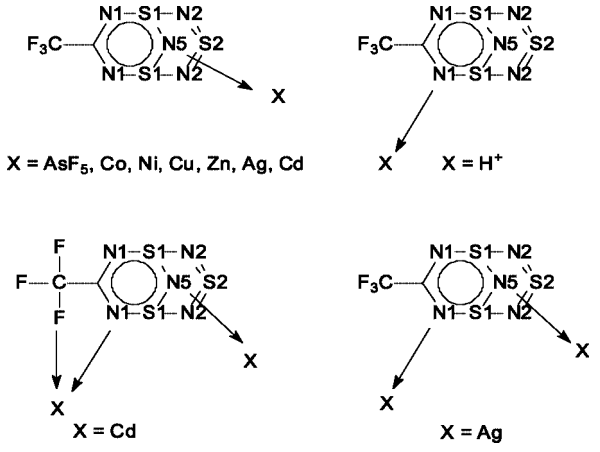
The large number of different lone pairs and low-lying orbitals enables the versatile chemistry of $F_3CCN_5S_3$. It can act as a donor to Lewis acids in many different ways. Coordination through the bridging nitrogen atom N5, which, according to theoretical calculations, carries the highest negative charge, is preferred by hard transition metal cations. $F_3CCN_5S_3$ can coordinate as a terminal ligand, but is also able to bridge Lewis acid centers through the bridging nitrogen atom and a nitrogen atom next to the ring carbon. This allows the formation of eight-membered metallacycles. Surprisingly, even the fluorine atoms of the trifluoromethyl group are able to form an additional bond, which makes $F_3CCN_5S_3$ a tridentate ligand. A comparison of the different complexes shows that $F_3CCN_5S_3$ is a very flexible ligand, which can be seen as well in the possible angle between the S–N5–S plane and the N5–metal contact, which varies in a wide range between –13.1° (M = Cd) and +27.5° (M = Cu). The resulting structures depend on the ionic radii and the hardness of the metal cations. Scheme 4 shows the four possible coordination modes known so far. Together with the known reactions with Lewis bases, the chemistry of $F_3CCN_5S_3$ is very versatile and makes the bicycles of the type RCN_5S_3 an interesting class of compounds to investigate and understand the chemistry of sulfur-nitrogen compounds. Reactions with ligands containing other organic substituents and with other transition metals have been performed as well. They resulted in decomposition of the sulfur-nitrogen heterocycle, but in some cases, when decomposition products can be isolated, an interesting chemistry can be anticipated. These investigations, for example the formation of the eight-membered planar heterocycle $[RCN_4S_3]^+[AsF_6]^-$ from the reaction of RCN_5S_3 with $[Hg(SO_2)_x](AsF_6)_2$, will form part of a separate publication.[20]



Scheme 4. Observed coordination modes of $F_3CCN_5S_3$.

Experimental Section

General: All manipulations of the solid, air-sensitive materials were performed with the exclusion of oxygen and moisture under dry nitrogen. The reactions were carried out in lambda-type glass vessels with Teflon valves using liquid sulfur dioxide as solvent, which was transferred via a vacuum line. Sulfur dioxide was dried over P_4O_{10} and distilled prior to use. The starting materials $F_3CCN_5S_3$[1a] and $[M(SO_2)_x](AsF_6)_2$ (M = Co, Zn, Cu, Cd)[7] were prepared according to published procedures. IR spectra were obtained with a Perkin–Elmer Paragon 500 FT-IR spectrometer as Nujol or Kel-F mulls. ^{19}F NMR spectra were recorded with a Bruker DPX 200 spectrometer in CD_3CN (chemical shifts are given with respect to $CFCl_3$), and melting points with a Gallenkamp melting point apparatus in sealed melting point capillaries.

$[Co(F_3CCN_5S_3)_2(OSO)_2(FAsF_5)_2]$ (1): A 10 mL portion of SO_2 was condensed onto a mixture of $F_3CCN_5S_3$ (0.25 g, 1.0 mmol) and $[Co(SO_2)_4](AsF_6)_2$ (0.35 g, 0.5 mmol) at –196 °C via a vacuum line. The reaction mixture was allowed to warm slowly to room temperature, and a brown-black solution was formed. After slow removal of the solvent, a brown-black solid remained. Careful washing of the reaction mixture with cold (–40 °C) liquid sulfur dioxide yielded orange crystals of the title compound (0.35 g, 0.3 mmol, 60%), m.p. 100–110 °C (dec.). ^{19}F NMR (200 MHz, CD_3CN, 20 °C): δ = –67.1 (q, $^1J_{F,As}$ = 930 Hz, 12 F, AsF_6^-), –75.9 (s, 12 F, CF_3) ppm. IR: $\tilde{\nu}$ = 1335 w, 1313 m, 1290 sh, 2112 m, 1295 sh, 1181 m, 1133 m, 1030 m, 1018 m, 968 w, 895 w, 816 w, 796 w, 777 m, 750 sh, 719 s, 704 m, 670 m, 661 m, 586 m, 529 m, 518 m, 506 m, 491 w cm^{-1}.

$[Zn(F_3CCN_5S_3)_2(OSO)_2(FAsF_5)_2]$ (3): Similar to the preparation of **1**, an orange solution was formed from $F_3CCN_5S_3$ (0.20 g, 0.8 mmol) and $[Zn(SO_2)_2](AsF_6)_2$ (0.23 g, 0.4 mmol). After slow removal of the solvent, a red-black oil remained. Careful washing of the reaction mixture with cold (–40 °C) liquid sulfur dioxide yielded yellow crystals of the title compound (0.27 g, 0.25 mmol, 63%), m.p. 90 °C (dec.). ^{19}F NMR (200 MHz, CD_3CN, 20 °C): δ = –67.3 (q, $^1J_{F,As}$ = 930 Hz, 12 F, AsF_6^-), –75.9 (s, 12 F, CF_3) ppm. IR: $\tilde{\nu}$ = 1509 w, 1482 m, 1455 sh, 1145 m, 1396 m, 1362 m, 1313 s, 1213 s, 1182 s, 1139 s, 1023 m, 1019 m, 968 w, 891 w, 806 w, 788 m, 760 sh, 724 s, 704 m, 661 m, 586 m, 528 m, 517 m, 519 sh, 490 w cm^{-1}.

$[Cu(\mu\text{-}F)(F_3CCN_5S_3)_2(\mu\text{-}F_2AsF_4)]_2$ (4): $F_3CCN_5S_3$ (0.20 g, 0.8 mmol) and $[Cu(SO_2)_2](AsF_6)_2$ (0.23 g, 0.4 mmol) formed a brown-black solution. After slow removal of the solvent, a yellow-brown solid remained. Careful washing of the reaction mixture with cold (–40 °C) liquid sulfur dioxide yielded blue crystals of the title compound (0.20 g, 0.13 mmol, 65%), m.p. 110 °C (dec.). ^{19}F NMR (200 MHz, CD_3CN, 20 °C): δ = –67.1 (q, $^1J_{F,As}$ = 930 Hz, 12 F, AsF_6^-), –75.9 (s, 12 F, CF_3) ppm. IR: $\tilde{\nu}$ = 1344 w, 1300 w, 1246 m, 1218 m, 1199 m, 1178 m, 1146 m, 1023 sh, 1005 m, 979 sh, 957 sh, 894 w, 850 w, 818 w, 805 w, 783 m, 773 m, 754 m, 721 s, 698 m, 663 m, 588 m, 566 w, 552 w, 528 sh, 516 w, 504 w, 489 w, 454 w cm^{-1}.

$[Cd(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)(\eta^2\text{-}F_2AsF_4)_2]_2$ (5): $F_3CCN_5S_3$ (0.20 g, 0.8 mmol) and $[Cd(SO_2)_2](AsF_6)_2$ (0.25 g, 0.4 mmol) formed an orange solution. After slow removal of the solvent, orange crystals of the title compound (0.39 g, 0.2 mmol, 100%) remained, m.p. 159 °C (dec.). ^{19}F NMR (200 MHz, CD_3CN, 20 °C): δ = –67.0 (q, $^1J_{F,As}$ = 932 Hz, 12 F, AsF_6^-), –75.9 (s, 12 F, CF_3) ppm. IR: $\tilde{\nu}$ = 1498 vs, 1474 s, 1446 s, 1391 w, 1368 s, 1343 m, 1299 w, 1228 m, 1197 m, 1168 m, 1106 sh, 1028 m, 1005 m, 956 w, 814 m, 790 m, 770 s, 750 sh, 725 vs, 710 vs, 666 s, 606 m, 585 m, 571 sh, 550 w, 542 w, 518 sh, 510 m, 490 w cm^{-1}.

Crystallographic Analysis: The single-crystal X-ray structure determinations were carried out with a Siemens P4 diffractometer or a Stoe IPDS using Mo-K_α (λ = 0.71073 Å) radiation with a graphite monochromator. The crystals were mounted onto a thin glass fiber using Kel-F oil. Details of the data collection and refinement are given in Table 2. The structures were solved by direct methods (SHELXS).[21] Subsequent least-squares refinement on F^2 (SHELXL 97-2) located the positions of the remaining atoms in the electron density maps.[21] All atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions using a riding model and refined isotropically in blocks. The data were corrected for absorption (DIFABS).[22] Graphical representations of the structures were prepared with the program DIAMOND.[23] CCDC-265908 (**1**), -265907 (**3**), -265909 (**4**), and -265910 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We are grateful to the BFK NaWi, Universität Bremen, for financial support and Mr. Peter Brackmann for collecting the X-ray data.

New Avenues in Inorganic Chemistry

Among the chemical disciplines, inorganic chemistry has traditionally been open to new directions into materials. Visions of future technologies challenge the inorganic chemist to produce materials with new and, in particular, designer properties, sometimes with surprising results. For instance, the demand for miniaturization led to the discovery that a decrease in size does not give a continuous trend in properties.

Inorganic chemistry has a role in materials science

Nanoscience, and in consequence nanotechnology, both deal with the special properties and the pattern of behaviour of any kind of material on the nanometer scale. At these dimensions the classical differences between physics, chemistry, and biology become meaningless. This can be considered as a scientifically new, holistic concept. Nanoscience and -technology, therefore, are not to be considered as novel scientific disciplines in a classical sense. Rather they unify apparently different fields on the nanoscale. Classical physical laws can no longer be applied to describe the propeties of a particle of any chemical composition if its dimension falls below a critical dimension. The investigation of individual nanoparticles, especially with respect to their electronic, optical or magnetic properties, has therefore been in the focus of interest for many research groups around the world over the last few decades. Consequently, our knowledge on the properties of, for instance, semiconductor and metal nanoparticles, is quite advanced. We indeed now understand the dramatic change of properties on the way from the bulk state to the nano state: quantum size effects begin to dominate and corresponding theories replace those of classical physics.

Nanoscience blurs the borders between disciplines

There is, however, still a dramatic gap in our knowledge on the behaviour of three-, two- and one-dimensional arrangements of those nanoparticles. How do they communicate? What is the role of the matter in between? Which kind of forces hold organized particles together? How do nanoparticles interact with biomolecules? Numerous other questions can be formulated for these arrangements. Last but not least, it is important to think about applications of communicating nanoparticles in future electronic devices, sensors, storage systems etc.

In many countries, funding bodies have initiated projects with the goal of bringing together physicists and chemists in order to find answers to the numerous questions arising in connection with the organinization of nanoparticles. Some of the relevant results of a research program supported by the Deutsche Forschungsgemeinschaft (SPP 1072), entitled "Semiconductor and Metal Nanoparticles as Building Blocks for Organized Structures" are now published as peer reviewed papers in this issue of the *European Journal of Inorganic Chemistry*. Besides producing a series of important results, a second effect has been reached by the program: several groups started successful collaborations, especially fruitful between physical and chemical research partners, since, as mentioned before, these disciplines meet each other on the nanoscale. From the publishing point of view another consequence was evident: since the peer review was necessarily international, cross-border stimulation of ideas was a interesting side-effect, illuminating new aspects of the study. Some authors specifically mentioned that the comments were particularly valuable.

International and interdisciplinary contacts stimulate innovative research

As a large part of the acquired results has already been published elsewhere in the course of the last past years, this issue contains an unusual number of microreviews. We hope that this collection of results from cooperative research will stimulate still more groups to initiate interdisciplinary and international collaborations in the field of nanoscience and nanotechnology.

COVER PICTURE

The cover picture shows one-, two- and three-dimensional arrays of nanoparticles (represented by the cluster in the centre). The bottom right corner illustrates the self-assembly of a monolayer of nanoparticles from a drop of solution. Also displayed is the AFM imaging of nanoparticles (top right), the interaction of a nanoparticle array with an electrical field (top left), and the immobilisation of nanoparticles on DNA (bottom left). All these interactive aspects of research on nanoparricles that are used as buiding blocks for organized systems are covered in a series of papers in this issue. The artwork was performed by Michael Noyong, RWTH Aachen.

The linking of nanosized clusters is especially interesting if the following conditions are fulfilled: The nano-objects, as in the present case, have interesting properties like *well-defined* functionalized external and internal surfaces, linking processes follow *well-defined* rules and occur with respect to formation of discrete as well as extended structures under mild conditions in different phases, i.e. in the gas, solution and solid phase. In the present microreview it is shown that the wheel- and sphere-shaped nanosized molybdenum-oxide based clusters fulfil these conditions while extensive linking is observed even under one-pot conditions, which means that the clusters primarily formed by self-assembly can become further linked in the same phase.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

The chemistry of varying connectivity is a fascinating subject. Nature has long made use of this phenomenon as a means to induce structural diversity. From dazzling diamonds to charry coals, from liquid aniline to its conducting plastic polymer,[1] the varying fluidity of the membranes,[2a] from a basic building unit to a variety of supramolecular structures,[2b–2f] from crystalline quartz to ornate shells of diatoms and related bio- (or bio-mimetic) architectures,[2g–2k] are but only a few illustrations of varying connectivity. The underlying principle in all cases is nearly the same, varied but iterative linking of basic building blocks. The tale becomes especially interesting from a chemist's point of view if the above principle can be deliberately realized in a reaction system which has the intrinsic potential to show connectivity variability under different conditions,

Achim Müller (left) studied chemistry and physics at the University of Göttingen and received his Ph.D. (1965) and his Habilitation (1967) there. In 1971, he became professor at the University of Dortmund (Germany), and in 1977 accepted the chair of Inorganic Chemistry at the University of Bielefeld, where he is still Professor of the Faculty of Chemistry. His research involves the chemistry of transition metals, particularly inorganic supramolecular chemistry and bioinorganic chemistry in synthesis, spectroscopy, and theory. He has published, besides numerous original papers, more than 35 reviews and is coeditor of several books, including "The Chemistry of Nanomaterials" with C. N. R. Rao and A. K. Cheetham in 2004 (Wiley-VCH). The latest of his very many national and international awards in 2005 are an honorary doctorate of the University Pierre et Marie Curie (Paris) and an award, the Premio Elhuyar Goldschmidt, of the Real Sociedad Española de Química (RSEQ, Spanish Chemical Society). He also delivered this year's annual Lewis Lecture at the University of Cambridge.

S. Roy (right) obtained his M. Sc from the Indian Institute of Technology, Delhi, India, and has just completed his doctoral dissertation under the supervision of Prof. A. Müller at the University of Bielefeld.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

e.g. in the gas phase, in solution or under solid-state conditions. The solutions of oxoanions of the early transition metals, in particular the polyoxomolybdates under reducing conditions considered here, provide spectacular possibilities to explore the enormous connectivity variety that can be achieved by linking together metal-oxide based building blocks or even the resulting nanosized clusters.[3] Examples include spherical nanocapsules with unique receptor properties like those of the $\{Mo_{132}\}$ Keplerate type,[4] the giant wheel-type cluster anions like $\{Mo_{154}\}$,[5] and the "blue lemon" $\{Mo_{368}\}$-type species[6] (all formed from metal-oxide fragments as building blocks) as well as the formation of chains or layers from these clusters which themselves act as building blocks. In this microreview an account of such covalent structuring in the solid state leading to periodicity is depicted as a concluding section and is preceded by different types of "super-structuring" in the gas phase, in solution and on surfaces. The unprecedented linking versatility to be illustrated shortly is a consequence not only of the uniformly nanoscaled structured surfaces but especially of the characteristic/unique functionalizations [with the option for an interesting type of "scale chemistry, in which the size of the "secondary building blocks" (SBUs) in a structure is increased while maintaining the same connectivity between them [...]" (see ref.[7])]. With respect to the structural variety of nanosized discrete species, the other polyoxometalates like the polyoxotungstates behave completely different from the polyoxomolybdates, i.e. they do not show the versatility of nanosized structures.

1. Structuring in the Gas Phase

"Uncharged" molybdenum-oxide giant spheres with a molecular mass of about 16 kDa can be "kicked out" like soccer balls into the gas phase using matrix-assisted laser desorption and ionization (MALDI) and be detected by time of flight (TOF) mass spectrometry.[8] These findings confirmed the existence of such giant clusters in the gas phase and opened a wide range of nontrivial experiments, i.e. single-molecule spectroscopy of nano-objects or the epitaxial growth of functionalized supramolecular layers or cluster collectives suitable for electronic devices (quantum-dot cellular automata). The practically neutral spherical clusters studied here, for the aforementioned related investigations, cocrystallized in a matrix of DCTB (2-[(2*E*)-3-(4-*tert*-butylphenyl)-2-methylprop-2-enylidene]malononitrile).

MALDI spectra for two spherical species of the type $[\{(Mo)Mo_5\}_{12}\{M_{30}\}]$ in the DCTB matrix were obtained. As main products, single spheres of the types $[\{Mo\}_{72}\{Fe\}_{30}(Mo)_6]$ (molecular mass 15.93 kDa with nearly all decorations, but without the crystal water), $[\{Mo_{72}\}\{Mo_{30}\}]$ (15.94 kDa) singly and doubly charged, and remarkably, also oligomers with 2, 3, 4 and 5 spheres, again singly and doubly charged, were found. Taking into account the molecular mass of DCTB (250 Da), the mass distribution over the peaks covers the complete range from the fully ligand decorated (together with only a few matrix molecules) to the completely undecorated giant spheres (Figure 1).

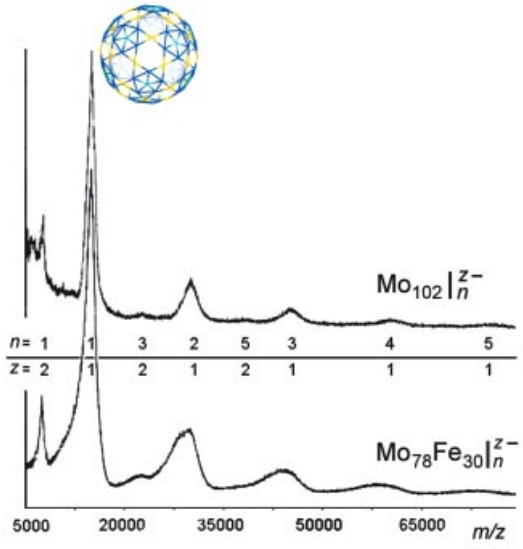

Figure 1. MALDI TOF mass spectra of the $[\{(Mo)Mo_5\}\{M\}_{30}]$-type species (M = Fe, Mo) and their oligomers (for details see ref.[8]).

2. Super Structuring in Solution

An interesting cluster connectivity was accomplished with super-structuring, and highlighted also as "rounding up"[9] of a huge number of $\{Mo_{154}\}$-type nanowheels in aqueous solution to vesicular nanoassemblies, i.e. to an inorganic skinned drop of water (for details on the topic not mentioned here, see ref.[10]).

The $\{Mo_{154}\}$ based vesicles, almost monodisperse, were characterized by light-scattering data (DLS and SLS) as well as transmission and scanning electron microscopy, which revealed spherical hollow structures with an average, hydrodynamic radius of about 45 nm and comprising approximately 12×10^2 $\{Mo_{154}\}$ wheel-shaped clusters (Figure 2). The clusters appear to lie flat and homogeneously distributed on the vesicle surface. A question may arise as to whether those entities are really hollow and not solid. It can be shown that they are, apart from the solvent inside.[11]

The unique/unprecedented phenomenon of self-assembling $\{Mo_{154}\}$-type nano-objects into a spherical vesicle is still not completely understood. However, it is expected that here the counter cations Na^+, H^+ and especially the different types of confined structured water play, besides attracting van der Waals forces, a crucial role in the story of vesicular stabilization. (The aqueous solution of the clusters is a medium strong acid, even "dissolving" metals like Zn.) Assuming that all the nanowheels are distributed on the surface in almost hexagonal closest packing, the center-to-center distance between two adjacent nanowheels would be around 4.9 nm, whereas the diameter of an individual nanowheel is according to X-ray crystallography 3.6 nm. This infers that the nanowheels are not touching each other on the vesicle surface.

As mentioned above, water assemblies and counter cations are expected to play an important role in filling gaps and holding the overall assemblies together, while the struc-

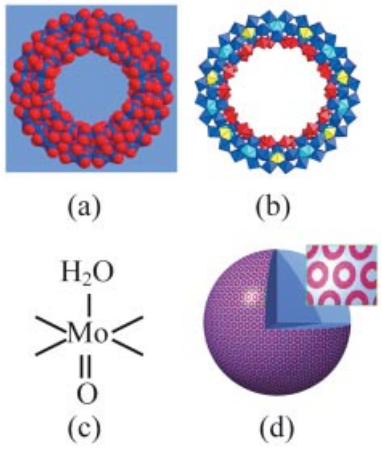

Figure 2. Structure of the 3.6 nm size $\{Mo_{154}\}$-type nanowheel with a hydrophilic surface and nanosized central cavity as well as the related vesicle. (a) Space-filling representation (Mo atoms blue and light blue; O atoms red). (b) Polyhedral representation, demonstrating the abundance of pentagonal $\{(Mo)Mo_5\}$ units (in blue) probably influencing the water structure ($\{Mo_2\}$ units red; $\{Mo_1\}$ units yellow). (c) The typical smallest fragment with a metal atom and its coordination sphere, i.e., with one of the 70 H_2O ligands causing the extreme hydrophilic nature that is responsible for the interaction with solvents such as water. (d) Schematic plot of the vesicle structure ($\approx$ 45 nm radius) formed from ca. 12×10^2 nanowheels in aqueous solution; the inset shows enlarged nanowheels.

tured water would in a way especially explain the stability of the vesicles! Indeed, the integration of a large number of nano-objects on an ordered spherical surface seems to be highly *anti*-entropic and hence a highly unlikely event (Figure 2). But the release of some of the "local" strongly hydrogen bonded water molecules from the vicinity of the clusters to the "bulk" water pays the high price for the mentioned entropy decrease.

These results are also interesting as the molecular $\{Mo_{154}\}$-type wheels show, because of the abundance of 70 coordinated H_2O ligands, an extremely hydrophilic surface causing a well-defined hydration shell. This again causes extreme solubility, which for more than 200 years prevented chemists from the time of Scheele and Berzelius who performed the first related experiments, from isolating them in a crystalline state.[12a] Now it can be shown by dielectric relaxation studies[12b] that there are different kinds of confined water in and on these systems; for instance the water inside the wheel-type cavity is more strongly fixed (thus less mobile) than the water at the surface, while both are probably involved in the stabilization of the vesicles. This correlates with the above-mentioned hydrophilicity and especially the strong cluster surface water interaction.

3. Encapsulation by Surfactants and Surface Structuring: Films and Monolayers

The motivation to examine "Surfactant Encapsulated Clusters" (SECs) rather than only "naked" ones had the following base: the surfactant shell improves the *stability* of the encapsulated cluster against *fragmentation*, enhances the *solubility* in nonpolar, aprotic organic solvents, neutralizes their *charge*, thus leading to discrete, *electrostatically neutral* assemblies, while altering the *surface chemical properties* (e.g. self-aggregation, surface adhesion, wetting behavior) in a predictable manner. Some related investigations[13,14] are reviewed here, also deliberately with respect to some details.

The discrete hybrid $(DODA)_{40}(NH_4)_2[(H_2O)_n \subset Mo_{132}O_{372}(CH_3COO)_{30}(H_2O)_{72}]$ ($n \approx 50$) for example is formed by spontaneous self-assembly (see Figure 3). It consists of a hollow giant spherical isopolyoxomolybdate core covered by a hydrophobic shell of dimethyldioctadecylammonium

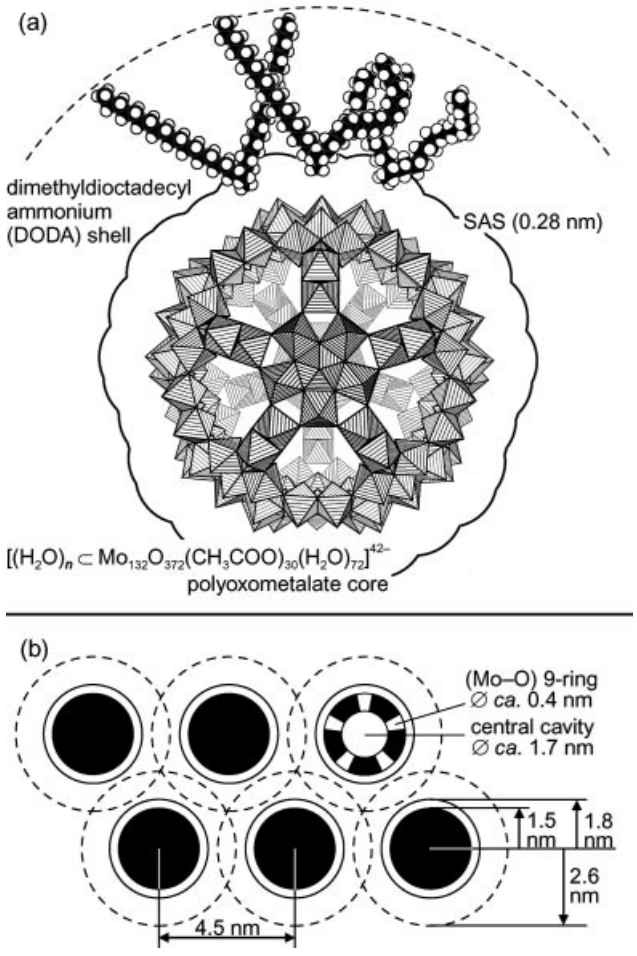

Figure 3. (a) Schematic representation of the surfactant-encapsulated cluster (SEC). The Mo–O framework of the $\{Mo_{132}\}$-type cluster is shown in polyhedral representation. The DODA amphiphiles, only a fraction of which are represented in the Scheme, form a hydrophobic shell around the cluster. Molecular dynamics simulations of a single SEC placed within a periodic solvent-filled ($CHCl_3$) box indicate that in solution the relative density of the appending C_{18} chains decreases as the radial distance from the cluster increases. Due to the conformational flexibility of the C_{18} chains, the external boundary of the SEC (represented by the broken line) is not sharply defined. (b) Schematic representation of a single SEC layer according to TEM data and molecular models. The SECs arrange on a 2D lattice to form a closest packing. Surfactant shells of neighboring SECs locally interpenetrate one another. One of the SECs is displayed cross-sectioned to further highlight the supramolecular architecture.

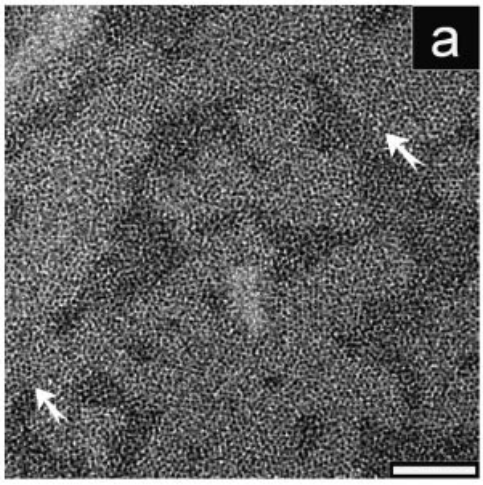
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(DODA) cations, which was the basis for the generation of well-defined films and monolayers.[13] The structural characterization of the nanoporous core-shell particles was based on small-angle X-ray scattering (SAXS) data (on solutions of the encapsulated clusters), transmission electron microscopy (TEM) investigations, FT-IR and UV/Vis spectroscopy, as well as the determination of the molecular area of the encapsulated cluster by Langmuir–Blodgett (LB) film investigations.[13] Computer modeling of the solvent-accessible surface of the encapsulated cluster yielded a central cavity with a volume of 1.5(±0.3) nm^3. The cavity is occupied by approximately 50(±15) H_2O molecules, which are, in the case of the present acetate system with a hydrophobic shell interior, not densely packed. The covered surface area of 84 $Å^2$/DODA indicates a rather tight packing of the amphiphiles at the cluster/capsule surface.

The discrete cluster hybrids have been directly imaged by transmission electron microscopy.[13] Figure 4a shows a thin film originally cast onto a water surface. The inorganic cores of $(DODA)_{40}(NH_4)_2[(H_2O)_n \subset Mo_{132}O_{372}(CH_3COO)_{30}(H_2O)_{72}]$ ($n \approx 50$) appear as dark spots embedded in a bright matrix of surfactant molecules. Both the diameter of the dark objects (ca. 3 nm), as well as the average distance between them (ca. 4.5 nm), match the film structure depicted in Figure 4b. The image shows monolayer regions, regions consisting of a bilayer (darker) and the uncovered substrate (brighter), while small domains exhibit hexagonal arrays of SECs corresponding to a two-dimensional dense packing of spherical particles (arrows). The order improves in thicker films and becomes three-dimensional. An ordered region is shown in Figure 4b; the related electron diffraction pattern (insert) clearly reveals long-range order (spots rather than rings) and a threefold symmetry for the pattern of reflections corresponding to a spacing of 4.2 nm. In accordance with the presence of local fourfold symmetry projections it can be assumed that the SECs are arranged on a fcc lattice with the most dense (111) planes preferentially oriented parallel to the substrate, as is the case of latex films. It may therefore be concluded that the diffraction pattern reflects the structure from the triangular array of particles in a (111) plane at normal orientation to the beam, and that the packing of the SECs is best described within a fcc lattice with a cubic unit-cell axis of approximately 6 nm.

A characteristic feature of the present type of SEC is that it spreads at the air-water interface. This property was used to measure its molecular area. From the compression isotherm of a monolayer of the cluster (Figure 5), a molecular area of 15 nm^2 at the collapse point could be determined, which corresponds to the densest possible packing. Based on the assumption of a void-free monolayer in which the inorganic cluster cores are packed in a hexagonal array (Figure 3b), a core-to-core distance of 4.2 nm was obtained, a result that is in excellent agreement with the TEM data. The molecular area for noninteracting SECs determined at the onset of the isotherm ($\pi = 0$) is 32 nm^2, which corresponds to a diameter (of the spherical projection) of 6.4 nm.

Due to the unique supramolecular architecture of the surfactant encapsulated cluster (SEC) as well as its high solubility in common organic solvents, this aggregate shows promising perspectives for future applications in host-guest chemistry and homogeneous size-selective catalysis.



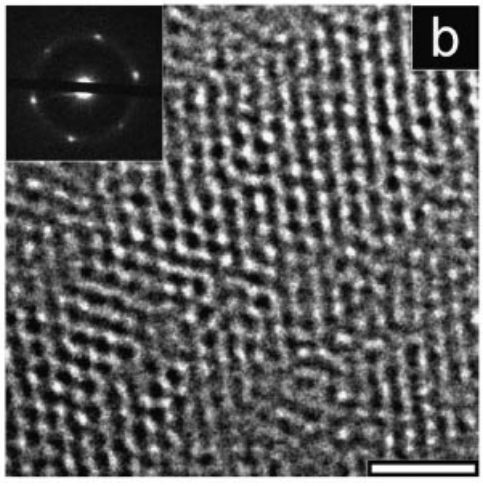


Figure 4. Shown is (a) a TEM micrograph of a thin film of SECs (scale bar 50 nm). Extended monolayers, interspersed with holes and doublelayer regions, are clearly visible (two arrows mark some regions of apparent hexagonal order). (b) TEM micrograph of an ordered region of a thicker film at high magnification (scale bar 20 nm). The insert shows a low-angle electron diffraction pattern (elastically filtered) recorded from a larger area (5 μm^2) containing the region shown.

4. Extended Structuring in the Solid State

Controlled assembly of building blocks by *specific linking* in a self-assembly process following an "Aufbau" principle leading to the metal-oxide based nanoscaled clusters as mentioned above, inevitably comes up with an imminent question. Is it possible to use those self-assembled structures as "secondary building blocks" to generate even "*extended*" complex topologies by "*extended" linking*? In our

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

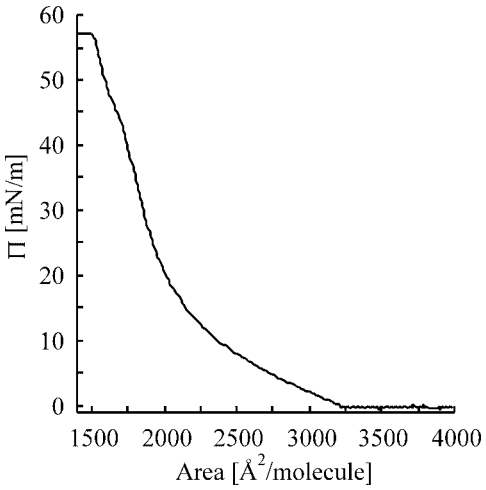

Figure 5. Surface pressure-area ($\pi - A$) isotherm of the SEC at the air-water interface.

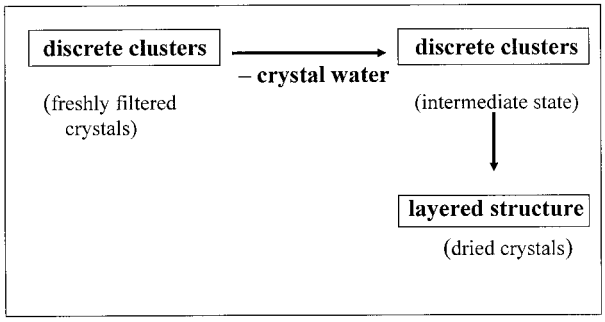
case the question was whether it is possible to "trigger" a special aggregation-type process to extensively link [(pentagon)$_{12}$(linker)$_{30}$]-type species and/or the circular {Mo$_{154}$}-type nano-objects, as "secondary building blocks". In fact it was possible to find an easy solution to the problem. A simple condensation-type reaction with the loss of water molecules solves the problem by triggering a self-organization type process even under solid-state conditions at room temperature, thereby getting the primarily formed parent-type nano-objects linked in the same phase. In the following Section we will discuss five prototypal cases of such processes, which elegantly demonstrate the basic principles of "scale chemistry"[7a] in the context of connectivity.

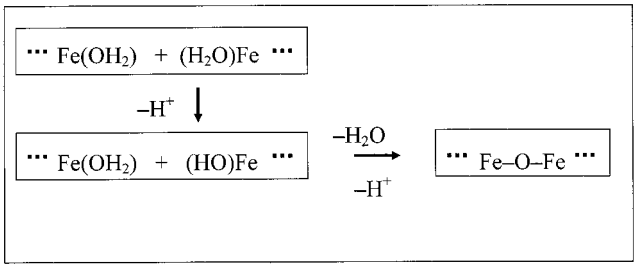
4.1 Cross-Linking the [{(Mo)Mo$_5$}$_{12}${Fe}$_{30}$]-Type Capsules According to Their Acidic Properties to 2D Layers: A Remarkable Room-Temperature Solid-State Reaction

A well-known reaction in inorganic chemistry is a condensation process in aqueous solution between acidic [M^{III}(H$_2$O)$_6$]$^{3+}$-type complexes with the resulting loss of protons and water that leads to the formation of iron polycations via M–O–M linkages.[15] Such a reaction has a very low activation energy and hence could in principle proceed in the present [{(Mo)Mo$_5$}$_{12}${Fe}$_{30}$]-type capsule situation because of the abundance of 30 [Fe(H$_2$O)$_2$]$^{3+}$groups as linkers.[16a]

Correspondingly, it was in fact observed that even in a room-temperature solid-state reaction the [{(Mo)Mo$_5$}$_{12}$-{Fe}$_{30}$]-type nano-objects become cross-linked.[16b,16c] The rapid loss of loosely bound crystal water molecules leads to a situation where the discrete spherical clusters are abundant in the compound [{(Mo)Mo$_5$}$_{12}$Fe$_{30}$O$_{252}$(CH$_3$COO)$_{12}${Mo$_2$O$_7$(H$_2$O)}$_2${H$_2$Mo$_2$O$_8$ (H$_2$O)}(H$_2$O)$_{91}$]·ca. 150 H$_2$O, i.e. the corresponding freshly filtered monoclinic crystals can come into contact, which is a condition for the interaction. This finally leads to the formation of [H$_4$Mo$_{72}$Fe$_{30}$O$_{254}$(CH$_3$COO)$_{10}${Mo$_2$O$_7$(H$_2$O)}{H$_2$Mo$_2$O$_8$(H$_2$O)}$_3$(H$_2$O)$_{87}$]·ca. 80 H$_2$O, with a layered structure forming platelike crystals (see Schemes 1 and 2 and Figure 6). It is assumed that the finally released H$^+$ ions protonate the spherical cluster units. (Note: [{(Mo)-Mo$_5$}$_{12}${Fe}$_{30}$]-type clusters can also be obtained as discrete entities in rhombohedral crystals, where the reaction does not proceed, probably because of a different type of packing.) The (nearly) electrical neutrality of the cluster units facilitates the easy loss of water and hence cross-linking. The reaction steps (see Scheme 1 and Scheme 2) involved in cross-linking clearly show as expected a decrease in the volume of the unit cell.



Scheme 1.



Scheme 2.

4.2 "Necklace"-Type Linking of Spherical Capsules

From two-dimensional layers to a one-dimensional chain or necklace, a transition, which might initially seem problematic but, which in fact, follows the same thread of chemical logic. The formation of one-dimensional chains of related similar nano-objects involves, in principle, a reaction of the same type, which is based on a compound containing (nearly neutral) discrete [{(Mo^{VI})Mo$^{VI}_5$}$_{12}${Mo$^{V}_6$Fe$^{III}_{24}$}-(CH$_3$COO)$_{20}$O$_{258}$(H$_2$O)$_{84}$]$^{2-}$ clusters. When the black crystals containing the mentioned clusters are dried, the latter becomes linked to form one-dimensional chains with the stoichiometry [{(Mo^{VI})Mo$^{VI}_5$}$_{12}$ {Mo$^{V}_6$Fe$^{III}_{24}$} (CH$_3$COO)$_{20}$-O$_{258}$(H$_2$O)$_{82}$]$^{2-}$. The reaction is triggered by the rapid loss of crystal water molecules (Figure 7 and Figure 8),[17] which causes the obligatory decrease of inter-sphere distances and leads to the situation where an Mo=O group of one discrete sphere can formally act as a ligand while replacing H$_2$O groups attached to Fe^{III} centers of an adjacent sphere in an

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

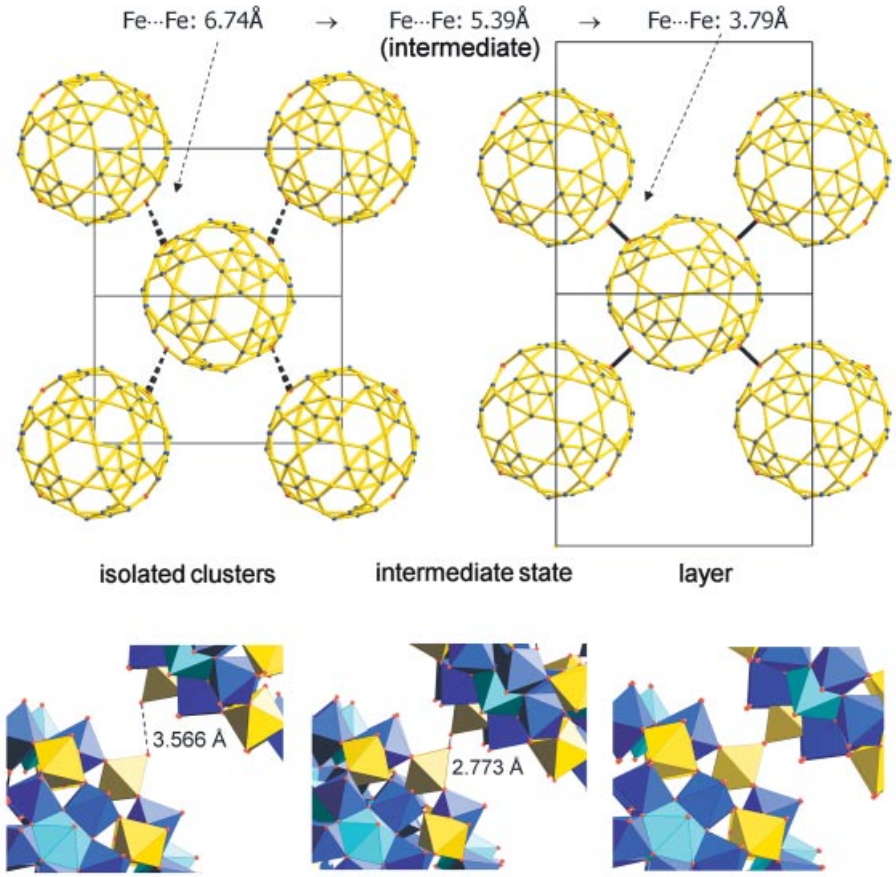


Figure 6. Wireframe representation (in yellow/blue) of the metal skeleton of the $\{Mo_{72}Fe_{30}\}$-type cluster units indicating their covalent cross-linking to a layer structure (top right). The solid-state room-temperature conversion process leading to its formation takes place according to Scheme 1 and Scheme 2 given in the text. The reaction proceeds from discrete cluster units (top left) present in the wet monoclinic crystals, freshly filtered from the mother liquor, via an intermediate state (top middle) with discrete units positioned at the minimum possible distances without covalent bond formation to the final (rhombic) crystalline product. (Note: the same does not occur for rhombohedral crystals with discrete units.[16a]) The related segment demonstrating the linking is given in polyhedral representation (FeO_6 yellow; Mo polyhedra blue).

S_N-type reaction. It is important to note that this mechanism is much more complicated than that in the above-mentioned cross-linking case. It should further be noted that the present clusters due to their lower symmetry do not allow an easy further higher-symmetrical cross-linking, i.e. with two-dimensional periodicity.

In the present case and in that of the previous Section (4.1), it should in principle also be possible to form oligomers when the existing boundary conditions prevent extended linking.

4.3 Cross-Linking of the Spherical Clusters Exhibiting Encapsulated "Guests", i.e. Composites with Nucleus-Shell Topology

The chemistry of connectivity could become even more exciting if it is possible to "cross-link" not only empty spherical capsules like those described above, but also "host-guest"-type composites – especially those with unusual host-guest interactions – to a network. The above-mentioned experiments have shown that it is possible to connect $[\{(Mo)Mo_5\}_{12}\{Fe\}_{30}]$-type moieties, but the question arises, can such moieties, which are reacting to become linked, contain guests?

Interestingly, the cavities inside the (practically uncharged) $[\{(Mo)Mo_5\}_{12}\{Fe\}_{30}]$-type clusters are large enough to host Keggin-type anions with a diameter of ca. 14 Å. The latter can be incorporated into the cavity of the former by merely adding them to a solution ambient to the generation of the host cluster shells.[18] The resulting molybdenum-oxide based "host-guest" composite with an encapsulated Keggin ion presents an unprecedented noncovalent, i.e. supramolecular host-guest interaction (Figure 9).[19] Here the Keggin ion (guest) can, in principle, also act as a "kind of template" for the generation of the host as it accelerates its formation.

It finally turned out that these "host-guest" supramolecular nanocomposites can be linked in a way that is identical to that of the empty spherical capsules to form layers (see Section 4.1). In other words, these host-guest nanocomposites also undergo a cross-linking type of solid-state condensation reaction at room temperature to form a layered net-

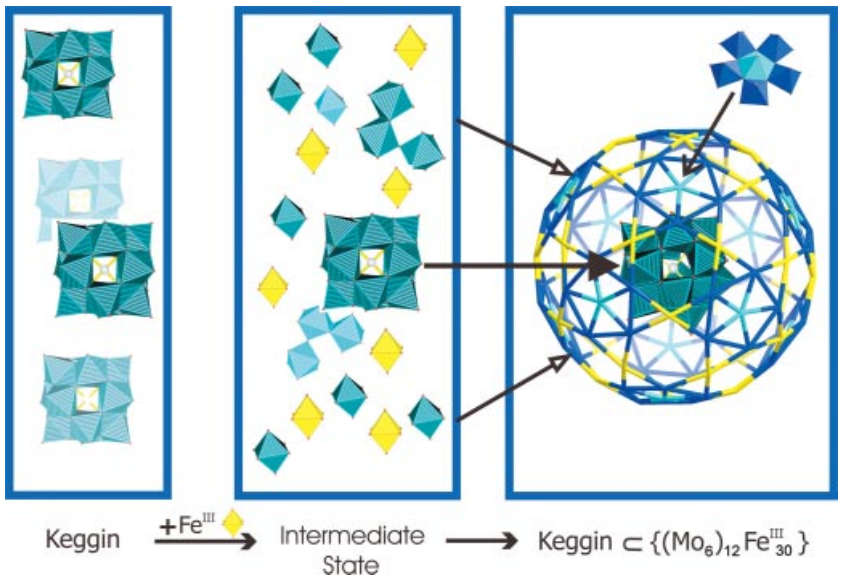

Figure 9. Reaction Scheme showing the decomposition of part of the Keggin anions $\{PMo_{12}O_{40}\}^{3-}$ (left, polyhedral representation) in the presence of Fe^{3+} in aqueous solution, leading finally to the formation of the spherical $\{(Mo)Mo_5\}_{12}\{Fe\}_{30}$-type cage [with wireframe representation of the capsule's Mo atoms (in cyan and dark blue) and Fe atoms (in yellow)] which has one of the remaining nondecomposed Keggin anions encapsulated (polyhedral representation) thus forming the unusual supramolecular species with core-shell topology: guest ⊂ [(pentagon)$_{12}$(linker)$_{30}$] (FeO_6 octahedra yellow).

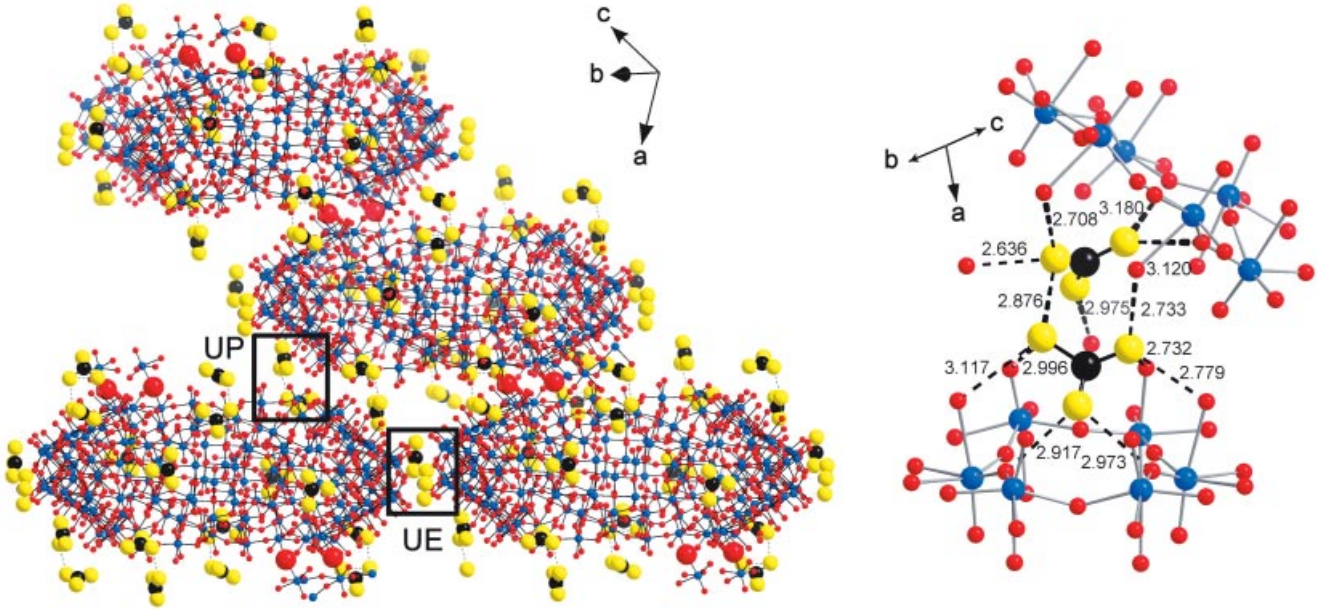

Figure 10. Left: ball-and-stick representation of four $\{Mo_{154}\}$-type rings of the compound $^{1}_{\infty}\{(NH_3CONH_2)_{14}[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{68}]\}\cdot$ca. 350 H_2O "glued" with two types of protonated urea molecules [viz., equatorial (UE) as well as polar (UP)]. The atoms of the urea (type) units and the oxygen atoms which covalently connect adjacent rings have been enlarged for clarity (molybdenum blue; oxygen red; carbon black; nitrogen and oxygen atoms of urea units which could not be clearly distinguished using single-crystal X-ray structure analysis, yellow). Right: interaction between polar UP-type units among themselves as well as with oxygen atoms of two hexagonal $\{Mo_6O_6\}$ ring sites showing the (weak) potential receptor property of the cluster. The difficulty of distinguishing exactly between O and N atoms of UP is mainly caused by a O=Mo–H_2O disorder at the cluster surface (for details see ref.[20]).

work, where each individual nanocomposite acts as a "secondary building block".

4.4 Linking the {Mo_{154}}-Type Circular Clusters to Chains

Like the [(pentagon)$_{12}$(linker)$_{30}$]-type nano-objects above, the {Mo_{154}}-type wheels can also be linked to form a one-dimensional chain of the type $^{1}_{\infty}${Mo_{154}}. For instance, using protonated urea as a "gluing" agent it is possible to achieve such linking. The protonated urea reduces the repulsion of approaching negatively charged rings, thereby facilitating condensation between them and ultimately leading to a covalent Mo–O–Mo connectivity (see Figure 10 and ref.[20]). These findings can lead to new gateways in host-guest chemistry as the protonated urea molecules are "attached" to the nucleophilic {Mo_6O_6}-type "receptors" on the cluster surface [note also a new (A. Müller et al., unpublished) synthetic method for the formation of $^{1}_{\infty}${Mo_{154}}-type chains with "guest free" {Mo_6O_6} rings as well as with other cationic substrates like guanidinium].

4.5 Linking the {Mo_{154}}-Type Circular Clusters to Layers

The {Mo_{154}}-type units are not only one-dimensionally connected to form chains but also into $^{2}_{\infty}${Mo_{154}}-type layers. The basic principle involves the assembly of {Mo_{154}}-type rings as synthons by inducing a synergetically activated functional complementarity on their surface sites. The title of the corresponding paper was "*Assembling nanosized ring-shaped synthons to an anionic layer structure based on the synergetically induced functional complementarity of their surface sites*: $Na_{21}[Mo_{126}^{VI}Mo_{28}^{V}O_{462}H_{14}(H_2O)_{54}(H_2PO_2)_7]\cdot xH_2O$ ($x \approx 300$)".[21] Because of the increased electron density (or nucleophilicity) of the considered Mo=O group (pointing outside of the ring), caused by the coordinated $H_2PO_2^-$ ligand, the related ring formally acts as a ligand resulting in the substitution of the H_2O ligand at a corresponding Mo=O group of another adjacent ring which has no coordinated $H_2PO_2^-$ ligand. (Four such covalent connectivities are formed per ring.) The layered structure also leads, topologically speaking, to the formation of a system of "tubular"-type nanochannels (Figure 11). They present a possibility for the construction of a new class of materials with well-defined channel cavities (3.4 nm diameter) once the channels are freed of water and cations! Such layered networks with specific channel dimensions might be useful for size- and shape-selective reactions especially under catalytical conditions. These systems are especially attractive as they are electron rich (note: the delocalized electrons cause the blue color). It should further be mentioned that not only linking to extended structures with periodicity could be achieved but also the formation of a dimeric species.[22]

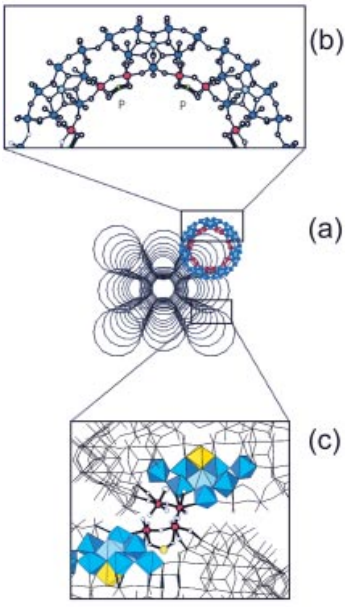

Figure 11. (a) Perspective view of the cluster framework of $Na_{21}[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{54}(H_2PO_2)_7]\cdot$ca. 300 H_2O along the crystallographic *c* axis, showing the abundance of nanotubes. For clarity, only one complete ring (without the $H_2PO_2^-$ ligands) is shown in polyhedral representation. With respect to the other rings, only the centers of the {Mo_1} units are given and connected. (b) Ball-and-stick representation of the upper half of a ring segment showing the principal positions of the $H_2PO_2^-$ ligands. (c) Detailed view [perpendicular to (a) and (b)] of the bridging region between two cluster rings emphasizing one {Mo_8}, one {Mo_1} unit (in polyhedral representation) as well as one {Mo_2} unit and one $H_2PO_2^-$ ligand (without hydrogen atoms; ball-and-stick representation). The bridging (disordered) oxygen center is depicted as a large hatched circle. Colour code: {Mo_2} red; {Mo_8} blue (central MoO_7 pentagonal-bipyramid, light blue); {Mo_1} yellow; P green.[21]

5. Concluding Remarks

Our investigations touched upon here are especially interesting because of the unprecedented discrete nano-objects' properties. The spherical nanoclusters for example can be considered as "artificial cells" while they also have a strong intrinsic tendency of "responsive reactivity".[23,24] This feature, together with the well-known catalytic properties of polyoxomolybdate clusters, could in principle lead to the emergence of a novel type of molecular catalyst and host-guest system from which functional nanodevices may evolve. One important point in this regard is the fact that several of the nano-objects (the porous capsules are, especially under O_2 free conditions, stable in solution) allow easy and different types of manipulations, for instance the specific affinity of the spherical capsules to cations can be "tuned" due to the modification variability of both the internal cavity shell as well as the overall charge.[3f]

Although in this short voyage, various facets of covalent and noncovalent connectivity related to different states of matter have been highlighted, from "vesicular structuring" in solution via oligomeric assemblies in the gas phase to covalent connectivity in the solid state, it seems that a lot of discoveries in this context are still possible! The reason for the enormous versatility is really a consequence of the nanoscaled and especially appropriately functionalized surfaces, which resulted for instance in an interesting study to observe nucleation intermediates (title of the paper: "Kinetic Precipitation of Solution-Phase Polyoxomolybdate [...]:

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A Window to Solution-Phase Nanostructure").[25] An especially interesting challenge for the future will also be to place (discrete) oligomers observed in the gas phase[8] on surfaces in order to study their electronic properties.

[11] The answer also came from a combination of DLS and SLS studies on the solutions containing those vesicles. The results of a DLS measurement performed on the aqueous $\{Mo_{154}\}$ solution showed that the aggregates were almost monodisperse, with an average hydrodynamic radius R_h of 45 nm. SLS data, analyzed through the Zimm plot, indicated that the average radius of gyration R_g was almost equal to the hydrodynamic radius R_h as observed from DLS studies. It is known that for a *solid* spherical particle, the relationship between the two radii is $R_g = 0.77R_h$. If the aggregates were solid spheres with R_h around 45 nm, an R_g value of 34 nm would be expected, which was clearly not the case. As an increasing fraction of the total mass of a spherical object is distributed closer to the sphere's surface, the ratio R_g/R_h increases; the ratio approaches a value of 1 as the corresponding spherical object has all of its mass on its surface. The scattering data thus indicated that the aggregates in solution were not "solid clusters", but vesicle-like hollow spheres. (Solvents inside the spheres do not contribute to the light scattering.) Moreover the mass of the aggregates (M_w) determined from the Zimm plot (which excludes any contained solvent) corresponded approximately to 1,165 individual nanowheels. Because a solid $\{Mo_{154}\}/\{Mo_{152}\}$-type nanocrystal with a 45 nm radius would contain more than 14,000 individual molecules, the estimated M_w value also suggested that those aggregates must have a hollow interior with 1,165 nanowheels homogeneously distributed on the surface of the vesicle.

Magnetic Nanoparticle Superstructures

Michael Giersig*[a] and Michael Hilgendorff*[a]

Keywords: Nanoparticles / Ferrofluids / Nanosphere lithography / Nanoshadows

The aim of this microreview is to present recent advances in the preparation of magnetic nanoparticle superstructures from ferrofluids and by nanosphere lithography. Different successes of methods presented in this article to create magnetic nanoparticles will be discussed in view of different requirements of available assembling techniques. Theoretical aspects of nanoparticle assemblies and their assembled layer magnetic properties are not reviewed here.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

1. Introduction

For the design of novel nanostructured devices one needs a technique for preparing highly symmetric periodic particle arrays (PPA) within the range of several microns, on an industrial scale. Different routes have been investigated in the past to obtain small particles, which can be assembled in large areas of high symmetry. These approaches typically apply "scale down" techniques, e.g. ball milling of bulk materials, and "bottom up" techniques, e.g. cluster or nanoparticle growth from precursors in gaseous or liquid phases. The latter, i.e. the wet chemical synthesis of inorganic colloidal particle fluids, is most elegant from a chemist's point of view.[1]

Inorganic colloidal fluids are stable dispersions of nanoscale clusters or fine particles – which can be crystalline or amorphous – in a solvent.[2] If the dispersed material is known to exhibit ferromagnetic behavior in the bulk material, colloidal suspensions thereof are called ferrofluids or magnetic fluids.[3] One can develop PPA with ferrofluids having a standard particle size distribution $< 10\%$ by simply drying a drop of solution on suitable substrates. This self-assembly technique has been improved through use of

Michael Giersig studied at the A. Mickiewicz University of Poland. He carried out his diploma research work at the Fritz-Haber-Institute of the Max-Planck-Gesellschaft in Berlin and received his diploma in physics at the Freie Universität Berlin in 1984. He continued to work at the Fritz-Haber-Institute. He received his PhD in chemistry at the Freie Universität Berlin in 1988. Subsequently he continued with his postdoctoral work at the Institute for Molecular Genetics of the Max-Planck-Institut in Berlin. At the end of 1989 he took up a post at the Hahn-Meitner-Institute in Berlin, Department of Physical Chemistry, where he was awarded twice with a research prize. In 1995 he received an international accolade in the form of a 2-year stay at the University of Melbourne, Department of Physical Chemistry. After his return he habilitated at the University of Potsdam, Faculty of Physical Chemistry in 1999. In 2000 Michael Giersig was appointed professor at the Technological University, department of physics in Poznan, Poland. He is the author/co-author of over 140 scientific journal and conference articles and book chapters. He joined the research center caesar in April 2003 to establish the group "nanoparticle technology". The work of the group focuses on the creation of 2-D and 3-D nanostructures, based on single nanoparticles as well as the fabrication of nanostructured surfaces with a size of a number of square centimeters. A further focal point is the optical, structural as well as magnetic characterization of nanostructures.

Michael Hilgendorff received his diploma in chemistry in 1993 (University of Hannover), where he investigated the photocatalytic degradation of carbon tetrachloride on platinized titanium dioxide particles. He then worked on ZnO colloids and transparent electrical conductive electrodes at the University of Würzburg, where he received his PhD in 1999. In February 1999 he joined the group of Michael Giersig at the Hahn-Meitner-Institute in Berlin to work within the priority program of the Deutsche Forschungsgemeinschaft (DFG) on "Semiconductors and metal clusters as building blocks for nanostructured materials". He joined the group "nanoparticle technology" at caesar in April 2003, where he is responsible for the development of new and the optimization of existing inorganic colloid syntheses.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

different coating techniques (e.g. spin coating, dip coating, or spraying) in combination with applied external forces. The origin of these external forces is either mechanical, and is used for the preparation of Langmuir–Blodgett (LB) films,[4] or electrostatic, which is then used for layer-by-layer (LbL) assembly applying polyelectrolytes.[5] The use of external electric and magnetic fields to improve the self-assembly of charged and magnetic nanoparticles, respectively, has also been reported.[6,7]

Despite all those successes, there are some applications that cannot be solved by the use of ferrofluids. One reason is the limitation of perfectly ordered nanostructures to about one micron squared. A second result from the question: "How can we arrange highly ordered magnetic nanoparticles on substrates having a distance larger than 100 nm?". To overcome these problems, a lithographical technique applying organic colloids – Nanosphere Lithography (NSL) – has been further optimized.[8]

The formation of monolayers of self-assembled colloidal particles (mainly polystyrene and silica submicron-sized, monodisperse spheres) is well established and has been widely used in various fields of research.[9] Well-ordered latex particle films were used, among others, as masks that allow the production of regularly arranged triangular-shaped structures on almost arbitrary substrates. Through the evaporation of different materials through the mask, it was possible to prepare nano-sized particles with diverse optical[9,10] or magnetic properties.[10] There are many different monolayer fabrication methods based on electrophoresis,[6] electrostatic deposition,[11] the Langmuir–Blodgett technique, spin-coating,[12] the controlled evaporation of solvents from a solution containing latex particles on a hydrophilic substrate,[13] or non-photolithographic methods.[14] Many authors used the method of Micheletto et al.,[13a] or other drying-based methods and pointed out that a hydrophilic surface is crucial for monolayer depositions.[15] To deposit PS latex particles onto hydrophobic substrates it is necessary to use an alternative method that involves assembly onto a liquid–gas or a liquid–liquid interface.[8]

In this microreview we will provide an overview of assemblies of ferrofluids, as well as some improvements of NSL by changing the shadows below – and the interstices between – hexagonal-ordered monolayers of submicron spheres. For an overview of theoretical aspects of nanoparticle assemblies see.[16] Detailed information on magnetic properties are available by Leslie-Pelecky and Rieke,[17] Binns,[18] and Spasova and Farle.[19] A short summary is given in ref.[20].

2. Superstructures from Ferrofluids

Syntheses: The most important prerequisite for the preparation of magnetic nanoparticle superstructures from ferrofluids is the control over particle size and size distribution during syntheses. Many wet chemical routes have been developed in recent years. Syntheses of monometallic magnetic particles such as Fe,[21] Co,[7b,21a,21b,22] or Ni,[21a,21b,23] have been successfully done by electrochemical reduction,[22i,23d] chemical reduction by Li,[23c] hydroborides,[21b,22j–22l] or polyols[24] of metal salts, thermal decomposition (initiated by conventional methods[7b,21e,22a,22b,22e–22h,22m,23a,23b] or by ultrasound[21d]) of zero-valent metal-organic compounds in organic solvents in the presence of bulky stabilizers such as: *i*) fatty acids (in combination with organic amines or phosphanes); *ii*) polymers, or; *iii*) surfactants. In the case of *i*), the fatty acids act as stabilizing compounds, i.e. to overcome oxidation, Van der Waals, and dipole–dipole interactions, while the amines or phosphanes control the particle growth. Surfactants can be used as stabilizers for inorganic nanomaterials dispersed in organic solvents or as compounds forming stable micelles in heterogeneous oil-in-water systems, e.g. sodium dodecyl sulfate (SDS). Other surfactants, e.g. alkylammonium bromides (DDAB, CTAB) or Aerosol OT (AOT), form a stable emulsion of water droplets in hydrophobic solvents (reverse micelles). Figure 1 shows a typical result of Co-particles prepared by thermal decomposition of octacarbonyldicobalt in dichlorobenzene.

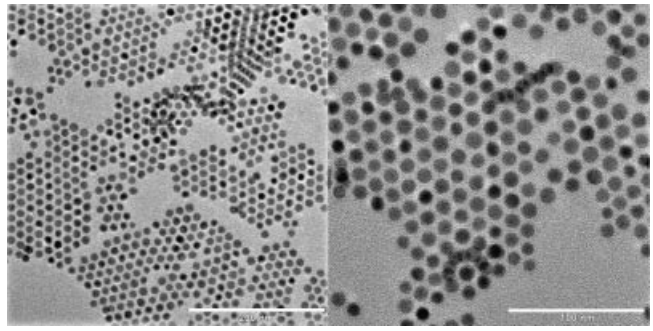

Figure 1. TEM images at different magnifications of monodisperse 10 nm Co particles self-assembled on a carbon-coated Cu grid.

The development of bimetallic ferrofluid syntheses has been based on existing synthetic procedures of monometallic ferrofluids. In general, they have been produced by thermal decomposition of bimetallic zero-valent metal-organic compounds[25] or in-situ or successive thermal decomposition of zero-valent monometallic metal-organic compounds,[26] as well as by in-situ or successive reduction of metal salts,[27,28] or combinations thereof.[29] In summary, bimetallic particles form alloys, core-shell particles, or cluster in cluster particles,[24] are all dependent largely, but not exclusively, on reaction kinetics. Applied methods and properties of these fluids have been summarized in ref.[20].

The most common preparation of magnetite (Fe_3O_4) ferrofluids was developed by Massart about 20 years ago and described in detail in 1987.[30] The synthesis was based on the co-precipitation of Fe^{II} and Fe^{III} salts in aqueous solutions stabilized by repulsive electrostatic forces. TEM investigations show typically aggregated particles, consisting usually of a mixture of ferrimagnetic magnetite, and maghemite (γ-Fe_2O_3), and paramagnetic hematite (αFe_2O_3). The ratio of the different iron oxide phases is directly compared to the expense associated with performing the synthe-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sis under oxygen free conditions, because γFe_2O_3 and α-Fe_2O_3 are oxidation products of Fe_3O_4. Figure 2 provides typical images of magnetite particles prepared in aqueous medium (a) and after their transfer to toluene (b).

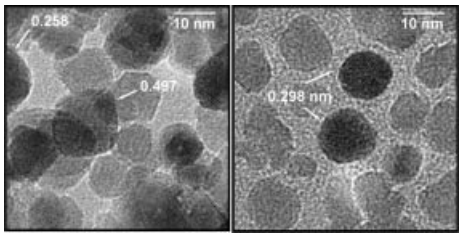

Figure 2. Typical TEM images of iron oxide particles; a) prepared in aqueous solution by Massart method and b) the same particles dried from a toluene solution after adsorbing oleic acid on their surface. The distances shown in the images are the result of fast Fourier analysis, indicating typical lattice planes of magnetite (redrawn with permission from ref.[16a]).

Since these reports, several optimizations have been discovered to produce ferrofluids useful for new applications. One of them was concerned with the possibility of changing the magnetic properties of the inverse Fe_3O_4 spinell by replacing Fe^{II} with Co^{II}, Ni^{II}, Mn^{II}, or Zn^{II} ions.[31]

Additionally, many reports dealt with solving the classic problem of nanoparticle aggregation in aqueous solutions (Figure 2, a). To overcome such aggregation, new preparations have involved micellar solutions,[32] as well as the transfer of iron oxide particles from aqueous to nonpolar solvents by hydrophobizing the surface by adsorbing bulky stabilizers such as fatty acids (Figure 2, b).[33]

Different methods have been applied to decrease particle size distribution. One method that has been successfully applied involves synthesis of iron oxides in reverse micelles. A second method dealt with a size selective precipitation after transfer of iron oxide particles to nonpolar organic solvents. Most recently, Sun et al.[34] have developed a very successful method to achieve monodisperse Fe_3O_4 nanoparticles without a size selection procedure. This method is based on the reduction of iron(III) acetylacetonate by 1,2-hexadecanediol and further thermal decomposition at high temperatures (solvent: diphenyl ether, b.p. 265°C) in the presence of oleic acid and oleylamine as stabilizers. As a result, small Fe_3O_4 nanoparticles (diameter ca. 4 nm) having a particle size distribution of ca. 5% are formed and can be further grown by seed-mediated growth.[35] A further method to obtain monodisperse maghemite (γ-Fe_2O_3) particles based on the preparation of Fe particles by the thermal decomposition of carbonyliron and their further oxidation to the oxide has been published by Hyeon et al.[36] A detailed investigation of the structural, magnetic, and electronic properties of iron oxide nanoparticles prepared by decomposition of iron(II) and iron(0) precursors in the presence of different organic solvents and surfactants has been published in ref.[37].

Table 1 provides an overview of successful syntheses and surface properties, determining the applicability of different assembling methods, of various magnetic colloids.

General observations for wet chemical ferrofluid preparations are increasing particle sizes with decreasing precursor concentrations and decreasing chain length of the stabilizers, and increasing size distributions with increasing final particle sizes. As one challenge of syntheses is to achieve a narrow size distribution, the reverse micelle technique and the so-called "hot injection" technique have been successfully applied, especially for the preparation of larger particles (diameters $>$ 5 nm – 15 nm). Using the latter method, standard size deviations $<$ 10% have been experimentally demonstrated (standard size deviations of ca. 5% have been predicted theoretically by choosing a proper combination of solvent and stabilizers[38]). Moreover, the hot-injection technique has been employed to facilitate a further growth of primary prepared particles (seed particles) by reactive precipitation of precursors on the surface of seed particles.

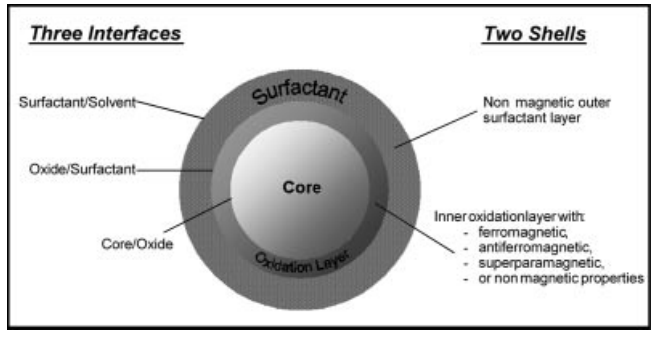

Figure 3. Sketch of a magnetic nanoparticle representing the usual result of colloid chemical synthesis. The desired core material is covered with an inner oxidation layer of the core material and an outer surfactant layer that is necessary to overcome attractive forces. As a result, three interfaces are present, which determine the nanoparticles properties (adapted with permission from ref.[16a]).

Table 1. Overview of successful syntheses and surface properties of various magnetic colloids.

Synthesis		Materials	Surface properties
D	Decomposition	metals, their alloys, and oxides prepared by post oxidation	uncharged, hydrophobic
E	Electrolysis	metals and their alloys	charged, hydrophobic
R	Reverse micelles	metals, their alloys, and oxides	charged, hydrophobic
M	Micelles	magnetic latex spheres formed by emulsion polymerization	charged, hydrophilic
O	Organohydroborate reduction.	metals and their alloys	charged, hydrophobic
P	Polyol reduction	metals and their alloys	various
C	Combination	metal alloys	uncharged, hydrophobic
H	Hydrolysis and condensation	iron oxides	charged, hydrophilic

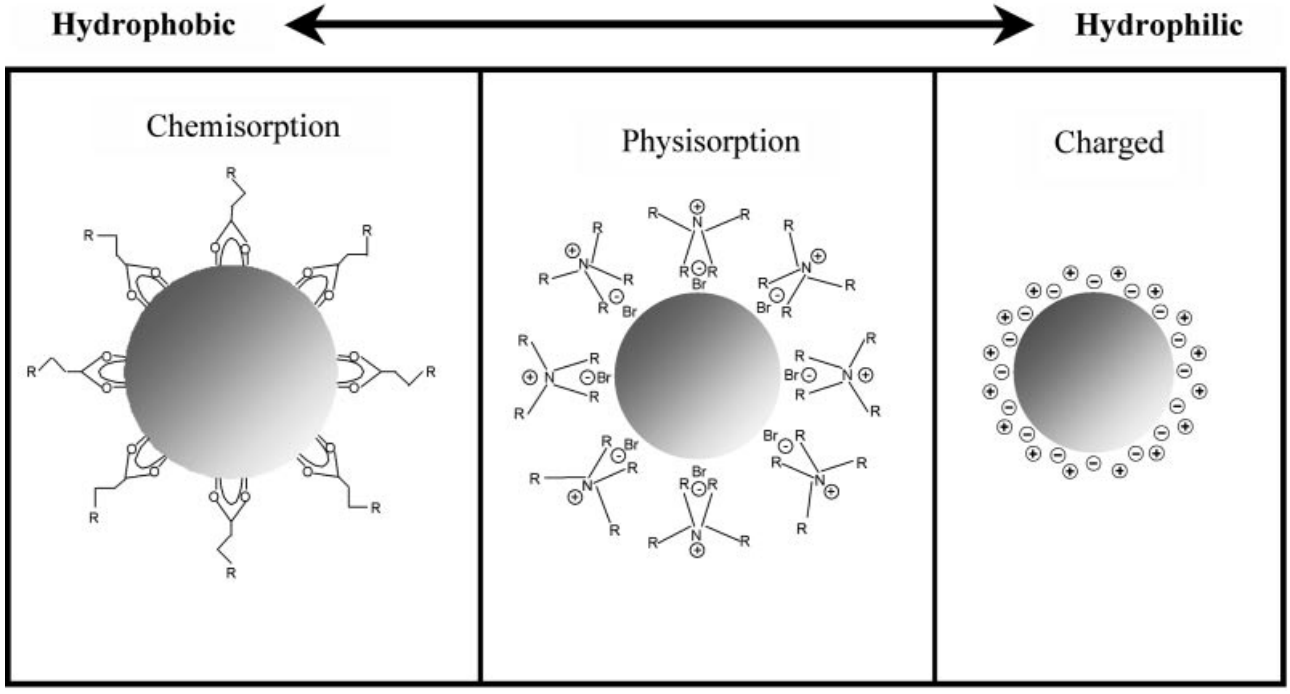

Figure 4. Sketches of models describing the particle surface under different conditions. The chemisorption, i.e. the dissociative adsorption of stabilizers, is most often used in hydrophobic solvents (e.g. toluene). The physisorption has been successfully used to stabilize colloids by tetraalkyl ammonium salts in polar organic solvents (e.g. THF). Simply charged surfaces are in principle limited to aqueous suspensions.

The main result of wet chemical preparations of nanoparticles is the fact that one produces composite particles consisting of a core of the desired material, a protecting outer surface layer, and an intermediate inner surface layer of – most often – unknown composition. Figure 3 and Figure 4 give a schematic overview of the "composite" nanoparticle and its different surface properties (with respect to different preparation routes) that are mainly determined by the outer protecting surface layer.

Assembly: Concerned with the control of particle evolution during syntheses by kinetic rather than thermodynamic control of particle size and particle size distribution, is the phenomenon of self-assembly, which was first investigated using submicron spheres of PS latex or SiO_2 dispersed in water. This work concluded that self-assembly is conditional on the narrow size distribution of the particles (standard deviation ca. 5%), i.e. a narrow distribution of the sum of repulsive and attractive forces between particles in a colloidal solution. Thus, this conclusion is not limited to well-separated single particles. It holds also for aggregates of particles often found in aqueous systems, assuming that equal forces interact between aggregates of similar size.

Various methods have been applied for assembling magnetic colloids in recent years. The different methods and their requirements – mainly concerned to the surface properties of the nanoparticles, which are different for different preparation conditions – are summarized in Table 2 (in view of Table 1).

2.1 Self-Assembly

The most simple particle layer preparation method, which allows the application of external forces, is drying a drop of solution on a flat substrate – solid or liquid. This procedure results in a particle monolayer if the inorganic material concentration of the fluid is in the order of about 10^{-4} M. The monolayer typically consists of particle *sheets* of high symmetry interrupted by *empty* areas containing excess stabilizer (Figure 5).

The particle sheets can self-assemble into hexagonal-ordered arrays as shown in Figure 1, or into cubic-ordered arrays,[39,37] depending on the stabilizers nature and/or the particles shape, respectively. Increasing the ferrofluid concentration can increase the particle area density and the number of layers formed by self-assembly on a substrate. Increasing the concentration results in multilayers forming three-dimensional crystals of various symmetry, e.g. hcp, fcc, bcc, or tetragonal, but with multiple defects. Figure 6 shows a three-dimensional crystal prepared by drying a drop of a monodisperse Co-colloid shown in Figure 1.

One major requirement for technological applications of ferrofluids is their assembly into ordered structures of several mm^2 in size. Self-assembling of colloids on aqueous surfaces allows for the preparation of continuous layers of several mm^2 in size typically consisting of well-ordered *cores* interrupted by grain boundaries between cores of different orientation. There is no principle difference between nano-sized inorganic and micron-sized organic colloids.

Table 2. Overview of successful assembling methods, their requirements, and their applicability for colloids prepared by methods summarized in Table 1.

Assembling Method		Requirements	Applicable for
SA	**S**elf-**A**ssembly: self organization of colloidal particles into symmetric arrays during their deposition on flat substrates, i.e. flat solid- or liquid surfaces, or their precipitation into large particulate crystals from over-saturated liquids	narrow distribution of interacting forces between the colloidal particles	D, M (latex), R, and C
IA	External field **I**mproved **A**ssembly:		
	LB: mechanical force-improved assembly on aqueous surfaces	hydrophobic properties	D, E, R, O, P, and C
	MDT: magnetic force-improved assembly on flat surfaces	ferro- or superparamagnetic properties	D, R, M, C, and H[a]
	EDT: electric force-improved assembly on flat surfaces	charged colloids	R, M, and H[a] [b]
LbL	**L**ayer-**b**y-**L**ayer assembly: alternative deposition of polymers and colloids on solid surfaces of various geometry	charged colloids and aqueous solvents by use of polyelectrolytes	all[c]

[a] Particles available by the methods E, O, and P are typically too small to be influenced by external electric and magnetic fields during deposition at room temperature. [b] EDT approach has not yet been demonstrated for magnetic colloids to the authors' knowledge. [c] Applicability is dependent on the solubility of polymers in different solvents.

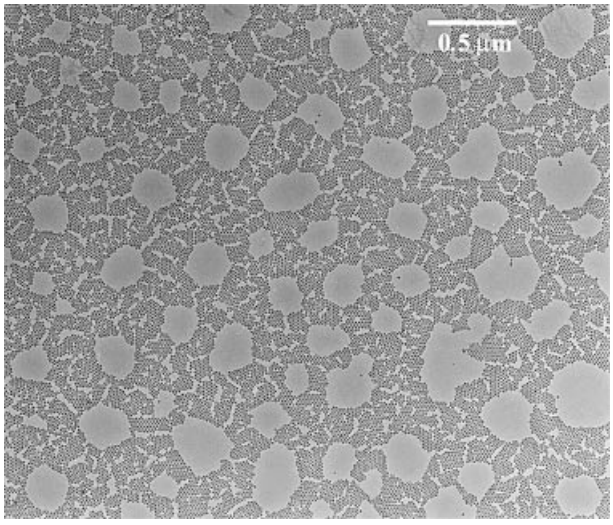

Figure 5. Typical TEM image of a sheet-like self-assembled film obtained by drying a drop of ferrofluid on a carbon-coated Cu grid (adapted with permission from ref.[16b]).

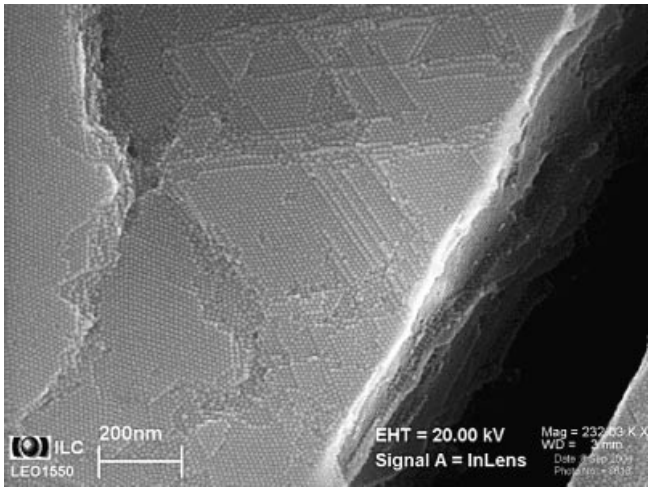

Figure 6. SEM image of a colloidal crystal prepared from a concentrated solution of highly monodispere Co nanoparticles (courtesy of E. Majkova).

The core size can be improved by adding special surfactants (or simply soap) to the aqueous phase that will change its surface tension and/or the interaction of the particulate depletion layer. The latter refers to theoretical descriptions developed by Debye, Hückel, and Onsager (see common textbooks of physical chemistry).

Figure 7 presents a typical result of particle assembly on a water surface. The visible structure results from isolated second layer islands. A perfect monolayer would not be visible at this magnification, demonstrating the problem of TEM investigations to show both, symmetry as well as large-area substrate coverage in case of nanoscale materials. It is obvious from Figure 8 that the symmetry of the assembled layer is decreased compared to the layer shown in Figure 1. Nevertheless, assembling on water surfaces allows (and is limited) to prepare monolayers of, for example, narrow symmetry distribution, but over several mm^2. Furthermore, this technique allows applying external magnetic fields during monolayer formation; static, as well as rotating magnetic fields. The latter may have some advantages in preparing assembled layers of circular geometry.

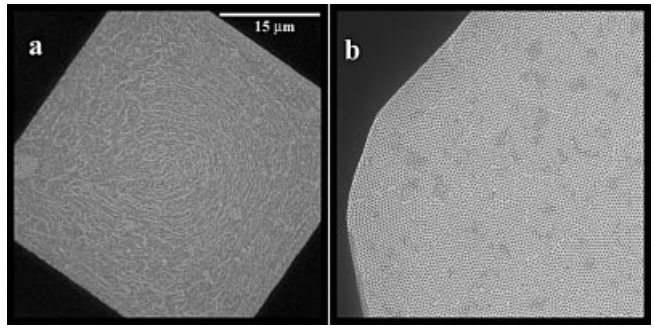

Figure 7. a) One mesh of a complete covered Cu grid. The structure results from islands of a double layer as can be seen in b. b) Higher magnified image showing the degree of ordering (adapted with permission from ref.[16b]).

Further optimizations have been available by applying the LB technique, dealing with mechanical force to increase the core size of self-assembled particle layers on water surfaces.[4] The preparation of large-scale three-dimensional

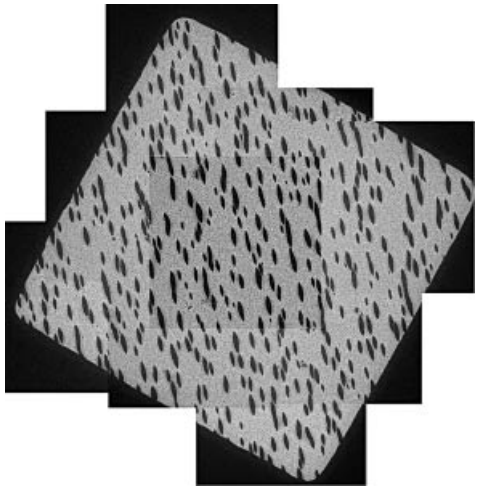

Figure 8. TEM image constructed from 11 micrographs. The mesh is 45 μm × 45 μm. The insert demonstrates that the structure is the same on at least four meshes (adapted with permission from ref.[16b]).

colloidal crystals grown from over-saturated fluids, has also been reported.[29j,29k]

2.2 Magnetophoretic Deposition Technique (MDT)

Ordering phenomenon in ferrofluids placed in external magnetic fields have been observed and theoretically calculated in literature. More recently, the formation of ordered stripes and hexagonal sheets has been experimentally observed while drying a thin liquid film of a ferrofluid on a substrate in an applied external magnetic field.[7b,16] Theoretical calculations of Lacoste and Lubensky showed that the shape of ordered structures, which are obtainable by drying a thin layer of ferrofluid under the influence of an external magnetic field applied in an identical plane to the liquid layer, can be completely different. Stripes as well as hexagonal sheets are available and can be made to coexist simply by changing the strength of the applied magnetic field and/or the concentration of the particles.[40] We found experimentally that the direction of the applied magnetic field is a further important parameter.[7b,16]

Figure 8 is shown for two reasons. Firstly, it demonstrates the coexistence of stripes (triple layers in this case) and sheets (monolayers, not really visible at this magnification) and confirms theoretical calculations. Secondly, it has been constructed from eleven single images to demonstrate large-area ordering within several μm^2, which is one major problem of TEM investigations of nanoscale materials. (One mesh of a carbon-coated copper grid, typically used in TEM investigations of colloids, 45 μm by 45 μm in size, is shown.).

Detailed investigations of MDT showed that the size of stripes (Figure 9) as well as sheets (as in Figure 5) of high symmetry, interrupted by isotropic regions of low (or no) symmetry and *empty* regions,[7b,16] can be increased by increasing the strength of the applied magnetic field. Figure 10 shows TEM images of the creation of multidimensionally ordered diluted Co colloids of the same concentration using MDT with external applied magnetic fields of 0.8 T (monolayer, upper left), 1.5 T (double layer, upper right), and 6 T (triple layer, lower left). The lower right image shows a triple layer prepared in the absence of a magnetic field for comparison.

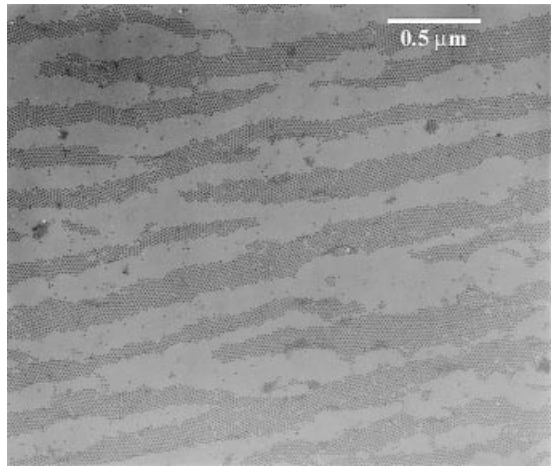

Figure 9. TEM image at low magnification showing a large-area of chains deposited at 0.8 T in perpendicular arrangement (adapted with permission from ref.[7b]).

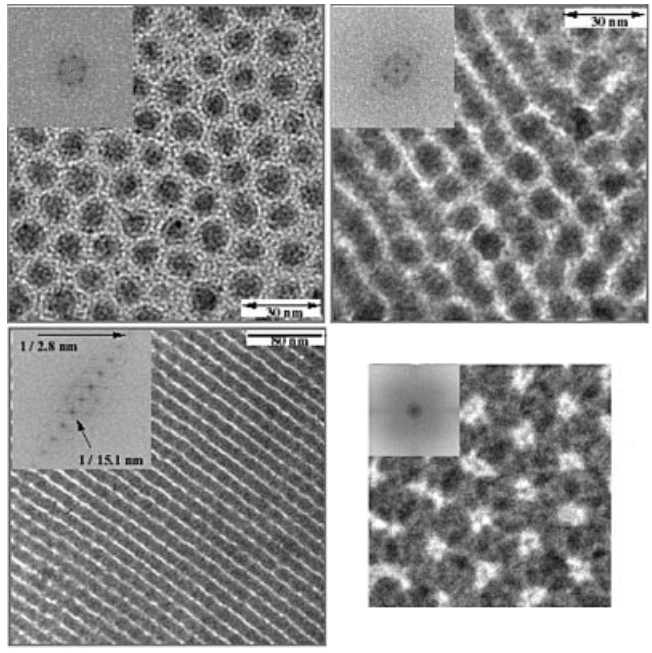

Figure 10. TEM images of the creation of multidimensionally ordered Co colloids of the same concentration using MDT with external applied magnetic fields of 0.8 T, mono layer (upper left), 1.5 T, double layer (upper right), and 6 T, triple layer (lower left). The lower right image shows a triple layer prepared in the absence of a magnetic field for comparison (redrawn with permission from ref.[7b]).

By increasing the concentration of colloids one can obtain micron-sized rod-shaped colloidal crystals by MDT grown perpendicular (magnetic field applied perpendicular to a substrate) or parallel (magnetic field applied parallel to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a substrate) on a substrate as can be seen in Figure 11 and Figure 12.[41]

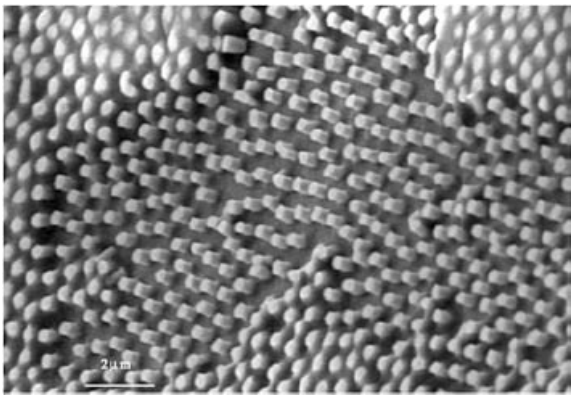

Figure 11. SEM picture of randomly distributed rods prepared by drying in air on substrate in a magnetic field of 0.8 T perpendicular to a Si/Si_3N_4 substrate (adapted with permission from ref.[41]).

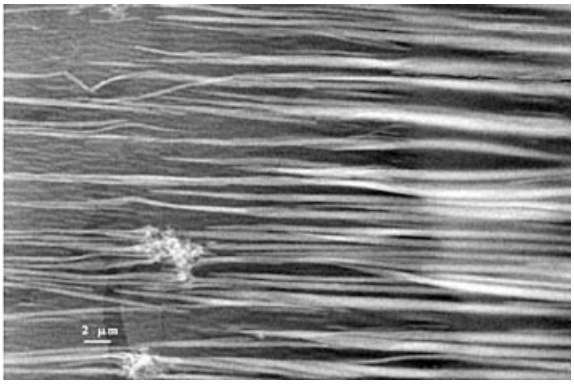

Figure 12. SEM picture of rods prepared like in Figure 11, however, with the magnetic field of 0.8 T parallel to the substrate (adapted with permission from ref.[41]).

Most recently, the perpendicular magnetic field-directed growth of such rods has been discussed in detail by the Pileni group.[42] Meanwhile, the magnetic field-directed growth of rods from bimetallic $CoPt_3$ colloids also has been published.[43]

Despite all those successes, the maximum size of defect-free inner superstructures available by applying MDT is limited to the lower μm range.[7b,16]

2.3 Layer-by-Layer Deposition (LbL)

Different to other assembling methods is the LbL technique, The LbL technique based on polymer-mediated self-assembly by alternatively adsorbing oppositely charged polymers (polyelectrolytes) or polymer and nanoparticles on solid substrates.[5,44] The LbL approach is, in principle, applicable for ferrofluids prepared by all methods presented in Table 1 with one restriction. Dealing with polyelectrolyte (the most common technique) requires typically aqueous solutions and charged colloids; therefore it is generally limited to ferrofluids containing iron oxide. The advantages of this technique are the availability of assembled layers (mainly layers of aggregates in case of aqueous iron oxide colloids) on curved substrates, i.e. latex spheres, and free-standing films including hollow spheres. As a result, nanoparticle layers of different thicknesses alternatively divided by layers of polymer have been published to be available.

A certain number of articles concerning the preparation of photonic crystals from magnetized latex spheres are available.[5d–5f,45] Two different routes were used to prepare magnetic organic/inorganic hybrid spheres. One dealt with the synthesis of magnetite incorporated in polymeric microspheres produced by emulsion polymerization.[46] The second method applied the LbL approach to prepare latex particles covered with magnetite[5c–5f]

These microspheres have then been used for the preparation of three-dimensional crystals. The photonic band gap of these crystals could be varied by varying the distance between the microspheres within a colloidal crystal by applying MDT. Increasing the applied magnetic field resulted in decreasing particle distances and blue shift of the Bragg diffraction wavelength. Unidirectional shifts have been observed with increasing NaCl concentration in aqueous solutions and decreasing dielectric constants of non-aqueous solutions.

The Farle group has used the LbL approach to prepare magnetite-covered latex particles.[5d–5f] Figure 13 shows TEM micrographs of uncoated PS particles (a) and polyelectrolyte-modified PS particles with (b) one, (c) two, (d) three Fe_3O_4 nanoparticles/polyelectrolyte layers. The average diameters of the composite particles are 650, 770, and 960 nm, respectively. The insert pictures in (b) clearly show Fe_3O_4 particles on the PS particles, many of them existing as aggregates.

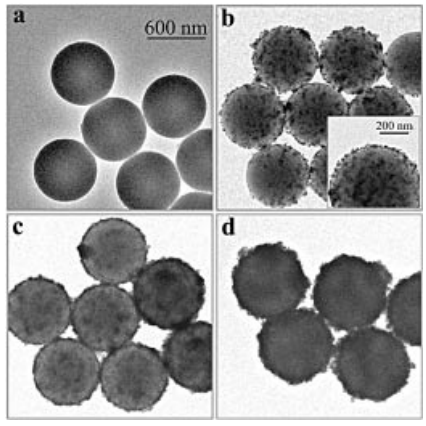

Figure 13. TEM micrographs of uncoated PS particles (a), and polyelectrolyte-modified PS particles with (b) one, (c) two, (d) three Fe_3O_4 nanoparticles/polyelectrolyte layers. The average diameters of the composite particles are 650, 770, and 960 nm, respectively. The insert pictures in (b) show clearly Fe_3O_4 particles on the PS particles; many of them existing as aggregates (adapted with permission from ref.[5g]).

These particles were then coated with SiO_2-covered Au particles.[5e,5f] The use of SiO_2-covered Au particles became necessary because the requirement of a negatively charged surface of Au colloids (as prepared Au particles by the applied method are positively charged). This approach in-

volves coating of microspheres with a high refractive material prior to the colloid crystal formation. Figure 14 demonstrates the successful preparation of latex@magnetite@gold core-shell nanostructured microspheres. Properties of photonic band gap behavior of colloidal crystals prepared from these particles are under investigation.

