δ = 22.68 ppm. EIMS: m/z (%) = 285 (100) [M$^+$], 152 (82), 148 (61), 125 (90), 121 (80), 97 (44), 91 (19), 78 (25).

Diethyl [(*p*-Nitrobenzylidene)aminomethyl]phosphonate (3b): Yield: 85%. IR (Nujol): $\tilde{\nu}$ = 1654, 1604, 1523, 1454, 1404, 1360, 1266, 1097, 1016, 966, 847 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.34 (t, $^4J_{H,P}$ = 6.9 Hz, 6 H), 4.01–4.24 (m, 6 H), 7.91 (d, J = 8.0 Hz, 2 H), 8.26 (d, J = 8.0 Hz, 2 H), 8.40 (d, $^4J_{H,P}$ = 5.1 Hz, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 16.4 (d, $^3J_{P,C}$ = 5.7 Hz, CH_3), 57.7 (d, $^1J_{P,C}$ = 152.7 Hz, NCH_2), 62.7 (d, $^2J_{P,C}$ = 6.6 Hz, OCH_2), 123.8 (CH_{Ar}), 130.5 (CH_{Ar}), 140.9 (q), 149.2 (q), 163.2 (d, $^3J_{P,C}$ = 22.0 Hz, CH=N) ppm. ^{31}P NMR ($CDCl_3$): δ = 21.77 ppm. EIMS: m/z (%) = 300 (36) [M$^+$], 163 (60), 152 (96), 125 (82), 108 (100), 90 (95), 81 (42).

Diethyl [(Ferrocenylmethylidene)aminomethyl]phosphonate (3c): Yield: 94%. IR (Nujol): $\tilde{\nu}$ = 1642, 1473, 1448, 1398, 1241, 1166, 1035, 972, 828, 778 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.38 (t, $^4J_{H,P}$ = 3.3 Hz, 6 H), 3.92 (d, 2 H, $^2J_{H,P}$ = 18 Hz), 4.08–4.25 (m, 4 H), 4.23 (s, 5 H), 4.36 (t, J = 1.8 Hz, 2 H), 4.64 (t, J = 1.8 Hz, 2 H), 8.19 (d, $^4J_{H,P}$ = 4.8 Hz, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 16.3 (d, $^3J_{P,C}$ = 5.7 Hz, CH_3), 57.2 (d, $^1J_{P,C}$ = 150.7 Hz, NCH_2), 62.4 (d, $^2J_{P,C}$ = 6.5 Hz, OCH_2), 68.5 (2 × CH, Cp), 69.1 (5 × CH, Cp), 70.6 (2 × CH, Cp), 79.7 (d, $^4J_{P,C}$ = 9 Hz, q, Cp), 166.2 (d, $^3J_{P,C}$ = 19.5 Hz, CH=N) ppm. ^{31}P NMR ($CDCl_3$): δ = 22.77 ppm. EIMS: m/z (%) = 363 (86) [M$^+$], 298 (100), 224 (39), 260 (48), 121 (63), 81 (25), 65 (9), 56 (24).

General Procedure for the Preparation of 1,4-Disubstituted-2-aza-1,3-butadienes 5: *n*-Butyllithium (1.6 M in hexane, 3 mL) was added dropwise to a solution of the appropriate diethyl phosphonate **3** (4.64 mmol) in dry THF (20 mL) at –78 °C under nitrogen. A solution of an equimolar amount of the appropriate aldehyde **4** (4.64 mmol) in dry THF (10 mL) was added dropwise to this stirred

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solution and the mixture was stirred for 1.5 h. Then, the reaction mixture was allowed to reach room temperature and was heated at reflux temperature overnight. After the solution had cooled to room temperature, the solvent was evaporated under reduced pressure and the crude product was stirred with water (50 mL) and then extracted with dichloromethane (4 × 50 mL). The combined organic layers were dried with anhydrous Na_2SO_4 and, after filtration, the solution was concentrated to dryness to give a crude product which was crystallized from dichloromethane/diethyl ether (1:10).

4-Ferrocenyl-1-(*p*-methoxyphenyl)-2-aza-1,3-butadiene (5a): Yield: 90%; m.p. 175–176 °C. IR (Nujol): $\tilde{\nu}$ = 1605, 1511, 1456, 1395, 1240, 1162, 1107, 1074, 1046, 1024, 990, 985, 830, 741 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.86 (s, 3 H), 4.15 (s, 5 H), 4.28 (t, J = 1.6 Hz, 2 H), 4.43 (t, J = 1.6 Hz, 2 H), 6.70 (d, J = 14.0 Hz, 1 H), 6.94 (d, J = 8.0 Hz, 2 H), 7.18 (d, J = 14.0 Hz, 1 H), 7.75 (d, J = 8.0 Hz, 2 H), 8.18 (s, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 55.3 (CH_3O), 67.0 (2 × CH, Cp), 69.0 (2 × CH, Cp), 69.3 (5 × CH, Cp), 81.5 (q, Cp), 114.2 (CH_{Ar}), 128.3 (CH=CH), 129.4 (q), 129.9 (CH_{Ar}), 139.7 (CH=CH), 158.0 (q), 161.5 (CH=N) ppm. EIMS: m/z (%) = 345 (100) [M^+], 280 (77), 278 (10), 121 (31), 56 (23). $C_{20}H_{19}FeNO$ (345.22): calcd. C 69.58, H 5.55, N 4.06; found C 69.35, H 5.40, N 4.15.

4-Ferrocenyl-1-(*p*-nitrophenyl)-2-aza-1,3-butadiene (5b): Yield: 50%; m.p. 223–224 °C. IR (Nujol): $\tilde{\nu}$ = 1600, 1514, 1454, 1335, 1182, 1109, 1030, 957, 745, 698 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 4.12 (s, 5 H), 4.32 (t, J = 1.6 Hz, 2 H), 4.42 (t, J = 1.6 Hz, 2 H), 6.87 (d, J = 13.0 Hz, 1 H), 7.21 (d, J = 13.0 Hz, 1 H), 7.89 (d, J = 8.1 Hz, 1 H), 8.22 (s, 1 H), 8.23 (d, J = 8.1 Hz, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 67.5 (2 × CH, Cp), 69.6 (5 × CH, Cp), 69.9 (2 × CH, Cp), 80.4 (q), 124.2 (CH_{Ar}), 128.5 (CH_{Ar}), 134.0 (CH=CH), 138.6 (CH=CH), 142.3 (q), 148.5 (q), 154.7 (CH=N) ppm. EIMS: m/z (%) = 360 (100) [M^+], 330 (19), 295 (23), 265 (21), 192 (34), 165 (30), 121 (62). $C_{19}H_{16}FeN_2O_2$ (360.19): calcd. C 63.36, H 4.48, N 7.78; found C 63.54, H 4.35, N 7.69.

1-Ferrocenyl-4-(*p*-methoxyphenyl)-2-aza-1,3-butadiene (5c): Yield: 85%; m.p. 102–103 °C. IR (Nujol): $\tilde{\nu}$ = 1645, 1605, 1565, 1514, 1250, 1176, 1107, 1038, 969, 826 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.82 (s, 3 H), 4.22 (s, 5 H), 4.47 (t, J = 1.6 Hz, 2 H), 4.73 (t, J = 1.6 Hz, 2 H), 7.34 (d, J = 14.0 Hz, 1 H), 7.40 (d, J = 8.0 Hz, 2 H), 7.82 (d, J = 14.0 Hz, 1 H), 7.88 (d, J = 8.0 Hz, 2 H), 8.21 (s, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 55.2 (CH_3O), 68.7 (2 × CH, Cp), 68.9 (5 × CH, Cp), 71.1 (2 × CH, Cp), 80.4 (q), 114.1 (CH_{Ar}), 127.5 (CH_{Ar}), 127.6 (CH=CH), 129.3 (q), 141.0 (CH=CH), 159.0 (q), 161.5 (CH=N) ppm. EIMS: m/z (%) = 345 (100) [M^+], 318 (40), 279 (24), 278 (14), 186 (43), 121 (66), 56 (39). $C_{20}H_{19}FeNO$ (345.22): calcd. C 69.58, H 5.55, N 4.06; found C 69.33, H 5.28, N 4.21.

1-Ferrocenyl-4-(*p*-nitrophenyl)-2-aza-1,3-butadiene (5d): Yield: 40%; m.p. 182–183 °C. IR (Nujol): $\tilde{\nu}$ = 1561, 1508, 1438, 1337, 1225, 1177, 1123, 1107, 1033, 750, 696 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 4.24 (s, 5 H), 4.56 (t, J = 1.6 Hz, 2 H), 4.78 (t, J = 1.6 Hz, 2 H), 6.87 (d, J = 13.4 Hz, 1 H), 7.52 (d, J = 8.0 Hz, 2 H), 7.55 (d, J = 13.4 Hz, 1 H), 8.18 (d, J = 8.0 Hz, 2 H), 8.35 (s, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 69.4 (2 × CH, Cp), 69.6 (5 × CH, Cp), 72.1 (2 × CH, Cp), 79.6 (q), 124.2 (CH_{Ar}), 125.2 (CH=CH), 126.6 (CH_{Ar}), 143.7 (q), 146.4 (q), 146.5 (CH=CH), 165.9 (CH=N) ppm. EIMS: m/z (%) = 360 (100) [M^+], 333 (22), 192 (22), 186 (34), 165 (27), 120 (63), 56 (33). $C_{19}H_{16}FeN_2O_2$ (360.19): calcd. C 63.36, H 4.48, N 7.78; found C 63.19, H 4.29, N 7.62.

1,4-Bis(*p*-methoxyphenyl)-2-aza-1,3-butadiene (5e): Yield: 85%; m.p. 170–172 °C. IR (Nujol): $\tilde{\nu}$ = 1647, 1609, 1553, 1510, 1454, 1423, 1373, 1311, 1280, 1255, 1174, 1111, 1024, 986, 943, 875, 813 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.80 (s, 3 H), 3.84 (s, 3 H), 6.86 (d, J = 8.0 Hz, 2 H), 6.91 (d, J = 14.1 Hz, 1 H), 6.94 (d, J = 8.0 Hz, 2 H), 7.40 (d, J = 8.0 Hz, 2 H), 7.44 (d, J = 14.1 Hz, 1 H), 7.76 (d, J = 8.0 Hz, 2 H), 8.25 (s, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 55.2, 55.3, 114.0, 114.1, 127.8, 129.2, 129.4, 130.0, 140.4, 159.2, 159.7, 161.8 ppm. EIMS: m/z (%) = 267 (100) [M^+], 252 (44), 236 (28), 160 (69), 121 (35), 91 (28). $C_{17}H_{17}NO_2$ (267.33): calcd. C 76.38, H 6.41, N 5.24; found C 76.20, H 6.67, N 5.12.

1,4-Bis(ferrocenyl)-2-aza-1,3-butadiene (5f): Yield: 87%; m.p. 253–255 °C. IR (Nujol): $\tilde{\nu}$ = 1649, 1580, 1102, 1023, 1041, 1003, 966, 829, 810 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 4.15 (s, 5 H), 4.22 (s, 5 H), 4.27 (s, 2 H), 4.40 (s, 2 H), 4.45 (s, 2 H), 4.72 (s, 2 H), 6.60 (d, J = 13.2 Hz, 1 H), 7.05 (d, J = 13.2 Hz, 1 H), 8.11 (s, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 66.80 (2 × CH, Cp), 68.61 (2 × CH, Cp), 69.00 (2 × CH, Cp), 69.20 (10 × CH, Cp), 71.00 (2 × CH, Cp), 80.81 (q, Cp), 82.11 (q, Cp), 126.32 (CH=), 140.32 (=CH-N), 159.82 (CH=N) ppm. EIMS: m/z (%) = 423 (100) [M^+], 358 (60), 212 (32), 186 (28), 121 (64), 56 (25). $C_{23}H_{21}Fe_2N$ (423.12): calcd. C 65.29, H 5.00, N 3.31; found C 65.40, H 4.88, N 3.50.

Preparation of the Mixed-Valence Compound $5f^+I_3^-$: A sample of this mixed-valence compound was prepared by adding a solution of iodine (0.030 g, 0.12 mmol) in dry benzene (5 mL) to a solution of 1,4-diferrocenyl-2-aza-1,3-butadiene (0.1 g, 0.24 mmol) in the same solvent (50 mL). The reaction mixture was stirred at room temperature under nitrogen for 1 h and the dark-purple microcrystals formed were collected by filtration and washed with three portions of benzene and one portion of diethyl ether. The solid obtained was dried in a dessicator overnight. FAB MS: m/z (%) = 424 (100) [M^+ + 1]. $C_{23}H_{21}Fe_2I_3N$ (803.82): calcd. C 34.33, H 2.61, N 1.74; found C 34.23, H 2.38, N 1.58.

Supporting Information: Crystal data of **5b**, **5d**, and **5f**, optical absorption data of oxidized species and the procedure for their analysis with the Marcus–Hush model, and ^{57}Fe Mössbauer and EPR spectra are provided.

Acknowledgments

We gratefully acknowledge the financial support of the DGI, Ministerio de Ciencia y Tecnología, Spain (projects MAT2003-04699 and CTQ2004-02201), the Fundación Séneca (CARM) (project no. PB/72/FS/02), and DGR, Catalunya (2001 SGR00362). The Biotechnology and Biological Sciences Research Council, UK, is also thanked for funding (D.J.E.).

[37] The proportion of mixed-valence species at half-oxidation (*P*), where $P = K_c^{1/2}/(2 + K_c^{1/2})$ is generally used to compute the intensity of corrected spectra. The comproportionation constant, K_c, which is related to the thermodynamic stability of the mixed-valence compound, of the equilibrium of comproportionation, $[Fe^{II}\text{-L-}F^{II}] + [Fe^{III}\text{-L-}F^{III}] \leftrightharpoons 2[Fe^{II}\text{-L-}F^{III}]$, was calculated for **5f** from the electrochemical data, giving a value of 3.6×10^3. With such a high value of K_c, *P* is almost 100% so that the dependency on K_c is very small and it is not necessary to correct the intensity of the spectrum.

[39] a) D. E. Richardson, H. Taube, *J. Am. Chem. Soc.* **1983**, *105*, 40–51; b) J. Halpern, L. E. Orgel, *Discuss. Faraday Soc.* **1960**, *29*, 32–41.

[40] According to Hush and Marcus, for symmetrical weakly coupled class II mixed-valence complexes the activation barrier to electron transfer is given by $\Delta G_{MM'}^* = \lambda_{MM'}/4 - V_{MM'} + (V_{MM'}^2/\lambda_{MM'})$; see ref.[41]. With the parameters given in Table 5 for $\mathbf{5f}^{+\cdot}$, a value of $\Delta G_{MM'}^* + \Delta G^\circ_{MM'} = 7.4$ kcal mol^{-1} is obtained for the 4-Fe^{3+} + 1-Fe^{2+} → 4-Fe^{2+} + 1-Fe^{3+} process. The corresponding first-order rate constant (k_{th})can be calculated from $k_{th} = k \cdot \nu_n \cdot \exp(-\Delta G_{MM'}^*/RT)$ where $k = 1$, since the reaction is adiabatic, and the nuclear frequency factor, ν_n, is $2.00 \times 10^{+13}$ s^{-1}, as determined from $\nu_n = [2(V_{MM'})^2/h] \cdot [(\pi^3/\lambda_{MM'}RT)^{1/2}]$. This gives a value for k_{th} of $8.8 \times 10^{+7}$ s^{-1} at 300 K.

A series of new titanocene phosphanes **3**–**6** have been prepared by replacing both chloride atoms at the titanium atom of the complexes [$TiCl_2(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4(CH_2)_2PR_2\}$] (**1**: R = Ph; **2**: R = Cy) by sodium fluoride or sodium benzoate in two-phase systems. Treatment of these new metalloligands with the binuclear complex [(*p*-cymene)$RuCl_2]_2$ affords the targeted titanocene difluoride and titanocene dibenzoate bimetallic ruthenium complexes **8**–**11**. The first chiral Ti–Ru bimetallic complex **12** bearing a binaphthyloxy ligand at the titanium centre has been synthesised in this way. In each series, an X-ray crystal structure has been determined.

Introduction

Complexes containing early as well as late transition metals are particularly attractive materials owing to their potential application in homogeneous catalysis.[1–3] Indeed, the coordination of the substrate to one of the two metals may increase its reactivity towards the other. Such compounds, which often show a cooperative effect, may constitute a new class of catalysts that are able to improve the efficiency of known processes or to give new reactions. Nevertheless, probably because of their laborious access, only a few early–late bimetallic complexes have been tested in catalysis.[4] Our strategy to construct such systems was to first synthesise a titanocene dichloride phosphane complex and then to treat these early metal ligands with the binuclear complex [(*p*-cymene)$RuCl_2]_2$.[5] We obtained a series of Ti–Ru heterobimetallic complexes in sufficient amounts to carry out a screening of their catalytic behaviour.[6–8] Another aspect of interest of this approach is the structural flexibility of the titanocene phosphane as regards a possible tuning of the bimetallic complexes towards the target catalytic reaction. Indeed, by replacing the two chloride atoms on the titanium atom by other ligands it should be possible to design new phosphanes and therefore to expand substantially this class of bimetallic complexes. Here we report the synthesis and the characterisation of a series of new Ti–Ru bimetallic complexes by using this strategy.

Results and Discussion

Titanocene dibenzoate can be synthesised, in good yields, from the reaction of titanocene dichloride with sodium benzoate in a biphasic system ($CHCl_3/H_2O$).[9] Therefore we carried out the reaction with the titanocene dichloride phosphanes **1** and **2** under similar conditions (Scheme 1). The colour of the reaction mixture, initially red, turned slowly to orange. After this treatment, titanocene dibenzoate phosphanes **3** and **4**, respectively, were isolated as orange powders in good yields. The NMR spectroscopic data of **3** and **4** are very similar to their dichloride counterparts **1** and **2**, with additional resonances for the benzoate hydrogens. The IR spectra exhibit two (COO) stretching bands around 1630 and 1320 cm^{-1}, consistent with the monodentate coordination of the benzoate ligands.[10] Thus, in one step, both the steric and electronic features of the titanocene phosphanes **1** and **2** have been modified. In an extension of this procedure, we conducted a reaction between sodium fluoride and the titanocene dichloride phosphanes **1** and **2** under similar conditions. The halide exchange proceeded smoothly and led to the titanocene difluoride phosphanes **5**, and **6**, respectively, in very good yields. The $^{19}F\{^1H\}$ NMR spectrum of **5** shows singlets at δ = 64.3 ppm in the range reported for [Cp_2TiF_2].[11] The $^{19}F\{^1H\}$ NMR spectrum of **6** also contains a singlet but with a chemical shift shifted slightly downfield at δ = 86.8 ppm. All other NMR spectroscopic data of **5** and **6** are in accordance with their structural features. At this point we should mention that [Cp_2TiF_2] has recently been converted, under mild conditions, into [Cp_2TiH], which has proved to be a very effective catalyst for the hydrosilylation of lactones[12] and the dehydropolymerisation of silanes.[13] The potential of the bimetallic complexes constructed with the fluorinated titanocene phosphane is thus reinforced.

These results prompted us to use the same strategy to convert the titanocene dichloride phosphanes **1** and **2** into optically active ligands. According to well-known procedures for the resolution of titanium metallocenes,[14–18] we carried out the reaction of one equivalent of sodium bi-

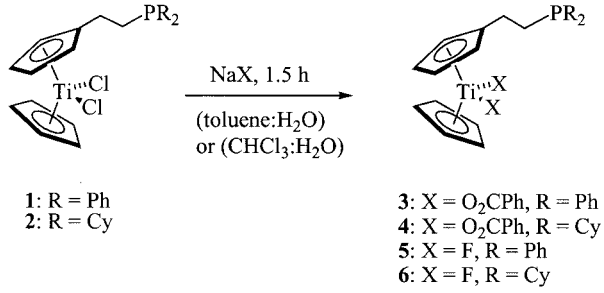
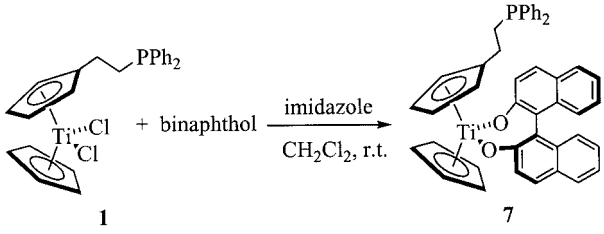


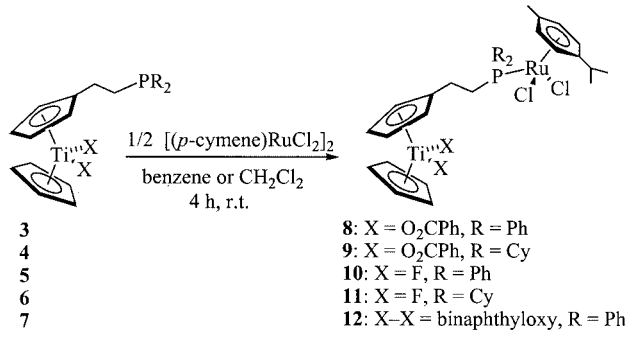
Scheme 1.

naphtholate with **1** in THF at room temperature to afford the desired titanocene binaphtholate phosphane **7**. However, a careful study of the ^{1}H NMR spectrum of the crude product revealed that a partial loss of the $Cp(CH_2)_2PPh_2$ moiety occurs in this reaction. At this step, purification by chromatography is effective but led to a dramatic loss of yield. Therefore we conducted this reaction under milder conditions and used binaphthol directly along with imidazole as an HCl trap (Scheme 2). The reaction proceeded cleanly without any side product formation and in very good yield. The ^{1}H NMR spectrum of **7** differs from that of the precursor phosphane **1** in that it displays four signals for the substituted Cp instead of two. This anisochrony is indicative of a loss of symmetry due to the introduction of binaphthol. The $^{31}P\{^1H\}$ NMR spectrum of **7** displays a single peak at δ = –14.3 ppm, which is shifted slightly downfield with respect to **1**. Thus, starting from a readily commercially available chiral diol, a pure optically active phosphane is available without the usual difficulties of chiral ligand synthesis (resolution, measurement of optical purity, etc.). Finally, it is worth mentioning that all attempts to convert **2** into an optically active phosphane by either the sodium binaphtholate or imidazole routes were unsuccessful.



Scheme 2.

Once this series of new titanocene phosphanes had been prepared, we investigated their complexation with ruthenium by following the procedure previously described for the titanocene dichloride phosphanes **1** and **2**.[5,6] Thus, the treatment of **3**–**6** with 0.5 molar equivalents of the binuclear complex $[(p\text{-cymene})RuCl_2]_2$ in benzene gave the targeted early–late bimetallic complexes **8**–**11**, respectively, in good yields (Scheme 3). The ^{31}P NMR chemical shifts of these complexes, in the δ = 20 ppm range, correspond to a downfield shift of 30–40 ppm relative to the free ligands. As expected, the two carboxylate stretching bands in the IR spectra of **8** and **9** are similar to those reported for the free titanocene phosphanes. The $^{19}F\{^1H\}$ NMR chemical shifts of **10** and **11** show signals in the range of $[Cp_2TiF_2]$ at δ = 62.3 and 62.5 ppm, respectively. This suggests that the dicyclohexylphosphane group is responsible for the deshielding of the signal in the $^{19}F\{^1H\}$NMR spectrum of **6**. All other spectroscopic data of the bimetallic complexes **8**–**11** are in accordance with their structural features.



Scheme 3.

We then carried out the reaction of the optically active phosphane **7** with 0.5 molar equivalents of the binuclear complex $[(p\text{-cymene})RuCl_2]_2$ in CH_2Cl_2. Purification of the crude product by flash chromatography on silica, in order to remove an excess of $[(p\text{-cymene})RuCl_2]_2$, allowed the isolation of the first chiral Ti–Ru bimetallic complex **12**. The $^{31}P\{^1H\}$ NMR spectrum of **12** shows a single peak at δ = 24.7 ppm, which is shifted downfield with respect to **7**. The ^{1}H NMR spectrum of **12** exhibits a marked anisochrony not only for the substituted Cp, as for **7**, but also for the *p*-cymene fragment on the ruthenium centre − a chemical shift gap of 0.25 ppm between both methyl protons of the isopropyl group is observed. At this point, we should mention that the synthesis and the characterisation of chiral early–late bimetallic complexes are remarkably scarce in the literature.[19,20]

Crystals of **8** suitable for X-ray measurements were obtained by slow diffusion of pentane into a saturated dichloromethane solution of the complex. The asymmetric unit contains the bimetallic complex, one dichloromethane solvate and one benzoic acid molecule (originally present as an impurity in the sample). The structure of the complex consists of two fragments: a titanocene moiety with a tetrahedral geometry and a ruthenium moiety with a usual three-legged piano stool structure (Figure 1).[21,22] These two blocks are tethered together through a phosphanylethylene bridge. Most of the structural features of the titanocene dibenzoate fragment within the bimetallic complex **8** are similar to those reported for $[Cp_2Ti(O_2CPh)_2]$,[9,10] as the lengths of the C–O bonds to the coordinated and uncoordinated oxygen atoms are significantly different, the angles at the coordinated oxygen atoms (Ti–O–C) are large and both benzoate ligands tilt with respect to the O(1)–Ti–O(2) plane, with dihedral angles of 42.6(2)° and 29.9(2)°, respectively. Despite the fact that benzoate ligands are rather bulkier than chloride atoms, the phosphorus atom

remains located on the open side of the titanocene but not exactly in the bisecting plane. This asymmetry is induced by a π-stacking effect observed between one phenyl ring of a benzoate ligand and one phenyl ring of a diphenylphosphanyl group. Finally, the cocrystallised benzoic acid molecule forms a hydrogen bond with the oxygen atom O(2) of one benzoate ligand.

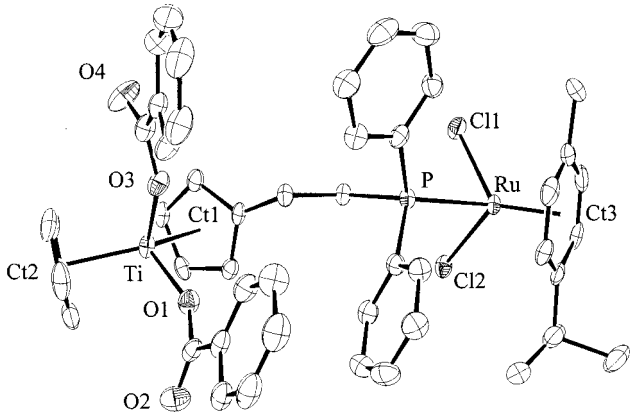


Figure 1. Molecular structure of complex **8**. The CH_2Cl_2 solvate molecule and the benzoic acid have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ti–Ct1 2.049(3), Ti–Ct2 2.054(4), Ti–O1 1.947(2), Ti–O3 1.956(2), Ru–Ct3 1.707(3), Ru–P 2.3516(8), Ru–Cl1 2.4182(9), Ru–Cl2 2.4211(8); Ct1–Ti–Ct2 132.4(2), O1–Ti–O3 90.8(1), Ct3–Ru–P 130.6(1), Ct3–Ru–Cl1 127.3(1), Ct3–Ru–Cl2 124.7(1), P–Ru–Cl1 85.25(3), P–Ru–Cl2 85.89(3), Cl(1)–Ru–Cl(2), 89.16(3) Ti–O(1)–C(35) 152.9(2), Ti–O3–C42 142.4(2).

Crystals of **10** suitable for an X-ray study were also obtained by layering techniques with $CDCl_3$/hexane (the sample came from a NMR solution). The asymmetric unit contains two independent complexes of **10** and six $CDCl_3$ solvate molecules. The two molecules exhibit an almost identical conformation with opposite orientations of the *p*-cymene ligand. The molecular structure of complex **10**, represented in Figure 2, is very similar to the one with two chlorides.[5] The diphenylphosphanyl group is on the open side of the titanocene, near a bisecting position, with both phenyls rings directed toward the titanium atom and the ruthenium away from it in the least congested environment. As expected, the Ti–F bond lengths [<Ti–F> = 1.91(2) Å, mean over four distances] are shorter than the Ti–Cl bond lengths [2.35(3) Å] and the F–Ti–F angle [95(1)°, mean over two angles] similar to the one with chlorides [Cl–Ti–Cl = 95.26(8)°]. These structural parameters are close to those observed for other titanocene difluoride derivatives.[23,24]

Recrystallisation attempts of **12**, starting from a racemic mixture, proved to be difficult, but finally succeeded by slow evaporation under air of a CH_2Cl_2/pentane solution of the crude product. Its molecular structure is shown in Figure 3. The asymmetric unit contains the bimetallic Ti–Ru compound, one additional binaphthol molecule and 2.5 dichloromethane solvates. Contrary to the bimetallic complexes **8** and **10**, the PPh_2 substituent is rotated from the bisecting position, leading to a dihedral angle between the Ct(1)–Ti–Ct(2) plane and the Ct(1)–C(11)–Ct(2) one [C(11) being the

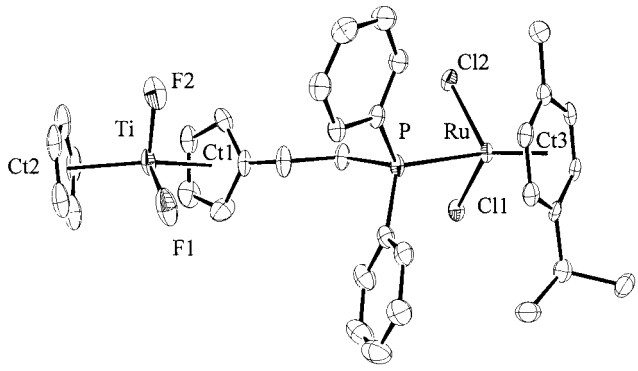

Figure 2. Molecular structure of complex **10**. The $CDCl_3$ solvate molecules have been omitted for clarity. Selected bond lengths [Å] and angles [°] [data in square brackets correspond to the second indepedent molecule]: Ti–Ct1 2.050(5) [2.055(5)], Ti–Ct2 2.065(5) [2.056(5)], Ti–F1 1.891(3) [1.905(4)], Ti–F2 1.937(3) [1.896(4)], Ru–Ct3 1.707(4) [1.709(4)], Ru–P 2.347(1) [2.344(1)], Ru–Cl1 2.4180(12) [2.4093(13)], Ru–Cl2 2.4126(13) [2.4200(11)]; Ct1–Ti–Ct2 132.6(2) [136.2(2)], F1–Ti–F2 93.70(14) [95.7(2)], Ct3–Ru–P 131.0(1) [130.6(1)], Ct3–Ru–Cl1 126.1(1) [126.1(1)], Ct3–Ru–Cl2 127.7(1) [127.3(1)], P–Ru–Cl1 84.35(3) [83.47(3)], P–Ru–Cl2 86.92(4) [86.74(4)], Cl1–Ru–Cl2 86.80(4) [86.84(4)].

methylene carbon atom attached to the Cp ring] of 67°. Thus, the areneruthenium moiety lies in an open area and not above the bulky binaphtholate group. The structural parameters of the chelate ring formed are similar to those described in the literature.[14–17] The bite angle O(1)–Ti–O(2) is equal to 92.0(1)° and the dihedral angle between the naphthalene planes [64.8(1)°] is contracted from that of cocrystallised "free" binaphthol (90° is generally observed). It is noteworthy that two different Ti–O bond lengths are observed [Ti–O(1) = 1.915(2) Å and Ti–O(2) = 1.981(2) Å]. This can be explained by the presence of a hydrogen bond pointing from a hydroxide group of the "free" binaphthol molecule toward the O(2) atom [O(3)–H···O(2) = 1.75 Å]. In fact, this binaphthol molecule plays an active role in the crystallisation process in connecting two adjacent molecules: the second hydroxy group points between the two chlorine atoms of the Ru moiety of an adjacent complex [O(4)–H···Cl(1) = 2.35 Å and O(4)–H···Cl(2) = 2.70 Å].[25]

Conclusions

This study provides a straightforward access to a series of new early–late transition metal complexes. The substitution of both chloride atoms of a titanocene phosphane by other ligands such as benzoate, fluoride or binaphtholate is the key step of this new route. The phosphanes so formed react readily with the binuclear complex [(*p*-cymene)-$RuCl_2$]$_2$ to give the targeted bimetallic complexes. The structures of three of them have been confirmed by X-ray diffraction studies. Assessment of the catalytic behaviour of these early–late bimetallic complexes is currently being studied in our laboratory. The design of new titanocene phosphanes inspired by the fruitful chemistry of $[Cp_2TiCl_2]$ is also in progress.

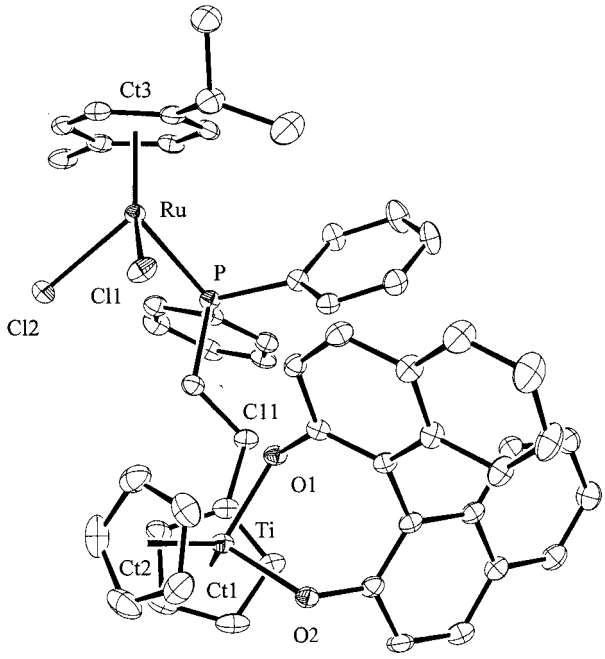

Figure 3. Molecular structure of complex *rac*-**12**. Only one enantiomer is shown for clarity. The free binaphthol molecule and the CH_2Cl_2 solvate molecules are also not shown. Selected bond lengths [Å] and angles [°]: Ti–Ct1 2.099(3), Ti–Ct2 2.088(4), Ti–O1 1.915(2), Ti–O2 1.981(2), Ru–Ct3 1.703(3), Ru–P 2.3442(8), Ru–Cl1 2.4210(7), Ru–Cl2 2.4157(8); Ct1–Ti–Ct2 130.48(13), O1–Ti–O2 91.96(9), Ct3–Ru–P 130.95(9), Ct3–Ru–Cl1 126.04(9), Ct3–Ru–Cl2 126.42(9), P–Ru–Cl1 84.97(3), P–Ru–Cl2 86.80(3), Cl1–Ru–Cl2 87.22(3).

Experimental Section

General Remarks: All reactions were carried out under an atmosphere of purified argon. The solvents and eluents were dried by the appropriate procedures and distilled under argon immediately before use. Standard Schlenk techniques and conventional glass vessels were employed. Elemental analyses were carried out with a EA 1108 CHNS-O FISONS Instruments. ^{1}H (500 MHz), ^{19}F (282 MHz) and ^{31}P{^{1}H} (202 MHz) spectra were collected on a Bruker 500 MHz Avance DRX spectrometer. Chemical shifts are quoted relative to internal TMS (^{1}H), external $CFCl_3$ (^{19}F) or external H_3PO_4 (^{31}P). IR spectra were obtained with a Bruker IFS 66v spectrometer. The titanocene phosphanes **1** and **2** were synthesised as reported previously.[5,6]

[Ti(O$_2$CPh)$_2$(η^5-C$_5$H$_5$){η^5-C$_5$H$_4$(CH$_2$)$_2$PPh$_2$}] (3): A 100-mL flask was charged with $PhCO_2Na$ (0.3 g, 2 mmol), [$TiCl_2$(η^5-C_5H_5){η^5-$C_5H_4(CH_2)_2PPh_2$}] (**1**; 0.4 g, 1 mmol), 5 mL of degassed water and 44 mL of $CHCl_3$. The mixture was stirred for 1.5 h during which time the colour turned to orange. Then, the organic phase was removed, washed with 5 mL of water, dried with $MgSO_4$, filtered and the solvents evaporated to dryness to yield an orange powder (0.45 g, 75% yield). IR (KBr): ν(COO) = 1634, 1324 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 2.17 (t, $^3J_{H,H}$ = 8 Hz, 2 H, CH_2), 2.61 (pseudo q, $^3J_{H,H}$ = $^2J_{H,P}$ = 8 Hz, 2 H, CH_2), 6.42 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 2 H, C_5H_4), 6.59 (s, 5 H, C_5H_5), 6.61 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 2 H, C_5H_4), 7.16–7.20 (m, 10 H, PPh_2), 7.44 (pseudo t, $^3J_{H,H}$ = 7 Hz, 4 H, Ph), 7.54 (t, $^3J_{H,H}$ = 7 Hz, 2 H, Ph), 8.03 (d, $^3J_{H,H}$ = 7 Hz, 4 H, Ph) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –14.87 (s, PPh_2) ppm. $C_{38}H_{33}O_4PTi$ (632.51): calcd. C 72.16, H 5.26; found C 72.00, H 5.02.

[Ti(O$_2$CPh)$_2$(η^5-C$_5$H$_5$){η^5-C$_5$H$_4$(CH$_2$)$_2$PCy$_2$}] (4): This compound was obtained following the above procedure but with [$TiCl_2$(η^5-C_5H_5){η^5-$C_5H_4(CH_2)_2PCy_2$}] (**2**) and toluene/H_2O as the biphasic system (0.38 g, 62% yield). IR (KBr): ν(COO) = 1635, 1326 cm^{-1}. ^{1}H NMR (C_6D_6): δ = 1.10–1.90 (m, 24 H, Cy + CH_2), 2.85 (pseudo q, $^3J_{H,H}$ = $^2J_{H,P}$ = 8 Hz, 2 H, CH_2), 6.14 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 2 H, C_5H_4), 6.28 (s, 5 H, C_5H_5), 6.41 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 2 H, C_5H_4), 7.35 (t, $^3J_{H,H}$ = 8 Hz, 2 H, Ph), 7.39 (pseudo t, $^3J_{H,H}$ = 8 Hz, 4 H, Ph), 8.54 (d, $^3J_{H,H}$ = 8 Hz, 4 H, Ph) ppm. ^{31}P{^{1}H} NMR (C_6D_6): δ = –3.79 (s, PCy_2) ppm. $C_{38}H_{45}O_4PTi$ (644.60): calcd. C 70.80, H 7.04; found C 70.54, H 7.16.

[TiF$_2$(η^5-C$_5$H$_5$){η^5-C$_5$H$_4$(CH$_2$)$_2$PPh$_2$}] (5): A 100-mL flask was charged with NaF (0.065 g, 1.54 mmol), [$TiCl_2$(η^5-C_5H_5){η^5-$C_5H_4(CH_2)_2PPh_2$}] (**1**; 0.36 g, 0.78 mmol), 4 mL of degassed water and 36 mL of $CHCl_3$. The mixture was stirred for 1.5 h during which time the colour turned to deep yellow. Then, the organic phase was removed, washed with 5 mL of water, dried with $MgSO_4$, filtered and the solvents evaporated to dryness to yield a yellow powder (0.16 g, 50% yield). ^{1}H NMR ($CDCl_3$): δ = 2.29 (t, $^3J_{H,H}$ = 8 Hz, 2 H, CH_2), 2.65 (pseudo q, $^3J_{H,H}$ = $^2J_{H,P}$ = 8 Hz, 2 H, CH_2), 6.05 (pseudo s, 2 H, C_5H_4), 6.38 (m, 7 H, C_5H_5 + 2 H C_5H_4), 7.25–7.35 (m, 6 H, PPh_2), 7.37–7.44 (m, 4 H, PPh_2) ppm. ^{19}F NMR ($CDCl_3$): δ = 64.28 (s, TiF_2) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = –14.99 (s, PPh_2) ppm. $C_{24}H_{23}F_2PTi$ (428.28): calcd. C 67.31, H 5.41; found C 66.82, H 5.26.

[TiF$_2$(η^5-C$_5$H$_5$){η^5-C$_5$H$_4$(CH$_2$)$_2$PCy$_2$}] (6): This compound was obtained following the above procedure but with [$TiCl_2$(η^5-C_5H_5){η^5-$C_5H_4(CH_2)_2PCy_2$}] (**2**) and toluene/H_2O as the biphasic system (0.17 g, 50% yield). ^{1}H NMR (C_6D_6): δ = 1.10–1.27 (m, 12 H, Cy), 1.55–1.84 (m, 12 H, Cy+CH_2), 2.87 (pseudo q, $^3J_{H,H}$ = $^2J_{H,P}$ = 8 Hz, 2 H, CH_2), 5.84 (pseudo s, 4 H, C_5H_4), 5.99 (s, 5 H, C_5H_5) ppm. ^{19}F NMR (C_6D_6): δ = 86.76 (s, TiF_2) ppm. ^{31}P{^{1}H} NMR (C_6D_6): δ = –3.41 (s, PCy_2) ppm. $C_{24}H_{35}F_2PTi$ (440.37): calcd. C 65.46, H 8.01; found C 65.15, H 8.22.

[Ti{(*R*)-Binaphtholate)}(η^5-C$_5$H$_5$){η^5-C$_5$H$_4$(CH$_2$)$_2$PPh$_2$}] (7): Imidazole (0.14 g, 2.15 mmol) in 10 mL of dichloromethane and (*R*)-binaphthol (0.32 g, 1.13 mmol) in 25 mL of dichloromethane were successively added to a solution of [$TiCl_2$(η^5-C_5H_5){η^5-C_5H_4-$(CH_2)_2PPh_2$}] (**1**; 0.52 g, 1.13 mmol) in 25 mL of dichloromethane at room temperature. The mixture was stirred for 4 h. After filtration, the solvent was removed from the filtrate under reduced pressure and 40 mL of toluene was added to the resulting product. Filtration through celite and evaporation of the solvent afforded **7** (0.5 g, 70% yield) as a red solid. ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 1.65–1.75 (m, 2 H, CH_2), 2.20–2.35 (m, 2 H, CH_2), 5.28–5.35 (m, 1 H, C_5H_4), 5.85–5.95 (m, 1 H, C_5H_4), 5.98–6.04 (m, 1 H, C_5H_4), 6.09 (s, 5 H, C_5H_5), 6.60–6.66 (m, 1 H, C_5H_4), 7.15–8.15 (m, 22 H, phenyl-*H* and binaphthyl-*H*) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$, 202 MHz): δ = –14.3 (s, PPh_2) ppm. $C_{44}H_{35}PTiO_2$ (674.59): calcd. C 78.34, H 5.23; found C 78.48, H 5.29. $[\alpha]_D^{20}$ = –2163 (*c* = 0.1, CH_2Cl_2).

[(*p*-Cymene)RuCl$_2$}{(η^5-C$_5$H$_5$)[μ-η^5:η^1-C$_5$H$_4$(CH$_2$)$_2$PPh$_2$[Ti(O$_2$CPh)$_2$}] (8): A 25-mL Schlenk flask was charged under argon with **3** (0.45 g, 0.71 mmol), [(*p*-cymene)$RuCl_2$]$_2$ (0.16 g, 0.27 mmol) and degassed benzene. The mixture was stirred at room temperature for 4 h, during which time a brick-red precipitate slowly formed. The solvent was removed by filtration and the red residue was dried under vacuum (0.38 g, 75% yield). IR (KBr): ν(COO) = 1636, 1355 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.74 [d, $^3J_{H,H}$ = 7 Hz, 6 H, CH-

(CH_3)$_2$], 1.81 (s, 3 H, CH_3), 2.17 (m, 2 H, CH_2), 2.45 [sept, $^3J_{H,H}$ = 7 Hz, 1 H, CH(CH$_3$)$_2$], 2.63 (m, 2 H, CH_2), 5.01 (d, $^3J_{H,H}$ = 6 Hz, 2 H, *p*-cymene), 5.18 (d, $^3J_{H,H}$ = 6 Hz, 2 H, *p*-cymene), 6.14 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 2 Hz, 2 H, C$_5H_4$), 6.48 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 2 Hz, 2 H, C$_5H_4$), 6.49 (s, 5 H, C$_5H_5$), 7.19 (pseudo t, $^3J_{H,H}$ = 6 Hz, 4 H, PPh$_2$), 7.25–7.35 (m, 6 H, PPh$_2$), 7.49 (t, $^3J_{H,H}$ = 8 Hz, 2 H, Ph), 7.56 (pseudo t, $^3J_{H,H}$ = 8 Hz, 4 H, Ph), 7.82 (d, $^3J_{H,H}$ = 8 Hz, 4 H, Ph) ppm. ^{31}P{^{1}H} NMR (202 MHz, CDCl$_3$): δ = 24.99 (s, PPh$_2$) ppm. $C_{48}H_{47}Cl_2O_4PRuTi$ (938.70): calcd. C 61.42, H 5.05; found C 60.92, H 5.21.

[(*p*-Cymene)RuCl$_2$\{(η^5-C$_5$H$_5$)[μ-η^5:η^1-C$_5$H$_4$(CH$_2$)$_2$PCy$_2$]Ti(O$_2$CPh)$_2$\}] (9): This compound was obtained following the above procedure but with **4** (0.41 g, 80% yield). IR (KBr): ν(COO) = 1635, 1328 cm^{-1}. ^{1}H NMR (CDCl$_3$): δ = 0.85–2.17 (m, 24 H, Cy + CH_2), δ = 1.24 [d, $^3J_{H,H}$ = 7 Hz, 6 H, CH(CH_3)$_2$], 2.02 (s, 3 H, CH_3), 2.60 (m, 2 H, CH_2), 2.75 [sept, $^3J_{H,H}$ = 7 Hz, 1 H, CH(CH$_3$)$_2$], 5.01 (pseudo s,, 4 H, *p*-cymene), 6.37 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 2 H, C$_5H_4$), 6.55 (pseudo t, $^3J_{H,H}$ = $^4J_{H,H}$ = 3 Hz, 2 H, C$_5H_4$), 6.60 (s, 5 H, C$_5H_5$), 7.46 (pseudo t, $^3J_{H,H}$ = 8 Hz, 4 H, Ph), 7.50 (t, $^3J_{H,H}$ = 8 Hz, 2 H, Ph), 8.07 (d, $^3J_{H,H}$ = 8 Hz, 4 H, Ph) ppm. ^{31}P{^{1}H} NMR (CDCl$_3$): δ = 25.84 (s, PCy$_2$) ppm. $C_{48}H_{59}Cl_2O_4PRuTi$ (950.80): calcd. C 54.70, H 6.61; found C 54.55, H 6.41.

[(*p*-Cymene)RuCl$_2$\{(η^5-C$_5$H$_5$)[μ-η^5:η^1-C$_5$H$_4$(CH$_2$)$_2$PPh$_2$]Ti[(*R*)-binaphtholate)]\}] (12): [(*p*-cymene)RuCl$_2$]$_2$ (0.041 g, 0.07 mmol) in 5 mL of dichloromethane was added to a solution of **7** (0.1 g, 0.15 mmol) in 10 mL of dichloromethane at 0 °C. The mixture was stirred at room temperature for 4 h. The solvent was then removed in vacuo. Purification by flash chromatography on silica (toluene/THF, 50:50) under argon and at 10 °C afforded **12** as an orange solid (0.070 g, 50% yield). Complex **12** in its racemic form, which was used to obtain suitable crystal for X-ray diffraction, was prepared in a similar way. ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 0.70 [d, $^3J_{H,H}$ = 7 Hz, 3 H, CH(CH_3)$_2$], 0.95 [d, $^3J_{H,H}$ = 7 Hz, 3 H, CH(CH_3)$_2$], 1.67–1.80 (m, 1 H, CH_2), 1.87 (s, 3 H, CH_3), 2.00–2.19 (m, 1 H, CH_2), 2.45–2.65 (m, 1 H, CH_2), 2.54 [sept, $^3J_{H,H}$ = 7 Hz, 1 H, CH(CH$_3$)$_2$], 2.74–2.96 (m, 1 H, CH$_2$), 4.76–4.81 (m, 1 H, C$_5H_4$), 4.88 (d, $^3J_{H,H}$ = 6 Hz, 1 H, *p*-cymene), 5.19 (d, $^3J_{H,H}$ = 6 Hz, 1 H, *p*-cymene), 5.28 (d, $^3J_{H,H}$ = 6 Hz, 1 H, *p*-cymene), 5.39 (d, $^3J_{H,H}$ = 6 Hz, 1 H, *p*-cymene), 5.97–6.04 (m, 1 H, C$_5H_4$), 6.09–6.15 (m, 1 H, C$_5H_4$), 6.20 (s, 5 H, C$_5H_5$), 6.49–6.57 (m, 1 H, C$_5H_4$), 6.80–8.00 (m, 22 H, Ph and binaphthyl) ppm. ^{31}P{^{1}H} NMR (CDCl$_3$, 202 MHz): δ = 24.66 (s) ppm. $C_{54}H_{49}Cl_2O_2PRuTi$ (980.78): calcd. C 66.13, H 5.04; found C 66.60, H 5.10. $[\alpha]_D^{20}$ = –1920 (*c* = 0.1, CH_2Cl_2).

X-ray Crystallographic Study of 8: $C_{48}H_{47}Cl_2O_4PRuTi\cdot C_7H_6O_2\cdot 0.5(CH_2Cl_2)$, *MW* = 1103.28, monoclinic, space group *C*2/*c*, *a* = 25.0136(3), *b* = 18.9231(2), *c* = 21.2279(3) Å, β = 98.595(1)°, *V* = 9935.1 (2) Å^3, *Z* = 8, D_{calc} = 1.475 g cm^{-3}; *F*(000) = 4536. The structure was solved by the heavy-atom method using SHELXS97.[26] Refinement, based on F^2, was carried out by full-matrix least-squares with the SHELXL97 and WINGX programs.[26,27] Non-hydrogen atoms were refined anisotropically. H atoms were included in calculated positions and included in the refinement with a riding-motion model with U_{iso} = 1.2U_{eq} of the carrier atom (1.5 for methyl groups and OH). Convergence was reached at wR_2 = 0.125 for all data (11386 intensities), R_1 = 0.047 for 7904 intensities with $I > 2\sigma(I)$ and *S* = 1.044 for 615 parameters. The residual electron density in the final difference Fourier map was 1.12 and –1.18 e Å^{-3}.

X-ray Crystallographic Study of 10: $C_{34}H_{37}Cl_2F_2PRuTi\cdot 3(CHCl_3)$, *MW* = 1092.6, triclinic, space group $P\bar{1}$; *a* = 9.716(5), *b* = 17.008(5), *c* = 28.927(5) Å, α = 75.609(5)°, β = 82.660(5)°, γ = 81.094(5)°, *V* = 4554 (3) Å^3, *Z* = 4, D_{calc} = 1.593 g cm^{-3}; *F*(000) = 2192. The structure was solved by the heavy-atom method using SHELXS97.[26] Refinement, based on F^2, was carried out by full-matrix least-squares with the SHELXL97 and WINGX programs.[26,27] Non-hydrogen atoms were refined anisotropically. H atoms were included in calculated positions and included in the refinement with a riding-motion model with U_{iso} = 1.2U_{eq} of the carrier atom (1.5 for methyl groups). Two independent molecules of **10** are present in the asymmetric unit and one of them has a disordered cyclopentadienyl ring over two positions with occupancies refined to 0.53:0.47. Among the six chloroform solvates present in the asymmetric unit, three are disordered over two positions with occupancies refined to 0.59:0.41, 0.90:0.10 and 0.90:0.10. The chlorine atoms with occupancies equal to 0.10 were isotropically refined Convergence was reached at wR_2 = 0.119 for all data (18928 intensities), R_1 = 0.051 for 15240 intensities with $I > 2\sigma(I)$ and *S* = 1.039 for 1047 parameters. The residual electron density in the final difference Fourier map was 1.25 and –1.03 e Å^{-3}.

X-ray Crystallographic Study of 12: $C_{54}H_{49}Cl_2O_2PRuTi\cdot C_{20}H_{14}O_2\cdot 2.5(CH_2Cl_2)$, *MW* = 1479.4, triclinic, space group $P\bar{1}$; *a* = 12.8350(4), *b* = 15.5480(5), *c* = 19.4240(6) Å, α = 112.361(2)°, β = 97.889(2)°, γ = 105.773(2)°, *V* = 3321.2 (2) Å^3, *Z* = 2, D_{calc} = 1.479 g cm^{-3}; *F*(000) = 1518. The structure was solved by the heavy-atom method using SHELXS97.[26] Refinement, based on F^2, was carried out by full-matrix least-squares with the SHELXL97 and WINGX programs.[26,27] Non-hydrogen atoms were refined anisotropically. H atoms were included in calculated positions and included in the refinement with a riding-motion model with U_{iso} = 1.3U_{eq} of the carrier atom. Two of the three dichloromethane solvates are disordered: one, located close to an inversion centre, was refined with an occupation factor of 0.5, the other is disordered over two positions with occupancies refined to 0.77:0.23. Convergence was reached at wR_2 = 0.129 for all data, R_1 = 0.049 for 12707 intensities with $I > 2\sigma(I)$ and *S* = 1.053 for 841 parameters. The residual electron density in the final difference Fourier map was 1.8 and –1.7 e Å^{-3} close to a disordered dichloromethane solvate.

CCDC-256921 (for **8**), -256922 (for **10**) and -225303 (for **12**) contain the supplementary crystallographic data for this paper. These

Induction of Columnar Mesomorphism in Tetracoordinated Ionic Silver(I) Complexes Based on Chelate 4,4′-Disubstituted 2,2′-Bipyridines

Daniela Pucci,*[a] Giovanna Barberio,[a] Anna Bellusci,[a] Alessandra Crispini,[a] Massimo La Deda,[a] Mauro Ghedini,[a] and Elisabeta Ildyko Szerb[a]

Keywords: Bipyridine ligands / Silver / Metallomesogens / Ionic / Luminescence

The reaction of silver triflate (AgOTf) and silver dodecyl sulfate (AgDOS) with two nonmesomorphic 4,4′-disubstituted 2,2′-bipyridines, L^n, yielded a series of bis-chelate ionic silver complexes $[Ag(L^n)_2]X$. Complexation induced columnar mesomorphism in all the silver(I) tetra-branched bipyridine derivatives and the role of the counterion proved to be crucial in the generation of different symmetries of the mesophase. Remarkably, all silver(I) complexes exhibit emission at room temperature both in solution and in the solid state.

Introduction

Metallomesogens are a fascinating branch of nanostructure materials research,[1] as they join a current goal in supramolecular chemistry,[2] such as the self-assembly of coordinated species, with new functionalities provided from liquid crystalline properties.[3]

Our interest in this field has recently prompted us to employ nonmesogenic 4,4′-disubstituted 2,2′-bipyridines as building blocks in the synthesis of new coordination complexes, the mesomorphic properties of which are induced through the self-assembly of half-disc shaped $[LMCl_2]$ complexes (M = Pd, Pt, Ni, Zn) to full disc-shaped supramolecules, by the complementary shape approach. The complexes are liquid crystals regardless of the metal ion coordination geometry. The molecular organisation in the mesophase was mainly driven by intermolecular attractive interactions, with small structural variations having only subtle effects on the overall properties.[4]

Encouraged by these results, an electrostatic interaction was introduced to the molecular architecture and consequently to the supramolecular assembly. The synthesis of coordinatively saturated homoligand silver(I) complexes based on 2,2′-bipyridine ligands functionalised with amidic substituents in 4,4′-positions and with triflate as the counterion has been reported previously.[5] For the first time metallomesogens with tetracoordination around the silver(I) centre, based on chelate bipyridine ligands, were obtained. For these novel ionic liquid crystals a tetra-branched geometry induced mesomorphic molecular structures, such as columns. However, the presence of the amidic substituents introduced order in the structure, probably because of the ability to form H-bonding interactions, which lead to high transition temperatures.[5]

Novel examples of silver(I) complexes based on the nonmesomorphic 2,2′-bipyridines functionalised in 4,4′-positions with different substituents have been synthesised, as an alternative route to obtain low-temperature nonconventional ionic thermotropic metallomesogens. Four cationic bis-chelate silver complexes $[Ag(L^n)_2]X$ (Scheme 1) displaying columnar mesomorphism induced upon complexation are described here. These complexes are mesogenic even though they show pseudo-tetrahedral geometry around the metal centre, which would usually prevent the appearance of mesomorphic behaviour.[6]

The synthesis of metal complexes represents a challenge for obtaining new functional liquid crystalline materials where a wide choice of combinations of both metals and ligands would enhance preselected properties such as charge transport or luminescence.[1] Among the few reports on photoactive metallomesogens, few systems involve the use of the silver(I) ion,[7] although the various coordination modes of Ag^I, combined with the presence within the Ag complexes of large π systems as ligands,[8] would represent an ideal mode to expand the applicability of metallomesogens in the field of electro-optics.

Because many practical applications require liquid crystalline materials luminescent at room temperature, our investigations have reached this goal, giving rise to silver(I) complexes which exhibit emission at room temperature.

Moreover, the effect of the triflate (OTf) and the dodecyl sulfate (DOS) counterions on the mesogenic and photophysical properties have been investigated.

In the description of the $[Ag(L^n)_2]X$ complexes, dendrimeric terminology has been used in order to distinguish be-

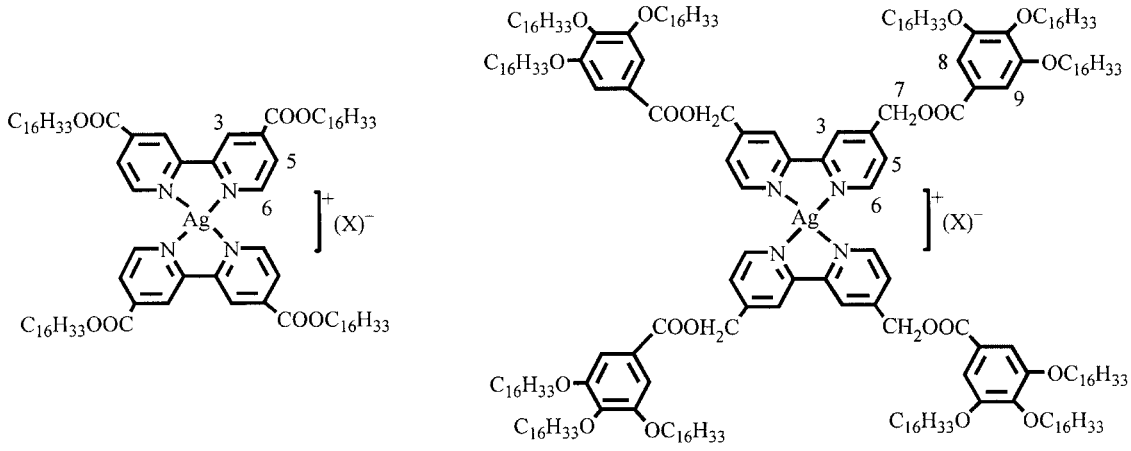
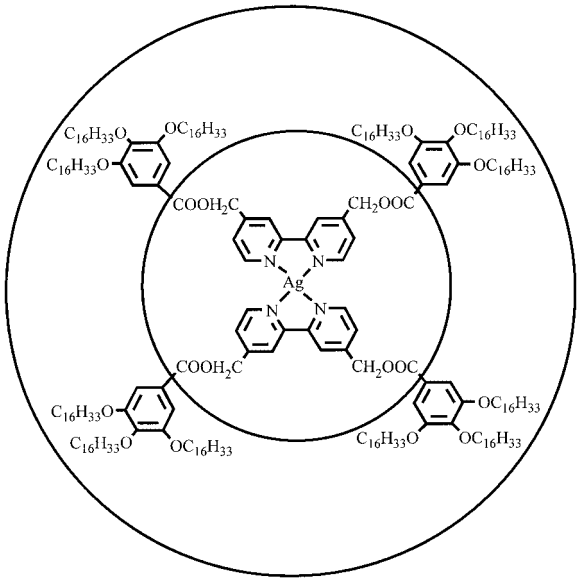


Scheme 1.

tween the different types of substituents on the bipyridine cores. Therefore all the silver derivatives are referred to as first-generation tetra-branched compounds, and the L^2 derivatives, **3** and **4**, as second-generation 12-branched compounds (Scheme 2).



Scheme 2.

Results and Discussion

Synthesis

The reaction of L^n ligands with the appropriate silver salts (AgOTf and AgDOS) in a 1:2 metal-to-ligand stoichiometry, in dichloromethane, led to the formation of $[Ag(L^n)_2][X]$ complexes, **1**–**4**, in very good yields. The stoichiometry and purity of all compounds were confirmed using elemental analyses, IR and ^1H NMR spectroscopy. In these cationic bis-chelate silver derivatives, the silver atom is in a distorted tetrahedral geometry coordinated by four nitrogen atoms of the two bipyridines, as already found in the crystal structure determination of nonsubstituted 2,2′-bipyridine silver complexes with anions such as $(BF_4)^-$ and $(PF_6)^-$.[9,10]

Liquid Crystalline and Photophysical Properties

Although the ligands L^n are not liquid crystals, the complexation to different silver salts gave rise to the new series of complexes, **1**–**4**, which all showed thermally reproducible mesomorphism, characterised by a combination of optical microscopy (POM), differential scanning calorimetry (DSC) and powder X-ray diffraction analysis at variable temperature (PXRD). The thermal data of the $[Ag(L^n)_2]X$ series are summarised in Table 1 and the relative phase diagram is reported in Figure 1.

All the complexes **1**–**4** showed, after a crystal-to-crystal transition, enantiotropic columnar phases, with melting temperatures under 100 °C. The results from POM suggested, for both triflate complexes (**1** and **3**), the presence of a hexagonal mesophase with the typical fan-shaped optical texture with homeotropic areas (Plate 1 in Figure 2). As regards the dodecyl sulfate derivatives (**2** and **4**), they exhibit a different optical behaviour: for complex **2**, a texture with Maltese crosses appeared after annealing on cooling from the isotropic melt, which developed in the fingerprint texture reported in Figure 2 (plate 2); while complex **4** exhibits a fine columnar fan-like texture (plate 3 in Figure 2).

The columnar nature of the mesophases shown by complexes **1**–**4** has been confirmed by PXRD at variable temperature; the X-ray diffraction data are listed in Table 2.

The XRD patterns of the triflate complexes, **1** and **3**, are typical of a two-dimensional hexagonal lattice with the three peaks in the low angle region in the ratio $1:(3)^{1/2}:2$. In both cases, the wide angle region displayed a broad halo centred at 4.6–4.7 Å, typical of liquid-like correlations be-

[a] Number of molecules calculated according to the formula $n = V_{cell}(N_A/M)\rho$ assuming a density of 1 g cm^{-3}, where N_A is the Avogadro constant; V_{cell} is calculated assuming a height of 3.6 Å for **1** and 4.6 Å for **3**.

tween side chains, while only in the case of complex **1** is a peak present at 3.6 Å, corresponding to the distance between adjacent cores. These differences account for a more ordered hexagonal phase in the case of complex **1**, in which there is a reduced number of aliphatic peripheral chains around the central core. The crystallinity of the mesophase in this case is also confirmed by the huge difference in the transition enthalpy values for the Col_h–I transitions of **1** and **3**, as reported in Table 1. Remarkably, the lattice parameter of **1** (a_{hex} = 51.6 Å) is significantly greater than that of complex **3** (a_{hex} = 43.2 Å), which has bulkier substituents on the 2,2′-bipyridines and greater side-chain density. This difference, which has already been observed in other polycatenar compounds with variable length alkyl chains,[11] reflects the different organisation of the molecules within the columns depending on the number of the alkyl chains. For the Col_h phase of **1**, approximately three molecules instead of just the one calculated for complex **3** can be found in the cross-section of the columns when the height of the columnar slice is assumed to be 4.6 Å (Table 2), indicating that the overall organisation between the molecular cores is of an edge-to-edge type. In the case of the second-generation 12-branched complex **3**, the four phenyl rings and 12 chains per molecule can completely sur-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

round the molecular cores, reducing the number of molecules in the cross-section of each unit cell.

The symmetry of the columnar mesophases changes on going from the OTf to the DOS derivatives. In fact, both DOS derivatives **2** and **4** showed X-ray diffraction patterns of a rectangular columnar mesophase, characterised by two sharp fundamental peaks in the low angle region (Figure 3).

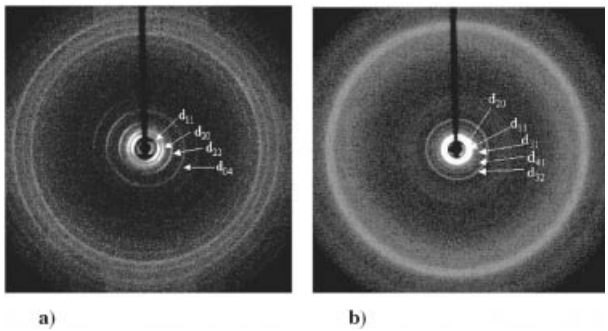

Figure 3. X-ray diffraction patterns of nonaligned samples of the rectangular columnar phases of (a) complex **2** at 87 °C on heating and (b) complex **4** at 84 °C on heating.

.

The change in the shape of the counterion destabilises the hexagonal phase, favouring rectangular phases at higher temperatures. The mesophase crossover from Col_r to Col_h is generally associated with the increase of the side-chain lengths or with the different size of the metal centres,[5,12,13] and, in both cases, the effect is a greater core–core interaction, which favours the formation of the Col_r phase. In a Col_h phase a rotationally averaged shape of the molecules gives a circular projection along the column's axis and the mesogenic plane is perpendicular to the column's axis. A distortion from Col_h to a Col_r is obtained when the molecules project an elliptical shape along the column's axis (Figure 4).[14]

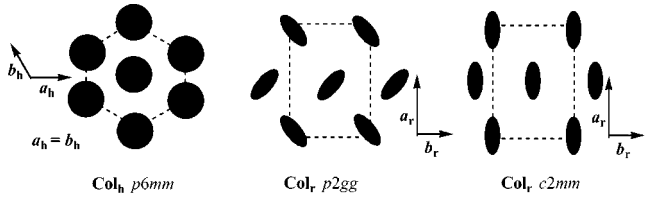

Figure 4. Schematic representation of the 2D lattices of the different columnar mesophases observed and their associated plane groups.

In this case the presence of the DOS counterion, which because of its shape can be organised with the flexible aliphatic chain aligned in the direction of the aliphatic periphery of the cation, hinders the molecular rotation of the nondisclike molecules, generating an elliptical cross-section. Within the rectangular arrangements, two different symmetries characterised by two different plane groups can be distinguished. The indexation of the two spectra showed that the reflection conditions for the *c2mm* plane group are verified in the case of complex **2**, with the (11) reflection being at a smaller angle ($d_{11} > d_{20}$), while the *p2gg* plane group is assigned to the Col_r phase of the second-generation 12-branched complex **4** (Table 2). Indeed the presence of a further aliphatic chain of the DOS counterion induces a more pronounced effect on the second-generation tetrabranched complex **2** with respect to the second-generation 12-branched complex, in which the volume fraction of the flexible chains completely surrounds the polar inner sphere.

Another important feature of the two rectangular columnar mesophases is the notable difference in the organisation within the columns evidenced by the high angle region of the XRD spectra. While in the XRD spectrum of **4** only a broad halo centred at 4.7 Å is present, typical of liquid-like correlations between side chains; in the case of **2**, three distinct reflections are observable at 4.6, 4.3 and 4.0 Å, indicative of a crystalline rectangular mesophase (Figure 3). This is confirmed also by the difference in the enthalpy values associated with the transitions to the isotropic liquid (Table 1).

A photophysical study has been performed on compounds **1**–**4**, in dichloromethane solution at room temperature, to assess the absorption and luminescence properties of the single subunits (Table 3).

The absorption features of the ligands are very similar to each other, and characteristics of these chromophores:[4b] π–π* excitations on aromatic rings give rise to two main bands at 240 and 300 nm (Table 3), which appear with a shoulder because of a vibrational progression. A weak low-energy band at about 330 nm is assigned to an n–π* transition. In the L^2 spectrum some differences are found: in particular, the band maximum at 278 nm is blue-shifted and more intense with respect to the corresponding band in L^1; this is attributed to the introduction of three hexadecyloxybenzyl substituents which stabilise the π orbital on the pyridine ring by exerting a weak electron-donating effect. Moreover, the aromatic transitions localised on the phenyl rings of the substituents contribute to the intensity of the

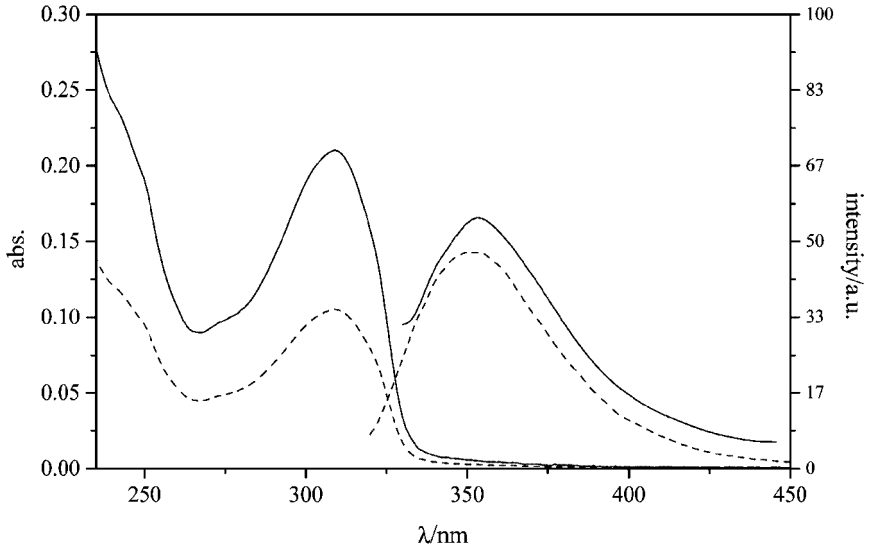

Figure 5. Absorption and emission spectra of **1** (solid line) and **3** (dashed line) in dichloromethane solution.

278-nm band. Metal complexation of both ligands induces a slight red-shift of the absorption bands in their derivatives (Figure 5), while, as expected, in solution no appreciable spectral differences are attributed to the influence of the two counterions. In the spectra of complexes **1** and **2** a weak band is visible at 275 nm, attributed to a ligand-to-metal-charge transfer;[15] the same feature in the spectra of **3** and **4** is probably hidden by the intense band at 278 nm.

The emission spectra of the ligands show a maximum at 350 (L^1) and 355 nm (L^2), which is ascribable to the deactivation of the π–π*-related state (Table 3); the measured quantum yields are comparable with those found for similar compounds.[4b] All the first-generation tetra-branched complexes showed the same luminescence observed in their corresponding ligands,[4b] and attributed to a ^{1}LC (ligand centred) transition. The observed quantum yields for these complexes are reduced because of the presence of the heavy atoms which induce $^1LC \rightarrow {}^3LC$ intersystem crossing.[16] In solution, no spectral differences are attributable to the counterion and the differences among Φ-values of the L^1 and L^2 derivatives are within the range of experimental uncertainty. Remarkably, in analogy to the corresponding ligands, the second-generation 12-branched complexes **3** and **4** have a quantum yield higher than that of complexes **1** and **2**.

A study of the photophysical properties of both ligands and complexes **1**–**4** has been performed also in the solid state, with the intention of examining the influence of the crystal packing on the luminescence features. No significant differences have been recorded with respect to the spectra in solution (Table 3).

Conclusions

The general preference of the silver(I) ion in liquid crystals reported to date is for linear 2-coordination or for tetra-coordination in macrocycle derivatives.[1,17] However, often the structure and packing of the ionic silver complexes are influenced by the argentophilic interaction (Ag–Ag contacts) and by the presence of coordinating counterions, which can induce the coordination number to increase up to six. This change in the network dimensionality has led to a drawback for the silver complexes, namely that their high clearing temperatures and their poor thermal stability have meant that their physical properties have been scarcely investigated.

We have recently reported a new class of chelate silver bipyridine with a coordinative saturation around the metal centre. These complexes exhibited columnar mesomorphism at very high temperatures, as the presence of amidic functionalities on the bipyridine ligands gives rise to H-bonding interactions.[5] In order to overcome this structural limitation new ligands with different substituents have been used for the synthesis of a novel class of ionic $[Ag(L^n)_2][X]$ complexes with a tetracoordination around the silver centre. The coordination of the two nonmesomorphic ligand units, with different molecular features, namely rod-like for L^1 and hemi-disc for the hexacatenar L^2, to the silver atom gives rise to a starlike molecular shape because of the pseudo-tetrahedral coordination around the metal centre, and induces liquid crystalline behaviour in the resulting complexes. In particular, it seems that the difference in the molecular anisotropy and the volume of the cationic cores of the two ligands L^n does not perturb the molecular arrangement and the mesophase induction. Thus, all complexes show columnar mesomorphism, regardless of the nature and number of branchings on the organic ligand with a lowering by 100–200 °C of the clearing temperatures with respect to the similar amidic Ag^I complexes.[5]

However, the enhancement of the aliphatic periphery in the second-generation 12-branched compounds allows the transition from crystalline to liquid crystalline mesophases.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The symmetry of the mesophase of the four derivatives strongly depends on the structural role of the counterion, which drives the organisation of both the single molecular units and of the overall supramolecular motifs. Indeed the triflate anion has been found to promote the hexagonal phase while rectangular phases seem to be stabilised by the dodecyl sulfate anion which, because of its shape, can be organised with the flexible aliphatic chain aligned in the direction of the aliphatic periphery of the cation, hindering the molecular rotation of the nondisclike molecules and thus generating an elliptical cross-section. This change of mesophase morphology is related to the balance between the two microsegregate regions of the molecules, as evidenced by the different perturbation induced by the DOS anion on the two derivatives. Indeed for the second-generation 12-branched complex **4**, in which the volume fraction of the flexible chains completely surrounds the polar inner sphere, the presence of the aliphatic chain of the DOS counterion induces a less pronounced effect on the symmetry (*p2gg* lattice) than that on complex **2** (*c2mm* lattice).

The influence of the counteranion on thermal behaviour follows the same trend: the molecular arrangement in the solid phase of the dodecyl sulfate derivatives is more effective than that of the triflate complexes, which tend to melt at lower temperatures and show a wider mesophase range with respect to the homologues in the dodecyl sulfate series.

Moreover, complexes **1**–**4** show luminescence at room temperature both in solution and in the solid state, which is not a common feature for Ag^{I} derivatives,[8] and therefore they represent interesting materials for applicative purposes requiring room temperature luminescent liquid crystals.

Experimental Section

Materials and Measurements: Silver triflate (AgOTf) was purchased from Aldrich and used as received. Also the solvents were used as received from commercial sources without further purification. Ligands, dihexadecyl 2,2′-bipyridine-4,4′-dicarboxylate (L^1) and 4,4′-bis(3,4,5-trihexadecyloxybenzoyloxymethyl) 2,2′-bipyridine (L^2) were synthesised as previously reported.[4a,4c]

Infrared spectra were recorded with a Spectrum One FT-IR Perkin–Elmer spectrometer and ^{1}H NMR spectra with a Bruker AVANCE-300 spectrometer, in $CDCl_3$ solution, with TMS as internal standard. Elemental analyses were performed with a Perkin–Elmer 2400 analyser.

The textures of the mesophases were studied with a Zeiss Axioscope polarising microscope equipped with a Linkam CO 600 heating stage. The transition temperatures and enthalpies were measured with a Perkin–Elmer Pyris 1 Differential Scanning Calorimeter with a heating and cooling rate of 10 °C/min. The apparatus was calibrated with indium. Two or more heating/cooling cycles were performed on each sample.

Spectrofluorimetric grade dichloromethane (Acros Organics) was used for the photophysical investigations in solution, at room temperature. A Perkin–Elmer Lambda 900 spectrophotometer was employed to obtain the absorption spectra, while the uncorrected emission spectra, all confirmed by excitation ones, were recorded with a Perkin–Elmer LS 50B spectrofluorimeter, equipped with a Hamamatsu R928 photomultiplier tube. Emission quantum yields were determined using the optically dilute method[18a] on aerated solutions with absorbance at excitation wavelengths <0.1; $Ru(bipy)_3Cl_2$ (bipy = 2,2′-bipyridine) in water was used as standard (Φ = 0.028).[18b] The experimental uncertainty on the molar extinction coefficients is 10%, while on the emission quantum yields it is 15%. The examined compounds are fairly stable in dichloromethane, as demonstrated by the constancy of their absorption spectra over a week.

The powder X-ray diffraction patterns were obtained by using a Bruker AXS General Area Detector Diffraction System (D8 Discover with GADDS) with Cu-K_α radiation; the high sensitive area detector was placed at a distance from the sample of 10 cm and equipped with a CalCTec (Italy) heating stage. The samples were heated at a rate of 5.0 °C min^{-1} to the appropriate temperature. Measurements were performed by charging samples in Lindemann capillary tubes with an inner diameter of 0.5 mm.

Synthesis of Complexes: All silver complexes were prepared in a similar fashion from the appropriate ligands and silver salts. The synthesis of complex **1** is described in detail below while for all others only yields, ^{1}H NMR, IR and elemental analysis data are reported.

Bis(dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate)silver(I) Triflate [$(L^1)_2$Ag](OTf) (1): A solution of AgOTf (15 mg, 0.0575 mmol) and L^1 (80 mg, 0.115 mmol) in dichloromethane (10 mL) was stirred under nitrogen (24 h, 40 °C), with the vessel protected from light. The mixture was then filtered through Celite and concentrated under reduced pressure. The product was collected as a yellow solid in 96% yield (90 mg) after precipitation by diethyl ether; thermotropic behaviour is shown in Table 1. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.87 (t, $^3J_{H,H}$ = 6.4 Hz, 12 H, CH_3), 1.25 (m, 104 H, $(CH_2)_{13}CH_3$), 1.84 (m, 8 H, $CH_2(CH_2)_{13}CH_3$), 4.43 (t, $^3J_{H,H}$ = 6.8 Hz, 8 H, OCH_2), 8.07 (d, $^3J_{H,H}$ = 5.1 Hz, 4 H, H-5), 8.81 (s, 4 H, H-3), 8.92 (d, $^3J_{H,H}$ = 5.1 Hz, 4 H, H-6). IR (KBr): $\tilde{\nu}$ = 1726 cm^{-1} (C=O), 1288, 1255 cm^{-1} (OTf). $C_{89}H_{144}AgF_3N_4O_{11}S$ (1643.07): calcd. C 65.06, H 8.83, N 3.41; found C 65.16, H 8.90, N 3.34.

Bis(dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate)silver(I) Dodecyl Sulfate [$(L^1)_2$Ag](DOS) (2): The product was collected as a pale yellow solid in 82% yield (83 mg); thermotropic behaviour is shown in Table 1. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.87 (t, $^3J_{H,H}$ = 6.8 Hz, 15 H, CH_3), 1.25 (m, 122 H, $(CH_2)_nCH_3$), 1.84 (m, 10 H, $CH_2(CH_2)_nCH_3$), 4.10 (t, $^3J_{H,H}$ = 6.8 Hz, 2 H, O_3SOCH_2), 4.45 (t, $^3J_{H,H}$ = 6.6 Hz, 8 H, OCH_2), 8.10 (dd, $^3J_{H,H}$ = 5.1, $^4J_{H,H}$ = 1.5 Hz, 4 H, H-5), 8.86 (s, 4 H, H-3), 9.07 (d, $^3J_{H,H}$ = 5.1 Hz, 4 H, H-6). IR (KBr): $\tilde{\nu}$ = 1720 cm^{-1} (C=O), 1254, 1230 cm^{-1} (DOS). $C_{100}H_{169}AgN_4O_{12}S$ (1759.39): calcd. C 68.27, H 9.68, N 3.18; found C 68.33, H 9.58, N 3.05.

Bis[4,4′-bis(3,4,5-trihexadecyloxybenzoyloxymethyl)-2,2′-bipyridyl]-silver(I) Triflate [$(L^2)_2$Ag](OTf) (3): The product was collected as a white solid in 92% yield (211 mg); thermotropic behaviour is shown in Table 1. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.85 (t, $^3J_{H,H}$ = 6.2 Hz, 36 H, CH_3), 1.25 (m, 312 H, $(CH_2)_{13}CH_3$), 1.83 (m, 24 H, $CH_2(CH_2)_{13}CH_3$), 4.02 (t, $^3J_{H,H}$ = 6.8 Hz, 24 H, OCH_2), 5.53 (s, 8 H, H-7), 7.32 (s, 8 H, H-8,9), 7.57 (d, $^3J_{H,H}$ = 4.9 Hz, 4 H, H-5), 8.32 (s, 4 H, H-3), 8.64 (d, ^3J = 5.0 Hz, 4 H, H-6). IR (KBr): $\tilde{\nu}$ = 1709 cm^{-1} (C=O), 1252, 1220 cm^{-1} (OTf). $C_{245}H_{424}AgF_3N_4O_{23}S$ (3991.00): calcd. C 73.73, H 10.71, N 1.40; found C 73.52, H 10.56, N 1.41.

Bis[4,4′-bis(3,4,5-trihexadecyloxybenzoyloxymethyl)-2,2′-bipyridyl]-silver(I) Dodecyl Sulfate, [$(L^2)_2$Ag](DOS) (4): The product was collected as a beige solid in 78% yield (184 mg); thermotropic behav-

Formation, Structure, and Reactivity of Gaseous $Ni_2O_2^+$

Konrad Koszinowski,[a,b] Maria Schlangen,[a] Detlef Schröder,[a] and Helmut Schwarz*[a]

In memoriam Chava Lifshitz

Keywords: Catalysis / C–H bond activation / Gas-phase reactions / Metal clusters / Nickel / Transition-metal oxides

The dinuclear metal dioxide $Ni_2O_2^+$ is prepared by the reaction of gaseous Ni_2^+ with N_2O in a Fourier-transform ion-cyclotron-resonance (FT-ICR) mass spectrometer. The title compound oxidizes CO, thus proving the catalytic activity of Ni_2^+ for mediating oxygen-atom transfer from N_2O to CO. Whereas $Ni_2O_2^+$ does not react with H_2 and CH_4, it accomplishes C–H bond activation of ethane, propane, and *n*-butane. In comparison to the previously studied metal-oxide clusters $Mn_2O_2^+$ and $Fe_2O_2^+$, $Ni_2O_2^+$ exhibits an enhanced reactivity, which is ascribed to a lower oxygen-binding energy.

1. Introduction

For more than two decades, the gas-phase chemistry of diatomic transition-metal oxide cations MO^+ has been an area of active research.[1–5] The interest in these species mainly results from the fact that they are the simplest conceivable model compounds for catalytically active transition-metal oxides in the condensed phase, whose structural complexity often is prohibitive for direct mechanistic studies.

With routine methods for the generation of gaseous metal clusters at hand today,[6,7] polynuclear $M_mO_n^+$ species can be investigated as well. These cluster ions are supposed to be more realistic models for neutral, bulk transition-metal oxides than isolated MO_n^+ species, because they exhibit lower charge densities and incorporate some degree of aggregation. Nonetheless, the number of reactivity studies on $M_mO_n^+$ clusters still is limited.[8] So far, research activities have focused on $V_mO_n^+$,[9,10] their heavier homologues $Nb_mO_n^+$ and $Ta_mO_n^+$,[9] $Mn_2O_2^+$,[11] $Fe_mO_n^+$,[12,13] and Pt_mO^+.[14] In addition, reactions of the dinuclear cluster ions $Ti_2O_2^+$ and $Co_2O_2^+$ have been investigated;[15,16] however, these studies did not address the problems of C–H bond activation or oxygen-atom transfer, which are prime challenges in the context of catalysis.[17]

In the present contribution, we report on the gas-phase synthesis and reactivity of $Ni_2O_2^+$. As a group 10 element, nickel has a rather high electronegativity and is less oxophilic than earlier 3*d* metals. It will be interesting to see whether the accordingly expected lower stability of $Ni_2O_2^+$, compared to the previously studied cations $Mn_2O_2^+$ and $Fe_2O_2^+$, results in an enhanced reactivity of the title compound.

2. Results and Discussion

2.1 Formation of $Ni_2O_2^+$

Ni_2^+ reacts with N_2O by oxygen-atom transfer, Equation (1). The resulting Ni_2O^+ continues to abstract oxygen from N_2O, thereby forming $Ni_2O_2^+$, Equation (2), as the final product under ICR conditions.

$$Ni_2^+ + N_2O \rightarrow Ni_2O^+ + N_2 \quad (1)$$

$$Ni_2O^+ + N_2O \rightarrow Ni_2O_2^+ + N_2 \quad (2)$$

The occurrence of these processes under thermal conditions implies $D_0(Ni_2^+–O) \geq D_0(N_2–O) = 161$ kJ·mol^{-1}[18] as well as $D_0(Ni_2O^+–O) \geq D_0(N_2–O)$; the first lower limit is completely in line with $D_0(Ni_2^+–O) = 457.6 \pm 3$ kJ·mol^{-1} reported by Vardhan et al.[19] Both reactions exhibit rather moderate efficiencies (Table 1). Interestingly, several mononuclear transition-metal cations M^+, including Ni^+, have been found not to react at all with N_2O at thermal energies, although oxygen transfer is allowed thermochemically.[2,20,21] The existence of barriers associated with these processes has been rationalized by spin restrictions,[22] as MO^+ correlates with atomic $O(^3P)$, whereas N_2O yields $O(^1D)$ upon adiabatic oxygen release.[2,23] Possibly, the presence of more electronic states in the Ni_2^+ cluster opens new spin-allowed reaction paths not available for the mononu-

 DOI: 10.1002/ejic.200500040

clear system and thus leads to the enhanced reactivity observed.

Table 1. Bimolecular rate constants k, efficiencies φ, and branching ratios (b.r.) for reactions of dinuclear nickel clusters at 298 K.

Reactants	k [cm^3 s^{-1}][a]	φ	Products	b.r. (%)
$Ni_2^+ + N_2O$	3.0×10^{-11}	0.04	$Ni_2O^+ + N_2$	100[b]

[a] Uncertainties of the absolute rate constants estimated at 30%.[40] [b] In addition, $Ni(N_2O)^+$ is formed, see text for discussion.

In addition to oxygen-atom transfer, Ni_2^+ undergoes two side reactions. The first one yields atomic Ni^+ (ca. 7% branching ratio, b.r.) such that the neutral byproduct(s) cannot be inferred unambiguously. One possible suggestion for the latter might be NiO and N_2. According to this assignment, the formation of Ni^+ would result from spontaneous fission of part of the Ni_2O^+ clusters generated after initial O-atom transfer. For this reaction to be exothermic, the relation $D_0(Ni^+–Ni) + D_0(N_2–O) = 393 \pm 2$ kJ·mol^{-1} ≤ $D_0(Ni–O)$ should hold, which is consistent with the reported value $D_{298}(Ni–O) = 382 \pm 17$ kJ·mol^{-1} within error bars.[18] As a direct probe for the involvement of Ni_2O^+ in the generation of Ni^+, the former is subjected to a double-resonance experiment.[24] In this experiment, continuous resonant irradiation ejects all Ni_2O^+ ions formed and thus prevents the build-up of any consecutive products. The effectiveness of this measure is clearly seen from the complete removal of $Ni_2O_2^+$ upon resonant irradiation on Ni_2O^+. In contrast, the amount of Ni^+ generated is not affected, which disproves the involvement of Ni_2O^+ as its precursor, unless the dissociation of Ni_2O^+ occurs faster than the time scale of ion ejection, $\Delta_{eject}t \approx 1$ ms. Alternatively, the formation of Ni^+ can be rationalized by reaction with residual traces of oxygen present in the high vacuum system, Equation (3). The exoergicity of this process has been demonstrated previously.[19]

$$Ni_2^+ + O_2 \rightarrow Ni^+ + NiO_2 \quad (3)$$

However, we cannot rigorously rule out the possible origin of Ni^+ from electronically excited reactant Ni_2^+ either. The thermochemical relations so far discussed rely on the assumption that all reactant cluster ions are in the electronic ground state. Yet, this assumption not necessarily appears valid in light of the results presented next.

The second side reaction (ca. 15% b.r.) leads to the formation of NiN_2O^+. As the abundance of this ion is not affected by continuous ejection of Ni_2O^+ in a double-resonance experiment, the former cannot be generated in a consecutive reaction of neither Ni_2O^+ (nor $Ni_2O_2^+$). Furthermore, NiN_2O^+ cannot result from a consecutive reaction of Ni^+ either because direct association processes are highly unlikely given the small size of the molecular systems under study as well as the low pressure regime of the experiments (and are observed neither for Ni_2^+, Ni_2O^+, nor $Ni_2O_2^+$). Last but not least, the temporal evolution of the abundance of NiN_2O^+ agrees with that of a primary product within the limits of the kinetic scheme applied[25] in that it appears to be formed by a formally direct exchange of Ni for N_2O, Equation (4). At longer reaction times, the yield of NiN_2O^+ declines while NiH_2O^+ emerges as new product ion. A double-resonance experiment confirms that the latter originates from the former. Because traces of water, like oxygen, are inevitably present in the vacuum system, the formation of NiH_2O^+ can obviously be rationalized by a substitution of N_2O for H_2O, Equation (5). The facile occurrence of this exchange suggests that NiN_2O^+ contains an intact N_2O ligand and the ion is thus assigned to correspond to a $Ni(N_2O)^+$ complex.[26]

$$Ni_2^+ + N_2O \rightarrow Ni(N_2O)^+ + Ni \quad (4)$$

$$Ni(N_2O)^+ + H_2O \rightarrow Ni(H_2O)^+ + N_2O \quad (5)$$

Whereas the secondary exchange reaction is substantially exothermic, $D_{298}(Ni^+–H_2O) = 184 \pm 3$ kJ·mol^{-1}[27] vs. $D_0(Ni^+–N_2O) = 105.7 \pm 0.3$ kJ·mol^{-1},[28] the first one is strongly endothermic for ground-state Ni_2^+ ($D_0(Ni^+–Ni) = 204 \pm 10$ kJ·mol^{-1})[29] and should therefore not take place at ambient temperatures. The occurrence of this reaction may thus point to the presence of thermally not equilibrated reactants. Although the generation of electronically excited, long-lived metal clusters in a Smalley-type cluster ion source has not been reported to the best of our knowledge,[30] its involvement might be considered in the present case and warrants further investigation.

In order to assess the effect of the thermalization procedure on the reaction channel in question, the number of argon pulses applied was varied between 0 and 20. Yet, no decrease in the combined abundances of $Ni(N_2O)^+$ and $Ni(H_2O)^+$ was observed. This result is in fact not at all surprising because the Ni_2^+ ions present in the analyzer cell of the FT-ICR mass spectrometer already have undergone a large number of collisions with helium atoms in the supersonic expansion occurring in the Smalley-type cluster-ion source. If any electronically excited $Ni_2{}^+$* survived these conditions, it should not be quenched by collisions with argon atoms either. The absence of any reaction with argon also suggests a lower limit for the bond dissociation energy of the hypothetical excited $Ni_2{}^+$* cluster (if the operation of kinetic barriers is neglected), whereas the substitution of one Ni atom by N_2O according to Equation (4) yields an upper limit of $D_0(Ni^+–Ar) = 54.69 \pm 0.06 \leq D_0(Ni^+–Ni^*) \leq 105.7 \pm 0.3$ kJ·mol^{-1}.[28,31] Ligands L stronger than N_2O then should react with $Ni_2{}^+$* in a similar manner to afford NiL^+ complexes. However, the nickel dimer prepared did neither react with Xe, CO, nor H_2O, although at least the latter two clearly bind Ni^+ more strongly than N_2O does [$D_0(Ni^+–CO) = 175 \pm 11$ kJ·mol^{-1},[29] $D_{298}(Ni^+–H_2O) = 184$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

± 3 kJ·mol^{-1}].[27] Hence, these experiments do not support the generation of electronically excited, long-lived Ni_2^+ in the cluster-ion source.

