Flourishing on a Foundation of Strength and Depth

In 1997 the emergence of the European Journals was heralded in an editorial (En Route to European Journals of Inorganic and Organic Chemistry). The importance of a good foundation was emphasized. On that foundation the journals were established seven years ago. These years have been a time of consolidation to fuse the group of owner societies into the Editorial Union of Chemical Societies (EUChemSoc), to expand this union, and to achieve its challenging aims explicitly stated in the editorial (1999) of the European Journal of Inorganic Chemistry: "It is our most dedicated goal to reach the level of the top-3 Inorganic Chemistry journals on a world wide scale within three to five years". Where does the EurJIC stand five years down the road? With an Impact Factor of 2.482 the journal certainly has reached this level. The first boards have attained their goals admirably. The phase of consolidation is over − it is time to press on!

From the same editorial I quote: "We expect gradually to move to a system where a limited number (of Editorial Board members) each cover a certain subfield within … Inorganic Chemistry." This change has been realised from 2005. The Editorial Board has been expanded to include experts in coordination and supramolecular chemistry; organometallic chemistry and catalysis; bioinorganic chemistry and metal ions in biology; main-group chemistry; solid-state and materials chemistry; and physical and theoetical inorganic chemistry. Although the Editorial Board members primarily advise on matters in their field of competence, one Editorial Board member representing the chemical societies of France, Germany, Italy, the Netherlands, and Spain is responsible to the EUChemSoc who owns the journal. These are the countries in EUChemSoc from which we receive the largest number of manuscripts. The smaller chemical societies involved − those of Belgium, Greece, Hungary, and Portugal − shall supply one member in turn. An interesting statistic in this regard is the source of the submitted manuscripts. More than 60% come from other countries. EurJIC is indeed "made in Europe for the world".

Expertise in the Editorial Board

Two of the original members have retired to make way for members in new fields. Jaume Casabó has dedicated many years to publishing. Since 1994 he has been Editor of the Spanish Chemical Society (RSEQ) and prepared the way for the amalgamation of its journal into EurJIC. In addition to his work as Editorial Board member of EurJIC from 1999, he initiated the Spanish membership journal and was its first editor until 2000. Bernard Meunier took on the position in the Board for France in 1998. Although his recent prestigious appointment as President of the CNRS will leave him little time for editorial duties, he remains faithful to the concept of European publishing as member of the Editorial Advisory Board of *ChemBioChem*. On behalf of the Editorial Board and the Editorial Office of EurJIC I warmly thank both of them for their invaluable work at a crucial period for the journal and wish them every success in the future. I enjoyed the close cooperation and very much appreciated their advice.

We welcome three new members, Pablo Espinet, Rinaldo Poli and João Rocha. Their expertise in all aspects of organometallics, catalysis, materials and theoretical chemistry comes at the right time as EurJIC is expanding into these important areas of inorganic chemistry. I look forward to working with them more closely and hope that they will enjoy being ambassadors for the journal.

Simultaneously, the regular rotation in the Advisory Board has begun. About one-third of the Board have retired and eleven new members join this month. There is not enough space to mention the contributions of all whose term of office has now ended, but I thank all of them for their part in the development of the journal. When we pondered the new composition of the International Advisory Board we recognised that Austria, the Czech Republic, and Sweden − the Associate

Thanks to outgoing International Advisory Board Members

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Member countries, who actively support the journal but for one reason or another could not merge a journal − should also be represented. The names of all current members are given on the second masthead page. With these advisors your interests in inorganic chemistry, whatever they are, will receive expert attention.

Applications and basic research

Table 1 shows a selection of papers published in 2004 that have already been multiply cited. First it is clear that our authors come from all over the world. Second the papers cover the wide range of the fields mentioned above. perties all get a They focus on the structure and reactivity of inorganic compounds. Applications are clearly very important. Luminescent, photoluminescent, magnetic and electrochemical properties all get a look in. Bioinorganic, supramolecular and cluster chemistry, coordination polymers and main-group chemistry are all there. Ionic liquids and theoretical modelling also get a mention. And finally, international cooperations are a strength of the journal. EurJIC is indeed international and covers all aspects of modern Inorganic Chemistry.

Change characterises life, so it is unremarkable that scientific publishing, too, faces new challenges. The most controversial discussions on open access will continue in 2005, debating the issues of "Who pays?" and "Can we maintain the quality if an author pays?" The progress I wish to highlight here has been achieved: the standardisation of the measures for quoting the number of downloads. Without standards, usage figures could and did look good, but very often the highest figures were not the best and com-

parisons were meaningless. Since January 2004, *Wiley InterScience* usage statistics have been COUNTER-compliant. What lies behind this new standard statistic?

COUNTER stands for Counting Online Usage of NeTworked Electronic Resources and "has been developed to provide a single, international, extendible Code of Practice that allows the usage of online information products and services to be measured in a credible, consistent and compatible way using vendor-generated data." Comparisons can now be reliably made between all COUNTER-compliant statistics. You can find out more about COUNTER under http://www.projectcounter.org/.

I wish all our readers and authors a Happy New Year. May the year 2005 bring you peace and prosperity, and success in all your endeavours.

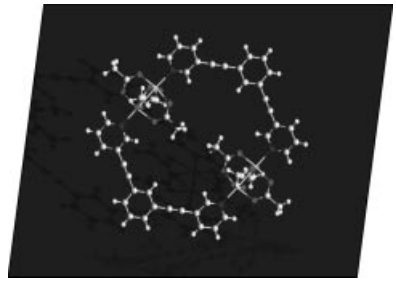
COVER PICTURE

The cover picture shows the hexagonal 2:4 coordination complex formed between 1,3-bis(3′-pyridylethynyl)benzene and copper(II) acetate. The ligand, synthesized by the Sonagashira coupling of 1,3-ethynylbenzene with 3-bromopyridine, was designed to form hexagonal coordination complexes with metals that favor linear coordination geometry. In this example the dimeric copper(II) acetate paddlewheel forms an almost linear connection between a pair of dipyridyl ligands. Details are discussed in the Short Communication by E. Bosch et al. on p. 45 ff.



MICROREVIEW

Contents

27 **M. A. Carreon, V. Guliants***

Ordered Meso- and Macroporous Binary and Mixed Metal Oxides

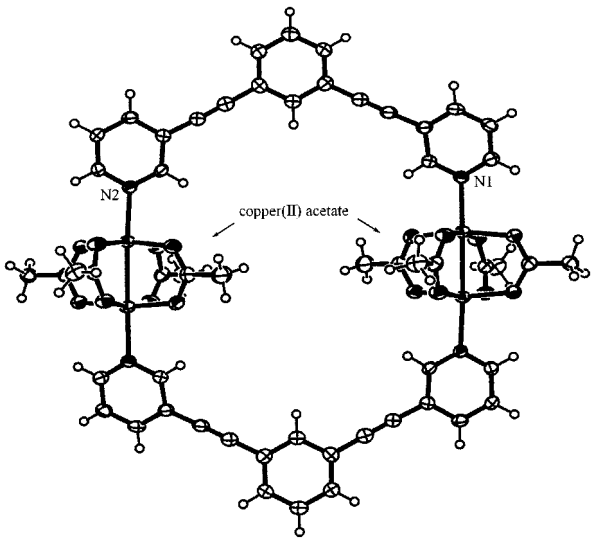
Keywords: Mesoporous / Macroporous / Transition metal oxides / Catalytic applications

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

SHORT COMMUNICATIONS

45 **N. Schultheiss, J. M. Ellsworth, E. Bosch,* C. L. Barnes**

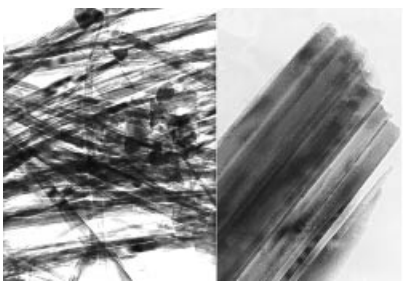
Formation of Hexagonal Coordination Complexes



Keywords: Crystal engineering / N ligands / Metallacycles / Microporous materials

47 **H. Zhang, S. Zhang,* M. Zuo, G. Li, J. Hou**

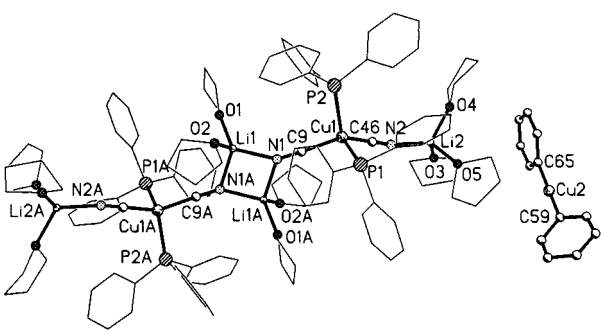
Synthesis of ZnS Nanowires and Assemblies by Carbothermal Chemical Vapor Deposition and Their Photoluminescence



Keywords: Chemical vapor deposition / Luminescence / Nanostructures / Self-assembly / Zinc

51 **R. P. Davies,* S. Hornauer**

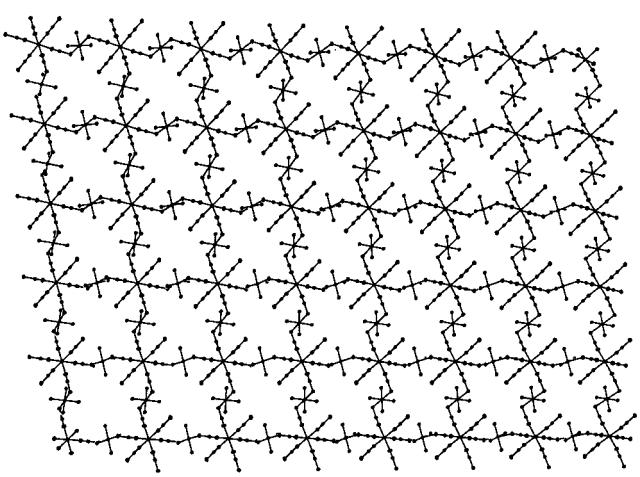
Lithium Cyanocuprates: Structural Studies of a Phosphane Adduct of a "Lower-Order" Lithium Cyanocuprate



Keywords: Cuprates / Lithium / Reaction intermediates / Michael addition

55 **J.-M. Shi,* W. Xu, B. Zhao, P. Cheng, D.-Z. Liao, X.-Y. Chen**

A 2D Thiocyanato-Bridged Copper(II)-Manganese(II) Bimetallic Coordination Polymer with Ferromagnetic Interactions

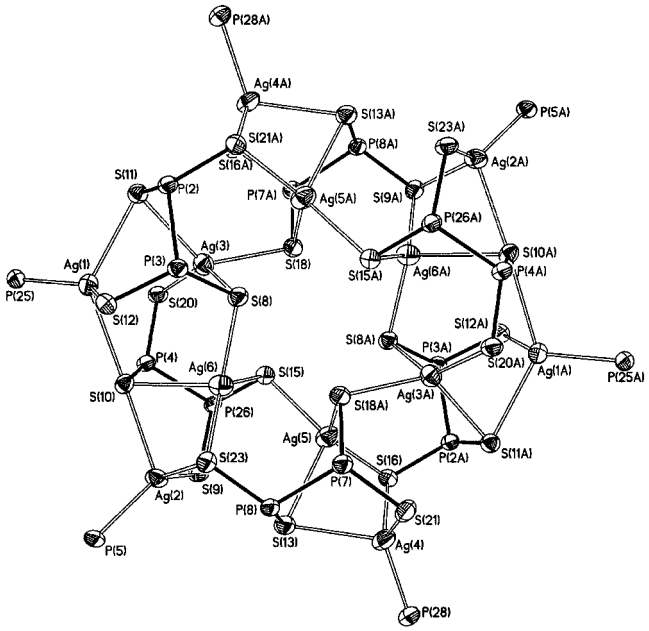


Keywords: Structure elucidation / Magnetic properties / Bridging ligands / Manganese

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

59 **D. Fenske,* A. Rothenberger, M. S. Fallah**

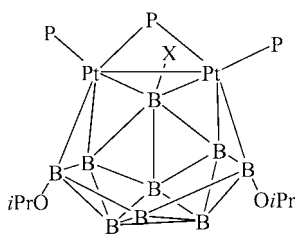
Oxidation of a One-Dimensional Coordination Polymer and Synthesis of the Macrocyclic Silver Complex $[Ag_{12}(PhS_2P{-}PS_2Ph)_6(dppeS)_6]$



Keywords: Silver / Chalcogenides / Macrocycle / P ligands / S ligands

63 **J. Dou,* L. Wu, Q. Guo, D. Li, D. Wang**

A New Strategy for the Preparation of Metallaboranes − Solvothermal Synthesis and Structural Characterisation of Two Nido 11-vertex Diplatinaundecaborane Clusters

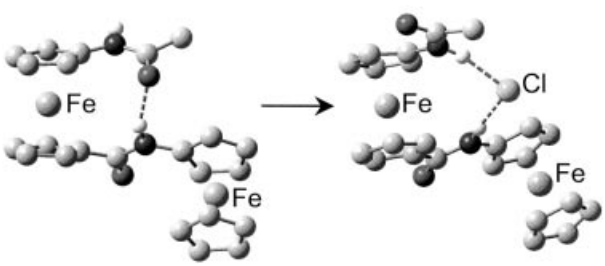


X = Cl, O*i*Pr

Keywords: Diplatinaundecaborane / Deboronation / Hydrothermal synthesis

66 **K. Heinze,* M. Schlenker**

Anion-Induced Motion in a Ferrocene Diamide



Keywords: Anion recognition / Anion sensing / Hydrogen bonds / Metallocenes / Receptors

EurJIC
European Journal of Inorganic Chemistry

1. General Information

The *European Journal of Inorganic Chemistry* (*EurJIC*) is published twice monthly.

Manuscripts should be submitted online using our online submission service at http://www.manuscriptXpress.org. You should prepare a **single file containing all tables, graphics, supporting information (where appropriate) etc.** Acceptable file formats are **Microsoft Word, Rich Text Format, Postscript and PDF**. Avoid the use of page breaks even between the title page and the introduction. If graphics are included at the end of the manuscript, try to fit as many as possible onto a single page. The file should have margins of 2 cm and be 1.5-line spaced.

Authors can follow the progress of their manuscript on their **personal homepage**, which is created automatically upon initial registration. This homepage is the same for the family of Wiley-VCH European journals and can be used to **store the latest version of a submitted paper** and to **upload the document file after acceptance**. Your referee reports for the family of Wiley-VCH European journals are also archived here.

No paper copies of the manuscript are required when using this system.

- The author must inform the editor of all manuscripts submitted, soon to be submitted, or in press at other journals that have a bearing on the manuscript being submitted.
- The correspondence author of a Microreview will receive a complimentary copy of the journal along with a PDF file of his/her paper restricted to 50 printouts; the correspondence author of other articles will receive a PDF file restricted to 25 printouts. Colour figures can be reproduced. Unless essential for the understanding of a paper, authors will be requested to make a contribution towards the costs of colour reproduction. Details will be provided after acceptance of the manuscript.
- We encourage authors to submit pictures for the cover page. A template of our cover page, **eurjiccover.pdf**, can be reached by clicking the link "For Authors" on our journal homepage (http://www.eurjic.org), to help you visualize the final effect of your design.

IMPORTANT: Any manuscript already available on personal/group web pages will be considered by the editors as already published and will not be accepted.

2. Types of Contributions

EurJIC publishes articles on inorganic, organometallic, bioinorganic, physical inorganic and solid-state chemistry. All contributions undergo peer review. An author may appeal against the decision on his/her manuscript, in writing. Three types of contributions are accepted for publication:

- **Full Papers** are articles with an Experimental Section that describe a significant contribution to the development of an area of research of importance. There are no restrictions placed on the length of a Full Paper.
- **Short Communications** are brief reports on results of high significance and urgency. Generally, they are no longer than 12−16 double-spaced pages or 3−4 typeset pages. An Experimental Section (as a separate paragraph or as part of the references) is desirable; if it is not included in the paper, the experimental data should be submitted as Supporting Information for refereeing purposes, and marked as such. A justification for urgent publication should accompany submission.
- **A Microreview** introduces the reader to a particular area of an author's research through a concise overview of a selected topic. As a rule, Microreviews are written on invitation, although unsolicited articles are also welcome. It is recommended, however, to contact the editor before submitting an unsolicited Microreview. The content should balance scope with depth; it should be a focused review of 25−30 double-spaced pages or 6−8 typeset pages. Reference to important work from others that is significant to the topic should be included. Microreviews will be refereed but will have no Experimental Section.

3. Manuscript Preparation

3.1 General

The whole of the manuscript should be 1.5-line spaced and in a large script (Times New Roman, 12 pt). We recommend that you prepare your text with **Microsoft Word (PC or Macintosh versions)** (see Section 3.2). Use the automatic pagination function incorporated in your word processor to number the pages; do not insert page numbers by hand. Leave a 2-cm margin around the perimeter of each page. **The figures, schemes and graphical abstract in the accepted version should be camera-ready**. Consult a current issue of the journal for an overview of the format. A manuscript should comprise: □ Title Page □ Keywords □ Abstract □ Main Text including Introduction, Results and Discussion etc. □ Experimental Section □ Acknowledgments (optional) □ Captions □ Tables □ References □ Schemes and Figures □ Graphical Abstract. □ For Microreviews only: Biographical sketches and a portrait-quality photograph of all authors.

3.2 Text

The text should be typed with carriage returns (hard returns) only at the end of a paragraph, title, heading and similar features. Avoid end-of-line word divisions.

Abbreviations and acronyms should be used sparingly and consistently. Where they first appear in the text, the complete term — apart from the most common ones such as NMR, IR, THF, *t*Bu etc. — should also be given.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In the Experimental Section, quantities of reactants, solvents etc. should be included in parentheses [e.g. A solution of triphenylphosphane (500 mg, 1.91 mmol) in dichloromethane (15 mL) was added to.....].

NMR spectroscopic data should be quoted as in the following example: ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 1.3 (s, 18 H, $SiMe_3$), 0.9 (d, $^3J_{H,H}$ = 5.7 Hz, 2 H, 2-H) ppm. For each chemical shift, additional information should be given in the order: multiplicity, coupling constant, number of protons, assignment. The NMR data of different nuclei should be listed in ascending order of atomic weight (e.g. ^{1}H, ^{13}C, ^{19}F, ^{29}Si.....).

The purity of all new compounds should be verified by elemental analysis to an accuracy within ±0.4%. In special cases, for instance when the compound is unstable or not available in sufficient quantities for complete analysis, the exact relative molecular mass obtained from a high-resolution mass spectrum and a clean ^{13}C NMR spectrum (as additional material for inspection by the referees) should be supplied.

Symbols of physical quantities, but not their units (e.g. *T* for temperature, *J*, *a*), stereochemical information (*cis*, *trans*, *Z*, *R*), locants (*N*-methyl), symmetry and space groups ($P2_1/c$), and prefixes in formulas or compound names (*t*Bu, *tert*-butyl) **must be in italics**. Latin phrases, such as "in situ", should not.

Stereochemical descriptors, such as D- and L-, and molar (M) or normal (N) should be in **small capitals**.

Use character formatting for italic and bold characters. Avoid any *special style sheets* to format these features. Write *capital letters* using the keyboard (shift + letter key), **not** the format "Capital letter" in Word.

Use only characters from the Symbol and Normal Text character sets, especially when inserting Greek letters and characters with umlauts, accents, tildes, etc.: α, Å, ã, ä, à.

There are three types of hyphens: normal dashes (-), en dashes (−), and em dashes (—). Use these as illustrated — spacing is important too — in the following examples:

well-known reaction	C−H bond
six-membered ring	Tables 2−4
3-position of the ring	carbon−oxygen bond
signal-to-noise ratio	C−N stretch
Mo-K_α	Diels−Alder reaction
1,2-dicyanobutane	structure−activity relationship
p-*tert*-butylphenol	80−100 mg
(−)-tartaric acid	carried out at −10°C
$[M^+ - CH_3]$	cm^{-1}

Use the symbol × where appropriate, rather than the letter x:
... washed with water (2 × 150 mL) ...
Use the double quotation marks "..." rather than „...“, "..." or «...»

Graphics (including structural formulas, schemes, figures, equations and small graphical items that appear in captions) must be submitted camera-ready on separate pages after acceptance of the manuscript (see Section 3.5).

Lines or **arcs**, for example to indicate ring compounds, cannot be used within the text. Another method for indicating such compounds must be devised. Please contact the Editorial Office if any help is needed.

If practical, authors should use a systematic name (IUPAC or Chemical Abstracts) for each title compound in the Experimental Section. Please try to avoid complicated, multi-line names if a simpler version (e.g. alcohol **4**, ketone **5**, compound **6**) could be used instead.

3.3 Tables

Use the Insert Table command from the Table menu or use the Insert Table button on the Standard toolbar for creating tables, and use tabs ONLY to move between cells.

3.4 References

We strongly recommend the use of the Endnotes feature of Word. If you prefer not to use this function, references should be indicated by numbers in square brackets as superscripts and, if applicable, after punctuation (example: text.[1]). Use the Format Font menu.

Journal titles should be abbreviated according to the Chemical Abstracts Service Source Index (CASSI).

The Author is responsible for correct citations. The *European Journal of Inorganic Chemistry* is a member of Cross Ref. (http://www.crossref.org), a service which links reference citations to the online content that those references cite. This can only function if the citations are accurate. Please ensure that only one reference is cited under each reference number or that a composite reference is subdivided into parts a), b) etc. For example:

[1] A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1−15.
[2] R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

or

[1] a) A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1−15; b) R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

but not

[1] a) A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1−15; R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

3.5 Graphics

Graphics are schemes, figures, equations and small graphical items that appear in captions. Graphics differ fundamentally from the text portion of your manuscript in that they must be scanned or electronically processed.

In the revised version please submit **each graphic in its own file** within a graphic folder. The following formats are preferred: *.cdr, *.cdx, *.wmf (windows metafile), *.pct, *.tif, *.eps. For good reproduction the resolution should be a minimum of 300 dpi.
Consult the following table for the appropriate size of lettering. Lettering smaller than 3.0 mm will reproduce poorly. Please use only one size of lettering per graphic and a font like Times New Roman, which distinguishes between l (small L) as in HCl (hydrochloric acid) and I (capital i) as in HCI (iodocarbene).

Table 1. Guide for preparing graphics

Letter Size	Font	Maximum Graphic Width[a] 1-Column Format	2-Column Format
	Times New Roman		
3.0 mm	12	13 cm	26 cm
3.5 mm	**14**	**15 cm**[b]	–
4.0 mm	**16**	**17 cm**[b]	–
4.5 mm	18	19 cm	–

[a] Most graphics are in 1-column format. [b] We prefer lettering of 3.5 or 4.0 mm with maximum graphic widths of 15 or 17 cm, respectively.

The settings for one-column graphics constructed with Chem Draw can be found in the template **eurjourn.zip**, which can be reached by clicking the link "For Authors" on our journal homepage (http://www.eurjic.org). These settings are: Print Setup: Orientation Portrait. Caption and Label Settings: Font Times New Roman, Font Style Standard, Size 12.

Note that the graphical abstract must be in one-column format and in black-and-white.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These settings help ensure the correct letter-size-to-graphic-width ratio for best reproduction.
Use abbreviations such as R^1, R^2 (not R_2), R′, R″, Ph, Me, Et, *i*Pr, *t*Bu, Ph, Bn (benzyl), Bz (benzoyl), Hal, L, M (metal), X (heteroatom).

4. Crystallographic Data

Authors must deposit the data of X-ray structure analyses in a crystallographic database before submitting their manuscript, so that referees can access the information electronically. The two databases, the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have the same procedure for the deposition of data and both will be pleased to provide help. In general, you will receive a depository number from the database two working days after electronic deposition. Send your data to the appropriate address below and quote the standard text, including the depository number, in your manuscript.

- **For all compounds without C−H bonds:**

Fachinformationszentrum Karlsruhe (FIZ)
76344 Eggenstein-Leopoldshafen, Germany
Phone: +49-(0)7247/808-205
Fax: +49-(0)7247/808-666
E-mail: crysdata@fiz-karlsruhe.de
FTP: ftp.fiz-karlsruhe.de (under path /pub/csd)
WWW: http://www.fiz-karlsruhe.de (under "Products and Services ")

Further details of the crystal-structure investigation(s) may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number(s) CSD-....

- **For all compounds with at least one C−H bond:**

Cambridge Crystallographic Data Centre (CCDC)
12 Union Road, Cambridge CB2 1EZ, UK
Phone: +44-(0)1223/336-408
Fax: +44-(0)1223/336-033
E-mail: deposit@ccdc.cam.ac.uk
WWW: http://www.ccdc.cam.ac.uk

CCDC-****** contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

NOTE: Please use the free online **Checkcif** service provided by the International Union of Crystallography and submit the Checkcif report along with your manuscript: http://journals.iucr.org/services/cif/checkcif.html.

Finally, before you return your revised manuscript, please update your database entry if necessary.

5. Electronic Supporting Information

A manuscript may include Electronic Supporting Information which will be accessible only on the WWW. Authors must keep a copy to make available to readers who do not have access to the internet. As this material [text, tables, schemes, figures **but not crystallographic (CIF) data**, which must be submitted to either the FIZ or the CCDC] undergoes the peer review process, it must be included, clearly marked as "Supporting Information to be published electronically", when the paper is submitted. The following file formats are accepted: MS Winword or ASCII (*.doc, *.txt), MS Excel (*.xls), Encapsulated Postscript (*.eps), Portable Document Format (*.pdf), graphics embedded in MS Winword; if you wish to submit other formats, please consult the Editorial Office. When preparing such material, authors should keep in mind that — once accepted — it will be made available as provided by the author and not edited. Material accepted for electronic publication will be available mostly as PDF files (Adobe Acrobat Reader required) by following the Table of Contents link of EurJIC's WWW home page. A standard text will be added on the first page of the article in the printed version:

- Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

The supporting information file must start with the title of the paper, the authors and the CASSI abbreviation of the journal to which it was submitted (e.g. *Eur. J. Inorg. Chem.*).

6. Basic Keyword List

To increase the relevance of articles found by search engines of Wiley InterScience, we have compiled a keyword catalogue common to our chemistry journals that is printed here and is also available online (http://www.eurjic.org).

To assist you in finding keywords they are listed according to categories. You may choose keywords from any category. As with all such records, a few guidelines facilitate the catalogue's use, and these are briefly explained below:
1. As many as possible, but at least two, of the maximum of five keywords assigned to an article must come from this list.
2. Named reactions will be incorporated only in exceptional cases. Generally the reaction type is selected instead. For example, Diels−Alder reactions will be found under "Cycloadditions" and Claisen rearrangements under "Rearrangements".
3. Heteroanalogues of compounds are mainly classified under the C variants, for example, (hetero)cumulenes, (hetero)dienes. A few aza and phospha derivatives are exceptions.
4. Compounds with inorganic components that are central to the article are listed under the element, for instance, iron complexes under "Iron". Some group names like "Alkali metals" exist alongside the names of important members of the group like "Lithium". In such cases the group name is used for these members only when comparative studies are described. The members not appearing separately are also categorised under the group name.
5. A keyword in the form "N ligand" is only chosen if a considerable portion of the paper deals with the coordination of any ligand ligating through the atom concerned.
6. Spectroscopic methods are assigned as keywords only if the article is about the method itself, or if the spectroscopic technique has made an important contribution to the problem under investigation.
7. "Structure elucidation" is intended only if the crux of the paper is a structural elucidation or if a combination of several spectroscopic techniques were needed for conclusive solution of the structure.
8. An attempt has been made to avoid synonyms and to select more general concepts rather than specialized terms. Thus, the term "Double-decker complexes" is excluded in favour of "Sandwich complexes".

This list will be a "living" catalogue to be flexible enough to absorb the new developments in chemistry. We therefore welcome all suggestions from our authors that might improve its user-friendliness.

Ordered Meso- and Macroporous Binary and Mixed Metal Oxides

Moises A. Carreon[a,b] and Vadim V. Guliants*[a]

Keywords: Mesoporous / Macroporous / Transition metal oxides / Catalytic applications

A critical review is provided of the principles guiding the synthesis of meso- and macroporous metal oxides on multiple length scales in the presence of surfactant mesophases and colloidal arrays of monodisperse spheres, and correlations between the synthesis conditions and the properties of the resulting meso- and macroporous oxides, such as thermal stability, pore structure, elemental and nanophase compositions of the inorganic wall, etc. The thermal stability of mesostructured metal-oxide phases, in particular, is discussed in terms of charge-matching at the organic–inorganic interface, the strength of interactions between inorganic species and surfactant headgroups, the flexibility of the M–O–M bond angles in the constituent metal oxides, the Tammann temperature of the metal oxide, and the occurrence of redox reactions in the metal-oxide wall. The ordered meso- and macroporous transition-metal-oxide phases are highly promising for a range of potential applications in separations, chemical sensing, heterogeneous catalysis, microelectronics, and photonics as, respectively, insulating layers of low-dielectric-constant and photonic-bandgap materials. Furthermore, the functionalization of the internal pore surfaces in these materials and deposition of functional nanoparticles within the pores offer numerous new possibilities for molecular engineering of catalytic and other advanced nanostructured materials displaying quantum-confinement effects. The emerging catalytic applications of these novel metal-oxide phases are discussed in particular detail.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

1. Introduction

Highly ordered mesoporous inorganic oxides were first reported by the researchers at Mobil Research and Development Corporation over a decade ago.[1–3] These materials, with well-defined pores up to about 3 nm in diameter, belong to the novel family of so-called M41S aluminosilicate molecular sieves[1–3] that break past the pore-size constraints of largely microporous zeotypes. Extremely high surface areas (>1000 m^2/g), finely tuned pore sizes, and flexible wall-compositions are among the many desirable properties that have made such mesoporous materials the focus of great interest for applications in heterogeneous catalysis. The preparation of the M41S phases represents a

Vadim V. Guliants was born in Baku, USSR. He studied Chemistry and obtained a Diploma with Highest Honors at Moscow State University in 1987. He received his Ph.D. in Chemistry at Princeton University in 1995 with Profs. J. B. Benziger and S. Sundaresan in the area of materials chemistry of catalytic vanadium-phosphorus oxides. After holding a research position in the area of molecular modeling, synthesis and physico-chemical characterization of crystalline microporous oxides at Praxair Inc. (Tonawanda, NY), he joined the Chemical Engineering Faculty at the University of Cincinnati in 1999. He is currently Associate Professor and Associate Head of the Department of Chemical and Materials Engineering at the University of Cincinnati. His current research is focused on the self-assembly of ordered meso- and macroporous metal oxides for applications in heterogeneous catalysis, biocatalysis and separations.

Moises A. Carreon was born in Morelia, Mexico, in 1974. He received his Bachelor's degree in Chemical Engineering at the Universidad Michoacana (UMSNH) in 1996, where he also received his Master's degree in Materials Science and Engineering in 1999. He obtained his Ph.D. degree in the Department of Chemical and Materials Engineering at the University of Cincinnati in 2003 under the supervision of Professor Vadim V. Guliants working on the hierarchical design of novel macro- and mesoporous vanadium-phosphorus-oxide phases for the selective oxidation of lower hydrocarbons. Currently he is a post-doctoral fellow in the Materials Chemistry Research Group, Chemistry Department at University of Toronto. His research centers on the molecular engineering of ordered periodic mesoporous transition metal oxides for nanotechnological applications.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

new approach in organic-template-assisted synthesis, where, instead of individual organic molecules (as in the case of zeotypes), self-assembled molecular aggregates or supramolecular assemblies are employed as the structure-directing agents.

The discovery of M41S silicas has stimulated the search for other ordered mesostructured materials with non-silicate compositions over the last decade.[4] The general self-assembly pathway for mesostructured metal oxides is illustrated in Figure 1. Mesoporous *mixed* metal oxides are particularly promising as heterogeneous catalysts because of their tunable surface compositions, metal oxidation states (via organic-inorganic interfacial chemistry), and wall structures − amorphous or nanocrystalline (Figure 2). Furthermore, their electronic properties and the surface structure, which are critical parameters for the catalytic performance of any catalyst, are expected to change greatly in the nano regime,[5] thereby offering new, exciting possibilities for the molecular engineering of mixed metal oxides with unique catalytic, optical, and electrical properties. Ordered macroporous materials templated by ordered arrays of colloidal spheres and other shapes have recently attracted considerable attention from the scientific community.[6] The macroscale templating approach consists of the three distinct processing steps shown in Figure 3. First, the interstitial voids of the monodisperse colloidal latex sphere (approx. 100 nm to 50 μm in diameter) arrays are filled with precursors of various classes of materials, such as ceramics, semiconductors, metals, monomers, etc. In the second step, the precursors condense around the spheres and form a solid framework. Finally, the spheres are removed by either calcination or solvent extraction to form the 3D ordered macroporous structures. In this paper we critically review the current state of the art for the synthesis and emerging catalytic applications of meso- and macroporous *binary* and *mixed* metal oxides. We first discuss the structures and self-assembly mechanisms of mesoporous oxides for *silicate* compositions, since these compositions have been investigated in much greater detail than structurally similar metal oxides. We then outline synthesis guidelines for the novel

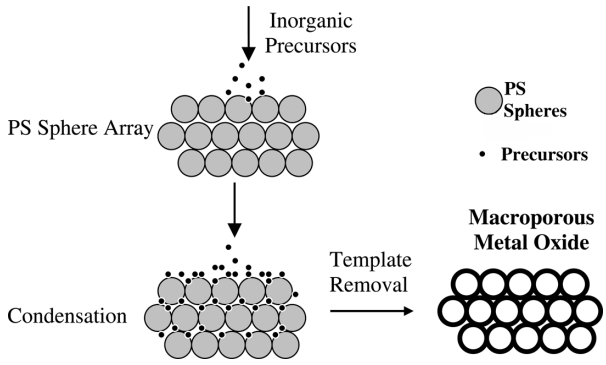

Figure 3. General procedure for the synthesis of highly ordered *macroporous* mixed-metal oxide phases employing polystyrene (PS) spheres.

mesoporous metal oxides with flexible compositions and improved thermal stability that are desirable for applications in heterogeneous catalysis. Finally, we discuss recent advances in the macroscale self-assembly of mixed metal oxides and their emerging catalytic applications.

2. Ordered Mesostructured Oxides

2.1. Structural Characteristics

Several common ordered pore-structures encountered in the M41S family are shown in Figure 4. The 2D hexagonal phase with *P6mm* symmetry, templated by hexagonal close-packed cylindrical arrays of surfactants, is the most common ordered structure. Lamellar phases are unstable upon surfactant removal, which causes the collapse of the expanded layered structures. Various cubic phases have also been reported. In the case of mesoporous silica, the bicontinuous cubic gyroid phase with *Ia3d* symmetry is found in alkali-catalyzed syntheses. This phase, with its system of interconnected pores, is much more attractive than the 2D hexagonal phase for applications requiring diffusion of species into and out of the pore network. The *Pm3n* phase templated by spherical surfactant micelles in a cubic close-packed arrangement is found in both acid- and alkaline-catalyzed syntheses of mesoporous silica.[1–3]

Figure 4. Representative members of the M41S family.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The pioneering work of Kresge et al.[1,3] and Beck et al.[2] involved only alkaline-catalyzed syntheses, and the silicates reported in their papers are referred to as MCM-41 (*P6mm*, the 2D hexagonal phase), MCM-48 (*Ia3d*, the cubic phase), and MCM-50 (the lamellar phase). The 2D hexagonal mesoporous silicas prepared by Inagaki et al.[7] from surfactant-intercalated kanemite are referred to as FSM-16. Subsequent reaction in an acidic medium led to ordered mesoporous silicas with similar pore symmetries but distinct wall properties: SBA-1 (*Pm3n*, the cubic phase), SBA-2 ($P6_3/mmc$, the 3D hexagonally packed spherical micelle phase), and SBA-3 (*P6mm*, the 2D hexagonally packed cylinders).[8] Other surfactant-templated phases include disordered materials with a wormhole network of channels, such as KIT-1[9] and MSU-1,[10] a well-defined intergrown cubic hexagonal phase STAC-1,[11] and ordered nonionic alkyl-EO_x-templated materials, for example the cubic SBA-11 (*Pm-3m*) and 3D hexagonal SBA-12 ($P6_3/mmc$).[12] Using the same methodology, triblock-copolymer-templated materials with much larger pores have also been synthesized in acidic systems, for example the 2D hexagonal (*P6mm*) SBA-15[13] and cubic cage (*Im-3m*) SBA-16 structures.[12]

Several aspects of the ordered mesoporous oxides have been reviewed by Brinker (recent advances in porous inorganic materials),[14] Vartuli et al. (synthesis of the M41S family),[15] Stucky et al. (biomimetic synthesis of mesoporous materials),[16] Raman et al. (porous silicates templated by surfactants and organosilicate precursors),[17] and Guliants et al. (mesoporous inorganic films and membranes).[18] Several synthetic strategies for the molecular design of mesoporous oxides, including those with non-siliceous compositions, have been recently reviewed by Soler-Illia et al.[19] However, thermal stability considerations for mesostructured metal oxides were not discussed in those reviews.

2.2. Self-Assembly Mechanisms And Stability Considerations

2.2.1. Liquid Crystal Templating Mechanism

A "liquid crystal templating" (LCT) mechanism of formation was proposed by the Mobil researchers, based on the similarity between liquid crystalline surfactant assemblies (i.e. lyotropic phases) and M41S.[1–3] Two mechanistic pathways were proposed to explain formation of MCM-41 containing 2D hexagonal arrays of cylindrical mesopores: 1) condensation and cross-linking of the inorganic species at the interface with a pre-existing hexagonal lyotropic liquid crystal (LC) phase, and 2) ordering of the surfactant molecules into the 2D hexagonal mesophase mediated by the inorganic species, followed by their condensation and cross-linking.

In both pathways the inorganic species, which are negatively charged at the high synthesis pH, preferentially interact with the positively charged alkylammonium headgroups of the surfactants and condense into a solid, continuous framework. The resulting organic-inorganic mesostructure could be alternatively viewed as a hexagonal array of surfactant micellar rods embedded in a silica matrix. Removal of the surfactant produces an open mesoporous MCM-41 framework. These mesophases, with pore diameters greater than 2.5 nm, generally display type IV nitrogen adsorption–desorption isotherms at 77 K, which are characteristic of mesoporous materials with an ordered, unimodal pore-size distribution. The second mechanistic pathway of LCT was proposed as a cooperative self-assembly of the alkylammonium surfactant and the silicate precursor species below the critical micelle concentration (CMC).[1–3] It is well established that no preformed LC phase is necessary for the MCM-41 formation, but, to date, the mechanistic details of the MCM-41 synthesis have not yet been fully agreed upon. Several mechanistic models have been advanced, although all share the basic idea that the silicate species promote LC phase formation below the CMC.[1–3]

2.2.2. Inorganic-Species-Driven Self-Assembly

Davis et al.[20] found that a hexagonal LC phase does not develop during the MCM-41 synthesis, based on an in situ ^{14}N NMR spectroscopic study. They proposed that, under the synthesis conditions reported by Mobil, the formation of MCM-41 begins with the deposition of two to three monolayers of silicate precursors onto isolated surfactant micellar rods. The silicate-encapsulated rods are randomly ordered, and eventually pack into a hexagonal mesostructure. Heating and aging completes the condensation of the silicates into the obtained MCM-41 mesostructure.

Steel et al.[21] postulated that surfactant molecules assemble directly into the hexagonal LC phase upon addition of the silicate species, based on their ^{14}N NMR spectroscopic data. The silicates organize into layers, with rows of cylindrical rods intercalated between the layers. Aging the mixture causes the layers to pucker and collapse around the rods, which then transform into the surfactant-containing 2D hexagonal MCM-41 structure.

The "charge density matching" mechanistic model proposed by Monnier et al.[22] and Stucky et al.[23] suggests that MCM-41 could be derived from a lamellar phase. The initial phase of the synthesis mixture is layered, as detected by X-ray diffractometry (XRD), due to the electrostatic attraction between the anionic silicates and the cationic surfactant head-groups. As the silicate species begin to condense, the charge density is reduced. Accompanying this process, a curvature is introduced into the layers to maintain the charge-density balance with the surfactant headgroups, which transforms the lamellar phase into a hexagonal mesostructure.

Under synthesis conditions that prevent condensation of the silicate species, such as low temperatures and high pH (ca. 14), a truly cooperative self-assembly of the silicates and surfactants was found to be possible. Firouzi et al.[24] showed, through ^{2}H and ^{29}Si NMR spectroscopy and neutron scattering, that a micellar solution of CTAB (cetyltrimethylammonium bromide) transforms into a hexagonal phase in the presence of silicate anions. This is consistent with the effect of electrolytes on micellar phase-transi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tions.[25] The silicate anions ion-exchange with the surfactant halide counterions to form a "silicatropic liquid crystal" (SLC) phase that involves silicate-encrusted cylindrical micelles. This SLC phase exhibited behavior very similar to typical lyotropic systems, except that the surfactant concentrations were much lower and the silicate counterions were reactive.[26] Heating the SLC phase caused the silicates to condense irreversibly into MCM-41. Firouzi et al.[24,26] also demonstrated that, in addition to the charge-balance requirement (i.e. electrostatic interaction), there was preferential bonding of the alkylammonium head-groups to multi-charged D4R (double four-ring, $[Si_8O_{20}]^{8-}$) silicate anions under the high pH conditions.

All these previous theories have regarded the formation of MCM-41 as a series of events that occur homogeneously throughout an aqueous solution. Recent work has shown, however, that MCM-41 might be formed heterogeneously. Regev,[27] for example, has found evidence for MCM-41 intermediate structures in the form of clusters of rod-like micelles "wrapped" by a coating of silicate from low-temperature transmission electron microscopy (TEM) and small-angle X-ray scattering. These clusters of elongated micelles were found before precipitation occurred. According to Regev,[27] as the reaction progresses, the silicate species diffuse to, and deposit on, the individual surfaces of the micelles within the cluster. The clusters of elongated micelles therefore eventually become clusters of silicate-covered micelles. Thus, the clusters of micelles serve as nucleation sites for MCM-41 formation.

Frasch et al. have proposed a modified mechanism for the formation of 2D hexagonal silica.[28] The silicate–counterion exchange at the micellar surface was followed by fluorescence techniques using pyrene or dipyrenylpropane as fluorescent probes. The variation of the properties of CTAB and CTACl (cetyltrimethylammonium chloride) micelles upon the successive addition of a large excess of base [NaOH or TMAOH (tetramethylammonium hydroxide)] and silicate species was studied. Their results showed that, prior to the formation of the ordered mesophase, the interactions between the silicate species and surfactant micelles are weak. They therefore proposed a new model for the formation of mesostructured silica in which the key step is the formation of siliceous pre-polymers. According to this model, the growing pre-polymers interact with an increasing number of surfactant molecules to form hybrid silica-surfactant micellar aggregates. Further polymerization of these complexes takes place during the precipitation/aging process to give ordered mesostructured silica. The formation of mesoscopically ordered silica/surfactant composites under acidic synthesis conditions was studied by time-resolved in situ small-angle X-ray scattering (SAXS) using synchrotron radiation.[29] The various proposed mechanisms of formation of ordered mesostructured phases have been recently reviewed by Zana et al.[30] Recently, Linden et al.[31] have followed the initial stages of the formation of SBA-15 by in situ SAXS/XRD using synchrotron radiation. The authors proposed that the first step in the formation of an SBA-15 mesostructure is the liquid–liquid phase separation of spherical P123-silicate hybrid micelles; nucleation and growth of the 2D hexagonal phase then takes place.

2.3. Thermal Stability of Mesostructured Phases

The high thermal stability of mesostructured phases is perhaps the most critical requirement for their applications in heterogeneous catalysis. In general, the thermal stability of mesostructured metal-oxide phases depends on: (1) the degree of charge-matching at the organic–inorganic interface, (2) the strength of interactions between inorganic species and surfactant head-groups, (3) the flexibility of the M–O–M bond angles in the constituent metal oxides, (4) the Tammann temperature of the metal oxide, and (5) the occurrence of redox reactions in the metal-oxide wall.

The *charge-matching* at the organic–inorganic interface enables control over the wall composition and facilitates cross-linking of the inorganic species into a robust mesostructured network. A knowledge of the electrokinetic behavior (i.e. the isoelectric points) of the inorganic species in solution is required for fine-tuning electrostatic and other interactions at the inorganic–organic interface in order to obtain thermally stable mesoporous phases.[32] The isoelectric points of common transition-metal solid oxides and hydroxides are shown in Table 1.[32,33] The presence of strong *covalent bonds* between metal-oxide species and surfactant head-groups, for example metal–N bonds, means that harsh conditions, such as combustion, are required for surfactant

Table 1. Isoelectric points of common transition metal oxides.[28,29]

Metal oxide	Isoelectric point	General comments
V_2O_5	0.5	oxovanadium(v) species
MoO_3	<0.5	NA
Nb_2O_5	<0.5	NA

removal, and these may lead to collapse of the mesostructure. Similarly, *rigid M–O–M bond angles* that are unable to accommodate the curvature of the inorganic–organic interface may result in the formation of only lamellar or dense metal-oxide phases. On the other hand, metal-oxide species should possess low lattice mobility at elevated temperatures in order to prevent transformation of the mesostructured metal oxides into more thermodynamically stable dense phases. The mobility of metal ions or atoms in a crystalline metal oxide increases rapidly in the vicinity of its *Tammann temperature*, defined as $0.5–0.52T_m$, where T_m is the melting point in Kelvin.[34] Therefore, it is not surprising that the low Tamman temperature of some transition- metal oxides[5,35] translates into a limited thermal stability of the corresponding mesostructures (Table 2). Finally, the structural collapse of mesophases may be caused by *redox reac-*

tions occurring in the metal-oxide wall during surfactant removal or catalytic reaction.

Accordingly, we review below the synthesis, pore structures, elemental and nanophase compositions, thermal stability, and emerging applications of mesoporous metal oxides in heterogeneous catalysis.

2.4. Binary Mesostructured Metal Oxides

The mesostructured binary transition metal oxides that are promising for applications in heterogeneous catalysis are summarized in Table 3. High-resolution TEM images of the three most-common porous structures observed in mesostructured metal oxides − lamellar, hexagonal, and cubic − are illustrated in Figure 5, Figure 6 and Figure 7, respectively. Metal oxides containing 2D hexagonal and cubic mesopore structures are characterized by the unimodal pore-size distributions and type IV adsorption–desorption isotherms typical of mesoporous materials (Figure 8).

Vanadium-, molybdenum-, and niobium-based mixed metal oxides are particularly promising as catalysts or catalytic supports for selective oxidation reactions.[36–50] For example, supported vanadium oxide catalysts are widely used for the partial oxidation of olefins,[51] aromatics,[52] and methanol,[53] the selective catalytic reduction of NO_x,[54] and ammoxidation of aromatics.[55] Molybdenum- and niobium-based oxides are catalytically active in the selective oxidation and reduction of hydrocarbons.[39] Mesostructured vanadium oxide was reported for the first time by Luca et al.[56] They suggested that anionic vanadate species self-assemble with the cationic head-group of cetyltrialkylammonium chloride surfactant (CTACl) in alcoholic media to produce the mesostructure. Although the structural order was retained after low-temperature calcination, both porosity studies and thermogravimetric analysis indicated that the surfactant was only partially removed, thus leading to thermally unstable phases. Other attempts to prepare mesoporous vanadium oxide have been reported. Whittingham et al.[57] have prepared a mesostructured, layered vanadium oxide by hydrothermal treatment of V_2O_5 in the presence of dodecyltrimethylammonium bromide (DTAB). However, the DTAB surfactant was not removed upon cation exchange. Sayari et al.[58] have synthesized lamellar and hexagonal mesostructured vanadium oxide by hydrolyzing oxovanadium triisopropoxide in the presence of dodecylamine, although no attempt was made to remove the surfactant. A mesostructured vanadium oxide obtained from the assembly of triblock copolymers with VCl_4 has been re-

ported by Stucky et al.,[59] although it lost its mesoscopic order upon calcination. Liu et al.[60] have reported the synthesis of mesostructured V_2O_5 by electrochemical deposition using nonionic surfactants. The final wormhole mesostructure was found to contain 3–4 nm pores. Although the complete removal of the surfactant was reported by the authors, no surface area or pore data were provided. The low Tammann temperature of V_2O_5 (472 K), as well as the cycles of redox reactions during surfactant combustion, account for the poor thermal stability of this oxide system.

Mesostructured molybdenum oxides have also been reported by Whittingham et al.[57] and Stucky et al.[59] A layered structure with a repetitive interplanar distance of 22 Å was prepared by hydrothermal reaction of molybdic acid with DTAB.[57] A mesostructured molybdenum oxide with larger ordering lengths (100 Å) was successfully synthesized by the assembly of triblock copolymers with $MoCl_5$. However, the obtained mesostructured materials were unstable upon calcination.[57,59] Incomplete condensation of the inorganic frameworks, the cycles of redox reactions during surfactant combustion, as well as the low Tammann temperature of the constituent metal oxides, are mainly responsible for the poor thermal stability of these metal-oxide mesophases. On the other hand, thermally stable mesoporous Nb_2O_5 has been obtained by Ying et al.[61,62] in the presence of amines as structure-directing agents. They proposed a ligand-assisted liquid-templating mechanism for the formation of thermally stable mesoporous Nb and Ta oxides. The formation of covalent bonds between Nb and the N-atom of the amine template directs the interaction between the organic and inorganic species. The improved thermal stability of mesoporous niobium oxide is probably due to the relatively high Tammann temperature of niobium oxide (892 K). High specific surface areas (approx. 600 m^2/g) were observed for these mesophases after template removal by acid/solvent extraction with triflic acid. In a different approach, Stucky et al.[59,63] have prepared mesoporous niobium oxide with pores of about 50 Å and a surface area of about 190 m^2/g using triblock copolymers as structure-directing agents. The improved thermal stability of these phases was attributed to weak H-bonding interactions between the template and inorganic walls, making the template removal possible without damaging the inorganic framework.

Titania possesses very interesting catalytic, photochemical, and electrical properties, which make it an attractive system for several applications. For instance, TiO_2 is commonly used as a photocatalyst.[64,65] Crystalline titania modified with sulfate ions is an active catalyst for low-temperature esterification, isomerization, alkylation, and cracking of hydrocarbons.[66,67] Other applications of titania are as an electrode material in electrochemistry, a capacitor in electronics, in humidity and gas sensors, and in photovoltaic solar cells.[68]

Mesoporous TiO_2 has been obtained using different synthetic approaches.[59,63,69,70] Stucky et al.[59,63] have employed hydrogen bonding to direct the synthesis and obtained large-pore (ca. 65 Å) hexagonal and cubic mesoporous TiO_2 with a specific surface area of 200 m^2/g. Interestingly, the walls of the TiO_2 mesostructure were built of nanocrystalline anatase, which is promising for potential applications in photocatalysis, since anatase is the most photocatalytically active crystalline phase of TiO_2.[65] In a different approach, charge matching between cationic surfactants and anionic peroxytitanates was used to produce mesoporous TiO_2 [69] with a surface area of 310 m^2/g and a pore size of about 36 Å. The final mesostructure, however, was found to lack long-range order, thus suggesting the formation of a wormhole pore network. A nonaqueous route for the preparation of mesostructured titania was studied by Kuperman et al.[70] The final mesoporous structures, with surface areas of up to 420 m^2/g, were thermally stable only when silanol groups were incorporated into the inorganic framework by the gradual exposure of the inorganic framework to 7–15 wt.-% of Si_2H_6. The composite was then heated to 125 °C and the excess of unreacted Si_2H_6 was removed under vacuum.

Zirconium oxide is a particularly interesting catalytic system, and has found many uses in chemical and petrochemical processes because it possesses acidic, basic, and redox properties. For example, it is an effective catalyst for the selective formation of isobutane and isobutene from synthesis gas,[71,72] and acts as a superacid (sulfated ZrO_2) in the isomerization and cracking of paraffins and alkylation and acylation of aromatics.[73–76] Crystalline *stable* tetragonal or cubic zirconia is required in most catalytic applications. For example, the tetragonal ZrO_2 phase has been claimed as the active phase in *n*-butane isomerization[76,77] and alkylation and acylation of aromatic compounds.[78,79]

Wong and Ying[80] have studied the formation of mesostructured ZrO_2 directed by anionic and nonionic surfactants. High-surface-area (360 m^2/g), mesoporous ZrO_2 was obtained only when alkyl phosphate surfactants were used. They associated the enhanced thermal stability of the final mesoporous structure with the presence of the phosphate groups on the ZrO_2 surface after the surfactant removal. However, no specific details were provided for the role of phosphate in stabilizing the ZrO_2 mesostructure.

Other mesoporous zirconia with pore sizes between 58 and 62 Å[59,63] and wormlike zirconia[70] have been also reported. For instance, thermally stable mesoporous zirconia with a surface area of about 280 m^2/g has been prepared,[59] although the mesostructure was only stable when SiO_2 was incorporated into the zirconia wall during synthesis. Mesoporous zirconia with both amorphous[70] and tetragonal nanocrystalline[59,63] walls has also been prepared, thus allowing an exploration of the role of the extended crystal structure on the catalytic properties of this metal oxide.

Sulfated hafnium oxide is another attractive superacid system for selective alkane isomerization.[81] The thermally stable hafnium oxide reported by Sayari et al.[82] exhibits a high surface area (ca. 200 m^2/g) and a wormhole pore-structure without long-range structural order. The pore diameter evaluated by the Horvath–Kawazoe method was only 11 Å, thus indicating the formation of a microporous phase. Mesoporous HfO_2 with large pores (70 Å) has also been

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

prepared by a neutral self-assembly approach employing Pluronic P-123 as a structure-directing agent.[59,63]

Tantalum oxide is yet another interesting metal-oxide system with potential applications in photocatalysis, such as photocatalytic water splitting.[83–85] Hexagonal mesoporous Ta_2O_5 with pore sizes in the 20–40 Å range and specific surface areas of up to 500 m^2/g was reported for the first time by Antonelli and Ying.[86] The synthesis was directed by covalent bonding between the primary alkylamine headgroups and Ta atoms in a ligand-assisted liquid-templating mechanism. Similar to the synthesis of mesoporous Nb_2O_5, mesoporous Ta_2O_5 has also been obtained in the presence of nonionic surfactants (Pluronic P-123) by neutral self-assembly directed by hydrogen-bonding interactions.[59,63]

Other reported mesostructured binary oxides with potential applications in catalysis are NiO and MnO_2. Nickel-oxide-based catalysts have been used successfully in the partial oxidation of olefins, nitroxidation of hydrocarbons into nitriles, and partial oxidation of isobutylene into methylacrolein.[87] Manganese oxides show catalytic activity in the oxidation of alkanes.[88] Shih et al.[89] have investigated the synthesis of mesostructured nickel oxide in the presence of CTAB. The NiO mesostructure was thermally unstable and collapsed upon thermal treatment. Since NiO exhibits a high Tammann temperature (1129 K), the limited stability of this mesostructured oxide may be associated with a low degree of cross-linking, redox reactions, and rigidity of the Ni–O–Ni framework. However, the addition of sodium silicate during the NiO synthesis produced a thermally stable mesostructure with a surface area of 530 m^2/g. The addition of silicate (Si/Ni = 0.2–0.5) is believed to strengthen the inorganic mesostructure. It was suggested that the resultant mesophase had a structure of SiO_4 tetrahedra linked together by Ni atoms on every corner to produce a robust mesostructure. Mesostructured lamellar manganese oxide has been prepared by Suib et al.[90] by employing $(C_{12}H_{25})NMe_3OH$ as a surfactant. However, no information was provided on the surfactant removal from these lamellar manganese oxides.

Other reported mesostructured transition-metal oxides include Y_2O_3, WO_3, and ReO_2: yttrium oxide is used as a matrix for solid-state lasers and luminescent systems,[91] rhenium oxides exhibit interesting electrical conductivity properties,[92] while tungsten oxides have found applications as semiconductor materials.[59,63] Lamellar and hexagonal mesostructured yttrium oxides have been prepared by employing anionic surfactants, such as sodium dodecylsulfate.[91] In this case, removal of the surfactant led to high surface areas (ca. 550 m^2/g) and mesoporous structures with pores of about 30 Å. Mesostructured rhenium oxide exhibiting wormhole channels occupied by surfactant molecules has been prepared employing dodecylamine as a surfactant.[92] However, no porosity was observed after the surfactant removal, indicating that the mesostructure collapses under oxidizing conditions, while the pores were blocked with residual pyrolyzed carbon after a thermal treatment in an inert atmosphere. Mesostructured tungsten oxide has been prepared in the presence of DTAB; however, DTAB removal by cation exchange was not successful.[57] High surface area WO_3 (125 m^2/g) displaying pores of about 50 Å has also been prepared by employing Pluronic P-123 as a structure-directing agent.[59,63]

Iron oxide is another interesting catalytic system that has been used to catalyze the oxidative dehydrogenation of hydrocarbons. For example, hematite is an active catalyst for transforming butane[93,94] and ethylbenzene.[95] High-surface-area (274 m^2/g) mesoporous iron oxides have been synthesized by sonochemical synthesis.[96,97] Iron(III) ethoxide was used as the inorganic precursor and CTAB as surfactant. Since the self-assembly process is directed by strong coulombic interactions, the improved thermal stability of mesostructured iron oxide may be associated with its relatively high Tamman temperature (919 K).

In addition to the above-mentioned applications in catalysis, these metal oxides (Table 3) may also be used as mesoporous hosts for the growth of functional nanoparticles, such as supported metals for applications in catalysis and semiconductor nanoparticles for electronic and optical applications.[98–100]

2.5. Mesostructured Mixed-Metal Oxides

Mixed-metal oxides are particularly attractive as catalysts for the selective oxidation of lower alkanes. For example, vanadium-phosphorus oxides are highly active and selective for the oxidation of *n*-butane to maleic anhydride.[101–105] The recently reported bulk mixed Mo-V-Sb-Nb oxides[101–104] are active and selective for the oxidation of propane to acrylic acid, and it is well known that the most efficient catalysts for propane ammoxidation are based on bulk mixed-metal oxides (i.e. vanadium antimonates or promoted molybdates).[110,111] V-Mg oxides are very active in the oxidative dehydrogenation of light alkanes to alkenes.[112,113] Mesostructuring of these complex metal-oxide systems offers the possibility to design novel catalytic materials with high surface areas, controlled porosities, tunable surface compositions, and improved catalytic performance. Examples of mesostructured mixed-metal oxides most relevant to applications in catalysis are summarized in Table 4.

One of the most remarkable mixed-metal oxide systems is the vanadium-phosphorus-oxide (VPO) system for the oxidation of *n*-butane to maleic anhydride, which is the only industrial vapor-phase oxidation of an alkane.[101–105] Few reports exist on the synthesis of mesostructured VPO materials. Iwamoto et al.[114] have reported the synthesis of mesostructured hexagonal vanadium-phosphorus oxide materials using alkyltrimethylammonium surfactants (C_{12}–C_{16}). However, the mesostructure in these materials was lost upon calcination. Doi and Miyake[115] have reported the synthesis of a novel hexagonal mesostructured VPO compound from the VPO catalyst precursor $VOHPO_4 \cdot 0.5H_2O$ by surfactant intercalation and subsequent hydrothermal treatment. However, these materials suffer from poor thermal stability and low phosphorus content that are detri-

mental for their use as heterogeneous catalysts. Amoros et al.[116] have described the synthesis of hexagonal mesostructured oxovanadium phosphates, denoted as ICMUV-2. However, the removal of surfactant from their vanadium phosphates resulted in the collapse of the mesostructure. Mizuno et al.[117] have described the synthesis of hexagonal, cubic, and lamellar mesostructured vanadium-phosphorus-oxides that lose their structural order upon calcination. We recently reported novel hexagonal, cubic, and lamellar VPO phases, which displayed improved thermal stability, desirable chemistries (i.e. the P/V ratios and vanadium oxidation states), and pore structures for the partial oxidation of lower alkanes.[118–120] We demonstrated in these studies that the V oxidation state and the surface P/V ratios can be tuned, respectively, by post-synthesis thermal treatment (i.e., oxidizing vs. reducing atmosphere) and inorganic–organic interfacial chemistry (i.e., the surfactant functionality).[118,121] The N_2 adsorption–desorption isotherm measurements indicated that these novel VPO phases have a broad size-distribution in the micropore range. However, complete removal of the surfactant and achievement of thermal stability for the mesoporous VPO system still represents a major challenge.[121] The incomplete cross-linking of the VPO framework, its redox properties, and the low Tammann temperature of the constituent oxides have so far prevented the preparation of thermally stable mesoporous VPO phases.

The Nb and Ta oxides possess moderately strong Lewis and Brønsted acidity and are promising as solid-acid catalysts and catalytic supports.[50] The mesoporous mixed Nb/Ta (ca. 1:1) oxide displaying a wormhole pore structure was prepared by a neutral templating method.[122] Interestingly, the resultant mesostructure displayed not only high thermal stability, but also the presence of nanocrystalline walls. However, as the crystallinity of the mesostructure increased with calcination time, the BET surface areas decreased from 168 to 22 m^2/g, suggesting the densification of the final mesostructure. In order to prevent this decrease in surface area, Antonelli et al.[123] have employed the ligand-assisted method to prepare mesoporous V-Nb oxides (5–15 mol.-% V in mesoporous niobium oxide). Although high-surface-area composites (500–830 m^2/g) were reported, only disordered wormhole pore structures were obtained, with walls about 2.0–2.3 nm thick. Chao and Ruckenstein have succeeded in the preparation of mesoporous Mg-V oxides (Mg/V = 0.5–10) with relatively high surface areas (i.e. 70–250 m^2/g) and wormhole-like pores that are promising for the oxidative dehydrogenation of alkanes.[112–113] The pore size of these composites could be fine-tuned by changing the pH. They proposed a self-assembly mechanism in which anionic polyvanadate species associated with an Mg^{2+} cation condense around positively charged surfactant micelles. The thermal stability of this system was attributed to the incorporation of Mg cations into the inorganic oxovanadium

framework. Figure 9 shows the typical wormhole-like mesoporous structure of mixed transition-metal oxides.

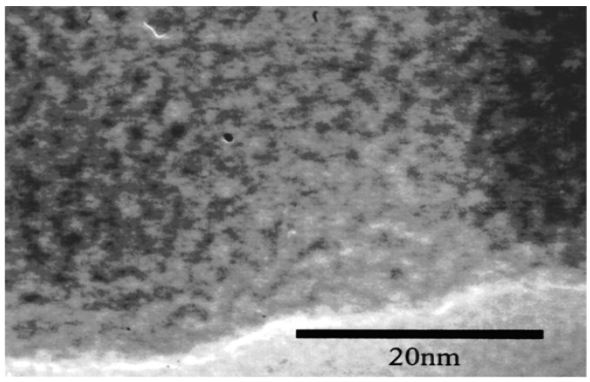

Figure 9. TEM of mesostructured vanadium-magnesium oxide exhibiting wormhole channels occupied by surfactant molecules.[112]

Mesoporous titanium phosphate is another example of a mixed-metal oxide obtained by a templated self-assembly approach.[124–126] Crystalline phosphated titania is catalytically active in the isomerization and alkylation of hydrocarbons.[66–67] Mesoporous titanium phosphate was prepared by a neutral templating route employing poly(ethylene oxide)s as surfactants.[124] The final mesostructure displayed thermal stability and high surface area (≈ 350 m^2/g). The relatively high thermal stability of mesoporous titanium phosphate was associated with a high degree of condensation of the amorphous titanium phosphate framework, which prevents crystallization and densification of the mesostructure. However, the obtained mesostructures were highly disordered, suggesting that weak hydrogen-bonding interactions between the surfactant and inorganic species lead to a decrease in the structural order. The synthesis of mesoporous phosphated titania (P/Ti = 1 and 2) has also been directed by electrostatic interactions.[125] In this case, disordered mesostructures with much higher surface areas (up to 740 m^2/g) and wormhole-like pores were obtained after surfactant extraction. However, the surface area decreased by about 60 % upon calcination. Titanium phosphates possessing ordered hexagonal mesostructure have been obtained by Schüth et al. in the presence of alkyltrimethylammonium bromides.[126] Interestingly, the pore analysis showed a type-I isotherm that is characteristic of microporous materials after surfactant removal by calcination, which suggests the formation of a hierarchical porous structure in which the micropores are most likely incorporated in the walls of the mesostructure.

Low-temperature alkane isomerization is of great interest to the petrochemical industry since branched alkanes are important gasoline products and additives.[104] Superacids, such as ZrO_2-SO_4 and ZrO_2-PO_4, catalyze alkane isomerization and other reactions demanding high acidity.[73–75] Highly ordered and thermally stable hexagonal mesoporous ZrO_2-SO_4 and ZrO_2-PO_4 have been reported by Schüth et al.[127] In these studies, the improved thermal stability was associated with the presence of the sulfate and phosphate groups, which strengthen the walls of ZrO_2. The authors proposed that uncondensed ZrOH groups bond with phosphate groups, thereby increasing the extent of cross-linking and enhancing the stability of the mesophase upon surfactant removal.

Mixed yttrium-zirconium oxide is an example of a catalytic system that is promising for the Fischer–Tropsch synthesis.[128] Yttria is commonly used to stabilize the tetragonal or cubic ZrO_2 phase.[129,130] When Y is incorporated into the ZrO_2 lattice, oxygen vacancies are created to preserve the lattice neutrality. It has been suggested that the active sites for CO hydrogenation are these oxygen vacancies.[128] Mesoporous yttria-zirconia with nanocrystalline walls, wormhole pore channels of about 20 Å, and 100–250 m^2/g BET surface areas has been reported by Ozin et al.,[131] whereas Gedanken et al.[132] have prepared lamellar and hexagonal Y/Zr (1:1) oxide mesostructures by a sonochemical method employing sodium dodecyl sulfate as the surfactant. Mesoporous structures with surface areas of about 245 m^2/g were obtained after surfactant extraction with sodium acetate. However, a nonuniform pore-size distribution was observed, and the mesoporous mixed-metal oxide collapsed upon thermal treatment due to poor cross-linking of the inorganic framework and its redox properties.

The use of nanoparticles as building blocks instead of molecular precursors is an attractive route to mesoporous metal oxides with nanocrystalline walls that display improved thermal stability and show significant promise for structure-sensitive catalytic reactions. Ying et al.[133] have employed colloidal ZrO_2 nanocrystals to prepare mesoporous mixed tungsten-zirconium oxide. They proposed that this self-assembly process is driven by attractive forces between negatively charged metatungstate ions (I^-), positively charged ZrO_2 nanoparticles (C^+), and hydrogen-bonded polymer surfactants (S^0H^+). The same synthesis pathway has been used successfully to prepare mesoporous tungsten-titanium oxide. Honma et al. have reported a novel methodology to prepare ordered mesoporous nanocomposites with crystalline oxide frameworks employing functional nanocrystals as the building blocks.[134] Ordered mesoporous nanocomposites consisting of electrochemically active nanocrystals and semiconductive glass in the TiO_2-P_2O_5-M_xO_y systems (where M is a metal ion) were formed. Other mesoporous mixed-metal oxides, such as Zr-Ti and Zr-W oxides, have also been reported by Stucky et al.[59,63]

3. Ordered Macroporous Oxides

3.1. Structural Characteristics

Colloidal crystals consisting of three-dimensional ordered arrays of monodispersed spheres can be used as novel templates for the preparation of highly ordered macroporous inorganic solids that exhibit precisely controlled pore sizes and highly ordered 3D porous structures. The macroscale templating approach typically consists of three steps. First, the interstitial voids of the monodisperse sphere arrays are filled with precursors of various classes of materials, such as ceramics, semiconductors, metals, monomers,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

etc. In the second step, the precursors condense and form a solid framework around the spheres. Finally, the spheres are removed by either calcination or solvent extraction.

The success of forming macroporous ordered structures is mainly determined by van der Waals interactions, wetting of the template surface, filling of the voids between the spheres, and volume shrinkage of the precursors during the solidification process. The colloidal crystal templating method may be used in combination with sol-gel, salt solution, nanocrystalline, and other precursors to produce the inorganic 3D macrostructures.[6] The colloidal-crystal templates used to prepare 3D macroporous materials include monodisperse polystyrene (PS), poly(methyl methacrylate) (PMMA), and silica spheres. A typical SEM image of a colloidal array of polystyrene spheres used as a template in the synthesis of macroporous inorganic materials is shown in Figure 10. Prior to precursor infiltration, these monodisperse spheres are ordered into close-packed arrays by sedimentation, centrifugation, vertical deposition, or electrophoresis.[135] The final inorganic macroporous structure after the removal of spheres contains the ordered interconnected pore structure shown in Figure 11.

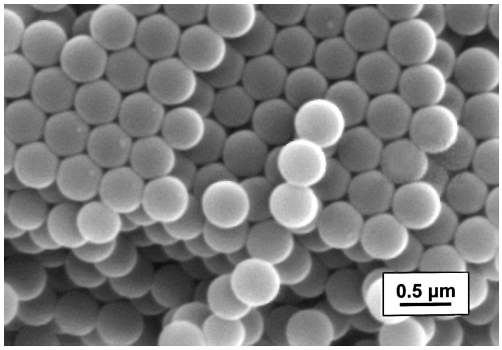

Figure 10. SEM image of an ordered array of ~400 nm polystyrene spheres.[173]

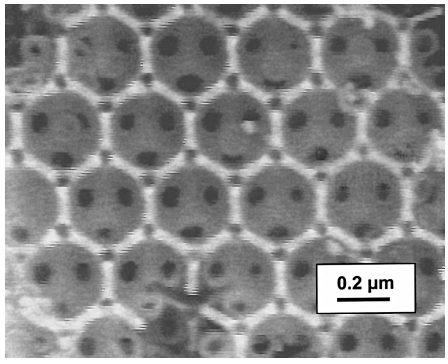

Figure 11. SEM image of a macroporous inorganic material. The walls consist of ~20 nm $(VO)_2P_2O_7$ crystals (modified from ref.[173]).

3.2. Macroporous Binary and Mixed-Metal Oxides

Several synthesis methods have been used in the past to prepare 3D macroporous inorganic materials. These include sol-gel, salt precipitation, nanocrystal infiltration, and polymerization. All these synthesis methods rely on the use of a polymeric or inorganic template, usually in a form of spheres packed in a periodic fashion. Bulk ordered transition metal macroporous oxides prepared by the sol-gel[136–145] and other methods[146–158] are summarized in Table 5 and Table 6, respectively. The most representative methods to prepare inorganic macrostructures are briefly discussed below.

Macroporous inorganic frameworks have been successfully prepared using the sol-gel method, in which metal alkoxides dissolved in alcohol are impregnated into the voids of the colloidal (polymer) sphere arrays. Hydrolysis and condensation take place at the sphere surface to form the inorganic framework. Subsequent heat treatment to remove the polymer spheres results in an ordered macroporous metal oxide. The final macropore dimensions are about 15–30 % smaller than those of the original spheres due to the shrinkage of the inorganic framework. This is caused by a large volume loss during the sol-gel process as the alcohol is evaporated. Significant shrinkage of the inorganic framework during template removal by heat treatment results in severe cracking and loss of long-range order. Therefore the sol-gel method, in combination with heat treatment to remove polymer spheres, has not resulted to date in highly ordered macroporous materials for photonic bandgap applications, for which long-range order is required. Several single, binary, and tertiary oxides have been prepared using sol-gel chemistry: SiO_2;[136] TiO_2, ZrO_2, SiO_2;[137] TiO_2, ZrO_2, Al_2O_3;[138] SiO_2, TiO_2, ZrO_2, Al_2O_3, Fe_2O_3, Sb_4O_6,

Precipitation of metal salts, such as acetates and oxalates, and oxides within the colloidal polymer-sphere arrays, and subsequent chemical conversion of the inorganic precursors, is an alternative method to prepare ordered macroporous structures. This procedure is less sensitive to atmospheric humidity and allows the formation of ordered 3D macroporous structures for compositions difficult to prepare by sol-gel techniques. Yan et al.[147] have reported the synthesis of macroporous NiO with 250–500 nm voids by templated precipitation and subsequent chemical conversion of the inorganic precursors. The metal salt solution (acetates or nitrates) penetrates the void spaces between the spheres, and subsequent calcination of the macrocomposite removes the spheres and produces the desired metal oxide. A number of ordered macroporous inorganic oxides have been prepared by the salt precipitation method: MgO, Cr_2O_3, Mn_2O_3, Fe_2O_3, Co_3O_4.[148]

Ordered macroporous materials may be prepared by filling the void spaces of colloidal sphere arrays with nanoparticles. This method offers the great advantage of incorporating specific nanoparticles of desirable crystalline phases into the wall structure of the macroporous framework. Another major advantage of this method is that it results in very little shrinking and cracking of the 3D framework during template removal. Typically, the pore shrinkage is limited to 5–10 %. Subramania et al.[149] have used monodisperse PS spheres to template colloidal dispersions of silica and titania and form 3D structures with 320–525 nm macropores. Vlasov et al.[150] have used CdSe nanocrystals templated against monodisperse silica spheres to synthesize macroporous CdSe semiconductors.

Polymerization of organic precursors around colloidal silica-sphere arrays is a common method to produce ordered macroporous polymeric materials. The colloidal arrays of spheres are filled with a liquid monomer, which is subsequently polymerized by heat treatment or UV irradiation. Macroporous polyurethane, poly(acrylate/methacrylate), PMMA, polystyrene, epoxy, and poly(methyl acrylate) have been prepared using this methodology.[151–153]

Other miscellaneous techniques for the preparation of inorganic macrostructures include spraying techniques,[154,159] electrodeposition,[155–157,160] and inverse opal templating.[152,158] Spraying techniques have been used mainly in the preparation of macroporous films. Macroporous TiO_2, for example, has been prepared by spray pyrolysis by depositing titanyl acetylacetonate onto silica spheres,[154] and macroporous Au has been synthesized by ion spraying.[159] Electrodeposition techniques offer excellent control over the degree of filling and wall thickness. Growth of the desirable macrostructure occurs galvanostatically or potentiostatically. Macrostructures of CdS, CdSe,[155,156] ZnO,[160] polypyrrole, polyaniline, and poly(bithiophene)[157] have been successfully prepared by electrodeposition. In the inverse opal templating method, 3D macroporous structures prepared by templating with opal structures can be subsequently used to form another opal replica. A wide range of compositions, (TiO_2, ZrO_2, Al_2O_3, polypyrrole, PPV (polyphenylene-vinylene), CdS, AgCl, Au, Ni) [158] have been prepared by this method.

Macroporous vanadium-phosphorus-oxide (VPO) phases with remarkable compositional, structural, and morphological properties have been synthesized by employing monodisperse polystyrene sphere arrays as a template.[141,142] Colloidal polystyrene spheres were ordered into closed-packed arrays by sedimentation or centrifugation. Depending on the choice of VPO source and template-removal method, various crystalline VPO phases were obtained. The macroscale-templated synthesis produced VPO phases with unprecedentedly high surface areas (75 m^2/g), desirable macroporous architectures, optimal bulk compositions (P/V ≈ 1.1), desirable vanadium oxidation states (+4.1 to +4.4), and preferential exposure of the surface (100) planes of vanadyl(IV) pyrophosphate, $VO_2P_2O_7$, which is the proposed active and selective phase for *n*-butane oxidation to maleic anhydride.

The ability to control wall thickness, pore size, and elemental and phase compositions makes colloidal sphere array templating a versatile, attractive, and flexible route for the synthesis of highly ordered macroporous materials with fine-tuned pore and framework architectures. The wall thickness of macroporous structures can be controlled by the hydrolysis/condensation rates of the inorganic precursors,[139] the packing of the PS spheres,[142] and by forming core-shell structures at the sphere surface (i.e. deposition of polyelectrolyte multilayers at the sphere surface).[145] The pore size can be easily manipulated in the range of the sphere sizes, which are typically between 100 nm and 50 μm

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in diameter. Even smaller spheres (20 nm) can be prepared and used to template small-pore materials.[6] Furthermore, it is possible to build macroporous structures containing a specific crystalline phase by incorporating nanoparticles of desired phases in the voids of sphere arrays.[149,150] Depending on the choice of the inorganic sources and template-removal method, various crystalline phases can be obtained.[142] This suggests that the most critical aspects in the preparation of these macroporous structures are the ability of the precursors to infiltrate and condense between the spaces of the colloidal spheres without swelling or destroying the template, as well as the ability to avoid excessive grain growth, as this leads to a decrease in macroporosity and structural order.

4. Emerging Catalytic Applications

4.1. Mesoporous Metal Oxides

Finely tuned pore sizes, metal oxide wall structures and compositions, high surface areas, and enhanced accessibility of the active surface sites in ordered mesoporous metal oxides are highly attractive for diverse catalytic applications. A thorough review of emerging applications of mesoporous transition metal oxides in catalysis is given here. Reported examples of catalytic mesoporous metal oxides are summarized in Table 7.

Some early examples of catalytic mesoporous silicates have been reviewed by Sayari.[159] More recently, Ogawa et al.[160] have reported the use of Al-containing mesoporous silica films as nanoreactors for organic photochemical reactions. An adsorbed azobenzene derivative incorporated in the film exhibited photochemical isomerization upon UV/Vis irradiation at temperatures as low as 80–300 K. However, no comparison with conventional nonmesoporous systems was conducted. Ikeue et al.[161] have reported Ti-containing porous silica films that exhibit high photocatalytic activity in the reaction of CO_2 with H_2O to produce CH_4 and CH_3OH as the main products. The quantum yield of these mesoporous Ti-silica films was 0.28 %, which is significantly higher than the value of 0.02 % obtained with titanium oxides anchored on a transparent porous silica glass (PVG). Such improvement in the reactivity may be attributed to the higher surface area and ordered pore structure of the mesoporous Ti-silica films. Soga et al.[162] have prepared aluminoxanes adsorbed on mesoporous silica that display ethylene polymerization activity in a catalytic system containing bis(cyclopentadienyl)zirconium dichloride. Furuya et al.[163] have used Ti-mesoporous silica to oxidize cyclohexene to cyclohexene oxide with *t*BuOOH in the presence of benzene and cyclohexane with 99 % selectivity at 98 % conversion. Methanol oxidation over Nb_2O_5/SiO_2 and Nb/MCM-41 has been studied by Wachs et al.[164] Although their results showed that the dispersed Nb species in both catalysts were the active and selective sites for methanol oxidation, Nb/MCM-41 displayed higher overall activity due to a better dispersion of isolated NbO_4 species per unit mass of this catalyst.

Only a few reports exist on catalytic applications of mesoporous transition metal oxides. Yussuf et al.[165] have reported the photocatalytic behavior of mesoporous titania films. They found that the photocatalytic activity of the films for the oxidation of NO_x was higher for the mesoporous films than for conventional gel films, probably due to

Table 7. Emerging catalytic applications of mesoporous metal oxides.

the higher surface areas of the mesoporous films. In a different study,[166] mesoporous Ta_2O_5 doped with NiO was found to display higher photocatalytic activity than nonporous amorphous and crystalline NiO-Ta_2O_5. It was claimed that the higher surface areas and better NiO dispersion over the mesoporous Ta_2O_5 host were responsible for the superior catalytic performance of these materials. The photocatalytic activity of mesoporous phosphated titanium and niobium oxide catalysts has been studied in the dehydrogenation of 2-propanol to acetone.[167] Surprisingly, a lower activity of the mesoporous Ti and Nb oxides was observed than for the bulk anatase phase. The amorphous nature of the mesoporous walls and the surface defects in these mesoporous oxides are probably responsible for the recombination of photogenerated electron-hole pairs and the poor catalytic performance.

Gedanken et al.[168] have studied the oxidation of cyclohexane to cyclohexanol and cyclohexanone over a mesoporous Fe_2O_3-TiO_2 catalyst. The mesoporous catalysts displayed about a 5 % higher cyclohexane conversion under the same conditions as compared to catalysts in which Fe_2O_3 was incorporated into nonporous TiO_2. Yoshitake and Tatsumi[169] have incorporated vanadium oxide into mesoporous TiO_2 and studied these novel catalysts in propene oxidation reaction. They found that the rate of propane oxidation to CO and CO_2 was about 18 times higher with mesoporous VO_x-TiO_2 catalysts than with conventional VO_x-TiO_2 (i.e. a nonporous TiO_2 matrix). The high surface areas displayed by these mesoporous catalysts and improved dispersion of active surface sites in the mesoporous hosts are responsible for their enhanced catalytic performance.

The catalytic performance of ordered mesostructured vanadium-phosphorus-oxides in selective *n*-butane oxidation has been studied by Carreon and Guliants.[121] Mesostructured VPO was evaluated in the oxidation of *n*-butane to maleic anhydride. Selectivities to maleic anhydride of up to 40 mol-% were observed at 673 K at about 10 % *n*-butane conversion. A conventional organic VPO catalyst containing well-crystallized vanadyl(IV) pyrophosphate, the proposed active and selective phase for *n*-butane oxidation to maleic anhydride, displayed selectivities to maleic anhydride of 50 mol-% under the same reaction conditions. The limited thermal stability of mesostructured VPO during *n*-butane oxidation led to the gradual loss of the structural order and poor catalytic performance. These results further suggested that crystalline vanadyl(IV) pyrophosphate is required for this alkane oxidation reaction.

Other potential applications of mesoporous metal oxides, such as in fuel cells, as semiconductors, cathode materials, superparamagnets, etc., have been discussed recently by He and Antonelli[170] and are outside the scope of this review.

4.2. Macroporous Metal Oxides

Ordered macroporous films and membranes are novel monolithic materials with potential applications in heterogeneous catalysis, bioseparations, as well as membrane supports for the separation of small molecules. Due to their high surface area (up to 230 m^2/g) and unimodal large pores, these macroporous structures are highly attractive for a variety of separation and catalytic applications involving large molecules.

Only a few examples of catalytic applications have been reported for bulk macroporous solids. Stein et al.[171,172] have used ordered macroporous silica as a support for catalytically active species. For instance, they found that γ-$SiW_{10}O_{36}$ polyoxometalate clusters incorporated into the walls of macroporous silica exhibit catalytic activity for the epoxidation of cyclooctene.[171] In another study, they[172] compared different pore structures (macro, meso and nonporous silica surfaces) with the activity of silica samples doped with transition-metal-substituted polyoxometalates (TMSPs). Although the three types of catalysts showed comparable conversions in the epoxidation of cyclohexene to cyclohexene oxide, the open macroporous structure supported a greater number of TMSP clusters at its surface, thus leading to improved cluster retention during the catalytic reaction. The recently reported macroporous VPO represents the first example of a macroporous transition mixed-metal oxide employed in the selective oxidation of lower alkanes.[173] The catalytic performance of this VPO phase was evaluated in the partial oxidation of *n*-butane to maleic anhydride. The observed yield of maleic anhydride was greater than 50 % for macroporous VPO.[173] Under similar reaction conditions, the yield of maleic anhydride was about 40 % for the conventional organic VPO catalyst. The ordered open-pore structures, the high surface areas (>40 m^2/g), and the presence of nanocrystalline $(VO)_2P_2O_7$ in macroporous VPO resulted in improved catalytic performance. The successful preparation of these catalytically active bulk phases ushers in new and exciting opportunities for the design of macroporous films and membranes for various applications in biocatalysis and bioseparations. Other nanotechnological applications of these novel meso- and macroporous metal-oxide phases have been recently reviewed.[18]

5. Concluding Remarks

The present review of mesostructured binary and mixed-metal oxides demonstrates that complete surfactant removal and the attainment of high thermal stability are some of the critical challenges in the synthesis of mesoporous metal oxides. Incomplete cross-linking of the inorganic frameworks, strong covalent bonds between the inorganic species and surfactant molecules, the rigidity of the M–O–M bond angles, the low Tammann temperature of the constituent metal oxides, and bulk redox reactions are among the most notable causes of the limited thermal stability of mesoporous binary and mixed-metal oxides.

Several synthetic strategies are promising to overcome the limited thermal stability of mesostructured transition metal oxides. One proposed strategy is to strengthen the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

inorganic framework by increasing cross-linking with silicate[89] and phosphate[174] species prior to surfactant removal. Another strategy consists in avoiding strong electrostatic interactions at the organic–inorganic interface, instead directing the synthesis through weak hydrogen-bonding interactions, and consequently improving the thermal stability of the final mesostructure.[59,63]

Furthermore, the lattice oxygen mobility during surfactant combustion may be lowered and, as a result, the thermal stability of the mesostructure improved by employing oxides with high Tammann temperatures (Table 1). For example, Nb_2O_5 [61,62] and ZrO_2 [80] mesostructures with relatively high Tammann temperatures (Table 1) display good thermal stability. Similarly, thermally stable mesoporous mixed-metal oxides may be obtained by employing oxides with a high Tammann temperature as the major structural component. For instance, thermally stable mesoporous V-Mg oxide,[112,113] V-Nb oxide,[123] and Y_2O_3-ZrO_2 [138] have been successfully prepared. In all these cases oxides with high Tammann temperature (i.e. Mg, Nb, and Zr oxides) were used as the major component in the mixed-metal oxide system.

The use of a liquid crystalline L_3 phase represents another attractive alternative for the preparation of mesoscopic mixed-metal oxides with open-pore structures without the need for surfactant removal. The L_3 phase consists of a surfactant bilayer forming a sponge-like structure with randomly distributed mesopores interconnected in all three dimensions.[175,176] The pore diameter in the L_3 phase increases with increasing solvent content, thus providing a procedure by which the pore diameter can be tuned to a specific size. Only the solvent, rather than the surfactant molecules, occupies the primary pore volume. Therefore, the void space is immediately available for the condensation of an inorganic framework without the need to remove the surfactant. The only limitation of this approach is that the resultant mesostructures must be used at temperatures below the surfactant decomposition temperature (i.e. about 600 K) to avoid the collapse of the mesostructure.

For many structure-sensitive catalytic applications, such as the selective oxidation of lower alkanes over bulk mixed-metal oxides, it is highly desirable to have a well-defined crystalline catalytic phase. Therefore, the self-assembly of nanocrystalline building blocks into mesostructured metal-oxide phases represents a highly promising method to prepare mesoporous metal oxides with nanocrystalline walls.[140] In this respect, the macroscale-templated synthesis of nanocrystalline mixed-metal oxides is an attractive approach for the design of catalytic phases that possess remarkable ordering on the macroscale (>50 nm for pore architectures) displaying nanocrystalline walls.

Meso- and macroscale self-assembly approaches are particularly attractive for the design of novel catalytic phases on multiple length-scales that possess unique pore structures, flexible compositions, and tunable surface active sites. These unique porous structures with finely tuned surface active sites are highly promising as improved catalysts for a variety of selective alkane oxidation reactions. Moreover, it is expected that these novel model catalytic systems would lead to an improved fundamental understanding of the relationships between the molecular structure and catalytic properties of a broad range of industrially relevant catalytic systems.

Formation of Hexagonal Coordination Complexes

Nate Schultheiss,[a] Joseph M. Ellsworth,[a] Eric Bosch,*[a] and Charles L. Barnes[b]

Keywords: Crystal engineering / N ligands / Metallacycles / Microporous materials

The synthesis of the ligand 1,3-bis(3′-pyridylethynyl)benzene and the coordination complex formed with copper(II) acetate is described. The complex is hexagonal with two ligands bridged by paddlewheel-shaped dimeric copper(II) acetate moieties. The complexes are packed in such a way that the benzene rings from two separate complexes penetrate into the central cavity.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The synthesis of porous solids is a research area of current interest.[1−4] For example solids that contain channel-like void spaces are attractive goals with potential applications in molecular adsorption, ion exchange, and also heterogeneous catalysis. Hexagonal channels and cavities are often found in nature, and several approaches to the synthesis of hexagonal channels have been reported. Moore, for example, reported the formation of a purely organic porous solid with wide channels based on the π-stacking and hydrogen bonding of a planar hexagonal macrocycle comprising six phenols linked by *meta*-ethynyl groups.[5] Robson reported a coordination chemistry approach and characterized a large hexagonal complex on self-assembly of 2,4,6-tris(4′-pyridyl)-1,3,5-triazine with copper(II) acetate.[6] That coordination network did not contain channels because of the offset packing of adjacent sheets of the coordination network. In this report we describe a different coordination chemistry approach to the preparation of hexagonal channels.

Results and Discussion

As ligand we chose to prepare the bidentate ligand 1,3-bis(3′-pyridylethynyl)benzene, **1**, and to self-assemble this with metals that favor linear coordination as shown in Equation (1). Sonagashira coupling[7] of 3-bromopyridine with 1,3-diethynylbenzene yielded the ligand **1** in good yield as shown in Equation (2).[8] We then allowed the ligand **1** to self assemble with copper(II) acetate in acetonitrile solution and obtained green diamond-shaped crystals.[9] Elemental analysis of the bulk solid indicated that a 1:2 ligand/Cu^{II} complex was formed. Single-crystal X-ray analysis revealed this to be a hexagonal 2:4 coordination complex as shown in Figure 1.[10]

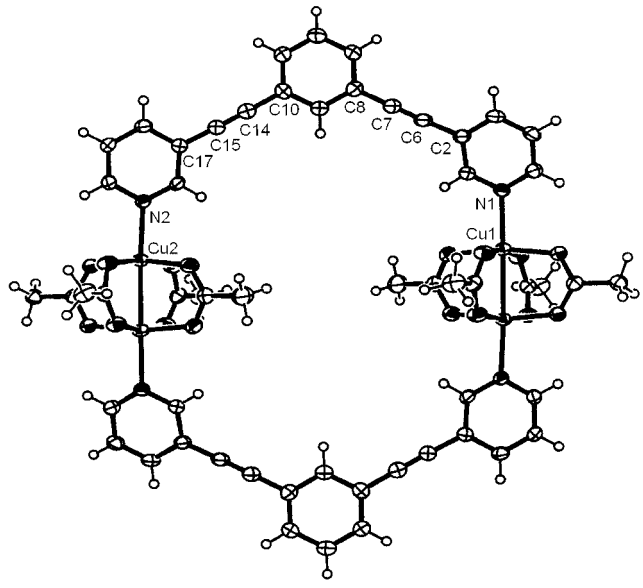

Figure 1. Ortep view of the 2:4 complex formed between **1** and copper(II) acetate; ellipsoids drawn at the 50% probability level

(2)

The complex between two ligands and two copper(II) acetate dimeric units forms a slightly irregular hexagon as shown in Figure 1. The copper(II) acetate linkage gives longer sides with a N(1)−N(2) distance of 6.957 Å, while the C(2)−C(8) and C(10)−C(17) distances are 4.067 and 4.065 Å, respectively. The copper acetate paddlewheel forms an almost linear connection between the pair of ligand molecules with nitrogen−copper−copper angles of 174.82(6) and 177.43(7)°. The copper−nitrogen bond lengths of 2.185(2) and 2.175(2) Å and the copper−copper bond length of 2.6053(5) Å are normal. The copper−oxygen bond lengths range from 1.959(2) Å to 1.987(2) Å, and the oxygen−copper−oxygen bond angles on each side of the paddlewheel range from 87.56(9) to 92.32(9)°. The alkynes are undistorted with normal triple bond lengths of 1.190(4) and 1.191(4) Å and angles about the sp C atoms between 177.3(4) and 179.3(4)°. The pyridyl rings are slightly twisted with respect to the central benzene ring with torsional angles of approximately 28 and 13°.

Unfortunately, the hexagonal complexes do not stack on top of each other to form porous materials − instead individual complexes stack in an offset manner with the end of two complexes partially penetrating the central cavity of a third complex. This is shown in Figure 2.

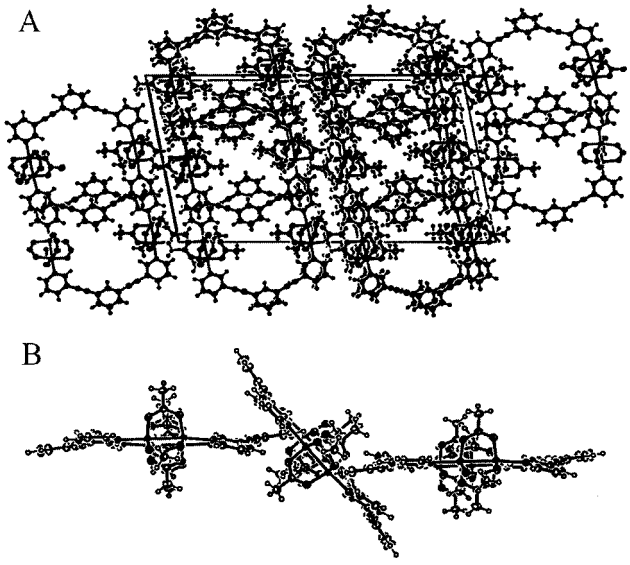

Figure 2. **A:** The packing in the unit cell viewed along the a axis; **B:** view showing the partial penetration of two complexes into a central tilted complex.

Synthesis of ZnS Nanowires and Assemblies by Carbothermal Chemical Vapor Deposition and Their Photoluminescence

Hua Zhang,[a] Shuyuan Zhang,*[a] Ming Zuo,[a] Gongpu Li,[a] and Jianguo Hou[a]

Keywords: Chemical vapor deposition / Luminescence / Nanostructures / Self-assembly / Zinc

A carbothermal method combined with CVD has been developed to synthesize ZnS nanowires and their self-assemblies at low temperatures. In this process, active carbon serves as reductant to react with sulfur, which then goes on to form ZnS nanowires. X-ray diffraction and X-ray photoelectron spectroscopy studies indicate that the samples are single-crystal wurtzite ZnS and are rich in sulfur. The nanowires have diameters ranging from 20 to 60 nm. High-resolution electron microscopy shows the [100] growth direction for the monodispersed nanowires and the different crystal orientation for the nanowires constituting the assembly. The photoluminescence (PL) peak is located at 490 nm. A vapor-solid (VS) mechanism might explain the formation of ZnS nanowires.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Recently, there has been considerable interest in well-arranged nanostructures prepared by various methods, including template synthesis[1] and electrochemical deposition,[2] as they have potential applications in many areas, such as infrared photo detectors,[2] field emissions,[3] and as substrates for photocatalysis and photovoltaics.[4] As they are probably building blocks for well-ordered nanostructures and nanodevices,[5−7] one-dimensional nanomaterials have recently attracted much attention.[8−11] ZnS is an important II-VI semiconductor that possesses unique properties and has potential applications in numerous areas like optics,[12] electronics,[13] photocatalysis,[14] etc., and is especially promising in electric nanodevices. Except for our previously prepared ordered constructions[15] like flowers and sheets, only nanocombs[16] and microrods[17] composed of regularly arranged ZnS nanowires have been reported. ZnS nanowires and their assemblies have often been prepared by both solution methods[18] and thermal evaporation.[19] For the latter, ZnS powder precursors have generally been thermally evaporated under at 900−1600 °C. For example, ZnS-Si-ZnS triaxial nanowires[20] have been prepared by heating a mixture of SiO and ZnS powders to 1300 °C for 1 h and then to 1600 °C for 1.5 h. The obtained product was a composite material containing cubic Si and zincblende-structured ZnS. Wang's group[21] has employed a silicon wafer and Au films as substrate and catalyst, respectively. Wurtzite phase ZnS nanowires were successfully prepared by heating ZnS powders to 900 °C for 2 h,. According to Li and co-workers,[22] Zn/ZnS nanocables can be fabricated by thermal evaporation of ZnS and a graphite-powder mixture at 1300 °C for 5 h. In spite of these reports it is still a challenge to explore other new and versatile alternatives for the synthesis of pure ZnS nanowires and their assemblies at lower temperatures.

Here, we demonstrate that pure, wurtzite-phase ZnS nanowires can be prepared by a carbothermal, chemical-vapor-deposition method (CVD) by heating a mixture of activated carbon, sublimed sulfur and anhydrous $ZnCl_2$ powders to 500 °C. In addition, we have found that some self-assembled structures composed of ZnS nanowires coexist in the samples. Because of its lower temperature and versatility, this new fabrication method might present a new and easy way to form various kinds of sulfides. The green-blue emission of the as-grown ZnS nanowires and their assemblies may have potential applications in electronic/optical nanodevices.

Results and Discussion

The X-ray diffraction (XRD) pattern (see Supporting Information) of the as-prepared samples shows that the samples are well crystallized. All the peaks can be indexed as (100), (002), (101), (110), (103) and (112) crystal planes corresponding to JCPDS card 36-1450, which suggests that the samples are pure, wurtzite-phase, structured ZnS with lattice parameters $a = 3.820$ Å and $c = 6.257$ Å.

The Zn and S content in the ZnS nanowires was obtained from the X-ray photoelecton spectroscopy (XPS) patterns (Figure 1). No impurities, such as trace metals and other

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

sulfides, are observed in the complete spectrum (see Supporting Information). The binding energy for Zn $2p^3$ (Figure 1a) is 1023.25 eV, which is a slight increase compared with that reported in the database[23] compiled and evaluated by Wagner, thus indicating a small difference in the chemical state of zinc in our samples. Curve 1 in Figure 1b shows the pattern of S $2p^3$ with two shoulders at about 162 and 164 eV. In order to determine the chemical states of sulfur, curves 2, 3 and 4, centered at 162.40, 163.40 and 164.60 eV, respectively, were fitted accompanied by their combined curve 5. Curves 2 and 3 represent the sulfur in ZnS; a small amount of elemental sulfur is responsible for curve 4. Therefore, the ratio of S to Zn in ZnS is about 1.077:1, which shows the richness of S instead of the sulfur deficiency generally found in previous papers.[24]

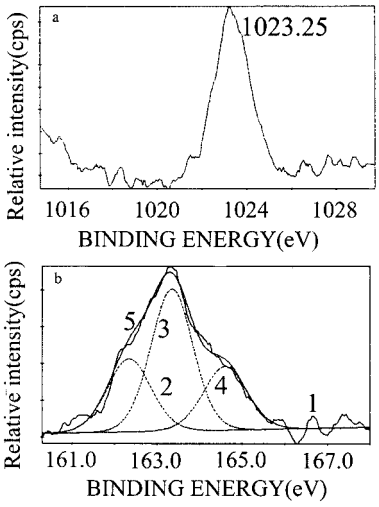

Figure 1. XPS patterns of the ZnS sample: (a) Zn $2p^3$ (b) S $2p^3$

Figure 2a displays a typical low-magnification transmission electron microscopy (TEM) image, which shows that the products consist of nanowires with uniform diameters ranging from 20 to 60 nm. The wires are long, straight and smooth with few other particles present. The electron diffraction (ED) pattern (inset) taken from a single nanowire (Figure 2b) can be indexed as the (100) and (001) planes of wurtzite-phase ZnS. Figure 2c shows a high-resolution electron microscopy (HREM) image, with a measured spacing of about 0.626 nm corresponding to the (001) plane. It can be clearly observed that the growth direction of the wire is perpendicular to [001], i.e. the [100] direction. The inset in the HREM image of another wire shows the two-dimensional lattice spacing, from which the (101) crystal plane, with a measured spacing of 0.293 nm, can clearly be seen.

Some regularly assembled structures, shown in Figures 3a and b, have been found in the as-prepared samples. From the high-magnification TEM image (Figure 3b) the characteristics of the wires can clearly be seen, especially from the different contrast and the places indicated by the arrows. These nanowires, with smooth surfaces and diameters in the range of 10−60 nm, are self-organized in the radial direction and are nearly parallel to each other, while in the thickness direction the self-organization can't be comfirmed from the contrast; this is different to the case of microrods,[17] where the assembly happens in two dimensions. The (001) and (002) crystal planes of the wurtzite phase can be identified in the ED pattern. The HREM image taken from the frame-labeled area is shown in Figure 3c. There are two different lattice spacings related to the two neighboring single nanowires. One is 0.313 nm, corresponding to the (002) plane, and the other is 0.227 nm, corresponding to the (102) plane. This indicates that not all the nanowires making up the assembly grow along the same crystal orientation.

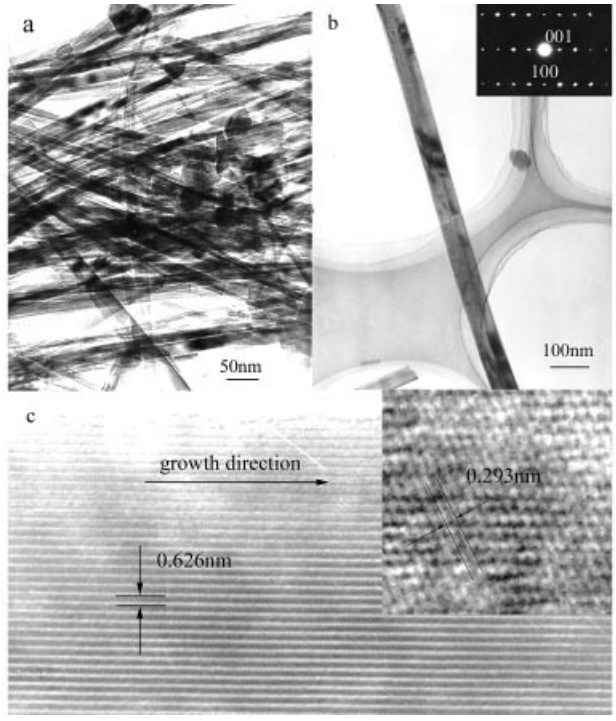

Figure 2. (a) TEM image of ZnS nanowires; (b) TEM image of a single ZnS nanowire and its ED pattern (inset); (c) one-dimensional and (inset) two-dimensional HREM images of a ZnS nanowire

The room-temperature photoluminescence (PL) spectrum of the as-synthesized ZnS nanowires and assemblies was measured with excitation and filter wavelengths of 313 nm and 350 nm, respectively. As shown in Figure 4, a strong emission peak is located at 490 nm, which is similar to that of the well-known ZnS-related luminescence (at about 480 nm) produced by zinc vacancies.[25] The ZnS nanomaterials reported previously have ultra-violet emission with bands in the range 400−450 nm[26−27] associated with the sulfur vacancy. It has been reported in previous work on ZnS that the vacancy states lie deeper in the gap than the interstitial states.[28] Therefore, in the case of the sulfur-rich nanowires containing no impurities reported here, we reasonably believe that the green-blue luminescence is attributed to zinc vacancies rather than the vacancy and interstitial sites of sulfur.

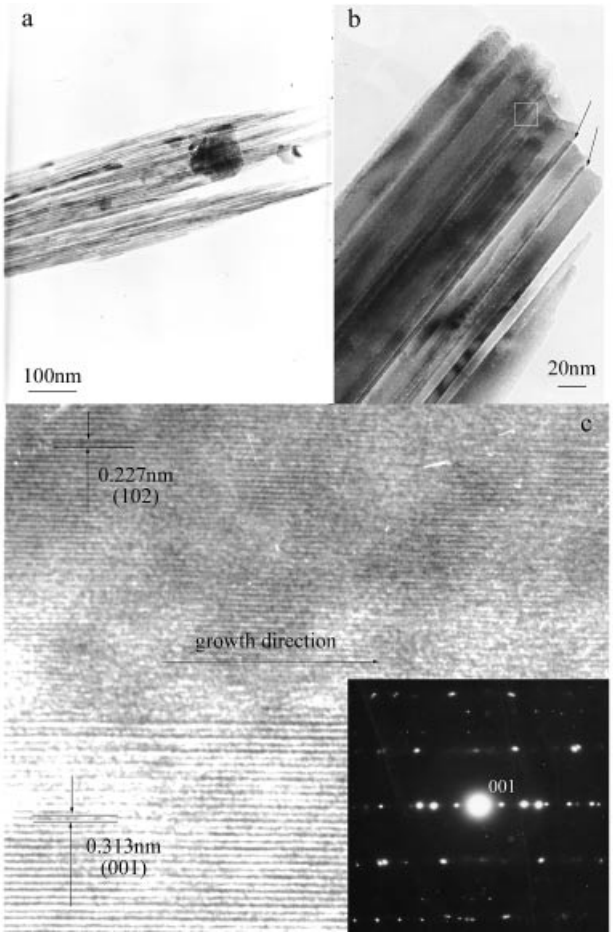

Figure 3. (a) and (b) TEM images of self-assembled ZnS nanowires and (inset) their ED pattern; (c) HREM image taken from the two, neighboring, frame-labeled single nanowires with two different lattice spacings: one is 0.313 nm corresponding to the (002) crystal plane, and the other is 0.227 nm corresponding to the (102) crystal plane: this indicates the different growth direction of the constituent nanowires

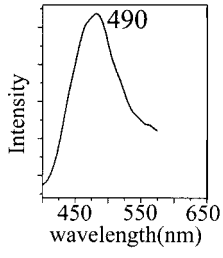

Figure 4. Room-temperature PL spectrum of the as-synthesized ZnS sample with excitation at 313 nm and a filter at 350 nm; the green-blue emission peak is located at 490 nm

To the best of our knowledge, the carbothermal reduction method is usually used to fabricate oxides,[29] carbides[30] and nitrides,[31] in which active carbon or graphite generally reacts with source chemicals containing O or N to generate intermediate compounds. It is well known that active carbon can serve as a reductant and react in a furnace with sulfur to generate CS_2, which can act as a sulfur source in the fabrication of sulfides.[32] Due to the low boiling point of CS_2 (b.p. 46.26 °C) and low melting point of $ZnCl_2$ (m.p. 318 °C),[33] there is enough vapor to react and the one-dimensional characteristic of CS_2 could contribute to the formation of ZnS nanowires. According to these ideas, we designed the above-described experiments and found that ZnS nanowires were synthesized successfully. In the absence of active carbon we only obtained nanoparticles. This synthesis method can be understood in terms of carbothermal CVD. The growth of one-dimensional nanomaterials by thermal evaporation is often explained by a vapor-liquid-solid (VLS)[34] or vapor-solid (VS)[35] growth mechanism. For example, the silicon nanowires reported by Yu[36] were synthesized on solid substrates by the VLS mechanism using Au or Zn nucleation catalysts. In this case, the presence of a big particle at the tip of the nanowire is commonly considered to be evidence for the operation of the VLS mechanism. Jiang's group has fabricated ZnS nanoribbons[37] by a VS mechanism through hydrogen-assisted thermal evaporation. Comparing the features of these two mechanisms, and with no tip-located particles present, the VS explanation may be operative in the formation process of our ZnS nanowires. The experimental conditions and the anisotropy might provide the external and internal driving forces for the crystal growth. Once the nucleation starts, the crystal grow in the preferential orientation of the ZnS crystal planes.

Conclusion

In summary, ZnS nanowires and their self-assemblies have been successfully prepared for the first time by a carbothermal CVD method at low temperature. The as-prepared samples are wurtzite-phase, single nanocrystals with uniform morphology. The mono-dispersed nanowires grow along the [100] direction and those nanowires constituting the self-assemblies grow in different crystal orientation. Possibly due to their sulfur-rich nature, the samples show strong green-blue emission at room temperature, which is consistent with the luminescence of the zinc vacancy. The growth of our ZnS nanowires can be explained by a VS mechanism. Because of its easy operation and versatility, this carbothermal CVD route may be extended to the synthesis of other kinds of sulfide semiconductor nanowires. Further improvements of the equipment and studies on the application of ZnS nanowires and their self-organized structures are in progress.

Experimental Section

All the employed reactants were commercial and analytical grade without any further purification. A thoroughly blended powder mixture of sublimed sulfur (S), active carbon (C), and anhydrous zinc chloride ($ZnCl_2$) with a molar ratio of 4:1:2 was put into a porcelain boat which was placed in the bottom of a short quartz tube (approx. 25 mm diameter and 10 cm length) closed at one end. The short tube was placed with the open end downstream in the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

center of a long quartz tube (approx. 50 mm diameter and 1 m length) mounted in a horizontal furnace, which was sealed and high-purity nitrogen was passed through it for 2 h to purge the air from the system. After heating to 500 °C for 2 h, the tube furnace was allowed to cool to room temperature in a constant flow of nitrogen. White samples were collected from the inner wall of the short tube, and then washed with distilled water and absolute ethanol several times. The purity and phase structure of the products were obtained by X-ray powder diffraction (XRD) analysis, which was performed with a D/max-γA X-ray diffractometer (λ = 0.15405 nm). The composition of the samples was determined by XPS with an ESCALAB MKII electron spectrometer using Mg-K_α radiation as the source. The morphologies and microstructure were observed and analyzed by TEM and HREM with a JEOL-2010 transmission electron microscope using an acceleration voltage of 200 kV. The PL measurements were carried out with a HITACHI850-type visible-ultraviolet spectrophotometer with a 313 nm excitation and a 350 nm filter at room temperature. The XRD pattern and the complete XPS spectrum of our sample are available as Supporting Information.

Lithium Cyanocuprates: Structural Studies of a Phosphane Adduct of a "Lower-Order" Lithium Cyanocuprate

Robert P. Davies*[a] and Stefan Hornauer[a]

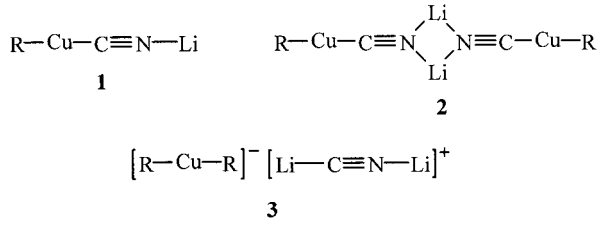
Keywords: Cuprates / Lithium / Reaction intermediates / Michael addition

Addition of PPh_3 to the "lower-order" cyanocuprate PhCuCNLi results in a significant increase in reactivity in 1,4-Michael addition reactions. This is explained by a marked structural change in the cyanocuprate reagent, observed in both THF solution and the solid state, to give $[Ph_2Cu]^-$ cuprate anions and a $[Cu_2Li_4(CN)_4(PPh_3)_4(THF)_{10}]^{2+}$ dication.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Lithium cyanocuprates are commonly used in the regioselective formation of new carbon−carbon bonds, and have been shown to have significant advantages for certain reactions over classical Gilman reagents prepared from copper(I) halides.[1,2] Cyanocuprates can conveniently be divided into two distinct groups based upon their composition and reactivity: "*lower order*" cyanocuprates formed from the 1:1 reaction of CuCN and LiR (R = organo group) to give species of the general formula RCu(CN)Li; and "*higher order*" species from the 1:2 reaction of CuCN and LiR and hence with the formulation $R_2Cu(CN)Li_2$. Spectroscopic studies of lower-order cyanocuprates both in solution[3] and the solid state[4−7] have shown **1**, or aggregates of **1** such as **2**, to be the most likely structural motif for these species (Scheme 1). Hence $[(Me_2PhSi)_3C-Cu(CN)Li(THF)_3]$[4] is a monomer (**1**) in the solid state, whilst $[(Me_2PhSi)_3CCu(CN)Li(THF)_2]_2$,[4] $[(C_6H_3_2,6\text{-}Trip_2)Cu(CN)Li(THF)_2]_2$ [5] (Trip = $-C_6H_2$-2,4,6-iPr$_3$), $[Me_3SiCH_2CuCNLi(OEt_2)_2]_2$,[6] and $[t\text{BuCu(CN)Li-}(Et_2O)_2]_\infty$ [7] are all dimers (**2**). However, the structure of higher-order cyanocuprates has been the subject of much more controversy with arguments centering on whether the cyanide group remains bound to the copper or not. Again recent crystallographic studies have played a major part in this discussion with structural characterization of the higher order cyanocuprates $[t\text{Bu}_2\text{Cu}\{\text{Li(THF)-(pmdeta)}\}_2\text{CN}]$[7] and $[(2\text{-}C_6H_4CH_2NMe_2)_2Cu\{Li-(THF)_2\}_2CN]_\infty$ [8] both revealing ionic compounds consisting of $[R_2Cu]^-$ cuprate anions and $[Li-CN-Li]^+$ cations (**3**). In contrast, infrared spectroscopic,[9] NMR spectroscopic,[10−13] cryoscopic,[14] and kinetic reactivity[15,16] studies of these higher-order cuprates have been less conclusive predicting several possible solution structures. However, the current consensus as laid out by Krause in a recent review,[17] is that the reactive solution species consists of a cuprate anion $[R_2Cu]^-$ and a $[Li-CN-Li]^+$ cation, either as a solvent-separated ion pair (SSIP), such as **3**, and similar to the structures observed in the solid-state characterizations, or possibly as some form of contact-ion pair (CIP).



Scheme 1. Solid-state structural motifs for lower-order (**1**, **2**) and higher-order (**3**) lithium cyanocuprates

Despite these recent advances, there are still many gaps in our knowledge of cyanocuprates, and this is particularly true when we consider the use of additives. Boron trifluoride, alkali-metal halides and phosphanes amongst others have all been employed as additives for lithium cyanocuprates in order to enhance the stability, selectivity and/or reactivity of these species.[1] Despite their reported success in this field, little is know about their mode of operation and the effect they have upon the molecular structure of the organocopper reagents. This paper reports on the first structural characterization of a phosphane adduct of a lithium cyanocuprate and discusses its reactivity in Michael addition reactions.

Results and Discussion

Addition of triphenylphosphane to a THF/toluene solution of the lower-order cyanocuprate PhCuCNLi (formed

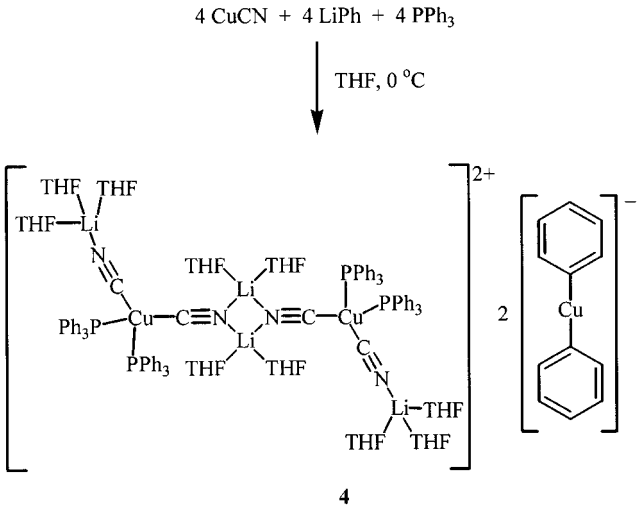
E-mail: r.davies@imperial.ac.uk

from the 1:1 reaction of CuCN and LiPh) at 0 °C gave a clear yellow solution from which crystals of **4** were grown at −30 °C (Scheme 2). X-ray structural studies show **4** to be an ionic species comprising a centrosymmetric $[Cu_2Li_4(CN)_4(PPh_3)_4(THF)_{10}]^{2+}$ dication and two symmetry-related $[CuPh_2]^-$ cuprate anions (Figure 1).



Scheme 2. Synthesis of **4**

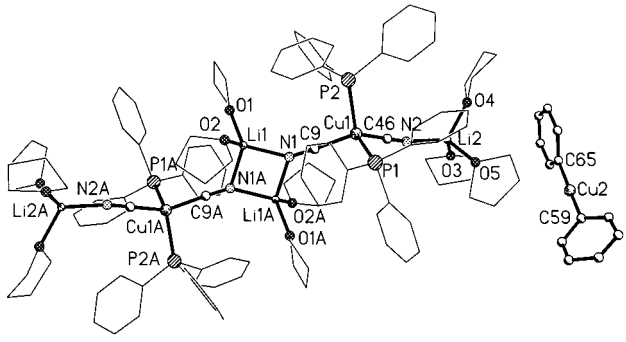


Figure 1. Molecular structure of **4**; only one of the two symmetry-related $[CuPh_2]^-$ cuprate anions is shown for clarity

The dication in **4** is unprecedented, containing both Li^+ and Cu^I ions linked together through cyanide groups, and can perhaps best be thought of as two PPh_3-complexed $[Cu(CN)_2]^-$ anions aggregated with four THF-solvated Li^+ cations. The copper atoms in the dication are approximately tetrahedral, and bond to two PPh_3 groups [Cu(1)−P(1) 2.294(2) Å; Cu(1)−P(2) 2.299(2) Å] and to the carbon atoms of two cyanide groups [Cu(1)−C(9) 1.944(6) Å; Cu(1)−C(46) 1.952(9) Å]. These Cu−CN distances are therefore longer than those observed in previously reported lower-order cyanocuprates (mean, 1.906 Å),[4−7] but are similar to the Cu−CN distances of 1.964(4) and 1.948(5) Å reported for $[Cu_2(CN)_2(PPh_3)_4(hppH)]$ (hppH = 1,3,4,6,7,8-hexahydro-2*H*-pyrimido[1,2-*a*]pyrimidine), which also contains a $Cu^I(CN)_2(PPh_3)_2$ metal center.[18] Two different lithium ions are observed in the asymmetric unit of **4**: Li(1) bridges two cyanide groups at their nitrogen ends [Li(1)−N(1) 2.036(12) Å; Li(1)−N(1A) 2.095(12) Å] and is solvated by two THF molecules [mean Li−O, 1.919 Å], whereas Li(2) is terminally bound to just one cyanide group [Li(2)−N(2) 1.90(4) Å] and has its quadruplet completed by three THF molecules [mean Li−O, 1.87 Å]. In keeping with all previously reported lithium cyanocuprates,[4−7] the cyanide carbon atoms in **4** are essentially linear [Cu(1)−C(9)−N(1), 175.5(6); Cu(1)−C(46)−N(2), 176.2(8)°] and the CN unit is bent out of the plane of the central Li_2N_2 ring (by 12.6°).

The $[Ph_2Cu]^-$ cuprate anions in **4** contain close to linear Cu^I centers [C(59)−Cu(2)−C(65), 174.8(4)°] with C−Cu bond lengths of 1.900(11) Å [Cu(2)−C(59)] and 1.931(11) Å [Cu(2)−C(65)]. The dihedral angle between the phenyl rings is 59.1°. These units are therefore structurally very similar to the $[R_2Cu]^-$ cuprate anions observed in the higher-order cyanocuprates $[tBu_2CuLi_2(CN)(THF)_2(pmdeta)_2]$[7] and $[(2\text{-}C_6H_4CH_2NMe_2)_2Cu\{Li(THF)_2\}_2CN]_\infty$.[8]

Low temperature (−100 °C) ^1H-decoupled ^{13}C NMR spectroscopy carried out on an aliquot of the CuCN + PhLi + PPh_3 reaction mix after stirring for 10 min at 0 °C in toluene/THF solution shows singlets at δ = 174.20 and 144.27 ppm for the phenyl *ipso* carbon and the cyanide carbon resonances, respectively. The chemical shift of the *ipso* carbon is therefore downfield from the value observed for PhCuCNLi in the absence of phosphane (δ = 166.05 ppm),[3] indicating some structural change has occurred. Bertz has previously reported the chemical shifts of the *ipso* carbon atoms of the higher-order cyanocuprate formed from CuCN +2 PhLi and also of the Gilman reagent from CuI +2 PhLi as 174.33 and 174.13 ppm, respectively (in $[D_8]$THF at −78 °C).[10] Based on these almost identical NMR shifts, he was able to argue that $[CuPh_2]^-$ cuprate subunits were present in each case. The fact that we observe the *ipso* carbon shift to be of an almost identical value to those observed by Bertz confirms that diphenylcuprate anions are present in solution for **4** as well as in the solid state. The cyanide ^{13}C NMR resonance (δ = 144.27 ppm) differs from that observed for PhCuCNLi in the absence of PPh_3 (δ =148.50 ppm)[3] and is significantly upfield from the $[Li_2CN]^+$ cation cyanide resonance reported for higher-order cyanocuprates (mean, δ = 158.80 ppm).[10] However, the resonance is close to the range of reported values for lower-order cyanocuprates (δ = 45.51−151.20 ppm),[3−7] suggesting that "CuCNLi" units, similar or identical to those observed in the cation of **4**, are present in solution.

Infrared spectroscopic characterization of the addition product of PhLi and CuCN (PhCuCNLi) gave a cyanide stretch in THF solution at 2137 cm^{-1} (cf. 2133 cm^{-1} previously reported for MeCuCNLi).[9] On addition of PPh_3, this peak decreases significantly in size and a new peak is observed at 2120 cm^{-1}. This new absorption differs in frequency from the cyanide stretch reported for the higher-order cyanocuprate formed from CuCN + 2MeLi (2115 cm^{-1}), attributable to $[Li{-}CN{-}Li]^+$,[9] and instead can be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

assigned to a cyanide stretch in a $[Cu(PPh_3)_2CNLi]^+$ unit, which is also in agreement with the ^{13}C NMR spectroscopic and X-ray crystallographic observations (vide supra).

^{31}P NMR spectroscopy on the reaction mixture in THF containing excess triphenylphosphane (CuCN + PhLi +1.5 PPh_3) reveals one peak ($\delta = -2.54$ ppm) at room temperature. On cooling to −100 °C, this peak splits into two new resonances: a broad peak at $\delta = 0.04$ ppm and a sharp peak at $\delta = -7.76$ ppm. These resonances can be assigned to $[Cu(CN)_2]^-$-complexed PPh_3 and free PPh_3, respectively, and interchange of the two types of PPh_3 occurs at room temperature on the NMR time scale. ^7Li NMR spectroscopy on the same reaction mixture reveals two resonances ($\delta = -2.44$ and -3.37 ppm), consistent with the bridging and terminal lithium atoms present in the cation of **4**.

The addition of the phosphane therefore results in a considerably different structural motif for **4** relative to all previously reported lower-order cyanocuprates (**1**, **2**), and the most significant difference, in terms of its effect on the reactivity, undoubtedly is the generation of $[Ph_2Cu]^-$ cuprate anions. The observed increased reactivity of higher- than lower order cyanocuprates has previously been attributed to the presence of such $[R_2Cu]^-$ cuprate units,[17] and it seems likely that any increase in reactivity for PhCuCNLi on addition of PPh_3 is due to the generation of these anions. However, although it has previously been suggested that addition of PPh_3 to cuprates does indeed increase their reactivity,[1] no systematic studies have been reported. We therefore obtained logarithmic reactivity profiles (LRPs)[15] to compare the rates of reaction of (a) PhCuCNLi, (b) PhCuCNLi + PPh_3 (**4**), and (c) $Ph_2CuCNLi_2$ in Michael addition reactions with 2-cyclohexanone (Table 1). The LRP was generated by quenching the reaction after a series of times spanning several orders of magnitude, and measuring the yields of 3-phenylcyclohexanone using GLC and the internal standard method.[15] The lower order cyanocuprate PhCuCNLi is very unreactive under these conditions with no product formation observed even after 1 h. However, addition of PPh_3 increases the yields significantly to 29% after 1 h. The yields are larger still for the higher order cyanocuprate and this can be explained by double the concentration of cuprate anions in solution for $Ph_2CuCNLi_2$ than **4**, and also by the differing nature of the cations in the two reagents, with the larger more sterically hindered cations in **4** likely to favor the formation of SSIPs rather than the more reactive CIP species.[16]

Table 1. LRP data for reactions of (a) PhCuCNLi, (b) **4** and (c) $Ph_2CuCNLi_2$ with 2-cyclohexanone in THF, showing the yields (%) of 3-phenylcyclohexanone

Reagent[a]	Time [h]			
	0.001	0.01	0.1	1
(a) PhCuCNLi	0	0	0	0
(b) PhCuCNLi + PPh_3 (**4**)	1	3	22	29
(c) $Ph_2CuCNLi_2$	19	53	66	70

[a] Reactions were carried out at −78 °C on a 1 mmol scale at 0.1 M in THF. Quench: 6 mL of saturated aqueous ammonium chloride/ammonia (90:10).

Conclusion

Addition of PPh_3 to the "lower-order" cyanocuprate PhCuCNLi drastically alters its structure by promoting the formation of $[CuPh_2]^-$ cuprate units both in THF solution (observed using multi-nuclear and variable temperature NMR spectroscopy) and in the solid state (observed using single-crystal X-ray diffraction). Such cuprate units have been previously reported in "higher-order" cyanocuprates and Gilman cuprates, but this is this first time they have been observed in a formally "lower-order" cyanocuprate. The addition of PPh_3 is also shown to increase the reactivity of PhCuCNLi in Michael addition reactions with 2-cyclohexanone, and this increase in reactivity can be explained by the observed structural changes in the reagent on addition of phosphane, in particular the generation of the anionic $[R_2Cu]^-$ cuprate units.

Experimental Section

General Remarks: CuCN (Fluka > 99%), PPh_3 (Aldrich 99%) and 2-cyclohexene-1-one (Lancaster Synthesis 97%) were used without further purification. Pure, halogen-free PhLi was synthesized prior to use by reaction of equimolar amounts of PhI with *n*BuLi in hexane at 0 °C.[19] THF and diethyl ether were distilled from over sodium wire/benzophenone. Unless otherwise stated, all manipulations were carried out under nitrogen using either a glove box or double-manifold vacuum line. Dry ice/2-propanol baths were used for reactions at −78 °C. GC analyses were performed with an Agilent GC4890 gas chromatograph equipped with FID detector and a 25-m SGE BPX5 capillary column [0.22 mm i.d., 0.25 micron film, cross-linked 5% phenyl (equiv.) polysilphenylene-siloxane]. The GC was calibrated with authentic product (3-phenylcyclohexanone) and dodecane (Aldrich 99%) as internal standard. NMR spectra were recorded on a Jeol EX270 Delta Upgrade or a Bruker AM-500 spectrometer. External standards used were TMS (^1H, ^{13}C) 85% H_3PO_4 (^{31}P) and LiCl/D_2O (^7Li).

Synthesis of $[Cu_2Li_4(CN)_4(PPh_3)_4(THF)_{10}]\cdot 2[Ph_2Cu]$ (4): A solution of PhLi (1.8 M in cyclohexane/diethyl ether; 1.1 mL, 2.0 mmol) was added to a suspension of CuCN (0.180 g; 2.0 mmol) in THF (10 mL) at −78 °C followed by dropwise addition of PPh_3 (0.577 g; 2.2 mmol) in THF (5 mL). The resulting clear yellow solution was warmed to 0 °C, filtered through celite and reduced in vacuo to 10 mL. On storage for 72 h at −30 °C, crystals of **4** were obtained in 46% yield (0.57 g). M.p. 118−122 °C (dec.). Note that NMR studies on the reaction mix, as detailed in the main text, indicate a near quantitative yield based on PhLi and CuCN consumption. Due to the extreme air and moisture sensitive nature of **4** we were unable to obtain satisfactory elemental analyses. ^1H NMR spectroscopy (270 MHz, [D$_6$]DMSO, 298 K): $\delta = 7.09-7.44$ (m, 70 H, P*Ph*$_3$, Cu*Ph*$_2$), 3.58 (m, 20 H, THF), 1.72 (m, 20 H, THF) ppm − note that some THF was lost during the isolation procedure. ^{13}C NMR spectroscopy (101 MHz, THF, 173 K): $\delta = 174.20$ (CN), 141.33 (Cu-*ipso*-Ph), 137.49−124.97 (Cu-*o*/*m*/*p*-*Ph*, P*Ph*$_3$), 67.57 (THF), 25.84 (THF) ppm. ^{31}P NMR spectroscopy (109.38 MHz, THF, 298 K): $\delta = -2.54$ ppm. ^7Li NMR spectroscopy

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(194.31 MHz, THF, 298 K): $\delta = -2.44, -3.36$ ppm. IR (THF, 25 °C): $\tilde{\nu} = 2120$ (s) cm^{-1} (C≡N).

Logarithmic Reactivity Profiles (LRPs): The three cuprate reagents used were prepared as follows: (a) PhCuCNLi. CuCN (4 mmol, 358 mg) and PhLi (4 mmol, 336 mg) were weighed out into a 250 mL Schlenk flask equipped with a stirrer bar, and cold THF (40 mL, −78 °C) was added, and the flask was maintained at a temperature of −78 °C. The reaction mixture was stirred for 6 min and then warmed up to 0 °C for 6 min to anneal the reagent before it was cooled back to −78 °C; (b) PhCuCNLi + PPh_3 (**4**). CuCN (4 mmol, 358 mg) and PPh_3 (4 mmol, 336 mg) were weighed out into a 250 mL Schlenk flask equipped with a stirrer bar. PhLi (4 mmol, 336 mg) was weighed out into a separate Schlenk flask equipped with a stirrer bar. Cold THF (20 mL, −78 °C) was added with a syringe into each Schlenk flask, and both solutions were stirred for 10 min at room temperature making sure that the PhLi had completely dissolved. Both Schlenk flasks were then immersed in a cooling bath (−78 °C), and the PhLi solution was transferred with a cannula into the THF suspension of $CuCN/PPh_3$. The reaction mixture was stirred for 6 min and then warmed up to 0 °C for 6 min to anneal the reagent before it was cooled back to −78 °C; (c) $Ph_2CuCNLi_2$. CuCN (4 mmol, 358 mg) and PhLi (8 mmol, 672 mg) were weighed out into a 250 mL Schlenk flask equipped with a stirrer bar. Cold THF (40 mL, −78 °C) was added, and the flask was maintained at a temperature of −78 °C. The resulting cloudy suspension was stirred at −78 °C for 18 min to give a clear yellow solution.

For all cuprates (a)−(c): After a further 6 min of stirring at −78 °C, 10 mL of the reagent was transferred with a syringe into each of four 25 mL flasks. The flasks were predried overnight in an oven at 120 °C and taken into the glove box where they were equipped with a stirrer bar and a rubber septum. They were kept under a positive nitrogen pressure throughout the experiment. A solution of 2-cyclohexene-1-one (96 mg, 1 mmol) in THF (1 mL) was added to the flask with a syringe. The stopwatch was started when the plunger was pushed. After the appropriate LRP time, a quench solution consisting of 6 mL of saturated aqueous ammonium chloride/ammonia (90:10) was injected. The LRP times used were 1 h = 60 min, 0.1 h = 6 min, 0.01 h = 36 s, 0.001 h = 4 s. After quenching the reaction, the flask was removed from the dry ice/2-propanol bath and warmed in warm water until it reached room temperature. The internal GC standard (dodecane, 227 μL, 1 mmol) was then added. The aqueous layer was removed using a pipette, and the organic layer filtered into a vial. The flask and residue were rinsed with diethyl ether (5 mL), and the combined organic layer and ether extract were dried over $MgSO_4$. A sample of the quenched reaction mixture was then run on the GC to ascertain the percentage yield of 3-phenylcyclohexanone. Repeat experiments indicated an experimental error of up to a maximum of ±10% (see reference 15 for a thorough discussion of experimental errors in LRP studies of cuprates).

X-ray Crystallographic Data for 4: $C_{147}H_{168}Cu_4Li_4N_4O_{10}P_4$, $M_r = 2556.65$, monoclinic, space group $P2_1/c$, $a = 20.240(2)$, $b = 16.112(3)$, $c = 24.575(3)$ Å, $\beta = 113.37(2)°$, $V = 7356.6(18)$ Å^3, $Z = 2$ (C_i symmetry), $\rho_{calcd.} = 1.154$ g·cm^{-3}, Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 0.668$ mm^{-1}, $T = 230(2)$ K. 14981 unique data ($R_{int} = 0.1147$, $\theta < 27.24°$) were collected on a Nonius Kappa CCD diffractometer. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 values of all data using the SHELXTL and SHELX-97 program systems,[20] to give $wR2 = 0.3492$, conventional $R = 0.1069$ for 7011 observed absorption-corrected reflections with $F^2 > 2\sigma(F^2)$, $S = 1.035$, 667 parameters. Residual electron density extrema ±1.165 e·Å^{-3}. Since it proved impossible to differentiate between the cyanide carbon and nitrogen atoms crystallographically, these atoms have been assigned based on previously reported structural characterizations of cyanocuprates, all of which contain the cyanide unit attached to the copper through the carbon end and linear carbon atoms.[4,7] CCDC-226575 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.): +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

A 2D Thiocyanato-Bridged Copper(II)-Manganese(II) Bimetallic Coordination Polymer with Ferromagnetic Interactions

Jing-Min Shi,*[a] Wei Xu,[a] Bin Zhao,[b] Peng Cheng,*[b] Dai-Zheng Liao,[b] and Xiao-Yan Chen[b]

Keywords: Structure elucidation / Magnetic properties / Bridging ligands / Manganese

The first ferromagnetic coupled, thiocyanato-bridged copper(II)-manganese(II) bimetallic 2D polymer $\{[Cu(ipa)_2]_2Mn(NCS)_6\cdot 2H_2O\}_n$ (ipa = 1,2-propanediamine) has been synthesised and characterised by a single-crystal X-ray structure determination and variable temperature magnetic susceptibility studies.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Recently, the field of molecular magnetism has attracted considerable attention and major advances have been made both in the theoretical description and applications of new molecular-based materials.[1] In particular, special attention has been paid to the design and construction of multi-dimensional homo- and heterometallic coordination polymers in order to undertake theoretical studies of their magnetic properties and develop high *T*c molecular-based magnets.[2] The thiocyanate anion, which exhibits an ambidentate character with end-to-end or end-on coordination modes, can be expected to play a key role in the design of polymetallic coupling systems. A certain number of polynuclear complexes have been synthesised with discrete 1-, 2- and 3D crystal structures and some of them exhibit interesting ferromagnetic coupling properties, e.g. the 1D uniform chain complexes[3] $Co(NCS)_2(Hlm)_2$ and $Ni(NCS)_2(Hlm)_2$. The heterometallic species, however, are quite limited and show low-dimensional structures,[4−8] whereas large numbers of cyanato-bridged analogues have been reported and some exhibit interesting magnetic properties. The 1D copper(II)-manganese(II) heterometallic compound $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$ [4] derived from $K_2[Mn(NCS)_4(H_2O)_2]$ as a precursor has also been described. The chains of Mn^{II} (S = 5/2) and Cu^{II} (S = 1/2) ions structurally ordered in an alternating manner are of intense interest as potential building blocks in the synthesis of molecular-based ferromagnetic materials.[9] In this area, the novel 2D complex $\{[Cu(ipa)_2]_2Mn(NCS)_6\cdot 2H_2O\}_n$ was successfully constructed from a heterometallic octanuclear square lattice as a subunit and it exhibits interesting ferromagnetic coupling between adjacent Mn and Cu ions. In this species, the Cu and Mn atoms are alternately arrayed and are connected by thiocyanate bridges. To the best of our knowledge, in the reported compounds comprising SCN^- bridges, this is the first time that the octanuclear lattice of $Cu_4Mn_4C_8N_8S_8$ has been fabricated from SCN^- bridges and further assembled into a fascinating 2D structure. Remarkably, this ferromagnetic behaviour is absent for the systems containing Cu and Mn ions.

Figure 1 shows the coordination diagram for the complex with the atom numbering scheme. It indicates that the complex consists of two types of distinct building blocks, namely $Mn(NCS)_6$ and $Cu(ipa)_2(SCN)_2$. Each copper atom exhibits an elongated octahedral coordination environment: the equatorial plane is formed from four nitrogen atoms of two ipa ligands with Cu−N distances of 1.988(3) to 2.024(3) Å and the axial positions are occupied by the sulfur atoms of the thiocyanate bridges. The Cu-S separations are not identical and the two types of Cu1−S1 bonds have distances of 2.9635(16) and Cu2−S2 3.0214(16) Å which are shorter than those of other reported complexes.[10] The coordination sphere around the Mn^{2+} centre displays octahedral geometry and is completed by six N atoms from the thiocyanate ions. Four of the N atoms are from four bridging SCN^- anions with Mn−N distances of 2.185(4) to 2.218(4) Å and the other two come from two terminal SCN^- anions which occupy the remaining apical positions of the Mn centre with the Mn−N distances of 2.275(4) Å being longer than those in the equatorial plane. The symmetry elements of the crystal, namely the inversion centres, are located on the Mn and Cu atoms. This is shown clearly in Figure 1 and Figure 2. Interestingly, the equatorial planes of the Cu1 and Cu2 ions run almost parallel to that of the Mn ion with dihedral angles of 9.7°. The

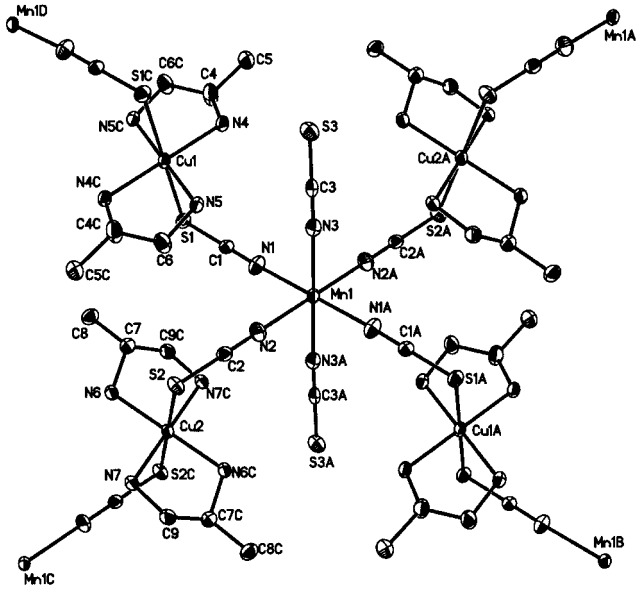

Figure 1. Diagram of the title complex with the atom numbering scheme; H atoms and water molecules are omitted for clarity

S(SCN)−Cu−N(ipa) angles, which are between 82.61(10)° and 95.99(12)°, indicate that the Cu−S bond is nearly perpendicular to the equatorial plane of the Cu ion. Each Mn ion has four Cu ions as the nearest metal centers, while the Cu ion has two Mn ions in its vicinity which is consistent with the Mn:Cu molar ratio. Adjacent Cu and Mn ions are connected through SCN^- bridges to form a 32-membered $Cu_4Mn_4C_8N_8S_8$ square lattice subunit of dimensions 9.118×10.089 Å. Mn atoms are located on the vertexes of squares and Cu atoms lie on the middle points of the edges. Importantly, the square subunits are further assembled into a 2D polymer. The distances between the neighbouring Mn···Cu pairs are 5.683 Å for Mn1···Cu1 and 5.717 Å for Mn1···Cu2.

The plot of μ_{eff} versus T is shown in Figure 3. At room temperature μ_{eff} is 7.00 μ_B which is slightly greater than the expected value for an isolated Mn ion and four Cu ions (6.86 μ_B for $g_{av} = 2$). The μ_{eff} value increases gradually with decreasing temperature from 7.00 μ_B at 300 K, reaching a maximum value of 7.32 μ_B at 5 K. This magnetic behaviour indicates ferromagnetic interactions between the $\mu_{1,3}$-NCS-bridged Mn^{II} ion and the Cu^{II} ion which is supported by the fact that the magnetic susceptibility values obey the Curie−Weiss law with a positive Weiss constant $\theta = 1.36$ K.

Theoretically, the exchange interaction between Mn^{II} and Cu^{II} is most likely antiferromagnetic in nature because it is extremely difficult to reach strict orthogonality between the magnetic orbitals for a M(high-spin d^5)-M′(d^1) pair irrespective of the local symmetry of each.[11] Also, to the best of our knowledge, this concept has been somewhat confirmed by previously reported Mn^{II}-Cu^{II} couplings. Unexpectedly, the title compound exhibits ferromagnetic interactions and represents the first example of a Mn^{II}-Cu^{II} system. Indeed, as mentioned in the description of the structure, all the Mn−NCS−Cu angles are close to 90 degree

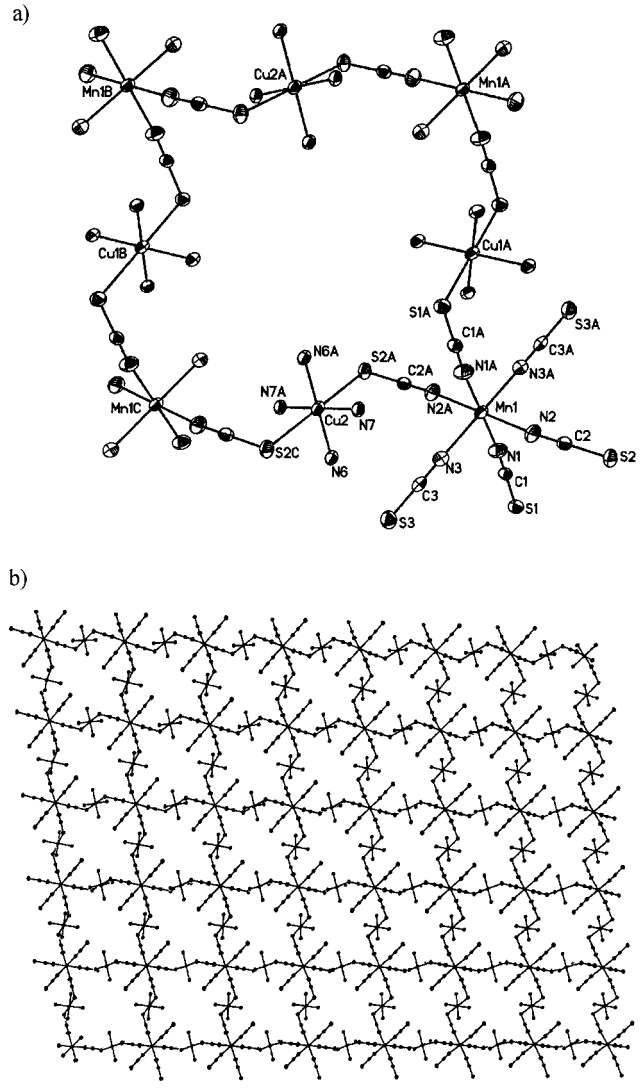

Figure 2. a) 32-membered square lattice motif of $Cu_4Mn_4C_8N_8S_8$; b) view along the [001] direction showing the 2D structure; the H atoms, C atoms in the ipa ligand and solvent molecules are omitted for clarity

and the S atom is in the apical position of the Cu^{II} centre. Therefore, the small spin density of the d_{z^2} type orbital of the Cu^{II} centre interacts with that of the $d_{x^2-y^2}$ type magnetic orbital of the Mn^{II}. This situation occurs because of strict orthogonality and results in a ferromagnetic contribution. On the other hand, the $3d^5$ electrons of the Mn^{II} display a sphere-type distribution, thus partial overlapping of the magnetic orbitals of the Cu^{II} and Mn^{II} ions inevitably occurs which causes an antiferromagnetic contribution to the Cu^{II} and Mn^{II} system. The two kinds of interactions conflict in an antagonistic process but the ferromagnetic contribution may predominate, however, and this should be responsible for the ferromagnetic coupling between Cu^{II} and Mn^{II}.

Taking into account the complex magnetic treatment for multi-dimensional systems containing paramagnetic centres, only approximate models were employed to fit the experimental data so far obtained. In this context, the pentanuclear Mn-Cu_4 system was considered as the smallest repeat unit in order to analyse the magnetic properties of the 2D structure. Equation (2) was obtained based on an isotropic Hamiltonian presented as in Equation (1) with interactions between Cu ions neglected due to the long distance between them.

$$\hat{H} = -2J\hat{S}_{Mn}(\hat{S}_{Cu1} + \hat{S}_{Cu2} + \hat{S}_{Cu3} + \hat{S}_{Cu4}) \quad (1)$$

$$\chi_M = Ng^2\beta^2A/4k_BT + TIP \quad (2)$$

$A = 165 + 84\exp(-9J/kT) + 35\exp(-16J/kT) + 10\exp(-21J/kT) + 252\exp(-5J/kT) + 105\exp(-12J/kT) + 30\exp(-17J/kT) + 70\exp(-10J/kT)$

$B = 5 + 4\exp(-9J/kT) + 3\exp(-16J/kT) + 2\exp(-21J/kT) + \exp(-24J/kT) + 12\exp(-5J/kT) + 9\exp(-12J/kT) + 6\exp(-17J/kT) + 6\exp(-10J/kT)$

where J is the Heisenberg exchange constant between adjacent Mn^{II} and Cu^{II} ions, S_{Mn} and S_{Cu} are spin operators corresponding to Mn and Cu, respectively, and the temperature-independent paramagnetism TIP = 3.0×10^{-4}. The theoretical model gave a good fitting of the experimental results. The agreement factor $R = 5.8\times10^{-4}$ [R was defined as $R = \Sigma(\chi_{obsd.} - \chi_{calcd.})^2/(\chi_{obsd.})^2$], $g = 2.04$ and $J = 0.13\ cm^{-1}$. The sign and magnitude of the J value suggest that weaker ferromagnetic coupling exists between adjacent Cu^{II} and Mn^{II} centres bridged by SCN^- anions.

To further support the nature of the interaction provided by the temperature dependence of the magnetisation, the field dependence of the magnetisation for the complex was measured in a field of 0−50 kOe at 7 K. The experimental values of M for the title compound were compared with those calculated by the Brillouin function corresponding to an $S = 9/2$ spin state with $g = 2$ (Figure 4). The plot of M vs. H approaches the Brillouin curve based on $S = 9/2$, although experimental values do not reach a magnetic saturation value of 9. This behaviour confirms that the ground state of $S = 9/2$ results from ferromagnetic interactions between the Mn and Cu ions of the pentanuclear system.

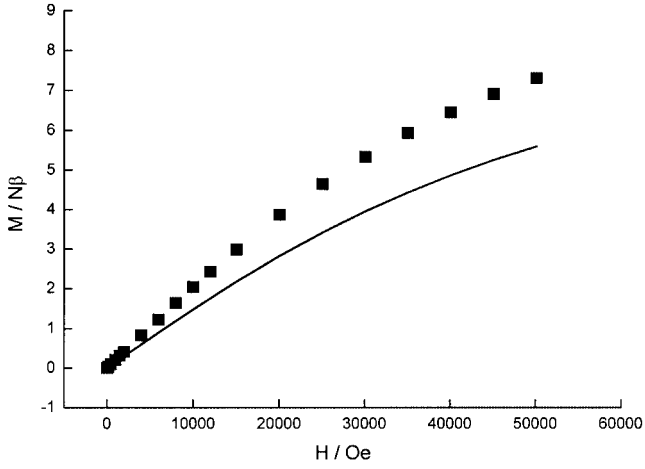

Figure 4. Plot of M versus H (squares) and the Brillouin curve for four independent Cu^{II} ions and one Mn^{II} ion

In conclusion, a novel 2D heterometallic polymer has been assembled from 32-membered $Cu_4Mn_4C_8N_8S_8$ square lattices as subunits fabricated from SCN anions bridges. It shows a fascinating topological motif which is relatively rare in SCN-bridged complexes. Magnetic studies revealed intriguing ferromagnetic couplings between adjacent Cu^{II} and Mn^{II} ions which is the first report of such a phenomenon in Cu^{II}-Mn^{II} systems.

Experimental Section

General: Infrared spectra were recorded with a Bruker Tensor 27 infrared spectrometer in the 4000−500 cm^{-1} region using KBr discs. C, H and N elemental analyses were carried out on a Perkin−Elmer 240 instrument. Variable-temperature magnetic susceptibilities of microcrystalline powder samples were measured in a magnetic field of 1 kOe in the temperature range of 5−300 K on a SQUID magnetometer. The data were corrected for magnetisation of the sample holder and for diamagnetic contributions which were estimated from Pascal's constants.

Synthesis of the Complex: All chemicals were of analytical grade and were used without further purification. $Cu(ipa)_2(ClO_4)_2$ (ipa = 1,2-propanediamine) (0.1949 g, 0.58 mmol) and $Na_4Mn(NCS)_6\cdot9H_2O$ (0.4199 g, 0.64 mmol) were each dissolved in H_2O (10 mL), the two solutions were mixed together and the resultant mixture stirred for a few minutes. Purple single crystals were obtained after the resultant solution was allowed to stand at room temperature for several days. Yield: 0.2027 g (81%). $C_{18}H_{44}Cu_2MnN_{14}O_2S_6$ (863.05): calcd. Cu, 14.73, Mn, 6.37, C 25.05, H 5.14, N 22.73; found Cu, 14.28, Mn, 5.93, C 25.37, H 5.58, N 23.15%. The IR spectrum shows a characteristic strong and sharp absorption peak for the NCS^- groups at 2084 cm^{-1} and the sharp peaks due to the NH and NH_2 groups appear at 3462, 3305 and 1583 cm^{-1}.

X-ray Crystallographic Analysis of the Complex:[12] A single-crystal of dimensions 0.15 × 0.12 × 0.08 mm was selected and subsequently glued to the tip of a glass fibre. The determination of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

crystal structure at 25 °C was carried out on a Bruker Smart-1000 CCD X-ray diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Corrections for *Lp* factors were applied and all nonhydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located from a difference Fourier map and refined isotropically using a riding model with displacement parameters. The programs for structure solution and refinement were SHELXS-97[13] (Sheldrick, 1990) and SHELXL-97[14] (Sheldrick, 1997), respectively. The crystal belongs to the triclinic space group $P\bar{1}$ with a = 9.118(5), b = 10.089(5), c = 11.434(6) Å, α = 74.652(7), β = 66.775(7), γ = 72.358(8)°, V = 908.4(8) Å^3, Z = 1, empirical formula $C_{18}H_{44}Cu_2MnN_{14}O_2S_6$, molecular mass 863.05, D_c = 1.578 g·cm^{-3}, $F(000)$ = 445, θ range 2.49−26.36°, index ranges $-11 \le h \le 11$, $-12 \le k \le 8$, $-14 \le l \le 14$. A total of 5076 reflections were collected, 3574 were independent (R_{int} = 0.0238) and 2422 observed reflections with $I > 2\sigma(I)$ were used in the succeeding refinement. The final refinement including hydrogen atoms converged to R = 0.0453, wR = 0.0979, $(\Delta\rho)_{max.}$ = 0.644 eÅ^{-3}, $(\Delta\rho)_{min}$ = −0.579 eÅ^{-3}.

Oxidation of a One-Dimensional Coordination Polymer and Synthesis of the Macrocyclic Silver Complex $[Ag_{12}(PhS_2P-PS_2Ph)_6(dppeS)_6]$

Dieter Fenske,*[a] Alexander Rothenberger,[a] and Maryam Shafaei Fallah[a]

Keywords: Silver / Chalcogenides / Macrocycle / P ligands / S ligands

The cluster chemistry with functionalised trimethylsilyl reagents was investigated. The oxidation of the one-dimensional coordination polymer $1/_\infty[\{Ag_2(PhS_2P–PS_2Ph)\text{-}dppe\}\cdot dppe]_\infty$ leads to the formation of $[Ag_{12}(PhS_2\text{-}P–PS_2Ph)_6(dppeS)_6]$ (dppeS = $Ph_2P(CH_2)_2P(S)Ph_2$]. The dianionic ligand $[PhPS_2–PS_2Ph]^{2-}$ could possibly give rise to a new class of macrocyclic transition-metal chalcogenides.

Introduction

Over the last few years we have been investigating the syntheses, structures and properties of a variety of silver-chalcogen clusters including the phosphane-stabilised nanoparticle $[Ag_{262}S_{100}(StBu)_{62}(dppb)_6]$ [dppb = 1,4-bis(diphenylphosphanyl)butane], which can be regarded as the largest ligand-protected silver sulfide complex characterised so far.[1] The general synthetic route to these species involves the reaction of AgX (X = halide, carboxylate) salts with tertiary phosphanes and subsequent reaction with trimethylsilyl chalcogenides.[1] Recently, we continued with earlier work where we investigated the potential of reactions between the sulfur-functionalised phosphane $P(S)(SSiMe_3)_3$ and late transition metal salts for the building up of transition metal clusters with functionalised phosphane ligands.[2] A discovery made during these investigations was that $P(S)(SSiMe_3)_3$ cannot be used as a source of $[PS_4]^{3-}$ anions. Instead a hexathiodiphosphonato tetraanion $[S_3P-PS_3]^{4-}$ is formed in reactions with late transition metal salts and this indicates that $P(S)(SSiMe_3)_3$ possibly undergoes disproportionation into $[(Me_3SiS)_2(S)P-P(S)(SSiMe_3)_2]$, elemental sulfur and $S(SiMe_3)_2$.[2d,2e] This reactivity prompted us to prepare new families of metal aggregates, which are accessible by the reaction of Ag_2S with P_2S_5 or by heating mixtures of elemental Ag, P and S.[3,4] Research in this area was motivated by the interest in sulfide-based glasses and their use as solid electrolytes.[3] For a wet-chemistry approach to these compounds, however, the use of solubilising organic groups is particularly promising. We therefore chose the related silylated reagent $PhP(S)(SSiMe_3)_2$, tertiary phosphanes and silver acetate (AgOAc) as starting materials. Here we wish to report the first result of these efforts and demonstrate the versatility of the P−S ligand $[PhS_2P-PS_2Ph]^{2-}$ generated in the reaction.

Results and Discussion

By the reaction of AgOAc with dppe [dppe = 1,2-bis(diphenylphosphanyl)ethane] and $PhP(S)(SSiMe_3)_2$ (Scheme 1), the one-dimensional coordination polymer $1/_\infty[\{Ag_2(PhS_2P-PS_2Ph)dppe\}\cdot dppe]_\infty$ (**1**) was obtained, and it was characterised by X-ray crystallography and ^{31}P NMR spectroscopy (Figure 1).

Analogous to the previously described reaction of $P(S)(SSiMe_3)_3$, the formation of a P−P bond was observed in reactions of AgOAc with $PhP(S)(SSiMe_3)_2$. In the solid-state structure of **1**, the dianion $[PhS_2P-PS_2Ph]^{2-}$ and one molecule of the neutral phosphane ligand dppe hold together a tricyclic arrangement of two tetrahedrally coordinated Ag^+ ions. An additional molecule of dppe completes the coordination sphere of the Ag atoms and acts as a bridging ligand between the $[Ag_2(dppe)(PhS_2P-PS_2Ph)]$ units (Figure 1). Bond lengths in **1** are within the range of commonly observed values.[4] S−Ag−S bond angles in **1** [96.20(5) and 96.88(5)°] are similar to those observed in a bis(diphenylphosphanyl)methane adduct of a silver thiocarboxylate {S−Ag−S [99.67(5)°]}.[5] It is worth noting that each S atom in **1** (coordination number: 2) coordinates one Ag atom only, and the C−P−P−C torsion angle in the $[PhS_2P-PS_2Ph]^{2-}$ ligand is 50.2(4)°. A change of this torsion angle means alternative orientations of the S-donor centres in the ligand $[PhS_2P-PS_2Ph]^{2-}$, and this might therefore result in different coordination modes of this ligand. Higher coordination numbers for the S-donor centres were found in the related complex $[Cu_6(P_2S_6)Cl_2(PPh_3)_6]$.[2b] X-ray structures of the closest related complexes of **1**,

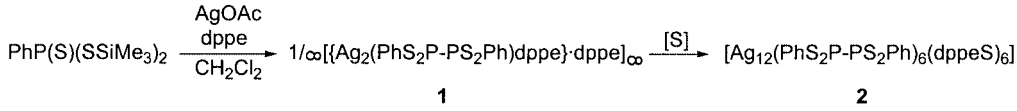

Scheme 1. Synthesis of **1** and oxidation leading to the formation of **2**

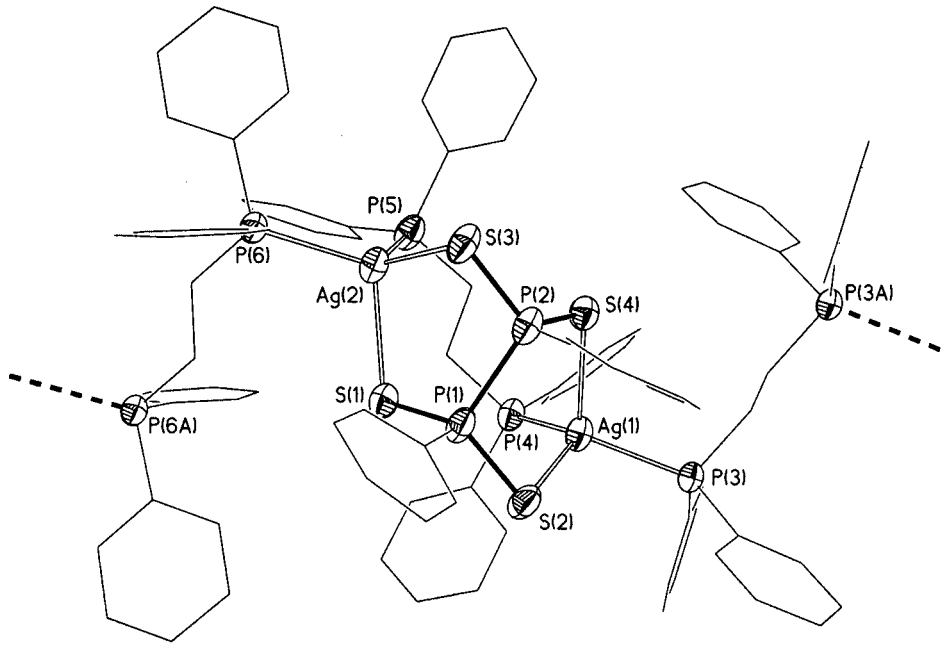

Figure 1. Structure of a dppe-bridged [{$PhPS_2$}$_2Ag_2$·dppe] unit in polymeric **1** (ellipsoids at 50%; connections to adjacent units are indicated; H atoms are omitted); selected bond lengths (Å) and angles (°): Ag−S 2.556(2)−2.631(2), Ag−P 2.475(2)−2.510(2), P−S 1.981(2)−1.992(2), P(1)−P(2) 2.262(3); C−P(1)−P(2)−C 50.2(4), S(2)−Ag(1)−S(4) 96.88(5), S(3)−Ag(2)−S(1) 96.20(5), S−Ag−P 103.89(6)−117.66(6), P−P−S 108.1(1)−108.8(1), S(1)−P(1)−S(2) 117.3(1), S(4)−P(2)−S(3) 116.0(1)

[$M_2(PhS_2P-PS_2Ph)$] (M = Li, K), have to the best of our knowledge not yet been determined.[6]

In solutions of **1**, two species, possibly rotamers, containing P−P bonds are present, which show two singlet resonances at δ = 84.4 and 81.2 ppm. A similar value (δ = 85.4 ppm) is observed in the ^{31}P NMR spectrum of [$Li_2(PhS_2P-PS_2Ph)$].[6b] The P−P bond formation during the preparation of **1** could be rationalized by the disproportion of $PhP(S)(SSiMe_3)_2$ into [$Ph(S)(SSiMe_3)P-P(S)(SSiMe_3)Ph$], which instantly reacts with AgOAc, elemental sulfur and $S(SiMe_3)_2$. The dppe ligands present in solution were oxidised to $Ph_2P(CH_2)_2P(S)Ph_2$ ($\delta_{P=S}$ = 45.6 ppm, $^3J_{P,P}$ = 58 Hz).[7] In **1**, the P^{III} centres of the dppe ligands and $Ph_2P(CH_2)_2P(S)Ph_2$ are identified by a broad singlet resonance (δ = 0.6 ppm) (P−Ag coupling has not been resolved).[7,5] In order to gain further mechanistic insight and to understand the formation of the $[PhS_2P-PS_2Ph]^{2-}$ dianion we tried to synthesise the postulated intermediate diphenyltetrathiodiphosphonic acid trimethylsilyl ester [$Ph(S)(SSiMe_3)P-P(S)(SSiMe_3)Ph$] in the absence of AgOAc by the reaction of $PhP(S)(SSiMe_3)_2$ with dppe. However, these attempts failed, and this indicates that P−P bond formation only occurs in the presence of AgOAc.

Storage of a reaction mixture containing crystals of **1** at room temperature for approximately three weeks produced colourless crystals of [$Ag_{12}(PhS_2P-PS_2Ph)_6(dppeS)_6$] (**2**) [dppeS = $Ph_2P(CH_2)_2P(S)Ph_2$] (Scheme 1). Initially, this was realised because the amount of crystalline precipitate in the reaction mixtures containing crystals of **1** increased, and a closer look revealed that only crystalline blocks of **2** were present. Further experiments have shown that **2** can also be obtained by filtering off crystals of **1** and storage of the filtrate for several weeks. Mixtures of both **1** and **2** were not observed. An X-ray analysis of **2** confirms the results from the ^{31}P NMR spectra, in which indication for the formation of dppeS is found. As a consequence, oxidation-induced fragmentation of polymeric arrangements of **1** gives rise to the macrocyclic complex **2** (Figure 2).

Complex **2** crystallizes in the space group $P\bar{1}$ with the inversion centre located in the middle of the molecule. Complex **2** is constructed from six corner-sharing distorted AgS_4 tetrahedra [Ag−S 2.553(3)−2.767(3)Å, S−Ag−S 89.4(1)−139.9(1)°] and forms a twelve-membered $[AgS]_6$ ring (Figure 2). The six S atoms of the ring are located on the corners of an octahedron with nonbonding S−S distances of about 3.64−4.04 Å. In the periphery, Ag(1) is co-

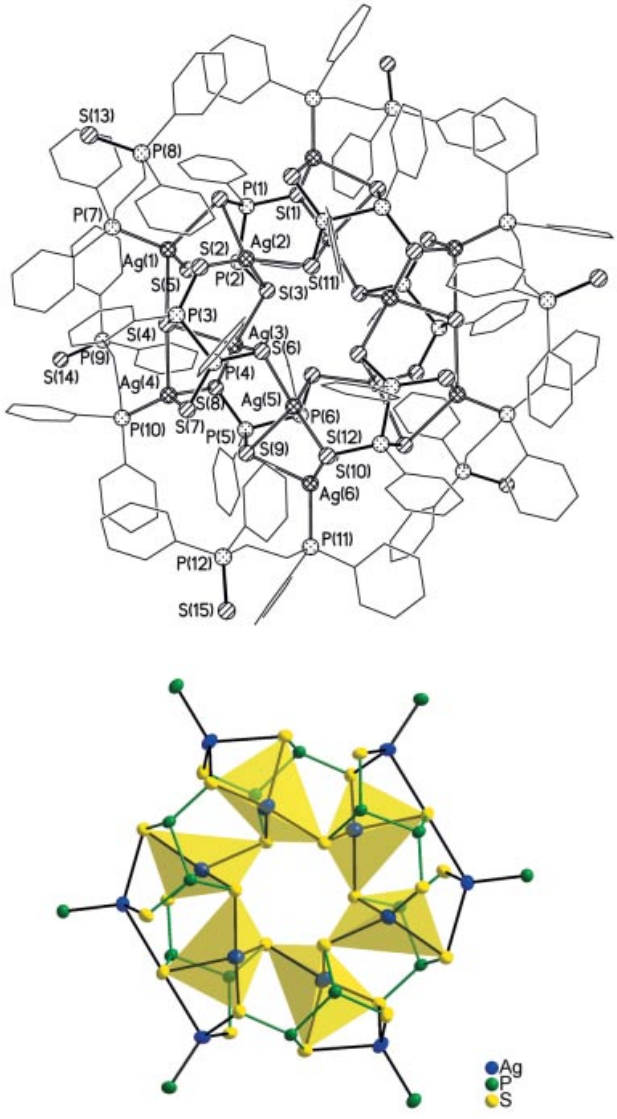

Figure 2. Molecular structure of **2** (H atoms are omitted) and structure of the core of **2** (C atoms and peripheral P and S atoms are omitted; ellipsoids at 50%;); selected ranges of bond lengths (Å) and angles (°): Ag−S 2.535(3)−2.952(4), Ag−P 2.430(3)−2.449(3), P−P 2.261(4)−2.275(5), P−S 1.988(4)−2.020(4), P−S_{dppeS} 1.955(5)−1.966(4); S−Ag−S 87.5(1)−139.9(1), S−Ag−P 91.1(1)−132.6(1), P−P−S 104.1(2)−110.7(2), S−P−S 119.1(2)−120.0(2)

ordinated by S atoms of two different AgS_4 tetrahedra, whilst Ag(4) and Ag(6) are located over the edges of the central AgS_4 units. One S atom of each $[PhS_2P-PS_2Ph]^{2-}$ ligand is not part of the $[Ag_6S_{18}]$ core and completes the tetrahedral coordination sphere of the outer Ag atoms, together with one P atom of the monodentate dppeS ligands (Figure 2). Signals for the chemically non-equivalent P atoms in the $[PhS_2P-PS_2Ph]^{2-}$ ligand in **2** can be observed in the ^{31}P NMR spectrum (AB spin system; two doublet resonances at δ = 82.0 and 79.4 ppm, $^1J_{P,P}$ = 56 Hz). In the Maldi TOF-MS the ions $[Ag(dppeS)]^+$, $[dppe]^+$ and $[dppeS]^+$ were detected. The coordination numbers of the S atoms in **2** are greater than those in the solid-state structure of **1**, and also the C−P−P−C torsion angle in **2** [55.45(5)−58.59(5)°] is about 5−8° wider than that observed in **1**.

Conclusion

The ability of the $[PhS_2P-PS_2Ph]^{2-}$ ligand to coordinate in a variety of modes is demonstrated. Slight changes in the C−P−P−C torsion angle should allow access to a range of new coordination modes with different arrangements of polyhedral building blocks, for example, MS_4 tetrahedra (M = Cu, Ag).[8] Further reactions currently under investigation include metathesis reactions of **1** with metal halides and the oxidation of **1** with elemental sulfur.

Experimental Section

General Remarks: All operations were carried out under purified nitrogen. Dichloromethane was refluxed over calcium hydride, heptane was dried with Na/benzophenone and freshly distilled. AgOAc and dppe were purchased from Aldrich and used without further purification. $PhP(S)(SSiMe)_2$ was prepared by a published method.[9]

1: $PhP(S)(SSiMe_3)_2$ (0.50 g, 1.44 mmol) was added to a pale yellow solution of AgOAc (0.24 g, 1.44 mmol) and dppe (0.57 g, 1.44 mmol) in dichloromethane (20 mL) at −40 °C. The solution instantly became colourless, and the mixture was stirred for 2 h and then warmed up to −10 °C. The reaction was kept at 0 °C for two days. The solvent was then reduced to about 15 mL. Upon addition of heptane (approximately 0.7 mL), a colourless precipitate was formed, which redissolved when the mixture was shaken. After storage of the solution at 0 °C for three weeks, colourless cuboctahedral crystals of **1** were isolated. ^{31}P NMR (101.256 MHz, $CDCl_3$, 25 °C, 65%H_3PO_4) δ = 84.4, 81.2 (s, PhS_2P-PS_2Ph), 0.8 ppm (br. s, Ph_2P-), an additional resonance was observed at δ = 45.0 ppm (d, $^3J_{P,P}$ = 60 Hz, $Ph_2P(CH_2)_2P(S)Ph_2$]. $C_{384}H_{348}Ag_{12}P_{36}S_{24}$: calcd. C 56.65, H 4.31; found C 57.03, H 3.92.

2: After formation of **1** (this was checked by determination of unit-cell dimensions of a small sample), the reaction was stored for four more weeks at 0 °C, and only blocks of **2** were isolated. Yield 0.41 g, 58% (based on AgOAc supplied; **2**, excluding lattice-bound CH_2Cl_2). M.p. 166−168 °C (decomposition into brown melt >172 °C). ^{31}P NMR (121.485 MHz, $CDCl_3$, 25 °C, 65% H_3PO_4): δ = 93.2, 89.4 (s, PhS_2P-PS_2Ph), 82.0 and 79.4 (dd, $^1J_{P,P}$ = 56 Hz, PhS_2P-PS_2Ph), 45.2 [br. m, $Ph_2P(CH_2)_2P(S)Ph_2$], 28.3 ppm [m, $^3J_{P,P}$ = 59 Hz, $Ph_2P(CH_2)_2P(S)Ph_2$] coupling to $^{107/109}Ag$ could not be identified unequivocally, $Ph_2P(CH_2)_2P(S)Ph_2$. IR (CsI, Nujol): $\tilde{\nu}$ = 1439 (P−Ph), 690, 612 (P=S), 579, 508, 466 cm^{-1} (tentatively assigned as P−P and P−S). MS (Maldi TOF), *m*/*z* (%) = 538.39 (30) [dppeSAg$^+$], 430.61 (100) [dppeS$^+$], 398.69 (8) [dppe$^+$]. $C_{228}H_{204}Ag_{12}P_{24}S_{30}$ (5943.7): calcd. C 46.07, H 3.46; found C 46.05, H 3.50.

X-ray Crystallography: Data were collected with a STOE STADI 4 diffractometer equipped with a CCD detector (**1**) and with a Stoe IPDS II diffractometer (**2**) using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (all data) with the SHELXTL program package.[10] Hydrogen atoms were placed in calculated positions, non-hydrogen atoms were assigned

anisotropic thermal parameters, atoms of lattice-bound solvent molecules were refined with isotropic thermal parameters. In order to identify further possible by-products unit-cell dimensions of crystals from different samples were repeatedly determined, and in each case, at first **1** and then **2**, were obtained as the only products that we were able to characterise.

Crystal Data for $1{\cdot}8C_7H_{16}{\cdot}6CH_2Cl_2$: $C_{384}H_{348}Ag_{12}P_{36}S_{24}$ (eight heptane and six CH_2Cl_2 solvent molecules per formula unit), M = 8141.93; trigonal, space group $R\bar{3}$; Z = 3; a = b = 31.214(4), c = 40.099(8) Å; V = 33835(10) Å^3; T = 197(2) K; $F(000)$ = 14568; $D_{calcd.}$ = 1.392 gcm^{-3}. 59537 reflections collected, of which 19049 were unique (R_{int} = 0.0615). 771 parameters; final wR_2 = 0.2367 (all data); R_1 = 0.0727 {$I > 2\sigma(I)$}; largest difference peak and hole 2.834, −0.947 e·Å^{-3}.

Crystal Data for $2{\cdot}18CH_2Cl_2$: $C_{228}H_{204}Ag_{12}P_{24}S_{30}$ (eighteen CH_2Cl_2 solvent molecules per formula unit) M = 5943.83; triclinic, space group $P\bar{1}$; Z = 1; a = 19.281(4), b = 20.329(4), c = 22.806(5) Å; α = 96.20(3), β = 114.11(3), γ = 108.83(3)°; V = 7419(3) Å^3; T = 130(2) K; $F(000)$ = 3732; $D_{calcd.}$ = 1.672 gcm^{-3}. 43858 reflections measured, of which 24516 were unique (R_{int} = 0.0860). 1432 parameters; final wR_2 = 0.2395 (all data); R_1 = 0.0859 {$I > 2\sigma(I)$}; largest difference peak and hole 2.457, -2.055 e·Å^{-3}.

A New Strategy for the Preparation of Metallaboranes − Solvothermal Synthesis and Structural Characterisation of Two Nido 11-vertex Diplatinaundecaborane Clusters

Jianmin Dou,*[a] Libin Wu,[a] Qingliang Guo,[a] Dacheng Li,[a] and Daqi Wang[a]

Keywords: Diplatinaundecaborane / Deboronation / Hydrothermal synthesis

Two novel nido 11-vertex diplatinaundecaborane clusters $[(\mu\text{-}PPh_2)(PPh_3)_2Pt_2B_9H_6Cl(O\textit{i}Pr)_2]$ (**1**) and $[(\mu\text{-}PPh_2)(PPh_3)_2Pt_2B_9H_6(O\textit{i}Pr)_3]$ (**2**) have been solvothermally synthesised and characterised by elemental analysis, IR, Raman, ^1H and ^{13}C NMR spectroscopy and single-crystal X-ray diffraction. The latter analysis revealed that two Pt atoms remain in neighbouring positions of the open Pt_2B_3 face in both clusters which were markedly different from the products obtained from the identical starting mixture under refluxing conditions.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Hydro(solvo)thermal techniques were originally developed by geochemists to mimic the conditions of mineral growth. They involve heating reaction mixtures in a sealed vessel such that reaction temperatures greater than the boiling point of the solvent can be reached, typically under autogenous pressure. The temperature regime available in hydro(solvo)thermal techniques, intermediate between low-temperature solution chemistry and high-temperature solid-state chemistry, can favour the formation of metastable kinetic rather than thermodynamic products. Recently, hydro(solvo)thermal techniques have attracted much attention in preparative chemistry[1] and have been employed extensively in the preparation of zeolites,[2] oxide and chalcogenide nanoparticles[3] as well as in the synthesis of molecular magnets[4] and coordination polymers.[5]

On the other hand, boron cluster chemistry has progressed considerably and developed into a fruitful area that includes boranes, carboranes, main group heteroboranes, metallaboranes, metallacarboranes and metallaheteroboranes. It has provided a lot of potentially useful applications, including boron neutron capture treatment (BNCT) of tumours, in solvent extractions, material science as well as in catalytic and host-guest chemistry.[6−8] The synthetic methods used to prepare metal-boron clusters are mostly conventional reactions at reflux temperature or cluster fusion processes.[9] To the best of our knowledge, there are no reports on the preparation of metallaboranes using hydro(solvo)thermal techniques in boron cluster chemistry. We have been exploring hydro(solvo)thermal techniques and introducing the strategy into the synthesis of metallaboranes. We now report two nido 11-vertex diplatinaundecaborane clusters $[(\mu\text{-}PPh_2)(PPh_3)_2Pt_2B_9H_6Cl(O\textit{i}Pr)_2]$ (**1**) and $[(\mu\text{-}PPh_2)(PPh_3)_2Pt_2B_9H_6(O\textit{i}Pr)_3]$ (**2**) prepared from the reaction of $[PtCl_2(PPh_3)_2]$ with $[B_{10}H_{10}]^{2-}$ in *i*PrOH under solvothermal conditions.

Results and Discussion

X-ray structural analyses revealed that the structures of these two clusters are very similar except for the substituent groups at position 11 in each case. They both have a *nido*-eleven-vertex $\{Pt_2B_9\}$ polyhedral skeleton with two Pt atoms in neighbouring positions of the open Pt_2B_3 face. These are the first examples of nido 11-vertex diplatinaundecaborane clusters in metallaborane chemistry characterised by X-ray diffraction. There is a PPh_2 group bridging two Pt atoms and the Pt−Pt distances [2.6672(11) Å for **1**, 2.6357(8)Å for **2**] are shorter than the Pt−Pt distances in the diplatinaborane $[(PMe_2Ph)_3ClPt_2B_{10}H_9(PMe_2Ph)]$ (2.863Å)[10] and considerably shorter than the Pt−Pt distances in $[Pt_3(\mu\text{-}PPh_2)_3Ph(PPh_3)_2]$[11] (average 3.0744Å) which also has a PPh_2 group as a bridging ligand. The Pt(7)−P(1) and Pt(8)−P(1) bond lengths are 2.314(4) Å in **1** and 2.2992(10) Å in **2**, and 2.299(4) Å in **1** and 2.3013(13) Å in **2**, respectively. The Pt(7)−P(1)−Pt(8) angle is 70.65(10)° in **1** and 69.91(3)° in **2**, values which are smaller than that in $[Pt_3(\mu\text{-}PPh_2)_3Ph(PPh_3)_2]$[11] [average 86.1(1)°]. Each Pt atom is also connected to one PPh_3 group and three B atoms. The Pt−P bond lengths [2.298(4)−2.3208(10) Å] are similar to the reported Pt−P bond distances in $[(PMe_2Ph)_2PtB_{10}H_{12}]$[12] and $[(PMe_2Ph)_2PtB_{10}H_{11}Cl]$[13] [2.309(1)−2.354(3)Å]. The Pt−B bond lengths are consistent with the corresponding distances found in the related compound $[(PPh_3)(PhCOS)PtB_{10}H_{11}]$

 DOI: 10.1002/ejic.200400731 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[2.263(19) Å].[14] A Cl atom remains at vertex 11 in cluster **1**, whereas a O*i*Pr group occupies the same position in cluster **2**. Both have two O*i*Pr group at positions 3 and 9. The bond lengths B−Cl [1.80(2) Å] and B−O [1.359(4)−1.393(4)Å] are in the ranges of the corresponding values in metallaborane clusters.[15]

Figure 1. When the reaction of $[PtCl_2(PPh_3)_2]$ with $[B_{10}H_{10}]^{2-}$ in *i*PrOH takes place under conventional reflux conditions under a dry N_2 atmosphere, three nido 11-vertex platinaundecaborane clusters $[(PPh_3)_2PtB_{10}H_{10}$-8-O*i*Pr], $[(PPh_3)_2PtB_{10}H_{10}$-9-O*i*Pr] and $\{(PPh_3)_2PtB_{10}H_{10}$–8, 10-$(OiPr)_2\}$ are obtained.[16] These species are markedly different from the products obtained under solvothermal conditions. The reason for this may be attributed to the high temperature of the solvothermal reaction. Another example is that the reaction of $[RuCl_2(PPh_3)_3]$ with $[B_{10}H_{10}]^{2-}$ in glycol also yield two deboronated clusters $[(PPh_3)ClHRuB_9H_6(PPh_3)_2(OCH_2CH_2OH)]$ and $[(PPh_3)$-$ClHRuB_9H_5(OCH_2CH_2OH)_2(PPh_3)_2]$.[17] This illustrates that deboronation can be occur easily at high temperature. Another case of deboronation of $[B_{10}H_{10}]^{2-}$ can be included: trans-$[Ir(CO)Cl(PPh_3)_2]$ reacts with $[B_{10}H_{10}]^{2-}$ in methanol at reflux to yield $[\{IrC(OH)B_8H_6(OMe)\}$-$(C_6H_4PPh_2)(PPh_3)]$, $[(MeCOO)(PPh_3)\{HIrCB_8H_7(PPh_3)\}]$ and $[1,1,2$-$(CO)_3$-1-(PPh_3)-2,2-$(Ph_2P$-*ortho*-$C_6H_4)_2$-*closo*-$(1,2$-$Ir_2B_4H_2)]$.[18]

Conclusion

We have introduced solvothermal techniques into the preparation of metallaborane clusters for the first time and obtained two novel nido 11-vertex diplatinaundecaborane clusters, in which one boron atom was deboronated and two Pt atoms remain in neighbouring positions of the open Pt_2B_3 face in both clusters. The isolation of these two clusters suggests that temperature can control the result of the reaction.

Experimental Section

Materials and General Methods: All chemicals were commercially purchased and used without further purification except *i*PrOH which was dried with CaH_2. Elemental analyses (C, H and N) were performed with a Perkin−Elmer 2400 II Elemental Analyser. IR spectra were recorded in the range 400−4000cm^{-1} with an Nicolet-460 FT-IR spectrophotometer using KBr pellets. Raman spectra were acquired on a Renshaw RM2000 spectrophotometer. ^{1}H NMR and ^{13}C NMR spectra were recorded using a Varian Mercury 400 (400 MHz) nuclear magnetic resonance instrument.

Synthesis of $[(\mu$-$PPh_2)(PPh_3)_2Pt_2B_9H_6Cl(OiPr)_2]$ (1) and $[(\mu$-$PPh_2)(PPh_3)_2Pt_2B_9H_6(OiPr)_3]$ (2): $(NEt_4)_2[B_{10}H_{10}]$ (303 mg, 8 mmol), $[PtCl_2(PPh_3)_2]$ (317 mg, 4 mmol) and distilled *i*PrOH (25 mL) were mixed in a Telfon lined autoclave under a dry N_2 atmosphere. The mixture was maintained at 170 °C for 96 h then slowly cooled to room temperature. TLC separation (silica G, CH_2Cl_2/light petroleum, 4:1) gave clusters **1** (R_f = 0.54, 18 mg, 2.9%) and **2** (R_f = 0.24, 77 mg, 12.4%). The single-crystals were obtained from an *n*-pentane/dichloromethane solution.

Cluster 1: $C_{54}H_{60}B_9ClO_2P_3Pt_2$ (M = 1356.85): calcd. C 47.80, H 4.42, found C 47.68, H 4.33. FT-IR (KBr): 3054 (m), 2970 (m), 2507 (vs), 1633 (s), 1434 (vs), 1234 (s), 1109 (s), 1095 (vs), 691 (s), 528 cm^{-1} (s).

Cluster 2: $C_{57}H_{67}B_9O_3P_3Pt_2$ (M = 1380.49): calcd. C 49.55, H 4.85, found C 49.13, H 4.56. FT-IR (KBr): 3050 (m), 2963 (m), 2509 (vs), 1634 (m), 1433 (s), 1382 (m), 1108 (vs), 691 cm^{-1} (vs); Raman: 3052.5 (m), 2513.8 (vs), 1583 (m), 1097 (m), 1000 (vs), 215 cm^{-1} (w). ^1H NMR (400.15 MHz, $CDCl_3$): δ = 0.659 (d, J = 6.0 Hz, 6 H, CH_3), 0.822 (d, J = 6.0 Hz, 6 H, CH_3), 1.101 (d, J = 6.4 Hz, 6 H, CH_3), 4.181 (7, J = 6.4 Hz, 1 H, CH), 4.462 ppm (7, J = 6.0 Hz, 2 H, CH). ^{13}C NMR (100.63 MHz, $CDCl_3$): δ = 23.452, 23.766, 25.475, (6 C, CH_3), 73.781 ppm (3 C, CH).

X-ray Crystallography: Data were collected on a Bruker SMART 1000 CCD diffractometer using Mo-K_α radiation. Both structures were solved by direct methods and subsequent Fourier difference techniques and then refined anisotropically for all nonhydrogen atoms by full-matrix least-squares calculations on F^2 using the SHELXTL program package. CCDC-245790 and -245791 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Anion-Induced Motion in a Ferrocene Diamide

Katja Heinze*[a] and Manuela Schlenker[a]

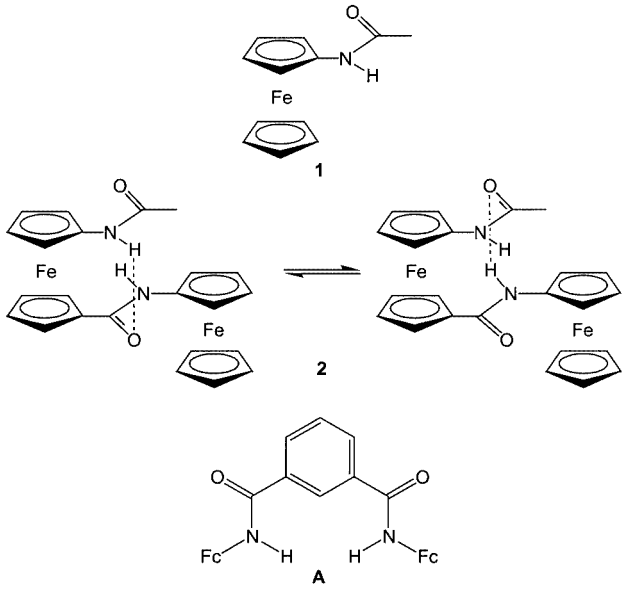
Keywords: Anion recognition / Anion sensing / Hydrogen bonds / Metallocenes / Receptors

An unsymmetrical diferrocene diamide has been reacted with chloride ions. The anion splits the intramolecular hydrogen bond of the receptor and is coordinated simultaneously by both amide groups of the receptor via hydrogen bonds. Chloride coordination changes the relative angular position of the cyclopentadienyl rings and the potential of the ferrocene/ferricinium redox couple.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Control of mechanical motions of single molecules by external stimuli has attracted great attention in relation to biological machines such as muscles and for the development of artificial molecular machines and devices. Various molecular machines have been reported, such as motors, shuttles, switches and tweezers that respond to stimuli such as protons (pH), electrons (redox processes) and light.[1−3] Here we describe an anion-driven molecular hinge where the opening of an intramolecular lock is transformed into an angular motion. Examples of such an interlocking mechanical motion are still rare;[4] most precedent machines, based on rotaxanes or catenanes, operate by individual motions of driving parts.



Scheme 1. Ferrocene amides **1**, **2** and Crabtree's receptor **A**[6] (Fc = ferrocenyl)

Results and Discussion

Recently, we prepared the unsymmetrical diferrocene diamide **2**, which possesses a dynamic intramolecular hydrogen bond in solution (Scheme 1, middle).[5] This dynamic bridge remains intact up to 55 °C, as shown by NMR and IR spectroscopy and corroborated by DFT calculations.[5] The amide protons of **2** do not undergo H/D exchange with D_2O in CH_2Cl_2, underlining this stability. Thus, the hydrogen-bond lock hinders the normally free rotation of the cyclopentadienyl rings of the disubstituted ferrocene.

Conversely, external hydrogen acceptors such as anions bind to amide groups.[7] This could, presumably, affect the internal hydrogen bond. Thus ferrocene amides **1**, which represents "one half" of **2** (Scheme 1), and **2** were treated with chloride ions in the non-coordinating solvent dichloromethane.

Addition of chloride ions as their tetra-*n*-butyl ammonium salts to the receptors **1** and **2** leads to the disappearance of the signal of the "free" NH groups (**1**: 3435 cm^{-1}; **2**: 3430 cm^{-1}) from the IR spectra (Figure 1, left) and a shift of the CO stretching signals to lower energy (Figure 1, right: **1**: 1685 → 1666 cm^{-1}; **2**: 1679/1660 → 1659 cm^{-1}) for both ferrocene amides, indicating that the chloride ions interact with the amide groups. As the strong signals of the CH vibrations of the tetra-*n*-butyl ammonium

cation strongly modify the baseline, integration of the NH stretching vibration signals proved unreliable. However, receptor **1** requires more chloride ions than receptor **2** to reach saturation − as seen qualitatively from the IR spectra (Figure 1).

To obtain deeper insight into the association process proton NMR spectra[8] were recorded during the addition of chloride ions (Figure 2). Several proton signals of the ferrocene amides are shifted significantly to lower field upon increasing chloride concentration. The shift is especially pronounced for signals of the amide protons H^1 and H^{21} and the neighboring cyclopentadienyl protons H^2 ("upper" cyclopentadienyl ring), H^{22} and H^7 ("middle" cyclopentadienyl rings) (see Figure 4 for atom numbering).

Saturation is reached at relative concentrations of approximately 1:50 (**1**:Cl^-) and 1:20 (**2**:Cl^-), respectively (Figure 3), which is in qualitative agreement with the IR data. Thus, diamide **2** has a much larger affinity to chloride ions than monoamide **1**. If the amide groups of **2** behaved independently the amount of anion needed to satisfy both groups of **2** should be about twice that needed for monoamide **1**, i.e. saturation would be expected at a **2**:Cl^- ratio of ca. 1:100. As this is obviously not the case the two amide groups of **2** bind chloride ions in a cooperative way.

Thorough investigation of the CIS (chemically induced shift) values of **2** revealed that the two NH groups, with their neighboring CH groups, display different affinity towards chloride ions, with H^1 and its neighboring H^2 having a stronger affinity than H^{21} and its neighboring H^{22} and H^7 (Figure 3, bottom). This finding is in contrast to observations made for the symmetrical diferrocene diamide **A** prepared by Crabtree[6] (Scheme 1, bottom) as the protons of the two amides of **A** are spectroscopically indistinguishable. The strongly shifted amide protons H^1 and H^{21} and the Cp protons H^2, H^7 and H^{22} allow us to map the sites of receptor **2** where anion coordination takes place (Figure 4). According to Figure 4, the chloride ion can approach the receptor at the "upper" amide group (H^1, H^2), at the "lower" amide group (H^{21}, H^7, H^{22}) or at both NH groups simultaneously in a different conformation of **2**. To prove that both amide groups are accessible for chemical attack, **2** has been reacted with excess sodium amide and

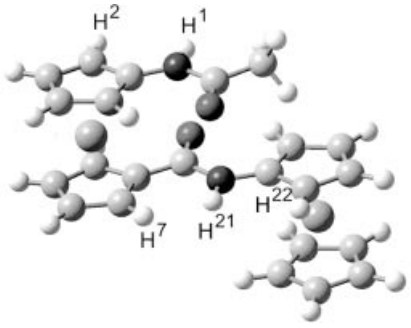

Figure 4. Protons of **2** affected by anion coordination

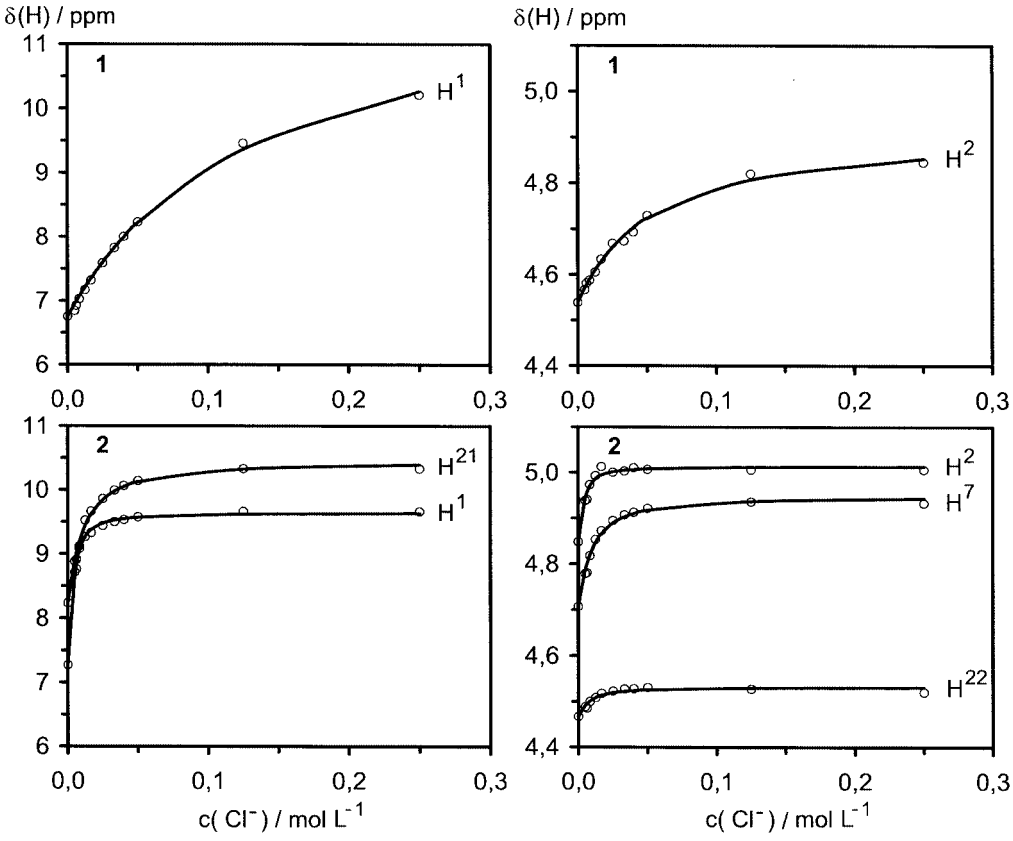

Figure 3. ^1H NMR titration plots of **1** (top) and **2** (bottom) with $(n\text{Bu})_4NCl$ in CD_2Cl_2 at 300 K (0.005 M)

quenched with D_2O. Proton NMR and IR spectra of the final product (see Supporting Information) show that **2** can be deprotonated either at H^1 or at H^{21} with equal probability.[9] Thus, sterically, H^1 and H^{21} are equally accessible.

The much stronger binding capability of **2** as compared to that of **1** is certainly due to a chelate effect, which has numerous precedents in anion recognition chemistry.[10] However, the cooperative binding of the two amide groups is much less pronounced for **2** than for the "unlocked" preorganised receptor **A** (Scheme 1, bottom).[6] Thus, we propose a stepwise mechanism of anion association to **2** (Figure 5).

According to DFT calculations (B3LYP, LanL2DZ; see Supporting Information), the chloride ion can associate to H^1 (Figure 5, structure **I**), to H^2 (Figure 5, structure **II**) or to both amide protons simultaneously (Figure 5, structure **III**).[11] This accords with the NMR spectroscopic data, which show that both amide protons interact with the chloride ion, and with the IR data, which show the disappearance of "free" NH groups upon chloride addition. All three minimum structures **I**−**III** possess two hydrogen bonds: structure **I** displays a hydrogen bond from H^1 to chloride and an intramolecular hydrogen bond from H^2 to O^1; **II** shows a hydrogen bond from H^2 to chloride and an intramolecular hydrogen bond from H^1 to O^2; and in structure **III** the chloride ion is attached to H^1 and H^2 simultaneously, which corresponds to the most stable structure. The loss of the intramolecular NH···O hydrogen bond in **III** explains the lower affinity of **2** compared to the preorganised receptor **A**.[6]

All the structures can be interconverted by hydrogen bond-making/breaking processes and concomitant relative rotation of the cyclopentadienyl rings. As the equilibria could not be frozen out down to 190 K on the NMR time scale (500 MHz), intermolecular[11] low-energy pathways should exist that easily interconvert **I**, **II** and **III** and their respective enantiomers.

For the lowest energy structure **III** the two cyclopentadienyl rings of the 1,1′-disubstituted ferrocene are rotated against each other by 95°, which is about twice the angle calculated for a light-driven ferrocene-based "molecular scissor" (49°).[4]

The native "locked" state of **2**, i.e. the intramolecular hydrogen bond, can be restored by removal of the chloride ions through the addition of excess thallium cations.[12] Angular motion of the cyclopentadienyl rings of **2** can thus be triggered by the presence or absence of chloride ions (Scheme 2, a). Thus the anion-based system presented resembles Lehn's cation-induced dynamic chemical device based on a *transoid/cisoid* rearrangement of terpyridines (Scheme 2, b).[3]

In addition to the angular motion induced by anion binding, the ferrocene moieties provide the electrochemical response expected for amide substituted ferrocenes.[10] Figure 6 shows the cyclic voltammograms of receptors **1** and **2** during the addition of chloride ions. For receptor **2**, the second oxidation becomes irreversible at higher chloride concentrations, probably due to the coordination of another anion to the charged receptor.

The anion-induced cathodic shift of the ferrocene/ferricinium oxidation wave is linear up to two equivalents of chloride ions for monoamide **1** (Figure 7). Due to the larger anion affinity of **2**, saturation is reached at 1.2 equivalents of chloride (Figure 7). As the maximum cathodic shifts $\Delta E_{1/2}$ are equal for both amidoferrocenes (30 mV within the linear range[13]), the slope of the $\Delta E_{1/2}$ vs. $[Cl^-]$ plot,

but controllable building block into larger arrays, e.g. in the backbone of peptides (R^1, R^2 = peptides in Scheme 2, a), or between fluorescent reporter groups may lead to novel hybrid (bio)materials with unconventional dynamics and (redox) functions.[14–16] Work in this direction is currently in progress.

Experimental Section

Compounds **1** and **2** were prepared by published procedures.[5] NMR: Bruker Avance DPX 200 at 200.15 MHz (^1H) at 303 K; chemical shifts (δ) in ppm with respect to residual solvent peaks as internal standard: CD_2Cl_2 (^1H: δ = 5.32 ppm). IR spectra were recorded on a BioRad Excalibur FTS 3000 spectrometer using CaF_2 cells in CH_2Cl_2. Cyclic voltammetry was performed using a glassy carbon electrode, a platinum electrode and a SCE electrode, 10^{-3} M in 0.1 M $n\text{Bu}_4\text{NBF}_4/CH_2Cl_2$; potentials are given relative to SCE. Computational method: density functional calculations were carried out with the Gaussian03/DFT[17] series of programs. B3LYP formulation of density functional theory was used employing the LanL2DZ basis set.[17] Harmonic vibrational frequencies and infrared intensities were calculated by numerical second derivatives using analytically calculated first derivatives. All points were characterised as minima or first-order saddle points by frequency analysis.

[11] Job Plots reveal that the receptor:chloride binding stoichiometry is 2:1 for both complexes (see Supporting Information), showing that the chloride ion is associated to two receptor molecules. This stoichiometry does not affect the dynamic behavior of the system as all calculated minimum structures (**I**−**III**) with 1:1 stoichiometry can form the corresponding 2:1 complexes. The 2:1 stoichiometry and the narrow solubility window of **1** and **2** prevented the determination of 2:1 binding constants $K^{21} = [(\mathbf{1})_2Cl^-]/[\mathbf{1}]^2[Cl^-]$ and $K^{21} = [(\mathbf{2})_2Cl^-]/[\mathbf{2}]^2[Cl^-]$, respectively. This prevented direct comparison with literature data on 1:1 binding constants of receptor/anion complexes (e.g. refs. 6 and 7). However, NMR spectroscopic data (at 0.005 M concentrations of **1** and **2**) can be fitted to 1:1 binding isotherms, giving $K^{11} = 7.8\ M^{-1}$ (**1**; based on H^1; $R^2 = 0.9976$), $K^{11} = 630\ M^{-1}$ (**2**; based on H^1; $R^2 = 0.9963$) and $K^{11} = 120\ M^{-1}$ (**2**; based on H^{21}; $R^2 = 0.9938$); which can be compared qualitatively to those measured for Fc-CO-NH-*n*Bu ($K^{11} = 4.7\ M^{-1}$ in $CDCl_3$ at 0.01 M[7l]) and for **A** ($K^{11} = 9500\ M^{-1}$ in CD_2Cl_2 at 0.001 M[6]). In addition, 2:1 complexes have been observed between Fc-CO-NH-py and the neutral guest glutaric acid: [11a] J. D. Carr, L. Lambert, D. E. Hibbs, M. B. Hursthouse, K. M. Abdul Malik, J. H. R. Tucker, *Chem. Commun.* **1997**, 1649−1650.

[12] Addition of solid $Tl(PF_6)$ to the chloride-loaded receptor **2** restores the original (chloride-free) ^1H NMR spectrum. Recharging with chloride anions again results in downfield shifts of the proton signals.

[13] Similar shifts were observed for the receptor **A**[6] and $(Cp\text{-}NHCOR)_2Fe$ in the presence of chloride: P. D. Beer, J. J. Davis, D. A. Drillsma-Milgrom, F. Szemes, *Chem. Commun.* **2002**, 1716−1717.

The Nature of the Spin-State Variation of $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ in Solution

Konstantin P. Bryliakov,*[a] Eduard A. Duban,[a] and Evgenii P. Talsi[a]

Keywords: Magnetic properties / Iron(II) complexes / Spin crossover / Liquid state / Solvent effects

Thermally-induced spin variation behavior of $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ in CD_3CN solution [low spin (LS)–high spin (HS)] was investigated. Variable temperature solution magnetic susceptibility measurements gave $\Delta H°_{LS-HS}$ = 39.7 ± 2.0 kJ·mol^{-1} and $\Delta S°_{LS-HS}$ = 135 ± 9 J·mol^{-1} K^{-1} values. These values are too high for a pure spin transition and reflect a significant contribution of chemical processes to the spin transition, namely, the detected dissociation of one bound acetonitrile molecule. Thus, LS–HS conversion should be regarded as a chemical equilibrium overlapped with a thermal spin crossover. The thermodynamic parameters for the overall process estimated from the variation of the NMR shifts with temperature ($\Delta H°$ = 40 ± 3 kJ·mol^{-1}, $\Delta S°$ = 137 ± 10 J·mol^{-1} K^{-1}) are in perfect agreement with those obtained by magnetic susceptibility measurements.

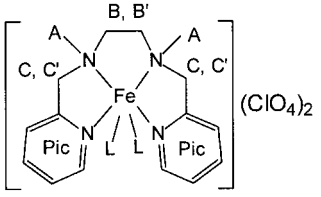
Introduction

In recent years, Que and co-workers reported a series of non-heme Fe^{II}(BPMEN)- and Fe^{II}(TPA)-type catalysts for stereospecific oxidation of hydrocarbons with H_2O_2 [TPA is tris(2-pyridylmethyl)amine ligand and BPMEN is *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)-1,2-diaminoethane ligand].[1−4] These species can be functional models for non-heme iron oxygenases, such as Rieske dioxygenases capable of olefin *cis*-dihydroxylation.[3] The catalysts reported were either diamagnetic or paramagnetic complexes, depending on the substituent at the 6-position of the pyridine rings. Interestingly, the parent $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ complex displayed solution spin-transition behavior in the temperature range −40 to +30 °C. However, the authors only mentioned this phenomenon and did not report a detailed spectroscopic/magnetic susceptibility investigation. Recently, a theoretical study appeared where the structure and spin states of Fe-BPMEN complexes were evaluated by DFT.[5] Apparently, knowledge on the nature of this low-to-high spin transition could be of help in understanding the reactivity of these systems.

The temperature-induced LS−HS transitions in Fe^{II} complexes[6−8] have been extensively studied over the last few years, mostly in the solid state; however, variable-temperature studies in solution have also appeared.[8−10] Solid-state spin equilibria in some diisothiocyanato iron(II) complexes with BPMEN type ligands were studied by Toftlund et al.[11] In this paper, we present a detailed magnetic susceptibility and ^{1}H NMR study of $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ in solution (**I**, Scheme 1) spin variation in [D_3]acetonitrile and the thermodynamic parameters of this reaction. The results of magnetic susceptibility measurements on solutions are compared with those obtained by a paramagnetic ^{1}H NMR study.



I, L= CH_3CN

Scheme 1. Complex **I**

Results and Discussion

At room temperature, complex **I** exhibits a magnetic moment of 4.1 μ_B in acetonitrile solutions, which is indicative of a spin-crossover system. Temperature-dependent magnetic susceptibility measurements were carried out to explore the equilibria that occur in acetonitrile solutions of complex **I** (see a in Figure 1, trace 1). Fitting the observed magnetic moment dependencies μ_{eff} versus T to Equation (5) (see Exp. Sect.) gave the limiting magnetic moment values μ_{LS} = 1.30 ± 0.1 μ_B and μ_{HS} = 5.45 ± 0.1 μ_B, which are higher than the spin-only values 0 and 4.90 μ_B, thus suggesting significant orbital contributions to the observed

magnetic moments (see ref.[8,11]). Spin transition is accomplished within the temperatures accessible for acetonitrile: the $\mu_{eff}(T)$ values practically level off in the higher and lower limits of the temperature range considered. The μ_{LS} value is in good agreement with the solid-state magnetic moment 1.40 μ_B (T = 294 K).

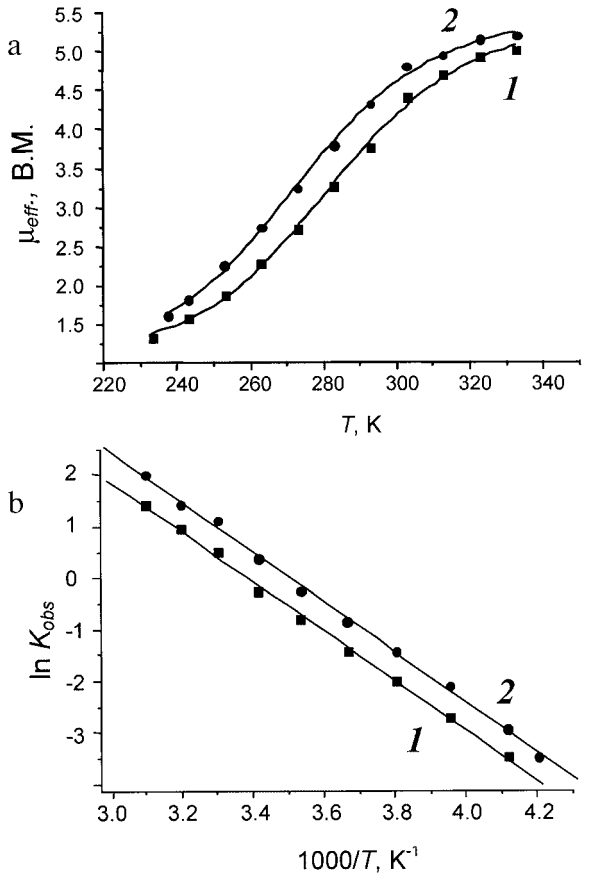

Figure 1. Fits of $\mu_{eff}(T)$ to Equation (5) for complex **I** (a) and linear fits of ln K_{obs} versus 1000/T (b) in [D_3]acetonitrile - trace 1 (■) and in [D_3]acetonitrile/[D_6]acetone - trace 2 (•) (in Table 1, see entries 1 and 7, respectively)

The equilibrium parameters $\Delta S°$ and $\Delta H°$ (see b in Figure 1, trace 1) measured in [D_3]acetonitrile gave $\Delta S°$ = 135 ± 9 J mol^{-1} K^{-1} (in which the contribution of R ln 5 arises from spin degeneracy of the HS state) and $\Delta H°$ = 39.7 ± 2.0 kJ mol^{-1}. Both values are substantially higher than those reported in the literature for solution spin-crossover systems.[7,10,12] This lead us to suggest that spin change in this system could overlap with other (chemical) processes. The fact that in other solvents (e.g. [D_6]acetone, see Supporting Information) a conventional Curie dependence of ^{1}H paramagnetic shifts is observed is in favor of dissociation of bound acetonitrile molecules at elevated temperatures, see Equation (1).

$$[Fe^{II}(BPMEN)(CH_3CN)_2]^{2+} \underset{}{\overset{K}{\rightleftharpoons}} [Fe^{II}(BPMEN)(CH_3CN)_{2-n}]^{2+} + n\,CH_3CN \quad (1)$$

LS HS

A similar behavior was previously proposed to describe the spin-state variation of $[Fe(Me_3tacn)(MeCN)_3]$ in solution.[9] The observed equilibrium constant [$K_{obs}(T) = C_{HS}/C_{LS}$] values should be related to the thermodynamic equilibrium constant as shown in Equation (2).

$$K_{obs}(T) = K/[L]^n \quad (2)$$

[L] is the concentration of acetonitrile in solution. Dilution of acetonitrile with a noncoordinating solvent would result in higher K_{obs} values, so that $K_{obs}([L_o])/K_{obs}([L_1]) = ([L_1]/[L_o])^n$. Also, taking the logarithm of Equation (2) and assuming that $\Delta H°$ is independent of acetonitrile concentration, one obtains Equation (3).

$$\Delta S°_{obs} = \Delta S° - nR \ln [L] \quad (3)$$

$\Delta S°_{obs}$ and $\Delta S°$ correspond to K_{obs} and K (i.e. ΔS related at some standard conditions), respectively, and R is the gas constant. Thus, the 1.63-fold decrease in CD_3CN concentration would result in a $(1.63)^n$-fold increase in the K_{obs} value and an nR ln(1.63) = 4n J mol^{-1} K^{-1} increase in $\Delta S°_{obs}$. Unfortunately, the low precision of μ_{eff} measurements did not allow reliable detection of these small effects. In the temperature range considered, such experiments with combined $CD_3CN/CDCl_3$, CD_3CN/CCl_4, CD_3CN/[D_6]acetone solvents (Table 1, Figure 1) showed a 1.3-fold increase in the value of K_{obs} with a 1.63-fold decrease in CD_3CN concentration and a 1.7-fold increase in the value of K_{obs} with a 2.65-fold decrease in [CD_3CN] (these values are lower than those expected, indicating that $\Delta H°$ also changes with changing CD_3CN concentration). In the $\mu_{eff}(T)$ – T diagram, this resulted in a $T_{1/2}$ change from 284 to 275 K (see a in Figure 1). The question, what is n in Equation (3), could be answered as follows: if both acetonitrile molecules dissociated at high temperatures, we should observe similar high-temperature spectra in [D_6]acetone and in [D_3]acetonitrile/[D_6]acetone combined solvent. However, the spectra are substantially different (Supporting Information), indicating, apparently, the existence of $[Fe^{II}(BPMEN)]^{2+}$ in the first case and $[Fe^{II}(BPMEN)(CD_3CN)]^{2+}$ in the second case. We conclude that the experimentally observed picture is consistent with dissociation of one acetonitrile molecule, therefore leading to a weaker ligand field.