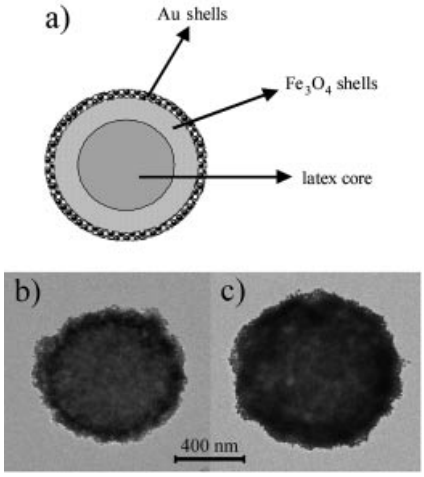

Figure 14. a) Schematic of a core (latex)-shell (Fe_3O_4 and Au nanoparticles) magnetic microsphere. b,c) TEM images of 640 nm PS microspheres: b) covered with two layers of magnetic Fe_3O_4 nanoparticles (d = 750 ± 20 nm) and c) after additional coverage with three layers of Au nanoparticles (d = 860 ± 20 nm) (redrawn with permission from ref.[5e]).

3. Superstructures by Nanosphere Lithography (NSL)

The main prerequisite to obtain highly symmetric nanostructured surfaces of large areas by use of NSL is the successful preparation of ordered monolayers of submicron spheres that are free of grain boundaries. To achieve this, we have developed a modified preparation technique based on the deposition of latex particles similar to a LB film on water. This method, involving surfactant-improved self-assembly on a liquid–gas interface (instead of a mechanical force-improved LB-assembly), allowed us to obtain large monolayers (a few cm^2) that could be applied directly onto various surfaces. Using this simple fabrication technique, it was possible to prepare monolayers as large as a few cm^2 with grain sizes of 1 mm^2 and above (using latex particles with diameters between 1000 nm and 500 nm), and areas of even 50 μm^2 without other structural defects (like point defects). Figure 15 shows one typical result of our modified method (right) in comparison to typical results of other methods (left).[8]

Figure 16 shows AFM images of nanostructured surfaces after evaporation of Ni through different masks and further removal of the latex particles by dissolution in THF. The hexagonal symmetry of triangular-shaped Ni islands is clearly visible.[8]

Those nanostructured substrates have been successfully used for the growth of hexagonal-ordered carbon nanotubes, grown perpendicular on a 1 cm^2 substrate, and having interstices > 100 nm (Figure 17). It has been found that the distance of perpendicular-aligned CNT's on substrates is a critical parameter in the preparation of field emission devices from CNT's.[47]

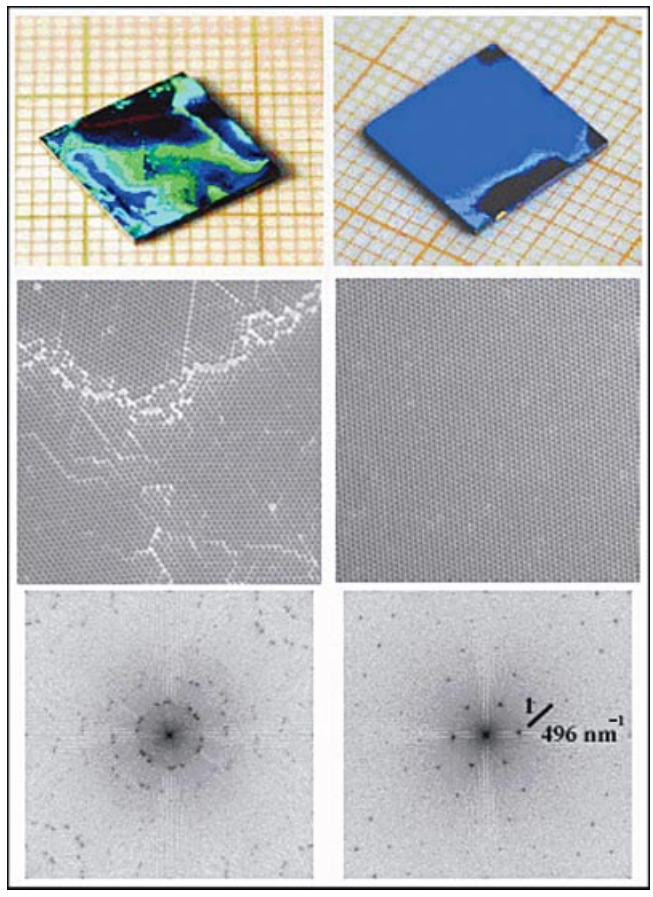

Figure 15. 1 × 1 cm^2 silicon wafers covered with 496 nm PS latex particles deposited as a monolayer. In contrast to the sample on the left side, most of the surface of the right one does not contain any grain boundaries, which are represented as a monochrome light interference (blue) color of the surface (right). In the second row, atomic force microscopy images are shown as representative examples for both samples. Additionally, quantitative information about the structures was obtained from a power spectrum of the pictures. Typical reflections for a polycrystalline structure are shown, in contrast to the right one which shows a power spectrum of perfectly ordered PS latex particles (adapted with permission from ref.[16a]).

3.1 The Shadow Approach

The structures obtained by NSL can become much more complex by varying the shadows below the microspheres of masks during evaporation. We have first developed computer simulations that predicted the structures resulting from the variation of the angle between the evaporation beam and the sample by tilting and/or rotating the sample under process. Figure 18 shows the principle experimental setup of the shadow approach.[48]

Meanwhile, a variety of predicted complex morphologies, ranging from cup-like structures to rods and wires, have

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

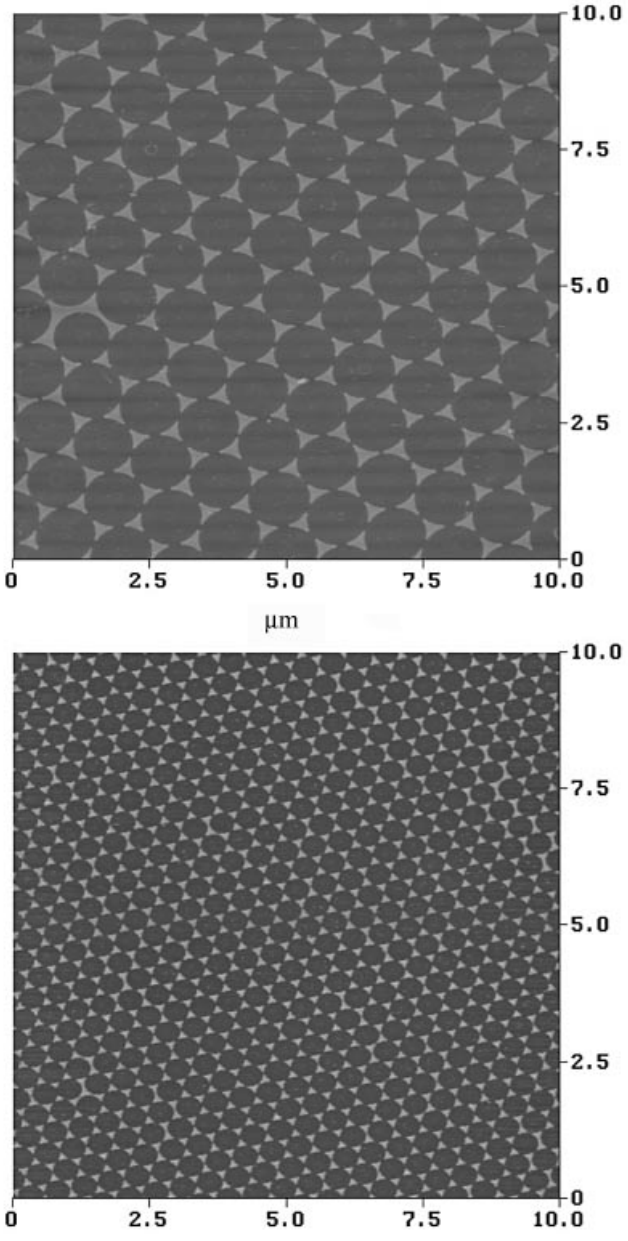

Figure 16. AFM image gallery showing 2-D magnetic Ni nanostructures created by deposition through different PS latex masks.

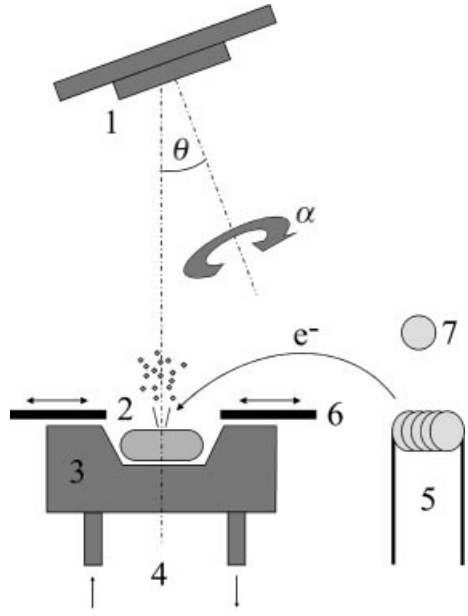

Figure 18. Schematic of the modified evaporation system. (1) Sample holder, (2) evaporation source, (3) crucible, (4) water cooling system, (5) electron beam source, (6) shutter, (7) magnetic field. The evaporation angle is q, and R the rotation angle of the sample (adapted with permission from ref.[48]).

been successfully prepared using this technique. Figure 19 and Figure 20 give examples of simulation and realization for one experimental setup, respectively.[48]

3.2 Fine Tuning of Interstices

The shadow approach could be further improved by changing the mask morphology, i. e. by decreasing the size and by changing the form of the interstices between the spheres through temperature processing. Figure 21 demonstrates the changes of size and form of interstices and the change of the interferometric color of a 540-nm PS latex mask annealed in 25 mL water/ethanol/acetone mixture by (A) 1, (B) 2, (C) 4, (D) 6, (E) 7, and (F) 10 microwave pulses.[49]

Applying temperature-treated masks in the shadow approach allowed for the preparation of particles with morphologies such as rings and rods. The combination of both processes allows an outstanding control of size and morphology of particles deposited on substrates. This efficient way is shown to scale down the size of metallic nanoparticles from 200 nm to 30 nm, while preserving the original nanosphere spacing and order. Nano-sized Fe rings produced by this method, having a diameter of 150 nm, show

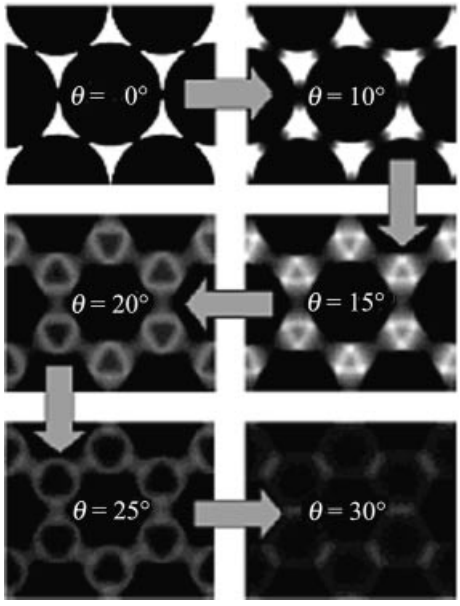

Figure 19. Simulation results for the evaporation through an hcp mask of ordered spheres, with evaporation angles q varying from 0° (perpendicular evaporation) to 30° (adapted with permission from ref.[48]).

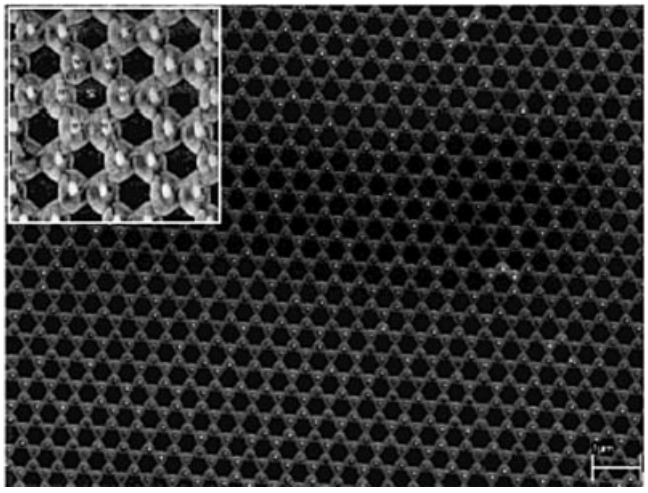

Figure 20. SEM image of a bimetallic structure, obtained by a two-step evaporation process. First step, evaporation of 150 nm Cr (with sample rotation at q = 25°), followed by a normal evaporation (q = 0°) of 15 nm Ni. The inset presents the scan in the AFM tapping phase mode of the same sample, which shows well-separated Ni spots inside the cup-like Cr structures. The diameter of the mask spheres was 540 nm (adapted with permission from ref.[48]).

ferromagnetic behavior, which has been predicted by mathematical modeling. Figure 22 shows a SEM picture of ordered Fe nanorings evaporated over an annealed 540-nm PS latex mask. The outer diameter of single rings is 150 nm and the width of the rings is 20–30 nm.[49]

Computer simulations that showed the possibility of creating periodic arrays of any other geometrical shapes confirmed all experimental results. Some examples are given in Figure 23.[49]

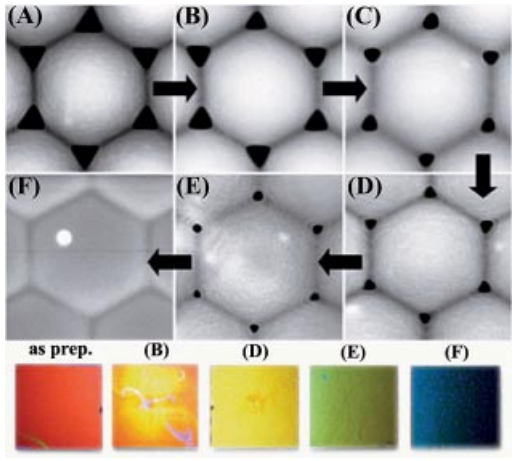

Figure 21. Change of interstices and interferometric color of a 540-nm PS latex mask annealed in 25 mL water/ethanol/ acetone mixture by (A) 1, (B) 2, (C) 4, (D) 6, (E) 7, and (F) 10 microwave pulses (redrawn with permission from ref.[49]).

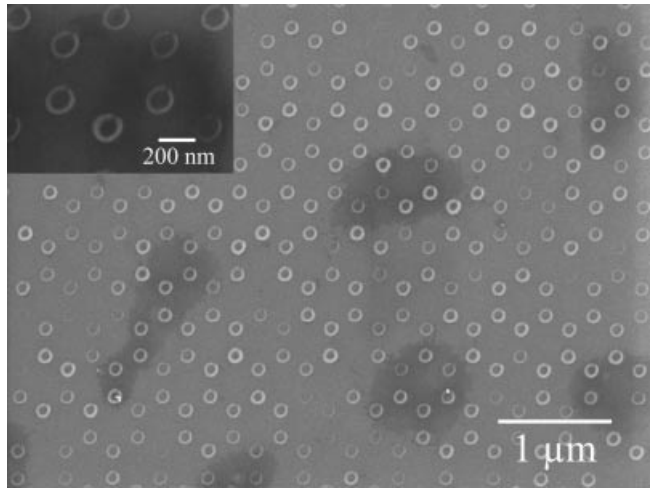

Figure 22. SEM picture of ordered Fe nanorings evaporated over an annealed 540-nm PS latex mask. The outer diameter of the single ring is 150 nm and the width of the ring is 20–30 nm (adapted with permission from ref.[49]).

Concluding Remarks

We have presented some principles of syntheses of inorganic colloidal magnetic particles, their properties, and recent advances in preparing assembled layers thereof on different substrates. The results are, of course, not necessarily limited to magnetic particles. The only restriction for non-magnetic materials is the applicability of MDT. Furthermore, we have shown, that organic colloids, used as lithographic masks, are interesting tools for the development of mm^2-sized nanostructured devices. As reduced size means increased reactivity, colloid chemistry is not able to provide solutions in all fields of device development.

Moreover, the applicability of inorganic colloidal magnetic particles is limited by their composite nature, the NSL is limited to two-dimensional structures and the quality of perfect NSL masks prepared from organic colloids is still a

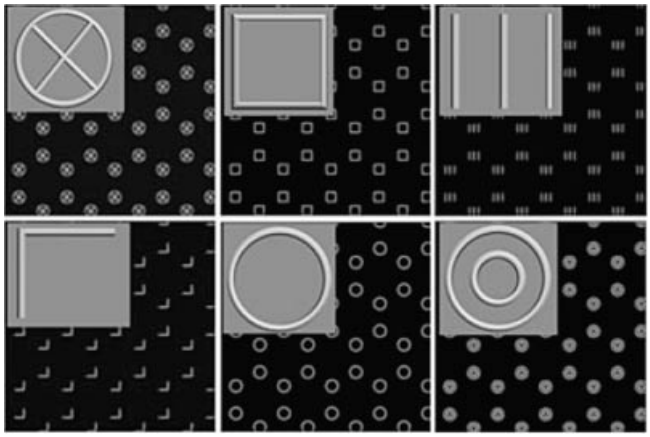

Figure 23. Computer simulation of some structures that should be available theoretically by evaporation through annealed PS masks (adapted with permission from ref.[49]).

challenge when PS latex particles 1000 nm $> d >$ 400 nm are used.

Nevertheless, from the point of view of the ease of sample handling all the methods presented here have great promise in aiding the development of devices relevant to electronic, pharmaceutical, and bioscience technologies.

The Effects of Organisation, Embedding and Surfactants on the Properties of Cadmium Chalcogenide (CdS, CdSe and CdS/CdSe) Semiconductor Nanoparticles

Johannes Frenzel,[a] Jan-Ole Joswig,[b,c] Pranab Sarkar,[b,d] Gotthard Seifert,[a] and Michael Springborg*[b]

Keywords: Cadmium sulfide / Cluster compounds / Density-functional calculations / Nanostructures / Semiconductors

An overview of recent density-functional-based studies on the structure, surface structure and electronic and optical properties of CdS, CdSe and CdS/CdSe semiconductor nanoparticles is given. In particular, the effects of organisation, embedding and surfactants on the properties of these particles are discussed and illustrated by our own results and literature examples. The surface stabilisation by ligands, core/shell embedding or superstructure organisation combined with electronic structure stabilisation of these nanoparticles directly influences their properties: for stabilised nanoparticles a size-dependent decay of the lowest optical excitation energy towards the value of the bulk is found, as observed experimentally.

1. Introduction

The optical and electronic properties of semiconductor nanoclusters are of great interest for a large variety of potential applications such as displays,[1] quantum dot lasers,[2] solar cells[3] and biological labels.[4,5] Examples of such systems are quantum dots embedded in solid-state structures, colloidal particles on surfaces or clusters in the gas phase. Much progress has been achieved in the controlled synthesis of such particles with a narrow size distribution.[6] Although this allows detailed investigations of the properties of such particles, especially as a function of their size,[7–10] a complete understanding of the basic physical and chemical processes that determine the properties of nanoclusters as a function of size, as well as of the influence of organisation, embedding and surfactants on their properties, is lacking.

The II–VI materials form an important class of semiconductor compounds, with CdS, CdSe, ZnS and ZnSe as their most prominent systems. These materials are often used in a colloidal form in which they form a kind of quantum dot. In the bulk phase, these compounds crystallise preferentially in the zincblende (sphalerite) or the wurtzite structure, although the energetic difference between these two structures is small. Therefore, the existence of both forms in colloidal solutions is not surprising although the basic processes of the structure formation are not yet known in detail. For core/shell nanoparticles, which are formed from a specific II–VI compound, embedded into another II–VI compound, it is known that the stress due to the lattice mismatch may lead to material instabilities and diffusion processes between the two compounds. These instabilities may limit the applicability of such quantum dot structures considerably.

As already mentioned, nanoparticles and colloids of semiconductors are of particular interest due to their electronic and optical properties. Important parameters that characterise these properties are the energies of the orbitals around the Fermi energy and their spatial distribution (e.g.

spatial localisation to the inner part of the particle, or near the surface of the particle, or delocalisation over the whole particle etc.). These properties may be strongly influenced by structural relaxations, the structure of the surface, adsorbed or bonded molecules at the surface (surfactants) and structural changes due to diffusion processes within the particle.

The nanoparticles that are experimentally investigated may contain between a few hundred and some 100000 atoms. Their properties are strongly influenced by the large number of atoms at the surface and their specific bonding properties. The lack of periodicity on the one hand and the relatively large number of atoms on the other hand make theoretical studies of their properties rather difficult. Despite studies of very small systems (see, for example ref.[11]), only a small number of investigations exist that focus on the electronic properties of such particles.[12–15] Very often the structural elements in such investigations are taken from the bulk system. Only in a few cases were the structures of the nanoparticles optimised when considering systems with just a few dozen atoms. Moreover, the precise role of surfactants, embedding, organisation and the surrounding media have been studied only marginally.

In this paper we will review our investigations on the effects of organisation, embedding and surfactants on the properties of CdS, CdSe and CdS/CdSe semiconductor

Johannes Frenzel graduated from the chemistry department of the Technical University of Dresden in 2003 and is now a PhD student in the group of Prof. G. Seifert. His studies are focussed on surface and organisation effects of nanoparticles with respect to their properties.

Jan-Ole Joswig studied chemistry at the Universities of Hamburg, Konstanz and Edinburgh and received his diploma in 1999. He continued working with Michael Springborg at the Universities of Konstanz and Saarland (Saarbrücken) to obtain his PhD in 2003. Currently, he is working as a post-doc at Helsinki University of Technology. His main research interests are the structural, electronic and optical properties of semiconductor and metal clusters and their size dependence.

Pranab Sarkar obtained his MSc in 1991 from the University of Burdwan (India) and his PhD in 1997 from the Indian Association for the Cultivation of Science, Jadavpur. After a post-doc stay at the University of Montreal (Canada) in the years 1997 and 1998, he became a reader in chemistry at the Visva-Bharati University, Santiniketan (India). During the years 2001–03 he undertook extended visits at the University of Saarland, Saarbrücken (Germany). His research interests include theoretical studies on semiconductor nanocrystals and quantum dynamics of real and model systems.

Gotthard Seifert studied Chemistry at the TU Dresden, where he received his diploma in 1975 and graduated with a Dr. rer. nat. (PhD) in 1979. From 1979–1992 he worked as a research assistant at the Institute of Theoretical Physics at the TU Dresden. In 1988 he got his habilitation in theoretical physics. In 1989 and 1990 he worked as a visiting scientist and visiting professor at the International School for Advanced Studies (SISSA) in Trieste and at the EPFL. In 1991 he was a visiting scientist at the Forschungszentrum in Jülich. From 1992–1998 he was again at the Institute of Theoretical Physics at the TU Dresden as a lecturer/professor. In 1998 he moved to the Universität Paderborn (Theoretical Physics) and in 2001 he became a professor of Physical Chemistry at the TU Dresden. His research interests are in the areas of quantum chemistry, cluster physics and chemistry and computational materials research.

Michael Springborg received his diploma in 1980 from the Technical University of Denmark where he also obtained his PhD in 1982. After post-doc stays at the Max Planck Institute for Solid-State Physics in Stuttgart (Germany) and Nordita, Copenhagen (Denmark), he became a scientific staff member in Physical Chemistry at the University of Konstanz in 1989. Since 2000 he is a full professor of Physical and Theoretical Chemistry at the University of Saarland, Saarbrücken (Germany). His research field is the development of theoretical methods and accompanying computer codes for the calculation of electronic and structural properties of materials, in particular of polymers and chain compounds as well as clusters and colloids, as well as fundamental aspects of the electronic density-functional theory. He has published around 150 scientific papers and one monograph on "Methods of Electronic-Structure Calculations" and has edited a book on "Applications of Density-Functional Methods."

nanoparticles over a wide size range, from clusters containing just a few atoms to nanoparticles with up to about 1000 atoms. The quantum mechanical calculations were done using density-functional theory (DFT) within a tight-binding approximation (DFTB).[16–19] First, the structure and stability of isolated CdS and CdSe clusters, both without and with surfactants, will be discussed as a function of cluster size, followed by a discussion of their electronic structure and optical properties. Subsequently, the so-called core/shell structures will be considered and, finally, the properties of periodically organised clusters will be studied.

2. Structure and Stability

Cadmium chalcogenide nanoparticles are observed with different shapes, e.g. the smaller ones are found to be more tetrahedral[20,21] and the larger particles tend to have a more spherical shape.[22,23] Their geometric structure resembles the structure of the infinite crystal, which in a first approximation can be explained by the existence of directional bonds and, in most cases, tetrahedral coordination as in the bulk.

When considering only naked clusters (i.e. neglecting any surfactants), this tetrahedral coordination is missing for the surface atoms, which leads to the existence of dangling bonds or surface states.[14,24–26] In fact, the influence of the surface becomes very important for particles with a diameter of just a few nanometres or less. For cadmium chalcogenides and other semiconductor particles there is only a small amount of experimental information available for such small clusters. These compounds are mostly dispersed in solutions in Lewis base-type organic solvents, leading to cadmium chalcogenide nanoparticles saturated with tributylphosphane/trioctylphosphane oxide (TOP/TOPO),[23,24] polyphosphate[27] or thiol groups,[20,21,28–31] such that the surface atoms are saturated and the surface states vanish.

In order to obtain some insight into the properties of these systems, naked CdS and CdSe clusters have also been studied theoretically, for example using empirical tight-binding models.[32,33] In these studies the atomic positions are usually fixed, and only a few studies have considered structural relaxations. With an empirical tight-binding scheme these were studied by Whaley et al.,[12–14] whereas a parameter-free density-functional method was used for small CdSe clusters by Eichkorn and Ahlrichs,[11] Troparevsky and Chelikowsky,[34] and Galli et al.[35] We have studied the properties of stoichiometric and nonstoichiometric CdS and CdSe clusters (with up to approximately 1000 atoms)[15,36,37] using a density-functional-based tight-binding method.[16–19] Structural relaxations of these clusters were also considered starting with structures that were cut out from the infinite periodic crystal, (i.e. with either a zincblende or wurtzite structure). However, other structures may also be relevant, for example the boron nitride cage-like structures suggested by Kasuya et al. recently.[38]

In our investigations we optimised all atomic positions of naked CdS and CdSe clusters. We found major structural changes in the outer parts of the clusters, while the inner parts largely kept the initial structure of the bulk material. The size of the surface region turned out to be independent of the particle size and consists of the outermost two layers of atoms (corresponding to a thickness of about 2–3 Å). Outward displacement of the sulfur atoms and inward displacement of the cadmium atoms can be recognised by analysing the radial distribution of the atoms (see Figure 1). Cadmium, as a typical metal atom, prefers high coordination numbers, whereas in many systems sulfur atoms are found with a low coordination number of two. For clusters with a large number of singly bonded surface atoms, Cd–Cd, but no S–S, nearest-neighbour bonds are formed in the structural relaxation (see Figure 2), independent of the initial structure. Other theoretical studies of CdS and CdSe gave similar results to ours,[13,15,36,37,39–41] and Galli et al.[35] found a self healing of the surface similar to previous reports.[34,42]

For clusters, stability is often discussed in relation to the energy gap between occupied and unoccupied states, i.e., in terms of molecular orbital theory, the gap between the highest occupied and lowest unoccupied molecular orbitals (the HOMO–LUMO gap[43,44]). The existence of magic numbers (i.e. of particularly stable clusters) is associated with the existence of a gap between the occupied and unoc-

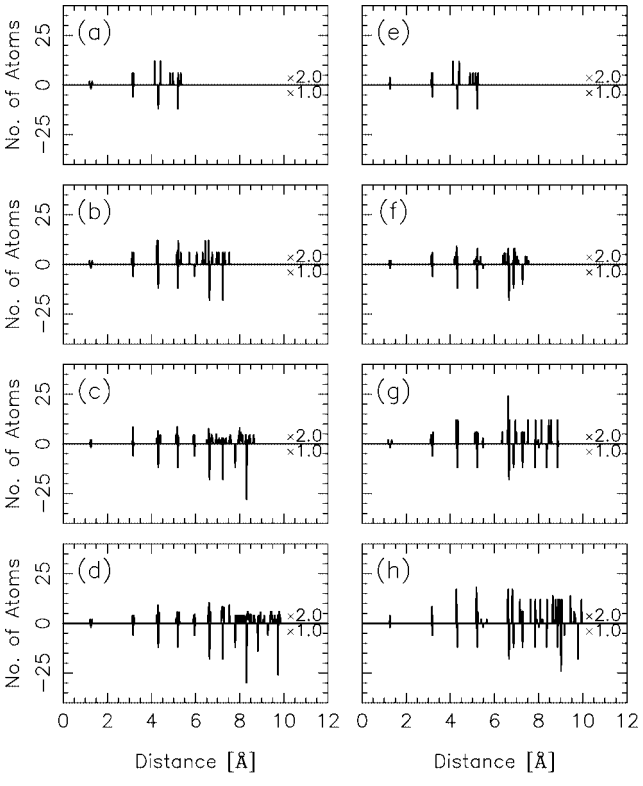

Figure 1. Radial distribution of cadmium and sulfur atoms for zincblende (left column) and wurtzite (right column) clusters of different sizes: (a) and (e) $Cd_{16}S_{16}$; (b) and (f) $Cd_{37}S_{37}$; (c) and (g) $Cd_{57}S_{57}$; (d) and (h) $Cd_{81}S_{81}$. Figure 2. A $(CdS)_{192}$ cluster as a spherical part of the zincblende bulk structure (middle). During structural relaxation Cd–Cd nearest-neighbour bonds are formed (left), while explicit surfactants $[Cd_{192}S_{118}(SH)_{164}]^{16-}$ maintain the initial structure of cluster (right).

cupied orbitals. When discussing the stability of II–VI semiconductor particles, one finds an interplay between structural and electronic effects. When considering the electronic structure in bulk of, for example, CdS, a large bandgap (2.58 eV)[45] arises due to the complete filling of the S 3p-like states (shell closing). The two 5s electrons per Cd atom first fill up this S 3p-like state (two unoccupied orbitals per atom) to form directed bonds that finally result in the tetrahedral coordination.

For singly unsaturated clusters (with underlying bulk structure) this combined atomic structure–electronic structure balance of the bulk is not fulfilled as the structure at the surface causes surface states, as mentioned before. However, it becomes valid for clusters that are modified at the surface, such that the fourfold coordination from the bulk is reconstructed for all cadmium atoms at the surface by sulfur-containing surfactants, e.g. –SR (R = organic residue). Within this approach, the S atoms carrying the surfactants are already saturated in a twofold coordination. Consequently, the resulting final clusters are described as $[Cd_mS_n(SH)_i]^{2(m-n)-i}$, with $2(m - n) - i$ being the charge of the cluster ensuring a non-zero HOMO–LUMO gap. This charge can easily be compensated in solution by the counterions.

In a recent investigation we examined passivated CdS clusters.[36] The results showed only a marginal structural distortion relative to the initial bulk structure without any diffusion of atoms or formation of homonuclear nearest-neighbour bonds at the cluster surface and, moreover, independent of whether the underlying structure was derived from the zincblende or wurtzite crystal structures. These findings are in agreement with experimental results for structurally characterised particles.[20,21,29–31,46–48]

Explicit surfactants have already been considered in the studies by Eichkorn and Ahlrichs,[11] who used density-functional methods for small CdSe clusters, as well as by Gurin[49] for CdS systems using ab initio (Hartree–Fock) methods. Galli et al.[35] did not find any differences in the structures of surfactant-capped and naked CdSe clusters.[50] Furthermore, we should add that surfactant molecules have been treated in other theoretical studies, for example within a tight binding,[13,14] semi-empirical[51] or classical force-field approach.[52]

3. Electronic Structure

One main reason for studying nanoparticles is that their electronic properties are strongly size-dependent and, hence, the possibility exists to tune these by varying the particle size. In the most simple approximation, this quantum-size effect (QSE) or quantum-confinement effect[7,8,53–56] can be understood by using the simple model of a particle in a box. In such a treatment, as well as in effective-mass models,[57–59] the specific structure of the particle is not considered. This means that the significant influence of the structure on the electronic properties, especially for small particles (i.e. those with less than 1000 atoms), is not taken

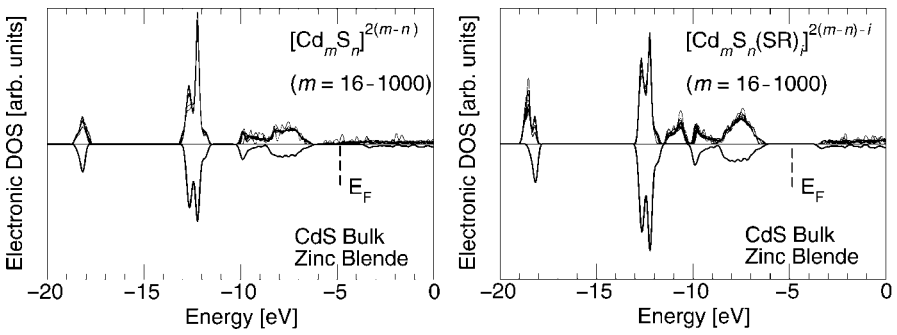

Figure 3. Electronic DOS (calculated with DFTB) of zincblende-derived CdS clusters (left panel, curves pointing upward) and of saturated, zincblende-derived CdS clusters with R = H (right panel curves pointing upward) vs. the bulk CdS electronic DOS (curves pointing downward).

into account. The cases in which the electronic properties were studied with consideration of the underlying structures (of which only a few also included the effects due to structural relaxation) were mentioned above.[11–14,16,17,32,33,57–59]

As for the bulk crystalline structures, the density of states (DOS) profiles of the zincblende- and the wurtzite-based clusters are very similar and they are also rather similar to the DOS of the corresponding bulk structures,[39–41,60–62] even for the smallest clusters (see Figure 3).[12,15,24,49]

The analysis of the radial charge-distribution (see Figure 4) in the clusters clearly indicates a surface region with a thickness of about 2.5 Å for CdS clusters, i.e. the region where significant structural relaxations occur (cf. Section 2). The charge transfer between Cd and S atoms in this region is much stronger than in the inner part of the clusters. No significant differences of this behaviour are observed between zincblende- and wurtzite-based structures. On the other hand, the effect is slightly more pronounced for the unrelaxed structures. This result is very similar to the situation for surfaces of crystalline CdS and CdSe.[39–41]

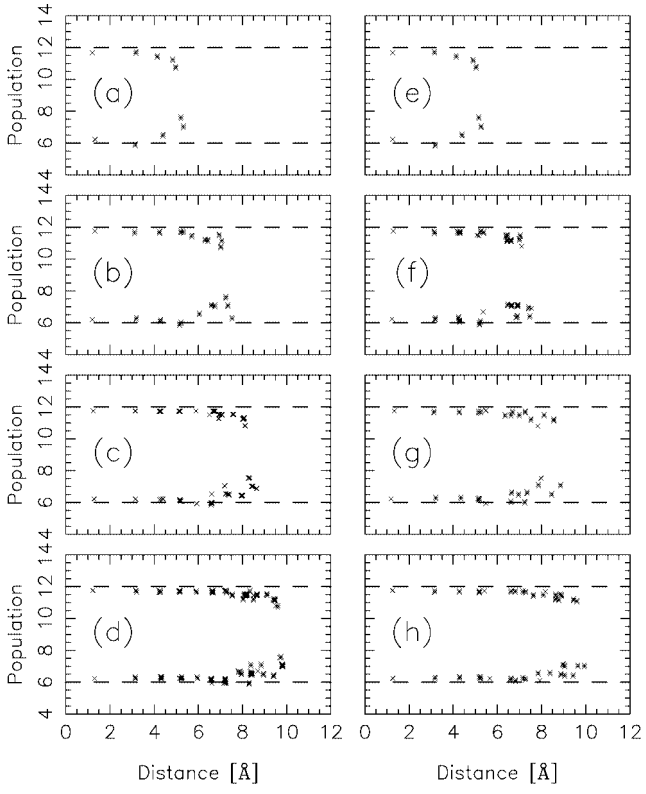

Figure 4. Radial distribution of Mulliken populations for zincblende (left column) and wurtzite (right column) clusters of different sizes: (a) and (e) $Cd_{16}S_{16}$; (b) and (f) $Cd_{37}S_{37}$; (c) and (g) $Cd_{57}S_{57}$; (d) and (h) $Cd_{81}S_{81}$. The horizontal dashed lines mark the number of valence electrons of the neutral atoms (12 for cadmium and 6 for sulfur atoms). Reprinted with permission from ref.[15] Copyright (2000) American Chemical Society.

The frontier orbitals, i.e. the HOMO and LUMO, are important for the reactivity (e.g. the binding of surfactants) as well as for the optical properties. The radial dependence of the HOMO and LUMO is shown for a series of clusters in Figure 5. With N_{ij} being the Mulliken gross population for the *j*th atom and *i*th orbital we define the density as:

$$\rho(\vec{r}) = \sum_j N_{ij} \left(\tfrac{2\alpha}{\pi}\right)^{2/3} \exp\left[-\alpha(\vec{r} - \vec{R}_j)^2\right]$$

with α being chosen "reasonably", i.e. so that illustrative figures result. Subsequently, we calculate the spherical average of this density. As one can see, the HOMO gets increasingly delocalised over the whole cluster with increasing cluster size, whereas, simultaneously, the extent of localisation of the LUMO to surface atoms increases. Therefore, the LUMO depends sensitively on variations of the cluster surface, such as structural relaxations or the presence of surfactants.[36,63]

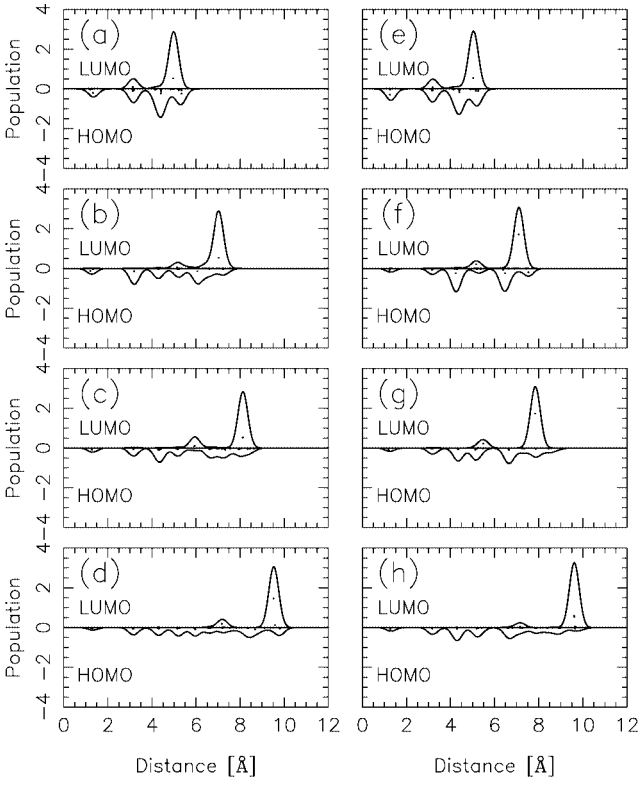

Figure 5. Spherical average of the atomic contributions to HOMO (curves pointing downward) and LUMO (curves pointing upward) broadened with Gaussian functions for zincblende (left column) and wurtzite (right column) clusters of different sizes: (a) and (e) $Cd_{16}S_{16}$; (b) and (f) $Cd_{37}S_{37}$; (c) and (g) $Cd_{57}S_{57}$; (d) and (h) $Cd_{81}S_{81}$. This function is defined in Section 3. Reprinted with permission from ref.[15] Copyright (2000) American Chemical Society.

The HOMO–LUMO energy gaps of both zincblende- and wurtzite-derived clusters are displayed in Figure 6 as a function of cluster size.[63] It can be seen that the relaxation does not have a significant influence on the trends in the size of the energy gaps themselves. However, for clusters with relatively large gaps the gap size is increased, on average by about 0.8 eV, after optimisation of the structures. As a function of cluster size the gap size is oscillating, but

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

does show a weak overall decrease with increasing cluster size. The oscillations are mainly due to the varying number of singly bonded surface atoms. The fact that the gap shows an overall decrease with increasing cluster size has also been found by other groups.[23,32,33,64,65]

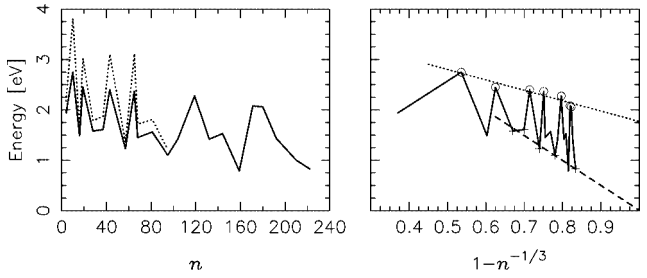

Figure 6. Left panel: HOMO–LUMO gap as a function of cluster size for zincblende-derived clusters. The gap is taken from unrelaxed spherical cut-outs of the zincblende crystal structures (solid curve) and for optimised structures of these clusters (dotted curve). Right panel: HOMO–LUMO gap as function of $1 - n^{-1/3}$, with n being the number of CdS pairs. The gap corresponds to the unrelaxed structures in the left panel. Trend lines are drawn through the gap maxima (dotted, open circles) and minima (dashed, plus signs, excluding the two smallest clusters) to accentuate the size dependence of the HOMO–LUMO gap. Reprinted with permission from ref.[63] Copyright (2003) American Chemical Society.

The gap size is drawn as a function of $1 - n^{-1/2}$ (n being the number of CdS pairs) for unrelaxed clusters in Figure 6. This plot accentuates the size dependence of the gap. Considering only the clusters with relatively large gaps, one can see that an overall decrease is expected for a particle in a box, as observed for CdSe nanoparticles.[66] The extrapolation leads to a bulk limit ($1 - n^{-1/2} \rightarrow 1$) of 1.75 eV. Considering an upward shift of 0.8 eV due to structural relaxation (as mentioned above), this extrapolated gap size is in agreement with the experimental value of the bulk bandgap for CdS (2.58 eV).

In contrast to this result, the gap for the clusters with the smallest gaps approaches a zero gap asymptotically, i.e. metallic behaviour. This result supports the above-mentioned character of the surface states in clusters with unsaturated cadmium surface atoms. In the case of very large particles, this would lead to a metallic-like surface if the metal atoms are not saturated with organic ligands.

With surface saturation in the case of cadmium sulfide clusters leading to $[Cd_mS_n(SH)_i]^{2(m-n)-i}$ (cf. Section 2), the irregularly oscillating behaviour of the HOMO–LUMO gaps and LUMO energies observed in the naked clusters vanishes.[36] Then, both the HOMO (mainly due to S 3p states) and the LUMO (due to Cd 5s states) energies show the same spatial delocalisation as well as a smooth dependence on the particle size, and for all structures the gap decreases toward the bulk value for larger structures (see Figure 7).

This model is rather sensitive to details of the surface structure, as a single missing ligand at one Cd atom already results in a dangling bond which, in turn, leads to a mid-gap state. The same happens if an S or Se atom has two or more dangling bonds.[14,24–26] However, these dangling

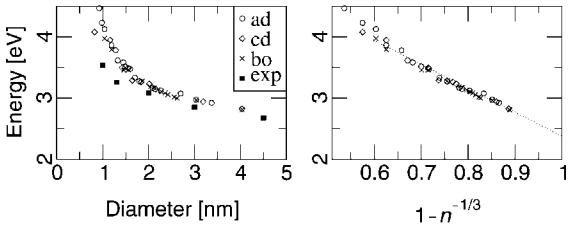

Figure 7. HOMO–LUMO gap of surface-saturated CdS clusters (R = H). The underlying cluster structures are spherical parts of the zincblende bulk structure centred either at a Cd–S nearest-neighbour bond (bo), a cadmium atom (cd) or an adamantane-like cavity (ad) and were fully optimised for the clusters up to 3 nm in diameter. Experimental values from ref.[80] of thiophenol-capped CdS clusters are also given.

bonds are reactive centres, which can easily find a reaction partner for stabilisation in an ionic solution.

To summarise, the surface atoms have a very strong influence on the optical and electronic properties of cadmium sulfide clusters, although this may be less pronounced for nanoparticles with diameters of some tens to hundreds of nanometres.

4. Optical Properties

In the preceding sections we have shown that the electronic structure of II–VI semiconductor nanoparticles is sensitive to the underlying atomic structure and, especially, that the surface has a basic influence on the orbitals closest to the Fermi level. For a more accurate description of optical properties, selection rules and collective effects in the excitation process have to be taken into account. This has been done in previous studies of cadmium sulfide, selenide, and telluride clusters by applying the effective-mass method for the calculation of the energetically lowest optical transitions;[57–59,67,68] in this model the underlying structure of the cluster is not considered. However, the structure has been included in the tight-binding calculations that have also been performed for these systems.[13,14,32,33,64,69–77] Nevertheless, except for a very few studies, structural relaxations as well as collective effects have not been taken into account, with the exceptions being, for example, the work of Whaley and co-workers[13] as well as the density-functional studies of Ahlrichs et al.[11,42] and Galli et al.[35] Chelikowsky et al.[34] have performed calculations of very small Cd_nSe_n clusters ($n \leq 8$) by employing the time-dependent local-density approximation (TDLDA).[78] In an earlier study we presented a systematic study of the optical properties of larger clusters[63] employing time-dependent density-functional response theory (TD-DFRT) as incorporated in the DFTB method (referred to as TD-DFRT-TB).[79] In that work, the optical spectra of naked stoichiometric CdS clusters were investigated. We did not find the onset peaks to be shifted with respect to the joint DOS, which is in agreement with the work of Ahlrichs.[42] Instead, depending on structural changes, the spectra show fluctuations of the lowest excitation energy with increasing cluster

size. Corresponding to the above-mentioned correlation of singly bonded surface atoms and the HOMO–LUMO gap energy oscillations (see Section 3), the smallest excitation energies of such clusters lie below the experimental bulk absorption value of 2.58 eV[45] and the values for the corresponding nanoparticles.[80] When subtracting the local density of states of all singly bonded surface atoms, a spectrum with a gap of about 3 eV is obtained, since the additional states at lower energies arise predominantly from cadmium 5s levels. The intense low-lying excitations in the spectra of clusters with a large number of unsaturated cadmium atoms indicate a collective character, as observed experimentally in metal clusters as surface plasmon excitations.[81]

Alternatively, the experimental results of Lifshitz et al.[82,83] on the excitation relaxation processes for CdSe systems suggest the presence of a sub-bandgap state with a clear dependence on the cluster structure. The authors argue that the recombination takes place at a low-symmetry site, such as one near the surface, and, furthermore, that the hole is delocalised, whereas the electron is localised at the surface, which is similar to our findings for the naked clusters. Using optical measurements Bawendi et al.[24] have observed that one or both charge carriers are surface-trapped. On the other hand, theoretical studies of CdS and CdSe[40,41] have found surface states just above the valence band (both in contrast to our results). In their study of CdSe clusters, Hill and Whaley[12] found surface states similar to ours in some cases, while other groups[14,73] have found surface states appearing close to the bottom of the conduction band.

In a recent study,[36] we explicitly and systematically included surfactants in calculations of the optical spectra of CdS nanoparticles (see Figure 8). For all clusters, the smallest excitation energies are found above 2.58 eV and, when extrapolating the particle size toward infinity (Figure 9), the experimentally observed asymptotic decay toward the bulk value of the absorption is recovered with increasing cluster size. Moreover, for larger particle sizes the HOMO–LUMO energy gap gives a good approximation of the lowest-energy transitions (TD-DFRT-TB spectra) for (CdS) clusters with more than 150 atoms.

Besides the discussed general size-dependence, single or a few unsaturated surface atoms (cf. Section 3) can cause surface-trapped states, which are observable in the optical spectra and may thus affect the luminescence process.

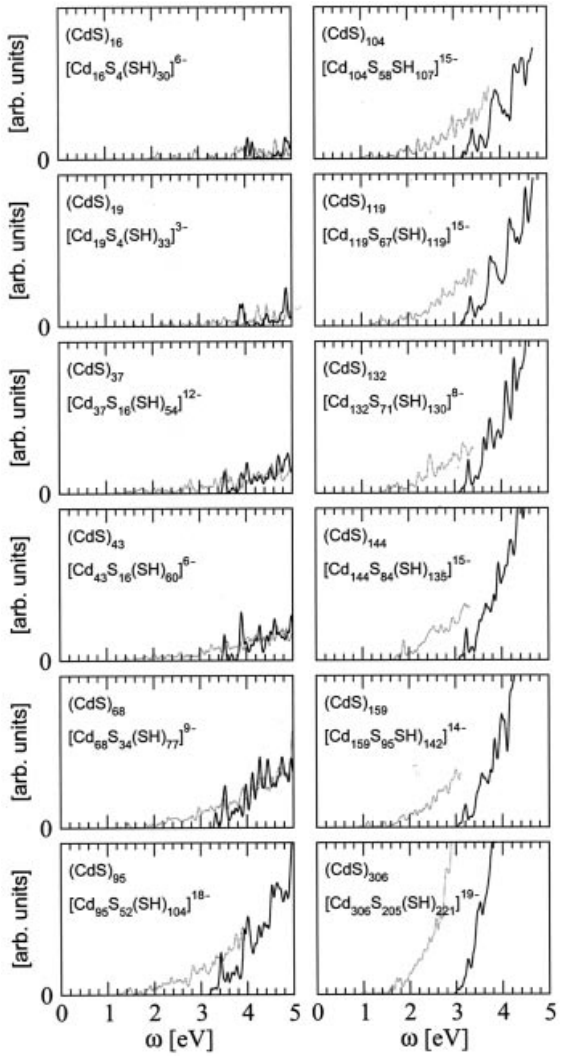

Figure 8. TD-DFRT-TB singlet excitation spectra of naked clusters (grey curves) and saturated clusters (black curves). The underlying structures were optimised, except for $(CdS)_{306}$ and $[Cd_{306}S_{205}(SH)_{221}]^{19-}$.

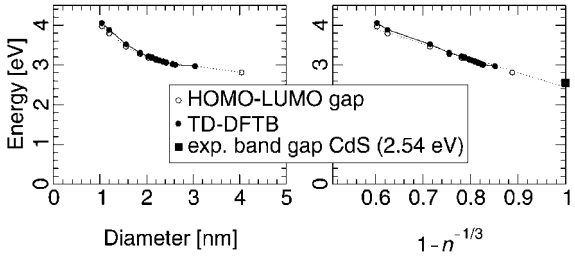

Figure 9. The calculated lowest energy transition (TD-DFRT-TB spectra) vs. HOMO–LUMO gap energy of surface-saturated CdS clusters (R = H, underlying structure: zincblende, bond centred). The results differ for small clusters (max. 2%) while they coincide for larger ones. The underlying structure was relaxed for clusters up to 3 nm in diameter.

5. Embedded Structures (Core/Shell Systems)

As we have seen in the preceding sections, the atoms closest to the surface are chemically active. This means, in turn, that this cluster can be stabilised by passivating the dangling bonds at the surface, with surfactants for example, as we have seen above, or by embedding the cluster in a host, in which case quantum dots may result.

Core/shell nanoparticles are intermediates between these two extremes as they consist of one material embedded into another with the thickness of the shell being finite. A large variety of material properties can be obtained by varying the two materials as well as the sizes of the two parts. Therefore, during the last decade much experimental work has been reported directed toward the synthesis of such

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

core/shell nanoparticles with tailored properties.[84–86] Core/shell systems that have been studied include CdSe/ZnS, ZnS/CdS, CdS/HgS, HgS/CdS, CdS/PbS, CdSe/ZnSe, CdSe/CdS, CdS/CdSe etc.[87]

In a recent study,[88] we presented theoretical results for the structural and electronic properties of CdSe/CdS and CdS/CdSe core/shell nanoparticles that have also been the focus of significant experimental interest,[89–92] although theoretical studies of these, or related, systems are extremely scarce.[76,93,94] In particular, only one of these studies[94] included any estimate of the energetics and structural properties of these materials and, to the best of our knowledge, no studies have addressed stability and diffusion processes. These processes, which are of importance for degradation, were also addressed briefly in our work.

The similarity between the CdS and CdSe lattice constants was our main motivation for choosing this semiconductor pair for our investigation. For naked CdS and CdSe clusters, we found[15,37,95] that zincblende- and wurtzite-derived clusters are energetically very close. Therefore, we decided to consider spherical parts of only the zincblende crystal structure with one semiconductor compound outside the other one and, subsequently, let the structures relax to their closest total-energy minima.

In Figure 10 we show the atomic Mulliken gross populations (related to the atomic charges) for the different clusters of our study as a function of the radial distance (i.e. of the distance to the geometric average of all nuclear coordinates). Similar to our previous results,[15,37,95] we observed a larger electron transfer from Cd to S than from Cd to Se in the general case, although the difference is marginal. Moreover, as for the pure, stoichiometric, naked CdS and CdSe clusters, we found an increased electron transfer in the outermost parts of the clusters although, in contrast to our results for the pure clusters, the width of this region depends on the cluster. As for the pure cluster, the absolutely outermost atoms are mainly Se and S atoms, whereas the metal atoms (in particular near the surface) tend to experience a structural relaxation so that they obtain a higher coordination. The pair of core/shell systems $Cd_{21}S_{21}$/$Cd_{16}Se_{16}$ and $Cd_{16}Se_{16}$/$Cd_{21}S_{21}$ is particularly interesting, because it is the only case for which the two systems have exactly the same numbers of Cd, S and Se atoms but where the complete core and shell have been interchanged. For this pair we found that the overall distribution of the Mulliken populations is very similar for the two systems, independent of which of them is the core and which is the shell (cf. the two uppermost panels in Figure 10). Moreover, we found that $Cd_{21}S_{21}$/$Cd_{16}Se_{16}$ is more stable than $Cd_{16}Se_{16}$/$Cd_{21}S_{21}$ by 32.2 eV. For the infinite systems, the gap of CdSe is smaller than that of CdS.[96,97] Therefore, we found that the most stable system is that of the large-gap core embedded into a small-gap shell.

The optical properties are determined by the properties of excitons that, to a first approximation, are mainly derived from the HOMO and LUMO. Therefore, we shall study the latter in some detail. Figure 11 shows a schematic representation of the radial dependence of these orbitals as

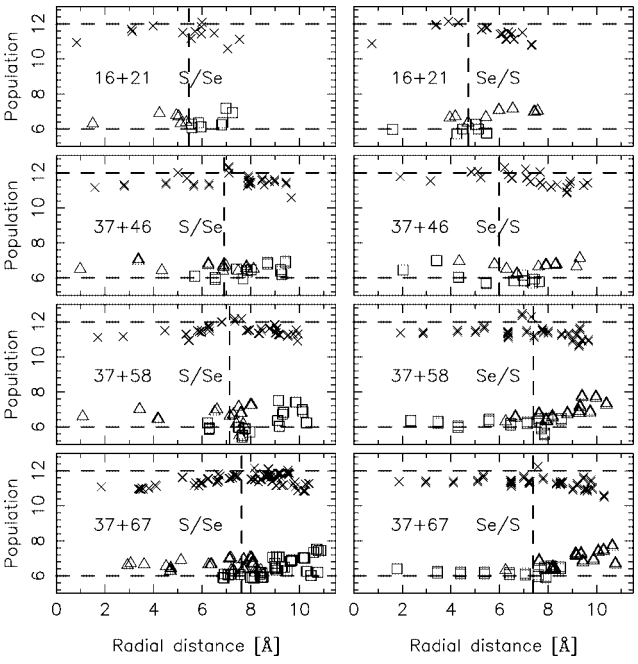

Figure 10. The radial distribution of Mulliken gross populations for different core/shell systems. Crosses, triangles and squares mark the populations of Cd, S and Se atoms, respectively. The horizontal dashed lines mark the number of valence electrons in the neutral atoms (12 for Cd and 6 for S and Se). The labels "N+M" and "A/B" on the panels denote a Cd_NA_N/Cd_MB_M core/shell system with A and B referring to S and Se. The vertical dashed lines show a crude separation of the system into a core and a shell part by being placed at the average of the radial distances of the outermost A atom and innermost B atom.

defined in Section 3. As indicated in the figure, the HOMO is localised to the shell region whereas the LUMO is localised to the core region in only one case ($Cd_{37}S_{37}$/$Cd_{58}Se_{58}$). This means that a charge transfer may take place upon excitation and, accordingly, that the excitons may be very long-lived. We stress that neither the HOMO nor the LUMO is confined to the complete core or shell, but each of the two orbitals is localised on a few atoms in either the core or the shell. Therefore, any standard relaxation process by which the exciton can relax may also be relevant here, although due to the obvious spatial separation of the HOMO and LUMO the process may be slow. This also means that the HOMO and LUMO may also be spatially separated for the other systems of our study, leading to long-lived excitons, but only for this single case does the spatial separation include a separation between core and shell.

For macroscopic CdSe/CdS interfaces the HOMO of the CdSe part lies at a higher energy than the HOMO of the CdS part.[96] On the other hand, the HOMO–LUMO energy gap of crystalline CdSe is smaller than that of crystalline CdS,[96,97] suggesting that the LUMO of CdSe and CdS will appear energetically relatively close to each other. This indicates that the HOMO of the core/shell system will be located on the CdSe part whereas the LUMO may be located on either part. Results like those of Figure 11 show that this simple expectation is only partly true. However, when the HOMO and LUMO are localised on different

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

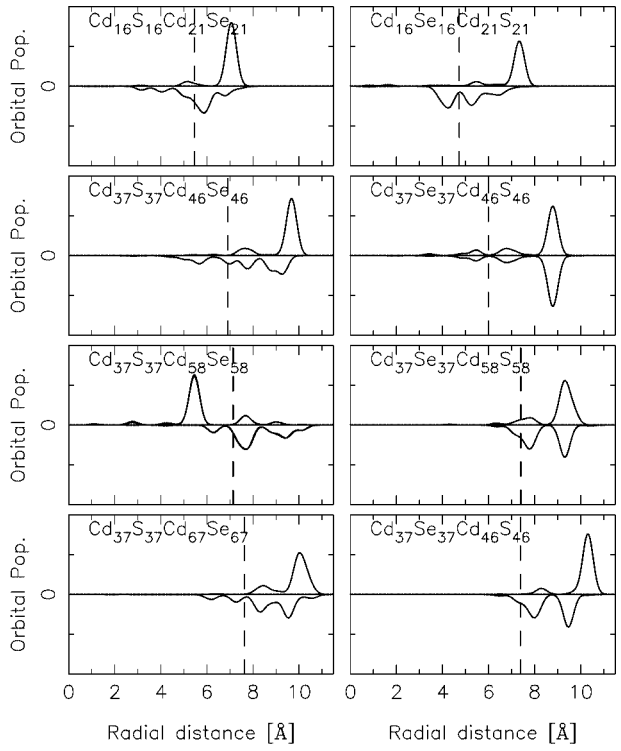

Figure 11. Schematic representation of the radial electron distribution of the HOMO (curves pointing downward) and of the LUMO (upward) for the same systems as in Figure 10. The vertical dashed lines mark the separation into a core and a shell part as in Figure 10. The function is defined in Section 3.

parts of the system, one may have a system that can act as a nanocapacitor whose excitons are particularly long-lived. On the other hand, this simple picture also suggests that the HOMO–LUMO energy gap of the core/shell systems is smaller than that of the individual components. Our calculated energy gaps, at most 1.15 eV, are indeed in agreement with this consensus.

We finally studied the energetics of diffusion of one S (Se) atom from the core to the shell and, simultaneously, one Se (S) atom from the shell to the core in various core/shell systems. This gives some first indications of the stability of these systems towards degradation. First, we simply interchanged two close S and Se atoms and subsequently allowed the structure to relax to the closest total-energy minimum. It turned out that in several cases the total energy (cf. Figure 12) was lowered by some electron volts, whereas it was increased in other cases. Subsequently, we followed the energetics along the reaction path for this interchange of a Se–S pair using the nudged-elastic-band method.[98] The resulting total-energy curves are shown in Figure 12, where it can be seen that the diffusion is connected with a fairly large energy barrier of several electron volts, which makes the diffusion highly unlikely despite the accompanying energy gain. In some of the cases of Figure 12 we observed a change in the HOMO–LUMO gap, but it was not possible to identify a correlation between the energy gain upon the interchange and the change in the gap. Finally, the large energy barrier for the transition suggests that quantum dots, which in principle are core/shell systems with a very thick shell, are also stable against degradation.

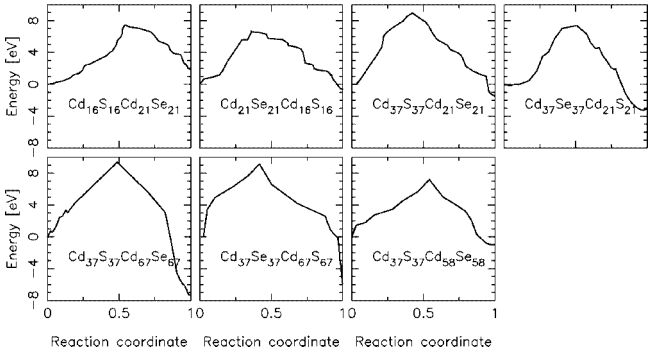

Figure 12. Variation in the total energy accompanying an interchange of a close pair of an S and an Se atom in some selected core/shell systems. The reaction coordinate is defined as being 0 before and 1 after the interchange.

6. Organised Structures

After having discussed the properties of single II–VI semiconductor nanoparticles, we now focus on the effects due to organisation. Because of their potential application as building blocks for electronic and optical devices, solvent-free particles (i.e., a non-liquid phase), either deposited on a substrate or incorporated into a solid phase, are advantageous to obtain adequate material handling. Some effort has been made to organise semiconductor nanoparticles, for example by Samokhvalov et al.[99] and Lahav et al.,[100,101] who have studied the collective electronic properties of self-organised CdS particles in hybrid Langmuir–Blodgett films. Similarly, Hilbron et al.[102] have obtained an arrangement by polymerisation of the surfactants. Recently, Feng et al.[103,104] have fabricated porous CdS frameworks that had been stabilised by metal ions similar to what is found for zeolites.

Weller and co-workers[30,31,105,106] have synthesised tetrahedral Cd_mS_n nanoparticles organised in a tetragonal superstructure. Their building-block structures are similar to those reported previously,[21,29] but have different organic ligands for stabilisation. The stoichiometries within the super network are, thus, $Cd_{17}S_4(SCH_2CH_2OH)_{26}$ and $Cd_{32}S_{14}[SCH_2CH(CH_3)OH]_{36}$ (corresponding to $Cd_{17}S_{32}$ and $Cd_{32}S_{50}$ for the case of naked clusters). These clusters have a tetragonal shape and are connected by shared corner atoms to form a network with a diamond-like superstructure. Both a single tetrahedron and the unit cell of the diamond-like superstructure are shown in Figure 13 for the smaller cluster only.

We have performed calculations using the DFTB method on saturated and unsaturated tetrahedral cadmium sulfide clusters, both in the gas phase and in the tetragonal superstructure. In the singly unsaturated clusters, strong deformations can be observed caused by the structural relaxation. However, less charge transfer within the single cluster

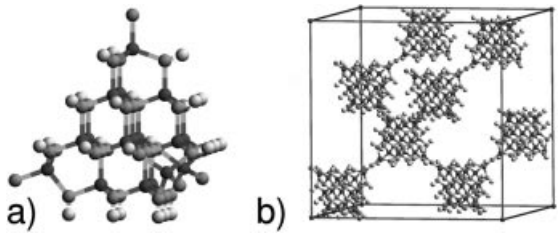

Figure 13. (a) Single tetrahedral $Cd_{17}S_{32}H_{24}$ cluster (unrelaxed) and (b) unit cell of the corresponding superstructure. Cd, S and H atoms are shown as dark grey, light grey and white spheres, respectively.

is observed when saturating the dangling bonds at the surface with hydrogen atoms and, moreover, the structural relaxations are marginal with respect to the initial (experimentally characterised) clusters.

The electronic properties, for example those given by the Mulliken gross populations (Figure 14), show a strong dependence on saturation. An influence of the periodic arrangement on the properties could, however, hardly be observed: the Mulliken populations and the density of states (Figure 15) are very similar for the single clusters and for the periodic structure. Nevertheless, due to their dense packing and covalent linking the surfactants itself are stabilised in the cavity. Likewise, the organisation of such nanoparticles in Langmuir–Blodgett films or their embedding in a polymer matrix strongly influences an ordering/fixation of the ligands. In all cases, the reproducibility of the single nanoparticles' surface structure is increased, thus affecting the cluster's electronic and optical properties (cf. Sections 3 and 4).

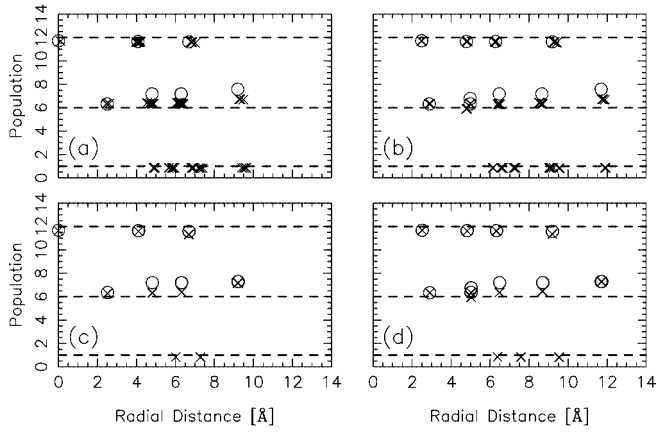

Figure 14. Radial distribution of the Mulliken gross populations in $Cd_{17}S_{32}$ and $Cd_{17}S_{32}H_{26}$ [(a) single tetrahedron, (c) periodic structure], and $Cd_{32}S_{58}$ and $Cd_{32}S_{58}H_{44}$ [(b) single tetrahedron, (d) periodic structure]. Open circles and crosses mark atoms in the unsaturated and the saturated clusters, respectively. The dashed lines mark the number of valence electrons of the single atoms in Cd (12), S (6) and H (1).

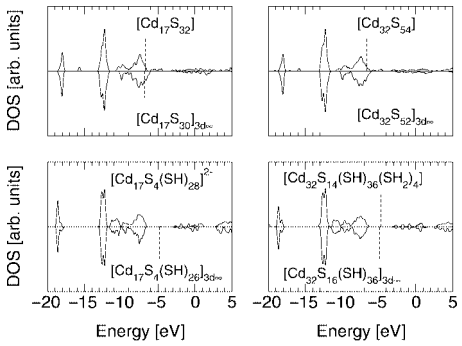

Figure 15. DOS of the tetrahedral clusters $Cd_{17}S_{32}$ (left column) and $Cd_{32}S_{54}$ (right column). The upper panels show the DOS for the clusters without surfactants and the lower panels show the DOS for clusters with surfactants (R = H). In each panel the curve pointing upward refers to the single cluster, whereas the curve pointing downward refers to the periodic superstructure. The dashed lines mark the Fermi levels.

7. Concluding Remarks

In this report we have reviewed results on the structural, electronic and optical properties of CdS and CdSe clusters and the effects of organisation, embedding and surfactants on these properties. In our own studies, we performed calculations for clusters with up to several hundred atoms using the DFTB method. The cluster structures were approximated to be spherical cut-outs of two crystal structures − zincblende and wurtzite − that are of relevance for the macroscopic materials under ambient conditions.

Surfactants attached to the unsaturated atoms of the surface have a strong influence on the structural properties: whereas naked clusters show strong relaxation effects, in particular in the surface layer, the saturation reduces the relaxation significantly such that the surface atoms essentially remain at their initial, unrelaxed positions. We also found that the underlying structure has a large impact on the electronic and, thus, also on the optical properties. The densities of states show, however, no large influence of cluster size on the positions of the evolving bands, but saturation gives additional states in comparison to the bulk DOS. Furthermore, we have shown that in the surface region of naked clusters, i.e. in the region where structural changes take place, the Mulliken gross populations suggest a higher charge transfer than the inner bulk-like part of the clusters. Also, the LUMO is located in this part, whereas the HOMO is delocalised over the entire cluster.

We have also shown that the trends in the size-dependent presentation of the HOMO–LUMO gap are already very well described by naked, unrelaxed clusters. These trends indicate, by extrapolation, that the gap approaches the bulk bandgap value for clusters with only a small number of singly bonded surface atoms and that it approaches a zero gap for clusters with a large number of unsaturated surface atoms. Again, we find a strong dependence of the electronic properties on the nature of the surface and the kind of saturation.

With respect to the optical properties, these findings are affirmed, since in the optical spectra the dependence on the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

number of singly bonded surface atoms was recovered, too. Saturation widens the HOMO–LUMO gap, since it is closed by states of singly bonded cadmium atoms in the gap. Thus, saturated CdS clusters have HOMO–LUMO gaps that are larger than the bulk bandgap, thus supporting using the simple theoretical picture of the particle in a box.

Similar effects could be observed in core/shell systems for which some of the effects could be well described as being due to saturation effects. For example, the Mulliken populations and, in some cases, also the delocalisation of the HOMO do not change at the core/shell interface. However, since the shell is unsaturated itself, it shows the same trends (larger charge transfer) as the one-compound clusters discussed above, although to a lesser extent. Except for one case, the core/shell systems investigated in this study do not show the total spatial separation of HOMO and LUMO that would lead to long-lived excitons. Diffusion between core and shell atoms is found to be rather unlikely, which suggests that embedded systems, and also quantum dots, are stable against degradation.

Finally, we have also investigated the effects of periodic organisation of tetrahedral clusters into superstructures, which have already been synthesised. The effects of saturation discussed above can also be found in these systems despite the different overall structure and the organisation. However, the periodic arrangement does not seem to lead to major changes in the electronic properties. Nevertheless, organisation prevents structural changes at the sites of conjunction, although this may be considered as nothing other than a special type of saturation. This shows again that saturation is a very important effect for properties of clusters, and studying them should be a central subject for any investigation of large, but finite, systems.

Comparison of the Magnetic and Optical Properties of Wide-Gap (II,Mn)VI Nanostructures Confined in Mesoporous Silica

Felix J. Brieler,[a] Petra Grundmann,[a] Michael Fröba,*[a] Limei Chen,[b] Peter J. Klar,*[b] Wolfram Heimbrodt,[b] Hans-Albrecht Krug von Nidda,[c] Thomas Kurz,[c] and Alois Loidl[c]

Keywords: Mesoporous materials / Diluted magnetic semiconductors / Host–guest systems / Nanostructures / $Cd_{1-x}Mn_xS$ / $Cd_{1-x}Mn_xSe$ / $Zn_{1-x}Mn_xS$

Arrays of highly ordered $Cd_{1-x}Mn_xSe$, $Cd_{1-x}Mn_xS$, and $Zn_{1-x}Mn_xS$ nanoparticles with x ranging from 0.01 to 0.3 and with lateral dimensions of 3, 6, and 9 nm were synthesised within mesoporous SiO_2 host structures of the MCM-41 and SBA-15 type. The hexagonal symmetry of these arrays (space group *p*6*m*) and the high degree of order were confirmed by X-ray diffraction and transmission electron microscope studies. Physisorption measurements show the progressive filling of the pores of the SiO_2 host structures, while photoluminescence excitation (PLE) and electron paramagnetic resonance (EPR) studies confirm the good crystalline quality of the incorporated (II,Mn)VI guest species. The effects of the reduction of the lateral dimensions on the electronic properties of the diluted magnetic semiconductor were studied by PLE spectroscopy. Due to the quantum confinement of the excitons in the nanostructures an increase of the direct band gap with decreasing particle size is observed. The magnitude of the confinement effects increases with increasing excitonic Bohr radius of the (II,Mn)VI, i.e. it is largest for (Cd,Mn)Se and smallest for (Zn,Mn)S. Moreover, an increased band-gap bowing with Mn content is observed for the Cd compounds and can be correlated with the modification of the magnetic properties. Surprisingly, no band-gap bowing with x is observed for the $Zn_{1-x}Mn_xS$ nanostructures. Analysis of the EPR linewidth and EPR intensity show that macroscopic magnetic properties such as the Curie–Weiss temperature are affected by the reduction of the lateral dimensions. The microscopic coupling between the Mn ions (e.g. the exchange constants J_{nn} and J_{nnn}) is not altered to a first approximation.

1. Introduction

The fabrication of ordered assemblies of particles on the nanometre scale is a challenge in material science, which has become more and more important over the last decades. With the availability of highly ordered arrays of particles well defined in size in the range of a few nanometres only, the understanding of the unusual dependence of electronic, optical and magnetic properties on size and shape of those nanoparticles has increased significantly. Most of the procedures to obtain 2D magnetic semiconductor nanostructures, i.e. quantum wells, require nonequilibrium growth conditions, which can be realised, for example, by molecular beam epitaxy (MBE) under ultra high vacuum or metal-organic vapour-phase epitaxy (MOVPE). In order to fabricate 0D quantum dots or 1D quantum wires, the conventionally used top-down approach (see Figure 1) is to start with two-dimensional quantum wells and to use a lithographic pattern definition followed by a pattern transfer, usually a subsequent etching procedure[1–7] or a controlled local diffusion process due to ion-bombardment.[8,9] Such top-down approaches usually only yield magnetic semiconductor nanostructures of good structural and optical quality for lateral sizes larger than about 50 nm. Below this size, fabrication-induced surface damage deteriorates the quality of the structures and has a strong undesired effect on optical and magnetic properties. This makes it difficult to separate intrinsic and extrinsic properties in a study of the electronic and magnetic properties as a function of lateral size of the nanostructure.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Felix J. Brieler is a PhD student in the group of Prof. Fröba in Gießen (Germany). He obtained his diploma in Chemistry on nanostructured semiconductors within mesoporous MCM-41 silica phases in the same group in Hamburg (Germany) in 2000. Since then, he has been working on his PhD thesis "nanostructured diluted magnetic semiconductors within mesoporous silica", which he will finish later this year. He stayed in Exeter (Great Britain) from April to May 1998 as an exchange student.

Petra Grundmann was born in 1961 and started her practical training in 1979 in Dresden (Germany). After completion in 1981 she worked in a research laboratory before she came to the Institute of Inorganic and Analytical Chemistry at the Justus Liebig University in Gießen (Germany) in 1993. She has worked in the group of Prof. Fröba since 2001.

Prof. Dr. Michael Fröba was born in Lübeck (Germany) in 1962 and studied chemistry in Würzburg and Hamburg. He obtained his PhD in 1993 in the group of Prof. Wolfgang Metz at the Institute of Physical Chemistry at the University of Hamburg (Germany). After that he stayed at the Lawrence Livermore National Laboratory (California, USA) from 1994 to 1996. He completed his Habilitation in 2000 at the University of Hamburg in Inorganic Chemistry. From 2000 to 2001 he was appointed associate professor (C3) at the University of Erlangen-Nuremberg (Germany). Since 2001 he is a full professor (C4) in Gießen and head of the Institute of Inorganic and Analytical Chemistry. He is author/coauthor of about 100 scientific publications, including several reviews and book articles. His research interests include porous materials with a focus on the template-directed synthesis and characterisation of mesoporous materials with different morphologies as well as the formation of nanostructures within different porous matrices.

Dr. Limei Chen is currently a researcher at the Physics Department of the Philipps-University of Marburg (Germany). She majored in Chemistry at Beijing Normal University (China) and obtained her BSc and MSc degrees in 1988 and 1991, respectively. In 1992 she obtained a scholarship from the British Council and UK Overseas Development Agency and worked at North East Wales Institute (UK) as a trainee where she obtained the Certificate of British Council Technical Training. From 1994 to 1997 she was the recipient of the first Norwich Research Park Studentship and obtained her PhD degree at the University of East Anglia (UK) in Physics. After a short spell as postdoctoral assistant at the University of East Anglia (UK), she started to work as a postdoctoral researcher at the Philipps-University of Marburg in 1998. Limei Chen is author/coauthor of about 25 scientific publications. Her research interests include magnetic and optical properties of novel nanostructures.

Dr. Peter J. Klar is currently a lecturer of Physics at the Philipps-University of Marburg (Germany). He obtained his Diploma in Physics at the University of Hamburg (Germany) in 1993,and his PhD at the University of East Anglia (UK) in 1997. After two short spells as postdoctoral assistant at the University of East Anglia and at the University of Surrey (UK) he moved on to the Philipps-University of Marburg in 1998. There he completed his Habilitation in Experimental Physics in 2004 and was appointed Privatdozent in 2005. He is author/coauthor of about 90 scientific publications, including several reviews and book articles. His research interests include physics of magnetic semiconductors and hybrids for spintronics, of III-N-V semiconductor structures for opto-electronics, of novel nanostructures ranging from nanomagnetism to applications in catalysis, and material and device characterisation in general.

Prof. Dr. Wolfram Heimbrodt was born 1954 in Berlin, Germany. He received his Diploma in Physics in 1980 from the Technical University of Dresden. He carried out his PhD. thesis in the group of Prof. Otfried Goede at the Humboldt-University of Berlin in 1985 working on the optical properties of isovalent impurities in II-VI semiconductors. Since 1986 he has worked as a postdoctoral Research Fellow in the Institute of Optics and Spectroscopy at the HU-Berlin. In 1993 he became the head of Group Spectroscopy of Semiconductor Microstructures in the Institute of Physics at the HU-Berlin and received his Habilitation in 1996, the main research interest being spintronics and magnetic semiconductors. Between 1996 and 1997 he worked as Senior Research Fellow with Prof. J. J. Davies at the University of East Anglia (UK). In 1997 he became a Professor of Experimental Physics at the Philipps-University Marburg (Germany).

Dr. Hans-Albrecht Krug von Nidda is a scientific employee and academic councillor at the University of Augsburg (Germany). He studied Physics at the Technical University in Darmstadt where he obtained his diploma in 1992. He was a PhD student in the group of Prof. Loidl, working on a project within the "Sonderforschungsbereich 252" (electronically highly correlated metallic compounds), and completed his thesis on electron spin resonance in heavy fermion compounds in 1997. Later, he moved with the group of Prof. Loidl to Augsburg where he is working as a postdoc and is supervisor of a sub group on electron spin resonance. Since 2000, he is the head of the subproject on metal-insulator transitions and order of microscopic degrees of freedom within "Sonderforschungsbereich 484" (cooperative phenomena in the solid state). During the winter term of 2001/2002, he stayed at the Kapitza Institute in Moscow within the scope of a Russian-German collaboration about defect states in low dimensional and magnetically frustrated systems. Currently, he is working on his habilitation thesis involving ESR in transition metal oxides.

Thomas Kurz is a PhD student in Augsburg (Germany). He obtained his Diploma in Physics about resistivity and magnetism in manganites in 2001. Since then, he has been working on his PhD thesis "magnetism in nanometer dimensions", which is a cooperation between the Philipps-University of Marburg (Germany) and the University of Augsburg. He is a member of the European Graduate College Marburg/Budapest. He stayed in Budapest (Hungary) as an exchange student in April 2003.

Prof. Dr. Alois Loidl is a full professor at the University of Augsburg. He studied Technical Physics in Vienna (Austria). In 1971, he finished his studies as a graduate engineer (Dipl.-Ing.) in nuclear physics and moved to the University of Frankfurt (Germany) where he performed his PhD in Solid State Physics. In 1981, he completed his Habilitation in Mainz (Germany) and was appointed professor (C2) at the Physical Institute in Mainz in 1983. After offers for a professorship from the University of Missouri-Columbia (Columbia, USA) and the University of Hannover (Germany), both in 1987, he was appointed as a university professor with tenure in Mainz. From 1991 to 1996, he was a full professor (C4) at the Institute of Solid State Physics at the Technical University of Darmstadt (Germany) and while there was also appointed executive director of the Physical Institute (1995). In 1996 he moved to the newly founded Center for Electronic Correlations and Magnetism at the University of Augsburg (Germany). He is an editor of the European Physical Journal B since 2000 and is author or coauthor of more than 400 scientific publications.

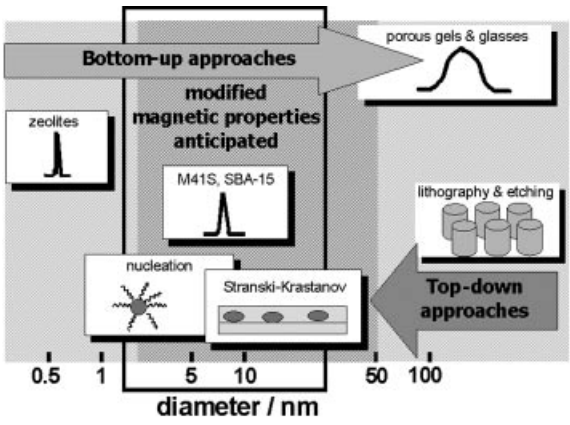

Figure 1. Bottom-up and top-down approaches for fabricating magnetic semiconductor nanostructures.

Alternatively, a large variety of so-called bottom-up approaches can be used to synthesise magnetic semiconductor nanostructures. Some of these approaches are also presented schematically in Figure 1. Examples are methods based on established growth techniques for 2D semiconductor structures (e.g. MBE or MOVPE) such as Stranski-Krastanov growth[10–18] or growth on patterned substrates.[19,20] There are also various fabrication techniques relying on nucleation and precipitation processes either in glass matrices (ranging from RF-sputtering techniques[21–24] to sol-gel methods[25–28]) or in solutions[29,30] (e.g. TOP/TOPO synthesis). All the bottom-up approaches mentioned so far yield good quality nanostructures down to sizes of a few nanometres. However, the ensembles of nanostructures fabricated in this fashion usually exhibit a rather broad Gaussian size distribution, which also manifests itself in measurements of the electronic and magnetic properties. In particular, in conventional magnetic measurements of such ensembles such as measurements of the magnetisation or of magnetic resonance, the results are strongly dominated by the larger magnetic particles, i.e. the "large size" wing of the distribution. The reason is very simple, such measurements are sensitive to the total number of magnetic ions and the amount of magnetic ions per nanostructure scales with its characteristic size e.g. for a spherical nanoparticle with the third power of its diameter. Therefore, it is desirable to define a sharp cut-off of the size distribution of the nanoparticles towards larger sizes.

One way of achieving this is by chemical synthesis of nanoparticle ensembles in a bottom-up approach using size-limiting matrices, which serve as a kind of "mini-reactor". Narrow particle size distributions can be obtained if a high quality of this nanoreactor is realised. As hosts for a size-limited synthesis only a few possibilities are worth considering: firstly, the utilisation of reverse micelles ("water-in-oil" droplets), which are already used widely in the synthesis of nanoparticles,[31–40] and secondly, the use of a porous substance which does not react with the precursors for the actual synthesis. In the large group of different porous substances the mesoporous materials seem to be the most promising approach for nanoparticle syntheses[41] since the size range, in which the pores – and therefore the nanoparticles – can be synthesised, covers a scale of several hundreds of nanometres and in particular sizes below 50 nm where changes of the particle properties due to confinement are anticipated (see also Figure 1).

In the case of reverse micelles the size of the micelle is governed by the volume of the water molecules inside and by the surfactant molecules at the surface of the micelle, i.e. the space inside the micelle where the chemical reaction or coprecipitation takes place can be varied for example by changing the amount of water in the original solution.[42] One of the surfactants often used to form reverse micelles in a nonpolar solvent is sodium di(2-ethylhexyl) sulfosuccinate, mostly denoted as Aerosol OT or Na(AOT). In a typical synthesis (see Figure 2), two micellar solutions, having the same water content (that is to say the same micelle size) and each containing one of the reactants, are mixed. When two of these micelles collide, they exchange their water contents in a micellar exchange process and the desired reaction occurs. After a few microseconds the previously formed "double-micelle" dissociates to form two independent reverse micelles, one containing the product while the other is only filled with water.

Figure 2. Micellar exchange process in a nonpolar solvent. The reaction takes place inside the water micelles (redrawn from ref.[42]).

When using mesoporous materials as hosts for the synthesis of nanoparticles, the narrow size distribution of the guest species is achieved by a narrow pore size distribution of the respective host material. In the last 12 years it has been a major goal in the synthesis of mesoporous substances to obtain materials which exhibit a high degree of long range order on the one hand and a narrow pore size distribution on the other. The quality of mesoporous materials has risen from poorly ordered so-called "disordered mesoporous foams" to high quality materials, which have very sharp pore size distributions. The high degree of long-range order can be demonstrated by TEM investigations or high-quality XRD measurements. A perfect arrangement of the pores over length scales of 300 nm and more is state of the art.[43]

Fine tuning of the pore size can be achieved by varying the nature of the structure directing agent (SDA). At first, long-chain tetraalkylammonium halides were used as SDA's for the synthesis of mesoporous materials of the M41S family. By varying the chain length of the hydrophobic alkyl group (usually containing 12 to 22 carbon atoms) the pore size can be altered very precisely in the range of about 1 nm.[44,45] However, the overall pore size is limited to about 4 nm when using these kinds of surfactants. The utilisation of swelling agents offered the possibility of expanding the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pore sizes to about 10 nm, but this was always accompanied with an overall loss of structural order, which was achieved in the first instance.

In 1998, new precursors for the synthesis of a new class of mesoporous materials were first introduced. These so-called triblock copolymers offer the possibility of expanding the pore size to about 30 nm.[46] Just by varying the synthesis temperature a fine tuning of the pore diameters was achieved and narrow size distributions with mean diameters in the range of 5 to 10 nm were obtained. However, the distributions do broaden when going to higher mean diameters.

Synthesising mesoporous materials with well defined pore diameters, i.e. narrow pore size distributions, is the first step to preparing reasonable hosts for the synthesis of nanoparticles which are formed inside the pores.

Introducing the precursor compounds into the pores of the respective size-limiting matrices is the next synthetic problem, which has to be addressed. The utilisation of reverse micelles has the advantage of a two-phase system. Using a precursor, which is only soluble in one of the phases (in this case water) prevents desired materials from forming outside of the mini-reactor and results in a very defined synthesis exclusively inside the size-limiting matrix.

In the case of mesopores as the size-limiting matrix, however, the formation of bulk materials outside the pore system can never be fully avoided. Only after the synthesis can one estimate the amount of bulk material formed during the synthesis. Wet impregnation techniques[41] and incorporation of the precursors from supercritical CO_2[47] can be applied to introduce guest molecules into the pores of the host material. Drying the impregnated materials is the crucial step in the synthesis to preventing the formation of bulk material on the outer surface of the host structure. After the introduction of the precursor the other reactants have to be introduced via the gas phase, which is to prevent the extraction of the first precursor from the pores and the consecutive precipitation outside the pores if the second reactant is introduced in a liquid form. Figure 3 gives a schematic representation of a mesopore directed synthesis of nanoparticles.

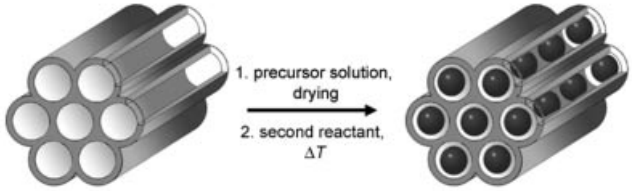

Figure 3. Schematic representation of nanoparticle synthesis inside a mesoporous host.

One of the most investigated semiconductor nanoparticles is cadmium sulphide, CdS.[2,10,31] The occurring quantum confinement, which is mostly reflected by a blue-shift of the band-gap energy, has been discussed extensively.[30,48–54] Other nanoscale semiconductor compounds, such as III-V semiconductors (e.g. GaAs or InP) or other II-VI semiconductors (e.g. CdSe, CdTe, ZnS, ZnSe, ZnTe), have also been studied in great detail (see recent reviews[42,55–58]), but to discuss all of them here would go beyond the scope of this micro-review. Instead, this work focuses on the synthesis and characterisation of Mn doped II-VI semiconductor nanostructures and describes in detail the effects of miniaturisation on the electronic, magnetic and optical properties of these materials.

The synthesis of the so-called "diluted magnetic semiconductor" (DMS) nanostructures is of great interest as semiconducting and magnetic properties are combined in one for the same nanostructure. Therefore, ordered arrays of nanometre-sized magnetic semiconductors are promising components for new devices in magneto- or spin electronics (e.g. magnetic hard disc media, non-volatile computer memory chips).[59] These materials are obtained, when a cation A of a binary semiconductor AB is randomly substituted by a magnetic ion M, leading to a $A_{1-x}M_xB$ formula. Physical properties, for example, band-gap energy or magnetic behaviour, are now not only a function of the particle size but also of the doping level x.

2. Synthesis

The first preparation of manganese doped ZnS nanoparticles with particle sizes ranging between 3.5 and 7.5 nm was reported by Bhargava et al. in 1994.[60] The quantum dots were synthesised by a precipitation approach in which diethylzinc and diethylmanganese in a toluene solution were treated with H_2S. However, in the case of liquid solution precipitation or self-organised growth methods, the particle size distribution is not very well defined. Similar results were also found in other approaches.[61–64] In particular, there is no sharp upper limit for the size, in contrast to the case of nanostructures synthesised inside nanoreactors such as reverse micelles or mesoporous materials. The existence of a sharp upper limit is desired in most investigations of the effects of reduced dimensions on the magnetic properties as the largest particles usually determine the results.

A synthesis of $Cd_{1-x}Mn_xS$ nanoparticles with a very sharp size distribution was reported by Pileni's group, by applying the reverse micelle technique.[65,66] The obtained particle sizes could be varied from an average size of about 1.8 to 3.2 nm and the reported manganese contents were $0 \leq x \leq 0.23$.

DMS nanoparticles were also synthesised inside mesoporous host structures. This approach for a host/guest system was first described in 2002 by our group, when $Cd_{1-x}Mn_xS$ was incorporated inside 3 nm wide pores of MCM-41 silica.[67] First, calcined MCM-41 silica was impregnated with an aqueous solution of cadmium and manganese acetate in the desired molar ratio. Afterwards the precipitate was filtered off, thoroughly dried and treated with H_2S at $T \leq 100$ °C. Powder X-ray diffraction and nitrogen physisorption proved the preservation of the host structure after the intrapore formation of the guest species and showed that the reaction had only taken place inside the pores and

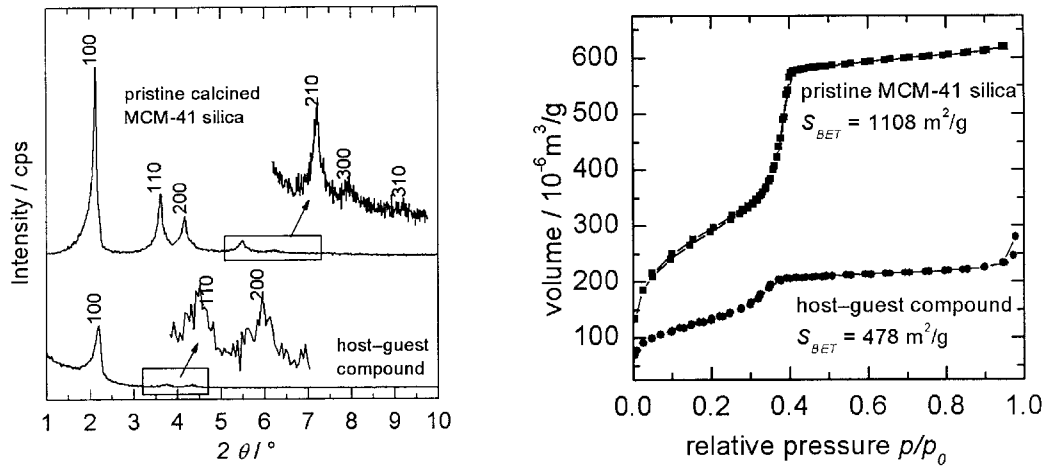

Figure 4. Powder X-ray diffraction patterns (left) and nitrogen physisorption isotherms (right) of MCM-41 silica and MCM-41 silica/$Cd_{1-x}Mn_xS$ host/guest compounds.[67]

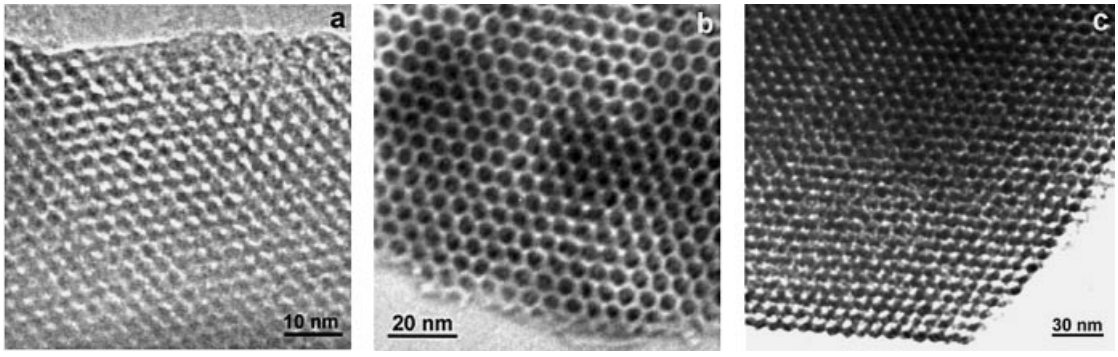

Figure 5. TEM pictures of different mesoporous host structures, a) MCM-41 silica with 3 nm pores, b) SBA-15 silica with 6 nm pores, c) SBA-15 silica with 9 nm pores.[70]

no bulk material was formed (Figure 4). The complete transformation of the acetates to the sulphides was proved by infrared and X-ray absorption spectroscopy. Similar results were obtained for other host/guest system based syntheses of nanoparticles, like $Cd_{1-x}Mn_xSe$ within MCM-41 silica[68] and $Cd_{1-x}Mn_xS$ within mesoporous thin films.[69]

A more detailed discussion on the size dependence of electronic, magnetic and optical properties was given in 2004, when the DMS compound $Zn_{1-x}Mn_xS$ was synthesised inside mesoporous hosts with different pore sizes.[70] For an accurate study three different mesoporous materials, each with cylindrical pores, were used: MCM-41 silica with 3 nm pores and furthermore two SBA-15 silica with 6 and 9 nm pores. The different pore sizes of the host materials were realised using different SDA's and different reaction temperatures (see above). A very high degree of order of the host materials was achieved, which was apparent from X-ray diffraction, sorption analyses and TEM investigations (see Figure 5).