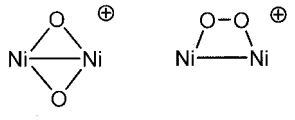
An alternative explanation for the formation of $Ni(N_2O)^+$ borrows from a recent study of Bohme and coworkers, in which termolecular processes were reported to account for the coupling of two or more NO_x molecules by transition-metal ions.[32] With respect to the present case, a plausible scenario for the formation of $Ni(N_2O)^+$ would involve a reaction of ground-state Ni_2^+ with two molecules of N_2O to yield NiO + N_2 as neutral byproducts. However, the low pressures sampled in the present experiments render the occurrence of termolecular reactions highly improbable, in contrast to the conditions applied by Bohme and coworkers.[32]

None of the different suggestions discussed above achieves a conclusive explanation of all experimental findings. Possible other rationalizations include the involvement of impurities and/or fast reacting intermediates that escape attention within the kinetic limits of the ICR studies.[25] Given the low efficiency of $Ni(N_2O)^+$ formation (only ≈ 6 out of 1000 collisions are successful), these factors might indeed be important while difficult to probe. Additional insight could possibly be gained from the application of other mass spectrometric techniques. Note, however, that the unknown origin of NiN_2O^+ by no means affects the reactivity studies of the title compound $Ni_2O_2^+$ which are described in the next section.

2.2 Structure and Reactivity of $Ni_2O_2^+$

The first aspect to be discussed is the structure of the $Ni_2O_2^+$ cluster formed upon reaction of Ni_2^+ with N_2O. Two alternatives appear most likely: The dioxide species **1** or the peroxide **2** (Scheme 1). To distinguish between these alternative structures, $Ni_2O_2^+$ is subjected to CID, which yields Ni^+ and Ni_2O^+ as ionic fragments, respectively (Equation 6).

$$Ni_2O_2^+ \rightarrow Ni^+ + NiO_2 \ 85\%$$
$$Ni_2O_2^+ \rightarrow Ni_2O^+ + O \ 15\% \quad (6)$$



1 **2**

Scheme 1.

This fragmentation pattern is consistent with the parent ion having structure **1**, whereas an additional channel under expulsion of O_2 might be expected for a peroxide species, **2**. As a further probe, $Ni_2O_2^+$ is exposed to $^{18}O_2$. In case of the peroxide **2**, a relatively facile exchange of the O_2 unit might occur. In contrast, the reaction observed experimentally is very slow (Table 1) and only brings about stepwise $^{16}O/^{18}O$ exchange, Equation (7). Therefore, the dioxide structure **1** is assumed most plausible for $Ni_2O_2^+$.[7,33]

$$Ni_2{}^{16}O_2^+ + {}^{18}O_2 \rightarrow Ni_2{}^{16}O{}^{18}O^+ + {}^{16}O{}^{18}O \quad (7)$$

For an evaluation of the oxidative power of $Ni_2O_2^+$, first its reaction with carbon monoxide is studied. While the efficiency of this process is low, $Ni_2O_2^+$ indeed succeeds in the oxidation of CO, Equation (8). Moreover, the resulting Ni_2O^+ also accomplishes oxygen-atom transfer to CO, Equation (9), though even less efficiently than $Ni_2O_2^+$. The stepwise release of atomic oxygen from $Ni_2O_2^+$ is yet another piece of evidence for the dioxide structure **1** rather than that of the peroxide **2** for the ionic reactant.

$$Ni_2O_2^+ + CO \rightarrow Ni_2O^+ + CO_2 \quad (8)$$

$$Ni_2O^+ + CO \rightarrow Ni_2^+ + CO_2 \quad (9)$$

As N_2O spontaneously re-oxidizes Ni_2^+ and Ni_2O^+, gaseous Ni_2^+ in effect catalyzes the oxidation of CO by N_2O. Similar catalytic activities have been reported for several mononuclear transition-metal cations[1,17] as well as for anionic[8] and cationic platinum clusters.[14] In contrast to $Ni_2O_2^+$, $Fe_2O_2^+$ does not transfer an oxygen atom to CO. This difference is a first indication that $Ni_2O_2^+$ is a more powerful oxidant than $Fe_2O_2^+$, as already an analysis of the formal oxidation numbers of the metals would suggest. The average formal oxidation state of +2.5 adopted by the metals in $M_2O_2^+$ is energetically more favorable for iron, whereas nickel strongly prefers an oxidation state of +2 in its compounds.[34] Vann et al. also investigated the reactivity of $Ni_mO_n^+$ clusters towards NO, but could not clearly establish the occurrence of oxygen-transfer processes.[35]

Next, $Ni_2O_2^+$ is exposed to hydrogen. From the absence of any reaction, an upper limit of $k \leq 3\times10^{-14}$ cm^3·s^{-1} can be derived which corresponds to $\varphi \leq 2\times10^{-5}$. For NiO^+, the reaction with H_2 to produce Ni^+ and H_2O does occur, but proceeds only with low efficiency although it is highly exothermic.[36] An analogous situation is encountered for the thoroughly studied system $FeO^+ + H_2$ where the interplay of potential-energy surfaces with different spins turns out to be crucial;[4,22] a similar importance of spin restrictions might be assumed for the reactions of NiO^+ and $Ni_2O_2^+$ with H_2. Unlike the case of oxygen transfer from N_2O towards Ni^+ vs. Ni_2^+, the transition from mononuclear NiO^+ to its dinuclear counterpart does not appear to weaken the effect of these spin restrictions in the particular case of H_2 oxidation.

The remaining reactions explored here are discussed in the context of C–H bond activation. To probe the reactivity of $Ni_2O_2^+$ in this regard, its reactions with CH_4, C_2H_6, C_3H_8, and n-C_4H_{10} are considered. First insights can be gained just from inspection of the overall efficiencies observed (Table 1). While no measurable reaction takes place in the case of methane ($k \leq 1\times10^{-13}$ cm^3·s^{-1}, $\varphi \leq 1\times10^{-4}$), the efficiencies rapidly increase for the larger alkanes and closely approach unity for *n*-butane. This trend correlates with C–H binding energies decreasing as a function of chain length.[18] In addition, a mere size effect can be ex-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pected to further enhance the increase in reactivity. Because of their higher number of internal degrees of freedom, larger substrates can dissipate intramolecularly the energy released upon complexation more effectively and thus lower the probability for dissociation back to the reactants. For NiO^+, unity efficiency is already reached in the reaction with ethane; the increased reactivity of NiO^+ is also reflected in its ability to activate methane.[3] Attenuation of reactivity associated with the transition from mononuclear to dinuclear transition-metal oxides is a general trend also observed for manganese[11] and iron.[12,13] The lower charge densities of the cluster ions and their higher degrees of valence saturation are likely reasons for the more moderate reactivities.[37] As stated initially, exactly these properties add to their attractiveness as model compounds for real catalysts in the condensed phase.

While $Mn_2O_2^+$, $Fe_2O_2^+$, and $Ni_2O_2^+$ have in common lower reactivities towards alkanes than their mononuclear counterparts, they nonetheless also show clear differences in their efficiencies. In contrast to the moderate to high efficiencies observed for the reactions of $Ni_2O_2^+$ with C_nH_{2n+2}, n = 2–4, those reported for the reactions of $Fe_2O_2^+$ are much smaller and even in the case of *n*-butane do not exceed $\varphi = 0.03$.[14] With respect to $Mn_2O_2^+$, only the reaction with *i*-C_4H_{10} was studied, but it did not occur at a measurable rate at all.[11] Thus, $Ni_2O_2^+$ proves to be the most reactive of the $M_2O_2^+$ clusters of late *3d* metals investigated so far.

The main product channel of the reactions of $Ni_2O_2^+$ with the alkanes studied yields $Ni_2H_2O_2^+$ and the corresponding alkene, Equation (10) with n = 2–4, thus corresponding to an oxidative dehydrogenation of the alkane. For the reduced product cluster, $Ni_2(OH)_2^+$ or $Ni_2O(H_2O)^+$ structures seem most likely.

$$Ni_2O_2^+ + C_nH_{2n+n} \rightarrow Ni_2H_2O_2^+ + C_nH_{2n} \quad (10)$$

In addition, mononuclear species $NiC_nH_{2n}^+$ are formed in the reactions with C_3H_8 and *n*-C_4H_{10}, Equation (11) with n = 3 and 4. Apparently, hydrogen transfer and complexation of the metal by the resulting alkene provide sufficient energy to cleave the Ni–Ni bond. In the case of *n*-C_4H_{10}, single and double dehydration occurs as well, Equation (12) and (13).

$$Ni_2O_2^+ + C_nH_{2n+2} \rightarrow NiC_nH_{2n}^+ + NiH_2O_2 \quad (11)$$

$$Ni_2O_2^+ + n\text{-}C_4H_{10} \rightarrow Ni_2C_4H_8O^+ + H_2O \quad (12)$$

$$Ni_2O_2^+ + n\text{-}C_4H_{10} \rightarrow Ni_2C_4H_6^+ + 2\ H_2O \quad (13)$$

An analysis of the kinetic data as well as a double-resonance experiment show that $Ni_2C_4H_8O^+$ also results from a secondary reaction of $Ni_2H_2O_2^+$. This process combines expulsion of H_2O with dehydrogenation of the organic substrate, Equation (14), thus demonstrating an appreciable reactivity of the primary product ion $Ni_2H_2O_2^+$. In addition, this species yields $Ni_2C_4H_{10}O_2^+$ upon reaction with *n*-C_4H_{10}, Equation (15). While this consecutive process formally corresponds to a substitution of H_2 by *n*-C_4H_{10}, it is better interpreted as a dehydrogenation of the alkane leading to a $Ni_2H_2O_2^+(C_4H_8)$ complex.

$$Ni_2H_2O_2^+ + n\text{-}C_4H_{10} \rightarrow Ni_2C_4H_8O^+ + H_2 + H_2O \quad (14)$$

$$Ni_2H_2O_2^+ + n\text{-}C_4H_{10} \rightarrow Ni_2C_4H_{10}O_2^+ + H_2 \quad (15)$$

In another secondary reaction with *n*-C_4H_{10}, $Ni_2C_4H_6^+$ forms $Ni_2C_8H_{12}^+$, Equation (16). This process is remarkable as it shows that $Ni_2C_4H_6^+$, though supposedly already binding 1,3-butadiene as a bifunctional ligand, still is capable of double dehydrogenation of *n*-butane.

$$Ni_2C_4H_6^+ + n\text{-}C_4H_{10} \rightarrow Ni_2C_8H_{12}^+ + 2\ H_2 \quad (16)$$

The reactions of $Ni_2O_2^+$ with C_3H_8 and *n*-C_4H_{10} display several similarities compared to the processes observed for $Fe_2O_2^+$ (for the latter, no reaction products could be detected upon exposure to C_2H_6).[13] For both clusters, dehydrogenation of the alkanes yielding $M_2H_2O_2^+$ corresponds to the main reaction channel, compare Equation (10). In analogy to Equation (12), $Fe_2O_2^+$ also accomplishes dehydration of *n*-C_4H_{10}. Sufficiently exothermic reactions of $Fe_2O_2^+$ with larger hydrocarbons lead to the cleavage of the metallic cluster core, thereby resembling the formation of $NiC_nH_{2n}^+$ in Equation (11). However, there are also some interesting differences between the reactivities of $Ni_2O_2^+$ and $Fe_2O_2^+$. The reactions of $Fe_2O_2^+$ with *n*-butane and larger alkanes yield protonated alkenes, thus allowing an estimation of the proton affinity of Fe_2HO_2, $PA(Fe_2HO_2) \approx 750$–815 kJ·mol^{-1}.[13] From the absence of $C_4H_9^+$ in the reaction of $Ni_2O_2^+$ with *n*-C_4H_{10}, one could infer the inequality $PA(Ni_2HO_2) > PA(Fe_2HO_2)$ under the assumption that protonation of the resulting olefin by $Ni_2H_2O_2^+$ is prevented on thermochemical rather than kinetic grounds. Another product in the reaction of $Fe_2O_2^+$ with *n*-C_4H_{10} is $Fe_2C_2H_6O_2^+$,[13] whereas $Ni_2O_2^+$ exclusively reacts in terms of C–H bond activation and thus exhibits a higher selectivity than $Fe_2O_2^+$, although it is clearly more reactive in terms of the overall reaction efficiency.

3. Conclusions

The cluster cation $Ni_2O_2^+$ can be generated by a gas-phase reaction of Ni_2^+ with N_2O. Analogous procedures might also be used for the efficient preparation of other $M_2O_2^+$ species (compare ref.[12] for the case of $Fe_2O_2^+$, however), whereas most synthetic protocols reported so far directly introduce oxygen in the cluster source[15] or alternatively rely on volatile metal carbonyls.[11,13,16] Evidence is presented that $Ni_2O_2^+$ prepared by the method described here exhibits a genuine dioxide structure.

The observed reactions of $Ni_2O_2^+$ probed can be divided into two classes: Oxygen-atom transfer and C–H bond activation. The first reaction type is operative in the oxidation of CO, a process which could easily be made catalytic if N_2O were provided for the regeneration of $Ni_2O_2^+$. C–H bond activation occurs upon reaction of $Ni_2O_2^+$ with the hydrocarbons ethane, propane, and *n*-butane. In contrast

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to its smaller homologue NiO^+, $Ni_2O_2^+$ does not activate methane, however, thus demonstrating the moderating effect of the transition from mononuclear ions to clusters. In a more general sense, this attenuation in reactivity can be considered as a closer resemblance to the behavior of transition-metal oxides in the condensed phase and thus as an improvement of the gas-phase model for applied catalysis. In comparison to $Mn_2O_2^+$ and $Fe_2O_2^+$, the reactivity of $Ni_2O_2^+$ still is remarkably high, which can be ascribed to a lowered stability of this compound with a formal oxidation state exceeding the value of +2 preferred for nickel.

Experimental Section

Experiments are performed by means of a Spectrospin CMS 47X Fourier-transform ion cyclotron resonance (FT-ICR) mass spectrometer[38] equipped with a Smalley-type[6] cluster-ion source developed by Bondybey, Niedner-Schatteburg, and co-workers.[7,10] In brief, the fundamental of a pulsed Nd:YAG laser (λ = 1064 nm, Spectron Systems) is focused onto a rotating nickel target. The metal plasma thereby generated is entrained in a synchronized helium pulse (15 bar backing pressure) and cooled by supersonic expansion. After passing a skimmer, the cationic components of the molecular beam are transferred into the analyzer cell where they are trapped in the field of a 7.05 T superconducting magnet.

After mass selection of the $^{58}Ni_2^+$ cluster by means of the FERETS ion-ejection technique,[39] argon gas is pulsed-in for ion thermalization. Ni_2^+ is then exposed to N_2O at a static pressure $p \approx 3\times10^{-7}$ mbar. Based on the pseudo first-order kinetic approximation, the temporal evolution of Ni_2^+, the primary product Ni_2O^+, and the consecutive product $Ni_2O_2^+$ is compared to a fit that yields bimolecular rate constants k for both the primary and consecutive reaction with absolute errors estimated to $\pm 30\%$.[40] Reaction efficiencies $\varphi = k/k_{cap}$ are calculated according to capture theory.[41] For the reactivity studies, $Ni_2O_2^+$ is generated by pulsing N_2O to mass-selected, thermalized $^{58}Ni_2^+$ and mass-selected prior to exposure to the static neutral substrate. Bimolecular rate constants and efficiencies are derived as described for the reaction of Ni_2^+ with N_2O. Collision-induced dissociation (CID) of $Ni_2O_2^+$ is accomplished by collision of the kinetically excited ions with pulsed-in argon gas.

New Cadmium(II) and Iron(II) Coordination Frameworks Incorporating a Di(4-pyridyl)isoindoline Ligand

Yanyan Mulyana,[a] Cameron J. Kepert,*[a] Leonard F. Lindoy,*[a] and John C. McMurtrie[a,b]

Keywords: Cadmium / Iron / Molecular framework

The metal-directed assembly of molecular frameworks incorporating the ditopic heterocyclic ligand 1-(4-pyridyl)imino-2-(4-pyridyl)isoindoline (**L**) associated with nonlinear coordination vectors, is presented. Two infinite metallo-arrays of empirical formula $[Cd\mathbf{L}(NO_3)_2(EtOH)]_n\cdot(1.4\,H_2O)_n$ and $[Fe\mathbf{L}_2(NCS)_2]_n\cdot\{(2\,CHClCCl_2)\cdot(1.4\,MeOH)\cdot(2.9\,H_2O)\}_n$ have been characterised. The X-ray structures of both arrays are reported. The cadmium(II) framework consists of co-aligned 1D coordinate polymer chains while the iron(II) framework consists of rhombic grids with 2D polymeric connectivity.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The assembly of metal-organic frameworks is an area of much current interest[1a–1k,2] since the porous structures characteristic of such materials frequently show selective guest molecule uptake (or exchange) from vapours,[3a–3e] solution[3a–3e] and gases[4a,4b] as well as promoting heterogeneous catalysis in a number of cases.[5] While a wide range of organic components has now been incorporated in such frameworks, nitrogen-containing heterocycles have been particularly common and a variety of derivatives of this latter type are available that provide coordination angles that range from 60° to 180°.[6a–6d]

We now report the synthesis of two new coordination frameworks incorporating iron(II) and cadmium(II) that are based on the new heterocyclic nitrogen derivative 1-(4-pyridyl)imino-2-(4-pyridyl)isoindoline (**L**). In comparison with the "classical" prototypical (linear) bis(pyridyl) ligand, 4,4′-bipyridyl,[6a–6d] the positions of the two pyridyl functions in **L** are more separated and the relative orientation of the coordination vectors is now angular. As occurs for other nonlinear bis(pyridyl) ligands such as 4,4′-dipyridyl sulfide,[7a,7b] a number of structural variations in the frameworks formed by **L** appeared possible. In part, the exploration of these possibilities provided a motivation for the investigation now reported.

L

Results and Discussion

Ligand Synthesis

Isoindoline ring generation has been reported previously from the reaction of aniline with *o*-phthalaldehyde.[8] Using this methodology, *o*-phthalaldehyde was condensed with 4-aminopyridine in the present study to yield the isoindoline derivative **L**; the ESI mass spectral, ^1H NMR and microanalysis results confirmed the successful synthesis of this product.

Synthesis and Structures of the Frameworks

Treatment of **L** with cadmium(II) nitrate in ethanol produced colourless crystals of $[Cd\mathbf{L}(NO_3)_2(EtOH)]_n\cdot(1.4\,H_2O)_n$ that were stable in air at room temperature and proved suitable for an X-ray diffraction study. An ORTEP[9] representation of the asymmetric unit, plus a diagram illustrating the cadmium(II) coordination geometry, are presented in Figure 1. Pertinent geometric details are listed in Table 1.

The isoindoline derivative **L** bridges cadmium(II) centres creating a 1D chain-like coordination polymer (see a and b

in Figure 2) with a repeating $[Cd\mathbf{L}(EtOH)(NO_3)_2]$ fragment that propagates parallel to the crystallographic c axis. The cadmium(II) ions are seven coordinate with approximate pentagonal bipyramidal stereochemistry. The pyridyl nitrogen atom N(4) binds within the pentagonal plane along with two nitrate anions (both bidentate). One pyramidal apex is occupied by an ethanol ligand while the other is occupied by the pyridyl nitrogen N(1) from an adjacent ligand in the chain. The individual chains propagate in a zigzag pattern reflecting the ca. 120° angle between the N donor atoms of the pyridyl groups which, in turn, is countered by a combination of the N(1^I)–Cd–N(4) coordination angle (104°) combined with a conformational contribution from the ligand (ca. 16°).

^{I} x, y, z + 1

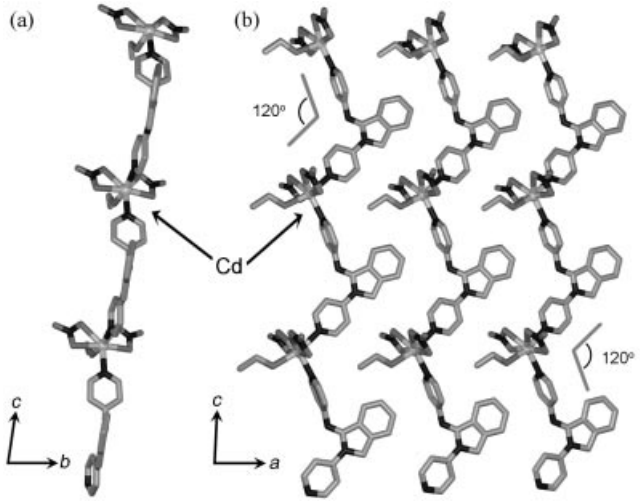

Figure 2. (a) The 1D coordinate polymer chains in $[Cd\mathbf{L}(NO_3)_2(EtOH)]_n\cdot(1.4\,H_2O)_n$ propagate parallel to the c axis. (b) Adjacent chains are aligned in sheets parallel to the ac plane. The individual chains display a 120° zigzag motif that derives from the angle between the N-donor directions countered predominantly by the coordination geometry at the cadmium(II) centre.

Adjacent 1D chains are co-aligned to produce sheets parallel to the ac plane.

These sheets are paired by a combination of offset face-to-face (π···π) interactions between the isoindoline components and edge-to-face (CH···π) interactions between the pyridyl groups of ligands in adjacent sheets (see Figure 1S in the Supporting Information). The isoindoline components involved in the offset face-to-face interactions are arranged with crystallographic inversion symmetry so that the five-membered rings overlap the six-membered rings with a mean plane-plane distance of 3.60 Å. The edge-to-face interactions between pyridyl groups occur with a CH_{edge}–

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Py_{plane} distance of ca. 2.91 Å. Both distances fall in the normal range for each interaction type.[10,11]

The crystal lattice is depicted in Figure 3. Pairs of sheets stack parallel to the *ac* plane to produce channels, occupied by disordered water molecules, that run parallel to the *a* axis (see Figure 2S, Supporting Information). The solvent accessible volume in these channels constitutes approximately 21% of the total crystal volume.

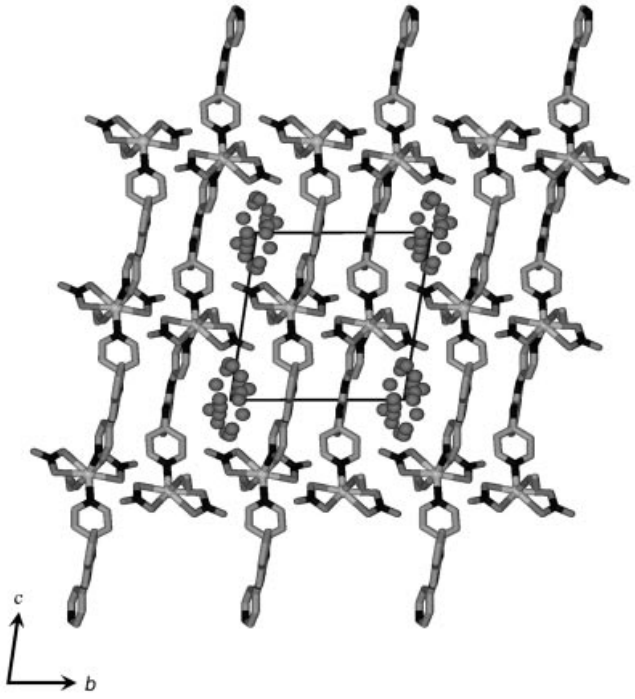

Figure 3. The crystal lattice viewed along the *a* axis. Disordered water molecules occupy channels between the paired sheets of polymeric complexes.

On reaction with iron(II) thiocyanate, **L** yielded the porous framework, $[Fe\mathbf{L}_2(NCS)_2]_n \cdot \{(2\,CHClCCl_2) \cdot (1.4\,MeOH) \cdot (2.9\,H_2O)\}_n$, in which the iron(II) ions subtend with two-dimensional polymeric connectivity. An ORTEP representation of the asymmetric unit and an illustration of the coordination geometry of the iron(II) centre are provided in Figure 4. Pertinent geometry details are listed in Table 2. The iron(II) centre has approximate octahedral stereochemistry with four pyridyl nitrogen atoms (from four separate ligand molecules) coordinated in equatorial positions and thiocyanato ligands *N*-coordinated in axial positions.

The above coordination connectivity results in infinite 2D rhombic grids (Figure 5) that propagate parallel to the *ab* plane; the grids have diagonal dimensions of 13 Å and 22 Å. The rhombic grids stack in the third dimension (along the *c* axis) with contiguous grids alternately offset. The observation of stacked rhombic grids is in contrast to our previous observation of an interpenetrated network structure with *trans*-4,4′-azopyridine (L′) of type $Fe_2(L')_4(NCS)_4 \cdot$(guest) which displays guest-dependent spin crossover.[2]

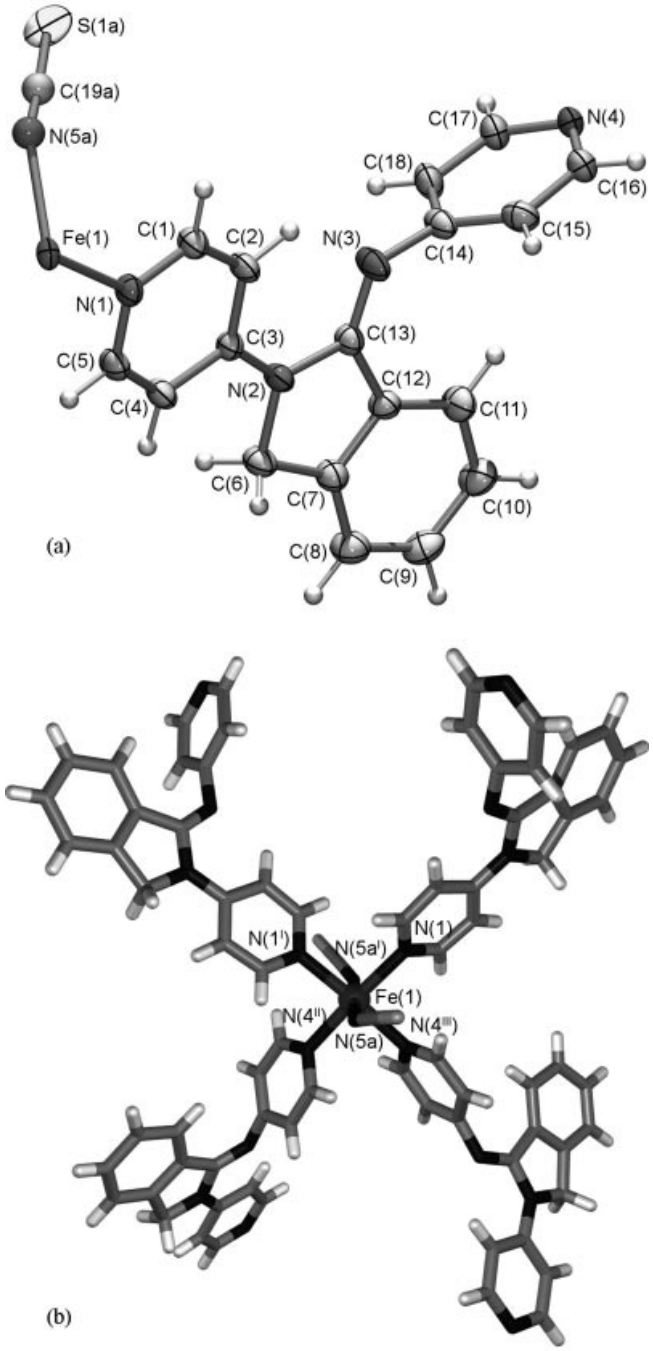

Figure 4. (a) An ORTEP representation of the asymmetric unit in $[Fe\mathbf{L}_2(NCS)_2]_n \cdot \{(2\,CHClCCl_2) \cdot (1.4\,MeOH) \cdot (2.9\,H_2O)\}_n$ (50% probability ellipsoids, solvent and the lower occupancy position of the disordered thiocyanato ligand omitted). (b) The coordination geometry at the iron(II) centre is approximately octahedral. Each iron(II) atom is equatorially bound to four pyridyl nitrogen atoms of four independent isoindoline ligands. Axial positions are occupied by thiocyanato groups.

A SQUID magnetism study of a vacuum-dried sample of the present framework was undertaken from 5 K to 300 K and showed a constant magnetic moment value corresponding to high spin iron(II) of μ_{eff}/μ_B = 5.2 between 80 and 300 K with no evidence for spin-crossover behaviour (zero-field splitting, rather than spin crossover, caused an

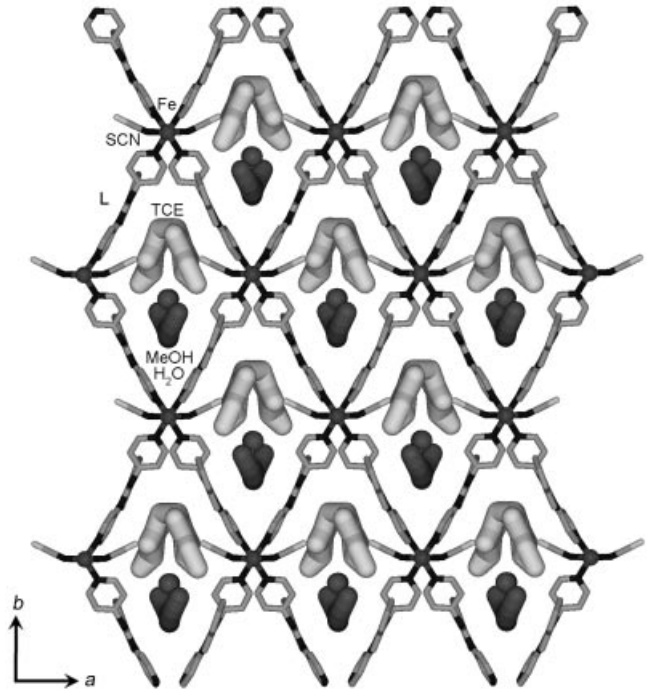

Figure 5. The difunctional isoindoline ligands connect iron atoms to produce rhombic grids. A section of each pore in the grid is occupied by disordered trichloroethylene and the remaining space in the pore is occupied by disordered water and methanol.

abrupt downturn in the effective magnetic moment below 50 K).

The pores in the present grid are solvated with a combination of water, methanol and trichloroethylene molecules. The polar water and methanol molecules are positioned on one side of each pore while the hydrophobic trichloroethylene molecules are positioned on the other. The overlap of the grids produces cavities occupied by trichloroethylene and continuous channels occupied by the water and methanol (this is illustrated in Figure 3S, Supporting Information). The solvent accessible regions in this framework constitute 42% of the total crystal volume and it is noted that solvent is rapidly lost from this product in air at room temperature with loss of crystallinity. Presumably the extensive solvation within the structure in this case provides an alternative to the formation of an interpenetrated arrangement that might otherwise serve to reduce the void volume.

Conclusions

Two new infinite molecular systems, one containing cadmium(II) and another containing iron(II), based on the nonlinear bis(pyridyl) ligand derivative **L** have been synthesised. The cadmium(II) framework is comprised of coaligned 1D coordinate polymer chains while the iron(II) framework consists of rhombic grids with 2D polymeric connectivity. Both crystal lattices are porous; the solvent accessible channels in the cadmium(II) framework constitute 21% of the crystal while those in the iron(II) framework constitute 42%.

Experimental Section

Reagents and Instrumentation: All reagents used for synthesis were obtained commercially and used without further purification. NMR spectra were recorded at 300 K on a Bruker DX300 Spectrometer. Low resolution electrospray mass spectra (ESI-MS) were obtained with a Finnigan LCQ-8 spectrometer. FTIR (DRIFTS) were collected with a Bio-Rad FTS-7 spectrometer. Magnetic susceptibility data were obtained using a Quantum Design MPMS SQUID magnetometer under an applied field of 1 T. The sample was first dispersed in petroleum jelly to prevent it from losing solvent. Diamagnetic corrections for the sample and sample holder were applied using Pascal constants. The magnetic susceptibility was measured from 5 K to 300 K. The final plot was obtained as μ_{eff}/μ_B value (where μ_{eff} is effective magnetic moment that equals to $(\chi_M T)^{1/2}$ and μ_B is Bohr magneton) as a function of temperature (K).

1-(4-Pyridyl)imino-2-(4-pyridyl)isoindoline Dihydrate (L·2H$_2$O): A mixture of *o*-phthalaldehyde (1.0 g, 0.007 mol), 4-aminopyridine (1.4 g, 0.014 mol), and glacial acetic acid (0.5 mL) in xylene (30 mL) was heated under reflux for 5 h to yield a yellow solution. Water was removed from the two-phase reaction using a Dean–Stark apparatus until the initial (two-phase) solution was homogeneous. The solution was then filtered and cooled in a refrigerator. The crude yellow product that precipitated was recrystallised from toluene to give a yellow microcrystalline solid of **L** as its dihydrate. Yield 1.5 g; 75%. $C_{18}H_{18}N_4O_2$ (322.4): calcd. C 67.07, H 5.63, N 17.38; found C 67.39, H 5.23, N 17.16. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 8.54 (t, 5 H), 7.9 (dd, J = 1.65, 1.53 Hz, 2 H), 7.5 (m, 2 H), 7.16 (m, 1 H), 6.93 (m, 2 H), 4.97 (s, 2 H, CH_2) ppm. Mass Spectrum (ESI-MS): Found 287.3 m/z, $[M + H]^+$ requires 287.13 m/z.

[CdL(NO$_3$)$_2$]$_n$·(0.5H$_2$O)$_n$: Ligand **L** (0.02 g) was dissolved in ethanol (1 mL) and the solution placed in one side of a H-shaped glass cell. In the other side was placed a solution of cadmium(II) nitrate tetrahydrate (0.02 g) in ethanol (1 mL). The tube was then slowly filled with ethanol so that minimal mixing of the solution took place. A small quantity of colourless crystals (yield ca. 10%) with formula $[CdL(NO_3)_2(EtOH)]_n \cdot (1.4\,H_2O)_n$ suitable for X-ray analysis formed over a period of two weeks. The crystals were isolated and appeared stable in air over several days. They were dried under vacuum over P_2O_5 before microanalysis. The ethanol ligand and 0.9 water molecules per cadmium(II) were lost from the sample during

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drying. $C_{18}H_{16}CdN_6O_{6.5}$ (532.8): calcd. C 40.58, H 3.03, N 15.77; found C 40.25, H 2.46, N 15.38.

$[FeL_2(NCS)_2]_n\cdot(H_2O)_n$: Iron(II) thiocyanate (0.08 mmol) in a mixture of trichloroethylene/methanol (2:1) 10 mL) was added to a solution of **L** (0.07 mmol) in the same solvent mixture (10 mL). The resulting red-orange solution slowly changed colour to red and after several days and orange crystals with formula $[Fe\mathbf{L}_2(NCS)_2]_n\cdot\{(2\,CHClCCl_2)\cdot(1.4\,MeOH)\cdot(2.9\,H_2O)\}_n$ suitable for X-ray structure determination formed. The crystals (0.03 g, 78%) were isolated and dried under vacuum over P_2O_5, resulting in loss of all solvate except one water molecule (per iron(II)), prior to microanalysis. $C_{38}H_{30}FeN_{10}OS_2$ (762.7): calcd. C 59.84, H 3.96, N 18.36; found C 59.19, H 3.56, N 18.13. A second preparation of this complex was carried out using a dichloromethane/methanol (2:1) solvent mixture. The unit cell constants for a crystal from this batch were determined to be the same as those in crystals obtained from the trichloroethylene/methanol crystallisation experiment.

X-ray Crystallographic Study: Data were collected at 150(2) K with ω scans to approximately 56° 2θ using a Bruker SMART 1000 diffractometer employing graphite-monochromated Mo-$K\alpha$ radiation generated from a sealed tube (0.71073 Å). Data integration and reduction were undertaken with SAINT and XPREP[12] and subsequent computations were carried out using the WinGX-32 graphical user interface.[13a,13b] Multi-scan empirical absorption corrections were applied to the data using the program SADABS.[14] The structures were solved by direct methods using SIR97[15] then refined and extended with SHELXL-97.[16]

In general, ordered non-hydrogen atoms were refined anisotropically. Partial occupancy non-hydrogen atoms were refined isotropically. Carbon-bound hydrogen atoms were included in idealised positions and refined using a riding model. Refinement residuals are defined as $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ for $F_o > 2\sigma(F_o)$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_c^2)^2]\}^{1/2}$ where $w = 1/[\sigma^2(F_o^2) + (\mathbf{A}P)^2 + \mathbf{B}P]$, $P = (F_o^2 + 2F_c^2)/3$ and A and B are listed with the crystal data for each structure.

$[CdL(NO_3)_2(EtOH)]_n\cdot(1.4\,H_2O)_n$: Formula $C_{20}H_{20}CdN_6O_7\cdot(H_2O)_{1.4}$, M = 594.04, triclinic, space group $P\bar{1}$ (no. 2), a = 9.105(2) Å, b = 12.106(3) Å, c = 12.494(3) Å, α = 80.891(4)°, β = 86.483(3)°, γ = 80.048(4), V = 1338.5(5) Å^3, D_c = 1.474 g cm^{-3}, Z = 2, crystal size 0.265 × 0.184 × 0.162 mm, colour colourless, habit multi-faced, temperature 150(2) K, λ(Mo-K_α) = 0.71073, μ(Mo-K_α) 0.869 mm^{-1}, T(empirical)$_{min,max}$ = 0.712, 0.869, $2\theta_{max}$ = 56.6, hkl range –11 to 12, –15 to 15, –16 to 16, N = 13064, N_{ind} = 6101 (R_{merge} = 0.0214), $N_{obsd.}$ = 5490 [$I > 2\sigma(I)$], N_{var} = 341, residuals $R_1(F, 2\sigma)$ = 0.0380, $wR_2(F^2$, all) = 0.1131, A = 0.0705, B = 0.7933, GoF(all) = 1.117, $\Delta\rho_{min,max}$ = –0.674, 1.014 e$^-$Å^{-3}.

Individual details: The water solvate is diffuse and was modelled with oxygen atoms in ten different positions, O(1W)–O(10W), with site occupancies between 0.1 and 0.2 to a total occupancy of 1.4 water molecules per asymmetric unit. H(7OE) attached to the ethanol oxygen atom O(7), was located in the difference map and refined (isotropically) with a 1.0 Å O–H bond length restraint.

$[FeL_2(NCS)_2]_n\cdot\{(2\,CHClCCl_2)\cdot(1.4\,MeOH)\cdot(2.9\,H_2O)\}_n$: Formula $C_{38}H_{28}FeN_{10}S_2\cdot(C_2HCl_3)_2\cdot(CH_4O)_{1.4}\cdot(H_2O)_{2.9}$, M = 1104.54, orthorhombic, space group *Pbcn* (no. 60), a = 13.045(3) Å, b = 22.026(5) Å, c = 17.824(4) Å, V = 5121(2) Å^3, D_c = 1.433 g cm^{-3}, Z = 4, crystal size 0.216 × 0.143 × 0.110 mm, colour orange, habit irregular, temperature 150(2) K, λ(Mo-K_α) = 0.71073, μ(Mo-K_α) 0.741 mm^{-1}, T(empirical)$_{min,max}$ = 0.810, 0.920, $2\theta_{max}$ = 56.6, hkl range –17 to 17, –29 to 29, –23 to 23, N = 20669, N_{ind} = 6279 (R_{merge} = 0.0571), $N_{obsd.}$ = 4288 [$I > 2\sigma(I)$], N_{var} = 270, residuals $R_1(F, 2\sigma)$ = 0.1017, $wR_2(F^2$, all) = 0.3240, A = 0.1762, B = 25.8136, GoF(all) = 1.038, $\Delta\rho_{min,max}$ = –1.781, 1.478 e$^-$Å^{-3}.

Individual details: The asymmetric unit comprises half of one iron(II) atom (Fe on twofold site), one ligand **L** and one thiocyanato ligand. The thiocyanato ligand displays minor disorder and was modelled in two positions, N(5a)–C(19a)–S(1a) and N(5b)–C(19b)–S(1b), with site occupancies of 0.8 and 0.2 respectively. The asymmetric unit also contained regions of smeared electron density associated with diffuse solvent molecules. Using three possible solvents (trichloroethylene, methanol and water), attempts were made to model this diffuse solvent. The most plausible model comprises 1 trichloroethylene (three positions with occupancies 0.5, 0.3 and 0.2), 0.7 methanol (two positions with occupancies 0.4 and 0.3) and 1.45 water (five positions with occupancies 0.4, 0.3, 0.25, 0.25 and 0.25) molecules per asymmetric unit. For comparative purposes, the electron density associated with the disordered solvent was removed from the intensity data using the SQUEEZE function of PLATON.[17a,17b] The cell void volume (in the absence of modelled solvent) was determined to be *c*. 2160 Å^3 which constitutes 42% of the total unit cell volume. The approximate electron count (determined by PLATON) associated with the cell void is 816 electrons (i.e. 102 electrons per asymmetric unit). This is reasonably consistent with the total count of electrons used in the disordered solvent model (87 electrons per asymmetric unit). The residuals obtained upon structure refinement after the application of SQUEEZE [$R_1(F,2\sigma)$ = 0.0463, $wR_2(F^2$,all) = 0.1240] were very acceptable and considerably lower than the residuals obtained upon refinement of the solvated model [$R_1(F,2\sigma)$ = 0.1017, $wR_2(F^2$,all) = 0.3240]. It appears from the SQUEEZE analysis that the high residuals in the reported structure are artefacts of (unavoidable) inadequacies in the solvent model. All disordered components (except water) were refined as rigid groups.

CCDC-258885 and -258886 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_requst/cif.

Supporting Information (see also footnote on the first page of this article): Figures showing how the sheets in $[Cd\mathbf{L}(NO_3)_2(EtOH)]_n\cdot(1.4\,H_2O)_n$ are paired through offset face-to-face π interactions and edge-to-face π interactions; the surface contours of the solvent accessible channels in $[Cd\mathbf{L}(NO_3)_2(EtOH)]_n\cdot(1.4\,H_2O)_n$ and a view of the $[Fe\mathbf{L}_2(NCS)_2]_n\cdot\{(2\,CHClCCl_2)\cdot(1.4\,MeOH)\cdot(2.9\,H_2O)\}_n$ lattice parallel to the *c* axis. In the latter case the grids stack along the *c* axis with adjacent grids offset from one another. The effect of this is to enclose the trichloroethylene in noncontinuous cavities while the water and methanol molecules occupy the continuous channels in the porous framework.

First Examples of Chalcofluoride Rhenium Cluster Complexes with Cubane-Like Anions $[Re_4Q_4F_{12}]^{4-}$ (Q = S, Se)

Yuri V. Mironov,[a] Spartak S. Yarovoi,[a] Dmitry Y. Naumov,[a] Natalia V. Kuratieva,[a] Svetlana G. Kozlova,[a,b] Arndt Simon,[c] and Vladimir E. Fedorov*[a,d]

Dedicated to Professor James A. Ibers on the occasion of his 75th birthday

Keywords: Tetrahedral rhenium cluster / Chalcofluoride complexes / Density functional calculations

Two rhenium tetrahedral cluster chalcofluoride compounds, $K_4[Re_4S_4F_{12}]\cdot 3.4H_2O$ (**1**) and $K_4[Re_4Se_4F_{12}]\cdot 6H_2O$ (**2**), have been synthesized for the first time by a reaction of $Re_4Q_4(TeCl_2)_4Cl_8$ (Q = S, Se) with molten KHF_2. Both compounds have been characterized by single-crystal X-ray diffraction methods. Compound **1** crystallizes in the trigonal space group $R\bar{3}$ with 24 formula units per cell [$a = b = 23.6503(3)$ Å, $c = 25.2697(7)$ Å, $V = 12240.6(4)$ Å^3 ($T = 293$ K)]; compound **2** crystallizes in the monoclinic space group $P\bar{1}$ with four formula units per cell [$a = 10.6451(3)$ Å, $b = 14.6853(4)$ Å, $c = 16.9349(5)$ Å, $\alpha = 66.8420(10)°$, $\beta = 84.8460(10)°$, $\gamma = 85.5740(10)°$, $V = 2421.69(12)$ Å^3 ($T = 293$ K)]. Hydrophilic terminal fluoride ligands of cluster anions are included in the hydrogen bond systems of their hydrate shells.

Introduction

Chalcohalide cluster complexes of the early transition metals like triangular $[M_3Q_7L_6]^{2-}$, tetrahedral $[M_4Q_4L_{12}]^{4-}$, and octahedral $[M_6Q_8L_6]^{4-}$ (M = Mo, W, Re; Q = S, Se, Te) complexes are well known in the literature.[1–6] In these complexes the outer ligands L are most often halide ions (Cl^-, Br^-, I^-) and some other simple ligands such as CN^- and SCN^-. Complexes with organic ligands L are known also. Whereas F^- in both inner and outer positions has been known for a long time from the solid state compounds $Nb_6F^i_{12}F^a_{6/2}$,[7] up to now none was known where a fluoride ion played the role of an outer L ligand in complexes, except for the recently described Mo_3 triangular thiofluoride complex $K_5[Mo_3S_4F_7(FHF)_2]\cdot 2H_2O$ and Re_6 octahedral thiofluoride complexes $[Re_6S_8F_6]^{4-}$ and $[Re_6S_8F_2(H_2O)_4]$.[8,9]

Here we present the successful syntheses, crystal structures, and some properties of the first representatives of tetrahedral chalcofluoride cluster complexes of rhenium $[Re_4Q_4F_{12}]^{4-}$ (Q = S, Se). Cubane-like chalcofluoride rhenium(IV) complexes with cluster anions $[Re_4S_4F_{12}]^{4-}$ and $[Re_4Se_4F_{12}]^{4-}$ were obtained by the reaction of $Re_4Q_4(TeCl_2)_4Cl_8$ (Q = S, Se) with molten potassium bifluoride KHF_2. These anionic complexes were isolated as potassium salts of compositions $K_4[Re_4S_4F_{12}]\cdot 3.4H_2O$ (**1**) and $K_4[Re_4Se_4F_{12}]\cdot 6H_2O$ (**2**) from aqueous solutions. Compounds **1** and **2** are the first examples of cubane-like clusters with fluoride ligands in the outer sphere of a cluster core $\{Re_4Q_4\}$.

Results

The prepared anionic complexes **1** and **2** are the first examples of cubane-like clusters with fluoride ligands in the outer sphere of a cluster core $\{Re_4Q_4\}$, namely $[Re_4S_4F_{12}]^{4-}$ and $[Re_4Se_4F_{12}]^{4-}$ (Figure 1).

Compound **1** crystallizes in the trigonal space group $R\bar{3}$. In the structure there are two different cluster anions $[Re_4S_4F_{12}]^{4-}$ with symmetries C_1 and C_3 respectively, however they are geometrically closely related. Re–Re distances are in the range 2.7277(5)–2.7448(5) Å, and Re–(μ_3-S) distances are in the range 2.310(2)–2.336(2) Å, which are close to those in the starting compound and analogous distances in related cubane rhenium thiohalides. The Re–F distances [1.980(5)–2.020(5) Å] are slightly greater than analogous bond lengths in mononuclear octahedral hexafluororhenates(IV) such as K_2ReF_6 (1.953 Å)[10] and K_3ClReF_6

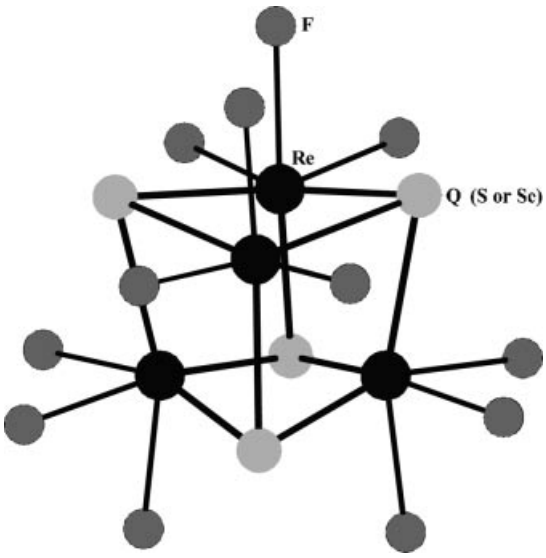

Figure 1. The structure of cluster anions $[Re_4Q_4F_{12}]^{4-}$ (Q = S, Se) in compounds **1** and **2**.

(1.837 Å).[11] In the structure the anions form slightly corrugated hexagonal parallel planes (001) which are linked through potassium cations and hydrogen bonds with additional water molecules.

The K atoms are mainly surrounded by O atoms of water molecules and F atoms of cluster anions. The K8 atom is located on the threefold axis and has a honeycomb-like arrangement of cluster anions (Figure 2).

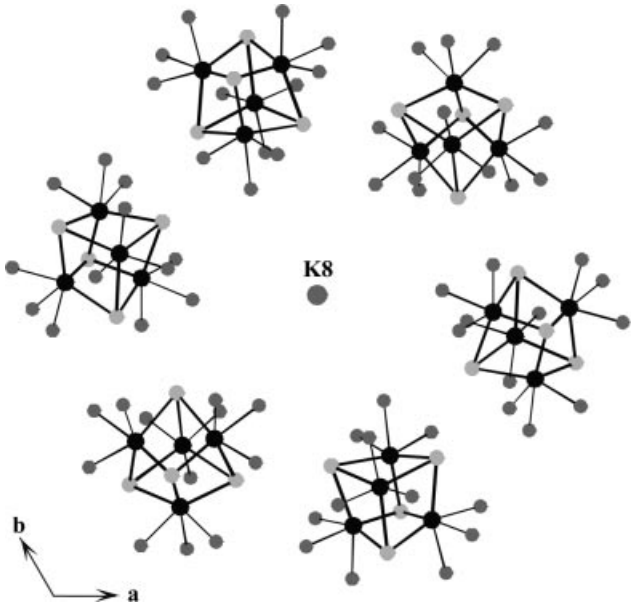

Figure 2. A fragment of the unit cell with honeycomb arrangement of the K8 atom in a projection along the *c* axis in compound **1**.

Compound **2** crystallizes in the triclinic space group $P\bar{1}$. There are two crystallographically independent cluster anions $[Re_4Se_4F_{12}]^{4-}$ in the unit cell. A general view of the mutual arrangement of the clusters in the structure of **2** is given in Figure 3. In the cluster complex the main interatomic distances like Re–Re [2.7527(5)–2.7817(5) Å], Re–(μ_3-Se) [2.4315(10)–2.4454(9) Å], and Re–F [1.987(5)–2.027(5) Å] are in good agreement with those for starting and related compounds. The environment of K atoms consists of fluorine atoms of cluster anions and oxygen atoms of water molecules.

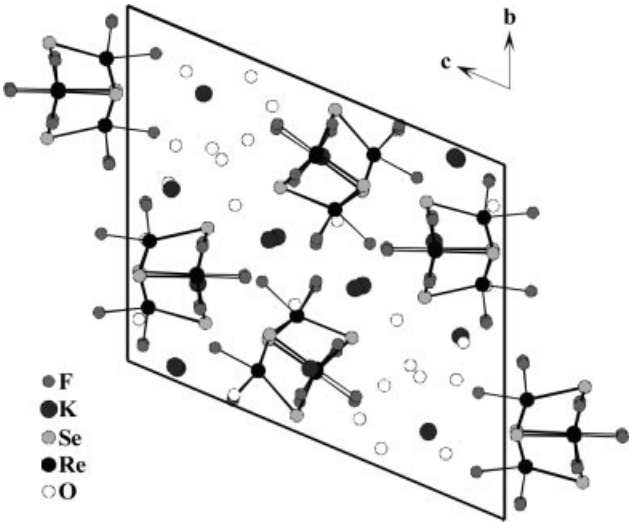

Figure 3. View of the unit cell in a projection along the *a* axis in compound **2**.

In both structures potassium atoms and water molecules connect the cluster anions through potassium ions and hydrogen bonds F···H–O and O···H–O.

NMR

Aqueous solutions of both compounds were studied by NMR on ^{19}F. The spectra of both solutions exhibit only one intensive line with chemical shifts δ^1_{iso} = –227 ppm (compound **1**) and δ^2_{iso} = –252 ppm (compound **2**) and a number of lines with relative intensities less than 0.5% of the strong lines (Figure 4). This experiment was repeated after one month to test the stability of the compounds in the solution, with no changes found in the spectra. It is worth noting that the experimental difference of the chemicals shifts, $\Delta\delta = \delta^1_{iso} - \delta^2_{iso}$ = 25 ppm, correlates with the

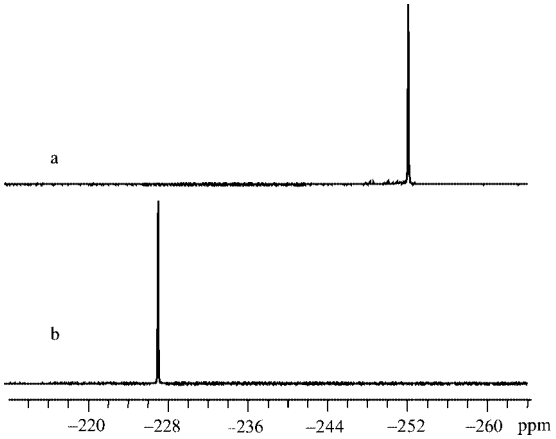

Figure 4. ^{19}F NMR spectra of compounds **1** (a) and **2** (b).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

DFT calculated difference of the isotropic NMR nuclear shielding, $\Delta\sigma = \sigma^2_{iso} - \sigma^1_{iso} = 21$ ppm, for the optimized structures of $[Re_4Q_4F_{12}]^{4-}$ models with symmetry T_d ($\sigma^1_{iso} = 337.9$ ppm and $\sigma^2_{iso} = 358.4$ ppm).

Electronic Structure

The calculated bond energies of the complexes $[Re_4Q_4F_{12}]^{4-}$ indicate that the bonding is energetically feasible, and it is stronger for the S complex (–113.40 eV) than for the Se complex (–109.64 eV). The calculated HOMO–LUMO gap is 2.55 eV for $[Re_4S_4F_{12}]^{4-}$ and 2.42 eV for $[Re_4Se_4F_{12}]^{4-}$. The calculated ionization potentials for these complexes are –5.9 eV (S) and –5.8 eV (Se).

The third degenerated HOMOs, $40t_2$ and $46t_2$, are antibonding in character for S and Se complexes and are largely centered on the rhenium atoms (65% of the 5d-valence orbitals), with the F and Q p-valence orbital contributions (Figure 5). The vacant MOs are formed from the valence orbitals of all atoms also. The exception is represented at levels $24a_1$ (for S) and $27a_1$ (for Se), which are formed mainly from atomic s orbitals of rhenium, chalcogen, and fluorine atoms. The calculated charge distribution suggests that these complexes can be formulated as $Re_4^{0.21+}S_4^{0.11-}F_{12}^{0.37-}$ and $Re_4^{0.19+}S_4^{0.09-}F_{12}^{0.37-}$. The value of a charge on Re atoms is slightly positive and on Q is slightly negative. This indicates the essentially covalent nature of bonding for a cluster core $\{Re_4Q_4\}$.

The dipole-allowed excitation energies for systems with a T_d symmetry are depicted in Figure 5. The energies calculated for proposed transitions are in qualitative agreement with experimental UV/Vis spectra. The uninterrupted weak absorption in the visible range (700–400 nm, $\varepsilon \leq 2\times10^2$) can be explained by electron-dipole transitions between HOMO and a nearby vacant MO (LUMO_LUMO2). The most intensive transitions occur in the UV region of absorption ($\varepsilon > 1\times10^3$) and can involve electron-dipole transitions between the HOMO and vacant MOs.

Experimental Section

$Re_4Q_4(TeCl_2)_4Cl_8$ (Q = S, Se) compounds were prepared as described previously.[12] All other reagents used were commercially available products of reagent grade quality. All experiments were performed in air. UV/Vis spectra were recorded in H_2O with an Ultraspec 3300 Pro spectrometer at room temperature in the range 200–1100 nm. Infrared spectra were recorded with a Bruker IFS-85. ^{19}F NMR spectra of aqueous solutions were obtained with a Bruker MSL-400 spectrometer in a magnetic field of 9.4 T at room temperature. The resonance frequency for ^{19}F was 376.308 MHz, pulse width (90°) 8 μs with a 2-s repetition rate for 3000 transients. Chemical shifts are reported with respect to an external standard C_6F_6. EMA = Electron microprobe analysis.

Preparation of $K_4[Re_4S_4F_{12}]\cdot3.4H_2O$ (1): $Re_4S_4(TeCl_2)_4Cl_8$ (0.35 g, 0.18 mmol) was heated with an excess of KHF_2 (5 g, 64 mmol) in a carbon glass vessel in air for 2 h at 300–310 °C. The fusion cake was washed with water (20 mL), and the remaining solid was dissolved in water (40 mL) to yield a green solution which was filtered and left for a day. A green precipitate formed; it was filtered and dried in air. Yield: 0.19 g (76%). Single crystals of **1** were obtained by dissolving the pure product in water with the addition of a small amount of KHF_2. The solution was left for 3 days in an open polyethylene tube. Dark brown crystals that formed were filtered and dried in air. EMA: $K_{4.1}Re_4S_{3.9}F_{12.1}$. Microanalysis for $H_{6.8}F_{12}K_4O_{3.4}Re_4S_4$: calcd. F 17.29, S 9.73; found F 16.95, S 9.90. IR (KBr): $\tilde{\nu}$ = (Re–F) = 512 (s), 466 (s) cm^{-1}. ^{19}F NMR (ppm): –227. UV/Vis (H_2O): λ, nm (ε, $L\,mol^{-1}\,cm^{-1}$): 230 (5458), 267 (5368), 317 (1965), 363 (1143) (700–400 uninterrupted weak absorption).

Preparation of $K_4[Re_4Se_4F_{12}]\cdot6H_2O$ (2): $Re_4Se_4(TeCl_2)_4Cl_8$ (0.6 g, 0.31 mmol) was treated as described for compound **1** (Yield: 0.29 g (58%)) and single dark green plate crystals of **2** were obtained in the same way as for compound **1**. EMA: $K_{4.1}Re_4Se_{3.8}F_{12.5}$. Microanalysis for $H_{12}F_{12}K_5O_6Re_4Se_4$: calcd. F 14.32; found F 14.68. IR

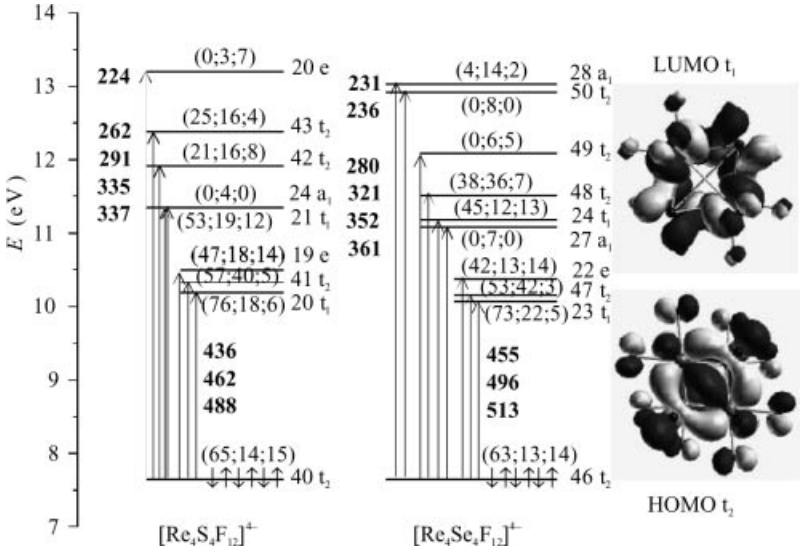

Figure 5. Electronic level schemes for $[Re_4Q_4F_{12}]^{4-}$ models and schematic figures of one from third degenerated HOMO and LUMO. The numbers and symmetry types of the calculated MOs are indicated. Numbers in brackets indicate the percentage of the contributing valence orbitals – 5d Re; 3p S; 4p Se; 2p F, respectively. The vertical arrows and integers (nm) show the calculated transitions.

(KBr): $\tilde{\nu}$ = (Re–F) = 500 (s), 455 (s) cm^{-1}. ^{19}F NMR (ppm): –252. UV/Vis (H_2O): λ, nm (ε, $L\,mol^{-1}\,cm^{-1}$): 265 (2667), 294 (3686), 334 (2429), 381 (sh) (750–430 uninterrupted weak absorption).

X-ray Structure Determination: Diffraction data for **1** and **2** were collected with a Bruker–Nonius X8Apex equipped with a 4-K CCD area detector with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature using standard techniques (Table 1). An empirical absorption correction using the SADABS program was applied. The structures were solved by direct methods employing difference Fourier syntheses and refined anisotropically by full-matrix least-squares techniques on F^2 using the SHELXL-97 Release 97-2 software package.[13] The hydrogen atoms of water molecules were not located. Crystal data, experimental details, and refinement results are summarized in Table 1 and have been deposited with the Fachinformationszentrum Karlsruhe.[14]

DFT Calculations: Density functional spin-restricted calculations (DFT) were carried out on $[Re_4Q_4F_{12}]^{4-}$ models by using the ADF2002 code.[15] The local-exchange VWN correlation potential was used for the local density (LDA) approximation;[16] Becke's nonlocal corrections to the exchange energy[17] and Perdew's nonlocal corrections to the correlation energy were added.[18] The ZORA (zeroth-order relativistic approximation) method was used to account for the scalar relativistic effects.[19] The STO basic set without core potentials was used for all atoms (ZORA/TZ2P). The tetrahedral symmetry, T_d, was imposed on the full geometry optimization of the ground electronic states for the $[Re_4Q_4F_{12}]^{4-}$ and $[Re_4Q_4F_{12}]^{3-}$ models. Calculations of the electronic binding energy were performed as $\Delta E_n = [Re_4Q_4F_{12}]^{n-} - (4Re + 4Q + 12F)$. The ionization potentials were computed as the energy differences between the $[Re_4Q_4F_{12}]^{3-}$ and $[Re_4Q_4F_{12}]^{4-}$, IP = $\Delta E_3 - \Delta E_4$. The atomic net charges for $[Re_4Q_4F_{12}]^{4-}$ complexes were obtained using the Hirshfeld analysis.[20] The isotropic NMR nuclear shieldings (^{19}F σ_{iso}) were calculated by the method of gauge including atomic orbitals (GIAO) with scalar relativistic effects.[21]

Salophan Complexes of Group IV Metals

Stanislav Groysman,[a] Ekaterina Sergeeva,[a] Israel Goldberg,[a] and Moshe Kol*[a]

Keywords: Salophan / Tetradentate ligands / N,O ligands / Coordination modes / Octahedral complexes / Titanium / Zirconium

The coordination chemistry of tetradentate Salophan ligands with titanium and zirconium alkoxides is described for the first time. Three new Salophan ligand precursors featuring different phenolate substituents (*ortho*-Me, *ortho,para*-di-Cl, *ortho,para*-di-*t*Bu) were synthesized in addition to the known prototypical Salophan precursor, by a sequence of condensation and reduction. All ligand precursors were reacted with the metal alkoxides $Ti(OiPr)_4$ and $Zr(OtBu)_4$. The unsubstituted Salophan led to a complex product mixture for both titanium and zirconium. The methyl-substituted ligand led to a clean complex only with zirconium, and the other ligands gave well-defined coordination chemistry with both metals. NMR analysis indicated that these Salophans acted as dianionic ligands, giving rise to hexa-coordinate complexes of C_2-symmetry. X-ray analysis of three complexes supported this view, and revealed that the ligands wrapping mode was *fac-fac* and that the orientation of the labile groups was *cis*. A partial hydrolysis of one of the titanium complexes led to a dinuclear bridging oxo complex in which the ligand wrapping mode had changed to *fac-mer*, as revealed from its crystal structure.

Introduction

Tetradentate diamino-diphenolate [ONNO]-type ligands exhibit a versatile chemistry with many transition and main-group elements.[1–4] Salan-type ligands bind to early transition metals almost exclusively in a *fac-fac* geometry, forming octahedral C_2-symmetrical complexes with the two labile groups in a *cis* geometry. This disposition is suitable for olefin polymerization catalysis.[2,5] In contrast, Salen-type ligands exhibit mostly a *mer-mer* geometrical preference, leading to *trans* disposition of the labile groups.[6] It would thus seem that the hybridization at the nitrogen atom, i.e. sp^2 or sp^3, plays a major role on the [ONNO] ligand wrapping mode.[7] In this regard, the coordination mode of Salan-type ligands, featuring an aromatic spacer between the two nitrogen donors (also known as Salophan ligands), is intriguing when compared with the common Salan ligands possessing an aliphatic spacer.

Lig^1H_2, the prototypical Salophan ligand that features no substituents on the phenolate rings, was studied by several research groups,[8,9] and its coordination behavior was reported to be versatile. Atwood and co-workers have shown that, upon binding to group III alkyls (Al, Ga), this ligand normally acts as a tetra-anionic ligand, forming complexes of varying nuclearity.[8a–8c] In most cases, the ligand was found to bind to the "central" Al in a "flat" fashion, forming the basis of a square-pyramidal complex. For Zn, this ligand acted as a dianionic ligand, forming a dimeric pentacoordinate complex.[8d] For Mo^{VI}, Lig^1H_2 may bind as a tetradentate dianionic ligand, wrapping around the metal in a *fac-fac* fashion forming octahedral complex, or as a tridentate tri-anionic ligand (one of the phenolates unbound and protonated), forming a *mer*-bis(homoleptic) complex.[9] As part of our continuing interest in various [ONNO]-type ligands, we report herein on the preparation of new Salophan-type ligands, and describe our initial results concerning their chemistry with Group IV metals.

Results and Discussion

Two readily available complexes, $Ti(OiPr)_4$ and $Zr(OtBu)_4$, were used as metal precursors for alcoholysis reactions with the ligand precursors. All reactions were performed by adding an ethereal solution of the corresponding ligand to a stirred solution of the metal precursor at –30 °C, followed by warming to room temp. and stirring for an additional hour. At first, we explored the reactivity of the prototypical ligand, Lig^1H_2. The reaction between Lig^1H_2 and $Ti(OiPr)_4$ led to the formation of a red material whose NMR spectra indicated a complex mixture featuring at least six different methyl groups. Under the same conditions, the reaction of Lig^1H_2 and $Zr(OtBu)_4$ also led to a complex mixture. We therefore turned to substituted ligands.

For this purpose, we prepared three additional Salophan-type ligands, having varying steric and electronic influence. In comparison to Lig^1H_2, Lig^2H_2 features electron-donating methyl groups at the *ortho* positions of the phenolate

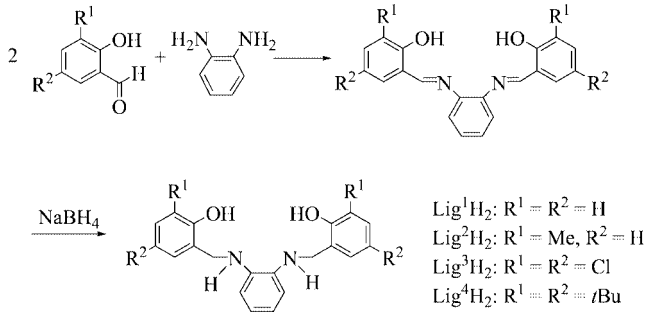
rings, Lig^3H_2 features electron-withdrawing chloro groups at the *ortho*, *para* positions, and Lig^4H_2 bears bulky electron-donating *t*Bu groups at the *ortho*, *para* positions. The ligands were prepared by a two-step route involving condensation between the corresponding 2-hydroxybenzaldehyde and 1,2-phenylenediamine, followed by reduction with sodium borohydride (Scheme 1). For Lig^1H_2 – Lig^3H_2, this route is practical, and leads to the desired ligand precursors smoothly in high yields. For Lig^4H_2, this route is not very effective, as the reduction of the Schiff-base intermediate is very slow, and leads to additional products. Fortunately, the solubility of Lig^4H_2 in methanol is low, so it may be purified by methanol washings of the crude product, or by column chromatography.



Scheme 1. Synthesis of Salophan ligands Lig^1H_2 – Lig^4H_2.

The reaction between Lig^2H_2 bearing methyl substituents and Ti(O*i*Pr)$_4$ led to an initial off-white solid whose color changed within a few minutes to deep-red. The ^{1}H NMR spectrum of this product exhibited broad signals that may indicate some equilibrating species. Recrystallization of this product from cold ether yielded bright-yellow crystals (**2**-Ti), whose solid-state structure was consistent with all subsequent structures (vide supra). However, dissolving these bright-yellow crystals in deuteriobenzene led to a deep red color in seconds, and the spectrum was consistent with the spectrum of the crude product, containing only broad absorptions. In contrast, the initially-formed Zr complex of this ligand, **2**-Zr, did not change color either in the solid phase or in solution for prolonged periods of time, and its ^{1}H NMR spectrum featured sharp absorptions. Interestingly, Lig^3H_2 that carries chloro groups, reacted cleanly with both titanium and zirconium to giving the well-defined **3**-Ti and **3**-Zr, respectively, albeit the smaller size of the Cl groups. The bulky Lig^4H_2, carrying *t*Bu groups near the metal center, also presented a well-behaved reactivity with both metals, yielding the species **4**-Ti and **4**-Zr cleanly.

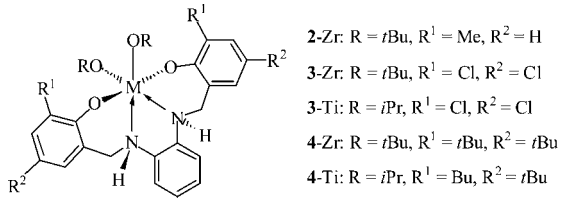


Figure 1. The C_2-symmetrical structure of Salophan-Group IV metal complexes.

Thus, relative to Lig^2H_2, both the electron withdrawing ligand Lig^3H_2 and the bulky ligand Lig^4H_2 lead to well defined products. The stable Salophan complexes obtained in this work are outlined in Figure 1.

The ^{1}H and ^{13}C NMR spectra support a C_2-symmetry of all these complexes as judged by the presence of two distinct aromatic doublets for the phenolate hydrogens, an AB system for the ligand methylene protons, and a single type of labile groups. The diastereotopic methyl groups of the isopropoxide ligands give rise to two peaks in both ^{1}H and ^{13}C NMR spectra of the titanium complexes. According to the presence of NH signals in the ^{1}H NMR spectra and the number of labile groups, these ligands bind to the metal centers in a dianionic fashion. Interestingly, the ligand methylene protons present an additional splitting, seemingly from the NH proton, and this splitting is different for the diastereotopic CH_2 protons. In the sterically congested **4**-Ti complex, two types of splitting are clearly observed (1.2 Hz, 2.7 Hz), while in the more open **3**-Ti complex, only one type of splitting (2.1 Hz) could be observed. For the zirconium species, only one of the AB signals exhibits this additional splitting, and it is consistent throughout the series (3.0–4.0 Hz).

X-ray quality crystals of the complexes **3**-Zr, and **4**-Ti, were obtained upon recrystallization from pentane, and their crystal structures were solved, in addition to the structure of **2**-Ti, obtained upon recrystallization from ether (for the crystal structures see Figure 2, Figure 3 and Figure 4). In agreement with the NMR spectroscopic data, the Salophan ligands wrap around the Group IV metals in a *fac-fac* mode to afford non-crystallographic C_2-symmetrical complexes. As previously observed for the complexes of the Salan series, the phenolate oxygen atoms are located mutually *trans* (160° for **2**-Ti, 156° for **3**-Zr, 160° for **4**-Ti), and the monodentate ligands are mutually *cis* (106° in **2**-Ti, 108° in **3**-Zr, 105° in **4**-Ti), and *trans* to the amine donors (159–166°). Thus, the exchange of the aliphatic spacer between

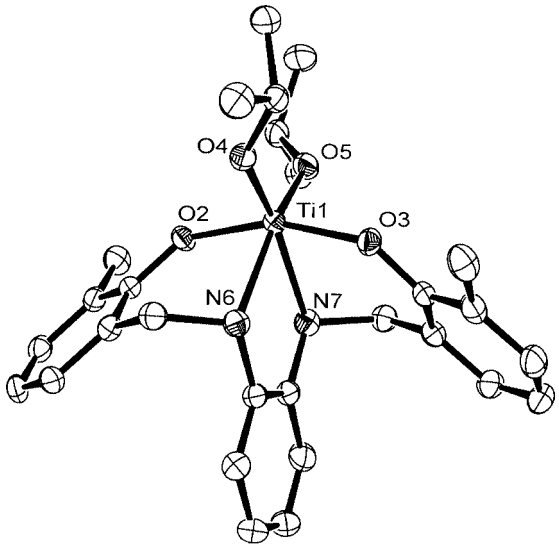

Figure 2. ORTEP representation (50% probability ellipsoids) of **2**-Ti; hydrogen atoms are omitted for clarity.

two amine donors by an aromatic one preserves the overall binding mode in this ligand family. Moreover, the N–M dative bonds for the potentially poorer σ-donor (aniline) are very close to the N–M dative bonds in the complexes featuring ethylene diamine backbone (2.31 Å for **4**-Ti vs. 2.29 Å for the analogous complex with the ethylene diamine backbone).[2b] The M–OPh bond lengths are also comparable to those reported for Salan complexes, with a slight difference for Zr {2.05 Å for **3**-Zr vs. 2.01 Å for [Salan]-$Zr(CH_2Ph)_2$}[2a] probably resulting from the bulkier monodentate ligands. Most notably, the metal is coplanar with the phenylene diamine unit for the sterically open **2**-Ti and **3**-Zr, while for the sterically congested **4**-Ti, the metal lies slightly outside the phenyl plane (see Figure 5).

We found that the titanium complexes are relatively unstable to hydrolysis. For example, the sterically congested complex **4**-Ti undergoes a slow decomposition when stored in a paraffin-sealed NMR tube outside the glovebox. The resulting main product, **4**-Ti-a, which is only slightly soluble in benzene, crystallizes out to give yellow crystals. The NMR spectrum of this compound is complicated, and shows a low symmetry of the ligand backbone, being composed of four *t*Bu peaks, two N–H signals, and four different methylene signals (coupled to two carbon atoms). In addition, the spectrum contains a single isopropoxide group. The X-ray structure determination disclosed a dinuclear structure with a $[Ti_2O]$ μ-oxo core (see Figure 6). Each Ti center is of nearly octahedral geometry, being surrounded by a bridging oxo ligand (Ti1–O 1.848 Å, Ti2–O 1.834 Å), and the isopropoxo ligand, in addition to the [ONNO] donor set of the Salophan ligand. The Ti–OPh distances differ significantly, with the Ti–OPh bond length *trans* to the oxo ligand being longer (1.928 Å vs. 1.847 Å).

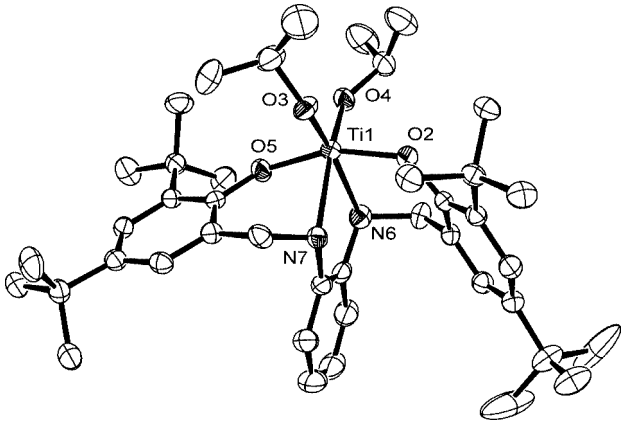

Figure 4. ORTEP representation (50% probability ellipsoids) of **4**-Ti; hydrogen atoms were omitted for clarity.

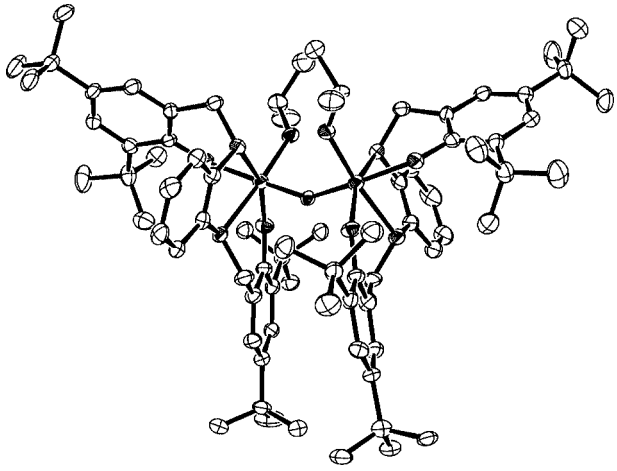

Figure 6. ORTEP representation of **4**-Ti-a, 50% probability; hydrogen atoms, and the crystallization solvent are omitted for clarity. One of the *t*Bu groups is disordered.

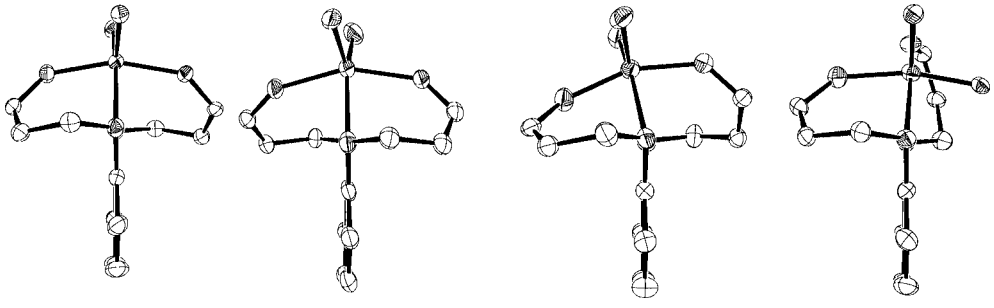

Figure 5. ORTEP representations of the cores of **2**-Ti, **3**-Zr, **4**-Ti, **4**-Ti-a (from left to right, respectively) along the plane of the phenylene ring, demonstrating the relative conformations of the phenylene diamine unit and the metal.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Most significantly, the ligand binds to the metal in a *fac-mer* mode for the first time. The Ti–N bond lengths are relatively different in this disposition: the Ti–N bond in the *mer* fragment is longer than in the *fac* fragment (2.275 and 2.278 Å for the former, and 2.211 and 2.222 Å for the latter), possibly indicating a stronger binding in the *fac* disposition. Finally, the metal is coplanar with the phenylene diamine unit in both parts of the molecule (Figure 5), as previously encountered in **2**-Ti and **3**-Zr complexes, and in contrast to its sterically congested precursor, **4**-Ti.

In conclusion, we have prepared a variety of new Salophan-type ligands, and their titanium and zirconium complexes. The coordination chemistry of these ligands with Group IV metals was found to depend on the phenolate substituents: The substituents-free Lig[1] led to complex mixtures, while the 2,4-dichloro- or di-*t*Bu-substituted ligands Lig[3] or Lig[4] led to a clean chemistry for both metals. The ligand bearing *ortho*-methyl groups Lig[2] formed a stable zirconium complex, and an unstable titanium complex. In all cases in which stable complexes were formed, they possessed C_2-symmetry on the NMR timescale, and their wrapping mode, being supported by X-ray structures, was found to be *fac-fac*, as previously found in Salan-Group IV complexes. The sterically congested di(isopropoxo) titanium complex **4**-Ti was found to undergo a facile (partial) hydrolysis, forming a μ-oxo product, in which the Salophan ligand coordinates to the metal in a *fac-mer* fashion. We are currently investigating the reactivity of these species, and exploring the chemistry of the newly prepared Salophan ligands with other early transition metals.

Experimental Section

Materials and Instrumentation: All syntheses of metal complexes were performed under dry nitrogen in a nitrogen-filled glovebox. Ether was purified by reflux and distillation under dry argon from Na/benzophenone. Pentane was washed with HNO_3/H_2SO_4 prior to distillation from Na/benzophenone/tetraglyme. Ti(O*i*Pr)$_4$ and Zr(O*t*Bu)$_4$ were purchased from Aldrich Inc and used without purification. NMR spectroscopic data for the ligand precursors were recorded with a Bruker AC-200 spectrometer in $CDCl_3$ and referenced to TMS (δ = 0.00) in proton spectra, or to the chemical shift of $CDCl_3$ in carbon NMR spectroscopy. NMR spectroscopic data for the metal complexes were recorded with a Bruker AC-200 or Bruker Avance 400 spectrometers and referenced to protio impurities in [D$_6$]benzene (δ, 7.15), and to ^{13}C chemical shift of benzene (δ, 128.70). Elemental analyses were performed by the microanalytical laboratory of the Hebrew University of Jerusalem. The metal complexes were analyzed within a few hours of being taken out of the freezer of the glovebox. The X-ray diffraction measurements were performed on a Nonius Kappa CCD diffractometer system, using Mo-K_α (λ = 0.7107 Å radiation). The analyzed crystals were embedded within a drop of viscous oil and freeze-cooled to ca. 110 K. The structures were solved by a combination of direct methods and Fourier techniques using the SIR-92 software,[10] and were refined by full-matrix least-squares with SHELXL-97.[11] The crystal data are summarized in Table 1. The crystals of **3**-Zr and **4**-Ti-a contain partly disordered *t*Bu groups, and partly disordered solvent, thus affecting to some extent the precision of the structure determination.

Lig^{1}H$_2$: A solution of salicylaldehyde (4.60 g, 38 mmol) and 1,2-phenylenediamine (2.05 g, 19 mmol) in 60 mL of methanol was placed in a 100 mL round-bottomed flask equipped with a magnetic stir-bar and a reflux condenser. After several minutes, a yellow solution had formed, followed by formation of an orange precipitate (Salophen intermediate). The reaction mixture was allowed to stand for 30 min at room temp. and sodium borohydride (2.86 g, 5 equiv.) was added in small portions to the stirred heterogeneous mixture. The orange precipitate gradually disappeared, and a bright yellow transparent solution formed. The reaction mixture was poured into 100 mL of water, and allowed to stand for several hours. The resulting white solid was isolated by vacuum filtration, washed several times with water, and dried under vacuum at 50 °C for 2 h, yielding 4.99 g of Lig^{1}H$_2$ (82% yield). The ^{1}H/^{13}C NMR spectra indicated its sufficient purity, being consistent with those previously described.[8]

Lig^{2}H$_2$: A solution of 2-methylsalicylaldehyde (0.95 g, 7.1 mmol) and 1,2 phenylenediamine (0.38 g, 3.5 mmol) in 30 mL of methanol was placed in a 100 mL round-bottomed flask equipped with a magnetic stir-bar and a reflux condenser. The resulting bright yellow solution was heated to reflux for 2 h. Upon cooling to room temp. an orange crystalline solid had formed. The solid was collected by vacuum filtration, and identified by ^{1}H NMR as a Salophen intermediate. The orange intermediate product was suspended in 60 mL of methanol, and ca. 5 equiv. of sodium borohydride were added. The reaction mixture became entirely homogeneous and colorless. The solution was poured into 100 mL of water, and the resulting white solid was isolated by vacuum filtration, and dried under vacuum. The yield of Lig^{2}H$_2$ was 0.49 g (40%). $C_{22}H_{24}N_2O_2$ (348.44): calcd. C 75.83, H 6.94, N 8.04; found C 75.81, H 6.92, N 8.18. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.21 (s, 2 H, O–*H*), 7.09 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H), 7.04 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H), 6.94 (s, 4 H), 6.79 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H), 4.38 (d, $^3J_{H,H}$ = 5.4 Hz, 4 H), 3.66 (t, $^3J_{H,H}$ = 5.2 Hz, 2 H), 2.21 (s, 6 H) ppm. ^{13}C NMR (50.29 MHz, $CDCl_3$): δ = 154.8 (*C*), 136.8 (*C*), 130.8 (*C*H), 126.9 (*C*H), 125.4 (*C*), 122.1 (*C*), 121.8 (*C*H), 119.9 (*C*H), 114.4 (*C*H), 48.2 (CH_2), 15.8 (CH_3) ppm.

Lig^{3}H$_2$: 2,4-Dichlorosalicylaldehyde (4.92 g, 26 mmol) was dissolved in ca. 30 mL of methanol and added dropwise to a stirred suspension of 1,2-phenylenediamine (1.41 g, 13 mmol) in 20 mL of methanol. The reaction color changed immediately, and the deep-orange Salophen intermediate crystallized out. The reaction mixture was allowed to stand for 20 min. Sodium borohydride (3 equiv., 2.78 g) was added in small portions to the vigorously stirred heterogeneous mixture. The resulting homogeneous bright yellow solution was poured into 100 mL of water, and extracted with two 50 mL portions of dichloromethane. The combined (yellow) organic phase was dried with anhydrous magnesium sulfate, filtered, and the solvent was removed. The resulting yellow solid was dried under vacuum at 50 °C for 2 h, yielding 3.22 g of pure Lig^{3}H$_2$ (54% yield). $C_{20}H_{16}Cl_4N_2O_2{\cdot}H_2O$ (476.18): calcd. C 50.45, H 3.81, N 5.88; found C 50.74, H 3.55, N 5.95. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.28 (d, $^4J_{H,H}$ = 2.5 Hz, 2 H), 7.14 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H), 6.90 (m, 2 H), 6.79 (m, 2 H), 4.37 (s, 4 H) ppm. ^{13}C NMR (50.29 MHz, $CDCl_3$): δ = 150.0 (*C*), 136.5 (*C*), 128.4 (*C*H), 127.7 (*C*H), 126.6 (*C*), 125.2 (*C*), 121.6 (*C*H), 121.4 (*C*), 114.4 (*C*H), 46.4 (CH_2) ppm.

Lig^{4}H$_2$: A homogeneous bright yellow solution of 3.98 g (17 mmol) of 2,4-di-*tert*-butylsalicylaldehyde and 0.89 g (8.5 mmol) of 1,2 phenylenediamine in 50 mL of methanol was heated to reflux in a 100 mL round-bottomed flask equipped with a magnetic stir-bar and a reflux condenser for 2 h, and then left at room temp. overnight. The orange solid that had formed was collected by vacuum filtration, and identified by ^{1}H NMR as a Salophen intermediate. The yield was 1.54 g (33%). The orange intermediate product was suspended in 60 mL of methanol, and ca. 10 equiv. of sodium borohydride were added, and the reaction mixture was stirred overnight. After hydrolysis, the bright-yellow solid was isolated by vacuum filtration. According to ^{1}H NMR, the solid contained at least two different products. The solid was washed several times with methanol, yielding the insoluble Lig^{4}H$_2$. Alternatively, Lig^{4}H$_2$ could be isolated by flash chromatography, using chloroform as an eluent; however, in this case the yield was lower. Drying under vacuum for 2 h at 100 °C, yielded 0.5 g of Lig^{4}H$_2$ (34% relative to the corresponding Salophen). $C_{36}H_{52}N_2O_2{\cdot}0.5\,H_2O$ (553.82): calcd. C 78.07, H 9.65, N 5.06; found C 78.43, H 9.67, N 5.12. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.98 (s, 2 H), 7.26 (d, $^4J_{H,H}$ = 2.2 Hz, 2 H), 7.04 (d, $^4J_{H,H}$ = 2.2 Hz, 2 H), 6.97 (s, 4 H), 4.35 (d, $^3J_{H,H}$ = 5.9 Hz, 4 H), 3.57 (t, $^3J_{H,H}$ = 5.9 Hz, 2 H), 1.37 (s, 18 H), 1.28 (s, 18 H) ppm. ^{13}C NMR (50.29 MHz, $CDCl_3$): δ = 153.3 (*C*), 142.0 (*C*), 136.9 (*C*), 136.4 (*C*), 124.2 (*C*H), 124.0 (*C*H), 122.3 (*C*), 121.9 (*C*H), 114.6 (*C*H), 49.0 (CH_2), 35.1 (*C*), 34.4 (*C*), 31.8 (CH_3), 29.9 (CH_3) ppm.

2-Zr: 80 mg (0.17 mmol) of Lig^{2}H$_2$ was treated with 67 mg (0.17 mmol) of Zr(O*t*Bu)$_4$. The resulting white solid was washed with a small volume of pentane. The yield was 105 mg (0.15 mmol, 89%). $C_{30}H_{40}N_2O_4Zr$ (583.87): calcd. C 61.71, H 6.91, N 4.80; found C 61.72, H 6.85, N 4.85. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.00 (t, $^3J_{H,H}$ = 4.6 Hz, 2 H), 6.54 (m, 2 H), 6.44 (d, $^3J_{H,H}$ = 4.7 Hz, 2 H), 6.30 (m, 2 H), 4.69 (d, $^2J_{H,H}$ = 11.9 Hz, 2 H), 3.58 (br. s, 2 H), 3.46 (dd, $^2J_{1,H-H}$ = 12.2, $^3J_{2,H-H}$ = 4.0 Hz, 2 H), 2.33 (s, 6 H), 1.51 (s, 18 H) ppm. ^{13}C NMR (50.29 MHz, C_6D_6): δ = 161.3 (*C*), 141.3 (*C*), 131.3 (CH), 128.4 (*C*H), 127.3 (*C*H), 126.6 (*C*), 125.7 (*C*H), 122.1 (*C*)116.8 (*C*H), 75.5 (*C*), 53.5 (CH_2), 33.3 (CH_3), 16.9 (CH_3) ppm.

3-Zr: 69 mg (0.15 mmol) of Lig^{3}H$_2$ was treated with 58 mg (0.15 mmol) of Zr(O*t*Bu)$_4$. The yield was 105 mg (0.15 mmol, 100%). X-ray quality crystals were obtained upon recrystallization from a minimal volume of pentane at –30 °C. $C_{28}H_{32}N_2O_4Cl_4Zr$ (693.60): calcd. C 48.49, H 4.65, N 4.04; found C 48.61, H 4.79, N 3.97. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.07 (d, $^4J_{H,H}$ = 2.6 Hz, 2 H), 6.36 (m, 2 H), 6.29 (d, $^4J_{H,H}$ = 2.6 Hz, 2 H), 6.02 (m, 2 H), 4.65 (d, $^2J_{H,H}$ = 12.8 Hz, 2 H), 3.58 (br. s, 2 H), 3.10 (dd, $^2J_{H,H}$ = 12.9, $^3J_{H,H}$ = 3.5 Hz, 2 H), 1.57 (s, 18 H) ppm. ^{13}C NMR (50.29 MHz, $CDCl_3$): δ = 156.9 (*C*), 139.8 (*C*), 129.7 (*C*H), 128.9 (*C*H), 128.2 (*C*H), 126.2 (*C*H), 124.9 (*C*), 123.7 (*C*), 120.9 (*C*), 76.8 (*C*), 52.9 (CH_2), 33.0 (CH_3) ppm.

4-Zr: Lig^{4}H$_2$ (63 mg, 0.12 mmol) was treated with Zr(O*t*Bu)$_4$ (53 mg, 0.13 mmol). The yield was 83 mg (0.11 mmol, 89%). $C_{44}H_{68}N_2O_4Zr$ (780.25): calcd. C 67.73, H 8.78, N 3.59; found C 67.67, H 8.91, N 3.71. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.30 (d, $^4J_{H,H}$ = 2.5 Hz, 2 H), 6.46 (m, 4 H), 6.36 (m, 2 H), 4.94 (d, $^2J_{H,H}$ = 12.3 Hz, 2 H), 3.73 (br. s, 2 H, N–H), 3.46 (dd, $^2J_{H,H}$ = 12.3, $^4J_{H,H}$ = 3.2 Hz, 2 H), 1.72 (s, 18 H), 1.55 (s, 18 H), 1.17 (s, 18 H) ppm. ^{13}C NMR (50.29 MHz, C_6D_6): δ = 159.0 (*C*), 141.2 (*C*), 138.3 (*C*), 136.3 (*C*), 127.1 (*C*H), 126.4 (*C*H), 126.1 (*C*H), 123.4 (*C*H), 122.7 (*C*), 75.7 (*C*), 54.3 (CH_2), 35.5 (*C*), 34.1 (*C*), 33.5 (CH_3), 31.9 (CH_3), 30.1 (CH_3) ppm.

3-Ti: Lig^{3}H$_2$ (45 mg, 0.10 mmol) was treated with Ti(O*i*Pr)$_4$ (28 mg, 0.10 mmol). The yield was 60 mg (0.10 mmol, 100%). $C_{26}H_{28}N_2O_4Cl_4Ti$ (622.19): calcd. C 50.19, H 4.54, N 4.50; found C 50.59, H 4.61, N 4.51. ^{1}H NMR (200 MHz, C_6D_6): δ = 7.10 (d, $^4J_{H,H}$ = 2.6 Hz, 2 H), 6.39 (m, 2 H), 6.34 (d, $^4J_{H,H}$ = 2.6 Hz, 2 H), 6.13 (m, 2 H), 5.29 (s, $^3J_{H,H}$ = 6.1 Hz, 2 H), 4.66 (br. d, $^2J_{H,H}$ = 12.9 Hz, 2 H), 3.78 (br. s, 2 H), 3.13 (dd, $^2J_{1,\ H-H}$ = 13.2, $^3J_{2,\ H-H}$ = 1.9 Hz, 2 H), 1.51 (d, $^3J_{H,H}$ = 6.2 Hz, 6 H), 1.43 (d, $^3J_{H,H}$ = 6.2 Hz, 6 H) ppm. ^{13}C NMR (50.29 MHz, C_6D_6): δ = 158.4 (*C*), 141.0 (*C*), 130.1 (*C*H), 129.1 (*C*H), 129.0 (*C*H), 128.8 (*C*), 126.2 (*C*H), 125.9 (*C*), 123.5 (*C*), 122.0 (*C*), 79.9 (*C*H), 53.7 (CH_2), 26.9 (CH_3), 26.8 (CH_3) ppm.