^{1}H NMR spectra of complex **I** in [D_3]acetonitrile gradually change from diamagnetic at −40 °C to paramagnetic at +60 °C (see a in Figure 2), indicating that the process in Equation (1) is fast on the NMR timescale. At high temperatures the spectrum is typical for high-spin Fe^{II} complexes,[9,13–14] and the peaks can be assigned unambiguously based on the relative intensities and linewidths of the peaks by assuming a dipolar line broadening mechanism.[15] The thermodynamic parameters estimated from NMR shifts according to Equation (9): $\Delta S°$ = 137 ± 10 J·mol^{-1} K^{-1} and $\Delta H°$ = 40 ± 3 kJ·mol^{-1} (see b in Figure 2), do not differ from those obtained by magnetic

measurements. In weaker coordinating solvents (e.g. [D_6]-acetone), **I** displays a paramagnetic spectrum from 130 to −10 ppm, which is indicative of loss of both coordinated CH_3CN molecules.

The phenomenon of ligand dissociation induced spin transition has a nice interpretation in terms of crystal field theory. If one looks at the Tanabe−Sugano diagram for the d^6 configuration (Figure 3), one can see that a conventional spin equilibrium $^1A_1(LS) \rightleftarrows {}^5T_2(HS)$ should be represented by the vertical arrow, which indicates gradual population of the higher lying $^5T_2$ HS state with increasing temperature. On the contrary, the spin conversion caused by ligand dissociation could be associated with the *horizontal* arrow, which represents the dislocation from the high-field region to the low-field one. In our case, an intermediate process seems to take place: an attempt to split the spin interconversion and ligand dissociation processes was made (see Supporting Information), and this revealed comparable contributions of both processes to the observed equilibrium.

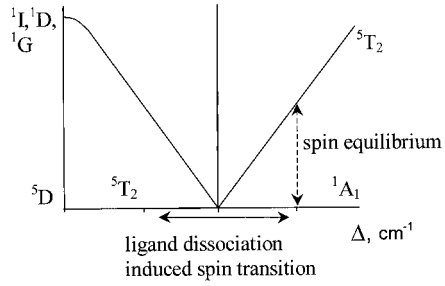

Figure 3. Schematic representation of the Tanabe−Sugano diagram (fragment) for d^6 configuration; the abscissa and ordinate are the crystal field parameter Δ and energy, respectively

In a series of works on bis(benzimidazole)pyridine iron(II) and other iron(II) complexes, it was shown that solvent effects can overlap with the true spin crossover,[16−22] so that substitution or dissociation of coordinated ligands lead to the change in spin state. As Toftlund mentioned, phenomena like these should not be considered as true spin-crossover interconversions.[23] LS/HS transition systems like the one presented (where the spin transition is due to the substantial contribution of the ligand dissociation, and thus weakening the ligand field splitting) seem to be fairly rare in the literature. In this paper we have reported the first measurements of thermodynamic parameters defining the LS/HS transition in $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ in solution, and demonstrated the high utility of the combined solution magnetic susceptibility/^{1}H NMR spectroscopic measurements for the detailed physico-chemical investigations of one of the few systems of this type documented so far.

Experimental Section

Materials: BPMEN[11] and **I**[1] were prepared as described. For solution magnetic susceptibility measurements, **I** was recrystallized

from CH_3CN/Et_2O at +4 °C.[1] Deuterated solvents ([D_3]acetonitrile, [D]chloroform) were dried with molecular sieves prior to use.

Physical Measurements: ^1H NMR spectra were recorded in standard 5-mm cylindrical glass tubes on a Bruker DPX-250 NMR spectrometer at 250.13 MHz and referenced to TMS (samples volume 0.50 cm^3 at 298 K). Operating conditions for ^1H NMR measurements: high temperature, spectral width 50 kHz, spectrum accumulation frequency 5 Hz; low temperature, spectral width 5 kHz, spectrum accumulation frequency 0.5 Hz; 90° pulse at 8.2 μs.

Solid state magnetic susceptibility was measured by the Faraday method, with $(NH_4)_2Fe(SO_4)_2{\cdot}6H_2O$ as calibrant. Solution magnetic susceptibility measurements were measured as a function of temperature (−50 to +70 °C) in deuterated solvents CD_3CN, CD_3CN/[D_6]acetone, CD_3CN/CCl_4 and $CD_3CN/CDCl_3$ by the Evans method,[24] with TMS as an internal reference. To prepare the "1.63-fold diluted" CD_3CN solutions, $CDCl_3$ was added to CD_3CN (0.61 mL) to make the volume 1.00 mL. To prepare the "2.65-fold diluted" CD_3CN solutions, [D_6]acetone was added to CD_3CN (0.375 mL) to make the volume 1.00 mL. To prepare the "2-fold diluted" CCl_4 solutions, CCl_4 was added to CD_3CN (0.500 mL) to make the volume 1.00 mL. Temperature uncertainty was ±1 °C. Special stem coaxial insert tubes (203 mm × 4 mm o.d.) with a capillary reference volume of 60 μL (50 mm × 2 mm o.d.) were purchased from Wilmad Glass Co. Mass magnetic susceptibilities χ_g ($cm^3\ g^{-1}$), were calculated from Equation (4).

$$\chi_g = -3\Delta f/4\pi f m + [\chi_o + \chi_o(d_o - d_s)/m] \quad (4)$$

Δf is the frequency shift in Hz of the reference compound, f is the spectrometer frequency in Hz, m is the mass in g of the complex in 1 cm^3 of the solution, χ_o is the mass susceptibility of the solvent in $cm^3\ g^{-1}$, and d_o and d_s are the densities of the solvent and solution, respectively. The term in square brackets disappears, because at the concentrations used (10−15 mM), the solution density was approximated as $d_s = d_o + m$. We note that the original Evans technique[24] was developed for the cylindrical sample axis perpendicular to the magnetic field, whereas for the sample axis parallel to the magnetic field, a factor of 3/4π rather than 3/2π[1,25] should be applied in Equation (4).[10,26] To take into account the solution volume changes with temperature, a correction was introduced in the m values so that $m = m_o h_o/h$, where m_o is the mass in g of the complex in 1 cm^3 of the solution at 298 K, and h_o and h are sample heights at 298 K and at the given temperature, respectively.
Multiplying the χ_g values by the molecular weight, the molar susceptibility χ_M was obtained. The latter was corrected for the diamagnetic contributions of BPMEN ligands, counteranions and Fe^{II} core electrons using Pascal's constants to give the corrected molar susceptibility χ_M'.[25] The latter was used to calculate the effective magnetic moment $\mu_{eff} = 2.828(\chi_M'T)^{1/2}$ (μ_B), where T is temperature in K.[26] μ_{eff} was fit to Equation (5) in a manner similar to that applied in ref.[10]

$$\mu_{eff}(T) = \{\mu_{LS}^2 + \mu_{HS}^2\,[\exp(\Delta S°/R)\exp(-\Delta H°/RT)]\}^{1/2} \{1 + \exp(\Delta S°/R)\exp(-\Delta H°/RT)\}^{-1/2} \quad (5)$$

μ_{LS} and μ_{HS} are the limiting magnetic moments of the low-spin and high-spin states, and $\exp(\Delta S°/R)\exp(-\Delta H°/RT)$ is the observed equilibrium constant $K_{obs} = [HS\text{-}Fe^{II}]/[LS\text{-}Fe^{II}]$.

Calculation of Observed Equilibrium Constant Values K_{obs}: Equation (5) implies a four-parameter fit that gives significant uncertainties for $\Delta S°$ and $\Delta H°$. For more precise $\Delta S°$ and $\Delta H°$ measurements, the solution equilibrium treatment of Crawford and Swanson was applied.[27] Namely, after μ_{LS} and μ_{HS} were obtained from Equation (5) (and averaged over all experiments), the probabilities of Fe^{II} to be in LS and HS forms were calculated as according to Equation (6) and $K_{obs}(T) = P_{HS}(T)/P_{LS}(T)$. Then, $\Delta S°$ and $\Delta H°$ were obtained from linear logarithmic plots of ln K_{obs} versus $1/T$.

$$P_{LS}(T) = (\mu_{HS}^2 - \mu_{eff}(T)^2)/(\mu_{HS}^2 - \mu_{LS}^2)$$
$$P_{HS}(T) = 1 - P_{LS}(T) \quad (6)$$

Calculation of $\Delta H°$ and $\Delta S°$ from the Temperature Dependence of the Observed ^1H NMR Chemical Shifts: For LS and HS forms in fast equilibrium, a single paramagnetically broadened ^1H resonance was observed, see Equation (7).

$$\delta_{obs} = \delta_{LS}P_{LS} + \delta_{HS}P_{HS} \quad (7)$$

δ_{LS} is the chemical shift for the diamagnetic state,

$$P_{LS}(T) = 1/(1 + K_{obs}).$$

$$P_{HS}(T) = K_{obs}/(1 + K_{obs}) \quad (8)$$

δ_{HS} stands for the chemical shift of the HS (paramagnetic) state. According to ref.[28−29] $\delta_{HS} = \delta_{dia} + \delta_{hf}$, where δ_{hf} is the hyperfine (contact + pseudocontact) contribution and diamagnetic contribution δ_{dia} is the same as δ_{LS}. Assuming that δ_{hf} has the theoretically expected Curie temperature dependence (C/T), one could calculate δ_{obs} according to Equation (9).

$$\delta_{obs} = \{\delta_{LS} + (\delta_{LS} + C/T)[\exp(\Delta S°/R)\exp(-\Delta H°/RT)]\}/\{1 + \exp(\Delta S°/R)\exp(-\Delta H°/RT)\} \quad (9)$$

C is a constant and $\exp(\Delta S°/R)\exp(-\Delta H°/RT) = K_{obs}$. Thus, $\Delta S°$ and $\Delta H°$ were obtained from the plots of δ_{obs} versus T.

Supporting Information (see also the footnote on the first page of this article): ^1H NMR spectroscopic data, spectra, chemical shift plots for complex **I** in different solvents.

Two Novel Inorganic-Organic Hybrid Frameworks Based on In^{III}-BTC and In^{III}-BTEC

Zheng-Zhong Lin,[a] Fei-Long Jiang,[a] Lian Chen,[a] Da-Qiang Yuan,[a] You-Fu Zhou,[a] and Mao-Chun Hong*[a]

Keywords: Indium(III) / Benzenemulticarboxylate

Hydrothermal reactions of $InCl_3$ with 1,3,5-benzenetricarboxylic acid (H_3BTC) or pyromellitic dianhydride produced $[In_2(BTC)_2(H_2O)_2]_n \cdot 2nH_2O$ (**1**) and $[In_2(H_2BTEC)_2(OH)_2]_n \cdot 2nH_2O$ (**2**), respectively (H_4BTEC = 1,2,4,5-benzenetetracarboxylic acid). The structure of **1** is a 2D double-layer network, while that of **2** is a 3D framework constructed from chains of corner-linked octahedra. Intense greenish-blue emissions at 494 nm (λ_{ex} = 325 nm) for **1** and 489 nm (λ_{ex} = 337 nm) for **2** were observed in the solid state.

Introduction

The development of organic-inorganic hybrid compounds constructed by the deliberate selection of metals and multifunctional exodentate ligands represents one of the most active research area in chemistry. The fascinating structures of these complexes together with their functional properties makes them highly prospective as a new class of materials.[1−4] 1,3,5-benzenetricarboxylic acid (H_3BTC) and 1,2,4,5-benzenetetracarboxylic acid (H_4BTEC) are two promising ligands which provide high symmetry, diverse charge and a multi-connecting ability which has been applied in the design of hybrid complexes exploiting both the diversity of metal coordination geometries and weak intermolecular forces such as π−π interactions and hydrogen bonding. The rigid conformation and strong coordinating ability of the carboxylate groups bestows excellent thermal properties on the resultant hybrid complexes. The use of H_3BTC and divalent metal ions has led to the generation of products consisting 1D chains,[5,6] 2D layers[7−11] and 3D structural frameworks.[12−16] H_4BTEC is a building block that has been commonly adopted in the design of hybrids in connection with transition[17−21] and rare earth metal elements.[22−24] In the search for a further class of hybrid materials we have introduced a trivalent metal, namely indium(iii), in order to investigate the influence of a change in the metal centre on the coordination architecture during the course of the assembly of the metal centres with H_3BTC or H_4BTEC. It was postulated that the incorporation of trivalent metal ions might create diverse structures different from those containing divalent metal ions because of the increased valence charge. Furthermore, compared with the systematic and extensive studies on M^{II}-BTC complexes, reports of M^{III}-BTC complexes are rare.[25,26] Although some literature reports concerning M^{III}-BTEC complexes have recently appeared, the metal centres incorporated were mostly confined to the rare earth metal elements,[23,24] Fe^{III} [27] or V^{III}.[28] There is a deficiency of the selection of the ^{III}A group elements as inorganic linkers. We addressed this situation by choosing In^{III} as the metal and a series of 3D In^{III}-BTC and 3D In^{III}-BTEC complexes with protonated pyridine or pyridine derivatives as templates and counter anions have been synthesised. Herein we describe a 2D double-layered In^{III}-BTC compound $[In_2(BTC)_2(H_2O)_2]_n \cdot 2nH_2O$ (**1**) and a 3D In^{III}-BTEC compound $[In_2(H_2BTEC)_2(OH)_2]_n \cdot 2nH_2O$ (**2**) showing characteristic $In^{III}O_4(OH)_2$ octahedral chains.

Results and Discussion

The formation of compounds **1** and **2** was found to be extremely sensitive to the pH value of the reaction mixture. Synthetic studies were carried out using pyridine as a basic reagent to adjust the pH value in the reaction system. In both systems, a pH value between 2 and 3 is an essential condition for the formation of **1** and **2**. For the preparation of In^{III}-BTC, a pH value ranging from 3 to 4 produces a mixture of **1** and a 3D porous coordination polymeric compound.[29] Likewise, two phases (compound **2** and a 3D porous In^{III}-BTEC framework[30]) also crystallise concurrently from the reaction system of **2** when a pH value of 3−4 is maintained. In both reaction systems, more basic pH values led to predominant formation of the 3D porous by-prod-

ucts. Furthermore, when the reactions were carried out without pyridine as a basic reagent, the yields of **1** and **2** were very low. Thus, to ensure a high yield of **1** and **2**, an appropriate amount of pyridine is needed to adjust the pH value around 3.

Compound **1** exhibits a double-layer sheet configuration (Figure 1) generated from the interconnection of two single-layers which are produced from the extension of honeycomb-like grids along the (100) plane. Three In^{III} centres and three BTC trianions form such a 6-membered grid with dimensions of about 7.4 Å × 9.2 Å. Inside the grids, each indium atom binds to six carboxylate oxygen atoms from four BTC groups and one water oxygen atom (O7) to form a slightly distorted pentagonal bipyramidal motif. The dihedral angle between the benzene plane of the BTC group and the plane defined by In, InA, and InB is about 12.6°. Consequently, the sheet adopts a slightly wavy configuration. A bidentate carboxylate arm (C9−O5−O6) lies out of the BTC benzene ring plane with a dihedral angle as high as 26° such that the carboxylate arms act as the bridges linking two single-layers into a double-layer. The other two carboxylate arms bond in a chelating bidentate mode and participate in the propagation of the grids. The two single-layers are related to each other through the twofold screw symmetry operation and the distance between them is about 3.8 Å. Because of the translation operation of the screw axis, the available sizes of honeycomb-like grids are significantly reduced. This explains the fact that **1** absorbs little nitrogen gas even after dehydration.[31] To balance the charge, O7 can be considered to be a coordinated water oxygen atom. This assumption is confirmed by bond valence calculations for O7 which give a result of 0.5.[32] The

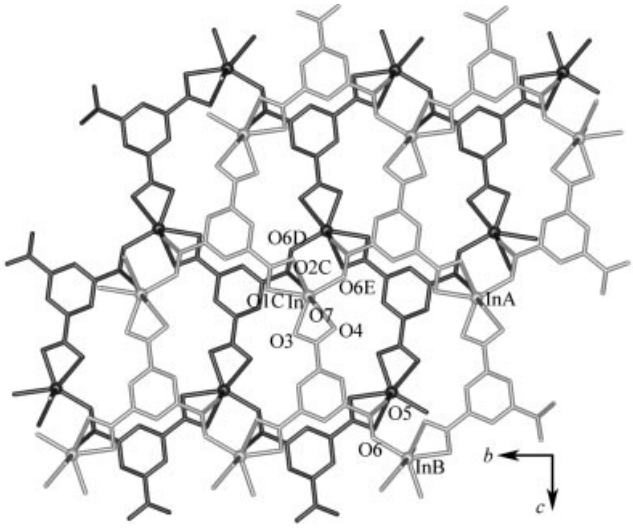

Figure 1. View of the double-layer in **1** interlinked by two single-layers displayed in black and light grey, respectively; free water and coordinated water molecules are not shown for clarity; selected bond lengths (Å): In−InA 8.979(1); In−InB 10.288(1); InA−InB 9.468(1); In−O7 2.167(3); In−O3 2.198(1); In−O4 2.292(1); In−O1C 2.271(3); In−O2C 2.304(4); In−O5D 2.138(5); In−O6E 2.144(3); selected bond angles (°): O7−In−O5D 178.0(1); O3−In−O7 89.0(1); O1C−In−O7 95.6(1); symmetry code: (A) x, $1 + y$, z (B) x, $1.5 - y$, $0.5 + z$ (C) x, $0.5 - y$, $-0.5 + z$ (D) $-x$, $-0.5 + y$, $0.5 - z$ (E) x, $1.5 - y$, $-0.5 + z$

In−O7 vectors are perpendicular to the double-layer plane and point towards the extra double-layer region. Furthermore, the double-layers are stacked in parallel separated by about 4 Å. This is sufficiently close such that the In−O7 vectors on the double-layers are interdigitated. Coordinated water oxygen atoms form strong hydrogen bonds with carboxylate oxygen atoms from adjacent double-layers [O7···O2A, 2.775(4) Å, (A):$1 - x$, $0.5 + y$, $0.5 - z$]. The free water molecules included in the honeycomb-like grids also form hydrogen bonds with the above coordinated water pendants of the double-layers [O8···O7, 2.679(7) Å]. Although some honeycomb structures have been found,[7,14,33] compound **1** is, to the best of our knowledge, unprecedented because of the double-layer conformation.

Compound **2** exhibits a 3D hybrid framework constructed from chains of corner-linked octahedra connected by carboxylate linkers (Figure 2). Each indium atom binds to four carboxylate oxygen atoms from four H_2BTEC groups and two other bridging oxygen atoms (O17 and O18) to form an octahedron. Bond valence calculations for O17 and O18 give a value of 1.3. Thus, the oxygen atoms (O17 and O18) can be considered to be μ-OH functions thereby balancing the negative charge in **2**. The octahedra are linked into infinite chains running along the [010] direction via μ-OH functions. Furthermore, two adjacent octahedra in one chain are bridged by two carboxylate arms from two different organic linkers. The octahedra are severely tilted and this is reflected by angles of 122.1(5)° (In1−O17−In1) and 122.2(5)° (In2−O18−In2), both being very far from the value 180° which would be expected if the chains of octahedra were perfectly linear. Each H_2BTEC group binds to four indium atoms, in a bidentate mode, situated in two different chains through the 1,5-carboxylate arms. The other two carboxylate arms are uncoordinated and protonated. Geometrically, the latter two carboxylate arms are coplanar with the phenyl ring whereas the other two are perpendicular to the phenyl rings. All phenyl rings are perpendicular to the directions of the chains. The chains are interweaved by organic linkers in such a way that the

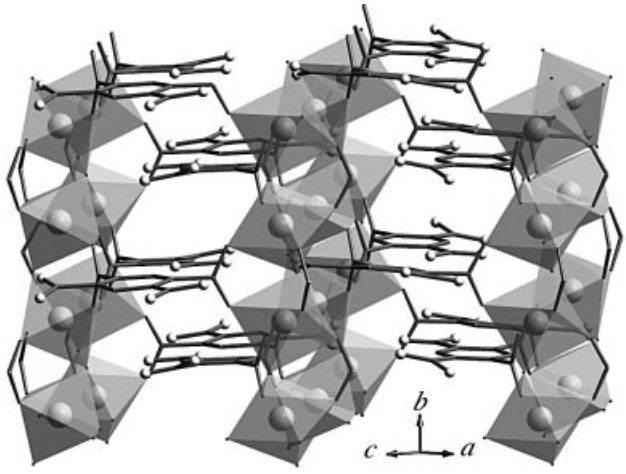

Figure 2. View of the interconnection between polyhedral chains and H_2BTEC groups in **2**; free water oxygen atoms are omitted for clarity

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

adjacent indium atoms in any chain are situated at approximately $y = 0$ and $y = 1/2$ while the phenyl rings located between two indium atoms are at approximately $y = 1/4$ on one side of the chain and $y = 3/4$ on the other side of the same chain (Figure 3). Such arrangement of metal and organic moieties is similar to that of the compound MIL-61.[28] These types of connections between the organic and inorganic moieties result in 1D polygonal tunnels. However, the uncoordinated carboxylic functions point towards these tunnels and reduce the effective sizes of the cavities. This helps understand why **2** absorbs little nitrogen gas even after dehydration.[31] Water molecules reside in the tunnels and give rise to hydrogen bonds with uncoordinated carboxylic functions [O19···O14 2.65(2) Å, O20···O5 2.629(8) Å, O19···O8A 2.859(4) Å, O20···O12B 2.915(3) Å. Symmetry code: (A) $-x$, $-0.5 + y$, $0.5 - z$; (B) $1 - x$, $1 - y$, $1 - z$].

Figure 3. The homogeneous nature of compounds **1** and **2** was shown by X-ray powder diffraction (XRPD) patterns (Figure 4). The powder patterns obtained experimentally for **1** (b) and **2** (e) are in agreement with the calculated patterns for **1** (a) and **2** (d), respectively. The exceptions are the lines at $2\theta = 16.5$ and 20.5° in **2** which are too intense in the experimental pattern. This phenomenon is a result of the preferred orientation of the crystallites.

The infrared absorption bands of **1** and **2** are listed in Table 1. In **1**, the absence of the characteristic bands at 1730−1690 cm^{-1} due to the protonated carboxylate groups indicates that complete deprotonation of H_3BTC occurs upon reaction with indium ions.[34] A strong absorption at 1731 cm^{-1} in **2** confirms the presence of the carboxylic acid function. Both results are in agreement with the crystallographic data.

Thermogravimetric (TG) analyses were carried out under air. The TG diagram (Figure 5) of **1** shows that the first weight loss of 10.1% occurring from about 50 °C to 167 °C

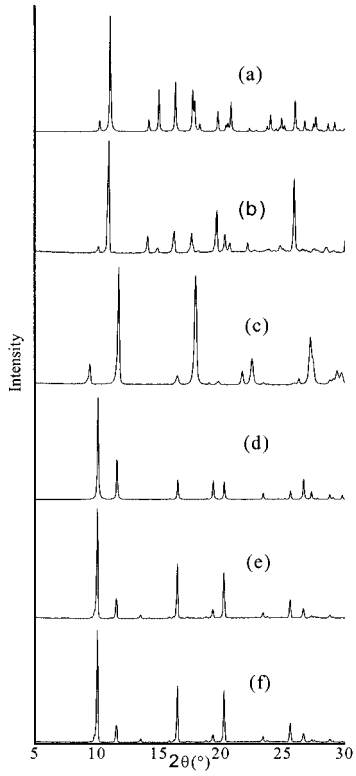

Figure 4. The calculated (a) and experimental (b) XRPD patterns for **1** and the calculated (d) and experimental (e) XRPD patterns for **2**; the patterns (c) and (f) correspond to the sintered samples at 180 °C for **1** and **2**, respectively

corresponds to the complete loss of free and coordinated water molecules (calculated: 10.1%), accompanied by the transformation of the framework of **1** indicated by the XRD pattern (see c in Figure 4). The second weight loss, occurring from about 424 °C to 554 °C, is the stage at which **1** dramatically loses its organic component. The light yellow

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

residue is In_2O_3 with a residual weight fraction of 38.4% (calculated: 38.8%). This was confirmed by XRD analysis.

Compound **2** also undergoes a two-step weight loss (Figure 5). The first weight loss of 4.53% from about 50 °C to 182 °C can be attributed to the loss of free water molecules (calculated: 4.48%). In contrast to compound **1**, XRD studies show that the framework of **2** remains intact after the loss of water molecules (see f in Figure 4). The second weight loss occurs in the temperature range of 380 to 570 °C, in which **2** dramatically loses weight and begins decomposing due to the loss of organic matter. The residue at 570 °C weighing 33.6% of the total is In_2O_3 (calculated: 34.53%). This was confirmed by XRD analysis.

Compounds **1** and **2** exhibit intense greenish-blue emissions in the solid state at 494 nm (λ_{ex} = 325 nm) for **1** and 489 nm (λ_{ex} = 337 nm) for **2**. Compared with the fluorescent analysis of other metal-BTC compounds,[33] we can assign the 494 and 489 nm emission bands to ligand-to-metal charge-transfer (LMCT) processes.

Experimental Section

Synthesis of $[In_2(BTC)_2(H_2O)_2]_n \cdot 2nH_2O$ (1): Compound **1** was synthesised hydrothermally from the reaction of $InCl_3$ (221 mg, 1 mmol), H_3BTC(210 mg, 1 mmol), pyridine (0.3 mL, 3.7 mmol) and H_2O (5 mL) (pH value 2−3) in a 30-mL Teflon-lined stainless steel vessel at 120 °C for 85 h. The reaction mixture was then cooled at a rate of 6 °C·h^{-1} to give the only product, namely colourless crystals of **1**. The crystals were collected and washed with *N*,*N*-dimethylformamide and distilled water. The yield was 85% (302 mg) based on $InCl_3$. Elemental analysis calcd. (found) for $C_9H_7InO_8$ (*fw* = 357.97): calcd. C 30.20 (30.17), H 1.97 (1.93). IR (KBr pellet [cm^{-1}]): $\tilde{\nu}$ = 3420 (vs, br), 3090 (m), 1619 (vs), 1583 (m), 1548 (s), 1441 (vs), 1384 (vs), 1114 (w), 1061 (w), 757 (s), 715 (m).

Synthesis of $[In_2(H_2BTEC)_2(OH)_2]_n \cdot 2nH_2O$ (2): Compound **2** was synthesised hydrothermally from the reaction of $InCl_3$ (221 mg, 1 mmol), pyromellitic dianhydride (218 mg, 1 mmol), pyridine (0.3 mL, 3.7 mmol) and H_2O (6 mL) (pH value = 2−3) in a 30-mL Teflon-lined stainless steel vessel at 160 °C for 85 h. The reaction mixture was then cooled at a rate of 6 °C·h^{-1} to give the only product, namely colourless crystals of **2**. The crystals were collected and washed with *N*,*N*-dimethylformamide and distilled water. The yield was 70% (280 mg) based on $InCl_3$. Elemental analysis calcd. (found) for $C_{20}H_{14}In_2O_{20}$ (*fw* = 803.95): calcd. C 29.88 (30.10), H 1.76 (1.80). IR (KBr pellet [cm^{-1}]): $\tilde{\nu}$ = 3489 (m, br), 3127 (m), 1731 (s), 1579 (vs), 1495 (m), 1444 (s), 1400 (vs), 1345 (m), 1275 (s), 1210 (s), 1047 (m), 796 (m).

Crystallographic Studies: The crystal data and structure determination parameters for **1** and **2** are listed in the Table 2.[35] Intensity data were collected on a Rigaku−Mercury CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation using the ω-2θ scan method at room temperature. The structures were solved by direct methods and all calculations were performed using the SHELXL-97 PC program. All nonhydrogen atoms were refined anisotropically. All hydrogen atoms were calculated in the ideal positions and refined isotropically. The structures were refined on F^2 using full-matrix least-squares methods.

Table 2. Crystallographic data for **1** and **2**.

Reactions of $K_2[Fe(CO)_3(PPh_3)]$: Reductive Sb−Sb Coupling with Ph_2SbCl To Form *trans*-$[Fe(CO)_3(PPh_3)(Sb_2Ph_4)]$ and Salt Metathesis with Me_3SbCl_2 To Yield *trans*-$[Fe(CO)_3(PPh_3)(SbMe_3)]$

Ingo-Peter Lorenz,*[a] Stefan Rudolph,[a] Holger Piotrowski,[a] and Kurt Polborn[a]

Dedicated to Professor Dr. Hubert Schmidbaur on the occasion of his 70th birthday

Keywords: Antimony / Coupling reactions / Iron / Metathesis

In contrast to the ferrate $K_2[Fe(CO)_4]$, the phosphane-substituted ferrate $K_2[Fe(CO)_3(PPh_3)]$ (**1**) reacts with the stibane derivative Ph_2SbCl by metal-assisted reductive Sb–Sb coupling to give the distibane complex *trans*-$[Fe(CO)_3(PPh_3)(Sb_2Ph_4)]$ (**3**). The distibane ligand in **3** is terminally η^1-coordinated *trans* to the phosphane ligand. However, the stiborane derivative Me_3SbCl_2 reacts with **1** in a metathetical substitution reaction to form the monostibane complex *trans*-$[Fe(CO)_3(PPh_3)(SbMe_3)]$ (**5**). Both compounds have been characterized by spectroscopic (IR, NMR, MS), analytical (C, H) and X-ray diffraction analyses.

Introduction

Molecules containing transition metal−phosphorus frameworks are among the most frequently reported in coordination and cluster chemistry. The most common examples show terminal metal−PR_3, -PR_2- and -PR- modular systems, as well as their metal-bridging analogs.[1] Simple diphosphanes of the type $R_2X-X-PR_2$ (X = CH_2, NH, O) considerably increase the potential variety and applicability of these compounds. While the analogous arsane and diarsane homologues exist in great numbers with similar structural motifs, analogous examples of antimony and bismuth species are much less common.[2,3] Weaker σ-donor and π-acceptor interactions in antimony and bismuth compounds may be a reason for this. Therefore, only monostibane and methylidene-bridged distibane complexes (X = CH_2) obtained by substitution reactions, as in the case of phosphorus and arsenic compounds, have been structurally characterized. Mixed bispentelane complexes with Sb participation are not, to the best of our knowledge, known.

We report here the synthesis and structural characterization of the distibane ligand Sb_2Ph_4 bound to iron; it is produced by a metal-assisted reductive Sb−Sb coupling reaction in the presence of a coordinated phosphane ligand (PPh_3). Thus, we have successfully synthesized the first η^1-(Sb_2Ph_4)-coordinated complex as well as a very rare example of a mixed bispentelane complex. We also report the synthesis of a second mixed bispentelane complex by the metathetical reaction of $K_2[Fe(CO)_3(PPh_3)]$ with Me_3SbCl_2.

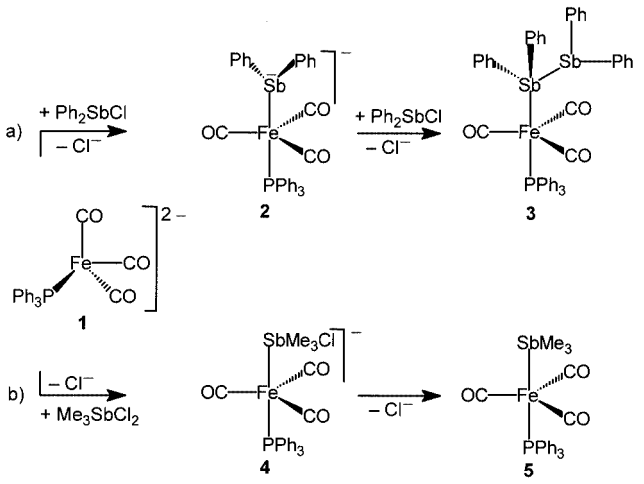
Results and Discussion

One synthetic route to pentelane complexes of iron(0) is the catalytic reaction of $Fe(CO)_5$ with the pentelanes ER_3 (E = P, As, Sb).[4−6] A similar route is the reaction of $Na_2[Fe(CO)_4]$ with one equivalent of Ph_2ECl (E = P, As), which gives first the monosubstituted ferrate $Na[Fe(CO)_4(EPh_2)]$ and then, upon reaction with a second equivalent of Ph_2ECl, the neutral dipentelane complex $[Fe(CO)_4(E_2Ph_4)]$ by E−E coupling.[7] Thus, mixed phosphanylarsane complexes can be obtained. Attempts to form distibane complexes of iron(0) have thus far been unsuccessful. Similarly, the reaction of the phosphane-substituted ferrate $K_2[Fe(CO)_3(PPh_3)]$ (**1**) with two equivalents of Ph_2SbCl proceeds with elimination of KCl to yield the first η^1-coordinated tetraphenyldistibane ligand by ferrate-assisted reductive Sb−Sb coupling of two Ph_2SbCl molecules. The resulting complex, *trans*-$[Fe(CO)_3(PPh_3)(Sb_2Ph_4)]$ (**3**), was structurally characterized by X-ray analysis.

The first mononuclear distibane complexes of the type $[M(CO)_5(Sb_2R_4)]$ (M = Cr, W; R = CH_3, C_2H_5, C_6H_5) were synthesized by photochemically induced substitution of $M(CO)_6$ (in THF) with the intact distibanes, but were only spectroscopically characterized.[8] The analogous diphosphane complexes, however, have already been synthesized and structurally characterized by Vahrenkamp et al.[9,10]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200400683

In our case, the distibane molecule is synthesized from monostibane derivatives bound to a metal by template-control and is incorporated as an η^1-bound ligand *trans* to the PPh_3 ligand (see a in Scheme 1). Attempts to obtain mixed bispentelane complexes of the type $R_3EFe(CO)_3E'R_3$ were previously unsuccessful because of symmetrization reactions.



Scheme 1. Synthesis of **3** and **5**

The reductive Sb−Sb coupling reaction of **1** is similar to the Wurtz reaction and proceeds by two steps: electrophilic attack on the iron(II−) center of **1** by the first stibane (Sb^{3+}), followed by elimination of KCl. The monoanionic stibane complex **2**, with the negative charge located mainly on antimony, may be formed as an intermediate. As a result, the electrophilic attack of the second stibane occurs at the coordinated antimony, and leads to the formation of a neutral tetraphenyldistibane complex, **3**, with one Fe(0) and two Sb^{II} centers, and thus the formal redox reaction is completed.

The energy (1883 cm^{-1}) of the single ν(CO) absorption in the IR spectrum of **3** (*E′* symmetry) is similar to the single ν(CO) absorption of the symmetrical species *trans*-$[Fe(CO)_3(PPh_3)_2]$ (1886 cm^{-1}).[11] The signal in the $^{31}P\{^1H\}$ NMR spectrum of **3** is found at δ = 86.4 ppm. The ^1H and $^{13}C\{^1H\}$ NMR spectra show only the multiplets due to the phenyl protons (δ = 7.26−7.59 ppm) and phenyl-C atoms (δ = 126−131 ppm), in addition to one signal for the CO ligand (δ = 212 ppm).

If the ferrate **1** is treated with an excess of the stiborane derivative Me_3SbCl_2 no coupling reaction occurs; instead, a simple salt-metathesis reaction results in the formation of the novel mixed-dipentelane complex *trans*-$[Fe(CO)_3(PPh_3)(SbMe_3)]$ (**5**). As in the case of **3**, the formation of **5** can also occur via the intermediate **4**, which is formed by an electrophilic attack of Me_3SbCl^+ on the nucleophilic ferrate dianion (Scheme 1b).

The spectroscopic data of **5** (IR: ν(CO) = 1877 cm^{-1}; $^{31}P\{^1H\}$ NMR: δ = 85.5 ppm) are similar to those of **3**, except for the methyl-group signals in the NMR spectra (^1H NMR: δ = 1.31 ppm; $^{13}C\{^1H\}$ NMR: δ = 40.1 ppm).

Comparison of **3** and **5** is best achieved by single-crystal X-ray diffraction analysis.[12] Relevant bond lengths and angles are tabulated in the legends of the corresponding figures. As expected, the Fe center is trigonal-bipyramidally configured with the phosphane and distibane ligands in *trans*-axial positions. The Fe1−P1 and Fe1−Sb1 bond lengths are 2.188(2) and 2.457(1) Å, respectively, and the P1−Fe1−Sb1 bond angle of 177.99(6)° indicates a nearly linear P1−Fe−Sb1 arrangement (Figure 1). The three CO ligands surround the central iron in a trigonal planar grouping with the sum of angles at Fe(1) being exactly 360°. As Figure 2 shows, the Sb_2Ph_4 ligand exists in the gauche conformation, and differs by approximately 4° from the *trans* conformation. The Sb1−Sb2 bond length of 2.828 Å is slightly shorter than that of the free stibane Sb_2Ph_4 (2.844 Å).[13] The $Sb-C_{Ph}$ bond lengths around the two Sb centers are quite different. The bonds to Sb1 are 2.130(6) and 2.132(7) Å, whereas bonds to Sb2 are distinctly longer [2.138(9) and 2.145(7) Å], although both pairs are shorter than those in free tetraphenyldistibane (2.16 and 2.18 Å). Both Sb centers show a strongly distorted tetrahedral configuration. The steric demand of the nonbonding Sb2 MO

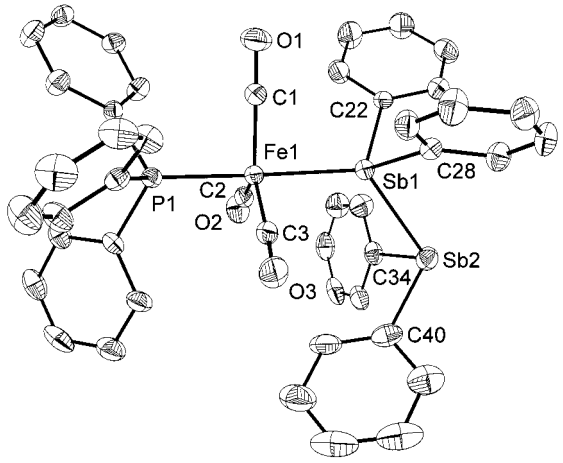


Figure 1. Molecular structure of **3** in the solid state; selected bond lengths (Å) and angles (°): Fe1−P1 2.188(2), Fe1−Sb1 2.457(1), Sb1−Sb2 2.8282(7), Fe1−C1 1.752(7), Fe1−C2 1.758(7), Fe1−C3 1.776(8), Sb1−C22 2.130(6), Sb1−C28 2.132(7), Sb2−C40 2.138(9), Sb2−C34 2.145(7); P1−Fe1−Sb1 177.99(6), Fe1−Sb1−Sb2 125.62(3), C1−Fe1−C2 119.6(3), C1−Fe1−C3 118.3(3), C2−Fe1−C3 122.1(3), C22−Sb1−C28 100.5(2), C22−Sb1−Sb2 98.6(2), C22−Sb1−Fe1 113.7(2), C28−Sb1−Fe1 114.5(2), C28−Sb1−Sb2 100.0(2), C40−Sb2−C34 98.4(3), C40−Sb2−Sb1 94.9(2), C34−Sb2−Sb1 98.1(2)

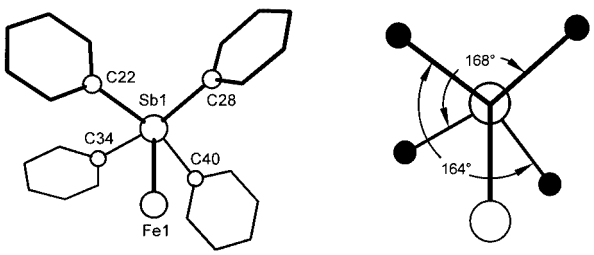

Figure 2. Conformation of the Sb_2Ph_4 ligand in **3** [Newman projection along the Sb1−Sb2 axis with dihedral angles (°)]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

leads to an 11−14° reduction of the bond angles compared to those of coordinated Sb1. In the same fashion, the Fe(CO)$_3$(PPh$_3$) group bound to Sb1 forces a greater deformation from an ideal tetrahedral configuration about Sb1, with the Fe1−Sb1−Sb2 angle of 126° differing most of all.

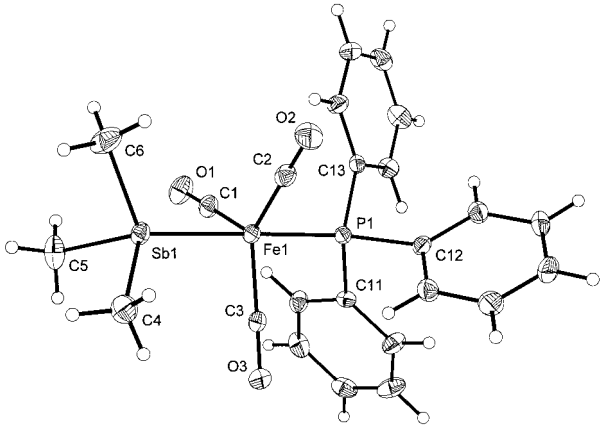

Figure 3. Molecular structure of **5** in the solid state; selected bond lengths (Å) and angles (°): Fe1−P1 2.199(1), Fe1−Sb1 2.463(6), Fe1−C1 1.769(5), Fe1−C2 1.778(5), Fe1−C3 1.778(4), Sb1−C4 2.094(5), Sb1−C5 2.118(5), Sb1−C6 2.114(5), P1−C_{Ph} 1.835(4); P1−Fe1−Sb1 177.56(4), C1−Fe1−C2 121.8(2), C1−Fe1−C3 119.5(2), C2−Fe1−C3 118.4(2), C4−Sb1−Fe1 116.62(15), C5−Sb1−Fe1 117.54(15), C6−Sb1−Fe1 118.46(16), C_{Ph}−P1−Fe1 ca. 115.7, C_{Ph}−Fe1−C5 ca. 102.6

The molecular structure of **5** (Figure 3) is similar to that of **3**; the analogous bond lengths and angles at the central iron are practically identical. The Newman projection of **5** shows the almost perfectly staggered conformation of the Me, CO, and Ph substituents along the Sb1−Fe1−P1 axis (Figure 4).

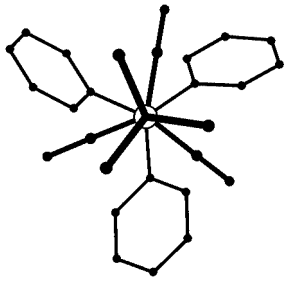

Figure 4. Newman projection of **5** along the Sb1−Fe1−P1 axis

Our new reductive Sb−Sb coupling reaction of two molecules of Ph$_2$SbCl to give the η^1-ligand Sb$_2$Ph$_4$ in **3** is explained by the presence of [Fe(CO)$_3$(PPh$_3$)]$^{2-}$ (**1**) (as suitable reducing agent) and by the activating and at the same time stabilizing effect of the complex fragment Fe(CO)$_3$(PPh$_3$). The *trans*-directing influence of PPh$_3$ may also play a positive role in the formation of the mixed dipentelane complex **3**. An analogous effect is also found in the reaction of **1** with the stiborane Me$_3$SbCl$_2$ to give **5**. However, in the case of the nonsubstituted ferrate Na$_2$[Fe(CO)$_4$], the corresponding Sb−Sb coupling reaction and distibane formation, as well as Fe−Sb bond formation, are not possible. When the monoanionic metalates [CpM(CO)$_n$]$^-$ (M = Fe, n = 2; M = Mo, W, n = 3) are reacted with Me$_2$SbBr, for example, a simple salt-metathesis reaction to form the metallostibanes [{Cp(CO)$_n$M}SbMe$_2$] is observed.[14] An Sb−Sb coupling reaction similar to the Wurtz reaction was recently reported in the reaction of Ph$_2$SbI with the metals Sm or Y in THF.[15] Further investigations with respect to the general application of this simple and elegant synthesis using other substituted phosphanes (PR$_3$ where R ≠ Ph) or coupling different pentelanes [e.g. Sb−E (E = P, As)] are in progress.

Experimental Section

All operations were carried out under an Argon atmosphere with complete exclusion of oxygen and moisture (Schlenk techniques). Solvents were dried and then saturated with argon. The following instruments were used for the spectroscopic and analytical measurements: IR: Nicolet 520 FT-IR spectrometer. ^{31}P NMR: Jeol 6SX

270 (85% H_3PO_4 as standard). X-ray analysis: ENRAF-Nonius CAD 4-diffractometer and Nonius Kappa CCD-diffractometer. Elemental analysis: Elementar vario EL (W. C. Heraeus). Melting Print: Büchi-510 (m.p. were not corrected).

Synthesis of 3: $K_2[Fe(CO)_3(PPh_3)]$ (**1**; 124 mg, 0.259 mmol) and Ph_2SbCl (353 mg, 0.518 mmol) were dissolved in 10 mL of THF, upon which the solution immediately turned deep red. After stirring for 2 h and filtering, the solvent was distilled off in vacuo to yield a viscous brownish oil. Repeated recrystallization from CH_2Cl_2/*n*-hexane resulted in a microcrystalline solid, which was dried in vacuo. Yield: 154 mg (63%), orange brown crystals, m.p. 137 °C. IR (KBr): ν(CO) = 1883 cm^{-1}. ^{13}C NMR ([D_6]acetone): δ = 126−131 (Ph), 212 (CO) ppm. $^{31}P\{^1H\}$ NMR: δ = 86.4 ppm. $C_{46}H_{37}FeO_3PSb_2$ (954.09): calcd. C 57.9, H 3.9; found C 57.9, H 3.8.

Synthesis of 5: $K_2[Fe(CO)_3(PPh_3)]$ (**1**; 275 mg, 0.573 mmol) was dissolved in 20 mL of THF containing Me_3SbCl_2 (136 mg, 0.573 mmol). The color of the solution changed to red, and a fine, light-colored precipitate of KCl formed. After stirring for 2 h and careful decantation, the solvent was distilled off in vacuo. The red-brown residue was recrystallized several times to give analytically pure **5**. Yield: 179 mg (55%), red-brown crystals, m.p. 121 °C. IR (KBr): ν(CO) = 1877 cm^{-1}. ^1H NMR ([D_6]acetone): δ = 1.31 (s, 9 H, Me), 7.22−7.63 (m, 15 H, Ph) ppm. $^{13}C\{^1H\}$ NMR ([D_6]acetone): δ = 40.1 (s, Me), 126−131 (m, Ph), 209 (s, CO) ppm. $^{31}P\{^1H\}$ NMR ([D_6]acetone): δ = 85.5 ppm. $C_{24}H_{24}FeO_3PSb$ (567.99): calcd. C 50.7, H 4.3; found C 51.6, H 3.7.

Nonquenchable Chemical Order−Disorder Phase Transition in Yttrium Oxyfluoride

Igor Levin,*[a] Qing Z. Huang,[a] Lawrence P. Cook,[a] and Winnie Wong-Ng[a]

Keywords: Phase transitions / Yttrium / X-ray diffraction / Order−disorder transitions

A chemical order–disorder polymorphic phase transition in yttrium oxyfluoride (YOF) was studied in situ by X-ray and neutron powder diffraction. The high-temperature form of YOF crystallizes with a cubic $Fm\bar{3}m$ fluorite structure in which the O and F atoms are disordered among the tetrahedrally coordinated sites. The low-temperature form of YOF exhibits rhombohedral $R\bar{3}m$ symmetry and evolves from the high-temperature form by the phase transition associated with the ordering of the O and F atoms. The transition occurs around 560 °C. The superstructure contains layers of $[OY_4]$ and $[FY_4]$ tetrahedra alternating along the *c*-axis of the trigonal cell (parallel to the <111> direction of the parent cubic structure). The ordering of the O and F atoms is accompanied by the significant displacements of the Y, O, and F atoms from their ideal positions in the cubic phase. Bond valence sum calculations indicate considerable bond strain for both O and F in the cubic structure; the strain is relieved in the ordered low-temperature phase. The order–disorder transition in YOF is completely reversible and exhibits fast nonquenchable kinetics.

Introduction

Phase equilibria in the Ba−Cu−Y−F−O system have become the subject of intensive investigation after the BaF_2−Cu−Y precursor films, deposited on RABiTS and annealed in water vapor, demonstrated the potential for producing high quality $Ba_2YCu_3O_{6+x}$ (Y-213) superconductor tapes.[1] One of the critical questions in studies of phase equilibria in this system concerns the existence of the transient fluorine-containing low-temperature melts, which could control formation of the Y-213 phase. Recent systematic studies of melting temperatures in the $BaF_2-YF_3-Y_2O_3-CuO_x$ subsystem using differential thermal analysis (DTA) showed a peak at T = 560 °C that could be attributed to such a transient melt.[2] However, subsequent analyses of these samples using variable-temperature X-ray powder diffraction demonstrated that this DTA event is associated with a nonquenchable phase transition in the stoichiometric yttrium oxyfluoride.[2] The crystal structure of YOF has been studied previously.[3,4] Zachariasen[3] reported both rhombohedral and tetragonal room-temperature forms of YOF. The tetragonal form is stabilized by the excess fluorine and occurs for the compositions YO_nF_{3-2n} with $0.7 < n < 1.0$, whereas the rhombohedral structure is stable for the stoichiometric composition with n = 1. Both structures have been described as derivatives of the cubic fluorite archetype with the ordering of oxygen and fluorine atoms into distinct tetrahedrally coordinated sites. Later X-ray diffraction studies by Bevan and Mann[4] confirmed the rhombohedral structure of stoichiometric YOF with the space group $R\bar{3}m$ (a = 3.797 Å, c = 18.89 Å). Zachariasen[2] has alluded to the potential existence of the disordered high-temperature cubic fluorite phase; however, all attempts to quench the cubic form were unsuccessful. Later studies[3−7] confirmed the existence of the rhombohedral ⇄ cubic phase transition in YOF at 560−570 °C, but provided few details on the evolution of structural parameters upon this phase change. In the present contribution, we report a detailed study of such nonquenchable order−disorder phase transition in stoichiometric YOF as analyzed in situ by variable-temperature X-ray and neutron powder diffraction.

Results and Discussion

The room temperature X-ray powder diffraction patterns of YOF, both slowly cooled and quenched from 600 °C, were completely indexable according to the rhombohedral (R) unit cell with lattice parameters a_R = 3.800(5) Å and c_R = 18.863(9) Å. In addition to the major YOF phase, the sample contained small amounts of Y_2O_3. As the Y_2O_3 reflections do not overlap with those of YOF, they do not affect the refinement of the YOF structure and were excluded from the analysis. In situ studies of the YOF sample with high-temperature X-ray diffraction revealed a reversible phase transformation to a cubic (C) structure as inferred from the disappearance of the rhombohedral reflec-

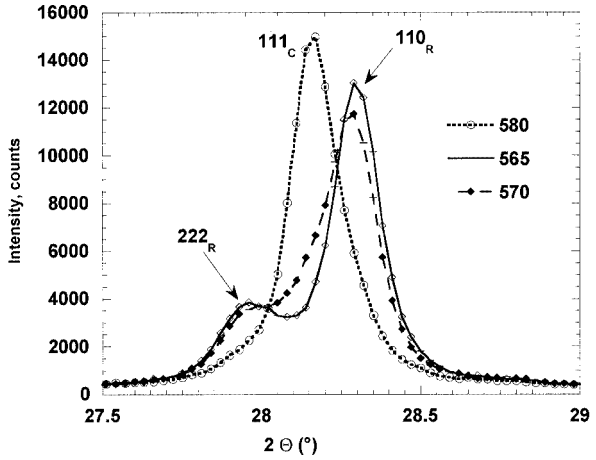

Figure 1. Evolution of the $222_R/110_R$ and 111_c reflections upon heating/cooling across the rhombohedral ⇄ cubic transition during in situ X-ray powder diffraction measurements

tion splitting (Figure 1). The transition occurred at $T_0 \approx$ 575 °C, which is in reasonable agreement with T_0 = 565 °C deduced from the DTA measurements (Figure 2).

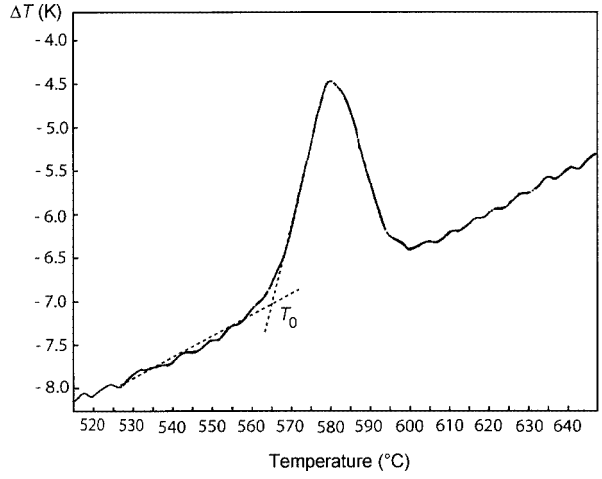

Figure 2. DTA plot for YOF; the transition temperature was determined from the extrapolated intersection of the baseline with the linear portion of the rising peak

Structural refinements using neutron powder diffraction data (Table 1, Figure 3, a) and the initial atomic positional parameters from ref.[4] confirmed that the low-temperature

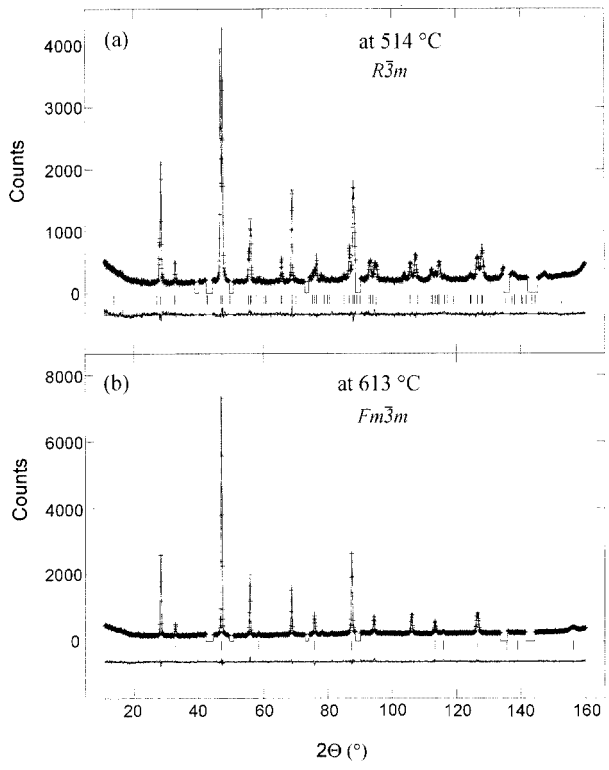

Figure 3. (Upper) Experimental (crosses) and calculated (line) neutron powder diffraction profiles of YOF acquired at a) 514 °C (rhombohedral phase), and b) 613 °C (cubic phase); regions containing reflections of the impurity phase were excluded from the fit; (lower) residual; the fitting reliability parameters are R_{wp} = 6.22%, χ = 1.18 for T = 514 °C, and R_{wp} = 6.32, χ = 1.20 for T = 613 °C

YOF polymorph crystallizes with a rhombohedral $R\bar{3}m$ superstructure. The superstructure features layers of [FY_4] and [OY_4] tetrahedra alternating along the c_R-axis (Figure 4). The atomic positional and displacement parameters refined for T = 514 °C are summarized in Table 2. In the rhombohedral structure, all three species, Y, O, and F, exhibit appreciable displacements (v_Y = 0.0082c_R, v_F =

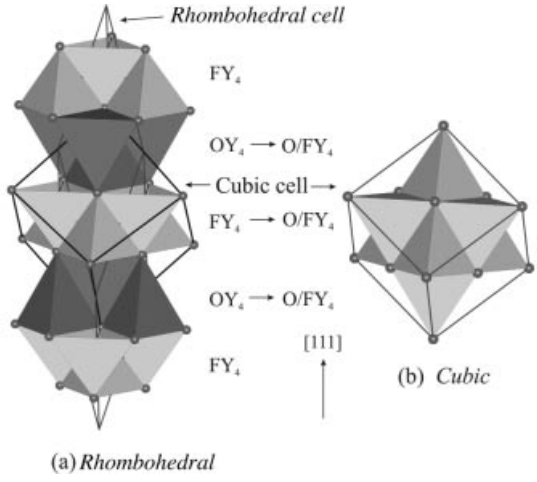

Figure 4. Schematic representation of the refined YOF rhombohedral (left) and cubic fluorite (right) structures

$0.0052c_R$, $v_O = 0.0039c_R$) from the ideal positions in the cubic fluorite; the displacements occur along the *c*-axis, which is parallel to the $<111>_c$ direction of the cubic fluorite. The resulting Y−F bond distances (2.435 Å and 2.4412 Å) are significantly longer than the corresponding Y−O distances (2.297 Å and 2.2763 Å). Refinements of anisotropic temperature parameters did not reveal any significant anisotropy of displacements and produced little effect on the quality of the fit; therefore, in the final refinement run, the temperature parameters were assumed to be isotropic. As the site occupancies refined for the O and F positions were within the estimated standard uncertainties (2%) from the ideal values of unity, both positions were assumed to be fully occupied. Both $[FY_4]$ and $[OY_4]$ tetrahedra are appreciably distorted (Figure 5) as seen from comparison of both Y−F−Y (115.4°/103.0°) and O−Y−O (114.1°/104.3°) angles with a value of 109.47° in a perfect tetrahedron.

Table 2. Selected bond distances, and calculated BVS values for the YOF polymorphs

2.3611(1)	2.3611(10)
BVS = 1.16 v.u.	*BVS* = 1.57 v.u.
Average *BVS* = 1.37 v.u.	

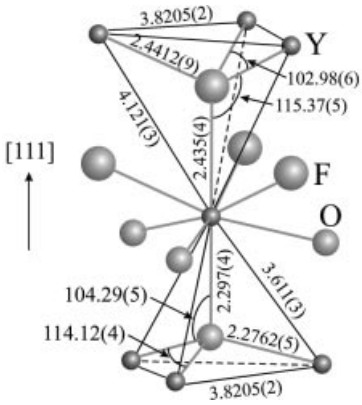

Figure 5. Coordination environment of the Y atoms in the YOF rhombohedral structure at 514 °C; selected bond distances and angles are indicated

Heating the YOF sample in situ during the neutron diffraction measurements caused a reversible phase transition to the cubic structure (Figure 6); the transition temperature T = 520 °C in the neutron experiments is lower than that determined with both DTA and X-ray diffraction. The lower value of T_0 from the neutron measurements was attributed to the temperature gradient in the furnace (up to 10 °C) combined with slow conduction of heat from the vacuum of the furnace through the container wall to the YOF powder. The neutron diffraction patterns recorded at T = 500 °C and T = 540 °C (on the thermocouple) contained single rhombohedral and cubic phases, respectively. In contrast, the neutron diffraction pattern recorded at 520 °C contained a two-phase mixture. Given the nonquenchable kinetics of the rhombohedral ⇄ cubic phase transition, the coexistence of these two phases at T = 520 °C for a prolonged time was attributed to thermal gradients across the relatively large neutron sample. The temperature dependence of the lattice parameters refined for the YOF polymorphs is summarized in Figure 7. The rhombohedral ⇄ cubic transition appears to be a first-order transition and is accompanied by a volume change of about 0.6%.

A structural model based on the ideal cubic fluorite structure (space group $Fm\bar{3}m$) with a disordered mixture of F and O atoms on the fourfold coordinated sites (Table 2) provided a satisfactory fit to the experimental data at T =

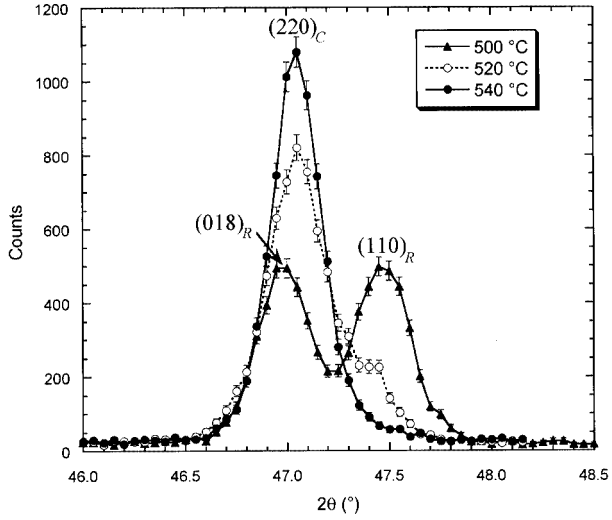

Figure 6. Evolution of the $110_R/108_R$ and 220_c neutron reflections upon heating/cooling across the rhombohedral ⇄ cubic transition; at T = 520 °C (on the thermocouple) a two-phase mixture is observed, presumably due to the thermal gradients in the sample

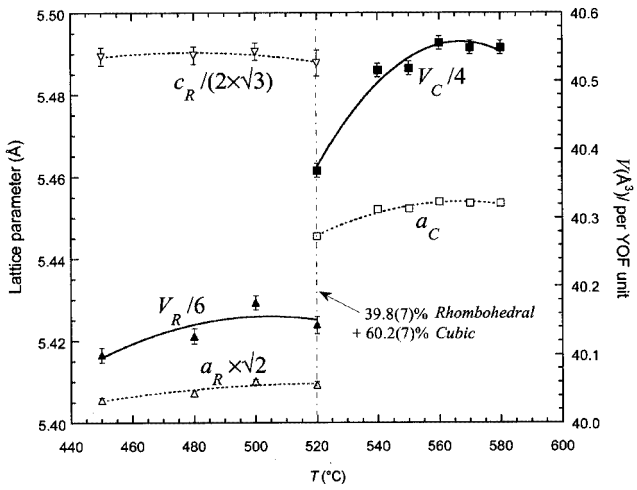

Figure 7. Temperature dependence of the lattice parameters for the rhombohedral and cubic phase; a significant volume change upon the rhombohedral ⇄ cubic transition is observed

613 °C (see b in Figure 3). The symmetries of the high-temperature cubic and low-temperature rhombohedral phases obey a group−subgroup relation.

Bond valence sum (BVS) calculations for this cubic structure indicate strong under- and over-bonding for the O and F atoms, respectively, whereas the bond requirements for Y are closely satisfied. Such strong deviations from the ideal BVS values suggest the existence of *local* atomic displacements in the cubic structure aimed to accommodate the bonding requirements of the O and F atoms. Indeed, values of the temperature/displacement parameters for the Y and O atoms increased discontinuously upon transition to the cubic phase (Figure 8), which can be attributed to disordered local displacements of these atoms from their ideal positions in the cubic structure. Interestingly, temperature parameters for the over-bonded F atoms displayed no evidence for such local displacements. In contrast to the cubic phase, the low-temperature rhombohedral phase features nearly ideal BVS values for both O and F atoms. The BVS analyses suggest that simultaneous satisfaction of the bonding requirements for the O and F atoms, which cannot be achieved in the ideal cubic fluorite arrangement, provides a driving force for the O/F ordering and the associated ion displacements. Fast nonquenchable kinetics for the O/F order−disorder transition in YOF can be attributed to the high anion mobility often observed in fluorite-based ion conductors.

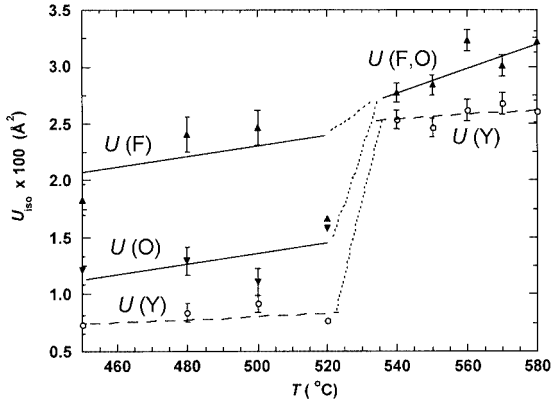

Figure 8. Temperature dependence of the isotropic temperature/displacement parameters, U_{iso}, for the Y, O, and F atoms in the YOF polymorphs; the U_{iso} parameters for both Y and O, but not F, exhibit a discontinuous increase upon the rhombohedral ⇄ cubic transition; such an abrupt increase in the magnitude of U_{iso} suggests the presence of local disordered displacements of both Y and O atoms in the cubic phase

Conclusions

YOF crystallizes with two polymorphs separated by the F/O order−disorder phase transition at T = 560 °C. The high-temperature form features a cubic $Fm\bar{3}m$ fluorite structure − the O and F atoms are disordered on the tetrahedrally coordinated sites. The ordering of F and O atoms upon transition to the low-temperature phase yields rhombohedral $R\bar{3}m$ symmetry and the lattice parameters $a_R \approx a_C/\nu 2$, $c_R \approx 2a_C\nu 3$. This fluorite-based superstructure contains layers of $[OY_4]$ and $[FY_4]$ tetrahedra alternating along the *c*-axis of the trigonal cell (parallel to the <111> direction of the parent cubic structure). The ordering of the O and F atoms is accompanied by the displacements of the Y, O, and F atoms from their ideal positions in the cubic phase. Bond valence sum calculations indicate considerable bond strain for both O and F in the cubic structure. The refinements suggest significant local displacements for the O and Y atoms (but not F), which are likely aimed to satisfy the bonding requirements of the anions. The bond strain about both O and F is relieved in the ordered low-temperature phase. The order−disorder transition in YOF is reversible and exhibits fast nonquenchable kinetics.

Experimental Section

Polycrystalline samples of YOF were prepared using powders of Y_2O_3 (Alfa Industries, lot # 093080, 99.999% purity, metals basis) and anhydrous YF_3 packed under Ar (Alfa Aesar lot # D10 K11, 99.9% purity, metals basis). Prior to use, the Y_2O_3 was preheated at 600 °C for 1 h to remove moisture. A 5-g mixture of Y_2O_3 and YF_3 in equimolar proportion was weighed in an Ar-filled glovebox with a continuously recirculating purifier, which removed contaminants to <1 ppm by volume. The powder mixture was transferred to a thermoanalyzer and annealed overnight at 500 °C in flowing Ar; the powder was contained in a platinum-lined crucible to prevent any reaction of YF_3 with the ceramic crucible. This procedure was repeated with intermediate grindings five times. The total mass lost during synthesis was 0.4 wt.-%.

Simultaneous differential thermal analysis/thermogravimetric analysis (DTA/TGA) experiments were completed in a Mettler TA1 thermoanalyzer outfitted with Anatech digital control and data acquisition electronics. DTA crucibles were fabricated from high purity Pt tubing, and experiments were conducted at a ramp rate of 10 °C/min. Phase-transition onset temperatures during heating were determined from extrapolated intersection of the baseline with the linear portion of the rising peak. The DTA apparatus was calibrated against the α→b quartz transition (571 °C) and the NaCl melting point (801 °C); DTA temperatures were estimated to have < ±3 °C standard uncertainty.

High-temperature X-ray diffraction (HTXRD) measurements were conducted in a Siemens 5000 θ−θ diffractometer equipped with a high-temperature furnace and a position sensitive detector. Cu-K_α radiation was used. The samples were prepared by applying a thin layer of powder (finely ground as an ethanol slurry) to a Pt heating band. The X-ray diffraction experiments were conducted under He gas flow.

Neutron powder diffraction data for Rietveld analysis were collected on the BT1 diffractometer at the Center for Neutron Research at the National Institute of Standards and Technology, using a Cu(311) monochromator with a wavelength of 1.5402(2) Å, and an array of 32 He-3 detectors at 5° intervals. Collimation of 15′, 20′, and 7′ arc were used before and after the monochromator, and after the sample, respectively. The YOF sample was held in a vanadium cylindrical sample container and heated in a furnace under vacuum. The data were collected over the 2θ range 3−168 ° at 11 temperatures between 450 °C and 613 °C. The GSAS package[8] was used for Rietveld structural refinements.

Bioorganometallic Chemistry: Reactions of Methyltitanocene Cation Complexes with a Singly Deprotected Methyl Glucopyranoside

Birgit Meyer zu Berstenhorst,[a] Gerhard Erker,*[a] Gerald Kehr,[a] Julia-Christina Wasilke,[a] Jens Müller,[a] Hartmut Redlich,[a] and Jutta Pyplo-Schnieders[a]

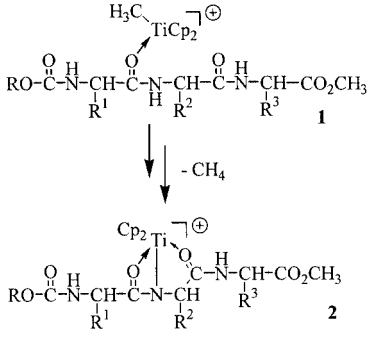
Keywords: Carbohydrate complexes / Titanocene / Zirconocene / Lewis acid / Chelate complexes / Bioorganometallic chemistry

The dimethyltitanocene/$B(C_6F_5)_3$ system reacts with the 4-unprotected methyl α-D-glucopyranoside derivative **5** ("HO-carb.") to yield the ionic complex $[Cp_2Ti(O\text{-carb.})]^+[MeB(C_6F_5)_3]^-$ (**10a**). Spectroscopic studies have led us to believe that **10a** is characterized by an internal ether-chelate structure in solution that involves coordination of the 6-OCH_2Ph oxygen atom. Treatment of **10a** with trimethylphosphane gives the open, non-chelated complex **11a**, in which the phosphane coordinates to the metal center. Reaction of the THF-stabilized salt $[Cp_2TiCH_3(THF)]^+[BPh_4]^-$ (**12a**) with **5** gave complex **13a**, with coordinated THF. Experiments with bis(methylcyclopentadienyl)titanium systems gave analogous results (complexes **10b**, **11b** and **13b**). Zirconocenes react differently. Addition of dimethylzirconocene (**14a**) or dimethylbis(methylcyclopentadienyl)zirconium (**14b**) to **5** gave the neutral complexes **15a**, **15b** and methane. Treatment of **15a** (**15b**) with $B(C_6F_5)_3$ again resulted in the formation of an ionic chelate complex **16a** (**16b**). A non-chelated complex **18** was formed by treating the THF-stabilized salt $[Cp_2ZrCH_3(THF)]^+[BPh_4]^-$ (**17**) with **5**.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Titanocene dichloride is a potent anti-cancer agent.[1,2] In contrast to other metal-containing anti-cancer drugs, such as, for example, the "cisplatinum" derivatives, the mechanism of the biological action of $[Cp_2TiCl_2]$ and its congeners has remained less understood,[3a,3b] but it seems to be different from that of the cisplatinum cancerostatica.[3c−3f] Therefore, it is of interest to learn about the chemistry that titanocene derivatives and similar compounds undergo with typical "bio-molecules".[4] For carrying out such model reactions and for monitoring their mechanistic course, the use of the corresponding methyl-Group 4 metallocene derivatives have been of advantage, although they are not the actual biologically active in vivo species.

We have recently shown that, e.g., methyltitanocene cation reacts quite selectively with a variety of oligopeptide derivatives.[5,6] The $[Cp_2TiMe]^+$ molecule was shown to add preferentially to specific internal carbonyl positions of, e.g., a tripeptide under kinetic control (see Scheme 1). Under thermodynamic control it then migrates along the peptide chain. Eventually, it binds to specific favored positions at the chain by means of deprotonation with evolution of methane.[5]



Scheme 1

We have now begun to carry out similar studies on the reactions of methyl titanocenes and related compounds with another important class of biomolecules, the carbohydrates.[7] In an initial series of experiments we have treated a variety of methyltitanocene complexes with a suitably protected glucopyranoside derivative that contained a single active −OH group. Reactions were carried out with titanocene and zirconocene derivatives and were shown to feature some remarkable differences.

Results and Discussion

We have employed methyl 2,3,6-tri-*O*-benzyl-α-D-glucopyranoside (**5**) as the carbohydrate reagent for this study.

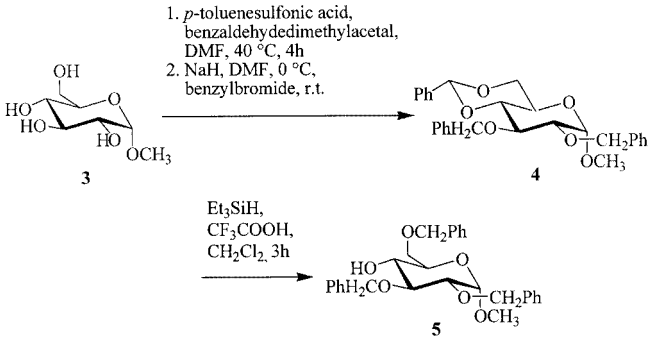
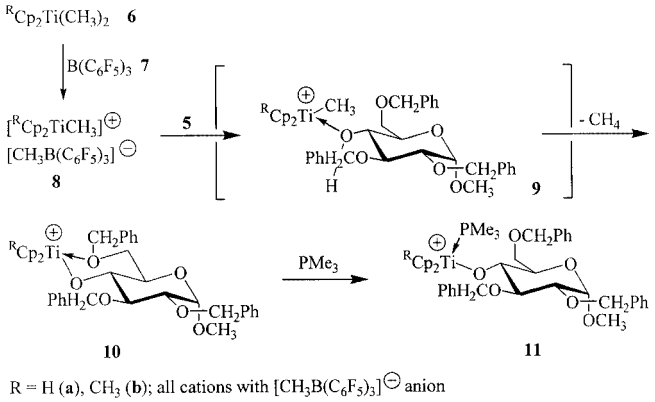


Scheme 2



R = H (**a**), CH_3 (**b**); all cations with $[CH_3B(C_6F_5)_3]^{\ominus}$ anion

Scheme 3

It was synthesized as depicted in Scheme 2.[8] Treatment of methyl α-D-glucopyranoside (**3**) with 2 equiv. of benzaldehyde dimethyl acetal and 0.2 equiv. of *p*-toluenesulfonic acid led to the 4,6-*O*-benzylidene acetal of glucose. The raw product was deprotonated by using sodium hydride in mineral oil at 0 °C for 2 h. Reaction with benzyl bromide, overnight at room temperature, gave the methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside **4**. Regioselective reductive cleavage of the acetal function to generate the 4-unprotected carbohydrate derivative was carried out by using triethylsilane in the presence of trifluoroacetic acid. Chromatographic workup eventually gave methyl 2,3,6-tri-*O*-benzyl-α-D-glucopyranoside (**5**) with an unprotected hydroxy group at C-4.

We used two pairs of titanocene and zirconocene reagents, namely the parent $[Cp_2M]$ derived compounds and their $[(MeC_5H_4)_2M]$ analogues, to ensure general reproducibility of our results. We first treated dimethyltitanocene (**6a**) with the carbohydrate derivative **5**. It turned out, however, that $[Cp_2TiMe_2]$ (**6a**) proved to be unreactive towards the free "4-OH sugar derivative" **5** in dichloromethane at room temperature. Similarly, the carbohydrate derivative **5** was recovered unchanged from the solution upon its attempted reaction with $[(CH_3-C_5H_4)_2TiMe_2]$ (**6b**).

The reaction conditions were, therefore, changed as follows: a solution containing **5** and 1 mol-equiv. of the strong Lewis acid $B(C_6F_5)_3$ (**7**)[9] was added dropwise to a dichloromethane solution of $[Cp_2TiMe_2]$ (**6a**). A rapid methane evolution was observed. Workup after 2 h at ambient temperature gave the salt $[Cp_2Ti(O\text{-carb.})]^+[MeB(C_6F_5)_3]^-$ (**10a**) as a red-brown solid in a yield of 70%. Under these conditions it can safely be assumed that the reagent $[Cp_2TiCH_3]^+[MeB(C_6F_5)_3]^-$ (**8a**) is generated in situ.[10] This is much more reactive than its neutral 16-electron precursor **6a** and is rapidly attacked by the free −OH group of **5**, potentially by involvement of a reactive coordinated intermediate **9a** to yield the product **10a** with liberation of 1 mol-equiv. of methane (see Scheme 3).

Complex **10a** features an optical rotation of $[\alpha]_D^{25} = +210$. It shows three separate ^1H NMR AB spin systems of the $-OCH_2Ph$ benzyl protective groups, and an AB part of an ABM spin system of the 6-H/H′ methylene hydrogen atoms (for the respective ^1H NMR chemical shifts see Table 1). The cyclopentadienyl groups at the titanium atom in **10a** are diastereotopic; they give rise to equal-intensity pairs of ^1H (δ = 6.60, 6.62 ppm) and ^{13}C (δ = 118.6, 121.4 ppm) NMR signals. This means that the titanium center in **10a** is pseudo-tetrahedrally coordinated by two η^5-Cp ligands, the carbohydrate 4-O oxygen atom and a fourth neutral donor ligand. In principle this could be the methyl group of the $[MeB(C_6F_5)_3]^-$ counteranion {tight ion pair formation between Group 4 metallocene $[Cp_2MR]^+$ cations and the $[MeB(C_6F_5)_3]^-$ anion is frequently observed}[11,12] or alternatively an internal ether oxygen coordination involving either the 3-OCH_2Ph or the 6-OCH_2Ph oxygen atom. A comparison with some typical ^{13}C NMR chemical shifts of related complexes (see below) enables us to assume that **10a** is characterized by an internal ether-chelate structure in solution that involves coordination of the 6-OCH_2Ph oxygen atom. The reaction between **5** and the in situ generated methylbis(methylcyclopentadienyl)titanium cation system **8a** gave analogous results (see Scheme 3 and Tables 1 and 2).

In order to answer this structural question, we treated both the complexes **10a** (R = H) and **10b** (R = CH_3) with PMe_3. It is known that trimethylphosphane serves as a stronger donor towards titanocene cation complexes than ethers. Thus, the formation of an open, non-chelate adduct is expected. The reaction of complex **10a** with PMe_3 in toluene at room temperature is instantaneous. The PMe_3 adduct **11a** was isolated as a brown solid in 67% yield ($[\alpha]_D^{25} = -44$). The ^1H NMR resonance of the PMe_3 ligand of **11a** occurs at δ = 0.78 ppm (d, $^2J_{H,P}$ = 9.1 Hz). Complex **11a** shows a pair of Cp resonances at δ = 5.31 and δ = 5.39 ppm, each of them is split into a doublet ($^3J_{H,P}$ = 2.8 Hz) by the *Ti*-coordinated PMe_3 ligand. The ^{31}P NMR resonance of the [Ti]−PMe_3 unit in **11a** was located at δ = 4.2 ppm. Complex **10b** reacts analogously with PMe_3 to yield the 1:1 addition product **11b** (63% isolated; $[\alpha]_D^{25} = -58$; ^{31}P NMR: δ = 3.2 ppm).[13]

For comparison we have also treated the THF-stabilized salt $[Cp_2TiCH_3(THF)]^+[BPh_4]^-$ (**12a**)[14] with **5**. This reaction does not proceed below room temperature. At room temperature evolution of methane is observed. The reaction is not as clean as the systems described above. Formation of a mixture of two major products in a 5:1 ratio is observed plus several minor components. Some further de-

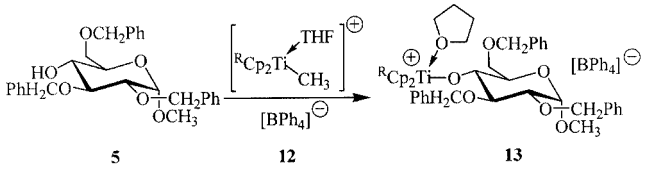
composition took place with time at ambient temperature. From the spectroscopic features we assign the structure of the "open" THF adduct **13a** to the main product of the reaction [^{1}H NMR: δ = 5.93/5.98 (Cp) ppm] (see Scheme 4 and Tables 1 and 2). It may be that the minor component [^{1}H NMR: δ = 5.76/5.79 (Cp) ppm] features an internal chelate, but this remains inconclusive at this time. The corresponding reaction of $[(MeC_5H_4)_2TiCH_3(THF)]^+[BPh_4]^-$ (**12b**) with **5** was only slightly cleaner. It gave the THF-stabilized product **13b**, which was characterized spectroscopically.



5 **12** **13**

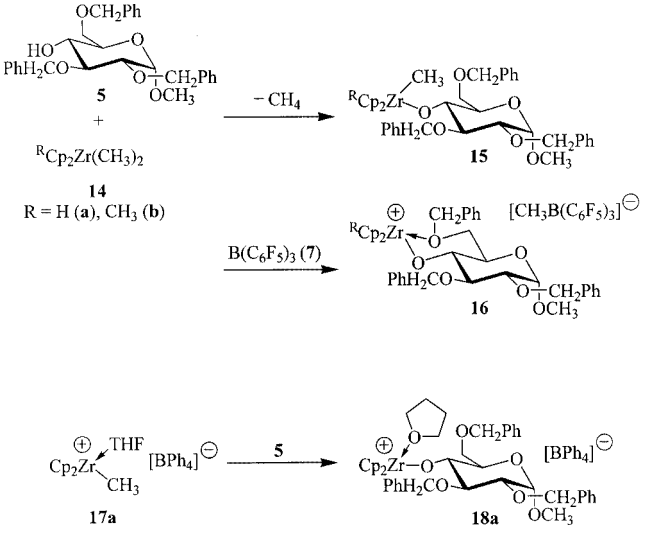
R = H (**a**), CH_3 (**b**)

Scheme 4

One obtains an indication of the essential structural differences between the (internal chelate) complexes **10** and their open counterparts **11/13** upon inspection of some of their characteristic spectroscopic data (see Tables 1 and 2). The ^{13}C NMR chemical shifts are especially useful for this structural assignment (see Table 2). As can be seen from the compilation of data in Table 2, the ^{13}C NMR chemical shifts of the core carbon atoms C-1, C-2 and C-3 are within a close range in the series of the complexes **10a**,**b**, **11a**,**b**, and **13a**,**b**. This also extends to the ^{13}C NMR shifts of the benzyl-CH_2 groups of the 2-OCH_2Ph units. The 3-OCH_2Ph ^{13}C NMR resonance shows a small, but unsystematic variation in this series. However, we note a marked shift ($\Delta\delta \approx 5-7$ ppm) to smaller δ values for the 6-OCH_2Ph resonance on going from the (chelate) **10a**,**b** systems to their (open) counterparts **11a**,**b** or **13a**,**b**. At the same time this change of the coordination pattern is revealed at the C-4 ($\Delta\delta \approx 5-6$ ppm) and the C-6 ($\Delta\delta \approx 5$ ppm) ^{13}C NMR chemical shifts. The C-5 ^{13}C NMR resonance actually features the reverse chemical shift variation ($\Delta\delta \approx -4$ to -5 ppm). Also an additional indication is given by the change of the magnitude of the 6/6′-H, 5-H coupling constants from $^3J_{ae}$ = 10.1 Hz and $^3J_{aa}$ = 3.9 Hz (**10a**) to $^3J_{H,H}$ = 3.8 Hz and 1.5 Hz in **11a**.

Similar structural and spectroscopic effects are noticed in the related zirconocene series. However, some of the chemistry of the reactions of **5** with the methylzirconocene derivatives is markedly different. The zirconocene−*O*-glucopyranoside complexes were much more sensitive than their titanocene analogues. In most cases they decomposed when kept above −10 °C. This severely hampered their isolation but some of these compounds could be characterized spectroscopically in solution at low temperatures.

In contrast to the titanocene system, dimethylzirconocene (**14a**) reacted readily with **5** to give the neutral system **15a** and methane. Complex **15a** shows the typical set of an open metallocene−*O*-glucopyranoside complex (e.g. ^{13}C NMR signals of the glucopyranoside atoms C-4 at δ = 79.5 ppm, C-5 at δ = 71.3, C-6 at δ = 68.9 and of the 6-OCH_2 group at δ = 73.2 ppm). Subsequent treatment of **15a** with $B(C_6F_5)_3$ (**7**) resulted in the abstraction of the σ-methyl group at the zirconium atom[10] with formation of the cation complex **16a** {with $[MeB(C_6F_5)_3]^-$ anion}. The cation of **16a** features a shifting of the respective ^{13}C NMR resonances that again indicates internal coordination of the oxygen atom from the 6-*O*-benzyl group to the now strongly electrophilic zirconium center [**16a**: ^{13}C NMR signals of C-4 at δ = 87.1 ppm ($\Delta\delta$ = +7.6 ppm), of C-5 at δ = 67.2 ppm ($\Delta\delta$ = −4.1 ppm), of C-6 at δ = 74.8 ppm ($\Delta\delta$ = +5.9 ppm) and 6-OCH_2−Ph at δ = 80.0 ppm ($\Delta\delta$ = +6.8 ppm)]. The reaction of $[(MeC_5H_4)_2Zr(CH_3)_2]$ (**14b**) with **5** proceeded analogously to generate **15b**, which was subsequently converted into the salt **16b** by treatment with $B(C_6F_5)_3$. The complexes **15b** and **16b** exhibit similar NMR features (see Scheme 5 and Tables 1 and 2). The [Zr]−*O*-glucopyranoside series was complemented by the in situ generation of (the very sensitive) complex **18a** by treatment of $[Cp_2ZrCH_3(THF)]^+[BPh_4]^-$ (**17a**) with **5**. It shows the typical NMR spectra of an open, THF-stabilized zirconocene−*O*-glucopyranoside cation complex (see Scheme 5, and Tables 1 and 2).



Scheme 5

Our study shows that titanocene cation complexes that bear an *O*-bonded carbohydrate σ-ligand seem to be rather robust molecules (as opposed to their very sensitive zirconium analogues). These titanocene cations are rather straightforwardly formed by our convenient one-pot synthesis using an in situ generated methyltitanocene cation. With the weakly coordinating $[CH_3B(C_6F_5)_3]^-$ counterion we obtained evidence for internal chelate coordination by the 6-*O*-benzyl group, but slightly stronger donors seem to very effectively compete with this internal ether coordination and add to the electrophilic titanocene cation.[15] This observation probably leaves some room for speculations about the potential use of carbohydrate-derived titanocene cation complexes as agents in medicinal chemis-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

try.[2] Such systems might offer some advantages by adding transporting or target donor ligands to the titanocene unit in vivo, and one might envisage that suitably attached carbohydrate moieties might help to guide the titanocene towards its target structures.[16] We shall try to develop biocompatible derivatives of the titanocene systems presented in this paper in order to test their medicinal properties.

Experimental Section

General: All reactions were carried out under dry argon in Schlenk-type glassware or in a glove box. Solvents, including deuterated solvents used for NMR spectroscopy, were dried and distilled prior to use. NMR spectra were measured using a Bruker AC 200 P, a Varian Inova 500 or a Varian Unity Plus 600 NMR spectrometer. Most NMR assignments were made by carrying out a variety of 2D NMR experiments.[17] The coupling constants between vicinal hydrogen atoms at the carbohydrate moiety are designated as J_{aa} (i.e. axial-axial) and J_{ae} (axial-equatorial), respectively. The following instruments were used for additional physical characterization: IR spectroscopy: Nicolet 5DXC FT-IR spectrometer; melting points: DSC 2010 (TA instruments); elemental analyses: Foss Heraeus CHN-O-Rapid; mass spectrometry: Mircomass-Quatro LC-Z-electrospray mass spectrometer; optical rotation: Perkin−Elmer polarimeter 351.

Preparation of $[Cp_2Ti(O\text{-carb.})]^+[MeB(C_6F_5)_3]^-$ (10a): The carbohydrate **5** (464 mg, 1.00 mmol) and $B(C_6F_5)_3$ (**7**) (512 mg, 1.00 mmol) were dissolved in dichloromethane and added dropwise to a solution of dimethyltitanocene (**6a**) (208 mg, 1.00 mmol) in dichloromethane (25 mL). A change in the reaction color to deep red occurred and a gas was released. The reaction mixture was stirred for 2 h, the volatiles were removed in vacuo and the residue was washed with pentane resulting in 814 mg (70%) of the product as red-brown solid. M.p. (DSC): 131 °C (dec.). $[\alpha]_D^{25} = +210$ (c = 0.53, CH_2Cl_2). MS [ESI$^+$, $C_{38}H_{41}O_6Ti^+$ (641)]: m/z = 641 $[M]^+$, 209 $[Cp_2TiOMe]^+$. $C_{57}H_{44}BF_{15}O_6Ti$ (1168.7): calcd. C 58.58, H 3.80; found C 58.15, H 3.75. IR (KBr): $\tilde{\nu}$ = 3118, 2912, 1642, 1511, 1458, 1366, 1266, 1086, 952, 823, 738, 699 cm^{-1}. ^{1}H NMR (CD_2Cl_2, 253 K, 600 MHz): δ = 0.48 (br. s, 3 H, CH_3−B$(C_6F_5)_3$], 3.28 (s, 3 H, OCH_3), 3.52 (t, $^2J = {}^3J_{aa}$ = 10.1 Hz, 1 H, 6-H$_a$), 3.58 (m, 2 H, 2-H, 5-H), 3.79 (t, $^3J_{aa}$ = 8.9 Hz, 1 H, 3-H), 4.01 (dd, ^2J = 10.1, $^3J_{ae}$ = 3.9 Hz, 1 H, 6-H$_e$), 4.04 (d, ^2J = 13.8 Hz, 1 H, 6-OCH_2Ph), 4.40 (d, ^2J = 13.8 Hz, 1 H, 6-OCH_2Ph), 4.56 (d, ^2J = 12.2 Hz, 1 H, 3-OCH_2Ph), 4.66 (d, ^2J = 11.7 Hz, 1 H, 2-OCH_2Ph), 4.67 (d, $^3J_{ae}$ = 3.5 Hz, 1 H, 1-H), 4.75 (d, ^2J = 11.7 Hz, 1 H, 2-OCH_2Ph), 4.84 (d, ^2J = 12.2 Hz, 1 H, 3-OCH_2Ph), 4.88 (t, $^3J_{aa}$ = 8.7 Hz, 1 H, 4-H), 6.60 (s, 5 H, Cp$_A$), 6.62 (s, 5 H, Cp$_B$), 7.22, 7.27, 7.32−7.39, 7.47 (each m, 15 H, Ph) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2, 253 K, 151 MHz): δ = 9.9 [CH_3−B$(C_6F_5)_3$], 55.9 (OCH_3), 66.8 (C-5), 73.4 (2-OCH_2Ph), 73.8 (C-6), 75.2 (3-OCH_2Ph), 78.9 (C-2), 79.7 (6-OCH_2Ph), 81.1 (C-3), 95.2 (C-4), 98.6 (C-1), 118.6 (Cp$_B$), 121.4 (Cp$_A$), 127.9−130.0 (Ph), 130.9, 138.0, 138.9 (*ipso*-Ph), 136.3 [dm, $^1J_{C,F}$ = 247 Hz, *meta*-B$(C_6F_5)_3$], 137.4 [dm, $^1J_{C,F}$ = 243 Hz, *ortho*-B$(C_6F_5)_3$], 148.1 [dm, $^1J_{C,F}$ = 234 Hz, *para*-B$(C_6F_5)_3$] ppm [*ipso*-B$(C_6F_5)_3$ signal not observed]. ^{11}B{^{1}H} NMR (CD_2Cl_2, 298 K, 64 MHz): $\delta = -15$ ($\nu_{1/2}$ = 38.8 Hz) ppm.

Preparation of $[(MeC_5H_4)_2Ti(O\text{-carb.})]^+[MeB(C_6F_5)_3]^-$ (10b): Carbohydrate **5** (464 mg, 1.00 mmol) and $B(C_6F_5)_3$ (512 mg, 1.00 mmol) (**7**) were dissolved in dichloromethane and added dropwise to a solution of $[(MeC_5H_4)TiMe_2]$ (**6b**) (236 mg, 1.00 mmol) in dichloromethane (25 mL). A change in the reaction color to deep red occurred and a gas was released. The reaction mixture was stirred for 2 h, the volatiles were removed in vacuo and the residue was washed with pentane resulting in 1.09 g (91%) of the product as a brown solid. M.p. (DSC): 129 °C (dec.). $[\alpha]_D^{25} = +308$ (c = 0.53, CH_2Cl_2). MS [ESI$^+$, $C_{40}H_{45}O_6Ti^+$ (669)]: m/z = 669 $[M]^+$. $C_{59}H_{48}BF_{15}O_6Ti$ (1196.7): calcd. Apparent Allyl Rotation and Pd−N Bond Rupture in Allylpalladium Complexes with N-Donor Ligands − Evidence of an Associative Mechanism

Félix A. Jalón,[a] Blanca R. Manzano,*[a] and Belén Moreno-Lara[a]

Keywords: Allyl ligands / Fluxionality / N ligands / Palladium

The new didentate N-donor ligands 2-(4-methyl-1*H*-pyrazol-1-yl)pyrimidine (4Me-pzpm, **1**) and 2-(4-bromo-1*H*-pyrazol-1-yl)pyrimidine (4Br-pzpm, **2**) have been synthesised and used to obtain the allylpalladium derivatives [Pd(η^3-2Me-C_3H_4)(NN′)]X [X = BAr'_4^-, NN′ = **1** (**3**), NN′ = **2** (**4**); X = $CF_3SO_3^-$, NN′ = **1** (**5**), NN′ = **2** (**6**)]. In complexes **3**–**6** two types of fluxional process have been found: apparent allyl rotation that is observed as H_{syn}–H_{syn}, H_{anti}–H_{anti} interconversions and H^4–H^6 interchange of the pyrimidine protons that must involve Pd–N(pm) bond rupture. The influence of different factors on both processes — such as the nature of the N-donor ligand, counterion, solvent, complex concentration and addition of water — has been studied. It has been concluded that the apparent allyl rotation has a lower free energy of activation and in both cases the presence of a species with coordinating ability favours the process. Negative entropies of activation have been found. Associative mechanisms involving participation of five-coordinate intermediates have been proposed.

Introduction

The chemistry of (η^3-allyl)palladium complexes has received a great deal of attention because these derivatives can act as precursors or intermediates in different catalytic processes.[1] The fluxional behaviour of these systems, either directly related to the allyl group or to the ancillary ligands, has also been widely studied.[2] Besides the fundamental interest in these studies, the fluxional behaviour of allylpalladium derivatives has important implications in a variety of catalytic processes, especially those involving nucleophilic attack on (η^3-allyl)palladium intermediates in enantioselective synthesis.[3] One process frequently encountered in allylpalladium complexes is a mutual exchange of *syn* and *anti* groups.[4−12] This process is believed to occur through an η^3-η^1-η^3 pathway that in some cases is selective[6a,9a,10,13−16] due to steric or electronic factors. On the basis of theoretical calculations concerning the mechanism of the η^3-η^1-η^3 isomerisation in (η^3-allyl)palladium complexes, it has been proposed that the process involves tetracoordinate (η^1-allyl)palladium intermediates with coordination of a solvent molecule or an ancillary ligand.[17] A second dynamic process that is frequently observed in complexes with N-donor ligands is the apparent rotation of the allyl group.[18−28] In certain examples both of the aforementioned processes have been observed.[16,29−35] The apparent rotation is observed as a *syn-syn*, *anti-anti* exchange and/or an isomerisation process, depending on the molecular symmetry. Two main mechanisms have been proposed for the apparent allyl rotation: (i) associative mechanisms[20,28,29,32,35] that involve five-coordinate intermediates (coordination of the solvent, the anion or other molecules) that can undergo allyl pseudorotation, and (ii) dissociative mechanisms[18,19,21−23,25,26,31,33] with formation of T-shaped three-coordinate intermediates after dissociation of monodentate or didentate (partial dissociation) ligands. Consequently, one question that is open to debate is whether the apparent allyl rotation in derivatives with N-donor ligands involves Pd−N bond breaking or not. In the case of didentate ligands this question is interesting because it would involve the dissociation of one arm of a chelate, a subject of potential interest, especially in relation to catalytic processes. In some examples it has been reported that a ligand of higher basicity makes the apparent rotation more difficult,[21] while increased steric hindrance of the N-donor ligand can facilitate[20,29] or slow down[21] the process. Negative entropies of activation have been found in some cases[29,32] and it has been reported that the process takes place more easily with coordinating anions[19,29,31] or solvents such as DMSO.[20b] It has also been reported that the addition of ligand or water has a negligible effect on the process in a number of examples;[18,21] other examples have been described where the effect of adding ligand or chlorides is accelerative.[19,28,29] The effect of the anion has also been analysed.[29,31a] As far as the effect of the complex concentration is concerned, positive effects,[28,20b] at least to a limiting value, have been described but in some cases it has been found that this factor has no influence.[31a,35] In recent years we have been interested in the synthesis, structural characterisation and dynamic behaviour of allylpal-

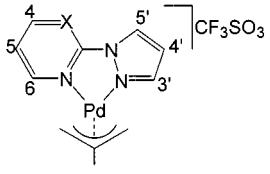
ladium(II) complexes with N-donor ligands containing pyrazolyl groups.[23−28,35] We have described the synthesis and fluxional behaviour of the complexes $[Pd(\eta^3\text{-}2Me\text{-}C_3H_4)(NN')]CF_3SO_3$ [NN′ = 2-(1*H*-pyrazol-1-yl)pyrimidine = pzpm (**I**); NN′ = 2-(1*H*-pyrazol-1-yl)pyridine = pzpy (**II**)][23] (see Scheme 1) where the *syn-syn*, *anti-anti* interconversion was detected along with an interchange process between the H^4 and H^6 protons of the pyrimidine ring in complex **I**. This last interchange is only possible through Pd−N(pm) bond rupture. Moreover, an NOE between the allylic H_{syn} and H_{anti} protons and $H^{5'}$ of the pyrazole ring was also detected in the case of complex **II** and this can only be explained through Pd−N(pz) bond rupture (see Scheme 1). Considering these facts, and given the similarities between our work and other results reported previously,[19] we proposed that it was possible that the apparent allyl rotation could also take place through an initial Pd−N bond rupture. In the work described here we have attempted to gain a further insight into these processes by looking for more data concerning the free energies of activation. More precisely, we were interested in determining whether or not the apparent allyl rotation processes and the H^4-H^6 pyrimidine proton interconversion have the same energy barrier and a common mechanism. Given that the H^4-H^6 interconversion must involve a Pd−N bond-breaking step, comparison of the free energies of activation for the two processes could provide information about the participation of Pd−N bond rupture in the apparent allyl rotation. As stated above, this aspect is now a matter of debate. We also decided to explore the influence on the processes of several factors such as the type of ligand, counterion, solvent, complex concentration and addition of water. These studies may prove useful in elucidating the type of mechanism (associative or dissociative) operating in the apparent allyl rotation process.

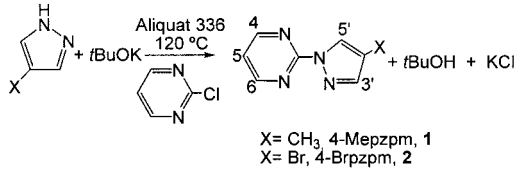


Scheme 1

Results and Discussion

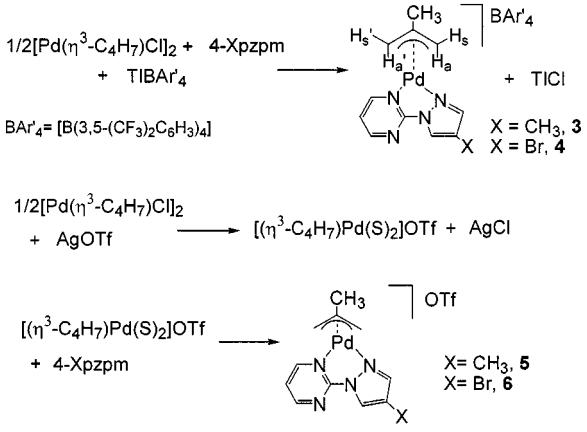
Synthesis of the New Ligands and Complexes

We decided to prepare allylpalladium complexes with two different ligands containing a pyrimidine ring (in order to study the H^4-H^6 interconversion process) and different 4-substituted pyrazole groups: 2-(4-methyl-1*H*-pyrazol-1-yl)-pyrimidine (4Me-pzpm, **1**) and 2-(4-bromo-1*H*-pyrazol-1-yl)pyrimidine (4Br-pzpm, **2**; Scheme 2). The results obtained on these complexes could be compared with those obtained with pzpm. The differences in the three ligands are limited to the substituent in the 4-position of the pyrazole, and so it is foreseeable that, if any influence exists, it will be only electronic in nature. The pK_a values for the three pyrazole heterocycles are as follows: 4-methylpyrazole 3.04; pyrazole 2.48; 4-bromopyrazole 0.63.[36] The new ligands were prepared by reaction of the deprotonated pyrazole rings with 2-chloropyrimidine (see Scheme 2 and Exp. Sect.).



Scheme 2

We synthesised allyl derivatives with two types of counterion: triflate (OTf), which has coordinative ability, and the voluminous tetrakis(3,5-trifluoromethylphenyl)-borate ($BAr'_4{}^-$), which is non-coordinating. In both cases the starting material was $[Pd(\eta^3\text{-}2Me\text{-}C_3H_4)Cl]_2$ and this was allowed to react in one step with a stoichiometric amount of the nitrogen ligands and $TlBAr'_4$ or, alternatively, in two steps with prior elimination of the chlorides with $AgCF_3SO_3$ and addition of the nitrogen ligands after the AgCl had been filtered off (see Scheme 3).



Scheme 3

The products are soluble in polar solvents such as acetone, dichloromethane and THF but are insoluble in hexane, pentane and diethyl ether.

Structural Characterisation

The new ligands and products were characterised by elemental analysis, and IR, ^1H and ^{13}C NMR spectroscopy. For the majority of the derivatives, HSQC experiments were also performed and, in some cases, NOE experiments were carried out.

The IR spectra of the ligands and complexes exhibit the stretching vibration bands for ν(C=N) (see Exp. Sect.). The

The resonances for the $BAr'_4{}^-$ anion are for **3**: δ = 7.79 (s, H*o*) and 7.68 (H*p*) ppm; for **4**: δ = 7.78 (s, H*o*) and 7.66 (H*p*) ppm.

allyl ligand gives rise to a band at 838 cm^{-1} in all the complexes due to the $\nu(C-CH_3)$ vibration. The presence of the corresponding counterions was confirmed by the presence of the expected bands (see Exp. Sect.).

The ^{1}H NMR spectroscopic data for the ligands and complexes are collected in Table 1. In the cases of derivatives **3** and **4**, due to some overlap with the resonances of the counterion, the spectra were recorded both in $CDCl_3$ and [D_6]acetone. The assignment for the nitrogen-ligand resonances was made on the basis of previous studies with similar ligands.[23,37] The $H^{3'}$ and $H^{5'}$ protons of the pyrazolyl rings appear as singlets both in the ligands and complexes as a result of the presence of the substituent in the 4-position. In the free ligands the H^5 proton of the pyrimidine ring appears as a triplet coupled to H^4 and H^6, which are equivalent. In the complexes the protons H^4 and H^6 are inequivalent due to coordination. However, signals for the two protons are only observed separately at room temperature in complex **6**. In the other cases these protons give rise to a single broad signal at this temperature. This phenomenon clearly indicates that the H^4-H^6 interconversion process previously detected in [Pd(η^3-2Me-C_3H_4)(pzpm)]CF_3SO_3 (**I**)[23] is also operating (see section on fluxional behaviour). In general, a shift towards higher frequency is observed for the corresponding resonances of the complexes with respect to the free ligands due to the ligand-to-metal σ-donation. As far as the allylic signals are concerned, a single resonance is observed at room temperature for the H_{syn} and also for the H_{anti} protons. This observation is not in accordance with a static situation of the complexes, where two different terminal allylic carbons would be expected due to the asymmetry of the nitrogen ligands. This constitutes a clear indication of a dynamic situation that involves a *syn-syn*, *anti-anti* interconversion, such as an apparent allyl rotation process, which will be analysed in the section on fluxional behaviour. The differentiation between the two methyl resonances of complex **3** [D_6]acetone was achieved with the help of NOE experiments. When $H^{5'}$ of the pyrazole ring was irradiated an NOE was found for the resonance at δ = 2.27 ppm. An NOE for the resonance at δ = 2.25 ppm and for the H_{anti} signal was also found when the H_{syn} resonance was irradiated.

The corresponding $^{13}C\{^1H\}$ NMR spectroscopic data are gathered in Table 2. The assignment for the nitrogen ligands was made on the basis of literature data[23,26,37−39] and HSQC experiments. In a similar way to the ^{1}H NMR spectra, a single signal was observed for the C^4 and C^6 pyrimidine carbons (in complex **4** this signal was not observed). A signal shift towards higher frequency with respect to the

free ligands is also seen. The allylic carbon resonances also reflect the apparent allyl rotation process as a single broad signal appears for the terminal carbons. The expected coupling with boron or fluorine is observed for the C_{ipso} and CF_3 carbons, respectively, of the BAr'_4 anion.[40]

Fluxional Behaviour

As stated previously, with these new allyl complexes we tried to obtain sufficient information concerning their fluxional behaviour to draw a conclusion as to whether the apparent allyl rotation process and the H^4-H^6 interconversion have the same energy barrier and follow a common mechanism. This information and the study of the influence of different factors could also shed light on the controversy surrounding mechanisms (associative or dissociative). In the case of derivative **I**,[23] the corresponding representation of free energy of activation versus coalescence temperature did not allow a conclusion to be drawn as to whether the two points for the apparent allyl rotation and the one for the H^4-H^6 interconversion were in a straight line — the information was insufficient to conclude, with certainty, whether the two process have the same energy barrier.

In order to analyse the dynamic behaviour of complexes **3**−**6** we performed variable temperature ^1H NMR studies under different conditions in order to obtain the coalescence temperatures (T_c) of the interconversion processes $H_{syn}-H_{syn}$, $H_{anti}-H_{anti}$ and H^4-H^6. For the majority of the complexes, two H_{syn} signals, two H_{anti} signals and separate signals for H^4 and H^6 were observed at low temperature, as one would expect for a static situation (see Table 1). An increase in the temperature allowed the corresponding coalescence temperatures to be determined. These values are given in Table 3 along with the δν values and the calculated free energies of activation.[41] However, in some cases it was not possible to determine the $\Delta G_c^{\ddagger}$ values. The reasons for this are that either the signals were not split at the minimum experimental temperature or the coalescence was not reached at the maximum temperature allowed by the solvent (in this case it is indicated that the T_c values are higher than the maximum temperature registered and the $\Delta G_c^{\ddagger}$ values

are higher than those calculated for these temperatures). In the following discussion we will detail our conclusions concerning the influence of different factors on the fluxional behaviour of our allyl complexes.

Effect of the Ligand

Comparison of the data for complexes **3** and **4** (Entries 1−4) on the one hand and for **5** and **6** on the other, as well as those for complex **I**[23] (Entries 5−9 and 13−15), gives an indication of the influence of the ligand. Unfortunately, in the case of complexes with the 4-Mepzpm ligand it was not possible to determine all the coalescence temperatures and obtain the corresponding data. In the case of complex **3** it was only possible to detect the $H_{anti}-H_{anti}$ interconversion process while for **5** the splitting of the H_{syn} signals was not achieved. As far as the allylic interconversions are concerned, and although it would be desirable to have more data, it seems that the type of ligand does not have a clear influence, especially concerning the type of pyrazole ring. With respect to the H^4-H^6 interchange, three sets of data are available in the case of compounds containing the triflate anion. In these compounds there is an increase in the coalescence temperature and in the free energy of activation on changing from 4Me-pzpm to pzpm to 4Br-pzpm, but the three points fit reasonably well ($R^2 = 0.9924$) to a straight line (with positive slope), which might again indicate the lack of influence of the type of pyrazole in the ligand on the process. It is possible that the electronic differences between the three ligands are not sufficient to clearly influence the processes under investigation. In any case, it is necessary to bear in mind that for the H^4-H^6 interchange process the bond that must be broken is between the palladium and the pyrimidine ring, not the pyrazole heterocycle.

Type of Interchange

Before analyzing the influence of other factors, it is important to consider carefully the data for complex **6**. Although the δν value for the $H_{anti}-H_{anti}$ interconversion (48.1 Hz, Entry 7) is clearly higher than that for the H^4-H^6 interchange (28.5 Hz, Entry 9), the T_c and $\Delta G_c^{\ddagger}$ values are markedly higher in the latter case. This clearly indicates that the H^4-H^6 interchange has a higher energy barrier and will also have a different mechanism than the apparent allyl rotation. In order to obtain more data for this complex, we decided to perform the same study with an NMR spectrometer of different magnetic field (500 MHz as opposed to 300 MHz). In this way, we could obtain four data points for the allylic interconversions (Entries 7, 8, 10 and 11) and two for the H^4-H^6 interchange (Entries 9 and 12). The corresponding data are represented in Figure 1. The points for the allylic interconversions fit very well to a straight line ($R^2 = 0.9985$) while the other two values have free energies of activation that are clearly higher (7.9−8.9 kJ·mol^{-1}). This trend is consistent with our previous conclusion that the H^4-H^6 interchange has a higher energy barrier than the apparent allyl rotation. The difference in free energy of activation between the two processes will also be clear in other plots presented in this paper aimed at evaluating the influence of other factors (see below).

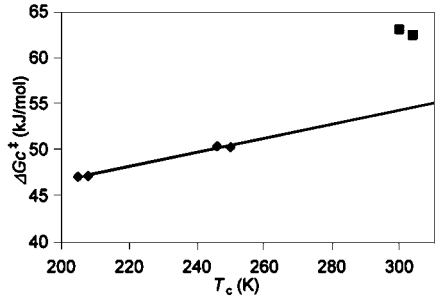

Figure 1. Linear plot of $\Delta G_c^{\ddagger}$ (kJ/mol) versus T_c (K) for complex **6** in [D$_6$]acetone (1.41×10^{-2} M) using data from 300 and 500 MHz NMR spectrometers (see Table 3): allylic interchange (diamonds, −−); ($R^2 = 0.9985$); H^4-H^6 interchange (squares)

Effect of the Counteranion

A comparison of Entries 1, 5 and 6 for the complexes with the 4-Mepzpm ligand and Entries 2−4 and 7−12 for those with the 4-Brpzpm ligand should give an indication of the influence of the counteranion on the processes in question. However, the lack of data for the 4-Mepzpm complexes precludes a clear conclusion from being drawn. However, with the 4-Brpzpm complexes (see Figure 2) it is possible to conclude that, at least in [D$_6$]acetone solution, there is a negligible influence of the anion on both the apparent allyl rotation and the H^4-H^6 interconversion. The data represented in Figure 2 also confirm the previous conclusion that the apparent allyl rotation has a lower free energy of activation than the H^4-H^6 interconversion.

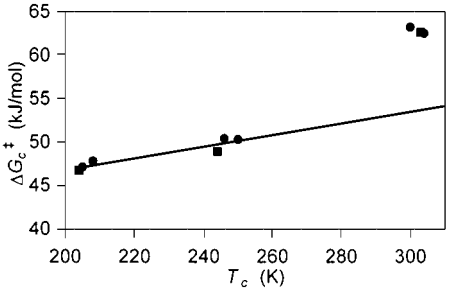

Figure 2. Linear plot of $\Delta G_c^{\ddagger}$ (kJ/mol) versus T_c (K) for complexes **4** and **6** in [D$_6$]acetone (1.41×10^{-2} M; see Table 3): **4** (squares); **6** (circles); allylic interchange (−−); $R^2 = 0.9706$

Effect of the Solvent

The studies described below are centred on complexes **4** and **6**, which contain the ligand 4-Brpzpm, because more coalescence points can usually be measured than for the 4-Mepzpm derivatives. For complex **4**, the data previously obtained in [D$_6$]acetone solution (Entries 2−4) were compared with those obtained in $CDCl_3$ at the same concentration (Entries 16−18). These data are represented in Fig-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ure 3. The coalescence temperature for the H^4-H^6 interchange in $CDCl_3$ was not reached and this is indicated by an arrow in the figure to reflect the fact that the actual value is higher than the one indicated. As far as the apparent allyl rotation process is concerned, higher $\Delta G_c^{\ddagger}$ values are obtained when the solvent is $CDCl_3$ and the same seems to apply to the H^4-H^6 interchange. Consequently, for this complex, which contains a counteranion (BAr'_4^-) that does not have coordinating ability, the presence of a solvent that it is able to coordinate has a positive effect on the processes.

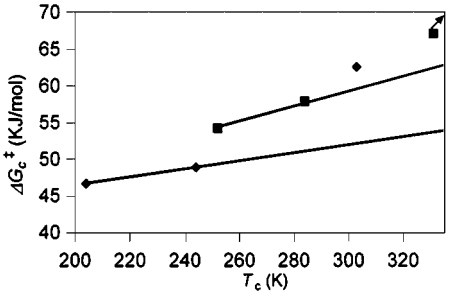

Figure 3. Linear plot of $\Delta G_c^{\ddagger}$ (kJ/mol) versus T_c (K) for complex **4** (1.41×10^{-2} M; see Table 3): $CDCl_3$ (squares); [D_6]acetone (diamonds); allylic interchange (−−)

A similar solvent effect is not observed in complex **6** where the anion (OTf^-) has coordinating ability. In this case the comparison is made between the [D_6]acetone (Entries 7−12) and CD_2Cl_2 (Entries 19−21) data. It can clearly be seen from Figure 4 that the solvent does not have any influence on the apparent allyl rotation, while for the H^4-H^6 interchange the conclusion is not as straightforward. Once again, this figure demonstrates the difference in free energy of activation between the apparent allyl rotation and the H^4-H^6 interchange.

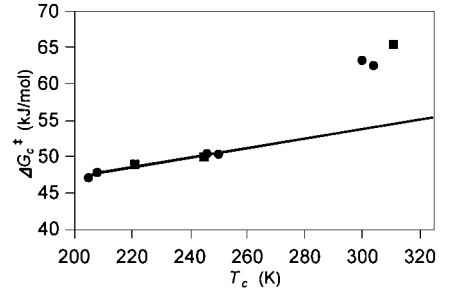

Figure 4. Linear plot of $\Delta Gc^{\ddagger}$ (kJ/mol) versus T_c (K) for complex **6** (1.41×10^{-2} M; see Table 3): CD_2Cl_2 (squares); [D_6]acetone (circles); allylic interchange (−−); $R^2 = 0.9914$

Effect of the Complex Concentration

In order to obtain information about the possible participation of bimolecular species in these processes, we carried out several variable temperature ^1H NMR studies with two different concentrations (1.41×10^{-2} and 7.05×10^{-3} M). For complex **6**, we performed the studies both in [D_6]acetone (Entries 7−12 and 25−27) and in CD_2Cl_2 solutions (Entries 19−24) and for complex **4** in $CDCl_3$ solutions (Entries 16−18 and 28−30). The coalescence of the H^4 and H^6 resonances was not reached up to the maximum temperature allowed by the solvent for complex **6** in CD_2Cl_2 or complex **4** in $CDCl_3$. When the results at the two concentrations are compared, it is possible to conclude that in the case of **6** in [D_6]acetone the three pairs of data are practically identical — the concentration does not influence either of the two processes. In the other two studies, there is insufficient information about the H^4-H^6 interchange and for the apparent allyl rotation the influence, if it exists, is very small (at least in the range of concentrations used).

Effect of the Addition of Water

The study of the influence of the addition of water was performed with complex **4** in $CDCl_3$ (Entries 16−18 and 31−32) in order to have a counterion and a solvent without coordinating ability. The data were obtained for a water-free $CDCl_3$ solution and after the addition of four mol of water per mol of product in this solution. The addition of water induces a general lowering of the coalescence temperatures, and the splitting of the H_{anti} resonances is not observed even down to −60 °C. However, the coalescence of the H^4-H^6 resonances, which was not achieved in the water-free solution, was observed at 17 °C after the addition of water. When the data for the allylic interconversions are taken into amount, it is concluded that the value obtained after the addition of water is 4.9 kJ·mol^{-1} below the straight line obtained with the data for the water-free solution. Consequently, at least in the situation where the counteranion and solvent are non-coordinating, the addition of water favours the apparent allyl rotation. We also studied the effect of the addition of water when there are species of coordinating ability in the reaction medium, for example for complex **6** in [D_6]acetone solution (comparison of Entries 7−9 with 33−35). In this case, there is no appreciable effect observed in the values of free energy of activation after the addition of water.

When the different plots for the apparent allyl rotation process are considered, a positive slope in the straight line obtained is observed. Although we do not believe that it is possible to give accurate data for the entropy of activation, it is clear that this parameter is negative.

It must be emphasised that our results indicate that care must be taken when studying these types of process in solvents that do not have coordinating ability. In solvents such as acetone, as observed previously,[35] the presence of small amounts of water does not influence the energy barrier of the process.

Conclusions of the ^1H NMR Variable Temperature Studies

We deduced that there is a lower energy barrier for the apparent allyl rotation process than for the H^4-H^6 interconversion and, consequently, the two processes follow different mechanisms. In the case of the apparent allyl rotation process, and concerning the effect of different factors

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

on this phenomenon, we can state the following: (i) a clear influence of the type of pyrazole present in the nitrogen-containing ligand is not found; (ii) the results are the same when, in [D_6]acetone solutions, the counterion is changed (cf. $BAr'_4{}^-$ versus OTf^-) or when, for the complexes with the OTf^- anion, two different solvents are used ([D_6]acetone and CD_2Cl_2); (iii) in the complex with the $BAr'_4{}^-$ anion, the free energy of activation values are higher in a non-coordinating solvent such as $CDCl_3$ than in [D_6]acetone; (iv) the complex concentration does not affect the process in the range studied; (v) when the complex contains a non-coordinating anion and the study is carried out in $CDCl_3$, the addition of water decreases the free energy of activation. However, the addition of water does not affect the dynamic behaviour in [D_6]acetone when the counterion present is OTf^-; (vi) the entropy of activation is negative.

In the case of the H^4-H^6 interconversion process it is more difficult to draw conclusions because only one $\Delta G_c^{\ddagger}$ data point could be obtained for each study. Despite this, we believe that the following general points can be made: (i) the type of anion, ligand or complex concentration does not have any influence when the solvent is [D_6]acetone; (ii) when both the solvent ($CDCl_3$) and anion ($BAr'_4{}^-$) are non-coordinating, the addition of water reduces the free energy of activation but this addition does not affect the values of $\Delta G_c^{\ddagger}$ in [D_6]acetone when the counterion is OTf^-; (iii) the entropy of activation is negative.

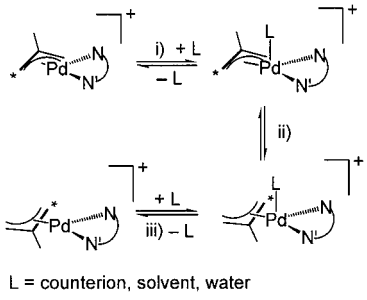
During the studies described here, broadening of the H_{syn} or H_{anti} resonances was not observed in any case after coalescence was achieved. This fact indicates that if the $H_{syn}-H_{anti}$ interconversion process (usually proposed to occur through an η^3-η^1-η^3 mechanism) exists, it must be of higher energy and is therefore not observed under the conditions used here.

Mechanistic Proposal

Apparent Allyl Rotation

The negative sign of the entropy of activation points to an associative process with the formation of five-coordinate intermediates. On the basis of some of the conclusions outlined above (ii, iii and v), it is possible to state that a species with coordinating ability (counteranion, solvent or water) clearly favours the process. We must consider that when the counterion is $BAr'_4{}^-$, the solvents are CD_2Cl_2 or $CDCl_3$ and water is not added, the two processes, although with higher energies of activation, do take place. It is possible that in these cases traces of water or Cl^- in the solvents (decomposition of CD_2Cl_2 or $CDCl_3$), or the low coordinating ability of the solvents, allows the process to occur. Conclusion iv indicates that bimolecular species are not formed and that the free nitrogen of the pyrimidine ring does not participate in the formation of the five-coordinate intermediates. It is necessary to consider that the formation of an "ion pair" between the cation and the anion should be favoured in concentrated solutions. This would be particularly true in the case of a non-coordinating solvent, such as complex **6** in CD_2Cl_2. This phenomenon has been found by other authors[20b] but, depending on the temperature and the concentration range, the effect can be rather small because of the existence of a limiting constant value.

It is also important to consider that the energy barrier for the apparent allyl rotation is lower than for the H^4-H^6 interconversion process. This latter process necessarily involves a Pd−N(pm) bond rupture, probably as the limiting step. Consequently, the apparent allyl rotation process should occur through a path that does not involve Pd−N(pm) bond rupture and has a lower energy of activation. The breaking of the Pd−N(pyrazole) bond is less likely because of the higher basicity of this heterocycle (except for the case of 4-Br-pyrazole) with respect to the pyrimidine ring [pK_a(pyrimidine) = 1.1]. This again makes a dissociative mechanism less likely and points to an associative pathway. The partial dissociation of the didentate N-donor ligand in the five-coordinate intermediate has sometimes been considered.[20b] In our case, however, this possibility can be excluded. Consequently, the associative mechanism[20,28,29,32,35] we propose would have the following steps (see Scheme 4): (i) formation of a five-coordinate intermediate through coordination of the anion, solvent or water (L); (ii) pseudorotation of the allyl group in the intermediate formed, which interchanges the two allylic terminals; and (iii) decoordination of the L group, leading to the final product in which the observed $H_{syn}-H_{syn}$, $H_{anti}-H_{anti}$ interchange has taken place.



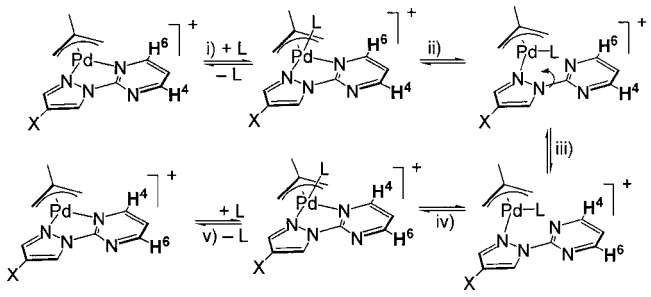
Scheme 4

H^4-H^6 Interconversion

The negative entropy of activation, the positive effect of the addition of water when both the solvent and the anion are non-coordinating, and the absence of other effects when the solvent is [D_6]acetone all indicate that, in this case, an associative mechanism is in operation. The mechanism should involve the following steps (see Scheme 5): (i) formation of the five-coordinate intermediate through coordination of the solvent, anion or water (L); (ii) Pd−N(pm) bond rupture; (iii) internal rotation of the ligand[19] through the C−N bond that links the two heterocycles in the tetracoordinate intermediate formed; (iv) recoordination of the pyrimidine ring through the other nitrogen atom; and (v) decoordination of the L group, leading to the final species

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in which the interchange between the positions of the H^4 and H^6 pyrimidine protons has taken place.



Scheme 5

Conclusions

New allylpalladium derivatives with N-donor ligands have been obtained and their fluxional behaviour studied. Two processes of apparent allyl rotation (observed as $H_{syn}-H_{syn}$, $H_{anti}-H_{anti}$ interconversions) and also H^4-H^6 interconversion of the pyrimidine protons have been observed. This last process must involve, probably as the limiting step, Pd−N(pyrimidine) bond rupture. It has been concluded that the apparent allyl rotation process has a lower free energy of activation. Consequently, this allyl rotation must not involve Pd−N bond rupture. The influence of factors such as counterion, solvent and addition of water has been studied and it is possible to conclude that the presence of a species with coordinating ability clearly favours both processes. A bimolecular mechanism can be excluded in both cases because the complex concentration does not affect the free energy of activation. Negative entropies of activation were obtained. Associative mechanisms with participation of five-coordinate intermediates have been proposed for both processes, with a step involving Pd−N(pyrimidine) bond rupture in the case of the H^4-H^6 interconversion.

On the basis of our studies it is possible to conclude that, for these types of process, the presence of traces of water in coordinating solvents like acetone does not affect the free energy of activation. However, this is not the case for non-coordinating solvents and great care must be taken in studies involving such solvents.

Experimental Section

General Comments: All manipulations were carried out under dry, oxygen-free nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents and degassed before use. The derivative $[Pd(\eta^3\text{-}C_4H_7)(\mu\text{-}Cl)]_2$ was synthesised according to a literature procedure.[42] Elemental analyses were performed with a Carlo Erba Instruments EA 1108 CHNS/O microanalyser (University of La Coruña). IR spectra were recorded as nujol mulls with a Perkin−Elmer PE 883 IR spectrometer. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded with a Varian Unity 300 and an Innova 500 spectrometer using $CDCl_3$, CD_2Cl_2 and $(CD_3)_2CO$ as solvents; the chemical shifts are given in ppm. Standard experimental conditions were employed.[25,26] The NOE difference spectra were recorded with the following acquisition parameters: spectral width 5000 Hz, acquisition time 3.27 s, pulse width 18 ms, relaxation delay 4 s, irradiation power 5−10 dB, number of scans 240. For ^1H-^{13}C g-HSQC spectra the standard Varian pulse sequences were used (V NMR 6.1 C software). The spectra were acquired using 7996 Hz (^1H) and 30154 Hz (^{13}C) spectral widths; 16 transients of 2048 data points were collected for each 256 increments. For variable-temperature spectra the probe temperature (±1 K) was controlled by a standard unit calibrated with a methanol reference. Free energies of activation (kJ·mol^{-1}) were calculated[41] from the coalescence temperature (T_c) and the frequency difference between the coalescing signals (extrapolated at the coalescence temperature) with the formula $\Delta G_c^{\ddagger} = a \cdot T \cdot [9.972 + \log(T/\delta\nu)]$, where $a = 1.914 \times 10^{-2}$. The estimated error in the calculated free energies of activation is ±1.1 kJ·mol^{-1}. *o* = *ortho*, *m* = *meta*, *p* = *para*.

2-(4-Methyl-1*H*-pyrazol-1-yl)pyrimidine (1): A mixture of 4-methylpyrazole (0.248 mL, 3 mmol), potassium *tert*-butoxide (600 mg, 6 mmol) and aliquat 336 (80 mg, 10%) was stirred at 120 °C for 30 min. 2-Chloropyrimidine (515 mg, 4.5 mmol) was then added at 120 °C and the reaction mixture was stirred at this temperature for 1 h. Extraction with dichloromethane (50 mL), removal of the solvent from the extract and flash chromatography of the residue on silica gel using ethyl acetate as the eluent allowed the isolation of **1**. Yield: 62% (298 mg). IR: $\tilde{\nu}$ = 1573 cm^{-1} [ν(C−N)]. $C_8H_8N_4$ (160.18): calcd. C 59.99, H 5.03, N 34.98; found C 59.70, H 5.29, N 34.62.

2-(4-Bromo-1*H*-pyrazol-1-yl)pyrimidine (2): A similar procedure to that used for **1** was applied for **2**. Amounts were as follows: 4-bromopyrazole (440.8 mg, 3 mmol), potassium *tert*-butoxide (600 mg, 6 mmol), aliquat 336 (80 mg, 10%) and 2-chloropyrimidine (515 mg, 4.5 mmol). Yield 60% (405.1 mg). IR: $\tilde{\nu}$ = 1570 cm^{-1} [ν(C−N)]. $C_7H_5BrN_4$ (225.05): calcd. C 37.36, H 24.89, N 2.24; found C 37.25, H 24.99, N 2.18.

$[Pd(\eta^3\text{-}C_4H_7)(4\text{-Mepzpm})]BAr'_4$ (3): 4-Mepzpm (24.3 mg, 0.152 mmol) and $TlBAr'_4$ (162.3 mg, 0.152 mmol) were added to a solution of $[Pd(\eta^3\text{-}C_4H_7)(\mu\text{-}Cl)]_2$ (30 mg, 0.076 mmol) in 10 mL of toluene. The mixture was stirred at room temperature for 1 h. The resulting suspension was filtered off. The solid was then extracted with dichloromethane (40 mL) and the solution was evaporated to dryness. The light-brown solid was washed with hexane and dried. Yield: 66% (119.1 mg). IR: $\tilde{\nu}$ = 1598 and 1566 [ν(C−N)], 1275, 890 (BAr'_4), 839 cm^{-1} ν[(C−CH_3), allyl]. $C_{44}H_{27}BF_{24}N_4Pd$ (1184.9): calcd. C 44.60, H 2.30, N 4.73; found C 44.52, H 2.44, N 4.69. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 298 K; BAr'_4 resonances): δ = 161.9 (q, $^1J_{B,C}$ = 50.0 Hz, 4 C, C_{ipso}), 135.0 (s, 8 C, C_o), 129.2 (m, 8 C, C_m), 124.7 (q, $^1J_{C,F}$ = 272.6 Hz, 8 C, CF_3), 117.7 (s, 4 C, C_p) ppm.

$[Pd(\eta^3\text{-}C_4H_7)(4\text{-Brpzpm})]BAr'_4$ (4): A similar procedure to that used for **3** was applied for **4**. Amounts were as follows: $[Pd(\eta^3\text{-}C_4H_7)(\mu\text{-}Cl)]_2$ (20 mg, 0.051 mmol), 4-Brpzpm (22.9 mg, 0.102 mmol) and $TlBAr'_4$ (108.9 mg, 0.102 mmol). The solid was pale brown in colour. Yield: 66% (83.7 mg). IR: $\tilde{\nu}$ = 1599 and 1568 [ν(C−N)], 1279, 890 (BAr'_4), 838 cm^{-1} ν[(C−CH_3), allyl]. $C_{43}H_{24}BBrF_{24}N_4Pd$ (1249.8): calcd. C 41.32, H 1.94, N 4.48; found C 41.67, H 2.19, N 4.49. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 298 K; BAr'_4 resonances): δ = 161.9 (q, $^1J_{B,C}$ = 49.3 Hz, 4 C, C_{ipso}), 134.9 (s, 8 C, C_o), 129.8 (m, 8 C, C_m), 124.7 (q, $^1J_{C,F}$ = 272.2 Hz, 8 C, CF_3), 117.7 (s, 4 C, C_p) ppm.

[Pd(η^3-C_4H_7)(4-Mepzpm)]OTf (5): $AgCF_3SO_3$ (104.3 mg, 0.406 mmol) was added to a solution of [Pd(η^3-C_4H_7)(μ-Cl)]$_2$ (80 mg, 0.203 mmol) in THF (20 mL). The mixture was stirred for 1 h and protected from light. The solution was filtered through Celite to eliminate AgCl. The ligand 4-Mepzpm (65 mg, 0.406 mmol) was then added and the mixture was stirred for 1 h. The solvent was evaporated to dryness and the pale-yellow residue was washed with diethyl ether. Yield 70% (133.7 mg). IR: $\tilde{\nu}$ = 1596 and 1565 [ν(C−N)], 1266, 1154, 1032, 784 and 639 (OTf^-), 839 cm^{-1} ν[(C−CH_3), allyl]. $C_{13}H_{15}F_3N_4O_3PdS$ (470.75): calcd. C 33.17, H 3.21, N 11.90; found C 33.46, H 3.11, N 12.23. $^{13}C\{^1H\}$ NMR (125 MHz, [D_6]acetone, 298 K): δ = 121.7 (q, $^1J_{C,F}$ = 322.2 Hz, 1 C, CF_3) ppm.

[Pd(η^3-C_4H_7)(4-Brpzpm)]OTf (6): A similar procedure to that used for **5** was applied for **6**. Amounts were as follows: Ag CF_3SO_3 (78.1 mg, 0.304 mmol), [Pd(η^3-C_4H_7)(μ-Cl)]$_2$ (60 mg, 0.152 mmol), 4-Brpzpm (68.4 mg, 0.304 mmol). The solid was white in colour. Yield: 80% (126.6 mg). IR: $\tilde{\nu}$ = 1597 and 1566 [ν(C−N)], 1269, 1147, 1034, 785 and 639 (OTf^-), 838 cm^{-1} ν[(C−CH_3), allyl]. $C_{12}H_{12}BrF_3N_4O_3PdS$ (535.62): calcd. C 26.91, H 2.26, N 10.46; found C 27.01, H 2.11, N 10.27. $^{13}C\{^1H\}$ NMR (125 MHz, [D_6]-acetone, 298 K): δ = 121.8 (q, $^1J_{C,F}$ = 322.2 Hz, 1 C, CF_3) ppm.

Preparation of NMR Spectroscopic Samples: Samples with a concentration of 1.41 × 10^{-2} M were prepared by dissolving the corresponding amount of the complex in 0.5 mL of the deuterated solvent. Samples with a concentration of 7.05 × 10^{-3} M were prepared by adding 0.5 mL of the corresponding deuterated solvent to the previous sample. Samples for the studies of Entries 31 and 32 (Table 3) were prepared by adding 0.510 μL (2.8 × 10^{-2} mmol) of water to the original solution. Samples for the studies of Entries 33−35 were prepared by adding 0.320 μL (1.76 × 10^{-2} mmol) of water to the original sample.

Acknowledgments

We are grateful to the Spanish DGES/MCyT (Project N. BQU-2002-00286) and the Consejería de Ciencia y Tecnología de la Junta de Comunidades de Castilla-La Mancha (PBI-02-002) for financial support.

Synthesis, Structure, and Photophysical and Electrochemical Properties of Cyclometallated Iridium(III) Complexes with Phenylated Bipyridine Ligands

Marc Lepeltier,[a] Terence Kwok-Ming Lee,[b] Kenneth Kam-Wing Lo,*[b] Loic Toupet,[c] Hubert Le Bozec,[a] and Véronique Guerchais*[a]

Dedicated to Professor David Carillo on the occasion of his 65th birthday

Keywords: Electrochemistry / Iridium / N ligands / Photochemistry

A series of cationic diiminoiridium(III) complexes [Ir(ppy-*N*,*C*)$_2$(L-*N*,*N*)](PF$_6$) has been prepared [Hppy = 2-phenylpyridine; L = 4,4′-*t*Bu$_2$dpbpy (**1**), 4,4′-Me$_2$dpbpy (**2**), 4,4′-Me$_2$pbpy (**3**), 4,4′-Me$_2$bpy (**4**)] and their photophysical and electrochemical properties studied. X-ray diffraction studies of complex **1** reveal a dihedral angle of about 33° between the pyridine rings, and that the two phenyl groups are also tilted with respect to the adjacent pyridine rings. All the complexes exhibit moderately intense and long-lived emission. The origin of the emission is tentatively assigned to a triplet metal-to-ligand charge-transfer ^{3}MLCT [dπ(Ir) → π*(diimine)] excited state, although the possibility of a triplet σ-bond-to-ligand charge transfer ^{3}SBLCT [σ(Ir–C) → π*(diimine)] cannot be excluded. The luminescence properties of the complexes are dependent on the substituents on the diimine ligands. Selective *N*-methylation of the diimine ligands has been achieved and their *N*,*C*-coordination to the Ir centre has been attempted.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Cyclometallated polypyridineiridium(III) complexes have attracted a great deal of interest due to their photophysical properties.[1−8] These systems exhibit luminescence emitted predominantly from triplet MLCT excited states with high quantum yields. Another interesting feature of these compounds is the possibility to tune the emission energy by simply modifying the cyclometallating and/or polypyridine ligands. One class of compounds that has been particularly well investigated for their photophysical properties and their use as dopants in organic light-emitting diode (OLED) devices are homoleptic neutral tris(cyclometallated) Ir^{III} complexes and related complexes.[2−4] The design of cationic cyclometalled Ir^{III} complexes [Ir(ppy-*N*,*C*)$_2$(bpy-*N*,*N*)]$^+$ (where bpy is 2,2′-bipyridine and Hppy is 2-phenylpyridine) has also been reported and their use as biological labelling reagents has been described recently.[5−8] A wide range of substituted 2,2′-bipyridines are now available, and, in particular, aromatic substituents can be introduced in the 6- and 6′-positions.[9,10] Such ligands are particularly attractive since they could adopt both *N*,*N* and *N*,*C* coordination. The latter coordination mode, involving orthometallation of the aryl group, requires prior *N*-protection of one pyridine ring in order to avoid the more facile *N*,*N*-coordination. It is anticipated that sequential *N*,*C*-coordination would allow access to polymetallic systems. We report herein the preparation, molecular structure, and photophysical and electrochemical properties of a series of cyclometallated diiminoiridium(III) complexes [Ir(ppy-*N*,*C*)$_2$(L-*N*,*N*)](PF$_6$) containing phenyl, methyl and/or *tert*-butyl substituents at various locations of the diimine ligands L. The effects of these different substituents on the luminescence properties of the complexes are discussed. We also describe here the selective *N*-methylation reactions of these ligands and attempts to coordinate them in an *N*,*C*-mode to the Ir centre.

Results and Discussion

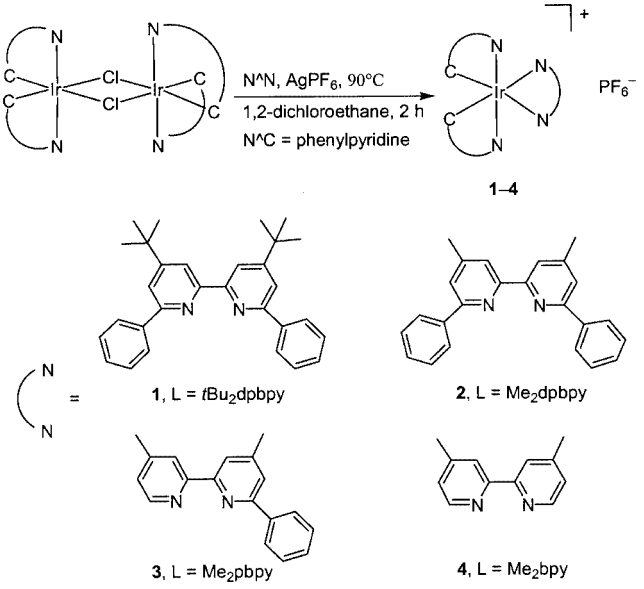
Synthesis and Characterization

The phenylated bipyridine ligands were prepared by classical procedures.[9,10] The phenylation reaction of 4,4′-dimethyl-2,2′-bipyridine (Me$_2$bpy) affords a mixture of monophenylated (Me$_2$pbpy) and diphenylated (Me$_2$dpbpy)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200400418

derivatives. They are readily separated by column chromatography and were isolated in 46% and 25% yield, respectively. Diphenylation of 4,4′-di-*tert*-butyl-2,2′-bipyridine (*t*Bu_2bpy) is similar to that of Me_2bpy.[10] The reaction is performed in refluxing THF, followed by hydrolysis and oxidation by manganese dioxide. After chromatographic purification, the diphenylated derivative *t*Bu_2dpbpy was isolated as a white solid in 84% yield; formation of the monophenylated product was not observed in this case.

The corresponding complexes [Ir(ppy-*N*,*C*)$_2$(L-*N*,*N*)](PF_6) [L = 4,4′-*t*Bu_2dpbpy (**1**), 4,4′-Me_2dpbpy (**2**), 4,4′-Me_2pbpy (**3**)] were then obtained from the reaction of the *ortho*-metallated dimer [Ir(ppy-*N*,*C*)$_2$(μ-Cl)]$_2$ and the appropriate diimine ligand L (Scheme 1). For comparison, the non-phenylated complex [Ir(ppy-*N*,*C*)$_2$(Me_2bpy-*N*,*N*)](PF_6) (**4**) was also prepared. The chloro-bridged dimer was synthesized following the procedure of Nonoyoma.[11] The coordination reactions of the diimine ligands to the Ir centre were performed in refluxing 1,2-dichloroethane; the use of methanol was avoided due to a protonation side-reaction of the diimine ligand. The presence of a silver salt is required, otherwise the starting material is recovered. All the complexes were crystallized from CH_2Cl_2/Et_2O and isolated as yellow crystals (yield: 70−80%). Complexes **1**−**4** were characterized by ^{1}H and ^{13}C NMR spectroscopy, and assignments were made on the basis of HMBC, HMQC, and COSY spectra. The heterocycles of the ppy ligands remain in a *trans* configuration as in the precursor dimer. Complexes **1**−**4** were formed as one isomer of low symmetry, as indicated by the NMR spectroscopic data. No *N*,*C*-chelation was thus observed under the reaction conditions used.



Scheme 1

The ^{1}H NMR spectrum of complex **3** shows two different sets of signals for the phenylpyridine ligands. In addition, the two N-heterocycles of the unsymmetric Me_2pbpy ligand are clearly distinguishable.

X-ray Crystal Structure of Complex 1

Crystals were obtained by slow diffusion of diethyl ether into a CH_2Cl_2 solution of **1**. The ORTEP diagram is depicted in Figure 1. Selected bond lengths and angles are listed in Table 1. Complex **1** (containing 1.5 H_2O molecules) exhibits a pseudo-octahedral geometry around the iridium centre, the two Ir−C bonds being in a *cis* position as in the precursor dimer. The Ir−N distances of the diimine ligand are similar to those of related complexes, and they are in accordance with a *trans* influence of the *C*-cyclometallating ligands. The slight lengthening of the Ir−N bond is similar to that observed for related cationic complexes.[5d,5g,6,12] The bite angle of the *t*Bu_2dpbpy ligand is similar to that of [Ir(ppy-*N*,*C*)$_2$(4′-R-6′-phenyl-2,2′-bipyridine-*N*,*N*)](PF_6) (R = $OCOC_6H_4OCOC_6H_4OC_6H_{13}$) [75.2(4)°].[5g] The bipyridine rings are not coplanar (dihedral angle 32.97°) and the 6,6′-diphenyl groups are also tilted with respect to the adjacent pyridine rings (dihedral angles 45.27° and 93.85°). This is probably due to steric reasons. Moreover, the phenyl rings are almost coplanar with the phenyl groups of the ppy

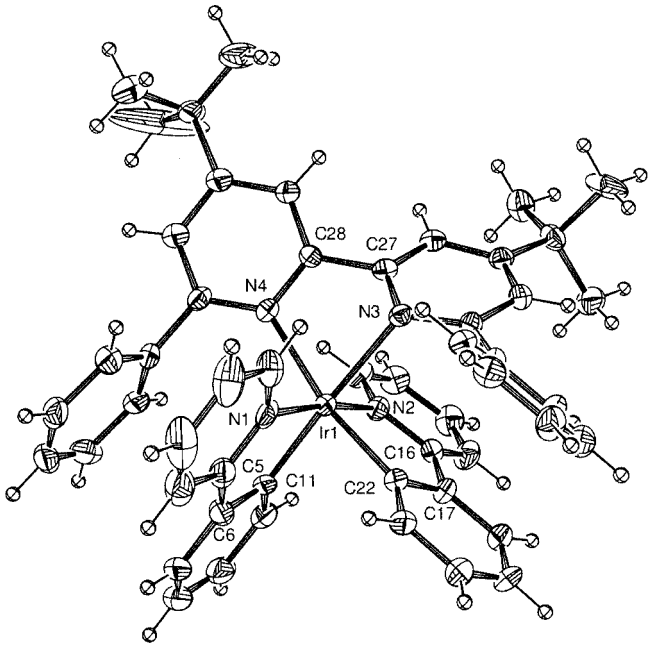


Figure 1. ORTEP representation of complex **1**; the unit cell contains 1.5 molecules of H_2O, which have been omitted for clarity, as has the PF_6^- counteranion

Table 1. Selected bond lengths [Å] and angles [°] for complex **1**

ligands. This feature has been previously reported for the above-mentioned monophenylated derivative.[5g]

Electronic Absorption Spectroscopy

The electronic absorption spectral data for complexes **1**−**4** in CH_2Cl_2 are summarized in Table 2. All complexes display intense absorption bands in the ultraviolet region at about 250−300 nm, which are assigned to spin-allowed intraligand ^{1}IL [$\pi \rightarrow \pi^*$(ppy and diimine)] transitions. In the visible region, weak absorption bands at about 345−445 nm are observed; these bands are attributed to spin-allowed ^{1}MLCT [$d\pi(Ir) \rightarrow \pi^*$(ppy and diimine)] transitions. In addition, weaker absorption bands and tailing at lower energy, corresponding to spin-forbidden ^{3}MLCT [$d\pi(Ir) \rightarrow \pi^*$(ppy and diimine)] transitions, are also observed. The absorption characteristics of these complexes are similar to those of related cyclometallated polypyridineiridium complexes.[1,5−8]

Table 2. Electronic absorption spectral data for complexes **1**−**4** at 298 K[a]

Complex	λ_{abs} [nm] (ε [M^{-1} cm^{-1}])
1	260 (49000), 300 (32000), 345sh (12000), 385sh (5200), 445sh (1600), 480sh (1000)
2	260 (48000), 300sh (29000), 345sh (12000), 385sh (5600), 445sh (1600), 475sh (900)

Luminescence Properties

Upon photoexcitation, complexes **1**−**4** display moderately intense and long-lived orange-yellow to greenish-yellow emission under ambient conditions and in low-temperature glass. The emission spectra of complexes **1**−**4** in CH_3CN at 298 K and alcohol glass at 77 K are shown in Figures 2−5. The photophysical data are listed in Table 3. The observed emission lifetimes in the microsecond and sub-microsecond time scales indicate the phosphorescent nature of the emission. The emission maxima occur at higher energy in less-polar CH_2Cl_2 than in more-polar CH_3CN. This observation is commonly made in other luminescent cyclometallated diiminoiridium systems.[1,5−8] In view of the low-lying π^*-orbitals of the diimine ligands, the emission is assigned to an emissive state of predominately ^{3}MLCT [$d\pi(Ir) \rightarrow \pi^*$(diimine)] character. However, the low reversibility of the oxidation waves of the complexes (see below) suggests the involvement of covalent Ir−C bond character in the HOMOs of the complexes. The possibility of a triplet σ-bond-to-ligand ^{3}SBLCT [$\sigma(Ir-C) \rightarrow \pi^*$(diimine)] emissive state thus cannot be totally ignored.[5a,7b,7c]

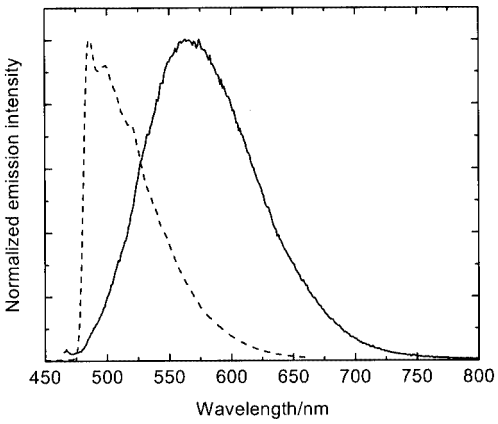

Figure 2. Emission spectra of complex **1** in CH_3CN at 298 K (− − −) and EtOH/MeOH (4:1, v/v) at 77 K (------)

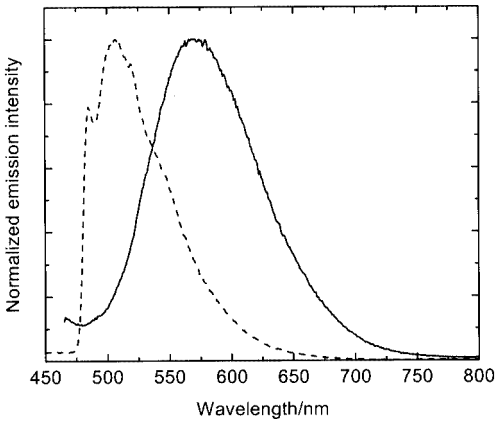

Figure 3. Emission spectra of complex **2** in CH_3CN at 298 K (− − −) and EtOH/MeOH (4:1, v/v) at 77 K (------)

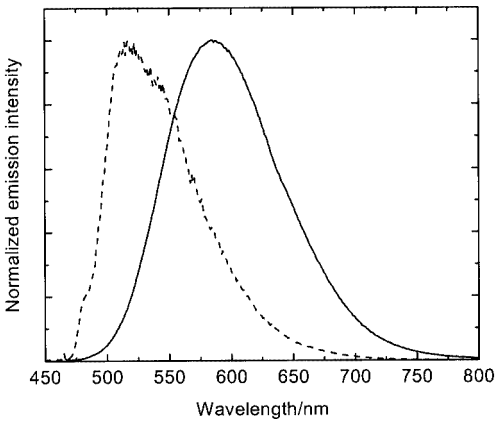

Figure 4. Emission spectra of complex **3** in CH_3CN at 298 K (− − −) and EtOH/MeOH (4:1, v/v) at 77 K (------)

Nevertheless, more detailed studies such as MO calculations are required to obtain a clearer picture of the electronic structures and excited-state nature of the complexes.

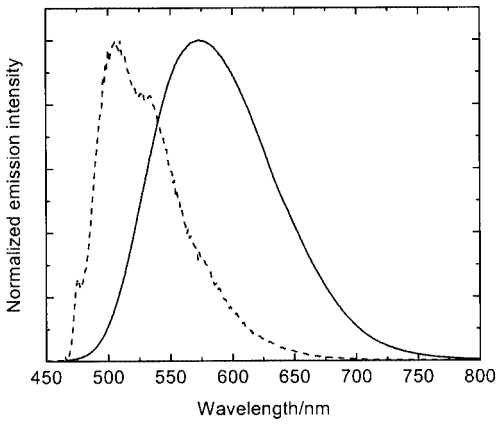

Figure 5. Emission spectra of complex **4** in CH_3CN at 298 K (– – –) and EtOH/MeOH (4:1, v/v) at 77 K (------)

The assignment of a ^{3}MLCT/^{3}SBLCT excited state is supported by the observation that the dimethyl complex **4** (λ_{em} = 573 nm in CH_3CN at 298 K) emits at noticeably higher energy than the non-substituted bipyridine analogue $[Ir(ppy\text{-}N,C)_2(bpy\text{-}N,N)]^+$ (λ_{em} = 606 nm).[1d] It is likely that the dimethyl substituents of complex **4** destablize the π*-orbitals of the Me_2bpy ligand, and thereby increase the ^{3}MLCT emission energy. The observation that the dimethylphenyl complex **3** (λ_{em} = 585 nm in CH_3CN at 298 K) emits at lower energy than complex **4** suggests that the phenyl ring at the 6-position of the bipyridine ligand of complex **3** lowers the energy level of the π*-orbitals due to electronic effects. Interestingly, the emission of the dimethyldiphenyl complex **2** occurs at almost the same energy as the dimethyl complex **4**, even though the former has two additional phenyl rings. The presence of two phenyl substituents in the 6- and 6′-positions does not lead to a bathochromic shift as would be expected for a more extended π-conjugated diimine ligand. A possible explanation is that in complex **2**, due to steric reasons, the two phenyl rings are not coplanar with the bpy moiety, and the degree of coplanarity of the bipyridine rings is also substantially reduced, as observed in the solid-state structure of complex **1** (see above). Thus, the lack of extensive π-conjugation raises the π*-level, and the ^{3}MLCT/^{3}SBLCT emission occurs at higher energy than expected. On the other hand, the di-*tert*-butyldiphenyl complex **1** (λ_{em} = 566 nm) emits at slightly higher energy than complex **2** (λ_{em} = 571 nm), probably due to the stronger electron-donating properties of the two *tert*-butyl substituents on the bipyridine ligand.

It is noteworthy that complex **1** (λ_{em} = 566 nm) emits at significantly higher energy than its phenyl-free counterpart $[Ir(ppy\text{-}C,N)_2(t\text{Bu}_2bpy\text{-}N,N)]^+$ (581 nm in CH_3CN).[8] This observation is in line with the crystal structure of complex **1**, which reveals that the two additional phenyl rings lower the π-conjugation between the two pyridine rings, and thereby destabilize the π*-orbitals of the diimine ligand, and increase the ^{3}MLCT/^{3}SBLCT emissive energy.

Upon cooling to 77 K, all four complexes display structural spectra and hypsochromic shifts in their emission maxima. These findings are commonly observed in other related luminescent cyclometallated polypyridineiridium complexes.[1,5–8] The emission decay is strictly single-exponential, with a lifetime of about 4–5 μs. In general, the emission is tentatively assigned to an excited state of predominantly ^{3}MLCT/^{3}SBLCT character.

Electrochemical Properties

The electrochemical data for complexes **1**–**4** are reported in Table 4. The cyclic voltammograms of the complexes in CH_3CN solution exhibit a reversible reduction at about −1.90 V vs. Fc/Fc^+. These waves can be assigned to the reduction of the bipyridine ligand as the cyclometallating ppy ligand is known to be reduced at much lower potential.[5d,6d] The cyclic voltammograms also exhibit an irreversible oxidation wave at a potential between 0.82 and 0.87 V vs. Fc/Fc^+. According to previous electrochemical studies on related complexes, these waves are attributed to metal-centered Ir^{III}/Ir^{IV} oxidation processes.[5a,7b,7c] The irreversible nature of this process suggests that the HOMOs may involve some covalent σ(Ir–C) character.[5a,7b,7c] By contrast, a quasi-reversible oxidation is observed for complex **4** containing the non-phenylated 4,4′-dimethyl-2,2′-bipyridine ligand. It is noteworthy that the same reversible oxi-

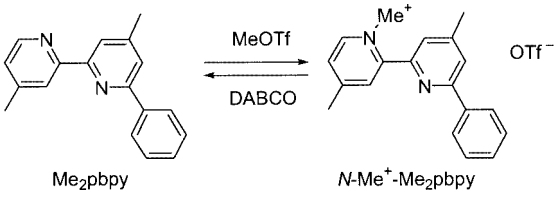
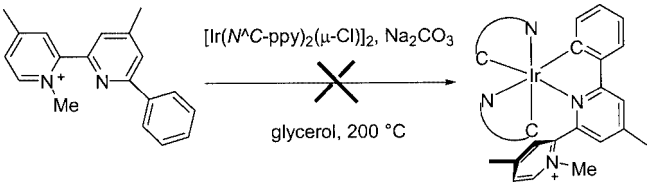
N-Alkylation Reactions and Attempts to Enforce N,C-Coordination of the Diimine Ligands

N-Protection by methylation of one pyridine ring of the above diimine ligands was performed in order to avoid *N*,*N*-coordination. The methylation reactions were performed with either MeOTf or $(Me_3O)(BF_4)$ as alkylating reagents in a chlorinated solvent. In the case of $t\text{Bu}_2$dpbpy, the reaction gives the dialkylated product. The desired monoprotected cations were obtained in a pure form after recrystallisation from a CH_2Cl_2/diethyl ether mixture as a white powder in moderate to good yield (36−56%). It is noteworthy that the monophenylated derivative Me_2pbpy undergoes selective methylation at the non-phenylated pyridine ring, probably due to steric reasons (Scheme 2). Thus, the phenylpyridine fragment of this compound is accessible for *N*,*C*-coordination. In addition, the *N*-methyl group can be readily removed in the presence of DABCO. A second *N*,*C*-coordination could be subsequently envisaged in the case of the diphenylated derivatives.



Scheme 2

It is noteworthy that the coordination of pyridinium ligands has not been reported for Ir so far, whereas examples are known for Ru, Rh, Pt and Pd complexes.[13,14] The classical procedures reported for the preparation of *fac*-tris-(cyclometallated) complexes have been applied for the cationic ligands.[2] The dimer $[Ir(ppy\text{-}N,C)_2(\mu\text{-Cl})]_2$ and [*N*-Me^+-Me_2pbpy](OTf) were refluxed at 200°C in glycerol in the presence of Na_2CO_3 (Scheme 3). However, this route



Scheme 3

was found to be inefficient, and the precursor dimer was partially recovered. Moreover, syntheses starting directly from $IrCl_3{\cdot}nH_2O$ to prepare the homoleptic complexes were also unsuccessful whatever the nature of the ligand. The fact that the bipyridine ligand may adopt a *transoid* conformation could induce a steric hindrance due to the presence of a substituent in the 4-position, especially in the case of the *t*Bu-substituted derivative.

Concluding Remarks

In conclusion, we have isolated a new series of luminescent cyclometallated diiminoiridium(III) complexes containing substituted bipyridine ligands. Upon photoexcitation, all the complexes are emissive in fluid solutions under ambient conditions and in low-temperature glass. The emission originates from an excited state of ^{3}MLCT [$d\pi(Ir) \rightarrow \pi^*$(diimine)] character, perhaps with some ^{3}SBLCT [$\sigma(Ir-C) \rightarrow \pi^*$(diimine)] character. Interestingly, instead of lowering the emission energy, addition of two phenyl substituents at the 6- and 6′-positions of the bipyridine ligand increases the emission energy of the complex. It is likely that the presence of the phenyl rings significantly lowers the degree of coplanarity of the bipyridine ligand, and thereby destabilizes the ^{3}MLCT emissive state. This is in line with the tilting of the two pyridine rings observed in the crystal structure of complex **1**. Our next target is to functionalize the 4,4′-dimethyl groups of the bipyridine ligand so that the complexes can be immobilized on a solid support. Related work is in progress.

Experimental Section

General Procedures: All manipulations were performed using Schlenk techniques under Ar. All solvents were dried and purified by standard procedures. All starting materials were used as received, MnO_2 was purchased from Merck. 6,6′-Diphenyl-2,2′-bipyridine (dpbpy), 6,6′-diphenyl-4,4′-dimethyl-2,2′-bipyridine (Me_2dpbpy) and 4,4′-di-*tert*-butyl-6,6′-diphenyl-2,2′-bipyridine ($t\text{Bu}_2$dpbpy) were prepared according to literature methods.[9,10] NMR spectra were recorded with Bruker DPX-200, AV 300 or AV 500 MHz spectrometers. ^{1}H and ^{13}C NMR chemical shifts are given versus $SiMe_4$ and were determined by reference to residual ^{1}H and ^{13}C solvent signals. Attribution of carbon atoms was based on HMBC, HMQC and COSY experiments. UV/Vis absorption spectra were recorded using a UVIKON 9413 spectrophotometer, and emission spectra were measured with a PTI C 60 fluorescence spectrophotometer. High-resolution mass spectra (HRMS) were performed with an MS/MS ZABSpec TOF at the CRMPO (Centre de Mesures Physiques de l'Ouest) in Rennes. Elemental analyses were performed by the Service central d'analyse du CNRS at Vernaison. Cyclic voltammograms were recorded using a PAR model 273 Autolab. The working electrode was polished Pt, the counter-electrode was a Pt wire, and a saturated calomel electrode (SCE) was used as the reference electrode. The Cp_2Fe/Cp_2Fe^+ redox couple was used as a secondary internal reference. Luminescence quantum yields were measured by the optically dilute method[15] using an aerated aqueous solution of $[Ru(bpy)_3]Cl_2$ (Φ_{em} = 0.028)[16] as the standard solution. Low-temperature (77 K) glass photophysical measurements were performed with the sample loaded in a quartz

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tube inside a quartz-walled Dewar flask filled with liquid nitrogen. The excitation source for emission lifetime measurements was the 355 nm output (third harmonic) of a Quanta-Ray Q-switched GCR-150-10 pulsed Nd-YAG laser. Luminescence decay signals from a Hamamatsu R928 photomultiplier tube were converted into potential changes by a 50 Ω load resistor and then recorded with a Tektronix Model TDS 620A digital oscilloscope.

4,4′-Di-*tert*-butyl-6,6′-diphenyl-2,2′bipyridine (*t*Bu$_2$dpbpy): PhLi (11 mL, 20 mmol; 1.8 M, cyclohexane/diethyl ether) was added to a solution of 4,4′-di-*tert*-butyl-2,2′-bipyridine (1.34 g, 5 mmol) in 20 mL of THF. After stirring at room temperature for 30 min, the reaction medium was refluxed for 12 h. The reaction mixture was then hydrolysed at 0°C and the residue extracted with CH_2Cl_2 (3 × 150 mL). The organic phase was dried with $MgSO_4$ and MnO_2 (12.5 g, 144 mmol) was added. The reaction medium was stirred for 12 h and then filtered through Celite. Chromatography on silica gel (heptane/ethyl acetate, 95:5) afforded a white powder (1.34 g, 84%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.61 (d, ^4J = 1.8 Hz, 2 H, H$^{3/5}$-Py), 8.17 (m, 4 H, Ph *ortho*), 7.78 (d, ^4J = 1.8 Hz, 2 H, H$^{3/5}$-Py), 7.50 (m, 6 H, Ph *meta* and *para*), 1.47 (s, 18 H, *t*Bu) ppm. ^{13}C {^{1}H} NMR (75.4 MHz, $CDCl_3$): δ = 162.0 (C$^{2/6}$-Py), 156.9 (C$^{2/6}$-Py), 140.6 (C^4-Py), 129.2 (Ph), 128.8 (Ph), 127.6 (Ph), 127.0 (Ph), 118.0 (C$^{3/5}$-Py), 117.4 (C$^{3/5}$-Py), 35.7 (*t*Bu), 31.2 (*t*Bu). HRMS: *m*/*z* = 420.2563 [M]$^+$; calcd. for $C_{30}H_{32}N_2$ 420.25655. $C_{30}H_{32}N_2$ (420.6): calcd. C 85.67, H 7.67, N 6.66; found C 85.05, H 7.94, N 6.27.

4,4′-Dimethyl-6-phenyl-2,2′-bipyridine (Me$_2$pbpy): The monophenylated derivative 4,4′-dimethyl-6-phenyl-2,2′-bipyridine was obtained during the preparation of Me$_2$dpbpy.[9] Chromatography on silica gel using ethyl acetate as eluent gave pure Me$_2$pbpy as a white powder. Yield: 46%. ^{1}H NMR (200 MHz, CD_3COCD_3): δ = 8.51 (d, ^3J = 4.8 Hz, 1 H, H^6-Py), 8.49 (d, ^4J = 1.2 Hz, 1 H, H^3-Py), 8.22 (m, 3 H, H$^{3/5}$-Py* and Ph *ortho*), 7.79 (d, ^4J = 1.8 Hz, 1 H, H$^{3/5}$-Py*), 7.52 (m, 3 H, Ph), 7.22 (dd, ^3J = 4.8, ^4J = 1.2 Hz, 1 H, H^5-Py), 2.50 (s, 3 H, MePy*), 2.48 (s, 3 H, MePy) ppm; (Py* = Ph-Py). HRMS: *m*/*z* = 260.1328 [M]$^+$; calcd. for $C_{18}H_{16}N_2$ 260.13135. $C_{18}H_{16}N_2$ (260.3): calcd. C 83.04, H 6.19, N 10.76; found C 82.93, H 6.33, N 10.10.

Synthesis of [Ir(ppy-*N*,*C*)$_2$(L-*N*,*N*)](PF$_6$) (1−4): The chloride-bridged dimer [Ir(ppy-*N*,*C*)$_2$(μ-Cl)]$_2$ (0.1 mmol), the appropriate bipyridine derivative L (0.2 mmol), and $AgPF_6$ (0.2 mmol) were mixed in 1,2-dichloroethane (10 mL). The reaction mixture was refluxed under Ar for 2 h. The solution was then concentrated to dryness and the product was extracted with CH_2Cl_2 (3 × 5 mL). Crystallisation from a CH_2Cl_2/diethyl ether mixture gave a yellow-green powder.

[Ir(ppy-*N*,*C*)$_2$(*t*Bu$_2$dpbpy-*N*,*N*)](PF$_6$) (1): Yield 76%. ^{1}H NMR (300 MHz, CD_3COCD_3): δ = 8.65 (dd, ^3J = 5.8, ^4J = 1.4 Hz, 2 H, H^6-Py), 8.60 (d, ^4J = 2.0 Hz, 2 H, H^3-Py*), 7.96 (td, ^3J = 8.2, ^4J = 1.4 Hz, 2 H, H^4-Py), 7.86 (dd, ^3J = 8.2, ^4J = 1.5 Hz, 2 H, H^3-Py), 7.42 (d, ^4J = 2.0 Hz, 2 H, H^5-Py*), 7.26 (td, ^3J = 8.2, ^3J = 5.8, ^4J = 1.5 Hz, 2 H, H^5-Py), 7.21 (dd, ^3J = 7.7, ^4J = 1.2 Hz, 2 H, H^3-Ph), 6.99 (m, 2 H, Ph* *para*), 6.76 (m, 8 H, Ph* *meta* and *ortho*), 6.48 (td, ^3J = 7.7, ^4J = 0.8 Hz, 2 H, H^4-Ph), 6.13 (td, ^3J = 7.7, ^4J = 1.2 Hz, 2 H, H^5-Ph), 5.29 (dd, ^3J = 7.7, ^4J = 0.8 Hz, 2 H, H^6-Ph), 1.43 (s, 18 H, *t*Bu) ppm. ^{13}C {^{1}H} NMR (75.4 MHz, CD_3COCD_3): δ = 168.0 (C^2-Py), 163.9 (C^4-Py*, C^6-Py*), 160.1 (C^2-Py*), 150.8 (C^6-Py), 146.8 (C^1-Ph), 141.9 (C^2-Ph), 138.6 (Ph* *ipso*), 138.1 (C^4-Py), 130.8 (C^6-Ph), 129.1 (C^5-Ph), 128.0 (Ph* *para*), 127.4 (Ph* *ortho* and *meta*), 125.8 (C^5-Py*), 124.1 (C^3-Ph), 121.7 (C^5-Py, C^3-Py*), 120.5 (C^4-Ph), 119.1 (C^3-Py), 35.4 (*t*Bu), 29.4 (*t*Bu) ppm; Py* = Ph-Py. tion of tBu$_2$dpbpy (250 mg, 0.60 mmol) in 10 mL of $ClCH_2CH_2Cl$. After refluxing for 15 h, the solution was concentrated to dryness. The residue was crystallized from a CH_2Cl_2/diethyl ether mixture in order to separate the *N,N*-dimethyl adduct and the diimine precursor. The product was isolated as a white powder by concentration of the resulting solution (112 mg, 36%). ^{1}H NMR (300 MHz, CD_3COCD_3): δ = 8.40 (d, ^4J = 2.3 Hz, 1 H, H^3-Py*), 8.28−8.22 (m, 4 H, H^5-Py*, H^5-Py, Ph *ortho*), 8.05 (d, ^4J = 1.4 Hz, 1 H, H^3-Py), 7.90−7.85 (m, 2 H, Ph* *ortho*), 7.76−7.66 (m, 3 H, Ph* *meta* and *para*), 7.59−7.50 (m, 3 H, Ph *meta* and *para*), 4.13 (s, 3 H, *N*-Me), 1.57 (s, 9 H, *t*Bu*), 1.50 (s, 9 H, *t*Bu) ppm. ^{13}C {^{1}H} NMR (75.4 MHz, CD_3COCD_3): δ = 170.6 (C^4-Py*), 163.4 (C^4-Py), 157.4 (C^6-Py), 156.9 (C^6-Py*), 154.7 (C^2-Py*), 151.3 (C^2-Py), 138.4 (Ph *ipso*), 133.3 (Ph* *ipso*), 131.2 (Ph*), 129.8 (Ph), 129.6 (Ph*), 129.4 (Ph*), 128.9 (Ph), 127.3 (Ph), 126.8 (C^5-Py*), 126.1 (C^3-Py*), 121.8 (C^3-Py), 119.1 (C^5-Py), 45.0 (*N*-Me), 36.6 (*t*Bu*), 35.4 (*t*Bu), 29.8 (*t*Bu), 29.2 (*t*Bu*) ppm; Py* = *N*-MePy. HRMS: *m*/*z* = 435.2784 [M]$^+$; calcd. for $C_{31}H_{35}N_2$ 435.2800.

1,4,4′-Trimethyl-6,6′-diphenyl-2,2′-bipyridinium Triflate: Me$_2$dpbpy (0.25 g, 0.74 mmol) was dissolved in 5 mL of $ClCH_2CH_2Cl$ in a Schlenk tube and MeOTf (83 μL, 0.74 mmol) was then added. The reaction mixture was stirred overnight and the solvent evaporated. The residue was extracted with 5 mL of CH_2Cl_2. Addition of diethyl ether precipitated the precursor compound; the monocation was then recovered as a white powder (176 mg, 48%) upon evaporation of the resulting solution. ^{1}H NMR (300 MHz, CD_3COCD_3): δ = 8.27 (d, ^4J = 1.9 Hz, 1 H, H^3-Py*), 8.22 (m, 2 H, Ph*), 8.13 (m, 2 H, H^5-Py, H^5-Py*), 7.88 (m, 3 H, Ph *ortho*, H^3-Py), 7.75 (m, 3 H, Ph *meta* and *para*), 7.55 (m, 3 H, Ph* *meta* and *para*), 4.22 (s, 3 H, *N*-Me), 2.85 (s, 3 H, Me*), 2.62 (s, 3 H, Me) ppm. ^{13}C {^{1}H} NMR (75.4 MHz, CD_3COCD_3): δ = 159.4 (C^4-Py*), 156.7 (C^6-Py*), 154.0 (C^2-Py*), 150.8 (C^2-Py, C^4-Py), 150.4 (C^6-Py), 138.9 (Ph* *ipso*), 133.0 (Ph *ipso*), 131.4 (Ph *para*), 130.3 (C^5-Py*), 129.8 (Ph*), 129.6 (C^3-Py*), 129.4 (Ph), 129.2 (Ph), 128.9 (Ph*), 127.1 (Ph*), 125.3 (C^3-Py), 122.8 (C^5-Py), 45.2 (*N*-Me), 20.9 (Me*), 20.4 (Me) ppm; Py* = *N*-MePy. HRMS: *m*/*z* = 351.1858 [M]$^+$; calcd. for $C_{25}H_{23}N_2$ 351.18612.

1,4,4′-Trimethyl-6′-phenyl-2,2′-bipyridinium Triflate: Me$_2$pbpy (0.10 g, 0.38 mmol) was dissolved in 5 mL of $CHCl_3$ in a Schlenk tube. The solution was cooled to −30°C and MeOTf (43 μL, 0.38 mmol) was then added. The reaction mixture was warmed up to room temperature and the solvent evaporated. The residue was washed with toluene (2 × 3 mL) and the residue extracted with 5 mL of $CHCl_3$. The solution was cooled to −20°C, filtered, and then concentrated to afford a white powder (90 mg, 56%). ^{1}H NMR (200 MHz, CD_3COCD_3): δ = 9.05 (d, ^3J = 6.6 Hz, 1 H, H^6-Py), 8.24 (d, ^4J = 1.8 Hz, 1 H, H^3-Py), 8.17 (d, ^4J = 1.6 Hz, 1 H, H$^{3/5}$-Py*), 8.16 (t, ^3J = 6.0 Hz, 2 H, Ph^3), 8.12 (dd, ^3J = 6.6, ^4J = 1.8 Hz, 1 H, H^5-Py), 7.78 (d, ^4J = 1.6 Hz, 1 H, H$^{3/5}$-Py*), 7.52 (td, ^3J = 6.0, ^4J = 1.8 Hz, 1 H, Ph^4), 7.49 (dd, ^3J = 6.0, ^4J = 1.8 Hz, 1 H, Ph^2), 4.52 (s, 3 H, *N*-Me), 2.80 (s, 3 H, MePy), 2.60 (s, 3 H, MePy*) ppm; Py* = *N*-MePy. HRMS: *m*/*z* = 275.1553 [M]$^+$; calcd. for $C_{19}H_{19}N_2$ 275.1548.

Deprotection of 1,4,4′-Trimethyl-6,6′-diphenyl-2,2′-bipyridinium Triflate: A solution of the salt (120 mg, 0.18 mmol) and DABCO (20 mg, 0.18 mmol) in 20 mL of DMF was refluxed for 2 h. After addition of 30 mL of water, the product was extracted with CH_2Cl_2 (2 × 20 mL). The organic phase was dried with $MgSO_4$. Evaporation of the solvent gave a white powder (50 mg, 82%) which was identified by ^{1}H NMR spectroscopy as Me$_2$dpbpy.

Attempts at *N,C*-Coordination: 1,4,4′-Trimethyl-6′-phenyl-2,2′-bipyridinium triflate (49 mg, 0.116 mmol) and Na_2CO_3 (49 mg, 0.46 mmol) were added to a solution of [Ir(ppy-*N,C*)$_2$(μ-Cl)]$_2$ (50 mg, 0.046 mmol) in 10 mL of glycerol. The reaction mixture was then heated to 200 °C for 24 h. Addition of water (10 mL) gave a brown precipitate, which was washed with diethyl ether (2 × 5 mL) and methanol (5 mL). ^{1}H NMR studies of the crude product showed the presence of the dimer precursor and an unidentified product.

Structural Determination of Complex 1: Single crystals for X-ray diffraction studies were grown by slow diffusion of diethyl ether into a CH_2Cl_2 solution of complex **1** at 20 °C. The samples were studied with a NONIUS Kappa CCD with graphite-monochromated Mo-K_α radiation. The data collection and refinement parameters are presented in Table 5. The structures were solved with SIR-97,[17a] which reveals the non-hydrogen atoms of the molecules. The whole structures were refined by full-matrix, least-squares techniques on F^2, with hydrogen atoms refined using the riding mode. Structures were solved by Patterson or direct methods. The structures were completed by subsequent difference Fourier techniques and refined by full-matrix least squares on F^2 (SHELXL-97) with initial isotropic parameters.[17] CCDC-225743 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [of from Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structural and Photophysical Characterisation of *fac*-[Tricarbonyl(chloro)-(5,6-epoxy-1,10-phenanthroline)rhenium(I)]

Angel A. Martí,[a] Gellert Mezei,[a] Lorena Maldonado,[a] Giovanni Paralitici,[a] Raphael G. Raptis,[a] and Jorge L. Colón*[a]

Keywords: Carbonyl ligands / Coincidental resonances / Facial isomers / Energy gap law / Rhenium

The structural and spectroscopic characterisations of *fac*-[Re(phen)$(CO)_3$Cl] (**1**) (phen = 1,10-phenanthroline), *fac*-[Re(ephen)$(CO)_3$Cl] (**3**) [ephen = 5,6-epoxy-1,10-phenanthroline (**2**)] and ephen are reported. The appearance of weak hydrogen bond networks in the crystal lattice of [Re(ephen)$(CO)_3$Cl] and ephen are discussed. Two different isomers of [Re(ephen)$(CO)_3$Cl] were identified by IR and NMR spectroscopy. Coincidental resonances were differentiated for these complexes by temperature-dependent NMR spectroscopy. Recrystallisation of the crude material allowed the separation of the two isomers. The spectroscopic data permitted the calculation of radiative and nonradiative luminescence rate constants which are consistent with the energy gap law.

Introduction

The first observation of electronically excited luminescence in carbonylmetal compounds at room temperature was reported by Wrighton and Morse in 1974 for [ReX$(CO)_3$Cl], where X is 1,10-phenanthroline and its derivatives.[1] Since then, a great variety of luminescent carbonylmetal complexes have emerged with applications in areas ranging from electronic and energy transfer to catalysis.[2] In the last few years, self-assembled multinuclear carbonylrhenium complexes have been prepared with interesting photophysical and photochemical properties.[3] In addition, carbonylrhenium compounds have been used to modify proteins with the aim of studying biological electron transfer pathways.[4]

Tricarbonylrhenium(I) complexes are d^6 species which undergo spin-forbidden charge transfer emissions after photoexcitation.[5] Excitation promotes an electron from rhenium-centred orbitals to π* ligand localised orbitals, whereupon internal conversion occurs to the triplet state (or mixed singlet-triplet state) followed by subsequent relaxation into the ground state with the emission of a photon.[1] These d^6 complexes are isoelectronic with tris(2,2′-bipyridine)ruthenium(II) and their emission properties are similar to other d^6 metal complexes which undergo electron transfer reactions from their excited states.[6]

The construction of supramolecular assemblies of photoactive metal complexes requires the availability of well-characterised and preferably easily synthesised moieties with functionalities that allow their attachment to other parts of the framework. Among the possibilities, epoxy group containing molecules are good candidates because they enable the easy formation of covalent bonds between a carbon atom and a specific anchoring group. This possibility has been explored by Shen and Sullivan who used an epoxidised phenanthroline for the attachment of a crown ether.[7] The phenanthroline was then coordinated to a tricarbonylrhenium centre to complete the photoluminescent system. These authors reported that treatment of [Re$(CO)_5$Cl] with 5,6-epoxy-1,10-phenanthroline (ephen, **2**) produced *fac*-[tricarbonyl(chloro)(5,6-epoxy-1,10-phenanthroline)rhenium(I)] {*fac*-[Re(ephen)$(CO)_3$Cl], **3**}. However, no detailed synthetic scheme or characterisation of this complex was reported. As stated above, detailed structural and photophysical characterisation of this complex is necessary if the intention is to use it as part of photoactive molecular frameworks. Here, we report the complete structural and photophysical characterisation of *fac*-[Re(ephen)$(CO)_3$Cl]. In addition, for comparison, we have determined the crystal structure of *fac*-[tricarbonyl(chloro)(1,10-phenanthroline)rhenium(I)] {*fac*-[Re(phen)$(CO)_3$Cl], **1**}. We also report the crystal structure of the ephen ligand.

Results and Discussion

Crystal Structure Description

The structure of **1** consists of a rhenium(I) atom octahedrally coordinated by a chelating phenanthroline ligand, a chloride ion and three carbonyl groups in a facial conformation (Figure 1 and Supporting Information; for Supporting Informations see also the footnote on the first page of this article). Selected bond lengths and bond angles are listed in Table 1. Although this molecule was prepared by Wrighton et. al ca. 30 years ago, this is the first time that its crystal structure has been reported.

The bond lengths in **1** agree with those in similar *fac*-(tricarbonylrhenium) compounds.[4,8] The average Re−N bond length is 2.179(3) Å which is shorter than the Re−N bond length of 2.211(3) Å for *fac*-[tricarbonyl(chloro)bis-(pyridine)rhenium] [$Re(py)_2(CO)_3Cl$], and 2.218(6) and 2.200(6) Å for *fac*-[tricarbonyl(chloro)bis(4,4′-bipyridine)-rhenium] [$Re(4,4'\text{-bpy})_2(CO)_3Cl$].[9]

Figure 2 shows an ORTEP representation of **2**·$CHCl_3$. The structure of **2**·$CHCl_3$ is similar to that of the parent ligand 1,10-phenanthroline with some evident exceptions (Supporting Information, Figure S1).[10] The insertion of oxygen atoms at positions 5 and 6 of the phenanthroline ligand disrupts the delocalised π-system aromaticity in the ligand. The effect of this disruption is that the two pyridine rings rotate relative to each other by ca. 6° (rotation about the C11−C12 axis).

The X-ray crystal structure of **2**·$CHCl_3$ shows a chloroform solvent molecule hydrogen-bonded to the nitrogen atoms of the ephen ligand. However, this bifurcated hydrogen bond is weak (H···N distances of 2.41 Å and 2.30 Å) and the crystals of **2**·$CHCl_3$ loses the chloroform molecule easily. This type of weak hydrogen bond has been well documented in the literature.[11] Mascal presented statistical evidence of C−H···N hydrogen bonding in a variety of crystal structures with H···N distances ranging from 2.05 to 2.45 Å.[12] An additional hydrogen bond between C1−H and the epoxy oxygen atom of a nearby **2**·$CHCl_3$ molecule (H···O 2.64 Å) adds stability to the crystal lattice (see Supporting Information, Figure S2).

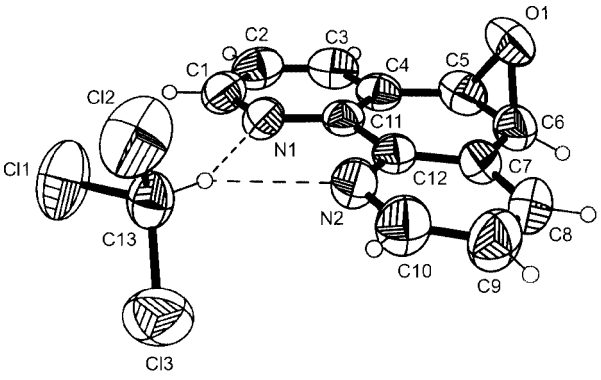

Figure 2. ORTEP representation of **2**·$CHCl_3$; ellipsoids are shown at the 50% probability level

Figure 3 shows an ORTEP representation of **3a**. For *fac*-[$Re(ephen)(CO)_3Cl$] we found two polymorphs, **3a** and **3b**, in which the chloride ion is *trans* to the chloro ligand in both forms (Supporting Information, Figure S1). There are no significant differences between the bond lengths and angles in **3a** and **3b**. The Re atom is in a distorted octahedral environment with the carbonyl groups in a facial arrangement as in the parent compound **1**. The most significant deviation from octahedral geometry can be seen for the chloride ion where C1−Re−Cl1 is 176.58(16)°

(Table 2). This angle is similar to that of 176.33(14)° in **1**. The bonds lengths and angles are similar to those of **1**, differing only in the ephen ligand. The distinguishing feature between the structures of the polymorphs **3a** and **3b** is the number of weak C−H···O hydrogen bonds (H···O < 2.67 Å) between adjacent molecules of **3a** and **3b**, respectively, with there being one for **3a** and three for **3b** (Supporting Information, Figures S3 and S4).

Infrared Spectroscopy

The IR spectrum of **1** (Figure 4) shows three bands in the 2100−1800 cm^{-1} region which can be attributed to the vibrations of the carbonyl groups in the facial conformation. Group theory predicts that a molecule with C_{3v} point group symmetry must possess two fundamental vibrational modes (both IR- and Raman-active), i.e. an A_1 symmetric stretching mode and a degenerate E stretching mode.[13] Since the symmetry of **3** is C_s, the local C_{3v} symmetry of the carbonyl groups is perturbed. Thus, changing the symmetry from C_{3v} to C_s causes the A_1 mode to become A′ and the degenerate E mode to split into A′ and A″.The carbonyl region of **1** was used to identify the facial isomer and exclude the presence of the meridional isomer.[14] A facial isomer must possess three intense bands in the carbonyl region {e.g., *fac*-[Re(phen)$(CO)_3$Cl] shows three intense bands at 2015, 1912 and 1890 cm^{-1}},[1] while the meridional isomer must possess two intense bands and one weak band at higher wavenumber[15] {e.g., *mer*-[Re$(CO)_3(PPh_3)_2$Cl] shows two intense bands at 1944 and 1894 cm^{-1}, while the weak band expected at ca. 2050 cm^{-1} was not observed}.[16] Figure 4 shows that the IR spectrum of molecule **1** exhibits three intense bands that characterise it as a facial isomer. Staal et al. studied the carbonyl vibrations in analogous complexes [M$(CO)_3$X(DBA)] (M = Mn, Re; X = Cl, Br, I; DBA = 1,4-diazabutadiene) with different substitutions on the DBA ligand.[15] These authors assigned the band above 2000 cm^{-1} to the symmetric stretching mode A′ of the carbonyl groups adjacent to the halogen atom. The next band at higher wavenumber was assigned to the asymmetric A″ mode of the carbonyl groups adjacent to the halogen atom and the last one at the highest wavenumber was assigned to the stretching mode of the carbonyl group *trans* to the halogen atom. Because of the analogy of this system with **1** and **3** we have based our assignment of the vibrational modes on that previous work.

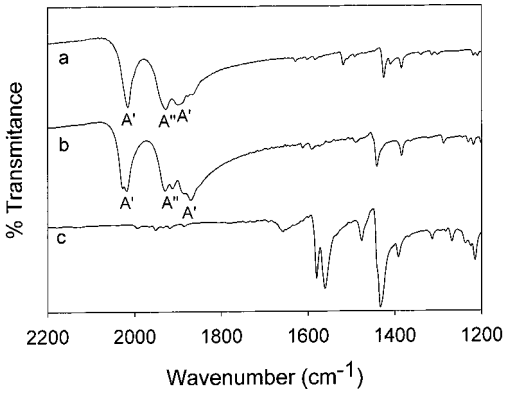

Figure 4. Infrared spectra including the carbonyl region for **1** (a), **3** (crude material) (b) and **2** (c)

In contrast, the spectrum of **3** is more complicated. Each band is split into two (see b in Figure 4), whereas **2** does not show any transition in this region (see c in Figure 4). The splitting of the carbonyl bands observed in the spectrum of **3** will be discussed in the next section along with the NMR spectroscopic results which shed light on the origin of this splitting.

NMR Spectroscopy

^{1}H NMR studies in DMF indicate that **2** possesses three signals in the aromatic region (doublets of doublets) attributable to the pyridine hydrogen atoms (the corresponding atoms in each pyridine ring are equivalent) and an upfield signal attributable to the aliphatic epoxide hydrogen atoms (singlet). ^{13}C NMR spectroscopy shows the signals of the five pyridine carbon atoms in the aromatic region and the epoxide carbon atoms upfield in the hydrocarbon region. These studies confirm that the solution structure of **2** is consistent with its crystal structure (see Supporting Information, Figure S5).

^{1}H NMR spectroscopy of **1** shows four signals in the aromatic region as expected. Six signals in the aromatic region of the ^{13}C NMR spectrum are consistent with the presence of the phenanthroline ligand. The CO carbon signals appear at δ = 190.69 and 198.63 ppm, the latter being assigned to the carbonyl group *trans* to the chloride ion (based on the *trans* effect).

The ^{1}H and ^{13}C NMR spectra of crude **3** are more complicated than would be expected based on the close similarity between **3** and **1** (Figure 5). The most distinctive feature of these spectra compared with those of **1** is that each peak is split. This is especially notable in the ^{13}C NMR spectrum which shows two close sets of resonances when only one is to be expected. Another intriguing finding is that the epoxide resonance in the ^{1}H NMR spectrum (δ = 5.17 ppm) is not split like the rest of the resonances. There are three possible explanations for these observations: (a) there is differentiation of the otherwise equivalent protons of the ephen ligand due to the loss of planarity, (b) there is a mixture of the *fac* and *mer* isomers, or (c) there is a mix-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

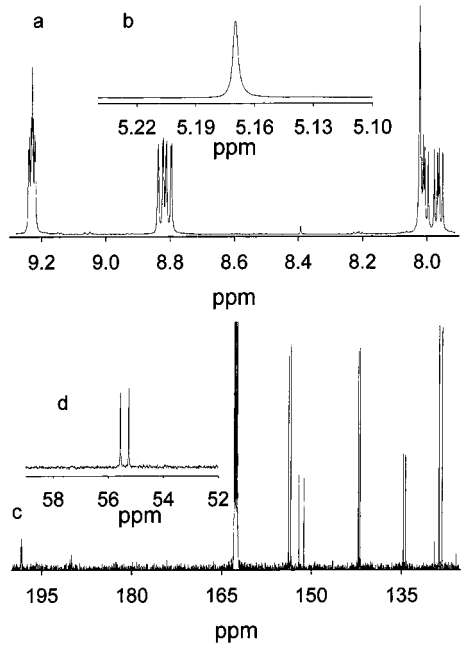

Figure 5. ^{1}H NMR spectrum of **3** (a); ^{1}H NMR high-field ephen hydrogen signals of **3** (crude material) (b); ^{13}C NMR spectrum of **3** (c); ^{13}C NMR high-field ephen carbon signals of **3** (d)

ture of *fac* isomers with the epoxide group of the ephen ligand oriented on different sides of the plane passing through the equatorial carbonyl groups (see Supporting Information, Figure S6).

The first explanation requires that the chemical environment around the protons and carbon atoms on different sides of the mirror plane bisecting the phenanthroline ligand be different enough to show different signals in NMR spectroscopy. The crystal structure shows only subtle differences which can be expected to be normalised by the dynamic environment of the solvent. In addition, this explanation does not account for the splitting of the carbonyl bands in the IR spectra. The splitting of the carbonyl bands appears to be consistent with the existence of two different isomers which leads us to favour either explanation (b) or (c).

In the case of explanation (b), the occurrence of *mer* and *fac* isomers would produce splitting of the bands in the ^{13}C NMR and ^{1}H NMR spectra and the occurrence of new bands in the IR spectroscopic carbonyl region compared with **1**. However, close inspection of the carbonyl region in the ^{13}C NMR spectrum indicates that these resonances are very close to those observed for *fac*-[Re(phen)(CO)$_3$Cl] (**1**). Because the carbonyl groups assume a very different orientation in the *mer* isomer than in the *fac* isomer, one would expect differentiation of the carbonyl signals. However, the spectra suggest that the carbonyl chemical environments of these two isomers are very similar (by the similarity of their carbonyl signals) which is inconsistent with the assignment of a mixture of *fac* and *mer* isomers. Moreover, the synthesis used for **3** is very similar to the one used for **1**, the latter being obtained with a 100% yield of the *fac* isomer.[16] Because of the similarity of these compounds we would expect the synthesis of **3** to also produce only the *fac* isomer. Finally, an octahedral complex with three carbonyl groups in the *fac* conformation would exhibit three intense bands in the carbonyl region (ca. 1900 to 2050 cm^{-1}) while a *mer* isomer must show two intense bands between 2000 and 1900 cm^{-1} and a weak band at ca. 2015 cm^{-1} which on some occasions is even absent.[14,16] As it is evident from Figure 4, the presence of two sets of three intense bands is consistent with the existence of two *fac* isomers.

Explanation (c) requires that the epoxy group has little or no influence on the coordination of the ephen ligand to the rhenium centre. If this is true, it could explain the presence of two closely spaced sets of resonances in both the ^{1}H and ^{13}C NMR spectra and also the observed 1:1 signal intensity ratio. However, only the isomer with the epoxy group *trans* to the chloride ion could be characterised by single-crystal X-ray diffraction. Attempts to crystallise the second isomer were unsuccessful. The structure of the isomer with the epoxy group *trans* to the chloride ion and the proposed structure of the isomer with the epoxy group *cis* to the chloride ion are presented in the Supporting Information (Figure S6).

The unexpected fact that the epoxide proton resonance is not split, prompted us to perform NMR measurements at a higher temperature (60 °C). The most significant difference is the splitting of the epoxide hydrogen resonance at 60 °C (Figure 6) compared with that at 25 °C. These resonances collapse into a single peak when cooled again to 25 °C. Previous studies of this complex at low temperature by Shen and Sullivan indicated that this signal also splits when the material is cooled to −60 °C.[7] This observation led the authors to conclude that a relatively low exchange barrier exists between the *trans* and *cis* isomers. However, the new temperature-dependent data we are presenting indicate that this is not the case. A low isomerisation barrier for this ligand would not produce a splitting of the epoxide signal upon a rise in temperature. Rather, an increase in temperature would increase the rate of isomerisation producing a single peak within the time of measurement of the instrument. Therefore, the appearance of two resonances at 60 °C is consistent with the existence of two *fac* isomers. An explanation could be that the factors which account for the chemical shift of these hydrogen atoms in both isomers cancel out to yield a single resonance at room temperature.

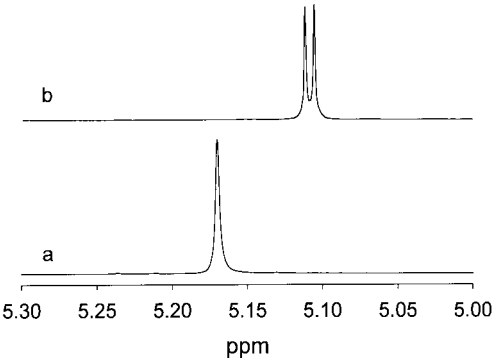

Figure 6. ^{1}H NMR spectrum of crude **3** showing the resonance signals for the hydrogen atoms attributed to the epoxide in the ephen ligand at 25 °C (a) and 60 °C (b)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These coincidental resonances can be differentiated at higher temperature because of the variation of the solvent's physical properties at those temperatures (e.g., density, viscosity, dielectric constant). The other peaks in both the ^{13}C and ^{1}H NMR spectra at 25 °C and 60 °C are very similar, with some minor displacements due to the change in temperature.

Finally, there is still the question of why we observe only one isomer in the crystal structure. We propose that the isomer with the epoxy group *trans* to the chloride ion is preferred during crystallisation because of a more favourable hydrogen bonding network. We also observed that along with the crystals, a yellow powder also precipitates and this could be the other isomer. Infrared spectra of the crystals and the powder (see Supporting Information, Figure S7) correlate exactly except for the carbonyl region which is consistent with the presence of two different isomers. In order to unequivocally assign the NMR spectra of both isomers we determined the ^{1}H NMR spectra of both the crystals and the yellow powder resulting from the recrystallisation of the crude material (see Supporting Information, Figure S8). The ^{1}H NMR spectrum of the crystals exhibit signals which are shifted downfield relative to those of the powder, again supporting our assignment of two different isomers.

Electronic Absorption and Luminescence Characterisation

One of the most distinctive features in the UV/Vis absorption spectrum of **3** is the presence of a peak near 385 nm corresponding to the MLCT band which can be assigned by analogy with its parent compound **1**. As is evident from Figure 7, this band is not present in the spectrum of **2** or that of the phenanthroline ligand (phen). The MLCT absorption maximum of **3** is red-shifted with respect to **1** which suggests that the epoxy oxygen atom draws electron density from the phenanthroline ring, facilitating the photoinduced metal-to-ligand charge transfer.[17]

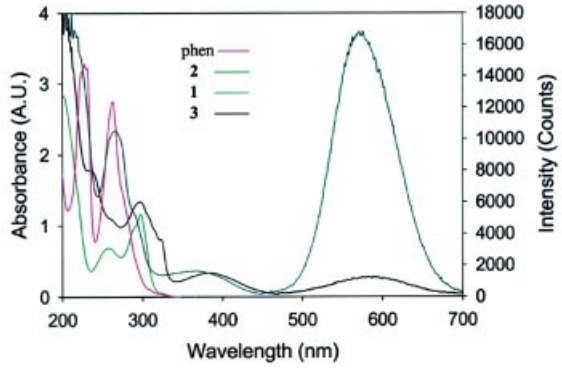

Figure 7. UV/Vis spectra of phen, **2**, **1** and **3**; luminescence spectra are shown for **1** and **3** in the region of 470−700 nm

Studies of **1** by Wrighton et al. indicated that upon absorption this complex undergoes intersystem crossing to the triplet state (or the mixed singlet-triplet state) with nearly 100% efficiency.[1] Luminescence measurements show a red shift in the emission band from 573 nm (**1**) to 585 nm (**3**) as shown in Figure 7.[18] This behaviour is consistent with previous studies using substituted phenanthrolines.[1,19] Quantum yield results (Table 3) indicate that the emission efficiency of **3** is less than that of **1**. In addition, the luminescence lifetime of **3** (15.1 ns) is also less than that of **1** (183 ns). To better understand the relaxation processes of the excited states of these two complexes we determined the radiative and nonradiative decay rate constants. Table 3 shows that the radiative decay rate constants remains basically unaffected while the nonradiative decay rate constant increases by a factor of 10 for **3** compared with that of **1**. Previous studies indicated that the nonradiative decay rate constant is affected by the energy gap.[20] The energy gap law states that the coupling between the vibrational levels of the ground and the excited state increases as the energy gap decreases.[21] A large coupling between the excited- and ground-state vibrational levels will increase the nonradiative decay rate constant. The increase in the nonradiative decay rate constant upon a decrease in the energy gap (as indicated in the red shift from 573 to 585 nm) is consistent with the energy gap law. However, because the aromaticity of the phenanthroline group is affected by the epoxye substitution in positions 5 and 6 a better comparison might be made with [Re(bpy)(CO)$_3$Cl] (**4**) in which the bpy (2,2′-bipyridine) ligand lacks the extensive aromatic delocalisation of phenanthroline. Also, **4** (similar to **3**) displays a lower emission energy and a shorter lifetime than **1**. Table 3 indicates that the energy gap of **3** is smaller than that in **4** while the nonradiative rate constant is larger for **4** than for **3**. The decrease in the energy gap (comparing **3** with **4**) can cause an increase in the coupling between the ground- and excited-state levels increasing the nonradiative pathways and hence the nonradiative rate constant. This behaviour is also consistent with the energy gap law. In addition, the increase in the nonradiative decay rate constant can also be attributed to new deactivation pathways available for the epoxidated phenanthroline ligand in comparison with the unmodified phenanthroline (e.g. thermal deactivation by vibrations of the epoxy oxygen atom and dipole coupling by hydrogen bonds to the epoxide). Tricarbonylrhenium complexes with substituted phenanthrolines like 5-nitro-1,10-phenanthroline and 1,10-phenanthroline-5,6-dione do not exhibit luminescence in dichloromethane at room temperature[1] and this can also be attributed to deactivation pathways due to phenanthroline substitution.

Table 3. Radiative and nonradiative decay rate constant for **1** and **3** in acetonitrile

	Emission $\lambda_{max.}$ [nm]	τ [ns]	φ	k_R [s^{-1}]	k_{NR} [s^{-1}]
1	573	183 ± 5	0.0177	9.67×10^4	5.37×10^6
3	585	15.1 ± 0.8	0.0013	8.61×10^4	6.61×10^7
4	580	25.6 ± 0.9	0.0039	1.56×10^5	3.89×10^7

Conclusion

The crystal structures of *fac*-[Re(phen)(CO)$_3$Cl], ephen and *fac*-[Re(ephen)(CO)$_3$Cl] have been reported. An exten-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sive hydrogen bonding network has been identified in the crystal lattices of **2** and **3**. IR and NMR spectroscopic studies allow the identification of two isomers of **3**. These isomers differ in the orientation of the epoxy oxygen atom relative to the chlorine atom and are nearly equally abundant. Luminescence experiments show an increase in the nonradiative decay rate constant for **3** consistent with the energy gap law. This increase can also arise due to new deactivation pathways available for **3** but not for **1** and **4**. Molecule **3** is potentially useful in synthesising donor-bridge-acceptor systems, photoactive polymers, modified surfaces and a variety of photoactive molecular frameworks involving rhenium centres since the epoxy functionality provides an easy way of forming covalent bonds. The photophysical and structural characterisation of **3** presented in this article is important for the synthesis and study of more complex structures involving this building block. Future studies will include the modification of layered zirconium phosphates using epoxyphenanthroline-based ligands for the covalent attachment of metal complexes to this material.

Experimental Section

Materials: All chemicals were purchased from Aldrich Chemical Co. and used as received. Acetonitrile was of spectrophotometric quality.

Syntheses: The syntheses of *fac*-[Re(phen)$(CO)_3$Cl] (**1**)[1] and ephen (**2**)[7] are described elsewhere. The published procedure for the synthesis of **1** was adopted for the synthesis of *fac*-[Re(ephen)$(CO)_3$Cl] (**3**). In a typical procedure, **2** (0.1068 g) and [Re$(CO)_5$Cl] (0.2001 g) were dissolved in toluene (30 mL). The solution was heated to reflux under N_2 for 1 h and the precipitate obtained was filtered and washed with diethyl ether. The yields were typically ca. 0.2116 g (ca. 80%). ^{1}H NMR of the crude material (DMF, 500 MHz): δ = 5.15 (s, 2 H), 7.97 (m, 2 H), 8.80 (m, 2 H), 9.22 (m, 2 H) ppm. ^{13}C NMR (DMF, 125 MHz): δ = 55.29, 55.59, 128.30, 128.80, 134.40, 134.74, 141.94, 142.21, 151.30, 152.12, 153.46, 153.82, 190.08, 190.31, 198.40, 198.50 ppm.

X-ray Crystal Structure Determinations: Crystals of **1** were grown by slow concentration of a saturated acetonitrile solution at 4 °C. Crystals of **2** were obtained by slow diffusion of hexanes into a saturated chloroform solution. For the crystal structure determination, a crystal of **2**·$CHCl_3$ was sealed in a quartz capillary in order to prevent solvent loss. Two polymorphs of **3** were obtained: **3a** by slow concentration of a saturated acetonitrile solution at 4 °C and **3b** by concentration of a saturated DMF solution at room temperature. X-ray diffraction data, collected from a single crystal in each case mounted atop a glass fibre with a Siemens SMART-CCD diffractometer,[22] were corrected for Lorentz and polarisation effects.[23] The structures were solved by direct methods using the SHELXTL program and refined by full-matrix least-squares methods on F^2.[24] Crystallographic details are summarised in Table 4. CCDC-239409 (**1**), -239410 (**2**), -239411 (**3a**) and -239412 (**3b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Spectroscopic Characterisation: UV/Vis absorption measurements were performed with an HP-8453 diode array spectrophotometer. Luminescence measurements were performed with an SE-900 spectrofluorimeter (Photon Technology International, PTI) using a 150-W xenon lamp as the excitation source and a PTI Model 710 photon counting detector with a Hamamatsu R1527P photomultiplier. The bandpass of the emission monochromator was 8.75 nm for the steady-state luminescence experiments at 384 nm and the spectra presented are uncorrected for the photomultiplier efficiency and lamp output. Time domain luminescence measurements were performed using a PTI GL-3300 N_2 pulsed laser coupled with a PTI 5020-ELT stroboscopic detector with a Hamamatsu R1527P photomultiplier. The excitation wavelength was 337 nm while emission was detected at 573 and 585 nm for **1** and **3**, respectively. The iterative reconvolution of the decay transients was performed using PTI Time Master 1.2 software. Quantum yields were determined using [Ru$(bpy)_3$]$(PF_6)_2$ in acetonitrile as a standard (φ = 0.062),[25] using the following formula:[26]

$$\phi = \phi_R \frac{I}{I_R} \frac{OD_R}{OD}$$

where φ_R is the quantum yield of the reference standard, I and I_R are the integrated intensities for the luminescent molecule and the standard, respectively. OD and OD_R are the optical densities for the luminescent molecule and the standard solution, respectively. Both quantum yield and lifetime measurements were performed in solutions purged with N_2 (99.9%) for 15 min. Knowledge of the quantum yield and luminescence lifetime allows the determination of the radiative and nonradiative rate constants as follows:

$$k_r = \frac{\phi}{\tau}$$

$$k_{nr} = \frac{(1-\phi)}{\tau}$$

NMR experiments were performed in [D_6]DMF with a Bruker-Advance DRX-500 spectrometer. IR spectra were recorded in KBr pellets with a Nicolet Magna 750 FTIR spectrometer or directly on the sample with a Bruker Tensor 27 FTIR spectrometer.

1,3,2-Diazaphosphinine (**1**) reacts successively with diphenylacetylene and diphenyl(1-propynyl)phosphane sulfide to afford the P,S-bidentate phosphinine **3**. Reaction of *n*BuLi with **3** followed by complexation with $[RuCl_2(C_{10}H_{14})]_2$ gave two diastereoisomers **5a**,**b**. Variable-temperature NMR spectroscopy and ONIOM DFT calculations were carried out to rationalize their formation. Complexes **5a**,**b** were used as catalysts in hydrogen-transfer hydrogenation (TON up to 200). Reaction of MeLi with **3** followed by complexation with $[PdCl_2(\eta^3\text{-}C_3H_5)]_2$ yielded two diastereomers **7a**,**b**, which were used as catalysts in the Suzuki–Miyaura cross-coupling reaction of aryl bromides with pinacolborane to yield the corresponding arylboronic esters (TON up to 799000).

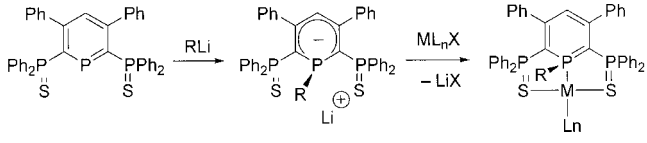
Introduction

Since the pioneering work of Grim and co-workers in the mid-1970s,[1] there has been a continuing interest in the chemistry of mixed tertiary phosphane/monochalcogenide (λ^3,σ^3)P−X (X = O, S) ligands.[2−7] These systems, which combine soft σ-donor (P) and good π-donor (O, S) binding sites, display very unique steric and electronic properties that differ markedly from those of classical bidentate phosphorus ligands. Most importantly, in some cases, these compounds have been employed to build very active catalysts. For example, in 1995 it was shown that a rhodium(I) complex of the monosulfide of dppm (dppm = $Ph_2PCH_2PPh_2$) could efficiently catalyze the carbonylation of methanol.[8] Later on, palladium(II) complexes of the same ligands were shown to be active catalysts for the ethylene/CO copolymerization.[9] On the other hand, P,O-mixed ligands, such as monoxides of dppm and dppe ($Ph_2PCH_2CH_2PPh_2$) and dppp ($Ph_2PCH_2CH_2CH_2PPh_2$), give better results than classical bidentate phosphanes in the cobalt-catalyzed hydroformylation of epoxides due to their hemilability.[10]

In 2002 we reported the synthesis of a new type of S,P,S-pincer ligand that incorporates a pseudo-ylidic λ^4-phosphorus atom as the central binding site (Scheme 1).[11,12] These tridentate ligands, which are readily available from the reaction of nucleophiles with phosphinines, were found to exhibit very specific electronic properties. Thus, their rhodium(I) complexes show a high reactivity towards small molecules such as O_2, CO_2, CS_2 and SO_2.[13] Furthermore, their palladium(II) complexes proved to be active catalysts in the Miyaura cross-coupling reaction that allows the synthesis of arylboronic esters from pinacolborane and haloarenes.[14]



Scheme 1

Exploiting the same strategy, Yoshifuji et al. reported this year on the synthesis of mixed P,S-systems of the type (RP=C−P=S) featuring a kinetically stabilized phosphaalkene (λ^3,σ^2-phosphorus atom) and a phosphane sulfide group.[15,16] A cationic palladium(II) complex of these new low-coordinate, phosphorus-based ligands was employed as a catalyst in the direct conversion of allyl alcohol to allylaniline.[17]

Initially, we postulated that the presence of two ancillary phosphane sulfide groups was a prerequisite for the stabilization of these new types of σ complexes. Indeed, it is well-known that 1-alkylphosphininyllithium salts usually react

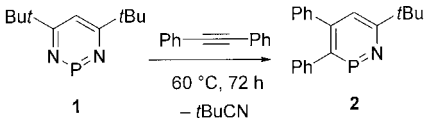
through their π-system with metal fragments to yield the corresponding η^5-coordinated complexes.[18−23] In this article, we show that anionic bidentate P,S-ligands featuring a pseudo-ylidic λ^4-phosphorus atom can be easily assembled from a diphenyl(2-phosphininyl)phosphane sulfide.

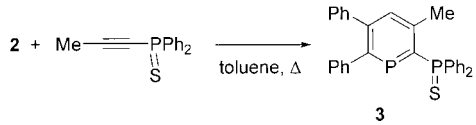
Results and Discussion

The synthetic strategy used for the synthesis of these new systems relies on the reactivity of 4,6-di-*tert*-butyl-1,3,2-diazaphosphinine (**1**) towards functionalised alkynes.[24,25] This precursor proved to be a very efficient source of tetrafunctionalised phosphinines through successive [4 + 2] cycloaddition/cycloreversion processes with functionalised alkynes. We first focused our work on the synthesis of diphenyl(3-R-5,6-diphenylphosphinin-2-yl)phosphane sulfide derivatives. Azaphosphinine **2**, which was only used as a transient species, was readily formed by warming equimolar amounts of **1** and diphenylacetylene at 60 °C in toluene for 3 d (Scheme 2).



Scheme 2

Compound **2** proved to be sufficiently reactive to undergo a second [4 + 2] cycloaddition/cycloreversion process with 1 equiv. of alkynyl-substituted diphenylphosphane sulfides in toluene at reflux. We chose Me−C≡C−P(S)Ph_2 for this reaction in order to increase the solubility of the ligand. We found that the reaction with diphenyl(1-propynyl)phosphane sulfide only yielded phosphinine **3**, which was isolated as an air-stable, white solid and was fully characterized by NMR techniques and elemental analysis. The presence of the diphenylphosphane sulfide group at the α-position of the phosphorus atom was evidenced in the ^{31}P NMR spectrum by a large $^2J_{P,P}$ coupling constant of 108.2 Hz (in $CDCl_3$ at 25 °C) (Scheme 3). The formulation proposed on the basis of NMR spectroscopic data was confirmed by an X-ray crystal structure analysis. A view of a molecule of **3** is presented in Figure 1; crystal data are summarized in the Exp. Sect. This structure deserves no particular comments as the metric parameters fall in the usual range for λ^3-phosphinines.