The intrapore formation of the nanoparticles was carried out the same way as described for the $Cd_{1-x}Mn_xY$ (Y = S, Se) nanoparticle preparation, only this time the impregnation/conversion cycle was repeated several times to achieve a higher filling of the pores. Again, no bulk material was formed outside the respective pore system and the mesostructure was still found to be intact after the synthesis.

3. Band Gap and Optical Properties

With photoluminescence-spectroscopic techniques it is possible to measure the dependence of the band-gap variation on particle size and doping level x. This was carried out for various DMS compounds, like $Cd_{1-x}Mn_xS$,[66–68,71,72] $Cd_{1-x}Mn_xSe$[68] and $Zn_{1-x}Mn_xS$,[70,73] synthesised either in reverse micelles or in mesoporous hosts.

Figure 6 shows a schematic diagram of the complex optical processes observable in wide-gap (II,Mn)VI semiconductors. The semiconductor band states with a direct band-gap transition and the 3d shells of the Mn^{2+} ions with their internal transitions form electronic subsystems of the (II,Mn)VI semiconductor which are coupled by energy transfer processes. In addition to semiconductor band-gap related luminescence and absorption, luminescence and absorption bands are observed due to the intra-3d-shell transitions of the Mn^{2+} ions. The states within the 3d shell are strongly affected by the crystal field of the lattice site of the corresponding Mn^{2+} ion. The majority of the Mn^{2+} ions

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are incorporated on cation sites with a tetrahedral crystal field. The lowest state is the $^6A_1$ state originating from the ^6S state of the free ion, and the next highest states are $^4T_1$, $^4T_2$, $^4A_1$ and ^4E originating from the ^4G state of the free ion. Absorption processes can take place between the $^6A_1$ ground state and the excited states. A yellow luminescence between the $^4T_1$ first excited state and the $^6A_1$ ground state is observed for all wide-gap (II,Mn)VI compounds, independent of Mn concentration for Mn incorporated onto the cation site. In addition, there are a few Mn^{2+} ions on other sites. These "defect" sites show a different crystal field splitting between the states of the 3d shell, and this leads to other absorption and luminescence bands. A prominent example is the red Mn^{2+} luminescence. Energy-transfer processes can take place between the band states and the Mn^{2+} 3d shells, as well as between Mn^{2+} 3d shells corresponding to different sites.

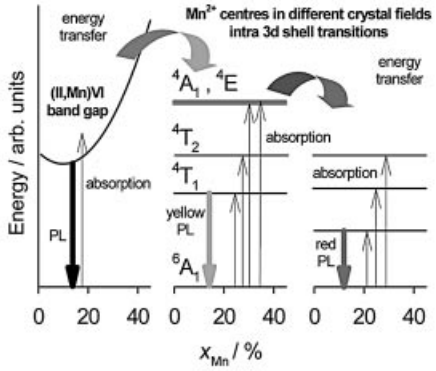

Figure 6. Schematic diagram of the optical processes observable in wide-gap (II,Mn)VI semiconductors. The abscissa values are the same for all three graphs.

In Figure 7 typical optical spectra of $Zn_{0.7}Mn_{0.3}S$ nanoparticles synthesised inside mesoporous hosts with different pore diameters are shown. The PL spectrum is dominated by the strong yellow luminescence originating from the $^4T_1 \rightarrow {}^6A_1$ internal Mn^{2+} 3d shell transition (exemplarily shown for the 6 nm sample, thick line in Figure 7).

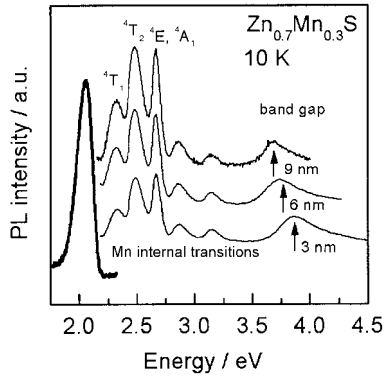

Figure 7. PLE spectra (thin lines) of $Zn_{1-x}Mn_xS$ nanoparticles with diameters of 3, 6 and 9 nm, respectively, detected on the yellow Mn luminescence. The Mn-related yellow PL band (thick line) of the 6 nm sample is shown as a typical example.

The internal Mn transitions arising from the $^4T_1$, $^4T_2$, ^4E and $^4A_1$ states are observable between 2.3 and 2.7 eV (the increase in intensity with increasing particle size simply reflects the increasing total amount of manganese) whereas the peak at the highest energy in each spectrum corresponds to the band gap related absorption. Because of the effective energy transfer from the band states into the Mn subsystem this peak is also detectable on the yellow PL.

The band gap related feature shifts to higher energies with decreasing particle diameter (i.e. shows a quantum confinement effect) whereas the energy positions of the Mn^{2+} internal transitions remain unaffected by the particle size (demonstrating that the energy positions are only determined by the local crystal field of the Mn site). The observed quantum confinement effects prove that during the synthesis $Zn_{1-x}Mn_xS$ is formed inside the SiO_2 pore system only. The energy positions of the Mn^{2+} internal transitions serve as a probe of the crystal field at the Mn site. In Figure 8 the energies of the lowest excited states of a Mn^{2+} $3d^5$ ion in a T_d symmetric ligand field with respect to the $^6A_1$ ground state are depicted for a bulk $Zn_{0.9}Mn_{0.1}S$ sample (full circles) and the $Zn_{0.7}Mn_{0.3}S$ nanostructures of different radii (open symbols). The curves have been calculated in the Tanabe–Sugano model[74] as a function of the crystal field parameter Dq with the Racah parameters B = 50 meV and C = 434 meV. The extracted crystal field parameters using the Tanabe–Sugano method are almost the same for bulk samples and nanostructures indicating the good quality of the nanostructures.

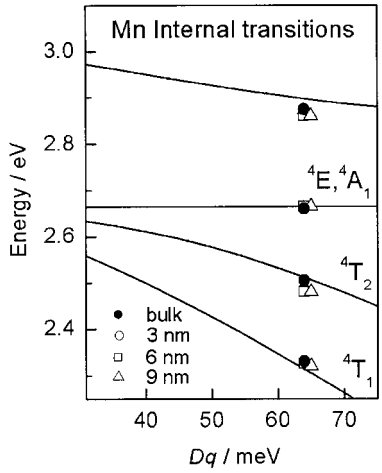

Figure 8. Energies of the internal transitions of Mn^{2+} ions in a T_d symmetric crystal field versus the field parameter Dq using the Racah parameters B = 50 meV and C = 434 meV, calculated in the framework of the Tanabe–Sugano model. Experimental points for $Zn_{0.9}Mn_{0.1}S$ bulk and $Zn_{0.7}Mn_{0.3}S$ nanostructures.

Figure 9 gives a comparison of the energy positions of the band gaps of nanoparticles of three (II,Mn)VI DMS's with different diameters as a function of Mn content x. A bulk reference curve is shown in the case of $Cd_{1-x}Mn_xSe$, but not for $Zn_{1-x}Mn_xS$ and $Cd_{1-x}Mn_xS$. For the sulphides, the band gaps of the 9 nm nanostructures are almost bulk-like. The quantum confinement of the excitons in the nano-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

particles evokes an increase in the direct band gap of about 350 meV for 3 nm $Cd_{1-x}Mn_xSe$ nanoparticles compared with the bulk. For the corresponding $Cd_{1-x}Mn_xS$ nanoparticles the confinement is only about 200 meV. In the case of the 3 nm $Zn_{1-x}Mn_xS$ nanoparticle the confinement energy compared to the bulk is about 180 meV. The decrease of the confinement energy going from (Cd,Mn)Se via (Cd,Mn)S to (Zn,Mn)S has two major reasons: (1) the exciton Bohr radius decreases throughout the series and (2) the corresponding bulk band gap increases, i.e. reduces the height of the confining potential given by the band-gap difference between the SiO_2 barrier and (II,Mn)VI semiconductor. The (Cd,Mn)S as well as the (Zn,Mn)S nanoparticle series clearly show, as expected, that the confinement effects increase with decreasing particle diameter. For both series the energy positions for the 9 nm wires almost correspond with those of the bulk band gaps.

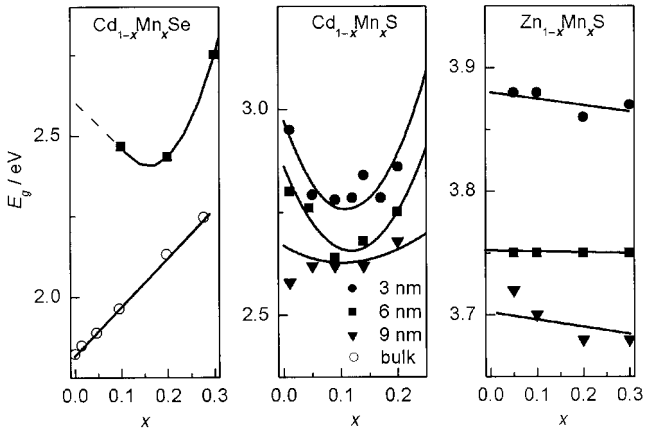

Figure 9. Band gaps of $Cd_{1-x}Mn_xSe$ nanoparticles (left), $Cd_{1-x}Mn_xS$ nanoparticles (middle) and $Zn_{1-x}Mn_xS$ nanoparticles (right) of different diameters as a function of composition x at $T = 10$ K. The solid lines are guides to the eye.

An interesting result is that both Cd-based nanoparticle systems exhibit a larger bowing of the band gap, depending on the Mn concentration, than do the corresponding bulk samples. This agrees with results reported for (Cd,Mn)S quantum dots by Levy et al.,[66] who also showed that the exchange interaction-induced band gap bowing becomes stronger with decreasing diameter for (Cd,Mn)S quantum dots synthesised in reverse micelles. Such a bowing is known for various bulk wide-gap (II,Mn)VI semiconductors.[75–78] Bylsma et al. derived the following expression for the band gap as a function of temperature T and Mn concentration x in DMS nanostructures [Equation (1)]:[79]

$$E_g(x,T) = E_0 + \Delta E x - \frac{AT^2}{T+B} - C\chi T \quad (1)$$

where the first three terms represent the commonly used description of the energy gap of a semiconductor compound comprising a linear shift in composition and a Varshni-like temperature dependence. The last term is specific to DMS and causes the bowing. It describes a contribution due to the magnetic susceptibility χ of the Mn ions. Both, the constant C as well as magnetic susceptibility χ, may be affected by the reduction of the lateral dimensions. The constant C is given by Equation (2).

$$C \sim 3m_c\alpha^2 + (m_{hh} + m_{lh})\beta^2 \quad (2)$$

where m_c, m_{hh}, and m_{lh} are the conduction-band and valence-band masses and α and β are the s–d and p–d coupling parameters. As $\alpha << \beta$ and m_{hh}, $m_{lh} > m_c$ in the (II,Mn)VI compound, the magnitude of C is mainly determined by β for which Larson et al. give the following expression [Equation (3)]:[80]

$$\beta = -32\frac{V_{pd}^2}{N_0}\left[\frac{U_{eff}}{(E_d + U_{eff} - E_{ev})(E_v - E_d)}\right] \quad (3)$$

where V_{pd} and U_{eff} are a hopping parameter depending on the manganese–anion distance and an electron-electron interaction parameter in the Hubbard fashion. The hopping parameter V_{pd} basically represents the hybridisation between the Mn 3d orbitals and the anion p orbitals in the bonding of the ternary (II,Mn)VI semiconductor compound. In the band structure of the (II,Mn)VI compound this is reflected by the energetic overlap of the anion p-orbital derived valence bands and the Mn 3d-orbital derived valence bands in the density of states as shown schematically on the left hand side of Figure 10. The electron-electron interaction parameter U_{eff} represents the on-site Coulomb repulsion energy which is required to add a sixth electron to the half-filled Mn 3d shell as shown schematically on the right of Figure 10. E_v and E_{3d} are representative energies of the p-like valence-band edge states and the Mn 3d related valence-band states, respectively.

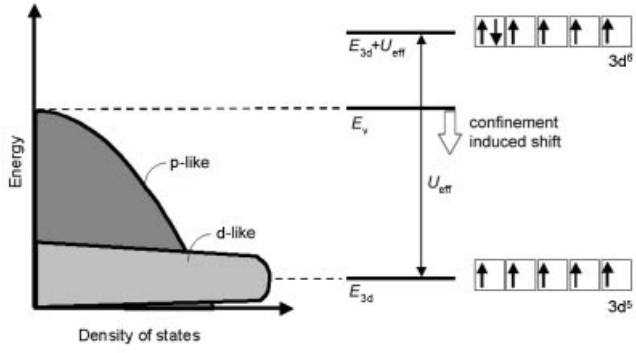

Figure 10. Schematic representation of the parameters contributing to the p–d exchange parameter β in the model by Larson et al.

The p–d coupling parameter β strongly depends on the energy separation between the p- and d-like valence-band states represented by E_v and E_{3d}, respectively [see Equation (3)]. The modified positions (compared to bulk) of the p- and d-related bands in the band structure of the nanoparticle causes an increase of the p–d exchange interaction, resulting in a possible contribution to the enhanced band-gap bowing in the nanostructures. Due to the quantum confinement, the top of the p-like valence band (E_v) of the $Cd_{1-x}Mn_xS$ nanostructures may shift significantly towards the Mn 3d states (E_{3d}), which are positioned about 3 eV below

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the valence-band edge of bulk material (see Figure 10). This enhancement effect is similar to that in bulk $Cd_{1-x}Mn_xY$ with Y = Te, Se, S where an increased p–d hybridization is observed with increasing band gap going from Te to S.[81] Similar results were also reported for the corresponding Zn series where the main Mn 3d photoemission feature was found at 3.5, 3.6 and 3.8 eV below the valence-band maximum of (Zn,Mn)Te, (Zn,Mn)Se and (Zn,Mn)S, respectively.[82]

The susceptibility χ itself is also affected by the reduced dimensionality. In virtual crystal and mean-field approximation, the expression for χ is given by Equation (4):

$$\chi = x_{\text{eff}} \frac{N_A S(S+1) g^2 \mu_B{}^2}{3k_B[T + \Theta(x)]} \quad (4)$$

x_{eff} (which is a magnetically effective Mn concentration accounting for antiferromagnetic pairing) as well as $\Theta(x)$ are modified in a nanostructure due to the increase of the surface-to-volume ratio. The number of nearest neighbours on the cation sublattice is reduced at the surface leading to an increase of the effective x. This also causes a reduction of the Curie–Weiss parameter Θ in a similar fashion (see section 4: "Magnetic properties"). The combination of both effects results in a stronger increase of χ with x in the nanostructures compared to the bulk.

Therefore, both the dependence of the p–d exchange parameter β and that of the susceptibility χ on reduced dimensionality are in accordance with the observed enhancement of the band-gap bowing in $Cd_{1-x}Mn_xS$ and $Cd_{1-x}Mn_xSe$ nanostructures as a function of x. It is worth mentioning here that the former effect is probably of less importance because a good description of the magnetic properties of the paramagnetic phase of the (II,Mn)VI nanostructures is obtained (see section 4), assuming that the exchange coupling between adjacent Mn ions J_{nn} (which is proportional to β^2) is not altered in the nanostructures. Moreover, the dependence of the band gap of bulk $Zn_{1-x}Mn_xS$ and the corresponding nanostructured samples on the Mn concentration x seems to be an exception from a general rule. Although bulk (Zn,Mn)Te[75,83] as well as (Zn,Mn)Se[76,79] exhibit considerable bowing effects, neither the bulk $Zn_{1-x}Mn_xS$[84] nor the nanostructured samples in Figure 9 exhibit significant bowing effects with increasing x.

4. Magnetic Properties

Undoped II-VI compounds (x = 0) are diamagnetic whereas Mn–VI compounds (x = 1) are paramagnetic at high temperatures and exhibit an antiferromagnetic phase at low temperatures. The degree of magnetic coupling between the spins of the Mn ions depends strongly on the average distance between them, i.e. on x. Consequently, a very rich magnetic phase diagram as a function of x and T arises for a typical (II,Mn)VI semiconductor alloy such as (Cd,Mn)S (see Figure 11). Decreasing the concentration x of magnetic ions in diluted magnetic II-VI alloys restricts the spin ordering effects to the lower temperature region. Nevertheless, phases determined by collective magnetic behaviour such as antiferromagnetic (AF) phases as well as a spin-glass phase (SG) are commonly observed in addition to the paramagnetic phase (P) (Figure 12 gives a schematic summary of collective and individual behaviour of magnetic systems). The P phase extends to lower temperatures with decreasing x. For example, for (Cd,Mn)S, a (disordered) AF phase which has a long-range spin ordering occurs below a critical temperature $T_N(x)$ for a sufficiently high Mn concentration $x > 0.8$ (beyond the miscibility gap). The corresponding phase transition is characterised by peaks at T_N in both the magnetic susceptibility and the specific heat. For Mn concentrations below the miscibility gap an SG phase is observed for temperatures below $T_{SG}(x)$. In the case of (Cd,Mn)Te even a transition to the AF phase has been reported for x = 0.7,[85] which means that it is still below the miscibility gap.

The spin-glass phase is characterised by an antiferromagnetic short-range ordering of the spins, as well as by frustration effects. The somewhat diffuse phase transition from the paramagnetic into the spin-glass phase leads to a peak at $T_{SG}(x)$ in the temperature dependence of the magnetic susceptibility, but no anomaly in the specific heat is observable. Neutron-scattering experiments have shown that small antiferromagnetically ordered clusters already appear above T_{SG}, which grow in size with decreasing temperature. Another surprising fact is that a spin-glass phase is observable not only above the percolation limit ($x \approx 0.2$), but also below. In the very low concentration range, a rather long-range interaction is necessary, in addition to the short-range superexchange interaction, to yield a spin-glass phase. The

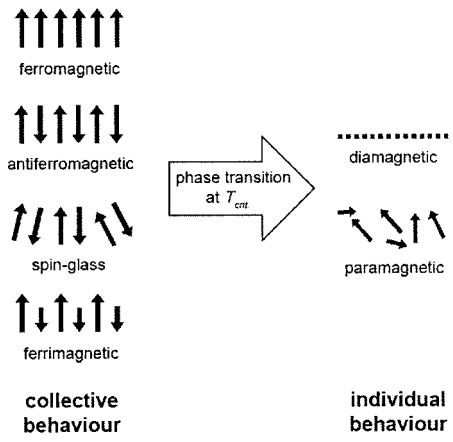

Figure 12. Schematic representation of the collective to the individual behaviour of magnetic systems.

spin freezing temperatures below the percolation concentration are very small, for example, between 0.1 K and 1 K for $x \approx 0.01$. The magnetic dipole-dipole interaction between more distant Mn^{2+} ions is proposed to be the required long-range interaction responsible for this spin-ordering mechanism, despite the fact that the dipole-dipole interaction might be too weak to cause the ordering at finite temperatures.[86]

In bulk (II,Mn)VI materials, the integral EPR signal corresponding to the Mn^{2+} absorption has a Lorentzian lineshape in the paramagnetic regime.[87] The overall intensity I_{tot} as well as linewidth ΔH of the Lorentzian are very sensitive to the spin-spin correlations between the Mn^{2+} ions. Not only changes of the magnetic order with temperature, e.g. transitions from the P phase to the SG phase or from the P phase to the AF phase, are reflected by the temperature dependence of ΔH and I_{tot}, but also by changes of the magnetic interactions within the paramagnetic phase itself due to a reduction of the lateral dimensions.

The EPR spectra for (II,Mn)VI nanoparticles synthesised either in reverse micelles or inside mesoporous hosts are very similar. As a typical example, the EPR spectra of $Zn_{1-x}Mn_xS$ nanoparticles with x varying from 0.01 to 0.3 synthesised inside the 6 nm wide pores of SBA-15 silica are shown in Figure 13.[70] All spectra were taken at 4 K and normalised to the same amplitude. These spectra are typical for exchange coupled Mn^{2+} ions within a II-VI semiconductor compound[88–90] and in nanostructured DMS compounds, for example $Cd_{1-x}Mn_xS$[91] and $Zn_{1-x}Mn_xS$.[70] The spectra can best be explained for low x. They basically consist of a sextet of sharp lines. This sextet, which is centred at a g value of $g = 1.999$, is associated with the allowed ($\Delta m_S = \pm 1$, $\Delta m_I = 0$) magnetic dipolar transitions between the hyperfine-split Zeeman levels of the $^6S_{5/2}$ (or, $^6A_1$) ground state of the Mn^{2+} 3d electrons. The hyperfine structure arises from the interaction between the $S = 5/2$ spin of the unpaired 3d electrons with the $I = 5/2$ spin of the ^{55}Mn nucleus. The hyperfine splitting characteristic for Mn^{2+} in ZnS amounts to about $\delta B_{HFS} = 7.0$ mT between neighbouring allowed transitions in zinc blende as well as in wurtzite structures.[10] The splitting observed in the spectrum of the sample with 1% Mn agrees well with this value.

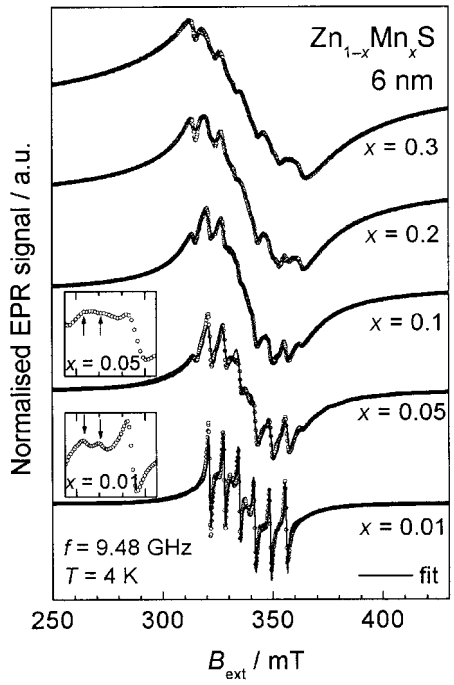

Figure 13. EPR spectra of 6 nm $Zn_{1-x}Mn_xS$ nanoparticles with x varying from 0.01 to 0.3 at $T = 4$ K. Insets: hyperfine transitions on an enlarged field scale for $x = 0.01$ (lower) and $x = 0.05$ (upper), the arrows indicate the positions of the forbidden transitions. Taken from ref.[70].

With increasing Mn content the dipolar interaction and exchange coupling merge the hyperfine structure into one broad resonance line, which is documented best for $x = 0.3$. But this broad line can already be identified for $x = 0.01$. The spectrum for $x = 0.01$ is satisfactorily described by the sum of the broad line and the hyperfine structure of six lines. Both the broad line and the hyperfine lines were assumed to be of Lorentzian shape. In addition it was necessary to take into account a slight linear increase of the hyperfine splitting with the external field due to second-order contributions.

A close inspection reveals that at low Mn concentration each hyperfine line exhibits a pair of satellites at lower external magnetic field associated with the forbidden ($\Delta m_S = \pm 1$, $\Delta m_I = \pm 1$) hyperfine transitions (see lower inset of Figure 13). The forbidden hyperfine transitions in the spectra with the lowest manganese content ($x = 0.01$) are typical for Mn^{2+} ions in the tetrahedral environment of a Zn site in a zinc blende crystal. In the case of a wurtzite crystal these lines are much more prominent and merge with the lines of the allowed hyperfine transitions, as is observed for samples with larger amounts of manganese ($x \geq 0.05$, see upper inset of Figure 13). Thus, it can be concluded that the crystal structure of the incorporated (II,Mn)VI semiconductors is zinc blende only for $x = 0.01$, whereas higher doping levels with Mn^{2+} result in a wurtzite structure. At the same time it has to be noticed that with increasing x an additional hyperfine structure of six lines with a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

larger splitting of about δB_{HFS} = 9.5 mT evolves and persists even at 30% Mn content. This hyperfine structure results from isolated Mn^{2+} ions on the surface of the $Zn_{1-x}Mn_xS$ nanoparticles. From a careful analysis of the intensities of the different signals it can be deduced that the majority of the Mn^{2+} ions are well incorporated into the $Zn_{1-x}Mn_xS$ nanostructures and only a small amount remains weakly bound at their surface.[92] This amount of aggregated Mn ions at the surface of the nanoclusters corresponds to less than 4% of the total amount of Mn in the nanostructure.[70]

The Curie–Weiss parameter Θ of the paramagnetic phase is a measure of the type and strength of the interaction between the manganese ions. It can be obtained experimentally either from plots of the inverse EPR intensity I_{tot}^{-1} versus temperature T or from plots of the inverse susceptibility χ^{-1} versus temperature determined by SQUID measurements. It is found that the experimentally determined Cure–Weiss parameter is usually well described in the high-temperature limit using Equation (5):[93,94]

$$\Theta(x) = -\frac{2}{3k_B}S(S+1)x[J_{nn}z^b_{nn} + J_{nnn}z^b_{nnn}] \quad (5)$$

where J_{nn} and J_{nnn} are the nearest neighbour (nn) and next-nearest neighbour (nnn) exchange coupling constants, respectively, between Mn ions on the cation lattice. The numbers of nn and nnn sites of the cation lattice are denoted by z_{nn} and z_{nnn}, respectively. For both wurtzite and zinc blende crystals z^b_{nn} and z^b_{nnn} are 12 and 6 respectively, in the bulk.

Figure 14 shows plots of the inverse EPR intensity I_{tot}^{-1} of 9 nm $Zn_{1-x}Mn_xS$ nanoparticles with x ranging from 0.01 to 0.3 as a function of the temperature. Similar results were also obtained for a series of $Cd_{1-x}Mn_xS$ nanoparticles with 3 to 9 nm diameters and a series of $Zn_{1-x}Mn_xS$ particles with diameters of 3 and 6 nm, each synthesised within mesoporous hosts. As in the case of bulk (II,Mn)VI, the slope of the $I_{tot}^{-1}(T)$ curve decreases with increasing doping level x and deviates from the Curie–Weiss behaviour at low temperatures, giving the curves a somewhat negative curvature. At first sight surprisingly, the particles with $x \geq 0.2$ do not show any indication for a phase transition into a spin-glass phase, in contrast to bulk material.[95] This result will be discussed further, when the EPR linewidth is analysed. Fitting the $I_{tot}^{-1}(T)$ plots in the high temperature regime (200 K to 300 K) following the Curie–Weiss dependence [Equation (6)]:

$$I_{tot}^{-1}(T) \sim \chi^{-1}(T) \sim (T + \Theta) \quad (6)$$

yields the Curie–Weiss parameter Θ as a function of x.

The corresponding plots for various particle diameters d (obtained by analysing the corresponding EPR data, as shown exemplarily for x = 0.1 in Figure 14, where a straight line is used for extracting the high-temperature Curie–Weiss parameter Θ) are shown in Figure 15 and show some clear trends. As expected, $|\Theta|$ increases with increasing x in each series. The $|\Theta|$ values obtained for the nanostructures are considerably lower than those found in corresponding bulk

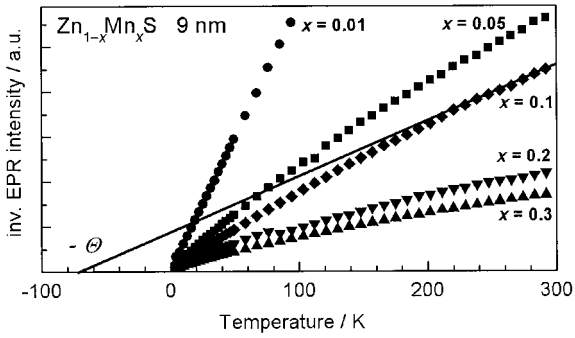

Figure 14. Temperature dependence of the inverse EPR intensity I_{tot}^{-1} of 9 nm $Zn_{1-x}Mn_xS$ nanoparticles.

(II,Mn)VI samples. These are represented by the solid lines in Figure 15 and are calculated using Equation (5). The exchange parameters are taken from the literature:[94,96] J_{nn} = –10.6 K and J_{nnn} = –4.7 K for (Cd,Mn)S and J_{nn} = –16.1 K and J_{nnn} = –0.6 K for (Zn,Mn)S. Moreover, in Figure 15, it appears that the $|\Theta|$ values show a tendency to decrease with decreasing particle diameter d at constant x. Both effects are due to the reduced lateral dimensions of the nanostructures. They occur because Mn ions on the surface of the (II,Mn)VI nanostructures incorporated inside the mesoporous SiO_2 matrices have reduced numbers of nearest neighbours $z^s_{nn} \approx z^b_{nn}/2$ and next-nearest neighbours $z^s_{nnn} \approx z^b_{nnn}/2$ compared to the bulk of the material. This becomes significant as the surface-to-volume ratio is strongly increased in the nanostructures. The effect can be estimated by dividing the volume V of the nanostructure into a volume V^s close to the surface (where the exchange effects differ from bulk) and a remaining bulklike volume $V^b = V - V^s$. The choice of the two volumes will differ for nearest neighbours and next-nearest neighbours because of the length of the scales involved, i.e. the nearest neighbour distance d_{nn} and the next-nearest neighbour distance d_{nnn}, are different. In the following the wurtzite structure is approximated by a zinc blende structure for simplicity. This is a good approximation here as only nearest and next-nearest

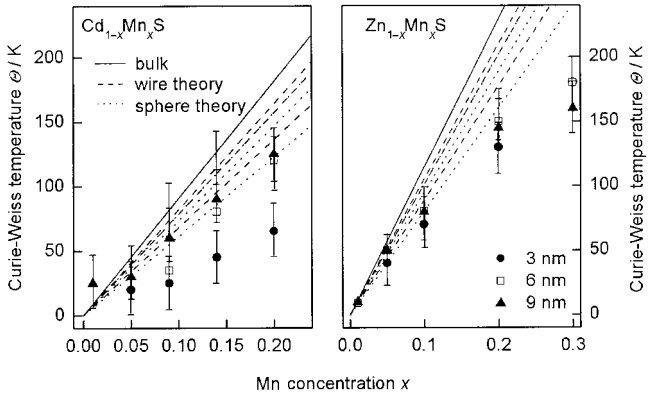

Figure 15. Plots of the Curie–Weiss temperature Θ versus Mn content x in percent obtained by analysing the EPR data of 3, 6, and 9 nm $Cd_{1-x}Mn_xS$ particles (left) and 3, 6, and 9 nm $Zn_{1-x}Mn_xS$ particles (right). The solid line is calculated using Equation (5), the dashed and dotted lines are calculated using Equation (8).

neighbours are considered. It holds that $d_{nn} = (1/2)^{0.5}a$ and $d_{nnn} = a$ where a is the lattice constant of the zinc blende lattice, $a \approx 0.55$ nm for (Zn,Mn)S and $a \approx 0.58$ nm for (Cd,Mn)S.[97] These values of the lattice constant were used for $Cd_{1-x}Mn_xS$ and $Zn_{1-x}Mn_xS$ independent of x in the following because its dependence on x is not known for the zinc blende modification. Two limiting cases for the shape of the nanostructure shall be considered: (i) an ideal wire structure of infinite length and diameter d and (ii) a spherical nanoparticle with diameter d where d is the pore diameter of the SiO_2 host matrix. One obtains the following definitions [Equation (7)]:

$$V^s_{nn} = V\left(1-\left(\frac{d-2d_{nn}}{d}\right)^{\delta}\right) \qquad V^s_{nnn} = V\left(1-\left(\frac{d-2d_{nnn}}{d}\right)^{\delta}\right) \tag{7}$$

with $\delta = 2$ for infinite wires and $\delta = 3$ for spheres. In both cases it holds that $V^b_{nn} = V - V^s_{nn}$ and $V^b_{nnn} = V - V^s_{nnn}$.

Rewriting Equation (5) including surface effects yields Equation (8).[91]

$$\Theta(x,d) = -\frac{2S(S+1)x}{3Vk_B}\left[J_{nn}\left(V^b_{nn}z^b_{nn} + V^s_{nn}z^s_{nn}\right) + J_{nnn}\left(V^b_{nnn}z^b_{nnn} + V^s_{nnn}z^s_{nnn}\right)\right] \tag{8}$$

Using Equations (5) and (8), the Curie–Weiss parameters have been calculated for $Cd_{1-x}Mn_xS$ and $Zn_{1-x}Mn_xS$ nanostructures assuming a wirelike and a spherical shape. Both the calculations, for the $Cd_{1-x}Mn_xS$ nanostructures as well as for the $Zn_{1-x}Mn_xS$ nanostructures, were carried out for d values of 3, 6, and 9 nm. The results of the calculations are also plotted in Figure 15. In both graphs, the dotted and dashed lines represent the results for a wirelike and a spherical shape, respectively. There are three calculated Θ curves for wire-shaped and three calculated Θ curves for sphere-shaped nanoparticles. For the wire and sphere shapes, the curves are assigned as follows to the corresponding d-values; the steepest curve corresponds to $d = 9$ nm, the intermediate curve to $d = 6$ nm and the least steep curve to $d = 3$ nm. Comparing experimental data and theoretical curves indicates that the theoretically derived reduction of the Curie–Weiss parameters Θ due to surface effects are, as expected, stronger for spherical nanoparticles compared to wire-shaped nanoparticles. The calculated reductions are of the right magnitude for both (Cd,Mn)S and (Zn,Mn)S nanostructures, but still smaller than those found in the experiment. Assuming that spherical particles yields a better agreement, this is in accordance with the TEM analysis of the (II,Mn)VI nanostructures. Figure 16 depicts a TEM image of (Zn,Mn)S nanostructures incorporated into an SBA-15 mesoporous SiO_2 matrix with a pore diameter d of 6 nm in a cross sectional view. The narrow "white" lines represent the SiO_2 walls of the pore systems. The dark regions are the (Zn,Mn)S nanoparticles. This view perpendicular to the pores reveals that the aligned pore channels are filled with the (Zn,Mn)S compound. It can clearly be seen that single "sphere-like" nanoparticles are present, but also that there is a tendency for these nanoparticles to agglomerate to denser "wire-like" structures. There is no evidence for larger particles being formed outside the pore system, i.e. the entire (Zn,Mn)S is confined inside the channels of the mesoporous host.

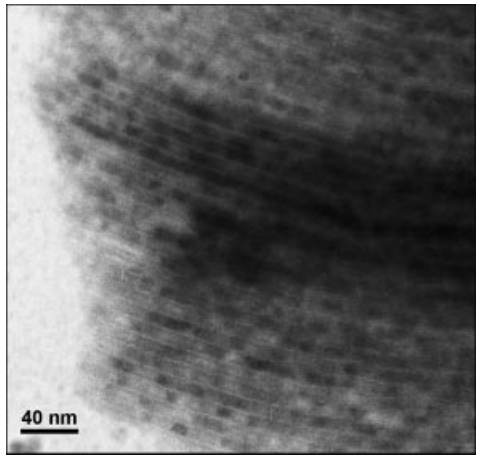

Figure 16. TEM image of (Zn,Mn)S nanostructures incorporated into 6 nm wide pores of SBA-15 silica.

In paramagnetic systems such as the (II,Mn)VI semiconductors, the EPR linewidth behaviour depends intimately on the physics of the inter-manganese spin-spin interactions. The EPR linewidth of bulk (Cd,Mn)- and (Zn,Mn)-chalcogenides has been widely studied.[87,98–101] The experimental results give a consistent picture, which can be summarized as follows: (i) In general, the EPR linewidth is found to increase with increasing Mn content and with decreasing temperature. The EPR line shape is Lorentzian for all samples in the paramagnetic regime. (ii) The EPR linewidth depends very strongly on the anion, i.e. Te, Se and S. For comparable Mn contents x and temperature T, it is found that the EPR line becomes broader as the atomic number of the anion increases from S to Se to Te.[87,98] (iii) There is a much weaker dependence on the type of nonmagnetic cation. The EPR line broadens as the atomic number of the cation decreases, e.g. $Zn_{1-x}Mn_xS$ signals are somewhat weaker and broader than $Cd_{1-x}Mn_xS$ signals for the same x and T.[98]

The EPR linewidth in manganese doped II/VI semiconductors with a high doping level x is found to diverge at low T due to the magnetic phase transition from the paramagnetic phase to the spin-glass phase, in particular for $x > 0.2$, i.e. above the percolation threshold in three dimensions. This additional broadening of the EPR linewidth occurs due to the divergence of the spin-spin correlation length in the vicinity of the paramagnetic to spin-glass phase transition. It is accompanied by a change of the EPR line shape, which becomes asymmetric.

As mentioned earlier $Zn_{1-x}Mn_xS$ and $Cd_{1-x}Mn_xS$ nanoparticles with $x \leq 0.3$ synthesised in mesoporous hosts do not show any signs of a paramagnetic to spin-glass phase transition. This is further substantiated by the correspond-

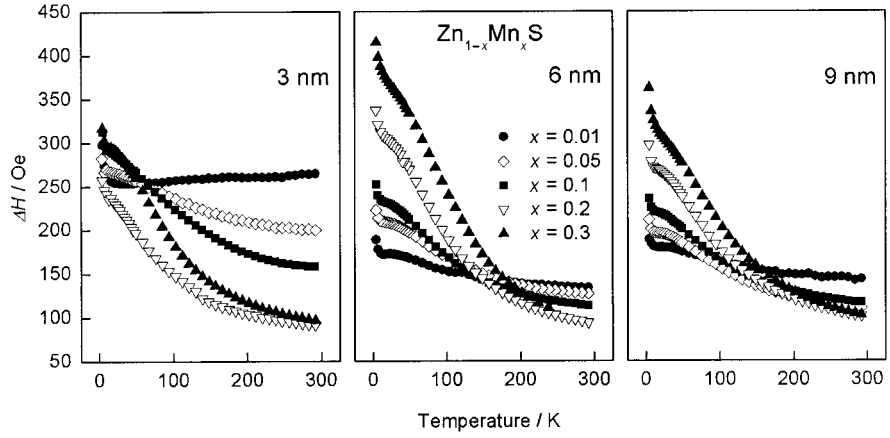

Figure 17. Plots of the EPR linewidth ΔH versus temperature for $Zn_{1-x}Mn_xS$ nanoparticles of different doping levels x and diameters of 3 nm (left), 6 nm (middle) and 9 nm (right).

ing EPR linewidths data in Figure 17 where the linewidth remains finite even at the lowest temperature. The critical Mn concentration x, above which the phase transition occurs, corresponds to the percolation threshold for the Mn ions on the cation sublattice. Obviously, the percolation threshold is increased due to the reduction of the lateral dimensions of the nanostructures and, thus, the magnetic phase transition is suppressed in the nanoparticles. Therefore, the linewidth behaviour is solely determined by the spin-spin interactions within the paramagnetic Mn subsystem.

In the following, the concentration dependence of the linewidth at low temperatures (T = 30 K) and at high temperatures (T = 290 K) will be analysed in more detail. Figure 18a and Figure 18b show plots of the linewidth at these temperatures for $Zn_{1-x}Mn_xS$ nanoparticles with different diameters and $Cd_{1-x}Mn_xS$ nanoparticles with different diameters, respectively. For both material systems, it can be seen from the left graphs that, at T = 30 K, the linewidth depends almost linearly on x. This can be understood as follows. At these temperatures the broadening is determined by a dipolar contribution in addition to an almost constant hyperfine contribution H_{HF}. Exchange narrowing effects due to nearest-neighbour exchange J_{nn} are negligible as basically all Mn ions with manganese nearest neighbours have formed antiferromagnetic pairs. The linewidth at low temperature can be described by Equation (9):

$$\Delta H = H_{HF} + H_{dip} \approx H_{HF} + C_{dip}x \quad (9)$$

where H_{dip} is the dipolar field at the site of a Mn ion in mean-field approximation.[102] The fits in the left graphs of Figure 18 show that the low temperature approximation in Equation (9) describes the observed linewidth behaviour in the nanoparticles very well, in particular for the 6 nm and 9 nm samples of both series. For the (Zn,Mn)S system, the value of H_{HF} of about 150 Oe determined for the 6 nm and 9 nm samples corresponds to half the extension of the six fine structure satellites in Figure 13. The value for the 3 nm samples is slightly larger. The linewidths of the series of $Cd_{1-x}Mn_xS$ nanoparticles show a similar dependence as that of the corresponding Zn-based series, but the linewidth is always smaller. It is worth pointing out that, as in bulk material, this simply reflects the difference in the cation size.

The high temperature behaviour [right graphs of Figure 18a and Figure 18b] can be explained semiquantita-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tively by considering the effect of the nearest-neighbour interaction J_{nn}, which determines the linewidth behaviour at temperatures, where the Mn nearest-neighbour pairs are broken up. For this purpose, the Mn ions in the nanostructure can be divided up into two classes: (i) isolated Mn ions without manganese nearest neighbours and (ii) Mn ions with one or more nearest neighbours. Furthermore, as in the case of the discussion of the Curie–Weiss parameter Θ, the volume of the nanostructure will be divided into a volume close to the surface V^s_{nn} and a bulklike volume V^b_{nn} [see Equation (7)] and the discussion will be based on a zinc blende lattice for simplicity.

The probabilities for the occurrence of two classes of Mn ions as a function of x at the surface and in the bulk of the nanoparticles are given by Equation (10):

$$p^b_{is} = (1 - x)^{z^b_{nn}} \qquad p^b_{nn} = 1 - p^b_{is}$$
$$p^s_{is} = (1 - x)^{z^s_{nn}} \qquad p^s_{nn} = 1 - p^s_{is} \tag{10}$$

The total linewidth as a function of x and diameter d is calculated according to Equation (11):

$$\Delta H(x,d) = \frac{V^b}{V}\sqrt{(\Delta H_{is}p^b_{is})^2 + (\Delta H^b_{nn}p^b_{nn})^2} + \frac{V^s}{V}\sqrt{(\Delta H_{is}p^s_{is})^2 + (\Delta H^s_{nn}p^s_{nn})^2} \tag{11}$$

It is assumed that in both volumes the linewidth contribution ΔH_{is} of the isolated manganese ions is well described by fits of the low temperature linewidth data according to Equation (9).

The linewidth contribution of the Mn ions with nearest neighbours is calculated in a similar fashion as in ref.[103] In both regions Equation (12) holds.

$$\Delta H_{nn} = \frac{H^2_{dip,nn} + H^2_{HF}}{H^i_{ex,nn}} \tag{12}$$

where $H_{dip,nn}$ is the mean dipolar exchange field for a Mn ion with at least one Mn nearest neighbour, which is approximated by Equation (13).

$$\left(H_{dip,nn}\right)^2 \approx \tfrac{3}{4} S(S+1)\mu_B{}^2 g^2 \left[\frac{\gamma}{d^6_{nn}}\right] \tag{13}$$

for the surface as well as the bulk region. γ is basically a scaling factor for the square of the dipolar field due to one nearest neighbour Mn ion.

H_{HF} is the constant value for the hyperfine broadening determined at low T and $H^i_{ex,nn}$ is the isotropic nearest-neighbour exchange field. The latter is calculated according to Anderson and Weiss,[103] Equation (14):

$$H^i_{ex,nn} = 2.83\frac{J_{nn}}{g\mu_0\mu_B}\sqrt{S(S+1)} \tag{14}$$

For both (II,Mn)VI systems, γ is the only free parameter in this calculation and its value is determined by the linewidth limit at high x in the right graphs of Figure 18a and b.

The calculations were carried out for all nanoparticles. In each case, they were performed for bulk as well as for spherical and wirelike shapes. Again $a \approx 0.55$ nm and $a \approx 0.58$ nm were used for (Zn,Mn)S and (Cd,Mn)S, respectively. In the case of the Zn-based nanostructures, the best agreement was obtained for $\gamma = 0.9$ independent of the size of the nanostructure, while, for the Cd-based series, the best agreement was obtained for smaller values of γ, i.e. $\gamma = 0.6$ for the 6 and 9 nm nanostructures and $\gamma = 1$ for the 3 nm nanostructures. Assuming that the Mn–Mn nearest-neighbour distance d_{nn} is MnS-like, $a \approx 0.56$ nm for all Mn pairs, one obtains $\gamma = 1$ for (Zn,Mn)S nanostructures and $\gamma = 0.6$ and 0.5 for (Cd,Mn)S nanostructures. However, considering the crudeness of the model and the uncertainty in the Mn–Mn nearest-neighbour distance, the parameters obtained for γ are reasonable.

The theoretical curves for $Zn_{1-x}Mn_xS$ nanoparticles as well as for $Cd_{1-x}Mn_xS$ nanoparticles are also plotted in the right graphs of Figure 18b. Considering the overall agreement between theory and experiment, it appears better when a spherical shape of the magnetic nanoparticles is assumed. In particular, the linewidth decrease with increasing x is too rapid when a bulklike situation is considered. The corresponding slope is reduced by surface effects as the probability for Mn ions with manganese nearest neighbours is much lower in the surface region V^s_{nn} than in the bulklike volume V^b_{nn} for $0 < x < 0.2$.

In conclusion, changes in the macroscopic observables, e.g. the Curie–Weiss parameter Θ and the EPR linewidth ΔH of the paramagnetic phase of (II,Mn)VI nanoparticles with sizes below 10 nm due to reduced dimensions are observable. It appears that the microscopic coupling between the Mn ions (e. g. the nearest neighbour and next-nearest neighbour exchange constants J_{nn} and J_{nnn}) is not altered to a first approximation. The macroscopic modifications arise mainly due to geometrical restrictions, i.e. the number of neighbours in the various shells around a manganese ion in the surface region are considerably reduced compared to a manganese ion in the bulk of the structure. This effect becomes increasingly important with decreasing lateral dimensions of the nanostructure.

5. Conclusions

We have synthesised and thoroughly characterised (II,Mn)VI nanoparticles with Mn contents ranging from 0 to 0.3 incorporated inside mesoporous SiO_2 matrices with pore sizes of 3, 6, and 9 nm. By careful characterisation of the samples we demonstrate that under these synthesis conditions most of the Mn ions are incorporated on cation

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sites of the II-VI host lattice and that the amount of Mn aggregated at the surface of the nanostructures is negligible. This allows us to thoroughly investigate the effects of reduced dimensionality on the magnetic and electronic properties of the (II,Mn)VI nanoparticles as a function of Mn content x and characteristic diameter d. Both, magnetic as well as electronic properties of the nanoparticles are modified due to the reduced lateral dimensions. We demonstrate by analysis of the EPR linewidth and EPR intensity that macroscopic magnetic properties such as the Curie–Weiss temperature are strongly affected by the reduction of the lateral dimensions whereas the microscopic coupling between the Mn ions (e.g. the exchange constants J_{nn} and J_{nnn}) is not altered to a first approximation. The macroscopic modifications arise mainly due to geometrical restrictions, i.e. the number of neighbours in the cation shells around a Mn ion in the surface region is considerably reduced compared to a Mn ion in the bulk. Due to the quantum confinement of the excitons in the nanostructures an increase of the direct band gap with decreasing particle size is observed. Furthermore, the band-gap bowing as a function of Mn content x is enhanced in the Cd compounds with decreasing nanostructure diameter d. This enhanced band-gap bowing can also be related to the alterations of the macroscopic magnetic properties [i.e. reduction of Curie–Weiss temperature $\Theta(x)$ and increase of effective Mn concentration x_{eff}], which occur due to the increase of the surface-to-volume ratio with decreasing nanostructure size.

Our work demonstrates that incorporating magnetic materials into mesoporous silica host matrices with adjustable, well-defined pore sizes in the range of 2 to 10 nm is an ideal approach for studying nanomagnetic phenomena as a function of particle size.

The Assembling of Semiconductor Nanocrystals

Alexey Shavel,[a] Nikolai Gaponik,[a,b] and Alexander Eychmüller*[a,b]

Keywords: Nanostructures / Colloids / Layer-by-layer assembly / Interactions

Recent accomplishments in arranging semiconductor nanoparticles in a desired manner are reviewed. Coupling mechanisms utilized for this purpose include electrostatic and covalent interactions, methods like layer-by-layer assembly, solvent-controlled precipitation and surface amination for covalent attachment of nanoparticles are employed. Dipole–dipole interactions are operative in nanocrystal solids and fast Förster energy transfer is observed.

Introduction

Ordered assemblies of nanocrystalline materials have received increasing interest in recent years. Nanoparticles (often referred to as artificial atoms) are used to build up artificial molecules and solids.[1] These arrays and superlattices offer new perspectives for the application of nanoparticles for example in optoelectronic devices. Various approaches toward assembling nanocrystals are known. Three-dimensional superlattices of semiconductor nanoparticles have been built up via self organization[2] and crystallization.[3–5] Another main route towards ordered structures of nanocrystals is covalent binding with and without special linker molecules.[6] These efforts have a direct correlation with the investigations in the fields of covalent coupling of nanoparticles to biomolecules and surface

Alexander Eychmüller studied physics at the University of Göttingen. In 1987 he obtained his Ph. D., working on proton transfer reactions under the supervision of Dr. K.-H. Grellmann and Prof. A. Weller at the Max Planck Institute for Biophysical Chemistry. After a postdoctoral year at UCLA working with Prof. M. A. El-Sayed on gas phase metal clusters he joined the group of Prof. A. Henglein at the Hahn-Meitner-Institute in Berlin where he became involved in the research on semiconductor quantum dots. In 1994 he moved with Prof. H. Weller to the University of Hamburg focusing his scientific interests on the photophysical and structural properties of semiconductor nanocrystals. The habilitation in 1999 and the venia legendi in 2000 were followed by an offer of a chair in Physical Chemistry and Electrochemistry at the Technical University of Dresden in 2005.

Alexey Shavel was born in 1974 in Vitebsk, Belarus. He studied chemistry at the Belarusian State University from 1991 until 1996. From 1996 to 2002 he worked in the National Academy of Science of Belarus as a junior research scientist. In 2002 he started to work on his Ph. D. under the guidance of Dr. Alexander Eychmüller on the preparation of the nanoparticle superstructures.

Nikolai Gaponik studied chemistry and obtained his Ph. D. (2000) at the Belarusian State University working under the supervision of Prof. D. V. Sviridov on the electrochemical and photoelectrochemical properties of the composite materials based on conducting polymers and semiconductor nanocrystals. He worked as a visiting scientist at the LMU Munich with Dr. M. Gao and Prof. J. Feldmann in 2000. In October 2000 he joined the group of Prof. H. Weller and Dr. A. Eychmüller at the University of Hamburg first as a DAAD-fellow and finally as a research scientist. His current research interest focuses on the synthesis, characterization and applications of semiconductor nanocrystals.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

functionalization of nanocrystals.[7] Here we report on recent advances made in our Hamburg group in the preparation and the characterization of various assemblies of II-VI semiconductor nanocrystals (SC NCs). We will outline our efforts in the layer-by-layer assembling of SC NCs with and without interfacial polyelectrolytes. This method has been used to coat flat and porous solids as well as spherical microbeads. The latter may also be plated by solvent controlled precipitation of SC NCs onto them as will be shown in the subsequent paragraph. This will be followed by a survey of our experimental work devoted to the covalent coupling of nanoparticles amongst them as well as to flat and curved surfaces. The article will be finalized with a summary of our current theoretical understanding about the interparticle interactions and a kinetic study of Förster energy transfer in SC NC solids.

Layer-by-layer Assembly of Semiconductor Nanocrystals

LbL Assembly on Flat and/or Porous Surfaces

Uniform and multicomponent thin films consisting of functional molecules and/or nanocrystals may be formed by applying the so-called layer-by-layer (LbL) assembly technique. Figure 1 shows, schematically, the LbL procedure which was originally introduced for the assembly of polymer electrolytes[8] and, which was recently adapted to the deposition of charged nanocrystals both on flat[9,10] and on curved surfaces.[11,12] As is seen from Figure 1 the formation of monolayers of deposited material is based on the electrostatic interaction between the nanocrystals and the surface. Alternation of the sign of the charges of the species to be deposited allows the multilayers to grow quite thick, while the introduction of new components in one of the layers yields the opportunity of virtually nonlimited but controllable variations of LbL-multistructure compositions.[13,14] The application of the method described to the modification of artificial opals yielded intrinsically light emitting photonic crystals, which were successfully used for investigations on photonic confinement phenomena.[15,16]

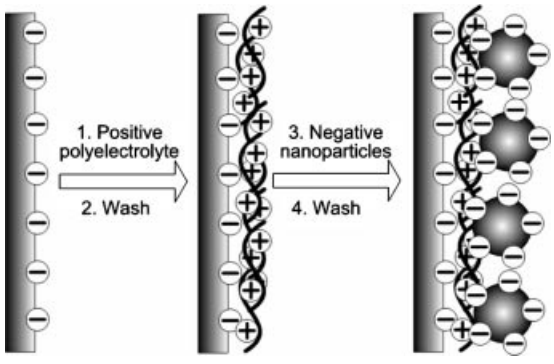

Figure 1. Schematic representation of the LbL assembly involving polyelectrolyte molecules and oppositely charged nanoparticles. The procedures 1–4 can be repeated to assemble more PE/nanoparticles bilayers.

The following standard cyclic procedure is normally used for the preparation of layered structures of negatively charged nanocrystals: (i) dipping of the substrate into a solution of polyelectrolyte (PE) (e.g. 5 mg ml^{-1} in 0.5 M NaCl) for 10 min [poly(ethyleneimine), PEI, was used for the first layer and poly(diallyldimethylammonium chloride), PDDA, for the second and further layers]; (ii) rinsing with water for 1 min; (iii) dipping into aqueous dispersions of the nanocrystals for 20 min; (iv) rinsing with water again for 1 min (cf. Figure 1). On each of the exposed surfaces, this procedure results in a 'bilayer' consisting of a polymer/NC composite. The cycle can be repeated as many times as necessary to obtain a multilayer film of desired thickness. The thickness of the LbL film depends linearly on the number of 'bilayers'. Moreover, a linear dependence of the absorption in the region of the first absorption maximum on the number of bilayers was observed.[17,18]

It is mentioned that in some cases the LbL assembly appeared to be nonefficient. When using freshly prepared colloidal solutions of nanocrystals we occasionally observed incomplete layer formation. Low-molecular weight byproducts of the synthesis as well as the smallest nanocrystal precursors could be responsible for this because they may be attracted by the polyelectrolyte sub-layers with higher efficiency than the nanocrystals themselves. We assume that aging of nanocrystal colloidal solutions leads to the reduction of the activity of those poisoning species due to their association with particle shells, aggregation and precipitation, etc. To avoid this problem, i.e. to make nanocrystal colloidal solutions useful for LbL assembly without aging them, we developed an electrophoretic activation of the colloidal solutions of thiol-capped nanocrystals. The nanocrystal solution that is to be activated is placed in a two-electrode electrochemical cell and a 1.5–2 V potential is applied to the cell. The commonly used electrodes are flat stainless steel or ITO-glass plates with a 1 cm^2 working surface and 5 mm gap in between. The current density drops from ca. 100–120 μA cm^{-2} in the very beginning down to 5–10 μA cm^{-2} after 1 h of this treatment. The above-mentioned byproducts, and possibly other charged species, are electrophoretically assembled or reacted at the electrodes and the thus cleaned activated solutions can be used for the LbL deposition as usual after removal from the cell.

Electrostatic Assembly of NCs

However, in these LbL systems the distance between donors and acceptors can not be shorter than the thickness of the polyelectrolyte monolayer. In order to avoid this limitation, which may be unfavorable for efficient interparticle interactions (see below), a new kind of a LbL structure has been generated.[19] The building blocks of the system were water soluble CdTe NCs with opposite surface charges (the charge of the CdTe NCs depends on the kind of stabilizer[20]), which were LbL assembled without polyelectrolytes between the particle layers. However, we encountered intrinsic limitations such as an easy removal of the already

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

deposited layers and the unbeneficial balance of charges during the film growth.[21] These limitations might have less influence in the case of the assembly of only one NC bilayer, while at the same time the inter-layer distance in this case would be further reduced leading to more efficient interactions. Bilayers of oppositely charged NCs can indeed be formed by a direct assembly of water-soluble CdTe NCs capped with amino- and carboxyl-group terminated short chain thiols. The preparation of this layered structure was performed in two steps. In the first step a polyelectrolyte sub-layer was formed followed by this standard procedure: (i) dipping of the substrate into PEI solution for 20 min; (ii) rinsing with water for 1 min; and (iii) dipping into poly-(sodium 4-styrene sulfonate) (PSS) solution (iv) and final rinsing in water. The first PEI layer was used to improve the quality of the layered structure in terms of uniform surface coverage.[10] In the second step, close-packed nanoparticle structures on the surface of the polyelectrolyte's bilayer were assembled as follows. The substrate with the PE bilayer was (i) dipped into aqueous dispersions of the 2-mercaptoethylamine (MA)-capped nanocrystals for 20 min, (ii) rinsed with water for 1 min and finally (iii) dipped into an aqueous dispersion of the mercaptopropionic acid (MPA)- or thioglycolic acid (TGA)-capped nanocrystals, again for 20 min. Such a procedure results in a layered structure consisting of a support/polymer/NCs-NCs composite. Typical absorption and photoluminescence spectra of the system are shown in Figure 2. The composite of the nanoparticles exhibits absorption only from the bottom layer of NCs (the absorption from the top NC layer is below the limit of the sensitivity of our spectrophotometer). At the same time emission associated mainly with the top layer is observed, which is taken as a first hint to efficient energy transfer (see below).

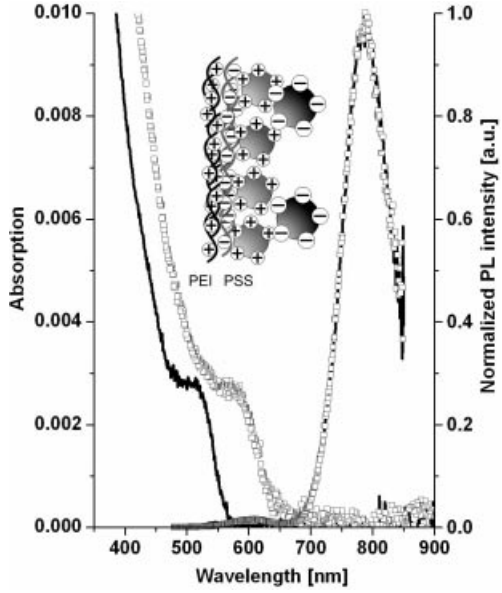

Figure 2. Examples of two close-packed structures utilizing MA-capped CdTe NCs (positively charged) of ca. 2 nm (black solid lines) and 4 nm (open squares) as the bottom layer. MPA-capped nanocrystals (negatively charged) of 6–8 nm in diameter were used as the top layer in both structures shown. While the absorption spectra of the structures show only the features corresponding to the bottom layer, the photoluminescence of the top layer (centered at ca. 780 nm) dominates in both structures.

LbL Assembly on Microbeads

The LbL assembly of NCs on the surface of the polymer [polystyrene, PMMA, melamineformaldehyde (MF) etc.] or silica beads opens up an opportunity to create submicro-sized objects exhibiting the properties of nanosized components.[22,23] In this case the LbL assembly can be done by suspension of the beads in solutions of the corresponding layer component. The contents of the solutions are generally the same as for the procedures described above. Repetitive centrifugations from pure water suspensions are used for washing of the beads and removal of excessive or nonspecifically adsorbed reactants. Figure 3 shows typical TEM images of the LbL modified beads. The modified beads retain the luminescence properties of the NCs used with a slight red shift of the luminescence maximum due to energy transfer from the smallest to the largest NCs in the assembled surface film.[11,24] The comparatively large size of the beads enables them to be manipulated by optical tweezers or to be used as a tip mounted at the end of an optical fiber. Thus, the beads can be used as subwavelength-sized light sources for photonic applications[25] or for the selective amplification of a signal in scanning near-field optical microscopy (SNOM).[26] The LbL modified beads of larger sizes (>2 μm) show an efficient coupling of the light emitted by the NCs with the whispering gallery modes of the spherical microresonators.[27–29] The use of beads made from materials that can be dissolved after LbL deposition of the polyelectrolytes (like e.g. MF, $MnCO_3$, etc.) allows the formation of hollow polyelectrolyte/NCs shells.[30–32] The shells are promising as microcapsules for drug delivery systems where the luminescence of inserted nanocrystals can be used for the monitoring of the delivery process.[33]

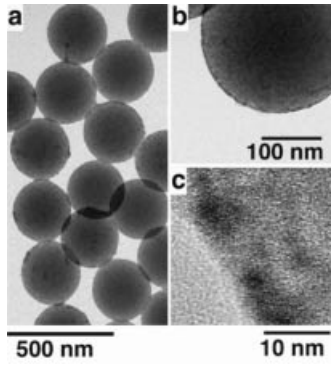

Figure 3. TEM and high-resolution TEM images of CdTe nanocrystals on polystyrene beads with increasing resolution from a) to c). The efficient coverage of the beads with nanocrystals is clearly seen in c) where the crystal structure of individual nanocrystals is resolved. Solvent-Controlled Precipitation

Another method of coating microspheres has been established through the controlled precipitation of nanocrystals by means of their aggregation in solution onto latex spheres.[34] The approach is a variation of heteroaggregation phenomena in a colloidal environment. The aggregation of NCs onto colloidal beads was induced by the solvent-nonsolvent pair precipitation technique which is normally successfully used to separate semiconductor nanocrystals by size. Colloidal cores statistically harvest aggregated nanocrystals, which consequently leads to the formation of a shell. Moreover, the thickness of the shell can efficiently be controlled through the proper choice of the concentration ratio of the colloidal particles serving as the cores and the precipitated species. Luminescent CdTe NCs were stabilized with TGA and thus exhibit a negatively charged surface, which was used to coat negatively charged sulfate stabilized polystyrene spheres, 468 nm in diameter. The latex spheres were precovered by an electrostatically adsorbed monolayer of positively charged polyallylamine hydrochloride (PAH). This modification was done in order to obtain a positively charged surface for better adhesion of the negatively charged NCs. Upon the addition of the NCs into the latex solution a monolayer of the NCs on the surface of the PS latex is formed due to the electrostatic interaction between the carboxylic groups of the NCs' stabilizer and the surface amino groups of the PAH-modified PS latex. The dropwise addition of ethanol (well known as "nonsolvent" for thiol-stabilized NCs[20]) to the latex NCs mixture initiates the aggregation of the NCs and allows for the creation of thicker shells on the beads. In the water/ethanol mixture (80% ethanol) the precipitation of the CdTe NCs on the latex spheres takes only minutes.

Alternatively, CdTe nanocrystals stabilized with MA, and thus being positively charged, were used for the solvent controlled precipitation by governing the pH of the solution. Earlier it has been demonstrated that these nanocrystals are stable and soluble in water in a pH region of 5.5–7 and tend to aggregate at higher pH values. Both, polystyrene and melamine formaldehyde spheres were used for the pH-controlled precipitation. The PS spheres were originally negatively charged and were used as is while the MF spheres were premodified with a monolayer of negatively charged PSS. A pH of 9 was found to be optimal for the complete precipitation of all CdTe NCs present in the solution. Confocal microscopy images of the CdTe-modified PS and MF spheres (Figure 4) demonstrate the efficient coverage and the luminescence properties of the core-shell composites formed.

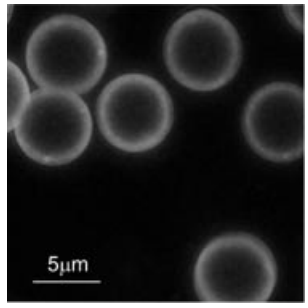

Figure 4. Confocal microscopy image of the luminescent CdTe nanocrystal shells assembled by the solvent controlled precipitation on 5 μm diameter melamine formaldehyde (MF) spheres. Reproduced from ref.[34]

Covalent Coupling of SC NCs

Interparticle Linking

Besides electrostatic coupling of NCs the generation of covalent bonds between selected nanocrystalline entities constitutes a very attractive and vast field. As an example of bridging two different sorts of NCs, we investigated the linkage of CdTe nanocrystals stabilized by TGA and MA.[35] The coupling has been carried out directly at the ligands without using an additional bridging molecule but with the aid of a carbodiimide acting as a mediator for the reaction. The reaction is described in Scheme 1. All solutions used were Ar saturated. The aqueous colloidal solution of TGA-stabilized nanocrystals (ca. 10^{-3} M according to the Cd^{2+} concentration) has been buffered to pH 5.75 by phosphate buffer and mixed with a freshly prepared solution of *N*-cyclohexyl-*N*′-[2-(*N*-methylmorpholino)ethyl]carbodiimide-4 in phosphate buffer (pH 5). After 5 min of stirring the solution was centrifuged and the precipitate redissolved in borate buffer (pH 8.65) using an ultrasonic bath. An aqueous colloidal solution of MA-stabilized nanocrystals (ca. 10^{-3} M according to the Cd^{2+} concentration) has been added and stirred for a further 90 min. While stirring the solution becomes turbid and the assembled CdTe nanocrystals precipitate. A mixture of the CdTe nanocrystal solutions without the addition of carbodiimide, and with the same buffer solutions, was used as a control experiment. In both cases the molar ratio between the different nanocrystals was approximately 1:1. The mixed nanoparticles stabilized with TGA and MA also precipitate because of electrostatic interactions.

The absorption and emission spectra of the linked and mixed nanocrystals were almost identical indicating that no obvious electronic interaction between the different nanocrystal cores seems to occur. Investigations using IR spectroscopy have been carried out in order to prove the assumption of the formation of an amide bond between the MA- and TGA-stabilized nanoparticles. The most pronounced IR absorption bands of the pure CdTe nanocrystals occur at 3500–3000 cm^{-1}, ν(OH, H_2O); 2950 cm^{-1}, $\nu(CH_2)$; 1590 cm^{-1}, $\nu_{as}(COO^-)$; 1450 cm^{-1}, $\nu_s(COO^-)$; and 1400 cm^{-1}, (δ OH) for the TGA-stabilized nanoparticles and at 3460 cm^{-1}, $\nu_{as}(NH_2)$; 3250 cm^{-1}, $\nu_s(NH_2)$; 2800 cm^{-1}, $\nu(CH_2)$; 1600 cm^{-1} (δ NH_3^+); 1490 cm^{-1}, (δ NH_3^+); and 1110 cm^{-1}, ν(CN) for the MA-stabilized nanoparticles. The IR spectra of the MA-stabilized nanocrystals show IR absorption bands that belong to both amine and protonated amine groups, indicating their coexistence on the nanocrystal surface. In the IR spectra of both nanocrystals the S–H

vibrations (ca. 2580 cm^{-1}) are undetectable as is assumed for covalently bound thiols to the nanocrystal surface.

Figure 5 shows the IR spectra of the linked (solid line) and mixed (dotted line) nanocrystals. The main differences between the spectra in Figure 5 are marked with arrows. The IR absorption bands belonging to the valence vibrations of the carboxyl group [1550 cm^{-1}, $\nu_{as}(COO^-)$; 1370 cm^{-1}, $\nu_s(COO^-)$] are red shifted relative to the pure TGA-stabilized nanocrystals because the counterion has been changed. Whereas the spectra of the mixed nanocrystals show a broad band around 3200 cm^{-1} [ν(OH), $\nu(H_2O)$ and $\nu(NH_3^+)$] the band at 3250 cm^{-1} {ν[NH (CONH)]} in the spectra of the linked nanocrystals indicates the existence of an amide bond. Shoulders at this band indicate that some ligands remain unreacted; this is assumed to be because of steric hindrances. In the spectra of the linked nanocrystals the intensity ratio between the two bands belonging to the stretching modes of the carboxyl group has changed when compared to the spectra of the mixed nanocrystals. This is to be expected if a part of the TGA ligands have reacted with the MA. Characteristic amide group vibrations in the fingerprint region cannot be detected because of superimposition with other normal modes. The amide I band (ca. 1650 cm^{-1}), especially, is only indicated as a shoulder in the strong carboxyl group stretching band. The strong absorption bands at 1100 cm^{-1} in both spectra mainly belong to adsorbed phosphate groups originating from the buffer solutions.

Covalent Linking of CdTe NCs to Flat Surfaces

While the covalent coupling of SC NCs is still in infant status the acting chemistry as described in the preceding paragraph may well be applied to the coupling of NCs to pretreated surfaces. Accordingly, we used appropriate fractions of CdTe NCs for the conjugation with various substrates like glass, silica or silicon with different shapes of the surfaces.[36] A general illustration of the binding of the acid-stabilized NCs to aminated surfaces with the aid of carbodiimide as a mediator in the formation of the amide bond is shown in Figure 6 (inset).

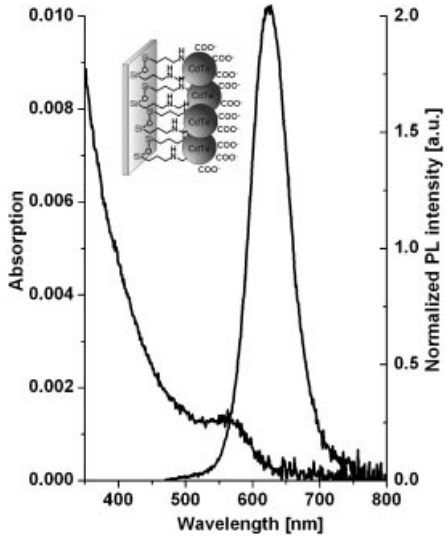

Figure 6. Absorption and luminescence spectra of CdTe NCs conjugated with a flat glass substrate. Excitation wavelength 450 nm. The inset shows a schematic representation of the structure.

The silicon wafers, quartz and glass slides were pretreated before conjugation in the following manner: the glass and quartz slides as well as the silicon wafers (with a 400 nm SiO_2 layer) were cleaned by sonication, first in 0.1 M NaOH solution, then in methanol, and finally in pure water for 15 min each. To form an amino-terminated layer on their surface, the substrates were immersed in a 6 vol.-% solution of 3-(aminopropyl)triethoxysilane in 95% methanol (named below as "3APTES solution") under sonication for 15 min followed by thorough rinsing with methanol. Drying was performed by a thermal treatment at 120 °C for half an hour in an oven.

The details of the linking of the CdTe NCs to flat substrates are as follows. An appropriate amount (0.1–0.5 mL)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of an aqueous solution of CdTe NCs was mixed with 0.5 mL of MES buffer [2-(*N*-morpholino)ethanesulfonic acid 0,1 mM] and 8 mL of Milli-Q water. The preliminarily cleaned aminated substrate was dipped into this solution. Subsequently, 0.5 mL of a solution of 1-Ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride 0.025 M and *N*-hydroxysuccinimide 0.025 M (named below as "EDC/NHS solution") was added under vigorous stirring which was continued for another 10 min. After conjugation, the slides were washed three times in Milli-Q water and rinsed thoroughly in acetone and toluene and dried under vacuum conditions. Figure 6 shows optical spectra of the modified slides. The PL properties of the films prepared were found to be at least one order of magnitude more stable in time as compared to analogously LbL-assembled monolayer films. Although the surface coverage estimated from the optical densities of the modified glass slides is roughly 100% (i.e. one monolayer), the formation of islandlike multilayers could not be excluded.[9]

Covalent Linking of CdTe NCs to Spherical Surfaces

The method described is not limited to flat substrates but is of more generality, as seen by our successful attempts to coat glass spheres of micron size by CdTe NCs.[36] A dispersion (5 wt.-% in 10% solution of ethanol in water) of borosilicate glass microspheres (2 ± 0.5 μm, Duke Sci. Co., USA) was treated with 0.1 M NaOH for 15 min under sonication and washed three times in methanol by centrifugation. The treated microspheres were immersed in the 3APTES solution under sonication for 15 min and washed thoroughly with methanol by centrifugation. The final methanol dispersion was heated to boiling point for 1 h. After that, the microspheres were separated from the methanol, redispersed in 0.5 mL of MES buffer and subsequently 0.1 mL of an aqueous solution of CdTe NCs and 0.5 mL of the EDC/NHS solution was added to the dispersion under vigorous shaking which was continued for another 10 min. The conjugation was terminated by the addition of an excess amount of 0.1 M glycine solution. The spheres were washed three times with Milli-Q water and stored in an appropriate solvent, like water or DMF. In Figure 7 we display a fluorescence microscopy image of the glass spheres conjugated with the CdTe NCs. The persistency of the luminescence of the NCs is nicely seen. This luminescence is not altered for at least 3 months. The inset shows a SEM image of one particle of the same sample providing an impression of the coverage of the spheres with nanoparticles.

Figure 8 shows some optical properties of conjugates of CdTe NCs with silica beads. For the generation of these conjugates we used CdTe NCs of two different sizes, namely 3–4 nm in diameter and 6–8 nm in diameter, respectively. The absorption spectra of the conjugates possess well-pronounced first electronic transitions and strong emissions. The position of the absorption and luminescence maxima relate well to the sizes of the NCs in agreement with the size quantization effect operative in semiconductor nanoparticles of such sizes. It is seen that the emission of the larger particles reaches into the near-IR spectral region and that absorption spectra of monolayers of NCs have been gained in this study.

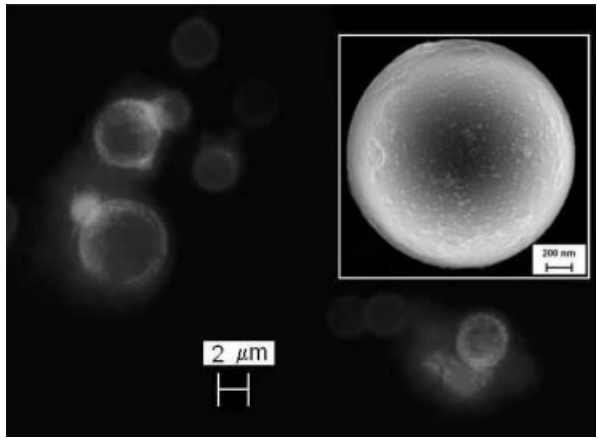

Figure 7. Fluorescence microscopy image of glass spheres conjugated with CdTe NCs. The inset shows a SEM image of one of those particles. Reproduced from ref.[36]

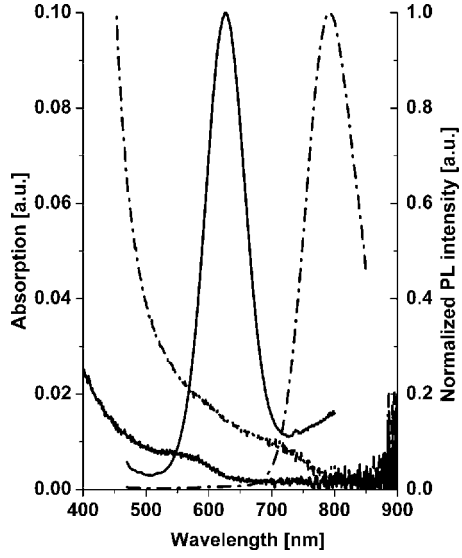

Figure 8. Absorption and luminescence spectra of silica particles conjugated with CdTe NCs of two different sizes. Reproduced from ref.[36]

For the preparation of the silica beads we used a well-known literature method.[37] Tetraethyl orthosilicate (1.5 ml) was added to a solution of ammonium hydroxide (2 mL) in ethanol (50 mL) in order to prepare particles at around 100 nm. The reaction mixture was stirred for 24 h to yield silica nanoparticles. The amino functionalization of the particles' surface was accomplished by the addition of 25 μL of 3APTES to the reaction mixture and continuing stirring for an additional 24 h. After this, the mixture was heated to boiling point for 1 h. The cooled mixture was washed three times with ethanol by centrifugation to give a stable dispersion of amino-functionalized silica spheres. Before conjugation, the silica particles were transferred into

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

DMF by consecutive centrifugation with the addition of fresh portions of DMF.

Conjugates of CdTe NCs with aminated silica beads have been prepared as follows. 0.05 mL of aqueous solutions of the CdTe NCs and 0.25 mL of the dispersion of the aminated silica particles in DMF were added to 0.70 mL of DMF. Then, 0.5 mL of the EDC/NHS solution (in DMF) was added with vigorous shaking. The shaking was continued for another 5–20 min. The conjugation was stopped by centrifugation of the silica particles. The conjugated silica particles were washed three times with pure DMF and stored as dispersions in the dark.

Dipole–Dipole Interactions in Layers of Nanocrystals

As described above, various methods of assembling, arranging and coupling of SC NCs have been explored but still only little is known about the properties of the solids evolving from these procedures. Some work has been published by Heath et al. on collective properties of interacting metal nanoparticles.[38,39] Depending on the interparticle distance, those solids reflect dipole–dipole interactions followed by pure electronic coupling when the particles come into closest contact. Later, Remacle and Levine performed theoretical studies on electron-transfer processes with arrays of quantum dots.[40] A shift of the first electronic absorption of small cadmium sulfide clusters to lower energies compared to their solutions was first published by Voßmeyer et al.[41] for closely packed layers of cadmium sulfide nanocrystals. The layers were built up from solutions of the clusters by a spin-coating technique and were examined by absorption spectroscopy. Besides some further studies on Förster energy transfer in semiconductor quantum solids consisting of particles of different sizes[24,42] little is known about the interaction between identical semiconductor nanoparticles. For this purpose cluster crystals are ideal candidates.

For our first studies we chose the cluster crystal compound $Cd_{17}S_4(SCH_2CH_2OH)_{26}$, which had been prepared according to the literature.[3] The structure of this thiol-stabilized molecular-like cadmium sulfide nanocrystal is known from single-crystal X-ray diffraction studies. In Figure 9 the internal structure of the cluster is shown.[3,43] It represents a tetrahedral cut out from the bulk cubic structure consisting of four adamantane-like cages capped with barrelane-like cages at the four tips of the tetrahedron. This tetrahedron has an edge length of 1.4 nm. It is also seen from Figure 9 that neighboring clusters are bound covalently via a bridging sulfur atom from the ligand at each tip of the tetrahedra. A 3D network is formed in this manner in a cubic diamondlike superstructure. Single crystals with sizes in the millimeter range are obtained via this preparation route. Because of absorption coefficients of the clusters as high as 84 000 $L\,mol^{-1}\,cm^{-1}$ it is not possible to perform absorption spectroscopy on these kinds of solids. Consequently, absorption spectra of compact layers created by spin coating of concentrated solutions of the dissolved cluster material were recorded. Figure 10 shows these spectra in comparison with a spectrum of the corresponding cluster solution of $Cd_{17}S_4(SCH_2CH_2OH)_{26}$ nanocrystals.[44] The spectrum of the compact layer recorded in transmission geometry (dashed line) was found to be shifted to lower energies in comparison to the spectrum of the cluster solution (solid line) without showing any significant broadening of the first electronic transition. Surprisingly, the absolute value of the red shift varied with the thickness of the compact layer. The maximum of the red shift in comparison to the spectra of the clusters in solution was about 70 meV at an optical density of about 0.1 at the absorption maximum. Although the compact layers appear totally transparent in the visible region a scattering background is seen in the spectra of compact layers (cf. e.g. Figure 10, dashed line). In order to avoid any measuring artifacts in the experiment an integrating sphere was used. The absorption measurement of the same layer in this different set-up resulted in significantly different signals, i.e. in the removal of the scat-

tering background (dotted line in Figure 10). Furthermore, the spectrum remains red shifted in comparison to the solution spectrum but by a smaller number than deduced before. Additionally, the measurement in the integrating sphere no longer showed a dependence on the thickness of the layers. Thus, regarding the discussion of the energetic position of an absorption band it is extremely important to suppress artifacts caused by scattering. Keeping this in mind a red shift of the first electronic transition in the compact layer of about 29 meV in comparison to the isolated cluster in solution was observed. This energy difference is taken as an indication of cluster–cluster interaction in a closely-packed layer of NCs.

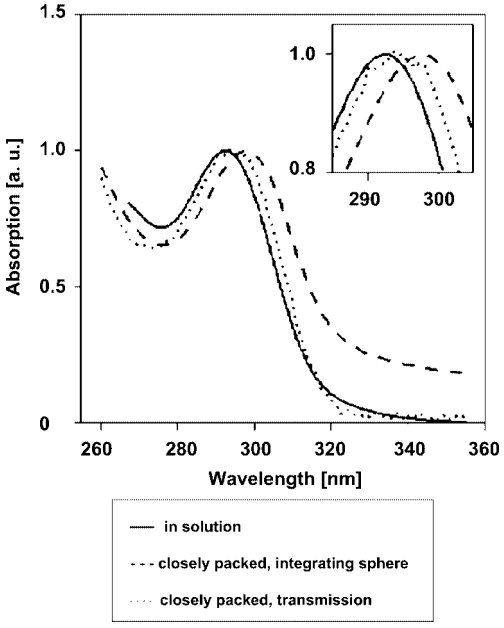

Figure 10. Absorption spectra of a compact layer of $Cd_{17}S_4(SCH_2CH_2OH)_{26}$ nanoparticles in comparison to the spectrum of the same particles in solution (solid line). Significant scattering is observed when the layer is measured in transmission geometry (dashed line) instead of measuring in the integrating sphere (dotted line). The inset provides a closer look on the resulting changes in the position of the maximum of the transition band depending on the experimental setup. (solution: cell thickness: 1 cm, OD = 1.15, calculated concentration: 0.7 μmol/L, integrating sphere: OD = 0.14, calculated film thickness: 30 nm, in transmission: OD = 0.26, calculation of film thickness is difficult because of scattering background, estimated to be 25 nm). Reproduced from ref.[44] with permission, copyright 2002 American Chemical Society.

In Figure 11 the interaction between the transition dipole moment of the absorbing particle and the induced dipole moments in the neighboring particles is sketched schematically. Analogous to the additional coulomb term for the determination of the transition energy by the Brus formula,[45] this interaction lowers the original transition energy of the absorbing particle.

Using text book equations for the values of the oscillator strength, the respective transition dipole moment and the polarizability volume, a potential energy of –51.2 meV for the interaction between the dipole of the absorbing cluster

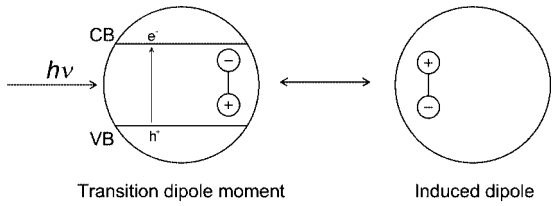

Figure 11. Schematic view of the interaction of the transition dipole moment of a particle appearing with the absorption process and the induced dipole moment of a neighboring particle. Reproduced from ref.[44] with permission, copyright 2002 American Chemical Society.

and the induced dipoles in adjacent clusters (cf. Table 1) is obtained for a distance between the particles (center to center) of 1.4 nm. It was also taken into account that for tetrahedrally shaped particles the polarizability volume decreases (57.0 Å^3), leading to a reduced shift of –14.2 meV to lower energies. Comparing these results with the value of the experiment (–29 meV), these simple calculations readily explain the red shift of the absorption band of the clusters in the compact layer in comparison to the isolated clusters in solution.

Table 1. Red shift of the first electronic transition of compact layers of CdS nanocrystals in comparison to the corresponding transition of the same clusters in solution. The experimental values for the different cluster sizes as well as the calculated results are shown. The theoretical results for both, spherically or tetrahedrally shaped particles are given. Note that for both particle sizes the experimental value fits between the values of the assumed particle shapes.

	Experimental	Calculated spherical	Calculated tetrahedral
cluster sizes	ΔE [meV]	ΔE [meV]	ΔE [meV]
d = 1.8 nm	12	27.2	6.7
d = 1.4 nm	29	51.2	14.2

Comparable results are found for the larger homologue cluster $Cd_{32}S_{14}[SCH_2CH(CH_3)OH]_{36}$ (cf. Table 1).

In an attempt to study the optical properties of the crystalline material itself, i.e. without dissolving the cluster crystals, reflection spectroscopy has been performed. For this, we milled the crystals down to grain sizes of about 2 μm and measured the diffuse reflection in an integrating sphere. In Figure 12 the UV/Vis absorption spectrum of this compound in solution is shown together with the reflection spectrum of the crystalline material. It is clearly seen that in the spectra of the crystalline material the first electronic transition is shifted to lower energies by about 150 meV, which is considerably more than observed in the films (29 meV, see above). Additionally, the transition is broadened from a full width at half maximum of about 390 meV to about 520 meV, which has not been observed in the spin-coated films consisting of the same particles. For the larger red shift a more densely packed structure of the crystals compared to the films is held responsible while for the broadening we propose a model of quantum mechanical coupling. For calculating the dependence of the electronic interaction on the distance between the coupling systems we used a periodical box potential according to Kronig and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Penney[46] for simulating both the crystalline arrangement of the particles with very small distances between them and the situation in solution with large distances between the particles. In this model, the boxes representing the particles (size 1.4 nm) are separated by potential walls. The height of these energy barriers was chosen to be 3 eV and the separation of the boxes (i.e. the interparticle distance) was varied between 20 nm, reflecting large distances, and 0.7 nm, modeling the situation with neighboring clusters. The effective masses of the charge carriers were taken from the literature (0.2 and 0.7 for electrons and holes, respectively[47]). The 3D arrangement of the particles was taken into account by multiplying the 1D results by three. According to Brus[45] the transition energy is then calculated by addition of the bulk band gap and the Coulomb interaction. For large distances between the clusters a transition energy of 3.92 eV was obtained, which is in fair agreement with the experimental value (4.24 eV). For the clusters with small distances between the inorganic cores we obtained the formation of a sub-band for the electron states, which spans about 75 meV (for 1D) for a separation of 0.7 nm. Due to the larger effective mass of the holes a narrower sub-band (1.5 meV) is observed for this charge carrier. The centers of the sub-bands remain at exactly the same energetic positions as the discrete levels in the case of the solution. Thus, it turns out that for the electronic interaction of semiconductor particles in close contact a broadening of the transition band is expected without a significant change of the transition energy. The shift of the transition energy in the crystalline material is then only due to dipole–dipole interactions of adjacent particles.

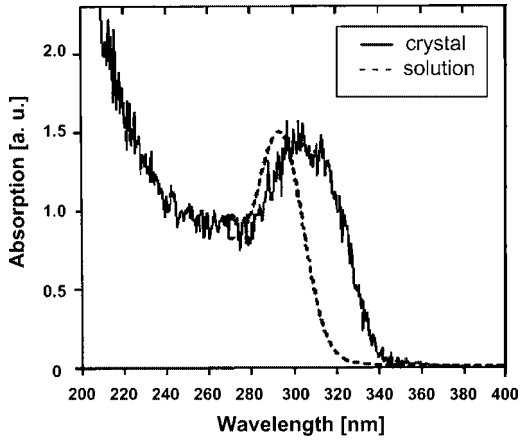

Figure 12. Absorption spectrum of $Cd_{17}S_4(SCH_2CH_2OH)_{26}$ nanocrystals dispersed in solution (dotted line) and reflection spectrum of micron-sized crystals of the same compound (solid line). Reproduced from ref.[43] with permission, copyright 2001 American Chemical Society.

Rapid Förster Energy Transfer

To investigate the Förster energy transfer from smaller (green emitting, PL maximum at approx. 555 nm) to bigger NCs (red emitting, 650 nm) in LbL-layered assemblies, two different structures both consisting of 10 polyelectrolyte/NCs bilayers have been prepared. The first structure consists of five bilayers of the same NCs size followed by five bilayers of the other NCs size on top, while the second structure consists of alternating bilayers of NCs of both sizes, as is schematically shown in Figure 13. The disappearance of the green PL band and the simultaneous relative amplification of the red emission is inherent for both structures and is a consequence of the Förster energy transfer (FRET), i.e. energy transfer takes place between donor and acceptor NCs, when the interparticle distance is smaller than the so-called Förster radius. At the same time the efficiency of the FRET appears to be relatively higher in the case of alternating layers. Indeed, the mean distance between the NCs of different sizes is smaller in the case of the alternating structure. In the other case only the closest red and green NC layers participate in the energy transfer efficiently, while others are too far apart. Furthermore, the applicability of the LbL method to the creation of even more complex structures has been demonstrated. This structure consisted of alternating bilayers of NCs of three different sizes with a gradual decrease of the electronic band gap and it shows PL originating from the biggest NCs only, while the features corresponding to all the NCs' sizes appear in the absorption spectrum (not shown here).

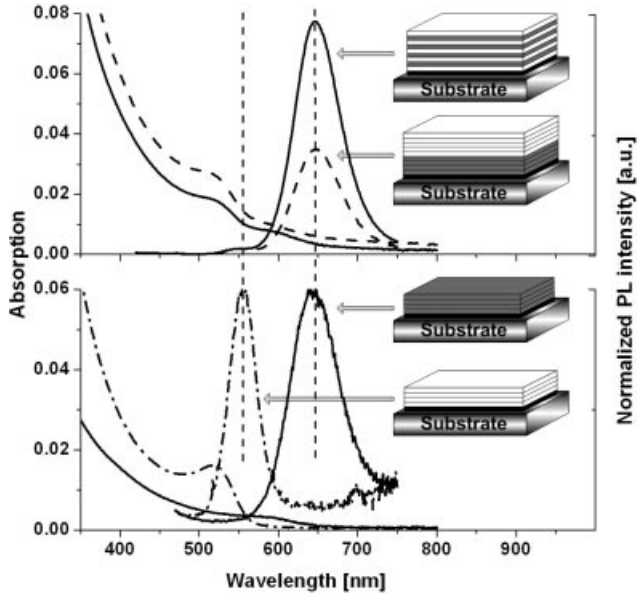

Figure 13. Absorption and PL spectra of the LbL formed assemblies sketched on the right hand side. Green and red layers correspond to the emission color of the particles constituting the assembled PE/NCs bilayers.

The FRET efficiency for thin alternating films of NCs of 2.4 and 3.5 nm in size with PDDA as opposite polyelectrolyte was estimated to be as high as 50% with an average interlayer energy-transfer rate of $(254\ ps)^{-1}$ reaching the value of $(134\ ps)^{-1}$ for certain subspecies in the inhomogeneous distribution of the donor NCs having larger spectral overlap with the acceptor NCs.[48]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

As described above a LbL composite can be prepared with NCs as building blocks only, i.e. without polyelectrolytes in between the NC layers. These structures have been made in order to study Förster energy transfer in nanocrystal solids, assuming that the FRET will be facilitated by a smaller mean interlayer distance. The bilayer structure is supposed to be composed of MA-capped CdTe NCs (donors) in the bottom layer and TGA-capped CdTe NCs (acceptors) in the top layer (Figure 2). For comparison, two monolayer samples comprising only donors (MEA-capped CdTe NCs) or only acceptors (TGA-capped CdTe NCs) are also deposited on the polymer under layer. For both NC sizes the electronic transitions can be distinguished in the absorption spectrum of the bilayer sample, although the contribution of the acceptor NCs is reduced in comparison to the monolayer sample. This is not surprising because the bottom layer of the donor NCs is deposited on a polymer under layer in both cases, favoring the attachment of the NCs, while the top layer of acceptor NCs in the bilayer sample is deposited onto a preformed donor NC layer, which is apparently limited in its ability to attract and accommodate oppositely charged NCs in comparison to a polymer under layer. This is indicated schematically by an incomplete layer of acceptor NCs in the inset of Figure 2. The use of electric-field directed layer-by-layer assembly (EFDLA),[49] which relies on the additional attraction of NCs by applying an electric field to the substrate may allow this problem to be overcome. The absorption spectrum of the bilayer sample can be reproduced by a linear superposition of 1.0× the donor and 0.33× the acceptor absorption spectra. PL spectra show that almost all of the emission from the bilayer sample originates from the acceptor NCs, while the contribution from the donor NCs is strongly diminished. From the quenching of the donor and the enhancement of the acceptor NC PL in the bilayer sample, the efficiency of energy transfer in the bilayer structure is estimated to be ≈80%.

In order to determine the energy-transfer rate, we analyzed streak camera data binned by wavelengths rather than time. Figure 14 compares the PL decay of the donor NCs in the bilayer sample with the PL decay of the donor NCs in the monolayer sample at the same wavelength. To ensure that the donor decay in the bilayer sample is not affected by PL cross-talk from the acceptor NCs we chose a wavelength-binning region of interest from 500 nm to 525 nm. For both samples the PL transients appear as nonexponential decays as is typical for thiol-capped CdTe NCs.[48,50] Nevertheless, one can deduce a *1/e* decay time which decreases from 286 ps for the monolayer sample down to 57 ps for the bilayer sample. A transfer rate of $(71\ \text{ps})^{-1}$ is calculated from these numbers which is 3.5 times higher than the average transfer rate reported before for a CdTe NC bilayer structure with a polymer linker between the layers.[48] If one chooses the wavelength-binning region of interest as being more shifted to the high energy side of the donor spectrum (from 475 to 500 nm), an energy transfer time as low as 50 ps is derived, which is very close to the energy transfer rates of $(38\ \text{ps})^{-1}$ predicted by Klimov et al.[51] We attribute this increase in the energy transfer rate to the reduced average distance between the NC layers by eliminating a polymer linker in between. From the decay times provided above we derive an energy transfer efficiency of 80%, consistent with the efficiency we have calculated from time integrated PL spectra.