4-Ti: Lig^{4}H$_2$ (47 mg, 0.09 mmol) was treated with Ti(O*i*Pr)$_4$ (24 mg, 0.09 mmol). The yield was 63 mg (0.09 mmol, 100%). Recrystallization from pentane (ca. 1 mL) afforded yellow-orange crystals of X-ray quality. $C_{44}H_{68}N_2O_4Ti$ (708.84): calcd. C 71.17, H 9.10, N 3.95; found C 71.42, H 9.14, N 3.96. (400 MHz, C_6D_6): δ = 7.31 (d, $^4J_{H,H}$ = 2.5 Hz, 2 H), 6.55 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H), 6.48 (s, 4 H), 5.03 (s, $^3J_{H,H}$ = 6.1 Hz, 2 H) 4.79 (dd, $^2J_{H,H}$ = 12.5, $^3J_{H,H}$ = 1.2 Hz, 2 H), 4.00 (br. s, 2 H), 3.51 (dd, $^2J_{H,H}$ = 12.6, $^3J_{H,H}$

NMR T_1-Relaxation Measurements on Paramagnetic Organolanthanides: An Alternative Tool for Structure Determination in Solution

Laurent Brachais[a] and Marc Visseaux*[a,b]

Keywords: Spin-lattice relaxation times / Paramagnetic complexes / Lanthanides / NMR spectroscopy

^{1}H NMR investigations were conducted on four paramagnetic organolanthanides, all bearing the tetraisopropylcyclopentadienyl ligand Cp^{4i} (HC_5iPr_4) in order to verify whether or not interactions observed in the solid state are maintained in solution. In some cases variable-temperature experiments were necessary to enhance the resolution and determine the best conditions for the study. The 1D NMR spectrum could be interpreted in every case. Complementary 2D COSY experiments allowed the full attribution of the signals. T_1 (^{1}H) relaxation values were determined for all the paramagnetic complexes at the most suitable temperature, and compared with those of the diamagnetic KCp^{4i}. The same tendency was observed, with particular features concerning the isopropyl groups. Among the four methyl groups, one exhibits a much higher T_1 value and one a much lower value; the two others are intermediate. This was interpreted as the result of a privileged conformation of the Cp^{4i} ligand: the two α-isopropyl groups take up a spatial orientation with one methyl group in the *exo* position, opposite to the metal atom, whereas the methyl groups of the two β-isopropyl groups are equidistant from the metal atom. Whatever the nature of the metal (Nd, Sm), the oxidation state (Sm^{II}, Sm^{III}) or the temperature (298, 363 K), this conformation is retained. The structure in solution seems to be different from that previously determined in the solid state.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Organolanthanide complexes have recently received a growing interest, due in part to their use as catalysts for polymerisation.[1–4] Investigations of the catalytic mechanisms are conducted starting from their molecular structures usually computed from X-ray diffraction data. However, these data reflect a solid-state organisation that is often different from the solution structure involved during reactions.

We recently synthesised a series of complexes bearing the voluminous Cp^{4i} ligand (Cp^{4i} = HC_5iPr_4).[5,6] X-ray studies showed a particular behaviour for several of them: one methyl(Cp^{4i})–lanthanide interaction, possibly agostic, was observed in the X-ray structure of [Ln(Cp^{4i})$_2$(BH_4)] (Ln = Nd, Sm), as well as in divalent [Sm(Cp^{4i})$_2$], whereas [Ln(cot)Cp^{4i}] (cot = C_8H_8) displays an unusually short cot–metal distance. We also established that organolanthanides bearing this Cp^{4i} ligand afford highly *trans*-stereospecific catalysts toward isoprene polymerisation upon activation with BuLi,[6] which is in accordance with the steric hindrance around the metal atom.[7,8] Moreover, [Sm(Cp^{4i})$_2$] was found to be efficient for ε-caprolactone polymerisation, whereas it remained unsolvated in the presence of THF.[5] It was therefore of interest to study thoroughly the stereoelectronic environment of the metal atom in such complexes, and whether or not the interactions observed were maintained in solution, since molecular complexes of lanthanides often behave differently in solution with respect to the solid state.[9]

NMR spectroscopy is a powerful technique that can give additional information, and is thus a complement to X-ray diffraction for studying three-dimensional structures in solution.[10] NMR studies on organolanthanide compounds are still mainly restricted to the diamagnetic derivatives (La, Lu, Y, Sc),[11] while the best catalysts are obtained in the more paramagnetic neodymium and samarium series.[12–14] However, even if the results usually suffer from the loss of resolution of the spectra due to the intrinsic properties of the lanthanide atom, this paramagnetism is able to give some information concerning the complex geometry.[15,16] NMR spectroscopy of paramagnetic molecules has been widely studied and discussed, particularly in terms of chemical shifts,[17] and many lanthanide complexes are used as shift reagents. Paramagnetic metals are also involved in a large number of natural compounds, such as proteins, and their presence usually complicates the study of such compounds. Bertini and co-workers have recently reviewed the

field of paramagnetic NMR spectroscopy of biological compounds.[18] It has been increasingly recognized that, besides contributing to line broadening, the electron–nucleus interactions contain useful structural information. Many of the relevant effects that the presence of paramagnetic metals has on the behaviour of the compound nuclei have to do with the metal's magnetic susceptibility. Most of these effects have been well known since the1950s and 1960s, but a few have been described more recently. Concerning lanthanide complexes, the effect of paramagnetism on the spin–lattice relaxation has been studied but mostly with coordination complexes in aqueous media.[19]

Different techniques have been found to calculate distances from T_1 relaxation rates.[20,21] These methods are, however, complicated to undertake due to the high number of parameters they involve. In particular, the comparison of T_1 values obtained for different compounds should be made at the condition of T_{1min}. This is an important problem in the case of paramagnetic compounds because the T_{1min} is usually only reached at low temperature, which induces an additional loss of resolution, and the poor resolution observed prevents the computation of T_1.

In the present study we compare the molecular structures of several organolanthanide complexes in solution, based on their paramagnetic ^1H NMR spectroscopic data. Moreover, we examine paramagnetic samarium and neodymium complexes to overturn the general idea that comprehensive NMR studies are not possible for compounds of these metals.

The choice of organometallic complexes, presented in Table 1, allows the study of different parameters and their influence on the structure. These parameters are: the metal, the oxidation state of the metal, the nature of the ligands (cot, Cp^{4i}), the solvent and the temperature.

Results and Discussion

Choice of Temperature and Signal Assignment

As a first approach, the temperature dependence of the chemical shifts of the complexes was studied. It is well known that paramagnetic organolanthanides display temperature-dependent NMR spectra with respect to both chemical shifts and resolution.[17]

The goal of this experiment was to determine the best temperature for T_1 measurement, i.e., the temperature at which the spectrum exhibits a good enough resolution with no signal overlaps. For most of the complexes this was reached near the highest temperature of the study, typically a few degrees below the solvent boiling point (near 363 K, Figure 1). This was particularly the case of the neodymium complex $[Nd(cot)Cp^{4i}]$ due to the strong paramagnetic character of this metal. In fact, this latter complex gives broad lines even at high temperature but it was possible to distinguish all signals with only two recovering lines, while at room temperature most of the lines could not be distinguished from the noise.

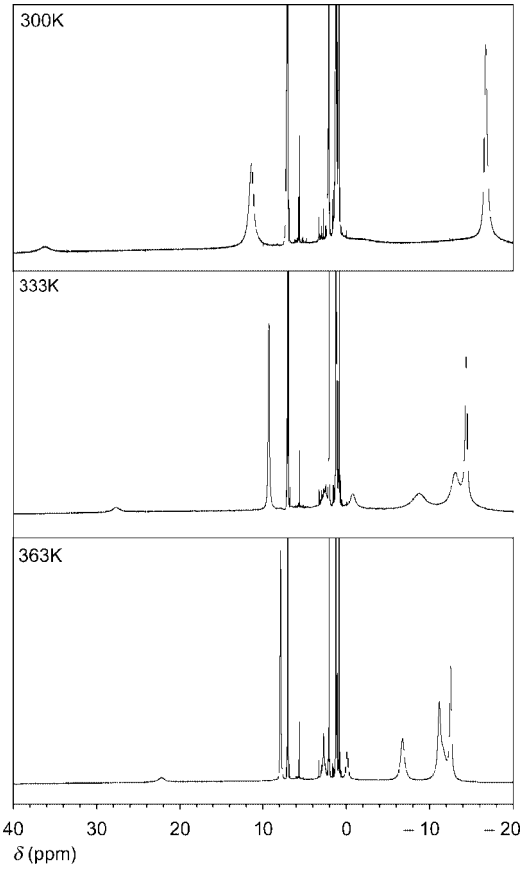

Figure 1. Evolution of the ^1H NMR spectrum of $[Nd(cot)Cp^{4i}]$ (in C_7D_8) with temperature.

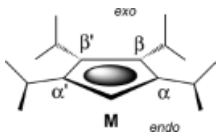
After the temperature had been chosen, it was necessary to complete the assignment. Actually, whatever the complex, there are four non-equivalent methyl groups and two non-equivalent methyne groups all belonging to the four isopropyl groups attached to the Cp unit. This indicates that there are two different types of isopropyl groups. Ac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cording to the symmetry of the Cp^{4i} ligand, two equivalent isopropyl groups are located in an α-position to the Cp methyne group (HCp) and the second type is attributed to both isopropyl groups located in the β-position of the HCp group (Scheme 1).



Scheme 1. Representation of the Cp^{4i} ligand showing the different types of isopropyl groups and the two different sides of the molecule when a metal atom is coordinated.

The presence of four non-equivalent methyl groups for two non-equivalent isopropyl groups means that both methyl groups belonging to the same isopropyl group are non-equivalent (Figure 2). This is explained by the presence of the metal atom located on one side of the Cp plane. Thus, there are two different Cp sides: one *endo* side and one *exo* side. Such a molecular arrangement obviously affords a diastereotopic system of methyl groups.[22,23]

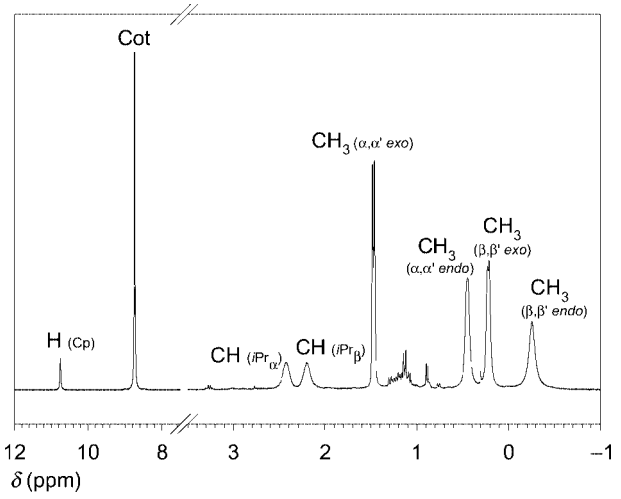


Figure 2. 500 MHz ^{1}H NMR spectrum and assignment of the complex [Sm(cot)Cp^{4i}] recorded at 298 K.

It is noteworthy that the spectrum of KCp^{4i} displays only signals of two types of methyl groups: one type corresponding to the α-isopropyl groups and the other one to the β-isopropyl groups. The geometry of this compound is different from that of the complexes under study as KCp^{4i} is an ionic compound, which means that the potassium ion is not linked to the Cp ring, as neodymium or samarium can be, and therefore *endo* and *exo* sides do not exist. The NMR spectrum can be explained in terms of symmetry if the potassium ion is not coordinated face-on to the Cp ring, with both sides becoming equivalent, or if it alternatively roams quickly from one side to the other in THF.[24] Finally, the methyl groups belonging to the same isopropyl group are enantiotopic in KCp^{4i}.

The next step in the assignment procedure was to connect methyl groups with methyne groups of the same isopropyl group. This was done with a 2D-COSY experiment, which gives correlations between coupled protons (Figure 3). For some complexes, like [Nd(cot)Cp^{4i}], no correlation could be observed due to the very fast relaxation occurring in this compound. As a matter of fact, the incremental delay placed in the 2D sequence to create the second dimension results in a complete relaxation of protons prior to the acquisition step and thus no signal could be detected. Assignment could be achieved for Sm complexes as well as for the potassium salt.

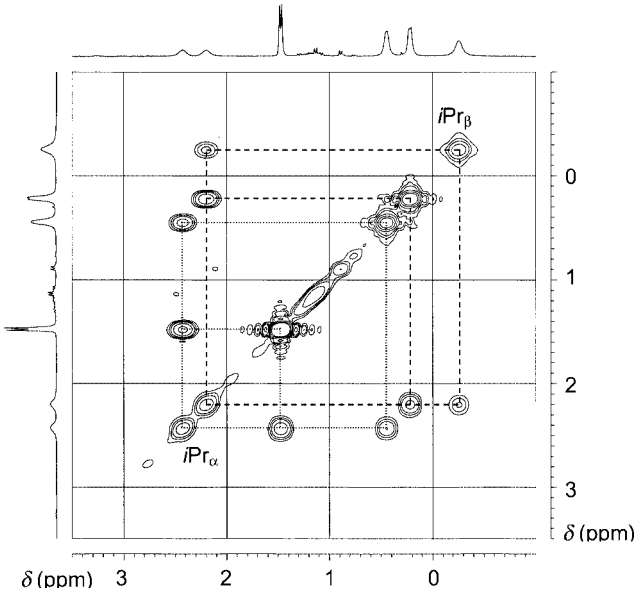

Figure 3. 2D COSY map of the complex [Sm(cot)Cp^{4i}] recorded at 298 K. Assignments of both types of isopropyl groups are shown.

Two uncertainties still remained at this stage of our studies, namely the identification of the α- and the β-isopropyl groups and the *exo*- and *endo*-methyl groups. The first problem was solved by performing an NOE-difference experiment in which the HCp signal was irradiated. We observed a significant variation of one H(*i*Pr) signal intensity, and this isopropyl group was thus assigned to the closest (α and α′) position. Such an experiment could not be conducted on all complexes due to fast relaxation but was unambiguous for [$Sm(BH_4)(Cp^{4i})_2$]. These results were further generalized to the other complexes. The identification of *endo* and *exo* groups was achieved by measuring T_1 values (see below).

Relaxation Study

The non-paramagnetic KCp^{4i} was first studied as a reference. As we remarked previously, the potassium cation does not generate the asymmetry at the Cp ring that is the origin of the *endo* and *exo* sides noticed in the other complexes. Moreover, the metal should have very little influence on the Cp^{4i} relaxation rates since it is not paramagnetic, in contrast with the other complexes under study. The relaxation times of KCp^{4i} are reported in Table 2. These values are similar to those usually observed for small organic molecules. The α- and β-methyne signals exhibit relaxation times

of 2.77 and 2.11 s, respectively, which are rather different. However, in such diamagnetic compounds dipolar relaxation is predominant over other relaxation processes, and this can explain the observed difference. The β-methyne protons feel the influence of methyl groups belonging to the same isopropyl group as well as that of methyl groups belonging to both neighbouring isopropyl groups. In the case of α-methyne protons, however, there is only one neighbouring isopropyl group, which induces a less efficient dipolar relaxation. The α- and β-methyl groups display relaxation times of 1.60 and 1.84 s, respectively; this small difference seems to be not very significant. The relaxation times measured for KCp^{4i} are of no structural interest but are interesting for comparison with those measured for paramagnetic complexes.

As expected, all paramagnetic complexes display relaxation times that are drastically smaller than those reported for KCp^{4i}. This decrease is due to the presence of the paramagnetic metal, although the distances between the protons and the metal atom may also have a strong influence.

Straight lines corresponding to relaxation of [Sm(cot)Cp^{4i}] protons are shown in Figure 4 as an example; the relaxation times of the different complexes under study are reported in Table 2.

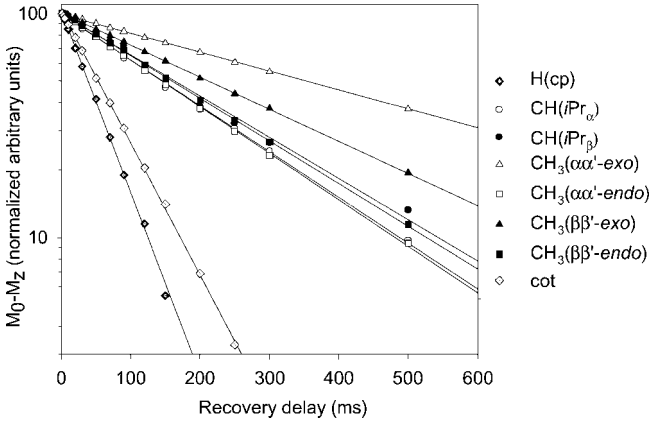

Figure 4. [Sm(cot)Cp^{4i}] T_1 (^{1}H) relaxation plots recorded at 298 K.

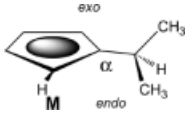
As regards to the variety of the complexes under study, the nature of the metal can be evaluated by comparing both [Sm(cot)Cp^{4i}] and [Nd(cot)Cp^{4i}]. Samarium complexes usually give ^{1}H NMR spectra that are better resolved than those corresponding to neodymium derivatives, which display spectra with very broad lines.[5,6,25] From this consideration, one would expect smaller T_1 values for neodymium than for samarium complexes; the T_1 values reported in Table 2 confirm this. As a matter of fact, [Nd(cot)Cp^{4i}] T_1 values are much smaller than those observed for [Sm(cot)Cp^{4i}]. The ratio T_1([Sm(cot)Cp^{4i}])/T_1([Nd(cot)Cp^{4i}]) has values of between 10, for the cot protons, and 30, for the isopropyl methyne groups. Nevertheless, it is noteworthy that in both complexes the same tendency in the T_1 distribution is observed: the HCp proton has the shortest T_1 relaxation in both compounds, followed by the cot protons. Such small HCp T_1 values were not observed for KCp^{4i}. Obviously, the diamagnetic character of the compound explains the larger T_1 values, but in the case of KCp^{4i} HCp exhibits the largest T_1 value. As explained previously, dipolar relaxation is the most important relaxation mechanism in KCp^{4i} and HCp is the most distant proton from the other ones, thus explaining the lack of efficiency in its relaxation mechanism. In the cases of both [Sm(cot)Cp^{4i}] and [Nd(cot)Cp^{4i}], paramagnetic relaxation dominates and the smaller HCp T_1 values, as compared to those of other nuclei, indicate that HCp is the nearest proton to the metal ion. This is valid for all complexes under study since they all display very small HCp T_1 values.

Other interesting T_1 values are those of the methyl groups. In all complexes T_1 values corresponding to the four non-equivalent types of methyl groups could be measured, leading each time to the same tendency: i) one value is much higher than the others; ii) two types of methyl groups have intermediate values of the same order; iii) the last type of methyl groups exhibits a T_1 value a little bit smaller than the intermediate value; iv) the methyl groups exhibiting the smallest and largest T_1 values belong to the same type of isopropyl groups located in the α-position to HCp, and thus methyl groups with intermediate T_1 values belong to isopropyl groups in the β-position to HCp.

These results give important information concerning the complexes' geometry. It seems that α-isopropyl groups take an orientation in which one methyl group is far from the paramagnetic centre while the other one is much closer to the metal atom. Taking into consideration that the metal atom is located beneath the Cp ring plane, this means that the α-isopropyl groups take an orientation in which one methyl group (with the largest T_1 value) is located on the *exo* side of the Cp ring plane while the other one (with the smallest T_1 value) is located on the *endo* side of this plane. This conformation most likely places the *exo*-methyl group in the plane perpendicular to the Cp ring. In this situation, this methyl group is located as far as possible from the para-

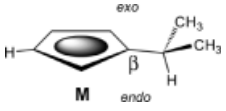
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

magnetic centre. It is noteworthy, given the tetrahedral geometry of sp^3-carbon atoms, that in this case the *endo*-methyl groups are not as close as possible to the metal atom. Also, this conformation places the α-isopropyl methyne groups slightly on the *endo* side but not far from the Cp ring plane (Scheme 2). Thus, whereas the diastereotopic nature of the methyl groups does not give any information about possible free rotation of isopropyl groups on the basis of chemical shifts, the fact that such a T_1 difference can be observed for methyl groups belonging to the same isopropyl groups clearly indicates a tendency to hindered rotation.



Scheme 2. Conformation of the α-isopropyl group, with one methyl group as far as possible from the metal atom.

We can see that β-isopropyl methyne groups have relaxation times close to those measured for α-methyne groups. If we consider that paramagnetic relaxation, and thus the proximity of the metal atom, is the predominant mechanism of relaxation, this indicates that α- and β-methyne groups are approximately at the same distance from the metal atom. Nevertheless, β-methyl groups adopt a quite different orientation from their α homologues, since they display relaxation times between both values observed for α-methyl groups. Moreover, the difference between both methyl groups belonging to the same β-isopropyl group is smaller than that measured between α-isopropyl methyl groups. This suggests an orientation of the β-isopropyl groups in which the methyl groups probably have positions not far from the plane of the Cp ring. According to the fact that the α-*endo*-methyl groups have the shortest relaxation time (as compared to other methyl groups), the β-methyl groups might be on the *exo* side due to their larger T_1 value (Scheme 3).



Scheme 3. Conformation of the β-isopropyl group, with the two methyl groups nearly equidistant to the metal atom.

All these structural considerations are valid for the complete series of paramagnetic complexes under study, whatever the metal or its oxidation state. A comparison of [Sm(cot)Cp^{4i}] and [Sm(Cp^{4i})$_2$(BH_4)] shows the influence that other ligands might have on the Cp^{4i} relaxation. In fact, replacing the cyclooctatetraenyl ligand by a borohydride and a second Cp^{4i} ligand induces a small decrease of the T_1 values. This indicates that if the general geometry of Cp^{4i} is the same, the distances between the metal atom and the Cp^{4i} ligand should be different in both complexes. Actually, the Sm–CP distances have been found to be 2.40 Å in [Sm(cot)Cp^{4i}][5] and 2.44 and 2.47 Å in [Sm(Cp^{4i})$_2$(BH_4)][6] (CP is the centroid of the Cp^{4i} ring). Although the distance is slightly shorter in the cot complex, the T_1 values are higher. However, the geometry of the two complexes is different: [Sm(cot)Cp^{4i}] is a metallocene of Sm^{III}, while [Sm(Cp^{4i})$_2$(BH_4)] bears one additional ligand.

X-ray diffraction analyses also indicate that [Sm(Cp^{4i})$_2$(BH_4)] exhibits one very short Sm–H(CH_3) distance (2.50 Å). This could be due to an agostic interaction. A similar feature, though less pronounced, has also been detected in other [Ln(cot)Cp^{4i}] complexes (Ln = Nd, Sm). According to our NMR experiments, it seems that such an interaction, which should lead to a much smaller T_1 value, is not retained in solution.

Changing the oxidation state of the metal also has important effects on the relaxation times. [Sm(Cp^{4i})$_2$] has a much lower relaxation time than [Sm(Cp^{4i})$_2$(BH_4)], while its Sm–CP distances are slightly longer, as expected for Sm^{II} (2.51 Å);[5] the more pronounced paramagnetism of Sm^{II} against Sm^{III} is responsible for the important decrease of the T_1 values.

As previously noticed, these changes do not influence the Cp geometry; the differences in relaxation times are undoubtedly due to the different electronic configurations of the metal to which the paramagnetism is strongly bound.

Finally, [Sm(Cp^{4i})$_2$(BH_4)] was submitted to T_1 measurements at two different temperatures (room and high temperature), while other complexes were generally studied at high temperature only due to the better resolution under these conditions. This was done mainly to verify that the geometry of the complexes does not change in the range 298–373 K. Obviously, some differences are to be expected when comparing T_1 values measured at both temperatures since temperature influences the motion of the complexes. However, whatever the temperature of the study, the same conclusions can be drawn concerning the [Sm]-Cp^{4i} geometry. The most probable conformation of the Cp^{4i} ligand in all the complexes under study is represented in Figure 5.

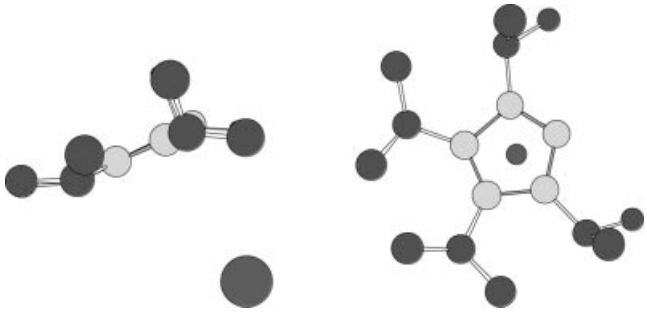


Figure 5. 3D representation of the [Cp^{4i}-Sm] moiety of [Sm(cot)-Cp^{4i}] orthogonally to the Cp ring (left) and in the Cp ring plane (right).

In order to validate our approach, Ln–H distances were calculated from T_1 data. It is well known that relaxation rates are proportional to $1/r^6$, where r can be considered as the metal–H distance, since paramagnetic relaxation is the dominant relaxation process.[21] Under our experimental conditions, only relative distances are easily accessible. For each complex under study, we took as reference the Ln–H(Cp) distance found in its X-ray structure. Among all Ln–

H distances, the latter is supposed to fluctuate the least from the solid state to the solution due to the rigid plane structure of the Cp ring. All other distances given in Table 3 were calculated from this reference. One can see that the computed distances fit quite well with those determined from X-ray studies. As expected, a significant difference is found between *endo*- and *exo*-CH_3αα′. On the other hand, whereas in the solid state the Cp^{4i} ligand displays *endo*- and *exo*-CH_3ββ′, this seems to be no longer the case in solution. The Ln–H(CH_3ββ′) distances take values that are quite similar, which corresponds well to methyl groups both located close to the plane of the Cp ring.

Conclusions

Structural information for four paramagnetic organolanthanides has been deduced by ^{1}H NMR spectroscopy. Despite the paramagnetism, the molecular conformation of the hyperbulky tetraisopropylcyclopentadienyl ligand involved in these complexes was fully resolved from 1D, 2D COSY and T_1 relaxation experiments.

The specific conformation is retained at high temperature, whatever the other surrounding ligands and the nature (neodymium or samarium) and the oxidation state (divalent or trivalent) of the lanthanide atom. The molecular structure in solution differs from that previously observed in the solid state. Such a conclusion can be drawn thanks to T_1 relaxation experiments.

This contribution shows that structural features may not be retained in solution in the case of the bigger early lanthanides, and this should be taken into consideration when performing mechanistic studies. Finally, the paramagnetism of lanthanide complexes does not necessarily preclude extensive NMR investigations for the determination of their conformation in solution.

Experimental Section

General Remarks: All complexes were prepared as published.[5,6] The potassium derivative KCp^{4i} was obtained by the classical reaction of KH with HCp^{4i} in THF. All samples were dissolved in [D_8]-toluene previously dried with Na/K alloy. Toluene was chosen as solvent due to its higher boiling point than benzene. Toluene transfer was performed by vacuum distillation into NMR tubes equipped with a Teflon valve (Young). After transfer, samples were stored under argon pressure. For KCp^{4i} [D_8]THF was used as solvent due to its poor solubility in toluene or benzene. All NMR experiments were recorded with a Bruker Avance 500 spectrometer working at a field of 11 T. Initially, several spectra were recorded as a function of temperature in order to determine the best conditions for the relaxation-time measurements. The highest resolution, and thus the best conditions, were usually reached at 363 or 373 K, depending on the nature of the complex. Assignment of the proton signals was performed with a 2D COSY experiment. The classical sequence using magnitude correction was used. No gradients were used for the complexes containing a paramagnetic metal because the additional delays involved in the pulse sequence result in a complete loss of magnetisation due to the very short relaxation time of the compounds under study. A gradient field 2D-COSY pulse sequence was used for the only non-paramagnetic complex (KCp^{4i}). In this case, the *Z*-gradient powers were set to 10% while the gradient pulse and the delay for gradient recovery were 1 ms and 100 μs, respectively. In order to complete the assignment of the *exo* and *endo* substituents, a 1D NOE-difference experiment was performed; the HCp signal was irradiated to indicate the closest α-and α′-isopropyl groups. Pulse lengths were calibrated prior to each relaxation-time measurement. Typically, the 90° proton pulse was 5.6 μs at an attenuation of 0 dB. T_1 measurements were performed by using the conventional inversion recovery technique. Several experiments of 256 scans were recorded with 20 different durations between the 180° and the 90° pulses. These experiments were recorded in a random order of the durations to minimize errors due to adjustment drifts occurring as a function of the time. The delay between each scan was chosen to be much larger than five times T_1. After Fourier transformation, the intensities of the different signals were collected and the curves $\ln(M_0 - M_Z)$ were drawn as a function of the delay between the 180° and the 90° pulses. The constant M_0 was evaluated by averaging two experiments involving long delays much larger than five times the T_1. The slopes of the obtained straight lines were then computed and led thus to the T_1 values, which are known to be the opposite reverse of the slopes ($-1/T_1$).

Acknowledgments

The authors wish to thank Prof. H. Sitzmann for a gift of the Cp^{4i} ligand and Prof. A. Dormond and Dr. D. Barbier-Baudry for helpful discussions.

The First X-ray Characterized Monosubstituted Ferrocenyl Azacrown Chalcone: Focus on Its Calcium Interaction/Electrochemical Detection Studies

Béatrice Delavaux-Nicot,*[a] Jérôme Maynadié,[a] Dominique Lavabre,[b] Christine Lepetit,[a] and Bruno Donnadieu[a,c]

Keywords: Calcium / Cations / Crown compounds / Ferrocene / Sensors

The first X-ray characterization of an azacrown ferrocenyl chalcone [$(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4$-*p*-aza-15-crown-5)] (**2**) is reported. Its cation electrochemical detection capabilities have been evaluated and its behaviour towards protonation and calcium addition has been thoroughly examined. The uncommon ligand–Ca^{2+} interaction process involves three species of different stoichiometry in equilibrium in solution. Their association constants have been calculated. These species are formed by interaction of calcium with both the azacrown and CO functions of compound **2**, as evidenced by NMR and IR spectroscopy. The theoretical MESP analysis also suggests that, contrary to its *N*-ethyl-substituted homologue [$(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4NEt_2)$] (**1a**), both coordination sites of **2** are involved in this interaction process. The study highlights that the CO group of **2** improves the selectivity of the cation electrochemical detection when compared to the known compound [$(C_5H_5)Fe(C_5H_4$-$CH{=}CHC_6H_4$-*p*-aza-15-crown-5)].
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Although a plethora of redox-active or fluorescent molecules have proved their usefulness as ion sensors,[1] ferrocenyl receptors that contain two types of signaling units, i.e. electroactive and fluorescent, are rare.[2] They could be the keystone of new families of ion chemo-sensors that can either sense different guests or display two or more macroscopic observable events upon addition of a certain analyte.[2c,3a] The fabrication of these systems and their integration into different supports (e.g. electronically conducting polymeric supports and optical fiber) would lead to novel prototype molecular sensory devices for commercial use.[1b,2a]

Recently, we have investigated the synthesis of electroactive receptors that combine a ferrocenyl unit and a purely organic fluorescent ion sensor subunit containing an R-amino complexing moiety (-$COCH{=}CHC_6H_4$-*p*-R):[2b] In particular, the disubstituted compound [$Fe(C_5H_4$-$COCH{=}CHC_6H_4NEt_2)_2$] behaves as a new type of multiresponsive calcium-sensing device in CH_3CN.[4] Its monosubstituted counterpart [$(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4$-$NEt_2)$] (**1a**) is not fluorescent. However, interposition of the conjugated -$COCH{=}CHC_6H_4$- spacer between the ferrocene unit and the NEt_2 ionophore in this compound allows an electronic communication through the link.[2b] This important property suggests that molecules containing this fluorescent organic fragment could be electrochemical sensors. Other research teams have also shown a great deal of interest in the studies of related compounds (analogs of **1a**) incorporating a CO function directly linked to a ferrocenyl moiety,[5] and tested these compounds in applications such antimalarial activity[6] or as potential anticancer drugs.[7] However, none of these compounds was evaluated for electrochemical sensing.

In an earlier study,[8] we focused on the effect of the insertion of a -CH=CH- unit into the conjugated link of compound **1a**, and evaluated three *N*-alkyl ferrocenyl derivatives with a variable spacer length towards cation electrochemical detection (Scheme 1).

Redox-active ionophores based on covalently linked crown ether–metallocene systems have received much attention in recent years because they provide a good selective electrochemical response to the presence of a guest cation.[9] In the present study, we have investigated the influence of the substituent of the nitrogen atom on the cation electrochemical detection and have replaced the diethylamino group of **1a** by the aza-15-crown-5 residue to synthesize compound **2** (Scheme 2). Furthermore, we have pursued our interest in understanding and quantifying the nature of the complex process leading to the calcium electrochemical detection. To the best of our knowledge, this is not a

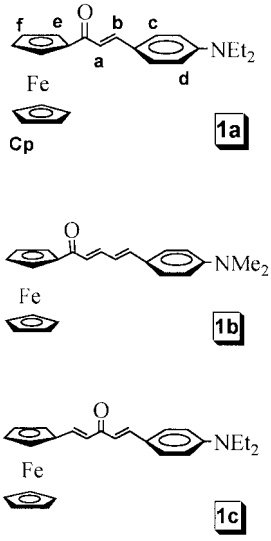

Scheme 1. Compounds **1a**–**c**.

common approach in this research field of ferrocenyl chemistry.

In this paper we report the X-ray and electrochemical characterization of the azacrown compound **2**, together with its cation electrochemical detection abilities. We describe the preparation and characterization of its protonated derivative [**2**H][BF_4] (**3**) and the investigation of thorough ^1H and ^{13}C NMR measurements concerning the interaction of compound **2** with calcium. In addition, we have recorded mass and IR spectral data that provide interesting information about the complex equilibrium that occurs during this interaction. Finally, we compare these results with those obtained in the previous study concerning the *N*-substituted methyl and ethyl compounds.[8] Furthermore, in agreement with experimental data, the theoretical MESP analysis of compounds **1a** and **2** indicates that both coordination sites of **2** are involved in this interaction process.

Results and Discussion

Synthesis and Characterization of Compound 2

We synthesized compound **2** by treatment of acetylferrocene with the appropriate crown aldehyde according to the improved procedure reported for **1a**–**c**[8] (Scheme 2). This new procedure allows a significant improvement on the isolated yield of **2** when compared to our original procedure.[2b] The product was isolated in good yield (65%) as a red powder. The IR spectrum of molecule **2** exhibits a ν(CO) stretching vibration at 1647 cm^{-1} in CH_3CN or in KBr. This low value is due to the conjugation of the CO bond with the double bonds of the π-system (-CH=CHC_6H_4- moiety) in the molecule.[2b,10a–10d] We could observe clearly both the characteristic strong stretching vibrations associated with the methylene groups of the crown in the 2873–2941 cm^{-1} range in CH_3CN[11a] and the asymmetrical stretching C–O–C vibrations as a broad band near 1125 cm^{-1}.[11b]

2D NMR experiments were undertaken in CD_3CN in order to provide a complete assignment of each signal (see Experimental Section). In comparison to compound **1a**, which has nearly the same signals in this solvent, the three CH_2 crown signals observed at δ = 3.57 (br. s), 3.62 (m), and 3.74 (t) ppm, respectively, appear as the ^1H NMR signature of the compound **2** (see Figure S1 in the Supporting Information). Interestingly, a low-field HMQC experiment allowed the verification of a clean correlation between the C_{ipso}-N carbon atom of the phenyl ring and the protons of the CH_2 crown groups α to the nitrogen atom (H_p). This feature is also observed for **1a** and **1c** between the C_{ipso}-N carbon atom and the protons of the CH_2 ethyl groups. Variable temperature NMR experiments in CD_3CN gave no further information.

Crystals of **2** suitable for X-ray structural analysis were obtained by slow recrystallization from CH_3CN. A perspective view of the molecule is shown in Figure 1, crystallographic data for compound **2** are provided in Table 1, and selected bond lengths and angles are listed in Table 2.

N–C(19)	1.462(4)	N–C(19)–C(18)	115.1(2)

The Cp rings of the compound are nearly eclipsed, with a tilt angle of 7°. The bond lengths within the ferrocenyl moieties[12] as well as the C=O, C_5H_4–C_1, and C=C distances compare well with values reported in the literature[12,13] and values obtained for the *N*-alkyl compounds **1b** and **1c**.[8] In compound **2**, the ethylenic bond is *cis* to the CO function, as for the two structurally characterized compounds **1b** and **1c**, and the conjugated organic chain is also almost planar. The crown moiety is essentially perpendicular to this link, with a torsion angle of 103° and 76° for C7–N–C10–C11 and C7–N–C19–C18, respectively. The observed disorder of the oxygen ring atoms illustrates the degree of flexibility of the crown moiety.[14] Its C–C and C–O distances are in the expected range of values.[15] To the best of our knowledge, this molecule is the fourth structurally characterized example of a monosubstituted compound presenting a $C_5H_4COCH{=}CHC_6H_4$ linkage.[8,12a] The C–N distance in **2** [1.375(4) Å] is close to the values observed for **1b**, **1c**, and $[(C_5H_5)Fe(C_5H_4COC_6H_4NH_2)]$[10d] [1.385(4), 1.384(5), and 1.368(9) Å, respectively]. As expected, these distances are longer than that in $[(C_5H_5)Fe(C_5H_4\text{-}COCH{=}CHC_6H_4NO_2)]$[12a] [1.224(11) Å], which bears an electron-withdrawing NO_2 function.

It is noteworthy that the C1a–N distance of around 9.0 Å is significantly shorter than in **1b** and **1c** (11.5 and 11.4 Å, respectively). The distance between the iron atom and the crown carbons (C11, C12) is approximately 9.5 Å. The shortest distance between the Cp unit and the crown ring is the C2B–C12 distance of 7.8 Å.

Electrochemical Studies: Characterization of Compound 2

The electrochemical properties of compound **2** were investigated in CH_3CN (Table 3) and a typical voltammogram of this species is shown in Figure 2. The shape of the cyclic voltammogram is not altered either by multiple successive scans or by change of the scan rate. As shown in Figure 2 and Table 3, compounds **1a** and **2** exhibit similar electrochemical characteristics. For these compounds the first wave observed in the cyclic voltammograms (CV), at $E_{pa} \approx 0.70$ V, is due to the oxidation of the ferrocene moiety and corresponds to a quasi-reversible process whose $E_{1/2}$ value was determined by linear voltammetry. The first irreversible oxidation process of compound **2**, whose $E_{1/2}$ value is 0.92 V, may be attributed to the oxidation potential of the organic amine moiety ($E_{1/2}$ Org).[8] Moreover, it lies in the range of values reported for the oxidation of some azaferrocenyl compounds.[16] Interesting studies on the oxidation of organic and ferrocenyl aromatic and aliphatic amines[17–20] and our previous results[1d,8] suggest that different and/or competitive mechanisms (e.g. amine protonation or radical coupling) may be responsible for the second and third well-defined irreversible organic oxidation waves situated at E_{pa} = 1.20 V and 1.65 V. In reduction, the single wave observed (E_{pa} = –1.76 V) is attributed to a reduction process mainly located on the CO function.

As illustrated by the first organic oxidation potential, the organic moiety of compound **2** is slightly more difficult to oxidize than that of **1a**. This is probably due to the presence of the electron-withdrawing oxygen atom, which decreases the donor strength of the nitrogen atom. Under similar conditions, the same phenomenon is also observed in the case of the organic compounds $[CHOC_6H_4NEt_2]$ and $[CHOC_6H_4\text{-}p\text{-aza-15-crown-5}]$. An anodic shift (60 mV) of the oxidation potential of the organic moiety is observed for the second compound when compared to the first one. It is noticeable that the E_{pa} value of the "CO" reduction process of **2** may vary but its $E_{1/2}$ is always very close to that of the *N*-alkyl compound **1a**.

Electrochemical Calcium Recognition Ability of Compound 2

Electrochemical tests were first performed with **2** (10^{-3} M) in acetonitrile in the presence of various cations (Li^+, Na^+, K^+, Ba^{2+}, Mg^{2+}, Ca^{2+}, Cu^+, Cu^{2+}, and Zn^{2+}). Complex changes occurred in the presence of copper cations and give rise to unclear detections that have not been studied further. As for compound **1a**, compound **2** is poorly sensitive to the presence of cations other than Mg^{2+} and Ca^{2+}. The design of chemosensors that are specific to these biologically relevant cations is a challenging task for many groups.[21] However, for the Mg^{2+} cation, the detection was rather inefficient and peculiar: with one equivalent of salt the iron potential very slowly shifted anodically ($\Delta E_{1/2}$ = 50 mV after 2 h), whereas an incomplete decrease of the intensity of the organic wave was observed, even in salt excess.

As the Ca^{2+} electrochemical sensing was very clear for compound **2** we were especially interested in it. Addition of one equiv. of $Ca(OSO_2CF_3)_2$ to compound **2** induced a clear shift of the $Fe^{II/III}$ couple to anodic potential ($\Delta E_{1/2}$ = 70 mV; Figure 3). This shifted wave still corresponds to a quasi-reversible process ($E_{1/2}$ = 0.70 V, ΔE_p = 81 mV, R_{Ip} = 1.0). Simultaneously, the waves corresponding to the oxidation processes of the organic part of the molecule disappeared. The reduction process is also strongly perturbed (see Figure S2 in the Supporting Information): a very broad, ill-defined reduction wave could be observed around –0.8 V while a new reduction process appeared at –0.19 V (vide infra). Furthermore, when an equimolar mixture of Li^+, Na^+, K^+, Ba^{2+}, Zn^{2+} (4 equiv.) in the presence of 1 equiv. of Ca^{2+} was added to an acetonitrile electrochemical solution of **2**, the same electrochemical characteristics as those induced by Ca^{2+} alone were obtained.

The results obtained here are similar to those obtained for **1a** upon calcium addition. Consequently, in this family of compounds, the cation detection is more sensitive to the nature of the Fe–N spacer than to the nature of the aza group.

Upon comparing the reported data concerning the electrochemical detection of lithium by [(C_5H_5)Fe-$(C_5H_4CH{=}CHC_6H_4NMe_2)$][16] and by [$Fe(C_5H_4CONR_2)_2$][22] with the changes observed by cyclic voltammetry for compound **2** upon calcium addition, it appears that the Ca^{2+} complexation process could involve the whole organic part of molecule **2** since *both* its oxidation and reduction processes are entirely perturbed. Therefore, to determine in particular whether the azacrown moiety and/or the CO function were involved in this complexation (or interaction) process, a thorough NMR study was undertaken.

NMR Spectroscopic Study: Treatment of Compound 2 with H^+ and Ca^{2+}

To investigate the complexation at the nitrogen atom, compound **2** was protonated. In CH_3CN, treatment of compound **2** with $HBF_4{\cdot}Et_2O$ in a 1:1 stoichiometry turned the solution from red to pink and afforded the protonated species [**2**H][BF_4] (**3**; Scheme 2). This new compound was isolated in good yield (80%). As described in the Experimental Section, elemental analyses and mass spectra are also in agreement with the proposed formula for **3**. In the solid state (IR spectrum, KBr), its elongation vibration ν(NH^+) could be located in the expected range 3030–3100 cm^{-1}.[1d,2b,23a]

The characterization of this compound was fully achieved by ^1H and ^{13}C 2D NMR measurements. In the ^1H NMR spectrum (CD_3CN, 293 K, 400 MHz) the protonation reaction was confirmed by the presence of a new signal at δ = 8.48 ppm attributed to the proton of the NH^+ group.[1d,23b] The NCH_2 crown protons α to the nitrogen atom H_p appear as a downfield-shifted multiplet (δ = 3.90 ppm) compared to **2**, as shown in Figure 4. The HMQC measurements indicated that the H_q and H_r protons of the crown groups are diastereotopic (see Experimental Section).

Tables 4 and 5 clearly highlight that compounds **2** and **1a** have a similar NMR behaviour towards protonation. However, the $\Delta(\delta CH_p)$ value of **2** is smaller than that of **1**, which is probably due to the flexibility of the crown moiety. Stronger perturbations of the phenyl ring of **2** are observed upon protonation: the $\Delta(\delta H_d)$ values are 1.16 ppm and 0.82 ppm for **2** and **1a**, respectively. For both compounds, the CH_d and C_{ipso}-C carbon shifts are also sensitive to the important structural variations that occur.[9] Finally, the CH_c, CH_e, CH_f, and CO groups present the smallest variations.

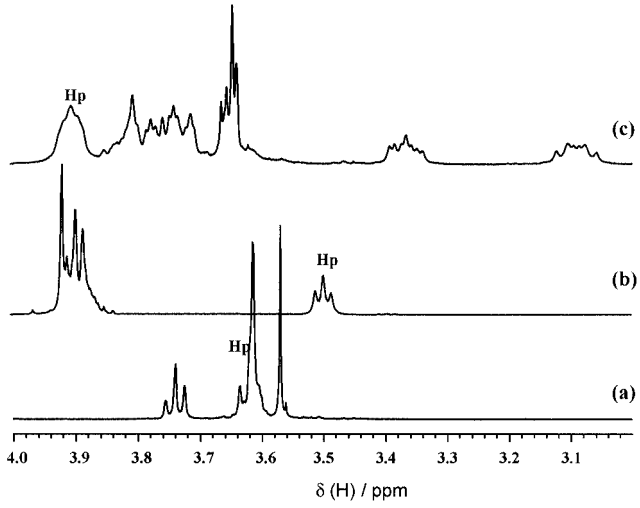

Figure 4. ^1H NMR (400 MHz, CD_3CN) spectra in the δ = 3.0–4.0 ppm range: crown region of (a) **2**, (b) **2** + 1 equiv. Ca^{2+}(c) **2** + 1 equiv. H^+.

To get an insight into the ligand–Ca^{2+} interaction process responsible for the electrochemical detection of calcium, the ^1H NMR spectra of this compound were recorded in CD_3CN both with and without one equivalent of calcium salt. To properly ascertain the variations of the shift observed, 2D NMR measurements were also performed (see Experimental Section).

As indicated in Table 4, the H_a, H_c, and H_d protons of compound **2** present similar downfield shift variations upon addition of Ca^{2+} as those induced by protonation of **2**, but with smaller magnitudes. In addition, calcium addition induces drastic downfield shifts of the H_d aromatic protons and of the azacrown protons H_{q-t}, and an upfield shift for the H_p crown protons adjacent to the nitrogen atom (see Figure 4). This phenomenon has been previously ascribed to conformational changes resulting from Ca^{2+} crown complexation.[24] This is also reminiscent of the NMR behaviour of organic aza-15-crown-5 compounds[25] and of the ferrocenylazacrown compound $[(C_5H_4CH_2N(C_{12}H_{24}O_5)Fe(C_5H_4)]_2$[26] towards alkali or alkaline-earth metal cations.

Tables 4 and 5 also illustrate how alkyl compound **1a** and crown compound **2** behave differently upon addition of one equivalent of calcium. In particular, the noticeable differences for compound **2** are that (i) the H_p shift occurs, (ii) the H_b proton is not affected, and (iii) the CH_d carbon atoms are strongly perturbed whereas the CO group is only moderately perturbed. The observed shifts with a 1:1 stoichiometry suggest that a preferred azacrown interaction occurs but that a competitive CO interaction may also exist. The studies of the effect of salt concentration presented in the two following sections reinforce this interpretation.

Mass Spectrometry, IR Spectroscopy, and a Theoretical Approach

First, to confirm that strong enough interactions may exist between ligand **2** and the $Ca(OSO_2CF_3)^+$ unit, mass spectra were recorded with samples of **2** (10^{-2} M) containing 0.5, 1, 2, and 4 equivalents of salt, respectively. These mass measurements revealed peaks for the three following species **2**M, $(\mathbf{2})_2$M, and $\mathbf{2}M_2$, where M is the calcium salt (see Experimental Section). This also indicates that different adducts may be present in these mixtures.

In order to confirm further the above NMR hypothesis, complementary investigations were performed. For the IR studies, stepwise addition of Ca^{2+} to a solution of **1a** at the NMR concentration led to a decrease in the intensity of the ν(CO) vibration at 1647 cm^{-1} and to the appearance of a new band located at 1630 cm^{-1}. An excess of salt (up to 10 equiv.) increased the intensity of this new vibration at the expense of the original ν(CO) vibration of the free ligand, which still remained. This is consistent with the proposed equilibrium between the two main species: the free form **1a**, and its 1:1 complexed form [**1a**$Ca(OSO_2CF_3)_2$].[8] In this case, interaction of Ca^{2+} with the CO function classically induces the lowering of the wavenumber.

In contrast, addition of one equivalent of Ca^{2+} to a solution of the crown compound **2** first led to a decrease of its main ν(CO) vibration at 1647 cm^{-1} while a new band appeared at higher wavenumber (1655 cm^{-1}, see Figure 5, part a). This is consistent with a preferred N-crown complexation,[27] which decreases the force constant of the C_{ipso}-N bond and the resonance with the conjugated system, thus strengthening the ν(CO) vibration mode. Furthermore, protonation of **1** and **2** at the nitrogen site also induces a significant shift of the ν(CO) vibration mode to higher wavenumber (from 1647 cm^{-1} to 1659 cm^{-1}). These latter results strengthen our interpretation.

When more calcium salt was added, the main feature observed was the increase of a new broad band centered at 1640 cm^{-1}; the intensity of the band situated at 1655 cm^{-1} also increased slightly (see part b of Figure 5). This latter phenomenon may be interpreted as the result of the formation of one species where Ca^{2+} is now interacting with CO. It is also consistent with the formation of a $\mathbf{2}M_2$ adduct which could potentially interact at high salt concentration through both its CO and azacrown groups. In conclusion, the CO group acts here as a Ca^{2+} IR sensitive probe.

Thus, the IR studies show that Ca^{2+} interacts with both possible coordination sites of **2**. As shown below, this is supported by a comparative theoretical investigation of the molecular electrostatic potential (MESP) of compounds **2** and **1a**.

The gas-phase molecular electrostatic potential (MESP) was computed for the experimental geometries of **1a** and **2** at the B3PW91/6-31G** level. The MESP has been shown to be weakly sensitive to the level of calculation.[28] A MESP minimum value of –0.101 a.u. is obtained for **1a**. Part a of Figure 6 displays the MESP isosurface for a value of –0.080 a.u. There is a continuous negative MESP region formed by the joining of the two lone-pair regions of the oxygen atom of the carbonyl moiety. This suggests that the minima of the MESP are located near the lone pairs of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

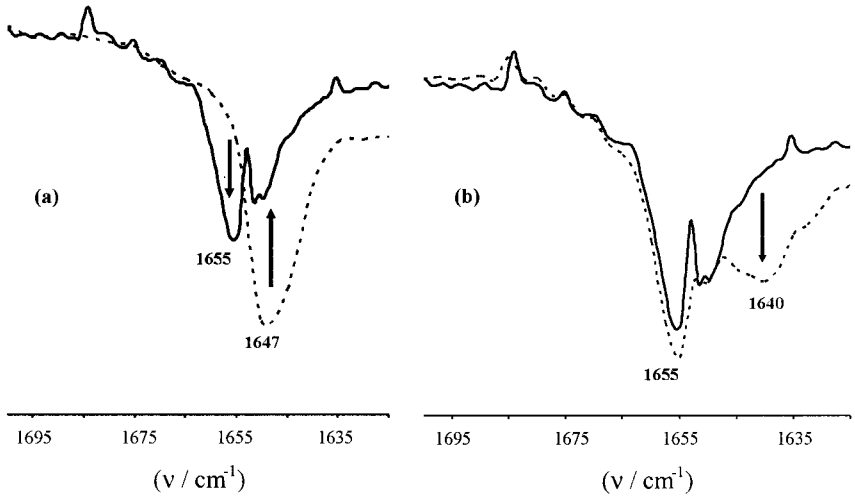

Figure 5. Segmented IR spectra of: (a) **2** (dashed line), **2** + 1 equiv. of $Ca(OSO_2CF_3)_2$ (solid line); (b) **2** + 1 equiv. of $Ca(OSO_2CF_3)_2$ (solid line), **2** + 4 equiv. of $Ca(OSO_2CF_3)_2$ (dashed line) in CH_3CN at NMR concentration.

oxygen atom of the carbonyl group. The carbonyl group is therefore expected to be the preferential binding site of the calcium cation. The picture is different for **2**. A similar MESP minimum value of –0.104 a.u. was computed at the same level. Again, the minima of the MESP are located near the lone pairs of the oxygen atom of the carbonyl group. However, as shown in part b of Figure 6, the lone pairs of the oxygen atoms of the crown moiety display a slightly less negative value of MESP than that of the carbonyl group. This suggests that these sites will now compete with CO for the calcium cation binding.

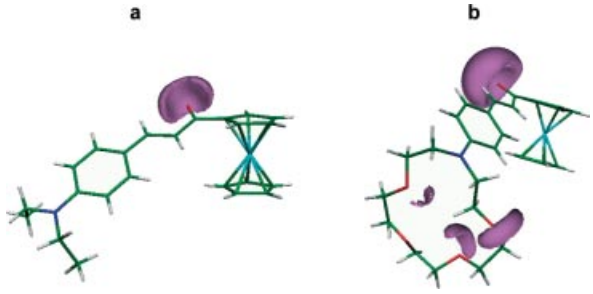

Figure 6. a) compound **1a**, MESP isosurface (–0.080 a.u.) and b) compound **2**, MESP isosurface (–0.055 a.u.), computed at the B3PW91/6-31G**level. Iron atom in sky-blue, nitrogen atom in deep blue, oxygen atom in red, and carbon atoms in green.

Analysis of the ^{13}C NMR Data and Proposition of a Ca^{2+} Interaction Model

To determine the number, the stoichiometry, and the values of the association constants of the calcium adducts involved, this interaction process was further studied by NMR spectroscopy. The variation of the ^1H and ^{13}C NMR chemical shifts was studied when changing the $Ca(OSO_2CF_3)_2$ concentration in CD_3CN. At 293 K, contrary to compound **1a**, the width of the ^1H NMR peaks observed for compound **2** was sometimes too great to allow an accurate assignment. Fortunately, the chemical shift variations of seven protons of **2** at 323 K could be successfully plotted against the calcium concentration. Figure 7 clearly illustrates a decreasing effect following the order $\Delta\delta H_d > \Delta\delta H_p > \Delta\delta H_c > \Delta\delta H_a > \Delta\delta H_b \approx \Delta\delta H_e, \Delta\delta H_f$, thereby corroborating a preferred crown complexation. It is noteworthy that the H_p protons are also the only protons of the crown ring whose shift variation can be clearly followed vs. the salt concentration at 323 K.

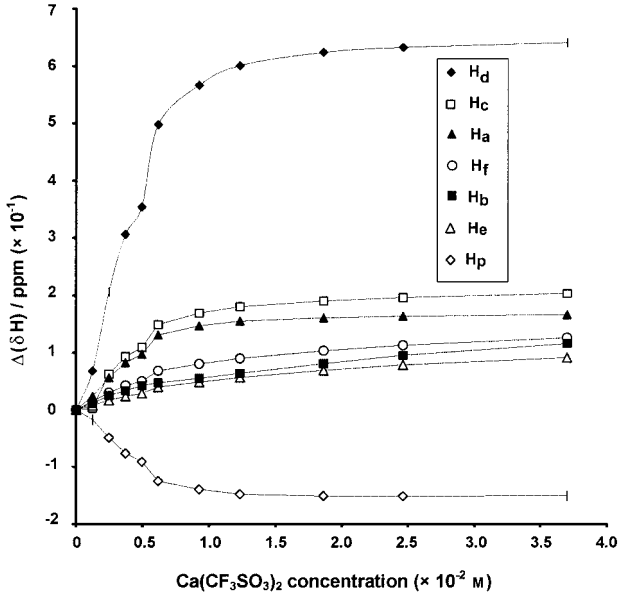

Figure 7. ^1H NMR chemical shift variations of the mentioned protons of **2** (6.2×10^{-3} M) vs. the $Ca(OSO_2CF_3)_2$ concentration in CD_3CN at 323 K. See atom labeling in Scheme 2.

At 293 K, as shown in Figure 8, the ^{13}C NMR study provides more information about the azacrown compound. As expected, the largest carbon shift variations occur for the CH_d and C_{ipso}-C carbons. The main feature is that the CO and the CH_b carbon shifts vs. Ca^{2+} concentration yield values larger than those observed for the CH_p groups involved in the crown complexation. This feature clearly indicates

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that a Ca^{2+}–CO interaction also occurs.[4,8] Thus, Figures 7 and 8 illustrate clearly the resulting effect of a double-site interaction process that involves not only the crown ring but also the CO conjugated moiety. To the best of our knowledge, this is the first time that a thorough ^{13}C NMR investigation has shown the possibility of such a competitive process with a ferrocenyl ligand.

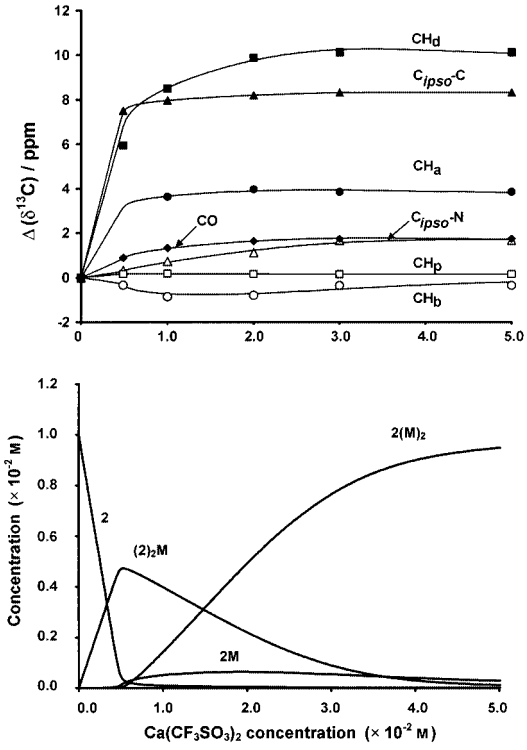

Figure 8. Top: ^{13}C NMR chemical shift variations of the mentioned protons of **2** (1×10^{-2} M) vs. the $Ca(OSO_2CF_3)_2$ concentration in CD_3CN at 293 K. Experimental values (dots) and calculated (lines) curves obtained by fitting the data. See atom labeling in Scheme 2. Bottom: Concentration of the formed species vs. calcium concentration. [**2**] = (1×10^{-2} M).

The continuous shifts of the sharp peaks observed during the calcium titration experiments are indicative of the presence of fast equilibria on the NMR timescale. So, for each calcium concentration, only a time-averaged spectrum of the ligand and/or the ligand–calcium complexes is observed. For example, in the ^{13}C NMR spectra, any observed chemical shift δC_i (where i corresponds to a specific site) is, in fact, a mole fraction weighted average of the shifts observed in the free and complexed molecules, see Equation (1).

$$\delta C_i = \sum(\delta C_{ij} X_j \alpha_j) = \delta C_i^{L} X_L + \delta C_i^{LM} X_{LM} + 2\delta C_i^{L2M} X_{L2M} + \delta C_i^{LM2} X_{LM2} \quad (1)$$

where L is the ferrocenyl ligand **2**, M is the calcium cation, and X the mole fraction of the considered species, and α_j its stoichiometric coefficient.The clear advantage of the global curve-fitting method, i.e. the simultaneous fitting of the data related to all signals, is that it can discriminate between several L_nM_m complex binding models.[29] We have previously reported the method used to determine the association constants for the different L_nM_m complexes present in solution.[30,31] In the present work, the fitted data were the δC_i for the seven curves shown in Figure 8. The following equilibria were considered and are described in the expressions below.

$$L + M \rightleftharpoons LM \qquad K_1$$

$$LM + L \rightleftharpoons L_2M \qquad K_2$$

$$LM + M \rightleftharpoons LM_2 \qquad K_3$$

In Figure 8, we display the ^{13}C NMR experimental data points together with the corresponding theoretical fit curves. A complete agreement between theory and experiment could only be obtained by taking into account the existence of three species [**2**M, (**2**)$_2$M, **2**M$_2$] of different stoichiometries and their corresponding association constants ($K_1 = 1.99\times10^3$, $K_2 = 8.09\times10^4$, $K_3 = 1.07\times10^3$ M^{-1}; values given with ±15% error). The other unknowns are the seven calculated δC_i values for each of the three species [**2**M, (**2**)$_2$M, **2**M$_2$] as indicated in Equation (1). Their adjusted $\Delta\delta C_i$ values are given in the Supporting Information (Table S6). The set of association constant values also gave a good curve fit in the case of the ^1H NMR spectroscopic data (see Figure S3). However, since the experimental temperature is different, the equilibrium can be modified. Therefore, this latter result must be considered with caution. As shown in Figure 8 (bottom), the calculated concentrations of the formed species vs. calcium concentration indicate that while (**2**)$_2$M is the main stoichiometry at low concentration, **2**M$_2$ is the major compound at high calcium concentration as for the alkyl compound **1c**.[8] Contrary to the alkyl compounds **1a**–**c**, (**2**)$_2$M may exist in significant amounts.

The model used to calculate the association constants does not make any distinction between the two sites of interaction – azacrown ring and unsaturated ligand CO system. However, association constants two to four orders of magnitude larger than for the alkyl compounds **1a**–**c** were found under the same experimental conditions.[8] The main difference is that these latter compounds do not interact through their nitrogen site. This suggests that the preferential complexation of the azacrown moiety stabilizes the formed adducts of **2**. It should be noted that for the **2**M compound, the calcium ion diameter of 1.98 Å closely fits the crown-ether cavity, which is 1.7–2.2 Å,[32] and the double charge of this cation promotes a good electrostatic interaction. This may explain the stability of such a complex. Considering a **L**$_2$M species, high values of the association constants have also been found for related *organic* ligands after treatment of their UV/Vis data.[30] In conclusion, in the range of ligand concentrations considered (from 6.2×10^{-3} to 1×10^{-2} M), several species compete. In a future paper, we will show that this NMR analysis is in full agreement with the results of a UV/Vis spectroscopic study realized with compound **2** and Ca^{2+}.

From a coordination point of view, as previously demonstrated, the Ca^{2+}–ligand interaction may occur with the crown moiety and/or with the unsaturated CO moiety. Con-

sidering first the CO–Ca^{2+} interaction, a screening of the CCDC database shows that the Ca^{2+} cation may interact with six to nine donor atoms of an organic ligand exhibiting a –C=C–C=O linkage.[33] Considering now the crown group, although numerous calcium-containing structures are known, the X-ray structures of only a few azacrown calcium complexes have been reported.[15,24,34] In these latter references, concerning purely organic ligands, the calcium is complexed to the crown moiety and the coordination shell of the calcium is completed (or not) with oxygen provided by another part of the organic ligand, or by a solvent molecule (methanol or water). Otherwise, a sandwich complex of Ca^{2+} with two 18-crown-5 ligands has been recently structurally characterized by Akutagawa et al.,[35] which suggests that a similar arrangement may exist for the $(\mathbf{2})_2$M azacrown compound. Moreover, under our experimental conditions, the triflate ion may also interact with the Ca^{2+} cation, for example through its O or F atoms, thereby increasing the number and nature of possible donor atoms and interacting modes.[36]

Unfortunately, it was not possible to obtain any X-ray structure of $\mathbf{2}Ca^{2+}$, but in the light of the above cited references[15,24,34–36] we may infer that several interacting formulations can be considered for one definite stoichiometry. For example, the $(\mathbf{2})_2$M species could be formed by interaction of two carbonyl groups of two different ligands with the same calcium, by interaction of one CO group of one ligand and one crown group of another ligand with calcium, or by sandwich complexation of calcium by two crown groups of different ligands.

As far as the $\mathbf{2}M_2$ species is concerned, the possibility of having two coordination sites of the same ligand simultaneously involved in the Ca^{2+} interaction, one located close to the negative site (CO) and the other to the positive (azacrown) site of **2**, is supported by the recent description of a dimeric X-ray structure of an interesting $[LPb^{2+}]_2$ chemosensor.[37]

In conclusion, to satisfy a required stoichiometry and to complete the calcium coordination sphere, one or both interacting sites, different anion binding modes, solvent molecules, or, if necessary, several ligands can be involved. However, in the reported equilibria, electrostatic interactions or weak intermolecular interactions (for example with adjacent phenyl groups), rather than classical complexation reactions, may also be considered. Finally, let us remark that the IR data corroborate the NMR analysis when increasing the Ca^{2+} concentration.

NMR tests were also performed with **2** in the presence of lithium, sodium, and potassium triflate, and showed weak proton-shift variations when compared to those due to the interaction with calcium (see Figures S4 and S5). Therefore, in these cases, a thorough NMR study was not appropriate. However, for example, the $\mathbf{2}Na^+$ adduct could be detected by mass spectrometry by a peak situated at m/z = 556 (FAB, and ES positive mode). For the $Ba(OSO_2CF_3)_2$ salt, a good ligand–Ba^{2+} interaction exists (see Figure S4) and the **2**M, $(\mathbf{2})_2$M, and $\mathbf{2}M_2$ species were detected by mass spectroscopy (ES). Because the Ba^{2+} electrochemical detection was not efficient, the **2**–Ba^{2+} interaction was not studied. As far as the Mg^{2+} cation is concerned, a thorough NMR study was not appropriate.

Pathway Between Calcium Interaction and Its Electrochemical Detection

In the above sections, we have shown that the protonation of ligand **2** affords the well-defined product **3**, whereas interaction of ligand **2** with calcium triflate affords different products (see also Figure 4). It must be pointed out that, in contrast, under our standard electrochemical conditions the protonated compound **3** leads to similar electrochemical characteristics as **2** in the presence of one equivalent of calcium triflate. In particular, for compound **3**, a new reduction wave at $E_{1/2}$ = –0.19 V (ΔE_p = 224 mV) was also clearly detected (vide supra), and is attributed to the NH^+ reduction process. How could these two different reactions − calcium interaction with ligand **2** and its protonation − lead to the same electrochemical characteristics (detection)?

In light of the outcome of the electrochemical detection of calcium by alkyl compounds **1a**–**c**,[8] we suspected a peculiar role of the nBu$_4$NBF$_4$ electrolyte in the $Ca(OSO_2CF_3)_2$ electrochemical detection. Therefore, for compound **2**, the calcium interaction process with $Ca(OSO_2CF_3)_2$ was re-examined in the presence of the nBu$_4$NBF$_4$ supporting electrolyte, following the same procedure as that detailed previously.[8] The main conclusion is that, as for the alkyl compounds **1a**–**c**, the three components in the mixture (Ca^{2+}, BF_4^-, H_2O) are responsible for the formation of the protonated species **3** (as a selected representative illustration see Figure 9). The small amount of water can be provided by the electrochemical or the NMR medium. There is no interaction between ligand **2** and the nBu$_4$NBF$_4$ electrolyte salt. In fact, the protonation reaction follows the $Ca(OSO_2CF_3)_2$ interaction process with ligand **2** only when the BF_4^- anion is present in the medium. Thus, in this case, the protonation reaction is the ultimate reaction step. Consequently, in the presence of the nBu$_4$NBF$_4$ electrolyte, the observed electrochemical calcium detection does not directly correspond to the $Ca(OSO_2CF_3)_2$ interaction process but is induced by it. The positive potential shift ($\Delta E_{1/2}$) of iron observed for ligand **2** upon Ca^{2+} addition corresponds, in fact, to that induced by ligand protonation. Thus, the $\Delta E_{1/2}$ of the Fe^{II}/Fe^{III} couple represents the difference of the oxidation potential between the protonated form [$Fe^{II}NH^+$] and the neutral form of the compound. For compounds **1a**–**c**, increasing the distance between the redox center and the amino site decreases the $|\Delta E_{1/2}|$ value of the Fe oxidation process. We have shown here with compound **2** that modifying the nature of the amine has no effect on the electrochemical detection. In fact, the C1–N distance in the new compound **2** is close to that of **1a**. According to the rule devised by Plenio et al.[38], the through-bond electronic communication along the conjugated chain responsible for the detection must be the same for **1a** and **2**, and is effec-

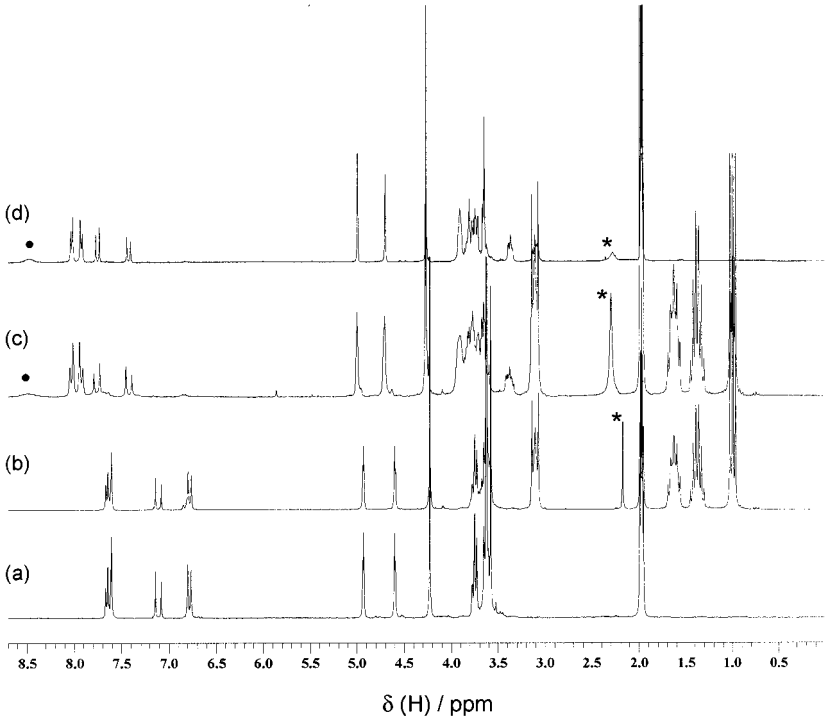

Figure 9. ^{1}H NMR (250 MHz, CD_3CN) spectra in the δ = 0–8.7 ppm range of (a) **2**, (b) **2** + 1 equiv. of nBu$_4$NBF$_4$, (c) mixture (b) + 1 equiv. of Ca(OSO$_2$CF$_3$)$_2$ after 4 h, (d) compound **3**. * H_2O, · NH^+.

tively better than that for **1b**,**c**, which have a longer C1–N distance. Our findings are also in agreement with those obtained for the Mg^{2+} electrochemical detection by compounds [(C_5H_5)Fe(C_5H_4CH=CHC_6H_4R)] (R = NMe_2 and N-azacrown-5), leading to the same $\Delta E_{1/2}$ value, and for which a through-bond electronic communication has been proposed.[39]

Concluding Remarks

We have evaluated the first structurally characterized ferrocenyl azacrown chalcone compound **2** for its electrochemical cation detection ability. A remarkable sensing of the Ca^{2+} cation is possible. This sensing relies on a complex interaction that involves not only the CO moiety of this receptor, as for its simple alkyl homologues **1a**–**c**, but also the azacrown ring, as evidenced by IR spectroscopy and MESP calculations. This interaction gives rise to the formation of three species of different stoichiometry in equilibrium in solution. This kind of phenomenon is not usual for ferrocenyl compounds. This was especially evidenced by experiments varying the ligand/cation concentration ratio and using different techniques such as mass spectrometry and IR and 2D NMR spectroscopy.

In our compounds the CO function plays a role as a coordination site for the interaction and does not interrupt the electronic communication between the terminal N donor and the ferrocenyl center, which can sense the variation of the electronic density. In contrast, the CO group can change the selectivity for the cation electrochemical detection. In fact, under our experimental conditions, the CO-free compound [(C_5H_5)Fe(C_5H_4CH=CHC_6H_4-*p*-aza-15-crown-5)] detects the Li^+[16] Na^+ and K^+[39] cations through crown–cation interactions with a magnitude of the cathodic shifts of 110, 60, and 20 mV, respectively, for the Fe^{II}/Fe^{III} couple. One reason for this difference may be that for compound **2** these N–cation interactions are weakened by the charge transfer due to the presence of the electron-withdrawing CO group. For compound **2**, in these cases, the CO–cation interactions are also probably too weak to be electrochemically detected or to promote the final protonation responsible their detection.

In comparison to the **2**–Ca^{2+} interactions, **2**–Ba^{2+} interactions are probably different because the Ba^{2+} cation is larger, has a lower charge density, and a preference for intermolecular associations. These kinds of interactions do not allow the final Ba^{2+} electrochemical detection by compound **2**. The stability of these **2**–Ba^{2+} interactions is demonstrated by the addition of the nBu$_4$NBF$_4$ supporting electrolyte, which does not induce any change of the NMR spectra.

Overall, regarding the field of ferrocenyl chemistry, we have reported solid evidence for a novel and rare example of a ligand–cation complex equilibrium. Furthermore, we have also shown that this new X-ray characterized ferrocenyl azacrown ligand leads to a peculiar and rather selective electrochemical calcium detection in which the CO function plays a key role. These results also clearly highlight that the Ca^{2+}detection or sensing by ligand **2** is not a simple Ca^{2+} molecular interaction or recognition process.

Experimental Section

Materials: Toluene and THF were distilled from over sodium/benzophenone, whereas pentane, dichloromethane, and CH_3CN (pure SDS) were distilled from over CaH_2 and stored under argon. EtOH (analytical grade, purex SDS) was simply degassed. [$(C_5H_5)Fe(C_5H_4COMe)$] (95%; Aldrich), [C_6H_5-*p*-aza-15-crown-5] (98%; Acros), and HBF_4 (54% in Et_2O; Aldrich) were obtained from the indicated suppliers. $Ca(OSO_2CF_3)_2$ (96%; Strem) was used without purification. $LiOSO_2CF_3$ (99%; Strem), $NaOSO_2CF_3$ (97%; Fluka), $Ba(OSO_2CF_3)_2$ (97%; Fluka), $KOSO_2CF_3$ (99%; Acros), $Zn(OSO_2CF_3)_2$ (98%; Aldrich), and $Mg(OSO_2CF_3)_2$ (98%; Fluka) were obtained as indicated. All these salts were dried under vacuum, weighed, and added to solution under an argon atmosphere. [$CHOCH{=}CHC_6H_4$-*p*-aza-15-crown-5] was prepared according to the published procedure.[40]

General Instrumentation and Procedures: All syntheses were performed under a nitrogen atmosphere using standard Schlenk tube techniques. IR spectra were recorded on a Perkin–Elmer GX FT-IR spectrophotometer. Samples were run as KBr pellets or in CH_3CN. Elemental analyses were carried out on a Perkin–Elmer 2400 B analyzer at the L. C. C. Microanalytical Laboratory in Toulouse. Mass spectra were obtained at the Service Commun de Spectrométrie de Masse de l'Université Paul Sabatier et du CNRS de Toulouse (fast atom bombardment, FAB>0; or desorption chemical ionization, DCI) were performed on a Nermag R 10-10H spectrometer. A 9 kV xenon atom beam was used to desorb samples from the 3-nitrobenzyl alcohol matrix. Other spectra were performed on a triple quadrupole mass spectrometer (Perkin–Elmer Sciex API 365) using electrospray as the ionization mode. The infusion rate was 5 μL min^{-1}. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AC 200, AM 250, DPX 300, and AMX 400 spectrometers and are referenced to external tetramethylsilane. For 2D NMR experiments, the observation frequencies were in the range 400.13 MHz for ^{1}H and 100.62 MHz for ^{13}C.

Electrochemical Studies: Voltammetric measurements were carried out with a home-made potentiostat[41] using the interrupt method to minimize the uncompensated resistance (iR drop). Experiments were performed at room temperature in an airtight three-electrode cell connected to a vacuum/argon line. The reference electrode consisted of a saturated calomel electrode (SCE) separated from the solution by a bridge compartment filled with the same solvent and supporting electrolyte solution. The counter electrode was a platinum wire of about 1 cm^2 apparent surface. The working electrode was a Pt electrode (1 mm diameter). The supporting electrolyte [nBu$_4$NBF$_4$ (99%; Fluka electrochemical grade) or Et$_4$NBF$_4$ (99%; Aldrich)] was melted and dried under vacuum for one hour. All solutions measured were 1.0×10^{-3} M in the organometallic complex and 0.1 M in supporting electrolyte. The solutions were degassed by bubbling argon before experiments. With the above reference, a value of $E_{1/2}$ = 0.45 V vs. SCE was obtained for 1 mM ferrocene (estimated experimental uncertainty of ±10 mV). Cyclic voltammetry was performed in the potential range –2 to 2 V vs. SCE scanning from 0 toward 2 V/SCE for oxidation studies (and from 0 towards –2 V/SCE for reduction studies) at 0.1 V s^{-1}, at room temperature. Before each measurement, the electrode was polished with Emery paper (Norton A621). To calculate the half-wave potential ($E_{1/2}$), the method is as follows: a quasi-steady-state behavior (at Pt working electrode: 1 mm of diameter) was obtained by the use of linear voltammetry at 5 mV s^{-1}.

Proton NMR Titration Studies: Proton and carbon NMR titrations were typically performed as followed. A solution (500 μL) of the receptor in a deuterated solvent (10^{-2} M) was added with a microsyringe to NMR tubes containing the appropriate quantities of solid $Ca(OSO_2CF_3)_2$ under inert atmosphere, and the NMR spectrum of the receptor was monitored. The samples of calcium salt were prepared by evaporating the corresponding calculated volumes of a standard solution (10^{-2} M) in acetonitrile. Stability constants were evaluated from titration data using the method indicated in the text.

[$(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4$-*p*-aza-15-crown-5)] (2): A mixture of [$(C_5H_5)Fe(C_5H_4COMe)$] and $CHOC_6H_4$-*p*-(aza-15-crown-5) (1:1; 0.66×10^{-3} M), and five equiv. of NaOH was dissolved in ethanol (15 mL) and stirred for 24 h at room temperature. The mixture was evaporated to dryness and the residue was dissolved in dichloromethane (10 mL). The solution was filtered off and the solvent evaporated to dryness (twice). The product was purified by column chromatography on alumina (eluent: pentane/CH_2Cl_2) and the obtained red phase was extracted with THF as eluent. After evaporation of the solvent, the product was washed with pentane (30 mL) and dried to afford the desired product as a deep orange powder in 65% yield. ^{1}H NMR (CD_3CN, 293 K): δ = 3.57 (m, 4 H, H$_t$), 3.62 (m, 8 H, H$_p$, H$_s$), 3.63 (m, 4 H, H$_r$), 3.74 (t, $^3J_{Hp,Hq}$ = 6.3 Hz, 4 H, H$_q$), 4.22 (s, 5 H, C_5H_5), 4.59 (t, $^3J_{He,Hf}$ = 1.9 Hz, 2 H, H$_f$), 4.93 (t, $^3J_{He,Hf}$ = 1.9 Hz, 2 H, H$_e$), 6.77 (d, $^3J_{Hc,Hd}$ = 9.0 Hz, 2 H, H$_d$), 7.11 (d, $^3J_{Ha,Hb}$ = 15.5 Hz, 1 H, H$_a$), 7.62 (d, $^3J_{Hc,Hd}$ = 9.0 Hz, 2 H, H$_c$), 7.63 (d, $^3J_{Ha,Hb}$ = 15.5 Hz, 1 H, H$_b$) ppm. ^{13}C{^{1}H} NMR (CD_3CN, 293 K): δ = 52.86 (CH$_p$), 68.48 (CH$_q$), 69.76 (CH$_e$), 69.78 (CH$_t$), 70.21 (C_5H_5), 70.30 (CH$_s$), 70.96 (CH$_r$), 72.63 (CH$_f$), 83.35 (C_{ipso}-C_5H_4), 112.05 (CH$_d$), 118.59 (CH$_a$), 122.84 (C_{ipso}-C), 130.64 (CH$_c$), 141.06 (CH$_b$), 150.00 (C_{ipso}-N), 192.50 (CO) ppm. Computational Details: The molecular electrostatic potential (MESP) has been extensively used by chemists for probing molecular structure and reactivities.[42] It is the potential generated by the molecular charge distribution as experienced by a positive charge. The topological analysis of the MESP, proposed by Gadre at al.,[43] is a very valuable tool for exploring the sites of reactivity of a molecule as well as their relative strengths. The deepest minimum in the MESP distribution can generally be taken as the most favorable position for an approaching positive charge. The minima in the MESP indicate localization of electron density and can be treated as potent sites of electrophilic attack. The molecular electrostatic potential (MESP) was computed for the experimental geometries at the B3PW91/6-31G** level using Gaussian98.[44] Visualization of the MESP isosurfaces was performed with molekel.[45]

Curve-Fitting Method: In the cited references 4, 8, 30, and 31, D. Lavabre has performed all the simulations and parametric adjustments by relying on his homemade software, SA version 3.

Crystallographic Study: Data were collected at low-temperature (160 K) on a four-circle Kappa CCD XCALIBUR diffractometer from Oxford Diffraction using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and equipped with a nitrogen low-temperature device (CRYOSET). Final unit-cell parameters were obtained by means of a least-squares refinement of 5768 reflections. The structure was solved by direct methods using SIR92[46] and subsequent Fourier maps. The model was refined by least-squares procedures on F^2 using SHELXL97[47] implemented in WinGX.[48] Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[49] All hydrogen atoms attached to carbon were introduced at their idealized positions [d(CH) = 0.93 Å] and were refined using a riding model. They were given isotropic thermal parameters 20% higher than those of the atom to which they are attached. The oxygen atom O(4) was found to be statistically distributed over two sites and was refined accordingly. All non-hydrogen atoms were anisotropically refined, and the weighting scheme used in the last refinement cycles was $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$. For all compounds the criteria for a satisfactory complete analysis were the ratios of the root-mean-square shift standard deviation being less than 0.1 and no significant features in final difference Fourier maps. Drawing of the molecule was realized with the help of ORTEP3[50] with 50% probability displacement ellipsoids for non-hydrogen atoms.

CCDC-245554 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also the footnote on the first page of this article): Figure S1. The ^{1}H NMR spectra of compounds **1a** and **2** in the δ = 1–8 ppm range. Figure S2. The cyclic voltammogram of **2** after Ca^{2+} addition, in reduction. Figure S3. The calculated curves obtained by fitting the ^{1}H NMR spectroscopic data of compound **2** at 323 K. Figure S4. The compared NMR spectra of compound **2** with 1 equiv. of Li^+, Na^+, K^+, Ba^{2+} and Ca^{2+}, respectively. Table S5. The ^{1}H NMR shift variations of compound **2** upon addition of one equiv. of the indicated salts. Table S6 shows the calculated $\Delta\delta C_i$ values for the three species **2**M, (**2**)$_2$M, and **2**M_2. S7 shows the NMR shifts for the interaction of one equiv. of $Ca^{2+}$with compound **2**, in CD_3CN at 323 K.

Acknowledgments

The authors would like to thank CALMIP (calcul intensif en Midi-Pyrénées, Toulouse, France) for use of their computing facilities and Professor Gadre for fruitful discussions.

Influence of Tertiary Phosphanes on the Coordination Configurations and Electrochemical Properties of Iron Hydrogenase Model Complexes: Crystal Structures of $[(\mu\text{-}S_2C_3H_6)Fe_2(CO)_{6-n}L_n]$ (L = PMe_2Ph, n = 1, 2; PPh_3, $P(OEt)_3$, n = 1)

Ping Li,[a] Mei Wang,*[a] Chengjiang He,[a] Guanghua Li,[b] Xiaoyang Liu,[a,b] Changneng Chen,[c] Björn Åkermark,[d] and Licheng Sun*[a,e]

Keywords: Binuclear iron complexes / Bioinorganic chemistry / Carbonyl displacement / Fe-only hydrogenase / P ligands

A series of mono- and disubstituted diiron complexes $[(\mu\text{-pdt})Fe_2(CO)_5L]$ [pdt = 1,3-propanedithiolato; L = PMe_3 (**2**), PMe_2Ph (**3**), PPh_3 (**4**), $P(OEt)_3$ (**5**)] and $[(\mu\text{-pdt})Fe_2(CO)_4L_2]$ [L = PMe_2Ph (**6**), PPh_3 (**7**), $P(OEt)_3$ (**8**)] were prepared as Fe-only hydrogenase-active-site models by controllable CO displacement of $[(\mu\text{-pdt})Fe_2(CO)_6]$ by tertiary phosphanes. The coordination configurations of **3**–**6** were characterized by X-ray crystallography. Disubstituted diiron complex **6** features an apical/apical coordination mode, instead of the typical *transoid* basal/basal configuration. The electrochemistry of **2**–**6** and **8** was studied by cyclic voltammetry to evaluate the effects of different tertiary phosphane ligands on the redox properties of the iron atoms of model complexes.

Introduction

The Fe-only hydrogenases, which can effectively catalyze the reduction of protons to dihydrogen in numerous microorganisms,[1,2] are of significance to the economical production of H_2. The composition and the structure of the active site of Fe-only hydrogenases have been established by high-resolution X-ray crystallographic and spectroscopic studies of Fe-only hydrogenases isolated from *Desulfovibrio desulfuricans* and *Clostridium pasteurianum*.[3,4] These achievements in molecular biology and protein crystallography provide an opportunity for chemists to chemically mimic the structure and function of the Fe-only hydrogenase-active site and to explore cheap and efficient catalyst candidates for proton reduction.

The propanedithiolato-bridged dinuclear complex $[(\mu\text{-pdt})Fe_2(CO)_6]$ (**1**) bears remarkable structural similarities with the active site of Fe-only hydrogenase. The introduction of good donor ligands, such as cyanide, tertiary phosphanes and isonitriles, in the $[(\mu\text{-pdt})Fe_2(CO)_6]$ complex renders the iron atoms more electron-rich and more protophilic. In recent years, there have been numerous reports regarding the CO displacement of $[(\mu\text{-pdt})Fe_2(CO)_6]$ by CN^-,[5–9] PR_3[10–13] and CNR,[14,15], as well as the protonation and electrochemistry of the CN^-- and PR_3-substituted derivatives.[16–19] Tertiary phosphane ligands are preferably used in many model complexes of the Fe-only hydrogenase-active site for the following reasons: 1) The electronic characteristics of tertiary phosphane ligands towards the Fe atom are similar to those of CN^- ligands. 2) The steric and electronic properties of PR_3 are tunable by changing the R groups. 3) The replacement of CN^- by PR_3 can avoid the complications of protonation on the cyanide nitrogen atom. Although CO-displacement reactions of $[(\mu\text{-SR})_2Fe_2(CO)_6]$ with tertiary phosphanes have been extensively studied since the 1970s,[19–23] to the best of our knowledge, only a limited number of structurally characterized PR_3-monosubstituted derivatives of diiron dithiolate complexes have been reported in the literature.[11–13] In addition to the crystal structures of PMe_3-disubstituted complexes $[(\mu\text{-SR})_2Fe_2(CO)_4(PMe_3)_2]$ (R = Me, Et)[17,24] and $[(\mu\text{-SRS})Fe_2(CO)_4(PMe_3)_2]$ (R = CH_2CH_2, $CH_2CH_2CH_2$),[10,17] the coordination configurations of other PR_3-disubstituted complexes, $[(\mu\text{-pdt})Fe_2(CO)_4L_2]$ (L = PMe_2Ph, PPh_3), are still not known. Albeit complex $[(\mu\text{-pdt})Fe_2(CO)_4(PMe_2Ph)_2]$ was reported recently[17] and the PPh_3-disubstituted complexes $[(\mu\text{-SR})Fe_2(CO)_4(PPh_3)_2]$ (R = Me, Ph) were pre-

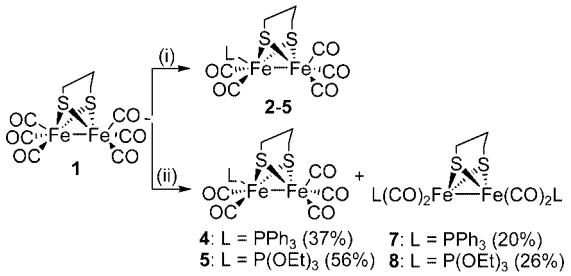
pared in the early 1970s,[25–27] the coordination positions of PMe_2Ph and PPh_3 in these diiron complexes are hitherto unknown. A series of PR_3-substituted diiron complexes, [(μ-pdt)$Fe_2(CO)_5$L] [L = PMe_3 (**2**), PMe_2Ph (**3**), PPh_3 (**4**), $P(OEt)_3$ (**5**)] and [(μ-pdt)$Fe_2(CO)_4L_2$] [L = PMe_2Ph (**6**), PPh_3 (**7**), $P(OEt)_3$ (**8**)], were prepared for a systematic study of the influence of phosphane ligands on the coordination structures and the redox potentials. Here we describe the preparation, spectroscopic characterization and the coordination configurations of complexes **2**–**8**, as well as the electrochemical properties of complexes **2**–**6** and **8**. The X-ray crystallographic study shows that the PMe_2Ph ligands on the Fe atoms of **6** are in an apical/apical coordination mode, which is in contrast with the *transoid* basal/basal configuration of [(μ-pdt)$Fe_2(CO)_4(PMe_3)_2$][10] and the recently reported complex [(μ-pdt)$Fe_2(CO)_4(PTA)_2$] (PTA = 1,3,5-triaza-7-phosphaadamantane).[12]

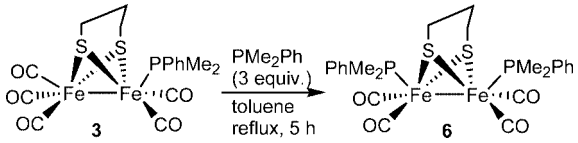
Results and Discussion

Preparation and Spectroscopic Characterization of Complexes 2–8

Monosubstituted complexes [(μ-pdt)$Fe_2(CO)_5$L] (**2**–**5**) were readily prepared in moderate to good yields by treating **1** with PR_3, according to literature procedures (see Scheme 1).[20,26] Different solvents, namely, hexane, benzene and toluene, were used for the individual reactions in the light of the solubility of the tertiary phosphanes. The reaction of **1** with 1 equiv. of a less bulky tertiary phosphane (L = PMe_3, PMe_2Ph) can be controlled at the monosubstituted stage at room temp. Complex **5** was obtained by treating **1** with 1 equiv. of $P(OEt)_3$ in refluxing toluene. PPh_3 (2 equiv.) is required to obtain **4** in good yield for the displacement of CO in **1** by PPh_3 in refluxing toluene. The PMe_2Ph-disubstituted complex **6** was obtained in satisfactory yield either by treatment of the monosubstituted complex **3** with an additional equiv. of PMe_2Ph in refluxing toluene (see Scheme 2) or by a straightforward reaction of the all-CO complex **1** with 4 equiv. of PMe_2Ph. The formation of PPh_3-disubstituted complex **7** is more difficult than that of the PMe_3-[10] and PMe_2Ph-disubstituted derivatives,[17] presumably due to the large bulk of the PPh_3 ligand. The reaction of **1** with PPh_3 in a molar ratio of 1:4 (**1**/PPh_3) in refluxing toluene for 5 h afforded the PPh_3-monosubstituted complex **4** as a major product together with a low yield of the PPh_3-disubstituted complex **7**. With the PPh_3-monosubstituted complex **4** as a starting reactant, the reaction also gave **7** in low yield after 10 h of reflux in toluene but the major part of **4** did not react, even in excess PPh_3. A similar behaviour to PPh_3 was found for the double CO-displacement of **1** by $P(OEt)_3$. The reaction of **1** with 4 equiv. of $P(OEt)_3$ in refluxing toluene gave **5** as the major product and the $P(OEt)_3$-disubstituted complex **8** in low yield. All complexes (**2**–**8**) are relatively thermo- and air-stable in the solid state. The PPh_3 derivatives, **4** and **7**, are less stable in solution than their analogous PMe_3-, PMe_2Ph- and $P(OEt)_3$-substituted diiron complexes. In toluene at room temp., dissociation of the PPh_3 ligand in **4** and **7** was indicated by ^{31}P NMR spectral studies.