Scheme 3

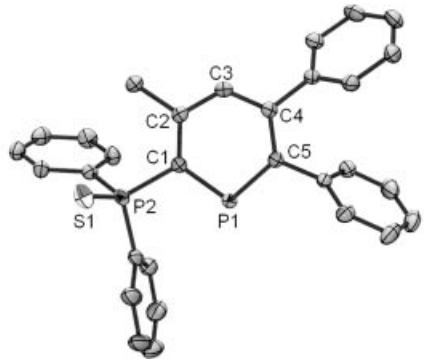


Figure 1. ORTEP view of a molecule of ligand **3**; ellipsoids are scaled to enclose 50% of the electron density; the numbering is arbitrary and different from that used in the assignment of the NMR spectra; selected distances [Å] and bond angles [°]: P1−C1 1.739(2), C1−C2 1.406(2), C2−C3 1.395(2), C3−C4 1.392(2), C4−C5 1.404(2), C5−P1 1.736(2), C1−P2 1.824(2), P2−S1 1.954(1); P1−C1−C2 124.4(1), C1−C2−C3 120.8(2), C2−C3−C4 126.6(2), C3−C4−C5 121.7(2), C4−C5−P1 123.9(1), C5−P1−C1 102.60(7), P1−C1−P2 115.1(1); (mean plane C1−C2−C4−C5)−P1 0.45, (mean plane C1−C2−C4−C5)−C3 0.8

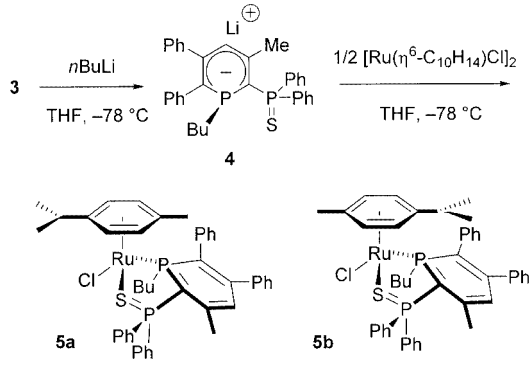
As previously explained, the synthesis of the corresponding 1-alkylphosphininyllithium salts can be conventionally achieved by treating equimolar amounts of phosphinines with nucleophiles. Thus, **3** was treated with *n*-butyllithium in THF at −78 °C to afford the lithium salt **4**, which was identified by ^{31}P NMR spectroscopy. The lithium salt **4** appears as an AB system [δ = −37.6 (P−Bu) and 42.4 ppm (PPh_2) in THF at 25 °C; $^2J_{P,P}$ = 151.9 Hz]. The chemical shift of the ring phosphorus atom (δ = −37.6 ppm) is similar to those of other 1-alkylphosphininyllithium salts.[14,23]

Reaction of **4** with the dimer [Ru(η^6-$C_{10}H_{14}$)Cl_2]$_2$ was carried out in THF at low temperature. After warming to room temperature, the ^{31}P NMR spectrum of the crude mixture indicated that two complexes **5a** and **5b** had formed in a 3:1 ratio (Scheme 4).



Scheme 4

Both complexes appear as an AB spin-system with close chemical shifts (δ = 40.7 and 44.3 ppm for **5a** and δ = 43.4 and 45.9 ppm for **5b**) and $^2J_{P,P}$ coupling constants (115.5 Hz for **5a** and 97.2 Hz for **5b**). The only major difference between **5a** and **5b** in the ^1H NMR spectra arises from

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the chemical shifts of the aromatic protons of the cymene ligand: in **5a** two hydrogen signals are shifted to high field (doublets at δ = 3.17 and 3.69 ppm with $^3J_{H,H}$ = 5.5 and 6.1 Hz, respectively) compared with those of **5b** (doublets at δ = 4.13 and 4.17 ppm with $^3J_{H,H}$ = 6.0 and 5.6 Hz, respectively) and other reported complexes.[26] Fortunately, complex **5a** proved to be insoluble in diethyl ether, thus allowing the separation of the two diastereomers. Single crystals of complex **5a** were obtained at room temperature from C_6D_6 as solvent (crystals deposited during the recording of the NMR spectra). An ORTEP view of a molecule of **5a** is presented in Figure 2; crystal data are presented in the Exp. Sect. As can be seen, the complex adopts a classical pianostool structure with the *n*-butyl substituent at the phosphorus atom pointing backwards probably to avoid steric congestion with the cymene ligand. The most interesting finding is related to the external P−C and P=S bond lengths. The shortening of the C1−P2 bond from 1.824(2) in **3** to 1.745(2) Å in **5a** and the elongation of the P2=S1 bond from 1.954(1) in **3** to 2.0283(7) Å in **5a** suggests a slight delocalization over the P1−C1−P2−S1−Ru1 skeleton. This induces a relocalization of the internal P−C and C−C bonds within the phosphinine ring: for instance, C2−C3 and C4−C5 shorten [1.372(3) and 1.376(3) Å, respectively] with respect to the free ligand [1.395(2) and 1.404(2) Å] whereas C1−C2, C3−C4 and C5−P1 lengthen [1.422(3), 1.435(2) and 1.805(2) Å in **5a** compared with 1.404(2), 1.394(2) and 1.736(2) Å in **3**]. The S−Ru bond [2.4239(5) Å] falls in the usual range of P=S−Ru bond lengths.[27,28] As previously noted in the structures of Ni, Pd, Pt and Rh complexes,[12,13] the phosphorus atom and the C3 carbon atom lie out of the plane defined by the C1, C2, C4 and C5 atoms by 12.6° and 1.8°, respectively, to yield a boat-like conformation. The phosphorus atom is now pyramidal (sum of angles at P1 = 313.8°) and compares well with classical tertiary phosphanes.

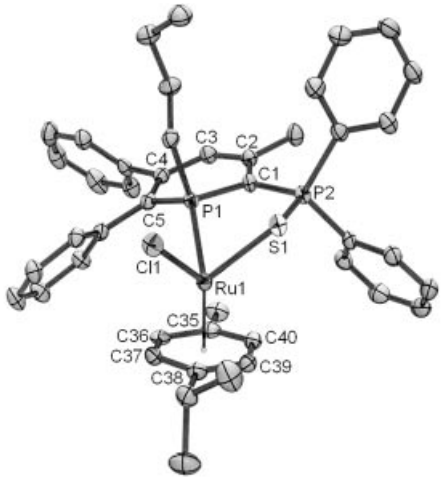


Figure 2. ORTEP view of a molecule of complex **5a**; ellipsoids are scaled to enclose 50% of the electron density; the numbering is arbitrary and different from that used in the assignment of the NMR spectra; selected distances [Å] and bond angles [°]: P1−C1 1.790(2), C1−C2 1.422(3), C2−C3 1.372(3), C3−C4 1.435(2), C4−C5 1.376(3), C5−P1 1.805(2), P1−Bu 1.852(2), C1−P2 1.745(2), P2−S1 2.0283(7), Ru1−P1 2.3351(5), Ru1−S1 2.4239(5), Ru1−Cl1 2.4186(5), Ru1−C35 2.237(2), Ru1−C36 2.239(2), Ru1−C37 2.196(2), Ru1−C38 2.276(2), Ru1−C39 2.257(2), Ru1−C40 2.189(2), Ru1−Ct 1.725, C35−C36 1.442(3), C36−C37 1.401(3), C37−C38 1.420(3), C38−C39 1.408(3), C39−C40 1.430(3), C40−C35 1.402(3); P1−C1−C2 121.1(1), C1−C2−C3 122.5(2), C2−C3−C4 125.3(2), C3−C4−C5 125.1(2), C4−C5−P1 119.2(1), C5−P1−C1 102.82(8), P1−C1−P2 111.9(1); (mean plane C1−C2−C4−C5)−P1 12.55, (mean plane C1−C2−C4−C5)−C3 1.75

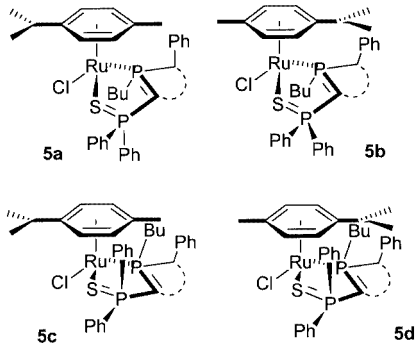
Additional experiments were carried out in order to see which factors control the ratio between **5a** and **5b**. However, whatever the experimental conditions used (concentration and reaction temperature) the 3:1 ratio initially obtained could not be significantly modified. Variable-temperature NMR experiments were also carried out on the mixture of **5a** and **5b** but, even under reflux in THF, no interconversion could be observed. The stereochemistry of **5a** could not be established on the sole basis of its NMR spectroscopic data. In theory, four diastereomers can be formed (**5a**,**b**,**c**,**d**; Scheme 5) depending on the orientation of the substituent at the phosphorus atom (backwards in **5a** and **5b**, inwards in **5c** and **5d**) and on the orientation of the methyl and isopropyl groups of the cymene ligand. Although simple molecular modelling strongly suggests that diastereomers **5c** and **5d** could not be formed because of the important steric congestion between the cymene ligand and both the substituent at the phosphorus atom and one of the phenyl groups of the diphenylphosphane sulfide group, the four diastereomers were computed using the ONIOM method at the B3LYP/UFF level (see Exp. Sect. for details on basis sets and partition of the molecule into QM and MM shells). In these calculations the *n*-butyl group at the phosphorus atom was replaced by a methyl group to minimize the degrees of freedom. Optimizations of the theoretical complexes **5c** and **5d** failed and no minima could be located, the ligand being displaced away from the Ru−Cl fragment during the optimization. The introduction of an *n*-butyl group at the phosphorus atom would not yield a different result due to the bulkiness generated by the alkyl chain. However, two minima could be located for structures **Ia** (model of **5a**) and **Ib** (model of **5b**). Two views of these theoretical structures are presented in Fig-



Scheme 5

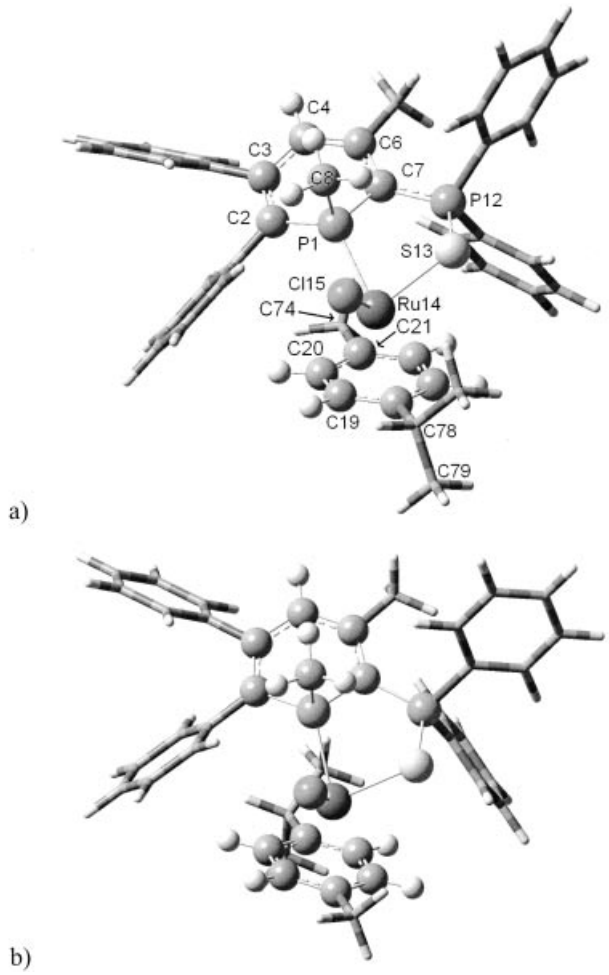

Figure 3. Optimized structures of model complexes **Ia** (a) and **Ib** (b) obtained at the ONIOM(B3LYP/UFF) level of theory; atoms included in the QM part are shown in ball-and-stick format and atoms included in the MM part are represented by tubes; the numbering is the same for **Ia** and **Ib**

ure 3; fully labelled molecules of **Ia**,**b** are presented in the Supporting Information. The most significant bond lengths and bond angles of **Ia,b** are reported in Table 1. As can be seen by examining these data, there is an acceptable fit between theoretical and experimental parameters. In **Ia** the P,S-ligand and the Ru−Cl, Ru−S and Ru−P bond lengths are very close to those of the X-ray structure of **5a**: for instance, in **Ia** the P1−C2, C7−P12, P12−S13, Ru14−S13 and Ru14−P1 bond lengths are 1.812, 1.757, 2.061, 2.449 and 2.385 Å, respectively, versus 1.805, 1.745, 2.028, 2.424 and 2.335 Å in **5a**. The only discrepancies arise in the cymene ring. Despite excellent agreement between the C−C bond lengths (for example C19−C20, C74−C21, C78−C79 are 1.407, 1.511 and 1.534 Å, respectively, in **Ia** versus 1.401, 1.511 and 1.534 Å in **5a**), the cymene ring is too far away from the ruthenium atom (the C16−Ru14 distance is 2.328 Å in **Ia** compared to 2.189 Å in **5a**). Modification of the basis set for Ru (all-electron basis sets rather than ECP) was not performed due to the already long computational time. The same trends are observed between **Ia** and **Ib** and deserve no other comment.

Table 1. Selected bond lengths [Å] for calculated structures **Ia**,**b**

	Ia	**Ib**
P1−C2	1.812	1.810
C2−C3	1.388	1.387
C3−C4	1.440	1.439
C4−C6	1.386	1.386
C6−C7	1.429	1.431
C7−P1	1.806	1.814
P1−R8	1.851	1.851
C26−C2	1.492	1.491
C37−C3	1.491	1.491
C48−C6	1.512	1.513
C7−P12	1.757	1.759
P12−S13	2.061	2.059

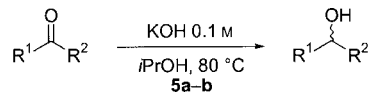
C19−Ru14	2.228	2.291
C20−Ru14	2.327	2.361
C21−Ru14	2.321	2.442
C74-cycle	1.499	1.499
C78-cycle	1.517	1.519
C79−C78	1.531	1.532
C80−C78	1.536	1.530

Single-point calculations at the B3LYP level of theory carried out on both optimized ONIOM structures revealed that the model complex **Ia** is more stable than the isomer **Ib** ($\Delta\Delta H = -4.8$ kcal/mol), thus confirming the experimental results. Most importantly, no transition state could be located between **Ia** and **Ib**, the rotation of the cymene ligand around its centroid−ruthenium axis being completely blocked by the two peripheral phenyl groups. This result allows us to rationalize why no interconversion between **5a** and **5b** is observed, even under heating.

The catalytic activity of complexes **5a,b** in the transfer hydrogenation of ketones was tested (Scheme 6).[29−34] Reactions were conducted in 2-propanol as a proton source and solvent and KOH as base using 0.5 mol % of catalysts in most cases. The results are summarized in Table 2. As can be seen, although conversion is acceptable, long reaction times are needed to achieve complete conversions. It must be noted that no efforts have been made, so far, to improve these figures (solvents, role of the base, amount of catalyst).



Scheme 6

The synthesis of a $[Pd(\eta^3\text{-}C_3H_5)]^+$ complex of the lithium salt **4** was also investigated. As previously reported for the synthesis of **5a**,**b**, reaction of phosphinine **3** with methyllithium in THF at −78 °C afforded the lithium salt **6**, which was identified by ^{31}P NMR spectroscopy. Like **4**, the lith-

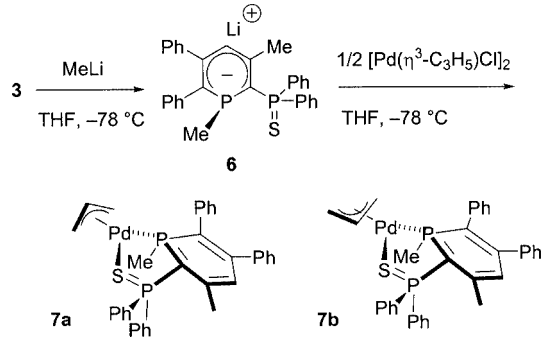
[a] Yields were determined by ^{1}H NMR spectroscopy, mass spectrometry or GC. [b] In days. [c] 1 mol % of catalyst. [d] 0.8 mol % of catalyst.

ium salt **6** appears as an AB system with comparable chemical shifts [δ = −40.7 (P−Me) and 42.5 ppm (PPh_2) in THF at 25 °C; $^2J_{P,P}$ = 156.7 Hz]. Reaction of **6** with the dimer [Pd(η^3-C_3H_5)Cl]$_2$ was carried out in THF at low temperature. After warming to room temperature, the ^{31}P NMR spectrum of the crude mixture indicated that complexes **7a** and **7b** had formed in a 3:1 ratio (Scheme 7). Complexes **7a** (major isomer) and **7b** (minor isomer) appear as an AB spin-system with very similar chemical shifts (δ = 24.6 and 52.4 ppm for **7a** and δ = 23.4 and 52.0 ppm for **7b**) and $^2J_{P,P}$ coupling constants (135.8 Hz for **7a** and 132.7 Hz for **7b**). Separation of complexes **7a** and **7b** could not be achieved despite many attempts. These complexes were, however, fully characterized by ^{1}H and ^{13}C NMR spectroscopy, and elemental analysis. In the ^{1}H NMR spectrum of **7**, two sets of five non-equivalent η^3-allyl proton resonances are observed. One of the signals of the minor isomer **7b** overlaps with those of the major isomer **7a**.

Isomer interconversion was investigated by variable-temperature NMR experiments but no conversion was observed. We suppose that the rotation of the allyl moiety is disfavoured by a repulsive interaction between the CH_2 allyl



Scheme 7

group and the phenyl group in the C6 position of the phosphinine ring. A similar phenomenon has already been reported for other complexes.[35,36]

Crystals of **7a** suitable for X-ray analysis were obtained by slow diffusion of hexanes into a solution of complexes **7a**,**b** in $CDCl_3$. An ORTEP view of **7a** is presented in Figure 4 and the refinement parameters are given in the Exp. Sect. This structure confirms the η^3-coordination of the allyl moiety and also that the geometry around the palladium atom is trigonal-planar. The P1−Pd [2.2778(6) Å] and the S1−Pd [2.3371(6) Å] bond lengths are similar to classical phosphane−palladium and P=S−Pd bond lengths,[36] although the P1−Pd distance is greater than in previously reported tridentate palladium complexes.[12] The Pd−C32, Pd−C33, Pd−C34 [2.138(3), 2.137(3), 2.199(3) Å] and C32−C33 and C33−C34 [1.359(4) and 1.383(5) Å] bond lengths and the C32−C33−C34 angle [123.8(3)°] are in the typical range of η^3-allylpalladium complexes.[37−40] The geometry of the phosphinine moiety is similar to that in complex **5a** and deserves no further comment. In the major isomer an H,C-HSQC NMR experiment showed that the signals of the two hydrogen atoms of the CH_2 allyl fragments at δ = 2.16 and 2.52 ppm are connected, as are those at δ = 3.00 and 4.21 ppm. An H,H-NOESY experiment also revealed that, in this same isomer, the P−Me group (C6 in the ORTEP view) is in the spatial neighbourhood of only two hydrogen atoms of the CH_2 allyl fragments (at δ = 2.16 and 2.52 ppm) and is far from the CH and the other CH_2 fragments (at δ = 4.89, 3.00 and 4.21 ppm, respectively). The major isomer is therefore complex **7a**.

The catalytic activity of complexes **7a**,**b** was tested in the Suzuki−Miyaura cross-coupling reaction, which allows the synthesis of arylboronic esters from haloarenes and phenylboronic acid (Scheme 8).[41−49] The reactions were conduc-

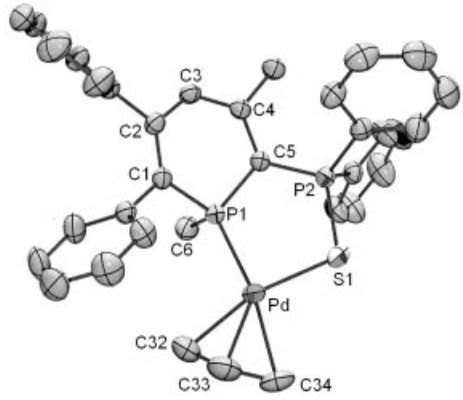


Figure 4. ORTEP view of one molecule of complex **7a**; ellipsoids are scaled to enclose 50% of the electron density; the numbering is arbitrary and different from that used in the assignment of the NMR spectra; selected distances [Å] and bond angles [°]: P1−C1 1.802(2); C1−C2 1.360(3), C2−C3 1.444(3), C3−C4 1.378(3), C4−C5 1.422(3), C5−P1 1.756(2), P1−C6 1.828(2), C5−P2 1.733(2), P2−S1 2.0288(8), Pd1−P1 2.2778(6), Pd−S1 2.3371(6), Pd−C32 2.138(3), Pd−C33 2.137(3), Pd−C34 2.199(3), C32−C33 1.359(4), C33−C34 1.383(5); P1−C1−C2 117.2(2), C1−C2−C3 123.4(2), C2−C3−C4 124.5(2), C3−C4−C5 121.0(2), C4−C5−P1 117.5(2), C5−P1−C1 101.7(1), P1−C5−P2 117.8(1), C32−C33−C34 123.8(3); (mean plane C1−C2−C4−C5)−P1 21.7; (mean plane C1−C2−C4−C5)−C3 7.3

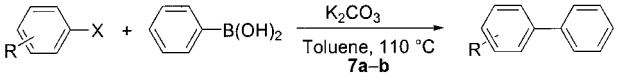
ted in toluene in the presence of K_2CO_3 using 0.0001 mol % of catalyst in most cases. The results are summarized in Table 3. As can be seen, the conversions obtained in the transformation of aryl bromides are acceptable: turnover numbers (TONs) fall in the range of 242000 for electron-rich arenes (4-bromoanisole) to 799000 for electron-deficient species (4-bromoacetophenone). It must be noted that no efforts were made to improve these results (solvents, role of the base). However, under the same experimental conditions (toluene at reflux), no reaction was observed with the less-reactive aryl chlorides, even when using 2.0 mol % of catalyst.



Scheme 8

Table 3. Suzuki−Miyaura reaction of aryl halides using complex **7** as catalyst; conditions: aryl bromide (1.0 mmol), phenylboronic acid (1.5 mmol), K_2CO_3 (2.0 mmol) catalyst **7** (0.0001 mol % unless stated otherwise), 10 mL of toluene, 110 °C, 24 h

Entry	Substrate	Yield (%)[a]	Benzene (%)[a]	TON

[a] Yields were determined by GC. [b] 0.01 mol % of catalyst.

Conclusion

We have developed an access to a new class of ligands that features a pseudo-ylidic phosphorus atom and a P=S ancillary arm. Interestingly, this allows to show that coordination through the phosphorus atom in 1-alkylphosphininyllithium salts does not require the presence of two pendant ancillary P=S ligands. Although the catalytic activity of the (cymene)Ru derivatives in the transfer hydrogenation of ketones was found to be modest, interesting conversion yields were obtained in the Pd-catalysed synthesis of arylboronic esters from bromoarenes and phenylboronic acid. Further studies are now focusing on the synthesis of other transition-metal complexes and investigation of their catalytic properties.

Experimental Section

General Remarks: All reactions were routinely performed under argon or nitrogen with Schlenk and glove-box techniques and dry deoxygenated solvents. Dry THF and hexanes were obtained by distillation from Na/benzophenone, dry diethyl ether from $CaCl_2$ and then NaH, and dry CH_2Cl_2 from P_2O_5. $CDCl_3$ was dried with P_2O_5 and stored over Linde molecular sieves (4 Å). C_6D_6 was used as purchased and stored in the glovebox. $[PdCl(C_3H_5)]_2$ was purchased from Fluka. NMR spectra were recorded with a Bruker Avance 300 spectrometer operating at 300.0 MHz for ^1H, 75.5 MHz for ^{13}C and 121.5 MHz for ^{31}P. Solvent peaks are used as internal reference relative to $SiMe_4$ for ^1H and ^{13}C chemical shifts (ppm); ^{31}P chemical shifts are quoted relative to an 85% H_3PO_4 external reference. Coupling constants are given in Hz. Mass spectra were obtained at 70 eV with an HP 5989B spectrometer coupled to an HP 5980 chromatograph by the direct inlet method. Elemental analyses were performed by the "Service d'analyse du CNRS", at Gif sur Yvette, France. Diazaphosphinine **1**,[24] diphenyl(1-propynyl)phosphane sulfide[50] and $[RuCl_2(\eta^6\text{-}C_{10}H_{14})]_2$ [51] were prepared according to reported procedures.

Phosphinine 3: Diphenylacetylene (3.79 g, 21 mmol) was added to a solution of diazaphosphinine **1** in toluene (8×10^{-5} mol/mL, 20 mmol) and the mixture was stirred at 60 °C for 72 h. Consumption of **1** (δ = 269.0 ppm) and formation of the 5,6-diphenyl-1,2-azaphosphinine **2** (δ = 267.4 ppm) was checked by ^{31}P NMR spectroscopy. Diphenyl(1-propynyl)phosphane sulfide (3.44 g, 22 mmol) (δ = 18.8 ppm) was then added and the solution was stirred at 120 °C for 96 h. After evaporation of the solvent, the solid was washed with hexanes (3 × 20 mL) and MeOH (20 mL) and the resulting solid was dissolved in hot MeOH and stored at 0 °C. The white solid that separated was washed several times with cold MeOH (3 × 30 mL). After drying, **3** was recovered as a white solid. Yield: 6.0 g (62%). Crystals suitable for X-ray crystallography were obtained by slow diffusion of hexanes into a solution of **3** in CH_2Cl_2. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.67 (s, CH_3), 7.00−7.98 (m, 21 H, CH of Ph and H4) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C): δ = 25.4 (d, $^3J_{C,P_B}$ = 8.2, CH_3), 127.2−133.5 (m, CH of Ph), 132.9 (dd, J_{C,P_B} = 84.6, J_{C,P_A} = 5.3, C), 138.6 (vt, $^3J_{C,P_A}$ = $^3J_{C,P_B}$ = 12.8, C4H), 141.3 (s, C), 141.7 (s, C), 148.0 (dd, J_{C,P_B} = 9.1, J_{C,P_A} = 3.8, C), 149.0 (dd, J_{C,P_B} = 12.8, J_{C,P_A} = 4.5, C), 159.4 (dd, J_{C,P_B} = 76.3, J_{C,P_A} = 67.2, C), 166.2 (dd, J_{C,P_B} = 58.9, J_{C,P_A} = 14.3, C) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 42.6 (d, $^2J_{P_A,P_B}$ = 108.1, P_BPh_2), 226.7 (d, $^2J_{P_A,P_B}$ = 108.1, P_A) ppm. MS (CH_2Cl_2): *m/z* = 479 [M^+], 447 [M − S]$^+$, 416 [M − PS]. $C_{30}H_{24}P_2S$ (478.49): calcd. C 75.30, H 5.06; found C 74.97, H 4.72.

Lithium Salt 4: A solution of BuLi (0.235 mL, 1.6 M, 0.38 mmol) was added through a syringe into a solution of **3** (180 mg, 0.38 mmol) in THF (6 mL) at −78 °C. The solution was warmed to room temperature and stirred for 20 min. After evaporation of the solvent, the solid was washed several times with hexanes (3 × 2 mL). After drying, **4** was recovered as a red solid. Yield: 100%.^{31}P NMR (121.5 MHz, THF, 25 °C): δ = −37.6 (d, $^2J_{P_A,P_B}$ = 151.9, P_A−Bu), 42.4 (d, $^2J_{P_A,P_B}$ = 151.9, P_BPh_2).

Ruthenium Complexes 5a,b: A solution of BuLi (0.235 mL, 1.6 M, 0.38 mmol) was syringed into a solution of **3** (180 mg, 0.38 mmol) in THF (6 mL) at −78 °C. The solution was warmed to room temperature and stirred for 20 min. Complete formation of the lithium salt **4** was checked by ^{31}P NMR spectroscopy. In a glovebox, $[RuCl_2(cymene)]_2$ (115 mg, 0.19 mmol) was added to the solution and the solution was stirred for 1 h. After removing the solvent,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the resulting solid was dissolved in toluene and filtered through Celite. After drying, **5** was recovered as a red solid containing a mixture of two diastereoisomers (25:75). Yield: 242 mg (80%). The major diastereoisomer, which is insoluble in diethyl ether, could be obtained by washing the red solid several times with diethyl ether (3 × 10 mL). The resulting filtrate was kept at 0 °C overnight during which time the minor diastereoisomer separated as a red solution.

Major Diastereoisomer 5a: Yield: 150 mg (49%). Crystals suitable for X-ray crystallography were deposited from a solution of **5a** in C_6D_6. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.97 (d, $^3J_{H,H}$ = 7.0, 3 H, *CH*$_3$−CH of cymene), 0.97 (t, $^3J_{H,H}$ = 7.2, 3 H, CH_3 of *n*Bu), 1.17 (d, $^3J_{H,H}$ = 6.7, 3 H, *CH*$_3$−CH of cymene), 1.50−1.58 (m, 2 H, CH_2 of *n*Bu), 1.72 (s, 3 H, CH_3 of phosphinine), 1.95 (s, 3 H, Ar−*CH*$_3$ of cymene), 2.14−2.28 (m, 1 H, CH_2 of *n*Bu), 2.32−2.50 (m, 1 H, CH_2 of *n*Bu), 2.52−2.69 (m, 1 H, CH_2 of *n*Bu), 2.99−3.09 (m, 2 H, Ar−*CH* of cymene and CH_2 of *n*Bu), 3.17 (d, $^3J_{H,H}$ = 5.5, Ar−H of cymene), 3.69 (d, $^3J_{H,H}$ = 6.1, Ar−H of cymene), 4.67 (d, $^3J_{H,H}$ = 6.1, Ar−H of cymene), 5.06 (d, $^3J_{H,H}$ = 5.5, Ar−H of cymene), 5.43 (d, $^4J_{H,P}$ = 6.3, H4), 6.88−7.12 (m, 12 H, H of Ph), 7.55−7.58 (m, 2 H, H of Ph), 7.69−7.80 (m, 4 H, H of Ph), 7.88−7.95 (m, 2 H, H of Ph) ppm. ^{13}C NMR (75.5.5 MHz, C_6D_6, 25 °C): δ = 13.2 (s, CH_3 of *n*Bu), 15.4 (s, Ar−CH_3 of cymene), 18.2 (s, CH_3 of isopropyl), 22.9 (vt, $\Sigma J_{C,P}$ = 5.1, CH_3 of isopropyl), 23.6 (d, $^3J_{C,P_A}$ = 11.6, CH_2 of *n*Bu), 24.5 (s, CH_3 of phosphinine), 25.9 (d, $^2J_{C,P_A}$ = 7.5, CH_2 of *n*Bu), 29.1 (s, CH of isopropyl), 42.5 (d, $^1J_{C,P_A}$ = 19.8, P_A−CH_2), 60.0 (dd, $^1J_{C,P_A}$ = 104.9, $^1J_{C,P_B}$ = 55.9, C2), 67.5 (s, C of cymene), 75.1 (s, CH of cymene), 87.1 (s, CH of cymene), 89.1 (s, CH of cymene), 90.4 (d, $^2J_{C,P_A}$ = 9.1, CH of cymene), 94.4 (s, C of cymene), 99.3 (dd, $^1J_{C,P_A}$ = 43.8, $^3J_{C,P_B}$ = 7.6, C6), 112.6 (dd, $J_{C,P}$ = 12.8, $J_{C,P}$ = 6.8, C4H), 114.8 (d, $J_{C,P}$ = 9.1, C), 123.3−132.8 (m, CH of Ph), 134.1 (m, C), 134.7 (m, C), 141.8 (dd, $J_{C,P}$ = 15.9, $J_{C,P}$ = 2.3, C), 144.2 (d, $J_{C,P}$ = 5.3, C3), 145.1 (d, $J_{C,P}$ = 7.6, C5), 150.2 (d, $J_{C,P}$ = 1.5, C) ppm. ^{31}P NMR (121.5 MHz, C_6D_6, 25 °C): δ = 40.7 (d, $^2J_{P_A,P_B}$ = 115.5, P), 44.3 (d, $^2J_{P_A,P_B}$ = 115.5, P) ppm.

Minor Diastereoisomer 5b: Yield: 33 mg (11%). ^{1}H NMR (121.5 MHz, C_6D_6, 25 °C; selected data): δ = 0.88−2.44 (m, 25 H, Bu, *i*Pr, 3 × Me), 4.13 (d, $^3J_{H,H}$ = 6.0, Ar−H of cymene), 4.17 (d, $^3J_{H,H}$ = 5.6, Ar−H of cymene), 4.91 (d, $^3J_{H,H}$ = 6.0, Ar−H of cymene), 4.96 (d, $^3J_{H,H}$ = 5.7, Ar−H of cymene), 5.31 (d, $^4J_{H,P}$ = 5.5, H_4), 6.70−8.25 (m, 20 H, H of Ph) ppm. ^{31}P NMR (121.5 MHz, C_6D_6, 25 °C): δ = 43.4 (d, $^2J_{P_A,P_B}$ = 97.2, P), 45.9 (d, $^2J_{P_A,P_B}$ = 97.2, P). $C_{44}H_{47}ClP_2RuS$ (806.34): calcd. C 65.54, H 5.87; found C 65.22, H 5.48.

Hydrogenation of Ketones: A mixture of complexes **5a**,**b** (8 mg, 0.01 mmol, 0.5 mol %) was added to a solution of ketone (2 mmol, 1 equiv.) in KOH/2-propanol (0.1 M, 10 mL). The mixture was stirred at 80 °C for 2.5 d. The progress of the reaction was monitored by GC, mass spectrometry or ^{1}H NMR spectroscopy. The mixture was then neutralized with a saturated solution of 3 M HCl (3 mL) and $NaHCO_3$ (15 mL), and it was then extracted with dichloromethane (3 × 15 mL). The organic layers were collected and dried with $MgSO_4$ and the solvents evaporated to yield the corresponding alcohol. The alcohols were characterised by comparing their ^{1}H and ^{13}C NMR spectra with reported NMR spectroscopic data and by mass spectrometry.

Characterization of Secondary Alcohols: 4-Heptanol,[52] 1,3-diphenyl-2-propanol,[53] *syn*-2,5-dimethylcyclohexanol,[54] 1-phenylethanol,[55] diphenylmethanol,[56] 1-(*p*-bromophenyl)ethanol,[57] bis(*p*-methoxyphenyl)methanol.[58]

Lithium Salt 6: A solution of MeLi (0.235 mL, 1.6 M, 0.38 mmol) was added through a syringe into a solution of **3** (180 mg, 0.38 mmol) in THF (6 mL) at −78 °C. The solution was warmed to room temperature and stirred for 20 min. After evaporation of the solvent, the solid was washed several times with hexanes (3 × 2 mL). After drying, **6** was recovered as a red solid. Yield: 100%.^{31}P NMR (121.5 MHz, THF, 25 °C): δ = −46.7 (d, $^2J_{P_A,P_B}$ = 156.7, P_A−Me), 42.5 (d, $^2J_{P_A,P_B}$ = 156.7, P_BPh$_2$) ppm.

Palladium Complexes 7a,**b:** A solution of MeLi (0.156 mL, 1.6 M, 0.25 mmol) was added through a syringe into a solution of **3** (120 mg, 0.25 mmol) in THF (5 mL) at −78 °C. The solution was warmed to room temperature and stirred for 20 min. Complete formation of the lithium salt **6** was checked by ^{31}P NMR spectroscopy. In a glovebox, $[PdCl(C_3H_5)]_2$ (44 mg, 0.12 mmol) was added to the solution and the mixture stirred for 1 h. After removing the solvent, the resulting solid was dissolved in CH_2Cl_2 and filtered through Celite. After drying, **7** was recovered as a brown solid containing a mixture of two diastereoisomers (25:75). No further purification was carried out to separate the two diastereoisomers. Crystals of **7a** suitable for X-ray diffraction were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **7a**,**b** Yield: 123 mg (77%).

Major Diastereoisomer 7a: ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.19 (d, $^2J_{H,P_A}$ = 8.1, 3 H, P_AMe), 1.65 (s, 3 H, Me), 2.16 (d, $^2J_{H,H}$ = 13.2, 1 H, CH_2 allyl), 2.52 (d, $^3J_{H,H}$ = 6.4, 1 H, CH_2 allyl), 3.00 (dd, $^2J_{H,H}$ = 13.2, $^3J_{H,H}$ = 10.4, 1 H, CH_2 allyl), 4.21 (vt, $^2J_{H,H}$ = $^3J_{H,H}$ = 6.5, 1 H, CH_2 allyl), 4.89 (m, CH allyl), 5.57 (d, $^4J_{H,P_A}$ = 5.9, H4), 7.04−8.09 (m, 20 H, H of Ph) ppm. ^{13}C NMR (75.5.5 MHz, $CDCl_3$, 25 °C): δ = 17.1 (dd, $^1J_{C,P}$ = 20.6, $^3J_{C,P}$ = 2.7, P_AMe), 25.9 (dd, $^3J_{C,P}$ = 4.2, $^3J_{C,P}$ = 3.1, Me), 55.0 (dd, $J_{C,P}$ = 111.7, $J_{C,P}$ = 54.2, C2/6), 59.6 (d, $^2J_{C,P}$ = 5.7, CH_2 allyl), 69.1 (dd, $^2J_{C,P}$ = 32.4, $^4J_{C,P}$ = 4.5, CH_2 allyl), 109.8 (dd, $J_{C,P}$ = 47.9, $J_{C,P}$ = 5.1, C2/6), 113.4 (dd, $J_{C,P}$ = 12.6, $J_{C,P}$ = 10.1, C4), 117.0 (d, $^2J_{C,P}$ = 6.4, CH allyl), 125.1−133.1 (m, CH and C of Ph), 136.9 (dd, $J_{C,P}$ = 78.1, $J_{C,P}$ = 7.2, C3/5), 143.5 (dd, $J_{C,P}$ = 8.8, $J_{C,P}$ = 2.9, C3/5), 144.4 (d, $J_{C,P}$ = 15.6, C of Ph), 145.4 (d, $J_{C,P}$ = 1.9, C of Ph) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 24.6 (d, $^2J_{P,P}$ = 135.8, P_A), 52.4 (d, $^2J_{P,P}$ = 135.8, P_BPh$_2$).

Minor Diastereoisomer 7b: ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.16 (br. s, 3 H, PMe), 1.65 (s, 3 H, Me), 1.72 (d, $^2J_{H,H}$ = 13.3, 1 H, CH_2 allyl), 2.90 (d, $^2J_{H,H}$ = 13.4, 1 H, CH_2 allyl), 3.18 (d, $^2J_{H,H}$ = 7.0, 1 H, CH_2 allyl), 5.01 (m, 1 H, CH allyl), 7.04−8.09 (m, 20 H, H of Ph) ppm; signals of 1 H of CH_2 allyl and H4 were not observed. ^{13}C NMR (75.5.5 MHz, $CDCl_3$, 25 °C): δ = 18.2 (dd, $^1J_{C,P}$ = 20.0, $^3J_{C,P}$ = 2.7, P_AMe), 25.9 (m, Me), 55.0 (m, C2/6), 59.1 (d, $^2J_{C,P}$ = 5.1, CH_2 allyl), 70.0 (m, CH_2 allyl), 108.7 (m, C2/6), 113.6 (dd, $J_{C,P}$ = 12.8, $J_{C,P}$ = 9.5, C4), 116.8 (d, $^2J_{C,P}$ = 6.3, CH allyl), 124.4−133.5 (m, CH and C_q of Ph), 136.2 (d, $J_{C,P}$ = 83.9, $C_{3/5}$), 143.2 (dd, $J_{C,P}$ = 11.7, $J_{C,P}$ = 3.0, C3/5), 144.2 (d, $J_{C,P}$ = 8.8, C of Ph), 145.7 (d, $J_{C,P}$ = 2.1, C of Ph) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 25 °C): δ = 23.4 (d, $^2J_{P,P}$ = 132.7, P−Me), 52.0 (d, $^2J_{P,P}$ = 132.7, PPh_2) ppm. $C_{34}H_{32}P_2PdS$ (641.00): calcd. C 63.70, H 5.03; found C 63.46, H 4.81.

Suzuki−Miyaura Reaction of Aryl Halides: Catalyst **7** as a toluene solution (1.00 mL), made up to the correct concentration by multiple volumetric dilutions of a stock solution, was added to a mixture of the aryl halide (1.0 mmol), $PhB(OH)_2$ (0.183 g, 1.5 mmol) and K_2CO_3 (0.276 g, 2.0 mmol) in toluene (10 mL). The resultant mixture was then heated at 110 °C for 24 h, cooled and quenched with HCl(aq) (2 M, 40 mL). The organic layer was removed and the aqueous layer was extracted with toluene (3 × 50 mL). The combined organic layers were washed with water, dried ($MgSO_4$), fil-

tered and the solvent removed under reduced pressure. The residue was dissolved in toluene (6 mL), hexadecane (0.068 M in CH_2Cl_2, 1.00 mL, internal standard) was added and the conversion into product determined by GC.

Characterizations of Suzuki−Miyaura Coupling Products: The NMR spectra of the biphenyl compounds were compared with those of commercial products (Aldrich); 4-methylbiphenyl,[59] 4-methoxybiphenyl,[59] 4-acetylbiphenyl.[60]

X-ray Crystallographic Study: Crystals of **3** and **7a** suitable for X-ray diffraction were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **3** and **7a**. Crystals of **5a** suitable for X-ray diffraction deposited overnight from a solution in C_6D_6. Data were collected at 150.0(1) K with a Nonius Kappa CCD diffractometer equipped with an Mo-K_α (λ = 0.71070 Å) X-ray source and a graphite monochromator, using φ and ω scans. The crystal structures were solved by using SIR 97[61] and SHELXL-97.[62] For ORTEP drawings ORTEP III for Windows was used.[63] Further details can be found in Table 4. CCDC-242764 to -242766 (for **3**, **5a** and **7a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Mmethods: All calculations were performed with the Gaussian 03 set of programs using the ONIOM method.[64] The two complexes were optimized at the ONIOM(B3LYP/UFF) level,[65] where the QM part was treated within the framework of density functional theory at the B3LYP level (B3 for Becke's three-parameter exchange functional[66] and LYP for the Lee−Yang−Parr non-local correlation functional[67]) and the UFF force field[68] was used for the molecular mechanic calculations. In all calculations (QM and QM/MM), the lanl2dz basis set was used for the ruthenium atom.[69] The 6-31+G(d) basis set was used for all atoms directly bound to the ruthenium centre (P, S, Cl atoms as well as the C atoms of the aromatic part of the cymene ligand). The C and H atoms of the phosphinine ring were calculated using the 6-31G(d) basis set. Full optimizations were realized at the ONIOM level, followed by analytical computation of the Hessian matrix to confirm the nature of the located minima on the potential energy surface. A single-point calculation was performed on the ONIOM optimized structures at the B3LYP level of theory using the 6-31G(d) basis sets for C, H, P, S, and Cl atoms and the lanl2dz basis set for Ru.

Supporting Information: See footnote on the first page of this article. Fully labelled structures of **Ia** and **Ib** and the geometrical parameters of the theoretical structures.

Acknowledgments

This work was supported by the CNRS, the Ecole Polytechnique and the DGA. M. D. thanks the DGA for financial support. The authors would like to thank IDRIS (Paris XI Orsay University) for the allocation of computer time.

Synthesis and Characterisation of Novel Complexes Containing Group 15 Elements and Their Potential Use as Molecular Precursors for the Formation of Transition Metal Pnictides

Manfred Scheer,*[a] Ulf Vogel,[a] Uta Becker,[a] Gabor Balazs,[a] Petra Scheer,[b] Wolfgang Hönle,[c] Michael Becker,[d] and Martin Jansen[d]

Dedicated to Prof. Dr. M. Veith on the occasion of his 60th birthday

Keywords: Cobalt / Cluster compounds / Phosphorus / Thermochemistry / Tungsten

The reaction of $[\{W(CO)_5\}_2PCl]$ with $K[Co(CO)_4]$ yields the novel compounds $[\{W(CO)_4Co_2(CO)_6\}\{\mu_3\text{-}PW(CO)_5\}_2]$ (**3**) and $[\{(CO)_4WCo_3(CO)_6\}\{\mu_3\text{-}PW(CO)_5\}_3]$ (**4**) along with known derivatives $[Co_2(CO)_6\{\mu,\eta^2\text{-}PW(CO)_5\}_2]$ (**1**) and $[Co_3(CO)_9\{\mu_3\text{-}PW(CO)_5\}]$ (**2**). The complex $[\{W_2(CO)_8(\mu\text{-}CO)\}\{\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}PW(CO)_5\}_2)]$ (**5**) was synthesised by treating $Na_2[W_2(CO)_{10}]$ with PBr_3. Reaction of $K[Mn(CO)_5]$ with $SbCl_3$ affords $[Sb\{Mn(CO)_5\}_3]$ (**6**) in high yields. The spectroscopic and structural characterisation of the novel products is discussed, as well as the thermolytic behaviour of **2**, **3** and **6** for the potential formation of novel phases of transition metal pnictides.

Introduction

One of our research interests is focused on the synthesis of P_n ligand complexes[1] starting from P_1-containing compounds. The use of $[(CO)_5CrPCl_3]$ or L_nMPCl_2 in the reaction with transition-metal metalates leads to novel as well as known P_n ligand ($n \geq 2$) complexes under special conditions in low-temperature reactions.[2] However, the use of complexes of the type $[(L_nM)_2PX]$ [$L_nM = M(CO)_5$; M = Cr, W] in these reactions gives the formation of only P_2-ligand complexes that are probably formed via an intermediate of the composition $[L_nM{\equiv}P{\rightarrow}M(CO)_5]$.[3]

In continuation of these investigations we have focussed our interests particularly on products containing, besides the transition metal and the group 15 element ligand, only CO. The general interest in this type of complex is the challenge of their use as molecular precursors for the generation of novel, metastable phases[4] of transition metal pnictides by eliminating CO ligands quantitatively at moderate temperatures and ending up with a solid of a given non-metal/metal composition. Transition metal pnictides were usually obtained by high-temperature routes.[5] This idea was supported by a previous report by Gladfelter et al. on the use of $[\{Co(CO)_3\}_2(\mu,\eta^2\text{-}E_2)]$ (E = P, As) as molecular precursors for the generation of CoE layers by CVD techniques.[6]

We describe here the synthesis of novel E_1 ligand complexes starting from different E_1 sources and the first investigations of the thermolysis behaviour of selected products under high vacuum as well as inert gas atmosphere conditions with MS control.

Results and Discussion

Looking into the details of existing Co/P complexes one example for these potential precursor compounds is $[Co_2(CO)_6(\mu,\eta^2\text{-}P_2\{W(CO)_5\}_2)]$ (**1**), which was described by Huttner et al. as a product of the reaction between the chlorophosphinidene complex $[\{W(CO)_5\}_2PCl]$ and $K[Co(CO)_4]$.[7] They observed **1** as the only product if the reaction is carried out at room temperature. In agreement with our general reaction methodology we found that, by carrying out this reaction at low temperature, it is possible to isolate three further products.

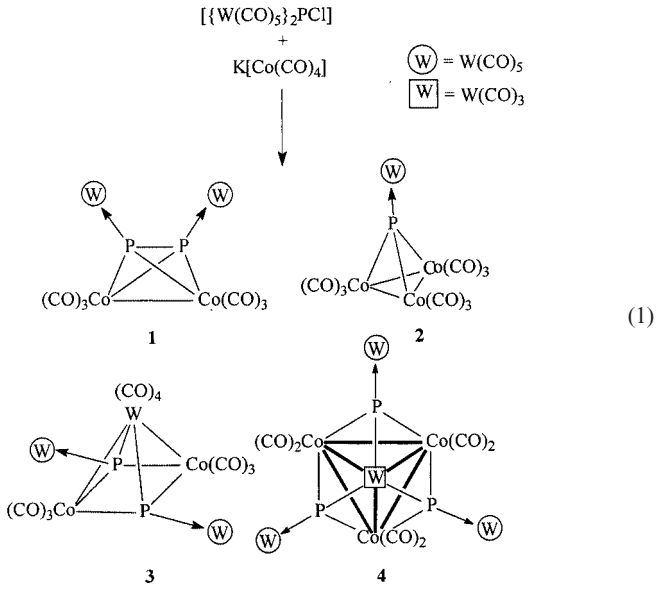
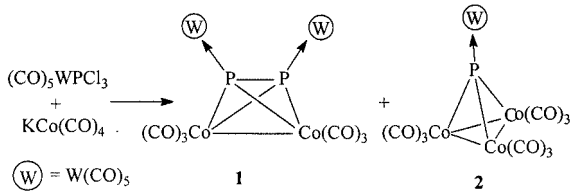
Reaction between the chlorophosphinidene complex [{W(CO)$_5$}$_2$PCl] and K[Co(CO)$_4$] in THF at −78 °C yields the novel products **3** and **4** as well as the previously described complexes **1**[7] and **2** [Equation (1)].[8] Vahrenkamp has obtained the latter product from the reaction of [(CO)$_5$WPH$_3$] with Co$_2$(CO)$_8$.[8] Complexes **1** and **2** can also be obtained by the reaction of [Cl$_3$PW(CO)$_5$] with K[Co(CO)$_4$] in THF at −78 °C [Equation (2)]. Column chromatographic workup was necessary for the separation of the products, leading to reduced yields.

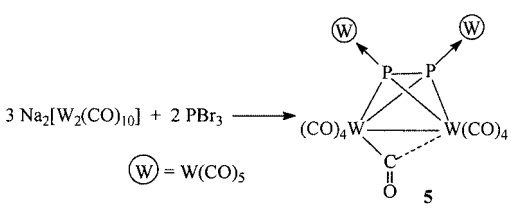


(1)



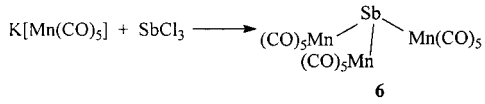
(2)

Other P_1 starting materials are the non-coordinated phosphorus trihalides. We recently found that the reaction of PCl$_3$ with Na$_2$[W$_2$(CO)$_{10}$] at ambient temperature leads to the formation of [{W(CO)$_5$}$_2$PCl], [W(CO)$_5$PCl$_3$] and [(CO)$_5$W(μ,η^2:η^1:η^1-P$_2$Cl$_2${W(CO)$_5$}$_2$)], the latter complex containing a novel ClP=PCl ligand.[9] We have found that with a different stoichiometric ratio (1:1.5) the reaction of PBr$_3$ with Na$_2$[W$_2$(CO)$_{10}$] in toluene results in the formation of **5** [Equation (3)]. Complex **5** is the first homoleptic complex of phosphorus and carbonyltungsten.



(3)

Furthermore, the reaction of SbCl$_3$ with K[Mn(CO)$_5$] in THF at low temperatures leads to the homoleptic metallostibane **6** [Equation (4)], which was obtained in 52% yield. Complex **6** has been described previously in the literature, but the authors only characterised it at low temperature and found that the compound decomposes at room temperature.[10] However, by performing the workup of the reaction mixture very rapidly at room temperature, we were able to isolate **6** in high yields as a crystalline solid that can be stored under inert gas for months at room temperature without decomposition.



(4)

All compounds were characterised by IR, and ^{31}P NMR spectroscopy and mass spectrometry. The data for **1** and **2** were found to be identical with the values described in the literature. An X-ray structure analysis was carried out for **2**, which, due to a lower measurement temperature, resulted in slightly better *R* values than the previously described measurement[8] and is therefore included in this paper.

Complex **3** forms red crystals and compound **4** forms black crystals that are slightly soluble in hexane and readily soluble in toluene and CH_2Cl_2. The black crystals of **5** are only slightly soluble in toluene and CH_2Cl_2. The black, crystalline complex **6** is soluble in hydrocarbons and other organic solvents, but solutions must be kept at low temperature to avoid decomposition. The IR spectra of the products show various absorptions in the region of terminal carbonyl ligands. In the mass spectra of **3**, **4** and **5** only fragments were observed, whereas for **6** the appropriate molecular-ion peak and peaks for subsequent loss of all CO ligands were detected.

The ^{31}P NMR spectrum of **3** shows a broad signal at δ = −40 ppm which is probably due to the quadrupole moment of the ^{59}Co nuclei. Compound **4** reveals a singlet at δ = −135 ppm in the ^{31}P NMR spectrum, which shows two tungsten satellites ($J_{P,W}$ = 87.2 and 131.2 Hz). The larger coupling constant can be assigned to the coordinative bonding to the [W(CO)$_5$] moiety, while the smaller one reflects the coupling to the central cluster atom W4 (see below). This assignment is supported by the intensity ratio of the satellites, which is almost 3:1. The ^{31}P NMR spectrum of **5** shows a singlet at δ = −123 ppm, which exhibits only one pair of tungsten satellites ($^1J_{P,W}$ = 116 Hz), which can be assigned to the coupling to the coordinatively bound [W(CO)$_5$] moieties. The expected second pair of satellites should possess a smaller coupling constant and therefore seems to be hidden in the broadening of the signal.

The novel products were also characterized by single-crystal X-ray diffraction. The molecular structure of **3** (Figure 1) reveals a *cyclo*-Co$_2$P$_2$ moiety — the torsion angle Co−P−P−Co is 16.52(7)° — that is capped by a W(CO)$_4$ group. This *nido* structure is expected for this 14-skeletal -

electron compound. The lone pair of each phosphorus atom is further coordinated to a $[W(CO)_5]$ fragment. The carbonyl ligands of the atom W1 are in eclipsed positions to the ring atoms resulting in a quadratic antiprismatic coordination pattern around the atom W1, which is unusual for tungsten. The same structural arrangement has been found for the capping Cr atom in the isostructural complex $[(CO)_4CrCo_2(CO)_6\{\mu_3\text{-}AsCr(CO)_5\}_2]$.[11] The average Co−P bond length (2.265 Å) is within the usual range. The bond lengths from phosphorus to the capping tungsten atom are 2.430(3) and 2.439(3) Å, respectively. They are surprisingly short in comparison to $[W(CO)_4\{\eta^4\text{-}P_4\langle W(CO)_5\rangle_4\}]$,[12] where the average W−P distance within the cluster core is found to be 2.604 Å. In contrast, the Co−W bond lengths with [2.807(2) and 2.787(2) Å] are unusually long compared, for example, with the bond lengths in the cluster $[\{Co(CO)_2(\mu\text{-}CO)\}_3W(CO)_2Cp]$ [2.715 Å (av)].[13]

The molecular structure of **4** (Figure 2) shows a distorted tetrahedral WCo_3 cluster core (angles between 58° and 62°), in which each of the Co_2W faces is bridged by one phosphorus atom. The lone pairs of these three P atoms are additionally coordinated to $[W(CO)_5]$ fragments. This structure is in agreement with the EAN rule,[14] which predicts a tetrahedral geometry for a 60-valence-electron cluster. A comparison of the average Co−Co bond lengths of **4** with those of the compound $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$,[15] which also possesses phosphorus-capped Co_3 faces, shows similar values (2.558 Å vs. 2.578 Å). However, the Co−W bond lengths of **4** [2.662 Å (av)] are slightly shorter than in $[\{Co(CO)_2(\mu\text{-}CO)\}_3W(CO)_2Cp]$[13] [2.715 Å (av)], which has a similar cluster core. This longer Co−W bond length is attributed to the absence of capping P atoms in the latter compound.

The central structural feature of the molecular structure of **5** (Figure 3) is a distorted tetrahedral W_2P_2 core, where the lone pairs of each phosphorus atom coordinate to a $[W(CO)_5]$ moiety. The two phosphorus atoms are shifted significantly towards the atom W2 [W1−P1 2.610(2), W1−P2 2.636(2), W2−P1 2.500(2), W2−P2 2.514(2) Å]. This asymmetry is electronically compensated for by the semibridging CO ligand between the two W atoms (W1−C5 2.086(6) Å, W2···C5 2.750 Å). The P1−P2 distance [2.062(2) Å] is slightly shorter than in the tetrahedral complexes $[\{Cp(CO)_2W\}_2(\mu,\eta^2\text{-}P_2)]$ [2.104(4) Å][16] and

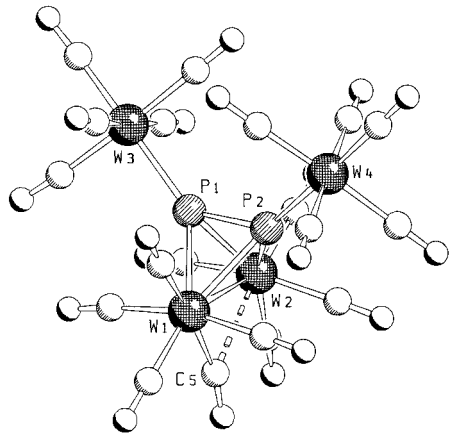

Figure 3. Molecular structure of **5** in the crystal; selected bond lengths [Å] and angles [°]: W1−W1 3.0819(6), W1−P1 2.610(2), W1−P2 2.636(2), W2−P1 2.500(2), W2−P2 2.514(2), W3−P1 2.484(2), W4−P2 2.477(2), P1−P2 2.062(2), W1−C5 2.086(6), W2···C5 2.750; P1−W1−P2 46.29(5), P1−W1−W2 51.29(4), P2−W1−W2 51.45(4), P1−W2−P2 48.58(5), P1−W2−W1 54.57(4), P2−W2−W1 55.08(4), P2−P1−W1 67.50(7), P2−P1−W2 66.07(7), P2−P1−W3 137.00(9), P1−P2−W1 66.20(6), P1−P2−W2 65.36(7), P1−P2−W4 133.70(9)

[{Cp*(CO)$_2$W}$_2$(μ,η^2:η^1-P$_2$){W(CO)$_5$}] [2.092(4) Å].[17] The W1−W2 bond length [3.082(1) Å] is similar to that in the latter complex [3.092(1) Å].

The X-ray structure analysis of **6** reveals two independent molecules in the unit cell with similar bond lengths and angles (Figure 4 shows molecule A). The central antimony atom is surrounded by three Mn(CO)$_5$ moieties and adopts a trigonal pyramidal geometry with Mn−Sb−Mn angles ranging from 107.91(2)° to 111.00(2)°. The average Mn−Sb bond length [2.808(1) Å] is significantly longer than in other complexes with a similar bonding situation (cf. [(F$_3$C)$_2$SbMn(CO)$_5$] 2.663(1) Å[18]); these long bonds reflect the steric crowding of the antimony atom by the bulky pentacarbonylmanganese groups, which themselves show a slightly distorted octahedral coordination.

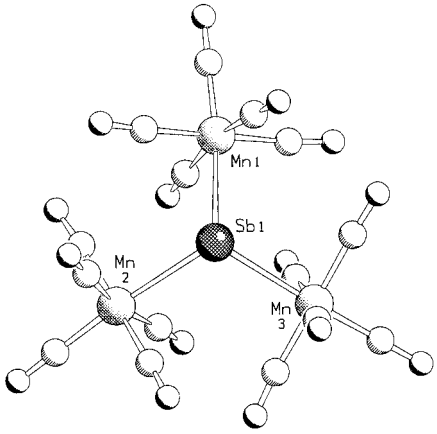

Figure 4. Molecular structure of **6** in the crystal (molecule A); selected bond lengths [Å] and angles [°]: Sb1−Mn1 2.8135(8), Sb1−Mn2 2.8027(7), Sb1−Mn3 2.7928(8); Mn1−Sb1−Mn2 110.02(2), Mn1−Sb1−Mn3 108.22(2), Mn2−Sb1−Mn3 109.71(2)

Thermogravimetric measurements were carried out on the clusters **2**, **3** and **6** under high vacuum as well as on **3** and **6** under inert gas flow conditions, and were combined with MS control of the volatile products in the temperature range up to 1000 °C. Thermogravimetric analysis of **3** under vacuum conditions shows that it decomposes in two steps: between 90 and 130 °C with a mass loss of about 39%, and between 540 and 640 °C with a further mass loss of about 11%, both of which are accompanied by W(CO)$_6$ elimination.[19] The second step also occurs with elimination of Co- and P-containing moieties.

The thermogravimetric analysis of **2** in high vacuum shows a two-step decomposition in the temperature range of 65 to 165 °C (first step 65−134 °C, second step 134−165 °C), with a mass loss of about 62% due to the elimination of CO and W(CO)$_6$,(Figure 5)[19] that leaves a CO-containing sample with the formal composition Co$_3$P(CO)$_3$.[20] In contrast, complex **6** decomposes by Mn(CO)$_n$ elimination in two steps (between 65−120 °C and 120−180 °C) with an overall mass loss of about 67% that leaves a nearly C-free sample with the composition Mn$_2$Sb.[21] However, if the thermogravimetric experiments are carried out under a flow of an inert gas (Ar or He) there is a significant change in the decomposition behaviour, which is characterised mainly by CO elimination. For **2** the only detectable volatile material is CO, leading to a mass loss of about 50% in the temperature range 120−180 °C (Figure 5). For **6**, CO and Mn(CO)$_n$ fragments are eliminated in two steps between 100 °C and 200 °C, and this is accompanied by a weight loss of 56%. The remaining amorphous solids have the compositions Co$_3$WP and SbMn$_{2.6}$, respectively,[22] and are very sensitive to oxygen.

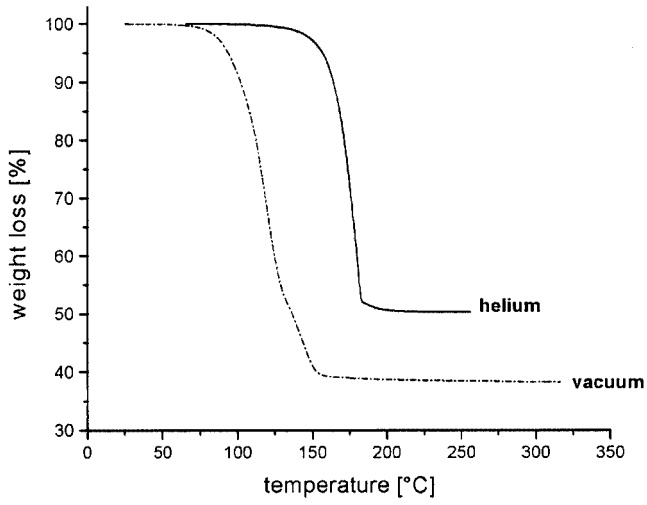

Figure 5. Thermogravimetric analysis of **2** in helium gas (solid line) and in vacuo (dashed line)

Initial attempts to obtain crystalline materials suitable for powder XRD characterisation were carried out by heating the remaining solids at 550 °C for 500 h. While no novel phase could be observed for the compound generated from **2**, reflections of a hexagonal phase could be indexed for the solid originating from **6**, with $a = b = 5.139$, $c = 13.017$ Å; and $V = 297.7$ Å^3.[23]

Conclusion

Our results have shown that novel cluster complexes of naked group-15 elements can be obtained by reacting pnicogen halide complexes with transition metal metalates at low temperature. These cluster compounds with naked group-15 elements and CO as the only ligands can be used as potential precursors for the generation of novel solids. Their decomposition occurs at relatively low temperatures of up to 200 °C, and the composition of the remaining amorphous solids is partially controlled by the composition of the metals of the employed cluster core. Whereas the thermolysis under high-vacuum conditions leads partially to the elimination of CO and metalcarbonyl fragments, the better way to obtain non-metal/metal materials from single-source precursors is to carry out the thermal decomposition under a flow of inert gas. There are some indications that the presence of bonds between the transition metals in the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molecular precursor compound is one precondition for the exclusive elimination of CO. Thus, for cluster **2** only CO elimination occurs under the latter conditions, whereas the Sb-linked complex **6**, which possesses only Sb−Mn bonds loses $Mn(CO)_n$ units. Furthermore, the stability and the vapour pressure of the eliminated moieties also influence the decomposition behaviour.

The preliminary results presented in this paper show that the use of CO-containing molecular precursors for the preparation of novel transition metal pnictides seems to be of substantial potential. Nevertheless, further research is necessary to obtain more information about the structure and the properties of these novel compounds.

Experimental Section

General Remarks: All manipulations were performed under dry nitrogen using standard glove-box and Schlenk techniques. All solvents were freshly distilled from appropriate drying reagents immediately prior to use. IR spectra were obtained with a Bruker IFS280 spectrometer, and ^{31}P NMR spectra were recorded at room temperature with a Bruker AMX 300 spectrometer (^{31}P: 121.49 MHz) using 85% H_3PO_4 as an external standard; mass spectra were recorded with a Varian MAT-711 spectrometer. $[\{W(CO)_5\}_2PCl]$,[7] $[Cl_3PW(CO)_5]$[24] and $K[Co(CO)_4]$[25] were synthesised according to literature procedures.

Reaction of $[\{W(CO)_5\}_2PCl]$ with $K[Co(CO)_4]$: $K[Co(CO)_4]$ (0.33 g, 1.55 mmol) was added to a solution of $[\{W(CO)_5\}_2PCl]$ (1.11 g, 1.55 mmol) in 20 mL of THF at −78 °C. After stirring for 30 min, the mixture was allowed to reach room temperature within 1 h and was stirred for an additional 1 h. The reaction mixture was filtered through Celite, 5 mL of silica gel was added and all solvents were removed in vacuo. Products **1**, **2**, **3** and **4** were separated by column chromatography on silica gel.

$[Co_2(CO)_6(\mu,\eta^2\text{-}P_2\{W(CO)_5\}_2)]$ (1): After elution of a purple fraction with hexane/toluene (10:1) crystals of **1** were obtained by recrystallisation from CH_2Cl_2 (0.11 g, 15% based on P). The analytical data agreed with the literature values.[7]

$[Co_3(CO)_9(\mu_3\text{-}P\{W(CO)_5\})]$ (2): This compound was eluted with hexane as a yellowish-brown fraction and obtained as brown platelets after recrystallisation from CH_2Cl_2 (0.036 g, 3% based on P). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 41.0 ppm (s, br). The analytical data agreed with the literature values.[8]

$[(CO)_4WCo_2(CO)_6\{\mu_3\text{-}PW(CO)_5\}_2]$ (3): Elution of a brown fraction with hexane/toluene (5:1) and recrystallisation from CH_2Cl_2 yielded **3** as black, metallic crystals (0.07 g, 7% based on P). IR (KBr): ν(CO) = 2090 (sh), 2064 (s, br), 2046 (sh), 2014 (w), 2007 (w), 1991 (sh), 1960 (sh), 1947 (vs, br), 1932 (sh) cm^{-1}. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −40.0 (s, $w_{1/2}$ = 500 Hz) ppm. EI-MS: *m*/*z* (%) = 821.3 (0.6) $[(CO)_{13}PCoW_2]^+$, 457.5 (3.6) $[PCoW_2]^+$. $C_{20}Co_2O_{20}P_2W_3$ (1291.57): calcd. C 18.60; found C 18.09.

$[WCo_3(CO)_{12}\{\mu_3\text{-}PW(CO)_5\}_3]$ (4): A brown fraction eluted with hexane/toluene (2:1) yielded a small amount of **4** after recrystallisation from CH_2Cl_2 (0.015 g, 2% based on P). IR (KBr): ν(CO) = 2076 (s), 2070 (sh), 2017 (sh), 2003 (sh), 1984 (sh), 1943 (vs, br), 1919 (sh), 1891 (sh) cm^{-1}. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −135.3 ppm (s, $J_{P,W}$ = 87.2, 131.2 Hz) cm^{-1}. $C_{24}Co_3O_{24}P_3W_3$ (1493.52): calcd. C 19.30; found C 19.01.

Reaction of $[Cl_3PW(CO)_5]$ with $K[Co(CO)_4]$: A solution of $K[Co(CO)_4]$ (1.26 g, 6.00 mmol) in 40 mL of THF was added dropwise to a solution of $[Cl_3PW(CO)_5]$ (0.922 g, 2.00 mmol) in 40 mL of THF at −78 °C. After 30 min, the reaction mixture was allowed to warm to room temperature and stirred for an additional 14 h. All volatiles were removed in vacuo and $[W(CO)_6]$ was removed by sublimation under high vacuum at 50 °C. The residue was dissolved in CH_2Cl_2, 5 mL of silica gel was added, and the solution was reduced to dryness. Compounds **1** and **2** were separated by column chromatography. Compound **1** was eluted with hexane (yellow-brown fraction) and obtained by recrystallisation from CH_2Cl_2 (0.12 g, 12% based on P). Elution with hexane/toluene (10:1) yielded a purple fraction from which **2** could be isolated after recrystallisation from CH_2Cl_2 (0.16 g, 10.2% based on P).

$[W_2(CO)_9(\mu,\eta^2\text{:}\eta^1\text{:}\eta^1\text{-}P_2\{W(CO)_5\}_2]$ (5): Solid $Na_2[W_2(CO)_{10}]$ (0.768 g, 1.11 mmol) was added at room temperature to a solution of PBr_3 (0.2 g, 0.74 mmol) in 50 mL of toluene, which immediately became purple. The solution was stirred for 3 hours and the solvent removed in vacuo. Extraction of the remaining solid twice with 10 mL of CH_2Cl_2 and reduction of the solvent volume to about 10 mL yielded black crystals of **5** after one day at 4 °C (0.15 g, 30%). Further reduction of the solvent volume gave more product. The ^{31}P NMR spectrum of the crude reaction mixture in $[D_8]THF$ shows singlets at δ = 103.5 and −90.8 ppm besides the major singlet at δ = −122.7 ppm for **5**. IR (CH_2Cl_2): ν(CO) = 2051 (vs), 2035 (s), 1999 (m), 1956 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −122.6 (s, $^1J_{P,W}$ = 116 Hz) cm^{-1}. $C_{19}O_{19}P_2W_4$ (1329.55): calcd. C 17.16; found C 17.23.

$[\{(CO)_5Mn\}_3Sb]$ (6): A solution of $K[Mn(CO)_5]$ (2.20 g, 9.40 mmol) in 50 mL of THF was added to a solution of $SbCl_3$ (715 mg, 3.13 mmol) in 50 mL of THF at −78 °C over a period of 1 h. The reaction mixture was stirred at low temperature for an additional 1 h before the cold bath was removed and the solution warmed to room temperature. All solvents were evaporated in vacuo and the remaining residue was extracted with pentane. Filtration through Celite and storage at −30 °C yielded **6** as black needles (1.16 g, 52%). *Note:* Care has to be taken that the operations carried out at room temperature are performed as quickly as possible to avoid decomposition. IR (KBr): ν(CO) = 2105 (m), 2071 (s), 1980 (vs, br) cm^{-1}. EI-MS: *m*/*z* (%) = 706.7 (20) $[M^+]$, 678.7 (22) $[M^+ - CO]$, 594.7 (2) $[M^+ - 4\ CO]$, 566.7 (7) $[M^+ - 5\ CO]$, 538.7 (20) $[M^+ - 6\ CO]$, 510.7 (43) $[M^+ - 7\ CO]$, 482.6 (3) $[M^+ - 8\ CO]$, 454.6 (9) $[M^+ - 9\ CO]$, 426.6 (21) $[M^+ - 10\ CO]$, 398.6 (19) $[M^+ - 11\ CO]$, 370.6 (17) $[M^+ - 12\ CO]$, 342.6 (9) $[M^+ - 13\ CO]$, 314.6 (8) $[M^+ - 14\ CO]$, 286.6 (27) $[M^+ - 15\ CO]$. $C_{15}Mn_3O_{15}Sb$ (706.72): calcd. C 25.49; found C 25.34.

Thermogravimetric Analysis: Thermogravimetric analyses were carried out with a thermobalance STA 409 from Netzsch either in vacuo or with a dynamic helium gas flow (70 mL/min) at a heating rate of 5 K/min. The balance was coupled to a quadrupole mass spectrometer QMG 422 (Balzers) that includes a skimmer system for measurements under normal pressure.

X-ray Structure Determination and Details of Refinement: Data were collected with a STOE STADI4 four-cycle diffractometer for complexes **2**, **3** and **4** and for complexes **5** and **6** on an IPDS area-detector diffractometer using Mo-K_α (λ = 0.71069 Å) radiation. Machine parameters, crystal data and data collection parameters are summarised in Table 1. The structures were solved by direct methods using SHELXS-86,[26a] with full-matrix least-squares refinement on F^2 in SHELXL-93[26b] with anisotropic displacement for non-H atoms. Hydrogen atoms were placed in idealised posi-

tions and refined isotropically according to the riding model. Due to the low crystal quality of **4**, only the heavy atoms W, Co and P were anisotropically refined, leaving a relatively large residual electron density. The two independent molecules of the molecular structure of **6** were tested to be identical, but this resulted in noteworthy differences in angles and bond lengths. Attempts to refine the data set of **6** in the higher monoclinic space group resulted in a R_{int} value greater than 0.50. Thus, it can be concluded that the two molecules are independent in the triclinic unit cell. CCDC-245196 to -245200 (**2**−**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

3D-Coordination Cluster Polymers $[Ln(H_2O)_3Re_6Te_8(CN)_6]\cdot nH_2O$ (Ln = La^{3+}, Nd^{3+}): Direct Structural Analogy with the Mononuclear $LnM(CN)_6\cdot nH_2O$ Family

Sofia B. Artemkina,[a] Nikolai G. Naumov,*[a] Alexander V. Virovets,[a] and Vladimir E. Fedorov[a]

Keywords: Rhenium / Cluster compounds / Structure elucidation / Cyanide ligand / Lanthanides

Using the hydrothermal method two novel 3D-coordination complexes $[Ln(H_2O)_3Re_6Te_8(CN)_6]\cdot nH_2O$ (Ln = La^{3+}, Nd^{3+}) have been synthesised and structurally characterised. For compound $[La(H_2O)_3Re_6Te_8(CN)_6]\cdot 4H_2O$ (**1**) the unit cell parameters are: Space group $P6_3/m$, a = 9.3060(13), c = 20.528(4) Å, V = 1539.6(4) Å^3, R_f = 0.0597. For compound $[Nd(H_2O)_3Re_6Te_8(CN)_6]\cdot H_2O$ (**2**) the unit cell parameters are: Space group $P6_3/m$, a = 9.3030(10), c = 20.222(4) Å, V = 1515.7(4) Å^3, R_f = 0.0226. The structures of the cluster compounds are topologically analogous to the mononuclear polymeric complex $LaCr(CN)_6\cdot 5H_2O$.

Introduction

Octahedral cluster cyano complexes of transition metals have been intensively studied during the past decade (selected references: $[Re_6Q_8(CN)_6]^{4-}$ [1−3], $[Mo_6Q_8(CN)_6]^{7-}$ [4,5], $[W_6Q_8(CN)_6]^{6-}$ [6], $[Nb_6Cl_{12}(CN)_6]^{4-}$ [7,8] and heterometallic $[Re_{6-x}Mo_xS_8(CN)_6]^{5-}$ [9]). These anions are topological analogues of hexacyanometalate ions $[M(CN)_6]^{n-}$ and the anions can form polymeric arrays based on covalent cyano-bridged interactions with transition metals, for instance ···−Re_6−C≡N−M−N≡C−Re_6−··· (selected references: Re:[10−13], W:[14], Nb:[8]). Despite the equivalent disposition of terminal cyano groups in $[M(CN)_6]^{n-}$ and $[M_6Q_8(CN)_6]^{n-}$, it is difficult to expect isotypical structures when $[M(CN)_6]^{n-}$ is changed to $[M_6Q_8(CN)_6]^{n-}$. The reason is the larger size of cluster cyanides compared with mononuclear ones. This increase of linear size leads to a corresponding increase in pore volume, hence the network has a tendency to distort, collapse or to be interpenetrated.

Indeed, from the widely diverse family of cluster cyano-bridged polymers, only three compounds exhibit a direct structural analogy with mononuclear cyanometallates, namely: $Fe_4[Re_6Te_8(CN)_6]_3\cdot 27H_2O$, $Ga_4[Re_6Se_8(CN)_6]_3\cdot 38H_2O$,[15] and $(Me_4N)_2Mn[Nb_6Cl_{12}(CN)_6]$ [16] which crystallises in the highly symmetrical space group $Fm\bar{3}m$ and has an ordinary six-connected network equivalent to the well-known Prussian Blue net.[8] All other reported cluster networks have no examples in the family of mononuclear cyanometallates.

In this paper we report the synthesis and structures of two new coordination compounds based on the cluster complexes $[Re_6Te_8(CN)_6]^{3-}$ and Ln^{3+} (La^{3+}, Nd^{3+}).These compounds demonstrate another example of the direct structural analogy between compounds built from mononuclear $[M(CN)_6]^{n-}$ and cluster expanded $[M_6Q_8(CN)_6]^{n-}$ anions.

Results and Discussion

Syntheses of 1 and 2: The interaction of $K_4Re_6Te_8(CN)_6$ with $LnCl_3\cdot nH_2O$ under hydrothermal conditions described in the Exp. Sect. gave solid products which consisted of thin dark hexagonal plates of compounds **1** and **2**. X-ray diffraction patterns showed that the bulk samples were single phases with unit cell parameters as follows: **1**: a = 9.316(3), c = 20.521(4); **2**: a = 9.307(3), c = 20.213(4) Å. Chemical analysis (EDAX) of the crystals showed that they contained no potassium. The magnetic susceptibility of **1** is μ_{eff} (298) = 1.81 μ_B which corresponds to one unpaired electron per formula unit $[La(H_2O)_3Re_6Te_8(CN)_6]\cdot 4H_2O$. The magnetic susceptibility of **2** is μ_{eff} (298) = 4.18 μ_B. This value is very close to μ_{eff} = 4.24 μ_B calculated using the equation $\mu^2_{eff} = \mu^2(Nd^{3+}) + \mu^2([Re_6Te_8(CN)_6]^{3-})$ and corresponds to the presence of two noninteracting paramagnetic centres in the structure, namely Nd^{3+} and $[Re_6Te_8(CN)_6]^{3-}$. Based on magnetic and stoichiometric considerations, we postulate that the cluster complex $[Re_6Te_8(CN)_6]^{4-}$ has undergone one-electron oxidation during the reaction. Redox transformations of $[Re_6Te_8(CN)_6]^{4-}$ have been studied pre-

viously[17] and it was found that the cluster complex is characterised by an oxidation potential low enough to be oxidised with oxygen dissolved in an aqueous solution. In fact, $[Re_6Te_8(CN)_6]^{4-}$ can lose one electron and the resultant $[Re_6Te_8(CN)_6]^{3-}$ can be isolated as a salt with an organic cation, i.e. $(Et_4N)_2(H)[Re_6Te_8(CN)_6]\cdot 2H_2O$.[18]

Structures of Compounds 1 and 2: Compounds **1** and **2** crystallise in the hexagonal space group $P6_3/m$ and they have identical coordination networks, i.e. $[Ln(H_2O)_3Re_6Te_8(CN)_6]_{3\infty}$. Structure **1** contains one rhenium atom (Re1), two tellurium atoms (Te1, Te2), one cyano group (C1, N1), Ln1, and O1 (coordinated water) in its asymmetric unit (Figure 1). The centre of the cyanocluster is located in the special position *2a* of the $P6_3/m$ space group and has $\bar{6}$ crystallographic symmetry close to the ideal O_h. Each rhenium atom is coordinated to one cyano group forming an almost linear Re−C−N fragment. Selected bond distances of structures **1**, **2** and other related complexes are listed in Table 1 for comparison. Comparing the bond lengths Re−Re, Re−Te, Re−C and C−N in $[Re_6Te_8(CN)_6]$ we can say that the oxidation does not significantly affect these distances (within the limits of the errors obtained).

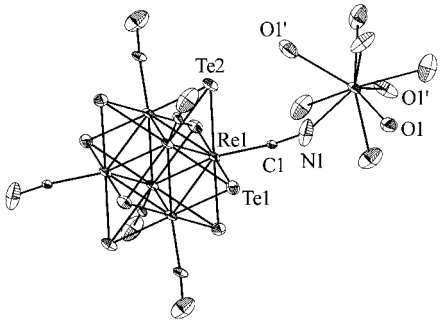

Figure 1. Asymmetric unit of the coordination network of $[Ln(H_2O)_3Re_6Te_8(CN)_6]_{3\infty}$ in the crystal structures of **1** and **2**; the atoms are shown at the 50% probability level

The lanthanide atom Ln1 (La^{3+} as well as Nd^{3+}) is located in the special position *2c* (1/3, 2/3, 1/4) with $\bar{6}$ symmetry. It is coordinated by six nitrogen atoms from the CN groups of different cluster anions and three water molecules. The coordination polyhedron of Ln1 is a regular tricapped trigonal prism (Figure 2) with bond lengths La−O 2.63(3), La−N 2.57(3) Å for **1** and Nd−O 2.645(15), Nd−N 2.537(11) Å for **2**.

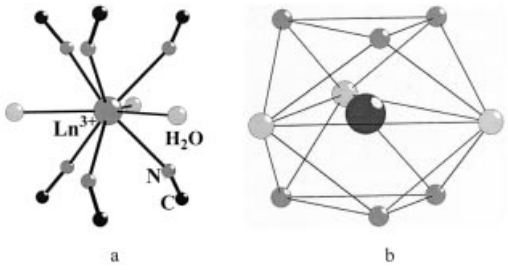

Figure 2. Coordination environments of Ln^{3+} in the crystal structures of **1** and **2** (a); coordination polyhedron around the Ln^{3+} cations (b)

The cluster complex $[Re_6Te_8(CN)_6]^{3-}$ is linked via lanthanide cations to produce a 3D-coordination network $[Ln(H_2O)_3Re_6Te_8(CN)_6]_{3\infty}$. Cluster complexes form six bridging cyano groups with Ln^{3+}. Six nitrogen atoms and three water molecules constitute the coordination sphere of the lanthanide cations as shown in Figure 2. In the network, the cluster complexes and Ln^{3+} cations are arranged in layers (Figure 3, *a*) parallel to the crystallographic *ab* plane and their packing can be presented as a sequence ···ABAC··· (A = cluster complex; B and C = lanthanide cations). For polymeric compounds based on octahedral cluster complexes, this kind of network has a sufficiently high packing coefficient of 69% (i.e. the coordination network occupies 69% of the cell volume).[19]

The connectivity of the network can be described as a (6,6)-connected net according to the nomenclature detailed in a review.[20] The nodes are Ln^{3+} lanthanide cations in a regular triangular prismatic environment of six nitrogen atoms belonging to the cluster complexes, the cluster complexes being coordinated to Ln^{3+} cations via six octahedrally arranged cyano groups. Rare earth cations have larger ionic radii than *3d* transition metals which drives the formation of the new type of network of octahedral cluster cyanometallates.

In compounds **1** and **2**, the coordination networks are isostructural while the total amount and locations of solvent water molecules in **1** and **2** are different. In the final difference electron density map of **1**, two peaks were found. One of them, assigned to O(1 W), is located on a mirror plane (position *6h*). In the unit cell, these atoms form an equilateral triangle with O···O distances of 3.02 Å around a special point of $\bar{6}$. The U_{eq} parameter is quite high (0.21

$Å^{-2}$) but our attempt to refine the site occupancy factor (s. o. f.) did not give any improvement in the residuals. The second peak, assigned to O(2 W), was found in a *4f* special position (1/3, 2/3, *z*). This atom is located between three nitrogen atoms of the CN groups with O···N distances equal to 2.60 Å. The refinement of its s. o. f. resulted in a value of 0.5 with $U_{eq} = 0.085$ $Å^{-2}$.

In **2**, the final difference electron density map contained only one suitable peak which was assigned to an oxygen atom disordered over three positions around the special point of a $\bar{6}$ axis forming a triangle on a mirror plane. The O···O distances in the triangle of 1.34 Å are short, indicating that only one of three symmetrically related positions is actually occupied. Therefore, the s. o. f. was set to 33%. The resultant $U_{eq} = 0.079$ $Å^{-2}$ is as expected for solvent water molecules.

Structural Analogy with Mononuclear Compounds: Compounds **1** and **2** possess symmetry and a packing motif equivalent to mononuclear complexes with the general formula $LnM(CN)_6{\cdot}nH_2O$ or $ALnM(CN)_6{\cdot}nH_2O$. Indeed, compounds **1**, **2**, $[La(H_2O)_3Cr(CN)_6]{\cdot}2H_2O$[21], $[La(H_2O)_2Fe(CN)_6]{\cdot}2H_2O$[22] and $Cs[Ce(H_2O)_3Fe(CN)_6]{\cdot}H_2O$[23] crystallise in the space group $P6_3/m$. The cell parameters as well as the bond distances Ln−O(H_2O) and Ln−N(CN) are listed in Table 2. The packing of the cluster cores in **1** and **2** mimics the packing of the cations Cr^{3+}, Fe^{3+} and Fe^{2+} (Figure 4), as well as the packing motives of the lanthanide cations La^{3+}, Ce^{3+} and Nd^{3+}. A comparison of the angles in the coordination networks of **1**, **2** and $[La(H_2O)_3Cr(CN)_6]{\cdot}2H_2O$ revealed a moderate variation.

In these five structures, the coordination sphere of the lanthanide cation is tricapped trigonal prismatic containing six nitrogen atoms and three water molecules (Figure 2), except for $[La(H_2O)_2Fe(CN)_6]{\cdot}2H_2O$ in which one water molecule is absent and a two-capped trigonal prism (hendecahedron) is formed. Other known Ln−$[M(CN)_6]$ compounds crystallising in the orthorhombic system include[23−27] ($TlTmRu(CN)_6{\cdot}3H_2O$, $ErFe(CN)_6{\cdot}4H_2O$, $NdCo(CN)_6{\cdot}4H_2O$, $GdKFe(CN)_6{\cdot}3H_2O$, $YbKFe(CN)_6{\cdot}3.5H_2O$) and examples in the monoclinic system include[23,28−30] $CsLnFe(CN)_6{\cdot}5H_2O$ (Ln = Ce, Pr, Nd), $SmFe(CN)_6{\cdot}4H_2O$, $SmKFe(CN)_6{\cdot}3H_2O$ and $SmCo(CN)_6{\cdot}4H_2O$. However, their crystal structures exhibit similar packings of the building blocks and motives to those seen in coordination networks.[31]

In conclusion, we have prepared two new coordination compounds based on the cluster complexes $[Re_6Te_8(CN)_6]^{3-}$ and Ln^{3+} (La^{3+}, Nd^{3+}). These com-

pounds exhibit a direct structural analogy with the $LnM(CN)_6\cdot nH_2O$ family.

Experimental Section

General: $K_4[Re_6Te_8(CN)_6]$[3] was prepared from polymeric Re_6Te_{15}.[32] All other reagents were used as purchased. Infrared spectra were measured in KBr disks with a Bruker IFS-85 spectrometer. X-ray powder diffraction data (XPD) were obtained with a Philips APD 1700 powder diffractometer using Cu-K_α radiation. Magnetic measurements were performed with a Quantum Design SQUID magnetometer, field 5 kOe.

X-ray Structural Studies: The diffraction measurements were performed by standard techniques at 298(2) K with an Enraf−Nonius CAD4 diffractometer (graphite-monochromated Mo-K_α radiation). Face-indexed absorption corrections were applied. The crystal structures were solved by direct methods and refined by full-matrix least-squares methods using SHELX-97.[33] Hydrogen atoms of the water molecules were not located. Dark hexagonal plates of **1** and **2** were selected from the reaction products.

Crystallographic Data for 1: $C_6H_{14}La_1N_6O_7Re_6Te_8$, FW = 2559.16, hexagonal crystal system, space group $P6_3/m$, a = 9.3060(13), c = 20.528(4) Å, V = 1539.6(4) Å^3, Z = 2, $D_{calcd.}$ = 5.443 g·cm^{-3}, μ = 32.299 mm^{-1}. Total 2416 reflections were collected up to $\theta_{max.}$ = 24.97°, of which 939 independent (R_{int} = 0.1394). Final residuals are: $R1$ = 0.0597, $wR2$ = 0.1339 for 493 $F_{hkl}(4\sigma)$, $R1$ = 0.0941, $wR2$ = 0.1578 for all unique reflections.

Crystallographic Data for 2: $C_6H_8N_6NdO_4Re_6Te_8$, FW = 2510.45, crystal system is hexagonal, space group $P6_3/m$, a = 9.3030(10), c = 20.222(4) Å, V = 1515.7(4) Å^3, Z = 2, $D_{calcd.}$ = 5.501 g·cm^{-3}, μ = 33.108 mm^{-1}. Total 3537 reflections were collected up to $\theta_{max.}$ = 27.46°, of which 1196 independent (R_{int} = 0.0633). Final residuals are: $R1$ = 0.0226, $wR2$ = 0.0441 for 616 $F_{hkl}(4\sigma)$, $R1$ = 0.0606, $wR2$ = 0.0585 for all unique reflections.

Further details of the crystal-structure investigation(s) may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number(s) CSD-413628 (for **1**) and CSD-413629 (for **2**). X-ray powder patterns of samples **1** and **2** are also included.

Preparation of $[La(H_2O)_3Re_6Te_8(CN)_6]\cdot 4H_2O$ (1): A mixture of $LaCl_3\cdot 7H_2O$ (0.033 g, 0.09 mmol) and $K_4Re_6Te_8(CN)_6$ (0.050 g, 0.02 mmol) was placed in a glass ampoule (15 mL) and an aqueous solution of ammonia was added to the mixture to adjust the pH to 9. The ampoule was sealed and heated at 140 °C for two days. The ampoule was then gradually cooled. The product consisted of dark hexagonal plates and a thin light precipitate as well as a reasonable quantity of a dark crystalline powder. The dark plates were selected, washed with water and dried in air. Yield ca. 0.020 g (39%). In our opinion, the presence of ammonia in the reaction solution results in better crystallisation. IR: ν_{CN} 2098−2085 (broad), ν_{OH} 1610; δ_{HOH} 3572 (broad); ν_{Re-C} 453 cm^{-1}. μ_{eff} (298 K) = 1.81 μ_B.

Preparation of $[Nd(H_2O)_3Re_6Te_8(CN)_6]\cdot H_2O$ (2): The same method was used to prepare **2**, $NdCl_3\cdot 6H_2O$ (0.040 g, 0.10 mmol) being the source of Nd^{3+}. Yield ca. 0.015 g (30%). IR: δ_{HOH} 3559, 3521; ν_{CN} 2081; ν_{OH} 1566; ν_{Re-C} 454 cm^{-1}. μ_{eff} (298 K) = 4.18 μ_B.

[19] The packing coefficient was calculated using the program KPACK. The KPACK calculating method is similar to that used in OPEC (Gavezzotti, 1983) and is based on equidistant distribution of testing points (200 points/Å^3). The crystal structure is supposed to be a superposition of atomic spheres of van der Waals radii. The packing coefficient is equal to the ratio of the number of testing points belonging to one or more atomic spheres and the total number of points. The procedure was described in detail in A. V. Virovets, N. V. Podberezskaya, *Kristallografiya* **1992**, *37*, 1017−1019 (in Russian).

Dioxovanadium(V) Complexes of ONO Donor Ligands Derived from Pyridoxal and Hydrazides: Models of Vanadate-Dependent Haloperoxidases

Mannar R. Maurya,*[a] Shalu Agarwal,[a] Cerstin Bader,[b] and Dieter Rehder*[b]

Keywords: Vanadium / Hydrazones / Catalytic bromination / Pyridoxal

[$VO(acac)_2$] reacts with H_2L [H_2L are the hydrazones H_2pydx-inh (**I**), H_2pydx-nh (**II**), or H_2pydx-bhz (**III**); pydx = pyridoxal, inh = isonicotinohydrazide, nh = nicotinohydrazide, bhz = benzohydrazide] in dry methanol to yield the oxovanadium(IV) complexes [VOL] (H_2L = **I**: **1**; H_2L = **II**: **4**) or [VO(pydx-bhz)]. These complexes, when exposed to air, convert into the corresponding dioxovanadium(V) complexes [VO_2HL] (H_2L = **I**: **2**; H_2L = **II**: **5**; H_2L = **III**: **7**). Aqueous solutions of vanadate and the ligands at pH = 7.5 give rise to the formation of [$K(H_2O)_3$][VO_2(pydx-inh)] (**3**), [$K(H_2O)_2$][VO_2-(pydx-nh)] (**6**) and [$K(H_2O)_2$][VO_2(pydx-bhz)] (**8**). Treatment of **6** and **8** with H_2O_2 generates the oxo(peroxo)vanadium complexes [$VO(O_2)L$] (H_2L = **II**: **9**; H_2L = **III**: **10**). Complexes **9** and **10** are capable of transferring an oxo group to PPh_3. Acidification of **8** with HCl afforded a hydroxo(oxo) complex. The crystal and molecular structures of ligand **I** and complex **3** have been solved by single-crystal X-ray diffraction. In the anion **3**, the vanadium atom is in a distorted tetragonal-pyramidal environment (τ = 0.23). The K^+ ion is coordinated to four water molecules (two of which bridge to a neighbouring K^+ ion), the pyridine nitrogen atom of an isonicotinic moiety, the equatorial oxo group of the VO_2^+ fragment, and the alcoholic group of the pyridoxal moiety, which links adjacent layers in the three-dimensional lattice network. In the presence of KBr/H_2O_2, the anionic complexes **3**, **6** and **8** catalyse the oxidative bromination of salicylaldehyde in water to 5-bromosalicylaldehyde in ca. 40% yields with ca. 87% selectivity.

Introduction

Recent interest in vanadium coordination chemistry[1,2] with *ON* oligodentate ligands arises from the potential of these complexes as insulin-enhancing or insulin-mimetic agents,[3] their model character for vanadate-dependent haloperoxidases occurring in fungi and marine algae[4] and, in relation to these enzymes, their use in oxo-transfer catalysis and oxidative halogenation. Vanadate-dependent haloperoxidases contain $VO(OH)O_2^{2-}$ (HVO_4^{2-}) coordinated to the N^{ε} of a histidine in an overall trigonal-bipyramidal coordination.[5] These enzymes, and models of their active centre, catalyse the oxidation of halides by peroxide to hypohalous acid [which further halogenate non-enzymatically hydrocarbons; Equation (1)],[6] and the oxidation of organic (prochiral) sulfides to (chiral) sulfoxides.[7,8] Peroxo and hydroperoxo complexes have been proposed to act as the active intermediates.[6,9] The peroxo form, containing peroxovanadate $HVO_3(O_2)^{2-}$ attached to histidine, and in a tetragonal-pyramidal geometry, has been structurally characterised.[10]

$$Hal^- + H_2O_2 + RH + H^+ \rightarrow RHal + 2\,H_2O \quad (1)$$

We have previously reported on dioxovanadium(V) complexes with *ONO*, *NNO* and *NNS* functional ligands, derived from hydrazones based on the carbonyl components salicylaldehyde or 2-acetylpyridine, and the hydrazides of isonicotinic or benzoic acid, or *S*-benzyldithiocarbazate,[11] and reduced Schiff bases derived from salicylaldehyde and various amino acids.[12] Anionic and neutral *cis*-dioxovanadium(V) complexes with tridentate (*ONO*) *N*-salicylidenehydrazide ligand systems as models for vanadate-dependent haloperoxidases have recently been reviewed by Plass.[13] The present work is an extension to hydrazones formed from the biogenic carbonyl constituents pyridoxal (vitamin B_6; HpydxOH), and the hydrazides of nicotinic acid (H_2nh), isonicotinic acid (H_2inh) or benzoic acid (H_2bhz; see Scheme 1), which reveals novel structural features, and reactivity patterns that model the haloperoxidase activity.

Results and Discussion

Scheme 2 provides an overview of the complexes reported in this contribution. Structures of these complexes are based on spectroscopic (IR, UV/Vis, EPR, ^{1}H and ^{51}V NMR) data, thermogravimetric studies, elemental analyses and X-ray diffraction analyses of the ligand H_2pydx-inh (**I**) and complex **3**.

Synthesis and General Characteristics

Reaction between equimolar amounts of $[VO(acac)_2]$ and ligand **I** or **II** (Scheme 1) in dry, refluxing methanol gave the oxovanadium(IV) complex [VO(pdyx-inh)] (**1**) or [VO(pdyx-nh)] (**4**), respectively. According to elemental analyses and thermogravimetric studies, there is no coordinated additional ligand such as water or methanol present in the isolated, solid compounds; **1** and **4** exhibit a magnetic moment, at ambient temperature of 1.32 and 1.41 μ_B, respectively; the spin-only value for a d^1 system is 1.73 μ_B. The magnetic data can be interpreted in terms of antiferromagnetic exchange interaction,[14] implying close contacts between the monomers or the formation of dinuclear complexes such as $[\{VO(L)\}_2\mu\text{-}O]$. Although dinuclear complexes of this type are well documented,[15] the size of the magnetic moments and the low wave number for the V=O stretch (888 cm^{-1}) suggest intermolecular interactions of the kind (L)V=O···VO(L),[16] and thus an effective coordination number of 5. Anisotropic EPR data of DMSO solutions (see Exp. Sect.) correspond to those expected for the equatorial donor set shown for **1** and **4** in Scheme 2, i.e. $O_{phenolate}N_{imine}O_{enolate}$, plus a relatively weakly bonding equatorial ligand such as water or DMSO.[17]

On aerial oxidation of **1** in methanol, the dioxovanadium(V) complex $[VO_2(Hpdyx\text{-}inh)]$ (**2**) was obtained. The intermediate complex **1** can be isolated from the methanolic solution prior to aeration. Equations (2) and (3) represent the synthetic procedures.

$$\underset{\mathbf{I}}{[VO(acac)_2]} + H_2pydx\text{-}inh \rightarrow \underset{\mathbf{1}}{[V^{IV}O(pydx\text{-}inh)]} + 2\ Hacac \quad (2)$$

$$2\ \underset{\mathbf{1}}{[VO(pydx\text{-}inh)]} + H_2O + 1/2\ O_2 \rightarrow 2\ \underset{\mathbf{2}}{[V^{V}O_2(Hpydx\text{-}inh)]} \quad (3)$$

Similarly, the complex [VO(pydx-nh)] (**4**), can be oxidised in methanol to $[VO_2(Hpydx\text{-}nh)]$ (**5**). Further, complexes **2** and **5** were obtained from the reaction of potassium vanadate (which, at ambient pH, is actually present as a mixture of vanadates; vide infra), generated in situ by dissolving V_2O_5 in an aqueous solution of KOH, with solutions of the potassium salts of ligands **I** or **II** and adjustment of the pH of the reaction mixture to 6.0. Adjustment of the pH of these solutions to 7.5 results in the formation of a mixture of $[K(H_2O)_3][VO_2(pydx\text{-}inh)]$ (**3**) and **2** [Equation (4)], or $[K(H_2O)_2][VO_2(pydx\text{-}nh)]$ (**6**) and **5**, respectively. The final pH of the reaction mixture plays an important role in that a decrease in pH (e.g. to pH = 6.5) increases the yield of the neutral complexes **2** or **5**. This pH dependence is possibly due to the actual vanadate species present in solution: At pH = 6, $H_2VO_4^-$ is in equilibrium with $H_2V_2O_7^{2-}$, $V_4O_{12}^{4-}$(dominant species), $V_5O_{15}^{5-}$ and $V_{10}O_{28}^{6-}$; at pH = 7.5, decavanadate disappears, and monovanadate (again in equilibrium with divanadate, tetravanadate as the main species, and pentavanadate) is present in the mono- and diprotonated forms (the pK_a for $H_2VO_4^-$ is around 8.1).[18] The two complexes **2** and **3**, or **5** and **6**, can be separated by fractional crystallisation from methanol, where the neutral complex crystallises first. Complexes **7** and **8** were prepared similarly from $[VO(acac)_2]$ and "KVO_3", respectively. Addition of H_2O_2 to the methanolic solution of **6** and **7** yields the oxomono(peroxo)vanadium(V) complexes **9** and **10** [Equation (5)].

$$K_{3-x}H_xVO_4 + K_2pydx\text{-}inh \rightarrow \underset{\mathbf{2}}{[VO_2(Hpydx\text{-}inh)]} + \underset{\mathbf{3}}{[K(H_2O)_3][VO_2(pydx\text{-}inh)]}\ (x = 1, 2) \quad (4)$$

$$[VO_2L]^- + H_2O_2 \rightarrow [VO(O_2)L]^- + H_2O \quad (H_2L = \mathbf{II}\text{: }\mathbf{9};\ H_2L = \mathbf{III}\text{: }\mathbf{10}) \quad (5)$$

Potassium vanadate reacts with 30% aqueous H_2O_2 to generate $K[VO(O_2)_2(OH/H_2O)_x]^{n-}$. In the presence of the potassium salt of ligand **III**, the peroxo complex $K[VO(O_2)(pydx\text{-}bhz)]$ (**10**) forms; see idealised Equation (6).

$$KH_2VO_4 + K_2pydx\text{-}bhz + H_2O_2 \rightarrow K[VO(O_2)(pydx\text{-}bhz)] + 2\ KOH + H_2O \quad (6)$$

The peroxo complex of ligand **I** could not be isolated in the solid state by any of the above methods due to its instability at ambient temperature. The formation of a peroxo complex in solution by treatment of **8** with H_2O_2 has also

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

been established by electronic absorption spectroscopy. The spectral changes are depicted in Figure 1. The band for $[VO_2(pydx\text{-}bhz]^-$ (**8**) at 404.5 nm shifts to 424 nm along with an increase in intensity on dropwise addition of H_2O_2, while the band at 329 nm only marginally shifts to 333 nm with partial reduction in intensity. The amount of peroxo complex formed depends upon the amount of H_2O_2 added. The final spectral pattern is similar to that obtained for the isolated peroxo complex **10** in methanol.

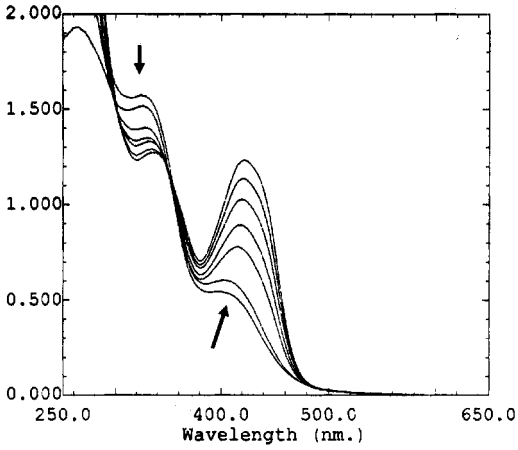

Figure 1. Titration of $[K(H_2O)_2][VO_2(pydx\text{-}bhz)]$ (**8**) with 30% H_2O_2; the spectra were recorded after successive addition of 2-drop portions of H_2O_2 to 10 mL of a ca. 10^{-4} M solution of **8** in MeOH

The peroxo complexes **9** and **10** undergo oxygen transfer reactions with PPh_3 in methanol to give the corresponding dioxovanadium(V) complexes **6** and **8** [Equation (7)].

$$[VO(O_2)L]^- + PPh_3 \rightarrow [VO_2L]^- + OPPh_3;\ (H_2L = \mathbf{I} \text{ or } \mathbf{III}) \quad (7)$$

Structure Description

An ORTEP plot and cell drawing of the ligand H_2pydx-inh (**I**) along with the atom-labelling scheme is presented in Figure 2 and selected structure parameters in Table 1. The bond parameters are well within the expected range. From the bond lengths *d*(C6−O1) [1.223(2) Å] and *d*(C6−N2) [1.363(3) Å], and the angles at C6 (av.120.0°) and N2 [116.0(2)°] it is clear that in the free ligand the ketonic form

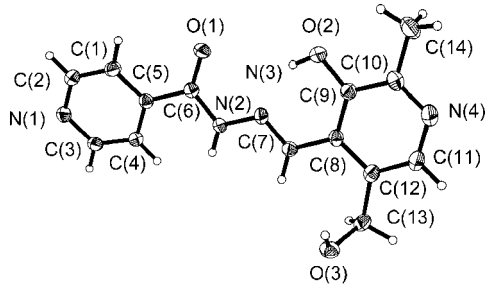

Figure 2. ORTEP plot (at the 50% probability level) of the ligand H_2pydx-inh (**I**)

prevails. This is further confirmed by an intermolecular hydrogen bond N2H···O3HCH$_2$ (1.970 Å). Additional close intermolecular contacts exist between adjacent molecules via C3H and O1 (2.575 Å) of the isonicotinic acid moieties, as well as isonicotinic N1 and pyridoxal O3HCH$_2$ (2.749 Å).

Figure 3 shows an ORTEP plot and a schematic drawing for the vanadium and potassium coordination environments of **3**; Figure 4 is a representation of the 3D arrangement of the molecular units. Selected structure parameters are collated in Table 1. The geometry of the anion can be described in terms of a tetragonal pyramid, distorted towards a trigonal bipyramid. The τ value {[∠(O3−V−O4) − ∠(O2−V−N3)]/60} is 0.23 (τ = 0 vs. 1 for ideal tetragonal-pyramidal vs. trigonal-bipyramidal arrangements), reflecting a common situation encountered with pentacoordinate oxovanadium complexes. For rare examples of a distorted trigonal-bipyramidal arrangement, see ref.[19] The *cis*-dioxovanadium unit is coordinated through the phenolate oxygen atom O4 of pyridoxal, the imine nitrogen atom N3, and the enolate oxygen atom O3 of the isonicotinic acid hydrazone. Together with the doubly bonded O2, bridging to the potassium ion, these functions form the tetragonal plane. The angle at O2 is 133.67(7)°. The bond lengths

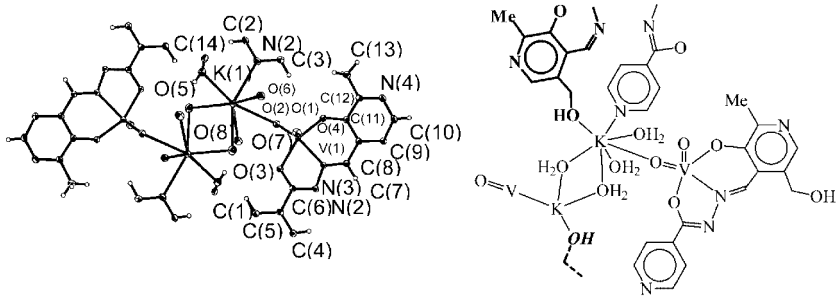

Figure 3. ORTEP plot (30% probability level) of $[K(H_2O)_3](VO_2(pydx\text{-}inh)]$ (**3**), and a schematic drawing of the vanadium and potassium environments; bold parts refer (to connections) to planes above and below

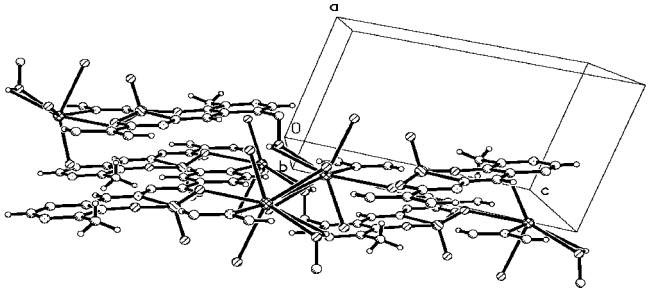

Figure 4. Section from the crystal lattice of **3**, showing the supramolecular arrangement

d(V−N3) [2.1233(13)], *d*(V−O3) [1.9906(11)] and *d*(V−O4) [1.8886(11) Å] are in agreement with literature values for imine, enolate and phenolate coordinating to the vanadium centre. Further, the bond lengths *d*(N2−N3) [1.3969(18)], *d*(N2−C6) [1.302(17)] and *d*(O3−C6) [1.3053(18) Å] are consistent with the enolate mode of coordination, supported by a comparison with the respective parameters for the free ligand (Table 1), in which the carbonyl form is present. The apical V=O bond, *d*(V−O1) = 1.6318(12) is in the expected range, while the basal V=O bond, *d*(V−O2) = 1.66332(12) Å, is slightly elongated as a consequence of covalent bonding contact to the K^+ ion.

The K^+ ion links three complex anions through the basal oxo group of VO_2^+ (O2), the pyridine nitrogen atom of an isonicotinic acid moiety (N1) and the alcoholic oxygen atom of a pyridoxal moiety (O5). In addition, four water molecules (three per molecular unit) are coordinated to K^+, resulting in the coordination number 7 for each potassium ion. In the dinuclear rhombohedral $\{K_2(\mu\text{-}OH_2)_2\}$ core, the angles are 85.31(4) at O8 and 94.69(4)° at K1; *d*(K1···K1#) amounts to 3.818 Å. O5 on K1 and O5# on K1# link to adjacent planes. Supramolecular links are further established by one of the terminal water molecules, which is hydrogen-bonded to the ring nitrogen atom of the pyridoxal moiety, N4···H_2O6 = 2.848 Å.

For the structures of the related complexes **2**, **5** and **7**, **6** and **8**, and the peroxo complexes **9** and **10**, we assume a ligand arrangement corresponding to that in **3**; cf. Scheme 2.

Thermal Studies

The complexes [VO(pydx-inh)] (**1**) and [VO(pydx-nh)] (**4**) lose about 75% of their mass between 250 and 450 °C in two overlapping steps, which corresponds to the loss of the organic components minus 1.5 oxygen atoms per molecule (3 per two molecules) (calculated mass loss: 74.1%). Consequently, the remaining product is V_2O_5. The TGA profiles of the dioxovanadium(v) complexes $[K(H_2O)_3][VO_2(pydx\text{-}inh)]$ (**3**), $[K(H_2O)_3][VO_2(pydx\text{-}nh)]$ (**6**) and $[K(H_2O)_3][VO_2(pydx\text{-}bhz)]$ (**8**) show that these complexes contain three (**3**) or two (**6** and **8**) water molecules per formula unit. The loss of this water in the temperature range 95−220 °C is indicative of coordinated water. On further increasing the temperature, the water-free species $K[VO_2(pydx\text{-}inh)]$ and $K[VO_2(pydx\text{-}nh)]$ decompose in one step between 220 and 350 °C to form KVO_3. The total loss corresponds to the loss of ligand minus 1 oxygen atom. A mass loss of 8.6%, equivalent to two water molecules (calcd. 8.93%) for **7** in the temperature range 80−135 °C, suggests that this is just water of crystallisation. Complexes **2**, **5** and the water-free form of **7** have decomposition patterns similar to those of the respective forms of **3**, **6**, and **8** after loss of water. They all yield V_2O_5 as the final product.

IR Spectroscopic Studies

The IR spectra of the ligands exhibit two bands at 3230 and 1678 [H_2pydx-inh (**I**)], 3250 and 1673 [H_2pydx-nh (**II**)] and 3210 and 1677 cm^{-1} [H_2pydx-bhz (**III**)] due to ν(NH) and ν(C=O) stretches, respectively, indicative of their ketonic nature in the solid state; cf. also Figure 1. The absence of these bands in the spectra of all complexes is consistent with enolisation and replacement of H by the metal ion. A new band appearing in the region 1220−1262 cm^{-1} is assigned to the $\nu(C-O_{enolic})$ mode. The $\nu(C=N_{azomethine})$ stretch of the free ligands appears as a weak band at 1617−1637 cm^{-1} along with the ν(C=N) stretches of the pyridine rings. A very sharp band at 1596−1608 cm^{-1} in the complexes is indicative of the coordination of the azomethine nitrogen atom. A ligand band appearing at 1017 (**I**), 1010 (**II**) and 1028 cm^{-1} (**III**) due to ν(N−N) undergoes a shift to higher wave numbers by 5−45 cm^{-1} upon complex formation. The high frequency shift of the ν(N−N)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

band is expected because of diminished repulsion between the lone pairs of adjacent nitrogen atoms.[20] The ligands exhibit a medium-intensity ν(OH) band covering the region 2300−2700 cm^{-1}, which is due to intramolecular hydrogen bonds. On complexation, this band broadens and gains intensity due to the involvement of the CH_2OH group in hydrogen bonding. All of the dioxovanadium(v) complexes exhibit two or three sharp bands in the 885−950 cm^{-1} region, corresponding to the *cis*-$[VO_2]^+$ structural unit. The peroxo complexes **9** and **10** show three IR-active vibration modes associated with the peroxo moiety $[V(O_2)^{3+}]$ at 894−917, 707−717 and 553−574 cm^{-1}, which are assigned to the O−O intra-stretch (ν_1), the antisymmetric $V(O_2)$ stretch (ν_3), and the symmetric $V(O_2)$ stretch (ν_2).[21] The presence of these bands confirms the common η^2-coordination of the peroxo group.[21] In addition, both peroxo complexes exhibit an intense ν(V=O) at 946−970 cm^{-1}.

Electronic Spectra

The absorption maxima of the ligands and complexes along with their extinction coefficients are listed in Table 2. The UV spectra of H_2pydx-inh (**I**) shows three absorption bands at 216, 285.5 and 342 nm, while H_2pydx-bhz (**III**) displays four bands at 206, 296.5, 306 and 335 nm, probably belonging to the transitions φ → φ*, π → π* and *n* → π*, with the π → π* band split into two components in the case of **III**. A weak shoulder associated with the second band is traced back to association by hydrogen bonding. All of the complexes invariably showed this band, indicating the existence of hydrogen bonding in these complexes in solution as well.[22] The φ → φ* transition is only observed in the

oxovanadium(IV) complexes; the two other bands are significantly shifted towards lower wavelengths with respect to the uncoordinated ligands. The dioxovanadium(V) complexes are dominated by an intense band at 404.5−421 nm, which is assigned to a ligand-to-metal charge transfer (LMCT) from the phenolate oxygen atom to an empty d-orbital of the vanadium ion.

NMR Spectroscopic Studies

The coordinating modes of the ligands were confirmed by comparing ^{1}H NMR patterns of the ligands and the complexes. The relevant spectroscopic data are collected in Table 3. The broad signal appearing at δ = 13.14−13.29 ppm, due to the phenolic OH group, disappears in the spectra of the complexes. A significant downfield shift ($\Delta\delta$ = 0.84−1.33 ppm) of the signal for the azomethine (−CH=N−) proton in the complexes relative to the corresponding ligands demonstrates the coordination of the azomethine nitrogen atom. The signals due to the NH group (which is hydrogen-bonded to the alcoholic pyridoxal OH group, viz. NH···OHCH$_2$; see the structure description for **I** above) and OH protons could not be located in the δ = 0−15 ppm region in the spectra of the ligands. However, appearance of a broad signal at $\delta \approx$ 5.8 ppm in all complexes, which we allocate to CH$_2$O*H*, suggests the breaking down of hydrogen bonding and coordination of the enolate oxygen atom of the hydrazone moiety, further supported by the absence of the NH proton signal in the complexes. The methylene and methyl protons of the pyridoxal moiety of the ligands resonate at δ = 4.76 and 2.60 ppm, and these signals appear in the complexes with slight shifts in their positions. Aromatic protons appear in the expected regions in the spectra of the ligands as well as of the complexes with minor variations in their positions. All these data are consistent with the conclusions drawn from the IR spectral studies and support the dibasic, tridentate *ONO* coordination mode.

Further characterisation of the complexes was obtained from ^{51}V NMR spectra; values of specific compounds, where solubility permitted data to be recorded, are presented in the Exp. Sect.. The resonances are somewhat broadened due to quadrupolar interaction (^{51}V: nuclear spin = 7/2, quadrupole moment = -0.05×10^{-28} m^2); the line widths at half-height are approximately 200 Hz, which is still considered comparatively narrow in ^{51}V NMR spectroscopy.[23] The dioxovanadium(V) complexes **3**, **6** and **8** show one strong resonance between δ = −532 and −534 ppm in [D$_6$]DMSO, an expected value for dioxovanadium(V) complexes having a mixed *O*/*N* donor set.[23,24] Complex **8** exhibits distinct solvent dependence. In [D$_6$]DMSO, the ^{51}V NMR signal appears at δ = −534.2 ppm, while in CH$_3$OH/CD$_3$OD it appears at δ = −546.8, possibly indicating the participation of the solvent in coordination. Similarly, the neutral dioxovanadium(V) complex **7** gives rise to a signal at δ = −535.7 ppm in [D$_6$]DMSO and at δ = −546.7 ppm in CH$_3$OH/CD$_3$OD. The peroxo complex **10** displays a ^{51}V NMR signal at δ = −586.0 ppm in [D$_6$]DMSO. This upfield shift with respect to the dioxo complexes **7** and **8** is commonly observed as an oxo group is replaced by the side-on coordinated peroxo group.[23,25]

Reaction with HCl

For the catalytic activity of vanadate-dependent haloperoxidases, the presence of a coordinated hydroxo ligand has been proposed on the basis of kinetic investigations.[6] The generation of hydroxo(oxo) species has been accomplished for [K(H$_2$O)$_2$][VO$_2$(pydx-bhz)]·H$_2$O (**8**) on reaction with HCl: Addition of HCl-saturated methanol to a methanolic solution of **8** results in a colour change from yellow to orange with gradual shift of the 404.5-nm band in the electronic absorption spectrum to 420 nm, along with a slight broadening and decrease in intensity of the absorption maximum (Figure 5). Addition of further HCl results in an increase in intensity of the 333-nm band, disappearance of the 265-nm band, and appearance of two new bands at 317 and 308 nm. In addition, a shoulder starts to appear at ca. 360 nm. The intensity and position of the 237-nm band remain constant. Corresponding results have been obtained with HClO$_4$ (dissolved in a minimum amount of methanol and added dropwise to a methanolic solution of **8**). We interpret this result in terms of the formation of an hydroxo(oxo) complex of composition [VO(OH)(H$_2$pydx-bhz)]$^{2+}$ via [VO$_2$(Hpydx-bhz)] and [VO$_2$(H$_2$pydx-bhz)]$^+$ on acidification as shown in Equation (8). The formation of the intermediate species, protonated at the pyridine nitrogen atom, viz. [VO$_2$(Hpydx-bhz)], is based on the fact that the electronic absorption spectrum of a solution of **8** obtained after addition of 4 drops of HCl nearly matches the spectrum of authentic complex **7**. The protonation of the N atom of the hydrazide moiety not involved in coordination is documented by a newly arising medium-intensity band in the IR at 3205 cm^{-1} (free Schiff base: 3210 cm^{-1}) on acidification of **8**. A comparable protonated Schiff-base complex, viz. [VO$_2$(Hsal-bhz)] (where H$_2$sal-bhz is the hydrazone derived from salicylaldehyde and benzohydrazide) has been structurally characterised.[26]

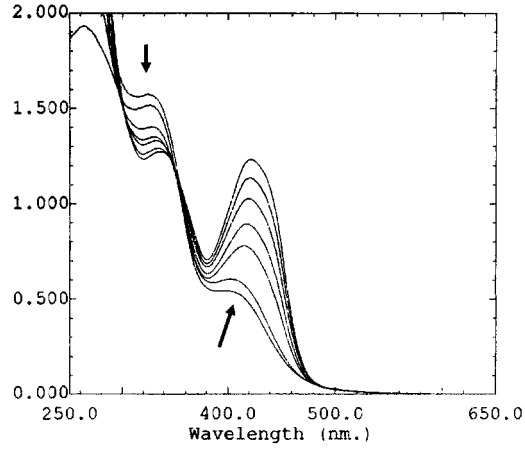

Figure 5. Titration of [K(H$_2$O)$_2$][VO$_2$(pydx-bhz)] (**8**) with a saturated solution of HCl in MeOH; the spectra were recorded after addition of 2-drops portions of MeOH/HCl to 10 mL of ca. 10^{-4} M solution of **8** in MeOH

$$[VO_2(pydx\text{-}bhz)] \xrightarrow{H^+} [VO_2(Hpydx\text{-}bhz)] \xrightarrow{H^+} [VO_2(H_2pydx\text{-}bhz)]^+ \rightarrow [VO(OH)(H_2pydx\text{-}bhz)]^{2+} \quad (8)$$

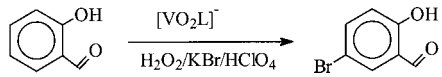
8 **7**

Hydroxo(oxo)vanadium complexes have previously been generated on acidification of $K[VO_2(sal\text{-}inh)H_2O]$ and $[K(H_2O)_2][VO_2(Clsal\text{-}sbdt)]$ ($H_2Clsal\text{-}sbdt$ = ligand derived from salicylaldehyde and *S*-benzyldithiocarbazate).[11] An hydroxo(oxo) complex, $[VO(OH)(LH)]^+$ {where LH = *N*-(2-hydroxyethyl)-*N*′-[(*o*-hydroxyphenyl)methyl]ethylenediamine}, has been reported to form from a dinuclear dioxovanadium(v) precursor in a similar manner.[27] $[V^VO(OH)(8\text{-oxyquinolinate})_2]$[28a] and $[V^{IV}O(OH)Tp(H_2O)]$ [Tp = tris(3,5-diisopropyl-1-pyrazolyl)borate(1−)][28b] have been characterised in the solid state. On addition of a methanolic solution of KOH to $[VO(OH)(H_2pydx\text{-}bhz)]^{2+}$, the solution acquired the original spectrum of **8**; the reaction is thus reversible. This reversibility is an important observation in the context of the active-site structure and the catalytic activity of vanadate-dependent haloperoxidases, for which a hydroxo ligand at the vanadium centre has also been made plausible on the basis of X-ray diffraction data.[29]

Oxidative Bromination of Salicylaldehyde

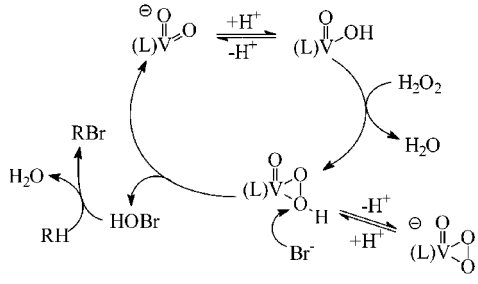
Oxidative bromination catalysed by V_2O_5 and oxovanadium(v) complexes has been reported earlier using H_2O_2/Br^-.[30] During this process, vanadium reacts with 1 or 2 equiv. of H_2O_2, forming mono(peroxo) $[VO(O_2)^+]$ or bis(peroxo) $[VO(O_2)_2^-]$ species, which ultimately oxidise bromide, possibly by formation of a hydroperoxo intermediate. The oxidised bromine species (Br_2, Br_3^- or, most likely, HOBr) then brominates the substrate.[4,31]

We have observed that the complexes **3**, **6** and **8** satisfactorily catalyse the oxidative bromination of salicylaldehyde, using H_2O_2/KBr in the presence of $HClO_4$ in aqueous solution; cf. Equation (9). A maximum conversion of 40−46% of salicylaldehyde was found. In the case of **3** as the catalyst, GC analysis revealed the presence of three products in the ratio 8.8:86.6:4.3%, with 5-bromosalicylaldehyde being the major product. Thus, based on GC, the selectivity of the formation of 5-bromosalicylaldehyde is 86.6% with respect to salicylaldehyde conversion. On purification of the crude product by column chromatography, 5-bromosalicylaldehyde was obtained in 40% yield (related to salicylaldehyde). The average yields of pure 5-bromosalicylaldehyde for **6** and **8** as catalysts were 34.7% and 36.5%, respectively; the selectivity of formation of 5-bromosalicylaldehyde was again about 87%. In the absence of the catalyst, the reaction mixture did not produce any brominated product. Similarly, acid (here $HClO_4$) was found to be essential to carry out catalytic bromination. The complexes slowly decompose during the reaction; decomposition is slowed down, if $HClO_4$ is successively added in portions (see Exp. Sect.). Using CH_3COOH as solvent as well as the acid supplier, efficiently produced 5-bromosalicylaldehyde within 2 h of reaction time, but relatively fast decomposition of the complexes took place.



(9)

As hydroxo(oxo) species such as $[VO(OH)(H_2pydx\text{-}bhz)]^{2+}$ very likely form upon acidification of $[K(H_2O)_2][VO_2(pydx\text{-}bhz)]$ (**8**), and oxo(peroxo) species **10** are obtained upon treatment with H_2O_2 in methanol, the formation of an active oxo(peroxo) via a hydroxo(oxo) complex is likely to occur in the presence of acid as well as H_2O_2 during the catalytic reaction.[4] Activation of peroxide by coordination to vanadium may then be succeeded by formation of an intermediate hydroperoxo complex, which allows nucleophilic attack of the bromide,[21] followed by release of hypobromous acid which then brominates salicylaldehyde. A catalytic cycle is proposed in Scheme 3. It should be noted here that recent electrospray ionisation MS studies in the peroxovanadium/bromide system indicated the formation of a hypobromite species, $[VO(OH)(H_2O)_3OBr]^+$, the stability of which is supported by ab initio calculations.[32]



Scheme 3

Conclusion

Pentacoordinated neutral and cationic dioxovanadium complexes containing a ligand system providing a dianionic *ONO* donor set and thus modelling the active site of vanadate-dependent haloperoxidases have been synthesised and characterised. The cationic complexes of the general composition $[K(H_2O)_n][VO_2(ONO)]$ can be converted in situ on acidification to hydroxo(oxo) complexes $[VO(OH)(H_2ONO)]^{2+}$ and to the peroxo complexes $K[VO(O_2)(ONO)]$, and thus to species assumed to be intermediates in the bromoperoxidase activity of the enzymes. The complexes are in fact active in bromination of salicylaldehyde in the presence of H_2O_2, Br^- and acid, and hence may also be considered *functional* models. The *ONO* ligands employed are hydrazones containing pyridoxal (vitamin B_6) and nicotinohydrazides as components, and thus biogenic molecular moieties.

The complex $[K(H_2O)_3][VO_2(pydx\text{-}inh)]$ (where pydx-inh is the doubly deprotonated condensation product from

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pyridoxal and isonicotinohydrazide), which has been structurally characterised, contains the ligand in the enolate form (the free ligand constitutes the ketonic form). The seven-coordinate potassium ion links to three different $[VO_2(pydx\text{-}inh)]^-$ anions and thus generates, together with hydrogen bonds, a complex supramolecular, three-dimensional network.

Experimental Section

Materials and Instrumentation: V_2O_5, NH_4VO_3, isonicotinohydrazide, benzoyl chloride, hydrazine hydrate (Loba Chemie, India), pyridoxal hydrochloride (Fluka Chemie, GmbH, Switzerland), acetylacetone (Hacac) (Aldrich, U.S.A.), and 30% aqueous H_2O_2 (Qualigens, India) were used as obtained. Other chemicals and solvents were of analytical reagent grade. Benzohyrazide was prepared by the reaction of a twofold excess of hydrazine hydrate with ethyl benzoate, which in turn was obtained by refluxing benzoyl chloride in an excess of absolute ethanol. $[VO(acac)_2]$ was prepared according to the method reported in the literature.[33] The microanalytical section of the Central Drug Research Institute, Lucknow, India, performed elemental analyses of the ligands and complexes. IR spectra were recorded as KBr pellets with a Perkin−Elmer model 1600 FT-IR spectrometer. Electronic absorption spectra were measured in methanol or DMF with a UV-1601 PC UV/Vis spectrophotometer. ^{1}H NMR spectra were obtained with a Bruker 200, and ^{51}V NMR spectra with a Bruker Avance 400 MHz spectrometer at 94.73 MHz with the common parameter settings. NMR spectra were usually recorded in $[D_6]$DMSO, and $\delta(^{51}V)$ values are quoted relative to $VOCl_3$ as external standard. Selected ^{51}V NMR spectroscopic results have also been obtained in CD_3OD. Thermogravimetric analyses of the complexes were carried out under oxygen using a TG Stanton Redcroft STA 780 instrument. Magnetic susceptibility measurements of oxovanadium(IV) complexes were carried out at room temperature by the Scientific Instrumentation Centre of the Indian Institute of Technology in Roorkee. EPR spectra were recorded with a Bruker ESP 300E spectrometer between 9.42 and 9.47 GHz, and EPR parameters were adjusted by simulation with the Bruker program system SimFonia. All reaction products obtained from the catalytically conducted reactions were identified by recording their m.p., ^{1}H NMR and IR spectra after purification and separation by column chromatography on silica gel using CH_2Cl_2 as an eluant. The product mixture obtained before purification was additionally analysed with a Shimadzu 14B gas chromatograph, fitted with an SE-52 packed column, coupled with an FID detector, and the identity of the products confirmed by checking against the GC-MS reference system Shimadzu QP-5000. Crystal structure data were collected with a Bruker SMART Apex CCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 153(2) K. In the case of ligand **I**, all hydrogen atoms (except H3A) were placed into calculated positions and included in the last cycles of refinement. H3A of ligand **I** and all H atoms of complex **3** were found. The program systems SHELXS 86 and SHELXL 93 were used throughout. Crystal data and details of the data collection and refinement are collated in Table 4. CCDC-233587 (**I**) and −233586 (**3**) contain the supplementary crystallographic data of this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving/

Preparation of Ligands

H_2pydx-inh (I): A mixture of pyridoxal hydrochloride (1.02 g, 5 mmol) and isonicotinohydrazide (0.685 g, 5 mmol) in 50 mL of methanol was refluxed using a water bath for 4 h. After reducing the solvent volume to ca. 15 mL, the mixture was cooled to room temperature within 3 h. During this time, a light orange solid of **I** precipitated, which was filtered off, washed with methanol and dried. **I** was recrystallised from methanol to give a crystalline solid. Yield 1.15 g (81%). $C_{14}H_{14}N_4O_3$ (286.3): calcd. C 58.74, H 4.90, N 19.58; found C 58.69, H. 4.82, N 19.41. IR (KBr): $\tilde{\nu}_{max.}$ = 3230 (NH), 1678 (C=O), 1620, 1600 (ring C=N and C=N), 1017 (N−N) cm^{-1}.

H_2pydx-nh (II) and H_2pydx-bhz (III): These ligands were prepared according to the procedure outlined for **I**.

II: Yield 1.12 g (78%). $C_{14}H_{14}N_4O_3$ (286.3): calcd. C 58.74, H 4.90, N 19.58; found C 58.82, H 4.85, N 19.48. IR (KBr): $\tilde{\nu}_{max.}$ = 3250 (NH), 1673 (C=O), 1617 (ring C=N, C=N), 1025 (N−N) cm^{-1}.

III: Yield 1.07 g (75%). $C_{15}H_{15}N_3O_3$ (285.3): calcd. C 63.18, H 5.26, N 14.74; found C 63.00, H, 5.34, N 14.68. IR (KBr): $\tilde{\nu}_{max.}$ = 3210 (NH), 1677 (C=O), 1637, 1624 (ring C=N, C=N), 1045 (N−N) cm^{-1}.

Preparation of Complexes

[VO(pydx-inh)] (1) and [VO_2(Hpydx-inh)] (2): A stirred solution of H_2pydx-inh (0.570 g, 0.002 mol) in dry methanol (20 mL) was treated with [$VO(acac)_2$] (0.530 g, 0.002 mol), dissolved in dry methanol (10 mL), and the resulting reaction mixture was refluxed using a water bath for 5 h. After cooling to room temperature, a brown precipitate of **1** was filtered off, washed with methanol and dried. Compound **1** was suspended in methanol (50 mL), and air was slowly passed through the suspension at ca. 40 °C for ca. 24 h with occasional shaking. During this period of time, the brown suspension slowly disappeared and crystalline orange-red solid **2** separated. This was filtered off, washed with methanol and dried in vacuo. For the direct preparation of **2**, it is not necessary to isolate **1**.

Data for 1: Yield 0.35 g (50%). $C_{14}H_{12}N_4O_4V$ (351.2): calcd. C 47.86, H 3.42, N 15.95; found C 47.43, H 3.61, N 15.86. IR (KBr): $\tilde{\nu}_{max.}$ = 1601 (C=N), 1262 (C−O, enolate), 1060 (N−N), 888 (V=O) cm^{-1}. EPR (DMSO, 98 K): g_{xy} = 1.984, g_z = 1.949; A_{xy} = 55.1, $A_z = 159.7 \times 10^{-4}$ cm^{-1}.

Data for 2: Yield 0.48 g (65%) based on [$VO(acac)_2$]. $C_{14}H_{13}N_4O_5V$ (368.2): calcd. C 45.65, H 3.53, N 15.22; found C 45.39, H 3.72, N 15.44. IR (KBr): $\tilde{\nu}_{max.}$ = 1599 (C=N), 1257 (C-O, enolate), 1055 (N−N), 956, 908 (sym. and antisym. VO_2^+) cm^{-1}.

[$K(H_2O)_3$][VO_2(pydx-inh)] (3): Vanadium(V) oxide (0.91 g, 0.005 mol) was suspended in aqueous KOH (0.30 g, 0.005 mol in 10 mL H_2O) and stirred with occasional heating at 50 °C for 2 h. The potassium vanadate solution thus generated was filtered. A filtered solution of H_2pydx-inh (1.42 g, 0.005 mol), dissolved in 20 mL of aqueous KOH (0.56 g, 0.010 mol), was added with stirring, and the pH of the reaction mixture was cautiously adjusted to 7.5 with 4 M HCl. After 2 h of stirring, the precipitated yellow solid was filtered off, washed with water followed by acetone, and dried. On crystallisation from ca. 50 mL of methanol, **2** precipitated as an orange-red solid, which was filtered off and dried in vacuo over silica gel. For the data of **2**, see above. After reducing the volume of the filtrate to ca. 15 mL and keeping it at ca. 10 °C, yellow crystalline **3** slowly precipitated within 2 d. This was filtered off, washed with cold methanol and dried. Yield 1.58 g (68%). $C_{14}H_{18}KN_4O_8V$ (460.4): calcd. C 36.52, H 3.91, N 12.17; found C 36.33, H 3.85, N 12.26. IR (KBr): $\tilde{\nu}_{max.}$ = 1596 (C=N), 1257 (C−O, enolate), 1055 (N−N), 955, 909 (sym. and antisym. VO_2^+) cm^{-1}. ^{51}V NMR ([D_6]DMSO): δ = −532.0 ppm.

[VO(pydx-nh)] (4) and [VO_2(Hpydx-nh)] (5): Complex **4** was prepared analogously to **1**, replacing H_2pydx-inh for H_2pydx-nh. Air was slowly passed through the methanolic suspension (50 mL) of **4** at ca. 40 °C for ca. 24 h with occasional shaking. After cooling to ca. 10 °C for 2 d, yellow crystalline **5** slowly preciptated, which was filtered, washed with methanol and dried in vacuo.

Data for 4: Yield 0.61 g (86.8%). $C_{14}H_{12}N_4O_4V$ (351.2): calcd. C 47.86, H 3.42, N 15.95; found C 47.94, H 3.31, N 15.98. IR (KBr): $\tilde{\nu}_{max.}$ = 1608 (C=N), 1248 (C−O, enolate), 1050 (N−N), 888 (V=O) cm^{-1}. EPR (DMSO, 98 K): g_{xy} = 1.984, g_z = 1.942; A_{xy} = 56.7, $A_z = 161.2 \times 10^{-4}$ cm^{-1}.

Data for 5: Yield 0.40 g (54%) based on $VO(acac)_2$. $C_{14}H_{13}N_4O_5V$ (368.2): calcd. C 45.65, H 3.53, N 15.22; found C 45.83, H 3.36, N 15.17. IR (KBr): $\tilde{\nu}_{max.}$ = 1597 (C=N), 1234(C−O, enolate), 1064 (N−N), 961, 942, 884 (sym. and antisym. VO_2^+) cm^{-1}.

[$K(H_2O)_2$][VO_2(pydx-nh)] (6): This complex was prepared from KVO_3 and H_2pydx-nh by the method outlined for **3**. The crude mass obtained on crystallisation from methanol gave a 1.45 g (66%) yield of **6**. $C_{14}H_{16}KN_4O_7V$ (417.3): calcd. C 38.01, H 3.65, N 12.67; found C 38.20, H 3.74, N 12.56. IR (KBr): $\tilde{\nu}_{max.}$ = 1606 (C=N), 1258 (C−O, enolate), 1042 (N−N), 940, 923 (sym. and antisym. VO_2^+) cm^{-1}. ^{51}V NMR ([D_6]DMSO): δ = −532.0 ppm.

[VO_2(Hpydx-bhz)]·2H_2O (7): A stirred solution of H_2pydx-bhz (0.570 g, 2 mmol) in methanol (20 mL) was treated with [$VO(acac)_2$] (0.530 g, 2 mmol), and the reaction mixture was refluxed using a water bath for 5 h to give a brown solution. After cooling to ambient temperature, a current of air was passed through this solution for ca. 20 h; during this procedure, yellow complex **7** slowly precipitated. This was filtered off, washed with methanol and dried in vacuo. Yield 0.68 g (84%) based on [$VO(acac)_2$]. $C_{15}H_{18}N_3O_7V$ (403.3): calcd. C 44.66, H 4.47, N 10.42; found C 44.75, H 4.36, N 10.28. IR (KBr): $\tilde{\nu}_{max.}$ = 1599 (C=N), 1220 (C−O, enolate), 1063 (N−N), 940, 918, 888 (sym. and antisym. VO_2^+) cm^{-1}. ^{51}V NMR: δ: −535.7 ppm ([D_6]DMSO); −546.4 ppm (MeOH/CD_3OD).

[$K(H_2O)_2$][VO_2(pydx-bhz)] (8): Complex **8** was prepared from KVO_3 (generated in solution from V_2O_5 and KOH) according to the procedure outlined for **3**. Recrystallisation from methanol gave **8** in pure form as a yellow crystalline material. Yield 1.48 g (66%). $C_{15}H_{17}KN_3O_7V$ (441.4): 40.82, C 3.88, N 9.52; found C 40.73, H 3.97, N 9.41. IR (KBr): $\tilde{\nu}_{max.}$ = 1597 (C=N), 1222 (C−O, enolate), 1063 (N−N), 938, 915, 888 (sym. and antisym. VO_2^+) cm^{-1}. ^{51}V NMR: δ = −534.2 ppm ([D_6]DMSO); −546.9 ppm (MeOH/CD_3OD).

K[$VO(O_2)$(pydx-nh)]·H_2O (9): Complex **6** (900 mg, 2 mmol), dissolved in 20 mL of MeOH, was treated with 30% aqueous H_2O_2 (3 mL, 26.5 mmol) while stirring the reaction mixture at 10 °C, which caused darkening of the solution. After 2 h of stirring, the volume was reduced to ca. 10 mL and the solution was kept at 10 °C overnight. Yellow crystals precipitated, which were filtered off and dried in vacuo. Yield 0.30 g (34%). $C_{14}H_{14}KN_4O_7V$ (440.33): calcd. C 38.19, H 3.20, N 12.72; found C 38.0, H 3.33, N 12.61. IR (KBr): $\tilde{\nu}_{max.}$ = 1603 (C=N), 1250 (C−O, enolate), 1043 (N−N),

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

946 (V=O), 894 (O−O), 707 [$V(O_2)$ antisym.], 574 [$V(O_2)$ sym.] cm^{-1}.

K[VO(O$_2$)(pydx-bhz)]·H$_2$O (10). Method 1: A 30% aqueous solution of H_2O_2 (2 mL, 17.6 mmol) was added to an aqueous solution of KVO_3 (2 mmol), prepared as outlined above. The potassium salt of H_2pydx-bhz was prepared separately by treating **III** (0.570 g, 2 mmol) with KOH (0.168 g, 3 mmol) in water (10 mL) followed by filtration. This solution was added dropwise to the above solution with constant stirring. After 2 h of stirring, the orange solid that had precipitated was filtered, washed with water and dried. The crude mass was recrystallised from methanol. Yield 0.14 g (16%). **Method 2:** This method parallels the one adopted for **9**, using **8** and H_2O_2. Yield 0.48 g (22%). $C_{15}H_{15}KN_3O_7V$ (439.3): calcd. 41.01, H 3.44, N 9.56; found C 40.87, H 3.41, N 9.45. IR (KBr): $\tilde{\nu}_{max.}$ = 1596 (C=N), 1246 (C−O, enolate), 1033 (N−N), 970 (V=O), 917 (O−O), 717 [$V(O)_2$ antisym.], 553 [$V(O)_2$ sym.] cm^{-1}. ^{51}V NMR ([D$_6$]DMSO): δ = −536.0 ppm.

Reactions of 9 and 10 with PPh$_3$: PPh_3 (0.39 g, 1.5 mmol) was added to complex **9** or **10** (1 mmol), dissolved in dry methanol (20 mL), and the reaction mixture heated under reflux for 8 h. After reduction of the volume to ca. 10 mL, the solution was kept at 10 °C to yield a yellow precipitate. This was filtered, washed with methanol and dried in vacuo. Yield ca. 50%. The analytical and spectroscopic data of the complexes thus obtained match well with those of **6** and **8**, respectively. The formation of $OPPh_3$ was documented by ^{31}P NMR spectroscopy.

Catalytic Oxidative Bromination of Salicylaldehyde: In a typical reaction, salicylaldehyde (0.244 g, 2 mmol) was added to an aqueous solution of KBr (0.5 g, 4 mmol, in 4 mL H_2O), followed by addition of aqueous 30% H_2O_2 (1.93 g, 15 mmol). This mixture was treated whilst stirring with the catalyst (0.02 g) and 70% $HClO_4$ (1 mmol). Addiditional 1-mmol portions of $HClO_4$ were added during the course of the reaction every hour. After 4 h of reaction time, the white precipitate that had formed was filtered off, washed with water followed by diethyl ether, and dried. The crude mass was dissolved in CH_2Cl_2, and insoluble material, if any, was removed by filtration. The filtrate was concentrated to ca. 5 mL and chromatographed on silica gel (column dimensions 30 × 2.5 cm) with CH_2Cl_2 as eluant. The first fraction was collected and the solvents were evaporated to dryness to give 5-bromosalicylaldehyde. Alternatively, the filtered dichloromethane solution of the crude material was analysed by GC-MS.

Oxidative Dehydrogenation of Secondary Amines: The Case of the *N*,*N*,*N*′-Tris(2-pyridylmethyl)-*o*-phenylenediamine Ligand when Coordinated to Iron Dichloride

Ahmed Machkour,[a] Dominique Mandon,*[a] Mohammed Lachkar,[b] and Richard Welter[c]

Keywords: Ferrous complexes / Dioxygen activation / Oxidative dehydrogenation

We report the preparation and the X-ray crystal structure of the iron complex [Fe(L^1)Cl][Cl] [L^1 = *N*,*N*,*N*′-tris(2-pyridylmethyl)-*o*-phenylenediamine], and its reactivity towards molecular dioxygen. Upon exposure to dry O_2, coordinated L^1 is oxidatively dehydrogenated to the aldimine ligand L^2. The ferric cation [Fe(L^2)(CH_3CN)]$^{3+}$ is thus obtained, and characterized by UV/Vis and EPR spectroscopy, and X-ray diffraction analysis. The free L^2 ligand can be recovered after decomplexation.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Modelling of the active site of non-heme iron-containing oxygenases is one of the main reasons that led to the important development of the chemistry of iron complexes with (aminomethyl)pyridyl-containing ligands.[1−4] Oxygen-atom-transfer processes, however, and all their related chemistry, represent only a part of what Nature is able to carry out. Oxidative dehydrogenation of amines under aerobic conditions is another important process encountered in biochemistry — it is suspected to be one of the possible reasons for cell ageing, and is believed to be catalysed, in some cases, by iron-containing sites.[5] A search of the chemical literature reveals that most of the related published work involves Ni, Ru, Os and Cu complexes, only a limited number of studies being available in the chemistry of iron.[6] Examples taken from the chemistry of iron complexes with (aminomethyl)pyridyl-containing ligands include disproportionation of anionic species under strongly oxidizing conditions, to yield the corresponding coordinated imine as one of the reaction products,[7,8] or, more recently, the indirect demonstration that a tetrapyridine ligand can be desaturated under oxidative conditions.[9] In these cases, however, we could not find any direct evidence that molecular dioxygen is involved during these desaturation process, although O_2 is postulated as one of the key reagents in biologically occurring processes.[5] In the course of our investigations on the biomimetic use of molecular dioxygen with simple iron complexes,[10,11,13] we prepared the new compound [Fe(L^1)Cl][Cl] [L^1 = *N*,*N*,*N*′-tris(2-pyridylmethyl)-*o*-phenylenediamine] and found that, upon exposure to dry dioxygen, [Fe(L^1)Cl][Cl] in solution in acetonitrile smoothly converts to the ferric complex [Fe(L^2)(CH_3CN)][OH][Cl]$_2$, where L^2 is a dehydrogenated form of L^1, i.e. the corresponding imine. This clean reaction, together with the crystal structures of the two new complexes, is reported in this article. This work directly illustrates the fact that molecular dioxygen, as is believed to be the case in natural systems, can, at least at an early stage, induce a clean process of desaturation of acyclic amines by reaction with aferrous complex.

Ligand L^1 was prepared according to a published procedure.[14] The metallation by iron dichloride was carried out anaerobically according to a standard method,[11] and afforded [Fe(L^1)Cl][Cl] almost quantitatively as a stable greenish-yellow solid, as indicated in Scheme 1.[12] The UV/Vis spectrum of [Fe(L^1)Cl][Cl] in an acetonitrile solution displays three maxima {λ (ε [10^3 mmol·cm^2]) = 258 (10.24), 306 (sh.) and 407 (2.67) nm}.

Single crystals could be obtained by slow diffusion of diethyl ether into an acetonitrile solution of [Fe(L^1)Cl][Cl].[15] An ORTEP diagram of the cation [Fe(L^1)Cl]$^+$ is shown in Figure 1. The X-ray structure analysis reveals that the iron atom is coordinated in a distorted octahedral fashion. The metal−nitrogen distances are all above 2.19 Å, which is indicative of a high-spin state for the metal atom, and are

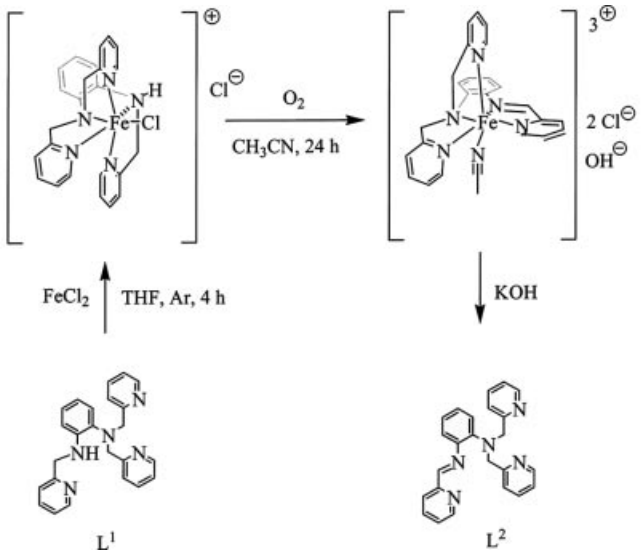

Scheme 1

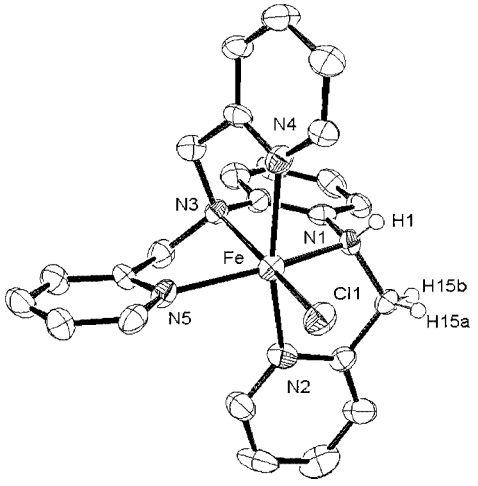

Figure 1. ORTEP diagram of the cation $[Fe(L^1)Cl]^+$ with a partial numbering scheme; all hydrogen atoms except the amine and the H15 methylene ones have been removed for clarity; selected bond lengths [Å] and angles [°]: Fe−Cl1 2.332(2), Fe−N1 2.196(6), Fe−N2 2.238(6), Fe−N3 2.240(6), Fe−N4 2.212(6), Fe−N5 2.195(6); N3−Fe−Cl1 167.83(17), N1−Fe−N5 149.0(2), N4−Fe−N2 159.0(2)

comparable to those reported in another complex with a more flexible pentadentate ligand.[16] The angles belonging to the five-membered metallacycle are found in the range 74−79°, the others being between 93° and 109°.

The addition of dry dioxygen to a solution of $[Fe(L^1)Cl][Cl]$ in acetonitrile resulted in a progressive darkening of its colour, which turned slightly green. Figure 2 displays the spectral variations observed by UV/Vis spectroscopy. A new intense absorption at $\lambda = 322$ nm is detected, and a weak and broader one at $\lambda = 694$ nm, whose intensities stabilised 24 h after the beginning of the reaction.

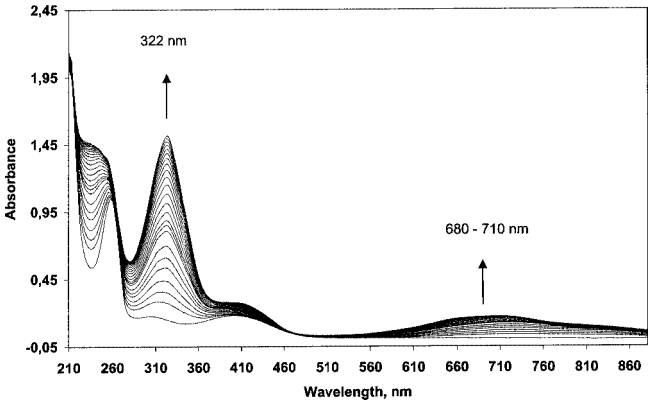

Figure 2. UV/Vis spectral changes observed upon oxygenation of $[Fe(L^1)Cl][Cl]$ at room temperature in acetonitrile solution (one trace per hour over 24 h)

The same experiment was carried out on a preparative scale, and a new complex, formulated as $[Fe(L^2)(CH_3CN)][OH][Cl]_2$, was obtained. The UV/Vis spectrum of this dark-green material in an acetonitrile solution displays several maxima {λ (ε [10^3 mmol·cm^2]) = 252 (sh. in solvent), 322 (17.36), 404 (3.23) and 694 (br., 1.59) nm}. The intensity of the new UV absorption suggested the presence of a new conjugated π system. In the IR spectrum, the ν_{O-H} vibration appears at 3418 cm^{-1}, and the band at 1651 cm^{-1} is assigned to the $\nu_{C=N}$ vibration. The EPR spectrum of an acetonitrile solution recorded at 90 K displays signals at $g_x = 2.460$, $g_y = 2.244$ and $g_z = 1.874$, indicating the presence of a rhombic low-spin iron species. The ^{1}H NMR spectrum displays a complex set of broad and paramagnetically shifted peaks lying between $\delta = 120$ and -15 ppm, consistent with the EPR data.

Attempts to crystallise this new compound as obtained directly after oxygenation were unsuccessful. However, single crystals could be obtained from a solution of the complex to which a small amount of $FeCl_2$ had been added.[17] All spectroscopic data remained unaffected by the presence of $FeCl_2$, whose only function was to help in obtaining single crystals by allowing the formation of the $FeCl_4^{2-}$ counteranion. An ORTEP diagram of the cation $[Fe(L^2)(CH_3CN)]^{3+}$ is shown in Figure 3.

The main feature of this structure is the modification of the ligand: the N7−C6 distance [1.294(4) Å] indicates the presence of an imine bond. Moreover, an almost planar conjugated pyridinyl-*o*-phenylenediamine system is formed, which is responsible for the intense absorption at $\lambda = 322$ nm in the UV/Vis spectrum. As expected from the EPR spectrum, the metal−ligand distances are all short (< 1.96 Å), which is consistent with a low-spin state for the metal atom in the solid state. The short N7−Fe distance [1.883(3) Å] corresponds to a strong coordination of the imine to the metal atom. We suggest that the new broad absorption at $\lambda = 694$ nm is due to an Fe→N=C metal-to-ligand charge transfer (MLCT) transition. It is noteworthy that the hydroxide is not coordinated to the iron atom — the acetonitrile ligand is preferred by the trication. This preference

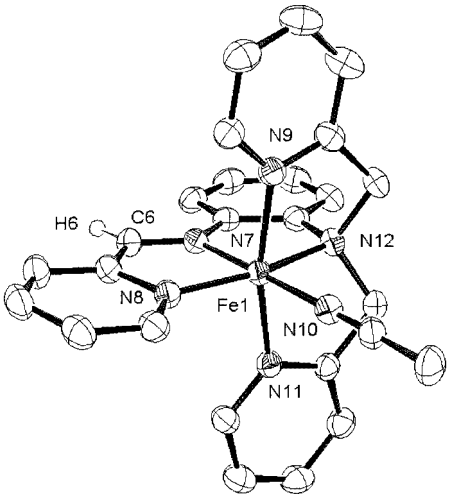

Figure 3. ORTEP diagram of the cation $[Fe(L^2)(CH_3CN)s]^{3+}$ with a partial numbering scheme; all hydrogen atoms except the aldimine one have been removed for clarity; selected bond lengths [Å] and angles [°]: Fe1−N7 1.881(3), Fe1−N8 1.955(3), Fe1−N9 1.972(3), Fe1−N10 1.951(3), Fe1−N11 1.960(3), Fe1−N12 1.989(4), N7−C6 1.294(4); N7−Fe1−N10 178.68(13), N8−Fe1−N12 166.82(14), N9−Fe1−N11 166.17(13)

may derive from the *trans* effect of the strong imine−Fe^{III} bond.[18]

Decoordination of the ligand could be achieved by treatment of a solution of $[Fe(L^2)(CH_3CN)][OH][Cl]_2$ with potassium hydroxide; L^2, obtained as a reddish oil, was characterised by ^{1}H NMR spectroscopy and mass spectrometry.

Iron complexes with the related pentadentate imine ligand *N*,*N*-bis(pyridin-2-ylmethyl)-*N*′-[(1*E*)-pyridin-2-ylmethylene]ethane-1,2-diamine ($SBPy_3$) have been previously obtained by direct reaction of iron salts with the stable free ligand.[19] In this case the iron(III) state was reported to be unstable, and only the diamagnetic iron(II) complex was fully characterized. At first glance, $SBPy_3$ looks similar to L^2. Thus, $[Fe(L^2)(CH_3CN)][OH][Cl]_2$ might be expected to be unstable. However, this is definitely not the case. This behaviour must be due to a major difference in the structure of $SBPy_3$ and L^2. The presence in the latter of a conjugation between the pyridyl, the imine and the aromatic moieties (from the *o*-phenylenediamine skeleton, absent in $SBPy_3$) seems to be crucial. This obviously provides both a different rigidity of the ligand and modified electronic properties, and, as a consequence, very different spectroscopic properties and stability patterns.

In summary, we provide in this article the first direct evidence for desaturation of a coordinated acyclic secondary amine initiated by the reaction of molecular dioxygen with a stable iron(II) complex. This reaction is certainly related to the peculiar structure of the ligand, and especially the presence of both a secondary amine and a non-innocent benzylic position close to the metal center. From a mechanistic point of view, oxidation of the iron(II) center to iron(III) by molecular dioxygen has been reported in the chemistry of dichlorotris[(2-pyridylmethyl)amino]iron(II) complexes,[13] and seems also to be a reasonable starting hypothesis here. However, the role of dioxygen in the overall reaction is, at present, not completely established. Mechanistic investigations are currently being carried out in our laboratory.

Experimental Section

Metallation of L^1: This reaction was carried out with 100 mg of L^1 according to the procedure detailed in ref.[14] The desired iron complex (130 mg, 90% yield) was obtained in microcrystalline form after workup. $C_{26}H_{26}Cl_2FeN_6$ (549): calcd. C 56.83, H 4.73; found C 57.01, H 4.82. The ^{1}H NMR spectrum displays a complex set of broad and paramagnetically shifted peaks lying between δ = 170 and −40 ppm. It is provided as Supporting Information.

Oxygenation of $[Fe(L^1)Cl][Cl]$ on a Preparative Scale: After addition of dry dioxygen by syringe to a solution of 100 mg of $[Fe(L^1)Cl][Cl]\cdot CH_3CN$ in acetonitrile, the medium was allowed to stand for 24 h. It was then concentrated and a dark compound precipitated by addition of diethyl ether. The dark-green solid was recrystallised from acetonitrile/diethyl ether, washed with diethyl ether and dried under vacuum (90 mg, 88% yield). $C_{26}H_{25}Cl_2FeN_6O$ $\{[Fe(L^2)(CH_3CN)][OH][Cl]_2\}$ (564): calcd. C 55.32, H 4.43; found C 55.19, H 4.28. The compound was also characterised by ES mass spectrometry. The spectra were recorded in the positive mode without addition of any acidic source because the compounds are somehow sensitive to protonation. High-power conditions were therefore used, and *m*/*z* values differing by −1 unit were generally observed. The traces are provided as Supporting Information. *m*/*z* (%) = 492 (100) $[\{Fe(L^2)(CH_3CN)\}\{OH\}]^{2+}$, 450 (5) $[\{Fe(L^2)\}\{OH\}]^{2+}$, 378 (6) $[L^2 - H]^+$. The EPR spectrum was recorded in solution (CH_3CN) at 30 K (power: 20.2 mW; modulation amplitude: 5.01G; modulation frequency: 100.00 kHz). The ^{1}H NMR spectrum displays a complex set of broad and paramagnetically shifted peaks lying between δ = 120 and −15 ppm. It is provided as Supporting Information.

Decomplexation: A green acetonitrile solution of $[Fe(L^2)(CH_3CN)][OH][Cl]_2$ (100 mg in 100 mL) was treated with an aqueous solution of KOH. The medium was extracted with dichloromethane, which was subsequently washed, dried and concentrated. The free imine (50 mg) was recovered as a light reddish-brown oil after addition of pentane. We could not avoid the presence of impurities in the decomplexation medium, detected by ^{1}H NMR as weak signals in the aromatic region. Attempts to purify L^2 by chromatography were unsuccessful, the imine being unstable on the stationary phases. For this reason we could not obtain any satisfactory elemental analysis. ^{1}H NMR ($CDCl_3$): δ = 8.56, 8.52, 8.44 (broadened doublets, 1 H each, α-pyridyl), 7.80−7.10 (m, 13 H, aromatic), 6.55 (s, 1 H, *H*C=N), 4.46 (s, 4 H, CH_2) ppm; additional weak signals were also present in the aromatic region. ES/MS: *m*/*z* = 378 $[L^2 - H^+]$ ($C_{24}H_{21}N_5$).

X-ray Crystallography: For details, see refs.[15,17]; CCDC-224186 and -224187 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

[12] Systematically, dichloroiron(II) complexes are obtained from $FeCl_2$ and ligands in anhydrous conditions, with dried solvents.[11,13] However, a general feature in this kind of chemistry is that, provided the reaction medium is kept under strictly anaerobic conditions, the presence of noticeable amounts of water in the solvent (up to 5% in technical grade CH_3CN for instance) does not induce significant changes in preparation, structure or stability of the complexes. The same observation accounts for complex $[Fe(L^1)Cl][Cl]$.

Influence on the Formation of Aragonite or Vaterite by Otolith Macromolecules

Giuseppe Falini,*[a,b] Simona Fermani,[b] Silvia Vanzo,[c] Marin Miletic,[c] and Giulia Zaffino[b]

Keywords: Biomineralization / Otoliths / Vaterite / Aragonite / Calcium carbonate / Polymorphism / Bioinorganic chemistry

Calcium carbonate polymorphism is one of the most challenging problems in biomineralization. Calcium carbonate exists in three crystalline forms: calcite, aragonite and vaterite. Otoliths of teleost fishes are made of vaterite and aragonite, located in different sacs and never mixed together. This paper presents a biochemical characterization of the intracrystalline macromolecules associated to the vateritic and aragonitic phases of otoliths. Experimental evidences from calcium carbonate overgrowth on the surface of otoliths and in vitro crystallization on the chitin-silk fibroin assembly organic matrix suggest that the intracrystalline macromolecules associated to the otolith influence the aragonite–vaterite polymorphism.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The term otolith refers to the ear bone of teleost fishes. These carbonatic structures are a part of the stato-acustical organ of advanced fishes that corresponds to the inner ear (labyrinth) and is responsible for the ability to hear and the equilibrium sense. The labyrinth includes three connected semicircular canals and three otolithic organs consisting of the sacculus, utricle and lagena,[1−3] each of which contains an otolith called sagitta, asteriscus and lapillus respectively. The asteriscus and lapillus are usually millimetre sized, but the sagitta can range from millimetre to centimetre size.[1] As sagittae are the largest otolith, they have been widely utilized in teleost growth rate and age assessment studies.[1]

Crystals of otoliths, once deposited, are metabolically inert, except under extreme stress. Thus, the otolith can potentially retain the variation in crystalline structure due to variation in the organic matrix or in the crystallization environment.[1]

Biomineralization of otoliths differs from that of vertebrate bone, molluscan shell and coral skeleton since the otolith epithelium is not in direct contact with the region of calcification. As a result, the calcification is heavily dependent upon the composition of the endolymphatic fluid surrounding the otolith.[4−6] However, the mineral crystalline units are associated with an organic matrix. Approximately half of the otolith matrix macromolecules are water insoluble[7] and, presumably, make up the structural framework for subsequent calcification. The soluble proteins are characterized by a high abundance of acidic amino acids, and are termed "otolin".[8] The most recently elucidated otolith water-soluble protein is characterized by a high content of acidic amino acids and can control the calcium carbonate morphology and polymorphism.[9]

Different polymorphs of calcium carbonate are linked to the different otolith organs. While aragonite is normal in sagittae and lapillus, most asteriscus are made of vaterite.[10,11] Vaterite is also the principal polymorph in many abnormal otoliths.[12] There is no accepted explanation for the formation of vateritic otoliths together with aragonitic ones.[13] Vaterite precipitates in supersaturated solutions that are far from equilibrium;[14] alternatively, matrix proteins may mediate vaterite formation, similarly as described for calcite and aragonite in mollusc shells.[15]

We present here a characterization of the intracrystalline acidic macromolecules associated to aragonitic and vateritic otoliths. The influence of such macromolecules on calcium carbonate polymorphism in fish otoliths is also analyzed and discussed.

Results

General Description

Figure 1 (a, b) gives a view of the otoliths lapillus and asteriscus of *Chondrostoma nasus nasus*. In the family of

Ciprinidi, sagitta is the smallest otolith, while lapillus and asteriscus can reach the size of millimetres. Their morphology has been well described.[13]

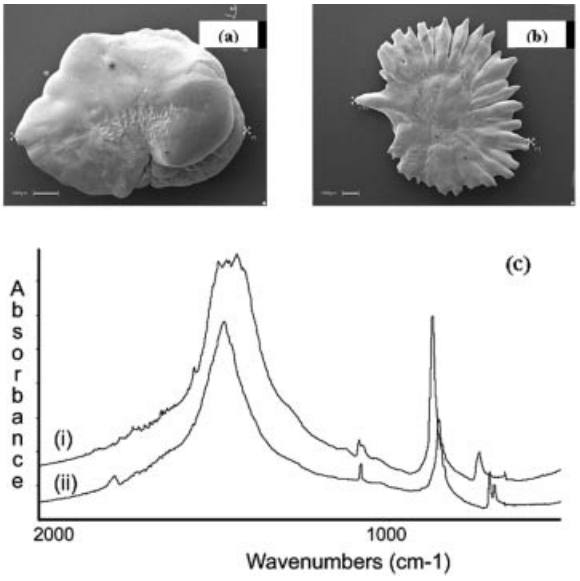

Figure 1. Scanning electron microscopy images of the anti-sulcal surface of otoliths lapillus (a) and asteriscus (b) from *Chondrostoma nasus nasus*; (c) FTIR spectra of asteriscus (i) and lapillus (ii) show the characteristic absorption peaks of vaterite and aragonite respectively[18]

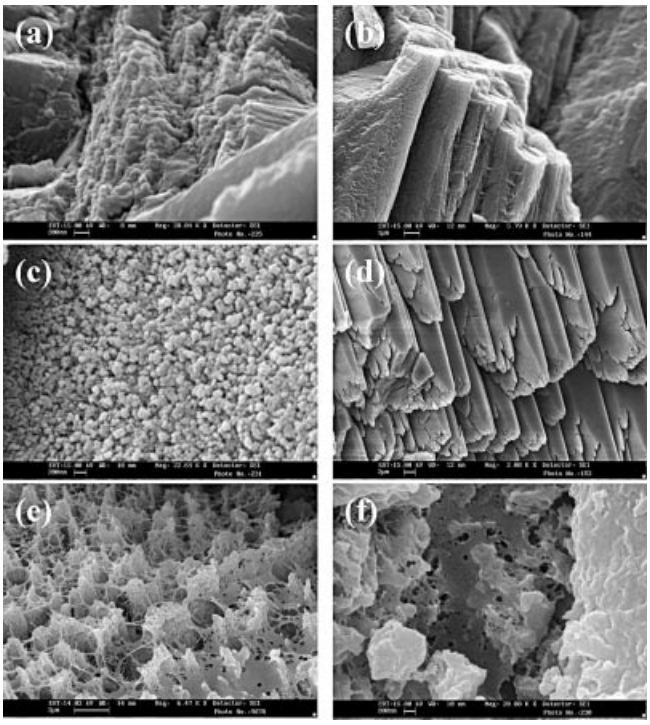

Figure 2. Scanning electron microscopy images of the textural organization of crystalline units in asteriscus (a) and (c) and lapillus (b) and (d); in (e) and (f) the insoluble organic matrix after fixation associated to asteriscus and lapillus respectively is shown

Lapillus and asteriscus were used as sources of aragonitic and vateritic associated intracrystalline macromolecules, respectively (see c in Figure 1). The textural organization in lapillus and asteriscus (Figure 2) has locally radial oriented crystalline units that change in size as a function of the polymorph. Those of aragonite appear as a long prism with an average thickness of about 5 μm (see a in Figure 2). Interestingly, this is the thickness of the crystalline units in the nacre of the shells.[3] Vaterite crystalline units in the asteriscus appear as small needles locally oriented (see b in Figure 2). Each crystalline unit, of either aragonite or vaterite, is embedded completely in an organic matrix (Figure 2, c and d). This organic matrix is partially water insoluble and its structure is observable after decalcification in the presence of fixatives. It makes a continuous network that can bridge all the crystalline units (Figure 2, e and f). In the pictures the fixed organic matrix appears to be full of holes and small fragments; we cannot exclude that this is an artifact of the drying process, as has been shown for others organic matrices.[16]

Acidic Macromolecules Associated to Aragonite and Vaterite

Cation exchange resin was used to extract the acidic intracrystalline macromolecules from the otoliths.[17] SDS-PAGE, amino acid analysis and FTIR spectroscopy were used to characterize the soluble macromolecules extracted from lapillus and asteriscus.

Figure 3 compares the major otoliths proteins of the two calcium carbonate polymorphs, aragonite and vaterite. In lines numbered 1 the molecular weight markers are reported, while lines 2−4 show the running gels of the soluble macromolecular assembly extracted from asteriscus (2), and lapillus (3, 4) at different concentrations. In the macromolecular gel lines some material was retained close to the top and a main band at about 67000 was observed. Other weak bands at higher molecular weight are present. However, there are differences between the macromolecules associated to aragonite (lines 3 and 4) and those associated to vaterite (line 2). Those associated to aragonite show a second main band at about 30000 while those of vaterite show a strong at about 40000. Many other minor bands are present in both the aragonitic- and vateritic-soluble macromolecular assemblies. Table 1 gives the amino acid composition of the proteic part of the soluble macromolecular assembly associated with aragonite (lapillus) and vaterite (asteriscus) in the otoliths. The total amino acid composition is quite similar; the main difference is a higher content of Glx in the macromolecules associated to vaterite. Figure 4 reports the FTIR spectra of intracrystalline soluble macromolecules associated to lapillus (aragonitic) and asteriscus (vateritic).

A protein amide I absorption band at 1654 cm^{-1} and a large absorption band at around 1100 cm^{-1} dominate the infrared spectrum of the ensemble of macromolecules from asteriscus (Figure 4).[18]

ppm	427	474

The IR spectrum of the lapillus macromolecules shows bands at 1100 and 1255 cm^{-1}, protein amide I absorption at 1653 cm^{-1}, and relatively strong carboxylate absorption bands at around 1575 and 1417 cm^{-1}.

In vitro Crystal Growth

SEM images of the mineral phases obtained from the overgrowth experiments are shown in Figure 5. Large rhombohedral crystals, along with many small needle-like ones, form on the surface of lapillus (Figure 5, b). The latter crystals almost completely cover the surface, with a few big rhombohedral crystals grown among them (Figure 5, d). Comparison with known morphologies of calcium carbonate polymorphs indicates that the rhombohedral ones are calcite while the needle-like ones are aragonite[3] (Figure 5, e).

On the asteriscus surface, however, the overgrowth of calcium carbonate produced different results. The calcite crystals are no longer well separated and grow in clusters on small regions of the asteriscus surface (Figure 5, a). Together with the typical {104} rhombohedral faces, the crystals show specific additional faces (Figure 5, c) that are more pronounced in the centre of the otoliths than on the edge. These additional faces are almost parallel to the calcite *c* axis. In some surface regions, aggregates of plate-like crystals were seen (Figure 5, e) that show a similar morphology to that of synthetic vaterite.[3]

Crystallization experiments of calcium carbonate were also carried out on a silk-fibroin/β chitin assembly in which the soluble macromolecules extracted from lapillus and asteriscus were adsorbed (Table 2). In all crystallization experiments, a mixture of calcite and vaterite was obtained. Calcite was observed on the substrate surface as small single crystals, with a rhombohedral appearance, while vaterite crystallized as crystalline aggregated spherulites (Figure 6, a and b). The mineral phase was identified by an FTIR technique (Figure 6, c).[18]

In the controls system, where no acidic macromolecules were adsorbed, calcite, as the main phase, and vaterite were formed. The pH at the end of the crystallization experiment was 7.8 and the average number of crystals (calcite plus vaterite) was about 9.6 per cm^2. In the presence of adsorbed acidic macromolecules extracted from lapillus, both calcite and vaterite were observed. However, with respect to the control, a higher density of crystallization was observed (about 26.6 crystal per cm^2), even if the average size, the polymorphic distribution and the final pH of the crystallization media were almost the same. A different scenario

Optical micrographs in cross polar of calcium carbonate aggregates grown in the β-chitin/silk fibroin assembly with or with out acidic macromolecules extracted from *Chondrostoma nasus nasus* aragonitic or vateritic otoliths; (a) calcite crystals and a few vaterite spherulites formed in the presence of aragonite associated acidic macromolecules; (b) vaterite spherulites and a few calcite crystals formed in the presence of vaterite associated acidic macromolecules; magnification 40×; (c) FTIR spectrum of the mineral phases associated to the β-chitin/silk fibroin assembly, showing absorption peaks characteristic of vaterite (*) and calcite (#)[18]

Discussion

Otoliths of the teleost fish *Chondrostoma nasus nasus* are deposits of calcium carbonate formed of aragonite and vaterite. Intracrystalline acid macromolecules associated at these two mineral phases have been studied. They are an assembly of proteins and glycoproteins with a wide range of molecular weights. A main band at about 67 000 seems to be common to both mineralized tissues. Differences are present in minor bands. A band at about 30 000 seems to be characteristic of lapillus macromolecules while one at about 40 000 is observed only in asteriscus macromolecules. This latter band has been reported previously.[19] The amino acid composition shows no strong, significant differences between the proteic regions of the acidic macromolecules extracted from aragonitic and vateritic otoliths. However, vateritic ones have a higher Glx content. High Glx contents have also been observed in acidic macromolecules associated to amorphous calcium carbonate.[20] If we consider that amorphous calcium carbonate has the highest solubility among calcium carbonates, and that vaterite is the most soluble calcium carbonate crystalline phase, we could speculate that a high Glx content may be associated with highly soluble calcium carbonate mineral phases.

FTIR spectra of the two families of acidic macromolecules show different absorptions in the region typical of carbohydrates (around 1000 cm^{-1}), suggesting a different degree of glycosilation. These differences may be correlated with the SDS-PAGE bands.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The control of acidic macromolecules over the mineral deposition was tested using two crystallization systems. Overgrowth experiments are a powerful tool to evaluate the effect of acidic macromolecules on mineral deposition since they are in a conformation that in many aspects is the closest to the native one. Two different families of mineral grew on the surface of the aragonitic lapillus. Calcite crystals grew with a regular rhombohedral habit, suggesting that no macromolecules interacted with them. These crystals do not show a preferential direction of growth, although this is not easy to state since the lapillus surface is quite rough. Together with the calcite crystals, many much smaller platelike crystals of aragonite were observed (ca. 1 μm versus more than 20 μm for calcite). These crystals almost completely covered the surface and gathered in clusters with no preferential orientation.

A different scenario appears on the asteriscus surface after the overgrowth experiments. The calcite crystals show a new crystalline face with respect to the regular rhombohedral calcite. This new face, almost parallel to the calcite *c* axis, has been observed previously by Albeck et al.[21] It was associated to a specific interaction of one (or more) soluble macromolecule(s) on a specific crystalline plane, stabilizing it and producing its appearance. This new face on the calcite crystals is more evident in the central part of the asteriscus than on the edges. This may be explained in terms of a higher concentration of the released macromolecules in the surrounding media of those regions.

On the surface of asteriscus, in regions distant from the calcitic one, vaterite was also observed. This polymorphic spatial specification could be associated to a different etching and hence to a different release of acidic macromolecules.

These observations indirectly confirm the SDS-PAGE and FTIR observations. The two families of acidic macromolecules associated to the aragonitic and vateritic otoliths are composed of different macromolecules, and they can interact with growing calcium carbonate in different ways.

Aragonite forms on the surface of aragonitic biomaterial[22] but, to our knowledge, this is the first example of the overgrowth of vaterite on a vateritic biomineral, under conditions where calcite precipitation is favored.

The ability of the acidic macromolecules to influence calcium carbonate polymorphism has also been tested using an artificial assembly made of silk fibroin and β-chitin. The silk-fibroin/β chitin assembly is not strictly relevant in otolith biomineralization, since neither β-chitin nor silk fibroin-like proteins has been shown to be present in the otolith insoluble matrix. However, this artificial assembly has been used successfully to verify the nucleating properties of acidic macromolecules extracted from mollusc shells. In search of an analogy between these two mineralized tissues, we used it to run crystallization experiments. Calcite and vaterite were observed in all crystallization experiments, irrespective of the presence of the acidic macromolecules. However, some interesting features arise from the crystallization results (Table 2). The substrate in which acidic macromolecules extracted from the lapillus were adsorbed showed no differences to the control in terms of polymorph distribution, crystal size and final chemical properties of the surrounding media. Calcite was the main crystalline phase, with few vaterite spherulites. The density of crystallization on the surface increased, suggesting that these charged macromolecules, once adsorbed on a substrate, favor the nucleation and growth of calcium carbonate.[23] No evidence for aragonite was obtained. This indicates that the artificial assembly does not cover the requirement for the acidic macromolecules' polymorphic control, or that these proteins are unable to control aragonite formation. In this case, a pure physical control should be addressed. In the presence of the acidic macromolecules extracted from the asteriscus the final pH of the crystallization media increased with respect to those of the control and lapillus (Table 2) and larger spherulites of vaterite made up the main phase on the matrix surface. This means that the system reached equilibrium at a higher supersaturation than did the control, justifying the formation of vaterite in the matrix.[24] Vaterite is metastable in water solution and spontaneously transforms into calcite;[25] the presence of large vaterite spherulites suggests that the system acidic macromolecules from asteriscus−artificial assembly favors and stabilizes vaterite formation.

Conclusion

Intracrystalline acidic macromolecules of otoliths influence calcium carbonate polymorphism. A preliminary characterization of these acidic macromolecules has been carried out, and their calcium carbonate nucleating properties have been tested using overgrowth and substrate-mediated approaches.

Experimental Section

Materials: Otoliths for this study were taken from the head of the fish *Chondrostoma nasus nasus* collected from the Isonzo river (Italy). After dissecting them from the fish ears, they were washed with sodium hypochlorite for 1 h to remove any organic superficial contaminant, then with Milli-Q water, and finally air-dried. No distinction was made between sex and left or right ear otoliths.

Morphological Investigations: Scanning electron microscopy (SEM) images were obtained by means of a Philips XL20 electron microscope on samples glued on an aluminium stub and gold sputtered. Prior to observations some otolith samples were mechanically broken to observe the inner morphology or decalcified in the presence of fixative to observe the insoluble organic matrix.[11]

Protein Extraction: Proteins were extracted using the cation exchange resin procedure.[24] Specifically, ground otoliths powder was poured into dialysis tubes and suspended in water (20 mL per 1.5 g of otolith). The sealed dialysis tube was then placed in a plastic cylinder. About one quarter of the cylinder, outside the dialysis tube, was filled with prewashed cation exchange resin and water was added to fill the cylinder. The cylinder was then closed with a stopper and rotated slowly and continuously in a propeller-like mode at room temperature to keep the powder and the resin in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

suspension. The water outside the dialysis tube was changed twice per day. Decalcification was complete in about three days, and the absence of mineral was checked by IR spectroscopy. The content of the dialysis tube was then dialyzed against water for two days. The resulting soluble and insoluble material inside the dialysis tube was subsequently separated by centrifugation. The final soluble material was then concentrated by lyophilization.

Polyacrylamide Gel Electrophoresis of Proteins: Tris-tricine ready-to-use Minigels of 15% polyacrylamide were employed. The gel ran at 100 V for 1.5−2 h and was developed with Blue Coomassie.

FTIR Spectrometry: IR analyses were carried out on dried soluble and insoluble matrices. Calcium carbonate formed in the chitin−silk fibroin assembly was removed mechanically before analysis. All spectra were recorded at 4 cm^{-1} resolution with a 32 scan with a Perkin-Elmer Model 1600 Fourier Transform Infrared Spectrometer (FTIR) from 4000 to 450 cm^{-1}. Powder sample and KBr were dried under a red lamp, careful mixed in a mortar, and pelleted with a press. A background spectrum was measured for pure KBr.

In vitro Crystal Growth: Two types of crystallization experiments were performed. Calcium carbonate crystals were overgrown on cleaned otoliths, or crystals were grown *de novo* in the presence of the soluble total macromolecular assemblage extracted from lapillus or asteriscus adsorbed on β-chitin and silk fibroin substrate.[15] The crystal growth procedure has been detailed previously.[26,27] Briefly, synthetic calcium carbonate crystals were grown for four days in a closed box, by slow diffusion of ammonium carbonate vapor into plastic Petri dishes containing the otoliths, or the nucleating substrate, overlaid by a 10 mM $CaCl_2$ solution. The obtained calcium carbonate crystals were rinsed with Milli-Q water, observed under optical microscope, and successively air-dried. For detailed morphological analysis, the crystals were gold coated and observed by SEM

The Hidden Equilibrium in Aqueous Sodium Carbonate Solutions − Evidence for the Formation of the Dicarbonate Anion

Klaus-Peter Zeller,*[a] Paul Schuler,[a] and Peter Haiss[a]

Keywords: Dicarbonate anion / Isotopic labeling / NMR spectroscopy / Oxygen transfer

Crossover ^{13}C NMR experiments between [^{13}C]carbonate and [^{18}O]carbonate in aqueous solution confirm the combined action of two oxygen-exchange modes. The isotopomeric carbon dioxides formed in the hydrolysis equilibrium of the labeled carbonate anions react with hydroxide with formation of hydrogencarbonate and with isotopomeric carbonate anions yielding the corresponding dicarbonate species, which, in the back reaction, form carbon dioxide and carbonate anions with distributed oxygen.

Introduction

In aqueous solutions of metal carbonates the carbonate ion suffers from partial hydrolysis into hydrogencarbonate, carbonic acid and dissolved carbon dioxide [reactions (1)−(4)]. An impressive number of techniques have been applied to determine the rate and equilibrium constants of the reaction steps involved. Much of this data has been collected.[1] Because of its kinetic instability in the presence of water,[2] the fraction of the solvated carbon dioxide present as carbonic acid is less than 1%.[3] From the first (apparent) and the second dissociation constant of "carbonic acid", and the ion product of water, the dependence of the composition of the $CO_2/HCO_3^-/CO_3^{2-}$ system on the pH value can be calculated. For example, a 0.01 M solution of sodium carbonate exhibits a pH value of 11.16 and the molar fractions of carbonic species are $x_{CO_3^{2-}} = 0.86$, $x_{HCO_3^-} = 0.14$ and $x_{CO_2} = 3 \times 10^{-6}$.

$$(1)\quad CO_3^{2-} + H_2O \rightleftharpoons HCO_3^- + OH^-$$

$$(2)\quad HCO_3^- + H_2O \rightleftharpoons H_2CO_3 + OH^-$$

$$(3)\quad H_2CO_3 \rightleftharpoons CO_2 + H_2O$$

$$(4)\quad HCO_3^- \rightleftharpoons CO_2 + OH^-$$

As shown in the pioneering work of Mills and Urey,[4] carbonate dissolved in ^{18}O-enriched water slowly exchanges its oxygen atoms with the oxygen atoms of the water. The rate of this oxygen exchange is mainly governed by the addition of hydroxide to carbon dioxide.[4,5] Himmelblau and Babb[6] have studied the rate of this reaction step by adding ^{14}C-labeled hydrogencarbonate to unlabeled hydrogencarbonate/CO_2 solutions and observing the appearance of $^{14}CO_2$. The values obtained by this method for the hydroxylation of carbon dioxide are much higher than those found by other techniques. This discrepancy points to a superimposition of an oxygen-exchange process between carbonic species.[7,8] A kind of molecular complex, written as $CO_2{\cdot}OH^-$ and supposed to be distinctly separated from HCO_3^- and $CO_2 + OH^-$, has been suggested for this purpose.[7] It is assumed that this complex is able to transfer OH^- to a second CO_2 molecule. The occurrence of cyclic oligomeric orthocarbonic acid was also proposed to account for the oxygen-transfer process.[8]

Tu and Silverman[9] have studied the kinetics of the oxygen exchange by adding ^{18}O-labeled carbonate to solutions containing ^{13}C-enriched carbonate. The rate of appearance of ^{18}O in the ^{13}C-enriched species was measured by mass spectrometry at pH values ranging from 8 to 10. A kinetic analysis revealed that the oxygen transfer can be described by the overall reaction (5).

$$(5)\quad {}^{13}CO_2 + C^{18}O_3^{2-} \rightleftharpoons {}^{13}CO_2{}^{18}O^{2-} + C^{18}O_2$$

The rate of the second-order reaction (5) was found to be competitive with the rate of the back-reaction (4). Therefore, the carbonate oxygen atoms are simultaneously exchanged between carbonic species [reaction (5)] and with the solvent water [reaction (4)].

In this contribution the parallel occurrence of two oxygen-exchange modes is directly observed by NMR spectroscopy and explained by a competitive addition of hydroxide and carbonate ions to carbon dioxide.

Results

Sodium [$^{18}O_3$]carbonate was prepared from tetraethyl orthocarbonate by stepwise hydrolysis with [^{18}O]water. The first acid-catalyzed step yields diethyl [carbonyl-^{18}O]carbonate, which was further transformed into sodium [^{18}O]carbonate by saponification. According to ^{13}C NMR measurements the sodium carbonate obtained consists of about 46% [$^{18}O_3$], 41% [$^{18}O_2$], 12% [^{18}O] and 1% unlabeled carbonate. This corresponds to an ^{18}O content in the water of 77%. The isotopic enrichment of the water used for hydrolysis was determined to be 80% ^{18}O. The somewhat lower value in the reaction product results from the presence of traces of [^{16}O]water during the synthetic procedure.

The distribution of the isotopomeric carbonate species could be established by ^{13}C NMR spectroscopy. The ^{18}O isotope bound to C causes a small high-field shift of the ^{13}C resonance frequency relative to the ^{16}O compound.[10] The ^{18}O isotope effect on the ^{13}C chemical shift is additive. Therefore, the four isotopomeric species $C^{18}O_{3-n}O_n^{2-}$ (n = 0, 1, 2, 3) should produce four equidistantly separated signals. The carbonyl-^{13}C resonances in ketones, aldehydes, esters and carboxylic acids are shifted up-field by about 0.05,[10b] 0.04,[10b] 0.04,[10b] and 0.03 ppm,[10b] respectively, when replacing ^{16}O by ^{18}O. Because of the lower double-bond character in the carbonate ion, a value of $\Delta\delta$ = 0.02 ppm per ^{18}O is expected (see Supporting Information for more details).

The ^{13}C NMR spectrum was measured in D_2O containing 1 equiv. of NaOD per ^{18}O-labeled Na_2CO_3. Under these conditions the relative amount of ^{18}O-labeled CO_2, formed according to the hydrolysis equilibrium in reactions (1)−(4), is suppressed by about two orders of magnitude and, thus, the oxygen exchange is slowed down. Indeed, repeated measurements within 12 h produced spectra with four signals separated by 0.016 ppm, with no detectable changes in their relative intensities.

In contrast, the ^{13}C NMR spectra of a 0.44 M solution in pure D_2O measured over several weeks showed an exchange of the oxygen atoms of the carbonate ion with the oxygen atoms of the solvent D_2O. Some selected examples are presented in Figure 1. It becomes evident that the carbonate species, separated by 0.018 ppm according to the number of incorporated ^{18}O atoms, lose the heavier oxygen atoms successively. After standing at 20 °C for 100 d, the carbonate consists of about 92% $C^{16}O_3^{2-}$. This is near the calculated end-point for statistical distribution of oxygen atoms from the labeled carbonate and the solvent D_2O (93.28% $^{16}O_3$, 6.59% $^{16}O_2{}^{18}O$, 0.15% $^{16}O^{18}O_2$, 0.001% $^{18}O_3$).

The intermolecular oxygen transfer between carbonic species was examined by means of a crossover experiment. A solution of 1 mg of sodium [^{13}C]carbonate (99% ^{13}C) and 31 mg of the ^{18}O-labeled sodium carbonate in 600 μL of D_2O was subjected to ^{13}C NMR spectroscopy. At t = 0 this solution is composed of 43.49% $Na_2C^{18}O_3$, 39.46% $Na_2C^{18}O_2{}^{16}O$, 11.75% $Na_2C^{18}O^{16}O_2$, 1.04% $Na_2C^{16}O_3$, 0.48% $Na_2{}^{13}C^{18}O_3$, 0.43% $Na_2{}^{13}C^{18}O_2{}^{16}O$, 0.13% $Na_2{}^{13}C^{18}O^{16}O_2$, and 3.19% $Na_2{}^{13}C^{16}O_3$. The total carbonate concentration

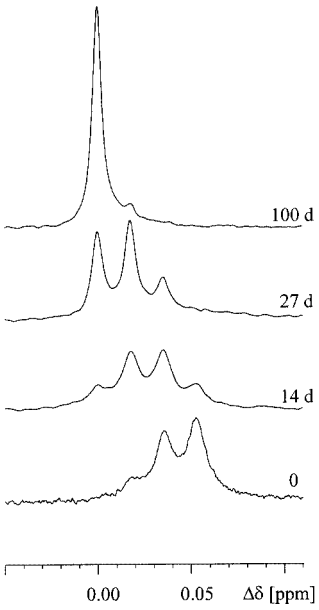

Figure 1. Time-dependent ^{13}C NMR spectra of a 0.44 M solution of $Na_2C^{18}O_{3-n}O_n^{2-}$ in D_2O at 20 °C

is 0.48 M. The ^{13}C,^{18}O-containing species result from the natural ^{13}C content in the ^{18}O-labeled carbonate. The ^{13}C-labeled isotopomers of this mixture amount to 4.23% of total carbonate and contribute to the ^{13}C NMR spectrum. The calculated ratio of the NMR-active isotopomers at t = 0 is: $^{13}C^{16}O_3^{2-}/^{13}C^{16}O_2{}^{18}O^{2-}/^{13}C^{16}O^{18}O_2{}^{2-}/^{13}C^{18}O_3{}^{2-}$ = 74.3:3.1:10.6:12.0. After infinite time, the total amount of ^{18}O and ^{16}O incorporated in the solution by the isotopomeric carbonates and D_2O should be statistically distributed. The resulting ratio of $^{13}C^{16}O_3{}^{2-}/^{13}C^{16}O_2{}^{18}O^{2-}/^{13}C^{16}O^{18}O_2{}^{2-}$ was calculated to be 94.1:5.8:0.1.

Provided that the statistical distribution is caused only by oxygen exchange between carbonic species and D_2O, this end-point should be approached in a monotonic manner. Inspection of the ^{13}C NMR measurements over a period of 154 d obviously reveals that this is not the case. Some representative measurements are given in Figure 2 (the complete set of data in form of schematic diagrams showing the relative amounts of $^{13}C^{16}O_{3-n}{}^{18}O_n^{2-}$ isotopomers as a function of time can be found in the Supporting Information).

The relative amounts of the four isotopomers $^{13}C^{16}O_{3-n}{}^{18}O_n^{2-}$ (n = 0−3) are plotted against time in Figure 3. It can be seen that the relative amount of $^{13}C^{16}O_3{}^{2-}$ decreases from 74% to a minimum of about 25% within 16 d. It then steadily increases again and slowly approaches the calculated end-point. On the other hand the curve representing $^{13}C^{16}O_2{}^{18}O^{2-}$ increases at the beginning and then reaches a plateau before slowly declining after about 25 d. The relative amount of $^{13}C^{16}O^{18}O_2{}^{2-}$ also passes through a maximum after about 15 d.

Discussion

The change of the relative intensities of the $^{13}C^{16}O_{3-n}{}^{18}O_n{}^{2-}$ species present in the carbonate mixture prepared from [^{13}C]- and [^{18}O]-labeled sodium carbonate indicates the parallel operation of two oxygen-exchange modes. At the beginning the vast majority of the carbonate consists of $^{12}C^{18}O_3{}^{2-}$ and $^{12}C^{16}O^{18}O_2{}^{2-}$. At this stage the overall reactions (5) and (5′) contribute mainly to the appearance of the ^{13}C NMR spectra.

(1′) $^{13}CO_3{}^{2-} + D_2O \rightleftharpoons D^{13}CO_3{}^- + OD^-$

(4′) $D^{13}CO_3{}^- \rightleftharpoons {}^{13}CO_2 + OD^-$

(5) $^{13}CO_2 + C^{18}O_3{}^{2-} \rightleftharpoons {}^{13}C^{18}O_2O^{2-} + C^{18}O_2$

(5′) $^{13}CO_2 + CO^{18}O_2{}^{2-} \rightleftharpoons {}^{13}CO_2{}^{18}O^{2-} + CO^{18}O$

Parallel to these exchange processes the ^{18}O-labeled carbonates, added as $^{12}C^{18}O_{3-n}{}^{16}O_n{}^{2-}$ or formed in the meantime as $^{13}C^{16}O_{3-n}{}^{18}O_n{}^{2-}$, lose ^{18}O as the result of the hydrolysis sequence [reactions (1′′) and (4′′)]. The [^{18}O]hydroxide ions expelled rapidly equilibrate with the large ^{16}O stock of the solvent D_2O [reaction (6)]; thus, in the back-reaction (hydroxylation of isotopomeric carbon dioxides) mainly ^{16}O is introduced. Therefore, the carbonic species are continuously depleted of their ^{18}O labeling. This reduces the amount of $^{12}C^{18}O_{3-n}{}^{16}O_n{}^{2-}$ species capable of transferring ^{18}O to $^{13}CO_2$, and the $^{13}C^{16}O_{3-n}{}^{18}O_n{}^{2-}$ species produced in the meantime will be degraded again. Therefore, as the reaction progresses the intensity of $^{13}C^{16}O_3{}^{2-}$ passes through a minimum before it steadily increases towards the value of about 94% calculated for the statistical distribution.

The direct observation of the oxygen-exchange processes in aqueous carbonate solution by ^{13}C NMR spectroscopy confirm the conclusion of Tu and Silverman.[9] The well-established up-take of oxygen atoms from water has to be combined with a process of transferring oxygen atoms be-

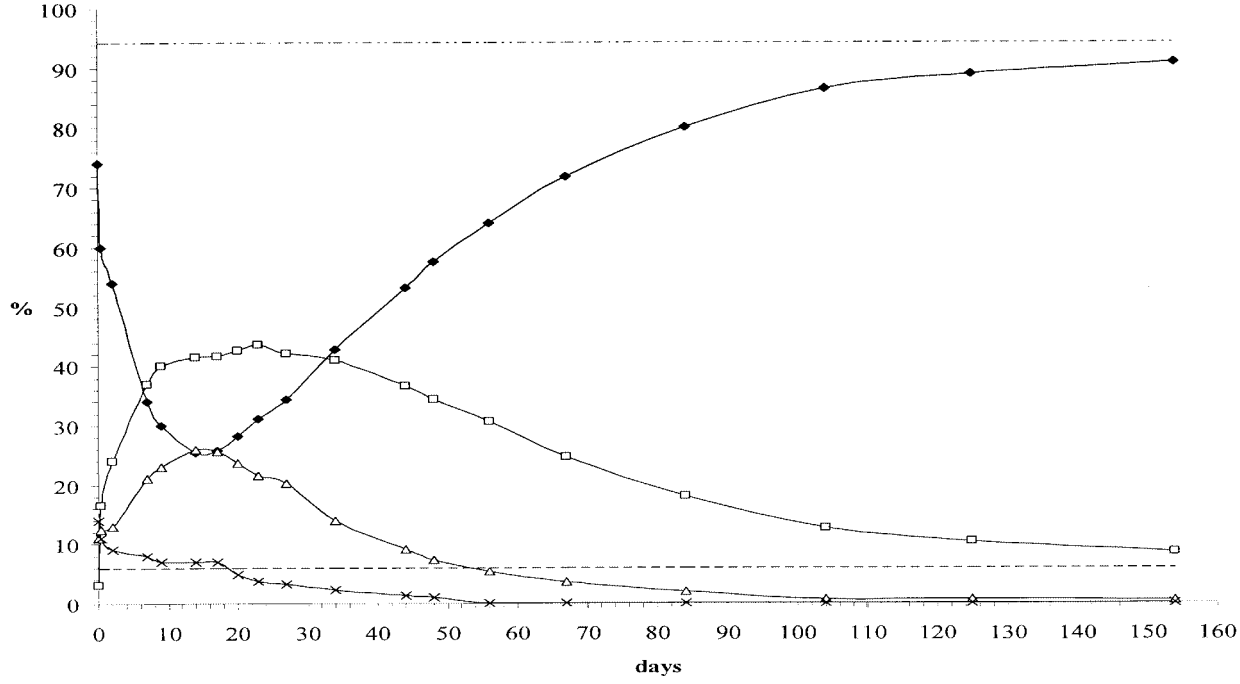

Figure 3. Change of the concentration of [^{13}C]carbonate species as a function of time (black diamonds: $^{13}C^{16}O_3{}^{2-}$; squares: $^{13}C^{16}O_2{}^{18}O^{2-}$; triangles: $^{13}C^{16}O^{18}O_2{}^{2-}$; X: $^{13}C^{18}O_3{}^{2-}$; – - - – : calculated end-point for $^{13}C^{16}O_3{}^{2-}$; – – – : calculated end-point for $^{13}C^{16}O_2{}^{18}O^{2-}$

tween carbonic species. The latter process remains hidden unless crossover experiments between carbon- and oxygen-labeled isotopomers of carbonate are performed.

(1") $^{13}CO_2{}^{18}O^{2-} + D_2O \rightleftharpoons D^{13}CO_2{}^{18}O^- + OD^-$

(4") $D^{13}CO_2{}^{18}O^- \rightleftharpoons {}^{13}CO_2 + {}^{18}OD^-$

(4''') $D^{13}CO_2{}^{18}O^- \rightleftharpoons {}^{13}CO{}^{18}O + OD^-$

(6) $^{18}OD^- + D_2O \rightleftharpoons D_2{}^{18}O + OD^-$

In terms of reaction mechanisms the hydroxylation of carbon dioxide is a nucleophilic addition of hydroxide to a carbonyl group, as shown in reaction (7). For reactions of this type the basicity is a main factor for determining the nucleophilic power of the nucleophiles.[11] From the nucleophiles present in an aqueous carbonate solution the CO_3^{2-} anion (pK_a = 10.33) is nearest to the OH^- ion (pK_a = 15.74) in its basicity. The addition of carbonate to CO_2 would lead to the dicarbonate anion [reaction (8)], which is the first member of the series of hypothetical oligomeric carbonate ions of the general formula $C_nO_{2n+1}{}^{2-}$.

(7) 
(8) 
Assuming a linear structure-reactivity relationship, the rate constant of reaction (8) can be roughly estimated as 54 $mol^{-1}\cdot L\cdot s^{-1}$ (see Supporting Information). This is in acceptable agreement with the rate constant of 114 ± 11 $mol^{-1}\cdot L\cdot s^{-1}$ [9] for the overall reaction (5) describing the oxygen exchange between carbonic species. Thus, the dicarbonate anion is a likely intermediate for this process.

Reaction (8) has also been proposed to account for the experimental finding that the solubility of CO_2 in a ternary, eutectic melt of Li_2CO_3, Na_2CO_3 and K_2CO_3 is 50 times higher than deduced from the electrochemical reduction of "free" CO_2.[12] In a theoretical investigation of the structure and stability of the dicarbonate ion at the HF MP2 and QCISD levels a remarkably high free enthalpy of reaction for process (8) in the gas phase could be derived (ΔG = −44 to −48 $kcal\cdot mol^{-1}$ at 298 K).[13] If, in aqueous solution, reaction (8) was similarly exergonic, the hydrolysis of CO_3^{2-} followed by reaction (8) should result in almost complete conversion of carbonate into dicarbonate according to the overall reaction (9).

(9) $2\,CO_3^{2-} + H_2O \rightleftharpoons C_2O_5^{2-} + 2\,OH^-$

However, because of solvation effects in aqueous solution the free enthalpies of the left-hand side and the right-hand side of reaction (8) are leveled. The free enthalpies of solvation of the carbonate ion and CO_2 in water are −314[14] and −4 $kcal\cdot mol^{-1}$,[15] respectively. The solvation effect for the $C_2O_5^{2-}$ ion in water can be estimated, on the basis of an electrostatic model,[14] as $\Delta G_{hyd.} \approx -220$ $kcal\cdot mol^{-1}$. An ionic radius, $r(C_2O_5^{2-})$, of 0.326 nm derived from the geometry-optimized structure[13] has been assumed for this purpose. From this it follows that, in water, reaction (8) is no longer exergonic and only small stationary concentrations of the dicarbonate ion are built up in a reversible reaction.

As briefly addressed in the introductory section a molecular complex between CO_2 and OH^- [7] and oligomeric cyclic orthocarbonates[8] have been discussed in the earlier literature as intermediates to explain the oxygen transfer between carbonic species. This hypothetical molecular complex is supposed to be able to exchange its CO_2 very rapidly with surrounding CO_2. This could offer an alternative rationalization for intermolecular oxygen transfer [reaction (10)].

(10) $HC^*O_3^- \rightleftharpoons C^*O_2\cdot{}^*OH^- \overset{{}^*CO_2\ C^*O_2}{\rightleftharpoons} {}^*CO_2\cdot{}^*OH^- \rightleftharpoons H^*CO_2{}^*O^-$

The suggested linear arrangement of the carbon and oxygen atoms[7] to describe the molecular complex is problematic. A hydrogen-bonded structure, which is essentially a hydroxide ion solvated by carbon dioxide, would be a representation in better agreement with structural theory. However, it is difficult to see how this mode of solvation can compete with the very strong hydration of OH^- in aqueous solution. Thus, it seems unlikely that a species like $CO_2\cdot OH^-$ can exist in water with a sufficiently long lifetime to react with CO_2 present in very low concentration.

The involvement of intermediate cyclic oligomeric orthocarbonates as species responsible for oxygen exchange between the carbonic species of a carbonate solution would require the formation of new C−O bonds between carbonate and/or hydrogencarbonate units. This is rather unlikely due to the low carbonyl activity of these ions. Indeed, the negatively charged oxygen atoms of carbonate coordinate with the proton of hydrogencarbonate rather than with the much less electrophilic carbon atom. The resulting hydrogen-bridged dimeric anion $[H(CO_3)_2]^{3-}$ is well known as a structural unit in the mineral trona.[16] Higher oligomeric hydrogen-bridged carbonates of the general formula $[H_{n-1}(CO_3)_n]^{(n+1)-}$ are also known.[17,18] Of course, in this type of oligomeric carbonate oxygen transfer from carbon to carbon is not possible.

In summary, both, the involvement of a molecular complex $CO_2\cdot OH^-$ and the intermediate formation of cyclic oligomeric orthocarbonates as rationalization of the observed oxygen transfer between carbonic species in aqueous carbonate solution can be excluded. However, the reversible formation of the dicarbonate anion $C_2O_5^{2-}$ readily explains this process. The corresponding dicarbonic acid is un-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

known, although its dialkyl esters are well characterized and are widely used as reagents in synthetic chemistry.[19]

Experimental Section

General Remarks: The ^{13}C NMR spectroscopic data were obtained with a Bruker AMX 600 spectrometer by single-pulse excitation without proton decoupling (flip angle 30°, delay time 10 s, acquisition time 5 s). During the intervals between the measurements of the crossover experiment the tightly closed NMR tube was stored at 20 ± 0.5 °C. Sodium [^{13}C]carbonate (99% ^{13}C) was purchased from Aldrich. [^{18}O]Water recycled from ^{18}F production in the PET center, University Hospital, Tübingen, with an ^{18}O enrichment of 80% was used in the synthesis of ^{18}O-labeled sodium carbonate.

Sodium [^{18}O]Carbonate: The ^{18}O-labeled carbonate was prepared according to the method of Hutchinson and Mabuni[20] for the synthesis of sodium [^{18}O]acetate. A rigorously dried flask equipped with a septum was charged with tetraethyl orthocarbonate (5 mL, 23.8 mmol) and dehydrated 4-toluenesulfonic acid (1−2 mg). [^{18}O]Water (200 μL, 9.1 mmol, 80% ^{18}O) was then injected under magnetic stirring. After a few minutes of exothermic reaction, the mixture became homogeneous. A 0.5 M solution of sodium methoxide in dry methanol (30 mL, 15 mmol) and [^{18}O]water (350 μL, 15.9 mmol) was added to the resulting ^{18}O-labeled ethyl carbonate and the mixture heated to 70−75 °C for 30 h. A white crystalline mass precipitated. The reaction mixture was dried first in a rotary evaporator (70 °C/30 Torr) and then with an oil pump (160 °C/10^{-3} Torr); yield 1 g (98%). The degree of ^{18}O-enrichment was determined by ^{13}C NMR spectroscopy of a 0.5 M solution in D_2O containing 1 equiv. of NaOD to suppress oxygen exchange with the solvent D_2O. Four equidistantly separated signals ($\Delta\delta$ = 0.016 ppm) could be detected for the carbonate ion in an intensity ratio of 46:41:12:1 caused by $^{18}O_3$, $^{18}O_2{}^{16}O$, $^{18}O^{16}O_2$ and $^{16}O_3$ species.

Measurements of the dependence of the isotopic effect on the ^{13}C chemical shift of aqueous sodium carbonate are given in the Supporting Information. In addition to Figures 2 and 3 of the main text the full set of time-dependent intensity distributions of the $^{13}C^{16}O_{3-n}{}^{18}O_n{}^{2-}$ ions (n = 0−3) are presented as schematic diagrams. The rate constant for the addition of $CO_3{}^{2-}$ to CO_2 is estimated based on a linear relation between log k and pK_a.

Rearrangement of the Active Ester Intermediate During HOBt/EDC Amide Coupling

Khaled A. Mahmoud,[a] Yi-Tao Long,[a] Gabriele Schatte,[b] and Heinz-Bernhard Kraatz*[a]

Keywords: Ferrocene / Hydroxybenzotriazole / Amide coupling / Amino acid / Electrochemistry

3-{[1′-(*tert*-Butyloxycarbonylamino)ferrocen-1-yl]carbonyl}-benzotriazole 1-oxide (**3**) has been successfully separated during the synthesis of benzotriazol-1-yl 1′-(*tert*-butyloxycarbonylamino)ferrocene-1-carboxylate (**2**) as an active ester for peptide coupling. The yield of **3** increased by using polar, rather than nonpolar solvents. The two compounds have been fully characterized and studied by X-ray crystallography and spectroscopic methods. The active ester derivative 2 formed a urethane bond with the glycine ethyl ester while the *N*-oxide **3** did not react. The X-ray structural analysis of **3** shows strong intermolecular hydrogen bonding involving the urethane group and the *N*-oxide of an adjacent molecule [N–O···H–N = 2.859(2) Å]. No hydrogen bonding is present in the solid state for compound **2**, while solution studies indicate the presence of intramolecular hydrogen bonding. Both complexes display a quasi-reversible single one-electron oxidation, the halfwave potentials $E_{1/2}$ for **2** and **3** were 672 ± 5 and 591 ± 5 mV, respectively.

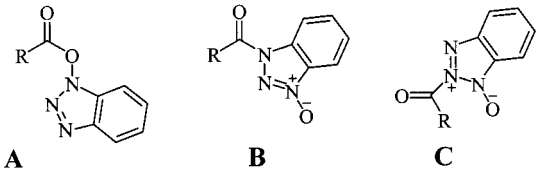
Introduction

1-Hydroxybenzotriazole (HOBt) is widely used in peptide synthesis as an activating agent for the acid component and for its ability to suppress racemization. The intermediate benzotriazole active ester **A** then reacts with an amino group to form the urethane bond.[1] The conversion of **A** into the *N*-oxide isomer **B** was reported.[2,3]



A **B** **C**

The *N*-oxide is favored in polar solvents, while the desired active ester **A** predominates in less-polar solvents.[4] It appears that the active ester **A** is the kinetic product, which is reactive towards rearrangement to the corresponding urethane form **B**.[5] In addition, Davies et al. proposed the intermediacy of isomer **C** to explain enhanced racemization rates for certain amino acid esters.[6] Formation of the *N*-oxide under mild conditions was reported by Lu and coworkers by reacting Os_3 clusters with HOBt.[7] ^{13}C NMR spectroscopy, used to identify the different isomers, confirmed the predominance of the active ester form **A** in DMSO,[8] while acetone stabilized the more polar zwitterionic *N*-oxide.[9] More recently, Carpino reported a detailed investigation into the reactivity of the guanidinium salts HBTU and HATU. It was shown that the *O*-substituted uronium salt is significantly more reactive in peptide coupling reactions than the *N*-substituted guanidinium salt.[10]

In the context of organometallic peptide conjugates, OBt-active esters provide a convenient route to labeling peptides under very mild conditions, which are also readily automated for solid-phase peptide synthesis (SPPS). This was shown by the use of benzotriazolyl ferrocenecarboxylate as a stoichiometric delivery reagent for the redox active ferrocene (Fc) group, or more recently by the use of one-pot reactions involving cobaltocenium carboxylic acid and TBTU and HATU.[11] Whether the active ester is used stoichiometrically or used as an intermediate in a one-pot reaction or during SPPS, there is the potential for lowered incorporation of the organometallic label due to different reaction kinetics. During the preparation and column separation of Fc-peptide conjugates, we along with other groups noticed the appearance of a red Fc-containing material, which also appears to possess an OBt substituent. However, it was not possible to properly identify this material. Given that the main role of OBt active ester intermediates is the preparation of organometallic peptide conjugates, we decided to investigate this in more detail. Here we describe our results of the study into the preparation of the OBt active ester **2** of 1′-(*tert*-butyloxycarbonylamino)ferro-

cene-1-carboxylic acid and its isomer 3-{[1′-(*tert*-butyloxycarbonylamino)ferrocen-1-yl]carbonyl}benzotriazole 1-oxide (**3**).