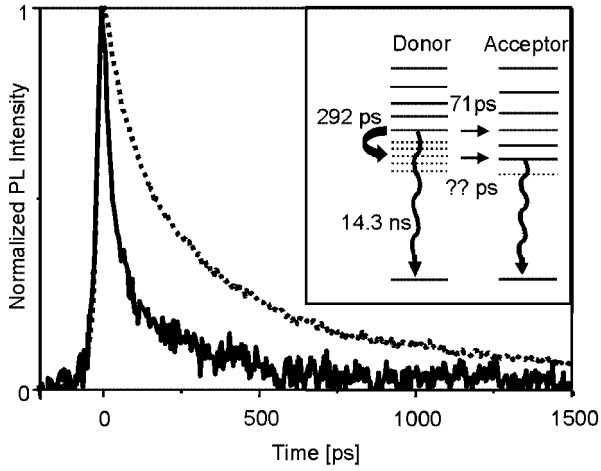

Figure 14. Fluorescence decays of the donor NCs in the monolayer donor sample (dotted line) and the donor NCs in the bilayer sample (solid line). In both samples the PL is integrated from 500 to 525 nm. The *1/e* times are 286 ps and 57 ps, respectively. The inset sketches the different decay channels of an exciton in a NC of the donor layer including the corresponding timescales. Thick solid lines represent the first excitonic transition, thin lines represent vibronic progressions and dashed lines indicate trap states from where the excitons decay nonradiatively. Apart from a resonant energy transfer of excitons in donor NC ground states, a recycling of trapped excitons by resonant transfer to a radiating state in an acceptor NC is also possible on an unknown time-scale. Reproduced from ref.[19]

Keywords: Colloids / Cross-linking / Nanostructures / Platinum / Self-assembly

Nanoparticle networks can be synthesized by the self-assembly of arrays of metal colloid particles linked by spacer molecules of different sizes. The particles are linked through reactive aluminum sites in a metal–organic shell around the metal particles. Rigid spacer molecules with functional groups at each end are used to bind at these reactive sites. The resulting networks have been characterized by various methods such as transmission electron microscopy (TEM), sorption analysis, X-ray absorption spectroscopy (XAFS), anomalous small angle X-ray scattering (ASAXS), metastable impact electron spectroscopy (MIES), and ultraviolet photoelectron spectroscopy (UPS). These investigations showed that the metal nanoparticles form aggregated networks with average distances between the metal particles that are determined by the sizes of the spacer molecules applied. In this way, porous as well as nonporous networks have been obtained. Whether accessible pores are formed depends on the type of spacer molecule. Furthermore, the properties of the metal particles have proved to be sensitive towards the reaction of the aluminum in the protective shells with the linker molecules.

Introduction

The assembly of nanosized metal particles into highly ordered arrays has become a new trend in chemistry over the past few years.[1–3] The resulting materials are expected to exhibit novel collective properties that make them very promising with respect to application in microelectronics or optics.[4,5] Superlattices of nanocrystals have already been reported,[6–12] but bottom-up syntheses of three-dimensional structures consisting of nanoparticles still remain a challenge for the synthetic chemist. Over the past couple of years we have developed a synthetic strategy for the preparation of arrays of three-dimensionally connected nanoparticles. The key feature of this synthesis is the formation of a reactive metal–organic colloidal protecting shell around the particles.[13] Reactive alkylaluminum groups in the protective shell allow substitution of the alkyl groups by other organic groups,[14] and the use of bifunctional substituents allows the linking of two metal particles and, consequently, the formation of larger networks of metal particles.[15,16] Using this approach it possible to cross-link different types of metal nanoparticles, such as Pt, Ni, and Co. The synthetic procedures have been adapted to the specific chemistry of the metal species, and the suitability of different alkyl groups in the protective shell has been investigated. The present review gives a survey of these results. In order to provide a consistent thread, however, we will focus here mainly on cross-linked Pt nanoparticles.

Synthesis of Pt Colloids

Different colloid particles, i.e. Pt, Ni, and Co, are considered in this survey, although the general synthetic concept will be demonstrated for Pt particles. In a typical synthesis, the Pt colloids were prepared as follows: $Pt(acac)_2$ (1.97 g, 5 mmol) was dissolved in 200 mL of toluene. Then, $Al(CH_3)_3$ (1.44 g, 20 mmol) was dissolved in 200 mL of tol-

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

uene and carefully added to the first solution over 4 h at 60 °C. After the gas evolution had stopped (24 h), the solution was filtered, and all volatile components were completely evaporated under vacuum to give 2.4 g of colloidal platinum powder in the form of a black, air-sensitive powder. The Pt colloid used for the experiments described here had a composition of 40% Pt, 14% Al, 31% C, and 6% H (by elemental analysis).

H. Bönnemann studied chemistry at the RWTH Aachen, Germany, where he received his PhD and habilitation. After two years of industrial research at Degussa, he became Professor for Industrial Chemistry at the RWTH Aachen, Germany, in 1981. Later on, he worked at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr, Germany, where he installed a research group with focus on nanoparticles and colloidal metals. In 2004 he became a scientific member of the Forschungszentrum Karlsruhe, Germany, where he has worked as leader of the Nanochemistry Laboratory at the Institute for Industrial Chemistry since January 2005. Fei Wen and Norbert Waldöfner worked as PhD students in his laboratory at the Max-Planck-Institut für Kohlenforschung.

Wolfgang Schmidt studied Chemistry at the University of Mainz, Germany, where he received his PhD in 1994. During his PhD studies, he had a research term at the Boreskov Institute of Catalysis in Novosibirsk, Russia. From 1995 to 1998, he worked as staff scientist at the University of Frankfurt and then became senior scientist in the Department of Heterogeneous Catalysis at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr. His work is focused on the preparation and characterization of nanoparticles and porous materials.

Klaus Angermund studied chemistry at the Heinrich-Heine University of Düsseldorf, Germany. From 1983 to 1986, he worked as a PhD student in the X-ray department at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr, Germany. In 1986, he obtained his Ph D in Chemistry from the University of Wuppertal, Germany. In 1987, he was awarded the Otto Hahn scholarship by the Max-Planck Society and worked from 1987 to 1988 as a postdoctoral fellow with Arnold Hagler at Biosym Technologies Inc. in San Diego (USA). Since 1989 he is a scientific co-worker at the Max-Planck-Institut für Kohlenforschung and head of the molecular modeling group. His research focuses on application of molecular modeling techniques to organometallic reactions, force field development and parameterization, and QM/MM methods.

Hartwig Modrow received his PhD in Physics from the University of Bonn, Germany, in 1999. At present, he is Oberassistent at this institute and acting head of the synchrotron radiation group, which specializes in the investigation of electronic and geometric structure of matter and their dynamics. Stephanie Modrow obtained her PhD in that group and is presently working as a patent attorney. Svetlana Zinoveva has been pursuing her PhD Thesis work in the synchrotron radiation group since 2003.

Josef Hormes studied Physics at the University of Bonn, Germany, where he received his PhD in 1975 and habilitation in 1984. After working for the University of Bonn, the Imperial College of London, and Stockholm University (Sweden), he was appointed Professor for Physics at the University of Bonn in 1988. In the period from 1988 to 1999, he was also the Director of the Synchrotron Radiation Laboratory at the University of Bonn. Since 1999, he is Director of the Center for Advanced Microstructures & Devices at the Louisiana State University (LSU) in Baton Rouge, USA, and Professor in the Department of Physics and Astronomy at LSU.

Volker Kempter received his Ph.D. in Physics from the University of Freiburg, Germany, in 1969. He is Prof. of Physics at the Technical University of Clausthal, Germany, where he leads the section for "Molecular Processes on Surfaces". His group specializes on the oxidation and corrosion of films and nanoparticles and on processes on ice surfaces. Lars Beuermann and Sergiy Rudenkiy work as PhD students in his group and Dr. Wolfgang Maus-Friedrichs, as senior scientist, focuses on the investigation of surfaces with relevance for applications in material science.

Heinz-Günter Haubold was leader of the SAXS group at the Institut für Festkörperforschung at the Forschungszentrum Jülich from where he retired in 2003. He designed and built up the user-dedicated ASAXS experiment JUSIFA at the synchrotron facility of HASYLAB at DESY Hamburg, Germany. His coworker Thomas Vad worked on the development of routines and models for the interpretation of ASAXS data.

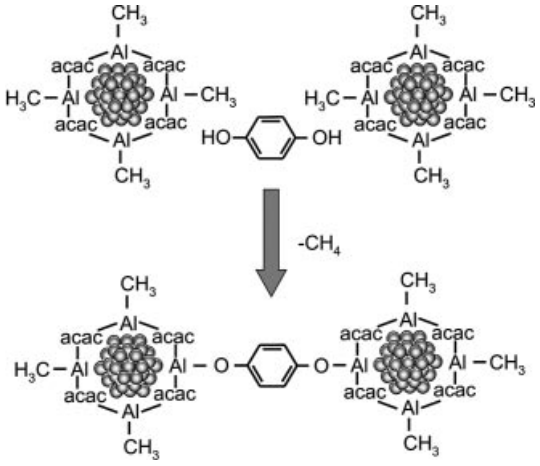
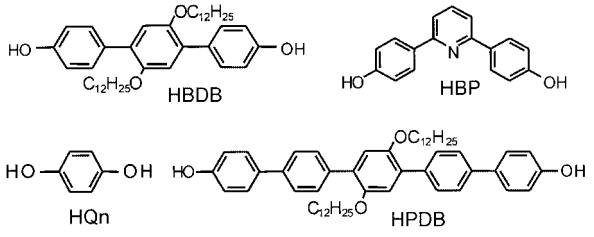
Formation of Pt Colloid Networks

As described above, Pt colloid particles were prepared by reducing $[Pt(acac)_2]$ with $Al(CH_3)_3$. These particles have highly reactive methylaluminum groups in the colloidal stabilizer, which allows protonolytic reactions at the protective shell with alcohols or carboxylic acids, while the metallic core remains intact. Several bifunctional organic spacer molecules have been used to cross-link the Pt colloid to form nanoparticle networks. One example using hydroquinone as the spacer is illustrated in Scheme 1.



Scheme 1. Principle of the protonolytic cross-linking mechanism.

Further spacer molecules used to cross-link protected colloid particles are shown in Scheme 2. The spacer compounds HBDB, HBP, and HPDB were kindly supplied by Prof. Dr. Joannis Kallitsis[17,18] of the Institute of Chemical Engineering at the University Patras, Greece. For simplicity, the abbreviations given in the scheme will be used when discussing the different molecules.



Scheme 2. Structures of the molecular spacers.

All reactions were performed in THF. The ratio of methylaluminum groups in the colloid to hydroxy groups in the molecular spacer was found to be 1:1. The molecular spacers were added dropwise into the Pt colloidal solution over 1 h. The quantity of reactive methylaluminum groups in the colloidal shell can be measured on the basis of the amount of gas (methane) evolved upon adding acetic acid to the Pt colloid. Since the reactive methylaluminum groups are statistically present on the colloidal surfaces, a 3D cross-linked nanoparticle network can be expected. The precipitate formed after the cross-linking reaction between the Pt colloid and the bifunctional molecular spacers can be isolated by simple filtration.

In the present work, several molecular spacers with different rigidity have been used to prepare Pt nanoparticle networks; their structures are depicted in Scheme 2. Here we will focus mainly on the more-rigid molecules hydroquinone (HQn), HBP, HBDB, and HPDB rod-like structures. The spacer lengths depend more or less on their conformational structures.

The introduction of HBDB and HPDB into the Pt colloidal solution caused a precipitate to form in 2 h. Compared with the results using hydroquinone and HBP as the spacers, these precipitates were produced rapidly and were very loosely suspended in the reaction medium. For some samples, the preparation conditions were varied to investigate the effect of this variation on the properties of the resulting materials. For example, the sample Pt/HBP was synthesized at 50 °C, while another sample, Pt/HBP2, was prepared at 25 °C using the same spacer molecule. In a similar manner, Pt/HBDB and Pt/HBDB2 were prepared at 50 and 25 °C, and Pt/HPDB and Pt/HPDB2 at 25 and 50 °C, respectively.

Characterization Methods

Transmission Electron Microscopy (TEM)

TEM measurements were performed using a Hitachi H 7500 instrument operating at an accelerating voltage of 120 kV. Energy-dispersive X-ray spectroscopy (EDX) analyses were performed to obtain a chemical analysis of the particles using an Oxford Instruments INCA EDX spectrometer attached to the microscope. The TEM samples were prepared by placing a drop of the colloidal dispersion onto a copper grid coated with a carbon film. High-resolution TEM measurements were performed on a Hitachi HF 2000 Instrument operating at 200 kV. In order to obtain a chemical analysis of the bimetallic catalysts, point-resolved EDX analyses were performed using a Noran Instruments EDX spectrometer attached to the microscope. The samples were prepared by placing a drop of the colloidal dispersion onto a copper grid coated with a lacey film.

Physisorption Analysis

Nitrogen sorption isotherms were recorded with a Micromeritics ASAP 2010 sorption analyzer at 77 K to evaluate the textural properties of the prepared porous materials. Prior to the measurements, the samples were evacuated at 80 °C for 12 h. The BET (Brunauer–Emmett–Teller) surface area was calculated from the adsorption data in the relative pressure interval from 0.06 to 0.20.

Anomalous Small-Angle X-ray Scattering (ASAXS)

For the characterization of nanostructures with typical metal-particle diameters and interparticle distances in the 1–10 nm regime, small-angle X-ray scattering (SAXS) is amenable for the determination of the structure parameters. Thus, anomalous small-angle X-ray scattering (ASAXS)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was applied to analyze the inter-particle distances of the as-prepared Pt network products, as the contributions from the organic parts and pore-like voids can be subtracted. Different Pt samples[15] were investigated by ASAXS at the JUSIFA beamline[19] at HASYLAB (DESY Hamburg, Germany). The contrast variation experiments were performed at two X-ray energies, namely E_1 = 11.437 keV and E_2 = 11.535 keV, near the Pt L_3 [$E(L_3)$ = 11.564 keV] absorption edge (for a detailed description, see ref.[16]).

Since ASAXS is not a very common characterization method, the principle of ASAXS measurements will be introduced here.

In the case of a low-concentration ensemble of uniform metal particles in a (negligible) low-molecular matrix, the particle scattering intensity can be written as:

$$\frac{d\Sigma}{d\Omega}(Q) = c_0 n^2 f_0^2 S^2(Q) V^2,$$

where c_0 (= $Nanoparticle_{article}/V_{sample}$) is the number density of the particles, n [= N_{atoms}/V (V = particle volume)] is the number density of the metal atoms within a particle, f_0 is the scattering amplitude, and $S^2(Q)$ is the intraparticle interference factor, i.e., the form factor of a particle.

For a spherical particle of radius R_0, the particle form-factor is defined by

$$S(Q) = 3\frac{\sin(QR_0) - QR_0\cos(QR_0)}{(QR_0)^3},$$

with the magnitude of the scattering vector Q being equal to $4\pi\sin\Theta/\lambda$ (λ is the X-ray wavelength and 2Θ is the scattering angle). In order to obtain more information on the (pure) particle scattering, it is convenient to perform ASAXS experiments. For the two-phase model, the total differential cross-section is given by

$$\frac{d\Sigma}{d\Omega}(Q) = c_0(n_p f_p - n_m f_m)^2 S^2(Q) V^2 + \frac{d\Sigma}{d\Omega_{bg}}(Q),$$

where n_p, f_p, n_m, and f_m are the number densities and atomic form-factors, respectively, of the particles (p) and the surrounding matrix (m). Besides the particle scattering, an additional background scattering term $d\Sigma/d\Omega_{bg}(Q)$ (which is proportional to Q^{-4} in most cases) contributes to the total differential cross-section, which, for the most part, originates from inhomogeneities in the matrix. Therefore, the SAXS intensity almost always contains a (in many cases non-negligible) contribution from the matrix if a SAXS experiment is performed at only one energy. Fortunately, the particle scattering can quite easily be separated from the matrix background if, for example for Pt particles, contrast-variation experiments are carried out at at least two different energies near the Pt L_3 absorption edge [E(Pt L_3) = 11564 eV]. As shown schematically in Figure 1, the atomic form-factors of the Pt particles vary significantly at energies close to the absorption edge, while those of all other elements, i.e. the matrix, remain more or less constant.

Thus, the atomic form-factors

$$f(E) = f_0 + f'(E) + if''(E)$$

of the mainly organic matrix components (C, H, O) remain almost constant in this energy regime. A simple subtraction of two SAXS curves measured at two different energies E_1 and E_2 yields the (almost) pure (Pt) metal-particle scattering

$$\frac{d\Sigma}{d\Omega_p}(Q) = \frac{d\Sigma}{d\Omega}(Q,E_1) - \frac{d\Sigma}{d\Omega}(Q,E_2)$$
$$= c_0 n^2\left[f_{Pt}^2(E_1) - f_{Pt}^2(E_2)\right]S^2(Q)V^2 \times \left\{1 - \frac{2n_m f_m}{n\left[f_{Pt}(E_1) + f_{Pt}(E_2)\right]}\right\}$$

(in the case of negligible f'' correction terms), which reduces to

$$\frac{d\Sigma}{d\Omega_p}(Q) = c_0 n^2\left[f_{Pt}^2(E_1) - f_{Pt}^2(E_2)\right]S^2(Q)V^2$$
$$= c_0\Delta(nf)^2 S^2(Q)V^2$$

$$\text{if } 2n_m f_m / \left\{n\left[f_{Pt}(E_1) + f_{Pt}(E_2)\right]\right\} \ll 1.$$

From the scattering curves thus obtained, the average particle sizes and particle–particle distances are accessible. Figure 2 shows how the thickness of the protective layer and the average distance between particles that are linked by different spacer molecules are accessible from the

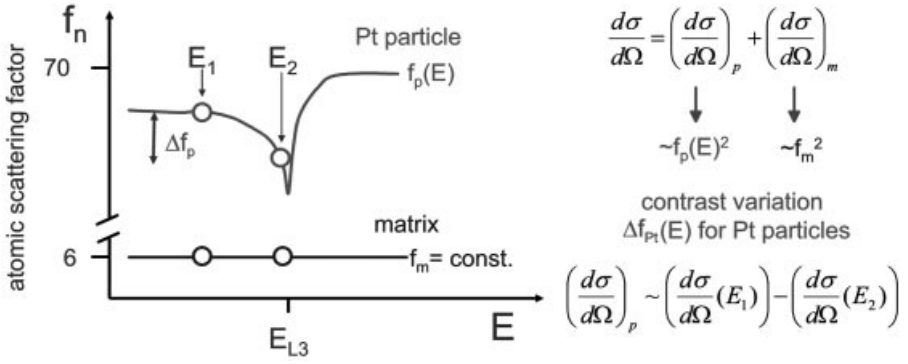


Figure 1. Schematic representation of the dependence of atomic scattering factors from the energies close to the absorption edge of an element (here Pt).

ASAXS data. Knowing the size (R_0) of the pure colloid particle allows calculation of the thickness of the protective shell (t_{ps}) from the particle–particle distance if the protected particles have direct contact, i.e. in solid aggregates of protected particles without spacer molecules. The distance (D_0) between cross-linked particles then allows calculation of the distance (l_{sp}) due to the spacer molecules by considering the thickness of the protective layer according to $l_{sp} = D_0 - (2t_{ps})$.

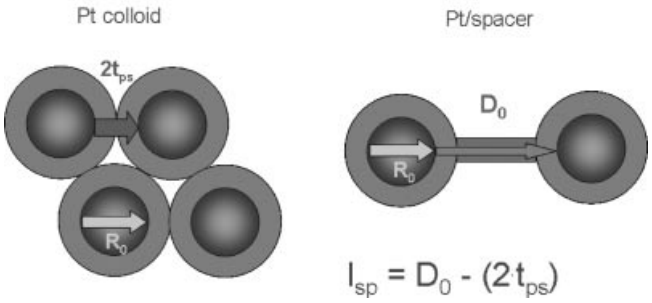

Figure 2. Model to calculate the thickness of the protective layer, t_{ps}, and the distance due to the spacer molecule, I_{sp}, from the particle–particle distance, D_0 (R_0 is the radius of the colloid particle, here Pt colloid).

X-ray Absorption Spectroscopy (XAFS)

The X-ray absorption spectra discussed in this article were measured in transmission mode at two different synchrotron radiation sources: at the ELSA storage ring at University of Bonn, Germany, and at the Center for Advanced Microstructures and Devices (CAMD). Detailed descriptions of the beamlines and instrumentation are found in the literature;[20,21] important parameters of the measurements are summarized in Table 1.

To prepare the samples for measurement at the Al K-edge, a very thin but homogeneous and pinhole-free layer of powder was fixed on an ultra-thin (6 μm) polypropylene film by application of pressure. For all other measurements, the dried colloids were mixed with boron nitride and pressed into pellets. The optimal sample thickness was found by trial and error and was chosen in such a way that the maximum absorption, μd, was not higher than 1.2. The entire process of sample preparation was undertaken in a glove box filled with argon. Sample transfer to the measurement station also took place under an inert gas atmosphere.

XANES data treatment consisted of subtraction of a linear background adapted to the pre-edge and normalization to an edge jump of one at the position given in Table 1. For EXAFS analysis, the UWXAFS package[22] was used.

Metastable Impact Electron Spectroscopy (MIES) and Photoelectron Spectroscopy (UPS)

The characterization of the surface of metal nanoparticles (nanoparticle) is of considerable technological relevance as:

- often a pre-stabilization, i.e. passivation of the particles against air and/or moisture, is required when it is planned to integrate them into nanostructures (or particle networks as in the present application);
- a termination of the nanoparticles by some particular active molecular group, with bifunctional character in the present case, is required in order to be able to interlink the nanoparticles within a customized nanostructure or particle network;
- some applications require a peptization of the nanoparticles, i.e. their embedding into a micelle of specific organic molecules, in order to prevent sintering of the reactive nanoparticles.

Thus, the availability of techniques that are able to concentrate specifically on the chemical properties and the electronic structure of the outermost layer of the nanoparticles is mandatory in order to design, characterize, and manipulate nanoparticles in particle networks or nanostructures in general. Ideally, the depth resolution of the employed surface-analytical technique should be tunable in the sense that, besides the information on the outermost layer, the corresponding information on the sub-surface region of the particles should also be provided for comparison.

MIES metastable He atoms are utilized to eject electrons from surfaces. Metastable He* atoms with thermal energy interact with condensed matter, including nanoparticles, by three different mechanisms depending on the electronic structure of the surface under consideration and its work function.[23,24] In the present work, only Auger neutralization (AN) and Auger deexcitation (AD) are observed. When molecular adsorption onto metals is studied, the situation can become complicated as a change of the mechanism from AN (on clean metals) to AD often takes place as a function of the adsorbate coverage because either an insulating surface is formed or the transfer of the He 2s electron into the metal, which is a prerequisite for the AN process, becomes inhibited because the metal becomes increasingly shielded by adsorbed species from access by the He* probe atoms.

Table 1. Results of Pt L_{III} EXAFS analysis for unconnected and two differently connected nanoparticle systems. Fitting was done in *r*-space between 0.15 and 0.32 nm using a *k*-weight of 3.

Pt L_3 Edge	Backscatterer	R [nm]	N	σ^2 [nm^2]	E_0 [eV]
Unconnected	Al	0.248 ± 0.002	0.8 ± 0.4	$2\times10^{-5}\pm3\times10^{-5}$	0.1 ± 6.3
	Pt	0.270 ± 0.002	4.0 ± 3.3	$11\times10^{-5}\pm6\times10^{-5}$	–0.5 ± 3.6
Connected	O	0.07 ± 0.001	0.7 ± 0.1	$5\times10^{-5}\pm1\times10^{-5}$	8.1 ± 1.6
(sebacic acid)	Al	0.253 ± 0.001	0.4 ± 0.1	$2\times10^{-5}\pm2\times10^{-5}$	2.9 ± 2.8

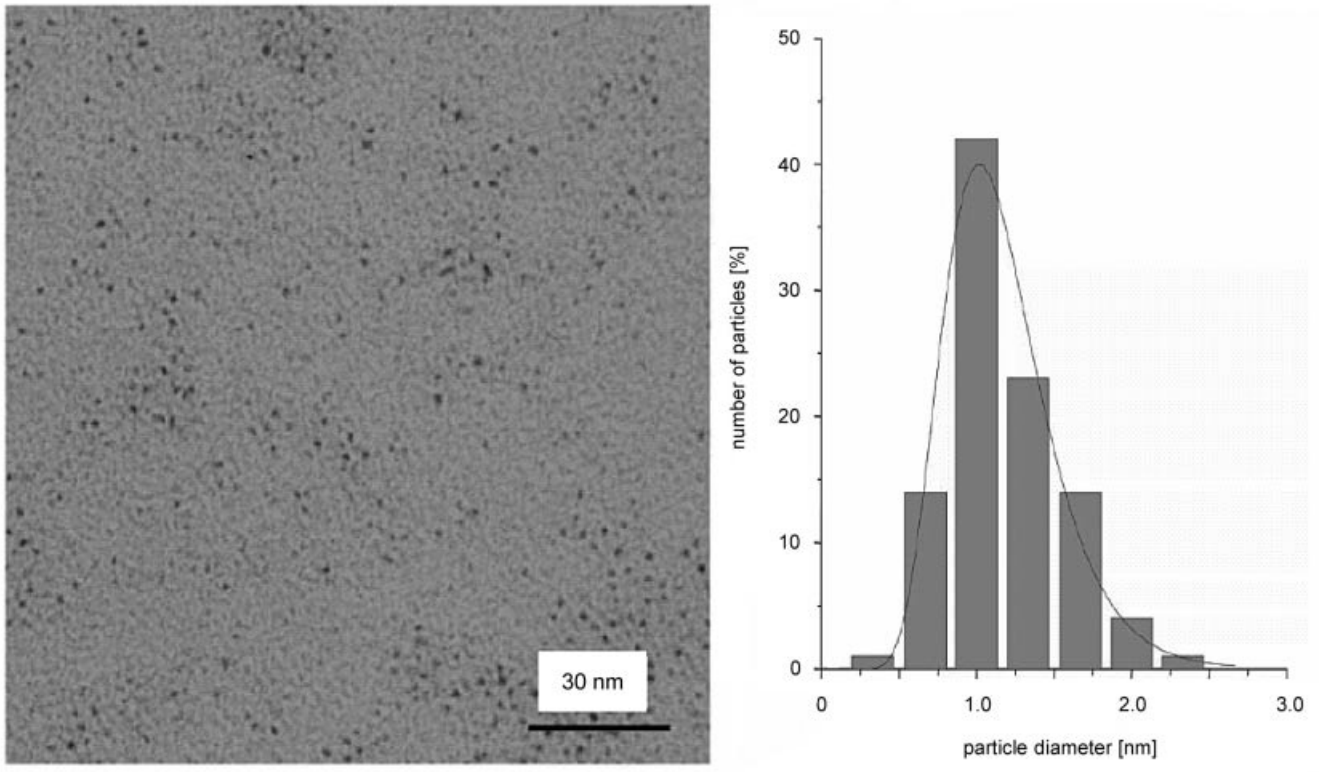

Figure 3. a) TEM image of Pt colloid particles and b) the corresponding particle size distribution (from ref. 16 with permission from IUCr).

While the energy balance of MIES (at least for the AD process) is quite similar to that of UPS (HeI) the depth information of MIES is "zero" because the Auger processes typically take place 4 a.u. in front of the surface and electrons are ejected from species in the outermost layer of the nanoparticles. On the other hand, the depth information of UPS (HeI) is about three monolayers (ML), therefore this technique provides information on the sub-surface region, although averaged over three monolayers. A more detailed introduction to MIES and its various applications in molecular and surface spectroscopy can be found in recent reviews.[23,24] Details of the apparatus employed for the present work can be found elsewhere.[25–27] For the characterization of the chemical composition of the bare surface as well as of films of nanoparticles the apparatus was equipped with a twin anode (Mg/Al) XPS source.

Characterization of Pt Colloids

TEM, ASAXS, and Sorption Analysis

A TEM image of the Pt colloid sample used and the respective particle size distribution is shown in Figure 3. The particles have an average diameter of 1.2 nm.

The particle sizes were confirmed by small-angle X-ray scattering experiments. The particle sizes determined for the Pt colloids by ASAXS were 1.2 ± 0.06 nm. The average distance between neighboring Pt particles in this solid was determined by ASAXS to be 0.36 nm. Assuming a direct contact between the protected particles, the thickness of the protective layer is thus 0.18 nm.

After evaporation of the solvent, nitrogen sorption experiments on the obtained powder resulted in specific surface areas (BET) in the range of only a few square meters per gram. From geometric considerations, spherical 1.2-nm Pt particles should have a specific surface area of about $230\ m^2\,g^{-1}$. This discrepancy can be explained by the extremely small voids that form between densely packed particles of this size − the nitrogen molecules are simply too large to fit into these voids. Thus, only the external surface areas of the Pt particle aggregates contribute to the BET surface area. The majority of the colloid particle surfaces are inside the aggregates and thus not accessible to the nitrogen.

XAFS Characterization of Particles Before Networking

Figure 4 shows the Pt L_3-edge XANES spectra of the Pt nanoparticles that, along with the spacer molecules, form the basic building blocks of the cross-linked systems under investigation in this study. Evidently, clear differences with the reference spectrum of a Pt foil are observed. For example, the characteristic resonances of the reference spectrum are present, but strongly damped. This is to be expected for nanoscaled systems. One reason for this resides in the large number of surface atoms (in this case about 75%) that do not possess complete nearest neighbor shells and for which surface relaxation effects prevent the ideal coherent addition of scattering paths. In addition, nanoscaled particles

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

frequently show increased local disorder, which is not described well using the standard Debye–Waller factor approach due to its partially anharmonic nature. A detailed discussion of such effects on nanoparticles[28–30] and a thorough general discussion of the consequences of such inharmonicity[31] can be found in the literature.

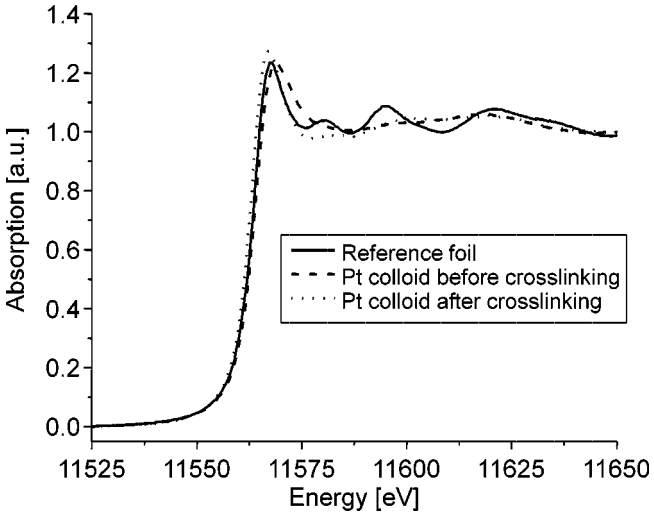

Figure 4. Pt L_3 XANES spectra of (top to bottom): Pt reference foil, Al-organically stabilized Pt colloid after cross-linking with sebacic acid, the same material before cross-linking. Measurements were performed at CAMD.

Intuitively less to be expected are the changes observed in the white-line area, where electronic rather than geometric structure is probed. The maximum intensity of the white-line feature is slightly reduced and shifted to higher excitation energy and features a less-steep slope to the high energy side. Calculations performed in the context of a previous in situ study on the synthesis of such particles[32] suggest that this can indicate an effect of a Pt–Al coordination to surface atoms.

These results are in agreement with the corresponding EXAFS analysis, whose results are summarized in Figure 5 and Table 1: in addition to the expected Pt–Pt coordination at a distance, which is slightly reduced relative to the Pt–Pt distance encountered in bulk Pt, an additional backscatterer located at a distance of about 2.5 Å is needed in order to achieve a fit with reasonably good quality. Clearly, this distance is too high for a second row element such as O or C, but is in good accordance with the distance expected for a coordinated Al atom. A more detailed discussion of the EXAFS analysis of the particles before cross-linking can be found in a previous publication.[33]

MIES and UPS

The concept of the surface characterization of nanoparticles is as follows. Normally, the metal particles need a "shell" that serves two purposes:

· *Passivation*: the long-term stability of the metal particles (the magnetic particles Fe, Ni, and Co in particular) against

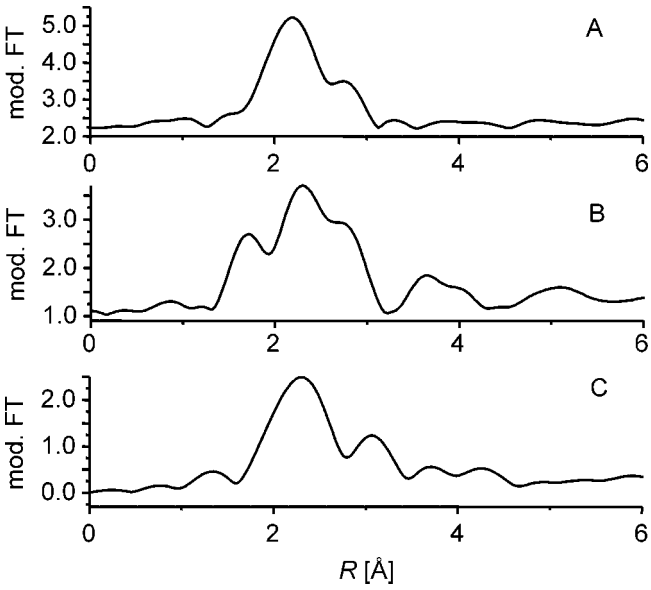

Figure 5. Non-phase-corrected radial distribution functions of (from top to bottom): a) the colloid before cross-linking, b) the colloid network with sebacic acid spacer, c) the colloid networked with HBP.

air and/or moisture has to be guaranteed prior to their integration into a nanoparticle network or, more generally, into a nanostructure;

· *Anchor Function*: the shell must allow for the reliable embedding of the nanoparticles into the custom-designed network, i.e. for the reliable interlinking of the particles in the network by "spacer" molecules.

In general, a two-step procedure must be pursued in order to get information on the composition and the electronic structure of the particles' shell:

· A planar film of the species from which the nanoparticles, Pt in the present case, are composed, has to be studied by MIES and UPS, eventually supported by techniques that give additional information on the chemical composition of the metal film prior to and after being subjected to the shell molecules (XPS), and on the film topology (STM). Then, the interaction of selected atomic and/or molecular species ("shell molecules"; see below) with this film has to be studied in the same way. This step provides "fingerprint spectra" that provide structural information that can be compared with that obtained in the second step on the nanoparticles from the same species as those that constitute the film, and also provide structural information on those molecules that potentially form the shell of the nanoparticles.

· The corresponding analysis is performed on the nanoparticles, which normally possess a shell resulting from wet-chemical procedures. An obvious complication arises from the fact that the composition of the shell produced in this way is, a priori, unknown, i.e. normally cannot be predicted on the basis of the wet-chemical procedures alone. A comparison of the results from the second step with a series of "fingerprint spectra", which have either been gathered in

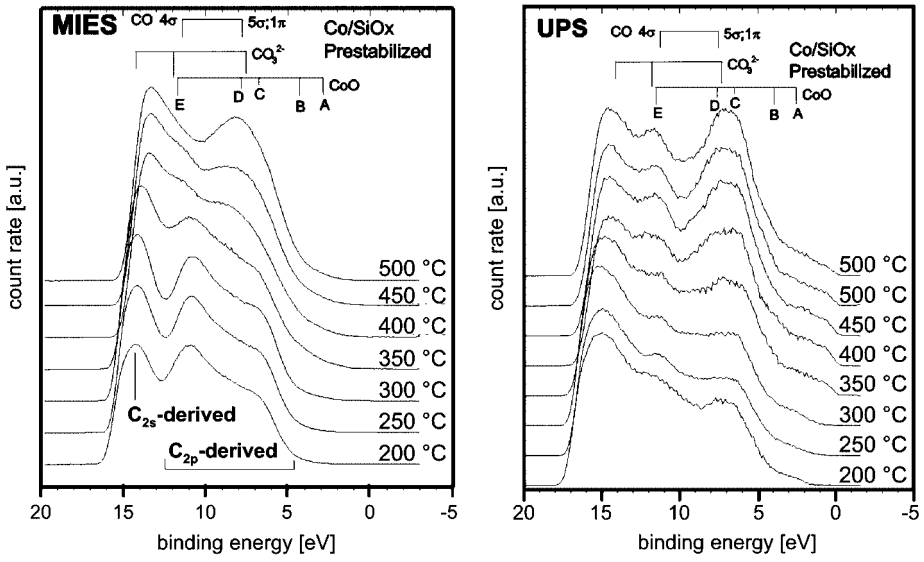

Figure 6. MIES and UPS spectra of Co nanoparticles pre-stabilized by soft oxidation. Deposition on SiO_x. The substrate temperature after deposition was varied between 200 and 500 °C.

the first step or are already available in the literature, is required.

For didactic reasons, the details of the above-mentioned procedure will be illustrated for Co nanoparticles possessing a shell produced by "soft oxidation". First, Co films were produced on SiO_x. These films were then exposed to O_2, CO, and CO_2 with in situ control by MIES/UPS. A detailed presentation of the results and their interpretation can be found elsewhere.[34] Secondly, pre-stabilized Co nanoparticles were deposited on SiO_x substrates from suspensions in toluene.[35] STM indicated that a closed layer of the particles was obtained. Figure 6 displays the MIES (a) and UPS (b) spectra of the surface-deposited, pre-stabilized Co nanoparticles as a function of surface temperature. Also shown are the energetic positions of the main structures resulting from step (1). For completeness, we have also indicated where the spectral features from carbonate (CO_3) groups bound to metallic surfaces[36] should be seen.

Below 250 °C some emission must still be attributed to the ionization of π-type MOs from the aromatic rings of residual toluene solvent molecules on the surface of the particles. From the comparison of the results at higher temperatures with those for gas-exposed planar Co films we estimate that most of the intensity observed in the valence band region (about 70%) is due to (Co–CO_x), with the rest being due to (Co–O) bonds.

For the formation of networks from Pt colloids the existence of an intact Al-organic colloidal protection shell is vital. The reactive methylaluminum groups present in the protecting shell provide the possibility to substitute organic groups at the Al; for the interlinking of the nanoparticles via organic spacer molecules these substituents must be bifunctional. The heating of Al-organic stabilized Pt nanoparticles with in situ control of MIES and UPS (HeI) has provided important information on the thermal properties of the Al-organic stabilization.[37] When heating a colloid network film consisting of Pt nanoparticles cross-linked by hydroquinone spacers, MIES shows the disappearance of the π-emission from the aromatic rings of the spacer molecules at binding energies, E_b, of between 4 and 8 eV. XPS, on the other hand, only indicates a small, unspecific change in the C 1s and O 1s intensities. This suggests the destruction of the spacer molecules (above 200 °C). Moreover, intensity develops at the Fermi level in the MIES spectra. This indicates that the Pt colloids (featuring metallic properties) become accessible to the He* probe atoms utilized for MIES. For temperatures above 200 °C the MIES spectra between E_b = 5 and 10 eV start to resemble more and more those of Al_2O_3 films.[36] This suggests that, as a consequence of the heating procedure, the Pt colloids are surrounded by some sort of (Al–O) network. This implies that most of the emission seen between E_b = 5 and 10 eV after heating would then be due to the ionization of O 2p orbitals from oxygen atoms of the (Al–O) network surrounding the Pt nanoparticles. XPS provides evidence that the Pt nanoparticles are present on the Si substrate employed for deposition up to 600 °C, although they are now stabilized by a Al–O network which has no bifunctional character anymore.

Spacer Molecules

Characterization of the Nanoparticle–Spacer Interaction by MIES and UPS

Some applications require a shell of organic molecules, in particular when the sintering of nanoparticles has to be avoided. Moreover, nanoparticle–organic spacer complexes are natural building blocks for networks of nanoparticles. Both applications impose similar problems for their characterization: the functional group, responsible for the nanoparticle–OM (OM: organic molecule) bond has to be iden-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tified, and the thermal stability of this bond has to be studied. Essentially the same procedure as described above for the pre-stabilization of the nanoparticles can be pursued, namely a comparison must be made with the fingerprint spectra obtained from the interaction of the same OMs (or at least originating from OMs with the same functional groups) with a planar surface possessing the same termination (the same "shell", see above) as the employed nanoparticles.

Here, we concentrate on the nanoparticle–spacer complexes as the peptization of nanoparticles by long-chain carboxylic acids (possessing a carbonyl group as functional unit) has been dealt with elsewhere.[35]

For illustration, Figure 7 presents MIES and UPS (HeI) spectra for Pt colloids cross-linked by hydroquinone (left) and chlorohydroquinone (right) spacers. For the as-prepared films there is practically no emission for binding energies smaller than 3.5 eV. Together with the fact that the work function of the as-prepared films is 4 eV (as estimated from the low-energy onset of the MIES spectra), we conclude that the studied films possess insulating character, with a bandgap of 7.5 eV. We have not interpreted the MIES/UPS spectra for binding energies above 11.5 eV because this range of binding energies is strongly affected by contributions from secondary and backscattered electrons The coarse structure of the MIES spectra for both networks was identified by comparison with fingerprint spectra available for *p*-CPC films (CPC = *para*-comylphenyl cyanate) on silicon.[38,39] While the MIES/UPS spectra from *p*-CPC show rather well-resolved fine structure due to the ionization of the π-MOs of the aromatic rings in particular, the present spectra show at most indications of a fine structure. From this comparison, we conclude that the emission between 4 and 11 eV is largely due to the ionization of the π- and σ-MOs of the aromatic rings in the spacers. In particular, the emission between 4 and about 8 eV is largely due to the ionization of the π-MOs. Apparently, as the inspection of Figure 7 shows, the main effect of the chlorination of the spacer molecules is a reduction of the emission in the range between 4 and 8 eV, i.e. a reduction in the emission from the ionization of the π-MOs. In addition, we see some fine structure in the MIES spectra in the range E_b = 3 to 7 eV which, as the comparison with the MIES results for 4(2)-CBM (CBM = conduction band minimum) suggests,[40] must be attributed to the ionization of the Cl 3p orbitals.

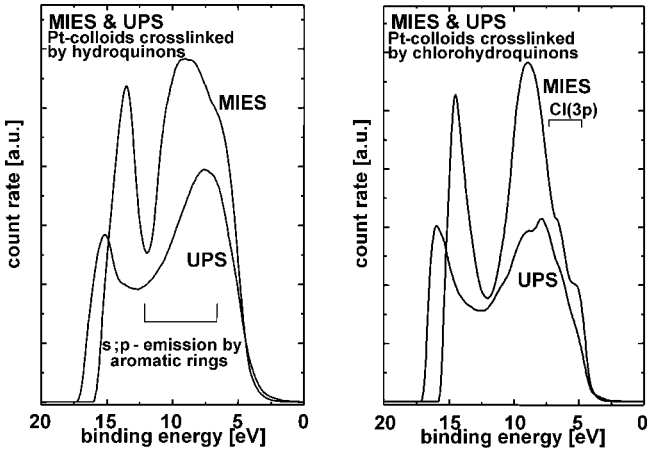

Figure 7. MIES and UPS (HeI) spectra for Al-organic-stabilized Pt colloids cross-linked with hydroquinone (left) and chlorohydroquinone (right) spacers.

Another instructive example for the study of the core–shell interaction is the functionalization of Pd nanoparticles by NR_4Cl molecules (R denotes alkyl groups of different length).[41] The reduction of metal salts with tetraalkylammonium hydrotriorganoborates is a general method for the preparation of metal colloids of elements of groups 6 to 11 in organic solvents. During the colloid formation, the stabilizing tetraalkylammonium salts are formed directly at the reduction center and act as powerful protecting agents for the metal particles. In early publications it was assumed that the protecting groups coordinate to the negatively charged metal cores of the colloid through NR_4 (model 1). The combination of X-ray absorption near edge structure (XANES) measurements with MIES and UPS (HeI) results suggests that the coordination of the stabilizing agent at the particle surface through metal–chlorine bonds is the more appropriate stabilization mode (model 2):[41] if model (1) were applicable, a comparatively well-localized spectral feature from the ionization of the Cl 3p atomic orbital should be seen in the MIES spectra at about E_B = 6 eV because the He* probe atom employed for MIES should interact with the charge cloud of the Cl atom.

Characterization of Pt Colloid Networks

TEM, ASAXS, BET, Modeling

The cross-linked Pt particles form solids which have been investigated by TEM. Comparison of TEM images of the cross-linked samples with those of simply protected Pt colloids show that the particle size of the colloids as well as their monodispersity have not changed after cross-linking (see Figure 8). Furthermore, particles seem to have larger distances between each other if larger spacer molecules are used.

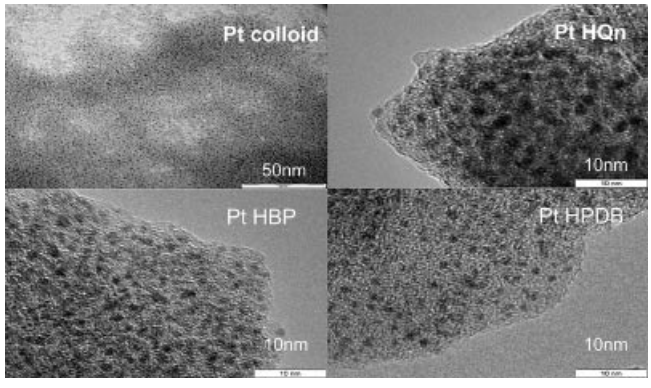

Figure 8. TEM images of protected Pt colloid particles and Pt particles cross-linked with HQn, HBP, and HPDB.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Because of the large side-chains of Pt/HBDB and Pt/HPDP, one might expect a more linear rather than a three-dimensional network. The TEM images of these samples indeed show areas where one could assume such a chain-like linear arrangement of the particles. The particles are lined up in one direction with more or less identical distances (see part d of Figure 8).

Nitrogen sorption analyses have been used to investigate whether accessible pore systems are obtained after the cross-linking of the Pt particles. The results show that a mesopore system is formed for Pt/HBP (50 °C) with an average pore size of about 31 nm and a pore volume of 0.4680 $cm^3 g^{-1}$. For Pt/HBP2 (25 °C), the pore volume is only 0.0696 $cm^3 g^{-1}$ with an average pore size of only 18 nm. These results show that the temperature applied during the network formation has an influence on the density of the pore system formed. For the networks with the larger molecules HBDP and HPDP, the amount of nitrogen adsorbed in physisorption experiments is extremely low, indicating that no accessible pore system has formed. This can be explained by the large -$OC_{12}H_{25}$ side-chains of the spacer molecules which probably block the pore entrances and the space between the colloid particles.

The small-angle X-ray scattering curves of different cross-linked samples at different energies (ASAXS) are shown in Figure 9.

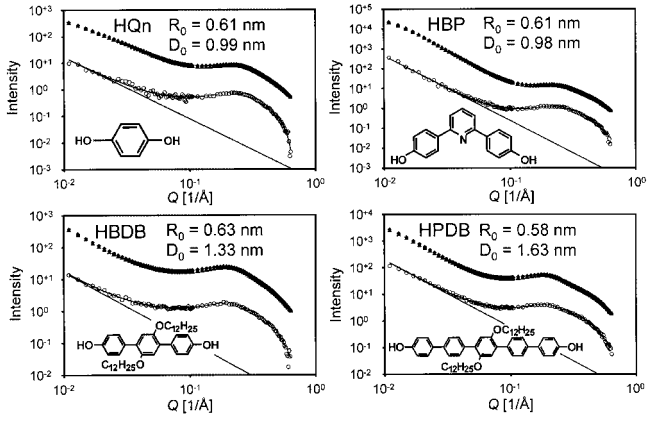

Figure 9. ASAXS curves of Pt particles cross-linked with different spacer molecules. For each plot, the lower curve (circles) is always the difference between the two upper curves (triangles) measured at two different energies (11437 and 11535 eV).

For the modeling of the scattering curves, a modified version of the so-called local monodisperse approximation (Pedersen[42]) is used:

$$\frac{d\sigma}{d\Omega}(Q) = \Delta\rho^2 \int_0^\infty N(D)\left(\int_0^\infty \Phi^2(Q,R)S(Q,R,D,t_{PS})N(R)dR\right)dD$$

where $\Delta\rho^2$ is the scattering contrast, and t_{PS} (= 0.18 nm) is the thickness of the Al-organic protecting shell, which was determined in an earlier study.[16] $\Phi^2(Q,R)$ is the particle form-factor for a sphere of radius R, where

$$\Phi(Q,R) = 3\frac{\sin(QR) - QR\cos(QR)}{(QR)^3}V_0(R),$$

and $V_0(R)$ is the particle volume. $N(R)$ is the log-normal size distribution of the platinum particles

$$N(R) = \frac{1}{\sqrt{2\pi}\sigma R}\exp\left[-\frac{1}{2\sigma^2}\ln^2\left(\frac{R}{R_0}\right)\right],$$

where σ is the half-width at half maximum (HWHM) parameter of the size distribution, and R_0 is the most frequently occurring radius. $N(D)$ is the distribution of the surface-to-surface distances D, which has to be taken into account due to the high flexibility of the spacer molecules. Here, $N(D)$ is modeled by the Gaussian distribution

$$N(D) = \frac{1}{\sqrt{2\pi}\sigma_g}\exp\left[-\frac{1}{2\sigma_g^2}(D - D_0)^2\right],$$

where D_0 denotes the mean distance (spacer–molecule length) between two particles and σ_g is the HWHM of the Gaussian distribution. The structure factor $S(Q, R, D, t_{PS})$ is given by

$$S(Q,R,D,t_{PS}) = (1 + 24\eta G(QL)/(QL))^{-1},$$

(see, for example, Kinning and Thomas[43]), where L is the distance between two particles of radius R,

$$L = 2R + 2t_{PS} + D,$$

η is the volume fraction of a sphere of radius $L/2$, and

$$G(A) = \alpha(\sin(A) - A\cos(A))/A^2 + \beta(2A\sin(A) + (2 - A^2)\cos(A) - 2)/A^3 + \gamma(-A^4\cos(A) + 4[(3A^2 - 6)\cos(A) + (A^3 - 6A)\sin(A) + 6])/A^5$$

with

$$\alpha = (1 + 2\eta)^2/(1 - \eta)^4$$
$$\beta = -6\eta(1 + \eta/2)^2/(1 - \eta)^2$$
$$\gamma = \eta\alpha/2.$$

The scattering behavior at low Q-values is modeled by a Q^{-p} power law, where p is the Porod exponent. This power law provides information on the whole particle system in the sample. The refined structure parameters for the seven samples are given in Table 2.

The Pt particle radii, R_0, as well as the polydispersities, σ, of all samples are in excellent agreement with one another. This can be expected, since the Pt particles used for the preparation of the nanoparticle networks stem from the same synthesis. The scattering contrast parameters, $\Delta\rho^2$, reflect, in general, the different volume fractions of the nanoparticle networks, and show therefore the same trend as the η parameters. The surface-to-surface distances, D_0, show partly significant differences between samples where the same spacer molecule was used for the interconnection of the Pt particles (HPDB, HPDB-2, and HBDB, HBDB-2).

Table 2. Refined structure parameters for a Pt colloid cross-linked with different spacer molecules according to the Pedersen model.

Sample	R_0 [nm]	σ	D_0 [nm]	σ_g [nm]	$\Delta\rho$ [10^{-4} nm^{-2}]	η	P
HQn	0.50(9)	0.021(8)	0.59(3)	0.10(1)	2.02(2)	0.142(7)	2.07(13)
HBP	0.50(9)	0.021(12)	0.64(3)	0.01(1)	1.82(3)	0.135(12)	3.18(11)
HBP-2	0.51(9)	0.021(9)	0.70(2)	0.01(1)	1.93(2)	0.139(8)	3.22(8)
HBDB	0.52(9)	0.020(8)	0.70(6)	0.01(1)	1.17(3)	0.108(9)	1.90(12)
HBDB-2	0.53(6)	0.019(5)	1.00(5)	0.07(4)	1.39(1)	0.118(6)	2.04(11)
HPDB	0.54(4)	0.020(3)	1.29(9)	0.37(9)	2.05(2)	0.143(7)	2.37(5)
HPDB-2	0.54(5)	0.021(4)	0.96(6)	0.30(1)	1.28(1)	0.113(5)	2.43(16)

The HWHM parameters, σ_g, are also quite different, so that the distance distributions range from almost delta-shaped functions (σ_g = 0.01 nm) to quite broad distributions (σ_g = 0.37 nm). These findings may indicate that these flexible and rather complex spacer molecules are extremely sensitive to small differences in the sample preparation process. The Porod exponents, p, show that the nanoparticle networks of most samples form chain-like structures ($p \approx 2$), and only for the samples HBP and HBP-2 is an exponent of $p \approx 3$ obtained, which indicates the formation of more compact structures (e.g., surface fractals). In order to crosscheck the conclusions drawn from the Porod exponents, the pair-correlation functions $g(r)$ were calculated from the structure factors according to

$$g(r) = 1 + \frac{1}{2\pi^2 c_0}\int_0^\infty (S(Q,R,t_{PS},D) - 1)\frac{\sin(Qr)}{Qr}Q^2 dQ\,.$$

The Pt particle concentration, c_0, is readily obtained from the relation

$$c_0 = \frac{\eta}{V_{HS}}$$

where the hard-sphere volume, V_{HS}, is given by

$$V_{HS} = \frac{\pi}{6}\int_0^\infty N(D)\left(\int_0^\infty N(R)L^3 dR\right)dD$$

$$= \frac{\pi}{6}\int_0^\infty N(D)\left(\int_0^\infty N(R)[2R + 2t_{PS} + D]^3 dR\right)dD\,.$$

Formal coordination numbers $\langle Z\rangle$ are obtained by integration of $g(r)$ over the volume of the first coordination shell:

$$\langle Z\rangle = 4\pi c_0 \int_{r_0-\Delta}^{r_0+\Delta} g(r) r^2 dr$$

where $g(r_0) = max$, and 2Δ is the total width of the coordination peak. Although the coordination numbers will probably not be correct on an absolute scale due to the influence of the polydispersities of the particles and the spacer molecules on the shape of the coordination peak, a qualitative comparison between the different samples is still possible.[16]

The particle concentrations, c_0, hard-sphere volumes, coordination-peak positions, r_0, and the average coordination numbers $\langle Z\rangle$ are given in Table 3.

Table 3. Particle concentrations, c_0, hard-sphere volumes, coordination-peak positions, r_0, and the average coordination numbers, $\langle Z\rangle$, of Pt particles cross-linked with different spacer molecules.

Sample	c_0 [10^{-2} nm^{-3}]	V_{HS} [10^1 nm^3]	r_0 [nm]	$\langle Z\rangle$
HQn	3.38(68)	0.42(8)	2.4(5)	2.4(4)
HBP	3.00(60)	0.45(9)	2.5(5)	2.1(4)
HBP-2	2.83(56)	0.49(9)	2.5(5)	2.2(4)
HBDB	2.10(42)	0.51(10)	2.6(5)	1.6(3)
HBDB-2	1.51(30)	0.79(15)	2.9(6)	1.6(3)
HPDB	1.24(25)	1.16(23)	3.3(6)	2.2(5)
HPDB-2	1.43(28)	0.79(15)	3.0(6)	1.8(4)

The lowest values for the coordination numbers are obtained for those samples with lowest Porod exponents, and higher coordination numbers correspond to larger Porod exponents, i.e. to the networks forming more compact structures. Thus, the results confirm that the scattering contributions at low Q-values are sufficiently well described by the power laws and that the above conclusions are obviously correct.

A further crosscheck of the least-squares results can be obtained from the Fourier transform of the SAXS intensities, the so-called radial distance distribution function[44]

$$\gamma(r) = \frac{r^2}{J_0}\int_0^\infty \frac{d\sigma}{d\Omega}(Q)\frac{\sin(Qr)}{Qr}Q^2 dQ\,,$$

where J_0 is the total scattering power

$$J_0 = \int_0^\infty \frac{d\sigma}{d\Omega}(Q)Q^2 dQ\,.$$

This function contains information on the particle sizes, and interparticle distances. Here, the particle radii are simply given by the corresponding maxima of the first peaks at $\gamma(r = R_1)$. Together with the maxima of the second peaks (at $r = R_2$), the interparticle distances ($d = R_2 - R_1$) and the surface-to-surface distances ($D_0 = d - 2R_1 - 2t_{PS}$) are readily obtained.[16] These values are of course only crude approximations, since the determination of particle radii and/or interparticle distances from the radial distance distribution functions is only reasonable for the case of monodisperse particle systems. Table 4 summarizes the results from the analysis of the distance distribution functions. The parameters are found to be consistent with those obtained from the least-squares analysis, and the significant differences in the D_0 compared to the least-squares results can be attributed to the influence of the particle-size and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

spacer-length distributions, as well as the moderate data quality (the average relative e.s.d.'s for the SAXS intensities are around 15%), which is also reflected by the fairly large e.s.d's of the refined least-squares model parameters (see Table 4).

Table 4. Structure parameters of Pt particles cross-linked with different spacer molecules calculated by the Fourier transform method.

Sample	J_0 [cm^{-1} nm^{-3}]	R_1 [nm]	R_2 [nm]	d [nm]	D_0 [nm]

Modeling of the Pt–Spacer Interaction

The interparticle distances analyzed by ASAXS were compared to those calculated from constructed Pt network structures. The spacer lengths were calculated using the MNDO method.[45] The construction of the network structures is based on the assumption of the presence of an Al-organic monolayer on the particle surface, while the corresponding bond lengths were taken from the literature and the Cambridge Structural Database: (1) Al–Pt: 0.232 nm;[46] (2) Al–C: 0.187 nm; (3) Al–O: 0.232 nm. The thus-constructed Pt nanoparticles (1.2 nm) with the cross-linked spacers BDM and HPDB are illustrated in Figures 10 and 11, respectively.

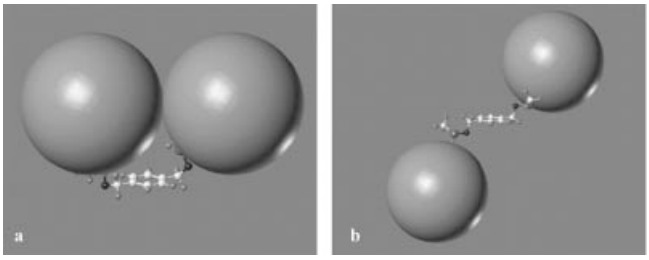

Figure 10. Modeled Pt–spacer–Pt units with BDM as the spacer: a) the minimum interparticle distance; b) the maximum interparticle distance.

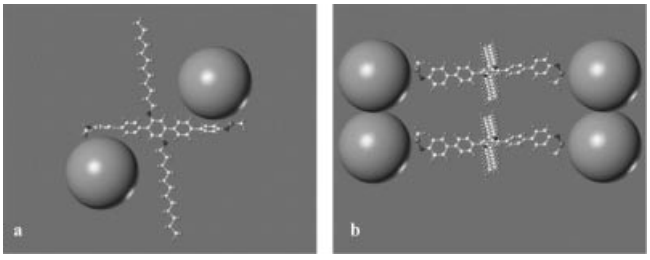

Figure 11. Modeled Pt–spacer–Pt units with HPDB as the spacer: a) the minimum interparticle distance; b) the maximum interparticle distance (another extreme case of minimum particle distance between different interlaced subunits is also shown).

Considering the rotation of Al–O bonds, two extremes are possible, namely the minimum and maximum interparticle distance, although another extreme case of minimum interparticle distance between different interlaced subunits is also shown in Figure 11b. Thus, one has to keep in mind that interparticle distances do not necessarily correspond to the length of the molecular spacers in the obtained network. The more flexible the spacer molecules and the anchoring group, the broader the particle–particle distance distribution is expected to be.

XAFS Characterization of Networked Particles

X-ray absorption spectroscopy can contribute in two ways to the characterization of networked particles, either indirectly, as the (partial) decomposition of the surfactant shell in a networked system should lead to notably reduced rates of agglomeration, and directly, if changes in the electronic structure and the geometry of the metal particles are observed. The indirect characterization is discussed in detail in ref.,[47] therefore here only the main results obtained from XAFS are summarized briefly considering Figures 12 and 13.

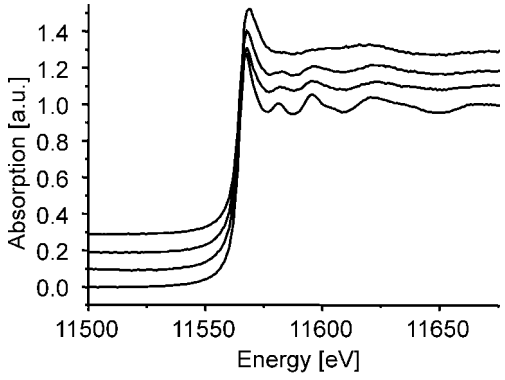

Figure 12. Pt colloid before cross-linking at (from top to bottom) room temperature, 160 °C, and 300 °C in comparison with a Pt foil reference (bottom).

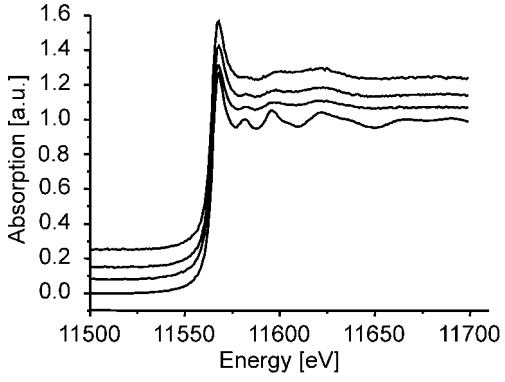

Figure 13. Pt colloid, cross-linked with chlorophenol at (from top to bottom) room temperature, 160 °C, and 300 °C in comparison with a Pt foil reference (bottom).

As the actual intensity of the shape resonances typical for platinum metal allows a rough qualitative estimate of the particle size and degree of ordering present in the sam-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ple, size-effects and effects of varying spacer molecules at different temperatures can be separated from each other. Only for the unmodified colloid does one observe a significant increase in the intensity of the shape resonances starting at 160 °C, which indicates that the particles undergo significant agglomeration processes at this temperature. In contrast to that, the system with a chlorophenol spacer shows a much smaller trend towards agglomeration even at 300 °C.

At the same time, it is worth noting that the room temperature spectra displayed in Figures 12 and 13 show differences in the white-line region, especially the maximum intensity of the white line and the shape of its high energy slope. The different white-line features change as a function of time in different ways: whereas the agglomerating particles feature a more and more intense white line upon approaching a status more similar to the bulk, the reverse is observed in the cross-linked system. This proves that the observed temperature-dependent changes in the electronic structure shown in Figures 12 and 13 are predominantly due to changes in the decomposing surfactant shell of the colloidal particles, whereas the spacers effectively prevent agglomeration.

With respect to the direct characterization, at first sight it may seem surprising that any changes in the structure of the particles occur at all as a consequence of the networking process even though such changes are clearly visible, as evident from the example presented in Figure 4, where the white-line intensity is increased notably and appears slightly shifted to lower energy, whereas the shape resonance region of the spectra is hardly influenced by the network formation with this type of spacer molecule. TEM studies verify that, in contrast to the situation encountered after the system has been exposed to thermal stress, which was discussed in the above paragraph, the geometry parameters of the individual cores, such as size and shape, remain identical. In addition, the connection of individual metal cores by spacer molecules leads to a preferred interparticular distance although not (necessarily) to a highly ordered long range structure, in which modification of electronic structure can be envisioned due to the necessity to introduce periodic boundary conditions.

Nevertheless, on looking at the Pt L_3-edge XANES spectra displayed in Figure 4 it is evident that the effects of spacer-induced changes in the electronic structure are observed. Therefore, the only explanation for such changes is that the surfactant shell around the particle core is restructured, either geometrically or with respect to the charge distribution, in such a way that considerable influence is exerted on the metal atoms. It is important to stress the implications of this statement, because it means that information on the particle size and shape [as obtained typically from TEM, but also using (A)SAXS] and the nature of the core [as obtained frequently using a diffraction-based technique, such as XRD (X-ray diffraction) or SAED (selected area electron diffraction)] is not sufficient to describe the nature of a nanoparticle, which in turn explains why the macroscopic (e.g. magnetic) properties determined by different researchers on particles of equal size and phase can vary drastically. In fact, a number of theoretical predictions and experimental results based on various experimental techniques,[48–51] including X-ray absorption spectroscopy,[52–57] can be found in the literature to describe such effects. Specifically, a more detailed review on such effects in general is found in ref.,[28] the width of accessible modifications. for example for the case of Co nanoparticles, is discussed in ref.,[56] and a detailed model how these changes influence electronic structure in terms of magnetic properties of Co particles is presented in ref.[57]

Returning to the class of particles discussed in this work, clearly such a modification must be traceable even more directly in the aluminum organic shell. In fact, as shown for selected examples in Figure 14, and discussed in more detail in ref.,[33] the cross-linking with sebacic acid leads to a dramatic change in the electronic structure of Al, increasing the intensity of the white-line drastically and shifting its energy position to a value typical for sixfold (oxygen) coordinated Al. At the same time, the changes induced by cross-linking with a mixture of decanol and sebacic acid spacers lead to a similar trend in the spectra, but to a notably smaller extent. All of these experimental results underline that a spacer-dependent, controlled change in the protection shell is in fact observed, which is especially pronounced when sebacylic acid is used, which leads to a didentate coordination of the spacer to the Al and a sixfold oxygen coordination, but less significant when the connection between the aluminum organic shell and spacer molecule involves just the OH bond.

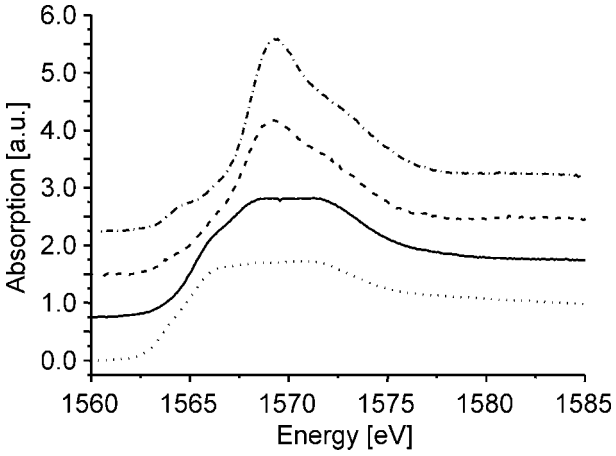

Figure 14. Al K XANES spectra of (from top to bottom) a Pt colloid networked with sebacic acid, the same networked with a mixture of decanol and sebacic acid, the same before networking, and trioctylaluminum.

As discussed in ref.,[33] an almost identical behavior is observed for a related system based on Co nanoparticle precursors, emphasizing once again that one is dealing with a spacer-induced effect on the aluminum organic shell that is dependent on the exact nature of the spacer molecule.

In fact, these differences are also reflected in the Pt L_3 EXAFS evaluation of particles after cross-linking with sebacic acid and HBP, respectively, as shown in Figure 5.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1 compares the results of this analysis for two such particles, one cross-linked with sebacic acid and the other with HBP. In contrast to the situation encountered for sebacic acid, where it is necessary to use an additional soft backscatterer like oxygen in the fit, this is not the case for HBP. At the same time, the presence of the HBP spacer seems to influence the Pt–Pt distance, which differs beyond the uncertainty of the fitting result and is increased almost to bulk level. As the core of the particles is only 1.2 nm in diameter, such a change can easily be attributed to a variation in core–surfactant interaction as a function of the local charge density on the aluminum atom. Consequently, a controlled tuning of the structure of the Pt core appears possible by choosing the spacer molecules. In fact, the multiplicity of choices becomes evident when looking at the variety of spectral signatures in the white-line region as a function of the spacer molecule, as shown in Figure 15. In combination with a detailed understanding of such effects, this may open a novel approach towards catalysts that are optimized in terms of both activity and accessibility of the catalytic centers.

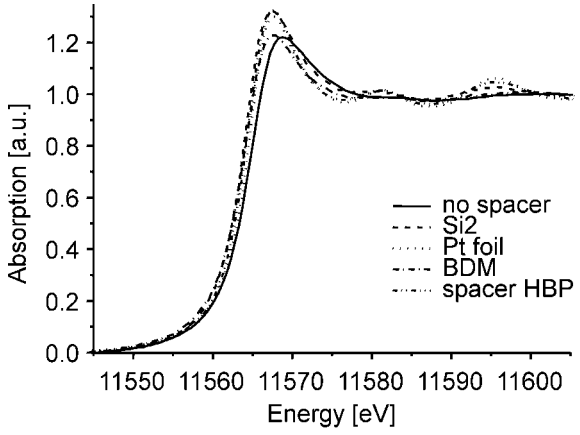

Figure 15. Pt L_3 XANES spectra of colloids with varying spacer molecules and a foil reference.

MIES and UPS Investigations

The obvious problems faced during the characterization of nanoparticle networks produced by a "bottom-up" strategy are threefold:

· Verification of the presence of the spacer molecules in the assembled network;

· Given the presence of the spacers in the nanoparticle–spacer compound, the bonding between the nanoparticles and the spacers needs to be verified;

· The verification of an ordered network composed of nanoparticles and spacers.

As far as the first point is concerned, the main task to be done is to distinguish between the spectral contributions from the organic molecules (OMs) of the particle's shell (Al-organic stabilization in the present case) and those from the spacers. A simple approach is the use of appropriately labeled spacers, i.e. those having a particular ligand atom attached to that produces a clear spectral signature that is well-separated from any of those from the OMs present in the shell. This strategy is similar to that illustrated above for the study of the interaction between and Pt and Pd nanoparticles with their respective protection shells (see above).

The verification of a link between a spacer and adjacent nanoparticles follows the strategy outlined above for obtaining information on the bond formation between nanoparticles and species forming their shell or between nanoparticles and spacer molecules. As a necessary condition, it can be stated that no free, unreacted functional groups (intended for bond formation with the nanoparticles) should be detectable by MIES. However, it is advisable to obtain topological information on the existence of an ordered nanoparticle–spacer structure in addition to the electronic structure information. Our strategy consists in combining MIES/UPS with STM and STS.

STM Investigations

For illustration, we present results for Pt nanoparticles interlinked by HBDB spacers. Figure 16 shows the STM results for Pt nanoparticles (about 1 nm average diameter, as determined by TEM) interlinked by the spacer molecules. The average size of the detected, close-packed aggregates is typically 7 nm. However, the ordered array seen in Figure 16 is apparently not that of single Pt nanoparticles separated by spacers, therefore each aggregate must consist of several interlinked Pt nanoparticles. The simplest structural unit producing aggregates of 7 nm consists of six Pt nanoparticles clustered around a central Pt nanoparticle. Interestingly, we find such compact structures very seldom. This indicates that the nanoparticle networks consist mainly of 1D structures, such as chains, that would escape detection by STM. This agrees with the ASAXS results, which indeed indicate that the nanoparticle networks of most samples consist of chain-like structures (see above).

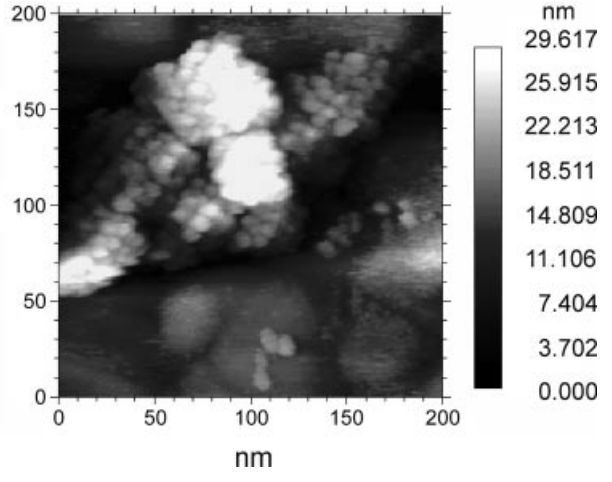

Figure 16. STM image of Pt nanoparticles (average diameter 1 nm) interlinked by HBDB spacers deposited on an Au substrate.

STS measurements, performed as a function of the temperature of the substrate onto which the nanoparticle array is deposited, confirm that the network structure possesses insulating behavior up to 200 °C. More detailed infor-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mation on the electronic structure of the network is furnished by the MIES/UPS spectra. They confirm the insulating character of the structure, which possesses a bandgap width of about 7 eV and gives spectra (not shown) similar to those of Figure 7.

Summary

Combining different analytical methods, such as TEM, ASAXS, UPS, MIES, XAFS, Sorption analysis, and STM, has allowed us to gain insights into the processes taking place during the network formation of nanoparticles cross-linked with different spacer molecules. Several new spacers with different molecular lengths and rigidity have been used to cross-link Pt colloids via protonolytic reaction to prepare network materials. In general, the materials that form upon cross-linking show no long-range order but rather form network-like structures. When using rigid molecular spacers such as those described above, TEM investigations have revealed that short-length spacers give rise to a densely packed material while long and rigid molecular spacers tend to produce 1D-type structures where the interparticle distance is considerably larger. These results are corroborated by ASAXS investigations. Physical sorption analyses have shown that mesoporous materials are produced for some systems. The shapes of the hysteresis loops of the sorption isotherms strongly depend on the type of molecular spacer used and also on the preparative conditions. Isotherms recorded on products prepared from long-length molecular spacers show that these materials hardly adsorb nitrogen. This is due to the blocking effect from the organic species and poorly defined porous structures. ASAXS measurements have revealed that the interparticle distance only reflects the conformation of the molecular spacers. Varying the preparative conditions with each defined molecular spacer leads to diverse pore structures but identical interparticle distances.

Significant differences between the electronic structures of Pt nanoparticles pre-stabilized with an Al-organic shell and cross-linked particles are observed at room temperature. The properties of the metallic nanoparticles are thus directly influenced by changes of the protective shell. Furthermore, it has proved possible to analyze subtle changes in the protecting shell. Although the Pt colloid modified with 3-chlorohydroquinone differs only in the additional cluster located on the second end of the space molecule, the chlorine can only be detected by MIES in the latter case, thus indicating different equilibrium positions of this molecule. Thermal treatment leads to a disintegration of the spacer molecules, as could be shown by MIES and XANES spectroscopy. A clear trend towards the formation of shape resonances under thermal loads is observed only for the unmodified particles. This indicates that it is driven not by agglomeration but by mere structural reordering within the colloidal metal cores. This agglomeration does not occur as easily for particles that are initially surrounded by spacer molecules, even after destruction of the spacer molecules. It was possible to correlate this observation to a suggested formation of an Al–O protecting shell by MIES.

Acknowledgments

The authors would like to thank Dr. Görigk from the JUSIFA Beamline at the Hasylab, Hamburg, for technical support. Furthermore, we would like to thank Mr. Spliethoff, Mr. Dreier, and Dr. Tesche from the MPI für Kohlenforschung for providing the electron micrographs and Dr. Weidenthaler from the MPI für Kohlenforschung for XPS and XRD investigations. Financial support of the Deutsche Forschungsgemeinschaft, Priority Program SPP 1072 (grant nos. Bo 1135, Ho 887, and Ke 155), and of the Max-Planck-Gesellschaft is gratefully acknowledged.

DNA-Based Assembly of Metal Nanoparticles

Christof M. Niemeyer*[a] and Ulrich Simon*[b]

Keywords: DNA / Materials science / Nanoparticles / Self-Assembly / Supramolecular Chemistry

In this microreview we describe the principles of DNA-based assembly of metal nanoparticles in one, two and three dimensions. Different methods of liquid-phase synthesis of metal nanoparticles as well as their functionalisation with DNA are introduced. The concepts developed up to now for the assembly are explained, with selected examples to illustrate the properties of these assemblies as well as emerging applications.

1. Introduction

Modern chemical synthesis of metal nanoparticles is rooted in the famous experiments of Michael Faraday in the mid-nineteenth century, who showed that the reduction of tetrachloroaurate $[AuCl_4]^-$ with phosphorus as a reducing agent in aqueous solution leads to ruby-red solutions.[1] Today, we know that this reaction leads to the formation of gold nanoparticles in the size range between 3–30 nm,[2] and that the red colour results from the collective oscillation of surface electrons induced by the electric field of the entering light.[3] Since that time many different synthetic routes have been developed in order to obtain metal nanoparticles of different size and shape, all of which, in principle, follow the same strategy, i.e. the reduction of a metal salt in the presence of a stabilizing organic ligand. In the early 1990s these nanoparticles became a new chapter in chemistry. The development of high resolution physical measurements together with the elaboration of theoretical methods applicable to mesoscopic systems brought forth a lot of fascinating ideas about how these nanoparticles can provide new technological breakthroughs, for example in

Ulrich Simon was born in Essen in 1963. He studied chemistry at the University of Essen and obtained his diploma in 1990. In 1992 he obtained his doctorate (Dr. rer. nat.) in Essen and his habilitation in 1999. Since May 2000 he has held the Chair of Inorganic Chemistry and Electrochemistry at the RWTH Aachen University. The main interest of his current research includes the synthesis and electrical properties of metal and semiconductor nanoparticles and of nanoporous materials as well as their application in molecular electronics and chemical sensing.

Christof M. Niemeyer is Professor of Chemistry at the University of Dortmund (Germany) where he holds the chair of Biological and Chemical Microstructuring. He was born in Cloppenburg and studied chemistry at the University of Marburg. His PhD thesis on the development of organometallic receptor molecules at the Max-Planck-Institut für Kohlenforschung in Mülheim/Ruhr under the supervision of Manfred T. Reetz was followed by a postdoctoral fellowship at the Center for Advanced Biotechnology in Boston (USA) with Charles R. Cantor, where he switched research fields to study biomolecular recognition systems. He went back to Germany, where he received his habilitation at the University of Bremen before moving to Dortmund in 2002. He is interested in semisynthetic DNA-protein and nanoparticle-conjugates and their applications in life-sciences, catalysis and molecular nanotechnology.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

nanoelectronic, diagnostic or sensing devices.[4–10] Basic research has disclosed that nanoparticles exhibit many properties that are somehow between that of a macroscopic solid or bulk material and that of a single atom or molecule.

Nanoparticles with a diameter of between one and several tens of nanometres, which fall in the intermediate size range between molecules and macroscopic solids, exhibit an electronic structure that is somewhere in between the discrete electronic levels of an atom or molecule and the band structure of a bulk material.[11] Although the concept of band structure can still be applied below a certain size these nanoparticles show a size-dependent splitting of the energy levels that replaces the continuum of the energy bands. In this intermediate state matter reveals new physical properties which now depend on the size of the object under consideration. As its origin is in the quantisation of electronic states, this size-dependent change of physical properties is called the *quantum size effect* (QSE) or *size quantisation effect*.

This raises fundamental questions about the design of "artificial molecules" or "artificial solids" built up from nanoscale subunits that finally lead to a new state of matter. This requires the ordered assembly of uniform nanoparticles in one, two or three dimension, leading finally to the formation of an artificial solid or super lattice. Such an array of nanoparticles exhibits delocalised electron states that depend on the strength of the electronic coupling between the adjacent nanoparticles, whereas the electronic coupling depends on the particle size, the nature and the covering density of the stabilizing organic ligands, on the particle spacing, and on the packing symmetry.[11]

Thus it is a great challenge to organize nanoparticles in one to three dimensions in order to study the electronic and optical coupling between the particles, and to even utilize these coupling effects for the set-up of novel nanoelectronic, diagnostic or nanomechanical devices.[9]

Several attempts have been made to assemble metal nanoparticles in one to three dimensions. These range from Langmuir–Blodgett techniques,[12] molecular self-assembly[13] via covalent linkage[14] and electrostatic coupling up to the deposition within or at pre-structured surfaces.[15] However, most of these methods suffer from a lack of recognition and binding specificity.

In contrast, biomolecules, such as proteins and nucleic acids, have almost perfect binding properties and biochemical functionality that have been optimised over billions of years of evolution. Since they are more readily available by synthetic chemical means and are more convenient to handle than proteins, nucleic acids have preferentially been used for the functionalisation of nanoparticles to provide highly specific binding sites.[16,17] Proteins have also been employed to extend the binding capabilities of inorganic nanoparticles, however, instead of simply utilizing their binding properties, a great challenge is the combination of the intrinsic functionality of many proteins, for instance, optic, catalytic, mechanic or switching capabilities, with the distinct properties of nanoparticles.[18] This topic, however, is beyond the scope of this review article, and we will instead focus here on DNA as a construction material in nanosciences.

The enormous specificity of Watson–Crick base-pairing allows the convenient programming of artificial DNA receptor moieties. The power of DNA as a molecular tool is enhanced by our ability to synthesise virtually any DNA sequence by automated methods[19] and to amplify any DNA sequence from microscopic to macroscopic quantities by the polymerase chain reaction (PCR).[20] Another very attractive feature of DNA is the great mechanical rigidity of short double helices, such that they behave effectively like a rigid rod spacer between two tethered functional molecular components on both ends up to approximately 100 nm. Moreover, DNA displays a relatively high physicochemical stability, and Nature provides us with a variety of highly specific enzymes that allow the processing of the DNA material with atomic precision and accuracy on the angstrom level. No other (polymeric) material offers these advantages, which are ideal for molecular construction in the range from about 5 nm up to the micrometer scale. Consequently, DNA has already been used extensively for construction on the nanometre scale,[21] and recent advances indicate its applicability for fabricating nanomechanical devices.[22,23] Hence, DNA holds the promise of allowing the bottom-up self-assembly of complex nanodevices, where, for example, in the course of further miniaturisation, conductive DNA-based structures could reduce time and cost in future nanofabrication.[24]

It is the aim of this microreview to acquaint the reader with the principle of DNA-based assembly of metal nanoparticles. Therefore, the second section introduces the different methods of liquid-phase synthesis of metal nanoparticles and their functionalisation with DNA. The third section will give an overview of the assembly of nanoparticles in one, two and three dimensions. The properties and the emerging applications of these assemblies will be discussed and illustrated with selected examples.

2. Materials Synthesis

2.1. Liquid-Phase Synthesis of Metal Nanoparticles

The synthesis of ligand-stabilized nanoparticles is usually based on the classical routes of colloid or organometallic chemistry. These are suitable for various metals, usually transition metals, as well as for many semiconductors which have technological applications in the bulk state.[7] Besides radiolytic[25] or photochemical[26] techniques and the controlled deposition of metastable organometallic compounds,[27–29] the most common ways of preparation are the chemical reduction of soluble metal salts by suitable reducing agents (e.g., hydrogen, boron hydride, methanol, citric acid, and others), and electrochemical reduction. In order to stabilize the nanoparticles, to control their size and shape and to prevent them from aggregating, organic ligands need to be added. These ligands are typical colloid chemical stabilizers or electron-donor ligands, like amines, phosphanes or thiols, which stabilize the particles electrostatically or ste-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rically. While the electrostatic stabilisation involves the coulombic repulsion between the particles caused by the charged surface of the nanoparticles and/or by the charge introduced by the respective ligand, steric stabilisation is achieved by ligand molecules that surround the particles as a protective shield. If DNA is used as a ligand, the negative charge of the ribose phosphate backbone introduces negative charge and leads to a predominantly electrostatic stabilisation of the nanoparticles.

The size of the particles is determined by the relative rates of nucleation and particle growth. However, the many control parameters affecting the particle size cannot be analysed separately, so that an established synthesis leading to a well-defined size for one particular metal cannot automatically be transferred to another metal. Nevertheless, many different liquid-phase synthetic routes have been developed which lead to distinct sizes with a narrow particle-size distribution, and which allow the preparation even in multigram scale.

For a detailed description of the synthesis and surface modification of metal nanoparticles the reader might be guided by Daniel and Astruc,[30] Bradley and Schmid,[7] and by Richards and Boennemann.[31] The following chapters will give a brief summary of synthetic routes in the liquid phase, with an emphasis on noble metal nanoparticles, that are typically applied for assembly processes in order to study size and coupling effects.

2.1.1. Chemical Reduction of Metal Salts

The salt reduction route with different types of stabilizing ligands and the wide range of chemical reduction agents has led to a huge variety of metal nanoparticles of different sizes and shapes, with the so-called Schmid cluster $[Au_{55}(PPh_3)_{12}Cl_6]$ being one of the most prominent examples.[32,33] Other examples are $[Pt_{309}phen^*_{36}O_{30}]$[33] or $[Pd_{561}phen_{36}O_{200}]$ (phen* = bathophenanthroline and phen = 1,10-phenanthroline).[34,35] These particles show an extremely narrow particle-size distribution and the idealised formulae of these compounds refer to the so-called geometric magic numbers. According to this model, the metal atoms tend to form a closed geometry of densest sphere packing, where one central atom is surrounded by a closed shell of 12 atoms as next neighbours and a second shell of 42 atoms surrounds this 13-atom arrangement to give a total of 55 atoms, and so on. Larger ligand-stabilized metal nanoparticles are typically not described by their atom number but by their mean diameter, whereas the size distribution typically increases with increasing particle size.

Another approach for the synthesis of nanoparticles involves block copolymers, which are able to form micelles upon addition of a polar or non-polar solvent. These micelles can be regarded as "nanoscopic reactors". After formation of the micelles in a non-polar solvent and addition of a soluble metal salt, the metal ions migrate into the hydrophilic core of the micelles where they are reduced to the metal by addition of a reducing agent. Consequently, the size of the nanoparticles depends on the size of the micelle as well as on the number of metal ions that have been provided to the micelle's core.

As most impressively demonstrated by Möller and coworkers, Au nanoparticles in polystyrene block polyethylene oxide (PS-b-PEO) hexagonally assembled micelles with rather regularly arranged particles 2.5, 4 or 6 nm in diameter can be obtained.[36,37] There, the association of PS-b-PEO for the formation of micelles in a non-polar solvent like toluene was utilized. After adding $LiAuCl_4$ to this solution, the salt was slowly dissolved as the Li^+ ions formed a complex with the polyethylene oxide. Thus, the $AuCl_4$ anions were incorporated as counterions into the micelles, where the nanoparticles were formed by reduction.

2.1.2. Electrochemical Composition of Metal Nanoparticles

An electrochemical route for the synthesis of nanoparticles from Pd or Ni and even from superparamagnetic Co has been developed by Reetz and co-workers.[38] This process, in which the particle size can be controlled in a simple manner by adjustment of the current density, makes use of a simple two-electrode setup in which the sacrificial anode consists of the bulk metal to be transformed into nanoparticles. The supporting electrolyte contains tetraalkylammonium salts, which act as stabilizing ligands in the abovementioned way. Thus, in the overall process the bulk metal is oxidized at the anode, the metal cations migrate to the cathode, and a consecutive reduction takes place with the formation of the ligand-stabilized nanoparticles. Particle sizes in the range of 1.4–4.8 nm and above with a narrow size-distribution can be obtained using this technique. The most striking advantage seems to be the broad variation of the corresponding ligand shell. Since the tetraalkylammonium ions are simply added to the reaction mixture, the thickness of the ligand shell can easily be varied by changing the length of the alkyl chain.

2.2. Synthesis of DNA-Functionalized Nanoparticles

The solid-phase synthesis of DNA oligomers as well as of other native and non-natural nucleic acid derivatives is nowadays routine technology, and DNA sequences up to about 120 nucleotides in length, modified with a large variety of chemical substituents, such as amino and thiol groups attached to the 3′- or 5′-terminus, are readily available by a multitude of commercial suppliers at relatively low costs. These materials are typically used in the synthesis of DNA-modified gold nanoparticles (DNA AuNPs). Most protocols for the synthesis of DNA AuNPs go back to the initial description of these materials by Mirkin and coworkers.[39] Briefly, citrate-stabilized AuNPs are simply mixed with DNA oligomers derivatized with alkylthiol groups at the 3′- or 5′-terminus, incubated for prolonged times of up to several days, and then purified by repeated centrifugation to remove unbound oligomers from the supernatant. The resulting DNA AuNPs are water-soluble and stable for months. Slight variations of the initial protocol have been reported by Mirkin[40] and Niemeyer.[41] The latter, for instance, has reported the synthesis of "oligofunc-

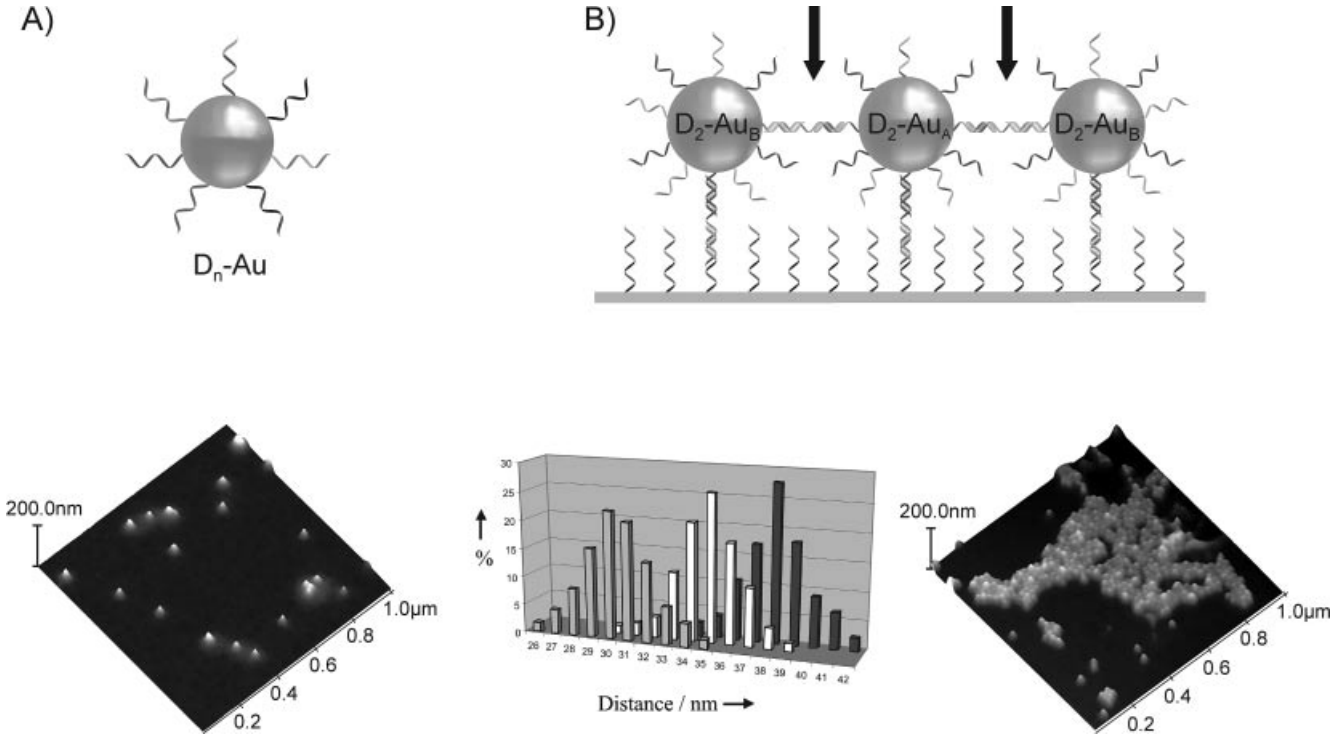

Figure 1. A) Schematic drawing of oligofunctional DNA–gold nanoparticle conjugates (**D_n-Au**) containing various coding oligonucleotides. B) Schematic drawing of DNA-directed immobilisation of cross-linked bifunctional DNA–gold nanoparticles (**D_2-Au**). Two different types of particles (**D_2-Au_A** and **D_2-Au_B**) are immobilized at surface-bound capture oligomers using one of the coding oligonucleotides and are simultaneously cross-linked using the second coding oligonucleotide. Note that both the immobilisation and the interparticle crosslinking is conducted by a trimolecular oligonucleotide linkage. Bottom: AFM images of layer assemblies prepared in the absence (left) or in the presence (right) of crosslinking oligonucleotide.[92] The inset shows the dependency of the particle's centre-to-centre distances on the length of the crosslinking oligomer used.[93]

tional" DNA AuNPs, that contain more than one coding sequence (**D_n-Au** in Figure 1).[42] The index *n* in **D_n-Au** denotes the number of different sequences attached to the nanoparticle, ranging from two (difunctional) up to seven (heptafunctional). The **D_n-Au** nanoparticles reveal almost unaltered hybridisation capabilities as compared to conventional monofunctional conjugates. Due to the extraordinary specificity of Watson–Crick base-pairing, the various oligonucleotide sequences can therefore be individually and selectively addressed as members of an orthogonal coupling system present at the particle's surface.

Applications of such oligofunctional DNA AuNPs are discussed below in Section 3.2.2. It is particularly noteworthy that it is most helpful for many applications to be able to quantify the coverage of the DNA AuNP's surface with DNA oligomers. To achieve this, the fluorescence-based assay of Demers et al.[43] is highly recommended. Moreover, DNA AuNP might, if necessary, be purified by gel electrophoresis, as described by Alivisatos and co-workers.[44,45]

Other approaches have been reported to increase the stability of DNA AuNPs, including the use of polymers[46] and dithiol[47] and trithiol linkers[48] between the DNA moiety and the gold particle. Interestingly, Brust and co-workers have used short peptides with the sequence CALNN to produce very stable AuNPs[49] that can also be further functionalised by attachment of DNA oligomers.

3. Nanoparticle Assemblies & Properties

3.1. Three-Dimensional Assemblies

3.1.1. DNA-Directed Self-Assembly

Following the initial approach of Mirkin's group, DNA hybridisation has been used to generate repetitive, three-dimensionally linked nanoparticle assemblies (Figure 2) where two non-complementary oligonucleotides are coupled in separate reactions with 13-nm gold particles by thiol adsorption.[39] A DNA duplex molecule containing a double-stranded region and two cohesive single-stranded ends, which are complementary to the particle-bound DNA, was used as a linker. Addition of the linker to a mixture of the two oligonucleotide-modified nanoparticles led to the aggregation and slow precipitation of the macroscopic DNA–nanoparticle network. This process is reversible. Since the nanoparticles contain multiple DNA molecules, the oligomerised aggregates are three-dimensionally linked, as can be seen by TEM. Typical images reveal close-packed assemblies of the colloids with uniform particle separations of about 6 nm, corresponding to the length of the DNA linker duplex.