Scheme 1. Reagents and conditions: (i) for **2**, L = PMe_3 (1 equiv.), hexane, room temp., 5 h; for **3**, L = PMe_2Ph (1 equiv.), benzene, room temp., 10 h; for **4**, L = PPh_3 (2 equiv.), toluene, reflux, 6 h; for **5**, L = $P(OEt)_3$ (1 equiv.), toluene, reflux, 3 h; (ii) L = PPh_3, $P(OEt)_3$ (4 equiv.), toluene, reflux, 6 h.



Scheme 2.

The products obtained were characterized by IR, ^1H and ^{31}P NMR spectroscopy and elemental analysis. The results of the elemental analyses for all products are in good agreement with the supposed compositions. Complexes **2**–**8** each show three or four infrared bands in the ν(CO) stretching region (1900–2050 cm^{-1}). The IR data of ν(CO) for **2**–**8** are listed in Table 1 for a comparison, together with the ν(CO) data of [(μ-pdt)$Fe_2(CO)_6$] and [(μ-pdt)$Fe_2(CO)_4L_2$] [L = PMe_3 (**9**)].[10,28,29] The ν(CO) bands are considered as a useful indicator for detecting the variation in the electron density of the Fe atoms in the model complexes of the Fe-only hydrogenase-active site. A comparison of the ν(CO) bands for the four subsets of mono- and disubstituted homologues in Table 1 (**2** vs. **9**, **3** vs. **6**, **4** vs. **7** and **5** vs. **8**) indicates that the introduction of a phosphane ligand has a considerable effect on the ν(CO) bands, while the difference in phosphane ligands appears to have a smaller influence on the shift values of the ν(CO) bands of **2**–**8**. The red shifts of 44–58 cm^{-1} for the first ν(CO) bands and of 29–38 cm^{-1} for the second ones are observed (see Table 1) as the monosubstituted complexes **2**–**5** are converted into their disubstituted homologues **6**–**9**. Compared with the all-carbonyl complex **1**, the average values of the three strong ν(CO) bands for the PR_3-disubstituted complexes are lowered by about 95, 89, 75, and 69 cm^{-1} for **9**, **6**, **7**, and **8**, respectively. The order of the red-shift values of the ν(CO) bands for **6**–**9** is consistent with the electron-donating capabilities of different phosphane ligands, which exhibit a clear ranking of $PMe_3 > PMe_2Ph > PPh_3 > P(OEt)_3$.

[a] The spectra were measured in CH_3CN unless stated otherwise. [b] For the PR_3-monosubstituted complexes **2**–**5**: $\Delta\nu = \nu(CO)_{mono} - \nu(CO)_{allCO}$ and for the PR_3-disubstituted complexes **6**–**9**: $\Delta\nu = \nu(CO)_{di} - \nu(CO)_{mono}$. [c] The spectrum was measured in $CHCl_3$.

Molecular Structures of Complexes 3–6

Complexes **4** and **6** were previously prepared according to the same reactions,[11,17] but until now their coordination configurations had not been structurally characterized. As the coordination positions of the phosphane ligands in the diiron complexes cannot be determined solely by the spectroscopic data, X-ray diffraction studies were undertaken for **3**–**6**. The molecular structures of **3**–**6** are displayed in Figure 1 and selected bond lengths and angles are listed in Tables 2 and 3. The central 2Fe2S structures of four complexes are all in the butterfly conformation as in previously reported models,[9–17] and each iron atom is coordinated with a pseudo-square-pyramidal geometry. The CO displacement by one or two molecules of tertiary phosphane ligands has only a small effect on the Fe–Fe distances [2.5048(10) Å in **3**, 2.5247(6) Å in **4**, 2.5142(9) Å in **5** and 2.5198(13) Å in **6**] as compared to that of [(μ-pdt)Fe_2-$(CO)_6$] [2.5103(11) Å].[28]

The coordination configurations of the monosubstituted complexes **3**, **4** and **5** are essentially identical with that of

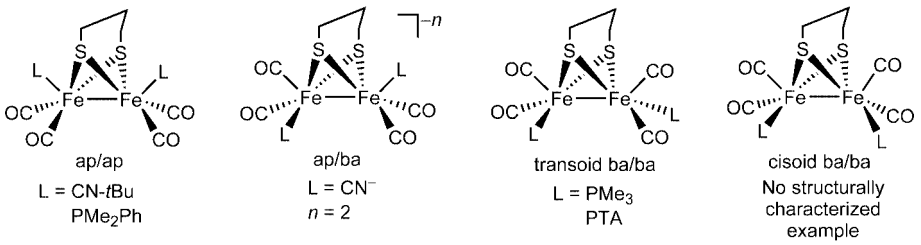
their analogues [{μ-S(C_6H_3-*m*-CH_3)S}$Fe_2(CO)_5(PPh_3)$],[11] [(μ-pdt)$Fe_2(CO)_5$(PTA)][12] and [{(μ-SCH_2)$_2$N(C_6H_4-4-Br)}-$Fe_2(CO)_5(PPh_3)$].[13] Tertiary phosphane ligands PMe_2Ph, PPh_3 and $P(OEt)_3$ are coordinated to an apical site on Fe(1) and roughly *trans* to the Fe–Fe bond. Both ^{31}P NMR and X-ray crystallographic analyses of **3**–**5** suggest that one CO displacement by tertiary phosphane in [(μ-pdt)$Fe_2(CO)_6$] affords only an apical isomer, as shown in Figure 1(a–c). One of the phenyl groups of the apical PPh_3 ligand in **4** and the sole phenyl group of the apical PMe_2Ph ligand in **3** are approximately facing the six-membered ring of the propanedithiolate. The angles of C(14)S(1)Fe(1) [114.9(2)°] and C(16)S(2)Fe(1) [114.04(18)°] in **3** are a bit wider than the corresponding angles of C(14)S(1)Fe(2) [110.7(2)°] and C(16)S(2)Fe(2) [111.93(19)°]. Compared with **3**, even larger differences between the counterpart angles C(24)S(1)Fe(1) [116.29(15)°] vs. C(24)S(1)Fe(2) [108.84(15)°] and C(26)S(2)-Fe(1) [116.62(15)°] vs. C(26)S(2)Fe(2) [109.71(15)°] are observed for the structure of **4**. It shows that the six-membered ring of the propanedithiolate in **3** and **4** is pushed away from the site occupied by an apical PMe_2Ph or PPh_3 ligand, leading to the tilt of the propanedithiolate ring towards the $Fe(CO)_3$ site. The P(1)Fe(1)Fe(2) angle is 10.17(17)° larger than the C(4)Fe(2)Fe(1) angle in **4**, while the difference between two angles is only 1.99(34) and 0.57(21)° for **3** and **5**, respectively. The PR_3 ligands used in the present work display the steric effects on the coordination structures in the order $PPh_3 >> PMe_2Ph > P(OEt)_3$. The Fe(1)–P(1) bond lengths of 2.2222(15) Å in **3**, 2.2566(9) Å in **4** and 2.1696(12) Å in **5** are similar to the values of Fe–P bond lengths reported for PR_3-coordinating diiron complexes.[9–13,17–19] The average Fe(2)–C(CO) bonds, 1.785–1.787 Å for **3**–**5**, are slightly shorter than in [(μ-pdt)$Fe_2(CO)_6$] [av. 1.800(3) Å],[28] and the average Fe(1)–C(CO) distance [1.757(9) Å] of **4** is considerably shortened by coordination of PPh_3 to Fe(1).

Theoretically, there are four possible coordination configurations for double-CO displacement by two identical non-carbonyl ligands on each iron atom of [(μ-pdt)$Fe_2(CO)_6$], that is, ap/ap, ap/ba, *transoid* and *cisoid* ba/ba configurations (see Scheme 3).[17] The first three possible configurations can each be related to one or two well-characterized examples, reported in recent years as biomimetic models of the Fe-only hydrogenase-active site.[5,10,12,15] The structurally characterized diiron propanedithiolate with an Fe–Fe bond for the *cisoid* ba/ba configuration model has not yet been reported. Only a protonated diiron complex with double-CO displacement by PMe_3 and CN^- on two iron atoms was found in a *cisoid* ba/ba configuration.[18] The X-ray single-crystal analysis shows that the PMe_2Ph-disubstituted complex **6** possesses an ap/ap coordination configuration, which is identical to the coordination mode of the large isocyanide ligand *t*BuNC,[15] but in contrast with the *transoid* ba/ba configuration of [(μ-pdt)$Fe_2(CO)_4(PMe_3)_2$] and [(μ-pdt)$Fe_2(CO)_4$(PTA)$_2$],[10,12] presumably due to the steric requirement of PMe_2Ph. It could be predicted that for tertiary phosphane ligands of large volume an ap/ap configuration should be sterically less crowded than a ba/ba and an ap/ba configuration. It is noteworthy that the complex [(μ-pdt)$Fe_2(CO)_4(CN)_2$]$^{2-}$ with two small CN^- ligands on each iron atom features an ap/ba configuration,[5] implying that not only the steric requirement but also the electronic effects of a ligand can influence the coordination configurations of diiron propanedithiolates. Another noticeable fact is that although the protonated species [(μ-H)(μ-pdt)$Fe_2(CO)_4(PMe_2Ph)_2$] is in a *transoid* ba/ba configuration in the crystalline state,[17] the coordination structure of its parent complex [(μ-pdt)$Fe_2(CO)_4(PMe_2Ph)_2$] is in an

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3. Four possible coordination configurations resulting from the L orientation.

ap/ap geometry in the crystalline state. In solution, the coordination configurations of the PR_3-substituted diiron complexes might be mobile structural forms.[12] It is unambiguous that there exists a rotation of CO and PMe_2Ph ligands during the protonation process of iron atoms in **6**, just as in the very recently reported isomerization in the protonation process of diruthenium propanedithiolate.[30]

The phenyl groups of the apical PMe_2Ph ligands in **6** both face the inner top side of the molecule, framing a glider-shape conformation with a C_2 symmetry. The dihedral angle between the S(1)C(9)C(9A)S(1A) and S(1A)-Fe(1)S(1) planes and the counterpart angle between the planes of S(1A)C(9)C(9A)S(1) and S(1A)Fe(1A)S(1) are found to have the same value (131.5°) for **6**. The average Fe–C(CO) bond of 1.741 Å in **6** is shortened, and meanwhile the average C–O bond [1.163(1) Å in **6**] is elongated by coordination of the PMe_2Ph ligands to the iron atoms, as compared with [(μ-pdt)$Fe_2(CO)_6$] [Fe–$C(CO)_{av.}$ 1.800(3) Å and C–$O_{av.}$ 1.136(1) Å].[28] The CO displacement by the better donating tertiary phosphane ligands enhances electron accumulation on the iron centers of a diiron dithiolate model, resulting in stronger back-bonding from the metal atoms to the CO ligands and at the same time weakening the CO triple bonds.

Cyclic Voltammograms of Complexes 2–6 and 8

The redox properties of model complexes are one of the interesting features in the structural and functional mimics of the Fe-only hydrogenase-active site. The cyclic voltammograms (CV) of complexes **2**–**6** and **8** were studied to evaluate the effects of different phosphane ligands on the redox properties of the central iron atoms. The CV measurements were carried out in CH_3CN and scanned in the cathodic direction as indicated in Figures 2, 3 and 4. The redox potentials of **2**–**6** and **8**, as well as their parent complex [(μ-pdt)$Fe_2(CO)_6$], are given in Table 4. A good CV of the PPh_3-disubstituted complex **7** was not obtained because of the poor solubility of **7** in CH_3CN.

Each phosphane-monosubstituted diiron complex displays four irreversible peaks, two oxidative and two reductive peaks. Compared with the electrochemical data of the all-carbonyl diiron complex **1** and other analogues,[9,29,31,32] the peaks at 0.33–0.52 V are assigned to the one-electron oxidation process of Fe^IFe^I to $Fe^{II}Fe^I$, and the more anodic peaks at 0.70–0.74 V are proposed to be the response of the further oxidation process of $Fe^{II}Fe^I$ to

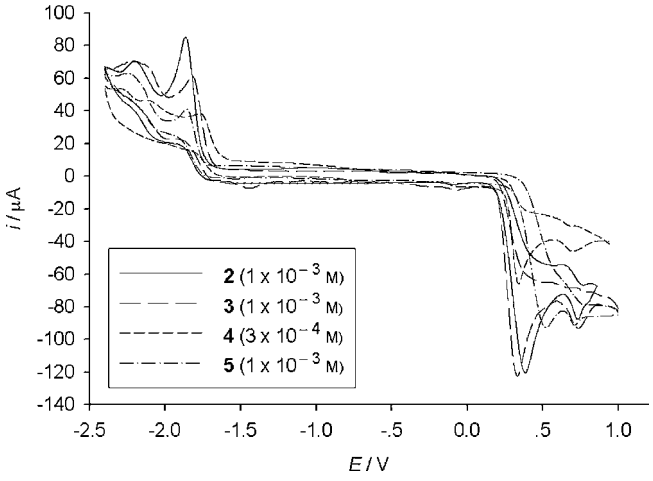


Figure 2. Cyclic voltammograms of complexes **2**–**5**.

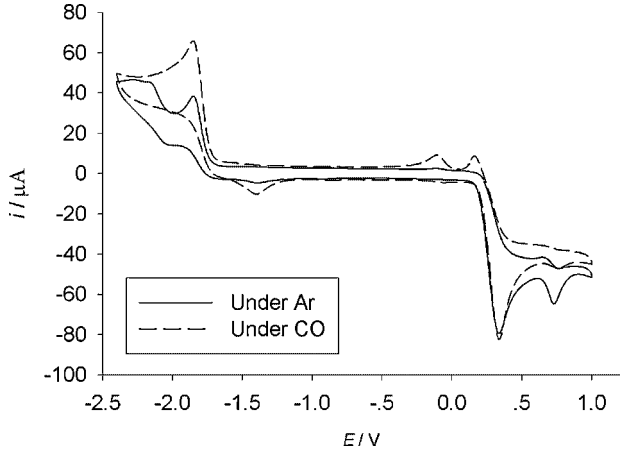

Figure 3. Cyclic voltammograms of **3** (1×10^{-3} M) under Ar and CO.

$Fe^{II}Fe^{II}$. Complexes **2**–**5** exhibit the first reductive peaks at –1.86, –1.82, –1.76 and –1.73 V, respectively, which are attributed to the reduction process of Fe^IFe^I to Fe^0Fe^I (E_1). The second reductive peaks for **2**–**5** in the range of –2.06 to –2.19 V, detected under Ar, were not observed when the CV measurement was carried out under CO (Figure 3). The CV control studies of **2**–**5** suggest that the more negative peaks at –2.06 to –2.19 V might be raised by the one-electron reduction process of Fe^IFe^I/Fe^IFe^0 for a CH_3CN-substituted species, [(μ-pdt)[$Fe(CO)_2(PR_3)$][$Fe(CO)_2$-$(NCCH_3)$].[12] The assignment of the third irreversible reductive peak for complex **4** at ca. –2.29 V is not clear. The first reduction potential is shifted in a cathodic direction

[a] nBu$_4$NPF$_6$ (0.1 M) in CH_3CN; scan rate: 0.1 V s^{-1}; working electrode: glassy carbon electrode of diameter 3 mm; reference electrode: non-aqueous Ag/Ag$^+$ electrode (0.01 M $AgNO_3$ in CH_3CN); counter electrode: platinum wire.

by ca. 290, 250, 190 and 160 mV for **2**–**5**, respectively, as compared to that of the all-carbonyl parent complex.[31] The better donor character of PMe_3 and PMe_2Ph renders the reduction of the iron core more difficult. Complexes **4** and **5**, with either a PPh_3 or a $P(OEt)_3$ ligand, display smaller cathodic shifts in CV relative to **2** and **3**. The reduction potential (E_1) for **5** is obviously less cathodic than that for complex **2** by 130 mV, indicative of a considerable influence of different phosphane ligands on the redox properties of the iron atoms of Fe-only hydrogenase-active-site model complexes.

As for previously reported CVs of PMe_3-disubstituted derivatives,[29] **6** and **8** each show only one reductive peak at ca. –2.2 V, which is attributed to the reduction process of $Fe^{I}Fe^{I}$ to $Fe^{0}Fe^{I}$. The second reductive peaks of **6** and **8** are not accessible within the solvent window in Figure 4. The first reductive peaks of **6** and **8** apparently move to more negative potentials by 400 and 460 mV, respectively, as compared with that of the corresponding monosubstituted homologues **3** and **5**. It suggests that the introduction of the second tertiary phosphane ligand exerts a stronger influence on the redox potentials of diiron complexes than the introduction of the first one. With the conversion of mono- to disubstituted derivatives, the anodic peak, assigned to the oxidation of $Fe^{I}Fe^{I}$ to $Fe^{II}Fe^{I}$, shifts from +0.33 to –0.06 V for the conversion of **3** to **6** and from +0.52 to +0.08 V for **5** to **8**. Another oxidative peak at +0.28 V for **6**, with a cathodic shift of 460 mV compared with the corresponding peak of **3**, is tentatively ascribed to the oxidation process of $Fe^{II}Fe^{I}$ to $Fe^{II}Fe^{II}$.

Experimental Section

General Procedures: All reactions and operations related to organometallic complexes were carried out under dry, oxygen-free dinitrogen with standard Schlenk techniques. Solvents were dried and distilled prior to use according to the standard methods. Commercially available chemicals, 1,3-propanedithiol, [$Fe(CO)_5$] and all tertiary phosphanes and phosphite, were reagent grade and used as received. The starting compound [(μ-pdt)$Fe_2(CO)_6$] (**1**) was prepared according to the literature.[28,33] Infrared spectra were recorded from KBr pellets with a JASCO FT/IR 430 spectrophotometer. ^{1}H and ^{31}P NMR spectra were collected with a Varian INOVA 400 NMR spectrometer. Elemental analyses were performed with a Thermoquest-Flash EA 1112 elemental analyzer.

Synthesis of [(μ-pdt)$Fe_2(CO)_5$L] [L = PMe_3 (2), PMe_2Ph (3)]: Trimethylphosphane (46 mg, 0.6 mmol) was added to a solution of hexacarbonyldiiron dithiolate **1** (240 mg, 0.6 mmol) in hexane (30 mL). The red solution was stirred for 5 h and the color turned dark red. After the solution was concentrated by solvent evaporation in vacuo, the crude product was purified by flash column chromatography on silica gel, first with hexane and then with hexane/CH_2Cl_2 (6:1) as eluents. Product **2** was obtained by cooling the concentrated hexane solution to –20 °C. Yield: 0.16 g (61%). $C_{11}H_{15}O_5PS_2Fe_2$ (434.0): calcd. C 30.44, H 3.48; found C 31.28, H 3.57. IR (KBr, νCO): $\tilde{\nu}$ = 2037, 1980, 1919 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.95 (m, 4 H, SCH_2), 1.71 (m, 2 H, CCH_2C), 1.48 (d, J_{P-H} = 9.19 Hz, 9 H, CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = 24.96 (PMe_3) ppm. Complex **3** was prepared by a procedure similar to that of **2**. The reaction of **1** (3.0 g, 7.8 mmol) with PMe_2Ph (1.07 g, 7.8 mmol) was carried out in benzene (100 mL). Analytically pure complex **3** was obtained by column chromatography on silica gel, with hexane and then hexane/CH_2Cl_2 (3:1) as eluents. Yield: 2.8 g (72%). $C_{16}H_{17}Fe_2O_5PS_2$ (496.1): calcd. C 38.74, H 3.45; found C 38.90, H 3.51. IR (KBr, νCO): $\tilde{\nu}$ = 2040, 1980, 1921 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.57, 7.41 (2 s, br., 5 H, Ph), 1.94 (m, 4 H, SCH_2), 1.80 (s, br., 6 H, CH_3), 1.66 (m, 2 H, CCH_2C) ppm. ^{31}P NMR ($CDCl_3$): δ = 32.66 (PMe_2Ph) ppm.

Synthesis of [(μ-pdt)$Fe_2(CO)_5$L] [L = PPh_3 (4), $P(OEt)_3$ (5)]: Triphenylphosphane (2.0 g, 6.5 mmol) was added to a solution of **1** (1.3 g, 3.2 mmol) in toluene (100 mL). The solution was refluxed for 6 h and the color turned purple-red. After the solution was concentrated by solvent evaporation in vacuo, the crude product was purified by flash column chromatography on silica gel with CH_2Cl_2 as eluent. Purple crystals of **4** were obtained by recrystallization in hexane/CH_2Cl_2. Yield: 1.2 g (64%). $C_{26}H_{21}O_5PS_2Fe_2$ (620.2): calcd. C 50.35, H 3.41; found C 50.29, H 3.45. IR (KBr, νCO): $\tilde{\nu}$ = 2044, 1984, 1931 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.69, 7.43 (2 s, 15 H, Ph), 1.73 (m, 4 H, SCH_2), 1.54 (m, 2 H, CCH_2C) ppm. ^{31}P NMR ($CDCl_3$): δ = 65.74 (PPh_3) ppm. Complex **5** was prepared by a procedure similar to that for **4**. The reaction of **1** (386 mg, 1.0 mmol) with $P(OEt)_3$ (0.17 mL, 1.0 mmol) was carried out in toluene (20 mL) for 3 h. Analytically pure complex **5** was obtained by recrystallization of the product in hexane/CH_2Cl_2 at –20 °C. Yield: 0.158 g (33%). $C_{14}H_{21}Fe_2O_8PS_2$ (524.1): calcd. C 32.08, H 4.04; found C 32.04, H 4.04. IR (KBr, νCO): $\tilde{\nu}$ = 2046,

1989, 1936 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 4.13 (s, 6 H, OCH_2), 2.05 (m, 4 H, SCH_2), 1.76 (m, 2 H, CCH_2C), 1.37 (s, 9 H, CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = 171.09 [P(OEt)$_3$] ppm.

Synthesis of [(μ-pdt)Fe$_2$(CO)$_4$(PMe$_2$Ph)$_2$] (6): Product **6** can be prepared directly from [(μ-pdt)Fe$_2$(CO)$_6$] in one pot according to the reported protocol[17] or by a stepwise CO displacement with **3** as a starting compound. The crystal suitable for X-ray analysis was obtained from a solution of hexane at –20 °C.

Synthesis of [(μ-pdt)Fe$_2$(CO)$_4$L$_2$] [L = PPh$_3$ (7), P(OEt)$_3$ (8)]: Compound **1** (2.5 g, 6.5 mmol) was dissolved in toluene (150 mL) and then an excess of PPh_3 (6.8 g, 26.0 mmol) was added. The red solution was refluxed for 6 h and the color turned dark red. The solution was concentrated by solvent evaporation in vacuo. Mono- and disubstituted complexes **4** and **6** were separated by column chromatography on silica gel with hexane/CH_2Cl_2 (2:1) and then CH_2Cl_2 as eluents. Product **4** was obtained from the first band (1.5 g, 37%) and **7** from the second band (1.1 g, 20%). $C_{43}H_{36}Fe_2O_4P_2S_2$ (854.5): calcd. C 60.44, H 4.25; found C 60.27, H 4.28. IR (KBr, νCO): $\tilde{\nu}$ = 1997, 1951, 1933 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.69, 7.34 (2s, 30 H, Ph), 1.85 (m, 4 H, SCH_2), 1.56 (m, 2 H, CCH_2C) ppm. ^{31}P NMR ($CDCl_3$): δ = 62.79 (PPh$_3$) ppm. Essentially the same procedure as for **7** was applied for the preparation of **8**, by refluxing a toluene solution (35 mL) of **1** (1.3 g, 3.4 mmol) and P(OEt)$_3$ (2.0 mL, 11.6 mmol) for 6 h. Product **5** was obtained from the first band (1.0 g, 56%) and **8** from the second band (0.57 g, 26%). $C_{19}H_{36}Fe_2O_{10}P_2S_2$ (662.3): calcd. C 34.46, H 5.48; found C 34.64, H, 5.63. IR (KBr, νCO): $\tilde{\nu}$ = 2002, 1960, 1935 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 4.15 (s, 12 H, OCH_2), 1.95 (m, 4 H, SCH_2), 1.70 (m, 2 H, CCH_2C), 1.36 (s, 18 H, CH_3) ppm. ^{31}P NMR ($CDCl_3$): δ = 175.43 [P(OEt)$_3$] ppm.

Crystal Structure Determination of Complexes 3, 4 and 6: The single-crystal X-ray diffraction data were collected with a Siemens SMART CCD diffractometer for **3** and **4** and with an AFE5R Rigaku diffractometer for **5** and **6** with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 K using the ω-2θ scan mode. Data processing was accomplished with the SAINT processing program.[34] Intensity data were corrected for absorption by the SADABS program.[35] The structure was solved by direct methods and refined on F^2 against full-matrix least-squares methods by using the SHELXTL97 program package.[36] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located by geometrical calculation, but their positions and thermal parameters were fixed during the structure refinement. Crystal data and parameters for data collections and refinements of complexes **3**–**6** are listed in Table 5. CCDC-218501 (**3**), -228422 (**4**), -255204 (**5**) and -253139 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Electrochemistry Studies of Complexes 2–6 and 8: Acetonitrile (Aldrich, spectroscopy grade) used for electrochemical measurements was dried with molecular sieves and then freshly distilled from CaH_2 under N_2. A solution of 0.1 M nBu$_4$NPF$_6$ (Fluka, electrochemical grade) in CH_3CN was used as electrolyte, which was degassed by bubbling with dry argon for 10 min before measurement. Electrochemical measurements were recorded using a BAS-100W electrochemical potentiostat at a scan rate of 200 mV/s. Cyclic voltammograms were obtained in a three-electrode cell under argon. The working electrode was a glassy carbon disc (diameter 3 mm) successively polished with 3- and 1-μm diamond pastes and sonicated in ion-free water for 10 min. The reference electrode was a non-aqueous Ag/Ag$^+$ electrode (0.01 M $AgNO_3$ in CH_3CN) and the auxiliary electrode was a platinum wire.

Coordination of Li^+, Ca^+, V^+, and Cu^+ to the Molecules S_8 and S_4 – A Computational Study

Yana Steudel,[a] Ming Wah Wong,*[b] and Ralf Steudel*[a]

Keywords: Ab initio calculations / S ligands / Cluster compounds / Lithium / Calcium / Vanadium / Copper

The complex formation between the Li^+ cation and the sulfur homocycle S_8 has been studied by ab initio MO calculations at the G3X(MP2) level of theory. Starting with various isomers of S_8, the formation of LiS_8 heterocycles and clusters is preferred over complexes with a monodentate ligand. The binding energies of the cation in the 23 complexes investigated range from –95 to –217 kJ·mol^{-1}. The global minimum structure of $[LiS_8]^+$ is of C_{4v} symmetry with the S_8 homocycle in the well-known crown conformation and four Li–S bonds of length 254.2 pm (binding energy: –156.5 kJ·mol^{-1}). The S–S bonds of the various ligands are slightly weakened by the complex formation and a more or less strong bond length alternation is induced. Relatively unstable isomers of S_8 (chair, tub, *exo–endo* ring, branched rings, triplet chain) are partly stabilized and partly destabilized by complex formation with Li^+. The interaction between the cation and the S_8 ligands is mainly due to ion–dipole attraction with little to moderate charge transfer (0.04–0.27 electrostatic units). In the four most stable isomers of $[LiS_8]^+$, the number of sulfur–sulfur bonds is at a maximum and the coordination number of Li^+ is either 4 or 3. Complexes of the type $[Li(S_4)_2]^+$ are much less stable than isomers with an eight-atomic ligand. The Li–S bond lengths in all of these complex cations (230–273 pm) depend on the coordination number of Li and on the atomic charge of the donating sulfur atom(s). In contrast to $[LiS_8]^+$, the complexes of composition $[MS_8]^+$ with M = Ca, V, and Cu are more stable as $[M(S_4)_2]^+$ than with an eight-atomic crown-shaped ligand.

Introduction

There are numerous metal complexes with *anionic* sulfur-containing ligands such as sulfide (S^{2-}), thiolate (RS^-), or polysulfide anions (S_n^{2-}).[1] These species are of tremendous importance in inorganic and biological chemistry, in geology and mineralogy as well as in industrial chemistry. However, the interaction of metal cations with *neutral* sulfur molecules S_n has not been studied systematically. This unsatisfactory situation is probably due to the fact that the interaction of neutral molecules with metal cations is comparably weak. Consequently, only a few solid coordination compounds are known in which sulfur molecules S_n function as neutral ligands. Examples include several silver salts with the cations $[AgS_8]^+$ and $[Ag(S_8)_2]^+$, respectively, and weakly coordinating anions,[2,3] the rhenium complexes $[Re_2X_2(CO)_6(S_8)]$ (X = Br, I)[4] and the rhodium compounds $[Rh_2(O_2CCF_3)_4]_n(S_8)_m$ with n/m = 1:1 and 3:2.[5] The X-ray structure determinations of these compounds revealed that the S_8 ligands exhibit basically the same crown-shaped ring conformation as the molecules in orthorhombic *cyclo*-octasulfur, and S_8 functions as either bi-, tri-, or tetradentate ligands or as a bridging ligand between two metal centers. The mean S–S bond lengths in these complexes are practically identical to the value determined for orthorhombic S_8 (205 pm[6]). The binding energy of gaseous $[Ag(S_8)]^+$ (C_{4v} symmetry) with respect to the free components has been calculated by various density functional and ab initio MO methods as between –208 and –247 kJ·mol^{-1}.[3] Related solid complexes with other sulfur ring sizes have not been reported.

However, a large number of complexes of univalent metal cations with various sulfur ligands, $[MS_n]^+$ with n = 1–21, have been generated in the gas phase and detected by ion cyclotron resonance (ICR) mass spectrometry. The metals include Ca, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Zn, Cu and many rare-earth elements.[7–10] The structures and relative energies of these complexes are only partially known from preliminary reports on density functional calculations of calcium-, scandium-, vanadium-, and copper-containing polysulfur cations.[9,10] These calculations (of which no details have been released yet) show that Ca^+ forms complexes with the S_3 ligand in a planar geometry and with the crown-shaped *cyclo*-S_8 ligand in a bi-, tri-, and tetradentate manner. Complexes of compositions $[Ca(S_3)]^+$, $[Ca(S_8)]^+$, $[Ca(S_3)(S_8)]^+$, and $[Ca(S_3)_3]^+$ have been found to be local energy minima on the potential energy surfaces (PES). The

most stable cationic complexes of Sc, V, and Mn with between four and eight sulfur atoms have been predicted to contain the sulfur exclusively in the form of S_2 ligands; for the vanadium complexes a singlet ground state has been assumed. In the case of copper, the ion of composition $[Cu(S_{12})]^+$ was predicted to be most stable as a 12-membered sulfur ring with the metal ion at the center.

To elucidate the possible structures of complexes between a univalent cation and a sulfur homocycle, we have previously studied the various isomers of composition $[LiS_6]^+$.[11] In this work we have investigated theoretically the interaction of the sulfur homocycle S_8 with gaseous Li^+ which serves as a simple model ion to allow calculations at a high level of theory. Besides S_6,[11] only the coordination of gaseous S_3 to Li^+ has been investigated previously by quantum-chemical calculations: $[LiS_3]^+$ is of C_{2v} symmetry.[12] In the case of $[LiS_6]^+$, 15 isomeric structures have been identified on the potential energy hypersurface (PES). The most stable structure is of C_{3v} symmetry and contains a chair-like S_6 ligand of similar geometry as that of solid S_6. The metal ion is linked to three equivalent sulfur atoms resulting in a binding energy of –134 kJ·mol^{-1}.[11] We define here the (adiabatic) binding energy as the energy difference between the complex and the sum of the energies of the two separated components in the same (or closest) conformation as found in the complex.

In the present work, we investigate the interaction of Li^+ with various isomers of S_8 to find out whether an activation of these molecules takes place. We did not intend to scan the total PES of this system. Instead, using existing knowledge of the various isomers of $[LiS_6]^+$[11] we investigated mainly the coordination of Li^+ to the previously studied isomeric cyclic forms of S_8 and to only one of the eight-atomic chains. In agreement with our earlier results (topological analysis),[11] all Li–S distances above 280 pm will be treated as nonbonding. In addition to the Li^+ complexes, we report on preliminary calculations of univalent cations of composition $[MS_8]^+$ with M = Ca, V, and Cu.

Results and Discussion

Structures and Energies

There are at least nine isomeric structures on the PES of the S_8 molecule.[13] The five stable eight-membered rings are of D_{4d} (**1**), C_s (**3**), C_2 (**4**), D_{2d} (**5**), and C_{2h} (**6**) symmetry (Figure 1). The crown-shaped structure (**1**) is the global energy minimum, while a spiral cluster with C_2 symmetry (**2**) is the next most stable structure. The two branched rings of the type S_7=S (**7** and **8**) are of C_1 symmetry and are much less stable. The least stable is the triplet open chain of C_2 symmetry (**9**). These isomers and their relative energies are shown in Figure 1.

Using the various S_8 isomers as ligands, we have located 20 isomeric structures on the PES of $[LiS_8]^+$ with coordination numbers (CN) of the metal atom of between 1 and 4. In addition, three cations with two S_4 ligands each were found to be minima on this PES. The absolute energies are given in Table S1 in the Supporting Information. The symmetries, relative energies, binding energies and dipole moments of all investigated Li^+ complexes are listed in Table 1. In the following discussion these various isomers will be discussed approximately in the order of increasing relative energy.

The global minimum structure of $[LiS_8]^+$ (**8a**) is of C_{4v} symmetry with a crown-shaped S_8 ligand and four Li–S

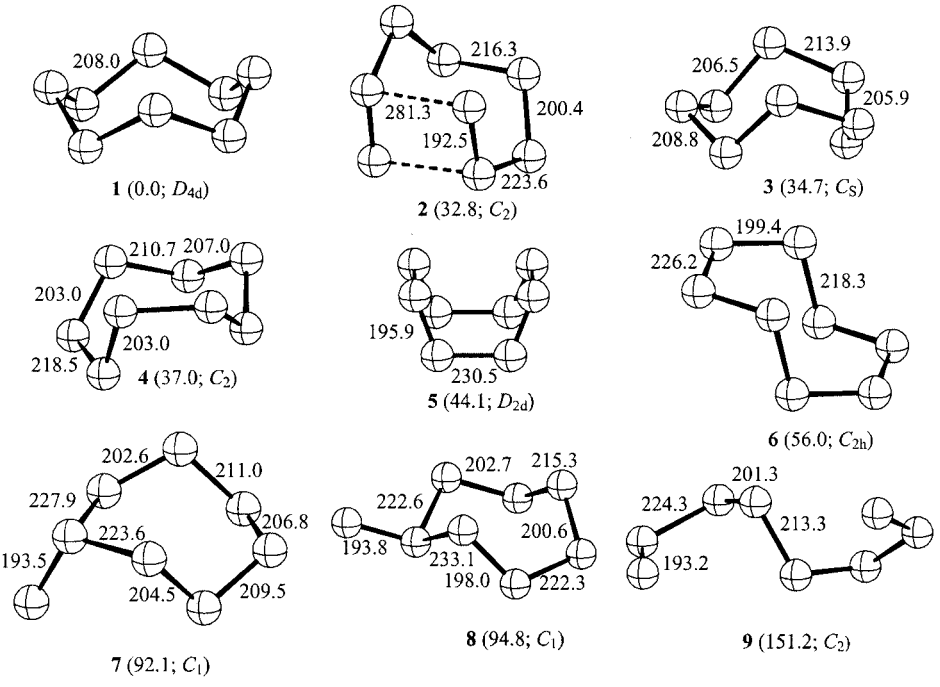

Figure 1. Various cyclic and chain-like isomers of the S_8 molecule with relative energies (kJ·mol^{-1}) and symmetries (according to ref.[13]).

[a] The numbers in parentheses indicate the S_8 isomer (Figure 1), which has been used to calculate the binding energy. [b] B3LYP/6-31G(2df,p) values.

bonds of length 263.1 pm (Figure 2). The metal atom is located on the upper lobes of the lone-pair orbitals of the four ring atoms no. 1, 3, 5, and 7. These orbitals form the HOMO of the S_8 molecule. In this way, the HOMO(S_8)–LUMO(cation) interaction is maximized, resulting in a binding energy of –156.5 kJ·mol^{-1}. The calculated S–S bond length of 209.1 pm is slightly larger than that calculated for the free S_8 molecule (208.0 pm), indicating a certain degree of activation. Bond angles and torsion angles of the Li^+ complexes are presented in Table 2.

The calculated structure of isomer **8a** is in agreement with the experimentally determined structure of the cation $[AgS_8]^+$, which is also of C_{4v} symmetry in solid $[AgS_8]$-[Al(hfip)] (hfip = hexafluoroisopropanolate)[3], and with the theoretically predicted structure of $[Ca(S_3)(S_8)]^+$.[10] On the other hand, the cation $[VS_8]^+$ has been predicted by density functional calculations to prefer the connectivity $[V(S_2)_4]^+$ (assuming a singlet electronic state) while a structure analogous to **8a** was not considered.[9] Below we show that the latter results are probably incorrect.

A structure with the Li^+ ion at the geometrical center of the S_8 ring is a first-order saddle point of D_{4d} symmetry (**TS1**) which connects two equivalent structures of the global minimum **8a** with a barrier height of 72.5 kJ·mol^{-1} (Figure 2). Via this transition state the Li^+ ion is able to oscillate back and forth through the center of the S_8 ligand. In **TS1**, Li^+ has the coordination number 8 with Li–S distances of 247.9 pm. A structure analogous to **TS1** with CN(V) = 8 was predicted as a high-energy minimum on the singlet PES of $[VS_8]^+$,[9] but we were unable to reproduce this result (see below).

The first equilibrium structure (**8b**) above the global minimum consists of an asymmetric twisted ring with the Li cation coordinated to four sulfur atoms with distances of between 247.3 and 272.9 pm (Figure 2). To a first approximation, this structure of relative energy 34.4 kJ·mol^{-1}, derived from the twist-form of S_8 (**4**), can be considered as a distortion of structure **8a**. The S–S bond lengths vary between 203.2 and 226.9 pm; the longest bond is characterized by an unusually small SSSS torsion angle of 6.3°. The overall motif of the homocycle (the order of signs of the torsion angles) is –+–++–++. The coordination pattern of the metal atom is pyramidal and the sum of the four neighboring SLiS angles is 303.3° (360° would result in a planar coordination sphere).

The second structure above the global minimum of $[LiS_8]^+$ is a complex containing the cluster-like S_8 ligand **2** (see Figure 1) with the Li atom coordinated to three sulfur atoms (isomer **8c** in Figure 2). The ligand has the same conformation as the related molecule S_7=O which has been studied by X-ray crystallography of single crystals.[14] The Li–S distances below 280 pm are 239.1, 250.8 and 260.8 pm. There are two S–S–S–S torsion angles close to zero (–2.6° at atoms 5678 and 7.4° at atoms 1287) while S–S bonds usually prefer a torsion angle close to 90°.[15] As a consequence, the S–S bond lengths vary between 193.0 and 246.9 pm. Structure **8c** is less stable than **8a** by only 37.5 kJ·mol^{-1}, while the cluster-like S_8 isomer **2** is less stable than the crown **1** by only 32.8 kJ·mol^{-1}. The binding energy with respect to **2** is –151.8 kJ·mol^{-1}. For the bond angles of **8c**, see Table 2.

The $[LiS_8]^+$ structure **8d** contains the eight-membered sulfur ring in an *exo–endo* conformation resulting in CN = 3 for the metal atom (Figure 2). This ion is of C_s symmetry and less stable than **8a** by 50.0 kJ·mol^{-1}. In this case, the metal atom is approximately located on the upper lobes of

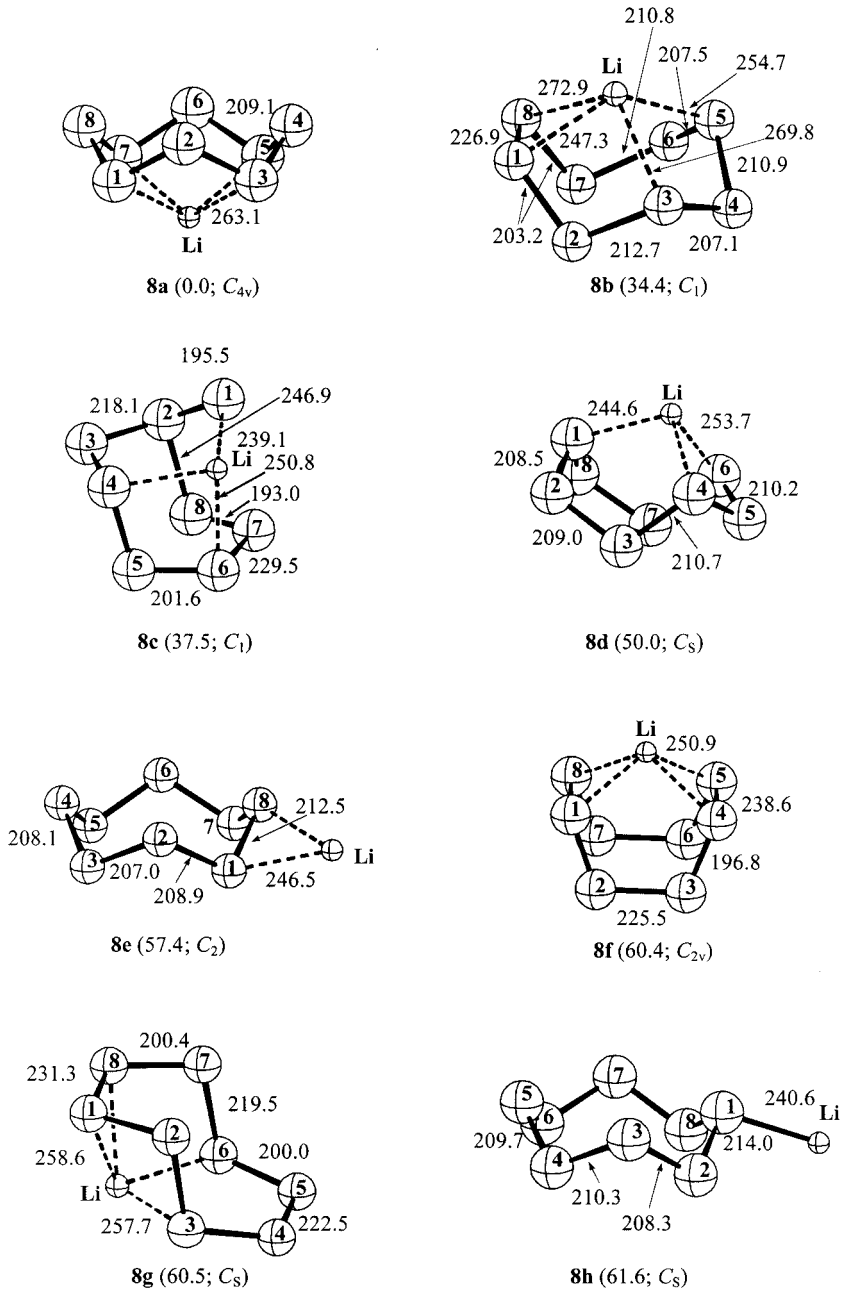

Figure 2. Structures of the eight lowest-energy isomers (**8a**–**h**) of composition $[LiS_8]^+$ (relative energies in kJ·mol^{-1} and symmetries are given in parentheses). Bond lengths in pm.

the lone-pair orbitals of the three ring atoms 1, 4, and 6. The three shortest Li–S distances are 244.6 pm (1) and 253.7 pm (2). As a consequence of the asymmetric coordination, the S–S bonds are no longer equivalent but their lengths range from 208.5 to 210.7 pm. This range is narrower than in the free ligand of identical conformation containing S–S bonds of between 205.9 and 213.9 pm. The free *exo–endo* shaped ligand is less stable than the crown structure by 34.7 kJ·mol^{-1}.[13] In other words, the coordination to Li^+ destabilizes the *exo–endo* form by 15.3 kJ·mol^{-1} because only three Li–S bonds are formed compared to four in **8a**. The binding energy of **8d** is –141.2 kJ·mol^{-1}.

The $[LiS_8]^+$ isomer **8e** consists of a crown-shaped S_8 ring with the Li cation located on one of the C_2 axes of the ring and bridging just one S–S bond, which becomes the longest bond in the ligand (212.5 pm). Because of the lower coordination number of 2, the binding energy of –99.2 kJ·mol^{-1} is significantly smaller (by 37%) than in the case of **8a** with CN = 4.

There are two $[LiS_8]^+$ isomers formally derived from the tub- or boat-like S_8 isomer **5** shown in Figure 1. Structure **8f** is of C_{2v} symmetry with CN(Li) = 4 and Li–S distances of 250.9 pm (Figure 2). The S–S bond lengths range from 196.8 to 238.6 pm. This structure is less stable than isomer

8a by 60.4 kJ·mol^{-1} compared to the relative energy of only 44.1 kJ·mol^{-1} for the free ligand.[13] The other isomer with a boat-shaped S_8 ligand (**8l**) has a relative energy of 84.3 kJ·mol^{-1}. This structure has no symmetry at all and contains a two-coordinate Li^+ ion with Li–S distances of 245.0 and 245.1 pm. The tub-like S_8 rings in **8f** and **8l** can approximately be thought of as being composed of four S_2 units because the S–S bond lengths alternate between rather small (194.0–199.8 pm) and much larger values (230.5–238.6 pm). As expected, the binding energy of **8l** (–116.2 kJ·mol^{-1}) is smaller than that of **8f** (–140.2 kJ·mol^{-1}). When we tried to optimize the geometry of a cube-like structure with connectivity $[Li(S_2)_4]^+$ (metal ion at the center of an arrangement of four parallel but independent S_2 molecules; starting symmetry D_{4h}) in analogy to the reported $[V(S_2)_4]^+$ structure,[9] we obtained structure **8f** instead.

A crown-shaped S_8 ring is also present in structure **8h** which is of C_s symmetry and less stable than **8a** by 61.6 kJ·mol^{-1} (see Figure 2). This structure resembles that of the S_8=O molecule[16] but the metal atom is in an equatorial position with an Li–S distance of 240.6 pm. Owing to the lower coordination number of 1, the binding energy is only –94.9 kJ·mol^{-1}, the lowest value among all complexes studied in this work. As expected, the distortion of the eight-membered ring by the metal ion induces a symmetrical S–S bond length alternation with the two longest bonds (214.0 pm) neighboring the Li–S bond (Figure 2). The average S–S bond length of 210.6 pm is now considerably larger than in free S_8 (208.0 pm). Attempts to optimize a similar structure with Li^+ in an axial position (as the oxygen atom in solid S_8O) resulted in isomer **8a**.

We found three isomeric $[LiS_8]^+$ cations derived from the chair conformation of S_8 (structure **6** in Figure 1; motif00–+–0+–+). The most stable of these, **8g**, with a relative energy of 60.5 kJ·mol^{-1}, contains the Li cation pyramidally coordinated to four sulfur atoms with distances in the narrow range of 257.7–258.6 pm (Figure 2). The other two iso-

mers with CN = 2 (**8m** and **8o**) are considerably less stable than **8g**, by 31.5 and 44.0 kJ·mol^{-1}, respectively (see Figure 3). The binding energies decrease in the order of decreasing relative stability (Table 1).

As has been shown previously, a characteristic feature of Li^+ complexes with sulfur-rich ligands is the bridging of single S–S bonds by the metal ion.[11] This type of bonding can also be seen in structure **8j** (Figure 3), which is a derivative of the twisted S_8 isomer **4** shown in Figure 1. Complex **8j** is characterized by an LiS_2 triangle with Li–S bonds of lengths 242.9 and 243.3 pm bridging a dramatically lengthened S–S bond of 230.2 pm. The remaining S–S bonds alternate in length symmetrically to a plane through the lithium atom and the midpoint of bond S4–S5 (symmetry C_s). This isomer with a binding energy of –104.2 kJ·mol^{-1} is less stable than **8a** by 71.3 kJ·mol^{-1}.

The asymmetrical structure **8i** is the most stable $[LiS_8]^+$ isomer with an S_7=S ligand with a relative energy of 65.6 kJ·mol^{-1}. It has the largest binding energy (–182.9 kJ·mol^{-1}) among all the $[LiS_8]^+$ structures. The metal ion coordinates to the exocyclic sulfur atom and very weakly also to two ring atoms. The seven-membered ring is considerably distorted compared to free S_7 and free S_7=S (**7**), as the SS bond lengths vary between 201.4 and 234.1 pm (Figure 3). The related isomer **8k** with the relative energy of 72.3 kJ·mol^{-1} contains the S_7 = S ligand in another connectivity (Figure 3). The metal atom is linked by a short bond (234.5 pm) to the exocyclic sulfur atom and by a much longer bond (250.3 pm) to one of the two atoms at which the HOMO of the S_7=S molecule is centered, resulting in a bicyclic structure similar to that of isomer **8c**. There are four additional complex cations containing various conformations and isomers of the S_7=S ligand. As a free molecule, S_7=S exists as two conformers (Figure 1) which are less stable then the S_8 crown (**1**) by 92.1 and 94.8 kJ·mol^{-1}, respectively.[13] The ion **8n** is of C_s symmetry (Figure 3). The metal atom is linked to the exocyclic sulfur atom with a rather short bond of 236.1 pm and to two ring

atoms with bond lengths of 260.1 pm forming a tricyclic structure. This type of interaction results in a binding energy of –155.2 kJ·mol^{-1}. The conformation of the seven-membered ring is very similar to that of the free S_7 molecule,[17] with one torsion angle of zero and a strong and symmetrical bond length alternation. The compact and cluster-like geometry of **8n** is less stable than **8a** by 93.4 kJ·mol^{-1}. This relative energy is practically identical to the relative energy of the most stable conformation of the free S_7=S ligand compared to the crown-shaped S_8 molecule.[13] Structure **8p** contains the metal atom coordinated just to the exocyclic sulfur atom of S_7=S, which carries the highest negative charge in the free ligand.[13] The exocyclic sulfur atom is in an axial position which is stabilized by the anomeric effect. The corresponding structure with the LiS group in an equatorial position (**8p′**) is also a minimum on the PES but slightly less stable than **8p**. Interestingly, on the PES of $[HS_8]^+$ a structure similar to **8p** with the hydrogen atom coordinated just to the exocyclic sulfur atom represents the global minimum structure.[18] We notice that the field strength of Li^+ is evidently not high enough to stabilize the S_7=S structure over the crown-shaped eight-membered ring as the proton does. Even less stable than **8p** are two isomers with other coordination patterns (structures **8q**,**r** in Figure 4 and Table 1). These structures will not be discussed in detail.

We found three minimal energy structures of composition $[LiS_8]^+$, each containing two S_4 ligands (Figure 5). However, these isomers are much less stable than all the complexes with the undissociated S_8 ligand, despite their larger binding energies (Table 1). This finding is in agreement with the corresponding results obtained for $[LiS_6]^+$ complexes.[11] The most stable of the $[Li(S_4)_2]^+$ complexes (isomer **8s**), with a relative energy of 132.9 kJ·mol^{-1}, is of D_{2d} symmetry with two planar LiS_4 heterocycles joined by a common Li atom. These two rings are perpendicular to each other. The *cis*-planar conformation of the two S_4 ligands corresponds to the global minimum structure of the free S_4 molecule.[19] The same holds for the most remarkable structure **8u** in which the two S_4 ligands are monodentate. This nine-atomic chain of C_2 symmetry consists of two planar segments of six atoms each, having the central three-atom unit S–Li–S in common. The torsion angle between the two planes is 126.5°. The relative energy of **8u** is 146.0 kJ·mol^{-1}. Complex **8v**, on the other hand, contains one chelating and one open-chain S_4 ligand, the latter in the *trans*-planar conformation (Figure 4) resulting in a relative energy of 178.9 kJ·mol^{-1}. In species **8v** the torsion angle between the two planar S_4 units is 159.8°. The binding energies of **8s**,**u**,**v** (–216.7, –203.6, and –212.0 kJ·mol^{-1}, respectively) are much higher than for the $[LiS_8]^+$ complexes with the eight-atomic ligands.

It is worth noting that the related complex of composition $[LiS_4]^+$ also exists as two isomers with either a monodentate or a bidentate S_4 ligand (see Figure 5). Both isomers are planar. The five-membered heterocycle **4a** (binding energy –124.7 kJ·mol^{-1}) is more stable than **4b** (binding energy –113.2 kJ·mol^{-1}). Addition of another S_4 to **4a** with formation of **8s** liberates –92.0 kJ·mol^{-1}.

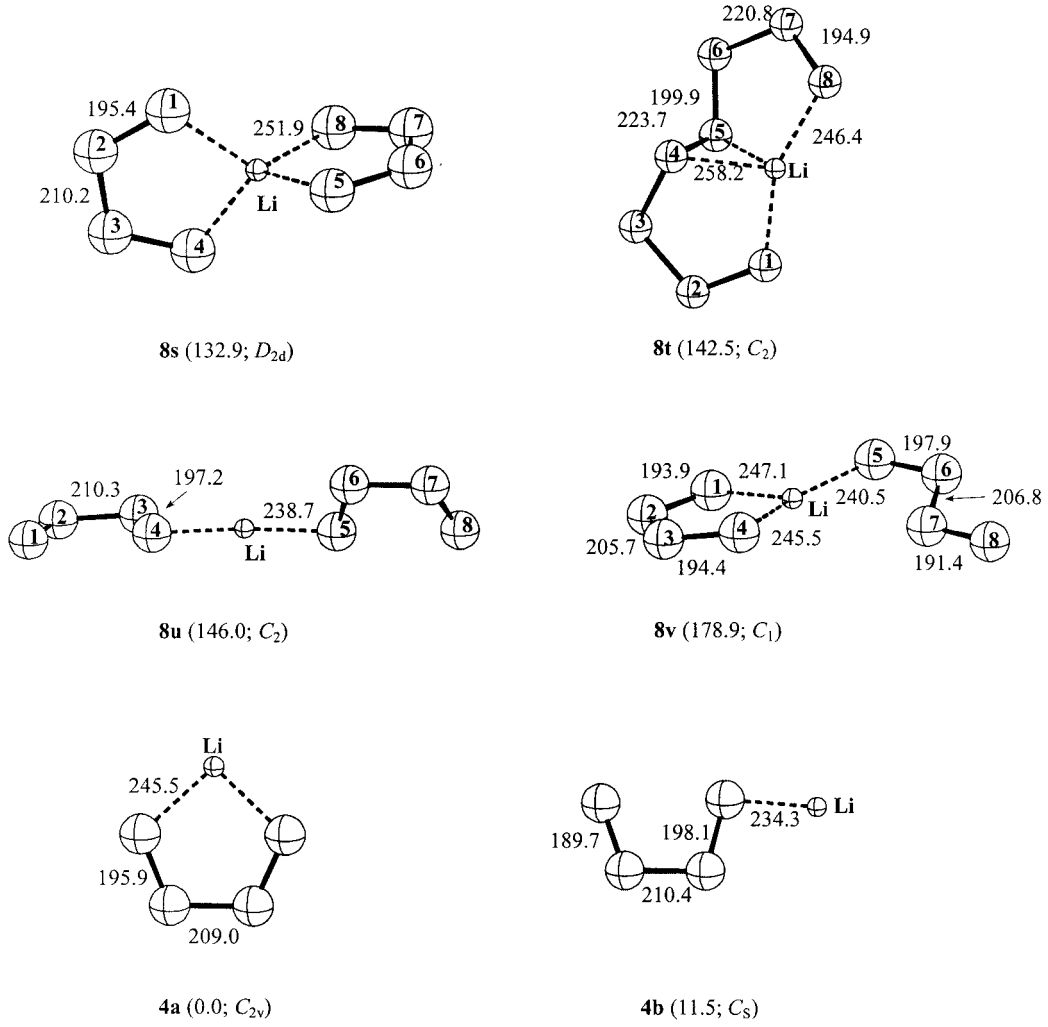
Because the S_8 molecule can also exist as a triplet chain (structure **9** in Figure 1), we have investigated its ability to coordinate to Li^+. The resulting triplet cation (**8t**) forms an eight-membered heterocycle with CN(Li) = 2+2 (Figure 5). Six torsion angles of this ring are within 10° of either 0° or 180°, that is, planarity (Table 2). Thus, this heterocycle is rather flat. The relative energy of 142.5 kJ·mol^{-1} is slightly lower than the corresponding energy of **9** (151.2 kJ·mol^{-1}). However, the binding energy (–165.3 kJ·mol^{-1}) is higher than in the case of the global minimum structure **8a** by 10 kJ·mol^{-1}. We did not consider other possible triplet chain structures with lower coordination numbers as they are expected to have lower binding energies. However, a singlet nine-membered $[LiS_8]^+$ heterocycle is less stable than the global minimum structure **8a** by only 81.7 kJ·mol^{-1}. Finally, we would like to mention that the connectivity $[Li(S_6)(S_2)]^+$ represents also a minimum on the PES of $[LiS_8]^+$, but this structure is even less stable than **8v**.

The present results and the calculations on complexes of the types $[LiS_6]^+$[11] and $[LiS_7]^+$[20] indicate that the global minimum structures always contain the most stable conformation of the ligand donating electron density to the metal atom through three or four atoms. Hence, we expect that other alkali metal cations form analogous symmetrical complexes with sulfur homocycles. However, univalent transition-metal polysulfur cations seem to prefer other structures and different compositions (see below).

Our present data together with previous results[11] allow the calculation of the reaction energy of the following gas-phase sulfurization reaction between the most stable species involved:

$[LiS_6]^+$ (**6a**) + ¼ S_8 (**1**) → $[LiS_8]^+$ (**8a**)

ΔE_o = –49.0 kJ·mol^{-1}, $\Delta H°_{298}$ = –47.8 kJ·mol^{-1}, $\Delta G°_{298}$ = –33.5 kJ·mol^{-1}



8s (132.9; D_{2d}) **8t** (142.5; C_2)

8u (146.0; C_2) **8v** (178.9; C_1)

4a (0.0; C_{2v}) **4b** (11.5; C_s)

Figure 5. Isomeric structures **8s**–**v** of composition $[LiS_8]^+$ and **4a**–**b** of composition $[LiS_4]^+$, all containing chain-like ligands (relative energies in kJ·mol^{-1} and symmetries are given in parentheses). Bond lengths in pm.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

One, therefore, would expect the cation $[LiS_6]^+$ to be unstable in the presence of an excess of S_8, for example in a mass spectrometric experiment. The lithium cation basicity of S_8 (**1**), that is, the negative Gibbs energy of the addition of Li^+ to S_8 producing **8a** at 298 K, is 122.7 kJ·mol^{-1}.

Atomic Charges

The atomic charges of the 23 complexes of composition $[LiS_8]^+$ calculated by the NBO approach are listed in Table S2 in the Supporting Information. The charge transfer from the polysulfur ligand(s) to the metal atom varies between 0.04 and 0.27 electrostatic units. In the various isomers all sulfur atoms linked to Li^+ are negatively charged while all others are positive or practically neutral, with the exception of exocyclic and terminal atoms, which are always negative. The metal ion clearly polarizes the valence electrons of the ligand(s) and thus induces dipole moments directed towards this cation. This can be seen, for example, in the charge distribution of the global minimum structure **8a**. The three-coordinate sulfur atoms bear a small negative charge of –0.03, while the two-coordinate atoms have a positive charge of +0.07 and Li^+ has gained 0.18 electrons from the ligand. Exocyclic sulfur atoms as in S_7=S are always negatively charged; therefore, Li^+ prefers to bind to these atoms except in the high-energy isomers **8q** and **8r**. A high degree of charge separation is also found in the three cations with S_4 ligands **8s**,**u**,**v**. In these complexes the charge differences between the metal atom and the coordinating sulfur atoms are considerably larger than 1 electrostatic unit. The structures of the latter three ions can be reproduced readily using point-charge model calculations.

Vibrational Spectra

To identify the species **8a** or similar cations containing crown-shaped S_8, one may use vibrational spectroscopy, as the bonds between two-coordinate sulfur atoms are excellent Raman scatterers and the metal–sulfur bonds will give rise to vibrations of high infrared intensity. In addition, the vibrational spectrum of a ligand contains information about the influence of the metal ion on the ligand. Therefore, we have compared the vibrational spectra of S_8 (**1**) and $[LiS_8]^+$ (**8a**) in Table 3. The additional atom increases the number of vibrational degrees of freedom by 3. Taking the lowering of the symmetry from D_{4d} to C_{4v} into account, the irreducible representation $2A_1 + B_1 + B_2 + 2E_1 + 3E_2 + 2E_3$ of S_8[21] changes to $4A_1 + A_2 + 3B_1 + 3B_2 + 5E$ for $[LiS_8]^+$. The three E_2 modes of S_8 split into B_1 and B_2 modes in $[S_8Li]^+$ while all E_1 and E_3 modes of S_8 end up as E modes in the cation. The vibrational transitions introduced by the Li atom are calculated at 254 cm^{-1} (A_1) and 222 cm^{-1} (E). As can be seen from the data in Table 3, the wavenumbers of the S_8 ligand are very similar to those of the free S_8 molecule in agreement with the weak interaction deduced above from the internuclear distances and the atomic charges.

Table 3. Calculated harmonic fundamental vibrations (cm^{-1}) of S_8 (D_{4d} symmetry) and of $[S_8Li]^+$ (C_{4v}) as well as infrared intensities (km·mol^{-1}) of the latter. Observed wavenumbers of S_8 (dissolved in CS_2) are given in parentheses (according to ref.[21]).

S_8	Symmetry	$[S_8Li]^+$	Symmetry	Infrared intensity

Other Metal Ions

To investigate the dependence of the reported structures on the metal ion, we have carried out preliminary calculations on some ions of composition $[MS_8]^+$ with M = Ca, V, and Cu using calculations at the CCSD(T)/6-31G*//B3LYP/6-31G*+ZPE level after mass spectrometric observations of such species have been reported (see Introduction). In particular, we were interested in the relative stabilities of isomeric complexes containing either one crown-shaped S_8 ligand or two chain-like chelating S_4 ligands. The thermodynamic results are summarized in Tables 4 and S3 (Supporting Information), and the molecular structures are shown in Figure 6. For the free metal ions, the most stable electronic configuration[22] was used to calculate the binding energies. It turned out that for all three cations, the complex with the connectivity $[M(S_4)_2]^+$ is more favorable energetically than the structures analogous to **8a**. The binding energy for $[Li(S_8)]^+$ is now obtained as –164.3 kJ·mol^{-1} rather than –156.5 kJ·mol^{-1} at the G3X(MP2) level (Table 1). The interaction of Ca^+ with S_8 (**1**) is relatively weak (binding energy only –71.4 kJ·mol^{-1}). In the case of Cu^+, the symmetry of the S_8 complex is only C_{2v} rather than C_{4v}, and $[V(S_8)]^+$ is even of C_s symmetry. The complexes $[Ca(S_2)_4]^+$ and $[Cu(S_2)_4]^+$ contain planar S_4 ligands and the metal atoms are tetrahedrally coordinated. $[V(S_4)_2]^+$ has an interesting although asymmetrical geometry (Figure 6) with the higher coordination number 6 for the metal atom and two tridentate S_4 ligands explaining its remarkable binding energy of –586.5 kJ·mol^{-1}. This nonplanar ion with SSSS torsion angles of 57° and 63° has a triplet ground state while the isomeric complex with the eight-atomic crown-shaped ligand is a quintet (Table 4), as is the free V^+ ion. Even more stable than $[V(S_4)_2]^+$ are the isomeric complexes $[V(S_2)(S_6)]^+$ and $[V(S_3)(S_5)]^+$ (not shown) which both prefer the singlet state. In contrast to the report by Dance et al.,[9] we could not locate a minimum structure

for $[V(S_2)_4]^+$. More details on the polysulfur complexes of transition metals will be published elsewhere.

Conclusions

Lithium cations form stable complexes with neutral sulfur molecules such as various isomers of S_8 and S_4 with binding energies ranging from –95 to –217 $kJ \cdot mol^{-1}$. The crown-shaped S_8 ring of D_{4d} symmetry coordinates to Li^+ as a tetradentate ligand resulting in a complex of C_{4v} symmetry, which represents the global minimum on the PES of $[LiS_8]^+$. The interaction is explained by ion–dipole attraction with a charge transfer of only 0.18 electrostatic units. Consequently, the vibrational spectrum of the S_8 ligand changes only slightly on complex formation, reflecting however the lower symmetry. Higher-energy conformers and isomers of *cyclo*-S_8 such as twisted, chair- and tub-like eight-membered rings, branched seven-membered rings (S_7=S) as well as the triplet and singlet chains also form complexes with Li^+ with the coordination number of the metal atom varying between 1 and 4. In general, the conformation of the ligand changes only very little on complex formation but the relative energy changes are sometimes considerable. Complexes of composition $[LiS_8]^+$ containing two S_4 ligands are much less stable than those with one S_8 or S_7=S ligand. The planar S_4 unit may coordinate either as a chelating dihapto ligand or as a chain-like monohapto ligand of either *cis*- or *trans*-conformation. Consequently, there are several types of $[Li(S_4)_2]^+$ complexes. We should note that our calculations may relate directly to experiments

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the gas phase, but not in a condensed phase, as Li^+ is strongly solvated in a dielectric medium. As a result, the lithium binding energies are expected to be absolutely smaller in solution. Complexes of composition $[MS_8]^+$ with M = Ca, V, and Cu prefer the connectivity $[M(S_4)_2]^+$ over $[M(S_8)]^+$ with CN(M) = 4 or 6 and binding energies in the range –266 to –586 kJ·mol^{-1}, but in the case of vanadium even more stable isomers of connectivities $[V(S_2)(S_6)]^+$ and $[V(S_3)(S_5)]^+$ have been located on the PES.

Computational Methods

Standard ab initio and density functional calculations were carried out with the GAUSSIAN 98 and 03 series of programs[23] at the G3X(MP2) level of theory.[24] This theory corresponds effectively to QCISD(T)/G3XL//B3LYP/6-31G(2df,p) energy together with zero-point vibrational and higher-level corrections. The G3X(MP2) theory represents a modification of the G3(MP2) theory,[25] with three important modifications: (1) B3LYP/6-31G(2df,p) geometry, (2) B3LYP/6-31G(2df,p) zero-point energy, and (3) addition of a *g* polarization function to the G3Large basis set for the second-row atoms at the Hartree–Fock level. These features are particularly important for the proper description of the sulfur-containing compounds examined in this work.[13,18,19] For instance, the geometries and stabilities of several cluster species are poorly predicted by the MP2 theory.[13]

Harmonic frequencies were calculated at the B3LYP/6-31G(2df,p) level to characterize stationary points as equilibrium structures, with all wavenumbers real, or transition states, with one imaginary wavenumber. The binding energy (ΔE) of the metal ion complexes were computed as the difference between the energy of the lithiated species and the total energy of the two free monomers in the same conformation as found in the complex. The Gibbs energy differences (ΔG) were computed from the equation $\Delta G_T = \Delta H_T - T\Delta S$, where ΔS is the entropy change and $\Delta H_T = \Delta H_0 + (H_T - H_0)$. The thermal correction ($H_{298} - H_0 = 6.197$ kJ·mol^{-1}) and the entropy value ($S_{298} = 133.017$ J·mol^{-1}·K^{-1}) of the lithium cation were taken from the JANAF compilation.[26] Unless otherwise noted, all relative energies of S_n molecules and $[LiS_8]^+$ ions reported in this publication are given as ΔE_o and correspond to the G3X(MP2) level, while all reported structural parameters of these species correspond to the B3LYP/6-31G(2df,p) level. The structures of all complexes of composition $[MS_8]^+$ (M = Ca, V, Cu) were examined by the density functional method B3LYP with the 6-31G* basis set with higher-level single-point energy calculations obtained at the CCSD(T)/6-31G* level. All structures were optimized initially without any symmetry constraint and were reoptimized with a higher symmetry after a local energy minimum was obtained. In the case of vanadium, the singlet, triplet, and quintet states have been investigated for both $[M(S_8)]^+$ and $[M(S_4)_2]^+$ species.

Supporting Information (see also footnote on the first page of this article): Absolute energies and atomic charges of the isomers of composition $[LiS_8]^+$ and total energies as well as zero-point energies (ZPE) of the complexes $[M(S_8)]^+$ and $[M(S_4)_2]^+$ and related species.

μ-η¹:η¹-*N*,*N*′-Imidazolidine-Bridged Dicopper(II/III) Complexes of a New Dinucleating μ-Bis(tetradentate) Schiff Base Ligand: Synthesis, Structural Characterization, ^{1}H NMR Spectroscopy, and Magnetic Coupling

Manindranath Bera,[a] Wing Tak Wong,[b] Guillem Aromí,[c] and Debashis Ray*[a]

Keywords: N,O ligand / Imidazolidine / Copper complexes / Magnetic properties

The copper coordination chemistry of a new imidazolidine-based doubly bridging μ-bis(tetradentate) ligand, H_3mhbai is studied. A new family of pentacoordinate dinuclear complexes of formula $[Cu^{II}_2(\mu\text{-mhbai})(\mu\text{-X})]\cdot 2H_2O$ (**1**–**4**) [X = OAc, NO_3, Cl, S_2COMe], where H_3mhbai stands for 2-(2-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-4-methyl-3-aza-but-3-enyl]-2-methyl-1,3-imidazolidine, were synthesized from the ligand, H_3mhbai in air. The complex **1** was structurally characterized by X-ray crystallography. The μ-η¹:η¹-*N*,*N*′-imidazolidine bridging mode between two copper(II) ions has been identified in this complex along with a nonhelical binding mode of the μ-bis(tetradentate) ligand. Variable temperature (2–300 K) magnetic susceptibility data of **1** show the presence of a weak antiferromagnetic exchange interaction between the two triply bridged magnetically isolated copper(II) (S = 1/2) ions. The $\chi_m T$ values start to drop at temperature below 50 K, to reach a value of 0.55 $cm^3 K mol^{-1}$ at 2 K for a coupling constant value of J = –2.2 cm^{-1}. The ^{1}H NMR spectrum of the weakly coupled complex **1** shows a total of seventeen hyperfine shifted peaks, as expected from the idealized C_s symmetry of the compound, spread over a very large window of chemical shift, spanning about 130 ppm.

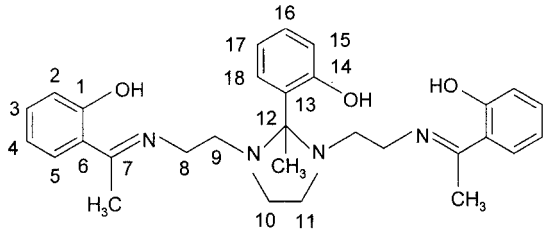
Introduction

Synthesis and characterization of novel dicopper(II/III) complexes of new diaza heterocyclic bridge[1] incorporated bis(polydentate) ligands is an active area of synthetic inorganic chemistry research during the last couple of years.[2–8] Studies on dicopper complexes of imidazolidine bridging ligands bearing additional chelating side arms in the 1- and 3-positions of the heterocycle are unknown. Dimetal complexes have the potential to provide new reactivity patterns and physical properties that could not be achieved with similar type of mononuclear complexes.[9] It is convenient to classify dinucleating ligands by the number and types of bridging groups that are used to assemble dimetal complexes. For an intimate dimetal complex having small metal–metal separation the maximum number of bridging groups is three. The diaza heterocyclic bridge containing new bis(polydentate) ligands can be developed from the known[10] imidazolidine ring formation reaction on the ethylenediamine segment of the tetramine backbone of the parent hexadentate ligand. This is some kind of chelate elaboration on the potential heterocycle bridge by Schiff base formation using ketones for the first time. Recently we have shown[11] that in absence of the imidazolidine bridging backbone the parent hexadentate ligand can give μ_4-oxo-bridged tetracopper(II) complex through ligand self-assembly. Double helical binding of the hexadentate ligand was also observed there. Dinuclear copper complexes with two metal ions in close proximity have received a great deal of attention in recent times.[12–15] Unlike other potential bridging units such as phthalazine, pyridazine, oxadiazole, thiadiazole, 1,8-naphthyridine,[9] neutral imidazolidine bridge-supported dicopper(II/III) complexes are unknown till date. Here, we report the coordination chemistry of μ-η¹:η¹-*N*,*N*′-imidazolidine-bridged dicopper(II/III) complexes of a new μ-bis(tetradentate) ligand, H_3mhbai {2-(2-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-4-methyl-3-azabut-3-enyl]-2-methyl-1,3-imidazolidine} (Scheme 1).



Scheme 1. 2-(2-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-4-methyl-3-azabut-3-enyl]-2-methyl-1,3-imidazolidine (H_3mhbai).

This dinucleating ligand feature a 2-(hydroxyphenyl)-imidazolidine bridge, linking two arms of imine-phenol groups and support dimetallic structures with a variety of exogenous bridging ligands. The complex also binds a water dimer showing a novel example of simple near-linear self-assembled water cluster $(H_2O)_2$ in a crystalline dimetal complex.[16] Recently, it has been discovered that certain imidazole compounds can stabilize similar infinite 1D water chains[17] as potential models of biologically relevant proton wires. Similar tetrameric water structure has also been identified recently in an organic macrocyclic ligand crystal host.[18] The present work also reports the X-ray structural characterization of a dicopper(II/III) complex of a new non-macrocyclic dinucleating ligand satisfying four coordination sites around each copper center and two of which are bridging. From variable temperature magnetic measurement a weak antiferromagnetic (J = –2.2 cm^{-1}) coupling was observed for complex **1** in a distorted square-pyramidal geometry. ^1H NMR study of complex **1** also shows that at room temperature the system remains largely paramagnetic due to the very weak nature of the observed antiferromagnetic coupling.

Results and Discussion

Syntheses and Spectroscopic Characterization Studies

The μ-bis(tetradentate) ligand H_3mhbai was synthesized by the known imidazolidine ring formation reaction with 2-hydroxyacetophenone and triethylenetetramine in a mol ratio of 3:1 under reflux for 5 h and isolated in the solid form following a modified Bailer route[19] (Scheme 2). The resulting Schiff base incorporated an imidazolidine ring from the reaction of the third ketone with the two inner adjacent secondary amine nitrogen atoms of trien.[20] The parent hexadentate ligand (H_2bahped) reported earlier[11] producing novel μ_4-oxo-bridged tetracopper(II) was synthesized as a yellow oil from a similar Schiff base condensation reaction of 2-hydroxyacetophenone and triethylenetetramine (trien) in a 2:1 mol ratio under reflux for 0.5 h. In the IR spectrum of the ligand H_3mhbai, the phenolic O–H stretchings of the two terminal rings are observed at 3443 cm^{-1}. The C=N stretching frequency of the ligand is observed at 1616 cm^{-1}. In the EI-MS of the ligand, the molecular ion peak (*m*/*z*) was observed at 500, confirming the formation of the desired imidazolidine ring containing ligand. In ^1H NMR spectra the characteristic central methyl protons and terminal methyl protons both appear as singlet at δ = 1.38 and 2.21 ppm, respectively. The characteristic central methyl carbon and terminal methyl carbon atoms appear at δ = 14.51 and 26.58 ppm in ^{13}C NMR spectra, respectively. The imidazolidine ring carbon at the hydroxyphenyl substitution appears at δ = 116.83 ppm. The imine carbon appears at δ = 164.29 ppm. Both ^1H and ^{13}C NMR spectroscopic data are comparable with the literature values.[10,21] The signals due to aromatic ring protons were observed in the 6.74–7.40 ppm region. The hydrogen atoms on the imidazolidine backbone appeared as a complex set of overlapping triplet resonance signals at 2.74–2.80 ppm. The reaction of different copper(II) salts with this hitherto unknown ligand in 2:1 molar ratio in alcoholic media at room temperature affords green $[Cu^{II}_2(\mu\text{-mhbai})(\mu\text{-X})]\cdot 2H_2O$ (**1**–**3**) [X = OAc, NO_3, Cl]. Use of a stoichiometric amount of $MeCOS_2^-$ in the reaction of H_3mhbai and $CuCl_2\cdot 2H_2O$ yields $[Cu^{II}_2(\mu\text{-mhbai})(\mu\text{-}S_2COMe)]\cdot 2H_2O$ (**4**) (Scheme 2). They represent a new family of 2-phenolate-substituted imidazolidine-bridged dicopper(II/III) complexes. All the complexes are insoluble in water and separate immediately from the reaction medium. The complexes are soluble in MeCN, DMF and DMSO. The molar conductivity values in DMF are in the range 12 to 29 $\Omega^{-1}cm^2mol^{-1}$ (28 °C), consistent with the nonelectrolytic formulations of the complexes. The infrared spectrum of the complex **1** shows stretching frequencies at 1586 and 1405 cm^{-1} corresponding to asymmetric and symmetric mode of OAc^- ion present.

For complex **2**, the characteristic $\nu_{(N=O)}$ frequencies for bridging NO_3^- group appear at 1378 cm $^{-1}$ and 843 cm^{-1}, respectively, and are similar to the reported values.[22] Complex **4** shows a group of bands between 1021 and 1203 cm^{-1} assigned to ν_{C-O} and ν_{C-S} coupled modes similar to the reported values[23] which are absent in complex **3**. The room temperature magnetic moments per Cu for all the four complexes are in the range of 1.66–1.98 μ_B. Electronic spectra of the complexes **1**–**4** in dimethylformamide solutions show several intense absorption bands in the visible region which are assigned to the allowed d-d and charge transfer transitions. All the complexes exhibit similar type broad bands in 602–627 nm region with molar extinction coefficient of 230–385 L mol^{-1} cm^{-1} for d-d transitions. The higher intensity charge transfer transitions are obtained at 359–370 nm and 268–274 nm range with molar extinction coefficients of 5170–10945 L mol^{-1} cm^{-1} and 15170–24730 L mol^{-1} cm^{-1}, respectively.

X-ray Structure of Cu^{II}_2(μ-mhbai)(μ-OAc)]·2 H_2O

The identity of the compound **1** is established through X-ray structure determination. An ORTEP view of **1** is shown in Figure 1. The selected bond length and bond angles are given in Table 1. Complex **1** consists of a neutral dinuclear [Cu_2(μ-mhbai)(μ-OAc)] molecule with a hydrogen-bonded water dimer. Each copper(II) atom is in a square-pyramidal N_2O_3 environment, made up of one amine nitrogen, one imine nitrogen, one terminal phenol oxygen atom from the dinucleating ligand and one axial acetate oxygen. The exogenous acetate group binds two copper atoms in μ-*syn*-*syn*-η^1:η^1-fashion. The μ-η^1:η^1-*N*,*N*′-imidazolidine and the phenolate groups bridge two copper atoms along the edge of the bi-square-pyramid. Two axial oxygen atoms, from the acetate group, complete the triply bridging motif in the dicopper complex. The μ-bis(tetradentate) ligand connects the copper atoms through μ-η^1:η^1-*N*,*N*′-imidazolidine and phenoxy bridges. The acetate bridging in *syn*-*syn* bidentate mode is common in diiron and dimanganese complexes[24] and also found in dicopper(II/III) complexes.[25,26] The dinucleating μ-bis(tetradentate) ligand shows a nonhelical binding mode for the dicopper(II/III) complex as against the double helical binding of two parent hexadentate ligands for a tetracopper[(II)$_4$] complex reported recently by us.[11] Two nitrogen atoms, one terminal and one bridging phenolate oxygen atom from one-half of the ligand are coordinated to one metal center forming one five-membered (N–Cu–N) and two six-membered (N–Cu–O) terminal and bridging chelate rings. The chelate bite angle for the five-membered ring is in the range

Table 1. Selected bond lengths and angles for $[Cu^{II}_2(\mu\text{-mhbai})(\mu\text{-OAc})]\cdot 2H_2O$ (**1**).

Bond lengths [Å]	
Cu(1)–O(1)	1.911(2)
Cu(1)–O(5)	2.190(2)
Cu(1)–N(2)	2.116(2)
Cu(2)–O(3)	1.955(2)
Cu(2)–N(3)	2.203(2)
Cu(1)–O(3)	1.953(1)
Cu(1)–N(1)	1.946(2)
Cu(2)–O(2)	1.934(2)
Cu(2)–O(4)	2.132(2)
Cu(2)–N(4)	1.955(2)
Bond angles [°]	
O(1)–Cu(1)–O(3)	89.70(7)
O(1)–Cu(1)–N(1)	91.66(9)
O(3)–Cu(1)–O(5)	102.64(7)
O(3)–Cu(1)–N(2)	89.98(7)
O(5)–Cu(1)–N(2)	96.80(9)
O(2)–Cu(2)–O(3)	91.29(8)
O(2)–Cu(2)–N(3)	156.85(8)
O(3)–Cu(2)–O(4)	101.46(7)
O(3)–Cu(2)–N(4)	160.18(8)
O(4)–Cu(2)–N(4)	97.90(8)
O(1)–Cu(1)–O(5)	94.60(9)
O(1)–Cu(1)–N(2)	168.38(9)
O(3)–Cu(1)–N(1)	161.74(9)
O(5)–Cu(1)–N(1)	95.39(8)
N(1)–Cu(1)–N(2)	85.07(9)
O(2)–Cu(2)–O(4)	98.34(9)
O(2)–Cu(2)–N(4)	90.07(9)
O(3)–Cu(2)–N(3)	86.70(8)
O(4)–Cu(2)–N(3)	104.67(8)
N(3)–Cu(2)–N(4)	84.33(9)

of 84.33(9)–85.07(9)° and for the six-membered rings it is in the range of 90.07(9)–91.66(9)° for terminal and 86.70(8)–89.98(7)° for bridging. The *cis* angles around the Cu(1) ion range from 85.07(9) to 102.64(7)° with an average value of 93.23° and that around the Cu(2) ion range from 84.33(9) to 104.67(8)° with an average value of 94.34°. The average *trans* angles around Cu(1) ion are 87.38 and 90.82° and that around Cu(2) ion are 87.81 and 88.38°. For acetate coordination the Cu(l)-O(5) distance of 2.190(2) Å differs from the Cu(2)–O(4) distance of 2.132(2) Å by 0.058 Å.

This difference in bond length of the two metal ions to the oxygen atoms of the *syn-syn* bidentate carboxylate bridge is usually not larger than 0.10 Å as in other diiron or dimanganese complexes. Endogenous phenolato and exogenous acetato bridging support the formation of the imidazolidine-bridged homodinuclear assembly. The Cu–Cu distance is 3.298(4) Å, which is in the normal range for other triply bridging molecules.[2,27] Longer Cu–N distances [Cu(1)–N(2) = 2.116(2) Å; Cu(2)–N(3) = 2.203(2) Å][28–31] are observed for the tertiary amine nitrogen atoms of the imidazolidine ring to both the copper(II) ions. The Cu–N_{imine} and Cu–O_{phenol} distances are in the normal range. The Cu–O distances for the bridging phenolate coordination indicate that the bridge is practically symmetric [Cu(1)–O(3) = 1.953(1) Å; Cu(2)–O(3) = 1.955(2) Å] for a dicopper complex. Similarly, the Cu(1)–O(5) and Cu(2)–O(4) distances show a high degree of symmetry with respect to the acetate bridge (Figure 2). The complex **1** shows an intricate hydrogen bonding between two water molecules and two terminal phenolic oxygen atoms, attaching a water dimer to the compound. The first water molecule O(6) gives rise intramolecular interactions with both the terminal phenolic oxygen atoms (Figure 1) [O(6)···O(1) = 2.889(3) Å; O(6)···O(2) = 2.931(3) Å]. The hydrogen bonded water molecule provides a pseudo macrocyclic ligand environment around two copper(II) centers. The second water molecule is further hydrogen bonded to the first one [O(7)···O(6) = 2.820(3) Å] and the distance is in between that of liquid water and regular ice (about 2.85 and 2.74 Å).[32] A unit cell packing pattern (Figure 3) is obtained for the complex **1** due to the involvement of the water dimer in the hydrogen bonding network with the complex. Intermolecular hydrogen bonding is operative between the second water molecule O(7) and one of the acetate oxygen atom of another dicopper molecule.

Magnetochemistry of Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O

The degree of magnetic superexchange interaction within the dinuclear complex [Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O (**1**) was evaluated by means of variable temperature bulk magnetic susceptibility measurements in the 2–300 K temperature range, under a constant magnetic field of 0.8 T. The results are presented in Figure 4 in a form of $\chi_m T$ vs. T plot, where χ_m is the molar magnetic susceptibility after correction for the diamagnetic contribution and that of temperature independent paramagnetism (which were combined in one unique parameter). In this plot, $\chi_m T$ remains almost constant over most of the temperature range, at its 300 K value of 0.88 $cm^3 K mol^{-1}$, consistent with two magnetically isolated Cu^{II} (S = 1/2) centers in the molecule. The product $\chi_m T$ starts drop at temperatures below 50 K, to reach a value of 0.55 $cm^3 K mol^{-1}$ at 2 K. These results indicate that the coupling between Cu^{II} ions within **1** is very weak and antiferromagnetic in nature. A quantitative description of this behavior was performed by fitting the experimental data to a theoretical model using the Bleaney–Bowers equation[33,34] as the expression for $\chi_m = f(T)$. The convention employed for the phenomenological description of the magnetic coupling is conveyed by the Heisenberg-Spin Hamiltonian $\boldsymbol{H} = -2\boldsymbol{J}\boldsymbol{S}_1\boldsymbol{S}_2$. Satisfactory fits could only be obtained when the data at lowest temperatures were excluded. This is presumably because at such temperatures, weaker effects begin to surface, which are not included in the model, such as intermolecular interactions. Thus, a least-squares procedure was carried out to model the data above 8 K. The best fit (Figure 4, solid line) ensued from J = –2.2 cm^{-1} and g = 2.17. The magnetic superexchange in dinuclear systems such as complex **1** has been explained in numerous previous examples in terms of the overlap between the magnetic orbitals of the Cu^{II} ions through the intermediacy of the bridging ligands.[35] In complex **1**, the metal ions are in a distorted square-pyramidal geometry, the apical positions being occupied by the oxygen atoms from the μ–AcO^- bridge. Therefore, the magnetic orbitals are $d_{x^2-y^2}$ and can only interact via the phenol bridging moiety. A magneto-structural study has established the correlation existing between the Cu–O–Cu angle and J in bis-(phenoxide)-bridged [Cu_2] complexes, and has shown the strong antiferromagnetic character of this coupling.[36] In the mentioned study, both μ-phenoxide groups occupy equatorial coordination positions from Cu^{II}, thereby providing for two strong exchange pathways. Complex **1** however, belongs to the smaller group of compounds displaying one phenoxide and one η^1:η^1:μ_2-acetate bridge. In this family, the magnetic coupling has been found to be much weaker[37–39] and in very few exceptions a ferromagnetic type of exchange has been claimed.[40] This is consistent with the fact that in these compounds there is only one possible pathway for the exchange. In addition, it has been argued that the angle between the equatorial planes around Cu^{II} exerts a significant influence on the magnitude of J.[41] In particular, a deviation of this angle from zero degrees causes the decrease of the energy gap between the symmetric (φ_s) and the antisymmetric (φ_a) combination of magnetic orbitals, diminishing the antiferromagnetic nature of the coupling. In compound **1**, the idealized Cu^{II} equatorial planes are significantly bent, forming an angle 38.32°, to which

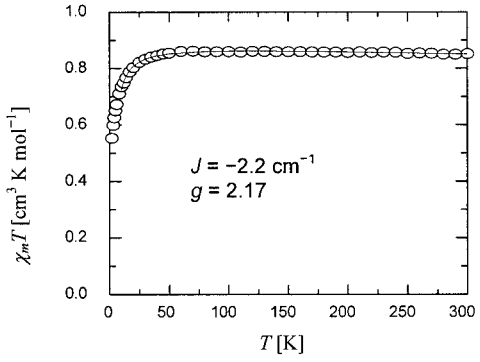

Figure 4. Plot of $\chi_m T$ vs. T per mol of complex [Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O (**1**). Data have been corrected for sample diamagnetic contributions and temperature independent paramagnetism. The solid line is the best fit to the experimental data above 8 K (see text for details).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

could be ascribed the small value of J calculated above. Comparisons of complex **1** with previous systems, however, are thwarted by the unique structural features imposed on this assembly by the dinucleating ligand. This is perhaps most evident in the unconventional orientation of the C–O bond of the bridging phenoxide with respect to the plane containing the Cu–O–Cu atoms from that bridge. Useful for this discussion could be the suggestion that μ-acetates and alkoxide bridges, when simultaneously present in this type of $[Cu_2]$ complexes, are *counter-complementary*, leading to a reduction of the $\varphi_s - \varphi_a$ energy gap and therefore, of the absolute value of J.[42] In the present case however, this mechanism can not operate because the AcO^- group is bound to the axial positions of Cu^{II} and, therefore, is not interacting with the magnetic orbitals of the metals.

EPR Spectroscopy of Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O

Powder X-Band (9.7857 GHz) EPR spectra were collected for complex **1** at room temperature and 77 K. The latter one is shown in Figure 5. In both the cases, the obtained spectra could be interpreted in terms of mononuclear Cu^{II} chromophores in a *quasi* axial geometry, which is in line with the above revelation that at these temperatures, the ions within the complex are essentially uncoupled. Thus, consistent with the asymmetric square-pyramidal geometry of the metal centers in **1**, with a *cis*-N_2O_2 equatorial donor set, three components of g can be observed, with $g = 2.17$ and $g_\perp$ split in two; $g_x = 2.12$ and $g_y = 2.07$. The lower field side of the parallel signal shows a shoulder that could be interpreted as the manifestation of small hyperfine splitting of this signal as a result of the coupling with the nuclear spin from $^{3/2}$Cu. The average isotropic g-factor resulting from these measured values is $g = 2.12$, which is in reasonable agreement with the value calculated from fitting the bulk magnetization measurements (see above).

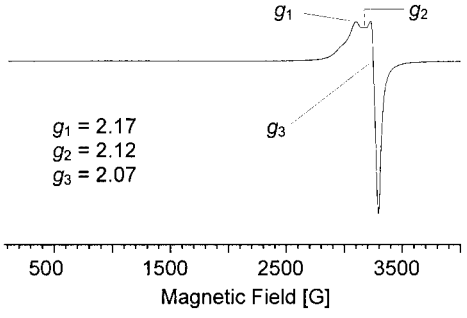

Figure 5. Powder X-band EPR spectrum of complex [Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O (**1**) at ca 77 K.

^{1}H NMR Spectroscopy of Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O

^{1}H NMR spectroscopy has been shown to be applicable to characterization of the structure and reactivity of dicopper(II/II) complexes with magnetic coupling that ranges from weakly ferromagnetic to strongly antiferromagnetic.[43] Few reports have described copper(II) complexes that produce narrow ^{1}H NMR resonances.[44–49] Paramagnetic NMR of dinuclear copper complexes has been used extensively in order to establish their relevance as models for metal sites in copper enzymes.[50] Construction of a library of compounds along with their NMR properties is beneficial in the context of bioinorganic modeling of naturally occurring metallo-enzymes. 250-MHz ^{1}H NMR spectroscopic data of complex **1** were collected in [D_4]methanol at room temperature. The T_1 value of almost every observed resonance has been determined for helping in the assignment of the spectrum. For this, it was taken into consideration that the relaxation time T_1 of protons within paramagnetic complexes is proportional to r^{-6}, where r is the distance from the observed H nucleus to the metallic center. The T_1 values and the chemical shifts, δ, of all resonances are collected in Table 2, whereas the spectrum with the assignment of the signals are shown in Figure 6. Complex **1** is only scarcely soluble in MeOH, therefore, a large number of scans needed to be collected before an acceptable signal-to-noise ratio could be attained. The spectrum of **1** shows a total of seventeen hyperfine shifted peaks, as expected from the idealized C_s symmetry of the compound, spread over a very large window of chemical shift, spanning about 130 ppm. This reflects the fact that at room temperature the system remains largely paramagnetic as a result of the very weak nature of the observed antiferromagnetic coupling. In addition, peaks attributed to MeOH and free ligand were detected. The assignment of the latter peaks was made on the basis of their smaller relative intensity with respect to the rest of the signals. The signals from the solvent were used as internal reference. Inspection of the intensity integrals of these seventeen resonances allowed their grouping into four sets of one (a), two (b), ten (c), and four (d) signals, respectively, integrating for six, three, two and one proton, as predicted from the structure of **1** (Figure 6, top). These groups correspond to the following categories of protons: Group "a", only one signal, which integrates for six protons, corresponding to the two equivalent methyl groups in α to the imine N atoms, and which was readily assigned; group "b", two signals with intensities equivalent to three protons each, arising from two inequivalent methyl groups, respectively. These correspond to the μ-acetate and to the methyl attached to the central five-membered ring of the ligand. The assignment of these two signals to either of both groups remains ambiguous since the distances of the protons to the Cu^{II} ions is very similar in both cases; group "c" is the most numerous. It includes ten signals with intensity ratios for two H nuclei. These result from the hydrogen atoms attached to the amine groups (six signals) and from those attached to the two external phenyl rings (which are equivalent). The peaks from the first sub-group are broader than these of the second, since the protons causing the former are crystallographically closer to the metal centers. Again, the assignment could be made almost unambiguously on the basis of the T_1 values. Where T_1 was so small that could not be measured, the broadness of the peaks was used as an approximate measure of the relative relaxation times. The resonances of the other sub-group are sharper

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and show the alternation of chemical shifts characteristic of π-delocalization mechanisms.[51] This, along with relaxation time data helped in the assignment of the resonances; group "d" is the last set of signals, which includes the four peaks from the central phenyl ring of the ligand (one proton per signal). Here is also evident a mechanism of π-delocalization of the electronic spin, which was useful in the assignment of the peaks. With this study, complex **1** enters the small group of binuclear [Cu_2] complexes of which, the ^{1}H NMR spectrum could be explained almost unambiguously and is a valuable contribution to the growing body of spectroscopic data which can be useful in the functional and structural study of the metallo-enzymes.