Results and Discussion

During the synthesis of the active ester **2**, from 1′-(*tert*-butyloxycarbonylamino)ferrocene-1-carboxylic acid (**1**), in the presence of HOBt and EDC, we prepared and isolated in addition to the desired product **2**, the zwitterionic *N*-oxide **3** (Scheme 1). We have no indication of the formation of the 2-ferrocenylated product.

The two forms are readily separated from each other by chromatography, giving **2** as an orange-red compound and compound **3** as a dark red crystalline compound. The experimental results show that the active ester **2** is the kinetic product, which undergoes rearrangement to the corresponding urethane form.[5] The rearrangement process is phase dependant; in dry dichloromethane the product **3** is obtained in 4% yield while in aqueous acetone the rearrangement is faster producing 11% yield of **3**. Although, we expected higher reactivity according to earlier reports,[10] the electron-withdrawing effect of the *N*-oxide group most likely deactivates **3** with respect to its reactivity with the amino acids. Thus, we did not observe any reactivity with glycine.

Compounds **2** and **3** were characterized by NMR spectroscopy ^{1}H, $^{13}C\{^{1}H\}$, DEPT-135 NMR, HMQC (Heteronuclear Multiple Quantum Correlation), and HMBC (Heteronuclear Multiple Bond Correlation). Table 1 summarizes the complete assignment of the NMR signals for compounds **2** and **3**. It is interesting to note that the signals due to H2, H5 and H2′, H5′ are observed at significantly different chemical shifts, indicating changes in the local environment due to the change in the substituent, which undoubtedly affects both C rings. Changes are also significant in the ^{13}C chemical shifts of the *ipso*-carbon atoms indicating that electronic differences due to the substituents are "seen" by the Fc system. C1 is affected more by the change from ester to amide *N*-oxide than C1′, the *ipso*-C to which the different substituent is attached. Comparing the chemical shifts for the proton H11 in **2** and **3**, this proton is particularly deshielded due to the proximity to the *N*-oxide group in **3**. The NH proton showed broad singlets at $\delta = 6.42$ and 5.75 ppm for **2** and **3**, respectively.

Both compounds exhibit a single broad absorbance in the visible region. For compound **2**, $\lambda_{max.} = 453$ nm, while for **3** the band is observed at $\lambda_{max.} = 484$ nm. This bathochromic shift clearly shows electronic coupling of the *N*-oxide OBt with the Fc group. Shifts were also observed for pyridine *N*-oxides (305−333 nm) and quinoline *N*-oxides (> 320 nm) with substituents that are in direct conjugation with the *N*-oxide group, and rationalized in terms of tautomer and resonance contributions. In quinoxaline di-*N*,*N*-oxide shifts are due to intramolecular charge transfer.[12]

The IR spectra of both compounds show two carbonyl bands. For compound **2** a band due to the active ester is observed at 1788 cm^{-1}. This band is absent in compound **3** and is replaced by an amide band at 1688 cm^{-1}. Both compounds exhibit a strong absorption around 1722 cm^{-1}, due to the carbamate carbonyl group on the other Cp ring.

these complexes are presented in Figures 1 and 2, respectively.

Compound **2** crystallizes in the polar orthorhombic space group $Pna2_1$ as a twinned racemic crystal, whereas compound **3** crystallizes in the monoclinic space group $P2_1/c$. In both complexes, the Cp rings are virtually parallel to each other [Cp−Fe−Cp angles: **2**: 2.1(3)°; **3:** 2.98(14)°]. The distances of the Fe atoms to the carbon atoms of the Cp rings are in the expected range in comparison to other ferrocene structures.[13]

For compound **2**, the bond lengths and angles of the Cp-ester-benzotriazole moiety are almost identical to those reported for Fc−CO−OBt.[14,15] The ester bond to the benzotriazole moiety in **2** is long [1.429(8) Å], as expected. The benzotriazole (Bt) substituent is rotated out of the ester plane by only 80.8(2)°, compared to 96.56(6)° in Fc−CO−OBt.[15] In the case of Fc−CO−OBt, this does not permit the efficient interaction between the two π-systems,[15] but increases reactivity of the carbonyl C atom towards external nucleophiles and therefore allows a faster reaction of the ester. A similar observation was made for (*S*)-3-(O^{γ}-methyl,N^{α}-triphenylmethylglutamyl)benzotriazole 1-oxide,[16] which bears the acyl and OBt groups on the same plane, resulting in a slower reactivity towards amines compared to the OBt active ester.[17] 3-(N^{α}-Tritylmethionyl)benzotriazole 1-oxide also exhibits the same structural features with coplanar OBt and acyl groups.[18] The geometry and conformation for a variety of ester and amide derivatives of HOBt and HOAt have been reported.[19,20] A more recent investigation into the reactivity of HATU showed that the *O*-substituted uronium salt is significantly more reactive in peptide coupling reactions than the *N*-substituted guanidinium salt,[10] in line with earlier investigations on OBt derivatives. In compound **3**, the planar OBt *N*-oxide, the urethane and the Cp ring to which it is attached are not coplanar [OBt *N*-oxide/Cp, 16.5(1)°; amide/Cp, 18.9(1)°]. Just like the parent benzotriazole-1-oxide and hydroxybenzotriazole, the heterocycle in compound **3** is essentially flat. In the *N*-oxide, the N−N bond lengths are shortened compared to hydroxybenzotriazole. For compound **3**, the N−N bond lengths in the heterocycle are non-equidistant. The distance between the N(O)−N are shorter and the distance N(12)−N(13) of 1.3084(19) Å indicates significant double bond character between the two nitrogen atoms. Similar observations were made have been made for (*S*)-3-(O^{γ}-methyl,N^{α}-triphenylmethylglutamyl)benzotriazole 1-oxide and 3-(N^{α}-tritylmethionyl)benzotriazole 1-oxide. As seen from Table 3, the urethane moieties in **2** and **3** are not coplanar with the Cp rings. The observed ω angle for **2** is close to the ideal value for a 1,2′ conformation (−72°), while **3** crystallizes in the 1,1′-conformation with $\omega = 13.3(8)°$.

atom attached to one of the nitrogen atoms of the Bt substituent, carrying a partial negative charge, and the amide proton in an adjacent molecule. The O(12)···N(21)* bond lengths of 2.859(2) Å indicates the presence of strong hydrogen bonding in the solid state.

The packing arrangements in **2** and **3** are very different (Figure 3). In compound **3**, the Fc groups are aligned with the NO groups of the Bt group in the adjacent molecules forming strands along the *c*-axis. In **2**, the molecules form a strand-like arrangement along the 2_1-axis with the Fc groups adjacent to each other.

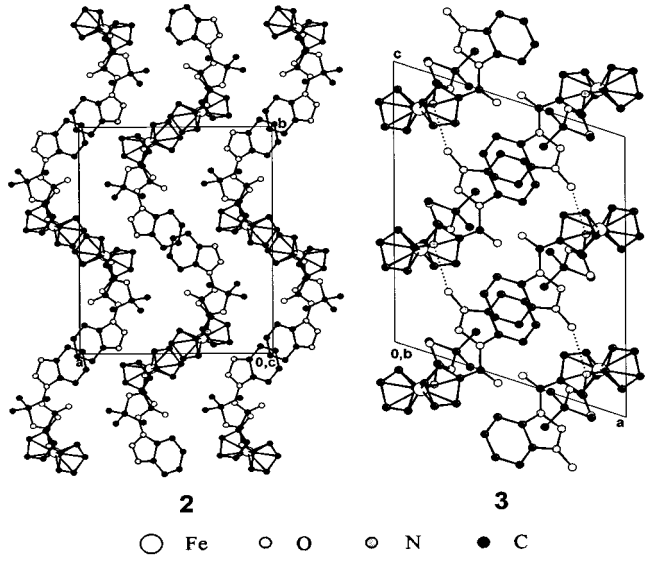

Figure 3. Packing diagrams for compounds **2** and **3**

Heinze recently[14] reported the structural properties of the acetylamino-analogue of compound **2**. In the solid state, the molecule displayed significant intramolecular hydrogen bonding. The Boc derivative **2** on the other hand, does not display any intramolecular hydrogen bonding involving the urethane NH group. Compound **3** on the other hand displays intermolecular hydrogen bonding in the solid state. This raises the question whether the presence of the Boc-

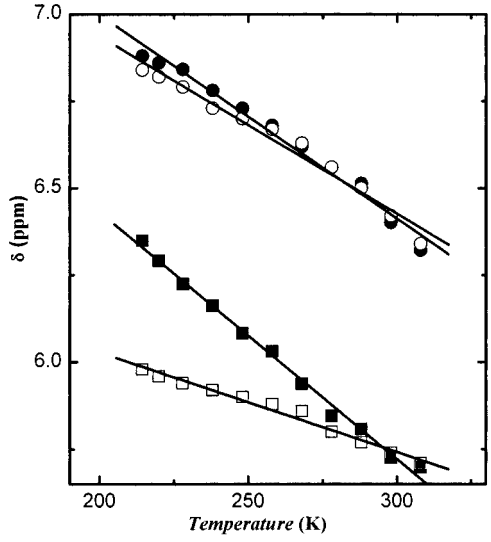

Figure 4. Temperature dependence of the chemical shifts for NH signals of compounds **2** (circles), **3** (squares) in $CDCl_3$ [open symbols indicate 1 mM; solid symbols indicate 50 mM]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protecting group can account for the differences in H-bonding behavior in the solid-state structures. Is the lack of intramolecular hydrogen bonding in compound **2** due to the spatial requirement of the bulky Boc carbamate group? In order to answer these questions, we decided to investigate the hydrogen-bonding behavior of compounds **2** and **3** in solution. Variable-temperature ^{1}H NMR studies of compounds **2** and **3**, recorded at 1 and 50 mM in $CDCl_3$ in the temperature range 215 and 308 K, showed a significant difference in the NH chemical shift between the two compounds with the temperature variation. A plot of $\Delta\delta$ versus T is shown in Figure 4. For compound **2**, the chemical shift of the amide NH was affected by temperature but the temperature dependence was independent of concentration (1 mM: -5.1 ppb K^{-1}; 50 mM: -6.4 ppb K^{-1}).

In contrast, compound **3** displayed a concentration dependent temperature behavior (1 mM: -2.8 ppb K^{-1}; 50 mM: -7.1 ppb K^{-1}), indicating the presence of intermolecular hydrogen bonding in compound **3** in solution. The temperature behavior of the NH chemical shift indicates the presence of intramolecular hydrogen bonding in compound **2** in solution.[11,21] However, the crystal structure does not show any hydrogen bonding, presumably as a result of crystal packing. Interestingly, the Cp protons in compound **2** undergo some temperature dependent changes, as is shown in Figure 5. The signals due to H2 and H5 in compound **2** are very broad at low temperatures (215−220 K) but appear at 228 K, and gradually sharpen. Heinze's Ac derivative displays a similar temperature behavior, which was interpreted as a possible interconversion between two ferrocenyl rotamers of the molecule. Our results suggest that a similar equilibrium may also exist for compound **2**. The Cp region of compound **3** does not change with temperature (Figure 6).

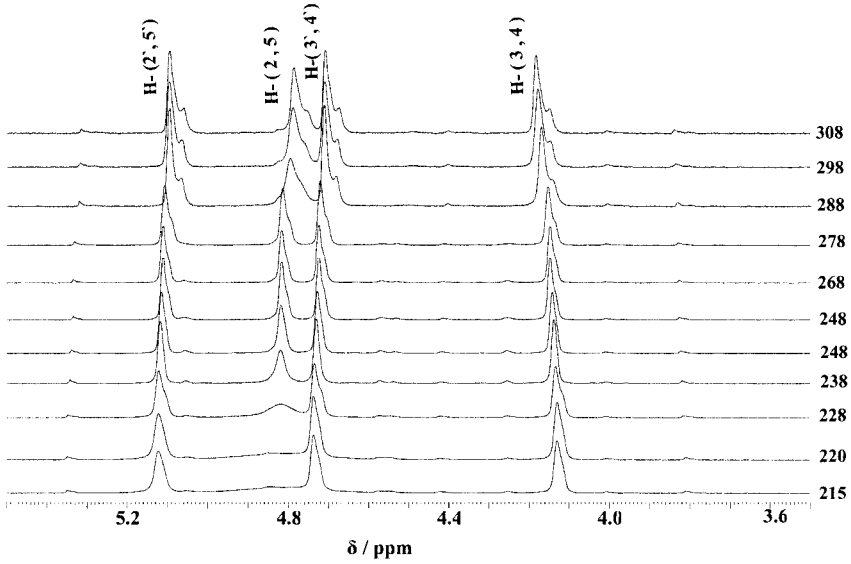

Figure 5. Variable temperature ^{1}H NMR spectra of **2** (50 mM, $CHCl_3$) in a region of 215−308 K

Figure 7 shows the electrochemical behavior of compounds **2** and **3**. Both compounds show a quasi-reversible single one-electron oxidation. The separation between oxidative and reductive peak potentials ΔE_p is about 96±5 mV for **2** (87±5 mV for **3**). The ratio of peak currents is close to unity for both compounds (**2**: $i_c/i_a = 1$; **3**: $i_c/i_a = 1.05$). As expected for *N*- and *O*-ferrocenylated systems, the halfwave potentials $E_{1/2}$ for **2** and **3** are significantly different. While $E_{1/2}$ = 672 ± 5 mV for the active ester **2**, the $E_{1/2}$ = 591 ± 5 mV for the *N*-oxide **3**.

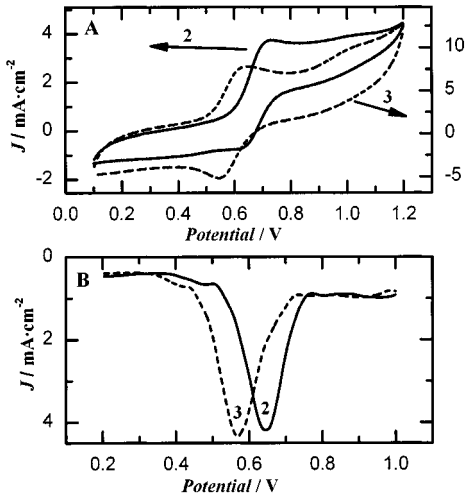

Figure 7. Electrochemical study of compounds **2** and **3** in CH_3CN/0.1 M TBAP: **A** shows the cyclic voltammetry at a scan rate of 100 mV/s (ΔE_p for the Fc/Fc^+ couple under identical conditions was 68 ±5 mV); **B** shows the differential pulse voltammetry at a scan rate 10 mV/s; for **2**: DPV, E_p = 643 ± 5 mV; for **3**, E_p = 566 ± 5 mV

Conclusion

In summary, we have prepared the two ferrocene−amino acid derivatives **2** and **3** and report their full characterization. Initially, compound **3** was obtained as a by-product in the preparation of the desired active ester. Reports on HATU active esters show this to be a common reaction in peptide synthesis. Importantly, this by-product was not reported in ferrocene chemistry. Given the importance of the Fc-OBt active ester intermediates in the preparation of Fc-bioconjugates and as a potential intermediate for the stepwise synthesis of ferrocenamide-based polymers, our finding is significant. Importantly, the reactivity towards peptide coupling is different. Whereas, the active ester derivative **2** undergoes amide bond formation with glycine ethyl ester and other amino acids and peptides,[22] the *N*-oxide **3** does not react. This is in contrast with earlier reports on the reactivity of HATU *N*-oxide derivatives, which were shown to undergo a slow conversion into the desired amide.

Experimental Section

General Procedure: The syntheses of 1′-(*tert*-butyloxycarbonylamino)ferrocene-1-carboxylic acid (**1**) was carried out using the published procedure.[23] All syntheses were carried out in air unless otherwise indicated. CH_2Cl_2 (BDH; ACS grade) used for synthesis was dried (CaH_2) and distilled prior to use. $CDCl_3$ (Aldrich) was dried (CaH_2), and stored over molecular sieves (8−12 mesh; 4 Å effective pore size; Fisher) before use. EDC·HCl, HOBt (Quantum), $MgSO_4$, and $NaHCO_3$ (VWR) were used as received. For column chromatography, a column with a width of 2.7 cm (ID) and a length of 45 cm was packed 18−22 cm high with 230−400 mesh silica gel (VWR). For TLC, aluminum plates coated with silica gel 60 F_{254} (EM Science) were used. NMR spectra were recorded with a Bruker Avance-500 spectrometer using a 5-mm broadband probe operating at 500.134 MHz (^1H) and 125.766 MHz ($^{13}C\{^1H\}$). Peak positions in both ^1H and ^{13}C spectra are reported in ppm relative to TMS. The ^1H NMR spectra are referenced to the residual $CHCl_3$ signal at δ 7.27. All $^{13}C\{^1H\}$ spectra are referenced to the $CDCl_3$ signal at δ = 77.23 ppm. Mass spectrometry was carried out with a VG Analytical 70/20 VSE instrument. Infrared spectra were obtained with a Perkin−Elmer model 1605 FT-IR.

Preparation of (Benzotriazol-1-yl) 1′-(*tert*-Butyloxycarbonylamino)-ferrocene-1-carboxylate (2) and 3-{[1′-(*tert*-Butyloxycarbonylamino)ferrocen-1-yl]carbonyl}benzotriazole 1-Oxide (3). Procedure A: Solid HOBt (4.05 mmol, 0.62 g) and EDC·HCl (4.05 mmol, 0.78 g) were added to a solution of 1′-(*tert*-butyloxycarbonyamino)-ferrocene-1-carboxylic acid (**1**) (3.68 mmol, 1.27 g) in CH_2Cl_2 (40 mL),. The reaction mixture was stirred at room temperature (20 °C) for 2 h and then treated with an aqueous solution of saturated $NaHCO_3$, citric acid (10%), and water. The organic phase was separated and dried with Na_2SO_4, and evaporated to dryness under reduced pressure. The crude product was purified by flash column chromatography (SiO_2, EthOAc/hexanes, 1:2) to give dark orange crystals of compound **2** (1.32 g, 78%) (R_f = 0.74), followed by red crystals of compound **3** (68 mg, 4%) (R_f = 0.42). **Procedure B:** The same mixture as described under **A** was stirred at room temperature for two hours in aqueous acetone (30 mL). The reaction mixture was dried under reduced pressure and redissolved in CH_2Cl_2. After the purification (vide supra), compounds **2** and **3** were obtained in yields of (1.15 g, 64%) and (180 mg, 11%), respectively.

Characterization of 2: FAB-MS (*m*/*z*): calcd. for $C_{22}H_{22}FeN_4O_4$ [M + 1]$^+$: 463.2; found 463.1. FT-IR (KBr (cm^{-1}): $\tilde{\nu}$ = 3322 (m, N−H), 1788, 1723 (s, C=O). [a] $R_1 = [\Sigma||F_o| - |F_c||]/[\Sigma|F_o|]$ for $[I > 2\sigma(I)]$. [b] $wR_2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)^2]\}^{1/2}$.

117.3, 115.7 (Ar Bt), 98.9 (C-1′, Fc), 80.5 [$C(CH_3)_3$], 74.8 (C-3 and C-4, Fc), 74.1 (C-2 and C-5, Fc), 71.6 (C-1, Fc), 67.0 (C-3′ and C-4′, Fc), 62.7 (C-2′ and C-5′, Fc), 28.5 [$C(CH_3)_3$] ppm.

Attempted Coupling of 3: A solution of H-Gly-OEt·HCl (0.24 mmol, 0.03 g) and Et_3N (0.4 mL) in dry CH_2Cl_2 (5 mL) was added to a stirring solution of **3** (0.22 mmol, 0.10 g) in dry CH_2Cl_2 (10 mL). The progress of the reaction was followed by TLC (EtOAc/hexanes/MeOH, 4:5:1). No product was observed after 24 h.

Electrochemical Measurements: The electrochemical experiments were carried out at room temperature using a CV-50 W voltammetric analyzer. A gold electrode (diameter 50 μm) was used as working electrode. 1 mM solutions of compounds **2** and **3** were prepared in 0.1 M tetrabutylammonium perchlorate (TBAP) solution in a CH_3CN. The measurements carried out at a low scan rate of 100, 10 mV/s for cyclic voltammetry (CV) and differential pulse voltammetry (DPV), respectively. A platinum wire (1 mm) was used as the counter electrode and a Ag/AgCl (BAS) was used a the reference electrode. The $E_{1/2}$ of the Fc/Fc^+ couple under the experimental conditions is 448(±5) mV (vs. Ag/AgCl).

X-ray Crystallography: Suitable crystals of compounds **2** (orange plate-like crystal; 0.15 × 0.15 × 0.10 mm) were obtained from an ether-layered solution of the compounds in chloroform, while **3** (dark red plate-like crystal; 0.25 × 0.20 × 0.13 mm) was obtained by slow evaporation from an ethyl acetate/hexane(3:1) solvent mixture. All measurements were made with a Nonius KappaCCD 4-Circle Kappa FR540C diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at −100 °C. An initial orientation matrix and cell was determined from 10 frames using φ scans.[24] Data were measured using φ- and ω-scans.[24] The data were processed using the standard Nonius software.[25] The structures were solved by direct methods (**2**: SIR-97; **3**: SHELXS-97)[26,27] and refined by full-matrix least-squares methods on F^2 with SHELXL-97−2.[28] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions (C−H bond lengths 0.95/0.99 Å; N−H bond lengths 0.88 Å) and were not refined. The isotropic thermal parameters of the hydrogen atoms were fixed at 1.2 times that of the preceding carbon or nitrogen atom. The carbon and oxygen atoms of one −C(O)O unit [labeled as C(15A), O(11A), O(12A), C(15B), O(11B), O(12B)] in **2** were disordered over two positions with site occupancy factors of 0.825(5) and 0.175(5). The refined absolute structure parameter [0.552(18)] for **2** was neither unity nor nil and was used as the scale parameter in the racemic twin refinement. The hydrogen atom at nitrogen atom N(21) in **3** was located from the Fourier difference map. Its coordinates were allowed to refine, whereas its isotropic thermal parameter was fixed at 1.2 times that of the preceding nitrogen atom. Data relating to the structure determination are presented in Table 4. CCDC-241248 (**2**), -236850 (**3**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Columnar Mesomorphism in Hexacatenar Tetrahedral (2,2′-Bipyridine)zinc Complexes and Homologous Palladium Derivatives

Giovanna Barberio,[a] Anna Bellusci,[a] Alessandra Crispini,[a] Mauro Ghedini,[a] Attilio Golemme,[a] Piotr Prus,[a] and Daniela Pucci*[a]

Keywords: Bipyridine ligands / Zinc / Palladium / Metallomesogens / Columnar structures

The synthesis and characterisation of novel liquid crystals which display columnar mesomorphism induced upon complexation of a series of nonmesomorphic hexacatenar 4,4′-disubstituted 2,2′-bipyridines (**L^n**) are reported. The introduction of different metal centres (Zn, Pd) causes the appearance of mesomorphism in all complexes regardless of the geometry around the metal ion. We therefore report the first examples of mesomorphism in tetrahedral zinc derivatives. The nature of the columnar phases is related to the self-assembly of the half-disc shaped [**L^{n}MCl$_2$**] (M = Zn, Pd) complexes into full disc-shaped supramolecules. The molecular organisation in the mesophase is mainly driven by intermolecular attractive interactions, as shown by the crystal structure of the model compound [**LPdCl$_2$**]. Preliminary measurements of photoconductivity have been performed on samples of [**L^{n}MCl$_2$**] complexes doped with C_{60} to increase absorption. Promising results were obtained.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The role of metal ions in the formation of molecular motifs and intermolecular interactions, which are unapproachable for organic liquid crystals and promote mesomorphism in nonmesogenic ligands, continues to make metallomesogens promising materials with novel and interesting properties.[1−6] In particular, the design of suitable metal-ligand combinations represents a challenge for obtaining new functional liquid crystalline materials by molecular self-assemblies.[7]

In this context, we recently reported[8] the synthesis of a series of nonmesomorphic dialkyl 2,2′-bipyridine-4,4′-dicarboxylates for which the complexation with various metal salts resulted in [(Bipy)MX$_2$] (M = Pd, Pt, Ni, Zn) species which self-assemble in dimers built up from attractive intermolecular interactions. This is described by the complementary shape approach.[9]

Due to the overall shape of the stacked units, these complexes exhibit lamellar mesomorphism which depends mostly on the geometry of the metal centre. In fact, the zinc homologues do not exhibit liquid crystalline properties due to their tetrahedral coordination. In continuation of our previous studies on the relationship between molecular structures, symmetry prerequisites and mesomorphism, we have been interested in the design of a further class of 4,4′-disubstituted 2,2′-bipyridines in order to induce, upon complexation, a molecular disc shape and columnar mesomorphism in the corresponding supramolecular metal aggregates. Moreover, since discotic liquid crystal systems have recently gained interest because of new applications in molecular electronics and optoelectronics,[10−12] we wanted to investigate if the design of supramolecular disc-like metallomesogens, with a long-range molecular order, would be advantageous for the enhancement of pre-selected properties such as charge transport or luminescence. The attractiveness of these systems is also demonstrated by the fact that during the preparation of the current article an apparently similar study was reported.[13] However, although the same methodology was used for inducing columnar mesophases in hemi-disc like complexes, Donnio et al. carried out their studies on terdentate ligands such as the 2,6-bis[3′,4′,5′-tri(alkoxy)phenyliminomethyl]pyridines and consequently the discrete building blocks show very different geometric features.

In the present work we report the synthesis of a series of hexacatenar 4,4′-disubstituted 2,2′-bipyridine ligands and related *cis*-dichloro zinc and palladium derivatives. The single-crystal X-ray structure of the palladium model complex [**LPdCl$_2$**] is also reported and discussed. The liquid crystalline properties of all [**L^{n}MCl$_2$**] (M = Zn, Pd) complexes which, in contrast to the free ligands, exhibit columnar mesomorphism are also described. It should be noted that rigid tetrahedral molecules usually seem to prevent mesophase formation[14] and the only examples of mesomorphic zinc derivatives to date exhibit either a trigonal-bipyramidal geometry with dithiobenzoate[1] or terpyridine

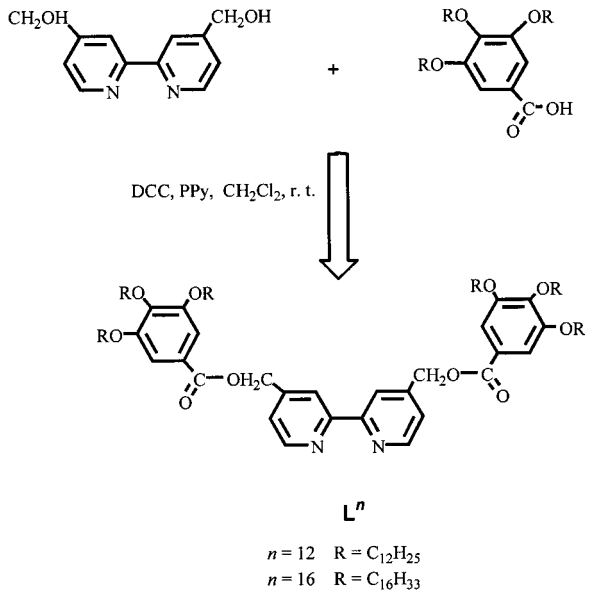
ligands[13,15] or a square-planar geometry when the metal centre is incorporated in a porphyrin or a phthalocyanine core.[1,16] Moreover, preliminary measurements of photoconductivity have been performed on samples of [$\mathbf{L^nMCl_2}$] doped with C_{60} to increase absorption. Promising results were obtained.

Results and Discussion

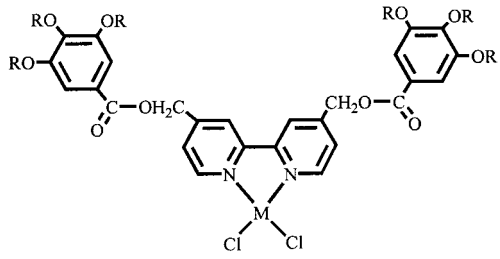
Synthesis and Characterisation

The hexacatenar $\mathbf{L^n}$ ligands (where n denotes the number of carbon atoms in the alkoxy chains) were prepared as white solids, in high yields, from the reaction of the 4,4′-bis(hydroxymethyl)-2,2′-bipyridine with the appropriate 3,4,5-trialkoxy-substituted benzoic acid using a DCC-PPY esterification (Scheme 1). The model ligand **L**, without the six alkoxy chains grafted on the peripherical phenyl rings, has been synthesised in an analogous manner by treating the 4,4′-bis(hydroxymethyl)-2,2′-bipyridine with benzoic acid.



Scheme 1. Synthetic route to the hexacatenar $\mathbf{L^n}$ ligands

The hexacatenar complexes [$\mathbf{L^nMCl_2}$] as well as the model complexes [$\mathbf{LMCl_2}$], were prepared by treatment of an equimolar amount of the appropriate ligand with $ZnCl_2$ (in dichloromethane at room temperature) or $[Pd(PhCN)_2Cl_2]$ (in chloroform at reflux), respectively.



[$\mathbf{L^nMCl_2}$]
M = Zn, Pd

The structures and purities of all the ligands and complexes were confirmed by IR and ^{1}H NMR spectroscopy and elemental analyses. In the ^{1}H NMR spectra of these complexes the H3 and H6 bipyridinic proton resonances shifted (by about 0.3 ppm) up and down field with respect to their organic precursors. These observations confirmed the coordination of the bipyridines to the metal fragments.

Single-Crystal X-ray Diffraction of [$\mathbf{LPdCl_2}$]

The [$\mathbf{LPdCl_2}$] complex was synthesised and then structurally characterised with the explicit intention of giving more insight into the molecular organisation in the 3D space of these new (2,2′-bipyridine)metal complexes in which the 4,4′-disubstituents are now different from the carboxylates with long alkyl chains already discussed in a previous paper.[8b] Moreover, in the absence of diffraction-quality crystals for any of the long-chain homologues, [$\mathbf{LPdCl_2}$] could be considered as a model compound and its molecular organisation taken as being representative for the discussion of the liquid-crystalline states of similar mesogenic complexes. The structure of [$\mathbf{LPdCl_2}$] is shown in Figure 1 and a selection of bond lengths and angles is reported in Table 1.

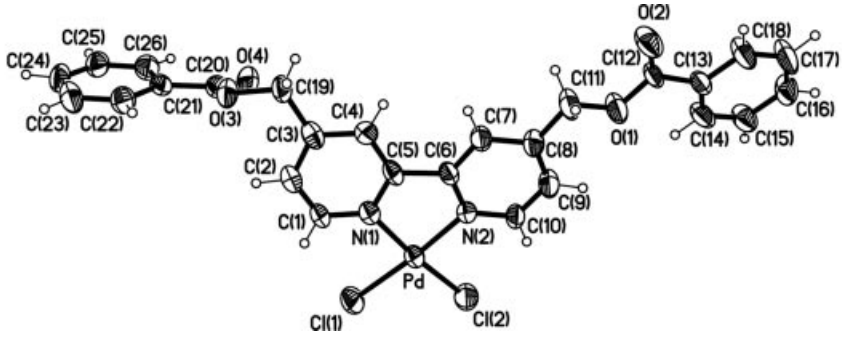


Figure 1. Molecular structure and atomic labelling scheme (50% probability thermal ellipsoids) of complex [$\mathbf{LPdCl_2}$]

Table 1. Selected bond lengths (Å) and angles (°) for complex **[LPdCl$_2$]**

Pd−N(1)	2.023(5)	Pd−N(2)	2.034(4)
Pd−Cl(1)	2.283(2)	Pd−Cl(2)	2.283(2)
N(1)−Pd−N(2)	80.9(2)	Cl(1)−Pd−Cl(2)	90.0(7)
N(1)−Pd−Cl(1)	94.0(1)	N(1)−Pd−Cl(2)	174.4(1)
N(2)−Pd−Cl(1)	174.9(2)	N(2)−Pd−Cl(2)	95.0(1)

The palladium atom has a distorted square-planar geometry and the bond lengths and angles around the metal ion and within the five-membered chelate ring are similar to those recently reported by us for the complex (dihexadecyl 2,2′-bipyridyl-4,4′-dicarboxylate)palladium(II) chloride.[8b] The two substituents on the 2,2′-bipyridine ligand run in opposite directions as shown by the dihedral angles C(4)−C(3)−C(19)−O(3) and C(7)−C(8)−C(11)−O(1) of 171.6(5) and −162.5(5)°, respectively. While the carboxylic oxygen atom O(2) points toward the internal part of the bipyridine ligand [C(12)−O(1)−C(11)−C(8) 180.0(5)°], O(4) shows a very different orientation [C(20)−O(3)−C(19)−C(3) −76.2(6)°]. The asymmetry in the conformation around the "CH_2−O" bond of the two substituents can be clarified by considering the crystal packing of molecules of the **[LPdCl$_2$]** complex.

The molecular organisation is dominated by intermolecular interactions of two main types: i) hydrogen bonds (C−H···O and "aromatic hydrogen bonds" C−H···π[17]) and ii) π−π contacts (Figure 2 a).

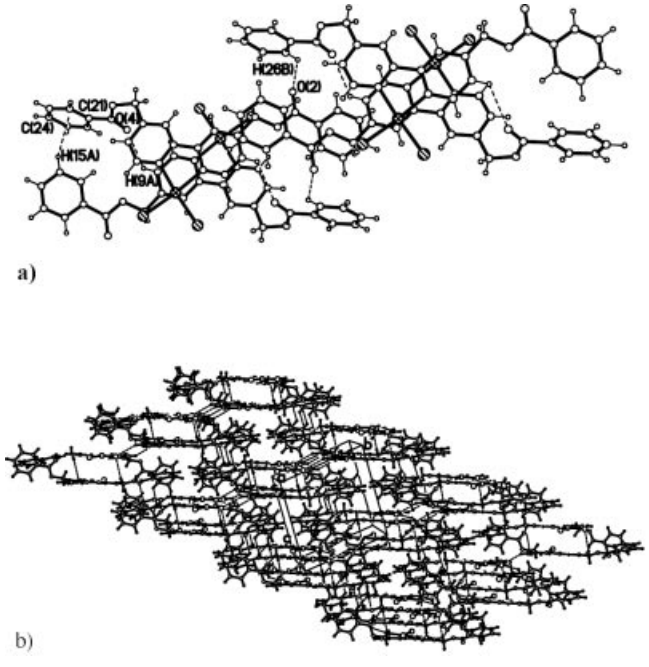

Figure 2. Ball and stick representation of interacting dimers of **[LPdCl$_2$]** viewed approximately down the *c* axis (top view) and repetition of dimers in 3D space with generation of a columnar arrangement (bottom view)

The association of molecules into dimers (superimposed approximately along the c axis) related by an inversion centre is characterised by the presence of hydrogen bonds between the carboxylic oxygen atoms and one of the pyridine hydrogen atoms [C(9a)···O(4) = 3.17(1) Å, H(9a)···O(4) 2.54(1) Å, C(9a)−H(9a)···O(4) 124.8(5)°, a = $-x$, $-y$, $-z$]. The reciprocal orientation of the C(21)/C(26) phenyl ring with respect to the centrosymmetric C(13)/C(18) ring with a dihedral angle of 66° is able to create an interesting intermolecular contact of the C−H/Ph type, for which the distance between H(15a) and the aromatic centroid X of the C(21)/C(26) ring (2.68 Å) and the C(15a)−H(15a)···X angle (147°) are indicative of the presence of a weak hydrogen C−H-π bond.[17] Moreover, the disposition of the pyridinic aromatic rings gives rise to a parallel displaced π−π stacking arrangement characterised by a centroid contact of 3.52 Å, an angle of 18° between the ring normal and the centroid vector and a corresponding horizontal displacement of 1.20 Å.[18] The M···M intermolecular separation of 5.6 Å within the dimer is significantly different from any weak Pd···Pd attractive interaction. The carboxylic oxygen atom O(2) which is not involved in any significant interaction within the dimer, assists in holding dimers together through the formation of hydrogen bonds with one of the hydrogen atoms of the peripheral phenyl rings (see a in Figure 2). In 3D space, the repetition of dimers which are stacked along the c direction and separated by layers of interacting aromatic rings (see b in Figure 2) is of particular interest in the discussion of the columnar organisation found for the analogous complexes **[L^{n}MCl$_2$]** with long alkoxy chains on the peripheral aromatic rings in the liquid crystalline state. Moreover, the absence of solvent molecules in the crystal packing enables us to view this molecular arrangement as a fingerprint for identification of future columnar liquid crystalline organisations.

Thermal Behaviour of [L^{n}MCl$_2$] Complexes

Although hexacatenar 2,2′-bipyridine ligands are not liquid crystals, all **[L^{n}MCl$_2$]** complexes show enantiotropic columnar mesomorphism which was investigated using polarised optical microscopy (POM), differential scanning calorimetry (DSC) and temperature dependent powder X-ray diffraction (PXRD) measurements. The thermal data of the **[L^{n}MCl$_2$]** series are summarised in Table 2.

For all **[L^{n}MCl$_2$]** complexes the results from POM suggested the presence of a columnar hexagonal mesophase, as indicated by the typical pseudo-focal-conics and areas of homeotropic orientation (Figure 3).

The dodecyloxy homologues feature two mesophases as shown by DSC and confirmed by subtle textural changes, such as the appearance in POM of fine disclination lines and deeper colours at the second order transition. This could indicate a transition between two hexagonal phases with different degrees of order within the columns. In the case of the palladium complexes, cooling from the isotropic liquid did not lead to crystallization but instead to solidification into a glassy state retaining the structure of the hexagonal mesophase.

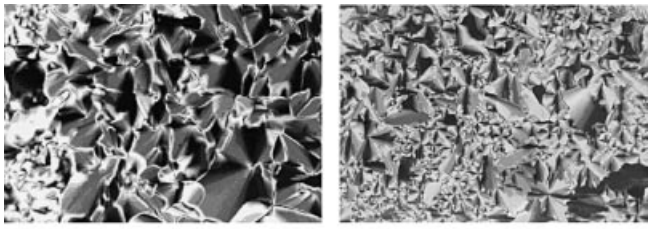

Plate 1 *Plate 2*

Figure 3. Polarised light optical photomicrograph of the texture exhibited by [L^nMCl_2] complexes; plate 1: texture of the hexagonal columnar mesophase of [$L^{12}ZnCl_2$] at 128 °C; plate 2: texture of the hexagonal columnar mesophase Col_{hd1} of [$L^{12}PdCl_2$] at 135 °C

The mesophases were also identified by temperature-dependent powder-XRD experiments. The X-ray diffraction patterns confirmed the results of optical microscopy. In all cases, in the small angle region a sharp high intensity peak and two lower intensity peaks at wider angles were indexed to the (1 0), (1 1) and (2 0) reflections. This is typical of a 2D hexagonal lattice (Table 3).

Moreover, in the case of [L^nMCl_2], a transition between hexagonal phases was observed. As shown in Figure 4 for [$L^{12}ZnCl_2$], in the wide angle region of the XRD spectrum recorded at 90 °C, the pattern consists of a broad diffuse scattering halo (B in Figure 4) at ca. 4.6 Å, corresponding to the liquid-like disorder of the aliphatic chains. Also observed was another broad diffuse band (C in Figure 4) at ca. 4.1 Å which is characteristic of the distance between adjacent cores (also definable as the stacking period in a column)[19] and, finally, a third less intense broad band (A in Figure 4) at ca. 8 Å possibly indicating a perpendicular stacking of the hemi-disc shaped molecules which is necessary to produce a disc-shaped dimer for the formation of the columnar phase.[20]

The proposed model of organisation in the hexagonal phase is in accordance with the calculated number of molecules in the cross section of the columns. This value, which was found to be around 2, was estimated by assuming a density of 1 g·cm^{-3} and a height for the columnar slice of 4.1 or 4.7 Å for M = Zn and 3.8 or 4.6 Å for M = Pd (Table 3). The transition Col_{h1} − Col_{h2} is accompanied by a decrease in the hexagonal lattice constant and a loss of the broad diffuse band centred at 4.1 or 3.8 Å (Table 3). These differences may characterise Col_{h2} as a more disordered hexagonal phase than Col_{h1}. Within the temperature range in which the first hexagonal phase may be observed, the lattice parameter was found to be temperature dependent. In fact, the low angle reflection shifted to a larger d spacing with decreasing temperature indicating a lattice expansion.[21]

A further increase in the number of carbon atoms in the side chains was not accompanied by any change of sym-

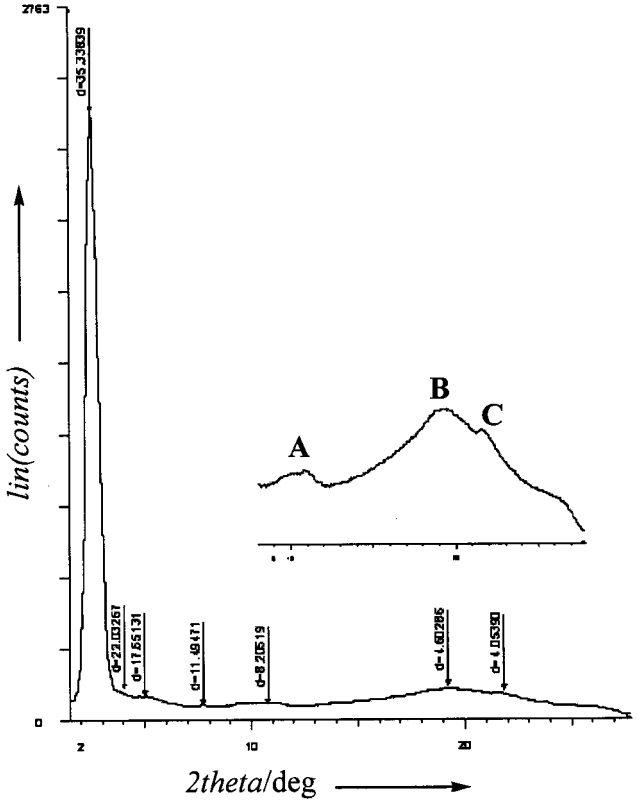

Figure 4. Powder X-ray diffraction pattern of the columnar hexagonal phase (Col_{h1}) at 90 °C for complex [$\mathbf{L^{12}ZnCl_2}$]

metry but a significant difference of the lattice parameter between [$\mathbf{L^{16}ZnCl_2}$] and [$\mathbf{L^{16}PdCl_2}$] was observed (Table 3). In fact, the noteworthy increase of *a* from 42.7 to 50.6 Å on going from the Zn^{II} to the Pd^{II} derivative is indicative of an increase of the size of the disk formed by the association of two molecules into a dimeric unit. At this particular length of the side chains, the geometry around the metal ion clearly plays an important role in the association of molecules into dimers. The flatness of the molecules in the case of the square planar Pd^{II} complex compared with the distorted tetrahedral Zn^{II} derivative encourages close proximity between the cores within the dimer (broad diffuse band in the XRD spectra at ca. 3.6 Å which corresponds to the distance between adjacent cores). In consequence, a larger horizontal displacement and an overall rise of the radius of the disk can be observed.

In both cases, a slight change of the position of the first peak in the low angle region was observed on increasing the temperature. A corresponding decrease in the intecolumnar distance to less than 1 Å was also observed. This slow change corresponds to a very low enthalpy (3.3 and 0.6 kJ/mol) and the absence of important optical textural changes.

Photoconductivity Measurements

Because of the incremental charge mobility induced by molecular self-assembling,[12] columnar mesophases have recently become attractive for their potential applications in organic photovoltaic and electroluminescent devices in which high conduction is required. In order to probe the effectiveness of our materials as photoconductors, we selected the longer chain length palladium and zinc derivatives and performed standard measurements as described in the Exp. Sect. Since pure samples show no absorption in the visible region, photogeneration was induced by doping with a small amount (0.05%) of C_{60} which is known as a good acceptor thereby promoting the formation of hole carriers. Phase transitions were not affected by the small amount of this dopant. Within our cells, it was not possible to obtain a homogeneous alignment of the mesophases using standard techniques and all the measurements were performed on unaligned samples. Figure 5 shows the ratio of the light and dark conductivities for [$\mathbf{L^{16}PdCl_2}$] at 633 nm over a temperature range which incorporates solid, columnar and isotropic phases.

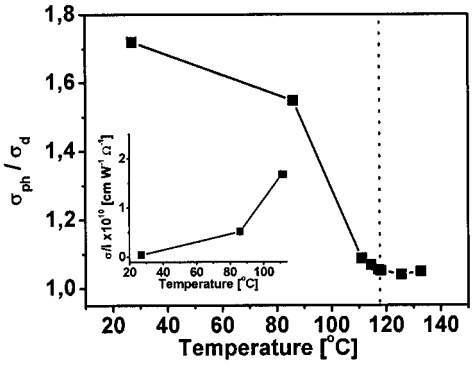

Figure 5. Ratio between the photoconductivity σ_{ph} and the conductivity in the dark σ_d for a 40 μm thick sample of complex [$\mathbf{L^{16}PdCl_2}$] doped with C_{60} as a function of temperature; the vertical line marks the I − Col_h transition; inset: normalised photoconduction measured as a function of temperature for the same sample; data were collected in an applied field of 8 V/μm and a wavelength λ = 633 nm

It is clearly visible that with decreasing temperature such a ratio starts to increase at the I-Col_h transition and keeps increasing upon further decreases in temperature. This is a signature of the reduced contribution of ionic (impurities) conduction at low temperatures compared with the contribution of electron (hole) hopping. The temperature dependence of the photoconductivity, normalised to the power density of the incident radiation, is shown in the inset of Figure 5, while its applied field dependence is shown in Figure 6. A proper comparison of conductivity with similar compounds would require mobility measurements which have not been yet carried out. Nevertheless, although the ratio of photo-conductivity to dark-conductivity is rather low, the measured values of the absolute photoconductivity are quite good, especially considering that the absorption coefficient for these samples at 633 nm is rather low ($\alpha \approx 16\ cm^{-1}$) and that for the relatively low values of the applied fields used, the photogeneration quantum efficiency should also be low.

The data in Figure 6 in fact show photoconductivity which is orders of magnitude higher than that measured for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

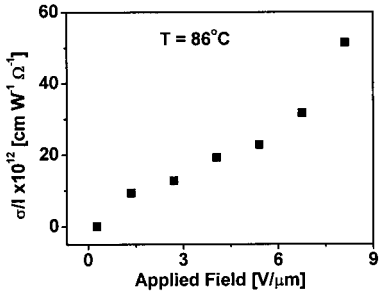

Figure 6. Normalised photoconduction at $\lambda = 633$ nm measured as a function of applied field for complex [$\mathbf{L^{16}PdCl_2}$] doped with C_{60}

standard photoconductors such as polyvinylcarbazole at the same applied field and with the same absorption coefficients. As a consequence, these results indicate that charge mobility in [$\mathbf{L^{16}PdCl_2}$] could be high and measurements are in progress to confirm this hypothesis. In the case of the related [$\mathbf{L^{16}ZnCl_2}$] complex, the measured photoconductivity is about two orders of magnitude lower. Since the measurements are in a preliminary stage, it is not possible at the moment to rationalise this behaviour.

Conclusions

A series of hexacatenar 4,4′-disubstituted 2,2′-bipyridines (**L″**) and the corresponding zinc(II) and palladium(II) complexes [$\mathbf{L''MCl_2}$] have been synthesised and characterised. Although the ligands are not mesomorphic, the association of the hemi-disc shaped molecules in face-to-face disc-shaped dimers induces columnar mesogenic properties for all the metal derivatives, regardless of the nature of metal atom. In fact, liquid crystal properties were also induced for the first time on tetrahedrally coordinated zinc complexes while for the palladium derivatives [$\mathbf{L''PdCl_2}$], the lamellar mesophases observed in dialkyl 2,2′-bipyridine-4,4′-dicarboxylate compounds[8a] are replaced by hexagonal columnar mesomorphism. Hence, it can be suggested that for all the new [$\mathbf{L''MCl_2}$] complexes in which the organic parts of the molecules have been modified through the introduction of further aromatic rings, the driving force in producing a supramolecular columnar arrangement is the existence of intermolecular interactions (hydrogen bonds, C−H−π and π−π contacts) between the large flat aromatic cores rather than dipolar or metal-metal interactions. The analysis of the crystal packing in the solid state of the model compound [$\mathbf{LPdCl_2}$] has given excellent insight into the future arrangements of the mesophases of the corresponding long chain derivatives, at least as far as the polar fragments of the molecules are concerned. The presence of long alkoxy chains in the [$\mathbf{L''MCl_2}$] derivatives gives rise to mesomorphism without interfering with the promesogenic columnar arrangement of the aromatic cores of the molecules.

Moreover, the thermal behaviour in each series was found to be insensitive to the nature of the metal atom and slightly decreases in the order Zn < Pd. This can be correlated with the overall supramolecular organisation rather than with the segregation effects of the simple molecular units.

These results show that by a careful choice of molecular building blocks, it is possible to finely modulate the interactions which determine the organisation of single molecules (association into dimers) in supramolecular architectures, giving rise to the desired functionalised metallomesogenic materials. For this class of derivatives, our goal was the design of metal-containing columnar liquid crystals in which the pre-selected property for improvement was the charge carrier mobility for charge transport. Preliminary measurements of photoconductivity, in samples of [$\mathbf{L''MCl_2}$] complexes doped with C_{60} to increase absorption in the visible, have given excellent results and further experiments are in progress.

Experimental Section

Materials and Measurements: All reagents were purchased from the following and used as received: 4,4′-Dimethyl-2,2′-bipyridine, benzoic acid, 1-bromododecane, 1-bromohexadecane, zinc chloride, 4-pyrrolidinopyridine (PPY) from Aldrich, methyl 3,4,5-trihydroxybenzoate from Lancaster and *N*,*N*′-dicyclohexylcarbodiimide (DCC) from Fluka. The solvents were used as received from commercial sources without further purification and were dried using standard methods when required. *cis*-Bis(benzonitrile)dichloropalladium,[22] 4,4′-bis(hydroxymethyl)-2,2′-bipyridine[23] and 3,4,5-trialkoxybenzoic acids[24] were prepared with slight changes following the methods described in the literature. Infrared spectra were recorded with a Spectrum One FT-IR Perkin−Elmer spectrometer and ^{1}H NMR spectra with a Bruker WH-300 spectrometer in [D_6]DMSO, $CDCl_3$ or CD_3OD with TMS as an internal standard. Elemental analyses were performed with a Perkin−Elmer 2400 analyser. The textures of the mesophases were examined with a Zeiss Axioscope polarising microscope equipped with a Linkam CO 600 heating stage. The transition temperatures and enthalpies were measured on a Perkin−Elmer Pyris1 Differential Scanning Calorimeter with a heating and cooling rate of 10 °C/min. The apparatus was calibrated with indium. Two or more heating/cooling cycles were performed on each sample. Spectrofluorimetric grade dichloromethane (Acros Organics) was used for the photophysical investigations in solution at room temperature. Absorption spectra were recorded with a Perkin−Elmer Lambda 900 spectrophotometer. The experimental uncertainty of the band maximum for the absorption spectra was 2 nm. The ligands and the complexes are stable in CH_2Cl_2 as demonstrated by the constancy of their absorption spectra over a week. The powder X-ray diffraction patterns were obtained using a Bruker AXS General Area Detector Diffraction System (D8 Discover with GADDS) with Cu-K_α radiation. The highly sensitive area detector was placed at a distance of 10 cm from the sample and equipped with a CalCTec (Italy) heating stage. The samples were heated at a rate of 5.0 °C min^{-1} to the appropriate temperature. Measurements were performed by placing samples in Lindemann capillary tubes with an inner diameter of 0.05 mm. Samples for photoconductivity measurements were prepared by mixing the complex [$\mathbf{L^{16}MCl_2}$] and 0.05% C_{60} in toluene and then evaporating the solvent. The resultant material was then transferred between two ITO-covered conducting glass slides by using the effect of capillarity within the isotropic phase. The thickness was controlled with glass spacers. The conductivity was measured by monitoring the voltage drop across a resistor in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

series with the sample cell. For temperature dependent measurements, a CalCTec (Italy) hot stage was used. For photoconductivity observations, an approximately 10^{-2} cm^2 sample was illuminated with 5 mW of light from a He-Ne laser at 633 nm.

X-ray Crystallographic Data Collection and Refinement of the [LPdCl$_2$] Structure: Orange crystals of [**LPdCl$_2$**] were formed at room temperature from a DMSO/ethanol mixture. Diffraction measurements were carried out at room temperature on a Siemens *R*3*m*/*V* automated four-circle diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The data were corrected for Lorentz, polarisation and X-ray absorption effects using the XABS2 program.[25] Details of the crystal data collection are listed in Table 4. Structure solution (Patterson method) and full-matrix least-squares refinements based on F^2 were performed with the SHELXS/L programs of the SHELXTL-NT software package (Version 5.10).[26] All nonhydrogen atoms were refined anisotropically. The hydrogen atoms were included in the refinement in their observed positions and then fixed as idealised atoms riding on the respective carbon atom. CCDC-241996 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis

Model Ligand: 4,4′-Bis(benzoyloxymethyl)-2,2′-bipyridine (L): 4,4′-Bis(hydroxymethyl)-2,2′-bipyridine (0.099 mg, 0.46 mmol), benzoic acid (0.112 g, 0.92 mmol) and DCC (0.208 g, 1.01 mmol) were suspended in dry dichloromethane (20 mL). PPY (0.013 g, 0.09 mmol) was added and the reaction was stirred at room temperature and under N_2 for a week. The colourless precipitate was removed by filtration and the solvent was evaporated. The crude product was recrystallised from chloroform/methanol giving a colourless solid. Yield 0.161 g (82%); m.p. 179 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 5.47 (s, 4 H, CH_2), 7.49 (m, 2 H, CH), 7.58 (m, 4 H, CH), 7.61 (m, 4 H, CH), 8.13 (dd, $^3J_{H,H}$ = 8.5, $^4J_{H,H}$ = 2.4 Hz, 2 H, H-5 bpy), 8.48 (s, 2 H, H-3 bpy), 8.70 (d, $^3J_{H,H}$ = 8.5 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1723 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, mol^{-1}·dm^3·cm^{-1}) = 282 nm (17800). $C_{26}H_{20}N_2O_4$ (424.46): calcd. C 73.57, H 4.57, N 6.60; found C 73.44, H 4.62, N 6.76. All **L^n** ligands were prepared similarly starting from 4,4′-bis(hydroxymethyl)-2,2′-bipyridine and the appropriate 3,4,5-trialkoxy-substituted benzoic acid. Therefore only yields, melting points, ^{1}H NMR data, IR data and elemental analyses are reported below.

4,4′-Bis[3,4,5-(tridodecyloxy)benzoyloxymethyl]-2,2′-bipyridine (L^{12}): Yield 0.62 g (78%); m.p. 73 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.88 (t, $^3J_{H,H}$ = 6.6 Hz, 18 H, CH_3), 1.26 [m, 108 H, $(CH_2)_5CH_3$], 1.78 [m, 12 H, $CH_2(CH_2)_5CH_3$], 4.03 (t, $^3J_{H,H}$ = 6.3 Hz, 12 H, OCH_2), 5.44 (s, 4 H, CH_2), 7.33 (s, 4 H, CH), 7.37 (d, $^3J_{H,H}$ = 4.7 Hz, 2 H, H-5 bpy), 8.49 (s, 2 H, H-3 bpy), 8.67 (d, $^3J_{H,H}$ = 4.7 Hz 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1720 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, mol^{-1}·dm^3·cm^{-1}) = 277 nm (39100). $C_{98}H_{164}N_2O_{10}$ (1530.39): calcd. C 76.91, H 10.80, N 1.83; found C 76.72, H 11.00, N 2.01.

4,4′-Bis[3,4,5-(trihexadecyloxy)benzoyloxymethyl]-2,2′-bipyridine (L^{16}): Yield 0.35 g (63%); m.p. 90 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = (t, $^3J_{H,H}$ = 6.6 Hz, 18 H, CH_3), 1.25 [m, 156 H, $(CH_2)_5CH_3$], 1.77 [m, 12 H, $CH_2(CH_2)_5CH_3$], 4.02 (m, 12 H, OCH_2), 5.44 (s, 4 H, CH_2), 7.33 (s, 4 H, CH), 7.37 (d, $^3J_{H,H}$ = 5.0 Hz, 2 H, H-5 bpy), 8.49 (s, 2 H, H-3 bpy), 8.68 (d, $^3J_{H,H}$ = 5.0 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1704 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, mol^{-1}·dm^3·cm^{-1}) = 278 nm (88700). $C_{122}H_{212}N_2O_{10}$ (1867.02): calcd. C 78.48, H 11.44, N 1.50; found C 78.55, H 11.50, N 1.70.

Zinc Complexes: All zinc complexes were prepared in a similar manner. The synthesis of [**LZnCl$_2$**] is described in detail below and for all other homologues only yields, ^{1}H NMR and IR data and elemental analyses are reported.

[4,4′-Bis(benzoyloxymethyl) 2,2′-bipyridyl]zinc(II) Chloride [LZnCl$_2$]: A suspension of $ZnCl_2$ (0.013 g, 0.094 mmol) and **L** (0.040 g, 0.094 mmol) in dichloromethane (10 mL) was stirred at room temperature for four days. By filtration through Celite and evaporation the final product was obtained as a colourless solid after recrystallisation from methanol. Yield 0.37 g (70%); m.p. 260 °C. ^{1}H NMR (300 MHz, CD_3OD, 25 °C, TMS): δ = 5.61 (s, 4 H, CH_2), 7.51 (m, 4 H, CH), 7.65 (m, 2 H, CH), 7.83 (m, 4 H, CH), 8.12 (d, $^3J_{H,H}$ = 7.3 Hz, 2 H, H-5 bpy), 8.75−8.68 (m, 4 H, H-3,6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1720 cm^{-1} (C=O). $C_{26}H_{20}Cl_2N_2O_4Zn$ (560.74): calcd. C 55.69, H 3.60, N 5.00; found C 55.48, H 3.58, N 4.74.

{4,4′-Bis[3,4,5-tridodecyloxy)benzoyloxymethyl]-2,2′-bipyridyl}-zinc(II) Chloride [L^{12}ZnCl$_2$]: Recrystallisation from dichloromethane/diethyl ether. Yield 0.160 g (86%); thermotropic behaviour in Table 2. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.88 (t, $^3J_{H,H}$ = 6.4 Hz, 18 H, CH_3), 1.26 [m, 108 H, $(CH_2)_5CH_3$], 1.79 [m, 12 H, $CH_2(CH_2)_5CH_3$], 4.03 (m, 12 H, OCH_2), 5.52 (s, 4 H, CH_2), 7.29 (s, 4 H, CH), 7.78 (d, $^3J_{H,H}$ = 5.3 Hz, 2 H, H-5 bpy), 8.24 (s, 2 H, H-3 bpy), 8.85 (d, $^3J_{H,H}$ = 5.3 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1718 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, mol^{-1}·dm^3·cm^{-1}) = 282 (30500), 297 (31400), 307 nm (27700). $C_{98}H_{164}Cl_2N_2O_{10}Zn$ (1666.67): calcd. C 70.62, H 9.92, N 1.68; found C 70.31, H 9.63, N 1.90.

{4,4′-Bis(3,4,5-tris[hexadecyloxy)benzoyloxymethyl]-2,2′-bipyridyl}-zinc(II) Chloride [$L^{16}ZnCl_2$]: Recrystallisation by chloroform/acetone. Yield 0.12 g (91%); thermotropic behaviour in Table 2. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.87 (t, $^3J_{H,H}$ = 6.7 Hz, 18 H, CH_3), 1.25 [m, 156 H, $(CH_2)_5CH_3$], 1.80 [m, 12 H, $CH_2(CH_2)_5CH_3$], 4.03 (m, 12 H, OCH_2), 5.52 (s, 4 H, CH_2), 7.28 (s, 4 H, CH), 7.77 (d, $^3J_{H,H}$ = 5.1 Hz, 2 H, H-5 bpy), 8.24 (s, 2 H, H-3 bpy), 8.86 (d, $^3J_{H,H}$ = 5.1 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1720 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, $mol^{-1}\cdot dm^3\cdot cm^{-1}$) = 282 (25600), 296 (27400), 307 nm (24600). $C_{122}H_{212}Cl_2N_2O_{10}Zn$ (2003.32): calcd. C 73.15, H 10.67, N 1.40; found C 73.38, H 10.90, N 1.48.

Palladium Complexes: All palladium complexes were prepared in a similar manner. The synthesis of **[$LPdCl_2$]** is described in detail below. For all other homologues only yields, ^{1}H NMR and IR data and elemental analyses are reported.

[4,4′-Bis(benzoyloxymethyl)-2,2′-bipyridyl]palladium(II) Chloride [$LPdCl_2$]: A solution of $[Pd(PhCN)_2Cl_2]$ (0.045 g, 0.12 mmol) and **L** (0.20 g, 0.17 mmol) in chloroform (10 mL) was heated to reflux for 7 h. Filtration and washing with methanol gave the final product as a pale yellow solid. Yield 0.08 g (80%); m.p. 322 °C. ^{1}H NMR (300 MHz, [D$_6$]DMSO, 25 °C, TMS): δ = 5.59 (s, 4 H, CH_2), 7.56 (m, 4 H, CH), 7.70 (m, 2 H, CH), 7.90 (d, 4 H, CH), 8.105 (dd, $^3J_{H,H}$ = 6.85, $^4J_{H,H}$ = 1.4 Hz, 2 H, H-5 bpy), 8.68 (s, 2 H, H-3 bpy), 9.075 (d, $^3J_{H,H}$ = 6.85 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1720 cm^{-1} (C=O). $C_{26}H_{20}Cl_2N_2O_4Pd$ (601.78): calcd. C 51.89, H 3.35, N 4.66; found C 51.63, H 3.35, N 4.62.

{4,4′-Bis[3,4,5-tri(dodecyloxy)benzoyloxymethyl]-2,2′-bipyridyl}-palladium(II) Chloride [$L^{12}PdCl_2$]: Recrystallisation from chloroform/methanol. Yield 0.21 g (93%); thermotropic behaviour in Table 2. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.87 (m, 18 H, CH_3), 1.26 (m, 108 H, $(CH_2)_5CH_3$], 1.78 (m, 12 H, $CH_2(CH_2)_5CH_3$], 4.02 (m, 12 H, OCH_2), 5.52 (s, 4 H, CH_2), 7.29 (s, 4 H, CH), 7.48 (d, $^3J_{H,H}$ = 5.2 Hz, 2 H, H-5 bpy), 8.18 (s, 2 H, H-3 bpy), 9.10 (d, $^3J_{H,H}$ = 5.2 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1723 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, $mol^{-1}\cdot dm^3\cdot cm^{-1}$) = 268 (36600), 304 (24700) 314 nm (23000). $C_{98}H_{164}Cl_2N_2O_{10}Pd$ (1707.71): calcd. C 68.93, H 9.68, N 1.64; found C 69.15, H 9.50, N 1.37.

{4,4′-Bis[3,4,5-tri(hexadecyloxy)benzoyloxymethyl]-2,2′-bipyridyl}-palladium(II) Chloride [$L^{16}PdCl_2$]: Yield 0.20 g (91%); thermotropic behaviour in Table 2. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.87 (t, $^3J_{H,H}$ = 6.5 Hz, 18 H, CH_3), 1.25 [m, 156 H, $(CH_2)_5CH_3$], 1.78 [m, 12 H, $CH_2(CH_2)_5CH_3$], 4.02 (m, 12 H, OCH_2), 5.52 (s, 4 H, CH_2), 7.29 (s, 4 H, CH), 7.49 (d, $^3J_{H,H}$ = 5.8 Hz, 2 H, H-5 bpy), 8.16 (s, 2 H, H-3 bpy), 9.11 (d, $^3J_{H,H}$ = 5.8 Hz, 2 H, H-6 bpy) ppm. IR (KBr): $\tilde{\nu}$ = 1721 cm^{-1} (C=O). UV/Vis (dichloromethane): $\lambda_{max.}$ (ε, $mol^{-1}\cdot dm^3\cdot cm^{-1}$) = 268 (43900), 304 (26400), 314 nm (22800). $C_{122}H_{212}Cl_2N_2O_{10}Pd$ (2044.35): calcd. C 71.68, H 10.45, N 1.37; found C 71.83, H 10.22, N 1.65.

Cu^{II} and Zn^{II} Coordination Chemistry of Pyrazole-Containing Polyamine Receptors − Influence of the Hydrocarbon Side Chain Length on the Metal Coordination

Carlos Miranda,[a] Francisco Escartí,[b] Laurent Lamarque,[a] Enrique García-España,*[b] Pilar Navarro,*[a] Julio Latorre,[b] Francisco Lloret,[b] Hermás R. Jiménez,[b] and María J. R. Yunta[c]

Dedicated to Prof. Dr. José Elguero

Keywords: Pyrazole macrocycles / Copper and zinc coordination / Acid-base and metal formation equilibria / Polyamine ligands / Paramagnetic NMR

The synthesis of a new macrocyclic receptor (**L⁴**) containing two 3,5-dimethylpyrazole units connected by dipropylenetriamine bridges is reported for the first time; pH-metric titrations indicate that **L⁴** shows six protonation steps in the pH range 2–11. In the absence of metal ions, the pyrazole moieties are not involved in acid-base processes in this pH range. Addition of Cu^{II} and Zn^{II} results in deprotonation of the pyrazole moieties which act as bis(monodentate) η^1:η^1 ligands. This induced deprotonation occurs at higher pH values than in the complexes of the analogous ligand containing diethylenetriamine bridges (**L¹**). The crystal structures of $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ and $[Zn_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ obtained by treatment of $Na_2[H_{-2}\mathbf{L^4}]$ with either $Cu(ClO_4)_2{\cdot}6H_2O$ or $Zn(ClO_4)_2{\cdot}6H_2O$ in methanol followed by recrystallisation from water/methanol also show the deprotonation of the pyrazole moieties. The coordination geometry around each metal ion is square-pyramidal and involves all nitrogen atoms of the macrocycle. The crystal structure of $[Zn_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ shows full involvement of all the nitrogen atoms of the macrocycle in the coordination to the metal ions. The coordination geometry can be defined as midway between a square pyramid and an irregular trigonal bipyramid. Treatment of neutral **L⁴** in methanol with $Cu(ClO_4)_2{\cdot}6H_2O$ yields a blue complex which, after heating in boiling water, crystallises as a red compound. Elemental microanalyses, ESI-MS and FAB-MS data of both forms of this complex are consistent with the formula $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$. Furthermore, these data along with the paramagnetic ^1H NMR spectrum of the red form of the compound suggest a structure in which the pyrazole rings are deprotonated while the central nitrogen atoms of the bridging chains are protonated and consequently uncoordinated. The change from the blue (square-pyramidal) to the red form (square-planar) can be ascribed to dissociation of the water molecules which occupy the axial positions in the Cu^{II} coordination spheres of the blue form. The variation of the magnetic susceptibility of the red complex $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ and the complex $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ with temperature has been studied in the 2–300 K temperature range. Fitting of the experimental data provides J values which are among the highest found for doubly pyrazolate-bridged dicopper(II) complexes {J = −299 cm^{-1} for red-$[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ and J = −286 cm^{-1} for $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$}. A trinuclear Cu^{II} complex of formula $[Cu_3(H_{-2}\mathbf{L^4})](ClO_4)_4{\cdot}2MeOH$ was also isolated after treatment of **L⁴** with $Cu(ClO_4)_2{\cdot}6H_2O$ solutions of higher concentration.

Introduction

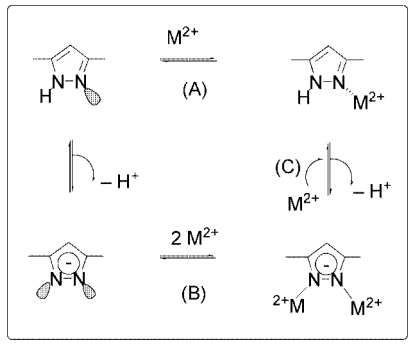
Over the last decades a large amount of research effort has been devoted to identifying the biological roles of metal ions such as Cu^{II} and Zn^{II}. In order to achieve such a goal, different parallel approaches have been followed. The most straightforward consists of directly studying the active site in the metalloenzymes. A second approach, which has proved very useful in some instances,[1−3] has been to mimic the chemical features of the metal sites using smaller sized coordination compounds as models. The knowledge ob-

tained from the way in which metalloenzymes activate small molecules like H_2, N_2, CO_2, etc. has also resulted in considerable interest in the development of catalysts for industrial purposes.

A second biological aspect of metal complexes that has to be taken into account is their implications in pharmacology. For instance, complexes of macrocyclic ligands such as bicyclams and their Zn^{II} complexes have shown useful applications as potent anti-HIV-1 agents and several Mn^{II} and Cu^{II} complexes of hexaazamacrocycles have found applications as SOD mimics.[4] Another point of interest concerns the use of chelate ligands for selectively complexing and removing excess amounts of metal ions from which arise undesirable effects such as the oxidative damage detected in several neurodegenerative disorders.[5] An illustrative example comes from the use of the ligand PBT1 (clioquinol) for removing excess Cu^{II} which accumulates in the neocortex following the oxidative damage produced in Alzheimer disease.[6]

Therefore, the preparation and study of the coordination chemistry of ligands featuring new characteristics in their interaction with metal ions represents a challenge in coordination and biomedical chemistry. Ligands including 1*H*-pyrazole fragments offer a wealth of possibilities in this respect. The pyrazole unit can behave as a monodentate ligand through its sp^2 nitrogen atom or, upon deprotonation, as an $\eta^1{:}\eta^1$ bis(monodentate) bridging ligand (Scheme 1).[7,8]

Recently, we have examined the acid-base behaviour, Cu^{II} coordination chemistry and dopamine recognition capabilities of a series of pyrazole-containing polyamine macrocycles of different topologies [see ligands **1** (**L**^{1}) to **3** (**L**^{3}) in Scheme 2].[9−11] Here we extend these studies to the metal ion Zn^{II}. Additionally, we report on the synthesis of the pyrazole-containing macrocycle 3,7,11,14,15,18,22,26,29,30-decaazatricyclo[26.2.1.1^{13,16}]dotriacontane-1(31),13,16(32),28-tetraene (**4**) (**L**^{4}) (see Scheme 2) which has only propylenic chains and the preparation of its disodium dipyrazolate salt **4′** [$Na_2(H_{-2}$**L**^{4})]. We discuss the effect of the propylenic chains on the acid-base behaviour and on the Cu^{II} and Zn^{II} coordination chemistry in aqueous solution. We also report different Cu^{II} and Zn^{II} complexes prepared either from **4** and **4′** or from the ligands **1**−**3** and we discuss the influence of the hydrocarbon chain length on the coordination features of these new complexes.

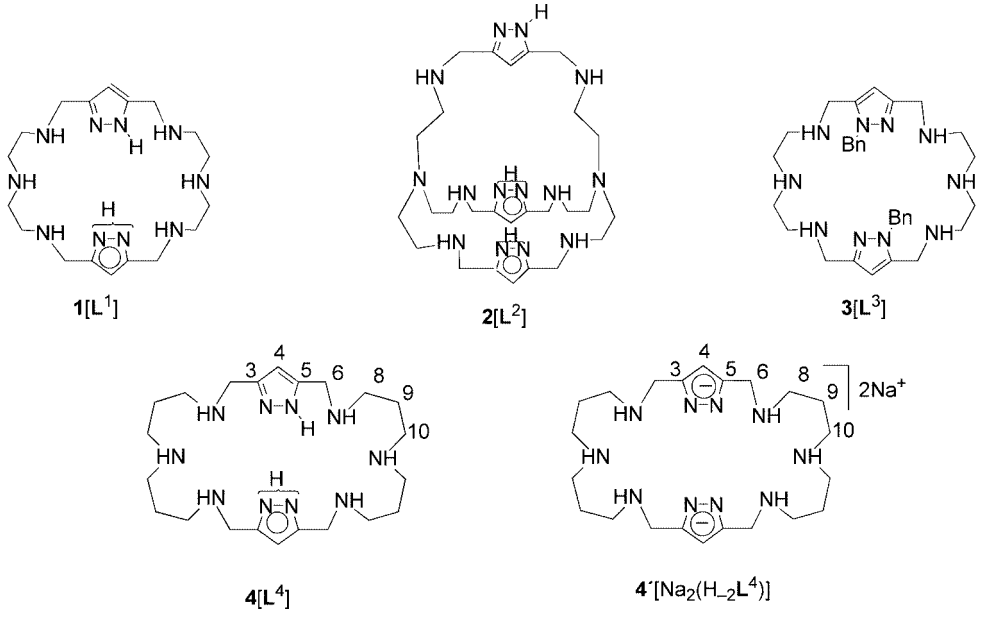


Scheme 1

Results and Discussion

Synthesis of 4 and 4′

The preparation of **4** was performed by a [2+2] dipodal condensation of 3,5-pyrazoledicarbaldehyde with *N*-(3-aminopropyl)-1,3-propanediamine in methanol at room temperature, followed by in situ reduction of the resultant Schiff base with $NaBH_4$. After careful purification firstly by chromatography and then by crystallisation from toluene, **4** (**L**^{4}) was isolated as a pure solid of melting point 154−156 °C in 49% yield. Compound **4** and its hydrochloride **4**·6HCl



Scheme 2

Table 1. Comparison of ^1H and ^{13}C NMR spectroscopic data (δ [ppm], D_2O) of **4** recorded at pH = 10.5 and 8.0 and **4**·6HCl recorded at pH = 3.7

[a] J = 7 Hz. [b] Broad signal.

(m.p. 265−268 °C) have been fully characterised by elemental analyses and NMR spectroscopy.

Table 1 shows a comparison of the ^1H and ^{13}C NMR spectroscopic data of the new ligand **4**, recorded in D_2O at pH = 10.5 and 8.0, with those of its hexahydrochloride **4**·6HCl recorded at pH = 3.7. The signals have been analysed on the basis of their HMQC and multiple-bond HMBC 2D NMR heteronuclear correlation spectra. The above ^1H NMR spectra are graphically compared in the Supporting Information [Figure 1S (A−C)] (for Supporting Information see also the footnote on the first page of this article).

As usually occurs for 3,5-disubstituted 1*H*-pyrazole derivatives, at pH = 10.5 (where the nonprotonated species predominates) **4** shows a very simple pattern of signals which indicates that because of the fast prototropic equilibrium of the pyrazole ring, the compound exhibits an average fourfold symmetry on the NMR time scale. The carbon atoms labelled C-3 and C-5 (for the labelling see Scheme 2) appear together as a sharp signal and the pairs of methylene carbon atoms C-6, C-8, C-9 and C-10 are magnetically equivalent.

In general, the pH-dependent variation of the NMR resonances of the β-carbon atoms and of the hydrogen atoms bound to the α-carbon atoms with respect to the protonated nitrogen atoms are of great help in establishing protonation sequences of polyamine molecules.[9] As can be derived from the basicity constants, the two first protonations of $\mathbf{L^4}$ occur in the pH range of 11−8. Thus, in the NMR spectra of **4** recorded at pH = 8.0 (Table 1), the carbon signal shifted the most upfield is that of carbon atoms C-9 ($\Delta\delta$ = −3.61 ppm), whereas the signal of carbon atoms C-8 and that of the quaternary carbon atoms C-3,5 do not experience significant shifts in this pH region. In the same way, the most downfield shifted ^1H signal is that of 10-H ($\Delta\delta$ = 0.61 ppm), clearly indicating that **4** is protonated firstly at the centre nitrogen atoms of the bridging chains. On the other hand, by comparing the NMR signals of **4** at pH = 8 and those of **4**·6HCl at pH = 3.7 (Table 1) it can be observed that after protonation of the aliphatic nitrogen atoms closer to the pyrazole rings, the most downfield shifted hydrogen signals are those of 6-H and 8-H ($\Delta\delta$ = 0.55 and 0.44 ppm, respectively) and that the signals of the methylene carbon atoms which experience the largest upfield variations are C-9 = −1.98 ppm) which are located in the β-position with respect to the above-mentioned nitrogen atoms.

Furthermore, in **4**·6HCl, the signals of the pyrazole carbon atoms C-3,5 and C-4 (located in the β- and γ-positions, respectively, in relation to the closer protonated aliphatic nitrogen atoms) also experience large upfield ($\Delta\delta$ = 6.20 ppm for C-3,5) and downfield ($\Delta\delta$ = 4.58 ppm for C-4) shifts. These variations are of a similar order to those previously reported for $\mathbf{L^1}$.[9] It is important to point out that such variations do not reflect any particular implication of the pyrazole subunits in the protonation process, since it is well known that β- and γ-aromatic carbon atoms belonging to polyamine-bridged cyclophanes containing benzene units also bear similar chemical shifts upon protonation.[12,13] Finally, we also obtained the disodium dipyrazolate salt **4′** [$Na_2(H_{-2}\mathbf{L^4})$] as a pure solid (m.p. 208−210 °C) in 98% yield, by heating the free ligand **4** to reflux with 2 equiv. of NaOH in MeOH.

Acid-Base Behaviour

Table 2 includes the stepwise protonation constants of the new receptor $\mathbf{L^4}$ and those previously reported for compounds **1** ($\mathbf{L^1}$) to **3** ($\mathbf{L^3}$).[9−11] The basicity constants of **4** ($\mathbf{L^4}$), with only propylenic chains are higher than those of $\mathbf{L^1}$ containing only ethylenic chains and are also higher than those of the compound with ethylenic chains and *N*-benzylpyrazole spacers ($\mathbf{L^3}$). The differences between the stepwise constants of $\mathbf{L^4}$ and those of $\mathbf{L^1}$ and $\mathbf{L^3}$ are particularly large for the fifth and sixth protonation steps (Table 2). The fifth and six protonations occur at the central nitrogen atoms of the polyamine chains of the macrocycle. Therefore, at this stage, the incoming proton will notice a lower elec-

trostatic repulsion from the adjacent polyammonium sites in **L⁴** than in **L¹** or in **L³** due to the presence of the larger propylenic chains.[14] Curiously, the basicities displayed by **L⁴** and the cryptand **L²** are rather similar even if their structures and numbers of nitrogen atoms are different.

The high degree of protonation that **L⁴** presents at physiological pH values (mean number of protons at pH = 7.4 is 3.02) makes this receptor a promising candidate for the coordination of anionic or polar species.

Metal Coordination in Aqueous Solution

The stability constants for the formation of Cu^{II} complexes of **4** (**L⁴**) together with those previously reported for the related receptors **1** (**L¹**) to **3** (**L³**) under the same experimental conditions are shown in Table 3.[11] The stability constants for the interaction of Zn^{II} with **L¹** to **L⁴** determined in this work are presented in Table 4.

With Cu^{II}, **L⁴** forms mononuclear $[Cu(H_xL)]^{(x+2)}$ complexes with $x = 0$, 1, 2 and 3 and dinuclear $[Cu_2(H_xL)]^{(x+4)}$ species with $x = -1$, -2 and -3. The extent of formation of each one of these complexes depends on pH, M/L molar ratio and concentration as can be seen in Figure 1 which shows the distribution diagrams for the Cu^{II} complexes of **L⁴** in molar ratios of 1:1 (Figure 1, A) and 2:1 (Figure 1, B), complexes of **L¹** in a molar ratio of 2:1 (Figure 1, C) and for the Zn^{II} complexes of **L⁴** and **L¹** in a molar ratio 2:1 (Figure 1, D and E, respectively).

The stability constant for the species $[Cu\mathbf{L^4}]^{2+}$ is intermediate between that found for $[Cu\mathbf{L^1}]^{2+}$ (**L¹** is the analogous macrocycle with ethylenic chains) and that of $[Cu\mathbf{L^3}]^{2+}$ (**L³** being the compound with ethylenic chains and *N*-benzylated pyrazole spacers) (Entry 4 in Table 3). The same situation occurs for the dinuclear $[Cu_2\mathbf{L}]^{4+}$ complexes (Entry 7). The sequence of five-membered chelate rings present in **L¹** leads to a stronger coordination to Cu^{II} than the sequence of six-membered rings present in **L⁴**. The situation for **L³** is different since the substituted spacers cannot be deprotonated and each one provides only an sp^2 nitrogen donor over all the pH ranges studied.

Deprotonation of the pyrazole spacers induced by coordination to metal ions is a characteristic feature of this heterocycle.[8,11,15–17] The structure of **L⁴** enables an analysis of the influence of the length of the hydrocarbon chain and thereby of the denticity of the chelate rings on such deprotonation processes. The distribution diagrams calculated for an M/L ratio of 2:1 shown in Figure 1 indicate that while the species $[Cu_2(H_{-2}L)]^{2+}$ with both pyrazole moieties deprotonated is already predominant in solution at pH ≈ 4.3 for **L¹**, a similar species is produced only at pH

[a] Charges omitted for clarity. [b] Values in parentheses are standard deviations in the last significant figure.

> 8 for **L⁴** (Figure 1, B). The first average deprotonation of $[Cu_2\mathbf{L^4}]^{2+}$ gives $pK_{a1} = 5.1$ and the second one $pK_{a2} = 8.1$.

However, care has to be taken in drawing such a conclusion since in the red solid red-$[Cu_2\mathbf{L^4}](ClO_4)_4\cdot 2H_2O$ {red-[**13**]$(ClO_4)_4\cdot 2H_2O$}, prepared from neutral **L⁴** and $Cu(ClO_4)_2\cdot 6H_2O$ (vide infra), the two pyrazole units are deprotonated while the central amino groups of both chains are protonated giving the ligand an overall charge of zero (see **13** in Scheme 3). Therefore, Cu^{II} coordination induces the ready deprotonation of the pyrazole nitrogen atoms which, in this complex, occurs at a lower pH than the deprotonation of the central propylenic chain. This is a particular feature of **L⁴** not observed in the related ligand **L¹** with ethylenic chains. The higher basicity of **L⁴** in its two first protonation steps should facilitate this situation. Such behaviour contrasts with that of the free ligands, for which neither deprotonation nor protonation processes occur at the pyrazole rings throughout the pH range of 2−11.[9,11] On the other hand, all the dinuclear Cu^{II} complexes are EPR-silent.

The stability constants gathered in Table 4 show that, as expected, the Zn^{II} complexes display remarkably lower stabilities than the Cu^{II} analogues (see for instance, Entries 4 in Table 3 and 4 for the $[M\mathbf{L}]^{2+}$ complexes). In all the Zn/L systems, formation of mono- and dinuclear complexes can be observed and for the Zn/**L²** system even a trinuclear species $[Zn_3(H_{-3}\mathbf{L^2})]^{4+}$ was detected. The degree of protonation of the mononuclear complexes reaches a value of 3 for **L¹** and **L²** {$[Zn(H_3\mathbf{L})]^{5+}$ species} and only of 1 for the systems Zn/**L³** and Zn/**L⁴** {i.e. $[Zn(H\mathbf{L})]^{3+}$ species}. The degree of protonation of the dinuclear Zn^{II} complexes varies between 0 and −3. In the case of the Zn/**L¹** system, it has not been possible to identify any nondeprotonated dinuclear species (see distribution diagram in Figure 1). A comparison with Cu^{II} shows that for Zn^{II}, the deprotonation of pyrazole is shifted approximately two units to higher pH values as a result of the poorer inductive effect exerted by this metal ion. Taking into account the crystal structure of $[Zn_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ and the spectroscopic data (vide infra) it is likely, that in the two species $[Zn_2(H_{-1}\mathbf{L^4})]^{3+}$ and $[Zn_2(H_{-2}\mathbf{L^4})]^{2+}$, both pyrazole groups are deprotonated. In $[Zn_2(H_{-1}\mathbf{L^4})]^{3+}$ one of the central nitrogen atoms of the bridging chain will be protonated. In the case of **L¹** the species $[Zn_2(H_{-1}\mathbf{L^1})]^{3+}$ cannot be detected and the only dinuclear species found in solution is $[Zn_2(H_{-2}\mathbf{L^1})]^{2+}$ (Figure 1, D and E). For the cryptand **L²** the situation is analogous to that of **L¹** and the species $[Zn_2(H_{-1}\mathbf{L^2})]^{3+}$ can be postulated as having the two pyrazole moieties involved in coordination to Zn^{II} being deprotonated, while the pyrazole in the noncoordinating bridge will be nondeprotonated and one of the amino groups in this region will be protonated. Such a situation has already been observed in the crystal structure of the analogous Cu^{II} complex of **L²**.[11] Finally, in the ligand with *N*-benzylated pyrazole spacers, the main species in solution at neutral pH, is $[Zn_2\mathbf{L^3}]^{4+}$. Deprotonation of the coordinated water molecules to give hydroxo species requires higher pH values.

Synthesis of Solid Zn^{II} Dinuclear Complexes from Polyamine Receptors with Ethylenic Chains 1 (L¹) to 3 (L³)

Some time ago the in situ deprotonation of ligands **1** (**L¹**) and **2** (**L²**) upon addition of NaOH, as well as the formation of Zn^{II} pyrazolate complexes was observed using NMR techniques in $[D_6]DMSO/D_2O$ mixtures.[18,19] However,

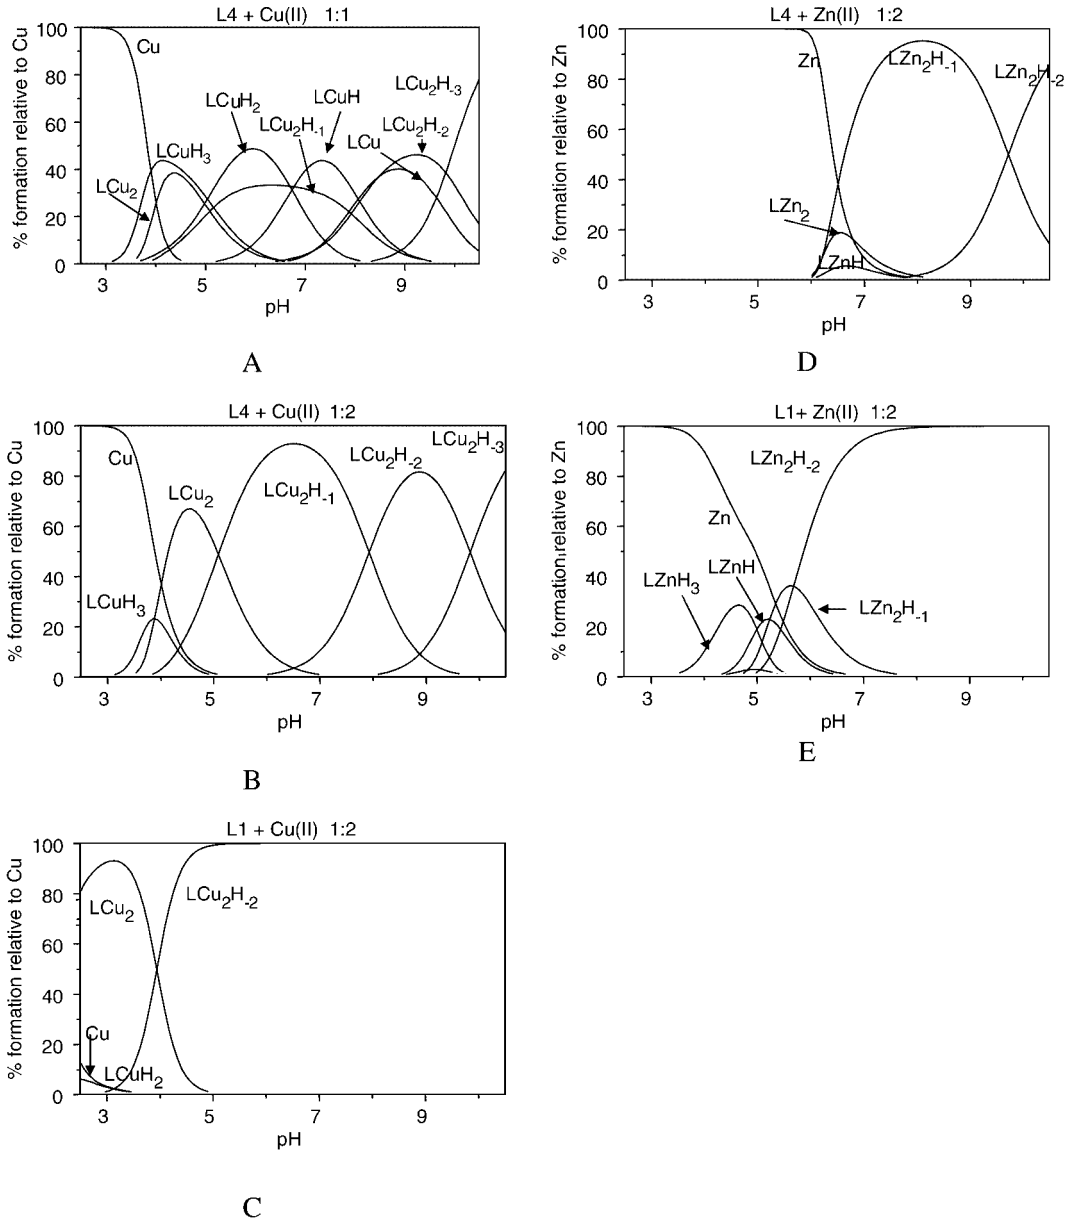

Figure 1. Distribution diagrams for the species existing in equilibrium in the systems: A) Cu^{II}/**L**^{4} molar ratio 1:1, B) Cu^{II}/**L**^{4} molar ratio 2:1, C) Cu^{II}/**L**^{1} molar ratio 2:1, D) Zn^{II}/**L**^{4} molar ratio 2:1, E) Zn^{II}/**L**^{1} molar ratio 2:1; the concentration of ligand is 1×10^{-3} M in all systems

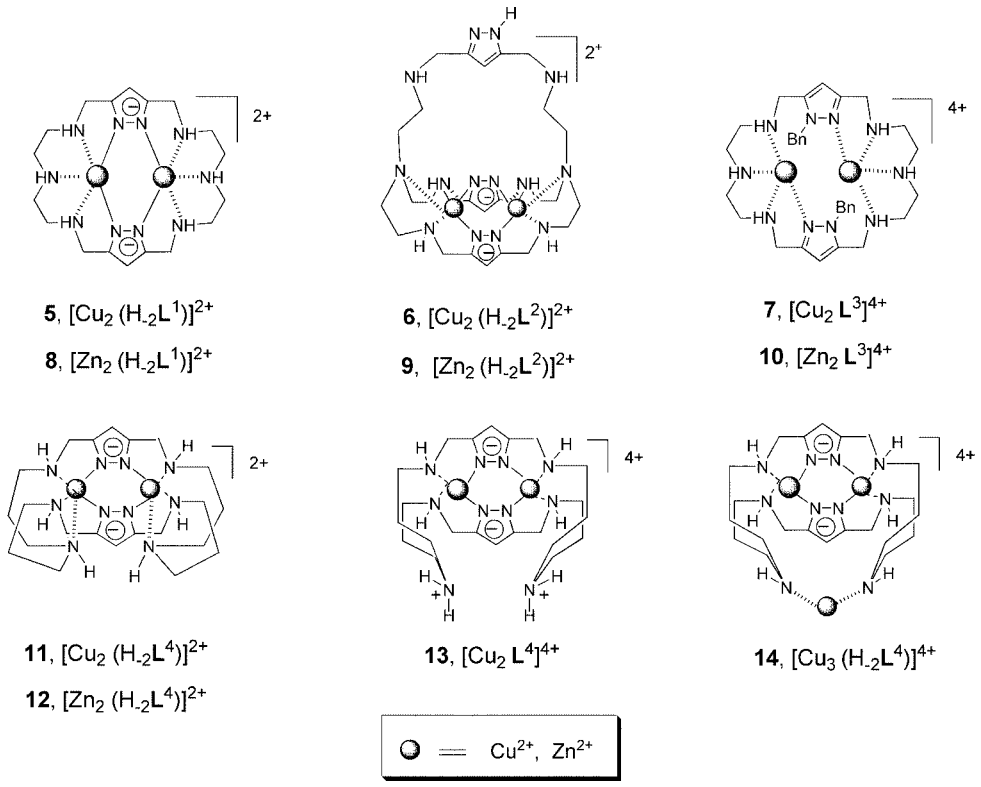
none of the latter mentioned complexes were either isolated or structurally characterised as solid compounds. However, by treating the neutral ligands **L**^{1} to **L**^{3} with $Zn(ClO_4)_2 \cdot 6H_2O$ in methanol (molar ratio M/L = 2:1) we have now isolated three new solid complexes which were recrystallised from water. The analytical and MS data of these compounds are consistent with the formulae $[Zn_2(H_{-2}\mathbf{L}^{1})](ClO_4)_2$ {[**8**]$(ClO_4)_2$}, $[Zn_2(H_{-2}\mathbf{L}^{2})](ClO_4)_2 \cdot 4H_2O$ {[**9**]$(ClO_4)_2 \cdot 4H_2O$} and $[Zn_2\mathbf{L}^{3}](ClO_4)_4 \cdot 6H_2O$ {[**10**]$(ClO_4)_4 \cdot 6H_2O$} (Scheme 3). Electrospray ionisation (ESI-MS) and fast atom bombardment (FAB-MS) mass spectrometry have been used for the characterisation of all the new Zn^{II} complexes.[20] Besides, in the case of [**8**]$(ClO_4)_2$, suitable crystals for X-ray analysis were grown from the aqueous solution (vide infra).

The above data support the fact that in the case of **L**^{1} and **L**^{2}, Zn^{II} coordination induces the deprotonation of the pyrazole rings to afford the pyrazolate bridging ligand without the need to add a base. On the other hand, considering that the structure of the starting ligand **L**^{3} corresponds to a constitutional isomer in which the 1-benzylpyrazole substituents are in positions opposite each other displaying C_2 symmetry[9] and taking into account the crystal structure of the analogous Cu^{II} complex [**7**]$(ClO_4)_4 \cdot 4H_2O$,[11] it is reasonable to assume that in the Zn^{II} complex [**10**]$(ClO_4)_4 \cdot 6H_2O$ the sp^2 nitrogen atoms of the pyrazole rings are also involved in the coordination to the metal ions.

The ESI (positive mode) and FAB mass spectra of complex {[**8**]$\cdot(ClO_4)_2$} show common peaks at *m*/*z* (%) = 615.1 (10) and 615.4 (10), respectively, which confirm the presence

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

of the dinuclear $[Zn_2(H_{-2}\mathbf{L^1})(ClO_4)]^+$ species, as well as intense peaks at *m*/*z* (%) = 453.4 (100) and 453.2 (47), respectively, corresponding to the species $[Zn(H_{-1}\mathbf{L^1})]^+$ generated by loss of $Zn(ClO_4)_2$.

Similarly, in both the ESI and FAB mass spectra of $[\mathbf{9}](ClO_4)_2{\cdot}4H_2O$, the protonated molecular ion $[Zn_2(H_{-2}\mathbf{L^2})(ClO_4)_2]H^+$ appears at *m*/*z* (%) = 893.2 (2) and 893.1 (23), respectively, and the ionic species $[Zn_2(H_{-2}\mathbf{L^2})(ClO_4)]^+$ is confirmed by the presence of intense peaks at *m*/*z* (%) = 793.2 (73) and 793.3 (63), respectively.

Finally, in the ESI (positive mode) and the FAB mass spectra of complex $[Zn_2\mathbf{L^3}](ClO_4)_4{\cdot}6H_2O$ appear common peaks which clearly support the proposed structure. At *m*/*z* (%) = 995.1 (5 and 44, respectively) appears a peak corresponding to the dinuclear $[Zn_2\mathbf{L^3}(ClO_4)_3]^+$ species formed from the molecular ion by loss of perchlorate and at *m*/*z* (%) = 733.5 (54) and 733.3 (23), respectively, a peak attributable to the ionic species $[Zn\mathbf{L^3}(ClO_4)]^+$ formed by successive loss of $Zn(ClO_4)_2$ and ClO_4^- can be observed.

Crystal Structure of $[Zn_2(H_{-2}L^1)](ClO_4)_2$ {[8](ClO4)2}

Crystals of $[Zn_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ suitable for X-ray analysis were obtained by concentrating aqueous solutions containing $\mathbf{L^1}$ and $Zn(ClO_4)_2$ at pH = 9. The structure consists of $[Zn_2(H_{-2}\mathbf{L^1})]^{2+}$ cations and perchlorate anions. Each Zn^{II} is coordinated by the three nitrogen atoms from one of the polyamine bridges and by one sp^2 nitrogen atom from each one of the pyrazole units which are deprotonated

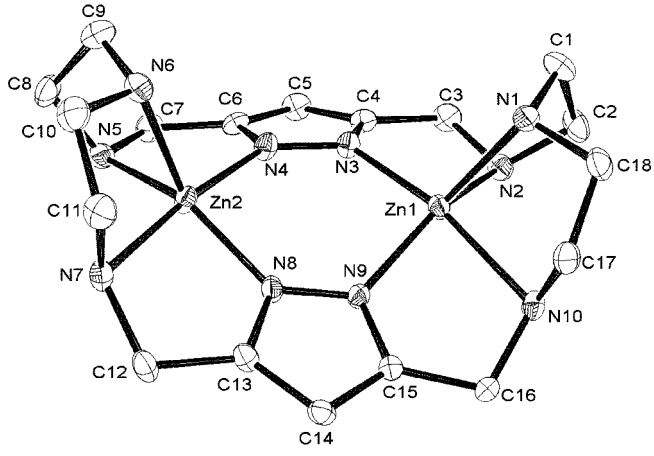


Figure 2. ORTEP drawing for the cation $[Zn_2(H_{-2}\mathbf{L^1})]^{2+}$ (**8**); thermal ellipsoids are drawn at the 30% probability level

and behave as bridging $\eta^1{:}\eta^1$-bis(monodentate) pyrazolate ligands (see Figure 2). The coordination geometry around each one of the metal ions can be defined as midway between a strongly distorted square pyramid and a trigonal bipyramid. The percentage of trigonal-bipyramidal units calculated by means of the facial planes[21] is 44.5% for the Zn1 site and 50.7% for the Zn2 site.

The shorter distances in the coordination spheres of both metal ions are those involving the pyrazolate sp^2 nitrogen atoms (see Table 5) and the largest ones are those of the amino groups adjacent to the pyrazole fragments. In order

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to achieve such a coordination geometry the central part of the chains are forced to move in the same direction giving something of a boat-like shape (Figure 2).

N7−Zn1−N8	78.3(2)

The Zn−Zn distance (3.99 Å) is close to those found for the analogous Cu^{II} complexes of $\mathbf{L^1}$ and $\mathbf{L^2}$, implying that the rigidity of the pyrazole spacer is the main factor controlling this parameter. It is interesting to remark that, as already observed in the systems Cu/$\mathbf{L^1}$ and Cu/$\mathbf{L^2}$,[11,17] Cu^{II} coordination causes the ready deprotonation of the pyrazole moieties without requiring any addition of base.

Synthesis of Cu^{II} and/or Zn^{II} Dipyrazolate Complexes $[Cu_2(H_{-2}L^4)](ClO_4)_2$ {[**11**]$(ClO_4)_2$} and $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[**12**]$(ClO_4)_2$} from **4′**

Synthesis and Spectroscopic Characterisation

In order to unequivocally obtain Cu^{II} and Zn^{II} dipyrazolate complexes we first used the disodium dipyrazolate salt **4′** (Scheme 2) as a starting material. Treatment of **4′** with $Cu(ClO_4)_2{\cdot}6H_2O$ (2 equiv.) in MeOH afforded a blue solid which, after being crystallized from a 2:3 water/MeOH mixture, gave the Cu^{II} dipyrazolate complex $[Cu_2(H_{-2}L^4)](ClO_4)_2$ {[**11**]$(ClO_4)_2$}.

The ESI (positive mode) mass spectrum of [**11**]$(ClO_4)_2$ in MeOH shows two intense peaks at *m*/*z* (%) = 671.0 (100) and 571.2 (58) which are assignable to the molecular species $[Cu_2(H_{-2}L^4)(ClO_4)]^+$ and $[Cu_2(H_{-3}L^4)]^+$, respectively. These confirm that the compound is a dinuclear Cu^{II} dipyrazolate complex. There also appears a fairly weak peak at *m*/*z* = 508.1 corresponding to the mononuclear $[Cu(H_{-1}L^4)]^+$ species which may be formed from the monoprotonated molecular ion $[Cu_2(H_{-1}L^4)(ClO_4)_2]^+$ by loss of $Cu(ClO_4)_2$.

The Zn^{II} dinuclear complex $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[**12**]$(ClO_4)_2$} (Scheme 3) was obtained by treatment of the sodium salt **4′** with 2 equiv. of $Zn(ClO_4)_2{\cdot}6H_2O$ according to a similar procedure to that previously mentioned. After crystallisation from a water/methanol mixture, the analytical and spectroscopic data of the white solid obtained were consistent with formula $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[**12**]$(ClO_4)_2$}. In its ESI (positive mode) mass spectrum, three main peaks detected at *m*/*z* (%) = 671.2 (32), 609.3 (27) and 509.4 (100) are attributable to the ionic species $[Zn_2(H_{-2}L^4)ClO_4]^+$, $[Zn(L^4)ClO_4]^+$ and $[Zn(H_{-1}L^4)]^+$, respectively.

The structure of $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[**12**]$(ClO_4)_2$} in solution was also fully characterised by NMR spectroscopy. In Tables 6 and 7 are gathered the respective ^1H and ^{13}C NMR spectroscopic data of this compound recorded in [D_6]DMSO together with those of the dipyrazolate salt **4′** and those of the free ligand **4**. Table 6 verifies that the ^1H NMR spectroscopic data of **4** and **4′** are similar. Each shows a single set of signals for all the methylene protons, the chemical shift differences between **4** and **4′** being lower than 0.2 ppm. However, in the ^1H NMR spectrum of $[Zn_2(H_{-2}L^4)]^{2+}$ (**12**) (Figure 3, A), the methylene protons 6-H_2, 8-H_2 and 9-H_2 which are neighbours of the pyrazole

Table 6. Comparison of the ^1H NMR spectra (δ [ppm], [D_6]DMSO) of the free ligand **4**, its sodium dipyrazolate salt **4′** and the Zn^{II} dipyrazolate complex [**12**]$(ClO_4)_2$

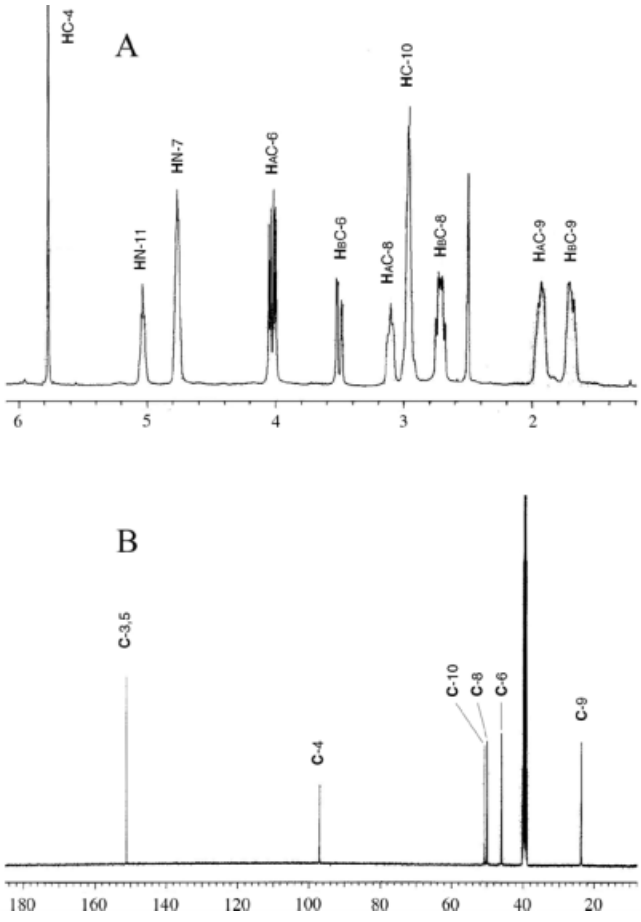

Figure 3. ^1H (A) and ^{13}C (B) NMR spectra of the Zn^{II} complex {[**12**]$(ClO_4)_2$} in [D_6]DMSO solution

moieties, appear in the spectrum as an AB spin system (Figure 3) suggesting that Zn^{II} coordination confers a rigid structure on the complex. Except for the 4-H pyrazole proton, all the other protons belonging to the macrocyclic cavity of **12** exhibit a generalised downfield chemical shift of their signals. It is interesting to note that in the ^1H NMR spectrum appear two signals at $\delta = 4.77$ and $\delta = 5.03$ ppm, which are attributable to the protons of the amino groups 7-H and 11-H, respectively. The triplet-like shape of these signals can be ascribed to their coupling with the neighbour methylene groups.

Table 7 shows the ^{13}C NMR signals of **4**, **4′** and [**12**]$(ClO_4)_2$ as well as the variations in the chemical shifts due to deprotonation of the pyrazole moieties which leads to **4′** [$\Delta\delta$ (2−1)] and the formation of the dinuclear Zn^{II} complex **12** [$\Delta\delta$ (3−2)].

In [D_6]DMSO, the C-3,5 quaternary carbon atoms of the free ligand **4** appear in the spectrum as a broad signal, while in the spectrum of **4′** this signal changes to a sharp singlet indicating that the slow prototropic equilibrium of the pyrazole rings has disappeared. Furthermore, as can be expected, upfield (δ =1.13 ppm for C-4) and downfield (δ = 0.34 ppm for C-3,5) variations of the pyrazole carbon signals confirm the formation of pyrazolate anions (Table 7).

Taking the ^{13}C NMR signals of **4′** as a reference, it can be observed that formation of the Zn^{II} dipyrazolate complex **12** induces strong downfield shifts in the signals of all the carbon atoms located in the α- positions to the nitrogen atoms involved in the complexation of the Zn^{II} ions. It also exerts strong upfield shifts on the signals of those located in the β- positions (Table 7).

*Crystal Structure of [$Cu_2(H_{-2}L^4)$]$(ClO_4)_2$ {[**11**]$(ClO_4)_2$}*

The crystallographic data were recorded at 150 K because some disorder found within the propylenic chains of the bridges and in the perchlorate counter anions prevented a satisfactory solution of the crystal structure from data collected at room temperature. Although even at low temperature some disorder persists, the solution is good enough for unequivocally identifying the structural characteristics of the coordination sites.

Crystals of [**11**]$(ClO_4)_2$ consist of $[Cu_2(H_{-2}\mathbf{L^4})]^{2+}$ cations and perchlorate anions. The coordination geometry around each copper atom is an irregular, axially elongated square pyramid. The base of the pyramid is formed by the two secondary nitrogen atoms of the polyamine bridge closer to the heterocycle and by two nitrogen atoms of two different pyrazolate units which act as $\eta^1{:}\eta^1$ bis(monodentate) anionic bridging ligands (Figure 4). The displacements of the metal ions from the plane of the nitrogen donors are 0.322(2) Å for Cu1 and 0.303(2) Å for Cu2. The central nitrogen atoms of the bridges occupy the axial positions. In both coordination sites, the Cu−N distances involving the sp^2 pyrazolate nitrogen atoms [Cu(1)−N(3) = 1.963(9) Å, Cu(2)−N(4) = 1.94(1) Å; Table 8] are much shorter than those of the secondary nitrogen atoms [Cu(1)−N(2) = 2.10(1) Å, Cu(2)−N(5) = 2.11(1) Å]. The Cu(1)−Cu(2) distance is 3.96 Å which is almost identical to those found in the crystal structures of $[Cu_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ {[**5**]$(ClO_4)_2$}[17,11] and $[Cu_2(H_{-1}\mathbf{L^2})](ClO_4)_3{\cdot}2H_2O$ {[**6**]$(ClO_4)_2(HClO_4){\cdot}2H_2O$}[11] as well as in several crystal structures of other pyrazole-containing complexes in which the pyrazolate anions exhibit the same coordination mode.[8,15,16] However, such a distance is not so fixed in some complexes of podand ligands containing pyrazole bridges.[22] It is also interesting to point out that the axial

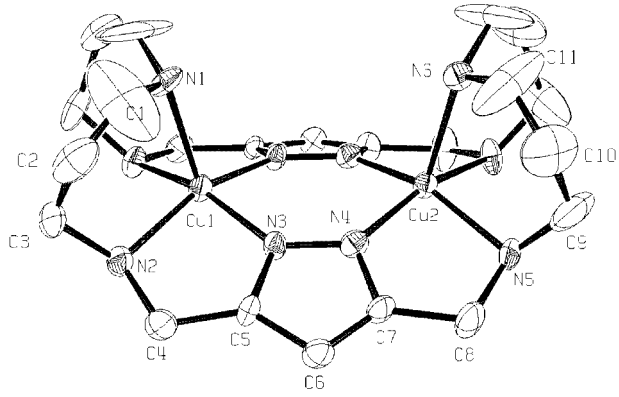

Figure 4. ORTEP drawing for the cation $[Cu_2(H_{-2}\mathbf{L^4})]^{2+}$ (**11**); thermal ellipsoids are drawn at the 30% probability level

elongation observed in this complex is much smaller than those previously reported for $[Cu_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ and $[Cu_2(H_{-1}\mathbf{L^2})](ClO_4)_3{\cdot}2H_2O$.[11] The complex again adopts a boat-shaped conformation with the side-chains folded towards the same side of the macrocyclic cavity.

Crystal Structure of [$Zn_2(H_{-2}L^4)$]$(ClO_4)_2$ {[12]$(ClO_4)_2$}

The crystallographic data were also recorded at 150 K because similar disorder to that found in the previous case was observed and this prevented a satisfactory solution from data recorded at room temperature. Crystals of [**12**]$(ClO_4)_2$ consist of $[Zn_2(H_{-2}\mathbf{L^4})]^{2+}$ cations and perchlorate anions. The coordination geometry around each Zn^{II} atom is very irregular and can be defined as a distorted square pyramid. Analogous to the previous structure, the base of the pyramid is formed by the two secondary nitrogen atoms of the polyamine bridge closer to the heterocycle and by two nitrogen atoms of two different pyrazolate units which act as $\eta^1{:}\eta^1$ bis(monodentate) anionic bridging ligands (Figure 5). The displacements of the metal atoms above the plane defined by the nitrogen donors are 0.595(2) Å for Zn1 and 0.554(2) Å for Zn2. The central nitrogen atoms of the polyamine bridges occupy the axial positions which in this case do not show any distortion. In contrast to the analogous Cu^{II} complex, the Zn−N distances of the sp^2 pyrazole nitrogen atoms in this case [Zn(1)−N(3) = 2.037(9) Å, Zn(2)−N(4) = 2.040(8) Å; Table 9] are close to those of their secondary nitrogen atoms in the centre of the bridge [Zn(1)−N(1) = 2.08(1) Å, Zn(1)−N(2) = 2.09(1) Å]. The largest M−N distances are found for the secondary nitrogen atom adjacent to the heterocycle. The Zn(1)−Zn(2) distance is again 3.96 Å confirming that it is fixed by the pyrazolate bridge. The conformation of the whole molecule is again boat-shaped with the central part of both chains folded towards the same side of the macrocyclic plane (Figure 5).

Table 9. Selected bonds lengths [Å] and angles [°] of [**12**]$(ClO_4)_2$

Parameter	Length/angle
Zn1−N1	2.08(1)
Zn1−N2	2.206(8)
Zn1−N3	2.037(9)
Zn2−N4	2.040(8)
Zn2−N5	2.196(8)
Zn2−N6	2.09(1)
N1−Zn1−N2	99.5(4)
N1−Zn1−N3	114.3(4)
N2−Zn1−N3	77.4(3)
N4−Zn2−N5	77.38(3)

Synthesis of Cu^{II} Dipyrazolate Complexes[$Cu_2(L^4)$]$(ClO_4)_4{\cdot}2H_2O$ {[13]$(ClO_4)_4{\cdot}2H_2O$} and [$Cu_3(H_{-2}L^4)$]$(ClO_4)_4{\cdot}2MeOH$ {[14]$(ClO_4)_4{\cdot}2MeOH$} from L^4

Synthesis and Spectroscopic Characterisation

It is interesting to point out that when we tried to obtain the dipyrazolate complexes $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {[**11**]$(ClO_4)_2$} by direct treatment of the neutral ligand **4** with $Cu(ClO_4)_2{\cdot}6H_2O$ in methanol, we observed very different behaviour to that previously described using the disodium dipyrazolate salt **4′** as a starting material. Thus, treatment of a methanolic solution of **4** (2.5×10^{-2} M) with $Cu(ClO_4)_2{\cdot}6H_2O$ (2 equiv.) at room temperature gave a blue precipitate which, after being vacuum-dried at 100 °C, afforded a blue solid of formula $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ in 71% yield. After redissolving this blue solid in boiling water for 5 min, a red solid slowly and unexpectedly crystallised. After being vacuum-dried at 100 °C, this resulted in a reddish-brown complex of formula $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ {[**13**]$(ClO_4)_4{\cdot}2H_2O$} (Scheme 3) in 61% yield. Surprisingly, this red complex had identical analytical data to the blue precursor mentioned above. Microanalysis performed by X-ray energy dispersive spectrometry confirmed the proposed Cu/Cl ratio. This can be explained if both the blue and the red forms of this complex correspond to dinuclear Cu^{II} dipyrazolate species which share the characteristic feature of having the two sp^3 nitrogen atoms located at the centre of the side chains protonated and, in contrast to $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {[**11**]$(ClO_4)_2$}, thereby not directly coordinated to the metal atoms (Scheme 3). The coordination

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the metal ion causes the release of the protons from the pyrazole fragments which are captured by the basic central nitrogen atoms of the bridges.

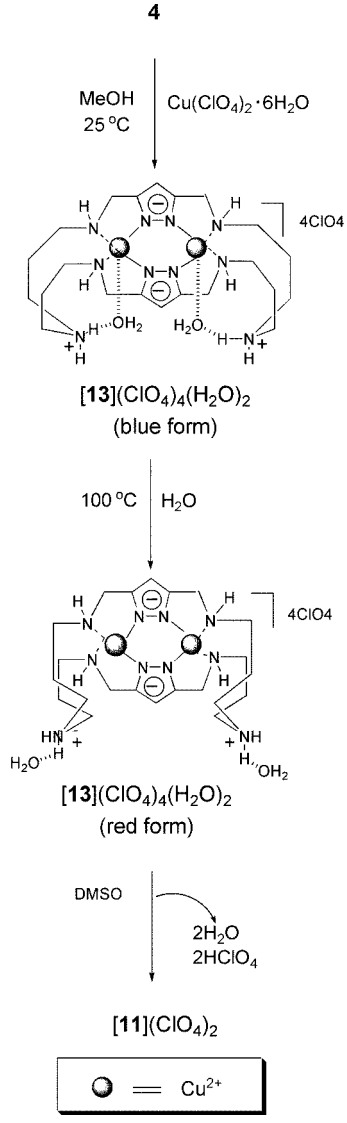
Furthermore, the ESI-MS data of either the precursor blue form or the red final form show identical peaks which appear with different relative abundances as shown in Table 10. In the negative mode, the molecular ion $[M - H]^-$, corresponding to $[Cu_2(H_{-1}\mathbf{L^4})(ClO_4)_4]^-$ appears at m/z = 969.4 with low relative abundance (see Table 10), together with a more intense peak at m/z = 1071.4 and the base peak at m/z = 869.4 assignable to the species $[M + ClO_4]^-$ and $[(M - ClO_4 - 2\ H]^-$, respectively, which agree with the proposed structure. Moreover, in the positive mode, two characteristic peaks appear at m/z = 871 and 771, assignable to the $[Cu_2(\mathbf{L^4})(ClO_4)_3]^+$ and $[Cu_2(H_{-1}\mathbf{L^4})(ClO_4)_2]^+$ species which correspond to dinuclear Cu^{II} dipyrazolate fragments containing partly protonated polyamine chains. On the other hand, in addition to the expected peak at m/z = 671 assignable to the most abundant fragment $[(H_{-2}\mathbf{L^4})Cu_2(ClO_4)]^+$, both the precursor blue and the final red forms of $[\mathbf{13}](ClO_4)_2(H_2O)_2$ show a characteristic peak at m/z = 547 attributable to $[(H_2\mathbf{L^4})(ClO_4)]^+$ which demonstrates the presence of protonated nitrogen atoms in the ligand structure.

Table 10. Comparison of the most significant peaks recorded in the ESI-MS data of the dinuclear Cu^{II} complex $\{[\mathbf{13}](ClO_4)_4{\cdot}2(H_2O)\}$ (1007.6) in both its blue and red forms

m/z	Composition	% blue	% red
Negative mode			
1071	$\{[Cu_2\mathbf{L^4}](ClO_4)_5\}^-$	35	14
969	$\{[Cu_2(H_{-1}\mathbf{L^4})](ClO_4)_4\}^-$	6	8
869	$\{[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_3\}^-$	100	100
Positive mode			
871	$\{[Cu_2\mathbf{L^4}](ClO_4)_3\}^+$	10	3
771	$\{[Cu_2(H_{-1}\mathbf{L^4})](ClO_4)_2\}^+$	10	4
671	$\{[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)\}^+$	100	59
569	$[Cu_2(H_{-3}\mathbf{L^4})]^+$	3	4
547	$\{[H_2\mathbf{L^4}](ClO_4)\}^+$	51	33
447	$[H\mathbf{L^4}]^+$	–	41
224	$[(\mathbf{L^4}/2)+H]^+$	–	100

Unfortunately, up to now, it has not been possible to obtain adequate crystals of either the precursor blue form or the red form suitable for X-ray analysis.

However, on the basis of the above observations, the colour changes observed can be tentatively attributed to the presence of the two water molecules which are bound in a different manner in both complexes. In the blue form they would be coordinated to the metal ion occupying the axial positions of the pentacoordinate environment (see Scheme 4, blue-[**13**]). In the red form the coordination environment around each Cu^{II} will be square-planar and the water molecules would not occupy the first coordination sphere of the metal ion (Scheme 4, red-[**13**]). In both cases the water molecules might be stabilised through $^+NH\cdots OH_2$ hydrogen bonds with the two protonated sp^3 nitrogen atoms located in the centre of the side chains. We previously reported these types of monohydrated ammonium groups in the crystalline structure of the dinuclear Cu^{II} complex $[\mathbf{6}](HClO_4)(ClO_4)_2{\cdot}2H_2O$[11] where one of the aliphatic nitrogen atoms of the noncoordinated bridge is protonated and hydrogen-bonded to a water molecule.



Scheme 4

In the complex $\{\text{red-}[\mathbf{13}](ClO_4)_2{\cdot}2H_2O\}$, the conformational change produced would be induced by the treatment of the starting precursor blue form with boiling water.

Finally, when we tried to obtain similar dinuclear complexes starting from a more concentrated solution of ligand $\mathbf{L^4}$ (**4**) (6.0×10^{-2} M) under similar reaction conditions [2 equiv. of $Cu(ClO_4)_2{\cdot}6H_2O$ at room temp.], we obtained another unexpected result. A bright green solid precipitated from the methanol solution which, after being vacuum-dried at 100 °C, gave a new trinuclear copper complex in low yield (28%). The analytical and MS data of this new complex are consistent with the formula $[Cu_3(H_{-2}\mathbf{L^4})](ClO_4)_4{\cdot}2MeOH$ $\{[\mathbf{14}](ClO_4)_4{\cdot}2MeOH\}$

(Scheme 3). The Cu/Cl (3:4) molar ratio was confirmed by X-ray energy dispersive spectrometry.

Since matrix-assisted laser desorption/ionisation (MALDI-TOF) mass spectrometry is actually among the most important ionisation methods for strong metal-ion complexes,[23] we used this technique in order to confirm the structure of the trinuclear complex. Table 11 shows the most significant trinuclear copper ions detected in the MALDI-TOF mass spectrum of {[**14**]$(ClO_4)_4$·2MeOH} using 2,5-dihydroxybenzoic acid (DHB) as a matrix. In a similar way as has already been observed in other MALDI-TOF mass spectra of copper complexes in which Cu^{II} ions are apparently simply reduced,[24,25] the composition of most of the ionic fragments gathered in Table 11 agree with different copper oxidation states due to partial or total copper reduction processes for which the source of the electrons may be the photoionised DHB matrix. Thus, at *m*/*z* = 635 appears the base peak corresponding to the skeletal trinuclear copper fragment $[Cu_3(H_{-2}\mathbf{L^4})]^+$ in which the three Cu^{II} atoms are reduced to Cu^{I}. Other characteristic ions which correspond to the proposed structure appear at *m*/*z* (%) = 734.3 (78) and 797.2 (27). Both peaks are attributable to the ionic species $[Cu_3(H_{-2}\mathbf{L^4})(ClO_4)]^+$ and $[Cu_3(H_{-2}\mathbf{L^4})(MeO)(MeOH)]^+$, respectively, in which two of the three Cu^{II} atoms have been reduced to Cu^{I}. The last mentioned species (*m*/*z* = 797.2) confirms the presence of two MeOH molecules in the complex and simultaneously suggests that one of these molecules may be acting as a bridge between two copper ions.

Table 11. Most significant peaks recorded in the MALDI-TOF-MS of [**14**]$(ClO_4)_4$·2MeOH corresponding to trinuclear copper fragments

m/*z* (%)	Composition[a]	Oxidation state
797.2 (27)	$\{[Cu_3(H_{-2}\mathbf{L})](MeO)(MeOH)\}^+$	2 Cu^+ + Cu^{2+}
750.3 (7)	$\{[Cu_3(H_{-2}\mathbf{L})](ClO_4)+(O)\}^+$	3 Cu^{2+}
734.3 (78)	$\{[Cu_3(H_{-2}\mathbf{L})](ClO_4)\}^+$	2 Cu^+ + Cu^{2+}
649.4 (26)	$\{[Cu_3(H_{-4}\mathbf{L}) +(O)]\}^{\cdot+}$	3 Cu^{2+}
635.4 (100)	$[Cu_3(H_{-2}\mathbf{L})]^+$	3 Cu^+

[a] [$(H_{-2}\mathbf{L})$ = ($C_{22}H_{40}N_{10}$) and $(H_{-4}\mathbf{L})$=($C_{22}H_{38}N_{10}$)].

Finally, at *m*/*z* = 750.3 and 649.4 are two peaks assignable to ionic fragments containing oxygen in which the Cu^{II} initial oxidation state has not changed. However, it is difficult to be certain if these ions are truly formed or are the result of secondary oxidation reactions in the matrix as was previously observed in other MALDI-TOF mass spectra of metallic complexes.[25]

Molecular Modelling Studies

In order to gain further insight into the molecular structures of both the dinuclear Cu^{II} [**13**]$(ClO_4)_4$·$2H_2O$ and the trinuclear Cu^{II} complex {[**14**]$(ClO_4)_4$·2MeOH}, we performed some modelling studies. Molecular mechanics models of complexes of a variety of metal ions have been recently developed[26] and have proved useful for ligand design. Use of a well-established biochemically oriented force field with specific metal parameters would allow the interactions of metal complexes and biological molecules to be studied and modelled. Among the well-established force-fields, AMBER[27] has found widespread use in the modelling of biological molecules and the development of suitable parameter sets which allows the modelling of metal complexes. This has produced results in good agreement with experimental observations without requiring additional changes.[28] For those reasons, in this work, molecular modelling studies were carried out using the AMBER method modified by the inclusion of appropriate parameters.

To check the consistency of the calculations we modelled the complex [**11**]$(ClO_4)_2$ (which has a known X-ray structure) according to the same procedure detailed in the Exp. Sect. with no restraints. Data obtained in this modelling study agree quite well with the crystallographic results, although the calculated Cu−Cu distances are shorter than the experimentally measured ones (0.12 Å, similar to maximum deviation obtained by Comba et al.).[29]

To study the copper complexes [**13**]$(ClO_4)_4$·$2H_2O$ and [**14**]$(ClO_4)_4$·MeOH, coordination numbers and geometries were selected according to the preferences of copper(II) and, taking into account all the experimental data for the synthesised complexes, red-[**13**] was assumed to be square-planar while blue-[**13**] and green [**14**] were assumed to be pyramidal. Thus, we modelled the blue and red forms of the dihydrated complex [**13**]$(ClO_4)_4$·$2H_2O$ with the results given in Figure 6 (A).

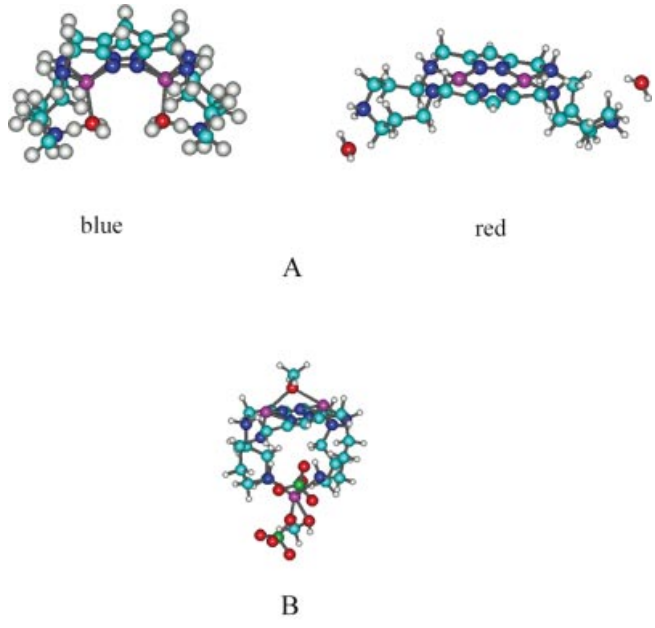

Figure 6. A) Molecular models of the blue and red forms of the complex [**13**]$(ClO_4)_4(H_2O)_2$; B) molecular model for the trinuclear complex [**14**]$(ClO_4)_4(MeOH)_2$

In the above complexes, the calculated Cu−Cu distance between the two metal ions coordinated with pyrazole ni-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trogen atoms is 3.52 Å for the red form of [**13**], denoting the rigidity of the bridge, and 4.03Å for its blue form which is more similar to the values found for [**11**] (calculated 3.84 Å, X-ray data 3.96 Å).

Since they have different connectivities, no attempt was made to compare the calculated molecular mechanics strain energies of the different coordination complexes since each one needs a different parameter set. PM3 calculations of the corresponding heats of formation, however, suggests that the red form of {[**13**]$(ClO_4)_4$·$2H_2O$} is more stable than the blue one.

Finally, a model for the green trinuclear Cu^{II} complex [**14**]$(ClO_4)_4$·2MeOH is given in Figure 6 (B). Coordination of the metal centres to the pyrazole sp^2 nitrogen atoms and the adjacent nitrogen atoms forces the central parts of both bridges to move upwards in the same direction thereby enabling the central nitrogen atoms to coordinate to a further metal ion provided there are other ancillary ligands that can assist the processes. In this case the methanol molecules could complete the coordination spheres. In [**14**], the calculated Cu−Cu distances between the third metal ion and the pyrazole-coordinated metal ion are 5.89 Å and 6.41 Å, respectively, while the distance between these two remains quite similar to that of 3.83 Å in the blue form of [**13**].

^{1}H NMR Spectra of {red-[13]$(ClO_4)_4$·$2H_2O$}

In order to obtain further information about the nature of the red complex $[Cu_2\mathbf{L^4}](ClO_4)_4$·$2H_2O$ {red-[**13**]$(ClO_4)_4$·$2H_2O$} (Scheme 3), we performed paramagnetic ^{1}H NMR spectroscopy. This technique is very useful for the study of magnetically coupled systems such as dinuclear Cu^{II}−Cu^{II} complexes.[30,31] However, in the case of mononuclear Cu^{II} complexes its usefulness is rather limited due to the large electronic relaxation time of Cu^{II} which consequently produces a large broadening of the signals. The information that this technique provides refers to the electronic properties, coordination geometry and conformational changes in solution.

The ^{1}H NMR spectrum of the red $[Cu_2\mathbf{L^4}](ClO_4)_4$·$2H_2O$ complex in $(CD_3)_2SO$ is shown in Figure 7 (A). It displays, in the downfield region, nine hyperfine-shifted signals (a−i) and four other signals (j−m) which are shifted upfield. When the temperature is raised up to 45 °C, the broad signals a−c and e move upfield, Figure 7 (B, C). This change is irreversible and at the same time the colour of solution changes from red-violet to blue, indicating a conformational change. The isotropically shifted resonances, longitudinal relaxation times (T_1) and line widths at half-height are reported in Table 12 for the red complex $[Cu_2\mathbf{L^4}](ClO_4)_4$·$2H_2O$ {red-[**13**]$(ClO_4)_4$·$2H_2O$}. The above-mentioned signals (a−c) display short T_1 values (< 1 ms) and broad line widths at half-height of around 2000 Hz. This, together with the proton integrations, permits the assignment of these signals to the protons of the CH_2 groups located α to the coordinated nitrogen atoms nearest to the Cu^{II} ion (see Scheme 5). When the temperature is raised up to 45 °C (see Figure 7, C), the broad signals which move upfield integrate for eight more protons, indicating an increase in the coordination number of the copper ion. In this sense, signal (e) which integrates for eight protons and can

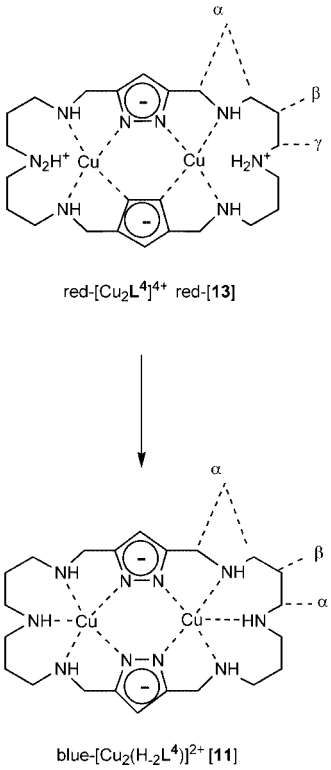
be assigned to CH_2 groups located γ to the coordinated nitrogen atoms in the red-violet $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ {red-[**13**]$(ClO_4)_4{\cdot}2H_2O$} complex, disappears completely in the ^{1}H NMR spectrum of the blue complex **13**. These results clearly illustrate a change in the coordination geometry from square-planar in the red form to pyramidal or five-coordinate in the blue form. The data also suggest that in the blue form, the nitrogen atoms in the centre of the bridges are coordinated to the metal ion. Therefore, in the weakly acidic solvent $(CD_3)_2SO$, the centre nitrogen atoms are deprotonated and the red complex gradually transforms to $[Cu_2(H_{-2}\mathbf{L^4})]^{2+}$ (**11**) (see Scheme 5). Indeed, this spectrum is identical to that obtained of a solution formed by directly dissolving $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ ([**11**]$(ClO_4)_2$] in the same solvent. The other signals (d and f−m), which correspond to the CH_2 groups β to the coordinated nitrogen atoms and to the pyrazole protons, display large T_1 values (100−150 ms). As described previously,[31] dinuclear Cu^{II} complexes have similar T_1 values and broad line widths.



Scheme 5

In addition, variable-temperature ^{1}H NMR spectra of red-$[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ were recorded from 293 to 323 K. The representation of the temperature dependence of the paramagnetic hyperfine-shifted resonances for some protons is shown in Figure 8. All signals are temperature-independent except for signals (a) and (b). Only signal (a) exhibits anti-Curie behaviour and furthermore signal (b) shows Curie behaviour. Extrapolated values at infinite temperatures for signal (a) indicate the existence of magnetic coupling.[31]

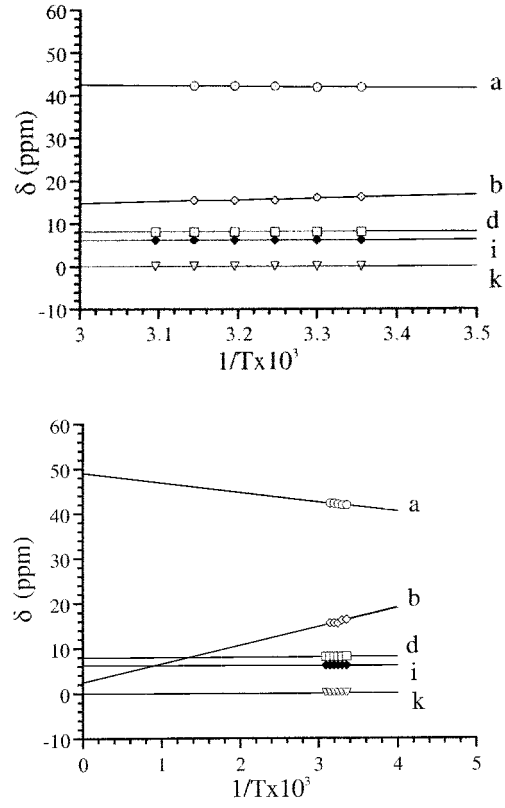


Figure 8. Temperature dependence of the isotropically shifted resonances of red-[**13**]$(ClO_4)_4{\cdot}2H_2O$; the insert shows the plot with the $1/T$ coordinate expanded

Magnetic Measurements of {red-[13] $(ClO_4)_4{\cdot}2H_2O$} and {[11] $(ClO_4)_2$}

The magnetic properties of $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {[**11**]$(ClO_4)_2$} and $[Cu_2(\mathbf{L^4})](ClO_4)_4{\cdot}2H_2O$ {red-[**13**]$(ClO_4)_4{\cdot}2H_2O$} are shown in Figure 9 in the form of $\chi_M T$ versus T, χ_M being the magnetic susceptibility per two copper(II) ions. The value of $\chi_M T$ at room temperature is 0.46 $cm^3{\cdot}mol^{-1}$ K for $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ and $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$, a value which is significantly lower than that expected for two uncoupled Cu^{II} ions. Upon cool-

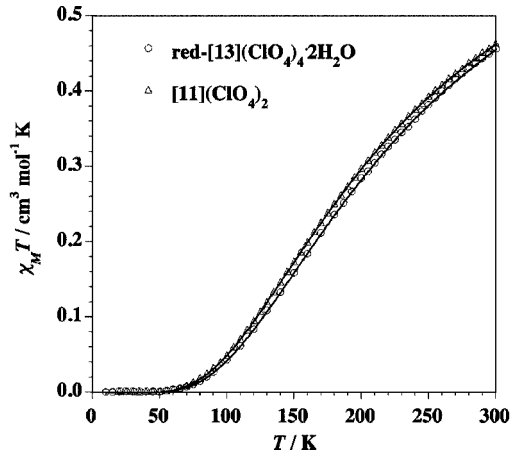

Figure 9. Plot of $\chi_M T$ vs. T for the complexes red-[**13**]$(ClO_4)_4{\cdot}2H_2O$ and [**11**]$(ClO_4)_2$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing $\chi_M T$ continuously decreases, vanishing at around 70 K. Moreover, the corresponding χ_M curves show maxima at 270 K (for $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$) and 255 K (for $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$] (see Supporting Information, Figure S2). This magnetic behaviour is characteristic of an important antiferromagnetic interaction between the Cu^{II} ions with singlet spin ground states.

We have interpreted the magnetic data according to the actual dinuclear nature of the complexes with the spin Hamiltonian $\mathbf{H} = -J\mathbf{S_1S_2}$. The fit of the magnetic data to the appropriate susceptibility expression derived from the van Vleck formula and assuming that the *g* factors for both Cu^{II} ions are identical, leads to $J = -299(7)$ cm^{-1} and $g = 2.09(1)$ for red-$[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ {red-**[13]**$(ClO_4)_2{\cdot}2H_2O$}, and $J = -286(6)$ cm^{-1} and $g = 2.07(1)$ for $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {**[11]**$(ClO_4)_2$}.

The observed *J* values lie in the upper range of the magnetic interactions found for related bis(μ-pyrazolato)-bridged dinuclear complexes. In fact, to the best of our knowledge, the highest *J* value observed for this family is $J = -412$ cm^{-1} for the compound $[Cu_2\mathbf{L^2}](BF_4)_2$ where L = 3,5-bis(*i*PrSCH$_2$)pyz.[32] The existence of σ-donor atoms as peripheral ligands may be responsible for these strong interactions.[33] However, the number of structurally characterised examples reported in the literature is still limited.[34]

The pathway for magnetic exchange is propagated through the bridging pyrazolate ligands. From the molecular structure of $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {**[11]**$(ClO_4)_2$} one can conclude that the unpaired electron in each metal centre is clearly described by a $d_{x^2-y^2}$ magnetic orbital which is coplanar with the pyrazolate skeleton. The significant overlap between these magnetic orbitals accounts for the strong antiferromagnetic coupling observed. Although the crystal structure of $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ is not available, the very close magnetic behaviour of the complexes $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2H_2O$ {red-**[13]**$(ClO_4)_4{\cdot}2H_2O$} and $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ allows us to predict a similar exchange pathway. This again supports the suggestion that deprotonation of the pyrazole rings has occurred in both structures.

Conclusions

The synthesis of a 2+2 polyamine macrocycle containing pyrazole spacers connected through methylene groups to dipropylenetriamine bridges (**L^4**) has been described here for the first time. The acid-base behaviour of **L^4** in water reveals that, like the analogous macrocycle containing diethylenetriamine bridges (**L^1**), the pyrazole spacers do not participate in any net protonation step in the pH range of 2−11. The number of protonation steps observed is equal to the number of amino groups in the bridges. ^{1}H and ^{13}C NMR spectroscopy support this conclusion. The overall basicity of **L^4** is, on the other hand, five orders of magnitude greater than that of **L^1**. The deprotonation of the pyrazole moieties can, however, be readily achieved in the presence of coordinated metal ions. Cu^{II} induces the deprotonation of the pyrazole rings at lower pH values than Zn^{II} due to its much stronger interaction with the ligand. On the other hand, pyrazole deprotonation is more readily achieved (at more acidic pH values) with the ligand **L^1** bearing ethylenic chains in the bridges with five-membered chelates than in **L^4** containing six-membered chelates and a higher overall basicity.

The higher basicity of **L^4** is also reflected in the different syntheses of the dinuclear solid complexes which we have carried out. In the case of **L^1**, treatment of $Cu(ClO_4)_2{\cdot}6H_2O$ with either neutral **L^1** or with its disodium salt $Na_2[H_{-2}\mathbf{L^1}]$ in ethanol followed by crystallisation from water leads to the formation of the same dinuclear complex $[Cu_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ in which the pyrazole groups are deprotonated thereby behaving as $\eta^1{:}\eta^1$ monodentate bridging ligands and the polyamine bridges are completely deprotonated. In the case of **L^4** the situation is different. Treatment of neutral **L^4** with $Cu(ClO_4)_2{\cdot}6H_2O$ in MeOH gives a blue solid complex which by heating in boiling water (for 5 min) followed by slow crystallisation leads to a red compound. The elemental analyses of both the blue and the red forms of this complex are consistent with the same empirical formula, i.e. $[Cu_2\mathbf{L^4}](ClO_4)_4{\cdot}2(H_2O)$. The ESI-MS and ^{1}H NMR paramagnetic data of the red complex clearly indicates that it is a dinuclear square-planar Cu^{II} complex in which the central nitrogen atoms of the bridging chains are not involved in the coordination to the metal ions and are therefore protonated. On the basis of both the elemental analysis of {red-**[13]**$(ClO_4)_4{\cdot}2H_2O$} and crystallographic data of polyamine receptors previously reported, it seems reasonable to suppose that the above-mentioned protonated nitrogen atoms may be hydrogen-bonded to water molecules [Scheme 4, **13** (red form)]. The blue form shows the same feature but in this case the coordination geometry should be pyramidal with the water molecules occupying the axial positions. The exchange between the two forms depends on both the temperature and the solvent. Therefore, the marked basicity of the propylamine chains facilitates the capture of the protons released from the pyrazole rings.

However, if $Cu(ClO_4)_2{\cdot}6H_2O$ is treated with the sodium salt $Na_2[H_{-2}\mathbf{L^4}]$ in methanol followed by crystallisation from water, the complex obtained is $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {**[11]**$(ClO_4)_2$} which is analogous to that obtained with **L^1** (Scheme 3). The crystal structure of $[Cu_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ shows a very irregular square-pyramidal coordination geometry in which the shorter distances are those involving the pyrazole nitrogen atoms and the axial ones are involved in both coordination sites by the central nitrogen atoms of the propylenic chains. Analogously, in the case of Zn^{II}, the crystal structures of $[Zn_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ {**[8]**$(ClO_4)_2$} and $[Zn_2(H_{-2}\mathbf{L^4})](ClO_4)_2$ {**[12]**$(ClO_4)_2$} also reveal similar coordination arrangements. In the three structures, the overall shape of the complex cations is boat-like with the central parts of the polyamine bridges displaced towards the same side of the macrocyclic ring.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Finally, treatment of concentrated solutions of **L⁴** with $Cu(ClO_4)_2 \cdot 6H_2O$ gives a trinuclear complex of stoichiometry $[Cu_3(H_{-2}\mathbf{L^4})](ClO_4)_4 \cdot 2MeOH$ in low yield which has been characterised by MALDI-TOF mass spectrometry. The boat-like arrangement of the macrocycle in the dinuclear complex seems to facilitate the process.

Experimental Section

General: All starting materials were purchased from commercial sources (Aldrich) and used without further purification. Solvents were dried using standard techniques.[35] The organic reactions were monitored by thin layer chromatography (TLC) on precoated aluminium sheets of silica gel. Compounds were detected with iodine and/or with phosphomolybdic acid. Flash column chromatography was performed in the indicated solvent system on silica gel (particle size 0.040−0.063 mm). Melting points were determined with a Reichert-Jung hot-stage microscope. ^1H and ^{13}C NMR spectra were recorded with Varian Unity Inova-300, Varian Unity Inova-400 or Varian Unity 500 spectrometers at room temperature, employing D_2O or [D_6]DMSO as solvents. The pH was calculated from the measured pD values using the correlation pH = pD − 0.4.[36] Chemical shifts are reported in parts per million (ppm) from tetramethylsilane but were measured against the solvent signals. Dioxane (δ = 67.4 ppm) was used as reference for the ^{13}C NMR spectra in D_2O. All assignments were performed on the basis of ^1H-^{13}C heteronuclear multiple quantum coherence experiments (gHSQC and gHMBC). IR spectra were recorded with a Perkin−Elmer 681 spectrometer. EI mass spectra were recorded with a Hewlett Packard 5973 spectrometer with a direct insertion probe (70 eV). Electrospray mass spectra were obtained with a Hewlett Packard 1100 MSD and FAB mass spectra with a VG AutoSpec spectrometer using an *m*-nitrobenzyl alcohol (NBA) matrix. Elemental analyses were provided by the Departamento de Análisis, Centro de Química Orgánica "Manuel Lora Tamayo", CSIC, Madrid, Spain. Cu−Cl ratios were provided by the SCSIE (University of Valencia) using X-ray energy dispersive spectroscopy with an EDAX DX4 detector and a Philips XL30 ESEM electronic microscope.

Synthesis of Ligands: Ligands **L¹** (**1**), **L²** (**2**) and **L³** (**3**) were prepared by treatment of the corresponding 3,5-pyrazoledicarbaldehydes with diethylenetriamine [**L¹** (**1**) and **L³** (**3**)] or tris(2-aminoethyl)amine **L²** (**2**) as reported previously in refs.[10,11], respectively.

3,7,11,14,15,18,22,26,29,30-Decaazatricyclo[26.2.1.1^{13,16}]dotriaconta-1(31),13,16(32),28-tetraene [L⁴ (4)]: 3,5-Pyrazoledicarbaldehyde (496 mg, 4.0 mmol) was dissolved in hot dry methanol (200 mL). The solution was then cooled to room temperature and added dropwise under argon to a stirred solution of *N*-(3-aminopropyl)-1,3-propanediamine (525 mg, 4 mmol) in dry methanol (120 mL) over 2.5 h. The reaction was monitored by TLC ($CHCl_3$/MeOH, 10:1) and when it was complete (ca. 12 h), $NaBH_4$ (912 mg, 24.0 mmol) was added portionwise over 15 min. The mixture was stirred for 2 h and the solvent removed in vacuo. The residue was purified by flash column chromatography (MeOH/30% aqueous NH_4OH, 49:1 to 45:5 mixtures). The fractions containing the product of R_f = 0.65 (TLC, MeOH/30% aqueous NH_4OH, 1:1) were concentrated to dryness. The residue was then extracted with boiling toluene and on concentration and cooling gave **L⁴** (**4**) as an oil which was crystallised from toluene to give a white solid (443 mg, 49%) m.p. 154−156 °C. IR (KBr): $\tilde{\nu}$ = 3500−3300 cm^{-1} (NH). MS (FAB$^+$, 3-nitrobenzyl alcohol matrix): *m*/*z* (%) = 447 (100) [MH^+]. $C_{22}H_{42}N_{10}$ (446.6): calcd. C 59.16, H 9.48, N 31.36; found C 58.92, H 9.62, N 31.11.

Preparation of L⁴·6HCl (4·6HCl): A mixture of **L⁴** (**4**) (223 mg, 0.5 mmol) and 1 M aqueous hydrochloric acid (4 mL) was stirred for 12 h. After addition of EtOH (50 mL), a white precipitate formed which was filtered off and dried under reduced pressure for 48 h to give a white solid (319 mg, 91%); m.p. 265−268 °C. MS (ESI positive mode, H_2O): *m*/*z* (%) = 447 (100) [(M − 6 HCl)H$^+$]. $C_{22}H_{42}N_{10} \cdot 6HCl \cdot 2H_2O$ (701.4): calcd. C 37.67, H 7.47, N 19.97; found C 38.05, H 7.70, N 19.78.

Preparation of 4′ [Na₂(H₋₂L⁴)]: To a stirred solution of **4** (45 mg, 0.1 mmol) in dry MeOH (2 mL), was added NaOH (8 mg, 0.2 mmol), previously dissolved in MeOH (1 mL). The mixture was stirred at room temperature for 12 h. The solvent was then evaporated and the residue dried under reduced pressure for 48 h to give **4′** as a white solid (48 mg, 98%); m.p. 208−210 °C. MS (ESI positive mode, H_2O/MeOH): *m*/*z* (%) = 491.2 (10) [M + H]$^+$, 469.3 (76) [M + 2 H − Na]$^+$, 447.3 (100) [M + 3 H − 2 Na]$^+$. $C_{22}H_{40}N_{10}Na_2$ (490.6): calcd. C 53.86, H 8.21, N 28.54; found C 53.87, H 8.16, N 28.57.

Syntheses of $[Zn_2(H_{-2}L^1)](ClO_4)_2$ {[8](ClO₄)₂}, $[Zn_2(H_{-2}L^2)](ClO_4)_2 \cdot 4H_2O$ {[9](ClO₄)₂·4H₂O} and $[Zn_2(L^3)](ClO_4)_4 \cdot 6H_2O$ {[10](ClO₄)₄·6H₂O} from Ligands L¹−L³ (1−3). General Procedure: Working under argon, a solution of $Zn(ClO_4)_2 \cdot 6H_2O$ (74 mg, 0.2 mmol) in dry MeOH (1 mL) was added with stirring to a solution of the polyamine ligand L¹−L³ (0.1 mmol), dissolved in 2 mL of the same solvent. After 12 h, the precipitate was collected by filtration and vacuum-dried at 100 °C over phosphorus pentoxide for 24 h. In all cases, the white solid thus obtained was crystallised from water.

{[8](ClO₄)₂}: Yield 55 mg, 77%. M.p. > 350 °C. MS (ESI positive mode, H_2O): *m*/*z* (%) = 615.1 (10) [M − ClO_4]$^+$, 453.4 (100) [M + H − $Zn(ClO_4)_2$]$^+$, 391.4 (75) [M + 3 H − 2 $ZnClO_4$]$^+$. MS (FAB$^+$, 3-nitrobenzyl alcohol matrix): *m*/*z* (%) = 616.9 (20) [(M + 2 H)$^+$ − ClO_4], 615.4 (12) [M$^+$ − ClO_4], 553.2 (100) [(M + 2 H)$^+$ − $ZnClO_4$], 453.2 (47) [(M + H)$^+$ − $Zn(ClO_4)_2$]. $C_{18}H_{32}N_{10}Zn_2(ClO_4)_2$ (718.2): calcd. C 30.16, H 4.47, N 19.55; found C 30.39, H 4.77, N 19.73.

{[9](ClO₄)₂·4H₂O}: Yield 78 mg, 80%. M.p. > 350 °C. MS (ESI positive mode, MeOH/H_2O): *m*/*z* (%) = 893.2 (2) [M + H]$^+$, 793.2 (73) [M − ClO_4]$^+$, 731.4 (58) [M + 2 H − $ZnClO_4$]$^+$, 631.4 (50) [M + H − $ZnClO_4$ − ClO_4]$^+$, 569.5 (100) [M + 3 H − 2 $ZnClO_4$]$^+$. MS (FAB$^+$, 3-nitrobenzyl alcohol matrix): *m*/*z* (%) = 893.1 (23) [M + H]$^+$, 793.2 (63) [M$^+$ − ClO_4], 695 (100) [(M + H)$^+$ − 2 ClO_4], 731.3 (56) [M + H − $Zn(ClO_4)$]$^+$, 631.3 (77) [M + H − $Zn(ClO_4)_2$]$^+$. $C_{27}H_{46}N_{14}Zn_2(ClO_4)_2 \cdot 4H_2O$ (968.5): calcd. C 33.48, H 5.62, N 20.24; found C 33.26, H 5.40, N 20.46.

{[10](ClO₄)₂·6H₂O}: Yield 91 mg, 75%. M.p. > 350 °C. MS (ESI positive mode, MeOH/H_2O): *m*/*z* (%) = 995.1 (5) [(M − ClO_4]$^+$, 833.0 (31) [M + H − $Zn(ClO_4)_2$]$^+$, 733.5 (54) [M − Zn − 3 ClO_4]$^+$, 671.2 (100) [M + 2 H − 2 Zn − 3 ClO_4]$^+$, 571.6 (91) [M + H − 2 $Zn(ClO_4)_2$]$^+$. MS (FAB$^+$, 3-nitrobenzyl alcohol matrix): *m*/*z* (%) = 996.1 (20) [(M + H)$^+$ − ClO_4], 995.1 (44) [M$^+$ − ClO_4], 897 (33) [(M + 2 H)$^+$ − 2 ClO_4], 895 (21) [M$^+$ − 2 ClO_4], 733.3 (23) [M$^+$ − $Zn(ClO_4)_2$ − ClO_4], 633.3 (30) [M$^+$ − $Zn(ClO_4)_2$ − $HClO_4$]. $C_{32}H_{46}N_{10}Zn_2(ClO_4)_4 \cdot 6H_2O$ (1207.5): calcd. C 31.84, H 4.81, N 11.61; found C 31.91, H 5.17, N 11.69.

Synthesis of M^{II} Dinuclear Complexes from the Disodium Dipyrazolate Salt 4′

Preparation of $[Cu_2(H_{-2}L^4)](ClO_4)_2$ {[11]$(ClO_4)_2$}: To a stirred solution of the sodium dipyrazolate salt **4′** (53 mg, 0.1 mmol) in MeOH (2 mL) was added a solution of $Cu(ClO_4)_2·6H_2O$ (74 mg, 0.2 mmol) in 2 mL of the same solvent dropwise under argon. The mixture was stirred at room temperature overnight and the desired complex $[Cu_2(H_{-2}L^4)](ClO_4)_2$ {[**11**]$(ClO_4)_2$} separated as a blue precipitate. This was isolated by filtration, dried under vacuum and crystallised from a water/methanol mixture (2:3) (16 mg, 21%); m.p. > 350 °C. MS (ESI positive mode, H_2O/MeOH): *m/z* (%) = 671.0 (100) $[M - ClO_4]^+$, 571.2 (58) $[M - ClO_4 - HClO_4]^+$, 508.1 (9) $[M + H - Cu(ClO_4)_2]^+$. $C_{22}H_{40}Cu_2N_{10}(ClO_4)_2$ (770.61): calcd. C 34.28, H 5.23, N 18.17; found C 34.05, H 4.98, N 17.96.

Preparation of Zn^{II} Dinuclear Complex $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[12]$(ClO_4)_2$}: To a stirred solution of the sodium dipyrazolate salt of **4′** (53 mg, 0.1 mmol) in MeOH (2 mL) was added a solution of $Zn(ClO_4)_2·6H_2O$ (74 mg, 0.2 mmol) in 2 mL of the same solvent dropwise under argon. The mixture was stirred at room temperature overnight and the title complex precipitated. It was then isolated by filtration, dried under vacuum and crystallised from a water/methanol mixture (2:3) to afford $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[**12**]$(ClO_4)_2$} as a white solid (27 mg, 35%); m.p. > 350 °C. MS (ESI positive mode, H_2O/MeOH): *m/z* (%) = 671.2 (32) $[M - ClO_4]^+$, 609.3 (27) $[M + 2\,H - Zn - ClO_4]^+$, 575.2 (51) $[M + H - 2\,ClO_4H]^+$, 509.4 (100) $[M + H - Zn(ClO_4)_2]^+$, 447.4 (64) $[M + 3\,H - Zn(ClO_4)_2 - Zn]^+$. $C_{22}H_{40}N_{10}Zn_2(ClO_4)_2$ (774.3): calcd. C 34.13, H 5.21, N 18.09; found C 33.99, H 5.24, N 17.97.

Synthesis of Cu^{II} Dinuclear Complexes from Ligand 4

Preparation of Cu^{II} Dinuclear Complex $[Cu_2L^4](ClO_4)_4·2H_2O$ {[13]$(ClO_4)_4·2H_2O$} (Blue and Red Forms): Working under argon, a solution of $Cu(ClO_4)_2·6H_2O$ (74 mg, 0.2 mmol) in dry MeOH (2 mL) was added with stirring to a solution of the polyamine ligand **4** (45 mg, 0.1 mmol) in 2 mL of same solvent. After 4 h, a blue precipitate had formed. This was filtered off and vacuum-dried at 100 °C over phosphorus pentoxide for 24 h to give a blue solid (72 mg, 71%); m.p. > 350 °C. MS (ESI negative mode, H_2O/MeOH): *m/z* (%) = 1070.9 (35) $[M + ClO_4]^-$, 968.8 (6) $[M - H]^-$, 869.0 (100) $[M - (HClO_4 + H)]^-$. MS (ESI positive mode, H_2O/MeOH): *m/z* (%) = 871.0 (10) $[(M - ClO_4]^+$, 771.0 (10) $[(M - (HClO_4 + ClO_4)]^+$, 710.2 (30) $[M - Cu(ClO_4)_2 + H]^+$, 671.1 (100) $[M - (2\,HClO_4 + ClO_4)]^+$, 608.1 (5) $[M - \{Cu(ClO_4)_2 + ClO_4\}]^+$, 547.3 (51) $[M - \{Cu(ClO_4)_2 + CuClO_4\} + 2\,H]^+$. $C_{22}H_{40}Cu_2N_{10}(ClO_4)_2(HClO_4)_2(H_2O)_2$ (1007.56): calcd. C 26.23, H 4.60, N 13.90; found C 26.21, H 4.54, N 13.69. When the above blue solid was heated to reflux in water (5 mL) for 5 min and the resultant blue aqueous solution allowed to stand at room temperature, a red precipitate was unexpectedly obtained upon slow evaporation of the solvent. This was filtered off, washed with methanol and vacuum-dried at 100 °C over phosphorus pentoxide for 24 h to give the complex {red-[**13**]$(ClO_4)_4·2H_2O$} as a brown-reddish solid (61 mg, 60%); m.p. > 350 °C. MS (ESI negative mode, H_2O/MeOH): *m/z* (%) = 1071.4 (100) $[M + ClO_4]^-$, 969.4 (15) $[M - H]^-$, 869.4 (83) $[M - (HClO_4 + H)]^-$. MS (ESI positive mode, H_2O/MeOH): *m/z* (%) = 871.0 (3) $[M - ClO_4]^+$, 771.0 (4) $[M - (HClO_4 + ClO_4)]^+$, 710.1 (22) $[M - Cu(ClO_4)_2 + H]^+$, 671.1 (59) $[M - (2\,HClO_4 + ClO_4)]^+$, 608.1 (23) $[M - \{Cu(ClO_4)_2 - ClO_4\}]^+$, 547.3 (33) $[M - \{Cu(ClO_4)_2 + CuClO_4\} + 2\,H]^+$, 447.4 (41) $[M - 2\,Cu(ClO_4)_2 + H]^+$, 224.3 (100) $[\{M - 2\,Cu(ClO_4)_2\}/2 + H]^+$. MS ($FAB^+$, 3-nitrobenzyl alcohol matrix): *m/z* (%) = 871.1 (3) $[M - ClO_4]^+$, 771.2 (12) $[M - (HClO_4 + ClO_4)]^+$, 710.3 (7) $[M - Cu(ClO_4)_2 + H]^+$, 671.2 (100) $[M - (2\,HClO_4 + ClO_4)]^+$, 608.3 (5) $[M - \{Cu(ClO_4)_2 - ClO_4\}]^+$, 659.2 (44) $[M - \{3\,HClO_4 + ClO_4\}]^+$, 507.3 (7) $[M - \{Cu(ClO_4)_2 + 2\,HClO_4\}^{·+}]$. $C_{22}H_{42}Cu_2N_{10}(ClO_4)_4·2H_2O$ (1007.56): calcd. C 26.23, H 4.60, N 13.90; found C 26.31, H 4.77, N 13.86.

Preparation of the Green Cu^{II} Trinuclear Complex $[Cu_3(H_{-2}L^4)](ClO_4)_4·2MeOH$ {[14]$(ClO_4)_4·2MeOH$}: Basic anion-exchange resin (DOWEX, 550A OH) was added in portions to a stirred solution of [**4**]·6HCl (100 mg, 0.14 mmol) in H_2O (20 mL) until a pH of 11−12 was reached. The resin was then filtered off and the solvent removed under reduced pressure. The resultant solid was crystallised from toluene to give **4** as a white solid of m.p. 154−156 °C. Then, working under argon, a solution of $Cu(ClO_4)_2·6H_2O$ (93 mg, 0.24 mmol) in dry MeOH (1 mL) was added with stirring to a solution of the above polyamine $\mathbf{L^4}$ (**4**) (56 mg, 0.12 mmol) in 1 mL of the same solvent. After 4 h, a green precipitate was formed. This was filtered off and vacuum-dried at 100 °C over phosphorus pentoxide for 24 h to afford compound [**14**]$(ClO_4)_4·2MeOH$ as a green solid; m.p. > 350. MS (FAB^+, 3-nitrobenzyl alcohol matrix): *m/z* (%) = 927.7 (6) $[M - (2\,MeOH + ClO_4H + 4\,H)]^+$, 867.7 (14) $[M - (2\,Me + 2\,ClO_4)]^+$, 827.7 (80) $[M - (2\,MeOH + 2\,ClO_4H + 4\,H)]^+$, 732.1 (59) $[M - (2\,MeOH + 2\,ClO_4H + ClO_4)]^+$, 671.3 (51) $[M - \{2\,MeOH + Cu(ClO_4)_2 + ClO_4\}]^+$, 633.2 (100) $[M - (2\,MeOH + 2\,ClO_4H + ClO_4)]^+$, 569.3 (37) $[M - \{2\,MeOH + Cu(ClO_4)_2 + HClO_4H + ClO_4\}]^+$. MS (MALDI-TOF, 2,5-dihydroxybenzoic acid matrix): *m/z* (%) = 851.2 (16) $[(M - (Me + MeO + 2\,ClO_4)]^+$, 797.2 (27) $[M - 3\,ClO_4 + ClO_4H]^+$, 750.3 (7) $[M - (MeOH + Me + 3\,ClO_4)]^+$, 734.3 (78) $[M - (2\,MeOH + 3\,ClO_4)]^+$, 672.3 (69) $[M - \{2\,MeOH + Cu(ClO_4)_2 + ClO_4\}]^+$, 649.4 (26) $[M - (MeOH + Me + 4\,ClO_4)]^+$, 635.4 (100) $[M - 2\,MeOH + 4\,ClO_4]^+$. $C_{22}H_{40}Cu_3N_{10}(ClO_4)_4·2MeOH$ (1097.14): calcd. C 26.27, H 4.41, N 12.77; found C 26.06, H 4.08, N 12.38.

X-ray Crystallography: Crystal data and details of the data collection for the complexes $[Zn_2(H_{-2}\mathbf{L^1})](ClO_4)_2$ {[**8**]$(ClO_4)_2$}, $[Cu_2(H_{-2}L^4)](ClO_4)_2$ {[**11**]$(ClO_4)_2$} and $[Zn_2(H_{-2}L^4)](ClO_4)_2$ {[**12**]$(ClO_4)_2$} are given in Table 13. The crystal data were collected with a Nonius Kappa CCD instrument (λ = 0.71073 Å). In the case of [**11**]$(ClO_4)_2$ and [**12**]$(ClO_4)_2$ the data were collected at 120 K. The crystals were monitored for decay during data collection and appropriate corrections were made where necessary. A profile analysis was performed on every reflection.[37] A semiempirical absorption correction, Ψ-scan based, was performed in each case.[38] Lorentz and polarisation corrections were applied and the data were reduced to F_o^2 values. The structures were solved by Patterson methods using SHELXS-86 with an IBM PENTIUM II 300 computer.[39] Isotropic least-squares refinements were performed using SHELXL-93.[40] The hydrogen atoms were placed in calculated positions. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were refined with a common thermal parameter. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[41] The molecular plots were produced using ORTEP.[42] CCDC-240640, -240641 and -240642 contain the supplementary crystallographic data for structures [**8**]$(ClO_4)_2$, [**11**]$(ClO_4)_2$ and [**12**]$(ClO_4)_2$, respectively. These data can be obtained free of charge via www.ccdc.cam.ac.uk/const/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; or E-mail: deposit@ccdc.cam.ac.uk].

Electromotive Force (emf) Measurements: The potentiometric titrations were carried out in 0.15 M NaCl at 298.1 ± 0.1 K using the experimental procedure (burette, potentiometer, cell, stirrer,

Weighting details: $\omega = 1/[\sigma^2(F_o^2) + (0.1000P)^2 + 0.0000P]$ where $P = (F_o^2 + 2F_c^2)^{1/3}$

microcomputer, etc.) fully described elsewhere.[43] The acquisition of the emf data was performed with the computer program PASAT.[44] The reference electrode was an Ag/AgCl electrode in a saturated KCl solution. The glass electrode was calibrated as a hydrogen ion concentration probe by titration of known amounts of HCl with CO_2-free NaOH solutions[45] and determination of the equivalent point by Gran's method[46] which gives the standard potential $E^{\circ\prime}$ and the ionic product of water [pK_w = 13.73(1)]. The computer program HYPERQUAD[47] was used to calculate the protonation and stability constants and the DISPO[48] program was used to obtain the distribution diagrams. The titration curves for each system (ca. 200 experimental points corresponding to at least three measurements, pH = 2−11, concentration of ligands 1×10^{-3} to 5×10^{-3} M) were treated either as a single set or as separated curves without significant variations in the values of the stability constants. Finally, the sets of data were merged and treated simultaneously to give the final stability constants.

Magnetic Measurements: Magnetic susceptibility measurements of polycrystalline samples were measured over the temperature range 2−300 K with a Quantum Design SQUID magnetometer using an applied magnetic field of 1 T. Diamagnetic corrections of the constituents atoms were estimated from Pascal's constants and a value of 60×10^{-6} cm^3·mol^{-1} was used for the temperature-independent paramagnetism of each copper(II) ion.

Paramagnetic ^{1}H NMR Spectroscopy: Paramagnetic ^{1}H NMR spectra were recorded with a Varian Unity 400 spectrometer operating at 400 MHz. 1D spectra were recorded in $(CD_3)_2SO$ with presaturation of the $(CH_3)_2SO$ signal during part of the relaxation delay. Because the relaxation times were diverse, a variety of NMR parameters were utilised. Acquisition times from 40 to 80 ms, relaxation delay times from 50 to 200 ms, presaturation times from 50 to 200 ms, spectral widths of 40 to 100 kHz and 256 to 1024 of scans were used. 1D spectra were processed using exponential line-broadening weighting functions as apodisation with values of 20−40 Hz. Chemical shifts were referenced to the residual solvent protons of $(CD_3)_2SO$ resonating at δ = 2.50 ppm relative to $SiMe_4$. ^{1}H longitudinal relaxation times were calculated using the inversion recovery pulse sequence[49] (d_1 − 180° − τ − 90° − acq), 18 values of τ were selected, (d_1 + acq) values were 200 ms and the number of scans was 512. The T_1 values were calculated from the inversion-recovery equation. Transversal relaxation times were obtained by measuring the line broadening of the isotropically shifted signals at half-height with the equation $T_2^{-1} = \pi \Delta\nu_{1/2}$.

Molecular Modelling: Molecular modelling studies were carried out using the AMBER method implemented in the Hyperchem 6.0 package[50] and modified by the inclusion of appropriate parameters. Where available, the parameters were analogous to those reported in the literature.[29,50] All others, namely those regarding the particular atomic connections of our ligands with the metal ion, were developed according to the Norrby procedures[28,51] in a similar way to the ones used in the MOMEC program.[52] The equilibrium bond lengths and angles were derived from experimental values on reasonable reference compounds. All additional parameters are given in the Supporting Information (Table S1). The starting structures were built using Hyperchem capabilities and geometries were minimised to a maximum energy gradient of 0.1 kcal/(Å mol) using the Polak−Ribiere (conjugate gradient) algorithm.

Synthesis and Characterisation of the First Cyanodiselenoimidocarbonate $[C_2N_2Se_2]^{2-}$ Complexes

Colin J. Burchell,[a] Stephen M. Aucott,[a] Alexandra M. Z. Slawin,[a] and J. Derek Woollins*[a]

Keywords: Selenium / Platinum / Coordination modes

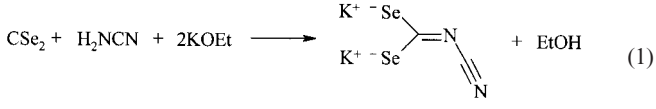
$[Pt(C_2N_2Se_2)(PR_3)_2]$ (PR_3 = PMe_2Ph, PPh_3) and $[Pt(C_2N_2Se_2)(PP)]$ (PP = dppe, dppm, dppf) were obtained by the reaction of the appropriate metal halide containing complex with potassium cyanodiselenoimidocarbonate. The dimeric cyanodiselenoimidocarbonate complexes $[M\{(C_2N_2Se_2)(\eta^5\text{-}C_5Me_5)\}_2]$ (M = Rh Ir)] were synthesised from the appropriate transition metal dimer starting material. The cyanodiselenoimidocarbonate ligand is *Se*,*Se*-bidentate in the monomeric complexes – the terminal CN group is approximately coplanar with the CSe_2 group, and the nitrogen atom is trigonal therefore reducing the planar symmetry of the ligands.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The coordination of chalcogen donor ligands is an important area.[1−12] Sulfur-based ligands, especially *S*,*S*-bidentate ligands, have a variety of industrial applications.[9−12] Relative to the significant interest in sulfur donor ligands, the selenium analogues are a rather understudied area. Metal selenides and metal polyselenides are well known and are readily prepared by direct reaction of the elements. There has been significant interest in ZnSe and CdSe semiconductors in photovoltaic devices because of their intermediate energy bandgap.[13] Hence organometallic compounds such as cadmium and zinc diselenocarbamato complexes[14] and selenoimidophosphonates[13] have been investigated as single-source precursors for deposition of these semiconductor materials. Other well-established selenium donor ligands include the selenoethers[15−18] and the pseudohalide selenocyanate.[19,20] However, there are very few *Se*,*Se*-bidentate ligands reported in the literature, which include a series of (diselenothiocarbonato)bis(phosphane)platinum compounds,[21] two triselenocarbonate complexes $[(\eta\text{-}^5C_5H_5)Co(CSe_3)(PMe_3)]$[22] and $[Ba(CSe_3)]$,[23] a (2,4-dioxo-3,3-pentanediselenolato)bis(phosphane)platinum complex,[24] two diselenocarbonimidato compounds,[25,26] $[\{CH[Si(CH_3)_3]_2\}_2Sn(SeSe)PC_6H_2[C(CH_3)_3]_3]$[27] and a series of $[Pt\{Se_2P(Se)(C_6H_5)\}(PR_3)_2]$ complexes.[28] As part of our program studying the properties of chalcogen donor systems we have recently reported a series of cyanodithioimidocarbonate complexes.[29] Here we describe the synthesis of the corresponding cyanodiselenoimidocarbonate complexes. Selected examples have been chosen for crystallographic study.

Results and Discussion

The synthesis of dipotassium cyanodiselenoimidocarbonate was reported by Jensen and Henriksen in 1970.[30] The original synthesis involved the dropwise addition of potassium hydroxide in water to cyanamide and carbon diselenide in dioxane at 0 °C. Our synthesis is essentially the same [Equation (1)], except the reaction was carried out in ethanol and potassium ethoxide was used in place of potassium hydroxide to prevent the generation of water during the reaction.



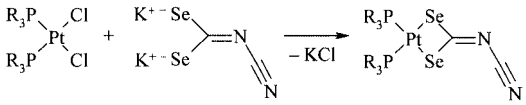
(1)

After suction filtration under nitrogen, the product was obtained as an impure off-yellow solid. In the IR spectrum, a strong ν(C≡N) band at 2127 cm^{-1} and a strong band at 1347 cm^{-1} assigned as ν(C=N) are observed. Purification proved unsuccessful, hence the dipotassium cyanodiselenoimidocarbonate was used as obtained for subsequent reaction.

The bis(phosphane)platinum complexes $[Pt(C_2N_2Se_2)(PR_3)_2]$ (PR_3 = PMe_2Ph, PPh_3) and $[Pt(C_2N_2Se_2)(PP)]$ (PP = dppe, dppm, dppf) were obtained by reaction of the appropriate $[PtCl_2(PR_3)_2]$ or $[PtCl_2(PP)]$ complex with excess potassium cyanodiselenoimidocarbonate in tetrahydrofuran. A large excess of the dipotassium salt was used as

[a] School of Chemistry, University of St. Andrews, St. Andrews, Fife KY16 9ST, UK
E-mail: jdw3@st-andrews.ac.uk

this gave a cleaner reaction. The solvent was evaporated under reduced pressure, and dichloromethane was added. The mixture was filtered through a Celite pad to remove precipitated KCl and any residual dipotassium cyanodiselenoimidocarbonate, and the filtrate was then concentrated to dryness to give the product [Equation (2)].



1 PR_3 = PMe_2Ph
2 PR_3 = PPh_3
3 PR_3 = 1/2dppe
4 PR_3 = 1/2dppm
5 PR_3 = 1/2dppf (2)

The microanalyses of all compounds were satisfactory, and all compounds showed the anticipated [M^+] peak in their mass spectra (Table 1). The ν(C≡N) vibrations are observed in the range 2174−2179 cm^{-1}, and the ν(C=N) vibrations can be seen in the region of 1492−1495 cm^{-1} (Table 2); these values are comparable with the corresponding (cyanodithioimidocarbonate)bis(phosphane)platinum complexes.[29] The ν(Pt−Se) bands all lie within the range 246−294 cm^{-1} (Table 2). The (cyanodiselenoimidocarbonate)bis(phosphane)platinum complexes **1**−**5** (Table 2) all show sharp singlets with platinum and selenium satellites in their $^{31}P\{^1H\}$ NMR spectra, and have similar δ values to the sulfur analogues.[29] The $^1J(^{195}Pt-^{31}P)$ coupling constants lie in the range 2620−3263 Hz, and the variations reflect the nature of the phosphane group. In all the complexes, *cis* and *trans* $^2J(^{31}P-^{77}Se)$ couplings can be observed (Table 2). The values noted are of similar magnitude to those found in the literature for bis(phosphane)platinum complexes containing selenium donor ligands. Some comparable examples are $[PtSe_2C_2(CO_2CH_3)_2(PPh_3)_2]$[31] [$^2J(^{31}P-^{77}Se)$ 52 Hz], $[Pt\{C_6H_2(CF_3)_3\}Se]_2(PPh_3)_2]$[32] [$^2J(^{31}P-^{77}Se)$ 47 Hz] and $[(CO)_6Fe_2(\mu_3\text{-}Se)_2Pt(PPh_3)_2]$[33] [$^2J(^{31}P-^{77}Se)$ 24 Hz]. The X-ray crystal structures of both **1** (Table 3, Figure 1) and **3** (Table , Figure 2) were obtained. In both examples, the X-ray analysis shows that the platinum core lies at the centre of a distorted square-planar coordination sphere. The distortion from idealised square-planar geometry (90°) can be illustrated by the P(1)−Pt(1)−P(2) bond angle of 94.46(9)° in **1** and 86.64(8)° in **3**. The corresponding Se(1)−Pt(1)−Se(2) bite angles in **1** and **3** are 77.37(4)° and 77.81(3)°, respectively. In the $PtSe_2C$ ring for **1**, the Pt−Se−C angles are 86.1(3)° and 86.9(3)°. The Se(1)−C(1)−Se(2) angle is 109.5(5)°. In compound **3**, the Pt−Se−C angles are 86.1(2)° and 85.9(2)°. The Se(1)−C(1)−Se(2) angle is 110.2(4)°. The nonbonded selenium distance is 3.08 Å and 3.09 Å for **1** and **3**, respectively, and both these values correspond to about 81% of the van der Waals radii of selenium, which implies that there is a significant interaction between the two selenium atoms. As observed in the sulfur analogues, N(1) is trigonal therefore reducing the planar symmetry of the ligand in both **1** and **3**. In **1**, the cyanodiselenoimidocarbonate ligand lies within the coordination plane with the exception of C(1)−N(1)−C(2)−N(2), which is hinged at an angle of 9° to the plane. In **3**, the whole complex is almost planar, however, there is a small hinge angle of 2° with respect to the coordination plane.

The dimeric cyanodiselenoimidocarbonate complexes $[M\{(C_2N_2Se_2)(\eta^5\text{-}C_5Me_5)\}_2]$ [M = Rh (**6**), Ir (**7**)] were synthesised and isolated in a similar manner to the (cyanodiselenoimidocarbonate)bis(phosphane)platinum complexes **1**−**5** by reaction of excess dipotassium salt with the appropriate transition metal dimer starting material [Equation (3)].Compounds **6** and **7** both gave satisfactory microanalyses and show the anticipated [M^+] peak in their mass spectra (Table 1). The ν(C≡N) vibrations are observed at

Table 1. Microanalytical (calculated values in parentheses) and mass spectrometric data for complexes **1**−**7**

Complex	C	H	N	*m/z*

Experimental Section

General: Unless otherwise stated, operations were carried out under oxygen-free nitrogen by using standard Schlenk techniques. All solvents and reagents were purchased from Aldrich, Alfa Aesar, BDH, Fisons and Strem and used as received. We are grateful to Johnson Matthey PLC for the loan of the precious metal salts. Diethyl ether and tetrahydrofuran were purified by reflux in the presence of sodium/benzophenone and by distillation under nitrogen. Hexane was purified by reflux in the presence of sodium and by distillation under nitrogen. Dichloromethane was heated to reflux in the presence of powdered calcium hydride and distilled under nitrogen. CD_2Cl_2 (99.6+ atom D) was used as received. Carbon diselenide was prepared as a dichloromethane solution by passing dichloromethane over elemental selenium at 600 °C.[34,35] The metal complexes $[\{RhCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)\}_2]$[36] and $[\{IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)\}_2]$[36] were prepared according to literature procedures. The complexes $[PtCl_2(PMe_2Ph)_2]$, $[PtCl_2(PPh_3)_2]$, $[PtCl_2(dppe)]$ [dppe = bis(diphenylphosphanyl)ethane], $[PtCl_2(dppm)]$ and $[PtCl_2(dppf)]$ [dppf = bis(diphenylphosphanyl)ferrocene] were prepared by the addition of stoichiometric quantities of the appropriate free phosphane or diphosphane to a dichloromethane solution of $[PtCl_2(cod)]$ (cod = cycloocta-1,5-diene). Infrared spectra were recorded (IR spectra as KBr discs, unless otherwise stated) with a Perkin−Elmer System 2000 FT/IR/Raman spectrometer. ^{31}P, ^{13}C and ^1H NMR spectra were recorded with a JEOL DELTA GSX 270 FT NMR spectrometer. Microanalysis was performed by the University of St. Andrews service. Fast atom bombardment (FAB) and electron ionisation (EI) mass spectra were performed by the EPSRC National Mass Spectrometer service.

$[Pt(C_2N_2Se_2)(PMe_2Ph)_2]$ (1): $[PtCl_2(PMe_2Ph)_2]$ (0.050 g, 0.0769 mmol) was dissolved in THF (20 mL), and potassium cyanodiselenoimidocarbonate (0.167 g, 0.580 mmol) was added as a solid in one portion. The resulting orange solution was stirred in the absence of light for 48 h. The solvent was evaporated in vacuo, and the remaining solid was extracted with dichloromethane (20 mL). The mixture was filtered through a Celite pad to remove precipitated KCl and washed with additional dichloromethane (30 mL). The filtrate was concentrated to dryness in vacuo to give a pale orange powder. The following compounds **2**−**7** were prepared and worked up in the same manner as platinum complex **1**. The product was recrystallised by vapour diffusion from chloroform/hexane to give X-ray quality crystals. Yield 0.027 g (52%). ^1H NMR

Final *R*1, *wR*2 [$I > 2\sigma(I)$]	0.0426, 0.0687	0.0314, 0.0533

(CD_2Cl_2): δ = 1.63 [d, $^3J(^{195}Pt-^1H)$ = 36 Hz, $^2J(^{31}P-^1H)$ = 10 Hz, 12 H, PMe], 7.48−7.69 (m, 10 H, aromatic H) ppm.

[Pt($C_2N_2Se_2$)(PPh_3)$_2$] (2): [$PtCl_2(PPh_3)_2$] (0.050 g, 0.0632 mmol) and potassium cyanodiselenoimidocarbonate (0.208 g, 0.722 mmol) gave the product as a beige powder. Yield 0.029 g (49%). ^{1}H NMR (CD_2Cl_2): δ = 7.24−7.52 (m, 30 H, aromatic H).

[Pt($C_2N_2Se_2$)(dppe)] (3): [$PtCl_2$(dppe)] (0.060 g, 0.0903 mmol) and potassium cyanodiselenoimidocarbonate (0.227 g, 0.788 mmol) gave the product as an orange powder. The product was recrystallised by vapour diffusion from chloroform/hexane to give X-ray quality crystals. Yield 0.049 g (67%). ^{1}H NMR (CD_2Cl_2): δ = 2.40−2.59 (m, 4 H, PCH_2CH_2P), 7.48−7.69 (m, 20 H, aromatic H) ppm.

[Pt($C_2N_2Se_2$)(dppm)] (4): [$PtCl_2$(dppm)] (0.060 g, 0.0923 mmol) and potassium cyanodiselenoimidocarbonate (0.211 g, 0.732 mmol) gave the product as a yellow powder. Yield 0.022 g (30%). ^{1}H NMR (CD_2Cl_2): δ = 3.89−4.18 (m, 2 H, PCH_2P), 7.25−7.71 (m, 20 H, aromatic H) ppm.

[Pt($C_2N_2Se_2$)(dppf)] (5): [$PtCl_2$(dppf)] (0.080 g, 0.0975 mmol) and potassium cyanodiselenoimidocarbonate (0.085 g, 0.295 mmol) gave the product as a yellow powder. Yield 0.044 g (45%). ^{1}H NMR (CD_2Cl_2): δ = 4.36 [br. m, 4 H, β-CH (C_5H_4)], 4.44 [br. m, 4 H, α-CH (C_5H_4)], 7.36−7.88 (m, 20 H, aromatic) ppm.

[{Rh($C_2N_2Se_2$)(η^5-C_5Me_5)}$_2$] (6): [{RhCl(μ-Cl)(η^5-C_5Me_5)}$_2$] (0.060 g, 0.0971 mmol) and potassium cyanodiselenoimidocarbonate (0.359 g, 1.246 mmol) gave a very dark red powder. Yield 0.037 g (42%). ^{1}H NMR (CD_2Cl_2): δ = 1.54−1.89(m, 30 H, η^5-C_5Me_5) ppm. Selected IR data (KBr): $\tilde{\nu}$ = 2162 [s, ν(C≡N)], 1492 [br., s, ν(C=N)], 279 (w), 259 [w, ν(Rh−S)] cm^{-1}.

[{Ir($C_2N_2Se_2$)(η^5-C_5Me_5)}$_2$] (7): [{IrCl(μ-Cl)(η^5-C_5Me_5)}$_2$] (0.040 g, 0.0502 mmol) and potassium cyanodiselenoimidocarbonate (0.268 g, 0.9308 mmol) gave an orange powder. Yield 0.021 g (39%). ^{1}H NMR (CD_2Cl_2): δ = 1.57−1.86 (m, 30 H, η^5-C_5Me_5) ppm. Selected IR data (KBr): $\tilde{\nu}$ = 2192 [s, ν(C≡N)], 1459 [br., s, ν(C=N)], 282 (w), 240 [w, ν(Ir−S)] cm^{-1}.

X-ray Crystallography: Tables 3 and 4 list details of data collections and refinements. For **1** and **3**, data were collected at 125 K with a Bruker SMART system. Intensities were corrected for Lorentz polarisation and for absorption. The structures were solved by the heavy atom method or by direct methods. The positions of the hydrogen atoms were idealised. Refinements were by full-matrix least squares based on F^2 using SHELXTL.[37] CCDC-233740 and -233741 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Octahedral Molybdenum Cluster Cyanide Complexes with Selenide and Halide Ligands in the Cluster Core

Yuri V. Mironov,[a] Vladimir N. Ikorskii,[b] Vladimir E. Fedorov,[b] and James A. Ibers*[a]

Keywords: Molybdenum / Clusters / Chalcohalide / Cyanide / Solid-state structures

Two new octahedral molybdenum cluster cyanide complexes with mixed selenide/halide ligands in the cluster core, $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**), have been synthesized by the reaction of Mo_6Cl_{12} or Mo_6Br_{12} with an aqueous solution of Cs_2Se_3, and then with an aqueous solution of KCN. Both compounds have been characterized by single-crystal X-ray diffraction methods. The compounds are isostructural and crystallize in the trigonal space group $P\bar{3}c1$ with two formula units per unit cell. The unit cell dimensions at 153 K are a = 9.8895(9) Å, c = 19.395(3) Å, V = 1642.7(3) Å^3 (**1**) and a = 9.9805(9) Å, c = 19.763(2) Å, V = 1704.9(3) Å^3 (**2**).

Introduction

Molybdenum(II) chloride comprising a Mo_6Cl_8 cluster core was discovered over 100 years ago. Complexes with the cluster cores Mo_6Q_8 (Q = S, Se, Te) and Mo_6Y_8 (Y = Cl, Br, I) are now well known,[1−4] and include anionic cyanide complexes.[5−8] Nevertheless, only limited number of complexes with the mixed chalcohalide core $Mo_6Q_xY_{8-x}$ are known. The first such cluster anion, $[(Mo_6SCl_7)Cl_6]^{3-}$, was obtained in 1982.[9] Since then other complexes with one or two halogen atoms substituted by chalcogen atoms have been synthesized. These include the species $[(Mo_6QY_7)Y'_6]^{3-}$ (VEC = 24) and $[(Mo_6QY_7)Y'_6]^{2-}$ (VEC = 23) (Y, Y′ = Cl, Br; Q = S, Se),[10,11] $[Et_4N]_3[(Mo_6TeCl_7)Cl_6]$ (VEC = 24),[12] $[Et_4N]_3[(Mo_6Se_2Cl_6)Cl_6]$ (VEC = 23), $[Ph_4P]_2[H_3O]_2[(Mo_6Se_2Cl_6)Cl_6]$ (VEC = 24),[13] $Cs_4[(Mo_6Q_2Br_6)Br_6]$ (VEC = 24),[14] and $Cs_{0.4}K_{0.6}[Et_4N]_{11}[(Mo_6Q_2Br_6)(CN)_6]_3\cdot 16H_2O$ (VEC = 24) (Q = S, Se).[14]

Herein we present the syntheses and structure determinations of two new Mo_6 cyanide complexes that possess mixed chalcohalide cluster cores.

Results

Syntheses

The Mo_6S_8 cluster unit may be synthesized from Mo_6Cl_{12} by its reaction with NaSH and NaOBu in refluxing *n*BuOH/pyridine.[15] This synthesis demonstrates that in solution the μ_3-halide ligands in the cluster core may be easily substituted by chalcogen ligands. Recently we found that the reaction in water of Mo_6Br_{12} with Cs_2S_3 leads to the formation of the tetrahedral molybdenum polysulfide $Cs_6[Mo_4S_{23.6}]$.[16] However, we find that the reaction of Mo_6Y_{12} (Y = Cl, Br) with Cs_2Se_3 leads to amorphous products that are different from those from the reaction with Cs_2S_3. To discover the structure of these products, we have "excised" the cluster core by treating these solids with KCN in boiling water, and then letting the resultant solutions evaporate. In this way, crystals in the form of hexagonal plates were obtained, and their structures have been determined by X-ray diffraction methods. These reactions take place without cluster decomposition, but with partial substitution of the Y ligands by Se to form $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**), both of which contain the cluster core $Mo_6Se_xY_{8-x}$. Both compounds are soluble in water, but the resulting solutions are not stable in air. Partial stabilization may be achieved by the addition of KCN to the solutions. Such differences in behavior of S and Se octahedral complexes were recently observed for Mo_6 chalcocyanide complexes. Whereas Mo_6Se_8 reacts with KCN to afford the octahedral $[Mo_6Se_8(CN)_6]^{7-}$ cluster anion,[6] in a similar reaction Mo_6S_8 affords the tetrahedral $[Mo_4S_4(CN)_{12}]^{6-}$ cluster anion.[7]

Structures

The structures of the compounds $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**) comprise a Mo_6 octahedron residing inside an $(SeY)_8$ pseudocube (Figure 1). Packing of the cluster anions in the unit cell is shown in Figure 2. The anions have crystallographically imposed $\bar{3}$ symmetry. As such, Se and Y atoms are disordered over the corners of the cube in an overall ratio

of 3.6:4.4 for Y = Cl, and 3.4:4.6 for Y = Br. Such disorder is common in $Mo_6Q_xY_{8-x}$ cluster complexes. Important distances are: Mo−Mo, 2.642(1) Å and 2.647(1) Å (**1**), 2.656(1) Å and 2.658(1) Å (**2**); Mo−(Se/Cl), 2.534(2)−2.553(1) Å (**1**); Mo−(Se/Br), 2.595(1)−2.607(1) (**2**) Å. Each Mo atom is further ligated with a terminal cyano ligand; the Mo−C distances are 2.196(9) Å (**1**) and 2.213(7) Å (**2**). The Cs atoms in both structures are surrounded by N and Se/Y atoms, as shown in Figure 3 for compound **1**.

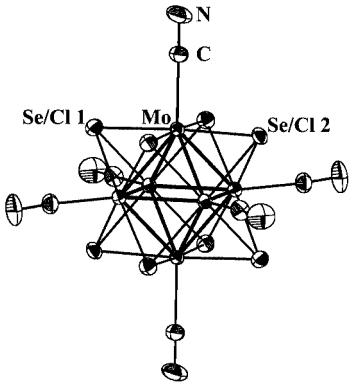

Figure 1. View of the $[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]^{5-}$ anion in **1**; displacement ellipsoids are drawn at the 50% probability level

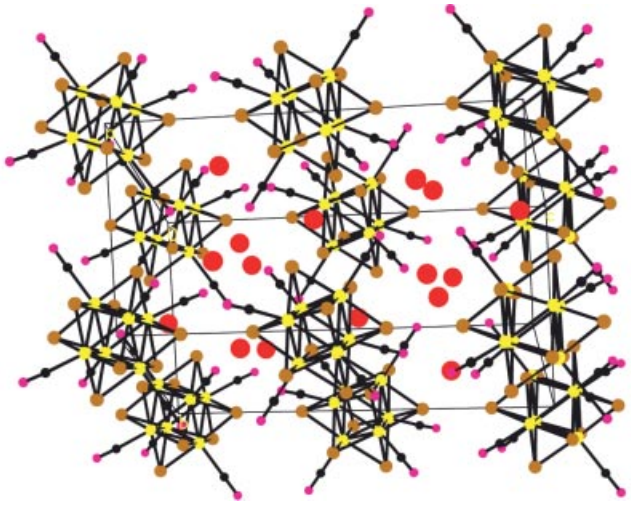

Figure 2. A view of the unit cell of $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**); the yellow circles are Mo, the brown circles are Se/Cl, the black circles are C, the small red circles are N, and the large red circles are Cs atoms

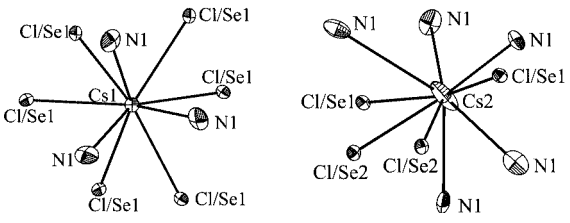

Figure 3. The coordination environments of atoms Cs1 and Cs2 in $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**); displacement ellipsoids are drawn at the 50% probability level

It is useful to compare metrical data as a function of VEC numbers for these complexes. For example, the average Mo−Mo distance is equal to 2.651(1) Å for $Cs_{0.4}K_{0.6}[Et_4N]_{11}[(Mo_6Se_2Br_6)(CN)_6]_3\cdot 16H_2O$ (VEC = 24),[14] 2.657(1) Å for compound **2** (VEC = 23.5), 2.700(3) Å for $K_7[(Mo_6Se_8)(CN)_6]\cdot H_2O$ (VEC = 21),[6] and 2.711(2) Å for $(Me_4N)_4K_2[(Mo_6Se_8)(CN)_6]\cdot 10H_2O$ (VEC = 20).[6] Although the differences are small, it is clear that the average Mo−Mo distance increases as the VEC value decreases.

Magnetism

Figure 4 displays the temperature dependence of the inverse magnetic susceptibilities of $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**). Both compounds are paramagnetic. Over the temperature range 78−300 K, the magnetic susceptibility data are well described by the Curie−Weiss law together with a temperature-independent term $N\alpha$ [Equation (1)] where $C = N\beta^2\mu_B^2/3k$.

$$\chi = C^*(T - \theta)^{-1} + N\alpha \quad (1)$$

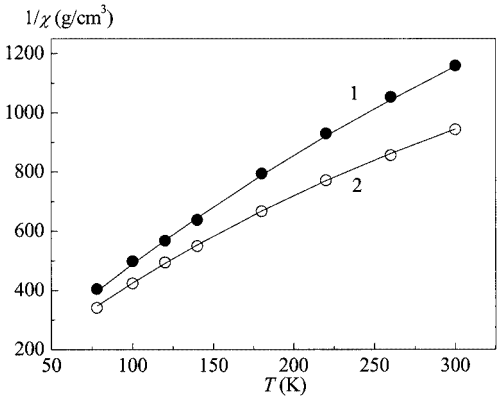

Figure 4. The temperature dependence of the inverse magnetic susceptibility of $Cs_5Mo_6Se_{3.6}Cl_{4.4}(CN)_6$ (**1**) and $Cs_5Mo_6Se_{3.4}Br_{4.6}(CN)_6$ (**2**); the solid curves were calculated from Equation (1)

Table 1 presents the parameters derived from the magnetic data. The effective magnetic moments of these complexes of 1.24 μ_B (**1**) and 1.27 μ_B (**2**) are less than the spin-only value of 1.73 μ_B. Hence, only part of the cluster complexes contains unpaired electrons. To estimate the number of clusters, *n* (Table 1), containing one unpaired electron (% per mol) we used the ratio $n = \mu_{eff}^2/[4S(S + 1)]\cdot 100\% = \mu_{eff}^2/3\cdot 100\%$, where $[4S(S + 1)]^{1/2}$ is the electron spin magnetic moment.

Discussion

As we noted previously,[17] crystal-structure determinations provide limited insight into the true nature of the cluster core in compounds such as the present ones in which Q/Y disorder at the cube corners of the $Mo_6Q_xY_{8-x}$ core

Table 1. Magnetic data

	C [cm^3·K/mol]	$-\theta$ [K]	$N\alpha$ [cm^3/mol]	μ_{eff} [μ_B]	n[a] (%)
$Cs_5Mo_6Se_{3.6}Cl_{4.4}(CN)_6$ (**1**)	0.191	6	$0.24\cdot10^{-3}$	1.24	51
$Cs_5Mo_6Se_{3.4}Br_{4.6}(CN)_6$ (**2**)	0.203	3	$0.39\cdot10^{-3}$	1.27	54

[a] Contents of paramagnetic components in **1** and **2**.

can arise in diverse ways. These include cocrystallization of different compounds, geometric disorder, orientational disorder, or a combination of these. Given the magnetic measurements, the simplest, but by no means unique interpretation, is that the compounds $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**) comprise solid solutions of $Cs_5[Mo_6Se_3Y_5(CN)_6]$ and $Cs_5[Mo_6Se_4Y_4(CN)_6]$ (Y = Cl or Br) in an approximate 1:1 ratio.

The substitution of inner halogen ligands by chalcogens in Mo_6 cluster complexes drastically decreases oxidation potentials [for example, +1.38 V for (Mo_6Br_8), +0.55 V for (Mo_6SBr_7), −0.056 V for ($Mo_6S_2Br_6$)].[14] For clusters that have VEC = 24, additional substitution of inner halogen atoms must lead to a similar cathodic shift because stabilization of species with a lower number of valence electrons occurs. Examples include the present $[Mo_6Se_4Y_4(CN)_6]^{5-}$ cluster anions (VEC = 23) and complexes with Mo_6Q_8 cores (VEC = 21, 20).[6,7]

Experimental Section

General: All reagents were used as purchased. Mo_6Br_{12} was synthesized by the reaction of Mo with Br_2 at 750 °C.[18] Mo_6Cl_{12} was synthesized by the reaction of Mo with $MoCl_5$ at 650 °C.[19] Cs_2Se_3 was synthesized by the reaction of Cs with Se in liquid ammonia. FT-IR data were collected with a Bio-Rad Digilab FTS-60 instrument. Microanalyses for C, H, and N were performed by Oneida Research Services, Whitesboro, NY, USA.

Synthesis of $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (1): Mo_6Cl_{12} (0.2 g, 0.2 mmol) and Cs_2Se_3 (0.8 g, 1.6 mmol) were placed in degassed boiling water (20 mL) for 1 h. KCN (0.5 g, 7.7 mmol) was then added to the mixture, which was boiled for another hour before filtering. The dark red-brown filtrate was evaporated to a volume of 5 mL and then cooled to room temperature. The dark crystalline product was filtered off, and was washed twice with cold water (2 mL) until the solution turned violet. The crystals were then washed twice with ethanol (10 mL) and then dried. Yield: 0.25 g (68% based on Mo). Semi-quantitative analysis of the crystals with an EDX-equipped Hitachi S-3500 SEM gave Cs:Mo:Se:Cl = 4.7:6:3.8:4.3. $C_6Cl_{4.4}Cs_5Mo_6N_6Se_{3.6}$ (derived from X-ray data) calcd. C 3.9, N 4.6; found C 4.1, N 4.8. IR (KBr): $\tilde{\nu}$ = 2085 s (ν_{CN}) cm^{-1}.

Synthesis of $Cs_5Mo_6Se_{3.4}Br_{4.6}(CN)_6$ (2): The synthesis above was followed with Mo_6Br_{12} substituted for Mo_6Cl_{12}. Yield: 0.28 g (69%). Examination of the crystals with an EDX-equipped Hitachi S-3500 SEM gave the ratio Cs:Mo:Se:Br = 5.2:6:3.5:4.7. $C_6Br_{4.6}Cs_5N_6Mo_6Se_{3.4}$ calcd. C 3.5, N 4.1; found C 3.5, N 4.5. IR (KBr): $\tilde{\nu}$ = 2092 s (ν_{CN}) (cm^{-1}).

X-ray Crystallography: Single-crystal X-ray diffraction data were collected on $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**) with the use of graphite-monochromotized MoK_α radiation (λ = 0.71073 Å) at 153 K with a Bruker Smart-1000 CCD diffractometer with the operating program SMART.[20] The crystal-to-detector distance was 5.023 cm. Crystal decay was monitored by recollecting 50 initial frames at the end of the data collection. Data were collected in groups of 606 frames, with a scan step of 0.3° in ω and with φ settings of 0°, 90°, 180°, and 270°. The exposure time was 15 s/frame. Cell refinement and data reduction were carried out with the program SAINT.[20] A face-indexed absorption correction was performed numerically with the use of XPREP.[21] The program SADABS[20] was then employed to make incident beam and decay corrections. Both structures were solved by direct methods, by means of SHELXS of the SHELXL[21] suite of programs, and were refined by full-matrix least-squares techniques.[21] Both structures were standardized through the use of the program TIDY.[22] $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) displays Se:Cl disorder. The Se:Cl occupancy values at each of the two crystallo-

graphically independent sites were refined. The results were: Se(1):Cl(1) = 0.472(8):0.528(8); Se(2):Cl(2) = 0.393(14):0.607(14). The position of the Cs2 atom in **2** is disordered over two symmetry-equivalent positions, the refinement of the occupancy value converged to 0.456(4). These occupancy values lead to the composition $Cs_{4.74(9)}[Mo_6Se_{3.62(3)}Cl_{4.38(3)}(CN)_6]$. The occupancy of atom Cs2 was set to 0.5 in subsequent refinements; this had no significant effect on the final metrical data. Given the hazards of establishing compositions through the refinement of X-ray data[23] we adopt the formula $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ for compound **1**. $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**) displays Se/Br disorder, but owing to the very similar X-ray scattering powers of Se and Br, no site occupancy refinement was possible. Rather, each site was assumed to contain Se:Br in the ratio 0.425:0.575, as determined from the EDX results. The final results are essentially independent of this ratio. The positions of the Cs1 atoms are well defined in both structures. The disorder of the Cs2 position in compound **2** has been modeled in a somewhat unsatisfactory way by the introduction of atoms Cs2 and "Cs3". Their combined occupancy values converged to 0.49(1) and were set at 0.5. Despite the differences in the Cs occupancy values, we consider the two compounds to be isostructural. Additional experimental details are given in Table 2, and in the crystallographic data files, which have been deposited with FIZ Karlsruhe.[24]

Magnetic Measurements: The magnetic susceptibility measurements on $Cs_5[Mo_6Se_{3.6}Cl_{4.4}(CN)_6]$ (**1**) and $Cs_5[Mo_6Se_{3.4}Br_{4.6}(CN)_6]$ (**2**) were carried out by the Faraday method at 10 kOe over the temperature range 78−300 K. Data were corrected for the diamagnetic contributions of -696×10^{-6} and -737×10^{-6} cm^3/mol for **1** and **2**, respectively.

Spin-Coating Preparation of Highly Ordered Photoluminescent Films of Layered PbI_2-Aminoalkyloxysilane Perovskites

Zi-Yong Cheng,[a] Bao-Li Shi,[a] Bao-Xiang Gao,[a] Mao-Lin Pang,[b] Shu-Yun Wang,[a] Yan-Chun Han,*[a] and Jun Lin*[b]

Keywords: Layered perovskite / Sol-gel / Films / Photoluminescence

By utilising 3-aminopropyltrimethoxysilane (APTMOS) cations and PbI_2 as the organic and inorganic precursors, respectively, a spin-coated film of a layered perovskite-type organic/inorganic derivative of APTMOS-PbI_4 was prepared. The structure of APTMOS-PbI_4 was characterised by X-ray diffraction (XRD), UV/Vis absorption and infrared red spectroscopy (IR). The film showed green emission from the excitons of the inorganic layers and a weak blue emission related to the small amount of gel of adjacent APTMOS cations. Furthermore, the significant effect of the size of the inorganic framework on the cross-linking degree of APTMOS molecules is discussed.

Introduction

The self-organisation of molecules into highly ordered architectures with layered structures has attracted a wide range of scientific and practical interest. The perfect combination of the organic and inorganic components provides tremendous mechanical strength and toughness that is not possessed by a single phase alone. To date, the most frequently used method for the synthesis of 2D nanostructured hybrids is the sol-gel process, employing organic silane molecules in the presence of surfactants which are used as structure directors due to their amphiphilic nature in a selective solution.[1a−1g] On the other hand, the layered compounds can also be obtained by intercalating the guest molecules, generally organic species such as alkylammonium salts, into the interlayer spaces of a pre-existing inorganic layered structure.[2a−2c] Recently, layered polysiloxane containing alkylammonium groups has been prepared by the sol-gel reaction of 3-aminopropyltrimethoxysilane (APTMOS) with hydrochloric acid, without using any surfactants or long-chain alkyl groups in the monomers.[3] Similarly, we reported a simple method of preparing a layered nanocomposite containing a silica network by a perovskite-type self-organisation.[4] Lead(II) chloride was employed as the inorganic layer in this superlattice material and photoluminescence in the ultraviolet region was observed due to the nature of the low-dimensional structure. In order to further explore the feasibility of this method and obtain luminescence in the visible region, lead(II) iodide (with a smaller band-gap and a larger "footprint" of the inorganic framework) and APTMOS cations were used in this study. It was observed that these materials can also be self-organised into a perovskite-type layered structure which shows green luminescence arising from the inorganic semiconductor of the lead(II) iodide layers. The expected structure of PbI_2-based perovskite and the simulated structure of the APTMOS molecule are shown in Figure 1.

Results and Discussion

Synthesis and Film Preparation

At the beginning of the experiment for the preparation of APTMOS·HI, we tried to simply mix the APTMOS with PbI_2 in a dilute hydroiodic acid solution but we were unable to obtain the final product as expected. HI is a very strong acid and a nucleophile and APTMOS is very susceptible to hydrolysis and polycondensation in an acidic environment. The Si−O, C−O and Si−C bonds are broken upon nucleophilic attack by I^-. Thus, a rigorous procedure for removing water and a low temperature bath of diethyl ether/dry ice were applied in order to avoid the occurrence of the above reactions. In spite of these precautions, the acid-base reaction between the head of the amine group of APTMOS and HI was not be impeded at low temperature.

The molecular formula $[(CH_3O)_3Si-CH_2-CH_2-CH_2-NH_3]_2PbI_4$ (APTMOS-PbI_4 for short) was defined by the single layers of the <100> oriented perovskite sheets which

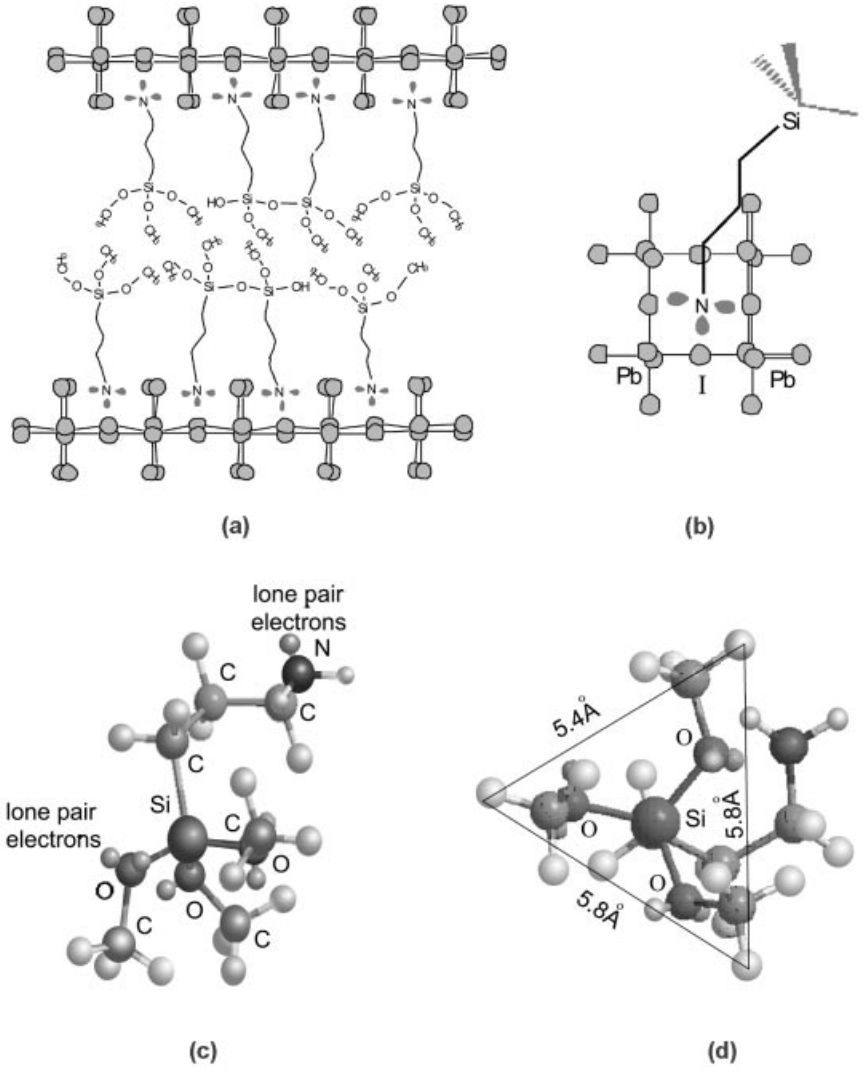

Figure 1. Schematic representation of the expected structure for APTMOS-PbI_4 perovskite and the simulated results of the dimensions of the APTMOS molecules; the APTMOS-PbI_4 layered superlattice consists of an extended framework of corner-sharing lead iodide octahedra alternating with a bilayer of APTMOS cations; (a) view parallel to the perovskite sheet of the APTMOS-PbI_4 structure, (b) view perpendicular to the perovskite sheet of the APTMOS-PbI_4 structure, (c) the profile of the APTMOS molecule, (d) the dimensions of the cross-section of the APTMOS molecule; the ball-and-stick model of the APTMOS molecule represents a favourable energy state

consist of corner-sharing metal halide octahedra, alternating with the ATMOS cation bilayers. Each octahedron has a Pb^{2+} cation in the centre and six I^- units as coordination anions. The four bridging I^- ions are shared by the two adjacent octahedra. Figure 1 (a and b) shows the model of the layered perovskite structure. From a view perpendicular to the perovskite sheets in the APTMOS-PbI_4 structures, each APTMOS cation is nominally located in a square defined by the four neighbouring Pb atoms and the Pb−I−Pb linkages can be regarded as the sides of the square (see b in Figure 1).[5] In contrast to the length of about 5.6 Å in Pb−Cl−Pb based structures,[6a] the PbI_2-based perovskite exhibits a larger framework of 6.4 Å for the Pb−I−Pb unit according to the single-crystal structure.[6b] The shape and relevant molecular dimensions of the APTMOS molecule are shown in parts c and d of Figure 1. These results were calculated using the MM2 force field with the Chem3D program (CambridgeSoft Corp.). The lengths of the sides of the silicon tetrahedra in an unhydrolysed APTMOS molecule are in a range of 5.4−5.8 Å. Thus, the PbI_2-based perovskites have enough space to accommodate the unhydrolysed APTMOS molecules in the self-assembly process. In contrast, in the preparation of the APTMOS-$PbCl_4$ perovskite, an intentional hydrolysis was applied before the film deposition for reducing the cross-sectional area of the APTMOS cations.[4]

Infrared Spectroscopy

The FT-IR spectra of APTMOS (a), APTMOS·HI (b) and the perovskite structure of APTMOS-PbI_4 (c) are given in Figure 2. In Figure 2 (see a), for APTMOS, the weak peaks at 3376 and 3298 cm^{-1} are due to asymmetric/symmetric N−H stretching vibrations of primary amine ($-NH_2$) groups. The locations and assignments of the other

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

absorption peaks are 2938 (ν_{as}, CH_2), 2832 (ν_s, CH_2), 1576 (δ, NH_2), 1469 (δ, CH_2), 1190 (ν_{as}, Si−CH_2), 1085 (ν_{as}, Si−OCH_3), 815 (ν_s, Si−OCH_3) and 450 cm^{-1}(δ, Si−OCH_3) (where ν_{as} stands for asymmetric stretching, ν_s for symmetric stretching, and δ for bending).[7a−7c] After treatment with dry HI gas, as shown in part b of Figure 2, the N−H stretching at 3298 and 3376 cm^{-1} disappeared. Instead, a broad band centred at 2900 cm^{-1} and a series of overtone peaks from 2000 to 2705 cm^{-1} were observed which are typical characteristics of organic amine salts. The weak absorptions at 3450 and 920 cm^{-1} due to silanols of hydrolysed APTMOS molecules could be observed, despite a rigorous procedure for removing water and the application of a low temperature during the preparation of the amine salt. Other than the absorption of the silanols at 3430 cm^{-1} becoming more strong, there were no great differences between the FT-IR spectrum of APTMOS-PbI_4 (see c in Figure 2) and that of APTMOS·HI (b in Figure 2). Note that the asymmetric stretching mode at 1085 cm^{-1} and the symmetric stretching mode at 817 cm^{-1} corresponding to the Si−OCH_3 group also remained as shown in Figure 2 (see c), indicating that a large amount of unhydrolysed APTMOS cations remained in the perovskite structure. The Si−O−Si bond also gives at least one very intense band in the 1100−1000 cm^{-1} region due to the asymmetric stretching mode. Thus, the mode corresponding to Si−O−Si or Si−O−C appearing in this region cannot be easily distinguished. As for the short open-chain alkylpolysiloxanes or small cyclic polysiolxanes, the asymmetric stretching of Si−O−Si shows a characteristic single band at 1000−1100 cm^{-1}.[1b] With progressively longer linear alkylpolysiloxanes or larger cyclic polysiloxanes, the band in this region splits into two or more overlapping components and becomes broader.[8a−8b] Base on this fact, the appearance of only a singlet absorption band at 1079 cm^{-1} for APTMOS-PbI_4 perovskite is consistent with the formation of a mixture which is composed largely of Si−OCH_3 functionalities, silanol groups and perhaps a small amount of short-chain polysiloxanes/small cyclic polysiloxanes. In contrast to the FT-IR spectrum of APTMOS-$PbCl_4$, where the Si−O−Si asymmetric stretching band is characteristic of long-chain linear siloxanes with two broad doublet peaks at 1107 and 1037 cm^{-1},[4] the APTMOS cations in the APTMOS-PbI_4 perovskite have less cross-linking because only one band is present in this region. This can be attributed to the fact that the space provided by the PbI_2-based framework is too large for the perpendicular APTMOS cations to form long Si−O−Si chains. The films of APTMOS-PbI_4 have poor stability compared with the APTMOS-$PbCl_4$ films and traditional organic/inorganic perovskites such as $(C_4H_9NH_3)_2PbI_4$. The APTMOS-PbI_4 films usually decomposed in air over several days and became colourless. The instability of the APTMOS-PbI_4 films may be ascribed to the large spaces in the PbI_2-based framework and the strong propensity for polycondensation between the adjacent APTMOS cations confined in the perovskite structure. These factors cause the layered perovskite structure to eventually collapse.