This assembly scheme can also be used for the generation of binary networks comprised of different types of particles. Due to the specificity of Watson–Crick base-pairing, only heterodimeric "A-B" composites of alternating particles are

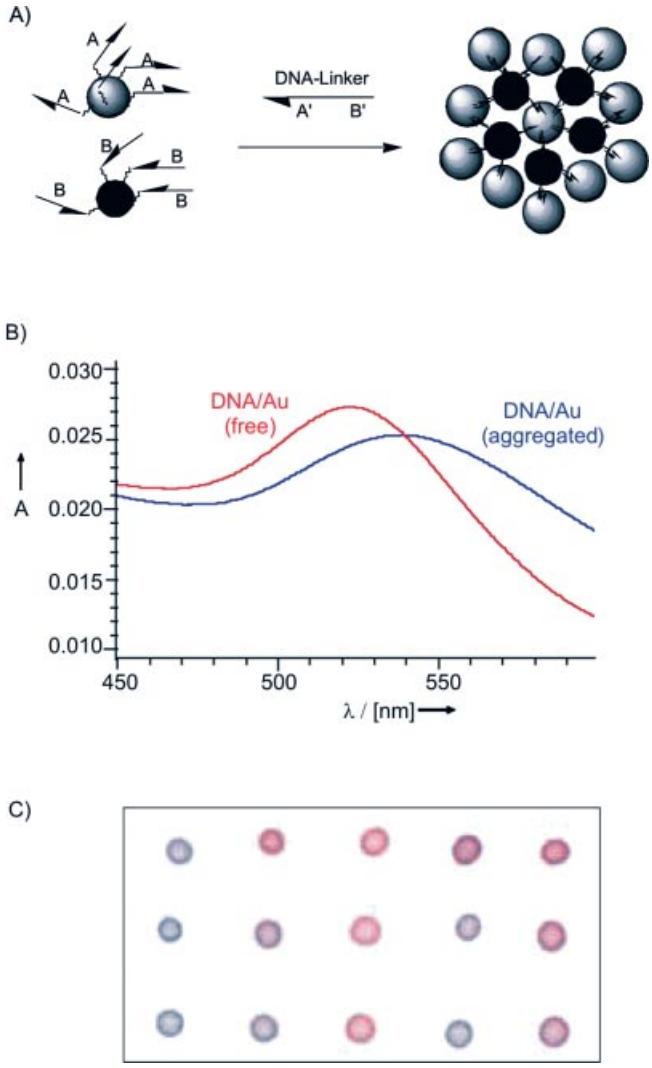

Figure 2. A) Three-dimensional assembly of gold colloids using DNA hybridisation. Two batches of gold particles are derivatized with non-complementary oligonucleotides by either 5′- or 3′-thiol groups. The nanoparticles are oligomerised with a single-stranded nucleic acid linker molecule. Note that only heterodimeric "A–B" linkages are present within the network. B) The network formation leads to a characteristic change in the plasmon absorption. The colour change can be used to macroscopically detect DNA hybridisation using an assay in which DNA/Au conjugates and a sample with potential target DNA is spotted on a hydrophobic membrane. C) Red spots indicate the absence of fully matched DNA, while blue spots are indicative of the presence of complementary target DNA. Data in part C) are reprinted from J.J. Storhoff et al. *Chem. Rev.* **1999**, *99*, 1849–1862. Copyright 1999, American Chemical Society.

formed (Figure 2). For example, two types of gold clusters of either 40 nm or 5 nm diameter have been assembled by DNA hybridisation. In the case of an excess of one particle, satellite-like aggregate structures can be generated and characterised by TEM. Similarly, it has been shown that oligonucleotide-functionalised CdSe/ZnS QDs can be specifically assembled with gold nanoparticles to form binary nanoparticle networks.[50] TEM analysis revealed that the hybrid metal/semiconductor assemblies exhibited the expected A-B structure, and fluorescence and electronic absorption spectroscopy indicated cooperative optical and electronic phenomena within the network materials.

Mirkin et al. have demonstrated that the oligomerisation of DNA-coated gold nanoparticles, depicted in Figure 2, can also be mediated by conjugates comprised of oligonucleotides attached to the streptavidin (STV) protein. Interestingly, the thermodynamically most stable oligomeric networks were only formed upon heating of the kinetically controlled adducts produced initially.[51] Additional topics of fundamental research on DNA/protein nanoparticle interaction concern the investigation of whether and how DNA-functionalised particles can be manipulated by DNA-modifying enzymes.[18] Particles of different morphology, especially rods and sticks, have also been assembled by means of DNA hybridisation.[52,53]

3.1.2. Materials Properties

Studies of DNA-linked gold nanoparticle assemblies concern the influence of the DNA spacer length on the optical,[54] electrical[55] and melting properties[56] of these networks. These experiments provided evidence that the linker length controls the size of the aggregates kinetically, and that the optical properties of the nanoparticle assemblies are governed by aggregate size.[54] In contrast, it has been found that the electrical properties of dry nanoparticle aggregates are not influenced by the linker length.[55] Although SAXS clearly indicates the linker length-dependent distances between particles in solution, the networks collapse upon drying to form bulk materials comprised of nanoparticles covered with an insulating film of DNA. These materials show semiconductor properties that are not influenced by the linker lengths.[55] The strongly cooperative melting effect of the nanoparticle networks[56] results from two key factors: the presence of multiple DNA linkers between each pair of nanoparticles, and a decrease in the melting temperature as DNA strands melt due to a concomitant reduction in local salt concentration. This mechanism, originating from short-range duplex-to-duplex interactions, is independent of DNA base sequences and should be universal for any type of nanostructured probe that is heavily functionalised with oligonucleotides.[56]

3.1.3. Applications

Gold nanoparticles functionalised with proteins have long been used as tools in biosciences.[57] For instance, antibody molecules adsorbed to 10–40-nm colloidal gold are routinely used in histochemistry for the biospecific labelling of certain regions of tissue samples and subsequent TEM analysis. In contrast, applications of DNA-functionalised Au particles were introduced only a few years ago by Mirkin and co-workers.[58] The DNA-directed nanoparticle aggregates depicted in Figure 2 can be used for simple and cheap sensors in biomedical diagnostics, for example for the detection of nucleic acids from pathogenic organisms. Therefore, the major field of applications of AuNP 3D-assemblies concerns the diagnostics of nucleic acid. Many excellent review articles are available[9,16,17,59,60] summarising this field of application. However, most of the analytical

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

applications are based on solid-supports (see below), and therefore we will highlight just a few representative examples of 3D assembly in homogeneous solution here.

The sensitive detection of nucleic acids in homogeneous solutions has been achieved by self-assembled oligomerisation[61] or by the use of DNA beacons tethered to nanoparticles.[62] DNA beacons are single-stranded DNA (ssDNA) molecules that form an intramolecular hairpin-loop structure.[63] Both ends are chemically modified with a fluorophore and a quencher dye, the latter of which, due to close spatial proximity, effectively quenches the fluorescence. Upon hybridisation with nucleic acid targets containing a sequence stretch complementary to the loop region of the beacon, the quencher is spatially removed from the fluorophore, which leads to a strong enhancement in fluorescence. A novel class of molecular beacons has been introduced in which the organic quencher dye is replaced by a gold nanoparticle.[62] The quenching efficiency was determined to be about 99.5%, which indicates that the fluorescent signal of the beacon increases about 200-fold upon hybridisation with a complementary target. This type of gold-oligomer-dye hybrid beacon allows the detection of single-base mutations more efficiently than conventional molecular beacons.

Another very interesting observation has been reported by Maeda et al.,[64,65] who discovered that the aggregation of gold nanoparticles even occurs by non-cross-linking DNA hybridisation. This principle might be utilized to design novel assays for the rapid detection of nucleic acid targets.

The DNA-directed assembly of AuNPs has been coupled with functional DNA structures that are capable of carrying out a specific cleavage reaction. With respect to the enzyme-like performance, such a sequence is called a "DNAzyme". The incorporation of a DNAzyme into the particle-interconnecting DNA oligonucleotides allows the rapid and sensitive detection of a range of targets, such as Pb^{2+} ions or adenosine.[66–68]

In addition to the immediate applications of 3D-assembly in diagnostics, the DNA molecules attached to the nanoparticles can also be utilized as actuators for the assembly and switching of (bio)chemical reactions.[22] For instance, gold nanoparticle–DNA molecular beacon conjugates have been exploited for the remote electronic control of DNA hybridisation.[69] Inductive coupling of a radio-frequency magnetic field (RFMF) with a frequency of 1 GHz to the 1.4-nm metal nanoparticle, which functions as an antenna in the DNA constructs, leads to an increase in the local temperature of the bound DNA, thereby inducing denaturation while leaving surrounding molecules relatively unaffected. Since inductive heating has already been applied to the treatment of cancer cells with magnetic-field-induced excitation,[70] the use of gold nanocrystal–DNA conjugates should allow extension of this concept to novel applications. For instance, complex operations, such as gene regulation, biomolecular assembly and enzymatic activity, of distinct portions of nucleic acids or proteins might be controlled, while the rest of the molecule and neighbouring species would remain unaffected. Moreover, because the control is not optical, this technology could even be applicable in highly scattering media.[69]

Another example concerns the reversible switching of gold nanoparticle aggregation by means of "fuelling oligonucleotides" F_a and F_d in Figure 3.[23] The base sequence of F_a is comprised of three stretches, a′ and b′, which are complementary to 23-nm Au-nanoparticle-bound 12-mer oligomers a and b, respectively, as well as stretch c′, which promotes hybridisation of F_a and F_d. The transformation cycle starts with state I, in which the DNA–nanoparticles are dispersed and reveal a characteristic plasmon absorption maximum at 526 nm. Upon addition of oligomer F_a, the particles aggregate (state II in Figure 3), and consequently the plasmon absorption band is damped and shifted towards longer wavelengths at about 625 nm. In the next step, oligomer F_d is added, which is fully complementary to F_a and can hybridize with it, starting at the dangling end stretch c′ of the duplex DNA interconnecting the nanoparticles. This process, schematically shown as an intermediate state III in Figure 3, leads to the formation of a waste duplex and the redispersion of the nanoparticles. Hence, an increase in absorbance at 526 nm occurs again. Because this paper demonstrated for the first time that nanoparticle aggregation can be reversed at room temperature under physiological conditions, applications in the area of switchable (bio)materials for technical purposes and prosthetics might be foreseen.[23]

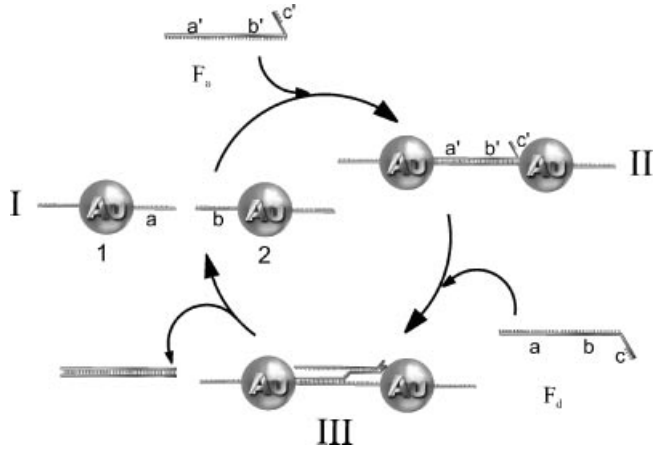

Figure 3. Schematic drawing of the reversible aggregation of DNA-modified gold nanoparticles utilizing fuelling oligonucleotides (F_a and F_d) containing three stretches (a, b and c) that are complementary to the gold-nanoparticle-bound 12-mer oligomers (a and b). Stretch c′ forms a dangling end in the aggregated particles (state II) which promotes the hybridisation of F_a and F_d (intermediate state III). Reprinted with permission, from ref.[23].

3.2. Two-Dimensional Assemblies

3.2.1. Assembly at Interfaces for Diagnostic Applications

In addition to the 3D assembly in homogeneous solution, the use of DNA-functionalised nanoparticles in the heterogeneous nucleic acid hybridisation with capture oligo-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nucleotides attached to solid supports has recently attracted much attention. Many groups have reported the DNA-directed immobilisation of gold nanoparticles to form supramolecular surface architectures,[71–80] and this approach has also been adopted to the specific sorting of DNA-functionalised quantum dots.[81] The specific nucleic acid-mediated immobilisation of gold nanoparticles can be utilized for the topographic labelling of surface-bound DNA targets. This readily allows the highly sensitive scanometric detection of nucleic acids in DNA-chip analyses by means of the gold-particle-promoted reduction of silver ions (Figure 4), which allows an almost 100-fold increase in sensitivity compared to conventional fluorescent DNA detection.[71] This approach has also been adopted for the array-based electronic detection of nucleic acid analytes.[79] To this end, DNA-functionalised nanoparticles have been immobilized in the gaps of microelectrodes by biospecific interaction. However, the particle density was too low to allow electron conduction between the electrodes. Thus, in a subsequent step, the nanoparticle assembly had to be metallized by reductive deposition of silver, which finally led to a conducting contact between the electrodes. The resulting decrease in ohmic resistance was used as a positive signal for the sensing of the biospecific interaction to be detected.[79]

The use of colloidal gold nanoparticles also allows signal enhancement in DNA hybridisation detection using a quartz crystal microbalance,[72,75] angle-dependent light scattering[82] and surface-plasmon resonance (SPR).[83]

The size-selective light scattering of 50- and 100-nm diameter Au nanoparticles has been used for the two-colour labelling of oligonucleotide arrays.[78] An alternative for the simultaneous determination of multiple DNA targets, the use of Raman-active dye labelled gold nanoparticles, has recently been explored.[84] The gold nanoparticles facilitate the formation of a silver coating that acts as a surface-enhanced Raman scattering promoter for the dye-labelled particles that have been captured by target molecules and an underlying chip in a microarray format. This approach provides the high sensitivity and high selectivity attributes of grey-scale scanometric detection but adds multiplexing and ratioing capabilities because a very large number of probes can be designed based on the concept of using a Raman tag as a narrow-band spectroscopic fingerprint.

DNA-tagged proteins have been immobilized at DNA-functionalised gold nanoparticles by specific nucleic acid hybridisation.[85] This approach has several advantages over the conventional methods to adsorb proteins to colloidal gold. The biofunctionalised nanoparticles not only retain

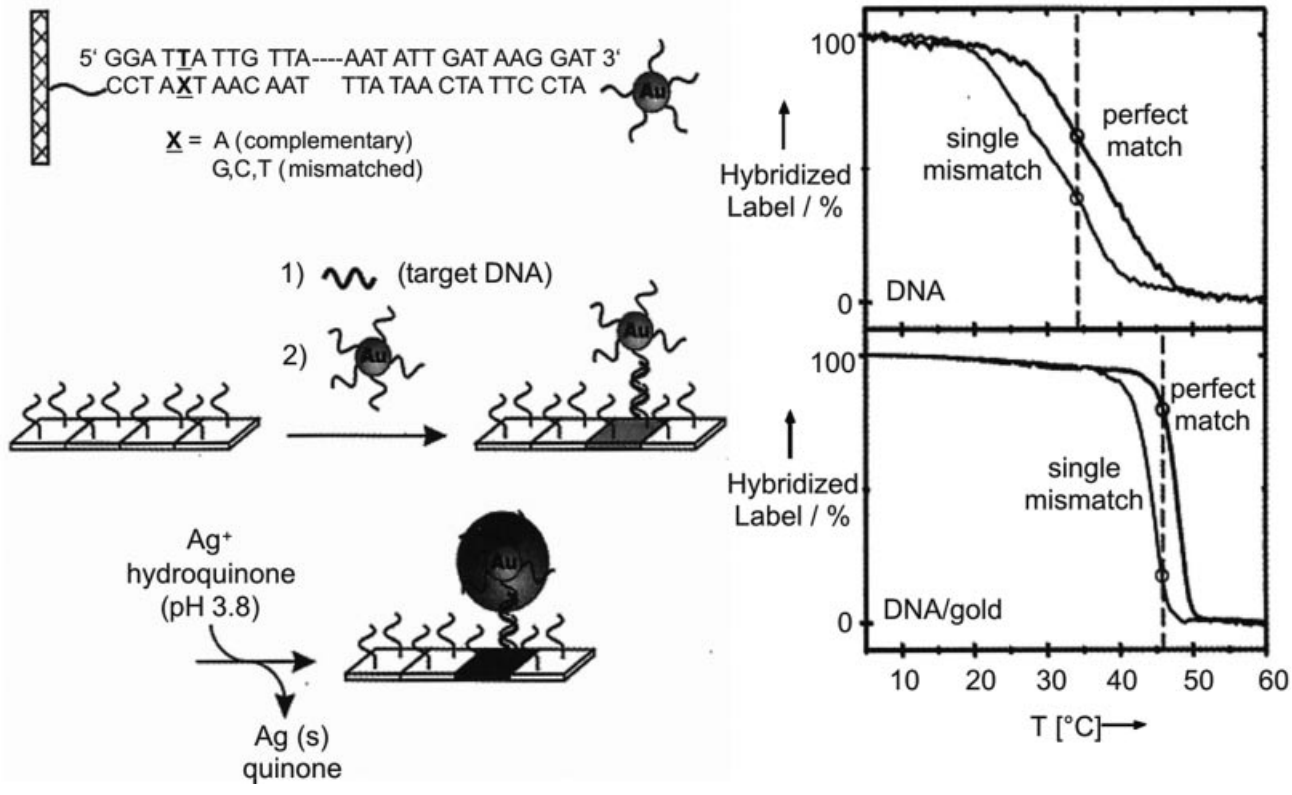

Figure 4. Scanometric detection of nucleic acids in DNA-chip analyses. Capture oligonucleotides immobilized on glass slides are used for specific binding of target nucleic acids. Oligonucleotide-functionalised gold nanoparticles are employed as probes in solid-phase DNA hybridisation detection. Subsequent to a silver enhancement step, the immobilisation of the colloidal gold probe is detected by scanning the glass substrate with a conventional flat-bed scanner. Despite its simplicity, this technique allows for an almost 100-fold increased sensitivity compared to fluorescent DNA detection. Moreover, due to the extraordinarily sharp melting behaviour of the immobilized DNA–nanoparticle networks (see melting curves on the right), this method allows for single-mismatch detection.  © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the undisturbed recognition properties of the proteins immobilized, but they also reveal an extraordinary stability that even allows for regeneration of the DNA-coated gold particles. These type of bioinorganic hybrid components have been used as reagents in sandwich immunoassays for the detection of proteins using the gold-particle-promoted silver development, allowing for the spatially-addressable detection of femtomolar amounts of chip-immobilized antigens.[85] Recently, this approach was adopted to difunctional DNA AuNPs, thereby significantly enhancing the versatility of nanoparticle probes.[86] Moreover, DNA AuNPs with antibody molecules attached have been used as probes in the sensitive detection of proteins by means of the biobarcode approach.[87–90] These types of metal nanoparticle-based detection systems have been recently reviewed elsewhere.[10,91]

3.2.2. 2D-Assembly for Novel Materials

While monofunctional DNA–nanoparticle conjugates containing just a single recognition site, i.e. an oligonucleotide sequence, were employed in the studies described above, we have recently explored oligofunctional gold nanoparticle conjugates containing different DNA sequences (**D_n-Au** in Figure 1).[42] This type of particle can be considered as a "versatile particle", since, due to the extraordinary specificity of Watson–Crick base-pairing, the various oligonucleotide sequences can be individually and selectively addressed as members of an orthogonal coupling system present at the particle's surface.

As an example, we have shown that difunctional DNA–nanoparticle conjugates (**D_2-Au**) containing two different DNA oligomers self-assemble by DNA hybridisation into surface-bound layers comprised of closely packed, cross-linked nanoparticles (Figure 1).[92] In this approach, the two different DNA sequences of **D_2-Au_A** were utilized such that particle-bound oligomer **1** was used for immobilisation purposes by connecting the particles to surface-bound capture oligomers **4** through the complementary linker **5**. The second type of particle-bound oligomers (**2**) of **D_2-Au_A** was used to establish cross-links to neighbouring particles (**D_2-Au_B** in Figure 1) by means of linker **6**, which is complementary to the sequences **2** and **3** attached to particles **D_2-Au_A** and **D_2-Au_B**, respectively. We reasoned that this approach should lead to densely packed and potentially even ordered monolayers of nanoparticles in which the distance between the individual particles should be adjustable by changing the length of **6**.[92] While the initial study clearly proved the concept of inter-particle DNA cross-linking, no influence of **6** on the interparticle distances was observed by scanning force microscopy (SFM) analysis.[92]

In a recent continuation using in situ SFM studies, we have shown that the self-assembly of difunctional DNA-modified gold nanoparticles at solid substrates does indeed generate particle layers with programmable interparticle spacings.[93] A comparison of these results with earlier work[55,92] indicated that the DNA spacers are highly sensitive to environmental conditions, particularly the degree of hydration of the DNA double helix. Further exploration and refinement of this approach, especially the careful design of the oligomer sequences involved,[94] may eventually pave the way towards nanostructured materials with programmable functionalities for a broad range of applications in materials research and nanobiotechnology.[93]

3.3. One-Dimensional Assemblies

Two fundamentally different approaches have been applied for the formation of one-dimensional assemblies of metal nanoparticles along a DNA backbone. The first approach is to immobilize pre-formed nanoparticles preferably at specific sites along the DNA backbone, while the second approach applies to the direct metallisation of the DNA double strand by reducing the charge-compensation cations (e.g. Ag^+, Pd^{2+}) that were introduced by ion-exchange before. Both procedures have their inherent advantages and disadvantages. While the site-selective immobilisation of pre-formed nanoparticles can take advantage of the precise size control and the defined surface chemistry of the well-elaborated synthetic routes, it is a difficult task to assemble the particles in direct contact to each other over extended domains with an interparticle spacing that is identical and small enough to allow direct dipolar coupling or even electronic transport along the array. The metallisation by metal-ion reduction has successfully led to the formation of highly-conductive nanowires, which could be applied as metallic interconnects. However, the nanoparticles formed during this process suffer from an extraordinarily broad size distribution. Thus, the metal structures along the DNA wires are highly disordered, and none of the size-specific electronic transport properties, which are based on single-electron tunnelling, could be observed or even utilized in nanodevices. In the following section we give an overview of the different methods that have been developed following these two strategies by means of selected examples.

3.3.1. Immobilisation of Nanoparticles on DNA

As previously demonstrated for proteins,[95] Alivisatos and co-workers showed for the first time that a discrete number of water-soluble Au_{55} clusters with one *N*-propylmaleimide ligand per cluster can couple selectively to a sulforyl group incorporated into ssDNA oligomers.[96] Oligonucleotides modified at either the 3′- or 5′-terminus with a free sulforyl group were coupled with an excess of the nanoparticles. After being combined with suitable oligonucleotide templates, parallel (head-to-tail) and antiparallel dimers (head-to-head) were obtained (**7a**–**7c**, respectively, see part B in Figure 5). The linear alignment of the clusters and the centre-to-centre distance, which ranged from 2–6 nm, were illustrated by means of TEM images. These nanoparticle–DNA conjugates have a high flexibility when the DNA backbone is nicked, while an un-nicked double helix significantly lowers the flexibility (for instance, see **7d** in Figure 5). UV/Vis absorbance measurements indicated changes in the spectral properties of the nanoparticles as a consequence of the supramolecular organisation.[97]

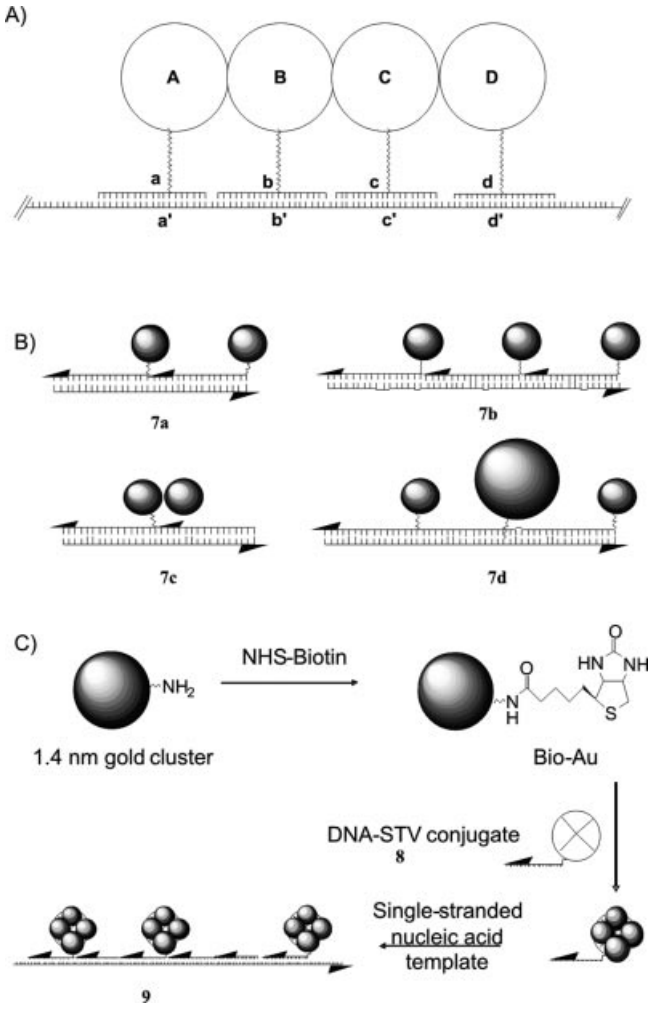

Figure 5. A) Schematic representation of DNA-directed one-dimensional assembly of four different nanoscale building blocks to form a stoichiometrically and spatially defined supramolecular aggregate. B) Assembly of nanocrystal molecules using DNA hybridisation. Conjugates from gold particles (represented as shaded spheres) and 3′- or 5′-thiolated oligonucleotides allow the fabrication of head-to-head (**7a**) or head-to-tail (**7b**) homodimers. A template containing the complementary sequence in triplicate effects the formation of the trimer **7c**. Aggregate **7d** has limited flexibility due to the un-nicked double helical backbone. C) DNA-directed assembly of biotinylated gold nanoclusters using covalent DNA-STV conjugates **8** as molecular adaptors. The nanocluster-loaded STV conjugates self-assemble in the presence of a single-stranded nucleic acid carrier molecule containing complementary sequence stretches to form biometallic aggregates, such as **9**. Reprinted with permission from C. M. Niemeyer, *Angew. Chem. Int. Ed.* **2001**, *40*, 4128–4158.

Noyong et al. have reported the synthesis of string-of-pearl-like alignments of 4-nm Au nanoparticles along DNA strands.[98] In the first step, *cis*-$[PtCl_2(NH_3)_2]$ (cisplatin) is incorporated into DNA-double strands of DNA plasmids. This platinum complex has a high affinity for nitrogen donor sites in nucleotides and therefore binds with high selectivity in neighbouring guanine-guanine nucleobases.[99] This process is well established in medicine, where cisplatin has been used as an anticancer drug for more than 30 years. In its intra-strand position Pt^{2+} is accessible for ligand exchange. Therefore, in a second step, the nanoparticles stabilized by cysteamine can selectively bind to the Pt^{2+} centre by exchange of the NH_3-ligands with H_2N-termini of the ligand shell (Figure 6).

The initial demonstration of the use of DNA as a framework for the precise spatial arrangement of molecular components was carried out with covalent conjugates of single-stranded DNA oligomers and the STV protein.[95] Using the STV-DNA conjugates **8** (Figure 5B) as model systems, a variety of essential basic studies on the DNA-directed assembly of macromolecules were carried out, which have been reviewed earlier.[100] The covalently attached oligonucleotide moiety supplements the STV's four native biotin-binding sites with a specific recognition domain for a complementary nucleic acid sequence. This biospecificity allows the use of DNA-STV conjugates as adapters to assemble basically any biotinylated compound along a nucleic acid template.[100] For example, the strong biotin-STV interaction and the specific nucleic acid hybridisation capabilities of the DNA-STV conjugates **8** have been utilized to organize gold nanoparticles (Figure 5C).[101] To this end, 1.4-nm gold particles containing a single amino substituent have been derivatized with a biotin group and the resulting biotin moiety subsequently used to organize the nanoparticles into a tetrahedral superstructure defined by the biotin-binding sites of the STV. Subsequently, the nanoparticle-loaded proteins self-assemble in the presence of a complementary single-stranded nucleic acid carrier molecule to form nanoparticle assemblies such as **9** (Figure 5C).

The strong biotin–STV interaction together with the specific nucleic acid hybridisation capabilities of DNA have recently been utilized for the controlled assembly of 5-nm Au particles along linear arrays of DNA triple cross-over molecules (TX).[102] As illustrated in Figure 7, the TX molecule consists of seven oligonucleotides, which are hybridized to form three double-stranded helices. These lie in a plane and are linked by strand exchange at four immobile crossover points. The design of the TX molecule is shown in part a of Figure 7. It contains two protruding stem loops, one each from the upper and the lower helices. Thus, a linear array of TX molecules can be obtained by designing three pairs of sticky ends. For illustration, their complementarity is represented by matching colour and geometric shape in part b of Figure 7. In order to template the assembly of 5-nm nanoparticles, streptavidin molecules were selectively bound to biotin groups, which are incorporated into the hairpin loops and are indicated by the small blue dots. In the next step, Au nanoparticles were conjugated to the streptavidin, resulting in a periodic sequence of uniform particles along the linear TX DNA. Figure 7 (parts c and d) shows SEM images of streptavidin/DNA-templated Au nanoparticle arrays. In the first template (c), only one stem loop in each TX molecule is modified with biotin groups, whereas in the second template (d) both stem loops are modified with biotin groups, leading to the formation of single and double rows of nanoparticles, respectively.[102] Kiehl and co-workers have reported similar approaches that use self-assembled DNA nanoarrays comprised of crossover

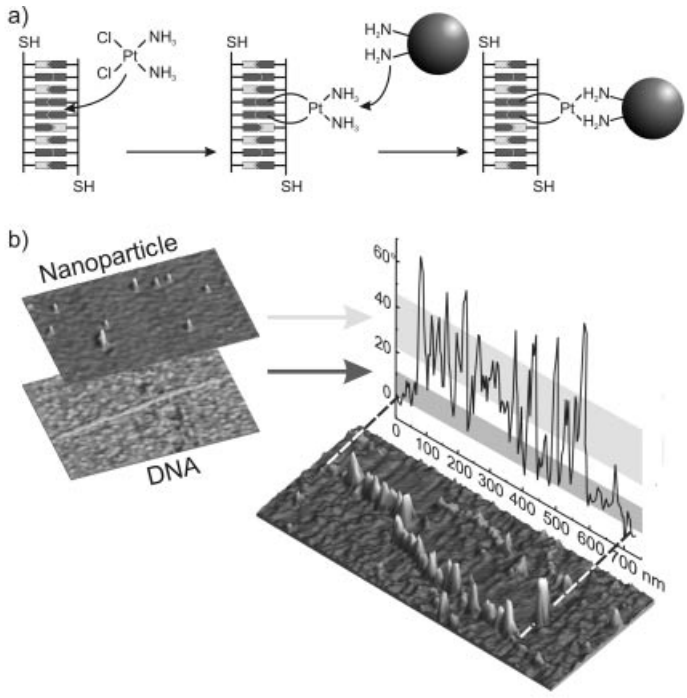

Figure 6. a) Scheme for the organisation of Au nanoparticles along DNA by coupling of NH_2-functionalised (cysteamine) Au nanoparticles at cisplatin-functionalised DNA by simple ligand replacement. b) AFM image (phase contrast) of DNA-aligned Au nanoparticles assembled on a silicon substrate (adapted from ref.[98]).

motifs to produce regular one- and two-dimensional assemblies of gold nanoparticles.[103,104] These reports suggest that programmable DNA arrays will open up novel, powerful routes to the production of precisely assembled nanoparticles.

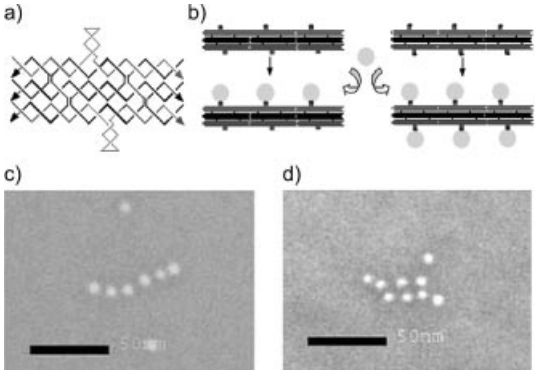

Figure 7. a) Design of the TX molecule and b) schematic drawing of the TX DNA-templated self-assembly of streptavidin linear arrays. c) and d) SEM images of the DNA-templated assembly of 5-nm Au particles (reproduced with permission from ref.[102]).

A first step towards device fabrication has been demonstrated by Kretschmer and Fritsche,[105] who have reported the integration of DNA-templated Au nanoparticles into microelectrode gaps. The microelectrode structures were fabricated by standard photolithography, and the assembly of nanowires consisting of Au nanoparticles in a string-of-pearl-like arrangement spanning the gap was achieved by dielectrophoresis. In a comprehensive study, the different control parameters of formation, the electrical transport properties and the stability of these arrays that lead finally to nanowires consisting of almost uniform nanoparticles that exhibit ohmic behaviour were analysed. The most important results of that work are displayed in Figure 8, which shows SEM images of nanowires bridging an electrode gap of 1 μm. Dielectrophoresis leads to a high number of nanowires, although the magnification shows that the main parts of these wires consist of pearl chains, whereas the diameter of the particles is about 15 nm. The zoom (inset in b) shows the excellent preservation of the individual particles.

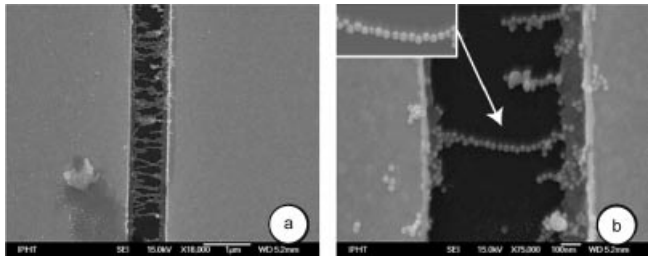

Figure 8. SEM images of microelectrode structure with immobilized DNA-templated nanowires (for explanation see text; reproduced with permission from ref.[105]).

By going to significantly smaller particles of 1.5 nm, which have a much greater potential to serve as building blocks in future nanoelectronic devices due to their enhanced charging energy, Hutchinson and co-workers have elaborated a method to organize the 1.5-nm gold particles

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

into linear chains with precisely controlled interparticle spacing over a range of 1.5–2.8 nm.[106,107] These chains are formed in solution by utilizing functional-group-directed self-assembly to organize ligand-stabilized gold nanoparticles onto DNA templates. In this configuration, the spacing between neighbouring nanoparticles is determined by the thickness of the ligand shell stabilizing the nanoparticles and can therefore be tuned at the molecular level by variation of the ligand shell at spacings of 1.5, 2.1 and 2.8 nm with a standard deviation of ≤20%. The ligands that are used for this immobilisation process are (2-mercaptoethyl) trimethylammonium iodide (TMAT, **1**), [2-(2-mercaptoethoxy)ethyl]trimethylammonium toluene-4-sulfonate (MEMA, **6**), and {2-[2-(2-mercaptoethoxy)ethoxy] ethyl}trimethylammonium toluene-4-sulfonate (PEGNME, **11**).

Because the interparticle spacing is enforced by the ligand shell rather than by the scaffold, the spacing is uniform even in nonlinear sections of the chain. This allows the assembly of particles over extended areas up to 1 μm in length and a total coverage of >90%. Figure 9 shows the immobilisation scheme and representative TEM images of linear nanoparticle chains of Au_n-TMAT, Au_n-MEMA and Au_n-PEGNME assembled on λ-DNA. The spacing between neighbouring nanoparticles increases systematically with increasing ligand shell thickness from 1.5 nm ± 0.3 nm in Figure 9A (Au_n-TMAT), through 2.1 ± 0.4 nm in Figure 9B (Au_n-MEMA) to 2.8 nm ± 0.4 nm in Figure 9C (Au_n-PEGNME). The interparticle spacing corresponds to the double thickness of the ligand shell assuming that the stabilizing ligands are in a fully extended conformation, i.e. 1.4 nm for TMAT-functionalised nanoparticles, 2.1 nm for nanoparticles stabilized by MEMA and 2.8 nm for PEGNME-functionalised nanoparticles. The small standard deviations indicate the reproducibility and reliability of this method for generating evenly spaced nanoparticle chains with a high degree of control.

Besides DNA, other chain-like bimolecules have also been used for the one-dimensional assembly. As an example, Bae et al. have recently demonstrated the assembly of one-dimensional arrays of 5-nm Au-nanoparticles using schizophyllan (SPG).[108] SPG is a natural polysaccharide produced by the fungus *Schyzophyllum commune*, which adopts a triple-helical conformation under native conditions. This structure was reversibly dissociated into single chains, which then served as the template for the assembly of the nanoparticles during triple-helix formation.

3.3.2. Metallisation of DNA

Direct metallisation of DNA has been employed by Braun et al. in order to create conductive silver wires.[109] In a multistep process, lithographically fabricated gold elec-

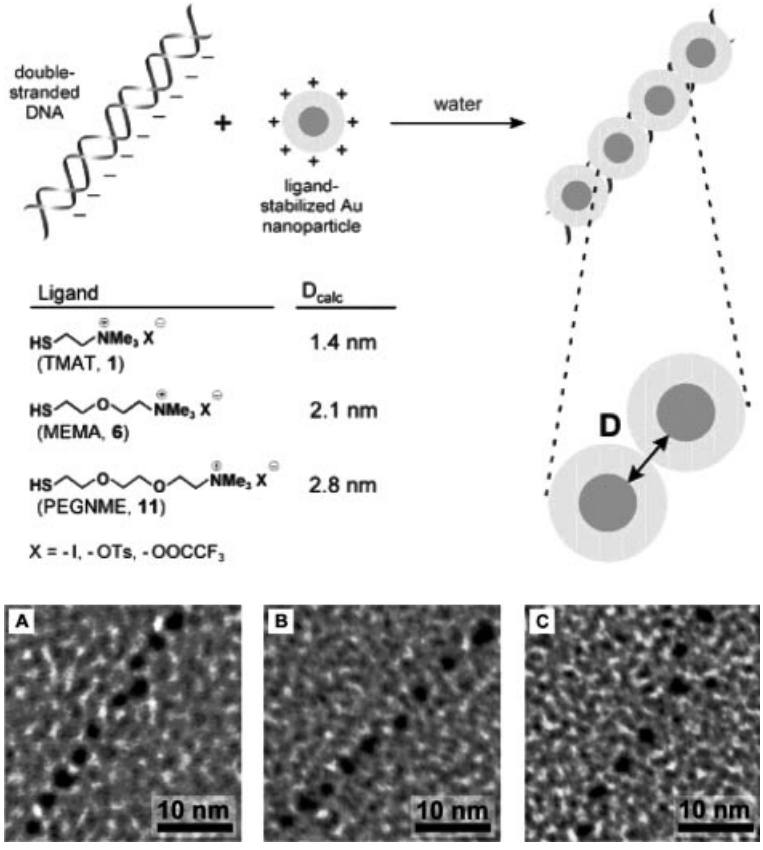

Figure 9. Schematic representation of the solution-phase formation of linear, close-packed DNA–nanoparticle assemblies. The three ligands used are shown in the figure. Below: the TEM images of linear, close-packed nanoparticle–DNA assemblies. The TEM micrographs demonstrate the use of three different ligands to produce linear arrays with different spacing between neighbouring nanoparticles (reproduced with kind permission from ref.[106]).

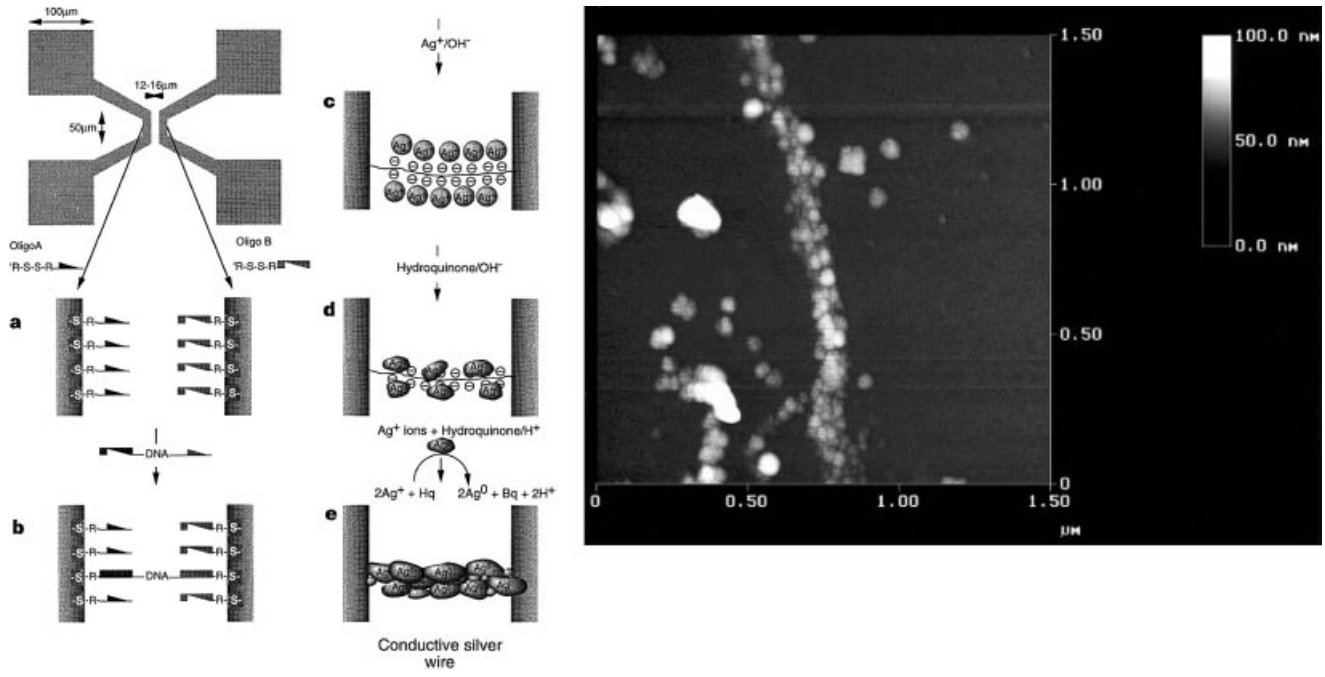

Figure 10. Left: Construction of a nanowire bridging the gap between two gold electrodes. The Ag^+ ions were deposited on the DNA bridge and subsequently reduced to form metallic nanoparticle agglomerates. Right: AFM image of the nanowires illustrating the granular structure (reproduced with permission from ref.[109]).

trodes were functionalised with disulfide-functionalised 12-base oligonucleotides. DNA that contains two 12-base sticky ends, where each of the ends is complementary to one of the two different sequences, was attached to the gold electrodes. Then, an Ag^+ solution was introduced to the surface, which induced an exchange of the charge-compensating Na^+ ions by Ag^+. Reduction with hydroquinone induced the formation of DNA-associated Ag^0 aggregates along the DNA strand. In a following development process, further Ag^+ was reduced to finally provide the metal growths, leading to individual silver nanowires with an average diameter of 100 nm with a pronounced granular structure.

The AFM image in Figure 10 indicates that the wire consists of grains 30–50 nm in diameter deposited along the DNA skeleton. Two-terminal electrical measurements on the silver wire showed that, depending on the silver growth conditions, the differential resistance at voltages beyond the plateau, which is caused presumably by Coulomb charging and/or corrosion effects, varies between 7 and 30 MΩ. Recent continuation of this work has demonstrated original and innovative concepts for tailoring the structural diversity and connectivity of DNA architectures, which is essential for the construction of more complex electronic components and circuits.[110,111]

A similar procedure has also been applied by Harnack et al.[112] and by Richter et al.[113] Harnack et al. have immobilized tris(hydroxymethyl)phosphane-capped gold nanoparticles 1–2 nm in diameter densely on calf thymus DNA. These particles are active catalysts for electroless plating of gold leading to the formation of nanowires with widths of 30–40 nm and electrical conductivities about one-thousandth that of bulk gold. Richter et al. metallized λ-DNA with palladium. The metallisation was accomplished in a two-step chemical deposition of the metal, involving binding of $Pd(CH_3COO)_2$ to the DNA and subsequent reduction with sodium citrate, lactic acid or dimethylborane. This reduction led to the formation of chains of Pd nanoparticles along the DNA (Figure 11). These wires were found to be conducting, exhibiting ohmic behaviour at room temperature. The authors developed this method further by using K_2PtCl_4 and K_2PdCl_4 as a metal source and by slight modification of the reducing conditions.[114] This led to the formation of ordered chains of nanoparticles, thus illustrating a remarkable control over the nucleation and growth processes.

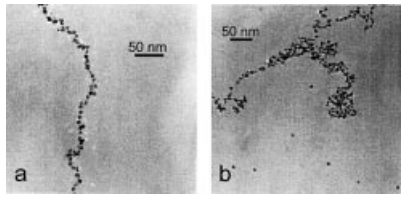

Figure 11. TEM micrographs of chains of a) Pt and b) Pd clusters grown on λ-DNA (reproduced with permission from ref.[114]).

4. Conclusions and Future Directions

This article is intended to provide an overview of the current state-of-the-art of DNA-based assembly of metal nanoparticles in one, two and three dimensions. The examples selected show that interdisciplinary research at the frontier between biomolecular chemistry, inorganic chemis-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

try and materials science leads to new materials with unique properties.

While the assembly process itself is based on the enormous specificity of nucleic acids, which can be tailored by virtue of synthetic organic chemistry, much remains to be done in the development of the basic building blocks, i.e. the DNA AuNPs. As such, there is still a tremendous demand for alternative methods to allow for compensation of typical problems arising in the biofunctionalisation of inorganic nanoparticles. In particular, harsh assembly conditions may lead to ligand-exchange reactions occurring at the colloidal surface. This often prevents the formation of stable bioconjugates and efficient supramolecular assembly. Moreover, the synthesis of nanoparticle–nucleic acid conjugates that are well-defined with respect to their stoichiometric composition is a great challenge, and it is particularly important, from a molecular engineering point of view, to generate sophisticated nanoarchitectures.

Another very important goal concerns the de novo design of nucleic acid sequences that allow efficient two- and three-dimensional self-assembly. Bioinformatic approaches appear to be well suited for solving this task,[94] although much remains to be done in the refinement of such tools. Once developed, one may anticipate a broad scope of applications for designing nucleic acid scaffolds to be used for both the assembly of surface-bound nanoparticle architectures as well as three-dimensional aggregates for bioanalytical and advanced materials research.

When DNA is used as a template for the assembly of nanoparticles, the examples given in this review show impressively that nanowires with metallic conductivity can be obtained. These results have already prompted exciting research on the set-up of functional devices of higher complexity. The works of Williams et al.,[115] who has utilized the recognition of DNA to bind carbon nanotubes to metallic contacts by self-assembly, and by Keren et al.,[110] who has described the self-assembly of segmented nanowires in a multi-step self-assembly process, are emphasised as promising examples. However, it is still a great challenge to develop these processes further in order to realize devices or even device architectures that are robust enough to be applied in nanoelectronic circuitry.

Template-Fabricated Gold Nanowires from Gas-Phase Transport Reactions

Ralf Köppe,*[a] Günter Schmid,[b] Sibylle Schneider,[a] and Hansgeorg Schnöckel*[a]

Keywords: Chemical vapour transport / Gold / Iodine / Nanostructures / Template synthesis

Aluminium oxide membranes are partially filled with solid nanowires of gold by chemical vapour transport (1000 to 650 °C) using iodine as the transport agent. The transport is due to the formation of gas-phase AuI.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The fabrication of solid-state nanostructures has mainly been motivated by their expected quantum-size physical phenomena. In particular, nanowires are interesting entities in which carriers are confined in the radial dimension although transport is possible along their axial dimension. Various fabrication techniques have been developed for the synthesis of the nanowires, including template synthesis[1] and the vapour–liquid–solid growth mechanism.[2]

Porous anodic alumina has frequently been used for the templated synthesis of nanowires since this porous template material consists of a self-assembled honeycomb array of uniformly sized parallel channels. Because of the transparent, thin, sheet-like character of the porous material it is often called "alumina membrane". Thus, arrays of aligned nanowires that are uniform in diameter can be obtained reproducibly by filling the pores of these membranes. Moreover, these membranes are thermally inert up to about 1000 °C.

Two successful strategies to fill these alumina nanotubes have been investigated so far, namely electrochemical deposition processes[3] and chemical processes involving degradation of precursors (inorganic or organometallic[1,4]) after immersing the template material in solution.

In this work we will report on our investigations to fill aluminium oxide membranes by means of chemical transport reactions in the gas phase in a chemical equilibrium. This type of reaction[5] can be characterised in a way where a solid or a liquid substance A reacts with a gas B to form only gaseous products [e.g. C, Equation (1)].

$$i\,A_{s,l} + k\,B_g + \ldots \rightleftharpoons j\,C_g \quad (1)$$

In a temperature gradient, i.e. areas of different temperature in a closed system (e.g. a sealed ampoule), a reversible decomposition of this gaseous product results in the formation of the solid/liquid A and the gas B again. From the outside the situation appears to be a sublimation or distillation of A, although the vapour pressure of the transported species A is negligibly small. In fact, the solid/liquid A is chemically transported.

In order to start with this new technique and to gain experience for the planned incorporation of semiconductor materials (see below), we decided to perform the synthesis of gold colloids inside aluminium oxide nanotubes, which has been thoroughly investigated by several research group before.[4] The chemical transport of gold by means of iodine has only been reported in a qualitative way;[6] the transport effect by chlorine was first described by Biltz.[7,8]

In this work we report on the chemical transport of gold by gaseous iodine in a temperature gradient between 1000 and 650 °C by means of AuI. Gaseous AuI is supposed to be the essential species of the transport mechanism according to Equation (2).

$$(650\,^{\circ}C)\ Au_{(s)} + \tfrac{1}{2}\,I_{2(g)} \rightleftharpoons AuI_{(g)}\ (1000\,^{\circ}C) \quad (2)$$

This mechanism is substantiated by calculations of the partial pressures of the gaseous species. These calculations are based on the thermodynamic data of some halides of gold which were experimentally not accessible until now, but which were recently provided by quantum-chemical investigations.[9,10]

Results

Chemical Vapour Transport

In a typical experiment, both 100 mg of gold and 50 mg of iodine were sealed in an evacuated quartz tube (outer diameter: 10 mm; wall thickness: 1 mm) of about 8 cm^3 vol-

ume. The ampoule was placed in an oven with two independently heated zones at 1000 and 650 °C (at 650 °C the total pressure in the ampoule is estimated to be 2 bar). After two days, irregular shaped crystallites consisting of gold were formed at the low-temperature side of the quartz ampoule. When placing aluminium oxide membranes at the low-temperature side, the colour of the template material changed from colourless before the transport reaction to purplish red after the experiment (Figure 1). This change of colour is an indication of the successful filling of the membrane with gold.[1] Within 48 h about 5 mg of gold are chemically transported. Performing the experiment under identical conditions but without iodine did not lead to any gas-phase transport of gold.

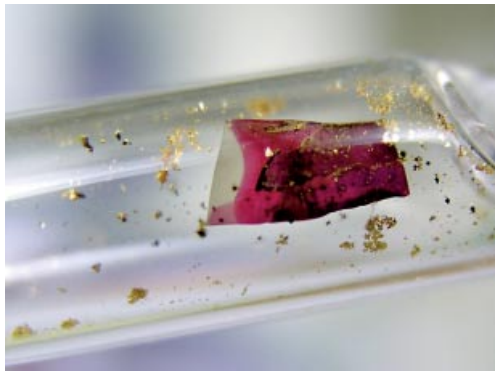

Figure 1. Low-temperature side of a quartz ampoule after chemical transport of gold with iodine.

Transmission Electron Microscopy (TEM)

The membranes were analysed by transmission electron microscopy (TEM). The samples were prepared by milling in a mortar and by suspending the material together with ethanol onto the copper grid by means of an ultrasonic bath. This preparation provides a qualitative view of the dimensions of the membrane and its filling. Figure 2 shows images of the partially filled alumina membrane, including a transverse and a top view of a channel filled with a solid gold nanowire of the exact diameter given by the membrane. As expected from the anodisation voltage of 40 V, channels with a diameter of 50 nm are observed.[1] The aspect ratio of the gold nanorods is about 8. Spherical colloids or flakes, as reported by the groups of Schmid[1] and Martin,[11] are not found.

Further investigations, for example the dissolution of the template material and the analysis of the free gold nanowires by TEM, are underway because, in contrast to the solubility of "as prepared" membranes, the heated template is not soluble in aqueous solutions of acids and bases and therefore this common technique cannot be applied.

Spectroscopic Characterisation

UV/Visible absorption spectra were recorded with an LOT Oriel SPEC II diode array and spectrograph with the

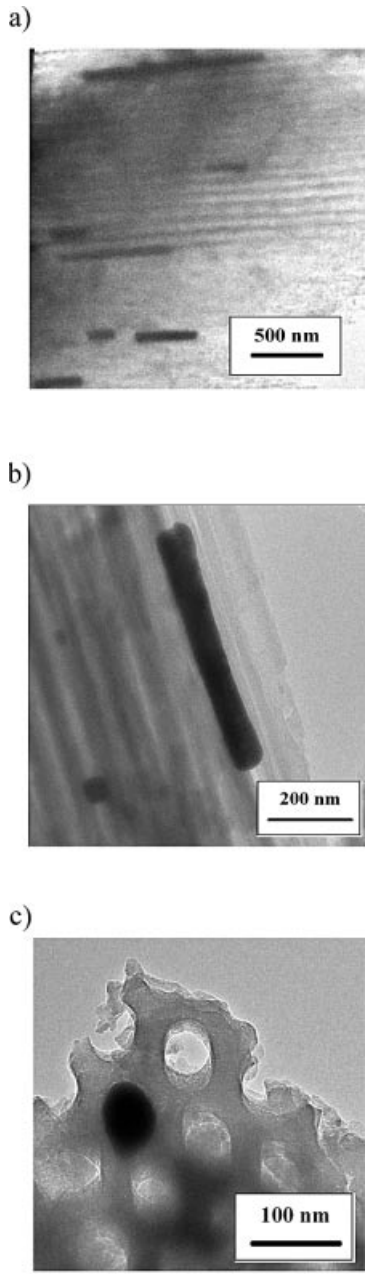

Figure 2. TEM images of the aluminium oxide membrane (channels of 50 nm diameter): a) several solid gold wires, b) transverse view and c) top view of a single wire.

template membranes oriented perpendicular to the incident beam. The absorption spectrum of a filled membrane, with λ_{max} at 550 nm, is shown in Figure 3. This observation is in line with earlier reports on aluminium oxide filled with gold wires and colloids by different methods. Martin et al. have analysed the effects of particle size and aspect ratio on the optical spectra of gold nanowires prepared by electrodeposition.[12] For an aspect ratio of gold nanowires (diameter 60 nm) of between 1.6 and 7.4, an absorbance maximum of 520 nm is reported. Furthermore, Schmid and Sawitowski have reported a bathochromic (red) shift of 20 nm when comparing tempered with untempered alumina (diameter 50 nm) filled with gold colloids. This shift is caused by an

increase of the dielectric constant after phase transformation leading to crystalline Al_2O_3 upon heating the samples to about 800 °C.[11,13] The extinction maximum (550 nm) found by us is in line with these reports.

Thermodynamic Considerations

In order to obtain information on the gas-phase species responsible for the observed transport of gold, we performed thermodynamic calculations on the partial pressures of the possible gaseous iodides of gold: AuI, AuI_3 and their dimers Au_2I_2 and Au_2I_6.

The reactions inside the quartz ampoule can be described by the following gas phase equilibrium involving Equations (3), (4), (5), (6), (7) and (8):

$$2\,AuI_{(g)} \rightleftharpoons Au_2I_{2(g)} \quad (3)$$

$$2\,AuI_{(g)} + 2\,I_{2(g)} \rightleftharpoons 2\,AuI_{3(g)} \quad (4)$$

$$2\,AuI_{3(g)} \rightleftharpoons Au_2I_{6(g)} \quad (5)$$

$$Au_{(s)} \rightleftharpoons Au_{(g)} \quad (6)$$

$$I_{2(g)} \rightleftharpoons 2\,I_{(g)} \quad (7)$$

$$Au_{(g)} + I_{(g)} \rightleftharpoons AuI_{(g)} \quad (8)$$

The values for the entropy and heat of formation of gaseous I atoms, I_2 and solid and gaseous gold were taken from the collection of thermochemical data of Binnewies.[14] However, experimentally deduced thermodynamic data of the gold iodides are not yet available. Fortunately, these species have been investigated by means of quantum-chemical methods taking into account electron correlation and relativistic effects.[9,10] Thermochemical data on the reactions that may be relevant for the transport experiment in the system gold/iodine are given in Table 1. In addition to the thorough work of Schultz and Hargittai,[10] Schwerdtfeger[9] has reported highly correlated calculations, especially on the AuI molecule. The data obtained − geometric structure, bond dissociation energy and vibrational frequency − are necessary to obtain the heat of formation and entropy of $AuI_{(g)}$, and therefore we mainly use these data for the following discussion. Solid AuI is not relevant for these calculations for the following reason: from thermogravimetric analysis we found that solid AuI is completely decomposed at 140 °C. This observation was confirmed by the calculation of the dissociation pressure by means of the reverse reaction (2′).

$$AuI_{(s)} \rightleftharpoons Au_{(s)} + 1/2\,I_{2\,(g)} \quad (2')$$

According to this calculation the vapour pressure of I_2 over solid AuI at about 200 °C should already be 3 bar, and at 650 °C, as in our experiments, no solid AuI should be present at all because the dissociation pressure should be more than 3 kbar.[14]

In order to describe the complex equilibrium situation in which seven gaseous species are involved (Au, I, I_2, AuI, Au_2I_2, AuI_3, Au_2I_6) quantitatively, one needs the six expressions [Equations (3–8)] of law of mass action given above and, additionally, the equation for the total pressure of iodine describing the mass balance of iodine:

$$p_{total}(I_2) = [p(I) + 2p(I_2) + p(AuI) + 2p(Au_2I_2) + 3p(AuI_3) + 6p(Au_2I_6)]/2$$

where $p_{total}(I_2)$ represents the pressure of I_2 before realisation of the chemical equilibrium. The calculated partial pressures are given in Figure 4 for a typical experiment. The gaseous Au-containing species with the largest partial pressure is monomeric AuI (1300 K: 9×10^{-3} mbar; 1000 K: 1×10^{-5} mbar). All data presented so far are mainly based on the theoretical calculations of Schwerdtfeger[9] (see above). However, the thermodynamic data from the quantum-chemical calculations of Schultz and Hargittai lead to an essentially similar situation.[10] The temperature dependence of $\Delta_R H^0$ and $\Delta_R S^0$ was not taken into account in the calculations due to several other uncertainties (see below).

Discussion

The reaction of gold with iodine in a sealed quartz ampoule in a temperature gradient leads to a chemical transport of gold from the high- to the low-temperature side. From thermochemical calculations we found that, in principle, the reaction given in Equation (2) is responsible for this transport. Gaseous gold is not the transport-relevant species as its vapour pressure in the temperature range under discussion is about three orders of magnitude lower than the partial pressure of AuI.[14] From a rough quantitative estimation of the transport rate based on diffusion processes as the main transport mechanism, only about 0.1 mg of Au should be transported within 24 h. Therefore, the observed higher transportation rate leads to the conclusion that both diffusion and convection contribute to the transport effect. This mechanism seems plausible as the total pressure in the ampoule can reach up to 4 bar in a typical

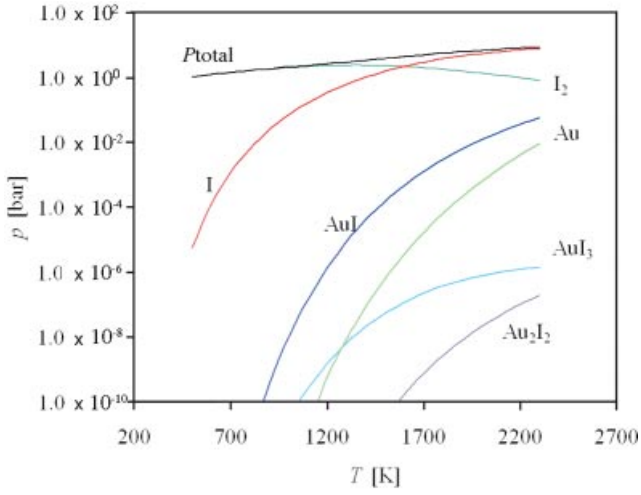

Figure 4. Partial pressures in a typical transport experiment [volume 8 cm^3, $m(I_2)$ = 50 mg].

experiment as the temperature gradient is large. Furthermore, the bond-dissociation energy of AuI is difficult to determine by quantum-chemical means. The calculated value (200.9 kJ mol^{-1}) is lower than the value determined by mass spectrometry [217.7 kJ mol^{-1} > D_0(Au–I) > 267.9 kJ mol^{-1}] [15] and microwave spectroscopy (276.3 kJ mol^{-1}).[16] Consequently, its vapour pressure and the transport rate can only be calculated within this uncertainty. [Estimations of the transport rate using these data lead to values of 0.4 (D_0 = 217.7 kJ mol^{-1}), 42.2 (267.9 kJ mol^{-1}) and 91.7 mg Au/24 h (276.3 kJ mol^{-1}), respectively].

In this work we have presented a novel method to fill aluminium oxide membranes by a gas-phase transport reaction. In order to be useful for this process, these reactions must fulfil the following prerequisites: a) the reaction must transport a bulk material in a temperature gradient and the reaction should work in a temperature range in which the vapour pressure of the relevant gaseous species exhibits significant changes; b) the reaction should take place in a temperature range below 1000 °C where aluminium oxide membranes are known to be thermally stable. Furthermore, the transport gas (here I_2) must be chemically inert with respect to the template material; c) to obtain long solid wires the supersaturation of AuI in the gas phase should be low. A low number of growing crystal seeds inside the template leads to a rather low degree of filling and the aspect ratio of these solid wires is high. In contrast, a high supersaturation, which is a consequence of a high transport rate, leads to a preferential crystallisation of gold outside the channels. Therefore, under these conditions perfect gold crystals are observed on the surface of the membrane.

We believe that this introduction of chemical-transport reactions to nanoscience is only the first step in a strongly developing field. This progress was made possible, and may be expanded in the future, because thermochemical calculations can now be supported by quantum-chemical investigations of unknown thermodynamical data also for hypothetical gaseous species.

Using this method it should be possible to fill almost any metal into alumina membranes, even those with a very low vapour pressure. Furthermore, alloys, mixed crystals with tunable composition[17] and semiconductor materials may be suitable. Therefore, based on the results presented here, we have started experiments for the transport of gold at lower temperatures in order to fill thermally less-stable nanoporous materials (e.g. zeolites). Furthermore, we intend to fill nanoporous aluminium oxide with the semiconductors GaP[18] or GaAs.[19] For this purpose, we first investigated an unexpected chemical-transport reaction [Equation (9)[20]] where only the elements gallium and phosphorus or arsenic are involved such that very pure semiconducting materials can be expected.[18,19]

$$GaX_{(s)} + X_{4(g)} \rightleftharpoons GaX_{5(g)}\ (X = P, As) \quad (9)$$

Experimental Section

Preparation of Aluminium Oxide Membranes: The mesoporous alumina membranes were produced by anodising electropolished, high purity aluminium plates in oxalic acid, using a lead plate cathode. Full details are given elsewhere.[1] The pore diameters are monodisperse and linearly related to the anodising voltage (40 V, 50 nm). The pores are perpendicular to the membrane surface and are packed in an ordered hexagonal array with a wall thickness comparable to the pore diameter. The membrane thickness, ranging up to several hundred microns, can be controlled by the time of the anodising process.

Acknowledgments

This project was supported by the Deutsche Forschungsgemeinshaft (Priority Program: "Semiconductors and Metal Clusters as Components for Organized Structures"). We thank Dr. H.-J. Himmel for recording the UV/Vis spectra. We also acknowledge the electron microscopy laboratory of the University of Karlsruhe.

Crystal Structures of $[K(2.2.2\text{-crypt})]_4[Pb_9Mo(CO)_3]$ − Isolation of the Novel Isomers $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ beside $[(\eta^4\text{-}Pb_9)Mo(CO)_3]^{4-}$

Li Yong,[a] Stephan D. Hoffmann,[a] and Thomas F. Fässler*[a]

Dedicated to Prof. Dr. H. H. Karsch on the occasion of his 60th birthday

Keywords: Cluster compounds / Cryptands / Isomers / Packing / Zintl anions

The reaction of $[Mo(CO)_3(MeCN)_3]$ with K_4Pb_9 in the presence of 2.2.2-cryptand (2.2.2-crypt) has been investigated. The transition metal complex $[K(2.2.2\text{-crypt})]_4[(\eta^5\text{-}Pb_9)Mo(CO)_3]$ (**1**), which contains a Pb_9^{4-} Zintl anion coordinated by Mo in an η^5-fashion, is isolated for the first time and characterized by single-crystal X-ray structure analysis. The 10 metal atoms in the $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ anion form a bicapped square antiprism, with the $Mo(CO)_3$ unit occupying a waist vertex position. The IR spectra of single crystals, as well as of the crude product, show clearly that only the $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ ion is formed. In contrast, the reaction of $[Mo(CO)_3(Mes)]$ with K_4Pb_9 under the same reaction conditions gives a mixture of compound **1** and its isomer $[K(2.2.2\text{-crypt})]_4[(\eta^4\text{-}Pb_9)Mo(CO)_3]$ (**2**). Compounds **1** and **2** were isolated without additional solvent molecules. The Pb–Mo, Pb–Pb, and Mo–C bond lengths and Mo–C–O bond angles in the η^4- and η^5-isomers are compared and the packing of compounds **1** and **2** is discussed.

Introduction

The chemistry of group 14 Zintl ions of the type E_9^{4-} (E = Si, Ge, Sn, Pb) is of growing interest due to the remarkable chemical reactivity of these clusters and their potential application in the preparation of ligand-free nanomaterials.[1] According to Wade's rules, an E_9^{4-} cluster adopts a discrete nine-vertex, 22-electron structure with C_{4v} point symmetry which can be described as a monocapped distorted square antiprism.[2] In the case of the Ge_9^{4-} cluster, progress has been made in the field of oxidative coupling reactions of these Zintl anions. Smaller oligomers such as the dimeric $[Ge_9\text{–}Ge_9]^{6-}$,[3] the trimeric $[Ge_9{=}Ge_9{=}Ge_9]^{6-}$,[4] and the tetrameric $[Ge_9{=}Ge_9{=}Ge_9{=}Ge_9]^{8-}$[5,6] and polymeric representatives[7] have been reported. Recently, a polymeric anion $^1_\infty[HgGe_9]^{2-}$ with Zintl ions as building blocks covalently linked by heteroatoms has been reported by our group.[8] Nucleophilic addition of $BiPh_3$ and $SbPh_3$ has also been realized in order to synthesize functionalized clusters like $[Ph_2Bi\text{–}Ge_9\text{–}BiPh_2]^{2-}$[9] and $[Ph_2Sb\text{–}Ge_9\text{–}SbPh_2]^{2-}$.[10] In the case of the Ge clusters, only one transition metal complex of the composition $[Ge_6\{Cr(CO)_5\}_6]^{2-}$ is known so far.[11]

Oxidative coupling reactions of the heavier homoatomic Sn_9^{4-} cluster have also been studied,[12] although no oligomers and polymers have been reported so far. In the case of the heavier homoatomic Sn_9^{4-} and Pb_9^{4-} Zintl clusters the research interests are mainly focused on their reaction with transition metal complexes. Although a few cases concerning the fragmentation of E_9^{4-} Zintl ions and the formation of clusters of different sizes have been reported recently,[13] in most cases the cluster ions stay intact and act as coordinating ligands to the transition metals. The resulting 10-atom heteroatomic Zintl ions are also called "metalated Zintl ions". The first NMR experiments involving the reaction of E_9^{4-} anions (E = Sn, Pb) with $[Pt(PPh_3)_4]$ in ethylenediamine (en) were described by Rudolph in 1983.[14] However, up to now only a few structurally characterized metalated Zintl ions have been reported, most of which are polystannide complexes, including $[Sn_9M(CO)_3]^{4-}$ (M = Cr, Mo, W),[15–17] $[Sn_9Pt_2(PPh_3)]^{2-}$,[18] and $[Sn_9Ni_2(CO)]^{3-}$.[18] Although the first synthesis of the Pb_9^{4-} Zintl ion by Joannis dates back to 1891,[19] and several important synthetic routes for the preparation of Pb_9^{4-} have been developed since then,[20] the reaction of Pb_9^{4-} with transition metal complexes has remained almost unexplored, and only three metalated complexes of the composition $[Pb_9M(CO)_3]^{4-}$ (M = Cr, Mo, W) have been reported.[16,21] It is worth pointing out that the $[Pb_9Mo(CO)_3]^{4-}$ ion has been characterized in the salt $Mo(CO)_3(en)_2[K(2.2.2\text{-crypt})]_4[Pb_9Mo(CO)_3]\cdot 2.5en$ (**3**), although it could not be obtained without $Mo(CO)_3(en)_2$.[16] In the reported complexes the ML_n fragment usually resides in a capping position, with the *nido*-E_9^{4-} ion

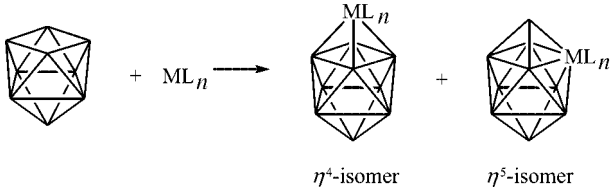
bound to the metal atom in an η^4-coordinative fashion (Scheme 1).



Scheme 1.

Recently, Eichhorn has reported an η^5-coordinated Zintl ion $[Sn_9W(CO)_3]^{4-}$, in which the $W(CO)_3$ unit occupies a waist vertex rather than sitting in a capping position.[17] The obtained product turned out to be a mixture of the η^5- and η^4-isomers in a ratio of 2:1. Metalated Sn_9^{4-} analogs of Ge_9^{4-} and Pb_9^{4-} acting as an η^5-ligand to a transition metal are still unknown. $[M(CO)_3(Mes)]$ (M = Cr, Mo, W) complexes are the most frequently used organometallic complexes for the reaction with E_9^{4-} Zintl ions, whereas their reaction with $[M(CO)_3(MeCN)_3]$ is still unexplored to the best of our knowledge. Herein we report the reaction of K_4Pb_9 with $[Mo(CO)_3(MeCN)_3]$ and the isolation of the first representative of a metalated η^5-Pb_9^{4-} Zintl ion in the solvate-free compound $[K(2.2.2\text{-crypt})]_4[(\eta^5\text{-}Pb_9)Mo(CO)_3]$ (**1**), where 2.2.2-crypt stands for 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane. According to the results of IR and X-ray analyses, the reaction affords exclusively the η^5-isomer. The reaction of K_4Pb_9 with $[Mo(CO)_3(Mes)]$ was also reinvestigated under the same reaction conditions. In contrast to the previous report,[16] we observed the formation of compound **1** together with its η^4-isomer $[K(2.2.2\text{-crypt})]_4[(\eta^4\text{-}Pb_9)Mo(CO)_3]$ (**2**).

$[K(2.2.2\text{-crypt})]_4[(\eta^5\text{-}Pb_9)Mo(CO)_3]$ (**1**)

$[K(2.2.2\text{-crypt})]_4[(\eta^4\text{-}Pb_9)Mo(CO)_3]$ (**2**)

$Mo(CO)_3(en)_2[K(2.2.2\text{-crypt})]_4[(\eta^4\text{-}Pb_9)Mo(CO)_3]\cdot 2.5en$ (**3**)

$K_2[K(2.2\text{-crypt})]_2[Pb_5\{Mo(CO)_3\}_2](en)_3$ (**4**)

Results and Discussion

Synthesis of Compounds 1 and 2

$[K(2.2.2\text{-crypt})]_4[(\eta^5\text{-}Pb_9)Mo(CO)_3]$ (**1**) was prepared by the slow addition of a toluene solution of $[Mo(CO)_3(MeCN)_3]$[22] to a solution of K_4Pb_9 in ethylenediamine (en) in the presence of 4 equiv. of 2.2.2-crypt. Within 2 h the color of the resulting reaction mixture changed from deep grey to deep reddish-brown. After careful layering with toluene, single crystals of compound **1** started to grow on the walls of the vessel and became visible within a few hours. After one week the solution became colorless, indicating the completeness of the crystallization. Black crystals suitable for single-crystal X-ray diffraction studies were obtained. No additional phases were formed, since the unit cells of several crystals of compound **1** were checked by X-ray diffraction and all of them turned out to be the η^5-complex.

The reaction of K_4Pb_9 with $[Mo(CO)_3(Mes)]$ under the same reaction conditions afforded an isomeric mixture of $[K(2.2.2\text{-crypt})]_4[(\eta^4\text{-}Pb_9)Mo(CO)_3]$ (**2**) and $[K(2.2.2\text{-crypt})]_4[(\eta^5\text{-}Pb_9)Mo(CO)_3]$ (**1**). Surprisingly, compound **2** obtained under these reaction conditions is solvate-free and does not contain an additional $Mo(CO)_3$ fragment as reported for compound **3**.[16] Repetition of the reaction led to variable ratios of the two isomers.

Crystal Structure Analyses of Compounds 1 and 2

Compound 1

The crystal structure analysis of compound **1** shows that the unit cell contains two $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ anions and eight $[K(2.2.2\text{-crypt})]^+$ cations. Four 2.2.2-crypt-coordinated K^+ cations per cluster clearly indicate a charge allocation of –4 for the 10-atom heteroatomic polyanion. Four $[K(2.2.2\text{-crypt})]^+$ units surround the cluster unit at a distance where interionic interactions can be excluded. The shortest Pb–K distance is 7.195 Å. During the refinement, relatively large difference Fourier peaks were located near the Pb atoms, indicating a disorder of the anions which could be resolved by applying a split model (ratio 0.85:0.15). A very similar disorder, even as far as the ratio of occupation is concerned, has been observed for $[(\eta^5\text{-}Sn_9)Mo(CO)_3]^{4-}$.

As emphasized in Figure 1, the $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ ion forms a bicapped square antiprism. The most important feature of this polyhedron is that the $Mo(CO)_3$ unit occupies a waist vertex. This *closo* antiprism is built up by a bottom square plane (Pb2–Pb5), a top square plane (Pb6–Pb8 and Mo), and two capping atoms (Pb1, Pb9). The data of the crystal structure determination of compound **1** are listed in the Exp. Sect., and selected bond lengths and angles for $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ are given in Table 1. The Mo–Pb bond lengths in $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ are different (Table 1), with the contacts of the Mo atom to the apical Pb9 atom and to the Pb2 and Pb5 atoms of the bottom square being remarkably shorter (2.962–3.063 Å) than those to the atoms Pb6 and Pb8 of the top square plane (3.220–3.241 Å). Since these two longer Mo–Pb distances are comparable to the two Pb–Pb contacts within the top square plane (3.278–3.285 Å), the whole cluster can be regarded as regularly shaped, even though the $Mo(CO)_3$ unit is in a waist position. Due to the higher coordination number of the Mo atom in $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$, the mean Mo–Pb distance of 3.1074 Å is slightly longer than that in the η^4-isomers (3.028 and 3.032 Å) in compounds **2** and **3**[16] (Table 2). This distance is also significantly longer than the sum of the covalent radii of the metals involved (2.834 Å).[23] The Pb–Pb distances within the top plane are approximately 0.2 Å longer than those in the bottom plane. However, the angles within the bottom plane (90.0 ± 0.9°) lie within a narrower range than those in the top plane (90.0 ± 2.9°). Similar to the different W–C distances in the related η^5- and η^4-$[(Sn_9)W(CO)_3]^{4-}$ complexes, the corresponding Mo–C distances in $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

longer (1.90 Å) than those in the η^4-isomer (1.88 Å). The C–O bonds in $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ are in the range from 1.22 to 1.23 Å and are therefore shorter than those in $[(\eta^4\text{-}Pb_9)Mo(CO)_3]^{4-}$ (1.22–1.27 Å). The Mo–C–O bond angles in $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ deviate strongly from linearity and range from 167 to 171°, which is in contrast to other carbonyl-containing E_9^{4-} moieties like $[(\eta^5\text{-}Sn_9)W(CO)_3]^{4-}$[17] and $[(\eta^4\text{-}Pb_9)Mo(CO)_3]^{4-}$,[16] and also to $[Mo(CO)_3(Mes)]$.[21]

[a] This work. [b] Ref.[16] [c] The square plane containing the atoms Pb2, Pb3, Pb4, and Pb5 is defined as the bottom plane; the other square plane in the 10-atom polyhedra is defined as the top plane.

Compound 2

The crystal structure analysis of compound **2** shows that the unit cell contains four $[(\eta^4\text{-}Pb_9)Mo(CO)_3]^{4-}$ anions and sixteen $[K(2.2.2\text{-crypt})]^+$ cations. Four 2.2.2-crypt-bound K^+ cations per cluster allow the clear charge allocation of –4 for the 10-atom heteroatomic polyanion. As observed in compound **1**, the four $[K(2.2.2\text{-crypt})]^+$ units in compound **2** are at a large distance from the polyanion and show no coordination to the cluster anion. The distances between the K^+ cations and the polyanions are longer than 7.37 Å. Due to the poor quality of the crystals the reflex intensities were low, and during the refinement relatively large difference Fourier peaks were located near the Pb atoms, indicating a disorder of the anions. Attempts to resolve the disorder were not successful.

As shown in Figure 2, the metal atoms of the $[(\eta^4\text{-}Pb_9)Mo(CO)_3]^{4-}$ ion again form a bicapped square antiprism, but this time with the $Mo(CO)_3$ unit in a capping position. The *closo* antiprism is built up by a bottom square plane (Pb2–Pb5), a top square plane (Pb6–Pb9), and two capping atoms (Pb1, Mo). The data of the crystal structure determination of compound **2** are listed in the Exp. Sect., and selected bond lengths and angles for the $[(\eta^4\text{-}Pb_9)Mo(CO)_3]^{4-}$ anion are given in Table 3. The contacts between the Mo atom and Pb6, Pb7, Pb8, and Pb9 of the top square plane are in the narrow range between 3.014 and 3.048 Å (average 3.028 Å), and are shorter than those observed in compounds **1** (average 3.107 Å) and **3** (average 3.032 Å). The Pb–Pb distances within the top plane range from 3.180 to 3.222 Å and are shorter than those within the bottom plane (3.249–3.428 Å). The Pb–Pb distances between the apical Pb1 and Pb2, Pb3, Pb4, and Pb5 of the bottom plane lie between 3.048 and 3.089 Å (average 3.074 Å) and are longer than those in compounds **1** (average 3.064 Å) and **3** (average 3.048 Å). The two planes have similar dimensions, which gives rise to a more regularly shaped 10-atom cluster than that observed in compounds **1** and **3**. The Pb–Pb distances within the top plane are approximately 0.122 Å shorter than those within the bottom plane. However, the angles within the top plane ($90.0 \pm 0.9°$) lie within a narrower range than those within the bottom plane ($90.0 \pm 1.9°$). In this respect, compound **2** is quite different from compounds **1** and **3**.

Although compounds **2** and **3** contain the same polyhedral core of 10 atoms, the Mo–C–O bond angles in these two compounds are significantly different (Table 2). The mean Mo–C–O bond angle (178°) in compound **3** is almost linear, whereas the corresponding angle in compound **2** deviates strongly from linearity (172°). As shown in Table 2, the Pb–Pb bond lengths within the bottom planes are almost identical (3.322 vs. 3.320 Å) despite the different location of the $Mo(CO)_3$ fragment. The elongation of the mean Mo–Pb distance in the η^5-isomer is a consequence of the higher coordination number. The two elongated bonds

Pb2–Pb5–Pb4	91.47(7)	Pb6–Pb9–Pb8	90.87(6)

(Mo–Pb6, Mo–Pb8) originate from the nonplanarity of the five coordinated Pb atoms.

Very recently, another compound of the composition $K_2[K(2.2\text{-crypt})]_2[Pb_5\{Mo(CO)_3\}_2](en)_3$ (**4**) with Mo–Pb and Pb–Pb bonds has been reported by our group.[24] The structure of the [{$(OC)_3Mo$}Pb_5{$Mo(CO)_3$}]$^{4-}$ anion (Figure 3b) contains a planar five-membered ring of lead atoms. The Pb–Pb bond lengths between 3.014(1) and 3.065(1) Å (average 3.041 Å) in compound **4** are significantly shorter than those in compounds **1** and **2** (d_{Pb-Pb} = 3.011–3.415 Å and 3.048–3.428 Å, respectively). Interestingly, the Mo–Pb distances (3.014–3.048 Å) in compound **2** are very similar to those in compound **4** (3.001–3.093 Å), but differ from those in compound **1** (2.962–3.241 Å). Compound **1** can be regarded as an intermediate in the fragmentation of the Pb_9^{4-} cluster and the formation of the novel Pb_5 cluster fragment in **4** (Figure 3).

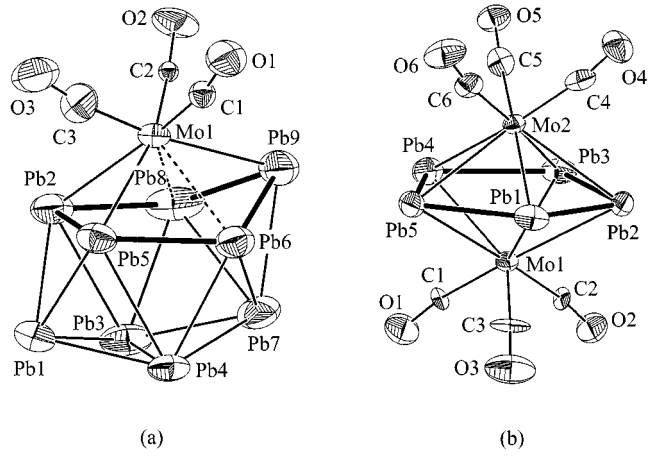

Figure 3. (a) Molecular structure of the *closo*-[(η^5-Pb_9)$Mo(CO)_3$]$^{4-}$ unit in compound **1** (thermal ellipsoids set at 80% probability) (dotted lines represent Mo–Pb distances >3.2 Å). (b) The structure of the *closo*-[η^5-Pb_5{$Mo(CO)_3$}$_2$]$^{4-}$ Zintl anion (thermal ellipsoids set at 80% probability).

Cluster Arrangements

The packing diagrams of compounds **1** and **2** are shown in Figures 4 and 5, respectively. Both compounds form distorted hexagonal layers. The distances between the cluster units within the same layers differ by less than 10% (distance range for **1** from 15.465 to 16.774 Å and for **2** from 15.066 to 16.477 Å). In compound **1** the interlayer distances between the centers of gravity of the clusters are 15.493, 15.853 (2×), and 15.144 Å. The orientation of the $M(CO)_3$ groups with respect to the layers has no significant influence on the distances between the clusters. Irrespective of their orientation the two different layers of clusters (I and II), one of which is shown in Figure 4a, arrange in a cubic-type packing as indicated in Figure 4b by the labels ABCA perpendicular to the *ab* plane (not along *c*).

In compound **2**, the distorted layers are packed pairwise along the *b* direction of the unit cell. Within the AA′ and BB′ layers (Figure 5) the $M(CO)_3$ groups of two layers are oriented towards each other, leading to a larger distance of 14.431 Å between these layers as compared to the A′B and B′A interlayer distance of 12.502 Å. Consequently, different intercluster distances of 16.617 and 14.308 Å occur. The relative orientation of the carbonyl groups of the $Mo(CO)_3$ unit might be the origin of the larger unit cell volume of **2** if compared to **1**.

IR Spectra

Single crystals of **1** and the crude product were carefully checked by solid-state IR analyses. The characteristic CO stretching vibrations of the η^5-isomer are found at 1809 and 1697 cm^{-1}. None of the characteristic peaks of the η^4-isomer ($\tilde{\nu}$ = 1813, 1736, and 1702 cm^{-1})[16] were detected (Table 4). The carbonyl bands of the η^5-isomer are red-shifted relative to those of the η^4-isomer. This red-shift has also been observed for the isomeric compounds $[(\eta^5\text{-}Sn_9)W(CO)_3]^{4-}$ ($\tilde{\nu}$ = 1805, 1701 cm^{-1}) and $[(\eta^4\text{-}Sn_9)W(CO)_3]^{4-}$ ($\tilde{\nu}$ = 1822, 1711, 1701 cm^{-1}; see also Table 4).

As already mentioned above, several crystals of compound **1** were checked by X-ray diffraction and identified as the η^5-isomer. The IR study gave further evidence that the reaction of $[Mo(CO)_3(MeCN)_3]$ with K_4Pb_9 yields exclusively one isomer (**1**). Our attempts to obtain a ^{207}Pb NMR spectrum of compound **1** were unsuccessful due to its poor solubility in the usual solvents (en, DMF, THF, DMSO, and toluene).

Conclusions

The reaction of $[Mo(CO)_3(MeCN)_3]$ with K_4Pb_9 in the presence of 2.2.2-crypt was investigated. A metalated Zintl ion $[K(2.2.2\text{-crypt})]_4[(\eta^5\text{-}Pb_9)Mo(CO)_3]$ (**1**) was isolated and characterized by single-crystal X-ray structure and IR analyses. The carbonyl (CO) stretching vibrations ($\tilde{\nu}$ = 1807, 1697 cm^{-1}) in the IR spectrum of compound **1** clearly show the exclusive formation of the $[(\eta^5\text{-}Pb_9)Mo(CO)_3]^{4-}$ isomer. The $[K(2.2.2\text{-crypt})]_4[(\eta^4\text{-}Pb_9)Mo(CO)_3]$ isomer (**2**), which has been isolated for the first time as a pure product, is formed together with its isomer **1** in the reaction of $[Mo(CO)_3(Mes)]$ with K_4Pb_9 under the same reaction conditions.

Experimental Section

The synthesis of compound **1** was carried out under argon in a glove-box or in a Schlenk line. The IR spectra were recorded from KBr pellets with a JASCO FT/IR-460 spectrometer. The X-ray crystal data were collected with a Nonius Kappa CCD device at the window of a rotating anode X-ray generator and processed with the SHELXS-97 and SHELXL-97 program packages.[25] The crystallographic data for the structures are summarized in Table 5. CCDC-258685 (**1**) and -258686 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. The elemental analyses were carried out by the Microanalytical Laboratory at TU Munich. Toluene (Merck) and en (Merck) were dried with K/CaH_2 (Fluka),

freshly distilled, and degassed. The binary phase of the formal composition "K_4Pb_9" was prepared by a high-temperature reaction (350 °C) from the elements K and Pb in the ratio of 4:9. Tricarbonyl(mesitylene)molybdenum and tris(acetonitrile)tricarbonylmolybdenum were prepared by heating $Mo(CO)_6$ (Alfa Inorganics) in an excess of mesitylene or MeCN under reflux under nitrogen according to the reported methods.[22]

K_4Pb_9 (100 mg, 0.049 mmol) and 2.2.2-crypt (74 mg, 0.2 mmol) were dissolved in en (ca. 1 mL) and stirred for 5 min. A yellow solution of $[Mo(CO)_3(MeCN)_3]$ (16 mg, 0.051 mmol) in toluene (ca. 2 mL) was then added to the green solution of K_4Pb_9. The resulting mixture was stirred at room temperature for another 2 h. After filtration, the filtrate was layered with toluene (2 mL). Within 48 h, dark-brown crystals of $[K(2.2.2\text{-crypt})]_4[Pb_9Mo(CO)_3]$ precipitated (48 mg, ca. 45% with respect to K_4Pb_9). Elemental analysis of the products from this reaction (3707.03): calcd. C 24.30, H 3.92, N 3.02; found C 24.49, H 3.60, N 3.18. The reaction of K_4Pb_9 (100 mg, 0.049 mmol) with $[Mo(CO)_3(Mes)]$ (15 mg, 0.049 mmol) was carried out under the same reaction conditions with the same workup procedure.

Generation and Characterization of Multilayer Systems Consisting of $Au_{55}(PPh_3)_{12}Cl_6$ Double Layers and SiO_2 Barrier Films

Torsten Reuter,[a] Stefan Neumeier,[a] Günter Schmid,*[a] Eva Koplin,[b] and Ulrich Simon[b]

Keywords: Gold / Multilayers / Impedance spectroscopy / Bénard–Marangoni effect / Crystallisation

Multilayer systems, consisting of $Au_{55}(PPh_3)_{12}Cl_6$ double layers and SiO_2 barrier films of different thickness, have been generated and characterised. The formation of the double layer between the barrier films was carried out by using spin-coating techniques. For the generation of the SiO_2 films, a plasma-assisted physical vapour deposition (PAPVD) procedure has been applied, based on an anodic plasma arc process. Samples of up to nine cluster/SiO_2 combinations have been produced and have been characterised by AFM and SEM. Impedance measurements showed that there is a characteristic thermally activated frequency dependence of the capacitance of the different systems. The cluster layers interact by dipoles formed in the double layers at low frequencies. It has also been shown that multilayer systems with SiO_2 films thicker than 15 nm tend to spontaneously crystallise. Furthermore, wetting problems during the spin-coating processes have been investigated.

Introduction

Au_{55} clusters, although known for almost 25 years,[1] are still the focus of intensive research, mainly because of their extraordinary electronic properties. The density of states in the valence and in the conduction bands is, compared with that in a bulk piece of metal, dramatically decreased with the result that a metal particle with an extremely small size of 1.4 nm follows quantum mechanical rules instead of the classical laws valid for a bulk metal with an infinitely large number of atoms. Indeed, it has been previously shown that Au_{55} clusters behave as quantum dots that have discrete electronic energy levels.[2,3] Au_{55} clusters act as switches that can be charged and discharged by single electrons, even at room temperature. It is important to mention that individual Au_{55} clusters do not exist in the bare form, and in all cases have to be protected by a shell of appropriate ligand molecules. The nature of such ligand molecules can vary from totally apolar to ionic, with a corresponding change in the solvents in which they are soluble from nonpolar media like alkanes to very polar media like water.[4,5] The existence of a ligand shell is not only necessary for synthetic reasons, but also for prevention of coalescence between bare particles and, last but not least, for profiting from the special electronic properties.

Our knowledge of the unique electronic properties of Au_{55} clusters prompted us already years ago to look for routes to two-dimensional (2D) organisations, an indispensable condition for the application of these quantum dots in nanoelectronic devices. Perfectly organised monolayers have been generated with limited extension by self-assembly.[6,7] More extended 2D arrangements could be prepared by using chemically modified surfaces[8] or by Langmuir–Blodgett techniques,[9] however, without giving ordered arrays. Artificial structures became available for the first time by using an AFM tip to electrochemically modify pre-prepared surfaces on the nanometre scale.[10] If the order of the clusters is not important, a very simple but effective method can be used. This is the spin coating of dilute solutions of ligand-modified Au_{55} clusters on appropriate surfaces. This technique has been used in the experiments described in this contribution. Spin coating indeed allows to reproducibly generate cluster double layers and, if necessary, monolayers, if the experimental conditions are carefully worked out. Here we report on the generation and on the electric properties of cluster double layers embedded between SiO_2 films of varying thickness. The reason for this research was to find out if thin cluster films, separated from each other by an insulating material, can still communicate with each other, perpendicular to the film plane. From former experiments we know that the horizontal electric conductivity of thin cluster films over extensions of dozens of nanometres is below the detection limit,[11] whereas tunnelling processes between clusters over shorter distances (20 nm) have been observed.[12] Since the layers under investigation are of millimetre dimension, horizontal measurements seem unnecessary. However, the question whether

electron tunnelling between cluster layers that are separated from each other by SiO_2 films of varying thickness will be possible is of general interest.

Results and Discussion

Generation of Cluster/SiO_2 Multilayers

The aim of this work was to generate and electrically characterise multilayer systems as shown schematically in Figure 1 with varying numbers of layers.

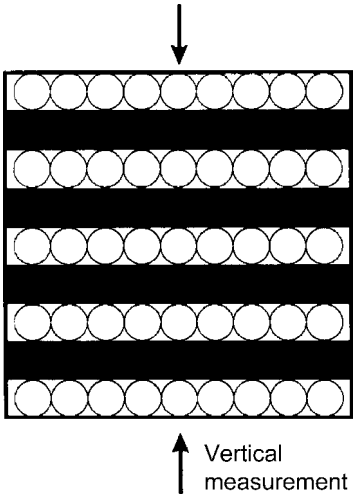

Figure 1. Sketch of a multilayered system consisting of nanoparticles and isolating barrier films.

The construction of the SiO_2 films was performed by plasma-assisted physical vapour deposition (PAPVD). The process is shown in Figure 2.

Figure 2a shows the relevant circuits of the system, and Figure 2b illustrates the process leading to the SiO_2 films. A piece of silicon in a carbon boat, which is linked to the anode, is positioned opposite the cathode, which consists of brass (1). The optimal pressure and the current conditions needed to generate 5 nm SiO_2 films were found to be 2×10^{-2} mbar O_2 and 75 A. After formation of a stable arc (2), the silicon begins to evaporate and moves towards the substrate (3). The jets of the cathode meet the silicon vapour and ionise it resulting in the anodic plasma (4). The anodic plasma expands into the vacuum reaching the substrate with the condensation of the silicon ions (5). Due to the presence of oxygen, SiO_2 is deposited (6). The stoichiometry is not perfect, and there may be a deficit of oxygen to a certain extent, but this should not influence the further steps. The time taken to produce a 5 nm SiO_2 film is only 3 s. As has been shown by the AFM investigations, the roughness of the as-prepared films is only 0.1 nm. Such surfaces are thus best suited for the generation of perfect cluster layers. Figure 3 shows a photograph of the whole apparatus.