At the bottom is a labeled 250 MHz 1H NMR spectrum of **1**. Asterisks * denote signals from free ligand (See text and Table 2 for details on the assignment).

Electrochemistry of [Cu^{II}_2(μ-mhbai)(μ-S_2COMe)]·2H_2O

The electron-transfer behaviour of the complex [Cu^{II}_2(μ-mhbai)(μ-S_2COMe)]·2H_2O (**4**) in dimethylformamide has been studied by cyclic voltammetry. A glassy-carbon working electrode with tetraethylammonium perchlorate (TEAP) as supporting electrolyte at 298 K were used. The cyclic voltammogram was recorded in the potential range of 0.0 to +0.9 V vs. saturated calomel electrode (SCE) at a scan rate of 50 mV s^{-1}. Complexes **1**–**3** do not display any characteristic cyclic voltammetric response within the above-mentioned potential window. Only the xanthate-bridged complex **4** exhibits a quasi-reversible response at $E_{1/2}$ = 0.504 V (ΔE_p = 132 mV). The observed quasi-reversible peak is assigned to an one electron transfer process [Equation (1) for ligand oxidation.The ligand centered oxidation is known in several sulfur-based ligand systems where thiyl radical formation is predicted for an instance when ligand-based oxidation occurs rather than metal-based.[52]

$$[Cu^{II}\{\mu\text{-MeO(C=S)S}^-\}Cu^{II}]^{3+} - e^- \leftrightarrow [Cu^{II}\{\mu\text{-MeO(C=S)S}^{\cdot}\}Cu^{II}]^{4+} + e^- \quad (1)$$

The quasi-reversible nature of the voltammogram indicate the formation of a methoxythiyl radical coordinated to a metal ion with a weak Cu–$^{-}$S(C=S)OMe bond. The absence of any voltammetric response in analogous acetate-bridged complex (**1**) also shows the easy oxidizing nature of thio derivatives.[52] At 298 K the oxidized species is stable at the voltammetric time-scale only.

Concluding Remarks

The results presented here demonstrate the synthesis, structural characterization and magnetic behaviour of imidazolidine-bridged Cu^{II}–Cu^{II} triply-bridged intimate complex supported by a new μ-bis(tetradentate) Schiff-base ligand. Complex **1** is the example of a new structurally characterized μ-η^1:η^1-*N*,*N*′-imidazolidine-bridged dicopper(II/III) complex. Neither triply-bridged structure nor the imidazolidine bridge is responsible for any strong magnetic interaction. Two copper(II) ions at a distance of 3.2984 Å show only a weak magnetic interaction. The isolated new dicopper(II/III) complexes have [Cu_2(μ-imidazolidine)]$^{4+}$ core and currently we are engaged in synthesizing analogues complexes of other 3d and 4d metal ions to explore the role of bridging imidazolidine moiety in the molecular structure and physical properties of new complexes.

Experimental Section

Materials and Physical Measurements: The chemicals used were obtained from the following sources: Triethylenetetramine and carbon disulfide from S.D. Fine Chem, India. 2-Hydroxyacetophenone from Spectrochem, Mumbai, India. Cupric acetate hydrate and cupric chloride dihydrate from SRL, India. Cupric nitrate trihydrate from E. Merck, India. All other chemicals and solvents were reagent grade materials and were used as received without further purification. The elemental analyses (C, H, N) were performed with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a Perkin–Elmer model 240 C elemental analyzer. ^{1}H and ^{13}C NMR spectra of the ligand were obtained with a Bruker AC 200 NMR spectrometer using TMS as the internal standard. ^{1}H NMR spectra of the complex were collected with a 250 MHz Bruker DXR 250 spectrometer. Longitudinal relaxation times (T_1) were measured using an inversion-recovery pulse sequence (180-τ-90°) with a 300 MHz Varian Unity-300 spectrometer. In all cases, the protio-solvent signal was used as reference and chemical shifts were quoted on the δ scale (down field shifts are positive). IR spectra were recorded with a Perkin–Elmer 883 spectrophotometer. The solution electrical conductivity and electronic spectra were obtained with a Unitech type U131C digital conductivity meter with a solute concentration of about 10^{-3} M and a Shimadzu UV 3100 UV/Vis-NIR spectrophotometer, respectively. Mass spectra were obtained with a Finnigan MAT 8200 (electron ionization, EIMS) instrument. The room temperature magnetic susceptibilities in the solid state were measured using a home built Gouy balance fitted with a polytronic d.c. power supply. The experimental magnetic susceptibilities were corrected for the diamagnetic response using Pascal's constants.[53] Magnetic measurements were carried out at the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (ca. 40 mg) by using a Quantum Design MPMS XL-5 SQUID susceptometer operating at a constant magnetic field of 0.8 T between 2 and 300 K. The experimental magnetic moment was corrected for the diamagnetic contribution from the sample holder. X-Band EPR measurements (9.7857 GHz) were performed at room temperature and ca. 77 K on powdered samples a Bruker Spectrometer (ESR, 300E), working with an oxford helium liquid cryostat for variable temperature. Electrochemical measurements were made using a PAR model 173 potentiostat/galvanostat, 175 universal programmer, 178 electrometer, and 377-cell system. A glassy carbon working-electrode, a platinum-wire auxiliary-electrode, and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. A digital series 2000 Omni Graphic recorder was used to trace the voltammograms. Electrochemical measurements were made under nitrogen.

Synthesis of 2-(2-Hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-4-methyl-3-azabut-3-enyl]-2-methyl-1,3-imidazolidine (H_3mhbai): A solution of triethylenetetramine (3.7 g, 25.3 mmol) in methanol (25 mL) was added dropwise to a methanolic solution (25 mL) of 2-hydroxyacetophenone (10.2 g, 74.9 mmol) with stirring at room temperature. The yellow solution was then refluxed for 5 h. The solvent was evaporated in air. The yellow solid was separated by filtration through G4 sintered bed and washed thoroughly with hexane and water. Finally the isolated compound was dried in vacuo with P_4O_{10}. Yield 9.3 g (75%), m.p. 184–186 °C. $C_{30}H_{36}N_4O_3$ (500.6): calcd. C 71.97, H 7.25, N 11.19; found C 71.51, H 7.62, N 11.49. Mass spectrum (EI): *m/z* 500 ($M^+ = L^+$). IR (cm^{-1}, KBr disk): $\tilde{\nu}$ = 3443 [w, ν(phenolic OH)], 1616 [s, ν(C=N)], 1371 [s, ν(phenolic C–O)], 835 [m, ν(CH_2)], 745 [m, ν(aromatic CH)]. ^{1}H NMR ($CDCl_3$, ppm): δ = 16.13 (s, 2 H, terminal phenolic OH), 12.03 (s, 1 H, pendant phenolic OH), 7.21–7.48 (m, 8 H, H^{2-5}), 6.74–6.89 (m, 4 H, H^{15-18}), 3.47–3.55 (m, 4 H, H^8), 2.86 (t, 4 H, H^9), 2.74–2.80 (m, 4 H, H^{10} and H^{11}), 2.21 (s, 6 H, $H_{terminal\ methyl}$), 1.138 (s, 3 H, $H_{central\ methyl}$). ^{13}C NMR ($CDCl_3$, ppm): δ = 164.29 (C^7), 162.38 ($C^{1,14}$), 132.48 (C^6), 130.68 ($C^{16,18}$), 128.00 ($C^{3,5}$), 119.18 (C^{17}), 118.88 (C^4), 118.39($C^{2,15}$), 116.83 (C^{12}), 49.61 (C^8), 49.44 (C^9), 49.10 (C^{10}), 26.58 ($C_{terminal\ methyl}$), 14.51 ($C_{central\ methyl}$).

Synthesis of the Complexes: A general procedure was followed for the preparation and isolation of all complexes of type [Cu^{II}_2(μ-mhbai)(μ-X)]·2H_2O. Details are given below for the representative cases.

[Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O (1): An aqueous solution (10 mL) of $Cu(OAc)_2$·H_2O (0.399 g, 1.9 mmol) was slowly added dropwise at ambient temperature to a magnetically stirred warm methanolic solution (15 mL) of H_3L (0.5 g, 0.9 mmol) during a period of 15 min. After complete addition a dark green compound was seen separating in solution. The whole reaction mixture was stirred for 1 h at room temperature. The solvent was evaporated in air. The green precipitate was filtered through a glass frit and washed with water followed by ethanol and hexane and finally dried in vacuo over P_4O_{10}. Yield: 0.61 g (85%). $C_{32}H_{40}Cu_2N_4O_7$ (719.8): calcd. C 53.40, H 5.60, N 7.78, Cu 17.65; found C 52.91, H 5.36, N 7.37, Cu 17.90. IR (cm^{-1}, KBr disk): $\tilde{\nu}$ = 3415 (b), 1605 (vs), 1586 (s), 1532 (s), 1405 (s), 1312 (s), 1201 (s), 869 (s), 755 (s). Molar conductance, Λ_M: (DMF) = 16.36 ohm^{-1}cm^{2}mol^{-1}. UV/Vis (DMF): λ_{max} (ε, L mol^{-1}cm^{-1}) = 616 (385), 368 (10945), 300 (11780) sh, 273 nm (24730). μ_{eff} (tot.): 2.43 μ_B; μ_{eff}/Cu: 1.71 μ_B.

[Cu^{II}_2(μ-mhbai)(μ-NO_3)]·2H_2O (2): This compound was prepared following the above procedure using $Cu(NO_3)_2$·3H_2O and triethylamine. The stirring was continued for 1 h. Yield: 0.54 g (75%). $C_{30}H_{37}Cu_2N_5O_8$ (722.7): calcd. C 49.85, H 5.16, N 9.69, Cu 17.58; found C 49.51, H 4.96, N 9.37, Cu 17.01. IR (cm^{-1}, KBr disk): $\tilde{\nu}$ = 3438 (b), 1611 (vs), 1588 (s), 1539 (s), 1453 (s), 1403 (s), 1378 (s), 1297 (s), 1201 (s), 824 (s), 735 (s). Molar conductance, Λ_M: (DMF) = 12.48 ohm^{-1}cm^{2}mol^{-1}. UV/Vis (DMF): λ_{max} (ε, L mol^{-1}cm^{-1})] = 602 (230), 361 (7045), 268 nm (16505). μ_{eff} (tot.): 2.35 μ_B; μ_{eff}/Cu: 1.66 μ_B.

[Cu^{II}_2(μ-mhbai)(μ-Cl)]·2H_2O (3): This compound was prepared following the above procedure using $CuCl_2$·2H_2O. The stirring was continued for 1 h. Yield: 0.56 g (80%). $C_{30}H_{37}ClCu_2N_4O_5$ (696.2): calcd. C 51.76, H 5.36, N 8.05, Cu 19.24; found C 51.33, H 5.67, N 8.34, Cu 19.18. IR (cm^{-1}, KBr disk): $\tilde{\nu}$ = 3396 (b), 1602 (vs), 1530 (s), 1319 (s), 1277 (s), 891 (s), 734 (s). Molar conductance, Λ_M: (DMF) = 29.26 ohm^{-1}cm^{2}mol^{-1}. UV/Vis(DMF): λ_{max} (ε, L mol^{-1}cm^{-1}) = 623 (110), 359 (5170), 272 nm (15170). μ_{eff} (tot.): 2.81 μ_B; μ_{eff}/Cu: 1.98 μ_B.

[Cu^{II}_2(μ-mhbai)(μ-S_2COMe)]·2H_2O (4): This compound was prepared following the above procedure, using $CuCl_2$·2H_2O and NaS_2COMe. The stirring was continued for 1 h. Yield: 0.59 g (77%). $C_{32}H_{40}Cu_2N_4O_6S_2$ (767.9): calcd. C 50.05, H 5.25, N 7.29, Cu 16.55; found C 50.41, H 4.96, N 7.81, Cu 16.62. IR (cm^{-1}, KBr disk): $\tilde{\nu}$ = 3410 (b), 1607 (vs), 1527 (s), 1318 (s), 1203 (s), 1144 (s), 1021 (s), 861 (s), 724 (s). Molar conductance, Λ_M: (DMF) = 20.18 ohm^{-1}cm^{2}mol^{-1}. UV/Vis (DMF): λ_{max} (ε, L mol^{-1}cm^{-1}) = 627 (225), 370 (8350), 315 (10380), 274 nm (19225). μ_{eff} (tot.): 2.68 μ_B; μ_{eff}/Cu: 1.89 μ_B.

X-ray Crystallographic Procedures for [Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O (1): The green plate-like single crystals of complex [Cu^{II}_2(μ-mhbai)(μ-OAc)]·2H_2O suitable for the X-ray analysis were grown by the slow evaporation of a acetonitrile/water solution of the complex. The intensity data of the complex were collected on Bruker SMART CCD X-ray diffractometer using a single crystal with dimensions $0.01 \times 0.22 \times 0.25$ mm^3 that uses graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by ω-scan method. Precise unit cell dimensions were determined by least-squares refinement of 25 strong reflections having 2θ values. Data were collected at 298 K. A total of 7019 reflections were recorded with Miller indices h_{min} = 0, h_{max} = 11, k_{min} = –14, k_{max} = 14, l_{min} = –21, l_{max} = 21. In the final cycles of full-matrix least-squares on F^2 all non-hydrogen atoms were assigned anisotropic thermal parameters and refinement converged at R = 0.034. The residual electron density is in the range +0.73 to –0.64 e·Å^{-3}. The positions of the H atoms bonded to C atoms were calculated (C–H distance

0.96 Å). The structure was solved on a PC 486 by using the DIRDIF92-PATTY programme system[54] and refined by full-matrix least-squares methods with use of the programme SHELX-97[55]/TEXSAN.[56] Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[57] Information concerning X-ray data collection and structure refinement of the compound is summarized in Table 3.

A Comparative Assessment of the Effect of the Lewis Acidity of the Central Tin Atom on Intramolecular Coordination of (3-Methoxypropyl)stannanes

Tomáš Lébl,*[a,c] Petra Zoufalá,[a] and Clemens Bruhn[b]

Keywords: Tin / Chelates / O ligands / Structure elucidation / Coordination modes

The recently studied set of (3-methoxypropyl)stannanes of general formula R_xSnCl_{4-x} [R = $(CH_2)_3OCH_3$, x = 4 (**1**), x = 3 (**2**), x = 2 (**3**) and x = 1 (**4**)] is extended with two new sets of (3-methoxypropyl)stannanes of general formula $RPh_{3-x}SnCl_x$ [x = 0 (**5**), x = 1 (**6**) and x = 2 (**7**)] and $RSn(S_2CNEt_2)_{3-x}Cl_x$ [x = 0 (**8**), x = 1 (**9**) and x = 2 (**10**)]. The molecular structures of **6**, **7**, **9** and **10** in the solid state were determined by X-ray diffraction. In compounds **6** and **7**, the 3-methoxypropyl ligand forms a C,O-chelate and the tin atom is coordinated as a distorted trigonal bipyramid with the oxygen and one chlorine atom in the axial positions. Compounds **9** and **10** are hexacoordinate with a distorted octahedral ligand arrangement. While the 3-methoxypropyl ligand in **10** also forms a C,O-chelate, the oxygen atom in **9** is not coordinated to the central tin atom. The structures in a non-coordinating ($CDCl_3$) and a coordinating solvent ([D_6]DMSO) were studied by multinuclear ^{1}H, ^{13}C and ^{119}Sn NMR spectroscopy. It is proposed that the structures found in the solid state are retained upon dissolution in $CDCl_3$. Compounds **5**, **8** and **9** also preserve their structures in [D_6]DMSO. On the other hand, an equilibrium, in which one or more molecules of solvent enter the coordination sphere of the central tin atom and cleave the oxastannacycle, is established in [D_6]DMSO solutions of **6**, **7** and **10**. A comparison of the $J_{^1H,^{119}Sn}$ coupling constants obtained from 1D ^{1}H,^{119}Sn HMQC and 2D ^{1}H,^{119}Sn J-HMBC spectra and the $J_{^{13}C,^{119}Sn}$ coupling constants derived from conventional 1D ^{13}C NMR spectra shows that the best indicator of the O→Sn donor–acceptor interaction in 3-methoxypropylstannanes is the $^3J_{^{13}C,^{119}Sn}$ value.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Organotin complexes containing C,Y-chelating ligands (i.e. organic substituents with a donor atom Y at a position where it is capable of intramolecular donor–acceptor interaction with the central metal atom) have been known for about thirty years.[1] Nevertheless, their manifold structures are still being intensively studied. Complexes of both transition and main-group metals are the subject of these studies. There are a number of reports detailing organostannanes containing either aromatic pincer-type ligands[2] or alkyl ligands substituted by a Lewis-basic heteroatom Y in a position enabling formation of five- or even six-membered heterostannacycles.[3]

Recently, we reported the synthesis and structures of the first set of (3-methoxypropyl)stannanes of the general formula R_xSnCl_{4-x} [R = $(CH_2)_3OCH_3$, x = 4 (**1**), x = 3 (**2**), x = 2 (**3**) and x = 1 (**4**)], which were studied for their considerable water solubility and appreciable in vitro trypanocidal activity.[4] We showed that the 3-methoxypropyl group can be bonded either as a monodentate ligand (Scheme 1, **A**) or as a bidentate C,O-chelating ligand (Scheme 1, **B**), and that this is dependent on the Lewis acidity of the central tin atom. However, the ^{119}Sn chemical shift gives unambiguous evidence for an O→Sn donor–acceptor interaction only if no other potentially bidentate ligand, such as a carboxylate group, is present in the coordination sphere. Moreover, even for R_4Sn (**1**), where the 3-methoxypropyl ligands do not form a chelate, all protons display ^{1}H-^{119}Sn HMQC correlations.[5] Therefore, the existence of the correlation itself cannot prove the existence of the oxastannacycle, and to distinguish between these two bonding modes (Scheme 1) in solution is a crucial issue of structural research.

In the case of the monodentate 3-methoxypropyl group (Scheme 1, **A**), there is only one scalar coupling pathway, that through the covalent bonds of the 3-methoxypropyl chain. On the other hand, if the oxastannacycle is closed (Scheme 1, **B**) there are two scalar coupling pathways − through the covalent bonds and through the coordinative O→Sn bond − which could be reflected in the magnitude of the $J_{^1H,^{119}Sn}$ and $J_{^{13}C,^{119}Sn}$ coupling constants.[5,6] The long-range $^{6+3}J_{^1H,^{119}Sn}$ coupling constants of 0.52, 1.86 and 2.24 Hz obtained for **1**, **3** and **4**, respectively, show that this parameter increases with the strength of the O→Sn interac-

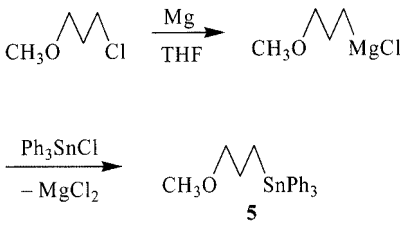
tion.[4] Since this limited set of results does not allow us to draw any final conclusion, two more sets of (3-methoxypropyl)stannanes were prepared. In the first set, of general formula $RPh_{3-x}SnCl_x$ [x = 0 (**5**), x = 1 (**6**) and x = 2 (**7**)], there is only one 3-methoxypropyl group in the coordination sphere and the Lewis acidity of the central tin atom is varied by substitution of phenyl groups by chlorine atoms. The latter set, of general formula $RSn(S_2CNEt_2)_{3-x}Cl_x$ [x = 0 (**8**), x = 1 (**9**) and x = 2 (**10**)], is composed of monorganotin compounds and variation of the Lewis acidity of tin is achieved by changing the number of chlorine atoms and strongly chelating *N*,*N*-diethyldithiocarbamate groups in the coordination sphere. These complexes were studied by X-ray diffraction, ^{13}C and ^{119}Sn CP/MAS NMR spectroscopy in the solid state and multinuclear ^{1}H, ^{13}C and ^{119}Sn NMR spectroscopy in solution in non-coordinating ($CDCl_3$) and coordinating ([D_6]DMSO) solvent. The obtained parameters are compared and are discussed with the aim of finding an indicator of the strength of the O→Sn donor–acceptor interaction.

Results and Discussion

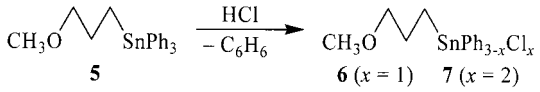
Syntheses

(3-Methoxypropyl)triphenylstannane (**5**) was synthesised as shown in Scheme 2. Treatment of chlorotriphenylstannane with excess (3-methoxypropyl)magnesium chloride, which was previously prepared from 1-chloro-3-methoxypropane and magnesium chips in THF, provided tetraorganostannane **5**, which was isolated as a white powder in a yield of 85% with respect to Ph_3SnCl.



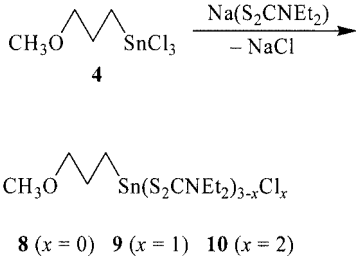
Scheme 2.

Chloro(3-methoxypropyl)phenylstannanes **6** and **7** were prepared from **5** by stepwise cleavage of phenyl groups upon treatment with HCl in $CHCl_3$ at room temperature (Scheme 3). The reaction proceeded selectively and both compounds were obtained as white crystals in yields of over 95%.



Scheme 3.

Treatment of **4** with an appropriate stoichiometric amount of sodium *N*,*N*-diethyldithiocarbamate in acetone at room temperature afforded carbamate complexes **8**, **9** and **10** (Scheme 4) as white or yellowish crystals in yields of 80, 83 and 59%, respectively.



Scheme 4.

Solid-State Structures

In the case of **5**, isolation of a single crystal suitable for X-ray crystal structure determination was unsuccessful. However, considering that **5** is a tetraorganotin compound, any coordination of oxygen to tin and consequent increase of its coordination number above four can be easily excluded, and thus it can be assumed that the structure is close to tetrahedral as in the majority of tetraorganotin compounds.[7]

The molecular structures of **6** and **7**, as determined by X-ray diffraction, are shown in Figures 1 and 2, respectively. Selected bond lengths and angles are given in Table 1.

Both complexes consist of discrete molecules with a structure that is very like that of **4**.[4] The central tin atom is coordinated as a distorted trigonal-bipyramid with the oxygen atom and one chlorine atom in the axial positions [Cl–Sn–O: 170.37(4)° and 172.6(1)°] (Figure 1). Compound **6** has a rather symmetrical equatorial plane containing two carbons of phenyl groups and one carbon of the 3-methoxypropyl group [C–Sn–C: 122.67(11)°, 119.48(11)°, 111.56(10)°]. However, the phenyl rings have different orientations: while one lies practically within the equatorial plane [C10–C5–Sn–C1: 4.2(3)°] the second one is oriented nearly along the axis of the trigonal bipyramid [C12–C11–Sn–O: –10.8(2)°]. This means that the tin atom is a stereocentre and **6** is chiral in the solid state. This asymmetry is also revealed in the ^{13}C CP/MAS NMR spectrum, where twelve signals are observed in the aromatic region. For compound

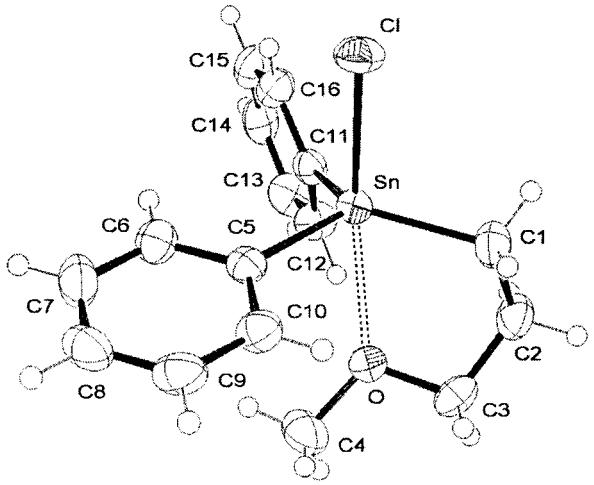

Figure 1. Solid-state structure of **6**.

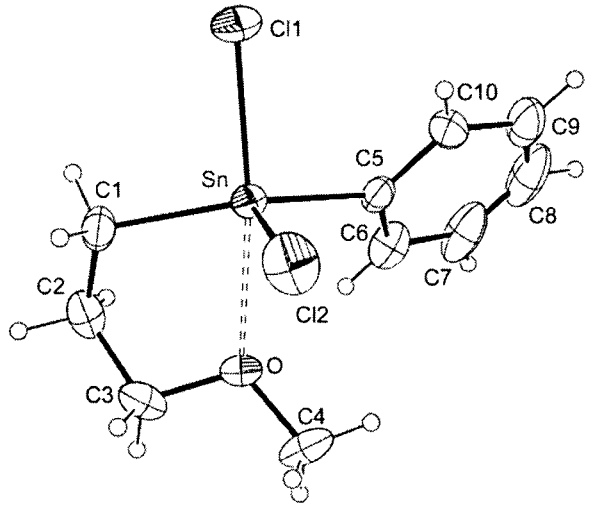

Figure 2. Solid-state structure of **7**.

7 (Figure 2), one phenyl group is replaced by the second chlorine atom and, consequently, the equatorial plane is less symmetrical [C–Sn–C: 140.2(2)°]. However, **7** still lacks a mirror plane and an inversion centre and therefore it is also chiral. The unit cells in crystals of both compounds consist of pairs of enantiomers, and thus **6** and **7** are racemates. The sum of angles in the equatorial plane of **6** and **7** (353.71° and 354.1°, respectively) is considerably smaller then 360° because both coordination polyhedra have the whole equatorial plane tilted towards the oxygen atom in a similar fashion to **4**.

In the case of **7**, the *trans* influence of the coordinated oxygen atom of the 3-methoxypropyl group causes the apical chlorine atom to have a slightly weaker bond to the central tin atom [Sn–Cl1: 2.425(2) Å] than the corresponding equatorial one [Sn–Cl2: 2.365(2) Å]. An analogous phenomenon is observed for compound **4**, where the Sn–Cl distance for the axial chlorine atom is 2.3904(12) Å while the distances for the equatorial bonds are 2.3317(14) and 2.3274(12) Å.[4] Although the structures of **6**, **7** and **4** are very similar, they differ markedly in the strength of the O→Sn coordination [Sn–O: 2.5505(18), 2.461(4) and 2.394(3) Å, respectively], which increases with the number of chlorine atoms in the coordination sphere, i.e. with the Lewis acidity of the central tin atom. Nevertheless, all the Sn–O bonds are slightly shorter than those found in **3** [Sn–O: 2.559(4) and 2.556(4) Å], where both oxygen atoms are coordinated to tin in a *cis* configuration.[4]

The crystal structure of $[RSn(S_2CNEt_2)_3]$ (**8**) was published recently.[8] An Sn–O intramolecular interaction is precluded [Sn–O: 5.427(1) Å] in this complex because of the penchant of dithiocarbamate to chelate tin and the steric crowding, given that the tin is already seven-coordinate. Thus, the 3-methoxypropyl group is bonded to tin only through carbon as a monodentate ligand and the structure is very close to those of other monorganotin tris(*N*,*N*-diethyldithiocarbamate) complexes such as $[MeSn(S_2CNEt_2)_3]$, $[BuSn(S_2CNEt_2)_3]$ and $[PhSn(S_2CNEt_2)_3]$.[9,10]

The molecular structures of the next two carbamate complexes in the set, $[RSn(S_2CNEt_2)_2Cl]$ (**9**) and $[RSn(S_2CNEt_2)Cl_2]$ (**10**), determined by X-ray diffraction, are shown in Figures 3 and 4, respectively. Selected bond lengths and angles are given in Table 2.

Complexes **9** and **10** also exist as discrete molecules. However, in contrast to previously discussed compounds, the tin atoms are hexacoordinate with a distorted octahedral ligand arrangement. The crystal structure of **9** resembles those of other monoorganotin complexes with two dithiocarbamate ligands and a chlorine atom in the coordination sphere, such as $[PhSn(S_2CNEt_2)_2Cl]$[11] and $[(MeO_2CCH_2CH_2)Sn(S_2CNMe_2)_2Cl]$.[12] The central tin atom is coordinated by four sulfur atoms from two bidentate dithiocarbamate ligands, the carbon atom of the 3-methoxypropyl substituent and the chlorine atom; the latter donor atoms are mutually *cis* [C11–Sn–Cl: 93.3(2)°]. The deviation of the coordination polyhedron from the ideal octahedral

geometry is especially apparent for the angles S2–Sn–S4, Cl–Sn–S1 and C11–Sn–S3, which are 153.86(6)°, 161.82(6)° and 166.2(2), respectively, instead of 180°. This distortion of the geometry is constrained by the small bite angles [S1–Sn–S2: 69.98(6)°, S3–Sn–S4: 69.86(6)°] of the dithiocarbamate ligands, which are typical for organotin dithiocarbamates.[10] The two dithiocarbamate groups are not equivalent, as becomes evident in the ^{13}C CP/MAS NMR spectrum (Figure 5), where four sets of signals for ethyl groups and two signals for the CS_2 group are observed. Nevertheless, they form unusually symmetrical chelates [Sn–S: 2.5658(18), 2.5980(19), 2.5693(19) and 2.615(2) Å].

The Sn–C [2.167(7) Å] and Sn–Cl [2.468(2) Å] bonds are longer than those of chloro(3-methoxypropyl)phenylstannanes **6** and **7**, and this can be ascribed to the lower Lewis acidity of the tin atom. On the other hand, the average Sn–S distance in **9** [2.587(15) Å] is considerably shorter than the comparable distance of 2.680(5) Å found for **8**,[8] which is a result of the higher Lewis acidity of the central tin atom caused by replacement of one dithiocarbamate ligand by chloride. In spite of this increased Lewis acidity, the oxygen atom of the 3-methoxypropyl group is not coordinated to tin as in **8**.

In the case of **10**, the distorted octahedral neighbourhood of the tin atom is composed of two chlorine atoms in mutual *cis* positions [Cl–Sn–Cl: 94.82(4)°], a four-membered chelate ring of the bidentate dithiocarbamate ligand and a five-membered chelate ring of the 3-methoxypropyl ligand arising from coordination of oxygen to tin. Thus, the molecular structure of **10** is very close to that of [(MeO$_2$CCH$_2$CH$_2$)Sn(S$_2$CNMe$_2$)Cl$_2$], where the ester carbonyl oxygen is also coordinated to tin.[13] Similarly to other organotin dithiocarbamate complexes, the dithiocarbamate ligand is bonded asymmetrically [Sn–S: 2.4728(10) and 2.6405(10) Å], with a typically small bite angle of 70.27(3)°, which is in part responsible for the distortion of the octahedral geometry.[10] The second most apparent deviation from an ideal octahedron is the bite angle of the 3-methoxypropyl ligand [C–Sn–O: 74.60(13)°]. In the solid-state structure of **10**, the ethyl groups are also non-equivalent and, consequently, the molecule lacks a mirror plane and inversion centre (Figure 4). In the ^{13}C CP/MAS NMR spectrum this is not shown for the CH_3 groups, and two signals were found only for the CH_2 groups. The unit cell in the crystal structure of **10** consist of a pair of enantiomers and thus it is also a racemate.

There is a considerable difference between the Sn–Cl distances [Sn–Cl: 2.4128(11) and 2.4309(10) Å] due to the different *trans* influence of sulfur and oxygen. Nevertheless, both distances are shorter than those found in **9** due to the higher Lewis acidity of the central tin atom in **10**. This is also demonstrated by the average Sn–S bond length of 2.557 Å, which is slightly shorter than that of **9** [2.587(15) Å] and **8** [2.680(5) Å]. Considering that the Sn–O bond length in **10** [2.475(3) Å] is longer than that of **4** and **7** [Sn–O: 2.394(3) and 2.461(4) Å, respectively], but shorter than that of **3** and **6** [Sn–O: 2.559(4), 2.556(4) and 2.5505(18) Å, respectively], it can be concluded that the

Lewis acidity of the central tin atom in **10** is in-between the Lewis acidities of the tin atoms in these compounds.

NMR Spectroscopy and Structures in Solution

The (3-methoxypropyl)stannanes were fully characterised in $CDCl_3$ solution by ^{1}H and ^{13}C NMR spectroscopy; the values of the ^{1}H and ^{13}C chemical shifts for **5**–**7**, **9** and **10** are given in the Experimental Section. The parameters for the other compounds have been published elsewhere.[4,8] In order to evaluate solution structures both in non-coordinating and coordinating solvents, ^{119}Sn NMR spectra were measured in $CDCl_3$ and [D_6]DMSO and also in the solid state. The values of the ^{119}Sn chemical shifts are summarised in Table 3. The coordinative behaviour of the 3-methoxypropyl ligand will be discussed in light of the $J_{^1H,^{119}Sn}$ coupling constants obtained from 1D ^{1}H,^{119}Sn HMQC and 2D ^{1}H,^{119}Sn J-HMBC NMR spectra[5] (Table 4) and $J_{^{13}C,^{119}Sn}$ values derived from conventional 1D ^{13}C NMR spectra (Table 5). The numbering used for the hydrogen and carbon atoms is given in Scheme 5.

Table 3. ^{119}Sn chemical shifts [ppm] for (3-methoxypropyl)stannanes in the solid state, $CDCl_3$ and [D_6]DMSO.

Scheme 5.

Although complex **7** (Figure 2) is chiral in the solid state, the inequivalency of the CH_2 hydrogen atoms is not seen in the 500 MHz ^1H NMR spectra of $CDCl_3$ solutions. On the other hand, there are only moderate differences between the ^{119}Sn chemical shifts in $CDCl_3$ solution and in the solid state (Table 3). Even the largest difference (57.2 ppm), found for **8,** is still far from that corresponding to a change of coordination number[14,15] and is probably caused only by crystal-packing forces. Therefore, it can be assumed that the structures found in the solid state are retained upon dissolution in $CDCl_3$.

The non-equivalence of the ethyl groups in **9** and **10** found in the solid-state structures (Figures 3 and 4) and in ^{13}C CP/MAS spectra disappears in solution due to a free rotation of the C–N bonds and was not observed even in [D_8]toluene at 180 K.

In the case of compounds **1**, **5**, **8** and **9**, where the 3-methoxypropyl group is bonded to the central tin atom only through carbon, the ^{119}Sn resonances in [D_6]DMSO are only slightly shifted to higher frequency with respect to those in $CDCl_3$ (Table 3). This shows that these compounds preserve their structures even in a strongly coordinating solvent such as [D_6]DMSO. On the other hand, the remaining compounds, i.e. those where the chelate ring of the 3-methoxypropyl ligand is closed in the solid state and in $CDCl_3$ solution, have ^{119}Sn resonances in [D_6]DMSO that are more or less shifted to lower frequency. This shows that the dynamic equilibrium already described in our previous paper[4] is established in which one or more molecules of solvent enter the coordination sphere of the central tin atom and cleave the oxastannacycle.

While only one broad ^{119}Sn resonance was observed in most cases, there is one broad resonance (δ = –470.3 ppm) and one sharp resonance (δ = –575.2 ppm) in the ^{119}Sn NMR spectrum of **10**. This likely indicates that an equilibrium of at least three species is established in [D_6]DMSO solution of **10** (Scheme 6). The broad signal with a chemical shift of δ = –470.3 ppm probably arises due to the equilibrium between hexacoordinate species **A** and **B**, which is fast on the NMR timescale. The difference between the chemical shifts of the observed resonances is 105 ppm (19.5 kHz) and therefore the sharp resonance at δ = –575.2 ppm could be assigned to heptacoordinate complex **C**, which is in a slow exchange regime on the NMR timescale.

The values of the $^2J_{^1H,^{119}Sn}$ coupling constants obtained for proton H1 (Table 4) clearly show that this parameter is mainly influenced by the number of polar groups (Cl, Et_2NCS_2) bonded to the central tin atom, and by the coordination number, and therefore do not bring any information about the O→Sn coordination. Comparison of $^3J_{^1H,^{119}Sn}$ coupling constants found for proton H2 in heptacoordinate and hexacoordinate compounds **8**, **9** and **10** (151.8, 153.9 and 283.1 Hz, respectively) denote that the closure of the oxastannacycle results in a considerable increase of this parameter. However, the 3-methoxypropyl group in pentacoordinate compounds **6** and **7** also forms a chelate but the values of the $^3J_{^1H,^{119}Sn}$ coupling constants observed for proton H2 (134.5 and 169.3 Hz) are similar to those in **8** and **9**, where the oxygen is not coordinated to tin, while another pentacoordinate compound with a chelating 3-methoxypropyl group (**4**) has this parameter almost two times higher (254.2 Hz). Thus, it is evident that $^3J_{^1H,^{119}Sn}$ coupling constants are also still strongly influenced by the coordination environment of the central tin atom and it is impossible to use this parameter to evaluate the coordinative behaviour of the 3-methoxypropyl ligand. Surprisingly, the changes of long-range $^4J_{^1H,^{119}Sn}$ coupling constants obtained for proton H3 (Table 4) do not exhibit any trend that could enable conclusions to be drawn about the coordination of oxygen to tin.

For the methoxy group of tetraorganotin compound **5**, it was impossible to obtain the exact value of the long-range $^6J_{^1H,^{119}Sn}$ coupling constant, but the trace of the sine modulation obtained from an $^1H,^{119}Sn$ J-HMBC experiment enabled us to estimate that the value is lower than 0.5 Hz. On the other hand, the values of this parameter in **6** and **7** (1.32 and 1.73 Hz, respectively) are considerably higher and increase with the strength of donor–acceptor bonding between the oxygen atom of the 3-methoxypropyl ligand and the central tin atom [Sn–O: 2.5505(18) and 2.461(4) Å, respectively] but they are still smaller than that of **4** (2.24 Hz), where the closure of the oxastannacycle is even more firm [Sn–O: 2.394(3) Å]. Thus, it seems that the long-range $^6J_{^1H,^{119}Sn}$ coupling constants of proton H4 reflect the strength of the O→Sn coordinative bond and the conclusions made on the basis of the values obtained for the first

set of (3-methoxypropyl)stannanes (**1**–**4**) are confirmed.[4] However, all dithiocarbamate complexes **8**, **9** and **10** have rather large long-range $^{6}J_{^{1}H,^{119}Sn}$ coupling constants (1.06, 2.46 and 3.24 Hz, respectively) for proton H4 even though the 3-methoxypropyl ligand forms a chelate only in the last one. Moreover, the value of 3.24 Hz obtained for **10** is significantly higher than that for **4** (2.24 Hz), where the O→Sn donor–acceptor interaction is stronger [Sn–O: 2.475(3) and 2.394(3) Å, respectively]. Thus, it is evident that this long-range coupling constant is also markedly dependent on the neighbourhood of the central tin atom and is also not very useful as an indicator of intermolecular donor–acceptor interactions.

The values of the $^{1}J_{^{13}C,^{119}Sn}$ and $^{2}J_{^{13}C,^{119}Sn}$ coupling constants obtained for carbons C1 and C2, respectively (Table 5), are influenced especially by the neighbourhood of the central tin atom and no effect of the coordinative behaviour of the 3-methoxypropyl ligand is apparent. In our previous paper,[4] we remarked that the compounds with an oxastannacycle of a 3-methoxypropyl ligand (**3** and **4**) have values of $^{3}J_{^{13}C,^{119}Sn}$ for carbon C3 lower than the corresponding values for 1-butyltin. This also holds true for new compounds **6**, **7** and **10** (Table 5). As in **3**, compound **6** has $^{3}J_{^{13}C,^{119}Sn}$ lower than $^{2}J_{^{13}C,^{119}Sn}$ (i.e., opposite to the trend usually observed for 1-butylstannanes).[15] It has been suggested that this phenomenon is caused by the sum of two scalar coupling pathway contributions − through the covalent bonds of the 3-methoxypropyl chain and through the coordinative O→Sn bond − of opposite signs. In [D_6]-DMSO solutions of **3**, **4**, **6**, **7** and **10**, the $^{3}J_{^{13}C,^{119}Sn}$ coupling constants increase by between 53 and 150 Hz (Table 5). This considerable change can be ascribed to the cleavage of the oxastannacycle because of the equilibrium discussed above in which the donor oxygen atom of the 3-methoxypropyl substituent is replaced by the stronger Lewis base [D_6]DMSO. On the contrary, compounds **1**, **5**, **8** and **9**, where the 3-methoxypropyl ligand does not form a chelate and which do not change structures upon dissolution in [D_6]DMSO, have values of this parameter in [D_6]DMSO even slightly lower than in $CDCl_3$ (Table 5). Thus, $^{3}J_{^{13}C,^{119}Sn}$ coupling constants seem to be a useful indicator of the strength of the O→Sn donor–acceptor interaction in (3-methoxypropyl)stannanes.

Experimental Section

General: THF was distilled from sodium benzophenone ketyl. $CHCl_3$ was distilled from P_2O_5. Other solvents were used without purification. The solution of HCl in $CHCl_3$ was prepared by absorption of dry gaseous HCl which was obtained by dropwise addition of hydrochloric acid into concentrated sulfuric acid. Mg chips, 1,2-dibromomethane, chlorotriphenylstannane and sodium *N*,*N*-diethyldithiocarbamate trihydrate were obtained from commercial sources. Preparation of 1-chloro-3-methoxypropane, tetrakis(3-methoxypropyl)stannane (**1**), chlorotris(3-methoxypropyl)-stannane (**2**), dichlorobis(3-methoxypropyl)stannane (**3**) and trichloro(3-methoxypropyl)stannane (**4**) has been described elsewhere.[4]

Microanalyses (C, H, N, S, Cl) were carried out using a Fison EA 1108 instrument in the Microanalytical Laboratory at the University of Pardubice.

Synthesis of (3-Methoxypropyl)triphenylstannane RPh_3Sn (5): A solution of 1-chloro-3-methoxypropane (3.00 g, 27.63 mmol) in THF (6 mL) was added to Mg chips (0.83 g, 34.14 mmol) which were previously activated by I_2 vapours. About 20% of the solution was added at once and the reaction was started by addition of 2 drops of 1,2-dibromethane. The rest of the solution was added dropwise in order to maintain the reflux. Then, the reaction mixture was refluxed for a further hour. After cooling to –50 °C, a solution of chlorotriphenylstannane (7.18 g, 18.63 mmol) in THF (6 mL) was added dropwise and the reaction mixture was then refluxed for 8 h. After cooling to room temperature, the reaction mixture was filtered and water (40 mL) was added. The mixture was extracted with diethyl ether (3 × 20 mL). The organic part was separated, dried with anhydrous Na_2SO_4 and the solvents were removed by rotary evaporation. The residue was recrystallised from $CHCl_3$/hexane solution and **1** (6.56 g, yield 85%) was obtained as white crystals, m.p. 49–51 °C. ^{1}H NMR ($CDCl_3$, 25 °C): δ = 1.84 (m, 2 H, $SnCH_2CH_2$), 2.31 (m, 2 H, $SnCH_2CH_2$), 3.17 (s, 3 H, OCH_3), 3.38 (t, $^{3}J_{HH}$ = 6.5 Hz, 2 H, CH_2OCH_3), 7.37 (m, 9 H, *m*-Ph, *p*-Ph), 7.56 (m, 6 H, *o*-Ph) ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 7.32 ($SnCH_2$), 26.4 ($SnCH_2CH_2$), 58.1 (OCH_3), 75.0 (CH_2OCH_3), 128.3 (*m*-Ph), 128.6 (*p*-Ph), 136.9 (*o*-Ph), 139.2 (*i*-Ph) ppm. $C_{22}H_{24}OSn$ (423.14): calcd. C 62.45, H 5.72; found C 62.25, H 5.53.

Synthesis of Chloro(3-methoxypropyl)phenylstannanes $RPh_{3-x}SnCl_x$ 6 and 7: A solution of HCl in dry $CHCl_3$ [10 mL (0.169 M) for **6**; 19 mL (0.169 M) for **7**] was added to **1** (0.5 g, 1.20 mmol) and the mixture was stirred at room temperature for 2 d. The solvent was then removed by rotary evaporation. The residue was recrystallised from $CHCl_3$/hexane solution.

Chloro(3-methoxypropyl)diphenylstannane (6): Yield: 0.43 g (96%), white crystals, m.p. 93–95 °C. ^{1}H ($CDCl_3$, 25 °C): δ = 1.79 (m, 2 H, $SnCH_2$), 2.15 (m, 2 H, $SnCH_2CH_2$), 2.96 (s, 3 H, OCH_3), 3.53 (t, $^{3}J_{HH}$ = 6.0 Hz, 2 H, CH_2OCH_3), 7.41 (m, 2 H, *p*-Ph), 7.43 (m, 4 H, *m*-Ph), 7.71 (m, 4 H, *o*-Ph) ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 14.7 ($SnCH_2$), 25.3 ($SnCH_2CH_2$), 73.0 (CH_2OCH_3), 128.6 (*m*-Ph), 129.2 (*p*-Ph), 135.6 (*o*-Ph), 140.4 (*i*-Ph) ppm. $C_{16}H_{19}ClOSn$ (381.48): calcd. C 50.38, H 5.02, Cl 9.29; found C 49.95, H 4.89, Cl 9.01.

Dichloro(3-methoxypropyl)phenylstannane (7): Yield: 0.42 g (98%), white crystals, m.p. 99–101 °C. ^{1}H ($CDCl_3$, 25 °C): δ = 1.96 (m, 2 H, $SnCH_2$), 2.19 (m, 2 H, $SnCH_2CH_2$), 3.29 (s, 3 H, OCH_3), 3.61 (t, $^{3}J_{HH}$ = 5.4 Hz, 2 H, CH_2OCH_3), 7.45 (m, 1 H, *p*-Ph), 7.64 (m, 2 H, *m*-Ph), 7.80 (m, 2 H, *o*-Ph) ppm. ^{13}C NMR ($CDCl_3$, 25 °C): δ = 22.2 ($SnCH_2$), 24.9 ($SnCH_2CH_2$), 58.5 (OCH_3), 71.7 (CH_2OCH_3), 129.0 (*m*-Ph), 130.6 (*p*-Ph), 134.8 (*o*-Ph), 141.0 (*i*-Ph) ppm. $C_{10}H_{14}Cl_2OSn$ (339.83): calcd. C 35.35, H 4.15, Cl 20.87; found C 35.03, H 3.95, Cl 20.63.

Synthesis of (3-Methoxypropyl)stannyl *N*,*N*-Diethyldithiocarbamates $RSn(S_2CNEt_2)_{3-x}Cl_x$ (8–10): A mixture of **4** (0.5 g, 1.67 mmol) and sodium *N*,*N*-diethyldithiocarbamate [1.19 g (5.29 mmol) for **8**; 0.76 g (3.37 mmol) for **9**; 0.38 g (1.69 mmol) for **10**] in acetone (10 mL) was stirred at room temperature for 2 h. The reaction mixture was then filtered and the solvent was removed by rotary evaporation. The residue was recrystallised from $CHCl_3$/hexane solution.

(3-Methoxypropyl)stannyl Tris(*N*,*N*-diethyldithiocarbamate) (8): Yield: 0.86 g (80%), yellowish crystals, m.p. 92–93 °C (for further characterisation of **8** see ref.[8]).

Chloro(3-methoxypropyl)stannyl Bis(*N*,*N*-diethyldithiocarbamate) (9): Yield: 0.72 g (83%), yellowish crystals, m.p. 66–69 °C. ^{1}H (CDCl$_3$, 25 °C): δ = 1.28 (t, $^3J_{HH}$ = 6.9 Hz, 12 H, CH$_2$C*H*$_3$), 1.83–1.96 (m, 4 H, SnC*H*$_2$C*H*$_2$), 3.28 (s, 3 H, OC*H*$_3$), 3.38 (t, $^3J_{HH}$ = 5.8 Hz, 2 H, C*H*$_2$OCH$_3$), 3.69 (q, $^3J_{HH}$ = 6.9 Hz, 8 H, NC*H*$_2$) ppm. ^{13}C NMR (CDCl$_3$, 25 °C): δ = 11.7 (CH$_2$*C*H$_3$), 25.9 (SnCH$_2$*C*H$_2$), 42.4 (Sn*C*H$_2$), 50.7 (N*C*H$_2$), 58.1 (O*C*H$_3$), 73.8 (*C*H$_2$OCH$_3$), 196.8 (N*C*S$_2$) ppm. $C_{14}H_{29}ClN_2OS_4Sn$ (523.82): calcd. C 32.10, H 5.58, Cl 6.77, N 5.35, S 24.48 ; found C 31.93, H 5.35, Cl 6.43, N 5.03, S 24.35.

Dichloro(3-methoxypropyl)stannyl *N*,*N*-Diethyldithiocarbamate (10): Yield: 0.40 g (59%), white crystals, m.p. 135–136 °C. ^{1}H (CDCl$_3$, 25 °C): δ = 1.35 (t, $^3J_{HH}$ = 7.1 Hz, 6 H, CH$_2$C*H*$_3$), 1.77 (m, 2 H, SnC*H*$_2$), 2.19 (m, 2 H, SnCH$_2$C*H*$_2$), 3.67 (t, $^3J_{HH}$ = 6.0 Hz, 2 H, C*H*$_2$OCH$_3$), 3.72 (q, $^3J_{HH}$ = 7.1 Hz, 4 H, NC*H*$_2$), 3.74 (s, 3 H, OC*H*$_3$) ppm. ^{13}C NMR (CDCl$_3$, 25 °C): δ = 11.7 (CH$_2$*C*H$_3$), 24.1 (SnCH$_2$*C*H$_2$), 35.2 (Sn*C*H$_2$), 51.7 (N*C*H$_2$), 58.6 (O*C*H$_3$), 71.4 (*C*H$_2$OCH$_3$), 192.8 (N*C*S$_2$) ppm. $C_9H_{19}Cl_2NOS_2Sn$ (411.00): calcd. C 26.3, H 4.66, Cl 17.25, N 3.41, S 15.60; found C 26.11, H 4.53, Cl 17.19, N 3.32, S 15.52.

NMR Spectroscopy: ^{1}H, ^{13}C and ^{119}Sn NMR spectra were recorded in a 5-mm tuneable probe with a Bruker AMX 360 (^{1}H: 360.14 MHz; ^{13}C: 90.57 MHz; ^{119}Sn: 134.28 MHz) or a Bruker AVANCE 500 spectrometer (^{1}H: 500.13 MHz; ^{13}C: 125.77 MHz; ^{119}Sn: 186.48 MHz). ^{1}H and ^{13}C chemical shifts are given in ppm with respect to Me$_4$Si, and ^{119}Sn chemical shifts with respect to Me$_4$Sn. The gradient-assisted 1D ^{1}H,^{119}Sn HMQC and 2D ^{1}H,^{119}Sn J-HMBC spectra were recorded as explained elsewhere,[5] with the Bruker AVANCE 500 spectrometer. ^{13}C and ^{119}Sn CP/MAS NMR spectra were recorded with a Bruker AVANCE 500 spectrometer equipped with a double-bearing CP/MAS probe at room temperature. The ^{119}Sn chemical shifts were calibrated indirectly to tetracyclohexyltin (δ = –97.35 ppm) and were allocated approximately to the centre of gravity of the signals.

X-ray Crystallography: Single crystals were prepared by diffusion of hexane into CHCl$_3$ solutions of the complexes. The diffraction experiments were carried out using Mo-K_α radiation (λ = 0.71073 Å) on a Stoe IPDS (for **6** and **9**) or a Stoe STADI (for **7** and **10**) diffractometer. The structures were solved by direct methods (SHELXS-86)[16] and refined by full-matrix least-squares on F^2 (SHELXL-97)[17] with anisotropic displacement parameters for all non-H atoms. Hydrogen atoms were placed in calculated positions and refined according to the riding model (Table 6).

CCDC-238979 (for **10**), -238980 (for **7**), -238981 (for **9**) and -238982 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

Financial support from the Ministry of Education, Youth and Sports of the Czech Republic (project LN 00 A028) and the Grant Agency of the Czech Republic (grant 203/04/0223) is gratefully acknowledged. We are grateful to J. Brus from the Institute of Macromolecular Chemistry of the Academy of Sciences of the Czech Republic for measuring ^{13}C and ^{119}Sn CP/MAS NMR spectra. T. L. and P. Z. thank Aleš Smička, who suddenly and tragically died on June 19th 2001 in Pardubice, for starting their investigations on (3-methoxypropyl)stannanes, and Prof. Jaroslav Holeček for fruitful discussions about chemistry and life, and all that helped us to finish this paper.

The Additive Nature of Energy Penalties in 10-Vertex *nido*-(Car)boranes

Farooq A. Kiani[a,b] and Matthias Hofmann*[a]

Keywords: Boranes / Carboranes / Density functional theory / Energy penalties / Structural increment system

A structural increment system, i.e. quantitative rules that govern the relative stabilities of 10-vertex *nido*-boranes and -carboranes, has been determined. Density functional theory computations at the B3LYP/6-311+G(d,p)//B3LYP/6-31G(d) level with ZPE corrections were carried out for 81 different boron hydride and carborane structures from $[B_{10}H_{12}]^{2-}$ to $C_3B_7H_{11}$ to determine their relative stabilities. A set of eleven disfavored geometrical features that destabilize a cluster structure relative to a hypothetical ideal situation were identified and weighted by so-called energy penalties. The latter show good additive behavior and allow us to reproduce the DFT computed relative energies mostly with an accuracy of 6.0 kcal mol^{-1}. Some unknown 10-vertex *nido*-carboranes that are thermodynamically more stable than their known isomers are also identified.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Assuming a hypothetical, ideal cluster and additive destabilizations caused by deviating structural features, one can derive corresponding energy penalties that allow an easy estimation of the thermodynamic stabilities of cluster isomers. Such quantitative rules weighting different disfavored structural features of a particular heteroborane cluster have already been determined for 6-[1] and 11-vertex[2] *nido*-(car)boranes and 11-vertex *nido*-hetero(car)boranes.[3] These rules not only indicate the thermodynamically most stable isomer for a given formula,[2,3] but also describe the relative stabilities of different isomers quite accurately.[1–3] These systematic studies also identified some still unknown clusters of competitive thermodynamic stability which might be synthesized in the future.[2,3] Some structural features have similar energy penalties in 6- and 11-vertex *nido*-boranes, -carboranes, and even -heterocarboranes.

Here we extend the structural increment approach to the more complex 10-vertex *nido* cluster; 6- and 11-vertex *nido* clusters are quite simple as they have only one kind of cage (i.e., of the same connectivity, identified by k_c) and one kind of peripheral (k_p) vertex. A *nido* 6-vertex cluster has five $3k_p$ and one $5k_c$ vertices ($\Delta k = 2$), and an 11-vertex *nido* cluster has five $4k_p$ and six $5k_c$ vertices ($\Delta k = 1$). The situation is more complicated in the 10-vertex *nido* family, however, due to two different types of peripheral vertices, i.e. two $3k_p$ ($\Delta k = 2$) and four $4k_p$ ($\Delta k = 1$) next to the four $5k_c$ vertices (see Figure 1). These three different types of vertices make the 10-vertex *nido* cluster more complex and therefore some new and additional structural features need to be introduced. These features and their corresponding energy penalties have been derived and are discussed in this paper.

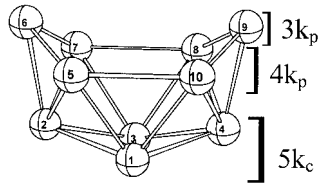

Figure 1. Cluster shape and numbering scheme for 10-vertex *nido*-boranes and -carboranes; 3*k*, 4*k*, and 5*k* indicate connectivities of peripheral (p) and cluster (c) vertices with respect to other cluster atoms.

Results and Discussion

Structural Features for 10-Vertex *nido*-Boranes and -Carboranes

Eleven energy increments corresponding to disfavoring structural features are sufficient to reproduce the relative stability order, as derived by DFT computations, for eighty-one 10-vertex *nido*-boranes and -carboranes ranging from $[B_{10}H_{12}]^{2-}$ to $C_3B_7H_{11}$. These energy penalties are listed in Table 1 and the corresponding structural features are illustrated in Figure 2.

The energy penalties can be divided into three main groups: *carbon structural features*, arising due to carbon-

[a] See ref.[1] [b] See ref.[2] [c] This work. [d] $C_{4k\rightarrow5k}$ is not an independent structural feature in the 10-vertex *nido* cluster, but results as the difference between $C_{3k\rightarrow4k}$ and $C_{3k\rightarrow5k}$.

atom positions, *hydrogen structural features*, arising due to hydrogen-atom placement, and *mixed structural features*, which involve both carbon and hydrogen atoms.

Carbon Structural Features

$C_{3k\rightarrow5k}$

A carbon atom at a 5*k* (vertices 1 through 4) rather than a 3*k* position (vertices 6 and 9) destabilizes a structure by 40.4 kcal mol^{-1}.

$C_{3k\rightarrow4k}$

A carbon atom has an energy penalty of 16.1 kcal mol^{-1} when it is at a 4*k* position (i.e. positions 5, 7, 8, or 10) rather than a 3*k* position.

CC and CC(3–5)

Two adjacent carbon atoms are unfavorable, but the amount of destabilization depends upon the carbon atoms' connectivities: for $\Delta k = 0$ and 1 the CC energy penalty is 14.1 kcal mol^{-1}, whereas for $\Delta k = 2$, (i.e., adjacent 3*k* and 5*k* C atoms), a considerably smaller CC(3–5) energy penalty of only 3.3 kcal mol^{-1} is found.

Hydrogen Structural Features

H(4–4)

A hydrogen atom bridging to two 4*k* vertices (rather than a 3*k* and a 4*k* boron vertex) results in an increased energy of the cluster by 12.7 kcal mol^{-1}.

BH_2

An *endo*-terminal hydrogen atom attached to a boron atom has an energy penalty of 5.0 kcal mol^{-1}.

HH

Adjacent hydrogen atoms are accompanied by an energy penalty of 2.9 kcal mol^{-1}.

Mixed Structural Features

CH_2

An *endo*-terminal hydrogen atom at a carbon atom results in an energy penalty of 32.6 kcal mol^{-1}. In all structures considered here, except **JR**, the CH_2 group is located at a 3*k* vertex.

CH–B

An *endo*-hydrogen atom bound to a carbon atom but bent towards a boron atom, i.e. bridging between a carbon atom and a boron atom, is disfavored by 32.1 kcal mol^{-1}.

3kC(H)

A 3*k* carbon atom in the presence of one or more bridging hydrogen atoms at the open face results in a 13.7 kcal mol^{-1} destabilization.

H(C)H

One or two carbon atoms entrapped between two hydrogen bridges through one connection only, incorporate a penalty of 8.7 kcal mol^{-1}.

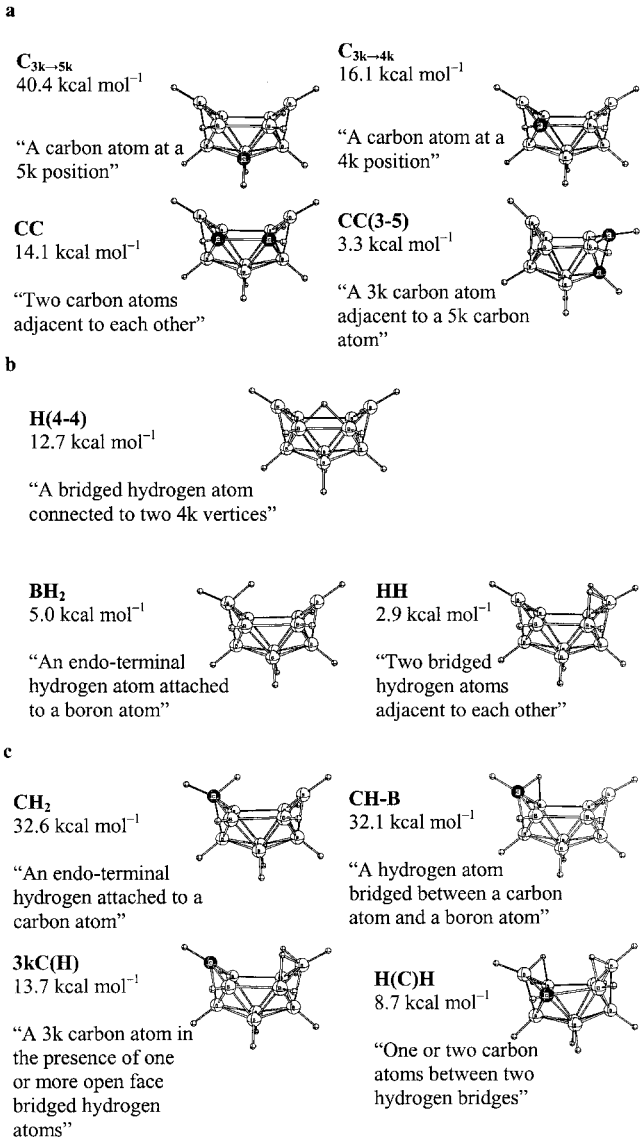

Figure 2. a) Carbon, b) hydrogen, and c) mixed structural features and their energy penalties.

A Comparison of Energy Penalties Between the 10-Vertex *nido* Cluster and the 6- and 11-Vertex *nido* Clusters

Some structural features in the 10-vertex *nido* cluster are also present in the 6- and/or 11-vertex *nido* clusters, i.e. HH, CC, BH_2, CH–B, and $C_{3k\rightarrow5k}$. All the features that were identified for all three cluster sizes are summarized in Table 1. Four comparable features are carbon structural features, one is a hydrogen structural feature, and two are mixed structural features. The remainder are entirely new and are described in the next section.

$C_{3k\rightarrow4k}$

Moving a carbon atom from a 3*k* vertex to a 4*k* vertex in the 10-vertex *nido* cluster requires 16.1 kcal mol^{-1}. This energy penalty is not observed in 6- or 11-vertex *nido* clusters because they lack 4*k* and 3*k* vertices, respectively.

$C_{3k\rightarrow5k}$

Moving a carbon atom from a 3*k* position to a 5*k* position involves an energy penalty of 40.4 kcal mol^{-1} in the 10-vertex *nido* cluster. The corresponding energy penalty in the 6-vertex *nido* cluster is 33 kcal mol^{-1}.

$C_{4k\rightarrow5k}$

This is not an independent structural feature of the 10-vertex *nido* cluster, but an energy penalty of 24.3 kcal mol^{-1} can be derived for it as the difference between $E_{inc}[C_{3k\rightarrow4k}]$ and $E_{inc}[C_{3k\rightarrow5k}]$. This value is quite close to the value of 28.0 kcal mol^{-1} for $C_{4k\rightarrow5k}$ in the 11-vertex *nido* cluster.[2]

CC

The CC energy penalty is essentially independent of the cluster size: values of 15, 14.1, and 16.0 kcal mol^{-1} apply for the 6-, 10-, and 11-vertex *nido* clusters, respectively.

HH

Two hydrogen bridges adjacent to each other, HH, have an energy penalty of 7 kcal mol^{-1} in the case of 6-vertex *nido*-boranes and -carboranes. This value is much larger (25.9 kcal mol^{-1}) in the case of 11-vertex *nido*-boranes and -carboranes. For the 10-vertex *nido* cluster, the energy penalty associated with HH is 2.9 kcal mol^{-1}. Hence, HH has very different energy penalties for the 6-, 10-, and 11-vertex *nido* clusters, although it should be kept in mind that the bridged hydrogen atoms have different connectivities in all these cases. In the case of 6-vertex *nido* clusters the bridged hydrogen atoms are connected to 3*k* peripheral vertices, whereas in the 11-vertex *nido* cluster the bridged hydrogen atoms are attached to all 4*k* peripheral vertices. In the case of a 10-vertex *nido* cluster, however, they are connected to a 3*k* vertex (6 or 9) on one side and to a 4*k* vertex on the other side.

CH–B

This has very similar energy penalties of 27, 32.1, and 33.1 kcal mol^{-1} in the 6-, 10-, and 11-vertex *nido* clusters, respectively.

CH_2

An *endo*-terminal hydrogen atom attached to a carbon atom in the 10-vertex *nido* cluster has an energy penalty of 32.6 kcal mol^{-1}, which is quite close to the CH_2 energy penalty of 30 kcal mol^{-1} and 33.2 kcal mol^{-1}for the 6-vertex and 11-vertex *nido* clusters, respectively. In the structure **JM**, there are two CH_2 moieties, each accompanied by one imaginary frequency.

In summary, carbon-related and mixed structural features are independent of cluster size.

New Structural Features for the 10-Vertex *nido* Cluster

There are four architectural features in the 10-vertex *nido*-boranes and -carboranes that are not present or not important in 6- and 11-vertex *nido*-boranes and -carbor-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

anes. These features are H(4–4), CC(3–5), 3*k*C(H), and H(C)H (see Figure 2). H(4–4) will be discussed later and H(C)H has already been discussed above. Here only CC(3–5) and 3*k*C(H) will be discussed.

CC(3–5)

When a 3*k* and a 5*k* carbon atom are adjacent to each other in the 10-vertex *nido* cluster, the energy penalty (3.3 kcal mol^{-1}) is only about one fourth of the CC value. This characteristic feature is accompanied by the distortion of the cluster structure in such a way that the 3*k* carbon atom lies almost in the plane of the 4*k* vertices [5,7,8,10, see Figure 2a, CC(3–5)]. This distortion counteracts the destabilization of the CC relationship and results in a diminished E_{inc}[CC(3–5)]. For the 6-vertex *nido* cluster a 3*k*–5*k* CC behaves the same way as a 3*k*–3*k* CC, but CC(3–3) is not possible in the 10-vertex cluster. Similarly, in the case of the 11-vertex *nido* cluster the energy penalty for a 4*k*–4*k* CC is the same as for 4*k*–5*k* CC or 5*k*–5*k* CC. In the 10-vertex *nido* cluster, CC(3–5) leads to significantly less destabilization as compared to more homogeneous CC relationships (3*k*–4*k*, 4*k*–4*k*, 4*k*–5*k*).

3kC(H)

A carbon atom at a 3*k* vertex in the presence of one or more open-face hydrogen bridges results in a thermodynamic stability reduction of 13.7 kcal mol^{-1}. This feature is not observed in $[C_2B_8H_{10}]^{2-}$, where there are no open-face hydrogen bridges, although it is present in 6,9-$C_2B_8H_{12}$ (Figure 3, **JS**). When there is an *endo*-terminal hydrogen atom at a 3*k* carbon atom (CH_2), or a bridged hydrogen atom between a carbon atom and a boron atom (CH–B), the 3*k*C(H) feature is not possible and no extra energy penalty is counted.

Hydrogen Placement Patterns

Hydrogen Bridges Occupy the Positions of Least Connectivity

In the 6- and 11-vertex clusters, there is only one kind of peripheral vertex each, and consequently all open-face edges are equally suited for hydrogen bridges. However, the open-face edges available for hydrogen bridges are not equivalent in the 10-vertex *nido* cluster due to different peripheral vertices. In all thermodynamically most stable isomers, the hydrogen bridges are located at 3*k*–4*k* edges. A hydrogen bridge between two 4*k* vertices, H(4–4), is 12.7 kcal mol^{-1} less stable [see Figure 2b, H(4–4)].

Hydrogen Placement Patterns are Primary to Carbon Placement Patterns

Williams' qualitative carbon placement rules[4,5] are quantitatively covered by $C_{3k\rightarrow4k}$, $C_{3k\rightarrow5k}$ and CC (see above). In the presence of extra hydrogen atoms, however, some more rules are needed. Figure 3 shows the 6,9- and 5,7-isomers of $C_2B_8H_{12}$[6,7] and their dianions.[8,9] A comparison of $[C_2B_8H_{10}]^{2-}$ and $C_2B_8H_{12}$ isomers demonstrates that carbon atoms occupy the least coordinated positions only when extra hydrogen atoms are absent. For example, *nido*-$[C_2B_8H_{10}]^{2-}$ (**HA**), without any *endo*-hydrogen atom, is the most stable $[C_2B_8H_{10}]^{2-}$ isomer as carbon atoms favor the positions of least connectivity. The doubly protonated *nido*-6,9-$C_2B_8H_{12}$ (**JS**), with bridging hydrogen atoms at positions 5/10 and 7/8, accumulates three structural features [H(4–4), 3kC(H), and H(C)H, each present twice], corresponding to a total energy penalty of 70.2 kcal mol^{-1}. This is 35.1 kcal mol^{-1} more than that of the most stable 5,7-$C_2B_8H_{12}$ (**JA**), where the carbon atoms are at positions of higher connectivity, i.e. $C_{3k\rightarrow4k}$ and HH are present. The computed energy difference is 44.5 kcal mol^{-1}.

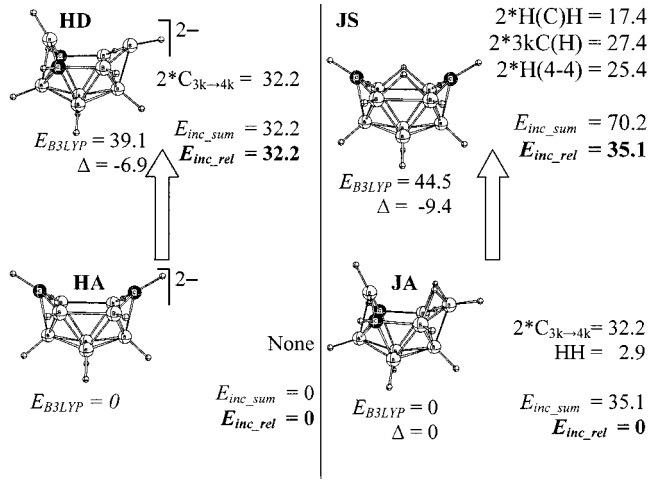

Figure 3. 6,9- and 5,7-isomers of $[C_2B_8H_{10}]^{2-}$ and $C_2B_8H_{12}$.

Comparisons of Relative Stabilities from Empirical Energy Penalties (E_{inc_rel}) and from DFT-Calculated Values (E_{B3LYP}) for 10-Vertex *nido*-Boranes and -Carboranes

Initially, energy penalties for those structural features that were already found to be important for 6- and 11-vertex *nido*-boranes and -carboranes[1,2] were considered. 10-Vertex *nido*-boranes and -carboranes were found to have some features common with their 6- and 11-vertex counterparts, but some additional features are needed. The final set of structural features is shown in Figure 2 and listed in Tables 2–6 (see below). A total of eighty-one 10-vertex *nido*-borane and -carborane isomers from $[B_{10}H_{12}]^{2-}$ to $C_3B_7H_{11}$ were computed, ten of which are known experimentally. The sum of energy penalties for all structural features gives E_{inc_sum} for each structure, which relative to the most stable isomer (isomer with least E_{inc_sum}) gives E_{inc_rel}. Computed relative energies are listed as E_{B3LYP}. The difference between E_{inc_rel} and E_{B3LYP} (E_{diff}) is equal to, or larger than, 6 kcal mol^{-1} in only six cases. The largest deviation (Δ = –9.4 kcal mol^{-1}) is found for **JS** (6,9-$C_2B_8H_{12}$). Three $C_4B_6H_{10}$ isomers were computed but four carbon atoms in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the 10-vertex *nido* cluster behave far less additively and cause large deviations (see Table 6 below). Tetracarboranes seem to have considerable hydrocarbon character. In the case of 6-vertex and 11-vertex *nido* clusters, the largest deviations are also observed for tetracarboranes. Our 10-vertex *nido*-(car)boranes study concentrates on mono- to tricarboranes.

nido-$[B_{10}H_{10+x}]^{(4-x)-}$ (x = 2–4) Isomers

Three structures have already been computed for *nido*-$[B_{10}H_{12}]^{2-}$ and the correct solution structure was reported to have μ-H: 5/6, 8/9 (**AA**, Figure 4).[10] Our increment system also predicts **AA** to be the most stable due to the absence of any structural feature (Table 2). Structure **AB** is slightly higher in energy than **AA** due to the structural feature HH. **AC**, with one imaginary frequency, has the structural feature H(4–4) twice due to two hydrogen atoms bridging two 4*k* vertices.

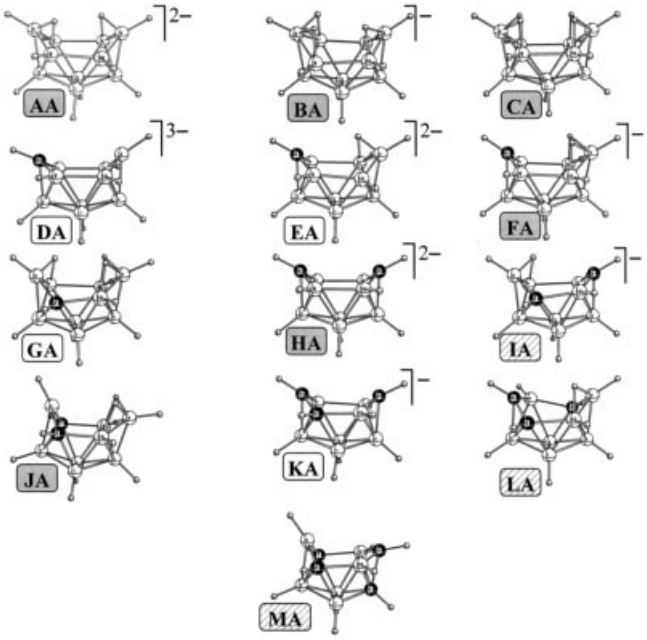

Figure 4. Most-stable isomers from *nido*-$[B_{10}H_{12}]^{2-}$ to -$C_4B_6H_{10}$. Known isomers are labeled with gray boxes. Those filled diagonally with grey lines are strong candidates for synthesis.

$B_{10}H_{14}$ (**CA**) can be easily deprotonated to give $[B_{10}H_{13}]^-$.[11] **BA**, (Figure 4) with bridging hydrogen atoms at the 5/6, 6/7, and 8/9 positions,[12] is the most stable $[B_{10}H_{13}]^-$ structure,[10] with only one structural feature, i.e. HH, as two hydrogen bridges at the 5/6 and 6/7 positions are adjacent to each other (Table 2). Hydrogen bridges at the 5/10, 6/7, and 8/9 positions (**BB**) involve one structural feature H(4–4). **BC** with one *endo*-H (structural feature BH_2) at position number 5 (a 4*k* vertex) is the transition state for a facile hydrogen rearrangement from the structure with bridging hydrogen atoms in the 5/6, 6/7, and 8/9 positions (**BA**) to the structure with bridging hydrogen atoms in the 6/7, 8/9, and 5/10 bridging positions (**BB**). **BD**, with BH_2 and HH, is the least favorable of the four isomers considered here. Two $B_{10}H_{14}$ structures were computed and the experimentally found structure[13] with four hydrogen atoms bridging to B5/6, B6/7, B8/9, and B9/10 positions (**CA**) was found to be computationally more stable than the structure with bridging hydrogen atoms at the 7/8 and 5/10 positions and an *endo*-H at 6,9 (**CB**, which corresponds to the prototypical 10-vertex *arachno* structure) by 38.1 kcal mol^{-1}. **CA** has the structural feature HH twice, but **CB** has the structural features $2BH_2$ + 2H(4–4), with an E_{inc_rel} of 29.6 kcal mol^{-1} with respect to **CA**. The difference between the computed and incremented relative energies (E_{diff}) is 8.5 kcal mol^{-1}.

nido-$[CB_9H_{10+x}]^{(3-x)-}$ (x = 0–3) Isomers

nido-6-$[CB_9H_{10}]^{3-}$ (**DA**, Figure 4) is the most stable $[CB_9H_{10}]^{3-}$ isomer, with the carbon atom at a 3*k* position (Table 3). *nido*-5-$[CB_9H_{10}]^{3-}$ (**DB**), with the $C_{3k\rightarrow4k}$ structural feature [$E_{inc}(C_{3k\rightarrow4k})$ = 16.1 kcal mol^{-1}], is thermodynamically 17.1 kcal mol^{-1} less stable than **DA**. The carbon atom is at a 5*k* position (structural feature $C_{3k\rightarrow5k}$) in *nido*-2-$[CB_9H_{10}]^{3-}$ (**DC**) and *nido*-1-$[CB_9H_{10}]^{3-}$ (**DD**), although **DC** is slightly more favorable. A "fine tuning increment" may be applied to differentiate between a 5*k* carbon atom at positions 1,3 (less favorable) and a 5*k* carbon atom at positions 2,4. A similar effect was also reported for the 11-vertex *nido* cluster where all vertices next to the apex (vertex number 1) are 5*k* but two vertices next to positions 2–6 are 4*k* and hence the apical position is slightly less favorable than positions 2–6.[2,3]

[a] E_{diff} is the difference between E_{inc_rel} and E_{B3LYP} [b] **FA** is an experimentally known structure. [c] **GB** has one imaginary frequency.

The most stable *nido*-6-$[CB_9H_{11}]^{2-}$ structure (**EA**, Figure 4) has one structural feature, i.e. 3*k*C(H), as a 3*k* carbon atom and a bridged hydrogen atom are present. *nido*-5-$[CB_9H_{11}]^{2-}$ (**EB**) has an *endo* hydrogen atom (structural feature BH_2) in addition to $C_{3k\rightarrow4k}$. **EC** differs with respect to the most stable isomer **EA** only in the positions of the hydrogen atom on the open face (the *endo*-terminal hydrogen atom on the carbon atom results in the high-energy structural feature CH_2 in **EC**). *nido*-1-$[CB_9H_{11}]^{2-}$ (**ED**) is highly unstable due to the presence of a carbon atom at a 5*k* position ($C_{3k\rightarrow5k}$).

Experimentally known[14] *nido*-6-$[CB_9H_{12}]^-$ (**FA**, Figure 4) has two structural features, HH and 3*k*C(H), each once. Both **FB** and **FC** have the carbon atom at vertex number 5 ($C_{3k\rightarrow4k}$), but different hydrogen positions result in one HH (two adjacent hydrogen bridges) in the former and H(C)H (a carbon atom between two hydrogen bridges) in the latter. The energy penalty for H(C)H is larger than that for HH, and therefore **FC** is suggested to be more favorable than **FB**, both computationally as well as by the increment system. The basic skeleton of *nido*-6-$[CB_9H_{12}]^-$ (**FD**) is identical to that of the most stable **FA** except that hydrogen atoms are bridging positions 5/6 and 8/9 in the latter but 8/9 and 9/10 in the former. The special hydrogen position in **FD** (a hydrogen atom is bridging a carbon atom and a boron atom) gives rise to the structural feature CH–B, with E_{inc}(CH–B) = 32.1 kcal mol^{-1}, and is responsible for the high relative energy of the cluster even though the carbon atom is situated at a least connected vertex. Each of the *nido*-2-$[CB_9H_{12}]^-$ (**FE**) and *nido*-1-$[CB_9H_{12}]^-$ (**FF**) clusters possess the structural features HH and $C_{3k\rightarrow5k}$, but the carbon atom at position 1 in **FF** is slightly more disfavoring.

The experimentally unknown *nido*-5-CB_9H_{13} (**GA**, Figure 4) is the most favorable CB_9H_{13} structure. The structural features, corresponding energy penalties, and relative stabilities of the five computed CB_9H_{13} isomers are listed in Table 3.

The relative stabilities of the 6- and 5-isomers of *nido*-$[CB_9H_{10+x}]^{3-x}$ (x = 0–3) are as follows: *nido*-6-$[CB_9H_{10}]^{3-}$ (**DA**) is 17.1 kcal mol^{-1} more stable than *nido*-5-$[CB_9H_{10}]^{3-}$ (**DB**), and *nido*-6-$[CB_9H_{11}]^{2-}$ (**EA**) and *nido*-6-$[CB_9H_{12}]^-$ (**FA**) are 8.6 and 6.6 kcal mol^{-1} more stable than their 5-isomers (**EB** and **FB**, respectively). However, in the case of the neutral clusters, 6-CB_9H_{13} (**GB**) is 11.2 kcal mol^{-1} less stable than *nido*-5-CB_9H_{13} (**GA**). An increased hydrogen content on the open face results in highly connected carbon atoms in the most stable isomer, as is observed in the case of 11-vertex *nido*-$CB_{10}H_{14}$.[2] This can be well explained in terms of the structural features. E_{inc_sum} for the different structural features of **DB**, **EB**, and **FB** is less than that of **DA**, **EA**, and **FA**; however, E_{inc_sum} favors 5-CB_9H_{13} (**GA**; E_{inc_sum} = 27.8 kcal mol^{-1}) rather than 6-CB_9H_{13} (**GB**; E_{inc_sum} = 35.6 kcal mol^{-1}) mainly due to the high-energy structural feature (CH_2) in the latter. No *nido*-CB_9H_{13} isomer is experimentally known. However, the computed (HF/6-31G*) geometry for *nido*-6-CB_9H_{13} (**GB**) has been reported.[15]

nido-$[C_2B_8H_{10+x}]^{(2-x)-}$ (x = 0–2)

Two structures, i.e. the most stable *nido*-6,9-$[C_2B_8H_{10}]^{2-}$ (**HA**, Figure 4),[8] and *nido*-5,7-$[C_2B_8H_{10}]^{2-}$ (**HD**),[9] are experimentally known. Three structural features, i.e. $C_{3k\rightarrow4k}$, $C_{3k\rightarrow5k}$, and CC reproduce the relative stability of any possible $C_2B_8H_{10}^{2-}$ isomer (see Table 4) as there are no hydrogen atoms. *nido*-6,9-$[C_2B_8H_{10}]^{2-}$ (**HA**) has no structural features as the carbon atoms are at the nonadjacent least-connected vertices. Addition of one bridging hydrogen atom to **HA** makes the situation highly unfavorable in *nido*-6,9-$[C_2B_8H_{11}]^-$ (**IC**) due to one H(4–4) and two 3*k*C(H) structural features. One carbon atom is located at a 4*k* vertex in the most stable *nido*-5,9-$[C_2B_8H_{11}]^-$ (**IA**, Figure 4), for which the sum of the energy penalties is less than that of **IC**. Experimentally known *nido*-5,6-$[C_2B_8H_{11}]^-$ (**ID**)[16] is higher in energy than its three unknown isomers *nido*-5,9-$[C_2B_8H_{11}]^-$ (**IA**), *nido*-5,7-$[C_2B_8H_{11}]^-$ (**IB**), and *nido*-6,9-$[C_2B_8H_{11}]^-$ (**IC**). *nido*-2,6-$[C_2B_8H_{11}]^-$ (**IE**), which contains the structural feature CC(3–5) as well as $C_{3k\rightarrow5k}$ and 3*k*C(H), is the highest-energy structure.

nido-5,7-$C_2B_8H_{12}$ (**JA**, Figures 3 and 4)[6] is the most stable neutral dicarba isomer (Table 5). *nido*-5,6-$C_2B_8H_{12}$

[a] E_{diff} is the difference between E_{inc_rel} and E_{B3LYP}. [b] Experimentally known isomer. [c] Strong candidate for synthesis. [d] **JM** has two imaginary frequencies.

(**JD**) and *nido*-5,7-$C_2B_8H_{12}$ (**JA**) represented the first case of skeletal isomers in *nido*-carboranes.[7] A large number of $C_2B_8H_{12}$ isomers (Table 5) was computed in order to obtain a reliable structural increment system for 10-vertex *nido*-carboranes. Calculated (HF/6-31G*) geometries for *nido*-6,9-$C_2B_8H_{12}$ (**JM**) and *nido*-6,9-$C_2B_8H_{12}$ (**JS**) have been reported before.[15]

nido-$[C_3B_7H_{10}]^-$ and -$C_3B_7H_{11}$

Three $[C_3B_7H_{10}]^-$ isomers have been computed, of which 5,6,9-$[C_3B_7H_{10}]^-$ (**KA**, Figure 4) is the most stable structure. Two *nido*-$C_3B_7H_{11}$ isomers are known: *nido*-5,6,9-$C_3B_7H_{11}$ (**LA**, Figure 4)[17] and *nido*-5,6,10-$C_3B_7H_{11}$ (**LD**), with a bridging hydrogen atom at the 7/8 position.[18] The increment system quite successfully reproduces the relative stability order of *nido*-$[C_3B_7H_{10}]^-$ and -$C_3B_7H_{11}$ structures (Table 6).

nido-$C_4B_6H_{10}$

The only known $C_4B_6H_{10}$ isomer is 5,6,8,9-$C_4B_6H_{10}$ (**MB**) reported by Stibr et al.,[19] but the 4,5,7,9-isomer (**MA**, Figure 4) is computed to be slightly preferred energetically (by 2.5 kcal mol^{-1}). For tetracarbaboranes from **MA** to **MG** (Table 6), deviations between the E_{B3LYP} and E_{inc_rel} are large when only the increments discussed above are applied. In the case of $C_4B_6H_{10}$, the four carbon atoms in a cluster result in a change of the behavior of carboranes, due to considerable hydrocarbon character. Hence, the additivity required by the increment system to be useful is not followed strictly and deviations of between 10.3 and

[a] E_{diff} is the difference between E_{inc_rel} and E_{B3LYP}. [b] Experimentally known isomer. [c] Strong candidate for synthesis.

25.1 kcal mol^{-1} are observed. However, applying an extra increment [$(CC)_2$ = 18.1 kcal mol^{-1}] for the adjacent carbon atoms in the cluster twice lowers the energy differences considerably (Table 6), and only **MD** remains with a large deviation. Larger deviations of tetracarbaboranes are also observed in 6- and 11-vertex *nido* clusters.

Conclusions

An increment system has been established for 10-vertex *nido*-boranes and -carboranes. Eleven architectural features have been identified (eight of major importance, with $E_{inc} > 5$ kcal mol^{-1}, and three of minor importance). The corresponding energy penalties have allowed us to accurately estimate the relative stabilities of 81, and probably more, 10-vertex *nido* isomers from $[B_{10}H_{12}]^{2-}$ to $C_3B_7H_{11}$. Applying our increment system, ten carboranes have been identified that are not yet known experimentally but are thermodynamically more stable than known isomers and hence should be synthesizable.

The relative energies of 10-vertex *nido*-carboranes can be accurately predicted from $[B_{10}H_{12}]^{2-}$ to $C_3B_7H_{11}$ using the increment approach (Figure 5). In all the above examples, there are six cases where the difference between the estimated relative energy based on increments (E_{inc_rel}) and computed relative energy (E_{B3LYP}) is equal to, or more than, 6 kcal mol^{-1}. The difference between the E_{inc_rel} and E_{B3LYP} is less than 2 kcal mol^{-1} in 31 cases. The largest deviation, namely 9.4 kcal mol^{-1}, is found for 6,9-$C_2B_8H_{12}$ (**JS**). The stability order is mostly the same according to the B3LYP-computed results and to the increment approach. However, it is slightly different in many $C_2B_8H_{12}$ cases where the energetic separations of the many isomers considered is very small (see Table 5). The energy penalties for three features – CC, CH–B, and CH_2 – are very similar to those derived for the 6- and 11-vertex *nido*-(car)boranes. A fourth feature, $C_{4k\rightarrow5k}$, also has an energy penalty quite similar to the 11-vertex *nido*-(car)borane value. This increment system is not limited to the representative 81 isomers it was derived from, but can be applied to many 10-vertex *nido*-carborane structures. A similar kind of increment system might be derivable for 10-vertex *nido*-heterocarboranes.

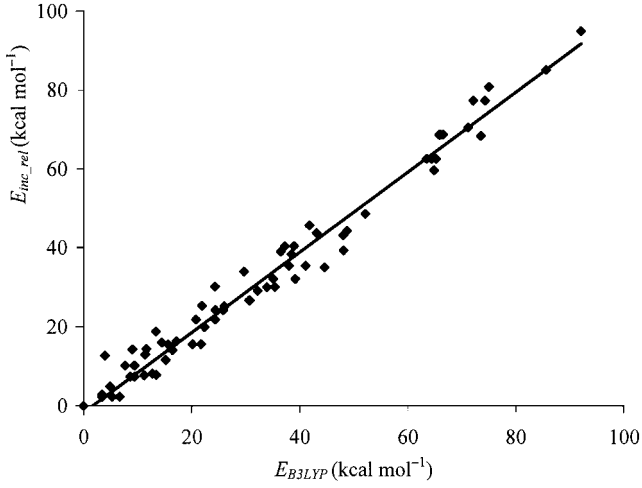

Figure 5. Structural increments accurately reproduce the relative stabilities of 10-vertex *nido*-(car)boranes computed by DFT methods.

Computational Details

Density functional theory was employed for successive optimization of all geometries at the B3LYP/3-21G and B3LYP/6-31G(d) levels, respectively, using the Gaussian 98 program.[20] Symmetry restrictions for different geometries, where applied, are given in Tables 2–6. All the structures, except five (**AC**, **BC**, **BD**, **GB** and **JM**, Tables 2, 3, and 5), presented in this paper are local minima at the B3LYP/6-31G(d) level as determined by frequency calculations. Single-point energies computed at the B3LYP/6-311+G(d,p) level, together with zero-point corrections at the B3LYP/6-31G(d) level, were used to derive relative energies for all the isomers. These computed relative energies are to be reproduced by a structural increment system. Certain geometrical features were identified and assigned reasonable preliminary energy penalties by comparison with suitable isomeric clusters. The values were refined through a statistical fitting procedure in order to obtain the final increment system. The Cartesian coordinates of structures fully optimized at the RB3LYP/6-31G(d) level and corresponding absolute energies

COVER PICTURE

The cover picture shows the proposed mechanism of the Co(salen)-catalyzed oxidation of a lignin model compound in water, as elucidated by several in-situ spectroscopic techniques. Catalytic oxygen activation can help to prevent the formation of hazardous side products in organic oxidations, especially if harmless solvents are used. The target in this work is lignin, which is found in wood and must be removed as selectively as possible before paper production. In view of avoiding chlorine as the oxidant, the idea is to catalytically enhance the oxygen delignification stage in the pulp bleaching sequence. Details are discussed in the article by T. Repo, B. M. Weckhuysen et al. on p. 2591ff.

Ionic Liquids with Fluorine-Containing Cations

Hong Xue[a] and Jean'ne M. Shreeve*[a]

Keywords: Ionic liquids / Fluorine / Cations / Quaternization

Interest in ionic liquids with fluorine-containing cations has grown markedly in recent years. The syntheses, characterization and properties of quaternary fluoroalkyl-substituted ammonium, imidazolium, triazolium, pyridinium, pyrazinium, pyridazinium, pyrimidinium, piperazinium, pyrrolidinium, oxazolidinium, and morpholinium salts have been studied in detail. By modifying the anion or the fluorine-containing substituent on the cation, a wide range of properties of fluorine-containing ionic liquids can be tuned, including viscosity, melting point, density, conductivity, solubility, liquid range, thermal and hydrolytic stability. They are promising solvents for electrochemical, photovoltaic, surfactant and synthetic applications. In this Microreview, only the literature dealing with ionic liquids that involve fluorine-containing cations is presented.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

1. Introduction

Ionic liquids are salts with low melting points (< 100 °C). Since ionic liquids exhibit extremely low vapor pressures, long liquid ranges, and are highly polar yet noncoordinating, they are good solvents for a wide range of organic and inorganic materials. These interesting compounds are achieved either by incorporating a bulky asymmetric cation into the structure in order to preclude good crystal packing and/or by selecting an anion in which there is considerable delocalization of the electron cloud over the molecular backbone that tends to decrease interionic interaction, e.g., bis(trifluoromethylsulfonyl)-amide or polyfluoro-β-diketonate. Results described in current publications indicate that replacing an organic solvent by an ionic liquid may lead to remarkable improvement in well-known processes. A number of reviews that cover the history, properties, and uses of ionic liquids are available.[1–9] These amazing liquids have been utilized not only as clean solvents, but also as catalysts for green chemistry and electrolytes for batteries, photochemistry, and electrosynthesis, and even as advanced heat transfer fluids and lubricants. Many of these types of ionic liquids are available commercially,[10] see, for example, Acros, Aldrich, Cytec, Strem and Merck.