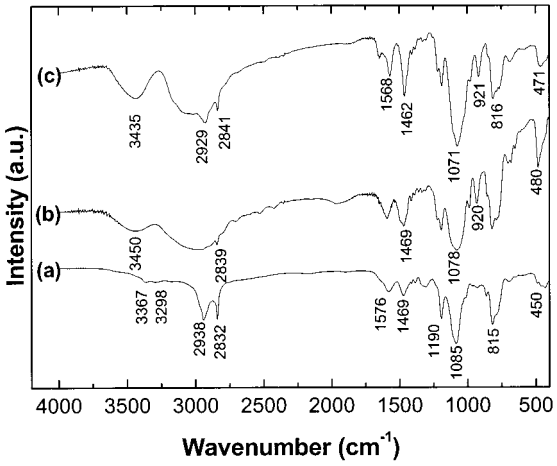

Figure 2. FT-IR spectra for 3-aminopropyltrimethoxysilane (APTMOS, a: using liquid film on KBr crystal disk), the amine salt of APTMOS (APTMOS·HI, b: KBr pellet) and the layered perovskite with a silica network (APTMOS-PbI_4, c: KBr pellet)

XRD

X-ray diffraction (XRD) is the most useful tool for the structural characterisation of a crystalline material. From the XRD pattern (Figure 3) of an APTMOS-PbI_4 film spin-coated on a fused silica plate, only 00*l* diffraction peaks were detected due to the extremely high degree of preferential orientation arising from the manner in which the sample was mounted. The 00*l* reflections can be counted as corresponding to $l = 1, 2, 3...$ or $l = 2, 4, 6...$ and we chose the latter based on previous literature for the layered perovskite-type organic/inorganic $(C_4H_9NH_3)_2PbI_4$ structure.[6b] The observation of these multiple order diffraction peaks supports the formation of a PbI_2-based perovskite structure in the films and the alternating layers stack perpendicularly to the substrate surface. The 00*l* reflections correspond to an extended network of corner-sharing metal halide octahedra with an interlayer distance of 1.91 nm separating the inorganic sheets. According to the structural properties of the general hybrid perovskites, the interlayer space decreases from Pb−Cl to Pb−Br and to Pb−I.[9] This can be attributed to the larger space provided by the inorganic frame and the alkyl chains can tilt or interdigitate. Compared with the APTMOS-$PbCl_4$ perovskite structure which has an interlayer space of 1.83 nm,[4] a small increase of 0.08 nm in APTMOS-PbI_4 was observed by XRD, rather than a decrease. This abnormal increase may be due to the unhydrolysed APTMOS molecules which have a longer chain and a larger silane tail which hinders the APTMOS molecules from tilting/interdigitation.

UV/Vis Absorption Spectroscopy

A simple way to confirm the formation of the layered perovskite structure is using UV/Vis absorption spectroscopy since exciton absorption can be observed at room temperature due to the quantum confinement effect.[10a−10c] Figure 4 shows the UV/Vis absorption spectrum of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

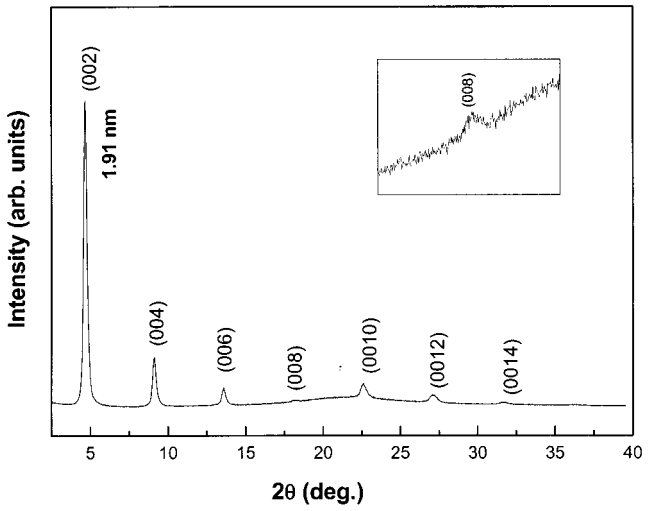

Figure 3. X-ray diffraction profiles for a spin-coated film of APTMOS-PbI_4 on a quartz plate; the inset is an enlarged figure for clarity

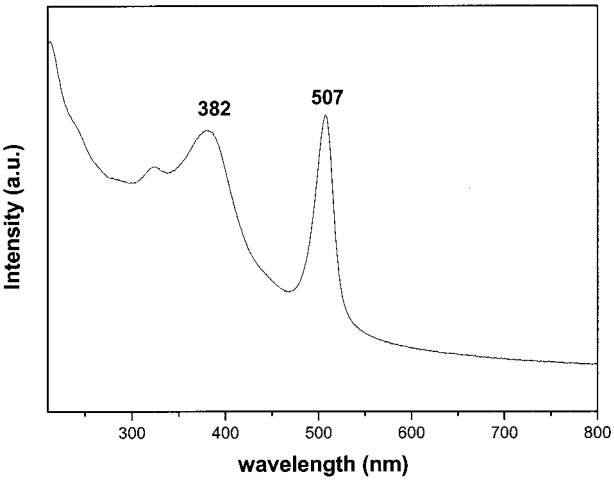

Figure 4. UV/Vis absorption spectrum for an APTMOS-PbI_4 spin-coated film on a quartz plate

APTMOS-PbI_4 films on a fused silica plate. Two strong absorption bands at 382 and 507 nm can be observed. The former is due to the band-gap absorption of the PbI_2-based perovskite structure with one layer of inorganic sheets. Generally, the top of the valence-band of this class of material consists primarily of a mixture of I ($5P_{xy}$), Pb (6s) and I ($5P_z$), whereas the bottom of the conduction-band consists primarily of the Pb ($6P_{xy}$) state.[10] Note that a strong and sharp absorption peak at 507 nm is present which is similar to the previously reported PbI_2-based perovskite structure with a single-layer inorganic sheet.[6b] This suggests that the extended 2D PbI_4^{2-} frameworks are sandwiched on both sides by the APTMOS cations with alkyl chains which have a much lower dielectric constant compared with the inorganic component. The two dimensionality of the layered structure combined with the dielectric confinement effect enables the formation of a stable exciton with a large binding energy in the PbI_4^{2-} semiconductor layer. As a result, the feature of the sharp absorption of excitons can be observed even at room temperature. This generally cannot be observed in bulk PbI_2. This is also the reason that the colour of the APTMOS-PbI_4 films is somewhat different from PbI_2. The difference in colour can be simply used to judge the formation of a layered perovskite structure in the spin-coating procedure.

Photoluminescence

From the photoluminescence spectra (Figure 5), a dominant emission of an exciton state at 518 nm was observed. In contrast to the $PbCl_2$-based perovskite, the band-gap of PbI_2-based perovskite is reduced and the luminescence absorption red-shifted from the ultraviolet to the visible region.[6b] As a result, the green luminescence could be seen when the spin-coated APTMOS-PbI_4 films were exposed to a hand-held UV lamp at room temperature. The photoluminescent properties of the $PbCl_2$-based layered perovskite structure incorporated with APTMOS cations have the features of a weak emission in the ultraviolet region originating from the exciton state and a strong blue emission at 440 nm which corresponds to the highly condensed siloxane network of the tails of the APTMOS cations.[4] Interestingly in Figure 5 one can see, apart from the strong emission of the exciton at 518 nm, that there is a strong background emission between 425 and 600 nm with a maximum at 456 nm. This should come from the organic component and is related to the photoluminescence of the sol-gel derived silica gel of the APTMOS cations.[8a,11a–11c] The weak intensity can be attributed to the reduced cross-linking between the APTMOS cations in the APTMOS-PbI_4 film. This result is consistent with the FT-IR spectrum (see c in Figure 2) which only demonstrates the existence of short Si–O–Si chains (one peak at 1071 cm^{-1}). Note that the shoulder emission analogues were generally observed at higher wavelengths in the previously reported organic-inorganic perovskites and were explained as being due to degradation or the presence of impurities.[6b,12]

Formation of the Perovskite Structure

We propose that the formation of the layered APTMOS-PbI_4 superlattice occurs mainly by an organic/inorganic perovskite-type self-organisation.[9] Such behaviour is different from that of long-chain amphiphiles because there are no strong interactions between the short alkyl chains of the APTMOS cations. The main driving force is the propensity of metal halides to format the extended corner-sharing networks of MX_6 octahedra. The ammonium "heads" of the organic cations interact with the halogens of the inorganic sheets in an ionic or hydrogen bonding manner and then hydrolysis and condensation may occur between some adjacent APTMOS molecules, leading to an alternating layered structure. Thus, the inorganic framework plays an important templating role for the APTMOS cations. In ad-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

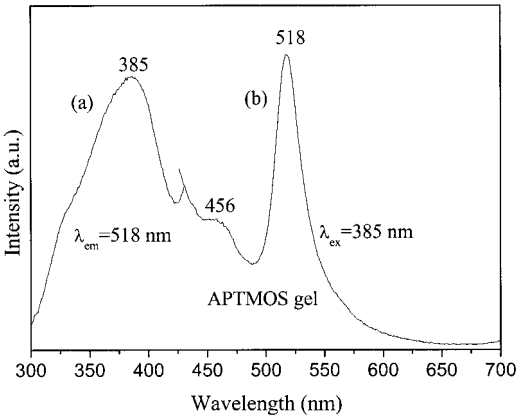

Figure 5. Photoluminescence excitation (a) and emission (b) spectra for an APTMOS-PbI_4 film on a quartz substrate

dition, the H-bonds between silanols have the effect of forming a tail-to-tail arrangement of the APTMOS cations.[13]

Conclusions

In this study, the spin-coating method was successfully used to prepare highly ordered perovskite-type films with a layered structure in which the lead iodide inorganic layer was sandwiched by the APTMOS cations. The films show strong green luminescence arising from the excitons of the inorganic semiconductor lead iodide layers and the weak blue emission relates to the hydrolysed APTMOS cations. The large framework provided by the inorganic layer impedes the APTMOS cations from forming a network with a high degree of cross-linking. This kind of self-organising system offers a potential method for the preparation of nano- and mesoporous silica films after the lead iodide template has been removed.

Experimental Section

Syntheses: The starting materials used in the synthesis were PbI_2 (99.999%, Aldrich) and 3-aminopropyltrimethoxysilane (>97%, Aldrich). HI gas was obtained by dropwise addition of water into a Schlenk tube containing an iodine-red phosphorus mixture. The liberated HI gas was dried using a $CaCl_2/P_2O_5$ mixture packed into the drying towers and collected by condensing into a liquid nitrogen trap. APTMOS (10 mL) was dissolved in absolute diethyl ether (150 mL, refined by heating to reflux for 12 h over sodium) and the solution was maintained at −78 °C in an acetone/dry-ice bath. The trap containing the solid hydrogen iodide was then removed from the liquid nitrogen and dipped into a bath with a K_2CO_3/ice mixture (−30 °C) to release the HI gas slowly. The small steam of HI gas was directed to flow into the APTMOS/diethyl ether solution, resulting in the formation of an APTMOS salt (APTMOS·HI, white precipitate). Note that the excess noxious HI gas was collected in a vacuum desiccator containing sodium hydroxide. The powder of APTMOS·HI was obtained after removal of the diethyl ether by evaporation in a vacuum at room temperature. The final APTMOS·HI powder was stored in an evacuated desiccator using $P_2O_5/CaCl_2$ as the desiccant at −25 °C.

Film Preparation: Dimethylformamide (DMF) was dried over calcium hydride for two days with stirring and was then distilled under reduced pressure. PbI_2 and APTMOS·HI (1:2 molar ratio) were dissolved in the dry DMF to form a clear solution (2.5 wt%). The solution was spin-coated on fused silica plates at 700 rpm for 3s and then 1500 rpm for 45s at room temperature in air. After drying at 70 °C under vacuum for 6 h, continuous and crack-free films of the PbI_2-based layered perovskite $[(CH_3O)_3Si-CH_2-CH_2-CH_2-NH_3]_2PbI_4$ were obtained. A small amount of APTMOS-PbI_4 powder was scraped off the substrates for FT-IR measurements.

Characterisations: The FT-IR spectra were recorded on a Bio-rad FTS 135 spectrometer with a nominal resolution of 4 cm^{-1}. The X-ray diffraction (XRD) of film samples was examined on a Rigaku-Dmax 2500 diffractometer using Cu-K_α radiation (λ = 0.15405 nm). The UV/Vis absorption spectrum was measured on a TU-1901 spectrophotometer. The photoluminescence excitation and emission spectra were recorded on a Hitachi F-4500 spectrofluorimeter equipped with a 150-w xenon lamp as the excitation source.

COVER PICTURE

The cover picture shows the pH dependency of the geometry of the tris(5-bromo-2-hydroxybenzyl)triaminoguanidinium cation $[H_6Br_3L]^+$. In the solid state, a conformation which is less favourable for the coordination of metal centres is predominant. In the presence of a basic metal salt, a partial change in the conformation can be observed, whereas in the presence of base even in the absence of metal ions, a complete conformation change takes place. In this way, the reaction of $[H_6Br_3L]^+$ with metal salts can be easily controlled. The formation of an $[M_3Br_3L]^{(3n-5)+}$ species as a triangular building block for use in supramolecular chemistry is also described in the article by I. M. Müller and D. Möller on p. 257 ff.

Proton Transfer to Hydride Ligands with Formation of Dihydrogen Complexes: A Physicochemical View

Vladimir I. Bakhmutov*[a]

Keywords: Hydrogen bonding / Dihydrogen bonding / Proton transfer / Dihydrogen complexes / Metal hydrides /Kinetics

Protonation of hydridic hydrogens has attracted increasing interest from chemists over the past decade. This review, focusing on key physicochemical data, describes general rules governing proton transfer to hydride ligands and discusses kinetic schemes for the protonation as a process starting from dihydrogen-bonded adducts and H-bonded contact ion pairs and ending in dihydrogen complexes as solvent-separated ion pairs or free ions. It has been shown that the particulars of proton transfer to hydride ligands and to conventional organic bases are similar. The difference between them is apparent in the contact ion pair formation step.

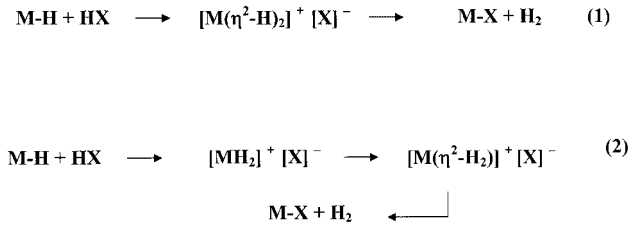
1. Introduction

Proton transfer to hydridic hydrogens with H_2 elimination, which has attracted great interest from chemists, plays a key role in various chemical and biochemical processes[1] occurring in solution and the solid state.[2] In the case of transition metal hydrides this reaction gives dihydrogen complexes[3] which can initiate, for example, catalytic ionic hydrogenation of unsaturated compounds.[4] The elucidation of the mechanism of proton transfer to hydride ligands has been a main goal from the beginning of the interest in the chemistry of dihydrogen complexes. Important aspects of acid-base reactivity, protonation and hydrogen bonding of transition metal hydride systems have already been the subject of several reviews.[5a–5d] Nevertheless, it seems to the author that a reader who is not familiar with transition metal hydride chemistry in particular, still needs a general physicochemical view on this important topic. This approach does not go into the details of hydride chemistry but provides (i) analysis of key results (earlier and recent) from the studies of the spectroscopic, kinetic and thermodynamic parameters which vary with the nature of the metal hydrides, acids and solvents used (ii) a description of the energy profile of proton transfer occurring via a chain of H-bonded intermediates and transition states (iii) a discussion of the driving force in each step of the overall process and also (iv) a comparison of the mechanism of proton transfer to hydride ligands with that operating in proton transfer to conventional organic bases.



Scheme 1

Dihydrogen complexes can be generated through direct proton attack on hydride ligands or an initial protonation of the metal centre[3] (Scheme 1) leading to classical hydrides $[MH_2]^+$ which then convert to dihydrogen complexes

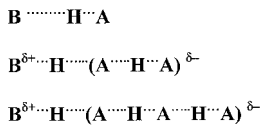
Vladimir I. Bakhmutov (born in 1948 in Moscow, Russia) obtained his Ph.D in 1974 at the Moscow State University and Doctor of Science Degree in 1984 at the Institute of Organo-Element Compounds of the Russian Science Academy (INEOS). He became a Head of the NMR department at INEOS in 1994. Currently he is an NMR spectroscopist at Texas A&M University, USA. He has authored or co-authored more than 220 research and review papers. He is author of the book "Practical NMR Relaxation for Chemists" (John Wiley & Sons) and contributor to two books. His research interests are in the field of NMR spectroscopy and transition metal hydride chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.



Scheme 2

$[M(\eta^2\text{-}H_2)]^+$ as the thermodynamic products of the reaction. Since protonation of hydride sites is kinetically preferable,[6] the second pathway (rather rare and resulting from a unique combination of steric and electronic features of the initial hydrides) has not been considered in this paper. For the same reason, we have not discussed H-bonded species H–M···H–X as intermediates in proton transfer to metal centres.[7a,7b] Finally, we have also not discussed H_2 elimination from dihydrogen complexes, the species being considered stable under the experimental conditions.

2. Reaction Intermediates: Spectroscopic (IR, NMR) and DFT Studies

Strong hydrogen bonds dominate in the protonation of usual organic bases.[8] For example, proton transfer from acetic acid, (H-A), to pyridine, (B), occurs via the H-bonded complexes in Scheme 2 which can be directly observed by ^1H and ^{15}N NMR spectroscopy in $CDClF_2/CDF_3$ at low temperatures.[8a] It is known now that the hydrogen bond strength increases with a partial proton transfer. For this reason, if the proton overcomes an energy barrier due only to its motion, this barrier must be very small.[8a] In full agreement with this statement, protonation of common organic bases is a very fast process. According to recent DFT calculations, a similar situation takes place for transition metal hydrides in the gas phase. When a strong acid, H_3O^+, is placed near a hydride molecule, for example $[CpRuH(CO)(PH_3)]$[9] or $[Cp_2NbH_3]$,[10] the proton is transferred directly to the negatively charged hydride ligand *without* an energy barrier. However such a single-step process is not realistic in solvents with a relatively small polarity such as THF, toluene and CH_2Cl_2 which are usually used for the protonation of transition metal hydrides. Under these conditions, even strong acids (HCl, HBr, CF_3COOH or CF_3SO_3H) become weak and attack hydride ligands in a molecular form.[11] For this reason, various unusual H-bonded intermediates can be located on the reaction coordinate of the proton transfer to the hydride ligand, leading to a relatively high energy barrier for the process.

Dihydrogen Bonding

The interaction between hydrogen atoms carrying opposite charges, known as dihydrogen bonding,[12] is a common phenomenon in modern chemistry. H···H bonds play an important role in crystal packing and molecular aggregation in the solid state[13a,13b] and also in the stabilisation of conformational molecular states in solution.[13c] The X–H···H–Y binding energy depends on the nature of the electropositive

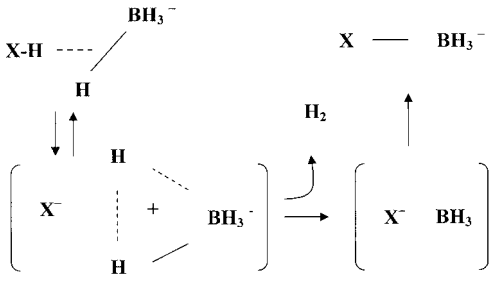


Figure 1. Schematic representation of the solid-state proton transfer to a hydridic hydrogen of the BH_4^- group via the dihydrogen bond[2]

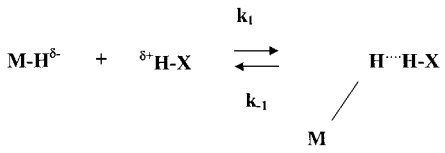

Scheme 3

and electronegative elements X and Y and covers the $-\Delta H^0$ region from 1[13b] to 7 kcal/mol.[2] Recent data [2,14] have demonstrated that dihydrogen bonding is an important preorganising factor in solid-state proton transfer. In fact, heating the solid complex, $NaBH_4$·triethanolamine, containing B–H···H–X bonds, results in loss of H_2 (Figure 1). Subsequently, the Lewis acidic and basic subunits, remaining in close proximity, combine to form new strong covalent bonds.[2] Likewise, dihydrogen-bonded adducts formed in solution by HX protons and negatively charged hydride ligands[15] (Scheme 3) may participate in the first step of proton transfer. In fact, such aggregates formed by $[CpRuH(CO)(PH_3)]$ or $[Cp_2NbH_3]$ and the relatively weak proton donors CF_3COOH and $(CF_3)_3COH$ have recently been located at energy minima in DFT calculations, even in the gas phase.[9,10]

Both IR and NMR techniques can be used to detect M–H···HX bonds. A combination of the two spectroscopic methods is best.[5c,5d] In the IR spectra, commonly recorded at low temperatures to avoid H_2 elimination, dihydrogen bonding is indicated by the new lower-frequency ν_{M-H} bands (or shoulders) which are shifted by 20–40 cm^{-1} from the corresponding values in the initial hydrides. The timescale of IR spectroscopy allows observation of both the free and H-bonded hydride molecules. In contrast, resonances from the free and coordinated hydrides in the ^1H NMR spectra are usually averaged even at low temperatures. However, upon dihydrogen bond formation, the signals of initial hydrides undergo remarkable high-field shifts (≈ 0.5–1 ppm) and their spin-lattice relaxation times (^1H T_1) are diminished due to additional proton-hydride dipole-dipole interactions.[16] It should be emphasised that the concurrent observation of both the effects is required for establishing a reliable NMR criterion for the presence of dihydrogen bonds. In rare cases, the application of Freon solvents "stops" the MH···HX bond formation even on the ^1H NMR timescale. For example, the ReH resonance of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

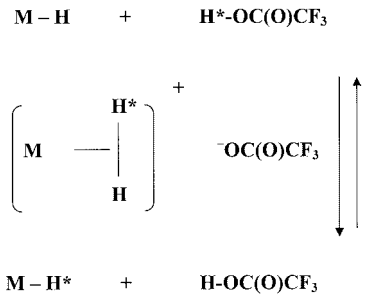

Figure 2. Schematic representation of a proton/hydride exchange occurring via a short-lived dihydrogen complex

[Cp*ReH(CO)(NO)] decoalesces in the presence of acidic alcohols at 96 K giving two resolved lines at –7.54 and –8.87 ppm, assignable to the free and dihydrogen bonded hydride, respectively.[17] A similar difference in the chemical shifts of M–H and M–H···HX has been reported for the [(triphos)Ru(CO)H_2]/$(CF_3)_2$CHOH system in TDF.[18] The difference in the chemical shifts is not as big as in the case of systems with classical hydrogen bonds, possibly due to insignificant electronic perturbations on the target nuclei. However more theoretical investigations of this NMR effect are needed.

According to DFT calculations,[9,10,15] dihydrogen bonding leads to slight elongations of M–H and X–H bonds in proportion to the acidity of the proton donors. For example, the M–H bond length in [M(NO)$(CO)_2(PH_3)_2$H···HX] adducts (M = Mo, W) increases by 0.04 Å. H···H distances in dihydrogen bonded species have been determined as 1.6–2.2 Å by ^{1}H T_1 relaxation time measurements in solution[5c,5d,16,18] and DFT calculations in the gas phase.[9,10,15] The $H^{\delta+}\cdots^{\delta-}$H–M angles have been calculated to be between 130° and 180°. Finally, polyhydride molecules such as [Cp_2NbH_3] can form bifurcated dihydrogen bonds[10] where coordination of HX molecules to the central and lateral hydride ligands occurs.

An unusually short H···H distance of 1.43 has been recently reported for the H-bonded complex [CpRu($PP^{Ph}PF$)H···HO_2CCF_3] which has been proposed as a new intermediate in proton transfer.[19] The H···H value has been determined by ^{1}H T_1 time measurements in [D_6]acetone. However, the ^{1}H and ^{31}P NMR spectra of the initial hydride [CpRuH($PP^{Ph}PF$)] in the absence and in the presence of the acid were indistinguishable. Therefore, the short ^{1}H T_1 relaxation times measured for the hydride (RuH) and proton (CF_3COOH) resonances (49 ms, 234 K, 300 MHz), are rather due to proton/hydride exchange occurring on the NMR timescale via a short-lived dihydrogen complex (Figure 2). Note that the same relaxation effect has previously been observed in a CD_2Cl_2 solution of the dihydride [ReH_2(CO)(NO)($POiPr_3)_2$] with CF_3COOH in which the dihydrogen complex was invisible.[20] However, this complex, with a very short ^{1}H T_1 time (5 ms, 200 MHz, 193 K), can be clearly detected by ^{1}H and ^{31}P NMR spectroscopy in the presence of a twentyfold excess of CF_3COOH.

The driving force for the formation of MH···HX bonds is the electrostatic attraction between the electrons of the polar M–H σ-bonds and H^+ from the proton donors. As in the case of classical H-bonds, the electrostatic component provides a dominant contribution to the total dihydrogen bonding energy[15,21] which depends on the nature of the transition metal hydrides, acids and solvents used. Enthalpies ($-\Delta H^0$), measured for the formation of MH···HX bonds in solution, vary between 2.0[22] and 7.6 kcal/mol.[5d] The influence of hydrides on dihydrogen bonding can be quantitatively scaled in terms of the basicity factor, E_j, determined via Equation (1)

$$E_j = \Delta H_{ij}/\Delta H_{11} P_i \quad (1)$$

where ΔH_{ij} are bond energies determined by IR spectroscopy, P_i is the proton donor ability of the OH acids and ΔH_{11} is the enthalpy of the standard H-bonded phenol complex.[5d] On this scale, the E_j factor varies in the range between 0.54 and 1.67. Effects of the metal are expressed, for example, as E_j = 1.09, 1.32 and 1.67 as recently obtained for PP_3FeH_2, PP_3RuH_2 and PP_3OsH_2, respectively.[23]

A good illustration of the solvent influence on dihydrogen bond formation is provided by the $-\Delta H^0$ values of 6.2, 5.8 and 3.1 kcal/mol for the interaction of [ReH_2(CO)(NO)$(PMe_3)_2$] with $(CF_3)_3COH$ in C_7D_{14}, hexane and [D_8]toluene, respectively.[7a,22b,22c] A similar trend was reported for the [CpRuH(CO)(PCy_3)]/$(CF_3)_2$CHOH system showing $-\Delta H^0$ values of 6.3 and 5.1 kcal/mol in hexane and the more polar CH_2Cl_2, respectively.[5d,9] The effects of the acidic component are demonstrated by the $-\Delta H^0$ values calculated as 8.4 and 9.7 kcal/mol for the interaction of [CpRu(CO)(PH_3)] with CF_3COOH and $(CF_3)_3COH$, respectively.[9]

Data on H···H bond formation rates is rather limited since the process is usually too fast for studies by standard kinetic techniques. Nevertheless, some estimations are possible from the low-temperature ^{1}H NMR experiments in Freon solutions.[17] As mentioned above, the Re–H signal of [Cp*ReH(CO)(NO)] decoalesces in the presence of acidic alcohols at 94 K. Under these conditions, the life time of the MH···HX complexes, τ, can be calculated via Equation (2)

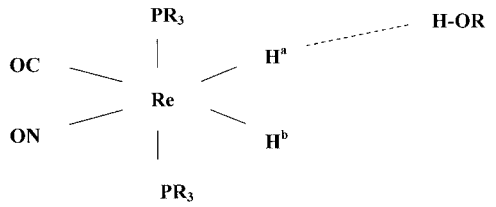
$$\tau = 1/k_1 = \sqrt{2}/\pi\cdot\Delta\nu \quad (2)$$

where Δν is the chemical shift difference for the free and bonded state expressed in Hz.[24] The calculation gives $\tau \approx 10^{-3}$ s, corresponding to the rate constant, k_1, of ca. 10^4 L/mol·s for concentrations of acidic alcohols of $< 10^{-1}$ mol/L.

Regioselective Dihydrogen Bonding

The location of the spectroscopically observed MH···HX adducts on the reaction coordinate of the proton transfer process is well supported by the variable-temperature IR and NMR spectra of the hydrides [$RuH_2(dppm)_2$], [$MeC(CH_2PPh_2)_3Re(CO)_2H$], [Cp*Ru($PCy_3$)$H_3$] and [(Cp-N)RuH($PPh_3)_2$] in acidic solution in which MH···HX species and dihydrogen complexes $[M(\eta^2\text{-}H_2)]^+$ $[X]^-$ coexist

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4

in a slow equilibrium.[5d,22a] An additional possibility is that of a regioselective attack on a hydride ligand with the formation of MH···HX bonds, ending in a proton/hydride exchange (see below).

Regioselective dihydrogen bonding has been observed for $[ReH_2(CO)(NO)(PR_3)_2]$ (R = Me, Et) in the presence of $(CF_3)_2CH\text{-}OH$ or $(CF_3)_3COH$ by variable-temperature ^1H NMR spectroscopy in $[D_8]$toluene or $[D_{14}]$methylcyclohexane.[22b] A fivefold excess of $(CF_3)_3COH$ causes a high-field shift of the ReH^a resonance (Scheme 4) by 1.24 ppm (193 K) while the ReH^b resonance is shifted by 0.04 ppm only. The same spectroscopic behaviour can be observed for the trihydride $[Cp_2NbH_3]$ upon addition of $(CF_3)_2CH\text{-}OH$. The central hydride ligand acts as a proton acceptor.[10]

Scheme 4 shows the $(CF_3)_3COH$ attack on the H^a ligand located trans to NO in $[Re(CO)H_2(NO)(PR_3)_2]$ ending in the formation of $H\cdots H^a$ bonds with $-\Delta H^0$ values of 6.2 and 3 kcal/mol in $[D_{14}]$methylcyclohexane and $[D_8]$toluene, respectively. In contrast, the weaker proton donor, $(CF_3)_2\text{-}CH\text{-}OH$, binds to both the hydride ligands. Nevertheless, even in this case, the $H\cdots H^a$ bonds are more preferable: $-\Delta H^0(H\cdots H^a) = 2.1$ kcal/mol and $-\Delta H^0(H\cdots H^b) = 1.7$ kcal/mol. All these effects, not explainable in steric terms, are directly associated with different electronic properties (hydridicity) of the hydride ligands. Finally, it should be pointed out that the oxygen atoms of the NO groups in $[Re(CO)\text{-}H_2(NO)(PR_3)_2]$ can accept a proton while no Re···H bonds have been found for these hydrides.[22c]

Contact H-bonded Ion Pairs

Protonation of the heteroatom Y of an organic base consists of a proton shift along a linear H-bond, O–H···Y, with the formation of an intimate ion pair, $O^-\cdots H\text{-}Y^+$, as the product of partial proton transfer. This H-bonded ion pair then converts to a solvent-separated ion pair to finally give free ions when the solvent polarity is sufficient for full proton transfer. In the limits of this concept, proton transfer to hydride ligands can be represented by Figure 3 where the reaction ends with the formation of solvent-separated ion pairs due to the relatively small permittivities of the solvents (THF, toluene, CH_2Cl_2) usually applied for protonation of transition metal hydrides.

The best experimental method for observing intimate ion pairs, $M(\eta^2\text{-}H_2)^+\cdots X^-$, is IR spectroscopy in which the positions of indicator bands (for example, ν_{MH} or ν_{CO}) attributable to contact ion pairs markedly depend on the nature of the proton donor HX, i.e. on H-bonded anions X^-.[5d]

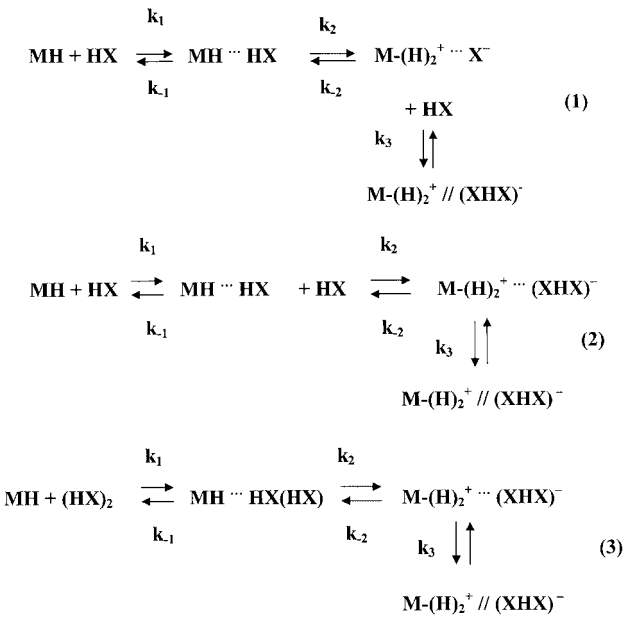


Figure 3. The schemes illustrating proton transfer to a hydride ligand via dihydrogen bonds with participation of two proton donor HX molecules: dimer $(HX)_2$ forms the dihydrogen bond (pathway 3); the second HX molecule initiates the formation of the solvent-separated or contact ion pair [pathway (1) or (2), respectively]

Such pairs have been found in hexane solutions of the hydride $[CpRuH(CO)(PCy_3)]$ protonated with $(CF_3)_2CHOH$, $(CF_3)_3COH$ and CF_3COOH, the IR spectra of which have shown ν_{CO} bands at 1972, 1978 and 2004 cm^{-1}, respectively.[9] In addition, the ν_{CO} frequencies of MH···HX complexes, simultaneously detected in these solutions, also depend reasonably on X^- (1931, 1935 and 1940 cm^{-1}) whereas the ν_{CO} bands of the solvent-separated ion pairs $[CpRu(H_2)(CO)(PCy_3)]^+//CF_3COO^-$ and $[CpRu(H_2)(CO)\text{-}(PCy_3)]^+//BF_4^-$ cannot be distinguished (2020 cm^{-1}, CH_2Cl_2).

As expected, increasing the solvent polarity from hexane to CD_2Cl_2 should lead to displacement of the positions of the equilibria in Figure 3 towards contact ion pairs due to stabilisation of species with a larger charge separation. In accord with this, the CH_2Cl_2 IR spectra of $[CpRuH(CO)(PCy_3)]$ in the presence of $(CF_3)_3COH$ exhibit ν_{CO} bands belonging only to contact ion pairs. In addition, the $[CpRuH(CO)(PCy_3)]/CF_3COOH$ system can show only intimate ion pairs, only solvent-separated ion pairs or both species simultaneously as a function of the CF_3COOH/hydride ratio.[5d,9] Unfortunately, thermodynamic aspects of conversions of H···H complexes to contact ion pairs remain unstudied. However, according to preliminary data,[7c] contact ion pairs are energetically preferable by only 0.2 kcal/mol, for example in CH_2Cl_2 solutions of the $[CpRuH(CO)(PCy_3)]/(CF_3)_3COH$ system.

In spite of reliable experiments concerning observations of contact ion pairs, the gas-phase DFT calculations[9,10] of the ion-pair structures $[CpRu(CO)(PH_3)(H_2)]^+\cdots OC(CF_3)_3^-$ and $[CpRu(CO)(PH_3)(H_2)]^+\cdots OCOCF_3^-$ or $[Cp_2NbH_2\text{-}(H_2)]^+\cdots OC(CF_3)_3^-$ and $[Cp_2NbH_2(H_2)]^+\cdots OCOCF_3^-$ have

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

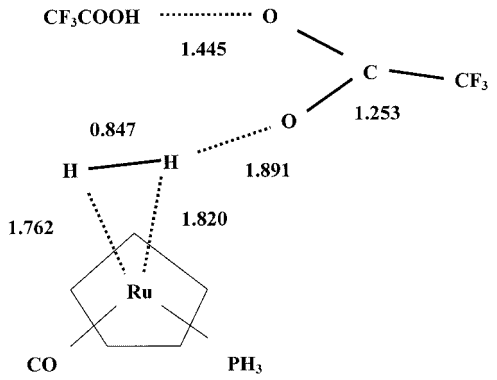

Figure 4. The DFT-optimised geometry of the hydrogen-bonded contact ion pair, $[CpRu(CO)(PH_3)(H_2)]^+\cdots[CF_3C(O)O\cdots H\cdots O(O)CCF_3]^-$ stabilised by the $[CF_3C(O)O\cdots H\cdots O(O)CCF_3]^-$ anion in the gas phase; the distances are given in Å

ended up in the initial dihydrogen-bonded complexes. In addition, the products of full proton transfer, i.e. free ions, were thermodynamically unstable and their energies were higher with respect to the reagents by 100 kcal/mol. Polar solvents could stabilise the charged species. In fact, calculations modelling CH_2Cl_2 led to reduced energies of the systems containing free ions. Nevertheless, the products of proton transfer remained 22 kcal/mol above the initial compounds. Again, no energy minima have been located for contact ion pairs. However, these intermediates have been calculated with minimal energies even in the gas phase if homoconjugated anions, $[RO\cdots H\cdots OR]^-$, are taken into consideration as an additional factor for charge stabilisation. Note that this factor has been well demonstrated by kinetic experiments on the protonation of transition metal hydrides in solution.[6] The calculations led to the structures $[CpRu(CO)(PH_3)(H_2)]^+\cdots[RO\cdots H\cdots OR]^-$ and $[Cp_2NbH_2(H_2)]^+\cdots[RO\cdots H\cdots OR]^-$, the optimised geometries of the former are shown in Figure 4. As can be seen, one of the dihydrogen atoms in $[CpRu(CO)(PH_3)(H_2)]^+\cdots[CF_3C(O)O\cdots H\cdots O(O)CCF_3]^-$ acts as a proton donor forming the H-bond with a length of 1.891 Å.[9] The corresponding Ru–H distance (1.820 Å) is slightly longer with respect to the free cationic dihydrogen complex (1.765 and 1.775 Å) while the H···H separations in the (H_2) ligands are very similar in both the species (0.847 Å). Finally the H–O bond in the ion pair involved into H-bonding is significantly elongated with respect to that in the free proton donor (1.253 Å and 0.98 Å, respectively).

Hartree–Fock calculations of the dihydrogen-bonded $Li-H^{\delta-}\cdots{}^{\delta+}H-F$ complex have shown that an electric field, applied along the molecular axis, leads to transfer of H atoms between two heavy atoms to give the dihydrogen $Li^+\cdots H-H\cdots F^-$ system.[25] Thus the transformation of the M–H···HX species to contact ion pairs can be interpreted as movement of two hydrogen atoms, under the field due to the charges, towards the state with a larger charge separation if the latter can be stabilised by a polar solvent and/or by homoconjugated anions. In contrast to proton transfer to usual organic bases, these movements require strong electronic perturbations. A priori, this circumstance should lead to significant energy barriers, separating dihydrogen-bonded complexes and contact ion pairs.

3. Kinetic Experiments

Table 1 lists kinetic data for the protonation of transition metal hydrides, obtained by the spectroscopic (NMR, UV, IR) and electrochemical methods with the application of usual or stopped-flow mixing techniques. The kinetic experiments have mostly been performed under pseudofirst-order conditions in which acids have been added in large excess.[11,26a–26d] The $[ReH_2(NO)(CO)(PR_3)_2]/CF_3COOH$ systems have been studied with comparable concentrations of the reagents.[26e] In all cases, the overall kinetic order has been found to be close to 2.

The data in Table 1 illustrate the dependences of the rate constants on the nature of the acid used. For example, the rate of proton transfer to [Cp*Fe(dppe)H] strongly increases with the acidity of the proton donor as $CF_3CH_2OH < (CF_3)_2CHOH < (CF_3)_3COH < CF_3COOH$.[26d] At the same time, the *cis*-hydride $[FeH_2PPh_3]$ shows very insignificant changes in the k values in the order $CF_3COOH < HCl < HBr$.[11] In addition, the rate constants are smaller for the stronger acids HBF_4 and CF_3SO_3H. The same effect has been reported for $[RuH_2(dppe)_2]$[26a] and $[ReH_2(NO)(CO)(PMe_3)_2]$ protonated with CF_3COOH and $[\{3,5\text{-}(CF_3)_2C_6H_3\}_4B]^-[H(OEt_2)]^+$.[26e] Thus, in common cases, the rate of proton transfer and the acid strength do not correlate. This result can be explained by the relatively small permittivities of the solvents (THF, toluene, CH_2Cl_2) where even strong acids exist in an equilibrium between molecular forms, ion pairs and free ions (Scheme 5). If free H^+ attacks a hydride, then proton transfer should be suppressed by the addition of X^- ions. However, NBu_4BF_4 does not affect protonation rates of *cis*-$[FeH_2PPh_3]$ by the action of HBF_4 in THF. This is good evidence for the parallel attack of the molecular form HX and the ion pair where ion pairs react slower than HX.[11]

Kinetic experiments on the acids HX and DX, carried out under pseudofirst-order conditions, have revealed inverse kinetic isotope effects, k_H/k_D (Table 2). The results can be interpreted either as the kinetic effects measured for a single-step proton transfer or as the inverse thermodynamic isotope effects in fast preequilibria.[11] In contrast to the effects on usual H-bonds,[27] the effects of deuterium on the thermodynamics of dihydrogen bonding are unknown. On the other hand, under pseudofirst-order conditions, the position of the kinetic preequilibrium should be completely shifted towards the dihydrogen bonds. Therefore, the hypothesis of a single-step proton transfer via a late transition state could be successful for interpreting the observed isotopic effects. A structure, similar to that of the contact ion pairs in Figure 4 with almost complete formation of new bonds, could represent such a transition state. The k_H/k_D values can then be calculated by Equation (3),[11] where $\nu_i(H)$ and $\nu_i^{\neq}(H)$ are the stretching frequencies in the

fundamental and transition states, respectively. As can be seen, Table 2 shows good agreements between the theoretical and experimental k_H/k_D values.

$$k(H)/k(D) = \exp\{7.06\ 10^{-4}[\textstyle\sum_i \nu_i(H) - \sum_i \nu_i^{\neq}(H)]\} \quad (3)$$

As in the case of classical organic bases, proton transfer to a hydride ligand is not a single-step process and occurs via dihydrogen-bonded intermediates. It follows from the previous section that the factor of the basicity, E_j, characterising the formation of H···H bonds, changes from 0.54 to 1.67. The effects of solvents on dihydrogen bonding are also insignificant. Thus dihydrogen bonding is a weak preorganising interaction which cannot be responsible for very big variations in rate constants of proton transfers (Table 1). For example, the k constant, measured for proton transfer from CF_3COOH to $[FeH_2PPh_3]$, $[ReH_2(NO)(CO)(PMe_3)_2]$ and $[RuH_2(dppe)_2]$, increases by six orders from $0.112\ 10^{-2}$ (25 °C) to $192\ 10^{2}$ (–90 °C) to $9.2\ 10^{4}$ (25 °C) l/mol.

IR monitoring of the $[CpRuH(CO)(PCy_3)]/(CF_3)_3COH$ (1:2) system has directly shown a slow (≈30 min) conversion of H···H complexes to intimate H-bonded ion pairs in nonpolar hexane.[9] The ^1H NMR spectra, recorded for the same hydride in the presence of 12 and 100 equivalents of $(CF_3)_3COH$ in $CDClF_2/CDF_3$ (2:1),[7c] support this observation. It is important to emphasise that the formation of H···H bonds is very fast on the NMR timescale even at 120 K. In contrast, the hydride signal, averaged between the intimate and solvent-separated ion pairs, is strongly broadened at 120 K, indicating retardation of ionpair transformations on the NMR timescale.

The schemes in Figure 3 represent proton transfers to hydride ligands with the participation of two proton donor molecules, emphasising the role of homoconjugated $[X\cdots H\cdots X]^-$ species in the kinetics of the process. Note that the second HX molecule initiates the formation of the solvent-separated or contact ion pair, corresponding to pathway (1) or (2).

Formally pathway (1) can be expressed via Equation (4). Since the formation of contact ion pairs is rate-determining (i.e. $k_2 << k_{-1}$ and $k_3[HX] >> k_{-2}$), the equation becomes

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3. Activation parameters for proton transfer to hydride ligands in solution

System	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ e.u.	Solvent	Ref.
$CpRuH(CO)(PCy_3)$/PFTB (1:2)	11.0	–19	hexane	[9]
$ReH_2(NO)(CO)(PiPr_3)_2$/CF_3COOH (1:1)	11.1	12.0	CD_2Cl_2	[26e]
$ReH_2(NO)(CO)(PMe_3)_2$/CF_3COOH (1:1)	13.5	36.8	CD_2Cl_2	[26e]
$ReD(PMe_3)_4(CO)$/CF_3COOD (1:1)	14.4	14.8	CH_2Cl_2	[26e]

Equation (5) and thus the reaction represents a first-order process with respect to the acid. It is easy to show that under the pseudofirst-order conditions (when the preequilibrium is shifted completely to H···H complexes) the measured rates become independent of HX concentration.

$$d[MH]/dt = -\{k_1k_2k_3[MH][HX]^2\}/\{k_{-1}k_{-2} + k_{-1}k_3[HX]\} + k_2k_3[HX] \quad (4)$$

$$d[MH]/dt = -(k_1/k_{-1})\cdot k_2[MH][HX] \quad (5)$$

Experimentally, this pathway has been well established from the IR spectra of the $[CpRuH(CO)(PCy_3)]/(CF_3)_3OH$ system in CH_2Cl_2 in which large variations in hydride/alcohol ratios did not affect a slow transformation of H···H complexes to H-bonded ion pairs with k values between 1.4 10^{-3} and 1.6 10^{-3} s^{-1}.[7a] Activation parameters for this step (Table 3) have been determined in hexane.[9] It is probable that such a mechanism operates for the protonation of the hydrides $[ReH_2(NO)(CO)(PR_3)_2]$ with CF_3COOH (Table 3) in CD_2Cl_2 where the reaction corresponds to first order kinetics on the acid at hydride/acid ratios ≥ 1.[26e]

In contrast, UV monitoring of the hydride [Cp*Fe(dppe)-H] protonated with a 30–200 fold excess of $(CF_3)_3COH$ or $(CF_3)_2CHOH$ (CH_2Cl_2) (pseudofirst-order conditions) led to the first-order dependence of the measured rates on the alcohol concentration.[26d] In the framework of pathway (1) the result can be interpreted according to Equation (6) obtained from equation (5) by assuming $k_3[HX] << k_{-2}$. It is clear that under the pseudofirst-order kinetic measurement conditions, this equation will show a first order dependence on the acid concentration.

$$d[MH]/dt = -(k_1/k_{-1})(k_2/k_{-2})k_3[MH][HX]^2 \quad (6)$$

On the other hand, the above data can be rationalised in the context of pathway (2) where a slow transformation of the H···H complexes to contact ion pairs is accompanied by the second HX molecule [Equation (7)].

$$d[MH]/dt = -\{k_1k_2k_3[MH][HX]^2\}/\{k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3[HX]\} \quad (7)$$

Then, at $k_2[HX] << k_{-1}$, Equation (7) converts to Equation (8).

$$d[MH]/dt = -\{k_1k_2k_3[MH][HX]^2\}/k_{-1}(k_{-2} + k_3) \quad (8)$$

The latter will correspond to the first-order process under the pseudofirst-order kinetic measurement conditions. Finally, the gas-phase and solution DFT calculations have revealed that proton transfer in the $[CpRu(CO)(PH_3)H]/CF_3COOH$ system is energetically preferable if the second HX molecule participates in each step of the process.[9] When the acid is initially a dimer, this situation corresponds, in kinetic terms, to Equation (9) [$(HX)_2$ = DM] showing first order kinetics for the DM acid.

$$d[MH]/dt = -k_1k_2k_3[MH][DM]/\{k_{-1}k_{-2} + k_{-1}k_3 + k_2k_3\} \quad (9)$$

To account for the dimerisation of CF_3COOH,[28] this scheme cannot be excluded when interpreting the kinetic data collected for the $[ReH_2(NO)(CO)(PR_3)_2]/CF_3COOH$ (1:1) system in CD_2Cl_2.[26e] It is clear that only detailed kinetic measurements for large variations in reagent concentrations can distinguish pathways 1–3. For obvious reasons, such experiments are often impossible. However, on the basis of the data presented in this section, pathway (1) can be taken as a general mechanism of proton transfer.

4. Proton/ HydrideExchange as a Measure of Proton Transfer

Intra- and intermolecular positional exchanges with the participation of hydride ligands are widely known.[6,29] Proton/hydride exchanges similar to those in Figure 2 are manifested in the ^1H NMR spectra as broadenings and coalescences of the hydride and HX resonances upon heating and can be quantitatively characterised with the help of a lineshape analysis or saturation transfer experiments.[24] As in the case of proton transfer, the exchange rates in Table 4 strongly depend on the nature of the hydrides and are sensitive to isotope displacements. The overall kinetic order of the exchanges is also equal to 2[6,26e] in agreement with almost negative activation entropies. The nature of the acids also has a significant influence on exchange rates: the exchange is faster when the anion of HX is capable of assistance.[26e]

According to the ^1H NMR spectroscopic data collected for an isomeric mixture of the hydride $[CpW(CO)_2(PMe_3)-H]$ in the presence of $[PhNH_3(OEt_2)]^+_{1-2}[B(Ar^f)_4]^-$, the proton/hydride exchange is fast only for the *trans* isomer.[6] It is obvious that this selective proton/hydride exchange is a good test for a proton attack on the hydride ligand.

The exchanges are highly regioselective in [D_8]toluene solutions of the $[ReH_2(NO)(CO)(PR_3)_2]/CF_3COOH$ system where only the H ligands, located *trans* to NO, are involved in the exchange (Table 4).[26e] Since this effect correlates

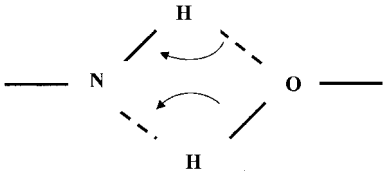

Scheme 6

with the regioselective dihydrogen bonding and Re···HOR bonds are not observed, the dihydrogen-bonded adducts can be taken as a starting point for the proton/hydride exchange process.

A priori, a hydride atom and an acidic proton can exchange their positions if both H atoms are bound to a metal centre in a transition state or an intermediate. It is clear that the solvent-separated ion pairs, $M(H_2)^+//X^-$, could play the roles of such states. Experimentally this statement can be supported by the equal rates measured for the proton/hydride exchange and the formation of dihydrogen complexes. This case is documented for the $[ReH_2(NO)(CO)(PiPr_3)_2]/CF_3COOH$ system in the relatively polar CD_2Cl_2:[26e] a line-shape analysis of the hydride resonances (a test for the exchange) and the ^{31}P NMR signals of $[ReH_2(NO)(CO)(PiPr_3)_2]$ and $[ReH(H_2)(NO)(CO)(PiPr_3)_2]^+$ $[CF_3COO]^-$ (a test for the formation of dihydrogen complexes) gave very similar rate constants (15–20 10^2 L/mol·s, –70 °C). In is clear that under these conditions, the proton/hydride exchange is a good probe for full proton transfer to a hydride ligand.

However, as in the case of usual organic bases, the situation can change. In fact, proton exchanges in organic acid/base pairs can occur without charge separation via the cyclic nonpolar transition states in Scheme 6 where N-H is a base and H-O is an acid. As a result, for example, the dihydrogen complexes $[ReH(H_2)(CO)(NO)(PR_3)_2]^+$ $[CF_3COO]^-$ are formed *slowly* in nonpolar toluene on the ^{31}P NMR timescale while *fast* proton/hydride exchanges still occur on the ^{1}H NMR timescale.[26e] The same effect can be observed in a CH_2Cl_2 solution of $[ReD(PMe_3)_4(CO)]$ and CF_3COOD. As follows from Table 4, the activation energies $\Delta H^{\ddagger}$ necessary for the exchanges are remarkably smaller than those for the formation of dihydrogen complexes (Table 3). In contrast, the isotopic effect k_H/k_D for the

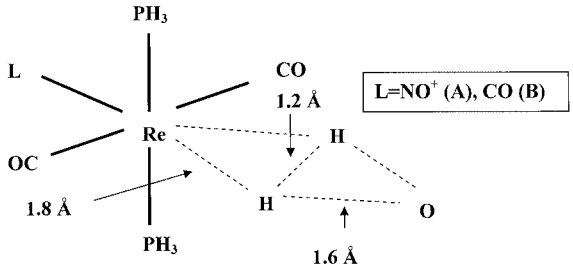

Figure 5. The models of the transition states **A** and **B**, suitable for proton/hydride exchange processes, obtained by EHT calculations on the basis of symmetrical pseudooctahedral geometry (H^+ and O^{2-} represent the acid)[26e]

exchange is larger. It becomes obvious, that in spite of the same starting point (dihydrogen bonded complexes), both processes occur via different transition states and thus such a type of exchange is not a measure of proton transfer and only accompanies the latter. Structures **A** and **B** in Figure 5 could be models of exchange transition states for the Re hydrides, where H^+ and O^{2-} represent the acid.[26e] The structures obtained by EHT calculations are not optimised but they do exhibit feasible features for the orbital interactions and explain the selectivity of the exchanges. For example, state **A** with a *trans* NO has a reasonable HOMO/LUMO gap (≈2.5 eV) and crucial participation of the oxygen orbitals in the binding of the H_2 unit to the metal centre. The orbital interactions are built up from d_{XY} and σ-type functions on the Re centre by the two s_H hydrogen orbitals and s, p_X and p_Y orbitals from the oxygen atom. Thus the appearance of H···H bonding is a main feature of the exchange transition state with participation of hydride ligands in contrast to the transition state in Scheme 6 which is typical of usual organic bases.

5. Energy Profile of Proton Transfer to Hydride Ligands

The discussed spectroscopic, kinetic and thermodynamic data are quite sufficient to describe, semiquantitatively, the energy profile of proton transfer to a hydride ligand in solution.[5c,5d,30] Figure 6 shows the energy as a function of the proton–hydride distance varying from an initial state to a

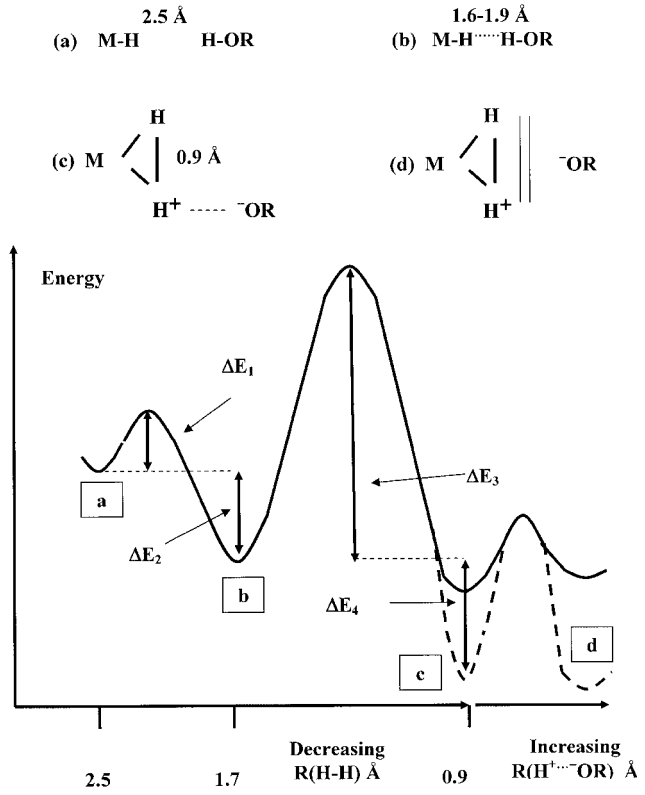

Figure 6. Energy profiles of proton transfer to a hydride ligand of a transition metal complex in solution: ΔE_1 = +3–4 kcal/mol, ΔE_2 = –5 to –7 kcal/mol, ΔE_3 = +10–14 kcal/mol and ΔE_4 = –7 kcal/mol, respectively; the energy is a function of the proton–hydride distance varying from an initial state (2.5 Å) to the final product (0.9 Å); conversion of the intimate ion pair to the solvent/separated ion pair is shown as a function of the $H^+\cdots O^-$ distance

final product. The averaged structural parameters of the initial hydrides and intermediates have been taken from the experimental measurements and DFT calculations. Since proton-hydride contacts of ≤ 2.4 Å, found for different compounds in the solid state, correspond to the appearance of weak bonding interactions,[13b] the H···H distance of 2.5 can be regarded as the starting point with zero energy. The proton transfer process ends with a structure in which the $H^{\delta+}\cdots^{\delta-}H$ distance becomes 0.9 Å, a typical value for dihydrogen ligands.[3]

The pattern in Figure 6 contains four energy minima occupied by the initial hydride, the dihydrogen-bonded complex, the intimate ion pair and the solvent-separated ion pair as a final product of the reaction. For simplicity, homoconjugated species, $[RO\cdots H\cdots OR]^-$, assisting proton transfer and stabilising the protonated products can be ruled out.

Usually, the formation of the H-bonded complexes is regarded as a very fast and diffusion-controlled process with no energy barrier.[5d] On the other hand, even ultra fast molecular reorientations in solution require energy for reorganisation of molecular environments. Since transition metal complexes reorient in solutions with energies of 3.0–4.5 kcal/mol, this magnitude can be taken as a reasonable first barrier, separating the free hydride molecules and the H···H complexes. Dihydrogen bonding results in systems with H···H separations between 1.6 and 1.9 Å. The energy of these systems is reduced by 2.0–7.6 kcal/mol. Note that the latter remarkably depends on the nature of hydrides and acids while the solvent influence is insignificant. The M–H and H–O bonds in the dihydrogen bonded adduct are only slightly elongated with respect to the initial hydride and the acid. The electronic perturbations are minimal and do not require significant energies. The next energy minimum is populated by contact ion pairs and stabilised by H-bonds with anions. This intermediate has the H···H separation very close to that in the dihydrogen complex and its H···O bond is strongly elongated. In spite of the significant structural changes, the depths of the energy minima occupied by dihydrogen- bonded complexes and contact ion pairs are very similar. Since the ion pair species were not localised in the gas-phase DFT calculations, the effect is certainly consistent with their stabilisation by polar solvents or homoconjugated anions $[RO\cdots H\cdots OR]^-$.

As in the case of classical acid/base pairs, the formation of contact ion pairs $M(H_2)^+\cdots X^-$ is the step of proton transfer. However, for transition metal hydrides this step requires significant changes in the M–H–H–X geometry and the H···H and X–H bond lengths. For this reason, the energy barrier separating the M–H···H–X and $M(H_2)^+\cdots X^-$ species increases to 11–13 kcal/mol (Table 3) in very good agreements with the DFT calculations[9] modelling proton transfer in the $[CpRuH(CO)PH_3]/CF_3COOH$ and $[CpRuH(CO)PH_3]/(CF_3)_3COH$ systems (heptane, CH_2Cl_2). Note that this step is responsible for the total kinetics of proton transfer and the large variation in the *k* constants in Table 1. The solvent-separated ion pair finishes the process with enthalpy changes between –2.4 and –9 kcal/mol.[7,5d,30] The NMR experiments on the $[CpRuH(CO)(PCy_3)]/(CF_3)_3COH$ system in $CDClF_2/CDF_3$ (2:1)[17] showed a low energy barrier separating the contact and solvent-separated ion pairs. Therefore, in the absence of quantitative kinetic data on the last step, the barrier between $M(H_2)^+\cdots X^-$ and $M(H_2)^+//X^-$ can be taken to be small.

6. Conclusion

The concept of hydrogen bonding, known since the beginning of the 20 century, has played a very important role in the understanding of the nature and properties of chemical compounds. The problem of dihydrogen bonding, as an interaction between oppositely charged hydrogen atoms, is significantly younger.[12a,13c,31] In spite of this, its fundamental significance in catalysis, bio-organic and supramolecular chemistry has been well recognised.

This microreview, ignoring details of hydride chemistry and focusing on key physicochemical data, discusses possible kinetic schemes for the protonation process and formulates a general mechanism whereby dihydrogen bonding is the preorganising interaction in proton transfer and proton/hydride exchanges. Protonation of hydride ligands occurs via intermediates, H···H complexes and H-bonded con-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tact ion pairs, and ends in dihydrogen complexes as solvent-separated ion pairs or free ions. General rules governing proton transfer to hydride ligands and conventional organic bases are very similar. The difference between the two is quantitative rather than qualitative in character and is apparent in the contact ion pair formation step. In the case of transition metal hydrides, this step, which determines the kinetics of the process, requires significantly larger activation energies and for this reason the total rate of proton transfer is remarkably slower.

In spite of the numerous studies considered in this article, some important mechanistic details of proton transfer are still unclear and could be the subject of further investigations, one of these being the regularity governing the participation of homoconjugated $[X\cdots H\cdots X]^-$ species. For example, it remains uncertain as to which intermediate step needs such $[X\cdots H\cdots X]^-$ assistance for dictating the total kinetic order of the process. Thermodynamic aspects of conversions of H···H complexes to contact ion pairs are also practically unstudied. To answer these fundamental questions, additional experimental and theoretical investigations are needed. Among various experimental approaches, NMR experiments at extremely low temperatures[8] seem to be very appropriate.

As in the case of conventional organic bases, proton/hydride exchanges in transition metal hydrides can be considered as a probe for full proton transfer. In this context, further theoretical work investigating models of transition states for both processes will be most interesting.

A New Ligand for the Formation of Triangular Building Blocks in Supramolecular Chemistry

Iris M. Müller*[a] and Daniela Möller[a]

Keywords: Tridentate ligands / Copper / Molybdenum

In this article we describe the synthesis, characterisation and metal binding properties of tris(5-bromo-2-hydroxybenzylidene)triaminoguanidinium chloride $[H_6Br_3L]Cl$ (**1**), which can be seen as a triangular building block for supramolecular chemistry. **1** crystallises either in a triclinic (**1a**) or a rhombohedral (**1b**) system depending on the used solvent . The pure ligand adopts a conformation unfavourable for the coordination of metal centres, but in the presence of a base or a basic metal salt, a change in the conformation can be observed. The reaction of **1** with $(NH_4)_6[Mo_7O_{24}]$ in the absence of further base results in the formation of small, red crystal needles with the formula $[Mo(O)_2(OH_2)(H_3Br_3L)]\cdot 2$ DMF (**2**), while the reaction of **1** with $CuCl_2$, sodium 5,5-diethylbarbiturate (NaH*bar*) and Et_3N leads to the formation of dark red-black crystals with the formula $(Et_4N)_2[\{Cu(Hbar)\}_3Br_3L]$ (**3**).

Introduction

There are two different ways of subdividing the rapidly growing field of supramolecular chemistry. One is by classifying the products that can be formed, namely polymers [1] or discrete cages and helical molecules.[2] The other way is based on the molecular building units, especially on the properties of the participating ligands. Up to now, the use of asymmetric or C_2 symmetric ligands has predominated, and despite their potential, far fewer C_3 symmetric ligands or ligands of higher symmetry have been employed for supramolecular coordination chemistry.[2] In particular, the C_3-symmetric ligands can be regarded as triangular building blocks, which should be suitable for the construction of most of the Platonic and Archimedic bodies. The smallest conceivable C_3 symmetric ligand is the carbonate dianion (Scheme 1, a). The guanidinium cation, which is isoelectronic with carbonic acid (Scheme 1, b; R = H), is known to be able to form metal complexes and can be modified chemically.[3]

A possible way of designing more stable products is to put the stabilizing chelate effect to use as in the case of the triaminoguanidinium cation (Scheme 1, c). Due to its character as a reducing agent, the introduction of protection groups is necessary, and if these also contain a donor atom, a tris(chelating) ligand with threefold symmetry will be formed (Scheme 1, d), which can be used to bind three metal centres as shown in Scheme 1 (e). The preferred coordination geometry of the metal centres determines the number and position of additional ligands. With the use of this strategy, different types of complexes, from monomeric species[4] to cage-like compounds with the outer shape of a doughnut,[4] a rectangular box,[5] a tetrahedron[6] and an octahedron,[5] can be prepared as described previously. The structural characterisation of large cage compounds by X-ray crystallography is often difficult due to rapid solvent loss and a typical high degree of disorder of both the counter ions and solvent molecules. The introduction of heavy atoms into the ligand should increase the scattering power of such oligomeric complexes and therefore improve the resolution and quality of the experimental X-ray data. With

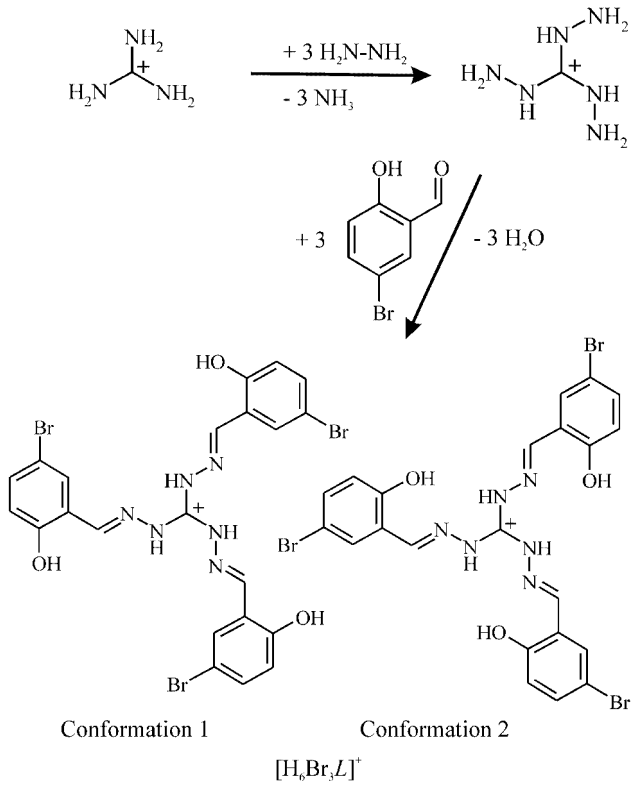
this goal in mind, we present here the synthesis and characterisation of tris(5-bromo-2-hydroxybenzylidene)triaminoguanidinium chloride and report on its metal binding properties.

Results and Discussion

Tris(5-bromo-2-hydroxybenzylidene)triaminoguanidinium chloride $[H_6Br_3L]Cl$ (**1**), can be easily obtained from triaminoguanidinium chloride and 5-bromosalicylaldehyde (Scheme 2).



Scheme 2

Diffusion of HCl into an aqueous solution of **1** leads to triclinic pale yellow crystals of **1a**, whose molecular structure (space group $P\bar{1}$) is shown in Figure 1 (a).[7] In the solid state, **1** adopts conformation 1 (Scheme 2), which is stabilized by close contacts between the hydroxy groups and the Cl^- anions (Table 1). This results in the formation of a two-dimensional hydrogen-bonded network.

Diffusion of HCl into a solution of **1** in DMF leads to rhombohedral pale yellow crystals of **1b** (space group $R\bar{3}$).[8] The conformation of the $[H_6Br_3L]^+$ cation is the same as that observed in **1a** (Figure 1, b). However, hydrogen bonds lead, in this case, to the formation of double layers, which enclose a layer of DMF molecules. The bond length and angles observed in **1a** and **1b** fall in the expected ranges. All carbon and nitrogen atoms show sp^2-hybridisation with the distance between the central carbon and the nitrogen atoms exhibiting an average value of 1.327(7) Å,

in accordance with a partial double-bond character. A propeller-like distortion can be observed, and the dihedral angles between the central CN_6 core and the aromatic systems adopt values between 1.5° and 22.3°. The ^1H NMR spectrum of **1** contains only a few sharp signals. This suggests that in solution one conformation must be dominant (Figure 2, a). The very weak interaction between H3 and H4 seen in the H,H-NOESY experiment suggests that in solution only conformation 1 will be of importance. It therefore appeared interesting to determine how readily conformation 1 can be transformed into conformation 2, which is the required conformation for the coordination of metal centres. In high-temperature ^1H NMR experiments (up to 80 °C), a shift of the signals can be observed, but no line-broadening can be seen. This indicates that no change in the conformation takes place within this temperature range.

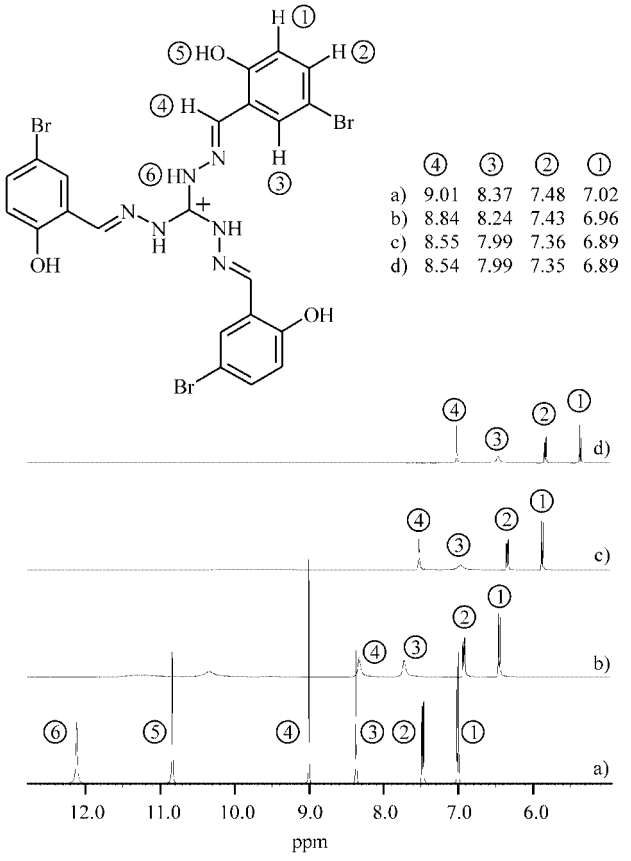

Figure 2. ^1H NMR in $[D_6]$DMSO and chemical shifts in ppm of **1**; a) pure solution; b) + 1 equivalent Et_3N; c) + 3 equivalents Et_3N; d) + 6 equivalents Et_3N

In contrast, the addition of one to six equivalents of base (triethylamine) to a solution of **1** leads to the upfield shift of the signals for H1−H4 and the broadening of the signals for H3 and H4 as depicted in Figure 2 (b−d). This phenomenon can be explained by the transformation of conformation 1 into conformation 2 upon deprotonation, with resulting long-range coupling between the affected protons, whose proximity is confirmed by the observed strengthening of their cross peak in the H,H-NOESY spectrum. In solution a base is able to transform the conformation of **1**, but can a metal ion achieve the same result by metalating its N and O atoms? The reaction of $[H_6Br_3L]Cl$ with neutral $CdCl_2$ in acetone leads, for instance, even at higher temperatures, only to the formation of crystals with the formula $[H_6Br_3L]_2[CdCl_4]$, in which the ligand still adopts conformation 1.[9]

The reaction of **1** with $(NH_4)_6[Mo_7O_{24}]$ as a basic metal salt results in the formation of small, red crystal needles. The X-ray structure shows a complex with the formula $[Mo(O)_2(OH_2)(H_3Br_3L)]\cdot 2DMF$ (**2**), whose asymmetric unit is shown in Figure 3 (a).[10]

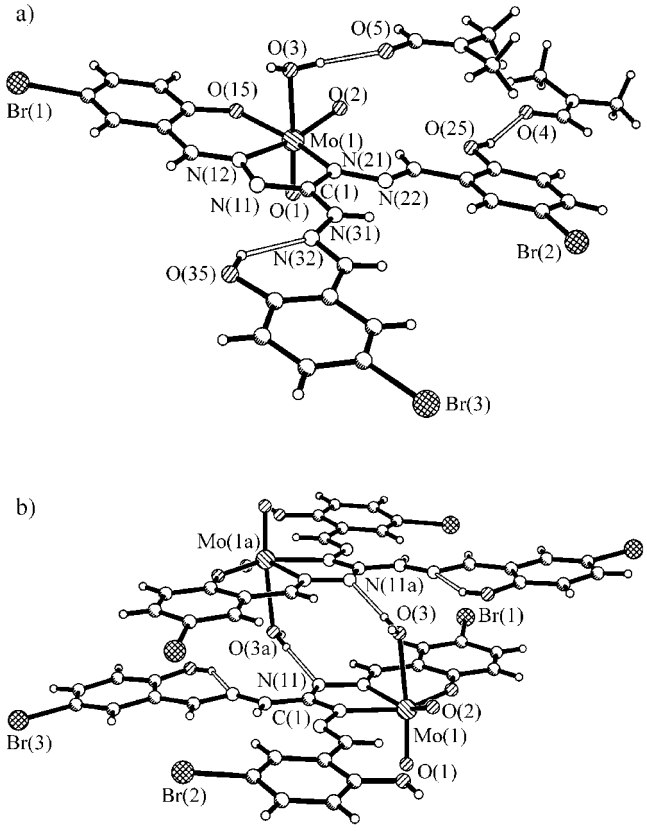

Figure 3. Crystal structure of **2**; a) asymmetric unit; b) hydrogen-bonded dimer

In **2** the ligand is partially deprotonated, and N12, N21 and O15 participate in the Mo(VI) coordination sphere. Two of the three arms of **1** (starting with N11 and N31) are transformed into conformation 2, the third arm (starting with N21) remains in conformation 1 and is stabilized by a strong hydrogen bond with a DMF molecule [*d*(H25···O4) = 1.87 Å, Table 1]. In this complex, $[H_3Br_3L]^{2-}$ coordinates to a Mo(VI) centre with a distorted octahedral geometry. Three of the four equatorial positions are occupied by the ligand, the fourth by a doubly bonded oxygen atom (O2). The two axial coordination sites contain a second oxygen atom (O1) and a water molecule (O3). Due to the relatively rigid geometry of the ligand, the distortion

at the metal centre can clearly be seen at the angles along the N21−Mo1−O15 [152.1(2)°] and N12−Mo1−O2 axes [153.8(2)°, Table 3]. The Mo atom is displaced at a distance of 0.32(1) Å from the O1/N21/O3/O15 equatorial plane towards the doubly bonded oxygen atom (O1). The $[H_3Br_3L]^{2-}$ ligand itself shows no further distortion due to the coordination. The observed bond lengths (Table 2) are within the tolerance of 3σ, similar to those in the isolated $[H_6Br_3L]^{+}$ cation. The propeller-like distortion of the ligand (dihedral angles of 3.5° to 7.1°) in **2** is lower or similar to that in **1a** and **1b**. Due to the chelation, the angles observed in the central part of the ligand in **2** are markedly different from those in **1**.

2 is electronically neutral; the ligand nitrogen N11 is deprotonated and stabilized by a strong hydrogen bond from the coordinated water molecule of a neighbouring complex [*d*(N11···H3b) = 1.89 Å, angle at H3b: 175°). This and a symmetry-related bridge results in the formation of dimers as shown in Figure 3 (b).

The reaction of $[H_6Br_3L]Cl$ with $CuCl_2$, sodium 5,5-diethylbarbiturate (NaH*bar*) and Et_3N at room temperature leads to the formation of dark red-black crystals with the formula $(Et_4N)_2[\{Cu(Hbar)\}_3Br_3L]$ (**3**).[11] The X-ray structure shows that the ligand is now fully deprotonated and coordinated to three Cu(II) centres (Figure 4).

The metal atoms exhibit square-planar coordination spheres, in which three positions are occupied by the ligand, the fourth by a partly deprotonated diethylbarbiturate anion ($Hbar^{-}$). The copper centres show only minor distortions from the idealised coordination geometry, with observed *trans* angles of 168(2)° and 171(5)° (Table 3). The metals lie almost in the ideal plane formed by the ligand, with a deviation of only 0.03(1) Å. Furthermore, the distortion of the ligand is limited despite the fact that it is involved in the coordination with three metal atoms. The bond lengths observed in **3** are similar to those in **1a** and **1b**. Only the first nitrogen atom in each arm is twisted slightly out of plane, which can clearly be seen in the sum of the observed angles (Table 2). The propeller like distor-

tion as gauged by its dihedral angle of 31.3° is significantly more pronounced for one of the phenyl groups than in previously reported compounds. The other two angles are 9.9° and 13.2°. This once again emphasises the high degree of flexibility of the $[Br_3L]^{5-}$ ligand. The H*bar*$^-$ ligands in **3** are still protonated at the second nitrogen atom. Two of the three *bar* ligands form hydrogen bonds with the carbonyl oxygen atom of an adjacent H*bar*$^-$ ligand (Figure 5, a), the third shows a close contact to a neighbouring acetonitrile molecule (Table 1). This results in the formation of the infinite chains depicted in Figure 5, b.

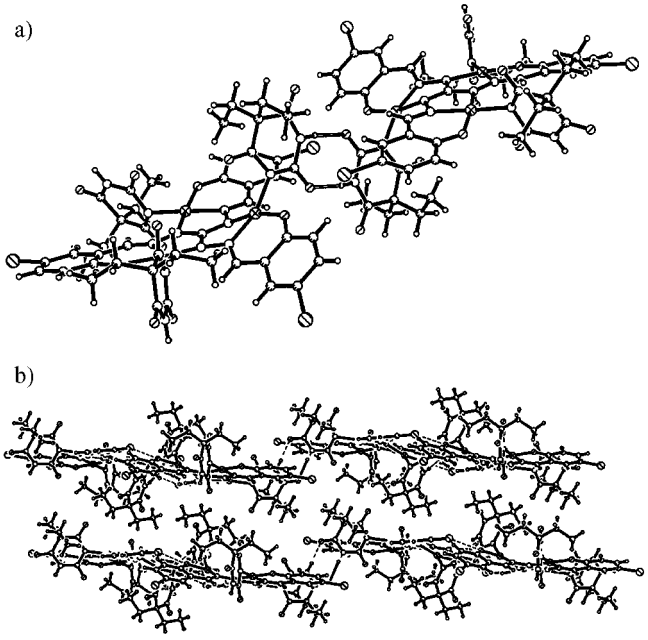

Figure 5. Packing diagram of **3** (countercations omitted for clarity); a) hydrogen-bonded dimer; b) stacking of two chains

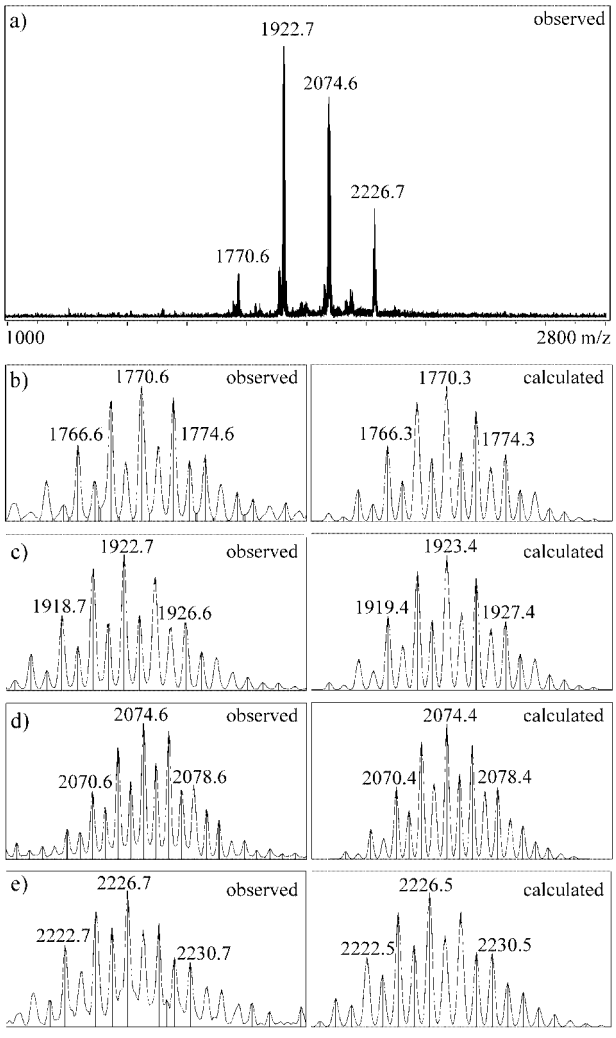

Figure 6. a) ESI mass spectrum for **3** in MeOH; b)−e) observed and calculated isotope pattern for the peaks observed in a).

The structure of **3** demonstrates that it is possible to bind three ligands, with a steric demand as high as that of H*bar*$^-$, to a M_3Br_3L unit. This is an important requirement when employing $[M_3Br_3L]^{3n-5}$ units for the construction of coordination polymers and cages. In fact, in the ESI mass spectrum of **3** in methanol, the only observed molecular ions can be explained by the formation of a dimeric species (Figure 6, a). Two $[Cu_3Br_3L]^+$ units are bridged by three monoanionic coligands: three OCH_3^-, $[C_{47}H_{33}N_{12}O_9Cu_6Br_6]^-$ (Figure 6, b); two CH_3O^-, one H*bar*$^-$, $[C_{54}H_{42}N_{14}O_{11}Cu_6Br_6]^-$ (Figure 6, c); one CH_3O^-, two H*bar*$^-$, $[C_{61}H_{49}N_{16}O_{13}Cu_6Br_6]^-$ (Figure 6, d); three H*bar*$^-$, $[C_{68}H_{57}N_{18}O_{15}Cu_6Br_6]^-$ (Figure 6, e).

In summary, we are able to show that $[H_6Br_3L]^+$ should be a suitable C_3-symmetric ligand for the formation of coordination cages and polymers. The free coordination sites at the metal centres bound by $[Br_3L]^{5-}$ can be occupied by a coligand with high steric demands, without the distortion of the $[M_3Br_3L]^{3n-5}$ unit or the C_3 symmetry. In the solid state, $[H_6Br_3L]^+$ adopts a conformation that is disadvantageous for the coordination of metal centres. Deprotonation by adding a base enables the transformation into the more favourable conformation. In this way, the reaction with metal ions can easily be controlled.

Experimental Section

Triaminoguanidinium chloride was prepared by literature methods.[12] 5-Bromosalicylaldehyde and sodium 5,5-diethylbarbiturate were purchased and used without further purification.

$[C_{22}H_{18}N_6O_3Br_3]Cl$ (1): Triaminoguanidinium chloride (4.681 g, 33.3 mmol) was dissolved in a hot mixture of H_2O (50 mL) and ethanol (100 mL). A solution of 5-bromosalicylaldehyde (20.0392 g, 99.7 mmol) in ethanol (140 mL) was slowly added. The resulting suspension was cooled to room temperature. **1** was crystallised from acetone (400 mL). Yield: 22.2691 g (32.3 mmol, 97%). $C_{22}H_{18}Br_3ClN_6O_3$ (689.58), calcd. values are given in parentheses, based on M + 1 H_2O: C 37.42 (37.34), H 2.57 (2.85), N 11.77 (11.88). ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 12.12 (s, 1 H, NH), 10.83 (s, 1 H, OH), 9.01 (s, 1 H, N=CH−), 8.37 [s(d), ^4J = 2.52 Hz, 1 H, C(6)−H], 7.48 [d(d), ^3J = 9.04, ^4J = 2.52 Hz, 1 H, C(4)−H], 7.01 [d, ^3J = 9.04 Hz, 1 H, C(3)−H] ppm. ^{13}C

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NMR (100 MHz, [D$_6$]DMSO, 25°C): δ = 156.38 (C2), 148.79 (C$^+$), 145.92 (C=N), 135.70 (C4), 128.70 (C6), 121.55 (C1), 118.50 (C3), 110.95 (C5) ppm. Crystals suitable for X-ray crystallography were grown by slow diffusion of HCl gas into a solution of **1** in water with Et_3N (pH 8−9, resulting in **1a**) or into a solution of **1** in DMF (resulting in **1b**).

[Mo(O)$_2$(OH$_2$)(C$_{22}$H$_{15}$N$_6$O$_3$Br$_3$)]·2(C$_3$H$_7$NO) (2): Solutions of tris(5-bromo-2-hydroxybenzylidene)triamminoguanidinium chloride (69.2 mg, 0.1 mmol) and ammonium heptamolybdate tetrahydrate (52.0 mg, 0.042 mmol) in DMF (1 mL each) were mixed. Water (1 mL) was added. Red crystals of **2** were formed after a couple of days. Yield: 28.0 mg (0.0297 mmol, 30%). $C_{28}H_{31}Br_3MoN_8O_8$ (943.3), calcd. values are given in parentheses, based on M + 1 H_2O: C 35.27 (34.99), H 3.68 (3.46), N 11.53 (11.66). ^{1}H NMR (400 MHz, [D$_6$]acetone, 25°C): δ = 11.67 (s, 1 H, N−H), 10.40 (s, 1 H, O−H), 9.69 (s, 1 H, O−H), 8.72 (s, 1 H, N=C−H), 8.54 (s, 1 H, N=C−H), 8.41 (s, 1 H, N=C−H), 7.84 [s(d), ^4J = 2.48 Hz, 1 H, C(6)−H], 7.52 [d(d), ^3J = 8.52, ^4J = 2.52 Hz, 1 H, C(4)−H], 7.51 [s(d), ^4J = 2.52 Hz, 1 H, C(6)−H], 7.36 [d(d), ^3J = 8.52, ^4J = 2.48 Hz, 1 H, C(4)−H], 7.35 [s(d), ^4J = 2.48 Hz, 1 H, C(6)−H], 7.34 [d(d), ^3J = 9.04, ^4J = 2.48 Hz, 1 H, C(4)−H], 6.90 [d, ^3J = 8.52 Hz, 1 H, C(3)−H], 6.88 [d, ^3J = 9.04 Hz, 1 H, C(3)−H], 6.83 [d, ^3J = 8.52 Hz, 1 H, C(3)−H] ppm.

[(C$_2$H$_5$)$_4$N]$_2$[{Cu(C$_8$H$_{11}$N$_2$O$_3$)}$_3$C$_{22}$H$_{12}$N$_6$O$_3$Br$_3$] (3): Tris(5-bromo-2-hydroxybenzylidene)triaminoguanidinium chloride (34.6 mg, 0.05 mmol), copper(II) chloride (20.24 mg, 0.15 mmol), sodium 5,5-diethylbarbiturate (20.9 mg, 0.10 mmol) and tetraethylammonium chloride (14.5 mg, 0.088 mmol) were dissolved in acetonitrile (2 mL) and triethylamine (1 mL). More triethylamine (1 mL) was slowly diffused into the reaction mixture. After three weeks dark red−black crystals of **2** were formed. Yield: 36.0 mg (0.022 mmol, 65.5%). $C_{62}H_{85}Br_3Cu_3N_{14}O_{12}$ (1648.78), calcd. values are given in parentheses, based on M + 2 CH_3CN + 2 H_2O: C 44.75 (44.86), H 5.10 (5.42), N 12.66 (12.68), Cu 11.2 (10.8).

X-ray Analysis: Intensity data for **1a** and **1b** were collected with an AXS Smart/CCD diffractometer (Mo-K_α radiation) and for **2** and **3** with a Nonius Kappa CCD (Mo-K_α rotating anode) always employing the ω scan method. All data were corrected for Lorentz and polarisation effects. Absorption corrections were performed for **1a** and **1b** by SADABS and for **2** and **3** by the Gauss method. **1a**−**3** were solved by using direct methods (SHELXS-97)[13] and refined by using a full-matrix least-squares refinement procedure (SHELXL-97).[14] The protons were placed at geometrically estimated positions. CCDC-241614 to -241617 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors would like to thank Manuela Winter (Anorganische Chemie II, Ruhr-Universität Bochum) for the data collection of **1a** and **1b**, Heike Schucht (Max Planck Institut für Bioanorganische Chemie, Mülheim) for the data collection of **2** and **3** and Robert Schoenen (Anorganische Chemie I, Ruhr-Universität Bochum) for the ESI spectrum.

Keywords: Polyoxometalates / N ligands / Silver / Organic-inorganic hybrids / Supramolecular chemistry

A 1D double-chain assembly based on the monosubstituted Keggin polyoxometalate (POM) with pendant ligands and of formula $\{[Ag_2(bppy)_3][Ag(bppy)_2][Ag(bppy)]_2PW_{11}Co(bppy)O_{39}\}\cdot 2H_2O$ (**1**) [bppy = 5-(4-bromophenyl)-2-(4-pyridinyl)pyridine] has been synthesised and characterised. The crystals of **1** belong to the space group $P\bar{1}$, $Mr = 5801.06$, $a = 18.720(4)$ Å, $b = 19.474(4)$ Å, $c = 19.815(4)$ Å, $\alpha = 96.30(3)$, $\beta = 96.07(3)$, $\gamma = 90.12(3)°$, $V = 7139(2)$ Å^3, $Z = 2$, $D_{calcd.} = 2.699$ Mg·m^{-3}. The final statistics based on F^2 are $GOF = 1.007$, $R_1 = 0.0620$ and $wR_2 = 0.1346$ for $I > 2\sigma(I)$. X-ray diffraction analysis revealed that the structure of **1** contains a 1D chain constructed from a monosubstituted tungstophosphate with one pendant conjugated ligand, five silver–bppy groups and two water molecules. The periphery of the Keggin cluster consists of five Ag–bppy groups so that a bicapped trisupporting Keggin structure is obtained. It is rare that a Keggin anion cluster is simultaneously coordinated to five transition metal atoms.

Introduction

The construction of various intriguing molecular frameworks based on inorganic polyoxometalates (POMs) and organic species with delocalised π systems is of significant contemporary interest owing to their interesting electrical and optical properties such as electrochromism, photochromism, conductivity and redox activity.[1−11] In recent years, research in this field has focused on functionalisation and immobilisation of POMs.[12−20] In addition, conjugated organic molecules and polymers are electrically active organic materials.[21] Thus, these hybrids should offer the potential for broadening the application of POMs in the field of material science.

Despite the deficient charge density on the surface oxygen atoms of many Keggin- and Dawson-type POMs, these oxygen atoms may nevertheless still be involved in more distant bonding with other cations. According to a basic concept, as the charge density on the surface oxygen atoms of the POM increases there should appear a significant affinity for the polyoxoanions to coordinate to transition metal complex cations. A frequent and effective method for obtaining such highly negative polyoxoanions is to substitute the six valent metal centres of W^{VI} and Mo^{VI} with lower valent metal atoms such as V^V and Nb^V. However, we noticed that the number of transition metal complexes supported by these kinds of POMs rarely exceeds two.[22−24] We previously reported a polyoxoanion coordinated to four transition metal complex moieties, i.e. $\{PW_9V_3O_{40}[Ag(2,2'\text{-bipy})]_2[Ag_2(2,2'\text{-bipy})_3]_2\}$ which contains a discrete, neutral molecular unit.[25]

In our ongoing efforts to develop synthetic and functional analogues of large inorganic clusters, we have explored an approach to the synthesis of POMs with covalently bonded pendant ligands which, as mentioned in our prior study on the interactions of adenosine triphosphate (ATP) and adenosine monophosphate (AMP) with 3d transition metal complexes in the presence of the monovacant polyoxotungstate anion α-$[SiW_{11}O_{39}]^{8-}$, leads to metal-substituted tungstosilicates and simultaneously increases the charge density on the surface oxygen atoms of POMs.[26−27] The strategy is to cross-link the inorganic clusters and to anchor the clusters via terminal ligand-support linkages and perhaps through H-bonding interactions thereby avoiding structural collapse.

Recently, the secondary metal coordination groups (SMGs) have been widely used to put POM clusters into high dimensional framework structures which has proved helpful in directing the formation of a given structure.[28−30] Hence, the synthetic strategy here starts firstly by generating a metal-substituted Keggin POM with a pendant-conjugated organic ligand as a building block. A suitable SMG as a connector must then be found in order to assemble the

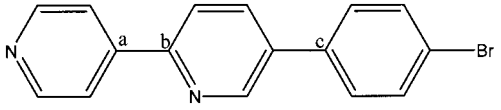
inorganic clusters into a high-dimensional network. Through this route, directed synthesis of a 1D double chain complex $\{[Ag_2(bppy)_3][Ag(bppy)_2][Ag(bppy)]_2PW_{11}Co(bppy)O_{39}\}\cdot 2H_2O$ (**1**) [bppy = 5-(4-bromophenyl)-2-(4-pyridinyl)pyridine] has been obtained. Compound **1** contains a chain structure constructed from a monosubstituted tungstophosphate with one pendant conjugated ligand, five silver-bppy groups and two water molecules. To the best of our knowledge, it is rare to observe a Keggin anion cluster simultaneously coordinated to five metal atoms, let alone extended into a 1D array.

Results and Discussion

Organic Ligand and Silver(I): Combining known transition-metal coordination environments with multifunctional multidentate ligands can generate interesting crystallographic architectures with implications for the rational design of functional solids. Linear bifunctional "spacer" or "rod" ligands have been used to propagate a number of motifs.[33−35] In this experiment, we chose bppy (see Scheme 1) as the organic ligand based on the following considerations: (i) One terminal N site in this molecule is advantageous for forming polyoxometalate complexes with pendant ligands. The middle N atom and the terminal Br atom are potential coordination sites which may help to extend the linkage into an unprecedented high-dimensional structure. (ii) The length of the linear molecule bppy (ca.13.2 Å) is sufficient to overcome the disadvantage of the repulsion of adjacent polyanions.



Scheme 1. The molecular structure of the organic ligand bppy; the angle $a-b\cdots c$ is ca. 180°, the length $N_t\cdots Br$ is ca.13.2 Å (N_t = terminal N)

Silver(I) exists in the following possible coordination environments: linear, T-shaped and tetrahedral. In its complexes, silver also displays an ability to coordinate readily to both hard and soft donor centers.[36−40] Considering that the coordination positions of two N atoms in a bppy ligand are similar to those in 2,4′-bipyridine, we anticipated that treatment of Ag with bppy would afford linear, T-shaped or diamond shaped structural subunits with the potential to link POMs into high-dimensional crystallographic architectures.

Synthesis: Compound **1** was synthesised by hydrothermal methods. The pH of the solution plays an important role in the isolation of phases of a given composition and structure. The starting material H_3PO_4 not only plays a central atom role but also adjusts the pH of the reaction mixture. When the pH value is beyond the range of 4.5−4.9 (values prone to the formation of mono-vacant polyoxometalates) the isolation of **1** was unsuccessful affording only amorphous powders. During the course of our reiterative experiments, a yellow crystalline phase besides compound **1** was observed when the reaction was allowed to proceed for three days but this disappeared upon prolonging the reaction time to four days. The material was identified as a salt of $[PW_{12}O_{40}]^{3-}$ by its IR spectrum (see Supporting information Figure S1(b); For Supporting Information see also the footnote on the first page of this article). This may indicate that $[PW_{12}O_{40}]^{3-}$ may initially form and then change to other species, e.g. compound **1**. The mechanism needs to be studied further.

Structure Description: Single-crystal X-ray diffraction analysis revealed that **1** consists of $\{[Ag(bppy)_2][Ag(bppy)]_2PW_{11}Co(bppy)O_{39}\}$ clusters linked by $Ag_2(bppy)_3$ units into an infinite 1D arrangement along the direction of the *a* axis (see Figure 1). The periphery of the Keggin cluster consists of five Ag-bppy groups and a bicapped tri-supporting Keggin structure is thus obtained (see Figure 2). Two adjacent chains form a double-stranded structure via Ag−Br linkages which further extends into a 3D framework via hydrogen bonding and π-π stacking interactions.

The monosubstituted tungstophosphate anion contains a paramagnetic Co^{II} centre covalently linked by a rigid, π-conjugated organic ligand on a peripheral octahedral site of the Keggin core. The P−O bond lengths range from 1.525(8) to 1.534(9) Å. The W−O_d (O_d = terminal oxygen) bonds are in the usual range of 1.669(11)−1.737(8) Å. All W−W distances are nearly equal, ranging from 3.412 to 3.488 Å (mean value: 3.440 Å) in each triplet except for the triplet substituted with a Co atom [W(1)−W(9): 3.382 Å]. The octahedral coordination Co is defined by one quadruple (bridging) oxygen atom (O_q), four triply bridging oxygens and one terminal N atom from the bppy ligand with the following bond lengths: Co(1)−O(25): 2.018(9), Co(1)−O(35): 2.049(8), Co(1)−O(13): 2.056(9), Co(1)−O(38): 2.087(10), Co(1)−O(3): 2.310(8) and Co(1)−N(1): 2.081(11) Å. The distance P(1)−O(3) is the longest of all the P−O bonds, whereas the distance Co(1)−O(3) is the shortest of all M−O_q linkages (M = W or Co). The most unusual structural feature of compound **1** is that nine surface bridging oxygen atoms of the Keggin anion $[PW_{11}O_{39}Co(bppy)]^{5-}$ are coordinated to five silver-bppy complex cations. To the best of our knowledge, such types of monosubstituted Keggin anions simultaneously supporting so many transition metal complexes has not been reported.

Another remarkable aspect of **1** is that the five silver atoms have different coordination environments: four-coordinate Ag(1) and Ag(2) and three-coordinate Ag(3), Ag(4) and Ag(5). The Ag(1) and Ag(2) atoms are defined by one terminal nitrogen atom of the bppy ligand and three bridging oxygen atoms of the pseudo-Keggin anion, respectively. The distances Ag(1)−O(15), Ag(1)−O(23), Ag(1)−O(21) are 2.402(8), 2.520(9) and 2.603(8) Å, respectively, while the distance Ag(1)−N(3) is 2.152(16) Å. The Ag(2) atom lies in the opposite position to Ag(1) in the POM cluster with the bond lengths of 2.337(8), 2.526(9), 2.684(47) and 2.181(13)

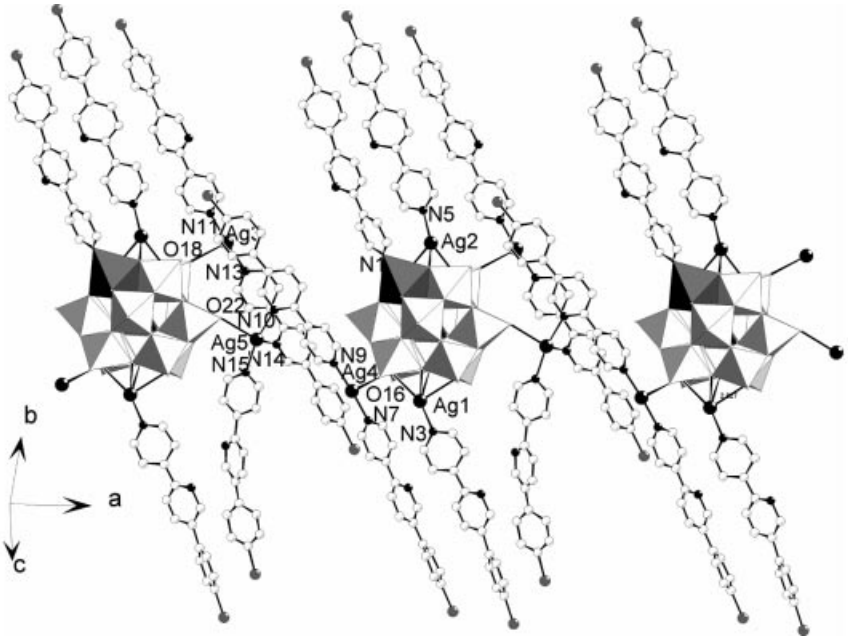

Figure 1. Polyhedral representation of the 1D chain structure of **1**; dark octahedra: {$Co^{II}O_4N$}; light octahedra: {$W^{VI}O_6$} and {PO_4}

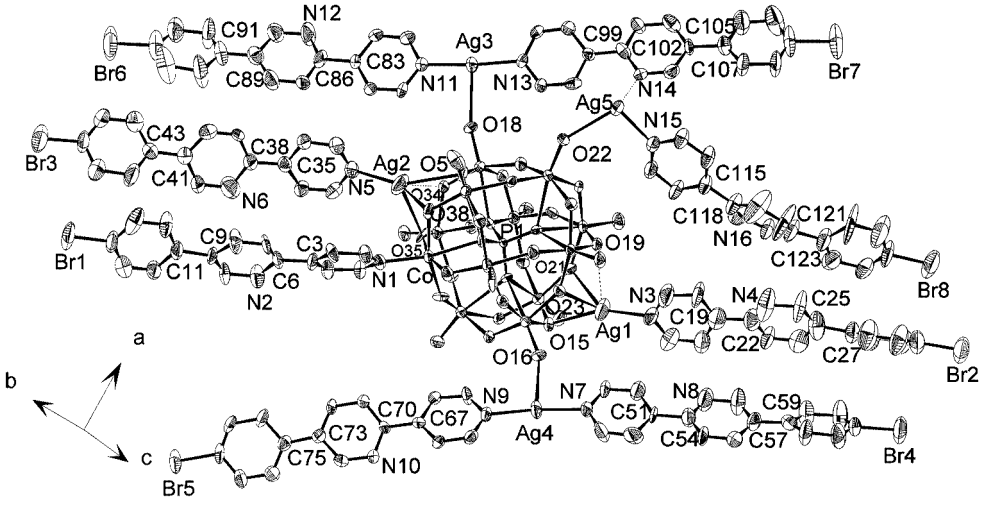

Figure 2. ORTEP view of the building block unit of the 1D chain of **1** showing the linkage mode of the polyanion and the silver-bppy fragments; ellipsoids are drawn at the 50% probability level

Å for Ag(2)−O(38), Ag(2)−O(35), Ag(2)−O(5) and Ag(2)−N(5), respectively. The proximity of the fourth oxygen atom O(19) to Ag(1), [Ag(1)−O(19): 2.823(41) Å] (the sum of the van der Waals radii of Ag and O is 3.20 Å),[41] implies a weak binding and leads to the coordination geometry around Ag(1) being a distorted square pyramid. Similarly, there is a weak interaction between Ag(2) and O(34) with a distance of 3.015(34) Å. The significant variation in the Ag(1) and Ag(2) − oxygen bond lengths may be due to the effect of the coordination environment described below. Ag(1) and Ag(2) cover two opposite faces of the polyanion to form a bicapped α-Keggin-type structure. As is known, in fully oxidised POMs (all W or Mo atoms in the VI oxidation state), terminal oxygen atoms are weakly basic and nonreactive. However, in compound **1**, three terminal oxygen atoms O(18), O(16) and O(22) further extend their linkages via Ag−bppy groups with distances of 2.627(32) Å for Ag(3)−O(18), 2.665(38) Å for Ag(4)−O(16) and 2.644(38) Å for Ag(5)−O(22). For the three-coordinate "T-shaped" Ag(3), Ag(4) and Ag(5) atoms, the other two coordination sites are occupied by N atoms from two bppy ligands with Ag−N distances in the range of 2.116(11)−2.227(12) Å. The bond angles are 175.0(4)°for N(11)−Ag(3)−N(13), 173.2(5)° for N(9)−Ag(4)−N(7) and 166.3(4)° for N(15)−Ag(5)−N(10). A longer distance of 2.839(51) Å between Ag(5) and a N donor atom of another bppy ligand is beyond the usual limits of covalent bonding and may be considered as a weak interaction. Therefore, the Ag(5) atom exhibits a coordination environment which is intermediate between "T-shaped' and tetragonal. Ag(4)

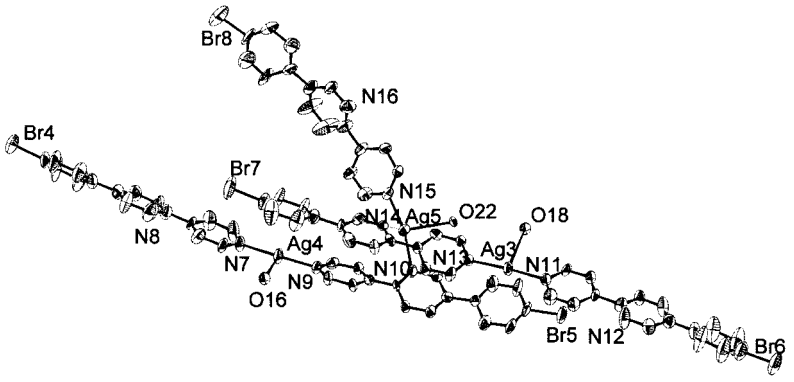

Figure 3. Coordination environments of the Ag(3), Ag(4) and Ag(5) atoms in **1**

and Ag(5) share three bppy molecules to form $[Ag_2(bppy)_3]^{2+}$ which connects adjacent polyanion clusters via Ag−O linkages into a chain structure (see Figure 3). Compound **1** shows that the charge deficient monosubstituted tungstophosphate is capable of bonding with transition metal complexes to form a high-dimensional structure. Compound **1** also shows the flexible coordination mode of silver(I) and provides a good prototype between polyoxoanions with surface-bound inorganic moieties and actually extended polyoxoanion-coordination compound assemblies.

In the crystal structure of **1**, an additional noteworthy fact is that the Br(8) atom lies significantly within the coordination sphere of Ag(1) at a distance of 3.179(51) Å in terms of the sum of the van der Waals radii (1.72 Å for Ag and 1.85 Å for Br).[42] Severe bending of the originally linear bppy containing Br(8) also reflects this interaction with a C(115)−C(118)···C(123) angle of 167.54° and a N(15)···Br(8) length of 12.95 Å (see Figure 2). Thus, taking the Ag(1)−Br(8) into account, a double-strand ladder structure is formed (see Figure 4). Additionally, the distance Ag(2)···Br(1) of 3.726(58) Å, which is beyond the sum of the van der Waals radii of Ag and Br, is too long to be considered as a significant interaction. For comparison, the ligand containing Br(1) is almost linear with the C3−C6···C11 angle being 176.73° and the N(1)···Br(1) length being 13.21 Å. These different interactions between Ag and Br may explain the above mentioned differences of the Ag(1) and Ag(2) − oxygen bond lengths. The two adjacent silver-silver distances of Ag(3)···Ag(3): 3.849(40) Å and Ag(4)···Ag(4): 3.598(34) Å are longer than the van der Waals contact distance (3.44 Å) of silver.[42] As shown in Figure 5, there are significant π-stacking interactions of ligands linked to Ag(3) or Ag(4) (the centre-to-centre and interplane distances are 3.849 and 3.598 Å, respectively.) which implies the formation of a 3D structure in compound **1**. However, ligand packing effects are not responsible for the pairing as is demonstrated by the crystal structure of $[3,5\text{-}Me_2pzH]_3$ which exhibits a planar trimeric association rather than a dimeric "packing".[43] On the contrary, ligand repulsion may actually prevent the silver atoms from fully eclipsing to give Ag−Ag contacts.[44]

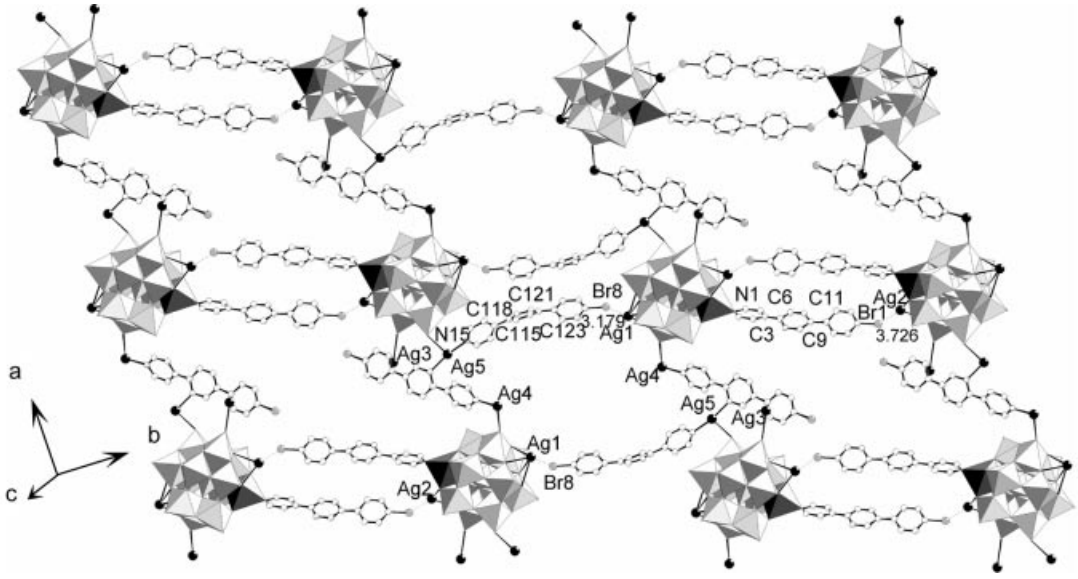

Figure 4. View of the 1D double-chain structure of **1** based on the interaction Ag(1)−Br(8); distances [Å]: Ag(1)···Br(8) 3.179(51), Ag(2)···Br(1) 3.726(58); some bppy groups are omitted for clarity; dark octahedra: $\{Co^{II}O_4N\}$; light octahedra: $\{W^{VI}O_6\}$

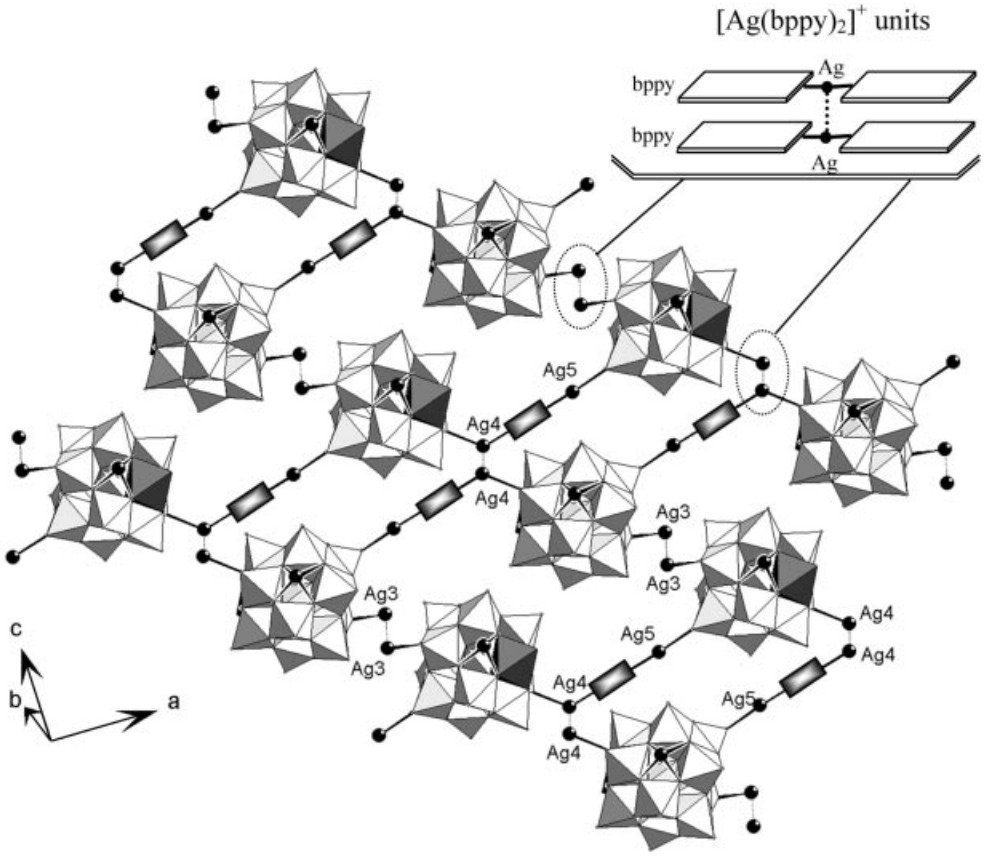

Figure 5. A schematic diagram of **1** showing the extension of 1D chains into a 3D sturctrure via π-stacking interactions of the ligands (see the inset) bonded to Ag(3) and Ag(4); Ag(3)···Ag(3) 3.849(40), Ag(4)···Ag(4) 3.598(34) Å; the dark rectangle blocks represent the covalent linkage of Ag(4) and Ag(5) via bppy groups; organic ligands are omitted for clarity; dark octahedra: $\{Co^{II}O_4N\}$; light octahedra: $\{W^{VI}O_6\}$

The interesting aspect of this structure is the multiple role of the conjugated organic bppy: its first function is to act as a pendant ligand to functionalise the polyanions. The second is to form SMG groups linking the polyanions into chains and the third function is to produce strong aromatic-aromatic interactions giving a 3D structure. 3D supramolecular architectures fabricated from layers by means of hydrogen bonds or π-stacking are common in coordination polymers.[45−46] However, such 3D supramolecular architectures constructed from 1D chains are rare.

The crystal structure of **1** is further strengthened by hydrogen bonding. Two waters of crystallisation have multipoint hydrogen bonding interactions with the organic ligands and the surface oxygen atoms of the POM. The short distances [Å] are (see Figure 6): Ow(1)···Ow(2) 3.070, Ow(1)···O(12) 2.949, Ow(1)···O(25) 3.018, Ow(2)···O(17) 2.902, Ow(2)···C(72) 3.146, Ow(2)···C(4) 3.195, Ow(3)···Ow(3) 2.779, Ow(3)···O(26) 3.057 and Ow(3)···O(7) 2.724.

In summary, the structure of **1** can be described as a monosubstituted tungstophosphate anion $[PW_{11}Co(bppy)O_{39}]^{5-}$ linked by Ag-bppy units into a 1D chain structure running along the direction of the *a* axis. The chains further extend into a double-strand structure based on the interaction of Ag(1) with Br(8) and the π-π interactions of the bppy ligands. These double-strand structures then form a 3D framework structure by hydrogen bonding and a number of π-π interactions of the bppy groups.

Bond valence sum calculations (BVS)[47] indicate that the W centres are in the highest oxidation state and that the Co atom possesses 2.223 of its formal oxidation state in compound **1**. The calculated valence sums for Ag(1) to Ag(5) are 0.902, 0.789, 0.895, 0.960 and 0.792, respectively, indicating the oxidation state of the Ag atoms is +1. The ESR spectrum at room temperature shows the paramagnetic signal of Co^{2+} with $g = 2.258$ which is consistent with the calculation result.[48]

FT-IR Spectrum, XPS Spectrum and TG-DTA Analysis: The IR spectrum [see Supporting Information Figure S1(a)] of **1** exhibits characteristic peaks of the Keggin anion at 999, 953, 885 and 814 cm^{-1}, attributable to ν (W−O_c−W), ν(W−O_b−W) and ν(W−O_d) (O_d = terminal oxygen, O_b = bridged oxygen of two octahedral sharing a corner, O_c = bridged oxygen of two octahedral sharing an edge), respectively. The informative bands at 1080 and 1048 cm^{-1} can be assigned to the P−O stretching vibrations in **1**. Compared with a typical value of about 1067 cm^{-1} for the Keggin anion,[49−50] the P−O stretch of the mono-substituted Keggin tungstophosphate ion splits into two bands because of the lower symmetry than that in the T_d parent Keggin

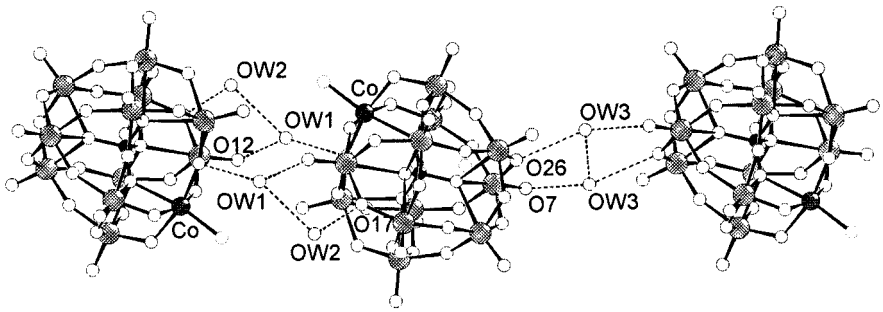

Figure 6. Hydrogen bonds between water and the POM (the silver atoms and organic ligands are omitted for clarity)

anion. The bands in the 3000−1080 cm^{-1} region can be attributed to characteristic vibrations of bppy. Comparatively, the P−O stretch of the by-product salt of $[PW_{12}O_{40}]^{3-}$ does not split into two bands but shows a peak at 1090 cm^{-1} [see Supporting Information Figure S1(b)].

The XPS spectrum (see Supporting Information Figure S2) shows a peak at 368.3 eV, attributable to Ag^{+}, a peak at 70.2 eV attributable to Br^{-} and a peak at 35.2 eV attributable to W^{6+}. These results further confirm the composition of compound **1**.

The TG curve (see Figure 7) shows that compound **1** is stable below 368 °C. A noteworthy finding is that there is still weight loss above 800 °C, indicating that organic material is still being lost even at the upper limit of measurement range. In this range, the DTA curve reveals three exothermic peaks at 396, 510 and 720 °C which correspond to the oxidation of the bppy ligands and/or a phase transformations of inorganic components, respectively. The thermal behaviour of **1** may be largely attributed to the effect of the pendant surface ligand, H-bonding and strong π-π stacking interactions.

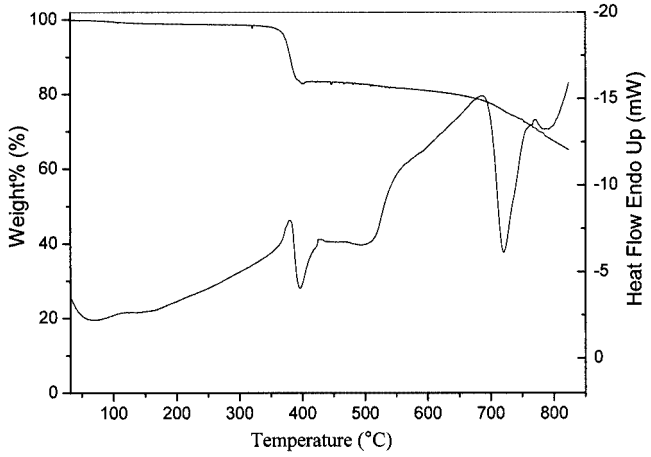

Figure 7. TG and DTA curves of compound **1**

Conclusion

A 1D double chain assembly based on the monosubstituted Keggin POM with pendant ligands has been synthesised and structurally characterised. The successful isolation of crystalline **1** suggests a promising approach for preparing extend arrays of polyoxometalate clusters. By generating metal-substituted polyoxometalates with increased negative charge density on the surface oxygen atoms of the POMs and introducing suitable structure-directing linkages via the secondary metal-ligand complex, rational design and synthesis of a target structure may be achieved, to a certain degree, under hydrothermal conditions. The conjugated organic bppy plays several roles in the structural formation. In particular, the 2′ N-donor is involved in forming a 1D chain through binding to the transition metal. Work on further extending these kind of linkages into 2 or 3D frameworks by this route is underway.

Experimental Section

Materials and Methods: All reagents were purchased and used without further purification; bppy was synthesised and identified by IR and ^{1}H NMR spectroscopy. Elemental analyses were carried out with an MOD 1106 elemental analyser. The infrared spectrum was recorded with an Alpha Centaur FT/IR spectrometer with a KBr pellet in the 4000−400 cm^{-1} region. XPS analysis was performed with a VGESCALAB MK II spectrometer with a Mg-K_{α} (1253.6 eV) achromatic X-ray source. The vacuum inside the analysis chamber was maintained at 6.2×10^{-6} Pa during analysis. The EPR spectrum was recorded with a Bruker ER 200D EPR spectrometer at 293 K. The thermal gravimetric analysis (TGA) and the differential thermal analysis (DTA) were carried out under N_2 with a Perkin−Elmer DTA 1700 differential thermal analyser at a rate of 10.00 °C /min in the range 30−800 °C.

Preparation of Compound 1: A mixture of $Na_2WO_4{\cdot}2H_2O$ (660 mg, 2 mmol), $Co(NO_3)_2{\cdot}6H_2O$ (291 mg, 1 mmol), $AgNO_3$ (213 mg, 1.3 mmol), bppy (62 mg, 0.2 mmol) and H_2O (10 mL) was adjusted to pH = 4.7 with dilute H_3PO_4 solution. The resultant mixture was sealed in a 25 mL Teflon-lined autoclave (70% full) and heated at 170 °C for 96 h. The autoclave was then cooled at 10 °C·per hour to room temperature. Pink crystals of **1** were obtained (yield: 82% based on bppy) along with an amorphous powder which was characterised as a simple compound by its IR spectrum [see Supporting Information Figure S1(c)]. The crystals were washed with water and dried in a desiccator at ambient temperature. The final pH value of the filtrate was 3.6. $C_{128}H_{92}Ag_5Br_8CoN_{16}O_{41}PW_{11}$: calcd. C 26.48, H 1.59, N 3.86; found C 26.51, H 1.63, N 3.82. IR (cm^{-1}): $\tilde{\nu}$ = 1610 (s), 1590 (m), 1540 (w), 1470 (s), 1420 (m), 1370 (w), 1080 (s), 1048 (s), 999 (m), 953 (s), 885 (s) 814 (s), 750 (m), 656 (w), 515 (w) and 417 (w).

X-ray Crystallographic Study: A single crystal of **1** with dimensions 0.18 × 0.10 × 0.08 mm was glued on a glass fibre. Data were collected on a CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71703 Å) at 293 K. Semi-empirical from equivalents were applied. The structure was refined by the full-matrix least-squares method on F^2 using the SHELXTL crystallographic software package.[31−32] Anisotropic thermal parameters were used to refine all nonhydrogen atoms. Hydrogen atoms were located in idealised positions. Selected bond lengths (Å) and angles (°) for compound **1** are listed in Table 1. Crystal data: $C_{128}H_{92}Ag_5Br_8CoN_{16}O_{41}PW_{11}$, triclinic, $P\bar{1}$, Mr = 5801.06, a = 18.720(4) Å, b = 19.474(4) Å, c = 19.815(4) Å, α = 96.30(3)°, β = 96.07(3)°, γ = 90.12(3)°, V = 7139(2) Å^3, Z = 2, $D_{calcd.}$ = 2.699 Mg·m^{-3}, μ = 11.935 mm^{-1}, crystal size: 0.18 × 0.10 × 0.08 mm. The final statistics based on F^2 are GOF = 1.007, R_1 = 0.0620 and wR_2 = 0.1346 for $I > 2\sigma(I)$. CCDC-238955 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information Available (see also footnote on the first page of this article): IR and XPS spectra for **1**.

Fine Tuning of MLCT States in New Mononuclear Complexes of Ruthenium(II) Containing Tris(1-pyrazolyl)methane, 2,2′-Bipyridine and Aromatic Nitrogen Heterocycles

Néstor E. Katz,*[a] Isabel Romero,[b] Antoni Llobet,*[b] Teodor Parella,[c] and Jordi Benet-Buchholz[d]

Keywords: Charge transfer / Ruthenium / N ligands / Scorpionate ligands

The syntheses of new mononuclear ruthenium(II) complexes of the type: [Ru(bpy)(L)(tpm)]$(PF_6)_2$ {tpm = tris(1-pyrazolyl)-methane; bpy = 2,2′-bipyridine; L = pz (pyrazine; **1**), 4,4′-bpy (4,4′-bipyridine; **2**), and bpe [*trans*-1,2-bis(4-pyridyl)ethylene; **3**]} are described, together with their spectroscopic, electrochemical, and photophysical properties. A complete assignment of the NMR resonances of the three species could be made in CD_3CN by bidimensional techniques. A fine tuning of the energies of MLCT (metal-to-ligand charge transfer) states in these complexes is disclosed when comparing, in CH_3CN, the values of their maximum absorption wavelengths for the most intense visible bands (λ_{max}) and their redox potentials for the Ru^{III}/Ru^{II} couples; this effect, relevant to the design of efficient photocatalysts, can be attributed to a decreasing order of $d_\pi(Ru) \rightarrow \pi^*(2,2'\text{-bpy})$ backbonding when decreasing the distance between both N atoms in the aromatic nitrogen heterocycle L that acts in a monodentate manner. Only the species with L = bpe emits at room temperature, pointing to the conclusion that MLCT excited states in this series become higher in energy than dd excited states when the value of λ_{max} is lower than 400 nm. These species are also useful building blocks for new dinuclear mixed-valent complexes.

Introduction

Polypyridylruthenium(II) complexes represent a keystone in the development of photochemistry and electron- and energy-transfer disciplines,[1] and, among other applications, have led to the design of molecular electronic devices,[2] including wires and switches.[3] Furthermore, polypyridylruthenium(II) complexes are often used as building blocks for the development of macromolecular assemblies of interest in biochemistry and clinical diagnosis,[4] as well as for the design of molecular machines.[5] In most of these areas, the synthetic strategy followed to obtain the desired compounds is by Ru^{II} substitution chemistry.[6] Unfortunately, full mechanistic studies on these reactions are scarce and, in many cases, incomplete.[7] As a result of these two factors, it is of primary importance to understand and control the electronic and steric factors exerted by different types of ligands in order to properly monitor their substitution processes.

Ruthenium(II) complexes of the type $[Ru(bpy)(L)(tpm)]^{2+}$ with the tripodal ligand tpm [tris(1-pyrazolyl)methane], the bidentate ligand bpy (2,2′-bipyridine), and monodentate ligands L (Cl^-, H_2O, O^{2-} or py) are well known.[8,9] A coarse control of MLCT (metal-to-ligand charge transfer) excited states can be achieved by changing substituents in the 4,4′-positions of bpy.[9–11] In this work, we report on the fine tuning of the energies of $d_\pi(Ru) \rightarrow \pi^*(bpy)$ MLCT states introduced by changing the nature of the ligand L in $[Ru(bpy)(L)(tpm)]^{2+}$ complexes with L = pz (pyrazine), 4,4′-bpy (4,4′-bipyridine), and bpe [*trans*-1,2-bis(4-pyridyl)ethylene]. These changes can be compared to the variations observed in the analogous series $[Ru(bpy)(L)(trpy)]^{2+}$ (trpy = 2,2′:6′,2″-terpyridine),[12–16] and can be related to the electronic and structural variations induced when going from a meridional (trpy) to a facial (tpm) coordination.[17] The control of MLCT excited sates is relevant in photocatalysis, as demonstrated by the extensive literature concerning artificial photosynthesis based on transition-metal complexes.[18–22] On the other hand, scorpionate ligands, like tpm, can be

used for obtaining luminescent supramolecular complexes.[23] The new complexes studied here are also useful building blocks for new, dinuclear, mixed-valent species, some of which will be reported in a subsequent paper. The structures of the ligands are shown in Scheme 1.

Results and Discussion

Synthesis and Solid-State Structures

The synthetic procedures followed to obtain complexes **1**−**3** are straightforward and involve the substitution of the anionic Cl^- ligand in the complex $[Ru^{II}Cl(bpy)(tpm)]^+$ by the desired monodentate ligand L (pz, 4,4′-bpy or bpe), as shown below.

$$[Ru^{II}Cl(tpm)(bpy)]^+ + L \xrightarrow[\text{reflux}]{MeOH/H_2O} [Ru^{II}(L)(tpm)(bpy)]^{2+} + Cl^-$$

The crystal structure of complex **1** was solved by means of a single-crystal X-ray diffraction analysis. Figure 1 shows the ORTEP diagram of the molecule along with the corresponding labeling scheme. The Ru center adopts a pseudo-octahedral type of geometry with three N atoms (N1, N3, N5) from the tpm ligand coordinated in a facial fashion. Two other positions are occupied by the 2,2′-bpy ligand (N7, N8), which acts in chelate manner, while the sixth one is occupied by the nitrogen atom, N9, of the monodentate pz ligand. The Ru−N bond lengths are within the range found for similar complexes previously described in the literature.[24,25] The bonding angles are also within the ranges found in the literature[24,25] and reflect the nature of the different ligands.

Complex **1** has a local pseudo-C_m symmetry with the mirror plane located in the plane formed by the pyrazine ring and the pyrazolyl group of tmp *trans* to the pyrazine. This symmetry is slightly disturbed by a 4.3° rotation of the bpy out of the mirror plane. The local C_m symmetry of the molecule is broken by the location of the anions in the crystal packing. These are arranged around the complex and together they form a one-dimensional 2_1 screw axis which gives the chirality to the crystal.

Spectroscopic and Redox Properties

Complexes of the type $[Ru(bpy)(L)(tpm)]^{2+}$ are well known in relation to catalysis.[8] However, the influence of slight variations in the structure of the ligands L on the spectral, electrochemical, and photophysical properties of these species has not been much studied; besides, there are no examples so far of mixed-valent species that incorporate tpm in their coordination sphere. As noted before,[9] the simplification introduced by having a poor π-backbonding ligand such as tpm would, in principle, disclose the role of the chromophoric ligands in controlling the spectroscopic, electrochemical, and photophysical properties of MLCT excited states.

NMR Spectroscopy

Figure 2 shows the aromatic region of the ^1H NMR spectrum of complex **1** in $[D]_3$acetonitrile, as a representative example; the COSY, NOESY and HSQC spectra together with all the NMR spectra for complexes **2** and **3** are provided as Supporting Information. The spectra can be unambiguously assigned thanks to molecular symmetry, the smaller coupling constants of five-membered pyrazolyl rings with regard to six-membered pyridyl and pyrazinyl

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rings, and with the aid of 2D NMR spectra. The symmetry lost in the solid state is recovered in solution and thus the two pyrazolyl rings *cis* to the pyrazine ligand become magnetically equivalent, as do the pyridyl moieties of bpy. Two intraligand NOE effects are observed for tpm between H4 and H1 and H8, together with a third interligand NOE between H3 of tpm and H20 of bpy (d_{H3-H20} = 2.46 Å); the latter is a key feature that allows us to assign the NMR resonances with total confidence. The pyrazine and the other ligands acting in a monodentate fashion — 4,4′-bpy and bpe — lose their symmetry upon coordination, a fact that is clearly manifested in their NMR spectra.

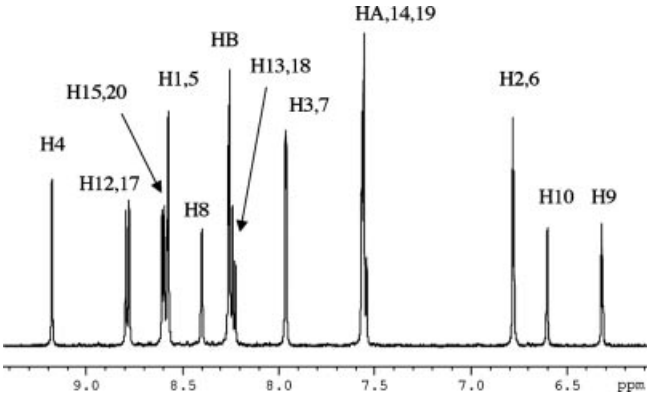

Figure 2. ^{1}H NMR spectrum showing the aromatic region of $[Ru(bpy)(pz)(tpm)]^{2+}$ in CD_3CN

UV/Vis Spectra

Table 1 shows the UV/Vis spectroscopic data of the three new complexes in CH_3CN together with that of $[Ru(bpy)(py)(tpm)]^{2+}$ for comparison purposes. Figure 3 shows the electronic spectrum of complex **1**, as a representative example. Bands between 200 and 300 nm are assigned to the $\pi-\pi^*$ transitions of tpm and bpy.[9] In the visible region, characteristic bands of $d_\pi(Ru) \rightarrow \pi^*(2,2'\text{-bpy})$ and $d_\pi(Ru) \rightarrow \pi^*(L)$ MLCT transitions are observed. Gaussian deconvolution of the spectrum of **1** (see Supporting Information) allows the assignment of the bands at 457 and 392 nm to the former MLCT, while the intermediate one at 418 nm corresponds to the latter MLCT. When the deconvoluted maxima of the $d_\pi(Ru) \rightarrow \pi^*(2,2'\text{-bpy})$ MLCT bands are compared in the series, a decreasing order of energies of the MLCT excited states is disclosed as follows: $[Ru(bpy)(pz)(tpm)]^{2+} > [Ru(4,4'\text{-bpy})(bpy)(tpm)]^{2+} > [Ru(bpe)(bpy)(tpm)]^{2+}$.

This fine tuning is consistent with the backbonding capabilities of the L ligands. As the second (uncoordinated) nitrogen of the aromatic heterocycle L is further away from the Ru center, the total backbonding effect from Ru to L is diminished, thus increasing the backbonding from Ru to the 2,2′-bpy ligand. This effect was not so evident in the series $[Ru(bpy)(L)(trpy)]^{2+}$,[12,13] due to the complications in the spectra produced by the presence of a second chromophoric ligand (trpy).

Electrochemistry

Table 1 includes the values for the redox potentials of the Ru^{III}/Ru^{II} and the $bpy^{0/-}$ couples present in the three complexes; the cyclic voltammogram for **1** is shown in the Supporting Information. The order disclosed by the MLCT bands is also shown in the decreasing values of $E_{1/2}(Ru^{III}/Ru^{II})$ redox potentials in the series: pz > 4,4′-bpy > bpe. The Ru^{II} state is stabilized when the total π-backbonding effects are maximized. The reduction potentials, $E_{1/2}(bpy^{0/-})$, of the ligand bpy are almost unchanged in this series.

Photophysical Properties

Figure 4 shows the emission spectrum of complex **3**, which is the only complex of this series that emits at room temperature in CH_3CN (λ_{em} = 606 nm at λ_{exc} = 400 nm). This value is consistent with the photophysical data of $[Ru(bpy)(py)(tpm)]^{2+}$ (py = pyridine).[9] Complexes **1** and **2** do not emit at room temperature and rearrange with loss of ligand L to give $[Ru(bpy)(CH_3CN)(tpm)]^{2+}$ as the final product. We thus conclude that the dd states become lower in energy than the MLCT states when the absorption maximum corresponding to the $d_\pi(Ru) \rightarrow \pi^*(bpy)$ transition is lower than 400 nm, with subsequent labilization of the ligand L. This result is consistent with that found before[9] when changing the substituents X in complexes of the type $[Ru(py)(tpm)(X_2bpy)]^{2+}$; in this case, changing the nature of X exerts a coarse control over the energies of the Ru → bpy MLCT excited states.

Dinuclear Species

Preliminary experiments indicated the formation of dinuclear species when reacting the mononuclear complexes described here with equimolar amounts of $[Ru(NH_3)_5(H_2O)](PF_6)_2$ under an Ar atmosphere. Oxidation of these new complexes with Br_2 gave the corresponding mixed-valent complexes $[Ru(bpy)(L)(tpm)Ru(NH_3)_5]^{5+}$ (L = pz, 4,4′-bpy, and bpe). They all show MMCT (metal-to-metal charge transfer) bands near 700 nm, as expected because of the high redox asymmetry between both metallic centers.[26] The properties of these species will be presented in a subsequent paper.[27] There are no reports of mixed-valent complexes that include tpm in their coordination spheres.

Conclusions

The spectroscopic and electrochemical properties of the new complexes described in this work disclose the following order of decreasing energies of Ru → bpy MLCT states: $[Ru(bpy)(pz)(tpm)]^{2+} > [Ru(4,4'\text{-bpy})(bpy)(tpm)]^{2+} > [Ru(bpe)(bpy)(tpm)]^{2+}$. This can be accounted for by the decreasing π-backbonding effects along the series. While a coarse control of the energies of the MLCT states in com-

plexes of the type $[Ru(py)(tpm)(X_2bpy)]^{2+}$ has been reported[9] by changing the nature of the substituents X on the 2,2′-bipyridine unit, a much finer control can be exerted by changing the π-backbonding abilities of the ligand L. Therefore, a whole range of Ru-bpy excited states can be finally obtained, which is relevant for the development of efficient photocatalysts.[18] Furthermore, these mononuclear species are useful building blocks for new mixed-valent

species that incorporate tpm in their coordination spheres.[27]

Experimental Section

Materials: All reagents were obtained from Aldrich Chemical Co. and used without further purification. CH_3CN was freshly distilled for electrochemical measurements.

Preparations: All synthetic manipulations were routinely performed under nitrogen using Schlenk tubes and vacuum-line techniques. Electrochemical experiments were performed in the dark under N_2 or Ar with degassed solvents. IR spectra were recorded with an FT Nicolet 205 spectrophotometer with a reflectance accessory. UV/Vis spectra were recorded with a Cary 50 Scan (Varian) spectrophotometer, with 1-cm quartz cells. Cyclic voltammetry (CV) measurements were carried out with an IJ-Cambria IH-660 equipment with a three-electrode cell. A glassy carbon disk electrode (3 mm diameter) from BAS was used as working electrode, platinum wire as auxiliary electrode, and SSCE as reference electrode. All CV experiments were recorded at a 200 $mV \cdot s^{-1}$ scan rate under nitrogen purging, in pure CH_3CN containing 0.1 M tetrakis(*n*-butyl)ammonium hexafluorophosphate (TBAH). The values for the redox potentials, $E_{1/2}$, were estimated from cyclic voltammetry as the average of oxidative and reductive peak potentials $(E_{p,a} + E_{p,c})/2$. NMR spectra were recorded in CD_3CN with a Bruker 500 MHz spectrometer. Elemental analyses were carried out using a CHNS-O Elemental Analyser EA-1108 from Fisons. Luminiscence spectra were recorded with a Shimadzu RF-5301 PC spectrofluorometer, provided with 1-cm fluorescence cells. Argon was bubbled through the solutions prior to the photophysical measurements.

Synthesis of [Ru(tpm)(bpy)(pz)](PF$_6$)$_2$ (1): A sample of $[RuCl(bpy)(tpm)]Cl \cdot 2H_2O$ (80 mg, 0.14 mmol), prepared as described before,[8] was added to a solution of pz (0.6 g, 7 mmol) in ethanol/water (1:1, 25 mL) and the mixture heated at reflux for 6 h. After cooling, the ethanol was evaporated and the remaining aqueous solution was loaded onto a Sephadex C-25 column. The unchanged chloro complex was eluted with 0.2 M LiCl, while the pz complex was eluted with 0.3 M LiCl. This last eluate was concentrated to 5 mL and then a concentrated solution of NH_4PF_6 (1 g in 2 mL of water) was added. After cooling, the precipitate was filtered and washed with cold water. It was then redissolved in acetone (5 mL), re-precipitated with diethyl ether (50 mL), washed with diethyl ether, and dried in vacuo over KOH. Yield: 38 mg (32%). $C_{24}H_{22}F_{12}N_{10}P_2Ru$ (841.07): calcd. C 34.30, H 2.63, N 16.60; found C 34.20, H 2.70, N 16.20. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ = 6.32 (dd, 1 H, H9), 6.60 (d, 1 H, J_{10-9} = 2.3 Hz, H10), 6.78 (dd, 2 H, H2), 7.56 (dd, 2 H, H14), 7.56 (d, 2 H, HA), 7.96 (d, J_{3-2} = 2.1 Hz, 2 H, H3), 8.24 (dd, 2 H, H13), 8.26 (dd, 2 H, HB), 8.40 (d, $J_{8,9}$ = 2.9 Hz, 1 H, H8), 8.57 (d, $J_{1,2}$ = 3.0 Hz, 2 H, H1), 8.60 (br. d, $J_{15,14}$ = 5.4 Hz, 2 H, H15), 8.78 (br. d, $J_{12,13}$ = 8.1 Hz, 2 H, H12), 9.18 (s, 1 H, H4), ppm. ^{13}C NMR (500 MHz, CD_3CN, 25 °C): δ = 76.0 (C4), 108.8 (C9), 110.3 (C2), 125.6 (C12), 126.5 (C14), 135.8 (C8), 135.9 (C1), 138.6 (C13), 144.3 (C10), 145.5 (CB), 147.4 (C3), 148.5 (CA), 153 (C15) ppm. NOEs: H4 with H1 and H8; H3 with H15.

Synthesis of [Ru(4,4′-bpy)(bpy)(tpm)](PF$_6$)$_2$·2H$_2$0 (2): A sample of $[RuCl(bpy)(tpm)]Cl \cdot 2H_2O$ (70 mg, 0.12 mmol) was added to a solution of 4,4′-bpy (1 g, 6.4 mmol) in ethanol/water (1:1, 25 mL) and the mixture heated at reflux for 6 h. After cooling, the ethanol was evaporated and the remaining aqueous solution was filtered to eliminate excess 4,4′-bpy. The filtrate was loaded onto a Sephadex C-25 column. The unchanged chloro complex was eluted with 0.2 M LiCl, while the 4,4′-bpy complex was eluted with 0.3 M LiCl. This last eluate was concentrated to 5 mL and then a concentrated solution of NH_4PF_6 (1 g in 2 mL of water) was added. After cooling, the precipitate was filtered, washed thoroughly with cold water, dried in vacuo over KOH, and recrystallized from acetone/diethyl ether. Yield: 37 mg (33%). $C_{30}H_{30}N_{10}O_2P_2F_{12}Ru$ (953.07): calcd. C 37.8, H 3.2, N 14.7; found C 38.1, H 2.7, N 14.1. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ = 6.30 (dd, 1 H, H9), 6.58 (d, $J_{9,10}$ = 2.2 Hz, 1 H, H10), 7.47 (dd, 2 H, HB), 7.55 (dd, 2 H, H14), 7.64 (dd, $J_{A,B}$ = 5.7, $J_{A,D}$ = 1.3 Hz, 2 H, HA), 7.82 (dd, $J_{C,D}$ = 5.1, $J_{C,B}$ = 1.4 Hz, 2 H, HC), 7.95 (d, $J_{3,2}$ = 1.9 Hz, 2 H, H3), 8.22 (ddd, $J_{12,14}$ = 8.5, $J_{12,13}$ = 7.7 Hz, 2 H, H13), 8.63 (d, $J_{8,9}$ = 2.8 Hz, 1 H, H8), 8.67 (dd, $J_{15,14}$ = 5.6, $J_{15,13}$ = 1.2 Hz, 2 H, H15), 8.73 (dd, $J_{D,C}$ = 5.1, $J_{D,A}$ = 1.3 Hz, 2 H, HD), 8.79 (d, $J_{12,13}$ = 7.7 Hz, 2 H, H12), 8.86 (d, $J_{1,2}$ = 2.6 Hz, 2 H, H1), 10.96 (s, 1 H, H4) ppm. ^{13}C NMR (500 MHz CD_3CN, 25 °C): δ = 74.9 (C4), 108.8 (C9), 110(C2), 122.8 (CC), 125.5 (C12), 126.8 (C14), 135.7 (C8), 136 (C1), 138.3 (C13), 144 (C10), 147.6 (C3, CD), 153.6 (C15), 154.2 (CA) ppm. NOEs: H4 with H1 and H8; H3 with H15 and HA.

Synthesis of [Ru(bpe)(bpy)(tpm)](PF$_6$)$_2$ (CH$_3$)$_2$CO (3): A sample of $[RuCl(bpy)(tpm)]Cl \cdot 2H_2O$ (100 mg, 0.17 mmol) was added to a solution of bpe (0.6 g, 3.3 mmol) in ethanol/water (1:1, 25 mL) and the mixture heated at reflux for 6 h. After cooling, the ethanol was evaporated and the remaining aqueous solution was filtered to eliminate excess bpe. The filtrate was loaded onto a Sephadex C-25 column. The unchanged chloro complex was eluted with 0.2 M LiCl, while the bpe complex was eluted with 0.3 M LiCl. This last eluate was concentrated to 5 mL and then a concentrated solution of NH_4PF_6 (1 g in 2 mL of water) was added. After cooling, the precipitate was filtered, washed thoroughly with cold water, dried in vacuo over KOH, and then recrystallized from acetone/diethyl ether. Yield: 29 mg (33%). $C_{35}H_{34}F_{12}N_{10}OP_2Ru$ (1001.1): calcd. C 42.0, H 3.4, N 14.0; found C 42.1, H 3.0, N 13.6. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ = 6.31 (dd, 1 H, H9), 6.59 (d, 1 H, H10), 6.77 (dd, 2 H, H2), 7.30 (d, 2 H, HB), 7.40(d, 1 H, HE), 7.49 (d, 2 H, H15), 7.50 (d, 1 H, HF), 7.55 (dd, 2 H, H14), 7.80 (d, $J_{C,D}$ = 5.8 Hz, 2 H, HC), 7.96 (d, 2 H, H3), 8.22 (ddd, 2 H, H13), 8.40 (d, 1 H, H8), 8.58 (d, 2 H, H1), 8.65 (dd, 2 H, H15), 8.78 (d, 2 H, H12), 9.18 (s, 1 H, H4) ppm. ^{13}C NMR (500 MHz, CD_3CN, 25 °C): δ = 76.3 (C4), 108.8 (C9), 110.1 (C2), 122.7 (CB), 123.2 (C13), 125.3 (C12), 126.7 (C14), 130.9 (CE), 133 (CF), 135.8 (C8), 136 (C1), 138.2 (C13), 144.2 (C10), 145.4 (CD), 147.7 (C3), 153.2 (C15), 153.7(CA) ppm. NOEs: H4 with H1 and H8; H3 with H8 and HA.

X-ray Structure Determination for 1: Yellow, needle-shaped crystals of **1** were grown by slow diffusion of diethyl ether into a concentrated acetone solution of the complex at room temperature. The crystal to be measured (700 × 40 × 20 μm) was isolated under inert conditions and immersed in perfluoropolyether as protection. Empirical formula $C_{24}H_{22}F_{12}N_{10}P_2Ru$, M = 841.53, monoclinic, space group $P2_1$, a = 10.3101(7) Å, b = 14.5022(10) Å, c = 11.1954(7) Å, β = 117.021(2)°, V = 1491.20(17) Å^3, Z = 2, μ = 0.746 mm^{-1}, $d_{calcd.}$ = 1.874 g/cm^3. The measurement was carried out with a Siemens P4 diffractometer equipped with a SMART-CCD-1000 area detector, a MACScience Co. rotating anode with Mo-K_α radiation, a graphite monochromator and a Siemens low-temperature device LT2 (T = −120 °C). The measurement range was 2.04−31.52°; 23212 reflections were collected of which 9439 were unique (R_{int} = 0.0574) and 8449 observed [$F > 4\sigma(F_o)$]. Full-

The Reaction of (Bipyridyl)palladium(II) Complexes with Thiourea − Influence of DNA and Other Polyanions on the Rate of Reaction

Matteo Cusumano,*[a] Maria Letizia Di Pietro,[a] Antonino Giannetto,[a] and Pasquale Antonio Vainiglia[a]

Keywords: Intercalation with DNA / Inhibition of ligand substitution

$[Pd(bipy)(py)_2](PF_6)_2$ reacts stepwise with excess thiourea to give $[Pd(tu)_4](PF_6)_2$. The kinetics of the second step, which refers to the replacement of bipyridyl in $[Pd(bipy)(tu)_2](PF_6)_2$, have been studied in water and in the presence of calf thymus DNA, sodium polyriboadenylate, sodium polyvinylsulfonate or sodium polymetaphosphate at 25 °C and pH = 7 and a fixed sodium chloride concentration. The reaction follows a first order course and a plot of k_{obs} against [thiourea]^2 affords a straight line with a small intercept. DNA inhibits the process without altering the rate law. The k_{obs} values decrease systematically on increasing the DNA concentration eventually tending to a limiting value. The values are larger at higher ionic strengths and the other polyanions show similar behaviour. The influence of DNA on the kinetics can be related to steric inhibition caused by noncovalent binding with the complex. Upon interaction with DNA, $[Pd(bipy)(tu)_2]^{2+}$ gives rise to immediate spectroscopic changes in the UV/Vis region as well as induced circular dichroism suggesting that the complex, like similar platinum(II) and palladium(II) species of bipyridyl, intercalates with the double helix. Such a type of interaction hampers the attack of the nucleophile at the metal centre inhibiting the reaction. The decrease in the rate of ligand substitution upon decreasing salt concentration but at a given DNA concentration is due to the influence of ionic strength on the complex–DNA interaction. The reactivity inhibition by single-stranded poly(A), polyvinylsulfonate or polymetaphosphate can be accounted for in terms of self-aggregation of the complex induced by the polyanion.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Since the discovery that square-planar complexes can intercalate[1] with DNA, many platinum(II) compounds containing aromatic ligands have been used[2] to study the basic features of this type of noncovalent interaction. These substances are thermodynamically stable and, furthermore, their kinetic inertness prevents undesired covalent interactions with the DNA nucleobases within the time needed for the experiments. The geometry and the ease of which their steric and electronic properties can be tuned by an appropriate choice of the ligands, renders platinum(II) complexes very suitable for studying intercalation with the DNA double helix. Palladium(II) complexes can also be used to study this type of noncovalent interaction with nucleic acids.[3] These substances share the thermodynamic stability and other chemicophysical properties of platinum(II) complexes but are less inert[4] and this feature makes them more amenable to study from a kinetic point of view. Various investigations have shown that the reactivity of a small molecule can be altered upon noncovalent interaction with DNA and RNA. Both inhibition[5] and enhancement[6] of reactivity of metal complexes have been observed. The influence on the kinetics may be related to the particular type of noncovalent interaction and, therefore, the study of the reactivity of a metal complex in the absence and in the presence of DNA or RNA can give interesting information about the interaction itself. In this paper we report the results of a kinetic investigation of the reaction between the palladium(II) complex $[Pd(bipy)(py)_2](PF_6)_2$ (bipy = 2,2′-bipyridyl; py = pyridine) and thiourea in water in the presence of double-helical DNA. The investigation was carried out at 25 °C and pH 7 at two different sodium chloride concentrations. In order to compare the influence of double stranded polyanions with single stranded, helical and random coiled polyanions, the reactions were studied in the presence of sodium polyriboadenylate [poly(A)], sodium polyvinylsulfonate (PVS) and sodium polymetaphosphate (PMP). In addition, the interaction of the complex with the polyanions has been studied by absorption and circular dichroism.

Results and Discussion

The electronic spectrum of $[Pd(bipy)(py)_2]^{2+}$ in water does not change over time although fast reversible spectro-

scopic variations can be observed on changing the pH of the solution. Such variations are not expected on the basis of the nature of the complex. Accordingly, ^{1}H NMR experiments show the presence of signals due to free pyridine in D_2O solutions of $[Pd(bipy)(py)_2]^{2+}$. These signals are not present if the spectrum is run in a poorly coordinating solvent such as deuterated acetone. It appears, therefore, that the complex undergoes hydrolysis within the preparation times of the solutions. Hydrolytic equilibria are common for square-planar complexes and lead to a wide range of products. In the present case, precise indications of the nature of the products are difficult to obtain either by UV/Vis or NMR spectroscopic measurements. However, previous studies on platinum(II) and palladium(II) complexes have shown[7] that hydrolysis produces monomeric aqua and hydroxo species as well as oligomeric species with bridging hydroxo or aqua groups.

Addition of sodium chloride, even in a large excess, to aqueous solutions of $[Pd(bipy)(py)_2]^{2+}$ alters the nature of the hydrolytic species in equilibrium without exchanging coordinated bipyridyl. However when thiourea is used, a bipyridyl is also replaced as well as the monodentate ligands coordinated to palladium. NMR spectra of the reaction mixtures in D_2O unambiguously show the signal corresponding to the released bipyridyl.

The rate of this process, which can be easily obtained by kinetic analysis of the spectroscopic variations over time (Figure 1), is largely independent of chloride and hydrogen ion concentration. Such independence suggests that the monitored process corresponds to the substitution of bipy in $[Pd(bipy)(tu)_2]^{2+}$ formed by the action of thiourea on the hydrolysis products [Equation (1)].

$$[Pd(bipy)(tu)_2]^{2+} + 2\,tu \rightarrow [Pd(tu)_4]^{2+} + bipy \quad (1)$$

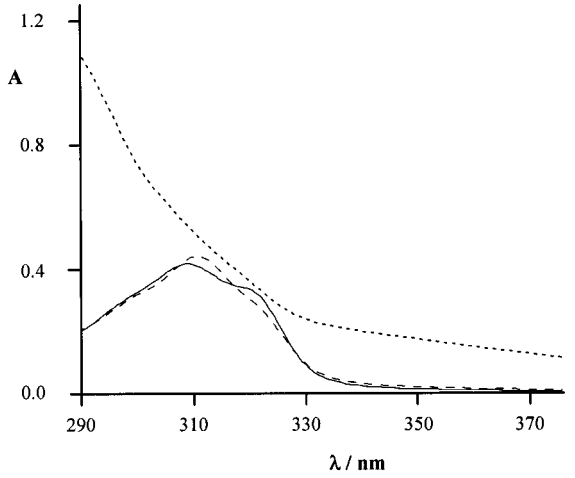

Figure 1. Spectroscopic changes at 25 °C and pH = 7 for the reaction of $[Pd(bipy)(py)_2]^{2+}$ in water (−), in the presence of Cl^- (− −) and with tu (···); $[Pd(bipy)]_{tot} = 3.75 \times 10^{-5}$ M

Thiourea, one of the strongest nucleophiles towards square-planar complexes,[4,8] replaces the monodentate ligands of the hydrolytic complexes in a fast step prior to substitution of bipy. In agreement with this observation, both the spectroscopic variations and the k_{obs} values are almost identical to those obtained upon treatment of a sample of independently synthesised $[Pd(bipy)(tu)_2]^{2+}$ with thiourea, under the same experimental conditions.

Under pseudo first-order conditions the reaction follows a first order course with respect to the complex. Plotting k_{obs} against $[tu]^2$ results in a straight line with a small intercept [Equation (2), Figure 2].

$$k_{obs} = k_1 + k_2 \cdot [tu]^2 \quad (2)$$

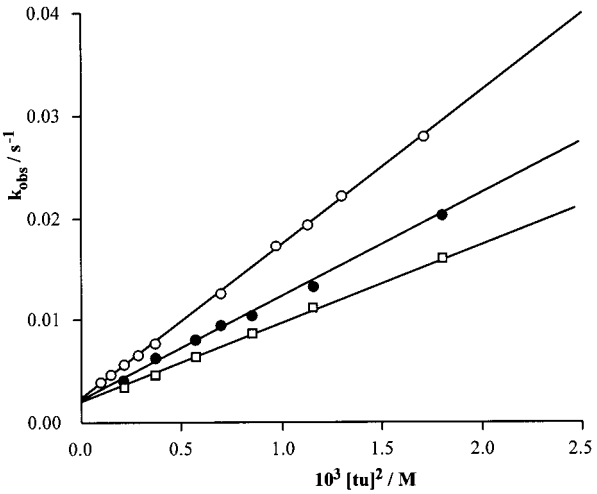

Figure 2. Plot of k_{obs} vs. $[tu]^2$ for reaction (1) [Equation (1)] at 25 °C and pH = 7; without DNA (open circles), in the presence of DNA at $I = 5.0 \times 10^{-2}$ M (filled circles), in the presence of DNA at $I = 2.2 \times 10^{-2}$ M, (squares) $[Pd(bipy)]_{tot} = 3.75 \times 10^{-5}$ M ; [DNA]/[complex] = 0.5

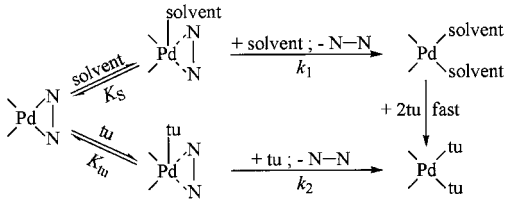
A possible mechanism that accounts for the experimental kinetic values is depicted below in Scheme 1.



Scheme 1

This scheme implies the attack of a first thiourea molecule at the palladium atom with formation of an intermediate which leads to the product upon interaction with another thiourea molecule. $[Pd(tu)_4]^{2+}$ also forms through the customary solvolytic pathway.[8] The intermediates can be described as having a structure in which the ligand is monodentate but rapidly exchanging its point of attachment with the central atom.[9] From this scheme the following Equation (3) can be postulated.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$k_{obs} = \frac{k_1 K_S^{''} + k_2 [tu]^2 K_{tu}}{(1 + K_S^{'} + [tu] K_{tu})} \quad (3)$$

K'_S = [solvent]·K_S and K''_S = [solvent]^2·K_S. Taking into account that the intermediates could not be detected even using a large thiourea concentration, both K_{tu} and K_S should be very small and (K_{tu}·[tu] + K'_S) < 1. Therefore, rate law (3) is very similar to experimental rate law (2). When the reactions are conducted in the presence of DNA, no change in the rate law is observed and this suggests that the mechanism is the same as it is in water. However DNA influences the rate of reaction which becomes lower with respect to that in water (Figure 2).

In addition, the presence of DNA induces dependence of the kinetics on the ionic strength. Thus, when DNA is present, the kinetic values become significantly lower as the salt concentration decreases (Table 1).

Table 1. Values of rate constants for reaction (1) [Equation (1)] at 25 °C and pH = 7; $[Pd(bipy)]_{tot} = 3.75 \times 10^{-5}$ M

$10^3 k_1$ [s^{-1}]	k_2 [$M^{-2} \times s^{-1}$]
3.4 ± 0.3	15.1 ± 0.3[a]
2.0 ± 0.2	10.3 ± 0.7[b]
2.0 ± 0.3	7.6 ±0.5[c]

[a] Without DNA. [b] With DNA 1.87×10^{-5} M; $I = 5.0 \times 10^{-2}$ M. [c] With DNA 1.87×10^{-5} M; $I = 2.2 \times 10^{-2}$ M.

The inhibition caused by DNA depends on its concentration. In Figure 3 the k_{obs} values at fixed ionic strength and at a given thiourea concentration are plotted against the concentration of DNA.

On increasing the DNA concentration, there is a systematic decrease in the rate constants which tend to a limiting value. In addition, the sensitivity of the k_{obs} values to the DNA concentration change increases as the ionic strength is lowered. The presence of other polyanions also inhibits reaction (1) and again the presence of polymetaphosphate, poly(A) or polyvinylsulfonate does not change the rate law but the k_{obs} values become lower in all cases compared with those of the reaction in water. For these polyanions (Figure 4) the kinetic values are also less sensitive to their concentrations at higher ionic strengths.

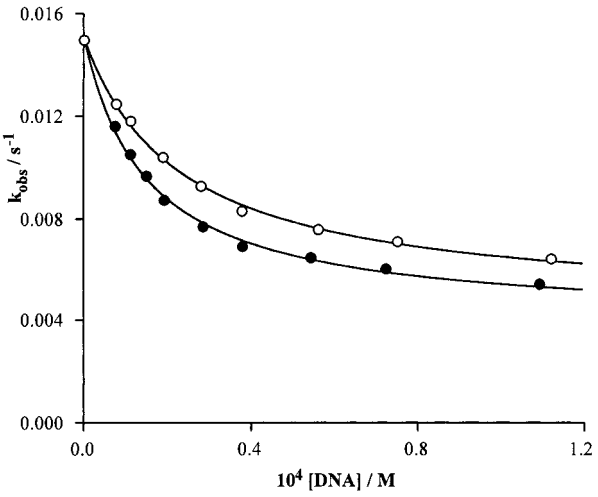


Figure 3. Plot of k_{obs} vs. [DNA] for reaction (1) [Equation (1)] at 25 °C and pH = 7; $[Pd(bipy)]_{tot} = 3.75 \times 10^{-5}$ M; [tu] = 2.91×10^{-2} M; $I = 5.0 \times 10^{-2}$ M (open circles); $I = 2.2 \times 10^{-2}$ M (filled circles)

The influence of the polyanion on the rate of bipyridyl substitution cannot be explained on the basis of concentration effects[10] arising from a particular distribution of the reactants driven by electrostatic interactions. While the dicationic complex tends to concentrate around the polyanion, the uncharged thiourea has no preference for any particular region of the solution. The inhibiting effect seems to be steric in origin and can be interpreted on the basis of noncovalent interactions between the complex and the

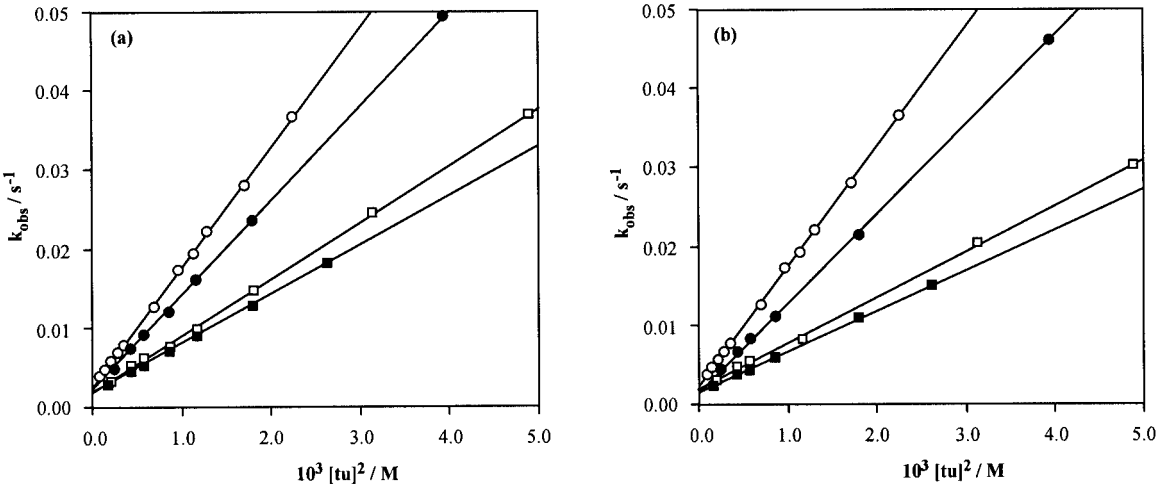

Figure 4. Plot of k_{obs} vs. [tu]^2 for reaction (1) [Equation (1)], at 25 °C and pH = 7, in water (open circles) and in the presence of polyanions (a) at $I = 5.0 \times 10^{-2}$ M and (b) at $I = 2.2 \times 10^{-2}$ M; $[Pd(bipy)]_{tot} = 3.75 \times 10^{-5}$ M, [PMP] = 7.50×10^{-5} M (filled circles), [Poly(A)] = 3.75×10^{-5} M (open squares), [PVS] = 1.87×10^{-5} M (filled squares)

polyanions. In principle, due to the lability of palladium(II) complexes, covalent binding could also occur with the DNA nucleobases. However, under our experimental conditions, the complex and the DNA are initially separate. The biopolymer is then added together with thiourea in a large excess. Thiourea is a much stronger nucleophile than the nucleobases and competition between the two nucleophiles is, therefore, highly unlikely.

In the absence of thiourea, addition of any of the polyanions to $[Pd(bipy)(tu)_2]^{2+}$(the actual chemical species involved in the process studied) produces immediate spectroscopic variations characterised by hypochromism (Figure 5 and 6).

The presence of noncovalent interactions between a small molecule and a chiral polyanion such as DNA or poly(A) is also indicated by the appearance of a CD signal in the spectroscopic region where the bound molecule absorbs. This CD signal is due to induced circular dichroism as a result of the rigid orientation assumed by the bound substance with respect to the helical axis of the polyanion. Figure 7 shows the CD spectra of the complex in the presence of increasing amounts of DNA and poly(A).

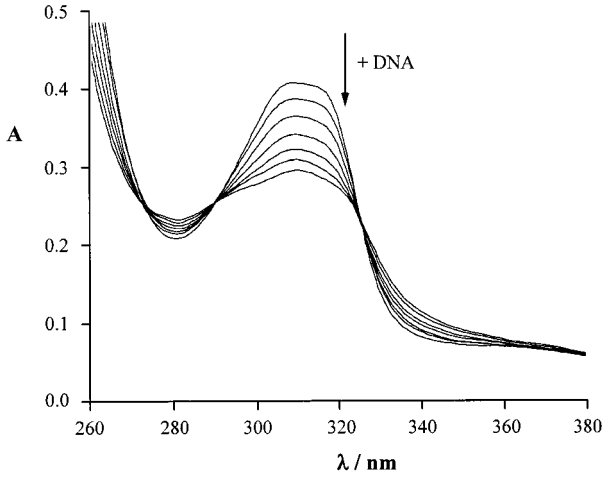

Figure 5. Spectroscopic changes for the interaction of $[Pd(bipy)(tu)_2]^{2+}$ (3.75×10^{-5} M) with DNA, at 25 °C and pH = 7; $I = 2.2 \times 10^{-2}$ M; [DNA]/[complex] = 0, 0.27, 0.52, 0.84, 1.14, 1.55, 2.03

As is well known, small molecules can interact noncovalently with double stranded DNA[11] either by surface binding or by intercalation. Both binding modes and especially intercalation imply shielding of the reaction centre, reducing the effectiveness of the incoming ligand and lowering the rate of substitution. Though neither absorption nor circular dichroism experiments can establish the type of noncovalent interaction between a small molecule and the DNA double helix, previous investigations[2d] have shown that $[Pt(bipy)(py)_2]^{2+}$, as well as many other dicationic platinum(II) and palladium(II) complexes of bipyridyl, intercalate with DNA. Similar conclusions can also be drawn for $[Pd(bipy)(tu)_2]^{2+}$ and its precursor $[Pd(bipy)(py)_2]^{2+}$. The binding constant for the interaction of $[Pd(bipy)(tu)_2]^{2+}$ with DNA at 25 °C and $I = 2.2 \times 10^{-2}$ M, obtained by the analysis of the spectrophotometric titration data via the McGhee von Hippel[12] equation is $(1.0 \pm 0.1) \times 10^5$ M^{-1}. Such a value is of the same order of magnitude as other similar platinum(II) and palladium(II) complexes.[2b,2d,3]

Intercalation may well account for the observed rate effect. Shielding of both sides of the square plane by the nucleobases hampers the attack of the incoming nucleophile thus inhibiting the substitution process. The decrease in the rate of ligand substitution at a given DNA concentration, as the salt concentration is reduced, is due to the influence[13] of ionic strength on the complex-DNA interaction. Due to competition of the interacting small molecule and the other cations present in solution for the anionic phosphate groups of DNA, ionic strength destabilises any type of noncovalent interaction between cationic species and this biopolymer. In addition, ionic strength influences DNA conformation. Increasing ionic strength reduces repulsion between phosphate groups allowing adjacent base pairs to get closer thus disfavouring intercalation. For the other polyanions, where intercalation is not possible, the reactivity inhibition can be interpreted on the basis of self-aggregation of the complex. Stacking of aromatic rings produces hypochromism[14] as experimentally observed upon interac-

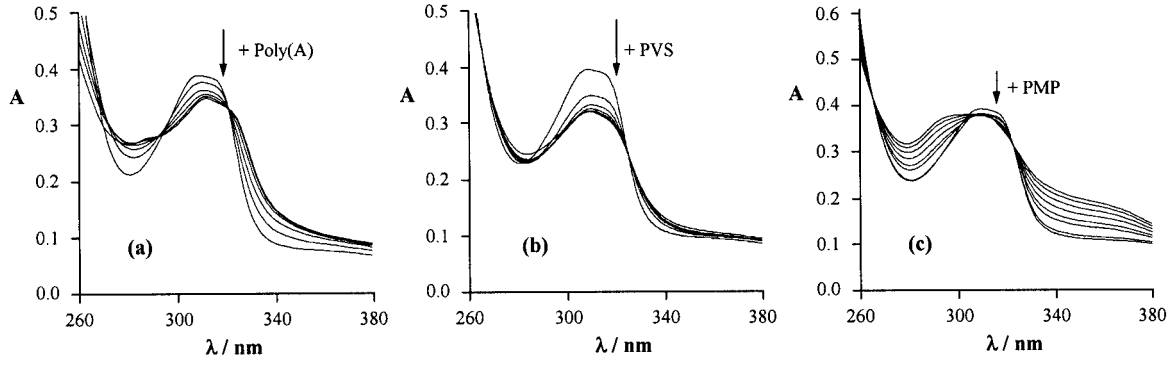

Figure 6. Spectrophotometric titration of $[Pd(bipy)(tu)_2]^{2+}$ (3.75×10^{-5} M), at 25 °C and pH = 7, with (a) poly(A) ([poly(A)]/[complex] = 0, 0.55, 1.02, 1.43, 1.79, 2.11), (b) PVS ([PVS]/[complex] = 0, 0.007, 0.014, 0.020, 0.027, 0.033), and (c) PMP ([PMP]/[complex] = 0, 5.8, 11.5, 22.5, 43.4, 80.9, 113.5, 142.2, 167.6); $I = 2.2 \times 10^{-2}$ M

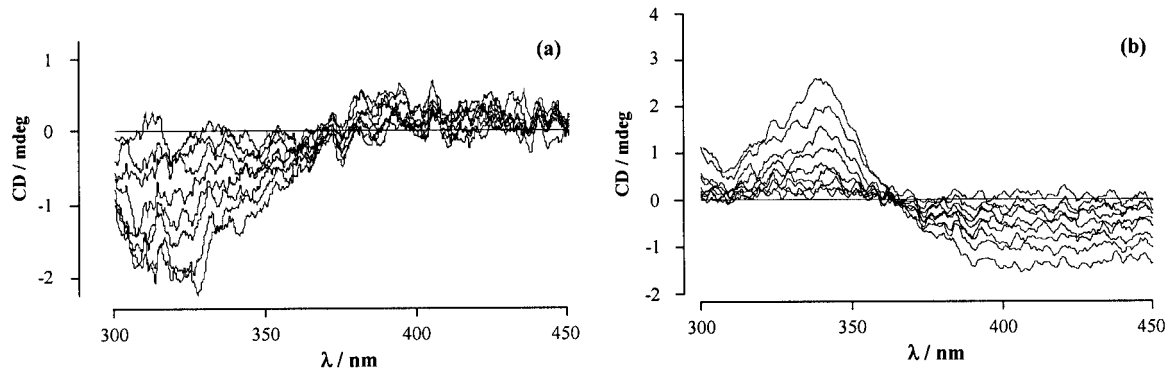

Figure 7. CD spectroscopic titration of $[Pd(bipy)(tu)_2]^{2+}$ (3.75×10^{-5} M) with (a) DNA and (b) poly(A) at 25 °C and pH = 7; $I = 2.2 \times 10^{-2}$ M

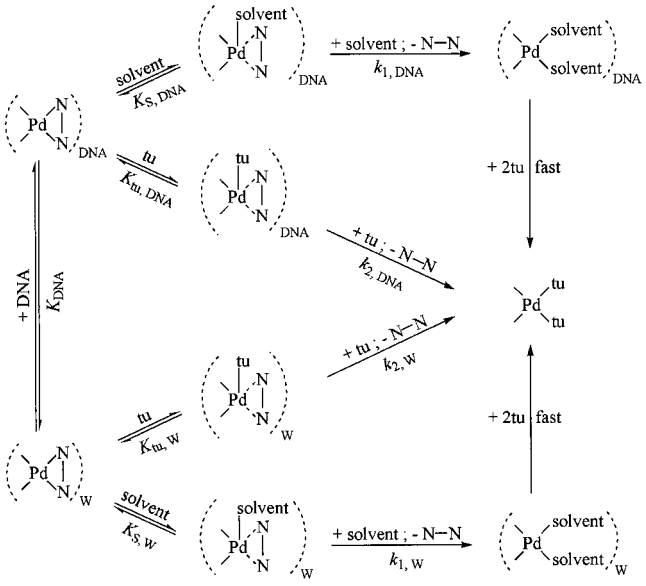
tion with the polyanions, while for poly(A) the observed hypochromism could be caused either by interaction of the adenine rings with the bipyridyl rings or by self stacking of the bipyridyl rings. Only the latter type of interaction is conceivable for PVS and PMP. In both cases, however, the interaction shields the reaction centre thus hampering attack of the nucleophile at palladium and so lowering the rate of reaction. Rate effects of other palladium(II) complexes upon the reaction with thiourea in the presence of polyvinylsulfonate have been previously reported.[6b] The observed acceleration of the rate of ethylenediamine substitution both for complexes of the type $[Pd(N-N)_2]^{2+}$ (N−N = ethylenediamine or *N*,*N*-substituted ethylenediamine) and $[Pd(bipy)(en)]^{2+}$ has been accounted for in terms of the enhanced acidity of the surfaces of the polyanions. These processes are acid catalysed and proceed faster in the proximity of a polyanion where the pH is lower than in the bulk.[15] In the case of $[Pd(bipy)(en)]^{2+}$, catalysis is observed even though the bipyridyl moieties undergo stacking and slow down the process. The accelerating effect, due to polyanion local acidity, probably prevails over the inhibition caused by stacking. The rate of bipyridyl replacement in $[Pd(bipy)(tu)_2]^{2+}$ is independent of the solution acidity and only inhibition, most likely due to self-stacking of the complexes, can occur as experimentally observed. The influence of the ionic strength on the rate of the reaction is similar to that observed for DNA and is again due to competition between the complex and the other cations present in solution for the negative charges of the polyanion.

The dependence of the k_{obs} values on the DNA concentration can be reasonably interpreted by assuming that the dicationic complex is partitioned between the DNA pseudo-phase and the bulk solution (Scheme 2). The DNA pseudo-phase includes the double helix itself, in which the complex is intercalated, and its electrostatic environment.

Taking into account that noncovalent interactions are much faster than the covalent steps involved in the scheme, the rate law according to Equation (4) may be deduced, where $K'_{S,W} = K_{S,W}\cdot[solvent]$, $K''_{S,W} = K_{S,W}\cdot[solvent]^2$, $K'_{S,DNA} = K_{S,DNA}\cdot[solvent]$, $K''_{S,DNA} = K_{S,DNA}\cdot[solvent]^2$; $k_{1,W}$ and $k_{1,DNA}$ are, respectively, the rate constants for replacement of monocoordinated bipyridyl by water in the



Scheme 2

bulk phase and in the DNA pseudophase, while $k_{2,W}$ and $k_{2,DNA}$ are the rate constants for replacement of monocoordinated bipyridyl by thiourea in the bulk phase and in the DNA pseudophase. $K_{S,W}$ and $K_{S,DNA}$ are, respectively, the equilibrium constants for formation of the monosubstituted solvo-intermediate in water and in the DNA pseudophase, while $K_{tu,W}$ and $K_{tu,DNA}$ are the equilibrium constants for formation of the monosubstituted thiourea-intermediate in water and in DNA pseudophase, respectively. K_{DNA} is the equilibrium constant for partitioning of the complex in water and in the DNA pseudophase.

$$k_{obs} = \frac{k_{1,W}K''_{S,W} + k_{2,W}K_{tu,W}[tu]^2 + [DNA]\left(k_{1,DNA}K''_{S,DNA}K_{DNA} + k_{2,DNA}K_{tu,DNA}K_{DNA}[tu]^2\right)}{1 + [DNA]\left(K_{DNA} + K_{DNA}K'_{S,DNA} + K_{DNA}K_{tu,DNA}[tu]\right) + K'_{S,W} + K_{tu,W}[tu]} \quad (4)$$

In the absence of DNA Equation (4) coincides with Equation (3). When the concentration of DNA is large enough, for a given thiourea concentration, the rate constant

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

k_{obs} assumes a constant value which is lower than that in water [Equation (5)].[16]

$$k_{obs} = \frac{k_{1,DNA}K^{''}_{S,DNA} + k_{2,DNA}K_{tu,DNA}[tu]^2}{1 + K^{'}_{S,DNA} + K_{tu,DNA}[tu]} \quad (5)$$

The good agreement between the experimental plot of k_{obs} against [DNA] and that obtained by fitting the data in accordance with Equation (4) supports the proposed scheme. In addition, the value of the binding constant of 6.5×10^4 M^{-1}, obtained from the fitting of the kinetic data[17] to the same equation at $I = 2.2 \times 10^{-2}$ M, is in fair agreement with that of $(1.0 \pm 0.1) \times 10^5$ M^{-1} determined spectrophotometrically under the same experimental conditions.

Experimental Section

Synthesis. [Pd(bipy)(py)$_2$](PF$_6$)$_2$: The compound was prepared according to a general procedure previously described[3,4] by heating an aqueous suspension of [Pd(bipy)Cl$_2$] with an excess of pyridine to reflux. After dissolution of the solid, NH_4PF_6 was added and the resultant complex precipitated as a pale yellow substance which was recrystallised from water-acetone. **[Pd(bipy)(tu)$_2$](PF$_6$)$_2$:** The compound was prepared in a similar way by treating [Pd(bipy)Cl$_2$] with thiourea in a ratio of 1:2. Both complexes were characterised by elemental analysis and ^{1}H NMR spectroscopy in [D$_6$]acetone.

DNA: Calf thymus DNA was purchased from Sigma Chemical Co. and purified as described previously.[18] DNA concentration, expressed in base pairs, was calculated spectrophotometrically using an ε_{260} value of 1.31×10^4 M^{-1}·cm^{-1}.[19] NaCl and other chemicals were of reagent grade and were used without further purification.

Poly(A): Polyadenylic acid was purchased from Pharmacia Co. and used as received. The Poly(A) concentration was calculated spectrophotometrically using an ε_{258} value of 9.8×10^3 M^{-1}·cm^{-1}.[20]

PVS and PMP: Sodium polyvinylsulfonate and sodium polymetaphosphate were also of reagent grade (Aldrich).

Methods: All experiments were carried out at 25 °C in a phosphate buffer 1×10^{-3} M ([KH$_2$PO$_4$]/[Na$_2$HPO$_4$] = 1.61) to maintain pH = 7 and sufficient NaCl to give the desired ionic strength. The pH was measured with a Radiometer PHM 62 instrument. Absorption spectra were recorded using a Lambda 5 Perkin–Elmer spectrophotometer. ^{1}H NMR spectra were recorded with a Bruker ARX-300 spectrometer. CD spectra were recorded with a J-810 Jasco polarimeter.

Kinetics: The kinetics of ligand substitution were followed spectrophotometrically in the range of 320–400 nm at 25 °C. In order to avoid competing covalent binding of the complex to the DNA nucleobases, the biopolymer was added to the complex and placed in a cuvette preheated to 25 °C together with thiourea. The concentration of the latter was at least twenty times larger than that of the DNA and the complex. A Perkin–Elmer Lambda 5 spectrophotometer was used to monitor the process. The absorbance changes were displayed on a PC interfaced with the spectrophotometer and pseudo first-order rate constants k_{obs} were obtained from nonlinear least-squares fits of the experimental data to $A_t = A_\infty + (A_0 - A_\infty)\exp(-k_{obs}t)$, where A_0, A_∞ and k_{obs} are the parameters to be optimised (A_0 = absorbance after mixing of the reagents, A_∞ = absorbance at completion of reaction). The k_{obs} values were reproducible to better than ±5%.

Binding Constant Determination: To a solution of complex (3.75×10^{-5} M) were added successive aliquots of DNA, also containing the complex, in a 10-mm stoppered quartz cell and a spectrum was recorded after each addition. The spectrophotometric data were analysed by a non least-squares fitting program using the McGhee and von Hippel equation.[12] The binding constant K_B was determined by the program using the extinction coefficient, the free complex concentration and the ratio of bound complex per mole of DNA. The extinction coefficient for the bound complex was determined by Beer's law plots in the presence of a large excess of DNA.

Supporting Information: All the kinetic data are available (see also footnote on the first page of this article).

[16] K_{DNA} is expected to be very large as experimentally found for many (bipyridine)platinum(II) and -palladium(II) complexes. Therefore, the values in parentheses both in the numerator and the denominator of Equation (4) should be much larger than the other terms.
[17] Owing to the large value of K_{DNA} the denominator of Equation (4) is approximately equal to K_{DNA}[DNA]. Thus, the value of the parameter P_3 obtained from the fitting of the kinetic data to $k_{obs} = (P_1 + P_2[DNA])/(1 + P_3[DNA])$ corresponds essentially to the value of K_{DNA}.

Stabilization and Destabilization of the Ru−CO Bond During the 2,2′-Bipyridin-6-onato (bpyO)-Localized Redox Reaction of [Ru(terpy)(bpyO)(CO)](PF_6)

Takashi Tomon,[a] Take-aki Koizumi,[a] and Koji Tanaka*[a]

Keywords: Carbonyl complex / Electrochemistry / IR spectroscopy / Ruthenium

Two stereoisomers of [Ru(terpy)(bpyO)(CO)](PF_6) ([**1**]$^+$ and [**2**]$^+$; terpy = 2,2′:6′,2′′-terpyridine, bpyO = 2,2′-bipyridin-6-onato) were prepared. The pyridonato moiety in the bpyO ligand of [**1**]$^+$ and [**2**]$^+$ is located *trans* and *cis*, respectively, to CO. Treatment of [**1**]$^+$ and [**2**]$^+$ with HPF_6 produced [**1**H]$^{2+}$ and [**2**H]$^{2+}$, both of which contain bpyOH (bpyOH = 6-hydroxy-2,2′-bipyridine). The difference in the pK_a values of [**1**H]$^{2+}$ (3.5) and [**2**H]$^{2+}$ (3.9) reflects the stronger electronic interaction between CO and the pyridonato moiety in the bpyO ligand in the *trans* position compared with that in the *cis* position. The molecular structures of [**1**](PF_6), [**2**](PF_6)·H_2O and [**2**H](PF_6)$_2$·2H_2O were determined by X-ray structure analyses. [**1**]$^+$ and [**2**]$^+$ undergo one, reversible reduction at $E_{1/2}$ = −1.65 V and −1.51 V, respectively, and one irreversible reduction at $E_{p,c}$ = −2.07 and $E_{p,c}$ = −2.13 V, respectively. Both reductions are assigned to redox reactions localized at the terpy and bpyO ligands. Irreversible reduction of [**1**]^0 results from reductive cleavage of the Ru–CO bond of [**1**]$^-$. On the other hand, a two-electron oxidation of [**2**]$^-$ almost regenerates [**2**]$^+$ because of the depression of the reductive Ru–CO bond cleavage of [**2**]$^-$ due to cyclometalation formed by an attack of oxygen of bpyO to the carbon of the Ru–CO bond. An unusually large shift of the ν(C≡O) band on going from [**2**]^0 (1950 cm^{-1}) to [**2**]$^-$ (1587 cm^{-1}) also supports a reversible cyclometalation driven by the bpyO-localized redox reaction.

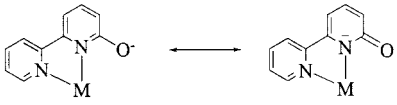
Introduction

Polypyridylruthenium complexes exhibit a unique electrochemical behavior[1] because of the low energy level of the π*-orbitals of the ligands. For example, redox reactions of polypyridyl ligands can be utilized as electron pools in photo-[2] and electrochemical[3] reduction of CO_2 catalyzed by polypyridylruthenium complexes. Modification of polypyridyl ligands may create new functionalities in addition to the role of the redox centers of ruthenium complexes. For example, a keto-enol tautomerism between 6-hydroxy-2,2′-bipyridine (bpyOH) and 2,2′-bipyridin-6(1*H*)-one (bpyO) [Equation (1)] would induce the acid-base equilibrium of bpyOH ligated to Ru [Equation (2)], followed by resonance between (2,2′-bipyridin-6-onato)- and (2,2′-bipyridin-6-olato)ruthenium complexes [Equation (3)].

(1)

(2)



(3)

A few metal complexes with bpyO have been reported to date,[4] but neither the equilibrium of Equation (2) nor the resonance of Equation (3) has been discussed. The acid-base equilibrium of Ru(bpyOH) complexes [Equation (2)] and the subsequent resonance of Ru(bpyO) ones [Equation (3)] may allow these complexes to undergo proton-coupled electron transfer. The ligand-localized redox reaction of metal−bpyO(H) complexes would influence the equilibrium of Equation (2) and the resonance of Equation (3). In connection with this, a drastic change of basicity of the free nitrogen of the 1,8-naphthyridine ligand of [Ru(bpy)$_2$(napy-κ*N*)(CO)]$^{2+}$ (napy = 1,8-naphthyridine) has been reported. One-electron reduction of napy resulted in an attack of the free nitrogen at the carbon atom of the Ru−CO bond to form a metallacyclic ring, which smoothly opened upon oxidation of the napy ligand.[5] Such reversible cyclometalation driven by ligand-localized redox reactions falls

into a new category in a number of metallacyclic complexes bearing five-[6] and six- membered[7] rings and containing CO as a cycle component.

In this work, we have prepared two geometrical isomers of $[Ru(terpy)(bpyO)(CO)]^+$ with regard to the orientation of bpyO ($[\mathbf{1}]^+$ and $[\mathbf{2}]^+$) and determined the pK_a values of their protonated complexes ($[\mathbf{1H}]^{2+}$ and $[\mathbf{2H}]^{2+}$). Two-electron reduction of $[\mathbf{1}]^+$, which has the pyridonato moiety of the bpyO ligand *trans* to CO, caused reductive cleavage of the Ru−CO bond, while two-electron reduction of $[\mathbf{2}]^+$, which has the pyridonato moiety of the bpyO ligand *cis* to CO, formed a metallacyclic ring due to an attack of the oxygen of bpyO at the carbon of the Ru−CO bond.

Results and Discussion

Syntheses and Structures of $[\mathbf{1}]^+$, $[\mathbf{1H}]^{2+}$, $[\mathbf{2}]^+$, and $[\mathbf{2H}]^{2+}$

There are two possible orientations of the pyridonato ring of bpyO in $[Ru(terpy)(bpyO)(CO)]^+$ (vide infra): one is in a position *trans* to CO ($[\mathbf{1}]^+$) and the other is in a position *cis* to CO ($[\mathbf{2}]^+$). The preparative pathways of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ are depicted in Scheme 1. Treatment of $[RuCl(terpy)(bpyOH)]^+$ with $AgPF_6$ under CO (15 atm) in 2-methoxyethanol produced $[Ru(terpy)(bpyO)(CO)]^+$ ($[\mathbf{1}]^+$).

The ^{1}H NMR spectra of the PF_6 salt of $[\mathbf{1}]^+$ clearly show the selective formation of one of the two isomers under these reaction conditions. X-ray analysis of $[\mathbf{1}](PF_6)$ demonstrated coordination of CO to Ru in the position *trans* to the pyridonato ring of bpyO (vide infra). On the other hand, the substitution reaction of an aqua ligand of $[Ru(terpy)(bpyO)(OH_2)]^+$ by CO (20 atm) in 2-methoxyethanol selectively produced the other isomer of $[Ru(terpy)(bpyO)(CO)]^+$ with CO in the position *cis* to the pyridonato ring of bpyO ($[\mathbf{2}]^+$). The ^{1}H NMR spectra of the crude product of $[\mathbf{2}](PF_6)$ did not show any contamination by $[\mathbf{1}](PF_6)$. It is worthwhile to note that the orientation of bpyOH in $[Ru(terpy)(bpyOH)Cl]^+$ is inverted in $[\mathbf{1}]^+$, whereas that in $[Ru(terpy)(bpyO)(OH_2)]$ is maintained in $[\mathbf{2}]^+$. Such a difference may result from an involvement of an attack of CO to pentacoordinate $[Ru(terpy)(bpyOH)]^+$ that would be produced in the reaction of $[Ru(terpy)(bpyOH)Cl]^+$ with Ag^+.

Treatment of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ with one equivalent of HPF_6 produced $[\mathbf{1H}]^{2+}$ and $[\mathbf{2H}]^{2+}$, respectively, in CH_3CN. The addition of one equivalent of Et_3N to $[\mathbf{1H}]^{2+}$ and $[\mathbf{2H}]^{2+}$ completely regenerated $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$, respectively, in CH_3CN [Equation (4)].

$$\underset{[\mathbf{1}]^+ \text{ and } [\mathbf{2}]^+}{[Ru(trpy)(bpy\text{-}O)(CO)]^+} + H^+ \rightleftharpoons \underset{[\mathbf{1H}]^{2+} \text{ and } [\mathbf{2H}]^{2+}}{[Ru(trpy)(bpy\text{-}OH)(CO)]^{2+}} \quad (4)$$

The ^{1}H NMR spectra of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ clearly confirm the protonation of the oxygen atom of the bpyO ligand, since treatment of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ with HPF_6 in CD_3CN shifts the pyridonate ring protons to lower magnetic field by 0.65−1.3 ppm, while the terpy and pyridine protons of bpyO shift by only 0.1−0.25 ppm upon protonation of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$. The pK_a values of hydroxypyridine in $[\mathbf{1H}](PF_6)_2$ and $[\mathbf{2H}](PF_6)_2$ were determined to be 3.5 and 3.9, respectively, by pH titrations in H_2O at 25 °C. The difference in the pK_a values of $[\mathbf{1H}]^{2+}$ and $[\mathbf{2H}]^{2+}$ can reasonably be ascribed to the stronger electronic interaction between CO and the pyridonato moiety in the bpyO ligand in the *trans* position compared with that in the *cis* position.

The crystal structures of the cations of complexes $[Ru(terpy)(bpyO)(OH_2)](PF_6)$ and $[Ru(terpy)(bpyOH)Cl](PF_6)$[8] are depicted in Figure 1 and the Supporting Information, respectively. The bond lengths and angles of $[Ru(terpy)(bpyO)(OH_2)]^+$ are listed in Table 1. The pyridonato ring of $[Ru(terpy)(bpyO)(OH_2)]^+$ and the hydroxypyridine ring of $[Ru(terpy)(bpyOH)Cl]^+$ are situated *cis* to the H_2O and Cl ligands, respectively. The C1−O1 and C−C bonds lengths of the pyridonato ring of bpyO in $[Ru(terpy)(bpyO)(OH_2)]^+$ are 1.288(5) Å and 1.368(7)−1.417(7) Å, and are similar to those in the 2-pyridonato ligands of $[Ru(terpy)(NC_5H_4O\text{-}\kappa N)_2(OH_2)]$[9] and *mer*-$[Pt(NH_3)_2(NC_5H_4O\text{-}\kappa N)Cl_3]$[10] ($NC_5H_4O\text{-}\kappa N$ = 2-pyridonato). The Ru1−O2 bond length is 2.152(3) Å, which is quite close to that in $[Ru(terpy)(NC_5H_4O\text{-}\kappa N)_2(OH_2)]$ (2.160 Å).[9] The interatomic O1···O2 distance [2.533(5) Å] be-

tween the pyridonato and the aqua ligands suggests hydrogen-bond formation between them.

The molecular structures of the ruthenium carbonyl complexes bearing bpyO ($[\mathbf{1}]^+$ and $[\mathbf{2}]^+$) and bpyOH ($[\mathbf{2H}]^{2+}$) were determined by X-ray crystal structure analysis. The crystal structures of the cations of these complexes are shown in Figure 2; selected bond lengths and angles are listed in Table 2. The pyridonato group of the bpyO ligand in $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ is situated *trans* and *cis,* respectively, to the CO ligand (Figure 2a and 2b). The orientation of bpyOH in $[\mathbf{2H}]^{2+}$ is the same as that in $[\mathbf{2}]^+$ (Figure 2c). The Ru1−N bond lengths of terpy in the carbonyl complexes are 1.989(3)−2.100(3) for $[\mathbf{1}]^+$, 2.006(9)−2.09(1) for $[\mathbf{2}]^+$, and 1.983(4)−2.098(4) for $[\mathbf{2H}]^{2+}$. These bond lengths are close to those of similar ruthenium carbonyl complexes such as $[Ru(terpy)(bpy)(CO)]^{2+}$ (1.989−2.086 Å)[3e] and $[Ru(terpy)(bpy)(py)]^{2+}$ (1.963−2.078 Å; py = pyridine).[11] The C1−O1 bond lengths of bpyO in $[\mathbf{1}]^+$ [1.250(4) Å] and $[\mathbf{2}]^+$ [1.26(1) Å] are in the range of a normal C=O double bond. It is worthwhile to note that the C1−O1 bond length in $[\mathbf{2H}]^{2+}$ [1.326(7) Å] is much longer than those in $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$, and is close to that of a C−O single bond. Furthermore, elongation of the Ru1−N1 bond length [2.112(4) Å], as well as the C1−O1 bond length of $[\mathbf{2H}]^{2+}$, compared with that of $[\mathbf{2}]^+$ [2.087(9) Å] demonstrates the decrease of the covalency of the Ru−N1 bond due to the protonation of the oxygen atom of bpyO in $[\mathbf{2}]^+$ [Equation (2)]. There seems to be a substantial strain in the coordination of bpyO to Ru in $[\mathbf{1}]^+$ because the C1−N1−Ru1−N4 dihedral angle [15.6(3)°] in $[\mathbf{1}]^+$ is much larger than the corresponding angle (C1−N1−Ru1−C26) in $[\mathbf{2}]^+$ [7(1)°]. This may be caused by repulsion between the lone-pair electrons of the bpyO oxygen atom and the π-electrons of the central pyridine ring of terpy. The shift of the oxygen atom of bpyO near the pyridyl ring of terpy in $[\mathbf{1}]^+$ to the position *cis* to the CO ligand of $[\mathbf{2}]^+$ will release the strain in the coordination of bpyO to Ru. A relatively short interatomic distance between

the oxygen atom of bpyO and the carbon atom of CO in [2]$^+$ of 2.55 Å implies a donor−acceptor interaction between them. An increase of the distance between the oxygen atom of bpyOH and the carbon atom of CO (O1···C26 = 2.62 Å) in [2H]$^{2+}$ is therefore explained by the decrease in the basicity of the oxygen atom of bpyO upon protonation.

Cyclic Voltammetry of [1](PF$_6$), [2](PF$_6$), [1H](PF$_6$)$_2$ and [2H](PF$_6$)$_2$

The cyclic voltammograms (CVs) of [1](PF$_6$) and [2](PF$_6$) were measured in CH$_3$CN (Figure 3). The CV of [1]$^+$ shows a nearly reversible redox couple at $E_{1/2}$ = −1.65 V ($E_{p,c}$ = −1.70, $E_{p,a}$ = −1.61 V) and a subsequent irreversible cathodic wave at $E_{p,c}$ = −2.07 V (Figure 3a), both of which are assigned to terpy- and bpyO-ligand-based redox reactions[12] by analogy with the redox behavior of

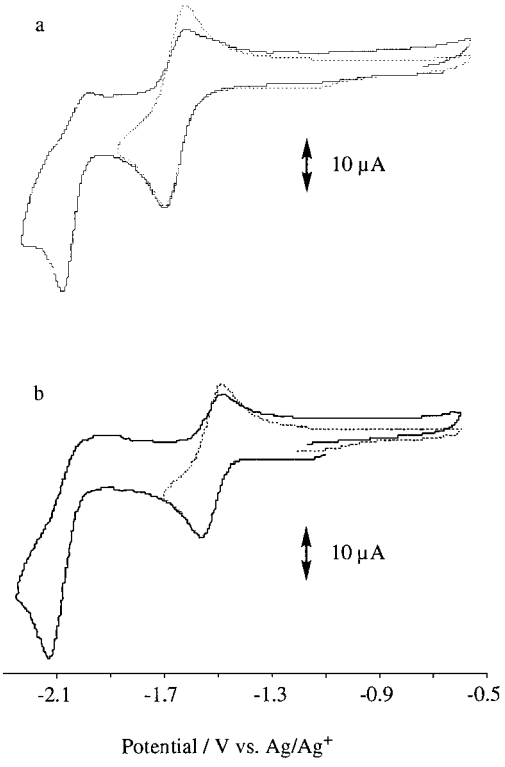

Figure 3. Cyclic voltammograms of [1](PF$_6$) (a) and [2](PF$_6$) (b) in CH$_3$CN under N$_2$; dE/dt = 100 mV·s^{-1}

[Ru(terpy)$_2$]$^{2+}$.[13] The irreversible reduction of [1]^0 probably results from a partial Ru−CO bond cleavage of [1]$^-$ (vide infra), because two-electron reduction of [Ru(terpy)(bpy)(CO)]$^{2+}$ leads to reductive Ru−CO bond cleavage (CO evolution), which is a key process in the electrochemical reduction of CO$_2$ catalyzed by this complex.[3e] The CV of [2]$^+$ also shows an almost reversible [2]$^+$/[2]^0 redox couple at $E_{1/2}$ = −1.51 V ($E_{p,c}$ = −1.55 and $E_{p,a}$ = −1.47 V) and an irreversible cathodic wave at $E_{p,c}$ = −2.13 V (Figure 3b). In contrast to the reductive cleavage of the Ru−CO bond of [1]$^-$, the irreversible reduction of [2]^0 is due to a cyclometalation caused by an intramolecular attack of the pyridonato oxygen at the carbonyl carbon atom (vide infra). The oxidation processes of [1]$^+$ and [2]$^+$ were also examined, but both complexes were not oxidized up to +1.0 V.

The CV of [1H]$^{2+}$ in CH$_3$CN displays four cathodic waves at $E_{p,c}$ = −1.40, −1.69, −1.85, and −2.05 V in the first potential sweep (Figure 4a).[14] The cathodic wave at $E_{p,c}$ = −1.40 V completely disappeared in the second potential sweep, while the other three cathodic waves at $E_{p,c}$ = −1.69, −1.85, and −2.05 V remained at almost the same potentials in multiscanning potential sweeps. The addition of one equivalent of Et$_3$N to the solution also caused the disappearance of the cathodic wave at $E_{p,c}$ = −1.40 V in the first potential sweep. However, the second cathodic wave became broad. Based on the fact that Et$_3$NH$^+$ undergoes an irreversible reduction at −1.75 V in CH$_3$CN on a glassy carbon electrode, the broad cathodic wave at $E_{p,c}$ = −1.69 V apparently results from overlapping of the terpy-

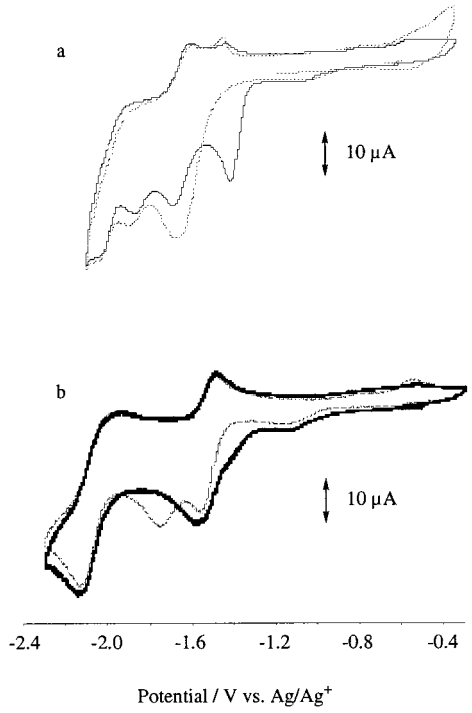

Figure 4. Cyclic voltammograms of $[\mathbf{1}H](PF_6)_2$ (a) and $[\mathbf{2}H](PF_6)_2$ (b) in the absence (−) and the presence (---) of 1.0 equiv. of Et_3N under N_2; $dE/dt = 100\ mV{\cdot}s^{-1}$

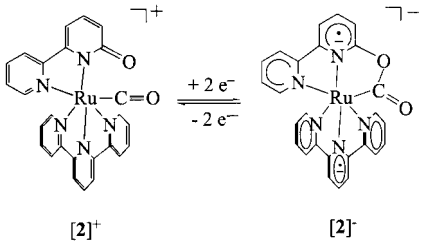
based reduction and an irreversible reduction of Et_3NH^+ produced in the reaction of $[\mathbf{1}H]^+$ with Et_3N. The CV of $[\mathbf{2}H]^{2+}$ displays a broad cathodic wave at $E_{p,c} = -1.58$ V and a subsequent irreversible cathodic wave at $E_{p,c} = -2.14$ V (Figure 4b).[15] Addition of one equivalent of Et_3N to the solution sharpened the cathodic wave at $E_{p,c} = -1.58$ V and resulted in an irreversible cathodic wave at −1.75 V due to the reduction of Et_3NH^+. These results indicate that the proton of the bpyOH ligand of $[\mathbf{1}H]^{2+}$ and $[\mathbf{2}H]^{2+}$ undergoes irreversible reduction at $E_{p,c} = -1.40$ and −1.58 V, respectively, to form $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ [Equation (5)].

$$\underset{[\mathbf{1}H]^{2+}\text{ and }[\mathbf{2}H]^{2+}}{[Ru(trpy)(bpy\text{-}OH)(CO)]^{2+}} + e^- \longrightarrow \underset{[\mathbf{1}]^+\text{ and }[\mathbf{2}]^+}{[Ru(trpy)(bpy\text{-}O)(CO)]^+} \quad (5)$$

IR Spectroscopy of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ under the Electrolysis Conditions

The IR spectra of $[\mathbf{1}](PF_6)$ show the ν(C≡O) band and the ν(C=O) band of bpyO at 1979 and 1620 cm^{-1}, respectively, in CD_3CN. The appearance of those bands at 1996 and 1612 cm^{-1} in the IR spectrum of $[\mathbf{2}](PF_6)$ is ascribed to the stronger electron-donor ability of bpyO located *trans* to CO compared to when it is *cis* to CO (the redox potentials of the reversible $[\mathbf{1}]^{+/0}$ and $[\mathbf{2}]^{+/0}$ couples were observed at −1.65 and −1.51 V, respectively, in CH_3CN). In other words, the resonance between metal pyridinolate and pyridonate forms of $[\mathbf{1}]^+$ [Equation (3)] is shifted more towards the pyridonato than in $[\mathbf{2}]^+$. It is worthwhile to note that the redox behaviors of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ are similar (one reversible and one irreversible reduction). However, there is a distinct difference between the IR spectra during the reduction and oxidation cycles of the two complexes. The ν(C≡O) band of $[\mathbf{1}]^+$ at 1979 cm^{-1} disappears completely during the controlled potential electrolysis of the complex at −1.70 V in CH_3CN, and a new ν(C≡O) band appears at 1932 cm^{-1} (Figure 5a). The 1932 cm^{-1} band is further shifted to 1853 cm^{-1}, with a lower peak intensity, when the electrolysis potential is changed from −1.70 V to −2.0 V (Figure 5b). The decrease of the peak intensity of the 1853 cm^{-1} band compared with those of the 1979 and 1932 cm^{-1} bands probably results from a gradual Ru−CO bond cleavage of $[\mathbf{1}]^-$; reoxidation of the solution at 0 V did not recover the peak intensity of the ν(C≡O) band of $[\mathbf{1}]^+$ at 1979 cm^{-1}. Besides the change of the ν(C≡O) band, two bands at 1605 and 1620 cm^{-1}, assigned to the stretching modes of the pyridine rings and the C=O group of the bpyO ligand of $[\mathbf{1}]^+$, respectively, moved to 1602 and 1618 cm^{-1}, and then to 1595 and 1581 cm^{-1} in the electrochemical reduction at −1.70 and −2.0 V. The red-shift of the band of the pyridonato ring of bpyO from 1620 to 1581 cm^{-1} upon two-electron reduction could be associated with a shift of the resonance of Equation (3) towards the pyridonato form.

The ν(C≡O) band at 1996 cm^{-1} of $[\mathbf{2}]^+$ shifts to 1950 cm^{-1} upon one-electron reduction of the complex at −1.70 V (Figure 5c). The 1950 cm^{-1} band of $[\mathbf{2}]^0$ vanishes completely under electrolysis at −2.05 V. Although no new bands assignable to ν(C≡O) were detected in the region 1800−1900 cm^{-1}, a new band emerged at 1587 cm^{-1} (Figure 5d). Re-oxidation of the resultant solution at 0 V almost recovered the IR spectrum of $[\mathbf{2}]^+$ [ν(C≡O) band at 1996 cm^{-1}].[16] Thus, the conversion between $[\mathbf{2}]^+$ and $[\mathbf{2}]^-$ in CH_3CN is a chemically reversible process, although $[\mathbf{2}]^0$ undergoes an irreversible reduction at −2.05 V. The 1587 cm^{-1} band of $[\mathbf{2}]^-$ is therefore assigned to the stretching mode of the O−C=O moiety of the five-membered metallacycle formed by the attack of the pyridonato oxygen at the carbonyl atom of the CO ligand [Equation (6)].