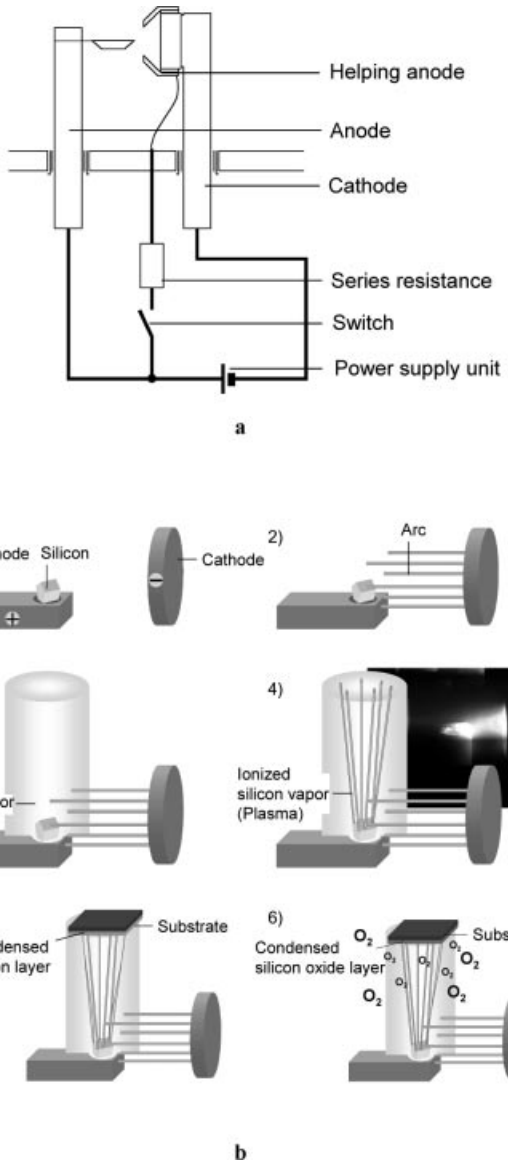

Figure 2. Illustration of the anodic plasma arc process. **a**: circuits for the PAPVD process, **b**: schematic drawing of the coating process using an anodic plasma arc.

To generate cluster double layers, diluted solutions of $Au_{55}(PPh_3)_{12}Cl_6$ clusters in dichloromethane (4.3×10^{-6} M) were used for spin coating. To cover a 1×1 cm^2 area, 50 μL are necessary, which are dropped onto a silicon wafer surface that is rotating at 100 revolutions per minute. After 5 s, the speed is accelerated to 4000 revolutions per minute, resulting in double layers, as can be seen from the AFM image in Figure 4.

The roughness was found to be 0.2 nm. The thickness of the film was determined by generating a cluster-free window by means of the AFM tip. The height profile is also shown in Figure 4. With a value of 5 nm, it agrees perfectly with a cluster double layer.

From the AFM sequences in Figure 5, it can be seen that the coating of the cluster layers with SiO_2 films occurs without destruction by the plasma process.

Figure 3. Photograph of the whole apparatus for the PAPVD process.

Beginning with a silicon wafer (a), spin coating results in a cluster double layer (b). Coating with a 5-nm SiO_2 film (c) occurs and the surface structure is maintained. As a typical example, Figure 6 shows a transmission electron microscopy image (TEM) of a sectioned piece of a seven-layer system. For better visualisation, a sample with 15-nm SiO_2 layers has been selected. For later electric measurements, only 5 nm films will be considered, since the resistance of the 15 nm films was too high.

As can be seen, the parallel cluster layers consist of individual particles and are without visible defects. The final SiO_2 film still exhibits a low surface roughness of ca. 0.7 nm.

Side Effects

Before discussing the electric properties of multilayers, some side effects will briefly be considered: hydrodynamic instabilities of the cluster layers, and thermodynamic instabilities and optical properties of the multilayers.

The homogeneous coverage of the Si wafers or the SiO_2 films by $Au_{55}(PPh_3)_{12}Cl_6$ clusters from dichloromethane solutions is only possible with solvent that contains moisture (this can be achieved by contact of CH_2Cl_2 with air for a couple of days). The use of absolutely dry solvents results in an insufficient wettability of the wafer surface, actually consisting of a very thin SiO_2 film if handled in air. Absolutely dry solvents cause the Bénard–Marangoni effect.[13–18] This effect deals with the evaporation of thin liquid films

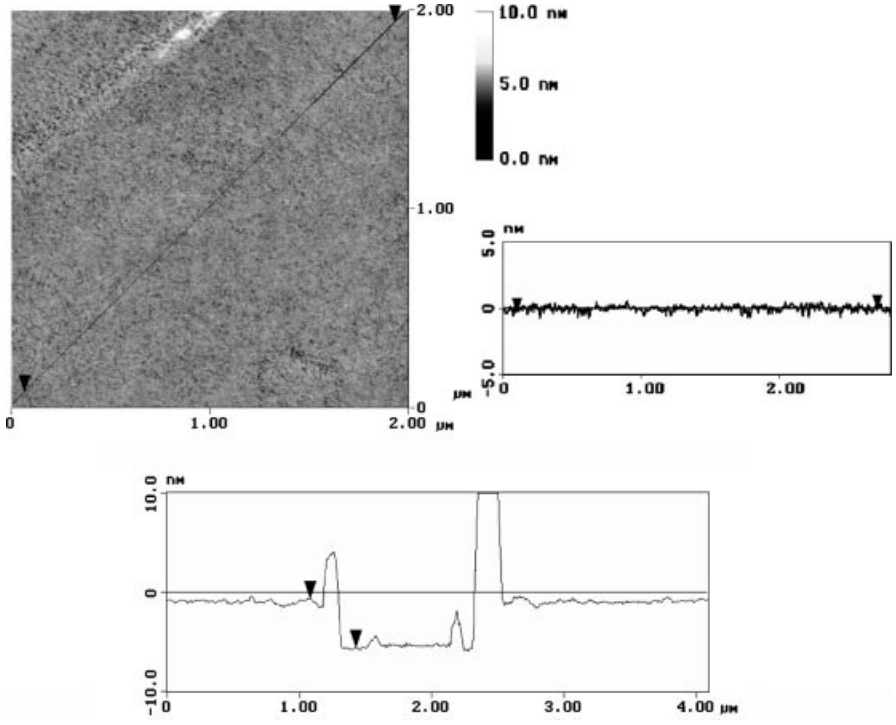

Figure 4. AFM image of a $Au_{55}(PPh_3)_{12}Cl_6$ double layer (left), roughness profile (0.2 nm) (right), and height profile (bottom) of 5 nm, generated by scratching a window into the layer with the AFM tip.

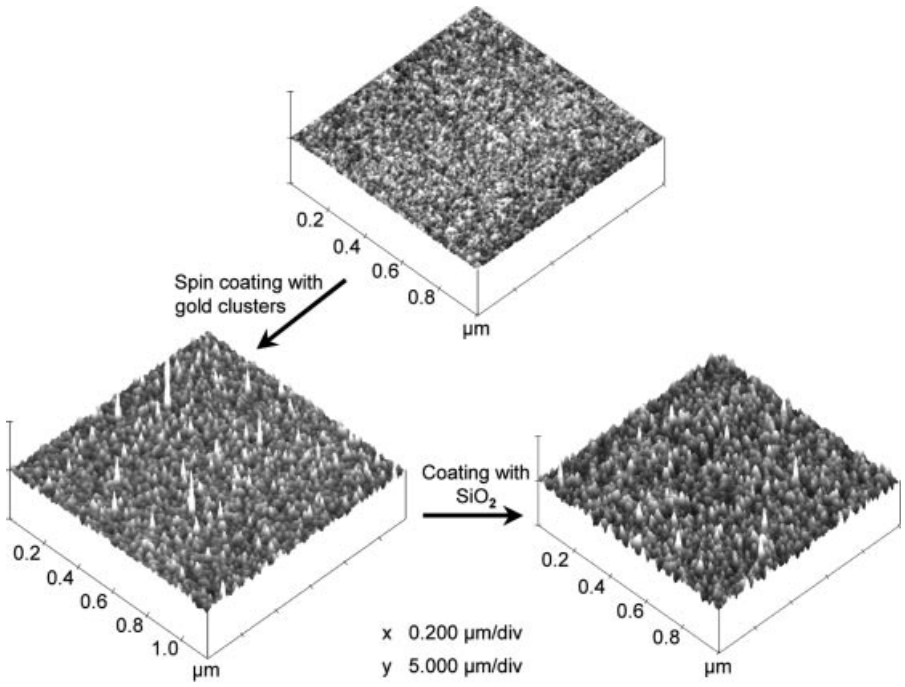

Figure 5. AFM images of a silicon wafer surface (top), a cluster double layer generated by spin coating (left) and a SiO_2 film on top of the cluster film (right), indicating that the SiO_2 does not destroy the cluster layer.

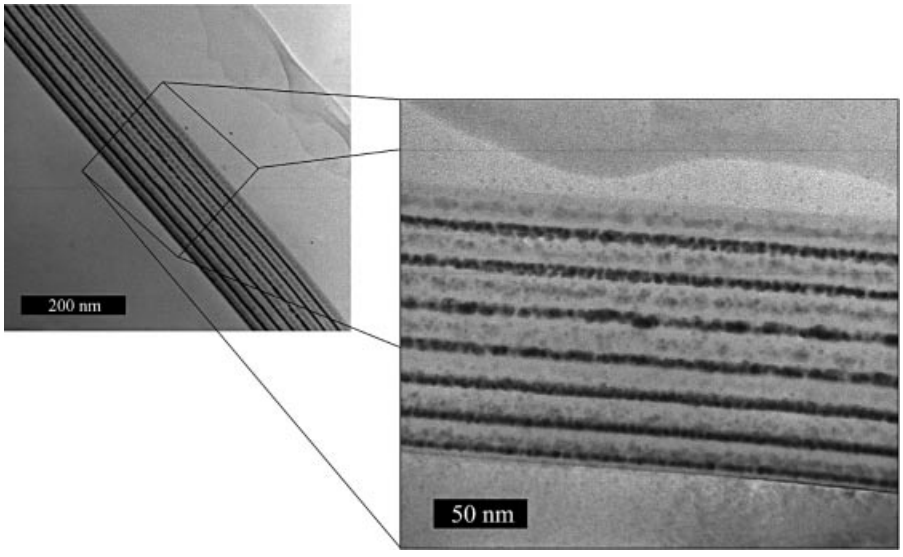

Figure 6. SEM image of a sectioned multilayer system consisting of seven cluster/SiO_2 combinations (black: cluster layers, grey: SiO_2 films).

on substrates. Hydrodynamic instabilities and surface tensions lead to diffusion processes from the warm substrate to the cooler liquid/air interface. A constant flow inside the liquid film is generated, which results in the formation of hexagonally oriented cells. At the borders of these cells, the particles, dissolved in the solvent, are deposited, and finally form hexagonal patterns. Figure 7 illustrates the Bénard–Marangoni effect, and Figure 8 shows light microscopy and scanning electron microscopy (SEM) images of some of the observed hexagonal patterns on glass (top) and on Si wafer (bottom), respectively.

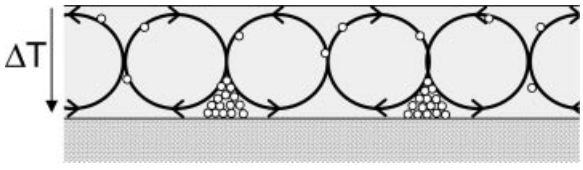

Figure 7. Illustration of the Bénard–Marangoni effect.

It should, however, be mentioned that the formation of such hexagonal structures is not expressed as much when spin-coating techniques are used, relative to simple addition

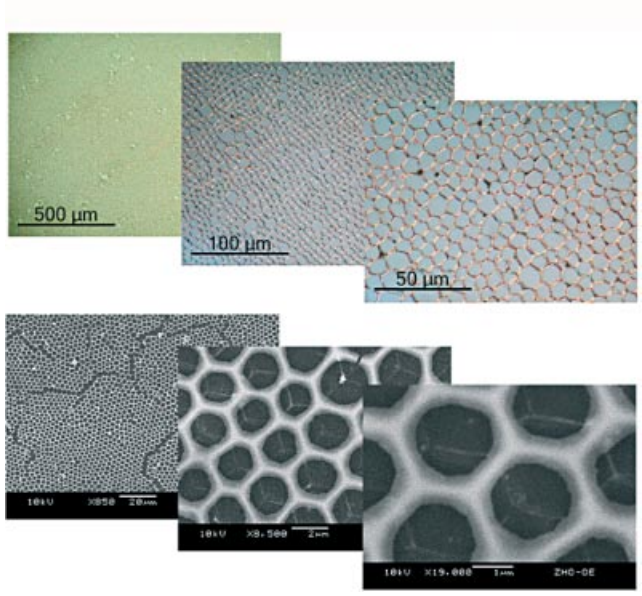

Figure 8. Light microscopy images (top) and SEM images (bottom) of the hexagonal patterns of $Au_{55}(PPh_3)_{12}Cl_6$ clusters on glass substrates (top) and on Si wafers (bottom), respectively. The structures form if the wetting conditions are not appropriate. Bars in the SEM images: 20 µm, 2 µm and 1 µm (from left).

of the cluster solution to the surface of a substrate. The concentrations of the solutions have little influence on the structure formation.

Another effect is observed that indicates the instability of the multilayers in the case of thicker SiO_2 interfaces. The SiO_2 films, generated by the discussed plasma process, are amorphous. In the cases of multilayers with SiO_2 films thicker than 15 nm, there is a tendency of the multilayer to spontaneously crystallise. This tendency is greater as the thickness of the SiO_2 films and the number of layers in-

Figure 9. Photograph of a crystallized multilayer sample.

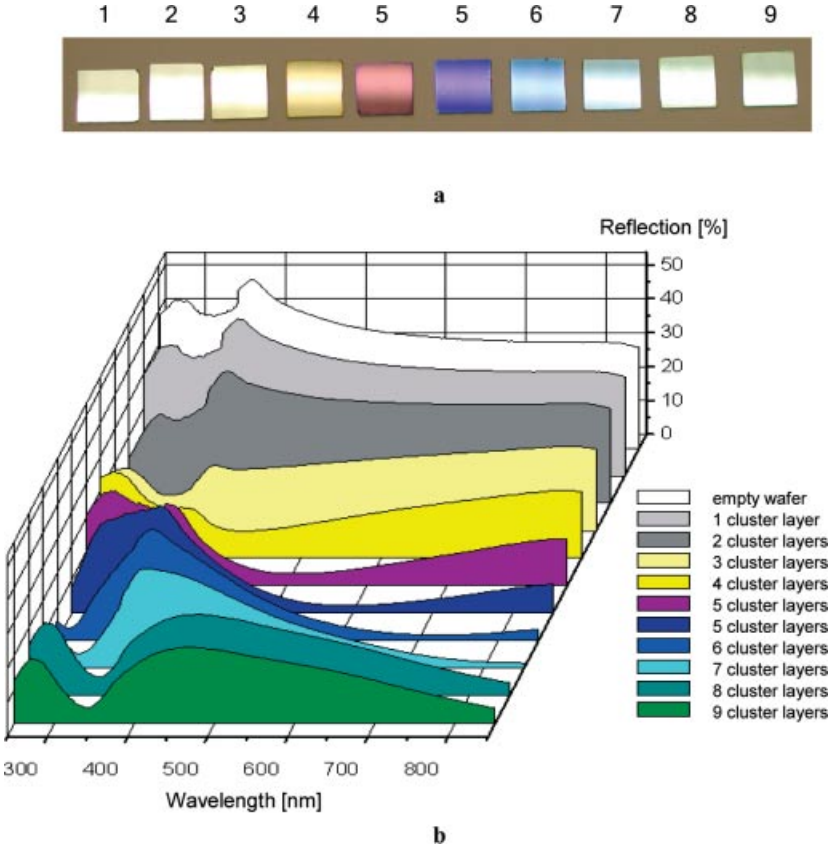

Figure 10. Changes in colour with increasing numbers of layers. **a**: photograph of multilayers consisting of 5-nm cluster layers and 30-nm SiO_2 films. **b**: UV/Vis spectra of the samples shown in **a**, measured in reflection.

crease. Figure 9 shows an optical image of a crystallised multilayer sample consisting of five cluster/SiO_2 combinations with 40-nm SiO_2 films. Three different types of crystallisation can be seen, macroscopically observable by different colours.

This phenomenon can be compared with the known metal-induced crystallisation of amorphous silicon.[19] Multilayers with SiO_2 intermediates that are <15 nm are stable with respect to crystallisation, whereas pure SiO_2 films that are even more than 15 nm thick are stable in the absence of gold clusters. This clearly indicates cluster-induced crystallisation.

A last phenomenon should be mentioned: the change in colour of the multilayers with increasing numbers of layers. As an example, the colour development and the UV/Vis spectra of a series of layered systems, consisting of cluster double layers and 30-nm SiO_2 films, are shown in Figure 10 (one to nine combinations).

It can be assumed that the reason for this observation is interference between the layers because of reflection and refraction. The fact that various numbers of SiO_2 films do not show any similar effects proves the influence of the gold cluster layers with a different refraction index in between.

Electrical Properties

For vertical measurements, the multilayer systems were contacted from the wafer side with conductive silver paint and from the top SiO_2 film by a gold contact that was made by evaporation of gold through a mask with a central hole with a diameter of 3 mm. As it turned out, reliable and reproducible current–voltage measurements were not possible with as-prepared multilayer systems. One of the reasons was the electrical behaviour of the silicon substrates, which masked the weak additional influence of the multilayers on top. Another reason was assumed to exist in the randomly oriented cluster double layers, which enabled the formation of differing individual conduction paths throughout the samples and therefore prevented reproducibility. In another paper involving this issue, we describe the investigation of multilayer systems with cluster monolayers and gold as a substrate. Thus, in this case perfect current–voltage measurements are possible.

The electric behaviour of the multilayers described in this contribution was investigated by capacitance measurements by means of complex impedance spectroscopy. Impedance spectroscopy (IS) is an experimental method for the analysis of charge carrier dynamics in an electrode/sample system. For this, an alternating electric field with a frequency range of 1–10^7 Hz is applied as an external perturbation of a system that is being tested under equilibrium conditions. By applying an electric field, local as well as translational charge carrier motion may be induced, which leads to the polarization of the sample. Thus, IS is a non-destructive method for the analysis of charge transport as well as of grain boundary and interface polarisation in a solid material. IS has been intensively applied to characterise three-dimensionally organized $Au_{55}(PPh_3)_{12}Cl_6$ clusters.[20–23] The results were very valuable, since for the first time it could be shown that these nanoparticles behave as quantum dots with extremely small capacities between each other allowing single electron transport between individual clusters.

From the impedance investigations of the above-mentioned multilayer systems, we expected information about their electrical capacitance which is dependent on the number of cluster/SiO_2 combinations. For detailed capacitance measurements, multilayers with 5-nm SiO_2 films and 5-nm $Au_{55}(PPh_3)_{12}Cl_6$ double layers have been selected because of the instability of thicker SiO_2 films (see above).

First, we studied the frequency dependence of the capacitance of 5-nm SiO_2 films relative to cluster-containing multilayers. The pure SiO_2 samples show a frequency independent capacitance at frequencies below 10^3 Hz (Figure 11). A dispersion region can be observed at higher fre-

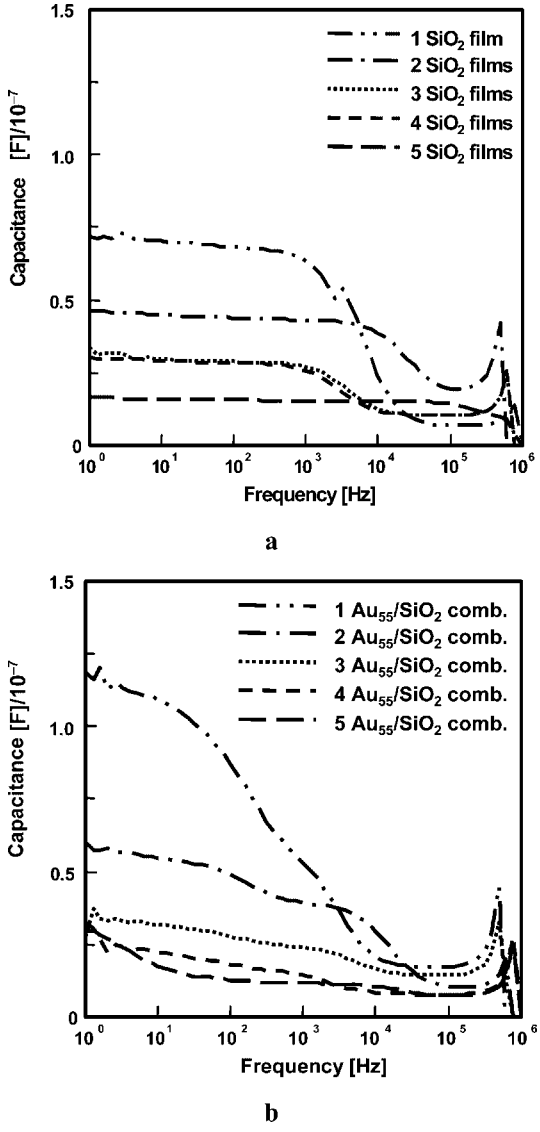

Figure 11. Frequency dependence of the capacitance in multilayered systems consisting of SiO_2 only (**a**) and of cluster/SiO_2 combinations (**b**).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

quencies, where a decrease in the capacitance is observed. Additional peaks at 10^6 Hz are due to measurement artefacts. The cluster-containing samples show a similar behaviour, although higher capacitance values are observed. In samples 1, 2, and 5, an additional dispersion region at low frequencies can be recognised.

The geometry of the sample is an important factor for the experimentally determined capacitance values. In Figure 11, one can see that the capacitance of the samples decreases with increasing thickness of the layers. This is in agreement with the model of a parallel-plate capacitor with the capacitance $C = \varepsilon_r \times \varepsilon_0 \times A/d$, where C = capacitance, ε_r = relative permittivity of the system, ε_0 = permittivity of vacuum, A = square face of the system, and d = total thickness. The geometric effects can be eliminated by calculation of the relative permittivity ε_r of the sample being tested. Physically ε_r describes the transparency of matter in electric fields and, thus, is a measure of the polarisability. Figure 12 shows the relative permittivity of the samples plotted against the layer thickness for two different frequencies.

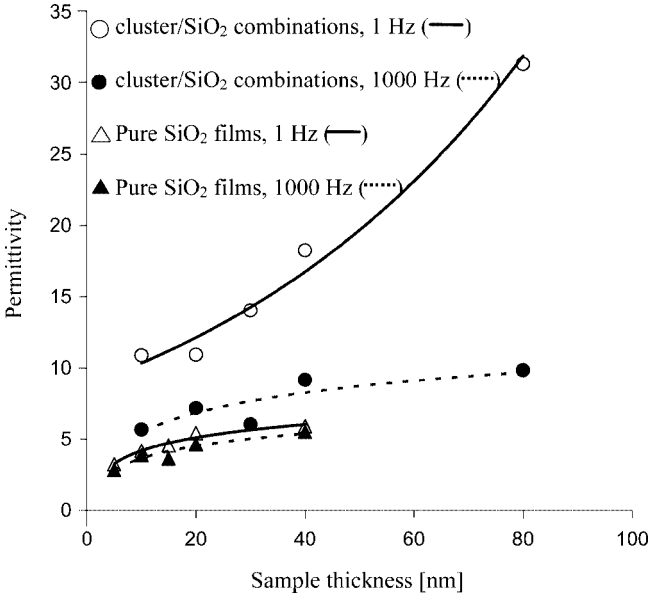

Figure 12. Illustration of the dependence of the relative sample permittivity on the sample thickness for two different measuring frequencies (The lines serve only as a guide for the eye).

It is clearly visible that the pure SiO_2 samples show a significantly smaller permittivity relative to the cluster-containing systems, and the permittivity only slightly increases with increasing layer thickness. The cluster/SiO_2 layer systems show increased permittivity with a pronounced progression as the number of the cluster layers increases. In all measurements, the permittivity at 1 Hz is larger than at 1 kHz, indicating that at low frequencies slow movement of charge carriers leads to an increase in the sample polarisation.

Samples without $Au_{55}(PPh_3)_{12}Cl_6$ clusters do not show significant changes in ε_r with increasing frequencies. Therefore, the increased polarisability of the multilayer systems must result from the presence of the cluster layers. We assign this phenomenon to the formation of dipoles in the cluster double layers and hence the formation of polarisation currents, as is indicated in Figure 13.

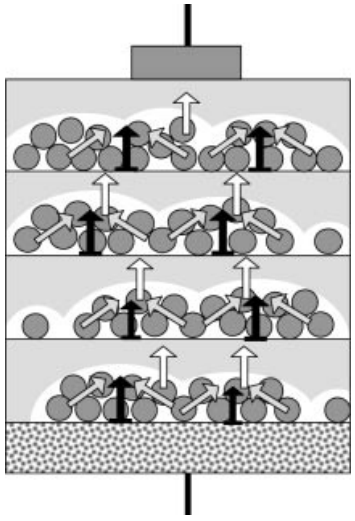

Figure 13. Illustration of the dipole formation in randomly oriented cluster double layers. Black and grey arrows indicate translational motion of charge carriers within the cluster layers parallel (black) to the applied electric field and disoriented (grey) with respect to the applied electric field. White arrows indicate the superposition of the local dipole moments forming a macroscopic dielectric polarisation.

Temperature-dependent capacitance measurements indicate a thermal activation of the polarisation processes in the cluster layers. In Figure 14, experimentally determined permittivity values at 1 Hz are plotted logarithmically versus the inverse temperature in an Arrhenius-like plot.

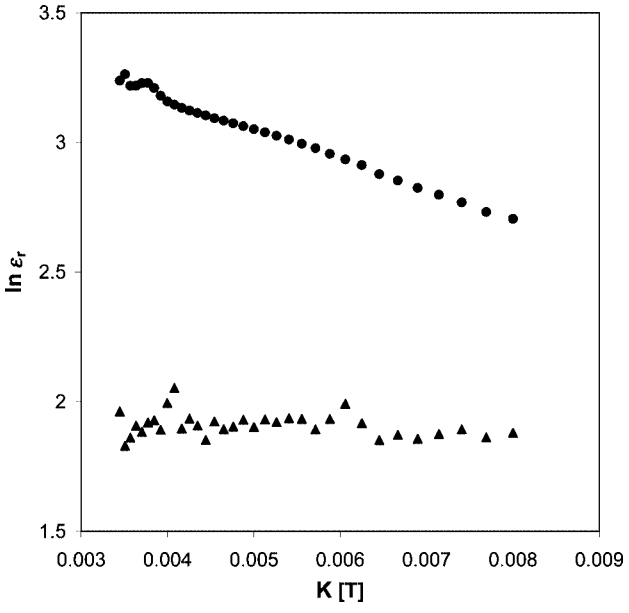

Figure 14. Arrhenius Plot of the temperature dependence of the capacitance for pure SiO_2 systems (triangles) and cluster/SiO_2 systems (dots).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The permittivity of pure SiO_2 samples is almost temperature independent, whereas cluster/SiO_2 systems show a temperature-dependent behaviour. For the latter structures an increase in the permittivity and therefore the number of polarization processes throughout the sample increases with increasing temperature.

Determination of the activation energy of the polarization processes in the sample by using the Arrhenius-relation gives a remarkably small value of 8.6 meV. However, this value is apparently lower than the activation energies determined for tunnelling processes between Au_{55} clusters, i.e. about 150 meV.[20–23] This might indicate that the polarisation process does not only reflect charge transport between the clusters within the layer, for which the activation energy measured was close to that of previous studies for pure cluster samples. We assume that additional local charge carrier transport occurs via defects in the oxide layer and/or at the interface between the clusters and SiO_2, which may exhibit smaller activation energies.

Conclusions

We have demonstrated the formation of multilayer systems, consisting of $Au_{55}(PPh_3)_{12}Cl_6$ double layers and SiO_2 barrier films of different thickness. The cluster double layer formation between the barrier films was performed by using spin-coating techniques, while the generation of the SiO_2 films resulted from a plasma assisted physical vapour deposition (PAPVD) process. Samples of up to nine cluster/SiO_2 combinations have been produced and have been characterised by AFM and SEM. Impedance measurements showed that there is a characteristic thermally activated frequency dependence of the capacitance of the different systems. The physical interpretation of this behaviour is the formation of dipoles in the non-ordered cluster double layers.

Experimental Section

Reagents and Physical Measurements: $Au_{55}(PPh_3)_{12}Cl_6$ was prepared as described.[24] Silicon wafers were used from SilChem, Freiberg, and consisted of n(As)-doped (111) silicon, 0.003 Ωcm, 375 μm. Silicon for SiO_2 layers: 99.999%, 0.2–1.5 mm, Balzers Materials, Liechtenstein. All solvents were reagent grade and used without further purification. CH_2Cl_2 for spin coating was kept in contact with air for 2–3 d in order to achieve the necessary water content. For optical imaging, a BX41 and a C3030 Zoom from Olympus, Hamburg, were used. AFM measurements were performed with a Nanoscope IIIa, Digital Instruments, Woodbury. SEM investigations were performed with a LEO 1530, LEO Elec-

tron microscopy, Cambridge. For TEM investigations, a CM 200 FEG, Philips, Eindhoven, was used. For a spin coater, Model 6700, Speciality Coating Systems, Indianapolis, was used. The UV/Vis spectra were recorded with a Cary 1Bio, Varian, Palo Alto. The impedance measurements were performed with a Solartron (Farnborough) Impedance Analyzer SI 1260 in combination with a high-impedance input amplifier Solartron (Farnborough) 1296. For the low-temperature measurements, a cryostat of a Physical Property Measuring System by Quantum Design was used.

The device for the anodic plasma arc process was homemade, using commercially available building blocks, if possible. The technical principles behind were taken from patents[25–27] with permission and help from the patent owner Dr. H. Ehrich, Physics Department, University of Duisburg-Essen. A schematic overview over the whole device is shown in Figure 15. Details are also described in ref.[28].

Formation of SiO_2 films: The holder for the silicon was a self-made carbon boat. The silicon wafer was purified with ethanol and dried with a dust-off nozzle before it was fixed by glue 20 cm above the silicon container. The shutter is installed between sample and wafer. The recipient was evacuated to 5×10^{-5} mbar, and oxygen was then allowed to enter up to a pressure of 2×10^{-2} mbar. After reaching a constant pressure, the helping anode was linked with the power circuit. The power between the helping anode and cathode was then increased until a stable discharge between cathode and anode was reached; under the conditions to generate 5-nm SiO_2 films, it was 75 A. After having reached a stable discharge, the supporting anode was separated from the circuit and the shutter was opened. For the measurement of the thickness of the film, a quartz resonator device was used, however, only for films thicker than 10 nm since it is too slow to register thinner films in a few seconds. In those cases a coating parameter had to be determined over the time the sample is in contact with the ion flow. For the 5-nm layers, 3 s are necessary. Usually, the coating rate is 1–3 nm sec^{-1}. It can be adjusted by tuning the power strength and the gas inlet. The temperature in the sample during the coating process was 25–35 °C.

Spin Coating: In a typical spin-coating experiment a 1×1 cm^2 Si wafer was carefully cleaned with ethanol. After drying with a dust-off nozzle, the wafer was fixed on the sample holder of the spin coater by evacuation. Rotation with 100 revolutions per minute was started, and 50 μL of a 4.3×10^{-6} molar cluster solution was dropped on by means of a glass syringe. The whole surface should now be wet. The spin coater was then closed, and the speed was accelerated to 4000 revolutions per minute and kept there for 25 s. Each sample was controlled microscopically before further use. The multilayers were produced by alternative layers of SiO_2 films and the clusters.

The Electronic Interaction Between $Au_{55}(PPh_3)_{12}Cl_6$ Monolayers Through SiO_2 Films

Stefan Neumeier,[a] Torsten Reuter,[a] and Günter Schmid*[a]

Keywords: Monolayers / Gold / Multilayers / Electronic tunnelling / Current-voltage characteristics

$Au_{55}(PPh_3)_{12}Cl_6$ monolayers embedded between 5-nm SiO_2 barrier films have been successfully generated. The cluster monolayers were obtained by spin coating of very dilute solutions. The SiO_2 films were prepared by means of a special anodic plasma arc technique. Systems of one up to eight cluster/SiO_2 combinations on a gold surface have been generated and investigated. In the voltage region between –5 and +5 mV, all samples exhibited linear current-voltage characteristics. Control samples with only SiO_2 show very different I-U behaviour. We interpret the behaviour observed as a result of electronic tunnelling from the cluster monolayers through the SiO_2 barrier films.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Monolayers of quantum dots are of general interest with respect to the electronic interaction between the dots in only two dimensions (2D). Whereas the electronic situation in individual quantum dots has been investigated by various researchers,[1–3] their interparticle behaviour is rather unknown. $Au_{55}(PPh_3)_{12}Cl_6$ and its derivatives are ideal quantum dots, since this compound is the only metal nanoparticle that shows well-expressed quantum behaviour already at room temperature.[1] Current investigations of the electric conductivity of 2D arrangements of $Au_{55}(PPh_3)_{12}Cl_6$ clusters over about 80 nm indicate that it is below the detection limit,[4] whereas the conductivity of only 20-nm areas shows a typical Coulomb blockade.[5] In this connection, there arose another interesting question, namely the ability of communication of extended monolayers in the vertical direction, separated from each other by insulating barriers. Variations of the insulating barriers (SiO_2) in thickness might provide evidence on the tunnelling limits. Furthermore, we might learn more about the storage capacities of cluster monolayers. Such information is of interest with respect to the development of novel floating gate transistors.[6–10] The corresponding behaviour of cluster double layers or thin films is the subject of another contribution in this issue.[4] There is a principal difference to be expected between thin films and monolayers. Dipolar interactions between cluster layers dominate the behaviour in thin films, whereas electronic tunnelling is observed in the case of monolayers.

In this contribution, we describe the current-voltage behaviour of multilayered systems consisting of $Au_{55}(PPh_3)_{12}Cl_6$ monolayers embedded between 5-nm SiO_2 films.

Results and Discussion

Generation of Cluster/SiO_2 Multilayers

The generation of the cluster monolayers was performed by means of spin coating and for the formation of the SiO_2 films the same plasma assisted physical vapour deposition (PAPVD) procedure has been applied as is described in detail in the related paper of ref.[4] For the current (I)-voltage (U) investigations we used a novel kind of contacting technique that is shown in Figure 1.

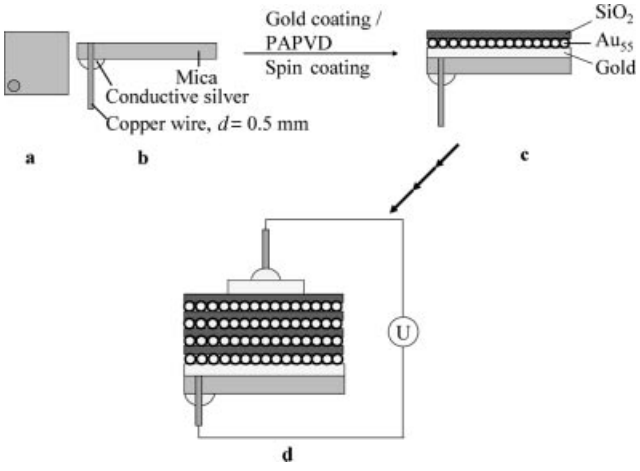

Figure 1. Construction of a $Au_{55}(PPh_3)_{12}Cl_6/SiO_2$ multilayer system.

A 1×1-cm^2 mica platelet was provided with a 0.5-mm borehole at the periphery (a). A 0.5-mm copper wire was plugged in in such a way that it ended exactly at the mica surface and was then fixed by conductive silver on the back side (b). A ca. 400-nm-thick gold film was then generated on the mica by means of PAPVD, followed by a first mono-

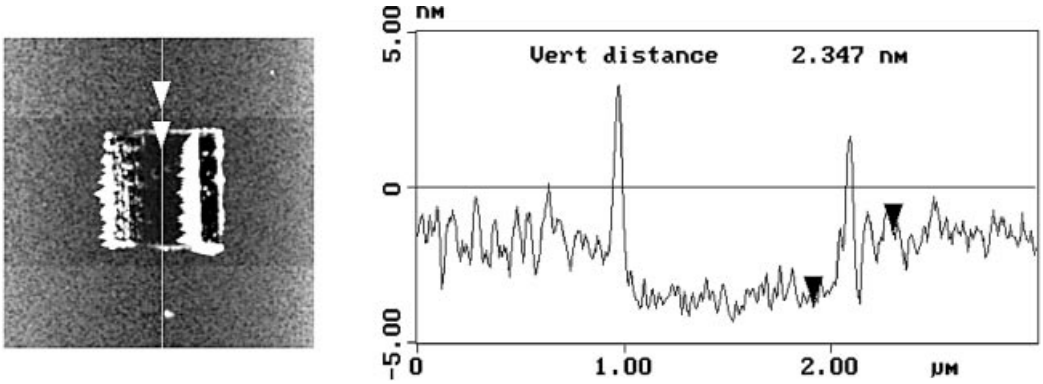

Figure 2. AFM image of a cluster monolayer with a scratched window (left) and the corresponding cross section (right).

layer of $Au_{55}(PPh_3)_{12}Cl_6$ clusters. This was produced by spin coating 50 µL of a 2.8×10^{-7} M cluster solution (c). The spin-coating process is described in detail in ref.[4] The next step consisted of the generation of a first 5-nm SiO_2 film by means of the anodic plasma arc process, also described in detail in ref.[4] Depending on the intended number of layers, the processes were repeated correspondingly. Figure 1d shows a system with four cluster/SiO_2 double layers. The final SiO_2 layer was contacted by a gold electrode 3 mm in diameter that was made by evaporating gold through a corresponding mask. Conductive silver was then used to fix a copper wire on top of the gold electrode. Control of the quality of the cluster monolayers was performed by AFM. Figure 2 views a cluster monolayer with a scratched window from above (left) and a cross section of that sample (right). The height of 2.4 nm agrees perfectly with the existence of a cluster monolayer containing randomly oriented clusters. The quality of the monolayers depends exclusively on the spin-coating conditions and the use of dichloromethane as solvent that has a distinct yield of moisture for improving the wetting conditions.[4]

As an example of the successful generation of cluster/SiO_2 multilayers, a transmission electron microscopic (TEM) image of a four-layered system is shown in Figure 3.

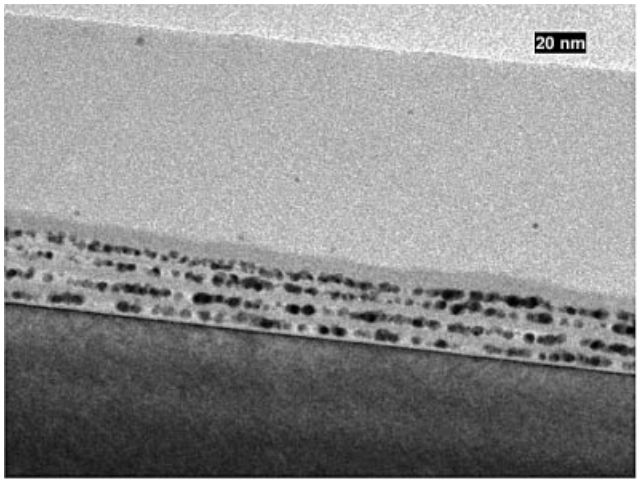

Figure 3. TEM image of a four-layered cluster monolayer/SiO_2 system.

As can be seen, the cluster monolayers are properly separated by the SiO_2 barrier films.

Electrical Measurements

Electrical measurements were performed by current-voltage registrations in the region from –5 to +5 mV. A control experiment with the gold layer alone showed the expected linear I-U characteristic, resulting in a current of 11 mA at 5 mV. Table 1 contains the measured values for four different-layered samples consisting of 1, 2, 4 and 8 cluster/SiO_2 combinations. In addition, two comparative values for 2 and 8 SiO_2 5-nm films are added. As can be seen from the values for the cluster/SiO_2 multilayers, the current values decrease with increasing numbers of layers; however, by far not to the same extent as SiO_2 films alone do.

Table 1. Current values of cluster/SiO_2 and SiO_2-only multilayer systems and of the pure gold surface.

Number of cluster/SiO_2 double layers	Current [mA] Cluster/SiO_2	Current [mA] SiO_2
0 (gold surface)	11	
1	8.8	
2	6.8	3.0
4	4.6	
8	2.9	0.9

Figure 4a shows a typical current-voltage plot for a two-layered cluster/SiO_2 array, resulting in 6.8 mA at 5 mV. The small steps are caused by the measuring technique and so are not system-immanent. In Figure 4b, the dependence of the current on the number of cluster/SiO_2 combinations is plotted and completed by the two SiO_2-only values.

Measurements at higher voltages were not possible because of the critical contact between the macroscopic wire and the nanoscopic part of the device.

These results can be interpreted as follows:

$Au_{55}(PPh_3)_{12}Cl_6$ monolayers, isolated from each other by 5-nm films of SiO_2, are electronically in contact with each other in the voltage region between –5 and +5 mV. This can clearly be followed from the significantly different behaviour of SiO_2 films without cluster monolayers in between. We assume that electronic tunnelling through the barrier

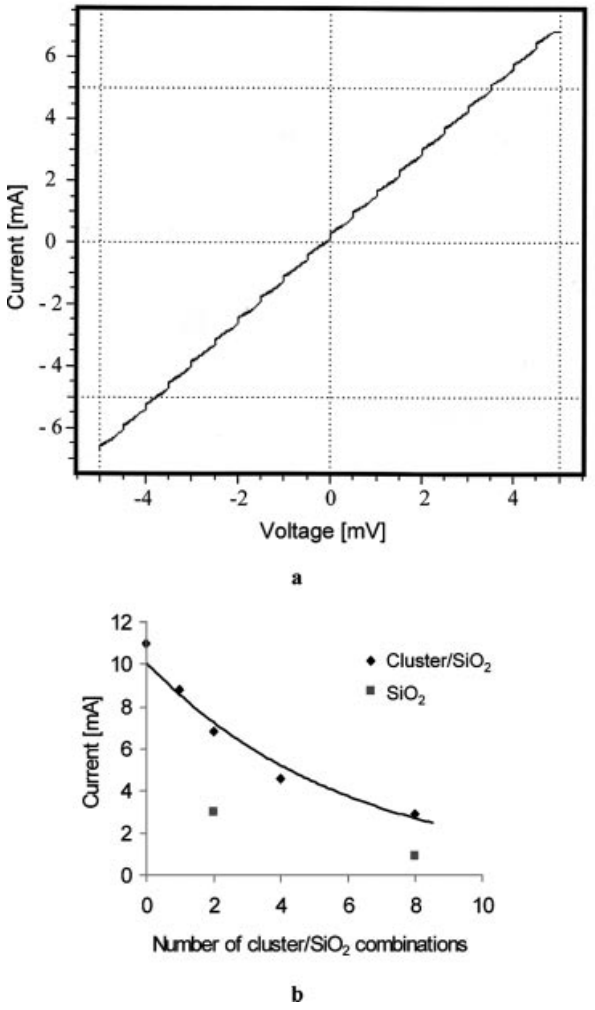

Figure 4. (a) Current-voltage plot of the two-layered $Au_{55}(PPh_3)_{12}Cl_6/SiO_2$ array; (b) dependence of current on the number of cluster/SiO_2 combinations and of SiO_2-only films. (The line serves only as a guide for the eye.).

layers occurs rather than electronic hopping, making the whole multilayer system an electronic unit. With increasing numbers of cluster/SiO_2 combinations, the currents decrease because of increasing tunnelling steps. The linear I-U characteristics, observed for all four investigated samples, indicate that there is no visible tunnelling blockade, which should have been observed in Coulomb blockades, in the layered systems. The tunnelling distance from cluster to cluster is, including the PPh_3 ligand shell, about 5.7 nm (5 nm SiO_2 + 2×0.35 nm for PPh_3). Figure 5 depicts the proposed process formally.

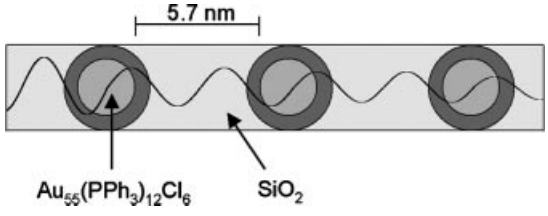

Figure 5. Illustration of the electronic tunnelling through a $Au_{55}(PPh_3)_{12}Cl_6/SiO_2$ multilayer system with decreasing amplitude.

An electronic wave, here arriving from the left, tunnels from cluster to cluster through the ligand shell and the SiO_2 film, however with decreasing amplitude leading to a kind of exponential decrease in current with increasing number of double layers, as can be observed in Figure 4b. The sloping curve approaches asymptotically the value zero for the current at a double-layer number >10. Since arrangements with more than eight layers turned out to be unstable towards crystallisation,[4] they could not be used for reliable measurements.

Conclusions

Multilayer systems consisting of monolayers of $Au_{55}(PPh_3)_{12}Cl_6$ clusters, separated from each other by 5-nm-thick SiO_2 films behave electronically like a tunnelling system, altogether reaching a maximum of over 60 nm in the case of eight cluster/SiO_2 double layers. This is a very valuable result with respect to the question of tunnelling distances. Compared with the behaviour of cluster double layers between SiO_2 barrier films, described in detail in ref.[4], where dipolar interactions between cluster layers dominate, this is obviously not the case with strictly monomolecular cluster layers, where electronic tunnelling happens. These results must be seen in relation to former measurements at three-dimensional assemblies of $Au_{55}(PPh_3)_{12}Cl_6$ clusters.[12–14] Since the gold electrode on top of the multilayer samples has a diameter of 3 mm, the tunnelling process from one electrode to the other is nothing but a kind of 3D system with considerably increased tunnelling distances, namely from 0.7 nm, considering only the PPh_3 ligand shell, up to about 5.7 nm in the samples described here. Since for systems with more than eight cluster/SiO_2 combinations the conductivity approaches that of pure SiO_2, the tunnelling distance reached might somehow be a natural limit. The 5.7 nm tunnelling distance is, compared with distances in former investigations,[15,16] a maximum value.

Experimental Section

Reagents and Physical Measurements: $Au_{55}(PPh_3)_{12}Cl_6$ was prepared as described previously.[11] CH_2Cl_2 for spin coating was kept in contact with air over a couple of days to enrich it with moisture. Mica sheets from PLANO, Wetzlar have been used (0.2 mm). Before use, upper layers were removed by a tape. Current-voltage measurements were performed with an IM 6e from Zahner Meßtechnik GmbH & CoKG, Kronach. Tungsten evaporation boats were from Balzer Materials, Liechtenstein. AFM measurements were performed with a Nanoscope IIIa, Digital Instruments, Woodbury. For spin-coating processes we used Model 6700, Speciality Coating Systems, Indianapolis. The device for PAPVD is described in detail in ref.[4]

Formation of SiO_2/Cluster Double Layers: The generation of the 5-nm SiO_2 barrier layers was performed analogously to the procedure described in ref.[4] For the preparation of the $Au_{55}(PPh_3)_{12}Cl_6$ monolayers, a CH_2Cl_2 solution (50 μL, 2.8×10^{-7} M) was applied for spin coating on the gold surface, generated on 1×1 cm^2 mica

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

platelets. For the gold coating, the same PAPVD system was used as the one used for the preparation of the SiO_2 films. Current: 30 A, pressure: 5×10^{-5} mbar. The coating rate was 5 nm/sec. For the evaporation of gold we used tungsten evaporation boats.

Current-Voltage Characterisation of Monolayer-Supported Au-Nanoclusters by Scanning Tunnelling Microscopy under Ambient Conditions

Volker Jacobsen,[a,b] Tao Zhu,[a,c] Wolfgang Knoll,[a] and Maximilian Kreiter*[a]

Keywords: Scanning probe microscopy / Surface plasmon resonance / Colloids / Monolayers / Nanostructures / Self-assembly

The current-voltage characteristics of a double-tunnel junction based on a gold crystallite with a diameter of ca. 2 nm, separated from a gold surface by ca. 1 nm was investigated by scanning tunnelling microscopy. The sample architecture was built by attaching gold nanoparticles covered with 2-mercaptosuccinic acid to an atomically flat gold surface which was covered by a self-assembled monolayer (SAM) of 6-amino-1-hexanethiol. Surface plasmon and infrared spectroscopy as well as STM imaging were employed to identify suitable preparation conditions and prove the existence of the desired architecture. No reproducible steps in the current-voltage characteristics are observed on this system under ambient conditions. Nonetheless, a sound signature for tunnelling through the double-tunnel junction is established by a quantitative fit of the averaged experimental data to a theoretical model of a single-tunnel junction. Firstly, the current on the particle is strongly reduced at low absolute external voltage and secondly the current voltage characteristics are asymmetric. Since both deviations from theory are absent in reference experiments on the bare monolayer, they may serve as a robust signature for double-tunnel junctions and open the door to the investigation of single-electron tunnelling under ambient conditions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The quantization of the electrical current into individual electron charges leads to unique features in the current-voltage characteristics of double-tunnel junctions in which the current flows across an isolated island with a sufficiently small capacitance. In many cases this geometry is realised by the tip of a scanning tunnelling microscope (STM), approaching a metallic nanoparticle, which is isolated from a metallic substrate by a thin isolating layer with a thickness in the nanometer range.[1] This geometry is shown schematically in Figure 1. A complete suppression of current at small applied voltages and a jump to a finite current at a well-defined bias voltage are observed in low temperature experiments, the "Coulomb blockade". If the voltage is further increased, then more current jumps, at a defined voltage spacing, are observed. This feature is termed "Coulomb staircase". Both effects are understood in terms of the charging of the island by single electrons, which leads to a change in its electrostatic potential, resulting in discrete electronic states spaced out in energy. The position of the jumps depends on the geometry of the double-tunnel junction (capacitance of the particle, resistance of the two-tunnel junctions) as well as the offset potential of the island.[2] This potential, although in general due to the charge distribution in the vicinity of the island, is commonly expressed in terms of an equivalent "background charge" which is not quantized and residing on the island itself. It leads to a corresponding shift in electronic potentials and, in turn, to a shift of the applied voltages for which current jumps are

observed. At a finite temperature, the sharp jumps are smeared out in energy on a scale corresponding to the thermal energy. As a consequence, the small steps in energy on systems with a large capacitance (small charging energy) are only observed at low temperature. Room temperature corresponds to a thermal energy of 25 meV. For this reason, only Coulomb blockades on small particles with correspondingly small capacitance can be observed in this temperature regime. An elegant route to small gold particles in a well-defined distance from a conducting substrate is based on the use of self-assembled monolayers as spacer molecules whose thickness can be adjusted to the Angstrom scale and on top of which gold nanoparticles with the appropriate size are deposited.

Several combinations of substrates, particles and organic functionalities of self-assembled monolayers have been used for such studies.

One strategy is based on the deposition of metallic particles coated by an insulating material on bare conducting substrates such as Pt_{309}phenanthroline$_{36}O_{30}$[3] and hexanethiol-capped clusters[4] on clean Au(111) as well as polyvinylpyrrolidone capped Au particles on graphite.[5]

Similarly, bare particles can be deposited on a monolayer-protected surface as was shown for clusters prepared under ultrahigh vacuum (UHV),[6,7] which were deposited on Au(111) protected by a monolayer of *p*-xylene-α-α′-dithiol ($C_8H_{12}S_2$). It must be noted, though, that this approach is restricted to vacuum techniques, since in ambient environments metal clusters need some stabilizing agents, thus preventing the use of bare clusters.

Probably, the best-defined systems are prepared by using a specific organic coating both on the particle and on the substrate, thus avoiding any influence of loosely bound contaminants. Examples for this strategy are heptanethiol-capped clusters on Au(111) coated with a decanethiol self-assembled monolayer,[8] and dodecanethiol-coated particles on Au(111) protected by a monolayer of *p*-xylene-α-α′-dithiol ($C_8H_{12}S_2$).[9] Other experiments on clusters coated with octanethiol/galvinol/mecaptohexylamine on Au coated by hexanethiol[10,11] have been reported.

Most of these experiments were performed under UHV at low temperatures[3,8,12] thus avoiding a smearing out of the steps in the $I(V)$ curve while at the same time avoiding fluctuations of the background charge by immobilizing possible contaminations. Also, at room temperature, Coulomb staircases have been measured under UHV and the results are in agreement with a modified classical theory that takes into account the thermal contribution.[7,12,13]

The high sensitivity of $I(V)$ on the background charge makes the detection of clear $I(V)$ curves under ambient conditions very difficult since all kinds of contaminations will enter and leave the vicinity of the tunnel barrier, leading to a background charge fluctuating quicker in time than the time needed for an $I(V)$ curve. On the other hand, this high sensitivity makes the measurement of single-electron tunnelling events a promising candidate for true transduction of single-molecular switching events if they are accompanied by a change in the associated electrostatic potential.[14] The feasibility of single-electron charging experiments at ambient conditions has been shown by addressing single clusters with an STM tip[10,11,15] and in an electrochemical experiment which was supplemented by STM experiments under UHV.[4] Still, in these cases no quantitative comparison to the classical theory was shown, probably due to the high temporal fluctuations in the overall architecture. It was noted that charged coatings may lead to an increased fluctuation of the background charge,[5] which was corroborated by the remarkable quality of the data from purely aliphatic SAMs.[8] Furthermore, in a polar environment a dielectric response has to be considered that reacts on time scales that are similar or slower than some of the time scales relevant for the experiment. As a consequence, the dynamics of the reorientation of polar species must be considered, leading to additional deviations from the simple picture of a static system with instantaneous dielectric response.[16]

Nonetheless, there are two important reasons to choose charged coatings of the particles and the substrate. Firstly, in order to attach further molecular functionalities some reactivity of the particle coatings is required. Secondly, at ambient conditions the immobilization has to withstand displacement by other molecules and therefore requires some robustness.

In this paper, we are investigating carboxyl-functionalized Au-nanoclusters on an amino-functionalized SAM in air. The goal of this paper is to unravel signatures of tunnelling through a double-tunnel junction in this polar system using STM experiments at ambient conditions. Firstly, the supramolecular geometry consisting of a 6-amino-1-hexanethiol monolayer bound to a gold substrate, decorated by gold nanoparticles coated with mercaptosuccinic acid (MSA) is thoroughly characterized. Scanning tunnelling investigations are shown with an emphasis on the changes of the $I(V)$ characteristics with time. Based on the observation that no reproducible step position of a Coulomb staircase can be identified, an alternative, fully reproducible signature of the $I(V)$ characteristics through a double-tunnel junction is developed which may serve as a signature of single-electron tunnelling even in a strongly fluctuating environment such as ambient air.

Results and Discussion

FTIR and Surface Plasmon Investigations

The deposition of the spacer layer as monitored by surface plasmon spectroscopy is displayed in Figure 2. The evolution of the minimum angle as a function of time (Figure 2b) indicates a quick first adsorption process, which terminates roughly at a thickness corresponding to a self-assembled monolayer of the 6-amino-1-hexanethiol. This process is followed by a second, slower deposition. The reflectivity curves in Figure 2a show that this additional thickness does not decrease upon rinsing with Milli-Q water, indicating a relatively strong affinity. Upon rinsing with 0.1 M HCl, the adlayer thickness is reduced to its value after the first quick deposition. This can be explained by

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

some additional 6-amino-1-hexanethiol molecules on top of the first monolayer, which are attached by dimerisation of the head amino groups and are removed after protonation in an acid environment.

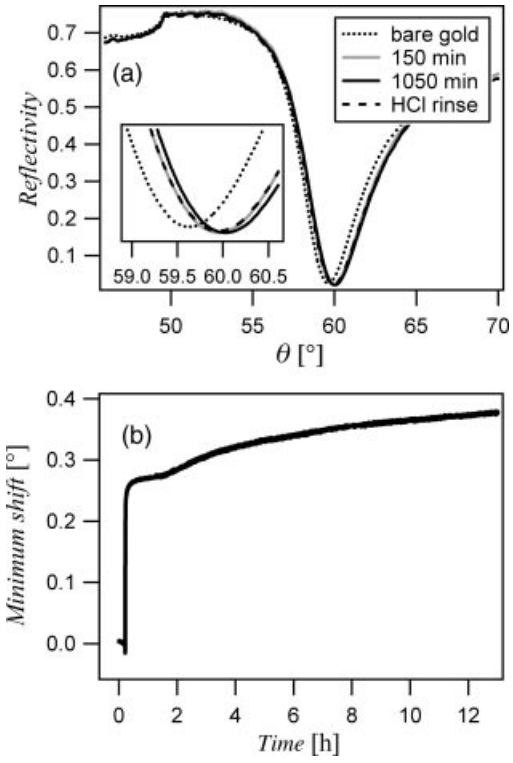

Figure 2. Surface plasmon investigation of the monolayer formation. (a) Reflectivity curves before deposition of 6-amino-1-hexanethiol, after 150 min and 1050 min deposition time and after rinsing with 0.1 M HCl, respectively. (b) Minimum angle shift as a function of time. In this range, the shift in the minimum angle is proportional to the surface coverage.

FTIR spectra of the gold substrates were taken after immersion in the thiol solution and after the rinsing steps. They are displayed in Figure 3.

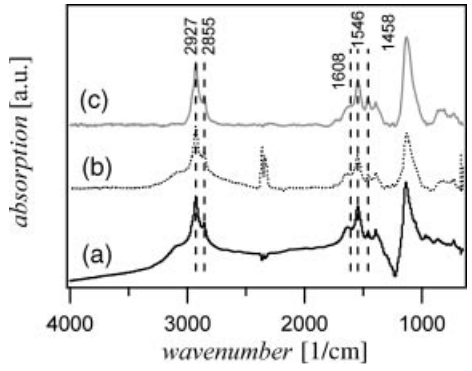

Figure 3. FTIR Spectra of the gold substrate (a) after immersion in the solution containing the 6-amino-1-hexanethiol (b) after rinsing with Milli-Q water (c) after rinsing with 0.1 M HCl.

The characteristic bands for a CH_2 chain are observed: an asymmetric stretching mode at 2927 cm^{-1} and a symmetric stretching mode at 2855 cm^{-1}, as well as a CH_2 scissoring band at 1458 cm^{-1}. The stretching modes are slightly shifted to higher wavenumbers compared to values obtained in solution (2924 cm^{-1} and 2853 cm^{-1}[17]) and in agreement with values found for a disordered monolayer with a density below the one found for the ideal crystalline packing of longer alkanethiols.[18] This finding is reasonable taking into account the influence of the amino head group and the relatively short alkyl chain whose energy in the chain-chain interactions is insufficient to form a 2D crystal. Peaks at 1546 cm^{-1} and at 1608 cm^{-1} are identified as the symmetric and asymmetric NH_3^+ deformation of the amine salt.

It is worth noting that some background signal is obtained before rinsing with HCl. This is attributed to the additional material which is also observed in surface plasmon spectroscopy and is interpreted in terms of additional 6-amino-1-hexanethiol molecules that bind to the self-assembled monolayer by dimerisation of the amino groups and which can be removed in an acid environment. A somewhat ill defined formation of SAMs from amino-terminated thiols is known from the literature. The formation of double layers has been reported,[19] as well as proper single SAMs[20,21] with the formation of carbamate at ambient conditions.[20] There is a possibility of a reverse incorporation of some molecules, i.e. the amino group pointing in the direction of the gold has been reported.[22] In the case discussed here, the clean IR spectrum as well as the thickness, corresponding to a self-assembled monolayer determined by surface-plasmon spectroscopy, point to the existence of a well-defined self-assembled monolayer after rinsing with HCl. From the IR spectra as well as from the observation that no molecular ordering could be resolved with the STM, a disordered monolayer can be deduced.

The deposition of MSA-capped gold particles was monitored in situ by surface plasmon spectroscopy as displayed in Figure 4. After 30 min the deposition speed slows down significantly but does not saturate completely even within 16 h, indicating a slow on-going particle aggregation after saturation of the main binding sites. Rinsing with HCl reduces the amount of Au particles by roughly 30% pointing to the removal of some weakly bound material. Remarkably, in addition to the horizontal shift of the plasmon curve, a slight broadening is observed, which may point towards an increased aggregation of loosely bound particles induced by the rinsing, which is expected to cause significant scattering and therefore an increase in optical absorption.

After deposition of the MSA-capped gold particles, bands at 1719 cm^{-1}, 1578 cm^{-1}, and 1392 cm^{-1} appear in the FTIR spectra (Figure 5), indicating the presence of carboxylic groups on the surface and therefore pointing towards successful deposition of the gold particles.

Imaging of the Particles with the STM

STM images of the substrates with immobilized gold nanoparticles are displayed in Figure 6. Atomically flat

gold terraces with lateral dimensions in the order of 100 nm are clearly seen in Figure 6a. Some particles are only partly visible in the image because they are swept away by the STM tip, these features are indicated by arrows. Figure 6b is obtained at slightly increased bias voltage and a set point current decreased to less than half the value used for the image in (a). Under these conditions stable imaging of the particles is achieved due to the increased distance of the tip to the surface.[23] An image taken on a single particle at reduced image size is shown in Figure 6c with a line profile across the particle displayed in Figure 6d. Firstly it can be seen that the particle has an apparent height of roughly 1.5 nm, which gives an estimate for the real dimension of the particle. Different I(z) characteristics on the particle and on the substrate, may lead to an error of some Angstroms in this height estimate. The apparent lateral size of 6 nm is dominated by the convolution with the geometrical shape of the tip and can therefore only provide an upper limit for the particle size. The surface of the gold terrace appears to be modulated in the range of roughly 1 Å, pointing towards a noncrystalline morphology of the amino-terminated thiol monolayer in agreement with the FTIR investigations. Atomic force microscopy was applied as a complementary method to investigate the surface topography independent from its electric response and an apparent particle height and density was found which was consistent with the results from the STM investigations.

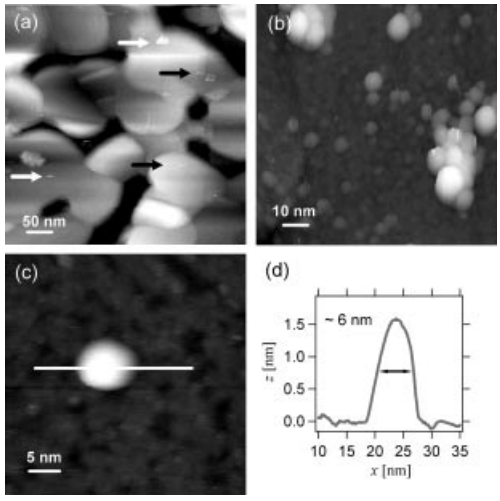

Figure 6. STM images. (a) The arrows indicate particles that are swept away during the imaging (401 mV, 93.4 pA). (b) Decreased tunnel current (500 mV, 38.5 pA). (c) Close-up of (b) (500 mV, 40.7 pA). (d) Line profile through (c).

Spectroscopy was performed by choosing an image frame such that one single particle covers roughly 50% of the image area as shown in Figure 7a, while reference measurements were taken on the same sample for an area without particles. Averaged $I(V)$ curves are displayed in Figure 7b, showing no significant difference between the two experiments, particularly, no pronounced steplike feature as is expected for a Coulomb blockade effect is observed. Single $I(V)$ curves taken on a particle are displayed in Figure 7c and are to be compared with the $I(V)$ curves taken on the pure SAM displayed in Figure 7d. These curves were chosen in a random fashion, i.e. no selection criteria were applied.

Both sets of curves show some differences in the shape of the individual curves, such as a significantly increased current in the uppermost curve in Figure 7d. The saturation at high negative currents is due to the maximum output of the electronics and does not reflect a real physical effect. Typical features of the individual curves taken on the particle are both steplike features as indicated by the vertical lines in the lowest curve and sudden "reverse" jumps which appear as an effective decrease in current at increasing voltage and are marked by arrows in two curves. The individual curves taken on the SAM do not show such behaviour.

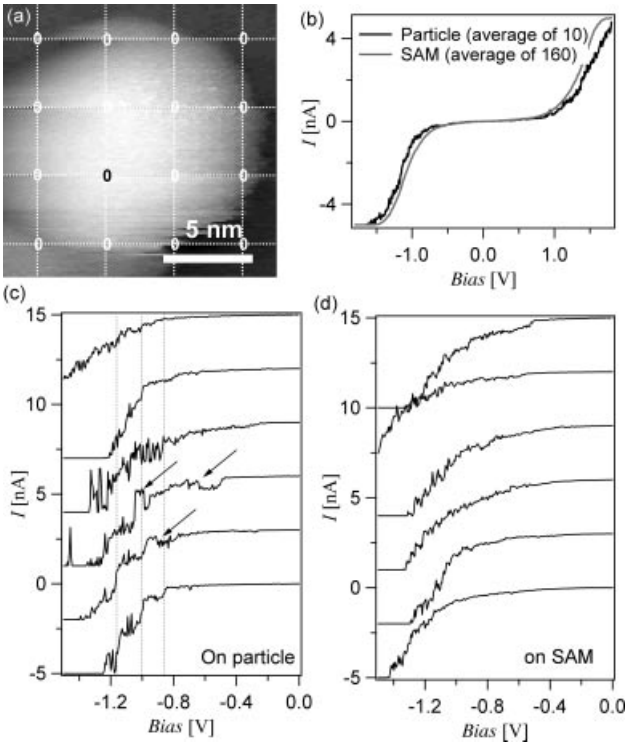

Figure 7. (a) Scanning tunnelling image of a Au nanoparticle (image size 15×15 nm^2). At the indicated 16 points, $I(V)$ spectra were taken during image acquisition (bias = 502 mV, I = 34 pA). (b) Average of 10 $I(V)$ curves obtained, indicated by the position marked in black in (a) compared to the average of all 160 $I(V)$ curves obtained with identical parameters (bias = 502 mV, I = 42.7 pA) on the same sample with no gold particles in the image range. (c) Sequence of individual curves obtained at the position marked by the black "0" in (a). The first six curves that were recorded are displayed, i.e. the data is chosen randomly. The features marked by the arrows and by the vertical dashed lines are explained in the text. (d) Sequence of individual curves randomly chosen from the spectra measured on a sample area without particles and averaged in (b). The curves in (c) and (d) are offset for clarity.

Similar current-voltage steps in single $I(V)$ curves were observed under ambient conditions[10,11,15] and have been assigned to a Coulomb staircase. In the system studied here, a reproducible measurement of the steplike features in the $I(V)$ curve was not possible, thus preventing a clear discrimination as to whether the steps are due to a Coulomb blockade or due to fluctuations of the background charge. The irreproducibility of the $I(V)$ curves as well as the "reverse jumps" may be interpreted as fluctuations of either the background charge or the entire double-tunnel-junction geometry with time, which occurs with high probability in polar systems.[5] On average a smooth $I(V)$ curve is obtained (see Figure 7b) when averaging over a set of experiments and all steplike features are averaged out.

The dI/dV curves acquired simultaneously with the data displayed in Figure 7c and d are shown in Figure 8a and b, respectively. On the SAM, no clear features are seen in the dI/dV representation in agreement with the observations on the $I(V)$ data. The individual curves taken on the particle show some features, which may be interpreted as maxima. They are again highly irreproducible from measurement to measurement. A comparison of the voltage for which apparent steps in the $I(V)$ data occur is made by marking the corresponding voltages in both Figure 7c and Figure 8a. No clear correlation is seen, giving additional evidence that extraction of Coulomb staircase-like behaviour from these experiments is either impossible or would require a very deep and careful statistical analysis.

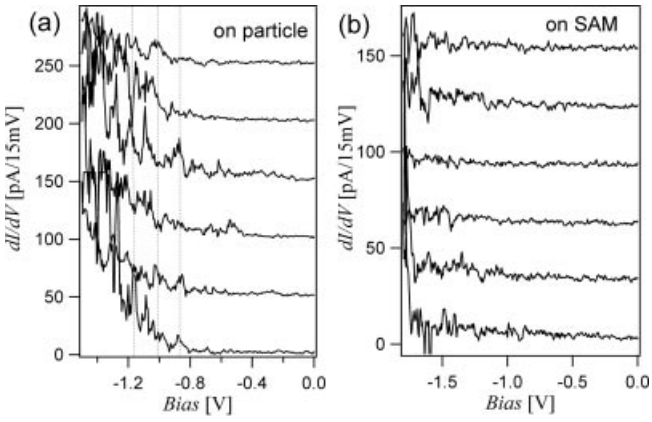

Figure 8. Single scans of the differential conductivity on the particle (a) and on the SAM (b). These data were obtained simultaneously with the curves in Figure 7c and d.

For this reason, an attempt is made with the following to extract information from the only data that can be obtained in a reproducible manner i.e. the averaged curves. Either $I(V)$ or dI/dV may be used for the analysis since they contain redundant information, though the observed effects are better visible with the dI/dV curves, which are therefore discussed below. Such averaged curves taken on a particle and on the SAM are shown in Figure 9a and b and Figure 9c and d, respectively.

A quantitative evaluation of these curves is done by comparing it to a fit based on an approach by Ukraintsev[24] for a single tunnel junction based on the one-dimensional WKB approximation which assumes comparable average density of states at the Fermi level for the tip and sample. This method, originally proposed as the "density of states deconvolution technique" is applied here to quantify the deviation from a normal response of a metal-metal contact. Following Ukraintsev, the measured dI/dV signal can be expressed as

$$\frac{\mathrm{d}I}{\mathrm{d}V}(z,V) = \frac{eA}{2}[T(z,eV/2) + T(z,-eV/2)] \quad (1)$$

with

$$T(z,\xi) = \exp[-2z\frac{8\pi^2 m_e}{\hbar^2}(\bar{\Phi} - \xi)] \quad (2)$$

Where e, m_e, $\hbar$ are the electron charge and mass and Planck's constant respectively, z the tunnelling distance, V the voltage, A a scaling parameter for the absolute value of the tunnel current and $\bar{\Phi}$ the average of the work functions of the tip and substrate material (Φ = 5.31 eV for Au.[25] An identical value is assumed for the Pt/Ir 90:10 alloy that the tip is composed of, based on the literature values of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

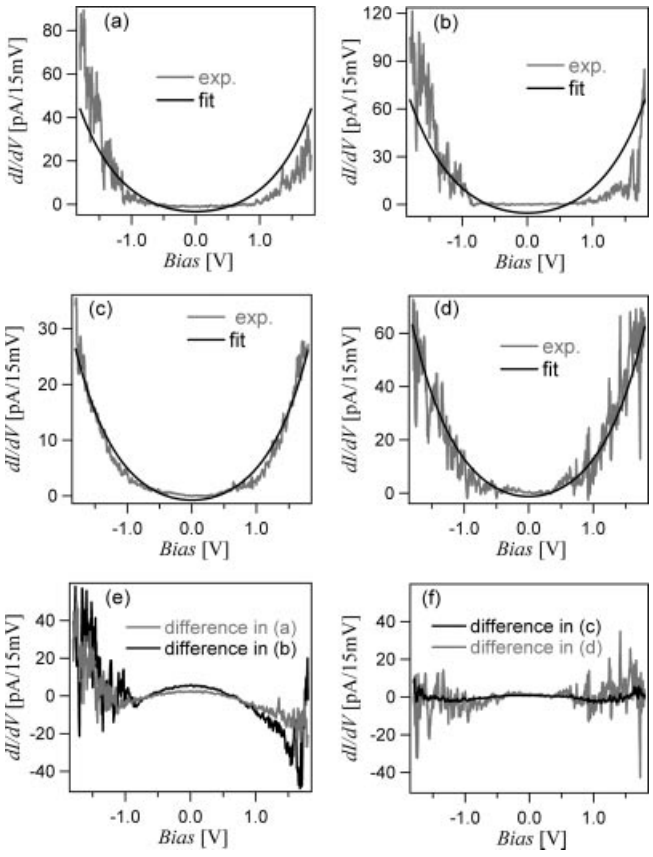

Figure 9. (a) and (b) dI/dV spectra obtained on two different gold nanoparticles The curves are averaged over 10 individual data sets and are representative of 20 particles that were studied. The fit of Equations 1 and 2 to the data using the approach of Ukraintsev is shown as a solid line. The fitting parameters are (d = 1.17 nm, A = 4.29×10^9 V s^{-1}) for (a) and (d = 1.11 nm, A = 1.63×10^9 V s^{-1}) for (b). (c) and (d) were obtained under identical experimental conditions as (a) and (b) on the bare SAM. (c) and (d) are averaged over 150 and 10 individual curves, respectively. The fitting parameters are (d = 1.2 nm, A = 3.92×10^9 V s^{-1}) for (c) and (d = 1.13 nm, A = 2.1×10^9 V s^{-1}) for (d). (e) Residual of the two fits of the gold particle in (a) and (b). (f) Residual of the two fits of the SAM in (c) and (d).

5.65 eV (Pt) and 5.27 eV (Ir)[25]). The remaining free parameters in this fit are the tunnel distance z and the overall scaling parameter A.

A good agreement of the fit with the experimental data was obtained on the pure SAM (Figure 9c and d), justifying the simplifications made by the model a posteriori. The difference spectra (Figure 9f) display only negligible deviations. This good agreement of the Ukraintsev-model, which assumes tunnelling through a vacuum, with our data is remarkable. It shows that a good fit is obtained, although instead of a vacuum, an amino-functionalized thiol is located in the tunnel barrier. The tunnel distance z used for the fit should be regarded as an effective value rather than a true measure of distance. Furthermore, it is noted that the average of 10 traces (Figure 9d) displays more noise that the average of 150 traces (Figure 9c), but the overall response is clearly reproduced in both data sets.

The situation is drastically different for the average spectra taken on the Au particles. The difference between the data and the fit as displayed in Figure 9e exhibits two systematic features, a negative curvature around 0 bias and an asymmetry with respect to the Bias = 0 axis. From the negative curvature a reduced conductivity at a low bias compared to the "normal" case is obvious. When averaging over 10 data sets no systematic steps can be seen as could be anticipated from the strong variations in position of the steps in the individual curves. Though, the steps in the individual curves lead to an increased random noise at higher absolute bias compared to the reference.

There are several possibilities that must be considered as a reason for these features. Single-electron tunnelling effects may play a role, which must be treated in the framework of a slowly reacting polarizable species around the tunnel junction. Furthermore, significant geometrical rearrangements during the scan may occur. Some influence of the chemistry seen at the tip, which consists of amino-terminated molecules on the plane surface. Carboxy groups on the particle may play a role as well. Though, one may argue that if the amino groups present on the plane surface do not lead to a response that differs significantly from the Ukraintsev picture, only small effects are to be expected from a carboxy-terminated surface.

Summary and Outlook

Gold nanoparticles functionalised with mercaptosuccinic acid were immobilized on a gold surface coated with a self-assembled monolayer consisting of 6-amino-1-hexanethiol. The formation of a well-defined geometry was followed by surface plasmon and infrared spectroscopy and proven by STM imaging.

Fluctuations in the $I(V)$ and dI/dV curves obtained with the STM under ambient conditions prevented a reliable observation of a Coulomb staircase in the system studied here. Jumps in the $I(V)$ characteristics are observed which could be interpreted in terms of a Coulomb staircase, but variations in background charge, capacitance or geometry of the double-tunnel junction can equally well account for these observations. These instabilities prevent the reproducible observation of signatures on single-electron tunnelling. A key outcome of this investigation is that we could show that the averaged response of a double-tunnel junction, although not displaying steps, significantly deviates from the response of the metal surface without particles. This was shown by fitting the data to the model proposed by Ukraintsev.[24] While the Ukraintsev model accurately describes the response of the SAM-coated surface on particles a reduced current around zero bias as well as a pronounced asymmetry of the $I(V)$ curves is observed. Although a full understanding of these effects requires further experimental and theoretical efforts, they provide a clear, robust signature for tunnelling through a surface-bound particle that is applicable to ambient conditions. These deviations probably carry a signature of molecular changes in the vicinity of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tunnel gap and may therefore be used as nanoscopic reporters for molecular events.

Experimental Section

Substrate Preparation: Microscopy cover slides are cleaned in an Ar/O_2 Plasma (Plasma System, 200G, Technics Plasma, 1 mbar, 90% Ar/10% O_2, 5 min, 300 W) and gold is thermally evaporated on the heated (320°) substrate. A gold film of 50 nm thickness is produced at an evaporation rate of 0.1 nm s^{-1}. This leads to atomically flat Au terraces with typical dimensions of 100 nm which are sufficient for scanning tunnelling experiments.[26] The samples were immersed in a 1 mM solution in ethanol of 6-amino-1-hexanethiol (obtained in the form of its hydrochloride from Dojindo, Japan) for 4 h and subsequently rinsed with ethanol (thrice), Milli-Q water (thrice), 0.1 M HCl (once), Milli-Q water (thrice), and ethanol (once), and dried with a N_2 gun.

Deposition of Au Nanoparticles: Carboxyl-functionalised gold nanoparticles were synthesized as described by Chen et al.,[27] based on the reduction of hydrogen tetrachloroaurate(III) ($HAuCl_4 \cdot 3H_2O$ from Sigma–Aldrich, USA) by sodium borohydride in methanol using 2-mercaptosuccinic acid (MSA, obtained form Acros Organics, Belgium) as the stabilizing thiol ligand. The particle size can be easily controlled by the initial molar ratio of MSA/$HAuCl_4$. In our case, the molar ratio is 1:1. In a 500 mL 3-neck round-bottomed flask, $HAuCl_4 \cdot 3H_2O$ (1.25 mmol) in milli-Q water (5 mL) and MSA (1.25 mmol) in methanol (245 mL) were mixed and vigorously stirred for 30 min at room temperature. A freshly prepared $NaBH_4$ (12.5 mmol) in a water solution (25 mL) was added dropwise at a rate of 60–80 drops per minute, and finished in ca. 5 min. After further stirring for 1 h, the precipitate was collected and washed by a repeated centrifugation-ultrasonic dispersion process in mixed methanol/H_2O, and finally dried in vacuo. The main product was collected as 220 mg powder.

The resulting nanoparticles have diameters of 2 nm with a relatively broad size distribution as confirmed by transmission electron microscopy.

The thiol-modified substrates are immersed in a suspension containing the MSA-capped Au particles ($\approx$ 0.25 mg ml^{-1}, in pH 7.5, 0.1 M Na HEPES Buffer) for between 5 and 60 min depending on the desired particle density on the surface. After deposition, the substrate is subsequently rinsed with Na HEPES Buffer (0.1 M), NaOH solutions (0.1 M), and Milli-Q water and dried with the N_2 gun.

Scanning Tunnelling Microscopy and Spectroscopy: Scanning tunnelling microscopy was performed with a homebuilt scanhead in combination with a commercial controller (RHK SPM 1000). For imaging, the "constant current" mode was used. $I(V)$ spectra that can be unambiguously assigned to topographic features in the image were obtained by interrupting image acquisition and taking the $I(V)$ curves along some preset lines, yielding a complete image with a rectangular grid where $I(V)$ curves were taken. dI/dV spectra were obtained simultaneously by superimposing a sinusoidal modulation on the bias voltage (amplitude 15 mV, frequency 10–40 kHz), which was fed into a lock-in amplifier (Femto, LIA-MVD-200).

Monolayer Analysis: Surface plasmon spectroscopy in the Kretschmann-configuration was performed on a homebuilt set-up, using a HeNe Laser (λ = 633 nm) as light source. This technique, which is described in detail in ref.[28] allows for the monitoring of the thickness of a homogeneous adlayer of known dielectric response from angle-dependent reflectivity measurements. For the deposition of MSA-capped Au particles the coverage as a function of time can be monitored up to an unknown scaling factor, which must be determined by complementary methods. The angle of the reflectivity minimum was monitored as a function of time by measuring three values for each point of the Reflectivity for θ at the last determined minimum position, slightly above and slightly below. The new minimum position was determined as the minimum of a parabola through these three points.

Infrared spectroscopy was performed with a Magna 850 Series II FTIR spectrometer (Nicolet) under grazing incidence.

Electrical Resistivity of Epitaxial Au Films Surface-Modulated by Arrays of Pt Nanoparticles

Keywords: Thin films / Gold / Conductivity / Platinum nanoparticles

Arrays of Pt nanoparticles with a high degree of hexagonal short-range order are deposited by means of self-assembly of diblock-copolymers on top of high quality epitaxial Au films and their influence on the electrical properties is studied. The temperature-dependent resistivity of the nanomodulated Au films is surprisingly well described by the classical size effect model of Fuchs–Sondheimer, which is based on a mixture of diffuse and specular surface scattering events. Especially, no specific influence of the interparticle distance of the nanoparticle array could be detected even though it was of the same magnitude as the elastic mean free path of the scattering electrons. Rather, the nanomodulation acts as randomly distributed scatterers leading to an overall decreased probability for specular reflections of conduction electrons at the sample surface.

Introduction

When sample dimensions are reduced as in thin films, surfaces become increasingly important having a strong impact on many of the sample properties like, e.g. electrical conductivity. Although it was speculated already one century ago[1] that the resistivity of thin metal films should deviate from the resistivity of corresponding bulk samples, it was only about 40 years later that Fuchs[2] and Sondheimer,[3] respectively, first developed models to describe the size effect of the electrical resistivity in thin films quantitatively. Along with continuous improvements of the experimental conditions (e.g. purification of starting materials, vacuum technology, analytical tools), sophisticated experiments revealed a large variety of interesting aspects.[4–25]

Common to all of these experiments were either epitaxially grown films with surfaces as flat as possible or polycrystalline films with a finite surface roughness representing a statistical distribution of the film thickness. The influence of a well-defined highly-ordered surface roughness, however, on the electrical resistivity of thin films has not yet been examined. In such a case, it could be speculated that the temperature-dependent resistivity should show deviations from the usually observed behavior whenever the electron mean free path would be a multiple of the characteristic distance between the artificial surface structures.

With the recent developments of powerful methods to produce ensembles of nanostructures on flat surfaces with a high degree of hexagonal short-range order and the individual nanostructures having dimensions approaching the Fermi wavelength of metals (typically some few nanometers), such a study has now become possible. In this work, thin metal films are patterned with a simple bottom-up technique based on molecular self-assembly.[26,27] Arrays of chemically clean Pt nanoparticles are prepared with a diameter of about 3 nm and an interparticle distance of about 30 nm. With these nanoparticles, it is possible to prepare nanomodulated thin metal films with a modulation length comparable to the mean free path of the electrons. The nanomodulated metal films have to fulfill several requirements to be suitable for such transport measurements: First, the metal film itself must be thin enough to ensure the necessary surface sensitivity of the resistivity. Second, it must be epitaxially grown without a magnetic seedlayer to minimize electron scattering within the film as well as additional spin scattering at the film/substrate interface, and third it must be chemically inert because of ex situ steps which are needed for the preparation of the metallic nanoparticles. Finally, the film has to be flat to guarantee that transport properties are governed by the nanomodulation and not by the intrinsic surface roughness of the sample. All these requirements are met by epitaxial Au films grown on sapphire with a Nb seedlayer.[28]

Results and Discussion

Size Effect of the Electrical Resistivity

The temperature dependence of the electrical resistivity in bulk metals is described by the Bloch–Grüneisen relation [Equation (1)].

$$\rho_{bulk} = \rho_{0,bulk} + K\left(\frac{T}{\theta_D}\right)^5 \int_0^{\theta_D/T} \frac{x^5 dx}{\left(e^x - 1\right)\left(1 - e^{-x}\right)} \quad (1)$$

Here θ_D is the Debye temperature, K is a material specific factor and $\rho_{0,bulk}$ is the residual resistivity. The electron mean free path due to impurities l_{imp} is related to the residual resistivity by $\rho_{0,bulk} = m \cdot v_{Fermi}/n \cdot e^2 \cdot l_{imp}$. For thin films, however, with a thickness approaching l_{imp}, scattering of the electrons at the surface can no longer be neglected. In the classical size effect model by Fuchs–Sondheimer (FS),[3] surface scattering is included and the resistivity of thin films ρ_{film} can be deduced from the resistivity of the bulk metal [Equation (2)].

$$\frac{\rho_{bulk}}{\rho_{film}} = 1 - \frac{3}{2\kappa} \int_0^1 du \cdot \left(u - u^3\right) \frac{(1-p)\left(1 - e^{-\kappa/u}\right)}{1 - p \cdot e^{-\kappa/u}} \quad (2)$$

Here $\kappa = t/l$ is the ratio between film thickness t and the electron mean free path l in the bulk metal. The so-called specularity parameter p, describes phenomenologically the surface scattering of the electrons. Complete specular scattering corresponds to $p = 1$ whereas complete diffuse scattering corresponds to $p = 0$.

Transport Measurements

Before investigating the influence of a controlled nanomodulation with nanoparticles on the electrical resistivity of the Au films, the resistivity of as-prepared Au films without artificial roughness needs to be addressed, which has been done in a recent study.[23] The high epitaxial quality and the small roughness of the Au films allowed a detailed analysis of the temperature dependence of the resistivity for film thicknesses even down to 2 nm. Surprisingly, the experimental data could be described best within the framework of the classical Fuchs–Sondheimer model[3] while an analysis based on the more physically motivated models of Mayadas–Shatzkes or Soffer[5] gave results that are not physically relevant. Further investigations on medium energy ion irradiated films also confirmed this finding.[24] None of the experiments performed on epitaxially grown Au films gave any hint of a strong influence of the Nb seedlayer on their transport properties. In addition, due to the small thickness of this layer (1 nm), its transition into the superconducting state was found to be suppressed. Furthermore, despite the high quality of the Au films, no influence of quantum effects on the resistivity could be observed and only the original classical size effect model was able to consistently describe the experimental results. Thus, it seems to be justified to analyze the resistivity of the present nanomodulated Au films within the framework of the Fuchs–Sondheimer model.

Nanomodulation of the Film Surface Using Pt Nanoparticles

Arrays of Pt nanoparticles with a high degree of hexagonal short-range order were deposited on top of epitaxially grown Au films (as described in more detail in the experimental section) serving as scattering centers for the conduction electrons. A slight increase in statistical roughness at the Au film surface can be expected due to the plasma treatment[29] necessary to remove organic precursors. However, since all of the preparation procedures have been performed simultaneously on both the nanomodulated as well as the reference film, all sample properties should be identical except for the nanomodulation. Thus, in case of any resistivity changes due to, e.g., the plasma-induced roughening at the surface, this effect will be present in both the nanomodulated as well as the reference Au film.

Figure 1 shows atomic force microscopy (AFM) pictures of an epitaxially grown Au film (thickness t = 25 nm) with one half serving as a reference film (parts a and b in Figure 1) and the other half being nanomodulated with Pt nanoparticles on its surface (parts c and d in Figure 1). Even though the combination of oxygen and hydrogen

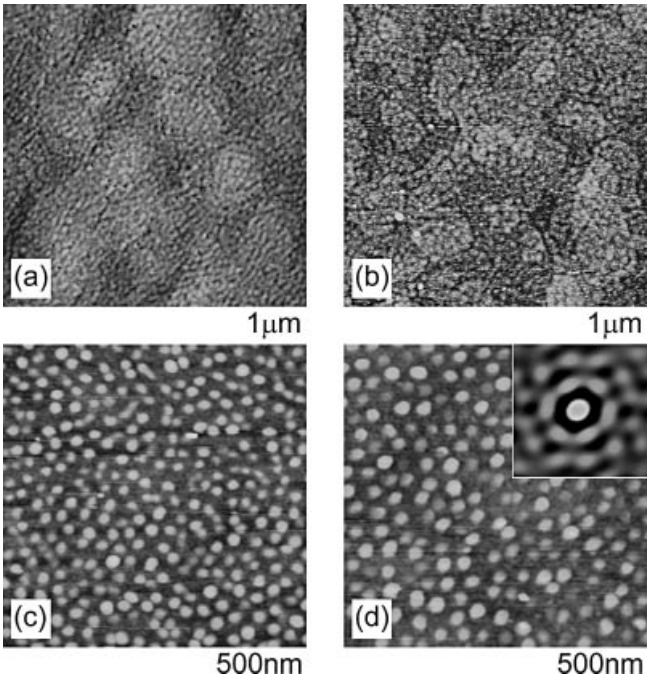

Figure 1. AFM images of the Au reference sample (a, b: z scale 3 nm) and the sample modulated with Pt nanoparticles (c, d: z scale 10 nm). The images were taken after polymer removal by the oxygen plasma (a, c) and after reduction of a thin Au oxide layer (thickness = 4 nm[29]), which is formed in the oxygen plasma by applying an additional hydrogen plasma step (b, d).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plasmas, which is required for the nanoparticle deposition, leads to a finite film roughness of the reference film of 0.23 nm_{rms} (Figure 1, a) and 0.28 nm_{rms} (Figure 1, b), respectively, the underlying terrace structure of the epitaxial Au film is still visible. After the oxygen plasma treatment, the Pt nanoparticles (Figure l, c) have a spacing of about 32 nm and a height of 3.7 nm, which is reduced to 2.9 nm by the subsequent hydrogen plasma (Figure 1, d). This decrease is due to the reduced nanoparticle volume in the metallic state as compared to the oxidized state, resulting from the exposure to an oxygen plasma. Although not perfectly ordered, the final nanoparticle arrangement exhibits a high degree of hexagonal short-range order as evidenced by the corresponding autocorrelation function shown in the inset of Figure 1 (d). Thus, deviations from the usually observed surface scattering effects induced by a statistical (random) surface roughness[4–25] can indeed be expected.

It has to be emphasized that it is not at all self-evident that stable metallic nanoparticles can be prepared on top of metal films. For Ag clusters, it was found that the clusters dissolve on epitaxial Ag films for temperatures $T > 300$ K whereas they are stable for $T < 225$ K.[30] Although Pt and Au are known to be fully miscible in the bulk, the diffusion constant turns out to be too small for Pt atoms to diffuse from the nanoparticles into the underlying Au film. Assuming a maximum temperature of 80 °C (required for the final conditioning of the nanomodulated sample, see below) which will be kept for a period of 3 days, a diffusion length $L = \sqrt{D \cdot t}$ of well below the interatomic distance can be estimated from published data for the diffusion constant $D = D_0 \cdot e^{-E/k_B T}$ with $D_0 = 9.5 \times 10^{-6}$ $m^2 s^{-1}$ and $E = 2.09$ eV.[31]

This estimate can experimentally be verified by means of X-ray Photoelectron Spectroscopy (XPS). Figure 2 (a) displays the Pt–4f core level spectrum (open symbols) of a nanomodulated sample acquired after annealing to about 80 °C in order to get rid of adsorbed water followed by an additional hydrogen plasma step in order to remove hydrocarbon adsorbates (see below). The Pt–4f spectrum can be well described by fitting[32] a single doublet (solid line) to the data using Doniach–Sunjic type line shapes.[33] As can be recognized in Figure 2 (a), the experimental binding energy position of the Pt–$4f_{7/2}$ core level agrees well with the value measured under identical conditions on a Pt reference sample (vertical solid line), but disagrees with published data[34] for the chemical shift observed in Pt_xAu_{100-x} intermetallic compounds (dashed line: $Pt_{75}Au_{25}$; dotted line: $Pt_{50}Au_{50}$; dash-dotted line: $Pt_{25}Au_{75}$). It is worth mentioning that the size of the final Pt nanoparticles (2.9 nm) matches the information depth of the spectroscopy (twice the photoelectron mean free path corresponding to 3 nm). Thus, significant intermixing between the Pt nanoparticles and the Au substrate can safely be excluded.

In addition to the binding energy position, the analysis of the line shape also provides valuable information about the electronic structure of the nanoparticles, which due to their reduced size of less than 3 nm, could be expected to show molecular/insulating rather than metallic properties. As can be seen in part a of Figure 2, the experimental core level spectrum exhibits a significant asymmetry towards higher binding energies (corresponding to lower kinetic energies of the outgoing photoelectrons) reflecting the creation of electron-hole pairs during photoemission in the vicinity of the Fermi energy E_F. This large asymmetry clearly indicates a high density of states at E_F[35] and, consequently, provides evidence that a particle size of about 3 nm is still large enough to maintain metallic properties of the nanodots allowing a strong coupling to the conduction electrons of the underlying Au film.

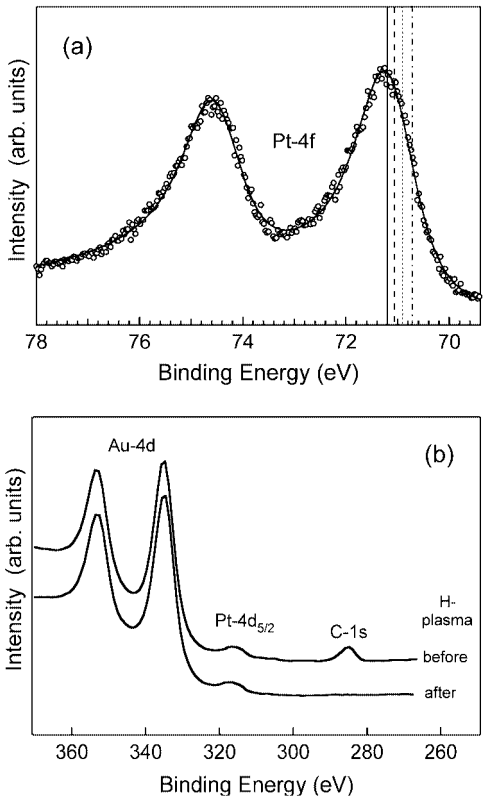

Figure 2. XPS core level spectrum of the Pt–4f doublet acquired after the final H-Plasma step (a) and C-ls binding energy range before and after annealing to about $T = 80$ °C followed by a hydrogen plasma treatment in order to remove adsorbates from the film surface (b). The vertical lines in (a) indicate the position of the Pt–$4f_{7/2}$ core level measured on a Pt reference sample (solid line) as well as the chemical shift observed for Pt_xAu_{100-x} intermetallic compounds[34] (dashed line: $Pt_{75}Au_{25}$, dotted line: $Pt_{50}Au_{50}$, dash-dotted line: $Pt_{25}Au_{75}$).