Hong Xue was born in 1969 in Changchun, China, and received his Ph. D. in polymer chemistry from Dalian University of Technology (China) in 1999. He held a postdoctoral position for two years at Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, and worked on living polymerization and chiral polymer materials. In 2002, he joined the group of Professor Jean'ne M. Shreeve as a postdoctoral fellow. His current research focuses on the syntheses and application of organofluorine compounds, ionic liquids and energetic materials.

Jean'ne M. Shreeve is a Montana native. She received a BA in chemistry from the University of Montana, MS in analytical chemistry from the University of Minnesota, and Ph. D. in inorganic chemistry from the University of Washington, Seattle. She joined the University of Idaho faculty in 1961, became department head in 1973, and, in 1987, assumed the role of Vice-President for Research and Graduate Studies. In January 2000, she returned to full time research. She was privileged to have worked with three of the finest gentlemen of fluorine chemistry – Professors George H. Cady, Harry J. Emeléus, and Oskar Glemser. Her research interests include the syntheses, characterization and reactions of new fluorine-containing compounds as exemplified by more than 370 refereed publications. In July 2004, she became Jean'ne M. Shreeve Chemistry Professor.

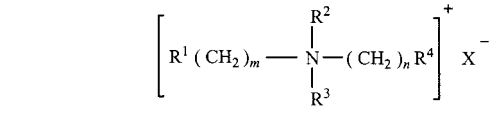
MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Earlier generations of ionic liquids were extremely water-sensitive – most often due to the presence of polychlorometallates as the anions. However, recently developed ionic liquids without halometallates, are water- and air-insensitive and possess remarkably high thermal stability. Typically, they are composed of bulky 1,3-dialkylimidazolium, alkylammonium, alkylphosphonium, or alkylpyridinium organic cations and inorganic/organic anions, such as NO_3^-, ClO_4^-, $CF_3SO_3^-$, PF_6^-, BF_4^-, $(CF_3SO_2)_2N^-$, $CF_3CO_2^-$.[1–9] Until now, the ionic liquid field has been extensively dominated by imidazolium salts with anions most frequently being fluorine-containing. Somenew fluoroanions, such as fluorohydrogenates,[11] tetrakis{*p*-[dimethyl(1*H*,1*H*,2*H*,2*H*-perfluorooctyl)silyl]-phenyl}borate,[12] perfluoroalkyl-β-diketonates,[13] tris(perfluoroalkyl) trifluorophosphates,[14] and perfluoroalkyl trifluoroborates,[15] have been reported as useful in the synthesis of new low melting salts.

Following the syntheses of the first fluorine-containing ionic liquids, 3-methyl-1-(2,2,2-trifluoroethyl)imidazolium salts, which were characterized as hydrophobic, highly conductive ambient-temperature molten materials,[16] the interest in ionic liquids with fluoroalkyl-substituted cations has grown markedly.[17–36] By modifying the anion or the fluorine-containing substituent on the cation, a wide range of properties of fluorine-containing ionic liquids can be tuned, including, for example, viscosity, melting point, density, conductivity, solubility, liquid range, thermal and hydrolytic stability, and heat of formation. The influence of inter-ion hydrogen bonding can be diminished by introducing fluorine-containing groups into the cation and especially when employing anions such as bis(trifluorosulfonyl)amide and perfluoroalkyldiketonate.[13,37] Excellent reviews of room-temperature ionic liquids with alkylimidazolium cations and fluoroanions are available.[38,39] A U.S. patent issued in 1998 claims a vast number of "hydrophobic ionic liquids," many of which have fluorine-containing cations.[22] In summarizing the inventions described in the patent, the authors conclude that when the cation and/or the anion is fluorinated, the hydrophobic ionic liquids of the invention have certain additional special properties, including 1) inertness to organic solvents and oxidizing agents; 2) resistance to corrosive acids and bases; and 3) resistance to extremes of temperature and pressure. The applications for the perfluorinated hydrophobic ionic liquids claimed in the patent encompass superior hydraulic, inert liquid diluents for highly reactive chemicals and solvents with a high capacity for dissolved gases such as oxygen, and useful for catalysis and for oil and gas separations where the desired product is partitioned between an aqueous and hydrophobic perfluorinated ionic liquid phase. These applications are, of course, in addition to all of those suggested for conventional ionic liquids. These points provide the raison d'être for further syntheses, characterization and study of new ionic liquids that contain the element fluorine. In this paper, only the literature dealing with ionic liquids that involve fluorine-containing cations is reviewed.

2. Syntheses and Properties of Quaternary (Fluoroalkyl)ammonium Salts

Since the report of a liquid ammonium salt, $EtNH_3^+NO_3^-$, early in the last century,[40] many additional quaternary ammonium salts have been synthesized and studied. Typically, introduction of greater asymmetry into the ionic species by decreasing the symmetry of the cation results in lowering of the melting point.[41] Until very recently only a very few (fluoroalkyl)ammonium salts, such as $(CH_3)_3(CH_2F)N^+X^-$ (X = Br, I), had been reported.[42] Selected quaternary ammonium salts containing polyfluoroalkyl groups (Figure 1), such as dimethylbis-(4,4,5,5,6,6,7,7,7-nonafluoroheptyl)ammonium chloride (m.p. 70–72 °C), were claimed in a patent.[43] However, the characterization was limited.



R^1, R^4 = fluoroalkyl; R^2 = alkyl; R^3 = alkyl or $R^1(CH_2)_m$-; X = anion

Figure 1. Quaternary ammonium salts containing polyfluoroalkyl groups.

Now a series of water- and thermally stable low-melting salts based on quaternary trialkyl(polyfluoroalkyl)ammonium cations has been synthesized and characterized. Metathetical reactions of the iodide salts with fluorine-containing anions resulted in new liquid salts (Scheme 1). The marked variations in melting points appear to be a function of the anion primarily and is essentially independent of the substituents on the cation. In this series, iodide salts of the triisooctyl(polyfluoroalkyl)amines are also liquids at 25 °C.[18] In some cases, the viscosities of these salts are remarkably low. Another novel iodide, diallyl(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)(methyl)ammonium iodide (m.p. 65–68 °C) has been described as an effective antimicrobial agent.[19]

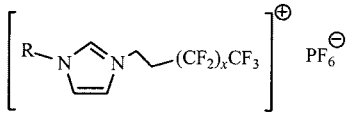
3. Syntheses and Properties of Quaternary Fluoroalkyl-Substituted Imidazolium Salts

An ionic liquid in which the cation is a polyfluoroalkyl-substituted imidazolium species derived from the antifungal drug miconazole becomes a soft yellow wax over a period of hours but is readily reliquified by heating to 92–96 °C (Scheme 2[20] It is stable in air to ≥ 150 °C. It also exhibits lyotropic liquid-crystalline behavior while inducing the gelation of benzene. 1-Alkyl-3-(polyfluoroalkyl)imidazolium hexafluorophosphates were employed as surfactants to promote the formation and stabilization of dispersions of perfluorocarbons in a conventional ionic liquid, such as 1-hexyl-3-methylimidazolium hexafluorophosphate [(6-mim)-PF_6] (Figure 2).[21]



R = Me, *n*Bu; *x* = 5, 7

Figure 2. 1-Alkyl-3-(polyfluoroalkyl)imidazolium hexafluorophosphates.

The presence of fluorine markedly increases the density of fluoroalkyl-substituted imidazolium ionic liquids and, in some cases, may cause increases in the melting points even in the presence of a constant anion (Scheme 3).[23] Some of the bis(polyfluoroalkyl)imidazolium salts are liquids with higher densities, e. g., the density of *N*,*N*′-bis(3,3,3-trifluoropropyl)imidazolium bis(trifluoromethylsulfonyl)amide (m.p. –62 °C) is 1.85 g cm^{-3}.

Among several highly halogenated, low-melting imidazolium salts which exhibit densities ranging from 1.95 to 2.80 g cm^{-3} are two highly brominated (polyfluoroalkyl)-imidazolium bis(trifluoromethylsulfonyl)amides with densities of 2.11 and 2.35 g cm^{-3} (Scheme 4). These dense, viscous liquids are thermally and hydrolytically remarkably stable.[24]

Quaternization of 1-(tetrafluoroethyl)imidazole with electrophiles such as RI (R = Me, Et, *n*Pr, *i*Pr, *n*Bu) followed by metathesis with $LiNTf_2$ or $AgBF_4$ gives rise to the first examples of ionic liquids with substituents at the nitrogen atom bonded through –CF_2–, i.e., CF_2CF_2H.[25]

Bis[(4,4,4-trifluorobutyl)imidazolium] quaternary salts based on *p*-*tert*-butylcalix[4]arenes have melting points >100 °C.[26]

A number of structurally different trimethylsilylated and tris[(oxyethyl)imidazolium] and tris[(oxyethyl)ammonium] ionic liquids built on the triazine ring, including polyfluorinated ones, were prepared and characterized (Scheme 5).[27] The physical and thermal properties were studied in this work, and the densities of the polyfluorinated triquaternary salts on the triazine frame were shown to lie between 1.69 and 1.88 g cm^{-3}.

4. Syntheses and Properties of Quaternary Fluoroalkyl-Substituted Triazolium Salts

Until recently, there were very few triazolium quaternary salts with melting points < 100 °C, especially polyfluoroalkylated or perfluoroalkylated triazolium compounds. Considerable attention has been devoted to changes in the properties of polyfluoroalkyl-1,2,4-triazolium ionic liquids as a function of the chain length and extent of fluorination of the chain, as well as the impact of a variety of anions (Scheme 6).[28] As the number of carbon atoms in the alkyl and polyfluoroalkyl substituent chains on the cation increases resulting in concomitantly less efficient packing in the solid, the melting points are observed to decrease. The density increases with elongation of the fluoroalkyl substituent and the degree of fluorination of the chain and decreases as the alkyl group becomes bulkier. The liquid ranges and the thermal stabilities of these ionic liquids are impressive covering, in many cases, over 400 °C and frequently decomposing at > 400 °C.

Scheme 6.

An efficient procedure for the syntheses of a family of perfluoroalkyl-containing triazolium quaternary salts, 1-alkyl-4,5-dimethyl-3-(perfluoroalkyl)-1,2,4-triazolium salts was developed (Scheme 7).[29] Although the molecular weight of the cation of 1-alkyl-4,5-dimethyl-3-(perfluorooctyl)-1,2,4-triazolium tetrafluoroborate is threefold greater than that of the 3-(trifluoromethyl) derivative, its melting point is 32 °C lower (98 °C vs. 130 °C) (Figure 3). In general, these ionic salts are not miscible with nonpolar organic liquids such as hexane but miscible with acetone and water.

4-Functionalized 1-alkyl- or 1-(polyfluoroalkyl)-1,2,4-triazolium salts were synthesized to give a series of triazolium cations that contain covalently bound anionic sites, such as sulfonate, fluorohomoallylic, fluorocarboxy, and fluoroalkanol groups, and were converted by metathesis with fluorine-containing salts to a wide range of low-melting salts (Scheme 8).[30] These functionalized triazolium salts possess many characteristics of excellent ionic liquids with respect to air, water, and thermal stability. Most of them exhibit phase-transition temperatures between –22 and ca. –68 °C,

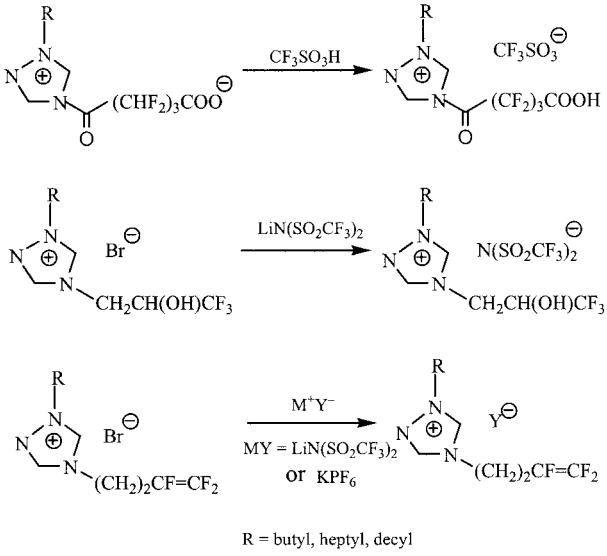
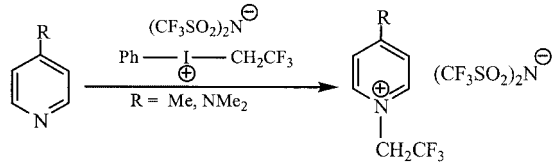
have decomposition temperatures between 254 and 408 °C, and densities between 1.45 and 1.61 g cm^{-3}.



Scheme 8.

5. Syntheses and Properties of Quaternary Fluoroalkyl-Substituted Pyridinium and Bipyridinium Salts

(Fluoroalkyl)pyridinium salts that melt at > 100 °C have been studied for more than 20 years.[44] However, in a one-step method using the powerful alkylating reagent, phenyl-(trifluoroethyl)iodonium bis(trifluoromethylsulfonyl)amide, direct trifluoroethylation of pyridine derivatives gave the 4-methyl-*N*-(trifluoroethyl)pyridinium salts, whose melting points are lower than 100 °C (Scheme 9).[31]



Scheme 9.

In addition, several bridged tetraquaternary salts derived from *N*,*N*′-bis(polyfluoroalkyl)-4,4′-bipyridine were found to meet the melting point criterion for ionic liquids (Scheme 10).[32]

All of the 4,4′-bipyridinium salts are stable in water and air and are thermally stable up to 340 °C as determined by DSC. They are generally soluble in acetone, ethyl acetate, DMF, and DMSO. The polyfluoroalkylated mono-, di-, and tetraquaternary 4,4′-bipyridinium salts are likely to have a considerable practical chemistry.

6. Syntheses and Properties of Quaternary Fluoroalkyl-Substituted Pyrazinium, Pyridazinium, Pyrimidinium, Piperazinium and Pyrrolidinium Salts

A variety of new quaternized salts of pyridazine, pyrazine, pyrimidine and 1,4-dimethylpiperazine that contain polyfluoroalkyl and alkyl substituents were synthesized and characterized (Scheme 11).[33] Many of these quaternary salts melt below 100 °C and therefore fall into the ionic liquid class. The thermal stability is largely a function of the cation with the pyridazinium compounds being the most stable. These salts also have the lowest melting points, and were prepared under the mildest reaction conditions. The pyridazinium bis(trifluoromethylsulfonyl)amide salts exhibit relatively high densities between 1.81 and 2.13 g/cm^3. The latter is one of the most dense ionic liquids excluding the hydrolytically unstable metal salts. Pyrazinium and pyridazinium salts are much less susceptible to hydrogen/deute-

rium exchange than the analogous imidazolium compounds which may allow for applications of the former liquid salts where the latter may not be suitable.

N-Alkylpyrrolidines are also readily quaternized with fluoroalkyl bromides and iodides to give ionic liquids when metathesized with lithium bis(trifluoromethylsulfonyl)-amide.[34]

7. Syntheses and Properties of Quaternary Salts Containing the Pentafluorosulfanyl (SF_5) Group

The first quaternary salts of pyridine, *N*-methylimidazole, *N*-propyltriazole, and pyridazine that contain the pentafluorosulfanyl (SF_5) group were found to be low melting (Scheme 12).[35] The presence of the pentafluorosul-

fanyl group markedly increases the densities of the bis(trifluoromethylsulfonyl)amide salts. The methylimidazolium, pyridinium, and pyridazinium salts exhibit densities of ca. 2 g cm^{-3}. However, $CF_3(CF_2)_5(CH_2)_2$– as a substituent on the ring also plays a major role in increasing the liquid densities relative to the C_8 alkyl or to shorter polyfluoroalkyl substitutents and, in some cases, to the polyfluoro(pentafluorosulfanyl)alkyl substitutents.

8. Syntheses and Properties of Fluoroalkyl-Substituted Oxazolidinium and Morpholinium Salts

A series of *N*-alkyl- and *N*-(fluoroalkyl)-substituted oxazolidinium- and morpholinium-based quaternary salts and their corresponding ionic liquids as well as ionic liquids obtained from quaternization of alkoxyethyl- and (fluoroalkoxy)ethyl-substituted morpholine compounds have been studied (Scheme 13).[36] All of the morpholinium bis(trifluoromethylsulfonyl)amide products are liquids at 25 °C and have interesting physical properties. They are stable thermally and have long liquid ranges. Overall, these ionic liquids with saturated core rings tend to exhibit greater thermal stabilities than those composed of unsaturated rings. This property plus the concomitant higher viscosities suggests higher temperature fluids applications.

9. Applications of Fluorocationic Ionic Salts

The fluorocationic ionic liquids reviewed here are still being investigated in different research fields. Fluorinated quaternary ammonium salts are useful as phase-transfer reaction catalysts, especially in basic media,[43] as surfactants,[42] or as antimicrobials.[19] Fluoroalkyl-substituted imidazolium salts have also been reported as surfactants in conventional ionic liquids.[21] Triazine-based polyfluorinated triquaternary imidazolium liquid salts were used as solvents in the rhodium-catalyzed hydroformylation of 1-octene which resulted in a significant increase in selectivity with preference for 1-nonanal.[27] Highly hydrophobic ionic liquids, such as some imidazolium, pyrazolium, triazolium, thiazolium, oxazolium, pyridinium, pyridazinium, pyrimidinium and pyrazinium salts, have applications in non-aqueous batteries, electrochemical capacitors, electroplating, catalysis and chemical separations.[16,22] A recent review (> 350 references), which essentially ignores ionic liquids with fluorine-containing cations, reports adequately on the syntheses of non-fluorine-containing ionic liquids and chemical and biochemical transformations in them.[45]

10. Conclusion

In conclusion, ionic liquids with fluorine-containing cations have many special and valuable characteristics in comparison with their non-fluorine analogues. It has been shown that by changing the fluoroalkyl chain or fluorine-containing moiety on the cation or the inorganic and organic anion, a wide range of tunable properties of these novel ionic liquids can be obtained. They are promising solvents for electrochemical, photovoltaic, surfactant and synthetic applications.

Synthesis and Properties of the Geometrically Controlled Mixed-Valence Tetrahedral $Ru^{II}_2Ru^{III}_2L_6$ Cluster

Ping Cai,[a] Ming-xue Li,[a,b] Chun-ying Duan,*[a] Feng Lu,[a] and Qing-jin Meng[a]

Keywords: Ruthenium / Mixed-valent compounds / Tetrahedral cluster

The reaction of $Ru(DMSO)_4Cl_2$ and *N,N′*-bis[1-(pyridin-2-yl)-ethylidene]benzidine (L) in the presence of $NaClO_4$ afforded the tetranuclear ruthenium compound, $Ru_4L_6{\cdot}10ClO_4$, by self-assembly. Magnetic and electrochemical measurements clearly indicated the presence of both Ru^{II} and Ru^{III} moieties within the tetrahedral ruthenium cluster. The Robin-Day Class II mixed-valence behavior was supported by the UV/Vis-NIR spectra with the electronic coupling parameter V_{ab} of 200 cm^{-1}. It is demonstrated that the mixed-valence $Ru^{II}_2Ru^{III}_2L_6$ cation was stabilized by controlling the coordination geometries of the ruthenium ions between octahedral and trigonal prismatic to fit the supramolecular structure of the tetranuclear cluster.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

It is well established that the self-assembly processes may generate, in a spontaneous and direct manner,[1] well-defined architectures that are dependent on numerous factors such as the nature of the coordination sites, the structures of the bridging ligands, the geometric preferences of the metal ions, and the weak noncovalent interactions. The application of metal–ligand interactions has proved particularly fruitful, and a considerable variety of frequently predesigned molecular architectures have been assembled.[2] Among them, polygonal and polyhedral compounds formed by self-assembly of transition metals have many special functional properties such as luminescence, redox activity and magnetism in addition to their particular structural features.[3] As the simplest platonic polyhedrons, tetrahedral clusters formed by self-assembly of the transition metals have attracted more attention because of their intrinsic beauty and interesting host–guest chemistry, as well as the fact that they illustrate some basic construction principles necessary to assemble high-symmetry clusters.[4]

On the other hand, mixed-valence species have played a dominant role as simple model systems in the investigation of electron-transfer (ET) processes.[5] With respect to the artificial ET model systems consisting of two redox centers separated by saturated or unsaturated spacers, enormous effort and ingenuity have gone into studying the details of the factors influencing the metal–metal interaction, and a great deal of progress has been made.[6] However, relatively little is known about the process of electron transfer between a single donor and acceptor as influenced by their inclusion into larger supramolecular assemblies.[7] In an effort to study electron delocalization in more symmetric polynuclear systems, we have adopted a synthetic approach to assembling high-nuclear mixed-valent metallomacrocycles.[8]

In this contribution, we report a new tetrahedral Ru_4L_6 complex assembled from the rigid imine-based ligand L, *N,N′*-bis[1-(pyridin-2-yl)ethylidene]benzidine, (Scheme 1) with two binding sites separated by a biphenyl group.[9] It is expected that the rigidity of the designed ligand imposes a special geometry on the metal centers by fitting them into the tetrahedral geometry of the cluster (Scheme 1) and that

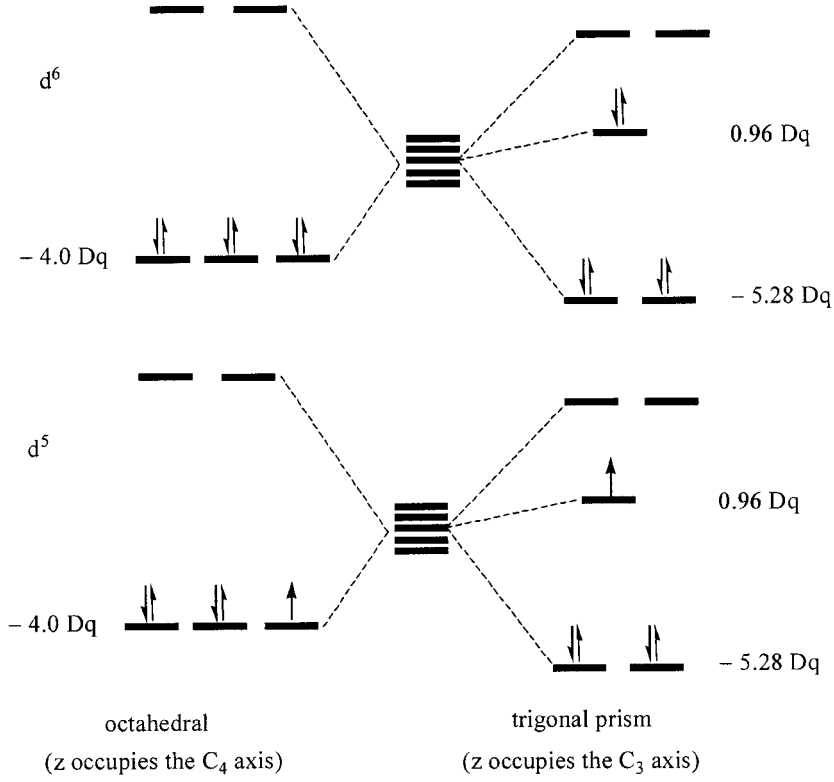

Scheme 2. The energy level of the *d* orbitals in the octahedral and trigonal prismatic coordination fields.

the resulting conformational restriction allows the modification of the redox potentials to form the mixed-valence species, similar to some metal proteins as well as many synthetic analogs.[8,10] In fact, tetranuclear copper and zinc cations $Cu_4L_6^{8+}$ and $Zn_4L_6^{8+}$ have been reported, in which the geometry at the metal center is between octahedral and trigonal prismatic,[9] but mixed-valence behavior was not exhibited, owing to the lack of suitable electronic structures. On the basis of the electronic structures of the d^5 and d^6 metal centers in the octahedral and trigonal prismatic coordination fields (Scheme 2),[11] it should be suggested that the Ru^{II} and Ru^{III} ions coexist in the clusters, because the Ru^{III} ion is more stable than the Ru^{II} ion in the trigonal prismatic coordination field, whereas the Ru^{II} ion has higher stability relative to the Ru^{III} ion in the octahedral coordination field.

Results and Discussion

Treatment of $Ru(DMSO)_4Cl_2$ with the imine-based ligand L in the presence of $NaClO_4$ afforded the tetranuclear ruthenium compound **1** in 44% yield by self-assembly. Elemental analysis and spectroscopic studies suggested the formula $Ru_4L_6{\cdot}10ClO_4$ for compound **1**. The ESI-MS spectrum exhibited an intense peak at *m*/*z* 316.4 corresponding to $[Ru_4L_6{\subset}ClO_4]^{9+}$, which was consistent with the formation of the tetrahedral species. The perchlorate anion was included within the cavity of the cluster like that of the copper and zinc analogs.[9] The tetrahedral ruthenium cation was the major species in the solution, even under the conditions of electrospraying. To determine the coexistence of Ru^{II} and Ru^{III} ions as well as their molar ratio, the temperature-dependent magnetic behavior of compound **1** was investigated (Figure 1). The effective magnetic moment (μ_{eff}) at room temperature of 2.58 μ_B was consistent with the

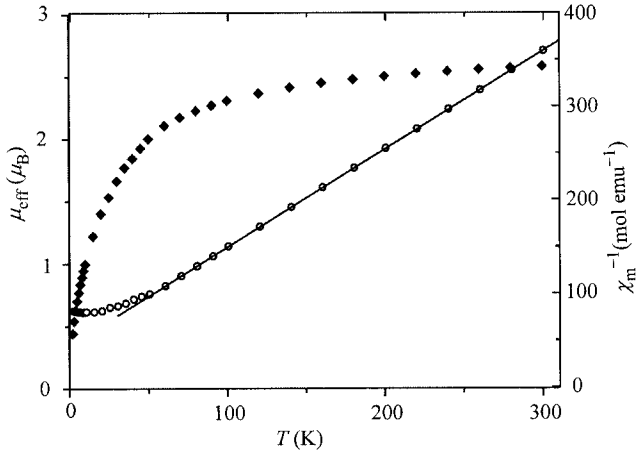

Figure 1. The temperature dependence of the molar magnetic susceptibility μ_{eff} and the reciprocal of the effective magnetic moment χ_m^{-1} for **1**. Open points represent the observed results, and the solid line represents the fitting curve based on the Curie–Weiss law.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

value expected for two independent Ru^{III} ions. The value of μ_{eff} decreased slightly with decreasing temperature (2.17 μ_B at 70 K). Below 70 K, the μ_{eff} decreased rapidly and reached 0.44 μ_B at 2 K. It seemed that the two Ru^{III} ions exhibited antiferromagnetic coupling, which was further suggested by a negative Weiss constant [θ = –35.5(2) K] using the data for temperatures greater than 70 K.

In the cyclic voltammograms (CV) of complex **1**, two metal-based reduction waves were observed in the region between 0.4 and 0.7 V and one metal-based broad wave at about 0.9 V. In order to obtain more accurate values of the reduction/oxidation peaks, the differential pulse voltammetry (DPV) technique was employed.[12] DPV measurements (Figure 2) of complex **1** exhibited three main peaks at 0.46, 0.60, and 0.89 V (vs. SCE). Considering the results of the CV experiments, it was helpful to confirm by DPV that the peaks at 0.6 and 0.46 V were reduction peaks, whereas the peak at 0.89 V corresponded to oxidation. Not surprisingly, the first redox potential is much smaller than that of the $[Ru(bpy)_3]^{2+}$ moiety and most of the mononuclear and polynuclear bpy–Ru complexes,[13] since the ruthenium centers in complex **1** are coordinated in a geometry between octahedral and trigonal prismatic, like those of the tetranuclear zinc and copper M_4L_6 complexes.[9] It seems that the peaks at 0.46 and 0.60 V of complex **1** were assigned to the single-electron reduction processes $[Ru^{II}_3Ru^{III}]/[Ru^{II}_4]$ and $[Ru^{II}_2Ru^{III}_2]/[Ru^{II}_3Ru^{III}]$, respectively. The broad peak at 0.89 V was due to the two overlapping single-electron oxidation processes $[Ru^{II}Ru^{III}_3]/[Ru^{II}_2Ru^{III}_2]$ and $[Ru^{III}_4]/[Ru^{II}Ru^{III}_3]$ (Gaussian deconvolution of such a band gives two peaks at 0.79 V and 0.91 V, respectively). It is postulated that such a conformation makes the Ru^{III} moiety exhibit higher stability relative to the common octahedrally coordinated geometry.

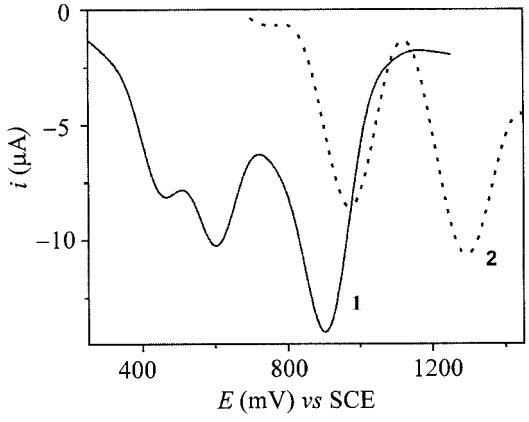

Figure 2. DPV of complexes **1** and **2** in CH_3CN solution (0.1 M NBu_4ClO_4; scan rate 20 mV/s).

To test such a hypothesis, the dinuclear ruthenium complex $[Ru_2(bpy)_4L](ClO_4)_4$ **2**, in which the ruthenium atom is octahedrally coordinated, was synthesized and characterized. DPV measurements for **2** exhibited two oxidation peaks at 0.93 and 1.30 V (vs. SCE) (Figure 2). The first oxidation potential of complex **2** was too high for the Ru^{III} species to be stable in the usual conditions. The ESI-MS spectrum of **2** exhibited one strong peak at *m*/*z* 304.5 corresponding to $[Ru_2(bpy)_4L]^{4+}$, which confirmed that there was no Ru^{III} ion in complex **2**. Clearly, the difference in the coordinative conformation of the metal centers in the two complexes was the important factor on controlling the redox potentials of the Ru^{III}/Ru^{II} couples.

The UV/Vis spectrum of complex **1** exhibits metal-to-ligand charge-transfer (MLCT) for Ru^{II} at 570 nm with a shoulder at about 520 nm, which is red-shifted relative to the same peak for complex **2** (460 nm) (Figure 3). Such results agree well with the related electrochemistry studies, which indicate that the coordination geometries of the ruthenium atoms in the two complexes are significantly different. In the near-IR region, complex **2** does not exhibit any obvious absorption band. However, complex **1** exhibits a LMCT absorption band corresponding to the Ru^{III} moiety at about 11000 cm^{-1} (ε = 5500 cm^2/mol) and a MMCT band at about 7500 cm^{-1} (ε = 2000 $cm^2 \cdot mol^{-1}$) with half-width of 4000 cm^{-1}, respectively. Intervalence charge-transfer bands in mixed-valence Ru^{III}/Ru^{II} complexes generally occurred in the near-IR region of the electronic spectra and had extinction coefficients of several hundred or a few thousand mol/$dm^3 \cdot$cm,[5,6] so both the position and the intensity of the 7500 cm^{-1} peak are consistent with an IT band. Assuming that the MV compound behaves as a Robin-Day Class II compound,[14] the IT absorption band of MV compounds can be modeled by classical Marcus-Hush theory[15] to obtain the electronic coupling parameter.[16] However, there are two Ru^{II} and two Ru^{III} in the complete tetrahedron. This means that the effective concentration in ion pairs Ru^{II}-Ru^{III} is actually four times the actual concentration (ε = 500 cm^2/mol). Considering that the Hush formula is valid for a simple binuclear system, i.e. a single Ru^{II}–Ru^{III} pair, the electronic coupling parameter of compound **1** can be given as 200 cm^{-1}. Significantly, the coordination environment of the metal centers in geometrically

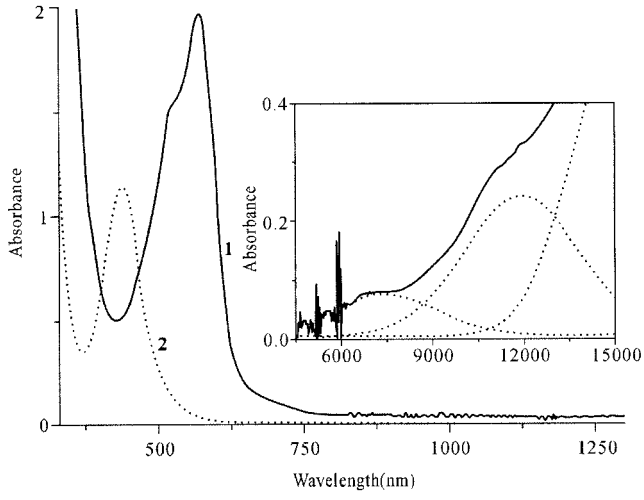

Figure 3. The UV/Vis-NIR spectra of the complexes **1** and **2** in acetonitrile (2.0×10^{-5} M). The insert showed the near-IR spectrum of the complex **1** in acetonitrile (5.0×10^{-5} M). The Gaussian fits (the dot lines) showed the LMCT band at 11000 cm^{-1} and the MMCT band at 7500 cm^{-1}, respectively.

constrained tetrahedral architectures plays an important role in controlling the redox potential of the Ru^{III}/Ru^{II} couples and modifying metal–metal interactions.

In summary, this paper describes a modular approach to a mixed-valence compound implemented by controlling the coordination geometry of ruthenium ions to fit the architecture in the tetranuclear cluster. Mixed-valence compounds have played a crucial role not only in the exploration of electron-transfer theory but also for addressing contemporary issues in electron-transfer research, especially when the emphasis in this field has shifted away from simple dinuclear MV species and focused on multinuclear supramolecular species.[17,18]

Experimental Section

General: All chemicals were of reagent grade quality; they were obtained from commercial sources and used without further purification. $Ru(DMSO)_4Cl_2$,[19] the ligand[9] and *cis*-$Ru(bipy)_2Cl_2 \cdot 2H_2O$[20] were synthesized according the literature methods. The elemental analyses of C, H, and N were performed with a Perkin–Elmer 240C elemental analyzer at the Analysis Center of Nanjing University. Electrospray mass spectra were recorded with a LCQ system (Finnigan MAT, USA) using methanol as the mobile phase. IR spectra were recorded with a Nicolet 170SX FT-IR spectrophotometer with KBr pellets in the 4000–400 cm^{-1} region. Variable-temperature magnetic susceptibility data were obtained on polycrystalline samples at 2–300 K in a magnetic field of 10 Koe after zero-field cooling using a MagLab System 2000 magnetometer. Diamagnetic corrections were estimated from Pascal's constants. Differential pulse voltammetry (DPV) was done with an EG and GPAR model 273 instrument in a three-electrode cell with a pure Ar gas inlet and outlet. The working electrode and counter electrode were Pt spirals, and the reference electrode was a saturated calomel electrode (SCE). DPV experiments were performed with a scan rate of 20 mV/s. Uv/Vis-NIR spectra were obtained in acetonitrile solution at room temperature with a Shimadzu 3100 spectrophotometer.

Preparation of Complex 1: The ethanol solution of the mixture $Ru(DMSO)_4Cl_2$ (0.58 g, 1.2 mmol) and the ligand L (0.71 g, 1.8 mmol) was refluxed for 12 h. Dark blue precipitate $(Ru_4L_6)(ClO_4)_{10}$ was formed when the solution was added to a saturated ethanol solution of $NaClO_4$. Purification was performed by chromatography on a neutral alumina column (20 × 1.5 cm) with CH_3CN/MeOH, 1:1 (v/v) as eluent. The dark-blue fraction was collected and concentrated to a small volume. Upon addition of ethanol, complex **1** was obtained as a dark solid. Yield 0.48 g (44%). $Ru_4C_{156}H_{132}Cl_{10}N_{24}O_{40}$ (3738.2): calcd. C 50.1, H 3.6, N 9.0; found C 49.8, H 4.1, N 8.7. UV/Vis (logε) in methanol: 287 (4.8), 448 (4.3), 481 (4.6) nm. IR: 3444 (ν_{C-H}), 1634, 1539, 1504, 1463 ($\nu_{C=C}$, $\nu_{C=N}$, ν_{C-N}), 1092, (ν_{Cl-O}), 837, 770, 736 (δ_{C-H}) cm^{-1}.

Preparation of Complex 2: $[Ru(bpy)_2Cl_2] \cdot 2H_2O$ (0.15 g, 0.31 mmol) and L (0.06 g, 0.15 mmol) were refluxed in ethanol (50 mL) for 12 h under nitrogen. When this solution was added to a saturated ethanol solution of $NaClO_4$, $[Ru_2(bipy)_4L](ClO_4)_4$ separated out as a red precipitate, which was collected by filtration, washed with water and ethanol for several times, and dried in vacuo over P_4O_{10}. Yield: 0.15 g (68%). $C_{66}N_{12}H_{54}Ru_2Cl_4O_{16}$ (1614.1): calcd. C 49.1, H 3.4, N 10.4; found C 49.2, H 3.2, N 10.3. ^1H NMR ([D$_6$]DMSO): δ = 8.87 (t, 2 H, Py), 8.67 (d, 2 H, Py), 8.62 (d, 2 H, Py), 8.50 (t, 4 H, bipy), 8.22 (m, 8 H, bipy), 8.01 (d, 4 H, Ph), 7.96 (m, 4 H, bipy), 7.86 (d, 2 H, Py), 7.72 (d, 4 H, bipy), 7.68 (d, 4 H, Ph), 7.35 (t, 2 H, bipy), 6.90 (d, 2 H, bipy), 6.84 (d, 4 H, bipy), 6.69 (d, 4 H, bipy), 1.62 (s, 6 H, CH_3) ppm. UV/Vis (log ε) in CH_3CN: 289 (4.2), 347 (3.2), 466 (3.4) nm. IR: 3426 (ν_{C-H}), 1464, 1445, 1422 ($\nu_{C=C}$, $\nu_{C=N}$, ν_{C-N}), 858, 766, 624 (δ_{C-H}), 1092, (ν_{Cl-O}) cm^{-1}.

Caution! Although no problems were encountered in this work, perchlorates are potentially explosive and should be handled with care.

A Binuclear Copper(II) Complex Containing the Pyrazine-2,5-dicarboxylate Ligand: Study of the Magnetic Exchange through the Pyrazine Bridge

Garikoitz Beobide,[a] Oscar Castillo,*[a] Urko García-Couceiro,[a] Juan P. García-Terán,[a] Antonio Luque,[a] Martín Martínez-Ripoll,[b] and Pascual Román[a]

Keywords: Copper / Density functional calculations / Magnetic properties / N ligands / Pyrazine

The compound $[Cu_2(\mu\text{-pzdc})(phen)_4](NO_3)_2\cdot 10H_2O$ (**1**; pzdc = pyrazine-2,5-dicarboxylato; phen = 1,10-phenanthroline) has been structurally and magnetically characterised. Theoretical calculations have allowed us to establish a plausible magneto-structural correlation for pyrazine-bridged complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

A lot of work has been devoted to the study of the magnetic interactions between two paramagnetic centres bridged by an aromatic ring.[1] The study of the spin delocalisation and polarisation effects is helpful in order to understand the nature of these magnetic interactions. The spin-polarisation mechanism itself provides a key tool for predicting the kind of magnetic interactions in high-spin organic molecules, and therefore for designing molecule-based magnets.[2] Nevertheless, the application of this strategy to transition metal complexes, which provide a more stable spin source than those based on organic radicals, is more tricky, and the spin-delocalisation effect must also be taken into account.[3] Metal complexes containing pyrazine-2,5-dicarboxylate (pzdc) ligands have seldom been investigated.[4] Until now, as far as we aware, a three-dimensional Mn^{II} complex[5] and a binuclear V^{V} complex[6] are the only structurally characterised examples with this ligand.

We report here the synthesis,[7] crystal structure[8] and magnetic properties of a complex with formula $[Cu_2(\mu\text{-pzdc})(phen)_4](NO_3)_2\cdot 10H_2O$ (**1**). In addition, a plausible magneto-structural correlation for pyrazine-bridged complexes is analysed by DFT methods.

Results and Discussion

The structure of compound **1** consists of water molecules of crystallisation, nitrate counterions and centrosymmetric $[Cu_2(\mu\text{-pzdc})(phen)_4]^{2+}$ binuclear units (Figure 1) in which a bidentate pzdc ligand bridges two copper atoms with an M···M distance of 7.112 Å. The distorted octahedral environment around each copper atom is completed by four nitrogen atoms of two phen ligands (phen1 and phen2). We can distinguish two long bonds in the *trans* position formed by an oxygen of the carboxylate group and a nitrogen of the phen2 ligand [Cu1–O41 2.271(3) Å, Cu1–N38 2.210(3) Å]. The four shortest bonds are nearly coplanar and are to two N atoms from phen1 [Cu1–N11 2.115(3) Å, Cu1–N18 2.011(2) Å], another one from phen2 [Cu1–N31 2.003(2) Å] and a one from the bridging ligand [Cu1–N1 2.184(2) Å]. This equatorial plane is almost perpendicular to the mean plane of the pzdc ligand [dihedral angle 81.7(2)°]. Similar distorted octahedral environments have been reported for other phen or 2,2′-bipyridine copper complexes.[9] The deviation of the metal atom from the pyrazine ring is quite significant [0.209(1) Å], probably due to the steric hindrance of the terminal ligands.

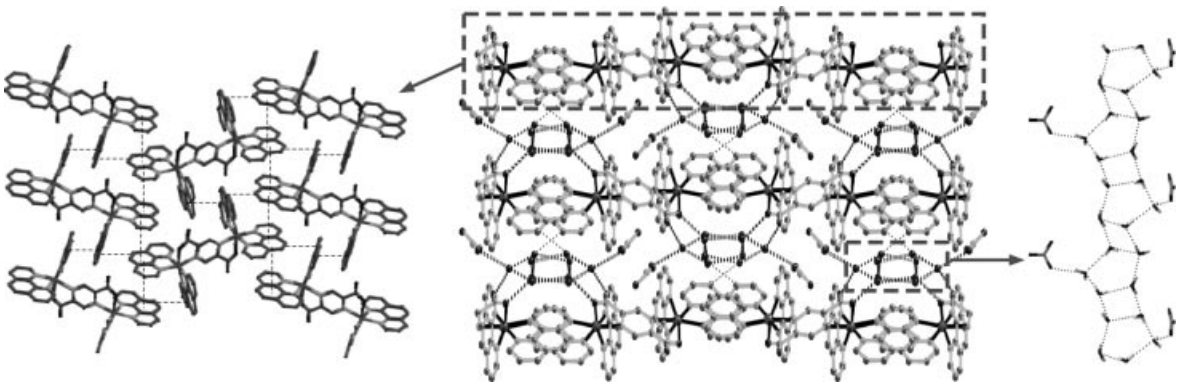

Figure 2. Crystal structure viewed along the [001] direction showing π–π interactions (dashed lines) within the cationic layers and hydrogen-bonded (dotted lines) chains of water molecules.

In the crystal structure (Figure 2), the cationic complexes are held together by means of face-to-face and edge-to-face π–π interactions between the aromatic phen ligands to form corrugated layers parallel to the *bc* plane. The water molecules are inserted in the interlayer space and are linked themselves by O_w–H···O_w hydrogen bonds to form zig-zag strips comprised of an alternating sequence of fused water pentamers and tetramers running along the [001] direction. The nitrate anions are attached to the edges of the pentagonal water ring by a hydrogen bond. There are no significant interactions between adjacent strips, therefore the water strips act as bridges between the cationic layers by means of a highly complex network of non-covalent interactions. Compound **1** shows a different crystal packing to those described in a recent study[10] of the most common packings of complexes based on phen ligands, and bears a very close resemblance to the compound [{Cu(ox)(phen)$_2$}·5H_2O].[11] Both compounds show a similar π–π interaction scheme within the corrugated complex layers. Due to this conformation, there is a similarity between the hydrophilic holes in the interlayer space, which leads to a similar arrangement of the solvated water molecules.

Variable-temperature magnetic-susceptibility measurements (2–200 K) show the presence of weak antiferromagnetic coupling, with values of $J = -5.7$ cm^{-1} and $g = 2.14$ obtained from the Bleaney–Bowers expression ($H = -JS_A \cdot S_B$) for a binuclear copper(II) complex. This antiferromagnetic coupling is mainly attributed to the magnetic interaction through the pyrazine ring. The contribution of the carboxylate groups can be considered negligible due to the long magnetic pathway involving these groups.

DFT methods have shown to give good estimates of the magnetic interactions.[12] A detailed description of the computational strategy adopted in this work is given elsewhere.[13] For the evaluation of the coupling constant, two separate DFT calculations were carried out, from which the energy of the highest spin (E_{HS}) and broken-symmetry singlet configuration (E_{BS}) are obtained. The magnetic coupling constant results from the energy difference between the triplet and singlet states ($E_{HS} - E_{BS} = -J$). The hybrid B3LYP method, as implemented in Gaussian 03, was used in all calculations.[14] The exact Hartree–Fock-type exchange was mixed with Becke's expression for the exchange functional and the Lang–Yong–Parr correlation functional was used. A basis set of double-ζ quality (triple-ζ for the transition metal atoms), proposed by Schäfer et al.,[15] was employed throughout.

The calculations were performed for an isolated $[Cu_2(phen)_4(\mu\text{-pzdc})]^{2+}$ dimer with an experimental geometry of $C\bar{1}$ symmetry, leading to a value of the magnetic interaction ($J_{calc} = -8.4$ cm^{-1}) similar to the experimental one ($J_{exp} = -5.7$ cm^{-1}). Figure 3 illustrates the spin densities for the ground state ($S = 0$) of the title compound. The spin-density distribution around the metal centre resembles a $d_{x^2-y^2}$ orbital with a significant contribution of d_{z^2}. The coordinated Cu1 and pzdc atoms (N1 and O41) carry spin densities with the same sign due to the spin-delocalisation effect. This situation is in sharp contrast to that of organic high-spin materials bridged by *m*-phenylenes,[2] in which the spin density alternates throughout the π-conjugated hydrocarbon network, as predicted by the spin-polarisation mechanism.

Most of the previously reported Cu^{II} complexes with pyz-type (pyz = pyrazine) bridging ligands coordinated at

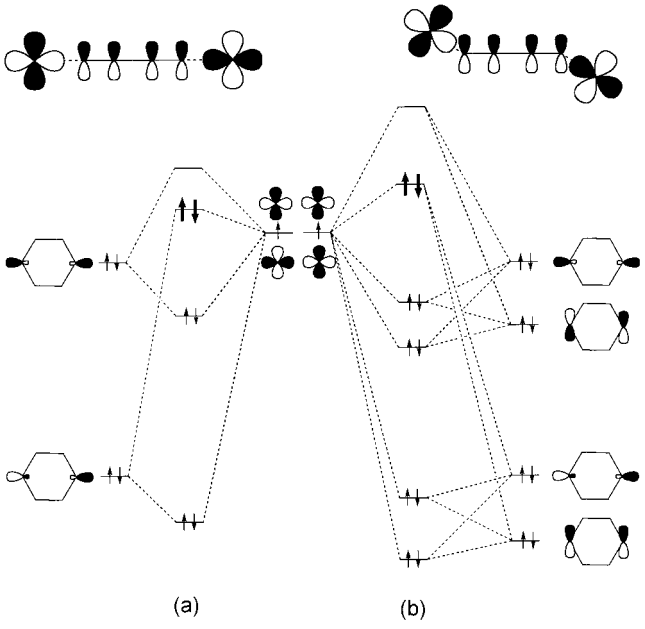
the equatorial sites show very weak antiferromagnetic interactions ($|J| < 4$ cm^{-1}).[16] However, there are a handful of pyz-bridged Cu^{II} complexes, specially with the tppz ligand [1,3,5,6-tetra(2-pyridyl)pyrazine], that present unusually large antiferromagnetic interactions,[17] with J values ranging from –35 to –61 cm^{-1}. A common structural feature of the latter compounds is the large displacement of the metal from the mean plane of the pyrazine bridge (0.34–0.56 Å) and/or the distortion of the pyrazine ring (dihedral angles between the two C–N–C planes of the pyz ring range between 8.8 and 11.0°). Due to the structural features of the title compound, we have restricted the present work to the analysis of the former structural parameter, which allows a σ-overlap between the metal $d_{x^2-y^2}$ orbital and the π-orbitals of the pyrazine ring; in an ideal planar system this d_σ–p_π overlap is not allowed (part a in Scheme 1). Taking into account these facts, the observed values of J could be attributable to an important contribution of the π-orbitals of the pyz-type ligand through a d_σ–p_π interaction, which is allowed by the structural distortion (Scheme 1, part b). The title compound represents an intermediate situation between the negligible values commonly observed and the cited unusually high values.



Scheme 1. Orbital interaction diagram showing the interaction between the two Cu $d_{x^2-y^2}$ orbitals and a) the σ-symmetry orbitals and b) the σ- and π-orbitals.

In order to determine the contribution of the π-orbitals of the bridging ligand to the magnetic behaviour, we carried out DFT calculations on a pyrazine-bridged dimeric Cu^{II} model for different values of the Cu–N_{pyz}···N_{pyz} angle (see details in Figure 4). The values obtained for the magnetic coupling constant indicate an exponential increase of the J value with a decrease of the Cu–N_{pyz}···N_{pyz} angle. The J value is –6.8 cm^{-1} at 180°, but reaches values as high as –144 cm^{-1} for an angle of 130°.

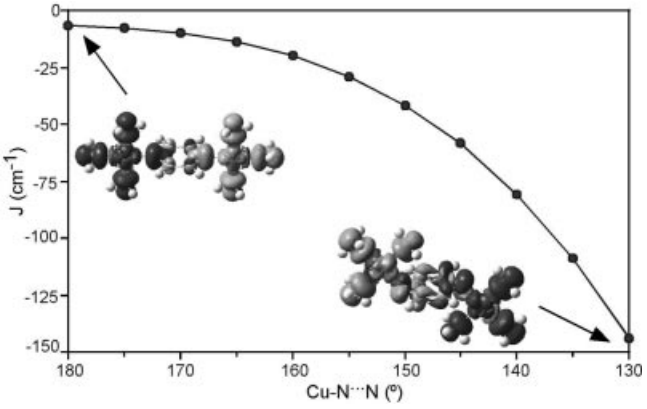


Figure 4. Calculated coupling constants for $[Cu_2(NH_3)_6(\mu\text{-pyz})]^{4+}$ as a function of the Cu–N_{pyz}···N_{pyz} angle. The inset graphics represent the spin-density distribution for the two extreme angles. Calculations have been performed in an idealised C_{2h} symmetry using the following bond lengths [Å] and angles [°]: Cu–N 2.00, C–N: 1.35, C–C 1.42, C–H 1.00, N–H 1.00, N–Cu–N 90.0, N–Cu–N–C 90.0, Cu–N_{pyz}···N_{pyz} 130.0–180.0.

As depicted in Scheme 1 (part a), when the Cu–N_{pyz}···N_{pyz} angle is 180°, the two Cu $d_{x^2-y^2}$ orbitals overlap with the two symmetry-adapted σ-orbitals of the pyrazine. The energy of these σ-orbitals is not equal, leading to a substantial energy difference between the two singly occupied orbitals of the dimer and, consequently, an antiferromagnetic coupling through the pyrazine is observed. If the Cu–N_{pyz}···N_{pyz} angle is not linear the overlap of the two Cu $d_{x^2-y^2}$ orbitals involves the symmetry-adapted σ- and π-orbitals of the bridge, and the energy difference between the two SOMOs increases, leading to an increase of the antiferromagnetic interaction (part b in Scheme 1). No simple relation between the spin density at the pyrazine bridge and the magnetic coupling constant has been found.

The experimental J value (–5.7 cm^{-1}) is comparable to that obtained for the model compound with a similar Cu–N_{pyz}···N_{pyz} angle (–9.8 cm^{-1}) taking into account the small singlet–triplet gap. In agreement with the trend shown in Figure 4, the pyrazine-bridged complex with the highest J value[16a] (–61.1 cm^{-1}) shows the greatest deviation of the metal from the mean plane of the pyrazine. However, the values of other tppz-based complexes cannot be fitted easily, due to the high distortion that the pyrazine ring presents.

Other structural factors, such as the Cu–N_{pyz} distance, the dihedral angle between the Cu^{II} equatorial plane and the pyrazine plane, the influence of the axial ligand, etc. seem to have a less decisive role on the magnetic properties (see Supporting Information).

Mechanistic Insights into the Oxidation of Veratryl Alcohol with Co(salen) and Oxygen in Aqueous Media: An in-situ Spectroscopic Study

Kaisa Kervinen,[a,b] Heikki Korpi,[a] J. Gerbrand Mesu,[b] Fouad Soulimani,[b] Timo Repo,*[a] Bernhard Rieger,[c] Markku Leskelä,[a] and Bert M. Weckhuysen*[b]

Keywords: Cobalt complexes / Schiff bases / Homogeneous catalysis / IR spectroscopy / Raman spectroscopy / UV/Vis spectroscopy

Many transition-metal complexes can perform catalytic oxidations, but their corresponding reaction pathways are still not clear. In this study, the mechanism of Co(salen)-catalyzed [salen = *N*,*N*′-bis(salicylidene)ethylenediamine] oxidization of veratryl alcohol (3,4-dimethoxybenzyl alcohol) by dioxygen in alkaline aqueous solution was elucidated with in-situ ATR-IR, Raman and UV/Vis spectroscopy. The mechanism of this reaction seems to start by formation of a bis-μ-hydroxo[(Co(salen)]$_2$ species, which explains the dramatic effect of pH on the reaction rate. Substrate coordination to this species leads to formation of a cobalt-bound veratryl alkoxo intermediate, to which oxygen molecule can bind. Formation of a μ-peroxo bridge between two such Co(salen) substrate units is observed in the UV/Vis spectra. Transfer of a hydrogen atom from the substrate to the peroxo bridge results in detachment of the product aldehyde and regeneration of the initial bis-μ-hydroxo[(Co(salen)]$_2$ species. In the overall cycle two substrate molecules are oxidized to aldehyde and molecular oxygen is reduced to water. The rate-limiting step is the detachment of the product molecule, which is aided by the methoxy substituents in the aromatic ring of the benzylic alcohol.

Introduction

Activation of molecular oxygen by transition-metal complexes for selective oxidations in water is an environmentally benign and economical alternative for many present day industrial processes.[1–3] Nevertheless, organic solvents are more commonly used, as stability and solubility of transition-metal complexes is often a problem in aqueous solutions.[2–7] Despite the importance, the mechanisms of transition-metal complex-catalyzed oxidation reactions are still not fully understood.[4] For example, Co(salen) [salen = *N*,*N*′-bis(salicylidene)ethylenediamine] has long been known to reversibly bind and activate dioxygen and its oxygen adducts are well characterized,[8–10] but it is not clear how these catalytic reactions proceed.[4,11] It has been suggested that the mononuclear superoxo species is usually responsible for catalyst activity in the oxidation of phenolic substrates, but no direct evidence is yet available.[3,4,12–14] There are less examples on the oxidation of benzylic substrates. It has been noted that the reaction mechanisms depend greatly on the nature of the substrate and its substituents.[3,15]

In this study, Co(salen) is used as a catalyst to oxidize a lignin model compound, veratryl alcohol (3,4-dimethoxybenzyl alcohol), to an aldehyde in alkaline water solution. Selective oxidation of lignin would be attractive for catalytic pulp bleaching[16–18] and for the search of renewable raw materials.[3,12] This reaction proceeds in the presence of molecular oxygen to reach TOF = 10–15 at optimum conditions (TOF = turnover frequency, moles of product per mol of catalyst per hour).[16] The effect of reaction conditions observed previously for this system suggest that a mononuclear superoxo complex is not responsible for catalytic activity.[16–17] However, direct proof for the intermediates involved in the catalytic cycle is lacking. Temperature and pH have a dramatic effect on the catalytic activity of this system, and thus it is vital that the mechanism is studied under real experimental conditions. Therefore, the Co(salen)-catalyzed reaction (Scheme 1) has been studied with a combination of in-situ ATR-IR, Raman and UV/Vis spectroscopy in aqueous solution at pH 12 and 80 °C.

The use of complementary techniques is a powerful way to monitor a catalytic reaction.[20–21] Different species show more intense absorptions in different regions of the electromagnetic spectrum. Electronic transitions usually give rise to absorption or emission in the ultraviolet or visible regions, whereas molecular vibrations give rise to absorption bands throughout most of the infrared region. Symmetrical

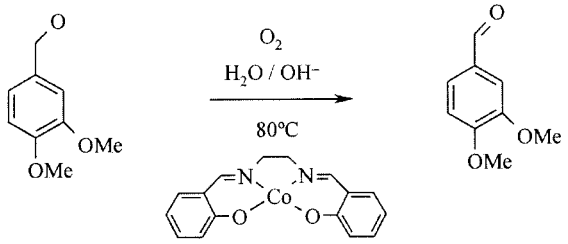

Scheme 1. Oxidation of veratryl alcohol by Co(salen) (**1**) and dioxygen in water.

molecules can be totally IR inactive, but exhibit intense vibrations in the Raman spectrum.[19] In this work, UV/Vis spectroscopy was used to study the reaction at low concentrations, whereas ATR-IR and Raman techniques require higher concentrations. Based on the combination of results, a mechanism for veratryl alcohol oxidation by Co(salen) in alkaline aqueous solution is proposed (Scheme 1).

Results and Discussion

ATR-IR Spectroscopy

Carbonyl compounds have distinct vibrations in the IR range, and therefore it is attractive to study the veratraldehyde formation by in-situ IR spectroscopy.[22–24] Metal-dioxygen complexes have also been extensively characterized by vibrational spectroscopic techniques.[24–28] [Co(salen)B]$_2O_2$ (B = py, pyO, DMF or other axial base) exhibits its ν(O–O) at 888–910 cm^{-1} and the oxygen bridge is regarded as a peroxo bridge. [Co(salen)]$_2O_2$ exhibits ν(O–O) at 1010 cm^{-1} and this bridge is regarded as being an intermediate between peroxo and superoxo species.[27] The superoxo-cobalt complexes exhibit ν(O–O) at a typical range of 1075–1122 cm^{-1}.[28]

Figure 1 shows a typical set of ATR-IR spectra obtained for the Co(salen)-catalyzed oxidation of veratryl alcohol with oxygen in water as a function of time. Mainly two vibrations are observed to form during the reaction. As expected, the aldehyde C=O vibration peak is appearing at 1675 cm^{-1}. A second strong vibration peak, which increases with reaction time, was observed at 993 cm^{-1}. The rate of formation of the peak at 993 cm^{-1} is faster than that of the peak at 1675 cm^{-1} (Figure 1), indicating that they belong to two different species. The change in the vibrations of the aromatic ring, of the methoxy groups and of the C–H bonds in the aldehyde compared to the alcohol are seen as shifts in vibration frequencies.[29]

Interestingly, the vibration at 993 cm^{-1} only appears when both, Co(salen) and veratryl alcohol, are present. This is shown in Figure 2. A weak vibration peak at 984 cm^{-1} is observed to appear when only Co(salen) is stirred at pH 12 in the absence of oxygen, but when substrate is added, a strong vibration peak forms at 993 cm^{-1} and the vibration at 984 cm^{-1} can no longer be observed. Neither one of the peaks is observed at a lower pH (no addition of NaOH, corresponds to a pH of about 9.5).

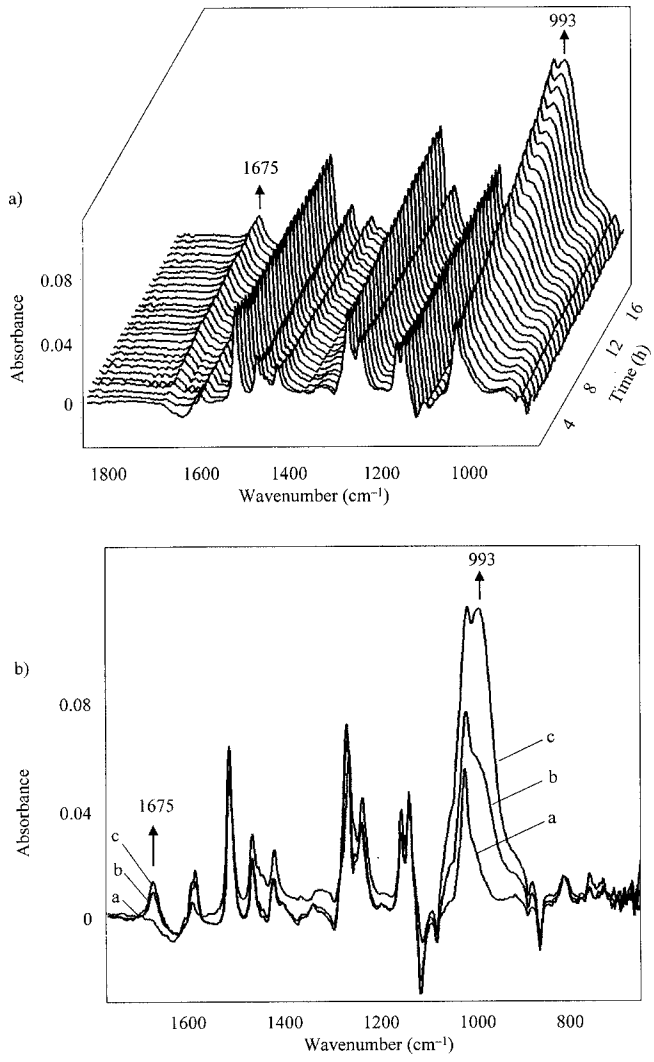

Figure 1. a) 3D plot of time-resolved ATR-IR spectra of the veratryl alcohol oxidation by Co(salen) and dioxygen in water at 80 °C and pH 12. b) Sample spectra were taken at 0 h (a), 8 h (b) and 16 h (c). (150 mg Co(salen) and 3 mL of veratryl alcohol in 90 mL of water/dioxane (5:1) mixture).

Hydroxo-metal complexes exhibit the MOH bending mode below 1200 cm^{-1}. If the hydroxo group is bridging two metal ions, the bending mode moves to lower energies and is seen at 955 cm^{-1} for bis-μ-hydroxo[Cu(bipy)$_2$] type complexes.[24] Thus, we assign the 984 cm^{-1} vibration to bis-μ-hydroxo[Co(salen)]$_2$ species as it appears in aqueous solution of Co(salen) at pH 12. Metal-bound alkoxides (M–OR) exhibit ν(C–O) at ca. 1000 cm^{-1}.[24] As the 993 cm^{-1} vibration appears in solutions of veratryl alcohol and Co(salen) at pH 12 under argon, we assign this vibration to a cobalt-bound veratryl alkoxo group.

If this assignment is valid, the vibration at 993 cm^{-1} should behave differently in the absence or presence of oxygen. This is indeed the case, as illustrated in Figure 3. The rate of formation of the 993 cm^{-1} peak decreases after the addition of oxygen. This is also the point at which the production of aldehyde starts. The peak at 993 cm^{-1} does not

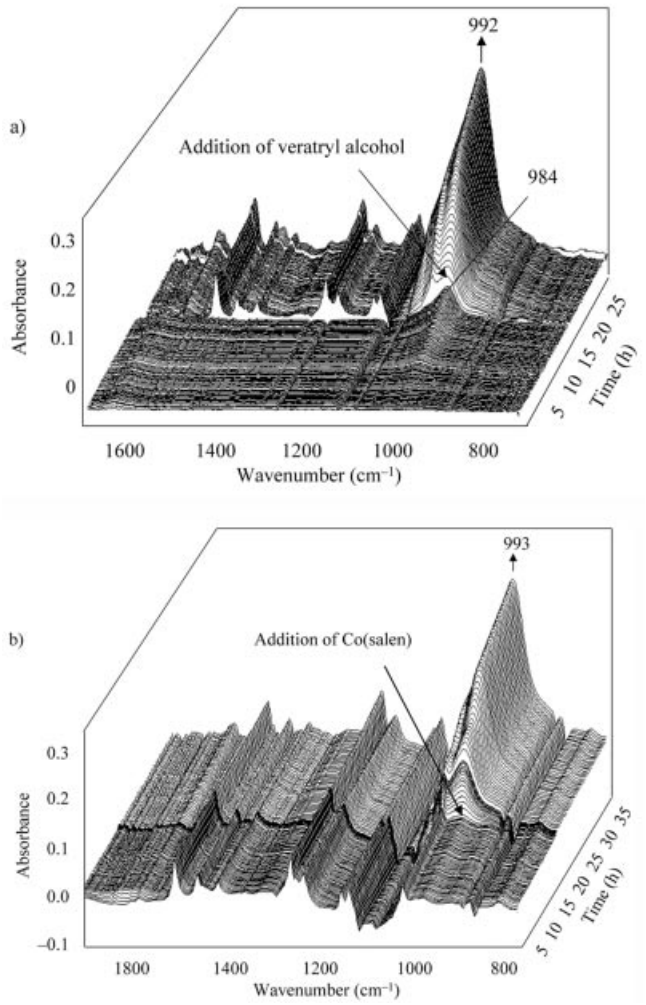

Figure 2. A strong vibration peak at 993 cm^{-1} appears after addition of veratryl alcohol (a) or Co(salen) (b) to the reaction mixture with other reagents. [150 mg Co(salen) and 3 mL of veratryl alcohol in 90 mL of water/dioxane (5:1) mixture at 80 °C and pH 12 under argon].

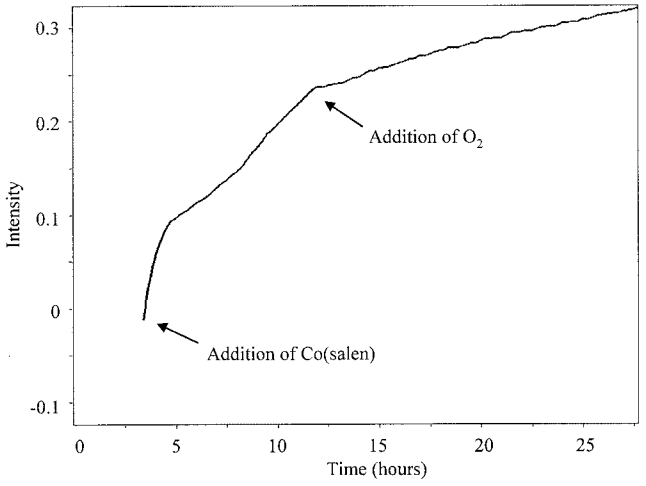

Figure 3. Appearance and increase in intensity of the vibration peak at 993 cm^{-1} monitored in a Co(salen) reaction in the absence and presence of oxygen. (150 mg Co(salen) and 3 mL of veratryl alcohol in 90 mL of water/dioxane (5:1) mixture at 80 °C and pH 12 initially under argon).

appear at temperatures lower than 70 °C nor at low pH values (with no addition of NaOH).

Summarizing, a vibration at 993 cm^{-1} appears at a temperature and pH range of an active system, but forms faster in the absence of oxygen. Thus it does not arise from the product nor from a oxygen-cobalt species, but from an interaction between the substrate and the complex. We assign this species to alkoxo-cobalt intermediate (Figure 3).

Raman Spectroscopy

Different oxygen bridges are more Raman or IR active depending on their symmetry and therefore it is important to use both techniques to determine the presence of oxygen-bridged cobalt complexes.[19,24] Raman spectroscopy is, however, even less sensitive than ATR-IR spectroscopy, and therefore a high concentration of reagents had to be used. The substrate exhibits vibrations at about the same frequencies as in the IR spectra. Figure 4 shows, that the only changes observed after an overnight measurement are the formation of a weak carbonyl vibration at 1675 cm^{-1} and shifts in the vibration peaks of the substrate.[29] Thus no peroxo or superoxo bridges could be observed in the Raman spectra of the Co(salen)-catalyzed reaction.

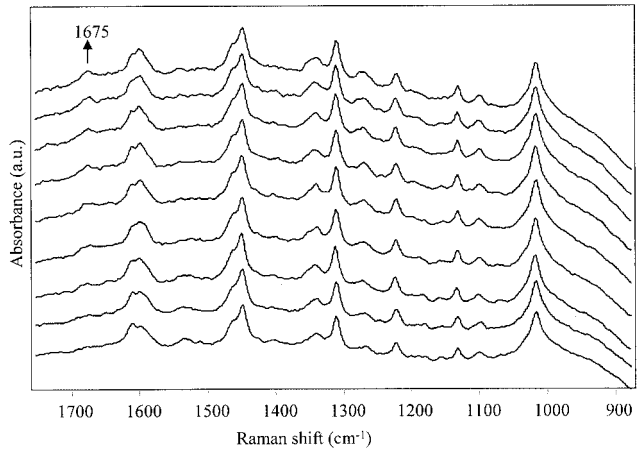

Figure 4. Raman spectra of Co(salen)-catalyzed veratryl alcohol oxidation. Vibration at 1675 cm^{-1} corresponds to the C=O bond of the product. Other peaks observed belong to the substrate.[29] (200 mg Co(salen) and 5 mL veratryl alcohol in 90 mL of water/dioxane mixture (3:1) at 80 °C and pH 12).

UV/Vis Spectroscopy

The oxygen complexes of cobalt have been widely studied by UV/Vis spectroscopy.[30–33] According to Lever and Gray, the bridging superoxo complexes of cobalt exhibit a single intense band in the electronic spectra in the region 300–400 nm, whereas a bridging peroxo has two absorption bands, at about 320 nm and 400 nm. A doubly bridged μ-hydroxo-μ-peroxo (OH, O_2^{2-}) has only one intense absorption band at about 375 nm and a shoulder at higher energies (about 290 nm).[30] Aldehydes also exhibit absorptions in the UV range arising from the n → π* transitions of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

free electron pair of the carbonyl oxygen and thus product formation can also be monitored by UV/Vis spectroscopy.[34]

Figure 5 shows the UV/Vis spectra of an experiment, in which NaOH was added to the reaction solution of Co(salen) and veratryl alcohol before oxygen (reactions 1–4). Co(salen) and veratryl alcohol in water at 80 °C and under argon exhibit absorption bands of similar intensity at 339 nm and 392 nm (1). At pH 12 the intensity of the absorption bands is enhanced, but they do not shift (2). Addition of an oxygen atmosphere shifts the absorption bands to 324 nm and 378 nm (3). Under argon the reaction solution is very reddish brown, but it turns to dark brown along exposure to oxygen. Under prolonged oxygen exposure the intensity of the absorption band at 324 nm decreases to a shoulder, while the band at 378 nm remains (4). This change suggests that a monobridged peroxo species transforms into a doubly bridged species. At these conditions this is most likely a μ-hydroxo-μ-peroxo bridge.[35]

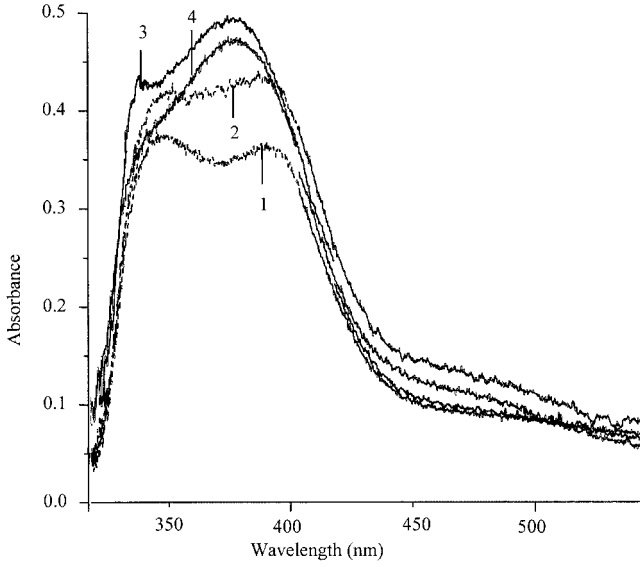

Figure 5. In-situ UV/Vis spectra of a solution of Co(salen) and veratryl alcohol in water under argon (1), after addition of NaOH to adjust pH to 12 (2), after addition of oxygen (3) and after 1 h of oxygen exposure (4). (10 mg of Co(salen) and 2 mL of veratryl alcohol in 120 mL of water at 80 °C).

If oxygen is added to a solution of Co(salen) and veratryl alcohol at low pH (no addition of NaOH), the absorption bands at 339 nm and 390 nm (5) are shifted to 300 nm and 378 nm (6). This implies that oxygen coordinates to the cobalt complex. After the addition of NaOH, the band at 378 nm does not shift, but an absorption band at 308 nm starts to arise, which is assigned to the n $\rightarrow$ π^* transitions in the C=O group of the aldehyde (7, Figure 6).[34,36]

Aldehyde formation can be monitored by UV/Vis spectroscopy as the appearance and growth of the absorption band at 308 nm and Figure 7 shows that the reaction rate increases with increasing reaction temperature. At 40 °C the rate of the reaction is so slow that practically no aldehyde is produced. Instead, at 60 °C the absorption band at

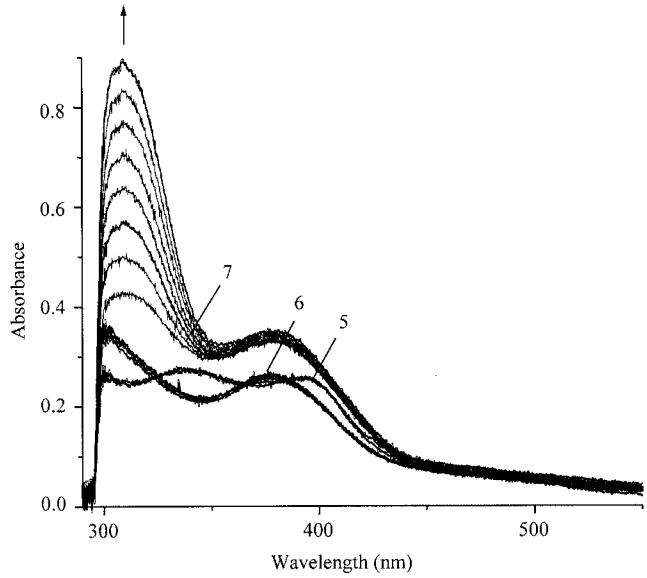

Figure 6. In-situ UV/Vis spectra of a solution of Co(salen) and veratryl alcohol in water at 80 °C under argon (5), after addition of oxygen (6) and after addition of NaOH to adjust pH to 12 (7). (10 mg of Co(salen) and 2 mL of veratryl alcohol in 120 mL of water at 80 °C).

308 nm starts to appear and at 80 °C its formation rate increases dramatically.

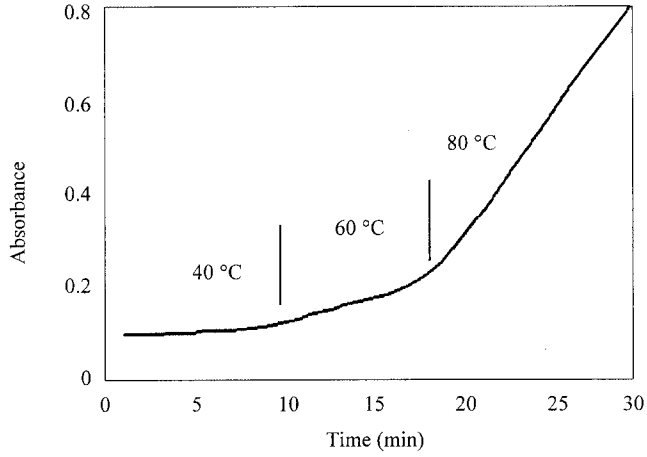

Figure 7. The rate of formation of the absorption band at 308 nm at different reaction temperatures.

Summarizing, a μ-peroxo bridge is observed to form when oxygen is introduced to the solution of Co(salen) and veratryl alcohol in water at 80 °C and pH 12. With time, a second bridge appears between the cobalt centers forming a doubly bridged μ-hydroxo-μ-peroxo species. Coordination of veratryl alcohol to the cobalt center followed by insertion of oxygen can also be seen at lower pH, but aldehyde formation does start before adjusting the pH to 12. Increasing temperature considerably enhances the rate of aldehyde production.

Reaction Monitoring Experiments

In our earlier studies it has been shown that substrate concentration strongly affects the activity of the system. It

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was especially noted that the substrate to Co(salen) ratio needs to be high for higher activity.[16] The formation of high amounts of an intermediate, in which the substrate is coordinated to cobalt at high reagent concentrations, can be observed in the ATR-IR spectra. Addition of oxygen slows down the formation of this species and initiates the formation of the aldehyde. At high concentrations of all reagents a oxygen-cobalt species is not observed, whereas at the low concentrations of the UV/Vis experiments oxygen insertion is seen to occur. Thus, to study the influence of oxygen pressure on the reaction at high and low concentrations, reaction-monitoring experiments were performed with a set-up from which samples can be taken during the experiment under higher oxygen pressures. The initial rates of reaction were also calculated.[37] Figure 8 summarizes the results of these experiments. At low concentrations [0.14 mM Co(salen) and 14 mM veratryl alcohol] the reaction rate is about the same under 1 and 10 bar oxygen pressure (Figure 8, experiments **1** and **2,** initial rates of 9.5 and 9.6 TOF_0, respectively[37]). At higher concentrations [0.41 mM Co(salen) and 41 mM veratryl alcohol] oxygen pressure significantly enhances the reaction rate (Figure 8, experiments **3** and **4**, initial rates of 1.8 and 16 TOF_0, respectively).

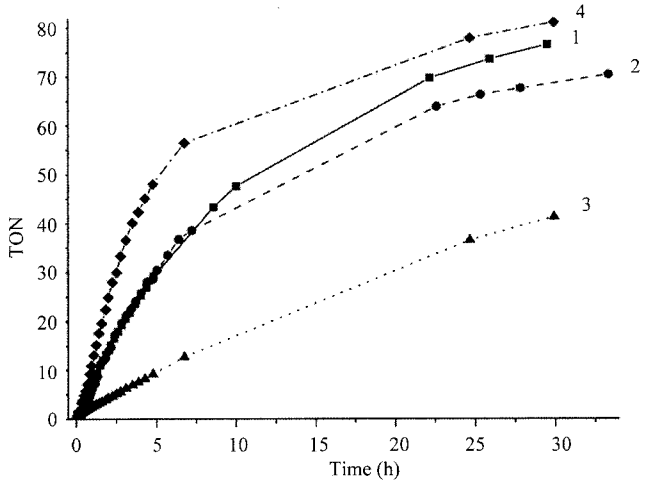

Figure 8. Oxidation activity (expressed as turnover number, TON, the moles of product per one mol of catalyst) at (1) 0.14 mM Co(salen), 14 mM veratryl alcohol and 1 bar oxygen, (2) 0.14 mM Co(salen), 14 mM veratryl alcohol and 10 bar oxygen, (3) 0.41 mM Co(salen), 41 mM veratryl alcohol and 1 bar oxygen and (4) 0.41 mM Co(salen), 41 mM veratryl alcohol and 10 bar oxygen.

Higher catalyst activity at low concentrations and low impact of added oxygen pressure on the catalytic system at low concentrations support the involvement of 2:1 $Co:O_2$ species in the catalytic cycle as the active species. In case of a mononuclear superoxo complex, increasing oxygen pressure should increase the reaction rate.[38]

As we have previously reported, the optimum pH for Co(salen)-catalyzed oxidation of veratryl alcohol is about 12.5.[16] The initial oxidation rate of Co(salen) increases from 5.2 h^{-1} to 9.6 h^{-1} when the pH is increased from 11.2 to 12.4. If the activity and the change in pH of the reaction are monitored simultaneously (Figure 9), it can be seen that the product formation and the OH^- ion consumption proceed hand in hand but no reasonable correlation between the conversions and the change in pH can be deduced.[39] Figure 9 also shows that the decrease in OH^- concentration slows down the reaction rate. Addition of NaOH at the end of a reaction restarts the oxidation activity.[16]

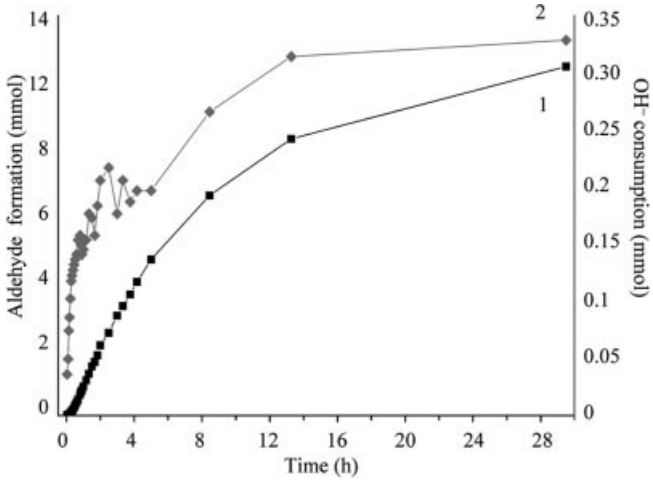

Figure 9. Rate of oxidation and total OH^- consumption in the Co(salen)-catalyzed reaction: (1) Formation of veratraldehyde and (2) consumption of OH^- ions. [0.14 mM Co(salen) and 14 mM veratryl alcohol at pH 11.6[40] and 80 °C] (TON: turnover number).

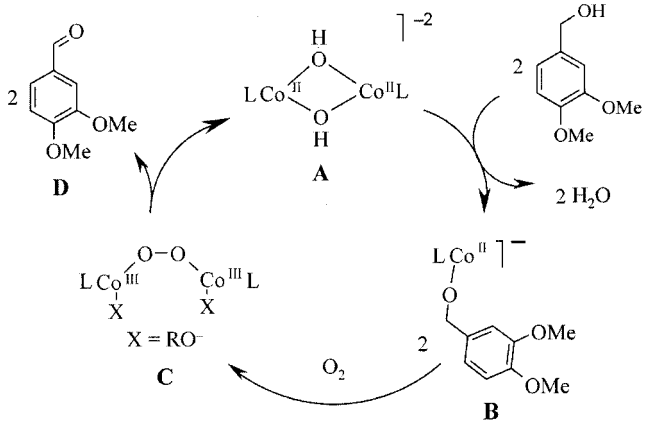
Discussion

Based on the presented results and supported by our earlier studies,[16–17] the oxidation of veratryl alcohol in water catalyzed by Co(salen) and oxygen is suggested to proceed through the steps described in Scheme 2.



Scheme 2. Suggested mechanism for veratryl alcohol oxidation by Co(salen) and dioxygen in alkaline aqueous solution.

The cycle of veratryl alcohol oxidation starts with a bis-μ-hydroxo[Co(salen)]$_2$ complex **A**, which can deprotonate a substrate molecule at temperature higher than 60 °C forming an alkoxo intermediate **B** and water. The intermediate **B** can be observed in the ATR-IR spectra. In the absence of oxygen, this species accumulates in the reaction. After

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

introduction of oxygen, the formation of a nonplanar μ-peroxo bridge between two alkoxy-Co(salen) units can be observed in UV/Vis spectra (intermediate **C**). The peroxo bridge of species **C** abstracts a proton from each substrate and veratraldehyde is formed as a product (**D**).

In the overall reaction, one activated oxygen molecule oxidizes two veratryl alcohol molecules to veratraldehyde, water is produced as the side product and the initial bis-μ-hydroxo[Co(salen)]$_2$ complex is regenerated in the cycle. The rate-limiting step seems to be the detachment of the product molecule. The methoxy substituents in the aromatic ring of veratryl alcohol seem to aid this step.[41] Table 1 summarizes the spectroscopic fingerprints of species **A**–**D**. Below the proposed steps of the mechanistic cycle are discussed in more detail.

Table 1. Spectroscopic fingerprints of species **A**–**D** (sh = shoulder).

Species	ATR-IR [cm^{-1}]	Raman [cm^{-1}]	UV/Vis [nm]
A	984	–	316, 375, 490 sh
B	993	–	339, 392
C	–	–	324, 378
D	1675	1677	308

Formation of Complex A

The reaction does not start before the addition of NaOH, and therefore it is apparent that OH^- ions are directly involved in generating the active species and not only acting as stoichiometric proton acceptors. As the pH gets lower during the reaction, possibly due to the formation of small amounts of veratrylic acid,[16] the concentration of the active species decreases and consequently the reaction rate slows down.

The catalytic activity can be regained by adding NaOH to the solution,[16] which is a clear indication that the active catalytic species is present only at higher pH. It has been shown that at higher pH values the Co(salen) complex exists rather as a hydroxo complex.[35,42] As the pH decreases the concentration of the hydroxo complex also decreases and the reaction slows down, whereas addition of NaOH shifts the equilibrium back towards the hydroxo species and the rate of reaction increases again. At the applied conditions in the beginning of the reaction, it is reasonable to expect, that the Co(salen) hydroxo complex exists most likely as a dimeric bis-μ-hydroxo[Co(salen)]$_2$ species **A**.[35,38,43] This species exhibits a vibration at 984 cm^{-1} (arising from bridging OH groups) and absorption bands at 316 nm and 375 nm with a shoulder at 490 nm.

Formation of the Intermediate B

According to UV/Vis spectroscopy, the substrate can replace the hydroxy group from the first coordination sphere of the cobalt center. This is seen as a shift of the absorption bands at 316 nm and 375 nm to 336 nm and 392 nm after addition of veratryl alcohol to the solution of Co(salen) at pH 12. It was already suggested before, that substrate coordination must be necessary for the reaction to occur as the strongly binding axial bases inhibit the reaction and the high substrate to metal ratio enhances it.[16–17] ATR-IR spectra show clearly that an intermediate species is formed between veratryl alcohol and Co(salen). This intermediate **B** exhibits a strong vibration at 993 cm^{-1} corresponding to the C–O bond of the metal-bound alkoxo group.[24] The vibration at 993 cm^{-1}, however, is observed to accumulate, especially in the absence of oxygen. The rate at which the intermediate **B** forms decreases after introduction of oxygen, as from that point on the aldehyde production starts. Nevertheless, the vibration peak at 993 cm^{-1} still grows. In other words, formation of species **B** is a fast step compared to the formation of species **C** and **D**.

The need of higher reaction temperatures is due to the formation of the alkoxo-metal intermediate **B**. The formation of the strong vibration peak at 993 cm^{-1} is not observed at 60 °C, but at 80 °C it accumulates. Also, a high pH is needed for the vibration 993 cm^{-1} to appear. Coordination of the substrate as an alcohol to cobaltcenter occurs also at low pH, as seen in UV/Vis spectra, but formation of the alkoxo species **B** requires deprotonation of the substrate. This seems to take place only at high temperature and pH, as seen by the appearance of the 993 cm^{-1} peak. UV/Vis spectroscopy shows as well that no aldehyde is formed at temperature below 60 °C and that raising temperature to 80 °C dramatically increases the rate of the reaction. Thus, the rate of reaction is dependent on the rate at which the substrate deprotonates and forms the intermediate **B**.

Formation of the Intermediate C

As discussed above, the introduction of oxygen atmosphere is needed to start the production of aldehyde.[34] UV/Vis spectra show shifts in the absorption bands of cobalt after addition of oxygen to a solution formerly under argon. These shifts suggest a formation of a peroxo bridge between two Co(salen) complexes.[30–32] Absorptions at 300 nm and 380 nm are observed when oxygen is added to a solution of Co(salen) and veratryl alcohol at low pH (below 10). Aldehyde production does not start in this solution before addition of NaOH. When oxygen is added to a solution of Co(salen) and veratryl alcohol at pH 12, absorption bands form at 324 nm and 392 nm. These absorptions are defined as arising from monobridged μ-peroxo complexes.[30,33] Thus, it is apparent that an oxygen bridge forms between two Co(salen) complexes under these reaction conditions and that the formation of the intermediate **C** is needed for the aldehyde production to start. A similar species has been reported in the oxidation of benzyl alcohol by $Co^{II}(bipy)_2$ complexes.[44]

The charge and geometry of the oxygen-bridged complex should be observable from the ATR-IR and Raman spectra. Superoxo and peroxo bridges exhibit vibrations at frequency ranges of 1100–1200 cm^{-1} and 760–920 cm^{-1}, respectively.[24] Nevertheless, no vibration peaks are ob-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

served to form in these regions in neither ATR-IR nor Raman spectra. The reason arises from the effect of concentration on the activity of the system. At the high concentrations needed for the ATR-IR and Raman measurements, the oxidation activity is quite low without an added oxygen pressure, as seen in Figure 8. The intermediate **B** forms in high amounts in these conditions and it could be regarded as a "dormant" species, whenever there is not enough oxygen to take the reaction further. Therefore, at the conditions of ATR-IR and Raman measurements the concentration of the oxygen-bridged species **C** is too low to be observed. However, the UV/Vis spectra are recorded at low concentrations and in these spectra the oxygen-bridged species **C** can easily be observed.

According to the literature, the peroxo bridge most probably forms through a mononuclear superoxo complex.[8,12] Oxygen molecule binds first to one cobalt center as a superoxo radical, which then binds to another cobalt complex forming a peroxo species. At these reaction conditions the dinuclear species is more stable and it forms fast. Thus the superoxo complex is so short-lived that it cannot be observed with the applied spectroscopic methods.

The Rate-Limiting Step

Alkoxo-metal species as a reaction intermediate have also been suggested for Co complexes mimicking horse liver alcohol dehydrogenase. In these reactions the product dissociation from the metal center was observed to be the rate-limiting step.[45] This is apparently also the case for the reaction under study. We have observed that a alkoxo-metal species similar to intermediate **B** is also formed in the reaction of Co(salen) with benzyl alcohol, although benzaldehyde is not produced by this system.[41] Thus, the reaction with benzyl alcohol seems to stop at the intermediate **B**, while with veratryl alcohol the aldehyde production starts directly after oxygen is introduced to the system. Thus, the methoxy substituents in veratryl alcohol aid the detachment of the product from the Co(salen) complex. Moreover, no alkoxo-metal intermediate is observed in the ATR-IR spectra of a similar system, in which (phenanthroline)copper-type [Cu(phen)] complexes are used as catalysts.[46] These complexes are more active than Co(salen) and can also catalyze the oxidation of benzyl alcohol to some extent. This implies that the alkoxo-metal intermediate is less stable or that such species does not even form in the Cu(phen)-catalyzed system.[23,46] The detachment step is preceded by abstraction of a hydrogen from the coordinated alkoxyl by the peroxo bridge. Thus, the methoxy substituents can be involved in making the α-H in the benzylic position more labile and easier to abstract.

The Regeneration of Complex A

High pH is needed to generate the bis-μ-hydroxo[Co(salen)]$_2$ species **A**, which can deprotonate the substrate. It seems that the overall OH^- consumption and alcohol oxidation are closely related, but the molar ratio of formed aldehyde and OH^- ions consumed varies from tens to hundreds.[16,39] This indicates that actually only a few substrate molecules are deprotonated by OH^- ions or that the OH^- ions are recovered during the reaction cycle. The latter suggestion supports the idea, that peroxo-bridged species **C** regenerates the bis-μ-hydroxo[Co(salen)]$_2$ species by abstracting a hydrogen from each of the two coordinated substrate molecules. Therefore, after initiation no "external" hydroxide ions are consumed in the reaction. Nevertheless, if the pH gets too low due to small amount veratryl acid formed as a side-product, the cobalt complex prefers to stay as a peroxo-bridged species **C** and the reaction stops. Thus addition of NaOH increases the reaction rate as it enhances the deprotonation step and keeps the species **A** as the dominating species in the solution.