$[\mathbf{2}]^+$ $[\mathbf{2}]^-$ (6)

This reversible ring-closing and -opening [Equation (6)] is also supported by the IR spectra of $[\mathbf{2}^*]^+$, which contains a $C^{18}O$ ligand. The ν(C≡^{18}O) band at 1946 cm^{-1} of $[\mathbf{2}^*]^+$ shifts to 1907 cm^{-1} and then to 1562 cm^{-1} upon electrolysis at −1.70 and −2.00 V, respectively (Figure 6). Thus, the 1562 cm^{-1} band of $[\mathbf{2}^*]^-$ can reasonably be associated with the isotropic shift of the 1587 cm^{-1} band of $[\mathbf{2}]^-$. Both $[\mathbf{2}]^-$

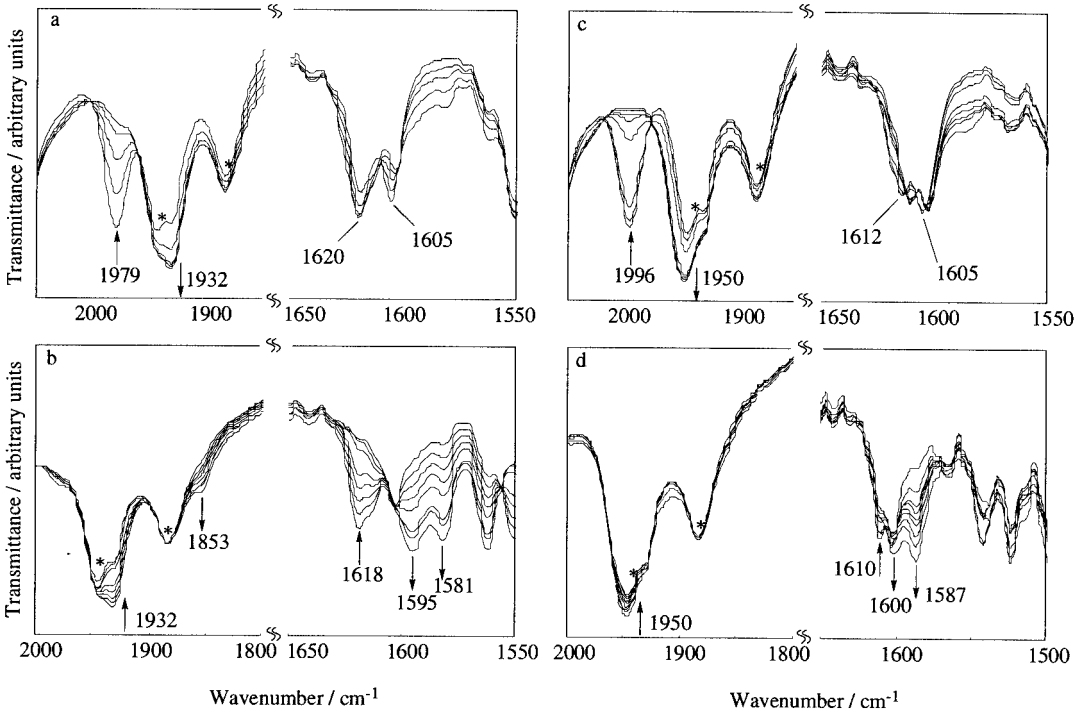

Figure 5. IR spectra of [**1**](PF_6) (a and b) and [**2**](PF_6) (c and d) under controlled-potential electrolyses at −1.70 V (a and c) and −2.00 V (b and d) in CD_3CN under N_2; * denotes CD_3CN peaks

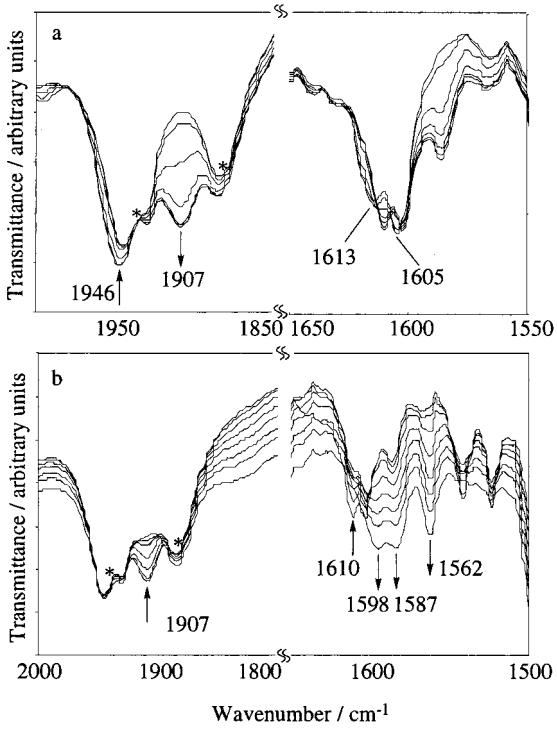

Figure 6. IR spectra of [**2***](PF_6) under controlled potential electrolysis at −1.70 V (a) and −2.00 V (b) in CD_3CN under N_2; * denotes CD_3CN peaks

and [**2***]$^-$ exhibit a band at 1587 cm^{-1}. This observation indicates the overlapping of the ring vibration mode of the bpyO moiety of [**2**]$^-$ with the stretching mode of the O−C=^{16}O group.

As described above, the hydroxyl proton of the bpyOH ligand of [**1**H]$^{2+}$ and [**2**H]$^{2+}$ undergoes irreversible reduction at around −1.50 V to form [**1**]$^+$ and [**2**]$^+$ in CH_3CN [Equation (5)]. In fact, the electrolysis of [**1**H]$^{2+}$ and [**2**H]$^{2+}$ in CH_3CN at −1.40 V causes the disappearance of the ν(C≡O) bands at 1992 and 2005 cm^{-1} of these complexes, and the appearance of the ν(C≡O) bands at 1979 and 1996 cm^{-1} of [**1**]$^+$ and [**2**]$^+$, respectively. Although the redox potentials of [**1**]$^+$ and [**2**]$^+$ are too negative to evaluate whether the pK_a values of the bpyOH ligand depend on the oxidation states of the complexes, the distinct difference in the Ru−CO bond stability between [**1**]$^-$ and [**2**]$^-$ is explained by the cyclometallation due to the intramolecular attack of the oxygen of bpyO at CO in the latter.

Conclusion

We succeeded in selectively synthesizing two isomers ([**1**]$^+$ and [**2**]$^+$) with a different orientation of bpyO at the ruthenium center. The hydrogen bond between the pyridonate oxygen and H_2O in [Ru(terpy)(bpyO)(OH_2)]$^+$ may play an important role in the preparation of [**2**]$^+$. [**1**]$^+$ and [**2**]$^+$ can be reversibly converted into [**1**H]$^{2+}$ and [**2**H]$^{2+}$ by the protonation of the oxygen atom of bpyO. Based on their pK_a's, CVs and IR spectra, the electron density at the ruthenium center of [**1**]$^+$ is higher than that of [**2**]$^+$. Such a difference is associated with the stronger *trans* influence of CO compared with the central pyridine of terpy, because the electron-withdrawing ability of CO induces the pyridonato

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure of the resonance between metal-pyridinolate and -pyridonate forms [Equation (3)]. The CVs of $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ show one reversible and one irreversible redox wave due to terpy- and bpyO-based redox reactions. The two-electron reduction of $[\mathbf{1}]^+$ is followed by a partial Ru−CO bond cleavage. On the other hand, the bpyO-based reduction of $[\mathbf{2}]^+$ causes cyclometalation by an attack of the pyridonato oxygen at the carbonyl carbon; re-oxidation of the resultant $[\mathbf{2}]^-$ almost recovers $[\mathbf{2}]^+$. Thus, cyclometallation caused by a bpyO-based reduction effectively supresses the reductive cleavage of a Ru−CO bond.

Experimental Section

Reagents: 2-Bromo-6-methoxypyridine, 2,2′:6′,2″-terpyridine and $AgPF_6$ were purchased from Aldrich Chemical Co., Inc. 2-(Tri-*n*-butylstannyl)pyridine was purchased from Lancaster Synthesis, pyridine hydrochloride from Kanto Chemical Co., Inc., NH_4PF_6 from Wako Pure Chemical Industries, Ltd., and Me_4NBF_4 from Nacalai Tesque. CD_3CN was purchased from Merck (for IR measurements) and Isotec (for NMR measurements). All solvents used for preparations were reagent grade and used without further purification. $[Ru(terpy)Cl_3]$ was prepared according to the literature method.[17]

Physical Methods: ^1H and ^1H-^1H-COSY NMR experiments were performed with a JEOL LA-500 spectrometer. IR spectra were recorded with a Shimadzu FTIR-8300 spectrophotometer. ESI-MS spectra were measured with a Shimadzu LCMS-2010 liquid chromatograph mass spectrometer. pH titrations were performed with a Hiranuma automatic titrator COM-980 Win. Aqueous solutions (3 mL) of $[\mathbf{1}H](PF_6)_2$ (1.0−1.5 mM) or $[\mathbf{2}H](PF_6)_2$ (1.0−1.5 mM) were titrated with an aqueous NaOH solution (0.1 N, f = 1.04) at 25 °C. Cyclic voltammograms were obtained in a one-compartment cell consisting of a glassy carbon working electrode, a platinum counterelectrode and an $Ag/AgNO_3$ (10 mM) reference electrode in CH_3CN containing Me_4NBF_4 (50 mM) and the complex (1 mM). The cyclic voltammetric data were collected with an ALS/Chi model 1660A electrochemical analyzer. IR spectra under controlled-potential electrolysis conditions were obtained using a thin-layer cell sandwiched between two KBr crystals with an Au mesh working electrode, a platinum wire counterelectrode, and an $Ag/AgNO_3$ (10 mM) reference electrode.[3d] The measurements were conducted in CD_3CN or CH_3CN containing the sample complex (10 mM) and Me_4NBF_4 (50 mM) as an electrolyte.

Preparation of 6-Methoxy-2,2′-bipyridine: A toluene solution (35 mL) containing 2-bromo-6-methoxypyridine (1.0 g, 5.32 mmol), 2-(tri-*n*-butylstannyl)pyridine (3.0 g), LiCl (2.2 g, 53 mmol), and $[PdCl_2(PPh_3)_2]$ (290 mg, 0.42 mmol) was deaerated by bubbling N_2 throug it. The mixture was then refluxed under N_2 for 18 h, and an aqueous solution (10 mL) of NaF (2.2 g, 53 mmol) was added to the solution at room temperature. The resultant solution was further stirred at ambient temperature for 30 min. An insoluble solid was filtered off, and the filtrate was treated with a 5% Na_2CO_3 aqueous solution in a separating funnel. The organic layer was dried with anhydrous sodium sulfate, and the solvents were evaporated to dryness under reduced pressure. The obtained oil was dissolved in $CHCl_3$/EtOAc (95:5, v/v), and purified on a silica gel column. Yield: 830 mg (83.7%). The identification of the compound was performed according to the literature (^1H NMR).[18]

Preparation of 6-Hydroxy-2,2′-bipyridine (bpyOH): A mixture of 6-methoxy-2,2′-bipyridine (700 mg, 3.76 mmol) and pyridine hydrochloride (10 g) was heated under N_2 at 210 °C for 90 min. After the reaction mixture had cooled to ambient temperature, the white solid that appeared was dissolved in H_2O (50 mL). The crude product was extracted from the aqueous solution with dichloromethane. The dichloromethane layer was further treated with a saturated aqueous $NaHCO_3$ solution. The organic layer was dried with anhydrous sodium sulfate, and the solvents were evaporated to dryness under reduced pressure. Recrystallization from CH_2Cl_2/hexane (1:1, v/v) gave a pale-yellow solid. Yield 520 mg (80.4%). The identification of the compound was performed according to the literature (^1H NMR).[19]

Preparation of $[Ru(terpy)(bpyOH)Cl]Cl\cdot H_2O$: BpyOH (40 mg, 0.23 mmol) and Et_3N (120 mg, 1.18 mmol) were added to a suspension of $[Ru(terpy)Cl_3]$ (100 mg, 0.22 mmol) in 2-methoxyethanol. The mixture was stirred under N_2 at 85 °C for 3 h, during which time the suspension gradually changed to a deep purple solution. After an insoluble solid was filtered off, the filtrate was concentrated to about 5 mL under reduced pressure. The resultant precipitate was separated by filtration and recrystallized from methanol. Yield 65 mg (49.6%). $C_{25}H_{21}Cl_2N_5O_2Ru$: calcd. C 50.42, H 3.55, N 11.76; found C 49.98, H 3.47, N 11.60. ESI-MS: m/z = 542 $[Ru(terpy)(bpyOH)Cl]^+$.

Preparation of $[Ru(terpy)(bpyO)(CO)](PF_6)$ {$[\mathbf{1}](PF_6)$}: A mixture of $[Ru(terpy)(bpyOH)Cl]Cl\cdot H_2O$ (90 mg, 0.15 mmol) and $AgPF_6$ (81 mg, 0.32 mmol) in 2-methoxyethanol was stirred under CO pressure (15 atm) at 85 °C for 24 h. After the solution had cooled to room temperature, the solution was filtered through a Celite layer to remove the AgCl precipitate and then concentrated to about 5 mL. Addition of an excess amount of an aqueous NH_4PF_6 solution gave a yellow precipitate, which was separated by filtration. The resultant product was recrystallized from acetone/ethanol (2:1, v/v) containing Et_3N (30 μL). Yield 100 mg (53.6%). ^1H NMR (500 MHz, CD_3CN): δ = 5.65 (d, 1 H, H^{A3}), 6.98 (d, 1 H, H^{A5}), 7.08 (dd, 1 H, H^{A4}), 7.39 (ddd, 2 H, H^{C4}), 7.61 (ddd, 1 H, H^{B5}), 7.69 (d, 2 H, H^{C3}), 8.05 (td, 2 H, H^{C5}), 8.09 (td, 1 H, H^{B4}), 8.21 (t, 1 H, H^{D4}), 8.26 (d, 1 H, H^{B3}), 8.31 (m, 4 H, H^{C6} and H^{D3}), 9.35 (d, 1 H, H^{B6}) ppm. $C_{26}H_{18}F_6N_5O_2PRu$: calcd. C 46.03, H 2.67, N 10.32; found C 45.86, H 2.79, N 10.33. ESI-MS: m/z = 534 $[Ru(terpy)(bpyO)(CO)]^+$.

Preparation of $[Ru(terpy)(bpyOH)(CO)](PF_6)_2$ {$[\mathbf{1}H](PF_6)_2$}: Yellow crystals of $[\mathbf{1}H](PF_6)_2$ were obtained by crystallization of $[\mathbf{1}](PF_6)$ from CH_3CN/H_2O (1:1, v/v) containing 1.5 equiv. of an aqueous HPF_6 solution (1 M). ^1H NMR (500 MHz, CD_3CN): δ = 6.97 (d, 1 H, H^{A3}), 7.41 (ddd, 2 H, H^{C4}), 7.68 (d, 2 H, H^{C3}), 7.76 (dd, 1 H, H^{A4}), 7.79 (ddd, 1 H, H^{B5}), 7.90 (d, 1 H, H^{A5}), 8.11 (td, 2 H, H^{C5}), 8.26 (td, 1 H, H^{B4}), 8.38 (t, 1 H, H^{D4}), 8.43 (d, 2 H, H^{C6}), 8.47 (d, 2 H, H^{D3}), 8.51 (d, 1 H, H^{B3}), 9.45 (d, 1 H, H^{B6}) ppm. ESI-MS: m/z = 267.5 $[Ru(terpy)(bpyOH)(CO)]^{2+}$.

Preparation of $[Ru(terpy)(bpyO)(OH_2)](PF_6)$: Na_2CO_3 (91 mg, 0.86 mmol) and Et_3N (0.4 mL) were added to a suspension of $[Ru(terpy)Cl_3]$ (250 mg, 0.57 mmol) in $MeOH/H_2O$ (1:2 v/v, 80 mL), and then the suspension was refluxed under N_2 for 150 min. The resultant solution was cooled to room temperature, filtered, and the filtrate was concentrated to dryness under reduced pressure. The resulting solid was dissolved in ethanol and any insoluble salt was removed by filtration. Then, the solution was concentrated to dryness, and the solid was purified by column chromatography on a Cosmosil column, with MeOH as eluent. An aqueous solution

(5 mL) of [Ru(terpy)(CO_3)(OH_2)] (60 mg) and bpyOH (30 mg, 0.17 mmol) was stirred at ambient temperature for 2−3 d, and the solution was then filtered. Addition of an excess amount of NH_4PF_6 to the filtrate gave [Ru(terpy)(bpyO)(OH_2)](PF_6) as a red-purple powder which was isolated by filtration, and recrystallized from acetone/H_2O (4:1, v/v). Yield 45 mg (11.8%). ^{1}H NMR (500 MHz, [D_6]acetone): δ = 6.71 (d, 1 H, H^{A3}), 6.89 (ddd, 1 H, H^{B4}), 7.30 (d, 1 H, H^{B3}), 7.56 (ddd, 2 H, H^{C4}), 7.62 (td, 1 H, H^{B5}), 7.67 (d, 1 H, H^{A5}), 7.79 (t, 1 H, H^{A4}), 8.05 (td, 2 H, H^{C5}), 8.11 (d, 2 H, H^{C3}), 8.20−8.25 (m, 2 H, H^{B6} and H^{D4}), 8.64 (d, 2 H, H^{C6}), 8.76 (d, 2 H, H^{D3}) ppm. $C_{25}H_{20}F_6N_5O_2PRu$: calcd. C 44.92, H 3.01, N 10.48; found C 45.16, H 3.20, N 10.44. ESI-MS: *m*/*z* = 524 [Ru(terpy)(bpyO)(OH_2)]$^+$.

Preparation of [Ru(terpy)(bpyO)(CO)](PF_6)·H_2O {[2](PF_6)·H_2O}: A 2-methoxyethanol solution of [Ru(terpy)(bpyO)(OH_2)](PF_6) (45 mg, 0.07 mmol) was stirred under CO pressure (20 atm) at 90 °C for 12 h. The reaction mixture was then concentrated to about 5 mL under reduced pressure. Addition of an excess amount of an aqueous NH_4PF_6 solution to the solution gave an orange precipitate, which was separated by filtration. Orange crystals were obtained by vapor diffusion of diethyl ether into an EtOH solution containing Et_3N (15 μL). Yield 22 mg (44.9%). ^{1}H NMR (500 MHz, CD_3CN): δ = 6.60 (d, 1 H, H^{A3}), 7.00 (d, 1 H, H^{B3}), 7.05 (ddd, 1 H, H^{B4}), 7.24 (d, 1 H, H^{A5}), 7.45 (ddd, 2 H, H^{C4}), 7.54 (dd, 1 H, H^{A4}), 7.81 (td, 1 H, H^{B5}), 7.90 (d, 2 H, H^{C3}), 8.07 (td, 2 H, H^{C5}), 8.12 (d, 1 H, H^{B6}), 8.39 (d, 2 H, H^{C6}), 8.42 (t, 1 H, H^{D4}), 8.54 (d, 2 H, H^{D3}) ppm. $C_{26}H_{20}F_6N_5O_3PRu$: calcd. C 44.83, H 2.89, N 10.05; found C 44.71, H 2.93, N 10.09. ESI-MS: *m*/*z* = 534 [Ru(terpy)(bpyO)(CO)]$^+$.

Preparation of [Ru(terpy)(bpyOH)(CO)](PF_6)$_2$·$2H_2O$ {[2H](PF_6)$_2$·$2H_2O$}: Orange crystals of [2H](PF_6)$_2$·$2H_2O$ were obtained by crystallization of [2](PF_6) from CH_3CN/H_2O (1:1, v/v) containing 1.5 equiv. of an aqueous HPF_6 solution (1 M). ^{1}H NMR (500 MHz, CD_3CN): δ = 7.14 (d, 1 H, H^{B3}), 7.27 (ddd, 1 H, H^{B4}), 7.42−7.45 (m, 3 H, H^{A3} and H^{C4}), 7.80 (d, 2 H, H^{C3}), 8.01 (td, 1 H, H^{B5}), 8.10−8.20 (m, 4 H, H^{A4}, H^{A5} and H^{C5}), 8.38 (d, 1 H, H^{B6}), 8.43 (d, 2 H, H^{C6}), 8.51 (t, 1 H, H^{D4}), 8.58 (d, 2 H, H^{D3}) ppm. $C_{26}H_{23}F_{12}N_5O_4P_2Ru$: calcd. C 36.29, H 2.69, N 8.14; found C 36.26, H 2.80, N 8.13. ESI-MS: *m*/*z* = 267.5 [Ru(terpy)(bpyOH)(CO)]$^{2+}$.

Preparation of [Ru(terpy)(bpyO)($C^{18}O$)](PF_6) {[2*](PF_6)}: Et_3N (0.1 equiv.) was added to a $CH_3CN/H_2{}^{18}O$ (4:1, v/v, 1 mL) solution of [2](PF_6) (40 mg) and the mixture was heated at 50 °C for 2 d. After the solution had cooled to room temperature, the solvent was removed completely. The orange solid thus obtained was recrystallized from CH_3CN/EtOH (1:4, v/v). The purity of the complex was checked by comparison of the parent peaks of *m*/*z* = 534 ([2]$^+$) and 536 ([2*]$^+$) in the ESI-MS, and of the ν($C^{16}O$) and ν($C^{18}O$) bands at 1996 and 1946 cm^{-1} in the IR spectra. Based on these results, the sample used in the experiments contained about 80% [2*](PF_6) and 20% [2](PF_6). Yield 18 mg. ESI-MS: *m*/*z* = 536 [Ru(terpy)(bpyO)($C^{18}O$)]$^+$.

Crystallographic Study of [Ru(terpy)(bpyO)(OH_2)](PF_6), [1](PF_6), [2](PF_6)·H_2O, and [2H](PF_6)$_2$·$2H_2O$: Crystals for X-ray analyses of the complexes were obtained as described above. A suitable single crystal for the measurement was mounted on a glass fiber. Data were collected at −100 °C on a Rigaku/MSC Mercury CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71070 Å). All data were collected and processed using the Crystal Clear program (Rigaku). All the calculations were carried out with the teXsan software package.[20] All structures were solved by direct methods and expanded using Fourier techniques. Refinements were performed anisotropically for all non-hydrogen atoms by the full-matrix least-squares method. Hydrogen atoms were placed at the calculated positions and were included in the structure calculation without further refinement of the parameters. Crystal data and processing parameters are summarized in Table 3. CCDC-240927 for [Ru(terpy)(bpyO)(OH_2)](PF_6), -217817 for [1](PF_6), -217818 for [2](PF_6)·H_2O and -217819 for [2H](PF_6)$_2$·$2H_2O$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

[8] The orientation of the bpyOH group in [Ru(terpy)(bpyOH)Cl]$^+$ was determined unequivocally by the X-ray crystal structure analysis but the quality of the crystals of the complex was not enough to allow a discussion of the bond angles and lengths (R_1 = 11.8%, R_w = 20.5%).

[12] The controlled-potential electrolysis of [**1**]$^+$ and [**2**]$^+$ at −1.80 V revealed that both complexes undergo one-electron reduction (n = 1.0) at the first cathodic wave. The potentials of the second cathodic waves of both complexes are too negative to determine the number of electrons by controlled-potential electrolysis. Based on the comparison of the peak currents of the first and the second waves of the complexes, both [**1**]^0 and [**2**]^0 are supposed to undergo one-electron reduction at the second cathodic wave.

[13] [13a] N. E. Tokel-Takvoryan, R. E. Hemingway, A. J. Bard, *J. Am. Chem. Soc.* **1973**, *95*, 6582. [13b] J. M. Calvert, T. J. Meyer, *Inorg. Chem.* **1981**, *20*, 27. [13c] B. Jing, W. Wang, M. Zhang, T. Shen, *Dyes Pigm.* **1998**, *37*, 177.

[14] The third cathodic wave of [**1**H]$^{2+}$ ($E_{p,c}$ = −1.85 V) was not assigned.

[15] A poorly resolved peak at about −1.40 V in the CV of [**2H**]$^{2+}$ (Figure 4b) results from H_2 evolution [Equation (5)]. Accordingly, addition of Et_3N to the solution converts [**2H**]$^{2+}$ to [**2**]$^+$. As a result, the pattern of the CV was sharpened and the irreversible cathodic wave of Et_4NH^+ was observed at −1.75 V.

[16] The first and second reductions of [**2**]$^+$ are associated with terpy- and bpyO-localized redox reactions, respectively. The second reduction causes metallocyclization of the complex. However, the oxidation processes of [**1**]$^-$ and [**2**]$^-$ are not clearly observed in the CV (Figure 3). The electrochemical oxidation of those two-electron-reduced complexes, therefore, was conducted at 0 V.

Towards the Design of Linear Homo-Trinuclear Metal Complexes Based on a New Phenol-Functionalised Diazamesocyclic Ligand: Structural Analysis and Magnetism

Miao Du,*[a] Xiao-Jun Zhao,[a,b] Jian-Hua Guo,[a] Xian-He Bu,*[b] and Joan Ribas*[c]

Keywords: Functionalised diazamesocyclic ligand / Copper(II) and Nickel(II) / Crystal structures / Magnetochemistry / Trinuclear complexes

The formation of two novel phenoxo-bridged linear trimetallic Cu^{II} and Ni^{II} complexes, $[Cu_3(\mu\text{-}\mathbf{L})_2](CH_3OH)_2(ClO_4)_2$ (**1**) and $[Ni_3(\mu\text{-}\mathbf{L})_2(CH_3OH)_2](ClO_4)_2$ (**2**), with a new diazamesocyclic ligand functionalised by additional phenol donor pendants ($H_2\mathbf{L}$ = *N*,*N*′- bis(2-hydroxybenzyl)-1,4-diazacycloheptane), has been achieved and both complexes have been characterised by IR spectroscopy, elemental analyses, conductivity measurements, thermal analyses and UV/Vis techniques. Single-crystal X-ray diffraction analyses revealed that both **1** and **2** have the similar phenoxo-bridged linear trinuclear cores. For **1**, two terminal and the central Cu^{II} ion are in square-planar environments with the adjacent intramolecular Cu···Cu separation of 2.9376(9) Å. For **2**, however, two terminal Ni^{II} ions are in square-planar environments and the central Ni^{II} ion assumes an octahedral geometry by axial coordination of two methanol ligands, the adjacent intramolecular Ni···Ni distance being 3.007(3) Å. In both cases, the 1,4-diazacycloheptane (DACH) ring adopts the normal boat configuration. The magnetic properties of complexes **1** and **2** have been investigated by variable-temperature magnetic susceptibility measurements in the solid state. Complex **1** displays a very strong antiferromagnetic coupling interaction between the neighbouring μ-phenoxo Cu^{II} centres with a *J* parameter of –314 cm^{-1} and the magneto-structural correlation for such complexes is discussed in detail. For complex **2**, the result indicates that both terminal Ni^{II} ions are diamagnetic and the central Ni^{II} shows typical paramagnetic behaviour. The presence of zero-field splitting for Ni^{II} with a *D* parameter of 11 cm^{-1}, being active at low temperature, is further corroborated by the magnetisation measurement at 2 K. Additionally, the interesting ESR spectra of **1** at different temperatures (from 298 K to 8 K) were investigated and interpreted.

Introduction

The development of routes and strategies for the design and preparation of polynuclear complexes of 3d metals in moderate oxidation states is of great importance in bioinorganic chemistry, magnetochemistry, materials chemistry and solid-state chemistry.[1] Trinuclear compounds can be classified as linear or nonlinear according to the arrangements of the metal centres and a number of linear trinuclear compounds have been structurally and magnetically characterised to date.[2] Of further importance is the fact that most of the known trinuclear complexes have two, three or four simple and/or intricate bridging ligands between the metal centres which usually contain simple anions such as chloride,[3] hydroxide,[4] acetate,[5] methoxide[6] or azide[7] and only a minority of them have the M_3 core bridged by just a single organic ligand. Thus, the rational design and preparation of such trinuclear complexes still remains a difficult challenge and attracts continuing interest.

As described in many other publications by us, we have been exploring the coordination chemistry of diazamesocyclic systems, especially the typical 1,5-diazacyclooctane (DACO) which exhibits an exceptionally strong ligand field, a unique configuration and the potential for further functionalisation.[8–11] It has been well demonstrated by us and others[12] that DACO modified by suitable functional pendants, such as heterocyclic, phenolic, thiol and carboxylic groups could be used as good building blocks for constructing polymeric systems with unique structures and properties. Based on our experimental findings, a general rule for the coordination chemistry of functionalised DACO compounds has been established according to the types and numbers of the additional pendant arms. the main reasons that justifies the continuous interest in such attractive system is the construction of other novel metal complexes with special frameworks and properties by modifying the backbone of the diazamesocycle, for example choosing 1,4-diazacycloheptane (DACH) as the initial material. Our preliminary results indicate that the metal complexes of the heterocycle-functionalised DACH derivatives usually exhibit similar structures to those of the corresponding DACO compounds but with a change in the coordination environments of the metal centres due to their different configurations (normally, boat-chair for DACO ring, and boat for DACH).[13] It should be noted that almost all metal centres chelated to DACO derivatives assume pentacoordinate geometries[8−12] but this is not the case for DACH.[13] For metal complexes with the DACO ligand bearing two phenol arms, phenoxo-bridged linear trimetallic Cu^{II} and Ni^{II} frameworks were obtained. The former exhibits a square pyramid/square plane/square pyramid Cu_3 core[10a] and the latter is the first square pyramid/octahedral/square pyramid Ni_3 complex.[10b] Thus, as a continuation of our work, we report herein the design and preparation of a new phenol-functionalised DACH ligand *N*,*N*′-bis(2-hydroxybenzyl)-1,4-diazacycloheptane (H_2**L**, see Scheme 1) and its Cu^{II} and Ni^{II} complexes $[Cu_3(\mu\text{-}\mathbf{L})_2](CH_3OH)_2(ClO_4)_2$ (**1**) and $[Ni_3(\mu\text{-}\mathbf{L})_2(CH_3OH)_2](ClO_4)_2$ (**2**). The magnetic properties of both complexes have been investigated and the magneto-structural correlation between **1** and related compounds has been discussed. Of further interest is the fact that relatively few trinuclear Cu^{II} compounds have been studied by ESR techniques[14] and, thus, the ESR properties of **1** at different temperatures (from 298 K to 8 K) were analysed in detail in this study.

Results and Discussion

Preparation, Characterisation and Spectra of Compounds 1 and 2

The new ligand H_2**L** was synthesised using an excess of 2-bromomethyl phenylacetate in order to largely obtain the doubly substituted product as described in detail in our previous report.[10a] The yield was moderate. All analytical and spectroscopic data are in good agreement with the theoretical requirements. The preparations of **1** and **2** were achieved directly by treatment of the ligand with the corresponding metal perchlorate and the ligand becomes doubly deprotonated when forming the metal complex.

In the IR spectra of H_2**L** and both complexes, the absorption bands resulting from the skeletal vibrations of the aromatic rings appear in the 1400−1600 cm^{-1} region. The broad band centred at ca. 3400 cm^{-1} results from the O−H stretching of the phenol groups (for H_2**L**) or the solvent methanol molecules (for **1** and **2**). The very strong bands at 1256 cm^{-1} (for H_2**L**), 1264 and 1247 cm^{-1} (for **1**) and 1261 cm^{-1} (for **2**) are the characteristic absorptions of the C−O groups of the phenol pendant arms. Additionally, in the IR spectra of both complexes, the strong bands that appear at ca. 1100 and 624 cm^{-1} suggest the presence of the perchlorate anions.[15]

The UV/Vis spectra of complexes **1** and **2** (CH_3CN and H_2O, respectively) have been investigated at room temperature. It is important to know the structures of the complexes in solution prior to spectroscopic discussions. Thus, the conductivities of both complexes were measured and the molar conductivities of **1** and **2** indicate both complexes behave as the typical 2:1 electrolytes in the corresponding solution, this being consistent with their solid structures. Evidently the phenoxo bridges are retained in solution. The visible spectrum of **1** shows a moderate shoulder band at ca. 558 nm and a more intense absorption band at 386 nm which can be assigned to the *d*−*d* component of Cu^{II} ions with a square-planar geometry and the charge-transfer (CT) transition band from the filled p_π orbital of the phenolic oxygen to the vacant *d* orbitals of Cu^{II}, respectively.[16] For complex **2**, two such types of absorptions appear at 498 nm and 362/324 nm (one is due to the terminal Ni^{II} CT and the other to the central Ni^{II} CT with different coordination geometries[2c]), respectively. In addition, the intense bands observed in the 200−300 nm region in the spectra of both complexes can be attributed to the π→π* ligand transitions.

Both **1** and **2** are air stable at room temperature but decomposition occurs at elevated temperature, however. Thermogravimetric analyses (from room temperature to 600 °C) indicate that for **1**, the first weight loss of 6.44% from 118 to 164 °C (peak: 132 °C) corresponds to the loss of two CH_3OH solvent molecules (calculated: 5.96%). The remaining substance does not lose weight upon further heating until a rapid weight loss in the 244−264 °C region (peak: 258 °C). Further heating to 600 °C induces a continuous and slow weight loss. The thermal behaviour of **2** is similar to **1**, the first weight loss of 5.84% from 85 to 160 °C (peak: 138 °C) corresponds to the release of two coordinated methanol ligands (calculated: 6.04%). The remaining coor-

dinated framework does not lose weight upon further heating until two consecutive weight losses occur in the 270−325 °C region (peak: 288 and 312 °C). As for **1**, further heating to 600 °C only shows a continuous and slow weight loss.

Single-Crystal X-ray Structures of Complexes 1 and 2

Structure Description of $[Cu_3(\mu\text{-}L)_2](CH_3OH)_2(ClO_4)_2$ (1)

An ORTEP diagram of complex **1** is shown in Figure 1 and selected bond lengths and angles are listed in Table 1. The structure consists of a discrete $[Cu_3(\mu\text{-}\mathbf{L})_2]^{2+}$ cation in which the ligands are doubly deprotonated, two perchlorate counter anions and two lattice methanol solvent molecules. The asymmetric unit is formed by half a molecule which exhibits inversion in the centre of the rhombohedral which itself consists of four phenol oxygen atoms [Cu(2) is just on this inversion centre]. Two terminal Cu(1) and Cu(1A) atoms, located in general positions, are centrosymmetrically related to each other and, hence, three Cu^{II} ions linked by the phenoxo bridges lie in a straight line. Each terminal Cu^{II} ion is coordinated to two nitrogen atoms from the DACH ring (Cu−N distances: 1.973(3) and 1.981(3) Å) and two phenolate oxygen donors (Cu−O lengths: 1.927(3) and 1.928(3) Å), adopting an approximately square-planar geometry (CuN_2O_2). The central Cu(2) atom is coordinated to four bridging phenolate oxygens (Cu−O lengths: 1.956(3) and 1.953(3) Å) which further link the other two Cu^{II} ions to form the linear Cu_3 array, resulting in a CuO_4 plane. Additionally, weak interactions between the central Cu(2) and the perchlorate anions (located in the axial position of the Cu^{II} coordination sphere) can be observed with a Cu(2)−O(3) distance of 2.589(3) Å which is significantly longer than the normal Cu−O coordination bond. The terminal Cu(1) ion is only ca. 0.035 Å above the basal least-squares plane and the central Cu(2) is located exactly on its coordination plane due to the site symmetry. The folding angle between the perfect square plane O(1)−O(1A)−O(2)−O(2A) and the best calculated plane N(1)−N(2)−O(1)−O(2) is 10.8° and the dihedral angle between the two Cu(1)−O(1)−Cu(2) and Cu(1)−O(2)−Cu(2) planes is 10.9°. The intramolecular Cu···Cu separation is 2.9376(9) Å whereas the Cu(1)−O−Cu(2) bridging angles are 98.31(12) and 98.38(11)° for O(1) and O(2), respectively. For the ligand, the DACH ring takes the normal boat configuration and the dihedral angle between two phenol planes is 117.6°. A pair of nitrogen atoms from DACH and two oxygen atoms of phenolate pendant arms are in *cis* positions in the coordination plane of the chelated Cu(1) atom.

Analysis of the crystal packing of complex **1** indicates that the trimers are well isolated in the unit cell, with the intermolecular contacts between the Cu^{II} centres above 5.8 Å. There exists only an intramolecular O(7)−H(7)···O(3) hydrogen bond between the methanol molecule and the per-

chlorate anion. The O···O separation is 2.995 Å with an H···O distance of 2.242 Å and the bond angle is 152.7° which is in the normal range for such a weak interaction.[17]

Structure Description of $[Ni_3(\mu\text{-}L)_2(CH_3OH)_2](ClO_4)_2$ (2)

A single-crystal X-ray determination indicates that the structure of complex **2** consists of a $[Ni_3(\mu\text{-}\mathbf{L})_2(CH_3OH)_2]^{2+}$ cation exhibiting a similar M_3 framework to **1** and two perchlorate anions. Selected bond lengths and angles for **2** are listed in Table 2. As depicted in Figure 2, the asymmetric unit is formed by half of the complex which shows an inversion centre [Ni(2)] in the middle of the rhombohedral plane. Since Ni(2) occupies the inversion centre, the resultant Ni(1)−Ni(2)−Ni(1A) array is linear. As in **1**, a pair of nitrogen atoms from DACH (Ni−N distances: 1.903(4) and 1.897(4) Å) and two oxygen atoms of the phenolate pendant arms (Ni−O lengths: 1.872(3) and 1.873(3) Å) are in a *cis* position. These positions constitute the approximate coordination plane of the terminal Ni(1) atom with a derivation from planarity of 0.022 Å. However, the central Ni(2) is six-coordinate: four phenol oxygen atoms are in the equatorial plane with Ni−O distances of 2.040(3) and 2.050(3) Å with two methanol ligands occupying the axial positions with Ni−O lengths of 2.067(3) Å. Thus, the coordination environment of Ni(2) can be described as a slightly distorted elongated octahedron with the *cis* O−Ni−O angles being in the range of 75.33(11)−104.67(11)°. In **2**, the folding angle between the perfect square plane O(1)−O(1A)−O(2)−O(2A) and the best calculated plane N(1)−N(2)−O(1)−O(2) is 6.3° and the dihedral angle between the two Ni(1)−O(1)−Ni(2) and Ni(1)−O(2)−Ni(2) planes is 8.7°. The intramolecular Ni···Ni separation is 3.007(2) Å and the Ni(1)−O−Ni(2) bridging angles are 100.39(13) and 98.98(14)° for O(1) and O(2), respectively. For the doubly deprotonated ligand, the DACH ring assumes the normal boat configuration and the dihedral angle between two phenol planes is 56°. Similar to **1**, the trinuclear subunits are well isolated in the unit cell with the intermolecular contacts between the Ni^{II} centres above 6.0 Å. An intramolecular O(3)−H(3C)···O(4) hydrogen-bonding interaction between the coordinated methanol molecule and the perchlorate anion can be observed and this further stabilises the structure. The O···O separation is 2.861 Å with an H···O distance of 2.074 Å and the bond angle is 160.8°, which is in the normal range for such weak interactions.[17]

ESR Spectra of Complex 1

For the interpretation of the ESR spectra of complex **1**, it is convenient to consider the relative energies of the states deduced by coupling the three $S = 1/2$ ions. A demonstration of these states and the corresponding energies can be found in the book of O. Kahn.[18] The spin diagram is given in Figure 3 in which the occurrence of *ZFS* in the state $|3/2, 1/2>$ is considered, giving two doublets corresponding to $m_s = \pm 3/2$ and $\pm 1/2$. As shown, $m_s = \pm 1/2$ is strongly anisotropic.[19]

The ESR spectra of **1**, as a function of temperature, are given in Figure 4. The easiest spectrum to interpret is that corresponding to the lowest temperature measured (8 K). The spectrum shows a very narrow almost isotropic band centred at $g = 2.05$. When the temperature is raised this signal broadens and at close to liquid nitrogen temperature it begins to appear as broad band near 1500 Gauss. The intensity of the spectrum diminishes as the temperature increases and at 298 K (final temperature we measured) the spectrum shows two clear and very broad signals, the first one centred at 3000 G ($g = 2.08$) and a new band centred at 1200−1300 G which corresponds to a *g* value of approximately 5.15. It must be pointed out that the difference in the intensities of the limiting spectra (room temperature and 8 K) is in the region of five orders of magnitudes (10^5).

At low temperature, only the $|1/2, 1>$ ground state is populated ($J = -314$ cm^{-1} according to the susceptibility measurements as described below). Thus the strong signal

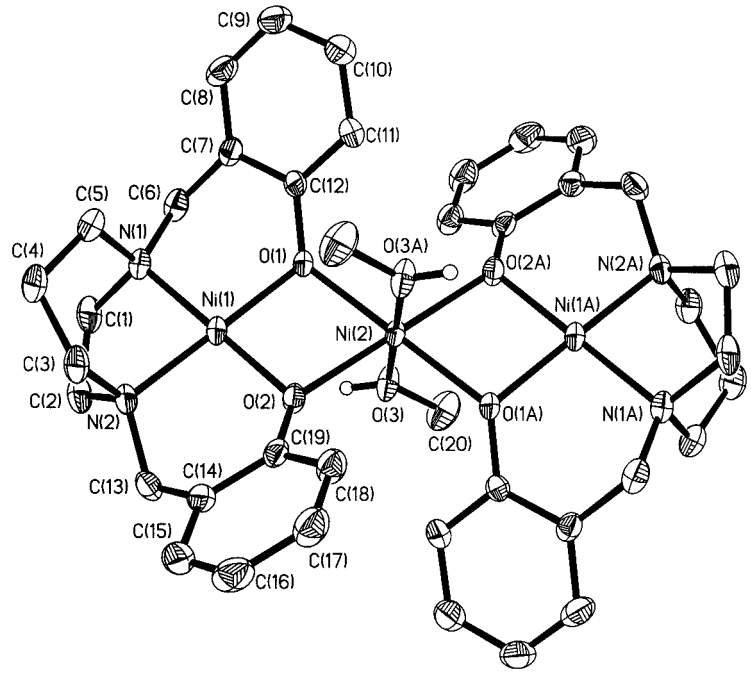

Figure 2. ORTEP structure of the molecular structure of **2** including atomic labelling of the asymmetric unit (hydrogen atoms and perchlorate anions are omitted for clarity) with displacement ellipsoids drawn at the 30% probability level

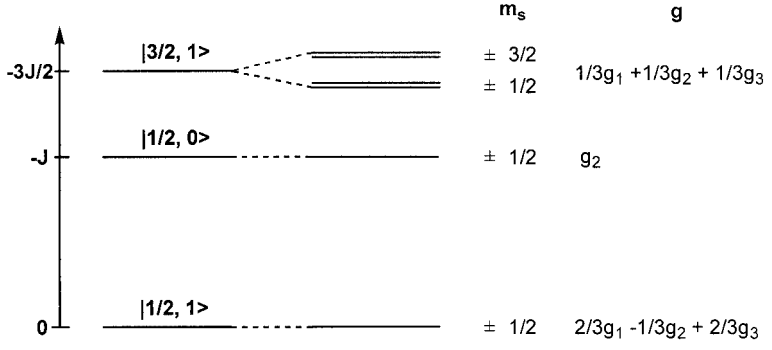

Figure 3. Spin levels, energies and g values in a trinuclear Cu_3 complex ($J < 0$)

at $g = 2.05$ is due to this ground state. This g value is an average of the g values of the three Cu^{II} ions ($g = 1/3\ [2g_{T1} - g_C + 2g_{T2}]$ where C and T are the central and terminal Cu ions).[19,20] The g values for the |1/2, 0> and |3/2, 1> states are different, provided that the individual g_i values are different.[20] If we assume that the rate of transition from the lowest to the excited multiplets is fast on the ESR time scale, the observed spectrum at a given temperature would be the thermal average of the spectra of three different multiplets. Therefore, the liquid helium temperature spectra should be those of the lowest doublet, while those at higher temperatures should also bear the contributions of the excited multiplets. For this reason, the anisotropy of the molecular g value is usually not well defined. Only in a few trinuclear Cu^{II} complexes is this anisotropy manifested.[21] In complex **1**, the observed g value is an average of two different Cu^{II} environments. On the other hand, in solid state, the trinuclear cations are not perfectly isolated from a magnetic point of view. Effectively, we have found a nonnegligible J' value (molecular-field approach, see below). As has been pointed out,[22] even an extremely weak value for the intermolecular exchange interaction leads to the exchange averaging effect which is responsible for the isotropic or quasi-isotropic spectra observed (such as in complex **1**).

Only on a few occasions for this kind of trinuclear Cu^{II} complex, has any evidence of signals attributable to a spin quadruplet been found. In contrast, this spin quadruplet is clearly visible at 4 K when the coupling is ferromagnetic because this is the ground state in this case.[5,23] A broad transition between $g = 4.25-5.5$ occurs and can be assigned to the transition between the ± 1/2 levels of the $S = 3/2$ system. Thus, this is undoubtedly the origin of the broad signal centred at $g \approx 5$ in complex **1**.

Magnetic Properties of 1 and 2

Complex 1

The magnetic properties of complex **1** in the form of a $\chi_M T$ vs. T plot are shown in Figure 5 (magnetic susceptibility per three Cu^{II} ions). The $\chi_M T$ value is 0.65 cm^3 mol^{-1} K at 300 K which is far from the value of 1.2 cm^3 mol^{-1} K corresponding to three isolated spin doublets. The $\chi_M T$ value decreases to 0.40 cm^3 mol^{-1} K upon cooling to ca. 80 K. At this point there is a clear plateau from 80 K to 10 K and, finally, there is a slight decrease to 0.38 cm^3 mol^{-1} K at 2 K. This curve suggests strong antiferromagnetic coupling between the Cu^{II} centres with the presence of very small intermolecular antiferromagnetic interactions being active only at very low temperature. Thus, in the light of the above structural discussion of complex **1**, we can interpret its magnetic behaviour through a simple model with only one intramolecular J parameter using the following spin Hamiltonian:

$$H = -J_1 (S_1S_2 + S_2S_3)$$

From this Hamiltonian it is possible to deduce a simple equation for $\chi_M T$ vs. T:[18]

$$\chi_M T = \frac{Ng^2\beta^2[1+\exp(J/KT)+10\exp(3J/2KT)]}{4K[1+\exp(J/KT)+2\exp(3J/2KT)]}$$

This equation has been completed by introducing a J' parameter and considering the possible small interactions between the trinuclear entities using the molecular-field approach:[18]

$$\chi_M = Ng^2\beta^2F(J,T)/(kT - zJ'F(J,T))$$

The fit of the magnetic data, assuming that the g factors are identical for Cu(1) and Cu(2), leads to $J = -314.0 \pm 0.8$ cm^{-1}, $J' = -0.5 \pm 0.01$ cm^{-1}, $g = 2.09$ and $R = 1.5 \times 10^{-6}$ (R is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2 / \Sigma[(\chi_M T)_{obs}]^2$).

Magneto-Structural Correlations in Cu_2O_2 Cores

Magneto-structural correlations in dinuclear Cu^{II} complexes bridged equatorially by pairs of hydroxo[24] or alkoxo[25] groups show that the major factor controlling the spin coupling between the $S = 1/2$ metal centres is the Cu−O(R)−Cu angle. Hatfield and Hodgson found a linear correlation between the experimentally determined exchange coupling constant and the Cu−O−Cu bond angle (φ) (see a in Figure 6).[24] Antiferromagnetic behaviour is observed for complexes with φ larger than 97.6°, while ferromagnetism appears for those with smaller values of φ. An apparently similar linear relationship for the alkoxo cases[25] shows that at angles around 95.6°, the exchange integral approaches zero, i.e. the point of experimental "accidental orthogonality". For such dimeric Cu^{II} complexes, Nieminen[26] described correlations between the singlet-triplet splitting energy and the Cu−O−Cu angle φ, the deviation d_c of the carbon atom connected to the bridging oxygen atoms from the Cu−O−Cu plane and the sum of the angles around the bridging oxygen atoms. Walz et al.[27] reported the influence of the coordination geometry around the Cu^{II} atom on the exchange interaction in alkoxo-bridged complexes. These experimental observations are consistent with studies using the angular overlap approach by Bencini and Gatteschi[28] as well as extended Hückel MO treatments by Hoffmann[29] and Kahn.[30] More recent ab initio and DFT calculations on simple model dimers examined the effects of the bridging angles, Cu−O distances, fold (hinge) angle along the O−O axis and degree of tetrahedral (for square-planar geometry) or sp → bpt (for square-pyramidal geometry) distortions at the Cu^{II} centres.[25,31−33] These theoretical studies showed that although the major factor affecting the magnetic exchange is the Cu−O−Cu

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

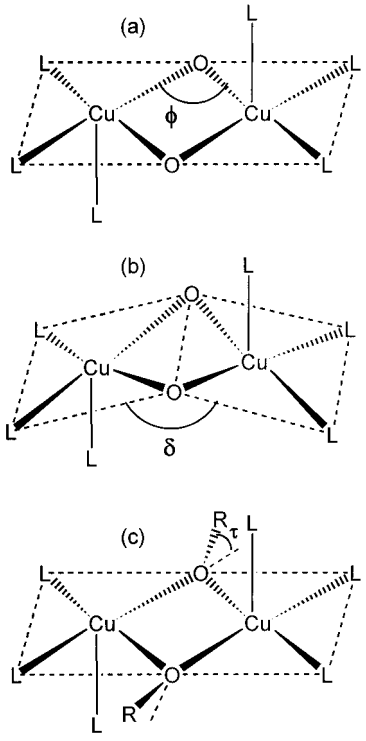

Figure 6. The three main factors in the Cu_2O_2 entities that tune the antiferromagnetic coupling in μ-phenoxo derivatives

bridge, other features can also significantly lead to the increase in the ferromagnetic contributions which effectively reduces any antiferromagnetic term associated with the hydroxo/alkoxo bridges. Among these features, we can underline the distortions of the coordination geometry of the Cu^{II} centre,[34,35] the variation in Cu−O bond lengths,[32] the hinge (roof shape) distortion of the core (δ, see b in Figure 6),[31−33,36] the torsion angle created by the H (or R) group with regard to the Cu_2O_2 plane (τ angle, see c in Figure 6)[32] and different electronic factors.[31,32,37,38] Some of these geometric factors are shown in Figure 6.

Roughly the same features discussed for the hydroxo-bridged complexes also seem apparent in alkoxo-bridged complexes. Thompson et al. found significant differences in magnetic coupling between μ-hydroxo (or μ-alkoxo) and μ-phenoxo complexes.[39] From this work, it is apparent that the slopes of the graphs ($2J$ vs. Cu−O−Cu angle) of the hydroxo and alkoxo cases are comparable but the absolute values of $-2J$ are larger for the alkoxo species. However, the slope of the graph for the phenoxo system is smaller and the absolute values of $-2J$ are inherently larger. For lower angles (95°) the J values approach zero for the alkoxo species but this is not the case for phenoxo bridging complexes. The range of the average angles for these phenoxo complexes is very small (from 99 to 105°). The couplings lie between $-700\ cm^{-1}$ (for smaller angles) and $-900\ cm^{-1}$ (for larger angles) as shown in Figure 7.[39] For $J = 0$ the Cu−O−Cu angle should be 77°, although this angle has not been experimentally observed at present. The observation of greater J values for −OR than −OH is due to the effect of replacing the hydrogen of the hydroxo with a more electronegative carbon group which reduces the electron density on the oxygen bridge.[36]

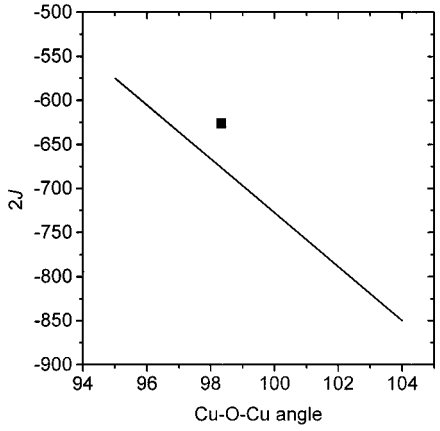

Figure 7. Schematic plot of the $2J$ values vs. Cu−O−Cu angles given by Thompson et al. in ref.[42] together with the point indicating the experimental value for **1**; in this figure the symbolism of $2J$ has been kept, although in the text we have used the Hamiltonian $-J$ instead of $-2J$

Similar correlations can be established for comparable macrocyclic dicopper(II) systems, such as "Robson" type macrocyclic complexes, formed by Cu^{II} ions acting as templates for the condensation of diformylphenols and various diamines. These systems contain phenoxo oxygen atoms bridging the two Cu^{II} centres and represent ideal systems for examining the exchange coupling via the phenoxo oxygen. The degree of distortional flexibility available to simple dimeric Cu^{II} complexes with hydroxo or alkoxo bridges can be expected to be reduced when the Cu−$(O)_2$−Cu entity is enclosed within the cavity of a macrocyclic ligand and, thus, one might expect a more straightforward relationship between the bridging angle and the exchange with respect to electronic perturbations. Only a few structural examples of this sort of complex have been reported in which the linker group between the azomethanide nitrogens is two-membered, thereby creating a five-membered chelate ring.[39] The Cu−$O_{phenoxo}$−Cu angles fall in the range 98.8−100.9°, this being at the lower end of the range of angles typical for phenoxo systems. In all cases, the molecules themselves and the dinuclear centres are almost flat. There are no unusual structural or electronic perturbations which might be expected to influence the exchange in a significant way in those complexes. Thus, the phenoxo bridging angle can be considered to be the principal factor controlling the spin coupling.

In summary, the main conclusion for phenoxo systems is that strong antiferromagnetic exchange will dominate in these complexes. For comparison with complex **1**, structural and magnetic parameters for some related [Cu_2(μ-OR)] complexes are listed in Table 3. In the present case, complex **1** belongs to the μ-phenoxo-bridged group of complexes. The Cu−O−Cu angles are 98.31(12) and 98.38(11)°, respectively, and the intramolecular Cu···Cu separation is 2.9376(9) Å. The hinge angle (δ) through the O(1)−O(2)

[a] The meaning of Greek symbols is given in Figure 6.

axis is 170°, i.e. very close to 180° which corresponds to an exactly planar structure. The torsion angles (τ) created by C(19) and C(12) (phenoxo ligands) from the Cu_2O_2 plane are 140/147.2 and 138.9/145.6°, respectively. Thus, we can expect strong antiferromagnetic coupling as experimentally observed. Plotting the 2*J* values indicated by Thompson et al. in reference 42 and adding the Cu−O−Cu angles and the 2*J* parameter for complex **1**, a rather good agreement can be observed (Figure 7). The difference could be due to the hinge angle (very small in this case) and, mainly, to the τ distortion (considerable in complex **1** as stated above).

Complex 2

The magnetic properties of **2** in the form of $\chi_M T$ vs. *T* plots are shown in Figure 8, these representing the magnetic susceptibility *per* Ni^{II} ion (the terminal ones are diamagnetic). The $\chi_M T$ value is 1.32 $cm^3\ mol^{-1}$ K at 300 K which is a typical value for an isolated Ni^{II} ion with $g > 2.00$. $\chi_M T$ is practically constant to 25 K and then decreases to 0.3 $cm^3\ mol^{-1}$ K at 2 K. This feature suggests typical paramagnetic behaviour for a Ni^{II} ion in which the *D* parameter and/or intermolecular interactions (usually antiferromagnetic) are active at low temperature. In an attempt to calculate the *D* value, we have fitted the experimental $\chi_M T$ values to the formula given by Kahn for a mononuclear Ni^{II} ion taking into consideration the *ZFS* of the $S = 1$ ground state.[18] The best fit values are $|D| = 11\ cm^{-1}$ and g (average) = 2.30. The *D* value is higher than that typical for Ni^{II} ions (close to 5−8 cm^{-1}), indicating that the possible intermolecular interactions are superimposed on this *D* value. The magnetisation measurement at 2 K corroborates the effect of the *D* parameter, i.e. the reduced magnetisation ($M/N\beta$) at 5 T is only consistent with 1.4 electrons instead of two electrons which should be the theoretical value for an isolated Ni^{II} ion with $g = 2.00$ (see inset in Figure 8).

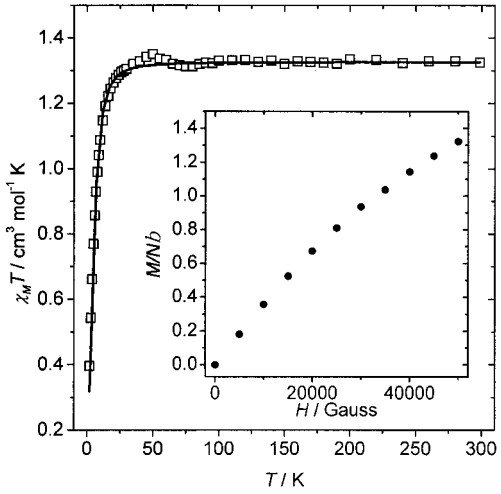

Figure 8. Plot of $\chi_M T$ vs. *T* for complex **2**; the solid line in the $\chi_M T$ curve represents the best fit for calculating the *D* value (see text); inset: plot of the reduced magnetisation ($M/N\beta$) vs. *H* at 2 K for complex **2**

Conclusions and Perspectives

Two novel linear phenoxo-bridged trinuclear Cu^{II} and Ni^{II} complexes were rationally designed and prepared based on a new diazamesocyclic ligand bearing two pendant phenol donors. From a magnetic point of view, the data for complex **1** show two features: the very strong antiferromagnetic coupling interaction between the neighbouring μ-phenoxo Cu^{II} centres and the small possible interactions between the trinuclear entities. The magneto-structural correlations for related complexes containing Cu_2O_2 cores have been analysed in detail. For **2**, both terminal Ni^{II} ions are diamagnetic and the central Ni^{II} shows typical paramagnetic behaviour. The zero-field splitting for Ni^{II} can be ob-

served and further corroborated by the magnetisation measurements. Additionally, the interesting ESR properties of **1** at different temperatures (from 298 K to 8 K) were investigated. Further studies of the coordination chemistry of such attractive systems are under way in our laboratory.

Experimental Section

Materials and Physical Measurements: With the exception of 2-bromomethyl phenylacetate, which was synthesised according to the reported literature procedure,[49] all of the starting materials and solvents for the syntheses and the analyses were obtained commercially and used as received. ^{1}H NMR spectra were recorded on a Bruker AC-P 400 spectrometer (400 MHz) at 25 °C with tetramethylsilane as the internal reference. FT-IR spectra (KBr pellets) were recorded on an AVATAR-370 (Nicolet) spectrometer and electronic spectra were acquired with a CARY300 (Varian) spectrophotometer. C, H and N analyses were performed on a CE-440 (Leemanlabs) analyser. Conductivities of the complexes were measured at room temperature using a DDS 11A conductometer. Thermal stability (TGA) experiments were carried out on a Dupont thermal analyser from room temperature to 600 °C under a nitrogen atmosphere at a heating rate of 10 °C/min.

Synthesis of the Ligand *N*,*N*′-Bis(2-hydroxybenzyl)-1,4-diazacycloheptane (H_2L): 2-Bromomethyl phenylacetate (8.12 g, 35.5 mmol) was added to a solution of DACH (1.54 g, 15.4 mmol) in C_2H_5OH (80 mL) with vigorous stirring at room temperature. Suitable portions of solid KOH were added to the above mixture to ensure that the pH value stayed at 7−8 for ca. 3 days. After filtration of the mixture, the solvent was removed by rotary evaporation. The residue was purified by silica gel column chromatography (CH_2Cl_2/CH_3OH/NH_3·H_2O from 10:10:1 to 5:5:1). The final product was obtained as a white solid in 55% yield (2.65 g, based on DACH). ^{1}H NMR ($CDCl_3$): δ = 1.91−1.97 (m, 2 H, CH_2), 2.79−2.85 (m, 8 H, CH_2), 3.80 (s, 4 H, CH_2), 6.75−6.84 (m, 4 H, Ph), 6.94 (d, J = 1.5 Hz, 1 H, Ph), 6.96 (d, J = 1.5 Hz, 1 H, Ph), 7.14−7.26 (m, 2 H, Ph). IR [KBr pellet (cm^{-1})]: 3432 b, 3043 m, 2934 m, 2912 w, 2876 w, 2841 m, 2717 w, 2627 w, 1933 w, 1897 w, 1784 w, 1613 s, 1590 vs, 1479 vs, 1458 vs, 1421s, 1383 w, 1357 s, 1349 s, 1334 m, 1307 w, 1256 vs, 1183 m, 1151 s, 1090 s, 1057 m, 1034 s, 1016 m, 983 s, 936 m, 917 m, 871 m, 850 w, 811 s, 755 vs, 720 m, 625 m, 595 w, 547 m, 459 s. $C_{19}H_{24}N_2O_2$ (312.41): calcd. C 73.05, H 7.74, N 8.97; found C 73.19, H 7.51, N 8.84.

[Cu_3(μ-L)$_2$](CH_3OH)$_2$(ClO_4)$_2$ (1): To a solution of H_2**L** (63 mg, 0.2 mmol) in $CHCl_3$ (20 mL) was slowly added a CH_3OH solution (15 mL) of $Cu(ClO_4)_2$·$6H_2O$ (110 mg, 0.3 mmol) with stirring and a brown powder of complex **1** precipitated gradually. The powder was filtered off, washed with methanol/water and dried under vacuum. Yield: 97 mg (90%). Single crystals of **1** suitable for X-ray analysis were obtained as follows: a solution of $Cu(ClO_4)_2$·$6H_2O$ in CH_3OH was carefully layered onto a solution of H_2**L** in $CHCl_3$ in a 3:2 molar ratio in a straight glass tube and rhombic brown crystals were observed after ca. two weeks. $C_{40}H_{52}Cl_2Cu_3N_4O_{14}$ (1074.41): calcd. C 44.72, H 4.88, N 5.21; found C 44.61, H 4.74, N 5.17. IR (cm^{-1}): 3446 b, 3061 w, 2940 w, 2905 w, 2860 m, 1598 s, 1574 w, 1482 vs, 1445 s, 1395 m, 1340 w, 1327 w, 1264 s, 1247 vs, 1212 m, 1198 m, 1102 vs, 1061 vs, 970 m, 923 m, 881 m, 864 m, 785 m, 773 s, 763 vs, 761 w, 642 m, 623 s, 577m. Λ_M (CH_3CN): 266 cm^2 Ω^{-1} mol^{-1}. λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) (CH_3CN): 558 (220) and 386 (520).

[Ni_3(μ-L)$_2$(CH_3OH)$_2$](ClO_4)$_2$ (2): The same synthetic procedure (for both polycrystalline and single-crystal preparation) for **1** was used except that $Cu(ClO_4)_2$·$6H_2O$ was replaced by $Ni(ClO_4)_2$·$6H_2O$. This afforded a red powder in 85% yield (or block-type single crystals). $C_{40}H_{52}Cl_2Ni_3N_4O_{14}$ (1059.83): calcd. C 45.33, H 4.95, N 5.29; found C 45.61, H 4.58, N 5.04%. IR (cm^{-1}): 3357 b, 3059 w, 3020 w, 2939 w, 2911 w, 2860 m, 1599 s, 1577 m, 1485 vs, 1457 vs, 1398 m, 1342 w, 1325 w, 1261 vs, 1208 m, 1112 vs, 1045 vs, 1027 vs, 972 m, 943 w, 927 m, 883 s, 867 m, 794 s, 767 vs, 734 m, 657 m, 624 s, 605 w, 590 m. Λ_M (H_2O): 182 cm^2 Ω^{-1} mol^{-1}. λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) (H_2O): 498 (340), 362 (1150) and 324 (1020).

Caution! Although no problems were encountered in this study, transition metal perchlorate complexes are potentially explosive and should be handled with proper precautions.

Magnetic Studies: The variable-temperature magnetic susceptibilities were measured at the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (30 mg) with a Quantum Design MPMS SQUID magnetometer operating at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants for all the constituent atoms. Magnetisation measurements were carried out at 2 K in the 0−5 T range. ESR spectra were recorded on powder samples at the X-band frequency with a Bruker 300E automatic spectrometer, varying the temperature between 8 and 298 K.

X-ray Crystallographic Data Collections and Refinements: Single-crystal X-ray diffraction measurements of **1** (brown, 0.30 × 0.25 × 0.20 mm) and **2** (red, 0.30 × 0.25 × 0.20 mm) were carried out with a Bruker Smart 1000 CCD diffractometer equipped with a graphite crystal monochromator situated in the incident beam for data collection at 293(2) K. The lattice parameters were obtained by least-squares refinements of the diffraction data of 781 (for **1**) and 582 (for **2**) reflections, respectively, and data collections were performed with Mo-$K\alpha$ radiation (λ = 0.71073 Å) by the ω scan

mode in the range of $2.21 < \theta < 26.39°$ (for **1**) and $2.00 < \theta < 25.00°$ (for **2**). There was no evidence of crystal decay during data collection for both complexes. All the measured independent reflections were used in the structural analyses and semi-empirical absorption corrections were applied using the SADABS program. The program SAINT[50] was used for integration of the diffraction profiles. Both structures were solved by direct methods using the SHELXS program of the SHELXTL package and refined with SHELXL.[51] Metal atoms were located from the *E*-maps and other nonhydrogen atoms were located in successive difference Fourier syntheses. The final refinements were performed by full-matrix least-squares methods with anisotropic thermal parameters for all the nonhydrogen atoms on F^2. All hydrogen atoms were first found in difference electron density maps and then placed in the calculated sites and included in the final refinement in the riding model approximation with displacement parameters derived from the parent atoms to which they were bonded. In the refinement of both complexes, a disorder model of the perchlorate anion was used (two constraint components for four oxygen atoms of the perchlorate anion have occupancy factors of 0.5) to make the oxygen atoms exhibit suitable displacement ellipsoids. A summary of the crystallographic data and structure refinements are listed in Table 4.

CCDC-232051 (for **1**) and -232052 (for **2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/cons/ retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

Highly Efficient Disproportionation of Dihydrogen Peroxide: Synthesis, Structure, and Catalase Activity of Manganese Complexes of the Salicylimidate Ligand

Meenal D. Godbole,[a] Michael Kloskowski,[c] Ronald Hage,[a] Annette Rompel,[c] Allison M. Mills,[b] Anthony L. Spek,[b] and Elisabeth Bouwman*[a]

Keywords: Catalase / Michaelis−Menten kinetics / Hydrogen peroxide disproportionation / Enzyme mimics / Manganese / Kinetics

Two complexes, $[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (**1**), and $[Mn(mesalim)_2(OAc)(MeOH)]\cdot MeOH$ (**2**), in which Hmesalim and Hetsalim are methyl and ethyl salicylimidate, respectively, have been synthesized, fully characterized by X-ray analyses, magnetic susceptibility, UV/Vis and IR spectroscopy, and their catalase activity has been studied. Complex **1** is dinuclear and shows an Mn–Mn distance of 3.37 Å while complex **2** is mononuclear. Both complexes catalyze the disproportionation of hydrogen peroxide into water and dioxygen; they show very high catalase activity exhibiting saturation kinetics in the presence of NaOH. The rate and turnover number of the catalyzed reaction increase dramatically when a few equivalents of base (NaOH) are added to the reaction mixture. The turnover numbers for hydrogen peroxide disproportionation increase from approximately 200 to more than 1500 per manganese ion in less than 2 min for both complexes after addition of a few equivalents of NaOH. Kinetic studies of the catalyzed reaction performed on the dinuclear complex **1** in the presence of 5 equiv. of NaOH, gives k_{cat} = 807 s^{-1} (± 16) and K_M = 0.091 M (± 0.003). The effective catalytic efficiency is k_{cat}/K_M = 8900 $M^{-1}s^{-1}$. The kinetic parameters of the mononuclear complex **2** in the presence of 5 equiv. of NaOH, are k_{cat} = 190 s^{-1} (± 4) and K_M = 0.022 M (± 0.001). The effective catalytic efficiency is k_{cat}/K_M = 8600 $M^{-1}s^{-1}$. The catalase activity of the mononuclear complex, $[Mn(mesalim)_2Cl]$ (**3**) has also been studied, and it shows turnover numbers that are comparable to those of complex **2**. ESI-MS analyses in deuterated solvents have been used to understand the nature of the active species formed on addition of 5 equiv. of NaOH.

Introduction

Manganese is present in the active sites of enzymes, such as superoxide dismutase (SOD), manganese catalase, extradiol dioxygenase, arginase and ribonucleotide reductase, the oxygen-evolving complex (OEC) of photosystem II (PSII), and lipoxygenase.[1] The mechanisms of action of these enzymes are very diverse and include oxo atom transfer (SOD, catalase, extradiol dioxygenase), the reduction of ribonucleotides to water and deoxyribonucleotides, the oxidation of thiosulfate to sulfate and the four-electron oxidation of water to dioxygen in Photosystem II.[2] The principal mechanism of defense of living cells makes use of superoxide dismutase or catalase enzymes to protect the cell structure against harmful and reactive oxygen species, such as superoxide radicals or dihydrogen peroxide. In addition to widely distributed heme-type catalases, a second class of relatively rare manganese catalases has been found in three bacteria, *Lactobacillus plantarum*,[3] *Thermus thermophilus*,[4] and *Thermoleophilium album*.[5] A dinuclear active site is present in these Mn-catalases, possessing either a $Mn^{II}-Mn^{II}$ or $Mn^{III}-Mn^{III}$ dimer bridged by a μ-(1,3)-carboxylate from glutamate and two μ-oxo bridges from solvent molecules that electronically couple the metal centers. The rate of oxygen evolution by these enzymes is very high, i.e. of the order of 10^5 to 10^6 molecules per second.[6]

There is high interest in understanding the chemistry of dinuclear manganese complexes, as much structural and mechanistic information regarding the activity of the enzyme could be obtained through studies on model complexes.[7,8] The interaction of hydrogen peroxide and dioxygen with dinuclear manganese complexes has been studied in detail by various groups using several structural as well

as functional model complexes.[9−11] Interaction of metal complexes of Schiff-base ligands with hydrogen peroxide has been a matter of study for a long time now, for many of these have been shown to be good oxidation catalysts[12] or enzyme mimics.[10,13,14]

In this paper, we report the synthesis, full characterization and catalase activity of two manganese complexes, $[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (**1**), and $[Mn(mesalim)_2(OAc)(MeOH)]\cdot MeOH$ (**2**), in which Hmesalim and Hetsalim are methyl and ethyl salicylimidate, respectively (shown in Figure 1). We also report the catalase studies on the complex $[Mn(mesalim)_2Cl]$ (**3**), the crystal structure of which has been recently reported.[15] In addition, a comparison of the structural and spectroscopic characteristics of the three complexes is made. The Hmesalim ligand is commonly used in organic syntheses as a precursor for several other ligands, such as oxazolines.[16] The transition-metal coordination chemistry of this simple ligand is, however, completely unexplored.

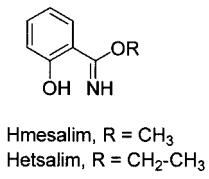

Figure 1. The ligands Hmesalim and Hetsalim

Results and Discussion

Synthetic Aspects

The ligand Hmesalim has been known for over 30 years and is commonly used as a precursor for the synthesis of heterocyclic ligands. Surprisingly, it has very rarely been used in transition metal chemistry. The coordination chemistry of this ligand, however, appears to be very rich.[17] Reaction of $Mn(ClO_4)_2$ with Hmesalim in ethanol unexpectedly results in the formation of the dinuclear, phenoxo bridged complex **1**, in which the methoxy group on the ligand is exchanged with the solvent ethoxy group. ESI-MS analyses of a solution of the ligand Hmesalim in ethanol shows two peaks, one for Hmesalim and another for Hetsalim, indicating that the presence of a Lewis acid is not necessary for solvolysis to occur. The complex **1** was synthesized by initially dissolving the Hmesalim ligand in ethanol, thus, in fact by the reaction of the manganese salt with Hetsalim formed (in situ). The mesalim-analog of **1** might also be formed in the solution but complex **1** is the sole product isolated from the reaction mixture. When the reaction is performed in methanol a green product is isolated, which has an IR spectrum similar to that of the complex **1**, but crystals good enough for structure determination could not be obtained and the product did not give good elemental analyses. The synthesis of complex **2** is more complicated. The recrystallization of a concentrated solution of the reaction mixture, by slow evaporation or ether diffusion, gave the complex **2** in pure form. Recrystallization of a dilute solution led to the formation of several polynuclear manganese clusters over time, thus making the isolation of this pure mononuclear compound difficult. In fact two novel clusters, a hexanuclear cluster with an interesting double-cubane structure, and another octanuclear cluster have been isolated and crystallographically characterized after attempts at recrystallization of the mononuclear complex **2**.[17]

Description of the Crystal Structures

The X-ray structures of the two new manganese complexes, $[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (**1**), and $[Mn(mesalim)_2(OAc)(MeOH)]$ (**2**) have been determined. Numerical data and details of the data collection and refinement are presented in Table 1.

A PLUTON projection of the dinuclear complex **1** is shown in Figure 2. Selected bond lengths and angles are given in Table 2. The molecule is located on an inversion center. Each manganese(II) ion is bound by four different etsalim ligands, in a distorted octahedral N_2O_4 geometry. Two *trans*-chelating ligands, one of which participates in a μ-phenoxo bridge to the other manganese center, form the equatorial plane of the octahedron. One axial site is occupied by the phenolate oxygen atom of a terminally binding ligand and the other by bridging phenolate oxygen from the symmetry-related manganese center.

The Mn−O and Mn−N distances are comparable to other Mn^{III} complexes of this type that are known in the literature.[18] The axial Mn−O(57) an Mn−O(17a) distances are considerably longer (0.2−0.4 Å) than the Mn−O(phenolate) distances in the equatorial plane. There are two μ-phenoxo bridges in the dinuclear core, separating the two manganese ions at a distance of 3.3705(5) Å. This distance is within the normal range of phenoxo-bridged Mn^{III} complexes.[18] The Mn(1)−O(17)−Mn(1a) angle of 103.99(6)° is also similar to those in Mn^{III}-salen com-

plexes.[18] Protonation of the imine nitrogen atoms on the two terminal ligands leaves two positive charges on the complex that are balanced by two perchlorate ions present in the crystal lattice. Each of the imine groups is involved in hydrogen bonding with perchlorate ions in the crystal lattice. The free imine group of the terminal ligand participates in an additional intramolecular hydrogen bond with the coordinated phenolate oxygen atom of the same ligand. (Table 4) (see Figure 1 in the Supporting Information; for Supporting Information see also the footnote on the first page of this article).

A PLUTON projection of the mononuclear complex **2** is shown in Figure 3. Selected bond lengths and angles are given in Table 3. The manganese(III) ion has a distorted octahedral N_2O_4 coordination environment. Two chelating mesalim ligand molecules are bound to the metal atom, *cis* to each other in a square plane. A methanol and a monodentate acetate molecule occupy the two remaining apical positions and complete the octahedron. The Mn−N and Mn−O distances involving the mesalim ligand are slightly longer than those in the complex $[Mn(mesalim)_2Cl]$ (**3**),[15] perhaps because the ligands are involved in extensive hydrogen bonding interactions. A PLUTON view of the hydrogen bonding in the crystal lattice is shown in Figure 4, and geometric parameters for the intermolecular hydrogen bonding interactions are listed in Table 4. The complex molecules are paired in a head-to-tail arrangement to form a dimer. Both oxygen atoms from the monodentate acetate ion of each complex molecule form bifurcated hydrogen bonds to each of the two *cis*-imine nitrogen atoms on the neighboring complex molecule and vice versa. Thus, the axially coordinated acetate molecule seems to enforce a *cis* coordination of the mesalim ligands to allow strong hydrogen bonding. The non-coordinated acetate oxygen atom of each complex molecule forms an additional hydrogen bond to the methanol molecule of a neighboring dimer and vice versa. The metal complex cocrystallizes with one independent molecule of methanol. The methanol solvent molecule undergoes intermolecular hydrogen bonding with itself, forming a six-membered ring. A view down the [001] direction of **2**·MeOH is presented in Figure 5.

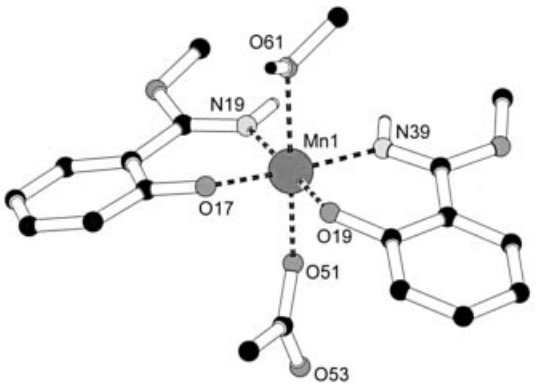

Figure 3. PLUTON projection of $[Mn(mesalim)_2(OAc)(MeOH)]$ (**2**); hydrogen atoms except those attached to nitrogen atoms and methanol are omitted for clarity

Spectroscopic Studies

Complexes **1** and **2** display ligand field bands that are very similar in position. The molar extinction coefficients of **1** are, however, approximately the double of those of absorption intensities of the mononuclear complex **2** because of the presence of two manganese centers and six ligands. In both complexes the peak at 304 nm is assigned to π-π* transitions within the ligands, because of its high intensity ($> 10^4$ $M^{-1}cm^{-1}$). The high-intensity band at 357 nm and shoulder at 418 nm can be assigned to the LMCT transition from the phenoxo oxygen to Mn^{III}.[19−21] The low-intensity peak at 567 nm ($\varepsilon = 277$ $M^{-1}cm^{-1}$ in the mononuclear complex and $\varepsilon = 400$ $M^{-1}cm^{-1}$ in the dinuclear complex) can be assigned to a d-d transition.[19] As the position of this

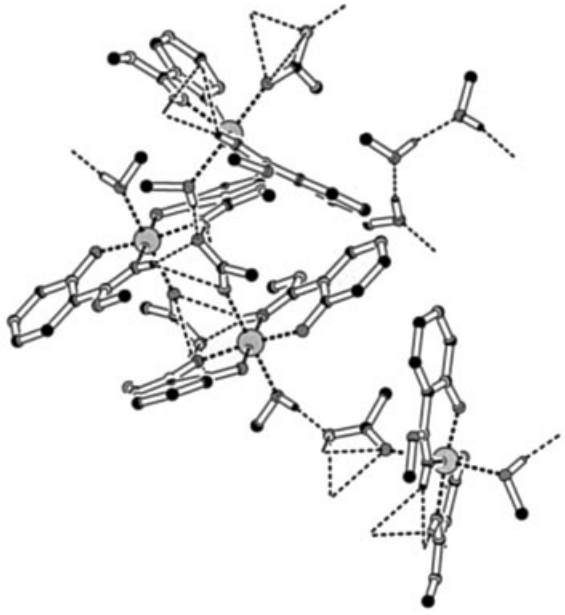

Figure 4. PLUTON projection of hydrogen bonding in [Mn(mesalim)$_2$(OAc)(MeOH)] (**2**)

band is independent of the anions,[15] it can be assigned to the $d_{xy} \rightarrow d_{x^2y^2}$ transition.[19] In addition to these bands complex **1** also shows a weak absorption at 976 nm (ε = 76 $M^{-1}cm^{-1}$). A band similar to this has also been reported for the dinuclear complex, $[Mn_2O(O_2CCH_3)_2(tacn)_2]^{2+}$, which has a band at 990 nm (ε = 28 $M^{-1}cm^{-1}$).[22] This band can be compared to that of manganese catalase from *Thermus thermophilus* also, where a broad tail is observed going into the near-IR region and a d-d transition is centered at approximately 492 nm.[23]

The IR spectrum of the free ligand displays a broad peak characteristic of the phenol O−H at 2538 cm^{-1}. The imine C=N frequency in the free ligand occurs at 1653 cm^{-1} and shifts to 1615−1605 cm^{-1} after complexation to Mn in all complexes. The presence of the perchlorate anion in the complex **1** is confirmed by a very intense band at 1088 cm^{-1}. For both complexes **1** and **2**, N−H stretching vibrations are seen at 3278 cm^{-1} and 3175 cm^{-1}, respectively. For complex **2**, the acetate vibrating modes could not be

exactly assigned because several ligand peaks were present in the region. Room temperature magnetic measurements for all complexes are consistent with the presence of Mn^{III}. Variable temperature magnetic susceptibility measurements were performed for complex **1**, and a plot of the effective magnetic moment versus temperature is shown in Figure 6. The steep decrease in magnetic moment at temperatures below 25 K is due to the zero-field splitting typical for Mn^{III} ions.

Catalase Activity and Kinetics

The catalase activity of three complexes $[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (**1**), $[Mn(mesalim)_2(OAc)(MeOH)]\cdot MeOH$ (**2**·MeOH) and $[Mn(mesalim)_2Cl]$ (**3**)[15] has been studied, both in the presence and absence of different amounts of sodium hydroxide (NaOH), because the enhancing effect of small amounts of NaOH on catalase activity has been reported recently.[24] Addition of hydrogen peroxide to alcoholic solutions of the new manganese−mesalim and −etsalim complexes leads to vigorous evolution of dioxygen. The green solutions of the complexes turn brown when NaOH is added, and when subsequently H_2O_2 is added to these alkaline solutions, the reaction mixture turns from brown to colorless, with a brown precipitate, meanwhile showing even more vigorous evolution of dioxygen. The total conversion of hydrogen peroxide disproportionation was measured using a manometric method, while the kinetic studies were performed on the basis of fluorescence quenching using an oxygen sensor.[11,25] The total catalytic activity as well as the rate of the reaction increases significantly when a few equivalents of NaOH are added. In Table 5 the turnover numbers for the disproportionation of H_2O_2 by the manganese complexes in the presence and absence of NaOH are compared. It is interesting to note that the mononuclear complexes **2** and **3** also show very high catalase activity and reach comparable turnovers of manganese ion per minute (TON ≈ 1500) as the dinuclear complex. In fact, the mononuclear complex **2** shows even higher turnover per manganese ion (1800) than the dinuclear complex **1** (1575). The complexes **2** and **3** show very similar catalase activity, possibly indicating that a similar active species is formed. A plot of the percentage conversion of hydrogen peroxide for complex **1** followed in time as a function of the amount of NaOH that is added is shown in Figure 7. The highest initial rate is observed when 5 equiv. of NaOH are added. When 7 equiv. of NaOH are added, the initial rate is lower than for 5 equiv. of NaOH, but the catalyst is active for a longer time, which results in turnover numbers above 3000 for complex **1** and 5 equiv. of NaOH in less than 2 min. A similar observation of a breakpoint in the rate acceleration when 5 equiv. of NaOH are added has been reported previously.[24] When more hydrogen peroxide is added at the end of a reaction, only very slow evolution of dioxygen occurs, indicating that the catalyst has decomposed. The reactions reach completion within the first two minutes. No lag phase is observed for the reaction with or without addition of NaOH. The blank reaction performed with Mn^{II} perchlorate yields only 190 turnover numbers in total after 4 min even in the presence of 5−6 equiv. of NaOH, while no reaction is observed in the absence of NaOH.

The kinetics for the catalase reaction of the two complexes **1** and **2** has been studied. Figure 8 shows saturation kinetics for the two complexes **1** and **2** in combination with 5 equiv. of NaOH each. Figure 9 shows Lineweaver−Burk plots of the two systems, demonstrating a linear relationship between the rate of substrate disproportionation and substrate concentration for both systems, from which the Michaelis−Menten parameters can be extracted. For the system consisting of complex **1** and 5 equiv. of NaOH, k_{cat} = 807 s^{-1} (± 16) and K_M = 0.091 M (± 0.003), and k_{cat}/K_M = 8900 $M^{-1}s^{-1}$ (Figure 9, a), and for the system consisting of complex **2** and 5 equiv. of NaOH, k_{cat} = 190 s^{-1} (± 4), K_M = 0.022 M (± 0.001), and k_{cat}/K_M = 8600 $M^{-1}s^{-1}$ (Figure 9, b). A comparison of the kinetic parameters for the two systems, **1** and 5 equiv. of NaOH and **2** and 5 equiv. of NaOH, shows that, in fact both of them have similar catalytic efficiency. The value of k_{cat}, the turnover efficiency of the complex **2** and 5 equiv. of NaOH system, is actually lower than the complex **1** and 5 equiv. of NaOH system, but this is compensated by the very low K_M value. Thus, the ratio k_{cat}/K_M becomes similar to that of complex **1** and 5 equiv. of NaOH. Apparently, the two complexes catalyze the reactions probably by different mechanisms, but ultimately reach similar catalytic efficiency. The nature of the mechanisms however, cannot be anticipated at the present moment. The complexes themselves, without addition of NaOH, also show good catalase activity (Table 5) but their Michaelis−Menten parameters could not be determined as they did not give saturation kinetics for the range of hydrogen peroxide concentrations studied.

Spectroscopic Studies on the Catalyst Solution

Ligand field spectra of complex **1** taken during stepwise addition of NaOH show small but clear changes with three distinct isosbestic points at 310, 350 and 392 nm. On addition of 1 and 2 equiv. of NaOH, hardly any changes are observed in the spectrum of complex **1**. On addition of successive equivalents of NaOH (3−10 equiv.), the peaks at 330 nm start growing in intensity and the peaks at 357, 418 and 565 nm decrease in intensity. At 5 equiv. of NaOH added, the same trend continues, and no new clearly defined peaks are formed. On addition of more equivalents of NaOH, the peak at 330 nm is of high intensity,[19−21] and the spectrum from 400 to 700 nm appears as a broad tail going into the visible region. A brown precipitate appears concomitantly in the solution, indicating degradation of the complex.

A frozen solution EPR spectrum of a reaction mixture containing only complex **1** and hydrogen peroxide in ethanol taken 3 minutes after the addition of hydrogen peroxide (i.e after the reaction has finished) shows a six-line signal typical of Mn^{II} (g = 2.01, A = 90 G). No EPR signal can be detected, however, after the stepwise addition of NaOH to a solution of **1**, nor after the subsequent addition of hydrogen peroxide, suggesting that manganese(II) or mixed-

Table 5. Disproportionation of hydrogen peroxide by the three Mn−mesalim complexes (TON = Turnover number; moles of substrate molecules converted per mol of the catalyst)

Complexes[a]	TON in H_2O_2 (without NaOH)	TON in H_2O_2 (5 equiv. NaOH)	Conversion (%) (5 equiv. NaOH)
$Mn(ClO_4)_2$	0[b]	190[b]	48%
$[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2]$ (**1**)	180	3150[c]	90%
$[Mn(mesalim)_2(OAc)(MeOH)]$ (**2**)	350	1810	91%
$[Mn(mesalim)_2Cl]$ (**3**)	270	1360	68%

[a] Reaction conditions: 1 mL of a 1 mM solution of the catalyst in methanol (**2**) or ethanol (**1**), H_2O_2 = 2 mmol, room temp., turnovers after 3 min (catalyst/H_2O_2 = 1:2000). [b] 5 mL of a 1 m M catalyst solution used (catalyst/H_2O_2 = 1:400). [c] 3.5 mmol of H_2O_2 used (catalyst/H_2O_2 = 1:3500).

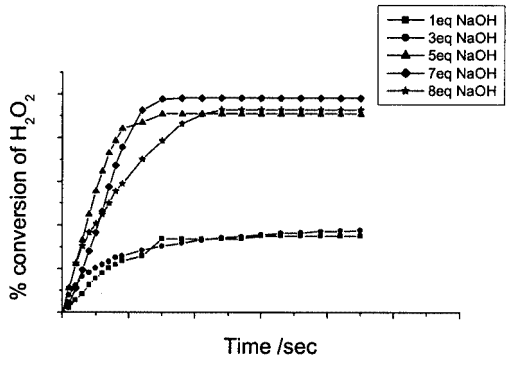

Figure 7. Conversion of H_2O_2 vs. time, with successive amounts of NaOH added; catalyst = complex **1** (1 μmol) and 3.18 mmol of H_2O_2 in 1 mL of ethanol

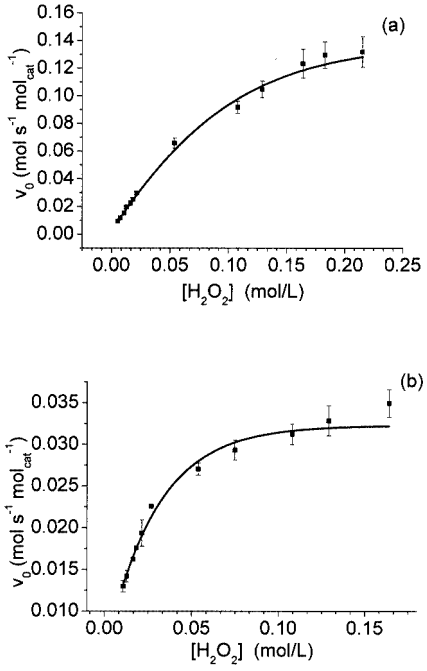

Figure 8. (a) Initial rate of substrate conversion versus substrate concentration at constant concentration of $[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (**1**) + 5 equiv. NaOH in ethanol and (b) $[Mn(mesalim)_2(OAc)(MeOH)]$ (**2**) + 5 equiv. NaOH in methanol

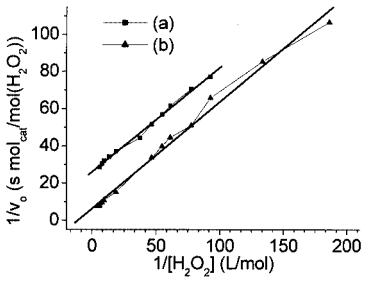

Figure 9. Lineweaver−Burk plot for (a) $[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (**1**) + 5 equiv. NaOH in ethanol, and (b) $[Mn(mesalim)_2(MeOH)(OAc)]$ (**2**) + 5 equiv. NaOH in methanol

valent manganese(III)/(IV) species are not formed in this case.

Positive mode ESI-MS analysis was used to understand the nature of the species formed on addition of NaOH to a solution containing complex **1**. To assist the assignment of peaks, the spectra were also measured from the solution of the complex prepared in [D_6]ethanol (C_2D_5OD). Nondeuterated ethanol was used as the solvent for elution. A part of the complex ions undergo exchange with deuterated ethanol, and because of this, a pattern of lines with species ranging from nondeuterated, partly deuterated to completely deuterated complex ions can be observed. Analyzing the pattern of the peaks, it is clear that the ethoxy group on the ligand is rather labile, and in the metal complex it exchanges rapidly with the ethoxy group of the solvent ethanol, consistent with the earlier observation during complex synthesis (see above). Tables listing full details, relative intensities and assignments are available as Supporting Informations.

A solution of complex **1** in ethanol exhibits peaks at 383.15 $[Mn^{III}(etsalim)_2]^+$, 429.22 $[Mn^{III}(etsalim)_2(EtOH)]^+$, 811.35 $[Mn_2^{III}(etsalim)_4(EtOH)-H^+]^+$ and 865.30 $\{[Mn_2^{III}(etsalim)_4](ClO_4)\}^+$. The presence of the latter two peaks suggests that the dinuclear core of the complex does persist in the solution. In deuterated ethanol the complex shows clusters of peaks at 383.15 $[Mn^{III}(etsalim)_2]^+$, 388.19 $[Mn^{III}(etsalim)([D_5]etsalim)]^+$ and 393.19 $[Mn^{III}([D_5]-etsalim)_2]^+$ and at 429.23 $[Mn^{III}(etsalim)_2(EtOH)]^+$, 434.26 $[Mn^{III}(etsalim)([D_5]etsalim)(EtOH)]^+$ and 439.29 $[Mn^{III}-$

$([D_5]etsalim)_2(EtOH)]^+$, as well as 5-line patterns for the dinuclear species in the ranges 811−831 and 865−885.

ESI-MS spectra of complex **1** and 5 equiv. of NaOH in ethanol reveal peaks at 451.26 $\{Na[Mn(etsalim)_3(EtOH) - H^+]\}^+$, 497.28 $\{Na[Mn(etsalim)_2(EtOH)_2 - H^+]\}^+$, 570.35 $\{Na[Mn(etsalim)_3]\}^+$, 787.47 $\{Na[Mn_2(etsalim)_4 - 2 H^+]\}^+$, 833.46 $\{Na[Mn_2(etsalim)_4(EtOH) - H^+]\}$, 850.57 $\{Na[Mn_2(etsalim)_4(EtOH)(O)]\}^+$, and 952.57 $\{Na[Mn_2(etsalim)_5 - H^+]\}^+$. The most interesting observation after addition of NaOH is the peak at 850.57, which is tentatively assigned to a dinuclear Mn−μ-oxo species. These assignments were all confirmed by the presence of the respective multi-line signals in the ESI-MS spectra with deuterated ethanol and NaOH in D_2O. Furthermore, in the deuterated solvent a group of peaks of low intensity at 959−974 is observed, which could possibly be assigned to a di-μ-oxo species, $\{Na^+[Mn_2^{IV}(etsalim)_4(EtOH)_3(O)_2]\}^+$. However, this species was not observed in nondeuterated ethanol which unfortunately makes unambiguous assignment of these peaks not possible. Addition of hydrogen peroxide to this reaction mixture did not give rise any other peaks in the ESI-MS spectrum, as most of it was degraded before the active species could be measured.

Discussion and Comparison to Other Systems

The k_{cat} and K_M values for the complexes **1** and **2** in combination with 5 equiv. of NaOH, can be compared to those of $[Mn(bpia)(\mu\text{-}OAc)]_2(ClO_4)_2$ [bpia = bis(pyridylmethyl)(*N*-methylimidazol-2-ylmethyl)amine] which are k_{cat} = 1100 s^{-1}, K_M = 31.5 mM and k_{cat}/K_M = 34000 $M^{-1}s^{-1}$.[11] The present complex **1** or **2** and 5 equiv. of NaOH systems show the second best activity that has been reported until now for the manganese catalase mimics with the Mn(bpia) system in the first position. For the present studies, addition of a few equivalents of base was used successfully for increasing the catalase activity as has already been reported for other systems.[24] The rate acceleration on addition of NaOH possibly correlates with the availability of an intramolecular hydroxide for substrate deprotonation and with binding of the substrate at the bridging site between Mn ions in the reductive O−O bond-cleavage step.[24] After addition of NaOH, there might be μ-oxo or μ-hydroxo bond formation between the two manganese ions as is demonstrated by the use of sodium hydroxide for the syntheses of several μ-oxo-bridged, dinuclear manganese complexes.[26] For the $[Mn(2\text{-}OH\text{-}salpn)]_2$ (k_{cat} = 4-22 s^{-1}) and $[Mn_2(salpn)O_2]$ (k_{cat} = 2500 s^{-1}) systems [salpn = *N*,*N*′-bis(salicylidene)-1,3-diaminopropane and 2-OH-salpn = *N*,*N*′-bis(salicylidene)-2-hydroxy-1,3-diaminopropane], the rate increases tremendously when the alkoxo-bridged dimer is replaced by a μ-oxo-bridged manganese dimer.[10] NaOH and *N*-methylimidazole were studied as bases in the catalase reaction with the manganese-mesalim and -etsalim complexes. Both bases increased the total conversion as well as the rate of the catalase reaction. The present system also gives higher catalytic efficiency than the recently reported $[Mn_2(L)_2Cl_2]$ system {L = 2-[bis(pyridin-2-ylmethyl)aminomethyl]-6-methoxyphenol}.[25]

The ligand field spectra recorded upon successive additions of NaOH indicate that the LMCT bands (300 nm and 360 nm) show clear changes with isosbestic points due to formation of one species from the original complex. Addition of more than 5 equiv. of NaOH results in formation of a precipitate, and the ligand field spectrum becomes broadened. ESI-MS analysis proved to be a useful tool for the interpretation of the species formed on addition of NaOH to the complex solution. The first role of NaOH may be to withdraw the proton on the imine nitrogen atom and thus make the complex more oxidizable. The removal of the proton from the imine nitrogen atom is evident from the peaks at 787.14 $\{Na^+[Mn_2(L)_4 - 2 H^+]\}^+$ and at 833.18 $\{Na^+[Mn_2(L)_4(EtOH) - 2 H^+]\}$ on addition of 5 equiv. of NaOH to the complex **1** solution, where both or at least one proton has to be withdrawn from the imine nitrogen atom on the etsalim ligand. The only species that could give a hint to the μ-oxo species formation was observed at 850.57, which could be assigned to a μ-oxo-bridged species with a relative intensity of 10%. Dinuclear Mn^{III}/Mn^{III} species have been proposed to be the active catalysts for H_2O_2 disproportionation in several manganese catalases as well as functional catalase model complexes. X-band EPR spectra recorded at 77 K did not show the formation of a Mn^{IV} species or a mixed-valent Mn^{II}/Mn^{III} or Mn^{III}/Mn^{IV} species, neither after addition of NaOH nor immediately after addition of hydrogen peroxide (i.e. during catalytic turnover). A brown precipitate that is insoluble in many solvents, characteristic of MnO_2, is formed at the end of the reaction. Thus, the catalytically inactive species formed at the end of the reaction is probably due to the decomposition of the metal complex to form insoluble Mn^{IV} oxides.

Conclusion

In this study the synthesis, crystal structures, full characterization and catalase studies of three manganese complexes have been presented. It has been shown that complexes **1**−**3** in combination with 5−6 equiv. of NaOH show very high catalase activity and are only surpassed by the Mn−bpia system reported by Krebs and co-workers.[11] However, compared to the Mn−catalase enzyme, the k_{cat} value is still 20−30 times lower than the manganese−catalase enzymes and thus the catalytic efficiency (k_{cat}/K_M) is still 200−300 times lower than that of the manganese−catalase enzymes. The turnover as well as the rate of the reaction increase remarkably with the addition of a few equivalents of NaOH to the catalyst solution. The complexes in combination with a few equivalents of sodium hydroxide (NaOH) are among the few catalase model systems that show turnover numbers up to 3000 in hydrogen peroxide disproportionation. ESI-MS analyses in deuterated solvents have been used to understand the nature of the active species formed on addition of 5 equiv. of of NaOH. The exact nature of the active species participating

during turnover, however, could not be confirmed at the present moment.

Experimental Section

Physical Measurements: UV/Vis/NIR measurements were performed with a Perkin−Elmer Lambda 900 UV/Vis/NIR spectrometer. IR spectra were recorded with a Perkin−Elmer FT-IR Paragon 1000 spectrometer. ^{1}H NMR spectra were recorded with a Bruker 300 DPX MHz spectrometer. Elemental analyses were performed with a Perkin−Elmer series II CHNS/O analyzer 2400. EPR measurements were performed at 77 K using a Jeol Esprit RE-2X spectrometer with a Jeol Esprit 330 ESRE data system. EPR *g* values were determined relative to DPPH as an external "*g*-marker" (g = 2.0037). Electrospray mass spectra were recorded with a Thermo Finnigan AQA apparatus. All solvents were of analytical grade and used without further purification unless stated otherwise.

Catalase Activity: Two different methods were carried out to get the turnover number, k_{cat}, the Michaelis constant, K_M, and k_{cat}/K_M. In the first experiment an aqueous solution of H_2O_2 was added to a solution of the complex at room temperature. Dioxygen evolution was observed instantaneously and monitored manometrically. In a typical experiment, to find out the total conversion of dihydrogen peroxide, H_2O_2 (2 mmol, 2000 equiv., 0.17 mL of a 35% aqueous solution) was added to the complex (1 mL of a 1 mM solution in EtOH for **2** and in MeOH for **1** and **3**) at room temperature. Dioxygen evolution was observed instantaneously and monitored manometrically. Initial rate measurements were performed by plotting the volume of dioxygen evolved versus time in seconds.

Kinetic Measurements: In the second experiment, for the kinetic studies, an optical oxygen sensor was used to measure the initial rates of the H_2O_2 decomposition. The complex was added to an aqueous H_2O_2 solution of increasing concentration and the initial rate was recorded. The data were fitted into the Michaelis−Menten equation, and the turnover number, k_{cat}, the Michaelis constant, K_M, and k_{cat}/K_M were determined from the double reciprocal Lineweaver−Burk plot (Figure 9). K_M is a criterion for substrate affinity, the turnover number, k_{cat}, can be interpreted as the rate of substrate conversion into the corresponding products and k_{cat}/K_M is a criterion for catalytic efficiency.

Syntheses: ***Caution:*** *Perchlorate salts are potentially explosive and should be handled with appropriate care!* The following abbreviations are used throughout the text: Hmesalim = methyl salicylimidate, Hetsalim = ethyl salicylimidate. All reagents and solvents were used as received with no attempt to remove water or molecular oxygen. The ligand Hmesalim was synthesized according to a published procedure.[16,27,28]

$[Mn_2(etsalim)_4(Hetsalim)_2](ClO_4)_2$ (1): The ligand Hmesalim (0.2 g, 1.32 mmol) was dissolved in absolute EtOH (10 mL). Manganese(II) perchlorate (0.108 g, 0.44 mmol) was added to the solution. The solution was stirred for 15 min and filtered. Green crystals were obtained after a few days by layering the reaction mixture with diethyl ether and hexane. Yield of crude product: 55% (0.156 g). UV/Vis (CH_3CN): $\lambda_{max.}$ (ε [$M^{-1}cm^{-1}$]) = 304 (38×10^3), 357 (20×10^3), 418 (2400), 565 (400), 971 (76) nm. IR (diamond): $\tilde{\nu}$ = 3268 (m), 1606 (s), 1588 (s), 1455 (s), 1399 (s), 1214 (m), 1088 (vs), 959 (m), 868 (m), 758 (s), 618 (s), 523 (s), 427 (s) cm^{-1}. $C_{27}H_{31}ClMnN_{30}O_{10}$ (1295.88): calcd. C 50.05, H 4.82, N 6.4; found C 50.0, H 5.07, N 6.67. μ_B = 4.8 BM per manganese(III). MS (ESI): m/z = 383 $[Mn^{III}(etsalim)_2]^+$, 429.22 $[Mn(etsalim)_2(EtOH)]^+$, 811.35 $[Mn_2(etsalim)_4(EtOH) - H^+]^+$, 865.30 $[Mn_2^{III}(etsalim)_4(ClO_4)]^+$.

$[Mn(mesalim)_2(OAc)(MeOH]\cdot MeOH$ (2): The ligand Hmesalim (1.85 g, 12.25 mmol) was dissolved in absolute MeOH (10 mL). Manganese(II) acetate (1 g, 4.08 mmol) was added to the solution, and the solution was stirred for 15 min. Then diethyl ether (20 mL) was added to the solution, and again the reaction mixture was stirred for 15 min. The solution was filtered, and crystals were grown in a few days by layering the MeOH/ether solution with hexane. Yield of crude product: 61.5% (1.2 g) UV/Vis (CH_3CN): $\lambda_{max.}$ (ε [$M^{-1}cm^{-1}$]) = 304 (16×10^3), 353 (9×10^3), 411 (1860), 562 (277) nm. IR (diamond): $\tilde{\nu}$ = 3446 (m), 3167 (m), 1609 (s), 1590 (s), 1542 (vs), 1452 (s), 1412 (s), 1330 (m), 1231 (vs), 1158 (s), 1098 (s), 863 (s), 748 (s), 626 (s), 492 (s) cm^{-1}. $C_{19}H_{23}MnN_2O_7\cdot 2MeOH$ (510.42): calcd. C 49.42, H 6.12, N 5.49; found C 49.12, H 6.51, N 5.86. μ_B= 4.6 BM. MS (ESI): m/z = 354.5 $[Mn^{III}(mesalim_2)]^+$, 415 $\{[Mn(mesalim)_2(OAc)] + H^+\}^+$, 447 $\{[Mn(mesalim)_2(OAc)(MeOH)] + H^+\}^+$ and 506 $\{[Mn(mesalim)_3] + H^+\}^+$.

X-ray Crystallographic Study: Intensity data for single crystals of **1** and **2** were collected at 150 K using graphite-monochromated Mo-K_α radiation, with a Nonius Kappa CCD diffractometer on rotating anode. A correction for absorption was considered unnecessary in the case of **1**. For **2**, a multi-scan absorption correction was applied using PLATON/MULABS (0.678−0.903 transmission range).[29] The structures were solved by direct methods using SHELXS-97[30] (**1**) or SIR97[31] (**2**), and refined on F^2 using SHELXL-97.[30] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms, and in particular those attached to nitrogen and oxygen atoms, were positively identified in a difference Fourier map. The position of the hydroxy hydrogen atom of the coordinated methanol molecule in **2** was refined with a restraint on the O−H distance. All other hydrogen atoms were constrained to idealized geometries and allowed to ride on their carrier atoms. All hydrogen atoms were refined with an isotropic displacement parameter related to the equivalent displacement parameter of their carrier atoms. Structure validation and preparation of molecular graphics were performed with the PLATON package.[29] CCDC-244114 (**1**) and -244115 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Anionic Phosphane − A New Ligand with a Phosphane and a Weakly Coordinating Heteroborate Moiety

Benno Ronig,[a] Herbert Schulze,[a] Ingo Pantenburg,[a] and Lars Wesemann*[b]

Dedicated to Professor Ekkehard Lindner on the occasion of his 70th birthday

Keywords: Boranes / Cluster compounds / Phosphane ligands / Tin

Reaction of chloropropyl-substituted stanna-*closo*-dodecaborate $[Cl(CH_2)_3SnB_{11}H_{11}]^-$ with the nucleophile $Li[CH_2PPh_2]$ provided a straightforward synthesis of an anionic phosphane $[Ph_2PCH_2SnB_{11}H_{11}]^-$. Derivatization of the phosphane was carried out in reaction with sulfur and hydrochloric acid to give $[Bu_3MeN][Ph_2P(S)CH_2SnB_{11}H_{11}]$ and the zwitterion $[Ph_2P(H)CH_2SnB_{11}H_{11}]$. In reaction with various transition metal electrophiles, complexation reactions were accomplished resulting in the isolation of *trans*-substituted palladium and platinum complexes $[Bu_3MeN]_2[trans\text{-}(Ph_2PCH_2SnB_{11}H_{11})_2MCl_2]$ (M = Pd, Pt), a neutral silver adduct $[(acetone)Ag(Ph_2PCH_2SnB_{11}H_{11})]$, and a linearly coordinated bisphosphane of gold $[Bu_3MeN][Au(Ph_2PCH_2\text{-}SnB_{11}H_{11})_2]$. The solid state structures of the ligand salt, the palladium and gold coordination compounds were determined and discussed.

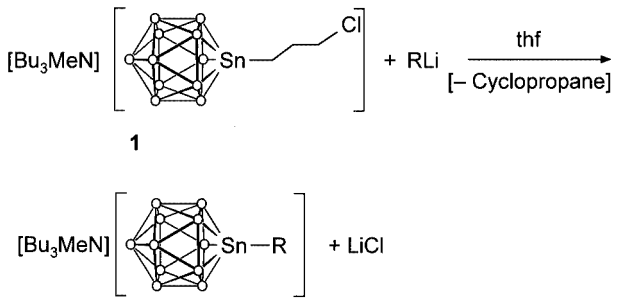
Introduction

In coordination chemistry phosphane ligands play a key role and are often used to control the properties of a certain transition metal complex. Phosphanes with an ionic moiety like sulfonate, carboxylate, ammonium or phosphonium are of interest for the synthesis of coordination compounds soluble in very polar solvents for two-phase catalysis purposes.[1] Recently Peters started to study systematically the coordination chemistry of monoanionic phosphane ligands provided with a tetracoordinated boron atom in the backbone of the ligand. Zwitterions with a cationic transition metal center have been isolated with chelating phosphides.[2−6] With the synthesis of the aluminate $Li[Al(CH_2PMe_2)_4]$ Karsch et al. found an anionic tetradentate phosphide.[7] Substitution reactions at the boron atom of borabenzene−trimethylphosphane with $K[PPh_2]$ resulted to give the phosphide $K[C_5H_5BPPh_2]$ in excellent yield.[8] Syntheses of monoboranephosphides $[R_2PBH_3]^-$ and examples for their coordination at Li, Al, Fe, Pd, and Pt can also be found in the literature.[9] Another class of anionic phosphanes, having a heteroborate as the anionic moiety, were presented by Teixidor.[10−11] Two diphenylphosphane groups are connected at the carbon atoms of the 7,8-dicarba-*nido*-undecaborate framework. This bis(diphenylphosphanyl)borate was shown to be a versatile ligand in transition metal chemistry.

Our group is interested in the coordination chemistry of ligands with a typical donor function and a weakly coordinating anionic moiety. Here we present a synthesis for a phosphane ligand connected at an anionic *closo*-heteroborate cluster.

Results and Discussion

Recently we found a method for the nucleophilic substitution at monoanionic alkylstanna-*closo*-dodecaborate.[12] Attack at the γ-chloropropyl-substituted cluster **1** with strong nucleophiles like RLi or RMgX resulted in the isolation of derivatives $[RSnB_{11}H_{11}]^-$ together with the formation of cyclopropane and the chloride anion as the leaving groups (Scheme 1).



Scheme 1. Nucleophilic substitution at the tin vertex with strong nucleophiles

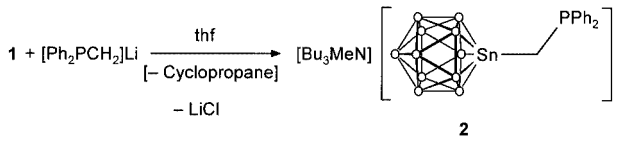
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200400636**

This method was transferred to the preparation of a new phosphane ligand by reacting the γ-chloropropyl-substituted heteroborate **1** with the anion $[Ph_2PCH_2]^-$ (Scheme 2).



Scheme 2. Syntheses of an anionic phosphane

The new phosphane **2** was characterized by NMR spectroscopy and X-ray structure analysis. In the ^{31}P NMR spectrum the resonance at $\delta = -15.5$ ppm showing tin satellites ($^2J_{P,Sn} = 71$ Hz) gives clear evidence for the successful coupling of the phosphane moiety at the anionic stannaborate cage. Single crystals suitable for X-ray structure analysis were prepared by slow diffusion of hexane into a dichloromethane solution of the coupling product **2**. The structure of the borate salt is depicted in Figure 1, and the data of the structure solution and refinement are listed in Table 1. This ligand is of interest to us since standard phosphane coordination chemistry can be combined with well-known B−H−M three-center-twoelectron bond coordination.[13] Anionic boron clusters show mono-, di- or trihapto coordination modes at transition metal centers. These agostic interactions can be detected either in the ^1H NMR spectrum from high-field proton resonances for the B−H−M unit or in the ^{11}B NMR spectrum exhibiting reduced $^1J_{BH}$ coupling constants.

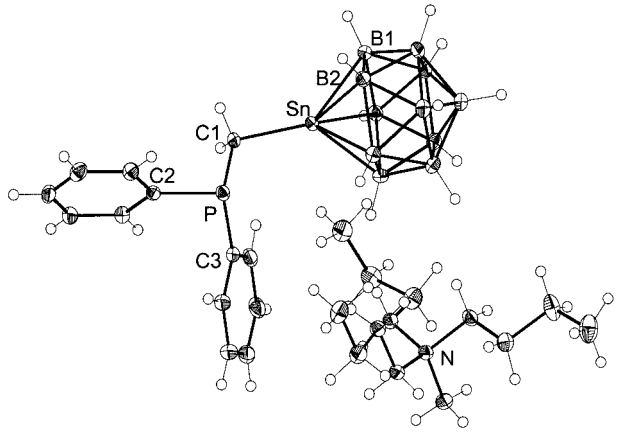


Figure 1. Molecular structure of the phosphane salt $[Bu_3MeN][Ph_2PCH_2SnB_{11}H_{11}]$ (**2**) in the solid state; interatomic distances in pm and angles in degrees (with estimated standard deviations in parentheses): Sn−C1 212.7 (2), Sn−B1 227.9(3), Sn−B2 228.1(3), Sn−B3 228.5(3), Sn−B4 228.9(3), Sn−B5 230.1(3), P−C1 182.9(2), P−C2 184.3(2), P−C3 184.7(2); P−C1−Sn 110.9, C1−Sn−B1 140.3(1), C1−Sn−B2 128.4(1), C1−Sn−B3 124.9(1), C1−Sn−B4 133.8(1), C1−Sn−B5 144.5(1)

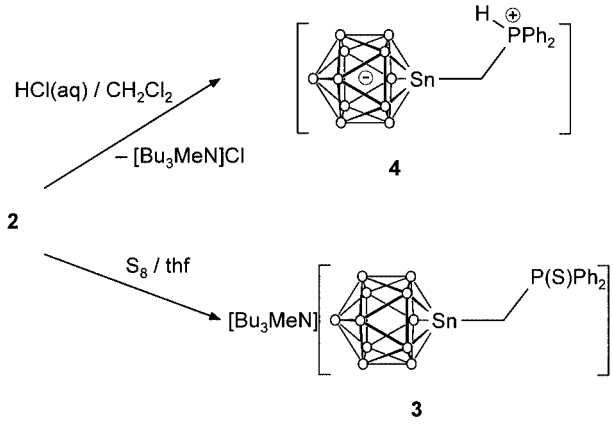
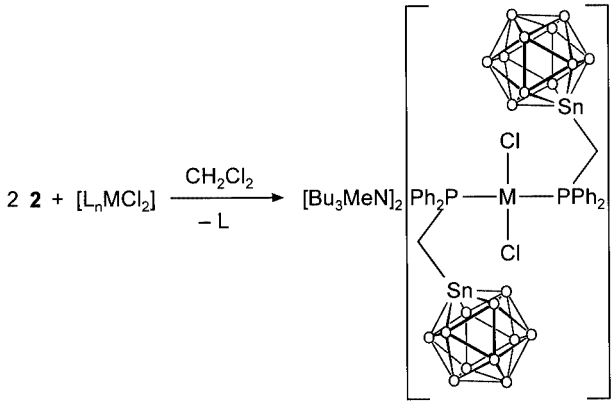
In reaction with elemental sulfur and hydrochloric acid two derivatives of the phosphane were synthesized and characterized (Scheme 3). The sulfur compound exhibits in the ^1H NMR spectrum a doublet ($^2J_{H,P} = 4.5$ Hz) with tin satellites $^2J_{H,Sn} = 100$ Hz at $\delta = 3.08$ ppm for the PCH_2Sn moiety. A characteristic signal at $\delta = 6.85$ ppm for the proton connected at the phosphorus *H*P and a down-field shift of 1.2 ppm for the resonance of the PCH_2Sn unit [4.26 ppm ($^2J_{H,P} = 12$ Hz, $-P-CH_2-Sn$, $^2J_{H,Sn} = 98$ Hz)] was detected in the case of the zwitterionic phosphonium borate.



Scheme 3. Reaction with sulfur and protonation of the anionic phosphane

First complexation reactions of the new ligand **2** were carried out with the following transition metal complexes: [*cis*-$(Ph_3P)_2PdCl_2$], [$(cod)PtCl_2$], [$AgBF_4$], and [$(Ph_3P)AuCl$] (Scheme 4, Scheme 5, Scheme 6). *trans*-Substituted coordination compounds **5** and **6** have been isolated and characterized with platinum and palladium chlorides. In the case of the platinum derivative the $^1J_{Pt,P}$ coupling constant of 1850 Hz allows unambiguous assignment for *trans*-coordination.[14] Obviously the anionic part of the ligand is not of the nucleophilicity to substitute the chloride atoms and form M−H−B bonds. The products **5** and **6** are stable towards moisture, and air and crystallization from CH_2Cl_2/hexane resulted in the isolation of single crystals in the case of the palladium complex.



Scheme 4. Complexation reaction with palladium and platinum coordination compounds (L_nMCl_2 = [*cis*-$(Ph_3P)_2PdCl_2$], M = Pd for **5**; L_nMCl_2 = [$(cod)PtCl_2$], M = Pt for **6**)

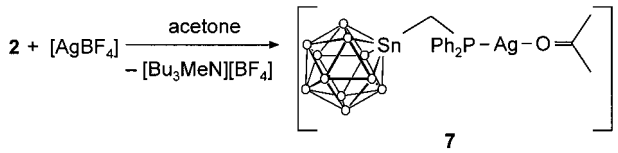
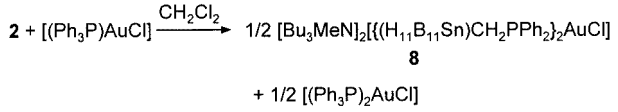
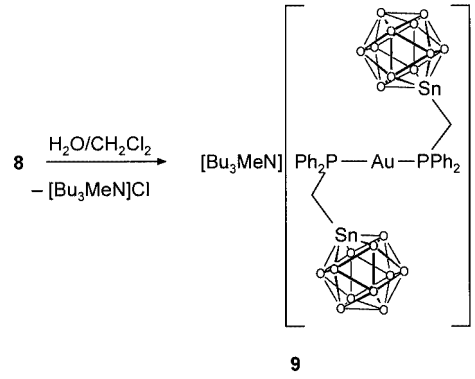


Scheme 5. Complexation with a silver electrophile, formation of a zwitterion





Scheme 6. Formation of a triply coordinated gold complex; loss of the chloride substituent under the contact with water

The salt **5** crystallizes under the inclusion of two equivalents of CH_2Cl_2 in the monoclinic space group $P2_1/n$, with the dianion lying on the twofold rotation axis. In Figure 2 the structure of the anion in the solid state is shown, and the data of the structure solution and refinement are listed in Table 1. The coordination at the palladium center is in close relation to the structure of [*trans*-$(Ph_2MeP)_2PdCl_2$] crystallizing in the same space group with almost identical Pd–P 233.06(12) pm and Pd–Cl 230.45(9) pm interatomic distances.[15]

A neutral silver complex was synthesized from the reaction of the phosphane **2** with $AgBF_4$ (Scheme 5). This zwitterionic molecule was characterized by NMR spectroscopy and elemental analysis and should be a versatile starting material for further complexation reactions. With respect to the phosphane ligand, the monosubstituted product was the only isolated silver complex, whereas in the case of [(Ph_3P)AuCl] two anionic phosphanes coordinate at the gold center (Scheme 6) to give a diphosphanyl chloride complex **8**.[16]

The primarily formed reaction product **8** was stirred with water to give the linearly coordinated complex **9** in high yield. The salt **9** was crystallized and the structure in the solid state was determined by X-ray diffraction. The molecular structure of the anion of **9** is shown in Figure 3, and the data of the structure solution and refinement are listed in Table 1.

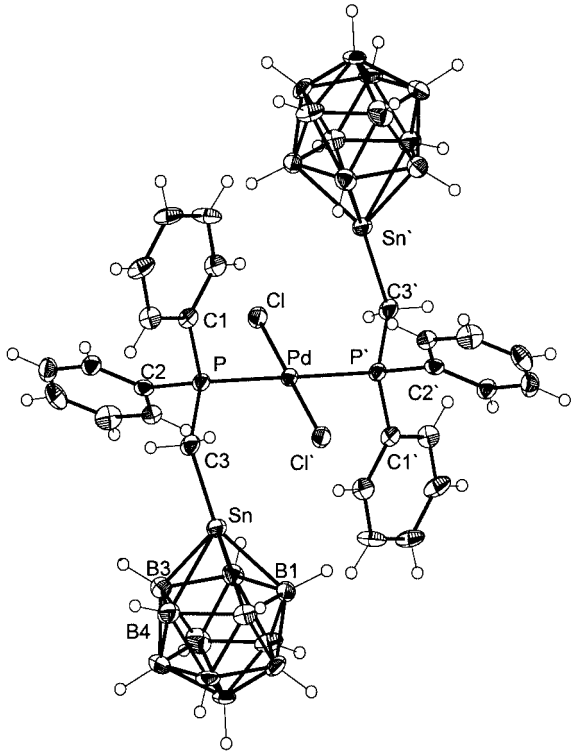


Figure 2. Molecular structure of the anion of $[Bu_3MeN]_2$-$[PdCl_2(PPh_2CH_2SnB_{11}H_{11})_2]$ (**5**) in the solid state; interatomic distances in pm and angles in degrees (with estimated standard deviations in parentheses): Pd–Cl 229.6(2), Pd–P 233.2(2), P–C3, 184.0(8), Sn–C3 211.7(7), Sn–B1 228.7(8), Sn–B2 228.9(9), Sn–B3 227.9(10), Sn–B4 228.8(10), Sn–B5 227.8(8), C3–Sn–B1 150.4(3), C3–Sn–B2 140.6(3), C3–Sn–B3 122.9(3), C3–Sn–B4 121.1(3), C3–Sn–B5 134.4(3), Cl–Pd–P 91.0(1), Cl′–Pd–P 89.0(1)

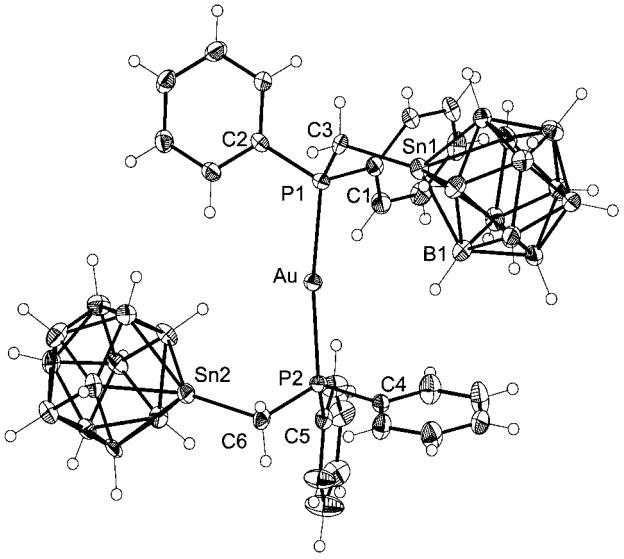

Figure 3. Molecular structure of the anion of $[Bu_3MeN]$-$[Au(PPh_2CH_2SnB_{11}H_{11})_2]$ (**9**) in the solid state. Interatomic distances in pm and angles in degrees (with estimated standard deviations in parentheses): P1–Au 231.0(2), P2–Au 231.4(2), C3–P1 181.6(7), Sn1–C3 213.7(6), C6–P2 187.8(8), Sn2–C6 214.6(7), P1–Au–P2 171.1(1), Au–P1–C3 113.5(3), P1–C3–Sn1, 113.9(3), Au–P2–C6 114.8(3), P2–C6–Sn2 109.1(4)

Nearly linearly coordinated gold(I) cations $[Au(PR_3)_2]^+$ are well-known in the literature and the metal−ligand bonding has been studied with respect to relativistic and non relativistic structure calculations.[17,18] In the crystal structure a very weak interaction (H−Au 268.0 pm) between a BH unit and the gold center, which results in the formation of dimer, can be detected (Figure 4). Stone et al. have found much shorter BH−Au interatomic distances in the range of 190−210 pm.[19] Nevertheless, we interpret this contact as a weak electrostatic interaction of the cationic gold fragment with the anionic borate moiety.

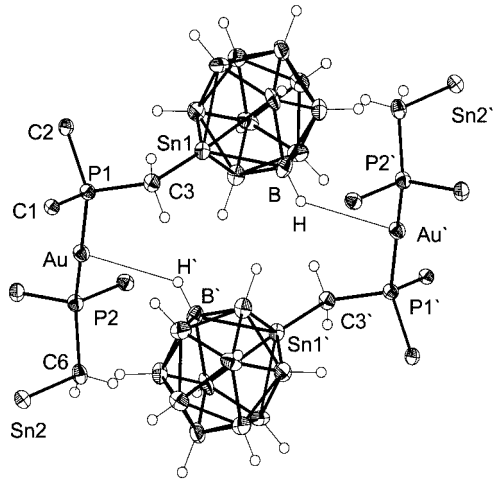

Figure 4. Weak interaction between a stannaborate cluster and gold center in compound **9**; H−Au 268.0 pm (all hydrogen atoms at calculated positions); phenyl substituents and boron cluster cages at Sn2 and Sn2′ have been omitted for the sake of clarity

To conclude, a synthesis for an anionic phosphane with two different coordination sites is presented: a diarylalkylphosphane nucleophile and an anionic borate where common B−H−M coordination can take place.

Experimental Section

General Procedures: All manipulations were carried out using Schlenk techniques under an atmosphere of dry N_2. All solvents were dried and purified by standard methods and were stored under dry N_2. $[Bu_3MeN]_2[SnB_{11}H_{11}]$ was synthesized following a modification of Todd's procedure.[25] The compounds $[Bu_3MeN][H_{11}B_{11}Sn-(CH_2)_3-Cl]$, [*cis*-$(PPh_3)_2PdCl_2$],[26] [$PPh_3$-CuCl],[27] and $Li[CH_2PPh_2]$[28] were synthesized by literature procedures. All other chemicals were purchased from Aldrich and were used without further purification. ^1H, ^{11}B, and ^{31}P NMR spectra were recorded on a Bruker AC 200 instrument and referenced to the deuterated solvent. Elemental analyses were carried out on a Hekatech EuroEA C,H,N,S,O elemental analyzer at Institut für Anorganische Chemie der Universität zu Köln.

$[Bu_3MeN][H_{11}B_{11}Sn-CH_2-P(C_6H_5)_2]$ (2): A solution of $[Bu_3MeN][H_{11}B_{11}Sn-(CH_2)_3-Cl]$ (6.17 g, 11.72 mmol) in THF (60 mL) was added to a solution of $Li[CH_2PPh_2]$ (3.14 g, 15.23 mmol) in THF (60 mL) dropwise at room temperature. After stirring overnight at room temperature all volatiles were removed. The residue was dissolved in CH_2Cl_2 (60 mL) and treated with water (3 × 30 mL). The organic phase was separated and stirred over anhydrous Na_2SO_4. After the solvent was removed, the yellow, semifluid raw product was dissolved in a little CH_2Cl_2 and washed with *n*-hexane and Et_2O. Removing the solvent resulted in isolation of the yellow, semifluid but translucent product. Yield: 77%, 5.85 g, 9.02 mmol. ^1H NMR (200 MHz, 25 °C, CD_2Cl_2): δ = 1.01 (t, 9 H, ^3J = 7.1 Hz, $-CH_2-CH_3$), 1.42 (m, 6 H, ^3J = 7.2 Hz, $-CH_2-CH_3$), 1.65 (m, 6 H, ^3J = 7.3 Hz, $-CH_2-CH_2-CH_3$), 2.98 (s, 3 H, $N-CH_3$), 3.06 (d, 2 H, $^2J_{H,P}$ = 4.5 Hz, $P-CH_2-Sn$), 3.16 (m, 6 H, ^3J = 7.3 Hz, $N-CH_2-CH_2-$), 7.39−7.54 ppm [m, 10 H, $-P-(C_6H_5)_2$]. $^{11}B\{^1H\}$ NMR (64 MHz, 25 °C, CD_2Cl_2): δ = −12.3 (s, B12), −17.0 (s, B2−6 and B7−11) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, 25 °C, C_3D_6O): δ = 13.8 (d, $^1J_{C,P}$ = 35 Hz, $-P-CH_2-Sn$), 16.8 (s, $-CH_2-CH_3$), 23.2 (s, $-CH_2-CH_3$), 27.6 (s, $N-CH_2-CH_2-$), 51.8 (s, $N-CH_3$), 65.2 (s, $N-CH_2-CH_2-$), 132.4 (d, $^3J_{C,P}$ = 7 Hz, C_{meta}, $-P-(C_6H_5)_2$], 132.8 (s, C_{para}, $-P-(C_6H_5)_2$], 136.0 (d, $^2J_{C,P}$ = 20 Hz, C_{ortho}, $-P-(C_6H_5)_2$], 143.3 ppm [d, $^1J_{C,P}$ = 14 Hz, C_{ipso}, $-P-(C_6H_5)_2$]. $^{31}P\{^1H\}$ NMR (81 MHz, 25 °C, C_3D_6O): δ = −15.5 ppm (s, $^2J_{P,Sn}$ = 71 Hz, $-P-(C_6H_5)_2$]. $C_{26}H_{53}B_{11}NPSn$ (648.32): calcd. C 48.17, H 8.24, N 2.16; found C 46.77, H 8.76, N 1.50.

$[Bu_3MeN][H_{11}B_{11}Sn-CH_2-P(S)-(C_6H_5)_2]$ (3): A solution of $[Bu_3MeN][H_{11}B_{11}Sn-CH_2-P(C_6H_5)_2]$ (**1**, 0.82 g, 1.26 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a suspension of sulfur (0.04 g, 1.26 mmol) in CH_2Cl_2 (20 mL). After stirring for 4 h at room temperature, the sulfur had dissolved by then, all volatiles were removed, and **2** was isolated as a yellow, hygroscopic solid. Yield: 89%, 0.76 g, 1.12 mmol. ^1H NMR (200 MHz, 25 °C, CD_2Cl_2): δ = 3.80 (d, 2 H, $^2J_{H,P}$ = 11, $^2J_{H,Sn}$ = 100 Hz, $-P-CH_2-Sn$), 7.51−7.95 ppm (m, 10 H, $-P-(C_6H_5)_2$]. $^{11}B\{^1H\}$ NMR (64 MHz, 25 °C, CD_2Cl_2): δ (ppm) = −11.8 (s, B12), −17.1 (s, B2−6 and B7−11). $^{31}P\{^1H\}$ NMR (81 MHz, 25 °C, CD_2Cl_2): δ = 40.98 ppm (s, $^2J_{P,Sn}$ = 46 Hz, $-P-(C_6H_5)_2$]. $C_{26}H_{53}B_{11}NPSSn$ (680.38): calcd. C 45.90, H 7.85, N 2.06, S 4.71; found C 44.17, H 7.88, N 2.02, S 4.65.

$[H_{11}B_{11}Sn-CH_2-P(H)-(C_6H_5)_2]$ (4): A solution of $[Bu_3MeN][H_{11}B_{11}Sn-CH_2-P(C_6H_5)_2]$ (**1**, 1.00 g, 1.54 mmol) in CH_2Cl_2 (20 mL) was stirred rapidly under a layer of diluted hydrochloric acid (25 mL) overnight. The resulting colorless solid was separated, washed with water and dried in vacuo. Yield: 94%, 0.65 g, 1.45 mmol. ^1H NMR (200 MHz, 25 °C, C_3D_6O): δ = 4.26 (d, 2 H, $^2J_{H,P}$ = 12 Hz, $-P-CH_2-Sn$, $^2J_{H,Sn}$ = 98 Hz), 6.85 (d, 1 H, $^1J_{H,P}$ = 12 Hz, $-P-H$), 7.78−7.94 (m, 10 H, $-P-(C_6H_5)_2$] ppm. $^{11}B\{^1H\}$ NMR (64 MHz, 25 °C, C_3D_6O): δ = −12.5 (s, B12), −17.3 ppm (s, B2−6 and B7−11). $^{31}P\{^1H\}$ NMR (81 MHz, 25 °C, C_3D_6O): δ = 33.27 ppm (s, $^2J_{P,Sn}$ = 59 Hz, $-P(H)-(C_6H_5)_2$]. $C_{13}H_{24}B_{11}PSn$ (448.94): calcd. C 34.78, H 5.39; found C 35.36, H 5.82.

$[Bu_3MeN]_2$[*trans*-$\{H_{11}B_{11}Sn-CH_2-P(C_6H_5)_2\}_2PdCl_2$] (5): A solution of $[Bu_3MeN][H_{11}B_{11}Sn-CH_2-P(C_6H_5)_2]$ (1.43 g, 2.20 mmol) in CH_2Cl_2 (25 mL) was added dropwise to a stirred solution of $(PPh_3)_2PdCl_2$ (0.77 g, 1.10 mmol) in CH_2Cl_2 (20 mL). After the mixture was stirred for 16 h at room temperature, the solvent was removed under reduced pressure, and the yellow residue was washed with benzene, toluene, and *n*-hexane (3 × 20 mL). The yellow product was isolated by filtration and dried in vacuo. Yield: 64%, 1.04 g, 0.70 mmol. ^1H NMR (200 MHz, 25 °C, CD_2Cl_2): δ (ppm) = 0.99 (t, 18 H, ^3J = 7.1 Hz, $-CH_2-CH_3$), 1.37 (m, 12 H, ^3J = 6.9 Hz, $-CH_2-CH_3$), 1.64 (m, 12 H, ^3J = 7.0 Hz, $-CH_2-CH_2-CH_3$), 2.99 (s, 6 H, $N-CH_3$), 3.17 (m, 12 H, ^3J = 8.3 Hz, $N-CH_2-CH_2-$), 3.43 (d, 4 H, $^2J_{H,P}$ = 7 Hz, $-P-CH_2-Sn$), 7.26−7.90 (m, 20 H, $-P-(C_6H_5)_2$]. $^{11}B\{^1H\}$ NMR (64 MHz, 25 °C, CD_2Cl_2): δ = −12.2 (s, B12), −16.8 ppm

Syntheses and Characterizations of Multidimensional Metal-Organic Frameworks Based on Rings and 1D Chains

Xiaoju Li,[a] Rong Cao,*[a] Yanqiong Sun,[a] Wenhua Bi,[a] Xing Li,[a] and Yanqin Wang[a]

Keywords: Bridging ligand / Polymers / Hydrothermal reaction / Hydrogen bonds

Four novel multidimensional coordination polymers, {[Cd(3-PYD)$_2$(H$_2$O)]·2H$_2$O}$_n$ (**1**), [Pb(3-PYD)$_2$]$_n$ (**2**), {[Cu$_{1.5}$(3-PYD)$_3$(H$_2$O)]·1.5H$_2$O}$_n$ (**3**) and [Zn(3-PYD)$_2$(H$_2$O)$_2$]$_n$ (**4**), have been hydrothermally synthesized from 3-(3-pyridyl)acrylic acid (3-HPYD). In **1**, 3-PYD in a head-to-head arranged fashion bridges Cd^{II}, generating a two-dimensional layer, which is further extended into a three-dimensional supramolecular network by hydrogen-bonding interactions. Compound **2** shows a two-dimensional wave-like layer that consists of {Pb(3-PYD)}$_4$ rings from head-to-tail arranged 3-PYD. Compound **3** is a twofold interpenetrating three-dimensional network consisting of {Cu(3-PYD)}$_6$ rings formed through the mixed head-to-head and head-to-tail arrangements of 3-PYD. However, **4** is a three-dimensional supramolecular framework constructed by one-dimensional zinc-3-PYD chains through hydrogen-bonding interactions.

Introduction

The rational design and syntheses of multidimensional coordination polymers have been of increasing interest recently in material science and chemical research.[1,2] This is justified not only by their unique application as functional materials but also by the particular structural diversity of their architectures,[3−5] which can be much greater than those of metal oxides and other simple inorganic solid materials, owing to incorporation of many organic ligands.[6] As a result, the selection of organic ligands with appropriate coordination sites linked by specific connectors is the key to forming metal-organic complexes with desirable physical and chemical properties.

Multidentate N- or O-donor ligands have been employed extensively as organic spacers in the construction of extended structures. For example, the use of 4,4′-bipyridine[7] and its analogues,[8] as neutral N-donor ligands, is a most promising approach towards the syntheses of extended metal-organic frameworks owing to their simple bridging mode and strong coordination ability to transition metal ions. However, assembly of these ligands with metal ions is heavily dependent on the presence of different counterions. Conversely, di-[9] or polycarboxylate[10] ligands, as O-donor ligands via anionic groups, are another candidate for the preparation of multidimensional coordination networks, owing to the rich coordination modes of the carboxylate groups, and can afford neutral metal-organic frameworks. Our research aim is to incorporate both neutral and anionic donor groups into a single organic ligand that can be used to construct desired coordination polymers. Different donor groups can hold great promise for incorporating accessibility, structural diversity and geometrical control of properties into the resulting coordination networks. Moreover, both neutral and anionic donor groups can coordinate to metal centers, and afford opportunities for generating neutral polymeric networks without counterions, thereby simplifying the control of final products.[11,12] In this context, extended coordination structures have been constructed using rigid pyridinecarboxylate ligands.[12−14] We employed 3-(3-pyridyl)acrylic acid (3-HPYD), which possesses an appropriate angle (120°) and a long arm between coordination sites. Assembly of 3-HPYD with metal ions not only can produce aesthetically beautiful complexes with useful properties, which can not be obtained by common pyridinecarboxylate ligands, but can also generate some predicted, controlled structural frameworks through changing the coordination nature of metal ions. However, few compounds with 3-HPYD have been reported.[14] Herein, we report the syntheses and characterizations of four coordination polymers: {[Cd(3-PYD)$_2$(H$_2$O)]·2H$_2$O}$_n$ (**1**), [Pb(3-PYD)$_2$]$_n$ (**2**), {[Cu$_{1.5}$(3-PYD)$_3$(H$_2$O)]·1.5H$_2$O}$_n$ (**3**) and [Zn(3-PYD)$_2$(H$_2$O)$_2$]$_n$ (**4**), constructed from 3-HPYD with different metal ions.

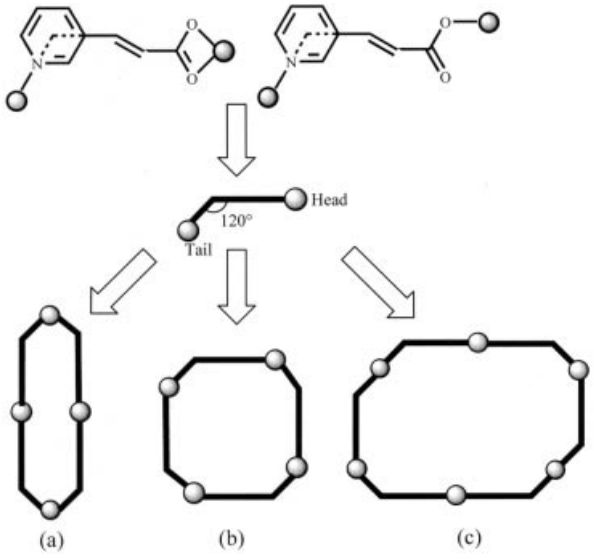
Results and Discussions

Syntheses

Two distinct characteristics of 3-HPYD, an angle of 120° and a long arm between pyridyl and carboxylate donor

 DOI: 10.1002/ejic.200400648 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

groups, render it ideal for the assembly of molecular polygons. Two types of polygons can be obtained from head-to-head or head-to-tail arrangement of the deprotonated 3-HPYD (3-PYD) when using four ML units with 120° corners (Scheme 1, a and b). In addition, their mixed arrangement can also generate other building units, such as a $\{ML\}_6$ basal ring (Scheme 1, c). Based on these points, we carried out a series of hydrothermal reactions of 3-HPYD and transition metal ions to formulate novel coordination polymers. As expected, when Cd^{II} and Cu^{II} was used as nodes, compound **1** based on $\{ML\}_4$ rings from the head-to-head arrangement of 3-PYD, and compound **3** based on $\{ML\}_6$ rings from the head-to-head and head-to-tail mixed arrangements of 3-PYD, were successfully obtained, respectively. However, the compound containing $\{ML\}_4$ rings from head-to-tail arrangement of 3-PYD was not obtained, although other transition metal ions, such as Co^{2+}, Ni^{2+}, Mn^{2+} and Zn^{2+}, were employed. Notably, the hydrothermal reaction of Zn^{2+} and 3-HPYD produced compound **4**, which was not from the ring units but from 1D zinc-carboxylate chains extended by hydrogen-bonding interactions. Pb^{2+}, which has an ample coordination preference,[15] was used to investigate further the conformation and arranged fashion of 3-PYD. Consequently, compound **2**, a 2D network consisting of $\{Pb(3\text{-PYD})\}_4$ basal rings from head-to-tail arrangement of 3-PYD, was produced. Accordingly, the diverse geometries of different metal ions may play critical roles in the assembly of metal-organic frameworks with various structures. This has also been testified to in some other research systems.[16]



Scheme 1. (a) $\{ML\}_4$ ring from head-to-head (or tail-to-tail) arrangement of 3-PYD; (b) $\{ML\}_4$ ring from head-to-tail arrangement of 3-PYD; (c) $\{ML\}_6$ ring from head-to-head and head-to-tail mixed arrangements of 3-PYD

Structural Descriptions

$\{[Cd(3\text{-PYD})_2(H_2O)]\cdot 2H_2O\}_n$ (1): Single-crystal X-ray diffraction analysis reveals that **1** is a 3D supramolecular network consisting of $\{Cd(3\text{-PYD})\}_4$ rings derived from head-to-head arranged 3-PYD. The asymmetric unit of **1** consists of one Cd^{II}, two 3-PYD, one coordinated water molecule and two free water molecules (Figure 1). Each Cd^{II} is in a distorted pentagonal bipyramidal geometry. The equatorial basal plane is determined by two chelating carboxylate groups from different 3-PYD and one coordinated water molecule. Cd−O bond lengths are in the range 2.303(8)−2.462(10) Å. Apical positions are occupied by two pyridyl nitrogen atoms from different 3-PYD, with an average Cd−N distance and N(1)−Cd−N(2) bond angle of 2.382(8) Å and 164.0(3)°, respectively. The Cd^{II} is approximately coplanar with the mean plane of the five equatorial atoms, with a deviation of 0.1000 Å. 3-PYD acts as a bridging ligand, through its pyridyl nitrogen atom and chelating carboxylate group, linking different Cd^{II} centers. Four 3-PYD with a head-to-head aggregation link Cd^{II} into a $\{Cd(3\text{-PYD})\}_4$ ring (Scheme 1, a), in which four metal ions and four 3-PYD are all in one plane (Figure 2, a). Based on $Cd^{II}\cdots Cd^{II}$ distances, the ring is 7.449 × 15.139 $Å^2$. Interestingly, each $\{Cd(3\text{-PYD})\}_4$ ring is surrounded by four other perpendicular $\{Cd(3\text{-PYD})\}_4$ rings through shar-

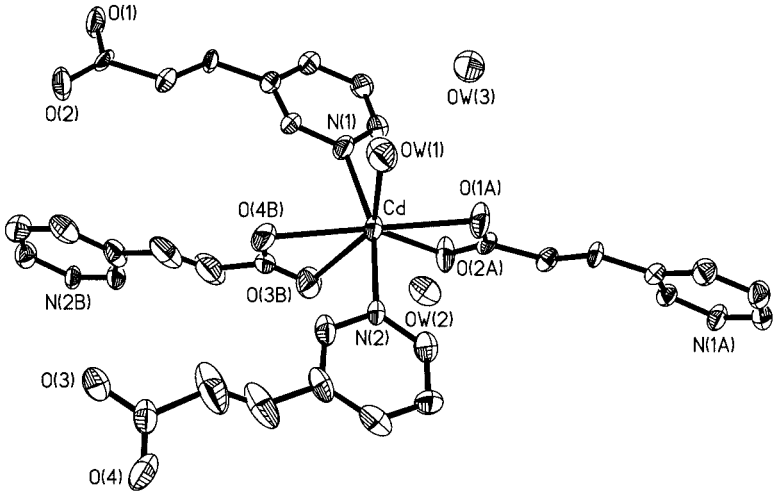


Figure 1. Coordination environment around Cd^{II} in **1** with the thermal ellipsoids at 30% probability level

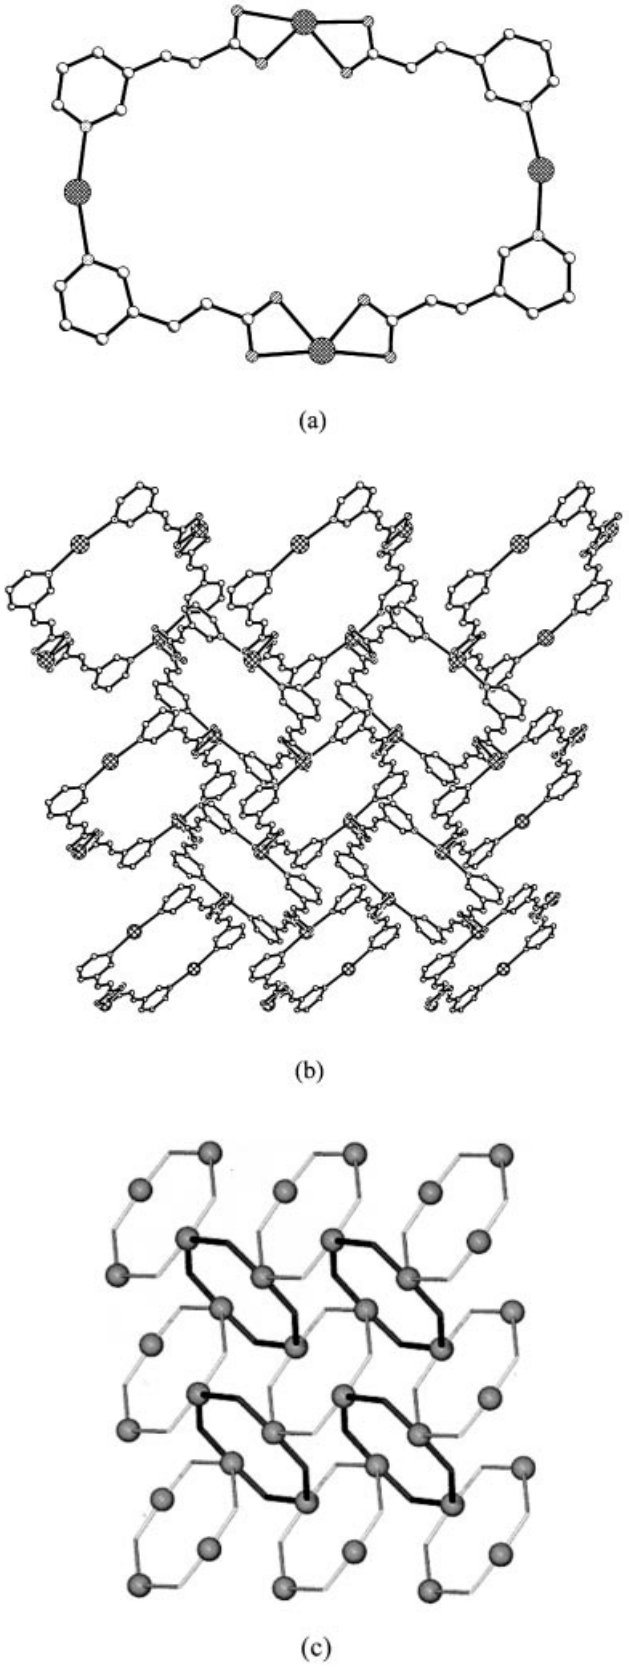

Figure 2. (a) $\{Cd(3\text{-PYD})\}_4$ ring from head-to-head arrangement of 3-PYD; (b) a 2D layer in **1** along the *c* axis; free water molecules omitted for clarity; (c) schematic showing the 2D layer derived from reciprocally vertical $\{Cd(3\text{-PYD})\}_4$ rings; only the Cd^{II} centers are shown for clarity, with the bonds representing bridging ligands

ing Cd^{II} joints, which may be due to the proper geometry of the metal ion. Thereby, a 2D layer framework is generated from the reciprocally vertical $\{Cd(3\text{-PYD})\}_4$ rings (Figure 2, b and c); the free water molecules are accommodated in the rings. Finally, neighboring layers are further extended into a 3D supramolecular architecture through hydrogen-bonding interactions between coordinated water molecules and carboxylate oxygen atoms [$OW(1)-H\cdots O(4)^i$ 2.701 Å; symmetry codes: (i) $x - 1/2, -y + 5/2, z - 1/2$] (Figure 3). Thus, hydrogen-bonding interactions play an important role in the construction and stabilization of the extended structure.

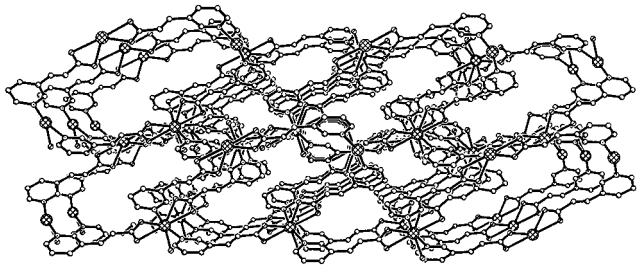

Figure 3. Packing structure of **1** along the *b* axis; free water molecules omitted for clarity

$[Pb(3\text{-PYD})_2]_n$ (2): 2 is a 2D wave-like layer based on $\{Pb(3\text{-PYD})\}_4$ rings from head-to-tail arranged 3-PYD. The four-coordinate Pb^{II} is in a highly distorted tetragonal pyramid geometry (Figure 4). The basal plane is defined by two pyridyl nitrogen atoms and two carboxylate oxygen atoms from different 3-PYD, while Pb^{II} occupies the apex. Pb^{II} deviates from the N_2O_2 basal plane by 0.9217 Å. Average Pb−N and Pb−O distances are 2.652(8) and 2.374(7) Å, respectively, and the N(1A)−Pb−N(2) and O(1)−Pb−O(3B) bond angles are 158.8(3) and 79.3(2)°, respectively. Unlike **1**, 3-PYD bridges Pb^{II} through its pyridyl nitrogen atom and monodentate carboxylate group, generating a head-to-tail aggregated $\{Pb(3\text{-PYD})\}_4$ ring (Scheme 1, b). In the $\{Pb(3\text{-PYD})\}_4$ ring, four Pb^{II} ions and four 3-PYD are *not* coplanar, which may be due to the different arrangement of 3-PYD and the coordination geometry of the metal ion. The $\{Pb(3\text{-PYD})\}_4$ rings are further extended into a 2D wave-like layer by sharing Pb^{II} joints and 3-PYD edges (Figure 5). Although there is large void space in the wave-like layer, no guest or water molecules are included. Adjoining layers are 4.348 Å apart, and there are no hydrogen bonding or other weak interactions between them (Figure 6).

$\{[Cu_{1.5}(3\text{-PYD})_3(H_2O)]\cdot 1.5H_2O\}_n$ (3): 3 is a twofold interpenetrating 3D framework based on $\{Cu(3\text{-PYD})\}_6$ rings formed through head-to-head and head-to-tail mixed arrangements of 3-PYD (Scheme 1, c). There are two crystallographically independent Cu^{II} centers (Figure 7). Cu(1) adopts a distorted square-pyramidal coordination geometry. Two *trans*-carboxylate oxygen atoms and two *trans*-pyridyl nitrogen atoms of different 3-PYD comprise the equatorial plane. Average Cu(1)−O and Cu(1)−N bond lengths are 1.960(2) and 2.024(4) Å, respectively. Cu(1) deviates from the mean plane determined by the four equatorial atoms by

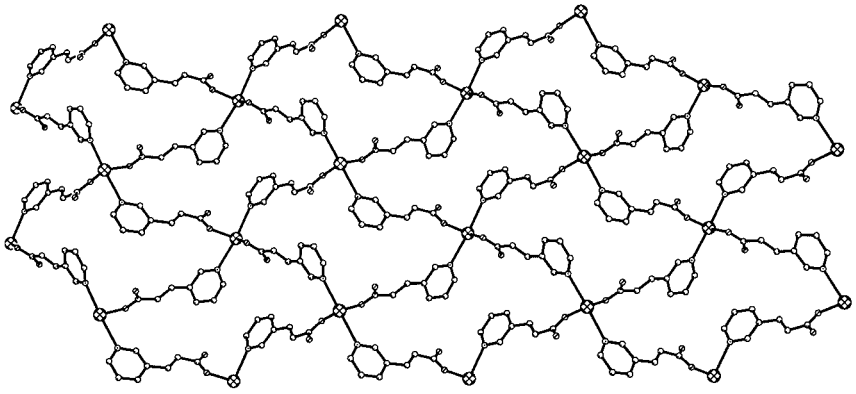

Figure 5. Two-dimensional wave-like layer in **2**

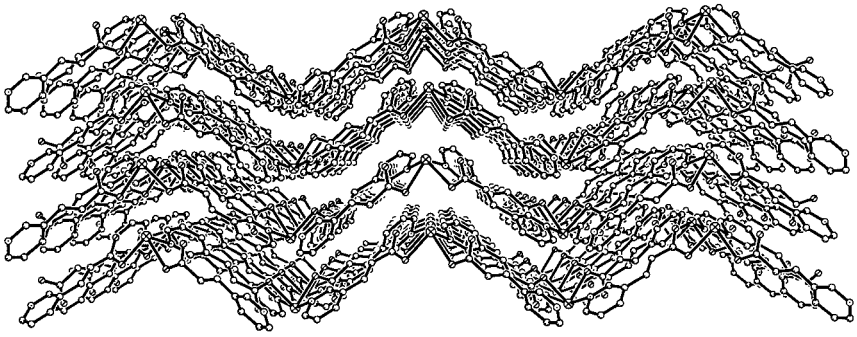

Figure 6. Packing diagram of **2** along the *a* axis

0.0827 Å. One water molecule occupies its axial position with the Cu(1)−OW(1) bond length is 2.403(3) Å. However, Cu(2) is in a square-planar geometry defined by two *trans*-carboxylate oxygen atoms [O(3) and O(3C)] and two *trans*-pyridyl nitrogen atoms [N3 and N(3C)] of different 3-PYD. The bond lengths of Cu(2)−O(3) and Cu(2)−N(3) are 1.959(3) and 2.008(3) Å, respectively. Similar to that in **2**, 3-PYD also uses its nitrogen atom and monodentate carboxylate group to bridge metal centers.

The most interesting feature of the structure is the chair-like $\{Cu(3\text{-PYD})\}_6$ ring arising from four Cu(1) atoms and two Cu(2) atoms connected by six 3-PYD through both head-to-head and head-to-tail aggregations (Figure 8, a). Each chair-like $\{Cu(3\text{-PYD})\}_6$ ring is further surrounded by six identical units through sharing the metal ions; thereby, a 3D framework is generated (Figure 8, b). However, owing to the absence of guest molecules to fill the large voids in the $\{Cu(3\text{-PYD})\}_6$ rings, the voids are filled via mutual interpenetration of independent equivalent frameworks to generate a twofold interpenetrating 3D architecture (Figure 9). Hydrogen-bonding interactions between coordinated water molecules and carboxylate oxygen atoms of 3-PYD as well as between uncoordinated water molecules and carboxylate oxygen atoms of 3-PYD, with lengths from 2.565 to 2.893 Å, further stabilize the whole framework.

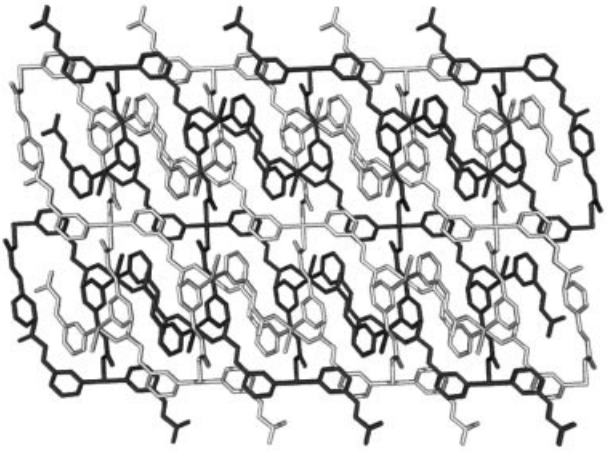

Figure 9. View of a twofold interpenetrating 3D network in **3** along the *b* axis

$[Zn(3\text{-}PYD)_2(H_2O)_2]_n$ (4): Unlike compounds **1**−**3** based on $\{ML\}_4$ or $\{ML\}_6$ rings, **4** is a 3D supramolecular framework constructed by 1D metal-3-PYD chains through hydrogen-bonding interactions. Figure 10 shows that each Zn^{II} is coordinated by four oxygen atoms from one chelating carboxylate group of 3-PYD, two water molecules, and two nitrogen atoms from different 3-PYD, in a distorted octahedral geometry. The equatorial plane is determined by N(2), O(3A), O(4A) and OW(2), while axial positions are occupied by N(1) and OW(1) with the N(1)−Zn−OW(1) bond angle being 176.31(4)°. There are two kinds of 3-PYD: one acts as a bridging ligand through its pyridyl nitrogen atom and chelating carboxylate group; the other serves as a terminal ligand through its pyridyl nitrogen atom participating in coordination, the carboxylate group is not involved in the coordination and acts as an acceptor of the hydrogen bonding. Hence, the Zn^{II} center is linked by bridging 3-PYD to generate a neutral 1D metal-3-PYD chain with the help of terminal 3-PYD (Figure 11). The 1D chains are further extended into a 3D supramolecular network through the abundant hydrogen-bonding interactions

IR Spectroscopy

The IR spectrum of **1** shows a strong, broad peak at 3413 cm^{-1}, which can be ascribed to the presence of water molecules. Characteristic carboxylate group bands appear at 1552 and 1400 cm^{-1} for asymmetric and symmetric vibrations, respectively. Δ, which represents the separation between ν_{asym}(COO) and ν_{sym}(COO) and reflects the coordination modes of the carboxylate groups,[17] is 152 cm^{-1}. For **2**, bands characteristic of the carboxylate group are exhibited at 1564 cm^{-1} for asymmetric vibrations and at 1354 cm^{-1} for symmetric vibrations; Δ is 210 cm^{-1}. For **3**, similar to **1**, the strong, broad band at 3433 cm^{-1} indicates the presence of water molecules. Absorption peaks at 1562 and 1378 cm^{-1} display the asymmetric and symmetric vibrations, respectively; Δ is 184 cm^{-1}. The single Δ in the three compounds is consistent with a single coordination mode of carboxylate group in their structures.[18] For **4**, the strong, broad peak at 3109 cm^{-1} also displays the presence of water molecules. Interestingly, besides the asymmetric (1546 cm^{-1}) and symmetric (1363 cm^{-1}) vibrations (Δ of ca. 183 cm^{-1}), the strong characteristic band at 1407 cm^{-1} indicates the presence of uncoordinated carboxylate group, which is in agreement with the results of its crystal structure.

Thermogravimetric Analyses

The thermal stability of **1**−**4** has been determined on polycrystalline samples in a nitrogen atmosphere by thermogravimetric analysis (TGA). For **1**, the weight loss of 11.55% from 61 to 118 °C is equivalent to the loss of one coordinated water molecule and two free water molecules [$3H_2O$/$Cd(3\text{-}PYD)_2(H_2O)]\cdot 2H_2O$, calculated: 11.68%). The second weight loss of 60.68%, from 331 to 900 °C, corresponds to the decomposition of **1**. The residual weight of 27.77% is ascribed to CdO (calculated: 27.75%). For **2**, TGA shows that chemical decomposition starts at 338 °C and ends at 398 °C with the weight loss of 55.59%; the remaining weight (44.41%) corresponds to PbO (calculated: 44.33%). For **3**, TGA exhibits two weight losses: One (7.52%) from 49 to 120 °C is attributed to the loss of coordinated water molecule and free water molecules ($2\cdot 5H_2O$/$[Cu_{1.5}(3\text{-}PYD)_3(H_2O)]\cdot 1.5H_2O$, calculated: 7.70%), suggesting the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

weak interaction of Cu(1)−OW(1) [2.403(3) Å]. The other (64.92%), from 245 to 478 °C, corresponds to the decomposition of **3**. In **4**, a weight loss of 9.12% from 119 to 160 °C displays the loss of two coordinated water molecules [$2H_2O$/$Zn(3\text{-PYD})_2(H_2O)_2$, calculated: 9.06%]. Above 268 °C, the framework starts to decompose.

Conclusions

Hydrothermal reactions of 3-(3-pyridyl)acrylic acid (3-HPYD) with different metal ions have afforded four coordination polymers based on $\{ML\}_4$ and $\{ML\}_6$ rings or metal-carboxylate chains, respectively. It may be conceivable to design and synthesize desired metal-organic frameworks when using the selected organic ligands with special conformations.

Experimental Section

Materials and General Methods: 3-(3-Pyridyl)acrylic acid was purchased from Aldrich and used without further purification; all other reagents were commercially available and used as purchased. Thermogravimetric experiments were performed using a TGA/SDTA851 instrument (heating rate of 15 °C min^{-1}, nitrogen stream). IR spectra were recorded as KBr pellets with a Magna 750 FT-IR spectrophotometer. Elemental analyses of C, H and N were determined using a Perkin-Elmer 240C elemental analyzer.

Synthesis of $\{[Cd(3\text{-PYD})_2(H_2O)]\cdot 2H_2O\}_n$ (1): A mixture of 3-HPYD (0.037 g, 0.25 mmol), $Cd(NO_3)_2\cdot 4H_2O$ (0.077 g, 0.25 mmol), KOH (0.014 g, 0.25 mmol) and H_2O (18 mL) was placed in a Teflon-lined stainless steel vessel and heated to 170 °C for 72 hours. The reaction system was then cooled to room temperature during 24 hours, and the resulting solution was filtered and left undisturbed in the air. After a day, light yellow block crystals of **1** (0.065 g) were obtained. Yield: 56% (based on Cd). $C_{16}H_{18}CdN_2O_7$ (462.72): calcd. C 41.53, H 3.92, N, 6.05; found C 41.55, H 3.82, N 6.13. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3413 (s), 1640 (s), 1552 (vs), 1478 (s), 1437 (w), 1400 (vs), 984 (s), 749 (m), 692 (s).

Synthesis of $[Pb(3\text{-PYD})_2]_n$ (2): $Pb(NO_3)_2$ (0.066 g, 0.20 mmol) and 3-HPYD (0.019 g, 0.125 mmol) in H_2O (18 mL) were stirred for 20 min, and then the pH was adjusted to 5 with Et_3N. After stirring for another 20 min, the mixture was transferred to a 25 mL stainless steel reactor with a Teflon liner and heated to 150 °C for 96 hours. The reaction system was then cooled to room temperature during 24 hours. A large amount of yellow cube-shaped crystals of **2** (0.078 g) was obtained. Yield: 78% (based on Pb). $C_{16}H_{12}PbN_2O_4$ (503.47): calcd. C 38.17, H 2.40, N 5.56; found C 38.12, H 2.48, N 5.55. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3445 (w), 1642 (s), 1564 (vs), 1420 (s), 1354 (vs), 1294 (m), 1242 (m), 806 (s), 693 (vs), 639 (vs).

Synthesis of $\{[Cu_{1.5}(3\text{-PYD})_3(H_2O)]\cdot 1.5H_2O\}_n$ (3): $Cu(NO_3)_2\cdot 3H_2O$ (0.036 g, 0.15 mmol) and 3-HPYD (0.030 g, 0.20 mmol) in H_2O (18 mL) were stirred for 20 min; the pH was then adjusted to 4 with Et_3N. After stirring for a further 20 min, the mixture was transferred to a 25 mL stainless steel reactor with a Teflon liner and heated to 165 °C for 96 hours. The reaction system was then cooled to room temperature during 24 hours. Blue block crystals of **3** (0.022 g) were obtained (based on Cu). Yield: 38%. $C_{24}H_{23}Cu_{1.5}N_3O_{8.5}$ (584.76): calcd. C 49.30, H 3.96, N 7.19; found C 49.27, H 4.10, N 7.11. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3433 (s), 3107 (w), 1644 (s), 1602 (w), 1562 (vs), 1474 (w), 1431 (s), 1378 (vs), 1053 (m), 988 (s), 805 (s), 693 (s), 606 (m).

X-ray Crystallographic Study: Intensity data for **1** and **2** were measured with a Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature;[19] empirical absorption corrections were applied by using the SADABS program. Measurements of **3** and **4** were conducted on a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at −100 °C.[20] Structures for **1**−**4** were solved by direct methods and refined on F^2 by full-matrix least-squares using the SHELXL-97 program package.[21] For **3**, C17, C18 and O6 were handled as disordered at two positions with occupancies of 50%. The positions of H atoms were generated geometrically (C−H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. Crystal data and structure determination summaries (Table 1) and selected bond lengths and angles (Table 2) for **1**−**4** are given here.

CCDC-245500 to -245503 contain the supplementary crystallographic data for this paper. Synthesis, Characterization, and Hydrolysis Products of $(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH_2$ − Structural Characterization of a Complex Containing η^1-, η^2-, and $\mu{:}\eta^1,\eta^1$-Pyrazolato Ligands and a Complex Containing a Terminal Hydroxo Ligand

Keywords: Hydrogen bond / N ligands / Aluminum / Pyrazolato ligands / Molecular orbital calculations

Treatment of alane–ethyldimethylamine with 3,5-di-*tert*-butylpyrazole (*t*Bu_2pzH) in a 2:3 molar ratio afforded $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH_2]$ in 57% yield. Hydrolysis of $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH_2]$ afforded variable mixtures of Al(*t*$Bu_2pz)_3$, $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2$Al-H(OH)], and $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(\eta^1$-*t*$Bu_2pz)]$. The structures of all new complexes were assigned from spectral and analytical data. In addition, the X-ray crystal structures of $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(OH)]$ and $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(\eta^1$-*t*$Bu_2pz)]$ were determined. $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(OH)]$ crystallizes as a dimeric molecule, and contains two bridging pyrazolato ligands, one η^2-pyrazolato ligand, as well as terminal hydrido and hydroxo ligands. The hydroxo and η^2-pyrazolato ligands possess a syn-relationship within the dimer. The hydroxy group proton does not participate in dihydrogen bonding, and instead appears to be intramolecularly hydrogen-bonded to the π-cloud of the η^2-pyrazolato ligand. The overall structure of $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(\eta^1$-*t*$Bu_2pz)]$ is very similar to that of $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(OH)]$, except that the η^1- and η^2-pyrazolato ligands have an anti-disposition within the dimer. Molecular orbital calculations were carried out on $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH(OH)]$ to understand the hydrogen bonding and the η^2-pyrazolato ligand coordination. The calculations predict that there is a 1.4 kcal/mol energy difference between η^1- and η^2-pyrazolato ligand coordination, which implies that the observed η^2-pyrazolato ligand occurs due to accommodation of the bulky *tert*-butyl groups. The intramolecular hydrogen bond between the hydroxo ligand proton and the π-cloud of the η^2-pyrazolato ligand is estimated to have a bond strength of 3.7 kcal/mol.

Introduction

The chemistry of aluminum complexes containing the bulky 3,5-di-*tert*-butylpyrazolato (*t*Bu_2pz) ligand has been an active area of research over the past several years.[1−4] Advances that have emerged from this work include the first examples of η^2-pyrazolato ligand coordination to a group 13 element,[2,3c] structural models for ligand species that occur in alumoxanes,[3b,3g] new coordination modes for acetylide groups,[3d,3f] as well as stabilization of bridging alkyl and hydride groups in pyrazolate-bridged dimers.[4] Roesky has reported the synthesis of the complex $[H_2Al(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2AlH_2]$, which was obtained by treatment of equimolar amounts of alane−trimethylamine with *t*Bu_2pzH,[3f] and has also described many reactions of this complex.[3b,3d,3e,3g] As part of our work relating to the synthesis of aluminum complexes with bridging hydride ligands,[4a] we have discovered a family of dimeric pyrazolato complexes that are derived from the reaction of alane−ethyldimethylamine with *t*Bu_2pzH in a 2:3 stoichiometry. These complexes are of the general formula $[(\eta^2$-*t*$Bu_2pz)AlH(\mu{:}\eta^1,\eta^1$-*t*$Bu_2pz)_2Al(X)H]$, where X = H, OH, or η^1-*t*Bu_2pz. In addition to providing additional rare examples of structurally characterized group 13 complexes containing η^2-pyrazolato ligands, this work describes the first crystal structure of a complex containing η^1-, η^2-, and $\mu{:}\eta^1,\eta^1$-pyrazolato ligands as well as a structurally characterized aluminum complex containing a terminal hydroxo ligand. Aluminum complexes containing terminal hydroxo ligands are very rare,[5] and have been of significant recent interest as models for species that might be present in methylalumoxanes used in olefin polymerization processes.[5,6] The terminal hydroxoaluminum ligand described herein is stabilized by formation of an intramolecular hydrogen bond to the π-cloud of an adjacent pyrazolato ligand, which constitutes a novel hydrogen bonding interaction for a terminal hydroxo complex.

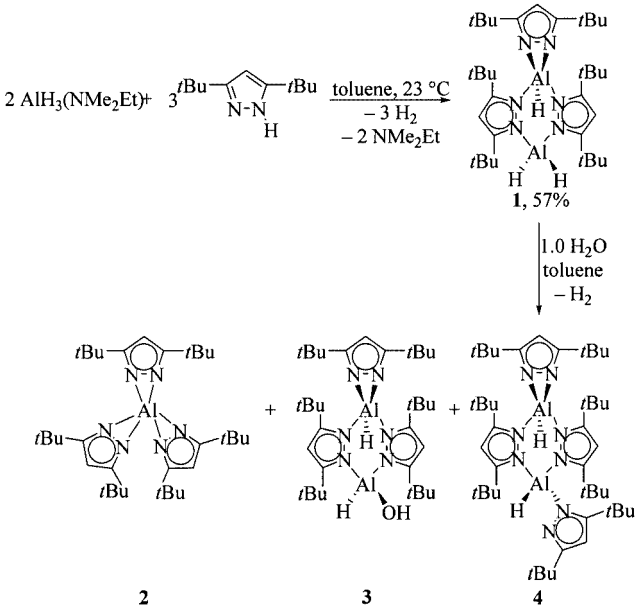
Results

Synthetic Chemistry

Scheme 1 outlines the synthetic approaches to the complexes that were prepared in this study. Treatment of alane−ethyldimethylamine with tBu$_2$pzH in a 2:3 stoichiometry led to the dimeric pyrazolato complex **1** in 57% crystallized yield. ^{1}H NMR spectroscopic analysis of the reaction product demonstrated that **1** was the only product formed, when extreme care was taken to exclude water from the reaction. The structure of **1** is proposed based upon spectral and analytical data and from correlation with the structurally characterized hydrolysis products **3** and **4** described below.



Scheme 1. Preparation and hydrolysis of **1**

In the ^{1}H NMR spectrum of **1** in [D$_8$]toluene at −90 °C, the *tert*-butyl methyl groups appear as three equal intensity singlets at δ = 1.73, 1.43, and 1.22 ppm. The hydride resonances are observed as 1:1:1 intensity broad singlets at δ = 6.1, 5.4, and 3.3 ppm, and the pyrazolato CH groups appear as singlets at δ = 6.32 and 6.20 ppm in a 1:2 ratio. The infrared spectrum shows the Al−H absorptions at 1962, 1905, and 1890 cm^{-1}. It was discovered that extended standing (> 1 week) of a hexane solution at 23 °C led to the slow decomposition of **1** to tBu$_2$pzH, **2**, and new compounds. As described below, the new compounds were obtained as pure materials and identified to be **3** and **4** from the hydrolysis of **1**.

Treatment of **1** with water (1 equiv.) at −78 °C in toluene led to immediate gas evolution and the formation of a white, insoluble precipitate. Workup of the reaction mixture, followed by fractional crystallization from hexane, afforded pure samples of **2** (8%), **3** (15%), and **4** (23%) as colorless crystalline solids. The identity of **2** was confirmed by comparison of its ^{1}H and ^{13}C{^{1}H} NMR spectra with those previously reported by Deacon.[2] The formulations of **3** and **4** were based upon their spectral and analytical data, and from their X-ray crystal structures as described below. The ^{1}H NMR spectrum of **3** in [D$_8$]toluene at ambient temperature showed resonances for one type of pyrazolato ligand, implying that exchange between the μ:η^1,η^1- and the η^2-pyrazolato ligands is faster than the NMR timescale. Upon cooling to −60 °C, three equal intensity singlets for the *tert*-butyl methyl groups are observed at δ = 1.47, 1.43, and 1.18 ppm and the pyrazolato methine resonances appear as a broad singlet at δ = 6.22 ppm. In addition, extremely broad resonances are observed at δ = 5.5 and 4.4 ppm in a 1:2 ratio, which correspond to some combination of the Al−H and Al−OH fragments. The low temperature ^{1}H NMR spectrum of **3** is very similar to that of **1** and indicates similar structures. The infrared spectrum of **3** shows a strong hydroxy stretch at 3227 cm^{-1} and aluminum−hydrogen stretches at 1961, 1908, and 1860 cm^{-1}. The low position of the hydroxy stretch is consistent with hydrogen bonding, yet there is no evidence in the crystal structure for dihydrogen bonding or intermolecular hydrogen bonding. Instead, it is likely that the hydroxy hydrogen atom is intramolecularly hydrogen-bonded to the π-cloud of the adjacent η^2-pyrazolato ligand. This possibility is explored below in more detail using molecular orbital calculations. The ^{1}H NMR spectra of **4** show little difference at room temperature and −80 °C, and reveal two equal intensity pyrazolato ligands. These data are consistent with slow exchange between the μ:η^1,η^1-pyrazolato ligands and the η^1- and η^2-pyrazolato ligand sites, but with rapid exchange between the η^1- and η^2-pyrazolato ligand sites. The infrared spectrum of **4** shows an aluminum−hydrogen stretch at 1937 cm^{-1}.

The yield of **3** could be increased to 45% in a one-pot reaction of alane−ethyldimethylamine with 3,5-di-*tert*-butylpyrazole in a 2:3 ratio, followed by addition of water (1 equiv.), stirring for 2 h, workup, and then fractional crystallization from hexane. Attempts to increase the yield of **4** did not meet with much success. Treatment of alane−ethyldimethylamine with tBu$_2$pzH in a 2:4 ratio, followed by workup, afforded a crude product consisting of **2** (68%), **3** (24%), and **4** (8%).

X-ray Crystal Structures of 3 and 4

Complexes **3** and **4** were characterized by X-ray crystallography in order to understand their three dimensional structures. The molecular structures of **3** and **4** are shown in Figures 1 and 2, respectively. The crystal data are given in Table 1.

Complex **3** consists of a dinuclear unit in a boat conformation held together by two μ:η^1,η^1-tBu$_2$pz ligands. One aluminum center is bonded to η^2-tBu$_2$pz and hydride ligands, while the other aluminum atom is bonded to hydroxo and hydride ligands. The hydroxo and η^2-pyrazolato ligands are *syn* to each other within the dimer. The aluminum−nitrogen bond lengths to five-coordinate Al(1) range between 1.936−1.968 Å, and are slightly shorter for four-coordinate Al(2) [1.914(3), 1.920(3) Å]. The

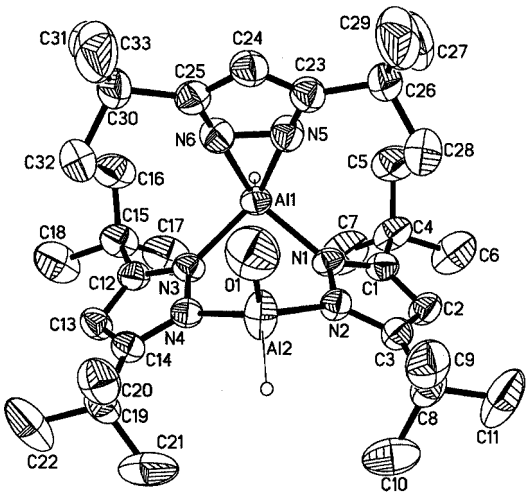

Figure 1. Perspective view of **3** with thermal ellipsoids at the 50% probability level

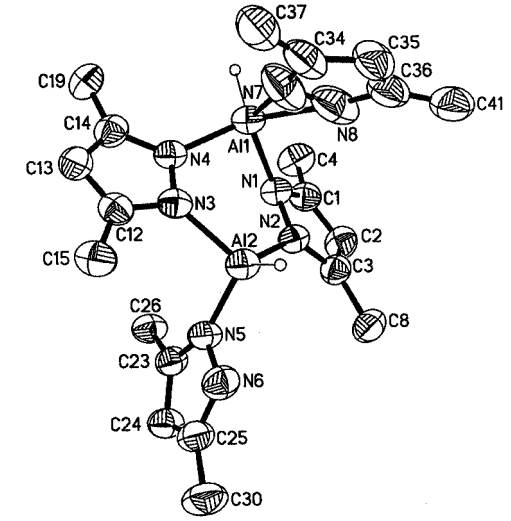

Figure 2. Perspective view of **4** with thermal ellipsoids at the 50% probability level; the *tert*-butyl methyl groups have been omitted for clarity

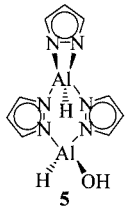
aluminum−oxygen bond length is 1.867(3) Å. The μ:η^1,η^1-pyrazolato ligands place the aluminum centers far enough apart [Al(1)−Al(2) 3.289(2) Å], so that hydrogen or oxygen atoms do not bridge in **3**. The N(5)−Al(1)−N(6) angle is 42.32(11)°, which is typical of η^2-pyrazolato ligands bonded to aluminum.[2,3c] All intermolecular OH···H(hydride) contacts are > 6 Å, and the closest intermolecular OH···O contact is > 4.3 Å. Thus, intermolecular dihydrogen bonding or intermolecular hydrogen bonding in **3** can be ruled out. The low hydroxy stretch noted above in the infrared spectrum of **3**, however, may be due to intramolecular hydrogen bonding between the hydroxy hydrogen atom and the π-cloud of the η^2-pyrazolato ligand (OH···centroid distance = 2.574 Å).

The molecular structure of **4** is similar to that of **3** except that it contains an η^1-*t*Bu$_2$pz ligand instead of a hydroxo ligand on the four-coordinate aluminum atom. The η^1- and η^2-pyrazolato ligands are *anti* to each other within the dinuclear unit to minimize steric interactions. The non-bridging pyrazolato ligand planes are nearly perpendicular to each other due to the steric hindrance of the *tert*-butyl groups. The five-coordinate Al(1)−N bond lengths range between 1.892−2.082 Å, and are slightly longer than those of the four-coordinate Al(2)−N bonds (1.871−1.933 Å). The Al(1)−N(7) bond length [1.892(3) Å] is much shorter than the Al(1)−N(8) bond length [2.082(4) Å], indicating unsymmetrical coordination of the η^2-pyrazolato ligand.[3c,7] The Al(2)−N(6) distance is 2.559(3) Å, which clearly demonstrates η^1-coordination. The N(7)−Al(1)−N(8) angle is 40.55(13)°, which is slightly smaller than the value in **3**. The Al(1)−Al(2) distance is 3.414(2) Å, which is slightly longer than in **3**, possibly due to increased steric crowding in **4**. Additionally, the intramolecular hydrogen bond in **3** may serve to reduce the aluminum−aluminum distance.

Molecular Orbital Calculations of 3

To gain better insight into the nature of the pyrazolato ligand bonding and the intramolecular hydrogen bond in **3**, molecular orbital calculations were performed. All calculations were carried out using the Gaussian suite of programs.[8] First we studied the model system **5**, in which the *tert*-butyl groups on the pyrazolato ligands were replaced by hydrogen atoms. Previous work from our laboratories indicated that replacement of alkyl groups by hydrogen atoms in pyrazolato ligands does not significantly affect the electronic structure of the molecule.[9] Optimization of **5** at the B3LYP/6-311++G(d,p) level of theory[10−13] led to the transformation of the η^2-pz ligand in **5** to an η^1-pz ligand. In addition, the π-cloud of the η^1-pyrazolato ligand twisted away from the hydroxy group hydrogen atom on the adjacent Al atom. Hence, **5** was not an acceptable theoretical model for **3**, which suggested that the bulky *tert*-butyl groups on the pyrazolato ligands in **3** may play an important role in determining the overall structure.



5

We next sought to carry out molecular orbital calculations on the full experimental molecule **3**. Since **3** has a large number of atoms, an ONIOM approach was employed to reduce the cost of the overall calculation.[14] The high level portion of **3** was the same as the model system and was calculated by B3LYP/6-311++G(d,p). The *tert*-butyl groups on the pyrazolato ligands were included in the low-level portion and were calculated by the AM1 semi-empirical method.[15,16] Figure 3 presents the results of this treatment. Optimization of **3** afforded a less dramatic movement of the η^2-pyrazolato ligand to the η^1-bonding mode

(Figure 3, a). The computed aluminum−nitrogen bond lengths were 1.89 Å and 2.43 Å, compared to 1.96 Å determined experimentally for both bonds. A constrained system was optimized in which the aluminum−nitrogen bonds were fixed at the experimentally observed distances. This treatment led to an energy increase of only 1.4 kcal/mol (Figure 3, c), and subsequent unconstrained optimization of this system afforded the structure shown in Figure 3 (a). This small energy difference indicates that the stabilization for the η^2-configuration is within the energy of crystal packing, and suggests that the η^2-*t*Bu$_2$pz ligand in **3** originates due to accommodation of the bulky *tert*-butyl groups. In both cases it is evident that there is an intramolecular hydrogen bond. In the fixed bond structure (Figure 3, c), the range of distances for the hydroxy hydrogen atom to the atoms in the pyrazolato ring core is 2.68−3.18 Å. In the case where the aluminum−nitrogen bond lengths were not frozen (Figure 3, a), these numbers have a slightly higher range of 2.61−3.56 Å. To obtain an estimate of the stabilization energy resulting from the hydrogen bond, the hydrogen atom on the hydroxy group was turned away from the pyrazolato ligand so that the hydroxy hydrogen atom was not in the proximity of the π-cloud of the η^2-pyrazolato ligand (Figure 3, b). The optimized geometry for this system had aluminum−nitrogen bond lengths of 1.88 Å and 2.32 Å. The distances from the oxygen atom of the hydroxo ligand to the atoms in the adjacent pyrazoato ligand ranged from 3.72−5.11 Å. Removing the ability to hydrogen bond from the system led to an ONIOM energy increase of 3.7 kcal/mol. This may be a slight underestimate of the true bond strength due to some steric differences in the low-level portion of the ONIOM calculation.

Discussion

The significance of this work resides principally in the unusual structures of **3** and **4**. Complex **4** is the first species that contains η^1-, η^2-, and μ:η^1,η^1-pyrazolato ligands within a single molecule. Many pyrazolato complexes have been reported that contain two of these coordination modes,[1,3b,17] but none until now has contained all three. Aluminum complexes containing η^2-pyrazolato ligands remain extremely rare,[2,3c] so **3** and **4** are additionally novel from this perspective.

Complex **3** is a rare example of an aluminum compound that contains a terminal hydroxo ligand.[18] The first structurally characterized aluminum complexes containing terminal hydroxo ligands were reported in 1987.[5d,5e] A terminal hydroxo ligand was structurally documented in $[Al_4Si_4H_8O_{20}\cdot 24H_2O]^{4-}$, and has a hydroxoaluminum−oxygen bond length of 1.783 Å.[5d] Each hydroxo ligand is extensively hydrogen-bonded to interstitial water molecules.

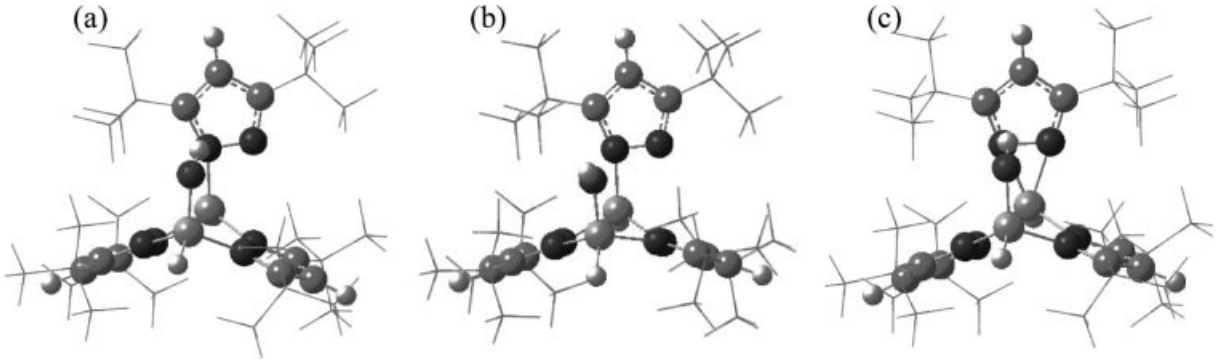

Figure 3. The three configurations of the model system with the DFT contribution as ball-and-stick and the AM1 portion as line drawing; (a) model system with intramolecular hydrogen bond; (b) model system with hydroxy group reversed so there is no intramolecular hydrogen bond; (c) model system with the aluminum−nitrogen bond lengths constrained to experimental values

The other initial report described the structure of quinuclidinium hydroxo(2,2′,2′′-nitrilotriphenoxy)aluminate, which contains an anionic aluminum center bonded to a terminal hydroxo ligand.[5e] The quinuclidinium ion is also associated with the oxygen atom through a N−H···O hydrogen bond. The aluminum−oxygen bond length is 1.765(2) Å. Recently, Roesky and co-workers have reported a series of aluminum complexes containing terminal hydroxo ligands.[5a−5c,18] The complexes are of the formula $L_{Ar}Al(OH)_2$,[5a] $\{L_{Ar}Al(OH)\}_2(\mu\text{-}O)$,[5b] and $L_{Ar}Al(OH)OAl(L_{Ar})(OCH{=}N\textit{t}Bu)$,[5c] where L_{Ar} = HC{(CMe)(2,6-iPr$_2$C$_6$H$_3$N)}$_2$. The aluminum−oxygen bond lengths in $L_{Ar}Al(OH)_2$ are 1.6947(15) and 1.7107(16) Å.[5a] In the solid state, this molecule forms dimeric units with $Al_2O_4H_2$ rings that contain intramolecular Al−O−H···O(H)(Al) hydrogen bonds. $\{L_{Ar}Al(OH)\}_2(\mu\text{-}O)$ exists as a monomer in the solid state, with aluminum−oxygen bond lengths of 1.738(2) and 1.741(3) Å.[5b] Infrared spectroscopy suggests that the hydroxy groups do not participate in hydrogen bonding. It was proposed that the hydroxo ligand hydrogen atoms reside within the shielding cone of the L_{Ar} aromatic rings, due to an unusually upfield resonance for these hydrogen atoms (δ = −0.30 ppm). $L_{Ar}Al(OH)OAl(L_{Ar})(OCH{=}N\textit{t}Bu)$ exists in the solid state with an eight-membered Al_2CHNO_3 ring that includes a strong O−H···N hydrogen bond.[5c] The aluminum−oxygen bond length is 1.727(2) Å. Parkin reported the synthesis of $[HB(Me_2pz)_3]Al(OH)_2$ in 1990, although this complex was not structurally characterized and it is therefore not clear if it contains terminal hydroxo ligands.[5f]

The metrics and stabilization of the terminal hydroxo ligand in **3** can be compared with those of the previously reported terminal hydroxo complexes noted above. The aluminum−oxygen bond length in **3** is 1.867(3) Å, which is considerably longer than the values in related terminal hydroxo complexes. However, the aluminum−oxygen bond length in **3** is similar to values observed in recently reported aluminum complexes containing bridging hydroxo ligands (1.81−2.09 Å).[19] The hydroxo ligand hydrogen atom in **3** participates in hydrogen bonding to the π-cloud of the adjacent η^2-pyrazolato ligand within the dimer, and thus constitutes a unique coordination environment for the hydroxo ligand. Apparently, the tBu$_2$pz ligands in **3** are so bulky that intermolecular hydrogen or dihydrogen bonding is not possible, and the only hydrogen-bond donor available is the π-cloud of the adjacent η^2-pyrazolato ligand. To the best of our knowledge, this is the first example of a hydrogen bond to the π-cloud of a pyrazolato ligand. Hydrogen bonding between nitrogen−hydrogen and oxygen−hydrogen bonds and the π-clouds of various neutral aromatic compounds is well precedented.[20] Since the tBu$_2$pz ligand is aromatic and possibly more electron rich than a neutral aromatic compound due to the formal negative charge, its π-system is probably a good hydrogen-bond acceptor. Molecular orbital calculations suggest that there is a preference for the formation of the O−H···pz$_\pi$ hydrogen bond, and that an estimate of the bond strength for this interaction is about 3.7 kcal/mol. This bond strength is in the range of a typical weak hydrogen bond, but is enough to orient the hydroxo ligand hydrogen atom. Molecular orbital calculations suggest that there is a very small energy difference (1.4 kcal/mol) between η^1- and η^2-pyrazolato ligands in **3**. It is possible that the hydrogen bond in **3** helps to stabilize the η^2-pyrazolato ligand, since the molecular orbital calculations suggested that there may be stronger hydrogen bonding to this ligand coordination mode compared to the η^1-pyrazolato ligand mode. The hydrogen bond in **3** requires that the hydroxo ligand hydrogen atom is pointed directly at the shielding cone of the aromatic tBu$_2$pz ligand. Thus, the ^{1}H NMR chemical shift of this hydrogen atom should be considerably upfield of where it would appear in the absence of this interaction. There is some ambiguity regarding the assignment of this resonance in **3**, since it appears in the same region as the aluminum-bound hydrido ligands. However, it resonates in the region of δ = 4.6−5.5 ppm. For comparison, the ^{1}H NMR chemical shift of the hydroxo ligand protons in $L_{Ar}Al(OH)_2$ was δ = 12.47 ppm.[5a] In $\{L_{Ar}Al(OH)\}_2(\mu\text{-}O)$, where it was proposed that the hydroxo ligand protons reside within the shielding cone of the LAr aromatic rings, the hydroxo proton resonance appeared at δ = −0.30 ppm.[5c] Roesky has argued that terminal Al−OH protons are strong Brønsted

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

acids, and should resonate at low fields in the ^{1}H NMR spectra in the absence of other effects.[5a] This speculation supports the low field position of the hydroxo ligand resonance in $L_{Ar}Al(OH)_2$. The hydroxo ligand resonance in **3** is considerably upfield of that in $L_{Ar}Al(OH)_2$, and therefore may be shifted due to the interaction with the shielding cone of the pyrazolato π-cloud.

Complex **3** is relevant to alumoxane chemistry,[12] since terminal hydroxo ligands may be present in some alumoxanes and the acidic hydroxo ligand hydrogen atom may activate polymerization precatalysts through protonation of a metal−alkyl bond. The existence of **3** must be related to the presence of the extremely bulky tBu$_2$pz ligands, which block further reactions such as protonation of hydrido or pyrazolato ligands. The stabilization of terminal hydroxo ligands in the previously reported aluminum complexes[5] is generally achieved only in the presence of very bulky ancillary ligands, which can block further reactions. Thus, terminal hydroxo ligands, if they occur in methylalumoxanes, probably occupy extremely hindered sites. The high Brønsted acidity of the aluminum-bound hydroxo ligand proton leads to a strong preference for hydrogen bond formation. As noted above, most of the known terminal hydroxo complexes of aluminum are stabilized by hydrogen bonding and have unique hydrogen-bond acceptors. The only exception is $\{L_{Ar}Al(OH)\}_2(\mu$-O), for which infrared spectroscopy suggested a non-hydrogen-bonded hydroxo ligand. In **3**, we have documented the presence of unique intramolecular O−H···pz$_\pi$ hydrogen bonding.

Experimental Section

General: All reactions were performed under dry argon using standard Schlenk and dry-box techniques. Solvents were distilled from various drying agents under argon prior to use. Alane−ethyldimethylamine was purchased from commercial sources. 3,5-Di-*tert*-butylpyrazole was prepared according to a literature procedure.[21] ^{1}H and ^{13}C{^{1}H} NMR spectra were obtained in dry, degassed [D$_8$]toluene, and were referenced to the residual proton or carbon atom resonances of this solvent. Infrared spectra were obtained using Nujol as the medium. Elemental analyses were performed by Midwest Microlab, Indianapolis, IN. Melting points were obtained on a Haake-Buchler HBI digital melting point apparatus and are uncorrected.

Synthesis of 1: A 100-mL Schlenk flask was charged with a 0.5 M solution of $AlH_3(NMe_2Et)$ in toluene (6.0 mL, 3.0 mmol) and was further diluted with toluene (40 mL). tBu$_2$pzH (0.811 g, 4.5 mmol) was added to this solution at 23 °C in small portions over 0.25 h. The mixture was stirred at 23 °C for 16 h. At this point, the volatile components were removed under reduced pressure to afford a white solid. This solid was dissolved in hexane (30 mL) and the solution was filtered through a 2-cm pad of Celite on a coarse glass frit. The filtered solution was placed in a −20 °C freezer for 24 h, during which time crystallization occurred. Removal of the solvent by cannula, followed by vacuum drying, afforded **1** as colorless crystals (0.505 g, 57%); m.p. 110 °C (dec). IR (Nujol): $\tilde{\nu}_{AlH}$ = 1961 (m), 1906 (m), 1885 (m) cm^{-1}. ^{1}H NMR ([D$_8$]toluene, 23 °C): δ = 1.40 [s, 54 H, C(CH_3)$_3$], 4.5 (br. s, 3 H, Al−H), 6.16 (s, 3 H, pz C−H) ppm. ^{13}C{^{1}H} NMR ([D$_8$]toluene, 23 °C): δ = 31.00 [s, C(CH_3)$_3$], 32.44 [s, C(CH$_3$)$_3$], 103.49 (s, pz C−H), 164.37 [s, C−C(CH$_3$)$_3$] ppm. $C_{33}H_{60}Al_2N_6$ (594.84): calcd. C 66.63, H 10.17, N 14.13; found C 66.84, H 10.10, N 13.95.

Hydrolysis of 1 to Afford 2, 3, and 4: A 100-mL Schlenk flask containing a solution of **1** (0.479 g, 0.805 mmol) in toluene (20 mL) was treated with water (14.5 mg, 0.805 mmol) at −78 °C. Gas evolution was immediately noted and small amount of insoluble white material precipitated. The mixture was stirred at −78 °C for 3 h and was then warmed to ambient temperature and was further stirred for 15 h. The volatile components were then removed under reduced pressure to afford a white solid. Dissolution of this solid in hexane (20 mL), followed by filtration through a 2-cm pad of Celite on a coarse glass frit to remove a small amount of insoluble white solid, afforded a colorless solution. Fractional crystallization of this solution at −20 °C afforded colorless crystals of **2** (0.035 g, 7.7%), **3** (0.075 g, 15%), and **4** (0.145 g, 23%). The order of crystallization was **3**, **2**, and **4**. The isolated yields were diminished due to the care that was required to achieve pure samples. NMR spectroscopic analysis of the white solid removed by filtration showed it to contain tBu$_2$pzH as well as a solid that was insoluble in [D$_1$]chloroform.

Complex 2: This compound was identified by comparison of its ^{1}H and ^{13}C NMR chemical shifts with the reported values.[2]

Data for 3: M.p. 145 °C. IR (Nujol): $\tilde{\nu}$ = 3227 (s, ν_{AlOH}), 1961 (m, ν_{AlH}), 1908 (m, ν_{AlH}), 1860 (m, ν_{AlH}) cm^{-1}. ^{1}H NMR ([D$_8$]toluene, 23 °C): δ = 1.41 [s, 54 H, C(CH_3)$_3$], 5.5, 4.6 (2 br. s, 3 H, 2 Al−H, Al−OH), 6.16 (s, 3 H, pz C−H) ppm. ^{13}C{^{1}H} NMR ([D$_8$]toluene, 23 °C): δ = 31.14 [s, C(CH$_3$)$_3$], 32.58 [s, C(CH$_3$)$_3$], 103.61 (s, pz C−H), 164.55 (s, C−C(CH$_3$)$_3$] ppm. $C_{33}H_{60}Al_2N_6O$ (610.83): calcd. C 64.87, H 9.90, N 13.76; found C 64.59, H 9.76, N 13.94.

Data for 4: M.p. 135 °C (dec). IR (Nujol): $\tilde{\nu}$ = 1937 (w, ν_{AlH}) cm^{-1}. ^{1}H NMR ([D$_8$]toluene, 23 °C): δ = 1.12 (s, 36 H, 4 C(CH_3)$_3$], 1.41 (s, 36 H, 4 C(CH_3)$_3$], 4.9 (br. s, 2 H, Al−H), 6.02 (s, 2 H, pz C−H), 6.22 (s, 2 H, pz C−H) ppm. ^{13}C{^{1}H} NMR ([D$_8$]toluene, 23 °C): δ = 31.00 [s, C(CH$_3$)$_3$], 31.39 [s, C(CH$_3$)$_3$], 31.94 [s, C(CH$_3$)$_3$], 33.31 [s, C(CH$_3$)$_3$], 101.12 (s, pz C−H), 106.93 (s, pz C−H), 162.12 [s, C−C(CH$_3$)$_3$], 168.69 [s, C−C(CH$_3$)$_3$] ppm. $C_{44}H_{78}Al_2N_8$ (773.10): calcd. C 68.36, H 10.17, N 14.49; found C 68.22, H 10.10, N 14.27.

X-ray Crystallography: Crystals of **3** (M = 610.83) and **4** (M = 773.10) were grown as described above and crystallized in the triclinic crystal system in the space group P$\bar{1}$. Relevant details and data are summarized in Tables 1−3. The crystals were mounted in thin glass capillaries under nitrogen. Diffraction data were collected with a Bruker P4 four-circle diffractometer coupled to a Bruker CCD area detector at 295(2) K, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved from the Patterson maps using SHELX-97[22] and refined against F^2 on all data by full-matrix least-squares with the same program. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included in the model at their geometrically calculated positions and held riding or observed on a difference fourier and refined. CCDC-185702 (**3**) and -185701 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK [Fax: (internat.) + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk]. Structure searches were conducted using the Cambridge Crystallographic Database, Version 5.25, November 2003.

Studies of the Nature of the Catalytic Species in the α-Olefin Polymerisation Processes Generated by the Reaction of Diamido(cyclopentadienyl)titanium Complexes with Aluminium Reagents as Cocatalysts

VanessaTabernero[a] and Tomás Cuenca*[a]

Keywords: Titanium / Diamido ligands / Olefin polymerisation / Trimethylaluminium / Methylaluminoxane

The reaction of the diamido(chloro)cyclopentadienyltitanium compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ [Cp^{Rx} = η^5-C_5H_5, η^5-$C_5(CH_3)_5$, η^5-$C_5H_4(SiMe_3)$; R′ = CH_2tBu, Pr] with the Grignard reagent MgClR (R = Me, CH_2Ph) affords the monomethyl and monobenzyl derivatives $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$. Upon addition of methylaluminoxane (MAO), the chloro- and alkyltitanium complexes show low activity towards the polymerisation of ethylene and styrene. However, no methylation was observed during the treatment of trimethylaluminium with the chloro compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$. Instead, these reactions give the dinuclear aluminium complexes $Al_2[1,2\text{-}C_6H_4(NR')_2]Me_4$ (R′ = CH_2tBu, Pr) through transmetallation of the diamido ligand, suggesting a deactivation process of the catalysts in the olefin polymerisation reactions. In an additional effort to model the catalytic species, stoichiometric reactions between the methyl derivatives $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Me$ and solid methylaluminoxane (MAO) were studied by NMR spectroscopy. Monitoring of these reactions revealed the formation of zwitterionic species depending on the nature of the solvent.

Introduction

In recent years, one of the achievements in transition metal organometallic chemistry has been the development of Ziegler−Natta catalysis for the polymerisation of ethylene and α-olefins and the research in this field has resulted in a good understanding of the mechanism of the olefin polymerisation process.[1−6] According to this, the minimum requirement for a catalyst precursor has been established as the existence of an unreactive ancillary ligand system (generally the cyclopentadienyl ligand) with at least two coordination sites which can be activated to provide a metal alkyl bond *cis* to a vacant coordination site for monomer binding. Descriptions of group 4 metal complexes with these features used as catalysts for olefin polymerisation have been extensive.[4,7−12] However, examples of precatalysts containing only one such group which can be active for olefin polymerisation are scarce.[13−15]

Over the past few years a growing interest in developing organometallic compound alternatives to classical group 4 cyclopentadienyl complexes has emerged. Some of the more significant recent developments have occurred with early and late transition metal systems. High-performance compounds bearing a chelate ligand such as diimino(pyridino)[16,17] (Fe and Co), imino(phenoxo)[13,18] (Ni), diamido[19,20] (Ti) and iminobis(phenoxo)[21−23] ligands(Zr) are examples which have provided excellent activity for α-olefin polymerisation and in some cases for promoting copolymerisation of an α-olefin with polar monomers[24] as well as living polymerisation.[25−27]

As part of our investigations directed at obtaining a new class of organometallic compounds combining cyclopentadienyl and diamido ligands, we recently published the synthesis of diamido(chloro)cyclopentadienyltitanium compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ [Cp^{Rx} = η^5-C_5H_5, η^5-$C_5(CH_3)_5$, η^5-$C_5H_4(SiMe_3)$; R′ = CH_2tBu, Pr] and as assessment of their behaviour as precatalysts for α-olefin polymerisation. As a continuation of this field, we report herein the synthesis of alkyl derivatives $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ and their activation with solid MAO to give active species in ethylene and styrene polymerisation reactions. To identify the nature of the catalytic species in the olefin polymerisation processes arising from the interaction of this class of precursor of organometallic complexes (with only one alkyl group bonded to the metal centre) with aluminium compounds as cocatalysts, the reactions of the chloro compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ with trimethylaluminium (TMA) and the methyl compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Me$ with solid methylaluminoxane (MAO) were tested. The objective of the present work was to gain a direct insight into the role of these species in polymerisation activity.

Results and Discussion

Synthesis of Dialkyl Derivatives

The reaction of 1 equiv. of MgClR (R = Me, 3 M solution in THF; R = CH_2Ph, 2 M solution in THF) with a solution of $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ [Cp^{Rx} = $\eta^5\text{-}C_5H_5$, $\eta^5\text{-}C_5(CH_3)_5$, $\eta^5\text{-}C_5H_4(SiMe_3)$; R′ = CH_2tBu, Pr] in hexane at −78 °C proceeds with substitution of the chloro ligand by the alkyl group affording the methyl and benzyl derivatives $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ (**1**−**12**) (Scheme 1, Table 1). The methyl (**1** and **2**) and the benzyl (**7** and **8**) compounds were isolated, after purification, as red and dark solids respectively, while the complexes **3**−**6** and **9**−**12** exist as red or dark oils which are difficult to handle and recrystallise due to their very high solubility in all common solvents. For compound **8**, the alkylation of the Ti−Cl bond in hexane is not totally effective due to steric hindrance at the titanium centre and a mixture of the chloro and the benzyl compounds is obtained. However, the reaction between $Ti(\eta^5\text{-}C_5Me_5)[1,2\text{-}C_6H_4(NCH_2t\text{Bu})_2]Cl$ and MgClBz in a polar solvent proceeds with the formation of the pure benzyl complex **8**.

	Pr	Me	(**6**)
		CH_2Bz	(**12**)

Complexes **1**−**12** are soluble in aromatic hydrocarbons, dichloromethane, chloroform, diethyl ether and alkanes (hexane and pentane). They are air- and moisture-sensitive in solution as well as in the solid state, although they can be stored unchanged for weeks under an inert gas. The complexes were characterised by the usual analytical and spectroscopic methods. In some cases, the ^1H NMR spectra of the $TiCp^{Rx}[1,2\text{-}C_6H_4(NPr)_2]R$ compounds in deuterated chlorinated solvents could not be obtained since the corresponding chloro compounds are formed in these solvents. In contrast, the $TiCp^{Rx}[1,2\text{-}C_6H_4(NCH_2t\text{Bu})_2]R$ derivatives can be dissolved in chlorinated solutions for long periods without transformation into the corresponding chloro compounds since the neopentyl substituent affords greater steric protection for the metal centre than the propyl substituent.

The NMR spectra of these compounds show patterns for the proton and carbon resonances similar to those described for the analogous chloro compounds.[28] The ^1H resonances (C_6D_6, room temperature) of the cyclopentadienyl protons appear at δ = 6.01−6.15 for the Cp and δ = 1.45−1.71 for the C_5Me_5 ligands. The $C_5H_4(SiMe_3)$ ring protons give AA′BB′ spin systems at δ = 6.13−6.53. The methyl protons of the $SiMe_3$ group exhibit one singlet located at δ = 0.17−0.31. The spectra for the propyl compounds show sets of multiplets and triplet resonances for the N-CH_2−CH_2−CH_3 fragment protons, while the expected signals for the neopentyl ligand protons can be observed in the spectra of the corresponding derivatives. The phenyl protons of the diamido ligands appear as two multiplets in the usual range. Furthermore, the ^1H NMR spectra show the expected signals assignable to the methyl and the benzyl ligands attached to titanium. Similar structural features to those described from ^1H NMR spectroscopy can be deduced from the $^{13}C\{^1H\}$ NMR spectra (C_6D_6, room temperature). These spectroscopic data are in agreement with C_s symmetry and are consistent with the presence of a mirror plane containing the Ti and C_α atoms of the alkyl groups bisecting the N−Ti−N angle of the chelate diamido ligand.

In this type of complex, the diamido ligand can adopt different coordination modes and has two possible conformation modes (*supine* or *prone*) relative to the cyclopentadienyl ring. A Nuclear Overhauser Enhancement (NOE) study of the benzyl complex **7** containing the Cp ligand enabled us to distinguish between these two possible dispositions. Irradiation of the Cp resonance resulted in a significant NOE enhancement in the methylene signals of the neopentyl group, while no NOE enhancements in the phenyl signals were observed. These observations suggest that the neopentyl group is located close to the Cp ring with the diamido ligand adopting a *supine* conformation, in accordance with the chemical shifts observed for the cyclopentadienyl ring protons in the ^1H NMR spectrum which are not influenced by phenylene magnetic anisotropy.[29] Similar results were obtained for the corresponding chloro derivatives which is consistent with the disposition found in the solid state using X-ray crystallography.[28]

Polymerisation Reactions

Given our interest in the polymerisation chemistry of group 4 diamido(cyclopentadienyl)-[15,30,31] or dialkoxometal complexes,[32] we undertook a study of α-olefin polymerisation processes of the alkyldiamido(cyclopentadienyl) compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ with methylaluminoxane (MAO) as a cocatalyst. The reaction conditions and the results are summarised in Table 2 and 3. The results

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

show the averages of two or more polymerisation runs which showed good reproducibility between them.

Table 2. Polymerisation studies of ethylene with $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ in the presence of MAO as cocatalyst

Table 2. Polymerisation studies of styrene with $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ in the presence of MAO as a cocatalyst

Entry	Catalyst[a]	Activity[b]	T_m(°C)
1	**1**	25	252
2	**2**	35	250
3	**3**	15	260
4	**4**	18	248
5	**7**	15	256
6	**8**	10	246
7	**10**	13	257

[a] Reaction conditions: temperature = 50 °C, 10 mg of precatalyst, molar ratio Al/Ti = 400, 50 mL of toluene, 5 mL styrene, 15 min. [b] g PS/mmol Ti h. [c] Determined by DSC.

When activated with MAO, low activities for ethylene homopolymerisation were obtained with the neopentyl compounds **1**−**3** and **7**−**8** (Entries 1−3 and 5−6), while moderate activities with the propyl complexes **4** and **10** (Entries 4 and 7) were observed (Table 2). These activity values show a pronounced dependence on the steric requirements of the diamido ligand with the higher activity observed for the smaller substituent on the nitrogen atom of the amido ligand. Similar control of steric crowding at the metal centre has been observed in bulky amidinato complexes.[33,34] The activities exhibited for these complexes are of the same order of magnitude as those described for similar diamido(cyclopentadienyl)titanium compounds,[35−37] although they are smaller than those reported for noncyclopentadienyl diamido complexes.[17,38,39] Polymer samples show melting point values (T_m measured by DSC) typical of high-density polyethylene.