Surface Sensitivity

Because the resistivity of very thin metallic layers is strongly influenced by surface scattering of the conduction electrons special care has been taken in order to minimize the influence of adsorbates[4,10] like water or hydrocarbons which will accumulate at the surface when exposing the samples to ambient conditions and to various solvents required to perform the lithographic steps. In Figure 3, the resistivity $\rho_{4\,K}$ measured at $T = 4$ K (which corresponds to the residual resistivity ρ_0) and the room temperature resis-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

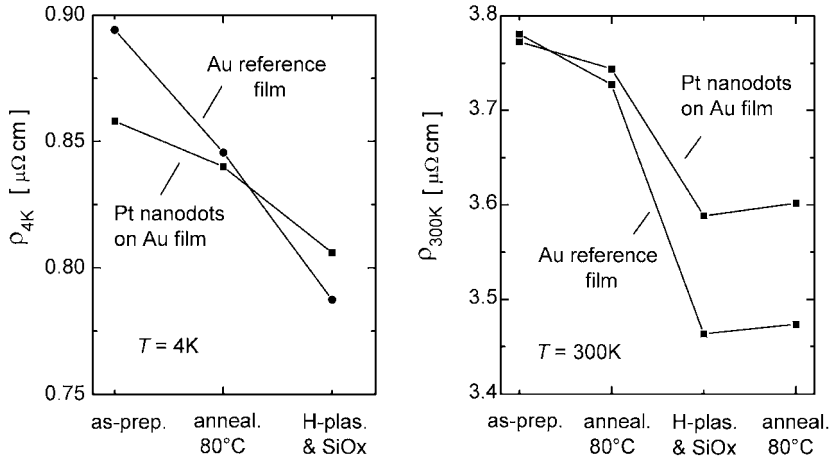

Figure 3. Resistivity at T = 4 K (left) and T = 300 K (right) of the Pt nanomodulated sample as compared to the reference film (thickness of both films: t = 25.4 nm). The resistivity of both samples decreases strongly with increasing surface cleanliness.

tivity $\rho_{300\,K}$ determined at T = 300 K of a nanomodulated Au film is compared with the values acquired from the corresponding Au reference film with both samples being treated simultaneously by the different preparational procedures. In the case of the as-prepared samples and the data taken in the cryostat without any additional treatments, the resistivity of the nanomodulated sample is found to be smaller than the reference film at both temperatures. This is opposite to what is expected for a nanomodulated sample, which should reveal a resistivity enhancement related to a smaller specularity parameter p due to the additional roughness induced by the nanoparticles.

In order to unravel whether adsorbates are responsible for this surprising result, in a first step, all samples were annealed within the cryostat to T = 80 °C for 3 days which is expected to remove the adsorbed water layer from the sample surface. After this procedure both, $\rho_{4\,K}$ and $\rho_{300\,K}$, are found to be reduced with the low temperature value of the reference film still being higher than the corresponding value measured for the nanomodulated film. In a second step, the sample surface was cleaned by removing all hydrocarbon adsorbates in a hydrogen plasma (5 min, 100 W, 0.01 mbar) as evidenced in Figure 2 (b) by means of a vanishing C-ls peak intensity followed by the in situ evaporation of an insulating layer (SiO), in order to protect the metallic film surface from re-adsorption of contaminants during sample transport under ambient conditions to the cryostat. Again, $\rho_{4\,K}$ as well as $\rho_{300\,K}$ are found to be significantly decreased as compared to the previous annealed state of the samples. Additionally and most gratifying, after this cleaning and protecting, the resistivity of the nanomodulated film is observed to be higher than the resistivity of the reference film for both temperatures which is consistent with the expected decrease of the specularity parameter p for the nanomodulated sample.

After carefully characterizing the resistivity as a function of temperature in this state of the samples, a further annealing cycle to T = 80 °C was performed. Since adsorbates/contaminants deposited by the ex situ preparation/transport should be located on top of the SiO protection layer rather than at the interface Au/SiO, in this case, no changes in resistivity are expected due to annealing. Such behavior can most notably be observed in Figure 3 within the experimental uncertainty. Thus, the addition of a protection layer after a hydrogen-plasma induced cleaning step allows for the analysis of the temperature-dependent resistivity $\rho(T)$ dominated by intrinsic surface scattering rather than by surface contaminations. Under these conditions, the influence of modulating a metal film surface by depositing an array of Pt nanoparticles on its electrical transport properties should be detectable.

Temperature Dependence of the Resistivity – Comparison with the FS Model

To determine the characteristic properties of a t = 25.4 nm Au film and to estimate the influence of the nanomodulation on its electrical properties, $\rho(T)$ was measured between 4 K and 300 K using the lock-in technique (Figure 4, open symbols) and the results were compared with the predictions of the classical size effect model of FS (Figure 4, solid lines). This was achieved by means of a numerical fitting procedure (for details see ref.[23,24]). The best fits to the experimental data have been added as solid lines to Figure 4 showing nearly perfect agreement between theory and experiment over the whole temperature range. While such a behavior has already been observed in previous studies on epitaxially grown Au films[23,24] it is rather surprising in the case of the nanomodulated film where deviations from the classical description are expected. On the other hand, after the more qualitative discussion of $\rho_{4\,K}$ and $\rho_{300\,K}$, as shown in Figure 3, the agreement between the experimental and theoretical results within the FS model legitimates extracting all relevant parameters e.g. the specularity parameter p, the electron mean-free path due to impurities l_{imp} and the Debye temperature θ_D. This allows a more detailed analysis of the electrical properties of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nanomodulated sample as compared with the corresponding Au reference. The resulting sets of parameters are summarized in Table 1 as obtained for the as-prepared, the annealed, as well as the SiO covered state.

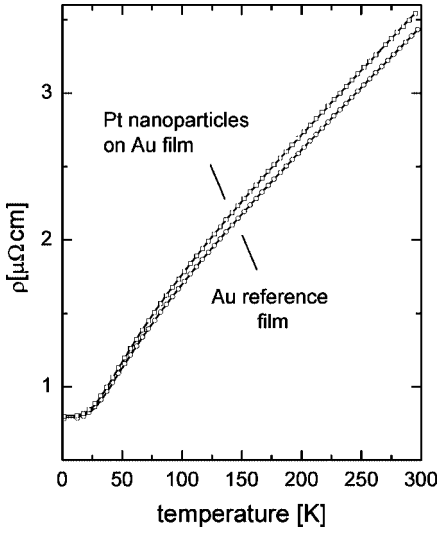

Figure 4. Temperature dependence of the resistivity of a Pt nanomodulated Au thin film sample as compared to the corresponding Au reference film (thickness of both films: t = 25 nm) after exposure to a hydrogen plasma and the in situ deposition of a SiO protection layer (open symbols). The solid lines represent the best fit to the experimental data using the FS model.

Table 1. FS fit parameters derived from the measured $\rho(T)$ curves of the Au reference sample and the nanomodulated sample in the as-prepared, the annealed and the SiO covered state.

	Au reference			Pt nanodots on Au		
	as-prep.	anneal.	SiO	as-prep.	anneal.	SiO
p	0.20	0.21	0.30	0.19	0.19	0.26
l_{imp} [nm]	700	819	697	854	905	805
θ_D [K]	185	190	178	189	191	184

For all measurements, the FS fit gives values for θ_D which are close to the bulk value of 184.6 K as obtained from fitting the temperature dependence of the resisitivity of Au bulk samples[36] with our fitting routine. The latter value itself agrees well with Debye temperatures deduced from resistivity measurements by other groups.[37,38] It is important to note that θ_D values for bulk Au extracted from transport measurements are found to be systematically larger than the corresponding values determined from XRD measurements by analyzing the temperature dependence of the Debye–Waller factor (165–170 K). This might be due to a different weighting of the real phonon density of states by the two different methods.

The similarity of the Debye temperatures extracted for the different states of the reference samples (as-prepared, annealed, SiO covered) confirms that the deposition of Pt nanoparticles on top of the epitaxially grown film using the micellar technique did not change its dynamic properties by, e.g., absorbing a significant amount of hydrogen during the hydrogen plasma treatment. This is also confirmed by analyzing l_{imp}, which determines the residual resistivity of the corresponding bulk material caused by impurities, grain boundaries or other lattice defects. This parameter remains roughly constant for both types of films (reference sample, nanomodulated sample) independent of the condition of the film surface (as-prepared, annealed, covered with SiO). In addition, the order of magnitude observed for l_{imp} in Table 1 also agrees well with the values observed for non-hydrogen plasma treated Au films of similar thickness, studied earlier.[23] Furthermore, the high value of about 800 nm observed for the electron mean free path due to impurities etc. of the corresponding (hypothetical) bulk material also confirms that the concentration of impurities is small and the grain size is large as compared to the sample thickness of t = 25 nm. This adds confidence that the Au films studied here can indeed be used as sensors for surface scattering processes (electron mean free path of the corresponding bulk material is much larger than the film thickness).

It is worth mentioning that by fitting the FS model to the temperature-dependent resistivity of a thin film, reasonable estimates can be extracted for the parameter l_{imp} describing the average distance between impurities or defects within the corresponding bulk material having the same morphology as the thin film. Thus, although the thin film resistivity is enhanced by surface scattering as compared to the bulk resistivity, the above analysis provides insight into the morphology of the thin film by means of impurity/defect concentrations, which is an important issue for the design of metallic interconnects[15,18] in microelectronics.

In Table 1, both parameters θ_D and l_{imp} do not vary significantly when the properties of the sample surface are changed. The appropriate quantity providing information on the condition of the sample surface (cleanliness and nanomodulation) is the specularity parameter p. For the as-prepared Au reference sample, the specularity parameter p = 0.203 is rather small. Only about one fifth of all electrons that contribute to the current are scattered specularly at the film surface or interface. As expected, p is slightly enhanced after moderate annealing of the sample in vacuo and p is increased further to 0.302 after removing all adsorbates by a hydrogen plasma and protecting the sample surface with a SiO layer. The probability of specular surface scattering is obviously significantly reduced by adsorbates on the film surface. Even though the probability of specular reflection is increased by almost 50% for the reference film due to an improved cleanliness at the surface, the absolute value of p is still rather small and only about 1/3 of all electrons are scattered specularly at the film surface or interface.

Once it is known that the specularity coefficient p of the Au reference sample is only 0.302 even in the best case, the effect of the Pt nanomodulation on the transport properties is expected to be comparatively small. To demonstrate the effect of modulating a Au surface by an array of Pt nanoparticles, the specularity coefficients p for the Au reference and the nanomodulated sample as extracted for the different surface conditions are summarized in Figure 5. In every case (as-prepared, annealed, SiO covered), the specularity coefficient p of the nanomodulated sample is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

smaller than that of the Au reference. The reduction of p due to the nanomodulation is most pronounced when the nonmodulated reference Au film exhibits a high degree of specular reflection (SiO covered state). Thus, the main conclusion of the present work is that the decoration or nanomodulation of an otherwise optimized Au surface with arrays of Pt nanoparticles showing a high degree of hexagonal short-range order just reduces the probability of specular reflection, as would be expected for randomly distributed additional scatterers.

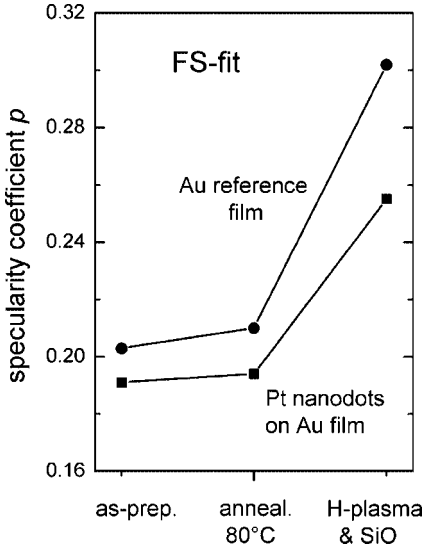

Figure 5. Specularity parameter p for the Au reference and the nanomodulated sample. By improving the surface cleanliness, p is enhanced. The nanomodulation generally leads to an increased probability of diffuse surface scattering as compared to the Au reference.

In order to better understand why diffuse surface/interface scattering dominates in the present experiment, the influence of the Nb seedlayer on electron transport has to be examined in more detail. Comparing the room temperature electrical resistivity of bulk Au (ρ = 2.2 μΩcm) and Nb (ρ = 15 μΩcm) and taking into account the different thickness of both materials (Nb: 1 nm, Au: 25.4 nm) it is obvious that electrical transport through the Nb layer can be neglected. The main impact of the seedlayer on the sample resistivity most likely is a change of the specularity parameter p at the interface between the Au film and the seedlayer as compared to a hypothetical interface between the Au film and the sapphire surface.

Investigations of specular electron scattering in Au films covered with 0.6 nm of Ta were observed to significantly increase the film resistivity by s–d scattering in contrast to Ag or Cu, which did not quench specular reflection.[11] Thus, it is very likely that scattering of the conduction electrons at the Au/Nb interface is not specular but rather diffuse. Unfortunately, this Nb seedlayer cannot be avoided if continuous, flat, epitaxially grown Au films are required as in our study. The only way to achieve Au films of similar quality is to use Fe or Cr seedlayers, which will worsen the conditions when compared with Nb because of the additional strong spin scattering at the interface, an effect which is well known, e.g., from magnetic (GMR) sensors.

Finally, it is worth mentioning, that Pt nanoparticles deposited directly onto the sapphire substrate before growing the Au film in order to avoid surface roughening induced by the plasma treatments did not result in an improved value of the specularity parameter p. Instead, l_{imp} of those films was found to be reduced to about 100 nm (as compared to 800 nm in the case of nanoparticles "on-top") probably due to a distorted epitaxial growth of the Au film on top of the Pt nanoparticles. For this sample configuration, an even further reduced specularity parameter was observed (0–0.1).

Conclusions

The influence of an array of Pt nanoparticles, prepared with a high degree of hexagonal short-range order on top of high quality epitaxial Au films on their electrical properties has been studied. It turned out that the temperature-dependent resistivity of the nanomodulated Au films are well described by the classical size effect model of Fuchs–Sondheimer. No indication could be detected that pointed to a specific effect of the nanoparticle array other than simply increasing the probability of diffuse surface scattering as would be expected for randomly distributed scatterers.

Experimental Section

Micellar Nanoparticles: Pt nanoparticle arrays were prepared using a method based on the self-assembly of suitable diblock-copolymers. A polystyrene(PS)-block-poly(2-vinylpyridine)(P2VP) copolymer was dissolved in an apolar solvent, where the copolymer chains assemble in spherical micellar objects with a hydrophilic P2VP core and a hydrophobic PS shell. The core of the micelle can be loaded with metal salts by adding the appropriate substance to the micellar solution. These metal salt loaded spherical micelles can easily be transferred onto substrates by dip coating, where, again by self-assembly, hexagonal arrays of micelles are formed. With the aid of a combined oxygen and hydrogen plasma process the micellar polymer can be removed, the metal salt can be reduced and spectroscopically clean arrays of metallic particles remain on the substrate. The hexagonal short-range order of the particles was not destroyed by the plasma process. Details on the preparation of micellar solutions and the plasma process can be found elsewhere.[26,27] For the work here, Pt nanoparticles were prepared with a diameter of about 3 nm and a spacing of about 32 nm.

Sample Preparation: The epitaxial Au films were prepared at about 300 °C on c-cut sapphire substrates with a 1 nm Nb seedlayer. The details are described in ref.[28] The samples are structured with standard photo lithography techniques and wet etching in I/KI solution[39] or etched in an RIE-plasma process (Oxford instruments, RIE-PlasmaLab 80Plus). The pattern is shown schematically in Figure 6. Twelve contacts allow four-probe measurements of the resistance on several segments of the sample.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

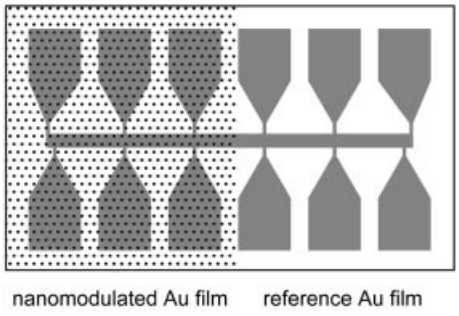

Figure 6. Sketch of a structured nanomodulated Au film sample. One half of the sample is covered with nanoparticles, the other serves as a reference. Four-probe measurements are possible on different segments on both sides.

In the size effect experiments, surface scattering properties of thin films were investigated by the temperature dependence of the resistivity and the specularity parameter p was determined by fitting to FS theory. For experiments on nanomodulated samples, one has to consider the ordinary size effect of thin films and the, probably, small influence of the nanomodulation. For this reason, both a nanomodulated Au film and a Au reference film are prepared in parallel on the same substrate as sketched in Figure 6. In this way, both films can be measured under identical conditions at the same time. All other processes (film growth, plasma exposure, lithography) were performed on the whole sample so that again both films undergo identical treatments and differ only by the nanomodulation. Such a relative measurement should enable the investigation of the influence of nanomodulation on thin film resistivity even if its effect is small.

The thickness of the epitaxial Au films was determined by means of a careful analysis of the Laue oscillations observed in the corresponding X-ray diffraction spectra using the program 'SUPREX'.[40,41] Because of the high quality of the films used in this study, an oscillating intensity could be observed over a wide range of angles covering the small angle as well as the large angle scattering regimes, respectively (for more details, see ref.[23]).

In order to control the chemical state of the Au surface and the Pt nanoparticles after the different preparational steps, the specimens were introduced into the analysis chamber of a commercial electron spectrometer (Fisons ESCALAB-210) and analyzed under ultrahigh vacuum conditions by means of XPS using monochromatized Al-K_α radiation ($h\nu$ = 1486.6 eV, spot size < 1 mm). Data were acquired using an overall energy resolution (electrons and photons) of between 0.5 and 1 eV, full width at half maximum (FWHM). At this point, it is important to note that by combining two separate chambers via a load-lock system, the plasma treatments and the XPS measurements could be performed in situ.

Nanoscaled Sn and Pb Particles Aligned in Al_2O_3 Tubes Obtained from Molecular Precursors

Michael Veith,*[a] Jacqueline Frères,[a] Peter König,[a] Oliver Schütt,[a] Volker Huch,[a] and Joel Blin[a]

Keywords: Tin and lead clusters / Nanoparticles / Al_2O_3 tubes / Alignment of metal clusters / Alkoxy- and siloxyaluminum amides

Tin and lead nanoparticles and metal sponges were prepared by reducing $Me_2Si(NtBu)_2Sn$ (**7**) and $Me_2Si(NtBu)_2Pb$ (**9**) with $[H_2AlOtBu]$ (**3**), $[HAl(OtBu)_2]$ (**13**), $[H_2AlOSiMe_2tBu]$ (**8**), and $[(Me_2tBuSiO)_2AlH]$ (**15**). Together with dihydrogen and the metals in their elemental state the monomeric compounds $[Me_2Si(NtBu)_2Al(OSiMe_2tBu)(THF)]$ (**10**) and $[Me_2Si(NtBu)_2Al(OtBu)(THF)]$ (**11**) can be obtained, to mention only two examples. Each monomer is stabilized by a THF molecule coordinated to aluminum, which on sublimation loses its donor molecule and dimerizes through Lewis acid–base interactions to the spiro compounds $[Me_2Si(NtBu)_2AlOSiMe_2tBu]_2$ (**12**) and $[Me_2Si(NtBu)_2AlOtBu]_2$ (**4**), respectively. The molecular structures of **10**, **11**, and **12** were determined by single-crystal X-ray diffraction techniques. The reduction of **7** at –115 °C is gradually indicated by a color change of the reaction mixtures from red to dark brown with increasing temperature and depending on the reducing agent used. The tin powders that were obtained were identified as β-tin using X-ray powder diffraction techniques and their average crystallite size depends on the polarity of the solvent and hydride used. Under certain conditions metal sponges are formed. Pycnometric measurements were carried out on the tin and lead sponges. These showed almost the known densities for the metals when helium was used whereas significantly smaller ones were measured in water. Porous alumina membranes of different pore diameters were filled with tin and lead particles. Metal nanoparticles were prepared within the tubes of the membranes by reduction of the metal amides in the pores. The infiltration process can be repeated up to ten times increasing the amount of particles within the tubes monitored by SEM. The obtained brown or black membranes were characterized by SEM, EDX, and UV/Vis analysis. The filled membranes show sharp impervious ranges in the UV/Vis spectrum between 270 and 525 nm and could therefore be used as wavelength filters.

Introduction

During the last years metal clusters and colloids have become more and more important as building blocks in the synthesis of organized nanostructured materials. Because of the various applications of metal nanoparticles many articles have emerged, especially in the field of surface-enhanced spectroscopy or photocatalysis. In addition, studies on the size-controlled synthesis and the self-assembly of clusters have appeared.[1,2] Interestingly, the majority of the publications deal with the synthesis and the properties of transition or noble metal nanoparticles,[3] whereas comparatively little is known about colloidal nanoparticles of main group metals.[4]

In this work we describe the preparation of tin and lead colloids and clusters on the nanometer scale using chemical control. The syntheses are based on an organometallic route, which we have already described in former reports.[5,6] In this route, tin and lead amides are reduced by siloxy- or alkoxyalanes in organic solvents leading to tin or lead particles, together with dihydrogen and siloxy or alkoxy compounds. A proposal for the mechanism of the formation of the aluminum compounds is given in this report. By controlling different parameters, e.g. temperature and concentration of the starting materials, it was possible to obtain tin and lead particles either stabilized as colloids or as metal powders and sponges.

We have been able to insert the metal particles into porous alumina membranes of different pore diameters. The membranes were produced for our use by G. Schmid et al., who have already used such membranes for one-dimensional ordering of gold colloids.[7]

Results and Discussion

Syntheses and Reaction Mechanism

Tin and lead particles can be efficiently obtained by reduction of tin or lead amides with siloxy- or alkoxyalanes in organic solvents. Besides dihydrogen, a siloxy- or an alkoxyaluminum amide is formed through ligand exchange.

E-mail: veith@mx.uni-saarland.de

In former publications we reported on the formation of the alkoxy(amino)alane [$(Me_3Si)_2N(H)AlOtBu$] (**1**) in a redox reaction between the lead amide $Pb[N(SiMe_3)_2]_2$ (**2**)[8] and a double equivalent of the *tert*-butoxyalane [$H_2AlOtBu$] (**3**)[9] [Equation (1)].[6] The spirocyclic compounds $[Me_2Si(NtBu)_2AlOtBu]_2$ (**4**) and $[Me_2Si(NtBu)_2AlOSiMe_3]_2$ (**5**) have been obtained by stoichiometric reactions of [$H_2AlOtBu$] (**3**) or [$H_2AlOSiMe_3$] (**6**),[10] respectively, with the cyclic diazastannylene $Me_2Si(NtBu)_2Sn$ (**7**)[11] [Equation (2)].[5]

$$\underset{\mathbf{2}}{Pb[N(SiMe_3)_2]_2} + 2\,\underset{\mathbf{3}}{[tBuOAlH_2]} \longrightarrow \underset{\mathbf{1}}{\{[(Me_3Si)_2N](H)Al(OtBu)\}_2} + H_2 + Pb \quad (1)$$

$$\underset{\mathbf{7}}{Sn(NtBu)_2SiMe_2} + \underset{\mathbf{3,6}}{[(RO)AlH_2]} \longrightarrow \underset{\mathbf{4,5}}{\tfrac{1}{2}\,[Me_2Si(NtBu)_2Al(OR)]_2} + H_2 + Sn \quad (2)$$

R = *t*Bu **3**, **4**; R = $SiMe_3$ **6**, **5**

Using a similar procedure we have recently treated the stannylene $Me_2Si(NtBu)_2Sn$ (**7**) with [$H_2Al(OSiMe_2tBu)$] (**8**) and the plumbylene $Me_2Si(NtBu)_2Pb$ (**9**) with [$H_2AlOtBu$] (**3**) in equimolar ratios [Equations (3)–(5)]. We were able to isolate the monomeric compounds $[Me_2Si(NtBu)_2Al(OSiMe_2tBu)(THF)]$ (**10**) and $[Me_2Si(NtBu)_2Al(OtBu)(THF)]$ (**11**), each monomer being stabilized by a donor solvent molecule [Equation (3)]. If the compounds **10** and **11** are sublimed, they release the solvent donors and dimerize to the spiro compounds $[Me_2Si(NtBu)_2Al(OSiMe_2tBu)]_2$ (**12**) or to **4** [Equation (4)]. Both spirocyclic compounds can also be prepared in solution by heating the reaction mixtures [Equation (4)]. The monomeric compounds **10** and **11** have until now not been observed, and as in our former workup the crude products were directly sublimed [Equation (5)].

Figure 1. In Figures 2 and 3 some ball-and-stick representations of the structures of the compounds **10** and **11**, which may be considered as molecular halves of the spirocyclic systems, are shown.

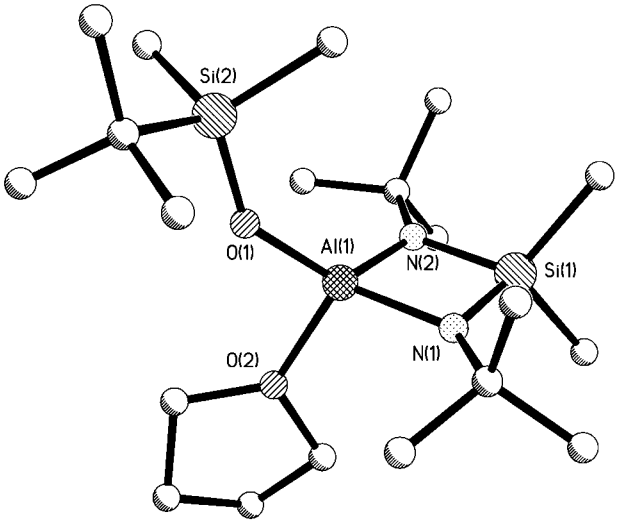

Figure 2. Selected bond lengths [Å] and angles [°] of **10**: Si(1)–N(2) 1.745, Si(1)–N(1) 1.730, Al(1)–N(1) 1.831, Al(1)–N(2) 1.824, Al(1)–O(1) 1.727, Al(1)–O(2) 1.877, O(1)–Si(2) 1,635, N(1)–Si(1)–N(2) 90.83, N(1)–Al(1)–N(2) 85.24, Al(1)–N(1)–Si(1) 92.01, Al(1)–N(2)–Si(1) 91.75, O(2)–Al(1)–O(1) 98.15, C(2)–Si(1)–C(1) 105.68.

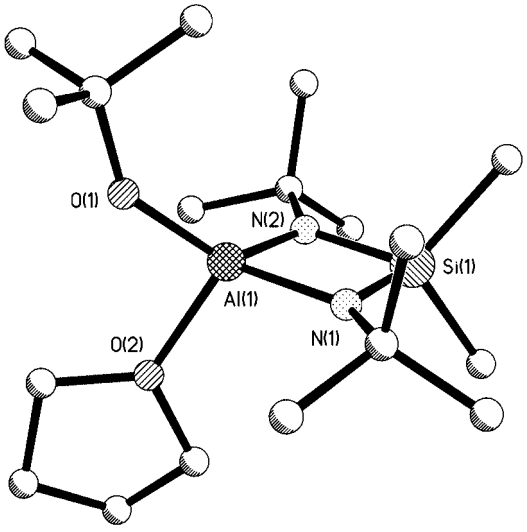

Figure 3. Selected bond lengths [Å] and angles [°] of **11**: Si(1)–N(2) 1.733, Si(1)–N(1) 1.720, Al(1)–N(1) 1.820, Al(1)–N(2) 1.823, Al(1)–O(1) 1.702, Al(1)–O(2) 1.895, N(1)–Si(1)–N(2) 91.15, N(1)–Al(1)–N(2) 85.24, Al(1)–N(1)–Si(1) 92.03, Al(1)–N(2)–Si(1) 91.50, O(2)–Al(1)–O(1) 94.63, C(2)–Si(1)–C(1) 105.5.

Both molecular structures differ from each other only in the oxy ligands at the aluminum atoms. The compounds have a 1,3-diaza-2-sila-4-aluminacyclobutane unit with the aluminum atoms in tetrahedral sites coordinated by two nitrogen and two oxygen atoms. The Al–N–Si–N four-membered rings are almost planar as may be deduced from the sums of the angle of 359.8° for **10** and 359.9° for **11**. The dimensions found in the rings and around the metal atoms are similar to those found in the corresponding spirocyclic molecules.

On treating the plumbylene **9** or the stannylene **7** with a double equivalent of the monohydridoalane [(*t*BuSiO)$_2$AlH] (**13**) in THF, the spiro compound **4** was formed, along with tri-*tert*-butoxyalane (**14**) [Equation (6)]. For this reaction, we assume a mechanism as shown in Figure 4.

$$\underset{\mathbf{7,\,9}}{M(N\mathit{t}Bu)_2SiMe_2} + 2\,\underset{\mathbf{13}}{[(\mathit{t}BuO)_2AlH]} \longrightarrow \tfrac{1}{2}\,\underset{\mathbf{4}}{[Me_2Si(N\mathit{t}Bu)_2Al\mathit{O}t\mathit{B}u]_2} + H_2 + M + \underset{\mathbf{14}}{Al(\mathit{O}t\mathit{B}u)_3} \qquad M = Pb,\ Sn \tag{6}$$

The corresponding reaction between the stannylene **7** and two equivalents of the siloxyalane [(Me$_2$*t*BuSiO)$_2$AlH] (**15**) did not lead to a spiro compound but to the monomeric THF adduct **10** [Equation (7)]. A further product in this reaction is most likely to be the alumosiloxane (Me$_2$*t*BuSiO)$_3$Al (**16**), but we have not been able to isolate or identify this compound yet.

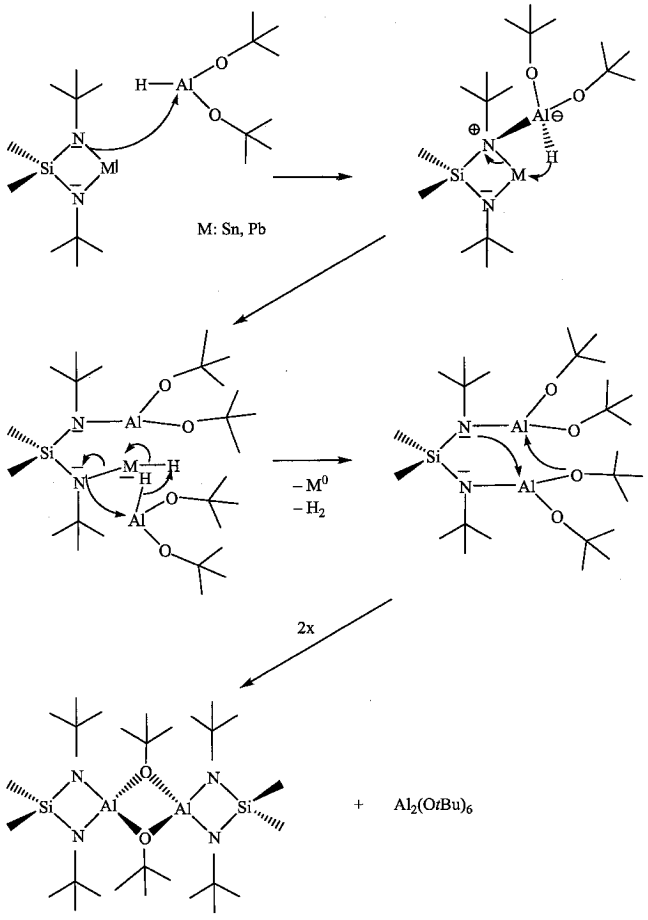

Figure 4. Mechanism for the reaction of Equation (6).

$$\underset{\mathbf{7}}{Sn(NtBu)_2SiMe_2} + 2\ \underset{\mathbf{15}}{[(Me_2tBuSiO)_2AlH]} \longrightarrow \underset{\mathbf{10}}{[Me_2Si(NtBu)_2Al(O\,SitBuMe_2)(THF)]} + H_2 + Sn + \text{further products}\ \underset{\mathbf{16}}{} \quad (7)$$

Materials Part

By using our reduction procedure of the tin and lead amides it is possible either to stabilize the tin and lead particles as colloids in solution or to obtain them as nanoscaled powders or metal sponges depending on the chosen reaction conditions (temperature or concentration of the starting materials). With regard to the lead formation we have already reported in detail on the different species that may be produced.[6] Here we mainly want to discuss our results from the reduction of the tin compounds.

The polarity of the solvents used has an important influence on the diameters of the tin crystallites that are produced. We studied the reactions of **7** with **3** or **6** [see Equation (2)] in different polar solvents or solvent mixtures, respectively (see Table 1).

Table 1. Average crystallite sizes from analysis of peaks in X-ray powder diffraction data. Reaction of $Me_2Si(NtBu)_2Sn$ (**7**) with $[H_2AlOtBu]$ (**3**) (a), or with $[H_2AlOSiMe_3]$ (**6**) (b).

(a) Medium	Average crystallite size	(b) Medium	Average crystallite size
THF	<20 nm	THF	20–30 nm
THF/thiophene (10%)	60–80 nm	THF/thiophene (10%)	60–80 nm
THF/TMEDA (10%)	160–180 nm	THF/TMEDA (10%)	200–220 nm
Toluene	500–520 nm	Toluene	800–820 nm

When the reaction is started at –115 °C (ethanol/liquid N_2) a clear yellow solution forms. By warming the reaction mixture to room temperature a dramatic color change from red to dark brown takes place. On further heating the mixtures above 40 °C, black suspensions are formed. Obviously, the tin particles are in the first instance formed in a colloidal form (clear intensively colored solutions) and with higher temperatures they grow and agglomerate to finally precipitate. When the siloxyalane **6** is used instead of $[H_2AlOtBu]$ (**3**) in solvents like toluene or THF as reductive agents, the reduction already starts at lower temperatures, since the color change is observed earlier on the temperature scale (Figure 5).

The precipitates that were obtained were isolated at room temperature and characterized by X-ray powder diffraction and revealed to be in all cases β-tin. In the X-ray powder diffraction diagrams of precipitates generated in polar THF, significantly broader diffraction signals appear compared to those of the powders obtained from toluene (Figure 6).

Using a modified Scherrer method it was possible to estimate an average crystallite size from the X-ray diffraction

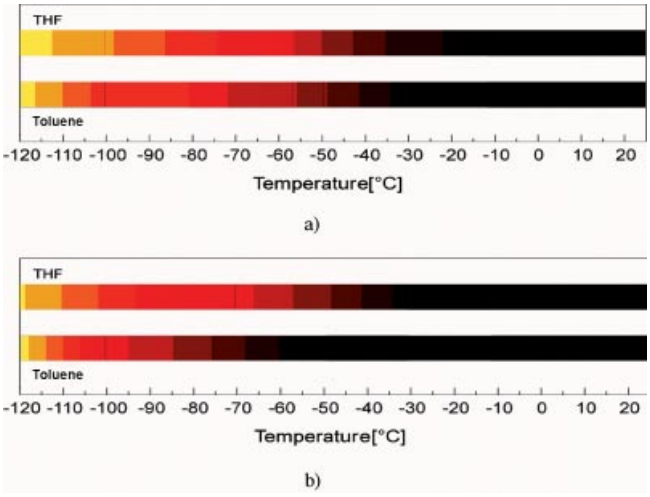

Figure 5. Colors of the reaction mixtures correlated with the temperature. Reaction of $Me_2Si(NtBu)_2Sn$ (**7**) with $[H_2AlOtBu]$ (**3**) (a), or with $[H_2AlOSiMe_3]$ (**6**) (b).

diagrams.[13] The results of this line analysis are shown in Table 1.

The tin particles formed by the reduction of $[Me_2Si(NtBu)_2Sn]$ (**7**) with the more reactive hydride **6** [R = $SiMe_3$, (b) in Table 1] show a larger average crystallite size than those formed when the hydride **3** [R = *t*Bu, (a) in Table 1] is used. This becomes very obvious when toluene is used as a solvent, because then the differences in the sizes are approximately 300 nm. The siloxy groups may have an influence on the most apolar solvent. On the other hand, in the more polar THF, the average crystallite sizes lie in both cases below 30 nm and using hydride **3** the crystallite size may even be below that of 20 nm. Obviously, the donor molecules like THF as well as thiophene and TMEDA in the solvent mixtures are able to stabilize the colloids in such a way that the crystallite growth is hindered. This can also be concluded from experimentally determined carbon/hydrogen contents of the precipitates generated from toluene and THF. They are, for those powders formed in THF, between 7 and 11 times higher than for those generated in toluene (Tables 2 and 3). So it is very likely that solvent molecules are coordinated on the surface of the particles. We have tried to perform HRTEM analyses on the powders, but observed high reactivities with oxygen prior to the measurements, almost excluding a proper experiment. Although we have no data for tin, we assume similar behavior as for lead.[6]

If the metal powders are allowed to interact with one another for longer times, or toluene is used as the solvent, the agglomeration continues and metal sponges are formed. In Figures 7 and 8 fragments of such a tin sponge and the corresponding SEM images are shown. The nanoscopic porosity of the sponges is clearly proved by the SEM images.

Several pycnometric measurements were carried out on the tin sponges. When water was used, an average density of 1.5 g/cm^3 was determined, indicating that some of the holes could not be penetrated by water. With the inert and smaller helium (which is able to fill the pores in a much

better way) we determined an average density of approximately 7 g/cm^3 for the same sponges, which is near the value of 7.3 g/cm^3 for pure tin.[14] For the sake of comparison we also measured the density of the corresponding lead sponges obtained from the reactions between the lead amides and the hydrides (see ref.[6]). With water, a value of almost 8 g/cm^3 was obtained, and with helium the density of approximately 11 g/cm^3 was again close to that of lead

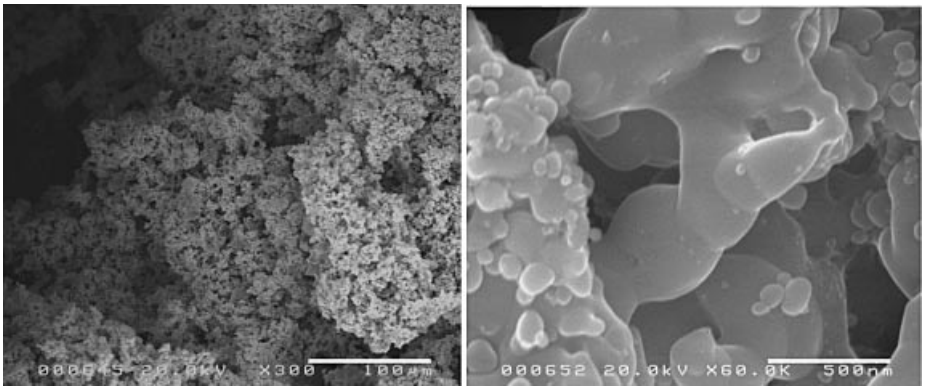

Figure 8. SEM images of a tin sponge to illustrate its high porosity. The two pictures have different scales.

(ref.[14]: 11.3 g/cm^3). The mean values of the pycnometric measurements for the metal sponges in water seem to indicate a higher porosity and smaller diameters of the channels for the precipitates of tin than for those of lead.

To fill porous alumina membranes as templates with lead or tin nanoparticles we used different techniques. We have recently reported on our first attempts to fill the membranes with lead particles.[6] We managed to fill the pores up to a certain extent by treatment of the templates with colloidal solutions of different concentrations, but because of the relatively large diameters of the particles in those colloids (up to 200 nm) they covered mainly the surface of the membranes and did not fill the much smaller pores with diameters of approximately 60 nm.

For new attempts we not only used membranes with various pore diameters of 25, 30, 50, 60, 80, 90, 120 and 300 nm,[7] but also varied the filling techniques. The thickness of the membranes varied between ca. 25 μm and 90 μm and the particle sizes in the membranes are linked to the diameters of the channels as checked by XRD on selected samples after destruction. We finally succeeded in the infiltration of the membranes. Table 4 gives an overview of different possibilities to fill the membranes with tin or lead particles.

Table 4. Possibilities for membrane filling.

(i) membrane + colloidal solution ⟶ diffusion
(ii) membrane + colloidal solution + followed by vacuum induction of the prepared particles
(iii) membrane + lead or tin amide solution ⟶ diffusion of the solution into the pores followed by reactions within the pores by addition of the hydride
(iv) same as in iii but with vacuum induction

For methods (i) and (ii) the membranes were put into already prepared colloidal solutions of the metal and were filled by pure or vacuum-induced diffusion. Methods (i) and (ii) led to dark membranes because of agglomeration of the metal particles on their surfaces. These membranes were not further investigated with regard to their optical properties. For methods (iii) and (iv) the membranes were treated, after careful washing with the solvents and drying, in a first instance with the stannylene or plumbylene solutions. In a second step, they were washed with a small amount of solvent in order to clean the surface. Finally, the metal clusters were synthesized within the membranes by reaction with the added hydrides. The channels of the membranes were filled with the amide solutions using vacuum-assisted diffusion. The routes (iii) and (iv) of Table 4 proved to be the most effective methods to fill the templates. Besides the different filling methods we also varied the concentrations of the reaction solutions, the temperature [<–100 °C for (i) and (ii) and 20 °C for (iii) and (iv)] and the filling time. Finally, we repeated the filling process several times. We cannot completely exclude a side reaction of the metal amides with remaining hydroxy groups on the inner surfaces of the alumina membranes; the concentrations of the stannylene solutions were chosen in such a way that these side reactions may be almost neglected. Furthermore, we could not observe spectroscopically any of the hydrolysis byproducts of the stannylene **7**. Also the molecular byproducts described in the first section of this article have not been isolated and separated for each filling process. In the following, we want to describe in more detail mainly the filling of the membranes with tin. The experiments with lead amides showed similar results, some of which have already been documented.[6] With increasing concentrations and filling time (or repetitions of the filling process) a significant color change of the originally transparent membranes from light brown to dark brown and finally to black is observed. The infiltration can be monitored by EDX analysis. Figure 9 contains spectra of (a) a non-treated 50 nm membrane, (b) a light brown and (c) a dark brown membrane after filling with tin particles.

The signal at 3.5 keV found in the EDX spectra is characteristic for tin and a comparison of these signals with the ones of aluminum at 1.8 keV confirms a higher Sn content for the dark brown membrane. The different intensities in color of the membranes treated with differently concentrated stannylene solutions (up to 210 mmol/L) are reflected in their UV spectra shown in Figure 10. In Figure 10 (a) and (b) the spectra are shown when the hydride **3** was used for reduction, whereas Figures 10 (c) and (d) contain the spectra for when the hydride **6** was used (the self absorption of the membrane is subtracted in the spectra on the right-hand side). With increasing concentrations of stannylene and longer filling times the maxima of the absorptions be-

come more intense and the bands are widened due to the bigger sizes and the larger amounts of particles. In addition, the absorption maxima are shifted towards higher wavelengths when the amount of aggregating tin clusters increases leading to an interaction of their plasmon resonances (see also ref.[6] for further discussion).

Already from a visual comparison it becomes evident that the different reactivities of the reductive agents **3** and **6** has only little influence on the color of the treated membranes as shown by their UV spectra. All filled membranes show almost identical absorption curves depending on the concentration of tin clusters.

Dark brown or black membranes result from very high concentrations of stannylene (>350 mmol/L). The absorption spectra show broad signals with very high intensities. Such a spectrum is presented in Figure 11 (concentration of stannylene **7**: 360 mmol/L; reductive agent hydride **3**). It shows an impervious range between 270 and 500 nm. Such a membrane could be used as a wavelength filter, which absorbs the light completely within a well-defined range. The transmission spectrum shown in Figure 12 (concentration of stannylene **7**: 411 mmol/L; reductive agent hydride **6**) underlines this possibility for use. Here one finds an impervious range between 250 and 525 nm.

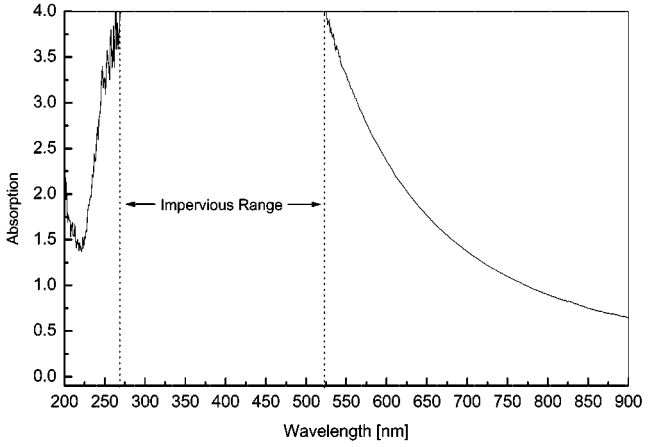

Figure 11. UV/Vis absorption spectrum of a very colored membrane; concentration of stannylene **7**: 360 mmol/L; reductive agent hydride **3**.

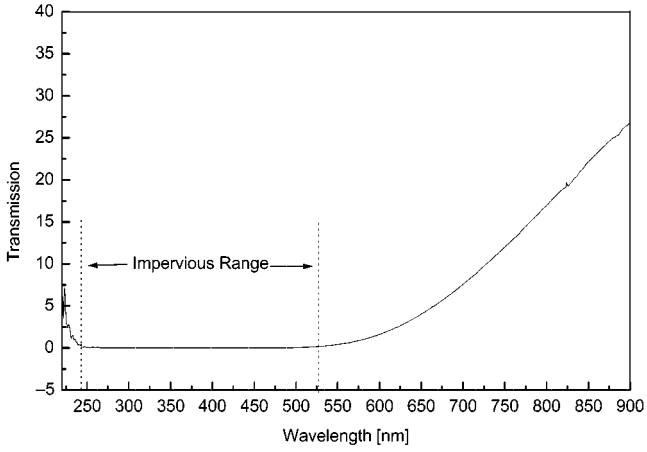

Figure 12. UV/Vis transmission spectrum of a very colored membrane; concentration of stannylene **7**: 411 mmol/L; reductive agent hydride **6**.

As mentioned above, we have used membranes with different pore diameters and the UV spectra of these membranes (filled under similar conditions) show a shift of the absorption maxima towards higher wavelengths (Figure 13). Obviously, the size of the metal clusters plays an important role.[6] As the absorption maxima shift with the pore diameter (with parallel increase of the metal particle diameters) one may use the process to produce wavelength filters of different absorption maxima.

We noticed an improvement in the infiltration of the membranes when we repeated the filling process several times. As expected, the filling of the channels is most effec-

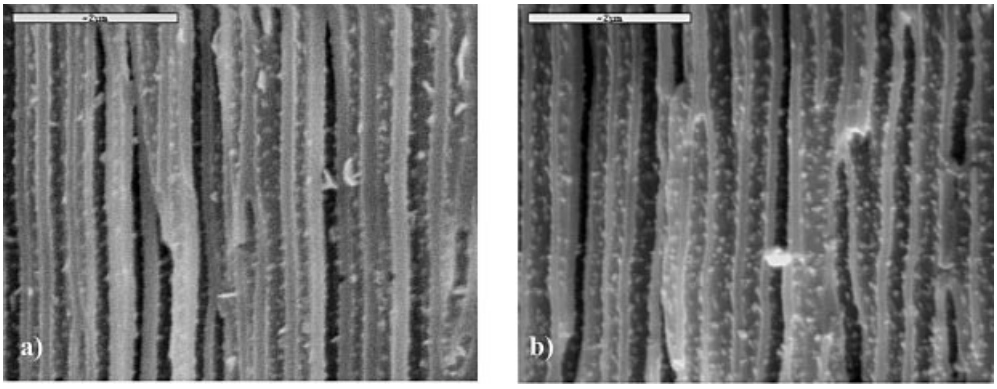

Figure 14. SEM images of (a) 5 and (b) 10 times filled 300 nm Al_2O_3 membranes to show the increase in the amount of lead particles within the pores (ca. 10 kV sputtered with approximately 10 nm Au).

tive for membranes with large pore diameters. The SEM images of a 300 nm Al_2O_3 membrane filled with lead particles after five and ten infiltrations are presented in Figure 14. They show an increase in the amount of lead clusters with repetitive filling. The repetition is nevertheless limited due to a blocking of the pores after ca. 7–8 cycles. The particles in the 300 nm pores have mean diameters of 80–90 nm.

Summary and Conclusion

Tin and lead nanosized particles and metal sponges have been prepared by reduction of molecular tin(II) and lead(II) amides with siloxy- and alkoxyalanes in non-aqueous media. The resulting molecular byproducts have been isolated and (structurally) characterized. Colloidal solutions of tin were obtained when the reaction mixture was slowly warmed from –115 °C to room temperature. With agglomeration of the particles in this solution, tin powders formed and precipitated, and have been identified as β-tin by EDX analysis. Their average particle size diameter can be controlled either by using different donor solvents or different hydrides as reducing agents. The smallest particles were obtained when *tert*-butoxyalane **3** was used as hydride and THF as donor solvent. The metal sponges were characterized by pycnometric measurements with helium and water and show a lower density compared with their value known from literature when water was used because of its surface tension and the high porosity of the metal precipitates. Porous aluminum oxide membranes with different pore diameters were used as templates for ordering tin or lead clusters within the pores. The metal particles were prepared by reduction of the metal amides within the membranes and the amount of particles could be increased by repetition of the filling process, which was an improvement in the infiltration compared to our former attempts. Differently colored membranes resulted from the filling process and were characterized by UV/Vis spectroscopy. Depending on the concentration of the starting materials and the pore diameters of the membranes they showed impervious ranges, which enabled these membranes to be used as wavelength filters.

Experimental Section

Physical Measurements: The elemental analyses of the compounds were carried out using a CHN analyzer from LECO™ Corporation, St. Joseph, MI, U.S.A. The NMR spectra were measured with Bruker 200 MHz spectrometers, model AC 200 F (^{1}H and ^{13}C spectra) and AC 200 P (^{29}Si spectra), using [D_6]benzene as solvent. The single-crystal X-ray analyses were performed either with an Image Plate (IPDS I), or a four-circle diffractometer (STADI 4) (Stoe, Dramstadt). The structure calculations were carried out with SHELXS97[15] and the graphical representation with Diamond 3.[16] The complete crystal structure data are deposited with the Cambridge Crystallographic Data Centre (CCDC), 12 Union Road, Cambridge CB2 1 EZ (UK) [CCDC-270194 (**10**), 270195 (**11**), and 270196 (**12**)]. The powder diffraction measurements of the tin and lead precipitates were performed in a glass capillary with a Stoe diffractometer, model STADIP, using Cu-K_α radiation with a wavelength of 1.540598 Å and a linear PSD detector. The measurements were analyzed with the software WinX^{Pow}. The electron microscopy (SEM) and energy-dispersive X-ray analyses (EDX) were performed with a scanning electron microscope CAMSCAN S4 with Si(Li) semiconductor detectors and with thin windows (Cameca and Noran). To perform the SEM analyses of the filled membranes, the membranes were covered with gold. The UV/Vis spectra were measured with a Perkin–Elmer spectrometer, model Lambda 35.

Synthetic Procedures: All compounds were synthesized under dry nitrogen using standard Schlenk techniques. The solvents were dried by refluxing with appropriate drying agents and distilled before being used.

[Me_2(N*t*Bu)$_2$Al(O*t*Bu)(THF)] (11): $Me_2Si(NtBu)_2Pb$ (**9**) (2.82 g, 6.92 mmol) in THF (25.0 mL) was added dropwise to a stirred solution of $[H_2AlOtBu]_2$ (**3**) (0.71 g, 3.46 mmol) in dry THF (25.0 ml) and allowed to react at room temperature for 24 h. The reaction mixture turned grey, the lead precipitated and gas (hydrogen) evolved. When the reaction was complete, the solution was separated from the lead and concentrated until crystals of [Me_2(N*t*Bu)$_2$Al(O*t*Bu)(THF)] (**11**) formed. After recrystallization of the crude product from THF, **11** (1.48 g, 3.97 mmol) may be obtained, at 4 °C, as colorless crystals (yield: 57%). Molecular mass: 372.60 g/mol. ^{1}H NMR (200 MHz, C_6D_6, 25 °C): δ = 0.45 [s, 3 H, Si(CH_3)$_2$], 0.57 [s, 3 H, Si(CH_3)$_2$], 1.09 (m, 4 H, THF), 1.37 (s, 18 H, N*t*Bu), 1.51 (s, 9 H, O*t*Bu), 3.82 (m, 4 H, THF) ppm. ^{13}C NMR (200 MHz, C_6D_6, 25 °C): δ = 7.09 [s, 1 C, Si(CH_3)$_2$], 7.27 [s, 1 C, Si(CH_3)$_2$], 24.81 (s, 2 C, THF), 34.12 (s, 3 C, O*t*Bu), 36.45 (s, 6 C, N*t*Bu), 49.50 (s, 2 C, quat. Preparation of Gold Nanoparticles on Ultrathin Films of Polythiophene and Polythiophene Derivatives

Carl Matthias Intelmann,[a] Hartmut Dietz,[a] and Waldfried Plieth*[a]

Keywords: Gold / Nanoparticles / Ultrathin films / Polythiophene / Polymer modification

Two different methods were used to immobilise gold nanoparticles on ultrathin films of polythiophene and polythiophene derivatives. The first method utilised ultrathin films of polythiophene to prepare gold nanoparticles by direct reduction of $HAuCl_4$. A uniform coverage of the polythiophene films with randomly distributed gold nanopraticles possesing a polydisperse size distribution was obtained. Size and size distribution of the gold nanoparticles could be controlled by time, concentration of Au^{3+}, and the addition of a cosolvent. With the second method, ultrathin films of polythiophene derivatives were esterified with thioctic acid, using either Steglich or Yamaguchi conditions. The dithiolane moiety of the thioctic acid was utilised to immobilise gold nanoparticles from a monodisperse gold sol. The gold nanoparticles were adhesive on the polymer films and were not removed by scotch tape tests. The samples with the obtained gold nanoparticles of both methods were analysed by scanning electron microscopy (SEM).

Introduction

Composite materials consisting of conducting polymers and metal nanoparticles are of great interest. Ordered structures as shown in Figure 1 would be the final goal because they are promising for further applications in micro- and optoelectronics.

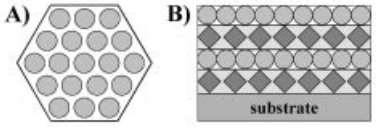

Figure 1. A) lateral hexagonal arrangement, B) sandwich layout.

Some review articles are available on gold nanoparticles, but it would be beyond the scope of this work to give a complete record. For the synthesis the work and reviews of Schmid et al.,[1,2] and for the assembly of gold nanoparticles the review of Daniel et al.[3] should be mentioned.

Holdcroft et al.[4,5] examined the oxidation of poly(3-hexylthiophene) (PHT) with gold trichloride in water-free solvents. The use of thick polymer films (>1 μm) yielded sandwich structures consisting of an oxidised PHT film, covered with a continuous gold layer. However, thinner polymer films (<0.25 μm) yielded only an irregular, nonuniform covering with gold. Holdcroft et al.[5] proposed the following reaction [Equation (1)].

$$3\,[P^0] + 4\,AuCl_3 \rightarrow 3\,[P^+][AuCl_4^-] + Au^0\downarrow \quad (1)$$

P is a sequence of four monomer units (thiophene rings) in the polymer.[5]

To obtain gold nanoparticles rather than nonuniform gold films, the polymer film has to be even thinner than the 0.25 μm that Holdcroft et al. used. For micro- and optoelectronic applications it is necessary to chemically deposit adhesive films especially on insulating substrates. Ultrathin, adhesive, and smooth polythiophene films were described by Fikus et al.[12–14] (Figure 2). These films can be chemically deposited on a variety of substrates, preferentially insulating, with the adhesion promoter 11-(thien-3-yl undecyl) trichlorosilane (TUTS) and are about 100 nm thick.

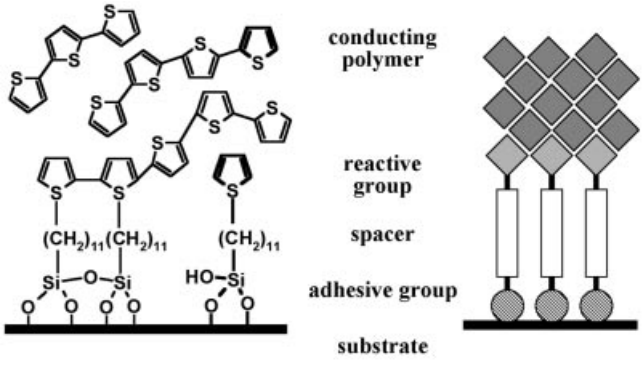

Figure 2. Layout of ultrathin polythiophene films using the adhesion promoter TUTS.

To circumvent complications with the use of water-free solvents it was of interest to determine whether the deposition of gold nanoparticles onto polythiophene films would

[a] Institute of Physical Chemistry and Electrochemistry, Dresden University of Technology,

E-mail: waldfried.plieth@chemie.tu-dresden.de

also be possible from aqueous solutions of $HAuCl_4$. Then the following reactions would be possible Equation (2) and Equation (3).

$$3\,[P^0] + HAuCl_4 \rightarrow 3\,[P^+][Cl^-] + Au^0\downarrow + HCl \quad (2)$$

$$3\,[P^0] + 4\,HAuCl_4 \rightarrow 3\,[P^+][AuCl_4^-] + Au^0\downarrow + 4\,HCl \quad (3)$$

Equation (2) was proposed by Freund et al.,[6] while Equation (3) was derived from Equation (1), which was proposed by Holdcroft et al.,[5] assuming that $HAuCl_4$ can be regarded as the hydrochloride of $AuCl_3$. The reduction of $HAuCl_4$ requires the incorporation of a dopant anion into the oxidised polymer to achieve charge neutrality. In the case of an excess of polythiophene, all of the $HAuCl_4$ is reduced and only Cl^- is available as a dopant anion, which is described in Equation (2). On the other hand, in the case of an excess of $HAuCl_4$ all of the polythiophene is oxidised, but not all of the $HAuCl_4$ is reduced. A combination of Equation (2) and Equation (3) is then an appropriate description of the polymer doping, as both anions Cl^- and $AuCl_4^-$ are available in solution and can be incorporated into the oxidised polymer.

The immobilisation of gold nanoparticles can be achieved by different ways,[3] but the most promising approach is the utilisation of the strong interaction between thiols and gold, where a gold–sulfide bond is formed.[10] In this work the dithiolane moiety of thioctic acid (Figure 3) is used to immobilise monodisperse gold nanoparticles. This moiety is a cyclic disulfide, which can be regarded as an equivalent of two thiol moieties and was utilised to form self-assembled monolayers (SAMs)[7,8] or as a stabilising agent for gold nanoparticles.[9] To achieve the immobilisation of the gold nanoparticles out of a gold sol, polymer films containing the thiophene derivative 3-methoxy thiophene (MOT) were prepared. The hydroxyl groups in the polymer (ROH) were then esterified with thioctic acid, as depicted in Figure 3.

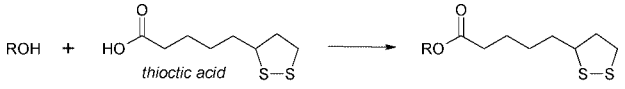

Figure 3. Reaction scheme: esterification with thioctic acid.

Figure 4 shows the layout of the polymer substrates with immobilised gold nanoparticles after the two steps of esterification (1) with thioctic acid and subsequent immobilisation of the gold nanoparticles (2) from a gold sol.

Two different methods were used to immobilise gold nanoparticles on ultrathin films of polythiophene and polythiophene derivatives. With the first method, ultrathin films of polythiophene were utilised to prepare gold nanoparticles by direct reduction of aqueous $HAuCl_4$, to yield polydisperse gold nanoparticles. Size and size distribution of the nanoparticles could be controlled by time, concentration of Au^{3+}, and the addition of a cosolvent. With the second method, ultrathin films of polythiophene derivatives were esterified with thioctic acid, using either Steglich or Yamaguchi conditions. The disulfide moieties of the thioctic acid were utilised to immobilise gold nanoparticles from monodisperse gold sol. The samples with the gold nanoparticles, obtained from both methods, were analysed by scanning electron microscopy (SEM).

Results and Discussion

1) Direct Process

The examined parameters were time, concentration of Au^{3+} and effects of the cosolvent, which are to be discussed. The results are summarised in Figure 5. A continuous gold

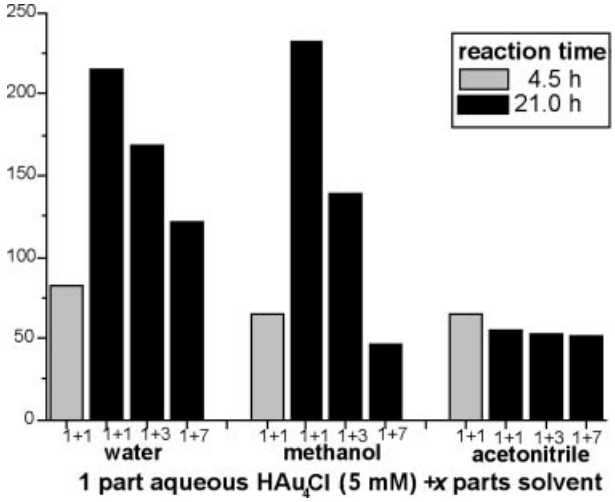

Figure 5. Direct process: mean gold nanoparticle size in relation to concentration, cosolvent, and time.

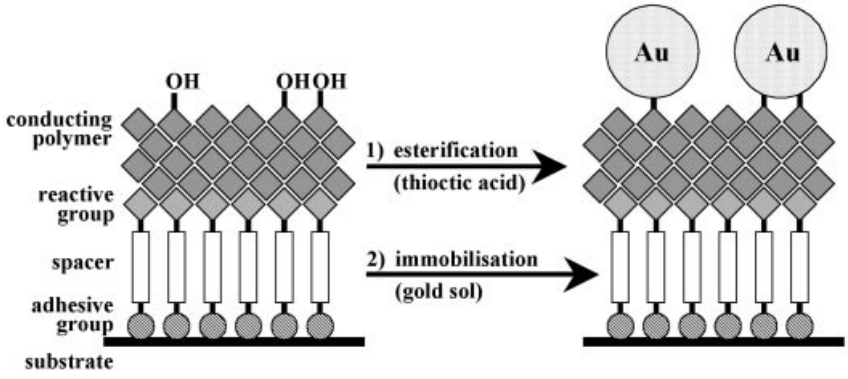

Figure 4. Polymer modification.

layer on the polythiophene films could not be observed, however, gold nanoparticles were visible on the surface of these films (Figure 6). This outcome was expected from the observations of Holdcroft et al.[4,5] with thin polymer films. The gold particles that were obtained were polydisperse and randomly distributed on the polythiophene films. It could be corroborated that undoped polythiophene was able to reduce aqueous gold salt solutions.

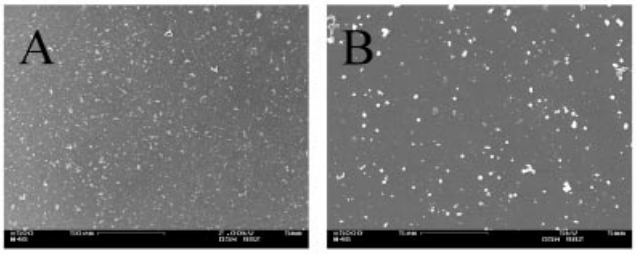

Figure 6. Direct process: typical SEM micrographs: A) 500×. B) 5,000× (5.08 mM of $HAuCl_4$, 4.5 h).

Concentration Dependence

The amount of Au^{3+} in the solutions was the same for all the experiments, because each experiment started with 0.5 mL of an aqueous $HAuCl_4$ solution (5.08 mM) and dilution was achieved by adding, either 0.5 mL, 1.5 mL, or 3.5 mL of solvent into the reaction flask. A decreased concentration of Au^{3+} resulted in smaller particles with a narrower size distribution (parts B and D in Figure 7). This trend could be observed when diluting with water, methanol, and acetonitrile and it was most pronounced with methanol.

Cosolvent Dependence

The presence of a cosolvent (methanol, acetonitrile) resulted in smaller particles with narrower size distributions (parts A and C in Figure 7). The dilution series with methanol yielded results that were little different from the dilution series with water, but were more pronounced, i.e. the decrease in particle size with increasing dilution was larger. The addition of acetonitrile, on the other hand, had a more significant effect on the deposition behaviour of the gold particles. The reduction of Au^{3+} to Au^0 proceeded via Au^+, which is stabilised by acetonitrile. Hence, the deposition of Au was very slow. At a constant number of nucleation centres and nuclei, the size of the nuclei was smaller after a constant time, as the rate of gold deposition was lower, resulting in very small gold particles. The influence of acetonitrile on the deposition was so substantial that there was little change of particle size in the dilution series.

Time Dependence on Particle Size

An increase in reaction time resulted in an increased particle size and a broader size distribution of the particles (parts A and B in Figure 7). Increasing the reaction time from 4.5 h to 21 h and therefore by almost a factor of four, yielded an increase in the particle size of four times.

Summary: Direct Process

The particle size (Figure 5) was increased by the factors, time and concentration. As the particles got larger, the size distribution (Figure 7) also broadened. Adding a second solvent other than water yielded in most cases smaller particles, an effect that could be explained with stabilising effects of the solvent molecules on the different gold species in solution. As a second effect of the solvent addition, the

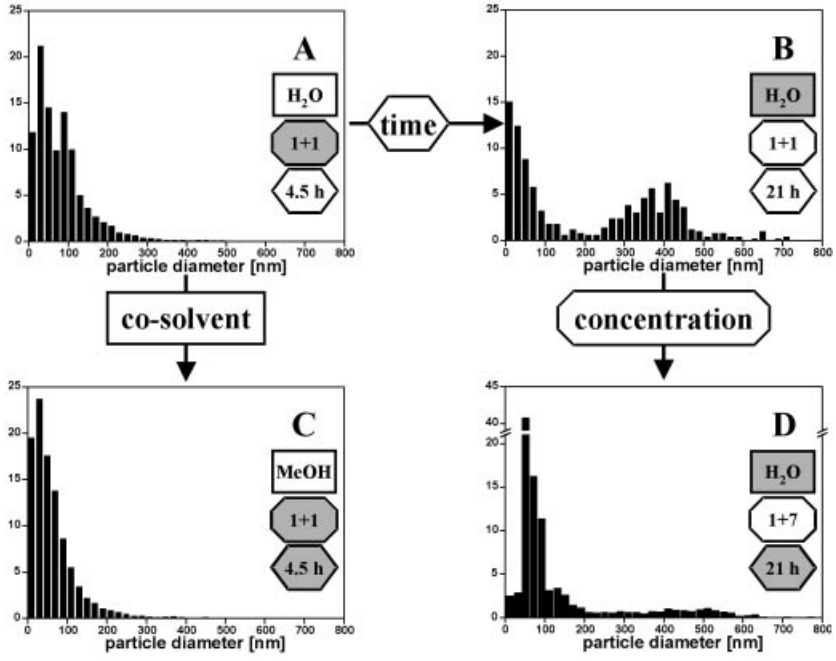

Figure 7. Direct process: particle size distributions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

size distribution became more homogeneous. To conclude this: Particle size and distribution could be positively influence by the addition of the solvents methanol and acetonitrile.

Polymer Modification

In a second set of experiments the polymer was modified by derivatising it with adhesion groups for the immobilisation of gold nanoparticles out of gold sols. The success of the polymer modifications was checked by adsorption experiments with gold sols. Gold sols of Roche Diagnostics were used. These gold sols were prepared with the citrate reduction method[18] with no further stabilising agent used other than citrate and had a mean particle size of 40 nm. For adsorption of the gold nanoparticles the modified polymer films were immersed into the gold sols. Immobilisation of the gold nanoparticles was achieved by cleavage of the disulfide bond of the thioctic acid and formation of two gold sulfide bonds, which was due to the high affinity of gold to sulfur.[9,10]

Polymer Film Modification through Esterification – Steglich Conditions

In Figure 8, as in all of the SEM micrographs, the gold nanoparticles appear as white to light grey dots, while the substrate with the modified polymer film appears in a dark grey. Figure 8 shows the different affinities of the modified polymer films towards the gold nanoparticles: on the unmodified polythiophene film (Figure 8, A) just a few gold nanoparticles were immobilised. The polythiophene film was used as blank test as it could not be esterified with thioctic acid and had a very low affinity to gold.[11] The modified polymethoxythiophene film (Figure 8, B) on the other hand was densely covered with gold nanoparticles, indicating a successful polymer modification.

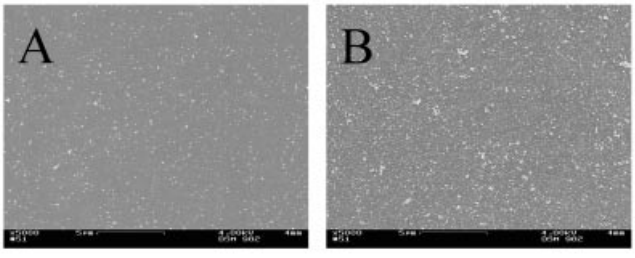

Figure 8. SEM micrographs of immobilised gold nanoparticles on modified polymer films (magnification 5,000): A) polythiophene, B) polymethoxythiophene (modified, Steglich conditions).

The differences in morphology of the copolymer films were examined. The copolymers were prepared from methoxythiophene with thiophene P(T/MOT) and methylthiophene P(MT/MOT), respectively. The films with thiophene (Figure 9, A) had a more homogeneous appearance, than those prepared with methylthiophene (Figure 9, B). This could be explained with a better coupling of the adhesion promoter TUTS with the thiophene, because of a minor steric hindrance of the monomers during polymerisation, due to the absence of the 3-methyl group. Polymer films with regions of different morphology could be observed with the methylthiophene containing copolymers, as shown in part B of Figure 9. These films had a rougher surface, so that more methoxy groups were accessible for esterification with thioctic acid. Thus, locally increased concentrations of dithiolane groups through the thioctic acid ester were available to immobilise more gold nanoparticles on these films. In Figure 9 (see part A) single gold nanoparticles were spread over the unmodified polythiophene film, while in Figure 9 (see part B) inhomogeneities lead to the formation of larger agglomerates of gold nanoparticles. Between the agglomerates regions of homogeneous coverage with single gold nanoparticles were allocated. The regions in the SEM micrograph that had a lighter appearance did not have a higher affinity to the gold nanoparticles compared with the darker regions.

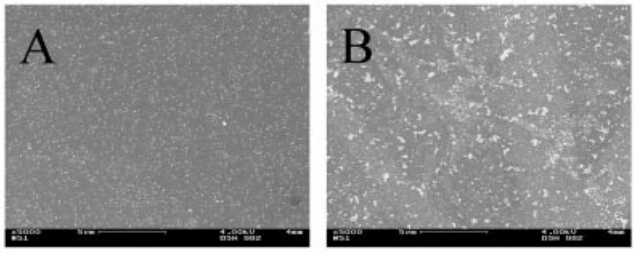

Figure 9. SEM micrographs of immobilised gold nanoparticles on modified polymer films (magnification 5,000): A) P(T/MOT), B) P(MT/MOT) (both modified, Steglich conditions).

The influence of different monomer ratios on the resulting polymers was examined with the copolymers from methoxythiophene with thiophene P(T/MOT). The morphology of the homopolymer films was smooth and homogeneous, as can be seen in Figure 8. With the addition of only small amounts of the other monomer to the polymerisation mixture the copolymer films were still homogeneous, e.g. methoxythiophene in thiophene T/MOT = 90:10 (v/v) (Figure 9, A).

As the monomer ratios were changed further until an equal mixture of the monomers was reached, the morphology of the copolymer films exhibited an increasing roughness. Also, the appearance of regions on the polymer film with different morphologies was observed, which could be indicating that these areas correspond to different segregated copolymers or even homopolymers, respectively.

Adhesion of the gold nanoparticles on the modified polymer films was tested with a scotch tape test. For this, one half of a substrate was covered with scotch tape, which was then quickly removed. SEM was used to examine the samples before and after the test, and no significant loss of gold nanoparticles was detected. Therefore, it can be concluded that the immobilised gold nanoparticles are covalently bound to the modified substrate.

Polymer Film Modification through Esterification – Yamaguchi Conditions

In the experiments examining the Yamaguchi esterification, the quality of the adhesion promoter allowed only the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

deposition of TUTS films with a high coverage of polysiloxane particles originating from the condensation of TUTS molecules. Thus, resulting in inhomogeneously deposited polymer films, as shown in Figure 10. Figure 11 shows that the polymer morphologies could be reproduced, although their surface structure was more coarse than previously described for the Steglich-modified polymer films in Figure 9. The defects in the polymer films (Figures 10 and 11) are due to the film preparation conditions and could not be eliminated. The immediate detection of the gold nanoparticles was impeded by the numerous polymer particles, but with careful examination the gold nanoparticles became apparent.

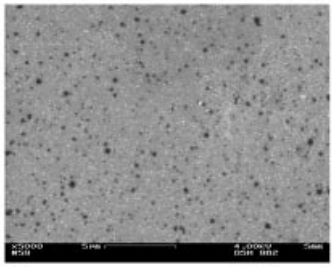

Figure 10. SEM micrograph of immobilised gold nanoparticles on modified polymer film (magnification 5,000): polymethoxythiophene (modified, Yamaguchi conditions).

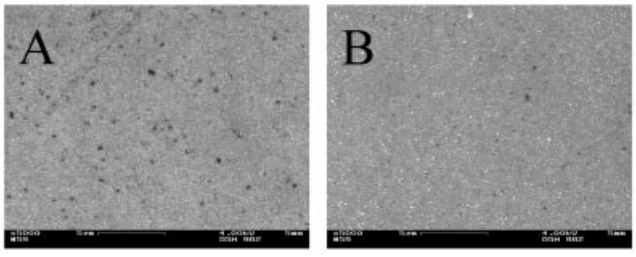

Figure 11. SEM micrographs of immobilised gold nanoparticles on modified polymer films (magnification 5,000): A) P(T/MOT), B) P(MT/MOT) (both modified, Yamaguchi conditions).

When comparing e.g. Figure 8B (Steglich conditions) with Figure 10 (Yamaguchi conditions) in the case of modified polymethoxythiophene, it became obvious that the two pathways for the esterification yielded either agglomerated or separated gold nanoparticles upon subsequent immersion into a gold sol. Also, the coverage of the Yamaguchi-modified polymer films with gold nanoparticles was lower than with the Steglich-modified films. The Yamaguchi-modified polymer films were more porous due to the defects in the pristine polymer films. Therefore, less thioctic acid ester moieties were accessible on the surface by the gold nanoparticles of the gold sol, resulting in a lower coverage of separated gold nanoparticles.

Conclusions

It was shown that gold nanoparticles could be immobilised by two different methods. A direct reduction process, utilising the polymer film of the substrate yielded polydisperse nanoparticles. The particle size of the nanoparticles and their size distribution could be controlled by the factors time, concentration, and the addition of a cosolvent. Monodisperse gold nanoparticles could be immobilised on further modified polymer films. These films were prepared by using thiophene derivatives bearing hydroxyl groups, which were then esterified with thioctic acid using either Steglich or Yamaguchi conditions. The latter method allows the immobilisation of a huge variety of nanoparticles, because those can be prepared ex situ. The only prerequisite for the nanoparticles is that they interact strongly with the dithiolane group of the thioctic acid ester to allow the immobilisation.

Experimental Section

1) Preparation of Ultrathin Films of Polythiophene and Polythiophene Derivatives: The polymer films were chemically deposited on silicon substrates, which were modified with the adhesion promoter 11-(thien-3-yl undecyl) trichlorosilane (TUTS).[12–14]
The pretreatment of the substrates and subsequent modification with TUTS was described in the literature.[12–14] Chemical deposition of the thiophene polymers was carried out in the following manner: the TUTS-modified substrates were placed in a solution of 1.0 g of $FeCl_3$ (anhydrous, Fluka, p.a.) and 25 mL of acetonitrile (<50 ppm water, Fisher Scientific, p.a.), then 100 μL of the respective premixed monomers were added. After 1 h of reaction time, the samples were cleaned in an ultrasonic bath with methanol (Merck, purum). The monomers (Aldrich, p.a.) were thiophene (T), 3-methylthiophene (MT), and 3-methoxythiophene (MOT), the monomer mixtures T/MOT = 90:10 (v/v) and MT/MOT = 90:10 (v/v).

2) Direct Process: Polythiophene substrates were immersed into an aqueous Au^{3+} containing solution: 0.5 mL of $HAuCl_4$ (5.08 mM) + $x \times 0.5$ mL of solvent (x = 0, 1, 3, 7; solvent = dist. water, methanol, acetonitrile). Immersion time was 4.5 h and 21 h, respectively. The examined parameters were time, concentration of Au^{3+} and effects of the cosolvent. After reaction, the substrates were rinsed with copious amounts of distilled water and subsequently dried with argon.

3) Polymer Modification: All the glassware used for the reactions was heated in vacuo and subsequently "aerated" with argon.
Polymer modification reactions were carried out in 100 mL Erlenmeyer flasks, each equipped with a rubber septum. The flasks were moved on a one-dimensional shaker during the reaction. Solvents were freshly dried prior to use, and all other chemicals were used as received.

3a) Polymer Film Modification through Esterification – Steglich Conditions: The esterification was carried out according to Steglich et al.[15] following the working procedure of Echegoyen et al.[16] Each solution was premade and then divided into five parts, which were then added to the different polymer substrates. The thioctic acid (9.4 mmol, 1.94 g) and DMAP (0.65 mmol, 0.08 g) were dissolved in 50 mL of dichloromethane and added to the polymer substrates. After 30 min a DCC solution (11.2 mmol, 2.32 g) in 25 mL of dichloromethane was added. After another 22 h, under gentle movement with the one-dimensional shaker, the modified substrates were cleaned in an ultrasonic bath with distilled water and ethanol for 5 min each and subsequently dried with argon.

3b) Polymer Film Modification through Esterification – Yamaguchi Conditions: The esterification was carried out according to Yamag-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

uchi et al.[17] Each reaction mixture was divided into four parts: three parts for modification of three individual substrates and one part for reaction control with GC-MS. The thioctic acid (1.2 mmol, 245.2 mg) was dissolved in 8 mL of THF, then triethylamine (1.2 mmol, 121.8 mg, 166 μL) was added after which the mixture was stirred for 10 min at 0 °C. 2,4,6-Trichlorobenzoyl chloride (1.2 mmol, 292.8 mg, 457 μL) was then added and stirred for another 10 min at 0 °C, followed by 2 h at room temperature. After removal of triethylamine hydrochloride by filtration through a syringe filter (PTFE, 0.2 μm pore width), the filtrate was evaporated in vacuo and the yellow, viscous residue was dissolved in 8 mL of dichloromethane. A solution of DMAP (2.4 mmol, 293.2 mg) in 8 mL of dichloromethane was then added to this. A polymer substrate was treated with a portion of 4 mL of this resultant solution for 48 h under gentle movement with the one-dimensional shaker. Finally the modified substrates were cleaned in an ultrasonic bath with distilled water and methanol for 5 min each and subsequently dried with argon.

3c) Gold Nanoparticle Adsorption: The modified polymer substrates were immersed in a gold sol for 1 h at 4 °C. The gold sol was prepared by Roche Diagnostics with the citrate reduction method[18] with no further stabilising agent used other than citrate. In the first experiments the substrates were placed face up in the adsorption flask, while later on the substrates were placed slightly tilted upside down in reaction tubes for adsorption. This orientation avoided the deposition of gold nanoparticles, which were destabilised from the gold sol during the progressing experiments. After adsorption the substrates were rinsed with copious amounts of distilled water and subsequently dried with argon.

Acknowledgments

We thank the Deutsche Forschungsgemeinschaft for financial support in the SPP 1072 "Halbleiter und Metallcluster als Bausteine für organisierte Strukturen", Frau Kern for the SEM micrographs, Dr. X. Cai, Dr. E. Jähne, Prof. Dr. H.-J. Adler (Institute for Macromolecular Chemistry, TU Dresden) for synthesis of the adhesion promoter TUTS, and Mr. Th. Kreuzer (Institute for Organic Chemistry, TU Dresden) for help and support during the polymer modifications; Roche Diagnostics for donating the gold sol.

Bottom-Up Synthesis and Top-Down Organisation of Semiconductor and Metal Clusters on Surfaces

Alexander M. Bittner,*[a] Xiao C. Wu,[a,b] Sinan Balci,[a] Mato Knez,[a,c] Anan Kadri,[d] and Klaus Kern[a]

Keywords: Cadmium sulfide / Nanocrystals / Metal clusters / Microcontact printing / Nanostructures / Template synthesis

Near-spherical dendrimers can be used as templates for bottom-up syntheses of semiconductor clusters. Starting from methanolic solutions of Cd^{2+}, sulfide, and poly(amidoamine) dendrimers, CdS clusters precipitate at the dendrimers. A preparation inside the dendrimers is only possible when the protonation of the latter is carefully controlled. The clusters have diameters above about 2 nm and show blue photoluminescence. The patterning and orientation of CdS/dendrimer clusters on flat surfaces are attained by microcontact printing. Depending on the ripening of the CdS/dendrimer suspension, a sub-micrometer stripe pattern develops inside the micrometer-scaled patterns; it extends over the complete surface. Rod-like plant virions with a different type of lateral organisation can be oriented on a flat substrate by applying mechanical forces during immobilisation from suspensions. These virions can also be employed as templates, in this case for creating metal structures by electroless deposition (chemical metal deposition). The structures are wire-like with diameters of 3–4 nm and are confined inside the central channel of the virions. The early stage of the metallisation process is analysed, and a model that accounts for the selectivity is presented.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The synthesis of well-defined clusters can be carried out by wet chemical means (under mild conditions) when the products are bound to a template. a range of organic templates, for example block copolymers[1] and biotemplates,[2,3] some of which are single molecules, are available for various semiconductor and metal clusters. The template can direct their size and shape, and it can even catalyse the growth. Typical examples are amphiphiles, which may organise into micelles by self-assembly.[1,4] The clusters are more or less strongly bound to the template, which can be removed to liberate pure clusters.[5] However, in many cases (e.g. for optical measurements) this removal is neither required nor an advantage, such as for photoluminescing CdS clusters at dendrimers.[6,7] The physical properties depend mainly on the cluster size and nature. Thus, while metal clusters reach the limit of quantised conductivity only for very small diameters (<2 nm), even relatively large semiconductor clusters (tens of nanometres) show quantised energy levels, which is reflected in their optical properties, especially photoluminescence.[8]

Nanoscale science and nanotechnology rely, in many cases, on the step-by-step assembly of nano-objects on substrate surfaces. An important issue is how to immobilise and orient the objects at defined sites of a given substrate. Considering that the simplest "bottom-up" syntheses for nano-objects employ molecular templates, soft matter manipulation might be important. On the other hand, standard photo- or electron-beam lithography is slow, expensive and often not compatible with soft matter. Hence, new "top-down" methods are called for, and microcontact printing has been developed into one of the most powerful tools in this respect. Recently, very large molecules such as DNA[9] and inorganic nanowires[10] have been shown to be printable.

Dendrimers are branched macromolecules, and the number of branches determines their generation (here eight terminal branches for generation 1, and 16 for generation 2) and hence their size. In contrast to most polymers, dendrimers have an extremely sharp size distribution. They have been used as templates for spherical clusters of metals and semiconductors;[11–17] cluster diameters are usually below 5 nm. Large rod- or tube-like biological molecules and supramolecular aggregates qualify as templates for quasi-one-dimensional nanostructures. They can be well defined in their chemical composition and also in their structure and symmetry. Examples are DNA,[18] plant virions,[19] phages,[20] protein tubes[21,22] and protein fibres,[23,24] all of

which are increasingly used for nanoscale structuring as functional units or as templates.[18–29] Apart from binding organic molecules, the best-known templating function is binding (or synthesis) of metal clusters and wires, as presented here for the tobacco mosaic virus (TMV).

As mentioned above, possible applications of semiconductor and metal clusters require a transfer to a substrate surface on a selected area in a defined orientation. For templated clusters, it is sufficient to transfer and orient the template as this results automatically in transfer/orientation of the clusters. The transfer method can be by adsorption, although microcontact printing offers selective placement in predefined arrays. Moreover, in certain cases − here aged CdS/dendrimer composites − the printing process results in sub-patterns that develop inside the printed patterns, and hence structuring on two length scales can be achieved in a single step. For many applications, however, the orientation of nonspherical nano-objects, for example in a parallel fashion, is more important than their exact placement. For this, a range of relatively simple methods is available. For example, laterally (parallel to the substrate surface) applied forces that act on a droplet of suspended nano-objects are well known for stretching and orienting DNA;[9,29,30] here they were tested for the orientation of virions.

The theme of this paper is the combination of "top-down" methods for orientation and placement of nano-objects with their "bottom-up" synthesis. Section 1 introduces a new pH-controlled synthesis method for CdS clusters inside poly(amidoamine) (PAMAM) dendrimer templates. The diameter of the clusters is so small that the energy levels are shifted, hence UV-excited photoluminescence is observed in the blue range of the spectrum. CdS/dendrimer composites can be patterned by microcontact printing. This method can, for certain composites, result in "patterned patterns", i.e. in structures with linear substructures. Section 2 is dedicated to linear structures only; it introduces two very simple orientation methods for TMV, namely blow-drying of a droplet, and exerting capillary forces on a droplet by suction with a filter paper. Both methods have been widely applied, but have not been documented in detail for TMV. The virions can be advantageously employed as templates for 3–4-nm-wide metal wires that are confined in the central channel of the virion; the focus is here on the initial stages of the electroless metal deposition process, and on the surprisingly high selectivity for the inner channel of TMV.

Results and Discussions

1. Synthesis and Organisation of Luminescent CdS Clusters in Micrometer and Sub-Micrometer Patterns

The simple and effective one-pot synthesis of CdS clusters from Cd^{2+} and S^{2-} at dendrimers is well documented.[6,7,15–17] When amine-based dendrimers are employed, their protonation has a pronounced effect on the shape, number and location of the formed nanocrystals. Good examples are near-spherical, amine-terminated PAMAM [poly(amidoamine)] dendrimers of generations 4 ($G4NH_2$) and 8 ($G8NH_2$), where the repeat unit is $N–(CH_2CH_2–CONH–CH_2CH_2)_2$ and the terminal groups are primary amines (NH_2). The Cd^{2+} ions appear to bind to the terminal amine groups, thus usually placing the clusters on the surface of the dendrimers rather than inside. However, Section 1.1 shows that a better control of morphology and size can be obtained by careful protonation of some of the amine groups, which has been discussed for poly(propylene imine) (PPI) dendrimers[31] but has not yet been applied for the synthesis of CdS. The use of hydroxy-terminated dendrimers (G4OH) is an interesting and viable alternative since Cd^{2+} binds only weakly to hydroxy groups.

The "bottom-up" synthesis at a template can be complemented by a "top-down" method to organise the dendrimer/CdS composites in a predefined pattern. Microcontact printing is especially attractive due to its speed, simple handling and variability.[7] Pure semiconductor clusters are difficult to print, so a two-step technique is usually employed: first, a thin layer or monolayer of an organic molecule is printed on a flat substrate to achieve a pattern with chemical contrast, for example hydrophilic/hydrophobic. The clusters are thereafter deposited on the structured susbstrate. A much simpler one-step process, in which the complete dendrimer/CdS composite is printed, could therefore be advantageous.[7] In this way, micrometer-sized areas can be selectively and densely covered with CdS clusters. However, the printing density depends on the age of the CdS/dendrimer suspension. Long ageing times (many days) are preferred due to an improvement of the optical quality. Section 1.2 presents and discusses a new organisation phenomenon that operates with composites aged for only two days: the formation of sub-micrometer line patterns inside the patterned areas.

1.1. Synthesis of CdS Clusters at and in Dendrimer Templates

Balogh et al. have defined three different types of metal–dendrimer nanocomposites according to the position of the metal nanoparticles on the dendrimers,[32] namely metal nanoparticles residing inside the dendrimers (internal type), outside the dendrimers (external type) and a mixed type. The formation of the different types is determined by the binding mechanism of the metal ions (which are synthetic precursors for the clusters), by immobilisation reactions, and by metal–dendrimer interactions during the formation of the nanoparticles. The same principle is employed for semiconductor clusters. According to the actual size of the synthesised nanoparticles (D_N), the diameter of the dendrimers (D_D) and the size of the nanoparticles calculated from the number of metal ions bound to each dendrimer (D_C), the constitution of the nanocomposites can be deduced. Thus, when D_N is smaller than both D_D and D_C, several nanoparticles are found per dendrimer. This occurs for large dendrimers (high generation numbers).[33] Here dendrimers can be called "nanoreactors", as nanoparticles are protected by dendrimer "ligands". However, the size of the nanoparticles cannot be simply estimated from the loading

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

factor of metal ions to the dendrimer. For example, stable colloidal solutions of CdS/G8NH_2 can be obtained only at NH_2/Cd^{2+} ratios lower than 2 (without control of pH). This indicates that the nucleation sites of the CdS nanoparticles are close to the terminal NH_2 groups. Therefore, CdS clusters are most probably found at the surface regions of the dendrimers, i.e., CdS nanoparticles are (weakly) bound to the terminal NH_2 groups. The diameter (D_N) of the CdS nanoparticles, calculated from the absorption band gap,[34] is about 2 nm,[6] which is smaller than the values of 9.7 and 3.4 nm calculated for D_D and D_C, respectively. Thus, the CdS/G8NH_2 nanocomposites reported by Wu et al.[6,7] belong to the external type, and consist of about two nanoparticles per dendrimer.

When D_N is similar to D_C, one nanoparticle should form per dendrimer. This is the case when the interactions between metal ions and internal functional groups of dendrimers are strong,[35,36] or when the loading of metal ions is confined inside the dendrimers.[15] In this case, the nucleation and also the growth of a nanoparticle is confined within a single dendrimer. The size of nanoparticles can be controlled by the loading factor of metal ions to dendrimers or by the variation of the dendrimer generation. While this is well known for metal/dendrimer composites, semiconductor/dendrimer composites require a more careful control of the protonation.[15] NH_2-Terminated dendrimers undergo various stages of protonation/deprotonation processes at different pH values.[31,37] Therefore, if one can control the protonation of the dendrimers, i.e., only protonate the terminal NH_2 groups and keep the tertiary N groups deprotonated, the CdS clusters should be confined inside the dendrimers. After the synthesis, the NH_3^+ groups can be deprotonated and further chemical modifications can be carried out. Another advantage is that aggregation effects should be reduced due to the repulsive interaction between protonated dendrimers.

1.1.1. pH-Dependent Behaviour of PAMAM Dendrimers

In order to distinguish the protonation processes of tertiary and primary N, various amounts of acid were added to dendrimer (+ Cd^{2+} + S^{2-}) solutions, and conventional pH measurements were carried out. Such measurements are difficult in methanol, but the effects of protonation on the absorption spectra are easily detectable and can be used qualitatively to elucidate the chemical behaviour of the dendrimers. An advantage of the spectroscopic method employed here is that disadvantageous measurement conditions, such as high electrolyte concentration and water as solvent, which are required for accurate pH measurements, can be avoided.

Figure 1 shows the evolution of the absorption spectra of G4OH and G4NH_2 dendrimers in aqueous solution as a function of added amounts of aqueous HCl. G4OH is terminated by OH groups and can therefore not be protonated at its termini, at least in the range of pH values employed. With increasing H^+/NR_3 ratio, the oscillator strength of the C–N bonds (both $\sigma\rightarrow\sigma^*$ and $n\rightarrow\sigma^*$ bonds) in G4OH obviously decreases at first. This can be seen clearly from the variations of absorbance of these two bands with the H^+/NR_3 ratio (see parts a and b in Figure 1) and can be divided into two stages: the rapidly decreasing stage corresponds to the protonation of tertiary N in G4OH, while the flat stage indicates the completion of the protonation process. G4NH_2 (Figure 1, parts c and d) is slightly different to G4OH as it shows a three-stage behaviour. First, the absorption spectra show a small red-shift, and the variation in absorbance is small. After this stage, the changes are similar to those found with G4OH, therefore the first stage should correspond to the protonation of primary N. Note that the changes in the spectra caused by adding HCl can be recovered by adding NaOH. This verifies that the changes are caused by reversible protonation processes.