A drawback of the Co(salen) catalytic system is that it suffers from irreversible oxidation. We have observed that this system can stay active for about 72–96 h, after which there is no more oxidation occurring even with further addition of NaOH. Thus, there is all the time a competing mechanistic path present, which causes the catalyst to deactivate. This could occur via the formation of doubly bridged μ-hydroxo-μ-peroxo species, which can be very stable.[35] UV/Vis spectra show a transformation in the bridging type of the oxygen complex from singly bridged peroxo towards a doubly bridged species. The presence of the substrate seems to protect the complex from deactivation. The activity is higher if the substrate to Co(salen) ratio is kept high.[16] Possibly, the coordinated substrate can prevent the insertion of a second bridge between cobalt centers. Careful balancing of the reaction conditions can minimize the damage caused by deactivation. For example, keeping the Co(salen) concentration low and veratryl alcohol concentration high dramatically improves the lifetime of the catalyst.[16]

Conclusions

The activities of transition-metal complex-catalyzed alcohol oxidations have remained low, normally in the order of TOF = 10 h^{-1} or less,[47] and therefore it is imperative to study the mechanisms of these reactions to be able to develop more active systems. In this work, the mechanism of Co(salen)-catalyzed oxidation of veratryl alcohol in alkaline aqueous solution was investigated in detail by in-situ spectroscopy. It was shown, that the combination of complementary in-situ spectroscopic techniques is a powerful approach to study a complicated catalytic system.

The obtained data support strongly a mechanism, in which substrate coordination is a key step in the catalytic cycle. Deprotonation and coordination of the substrate have been suggested before as reaction steps in similar systems, but direct proof is hard to find. Combination of in-situ UV/Vis and ATR-IR spectroscopy show, that veratryl alcohol is located in the coordination sphere of cobalt already at low pH values, but deprotonation and consequent alkoxo-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cobalt intermediate formation occurs only at pH 12 and above. The spectroscopic data also suggests that a dinuclear μ-peroxo[Co(salen)]$_2$ complex is involved in this oxidation reaction instead of the mononuclear superoxo-Co(salen) complex, which is usually assumed to be responsible for catalytic activity. The mononuclear superoxo complex can still be formed initially, but its lifetime is too short to be observed. Nevertheless, the effect of reaction conditions presented in earlier papers point strongly to the dinuclear peroxo species over the mononuclear superoxo complex as the active intermediate in the catalytic cycle of this particular reaction.[16–17] Thus, both the optimum reaction conditions and the spectroscopic data support the mechanism described in Scheme 2. Further studies with different benzylic alcohols can give more insight into the effect of substituents on the rate-limiting step. Also, additional spectroscopic methods, such as EXAFS, could give further evidence for the involvement of the dinuclear species in this reaction.

Experimental Section

Co(salen) (**1**) was purchased from Aldrich and used as received without further purification. 3,4-Dimethoxybenzyl alcohol (veratryl alcohol) was purchased from ACROS and Aldrich in 97% purity. The 3% impurity is veratraldehyde, which has been taken into account when calculating conversions and turnover numbers. 1,4-Dioxane, 3,4-dimethoxybenzaldehyde and 3,4-dimethoxybenzylic acid were purchased from Aldrich and used as received. The oxygen gas was obtained from AGA in Finland and from Hoek–Loos in The Netherlands and had a purity of 99%. Online ATR-IR spectra were recorded with a Mettler Toledo ReactIR™1000 spectrometer with a DiComp™ probe, which was fitted in a 100-mL two-neck round-bottomed flask containing the reaction solution. The measurements were done with a scan program of 128 scans per measurement at selected intervals with a resolution of 4 cm^{-1}. The wavelength range covered was 650–4000 cm^{-1}. The diamond absorption prevents to observe any vibrations at a wavelength range of 1900–2400 cm^{-1}. A more detailed description of the ATR-IR setup and the procedure of the oxidation experiments is presented elsewhere.[16–17,21] The solvent used in all ATR-IR experiments was a water/dioxane mixture (5:1) at 80°C, which was in all cases subtracted as the background. The amounts of reagents varied, and therefore their exact concentrations are specified at the appropriate sections of this paper or in relevant Figure captions. Oxygen was installed by the balloon technique.[16] All reagents were degassed and under argon when working in the absence of oxygen. The IR spectra were analyzed with the program ReactIR 2.2. The UV/Vis spectra were recorded with a Varian CARY50 spectrometer equipped with an optical fibre and an insertion probe with variable path lengths. The same procedure for the oxidation experiments was used as with the ATR-IR technique. The Raman spectra were recorded with a Kaiser RXN dispersive system with a Peltier element-cooled Andor CCD camera for detection and a laser of 532 nm (60 mW). In these experiments, the reaction was monitored from the outside of the glass flask by using a laser objective. The resolution was about 2 cm^{-1} and 10 scans were accumulated with an exposure time of 15 s. The reaction monitoring experiments were performed in a 500-mL glass vessel equipped with a magnetic stir-bar fitted inside a 1-L steel autoclave. 200 mL of 0.05 M NaOH (pH, 12.4) was used as solvent. Depending on the experiment, 86.9 mg (0.275 mmol) or 269 mg (0.83 mmol) of Co(salen) was used. Veratryl alcohol was added in 100:1 molar ratio to Co(salen). The autoclave was placed in an oil bath and the reaction mixture was stirred at 80 °C under 10 bar of oxygen pressure. Samples were cooled to room temperature and prepared for GC analysis by a method described earlier.[23] GC measurements were conducted with a GC/Fid Agilent 6890N instrument using a HP-5 (30 m × 320 μm × 0.25 μm) capillary column and equipped with a FID detector.

[36] The commercial veratraldehyde exhibits absorption maxima at 268 nm and 308 nm with a shoulder at 290 nm. Veratrylic acid shows absorption maximum at 250.4 nm with shoulders at 295 nm and 330 nm.
[37] The initial oxidation rates were calculated from the derivatives at time zero for the functions presenting the conversion of the aldehyde as a function of time. These functions were obtained from the linear fit for the conversion points as a function of time during the first 10% of aldehyde formation. The rate of the reaction decreases after the conversion of aldehyde is over 15%. The slope of the plot was multiplied with the substrate/metal molar ratio to get result in the form of TON/h = TOF (1/h).

[39] If the reaction is monitored according to the consumption of hydroxide ions vs. amount of aldehyde produced, more than ten equivalents of aldehyde is formed per consumed OH^- ion. For example, in an overall reaction in which pH decreased from 11.2 to 10.0, 30 moles of aldehyde was produced per 1 mol of hydroxide consumed.
[40] In these reactions initial pH 11.6 (0.005 M NaOH) was applied, as even modern pH electrodes seem to be too inaccurate for such a study in pH higher than 12.
[41] Although unsubstituted benzyl alcohol is not oxidized by this catalytic system, the vibration peak at 993 cm^{-1} is also visible in the corresponding ATR-IR spectra.

Synthesis, Structural, and Magnetic Characterization of $YCrMnO_5$

José A. Alonso,*[a] María J. Martínez-Lope,[a] María T. Casais,[a] José L. Martínez,[a] and Vladimir Pomjakushin[b]

Keywords: Magnetic properties / Ferrimagnetic ordering / High-oxygen-pressure synthesis / Crystal structure refinement / Neutron powder diffraction / X-ray diffraction

A new oxide of nominal stoichiometry $YCrMnO_5$ has been prepared in polycrystalline form by wet-chemistry procedures followed by thermal treatments under high-oxygen-pressure conditions. This material has been characterized by X-ray and neutron powder diffraction (NPD), magnetotransport and magnetization measurements. $YCrMnO_5$ is isostructural with RMn_2O_5 oxides (R = rare earths); its crystal structure has been Rietveld refined from NPD data in the space group *Pbam*, and it contains infinite chains of $(Cr,Mn)^{4+}O_6$ octahedra sharing edges, linked together by $(Mn,Cr)^{3+}O_5$ pyramids and YO_8 units. An important level of cationic disorder has been found between both metallic sites; the refined crystallographic formula is $Y[Mn_{0.47(1)}Cr_{0.53(1)}]_{oct}$-$[Cr_{0.37(1)}Mn_{0.63(1)}]_{pyr}O_5$. The magnetic susceptibility indicates the onset of magnetic ordering below $T_c \approx 85$ K; the magnetization isotherms are characteristic of a weakly ferrimagnetic material reaching a net magnetization of 0.25 μ_B/f.u. for $H = 50$ kOe. Low-temperature NPD patterns do not exhibit any additional magnetic contribution, confirming that a long-range magnetic ordering is not fully established.

Introduction

The family of RMn_2O_5 (R = rare earths) oxides was first described in the 1960s by Bertaut et al.,[1,2] that already recognized the extraordinary flexibility of the structure with regard to the substitutions of both R and Mn atoms allowing, for instance, the preparation of $RMnTiO_5$ phases. Some RMn_2O_5 materials have recently been revisited since they are among the few oxides that show a significant magneto-ferroelectric effect,[3–7] which implies a coupling between ferroelectricity and magnetic order in the system: the application of an external magnetic field leads to the appearance of an electrical polarization. The orthorhombic crystal structure of RMn_2O_5 (space group *Pbam*) is very interesting, since it contains infinite chains of $Mn^{4+}O_6$ octahedra, linked through $[Mn^{3+}O_5]$ pyramidal units and bicapped antiprisms $[RO_8]$. The shortest metal–metal distance seen in this family is Mn1–Mn1 = 2.750(2) Å in the Nd compound. Important implications on the physical properties of these oxides can be presumed from such short distances. RMn_2O_5 compounds are antiferromagnets at low temperatures,[8] and the magnetic structures, studied from neutron diffraction data, are rather complex and incommensurate with the chemical unit cell.[9] For most of these oxides, the magnetic structure is defined by the propagation vector $k = (1/2,0,\tau)$, with τ depending on the type of R.[10,11] The ordering of the Mn ions is helicoidal, and the magnetic moments are contained on the *ab* plane. The rare-earth ions also become ordered at lower temperatures according to a sinusoidal magnetic structure. The magnetic structure was subsequently revisited for R = Er and Tb,[12] and Dy,[13] and it seems that the amplitude of the moments for the Mn ions is also modulated. Exceptionally, $BiMn_2O_5$[9,14] and $LaMn_2O_5$[15] display a commensurate magnetic arrangement, defined by the propagation vectors $k = (1/2,0,1/2)$ and $k = (0,0,1/2)$, respectively.

With the aim to induce new magnetic interactions in the members of the RMn_2O_5 family, we recently designed and prepared $YFeMnO_5$,[16] which is obtained by replacing Mn^{3+} by Fe^{3+} in YMn_2O_5. A NPD study complemented with magnetic measurements demonstrated that $YFeMnO_5$ is a ferrimagnet below $T_c \approx 165$ K, and is characterized by the propagation vector $k = 0$.[16] This is the first reported member of a novel $RFeMnO_5$ (R = rare earths) series, where Mn^{4+} occupies the octahedral positions, whereas Fe^{3+} is placed at the pyramidal sites of the structure. In this paper we report on the preparation of a new material with stoichiometry $YCrMnO_5$, which is isostructural with the RMn_2O_5 compounds and is obtained by substitution of Cr by Mn cations. This oxide must be prepared under high O_2 pressure, and it has been characterized, from the structural point of view, from NPD data, complemented with macroscopic magnetic susceptibility and transport measurements.

Results

Preparation

$YCrMnO_5$ was obtained as a dark brown, polycrystalline powder. The preparation from the precursor powders requires the presence of moderate O_2 pressures in order to partially oxidize Mn and Cr to the tetravalent oxidation states. The presence of the competitive $YMnO_3$ perovskite, nominally containing Mn^{3+}, was minimized with thermal treatments under O_2 pressure. The final O_2 pressure is an important parameter, which was tuned after several unsuccessful trials: treatments at O_2 pressures above 55 bar led to an increase in the competitive $YCrO_4$ phase, which contains Cr^{5+}. Further, the use of finely divided and homogeneous precursors was found to be extremely important for a successful synthesis: the oxygenation process and the formation of the complex oxide are favoured by the use of reactive and homogeneous precursors. Figure 1 shows the XRD pattern of $YCrMnO_5$. It can be indexed in an orthorhombic unit cell, isotypic to RMn_2O_5, with no additional peaks that could indicate the presence of superstructures or departure from the mentioned symmetry. Minor impurities of the competitive $YMnO_3$ and $YCrO_4$ phases were always identified in the patterns.

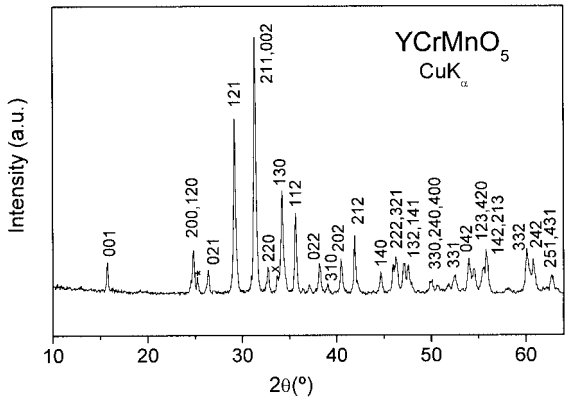

Figure 1. XRD pattern of $YCrMnO_5$, indexed in an orthorhombic unit cell with a = 7.2335(5) Å, b = 8.4953(5) Å, and c = 5.7069(4) Å. The star and the cross indicate the most intense reflections of $YCrO_4$ and $YMnO_3$, respectively.

Magnetic Measurements

The thermal variation of the *dc* susceptibility is shown in Figure 2. The magnetic susceptibility undergoes a remarkable increase below 100 K, revealing the onset of a magnetic transition at $T_C \approx 85$ K, determined from the susceptibility derivative, and an additional abrupt increment below 10 K. A linear Curie–Weiss fit in the high-temperature range 200–400 K gives a Weiss constant of $\theta_{Weiss} = -113(8)$ K, suggesting the presence of strong antiferromagnetic correlations, and an effective moment $\mu_{eff} = 5.60\ \mu_B$/f.u. In order to make clear the nature of the magnetic transitions, isothermal magnetization curves have also been measured. As can be seen in Figure 3, a hysteresis cycle is observed in the magnetization curves at 20 and 1.7 K, indicating the presence of a ferromagnetic component; in particular, at T = 1.7 K, the magnetization reaches 0.25 μ_B/formula at 50 kOe. The absence of saturation of the magnetic moments for the highest applied magnetic fields (50 kOe) is characteristic of ferrimagnetic materials or strongly canted ferromagnets. Above T_C, the magnetization curves at 150 K and 250 K present a linear behavior, corresponding to a paramagnetic state.

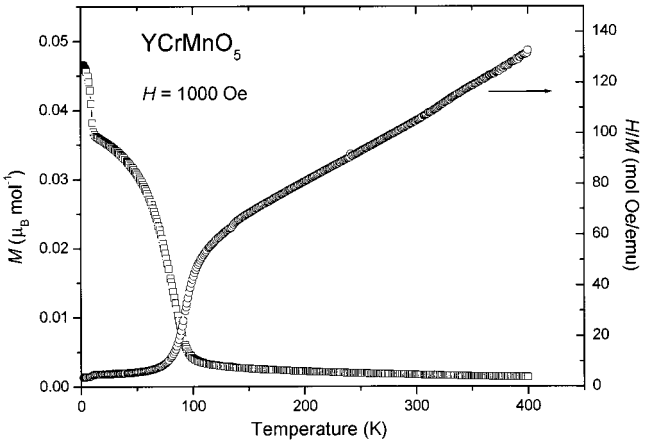

Figure 2. Thermal evolution of the magnetic susceptibility measured under a 1-kOe magnetic field. The right axis corresponds to the reciprocal susceptibility.

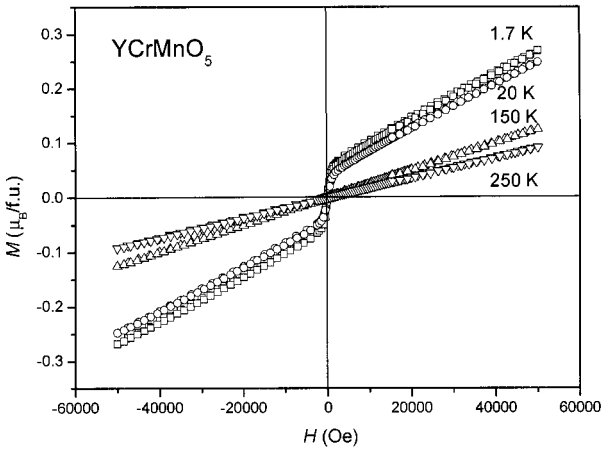

Figure 3. Isothermal magnetization curves.

Transport Properties

The temperature dependence of the electrical resistivity is shown in Figure 4. A semiconducting behavior is observed in the temperature range 160–385 K. A considerably high resistivity of $10^4\ \Omega$cm is observed at room temperature; below 160 K, the resistivity increases above $5 \times 10^6\ \Omega$cm and falls out of the measuring range of our equipment. The plot of ln ρ is linear with the reciprocal temperature, suggesting a thermally activated behavior; an Arrhenius fit gives an activation energy of 0.30 eV. The application of an external magnetic field of up to 90 kOe did not show any significant change in the resistivity, which ex-

cluded the presence of magnetoresistance in the measured temperature range, well above T_C.

Room-Temperature Neutron Diffraction: Crystallographic Structure

The crystallographic structure has been refined from the NPD pattern acquired at room temperature with wavelength $\lambda = 1.494$ Å. The pattern was fitted in the orthorhombic space group *Pbam*, with unit-cell parameters $a = 7.2335(5)$ Å, $b = 8.4953(5)$ Å and $c = 5.7069(4)$ Å. The crystal structure of $NdMn_2O_5$ was used as a starting model.[17,18] In the first refinement, Y atoms were placed at 4*g* (*x*,*y*,0) positions, Mn at 4*f* (0,½,*z*) sites, Cr at 4*h* (*x*,*y*,½) positions, and the four crystallographically independent oxygen atoms at 4*e* (0,0,*z*), 4*g*, 4*h* and 8*i* (*x*,*y*,*z*) positions. An unsatisfactory agreement between the calculated and observed patterns was found for this atomic distribution, leading to a discrepancy R_{Bragg} factor of 15%. The presence of antisite disorder between Cr and Mn cations was then checked; the refinement improved considerably, reaching a R_{Bragg} of 4.65%: In fact, the degree of antisite disordering was found to be extremely important in this sample, as shown in Table 1. In the final refinement, the partial occupancy of Cr/Mn at 4*f* and 4*h* positions was decoupled, allowing for the independent refinement of the occupancy factor at both sites; by doing so, the final refined stoichiometry was somewhat different to the nominal Cr/Mn = 1:1 composition, but the quality of the final refinement warrants the validity of this result. The refined crystallographic formula can be written as $Y[Mn_{0.47(1)}Cr_{0.53(1)}]_{4f}[Cr_{0.37(1)}Mn_{0.63(1)}]_{4h}O_5$, which corresponds to an empirical formula $YCr_{0.90(1)}Mn_{1.10(1)}O_5$. It is worth emphasizing that the refinement of the mixed occupancy factors of Cr and Mn over the same crystallographic site, which would be unfeasible by X-ray diffraction, is very precise by neutron diffraction given the opposite values of the scattering lengths for Cr (3.635 fm) and Mn (–3.73 fm). By the same reason, and given the comparable amounts of Cr and Mn found in both sites, the average scattering length of both sites is very weak, and the error in the determination of the corresponding positions and thermal factors is huge. As a result, in the final refinement, we fixed the positions to those determined by X-ray diffraction for both the 4*f* and 4*h* sites, and the thermal factors were fixed to 0.3 Å^2. The main structural parameters obtained in the fit are presented in Table 1. A selection of the most important atomic distances and angles is listed in Table 2. The goodness of the fit after the Rietveld refinement from the NPD data is displayed in Figure 5. The two minor impurities $YCrO_4$ (space group $I4_1/amd$, ref.[19]) and $YMnO_3$ (space group *Pbnm*, ref.[20]) were included in the refinement as second and third crystallographic phases;

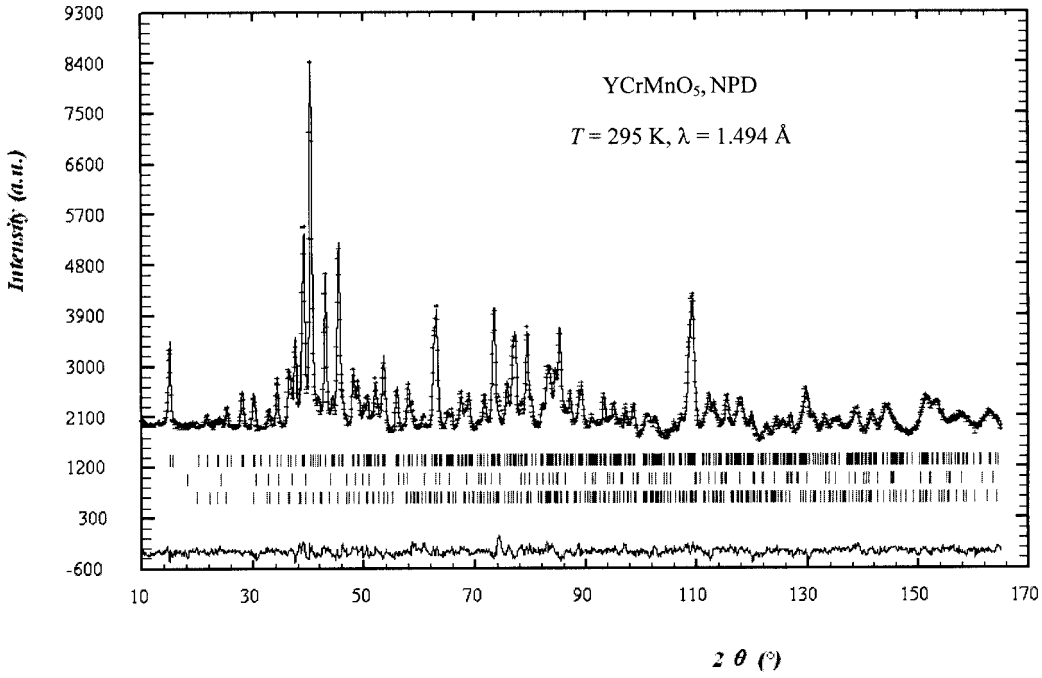

Figure 5. Observed (crosses), calculated (solid line) and difference (bottom line) NPD patterns at room temperature. The second and third series of Bragg positions correspond to the minor impurities $YCrO_4$ and $YMnO_3$, respectively.

from the scale factors, an amount of 1.34% and 2.03% of both impurities was estimated, respectively.

A view of the crystallographic structure along the *c* axis is displayed in Figure 6. There are two different oxygen environments for the atoms that occupy the 4*f* and 4*h* sites. At the 4*f* site, the $(Cr,Mn)^{4+}$ ions are inside the $M^{4+}O_6$ distorted octahedra, whereas at the 4*h* site, the $(Mn,Cr)^{3+}$ ions form $M^{3+}O_5$ distorted tetragonal pyramids. We assume that the Mn and Cr cations at the octahedral positions adopt a tetravalent oxidation state, whereas the metals at the pyramidal positions adopt a trivalent oxidation state, in order to preserve the electroneutrality of this oxide. Notice that the octahedral 4*f* positions are about half occupied by Cr and Mn, whereas the pyramidal 4*h* are about 2/3 occupied by Mn, probably because this irregular environment is well suited for the Jahn–Teller Mn^{3+} cation. The pyramids share edges to form dimer units M_2O_{10}, linked through O1 oxygen atoms. The structure contains infinite chains of $M^{4+}O_6$ octahedra, which share edges through the O2 and O3 oxygen atoms, that run along the *c* axis. The different chains of $M^{4+}O_6$ are interconnected through the M_2O_{10} pyramidal dimer units through the O3 and O4 oxygen atoms.

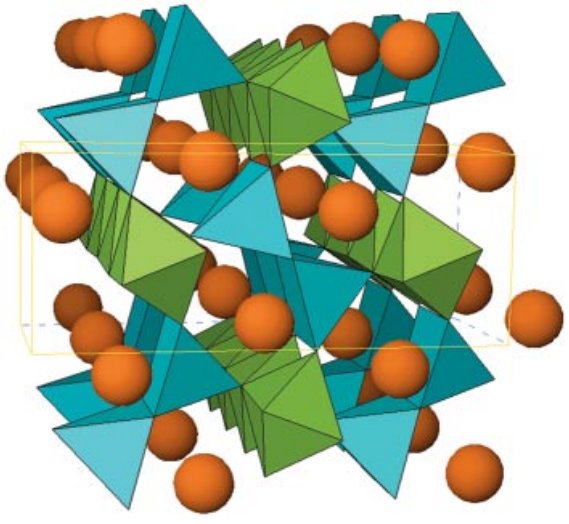

Figure 6. A view of the crystallographic structure of $YCrMnO_5$, approximately along the *c* axis. Octahedra (green) and tetragonal (turquoise) pyramids correspond to $(Cr,Mn)^{4+}O_6$ and $(Mn,Cr)^{3+}O_5$ polyhedra, respectively. Octahedra share edges, forming infinite chains along the *c* axis. Pyramids form dimer units, linking together the chains of the octahedra. Orange spheres represent the Y atoms.

Low-Temperature Neutron Diffraction Refinements

Three neutron diffraction patterns were collected below room temperature, with the hope of gaining information about the arrangement of Mn and Cr spins below the ordering temperature, T_C = 90 K. However, the low-temperature patterns collected at T = 1.5 K and 20 K did not contain any additional information, extra peaks or additional intensity on low angle Bragg reflections that could be attributed to the establishment of a long-range, ordered magnetic structure; the three patterns collected with λ = 1.886 Å could be perfectly refined by considering the crystal structure alone, with the expected shifts in unit-cell parameters and thermal factors. The upper limit of the ordered magnetic moments was determined from a simulation of a ferrimagnetic structure involving both magnetic sublattices. For the *Pbam* space group, there are two ferromagnetic Shubnikov groups: *Pb′a′m* and *Pb′am′*. The 4*f* and 4*h* sites have

symmetries 2 and *m*, respectively. This means that the admissible moment directions for both sites are along the *z* axis for *Pb′a′m*, and perpendicular to the *z* axis for *Pb′am′*. After trying both possibilities, the estimation for the upper limit was found to be similar in both cases, $\mu < 0.4\ \mu_B$. Table 3 lists the main structural parameters after the refinement. Figure 7 illustrates the quality of the Rietveld fit at 1.5 K; the main crystallographic phase and the two minor impurity phases, $YCrO_4$ and $YMnO_3$, are considered in the same way as those in the room temperature refinement.

Discussion

$YCrMnO_5$ is derived from the parent YMn_2O_5 oxide (containing one Mn^{3+} and one Mn^{4+} cation per formula) by full replacement of approximately half the Mn atoms by Cr atoms. The crystal structure of $YCrMnO_5$, refined from NPD data, is closely related to that of RMn_2O_5 oxides, as expected from the comparable ionic sizes for Cr^{3+} and Mn^{3+} (0.615 and 0.645 Å, respectively), and Mn^{4+} and Cr^{4+} (0.53 and 0.55 Å, respectively) in a sixfold coordination and in the high-spin state for both cations.[21] Since no structural details on the parent YMn_2O_5 have been reported, a comparison can be established with the crystal structure of $HoMn_2O_5$,[8] given the similarity in the ionic sizes of Y^{3+} (1.019 Å) and Ho^{3+} cations (1.015 Å) in an eightfold coordination.[23] In $HoMn_2O_5$ (and other RMn_2O_5 compounds), the $Mn^{4+}O_6$ octahedra are fairly flattened,[8,19] with two bonds significantly shorter than the remaining four bonds [e.g. a Mn1–O3 bond length of 1.836(8) Å for the Ho compound]; the average Mn–O distance is 1.902 Å. The same configuration is observed in $YCrMnO_5$, although

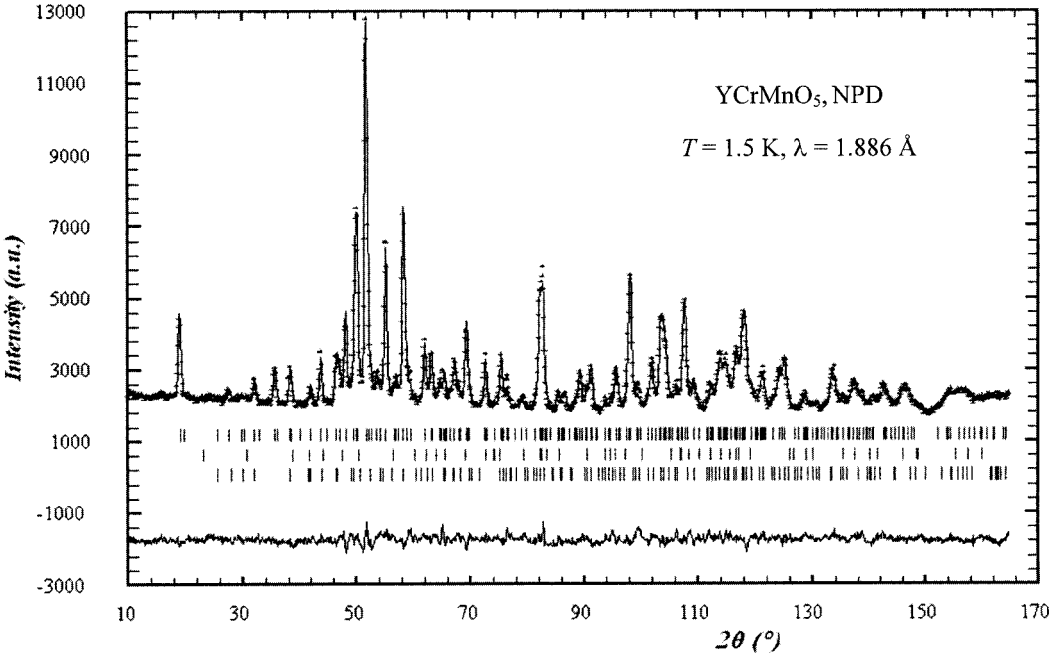

Figure 7. Observed (crosses), calculated (solid line) and difference (bottom line) NPD patterns for *T* = 1.5 K. The three series of Bragg positions correspond to $YCrMnO_5$, $YCrO_4$, and $YMnO_3$, respectively.

the individual and average $(Cr,Mn)^{4+}$–O distances are slightly longer, scaling with the greater size of Cr^{4+} cations; the average bond length is 1.927 Å. With regard to the tetragonal pyramids, $(Mn,Cr)^{3+}O_5$, the equatorial (Mn,Cr)–O1 and (Mn,Cr)–O4 bond lengths (forming the square basis of the pyramid) are similar to the corresponding Mn–O distances in the $Mn^{3+}O_5$ units of the RMn_2O_5 compounds, whereas the axial (Mn,Cr)–O3 bond length [1.932(8) Å] is shorter than that observed in $HoMn_2O_5$, where the Mn^{3+}–O3 bond in the axial position is the longest one in the $Mn^{3+}O_5$ pyramid [2.024(8) Å]. This is probably related to the Jahn–Teller character of Mn^{3+} cations, favoring an increase in the axial bond lengths in the $Mn^{3+}O_5$ pyramids, in contrast with the non-Jahn–Teller character of Cr^{4+} ($3d^5$ configuration). With respect to the oxygen coordination of the Y^{3+} cations, it can be described as $Y^{3+}O_8$ bicapped prisms, with average <Y–O> distances of 2.387 Å, which are in good agreement with the <Ho–O> bond lengths of 2.381 Å observed in $HoMn_2O_5$.

One of the most remarkable features of $YCrMnO_5$ is the high degree of antisite disordering exhibited by this compound, which implies that the octahedral positions are occupied by roughly 50% of Mn and Cr cations, and the pyramidal groups contain two thirds Mn and one third Cr cations. This feature could only be unraveled by a neutron diffraction study, thanks to the contrasting neutron scattering lengths of Cr and Mn. The trend of Cr and Mn cations sharing the same crystallographic positions is opposite to that found in $YFeMnO_5$, where a clear preference of Mn^{4+} for the octahedral positions and Fe^{3+} for the tetrahedral sites was observed.[16] The reason of this difference could be found in the relative ease of Cr vs. Fe to adopt the tetravalent oxidation state for incorporation into the octahedral positions.

The Cr/Mn antisite disordering has a dramatic influence on the magnetic properties of $YCrMnO_5$. It shows a ferromagnetic-like behavior, with $T_C \approx 85$ K and a weak magnetization at 1.7 K of 0.25 μ_B/f.u. for $H = 50$ kOe. This is reminiscent of the ferrimagnetic behavior determined for $YFeMnO_5$, which shows a superior magnetic ordering temperature of $T_C \approx 165$ K, and a saturation magnetization at low temperatures of 0.81 μ_B/formula: In $YFeMnO_5$, a NPD study demonstrated that Mn and Fe magnetic moments, at the 4*f* and 4*h* crystallographic sites of the *Pbam* space group, respectively, lie along the *z* direction and are antiferromagnetically coupled, giving rise to a global ferrimagnetic structure. Assuming a ferrimagnetic coupling between the magnetic moments at the octahedral and pyramidal positions in $YCrMnO_5$, the net magnetization could vary from zero for the hypothetical composition $YCr^{3+}Mn^{4+}O_5$ ($S = 3/2$ for Cr^{3+}; $S = 3/2$ for Mn^{4+}) to 2 μ_B/f.u. for the hypothetical $YCr^{4+}Mn^{3+}O_5$ ($S = 1$ for Cr^{4+}; $S = 2$ for Mn^{3+}) stoichiometry. Given the actual level of antisite disordering found by neutron diffraction, the net magnetization for ferrimagnetic ordering between octahedral and pyramidal positions in $Y[Mn_{0.47(1)}Cr_{0.53(1)}]_{oct}[Cr_{0.37(1)}Mn_{0.63(1)}]_{pyr}O_5$ would be of 1.16 μ_B/f.u.: This is significantly higher than that found experimentally. This fact, together with the absence of magnetic reflections in the neutron diagrams collected below T_C (at 1.5 and 20 K) demonstrate that there is only a partial long-range magnetic ordering, giving rise to ordered moments below the detection limit of the neutron diffraction technique (0.5–1 μ_B). The random occupancy of both octahedral and pyramidal positions by Cr and Mn cations hinders the establishment of a full long-range ferrimagnetic ordering between both magnetic sublattices below $T_C \approx 85$ K. For the same reason, the NPD technique does not provide any insight on the nature of the second anomaly observed in the susceptibility curve below 10 K; this probably results from a spin reorientation in the complex system, although an effect coming from the observed impurities cannot be disregarded.

Conclusions

We describe a new oxide obtained by replacing Mn by Cr in the parent YMn_2O_5 compound. The crystal structure of $YCrMnO_5$ is isotypic with that of RMn_2O_5 materials (space group *Pbam*), and contains chains of edge-linked $(Cr,Mn)^{4+}O_6$ octahedra connected by dimer groups of square pyramids $(Mn,Cr)^{3+}O_5$. A feature of the Cr compound is that the square pyramids are not elongated, showing shorter axial distances relative to the $Mn^{3+}O_5$ pyramids in RMn_2O_5. $YCrMnO_5$ is semiconducting with a large room-temperature resistivity; the magnetic susceptibility reveals the onset of a ferrimagnetic structure below $T_c \approx 85$ K. The low-temperature NPD patterns do not show any magnetic contribution, indicating that a full long-range magnetic ordering is not established down to 1.5 K, although the presence of ferrimagnetic interactions between two distinct sublattices are clearly displayed in the magnetization curves.

Experimental Section

$YCrMnO_5$ was prepared in polycrystalline form from citrate precursors obtained by a wet-chemistry procedure. Stoichiometric amounts of analytical grade Y_2O_3, $Cr(NO_3)_3{\cdot}9H_2O$, and $MnCO_3$ were dissolved in citric acid; the solution was evaporated slowly, leading to an organic resin which was dried at 120 °C and decomposed at temperatures of up to 600 °C in air. High oxygen pressure treatments were performed in a VAS furnace. About 2 g of the precursor powder was contained in a gold can during the oxygenation process. The sample was slowly heated up to 900 °C at a final pressure of 55 bar, and held at this temperature for 12 h. The product was finally cooled, under pressure, down to room temperature at 300 °C h^{-1}. Finally, the oxygen pressure was released.

The dc susceptibility measurements were performed in a commercial SQUID magnetometer. They were obtained under a 1 kOe magnetic field under field-cooling conditions and for the temperature interval $1.8 < T < 400$ K. Different isothermal magnetization curves were measured under magnetic fields ranging from –50 kOe to 50 kOe and at $T = 1.7$, 20, 150, and 250 K. Transport measurements were performed by the conventional four-probe technique in a pellet sintered under the synthesis conditions (900 °C under 55 bar O_2). Magnetotransport measurements were carried out un-

der magnetic fields of up to 90 kOe in a PPMS system from Quantum Design.

Neutron powder diffraction (NPD) diagrams were collected with the high resolution HRPT diffractometer of the SINQ spallation source, at the Paul Scherrer Institute, Villigen, Switzerland. The sample (2 g) was packed in a cylindrical vanadium holder with a 6-mm diameter. The room temperature pattern was collected with a wavelength of 1.494 Å. The sample was then cooled down in an orange cryostat, and three patterns were collected at 1.5, 20, and 120 K with a wavelength of 1.886 Å. In all cases, the high-intensity mode was used; the collection time was 4 h per diagram. The neutron diffraction patterns were analyzed with the Rietveld method,[22] using the FULLPROF program.[23] For the refinement of the profile, a pseudo-Voigt function was used to simulate the peak shape, and the background was fitted with a fifth-degree polynomial function. The coherent scattering lengths for Y, Cr, Mn, and O were, 7.75, 3.635, –3.73, and 5.803 fm, respectively. In the final run, the following parameters were refined: Background coefficients, zero-point, half-width, pseudo-Voigt, and asymmetry parameters for the peak shape; scale factor, positional, thermal factors, and unit-cell parameters.

Acknowledgments

Keywords: Molybdenum / S ligands / X-ray diffraction / Coordination modes

The tris(benzene-1,2-dithiolato) complex $(Li)_2[Mo^{IV}(C_6H_4S_2\text{-}1,2)_3]$ {$(Li)_2[Mo^{IV}(bdt)_3]$} (bdt^{2-} = $C_6H_4S_2$-1,2 dianion) was synthesized from $[MoCl_4(CH_3CN)_2]$, (H_2bdt), and *n*BuLi in THF. Complex $(Li)_2[Mo^{IV}(bdt)_3]$ undergoes aerial oxidation to give $Li[Mo^{V}(bdt)_3]$. Both complexes were crystallized from methanol as the salts $(PNP)_2[Mo^{IV}(bdt)_3]$ and $(PNP)[Mo^{V}(bdt)_3]$ {PNP^+ = bis(triphenylphosphoranylidene)ammonium cation}, and their molecular structures were determined by X-ray diffraction. The molybdenum(IV) complex $[Mo^{IV}(bdt)_3]^{2-}$ assumes a distorted trigonal prismatic coordination geometry (average twist angle φ = 24.8°) while the coordination geometry of $[Mo^{V}(bdt)_3]^-$ is best described as distorted octahedral (average twist angle φ = 34.1°).

Introduction

The first trigonal prismatic (TP) tris(dithiolene) metal complex, tris(*cis*-1,2-diphenylethylene-1,2-dithiolato)rhenium, was reported in 1965.[1] Ever since, the reasons for the formation of complexes with trigonal prismatic coordination geometry over octahedral complexes has been a subject for discussion.[2] Early explanations based on molecular orbital schemes indicated that metal centers with a *formal* d^0 electron configuration preferentially form trigonal prismatic tris(dithiolene) transition metal complexes. In the series of tris(benzene-1,2-dithiolato) complexes, $[W^{VI}(bdt)_3]$ is trigonal prismatic (twist angle φ = 0°),[3] while the geometry of $[W^{V}(bdt)_3]^-$ was found to be closer to octahedral (average twist angle φ = 33°) than to trigonal prismatic.[4] Surprisingly, the $[W^{IV}(bdt)_3]^{2-}$ complex exhibits a geometry close to perfect trigonal prismatic (average twist angle φ = 3.5°).[5] In the homologous series of molybdenum complexes $[Mo^{V}(bdt)_3]^-$ assumes a geometry analogous to the W^V complex, between octahedral and trigonal prismatic (average twist angle φ = 33.5°),[6] while the complex $[Mo^{VI}(bdt)_3]$ is, as expected, trigonal prismatic (average twist angle φ = 0°).[7] The molecular structure of $[Mo^{IV}(bdt)_3]^{2-}$ has not been reported. The pseudooctahedral geometry of the d^0 complex $[Zr^{IV}(bdt)_3]^{2-}$ is rather unexpected[8] when compared to the trigonal prismatic[9] d^0 complex $[Nb^{V}(bdt)_3]^-$. It appears that the stepwise reduction of the *formal* d^0 center in $[M^{VI}(bdt)_3]$ (M = Mo, W) complexes does not generally enhance the tendency for the formation of octahedral complexes, and that the geometry of a particular complex is not governed only by electronic factors. Ligand constraints,[10] matching of ligand and metal d orbital energies, symmetry of ligand π orbitals, inter-donor interactions, and the overall charge of the complex have been suggested to be additional important factors.[11]

The situation is further complicated by the non-innocent nature of the bdt^{2-} ligand. Wieghardt has shown that an intramolecular redox reaction can convert coordinated bdt^{2-} into a coordinated *o*-dithiobenzosemiquinonate(1–) radical anion by the reduction of the metal center. Under such conditions, the *spectroscopic* oxidation state of the metal differs from the formal oxidation state. The geometrical changes within the ligand that are associated with the intramolecular redox reaction have been outlined for square planar bdt^{2-} complexes.[12]

As part of our ongoing effort to shed light on the relationship between the *formal* oxidation state of the metal and the molecular structure of $[M(bdt)_3]^{n-}$ (M = Mo, W) complexes, we present here the preparation and molecular structure of the yet unknown derivative $(PNP)_2[Mo^{IV}(bdt)_3]^{2-}$. In addition, the previously described[6] complex anion $[Mo^{V}(bdt)_3]^-$ was prepared again, and the crystal structure of the salt $(PNP)[Mo^{V}(bdt)_3]$ was elucidated and compared to the molecular structure reported for $(nBu_4N)[Mo^{V}(bdt)_3]$.[6a]

Results and Discussion

Transition metal tris(benzene-1,2-dithiolato) complexes have been synthesized by the reaction of the hexahalides

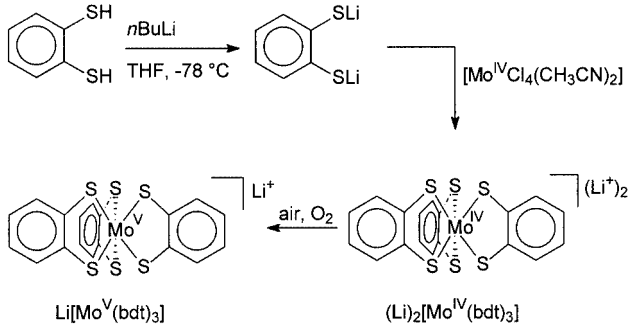
MX_6 with an excess of benzene-1,2-dithiol (H_2bdt) in CCl_4, a reaction that liberates gaseous HCl.[2d] Later Sellmann et al. showed that benzene-1,2-dithiol that is deprotonated with *n*BuLi (Li_2bdt) reacts with $[MoCl_4(THF)_2]$ to give $(Li)_2[Mo^{IV}(bdt)_3]$, while the reaction of benzene-1,2-dithiol with $[MoCl_4(THF)_2]$ gives $[Mo^{VI}(bdt)_3]$.[6b] Complex $[Mo^{VI}(bdt)_3]$ can be reduced to the complexes $[Mo^{V}(bdt)_3]^-$ and $[Mo^{IV}(bdt)_3]^{2-}$ with *n*BuLi.

We prepared $(Li)_2[Mo^{IV}(bdt)_3]$ by the deprotonation of H_2bdt with *n*BuLi at –78 °C in THF followed by the the dropwise addition of a DMF solution of $[MoCl_4(CH_3CN)_2]$ at –78 °C (Scheme 1). Below –40 °C the reaction mixture remained unchanged and colorless. Warming to above –40 °C led to a color change in the reaction mixture to deep blue, which is typical for solutions containing the $[Mo^{IV}(bdt)_3]^{2-}$ anion.[6b] The solution was warmed to room temperature, stirred at this temperature overnight, and then heated under reflux for 1 h. Standard workup procedures gave $(Li)_2[Mo^{IV}(bdt)_3]$ in 76% yield. Blue, air-sensitive crystals of $(PNP)_2[Mo^{IV}(bdt)_3]\cdot 6\,MeOH$ suitable for X-ray analysis were obtained by addition of a methanolic solution of PNPCl to a methanolic solution of $(Li)_2[Mo^{IV}(bdt)_3]$. Aerial oxidation of $(Li)_2[Mo^{IV}(bdt)_3]$ in methanol gave a green solution of $(Li)[Mo^{V}(bdt)_3]$. Addition of a methanolic solution of PNPCl yielded green, air-stable crystals of $(PNP)[Mo^{V}(bdt)_3]$ (Scheme 1).



Scheme 1. Preparation of $(Li)_2[Mo^{IV}(bdt)_3]$ and $(Li)[Mo^{V}(bdt)_3]$.

The ^1H NMR spectrum of complex $(Li)_2[Mo^{IV}(bdt)_3]$ exhibits two multiplets at δ = 7.37 ppm and δ = 6.57 ppm for the benzene protons, and the coupling pattern corresponds to a symmetrical AA′XX′ spin system (Figure 1). Two resonances for the benzene carbon atoms were observed in the ^{13}C NMR spectrum at δ = 119.8 ppm and δ = 126.5 ppm in addition to the signal for the *ipso*-carbon atom at δ = 155.1 ppm. The difference in the line widths of these signals appears to be an artifact of the data acquisition method.

The ^1H NMR resonances correspond well to the values reported for $(NEt_4)_2[W(bdt)_3]$.[5] The molecular structure of $(PNP)_2[Mo(bdt)_3]\cdot 6\,MeOH$ was determined by X-ray diffraction (Figure 2).

The overall solid state molecular structure of the complex anion $[Mo^{IV}(bdt)_3]^{2-}$ differs from that of the heavier homologue $[W^{IV}(bdt)_3]^{2-}$. The molybdenum(IV) ion in $[Mo(bdt)_3]^{2-}$ is coordinated by six sulfur atoms from three bdt^{2-} ligands in a strongly distorted trigonal prismatic fashion. The average twist angle φ[13] (see Figure 2, right) is 24.8° for $[Mo(bdt)_3]^{2-}$ compared to φ = 3.5° for $[W(bdt)_3]^{2-}$.[5] The three different twist angles observed for $[Mo(bdt)_3]^{2-}$ result from the noncoplanar arrangement of the two S_3 planes. The bending of the S–C–C–S plane away from the S–Mo–S–plane is small in $[Mo^{IV}(bdt)_3]^{2-}$ (about 0.8°) while large bending angles were observed for $[Mo^{VI}(bdt)_3]$ (13.1, 21.1, 30.0°)[7] and $[W^{VI}(bdt)_3]$ (13.5, 22.6, 32.1°).[3] On the basis of Fenske–Hall MO calculations it has been suggested that the bending of the ligand can be viewed as a second-order Jahn–Teller distortion, which is most favored for d^0 metal centers in a trigonal prismatic coordination environment.[14] While the electronic factors provide the principal driving force, the bulk of the dithiolate ligand also plays a role in determining the molecular structures. This becomes obvious when the three different bending angles for $[M^{VI}(bdt)_3]$ (M = Mo, W) complexes are considered.

For a comparison of the bond parameters in $[Mo^{IV}(bdt)]^{2-}$ and $[Mo^{V}(bdt)]^{-}$, which have been obtained under similar conditions (153–173 K) and with identical counterions, we determined the molecular structure of $(PNP)[Mo^{V}(bdt)_3]$ (Figure 3). The molecular structure of $(nBu_4N)[Mo^{V}(bdt)_3]$ has been determined previously at room temperature.[6a]

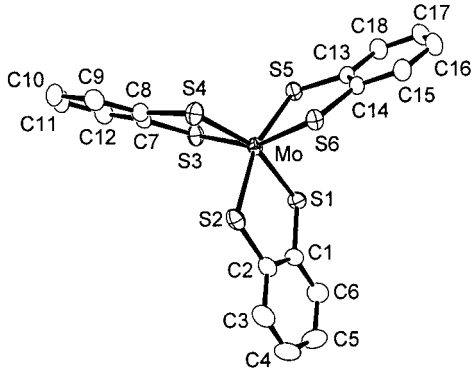

Figure 3. Molecular structure of $[Mo^{V}(bdt)_3]^{-}$ with the crystallographic numbering scheme. Hydrogen atoms have been omitted. Selected bonds lengths [Å] and angles [°]: Mo–S1 2.3880(8), Mo–S2 2.4020(8), Mo–S3 2.3702(7), Mo–S4 2.3778(8), Mo–S5 2.3999(8), Mo–S6 2.3785(7); S1–Mo–S2 81.81(3), S1–Mo–S3 95.42(3), S1–Mo–S4 160.05(3), S1–Mo–S5 82.89(3), S1–Mo–S6 102.93(3), S2–Mo–S3 107.72(3), S2–Mo–S4 79.91(3), S2–Mo–S5 162.41(3), S2–Mo–S6 92.28(2), S3–Mo–S4 82.64(3), S3–Mo–S5 82.31(3), S3–Mo–S6 154.62(3), S4–Mo–S5 116.31(3), S4–Mo–S6 85.78(3), S5–Mo–S6 82.73(2).

In both the PNP^+ and the nBu_4N^+ salts, the structure of the anion $[Mo(bdt)_3]^{-}$ is an unsymmetrical polyhedron, exhibiting a geometry between trigonal prismatic and octahedral (average twist angle φ = 34.1° for the PNP^+ salt and φ = 33.5° for the nBu_4N^+ salt). However, the $[Mo^{V}(bdt)_3]^{-}$ anions in the two salts show a considerable difference regarding the orientation of the S_3 planes that define the twist angle φ (Figure 2). While the anion in the nBu_4N^+ salt exhibits three rather similar angles (30.4, 34.4, 35.6°), which indicates an almost coplanar arrangement of the S_3 planes, three significantly different values were observed for $(PNP)[Mo(bdt)_3]$ (18.4, 36.3, 47.8°). The S1/S3/S5 plane in this complex is tilted by 7.2° with respect to the S2/S4/S6 plane. Crystal packing effects might be responsible for this observation, which again illustrates that electronic effects are not solely responsible for the molecular structure of $[M(bdt)_3]^{n-}$ complexes.

The "innocent" and "non-innocent" nature of ligands like bdt^{2-} has recently been discussed intensively.[12] For *O,O′*-coordinated catecholates or *o*-benzosemiquinonate(1–)-π-radicals a number of typical structural and spectroscopic features have been described, which allow the detection and identification of such ligands in coordination compounds.[15] The picture was not so clear for the corresponding *o*-dithio derivatives like bdt^{2-}. Recently square-planar complexes of the type $[M(bdt)_2]^{n-}$ ($M = Au^{III}$, Ni^{II})[12] have been described, and structural parameters associated with dithiolato(2–) and *o*-dithiobenzosemiquinonato(1–) coordination have been worked out. This allows, in principle, the assignment of the oxidation level of a benzene-1,2-dithiolato ligand in a complex. For complexes of the type $[M(bdt)_2]^{n-}$ this assignment becomes complicated if a benzene-1,2-dithiolate and an *o*-dithiobenzosemiquinonate ligand are coordinated at the same time, as the structural differences between the two ligand types are small. Statistical disorder problems may hamper the identification of the different oxidation levels of the ligand and this becomes even more complicated for complexes of the type $[M(bdt)_3]^{n-}$ with three bdt^{2-} ligands, each of which can undergo intramolecular oxidation.

We have studied the structural parameters in the series $[Mo(bdt)_3]^{n-}$ (n = 0, 1, 2, Figure 4) and found some trends in the Mo–S, S–C and C–C bond lengths. On the basis of the geometric parameters of the *o*-dithiolato ligands in $[Mo^{VI}(bdt)_3]$ and the paramagnetism observed for the complex, Bennet et al.[7] proposed, as early as 1976, the presence of a dithioketonic ligand species in $[Mo^{VI}(bdt)_3]$. On the basis of Wieghardt's investigations,[12] we believe that the ligand in $[Mo^{VI}(bdt)_3]$ is best described as an *o*-dithiobenzosemiquinonate(1–) radical anion.

In the series of $[Mo(bdt)_3]^{n-}$ complexes, the C–S bond lengths increase as the metal oxidation state changes from Mo^{VI} to Mo^{IV} (Figure 4). Mo^{VI} is capable of oxidizing the *o*-dithiolato ligand to a higher degree than Mo^{IV}, leading to a thioketonic ligand which is detectable by the decrease in the C–S bond lengths. This postulate is corroborated by an evaluation of the C–C bond lengths within the aromatic ring. In summary, the trends in the structural parameters

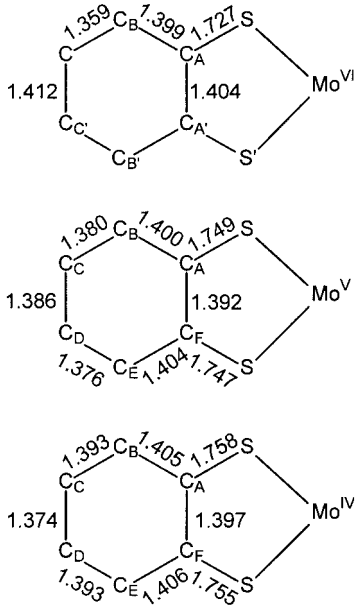

Figure 4. Average bond lengths [Å] for complexe anions of the type $[Mo(bdt)_3]^{n-}$ (n = 2, 1, 0) including literature data for $[Mo^{VI}(bdt)_3]$.[7]

indicate that the bdt^{2-} ligand is at least partially oxidized upon coordination to transition metals in high oxidation states (Mo^{VI}).

From the variation of the twist angle φ in the series $[Mo(bdt)_3]^{n-}$ (n = 0, 1, 2) it appears that the *formal* d electron configuration is not the only governing principle for the formation of certain coordination polyhedra. These results indicate once more that the stabilization of a trigonal prismatic coordination geometry does not only depend on the electronic situation at the central metal atom, but instead must be considered a complicated process involving various factors, including the counterions that are present.

Experimental Section

General Remarks: Unless stated otherwise, all manipulations were carried out under dry argon by means of standard Schlenk techniques. THF was freshly distilled from Na/benzophenone prior to use. Methanol was dried over magnesium and freshly distilled. The DMF purchased contained molecular sieves and was used as received. $[MoCl_4(CH_3CN)_2]$ was purchased from Aldrich.

$(Li)_2[Mo^{IV}(bdt)_3]$: A sample of benzene-1,2-dithiol (423 mg, 3.0 mmol) was dissolved in THF (20 mL). The solution was cooled to –78 °C and *n*BuLi (6.0 mmol, 2.4 mL of a 2.5 M solution in hexane) was added dropwise. $[MoCl_4(CH_3CN)_2]$ (320 mg, 1 mmol) in DMF (5 mL) was then added, and the reaction mixture was allowed to warm slowly to ambient temperature. While warming, the color of the solution turned deep blue. The reaction mixture was stirred overnight and then heated under reflux for 1 h. Thereafter all solvents were removed and the crude reaction product was washed with diethyl ether and dried in vacuo. Yield: 403 mg (0.76 mmol, 76%). $C_{18}H_{12}Li_2MoS_6$ (530.48): calcd. C 40.76, H 2.28; found C 41.43, H 2.40. ^1H NMR (200 MHz, [D$_7$]DMF): δ = 7.37 (dd, ^3J = 8.8, ^4J = 2.4 Hz, 6 H, Ar–H), 6.57 (dd, ^3J = 8.8, ^4J = 2.4 Hz, 6 H, Ar–H). ^{13}C NMR (50 MHz, [D$_7$]DMF): δ = 155.1 (*ipso*-C), 126.5 (Ar–C), 119.8 (Ar–C).

$(PNP)_2[Mo^{IV}(bdt)_3]\cdot 6\,MeOH$: Slow diffusion of a methanolic solution of PNPCl (PNPCl = bis(triphenylphosphoranylidene)ammonium chloride) into a solution of $(Li)_2[Mo^{IV}(bdt)_3]$ in methanol led to the precipitation of deep blue, air-sensitive single crystals of $(PNP)_2[Mo^{IV}(bdt)_3]\cdot 6$ MeOH which were suitable for an X-ray diffraction study. These crystals were characterized by X-ray diffraction only.

$(PNP)[Mo^{V}(bdt)_3]$: Complex $(Li)_2[Mo^{IV}(bdt)_3]$ dissolved in methanol was oxidized by exposure to air. A green solution of $Li[Mo^{V}(bdt)_3]$ resulted. Green crystals of $(PNP)[Mo^{V}(bdt)_3]$ were obtained by the slow addition of a methanolic solution of PNPCl.

X-ray Crystallographic Study of $(PNP)_2[Mo^{IV}(bdt)_3]\cdot 6\,MeOH$: A suitable crystal ($0.20\times0.10\times0.07$ mm^3) was mounted on a Bruker AXS APEX diffractometer equipped with a rotating molybdenum anode (λ = 0.71073 Å), a cooling device, and a graphite monochromator. $(PNP)_2[Mo(bdt)_3]\cdot 6$ MeOH, $C_{96}H_{96}N_2MoO_6P_4S_6$, M_r = 1785.93 g mol^{-1}, monoclinic, $C2/c$, a = 22.901(14), b = 16.245(8), c = 25.800(13) Å, β = 113.385(14)°, V = 8810(8) Å^3, Z = 4, $\rho_{calcd.}$ = 1.346 g cm^{-3}, μ = 0.419 mm^{-1}. 34636 structure factors ($-27 \le h \le 27$, $-19 \le k \le 19$, $-30 \le l \le 30$, 2θ-range 3.2–50.0°) were collected at –100 °C. An empirical absorption correction applied (T_{min} = 0.921, T_{max} = 0.971) before merging the data gave 7754 unique intensities (R_{int} = 0.058). Structure solution was performed with SHELXS,[16] and the subsequent refinement of 522 parameters against F^2 with 7754 unique intensities [6289 observed intensities $I > 2\sigma(I)$] was conducted with SHELXL.[17] The anisotropic thermal parameters for all non-hydrogen atoms were refined. Hydrogen atoms were added to the structure model at calculated positions. Final residuals: R_{all} = 0.0600, R_{obs} = 0.0460, $R_{w,obs}$ = 0.1182, *GOF* = 1.106. The molybdenum atom resides on a special position, namely, a twofold axis which bisects one of the benzene-1,2-dithiolato ligands. The asymmetric unit contains one half $[Mo^{IV}(bdt)_3]^{2-}$ anion, one PNP^+ cation, and three molecules of MeOH.

X-ray Crystallographic Study of (PNP)[2]: A suitable crystal ($0.48\times0.08\times0.02$ mm^3) was mounted on a Bruker AXS APEX diffractometer equipped with a rotating molybdenum anode (λ = 0.71073 Å), a cooling device, and a graphite monochromator. (PNP)[Mo(bdt)$_3$], $C_{54}H_{42}MoNP_2S_6$, M_r = 1055.13 g mol^{-1}, triclinic, $P\bar{1}$, a = 11.036(1), b = 13.882(2), c = 16.041(2) Å, α = 87.969(3), β = 75.861(3), γ = 87.512(3)°, V = 2380.0(5) Å^3, Z = 2, $\rho_{calcd.}$ = 1.472 g cm^{-3}, μ = 0.645 mm^{-1}. 19324 structure factors ($-13 \le h \le 13$, $-16 \le k \le 16$, $-19 \le l \le 19$, 2θ-range 3.0–50.0°) were collected at –120 °C. An empirical absorption correction applied (T_{min} = 0.747, T_{max} = 0.987) before merging the data gave 8382 unique intensities (R_{int} = 0.035). Structure solution was performed with SHELXS,[16] and subsequent refinement of 577 parameters against F^2 with 8382 unique intensities [6757 observed intensities $I > 2\sigma(I)$] was conducted with SHELXL.[17] The anisotropic thermal parameters for all non-hydrogen atoms were refined. Hydrogen atoms were added to the structure model at calculated positions. Final residuals: R_{all} = 0.0476, R_{obs} = 0.0335, $R_{w,obs}$ = 0.0757, *GOF* = 1.007. The asymmetric unit contains one molecule of (PNP)[Mo(bdt)$_3$].

CCDC-260986 (for $(PNP)_2[Mo^{IV}(bdt)_3]\cdot 6$ MeOH) and CCDC-260987 (for $(PNP)[Mo^{V}(bdt)_3]$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthetic, Structural, Spectroscopic, and Electrochemical Studies of Heteroleptic Tris(phthalocyaninato) Rare Earth Complexes

Yongzhong Bian,[a] Lei Li,[a] Daqi Wang,[b] Chi-Fung Choi,[c] Diana Y. Y. Cheng,[c] Pehua Zhu,[a] Renjie Li,[a] Jianmin Dou,[b] Rongming Wang,[a] Na Pan,[a,d] Dennis K. P. Ng,[c] Nagao Kobayashi,[d] and Jianzhuang Jiang*[a]

Keywords: Phthalocyanines / Sandwich complexes / Rare earths / Triple-decker complexes / Heteroleptic complexes

Three heteroleptic tris(phthalocyaninato) rare-earth triple-decker complexes [(Pc)M(Pc)M{Pc(α-$OC_5H_{11})_4$}] [M = Sm, Gd, Lu; Pc = phthalocyaninate; Pc(α-$OC_5H_{11})_4$ = 1,8,15,22-tetrakis(3-pentyloxy)phthalocyaninate] have been prepared as racemic mixtures by treating [M{Pc(α-$OC_5H_{11})_4$}(acac)], generated in situ, with the bis(phthalocyaninato) rare-earth double-decker complex [M$(Pc)_2$] in refluxing *n*-octanol. The molecular structures of the gadolinium and lutetium complexes have been determined by single-crystal X-ray diffraction analysis, both of which adopt the asymmetrical structure [(Pc)M(Pc)M{Pc(α-$OC_5H_{11})_4$}]. The outer Pc and Pc(α-$OC_5H_{11})_4$ rings are significantly domed, while the inner Pc ring is essentially planar. The ring-to-ring separation between the two adjacent Pc rings, as defined by the two N_4 mean planes, diminishes from [(Pc)Gd(Pc)Gd{Pc(α-$OC_5H_{11})_4$}] to [(Pc)Lu(Pc)Lu{Pc(α-$OC_5H_{11})_4$}] as a result of the smaller Lu^{III} ion. The decreased molecular symmetry for these complexes has also been revealed by the NMR spectra of the samarium and lutetium analogs, in which four sets of signals appear for the inner Pc ring protons due to the special disposition of the neighboring Pc(α-$OC_5H_{11})_4$ ring. Electrochemical studies have revealed four one-electron oxidations and up to five one-electron reductions for these complexes. The dependence of the phthalocyanine Q band as well as the first and second oxidation potentials on the size of the metal center indicates that substantial π-π interactions are present in these compounds.

Introduction

While monomeric chiral porphyrin and phthalocyanine derivatives have received increasing research interest in the past years,[1] chiral, sandwich-type tetrapyrrole metal complexes, however, still remain extremely rare.[2–4] Recently, we have reported a series of heteroleptic bis(phthalocyaninato) rare-earth complexes [M(Pc){Pc(α-$OC_5H_{11})_4$}] (M = Y, Sm–Lu) with a C_4 molecular symmetry.[5] As part of our continuing efforts in this regard, we have devised and prepared a new series of heteroleptic tris(phthalocyaninato) rare-earth triple-decker complexes [(Pc)M(Pc)M{Pc(α-$OC_5H_{11})_4$}] (M = Sm, Gd, Lu; Figure 1). In this paper, we report in detail the synthesis, structures, spectroscopic properties, and electrochemistry of these novel complexes. Due to the introduction of four 3-pentyloxy groups at the α-position of the outer Pc(α-$OC_5H_{11})_4$ ring, and the sandwich triple-decker molecular structure, these compounds are also intrinsically chiral in nature. However, due to the very small difference between the two enantiomers, they could not be separated and these triple-decker complexes have been found to exist as a pair of enantiomers co-crystallizing in the monoclinic *C*2/*c* system.

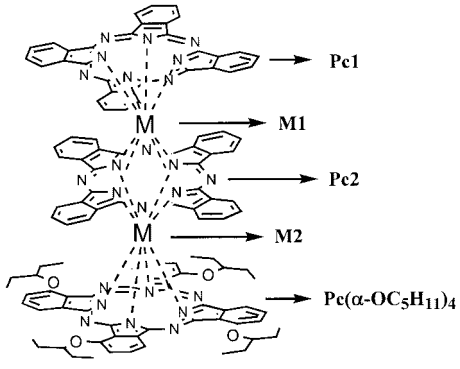

Figure 1. A schematic structure of the heteroleptic rare-earth triple-decker complexes [(Pc)M(Pc)M{Pc(α-$OC_5H_{11})_4$}] (**1**–**3**).

It is also worth pointing out that tris(phthalocyaninato) rare-earth triple-deckers were first briefly characterized by

mass spectroscopy in the 1980s.[6] Since then, both homoleptic and especially the heteroleptic complexes developed very recently have attracted increasing research interest as good systems to study the interactions between two 4f electronic systems in an isolated environment and as a new category of single molecular magnets.[7a,7b,8] To the best of our knowledge, only a very few tris(phthalocyaninato) triple-deckers have been structurally characterized, including the homoleptic tris[tetra(15-crown-5)phthalocyaninato]lutetium compound $[Lu_2\{Pc(15\text{-}C\text{-}5)_4\}_3]$ reported by Troyanov et al.[9] and the heteroleptic [(Pc)M{Pc(OC_8H_{17})$_8$}M′(Pc)] (M = Er, M′ = Lu; M = M′ = Er or Lu) reported by us.[7c] The present work adds the structural data of the intrinsically chiral [(Pc)M(Pc)M{Pc(α-OC_5H_{11})$_4$}] [M = Gd (2), Lu (**3**)]. These novel systems will also be of interest for further studies.

Results and Discussion

Synthesis of [(Pc)M(Pc)M{Pc(α-OC_5H_{11})$_4$}] [M = Sm (1), Gd (2), Lu (3)]

Two synthetic pathways have been reported to prepare heteroleptic rare earth(III) triple-decker complexes with two different kinds of phthalocyaninato ligands [(Pc′)M(Pc′)M(Pc′′)] or [(Pc′)M(Pc′′)M(Pc′)] (Pc′ ≠ Pc′′ = general phthalocyaninate). The first method involves the reaction between the monomeric [M(Pc′)X] and the metal-free H_2Pc′′ in a suitable ratio. This method has only been applied to prepare the lutetium triple-decker [(Pc)Lu{Pc(15-C-5)$_4$}Lu(Pc)].[10] The second pathway involves treatment of the monomeric [M(Pc′)X] with the double-decker [M(Pc′′)$_2$]. This method has been generally utilized to prepare a series of different kinds of tris(phthalocyaninato) rare-earth compounds recently,[7,8] and is also a convenient and efficient methodology to prepare mixed (porphyrinato)(phthalocyaninato) rare-earth triple-deckers, including [M_2(Pc′)$_2$(Por)] and [M_2(Pc′)(Por)$_2$] (Por = general porphyrinate).[11] In the present work, we employed the second methodology, using [M{Pc(α-OC_5H_{11})$_4$}(acac)] (M = Sm, Gd, Lu), generated in situ from the corresponding [M(acac)$_3$]·$n$$H_2$O (M = Sm, Gd, Lu) and metal-free H_2Pc(α-OC_5H_{11})$_4$, and [M(Pc)$_2$] as starting materials. Reaction of [M{Pc(α-OC_5H_{11})$_4$}(acac)] with the corresponding [M(Pc)$_2$] in refluxing *n*-octanol led to the heteroleptic triple-deckers [(Pc)M(Pc)M{Pc(α-OC_5H_{11})$_4$}] (M = Sm, Gd, Lu) in relatively good yields (24–42%). The reaction yield of these compounds is dependent on the size of the metal center: the yield is higher for lanthanides with a moderate size such as Sm and Gd, while the late lanthanide Lu analog gave a lower yield (Table 1). This result is in good accord with the trend observed for the mixed (porphyrinato)(phthalocyaninato) rare-earth triple-deckers [M_2(Pc)$_2$(TClPP)] and [M_2(Pc)(TClPP)$_2$] [TClPP = 5,10,15,20-tetrakis(4-chlorophenyl)porphyrinate].[12]

Spectroscopic Characterization

All the three new heteroleptic triple-deckers **1**–**3** were characterized by elemental analysis and various spectroscopic methods. Table 1 summarizes the analytical and mass spectroscopic data. The MALDI-TOF mass spectra of these compounds clearly show intense signals for the molecular ion $[M]^+$ or protonated molecular ion $[MH]^+$.

The diamagnetic lutetium(III) triple-decker [(Pc)Lu(Pc)Lu{Pc(α-OC_5H_{11})$_4$}] (**3**) gives a well-resolved ^{1}H NMR spectrum in $CDCl_3$. As shown in the ^{1}H-^{1}H COSY spectrum (Figure 2), the four most downfield signals (the doublets at δ = 9.07 and 8.86 ppm, and the triplets at δ = 8.71 and 8.64 ppm) are inter-correlated and can be attributed to one of the Pc rings. The other Pc rings' protons resonate as two typical AA′BB′ multiplets at δ = 8.48–8.50 and 8.00–8.03 ppm. The appearance of two sets of signals for the Pc rings confirms that the compound adopts an unsymmetrical structure, i.e. [(Pc)Lu(Pc)Lu{Pc(α-OC_5H_{11})$_4$}]. The former set of signals is tentatively assigned to the inner Pc ring as it is expected that the C_{4h} symmetry of the Pc(α-OC_5H_{11})$_4$ ring may impose a different environment to its neighboring ring protons, leading to four different signals. The remaining three aromatic signals from δ = 7.3 to 7.9 ppm are clearly due to the ring protons of Pc(α-OC_5H_{11})$_4$.

The aliphatic protons' signals can also be assigned unambiguously with the help of the ^{1}H-^{1}H COSY spectrum (Figure 2). The virtual quintet at δ = 4.46 ppm is due to the OCH proton, and the two multiplets at δ = 2.12–2.22 and 2.33–2.42 ppm can be ascribed to one set of the two diastereotopic methylene protons, which are correlated with the methyl protons resonating as a virtual triplet at δ = 1.50 ppm. The other set of methylene protons resonates as a quintet at δ = 1.68 ppm and its neighboring methyl protons resonate as a triplet at δ = 0.53 ppm. These results clearly show that a lowering of the symmetry of triple-decker complexes gives rise to more NMR signals.

Table 1. Analytical and mass spectroscopic data for the heteroleptic triple-deckers **1**–**3**.[a]

Compound	Yield [%]	$[M^+]$ or $[MH^+]$ [*m*/*z*]	Analysis [%][b] C	H	N
[(Pc)Sm(Pc)Sm{Pc(α-OC_5H_{11})$_4$}] (**1**)	40	2182.8 (2182.9)[b]	62.55 (62.39)[d]	4.04 (3.98)[d]	14.91 (14.99)[d]

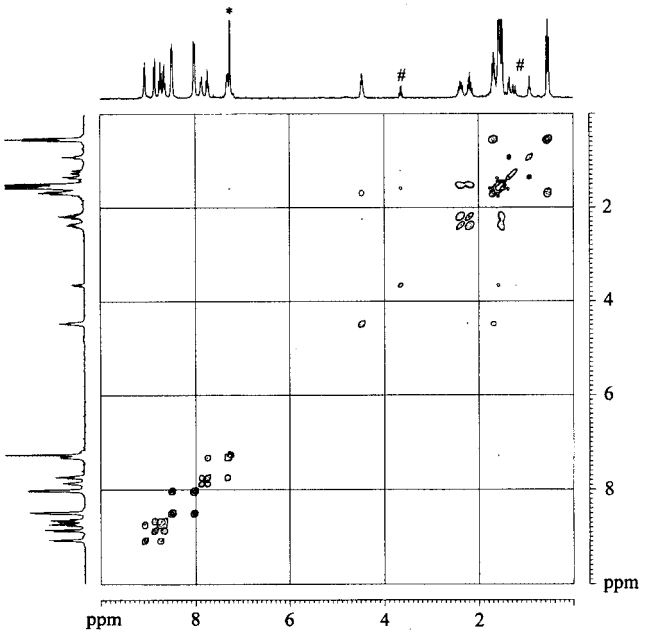

Figure 2. ^{1}H-^{1}H COSY spectrum of [(Pc)Lu(Pc)Lu{Pc(α-O-$C_5H_{11})_4$}] (**3**) in $CDCl_3$. The signals due to residual $CHCl_3$ and some impurities are denoted as * and #, respectively.

The ^{1}H NMR spectrum of the samarium(III) analog **1** shows similar spectral features, but some of the aromatic signals are overlapped and assignment could only be made by 2D NMR techniques. The total correlation spectroscopy (TOCSY)[13] spectrum (Figure S1a; see Supporting Information), in which the cross peaks indicate correlations between protons that belong to a common spin-system, is particularly useful. The spectrum clearly reveals that the two multiplets at δ = 7.92–7.97 and 7.62–7.69 ppm are correlated and can be assigned to the H_α and H_β protons of the outer Pc ring, respectively. The triplet at δ = 7.80 ppm, multiplet at δ = 7.62–7.69 ppm (overlapped with the outer Pc-H_β protons' signals), and the two doublets at δ = 7.52 and 7.11 ppm belong to a common spin system and can be attributed to the inner Pc ring. The multiplet at δ = 7.24–7.34 ppm contains overlapping signals for residual $CHCl_3$ and two sets of aromatic signals for Pc(α-$OC_5H_{11})_4$, which are correlated with the doublet at δ = 6.99 ppm. These correlations and the assignments are in agreement with the ^{1}H-^{1}H COSY spectrum (see Figure S1b in the Supporting Information).

The electronic absorption and MCD data of this series of compounds were measured in $CHCl_3$ and are shown in Figure 3. In general, the metal-dependent spectral features are analogous to those reported for related compounds [(Pc)M{Pc($OC_8H_{17})_8$}M{Pc($OC_8H_{17})_8$}],[7a] and thus could be assigned in the same manner. All the spectra of **1**–**3** show a typical Soret band at about 335 nm with a shoulder at the higher energy side at around 295 nm. The phthalocyanine Q bands appear around 643–652 nm as a very strong absorption with a weak satellite around 695–723 nm. Along with the decrease in the rare-earth ionic size from Sm to Lu, the Soret band for the three triple-deckers remains almost unchanged. In contrast, the main Q absorption band undergoes a blue shift and the satellite Q band is shifted to the red.

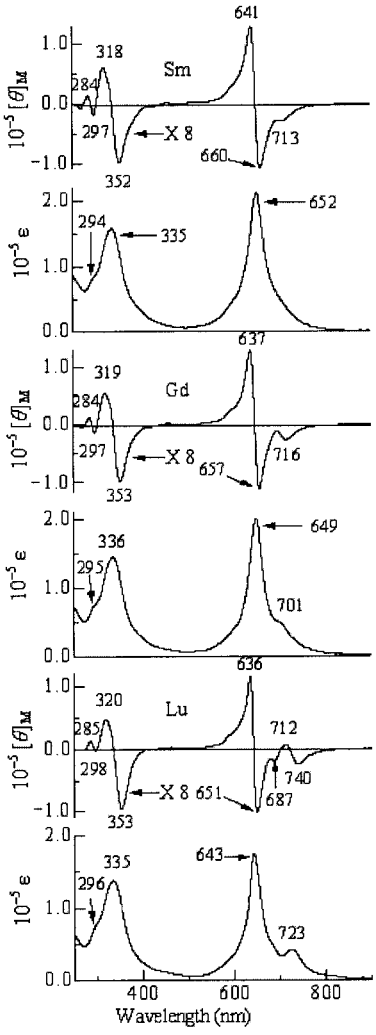

Figure 3. Electronic absorption and MCD spectra of [(Pc)M-(Pc)M{Pc(α-$OC_5H_{11})_4$}] (**1**–**3**) in $CHCl_3$.

The MCD spectra of **1**–**3** are different from those of the symmetrical mono(phthalocyaninato) metal and bis-(phthalocyaninato) rare-earth complexes in that splitting of the absorption bands appears in the Q-band region. It is also different from that of H_2Pc in that the MCD spectra clearly show the presence of pseudo Faraday-*A* terms. A symmetrical and intense pseudo *A* term is observed for **1**–**3** at 643–652 nm. Another unsymmetrical and weaker *A* term is also observed corresponding to the second Q band at 695–723 nm, which is well resolved for the Lu compound. In the Soret region, two symmetrical and weak pseudo *A* terms appear in the MCD spectra of **1**–**3**, corresponding to the Soret band at about 335 nm and its shoulder at around 295 nm. In the case of a cofacial eclipsed Pc dimer of low symmetry,[14] it has previously been found that both the electronic absorption and MCD spectra do not reflect the symmetry of the constituent Pc units. As shown by the X-ray structures (to be discussed in the following

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

section), compounds **1**–**3** have C_s symmetry so that Faraday *A* terms are not expected theoretically. However, since pseudo Faraday *A* terms are observed in Figure 3, we can further conclude that the absorption and MCD spectra of cofacial trimers do not reflect the molecular symmetry.

Structural Studies

Single crystals of [(Pc)M(Pc)M{Pc(α-$OC_5H_{11})_4$}] [M = Gd (**2**), Lu (**3**)] suitable for X-ray diffraction analysis were obtained by slow diffusion of MeOH into the corresponding $CHCl_3$ solutions. These compounds crystallize in the monoclinic system with a *C*2/*c* space group, but unfortunately two pairs of enantiomeric triple-decker molecules are contained in each unit cell,. Attempts to resolve the two enantiomers of the these triple-deckers by HPLC using a silica gel column coated with cellulose 2,3,6-tris(3,5-dimethylphenylcarbamate) were not successful due to the very small differences between the two enantiomers. The crystal structure of these compounds also contained solvated chloroform molecules, which come from the solvents used for recrystallization. The gadolinium and lutetium compounds have similar crystal structures.

The molecular structure of [(Pc)Gd(Pc)Gd{Pc(α-$OC_5H_{11})_4$}] (**2**) is shown in Figure 4. Each gadolinium ion is sandwiched between an outer phthalocyanine ligand, Pc or Pc(α-$OC_5H_{11})_4$, and the inner Pc ring. However, the two gadolinium ions in this compound are not exactly identical

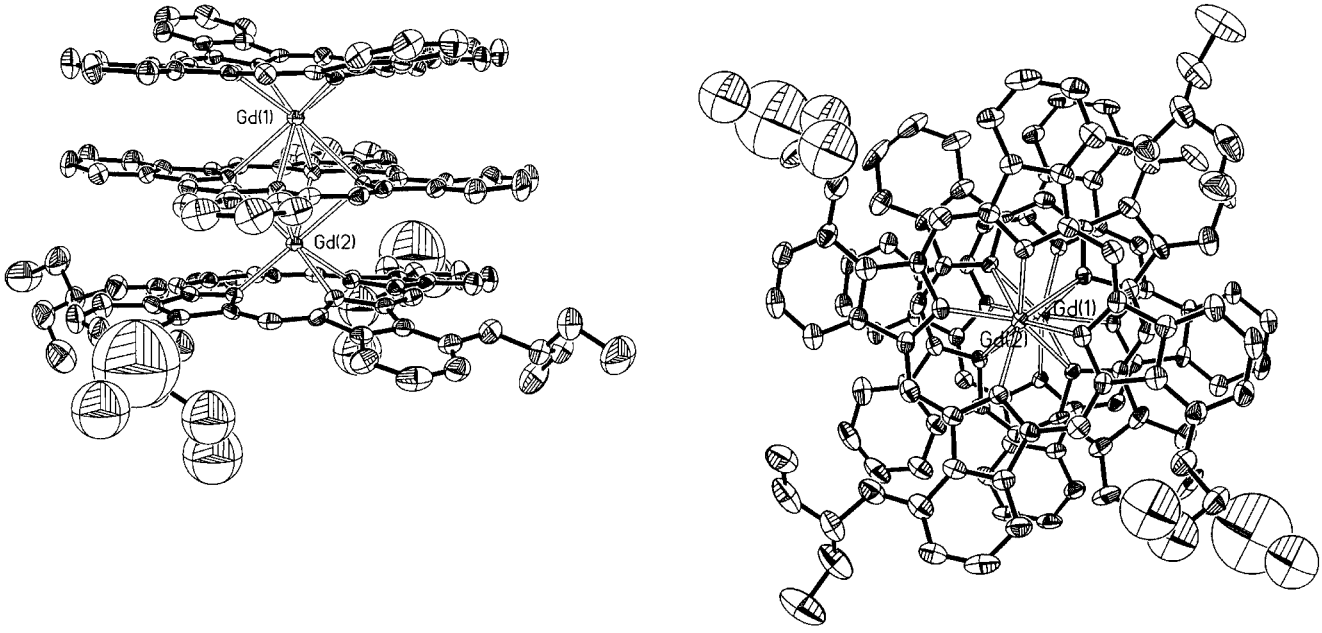

Figure 4. Molecular structure of [(Pc)Gd(Pc)Gd{Pc(α-$OC_5H_{11})_4$}] (**2**) in two different perspective views showing the 30% probability thermal ellipsoids for all non-hydrogen atoms.

Average twist angle between Pc2 ring and Pc(α-$OC_5H_{11})_4$ ring [°][b]	41.4	47.5

[a] The average dihedral angle of the individual isoindole rings with respect to the corresponding N_4 mean plane. [b] Defined as the rotation angle of one ring away from the eclipsed conformation of the two rings.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in terms of the distance from the inner and outer phthalocyanine ligands because of the difference in the ring-to-ring interaction between the inner and the two different outer phthalocyanine rings (Table 2). Both the outer Pc and Pc(α-$OC_5H_{11})_4$ rings adopt conformations that are domed toward the gadolinium cations (φ = 9.1 and 9.2°). The two unsubstituted Pc rings connected by Gd1 are rotated by an angle of 46.4°, and the central Pc and the outer Pc(α-$OC_5H_{11})_4$ ligands connected by Gd2 are rotated by 41.4°. The coordination polyhedra of both Gd1 and Gd2 are therefore a slightly distorted square antiprism. The displacements of the two gadolinium ions with respect to the three isoindole–nitrogen mean planes are Gd1–N_4(Pc1) = 1.295 Å, Gd1–N_4(Pc2) = 1.762 Å, Gd2–N_4(Pc2) = 1.800 Å, and Gd2–N_4[Pc(α-$OC_5H_{11})_4$] = 1.247 Å. The average Gd1–N(Pc1) bond length (2.376 Å) is significantly shorter than the average Gd1–N(Pc2) distance (2.634 Å), and the Gd2–N[Pc(α-$OC_5H_{11})_4$] (2.363 Å) bond length is shorter than Gd2–N(Pc2) (2.659 Å), as the central phthalocyanine ligand (Pc2) is shared by two gadolinium ions rather than one metal ion for the outer Pc1 or Pc(α-$OC_5H_{11})_4$ ligand. Similar data were obtained for the lutetium triple-decker **3**.

Electrochemical Properties

The redox behavior of the heteroleptic triple-deckers **1**–**3** was studied by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) in CH_2Cl_2. All the compounds exhibit four quasi-reversible one-electron oxidations and up to five quasi-reversible one-electron reductions, which can be attributed to the successive removal of electrons from, and addition of electrons to, the ligand-based orbitals, respectively. Figure 5 shows the voltammograms for [(Pc)-Lu(Pc)Lu{Pc(α-$OC_5H_{11})_4$}] (**3**), which are typical for the other rare-earth counterparts. Table 3 collects the half-wave potentials of all these processes for these triple-deckers. As can be seen, while the half-wave potentials of the third and fourth oxidations of [(Pc)M(Pc)M{Pc(α-$OC_5H_{11})_4$}] remain virtually unchanged, the half-wave potentials of the first and second oxidations correlate linearly with the ionic size of the rare-earth metal center and are slightly shifted in the cathodic direction with a decrease in the rare-earth ionic size. The half-wave potentials of all the reductions for **1**–**3** appear to reveal no systematic trends with ionic radius. The potential difference between Oxd_1 and Red_1 ($\Delta E_{1/2}$) for the three heteroleptic triple-deckers **1**–**3** is also dependent on the central rare-earth ionic size, diminishing from 1.02 V for the Sm compound to 0.84 V for the Lu analog, indicating an increase in the ring-to-ring π-π interaction in the same order.[15]

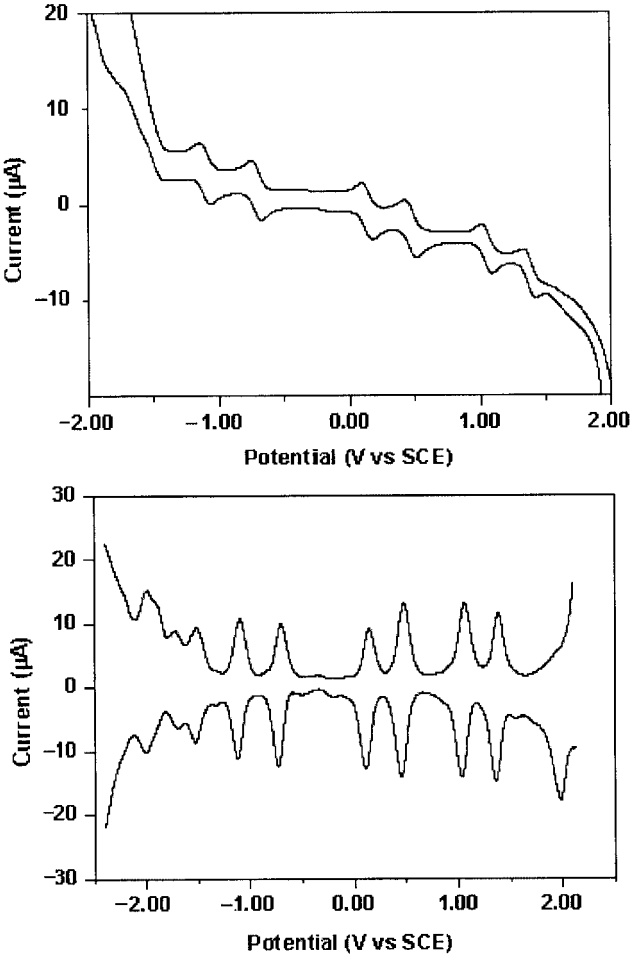

Figure 5. Cyclic voltammogram and differential pulse voltammogram of [(Pc)Lu(Pc)Lu{Pc(α-$OC_5H_{11})_4$}] (**3**) in CH_2Cl_2 containing 0.1 M $[Bu_4N][ClO_4]$ at a scan rate of 20 and 10 mV s^{-1}, respectively.

Conclusions

In summary, we have prepared novel heteroleptic tris-(phthalocyaninato) rare-earth complexes [(Pc)M(Pc)-M{Pc(α-$OC_5H_{11})_4$}] (M = Sm, Gd, Lu) as racemic mixtures. The compounds have been fully characterized by vari-

ous spectroscopic and electrochemical methods. The molecular structures of the Gd and Lu analogs with a lower molecular symmetry have also been determined by X-ray diffraction analysis and NMR spectroscopy. Introduction of four 3-pentyloxy groups onto the α-positions of one outer phthalocyanine ring in the tris(phthalocyaninato)-rare-earth compounds induces a chirality in the resulting triple-decker molecules. Trials on the separation of the two enantiomers have not yet been successful.

Experimental Section

General: *n*-Pentanol and *n*-octanol were distilled from over sodium. Hexane used for chromatography was distilled from anhydrous $CaCl_2$. Column chromatography was carried out on silica gel columns (Merck, Kieselgel 60, 70–230 mesh) with the indicated eluents. Dichloromethane for voltammetric studies was freshly distilled from CaH_2 under nitrogen. All other reagents and solvents were used as received. The compounds 3-(3-pentyloxy)phthalonitrile,[16] $H_2Pc(\alpha\text{-}OC_5H_{11})_4$,[17] $M(acac)_3{\cdot}nH_2O$,[18] and $Li_2(Pc)$[19] were prepared according to the literature procedures.

Electronic absorption spectra were recorded on a Hitachi U-4100 spectrophotometer. Magnetic circular dichroism (MCD) spectra were recorded on a Jasco J-725 spectrodichrometer, with a Jasco electromagnet that produces a magnetic field of up to 1.09 T. The magnitude of this was expressed in terms of molecular ellipticity per tesla, $[\theta]_M$/deg dm^3 mol^{-1} cm^{-1} T^{-1}. MALDI-TOF mass spectra were recorded on a Bruker BIFLEX III ultra-high resolution Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer with α-cyano-4-hydroxycinnamic acid as matrix. Elemental analyses were performed by the Institute of Chemistry, Chinese Academy of Sciences. Electrochemical measurements were carried out with a BAS CV-50W voltammetric analyzer. The cell comprised inlets for a glassy carbon disk working electrode of 2.0 mm in diameter and a silver-wire counter electrode. The reference electrode was Ag/Ag$^+$, which was connected to the solution by a Luggin capillary whose tip was placed close to the working electrode. It was corrected for junction potentials by being referenced internally to the ferrocenium/ferrocene (Fe^+/Fe) couple [$E_{1/2}$ (Fe^+/Fe) = 501 mV vs. SCE]. Typically, a 0.1 M solution of $[Bu_4N][ClO_4]$ in CH_2Cl_2 containing 0.5 mM of sample was purged with nitrogen for 10 min, then the voltammograms were recorded at ambient temperature. The scan rate was 20 and 10 mV s^{-1} for CV and DPV, respectively.

General Procedure for the Preparation of Triple-Decker Complexes 1–3: In a typical procedure, a mixture of $M(acac)_3{\cdot}nH_2O$ (M = Sm, Gd, Lu) (25 mg, ca. 0.05 mmol) and phthalonitrile (39 mg, 0.30 mmol) in *n*-pentanol (4 cm^3) was heated at 140 °C under nitrogen for about 8 h. The solvent was then removed in vacuo and the residue was subjected to chromatography on a silica gel column using $CHCl_3$ as eluent. The double-decker complex $M(Pc)_2$ was isolated and further purified by recrystallization from a mixture of $CHCl_3$/MeOH. The complex $M(Pc)_2$ (60 mg, ca. 0.05 mmol) was then treated with $M(acac)_3{\cdot}nH_2O$ (M = Sm, Gd, Lu) (25 mg, ca. 0.05 mmol) and metal-free phthalocyanine $H_2Pc(\alpha\text{-}OC_5H_{11})_4$ (43 mg, 0.05 mmol) in refluxing *n*-octanol (5 cm^3) for 3 h. After cooling to room temperature, the mixture was evaporated under reduced pressure and the residue was chromatographed on a silica gel column using $CHCl_3$ as eluent. Following two green fractions containing a small amount of $H_2Pc(\alpha\text{-}OC_5H_{11})_4$ and $M(Pc)_2$, respectively, a blue band containing the target heteroleptic triple-deckers [(Pc)M(Pc)M{$Pc(\alpha\text{-}OC_5H_{11})_4$}] was developed, which was collected and the solvents evaporated. The crude product was purified by repeated chromatography followed by recrystallization from $CHCl_3$/MeOH or hexane, giving black needles.

X-ray Crystallography: Crystal data and details of data collection and structure refinement are given in Table 4. Data were collected on a Bruker SMART CCD diffractometer with an Mo-K_α sealed tube (λ = 0.71073 Å) at 293 K, using a ω-scan mode with an increment of 0.3°. Preliminary unit-cell parameters were obtained from 45 frames. Final unit-cell parameters were derived by global refinements of reflections obtained from integration of all the frame data. The collected frames were integrated using the preliminary cell-orientation matrix. The SMART software was used for collecting frames of data, indexing reflections, and determination of lattice constants, SAINT-PLUS for integration of intensity of reflections and scaling,[20] SADABS for absorption correction,[21] and SHELXL for space group and structure determination, refinements, graphics, and structure reporting.[22] All the H-atoms in these compounds were obtained geometrically. These H-atoms were included in the subsequent least-squares refinement as fixed contributors. The final refinement with anisotropic temperature factors for non-H atoms led to R values of 0.0726–0.0757 for these compounds.