The $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ precatalysts were tested for styrene polymerisation upon activation with MAO but poor catalytic activities were found (Table 3). The observed activity values are markedly lower than those obtained with the well-known $CpTiCl_3$ used as a reference point.[40] The PS samples obtained are in the range typical for syndiotactic polymers (NMR spectroscopy), as expected for cyclopentadienyltitanium precatalysts,[41−46] with low molecular weights (as deduced from their T_m analyses).

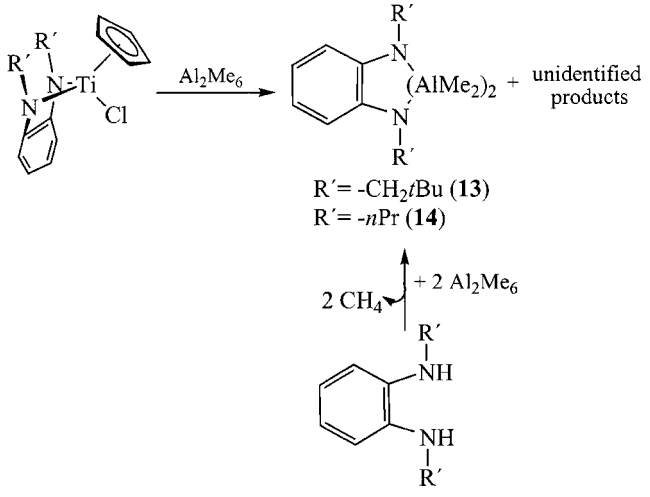
$B(C_6F_5)_3$ was also used as a cocatalyst in our polymerisation experiments but, unfortunately, no catalytic activity was observed even after using TIBA as scavenger in the reaction mixture. In the catalyst systems obtained by combining **1** or **2** with $B(C_6F_5)_3$, the colour of the solutions were different from those obtained in the reaction with solid MAO as a cocatalyst, suggesting that different species are formed. While **1** and solid MAO mixtures result in a green solution, a red colour was observed using $B(C_6F_5)_3$ as a cocatalyst. These results can be attributed to the ability of aluminium derivatives to abstract the diamido ligand providing the alkyl group requirement for polymerisation in a Ziegler−Natta manner, whereas this possibility is unavailable in the perfluoroborane compound.

The low activity trend observed for the $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ precatalysts in the α-olefin polymerisation reactions might be due to a catalyst decomposition process through ligand abstraction by MAO which may cause partial or complete loss of the ligand thus resulting in one or more inactive species for α-olefin polymerisation.[47] In an effort to model the nature of the catalytic species generated in these catalyst systems, the reactions of the cyclopentadienyldiamido, monochloro and monoalkyltitanium derivatives with trimethylaluminium (TMA) and solid methylaluminoxane MAO were examined.

Reactions of $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ with TMA

Attempts to obtain methyltitanium derivatives under the conditions described above from the $Ti(\eta^5\text{-}C_5H_5)[1,2\text{-}C_6H_4(NR)_2]Cl$ starting compound using alkylating aluminium reagents such as TMA were unsuccessful. The methylated products was not observed but evolution of the starting material by ligand transfer from titanium to aluminium occurred.

Treatment of a red-brown solution of the monochloro compound $Ti(\eta^5\text{-}C_5H_5)[1,2\text{-}C_6H_4(NCH_2tBu)_2]Cl$ in hexane at −78 °C with one equivalent of TMA resulted in the im-



Scheme 2

mediate formation of a yellow solution but the expected monomethyl titanium complex **1** was not observed (monitoring by NMR spectroscopy). Concentration of the solution enabled isolation of the amidoalane compound $Al_2[1,2\text{-}C_6H_4(NCH_2tBu)_2]Me_4$ (**13**) and a mixture of unidentified and intractable titanium species. Similarly, when the reaction was carried out in a Ti:Al molar ratio of 1:100, formation of the amidoalane was observed along with a more complicated final mixture of products. In an analogous reaction, treatment of $Ti(\eta^5\text{-}C_5H_5)[1,2\text{-}C_6H_4(NPr)_2]Cl$ with TMA (in a Ti:Al molar ratio 1:1 and 1:100) afforded the amidoalane compound $Al_2[1,2\text{-}C_6H_4(NnPr)_2]Me_4$ (**14**) (Scheme 2).

These aluminium compounds can be synthesised as pure substances through a direct route by treating $1,2\text{-}C_6H_4(NHR')_2$ (R′ = CH_2tBu, Pr) with 2 equiv. of TMA in toluene with partial precipitation of the aluminium compounds occurring in 1 h (Scheme 2). Reactions between amines and aluminium compounds are well known[48−50] and in the first step, an adduct of the type N−Al is probably formed which then eliminates methane generating the amidoaluminium compound.

Compound **13** was characterised by elemental analysis, while the elemental analysis values found for **14** were inaccurate due to the presence of small amounts of impurities which could not be removed although both aluminium compounds were also characterised by spectroscopic methods. The ^1H NMR spectra (C_6D_6, room temperature) show two different types of methyl groups with each signal corresponding to six protons (see Exp. Sect.). The proposed structural dispositions (Figure 1) are similar to those described for analogous compounds[18,51,52] in which two "$AlMe_2$" moieties are symmetrically chelated by a diamido ligand. They exhibit two aluminium centres with tetrahedral geometry and two nitrogen atoms forming a four membered butterfly shaped metallacycle. Methyl groups are positioned in two different chemical environments with two being located towards the phenyl group and the other being orientated in the opposite direction.

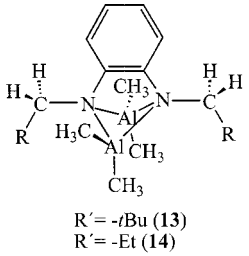


Figure 1. Proposed structural disposition for compounds **13** and **14**

Such reactions starting from monocyclopentadienyl diamido titanium compounds forming aluminium derivatives therefore indicate that transmetallation reactions offer a facile reaction pathway in early transition metal complexes. Similar transmetallation reactions have been proposed for group 4[53] and more recently for group 6[54] complexes bearing diamido ligands. We believe that the resistance of the monocyclopentadienyl diamido chloro titanium complexes to form the alkylated product in the reaction with aluminium reagents and the ligand transfer processes are associated with the low activity of the chloro complexes $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ for ethylene and styrene polymerisations. These results provide an insight into the nature of the catalytic species generated during the olefin polymerisation processes through interaction of the precatalyst based on titanium complexes with the aluminium reagents as cocatalysts.

Reaction between $Ti(\eta^5\text{-}C_5H_5)[1,2\text{-}C_6H_4(NCH_2tBu)_2]Me$ (1) and Solid MAO

In order to obtain a better understanding of the nature of the active species and the chemical behaviour of the $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ precatalyst systems in the ethylene and styrene polymerisation processes, the reaction of **1** with solid MAO was carried out using a stoichiometric 1:1 Ti/Al ratio and studied by ^1H NMR spectroscopy. Solid MAO was selected to avoid the inexorable presence of free TMA in commercial MAO[55] since this compound causes transmetallation which could be a crucial factor in the evolution of the reaction.

The ^1H NMR spectrum recorded immediately after mixing the reagents in CD_2Cl_2 at room temperature shows a broadening of Ti-Me resonance accompanied by a downfield shift with respect to the initial situation.[56] In the ^1H NMR spectrum of **1**, the methyl group protons appear at $\delta = -1.5$. After the reaction with MAO, this resonance overlaps with the corresponding MAO signals. These features are in accordance with the interaction of the methyl group of compound **1** with the aluminium atoms present in the MAO which act as Lewis acidic sites[57−61] (Structure A in Scheme 3) or, alternatively, with abstraction of this methyl group to generate an anionic aluminium centre which interacts with the cationic titanium atom through methyl group bridging (Structure B in Scheme 3). The broadness could be due to the closer position of the methyl group, initially bound to titanium, to the "diversification" centres provided by different Lewis acidic sites present in MAO.[62,63] The broadening of Ti-Me resonances of an adduct with MAO has also been reported by Talsi et al.[59,64] When the polarity of the solvent is high, as in this case, methyl group abstraction by MAO is favoured and solvent-separated ion pairs are preferentially formed.[65−67] After allowing the sample to stand for one day in solution, the ^1H NMR spectrum shows clear formation of the chlorinated compound $Ti(\eta^5\text{-}C_5H_5)[1,2\text{-}C_6H_4(NCH_2tBu)_2]Cl$ which indicates chloro abstraction from the solvent.

When the same reaction is carried out in a less polar solvent such as C_6D_6, the process proceeds in a different way. Initially, after mixing the reagents at room temperature for 5 min, the ^1H NMR spectrum features are consistent with the formation of the zwitterionic species in which the methyl ligand acts as a bridging group between the titanium and aluminium centres (Structure A in Scheme 3 favoured).

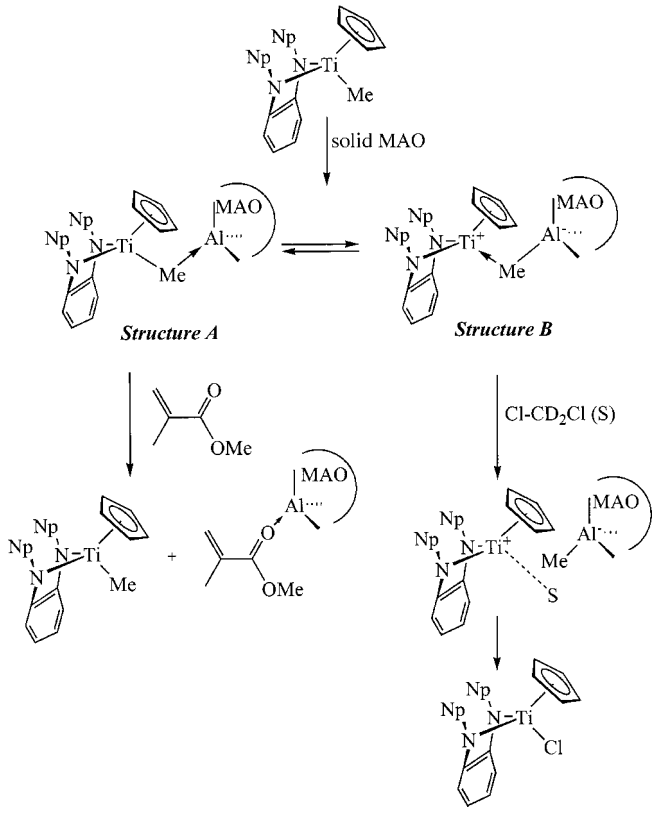

Scheme 3

It is believed that the formation of separated ions, in this case, is not favoured because there is no stabilisation conferred by solvent coordination. After 1 d in solution, no significant changes in the ^{1}H NMR spectrum were observed.

When the solution in C_6D_6 was saturated[68−70] with ethylene, polyethylene was not formed. However, the addition of a polar monomer such as methyl methacrylate (MMA) to the C_6D_6 solution caused the displacement of the MAO initially attached to the titanium centre. The ^{1}H NMR spectrum shows signals indicating the presence of the methylated compound **1** (Scheme 3) and a complicated set of resonances assignable to products exhibiting interactions between MMA and MAO.

Treatment of compound **1** with an excess of solid MAO was rather difficult to study by NMR spectroscopy because the signals of the products overlap with the MAO resonances. We suggest the excess aluminium centres provided by such a large amount of solid MAO, used generally for polymerisation runs, could cause the deactivation of the $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ catalysts by transmetallation reactions of the diamido groups in a similar way to observations made in the reaction of $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ with TMA.

Conclusion

The synthesis and characterisation of new monocyclopentadienyl diamido alkyl titanium $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ compounds from the reaction of the corresponding chloro derivatives with Grignard reagents has been described. After activation with methylaluminoxane, the diamido complexes exhibit low activity towards α-olefin polymerisation. While the chloro derivatives $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ can be easily methylated by reaction with MgClMe, reaction with trimethylaluminium results in the transmetallation of the diamido ligand to produce dinuclear aluminium compounds. This behaviour must be associated with the low activity of the chloro and alkyl derivatives in the ethylene and styrene polymerisations. The reactivity of the alkyl complexes $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]R$ with MAO has also been studied by NMR spectroscopy. This indicated the formation of intermediate species which can be considered to exert an important effect on the catalytic activity of these precatalysts in the α-olefin polymerisation process.

Experimental Section

General Considerations: All manipulations of air- and moisture-sensitive materials were performed under argon using Schlenk and high-vacuum line techniques or in a glove box model MO40-2. Solvents were predried with activated molecular sieves (4 Å) and were then purified by distillation under argon before use by employing the appropriate drying/deoxygenating agent. Deuterated solvents were degassed by several freeze-thaw cycles and stored in ampoules equipped with Young's Teflon valves over activated molecular sieves (4 Å). C, H and N microanalyses were performed with a Perkin−Elmer 2400 microanalyser. NMR spectra, measured at 25 °C, were recorded with a Varian Unity FT-300 (^{1}H NMR at 300 MHz, ^{13}C NMR at 75 MHz) spectrometer and chemical shifts were referenced to $SiMe_4$ via the ^{13}C resonances and the residual protons (^{1}H) of the deuterated solvent. MAO was purchased from Witco as a toluene solution (10% wt). Reagent grade styrene (Aldrich) was distilled under reduced pressure from calcium hydride and stored in a refrigerator under argon. The polymerisation solvent was dried by heating to reflux in the presence of sodium/benzophenone under argon. MgClMe (3 M solution in THF) and MgClBz (2 M solution in THF) were purchased from Aldrich and used as received. The chlorinated compounds $TiCp^{Rx}[1,2\text{-}C_6H_4(NR')_2]Cl$ [Cp^{Rx} = η^5-C_5H_5, η^5-$C_5(CH_3)_5$, η^5-$C_5H_4(SiMe_3)$; R′ = CH_2tBu, Pr] and the *N*,*N*′-dialkyl-1,2-phenylenediamines $1,2\text{-}C_6H_4(NHR')_2$ (R′ = CH_2tBu, Pr) were prepared as described in previous work.[28]

Preparation of MAO Samples: To obtain MAO with a reduced amount of TMA, a sample of commercial MAO was distilled under vacuum at 20 °C. The white powder obtained (polymeric MAO with residual TMA ca. 3 wt-%) was stored in dry box before use in the preparation of the samples. Calculated quantities of the desired compound and solid MAO were taken into the dry box to prepare the samples with the desired Ti/Al ratio. Solids were mixed and the selected solvent was added directly to the NMR tube equipped with a Young's Teflon valve. All operations were carried out at room temperature.

Polymerisation Procedure: For ethylene polymerisation, the typical procedure was as follows. Toluene (50 mL), solid MAO (Al/Ti = 400) and the desired precatalyst (10 mg) in a sealed glass vial were placed in a high-pressure glass reaction vessel (Büchi). Subsequently, the polymerisation temperature was adjusted and the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mixture was pressurized to 5 atm for 1 h before cracking the vial. After 15 min of venting of the ethylene gas and quenching with HCl/CH_3OH (10 mL), the reaction was stopped. The solution was then poured into a large excess of this solvent mixture and the resultant polyethylene was separated by filtration, washed several times (HCl/CH_3OH) and dried under vacuum overnight. Polymerisation of styrene was performed under argon in toluene at 50 °C using solid MAO as the cocatalyst according to the following procedure. Toluene (30 mL), styrene (5 mL) and MAO were injected into the Schlenk flasks with magnetic stirring at the desired temperature. The titanium compound was dissolved in toluene (5 mL) and added to the mixture. In a manner similar to the polyethylenes, the polystyrenes were coagulated with a large excess of acidified methanol and isolated by filtration.

Characterisation of Polymers: The thermal properties of the samples were studied using a Perkin−Elmer DSC 6 instrument calibrated by measuring the melting point of indium. Thus, 5−10 mg each of the dried polymers were fused into standard aluminium pans and measured using the following temperature programme for polyethylene samples: first a heating phase (10 °C/min) from 50 to 200 °C, followed by a cooling phase (−10 °C/min) to 50 °C. The peak maximum of the second heating curve was indicated as the melting point (T_m). ΔH_m derived from the data of the second heating course of the DSC was selected. Polystyrene samples were subjected to the following steps: heating at 10 °C/min from 30 to 270 °C and then cooling at 10 °C/min from this temperature to 30 °C and finally heating at 10 °C/min from 30 to 270 °C to obtain the melting peak temperature (T_m). The NMR-PS samples were prepared by dissolving the polymer in tetrachloro-1,2-dideuterioethane. The spectra were recorded at 25 °C.

Ti(η^5-C_5H_5)[1,2-C_6H_4(NCH$_2$*t*Bu)$_2$](CH$_3$) (1): A 3 M solution of MeMgCl in THF (0.42 mL, 0.93 mmol) was added to a solution of Ti(η^5-C_5H_5)[1,2-C_6H_4(NCH$_2$*t*Bu)$_2$]Cl (0.50 g, 1.27 mmol) in hexane (50 mL) at −78 °C. The cooling bath was removed and the reaction mixture was warmed to room temperature after stirring for 12 h. The resultant residue was filtered and the solution cooled to −40 °C to afford **1** as a red solid (0.35 g, 74%). $C_{22}H_{34}N_2Ti$ (374.40): calcd. C 70.58, H 9.15, N 7.48; found C 70.50, H 9.29, N 7.51. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.33 (s, 4 H, Ph), 6.15 (s, 5 H, C_5H_5), 3.89 (d, J = 12.6 Hz, 2 H, CH_2), 3.83 (d, J = 12.6 Hz, 2 H, CH_2), 0.71 (s, 18 H, *t*Bu), −0.90 (s, 3 H, CH_3) ppm. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.36 (m, 4 H, Ph), 6.28 (s, 5 H, C_5H_5), 4.01(s, 4 H, CH_2), 0.73 (s, 18 H, *t*Bu), −1.46 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 126.1, 118.9 (Ph), 124.8 (*ipso*-Ph), 113.1 (C_5H_5), 65.6 (CH_2), 33.3 (Ti-CH_3), 35.7 (*ipso*-*t*Bu), 28.6 (*t*Bu) ppm.

Ti(η^5-C_5Me_5)[1,2-C_6H_4(NCH$_2$*t*Bu)$_2$](CH$_3$) (2): Compound **2** was prepared by treating Ti(η^5-C_5Me_5)[1,2-C_6H_4(NCH$_2$*t*Bu)$_2$]Cl (1.86 g, 4.00 mmol) in hexane with a 3 M solution of MeMgCl in THF (1.33 mL) according to the procedure described for **1** and was obtained as a dark solid (1.40 g, 3.15 mmol, 78%). $C_{27}H_{44}N_2Ti$ (444.54): calcd. C 72.95, H 9.98, N 6.30; found C 72.98, H 9.87, N 6.15. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.22 (m, 4 H, Ph), 3.86 (d, J = 13.2 Hz, 2 H, CH_2), 3.67 (d, J = 13.2 Hz, 2 H, CH_2), 1.56 (s, 15 H, C_5Me_5), 0.96 (s, 3 H, CH_3), 0.91 (s, 18 H, *t*Bu) ppm. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.24 (m, 2 H, Ph), 7.18 (m, 2 H, Ph), 3.87 (d, J = 13.2 Hz, 2 H, CH_2), 3.59 (d, J = 13.2 Hz, 2 H, CH_2), 1.58 (s, 15 H, C_5Me_5), 0.78 (s, 18 H, *t*Bu), 0.57 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 124.6 (*ipso*-Ph), 123.3, 116.6 (Ph), 117.9 (*ipso*-C_5Me_5), 61.2 (CH_2), 50.5 (Ti−CH_3), 36.9 (*ipso*-*t*Bu), 29.5 (*t*Bu), 10.5 (C_5Me_5) ppm.

Ti[η^5-C_5H_4(SiMe$_3$)][1,2-C_6H_4(NCH$_2$*t*Bu)$_2$](CH$_3$) (3): Compound **3** was prepared by treating Ti[η^5-C_5H_4(SiMe$_3$)][1,2-C_6H_4(NCH$_2$-*t*Bu)$_2$]Cl (0.22 g, 0.47 mmol) with a 3 M solution of MeMgCl in THF (0.16 mL) according to the procedure described for **1** and was obtained as a red-brown oil (0.11 g, 2.46 mmol, 52%). The isolated oil consisted mainly of **3** and some LiCl as an impurity which could not be removed. The correct elemental analytical data could not be obtained, although satisfactory spectroscopic data were obtained. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.31 (s, 4 H, Ph), 6.53, 6.28 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 4.00 (d, J = 12.0 Hz, 2 H, CH_2), 3.95 (d, J = 12.0 Hz, 2 H, CH_2), 0.75 (s, 18 H, *t*Bu), 0.28 (s, 9 H, $SiMe_3$), −0.91 (s, 3 H, CH_3) ppm. ^{1}H NMR (300 MH, $CDCl_3$, 25 °C): δ = 7.33 (m, 4 H, Ph), 6.46, 6.31 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 4.00 (s, 4 H, CH_2), 0.73 (s, 18 H, *t*Bu), 0.19 (s, 9 H, $SiMe_3$), −1.49 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 125.5 (*ipso*-Ph), 126.2, 119.1 (Ph), 115.2 (*ipso*-C_5H_4), 120.1, 114.9 (C_5H_4), 66.1 (CH_2), 35.8 (*ipso*-*t*Bu), 33.2 (Ti−CH_3), 28.9 (*t*Bu), 0.29 ($SiMe_3$) ppm.

Ti(η^5-C_5H_5)[1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)$_2$](CH$_3$) (4): A 3 M solution of MeMgCl in THF (0.53 mL) was added to a stirred solution of Ti(η^5-C_5H_5)[1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)$_2$]Cl (0.54 g, 1.59 mmol) in hexane (50 mL) at −78 °C. The cooling bath was removed and the reaction mixture was slowly warmed to room temperature and stirred for 12 h. The residue was filtered and the solution concentrated and cooled. Compound **4** was obtained as a dark oil (0.37 g, 1.16 mmol, 73%). $C_{18}H_{26}N_2Ti$ (318.30): calcd. C 67.92, H 8.23, N 8.80; found C 68.30; H 8.15; N 9.01. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.33 (m, 2 H, Ph), 7.00 (m, 2 H, Ph), 6.11 (s, 5 H, C_5H_5), 3.67 (m, 4 H, CH_2), 1.35 (m, 4 H, CH_2), 0.65 (t, J = 7.5 Hz, 6 H, CH_3), −0.25 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 125.0, 115.1 (Ph), 129.7 (*ipso*-Ph), 113.1 (C_5H_5), 57.5 (N−CH_2), 35.9 (Ti−CH_3), 24.9 (CH_2), 12.1 (CH_3) ppm.

Ti(η^5-C_5Me_5)[1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)$_2$](CH$_3$) (5): A 3 M solution of MeMgCl in THF (0.17 mL) was added to a solution of Ti(η^5-C_5Me_5)[1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)$_2$]Cl (0.21 g, 0.51 mmol) in hexane (50 mL) at −78 °C. The cooling bath was removed and the reaction mixture was slowly warmed to room temperature and stirred for 12 h. After filtration, the resultant solution was concentrated and cooled to −20 °C. Complex **5** was obtained as a black oil (0.12 g, 0.31 mmol, 60%). $C_{23}H_{36}N_2Ti$ (388.43): calcd. C 71.12, H 9.34, N 7.21; found C 70.83, H 9.15, N 7.01. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.28 (m, 2 H, Ph), 6.89 (m, 2 H, Ph), 3.64 (m, 2 H, N−CH_2), 3.47 (m, 2 H, N−CH_2), 1.68 (s, 15 H, C_5Me_5), 1.60 (m, 4 H, CH_2), 0.80 (t, J = 7.5 Hz, 6 H, CH_3), 0.82 (s, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = 130.0 (*ipso*-Ph), 123.0, 113.4 (Ph), 119.5 (*ipso*-C_5Me_5), 53.3 (N−CH_2), 48.1 (Ti−CH_3), 23.4 (CH_2), 12.4 (CH_3), 10.7 (C_5Me_5) ppm.

Ti[η^5-C_5H_4(SiMe$_3$)][1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)$_2$](CH$_3$) (6): Compound **6** was prepared by treating Ti[η^5-C_5H_4(SiMe$_3$)][1,2-C_6H_4(NCH$_2$CH$_2$CH$_3$)$_2$]Cl (0.17 g, 0.41 mmol) with a 3 M solution of MeMgCl in THF (0.14 mL, 0.41 mmol) according to the procedure described for **4** and was obtained as a dark oil (0.11 g, 0.28 mmol, 68%). $C_{21}H_{34}N_2SiTi$ (390.48): calcd. C 64.60, H 8.78, N 7.17; found C 65.06, H 8.92, N 7.12. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.32 (m, 2 H, Ph), 6.99 (m, 2 H, Ph), 6.40, 6.29 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 3.78 (m, 4 H, CH_2), 1.36 (m, 4 H, CH_2), 0.67 (t, J = 7.5 Hz, 6 H, CH_3), 0.22 (s, 9 H, $SiMe_3$), −0.23 (s, 3 H, CH_3) ppm. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.22 (m, 2 H, Ph), 6.94 (m, 2 H, Ph), 6.47, 6.45 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 3.86 (m, 4 H, CH_2), 1.46 (m, 4 H, CH_2), 0.79 (t, J = 7.5 Hz, 6 H, CH_3), 0.19 (s, 9 H, $SiMe_3$), −0.69 (s, 3

H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 125.8 (*ipso*-C_5H_4), 125.0, 115.2 (Ph), 120.3, 115.5 (C_5H_4), 58.4 (N−CH_2), 35.0 (Ti-CH_3), 23.7 (CH_2), 12.0 (CH_3), 0.60 ($SiMe_3$) ppm, the signal for *ipso*-Ph is not observed.

Ti(η^5-C_5H_5)[1,2-C_6H_4(NCH_2tBu)$_2$](CH_2Ph) (7): A 2 M solution of BzMgCl in THF (0.63 mL, 1.27 mmol) was added dropwise to a stirred solution of Ti(η^5-C_5H_5)[1,2-C_6H_4(NCH_2tBu)$_2$]Cl (0.50 g, 1.27 mmol) in hexane (50 mL) at −78 °C. After the addition was complete, the reaction mixture was warmed to room temperature and stirred for 12 h. The white precipitate formed was filtered and the resultant solution cooled to −40 °C. A red-brown solid was collected after filtration which was characterised as **7** (0.30 g, 0.66 mmol, 53%). $C_{28}H_{38}N_2Ti$ (450.50): calcd. C 74.65, H 8.50, N 6.22; found C 74.30, H 8.40, N 6.10. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.35 (s, 4 H, Ph), 7.17, 6.86, 6.57 (t, t, d, 5 H, CH_2Ph), 6.01 (s, 5 H, C_5H_5), 3.89 (d, J = 13.8 Hz, 2 H, CH_2), 3.81 (d, J = 13.5 Hz, 2 H, CH_2), 0.89 (s, 2 H, CH_2Ph), 0.68 (s, 18 H, *t*Bu) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.50 (m, 2 H, Ph), 7.40 (m, 2 H, Ph), 6.97, 6.60, 6.32 (t, t, d, 5 H, CH_2Ph), 6.07 (s, 5 H, C_5H_5), 4.05 (d, J = 13.8 Hz, 2 H, CH_2), 3.97 (d, J = 13.5 Hz, 2 H, CH_2), 0.74 (s, 18 H, *t*Bu), 0.44 (s, 2 H, CH_2Ph) ppm. $^{13}C\{^1H\}$ NMR (75 MH, C_6D_6, 25 °C): δ = 150.0 (*ipso*-CH_2Ph), 126.4, 118.9 (Ph), 128.1, 127.8, 120.8 (CH_2Ph), 124.9 (*ipso*-Ph), 114.8 (C_5H_5), 65.8 (CH_2), 61.52 (CH$_2$Ph). 35.8 (*ipso*-*t*Bu), 29.1 (*t*Bu) ppm.

Ti(η^5-C_5Me_5)[1,2-C_6H_4(NCH_2tBu)$_2$](CH_2Ph) (8): Compound **8** was prepared by treating Ti(η^5-C_5Me_5)[1,2-C_6H_4(NCH_2tBu)$_2$]Cl (0.50 g, 1.07 mmol) in toluene (50 mL) at −78 °C with a 2 M solution of BzMgCl in THF (0.54 mL) according to the procedure described for **7**. Recrystallisation of the final product with pentane afforded **8** as a dark-red solid (0.40 g, 0.77 mmol, 72%). $C_{33}H_{48}N_2Ti$ (520.64): calcd. C 76.13, H 9.29, N 5.38; found C 76.43, H 9.37, N 5.61. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.23 (s, 4 H, Ph), 7.22, 7.12, 6.95 (t, t, d, 5 H, CH_2Ph), 4.05 (d, J = 13.5 Hz, 2 H, CH_2), 3.97 (d, J = 13.5 Hz, 2 H, CH_2), 2.67 (s, 2 H, CH_2Ph), 1.45 (s, 15 H, C_5Me_5), 0.95 (s, 18 H, *t*Bu) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.33 (m, 2 H, Ph), 7.21 (m, 2 H, Ph), 7.18, 6.95, 6.89 (t, t, d, 5 H, CH_2Ph), 3.92 (d, J = 13.5 Hz, 2 H, CH_2), 4.14 (d, J = 13.5 Hz, 2 H, CH_2), 2.39 (s, 2 H, CH_2Ph), 1.42 (s, 15 H, C_5Me_5), 0.86 (s, 18 H, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 151.3 (*ipso*-CH_2Ph), 127−128 (CH_2Ph), 123.7, 117.6 (Ph), 124.7 (*ipso*-Ph), 119.0 (*ipso*-C_5Me_5), 74.5 (CH$_2$Ph), 60.9 (CH_2), 37.4 (*ipso*-*t*Bu), 30.1 (*t*Bu), 10.6 (C_5Me_5) ppm.

Ti[η^5-C_5H_4($SiMe_3$)][1,2-C_6H_4(NCH_2tBu)$_2$](CH_2Ph) (9): Compound **9** was prepared by treating Ti[η^5-C_5H_4($SiMe_3$)][1,2-C_6H_4(NCH_2tBu)$_2$]Cl (0.22 g, 0.47 mmol) with a 2 M solution of BzMgCl in THF (0.23 mL) according to the same procedure described for **8** and was obtained as a red-brown oil (0.15 g, 0.28 mmol, 61%). $C_{31}H_{46}N_2SiTi$ (522.68): calcd. C 71.24, H 8.87, N 5.36; found C 70.80, H 8.72, N 5.20. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.33 (s, 4 H, Ph), 7.17, 6.86, 6.64 (t, t, d, 5 H, CH_2Ph), 6.51, 6.18 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 3.99 (d, J = 13.5 Hz, 2 H, CH_2), 3.93 (d, J = 13.8 Hz, 2 H, CH_2), 0.85 (s, 2 H, CH_2Ph), 0.71 (s, 18 H, *t*Bu), 0.31 (s, 9 H, $SiMe_3$) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.45 (m, 2 H, Ph), 7.38 (m, 2 H, Ph), 6.96, 6.66, 6.32 (t, t, d, 5 H, CH_2Ph), 6.34, 6.15 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 3.96 (s, 4 H, CH_2), 0.73 (s, 18 H, *t*Bu), 0.45 (s, 2 H, CH_2Ph), 0.28 (s, 9 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 150.8 (*ipso*-CH_2Ph), 126.5, 119.6 (Ph), 126−128 (CH_2Ph), 124.9 (*ipso*-Ph), 122.5, 115.9 (C_5H_4), 66.1 (CH_2), 60.2 (CH_2Ph), 35.9 (*ipso*-*t*Bu), 29.2 (*t*Bu), 1.6 ($SiMe_3$) ppm, the signal for *ipso*-C_5H_4 is not observed.

Ti(η^5-C_5H_5)[1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$](CH_2Ph) (10): A 2 M solution of BzMgCl in THF (1.27 mL) was added dropwise to a stirred solution of Ti(η^5-C_5H_5)[1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$]Cl (0.85 g, 2.51 mmol) in hexane (50 mL) at −78 °C. After the addition was complete, the reaction mixture was warmed to room temperature and stirred for 12 h. The white precipitate formed was filtered and the resultant solution cooled to −40 °C. A dark oil was collected after filtration and was characterised as **10** (0.69 g, 1.75 mmol, 70%). Due to its high solubility in all common solvents **10** could not be recrystallised and an accurate analysis was not possible. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.36 (m, 2 H, Ph), 6.97 (m, 2 H, Ph), 7.12, 6.84, 6.63 (t, t, d, 5 H, CH_2Ph), 6.01 (s, 5 H, C_5H_5), 3.57 (m, 4 H, CH_2), 1.63 (s, 2 H, CH_2Ph), 1.27 (m, 4 H, CH_2), 0.59 (t, J = 7.3 Hz, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 149.2 (*ipso*-CH_2Ph), 126.2 (*ipso*-Ph), 125.4, 114.5 (Ph), 125−128 (CH_2Ph), 115.5 (C_5H_5), 62.9 (CH$_2$Ph), 57.2 (N−CH_2), 23.9 (CH_2), 11.8 (CH_3).

Ti(η^5-C_5Me_5)[1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$](CH_2Ph) (11): Compound **11** was prepared by treating Ti(η^5-C_5Me_5)[1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$]Cl (0.80 g, 1.96 mmol) with a 2 M solution of BzMgCl in THF (0.98 mL) according to the procedure described for **10** and was obtained as a black oil (0.70 g, 1.51 mmol, 77%). $C_{29}H_{40}N_2Ti$ (464.53): calcd. C 74.98, H 8.68, N 6.03; found C 74.02, H 8.32, N 5.98. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.18 (m, 2 H, Ph), 6.69 (m, 2 H, Ph), 6.80−7.11 (m, 5 H, CH_2Ph), 3.50 (t, J = 8.4 Hz, 4 H, CH_2), 2.25 (s, 2 H, CH_2Ph), 1.71 (s, 15 H, C_5Me_5), 1.49 (broad, 4 H, CH_2), 0.75 (t, J = 7.5 Hz, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 150.9 (*ipso*-CH_2Ph), 126−128 (CH_2Ph), 123.0, 113.3 (Ph), 121.0 (*ipso*-Ph), 120.6 (*ipso*-C_5Me_5), 73.1 (CH$_2$Ph), 53.8 (N-CH_2), 22.5 (CH_2), 12.0 (CH_3), 11.0 (C_5Me_5) ppm.

Ti[η^5-C_5H_4($SiMe_3$)][1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$](CH_2Ph) (12): Compound **12** was prepared by treating Ti[η^5-C_5H_4($SiMe_3$)][1,2-C_6H_4($NCH_2CH_2CH_3$)$_2$]Cl (0.34 g, 0.83 mmol) with a 2 M solution of BzMgCl in THF (0.41 mL) according to the procedure described for **10** and was obtained as a black oil (0.25 g, 0.53 mmol, 64%). $C_{27}H_{38}N_2SiTi$ (466.58): calcd. C 69.51, H 8.21, N 6.00; found C 68.92, H 8.02, N 5.94. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.34 (m, 2 H, Ph), 6.92 (m, 2 H, Ph), 6.99, 6.84, 6.66 (t, t, d, 5 H, CH_2Ph), 6.40, 6.13 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 3.68 (t, J = 7.5 Hz, 4 H, CH_2), 1.68 (s, 2 H, CH_2Ph), 1.33 (m, 4 H, CH_2), 0.64 (t, J = 7.5 Hz, 6 H, CH_3), 0.19 (s, 9 H, $SiMe_3$) ppm. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 7.26 (m, 2 H, Ph), 6.99 (m, 2 H, Ph), 6.94, 6.64, 6.36 (t, t, d, 5 H, CH_2Ph), 6.45, 6.22 (AA′BB′ spin system, 2 H, 2 H, C_5H_4), 3.74 (t, J = 7.5 Hz, 4 H, CH_2), 1.46 (m, 4 H, CH_2), 1.39 (s, 2 H, CH_2Ph), 0.78 (t, J = 7.5 Hz, 6 H, CH_3), 0.22 (s, 9 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 149.8 (*ipso*-CH_2Ph), 125−128 (CH_2Ph), 125.4, 115.6 (Ph), 120.8, 118.1 (C_5H_4), 63.4 (CH$_2$Bz), 57.9 (N−CH_2), 24.0 (CH_2), 12.1 (CH_3), 0.78 ($SiMe_3$) ppm, the signal for *ipso*-C_5H_4 is not observed.

Al_2[1,2-C_6H_4(NCH_2tBu)$_2$]Me_4 (13): A 2 M solution of TMA (1.21 mL, 2.42 mmol) in toluene was added to a solution of 1,2-C_6H_4($NHCH_2tBu$)$_2$ (0.3 g, 1.21 mmol) in toluene (30 mL) at −78 °C. After stirring for 12 h, the solvent was completely removed and the resultant solid extracted successively with hexane/toluene mixtures. The resultant solution was concentrated and cooled to −20 °C to give a purple solid which was identified as **13** (0.32 g, 0.88 mmol, 73%). $C_{20}H_{38}Al_2N_2$ (360.50): calcd. C 66.64, H 10.62, N 7.77; found C 65.98, H 10.26, N 7.39. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 6.81 (m, 2 H, Ph), 6.97 (m, 2 H, Ph), 2.93 (s, 4 H, CH_2), 0.89 (s, 18 H, *t*Bu), −0.07 (s, 6 H, Al−CH_3), −0.90 (s, 6

N-Ferrocenyl-Substituted Planar-Chiral N-Heterocyclic Carbenes and Their Pd^{II} Complexes

Andreas Bertogg,[a] Francesco Camponovo,[a] and Antonio Togni*[a]

Keywords: Carbene ligands / Chirality / Ferrocenes / Nitrogen heterocycles / Palladium

The *N*-ferrocenyl-linked N-heterocyclic carbenes **1a** and **1b** were obtained by treatment of their imidazolium salts **12a** and **12b** with potassium *tert*-butoxide. The latter were shown to be accessible from (*R*)-1-amino-2-methylferrocene (**9**) and aminoferrocene, respectively, which were converted into the corresponding formamidines and then subjected to a novel cyclization procedure. Treating the ligand precursors **12a** and **12b** with $[Pd(OAc)_2]_3$ under different reaction conditions afforded the *trans*-pyridine-substituted Pd^{II} complexes **14a** and **14b** as well as their *trans*-triphenylphosphane-substituted counterparts **16a** and **16b** and, in the case of the chiral ligand precursor, the dinuclear Pd^{II} complex **15a**. Conformational analysis of the ligands based on the X-ray structures of **12a**, **12b** and **16a** revealed the dependence of the two torsion angles between the central imidazolium core and the adjacent ferrocenyl substituents on the steric and electronic properties of the observed systems.

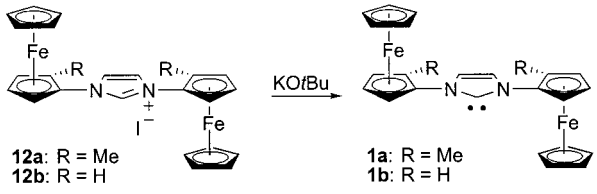
Introduction

Phosphanes bearing planar-chiral ferrocenyl groups are established ligands in coordination chemistry and have proven to be very successful in asymmetric catalysis.[1] Although N-heterocyclic carbenes (NHCs) may often act as phosphane substitutes, leading to considerably improved performances of the resultant catalysts,[2−5] both achiral and chiral ferrocenyl-substituted NHCs are still rare.[6−16] These can be divided into two classes: either directly *N*-ferrocenyl-substituted[6,7] or linked by a methylene, ethylene[10,11,16] or an ethenyl spacer.[12−15] The latter are of particular interest as bi- or tridentate ligands,[13,15] while for monodentate ligands it seems appropriate to further restrict the conformational freedom to the rotation around the two nitrogen−ferrocenyl bonds, thus leading to directly *N*-ferrocenyl-substituted carbenes.[17] Achiral *N*,*N*′-diferrocenyl-substituted imidazolium salts[18] are known in the literature but the reported yields of their synthesis are moderate and the salts resisted controlled deprotonation.[6]

Square-planar Pd^{II} complexes serve as catalyst precursors in numerous cross-coupling and Heck-type reactions. Recently, chiral monodentate NHCs have been shown to be the ligands of choice in Pd-catalyzed asymmetric α-arylations of carbonyl compounds, of which cyclic amide α-arylations gave the best results.[19] Pd complexes bearing chiral monodentate NHCs are still rare and complexes bearing planar-chiral monodentate NHCs are as-yet unknown. We reasoned that ligands showing the steric features of **1a** and **1b** attached to Pd^{II}, in combination with two halides and one potentially labile ligand, might lead to active systems for the above-mentioned asymmetric catalytic applications. We report here a new, high-yielding synthetic strategy leading to the isolation of both achiral and chiral imidazolium iodides **12a** and **12b** that can be deprotonated to the carbenes **1a** and **1b** (Scheme 1). Complexes showing the desired constitution were synthesized from $[Pd(OAc)_2]_3$ and proved to be active catalyst precursors in amide α-arylations.



Scheme 1

Results and Discussion

Ligand Synthesis

The chiral imidazolium iodide **12a** was synthesized from the known chiral acetal **2**[20] in ten steps in an overall yield of 30% (Scheme 2). Thus, stereoselective lithiation of **2** followed by electrophilic quenching with methyl iodide led to the planar-chiral acetal **3**, which was then converted into the aldehyde **4**. The carboxylic acid **6a**, which served as starting material in the following reaction sequence, was

produced by iodine-mediated oxidation of the aldehyde **4**[21] to the ester **5**, followed by saponification. Its achiral counterpart **6b** is accessible by carboxylation of monolithioferrocene generated in situ from ferrocene (Scheme 3).[22]

Apart from the cyclization procedure discussed below, another major challenge in the present ligand synthesis was the generation of the nitrogen-ferrocene bond. Since aminoferrocenes serve as intermediates in the synthesis of various ligands and optically active materials, this problem has attracted considerable interest.[23−28] One of the oldest routes[26] is based on a Curtius degradation of ferrocenecarboxylic acid chloride; other methods have used bromoferrocene[29−31] or ferroceneboronic acid[32] as starting material for copper-mediated amination reactions. Based on its simplicity and on the easy accessibility of its starting materials, we chose to use the Curtius rearrangement sequence, which, in our case, proved to be attractive both in terms of synthetic feasibility and the high isolated yields of the products. The chiral acid **6a** as well as the achiral acid **6b** were activated[33] and converted, in situ, into the ferrocenyl carbonyl azides **7a** and **7b**, which rearranged upon heating to the corresponding isocyanates. Addition of benzylic alcohol followed by heating generated the carbamic acid esters **8a**,**b** in a one-pot procedure from **6a**,**b** (Scheme 2 and 3). Reductive deprotection of the Cbz-protected amines **8a**,**b** led to the electron rich, strongly nucleophilic and air-sensitive amines **9a**,**b**.[34]

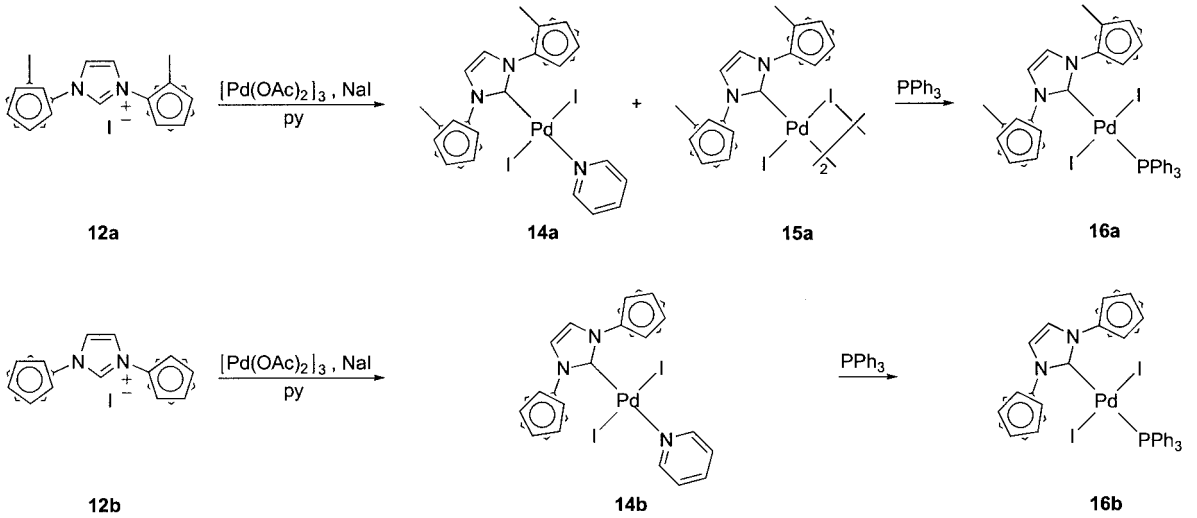
The most frequently used reaction sequence from primary amines to imidazolium salts involves condensation of the amines with a 1,2-dialdehyde to yield the corresponding diimine. Conversion of the latter with a one-carbon synthetic equivalent in the formal oxidation state of formaldehyde then leads to an imidazolium salt that is suitable for deprotonation. In contrast to a recently published procedure,[6] we decided not to construct the heterocyclic core of the target molecule by condensation of the ferrocenylamines with glyoxal, followed by cyclization with formaldehyde, due to low reported yields and demanding purifications. Instead, we chose to transform the ferrocenylamines **9a** and **9b** into *N*,*N*′-diferrocenyl-substituted amidines and to use the latter as intermediates in the cyclization sequence. The amidines **10a**,**b** were easily obtained from the amines **9a**,**b** by methinyl group transfer from *s*-triazine[35] and could be considered as being interesting potential ligands in their own right. The missing C_2 fragment was in-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corporated into the structures by treating the amidinate anions of **10a**,**b** with 2-bromo-1,1-diethoxyethane to give the acetals **11a**,**b**.[36] Addition of an excess of $BF_3{\cdot}OEt_2$ led to the desired cyclization and to the 4-ethoxy-4,5-dihydroimidazolium cation, which, under prolonged heating, eliminated ethanol to form the aromatic target core. The imidazolium iodides **12a**,**b** were obtained after anion exchange and column chromatography. It is noteworthy that in the high yielding reaction sequence from the carbamic acid esters **8a**,**b** to the imidazolium iodides **12a**,**b** only one chromatographic purification of the products and intermediates is required. Both chiral and achiral carbenes **1a** and **1b** were prepared by adding potassium *tert*-butoxide to a slurry of the imidazolium iodides **12a** or **12b** in pentane, followed by evaporation of the solvent and selective extraction of the products with benzene. The carbenes proved to be stable in solution in C_6D_6 over a period of 24 hours without any sign of decomposition, as ascertained by ^{1}H NMR spectroscopy. In the ^{13}C NMR spectra the diagnostic chemical shifts at δ = 221.1 ppm (**1a**) and 216.1 ppm (**1b**) were detected. Adding S_8 to either of the carbenes resulted in the formation of the corresponding thiones **13a** and **13b** (Scheme 2 and 3).

Synthesis of Palladium Complexes

A series of NHC-substituted Pd^{II} complexes were obtained from the reaction of the imidazolium iodides **12a**,**b** with $[Pd(OAc)_2]_3$ under different reaction conditions (Scheme 4). We reasoned that Pd complexes substituted with one NHC, two halides and one hemilabile ligand might be potent precatalysts for both Heck-type and cross-coupling reactions since, in both cases, at least one ligand stabilizing the active Pd^0 species as well as two free coordination sites *cis* to each other are required in the catalytic cycle. While the bulky and strongly bound carbene ligand is supposed to stabilize the active Pd^0 species and prevent precipitation of Pd black, the hemilabile ligand can be split off previous to oxidative addition of the aryl halide substrate. Pyridine seemed to be an advantageous hemilabile ligand as it can also be used in large excess as a solvent in the preparation of the catalyst precursor. Further advantage can be taken of its high dielectric constant, which allows complete dissolution of the imidazolium iodides, and of its ability to act as a base, which might facilitate the in situ deprotonation of the imidazolium iodides. Thus, reaction of **12b** and $[Pd(OAc)_2]_3$ in the presence of sodium iodide in pyridine afforded the pyridine-substituted complex **14b** regardless of whether one or two equivalents of the imidazolium iodide were used. Small amounts of the known complex $PdI_2(pyridine)_2$ were separated from the main product by column chromatography. Subjecting the chiral imidazolium iodide **12a** to the same reaction conditions resulted in an isolated equimolar mixture of both the pyridine-substituted complex **14a** and the equivalent iodo-bridged dinuclear derivative **15a**. Interestingly, the ^{1}H NMR spectrum of the chromatographed mixture showed that the iodo-bridged dimer **15a** contains two non-equivalent ferrocenyl ligands, thereby indicating restricted rotation around the Pd−C bond. This phenomenon has been observed before in an analogous bridged complex bearing two ethenyl-linked, diferrocenyl-substituted chiral NHCs that have been characterized by NMR spectroscopy and X-ray diffraction studies.[37] In analogy to that case it seems very likely that the observed anisotropy of the ferrocenyl substituents results from the typical butterfly conformation of the Pd_2I_2 core.[38] Upon adding triphenylphosphane, the mixture of the two chiral complexes **14a** and **15a** was cleanly converted into the carbene phosphane complex **16a**, whose *trans* configuration was determined by X-ray analysis (vide infra). The achiral, pyridine-substituted complex **14b**, under the same reaction conditions, gave the analogous complex **16b**. The *trans* configuration of both complexes **16a** and **16b** was further supported by the large coupling constants between the phosphorus nuclei and the carbene carbon nuclei.[39] Long-range coupling to the olefinic carbons of the NHC over four bonds and long-range coupling to the olefinic hy-



Scheme 4

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drogen atoms over five bonds were observed.[39] Selective saturation of the phosphorus hydrogen transition resulted in a decoupled ^{1}H NMR spectrum, as performed in the case of **16a**.

Crystal Structures and Conformational Analysis

Single-crystal X-ray analysis of the imidazolium iodides **12a** (Figure 1) and **12b** (Figure 2) showed the expected bond lengths and angles within the imidazolium cores, thus indicating that the steric and electronic features of the ferrocenyl subunits do not significantly alter the properties of the heterocycle. In both cations the ferrocenyl−imidazolium bond lengths lie in the range of a C−N single bond, thus excluding delocalisation of the π electrons between the cyclic moieties of the molecules. This conclusion is in agreement with the observed non-planar arrangement of the three connected cyclic subunits.[40] The ferrocenyl−methyl bond lengths in **12a** do not show any deviation from the expected value.

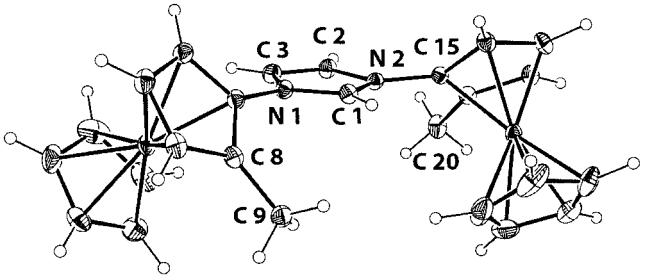


Figure 1. ORTEP view of the cation of **12a**, with 30% thermal ellipsoids; selected bond lengths [A] and angles [°]: C(1)−N(1) 1.327(3), C(1)−N(2) 1.332(3), C(2)−C(3) 1.346(4), N(1)−C(3) 1.378(3), N(2)−C(2) 1.387(3), N(1)−C(4) 1.426(3), N(2)−C(15) 1.420(3), C(8)−C(9) 1.498(4), C(19)−C(20) 1.492(3); N(1)−C(1)−N(2) 108.6(2), C(1)−N(1)−C(4)−C(8) 310.5(4), C(1)−N(2)−C(15)−C(19) 143.8(3)

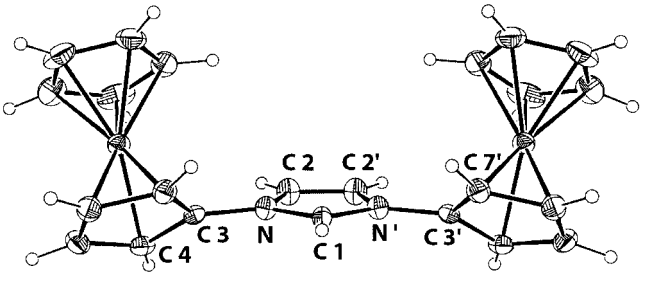

Figure 2. ORTEP view of the cation of **12b**, with 30% thermal ellipsoids; selected bond lengths [A] and angles [°]: C(1)−N(1) 1.329(8), C(2)−C(2′) 1.331(14), N−C(2) 1.380(8), N−C(3) 1.419(8); N−C(1)−N′ 108.4(8), C(1)−N−C(3)−C(4) 139.4(8), C(1)−N′−C(3′)−C(7′) 320.9(11)

X-ray analysis of the chiral Pd complex **16a** (Figure 3) reveals that the main structural features of **12a**, apart from the torsion angles, are preserved in the ligand. While the extent of delocalization in the heterocyclic fragment is slightly decreased and the N−C−N angle is reduced from 108.6(2)° to 104.9(3)°, the ferrocenyl−imidazolium bond lengths stay constant. The palladium−carbon bond of 2.004(3) Å lies in the typical range.[40]

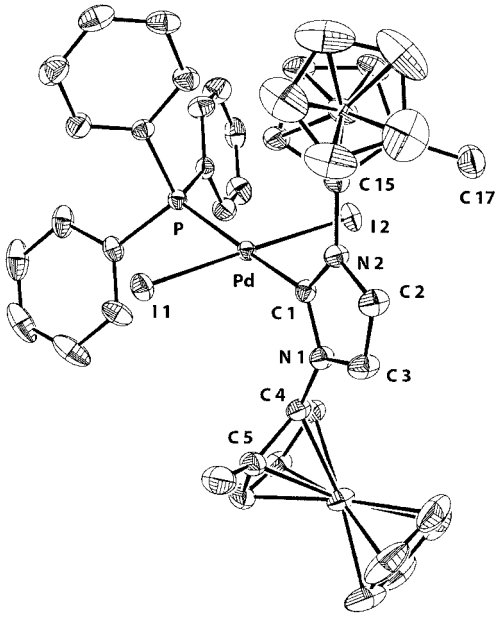

Figure 3. ORTEP view of the complex **16a**, with 30% thermal ellipsoids; hydrogen atoms are omitted for clarity; selected bond lengths [A] and angles [°]: C(1)−Pd 2.004(3), Pd−P 2.3298(9), Pd−I(1) 2.6280(5), Pd−I(2) 2.5932(5), C(1)−N(1) 1.351(4), C(1)−N(2) 1.359(4), C(2)−C(3) 1.323(5), N(1)−C(3) 1.385(4), N(2)−C(2) 1.386(5), N(1)−C(4) 1.426(4), N(2)−C(15) 1.430(4), C(5)−C(6) 1.489(6), C(16)−C(17) 1.502(6); N(1)−C(1)−N(2) 104.9(3), C(1)−N(1)−C(4)−C(5) 246.0(4), C(1)−N(2)−C(15)−C(16) 245.4(4)

Since the overall shape of the ligand and, as a consequence, its ability to efficiently transfer chirality in asymmetric catalytic reactions depends on its conformation, it is important to note that the latter is fully described by the two torsion angles between the central imidazolium core and the adjacent ferrocenyl substituents. Rotation around the two ferrocenyl−nitrogen bonds in solution at room temperature proved to be fast on the NMR timescale for **12b**, **13b**, **14b** and **16b**. No such conclusions can be drawn for their chiral counterparts due to symmetry restrictions. In the crystal structures, however, well-defined conformations could be studied. In **12a** torsion angles of 310.5(4)° and 143.8(3)° around C(1)−N(1)−C(4)−C(8) and C(1)−N(2)−C(15)−C(19), respectively, were detected. The corresponding angles in **12b** around C(1)−N−C(3)−C(4) and around C(1)−N′−C(3′)−C(7′) are 139.4(8)° and 320.9(11)°, respectively, whereas the C(1)−N(1)−C(4)−C(5) and C(1)−N(2)−C(15)−C(16) angles in **16a** are 246.0(4)° and 245.4(4)°, respectively. These at-first-sight arbitrary results can be rationalized by uncovering the forces that determine the torsion angles.

Conformational analysis of the solid-state structures of compounds **12a**, **12b**, **16a** and of two analogous achiral derivatives reported by Bildstein et al.[6] reveals that their conformations are mainly governed by two opposing forces: i) pseudo allylic repulsion[41] between the *ortho* substituents of the ferrocenyl fragments and the *ortho* substituents of the heterocycle, and ii) steric interactions between the substituents on the imidazolium core and the unsubstituted Cp

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ring. The orientation of the two ferrocenyl planes with respect to each other appears to be of minor importance, as can be seen by comparing the orientations in the crystal structures of, for example, **12a** and **12b**. Therefore, the two torsion angles in a molecule can be analyzed separately, thus simplifying the analysis: only the tilt angles ($0° \leq$ tilt angle $\leq 90°$) between the ferrocenyl planes and the heterocyclic plane need to be considered as relevant. As shown in Figure 4, all known tilt angles of the discussed imidazolium salts lie in a specific range between 36.2(3)° and 49.5(4)°, whereas the sulfur adduct **13b**[6] shows slightly larger angles of 53.7(3)°. This shows that even small atoms or substituents such as hydrogen, methyl or thiooxo attached to the position adjacent to the bond connecting the Cp and the heterocycle on either of the cyclic moieties exclude tilt angles near to 0° or 90°. The rotational potential energy changes around the energy minima seem to be small. Only in **16a**, where two substituents *ortho* to the flexible bond are present, is it not surprising to find considerably increased torsion angles of 65.4(4)° and 66.0(4)° (Figure 4).

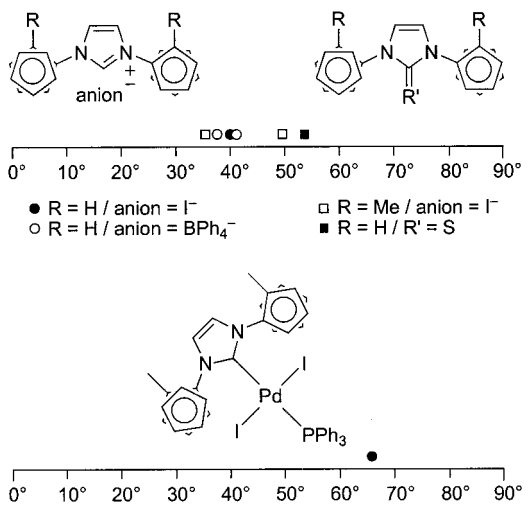

Figure 4. Tilt angles between planes of the Cp substituent and the heterocyclic core in imidazolium cations, in a thione and in a Pd-bound carbene ligand

Conclusion

The bulky, planar-chiral, *N*-ferrocenyl-substituted NHC **1a** as well as its achiral analog **1b** were synthesized by deprotonation of their imidazolium iodide precursors **12a** and **12b**. The latter were prepared by a synthetic strategy based on a Curtius degradation to form the ferrocenyl−nitrogen bond and a novel cyclization procedure to build up the heterocyclic cores of the target molecules. The reaction of **12b** with $[Pd(OAc)_2]_3$ in the presence of pyridine led to the *trans*-pyridine-substituted complex **14b**, but when **12a** was subjected to the same reaction conditions a mixture of the mononuclear complex **14a** and the dinuclear complex **15a** was isolated. Both **16a** and **16b** were obtained by addition of triphenylphosphane to **14b** and to a mixture of **14a** and **15b**, respectively.

First attempts to perform the catalytic asymmetric amide cyclizations[42] previously studied by Lee et al.[19] using the newly synthesized chiral ligand gave the expected cyclization product in 70% yield and 9% *ee*. Although this result does not compare favorably with that reported in the study mentioned above, where *ee* values of up to 70% were obtained, it shows the high activity of the observed system and marks a starting point for systematic variations in the chiral ligand. Efforts to shorten the ligand synthesis while introducing sterically more demanding groups attached to the ferrocenyl moieties are currently being undertaken.

Experimental Section

General Remarks: All experiments were conducted under argon or dinitrogen using standard Schlenk-type glassware or a glovebox. Unless otherwise stated, the reactions were carried out at room temperature. All solvents were stored over activated molecular sieves (4 Å) unless otherwise indicated. In the case of freshly distilled solvents, the following drying agents were used: CaH_2 for CH_2Cl_2, MeCN, MeOH and pyridine; Na/benzophenone for pentane; Na for benzene and C_6D_6. Chromatography was carried out with Merck silica gel 60. The NMR spectra were recorded with Bruker Avance 250 (250.1 MHz, ^{1}H; 62.5 MHz, ^{13}C; 101 MHz, ^{31}P), 300 (300.1 MHz, ^{1}H; 75.0 MHz, ^{13}C; 122 MHz, ^{31}P) and 500 (500.2 MHz, ^{1}H; 125 MHz, ^{13}C; 50.7 MHz, ^{15}N; 203 MHz, ^{31}P) spectrometers. ^{1}H and ^{13}C{^{1}H} NMR chemical shifts (δ) were referenced internally by the residual solvent signal relative to tetramethylsilane. ^{31}P NMR and ^{15}N NMR chemical shifts were referenced with respect to H_3PO_4 and $MeNO_2$, respectively. All spectra were recorded at room temperature. Optical rotations were measured in 1-dm cells with a Perkin−Elmer model 341 polarimeter at 22 °C. High-resolution MALDI mass spectra were measured by the analytical service of the Laboratorium für Organische Chemie of the ETH Zürich with an IonSpec ultima FT MALDI mass spectrometer. Elemental analyses were obtained with a Leco CHN-900 analyzer. All chemicals were purchased from Fluka, Aldrich, Acros, Lancaster or ABCR and were used without further purification. (2*S*,4*S*)-2-Ferrocenyl-4-(hydroxymethyl)-1,3-dioxane,[20] (2*S*,4*S*)-2-ferrocenyl-4-(methoxymethyl)-1,3-dioxane,[20] (2*S*,4*S*,R_{Fc})-4-(methoxymethyl)-2-(2-methylferrocenyl)-1,3-dioxane (**3**),[43] (*R*)-2-methylferrocenecarboxaldehyde (**4**),[43] and ferrocenecarboxylic acid (**6b**)[22] were prepared as reported.

Benzyl *N*-Ferrocenylcarbamate (8b): Ferrocenecarboxylic acid (1.25 g, 5.43 mmol, 1.0 equiv.), Bu_4NBr (349 mg, 1.10 μmol, 0.2 equiv.) and NaN_3 (723 mg, 11.0 mmol, 2.0 equiv.) were placed in a 100-mL Schlenk flask. Addition of 35 mL of distilled CH_2Cl_2 and pyridine (1.34 mL, 1.30 g, 16.5 mmol, 3.0 equiv.) caused the formation of an orange slurry. In a separate 10-mL Schlenk flask *N*,*N*-dimethylchlorosulfitomethaniminium chloride was prepared in situ by adding thionyl chloride (0.8 mL, 11.0 mmol) to a mixture of DMF (1.0 mL, 10.2 mmol) and 5 mL of benzene. After approximately 1 min, two phases separated, with the lower one containing the desired reagent. Addition of 730 μL of the fresh, clear and colorless *N*,*N*-dimethylchlorosulfitomethaniminium chloride to the vigorously stirred orange slurry during 3 min led to a clear wine-red solution and a white precipitate (presumably Bu_4NBr). After 1 h, water was added. Extraction of the organic layer with CH_2Cl_2, followed by drying with Na_2SO_4 and evaporation of the solvents led to an intensely red-colored oil. Benzylic alcohol (6 mL) was then added and the remaining pyridine was evaporated under vac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

uum. The resulting solution of ferrocenecarboxylic azide (**7b**) in benzylic alcohol was stored in a 100-mL round-bottomed flask at room temperature under argon overnight. Upon heating to 90 °C during 30 min, the red color disappeared. The resulting brown yellowish mixture was concentrated to dryness under reduced pressure by using a distillation apparatus. A pure, orange, solid product was obtained by column chromatography (CC; CH_2Cl_2 + 1% Et_3N) on silica gel. Yield: 994 mg (55%). ^{1}H NMR ($CDCl_3$): δ = 3.99 (s, 2 H, 2 Cp_{subst}−C*H*), 4.15 (s, 5 H, Cp), 4.48 (br. s, 2 H, 2 Cp_{subst}−C*H*), 5.17 (s, 2 H, CH_2), 5.86 (br. s, 1 H, N*H*), 7.34−7.40 (m, 5 H, phenyl) ppm. MS (HR MALDI): *m*/*z* = 335.0609 (calcd. for $C_{18}H_{17}FeNO_2$); found 335.0606 [M^+]. $C_{18}H_{17}FeNO_2$ (335.18): calcd. C 64.50, H 5.11, N 4.18; found C 64.42, H 5.30, N 4.03. CAS 98639-14-6.

Aminoferrocene (9b): Compound **8b** (962 mg, 2.87 mmol, 1.0 equiv.) was suspended in 35 mL of isopropyl alcohol in a dry 100-mL Schlenk flask. After degassing the suspension in an ultrasonic bath by passing argon over it, the reaction vessel was heated to 60 °C until the substrate had dissolved completely, resulting in a clear orange solution. Pd on charcoal (10% Pd, 301 mg, 261 μmol, 0.09 equiv.) was added at room temperature and H_2 was placed over the reaction mixture. After 90 min, the solvent was removed under reduced pressure, and the residue was taken up in distilled CH_2Cl_2 and filtered. The resulting yellow solution was concentrated to dryness. The pure product was isolated as an orange solid and stored in a glovebox. Yield: 553 mg (96%). ^{1}H NMR ($CDCl_3$): δ = 2.59 (br. s, 2 H, NH_2), 3.84 (t, *J* = 1.8 Hz, 2 H, 2 Cp_{subst}−C*H*), 3.99 (t, *J* = 1.8 Hz, 2 H, 2 Cp_{subst}−C*H*), 4.10 (s, 5 H, Cp) ppm. CAS 1273-82-1.

***N*,*N*′-Diferrocenylformamidine (10b):** In a glovebox, compound **9b** (2.42 g, 12.0 mmol, 1.0 equiv.) and 1,3,5-triazine (2.92 g, 36.0 mmol, 3.0 equiv.) were placed in a dry, 500-mL round-bottomed Schlenk flask. After taking the flask out of the glovebox, 42 mL of dioxane was added, the resulting suspension was degassed in an ultrasonic bath by passing argon over it, and the reaction vessel was heated to 100 °C for 4.5 h, which led to a wine-red solution and an orange precipitate. The strong smell of ammonia upon careful opening of the reaction vessel (preventing the entry of air) indicated product formation. The reaction solvents were evaporated to dryness under reduced pressure using a distillation apparatus. At the same time, excess 1,3,5-triazine was completely sublimed, leading to an analytically pure amorphous orange solid that was stored in a glovebox. Yield: 2.37 g (96%). ^{1}H NMR ($CDCl_3$): δ = 4.04 (t, *J* = 1.8 Hz, 4 H, 4 Cp_{subst}−C*H*), 4.20 (s, 10 H, 2 Cp), 4.26 (t, *J* = 1.8 Hz, 4 H, 4 Cp_{subst}−C*H*), 8.03 (s, 1 H, N=C*H*−N) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 60.5 (Cp_{subst}−*C*H), 65.1 (Cp_{subst}−*C*H), 67.2 (Cp_{subst}−C_{quat}), 69.2 (Cp), 150.2 (N=*C*H−N) ppm. MS (HR MALDI): *m*/*z* = 412.033 (calcd. for $C_{21}H_{20}Fe_2N_2$); found 412.032 [M^+]. $C_{21}H_{20}Fe_2N_2$ (412.09): calcd. C 61.21, H 4.89, N 6.80; found C 61.15, H 4.97, N 6.68.

***N*-(2,2-Diethoxyethyl)-*N*,*N*′-diferrocenylformamidine (11b):** Compound **10b** (500 mg, 1.23 mmol, 1.0 equiv.) was suspended in 10 mL of DMF in a 50-mL Schlenk flask and cooled to 0 °C. After addition of NaH (55−65% in mineral oil, 100 mg, 2.25 mmol, 1.8 equiv.), the mixture was kept at 0 °C for 5 min and then slowly warmed to room temperature, leading to gas evolution (H_2). After 100 min stirring at room temperature 2-bromo-1,1-diethoxyethane (380 μL, 477 mg, 2.45 mmol, 2.0 equiv.) was added and the clear red solution was quickly heated to 76 °C. After 90 min, the darkened, hot mixture was concentrated to dryness under vacuum. The crude product was dissolved in MeCN followed by filtration under argon. The pure product was isolated as a clear, red oil. Yield: 515 mg (79%). ^{1}H NMR (C_6D_6): δ = 1.16 (t, *J* = 7.1 Hz, 3 H, CH_3), 1.16 (t, *J* = 7.1 Hz, 3 H, CH_3), 3.44−3.54 (m, 2 H, CH_2CH$_3$), 3.68−3.78 (m, 2 H, CH_2CH$_3$), 3.81 (t, *J* = 1.8 Hz, 1 H, Cp_{subst}−C*H*), 3.81 (t, *J* = 1.8 Hz, 1 H, Cp_{subst}−C*H*), 3.98 (t, *J* = 1.8 Hz, 1 H, Cp_{subst}−C*H*), 3.98 (t, *J* = 1.8 Hz, 1 H, Cp_{subst}−C*H*), 4.02 (s, 5 H, Cp), 4.12 (d, *J* = 5.3 Hz, 2 H, NCH_2CH), 4.19 (s, 5 H, Cp), 4.31−4.35 (m, 4 H, 4 Cp_{subst}−C*H*), 5.13 (t, *J* = 5.2 Hz, 1 H, NCH$_2$C*H*), 8.28 (s, 1 H, N=C*H*−N) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 15.6 (CH$_2$*C*H$_3$), 52.5 (N*C*H$_2$CH), 60.3 (Cp_{subst}−*C*H), 61.7 (Cp_{subst}−*C*H), 64.0 (*C*H$_2$CH$_3$), 65.0 (Cp_{subst}−*C*H), 65.2 (Cp_{subst}−*C*H), 69.0 (Cp), 100.5 (NCH$_2$*C*H), 105.5 (Cp_{subst}−C_{quat}), 108.4 (Cp_{subst}−C_{quat}), 150.6 (N=*C*H−N) ppm. Methyl (*R*)-2-Methylferrocenecarboxylate (5): (*R*)-2-Methylferrocenecarboxaldehyde (**4**) (6.74 g, 29.6 mmol, 1.0 equiv.) and 120 mL of MeOH were added to a 1-L flask and cooled to 0 °C. Addition of KOH (16.6 g, 296 mmol, 10 equiv.) was followed by addition of I_2 (37.5 g, 148 mmol, 5.0 equiv.). After 4 h, the solvents were evaporated under reduced pressure at 0 °C (to prevent overoxidation to the corresponding ferrocenium cation) and the remaining residue was chromatographed on silica gel (CH_2Cl_2) to give a red oil. Yield: 5.87 mg (77%). ^{1}H NMR ($CDCl_3$): δ = 2.28 (s, 3 H, Cp−C*H*$_3$), 3.81 [s, 3 H, C(O)OC*H*$_3$], 4.12 (s, 5 H, Cp), 4.23 (t, J = 2.6 Hz, 1 H, Cp_{subst}−C*H*), 4.31 (t, J = 1.6 Hz, 1 H, Cp_{subst}−C*H*), 4.71 (dd, J_1 = 2.6, J_2 = 1.6 Hz, 1 H, Cp_{subst}−C*H*) ppm. CAS 12242-23-8.

(*R*)-2-Methylferrocenecarboxylic Acid (6a): Compound **5** (7.33 g, 28.4 mmol) was dissolved in 140 mL of EtOH in a 500-mL round-bottomed flask. An aqueous solution of NaOH (70 mL, 1.1 M) was added, then the reaction mixture was stirred for 4 h at room temperature and for a further 12 h at 60 °C. Water was then added and the organic impurities were extracted with *tert*-butyl methyl ether. The aqueous phases were acidified with 0.7 M aqueous HCl and extracted with CH_2Cl_2. The organic layers were dried with $NaSO_4$, the solvent was evaporated and the product was isolated in the form of red crystals. Yield: 6.45 g (93%). ^{1}H NMR ($CDCl_3$): δ = 2.31 (s, 3 H, C*H*$_3$), 4.20 (s, 5 H, Cp), 4.31 (t, J = 2.5 Hz, 1 H, Cp_{subst}−C*H*), 4.39 (t, J = 1.9 Hz, 1 H, Cp_{subst}−C*H*), 4.80 (dd, J_1 = 2.5, J_2 = 1.8 Hz, 1 H, Cp_{subst}−C*H*) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 14.8 (*C*H$_3$), 68.1 (Cp_{subst}−*C*$_{quat}$), 69.7 (Cp_{subst}−*C*H), 70.8 (Cp), 71.0 (Cp_{subst}−*C*H), 74.4 (Cp_{subst}−*C*H), 87.7 (Cp_{subst}−*C*$_{quat}$), 178.9 (*C*OOH) ppm. CAS 12241-80-4.

Benzyl *N*-[(*R*)-2-Methylferrocenyl]carbamate (8a): Compound **6a** (4.10 g, 16.82 mmol, 1.0 equiv.), Bu_4NBr (1.09 g, 3.44 mol, 0.2 equiv.) and NaN_3 (2.26 g, 34.4 mmol, 2.0 equiv.) were placed in a 500-mL Schlenk flask. Addition of 114 mL of distilled CH_2Cl_2 and pyridine (4.18 mL, 4.07 g, 515 mmol, 3.0 equiv.) gave an orange-red solution. In a separate 10-mL Schlenk flask, *N*,*N*-dimethylchlorosulfitomethaniminium chloride was prepared in situ by adding thionyl chloride (4.6 mL, 62.9 mmol) to a mixture of DMF (5.7 mL, 58.4 mmol) and 28 mL of benzene. After approximately 1 min, two phases separated, with the lower one containing the desired reagent. Addition of 2.29 mL of the fresh, clear and colorless *N*,*N*-dimethylchlorosulfitomethaniminium chloride to the vigorously stirred orange slurry during 3 min led to a clear wine-red solution and a white precipitate (presumably Bu_4NBr). After 1 h 25 min, 23 mL of benzylic alcohol was added and the remaining dichloromethane and pyridine were evaporated under high vacuum. The resulting solution of (*R*)-2-methylferrocenecarboxylic azide (**7a**) in benzylic alcohol was stirred at 90 °C during 10 min, which caused darkening of the reaction mixture. The resulting brownish-yellow solvents were evaporated to dryness under reduced pressure during 45 min at 90 °C by using a distillation apparatus. A pure, orange, solid product was obtained by CC (CH_2Cl_2 + 1% NEt_3) on silica gel. Yield: 4.72 g (81%). ^{1}H NMR ($CDCl_3$): δ = 1.95 (s, C*H*$_3$), 3.90 (t, J = 2.5 Hz, 1 H, Cp_{subst}−C*H*), 3.95−3.97 (m, 1 H, Cp_{subst}−C*H*), 4.06 (s, 5 H, Cp), 4.62 (br. s, 1 H, Cp_{subst}−C*H*), 5.18 (s, 2 H, C*H*$_2$), 5.89 (br. s, 1 H, N*H*), 7.34−7.38 (m, 5 H, phenyl) ppm. ***N,N′*-Bis[(*R*)-2-methylferrocen-1-yl]imidazolium Iodide (12a):** Compound **11a** (1.36 g, 2.45 mmol, 1.0 equiv.) was dissolved in 28 mL of distilled MeCN in a dry 100-mL Schlenk flask. After addition of $BF_3{\cdot}OEt_2$ (1.88 mL, 2.09 g, 14.7 mmol, 6.0 equiv.) at room temperature, which caused an immediate darkening of the reaction mixture, the reaction temperature was raised to 70 °C. After 3 h, additional $BF_3{\cdot}OEt_2$ (0.9 mL, 1.0 g, 7.0 mmol, 2.9 equiv.) was added and the reaction mixture was stirred for 15 h. Evaporation of the solvent under reduced pressure gave a brown yellowish solid. NaI (1.83 g, 12.3 mmol, 5.0 equiv.) and 28 mL of distilled MeOH were added and the resulting mixture was stirred at 70 °C for 2 h. After evaporation of the solvent, the crude product was first filtered through a silica-gel pad (CH_2Cl_2 + 5% MeOH) to remove excess NaI and borate waste, and then chromatographed on silica gel (CH_2Cl_2 + 5% MeOH) to give the product as a light-yellow foam. Yield: 1.03 g (71%). ^{1}H NMR (CD_2Cl_2): δ = 1.99 (s, 6 H, 2 CH_3), 4.28 (t, J = 2.7 Hz, 2 H, 2 Cp_{subst}−CH), 4.33 (s, 10 H, 2 Cp), 4.39−4.42 (m, 2 H, 2 Cp_{subst}−CH), 4.85 (dd, J_1 = 2.7, J_2 = 1.2 Hz, 2 H, 2 Cp_{subst}−CH), 7.85 (d, J = 1.5 Hz, 2 H, NCHCHN), 9.03 (t, J = 1.5 Hz, 1 H, N=CH−N) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 13.0 ($Cp_{subst}-CH_3$), 65.6 ($Cp_{subst}-CH$), 65.8 ($Cp_{subst}-CH$), 69.5 ($Cp_{subst}-CH$), 71.2 (Cp), 79.2 ($Cp_{subst}-C_{quat}$), 92.6 ($Cp_{subst}-C_{quat}$), 125.4 (NCHCHN), 137.3 (N=CHCHN) ppm. MS (HR MALDI): m/z = 465.0717 (calcd. for $C_{25}H_{25}Fe_2N_2^+$); found 465.0715 [M^+ − I]. $C_{25}H_{25}Fe_2IN_2$ (592.07): calcd. C 50.71, H 4.26, N 4.73; found C 50.93, H 4.49, N 4.68. $[\alpha]_{22}$ = +104 (c = 1, $CHCl_3$).

***N,N′*-Bis[(*R*)-2-methylferrocen-1-yl]imidazol-2-ylidene (1a):** A 20-mL Schlenk vessel was charged with compound **12a** (20 mg, 34 μmol, 1.0 equiv.) and KO*t*Bu (8 mg, 71 μmol, 2.1 equiv.) in a glovebox. Addition of 2 mL of distilled pentane caused the formation of an orange slurry. After stirring for 3.5 h, all volatiles were evaporated under reduced pressure, the residue was taken up in 1 mL of distilled deuterated benzene and filtered through a 4 Å frit, which led to a clear light-yellow solution. ^{1}H NMR (C_6D_6): δ = 2.26 (s, 6 H, 2 CH_3), 3.81 (t, J = 2.5 Hz, 2 H, 2 Cp_{subst}CH), 3.90 (t, J = 2.0 Hz, 2 H, 2 Cp_{subst}CH), 4.07 (s, 10 H, 2 Cp), 4.38−4.40 (m, 2 H, 2 Cp_{subst}CH), 7.01 (s, 2 H, NCHCHN) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 14.5 ($Cp_{subst}-CH_3$), 63.6 ($Cp_{subst}-CH$), 64.2 ($Cp_{subst}-CH$), 68.0 ($Cp_{subst}-CH$), 70.0 (Cp), 79.6 ($Cp_{subst}-CCH_3$), 99.8 ($Cp_{subst}-CN$), 120.8 (NCHCHN), 221.2 (NCN) ppm. ^{15}N NMR (C_6D_6): δ = −188.2 ppm.

***N,N′*-Bis[(*R*)-2-methylferrocen-1-yl]imidazole-2-thione (13a):** S_8 (4.1 mg, 128 μmol, 3.5 equiv.) was added to the solution of compound **1a** in benzene prepared above. After a reaction time of 30 min, ^{1}H NMR analysis of the solution showed complete and clean conversion. ^{1}H NMR (C_6D_6): δ = 1.94 (s, 6 H, 2 CH_3), 3.79 (t, J = 2.5 Hz, 2 H, 2 Cp_{subst}CH), 3.86 (t, J = 2.1 Hz, 2 H, 2 Cp_{subst}CH), 3.98 (s, 10 H, 2 Cp), 4.49−4.51 (m, 2 H, 2 Cp_{subst}CH), 7.01 (s, 2 H, NCHCHN) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 13.5 ($Cp_{subst}-CH_3$), 64.6 ($Cp_{subst}-CH$), 67.6 ($Cp_{subst}-CH$), 68.0 ($Cp_{subst}-CH$), 70.1 (Cp), 81.7 ($Cp_{subst}-CCH_3$), 96.5 ($Cp_{subst}-CN$), 119.6 (NCHCHN), 170.3 (NCN) ppm. MS (HR MALDI): m/z = 496.0359 (calcd. for $C_{25}H_{24}Fe_2N_2S$); found 496.0359 [M^+].

Palladium Complex 14b: Compound **12b** (200 mg, 354 μmol, 1.0 equiv.) and $[Pd(OAc)_2]_3$ (79.6 mg, 351 μmol, 1.0 equiv.) were dissolved in 7 mL of distilled pyridine in a dry 20-mL Schlenk flask. The resulting yellow solution was stirred for 3 h, then NaI (270 mg, 1.80 mmol, 5.1 equiv.) was added, leading to a color change to brown and the formation of a precipitate (other than NaI). After 18 h of stirring, all volatiles were evaporated under reduced pressure. The pure orange product was obtained by CC (CH_2Cl_2) on silica gel. Yield: 160 mg (59%). ^{1}H NMR (C_6D_6): δ = 3.99 (t, J = 1.9 Hz, 4 H, 2 Cp_{subst}-CH), 4.10 (s, 10 H, 2 Cp), 5.50 (t, J = 1.8 Hz, 4 H, 2 Cp_{subst}−CH), 6.22−6.26 (m, 2 H, py), 6.53 (tt, J_1 = 1.8, J_2 = 7.8 Hz, 1 H, py), 7.03 (s, 2 H, NCHCHN), 8.98−9.00 (m, 2 H, py) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 66.3 ($Cp_{subst}-CH$), 66.6 ($Cp_{subst}-CH$), 70.1 (Cp), 97.7 ($Cp_{subst}-C_{quat}$), 123.5 (NCHCHN), 123.9 (py), 136.8 (py), 151.1 (N−CPd−N), 154.4 (py) ppm. MS (HR MALDI): m/z = 795.7450 (calcd. for $C_{23}H_{20}Fe_2N_2I_2Pd$); found 795.7470 [M − py]$^+$ with the expected isotopic pattern. $C_{28}H_{25}Fe_2I_2N_3Pd$ (769.02): calcd. C 38.37, H 2.99, N 4.79, I 28.96; found C 38.57, H 3.08, N 4.59, I 29.08.

Palldium Complexes 14a and 15a: Compound **12a** (100 mg, 169 μmol, 1.0 equiv.) and $[Pd(OAc)_2]_3$ (38.0 mg, 169 μmol, 1.0 equiv.) were dissolved in 5 mL of distilled pyridine in a dry 20-mL Schlenk flask. The resulting clear, brown solution was stirred for 3.5 h, then NaI (132 mg, 879 μmol, 5.2 equiv.) was added to the darkened mixture, which caused a slight lightening of the color and the formation of a precipitate (other than NaI). After 15 h of stirring, all volatiles were evaporated under reduced pressure. An orange mixture of the two products was obtained by CC (CH_2Cl_2) on silica gel. Yield: 106 mg (54%). The mixture consists of 53.5 mg (59.2 μmol) of the mononuclear and 52.3 mg (31.7 μmol) of the dinuclear species, as determined by ^{1}H NMR spectroscopy. ^{1}H NMR (C_6D_6; resonances that belong to **14a** are designated with M, those belonging to **15a** with D): δ = 1.69 (s, 6 H, 2 CH_3, D), 2.01 (s, 6 H, 2 CH_3; D), 2.11 (s, 6 H, 2 CH_3, M), 3.86 (s, 10 H, 2 Cp, D), 3.92 (s, 10 H, 2 Cp, D), 3.97 (s, 10 H, 2 Cp, M), 4.02 (t, J = 2.6 Hz, 2 H, 2 Cp_{subst}−CH, M), 4.27 (t, J = 2.5 Hz, 2 H, 2 Cp_{subst}−CH, D), 5.64−5.68 (m, 2 H, 2 Cp_{subst}−CH, D), 5.71−5.75 (m, 2 H, 2 Cp_{subst}−CH, D), 6.00 (dd, J_1 = 2.5, J_2 = 1.0 Hz, 2 H, 2 Cp_{subst}−CH, M), 6.10−6.17 (m, 2 H, py, M), 6.39−6.48 (m, 1 H, py, M), 7.19−7.22 (m, 2 H, NCHCHN, D), 7.34 (s, 2 H, NCHCHN, M), 8.76−8.81 (m, 2 H, py, M) ppm.

Palladium Complex 16a: Addition of 1.5 mL of CH_2Cl_2 to a dry 20-mL Schlenk flask containing a mixture of **14a** and **15a** (97 mg, 123 μmol Pd^{II}, 1.0 equiv.) and triphenylphosphane (60.2 mg, 230 μmol, 2.8 equiv.) caused the formation of a clear red to orange solution. After 1 h of stirring, all volatiles were removed under reduced pressure and the residue was rinsed five times with pentane. Drying under reduced pressure yielded a pale-yellow solid. Yield: 115 mg (86%). ^{1}H NMR (CD_2Cl_2): δ = 2.08 (s, 6 H, 2 CH_3), 4.27−4.30 (m, 14 H, 2 cp and 4 Cp_{subst}−CH), 5.34 (t, 2 H, 2 Cp_{subst}−CH, J = 2.0 Hz), 7.29−7.33 (m, 6 H, PPh_3), 7.34−7.40 (m, 3 H, PPh_3), 7.43−7.49 (m, 6 H, PPh_3), 7.72 (d, 2 H, J = 1.0 Hz, NCHCHN) ppm. ^{13}C NMR (CD_2Cl_2): δ = 13.1 ($Cp_{subst}-CH_3$), 64.0 ($Cp_{subst}-CH$), 68.1 ($Cp_{subst}-CH$), 68.7 ($Cp_{subst}-CH$), 70.0 (Cp), 79.3 ($Cp_{subst}-CN$), 97.9 ($Cp_{subst}-CCH_3$), 124.6 (d, J = 5.6 Hz, (NCHCHN), 127.5 (d, J = 10.1 Hz, PPh_3), 129.9 (d, J = 2.3 Hz, PPh_3), 133.0 (d, J = 44.3 Hz, PPh_3), 135.4 (d, J = 11.0 Hz, PPh_3), 165.2 (d, J = 193.7 Hz, N−CPd−N) ppm. ^{31}P NMR (CD_2Cl_2): δ = 17.7 ppm. MS (HR MALDI): m/z = 958.9629 (calcd. for $C_{43}H_{39}Fe_2IN_2PPd$); found 958.9654 [M − I$^+$] with the expected isotopic pattern. $C_{43}H_{39}Fe_2I_2N_2PPd$ (1086.68): calcd. C 47.53, H 3.62, I 23.36, N 2.58, P 2.85; found C 47.60, H 3.73, I 23.11, N 2.51, P 3.02. $[\alpha]_{22}$ = +79 (c = 1, $CHCl_3$).

Palladium Complex 16b: A 100-mL Schlenk vessel was charged with compound **14b** (157 mg, 204 μmol, 1.0 equiv.) and triphenylphosphane (107 mg, 408 μmol, 2.0 equiv.). After addition of 3.0 mL of CH_2Cl_2, the cloudy orange mixture turned into a clear yellow solution within 5 min. After 2 h, the solvent was evaporated under reduced pressure, and the product was separated from excess PPh_3, as a yellow powder, by repeated washing with pentane. Yield: 195 mg (94%). ^{1}H NMR (CD_2Cl_2): δ = 4.26−431 (m, 14 H, 2 cp and 2 Cp_{subst}−*C*H), 5.18 (t, J = 2.0 Hz, 2 Cp_{subst}−*C*H), 7.24−7.61 (m, 15 H, PPh_3), 7.58 (d, J = 1.2 Hz, 2 H, NC*HCH*N) ppm. ^{13}C NMR (CD_2Cl_2): δ = 65.6 (Cp_{subst}−*C*H), 66.1 (Cp_{subst}−*C*H), 69.7 (Cp), 97.3 (d, J = 0.8 Hz, Cp_{subst}−*C*N), 123.6, (d, J = 5.6 Hz, (N*CHCH*N), 127.6 (d, J = 10.2 Hz, PPh_3), 130.0 (d, J = 2.3 Hz, PPh_3), 132.7 (d, J = 44.4 Hz, PPh_3), 135.2 (d, J = 10.9 Hz, PPh_3), 159.8 (d, J = 189.9 Hz, N−*C*Pd−N) ppm. ^{31}P NMR (CD_2Cl_2): δ = 16.7 ppm. MS (HRes MALDI): m/z = 930.9316 (calcd. for $C_{41}H_{35}Fe_2IN_2PPd$); found 930.9334 [M − I$^+$] with the expected isotopic pattern. $C_{41}H_{35}Fe_2I_2N_2PPd$ (1058.64): calcd. C 46.52, H 3.33, N 2.65; found C 47.30, H 3.44, N 2.63.

X-ray Crystallographic Study: X-ray structural measurements were carried out with a Bruker CCD diffractometer (Bruker SMART PLATFORM, with CCD detector, graphite monochromator, Mo-K_α radiation). The program SMART was used for data collection. Integration was performed with SAINT. The structure solution and refinement on F^2 were accomplished with SHELXTL 97. Model plots were made with ORTEP32. All structures were solved by direct methods. All non-hydrogen atoms were refined freely with anisotropic displacement parameters. Hydrogen atoms were refined at calculated positions riding on their carrier atoms. Weights were optimized in the final refinement cycles. A summary of the most important crystallographic data is given in Table 1. CCDC-239875 (**12b**), -239876 (**16a**) and -239877 (**12a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44 1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Support from the Swiss National Science Foundation is gratefully acknowledged. We thank Sebastian Gischig for performing the X-ray crystallographic studies of compounds **12a**, **12b** and **16a**.

[23] Aminoferrocene was first synthesized by Nesmeyanov (ref.[25]), who treated lithiated ferrocene with the *O*-benzyl ether of hydroxylamine and isolated the product in 25% yield. In the same year Arimoto and Haven synthesized aminoferrocene (ref.[26]) from ferrocenecarboxylic acid by using the Curtius synthetic strategy, but the overall yield was lower than 20%. Other approaches including Beckmann rearrangement from the oxime proved fruitless. Lehner and Schlögl, in 1970 (ref.[27]), reported the synthesis of planar-chiral (*R*)-1-amino-2-methylferrocene in 26% yield from (*R*)-2-methylferrocenecarboxylic acid by a modified procedure and determined its absolute configuration. The approach presented here differs from Schlögl's approach in various reaction conditions such as temperatures, solvents, the activation of the carboxylic acid and the fact that the sequence was performed in two steps in 82% yield. A recent example of a high yielding (80%) Curtius degradation sequence leading to achiral aminoferrocene can be found in ref.[28]

A New Type of Supramolecular Assembly by Hydrogen Bond Templating: Identification of Rare Monodentate Acetate Coordination in $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot T\cdot ClO_4$ (T = 2,6-Diaminopyridinium Cation, $C_5H_8N_3$ and 2-Aminopyridinium Cation, $C_5H_7N_2$)

Keywords: Iron trinuclear cluster / Hydrogen bond templating / Monodentate acetate / Supramolecular assembly

The complexes $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_8N_3\cdot ClO_4$ ($C_5H_8N_3$ = 2,6-diaminopyridinium cation) (**1**) and $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_7N_2\cdot ClO_4$ ($C_5H_7N_2$ = 2-aminopyridinium cation) (**2**) show novel self-assembled supramolecular structures in their crystals as elucidated by X-ray analysis. The structures contain $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ units as the building blocks. A detailed examination of the structures revealed that monodentate acetate, which is stabilised by a hydrogen-bond template T (2,6-diaminopyridinium cation in **1** and the 2-aminopyridinium cation in **2**), plays a directing role in forming these new types of hydrogen-bonded assemblies in **1** and **2**. Crystal data for **1** and **2** were determined by X-ray structure analysis.

Introduction

Oxo-bridged trinuclear iron clusters such as $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}RCOO)_6L_3]^{1+}$ (where L is a neutral monodentate ligand, e.g. H_2O and R is an alkyl or aryl group),[1] popularly known as "basic iron carboxylates", have been known for more than a century.[2] These trinuclear complexes are considered an important class of compounds because the $\{Fe_3(\mu_3\text{-}O)\}^{7+}$ unit has been proposed as the smallest building block for the formation of the iron core in ferritin, an iron storage protein.[3] However, examples of extended structures based on this building unit showing chain- or layer-like networks are scarce in the literature.[4,5] Recently, we reported a trinuclear iron(III) complex which aggregates to a 1D zig-zag chain-like structure through N−H···O hydrogen bonds.[5] In our continued efforts, we recently observed a new type of H-bonded supramolecular assembly in the complexes $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_8N_3\cdot ClO_4$ ($C_5H_8N_3$ = 2,6-diaminopyridinium cation) (**1**) and $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_7N_2\cdot ClO_4$ ($C_5H_7N_2$ = 2-aminopyridinium cation) (**2**). These species have $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ as a basic building block. The 2,6-diaminopyridinium cation (in **1**) and the 2-aminopyridinium cation (in **2**) play an important role in the templating of these H-bonded assemblies (Scheme 1) by stabilising a monodentate acetate coordinated to one of the iron centres in $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$. The stabilisation achieved here is through hydrogen bonding between the template (T) and monodentate acetate (Scheme 1). To the best of our knowledge, $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ is the first structurally characterised complex among "basic metal carboxylates" that has unusual monodentate acetate coordination.

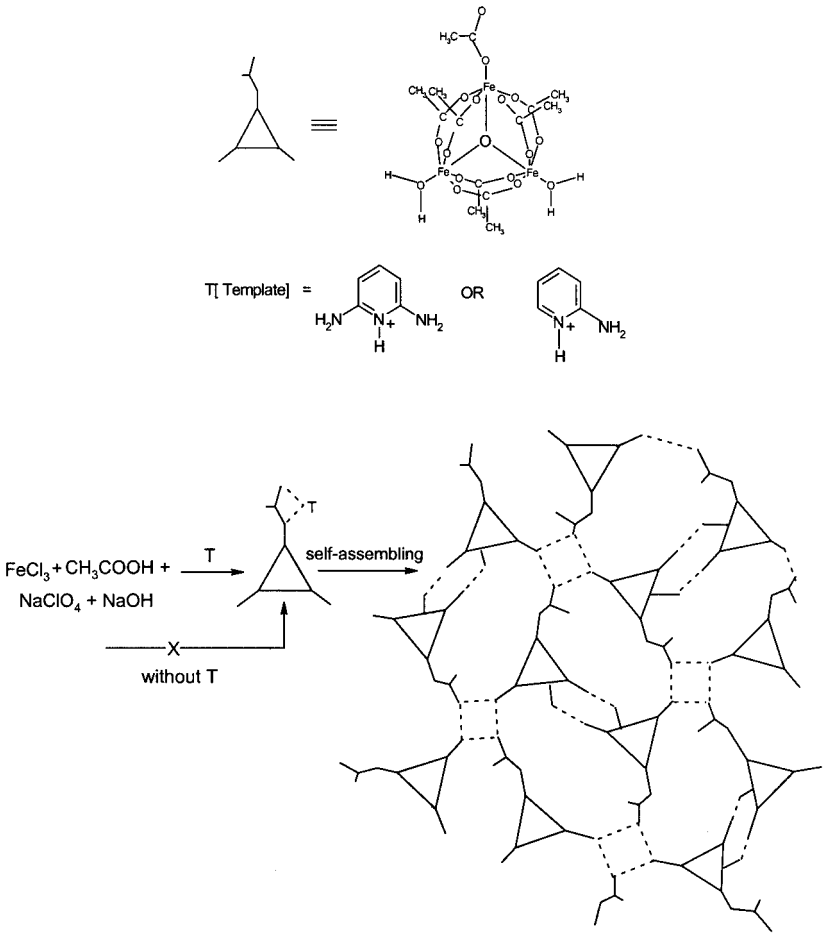
Results and Discussion

Compounds **1** and **2** were isolated from aqueous solutions (pH 3.5) by dissolving ferric chloride, acetic acid, 2,6-diaminopyridine (for compound **1**) or 2-aminopyridine (for compound **2**) and sodium perchlorate. The neutral complex $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ cocrystallises with 2,6-diaminopyridinium and 2-aminopyridinium perchlorate in **1** and **2**, respectively. Protonation of 2,6-diaminopyridine or 2-aminopyridine in **1** and **2** is not surprising because the synthesis of these complexes were carried out at a low pH value. Compounds **1** and **2** were obtained in moderate yields and gave elemental analyses consistent with formulae $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_8N_3\cdot ClO_4$ (**1**) and $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_7N_2\cdot ClO_4$ (**2**). Interestingly, compounds **1** and **2** both always crystallise with only one molecule of the respective aminopyridine regardless of the amount of aminopyridine used in the synthesis.



Scheme 1

Both the complexes crystallise in the monoclinic space group $P2_1/c$. The structural features of the $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ motif in **1** and **2** are comparable. The thermal ellipsoid plots of $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ in **1** and **2** are presented in Figure 1. Its overall structure is similar to that found in other trinuclear $\{M_3(\mu_3\text{-}O)\}$ compounds.[6] Unlike usual symmetric μ_3-oxotriiron(III) centres in basic metal carboxylates,[1] the unusual asymmetry in the present trinuclear structure $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ (in **1** and **2**) arises from the differences in the coordination environments of the three metal ions. Whereas one of the iron centres is coordinated to a monodentate acetate ligand, the other two are bonded to two water molecules. Monodentate acetate coordination is not unusual in transition metal chemistry although it is rare in basic iron carboxylate chemistry.[1] Among the basic carboxylate complexes in which the carboxylate is reported to act as a monodentate ligand, the formato complex $Fe_3O(OOCH)_7{\cdot}5H_2O$ is the best known example. Here, one of the formate ligands has been described as being monodentate in nature.[7] $[Fe_3(OH)(OOCCH_3)_7(NO_3)]{\cdot}nH_2O$ is another such example.[2c] However, the ambiguity of whether the extra carboxylate remain as an adduct (coordinated ligand) or a solvated carboxylic acid has not resolved in both these cases due to the lack of unambiguous characterisation data for the complexes especially single-crystal structure analyses. The crystal structure of an analogous complex, $[Cr_2Fe(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_3]\ NO_3{\cdot}CH_3COOH$, in which the seventh carboxylate remains as a solvate of acetic acid, has been described.[8] The crystal structures of **1** and **2** thus represent the first examples of a structurally characterised $\{Fe_3(O)\}^{7+}$ complexes (Figure 1) having monodentate carboxylate coordination at one of the metal centres. Relevant crystallographic data for **1** and **2** are presented in Table 1 and selected bond lengths and angles are listed in Tables 2 and 3, respectively.

At 298 K, the values of the effective magnetic moments for **1** and **2** were found to be 5.57 μ_B and 5.65 μ_B, respectively. These values are considerably smaller than the spin only value (10.25 μ_B) for a trinuclear cluster containing three high spin Fe^{III} ions (s = 5/2). This indicates an antiferromagnetic interaction between the three Fe^{III} centres in the trinuclear cluster. Similar antiferromagnetic interactions have been reported for $[Fe_3(\mu_3\text{-}O)(O_2CR)L_3]^{1+}$ complexes (R = alkyl groups, L = monodentate ligands).[1c,5b]

Hydrogen Bond Templating and Supramolecular Structure

2,6-Diaminopyridine and 2-aminopyridine are present in monoprotonated forms in the crystal structures of **1** and **2**

and are involved in noncovalent supramolecular interactions with monodentate acetates as depicted in Figure 2. We were unable to isolate $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ without adding 2,6-diaminopyridine or 2-aminopyridine (along with $NaClO_4$). This in itself suggests that these two amines are involved in the stabilisation of both the monodentate acetates which are coordinated to the $\{Fe_3\}$ clusters and the extended structures (vide infra). Indeed, as seen in Figures 2 and 3, the unusual iron-coordinated monodentate acetate anion is hydrogen-bonded to protonated 2,6-diaminopyridine (in **1**) and 2-aminopyridine (in **2**) and is directly involved in the construction of a new type of supramolecular network. A closer look at the structures (see Figure 3) suggests that these hydrogen-bonding assemblies would not have formed without involvement of the monodentate acetates and that the monodentate acetate could not have been incorporated if it were not stabilised by the 2,6-diaminopyridinium or 2-aminopyridinium cation (Figure 2). In other words, the 2,6-diaminopyridinium or 2-aminopyridinium cation acts as a hydrogen bond template, stabilising the monodentate acet-

ate anion which in turn is responsible for the formation of the novel layer-like hydrogen-bonded network of $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$.

Description of the Supramolecular Networks

There are two different types of intermolecular hydrogen bonds in the layer-like, 2D assembly formed in **1** (Figure 3a and Figure 4). These can be described as follows: (i) Type I: each hydrogen atom belonging to the Fe(2)-coordinated water molecule O(20) makes a hydrogen bond with a Fe(1)-coordinated monodentate acetate oxygen O(19). This results in a tetramer consisting of two O(20) waters and two O(19) acetate oxygen atoms (Figure 3a and Figure 4). (ii) Type II: one hydrogen atom attached to O(21)water [which is coordinated to Fe(3)] undergoes bifurcated H-bonding interactions with O(5) and O(10) from two different bidentate acetate anions from an adjacent Fe_3 cluster and vice versa (Figure 3a and Figure 4). The geometrical parameters of the hydrogen bonds involved in constructing this 2D supramolecular assembly are listed in Table 4. Because of the equivalency of the all Fe_3 clusters in the whole crystal, it was possible to have these two types of hydrogen bonds to form an infinite 2D layer network. In the layer, each $\{Fe_3\}$ cluster is surrounded by six identical clusters and is interlinked by both types (I and II) of hydrogen bonding. Interestingly, in the supramolecular network, Fe(1) of an $\{Fe_3\}$ cluster faces Fe(1) of an adjacent $\{Fe_3\}$ cluster. Similarly, Fe(2) and Fe(3) of the same $\{Fe_3\}$ cluster face Fe(2) and Fe(3) from two different adjacent $\{Fe_3\}$ clusters, respectively.

In the crystal structure of **2**, a similar layer-like assembly is formed from intermolecular hydrogen bonding interactions of $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]$ as

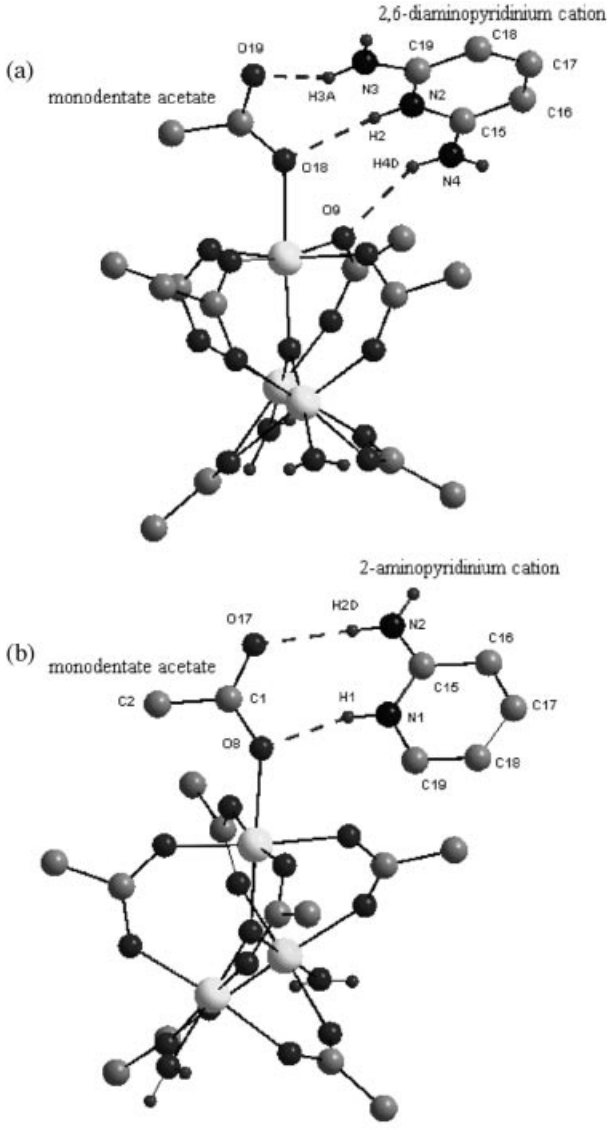

Figure 2. (a) Ball-and-stick representation of $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_8N_3^+$ showing N−H···O hydrogen bonding interactions between the 2,6-diaminopyridinium cation and the coordinated monodentate acetate ligand in **1**; hydrogen bonding parameters (Å, °): N(3)−H(3A)···O(19), 0.86, 2.08, 2.849 (7), 148.4; N(2)−H(2)···O(18), 0.86, 2.19, 3.045(6), 173.2; N(4)−H(4D)···O(9), 0.86, 2.21, 2.988(7), 151.1; (b) ball-and-stick representation of $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_7N_2^+$ showing N−H···O hydrogen bonding interactions between the 2-aminopyridinium cation and the coordinated monodentate acetate ligand in **2**; hydrogen bonding parameters (Å, °): N(2)−H(2D)···O(17), 0.86, 2.13, 2.932(6), 154.6; N(1)−H(1)···O(8), 0.86, 1.97, 2.804(5), 163.8

shown in (see Figure 3b). The hydrogen atoms of O(5)water [coordinated to Fe(1)] are hydrogen bonded to two O(17) acetate oxygen atoms from two different adjacent $\{Fe_3\}$ clusters resulting in a supramolecular $\{O_4\}$ cluster which consists of two O(5) waters and two O(17) acetate oxygen atoms. This is similar to the type I hydrogen bonding interaction in compound **1**. One hydrogen atom of O(12)water [coordinated to Fe(3)] undergoes a hydrogen bonding interaction with O(11) belonging to a bidentate acetate ligand from an adjacent $\{Fe_3\}$ cluster and vice versa. Unlike the

type II hydrogen bonds in compound **1**, the hydrogen atom of O(12)water does not undergo bifurcated hydrogen bonding interactions in compound **2** (see Figure 3b). The relevant hydrogen bonding parameters in compound **2** are summarised in Table 5.

In the crystal structures of both compounds **1** and **2**, the supramolecular hydrogen bonding interactions result in the layer-like two-dimensional networks (Figure 3). In the three-dimensional structure, the packing of these two-dimensional layers gives rise to nano-sized channels when viewed down to crystallographic *a* axis (Figure 5). The layers are well-separated in this stacking (along crystallographic *a* axis) with inter-layer distance of about 11 Å.

Removal of Template

Thermogravimetric analysis (TGA) of **1** under nitrogen showed an initial weight loss of ca. 25% at 240°C due to loss of 2,6-diaminopyridinium perchlorate. The compound is unstable beyond 245°C losing iron coordinated acetates

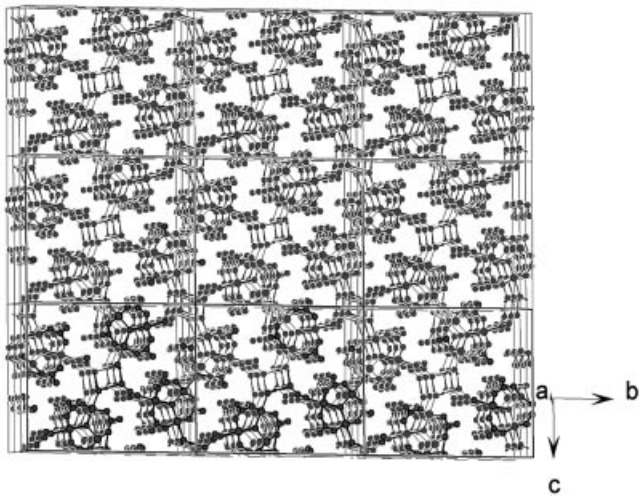

Figure 5. 3D structure of **1** (2,6-diaminopyridinium cation and perchlorate anion are not shown) showing the packing of the layers when viewed along the crystallographic *a* axis (3 × 3 × 3 cells)

including the (μ_3-O) atom with the decomposition of the trinuclear cluster (75.78% calcd, 75.44% obsd). As expected, the TGA curve of compound **2** is comparable with that of compound **1**. We wanted to check whether the template would be removed thermally but with retention of the supramolecular structure. The IR bands (700−850 cm^{-1}: γ-CH and pyridine ring bending bands, 2900−3350 cm^{-1}: N−H stretching vibrations) corresponding to the template gradually disappear on heating **1** and are completely lost when **1** is heated at 150°C for two hours. The resultant solid retains the {$Fe_3(\mu_3\text{-O})$} cluster as supported by the presence of $\nu_{as}(Fe_3O)$ vibrations at 660 cm^{-1} and 625 cm^{-1} in the IR spectrum but the solid loses its crystallinity as evidenced by X-ray powder diffraction studies. We also attempted to remove the template by washing **1** or **2** with an organic solvent in which 2,6-diaminopyridine and 2-aminopyridine are soluble but **1** and **2** are insoluble. However, we were not successful in removing the templates of **1** and **2** whilst maintaining their supramolecular structures (see Exp. Sect.). The fact that the amino bases (templates) cannot be removed from the crystal structure without resorting to heating the sample is probably due to the strong hydrogen bonding interactions of the template with the host trinuclear iron cluster.

Conclusion

A new type of layer-like network, constructed from an unusual trinuclear iron cluster [$Fe_3(\mu_3\text{-})(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)$] using supramolecular interactions, has been presented. The building complex unit represents the first example of a structurally characterised {$M_3(\mu_3\text{-O})$} cluster in which a carboxylate anion acts as a monodentate ligand. The 2,6-diaminopyridinium cation in **1** and the 2-aminopyridinium cation in **2** act as hydrogen bonding templates and stabilise the monodentate acetates which in turn result in the formation of novel supramolecular networks in **1** and **2**. Despite the amine groups of the template being free for metal coordination, the fact that the aminopyridines are not involved in the covalent bonding interactions is very significant. These results help the understanding of the basic principles of supramolecular chemistry.

Experimental Section

Chemicals and Reagents: Doubly distilled water was used throughout. All other chemical reagents were of analytical grade purity.

Physical Methods: TGA analyses of compounds **1** and **2** were performed with a Mettler Toledo Star System thermal analyser under nitrogen at a scan rate of 10°C min^{-1}. Powder X-ray diffraction data were collected with a Phillips PW 3710 diffractometer. Microanalytical (C, H, N) data were obtained with a Perkin−Elmer model 240C elemental analyser. The infrared spectra were recorded by using KBr pellets with a Jasco-5300 FT-IR spectrophotometer. Room temperature (298 K) solid state magnetic susceptibility was measured by using a Sherwood Scientific magnetic susceptibility balance. $Hg[Co(NCS)_4]$ was used as the standard. Diamagnetic corrections {-375×10^{-6} cgsu for $[Fe_3(\mu_3\text{-O})(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_8N_3\cdot ClO_4$ (**1**) and -366.5×10^{-6} cgsu for $[Fe_3(\mu_3\text{-O})(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_7N_2\cdot ClO_4$ (**2**), calculated from Pascal's constants,[9] were used to obtain the molar paramagnetic susceptibilities.

Synthesis of $[Fe_3(\mu_3\text{-O})(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_8N_3\cdot ClO_4$ (1): To a stirred aqueous solution (30 mL) of $FeCl_3$ (2 g, 12.33 mmol) were added CH_3COOH (10 mL), 2,6-diaminopyridine (9.16 mmol, 1 g) and $NaClO_4$ (36.75 mmol, 4.5 g), followed by drop wise addition of 1 M NaOH (until the pH of solution reached 3.5. Further addition of NaOH resulted in the formation of a precipitate). The resultant red solution was filtered into 100 mL beaker which was subsequently kept covered with perforated aluminium foil for a week at room temperature. The red crystals of **1** which formed during this time were separated by filtration, washed with cold water and dried at room temperature. Yield: 1.8 g (52% based on Fe). Selected data for **1**, IR (KBr pellet): $\tilde{\nu}$ = 3470 (w), 3350 (m), 3244 (w), 3013 (m), 2939 (m), 2471(w), 2378 (w), 1666 (s), 1601 (s), 1521 (s), 1442 (s), 1174 (m), 1101 (s), 939 (w), 817 (m), 775 (m), 717 (w), 661 (s), 619 cm^{-1} (s). $C_{19}H_{33}ClFe_3N_3O_{21}$ (842.48): calcd. C 27.09, H 3.95, N 4.99; found C 26.98, H 3.99, N 4.92.

Synthesis of $[Fe_3(\mu_3\text{-O})(\mu_2\text{-}CH_3COO)_6(H_2O)_2(CH_3COO)]\cdot C_5H_7N_2\cdot ClO_4$ (2): To a stirred aqueous solution (30 mL) of $FeCl_3$ (2 g, 12.33 mmol) were added CH_3COOH (10 mL), 2-aminopyridine (9.14 mmol, 0.861 g) and $NaClO_4$ (36.75 mmol, 4.5 g), followed by drop wise addition of 1 M NaOH (until the pH of solution reached 3.56. Further addition of NaOH resulted in formation of precipitate). The resultant red solution was filtered and was kept at room temperature for a week. The red crystals of compound **2** which formed during this time were separated by filtration, washed with cold water and dried at room temperature. Yield: 1.79 g (53% based on Fe). Selected data for **2**, IR (KBr pellet): $\tilde{\nu}$ = 3431 (w), 1670 (s), 1602 (s), 1446 (s), 1172 (m), 1103 (s), 773 (m), 659 (s), 615 (s), 522 cm^{-1} (m). $C_{19}H_{32}ClFe_3N_2O_{21}$ (827.47): calcd. C 27.58, H 3.89, N 3.38; found C 27.46, H 3.83, N 3.32.

Caution! *Although no problems were encountered in this work, care should be taken in the handling of perchlorate salts.*

Attempted Reaction for the Removal of the Template: Complex **1** (0.418 mmol, 0.352 g) was suspended in toluene (40 mL) and stirred for 24 h. The suspension was then filtered, washed with toluene and dried at room temperature in the air. The solid was identified as **1** by elemental analysis ($C_{19}H_{33}ClFe_3N_3O_{21}$: calcd. C 27.09, H 3.95, N 4.99; found C 27.15, H 3.89, N 4.93) and IR studies. Similar attempts with **2** for the removal of its template were also unsuccessful (both 2,6-diaminopyridine and 2-aminopyridine are soluble in toluene).

X-ray Crystallography: Data for **1** and **2** were collected at 293 K on an Enraf−Nonius Mach-3 diffractometer using graphite-monochromated Mo-K_α radiation. The structures were solved (SHELXS-97)[10] and refined over F^2 using the SHELXL-97 program.[11] All nonhydrogen atoms were refined anisotropically. The hydrogen atoms of the 2,6-diaminopyridinium and 2-aminopyridinium cations and the acetate ligands were assigned their positions on the basis of geometrical considerations and were allowed to ride upon the respective carbon and nitrogen atoms. The hydrogen atoms of the coordinated water molecules were located in the differential Fourier maps and were refined using isotropic thermal parameters. CCDC-234723 and -234724 (for compounds **1** and **2** respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at http://www.ccdc.cam.ac.uk/conts/retrieving.html. Keywords: Coordination polymers / Cyanides / Magnetic properties / Ruthenium

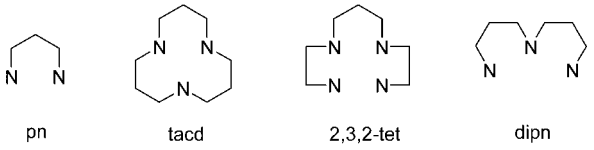
The dimetallic compounds $[Ni(2,3,2\text{-tet})]_2[Ru(CN)_6]\cdot 8H_2O$ (**1**), $[Ni(pn)_2]_2[Ru(CN)_6]\cdot 5H_2O$ (**2**) $[Ni(tacd)(H_2O)]_2[Ru(CN)_6]\cdot 8H_2O$ (**3**) and $\{[Cu(dipn)]_3[Ru(CN)_6]\}(ClO_4)_2\cdot 4H_2O$ (**4**) [2,3,2-tet = *N*,*N*′-bis(2-aminoethyl)-1,3-propanediamine, pn = 1,3-diaminopropane, tacd = 1,5,9-triazacyclododecane, dipn = dipropylenetriamine] have been prepared from the reaction of $[Ru(CN)_6]^{4-}$ with $[Ni(2,3,2\text{-tet})]^{2+}$, $[Ni(pn)_2]^{2+}$, $[Ni(tacd)(H_2O)]^{2+}$ and $[Cu(dipn)]^{2+}$, respectively. Compounds **1** and **2** contain a two-dimensional square network, compound **3** has a one-dimensional, crossed-double chain structure, while compound **4** has an unusual, two-dimensional, double-edged, honeycomb network. A very weak antiferromagnetic interaction is observed in **2**.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

In the past decade, metal cyanides such as $[M(CN)_6]^{n-}$ (M = V^{II}, Cr^{III}, Mn^{II}, Mn^{III} or Mn^{IV}, Fe^{II} or Fe^{III}) have been used as building blocks for the construction of a variety of coordination polymers with various interesting structures and properties.[1−28] The use of 4d-metal cyanides as building blocks, however, has not received much attention until more recently. Most of the examples are limited to the heptacyanometallate $[Mo^{III}(CN)_7]^{4-}$ and the octacyanometallates $[M^{IV/V}(CN)_8]^{3/4-}$ (M = $W^{IV/V}$, $Mo^{IV/V}$ or Nb^{IV}).[29] Only a few examples of coordination polymers containing $[Ru(CN)_6]^{4-}$ have been reported.[29p,30−33] We describe here a number of heterodimetallic coordination polymers made from the reaction of $[Ru(CN)_6]^{4-}$ with Cu^{2+} or Ni^{2+} in the presence of an amine ligand such as 2,3,2-tet, pn, tacd, or dipn [2,3,2-tet = *N*,*N*′-bis(2-aminoethyl)-1,3-propanediamine, pn = 1,3-diaminopropane, tacd = 1,5,9-triazacyclododecane, dipn = dipropylenetriamine]. One of our objectives was to compare the structure and magnetic properties of these polymers with the corresponding ones made from $[Fe(CN)_6]^{4-}$. A number of polynuclear cyano-bridged complexes containing $[Fe(CN)_6]^{4-}$ are known. For example, reaction of $[Ni(L)_3]X_2$ with $K_4[Fe(CN)_6]$ in water produces a 3D network, $[Ni(L)_2]_3[Fe(CN)_6]X_2$ [L = ethylenediamine (en), trimethylenediamine (tn); X = PF_6^-, ClO_4^-], which exhibits a ferromagnetic interaction between the nearest Ni^{II} ions through the diamagnetic Fe^{II} ion.[19] On the other hand, reaction of $Cu(ClO_4)_2\cdot 6H_2O$, ept and $K_4[Fe(CN)_6]$ produces the 2D molecule $\{[Cu(ept)]_3[Fe(CN)_6]\}(ClO_4)_2\cdot 5H_2O$ [ept = *N*-(2-aminoethyl)-1,3-diaminopropane], which exhibits little or no coupling between the copper atoms via the −NC−Fe−CN− bridges.[28]



Results and Discussion

Structure of $[Ni(2,3,2\text{-tet})]_2[Ru(CN)_6]\cdot 8H_2O$ (1)

The pale-pink, dimetallic compound **1** was obtained by reacting $Ni(CH_3COO)_2\cdot 4H_2O$ with one molar equivalent of 2,3,2-tet and $K_4[Ru(CN)_6]$. The structure was determined by X-ray crystallography; selected bond lengths and angles are summarized in Table 1. The compound is isomorphous to $[Ni^{II}(diamine)_2]_2[Fe^{III}(CN)_6]X$.[7,17,18] The asymmetric unit of **1** contains a $[Ni(2,3,2\text{-tet})]^{2+}$ cation, one-half of a $[Ru(CN)_6]^{4-}$ anion, and four water molecules (Figure 1a). The four equatorial cyanides of each $[Ru(CN)_6]^{4-}$ unit are coordinated to four *trans*-$[Ni(2,3,2\text{-tet})]^{2+}$ moieties to pro-

duce a square 2D network which has an aaa-type sequence (Figure 1b). The average Ru−C bond length of 2.03 Å and C≡N bond length of 1.156 Å are similar to those in $Mn_2[Ru(CN)_6]\cdot 8H_2O$.[30] The bond lengths of bridging [1.156(3) Å] and terminal cyanides [1.154(3) and 1.157(3) Å] are essentially identical. The Ni−N bond lengths in *trans*-$[Ni(2,3,2\text{-tet})]^{2+}$ range from 2.102(2) to 2.109(2) Å, and are similar to those in other *trans*-$[Ni(2,3,2\text{-tet})]^{2+}$ compounds.[34] There are N−H···O, O−H···N, O−H···O hydrogen-bond interactions in the crystal structure which are mainly between the water solvates and two of the amine nitrogens. The O···O distances range from 2.794(4)−2.880(5) Å and the N···O distances are 2.873(6) and 3.064(4) Å (Table S1, Supporting Information). The Ni···Ni separation through -NC−Ru−CN- is 10.06 Å, and the shortest interlayer Ni···Ni distance is 8.91 Å.

Structure of $[Ni(pn)_2]_2[Ru(CN)_6]\cdot 5H_2O$ (2)

Blue crystals of compound **2** were obtained by treating $Ni(CH_3COO)_2\cdot 4H_2O$ with 2 mol-equiv. of pn and 1 mol-equiv. of $K_4[Ru(CN)_6]$ in water. The structure was determined by X-ray crystallography; selected bond lengths and angles are summarized in Table 2. The asymmetric unit of **2** consists of a $[Ni(pn)_2]^{2+}$ cation, one-half of a $[Ru(CN)_6]^{4-}$ anion, and two and a half water molecules (Figure 2a). The four equatorial cyanides of each $[Ru(CN)_6]^{4-}$ unit are coordinated to four *trans*-$[Ni(pn)_2]^{2+}$ moieties to produce a square 2D network that is similar to that of compound **1** (Figure 2b). Bridging of the cyano group leads to only a small deviation of the C(cyanide)−Ru−C(cyanide) angles [89.63(11)−90.37(11)°] from a right angle, as in compound **1**. The average Ru−C bond length of 2.03 Å and C≡N bond length of 1.15 Å are similar to those in compound **1**; the bond lengths of bridging (1.152 Å) and terminal cyanides (1.146 Å) also show little difference. The separation of neighboring nickel atoms through −NC−Ru−CN− is 10.30 Å.

Structure of $[Ni(tacd)(H_2O)]_2[Ru(CN)_6]\cdot 8H_2O$ (3)

Red crystals of **3** were obtained from the reaction of $Ni(CH_3COO)_2\cdot 4H_2O$ with tacd and $K_4[Ru(CN)_6]$. Compound **3** has a 1D crossed double-chain structure (Figure 3b), as determined by X-ray crystallography. Selected bond lengths and angles are summarized in Table 3. The asymmetric unit consists of two $[Ni(tacd)(H_2O)]^{2+}$ cations, one $[Ru(CN)_6]^{4-}$ anion, and eight water molecules (Figure 3a). Each $[Ru(CN)_6]^{4-}$ unit is connected to four $[Ni(tacd)(H_2O)]^{2+}$ units through two axial and two equatorial cyanides, and each $[Ni(tacd)(H_2O)]^{2+}$ unit is connected to two $[Ru(CN)_6]^{4-}$ units in a *cis* fashion. This produces Ru−Ni squares. Each square is perpendicular to adjacent squares and this arrangement results in a zig-zag structure. The angles C(1)−Ru(1)−C(6), C(2)−Ru(1)−C(5), N(2)−Ni(1)−N(5) and N(1)−Ni(2)−N(6) are 91.5(2)°, 89.7(2)°, 90.7(2)° and 89.7(2)°, respectively. Each nickel(II) atom is coordinated to the three nitrogen atoms of tacd, two nitrogen atoms of cyanide and one oxygen atom of a

water molecule, forming a distorted octahedral geometry. The Ni−N(tacd) distances range from 2.099(4) to 2.106(4) Å for Ni(1) and 2.089(4) to 2.124(4) Å for Ni(2), which are within the normal range of Ni−N(amine) distances. The Ni−N(cyanide) distances range from 2.040(4) to 2.067(4) Å. The bridging C≡N distances of 1.142(6)−1.153(6) Å are similar to those in $Mn_2[Ru(CN)_6]\cdot 8H_2O$ [1.152(9)−1.165(8) Å].[30] The Ru−C bond lengths are 2.024(5)−2.043(5) Å. The Ru−C≡N bond angles are close to linear [176.9(4)−178.0(4)°] while the Ni−N≡C angles are bent [163.5(4)−170.3(4)°]. There is intramolecular hydrogen bonding between the coordinated water molecules, with an O(1)···O(2) distance of 2.847(5) Å. The uncoordinated water molecules are positioned between the chains and are hydrogen-bonded to the terminal cyanides of $[Ru(CN)_6]^{4-}$; the N···O distances range from 2.800(6) to 3.523(6) Å. The Ni···Ni separation through -NC−Ru−CN- is 10.38 Å, and the shortest interchain Ni···Ni distance is 9.56 Å.

Structure of $\{[Cu(dipn)]_3[Ru(CN)_6]\}(ClO_4)_2\cdot 4H_2O$ (4)

Green crystals of **4** were obtained from the reaction of $Cu(CH_3COO)_2\cdot H_2O$ with dipn, $K_4[Ru(CN)_6]$ and $NaClO_4$. The structure of **4** was determined by X-ray crystallography; selected bond lengths and angles are summarized in Table 4. The asymmetric unit consists of three $[Cu(dipn)]^{2+}$, one $[Ru(CN)_6]^{4-}$, two ClO_4^-, and four water molecules (Figure 4a). The Cu^{II} in each $[Cu(dipn)]^{2+}$ unit is five-coordinate and is bonded to two nitrogen atoms of two $[Ru(CN)_6]^{4-}$ and the three nitrogen atoms of a dipn. Each $[Ru(CN)_6]^{4-}$ is connected to six $[Cu(dipn)]^{2+}$ units through cyano bridges to form an unusual 2D double-edged honeycomb network (Figure 4b), which is similar to that of $\{[Cu(ept)]_3[Fe(CN)_6]\}(ClO_4)_2\cdot 5H_2O$.[28] The Ru−C bond lengths lie in the range 2.018(7)−2.044(8) Å. The bridging C≡N distances range from 1.144(10) to 1.159(9) Å, and are similar to those in $Mn_2[Ru(CN)_6]\cdot 8H_2O$.[30] The Cu−N(amine) bond lengths [2.007(7)−2.090(7) Å] are similar to those in $\{[Cu(ept)]_3[Fe(CN)_6]\}(ClO_4)_2\cdot 5H_2O$ (2.000−2.050 Å). The Cu−N≡C angles [153.7(6)−168.3(7)°] show significant deviations from 180°, and the Cu atom in each $[Cu(dipn)]^{2+}$ moiety has a distorted square-pyramidal geometry, with τ values of 0.16 for Cu(1), 0.38 for Cu(2) and 0.61 for Cu(3). There are N−H···O interactions in the crystal structure which involve mainly the water solvates and the amine nitrogen, with N···O distances ranging from 3.077(12) to 3.240(13) Å. Hydrogen bonding involving the perchlorate ion is also observed, with N···O distances ranging from 3.071(19) to 3.211(15) Å (Table S2, Supporting Information). The adjacent Cu···Cu separations are 6.590−8.270 Å, and the Cu···Cu distance through −NC−Ru−CN− is 10.093−10.318 Å.

Magnetic Properties

Figure 5 illustrates the temperature dependence of $\chi_M T$ and $\chi_M{}^{-1}$ per Ni_2Ru unit of compound **1**. The $\chi_M T$ value remains more or less constant from 300 K to 10 K. Below 10 K the $\chi_M T$ value decreases rapidly with decreasing temperature. A plot of $\chi_M{}^{-1}$ vs. T obeys the Curie−Weiss law with a Curie constant, C, of 2.468 $cm^3 \cdot K \cdot mol^{-1}$ and a Weiss constant, θ, of 0.01 K. The C value is slightly larger than the expected value of 2.00 $cm^3 \cdot K \cdot mol^{-1}$ for non-coupled, spin-only Ni ($S = 1$) and diamagnetic Ru ions. The very small Weiss constant suggests there is negligible magnetic interaction between the Ni^{II} centers through the diamagnetic $[Ru^{II}(CN)_6]^{4-}$ bridges.

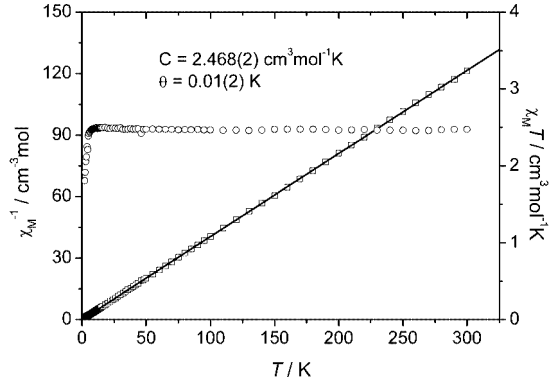

Figure 5. Temperature dependence of $\chi_M T$ (squares) and $\chi_M{}^{-1}$ (circles) for compound **1** per Ni_2Ru unit

The plot of $\chi_M{}^{-1}$ vs. T for compound **2** (Figure S1, Supporting Information) obeys the Curie−Weiss law with a Curie constant of 2.56 $cm^3 \cdot K \cdot mol^{-1}$ and a small negative Weiss constant of −2.95 K. The C value is slightly larger than the expected value (2.00 $cm^3 \cdot K \cdot mol^{-1}$) for non-coupled, spin-only Ni ($S = 1$) and diamagnetic Ru ions. The negative Weiss constant suggests that a very weak antiferromagnetic interaction between the Ni^{II} centers through the diamagnetic $[Ru^{II}(CN)_6]^{4-}$ bridges may be present.

For compound **3**, the plot of $\chi_M{}^{-1}$ vs. T in the range of 2−300 K (Figure S2; Supporting Information) obeys the Curie−Weiss law, with a small positive Weiss constant of 1.0 K and a Curie constant of 2.17 $cm^3 \cdot K \cdot mol^{-1}$. For compound **4**, the plot of $\chi_M{}^{-1}$ vs. T in the range of 2−300 K (Figure S3, Supporting Information) also obeys the Curie−Weiss law, with a small positive Weiss constant of +1.1 K and a Curie constant of 1.16 $cm^3 \cdot K \cdot mol^{-1}$. The small positive Weiss constants in compounds **3** and **4** do not necessarily imply ferromagnetic interaction between the Ni atoms through the −NC−Ru−CN− bridge, since we have no other supporting data available.

Conclusion

In this work four dimetallic assemblies made from $K_4[Ru(CN)_6]$ are reported. Although 3D NiFe assemblies have been obtained from the reaction of $[Ni(L)_3]X_2$ (L = en, tn; X = PF_6^-, ClO_4^-) with $K_4[Fe(CN)_6]$, similar reactions using $K_4[Ru(CN)_6]$ produce only either 2D (**1**, **2**) or 1D (**3**) compounds. In the case of CuM, however, both $[Cu(dipn)]_3[Ru(CN)_6]\}(ClO_4)_2 \cdot 4H_2O$ (**4**) and $\{[Cu(ept)]_3[Fe(CN)_6]\}(ClO_4)_2 \cdot 5H_2O$ have the same unusual, double-edged honeycomb structure.

In all the compounds there is little or no magnetic interaction between the paramagnetic metal centers through the diamagnetic $[Ru^{II}(CN)_6]^{4-}$ bridge. Compounds **1** and **3** involve interesting octahedral Ni^{II} coordination compounds, and it is notable that the magnetic moments of the less deformed NiN_6 octahedra in **1** and **2** reflect more spin-orbit coupling than the clearly more distorted octahedron in **3**.

Experimental Section

Reagents and Physical Measurements: *N*,*N*′-Bis(2-aminoethyl)-1,3-propanediamine (2,3,2-tet), 1,3-diaminopropane (pn), and dipropylenetriamine (dipn) were purchased from Acros. 1,5,9-Triazacyclododecane (tacd) was obtained from Aldrich. All other reagents and solvents were of reagent grade and used without further purification. Potassium hexacyanoruthenate(II) was prepared according to a literature method.[35] Infrared spectra were recorded as KBr discs in the region of 400−4000 cm^{-1} with an Avatar 360 FTIR spectrophotometer. Elemental analyses were carried out with an Elementar Vario EL Analyser. The variable-temperature magnetic susceptibilities for a collection of small single crystals of **1**−**4** were measured in the temperature range of 2−300 K using either an MPMS XL-5 SQUID (for **1**, **3**, **4**) or an Oxford MagLab 2000 system (for **2**).

Preparation of $[Ni(2,3,2\text{-tet})]_2[Ru(CN)_6] \cdot 8H_2O$ (1): An aqueous solution (10 mL) of 2,3,2-tet (38.7 μL, 0.24 mmol) and $K_4[Ru(CN)_6]$ (0.1 g, 0.24 mmol) was slowly added to a methanolic solution (10 mL) of $Ni(CH_3COO)_2 \cdot 4H_2O$ (0.06 g, 0.24 mmol). The resulting solution was filtered to remove some pale-pink precipitate and the filtrate was then allowed to stand in the dark at room temperature for a few days. The resulting pale-pink crystals were collected by filtration and washed with methanol and then diethyl ether (79 mg, 76%). $C_{20}H_{56}N_{14}Ni_2O_8Ru$ (839.22): calcd. C 28.62, H 6.73, N, 23.37; found C 28.38, H 6.81, N 23.51. IR (KBr): $\tilde{\nu}$ = 2066 s (C≡N) cm^{-1}.

Preparation of $[Ni(pn)_2]_2[Ru(CN)_6] \cdot 5H_2O$ (2): An aqueous solution (10 mL) containing pn (0.06 g, 0.8 mmol) and $K_4[Ru(CN)_6]$ (0.2 g, 0.48 mmol) was added dropwise to an aqueous solution (10 mL) of $Ni(CH_3COO)_2 \cdot 4H_2O$ (0.2 g, 0.8 mmol). The resulting blue solution was placed in the dark at room temperature for several days. The resulting blue crystals were filtered, washed with methanol and diethyl ether, and dried in air (225 mg, 74%). $C_{18}H_{50}N_{14}Ni_2O_5Ru$ (761.22): calcd. C 28.40, H 6.62, N 25.76; found C 28.49, H 6.51, N 25.52. IR (KBr): $\tilde{\nu}$ = 2062, 2094 (C≡N) cm^{-1}.

Preparation of $[Ni(tacd)(H_2O)]_2[Ru(CN)_6] \cdot 8H_2O$ (3): An aqueous solution (5 mL) of tacd (0.1 g, 0.24 mmol) and $K_4[Ru(CN)_6]$ (0.1 g, 0.24 mmol) was added dropwise to an aqueous solution (3 mL) of $Ni(CH_3COO)_2 \cdot 4H_2O$ (0.06 g, 0.24 mmol). The resulting blue solution was placed in the dark at room temperature for several days. The resulting red crystals were filtered, washed with methanol and diethyl ether, and dried in air. (178 mg, 83%). $C_{24}H_{62}N_{12}Ni_2O_{10}Ru$ (897.30): calcd. C 32.13, H 6.96, N 18.73; found C 32.14, H 6.91, N 18.75. IR (KBr): $\tilde{\nu}$ = 2066 s (C≡N) cm^{-1}.

Crystallographic Data Collection and Structure Determination: Diffraction data for a crystal of **1** or **3** were collected with a Bruker SMART CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) at 298 K. Data for a crystal of **2** was collected with a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 K. Data for a crystal of **4** was collected with a Rigaku AFC7R diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) at 298 K. The structure of **1** was solved by direct methods with PATTY,[36] the structure of **2** was solved by direct methods and refined by a full-matrix least-squares technique based on F^2 using the SHELXL 97 program,[37] and the structures of **3** and **4** were solved by direct methods with SIR92[38] and refined by a full-matrix least-squares technique based on F^2 using teXsan.[39] Hydrogen atoms were included but not refined. All calculations were performed with a Silicon Graphic computer, using the teXsan crystallographic software package from Molecular Structure Corporation. All crystallographic data and other details and parameters are summarized in Table 5. CCDC-242152 (**1**), -242160 (**2**), -242151 (**3**), and -242150 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: + 44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Trinuclear [NiFe] Clusters as Structural Models for [NiFe] Hydrogenase Active Sites[‡]

Dieter Sellmann,[a][†] Frank Lauderbach,*[a] and Frank W. Heinemann[a]

Keywords: Nickel / Iron / Cluster compounds / Carbonyl ligands / S ligands

[Fe($CH_3COCH{=}CHPh$)$(CO)_3$] reacts with [Ni('S_4')]$_x$ (x = 1, 2) or [Ni('$S_4C_3Me_2$')] ['S_4'$^{2-}$ = 1,2-bis(2-mercaptophenylthio)-ethane(2-),'$S_4C_3Me_2$'$^{2-}$ = 1,3-bis(2-mercaptophenylthio)-2,2-dimethylpropane(2-)] to afford trinuclear [NiFe] clusters [Ni('S_4'){Fe$(CO)_3$}$_2$] (**1**) and [Ni('$S_4C_3Me_2$'){Fe$(CO)_3$}$_2$] (**2**) and the dinuclear $Fe^{II}Fe^0$ complex [Fe(CO)('$S_4C_3Me_2$')Fe$(CO)_3$] (**3**). Clusters **1** and **2** have Ni–Fe bond lengths similar to those of active or reduced states of [NiFe] hydrogenases, a sulfur-dominated coordination sphere of Ni and iron-bound CO. Therefore, **1** and **2** may serve as structural model complexes for the [NiFe] hydrogenase active site. Combination of the '$S_4C_3Me_2$' ligand with $FeCl_2{\cdot}4H_2O$ yielded [Fe('$S_4C_3Me_2$')]$_2$ (**4**), the dinuclearity of which suggests that the '$S_4C_3Me_2$' ligand is less flexible than its ethylene-bridged derivative, which affords a tetrameric [Fe('S_4')]$_4$ complex reported earlier. Compound **4** reacts with 2 equiv. of CO to give [Fe(CO)('$S_4C_3Me_2$')]$_2$ (**5**), which like **4** is only sparingly soluble in all common organic solvents. Complex **5** easily loses CO even if stored in the solid state. [Fe($CH_3COCH{=}CHPh$)$(CO)_3$] reacts with **5** to afford **3** as the only product.

Introduction

Hydrogenases catalyze the reversible oxidation of molecular hydrogen according to $H_2 \rightleftarrows 2\ H^+ + 2\ e^-$ and, therefore, play a central role in hydrogen and energy metabolism in nature.[1] They are essential for many microorganisms, which acquire energy by the reduction of CO_2, carbonates, sulfates or nitrates.[2] These enzymes are of great biotechnological interest[3] as they can produce molecular hydrogen.[4] [NiFe] hydrogenases are the most predominant of the four major types of hydrogenases commonly known.[3,5] Figure 1

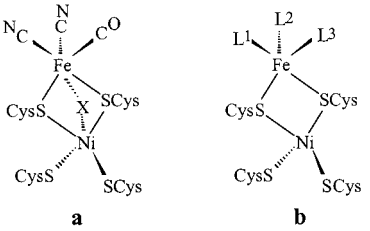

Figure 1. Schematic structure of the active center from (a) *D. gigas* in the oxidized form (X represents, probably, OH^- or O^{2-})[6a,6b] and (b) *D. vulgaris Miyazaki F* hydrogenase in the reduced form (L^1 = SO, CN or CO, L^2 = CN or CO, L^3 = CN or CO)[6c]

depicts the active centers of oxidized and reduced [NiFe] hydrogenases, consisting of Ni–S–Fe bridges.

The mechanism of the reversible H_2 oxidation is still poorly understood. [NiFe] hydrogenases exist in various redox states that can be labeled by their EPR spectra and individual ν(CO) frequencies.[3,7] The relationship between these redox states and the metal oxidation states is still unclear. Furthermore, it is not known if only one or both metal atoms are involved in the activation process. To shed light on these questions, several di- and oligonuclear compounds have been synthesized.[8] Despite intensive research, the number of compounds containing sulfur–bridged Ni *and* Fe centers remains very limited.[9] Recently, we succeeded in synthesizing such complexes as [('S_2')Ni–μ-('S_3')Fe(CO)$(PMe_3)_2$] ['S_2'$^{2-}$ = 1,2-benzenedithiolate(2–), 'S_3'$^{2-}$ = bis(2-mercaptophenyl)sulfide(2–)][10] and [('S_2'){Ni(PMe_3)}$_2$Fe(CO)('S_2')$_2$].[11] Moreover, the latter remarkably reduces protons to dihydrogen, affording the cationic species [('S_2'){Ni(PMe_3)}$_2$Fe(CO)('S_2')$_2$]$^+$.[11] This exciting result encouraged us to further synthesize such complexes without any abiological phosphane ligands and to investigate their reactivity towards protons and hydrogen. Herein, we report the synthesis of the new trinuclear [NiFe] clusters [Ni('S_4'){Fe$(CO)_3$}$_2$] (**1**) and [Ni('$S_4C_3Me_2$'){Fe$(CO)_3$}$_2$] (**2**). The reaction of these complexes with H^+ and H_2 is also investigated.

Results and Discussion

In order to obtain dinuclear [NiFe] complexes, [Fe(CH_3-$COCH{=}CHPh$)$(CO)_3$] and [Ni(L)]$_x$ (L = 'S_4', x = 1, 2;

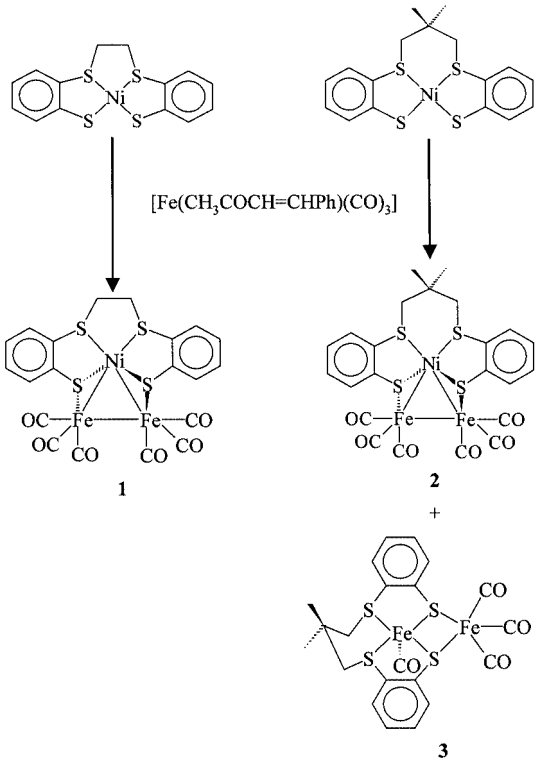
'$S_4C_3Me_2$', $x = 1$) were combined in equimolar ratio. Unexpectedly, this method did not yield dinuclear complexes but afforded instead the trinuclear clusters **1** and **2** (Scheme 1).



Scheme 1. Syntheses of [NiFe] clusters

During this reaction, the solution changed from bright red to dark red (L = 'S_4') or brown (L = '$S_4C_3Me_2$'). The complexes were isolated by column chromatography in 60% (**1**) and 29% (**2**) yield. During the preparation of **2**, an additional complex [Fe(CO)('$S_4C_3Me_2$')Fe(CO)$_3$] (**3**) could be isolated (vide infra). Clusters **1** and **2** have good solubility in THF and CH_2Cl_2, but are insoluble in pentane. According to their NMR spectra, both **1** and **2** are diamagnetic and possess a twofold symmetry in solution. For **2**, which in contrast to **1** does not exhibit a crystallographically imposed C_2 symmetry, this may be explained by a rapid movement of the neopentylene bridge in solution. Figures 2 and 3 depict stereo views of the molecular structures of **1** and **2**. The coordination spheres of the metal atoms in both clusters exhibit no significant differences. Selected bond lengths and angles (Table 1) illustrate the similar structural properties of these complexes.

Both complexes consist of a trinuclear arrangement of two Fe and one Ni atom that are linked by additional metal−metal interactions. The Ni−Fe distances in **1** (248.6 pm) and **2** (ca. 250 pm) closely resemble that of the active sites of reduced [NiFe] hydrogenases (ca. 255 pm).[12] The average Ni−$S_{thiolate}$ bond length, 217.7 pm (**1**) and 218.5 pm (**2**), matches perfectly the reported Ni−S bond lengths.[13] One known complex, [Ni('$S_4C_3Me_2$')], is the hypothetical residue when all [Fe(CO)$_3$] moieties of **2** are removed; it exhibits equal Ni−$S_{thioether}$ and Ni−$S_{thiolate}$ distances. The trinuclear clusters **1** and **2** show quite long Ni−$S_{thioether}$ bonds (227.8 pm in **1**, 227.4 pm in **2**) due to weaker back-bonding to the thioether ligands. This indicates a lower electron density at the Ni center, which may be caused by additional metal−metal interactions with the two iron atoms. Despite the resulting increased steric strain upon replacing an ethylene bridge in **1** with a neopentylene bridge in **2**, the structural parameters do not change significantly. Thus, only the S2−Ni−S3 angle in **2** (101.3°) is slightly larger than the corresponding S2−Ni−S2A angle in **1** (91.8°). This small variation does not decrease the $S_{thiolate}$−Ni−$S_{thiolate}$ angle in **2** as compared with **1**. Therefore, it is understandable that no dinuclear but only a trinuclear [NiFe] complex was observed. This argument agrees well with previous results on the influence of this angle on the selectivity of complex formation.[14] Very recently, two [Ni'S_4'$Fe_2(CO)_6$] ['S_4' = $(RC_6H_3S_2)_2(CH_2)_3$; R = Me, H] complexes have been reported.[15] In these complexes, which are nearly a perfect match of the structural properties of **1** and **2**, again the corresponding $S_{thioether}$−Ni−$S_{thioether}$ angles [144.88(5)°, R = Me) and 143.22(3)°, R = H] are too big to lead to dinuclear [NiFe] compounds.

Although the molecular structures of **1** and **2** and the methods of their preparation are very similar, complex **3** is formed only in the reaction with the neopentylene-bridged nickel complex [Ni('$S_4C_3Me_2$')]. IR monitoring of the synthesis carried out at 60 °C indicated an increased amount of **3** compared with **2**. Even then, we were unable to obtain exclusively one product. The two products could be separated by column chromatography and subsequent recrystallization. Dinuclear thiolate-bridged [Fe(CO)('$S_4C_3Me_2$')-Fe(CO)$_3$] (**3**) consists of one 18 and one 16 valence electron fragment, containing Fe^0 and Fe^{II}. Complex **3** is diamagnetic and soluble in THF and CH_2Cl_2, but is insoluble in

pentane. NMR results reveal that this complex is of twofold symmetry. Though in its crystal structure the molecules of **3** are not situated on a crystallographic mirror plane, the molecular structure exhibits a well approximated C_s symmetry. Figure 4 depicts a stereo view of the molecular structure of **3**, and Table 2 gives selected bond lengths and angles.

A rational synthesis of **3** was finally developed using fragments this complex consists of (Scheme 2). Treatment of the ligand with iron yielded the dinuclear compound **4**. The molecular structure of the diamagnetic dimeric complex **4** is shown in Figure 5. It exhibits a twofold symmetry and is sparingly soluble in common organic solvents. Two edge-linked square pyramids are formed by sulfur donors coordinating the Fe^{II} atoms. Table 3 shows selected bond lengths and angles. Regarding its dinuclearity, **4** clearly shows that the '$S_4C_3Me_2$' ligand is less flexible than its ethylene-bridged derivative 'S_4'. Reaction of the latter ligand with iron chloride affords the tetrameric [Fe('S_4')]$_4$ compound, as already reported.[16]

Complex **4** reacts with CO (2 equiv.) to give [Fe(CO)('$S_4C_3Me_2$')]$_2$ (**5**), which also shows low solubility in common organic solvents and slowly loses its CO ligand, even in the solid state at room temperature. Complex **5** can easily be identified by its IR ν(CO) frequency. As already reported, the [Fe(CO)('S_4')]$_2$ complex is a dimer.[17] It is anticipated that **5** also consists of a dimeric structure. If complex **5** is combined with [Fe($CH_3COCH{=}CHPh$)$(CO)_3$] (2 equiv.) and stirred at 60 °C for several hours, the solution's red color increases and the only IR detectable species in the reaction solution is **3**.

Reactivity of 2 and 3 towards Protons and H_2

IR monitoring indicated that compounds **2** and **3** decompose upon addition of one drop of HBF_4, with no hint of protonation or oxidation of the complexes after this treatment. The structural features of **1**−**3** encouraged us to investigate their reactivity towards hydrogen. Since **1** and **2** contain a sulfur-dominated distorted Ni coordination sphere, heterolytic splitting of the H_2 molecule might be possible, as was reported recently for related Ni−S complexes.[18] Complex **3** contains both a free coordination site and sulfur donors where hydrogen could bind and also be heterolyzed. However, even prolonged, high-pressure NMR experiments with **2** and **3** indicated no reaction between either complex and molecular hydrogen.

Summary

Although few di- and trinuclear [NiFe] complexes are known, we present here two examples of the small family of phosphane-free [NiFe] clusters that exhibit a sulfur-dominated coordination sphere of Ni, Ni−$S_{thiolate}$−Fe bridges, Ni−Fe bond lengths as in the reduced active site of [NiFe] hydrogenases, and iron-bound carbon monoxide. The clusters are stable for weeks, both in solution and in the solid state. When changing the bridging alkyl chain from an ethylene bridge in **1** to a neopentylene bridge in **2**, the structural parameters did not change. Unlike the synthesis of **1**, with **2** an additional dinuclear Fe complex (**3**) was formed. Higher yields of **3** were obtained for the synthesis at 60 °C. Even when the steric strain of the ligand in **1** was increased in **2**, their structural properties did not differ significantly. These new complexes demonstrate that *cis*-thiolate ligands can connect Ni and Fe, resulting in trinuclear [NiFe] clusters with a sulfur-dominated coordination sphere.

Experimental Section

General Remarks: All manipulations were carried out in absolute solvents under exclusion of air. '$S_4C_3Me_2$'−H_2,[13b] 'S_4'−H_2[19] ligands and the complexes [Ni('S_4')]$_x$ [20] (x = 1 or 2) and [Ni('$S_4C_3Me_2$')][13b] were prepared as described in the literature. IR: Perkin−Elmer 983, 1620 FT IR and 16PC FT-IR; NMR: Jeol FT-JNM-GX 270 and EX 270; mass spectrometry: Jeol MSTATION 700; elemental analysis: Carlo−Erba EA 1106 or 1108.

[Ni('S_4'){Fe(CO)$_3$}$_2$] (1): A solution of [Fe(CH_3COCH=CHPh)-$(CO)_3$] (460 mg, 1.609 mmol) in THF (20 mL) was added to 1/x equiv. of [Ni('S_4')]$_x$ (500 mg, 1.609 mmol). The reaction suspension was then stirred for 24 h and the obtained solid material was removed and the solution concentrated to dryness. The resultant residue was dissolved in toluene and separated by column chromatography (silica gel, 60 cm, eluent: toluene). After the first two starting material containing fractions were eluted, a large red product fraction was washed with MeOH from the silica gel and the solvents evaporated to dryness. The residue was redissolved in THF (20 mL) and pentane (120 mL) was added. The resulting brown microcrystalline material was washed with pentane (60 mL) and dried in vacuo. Yield 310 mg (60%). ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 8.06 (m, 2 H, C_6H_4), 7.70 (m, 2 H, C_6H_4), 7.32 (m, 4 H, C_6H_4), 3.60 (m, 2 H, CH_2), 2.38 (m, 2 H, CH_2). ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 213.3 (*C*O), 157.3, 133.0, 132.4, 130.0, 128.2, (C_6H_4), 42.4 (CH_2). IR (KBr): $\tilde{\nu}$ = 2028, 1993, 1942 (CO) cm^{-1}. MS (FD, THF): m/z = 646 [Ni('S_4'){Fe(CO)$_3$}$_2$]$^+$. $C_{20}H_{12}Fe_2NiO_6S_4$ (645.76): calcd. C 37.13, H 1.87, S 19.82; found C 38.91, H 2.08, S 19.36.

[Ni('$S_4C_3Me_2$'){Fe(CO)$_3$}$_2$] (2): A solution of [Fe(CH_3COCH=CHPh)$(CO)_3$] (736 mg, 2.573 mmol) in THF (40 mL) was added to [Ni('$S_4C_3Me_2$')] (1050 mg, 2.566 mmol). The reaction suspension was then stirred for 24 h and the resultant solid material was removed and the solution concentrated to dryness. The residue was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

then dissolved in a toluene/hexane (3:1) mixture, and a column for chromatography was prepared (silica gel, 60 cm, toluene/hexane, 3:1). Red and brown fractions were collected and the solvents were evaporated to dryness. The brown fraction was redissolved in THF (6 mL) and filtered; pentane (100 mL) was then added and the mixture was stored at −20 °C for 5 d, after which the solvent was decanted carefully and the resulting crystalline material was dried in vacuo. Yield 260 mg (29%). ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 8.13 (m, 2 H, C_6H_4), 7.61 (m, 2 H, C_6H_4), 7.30 (m, 4 H, C_6H_4), 3.18 (d, 2 H, CH_2, $^2J_{H,H}$ = 13.2 Hz), 2.64 (d, 2 H, CH_2, $^2J_{H,H}$ = 13.2 Hz), 0.84 (s, 6 H, CH_3). ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 212.5 (*C*O), 157.2, 137.0, 131.8, 131.4, 129.0, 127.9, (C_6H_4), 49.1 (CH_2), 36.3 (C_q), 28.1 (CH_3). IR (KBr): $\tilde{\nu}$ = 2033, 1992, 1957 (CO) cm^{-1}. MS (FD, THF): *m*/*z* = 688 [Ni('$S_4C_3Me_2$')$\{Fe(CO)_3\}_2$]$^+$. $C_{23}H_{18}Fe_2NiO_6S_4$ (687.80): calcd. C 40.09, H 2.63, S 18.61; found C 39.85, H 2.50, S 18.21.

[Fe(CO)('$S_4C_3Me_2$')Fe(CO)$_3$] (3). (a) The red fraction obtained from column chromatography during the synthesis of **2** (see above) was concentrated to dryness and redissolved in THF (6 mL). The solution was then treated with pentane (100 mL) and kept at −20 °C for 5 d, after which the solvent was decanted carefully and the resulting crystalline material was dried in vacuo. Yield 210 mg (14%). ^{1}H NMR (269.6 MHz, CD_2Cl_2): δ = 7.82 (m, 4 H, C_6H_4), 7.33 (m, 4 H, C_6H_4), 3.55 (d, 2 H, CH_2, $^2J_{H,H}$ = 9.7 Hz); 2.23 (d, 2 H, CH_2, $^2J_{H,H}$ = 10.0 Hz), 1.50 (s, 3 H, CH_3), 1.19 (s, 3 H, CH_3). ^{13}C{^{1}H} NMR (67.7 MHz, CD_2Cl_2): δ = 216.9, 213.9 (*C*O), 148.9, 141.2, 131.5, 131.5, 128.6, 127.4, (C_6H_4), 54.1 (CH_2), 36.8 (C_q), 32.6, 24.1 (CH_3). IR (KBr): $\tilde{\nu}$ = 2009, 1944, 1921 (CO) cm^{-1}. MS (FD, THF): *m*/*z* = 574 [Fe(CO)('$S_4C_3Me_2$')Fe(CO)$_3$}]$^+$. $C_{21}H_{18}Fe_2O_4S_4$ (573.88): calcd. C 43.92, H 3.16, S 22.33; found C 43.90, H 3.25, S 22.26. **(b)** A solution of [Fe(CH_3COCH=CHPh)(CO)$_3$] (66 mg, 0.23 mmol) in THF (10 mL) was added to a suspension of **5** (100 mg, 0.12 mmol) in THF (20 mL) and the resultant reaction mixture was stirred at 60 °C for 24 h. After filtration, the solution was then dried in vacuo, redissolved in THF (2 mL), and pentane (50 mL) was added. This mixture was then kept at −30 °C for 6 d to afford microcrystalline material that was isolated, washed with pentane (15 mL) and dried in vacuo. Yield 50 mg (38%).

[Fe('$S_4C_3Me_2$')]$_2$ (4): The ligand '$S_4C_3Me_2$'−H_2 (120 mg, 0.34 mmol) in MeOH (7 mL) was treated with LiOMe (2 equiv., 26 mg, 0.68 mmol) and added to a solution of $FeCl_2$·4H_2O (68 mg, 0.34 mmol) in MeOH (5 mL). The resultant brown microcrystalline precipitate was filtered off, washed with MeOH (20 mL) and dried in vacuo. Yield 125 mg (90%). ^{1}H NMR (269.6 MHz, [D$_7$]DMF): δ = 7.60 (m, 2 H, C_6H_4), 7.45 (m, 2 H, C_6H_4), 7.25 (m, 4 H, C_6H_4), 3.20 (s, 4 H, CH_2), 1.15 (s, 6 H, CH_3). ^{13}C{^{1}H} NMR (67.7 MHz, [D7]DMF): δ = 139.7, 134.6, 134.4, 129.1, 127.6, 125.9, (C_6H_4), 48.4 (CH_2), 38.2 (C_q), 26.2 (CH_3). MS (FD, DMF): *m*/*z*: = 406 [Fe('$S_4C_3Me_2$')]$^+$. $C_{34}H_{36}Fe_2S_8$·CH_3OH (843.95): calcd. C 49.76, H 4.77, S 30.36; found C 49.24, H 4.84, S 30.61.

[Fe(CO)('$S_4C_3Me_2$')]$_2$ (5): CO (2 equiv., 22.4 mL, 1 mmol) was added through a septum to a suspension of **4** (405 mg, 0.50 mmol) in DMF (20 mL). This mixture was then stirred for 12 h, and the resultant solid material was filtered off, washed with DMF (10 mL) and THF (20 mL), and dried in vacuo. Yield 315 mg (73%). ^{1}H NMR (269.6 MHz, [D$_7$]DMF): δ = 7.94−6.82 (m, 8 H, C_6H_4), 3.93 (d, 1 H, CH_2, $^2J_{H,H}$ = 11.3 Hz), 3.63 (d, 1 H, CH_2, $^2J_{H,H}$ = 11.6 Hz), 2.49 (d, 1 H, CH_2, $^2J_{H,H}$ = 11.6 Hz); 2.22 (d, 1 H, CH_2, $^2J_{H,H}$ = 11.3 Hz), 1.17 (s, 3 H, CH_3), 0.68 (s, 3 H, CH_3); ^{13}C{^{1}H} NMR (67.7 MHz, [D7]DMF): δ = 217.3 (*C*O), 157.1, 145.6, 145.1, 135.2, 133.7, 130.7, 129.8, 128.9, 128.7, 128.1, 126.5, 121.6 (C_6H_4), 50.7, 49.7 (CH_2), 36.1 (C_q), 31.9, 23.1 (CH_3). IR (KBr): $\tilde{\nu}$ = 1938 (CO) cm^{-1}. MS (FD, DMF): *m*/*z*: = 406 [Fe('$S_4C_3Me_2$')]$^+$. $C_{18}H_{18}FeOS_4$ (867.92): calcd. C 49.77, H 4.18, S 29.52; found C 49.77, H 4.18, S 28.60.

Table 4. Selected crystallographic data for [Ni('S_4')$\{Fe(CO)_3\}_2$] (**1**), [Ni('$S_4C_3Me_2$')$\{Fe(CO)_3\}_2$]·THF (**2**·THF), [Fe(CO)('$S_4C_3Me_2$')-Fe(CO)$_3$] (**3**), and [Fe('$S_4C_3Me_2$')]$_2$ (**4**)

Reaction of 2 and 3 with Protons: $HBF_4{\cdot}Et_2O$ (one drop) was added to a solution of **2** (5 mg, 0.007 mmol) or **3** (5 mg, 0.009 mmol) in CH_2Cl_2 (5 mL). IR monitoring showed a decrease in CO band intensity and many new small CO bands.

Reaction of 2 and 3 with Hydrogen: A solution of **2** (10 mg, 0.015 mmol) or **3** (10 mg, 0.017 mmol) in [D_8]THF (0.4 mL) in a high-pressure NMR tube (524-PV-1, Wilmad, USA) was treated with D_2O (one drop) and 15 bar of H_2. ^1H NMR spectra were then collected over the following 70 d. Between measurements, the high-pressure NMR tubes were rotated continuously.

X-ray Structure Determination of [Ni('S_4'){Fe(CO)$_3$}$_2$] (1), [Ni('$S_4C_3Me_2$'){Fe(CO)$_3$}$_2$]·THF (2·THF), [Fe(CO)('$S_4C_3Me_2$')-Fe(CO)$_3$] (3), and [Fe('$S_4C_3Me_2$')]$_2$ (4): Slow diffusion of pentane into a saturated THF solution of **1** at 10 °C yielded, after 4 weeks, black plates of **1**. Black blocks of **2·THF** were obtained by maintaining a layered saturated THF solution of **2** with pentane at −30 °C for 1 week. Slow diffusion of pentane into a saturated THF solution of **3** yielded dark brown crystals of **3**. A saturated DMF solution of **4** prepared at 120 °C was cooled to room temperature, filtered, and kept at −30 °C to give, after 8 weeks, black plates of **4**. Suitable single crystals were embedded in protective perfluoro polyether oil. Data were collected at 100 K with a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 71.073 pm), and a graphite monochromator. For **1** and **2** a numerical absorption correction was applied.[21] For **3** and **4**, a semiempirical absorption correction on the basis of multiple scans was performed.[22] Structures were solved by direct methods; full-matrix least-squares refinement was carried out on F^2 using SHELXTL NT 6.12[23] (**1**, **3**, **4**) or SHELXTL NT 5.1 (**2**).[24] All non-hydrogen atoms were refined anisotropically. All H atom positions were derived from a difference Fourier synthesis and refined with a fixed common isotropic displacement parameter. Selected crystallographic data are summarized in Table 4.[25]

Novel Binary Compounds of Group 15 Elements: Synthesis and Characterisation of $[Sb_4(PSiMe_2Thex)_4]$, $[Sb_4(AsSi\mathit{i}Pr_3)_4]$ and $[Sb_2(PSiPh_2\mathit{t}Bu)_4]$

Donna Nikolova[a] and Carsten von Hänisch*[a]

Keywords: Arsenic / Antimony / Cage compounds / Phosphorus

The low-temperature reactions of $Me_2ThexSiPLi_2$ (Thex = $CMe_2\mathit{i}Pr$) and $\mathit{i}Pr_3SiAsLi_2$ with $SbCl_3$ in a 3:2 molar ratio yields the cage compounds $[Sb_4(PSiMe_2Thex)_4]$ (**1**) and $[Sb_4(AsSi\mathit{i}Pr_3)_4]$ (**2**), respectively. The metal salt $SbBr_3$ reacts with $\mathit{t}BuPh_2SiPLi_2$ at –70 °C to give the bicyclic compound $[Sb_2(PSiPh_2\mathit{t}Bu)_4]$ (**3**). Compounds **1**–**3** were characterised by NMR and IR spectroscopy, mass spectrometry, elemental analysis and single-crystal X-ray diffraction. The structures of **1** and **2** reveal that the both compounds adopt a structure similar to those of realgar (As_4S_4). The central structural motif is an Sb_4Y_4 cage (Y = P, As), consisting of four five-membered rings with common edges. The bicyclic compound **3** is composed of five-membered and three-membered rings sharing a common Sb_2 bridgehead.

Introduction

The formation of homonuclear cyclic, polycyclic and cage-like compounds of group 15 elements has been the focus of intensive research efforts for a long time.[1–3] These studies have revealed a very diverse range of structure types, which extend from simple small rings like $P_3\mathit{t}Bu_3$ [2] through five- and six-membered rings, to polycycles and cages containing up to fourteen atoms.[3] Few analogous binary compounds containing a combination of heavier group 15 elements have been structurally characterised. Although not as widely studied as the organophosphorus homocycles, cyclic As/P and Sb/P compounds are known. The first P_2As heterocycle was synthesized by cyclocondensation of $\mathit{t}Bu_2P_2K_2$ with $\mathit{t}BuAsCl_2$.[4] Other reported species are the bicyclic compounds $[As_2(PAr)_2]$ and $[Sb_2(PAr)_2]$, which are obtained by the reaction of $ArP(SiMe_3)Li$ [Ar = 2,4,6-$(\mathit{t}Bu)_3C_6H_2$] with $Cp^*E'Cl_2$ (E′ = As, Sb) as well as $[(\mathit{t}BuP)_3As]_2$ and $[(\mathit{t}BuP)_3Sb]_2$.[5] The most recent extension of group 15 element chemistry is the formation of heterocyclic compounds containing Sb–As bonds. To the best of our knowledge, the only structurally characterised Sb/As heterocycle is the coordination complex $[Sb_2Cl_6\{o\text{-}C_6H_4(AsMe_2)_2\}]$.[6]

Herein we report on the synthesis and crystal structures of the cage and bicyclic compounds $[Sb_4(PSiMe_2Thex)_4]$ (**1**), $[Sb_4(AsSi\mathit{i}Pr_3)_4]$ (**2**) and $[Sb_2(PSiPh_2\mathit{t}Bu)_4]$ (**3**), obtained from the reactions of lithium phosphanides and arsanides with the antimony salts $SbCl_3$ and $SbBr_3$, respectively.[7]

Results and Discussion

The reaction of $Me_2ThexSiPLi_2$ (Thex = $CMe_2\mathit{i}Pr$) with $SbCl_3$ in a 3:2 molar ratio leads to the formation of **1**, which can be isolated as orange crystals by cooling the reaction mixture to −35 °C. Compound **1** crystallises in the orthorhombic space group $P4_2/n$. The central structural motif is an Sb_4P_4 cage (Figure 1). It consists of four Sb_3P_2 five-membered rings with common Sb–P–Sb edges. The structure can be thought of as being derived from an Sb_4 tetrahedron by placing bridging $PSiMe_2Thex$ fragments above four of the six edges. All of the phosphorus atoms are coordinated to two antimony atoms and one $ThexMe_2Si$ group, forming a trigonal-pyramidal environment; the Sb atoms possess no exocyclic ligands and also have a coordination number of three. The availability of the Sb–Sb bonds (Sb1–Sb1′′ and Sb1′–Sb1′′′) in the molecule is indicative of a reduction process that must have taken place parallel to the lithium chloride elimination reaction. The Sb–Sb bond length in **1** is 287.9 pm, which is in the usual range for single Sb–Sb bonds. Similar Sb–Sb bond lengths of 286.7 pm, for example, can be observed in $Sb_2(SiMe_3)_4$,[8] whereas in the polycycles Sb_8R_6 and Sb_8R_4 [R = $CH(SiMe_3)_2$] these bonds are slightly shorter (278.4–287.3 pm).[9] The Sb–P bond lengths in **1** are in the range 249.4–252.4 pm and therefore are similar to the spread of values observed in $[(tmeda)(Me_2NH)Na(CyP)_4Sb]_2$ (248.9–254.1 pm).[10] In the bicycle $[Sb_2(PAr)_2]$ (Ar = 2,4,6-$\mathit{t}Bu_3C_6H_2$) mentioned above these bonds are significantly longer (average value

257.3 pm).[5b] It is assumed that the longer Sb−P bonds in the latter compound are due to the large steric requirements of the 2,4,6-tBu$_3$C$_6$H$_2$ substituents. The Sb_4P_4 motif in **1** can be regarded as being related to the P_8 segment in the structure of Hittorf's violet phosphorus; an analogous P_8R_4 compound, however, could not be isolated in a pure form,[11] whereas a variety of transition metal complexes with P_8 ligands have been described in the literature.[12] The closest structural relative of **1** is the antimony cage Sb_8R_4 [R = CH(SiMe$_3$)$_2$], isolated from the reduction of RSbCl$_2$with Mg.[9]

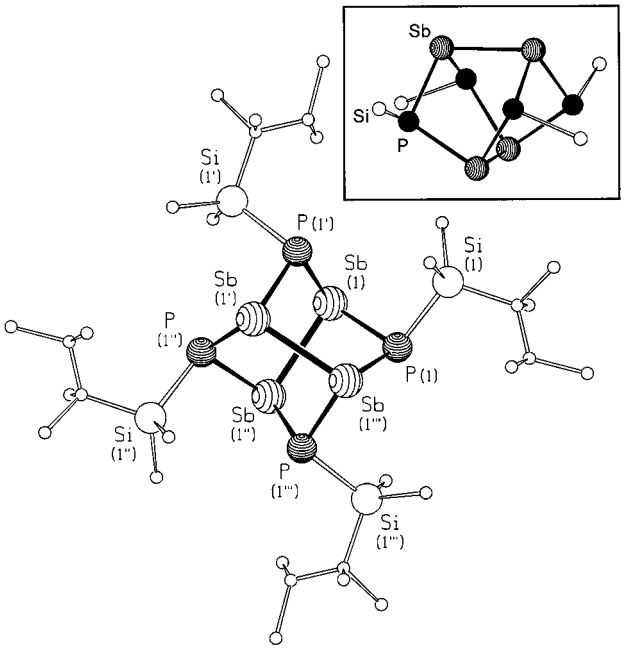

Figure 1. Molecular structure of **1** (inset: side view of the heavy atom frame); selected bond lengths [pm] and angles [°]: Sb(1)−P(1) 249.4(2), Sb(1′′′)−P(1) 252.4(2), Sb−Sb 287.9(1), P(1)−Si(1) 228.5(2); Sb(1′′)−Sb(1)−P(1) 90.42, Sb(1′′)−Sb(1)−P(1′) 104.71, P(1)−Sb(1)−P(1′) 92.97, Sb(1)−P(1)−Sb(1′′′) 102.23, Si(1)−P(1)−Sb(1) 105.10, Si(1)−P(1)−Sb(1′′′) 106.22

The $^{31}P\{^1H\}$ NMR spectrum of **1** displays, as expected, one singlet at $\delta = -104.5$ ppm. An additional singlet appears at $\delta = -65.1$ ppm in the $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture, which presumably can be attributed to significant amounts of (PSiMe$_2$Thex)$_n$ (n = 4 or 6), which is obtained as a by-product from the reduction process. Unfortunately, this by-product could not be isolated.

[Sb_4(AsSiiPr$_3$)$_4$] (**2**) is obtained from the reaction of iPr$_3$SiAsLi$_2$ and SbCl$_3$. It crystallises in the monoclinic space group $C2/c$ with two independent inversion-symmetric molecules in the elementary cell. The molecular structure of **2** (Figure 2) is almost identical to the phosphorus compound **1**, but with AsSiiPr$_3$ groups as building blocks instead of the PSiMe$_2$Thex fragments. The Sb−Sb bonds in **2** are slightly longer (288.1−289.0 pm) than those in **1**. The Sb−As bonds are in the range 260.1−261.6 pm, whereas in the coordination compound [Sb_2Cl_6{o-C_6H_4(AsMe$_2$)$_2$}] these bonds are significantly longer (266.4 pm).

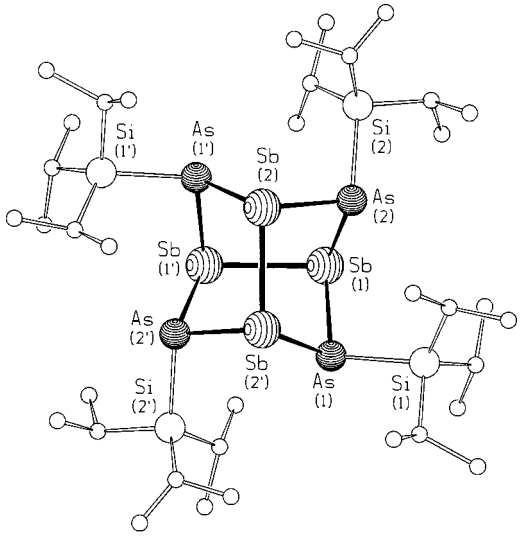

Figure 2. Molecular structure of **2**; selected bond lengths [pm] and angles [°]: Sb(1)−Sb(1′) 289.0(2), Sb(2)−Sb(2′) 288.4(2), Sb−As 260.1(2)−261.6(2), Si−As 239.3−240.2; Sb(1)−As(1)−Sb(2) 101.24(5), Sb(1′)−As(2)−Sb(2) 100.69(5), As(1)−Sb(1)−As(2) 93.72(5), As(1)−Sb(2)−As(2) 92.09(5), As(1)−Sb(1)−Sb(1′) 94.94(5), As(2′)−Sb(1)−Sb(1′) 103.96(5), As(1)−Sb(2)−Sb(2′) 103.99(5), As(2)−Sb(2)−Sb(2′) 95.46(5)

In the mass spectra of **1** and **2** the molecular ion peaks at m/z = 1184 and 1416, respectively, as well as the characteristic fragments [Sb_4P_4(SiMe$_2$Thex)$_3$]$^+$, [Sb_3P_4Me$_2$-(SiMe$_2$Thex)$_3$]$^+$ and [Sb_4As_4(SiiPr$_3$)$_3$]$^+$, [Sb_4(AsSiiPr$_3$)$_3$]$^+$, [Sb_4As_3(SiiPr$_3$)$_2$]$^+$, [Sb_2(AsSiiPr$_3$)$_2$]$^+$ can be observed.

The novel bicyclic compound **3** was isolated as yellow crystals from the LiBr elimination reaction of tBuPh$_2$SiPLi$_2$ and SbBr$_3$ in a 3:2 molar ratio. The compound crystallizes in the triclinic space group $P\bar{1}$. It is composed of five-membered P_3Sb_2 and three-membered PSb_2 rings sharing a common Sb_2 bridgehead (Figure 3). Both the P and the Sb atoms are three-coordinate, with the antimony atoms possessing no exocyclic ligands. The central Sb_2P_4 unit shows a non-planar configuration; the plane through Sb(1), Sb(2), P(4) is virtually perpendicular to the Sb_2P_3 ring. Examination of the bond lengths and angles found in the bicyclic Sb_2P_4 core of **3** indicates that there is a considerable amount of strain in this arrangement. The fold angles P(1)−Sb(1)−P(4) and P(3)−Sb(2)−P(4) are 86.11° and 104.3° respectively. The comparatively large difference between these angles results from the manner of orientation of the sterically demanding silyl groups coordinated to P(1) and P(3). The tBuPh$_2$Si substituent of P(1) is in a *trans* position to the Sb(1)−P(4) bond, whereas the silyl group bonded to P(3) is in a *cis* position to the Sb(2)−P(4) bond. The torsion angles Si(3)−P(3)−Sb(2)−P(4) and Si(1)−P(1)−Sb(1)−P(4) are 46.1° and 135.7° respectively. A similar molecular structure occurs in the homonuclear bicyclic compound tBu$_4$P$_6$ reported by Baudler and co-wor-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

kers.[13] However the arrangement of the *t*Bu groups in this structure is all-*trans*. Of particular interest in comparison of **3** with the other title compounds is the appearance of P−P bonds in the structure, resulting from oxidation of the P atoms and corresponding reduction of the Sb atoms to Sb−Sb bonds. The Sb−Sb bond in **3** is 276.8 pm, and is therefore shorter than the corresponding bonds in **1** and **2**. This bond shortening is possibly a consequence of the fact that the Sb_2 unit is bridged by the P(4) atom. The average P−P bond length is 219.6 pm, and the Sb−P bonds are 255.2 pm on average. These values lie in the usual range for single bonds between these elements.

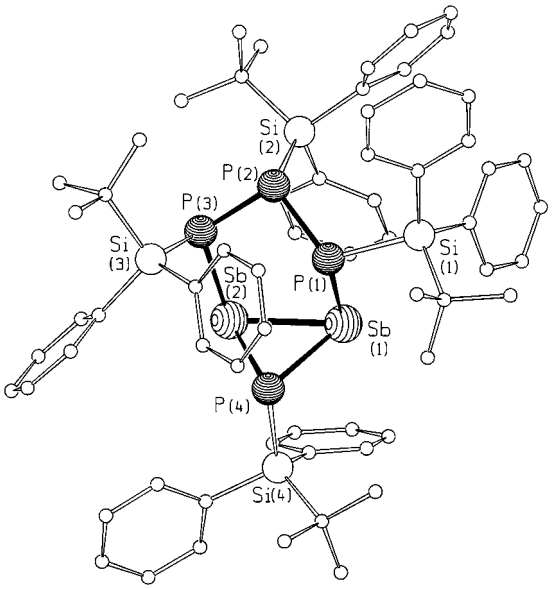

Figure 3. Molecular structure of **3**; selected bond lengths [pm] and angles [°]: Sb(1)−Sb(2) 276.8(2), Sb(1)−P(1) 255.3(2), Sb(1)−P(4) 255.3(2), Sb(2)−P(3) 255.9(2), Sb(2)−P(4) 254.4(2), P(1)−P(2) 219.9(2), P(2)−P(3) 219.9(2), P(1)−Si(1) 228.7(2), P(2)−Si(2) 229.4(2), P(3)−Si(3) 226.9(2), P(4)−Si(4) 227.8(2); Sb(1)−Sb(2)−P(4) 57.28(5), Sb(2)−Sb(1)−P(1) 92.63(4), Sb(2)−Sb(1)−P(4) 56.94(5), Sb(1)−P(4)−Sb(2) 65.77(6), Sb(1)−P(1)−P(2) 110.71(7), Sb(2)−P(3)−P(2) 112.99(6), P(1)−P(2)−P(3) 99.86(8), P(1)−Sb(1)−P(4) 86.11(6), P(3)−Sb(2)−P(4) 104.30(6)

The structure of **3** can be deduced from $^{31}P\{^1H\}$ NMR spectrum (Figure 4), which shows at room temperature two triplet signals at $\delta = -245$ and -31 ppm for the P(4) and P(2) centres, respectively. An additional broad signal appears at $\delta = -120$ ppm. At +70 °C the signal at $\delta = -120$ ppm appears as a doublet of doublets, which is consistent with chemically identical P(1) and P(3) atoms (AM_2X spin system, $^1J_{P,P} = 400$, $^2J_{P,P} = 96$ Hz). At −50 °C the $^{31}P\{^1H\}$ NMR spectrum of **3** shows four multiplets corresponding to the four different P atoms observed in the crystal structure (AEMX spin system). The mass spectrum of **3** does not show the molecular peak, although the characteristic fragment $[(PSi\textit{t}BuPh_2)_3]^+$ is observed at $m/z = 810$.

Experimental Section

General: All manipulations were carried out with rigorous exclusion of oxygen and moisture, using a Schlenk line and nitrogen atmosphere. Solvents were dried and freshly distilled before use. The starting materials $i\text{Pr}_3\text{SiAsH}_2$ and $\text{ThexMe}_2\text{SiPH}_2$ were prepared according to relevant procedures found in the literature.[14] $SbCl_3$ and $SbBr_3$ were obtained from Aldrich and sublimed before use. The ^1H and ^{31}P NMR spectra were recorded on a Bruker AC 250 spectrometer. All isolated compounds gave elemental analyses consistent with their formulas.

***t*BuPh$_2$SiPH$_2$:** A solution of $t\text{BuPh}_2\text{SiCl}$ (41.2 g, 0.15 mol) in 50 mL of THF was added dropwise to a solution of $[(\text{dme})\text{LiPH}_2]$ (19.5 g, 0.15 mol) in 150 mL of THF at 0 °C. After stirring the mixture overnight at room temperature, the THF was replaced by 100 mL of pentane. The precipitated lithium chloride was subsequently removed by filtration. After removal of the solvent, a vacuum distillation yielded 20 g (50%) of $t\text{BuPh}_2\text{SiPH}_2$, B.p.: 100−103 °C ($10^{-3}$ mbar). ^1H NMR (C_6D_6): $\delta = 1.20$ [s, 9 H, $C(CH_3)_3$], 1.73 (d, $^1J_{P,H} = 187$ Hz, 2 H, PH_2), 7.26 (m, 5 H, Ph), 7.78 (m, 5 H, Ph) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = 19.8$ [d, $^2J_{P,C} = 21.5$ Hz, $C(CH_3)_3$], 28.1 [d, $^3J_{P,C} = 6.8$ Hz, $C(CH_3)_3$], 129.9 (s, Ph), 135.7 (d, $J_{P,C} = 8.9$ Hz, Ph), 136.3 (d, $J_{P,C} = 8.9$ Hz, Ph). ^{31}P NMR (C_6D_6): $\delta = -252.2$ (t, $^1J_{P,H} = 187$ Hz) ppm.

1: *n*-Butyllithium [1.2 mL (1.92 mmol) of a 1.6 M solution] was added to a solution of $\text{ThexMe}_2\text{SiPH}_2$ (0.17 g, 0.96 mmol) in 5 mL of Et_2O at 0 °C. After stirring for 10 min, this solution was added to a solution of $SbCl_3$ (0.15 g, 0.64 mmol) in 15 mL of toluene at

Electronic Interactions in Ferrocene- and Ruthenocene-Functionalized Tetraazamacrcocyclic Ligand Complexes of $Fe^{II/III}$, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II}

Peter Comba,*[a] Gerald Linti,[a] Kathrin Merz,[a] Hans Pritzkow,[a] and Franz Renz[b]

Keywords: Macrocyclic ligands / Transition metals / Ferrocene / Ruthenocene

The syntheses of ferrocene- and ruthenocene-functionalized tetraazamacrocyclic ligands and their corresponding transition metal complexes are described. Reaction of *N*,*N*′-bis(2-aminoethyl)-1,3-propanediamine (2,3,2-tet) with 1,1′-diformylferrocene and 1,1′-diformylruthenocene produces the ligands fcmac and rcmac in 81–85% yield. Examination of their Cu^{II}, Ni^{II}, Co^{II}, Zn^{II} and $Fe^{II/III}$ complexes by IR, UV/Vis, EPR and Mössbauer spectroscopy as well as by electrochemical studies suggests electronic communication between the two metal centers of each complex. The molecular structure of $[Cu^{II}(fcmac)(FBF_3)]BF_4$, determined by X-ray structure analysis, is reported and shows that the distance between the two metals is 4.54 Å. Stability constants, determined by potentiometric titration, indicate that the copper(II) complexes are of similar stability as those with unfunctionalized tetraazamacrocyclic ligands (e.g. cyclam = 1,4,8,11-tetraazacyclotetradecane); stability constants of cobalt(II) complexes are about 2 log units smaller, those of nickel(II) and zinc(II) complexes are reduced by more than 10 log units. This selectivity is discussed on the basis of the structural studies.

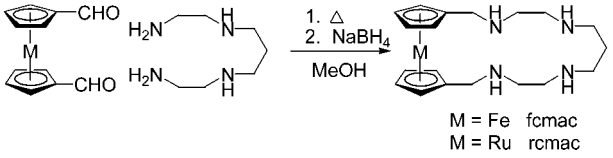
Introduction

A large variety of metallocene-functionalized macrocyclic ligands have been reported, including crown ethers as well as polyaza- and polythiamacrocycles, Schiff-base and mixed-donor ligand systems, with various binding motifs of the metallocene functional groups.[1−11] With metal ions coordinated to the macrocyclic ligands, tunable energy- and electron transfer processes have been suggested, observed and studied,[12] and molecular switches as well as artificial regulatory systems have been designed.[4] The majority of applications, however, have used the macrocyclic ligands or the macrocyclic ligand complexes as selective receptors for cations or anions, and the metallocene (usually ferrocene) substituents as electrochemical probes, in order to construct highly selective electrochemical sensors.[2,5,9,10] An important feature in these applications is the interaction between the metallocene site and the metal ion coordinated to the macrocyclic donor set, and this has been studied by a variety of electrochemical and spectroscopic techniques.[2,4,5,11]

We report here the synthesis and the structural, electrochemical, and spectroscopic characterization of cyclam-derived ferrocene- and ruthenocene-containing macrocycles, based on a Schiff-base condensation of 2,3,2-tet [2,3,2-tet = *N*,*N*′-bis(2-aminoethyl)-1,3-propanediamine] with 1,1′-diformylmetallocene, and their iron(II)/(III), cobalt(II), nickel(II), copper(II), and zinc(II) complexes. The structural and electrochemical data together with the stability constants, determined by pH titrations, suggest that these ligands may be used as electrochemical sensors for specific metal ions (Cu^{II}), and preliminary Mössbauer spectra of the iron complexes indicate that optical as well as thermal switching between different electronic states is possible; this latter application is currently under further investigation. Here, we report the preparative and structural data as well as stability constants, the spectroscopic and electrochemical characterization of the ligands and their complexes.



Results and Discussion

Syntheses and Structures

The synthesis of the ferrocene- and ruthenocene-substituted ligands fcmac and rcmac is a simple [1+1] Schiff-base condensation, followed by $NaBH_4$ reduction of the imines, which proceeds, as in published examples of similar ligands,[9] in high over-all yield (over 80%). Complexation

to iron(II)/(III), cobalt(II), nickel(II), copper(II), and zinc(II) results in dinuclear complexes in respectable yields.

The single crystal structure of $[Cu(fcmac)(FBF_3)]BF_4$ was solved by X-ray crystallography. A plot of the molecular structure is given in Figure 1 (a), and selected structural parameters are presented in Table 1. Crystals of $[Ni(fcmac)(NCCH_3)_2](BF_4)_2$ and $[Ni(rcmac)(NCCH_3)_2](BF_4)_2$ were also isolated but were not of high enough quality for a full structural analysis and submission of the data to CCDC. However, plots of these two structures also appear in Figure 1, and the determined approximate structural parameters are tabulated for comparison. The macrocycles are in the unusual *trans*-II (*S*,*S*,*R*,S; pseudo-*R*,S,*R*,*R*) configuration. This must be due to the unusually large and rigid ferrocene-appended chelate ring. However, the fact that all Cu−N distances (and the Ni−N distances) are in the expected ranges[13] indicates that little strain is imposed by the ferrocene or ruthenocene group on the macrocyclic ligand complex. This also follows from the other structural parameters; only the N1−M−N4 angles are slightly larger than usual. Another indication for the fairly strain-free geometry of the macrocyclic ligand copper(II) complex are the spectroscopic and electrochemical parameters and stability constants, which are all as expected for cyclam-type tetraazamacrocyclic ligand copper(II) complexes (see Tables 2 and 3 below; note, however, the stability constants of the other transition metal complexes and the relevant discussion). With respect to the geometry of the substituted metallocene group, the three structures are very similar to each other. The two Cp rings are staggered, and the only significant distortion is a small tilt of the two Cp planes by 5−7°, because of the coordination of the copper(II) or nickel(II) centers to the methylamine substituents at the Cp rings. The angles between the averaged Cp and the macrocycle planes are around 35°. The fact that, in terms of spectroscopic and electrochemical properties, all other macrocyclic ligand complexes show similar trends suggests that the structures of the complexes for which no structural data are available are also similar to those reported here.

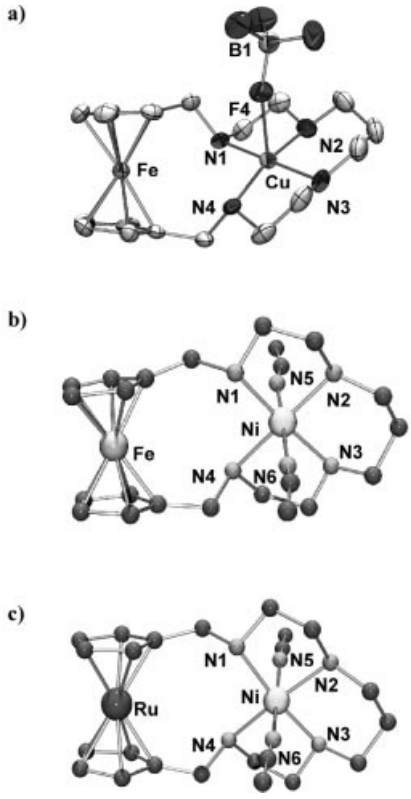

Figure 1. Structural plots of the molecular cations of $[Cu(fcmac)(FBF_3)]BF_4$, $[Ni(fcmac)(NCCH_3)_2](BF_4)_2$, and $[Ni(rcmac)(NCCH_3)_2](BF_4)_2$ (the structures of the two nickel complexes are of low quality and appear only for comparison (see text)

Complex Stabilities

Because of problems with the solubility of the ferrocene- and ruthenocene-appended macrocycles, the protonation constants and complex stabilities were determined in 1,4-dioxane/water mixtures. Similar solvent mixtures have been used for other ferrocene-functionalized macrocycles,[11] and those for cyclam (1,4,8,11-tetraazacyclotetradecane) have also been determined here under the same conditions for comparison (see Table 2). The two new ligands fcmac and rcmac have similar protonation constants, and these are also similar to those of another published ferrocene-functionalized cyclam ligand, FcCyclam, which is the 1,1′-ferrocenebis(methyl)-bridged 1,8-substituted cyclam ligand, bridged at 1,8-positions,[11] but the amine donors are significantly less basic than those of the unfunctionalized cyclam macrocycle. For the discussion of the complex stabilities we will concentrate here primarily on the complex formation constants of $[M(L)]^{2+}$, with L = fcmac, rcmac, FcCyclam and cyclam, and M = Cu^{2+}, as well as Co^{2+}, Ni^{2+}, and Zn^{2+}. The complex stabilities with fcmac and rcmac are nearly identical, and, as seen in the Cu^{2+} systems, they are significantly larger than those for the FcCyclam ligand system ($\Delta\log K \approx 10$). Note that the difference in solvent (water/dioxane, 3:7 vs. 7:3) probably does not lead to these large differences {$[Cu(cyclam)]^{2+}$ in H_2O: $\log K = 27.2$;[14] in water/dioxane, 3:7: $\log K = 23.5$} and the stability is smaller than that for cyclam ($\Delta\log K \approx 3$). The reduced stability (vs. cyclam) is due to a distortion from planarity of the CuN_4 chromophore (see below) and the interaction with the metallocene site. The difference between the fcmac/rcmac systems on one hand and FcCyclam on the other, which is also obvious from the protonation constants, must partially be due to the significantly different Fe···M (Cu) distances (4.5 Å, see Table 1, vs. 3.8 Å).[11]

More interesting is the variation of stabilities along the transition metal series. This usually follows the Irving−Williams series,[15] and for cyclam the corresponding $\log K$ values (measured in water)[16] for nickel(II), copper(II), and zinc(II) are 19.4, 27.2, and 15.5, respectively. It appears that fcmac and rcmac stabilize in particular copper(II); cobalt(II) and zinc(II) have stabilities which are a little lower than expected (see above), but nickel(II) is strongly destabilized. We attribute this behavior to the enforced *trans*-II configuration, which must be a result of the large and rather rigid ferrocene-appended chelate ring,

which enforces a considerable tetrahedral twist. The tetrahedral twist angles (angle between the planes N2/N3/Cu and N1/N4/Cu) for Cu(fcmac), Ni(fcmac), and Cu(cyclam) are 12°, 4°, and 0°, respectively. A deformation from planarity of the $M(N_4)$ chromophore is more destabilizing for nickel(II) than for copper(II), and the result in the present case (see structural parameters above) leads both to a substantial electronic destabilization and an increase in ligand strain for nickel(II). Probably, it is primarily ligand strain which leads to the relatively low stability of the nickel(II) complex. The result is a strong preference for copper(II), and this selectivity is an important prerequisite for efficient copper-selective sensors, based on fcmac, rcmac, and corresponding derivatives.

Spectroscopy and Electrochemistry

The guest-dependent shift of the Fc/Fc^+ couple in ferrocene-substituted host molecules has often been used to analyze the interaction between the ferrocene iron center and a guest molecule. With cationic guests (metal ions) the reduced form is generally stabilized (shifts towards more positive potentials by a few hundred millivolts).[6,17−20] Primarily, this is due to electrostatic effects, but direct electronic interactions might also contribute (see data in Table 3, see also below).[21] Similar shifts were also observed for the Rc/Rc^+ couple in complexes with rcmac ($[Cu(rcmac)](BF_4)_2$ 834 mV, $[Ni(rcmac)(NCCH_3)_2](BF_4)_2$ 716 mV, measured vs. $Ag/AgNO_3$ under the same conditions). The ligand rcmac

itself decomposes under the measurement conditions and therefore gives no interpretable voltammogram.

Another efficient tool to analyze metal···metal interactions in ferrocene-appended host molecules is the C−H out-of-plane bending vibration in ferrocene (815 cm^{-1}), shifted to higher energies (840 cm^{-1}) in the ferrocenium ion. The comparably small shifts[6] observed in the present examples indicate that the distance between the ferrocene (or ruthenocene) subunits and the guest metal ion is large, and that the metal···metal interaction is relatively weak. The fact that the shift with Cu^{2+} is largest correlates well with the observed reduction potentials, and this indicates that some electron transfer is involved.

Both the UV/Vis and the EPR spectra of $[Cu(fcmac)]^{2+}$ indicate that the CuN_4 plane is significantly distorted ($g_{x,y}$ = 2.06, g_z = 2.20, $A_{x,y}$ = 18 × 10^{-4} cm^{-1}, A_z = 197 × 10^{-4} cm^{-1}, λ_{max} = 557 nm; the corresponding data for a 15-membered N_4 macrocycle {$[Cu[15]ane\ N_4]^{2+}$; [15]ane N_4] = 1,4,8,12-tetraazacyclopentadecane, which is known to have a tetrahedral distortion similar to that of $[Cu(fcmac)]^{2+}$, with a twist angle of 16°},[22] are 2.05, 2.19, 24 × 10^{-4}, 194 × 10^{-4}, 582, respectively). This is as expected from the solid state structural data.

The isomer shifts δ_{IS} and quadrupole splitting values ΔE_Q in the ^{57}Fe Mössbauer spectra (10 K) of the fcmac complexes are also summarized in Table 3, where the corresponding values of ferrocene and fcmac·HCl appear for comparison. The parameters for fcmac·HCl (δ_{IS} = 0.392 mm s^{-1}, ΔE_Q = 2.350 mm s^{-1}) are typical for low-spin Fe^{II} in a metallocene coordination sphere and indicate, in comparison with ferrocene (δ_{IS} = 0.416 mm s^{-1}, ΔE_Q = 2.370 mm s^{-1}), a reduced electron density at the nucleus and an increased distortion of the iron center. The linear correlation of the reduction potentials with the isomer shifts[23] (see Figure 2) is significant and reflects primarily the electrostatic perturbation of the electronic properties of the ferrocene iron centers. For the Ni^{II}, Zn^{II}, and Co^{II} complexes of fcmac two slightly different doublets were observed, and upon irradiation (Ar laser, 514.5 nm) the relative populations were altered.[24] Preliminary results suggest that the corresponding Fe^{II} and Fe^{III} complexes, $[Fe(fcmac)]Fe(SO_4)_2$ and $[Fe(fcmac)](SCN)_3$, appear as thermally and optically induced switches. These features are currently under thorough investigation and will be published in due course.

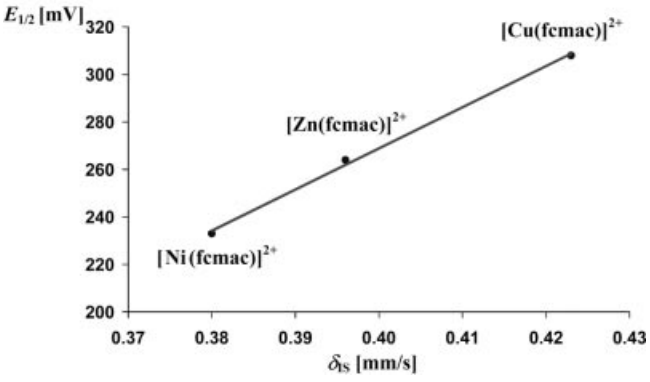

Figure 2. Correlation of the reduction potentials of $[Cu(fcmac)]^{2+}$, $[Ni(fcmac)]^{2+}$, and $[Zn(fcmac)]^{2+}$ with the corresponding Mössbauer isomer shifts

Conclusion

Two novel tetraazamacrocyclic ligands with metallocene (Fe, Ru) bridges and their heterodinuclear transition metal complexes [iron(II)/(III), cobalt(II), nickel(II), copper(II), and zinc(II)] have been prepared and fully characterized. The two main features are (i) that there is significant electronic communication between the metal centers, and this is due to a relatively short metal···metal distance {4.54 Å in the structurally characterized $[Cu(fcmac)(FBF_3)]BF_4$ complex}, and (ii) that the complex stabilities with the two macrocycles do not follow the usual Irving−Williams-type behavior; the copper(II) complexes have stabilities which are, as expected, similar to those with tetraazamacrocycles with the usual alkyl bridges; the nickel(II) complexes are unusually unstable. This is probably due to the uncommon *trans*-II configuration of the metallocene-substituted macrocycle, which induces considerable strain on and a distortion from planarity of the macrocycle.

Experimental Section

Measurements and Materials: Commercially available solvents and reagents were used without further purification. The syntheses of the ligands were carried out under argon. 1,1′-Diformylferrocene and 1,1′-diformylruthenocene were prepared as described in the literature.[25] NMR spectra were recorded with a Bruker AS 200 (^{1}H NMR 200.13 MHz, ^{13}C NMR 50.33 MHz) spectrometer. The spectra were referenced to the solvent signals. Mass spectra were recorded with a Finnigan 8400 instrument. IR spectra were recorded with a Perkin−Elmer 16C spectrometer as KBr pellets. UV/Vis spectra were measured with a Varian Cary 1E spectrometer in MeOH or MeCN. Potentiometric titrations were carried out in 1,4-dioxane/water (30:70 v/v, 0.1 M KCl) using a reaction vessel thermostatted at 25.0 ± 0.1 °C under nitrogen. The computer program HYPERQUAD[14,26] was used to calculate the protonation and stability constants. The concentrations of the ligands were 0.05 mmol/L; 0.8 equiv. of metal salts were used. Electrochemical measurements were obtained with a BAS100 W electrochemical analysis instrument. A glassy carbon working electrode and a platinum auxiliary electrode were used; 2×10^{-3} M solutions in CH_3CN with tetrabutylammonium hexafluorophosphate (0.1 M). Potentials were measured relative to $Ag/AgNO_3$ (0.01 M $AgNO_3$). The scan rate was varied from 10 to 100 mV s^{-1}. EPR spectra were recorded with a Bruker ELEXSYS E500 spectrometer (X band) as approximately 10^{-3} mol L^{-1} frozen solutions (liquid N_2) in DMF/water, 2:1. XSophe, version 1.0.2β, on a Linux workstation was used for the simulation of the spectra. A standard transmission Mössbauer spectrometer was used. The ^{57}Co source was kept at room temperature and the isomeric shifts are relative to Co in Rh. An argon ion laser was used for the irradiation at 514.5 nm and 35 mW/cm^2. The Mössbauer spectra were fitted with the software MOSFUN and RECOIL.

Syntheses of the Ligands

fcmac: A solution of 1,1′-diformylferrocene (1.00 g, 4.13 mmol) and 2.3.2-tet (0.66 g, 4.13 mmol) in absolute methanol (40 mL) was refluxed for 4 h. After cooling to room temperature, $NaBH_4$ (0.48 g, 12.69 mmol) in degassed water (10 mL) was added, and the reaction mixture was stirred overnight. The solvent was evaporated, and the water phase was extracted with CH_2Cl_2 (3 × 20 mL). The collected organic extracts were filtered through Celite, and the solvent was evaporated, yielding 1.24 g (3.35 mmol, 81%) of a brown and highly viscous oil. ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ = 1.49−1.79 (m, 2 H, CH_2), 2.10 (br. s, 4 H, NH), 2.37−2.84 (m, 12 H, CH_2), 3.39 (s, 4 H, Cp−CH_2), 4.00−4.30 (m, 8 H, Cp−H) ppm. ^{13}C NMR (CD_2Cl_2, 50.33 MHz): δ = 28.7 (1 C, CH_2), 48.1 (2 C, CH_2), 49.1 (2 C, CH_2), 49.4 (2 C, Cp−CH_2), 67.3 (4 C, Cp), 67.8 (4 C, Cp), 88.5 (2 C, Cq, Cp) ppm. UV/Vis (MeOH): λ = 309 (ε = 733 M^{-1}cm^{-1}), 436 (ε = 251 M^{-1}cm^{-1}) nm. MS-FAB (NBA): *m/z* = 371.1 $[M + H]^+$.

rcmac: As described for fcmac, the reaction of 1,1′-diformylruthenocene (0.50 g, 1.74 mmol) with 2.3.2-tet (0.28 g, 1.74 mmol) in absolute methanol (20 mL), followed by reduction with $NaBH_4$ (0.20 g, 5.29 mmol) in degassed water (5 mL) yielded 0.61 g (1.48 mmol, 85%) of rcmac as a yellow and highly viscous oil. ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1.42−1.98 (m, 6 H, CH_2 and NH), 2.49−2.77 (m, 12 H, CH_2), 3.21 (s, 4 H, Cp−CH_2), 4.38 (m, 4 H, Cp−H), 4.54 (m, 4 H, Cp−H) ppm. ^{13}C NMR (CD_2Cl_2): 28.0 (1 C, CH_2), 49.7 (2 C, CH_2), 50.2 (4 C, CH_2), 50.3 (2 C, Cp-CH_2), 70.2 (4 C, Cp-C), 71.5 (4 C, Cp−C), 94.0 (2 C, C_q, Cp−C) ppm. MS-FAB (NBA): *m/z* = 417.2 $[M + H]^+$.

fcmac$^+$PF$_6$: A solution of fcmac (478 mg, 1.29 mmol) and ferrocenyl hexafluorophosphate (427 mg, 1.29 mmol) in abs. CH_2Cl_2 (20 mL) was stirred at room temperature for 2.5 h. It was filtered, and the solvent was evaporated. The resulting brown solid was washed with Et_2O until washings were colorless. Drying in vacuo yielded 371 mg (0.72 mmol, 56%) of a brown powder. MS-FAB (NBA): *m/z* = 514.3 $[M]^+$, 371.3 $[M - PF_6]^+$. UV/Vis (MeOH): λ = 317 (ε = 353 M^{-1}cm^{-1}), 440 (ε = 197 M^{-1}cm^{-1}) nm. IR: $\tilde{\nu}$ = 3235 (w), 3078 (w), 2932 (w), 2833 (w), 2358 (w), 1457 (m), 1106 (w), 1040 (w), 840 (s), 557 (m) cm^{-1}.

Metal Complexes of fcmac and rcmac: Complexes of fcmac and rcmac were obtained by reaction of equal amounts of ligand and metal salt in methanol (0.5 mmol in 5 mL) at room temperature and stirring overnight. The resulting precipitate was filtered off, washed with methanol, and dried in vacuo. If necessary the compounds were recrystallized from acetonitrile. Single crystals for X-ray diffraction were obtained by ether diffusion into complex solutions in acetonitrile.

[Cu(fcmac)(FBF$_3$)]BF$_4$: Yield 46% of a pink solid. $C_{19}H_{30}B_2CuF_8FeN_4$ (607.38): calcd. C 37.57, H 4.98, N 9.22; found C 37.67, H 5.19, N 8.95. MS-FAB (NBA): *m/z* = 607.1 $[Cu(fcmac)(BF_4)_2]^+$, 520.1 $[Cu(fcmac)(BF_4)]^+$, 433.1 $[Cu(fcmac)]^+$. UV/Vis (MeCN): λ = 411 (ε = 302 M^{-1}cm^{-1}), 557 (ε = 150 M^{-1}cm^{-1}) nm. IR: $\tilde{\nu}$ = 3252 (m), 2922 (w), 2870 (w), 2358 (m), 2336 (w), 1636 (w), 1456 (w), 1420 (w), 1082 (s), 880 (w), 820 (w), 522 (w), 478 (w) cm^{-1}. Single crystals were obtained by ether diffusion into an acetonitrile solution.

[Ni(fcmac)(NCCH$_3$)$_2$](BF$_4$)$_2$: Yield 23% of a brown solid. $C_{19}H_{30}B_2F_8FeN_4Ni$ (602.62): calcd. C 37.87, H 5.02, N 9.30; found C 38.72, H 5.37, N 8.92. UV/Vis (MeCN): λ = 310 (ε = 223 M^{-1}cm^{-1}), 436 (ε = 84 M^{-1}cm^{-1}) nm. IR: $\tilde{\nu}$ = 3534 (s), 3232 (s), 2942 (m), 2876 (m), 2358 (w), 1636 (m), 1462 (m), 1430 (m), 1058 (s), 816 (m), 764 (w), 520 (m), 484 (w) cm^{-1}.

[Zn(fcmac)](ClO$_4$)$_2$×MeOH: Yield 21% of a brown solid. $C_{20}H_{34}Cl_2FeN_4O_9Zn$ (666.65): calcd. C 36.03, H 5.14, N 8.40; found C 36.47, H 5.24, N 8.59.

[Fe(fcmac)](SCN)$_3$: Yield 47% of a brown solid. MS-FAB (NBA): *m/z* = 542.1 $[Fe(fcmac)(SCN)_2]^+$, 484.1 $[Fe(fcmac)(SCN)]^+$. IR: $\tilde{\nu}$ = 3391 (m), 3068 (w), 2939 (w), 2042 (s, SCN), 1647 (m), 1443 (w), 1238 (w), 1039 (w), 828 (w), 478 (w) cm^{-1}.

[Fe(fcmac)]Fe(SO$_4$)$_2$×3MeOH: Yield 51% of a brown solid. $C_{22}H_{44}Fe_3N_4O_{11}S_2$ (772.27): calcd. C 34.22, H 5.74, N 7.25; found C 34.63, H 5.51, N 6.73. IR: $\tilde{\nu}$ = 3386 (s), 3217 (m), 3080 (m), 2923 (m), 2358 (m), 2343 (w), 1635 (m), 1458 (m), 1109 (s, SO_4), 1026 (s), 966 (w), 809 (w), 602 (w), 484 (w) cm^{-1}.

[Cu(rcmac)](BF$_4$)$_2$: Yield 64% of a violet solid. $C_{19}H_{30}B_2CuF_8N_4Ru$ (652.69): calcd. C 34.96, H 4.63, N 8.58; found C 35.02, H 4.74, N 8.33. MS-FAB (NBA): *m/z* = 479.4 $[Cu(rcmac)]^+$. UV/Vis (MeCN): λ = 532 (ε = 120 M^{-1}cm^{-1}) nm. IR: $\tilde{\nu}$ = 3251 (m), 3103 (w), 2930 (w), 2886 (w), 1418 (m), 1069 (s), 812 (m), 519 (w), 429 (w) cm^{-1}.

[Ni(rcmac)(NCCH$_3$)$_2$]](BF$_4$)$_2$: Yield 52% of a yellow solid. $C_{19}H_{30}B_2F_8N_4NiRu$ (647.84): calcd. C 35.23, H 4.67, N 8.65; found C 35.29, H 4.73, N 8.55. MS-FAB (NBA): *m/z* = 561.5 $[Ni(rcmac)(BF_4)]^+$. UV/Vis (MeCN): λ = 309 (ε = 201 M^{-1}cm^{-1}), 400 (ε = 36 M^{-1}cm^{-1}) nm. IR: $\tilde{\nu}$ = 3262 (m), 3228 (m), 2949 (w), 2879 (w), 1460 (m), 1420 (m), 1034 (s), 819 (w), 518 (w) cm^{-1}. Single crystals were obtained by ether diffusion into an acetonitrile solution.

[Cu(fcmac$^+$)](BF$_4$)$_2$PF$_6$: A solution of fcmac$^+$PF$_6^-$ (116 mg, 0.23 mmol) and Cu(BF$_4$)$_2$·6H$_2$O (78 mg, 0.23 mmol) in absolute methanol (7 mL) was stirred at room temperature overnight. The solution was filtered, and the solvent was evaporated. The resulting violet solid was dried in vacuo. Yield 98 mg (0.11 mmol, 49%). MS-ESI (MeOH): *m*/*z* = 502.6 [Cu(fcmac$_{ox}$)BF$_4$]$^+$, 434.6 [Cu(fcmac$_{ox}$)]$^+$. UV/Vis (MeOH): λ = 353 (ε = 1243 м$^{-1}$cm^{-1}), 489 (ε = 376 м$^{-1}$cm^{-1}), 609 (ε = 191 м$^{-1}$cm^{-1}) nm. IR: $\tilde{\nu}$ = 3419 (w), 3262 (w), 3114 (w), 2949 (w), 2921 (w), 1050 (s), 834 (s), 558 (m) cm^{-1}.

Crystal Structure Determinations: Crystal data and details of the structure determinations are listed in Table 4. Intensity data were collected at low temperature with a Stoe IPDS image plate (Mo-K_α radiation, λ = 0.71073 Å). The structures were solved by direct methods and refined by full-matrix least squares, based on F^2 with all reflections using the SHELXTL programs (G. M. Sheldrick, *SHELXTL NT*, v5.10, Bruker AXS, Madison, Wisconsin, USA, **1998**). CCDC-218906 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html [or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223-336-033; E-mail:deposit@ccdc.cam.ac.uk].

Table 4. Crystallographic data and data collection parameters for [Cu(fcmac)(FBF$_3$)]BF$_4$

Empirical formula	$C_{19}H_{30}B_2CuF_8FeN_4$
M_r	607.48
T [K]	203(2)
λ [Å]	0.71073
Crystal system, space group	orthorhombic, $P2_12_12_1$
Unit cell dimensions	a = 8.094 (2) Å
	b = 14.352 (3) Å
	c = 4.0611 (8) Å
Crystal size [mm]	0.30 × 0.30 × 0.05
Volume [nm^3]	4.717(2)
Z	8
Density (calculated) [g/cm^3]	1.711
Absorption coefficient [mm^{-1}]	1.596
F(000)	2472
Goodness-of-fit on F^2	0.961
Final R indices {$R1$ [$I > 2\sigma(I)$]; $wR2$ (all data)}	$R1$ = 0.0300; $wR2$ = 0.0713
Largest diff. peak/hole [e·Å^{-3}]	0.313/−0.391

Hybrid Magnetic Materials Based on Nitroxide Free Radicals and Extended Oxalato-Bridged Bimetallic Networks

Antonio Alberola,[a] Eugenio Coronado,*[a] Carlos Giménez-Saiz,[a] Carlos J. Gómez-García,[a] Francisco M. Romero,*[a] and Ana Tarazón[a]

Keywords: Magnetic properties / Heterometallic complexes / Hybrid materials / Radicals / Layered compounds

A series of hybrid organic-inorganic magnets of formula *p*-rad[$M^{II}Cr(ox)_3$] [M = Mn (**1**), Co (**2**), Ni (**3**), Zn (**4**)] and *m*-rad[$M^{II}Cr(ox)_3$] [M = Mn (**5**), Co (**6**)], in which *N*-methylpyridinium cations bearing a nitronyl nitroxide moiety in positions 3 (*m*-rad) or 4 (*p*-rad) of the pyridine ring coexist with the 2D honeycomb-like oxalato-bridged bimetallic lattice, has been prepared and studied by AC and DC magnetic susceptibility measurements and EPR spectroscopy. In general, the physical properties of these magnets are not altered significantly by the insertion of the nitronyl nitroxide radicals although these paramagnetic molecules seem to interact weakly with the inorganic network as demonstrated by EPR spectroscopy. Some differences can also be observed between the *p*-rad and *m*-rad series, i.e. *m*-rad derivatives have smaller values for the critical temperatures and coercive fields. We also report on the X-ray crystal structures and magnetic properties of *p*-rad[$Mn(H_2O)Cr(ox)_3]\cdot 2H_2O$ (**7**) and *m*-rad[$Mn(H_2O)_2Cr(ox)_3]\cdot 2H_2O$ (**8**), two extended oxalato-bridged compounds with new topologies. Compound **7** is antiferromagnetic and its structure is a 3D achiral lattice in which zigzag ferromagnetic MnCr chains (J/k = +0.8 K) are interconnected to form hellicoidal hexagonal channels with the cationic free radicals residing in the free space. Compound **8**, however, exhibits a ladder-like structural pattern with competing magnetic interactions and paramagnetic behaviour down to low temperatures.

Introduction

For more than fifteen years, magnetochemists have been successfully surmounting the challenge of designing and constructing new crystalline solid-state materials from molecular building blocks.[1,2] In the rational design of these compounds, the building blocks are not merely virtual units in which the crystal structure is subdivided in order to get a better understanding but, rather, they are real entities which are stable in solution and can be assembled to form a particular crystal lattice with interesting properties. The well-known concepts of structural coordination chemistry provide useful design methods for the purpose of lattice engineering, since coordination geometries are defined by strong and highly directional bonds. Fortunately, coordination chemistry also affords the basic ingredients of molecule-based magnetic materials, i.e. spin carriers (metal ions) and ligands through which magnetic interactions can occur.

The homoleptic tris(oxalatometallate) anions $[M(ox)_3]^{3-}$ ($M = Cr^{III}$, Fe^{III}, Ru^{III}) are rather inert metal complex ions which can be assembled with metal cations to give extended heterometallic systems.[3−5] The majority of the resultant structures are composed of edge-sharing octahedra and belong to two categories, namely a) 2D bimetallic compounds of formula $A[M'M(ox)_3]$ (A = quaternary onium cation, M′ = metal) with a honeycomb-layered structure[6,7] and b) 3D homometallic compounds of formulae $A[M'_2(ox)_3]$, $A[M'M(ox)_3]$ or $A[M'M(ox)_3](ClO_4)$ ($A = [M(bpy)_3]^{2+}$) with a cubic chiral packing.[8,9] Since the formation of each structural type depends on the use of a particular A^{m+} cation, these have been considered as templating agents for the host structure.[10] It has also been recognised that chirality plays a crucial role in this molecular recognition process, i.e. chiral tris(bipyridine) metal cations induce the spontaneous resolution of 3D chiral lattices with the same configuration as the tris(oxalatometalate) sites.[11] Cross effects (magnetochiral dichroism)[12] may arise from the combination of magnetic order and chirality in 3D oxalato-based compounds.[13] In general, multiproperty hybrid materials can be synthesised from functional A^{m+} cations which introduce an additional physical property in the magnetic system. In this context, 2D compounds containing paramagnetic decamethylferricenium species,[14,15] NLO-active molecules[16] and organic π-electron donors have been studied. The latter include the first examples of the coexistence of magnetic order and metal-like conductivity in a molecular solid.[17]

Nitronyl nitroxide (NN) radicals have become commonplace in the synthesis of purely organic magnetic materi-

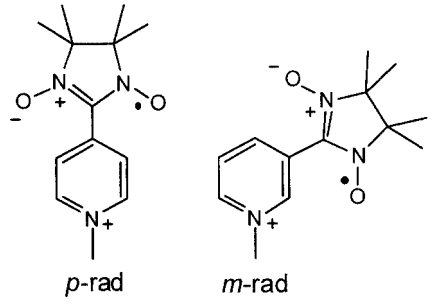
als[18] and mixed metal-radical magnets.[19−21] Cationic NNs of the *N*-alkylpyridinium type were reported by Awaga in combination with simple anionic metal complexes.[22−26] The same nitroxide cations have also been employed as bridging units in conjunction with the well-known bimetallic chains based on the opba ligand.[27−29] These studies prompted us to investigate the use of these free radicals as functional cations in the formation of oxalato-bridged extended bimetallic compounds. In a previous communication, we reported such a hybrid magnet based on a novel 3D achiral $[MnCr(ox)_3]^-$ lattice.[30] Herein, we extend these results to other first-row divalent metal ions. The influence of the position of the NN fragment with respect to the pyridinium ring is also discussed in this paper.

Results and Discussion

Synthesis and Characterisation: The cationic free radicals employed in this study were 1-methylpyridinium derivatives bearing an NN moiety in positions 4 (*p*-rad) or 3 (*m*-rad) of the pyridine ring (Scheme 1). They were synthesised as iodide salts by a previously described procedure.[22,23] Their reaction with $Ag_3[Cr(ox)_3]$ affords *p*(*m*)-rad$_3$[Cr(ox)$_3$] which was allowed to further react with a mixture of the corresponding metal cation, M^{2+}, and $[Cr(ox)_3]^{3-}$ to yield the family of compounds *p*(*m*)-rad[MCr(ox)$_3$]. From the study of the magnetic properties of these hybrid materials (vide infra), it became clear that they belong to the 2D type of structure.



Scheme 1

$$3\,p(m)\text{-radI} + Ag_3[Cr(ox)_3] \rightarrow 3\,p(m)\text{-rad}^+ + [Cr(ox)_3]^{3-} + 3\,AgI\downarrow \quad (1)$$

$$3\,MCl_2{\cdot}nH_2O + 2\,Ag_3[Cr(ox)_3] \rightarrow 3\,M^{2+} + 2\,[Cr(ox)_3]^{3-} + 6\,AgCl\downarrow \quad (2)$$

$$3\,p(m)\text{-rad}^+ + 3\,[Cr(ox)_3]^{3-} + 3\,M^{2+} \rightarrow 3\,\text{rad}[MCr(ox)_3] \quad (3)$$

All reactions were performed in ethanol/water mixtures. The different products *p*-rad[MCr(ox)$_3$]·*n*H$_2$O [M = Mn (**1**), Co (**2**), Ni (**3**), Zn (**4**)] can be obtained in moderate yields by fast precipitation, provided that a high ethanol/water ratio and rather concentrated solutions are used in the last step. The water content was evaluated by thermogravimetric analysis for all the compounds. The same experimental conditions were applied for the synthesis of the *m*-rad series. In this case, however, the yields were lower and the radical content in the final compounds (as estimated from elemental analysis) was smaller. The deficiency of cationic radicals has to be compensated for with the absence of some $[Cr(ox)_3]^{3-}$ anions, thus increasing the M/Cr ratio. This aspect was confirmed by SEM metal analyses. Adding an excess of the free radical and/or the divalent metal resulted in compounds with the correct stoichiometry, i.e. *m*-rad[MCr(ox)$_3$]·*n*H$_2$O [M = Mn (**5**), Co (**6**)]. The corresponding Ni^{II} and Zn^{II} compounds could not be obtained, however. Clearly, the more symmetric *p*-rad cation has a stronger affinity for the 2D honeycomb lattice than *m*-rad. It seems that the formation of the hexagonal cavities around the pyridinium cation is partially hindered by the presence of the bulky NN group in the *m*-position.

The precipitation of the manganese(II)-containing products (**1** and **5**) can be avoided if reaction (3) is performed in a more aqueous and/or a more dilute solution. Under these conditions, single-crystals of the 3D *p*-rad[MnCr(ox)$_3$(H$_2$O)]·2H$_2$O (**7**) and 1D *m*-rad[MCr(ox)$_3$(H$_2$O)$_2$]·2H$_2$O (**8**) compounds could be obtained by slow evaporation. The reaction conditions are therefore critical in the synthesis of the Mn^{2+} analogues. Due to the larger size of this cation, the formation of complexes with the tris(oxalate) chromate(III) species is reduced and a competition between these anions and the solvent water molecules occurs. Under less polar and/or more concentrated conditions (kinetic control), fast precipitation occurs and the well-known 2D phases are obtained. On the other hand, increasing the water content and/or working with more dilute solutions (thermodynamic control) induces the coordination of water molecules to the Mn^{2+} ions with a complete change in the crystal structure.

Crystal Structures of 7 and 8: The hybrid salt **7** crystallises in the monoclinic space group C_c. The conformation of the *p*-rad cation (Figure 1, a) with a torsion angle of 26.6(4)° between the NN fragment and the pyridine ring is similar to that found in other salts. The packing of the free radicals (Figure 2) forms zigzag chains running along the *z*-axis. The shortest contact between proximate radicals within the chain is O2···C10 [x, 1− y, z − 1/2, 4.312(5) Å]. The N−O functions are well separated from each other with a minimum intermolecular O1···O2 (x, 1− y, z − 1/2) distance of 6.891(5) Å. This situation is special in the context of magnetic materials containing nitroxide radicals, where shorter O···O contacts of about 3.5 Å are generally observed.

The oxalato-based inorganic lattice is also shown in Figure 2 and emphasises the role of the free radicals as directing agents for the whole structure. The zigzag chain motif of the packing of NN radicals is translated to the inorganic counterpart. Indeed, the 3D bimetallic network can be viewed, in a first step, as zigzag alternating Mn−Cr chains oriented in the same direction (continuous bonds). A detailed picture of this 1D fragment is given in Figure 3 where the linkage between neighbouring metal ions by

bis(bidentate) μ-oxalate bridges can be clearly seen. In contrast to the classical 3D network built up from homochiral building blocks which combine into helical chains, the chirality of the metal centres follows the sequence ···ΔΔΛΛΔΔ··· along the chains of **7**. Two distinct bis(bidentate) bridges are then found, i.e. one connecting metal centres of the same chirality [Mn1···Cr1: 5.421(3) Å] and a second one connecting centres of opposite chirality [Mn1···Cr1 (x, 2 − y, z + 1/2): 5.3927(16) Å].

The chains are linked by a new type of oxalate bridge (see Figure 1, b) which is simultaneously bidentate (towards chromium) and monodentate (towards manganese). As expected, the metal-metal distance [Mn1···Cr1e (x + 1/2, 3/2 − y, z + 1/2): 5.5977(14) Å] is higher when compared with the bis(bidentate) bridging mode. A water molecule occupies the vacant position in the Mn^{2+} coordination sphere at a distance Mn1−O15 = 2.138(2) Å. Previous reports concerning this unusual bridging mode are very scarce.[31−33] In complex **7**, the linkage (white rods in Figure 2) takes place between $Cr(ox)_3$ and $Mn(H_2O)(ox)_3$ units of opposite chirality. This results in the formation of an achiral 3-connected decagonal network. The decagonal units are arranged out of this plane in such a way that helical hexagonal channels are formed. Since the resultant network is achiral, both types of helices are found in the structure (Figure 4).

Interestingly, the radicals are tightly bound to the inorganic lattice through an extended hydrogen-bonded network. Short hydrogen bonds are found between the nitroxide oxygen atoms and two water molecules [Mn1−O15···O2−N3 (x + 1/2, 3/2 − y, z + 1/2): 2.733(4) Å; O17···O1−N2: 2.800(3) Å]. The water molecules of crystallisation are also linked to each other [O17···O16 (x + 1, y, z): 2.762(4) Å] and are hydrogen-bonded to the coordinated water [Mn1−O15···O17: 2.674(4) Å].

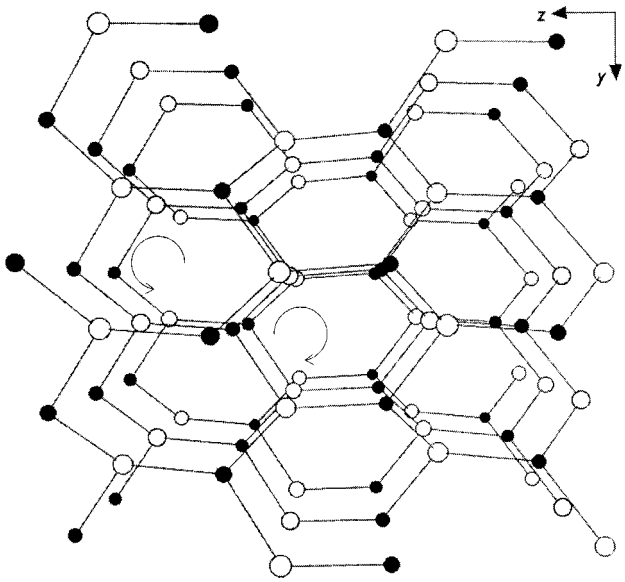

Figure 4. Perspective view along the a axis of the heterometallic lattice of **7** showing the metal connectivity and the helical channels formed; open circles = Mn, filled circles = Cr

The *m*-rad analogue **8** crystallises in the centrosymmetric $P\bar{1}$ space group. The cationic free radical (Figure 5, a) exhibits a more planar conformation with a torsion angle between the NN fragment and the pyridine ring of 15.51(10)°. The Mn^{2+} environment is markedly different with respect to **7** and only one oxalate anion now behaves in a bis(bidentate) manner with the other two (Figure 5, b) binding in the bidentate/monodentate mode occupying *trans* positions in the Mn^{2+} coordination sphere. This situation leaves two vacant *cis* positions which are occupied by water molecules. This causes the organisation of a ladder-like chain.[34−36]

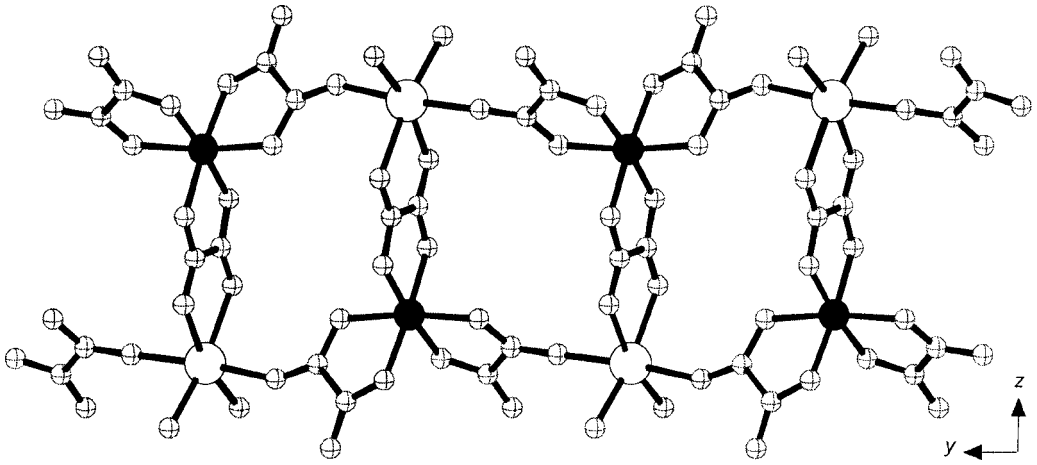

Figure 6. Projection of the crystal structure of **8** onto the *bc* plane, showing the oxalato-bridged MnCr ladder-like chains, open circles = Mn, filled circles = Cr

The steps of the ladder (Figure 6) are defined by bis(bidentate) bridges with an intermetallic distance Mn1···Cr1 = 5.4631(7) Å, while the bidentate/monodentate bridging mode propagates the lateral chains in the direction of the *b* axis. As expected, longer intermetallic distances [Cr1···Mn1($-x$ + 1, $-y$, $-z$ + 1) = 5.8370(7) Å and Mn1···Cr1($-x$ + 1, $-y$ + 1, $-z$ + 1) = 5.9902(7) Å] are found in this case. The chains are related by an inversion centre and the resultant ladder is achiral.

The free radicals (Figure 7) also form zigzag chains running along the *b*-axis. They can be viewed as chains of centrosymmetric dimers with the shortest intradimer distance of C40···C40 = 3.512(5) Å ($-x$, $-$,$-z$). The N−O moieties are even more isolated than in compound **7** and their minimum O···O distance in the crystal is 7.478(5) Å. Again, the water molecules of crystallisation are linked to each other [O3W···O4 W($-x$, 1$-$ y, 2 $-$ z) = 2.908(5) Å] and hydrogen-bonded to the coordinated water

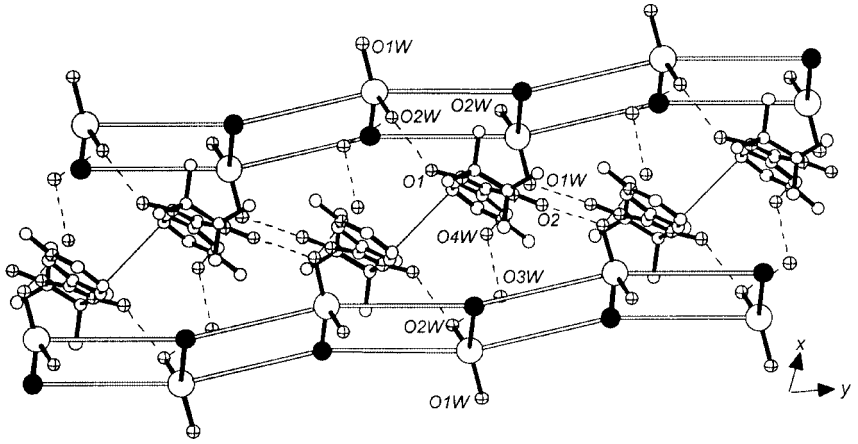

Figure 7. Projection of the crystal structure of **8** onto the *ab* plane, showing the radical zigzag chains of dimers and the oxalato-bridged ladder; oxalate anions have been replaced by straight rods: black [bis(bidentate)] and white (bidentate/monodentate); dotted lines refer to hydrogen bonds, open circles: Mn, filled circles: Cr

Table 1. Magnetic parameters for the series *p*-rad[$M^{II}M^{III}(ox)_3$] and *m*-rad[$M^{II}M^{III}(ox)_3$] (**1**−**7**): critical temperature (T_c), Weiss constant (θ), Curie constant (C), saturation magnetisation (M_{sat}) and coercive field at 2 K (H_{coer})

$M^{II}M^{III}$	*p*-rad					*m*-rad				
	T_c (K)	θ (K)	C (emu·K·mol^{-1})	M_{sat} (μ_B)	H_{coer} (G)	T_c (K)	θ (K)	C (emu·K·mol^{-1})	M_{sat} (μ_B)	H_{coer} (G)
MnCr	5.7	8.0	6.13	7.74	66	5.3	7.0	6.55	7.37	17
CoCr	13.8	10.0	5.37	6.22	4400	11.3	11.0	5.24	5.17	230
NiCr	15.5	17.2	3.14	5.57	1500	–	–	–	–	–
ZnCr	–	2.8	2.29	–	–	–	–	–	–	–

[Mn1−O2W···O3 W(x, y, z − 1) = 2.688(4) Å, Mn1−O1W···O4 W(1 − x, 1 − y, 1 − z) = 2.653(4) Å]. The nitroxide functions are bonded to coordinated and free water molecules [O1···O2 W(1 − x, 1 − y,1 − z) = 2.714(4) Å; O2···O1 W(2 − x, −y, 1 − z) = 2.719(4) Å]. The free radicals are thus held in the lattice by an intricate network of hydrogen bonds.

A view parallel to the chains (Figure 8) shows how these 1D organic and inorganic units alternate in the solid-state and also emphasises the role played by the oxalate anions in stabilising additional hydrogen bonds which link the ladders along the z direction.

Magnetic Properties of the Mn-Containing Hybrid Salts (1, 5, 7−8): It is interesting to compare these CrMn bimetallic compounds since only the noncrystalline materials obtained by fast precipitation (**1** and **5**) exhibit ferromagnetic ordering. Table 1 lists the values of χT (at 300 K), magnetisation (at 5 T), the coercive field and critical temperatures for all the compounds studied in this work. At room temperature, the four CrMn hybrid salts exhibit similar values of χT which lie close to the expected values for the sum of the isolated spins [nitroxide radical (S = 1/2), Mn^{2+} (S = 5/2) and Cr^{3+} (S = 3/2) cations]. On lowering the temperature, χT continuously increases (see Supporting Information) for all the compounds, suggesting the existence of short-range ferromagnetic interactions. Compounds **1** and **5** exhibit clear indications of ferromagnetic ordering, such as the onset of out-of-phase AC susceptibility signals below 5.7 K and 5.3 K, respectively (Figure 9). Hysteresis loops with very small coercive fields (66 G for **1**, 17 G for **5**) can also be observed. Both features clearly demonstrate that **1** and **5** belong to the 2D structural family of mixed-metal oxalates. In contrast, the magnetic behaviour of compounds **7**−**8** points to the presence of competing antiferromagnetic interactions. Both hybrid salts exhibit a rounded maximum in the χT vs. T curve and **7** even shows the presence of a sharp maximum at 6 K in the χ vs. T plot, a signature of antiferromagnetic ordering. Complex **8**, however, remains paramagnetic in the whole temperature range studied.

The magnetic properties of **7**−**8** can be understood by considering the crystal structures of these hybrid metal-radical salts. All previous studies have indicated that the Mn^{II}−Cr^{III} exchange coupling through bis(bidentate) oxalate anions is ferromagnetic. Indeed, the thermal variation (Figure 10) of the χT product for **7** (at temperatures above the Néel point) is well described in terms of a regular AB ferromagnetic chain model[37] with classical spins S_A = 5/2

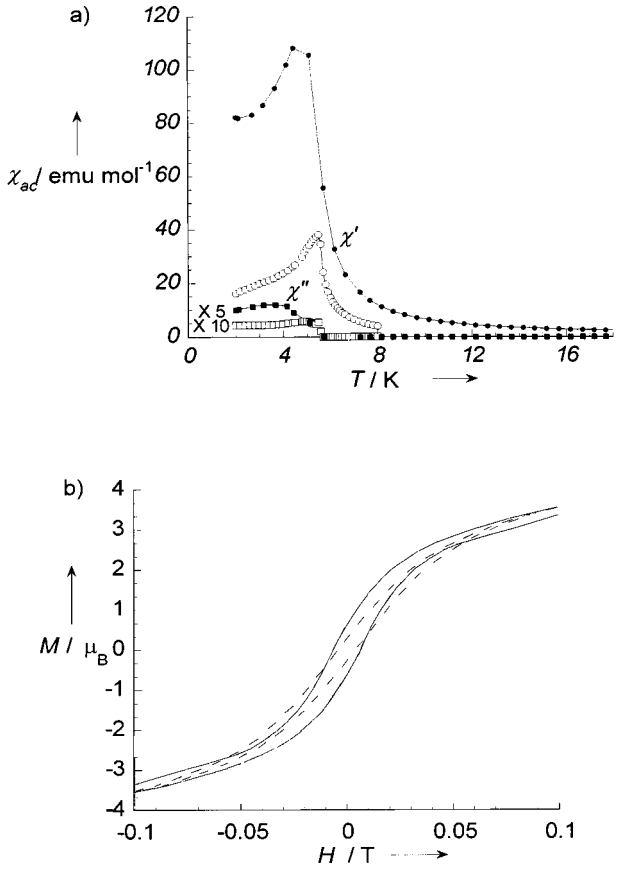

Figure 9. a) Temperature dependence of the real and imaginary components of the ac magnetic susceptibility of **1** (empty symbols, operating frequency: 1 Hz) and **5** (filled symbols, operating frequency: 110 Hz); b) low-field region of the hysteresis loops of **1** (solid line) and **5** (dashed line) measured at 2 K

and S_B = 3/2 ($H_{ex} = -J\Sigma S_{Ai}S_{Bi}$).[38] The best-fit value for the exchange coupling constant is J = +0.6 cm^{-1}, a value which is in agreement with previous observations. The antiferromagnetic order is then driven by weak antiferromagnetic interactions between the chains. These interactions are certainly transmitted through the bidentate/monodentate oxalate anion. The lower symmetry of this bridge decreases the efficiency of the ferromagnetic pathway (compared with the bis(bidentate) ligand) and the antiferromagnetic term becomes dominant, as has been shown recently in a chromium-manganese tetramer.[33] Antiferromagnetic ordering is generated in the inorganic lattice and the radicals seem to remain uncoupled to this magnetically ordered network, a hypothesis which is corroborated by the presence of a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

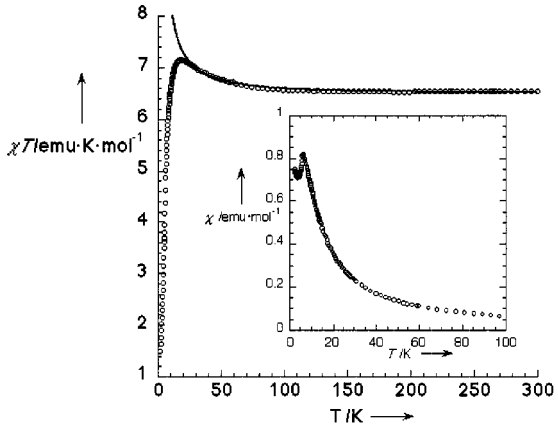

Figure 10. Thermal variation of the χT product (open circles) for **7**. The solid line represents the best-fit data for a ferromagnetic MnCr chain with $J = +0.6$ K; inset: temperature dependence of χ for the same compound

Curie tail at low temperatures. This is observed despite the fact that the nitroxide oxygen atom is hydrogen-bonded to the coordinated water molecule and, consequently, close to the manganese centre [Mn1···O2 ($x + 1/2$, $3/2 - y$, $z + 1/2$) = 3.8510(27) Å]. It seems that the magnetic interaction through this bridge is too weak to be appreciated in the temperature range of study.

The magnetostructural correlations found for complex **7** (ferromagnetic interaction transmitted through bis(bidentate) oxalate anions and antiferromagnetic coupling mediated via the asymmetric bridge) suggest the use of a spin-ladder chain model with competing interactions for the analysis of the magnetic properties of **8**.[39] Ferromagnetic interactions take place in the steps of the ladder, while the antiferromagnetic coupling propagates along the rungs, giving rise to a diamagnetic ground state. The free radicals can be considered as an independent paramagnetic contribution, as for **7**. In the absence of an exact solution for this system, the ladder chain can be approximated to a cluster-type model of isotropic spins (Figure 11).[40] The best-fit data for the two magnetic coupling parameters are $J = +0.8$ cm^{-1} and $j = -0.35$ cm^{-1}. As expected, the positive interaction is of the same order of magnitude as that estimated for the *p*-rad analogue.

Magnetic Properties of the Co-Containing Hybrid Salts (2 and 6): At room temperature, the value of χT for **2** (Figure S2a, see Supporting Information and the corresponding footnote on the first page of this article) is 5.88 emu·K·mol^{-1}. Subtraction of the radical and chromium(III) contributions leads to a reasonable value of 3.63 emu·K·mol^{-1} per cobalt(II) centre. On lowering the temperature, χ increases and eventually reaches saturation at a high value of 16.8 emu·K·mol^{-1} at 2.1 K, suggesting ferromagnetic ordering at low temperatures. Confirmation of the magnetic order (Figure 12) is provided by the observation of an out-of-phase signal in the AC susceptibility measurements below $T_C = 13.8$ K. Magnetisation hysteresis loops can be observed below this temperature with very high coercive field values ($H_{coer} = 4400$ G at 2 K) compared with those previously reported for CoCr oxalato-bridged 2D magnets. Saturation is almost reached in a 5 T field with a magnetisation value of 6.2 μ_B.

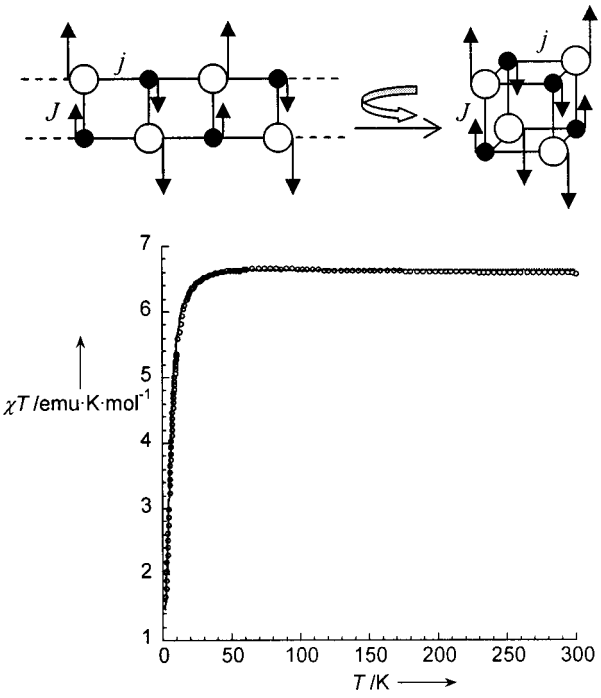

Figure 11. Top: 8-spin ring cubane model adopted for the spin-ladder chain; bottom: thermal variation of the χT product (open circles) for **8**; the solid line represents the best-fit data ($J = +0.8$ cm^{-1}; $j = -0.35$ cm^{-1})

Compound **6** exhibits (Figure S2b, Supp. Inf.) a room-temperature χT value of 5.52 emu·K·mol^{-1}. Taking into account the contributions of the radical and chromium(III) centres, a value of 3.27 emu·K·mol^{-1} per cobalt(II) centre can be calculated. This is close to the expected value for a free Co^{2+} ion showing orbital degeneracy. χ increases continuously on cooling and undergoes saturation with a value of 17.2 emu·K·mol^{-1} at 2 K. Compounds **2** and **6** show a similar thermal dependence in the DC susceptibility. The AC data, however, show clear differences between the *p*-rad and *m*-rad derivatives. The latter orders ferromagnetically at $T_C = 11.3$ K and exhibits a rounded maximum in the thermal dependence of the in-phase component. This is in contrast to the extremely sharp peak observed for the *p*-rad analogue (**6**). Also, field-dependent studies show a much smaller coercive field ($H_{coer} = 230$ G at 2 K) compared with that in **2**. The different magnetic behaviour of both compounds may be ascribed to the presence of metal defects and/or disorder in the *m*-compound which push the T_C to lower temperatures. The differences in coercive field values may also be explained in terms of a different morphology of the samples: The *p*-rad derivative (**2**) has an unusually large particle size (8 μm) compared with the other compounds (the particle size of **6** is 250 nm).

Magnetic Properties of the Ni-Containing Hybrid Salt (3): The value of χT at 300 K for **3** (3.53 emu·K·mol^{-1}) is slightly higher than the sum of the paramagnetic contri-

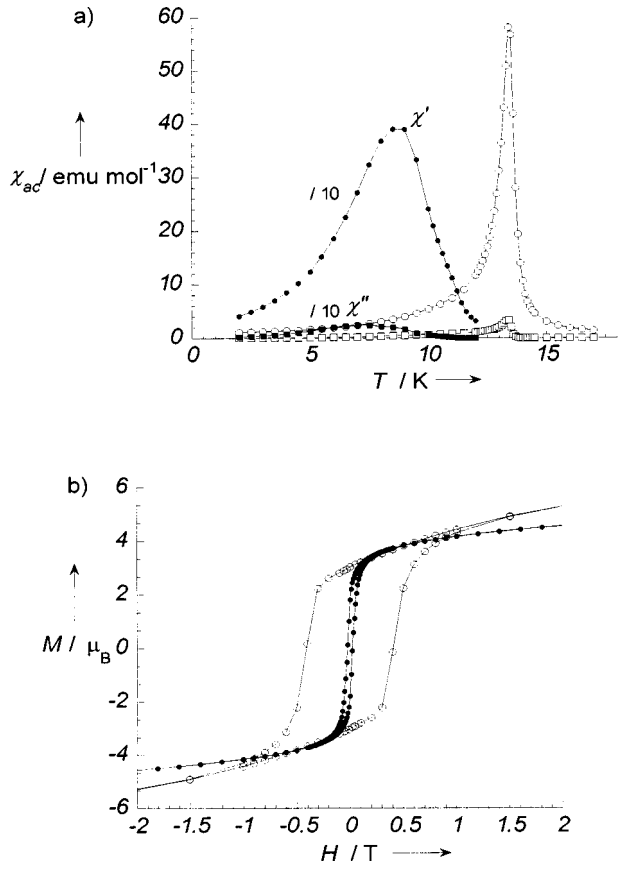

Figure 12. a) Temperature dependence of the real and imaginary components of the ac magnetic susceptibility of **2** (empty symbols) and **6** (filled symbols); operating frequency: 110 Hz; b) low-field region of the hysteresis loops of **2** (empty symbols) and **6** (filled symbols) measured at 2 K

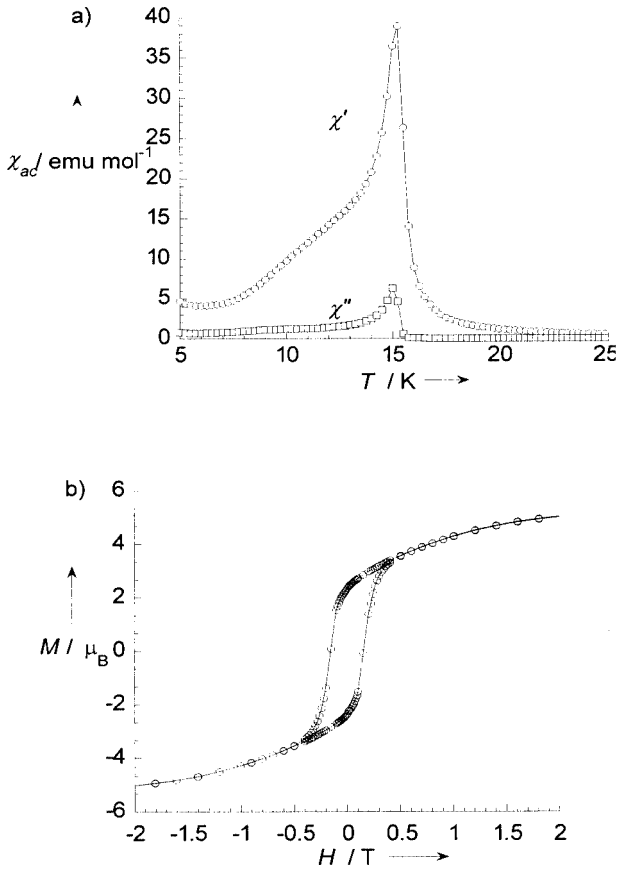

Figure 13. a) Temperature dependence of the real and imaginary components of the ac magnetic susceptibility of **3**; operating frequency: 110 Hz; b) low-field region of the hysteresis loops of **3** measured at 2 K

butions of the different spin carriers (Figure S3, Supp. Inf.). χ increases considerably upon cooling, indicating the presence of a ferromagnetically ordered phase at low temperatures. The onset of an out-of-phase signal in the AC susceptibility (Figure 13) measurements below T_C = 15.5 K provides further evidence of magnetic order. Again, magnetisation hysteresis loops were observed with very high coercive field values (H_{coer} = 1500 G at 2 K) compared with those previously reported for NiCr oxalato-bridged 2D magnets. Saturation is almost reached in a 5 T field with a magnetisation value of 5.6 μ_B.

Magnetic Properties of the Zn-Containing Hybrid Salt (4): This product exhibits room-temperature χT values that lie close to the sum of the calculated contributions for isolated Cr^{III} and free radical units. χT remains practically constant (Figure 14) upon cooling down to 10 K. Below this point, χT increases constantly upon decreasing the temperature, indicating that an intermolecular ferromagnetic interaction between radicals may also be present. In the absence of structural characterisation, it is difficult to ascribe this behaviour to particular intermolecular contacts so that an interaction between the free radical and the chromium(III) centres cannot be ruled out. The field dependence of the magnetisation shows typical Brillouin behaviour. As quoted in Table 1, saturation is not reached in a 5 T field.

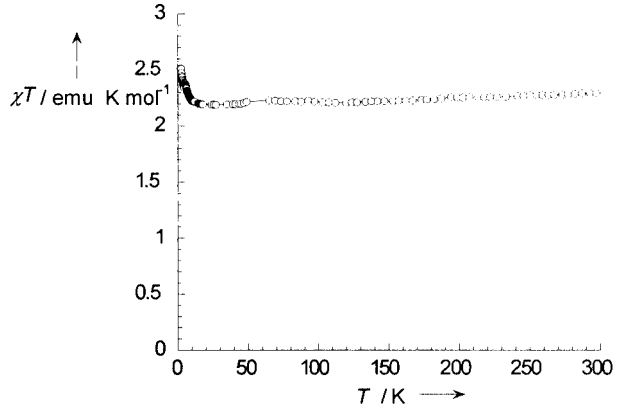

Figure 14. Thermal variation of χT for compound **4** measured in a 0.1 T field

EPR Spectroscopy: The magnetic transitions of the different compounds can be monitored by EPR spectroscopy. At room temperature, the EPR spectrum (Figure 15) of the paramagnetic derivative *p*-rad[ZnCr(ox)$_3$] (**4**) can be viewed as the sum of the contributions of the different spin carriers in the lattice. An asymmetric signal can be observed with a maximum at g = 4.1. This signal is characteristic of the $[Cr(ox)_3]^{3-}$ fragment with a zero-field splitting of the ground state.[41] In the g = 2.0 region, the expected free

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

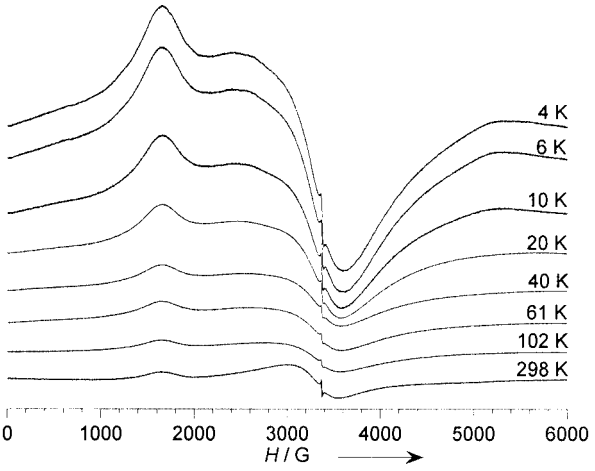

Figure 15. EPR spectra of *p*-rad[$ZnCr(ox)_3$] (**4**) at different temperatures

radical signal is superimposed with a weak contribution which originates from the chromium(III) centres. This feature is relatively broad (g = 2.057; ΔH_{pp} = 560 G) compared with previously reported salts based on *p*-rad (dipolar broadening). On lowering the temperature, the signal continuously broadens and becomes more asymmetric. At 3.2 K, the peak-to-peak width ΔH_{pp} is equal to 1130 G. A nitroxide impurity can be seen in the whole-temperature range at g = 2.005.

On the other hand, the EPR spectrum at room temperature (Figure 16) of *p*-rad[$MnCr(ox)_3$]·H_2O (**1**) shows a single line centred at g = 1.996 with a peak-to-peak width ΔH_{pp} = 350 G. The asymmetric signal of the chromium(III) moiety and the characteristic peak of the free radical are not observed. On lowering the temperature, the intensity of the signal increases and broadens to a peak-to-peak width value of 900 G at 7.6 K. Below the critical temperature, the signal splits into two components centred at g = 1.44 and g = 4.52 G. These features parallel the previously reported data for [$FeCp^*_2$][$MnCr(ox)_3$]. In this case, however, the

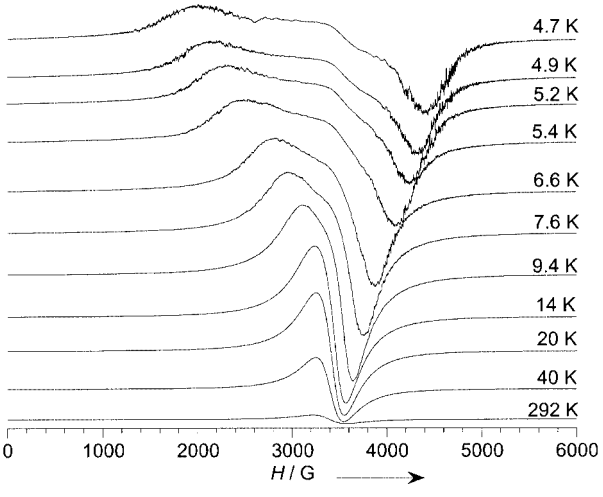

Figure 16. EPR spectra of *p*-rad[$MnCr(ox)_3$]·H_2O (**1**) at different temperatures

free radical does not show an intrinsic signal, indicating exchange interactions between the two magnetic sublattices.

The temperature dependence (Figure 17) of the EPR properties of the antiferromagnetic compound *p*-rad[$Mn(H_2O)Cr(ox)_3$]·$2H_2O$ (**7**) was investigated to allow comparison with the 2D ferromagnetic isomer *p*-rad[$MnCr(ox)_3$]·H_2O (**1**). The experiment was performed on a collection of single crystals. At room temperature, the EPR spectrum of **7** also shows a single line centred at the same g-value (1.996) with a peak-to-peak width ΔH_{pp} = 420 G. On lowering the temperature, the intensity of the signal increases, reaches a maximum around 12 K. It then decreases and broadens to a peak-to-peak width value of 560 G at 7.9 K. Below the Néel temperature the signal decreases dramatically, as expected for an antiferromagnetic ordered phase. A very weak anisotropic signal remains at low temperature which can be ascribed to the radical contribution and possible traces of chromium(III).

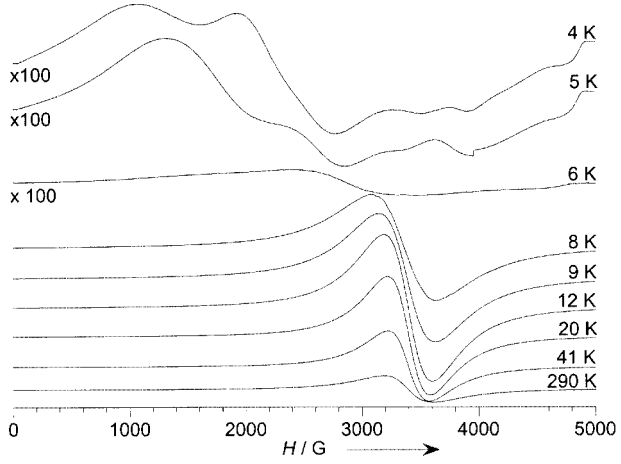

Figure 17. EPR spectra of *p*-rad[$Mn(H_2O)Cr(ox)_3$]·$2H_2O$ (**7**) at different temperatures

The EPR spectrum (Figure S4) of *p*-rad[$CoCr(ox)_3$]·$2H_2O$ (**2**) at room temperature is essentially featureless. The presence of the orbitally degenerate Co^{2+} cation induces a fast spin relaxation at high temperatures. Below 60 K, a broad and asymmetric feature appears at g = 1.54. On decreasing the temperature further, the signal becomes more intense and shifts slowly upfield. Below T_C, the main feature is accompanied by a small hump at very low fields which can be attributed to ferromagnetic resonance.

The temperature dependence of the EPR spectrum (Figure S5) for *p*-rad[$NiCr(ox)_3$]·H_2O (**3**) is similar to that observed for **1**. Only one broader signal (ΔH_{pp} = 1230 G) centred at g = 2.049 can be detected in the paramagnetic regime (the sharp line at g = 2.005 can be ascribed to a nitroxide impurity representing less than 0.01%). This is again an indication of the exchange interaction between the free radical and the magnetic network. At temperatures close to T_C, the main feature becomes anisotropic and a low-field component appears. This signal shifts downfield at a high rate (700 G/K) when decreasing the temperature, indicating the rise of the internal field in the solid.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

As expected, the systematic study of the EPR spectra reveals drastic changes which occur close to T_C for all the magnetically ordered compounds. In general, the shift of the radical resonance below the ordering temperature could be used to monitor the strength of the internal magnetic field. This has been the case in hybrid metal-radical layered systems of the brucite type[42] or in the family of compounds $[FeCp^*_2][MM'(ox)_3]$. In our case, however, the radical is not merely a spectator since it couples with the anionic lattice by exchange interactions. Compared with the decamethylferricenium derivative, where most of the spin density is located in the iron centre and hence sandwiched by Cp* molecules, the nitroxide radical is less protected from the surroundings and it can readily interact with the neighbouring spin carriers.

Conclusion

The ability of cationic nitronyl nitroxide type free radicals to act as countercations of oxalato-bridged bimetallic compounds has been studied in this work. Hybrid materials which combine nitroxide free radicals and ferromagnetic layers with similar magnetic properties as those previously observed in the quaternary onium analogues $[AR_4][MCr(ox)_3]$ (A = N, P) have been obtained. The syntheses of the latter proceed in high yield by fast precipitation in aqueous solutions due to the nonpolar character of the tetrabutylammonium or tetraphenylphosphonium cations. In our case, the presence of the radical moiety confers high polarity on the cation, solvation becomes more effective and precipitation of the extended compound is hindered. This is particularly the case for M = Mn (and also Zn) since the tris(oxalate)chromate(III) ligand has a lower affinity for this larger cation. Working in concentrated conditions and in less polar solvents (ethanol/water mixtures) invariably affords the hybrid 2D magnets as fine powders (*kinetic control*) while performing the syntheses in more dilute aqueous solutions (*thermodynamic control*) yields new heterodimetallic oxalato-based lattices which result from partial occupation, by water molecules, of the vacant positions of the divalent metal. We have shown that the size and shape of the free radical determines the geometry and dimensionality of these novel hybrid materials: *p*-rad stabilizes a 3D achiral network of hellicoidal hexagonal channels, while *m*-rad acts as countercation to a ladder-like anionic structure. The influence of the free radical in the structure of the inorganic host is made possible by the formation of hydrogen bonds which involve adventitious solvent molecules.

This family of compounds, in which ferromagnetic layers coexist with free radical species, can be considered as multifunctional hybrid magnets such as those based on the paramagnetic decamethylferricinium cation $[FeCp^*][M^{II}M^{III}(ox)_3]$. As was observed in this previously reported example, the paramagnetic cation (in this case, the nitronyl nitroxide free radical) has little influence on the ordering temperatures but has a marked effect on the coercive field values, although this effect can be correlated with other features such as the particle size. Both magnetic parameters (critical temperatures and coercive fields) are similar to those found in other families of 2D oxalate-based magnets with low T_C (around 5 K) and H_{coer} values for the Mn-containing compounds and higher ordering temperatures (11−15 K) for the Ni and Co complexes. The most important difference between the two families of hybrid magnets is that whereas the two magnetic sublattices are quasi-independent in $[FeCp^*][M^{II}M^{III}(ox)_3]$, a sizeable interaction between the free radicals and the inorganic layers has been indicated by EPR spectroscopic studies in the present case.

Further work on this topic will be directed towards the preparation of nitronyl nitroxide cationic free radicals based on tetraalkylammonium salts which can be more efficient templates of the 2D hexagonal oxalate-based network.

Experimental Section

General Procedure for the Preparation of Hybrid Magnets 1−6: $Ag_3[Cr(ox)_3]$ (0.08 mmol) was added to a solution of the cationic free radical (prepared as the iodide salts *p*-radI or *m*-radI) (0.25 mmol) in EtOH (5 mL, 96%) and H_2O (1 mL). After 30 min stirring, AgI was removed by centrifugation. In a separate beaker, a solution of $[M(H_2O)_n]Cl_2$ (M = Mn, Co, Ni, Zn) (0.25 mmol) in EtOH (5 mL, 96%) and H_2O (1 mL) was allowed to react with $Ag_3[Cr(ox)]_3$ (0.17 mmol). After stirring for 30 min, AgCl was removed by centrifugation. The two supernatant solutions were mixed and the precipitated green powder was collected by centrifugation.

Preparation of 7−8: The cationic free radical (*p*-radI or *m*-radI) (100 mg, 0.26 mmol) was added to a suspension of $Ag_3[Cr(ox)_3]$ in EtOH (5 mL). After 30 min stirring, AgI was filtered and a solution of $Mn(ClO_4)_2·6H_2O$ (32 mg, 0.088 mmol) in a minimum amount of water was added to the filtrate. The resultant green suspension became clear after addition of H_2O (2 mL) and the mixture was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

left undisturbed in the dark. Green single crystals suitable for X-ray structure analysis appeared within a few hours.

***p*-rad[MnCr(ox)$_3$(H$_2$O)]·2H$_2$O (7):** Yield: 94 mg (60%). IR (KBr): $\tilde{\nu}$ = 1630 (CO), 1376 (NO), 1140 cm^{-1} (NO). $C_{19}H_{25}CrMnN_3O_{17}$ (674.3): calcd. C 33.84, H 3.74, N 6.23; found C 33.73, H 3.75, N 6.14.

***m*-rad[MnCr(ox)$_3$(H$_2$O)$_2$]·2H$_2$O (8):** Yield: 96 mg (62%). IR (KBr): $\tilde{\nu}$ = 1634 (CO), 1378 (NO), 1139 cm^{-1} (NO). $C_{19}H_{27}CrMnN_3O_{18}$ (692.4): calcd. C 32.96, H 3.93, N 6.07; found C 32.78, H 3.86, N 6.19.

Physical Measurements: All magnetic measurements were carried out on powdered samples with a Quantum Design MPMS-XL-5 SQUID magnetometer. Variable temperature susceptibility measurements were carried out on polycrystalline samples in the 2−300 K temperature range at a magnetic field of 0.1 T. Diamagnetic contributions were corrected with Pascal's constants. Isothermal magnetisation measurements were collected in the H = 0−5 T field range at 2 K. The hysteresis studies were performed between 5 and −5 T, at 2 K, cooling the samples at zero field. AC measurements were performed at different frequencies with an oscillating magnetic field of 0.395 mT. The ESR spectra were recorded on powdered samples in the X-band region (ν = 9.47 GHz) with a Bruker E500 ELEXSYS spectrometer equipped with a helium cryostat in order to study the thermal dependence in the temperature range 300−3 K. IR transmission measurements of pressed KBr pellets were recorded at room temperature with a Nicolet Avatar 320 FT-IR spectrophotometer in the range 4000−400 cm^{-1}. CHN elemental analyses were carried out with a CE instruments EA 1110 CHNS analyser on samples dried under vacuum. Thermogravimetric measurements were carried out with a Mettler Toledo TGA/SDTA 851e apparatus.

X-ray Crystallographic Studies: X-ray diffraction data of **7** and **8** were collected at room temperature with a Nonius KappaCCD diffractometer using a graphite-monochromated Mo-K_α radiation source (λ = 0.71073 Å). The Denzo and Scalepack[43] programs were used for cell refinements and data reduction. The structures were solved by direct methods using the SIR97[44] program with the WinGX[45] graphical user interface. The structural refinements were carried out with SHELX-97.[46] All nonhydrogen atoms were refined anisotropically. A multiscan absorption correction, based on equivalent reflections, was applied to the data using the program SORTAV[47] ($T_{max.}/T_{min.}$ 0.8972/0.5899 for **7** and 0.995/0.898 for **8**). H atoms of water molecules were found from difference maps and were positionally refined with geometric restraints (O−H 0.82 Å and H···H 1.30 Å) and with U_{iso}(H) = 1.2U_{eq}(O). The remaining H atoms were placed in calculated positions and refined using a riding model with C−H = 0.97 Å and U_{iso}(H) = 1.2U_{eq}(C). All nonhydrogen atoms were refined anisotropically. Crystallographic data are summarised in Table 2.

CCDC-149375 and -236227 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

Novel Topotactic Conversion of an Organically Templated Vanadyl Phosphate Framework into Layered Structures

Minakshi Asnani,[a] Sanjeev Sharma,[a] Samuel E. Lofland,[b] Kandalam V. Ramanujachary,[b] Philippe A. Buffat,[c] and Arunachalam Ramanan*[a]

Keywords: Vanadyl phosphate / Topotactic / Intercalation / Ion exchange

This paper reports a novel topotactic exchange reaction of the ethylenediammonium intercalated mixed-valent vanadyl phosphate, $(H_3NCH_2CH_2NH_3)_{0.5}[V^{4+}_{0.45}V^{5+}_{0.55}O_2PO_4\{P(OH)_2\}_{0.483}]$, with monovalent cations at room temperature. Alkali metal ions and other monovalent cations (e.g. K^+, Rb^+, Tl^+, NH_4^+) behave similarly, leading to intercalated layered vanadyl phosphates (basal spacing about 6.3–6.5Å). The amount of cations incorporated between the layers is essentially dictated by the charge present on the layers (equivalent to the amount of V^{4+} present). The present approach has enabled us to obtain a new phase, $Tl_{0.45}VOPO_4{\cdot}0.33H_2O$, under ambient conditions. All the layered solids show low-temperature magnetic behaviour similar to hydrothermally synthesised products. Treatment with silver ions resulted in a new silver vanadium(V) phosphate $Ag_{3.5}VP_{1.5}O_8$ [monoclinic; a = 22.557(4), b = 7.973(3), c = 12.430(3) Å and β = 112.26(2)°] coated with silver metal nanospheres (ca. 15 nm) which, on heating above 400 °C, yielded a 2:1 mixture of two thermodynamically stable phases, $Ag_2VO_2PO_4$ and Ag_3PO_4.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Inorganic layered materials have received considerable attention as hosts for the intercalation of guest molecules and ion exchange reactions.[1] Intercalation compounds of vanadyl phosphate with aliphatic and aromatic amines,[2] heterocycles,[3] alcohols and diols[4] as well as carboxylic acids[5] and their amides[6] have been extensively studied. Vanadyl phosphates are important materials owing to their potential uses as sensors, fuel cells and catalysts for the oxidation of hydrocarbons.[7,8] Intercalated vanadyl phosphates can be synthesised either through direct hydrothermal treatment or via ion-exchange reactions.[9−16] The ion-exchange behaviour of several organically intercalated oxides is well-known.[17,18] However, to the best of our knowledge, exchange reactions with organically intercalated vanadyl phosphates have not been reported. In this paper, we describe a novel room temperature topotactic reaction of ethylenediammonium intercalated vanadyl phosphate with various metal ions. Our investigations reveal that only monovalent ions viz. K^+, Rb^+, Tl^+ and NH_4^+ undergo facile exchange reactions with ethylenediammonium intercalated vanadyl phosphate. The reaction with silver ions is unusual since it leads to the formation of a hitherto unknown silver vanadium phosphate coated with silver nanoparticles.

Results and Discussion

A single-crystal structure analysis of the parent compound, ethylenediammonium intercalated mixed-valent vanadyl phosphate, $(H_3NCH_2CH_2NH_3)_{0.5}[V^{4+}_{0.45}V^{5+}_{0.55}O_2PO_4\{P(OH)_2\}_{0.483}]$ (hereafter referred to as enVPO) has been reported earlier.[19] The crystal structure of this phase is analogous to that of $(H_3NCH_2CH_2NH_3)$ $[(VO)_2(PO_4)_2(H_2PO_4)]$ reported by Harrison et al.[20] except that the phosphate groups linking the vanadyl phosphate layers (VPO) are partially disordered in our case. The structure contains layers consisting of VO_5 square pyramids and PO_4 tetrahedra sharing vertices in the *ab*-plane. VO_5 groups in adjacent layers are connected through a disordered tetrahedral $PO_2(OH)_2$ unit and the unprotonated oxygen atoms of these tetrahedra can also be considered as a part of the vanadium octahedra with long V−O bonds (2.2 Å) (Figure 1). The VPO configuration results in puckered $[VO_2PO_4]^{2-}$ layers oriented in the [101] direction. The layers are connected by $PO_2(OH)_2$ tetrahedral units to form a 3D network along the *c*-axis. Ethylenediammonium cations occupy the cavities formed between the $PO_2(OH)_2$ tetrahedra in the interlayer region. The open framework structure of

enVPO makes the organic cation and the bridging phosphate group accessible to metal cation guest species. In this work, we attempted to exchange the ethylenediammonium cation with various metal ions. Before every exchange reaction, care was taken to ascertain the single-phase nature of enVPO using powder X-ray diffraction, TGA, DTA, cerimetric titration and EDAX. Initial reactions indicated that enVPO was quite stable in aqueous solutions for several days in the presence of lithium, sodium, cesium and various divalent metal ions (Mg^{2+}, Ca^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+} or Cu^{2+}). A reaction occurred only when the metal ion was potassium, rubidium, thallium, ammonium or silver. A preliminary analysis clearly showed the presence of both ethylenediammonium and phosphate groups in the filtrate.

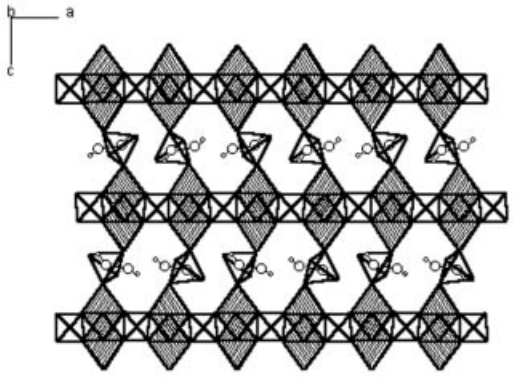

Figure 1. Crystal structure of enVPO viewed along *b* axis; during the exchange reaction, the bridging phosphate groups (coloured orange) and the ethylenediammonium cations leach out

Reactivity with Metal Ions and the Ammonium Ion

EnVPO undergoes a facile exchange reaction with K^+, Rb^+, Tl^+ and NH_4^+ under mild conditions to form metal or ammonium intercalated vanadyl phosphates, M_xVPO (M = K, Rb, Tl and NH_4). Powder X-ray diffraction patterns of the exchanged products were very different from that of parent enVPO (Figure 2) with a basal spacing of 7.9Å. The presence of dominant 00l reflections in the products indicates strong lamellar characteristics ($c \approx$ 6.3−6.5Å) similar to other metal intercalated layered vanadyl phosphates. In the cases of the potassium,[21−24] rubidium[21−26] and ammonium[26,27] incorporated solids, the observed basal spacings were similar to those reported in the literature. Furthermore, powder X-ray diffraction patterns of the exchanged products matched well with simulated patterns of metal intercalated vanadyl phosphates.[11,12] While the parent enVPO did not contain any water molecules, the exchanged products M_xVPO were hydrated as indicated by FTIR spectroscopy and thermal analyses. The amount of water and the phase changes of the solids were determined by TGA and DTA studies (Figure 3). Upon heating, all solids exhibited an initial weight loss below 100 °C. K_xVPO showed an additional weight loss of 6.3% in the temperature range 150 to 230 °C. Above this temperature there were no further weight losses. Rb_xVPO also showed similar thermal behaviour. $(NH_4)_xVPO$ exhibited two additional weight losses, namely 6.6% in the temperature range 130 to 200 °C and a broad weight loss of 8.3% in the temperature range 210 to 430 °C. Thallium intercalated vanadyl phosphate Tl_xVPO, exhibited a much lower weight loss (<2%) suggesting very little incorporation of water. It should be mentioned here that thallium intercalated vanadyl phosphate, Tl_xVPO has been synthesised for the first time by a low temperature method in this study. DTA of all the solids showed a broad endothermic peak corresponding to the loss of water molecules except in $(NH_4)_xVPO$ in which it also includes loss of ammonia. In all cases, the products were X-ray amorphous after heating above 300 °C.

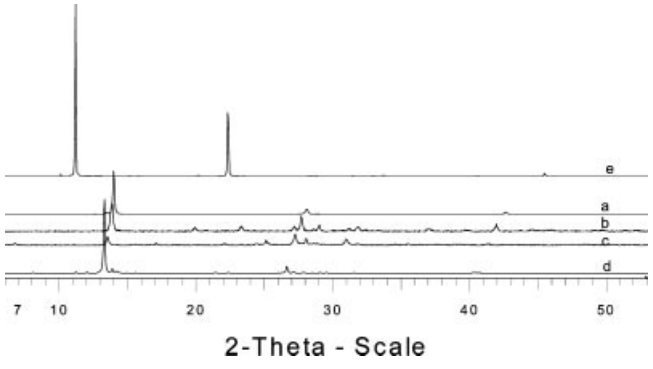

Figure 2. Powder X-ray patterns of (a) K_xVPO, (b) Rb_xVPO, (c) Tl_xVPO, (d) $(NH_4)_xVPO$ and (e) enVPO

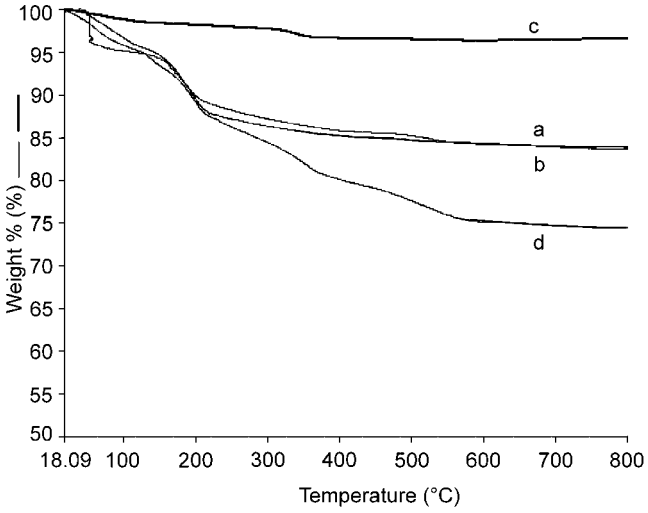

Figure 3. TGA curves of (a) K_xVPO, (b) Rb_xVPO, (c) Tl_xVPO and (d) $(NH_4)_xVPO$

The absence of the ethylenediammonium ion was further confirmed by FTIR spectroscopy. All the exchanged solids showed the presence of strong bands around 1055 and 940 cm^{-1} due to PO_4 groups, a peak around 990 cm^{-1} due to the V=O stretch and, similar to alkali metal intercalated vanadyl phosphates, a broad weak band around 680 cm^{-1} due to the V−O−P lattice.[10,11] In the case of $(NH_4)_xVPO$, additional peaks were observed around 3300 and 1350 cm^{-1} due to N−H stretching and bending vibrations. $$(H_3NCH_2CH_2NH_3)_{0.5}[V^{4+}_{0.45}V^{5+}_{0.55}O_2PO_4\{P(OH)_2\}_{0.483}] + 0.45M^+(aq) + yH_2O \longrightarrow M^+_{0.45}V^{4+}_{0.45}V^{5+}_{0.55}OPO_4.yH_2O + 0.5[H_3NCH_2CH_2NH_3]^{2+}(aq) + 0.966[H_2PO_4]^-(aq) + 0.034(OH)^-(aq) \quad (1)$$

studies revealed a plate like morphology for all solids which is similar to metal intercalated layered vanadyl phosphates.[11] Cerimetric titrations showed that the V^{4+}/V^{5+} ratio in the parent enVPO as well as in the metal exchanged products remained almost the same within experimental error. EDAX analysis indicated that the P/V ratio in the parent enVPO was about 1.5 which is closer to the composition established by a single-crystal X-ray diffraction analysis.[19] However, in the exchanged products, the P/V ratio was about 1 with $x \approx 0.5$ for all solids. On the basis of powder X-ray diffraction, TG, EDAX and chemical analyses, we established the general composition $M_xVOPO_4{\cdot}yH_2O$ for all the exchanged products (Table 1).

As in normal ion exchange reactions, we expected that the ethylenediammonium cations would be replaced by an equivalent amount of metal ions. However, our observations suggest that in addition to the organic cations diffusing out of the structure, the phosphate groups linking VPO layers also leached out as a result of excess alkali metal cations [Equation (1)]. It seems that the amount of metal cations incorporated between the layers of the final products is essentially dictated by the charge present on the layers (equivalent to the amount of V^{4+} present). Also, the amount of water molecules entering between the layers depends on the nature of the cation. During the exchange reaction, the oxidation state of vanadium remained the same, i.e. no redox reaction occurred between the species present in the aqueous solution and the mixed-valent vanadyl phosphate. Since the product (M_xVPO) shows a strong structural resemblance to the parent phase (enVPO) along the [101] direction, the reaction can be considered as *topotactic*.[28] The structural change taking part in the exchange reaction is shown in Scheme 1. During the exchange reaction, ethylenediammonium groups are exchanged by metal ions. In addition, the phosphate groups linking the layers are leached out due to the presence of excess metal cations. The scheme also shows the reduction in the basal axis during the transformation. The exchange reaction can be written as in Equation (1).

Our results indicate that exchange reactions take place only when diameter of the monovalent cation is in the range of 2.7−3.0 Å, i.e. similar to the kinetic diameter of the ethylenediammonium cation (2.8 Å). The reaction with thallium ions led to the formation of a yet uncharacterised solid, $Tl_{0.45}VOPO_4{\cdot}0.33H_2O$. The mild conditions that we employed here imply a broad scope for investigating exchange reactions of other organically intercalated solids and, in particular, metal phosphates in order to obtain new metastable phases.

We also examined whether the ion-exchange behaviour of M_xVPO prepared by the topotactic reaction is similar to that reported in the literature for related systems. For example, K_xVPO exhibits facile and complete ion exchange with ammonium ions. A similar observation has been reported by Zima et al.[29] where the ion exchange ceased after 14 days at $x = 0.15$. However, in our case a complete

conversion into $(NH_4)_xVPO$ was achieved within 2 days. The reverse reaction, i.e. conversion of $(NH_4)_xVPO$ to K_xVPO which has not reported so far, could also be achieved. However, in this case only partial ion exchange was observed (Figure 4). It is quite possible that the arrangement of the metal atoms and the stacking of vanadyl phosphate layers in M_xVPO may be different if the method of preparation is varied since a true equilibrium is possible only when crystals are grown under hydrothermal conditions. Powder X-ray diffraction is insufficient to give deeper insight into the complete crystal structure.

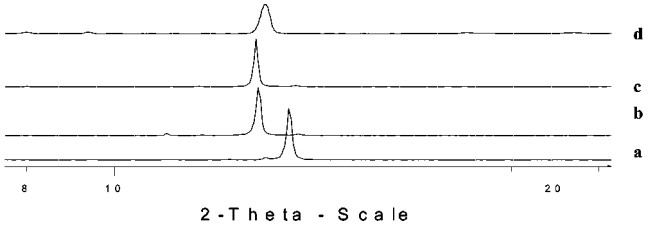

Figure 4. Powder X-ray diffraction patterns of (a) K_xVPO, (b) $(NH_4)_xVPO$ (c) ammonium exchanged K_xVPO and (d) potassium exchanged $(NH_4)_xVPO$

Magnetic Properties

Low-temperature magnetic measurements were performed on all metal exchanged products to establish the nature of their magnetic properties and spin concentrations. The magnetic behaviour of powdered samples of the mixed-valent M_xVPO is shown in Figure 5 in the form of a $1/\chi_m$ versus T plot. The susceptibility data for all samples were modelled over the temperature range 5 to 60 K according to the Curie−Weiss equation. While Rb_xVPO and K_xVPO showed ferromagnetic interactions, Tl_xVPO and $(NH_4)_xVPO$ showed antiferromagnetic interactions at low temperature. This behaviour is clear in the $\chi_m T$ versus T plots (Figure 6). The values of the Curie constants (0.38 and 0.39 emu K mol^{-1}) for the K and Rb compounds, respectively, are close to the values obtained for compounds of similar composition. Analogous behaviour was observed for the hydrothermally prepared $K_{0.5}VOPO_4{\cdot}2H_2O$ using the iodide method[30] and $NaBH_4$ as a reducing agent.[32] Our data is in accordance with that reported by Papoutsakis et al.[27] but is in contrast to the observations of Roca et al.[31] A plot of $\chi_m T$ versus T for $(NH_4)_xVPO$ and

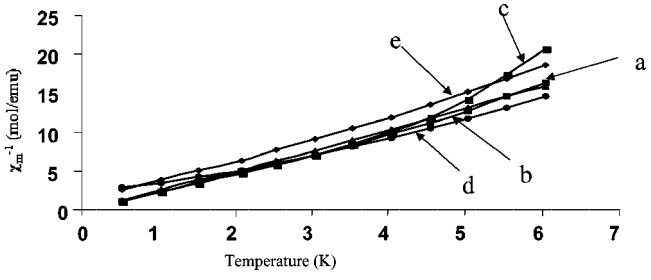

Figure 5. χ_m^{-1} versus temperature plots for (a) enVPO, (b) K_xVPO, (c) Rb_xVPO, (d) Tl_xVPO and (e) $(NH_4)_xVPO$; the susceptibilities have been corrected for the amount of reduced vanadium

Tl_xVPO shows a strong deviation below 25 K indicating antiferromagnetic nearest-neighbour exchange interactions. Similar magnetic behaviour has been observed for $(NH_4)VOPO_4$ prepared under hydrothermal conditions.[33,34] A fully reduced thallium vanadyl phosphate $Tl_3(V^{IV}O)(HV_2{}^{IV}O_3)(PO_4)_2(HPO_4)$ and fully oxidised $Tl(V^VO_2)(HPO_4)$ were reported to be paramagnetic even at low temperatures.[35] However, mixed valent $Tl_6V_6P_6O_{31}$ showed low temperature antiferromagnetic behaviour.[36]

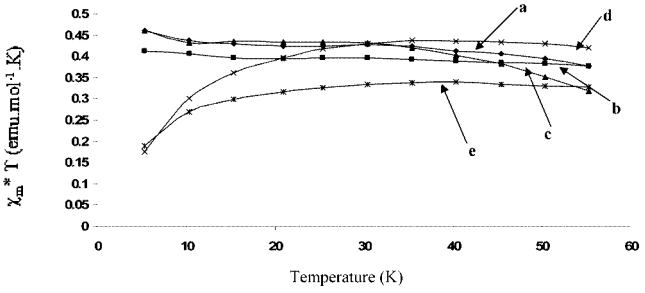

Figure 6. $\chi_m T$ versus temperature plots for (a) enVPO, (b) K_xVPO, (c) Rb_xVPO, (d) Tl_xVPO and (e) $(NH_4)_xVPO$; the susceptibilities have been corrected for the amount of reduced vanadium

Reactivity with Silver Ions

While the organic cation in enVPO could be readily exchanged with alkali metal or ammonium cations, different behaviour was observed with silver. A powder X-ray diffraction pattern of the product indicated a complete collapse of the parent layered structure. The reflections of this phase did not match with any of those reported previously. However, all peaks could be indexed to the monoclinic system with cell parameters, a = 22.557(4), b = 7.973(3) and c = 12.430(3) Å and β = 112.26(2)° using CRYSFIRE[37] (Figure 7).

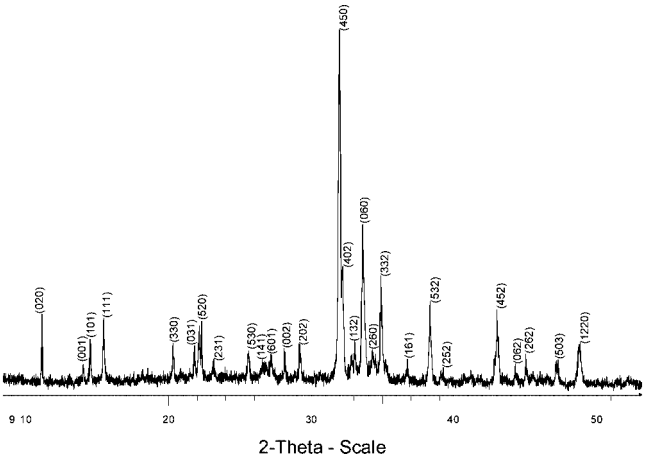

Figure 7. Powder X-ray diffraction pattern of $Ag_{3.5}VP_{1.5}O_8$

The solid did not show any appreciable weight loss as indicated by TG analysis (<3%) whereas DTA showed an endothermic peak around 620 K. TGA and DTA indicated the absence of organic groups which was further confirmed by FTIR spectroscopy and EDAX analysis. On the basis of

$$(H_3NCH_2CH_2NH_3)_{0.5}[V^{4+}_{0.45}V^{5+}_{0.55}O_2PO_4\{P(OH)_2\}_{0.483}] + 3.5Ag^+ \text{ (excess)} + H_2O \longrightarrow Ag_{3..5}VP_{1.483}O_{7..958} (\sim Ag_{3..5}VP_{1..5}O_8) + 2.966\ H^+ (aq) + 0.5\ (H_3NCH_2CH_2NH_3)^{2+} (aq) \quad (2)$$

EDAX, we determined the approximate composition of the solid to be $Ag_{3.5}VP_{1.5}O_8$. Cerimetric titrations confirmed that the solid was a fully oxidised vanadium(V) phosphate. The reaction of silver ions with enVPO can be written as in Equation (2) and (3).

$$(H_3NCH_2CH_2NH_3)^{2+} \rightleftharpoons (H_2NCH_2CH_2NH_2) + 2H^+ \longrightarrow Ag\ (metal) \quad (3)$$

To eliminate the possibility of photoreduction, the treatment of enVPO with silver ions was also carried out in dark. The products obtained under these conditions were identical. In order to confirm the presence of metallic silver and the cell parameters derived from powder X-ray pattern, we conducted electron microscopic studies on the silver exchanged enVPO product. The phase was found to be sensitive to the electron beam, resulting in rapid amorphisation. Transmission electron microscopic studies (Figure 8) clearly revealed the presence of nanospheres of silver metal particles (≈15 nm) decorated on plate like crystals of silver vanadyl phosphate. This was further confirmed by spot emission analysis. Since the fraction of silver metal in the sample was considerably low, its presence could not be observed in the powder X-ray diffraction pattern.

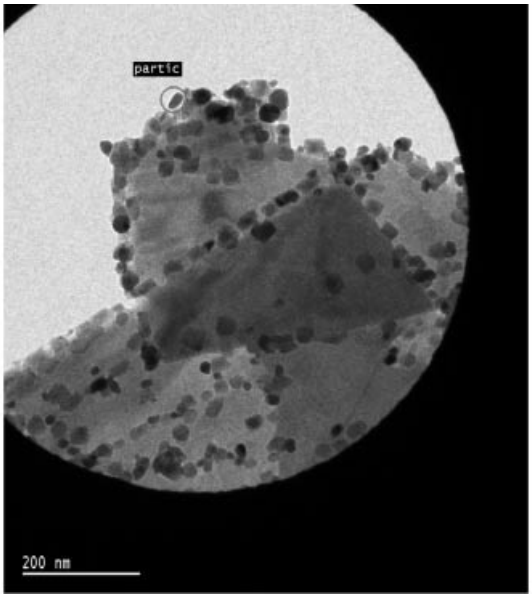

Figure 8. TEM of $Ag_{3.5}VP_{1.5}O_8$ showing nanoparticles of Ag (ca. 15 nm) on the AgVPO crystals

The exchanged products obtained in this work are all metastable. To probe the phase changes, if any, in $Ag_{3.5}VP_{1.5}O_8$, the sample was heated in air at various temperatures. A powder X-ray diffraction pattern showed (Figure 9) that the phase was stable up to 200 °C. Further heating in the temperature range 250 to 350 °C resulted in the loss of crystallinity. Interestingly, above 400 °C,

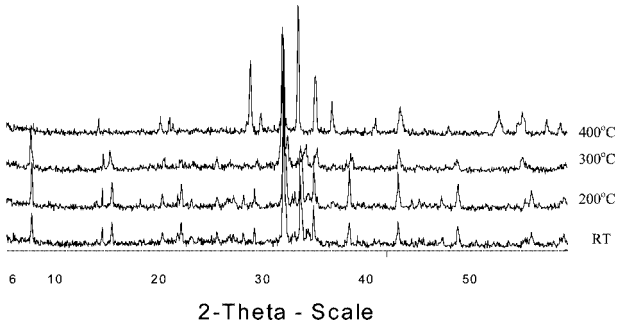

Figure 9. Powder X-ray diffraction patterns of $Ag_{3.5}VP_{1.5}O_8$ on heating: At 400 °C transformation to $Ag_2VO_2PO_4$ and Ag_3PO_4 takes place

$Ag_{3.5}VP_{1.5}O_8$ became completely transformed into a mixture of two thermodynamically stable phases, $Ag_2VO_2PO_4$ and Ag_3PO_4 [Equation (4)]. It should be remembered that TGA did not indicate any weight loss during this transformation. The presence of these two phases was further confirmed by refining the powder pattern using the Rietveld profile fitting technique (using TOPAS Version 2) on the basis of structural models reported for $Ag_2VO_2PO_4$ and Ag_3PO_4.[38,39] Using the software TOPAS 2, we also estimated the ratio of the two phases $Ag_2VO_2PO_4$ and Ag_3PO_4 to be 2:1 (Figure 10). On the basis of powder X-ray diffraction data and chemical analysis, we inferred the initial composition of the phase to be $Ag_{3.5}VP_{1.5}O_8$ according to the equation given below. EDAX analysis is also consistent with this observation.

$$Ag_{3.5}VP_{1.5}O_8 \xrightarrow{\Delta,\ 400^oC} Ag_2VO_2PO_4 + 0.5Ag_3PO_4 \quad (4)$$

The structural change taking part in the exchange reaction with silver ions is shown in Scheme 2. During the exchange reaction, ethylenediammonium groups are exchanged by metal ions. Unlike alkali metal cations, the phosphate groups linking the vanadyl phosphate layers remain intact. It appears that the initial reaction of enVPO with silver ions occurs via ion exchange to form silver intercalated vanadyl phosphate. It appears that the weakly acidic ethylenediammonium cations appearing in the aqueous phase dissociate to form ethylenediamine which reduces silver ions to metallic silver [Scheme 2, Equations (2) and (3)]. This mechanism is quite probable in view of the electron microscopic observation that nanoparticles of silver metal are deposited on the edges of the plate-like crystals.

In order to rationalise the occurrence of excess silver in the phase, we further investigated room temperature reac-

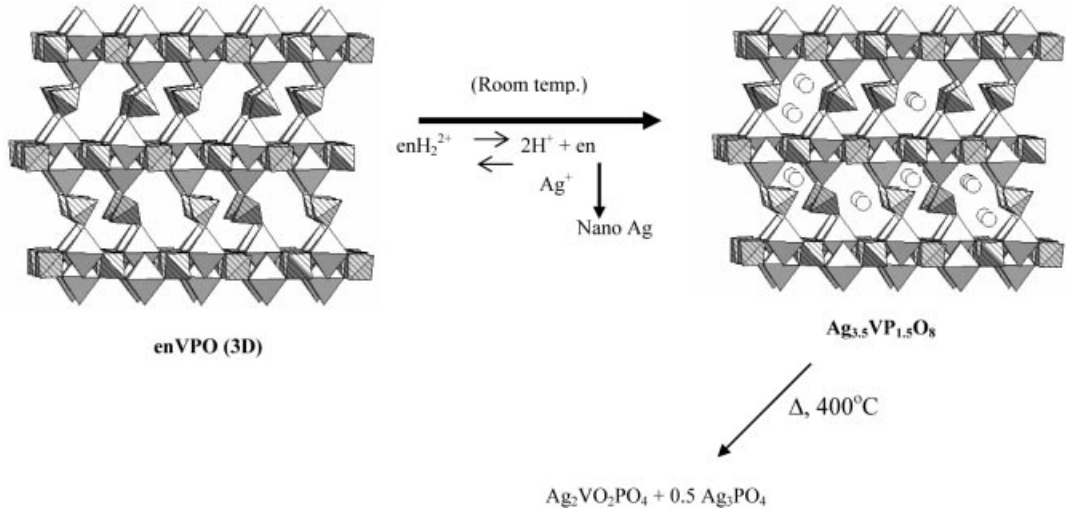

Scheme 2

tions of silver ions with other known vanadium phosphates such as $VOPO_4{\cdot}2H_2O$ and $VO(H_2PO_4)_2$. To our surprise, we obtained two possibly new phases whose powder X-ray patterns did not match with those of any other AgVPO phases reported in the literature. Also, the patterns did not show any resemblance to that of $Ag_{3.5}VP_{1.5}O_8$, suggesting that the reactions occur through different mechanisms. An EDAX analysis of the two phases indicated an Ag:V:P ratio of 2:1:1. SEM of the two solids revealed differences in morphology, i.e. a rod like morphology for the product from treatment of $VOPO_4{\cdot}2H_2O$ with silver whereas a globular morphology was observed for the phase resulting from treatment of $VO(H_2PO_4)_2$ with silver ions (Figure 11). The powder pattern of silver exchanged $VOPO_4{\cdot}2H_2O$ showed dominant 00l reflections and a basal spacing of 10.7 Å (Figure 12). However, all peaks corresponding to the solid obtained by treatment of Ag^+(aq) with $VO(H_2PO_4)_2$ could be indexed to the monoclinic system with $a = 10.904(7)$, $b = 23.196(2)$, $c = 5.680(2)$ Å and $\beta = 96.83(4)°$ using CRYSFIRE[37] (Figure 13). Since single-crystals could not be grown for these metastable products, further structural characterisations of these new silver vanadium phosphates are currently being attempted using ab initio computer modelling methods. Interestingly, both products undergo

transformation to $Ag_2VO_2PO_4$ upon heating to around 100 °C in air confirming that the Ag:V:P ratio is 2:1:1. $Ag_2VO_2PO_4$ has also been prepared previously by a solid state reaction carried out at high temperatures (>500 °C).[38] However, our method appears to be a convenient low temperature route for the preparation of single phase $Ag_2VO_2PO_4$. It is significant to note that silver vanadium phosphates are mostly synthesised using solid-state reactions whereas the soft chemistry route remains somewhat unexplored. It appears from our work as well as from other

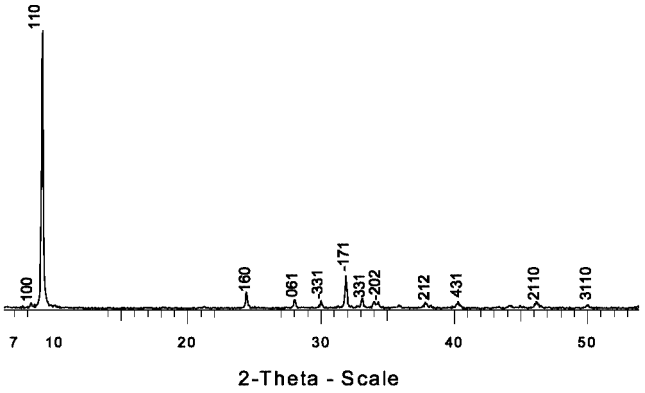

Figure 13. Powder X-ray diffraction pattern of the product obtained from the reaction of silver ions with $VO(H_2PO_4)_2$

reports available in the literature that vanadium based solids such as VO_2, V_2O_5, $NaVO_3$ etc. as well as vanadyl phosphates show unusual reactivity towards silver ions in aqueous solution at room temperature yielding fully oxidised vanadate or vanadium phosphate phases. For example, Kittaka[40] and Znaidi et al.[41] observed the formation of $AgVO_3$ by treatment of vanadium oxide xerogel with aqueous silver ions. We have also synthesised β-$AgVO_3$ nanorods coated with nanosilver through a reaction between organically intercalated vanadium oxides, $(org)_xV_2O_5$, with an excess of silver ions.[42,43] In this context, our observations and the earlier findings are quite significant for further investigations of the unusual reaction between vanadium compounds and silver ions. Further experiments are necessary to fully understand the reaction mechanism.

Conclusions

The reaction of enVPO with suitably sized aqueous cations viz. K, Rb, Tl, NH_4 at room temperature is *topotactic* and forms intercalated vanadyl phosphates, $M_{0.45}VOPO_4{\cdot}yH_2O$. Vanadyl phosphate shows unusual room temperature reactivity with silver ions under aqueous conditions. The reaction of enVPO with silver ions occurs through a different mechanism and forms a new metastable phase, $Ag_{3.5}VP_{1.5}O_8$. The current approach may be quite significant for the exploitation of using other organically intercalated phosphates in the formation of new phases particularly with alkali metal ions.

Experimental Section

Syntheses: All the reagents were obtained from Aldrich and were used without further purification. Ethylenediammonium intercalated vanadyl phosphate, $(H_3NCH_2CH_2NH_3)_{0.5}[V^{4+}{}_{0.45}V^{5+}{}_{0.55}O_2PO_4\{P(OH)_2\}_{0.483}]$ (enVPO) was synthesised by a hydrothermal reaction of ethylenediamine (en), vanadium pentoxide and phosphoric acid at 180 °C for 10 h as described earlier.[19] In a typical synthesis, V_2O_5 (0.2 g) was treated with H_3PO_4 (2 mL, 85%), en (0.17 mL) and distilled water (30 mL) in the molar ratio

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

V_2O_5:H_3PO_4:en:H_2O = 1:32.4:2.4:1515. The mixture was transferred to a 45 mL Teflon lined Parr acid digestion reactor and the reaction vessel was heated at 180 °C for 10 h under autogenous pressure before cooling to room temperature at 10 °C/h. The resultant green coloured powder was washed with distilled water, acetone and allowed to dry in air. Whenever we employed nickel or cobalt powder, we obtained a phase close to enVPO but with varying degrees in the oxidation state of the vanadium. In this work, the initial precursor enVPO was prepared in the absence of metal powders. Cerimetric titrations showed that the average oxidation state of vanadium was around 4.55. On the basis of EDAX, CHN analysis and cerimetric titration, we arrived at the approximate composition for enVPO given above. Exchange reactions were carried out by suspending enVPO (0.5 g) in an aqueous solution of the appropriate metal chlorides (75 mL, 2 M; for silver, silver nitrate was used) for two days at room temperature. Complete exchange took a longer time with lower concentrations of the metal salt (e.g. 4 d with 1 M and 6 d with 0.5 M aqueous solutions). With alkali metals and ammonium salts, there was no visible colour change. However, in case of silver ions, the progress of exchange was clearly evident from the colour change (from green to yellow) during the course of reaction. All the exchanged products were filtered, washed with distilled water and dried in air. A suspension of enVPO showed no reactivity towards lithium, sodium or divalent ions as shown by powder XRD, cerimetric titration, EDAX analysis and FTIR spectroscopy. For further ion exchanges of the layered VPO species synthesised in this study, M_xVPO (0.2 g) was suspended in an appropriate metal solution (0.5 g in 30 mL of distilled water) and stirred at room temperature (30 °C) for 2 d. The product was isolated by filtration, washed with distilled water and dried in air.

Methods: FTIR spectra were recorded in KBr pellets using a Nicolet 5DX spectrophotometer. TG/DT analyses were carried out using a Perkin−Elmer TGA7 and DTA7 system on well ground samples under a flow of nitrogen with a heating rate of 10 °C/min. SEM and EDAX were recorded using a Philips XL30 microscope. Room-temperature X-ray powder diffraction data were collected on a Bruker D8 Advance diffractometer using Ni-filtered CuK_α radiation. Data were collected with a step size of 0.02° and a count time of 2 s per step over the range $4° < 2\theta < 60°$. Transmission electron microscopic studies were carried out on a Philips CM 20 instrument operating at 200 kV. The susceptibility measurements as a function of temperature were performed with a SQUID magnetometer. Diamagnetic corrections were estimated using Pascal's constants. The average oxidation state of vanadium and the total vanadium content were determined using a cerimetric titration.

X-ray Absorption Spectra of Cu^{II} and Cu^{III} Complexes of *N*,*N*′-1,2-Phenylenebis(2-mercapto-2-methylpropionamide)

Giampaolo Barone,[a] Gianfranco La Manna,[b] and Dario Duca*[a]

Keywords: Copper / N,S ligands / X-ray absorption spectroscopy / Density functional calculations / Ab initio molecular orbital calculations

The X-ray absorption spectra of Cu^{II} and Cu^{III} complexes of *N*,*N*′-1,2-phenylenebis(2-mercapto-2-methylpropionamide) were recorded and analysed in solid phase. The EXAFS spectra of the two samples were refined with full multiple scattering path. Geometry optimisations on the Cu^{II} and Cu^{III} complexes were performed by the B3LYP density functional method, with the 6-31G(d,p) basis set, considering different spin multiplicities. The singlet state of the Cu^{III} complex was shown to be more stable than the triplet state, and a good agreement between the calculated and the corresponding experimental structure was found. Further single-point calculations on the optimised geometry were carried out at the Hartree–Fock level for obtaining molecular orbital eigenvectors and eigenvalues. The latter were employed as parameters in a new fitting approach to rationalise the shape of the K-edge of the XAS spectra.

Introduction

Stable mononuclear Cu^{III} complexes of chelating ligands can be obtained by electrochemical oxidation of the corresponding Cu^{II} complexes in solution.[1] The *N*,*N*′-1,2-phenylenebis(2-mercapto-2-methylpropionamide) Cu^{II} and Cu^{III} ions (Figure 1),[2] containing aliphatic thiolate groups in a square-planar coordination environment, can be considered as models of electron transfer copper proteins.[3−5]

X-ray absorption spectroscopy (XAS) is used to determine electronic and geometric structures of the metal centres in metal-containing proteins and model systems.[6] Indeed, information on the local environment of the probe atom can be extracted with high accuracy, by utilising fine structure analysis. Moreover, the shape and position of the absorption edge help to distinguish different oxidation states of the metal atoms in analogous complexes.[7] In particular, in the rising edge of the XAS spectra of the copper complex, a few weak peaks and shoulders might originate from transitions from 1s to 3d or 4p orbitals, which are typically attributed to bound state forbidden transitions.[6] This information is usually employed to determine the local symmetry of the transition-metal environments.[8−12]

When discussing XAS spectra, two distinct pictures are introduced: i) the photoexcitation of core electrons to bound state energy levels, in the edge region: the X-ray absorption near edge spectrum (XANES), and ii) the backscattering of the photoejected core electrons, mainly in the high energy part of the spectrum, namely the extended X-ray absorption fine structure (EXAFS). Multiple scattering (MS) EXAFS analysis allows one to neglect the contributions of the excitation of the core electrons to the bound state energy levels. MS analysis has successfully been extended into the XANES region analysis.[13−15]

A recent study on Cu^{II} and Cu^{III} complexes[8] concluded that the shape of the corresponding K-edge region depends on the electronic properties and the coordination geometry of the chelating ligand. Moreover, a shift of about 2 eV was observed in the assigned resonances when going from Cu^{II} to Cu^{III} species.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200400495**

The K-edge shape is usually very similar in complexes having the same ligands and different metal oxidation states.[7,8] The presence of three edge peaks was attributed to three electronic transitions involving the 1s, 3d and 4p orbitals of copper.[8] The positions and intensity of such transitions were evaluated by fitting the spectra and rationalised by empirical configuration interaction methods;[8] the parameters were obtained from X-ray photoelectron spectroscopy and XAS studies.

Cu^{III} complexes, characterised by chelating sulfur groups, have been recently studied by XAS, confirming that the high-spin d^8 electron configuration of Cu^{III} is stabilised by six bridged thiolate ligands.[16]

In the present work, the EXAFS spectra of the title complexes are shown, and an attempt to rationalise the XANES region by a new fitting procedure based on quantum mechanical information is carried out. For the latter, a qualitative picture of the transitions that are responsible for the XAS signals can be accomplished by the hopping of an electron from the lowest occupied molecular orbital to the lowest virtual ones,[17−19] within the frame of the orbital approximation, hence by employing a single-determinantal wave function. In the following fit procedure, the energetics determined in this way are used to reproduce the experimental XANES profile.

The necessary information from the electronic structure can be obtained by using quantum chemistry packages, such as G98W.[20] A more correct theoretical description should be given by overcoming the orbital approximation through the configuration interaction approach, for example by using recent versions of the CASSCF and CASPT2[21] methods. However, such algorithms are very time consuming, thus are not easily applicable to molecular systems of notable size, as those considered here.

Results and Discussion

1. EXAFS Spectra

The Cu^{III}-phmi (see Exp. Sect.) EXAFS spectrum, together with its Fourier transform, is shown, as an example, in Figure 2. The interatomic distances were extracted from the extended X-ray absorption fine structure, by the full multiple scattering theory,[22] and shows good agreement with previous X-ray crystallographic studies.[2]

These distances are compared with crystallographic reference data in Table 1, which also shows the calculated structural parameters and the relative energy values of the Cu^{II} and Cu^{III} complexes, at the indicated spin multiplicity.

The B3LYP[23] energy of the closed shell Cu^{III} compound was found to be 0.96 eV below the corresponding energy of the triplet spin state. The calculations for different spin states give rise to considerably different structural parameters (see Table 1). In the case of the Cu^{III} compound, the calculated structural parameters of the singlet-state species mostly match the corresponding experimental ones. This allowed us to conclude that the Cu^{III} compound is likely a singlet state, in agreement with the apparent absence of ESR signals.[2]

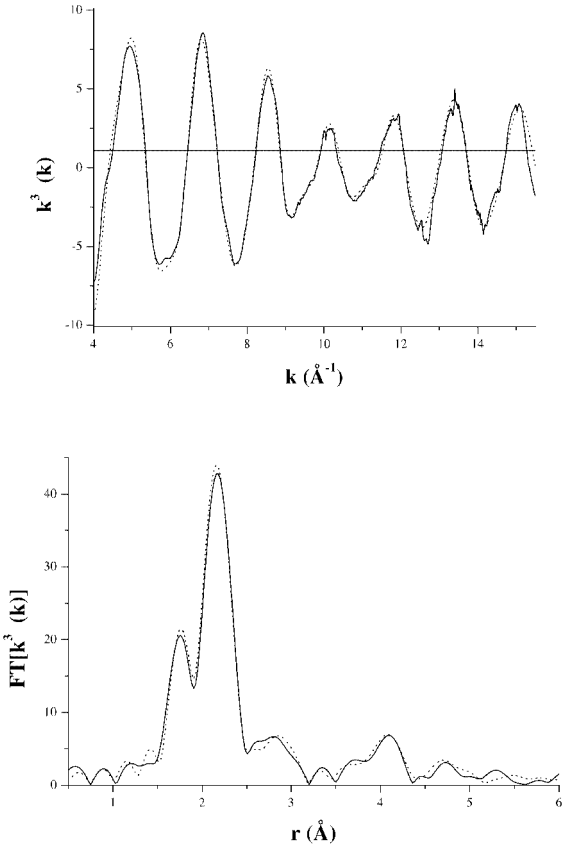

Figure 2. k^2-weighted EXAFS spectra and its fit (upper), $k^3\chi(k)$ vs. k, and the corresponding Fourier transforms (lower), FT[$k^3\chi(k)$] vs. r, of the Cu^{III}-phmi complex: the experimental and fit results are represented by the solid and dotted lines, respectively

Table 1. Distances and angles (Å and °), at given copper oxidation number (ON), obtained by geometry optimisation, at B3LYP/6-31G(d,p) level for different spin multiplicity (Spin), by X-ray crystallography[2] and by EXAFS analysis and calculated difference energy values ΔE (eV)

creases the metal−ligand distances of the atoms of the first coordination shell;[1,2,7,8] conversely, an increase in the spin multiplicity, at a given oxidation state of the metal, increases the same metal−ligand distances (see, for example, the calculated Cu−S or Cu−N distances).

2. K-edge Analysis

The K-edge region of both copper samples, together with their second derivative, is reported in Figure 3. In the inset, a portion of the low intensity pre-edge peak regions is highlighted. Two main changes are caused by the variation of the metal oxidation state: a) the position of the Cu^{III} K-edge is, as previously reported for other complexes,[8] shifted by about 2 eV in the energy axis; b) the spectrum curve in the first peak region, at about 8979−8981 eV, is seemingly slightly lower in the Cu^{II} sample; see the inset and the second derivative of the spectrum for details.

An attempt to interpret the K-edge transitions was carried out by using a molecular orbital (MO) Hartree−Fock (HF) description of the systems at the geometries previously optimised with the density functional (DFT) approach. This was needed to obtain reliable geometrical parameters through the DFT method and a further MO description, providing a set of HF eigenvalues to be used in our monoelectronic approach. In fact, the Kohn−Sham eigenvalues cannot be used for describing electronic vertical transitions.[24]

As reported in the Introduction, the edge electronic transitions were qualitatively described here in terms of hopping from the first occupied MO, which is essentially the 1s atomic orbital of the copper atom, to some of the lowest virtual MOs. Several approximations are inherent in this qualitative approach, orbital approximation and neglect of relativistic effects, inter alia.

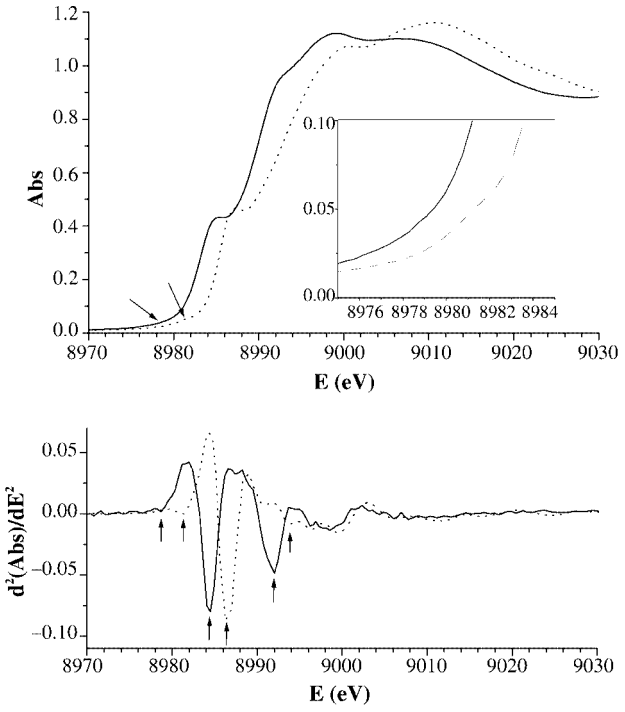

Figure 3. K-edge absorption Abs (upper) and its second derivative $d^2(Abs)/dE^2$ (lower) vs. the transition energy (E) of Cu^{II}-phmi (solid line) and Cu^{III}-phmi (dotted line); in the inset, a portion of the low intensity peak region is highlighted

The dipole strengths, $D = |<MO(1)|\boldsymbol{r}|MO(n)>|^2$, connecting the first occupied MO and the virtual MOs of the Cu^{II} and Cu^{III} systems, were numerically calculated by a home-made code based on the VEGAS algorithm.[25]

The transition energy values were considered as the differences between the eigenvalues of MO(1) and MO(*n*), where $n = 98-120$. In the case of the Cu^{II} complex, which is an open-shell system, only α-eigenvalues and eigenvectors were considered, but very similar values could be obtained by using the β-manifold. The values for the transition energies and *D* are reported in Table 2 for both Cu^{II} and Cu^{III} complexes.

Notably, in spite of the approximations introduced in the present treatment, the estimated frequency values for both compounds are just 0.3% lower than the experimental ones. Moreover, the transition energy values of the Cu^{III} complex are shifted towards higher values by about 3 eV, with respect to the corresponding transitions of the Cu^{II} complex, in line with the observed spectra. This is a clear indication that such a "naïve" treatment is able to account for the main features of the XAS spectrum.

Taking into account the results above, we tried to fit the experimental Cu^{II}-phmi and Cu^{III}-phmi XAS K-edge regions, considering the theoretical electronic transitions corresponding to the largest values of the *D* integrals. A single Gaussian function was assigned to each transition, having a full-width at half maximum (FWHM) equal to 1.5 eV and a height proportional to the corresponding *D* value. The resulting sets of Cu^{II} and Cu^{III} Gaussians were therefore two multifunction combs where the positions of the Gaussians were fixed by the DFT transition energies, and the relative intensities were modulated by the corresponding *D* values. Thus, the only two fit parameters, involving the core electronic transitions in both copper systems, were the position of the leading peak and its height.

One arctan function has been added in order to take into account the long-range trend of the EXAFS pattern, therefore, two more fit parameters are introduced. In fact, the arctan maximums, 1.1 (in absorption arbitrary units) both for the Cu^{II} and Cu^{III} systems, were qualitatively fixed by the analysis of the experimental spectra. The overall fitting process was finally performed within the 8950−9000 eV range, and the results are depicted in Figure 4. The good agreement between calculated and experimental spectra for both copper compounds is apparent ($R\chi^2 = 0.05$ and 0.15 for Cu^{II} and Cu^{III}, respectively).

The area under the leading peaks of the Cu^{II} and Cu^{III} systems proved to be very similar, whereas the mean of the same leading peaks, in agreement with the experimental results, were shifted by about 2.5 eV. An analogous shift can be observed between the mean values of the arctan functions employed to fit the Cu^{II} and Cu^{III} complex spectra. These findings, supported by the observation that the arctan slope parameter is very similar in both systems [5.9(7) and 6.3(4) for Cu^{II} and Cu^{III} species, respectively] point out clearly that the proposed fit procedure is quite heuristic.

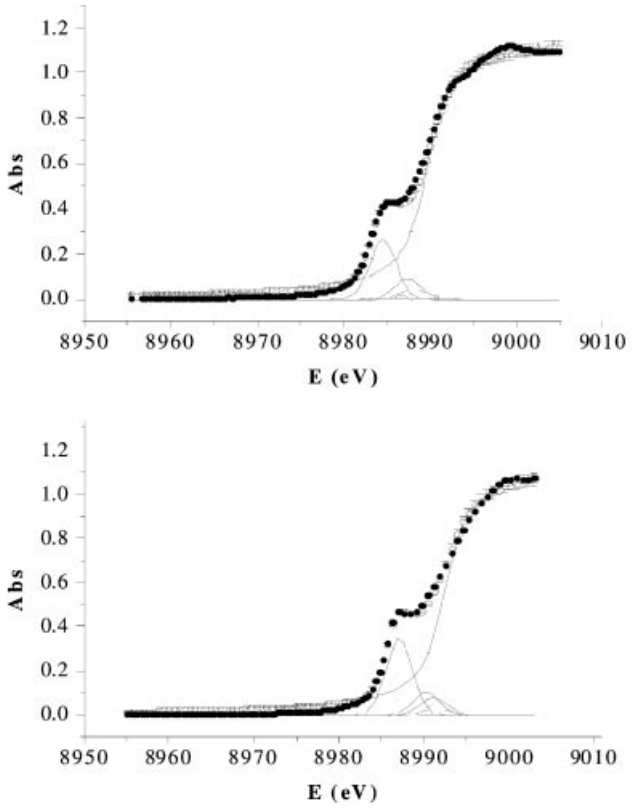

Figure 4. Fitting of the Cu^{II}-phmi (upper) and Cu^{III}-phmi (lower) XAS K-edge region: K-edge absorption Abs vs. transition energy *E*, experimental and fitting points are represented by filled and open circles, respectively; the continuous curves represent the fitting functions; the error bars (almost hidden and just visible on the points at higher energies), corresponding to the 2.5% of the fit values, visually show the agreement between experimental and fitted results

Conclusion

EXAFS spectra enable information on the interatomic distances of the considered systems to be obtained. The whole set of the obtained geometrical results confirms the values already determined by using different experimental techniques, validating the possibility of performing EXAFS spectral analysis along with quantum mechanical calculations. Moreover, this approach is able to discriminate between the atomic oxidation numbers and the molecular spin states.

The K-edge region shape has been reproduced well by a simple quantum mechanical description of the core vertical transitions in the orbital approximation combined with an accustomed fitting procedure.

Experimental Section

General Remarks: The XAS spectra on the K-edge of (PPh_4)-[Cu(*N*,*N*′-1,2-phenylenebis(2-mercapto-2-methylpropionamide)] (Cu^{III}-phmi) and $(NEt_4)_2$[Cu(*N*,*N*′-1,2-phenylenebis(2-mercapto-2-methylpropionamide)] (Cu^{II}-phmi) were recorded at the EMBL D2 bending magnet beam line of the DORIS storage ring (DESY,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Hamburg), running at 4.5 GeV and with a 50−100 mA ring current.

The samples were prepared by homogenising the powdered crystalline compounds (40 mg Cu^{III}-phmi and 30 mg Cu^{II}-phmi) in boron nitride and pressing the mixtures in 1-mm sample cells sealed with Kapton foil. The spectra were recorded at 20 K. Standard EXAFS analysis[26] was performed by the EXPROG[27] and EXCURVE98[22] programme packages. The full multiple scattering path was included in the fitting process of the molecular system. Its starting coordinates, excluding the hydrogen atoms, were taken from a previous X-ray crystallography study.[2]

Electronic Structure Calculations and Fitting Procedure: Quantum-mechanical calculations were performed at the B3LYP level, by the GAUSSIAN98 programme package,[20] by using the extended split-valence double-zeta 6-31G(d,p) basis set with full geometry optimisation.

The Cu oxidation states +2, with spin multiplicity of 2 for the complex, and +3, with spin multiplicities of 1 and 3, were considered. The calculations were performed by imposing C_{2v} symmetry on the ionic complexes.

Further calculations at the HF level were carried out in order to obtain eigenvalues and eigenvectors of the MOs needed to evaluate vertical transition energies and dipole strengths.

The number of the considered virtual MOs, 23 for both Cu^{II} and Cu^{III} systems, corresponding to the number of the calculated transition moment integrals, was fixed to take into account the energy range of about 6 eV characterising the shoulder width in the K-edge rising region. The integral was calculated by a Fortran home-made code employing the Monte Carlo routine VEGAS along with the random number generator RAN2.[24] The reliability of the numerical integration procedure was verified by checking the *ortho*-normalisation condition of the MOs.

The fitting function, designed to mimic the XANES profile, was defined as in the following:

$$f = \arctan(h,\eta,\sigma) + g_p(h_p,\eta_p,\sigma_p) + \sum_i^n g_i(h_i,\eta_i,\sigma_i)$$

where g_p and g_i are Gaussian functions, simulating the pivot peak, i.e. the largest one, and n minor peaks under the XANES profile. To reproduce the characteristic stepping behaviour of the latter, the arctan function was introduced.

The FWHM of all the Gaussians, σ_p and σ_i, were fixed to 1.5 eV, whereas h, the arctan maximum value, was set to 1.1 (arbitrary absorption units). The values of h_i/(arbitrary absorption units) and η_i/eV were defined as $h_i = A_i h_p$ and $\eta_i = B_i + \eta_p$. The A_i values corresponded to the calculated ratios between the dipole strength square of the given ith and the pivot transitions, whereas the B_i/eV parameters concerned the energy difference between the quantum mechanical and the fitting transition energy value, corresponding to the pivot peak.

Finally, f was driven by four fitting parameters, h_p (arbitrary absorption units), η_p (eV), η (eV) and σ (eV), which are the other significant parameters fixed by the quantum mechanical calculations.

In the fitting procedure, the simplex AMOEBA[24] minimised the restricted chi-squared function:

$$R\chi^2 = \frac{1}{m < E >} \sum_k^m \frac{(C_k - E_k)^2}{E_k}$$

where m is the number of experimental points considered in the fit, E_k and C_k the experimental and calculated absorptions and $<E>$ the average experimental absorption along the energy range analysed.

Oxidative Addition of Phenylselenyl Halides to Platinum(0) Complexes: Characterisation and Reactivity of the Products [PtX(SePh)-(*N*,*N*-chelate)(olefin)] (X = Cl, Br, I)

Vincenzo G. Albano,*[a] Vincenzo De Felice,[b] Magda Monari,[a] Giuseppina Roviello,[c] and Francesco Ruffo*[c]

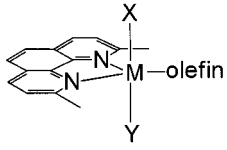
Keywords: Isomers / Oxidative addition / Platinum / Selenium

The oxidative addition of PhSeX (X = Cl, Br, I) to Pt^0 complexes of formula [Pt(*N*,*N*-chelate)(olefin)] is described. The reaction quantitatively affords the trigonal-bipyramidal products [PtX(SePh)(*N*,*N*-chelate)(olefin)] with the X and SePh fragments in the axial positions. NMR spectroscopic data have allowed us to gain insights into the geometrical isomerism of some of these complexes. The reactivity of the axial ligands towards electrophilic reagents is also investigated, and the molecular structures of [PtX(SePh)(dmphen)(dimethyl fumarate)] (X = Br, I) are compared.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Five-coordinate [M(X)(Y)(*N*,*N*-chelate)(olefin)] (**1**; M = Pd or Pt) complexes have proved to be particularly suitable for studying the coordination properties of several ions and molecules (Figure 1).[1] Due to their stability and inertness, metal adducts of a series of ligand fragments have been isolated,[1,2] including some containing ligands with poor stability in the "free" state.[3] For example, a variety of organometallic fragments can sturdily occupy an axial position in a series of compounds containing the same {MX(*N*,*N*-chelate)(olefin)} moiety, thus offering the possibility to assess trends.[2] Alternatively, unstable vinyl alcohol can be coordinated and its fairly rich chemical behaviour at the metal centre can be compared with that of a variety of olefins in the same environment.[3]

Recently,[4] we have focused our attention on five-coordinate complexes bearing organochalcogenide ligands ER (E = O, S, Se, Te) in the axial position. This study was started because coordinatively saturated Pt^{II} compounds with chalcogenide ligands were not known[5] and very limited information on the reactivity of these coordinated fragments was available.[6]



1

Figure 1. General formula for complexes **1**; M = Pd, Pt; X = Cl, Br, I, OR, SeR, TeR; Y = H, R, Ar, GeR_nCl_{3-n}, SnR_nCl_{3-n}, PbR_nCl_{3-n}, HgR, SeR, TeR

Our previous work[4a,4b] dealt with the characterisation of complexes of type **1** (M = Pt)[7] containing two organochalcogenide ligands obtained by oxidative addition of RE−ER molecules to suitable Pt^0 precursors **2** [Reaction (1) in Scheme 1]. During these studies we also found that, when E = Se, the reaction is a rare example of an equilibrium. This offered the uncommon opportunity to analyse the subtle effects of the ligand properties on the equilibrium.

In this paper we report on the addition of phenylselenyl halides to the same Pt^0 precursors [Reaction (2) in Scheme 1]. This has led to new five-coordinate compounds containing SePh and X in the apical sites. Analysis of the NMR spectroscopic and structural data of the new species revealed new information on the coordination properties of both organochalcogenides and halides. Furthermore, relevant aspects of the reactivity of the new compounds have been examined.

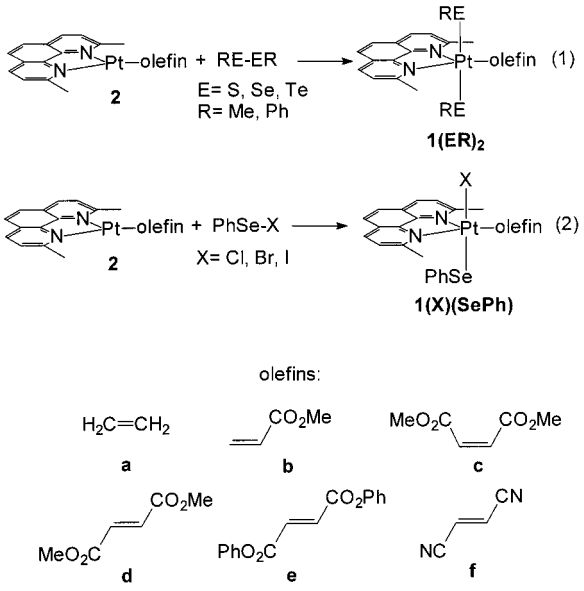

Scheme 1

Results and Discussion

Synthesis of the Complexes

Oxidative addition of the phenylselenyl halides was carried out with the three-coordinate precursors **2** shown in Scheme 1. The chelating ligand 2,9-dimethyl-1,10-phenanthroline (dmphen) was used due to its well-known ability to stabilise trigonal bipyramidal complexes of d^8 ions.[1] Olefins with increasing electron-acceptor properties were used: ethylene (**a**), methyl acrylate (**b**), dimethyl maleate (**c**), dimethyl fumarate (**d**), diphenyl fumarate (**e**) and fumarodinitrile (**f**). As a consequence the metal−olefin bond in the Pt^0 complexes containing **c**, **d**, **e** or **f** is characterised by a substantial π-backdonation contribution, thus enhancing the stability of the five-coordinate complexes by removing electronic density from the metal. These compounds are stable in solution and can be stored at room temperature for several days without appreciable decomposition. The ethylene or methylacrylate precursors are more sensitive to moisture, oxidising agents or heat, and were therefore freshly prepared before use.

All the additions were performed in chloroform, in which the complexes generally display reasonable solubility. The reactions were complete within a few seconds, as revealed by the change of the solution colour from yellow (red for ethylene derivative) to pink. The products were crystallised in high yield by dropwise addition of diethyl ether to the reaction mixture. The ethylene complex could be isolated in pure form only with Cl-SePh, while in the case of the other haloselenides it was always accompanied by significant impurities, which could not be removed even by careful crystallisation. The compounds are soluble in chloroform or dichloromethane with the exception of **[1f(Br)(SePh)]** (M = Pt), which displays a fair solubility only in tetrachloroethane.

Characterisation of the Products

The characterisation of the products was carried out by ^1H and ^{13}C NMR spectroscopy (Table 1) and elemental analysis. In two cases, namely **[1d(Br)(SePh)]** and **[1d(I)-(SePh)]**, the X-ray molecular structure was also determined.

Analysis of the ^1H NMR spectra confirmed that the additions proceed by activation of the selenium−halogen bond and unequivocally confirmed the trigonal bipyramidal geometry of the products. The most relevant features are the high-field shift of the olefin protons signals by at least 2 ppm with respect to the free alkene, as typically found in complexes of type **1**,[1] and the significant high-field shift of the PhSe- protons, which is attributable to the presence of a specific interaction between the phenyl ring of the selenide ligand and the rings of dmphen. This interaction is also present in the solid state, and has already been discussed for **[1(EPh)$_2$]** complexes.[4a]

As for the stereochemical aspects, the number of possible isomers depends on the symmetry of the alkene. Of course, ethylene (D_{2h}) affords only one isomer and the alkene protons resonate as an AB quadruplet. In the presence of dimethyl maleate (C_{2v}), two isomers[8] may exist according to the orientation of the olefin substituents. The NMR spectra of freshly dissolved **[1c(Cl)(SePh)]** and **[1c(Br)(SePh)]** suggest the presence of only one rotamer whose olefin protons resonate at $\delta = 4.31$ and $\delta = 4.28$ ppm, respectively. In both cases, on standing in solution, slow conversion (days to completion) to the thermodynamically stable isomers was observed. The chemical shifts of the olefin protons for the latter species are $\delta = 4.60$ and $\delta = 4.74$, respectively.

The correct geometry of the two isomers can be reasonably assigned by considering the NMR spectroscopic data of the known complexes [Pt(SePh)$_2$(dmphen)(dimethyl maleate)][4b] and [PtCl$_2$(dmphen)(dimethyl maleate)].[9] In the former species the olefin protons are necessarily oriented towards the SePh ligand, and resonate at $\delta = 4.34$ ppm. This value is very close to that found for the first, kinetically formed isomer of **[1c(Cl)(SePh)]**. In the dichloro species the maleate protons face the halide and their signal appears at $\delta = 4.79$ ppm, a value close to that found for the thermodynamically stable rotamer of **[1c(Cl)(SePh)]**. Hence, it is inferred that the olefin protons are likely to face the selenide ligand in the initially formed isomer, while they are oriented towards the chloride in the thermodynamically stable rotamer. This correlation can be reasonably extended to the bromo species **[1c(Br)(SePh)]**. It should be noted that an analogous relationship holds true for complexes of **1** bearing a halide and a hydrocarbyl group[7] in the axial positions. In all cases, the chemical shift of the maleate protons is higher in the isomer in which these nuclei are oriented towards the halogen.

Coordination of dimethyl fumarate or fumarodinitrile (C_{2h}) results in the formation of an enantiomeric couple, which, of course, is not distinguishable by NMR spectroscopy in the absence of a shift reagent. The olefin protons here are not equivalent, and resonate as doublets. It is interesting to note that the chemical-shift difference ($\Delta\delta$)

[a] At 200 or 300 MHz and 298 K. [b] At 50.2 or 75.4 MHz and 298 K; values given in square brackets. [c] $^{2}J_{Pt,H}$ and $^{1}J_{Pt,C}$ [Hz] in parentheses (when measurable). [d] Kinetically formed isomer. [e] Thermodynamically stable isomer. [f] Spectra recorded in $C_2D_2Cl_4$ ($^{13}C_2D_2Cl_4$: δ = 74.15 ppm as internal standard). [g] More abundant isomer.

between the CH= signals in the dimethyl fumarate complexes is close to that for the corresponding maleate rotamers. This is in agreement with the fact that one fumarate proton is oriented towards the halide, while the other faces the selenide ligand.

Finally, two enantiomeric couples are formed with methyl acrylate. Actually, two patterns are present in the NMR spectra of both [**1b(Cl)(SePh)**] and [**1b(Br)(SePh)**]. The spectrum of a freshly prepared solution of the latter compound shows the two isomers in a 2:1 ratio. After three

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hours the species are present in equimolar amounts, and within six days the conversion to the stable isomer is complete. In a similar fashion the isomeric ratio for the chloro derivative is initially 1:1 and after five days one isomer becomes by far the more abundant. The correlation mentioned above for the dimethyl maleate complexes (see Table 1) indicates that the carboxymethyl groups are oriented towards the halide in the thermodynamically stable isomer.

The X-ray Molecular Structures of [1d(Br)(SePh)] and [1d(I)(SePh)]

The crystals of the title species are isomorphous (see Exp. Sect.), therefore the molecules are strictly isostructural in the solid state and experience equal force fields. This situation allows close comparisons of the bond values so that even minor differences can be discussed. Figure 2 shows a perspective drawing of the molecules; an axial view is shown in Figure 3. Table 2 contains a comparison of the most significant bond parameters of the two species.

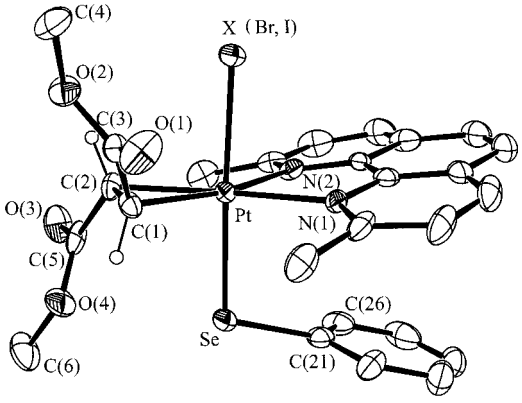

Figure 2. ORTEP drawing (30% probability thermal ellipsoids) of [PtX(SePh)(dmphen)(dimethyl fumarate)] [**1d(X)(SePh)**] (X= Br, I); only the olefinic hydrogens are shown for the sake of clarity

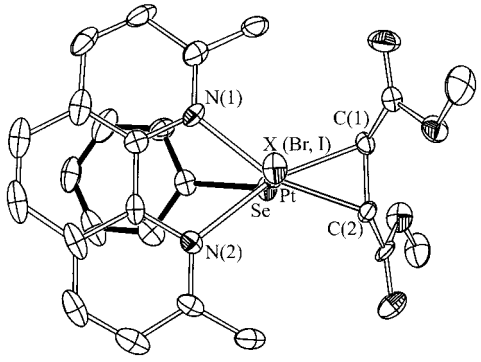

Figure 3. View down the X−Se−Pt axis (X = Br, I) of [PtX(SePh)(dmphen)(dimethyl fumarate)] [**1d(X)(SePh)**]; hydrogen atoms are omitted for clarity

The molecular geometry is as expected. The phenanthroline nitrogen atoms and fumarate double bond define the equatorial coordination plane, and the halide and selenide atoms occupy the axial positions. The molecules exhibit an asymmetric configuration because the C_2 symmetry of dimethyl fumarate does not match the idealised C_s symmetry of the remaining moiety. It should be noted that the phenyl ring of the SePh ligand is approximately placed above the central ring of the phenanthroline (Figure 2), while in the bis(phenylselenide) derivative [Pt(SePh)$_2$(dimethyl fumarate)(dmphen)] the phenyl rings match both pyridine rings from opposite sides.[4a] In that case we assumed the presence of preferential interactions between the ring dipoles. It is likely that the C_s geometry found in the present case allows an efficient crystal packing rather than a conformation that would optimise the intramolecular interactions. The non-equivalence of the axial ligands causes a tilting of the phenanthroline on the side of the less bulky halide ligand [angle between coordination and phenanthroline planes of 10.6(3)° and 10.5(4)° for bromide and iodide, respectively].

Table 2. Selected bond lengths [Å] and angles [°] for [**1d(Br)(SePh)**] and [**1d(I)(SePh)**]

	[1d(Br)(SePh)]	[1d(I)(SePh)]
Pt−Br	2.5195(9)	
Pt−I	–	2.6855(9)
Pt−Se	2.4537(9)	2.472(1)

Pt−Se−C(21)	103.6(2)	104.0(2)
I−Pt−C(1)	–	91.9(3)
I−Pt−C(2)	–	91.0(3)
I−Pt−N(1)	–	87.0(2)
I−Pt−N(2)	–	86.1(2)
Br−Pt−C(1)	91.7(3)	–
Br−Pt−C(2)	90.6(3)	–
Br−Pt−N(1)	87.5(2)	–
Br−Pt−N(2)	85.7(2)	–

Significant variations are observed for the bonding interactions of the axial ligands. The difference in the Pt−halogen distances [Pt−Br 2.520(1) and Pt−I 2.685(1) Å] is consistent with the difference between their covalent radii (0.19 Å). The Pt−Se interaction is 0.02 Å shorter in the bromide derivative [2.453(1) and 2.472(1) Å, respectively]. This effect, if compared with the even longer value found in the bis(selenide) derivative [Pt(SePh)$_2$(dimethyl fumarate)(dmphen)] [average value 2.517(1) Å],[4a] suggests a correlation of the Pt−Se distance with the electronegativity difference between the apical donor atoms. In other words, as the bonds in the linear Se−Pt−X unit (X = Br, I, Se) result from interactions with the same metal-atom orbitals, the ligand-to-metal donation is balanced between the competitors according to their donor properties, and the Pt−Se bond becomes stronger in the bromide and weaker in the bis(selenide) derivative.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The equatorial Pt−N and Pt−C interactions are affected much less by the changes in the axial ligands, and the differences are barely significant in terms of experimental errors. However, we note that, in agreement with the situation discussed for the axial ligands, the bonds in the bromide derivative are slightly, but systematically, shorter than in the iodide. The average values are as follows: Pt−N 2.180(7), 2.185(8) and Pt−C 2.086(8), 2.097(9) Å, respectively. Correspondingly, the olefin C=C distance is slightly longer in the bromide derivative [1.437(12) against 1.425(15) Å], and the C−C=C−C torsion angle is slightly higher in the bromide [46.1(9) against 44.5(9)°], indicating slightly more sp^3 rehybridisation where more donation is allowed.

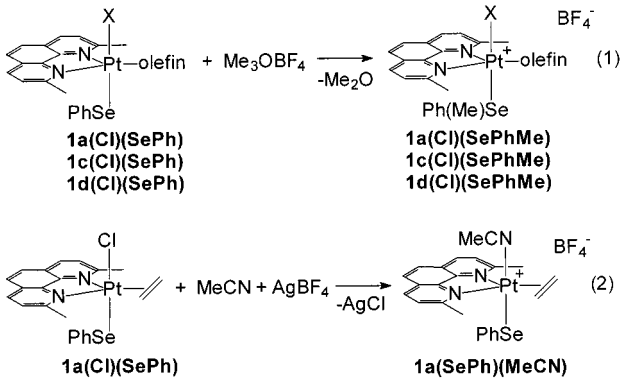
Reactivity

In no case was the oxidative addition of phenylselenyl halides to the platinum(0) precursors found to be an equilibrium. The reaction was quantitative even with fumarodinitrile, which stabilises the low oxidation state of the metal through a very effective π-backdonation. These results parallel those obtained when PhSe-SePh[4b] is allowed to react with the same complexes, while with MeSe-SeMe[4a] the reactions were found to be an equilibrium. However, these findings are not surprising since the Pt−X bond strengths[10] are relatively high compared to those of the other bonds that form or break in the reaction. Thus, the addition of the selenenyl halides is enthalpically driven towards the products. Furthermore, the above-mentioned intramolecular interaction between aromatic rings helps to stabilise the five-coordinate complexes.

Some relevant aspects of the reactivity of the new complexes have been explored. The ability of the coordinated SeR ligands to undergo electrophilic attack was confirmed by reacting [**1a(Cl)(SePh)**], [**1c(Cl)(SePh)**] (kinetic isomer) and [**1d(Cl)(SePh)**] with trimethyloxonium tetrafluoroborate (reaction 1 of Scheme 2). The corresponding products are formally monopositive cationic complexes bearing Se(Me)Ph as the axial ligand. Accordingly, the compounds are fairly soluble only in nitromethane. The presence of Me on selenium was confirmed by the presence of a singlet coupled to both ^{77}Se and ^{195}Pt in the ^{1}H NMR spectrum. Of course, upon addition of the methyl group, the selenium atom becomes stereogenic. In the presence of a prochiral olefin such as dimethyl fumarate, two diastereomeric couples form, and these were observed in solution for [**1d(Cl)(SePhMe)**] in an 8:3 ratio.

In the spectrum of [**1c(Cl)(SePhMe)**], which is obtained upon addition of trimethyloxonium tetrafluoroborate to the kinetic isomer of [**1c(Cl)(SePh)**], the CH= protons resonate as two doublets, while the methoxy groups are still equivalent. The lack of sensitivity of the methoxy protons towards the transformation of the selenide ligand suggests that the coordination stereochemistry of the olefin is retained. In solution, the compound slowly isomerises into the most stable isomer, as is the case for the parent compound.

Another aspect of this study has dealt with the reactivity of the other axial ligand — the halide. This can be replaced by a neutral ligand, for example acetonitrile, upon treatment with a silver salt (reaction 2 of Scheme 2). The reaction was performed with the ethylene compound [**1a(Cl)(SePh)**] and affords the corresponding monopositive cation of [**1a(SePh)(MeCN)**], which, again, is fairly soluble only in nitromethane.



Scheme 2

Conclusions

The chemistry described in this paper confirms the peculiar aptitude of trigonal bipyramidal complexes of platinum(II), such as **1**, to function as effective models for comparing the behaviour of ligands. Thus, new five-coordinate Pt^{II} complexes with a halide and the SePh ligand in axial positions have been isolated and relevant aspects of their reactivity elucidated. The availability of the new compounds has allowed a comparison of the coordination and spectral properties of halides and organochalcogenides in identical environments. NMR spectroscopy has also been employed for this homogeneous class of compounds to analyse the geometrical isomerism displayed by some of the compounds.

Experimental Section

General: ^{1}H and ^{13}C NMR spectra were recorded with Varian XL-200 or Varian Gemini spectrometers. The NMR spectroscopic data are reported in Table 1. ^{1}H and ^{13}C NMR chemical shifts are reported in δ units (ppm) relative to the solvent ($CHCl_3$: δ = 7.26 ppm; CHD_2NO_2: δ = 4.33 ppm; $^{13}CDCl_3$: δ = 77.0 ppm; $^{13}C_2D_2Cl_4$: δ = 74.15 ppm). Phenylselenyl chloride, phenylselenyl bromide, the diphenyl diselenide compound with iodine (1:1) and the trimethyloxonium salt were commercially available. Platinum(0) precursors were obtained according to a described method.[11] Solvents and reagents were of AnalaR grade and used without further purification.

Synthesis of Complexes 1 of Formula [PtX(SePh)(dmphen)(olefin)] (X= Cl, Br): A solution of the appropriate selenyl compound PhSeX (0.15 mmol) in a minimum amount of chloroform (0.5 mL) was added to a suspension of the three-coordinate compound **2a−f** (0.15 mmol) in chloroform (0.5 mL). After stirring at room temperature for 5 min, addition of diethyl ether afforded the deep rose-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

violet product, which was washed with diethyl ether and dried. **[1a(Cl)(SePh)]:** Yield: 75 mg (80%). $C_{22}H_{21}ClN_2PtSe$ (622.8) calcd. C 42.43, H 3.40, N 4.50; found C 42.12, H 3.22, N 4.37. **[1b(Cl)(SePh)]:** Yield: 85 mg (83%). **[1c(Cl)(SePh)]:** Yield: 100 mg (90%). $C_{26}H_{25}ClN_2O_4PtSe$ (738.8) calcd. C 42.27, H 3.41, N 3.79; found C 42.03, H 3.54, N 3.63. **[1d(Cl)(SePh)]:** Yield: 98 mg (88%). **[1e(Cl)(SePh)]:** Yield: 110 mg (85%). **[1f(Cl)(SePh)]:** Yield: 91 mg (90%). **[1b(Br)(SePh)]:** Yield: 87 mg (80%). **[1c(Br)(SePh)]:** Yield: 102 mg (87%). **[1d(Br)(SePh)]:** Yield: 96 mg (82%). $C_{26}H_{25}BrN_2O_4PtSe$ (783.3) calcd. C 39.87, H 3.22, N 3.58; found C 40.02, H 3.18, N 3.69. **[1e(Br)(SePh)]:** Yield: 112 mg (82%). **[1f(Br)(SePh)]:** Yield: 92 mg (86%). $C_{24}H_{19}BrN_4PtSe$ (717.2) calcd. C 40.19, H 2.67, N 7.81; found C 40.35, H 2.81, N 7.60.

Synthesis of [PtI(SePh)(dmphen)(dimethylfumarate)] [1d(I)(SePh)]: The 1:1 diphenyl diselenide compound with iodine (0.11 mmol) was added to a magnetically stirred suspension of **2d** (0.12 g, 0.22 mmol) in chloroform (1 mL). The dark-red solution was stirred at room temperature for 5 min. Subsequent addition of diethyl ether afforded the product, which was washed with diethyl ether and dried. Yield: 100 mg (80%).

Synthesis of Complexes 1 of Formula [PtCl(dmphen){Se(Ph)Me}-(olefin)]BF_4: A solution of trimethyloxonium tetrafluoborate salt (0.019 g, 0.13 mmol) in nitromethane (0.5 mL) was added to the appropriate coordinatively saturated compound [**1a(Cl)(SePhMe)**], [**1c(Cl)(SePhMe)**] or [**1d(Cl)(SePhMe)**] (0.13 mmol). After stirring at room temperature for 5 min, slow addition of diethyl ether to the resulting solution afforded the yellow product, which was washed with diethyl ether and dried. **[1a(Cl)(SePhMe)]:** Yield: 70 mg (74%).**[1c(Cl)(SePhMe)]:** Yield: 77 mg (70%). $C_{27}H_{28}BClF_4N_2O_4PtSe$ (840.7) calcd. C 38.58, H 3.36, N 3.33; found C 39.01, H 3.35, N 3.40. **[1d(Cl)(SePhMe)]:** Yield: 74 mg (68%).

Synthesis of [Pt(SePh)(dmphen)(MeCN)(ethylene)]BF_4 [1a(SePh)-(MeCN)]: A solution of silver tetrafluoroborate in acetonitrile (0.13 mmol) was added to a solution of five-coordinate product [**1a(Cl)(SePh)**] (0.13 mmol) in nitromethane under nitrogen at 273 K. After stirring for 30 min, the residual solid was filtered through a small Celite pad. The addition of diethyl ether to the resulting solution afforded the light-yellow product, which was washed with diethyl ether and dried. Yield: 74 mg (80%).

X-ray Crystallography: Crystals of suitable quality were grown from a 1:1 mixture of chloroform and diethyl ether. The X-ray intensity data for [**1d(Br)(SePh)**] and [**1d(I)(SePh)**] were measured with a Bruker AXS SMART 2000 diffractometer, equipped with a CCD detector. Cell dimensions and the orientation matrix were initially determined from a least-squares refinement on reflections measured in three sets of 20 exposures, collected in three different ω regions, and eventually refined against all data. For all crystals, a full sphere of reciprocal space was scanned by 0.3° ω steps, with the detector kept at a distance of 5.0 cm from the sample. The software SMART[12] was used for collecting frames of data, indexing the reflections and determining the lattice parameters. The collected frames were then processed for integration by the SAINT program,[12] and an empirical absorption correction was applied using SADABS.[13] The structures were solved by direct methods (SIR 97)[14] and subsequent Fourier syntheses and refined by full-matrix least-squares on F^2 (SHELXTL),[15] using anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms except the olefinic hydrogen atoms, which were located in the Fourier map and refined isotropically, were added in calculated positions, included in the final stage of refinement with isotropic thermal parameters, U(H), of 1.2 U_{eq}(C) [U(H) = 1.5 U_{eq}(C-Me)], and allowed to ride on their carrier carbon atoms. Crystal data and details of the data collection for all structures are reported in Table 3. CCDC-237837 and -237838 for [**1d(Br)(SePh)**] and [**1d(I)(SePh)**], respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge

Temperature-Controlled Solvothermal Syntheses, Structures and Characterizations of a Novel Class of Zn Complexes Constructed from 1,4-Bis[2-(5-phenyloxazolyl)]benzene

Shu-Mei Chen,[a] Can-Zhong Lu,*[a] Quan-Zheng Zhang,[a] Jiu-Hui Liu,[a] and Xiao-Yuan Wu[a]

Keywords: Complexes / N ligands / Crystal engineering / Coordination modes / Properties

Three novel complexes, $ZnCl_2(H_2O)(POPOP)\cdot POPOP$ (**1**), $[ZnCl_2(POPOP)]_n$ (**2**), and $\{Zn_2(CH_3COO)(POPOP)_{1.5}Cl_3\}_n$ (**3**) {POPOP = 1,4-bis[2-(5-phenyloxazolyl)]benzene}, of zinc–POPOP coordination polymers have been obtained from an identical starting mixture using temperature as the only independent variable. Complexes **1**–**3** all crystallize in the triclinic $P\bar{1}$ space group, but their Zn^{II} centers adopt different coordinations. Complex **1** consists of POPOP-coordinated zinc units and discrete POPOP molecules, **2** features an interesting zigzag chain structure, and **3** consists of unique ladder-like double-chains bridged by POPOP units. Furthermore, **1**–**3** display some different fluorescent emissions based on their different coordination architectures.

Introduction

Transition metal containing organic materials have attracted considerable recent interest because of their potential applications in optical and electrooptical devices such as organic light-emitting diodes (OLEDs), electrochromic, photovoltaic and photoconductive devices, and photorefractive optical elements.[1−9] Polynuclear d^{10} metal (Cu^I, Ag^I, Au^I, Zn^{II}, or Cd^{II}) complexes have also attracted extensive interest owing to their appealing structures and photoluminescent properties. A series of d^{10} metal organic frameworks have been described.[10,11] Some organic N-donors such as bipyridine or related species are often chosen to fabricate these various species.[12,13] Interest in the chemistry of transition metal−diimine compounds with a conjugated π-system has grown rapidly because of their unique physical properties. Molecular structure-property relationships of organic π-conjugated materials have been explored.[14−16] POPOP {POPOP = 1,4-bis[2-(5-phenyloxazolyl)]benzene} is a long π-conjugated ligand and often acts as a photoluminescent chromophore.[17] However, to the best of our knowledge, no studies have been reported based on POPOP with transition metals. To understand the coordination chemistry of POPOP and to prepare new materials with interesting structural topology and excellent physical properties, we have been particularly concerned with such polymers and attempted to prepare some materials with interesting physical properties.

In addition, the design and synthesis of novel coordination architectures controlled by varying the reaction conditions (including temperature,[18,19] metal/ligand ratio,[20] pH,[21] solvents,[22] and counter anions[23,24]) are of great interest in coordination chemistry and reactions. Appropriate control of the reaction conditions makes it possible to construct new materials with useful properties. For example, Forster and co-workers have carried out systematic studies on the role of synthesis temperature as an isolated reaction variable.[19] In this paper, we report the synthesis of three novel complexes of zinc−POPOP coordination polymers, $ZnCl_2(H_2O)(POPOP)\cdot(POPOP)$ (**1**), $[ZnCl_2(POPOP)]_n$ (**2**), and $\{Zn_2(CH_3COO)(POPOP)_{1.5}Cl_3\}_n$ (**3**), from identical starting materials but at different temperatures.

Results and Discussion

Synthesis and General Characterization

To design new organic−inorganic hybrid compounds with some multifunctional ligands, hydro(solvo)thermal synthesis is a powerful method. At such a relatively low temperature and under autogenous pressure, the problems of ligand solubility and reactivity are minimized, and appropriate O- and N-donor ligands can be selected by the metal centers for efficient molecular constructions during crystallization. Complexes **1**−**3** were synthesized simply un-

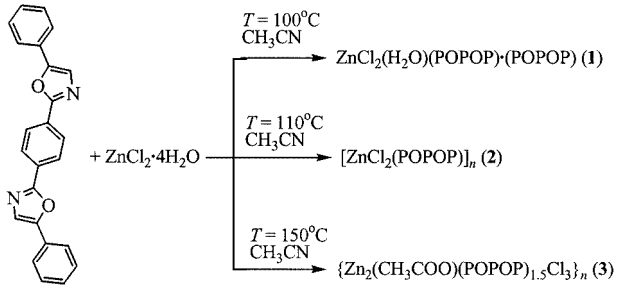
der solvothermal reaction conditions. As mentioned above, POPOP is a long π-conjugated ligand that can offer two N atoms for coordination. The synthesis of zinc−POPOP described here demonstrates that a single starting mixture can be used to obtain different zinc−POPOP structures by varying only the reaction temperatures. The same precursors under different reaction temperatures lead to three novel complexes, **1**−**3**, exhibiting different architectures with different coordination fashions (Scheme 1). The coordination numbers of Zn^{II} ions in **1**−**3** are the same, but their differing topologies are a discrete arrangement, a 1D zigzag chain arrangement, and a 1D ladder-like double-chain arrangement, respectively.



Scheme 1. Role of temperature in the synthesis of zinc−POPOP complexes

Crystal Structures of Complexes

$ZnCl_2(H_2O)(POPOP)\cdot(POPOP)$ (1)

The structure determination reveals that complex **1** is discrete, consisting of POPOP-coordinated zinc units and POPOP molecules (Figure 1). The zinc(II) atom exhibits a tetrahedral configuration coordinated by two chlorine atoms [Zn(1)−Cl(1) = 2.2238(4) Å, Zn(1)−Cl(2) = 2.2124(4) Å], one nitrogen atom of the POPOP ligand with a Zn(1)−N(1) bond length of 2.0629(11) Å, and one oxygen atom [Zn(1)−Ow1 = 2.0193(10) Å] of a water group. There are three crystallographically independent POPOP ligands with different orientations in one unit: one monodentately coordinates to one Zn center, while the other two do not participate in coordination and orient vertically to each other. Interestingly, each POPOP ligand is almost coplanar. Figure 2 shows that there is a discrete POPOP unit between two adjacent POPOP-coordinated zinc units in which Zn^{II} atoms are located on opposite direction mutually. These three units are parallel and combine to form a basic group by obvious π−π interactions, with distances of 3.518(5)−3.929(6) Å. A further POPOP molecule, which is vertical relative to the parallel layers, fills in the large cavity formed by the staggered arrangement of four groups.

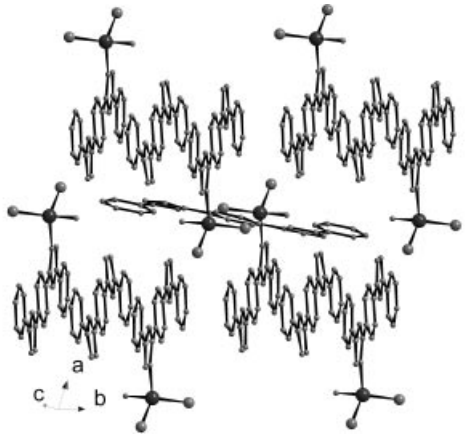


Figure 2. Ball-and-stick representation of the packing diagram of **1**

$[ZnCl_2(POPOP)]_n$ (2)

A single-crystal X-ray structural analysis shows that complex **2** has an interesting one-dimensional zigzag chain framework, which is built up by one POPOP linked to two Zn atoms. The zinc(II) atom has a tetrahedral configuration coordinated by two chlorine atoms [Zn(1)−Cl(1) = 2.2258(6) Å, Zn(1)−Cl(2) = 2.2114(7) Å] and two nitrogen atoms [Zn(1)−N(1) = 2.0596(12) Å, Zn(1)−N(2) = 2.0587(12) Å] from two different POPOP ligands (Figure 3). Cl−Zn−Cl and N−Zn−N bond angles are 115.15(3)° and 96.73(5)° respectively. N−Zn−Cl bond angles range from 105.96(3) to 109.56(3)°. The shortest Zn···Zn distance between POPOP ligands is 9.184 Å. Figure 4 shows that each Zn atom is coordinated by two POPOP ligands, i.e. each POPOP ligand is connected with two zinc atoms. Based on this coordination mode, the 1D infinite chain framework is formed. The most interesting feature of complex **2** is that such a coordination mode produces a unique zigzag chain structure. The two dihedral angles between the 5-phenyloxazolyl rings and the center benzene ring plane are 25.05°.

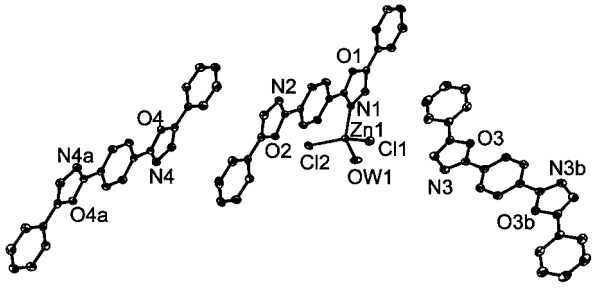

Figure 1. ORTEP drawing of $ZnCl_2(H_2O)(POPOP)\cdot(POPOP)$ (**1**), showing the local coordination of Zn^{II} and atomic numbering scheme (30% probability thermal ellipsoids)

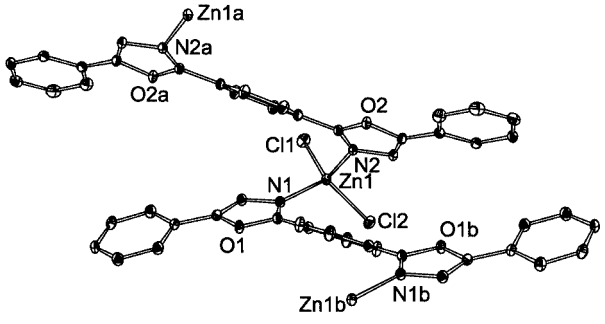

Figure 3. ORTEP drawing of $[ZnCl_2(POPOP)]_n$ (**2**)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This is presumably a consequence of the bridging nature of the ligands, with effective coordination to the metals being of primary importance.

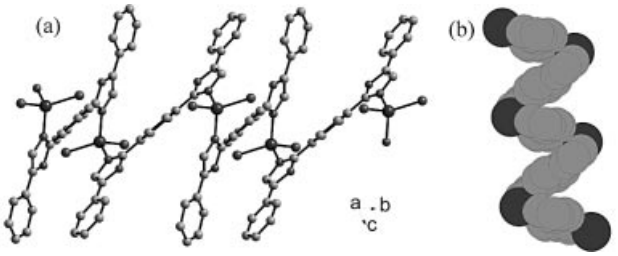

Figure 4. (a) Zig-zag chain structure in **2**; (b) space-filling plots of the zig-zag chain

{Zn$_2$(CH$_3$COO)(POPOP)$_{1.5}$Cl$_3$}$_n$ (3)

X-ray crystallographic analysis reveals that complex **3** consists of an infinite ladder-like double-chain bridged by POPOP ligands. The fundamental unit is shown in Figure 5. There are two crystallographically different Zn centers in the asymmetric unit, both displaying tetrahedral coordination geometry. The Zn(1) center is defined by two chlorine atoms [Zn(1)−Cl(1) = 2.2160(9) Å, Zn(1)−Cl(2) = 2.2166(10) Å], one nitrogen atom from a distorted POPOP ligand with a Zn(1)−N(2) bond length of 2.100(2) Å, and one oxygen atom [Zn(1)−O(4) = 2.007(2) Å] of a carboxylate group. N−Zn(1)−Cl bond angles are 109.64(7)° and 109.79(7)°, and O−Zn−Cl bond angles are 106.08(7)° and 113.99(7)°, respectively. O−Zn−N and Cl−Zn−Cl bond angles are 95.67(9)° and 119.12(4)° respectively. The Zn(2) center is coordinated by one chlorine atom [Zn(2)−Cl(3) = 2.2099(9) Å], two nitrogen atoms [Zn(2)−N(1) = 2.047(3) Å, Zn(2)−N(3) = 2.044(2) Å] from one rather distorted POPOP ligand and one slightly distorted POPOP ligand, and one oxygen atom [Zn(2)−O(5) = 1.964(2) Å] of a carboxylate group. Unlike in **1** and **2**, carboxyl groups, arising from the hydrolyzation of CH$_3$CN solvent, also coordinate with Zn atoms. There are also two crystallographically different POPOP ligands in the asymmetric unit: one is strongly distorted, with dihedral angles between the 5-phenyloxazolyl ring and the center benzene ring plane of 37.64° and 9.36° respectively,

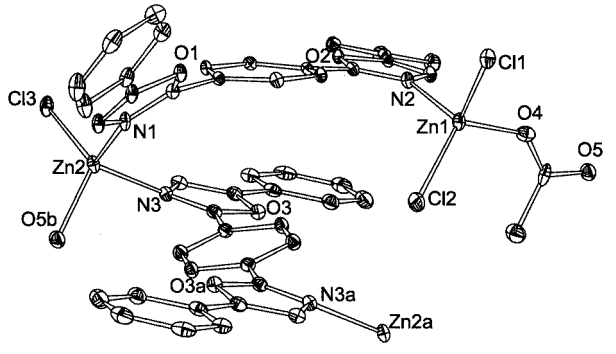

Figure 5. ORTEP drawing of {Zn$_2$(CH$_3$COO)(POPOP)$_{1.5}$Cl$_3$}$_n$ (**3**)

and coordinates to two different Zn centers. The second is slightly distorted, with dihedral angles of 25.91°, and coordinates to two symmetric relative Zn centers. In other words, each carboxyl group coordinates to two Zn atoms and each strongly distorted POPOP ligand provides two N atoms to coordinate with Zn atoms to form an interesting infinite chain. In addition, the slightly distorted POPOP ligands bridge two adjacent chains to produce the final ladder-like double-chain (Figure 6).

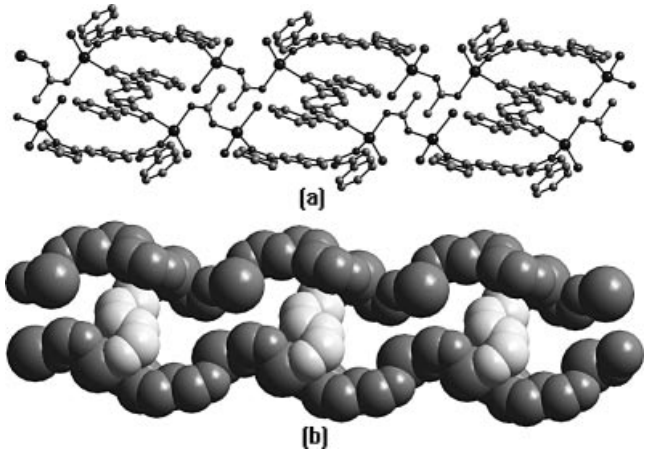

Figure 6. (a) 1D ladder-like double-chain structure in **3**; (b) space-filling plots of the 1D ladder-like double-chain (for clarity, only the backbone is shown)

The above structural descriptions show that temperature plays a crucial role in the formation of the complexes. A water molecule coordinates to Zn in complex **1**, but no water molecule exists in **2** or **3**. However, with increasing temperature some CH$_3$CN solvent was hydrolyzed to form CH$_3$COO$^-$ ligands in **3**. At the same time, the co-planar POPOP ligand also becomes distorted on going from complex **1** to **3**. Complexes **1**−**3** show increasing condensation and density at higher synthesis temperatures. Increasing temperatures also lead to changes in topological structure and favor higher overall dimensionality. The overall dimensionality of structures **1**−**3** also increases − from discrete at 100 °C, to a 1D chain at 110 °C, and a 1D double-chain at 150 °C, respectively. The successful preparation of **1**−**3** reveals a clear relationship between synthesis temperature and structure.

Thermogravimetric Analysis (TGA)

The stability of **2** and **3** was examined by thermogravimetric analysis (TGA), which revealed an onset temperature for decomposition above 330 °C. Such stabilities make the compounds potential candidates for practical applications.

Photoluminescence Properties

Emission spectra of complexes **1**−**3** in the solid state at room temperature show intense emissions at 452 nm (λ_{ex} = 396 nm) for **1**, 452 nm (λ_{ex} = 396 nm) for **2** and 460 nm (λ_{ex} = 397 nm) for **3**. To understand the nature of these

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

emission bands, we analyzed the photoluminescence properties of the POPOP ligand and found that the strongest emission peak for POPOP is at 448 nm, which is near to the above values. Notably, the four values do differ slightly, which may be attributable to ligand center charge transfer. Similar enhancements of intraligand fluorescence occur in (polypyridyl)metal polymers.[25−26] Especially, the emission intensity is strongest in complex **3**, and its emission peak is also slightly larger, which may be ascribed to the presence of (CH_3COO) coordinated to Zn atoms.

Conclusion

We have successfully combined Zn metal and POPOP {1,4-bis[2-(5-phenyloxazolyl)]benzene} to obtain three novel zinc−POPOP coordination polymers, $ZnCl_2(H_2O)$·(POPOP)·(POPOP) (**1**), $[ZnCl_2(POPOP)]_n$ (**2**), and $\{Zn_2(CH_3COO)(POPOP)_{1.5}Cl_3\}_n$ (**3**), with different coordination architectures under solvothermal reactions. We have also investigated the photoluminescence properties of POPOP with a d^{10} transition metal. Incorporation of Zn^{II} complexes into the π-electron system of a conjugated molecule revealed a clear relationship between synthesis temperature and structure.

Experimental Section

General Remarks: All syntheses were performed in poly(tetrafluoroethylene)-lined stainless steel autoclaves under autogenous pressure. Reagents were purchased commercially and were used without further purification. Elemental analyses of C and H were performed with an EA1110 CHNS-0 CE elemental analyzer. IR (KBr pellets) spectra were recorded with a Nicolet Magna 750FT-IR spectrometer. Fluorescent data were collected with an Edinburgh FLS920 TCSPC system. TGA analysises were carried under nitrogen with an STA449C integration thermal analyzer.

$ZnCl_2(H_2O)$(POPOP)·(POPOP) (1): A mixture of POPOP (0.036 g, 0.10 mmol), $ZnCl_2·4H_2O$ (0.10 g, 0.48 mmol) and CH_3CN (10 mL) was heated in a stainless steel reactor with a Teflon liner at 100 °C for 72 h. After cooling, within 24 h yellow crystals of **1** were obtained in 68% yield (0.030 g based on POPOP). $C_{48}H_{34}Cl_2N_4O_5Zn$ (883.06): calcd. C 65.45, H 3.89, N 6.36; found C 65.29, H 3.76, N 6.14. IR (KBr): $\tilde{\nu}$ = 3514 (m), 3124 (w), 1617 (m), 1594 (m), 1557 (w), 1483 (s), 1449 (w), 1416 (m), 1281 (m), 1151 (m), 1130 (w), 1025 (w), 948 (s), 849 (m), 827 (w), 762 (s), 722 (s), 688 (s), 564 (w), 492 (w) cm^{-1}.

$[ZnCl_2(POPOP)]_n$ (2): A mixture of POPOP (0.036 g, 0.10 mmol), $ZnCl_2·4H_2O$ (0.10 g, 0.48 mmol) and CH_3CN (10 mL) was heated in a stainless steel reactor with a Teflon liner at 110 °C for 72 h. After cooling, within 24 h yellow crystals of **2** were obtained in 65% yield (0.033 g based on POPOP). $C_{48}H_{32}Cl_4N_4O_4Zn_2$ (500.68): calcd. C 57.83, H 3.24, N 5.62; found C 57.58, H 3.15, N 5.64. IR (KBr): $\tilde{\nu}$ = 3454 (w), 3123 (w), 1649 (m), 1617 (m), 1595 (m), 1557 (m), 1483 (s), 1449 (w), 1416 (m), 1351 (w), 1271 (w), 1150 (s), 1130 (w), 1104 (w), 1027 (w), 981 (w), 947 (s), 868 (w), 849 (m), 829 (m), 762 (s), 722 (s), 687 (s), 659 (w), 564 (w), 492 (w) cm^{-1}.

$\{Zn_2(CH_3COO)(POPOP)_{1.5}Cl_3\}_n$ (3): A mixture of POPOP (0.036 g, 0.10 mmol), $ZnCl_2·4H_2O$ (0.10 g, 0.48 mmol) and CH_3CN (10 mL) was heated in a stainless steel reactor with a Teflon liner at 150 °C for 72 h. After cooling, within 24 h yellow crystals of **3** were obtained in 65% yield (0.037 g based on POPOP). $C_{38}H_{27}Cl_3N_3O_5Zn_2$ (842.72): calcd. C 54.42, H 3.25, N 5.01; found C 54.45, H 3.20, N 5.20. IR (KBr): $\tilde{\nu}$ = 3466 (w), 3123 (w), 3090 (w), 1615 (m), 1593 (m), 1559 (s), 1480 (s), 1415 (m), 1363 (w), 1239 (w), 1149 (m), 1124 (w), 1025 (w), 947 (s), 872 (w), 850 (m), 776 (m), 765 (s), 723 (s), 689 (s), 661 (w), 610 (w), 532 (w), 495 (w) cm^{-1}.

X-ray Crystallographic Study: X-ray intensities of complexes **1**−**3** were collected with a Bruker Smart CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å)

COVER PICTURE

The cover picture shows two examples of stable polynuclear ruthenium systems containing delocalized carbon-rich bridges with unusual topologies. In this work, the synthesis, the spectroscopic and voltammetric studies of a new family of bis(allenylidene) and mixed allenylidene–acetylide complexes are presented. The nature of the reduced species, which are mainly ligand-centered, is pointed out by means of ESR and IR spectroscopy. The UV/Vis and electrochemical studies show the large influence of the bridge on the electronic interaction between the redox centers and the fine tuning of this property. These new conjugated molecules appear to be promising alternatives to the classical bis(acetylide) systems for the construction of metal-containing unsaturated oligomers or polymers to mediate electron-transfer processes. Details are discussed in the article by S. Rigaut, D. Touchard et al. on p. 447 ff.

Introduction

Organometallic complexes with π-conjugated bridges are attracting interest for their electronic and structural properties in fields including liquid crystals,[1] nonlinear optical devices,[2] luminescence,[3] and electronic communication.[4−11] Electronic communication between two functionalities is a fundamental aspect related to a variety of complex systems ranging from life[12] to photoactive donor/acceptor processes[13] and electronic devices.[14] These properties are usually the result of their linear rigid structure and of their π-electron conjugation. Thus, it is crucial to understand the behavior of such systems with multiple redox components, the influence of the linkers, and to develop straightforward methods of access to them.

Dimetallic complexes have been obtained by coupling of organometallic terminal acetylides to bis(vinylidene) and bis(alkynyl) complexes.[4,5] By contrast, few dimetallic mixed alkynyl−vinylidene or alkynyl−allenylidene complexes have been selectively synthesized by activation of conjugated organic molecules.[10] For example, the activation of HC≡C−CH(OH)−C≡CH has led to a dimetallic system with a C_5 bridging ligand [$CpRu(PPh_3)_2$=C=C=CH−C≡C−$Ru(PPh_3)_2Cp$]BF_4.[10a] Highly conjugated molecules resulting from the coupling of an acetylide complex with a vinylidene[8,9] or an allenylidene[6] complex are also emerging examples.

Ruthenium systems[15] present opportunities for the synthesis of novel organometallic compounds as models for electron conduction, and with unusual and stable topologies.[16,17] The ruthenium [$RuCl_2(dppe)_2$] (dppe = $Ph_2PCH_2CH_2PPh_2$) species offers the possibility to easily link two carbon-rich chains to form reversible redox systems[16,18] with an optical transition highly dependent on the nature of the chain.[6,19] This fact gave us impetus to build polynuclear systems containing new types of delocalized carbon-rich bridges and linking reversible redox active moieties, especially allenylidenes. We now report the easy synthesis of stable dimetallic complexes containing a variety of new bis(allenylidene) bridges separated by a tunable conjugated linker and the synthesis of novel di- and triruthenium compounds containing mixed allenylidene and alkynyl groups. We further illustrate, in the light of UV/Vis and electrochemical studies, the large influence of the bridge on the electronic interaction between the redox centers.

Results and Discussion

The activation of terminal alkyne functionalities with the sixteen-electron species [$ClRu(dppe)_2$]$^+$ can be potentially employed to access polymetallic systems with carbon-rich unsaturated bridges, as previously shown with the synthesis

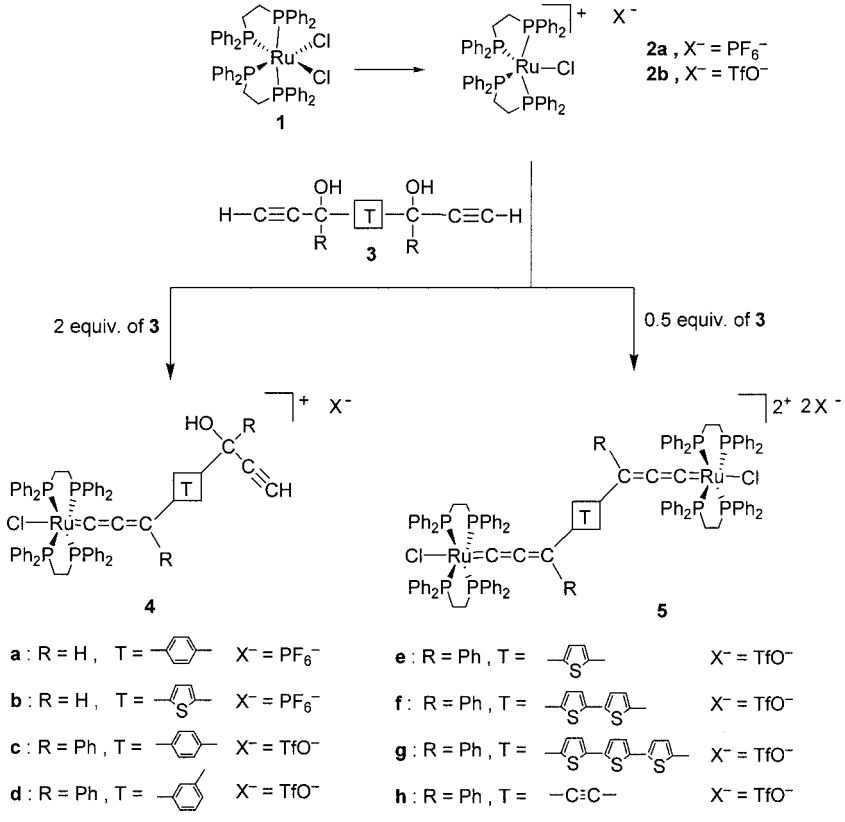
of bis(vinylidene) and bis(acetylide) derivatives.[20] Herein, we use the selective activation of a variety of functional groups with the intent of forming carbon-rich allenylidene ruthenium derivatives: (i) The simple or double activation of molecules containing two terminal propargylic alcohol functional groups, via the Selegue method,[21] offers access to mono(allenylidenes) or bis(allenylidenes).[22] (ii) New mixed terminal alkynyl−allenylidene functionalities separated by a phenyl linker were achieved by using an original step-by-step organometallic synthesis, i.e. by modification and activation of the organic carbon-rich ligand of mono- and dimetallic acetylides to introduce the conjugated allenylidene function.

It has to be noted that we described recently the protonation of a ruthenium bis(allenylidene), obtained by means of the Selegue strategy, into a bis(carbyne).[19] It is also noteworthy that Werner et al. obtained a similar bis(allenylidene) with rhodium [Cl(P*i*Pr$_3$)$_2$Rh=C=C=C(Ph)−*m*-C$_6$H$_4$−(Ph)C=C=C=Rh(P*i*Pr$_3$)$_2$Cl] by an identical approach.[23] A different kind of bis(allenylidene) not connected through the allenylidene functions such as (Ph$_2$C=C=C=Rh(P*i*Pr$_3$)$_2$−C≡C−)$_2$ was also synthesized by the same group.[24] However, no electrochemical studies were reported for these complexes.

Synthesis of Mono(allenylidene)ruthenium Complexes: The reaction of the 16-electron salts **2a** or **2b** with an excess of bis(propargylic) alcohols[25] **3a**−**h** leads to the formation of red monoallenylidene ruthenium complexes **4a**−**h** (41−81% yield) bearing a free propargylic alcohol group (Scheme 1). These allenylidenes are stable with respect to the addition of methanol to the C$_\alpha$ carbon.[26] The FTIR spectra of the allenylidenes **4a**−**h** show characteristic features for such compounds with $\nu_{C=C=C}$ = 1921−1939 cm^{-1} and $\nu_{C\equiv C}$ = 2100−2200 cm^{-1}. The ^{31}P NMR spectra display the equivalence of the four phosphorus nuclei and thus the relative *trans* disposition of the chlorine atom and of the allenylidene ligand. The characteristic allenylidene low-field ^{13}C signal for the C$_\alpha$ carbon nucleus appears as a quintuplet at δ = 288−320 ppm with $^2J_{P,C}$ = 15 Hz.

Synthesis of Bis(allenylidene)ruthenium Complexes: The free prop-2-yn-1-ol functionality of complexes **4a**−**h** can be activated with 1 equiv. of **2a** or **2b** in dichloromethane, leading to the slow formation of the bis(allenylidene) complexes **5a**−**h** (7 d). The same bridged molecules were also readily prepared by the assembly of 2 equiv. of **2a** or **2b** and 1 equiv. of the corresponding bis(propargylic) alcohol and isolated in 42−78% yield after stirring for 7 d (Scheme 1). The tertiary allenylidenes **5c**−**h** are more stable than the secondary allenylidenes **5a**−**b** (see Scheme 1). Hence, our studies have been mainly focused on these former complexes. For all complexes, the ^{31}P NMR spectrum demonstrates the high symmetry of the molecule with only one sharp singlet for the eight phosphorus nuclei. The two allenylidene groups are then equivalent, and therefore the ^{13}C NMR spectra show only one set of three different signals for the C$_\alpha$, C$_\beta$ and C$_\gamma$ carbon atoms. However, complex **5h**



Scheme 1

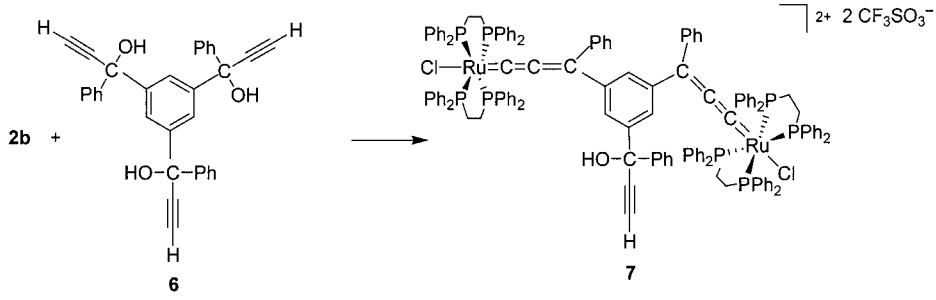
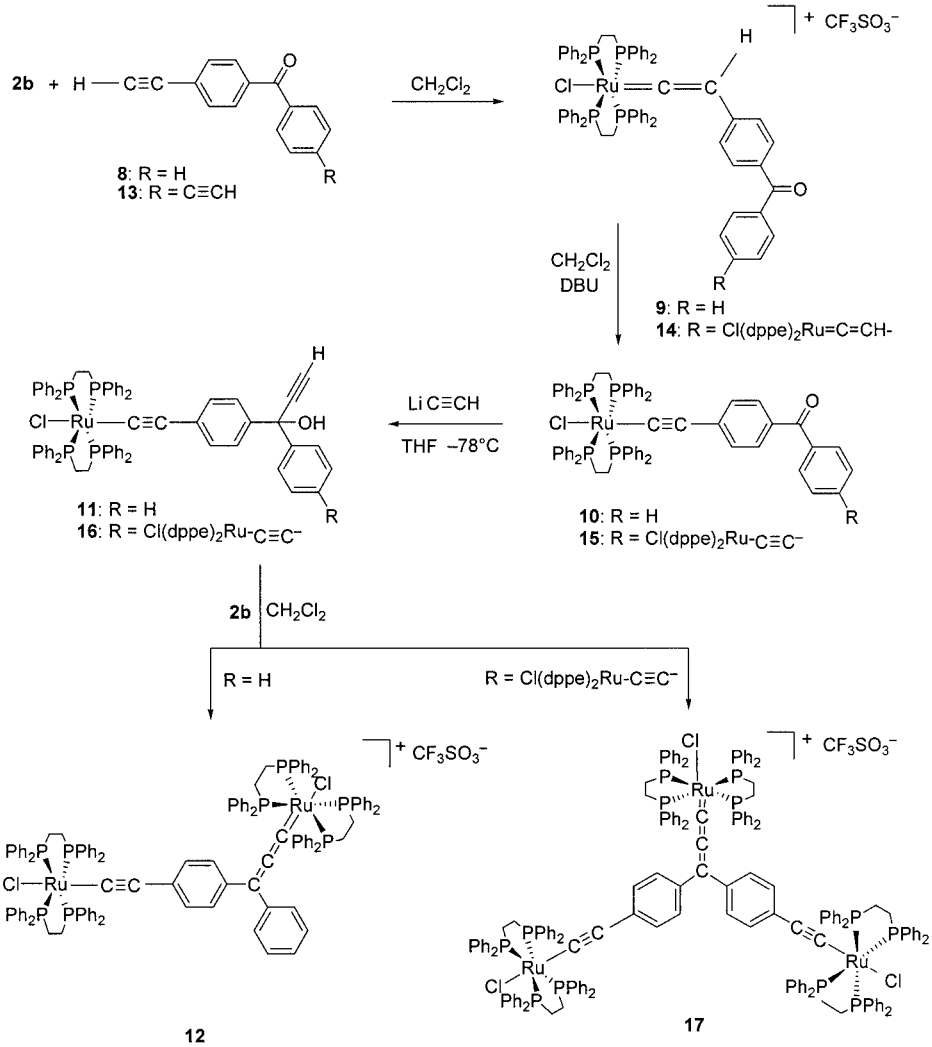


Scheme 2

with the triple bond is not stable enough in solution, and the ^{13}C NMR spectrum could not be obtained. Finally, the attempt to obtain a trisallenylidene complex by triple activation of the propargylic alcohol **6** with **2b** failed. Only the bis(allenylidene) complex **7** was recovered (Scheme 2), probably for steric reasons, as a trisallenylidene ruthenium complex was obtained when the propargylic alcohol functionalities were separated by a larger nonconjugated tripodal core.[27]

Synthesis of (Alkynyl−Allenylidene)ruthenium Complexes: The activation of terminal alkyne **8** or **13** bearing a ketone further convertible into a propargylic alcohol function with **2b**, led to the mono- (**9**) and the bis(vinylidene) (**14**) complexes in good yields (Scheme 3). The vinylidenes display characteristic FTIR vibration stretches $\nu_{C=C}$ = 1588 cm^{-1} and ν_{CO} = 1640 cm^{-1}. The ^1H NMR spectra shows a quintet for the vinylidene proton at δ = 4.82 ppm for **9** and at δ = 4.74 ppm for the two identical vinylidene protons of **14**



Scheme 3

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with $^4J_{PH}$ = 3 Hz. The low-field ^{13}C signal for the C_α carbon nucleus appears as a quintet at δ = 352 ppm for **9** and 354 ppm for **14**, and a singlet at δ = 195 ppm for the pendant ketone carbon nucleus is also observed. These vinylidene complexes can be easily deprotonated with a base such as DBU to form the neutral alkynyl−ruthenium derivatives **10** and **15**. The alkynyl−ruthenium complexes show characteristic vibration stretches $\nu_{C\equiv C}$ = 2057 for **10** and $\nu_{C\equiv C}$ = 2053 for **15**. The carbonyl group of these complexes is further converted into a propargylic alcohol function by action of lithium acetylide to give **11** and **16**. Characteristic FTIR vibration stretches are observed at $\nu_{\equiv C-H}$ = 3050, $\nu_{C\equiv CH}$ = 2135, $\nu_{C\equiv C}$ = 2065 cm^{-1} for **11** and $\nu_{\equiv C-H}$ = 3052, $\nu_{C\equiv CH}$ = 2136, $\nu_{C\equiv C}$ = 2068 cm^{-1} for **16**. Finally, the activation of these propargylic alcohol groups by the active 16-electron species **2b** leads to the isolation of the dimetallic mixed alkynyl−allenylidene **12** or of the trimetallic complex **17** bearing two alkynyl and one allenylidene groups. The overall yields for complexes **12** and **17** are 37 and 50% starting from **2b** after four steps, and they display two typical absorptions at 2040 and 1926 (**12**), 2008 and 1912 (**17**) cm^{-1}. The ^{13}C spectrum shows the presence of the allenylidene group with characteristic resonances for **12** and **17** at δ = 345 and 342 ppm respectively for C_α, and also of the acetylide group with δ = 135 and 134 ppm for C_α'.

Electrochemical and UV/Vis Studies: The bis(allenylidene) complexes are composed of two one-electron redox-active units and of a bridge that allows for electronic communication. To understand the nature of the redox behavior and the role of the linker, the cyclic voltammograms of **4** and **5** were recorded in CH_2Cl_2 solutions (0.1 M Bu_4NPF_6). The reduction potentials and other relevant data for all compounds are reported in Table 1. All complexes exhibite a linear dependence of the peak current on the square root of the sweep rate ($v^{1/2}$) from 60 to 600 mV·s^{-1}, as expected for a diffusion controlled process, and the ratio of the peak currents (i_{pa}/i_{pc}) is close to unity. These electrochemical studies show that the cationic monoallenylidenes **4c**−**h** can undergo a one-electron reduction, and the bis(allenylidenes) **5a**−**h**, **7**, two consecutive one-electron reductions. The cyclic voltammograms of complexes **4e** and **5e** are presented in Figure 1 for illustration. It is noteworthy that these tertiary monoallenylidenes undergo one reversible process, in contrast to secondary allenylidene complexes, which present an irreversible process.[22] The electrochemical behavior of the bis(allenylidenes) show several interesting features: (i) the two reversible processes are well separated from each other, and (ii) a significant anodic shift of both reduction potentials indicates that the reductions are thermodynamically favored with respect to the mononuclear analog when the two allenylidene moieties are conjugated in **5a**−**c**, **e**−**h**. For example the reduction of **4e** occurs at E° = −1.000 V vs. Fc, and reductions of the corresponding dimetallic complex **5e** are observed at less negative potentials, i.e. at E°_1 = −0.439 and E°_2 = −0.749 V vs. Fc. No such anodic shift is observed in the nonconjugated complexes **5d** or **7**, in which the allenylidene moieties are in a *meta* orientation on the phenyl linker. Indeed, for **5d**, the two reductions occur at E°_1 = −0.877 and E°_2 = −1.056 V vs. Fc, while **4d** shows a reduction wave at E° = −0.910 V vs. Fc. When two different redox processes exist for two otherwise identical redox systems in the same molecule, an important parameter is the comproportionation constant K_c. The large wave separation observed for each dimetallic complex (ΔE° > 180 mV) leads to large comproportionation constants [$K_c > 1.0\times10^3$; $-(RT/F)\ln(K_c) = \Delta E^\circ$] and establishes that all the monoreduced species are stable in solution with respect to disproportionation.[28]

It has already been mentioned that the reduction of allenylidene complexes mainly involves the allenylidene ligands,[29−32] in contrast to the oxidation of neutral acetyl-

ide, which occurs on the metal center.[33] Thus, the reduction processes of the mono- and the bis(allenylidene) can be attributed to the reduction of the carbon-rich chain in analogy to the mono(allenylidene) species *trans*-$[Cl(dppe)_2Ru{=}C{=}C{=}CPh_2]PF_6$ (**A1**) and *trans*-$[Cl(dppe)_2Ru{=}C{=}C{=}CMe_2]PF_6$ (**A2**). Nevertheless, this attribution was verified for **4c** and **5c** with the *p*-phenyl linker. For complex **4c**, the most appropriate reducing agent is the cobaltocene $[Cp_2Co]$ (i) as its reduction potential $E°$ is −1.33 V vs. ferrocene,[34] and (ii) it is ESR silent down to temperatures considerably below that of liquid nitrogen.[34b] We generated the reduced form in situ by dropping a crystal of cobaltocene in a THF solution of **4c** in a capped ESR tube. Reduced complex **4c** showed an intense and persistent signal (g = 2.0048) similar to that observed for **A1** (g = 2.0042), hence centered close to the free electron g value (a in Figure 2). The complex pattern could best be rationalized by the coupling of the unpaired electron with the four phosphorus nuclei and further coupling with the *ortho*, *meta* and *para* hydrogens of the phenyl groups, showing the delocalization of the single electron on the carbon-rich bridge.[35a] On the other hand, the first reduction of **5c** with decamethylferrocene ($E°$ = −0.590 V vs. ferrocene) or with a deficient amount of cobaltocene in the ESR cavity leads to the observation of a broad signal with g = 2.0244 (b in Figure 2). The observed shoulders may indicate some transition metal contribution (d-orbitals of the ruthenium atoms) resulting in the coupling of the free electron with the ^{99}Ru and ^{101}Ru isotopes (nuclear spin S = 5/2, and natural abundances of 12.7 and 17% respectively) with an estimated coupling constant of approximately 5 G.[35b] It is possible that the large number of magnetically independent nuclei on the chain together with this metal participation give rise to strongly overlapping resonance lines that cannot be resolved. However, this result suggests that the radical is highly centered on the organic bridge and is stabilized by delocalization along the carbon bridge between the ruthenium centers. Interestingly, further addition of cobaltocene leads to the two-electron reduction and to the disappearance of the signal, which suggest the formation of a diamagnetic doubly reduced species. ^{31}P NMR studies of the latter, obtained with 2 equivalents of cobaltocene, show a single signal with δ = 49.3 ppm consistent with a diacetylide species **18** (Scheme 4), that corroborates the communication through the bridge. Unfortunately, the spectra were broad, certainly because of the presence of residual paramagnetic compound (the reductant or first reduced species), and no exploitable proton or carbon spectra could be obtained.

IR studies, recorded in CH_2Cl_2, show the shift of the allenylidene band upon reduction of **4c** from 1925 cm^{-1} to a sharper but more intense band at 1948 cm^{-1}, similar to that observed for **A1** (from 1926 to 1945 cm^{-1}). This new value is somewhat different from that of true acetylide (2000 cm^{-1}) but coherent with the increase of the acetylide character of the reduced complexes, and with the presence of a delocalized electron mainly on the allenylidene carbon atoms of the chain (Scheme 4). Winter's et al. observed similar shifts for other reduced allenylidene complexes.[31] On the other hand, the first reduction of **5c** leads to a small opposite shift of the allenylidene band from 1912 to 1906 cm^{-1}. This last band is similar to that found for *trans*-$[Cl(dppe)_2Ru{-}C{\equiv}C{-}C(CH_3){=}C(H){-}C(CH_3){=}C{=}C{=}Ru(dppe)_2Cl]BF_4$ (**C**)[6] (1898 cm^{-1}) and consistent with the presence of delocalized allenylidene and acetylide moieties on the same bridge; two possible mesomeric forms are represented in Scheme 4. The second reduction leads to the vanishing of the former band, and to the concomitant formation a weak absorption at 1988 cm^{-1} (Figure 3). This corroborates the formation of a diamagnetic bis(acetylide) species such as **18**. It is noteworthy that all these observations are not related to the decomposition of the reduced species. Indeed, all reduced forms were thermally stable and reductions followed by oxidations with ferrocenium salt 30 min later led to the pure starting materials on the basis of ^{31}P NMR spectroscopy. Hence, in conclusion to these

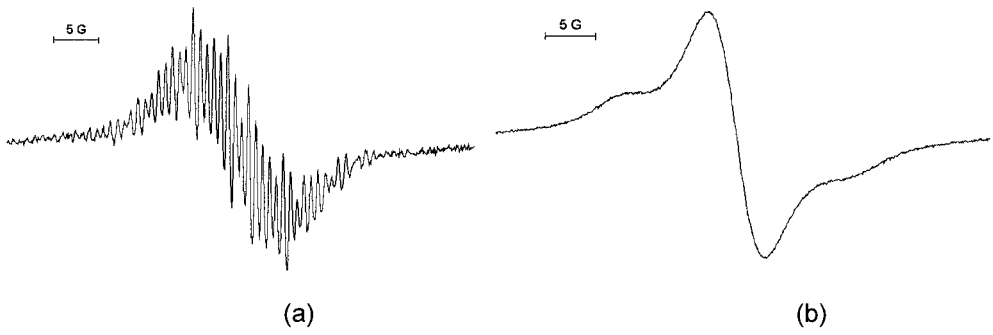

Figure 2. ESR spectra resulting from the reduction of (a) **4c** (g = 2.0048), and of (b) **5c** (g = 2.0244)

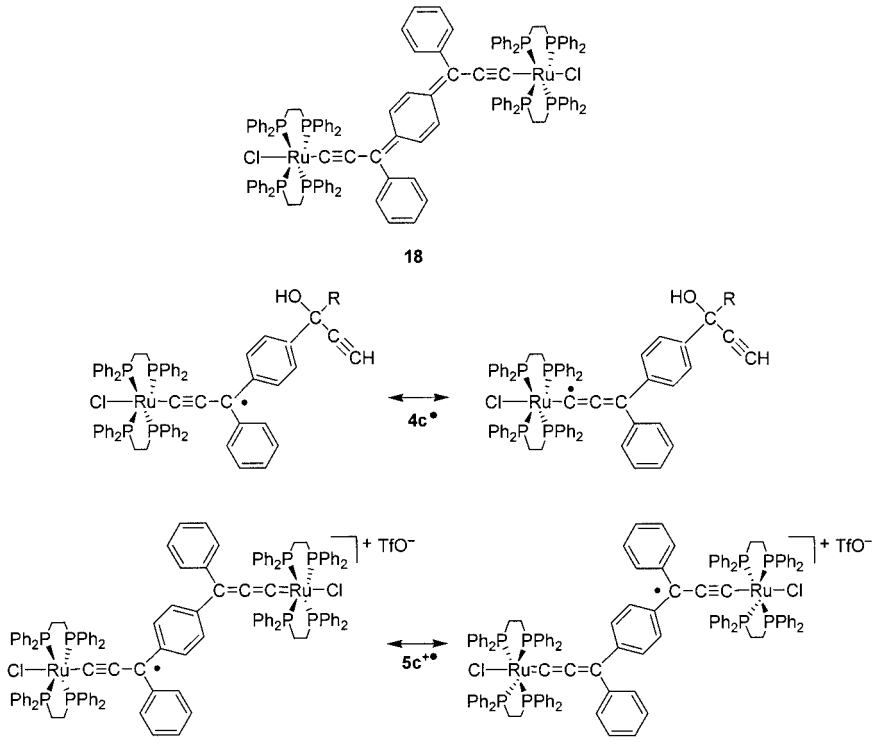

Scheme 4

spectroscopic studies, it is likely that all the electrons issued from reduction processes reside in an orbital with a significant carbon-rich ligand character but also with a non-negligible metal contribution.[32]

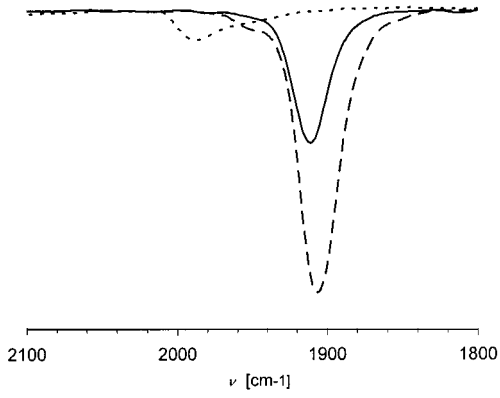

Figure 3. IR spectra of **5c** (—), its first (---), and second (···) reduced species

The dependence of redox potentials on the nature of the carbon-rich-ligand (Table 1) complexes is consistent with the ligand character of the LUMO. The reduction potential within the set of monoallenylidene species is located between 0.805 V and 1.027 V vs. ferrocene. A lower potential, that is, a higher electron stabilization along the chain is observed for **4h** with the triple bond as transmitter with $E^\circ = -0.805$ V vs. Fc. Within the series of bis(allenylidene) species, the variations of E° for both reductions are expected to be much greater. The complexes with the improved conjugation will show the stronger variation for both reduction processes in comparison to analogous monometallic species (Figure 1). According to common belief, the difference in electrochemical half-wave potential reflects the strength of interaction between the allenylidene moieties. There are, however, various additional factors that contribute to a stabilization of symmetrical mono- and bireduced complexes and especially electron delocalization. By contrast, when two redox centers are isolated from each other, E_1 and E_2 would be expected to be not only the same or similar but also very close to the potential of the comparable mononuclear analog.[36] The observed first and second reduction potentials of bis(allenylidene) species such as **5c** are less negative than those of the corresponding mononuclear species; this indicates considerable stabilization of the reduced forms by resonance and allows an analysis of the relative stabilization effects. The variation in potential is greater with less aromatic linkers (thiophene) relative to the phenyl transmitter, and the most efficient group to effect communication is the triple bond (**5h**). For example, this effect was already observed with dimetallic iron acetylides [Cp*(dppe)Fe−C≡C−R−C≡C−Fe(dppe)Cp*] (R = −2,5-C_4H_2S−, −*m*-C_6H_4−).[37] For the nonconjugated complexes **5d** or **7** (with $E^\circ_1 = -0.877$ and -0.890 V vs. Fc respectively) the first reduction potential is very close to that of the monometallic species ($E^\circ = -0.910$ V vs. Fc for **4d**) as the allenylide centers interact weakly. We also observed that the separation between the two processes (ΔE°) also depends on the nature of the transmitter. The ΔE° value of 180 mV ($K_c = 1.0 \times 10^3$) is observed with the nonconjugated systems **5d** and **7**. Surprisingly, the conjugated *p*-phenyl linker **5c** displays the same value, in contrast

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to the acetylide iron systems.[37] K_c assumes a value of 4 when the two redox sites are completely noninteracting and goes to much higher values as electronic and electrostatic interactions increase. Therefore, the present value is principally attributed to a structural rearrangement, solvation or electrostatic interactions. For the complexes **5a**, **5b**, **5e** and **5h**, this value is noticeably higher, and the greatest difference is observed with **5h** (ΔE° = 360 mV, $K_c = 1.0 \times 10^6$). We then assign this significant increase to an additional contribution from the resonance interaction between the allenylidene moieties through the linkers. Thus, in addition to the largest anodic shift, the less aromatic linkers with the shorter pathways display the greater differences in potential between the reduction processes (**5e**−**h**) in the following order: Triple bond > thiophene ≈ bithiophene ≈ terthiophene > phenyl.

UV/Vis studies were performed to compare mono- and dimetallic complexes. Figure 4 shows the absorption spectra obtained for **4c** and **5c**. The intense short-wavelength absorption band for the n−π* type transition originating from the dppe ligand at high energy remains unchanged. By contrast, the lower-energy transition is shifted from $\lambda_{max.}$ = 530 nm for **4c** to a broader band at $\lambda_{max.}$ = 588 nm for **5c**. This phenomenon is consistent with the observation made for the bis(carbyne) complex *trans*-[Cl(dppe)$_2$Ru≡C−HC=C(CH$_3$)−C$_6$H$_4$−(CH$_3$)C=CH−C≡Ru(dppe)$_2$Cl](BF$_4$)$_2$, which displays a broad band at $\lambda_{max.}$ = 559 nm, whereas the monometallic compound, *trans*-[Cl(dppe)$_2$Ru≡C−CH=C(CH$_3$)R](BF$_4$)$_2$, absorbs at $\lambda_{max.}$ = 426 nm.[19] For monoallenylidenes, the transition is attributed to the allowed transition from the metal-based HOMO-1 to the LUMO which is delocalized over the allenylidene ligand (the HOMO/LUMO symmetry is forbidden),[31] and accounts for the strong Metal-to-Ligand Charge Transfer (MLCT). Concerning the new broad band observed for the dimetallic species, an important MLCT character also seems to be present. This large bathochromic shift of the band is observed for all bis(allenylidenes) with respect to monoallenylidenes, except for compounds with nonconjugated linkers (Table 1). The $\lambda_{max.}$ value is almost the same for **4d** and **5d**, $\lambda_{max.}$ = 520 and 522 nm respectively, with the *m*-phenyl linker. By contrast, the decrease in the absorption energy in the bis(allenylidene)s **5c**, **5e**, **5f**, **5g** and **5h** is consistent with a more effective conjugated path between the two organometallic moieties, and with a decreasing energy of the LUMO, as observed in the electrochemical studies. Even though the tendency is the same in the UV/Vis studies, in electrochemistry, some differences are observed. The energy difference between the mono- and the bis(allenylidene) band ($\Delta\lambda$) follows the order: triple bond ($\Delta\lambda$ = 192 nm) > thiophene ($\Delta\lambda$ = 154 nm) > *p*-phenyl ($\Delta\lambda$ =58 nm), but with bithiophene ($\Delta\lambda$ = 70 nm) and terthiophene ($\Delta\lambda$ = 60 nm) the difference is barely larger than that for the phenyl group. This observation could be related to the well-known rotational disorder of oligothiophenes in the ground state and to the corresponding reorganization energy necessary in the excited state. In addition, an energy modification of the heavily metal-centered HOMOs arising from a lower metal d-orbital contribution in complexes with more extended π-conjugated ligands cannot be excluded.[32,38,39] It is noteworthy that the absorption bands are very broad, certainly including several transitions, and these conclusions need to be considered with care, even if similar trends were already observed in acetylide systems.[5e]

In conclusion, according to both UV/Vis and electrochemical studies, an important contribution from a less aromatic π-conjugated system undoubtedly increases the electronic communication between the allenylidene moieties and stabilizes the LUMO of the bis(allenylidene) complexes, the orbital in which the electrons are injected upon reduction. These results are consistent with the general result that the separation between energy levels continually diminishes in π-conjugated systems with decreasing aromaticity.

The cationic allenylidene complexes with one (**12**) or two (**17**) acetylide moieties were also studied (Figure 5, Table 2). They both show a one-electron reduction wave at E°_{red} = −1.170 and −1.240 V vs. Fc respectively, and **12** displays a one-electron oxidation wave at E°_{ox} = 0.140 V vs. Fc while **17** shows a two-electron oxidation wave at E°_{ox} = 0.120 V vs. Fc. In comparison to the monometallic complexes allenylidene **A1** and the acetylide *trans*-[Cl(dppe)$_2$Ru−C≡C−CHPh$_2$] (**B**),[40] we observed that for the bi- or trimetallic species the reduction and the oxidation(s) were more difficult to perform. This difficulty results from electronic communication through the bridge between one metal center and the other, and notably from the donor effect of the neutral acetylide−ruthenium group(s)

and from the withdrawing power of the cationic allenylidene−ruthenium moiety. In analogy to allenylidene and acetylide complexes, the reduction processes are attributed to the reduction of the carbon-rich bridges, and the oxidations are believed to be mainly metal-centered.[33] Interestingly, in complex **17**, the two acetylide moieties are oxidized at the same potential (two-electron wave). This shows the lack of interaction between these two metal centers in an oxidation process (Figure 5), whereas the variation of the oxidation potential between **17** and **12** is consistent with the presence of an additional electron donor acetylide in **17**. The UV/Vis spectra of **12** and **17** present very high $\lambda_{max.}$ values with a large ε for the presumed MLCT at lower energy than for **A1**.[6a] This phenomenon might be attributed to the admixing of some charge-transfer character of the acetylide to the allenylidene moiety and to the longer conjugated bridge. Finally, the original complex **12** can be considered as a bis(ruthenium) species with a delocalized bridge allowing nine carbon atoms to connect the two ruthenium centers, and it can be compared with the seven-carbon-atom bridge bis(ruthenium) complexes such as *trans*-[Cl(dppe)$_2$Ru−C≡C−C(CH$_3$)=C(H)−C(CH$_3$)=C=C=Ru(dppe)$_2$Cl]BF$_4$ (**C**).[6] The reduction potential is slightly higher and the oxidation potential is slightly lower for **12** than for **C**, both potentials are getting closer to those of the monometallic species. Hence, as observed for bis(allenylidenes), the aromatic cycle in the delocalized pathway and the slightly longer bridge lead to a decrease in the electronic coupling between the redox centers in the mixed complexes.

Conclusion

This work presents the synthesis, the spectroscopic, and the voltammetric studies of a new family of carbon-rich organometallic complexes with novel topologies. First, the formation of stable bis(allenylidene) complexes was reported, and the nature of their reduced species, which are mainly ligand-centered, was studied by means of ESR and IR spectroscopy. The general trends observed with polymetallic acetylides prevail in bis(allenylidene) species: (i) the allenylidene moieties can interact substantially through a linker if the linker is conjugated, and (ii) the UV/Vis and the electrochemical properties significantly depend on the nature of the linker. This opens the door to a potential fine tuning of their properties. In addition, the original step-by-step synthesis of mixed allenylidene−acetylide di- and trimetallic complexes with nine conjugated atoms were described and the existence of electronic communication between allenylidene and acetylide moieties was demonstrated. As the formation of a nanoscale network is needed for molecular electronic devices, these new long molecules, obtained via controlled preparations, are interesting alternatives to the classical bis(acetylides). Their abilities for *trans* chlorine atom substitution with an acetylide or a cumulenic chain make them interesting building blocks for the construction of metal-containing unsaturated oligomers and polymers to mediate electron transfer processes.

Experimental Section

General Remarks: All reactions were performed under argon or nitrogen with use of Schlenk techniques. The solvents were deoxygenated and dried by standard methods. Infrared spectra were recorded with a Nicolet 205FTIR spectrometer in solution for oils, and in KBr pellets for solids. The ^{1}H (300.13 MHz), ^{31}P (121.50 MHz) and ^{13}C (75.47 MHz) NMR spectra were recorded at 25 °C with a Bruker AV300 spectrometer. Elemental analyses were performed by the "Service Central d'Analyses du CNRS", Vernaison, France and CRMPO, Rennes, France. The synthesis of *cis*-[(dppe)$_2$RuCl$_2$] (**1**),[41] **2a**, and **2b**,[42] 1-phenyl-3-trimethylsilylpropynone,[43] 1,2-dibenzoylacetylene,[44] and of propargyl alcohols **3a**−**b**[25] were performed by using literature methods. Compounds **3c**−**d**,[45] **8**,[46] and **13**[47], reported in this section, were previously described.

HC≡C−(OH)C(Ph)−*p*-(C$_6$H$_4$)−(Ph)C(OH)−C≡CH (3c): In a Schlenk tube, acetylene (40 mmol) was dissolved in THF (40 mL) at −78 °C. Then, *n*BuLi (18.75 mL, 30 mmol, 1.6 M in hexane) was slowly added. The mixture was stirred at −78 °C for 30 min. In another tube, *p*-dibenzoylbenzene (3.57 g, 12.5 mmol) was dissolved in THF (10 mL) and added to the solution. The mixture was stirred overnight at room temperature before being hydrolyzed with a saturated NH_4Cl solution (10 mL). The crude product was extracted with diethyl ether (4 × 50 mL), washed with water (3 × 20 mL), and dried. Further purification was achieved by chromatography over silica gel (10% diethyl ether in pentane) to afford **3c** (3.29 g) as a white powder in 78% yield. ^{1}H NMR ($CDCl_3$): δ = 7.64−7.15 (m, 14 H, Ph), 5.68 (s, 2 H, OH), 3.31 (s, 2 H, C≡CH) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 145.19−125.64 (Ph), 87.08 (C≡*C*H), 75.53 (C−OH), 73.30 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2146 ($\nu_{C\equiv C}$) cm^{-1}. HRMS (EI): *m*/*z* = 338.1267; [M]$^+$; calcd. 338.1307.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

HC≡C−(OH)C(Ph)−*m*-(C_6H_4)−(Ph)C(OH)−C≡CH (3d): By the same procedure, from commercial *m*-dibenzoylbenzene (3.58 g), **3d** (3.04 g) was obtained as a white powder in 72% yield. ^{1}H NMR ($CDCl_3$): δ = 7.99−7.21 (m, 14 H, Ph), 3.34 (s, 2 H, OH), 2.83 (s, 2 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 144.56−123.44 (Ph), 86.25 (C≡*C*H), 75.73 (C−OH), 74.37 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2113 ($\nu_{C\equiv C}$) cm^{-1}. HRMS (EI): *m*/*z* = 338.1270; $[M]^+$, calcd. 338.1307.

HC≡C−(OH)C(Ph)−2,5-(thiophene)−(Ph)C(OH)−C≡CH (3e): *n*BuLi (6.74 mL, 10.7 mmol, 1.6 M) was added dropwise to a solution of thiophene (378 mg) in THF (20 mL) at −78 °C. After stirring for 1 h, 1-phenyl-3-trimethylsilylpropynone (2 g, 9.88 mmol) dissolved in THF (10 mL) was also added dropwise. The resulting mixture was stirred for 15 min at −78 °C and for 12 h at room temperature. Then, water (15 mL) and tetrabutylammoniumfluoride solution (18 mL, 1 M in THF) were added slowly, and the resulting mixture was stirred at room temperature for 2 h . The solution was extracted with diethyl ether (3 × 50 mL), and the organic layer was washed with aqueous solution of NH_4Cl. After drying with $MgSO_4$, the solvents were evaporated to afford a brownish oil. Further purification was achieved by flash chromatography on silica gel with a mixture of diethyl ether/pentane as eluent to give **3e** (1.62 g) as a white solid in 52% yield. ^{1}H NMR ($CDCl_3$): δ = 7.71−7.28 (m, 10 H, Ph), 6.88 and 6.82 (2 H, thiophene), 2.92 (s, 2 H, OH), 2.84 (s, 2 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 150.07−149.83 (C_{quat}, thiophene), 143.3−125.8 (Ph), 124.96−124.91(CH, thiophene), 85.56 and 85.51 (C≡*C*H), 75.17 and 75.14 (C−OH), 71.78 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2152 ($\nu_{C\equiv C}$) cm^{-1}. HRMS (EI): *m*/*z* = 344.0855 $[M]^+$; calcd. 344.0871. $C_{22}H_{16}O_2S$ (344.43): calcd. C 76.72, H 4.68; found C 76.42, H 4.58.

HC≡C−(OH)C(Ph)−5,5′-(2,2′-bithiophene)−(Ph)C(OH)−C≡CH (3f): By the same procedure, from 2,2′-bithiophene (1 g, 6.0 mmol), *n*BuLi (8.25 mL, 13.2 mmol), and 1-phenyl-3-trimethylsilylpropynone (2.67 g, 13.2 mmol), compound **3f** (1.5 g) was obtained in 74% yield as a brownish oil. ^{1}H NMR ($CDCl_3$): δ = 7.71−7.21 (m, 10 H, Ph), 6.94 (d, $^3J_{H,H}$ = 4 Hz, 2 H, thiophene), 6.87 (d, $^3J_{H,H}$ = 4 Hz, 2 H, thiophene), 3.31 (s, 2 H, OH), 2.86 (s, 2 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 148.63 and 143.39 (s, C_{quat}, thiophene) 137.91−125.77 (Ph), 126.01 and 123.04 (CH, thiophene), 85.45 (C≡*C*H), 75.28 (C−OH), 71.70 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2149 ($\nu_{C\equiv C}$) cm^{-1}. HR-MS (EI): *m*/*z* = 426.0730 $[M]^+$; calcd. 426.0748. $C_{26}H_{18}O_2S_2$ (426.56): calcd. C 73.21, H 4.25; found C 73.10, H 4.21.

HC≡C−(OH)C(Ph)−5,5′′-(2,2′:5′,2′′-terthiophene)−(Ph)C-(OH)−C≡CH (3g): By the same procedure, from 2,2′,5′,2′′-terthiophene (248 mg, 1.0 mmol), *n*BuLi (1.37 mL, 2.2 mmol) and 1-phenyl-3-(trimethylsilyl)propynone (445 mg, 2.2 mmol), compound **3g** (300 mg) was obtained in 59% yield as a brownish oil. ^{1}H NMR ($CDCl_3$): δ = 7.71−7.23 (m, 10 H, Ph), 6.98 (m, 4 H, thiophene), 6.91 (d, 2 H, $^3J_{H,H}$ = 4 Hz, thiophene), 3.31 (s, 2 H, OH), 2.86 (s, 2 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 148.85 and 143.66 (s, C_{quat}, thiophene) 136.54−126.11 (Ph), 124.87, 123.38 and 110.10 (CH, thiophene), 85.74 (C≡*C*H), 75.72 (C−OH), 72.16 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2146 ($\nu_{C\equiv C}$) cm^{-1}. HRMS (EI): *m*/*z* = 508.0633 $[M]^+$; calcd. 508.0625. $C_{30}H_{20}O_2S_3$ (508.68): calcd. C 70.84, H 3.96; found C 70.52, H 3.78.

HC≡C−(OH)C(Ph)−C≡C−(Ph)C(OH)−C≡CH (3h): By the same method as that for the formation of **3c** or **3d**, from 1,2-dibenzoylacetylene (2.93 g, 1.25 mmol), compound **3h** (2.90 g) was obtained as a white solid in 81% yield. ^{1}H NMR ($CDCl_3$): δ = 7.80−7.33 (m, 10 H, Ph), 3.61 (s, 2 H, OH), 2.76 (s, 2 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 140.82−125.97 (Ph), 84.87 (C≡*C*), 83.24 (*C*≡CH), 74.25 (*C*≡CH), 64.88 (C−OH) ppm. IR: $\tilde{\nu}$ = 2121 ($\nu_{C\equiv C}$) cm^{-1}. HRMS (EI): *m*/*z* = 286.0989; $[M]^+$; calcd. 286.0994. $C_{20}H_{14}O_2$ (286.33): calcd. C 83.90, H 4.93; found C 83.99, H 4.98.

1-[3,5-Bis(1-hydroxy-1-phenylprop-2-ynyl)phenyl]-1-phenylpropynol (6): By the same procedure as that for **3h**, from 1,3,5-tribenzoylbenzene(4.88 g, 12.5 mmol), compound **6** (4.09 g) was obtained in 70% yield as a white powder. ^{1}H NMR ($CDCl_3$): δ = 7.89−7.12 (m, 18 H, Ph), 5.67 (s, 3 H, OH), 3.24 (s, 3 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 145.94−122.91 (Ph), 87.11 (C≡*C*H), 75.35 (C−OH), 73.55 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2113 ($\nu_{C\equiv C}$) cm^{-1}. HRMS (EI): *m*/*z* = 468.1744 $[M]^+$; calcd. 468.1725. $C_{33}H_{24}O_3$ (468.55): calcd. C 84.60, H 5.16; found C 84.75, H 5.28.

4-Ethynylbenzophenone (8): In a Schlenk tube, *p*-bromobenzophenone (2.6 g, 9.9 mmol), CuI (180 mg, 0.99 mmol), and $[PdCl_2(PPh_3)_2]$ (690 mg, 0.495 mmol) were dissolved in Et_3N (40 mL) and THF (20 mL). Then, trimethylacetylene (1.81 mL, 1.386 mmol) was added, and the mixture was stirred for 48 h at 50 °C. After cooling, the solvent was removed and the crude product was extracted with diethyl ether and filtered through a celite pad. After evaporation, a yellow solid was obtained. In a flask, 2.4 g of this compound was dissolved in a mixture of THF/MeOH (25 mL) and KOH (12 mL, 1.6 M) was added slowly. The resulting dark mixture was stirred for 1 h at room temperature, and then the solvents were evaporated off. Purification, first by flash chromatography (silica gel, diethyl ether) and then by recrystallization in pentane, afforded **8** (1.51 g) as a pale yellow solid in 85% yield. ^{1}H NMR ($CDCl_3$): δ = 7.85−7.38 (m, 9 H, Ph), 3.22 (s, 1 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 195.93 (CO) 137.46−126.30 (Ph), 82.87 (C≡*C*H), 80.21 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2150 ($\nu_{C\equiv C}$), 1647 (ν_{CO}) cm^{-1}. HRMS (EI): *m*/*z* = 206.0730 $[M]^+$; calcd. 206.0732. $C_{15}H_{10}O$ (206.24): calcd. C 87.36, H 4.89; found C 87.15, H 4.87.

4,4′-Bis(ethynyl)benzophenone (13): Starting from 4,4′-dibromobenzophenone (1.69 g) and using the same procedure as that for the formation of **8**, we obtained **13** (0.98 g) as a pale yellow solid in 95% yield. ^{1}H NMR ($CDCl_3$): δ = 7.72−7.57 (m, 8 H, Ph), 3.23 (s, 2 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 195.06 (CO), 137.10−126.56 (Ph), 82.76 (C≡*C*H), 80.35 (*C*≡CH) ppm. IR: $\tilde{\nu}$ = 2158 ($\nu_{C\equiv C}$), 1645 (ν_{CO}) cm^{-1}. HRMS (EI): *m*/*z* = 230.0730 $[M]^+$; calcd. 230.0732. $C_{17}H_{10}O$ (230.27): calcd. C 88.67, H 4.38; found C 88.86, H 4.48.

Synthesis of Monoallenylidene Ruthenium Complexes (4a−b, X = PF_6; 4c−h, X = OTf): Dichloromethane (50 mL) was added to a mixture of $[Cl(dppe)_2Ru][X]$ (**2**) (0.5 mmol) and dipropargylic alcohol (**3**) (1 mmol). The resulting mixture was stirred at room temperature for 24 h, and the solvent was pumped to dryness. The resulting solid was washed with diethyl ether (4 × 25 mL) in order to eliminate the excess of organic reactant. Further purification was achieved by biphasic recrystallization in dichloromethane/pentane (1:2) to afford monoallenylidene complexes (**4a−h**) as powdery solids.

***trans*-[Cl(dppe)$_2$Ru=C=C=C(H)−*p*-(C_6H_4)−C(H)(OH)-(C≡C−H)][PF_6] (4a):** From **3a** (186 mg), complex **4a** (486 mg) was obtained as a deep red crystalline solid in 71% yield. ^{1}H NMR (CD_2Cl_2): δ = 9.20 (quint, $^5J_{PH}$ = 2.6 Hz, 1 H, Ru=C=C=CH), 7.53−6.88 (m, 44 H, Ph) 5.44 [d broad, $^4J_{H,H}$ = 2 Hz, 1 H, *H*C(OH)], 3.01 (m, 4 H, CH_2 dppe), 2.81 (m, 4 H, CH_2 dppe), 2.72 (d, $^4J_{H,H}$ = 2 Hz, 1 H, C≡CH) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 320.76 (quint, $^2J_{P,C}$ = 14.4 Hz, Ru=*C*), 221.91 (quint, $^3J_{P,C}$ =

Synthesis of Bis(allenylidene)ruthenium Complexes (5a−b, X=PF6; 5c−h, X=OTf): To a mixture of [Cl(dppe)$_2$Ru][X] (0.5 mmol) and dipropargylic alcohol (**3**) (0.2 mmol), dichloromethane (50 mL) was added. The resulting mixture was stirred at room temperature for 7 d, and the solvent was evaporated. The resulting solid was washed with diethyl ether (4 × 25 mL) in order to eliminate the organic reactant excess, and was precipitated three times with 60 mL of pentane after dissolution in dichloromethane (20 mL). Further purification was achieved by biphasic recrystallization in dichloromethane/pentane (1:2) to afford the bis(allenylidene) complexes **5a−h** as powdery solids.