C-Phosphoniophosphaalkenes as Precursors of $1\sigma^4,3\sigma^2$-Diphosphaallenes: Scope and Limitations

David Martin,[a,b] Heinz Gornitzka,[a] Antoine Baceiredo,*[a] and Guy Bertrand*[a,b]

Keywords: Phosphorus / Phosphaalkenes / Phosphacumulenes / Phosphorus ylides

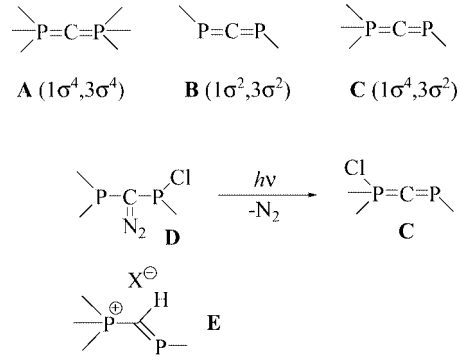
The study of a general synthetic route to $1\sigma^4,3\sigma^2$-diphosphaallenes involving the reaction of LiHMDS with *C*-phosphoniophosphaalkenes is reported. The choice of the base is critical since the precursors are highly electrophilic species that react cleanly with methyl-, butyl-, mesityl-, or *tert*-butyllithium to afford *C*-phosphanylphosphonium ylides. The role of the substituents at the σ^4-phosphorus centre has also been studied. The resulting phosphaallenes react cleanly with a Lewis acid and undergo [3+2] cycloaddition with azides to afford a five-membered heterocycle in a three-step process.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Among the possible neutral heterocumulenes featuring the PCP sequence, $1\sigma^4,3\sigma^4$-diphosphaallenes (carbodiphosphoranes) **A**[1] and $1\sigma^2,3\sigma^2$-diphosphaallenes **B**[2] have been known for many years. Recently, we reported the synthesis and characterisation of the first $1\sigma^4,3\sigma^2$-diphosphaallene **C** (Scheme 1), which features two different types of phosphorus–carbon "double" bonds.[3,4] Derivative **C** was prepared by elimination of N_2 from the phosphanyl(chlorophosphanyl)diazomethane **D**, which first leads to the corresponding transient carbene that then undergoes a 1,3-chlorine shift from one phosphorus to the other. However, the scope of this synthetic strategy is very limited in terms of starting materials (diazo precursors and chlorine migrating group).

Although phosphoniophosphaalkenes **E** can be readily prepared in high yields,[5] their reactivity has not been explored in detail. In particular, *C*-hydrogenophosphoniophosphaalkenes could afford the desired heterocumulene **C** by a simple deprotonation. Herein, we describe our results concerning this new and more general synthetic way to $1\sigma^4,3\sigma^2$-diphosphaallenes.



Scheme 1.

Results and Discussion

Phosphoniophosphaalkenes **3** were prepared in two steps by the method described by Grützmacher et al.[5] Two equivalents of phosphonium ylides **1** react with bis(diisopropylamino)chlorophosphane to give the corresponding *C*-phosphanyl phosphorus ylides **2**, with one equivalent of ylide **1** acting as a base to deprotonate the transiently formed *C*-phosphanylphosphonium salts. In the second step, the heterolytic cleavage of a P–N bond is achieved by addition of two equivalents of $BF_3{\cdot}OEt_2$, which affords the corresponding phosphoniophosphaalkenes **3** in good yields (72–95%) (Scheme 2). In the ^{31}P NMR spectra, compounds **3** display an AX system, with a low-field signal ($\delta \approx$ 300 ppm) characteristic of the phosphaalkene moiety, and a phosphorus–phosphorus coupling constant of about 130 Hz. In the ^{13}C NMR spectra, the signal for the PCP carbon atom appears as a doublet of doublets, with chemical shifts in the range δ = 95–100 ppm.

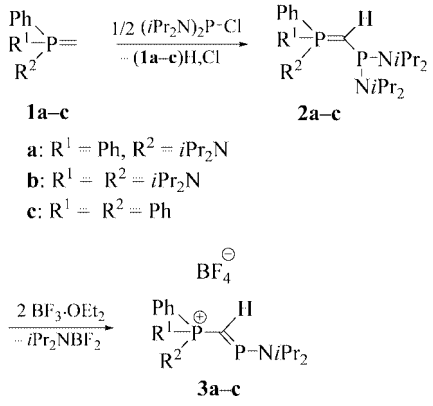
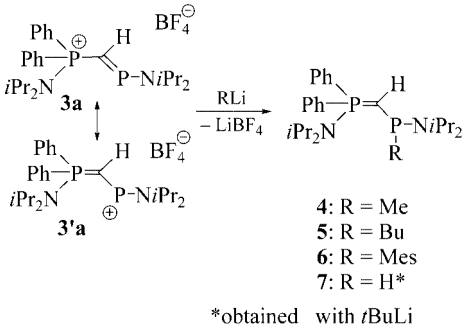


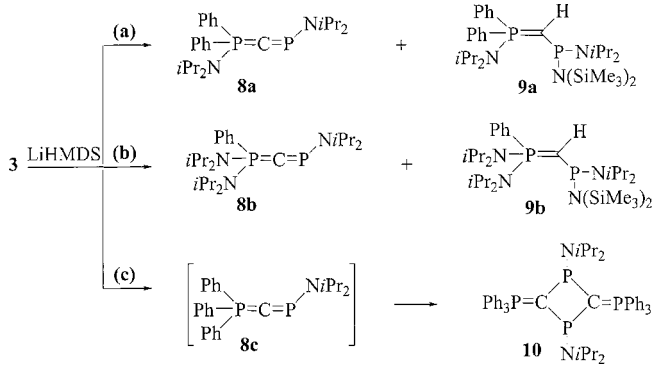
Scheme 2.

Phosphoniophosphaalkenes **3** are highly electrophilic species; they can be regarded as phosphenium salts substituted by a phosphonium ylide fragment (**3′**). Addition of methyl-, *n*-butyl- and mesityllithium to **3a** did not lead to the expected cumulenes; instead, the quantitative formation of the *C*-phosphanylphosphonium ylides **4**–**6** was observed (Scheme 3). This was indicated by the NMR spectroscopic data, in particular the disappearance of the characteristic low-field signal for the σ^2-phosphorus atom of compounds **3a** in the ^{31}P NMR spectrum. When the more sterically demanding *tert*-butyllithium was used, the *C*-phosphanylphosphonium ylide **7**,[6] featuring a P–H bond, was obtained in near quantitative yield. In the ^{31}P ^{1}H-coupled NMR spectrum, derivative **7** presents a characteristic doublet of doublets ($^2J_{P,P}$ = 160, $^1J_{P,H}$ = 220 Hz) at high-field (δ = –18 ppm) for the σ^3-phosphorus atom.



Scheme 3.

In order to prevent the nucleophilic attack at the σ^2-phosphorus atom we turned our attention to the bulky, but not reducing, lithium hexamethyldisilazide (LiHMDS). Addition of one equivalent of this strong base to a THF solution of **3a** afforded a mixture of compounds **8a** and **9a** in a 70:30 ratio (Scheme 4). The spectroscopic data for **9a** are again indicative of a phosphanylphosphonium ylide structure resulting from the addition of LiHMDS to the σ^2-phosphorus atom of **3a**. However, the major compound **8a** displays an AX system at δ = 313 and 41 ppm ($^2J_{P,P}$ = 190 Hz) in the ^{31}P NMR spectrum, the low-field signal being characteristic of a phosphaalkene moiety (Table 1). This new diphosphaallene **8a** was isolated as yellow crystals from a pentane solution in 55% yield, and its structure was unambiguously established by a single-crystal X-ray diffraction study (Figure 1).



Scheme 4.

Table 1. ^{31}P and ^{13}C NMR spectroscopic data (δ in ppm and J in Hertz), and selected structural parameters [bond lengths (pm) and bond angles (°)] for derivatives **8a**, **8b** and **8d**.[4]

	$\delta_{^{31}P}$ ($J_{P,P}$)	$\delta_{^{13}C}$ ($J_{P,C}$)	(σ^4)P–C	(σ^2)P–C	P–C–P
8a	313, 41 (190)	167 (37, 14)	168.4	164.1	115.0
8b	295, 59 (166)	163 (70)	166.9	162.9	125.3
8d	303, 61 (240)	170 (37, 10)	165.0	164.3	120.9

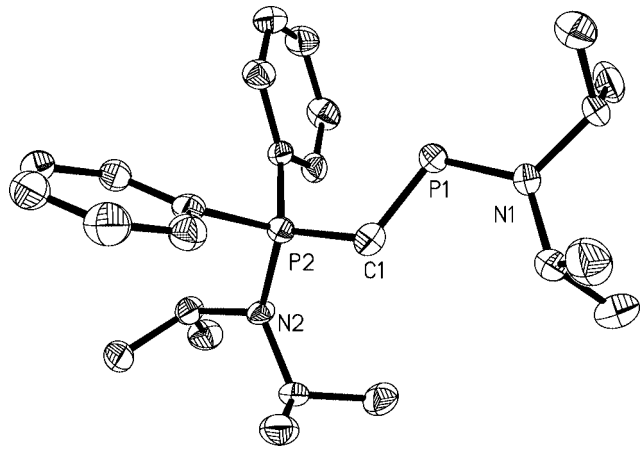


Figure 1. Structure of diphosphaallene **8a** (thermal ellipsoids drawn at 50% probability for non-hydrogen atoms; hydrogen atoms omitted for clarity).

Taking this result into account, one equivalent of LiHMDS was added to phosphoniophosphaalkene **3b**, in which one phenyl group has been replaced by a diisopropylamino substituent, as one would expect to have a more stabilized phosphonium fragment, and thus a less electrophilic σ^2-phosphorus centre. However, similar results were observed, and we isolated the phosphacumulene **8b** and the phosphanylphosphonium ylide **9b** in a 40:60 ratio (Table 1). Diphosphaallene **8b** was crystallised from a cold pentane solution, and its structure was established by an X-ray dif-

fraction study (Figure 2). With the more acidic phosphoniophosphaalkene **3c**, in which the σ^4-phosphorus atom is substituted by three phenyl groups, we did not observe any addition reaction. However, the expected cumulene **8c** was also not detected, even at low temperature, and the four-membered ring **10**[3] was characterised in solution. In this case the steric protection is probably not sufficient, and **8c** undergoes a head-to-tail dimerisation to afford heterocycle **10**,[3] as demonstrated by the presence of an A_2X_2 spin system at δ = 49 and 9 ppm ($^2J_{P,P}$ = 120 Hz) in the ^{31}P NMR spectrum.

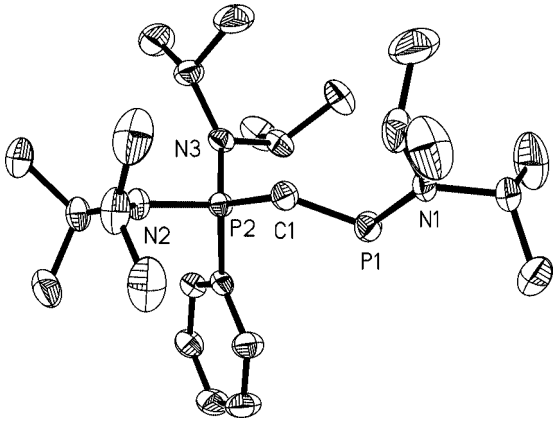

Figure 2. Structure of diphosphaallene **8b** (thermal ellipsoids drawn at 50% probability for non-hydrogen atoms; hydrogen atoms omitted for clarity).

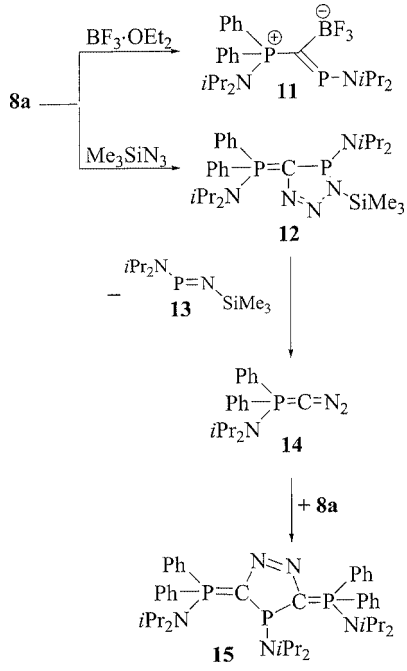
Derivatives **8a** and **8b** present very similar NMR spectroscopic data (Table 1) to those observed for the already known diphosphacumulene **8d**, which features two diisopropylamino and a chloro group bonded to the σ^4-phosphorus atom.[4] Their molecular structures are also very similar, with very short (σ^2)P–C bond lengths (162.9–164.1 pm); the values of the PCP angles (115.0–125.3°) are in good agreement with an sp^2-hybridized carbon atom.

Thanks to its ylidic character, compound **8a** readily reacts with Lewis acids, such as BF_3, to afford the corresponding complex **11**, which was characterised by multinuclear NMR spectroscopy. Of particular interest is the quadruplet observed in the ^{19}F NMR spectrum at δ = –49 ppm ($^1J_{F,B}$ = 40 Hz), which is characteristic of alkylfluoroborate complexes (Scheme 5).[7] On the other hand, the P=C π-bond of **8a** acts as a dipolarophile upon treatment with trimethylsilyl azide to afford the [3+2]-cycloadduct **12**, which was detected by ^{31}P NMR spectroscopy at low temperature (δ = 110 and 31 ppm, $J_{P,P}$ = 200 Hz). Above –20°C, compound **12** undergoes a clean fragmentation into iminophosphane **13** ($\delta_{^{31}P}$ = 283 ppm)[8] and diazomethylenephosphorane **14** ($\delta_{^{31}P}$ = 23 ppm; IR: $\tilde{\nu}$ = 2200 cm^{-1}).[9] Note that **14** can also act as a 1,3-dipole for the diphosphacumulene **8a** to afford heterocycle **15**,[10] which was isolated as a deep-red oil in 80% yield. In the ^{31}P NMR spectrum, compound **15** displays a doublet of doublets at δ = 5.9 ppm ($^2J_{P,P}$ = 157 and 148 Hz) for the phosphane fragment and two doublets centred at δ = 30 ppm for the two inequivalent phosphonium ylides. The absence of symmetry is probably due to the pyramidalisation of both the phosphane and the ylidic carbons, which appear as doublets of doublets at δ = 94 ppm ($J_{P,C}$ = 137 and 23 Hz) in the ^{13}C NMR spectrum. Heterocycle **15** was also obtained (75%) when half an equivalent of trimethylsilyl azide was added to **8a**.



Scheme 5.

Conclusions

In conclusion, we have demonstrated that phosphoniophosphaalkenes **3** are convenient precursors for $1\sigma^4,3\sigma^2$-diphosphaallenes of type **C**. The presence of bulky substituents at the σ^4-phosphorus centre is required to prevent dimerisation. Future work will focus on the preparation of new types of cumulenes using the potential reactivity of the σ^2-phosphorus atom of these phosphoniophosphaalkenes.

Experimental Section

General Remarks: All manipulations were performed under an inert atmosphere of argon using standard Schlenk techniques. Dry, oxygen-free solvents were employed. ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded on Bruker AC80, AC200, WM250 or AMX400 spectrometers. ^{1}H and ^{13}C chemical shifts are reported in ppm relative to Me_4Si as external standard. ^{31}P NMR downfield chemical shifts are expressed with a positive sign, in ppm, relative to external 85% H_3PO_4. ^{19}F chemical shifts are reported in ppm relative to F_3CCO_2H as external standard. IR spectra were recorded on a Perkin–Elmer spectrometer.

Preparation of *C*-Phosphanyl Phosphorus Ylides 2a,c: In a typical experiment, a THF solution of bis(diisopropylamino)chlorophosphane (0.2 g, 1 mmol) was added dropwise at –78 °C to a THF solution of two equivalents of ylide **1a**,**c**. The mixture was then warmed to room temperature. After stirring overnight, the solvent

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was removed under vacuum and the product was extracted with pentane. Compounds **2a,c** were purified by recrystallisation from hot acetonitrile.

2a: Yield: 0.47 g (89%), orange crystals, m.p. 98–100 °C. ^{1}H NMR (C_6D_6): δ = 1.90 (dd, $^2J_{P,H}$ = 4, $^2J_{P,H}$ < 1 Hz, 1 H, PC*H*P), 1.06 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.12 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.28 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 3.6 (d sept, $^2J_{P,H}$ = 7, $^3J_{H,H}$ = 7 Hz, 4 H, NC*H*), 4.0 (sept, $^3J_{H,H}$ = 7 Hz, 2 H, NC*H*), 7.80 (m, 4 H, H_{aro}), 7.12 (m, 6 H, H_{aro}) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 20.1 (dd, $^1J_{C,P}$ = 134 and 13 Hz, P*C*P), 24.2 (d, $^3J_{C,P}$ = 3 Hz, NCH*C*H$_3$), 25.0 (d, $^3J_{C,P}$ = 5 Hz, NCH*C*H$_3$), 46.0 (d, $^2J_{C,P}$ = 11 Hz, N*C*H), 127.8 (s, *C*H$_p$), 130.0 (d, $^3J_{C,P}$ = 3 Hz, *C*H$_m$), 132.9 (dd, $^2J_{C,P}$ = 93, $^4J_{C,P}$ = 3 Hz, *C*H$_o$), 134.0 (dd, $^1J_{C,P}$ = 100, $^3J_{C,P}$ = 3 Hz, *C*$_i$) ppm. ^{31}P{^{1}H} NMR (C_6D_6): δ = 50 and 35 (d, $^2J_{P,P}$ = 190 Hz).

2b: Yield: 0.53 g (96%), yellow powder, m.p. 113–115°C. ^{1}H NMR (C_6D_6): δ = 1.12 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.24 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.28 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.40 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.8 (dd, $^2J_{P,H}$ = 9 and 2 Hz, 1 H, PC*H*P), 3.86 (d sept, $^2J_{P,H}$ = 6, $^3J_{H,H}$ = 7 Hz, 4 H, NC*H*), 4.13 (d sept, $^2J_{P,H}$ = 13, $^3J_{H,H}$ = 7 Hz, 4 H, NC*H*), 7.1 (m, 2 H, H_{aro}), 8.0 (m, 3 H, H_{aro}) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): AB system centred at 56.0 ($^2J_{P,P}$ = 137 Hz).

2c: Spectroscopic data were identical to those reported in the literature.[5]

Preparation of *C*-Phosphoniophosphaalkenes 3a,c: In a typical experiment, a freshly distilled BF_3·OEt_2 solution (2 equiv.) was added dropwise at –78 °C to a CH_2Cl_2 solution of ylide **2a,c** (1 mmol). The mixture was warmed to room temperature and the volatile materials were removed under vacuum. The crude product was dissolved in CH_2Cl_2 and precipitated by vigorous stirring with Et_2O. The resulting powder was washed with Et_2O and dried under vacuum. Compounds **3a,c** were recrystallised from a CH_2Cl_2/Et_2O mixture at –30 °C.

3a: Yield: 0.37 g (72%), yellow crystals, m.p. 168 –170 °C. ^{1}H NMR ($CDCl_3$): δ = 1.24 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 3.6 (d sept, $^2J_{P,H}$ = 16, $^3J_{H,H}$ = 7 Hz, 4 H, NC*H*), 6.75 (dd, $^2J_{P,H}$ = 12, $^2J_{P,H}$ = 4 Hz, 1 H, PC*H*P), 7.80 (m, 10 H, H_{aro}) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 23.4 (broad, NCH*C*H$_3$), 49.2 (d, $^2J_{C,P}$ = 6 Hz, N*C*H), 95.5 (dd, $^1J_{C,P}$ = 105 and 56 Hz, P*C*P), 124.5 (dd, $^1J_{C,P}$ = 106, $^3J_{C,P}$ = 5 Hz, *C*$_i$), 129.8 (dd, $^2J_{C,P}$ = 13 Hz, *C*H$_{aro}$), 133.2 (d, $^3J_{C,P}$ = 10 Hz, *C*H$_{aro}$), 134.2 (s, *C*H$_p$) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 308 and 40 (d, $^2J_{P,P}$ = 133 Hz).

3b: Yield: 0.51 g (95%), colourless powder, m.p. 176–178 °C. ^{1}H NMR ($CDCl_3$): δ = 1.28 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.40 (d, $^3J_{H,H}$ = 7 Hz, 6 H, NCC*H*$_3$), 3.7 (d sept, $^2J_{P,H}$ = 16, $^3J_{H,H}$ = 7 Hz, 4 H, NC*H*), 3.9 (broad, 4 H, NC*H*), 6.22 (dd, $^2J_{P,H}$ = 12 and 6 Hz, 1 H, PC*H*P), 7.7 (m, 10 H, H_{aro}) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 23.6 (d, $^2J_{C,P}$ = 3 Hz, NC*C*H$_3$), 24.2 (broad, NCH*C*H$_3$), 48.7 (d, $^2J_{C,P}$ = 5 Hz, N*C*H), 50.0 (broad, N*C*H), 99.8 (dd, $^1J_{C,P}$ = 119 and 50 Hz, P*C*P), 124.2 (dd, $^1J_{C,P}$ = 125, $^3J_{C,P}$ = 3 Hz, *C*$_i$), 129.3 (d, $^2J_{C,P}$ = 14 Hz, *C*H$_{aro}$), 133.3 (d, $^3J_{C,P}$ = 6 Hz, *C*H$_{aro}$), 134.4 (s, *C*H$_{aro}$) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 303 and 53 (d, $^2J_{P,P}$ = 125 Hz).

3c: Spectroscopic data were identical to those reported in the literature.[5]

General Procedure for the Synthesis of Adducts 4–7: In a typical experiment, one equivalent of organolithium derivative (**4**: MeLi; **5**: *n*BuLi; **6**: MesLi; **7**: *t*BuLi;) in solution in hexanes was added to a THF solution of the phosphaalkene **3a** (0.43 g, 1 mmol) at –78 °C. The mixture was warmed to room temperature and the solvent was removed under vacuum. The resulting product was extracted with pentane and dried under vacuum. Derivatives **4**–**7** were obtained as orange oils and used without further purification.

4: Yield: 0.43 g (97%). ^{1}H NMR (C_6D_6): δ = 1.01 (d, $^3J_{H,H}$ = 7 Hz, 6 H, CHC*H*$_3$), 1.05 (d, $^3J_{H,H}$ = 6 Hz, 6 H, CHC*H*$_3$), 1.14 (d, $^3J_{H,H}$ = 7 Hz, 6 H, CHC*H*$_3$), 1.16 (d, $^3J_{H,H}$ = 5 Hz, 6 H, CHC*H*$_3$), 1.43 (d, $J_{P,H}$ = 7 Hz, 3 H, PC*H*$_3$), 1.65 (dd, $J_{P,H}$ = 9 and 3 Hz, 1 H, PC*H*P), 3.5 (m, 4 H, NC*H*), 7.1 (m, 6 H, H$_{aro}$), 7.7 (m, 4 H, H$_{aro}$) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 22.8 (dd, $^1J_{P,C}$ = 131 and 10 Hz, P*C*P), 23.0 (dd, $J_{P,C}$ = 14 and 20 Hz, P*C*H$_3$), 23.4 (s, CH*C*H$_3$), 23.7 (d, $J_{P,C}$ = 2 Hz, CH*C*H$_3$), 24.6 (s, CH*C*H$_3$), 24.8 (s, CH*C*H$_3$), 44.6 (d, $J_{P,C}$ = 8 Hz, N*C*H), 47.0 (d, $J_{P,C}$ = 5 Hz, N*C*H), 127.7 (s, *C*$_{aro}$H), 130.0 (dd, $J_{P,C}$ = 6 and 2 Hz, *C*$_{aro}$H), 132.0 (d, $J_{P,C}$ = 8 Hz, *C*$_{aro}$H), 132.9 (dd, $J_{P,C}$ = 9 and 2 Hz, *C*$_{aro}$H), 135.0 (dd, $J_{P,C}$ = 92 and 3 Hz, *C*$_i$) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 35 and 6 (d, $^2J_{P,P}$ = 107 Hz).

9b: Yield: 0.46 g (40%), yellow needles from pentane/THF, m.p. 121–122 °C. ^1H NMR (C_6D_6): δ = 0.53 (s, 9 H, SiCH$_3$), 0.55 (s, 9 H, SiCH$_3$), 1.06 (d, $^3J_{H,H}$ = 8 Hz, 12 H, NCC*H*$_3$), 1.15 (d, $^3J_{H,H}$ = 8 Hz, 12 H, NCC*H*$_3$), 1.24 (d, $^3J_{H,H}$ = 7 Hz, 6 H, NCC*H*$_3$), 1.26 (d, $^3J_{H,H}$ = 7 Hz, 6 H, NCC*H*$_3$), 1.79 (dd, $^2J_{P,H}$ = 9 and 2 Hz, 1 H, PCHP), 3.7–4.2 (m, 6 H, NC*H*), 7.2 (m, 3 H, H_{aro}), 8.1 (m, 2 H, H_{aro}) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 83 and 54 ($^2J_{P,P}$ = 170 Hz) ppm.

BF_3 Complex 11: One equivalent of $BF_3{\cdot}OEt_2$ was added to a THF solution (5 mL) of cumulene **8a** (0.8 g, 2 mmol) at room temperature. After stirring the mixture for 1 h, the solvent was removed under vacuum and the crude product was extracted with Et_2O. The solvent was removed under vacuum, and complex **11** was obtained as a yellow powder (0.6 g, 62%). M.p. 89–91 °C. ^1H NMR ($CDCl_3$): δ = 1.14 (br. d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 1.17 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCC*H*$_3$), 3.6 (br. m, 4 H, NC*H*), 4.0 (d sept, $^2J_{P,H}$ = 14, $^3J_{H,H}$ = 7 Hz, 4 H, NC*H*), 7.0 (m, 6 H, H_{aro}), 7.9 (m, 4 H, H_{aro}) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 23.2 (s, NCH*C*H$_3$), 49 (d, $^2J_{C,P}$ = 6 Hz, N*C*H), 128.1 (d, $J_{C,P}$ = 20 Hz, *C*H$_{aro}$), 129.0 (dd, $^1J_{C,P}$ = 115, $^3J_{C,P}$ = 8 Hz, C_i), 131.9 (s, *C*H$_{aro}$), 135.0 (d, $J_{C,P}$ = 10 Hz, *C*H$_{aro}$) ppm. ^{19}F NMR ($CDCl_3$): δ = –49 (q, $^1J_{B,F}$ = 40 Hz) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 326 (d, $^2J_{P,P}$ = 195 Hz), 57 (dq, $^2J_{P,P}$ = 195, $^3J_{P,F}$ = 8 Hz) ppm.

Heterocycle 15: Freshly distilled Me_3SiN_3 (13 μL, 0.1 mmol) was added to a THF solution (1 mL) of cumulene **8a** (80 mg, 0.2 mmol) at –78 °C. After warming to room temperature, the volatile materials were removed under vacuum to give compound **15** as a deep-red oil (110 mg (80%). ^1H NMR (C_6D_6): δ = 1.07 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCCH$_3$), 1.30 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCCH$_3$), 1.60 (d, $^3J_{H,H}$ = 7 Hz, 12 H, NCCH$_3$), 3.8 (d sept, $^2J_{P,H}$ = 16, $^3J_{H,H}$ = 7 Hz, 4 H, NCH), 7.0 (m, 6 H, CH$_{aro}$), 8.0 (m, 4 H, CH$_{aro}$), 8.4 (m, 4 H, CH$_{aro}$) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 24.1 (s, CH$_3$), 24.8 (s, CH$_3$), 47.6 (d, $J_{P,C}$ = 5 Hz, NCH), 94.0 (dd, $J_{P,C}$ = 137 and 23 Hz, PCP), 130.1 (s, HC$_{aro}$), 130.8 (s, HC$_{aro}$), 133.0 (dd, $J_{P,C}$ = 108 and 75 Hz, C$_i$), 134.8 (d, $J_{P,C}$ = 50 Hz, HC$_{aro}$), 134.9 (d, $J_{P,C}$ = 60 Hz, HC$_{aro}$) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 30.0 (dd, $^2J_{P,P}$ = 157 and 148 Hz), 5.9 (dd, $^2J_{P,P}$ = 157 and 148 Hz) ppm.

Crystallographic Data for 8a: $C_{54}H_{84}N_4OP_4$, M = 929.13, monoclinic, $P2_1/c$, a = 23.882(2), b = 7.920(1), c = 28.678(2) Å, β = 94.061(1)°, V = 5410.6(6) Å^3, Z = 4, T = 173(2) K. 22828 Reflections (7276 independent, R_{int} = 0.0698) were collected. Largest electron density residue: 0.305 e Å^{-3}, R_1 [for $I > 2\sigma(I)$] = 0.0641 and wR_2 = 0.1519 (all data) with $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$.

Crystallographic Data for 8b: $C_{25}H_{47}N_3P_2$, M = 451.60, triclinic, $P\bar{1}$, a = 8.158(1), b = 12.372(2), c = 15.531(2) Å, α = 112.822(2)°, β = 95.436(2)°, γ = 102.054(2)°, V = 1385.8(4) Å^3, Z = 2, T = 193(2) K. 9920 Reflections (5404 independent, R_{int} = 0.0336) were collected. Largest electron density residue: 0.377 e Å^{-3}, R_1 [for $I > 2\sigma(I)$] = 0.0457 and wR_2 = 0.1180 (all data).

All data for both structures were collected at low temperatures using an oil-coated shock-cooled crystal on a Bruker-AXS CCD 1000 diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-97)[11] and all non hydrogen atoms were refined anisotropically using the least-squares method on F^2.[12]

CCDC-259732 (for **8a**) and -259733 (for **8b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

A "User-Friendly" Chemical Approach Towards Paramagnetic Cobalt Phosphide Hollow Structures: Preparation, Characterization, and Formation Mechanism of Co_2P Hollow Spheres and Tubes

Hongwei Hou,[b] Qi Peng,[c] Shuyuan Zhang,[b] Qixun Guo,[b] and Yi Xie*[a,b]

Keywords: Cobalt / Materials science / Nanostructures / Phosphides

User-friendly chemistry principles have been implemented for the synthesis of hollow Co_2P structures. In comparison with the original organometallic approach, the resulting alternative route is safe, simple, and inexpensive. The X-ray diffraction (XRD) pattern, X-ray photoelectron spectra (XPS), field emission scanning electron microscope (FESEM) images, and transmission electronic microscope (TEM) images were used to characterize the products, which exhibit paramagnetic behavior down to 2 K, as determined with a commercial superconducting quantum interference device (SQUID) magnetometer. The experimental investigations suggest that the formation of Co_2P hollow structures, hollow spheres, and tubes can be explained by an aggregation mechanism and a thermodynamically governed regime. Initially formed Co_2P nanoparticles are driven to aggregate into Co_2P hollow spheres by the gas bubbles produced. The formation of Co_2P tubes then occurs from the hollow spheres via hollow vessels in a thermodynamically governed process. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Inorganic materials with hollow structures have opened up a new and challenging field in chemistry, biotechnology, and materials science due to their potential applications in controlled-release capsules, medical imaging, artificial cells, chemical sensors, encapsulation of products (cosmetics, inks, and dyes), shape-selective adsorbents, and catalysts.[1–4] Recently, the preparation of magnetic hollow structures has become a promising approach for investigating magnetic properties due to the formation of unusual magnetic domains, the generation of quantum effects, and other phenomena.[5] Besides magnetic functions, they have potential applications in catalysis, coatings, and composite materials, etc., owing to their low density and large surface area.[6] To the best of our knowledge, the studies on hollow structures of transition metal phosphides are much less advanced in comparison to other magnetic materials because of their difficult synthesis.[7–9] All the above factors have driven us to explore the possibility of the preparation of hollow structures of transition metal phosphides under mild conditions.

Up to now, organometallic approaches have been applied to grow transition metal phosphides. Recently, FeP nanorods and nanowires were synthesized in a trioctylphosphane oxide (TOPO)/trioctylphosphane (TOP) solvent system from $Fe(CO)_5$ by a solution-phase injection route.[10] Fe_2P nanorods produced by thermal decomposition of $Fe(CO)_5$ using a syringe pump have also been reported.[11] MnP nanoparticles have been produced by the reaction of $Mn_2(CO)_{10}$ with $P(SiMe_3)_3$ in TOPO/myristic acid.[12] However, the synthetic approach using zero-valent transition metal carbonyl complexes in coordinating solvents possesses several intrinsic disadvantages.[13] For instance, sophisticated equipment such as a glove box or a syringe pump are required, as is an inert gas. Secondly, the reactions are not easy to control. Furthermore, for the tubular structures, controlling this process is difficult and the internal cavity is not always continuous throughout the length.[14] For these fundamental and practical reasons, an alternative route using a "user-friendly" chemical method is much anticipated. This concept, which refers to the synthetic and processing procedures, is different to the traditional "green chemistry".

Among M_2P compounds (M = Mn, Fe, CO, Ni), only Co_2P has a C_{23} orthorhombic structure; the others have a C_{22} hexagonal structure.[15,16] Our previous research on Co_2P nanocrystallites and nanorods gave some interesting results,[17,18] and these attracted us to the unexplored Co_2P nanostructures with special morphologies. Here, for the first time, we report the formation of Co_2P hollow spheres and tubes from metal halides and yellow phosphorus in a mixture of absolute ethanol and water as solvent. We have man-

aged to eliminate the use of toxic carbonyl complexes, and have developed an easy process for the formation of Co_2P hollow spheres and tubes under solvothermal conditions. On the basis of a series of comparison experiments, a mechanism of formation of Co_2P hollow spheres and tubes was proposed and investigated. We expect that the novel tubular nature of Co_2P together with the tunable interior nanoparticle size of these hollow spheres may make them ideal entities for incorporating other species or surface modification, which might bring novel optical, electronic, and magnetic properties in the near future.

Results and Discussion

The typical XRD patterns of the samples obtained at 220 °C for 30 h and 48 h are shown in Figures 1a and b, respectively. All the diffraction peaks can be indexed to orthorhombic Co_2P [space group *Pnam*(62)] in the JCPDS card no.74-287. Compared with the standard diffraction patterns, no characteristic peaks for impurities such as P or CoP_3, can be detected.

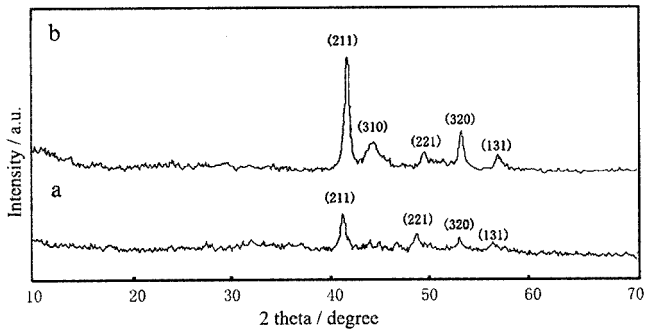

Figure 1. XRD patterns of the as-produced Co_2P hollow spheres (a) and tubes (b).

The purity and elemental composition of the products were determined by X-ray photoelectron spectroscopy (XPS); the XPS spectra of Co_2P are shown in Figures 2a and b. The Co $2p_{3/2}$ binding energy is 778.2 eV, which is in good agreement with the literature,[19] and the P 2p binding energy is 129.8 eV, consistent with our previous results (129.1 eV). From the integral peak areas of Co and P in the XPS spectra, the Co_2P samples obtained at 220 °C for 30 h have a Co/P molar ratio of 1.80:1 − the Co_2P samples obtained at 220 °C for 48 h have a molar ratio of 1.95:1 − both of which are close to the expected stoichiometry of Co_2P. No obvious impurities such as chloride or phosphate could be detected in any of the samples.

The morphology of the Co_2P samples obtained at 220 °C for 30 h is shown in Figure 3. The panoramic FESEM images (Figure 3a) show that the sample consists of a large quantity of nearly uniform spheres and clearly indicate that the spheres have diameters of around 1.2 μm; the TEM image (Figure 3b) reveals their partly overlapped hollow nature. The three obvious diffraction rings in the SAED pattern (Figure 3c) recorded from the hollow spheres can be identified as the (211), (310), and (131) planes of orthorhombic Co_2P. The HRTEM image (Figure 3d) clearly shows that the hollow spheres are aggregates of small particles with a size of 3–4 nm.

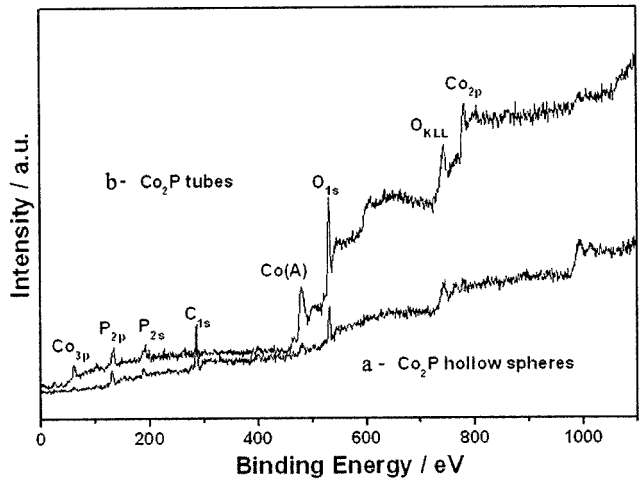

Figure 2. XPS analysis of the as-produced Co_2P hollow spheres (a) and tubes (b).

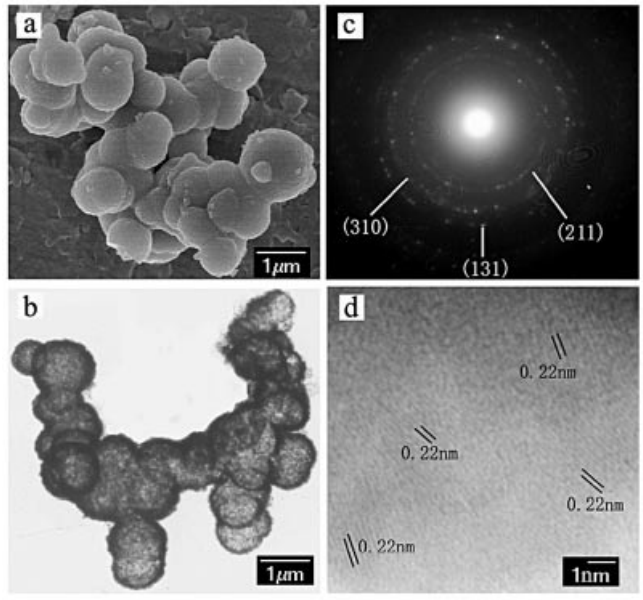

Figure 3. Morphology of the Co_2P hollow spheres formed at 220 °C after 30 h: (a) FESEM image; (b) TEM image; (c) SAED patterns; (c) HRTEM image.

The morphology of the Co_2P samples obtained at 220 °C for 48 h is shown in Figure 4. Both the FESEM and TEM images of the sample (Figure 4a–c) show that Co_2P here is present as tubular structures with a diameter of around 1 μm and length of 3–7 μm. The SAED patterns recorded from the tubes (Figure 4d) clearly show that the tubes are polycrystalline. Six easily observed diffraction rings can be identified as the (211), (310), (221), (131), (232), and (422) diffractions of orthorhombic Co_2P. The direct observation of the structure of the Co_2P tubes was performed by HRTEM, as shown in Figure 4e, which clearly shows that the tubes are aggregates of small particles.

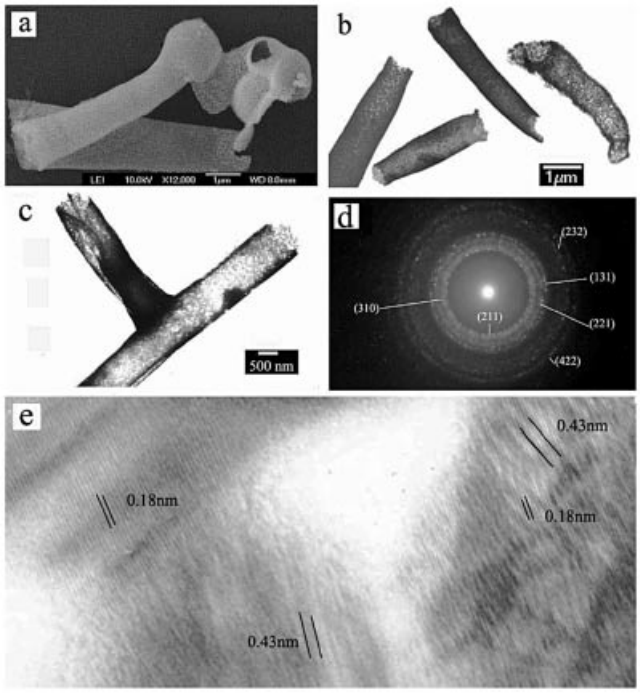

Figure 4. Morphology of the Co_2P tubes formed at 220 °C after 48 h: (a) FESEM image; (b) TEM image; (c) a typical tubular structure; (d) SAED patterns; (e) HRTEM image.

The magnetic properties of the Co_2P hollow spheres and tubes, which have similar properties, were measured with a commercial SQUID magnetometer (Quantum Design, MPMS). The temperature dependence of the magnetization for Co_2P hollow spheres and tubes measured in an applied magnetic field of 500 Oe between 2 K and 300 K is shown in Figure 5a, and the magnetic-field dependence of magnetization (M vs. H) at 2 K for both Co_2P hollow spheres and tubes is shown in Figure 5b. Both reveal that the Co_2P hollow spheres and tubes have no ferromagnetic characteristics and can be expressed as paramagnetic moments.[7–9] The results can be well described by the Curie–Weiss law, and agree well with those obtained from the M vs. H data. The Co_2P hollow spheres and tubes are paramagnetic with no evidence of ferromagnetic ordering, due to their C_{23} orthorhombic structure.[15] This is in agreement with the magnetic properties of Co_2P reported by Fujii, who reported that Co_2P exhibits ferromagnetism only in its hexagonal structure, and that orthorhombic Co_2P is a Pauli paramagnet.[16] The tube structures have stronger paramagnetic properties than the hollow spheres due to their better crystallinity.

The experimental investigations suggest that the formation of Co_2P hollow spheres and tubes can be explained as an aggregation mechanism in a thermodynamically governed process. Initially formed Co_2P nanoparticles are driven to aggregate into Co_2P hollow spheres by the bubbles of PH_3 and C_2H_4 produced. The formation of the Co_2P tubes is suggested to occur from the hollow spheres via hollow vessels in a thermodynamically governed process.

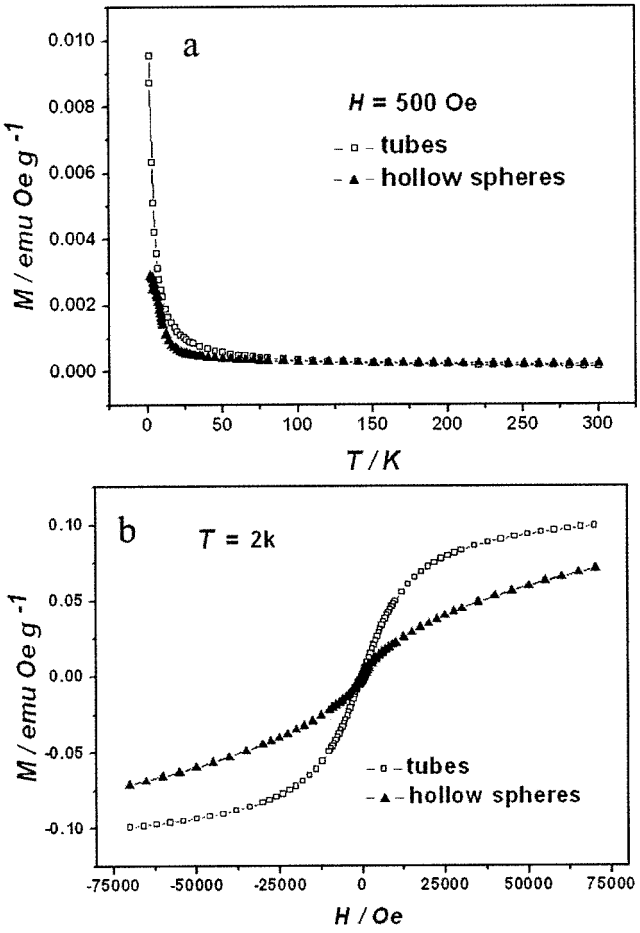

Figure 5. Magnetic properties of the Co_2P hollow spheres and tubes: (a) temperature dependence of magnetization under an applied magnetic field of 500 Oe; (b) magnetic-field dependence of the magnetization at 2 K.

In the present route the synthesis of Co_2P is based on the reaction of Co^{2+} with PH_3, which is produced by the reaction of yellow phosphorus with water and ethanol at 220 °C. Yellow phosphorus (melting point 44.1 °C and boiling point 280 °C) could form droplets dispersed in the aqueous solution to give a heterogeneous liquid–liquid two-phase system at elevated temperature. Obviously, the reactions easily occur at the interfaces of these two phases.

The reaction of phosphorus with water at high temperature and pressures has been studied by several authors who were primarily interested in the overall reaction and its products.[20–22] It is well known that ethanol reacts with yellow phosphorus at high temperatures and pressures.[23] In our approach, the system provides the appropriate conditions to initiate the reactions shown in Equations (1) and (2). Once generated, PH_3 would immediately react with the cobalt ion to form Co_2P, as shown in Equation (3). The by-product, H_3PO_3, undergoes a circular reaction with H_3PO_4, shown in Equations (4) and (5), which increases the amount of PH_3 and accelerates the reaction of PH_3 with the cobalt ion.[24,25] Reaction (3) continues until one of the raw materials runs out. The whole process can be formulated as shown in Scheme 1.

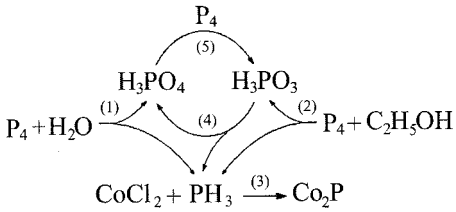

Scheme 1. Schematic growth path of Co_2P. (1)–(5) represent the corresponding reactions in the text.

After the initial nucleation, the newly formed Co_2P nuclei grow into nanoparticles. When the reaction was carried out at 220 °C for between 12 and 24 h, the nanoparticles grew gradually, as shown in Figures 6a and b. When the reaction time was prolonged to 30 h, a large quantity of nearly uniform hollow spheres of Co_2P was formed, as shown by the corresponding TEM images in Figure 6c. When the reaction time was extended further to 36 h, congregated hollow spheres were found in the product, as shown in Figure 6d.

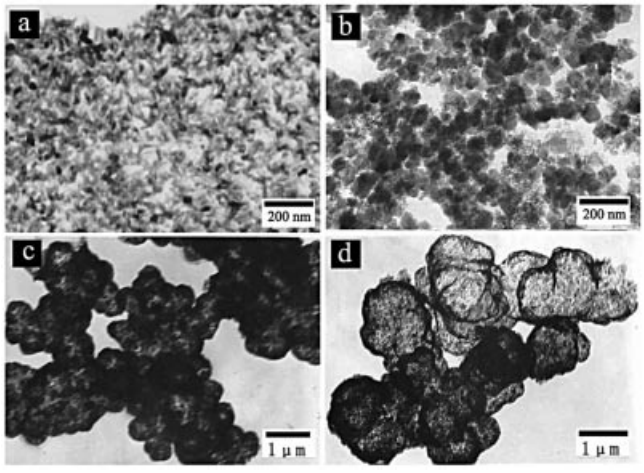

Figure 6. TEM images of the Co_2P structures formed in ethanol at 220 °C at different reaction times: (a) particles after 12 h; (b) particles after 24 h; (c) hollow spheres after 30 h; (d) congregated hollow spheres after 36 h.

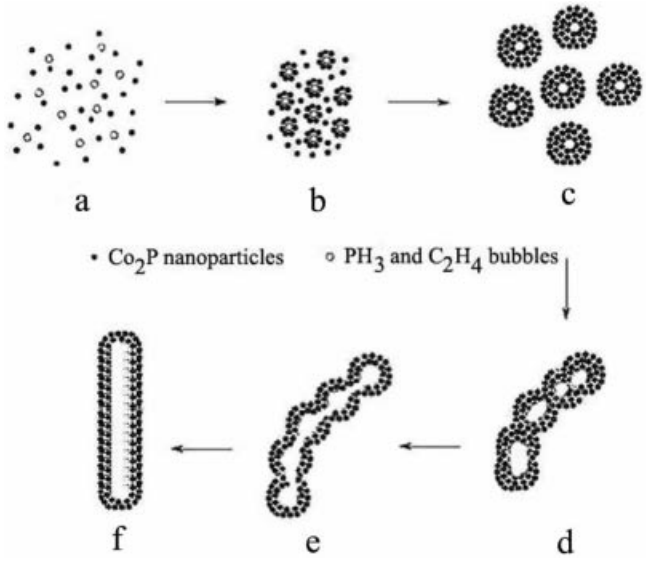
Based on these observations and the structure of the hollow spheres we were able to propose an aggregation mechanism, as shown in Scheme 2. The TEM results suggested that these newly formed nanoparticles have a tendency to aggregate at the interface of the gas bubbles and the solution. Similar to the reported case of monodispersed SiO_2 or ZnSe microspheres aggregating under the effects of gas bubbles,[26,27] the gas aggregation centers are the PH_3 and C_2H_4 bubbles in our approach. The mixture of ethanol and water used as solvent could effectively form the bubble templates that are important for the formation of hollow spheres. In comparison with our previous work on Co_2P nanorods,[18] it is easy to show that the gaseous C_2H_4 produced in this approach is the linchpin of the bubble templates as it is not involved in any further reaction and thus can provide the gas aggregation center. Driven by the minimization of interfacial energy, newly formed Co_2P nanoparticles may aggregate around the gas–liquid interface between the gas bubbles and the solution and then form Co_2P hollow spheres.



Scheme 2. Schematic illustration of a proposed mechanism for the formation of hollow Co_2P structures: (a) nanoparticles; (b) aggregated nanoparticles around the gas–liquid interface between PH_3 and C_2H_4 bubbles and the solution; (c) hollow spheres; (d) congregated hollow spheres; (e) connected hollow spheres; (f) tubes.

It was well known that in a thermodynamic process hollow spheres are generally less stable than tubes as they possess a higher internal energy; this favors the transformation of hollow spheres into tubes. When the reaction time was increased from 40 h to 42 h at 220 °C, these hollow spheres became attached end-to-end and a borderline could be detected only dimly (Figure 7a and b). When the reaction time was raised to 46 h, the tubular conductive structure had obviously formed (Figure 7c), as shown by the incurvate walls of the vessels and lack of borderline of the hollow microspheres. Finally, the rough vessels grew into smooth tubular structures (Figure 7d) after 48 h. The whole growth procedure from hollow spheres to Co_2P tubes is illustrated in Scheme 2.

Conclusions

In summary, we developed a "user-friendly" one-pot chemical approach to synthesize Co_2P hollow spheres and tubes, which exhibit paramagnetic behavior down to 2 K. In comparison with the original organometallic approach, this route is safe, simple, and inexpensive. The experimental investigations suggest that Co_2P hollow spheres are formed from the initially formed nanoparticles under the effect of PH_3 and C_2H_4 bubbles, and the Co_2P tubes form from the hollow spheres via hollow vessels in a thermodynamically governed process. The use of gas bubbles produced during the reaction to provide aggregation centers is a novel and effective method to fabricate hollow structures. Compared to other templated synthetic methods, this template-free method is very simple and convenient and avoids the introduction of impurities. It is therefore suitable for modern chemical synthesis. This idea might be extended to other solution systems in which easily aggregated monodispersed nanocrystals are produced during the reaction.

Experimental Section

Details of a typical experiment are as follows: $CoCl_2{\cdot}6H_2O$ (0.475 g, 2 mmol) and yellow phosphorus (1.24 g, 10 mmol) were placed into a 40-mL, Teflon-lined autoclave, which was then filled with absolute ethanol up to 80% of its capacity. To obtain Co_2P hollow spheres, the autoclave was heated to 220 °C for 30 h; To obtain Co_2P tubes, the autoclave was maintained at 220 °C for 48 h. In both cases the autoclave was then allowed to cool to room temperature, and the black precipitate was collected and washed with absolute ethanol and distilled water in sequence to remove any by-products and possible impurities. The final products were dried in vacuo at 60 °C for 3–4 h. The yields of the products synthesized by this method were above 80%.

The phase identification of the samples was performed with a Rigaku D/max-γA X-ray diffractometer equipped with Cu-K_α radiation (λ = 1.54178 Å). The purity and components were determined by X-ray Photoelectron Spectroscopy (XPS) with an ESCALab MKII X-ray photoelectron spectrometer with Mg-K_α radiation as the excitation source. The morphology of the products was determined with a field emission electron microscope (FESEM JEOL JSM-6700F) and transmission electron microscope (TEM Hitachi H-800). Further structural analysis was performed with a high-resolution transmission electron microscope (HRTEM JEOL-2010) and by selected area electron diffraction (SAED). The magnetic properties were measured with a commercial superconducting quantum interference device (SQUID) magnetometer (Quantum Design, MPMS).

C–H vs. N–H Bond Activation in Aminophosphane Ligands: Reaction of $[Cp^*Ru(MeCN)_2(PR^1{}_2NHR^2)]^+$ (R^1 = Ph, *i*Pr; R^2 = Ph, C_6F_5) with Alkynes

Manuel Jiménez-Tenorio,[a] M. Carmen Puerta,[a] and Pedro Valerga*[a]

Dedicated to the memory of Prof. Francisco González García (Universidad de Sevilla)[‡]

Keywords: Alkyne ligands / C–H activation / Half-sandwich complexes / Phosphane ligands / Ruthenium

The reaction of the complexes $[Cp^*Ru(MeCN)_2(PR^1{}_2NHR^2)]^+$ (R^1 = R^2 = Ph **1**; R^1 = *i*Pr, R^2 = C_6F_5 **2**; R^1 = *i*Pr, R^2 = Ph **3**) with 1-alkynes HC≡CR (R = H, *n*Bu, $SiMe_3$) or diynes $HC{\equiv}CCH_2XCH_2C{\equiv}CH$ (X = O, CH_2, CH_2CH_2) yields different products depending on the nature of the aminophosphane ligand. In some cases, alkyne coupling involving migration of the phosphane and N–H activation occurs, yielding amidobutadiene complexes of the type $[Cp^*Ru\{\eta^4\text{-}C_4H_3(R)_2\text{-}PR^1{}_2NR^2\text{-}\kappa^1N\}]^+$ or $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2XCH_2)PR^1{}_2NR^2\text{-}\kappa^1N\}]^+$. The complexes $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2OCH_2)\text{-}PPh_2NPh\text{-}\kappa^1N\}][PF_6]$ (**1a**) and $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2\text{-}OCH_2)PiPr_2NC_6F_5\text{-}\kappa^1N\}][PF_6]$ (**2a**) have been structurally characterized by X-ray crystallography. In other cases, for example the reaction of **3** with HC≡CR (R = *n*Bu, $SiMe_3$), C–H bond activation at the *ortho*-position of the phenyl ring of the phenylamino moiety and coupling to the alkyne fragment takes place. This results in the formation of the novel π-alkene complexes $[Cp^*Ru(MeCN)\{\eta^2\text{-}RCH{=}CH(C_6H_4)\text{-}NHPiPr_2\text{-}\kappa^1P\}]^+$ (R = *n*Bu **4**, $SiMe_3$ **5**), formally derived from the insertion of the alkyne into the *ortho*-C–H bond of the phenyl ring. The derivative $[Cp^*Ru(MeCN)\{\eta^2\text{-}nBuCH{=}CH(C_6H_4)NHPiPr_2\text{-}\kappa^1P\}][BPh_4]$ has been structurally characterized by X-ray crystallography. These compounds are related to the also structurally characterized olefin complex $[Cp^*Ru(MeCN)(\eta^2\text{-}MeOOCCH{=}CH_2)(PPh_2NHPh)][PF_6]$ (**6**), generated by reaction of **1** with methyl acrylate.

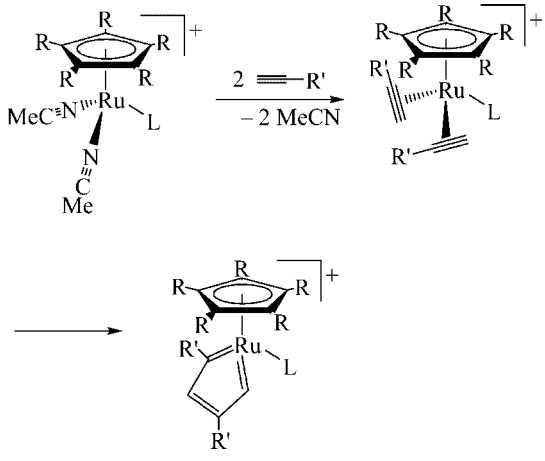
Introduction

Complexes of the type $[(C_5R_5)Ru(MeCN)_2(L)]^+$ (R = H, Me; L = CO, PR_3, $AsPh_3$, $SbPh_3$) are regarded as synthons for the corresponding cationic 14-electron fragments $[(C_5R_5)Ru(L)]^+$ due to the substitutionally labile character of the acetonitrile ligands.[1] The reactivity of these systems towards alkynes has been thoroughly studied both from the experimental and theoretical points of view.[1–5] The derivatives $[(C_5R_5)Ru(MeCN)_2(L)]^+$ react with alkynes to yield bis(π-alkyne) adducts which readily undergo oxidative alkyne coupling of the two alkyne ligands to form cationic ruthenacyclopentatriene complexes.

Ruthenacyclopentatriene complexes are key intermediates in the overall process, and the final products of the reaction are determined by the nature of L, the use of Cp or Cp* as co-ligands, and the nature of the substituents present in the alkyne.[1] When L is PR_3, migration of the phosphane from Ru to C occurs in most cases, generating



allyl carbene species.[2–4] These species behave as masked coordinatively unsaturated complexes that are capable of activating C–H bonds. In cyclopentadienyl complexes containing tertiary phosphane ligands the C–H activation process takes place at one of the aryl or alkyl substituents of the phosphane.[4,6]

At variance with this, in pentamethylcyclopentadienyl derivatives the C–H activation occurs at one of the methyl

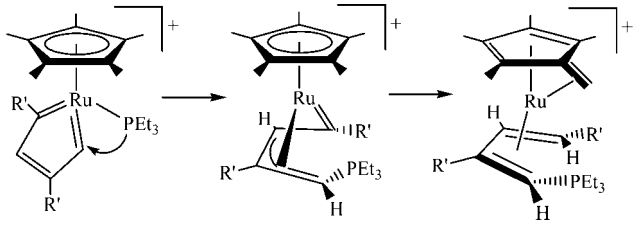
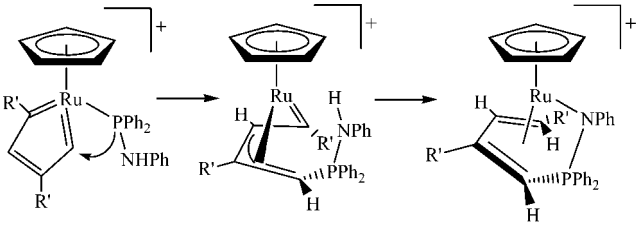
substituents of the Cp* ring to yield η^6-fulvene complexes.[6]



In all cases, the result of the phosphane migration to the organic fragment and the subsequent C–H activation process is the formation of η^4-butadiene species. Very recently, Kirchner and co-workers have reported the activation of alkynes by the aminophosphane complex $[CpRu(MeCN)_2(PPh_2NHPh)]^+$, which results in the formation of η^4-amidobutadiene complexes.[7] In this case phosphane migration also occurs, and is followed by an N–H bond activation process in the amino group rather than C–H bond activation.



Given the previously observed behavior differences between $[CpRu(MeCN)_2(PR_3)]^+$ and the homologous $[Cp^*Ru(MeCN)_2(PR_3)]^+$ complexes with respect to the C–H activation processes,[6] we have addressed the question of whether N–H or C–H activation should occur in the case of Cp* complexes containing aminophosphane ligands. Hence, we have studied the interaction of 1-alkynes with the cationic complexes $[Cp^*Ru(MeCN)_2(PR^1{}_2NHR^2)]^+$. We have found that either N–H or C–H activation may take place depending upon the aminophosphane ligand and the substituent on the alkyne. The detailed results are discussed below.

Results and Discussion

The complexes $[Cp^*Ru(MeCN)_2(PR^1{}_2NHR^2)]^+$ ($R^1 = R^2$ = Ph **1**; R^1 = *i*Pr, $R^2 = C_6F_5$ **2**; R^1 = *i*Pr, R^2 = Ph **3**) were prepared by treatment of $[Cp^*Ru(MeCN)_3][PF_6]$ with a stoichiometric amount of the corresponding aminophosphane in dichloromethane; they were isolated either as their PF_6^- (**1** and **2**) or BPh_4^- (**3**) salts.

Treatment of **1**, **2**, or **3** with either propargyl ether or 1,6-heptadiyne led to the isolation after purification, in moderate yields, of the corresponding amidobutadiene complexes $[Cp^*Ru(\eta^4\text{-}C_4H_3(X)PR^1{}_2NR^2\text{-}\kappa^1N)]^+$ [$R^1 = R^2$ = Ph, X = CH_2OCH_2 **1a**, $(CH_2)_3$ **1b**; R^1 = *i*Pr, $R^2 = C_6F_5$, X = CH_2OCH_2 **2a**, $(CH_2)_3$ **2b**; R^1 = *i*Pr, R^2 = Ph, X = CH_2OCH_2 **3a**, $(CH_2)_3$ **3b**]. In analogous fashion, treatment of **1** and **3** with 1,7-octadiyne also led to the corresponding amidobutadiene complexes **1c** and **3c**, respectively, whereas the reaction of **2** with 1,7-octadiyne yielded a mixture from which no pure compound could be isolated. The reaction of **1** with HC≡CR (R = H, *n*Bu) also afforded the corresponding amidobutadiene complexes $[Cp^*Ru\{\eta^4\text{-}C_4H_3(R)_2\text{-}PPh_2NPh\text{-}\kappa^1N\}][PF_6]$ (R = H **1d**, *n*Bu **1e**). All these compounds were characterized by NMR spectroscopy. The ^1H and $^{13}C\{^1H\}$NMR spectra are consistent with those reported for the related cyclopentadienyl amidobutadiene complexes.[7] One of the most distinctive spectral features of these complexes is the resonance for H^1 and C^1 in their respective ^1H and $^{13}C\{^1H\}$ NMR spectra. Given the fact that C^1 is the carbon atom to which the phosphorus atom is bonded, its $^{13}C\{^1H\}$ resonance appears as a doublet with a rather large $^1J_{C,P}$ coupling constant in the range 100–115 Hz. The hydrogen atom attached to C^1 appears as a doublet with a value for the $^2J_{H,P}$ coupling constant of around 16 Hz. C^2 is a quaternary carbon atom in all cases except for compound **1d**. In this case, the hydrogen atom attached to C^2 displays a large $^3J_{H,P}$ coupling constant of 28 Hz with the phosphorus atom in the *trans*-position. The $^{31}P\{^1H\}$ NMR spectra consist of one singlet in all cases, which is shifted to high-field by 20 to 35 ppm with respect

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to the position of the $^{31}P\{^1H\}$ NMR resonance for the corresponding bis(acetonitrile) parent compound **1**, **2**, or **3** respectively. This is fully consistent with the fact that migration of phosphorus from ruthenium to carbon has occurred.

The X-ray crystal structures of **1a** and **2a** were determined. ORTEP views of the cations $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2OCH_2)PPh_2NPh\text{-}\kappa^1N\}]^+$ and $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2OCH_2)PiPr_2NC_6F_5\text{-}\kappa^1N\}]^+$ are shown in Figures 1 and 2, respectively, together with a listing of selected bond lengths and angles.

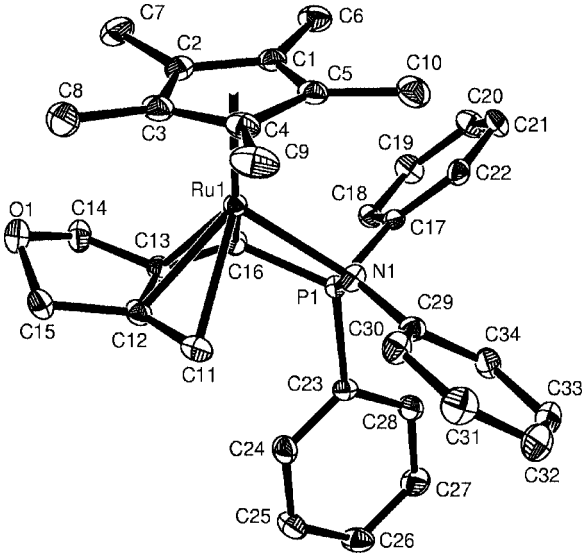


Figure 1. ORTEP drawing (50% thermal ellipsoids) of the cation $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2OCH_2)\text{-}PPh_2NPh\text{-}\kappa^1N\}]^+$ in complex **1a**. Hydrogen atoms have been omitted. Selected bond lengths [Å] and angles [°] with estimated standard deviations in parentheses: Ru1–C2 2.182(2), Ru1–C3 2.188(2), Ru1–C4 2.210(2), Ru1–C1 2.218(2), Ru1–C5 2.245(2), Ru1–N1 2.164(1), Ru1–C11 2.244(2), Ru1–C12 2.216(2), Ru1–C13 2.223 (2), Ru1–C16 2.217(2), P1–C16 1.766(2), C11–C12 1.401(3), C12–C13 1.420(3), C13–C16 1.413(3), N1–P1 1.599(2); Ru1–N1–P1 96.89(7), N1–Ru1–C16 72.30(7), N1–P1–C16 100.23(8), C11–C12–C13 128.1(2), C12–C13–C16 129.5(2).

The structures of the complex cations are very similar to those of the related cyclopentadienyl amidobutadiene complexes $[CpRu\{\eta^4\text{-}C_4H_3(CH_2CH_2CH_2)PPh_2NPh\text{-}\kappa^1N\}]^+$ and $[CpRu\{\eta^4\text{-}C_4H_3(n\text{Bu})_2PPh_2NPh\text{-}\kappa^1N\}]^+$.[7] The dimensions of the butadiene fragment are consistent with the delocalization of the double bonds, matching the values reported for the cyclopentadienyl complexes. The Ru1–N1 separation of 2.242(3) Å in **2a** is significantly longer than the corresponding Ru–N bond lengths observed in **1a** and in the cyclopentadienyl derivatives. This difference reflects the effect of the electron-attracting C_6F_5 group attached to the nitrogen atom in **2a**. On the other hand, all P–N and P–C separations have similar values, and are unexceptional.

The reactions of the pentamethylcyclopentadienyl bis(acetonitrile) complexes **1**–**3** with diynes or 1-alkynes examined so far seem to follow a pathway identical to that of the cyclopentadienyl derivative $[CpRu(MeCN)_2(PPh_2NHPh)]^+$, with phosphane migration, formation of an allyl carbene species, and an N–H bond activation process leading to the final amidobutadiene products.[7] However, we have found that in certain cases a different reaction pathway that leads to products other than amidobutadiene complexes is feasible.

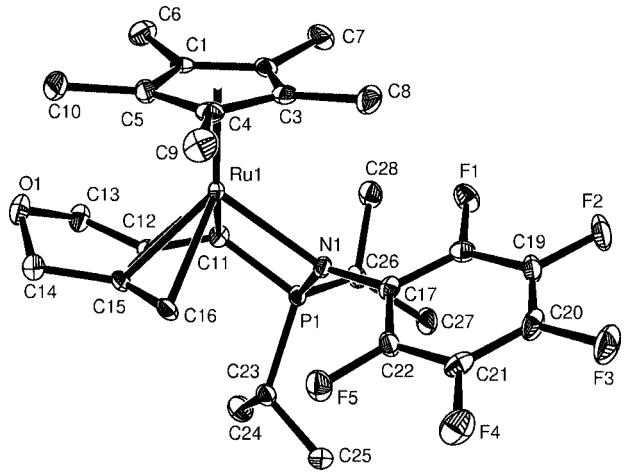

Figure 2. ORTEP drawing (50% thermal ellipsoids) of the cation $[Cp^*Ru\{\eta^4\text{-}C_4H_3(CH_2OCH_2)\text{-}PiPr_2NC_6F_5\text{-}\kappa^1N\}]^+$ in complex **2a**. Hydrogen atoms have been omitted. Selected bond lengths [Å] and angles [°] with estimated standard deviations in parentheses: Ru1–C1 2.167(4), Ru1–C5 2.189(3), Ru1–C2 2.198(4), Ru1–C4 2.216(4), Ru1–C3 2.242(4), Ru1–N1 2.242(3), Ru1–C16 2.208(4), Ru1–C15 2.227(4), Ru1–C12 2.219(4), Ru1–C11 2.208(4), P1–C11 1.771(4), C15–C16 1.392(5), C12–C15 1.425(5), C11–C12 1.410(5), N1–P1 1.605(3); Ru1–N1–P1 97.0(1), C11–Ru1–N1 70.2(1), N1–P1–C11 98.35(16), C16–C15–C12 128.1(3), C15–C12–C11 129.5(3).

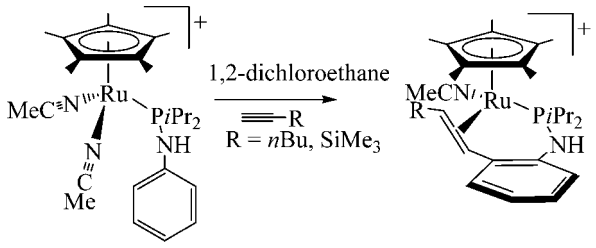
The reaction of **3** with 1-hexyne or $HC{\equiv}CSiMe_3$ in dichloroethane yielded yellow materials that show one singlet in their respective $^{31}P\{^1H\}$ NMR spectra slightly above δ = 100 ppm. This indicates that migration of the aminophosphane ligands does not take place in these two cases, at variance with all the other reactions studied in this work. Furthermore, the observed patterns in the ^1H and $^{13}C\{^1H\}$ NMR spectra of these substances are remarkably different from the expected ones for amidobutadiene complexes. The NMR spectra are consistent with the presence of coordinated acetonitrile and NH groups. A series of multiplet resonances in the ^1H NMR spectra in the range δ = 2.6 to 3.9 ppm are correlated to two tertiary carbon resonances in their respective $^{13}C\{^1H\}$ NMR spectra, as inferred from DEPT and gHSQC NMR experiments, thereby suggesting the presence of an η^2-CH=CH group in the complexes. The X-ray structure analysis performed on crystals resulting from the reaction of **3** with 1-hexyne revealed the formation of the complex $[Cp^*Ru(MeCN)\{\eta^2\text{-}n\text{BuCH=CH}(C_6H_4)\text{-}NHPiPr_2\text{-}\kappa^1P\}][BPh_4]$ (**4**). The product resulting from the reaction of **3** with $HC{\equiv}CSiMe_3$ was then identified as $[Cp^*Ru(MeCN)\{\eta^2\text{-}Me_3SiCH=CH(C_6H_4)NHPiPr_2\text{-}\kappa^1P\}][BPh_4]$ (**5**).

An ORTEP view of the cation $[Cp^*Ru(MeCN)\{\eta^2\text{-}n\text{BuCH=CH}(C_6H_4)NHPiPr_2\text{-}\kappa^1P\}]^+$ is shown in Figure 3, together with a listing of selected bond lengths and angles. The ruthenium atom in the complex cation is bonded to one acetonitrile ligand, to the phosphorus atom of the aminophosphane, and to an olefin ligand η^2-*n*BuCH=CH re-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



sulting formally from the insertion of the triple bond of a 1-hexyne molecule into one of the *ortho*-CH bonds of the NHPh group of the aminophosphane. The stereochemistry of the olefin ligand is *trans*. The C11–C12 separation of 1.42(1) Å, and the Ru1–C11 and Ru1–C12 bond lengths of 2.233(8) Å and 2.198(8) Å, respectively, compare well with the values found in other half-sandwich ruthenium η^2-alkene complexes, such as $[Cp^*Ru(\eta^2\text{-}CH_2{=}CH_2)(dippe)]^+$ [C–C: 1.43(2) Å; Ru–C: 2.24(1) Å and 2.25(1) Å; dippe = 1,2-bis(diisopropylphosphanyl)ethane][8] or $[Cp^*Ru(\eta^2\text{-}CH_2{=}CH_2)(CO)(PMe{i}Pr_2)]^+$ [C–C: 1.416(13) Å; Ru–C: 2.197(8) Å and 2.204(7) Å].[9]

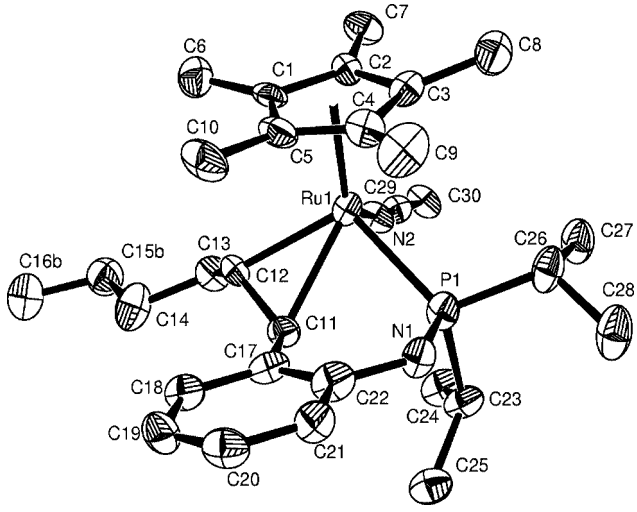


Figure 3. ORTEP drawing (50% thermal ellipsoids) of the cation $[Cp^*Ru(MeCN)\{\eta^2\text{-}n\text{BuCH=CH}(C_6H_4)NHPiPr_2\text{-}\kappa^1P\}]^+$ in complex **4**. Hydrogen atoms have been omitted. Selected bond lengths [Å] and angles [°] with estimated standard deviations in parentheses: Ru1–C1 2.227(8), Ru1–C2 2.254(8), Ru1–C3 2.247(9), Ru1–C4 2.227(8), Ru1–C5 2.208(9), Ru1–N2 2.032(7), Ru1–C11 2.233(8), Ru1–C12 2.198(8), Ru1–P1 2.327(2), P1–N1 1.688(7), C11–C12 1.42(1); Ru1–P1–N1 108.1(3), Ru1–N2–C29 169.1(7), C11–C12–C13 123.5(8), C12–C11–C17 122.7(8), C13–C12–C11–C17 139.2(9).

Complexes **4** and **5**, which incorporate only one alkyne molecule, are isolated even when compound **3** is allowed to react with an excess of the corresponding 1-alkyne. This fact indicates that the ruthenacyclopentatriene complex, which is a key intermediate in the process of formation of allyl carbene species, is not generated in the course of the reaction of **3** with 1-hexyne or $HC{\equiv}CSiMe_3$, and therefore an alternative reaction pathway leading to **4** and **5** is feasible.

For these processes we propose the reaction sequence shown in Scheme 1. After substitution of the first acetonitrile ligand by one alkyne molecule, the second acetonitrile molecule dissociates from the metal to generate a coordinatively unsaturated complex. If the addition of the second alkyne ligand is fast, then the resulting 18-electron bis(alkyne) complex undergoes oxidative alkyne coupling to yield a ruthenacyclopentatriene complex, and the course of the reaction would be as described previously.[1,7] However, in certain cases involving systems containing the strong electron-releasing aminophosphane iPr_2PNHPh, the metal center in the 16-electron intermediate is electron-rich enough to activate one C–H bond in the *ortho*-position of the phenyl ring to yield an orthometalated hydrido complex as a result of the oxidative addition reaction. This Ru^{IV} species is most likely in dynamic equilibrium with the 16-electron complex. Insertion of the alkyne into the ruthenium–hydride bond yields an alkenyl complex, which, upon addition of acetonitrile and reductive coupling of the alkenyl and phenyl fragments, leads to the final reaction product **4** or **5**. In the reaction of **3** with potentially chelating diynes the addition of the second alkyne to the 16-electron intermediate seems to be faster than the oxidative addition of the phenyl C–H and the subsequent alkyne insertion, and hence the amidobutadiene complexes **3a**–**c** are obtained.

The fact that reaction products similar to **4** or **5** are not observed in the course of the reaction of **1** or **2** with alkynes might be due to the following reasons: 1) in **1**, the PPh_2NHPh ligand is less basic than iPr_2PNHPh, and hence the corresponding 16-electron intermediate complex is probably not electron-rich enough to cleave *ortho*-C–H bonds prior to the entry of the second alkyne molecule, and 2) in the case of compound **2**, a final product analogous to **4** or **5** would involve C–F bond activation, a process which has a higher activation energy barrier than C–H bond activation.[10]

We must remark here that the proposed reaction sequence shown in Scheme 1, although reasonable, is only tentative. However, we must also point out the fact that spectroscopic evidence for the involvement of hydrido complexes in the formation of **4** has been obtained. In some instances, compound **4** was isolated accompanied by small amounts of other material which exhibits one hydride doublet resonance at $\delta = -10.89$ ppm, with a $^2J_{H,P}$ coupling constant of 43.9 Hz, in the ^1H NMR spectrum (Figure 4). The relatively large value of the $^2J_{H,P}$ coupling constant suggests a *transoid* disposition of the hydride and phosphane ligands. One singlet resonance at $\delta = 135.8$ ppm in the $^{31}P\{^1H\}$ NMR spectrum was attributed to this hydrido complex.

The reaction of **3** with an excess of 1-hexyne in [D_2]tetrachloroethane was monitored between 0 and 60 °C. Several intermediate species giving rise to singlets in the $^{31}P\{^1H\}$ NMR spectra were detected. One of these intermediate species is responsible for the doublet hydride resonance observed in the ^1H NMR spectrum. Although the isolation of any of these intermediate species was not possible, there is little doubt about the involvement of hydride species in the

process. Orthometalation processes at coordinatively unsaturated metal centers leading to hydrido-phenyl species have been well documented in the literature.[11–14]

We also carried out reactions of **1**, **2**, and **3** with several olefins. The only characterized product from these reactions was the η^2-alkene complex [Cp*Ru(MeOOCCH=CH_2)(MeCN)(PPh_2NHPh)][PF_6] (**6**), which was obtained from the reaction of **1** with methyl acrylate. The substitution of only one acetonitrile ligand in **1** was accomplished irrespective of the metal to methyl acrylate ratio used in the reaction. The protons of the η^2-CH=CH_2 group of the methyl acrylate ligand appear as multiplets at δ = 2.61, 3.45, and 3.52 ppm in the ^{1}H NMR spectrum, whereas the resonances for the carbon atoms appear as doublets at δ = 46.5 and 52.2 ppm, with $J_{C,P}$ coupling constant values of 5.4 Hz and 17 Hz, respectively.

The crystal structure of **6** was determined. An ORTEP view of the cation [Cp*Ru(η^2-MeOOCCH=CH_2)(MeCN)(PPh_2NHPh)]$^+$ is shown in Figure 5, together with a listing of selected bond lengths and angles. The coordination sphere around ruthenium is very similar to that of complex **4**, consisting of one Cp*, one acetonitrile ligand, one aminophosphane ligand, and the η^2-methyl acrylate ligand. The dimensions of the alkene ligand compare well with the values found for **4**, and for other compounds reported in the literature.[8,9] Only one diastereoisomer is present in the crystal. The methylcarboxylate group faces the acetonitrile ligand in an *exo*-disposition, pointing away from the Cp* group in order to minimize steric repulsions. The closest contacts between the methyl acrylate ligand and any atom from the aminophosphane ligand are around 3 Å or longer, which indicates no significant interaction between the aminophosphane and the olefin in this complex.

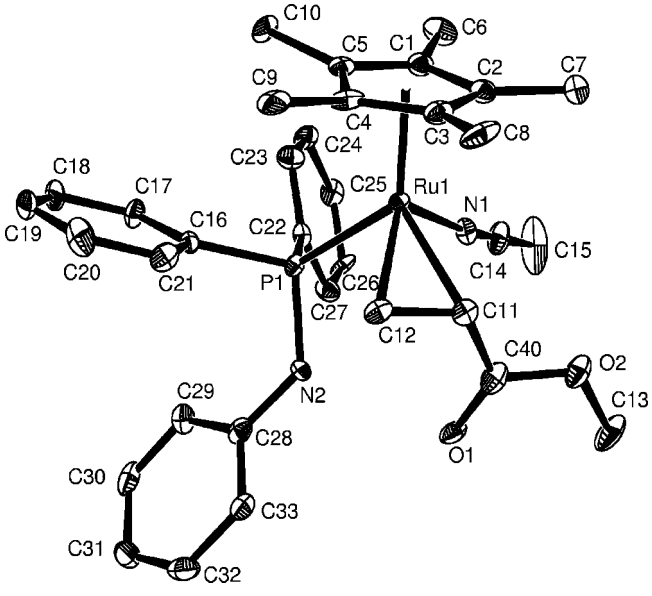

Figure 5. ORTEP drawing (50% thermal ellipsoids) of the cation [Cp*Ru(MeCN)(η^2-MeOOCCH=CH_2)(P*i*Pr_2NHPh)]$^+$ in complex **6**. Hydrogen atoms have been omitted. Selected bond lengths [Å] and angles [°] with estimated standard deviations in parentheses: Ru1–C2 2.200(5), Ru1–C1 2.215(5), Ru1–C3 2.229(5), Ru1–C4 2.245(5), Ru1–C5 2.282(6), Ru1–P1 2.342(1), Ru1–C11 2.185(5), Ru1–C12 2.181(5), Ru1–N1 2.063(4), C11–C12 1.411(7), C11–C40 1.456(8), N1–C14 1.143(7), N2–P1 1.675(5); Ru1–P1–N2 112.1(2), Ru1–N1–C14 173.0(5), C12–C11–C40 121.3(5).

We also studied the reactions of **5** with alkynes in order to check the possibility of alkene–alkyne coupling. However, this does not occur. The reaction of **5** with propargyl ether yielded red-orange crystals of the amidobutadiene complex **1a**. Likewise, the reaction with acetylene afforded the corresponding amidobutadiene derivative **1d**. Hence, the methyl acrylate and acetonitrile ligands behave as good leaving groups in these reactions, and are readily substituted by alkynes to give bis(alkyne) complexes, which follow the previously discussed reaction pathway to form amidobutadiene complexes by N–H activation.

Conclusions

We can conclude that the products of the reactions of [Cp*Ru(MeCN)$_2$(PR^1_2NHR^2)]$^+$ with alkynes are sensitive to the nature of the substituents in the aminophosphane ligand and in the alkyne. In some cases amidobutadiene complexes are generated by N–H activation, consistent with the behavior observed for their Cp counterparts. However, in other cases an alternative reaction pathway involving C–H activation is feasible. This process most likely involves orthometalation of the phenyl ring of an NHPh group and formation of Ru^{IV} hydrido species which are intermediates in the formation of the final products: η^2-alkene complexes formally derived from the insertion of one alkyne into the *ortho*-C–H bond of the NHPh group. Given the fact that the η^2-MeOOCCH=CH_2 ligand in the complex [Cp*Ru(η^2-MeOOCCH=CH_2)(MeCN)(PPh_2NHPh)]$^+$ (**6**) behaves as a good leaving group, it is reasonable to assume that the new ligands *i*Pr_2PNHC_6H_4CH=CHR (R = *n*Bu, $SiMe_3$) in complexes **4** and **5** should display a hemilabile character,[15] and hence their complexes might have potential catalytic activity, a possibility which is currently under investigation.

Experimental Section

General: All synthetic operations were performed under dry dinitrogen or argon following conventional Schlenk techniques. Tetrahydrofuran, diethyl ether, and petroleum ether (boiling point range 40–60 °C) were distilled from the appropriate drying agents. All solvents were deoxygenated immediately before use. The complex [Cp*Ru(MeCN)$_3$][PF_6] was obtained according to the literature.[16] The ligands PPh_2NHPh, P*i*Pr_2NHPh, and P*i*$Pr_2NHC_6F_5$, were prepared following suitable adaptations of published procedures.[17–21] 1-Alkynes, diynes, and methyl acrylate were purchased from Aldrich and used as received. NMR spectra were recorded on a Varian Unity 400 MHz or Varian Gemini 300 MHz spectrometer. Chemical shifts are given in ppm relative to $SiMe_4$ (^{1}H and $^{13}C\{^1H\}$), 85% H_3PO_4 ($^{31}P\{^1H\}$), or $CFCl_3$ (^{19}F). Microanalysis was performed on an elemental analyzer model LECO CHNS-932 at the Servicio Central de Ciencia y Tecnología, Universidad de Cádiz.

[Cp*Ru(MeCN)$_2$(PR^1_2NHR^2)][PF_6] (R^1 = R^2 = Ph 1; R^1 = *i*Pr, R^2 = C_6F_5 2): A stoichiometric amount of either PPh_2NHPh for **1** (1.67 g, 6 mmol), or *i*$Pr_2NHC_6F_5$ for **2** (1.79 g, 6 mmol), was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

added to a solution of [Cp*Ru(MeCN)$_3$][PF$_6$] (3 g, ca. 6 mmol) in dichloromethane (25 mL). The mixture was stirred at room temperature for 1 h. The solvent was then removed in vacuo. The residue was washed with several portions of diethyl ether, and finally with one portion of petroleum ether to give a yellow powder, which was dried in vacuo.

1: Yield: 4 g, ca. 90%. $C_{32}H_{37}F_6N_3P_2Ru$: calcd. C 51.89, H 5.04, N 5.7; found C 52.1, H 5.15, N 5.4. ^{1}H NMR (CD$_3$COCD$_3$, 298 K): δ = 1.45 [d, $J_{H,P}$ = 1.5 Hz, 15 H, C$_5$(C*H*$_3$)$_5$], 2.41 (d, $J_{H,P}$ = 1.5 Hz, 6 H, C*H*$_3$CN), 5.66 (d, $J_{H,P}$ = 13.8 Hz, 1 H, N*H*), 6.74, 7.01, 7.46, 7.71 (m, 15 H, C$_6$*H*$_5$) ppm. ^{13}C{^{1}H} NMR (CD$_3$COCD$_3$, 298 K): δ = 3.6 (s, *C*H$_3$CN), 9.1 [s, C$_5$(*C*H$_3$)$_5$], 87.9 [d, $J_{C,P}$ = 2.4 Hz, *C*$_5$(CH$_3$)$_5$], 119.1, 126.6, 128.7, 129.0, 130.4, 132.2 (*C*$_6$H$_5$) ppm. ^{31}P{^{1}H} NMR (CD$_3$COCD$_3$, 298 K): δ = 78.7 ppm (s).

2: Yield: 3.4 g, ca. 75%. $C_{26}H_{36}F_{11}N_3P_2Ru$: calcd. C 40.95, H 4.76, N 5.5; found C 40.8, H 4.88, N 5.3. ^{1}H NMR (CDCl$_3$, 298 K): δ = 1.61 [s, 15 H, C$_5$(C*H*$_3$)$_5$], 1.0–1.2 [m, 12 H, P{CH(C*H*$_3$)$_2$}$_2$], 2.39 [m, 2 H, P{C*H*(CH$_3$)$_2$}$_2$], 2.41 (s, 6 H, C*H*$_3$CN), 3.41 (d, $J_{H,P}$ = 12.7 Hz, 1 H, N*H*) ppm. ^{13}C{^{1}H} NMR (CDCl$_3$, 298 K): δ = 3.9 (s, *C*H$_3$CN), 10.3 [s, C$_5$(*C*H$_3$)$_5$], 17.4 [s, P{CH(*C*H$_3$)$_2$}$_2$], 29.0 [d, $J_{C,P}$ = 21.3 Hz, P{*C*H(CH$_3$)$_2$}$_2$], 86.0 [s, *C*$_5$(CH$_3$)$_5$] ppm. ^{19}F NMR (CDCl$_3$, 298 K): δ = –146.6, –161.0, –163.8 ppm. ^{31}P{^{1}H} NMR (CDCl$_3$, 298 K): δ = 116.5 ppm (s).

[Cp*Ru(MeCN)$_2$(P*i*Pr$_2$NHPh)][BPh$_4$] (3): This compound was prepared in a fashion analogous to that for **1** and **2**, starting from [Cp*Ru(MeCN)$_3$][PF$_6$] (1.5 g, ca. 3 mmol) and a stoichiometric amount of *i*Pr$_2$PNHPh (1.2 mL, 3 mmol) in dichloromethane (20 mL). The solvent was removed in vacuo and the residue washed with diethyl ether. Then, it was conveniently transformed into its [BPh$_4$]$^-$ salt by addition of MeOH and an excess of solid NaBPh$_4$ (1.5 g). The yellow precipitate was filtered, washed with EtOH and petroleum ether, and dried in vacuo. Yield: 2.16 g, 85%. $C_{50}H_{61}BN_3PRu$: calcd. C 70.91, H 7.26, N 5.0; found C 70.8, H 7.15, N 4.9. ^{1}H NMR (CD$_3$COCD$_3$, 298 K): δ = 1.45 [d, $J_{H,P}$ = 1.5 Hz, 15 H, C$_5$(C*H*$_3$)$_5$], 2.41 (d, $J_{H,P}$ = 1.5 Hz, 6 H, C*H*$_3$CN), 5.66 (d, $J_{H,P}$ = 13.8 Hz, 1 H, N*H*), 6.74, 7.01, 7.46, 7.71 (m, 15 H, C$_6$*H*$_5$) ppm. ^{13}C{^{1}H} NMR (CDCl$_3$, 298 K): δ = 3.2 (s, *C*H$_3$CN), 10.8 [s, C$_5$(*C*H$_3$)$_5$], 18.2, 18.3 [s, P{CH(*C*H$_3$)$_2$}$_2$], 29.7 [d, $J_{C,P}$ = 20.6 Hz, P{*C*H(CH$_3$)$_2$}$_2$], 93.5 [s, *C*$_5$(CH$_3$)$_5$], 121.6, 126.0, 135.7 (*C*$_6$H$_5$) ppm. ^{31}P{^{1}H} NMR (CD$_3$COCD$_3$, 298 K): δ = 101.1 ppm (s).

[Cp*Ru{η^4-C$_4$H$_3$(CH$_2$OCH$_2$)PPh$_2$NPh-κ^1*N*}][PF$_6$] (1a): A slight excess over the stoichiometric amount of propargyl ether (57 μL, 0.55 mmol) was added to a solution of **1** (0.37 g, 0.5 mmol) in dichloromethane (12 mL) and the mixture was stirred for 1 h at room temperature. The solvent was then removed in vacuo, and the residue washed with two portions of diethyl ether and one portion of petroleum ether. A red-orange powder was obtained, which was filtered off and dried in vacuo. It was recrystallized from a mixture of acetone and petroleum ether. Yield: 0.16 g, 44%. $C_{34}H_{37}F_6NOP_2Ru$: calcd. X-ray Structure Determinations: Crystal data and experimental details are given in Table 1. X-ray diffraction data were collected on a Bruker SMART APEX three-circle diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å) with a CCD area detector at the Servicio Central de Ciencia y Tecnología de la Universidad de Cádiz. Hemispheres of the reciprocal space were measured by omega scan frames with $\delta(\omega)$ 0.30°. Corrections for absorption and crystal decay (insignificant) were applied by semi-empirical methods from equivalents using the program SADABS.[22] The structures were solved by direct methods, completed by subsequent difference Fourier synthesis, and refined on F^2 by full-matrix least-squares procedures using the program SHELXTL.[23] The ligand *i*Pr$_2$PNH(C_6H_4)CH=CH*n*Bu in compound **4** showed orientation disorder at the end of the *n*Bu group. The set C(15)H$_2$ and C(16)H$_3$ was refined as two ethyl groups in complementary positions. Final refinements gave approximately 50% of each position. In this compound all non-hydrogen atoms except C15 and C15b were refined anisotropically, and hydrogen atoms were included at idealized positions and refined using a riding model. In the case of compounds **1a**, **2a**, and **6**, all non-hydrogen atoms were refined with anisotropic displacement coefficients, and all the remaining hydrogen atoms were refined using the SHELX riding model. The program ORTEP-3[24] was used for plotting.

CCDC260375 (for **1a**), -260376 (for **2a**), -260377 (for **4**), and -260378 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The

Acknowledgments

We thank the Ministerio de Educación y Ciencia (DGI, Project CTQ2004-00776/BQU) and the Junta de Andalucía (PAI FQM188) for financial support, and Johnson Matthey plc for generous loans of ruthenium trichloride.