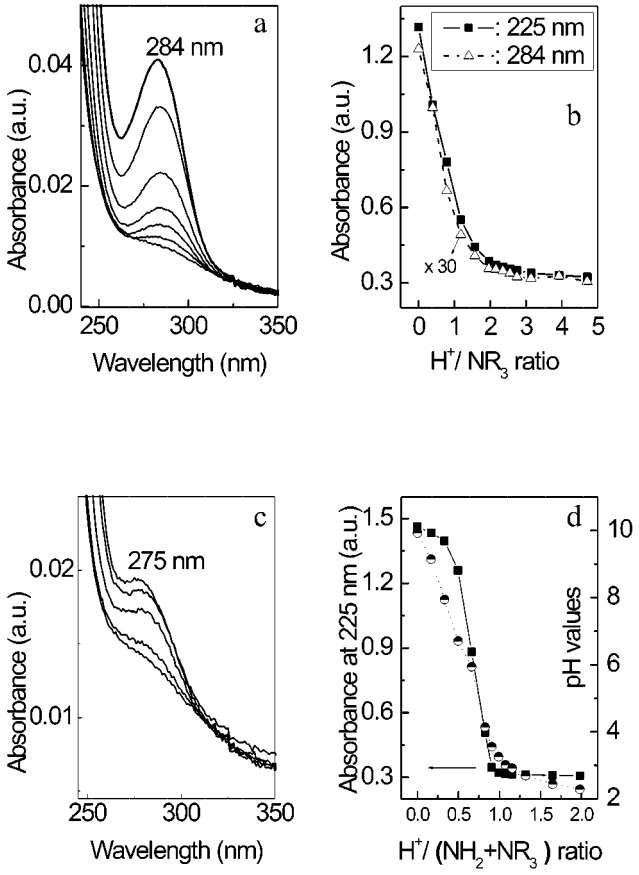

Figure 1. Evolution of absorption spectra of G4OH in aqueous solution, $H^+/(NH_2 + NR_3)$ ratios from top to bottom: 0, 0.39, 0.79, 1.18, 1.57, 2.36, 4.72 (a). Variations of absorbance at 225 and 284 nm vs. H^+/NR_3 ratios; note that the absorption intensity at 284 nm is scaled by a factor of 30 (b). Evolution of absorption spectra of G4NH_2 in aqueous solution, H^+/NR_3 ratio from top to bottom: 0, 0.66, 0.83, 0.91, 0.99 (c). Variations of absorbance (squares) at 225 nm and of pH values (circles) vs. $H^+/(NH_2 + NR_3)$ ratio (d).

In order to check the correlation between the variations in absorption and in protonation, several aliquots from each sample were taken and used for additional pH measurements. They show a good correlation (Figure 1, d). The position of the pH curve at pH 8 corresponds well to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

turning point of the absorbance at 225 nm [$H^+/(NH_2 + NR_3)$ ratio of 0.3], thus indicating the start of the protonation of the tertiary N. Therefore, the relatively flat part of the curve [H+/(NH_2 + NR_3) ratio 0.3–0.6] can be used to synthesise CdS nanoparticles inside dendrimers: The tertiary amine groups remain deprotonated, thus binding of Cd^{2+} is favoured here.

A good comparison with these results is afforded by the protonation behaviour of poly(propylene imine) (PPI) dendrimers, which has been investigated both experimentally and theoretically.[31] At pH 6–8, PPI dendrimers show the desired protonation behaviour. Compared to PPI dendrimers, NH_2-terminated PAMAM dendrimers possess additional amide groups. Since the protonation of amide groups can be neglected at the pH values discussed here, one can assume that PAMAM dendrimers behave similarly to PPI dendrimers.

These results can be extended to larger dendrimers, namely $G8NH_2$. Figure 2 (a) shows pH values for $G8NH_2$ and $G4NH_2$ plotted against the ratio $H^+/(NH_2 + NR_3)$. The pH values of $G4NH_2$ in 1 M aqueous KCl solution serve as a reference. The pH values for $G8NH_2$ at a low electrolyte concentration with methanol as solvent are similar to those at a high electrolyte concentration with water as solvent. Above pH 5 they overlap well, indicating a similar protonation behaviour. However, methanolic solutions exhibit unstable pH readings and long response times during the experiment, which is well known for non-aqueous systems with low electrolyte concentrations. Figure 2 (b) presents the absorption spectra of CdS/$G8NH_2$ nanocomposites in methanol synthesised at different $H^+/(NH_2 + NR_3)$ ratios. It is known that about two CdS nanoparticles bind per dendrimer at pH 10, which is indicative of at least two final nucleation sites at the surface of the dendrimer. In contrast, at pH 6–7, the CdS particle size increases (compared to the case at pH 10). If Cd^{2+} ions are confined inside the dendrimer, one final nucleation site is preferred. In this case, the CdS cluster size should increase, which was indeed observed. Hence, it is postulated that CdS is encapsulated inside the dendrimer when the synthesis is carried out at pH 6–8. After further decrease of the pH value, precipitates form; for these cases, only the absorption spectrum of the supernatant is shown.

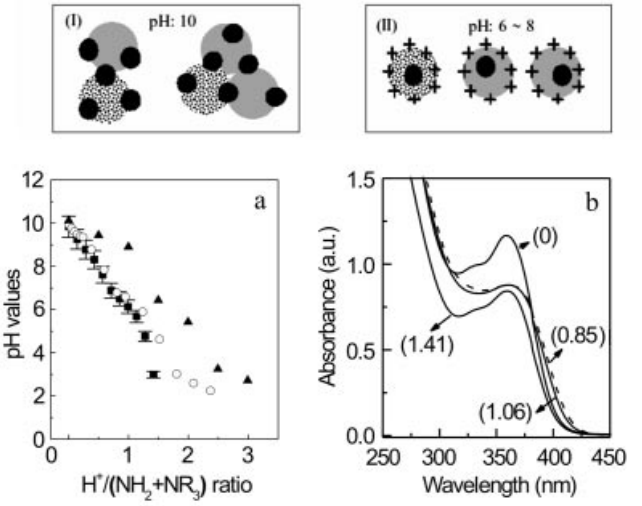

Figure 2. (a) pH values for $G8NH_2$ and $G4NH_2$ at different solvent and electrolyte concentrations vs. ratio $H^+/(NH_2 + NR_3)$. Solid squares: $G8NH_2$ in 0.16 M NaBr in methanol; open squares: $G8NH_2$ in 1 M aqueous NaCl; triangles: $G4NH_2$ in 1 M aqueous NaCl. Upper part (I): Possible morphology of CdS/$G8NH_2$ nanocomposites synthesised at pH 10. (b) Absorption spectra of CdS/$G8NH_2$ nanocomposites in methanol synthesised at selected $H^+/(NH_2 + NR_3)$ ratios; for 1.41 the supernatant was used. Upper part (II): Possible morphology of CdS/$G8NH_2$ nanocomposites synthesised at pH 6–8.

1.1.2. Binding of Cd^{2+} to PAMAM Dendrimers

In the following, syntheses at a pH of around 10 will be discussed for comparison. In these cases, CdS nucleates on

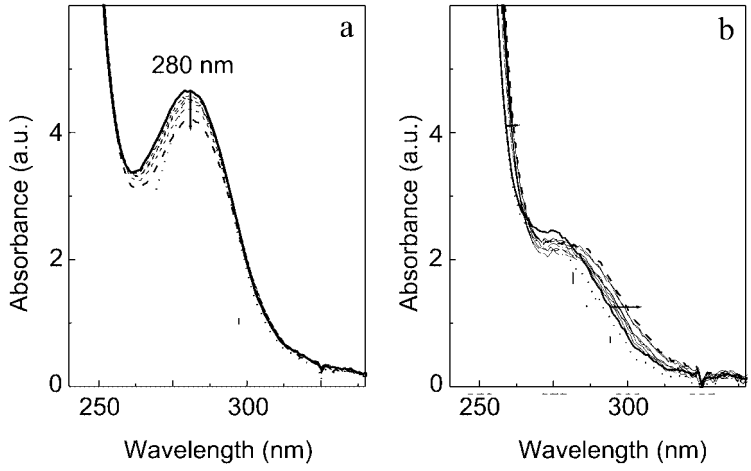

Figure 3. Effects of Cd^{2+} ions on the UV/Vis absorption spectra in methanol: (a) G4OH, ratios Cd^{2+}/NR_3 in direction of arrow (down): 0, 0.2, 0.4, 0.6, 1, 2; bottom spectrum: superposition of absorption spectra of pure G4OH and pure $Cd(CH_3COO)_2$. (b) $G4NH_2$, ratios $Cd^{2+}/(NH_2 + NR_3)$ in direction of arrow (right): 0, 0.08, 0.16, 0.24, 0.32, 0.4, 0.48, 0.64, 0.8; bottom spectrum: superposition of absorption spectra of pure $G4NH_2$ and pure $Cd(CH_3COO)_2$.

the outer dendrimer surface. The interaction strength of N-containing groups with metal ions normally follows the order $-NH_2 > -NR_3 > -CONHR$ (where R is an alkyl chain).[38,39] The example given in Figure 3 shows the effect of Cd^{2+} ions on the UV/Vis absorption spectra of G4OH and $G4NH_2$. The absorption spectrum of pure dendrimers shows two bands that are related to C–N bonds. The strong one around 220 nm results from the $\sigma\rightarrow\sigma^*$ transition of the C–N bonds, while the weak one around 270 nm corresponds to the $n\rightarrow\sigma^*$ transition of the C–N bonds. In order to show the change of the latter, the strong absorption peak of the former is not shown here. The interaction between Cd^{2+} and N-containing groups can be described as a donor–acceptor interaction (lone pair–cation) and is relatively weak. For the Cd^{2+}/G4OH system, the $\sigma\rightarrow\sigma^*$ and $n\rightarrow\sigma^*$ transitions of the C–N bonds show a small decrease in absorbance intensity and no shift of the band. The superposition of the absorption spectra of pure G4OH and pure $Cd(CH_3COO)_2$ with a Cd^{2+}/NR_3 molar ratio of 2:1 is also shown for comparison. It shows a negligible effect. For the Cd^{2+}-$G4NH_2$ system, the $\sigma\rightarrow\sigma^*$ and $n\rightarrow\sigma^*$ transitions of the C–N bonds show a small red-shift, thereby indicating an increased interference by Cd^{2+} ions compared with the case of G4OH. The superposition of the absorption spectra of pure $G4NH_2$ and pure $Cd(CH_3COO)_2$ with a $Cd^{2+}/(NH_2 + NR_3)$ molar ratio of 0.8 shows a small decrease in absorption due to dilution. Since the difference between G4OH and $G4NH_2$ is that $G4NH_2$ has primary amine groups, the interaction of Cd^{2+} with NH_2 groups must be stronger than its interaction with NR_3 groups, which also follows the usual trend in complex chemistry. Obviously, such an interaction favours binding to the outermost chemical groups, hence external type composites are obtained.

1.2. Microcontact Printing of Dendrimers and CdS\|Dendrimer Composites

The "top-down" patterning of flat substrate surfaces with dendrimers is based on interactions like electrostatic forces or hydrogen binding: the larger the dendrimer, the slower its surface diffusion and hence the simpler its selective transfer by microcontact printing. In this case, patterns do not change during and after printing, which is possible for short- and medium-chain thiols on gold.[40,41] First, a dendrimer solution is contacted with the patterned polymer stamp. In most cases the stamp has to be hydrophilic, which for the standard silicone material [poly(dimethylsiloxane)] (PDMS) is achieved with an O_2 plasma treatment. After drying, the stamp is contacted with the (hydrophilic) substrate. One can apply this process also to dendrimer/nanocluster composites because their transfer properties are imposed by the dendrimers, not by the clusters. In other words, the dendrimer functions as an adhesion promoter for "direct" printing. Thus, the usual two-step process, where a chemically functional (or hydrophobic/hydrophilic) pattern has first to be created before adsorbing the clusters or composites, can be avoided.[42] The transferred composite with CdS retains its luminescence properties, and patterning of various micrometre shapes has been demonstrated.[7] As shown in the following, careful variation of the synthesis and printing parameters allows for a better control and even for new organisation phenomena on the substrate surface.

1.2.1. Adsorption of PAMAM Dendrimers

A prerequisite for surface structuring with molecules (or by composites) is adsorption or immobilisation of the molecules. PAMAM dendrimers terminated by NH_2, COOH and OH groups can adsorb on oxides or OH-terminated surfaces via hydrogen bonds.[6,43] Part a of Figure 4 shows an example of the adsorption of G4OH, $G4NH_2$ and $G8NH_2$ dendrimers from solution onto oxidised Si wafers. The adsorption process is very fast and reaches nominal monolayer thickness (see below) for all three dendrimers within several minutes. Further immersion changes the ellipsometric thickness only slightly. Hence, a nominal monolayer is formed. The heights of the G4 and G8 monolayers

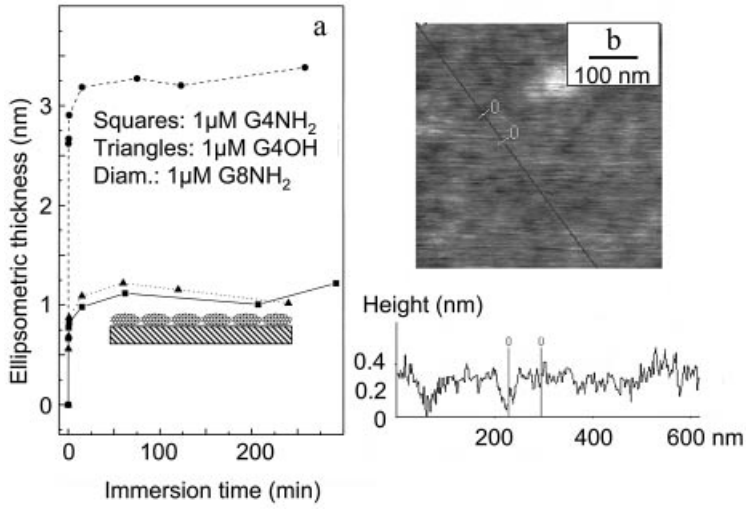

Figure 4. (a) Ellipsometric thickness of G4OH, $G4NH_2$ and $G8NH_2$ on oxidised silicon wafer surfaces measured in air after immersion, rinsing with ethanol and drying with argon. (b) Topographic intermittent contact AFM image of $G4NH_2$ monolayer on an oxidised silicon wafer; bottom part: height profile.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are around 1.2 and 3.3 nm, respectively, which means large deviations from their ideal spherical diameters of 4.5 and 9.7 nm.[44] The monolayer thicknesses are, however, close to the height of single G4 and G8 dendrimers on hydrophilic surfaces.[45] This indicates that a strong interaction with the hydrophilic surfaces deforms the dendrimers and they show an oblate morphology on these surfaces. A topographic AFM image of a $G4NH_2$ monolayer on a wafer is shown in Figure 4 (b). The white dot in the upper part is a defect, probably due to local multiplayer adsorption. Lateral structures were not observed. The image shows hillocks whose height cannot be determined exactly. The hillocks are ascribed to the $G4NH_2$ monolayer, which is quite flat, as can be seen from the height profile (<1 nm variation). Although the tip geometry plays a role in smoothing out the image, holes in the layer more than 5 nm in diameter should be easily visible. One can deduce that the coverage is smooth and dense. Due to this adsorption behaviour, dendrimers can be printed well on hydrophilic surfaces.[46]

1.2.2. Stripe Patterns of CdS/Dendrimer Composites

In the course of the microcontact printing experiments, an interesting new phenomenon of a "bottom-up" organisation inside "top-down" patterned areas was discovered. For this, only composites that have been aged for a short time (two days at ambient temperature in the synthesis solution) qualify, i.e. particles with a monodisperse size distribution (Figure 5, a).[6] For longer ageing times, Ostwald ripening occurs (for this reason the term "ageing" is preferred over "long term synthesis"). This not only increases the size of the CdS nanoparticles but it also changes the morphology of the whole nanocomposites, which is advantageous for the printing.[6] After two days, the average height (measured by AFM) of the nanocomposites is around 9 nm, and they have a regular shape. In contrast, after 22 days the height of the particles varies from 10 nm to 60 nm, and the distributions of both shape and size broaden considerably (Figure 5, b).

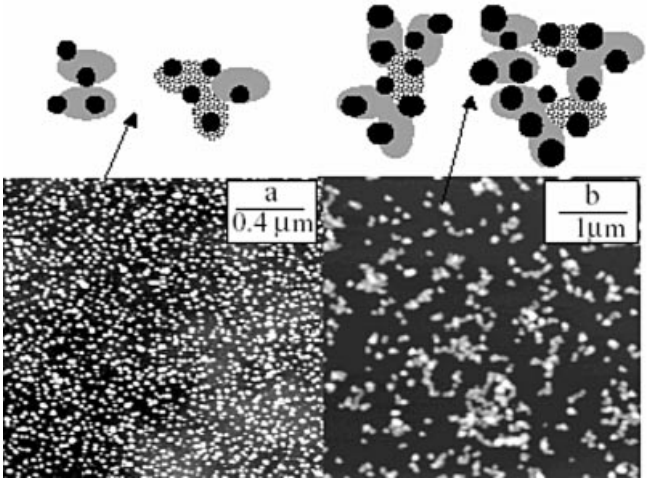

Figure 5. Topographic AFM images of $CdS/G8NH_2$ nanocomposites adsorbed on an oxidised silicon wafer after two days ageing (a) and after 22-days ageing (b). Upper parts: possible morphology for each case.

These relatively large composite aggregates can be organised into predefined micropatterns. First, a PDMS polymer stamp is produced by curing a liquid silicone prepolymer on a patterned silicon master. The patterned stamp is peeled off and treated with an oxygen plasma to create a hydrophilic stamp surface. This surface, in analogy to oxidised silicon wafers (Figure 5), is ideally suited for binding CdS/dendrimer composites aged for 22 d, simply by contacting the solution with the stamp and drying it. Conformal contact with a flat hydrophilic substrate transfers the composites exactly in the predefined pattern.

When the ageing time is reduced to only two days, the distribution of the composites on the substrate does not simply follow the pattern, rather a stripe structure several hundreds of nanometres wide develops inside the pattern, as can be seen in Figure 6. Note that the experiment was carried out in the same way, only the ageing time was shortened. The stripe structure appears to extend over the complete substrate. Hence a sub-micrometer "bottom-up" stripe patterning is obtained by using "top-down" micropatterning (>5 µm width). Height modulations on the stamp surface are not decisive: the same phenomenon occurs with unpatterned (flat) stamps (Figure 7), which are formed on flat, unpatterned silicon wafers. Such flat stamps usually transfer the adsorbed substance uniformly on the substrate.

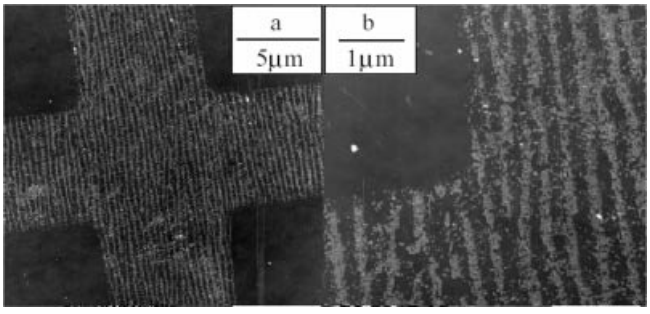

Figure 6. Topographic AFM images of $CdS/G8NH_2$ nanocomposites printed on an oxidised silicon wafer after two days ageing. A sub-micrometre stripe pattern develops inside the imposed cross-shaped pattern during the printing process.

While the structure formation is simple and straightforward, its physical interpretation is still unclear. An interesting question is whether the pattern is already present on the stamps. The inking process is the only chance for a mechanism based on fluid properties, such as dewetting. However, dewetting is excluded since it either results in structures confined to the borders of the printed pattern[47] or it yields foam-like structures in mobile molecular monolayers.[48] For some molecular systems, quite regular, but much larger, pattern widths (tens of micrometers) are found;[49,50] they depend on the orientation of the molecules on the surface, which should not play a role at the low coverages in the system under consideration. Indeed, the stripes presented here do not have uniform widths, but they extend over the complete micropatterned area. Similar, but better ordered,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

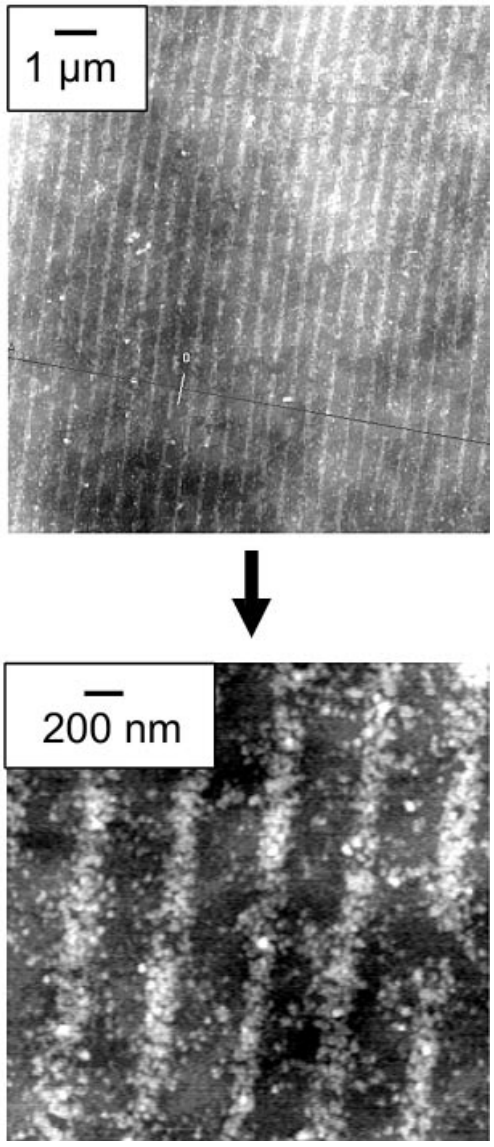

Figure 7. Topographic intermittent contact AFM image of CdS/$G8NH_2$ nanocomposites (aged for two days) printed on an oxidised silicon wafer with a flat stamp.

structures (linear arrays with sub-micrometer widths and a regular spacing) can be formed by dynamic monolayer film instabilities.[51] On the other hand, the composite does not form a complete monolayer, and the large CdS/dendrimer structures are not in all respects comparable with small molecules.

Another interesting point is the huge difference in behaviour between aged and fresh composites. This difference is unlikely to be chemical since both have chemical properties that are similar to pure dendrimers (see above). A clear difference is the (average) mass of the particles, which is relatively low for the fresh composites. However, possible mass-based mechanisms are hard to identify. For example, the stripe formation might suggest buckling, as observed upon heating, oxidation and cooling of PDMS,[52] or a standing wave, although a single acoustic resonance with a micrometre wavelength is unlikely.

2. Orientation of Plant Virions on Surfaces and the Synthesis of Metal Wires in Virions

When one-dimensional nanostructures or linear alignments of clusters are required, several supramolecular biotemplates can be advantageously employed for elegant syntheses (see Introduction). A good template for inorganic nanostructures is the tobacco mosaic virus (TMV). TMV is a tube-like assembly made up from around 2130 identical coat proteins helically organised around a helical single-strand RNA. Its length is about 300 nm and the outer diameter is 18 nm.[53] TMV has an inner channel with a diameter of 4 nm that is clad by the coat proteins. The interior of the channel is thus shielded from the environment; uranyl and most other cations cannot penetrate through the coat, and they have to diffuse in from either end.[26] TMVs are physically and chemically unusually stable − they can be suspended in several polar solvents (e.g. acetone and ethanol) without substantial changes of their structural integrity − and they tend to organise linearly in a head-to-tail fashion; in this way, the channel can be elongated to multiples of 300 nm.[28] Nanostructures can be created on the outer surface or in the interior channel.[28] The first case is analogous to nanostructures on other biomolecules such as DNA, whereas the second case is confinement templating, which has been documented for relatively few cases, for example peptide tubuli,[21] carbon nanotubes[54] and mesoporous silica.[55]

The nature of the coat proteins and the charges (TMV is negatively charged above its pI of 3.5) imply hydrophilicity and hydrogen-bonding capability, hence surfaces such as mica and oxidised silicon wafers are suitable for immobilisation. Due to the adsorption, TMV suffers some compression normal to the substrate surface.[28,56] Note that the adsorption on TEM grids is facile, too, since the standard carbon-coated polymer substrates are at least partially hydrophilic, much different from hydrophobic surfaces such as pure graphite or several polymers. Starting from this point, Section 2.1 investigates how to impose directional order, similar to the CdS/dendrimer stripes presented in Section 1.2.2, to adsorbed or adsorbing virions. Section 2.2 focuses on synthesising clusters and wires on and in a single TMV, so that the clusters are aligned by the linear biotemplate. This is obviously impossible with syntheses in near-spherical templates such as the dendrimers of Section 1.1.

2.1. Organising Tobacco Mosaic Virions in a Parallel Fashion by Lateral Forces

When oriented, but not necessarily patterned, assemblies of biomolecules are required, the simple application of directional mechanical forces during adsorption can be helpful. This method is well known for DNA,[9,29] but less so for much shorter (sub-micrometre) supramolecular units such as TMV. While TMV can organise in liquid-crystalline form at high concentrations, separate single virions form a statistically oriented assembly during adsorption to a substrate. Here it is demonstrated that single TMVs can be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

aligned by applying shear forces during adsorption on a flat substrate surface.

The first approach relies on forces exerted by a directional gas stream (during drying of a droplet) or by a directional flow of solvent (during suction drying of a droplet) (Figure 8). An Mg^{2+}-treated mica surface was covered with a droplet of TMV suspension (0.1 mg/ml), and a stream of argon was directed at it to remove the supernatant. Figure 9 (a) shows the mica surface with aligned adsorbed single virions. Note that the alignment is not perfect (the relative angle between the viral axes is not zero); on the other hand, nearly all virions on a given substrate were found to be oriented. Many virions aggregate linearly, i.e. they organise into objects about 18 nm wide (due to tip convolution effects not detectable by AFM) and hundreds of nanometres long. The pressure of the gas stream has to exceed a certain value ($\approx$ 7 bar); alignment with lower argon pressure was never observed. In a related experiment, a droplet of TMV suspension was placed on a hydrophobic flat PDMS surface and exposed to the argon stream. The aligned virions on the PDMS surface were transferred to an oxidised silicon wafer surface by microcontact printing (Figure 8, b) and visualised by AFM. The results were nearly identical to those shown in Figure 9 (a).

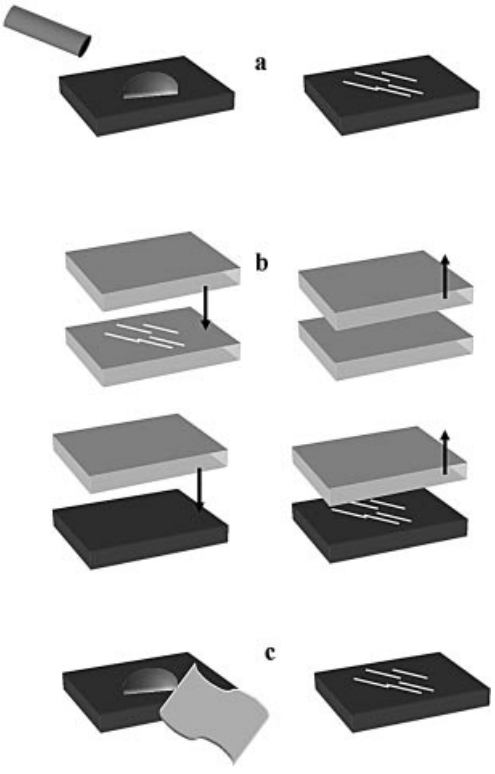

Figure 8. Orientation of nano-objects during their immobilisation by shear forces: (a) drying a droplet with a strong gas stream; (b) transfer of the oriented, adsorbed objects from PDMS to an oxidised wafer by microcontact printing with a flat PDMS stamp (top, arrows); (c) drying a droplet by suction with a filter paper.

An interpretation of this (top-down) process can be based on the initial attachment of only one end of the virion, since this is statistically much more likely than immediate contact of the complete virion. The virion is then free to rotate around the pivotal point for some time before it comes into contact with the substrate over its complete length. At this stage, lateral forces can act to orient the TMVs before they come into complete contact (Figure 8). The orientation is thereafter fixed, since the mobility of adsorbed TMV, especially on hydrophilic substrates, is very low. The alignment should, in both cases, be due to shear forces in the droplet, and it occurs during the diffusion to the surface. It is very unlikely that TMV, which adsorbs strongly on mica or silicon wafers, shows surface diffusion, which was never observed in any AFM experiment on mica or wafers or even graphite. A test verified that once a virion is adsorbed, it cannot reorient: placing a droplet of pure water on a surface coated with randomly adsorbed TMV, and thereafter subjecting it to an argon stream, did not produce aligned virions.

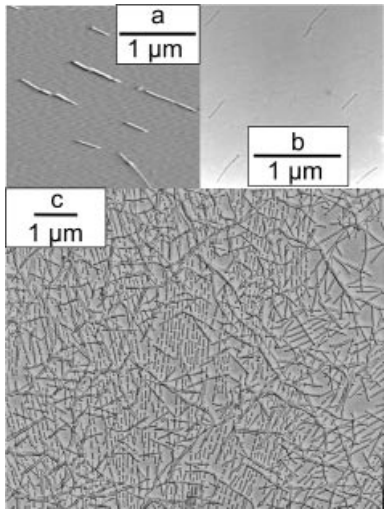

Figure 9. (a) AFM image (error signal) of TMV aligned by drying a droplet with an argon stream during adsorption on Mg^{2+}-treated mica. (b) Transmission electron micrograph (200 kV) of TMVs aligned by lateral forces (suction with filter paper) during adsorption on the carbon-coated polymer surface of a microscopy grid. No uranyl or other stain was applied. (c) as (b), but with higher TMV concentration and with silver shadowing to enhance the contrast (60 kV).

Coverage and orientation are not arbitrary, but in line with expectations: a droplet (max. 0.1 mL) with 0.1 mg mL^{-1} TMV provides sufficient material to deposit about eight monolayers of densely packed TMVs on the employed 1 cm^2 samples. However, coverages of only a tiny fraction of a monolayer were found. The typical diffusion time in the droplet to the surface is in the range of 1 h (for a droplet spread to 1 cm^2), while the droplet contact time was only 1 min, which should result in submonolayer coverage, as observed. In addition, in some cases (e.g. for graphite substrates or for the case of the hydrophobic stamp) a kinetic barrier due to colloid chemical effects can be present.[56] After the droplet contact time, the orienting force was applied; one can assume that the majority of the adsorbed virions are at this time contacting the surface with only one end. The gas stream exerts a force in the nanonew-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ton range: 7 bar acting on a 300 nm long and 18 nm wide area. This macroscopic force estimate is in line with forces required for (microscopic) AFM manipulation of TMV.[57]

Another promising possibility to align TMVs on a surface is to make use of laterally applied capillary forces, as is also possible for DNA[9] and carbon nanotubes.[58] A TMV suspension (20 μL, 10 mg mL^{-1}) was placed on a transmission electron microscope grid for 1 min, after which the droplet was removed by touching a filter paper to one side of the grid. The shrinking droplet caused a directional flow from the grid to the paper. Again, virions aligned in the direction of the flow, as shown in Figure 9 (see parts b and c). The difference between the figures is based on the much higher concentration of the suspension used for Figure 9 (c). Again, the objects more than 300 nm long are linearly aggregated TMVs. This alignment method, however, is only applicable for surfaces that show relatively weak interaction forces with the virions, such as carbon-coated TEM grids.[56]

In summary, the alignment of TMVs on surfaces can be obtained in several very simple ways based on lateral forces that act on a droplet of TMV suspension, which is, in turn, in contact with a substrate surface.

2.2. Clusters in Virions: Electroless Deposition

Metal clusters can be produced "bottom-up" with electroless deposition on, and also inside, TMV. The advantage of deposition inside the TMV channel is the inherent alignment of the clusters parallel to the viral axis. Here, only the initial and intermediate stages of the process are investigated. The first step is a sensitisation of the suspended virions with sub-2 nm Pd or Pt clusters (sources are Pd and Pt salts in aqueous solution). The clusters are, in fact, so small that identification of single clusters by (conventional) TEM is not possible; rather, the virions appear grey due to the presence of the clusters.[28] After removal of surplus metal ions, the suspension was mixed with a bath that contains the metal ion to be deposited (e.g. Ni^{II}) and a reductant (e.g. hypophosphite or dimethylamine borane, DMAB). The electron transfer from the reductant to the ion is catalysed by the Pd (or Pt) clusters, hence the deposition is limited to the location of the clusters. The deposition is autocatalytic, hence metal is continuously deposited on growing metal clusters. A side reaction is the evolution of hydrogen. The reaction is stopped by adding inhibitors or by drying the suspension, for example for analysis on a TEM grid. An important question is how the growing clusters develop into wires, and this question is obviously linked to the initial phase of the electroless deposition process.

When the original virus suspension contains phosphate, the reaction is limited to the outer viral surface, and relatively large (>30 nm diameter; not shown) coalescing clusters are found. Small clusters (<5 nm diameter) can be obtained by adsorption of noble metal salts, followed by reduction or by "mild" electroless deposition with hypophosphite.[19,26] Whenever the central viral channel can be found (e.g. in a cluster-free region), it is empty, proving the high selectivity of the reaction. The presence of phosphate is thought to result in insoluble deposits of metal phosphates (Co or Ni); these deposits, together with the noble metal clusters, act as very effective nucleation centres for the deposition.

In the absence of phosphate, the selectivity for channel metallisation is high, resulting in the deposition of wires. The selectivity for the channel is not easily explained. Electrostatic and complex chemistry arguments may favour the channel-cladding functional groups;[19,26,28] however, the observation of relatively large (>5 nm) clusters detached from the virions could mean that clusters initially form on the viral coat, but are unable to attach as strongly as in the presence of insoluble metal phosphates (see above). The by-product hydrogen may additionally exert mechanical forces, resulting in this detachment. The production of 3–4-nm-wide wires solely by wet chemical means cannot be achieved by any other process; however, chemical vapour deposition inside carbon nanotubes[54] appears to be an alternative to using TMV, while complete arrays of similar wires can be formed in mesoporous silica.[55] Figure 10 refers to an experiment where TMV was sensitised with Pd and metallised with Ni (in a DMAB-containing bath, see Experimental Section), but the process was interrupted before the time required for wires longer than 200 nm.[28] The lower part of Figure 10 shows the same image with different contrast, and with the positions of the wires marked as black lines. A number of wires already have remarkable lengths (>100 nm). Note that once again the TMVs in Figure 10 are linearly aligned, but that each orifice of the channels is still accessible (white arrows) and thus allows for electrolyte supply inside the TMVs. Hence, all distinct regions (here four) between the orifices appear to be metallised independently from their neighbours, resulting here in four wires.

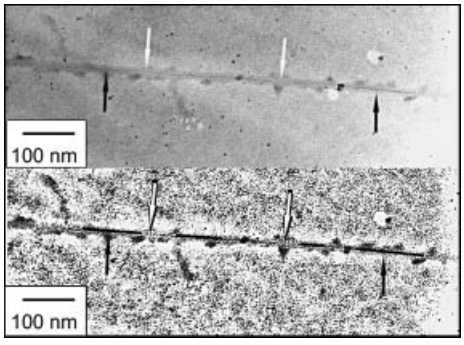

Figure 10. Transmission electron micrograph (200 kV) of Ni wires (<4 nm diameter) inside the TMV channel after electroless deposition in the absence of phosphate. Each gap between two virions is marked by white arrows and the wires by black arrows. The lower image is contrast-enhanced. The wires form upon nucleation and growth of Ni at sub-2 nm Pd clusters.

The mechanism is based on Pd or Pt nuclei that are rapidly covered by the metal (here Ni) that deposits from the electroless bath. Autocatalytic growth can result in depletion of reactive species and thus in size limitation.[59] However, the interior viral channel imposes a natural limit. Another limit is the solution concentration inside the channel: whenever two clusters have formed, a certain amount

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of metal ions is trapped between them. This amount has a maximum of 400 atoms (0.18 M Ni^{II}, 300 nm length, 4 nm diameter), yielding a spherical cluster of less than 3 nm diameter. Hence, more than two clusters inside a single virion can only grow when the first cluster forms deep inside the channel, and the later ones step by step closer to the viral orifice, in line with observations.[19,26] The same argument explains why more than two wires are never found inside a single virion. Wires form when the reductant is DMAB, which is thermodynamically and kinetically superior to hypophosphite (which is used for cluster synthesis). This implies that of the large number of Pd or Pt nuclei, only a very few are highly active. These few clusters start a rapid process of filling the viral channel with the deposit (Figure 11).

Figure 11. Mechanism of electroless cluster and wire deposition inside a channel: (a) tube-like template (e.g. TMV); (b) sensitisation: formation of very small noble metal clusters on the exterior surface and on the interior walls; (c) initial deposition: only a few very active clusters grow fast, the clusters on the exterior surface detach; (d) the clusters inside the channel can grow to, at maximum, two wires per channel when metal ions are supplied from the orifices of the channel.

Conclusions

A simple, wet chemical precipitation process can be used for the "bottom-up" synthesis of semiconductor nanoclusters when dendrimer templates are present. To this end, a synthesis method that produces CdS clusters at the outer surface of poly(amidoamine) dendrimers was modified to yield clusters inside the dendrimers. Control of the pH during synthesis allows for selective protonation of some of the amine groups in the dendrimer; relevant Cd^{2+} binding processes have been identified. The charge of the template is a decisive factor in a successful synthesis and should be considered also in other cluster syntheses. Elegant "top-down" organisation/patterning of the CdS/dendrimer composites on surfaces can be attained with microcontact printing. In addition to simple patterns, sub-micrometre wide stripes, made up from adsorbed composites, develop during printing inside micrometre-sized patterns. Thus, microcontact printing can result in a surprising way (synchronously) in not only "top-down" but also "bottom-up" structuring.

Metal wires 3–4 nm in diameter can be obtained by electroless deposition from solutions containing metal ions and reductants. They grow in the central channels of plant virions; the earlier stages of this process have been analysed, and a mechanism for the selective deposition in the channels presented. Clearly, the method is capable of producing other high aspect structures in narrow tubes. Removal of the coat proteins should be possible by oxidative or enzymatic treatment.[21] Organisation of the virions on flat substrates can be achieved during adsorption by application of external forces to a suspension droplet, resulting in parallel alignment. This method is well known from adsorption studies of other linear biomolecules, but works well even for the relatively short virion length of 300 nm.

Experimental Section

Poly(amidoamine) (PAMAM) dendrimer (generation 8) terminated with amine (Dendritech, Inc., Midland), here referred to as $G8NH_2$, was dissolved in 99.8% ethanol (Roth) with concentrations from 0.5 μM to 50 μM. $G8NH_2$ (200 μL) was diluted with methanol to 10 mL (5.5 μM $G8NH_2$), then 10 mL of 2 mM $Cd(CH_3COO)_2$ and 10 mL of 0.7 mM Na_2S in methanol were added to the dendrimer solution sequentially. After reaction, the nanocomposites were stored in a freezer at –35 °C to reduce the Ostwald ripening growth of nanoparticles, or they were aged at 25 °C for two and 22 days to induce ripening. The final concentration of $G8NH_2$ in the solution was 1.83 μM. The Cd^{2+}/S^{2-} ratio was kept at 3:1 since it was found that at this ratio CdS/$G8NH_2$ nanocomposites could be successfully printed. Before adsorption and printing, nanocomposites were dialysed (Slide-A-Lyzer 10000 MWCO caps, KMF, Lohmar) against methanol. Experiments with generation 4 dendrimers were conducted in a similar manner.

Absorption spectra from solutions were obtained with a Perkin–Elmer UV/Vis spectrometer Lambda 2. Photoluminescence and excitation spectra were taken with a Perkin–Elmer luminescence spectrometer LS 50B. The solutions were placed in quartz cuvettes for both instruments.

Silicon wafers [orientation (100), Crystal, Berlin] were terminated by silicon oxide with hydroxyl groups by the standard RCA procedure: 15 min immersion in a 65–75 °C hot 1:1:5 mixture of 25% NH_4OH (VLSI Selectipur, Merck), 31% H_2O_2 (VLSI Selectipur, Merck) and water (Millipore, 18 MΩcm) followed by 15 min immersion in a 65–75 °C hot 1:1:5 mixture of 37% HCl (Suprapur, Merck), 31% H_2O_2 and water. These samples are termed "oxidised silicon wafers".

Ellipsometric measurements were performed in air with an EL-X-02C ellipsometer (DRE, Ratzeburg) at 70° angle of incidence and 633 nm wavelength. The ellipticity of the HeNe laser beam was minimised with a λ/4 plate. Measurements were made at more than 4 points randomly picked across the sample and averaged. A two-layer transparent film model was used for the thickness calculations of dendrimer layers on oxidised silicon wafers. The refractive index of the dendrimers was fixed at 1.45.

Atomic force microscope (AFM) images of patterns were obtained in intermittent contact mode with a Thermomicroscopes Autoprobe M5, operated in non-contact and intermittent contact mode, with MikroMasch NSC11 tips or NCHR Pointprobe Nanosensors.

Poly(dimethylsiloxane) (PDMS) stamps (Sylgard 184, Dow Corning) were formed on flat polystyrene dishes or on patterned silicon wafer masters [IBM Zürich and Institute for Microelectronics Stuttgart (IMS); before first use the master was rendered hydrophobic with fluoroalkyltrichlorosilane vapour]. The stamps were activated by plasma oxidation in 1 mbar O_2 at 150 mW for 10 s (Technics Plasma 100-E). Hydrophilicity was ensured by contact angle measurements for various exposure times from 0 s to more than 10 s. Freshly activated flat stamps were covered with one drop (≈20 μL) of ink solution for 25 s, and then blown dry with argon. Freshly activated structured stamps were brought into conformal

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

contact with the inked flat stamp for 25 s, then peeled off and brought into conformal contact with freshly cleaned silicon wafers for 25 s, and finally peeled off from the substrates.

For the TMV alignment, freshly cleaved mica was treated for 5–15 min with 0.1–1 M aqueous $MgCl_2$. The surface was contacted with a droplet of TMV suspension (0.1 mg mL^{-1}). After 1 min (known to be sufficient for strong adsorption) a strong stream of argon (7–8 bar, 5 mm orifice) was directed at about 65° to the surface normal to remove the supernatant. Alignment by laterally applied capillary forces was achieved as follows: A Formvar/carbon-coated copper grid (300 or 400 mesh, SPI-Supplies) was dipped into ethanol (Roth Rotipuran) and air-dried. TMV suspension (20 μL, 10 mg mL^{-1}) was placed on the grid. After 2–3 min the solution was removed by placing filter paper on one side of the grid. TEM images were obtained with a Philips CM200 at 200 kV and − in this case after silver shadowing − in a Zeiss EM 10 at 60 kV.

TMV was metallised in the following way: First, a TMV suspension (0.1–0.2 mg mL^{-1}) was mixed with an equal volume of a 0.9 mM solution of Na_2PdCl_4 or K_2PtCl_4 (both p.a., Aldrich) in 1 M NaCl (p.a., Fluka), adjusted to pH 5–6 with 0.1 M HCl. After an incubation time of 10 min, the suspension was centrifuged at 14000 rpm for 10 min and the supernatant carefully removed. The pellet was resuspended in water and centrifuged again for 10 min at 14000 rpm in order to remove remaining Pd or Pt. This washing procedure was applied 2–3 times. Ni was deposited from 0.18 M $Ni(CH_3COO)_2{\cdot}4H_2O$ (p.a., Fluka), 0.28 M lactic acid (85% in water, Fluka) and 34 mM DMAB (dimethylamine borane, p.a., Aldrich) in water. The pH was adjusted to 6–7 with 1 M NaOH solution. TEM images were obtained with a Philips CM200 at 200 kV.

Patterning of Semiconductor Nanoparticles via Microcontact Printing

Xiao Chun Wu,[a] Li Feng Chi,*[a] and Harald Fuchs[a]

Keywords: Microcontact printing / Interaction / Interfaces / Nanocluster / Patterning / Semiconductors

Three general paths for patterning semiconductor nanoparticles stabilized with a short chain stabilizer via microcontact printing (μCP) are presented. The interface between the nanoparticles and surfaces has to be carefully designed to realize a successful direct or indirect printing.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Parallel patterning of functional materials is very important for many photonic and electronic applications, for example multiple color LEDs, color pixels for field-emission displays, and multichannel chemical sensors. Therefore, the parallel schemes of positioning of these functional materials in predetermined areas are of great scientific and technological interest. Apart from the standard patterning techniques such as lithography, recently developed nontraditional patterning methods such as microcontact printing (μCP),[1] nanoimprinting lithography (NIL),[2] scanning probe lithography,[3] and dip-pen nanolithography[4] have attracted a great deal of attention in the field of surface patterning. Among them, μCP and NIL have the advantages of low-cost, simplicity, rapidity, and high throughput (parallel process). μCP is more versatile because many different materials can be used as inks to directly print on flat and curved surfaces.

Generally speaking, the patterning of functional materials can be realized in the following two ways. The first is where the distribution of the functional materials themselves on the surfaces is in a patterned way. Thus, the functionality is naturally patterned.[5–7] For example, Won et al. bound dendrimers on a surface, then let gold ions adsorb to the dendrimers. By UV irradiation with a photomask, patterned Au nanoparticle structures were obtained.[7] The other method is where functional materials are homogeneously distributed on surfaces while another material on top or beneath the functional material is patterned. In this way, through the inhibition or activation of the functionality of functional materials by printed materials, the functionality is realized in a patterned way.[8] For example, Wang et al. first assembled semiconductor nanoparticles on surfaces using a layer-by-layer strategy. Then copper grids were placed on top of the nanoparticle films as an optical mask. Because of the strong enhancement of photoluminescence (PL) from the nanoparticles by irradiation, a strong contrast in PL was observed after removal of the grids.[8]

By means of μCP, there are three possible paths to the patterning of the functional materials: (1) They can be selectively adsorbed to a printed heterogeneous surface, as shown in part a of Scheme 1. (2) They can be bound to a structured stamp and be directly printed on a homogeneous surface, as shown in part b of Scheme 1. (3) They can be brought to a homogeneous layer (e.g. spin coating) on a surface and be patterned by an inactive structure, as shown in Scheme 1 (see part c, the inactive structure can also be beneath the active layers). Although the direct printing of functional materials is desirable, it is not easy to achieve since a compatible stamp-molecule-surface system is needed. Successful printing requires detailed studies of various printing conditions such as ink concentration and time, printing time, and the surface properties of both the stamp and substrate. Therefore, compared to the printing of well-known systems for example self-assembled monolayers (SAMs), the direct printing of functional materials is more complicated.[9–12] Therefore, up to now, the realization of the patterning of functional materials via μCP has been mainly based on the direct printing of SAM layers, rather than the functional materials themselves.[13–17] The advantages of printing SAM layers are that they are relatively simple and the interaction mechanisms among ink, substrate, and stamp are well-studied in these systems,[18–20] but one more step for selective adsorption is needed. Should the first two methods prove difficult to realize, the third method may prove a good choice. For example, Koide et al. first printed alkyltrichlorosilane on an ITO glass substrate, then an organic light-emitting diode was deposited on the patterned substrate by a standard deposition technique.[14] Since the stamped SAM can impede the hole injection into

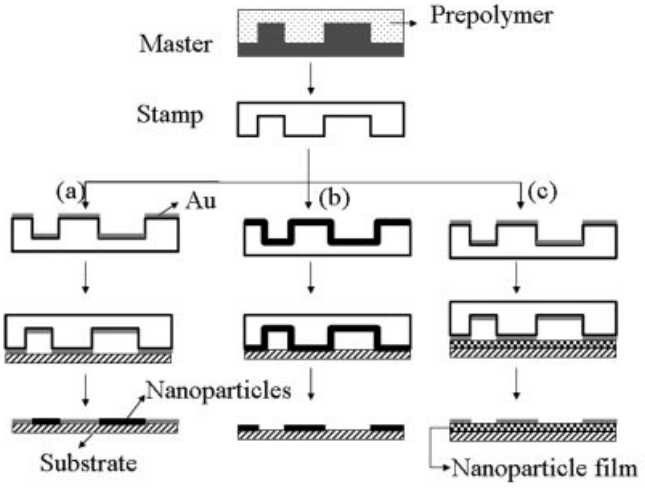
Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

the hole transport layers, this renders the stamped area essentially nonemissive. Although the whole substrate was covered with LED materials, only unpatterned regions show effective emission. In this way, patterned LEDs were obtained.



Scheme 1. Patterning of nanoparticles via (a) printing of block layer and adsorption of nanoparticles, (b) direct printing of nanoparticles, and (c) printing of block layer on the top of the nanoparticle layer.

Semiconductor nanoparticles show unique size-dependent optical properties and are of great interest for applications in optoelectronics, photovoltaics, and biological sensing.[21–25] Various chemical synthetic methods have been developed to prepare such nanoparticles. With the progress in the synthesis of nanoparticles using wet chemical syntheses, the synthesis of nanoparticles capped with so-called "stabilizers", which cap the surface of the nanoparticles during their growth, has been greatly improved and produced high-quality nanoparticles. Two different approaches have been developed to synthesize high-quality semiconductor nanoparticles. One is an organometallic synthesis based on the high-temperature thermolysis of precursors, first reported by Murray et al. in 1993,[26] and further improved later.[27–29] An alternative synthesis employs polyphosphates[30] or thiols[31,32] in aqueous media. With the success in obtaining high-quality nanoparticles, assembling them into devices becomes possible. Here we will explore the possibilities provided by the above-mentioned three paths to pattern high-quality CdTe nanoparticles stabilized with a short chain stabilizer (thioglycolic acid, TGA).

Results and Discussion

Selective Adsorption of Nanoparticles on a Patterned Surface

As mentioned in the introduction and shown in Scheme 1a, when nanoparticles show highly selective adsorption or binding onto certain surfaces, the patterning of them can be achieved through producing such surfaces in a patterned way. Recently, Loo et al. reported the direct printing of Au on a –SH terminated surface.[33] Here, we used this procedure to print a Au pattern and used this pattern as marks. Unprinted regions were further modified with different chemical groups in order to study the adsorption behaviors of a CdTe/TGA aqueous solution via hydrogen bonding, ligand exchange, or weak electrostatic forces. Part a of Figure 1 shows a topographic image of a printed Au line on a (3-mercaptoproply)trimethoxysilane (MPTMS) modified Si surface after the removal of MPTMS (O_2 plasma oxidation). A zoom-in image (not shown here) indicated that the unprinted region terminated with –OH groups was quite clean. After 3 h adsorption of a 1 mM CdTe/TGA aqueous solution, images were taken as shown in Figure 1 (b). CdTe nanoparticles showed random and inhomogeneous adsorption both on the hydrophilic –SiOH/Si surface and on the rough Au surface. The density of the nanoparticles was, however, very low. In the case of further modification with MPTMS, the thickness of the Au region increased to over 10 nm, indicating the formation of multilayers of MPTMS on the Au region. After adsorption of nanoparticles for 3 h, in the –SH region, we did not observe obvious adsorption (Supporting Information), indicating that no apparent ligand exchange was taking place between TGA and MPTMS. For (3-aminopropyl)dimethylethoxysilane (APDES) SAMs, the adsorption of nanoparticles on the $–NH_2$ region increased a lot compared to the case of the –SH terminated surface and showed less agglomeration than the –SiOH terminated surface, indicating greater electrostatic forces. However, the density of nanoparticles was still too low. Therefore, Scheme 1 (a) is not an effective path for patterning CdTe/TGA nanoparticles via simple hydrogen bonds, ligand exchange, and weak electrostatic forces.

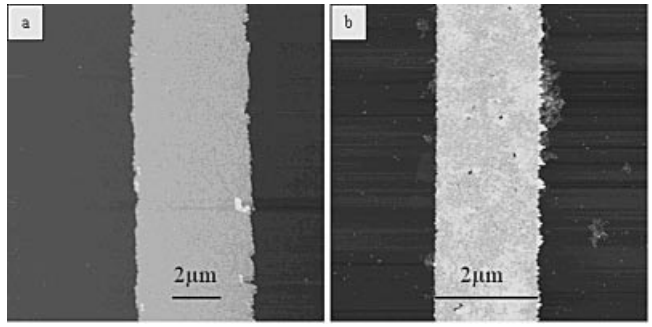


Figure 1. AFM images of Au patterns with –OH groups on unprinted regions before (a) and after (b) adsorption of a CdTe/TGA aqueous solution for 3 h.

Since the surface of the CdTe nanoparticle is capped with a layer of $SHCH_2COOH$ (TGA), the CdTe/TGA can in principle form multiple hydrogen bonds with the SiOH terminated surface. But the low-density inhomogeneous adsorption indicated that the hydrogen bonds between the TGA layer and the surface were weak and ineffective. This provides a hint that the TGA layer cannot be compared to some macromolecules for example poly(amidoamine) dendrimers. Dendrimer-stabilized nanoparticles show effective

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

adsorption on surfaces by multiple hydrogen bonds.[34] Here, the roughness of the surface might play a more important role as we could see that more particle aggregates adsorbed on the edges of the Au pattern and on the rough Au pattern. The formation of larger aggregates suggested that the interaction between the nanoparticles was stronger than that between the nanoparticles and the surface. The random adsorption of nanoparticles was also shown by the XPS measurements as signals of Cd, Te, and S from the nanoparticles were obtained (Supporting Information). For the –SH terminated surface, we did not see the obvious ligand exchange between TGA and MPTMS. The main reason for this was that TGA is not a viable ligand. For dodecylamine-stabilized CdSe/CdS core/shell nanoparticles, they showed strong adsorption on an $–NH_2$ or a –SH terminated surface because of strong ligand exchange.[35] This was also verified here by using tri-*n*-octylphosphane (TOPO) stabilized CdSe/CdS nanoparticles as shown in Figure 2. Figure 2 (a) shows an AFM image of printed Au on a –SH terminated surface. Figure 2 (b) presents the AFM image of this surface after adsorption of CdSe/CdS/TOPO in phenyloctane for 3 h. We could see a lot of nanoparticles dispersed on the –SH terminated regions because of strong exchange between TOPO and MPTMS. For the APDES modified surface, the positive charges are determined by the protonation of primary amino groups. The pK_a of the amino groups in solution is 10.6, it is lower in monolayers on solid substrates.[36] The surface pK_a of this layer is 3.9 by force titration and 4.3 by conventional contact angle wetting titration.[37] For a CdTe/TGA aqueous solution, the negative charges are determined by the deprotonation of carboxylate acid groups on the surface of the nanoparticles. The surface pK_a of –COOH terminated surfaces is 5.2 by electrochemical titration and 5.6 by contact angle titration.[38] In our case, the pH of the CdTe/TGA aqueous solution is ca. 7. Therefore the $–NH_2$ groups from the surface are basically uncharged and the –COOH groups from TGA are partially charged. This explains the low density of adsorption.

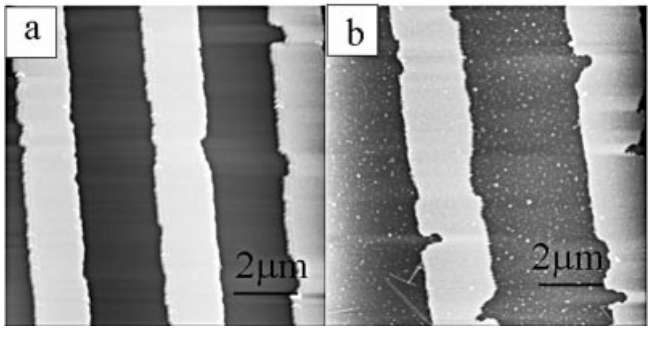

Figure 2. AFM images of Au patterns with –SH groups on unprinted regions before (a) and after (b) adsorption of a CdSe/TOPO solution for 3 h.

Direct Printing of Nanoparticles

We then followed Scheme 1 (b) to explore the possibility of directly printing nanoparticles. Although nanoparticles show no obvious adsorption on a hydrophilic OH terminated Si substrate, enough nanoparticles were left on the stamp by first adding 25 μL of nanoparticle dispersion to a hydrophilic stamp and then blowing it dry with N_2. Figures 3a, b, d, and e show topographic AFM images of printed nanoparticles at two different concentrations. At 1-mM concentration, nanoparticles can be printed homogeneously on the surface. The average height of nanoparticles is ca. 4.6 nm (Figure 3, c), similar to their diameter in solution. For the 2-mM concentration, the density of the nanoparticles on the printed regions was increased as expected. The average height of the nanoparticles is ca. 3.8 nm (Figure 3, e). This suggested that the nanoparticles mainly existed in the single form. Some larger aggregates of nanoparticles also formed at the 2-mM ink concentration as seen in Figure 3 (parts d and e), especially around the pattern edges. This has also been observed in the printing of other materials at higher ink concentrations.[39]

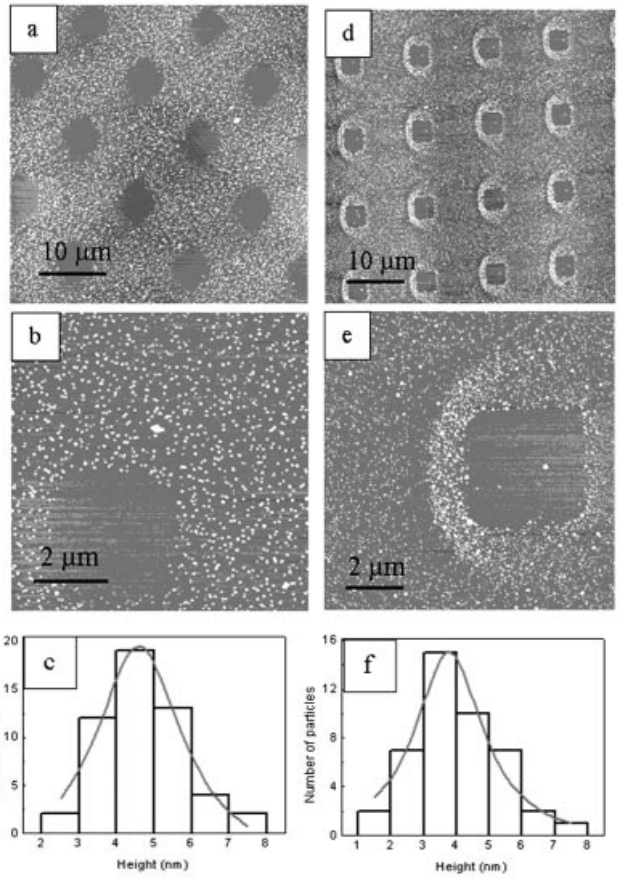

Figure 3. AFM images of printed CdTe/TGA nanoparticles on Si(100) surfaces with ink concentrations of 1 mM for (a) and (b) and of 2 mM for (d) and (e). Size distribution plots for (c) 1 mM and (f) 2 mM ink concentrations.

Printing Metal Structures on a Homogeneous Nanoparticle/Polymer Layer

For many practical applications, the stability of nanoparticles and the easiness of processing play very important

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

roles. It is therefore better to disperse the nanoparticles in a matrix, for example a polymer. Recently, Yang's group has succeeded in dispersing high-quality CdTe nanoparticles into polystyrene (PS) and polymethylmethacrylate (PMMA) blocks. The CdTe/PS block can be dissolved in chloroform and then easily spin-coated onto a Si (100) surface.[40] Wang et al. reported that metals deposited on stamps could be transferred to some polymer surfaces by printing above the glass transition temperatures of the polymers under certain pressures.[41] Here we found that metal transference could also be initiated at room temperature under pressure with a slightly longer printing time. Forty-nm Au was thermally evaporated on structured stamps. Through a conformal contact between the Au-coated stamp and the CdTe/PS/Si (100) substrate (1 h in contact with pressure), Au patterns were transferred to the substrate as shown in Figure 4 (a). The fluorescence of CdTe nanopaticles remained as evidenced by the optical bleaching of the fluorescence (Figure 4, b). The bright lines were derived from the gold scattering. The dark lines were from CdTe/PS films. Because of strong scattering from the gold, the photoluminescence from the nanoparticles was shadowed. Therefore, we used PL bleaching to verify the existence of the PL from the nanoparticles. The sample was first placed under a blue light for 10 min and then moved partially out of the irradiation region. A luminescence image was taken immediately after the movement. We could see that the part without the 10 min irradiation showed a strong PL in comparison with that with the 10 min irradiation. The gold part showed no bleaching. A pure CdTe/PS film on a Si substrate underwent a similar bleaching behavior as shown in Figure 4 (c).

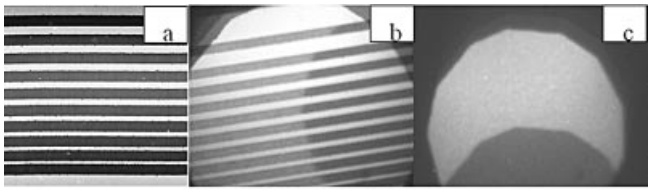

Figure 4. AFM (a) and luminescence (b) images of spin-coated CdTe/PS layer with printed Au patterns on top, and luminescence image (c) of spin-coated CdTe/PS layer.

In conclusion, we have presented several general strategies for the patterning of functional high-quality CdTe/TGA nanoparticles via μCP. Since the synthesis of CdTe/TGA nanoparticles is well-developed, a similar protocol can be adopted for the syntheses of other II-VI nanoparticles[31] or for the post-treatment of nanoparticle surfaces.[42] The patterning methods we have presented here therefore represent a general and easy process for the patterning of functional high-quality CdTe/TGA nanoparticles and also at the same time provide useful guides for patterning similar systems.

Experimental Section

A silicon substrate [WaferNet Co., Type N, 0.5 mm thick, orientation (100), resistivity 2–5 Ω cm] and SiO_2/Si substrate with 300-nm thick thermal SiO_2 were cut and ultrasonicated successively in acetone (p.a.), chloroform (p.a.), 2-propanol (p.a.), and water for 10 min. They were then cleaned with the standard RCA procedure: 15 min immersion into a 70 °C hot 1:1:5 mixture of NH_4OH (25%, Fluka, p.a.), H_2O_2 (31%, Fluka, p.a.) and water (Millipore, 18.2 MΩ cm); followed by a 15 min immersion into a 70 °C hot 1:1:5 mixture of HCl (37%, Aldrich, A.C.S. reagent), H_2O_2 (31%, Fluka, p.a) and water (Millipore, 18.2 MΩ cm). They were finally rinsed with water, and then dried under a stream of nitrogen. MPTMS (3-mercaptopropyltrimethoxysilane, 95%, Aldrich) and APDES [3-aminopropyl(dimethylethoxysilan), 97%, ABCR, Karlsruhe] SAMs were formed on SiO_2 surfaces by vapor deposition in a vacuum chamber for 15 h at room temperature. PDMS stamps (sylgard 184, Dow Corning) were formed on a patterned Si wafer master (IMS Stuttgart, before first use master was rendered hydrophobic with (fluoroalkyl)trichlorosilane vapor).

Printing of Au Structures: Au layers on hydrophobic stamps were deposited by thermal evaporation. A conformal contact between the Au-coated stamp and the MPTMS-modified (or PS-coated) Si substrate was initiated and kept for 1 min for the MPTMS-modified substrate and 1 h under pressure for the PS-coated substrate,[40] then the stamp was peeled off from the substrate. Because of the stronger interaction between Au and the substrate, Au patterns were transferred to the substrate. After 1 min 150-W O_2 plasma treatment, the SH region was oxidized and became an OH region (Templa System 100-E plasma system). This region can be used for further modification via silanization with different chemical groups.

Printing of Nanoparticles: A freshly activated stamp (1 mbar O_2 plasma, 300 W for 20 s) was covered with one drop (25 μL) of CdTe/TGA ink solution for 1 min, and then blown dry with N_2. It was put in a conformal contact with a clean Si (100) substrate for 25 s and then peeled off from the substrate.

Thioglycolic acid-capped CdTe (CdTe/TGA) nanocrystals (ca. 4 nm in size with a band edge photoluminescence maximum at 590 nm, 6% room-temperature quantum efficiency) in aqueous solution were obtained from the Photonics and Optoelectronics Group, Physics Department and CeNS, Ludwig-Maximilians Universität (Munich, Germany). CdTe nanoparticles distributed in a polystyrene (PS) block were obtained from the Key Lab of Supramolecular Structure and Materials, College of Chemistry, Jilin University, Changchun, P. R. China.

AFM measurements were performed with a commercial instrument (Digital Instruments, Nanoscope IIIa, Dimension 3000, Santa Barbara, CA) operated in tapping mode, silicon cantilevers (Nanosensors) of spring constant 250–350 kHz were used. XPS measurements were carried out with a VG ESCALAB 250 imaging XPS spectrometer. The samples were irradiated with monochromatic Al-K_α X-rays (15 kV, 150 W, 500 μm spot size).

Supporting Information Available: AFM images of the Au patterned surface with –SH and $–NH_2$ groups on un-patterned regions before and after adsorption of CdTe/TGA, as well as the XPS spectrum of the Au surface terminated with –OH groups after adsorption of CdTe/TGA.

Structures, Photoluminescence and Theoretical Studies of Two Zn^{II} Complexes with Substituted 2-(2-Hydroxyphenyl)benzimidazoles

Yi-Ping Tong,[a,b] Shao-Liang Zheng,*[a] and Xiao-Ming Chen*[a]

Keywords: Density functional calculations / N,O ligands / Photoluminescence / Pi interactions / Zinc

Two new Zn^{II} complexes of 2-(2-hydroxyphenyl)benzimidazole (Hpbm), and 5-amino-2-(1*H*-benzoimidazol-2-yl)phenol (Hapbm), namely $[Zn(pbm)_2]$ (**1**), and $[Zn(apbm)_2]\cdot C_2H_5OH\cdot H_2O$ (**2**), as well as the ligands themselves, have been prepared and characterized by X-ray crystallography and photoluminescence studies. Both **1** and **2** are neutral, mononuclear molecules that display strong photoluminescence in the blue regionand thus may serve as candidates for blue-light-emitting electroluminescent materials. The electronic transitions in the photoluminescent processes have also been investigated by means of time-dependent density functional theory (TDDFT) energy level and molecular orbitals analyses, which show that their absorption and luminescent properties are ligand-based.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Since the first report of a double-layer green organic electroluminescence (EL) device based on Alq_3 (Hq = quinolin-8-ol) in 1987,[1] metal chelate complexes of Al^{III}, B^{III}, and Zn^{II} have been extensively investigated for their electroluminescent properties.[2,3] Unfortunately, few systematic investigations of the luminescence properties of these complexes have been carried out as extensive structural information is only now becoming available[4,5] and computational techniques have only recently allowed reliable calculations of larger molecules.[5,6] For example, $[Zn(pbt)_2]_2$ [Hpbt = 2-(2′-hydroxyphenyl)benzothiazole] has been studied as an excellent white EL material,[7] even though its molecular structure and electronic characteristics based on the density functional theory (DFT) calculations have only recently been reported.[5]

Although blue-light-luminescent coordination complexes have been an active research field for two decades,[2,8–10] stable and strong blue-emitting metal complexes are still rare, unlike the other basic components of white emission (red and green). It has been shown that some d^{10} metal complexes with N,O-donor ligands may have the high glass transition temperatures required for stable light-emitting diodes and demonstrate nice blue-emitting EL properties.[2,3,5] Among them, Zn^{II} complexes have been proved to be important candidates for EL emitters for their excellent emitting properties[7] and low cost, in comparison with other d^{10} metal (e.g. Au^{I}) complexes.[10] We recently reported a class of blue/green light luminescent d^{10} metal complexes containing the new N,O-donor ligand Hophen (Hophen = 1*H*-[1,10]phenanthrolin-2-one) and the relation between molecular structure and luminescence properties with the help of X-ray single-crystal diffraction analyses and a DFT study of the ground electronic states.[11]

In our continuing efforts to design and synthesize blue-emitting materials, we now extend our focus to benzimidazole derivatives,[12] and report herein the syntheses, crystal structures, and luminescence properties of two neutral, monomeric Zn^{II} complexes, namely $[Zn(pbm)_2]$ (**1**) and $[Zn(apbm)_2]$ (**2**) [Hpbm = 2-(2-hydroxyphenyl)benzimidazole; Hapbm = 5-amino-2-(1*H*-benzoimidazol-2-yl)phenol] (Scheme 1). The electronic transitions in the photoluminescent process have also been studied by means of time-dependent density functional theory (TDDFT) calculations.

Results and Discussion

Synthesis and Characterization

For practical applications, neutral coordination compounds are usually required since they may possess impor-

tant characteristics for the performance of their EL properties, such as a relatively high glass transition temperature and thermal stability, easy sublimation, and an ability to form thin films under vacuum.[2,3] Therefore, neutral, mononuclear metal complexes should be expected to be excellent candidates for EL materials. Similar to the other complexes that can easily form thin films under vacuum,[3] both **1** and **2** can be prepared by mixing solutions of zinc acetate and the corresponding ligand in a 1:2 ratio in ethanol. Unfortunately, single crystals for X-ray diffraction were hard to grow, thus different methods, including conventional evaporation, diffusion, and hydrothermal methods were employed. In contrast, many solid EL metal complex materials have, in fact, only been identified by their chemical compositions rather than their structures. Some of their molecular structures may be much more complicated than their empirical formulae, since they may actually be characterized to be dimeric or multinuclear structures in the solid, such as the cases of $[Znq_2]_4$,[13] $[Zn(pbt)_2]_2$,[5] and $[Zn(oz)_2]_2$ [Hoz = 2-(2′-hydroxyphenyl)-2-oxazoline].[9] This fact shows that in the absence of X-ray structures, some conclusions about their luminescence properties may be controversial.[3] Fortunately, both **1** and **2** were found to be neutral, mononuclear molecules by X-ray crystallography, thus systematic investigations of their luminescence properties can be carried out. Our trials also imply that the crystallization conditions are important.

Thermogravimetric analyses (TGA and DTG) of **1** and **2** show their high thermal stability, with decomposition temperatures of 396 and 472 °C, respectively (Figure S1 in the Supporting Information), which are similar to other EL metal-organic materials.[5,12] Preliminary trials also proved that both readily form films under vacuum.

Crystal Structures

Single-crystal X-ray diffraction analyses revealed that both **1** and **2** are neutral, mononuclear molecules with the Zn^{II} ion being tetrahedrally coordinated by two deprotonated pbm or apbm ligands (Figure 1). The dihedral angles between two ligand planes of about 89° and 88°, respectively, indicate a slight distortion from an ideal tetrahedral geometry for **1** and **2**. The N–Zn–N and O–Zn–O angles [122.7(2)° and 110.1(1)° for **1**; 116.2(1)° and 114.0(1)° for **2**] are typical for a tetrahedral geometry. The Zn–O bond lengths of 1.932(1) and 1.931(2) Å in **1** and 1.932(3) and 1.944(3) Å in **2** are slightly shorter than those documented in the literature, whereas the Zn–N bond lengths of 1.951(2) and 1.953(2) Å in **1** and 1.958(3) and 1.975(3) Å in **2** are also slightly shorter than the literature values.[5,13,14] The two crystallographically unique ligands have dihedral angles (ca. 7.2° and 7.3° for **1**; 9.9° and 20.7° for **2**) between the benzimidazole and phenolate moieties which indicate that the ligands are only slightly non-coplanar in **1**, although one ligand is significantly non-coplanar in **2**. Head-to-tail π–π stacking interactions (interligand distance of ca. 3.60 Å) exist between two molecules and give rise to a dimeric supramolecular structure in **1** (Figure 2, a). Such supramolecular dimers are stacked by edge-to-face C–H···π interactions (H···π ca. 2.75 Å) (Figure 2, b) between benzimidazole and phenolate rings of adjacent molecules, giving rise to a three-dimensional supramolecular array, while the π–π stacking interactions are in a nonparallel mode between the ligand planes of adjacent molecules, with face-to-face distances of 3.35–3.60 Å in **2** (Figure 2, c).

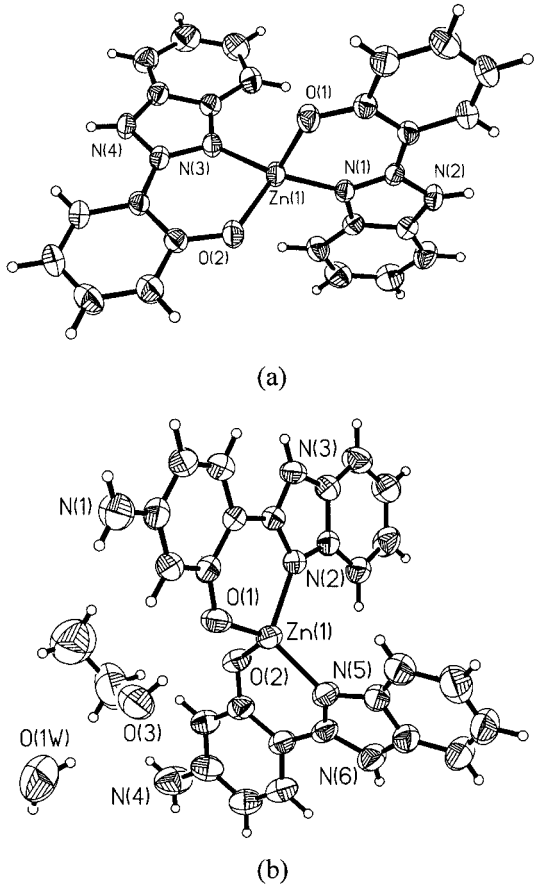

Figure 1. ORTEP views (at the 50% probability level) of **1** (a) and **2** (b).

There are also intermolecular hydrogen-bonding interactions in **1** and **2**. In **1**, the intermolecular hydrogen bonds [N(7)···O(2) = 2.796(2) Å; N(2)···O(3) = 2.822(2) Å] exist between the benzimidazole N–H groups and the deprotonated phenolate oxygen atom, furnishing a supramolecular dimer (Figure 2, a). However, the hydrogen-bonding interactions are more complicated in **2** owing to the existence of lattice water and ethanol molecules. The lattice water molecule forms two hydrogen bonds to two ethanol molecules [O(1w)···O(1) = 2.803(6) Å and O(1w)···O(2) = 2.944(6) Å], and accepts one hydrogen bond from a benzimidazole N–H group [N(1)···O(1w) = 2.855(6) Å] (Figure 3, a). Moreover, the ethanol molecule forms a hydrogen bond to the phenolate oxygen atom [O(1)···O(4) = 2.720(4) Å], and there are also intermolecular hydrogen-bonding interactions between the benzimidazole N–H groups and phenolate oxygen atoms [N(2)···O(6) = 2.791(4) Å; Figure 3, b].

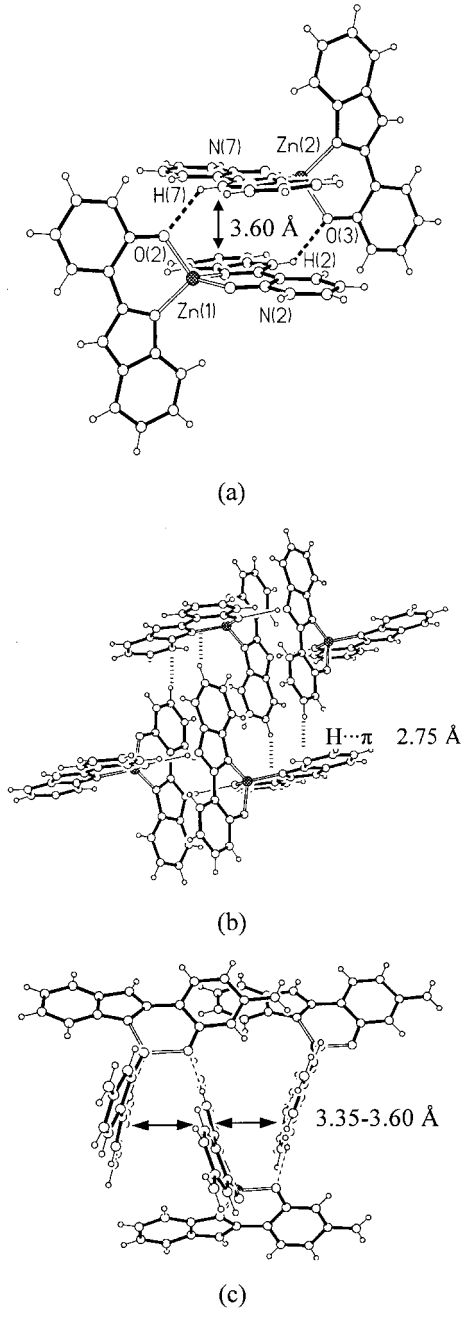

Figure 2. Perspective views of packing patterns in **1** (a, b) and **2** (c).

Neutral Hpbm and Hapbm were also crystallographically characterized. The dihedral angles (ca. 2.2° and 4.2°) between the phenolate and benzimidazole moieties for Hpbm and Hapbm indicate that both are basically coplanar. In the crystal structures of Hpbm and Hapbm, there is an intramolecular hydrogen bond between the phenolic and the imidazole groups [O(1)···N(1) = 2.554(2) Å for Hpbm and 2.563(2) Å for Hapbm] and intermolecular hydrogen bonds between the imidazole N–H groups and phenolic group oxygen atoms [N(2A)···O(1) = 2.821(3) for Hpbm and 2.826(2) Å for Hapbm] (Figure 4). These intermolecular hydrogen bonding and π–π interactions extend adja-

cent molecules into helical chains, where each pair of adjacent molecules exhibit offset π–π stacking interactions with face-to-face distances of around 3.43 Å in Hpbm and around 3.41 Å in Hapbm (Figure 5).

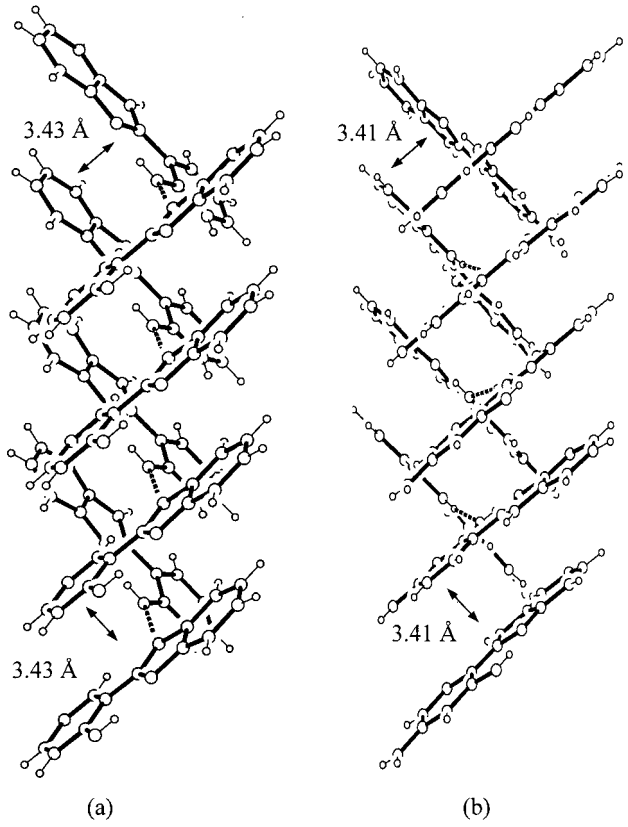

Figure 5. Perspective views of one-dimensional supramolecular arrays packed by hydrogen bonds and π–π stacking interactions in Hpbm (a) and Hapbm (b).

UV/Vis and Luminescent Spectra

The lowest-energy absorption bands of Hpbm and Hapbm in dichloromethane at 298 K occur at 323 and 325 nm, respectively, while those of their Zn^{II} complexes in dichloromethane are red-shifted slightly to 331 nm for **1** and 327 nm for **2,** with discernible shoulders at 343 and 340 nm, respectively (see Figure S2 in the Supporting Information).

The lowest-energy absorption maxima in UV spectra may correspond to S_0–S_n transitions with $n \geq 1$, as the S_0–S_1 transition may have a lower oscillator strength,[15–17] which are fully or partly transition-forbidden and too weak to be observed experimentally. According to our TDDFT calculations (Table 1), the lowest-energy absorption maxima (S_0–S_1 transition) are at 313 and 314 nm, with oscillator strengths of 0.44 and 0.78 for Hpbm and Hapbm, respectively. However, the lowest-energy absorption maximum for **1** should be attributed to the S_0–S_3 transition (wavelength: 364 nm; oscillator strength: 0.24), as the oscillator strength of the S_0–S_1 transition (wavelength: 370 nm) is only 0.04. Similarly, the lowest-energy absorption maximum for **2** can be attributed to the S_0–S_4 transition (wavelength: 344 nm; oscillator strength: 0.34), while its discernible shoulder is the S_0–S_1 transition (wavelength: 354 nm, oscillator strength: 0.16). The excited state–ground state (ES-GS) separations derived from the TDDFT calculations are in agreement with those observed experimentally.

For Hpbm and Hapbm, the S_0–S_1 transitions are mainly associated with transitions from the corresponding HOMOs to the LUMOs, as the coefficients in the configuration interaction wave functions are up to 0.63. As shown in Figure 6, the HOMOs are the π-bonding orbitals, while the LUMOs are the π*-antibonding orbitals, thus S_0–S_1 transitions can be assigned to be π→π* in nature.

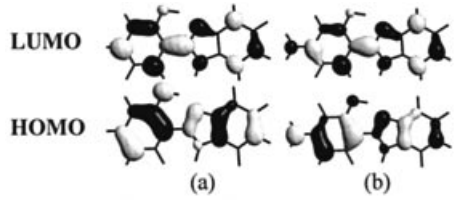

Figure 6. Contour plots of the relevant HOMOs and LUMOs of Hpbm (a) and Hapbm (b).

Similar to the corresponding ligands, the S_0–S_1 transitions of the Zn^{II} complexes are also mainly associated with transitions from the corresponding HOMOs to the LUMOs (Table S1 in the Supporting Information). As shown in Figure 7, the HOMOs are mainly the π-bonding orbitals of one deprotonated ligand, while the LUMOs are the π*-antibonding orbitals of another deprotonated ligand, thus the S_0–S_1 transitions can be assigned to be ligand-centered π→π* in nature (LCCT).

However, the S_0–S_3 transition (lowest-energy absorption maximum) of **1** is in fact mainly associated with the transitions from the corresponding HOMO–1 to LUMO and HOMO to LUMO+1, while the S_0–S_4 transition of **2** is mainly associated with the transitions from the corresponding HOMO–1 to LUMO+1 and HOMO to LUMO+1 (Table S1 in the Supporting Information), although such transitions are also assigned to be π→π* in nature.

Table 1. The calculated and experimental absorption wavelengths [nm] and their transition nature for **1**, **2**, Hpbm, and Hapbm, together with oscillator strengths.

	Transition nature	Wavelength			Oscillator strength
		Calcd.	Exp. in CH_2Cl_2	Exp. in solid	
Hpbm	π→π*	313	323	342	0.44
Hapbm	π→π*	314	325	348	0.78

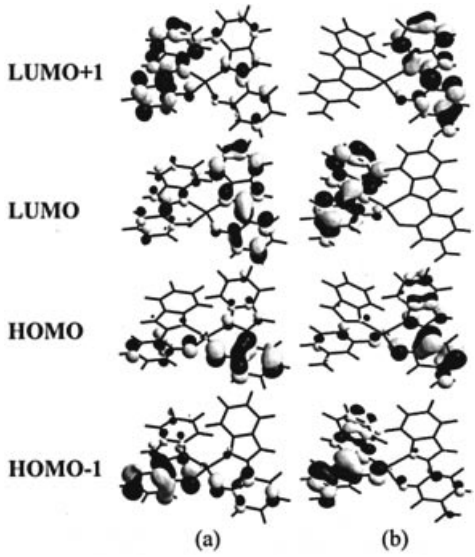

Figure 7. Contour plots of the relevant molecular orbitals (from HOMO–1 to LUMO+1) of **1** (a) and **2** (b).

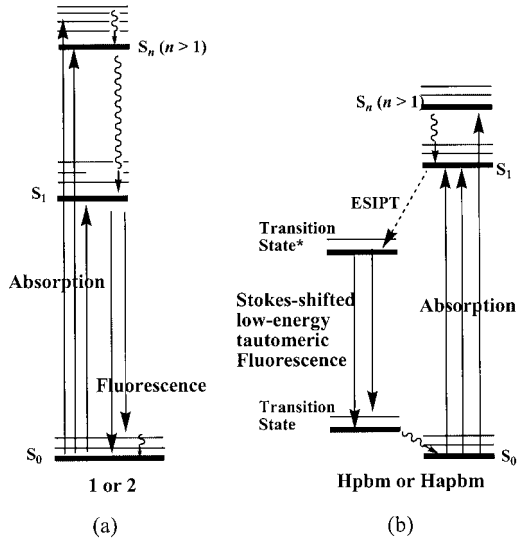

Scheme 2. The electronic transitions in the photoluminescent process of **1** or **2** (a) and Hpbm or Hapbm (b).

As has been noted,[11,18–20] the deprotonation and coordination of organic ligands to d^{10} metal ions can significantly reduce the energy gaps between the HOMOs and LUMOs. The TDDFT energy levels and experimental absorption spectra show that the S_0–S_1 energy separations of both Zn^{II} complexes become smaller than those of the corresponding ligands. According to the energy-gap law for radiationless deactivation,[17,21,22] the luminescence of the Zn^{II} complexes should be red-shifted compared with that of corresponding ligands. However, for the crystalline solid samples, Hpbm and Hapbm emit blue light with a maximum at 444 nm (λ_{ex} = 352 nm) and 426 nm (λ_{ex} = 365 nm) at 298 K, respectively, while **1** and **2** emit at 434 nm (λ_{ex} = 384 nm) and 419 nm (λ_{ex} = 379 nm), respectively (Figure 8). The violation of blue shifts can be ascribed to the excited state intramolecular proton transfer (ESIPT) of such organic compounds, which produces a strongly Stokes-shifted low-energy tautomeric fluorescence (Scheme 2).[12,23–25]

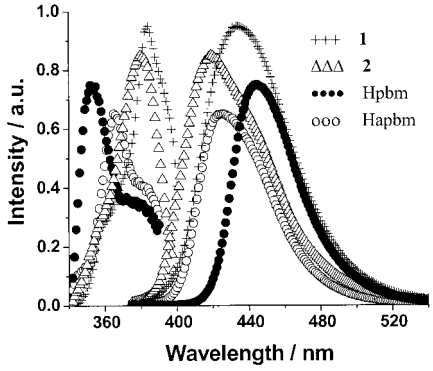

Figure 8. The excitation (left) and emission (right) spectra of **1**, **2**, Hpbm, and Hapbm in the solid state at 298 K. The corresponding excitation wavelengths, λ_{ex}, are 384, 379, 352, and 365 nm, respectively.

Moreover, the weakly electron-donating amino group can increase the electron density of the aromatic group and hence reduce the ES-GS separations slightly, consistent with the S_0–S_1 energy separations found in either the TDDFT energy levels or experimental absorption spectra of the planar Hpbm and Hapbm. On the other hand, in the absence of intramolecular hydrogen-bonding interactions (O–H···N), the 5-amino substitution may further twist the deprotonated ligand plane, as indicated by the experimental dihedral angle variation between the phenolate and benzimidazole rings of **2**, resulting in the reduction of the electron delocalization energy. Such a decrease of the delocalization energy is not favored for a π–π* transition as it may increase the energy separation. Compared with the weak electron-donating effect, the non-coplanar effect may be much stronger in **2**. In the current case, this hypothesis can be verified theoretically, as the higher ES-GS separations of **2** can be found in the TDDFT energy levels. Thus, compared to that of **1**, a significant blue shift (up to 15 nm) is observed in the luminescence of **2**. Similarly, compared to that of Hpbm, the higher emission energy of Hapbm in the non-coplanar ESIPT state is expected, although its S_0–S_1 energy separation is slightly reduced.

To the best of our knowledge, Zn^{II} complexes with aromatic heterocyclic ligands usually exhibit an emission transition that is an intraligand charge-transfer (ILCT). This is in good agreement with the assignment of the π→π* nature of the S_0–S_1 transitions for **1** and **2**. Similar to those of common Zn^{II} complexes,[18,19] the lifetimes of solid **1** and **2** are around 1.90(2) and 1.21(1) ns at room temperature.

Conclusions

Two neutral, mononuclear Zn^{II} complexes and their ligands have been prepared as possible candidates for blue-light-emitting EL materials. Systematic investigations of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

electronic transitions in the photoluminescent process of all compounds have been carried out based on the X-ray structural information, as well as the TDDFT energy level and molecular orbitals analyses, and these show that their absorption and luminescent properties are ligand-based. The photophysical studies further explain the spectral variation along with the effect of complexation with Zn^{II} cations and/or amino substitution.

Experimental Section

General Remarks: All the reagents and solvents employed are commercially available and were used as received without further purification. The C, H, and N microanalyses were carried out with an Elementar Vario El elemental analyzer. ^{1}H NMR spectra were recorded with a Varian INOVA500NB spectrometer. FTIR spectra were recorded with a Bruker Vector22 spectrometer in KBr pellets in the range 4000–400 cm^{-1}. The UV/Vis spectra were recorded with a Varian Cary-100 spectrometer. The steady-state fluorescent and fluorescence lifetimes were determined with an Edinburgh Instrument FLS920 fluorescence spectrophotometer. Thermogravimetric data (TG and DTG) were collected with a Perkin–Elmer TGS-2 analyser in flowing dinitrogen atmosphere at a heating rate of 10 °C min^{-1} by heating the microcrystals.

Synthesis of Hpbm and Hapbm: They were synthesized following methods similar to those reported in the literature.[26] Salicylic acid (0.138 g, 1 mmol) and *o*-phenylenediamine (0.108 g, 1 mmol) were mixed and stirred in syrupy phosphoric acid (3 mL) at a temperature of ca. 520 K for 5 h to give white analytically pure Hpbm after recrystallization of the crude product (ca. 10% yield). X-ray quality crystals were grown by slow evaporation of a solution in $CHCl_3$ for about one week. $C_{13}H_{10}N_2O$ (210.2): calcd. C 74.27, H 4.79, N 13.33; found C 74.02, H 4.81, N 13.49. ^{1}H NMR (500 MHz, [D_6]-DMSO): δ = 13.13 (s, 1 H), 13.12 (s, 1 H), 8.04 (dd, J = 1.50, 8.00 Hz, 1 H), 7.71 (d, J = 8.00 Hz, 1 H), 7.60 (d, J = 7.50 Hz, 1 H), 7.38 (m, 1 H), 7.28 (m, 2 H), 7.03 (m, 2 H) ppm. FTIR (KBr): $\tilde{\nu}$ = 3326 (vs), 1585 (s), 1492 (s), 1417 (s), 1320 (m), 1282 (m), 1262 (s), 1133 (m), 1037 (w), 911 (w), 840 (w), 798 (w), 727 (s), 591 (w), 522 (w), 464 (w) cm^{-1}.

Hapbm was similarly synthesized by reaction of *o*-phenylenediamine (0.108 g, 1 mmol) with 4-aminosalicylic acid (0.153 g, 1 mmol). X-ray quality crystals were grown by very slow evaporation of a solution of DMF over about one month. The yield was ca. 10%. $C_{13}H_{11}N_3O$ (225.2): calcd. C 69.32, H 4.92, N 18.66; found C 69.07, H 4.81, N 18.72. ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 12.96 (s, 1 H), 12.68 (s, 1 H), 7.65 (d, J = 8.10 Hz, 1 H), 7.51 (s, 2 H), 7.17 (dd, J = 3.00, 7.16 Hz, 2 H Hz,), 6.21 (dd, J = 2.10, 8.40 Hz, 1 H), 6.14 (d, J = 1.50 Hz, 1 H), 5.68 (s, 2 H) ppm. FTIR (KBr): $\tilde{\nu}$ = 3471 (m), 3381 (s), 3221 (s), 1631 (s), 1589 (s), 1553 (m), 1424 (s), 1363 (m), 1268 (s), 1198 (m), 1153 (m), 961 (w), 806 (m), 737 (s), 681 (w), 538 (w), 522 (w) cm^{-1}.

Synthesis of [Zn(pbm)$_2$] (1): A mixture of zinc acetate dihydrate (0.110 g, 0.5 mmol), Hpbm (0.210 g, 1.0 mmol), and water (10 mL) was heated in a 23-mL, Teflon-lined stainless-steel container at 110 °C for 4 d. After cooling to room temperature at a rate of 5 K per hour, the colorless crystals of **1** were isolated (yield ca. 0.17 g, 70%). $C_{26}H_{18}N_4O_2Zn$ (483.8): calcd. C 64.54, H 3.75, N 11.58; found C 64.32, H 3.84, N 11.72. ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 13.34 (s, 2 H), 7.98 (d, J = 7.00 Hz, 2 H), 7.58 (d, J = 8.00 Hz, 2 H), 7.25 (d, J = 8.00 Hz, 4 H), 7.05 (q, J = 7.00 Hz, 4 H), 6.80 (d, J = 7.50 Hz, 2 H), 6.68 (t, J = 7.00 Hz, 2 H) ppm. FTIR (KBr): $\tilde{\nu}$ = 3428 (m), 1798 (w), 1567 (s), 1478 (m), 1444 (m), 1407 (m), 1311 (w), 1251 (w), 1140 (w), 876 (w), 738 (w), 654 (w) cm^{-1}.

Synthesis of $[Zn(apbm)_2]\cdot C_2H_5OH\cdot H_2O$ (2): A filtered solution of Hapbm (0.45 g, 2 mmol) and potassium hydroxide (0.112 g, 2 mmol) in ethanol (80 mL) was added to a solution of zinc acetate dihydrate (0.22 g, 1 mmol) in ethanol (40 mL) at a temperature of 60 °C. The mixture was kept for 4 h at this temperature, and allowed to stand overnight at room temperature. The white precipitate was filtered, washed with ethanol, and dried under reduced atmosphere over silica gel at room temperature for 3 h to give **2** as pale-yellow microcrystals. X-ray quality crystals were obtained by very slow evaporation of a solution in ethanol over about 60 days (ca. 0.29 g, 50% yield based on Zn). $C_{28}H_{28}N_6O_4Zn$ (579.0): calcd. C 58.19, H 4.88, N 14.54; found C 58.33, H 4.58, N 14.42. ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 7.62 (d, J = 8.70 Hz, 2 H), 7.42 (d, J = 7.50 Hz, 2 H), 7.11 (t, J = 7.50 Hz, 2 H), 6.96 (t, J = 7.80 Hz, 2 H), 6.86 (d, J = 7.80 Hz, 2 H), 6.01 (dd, J = 2.10, 8.70 Hz, 2 H), 5.91 (d, J = 2.10 Hz, 2 H), 5.39 (s, 4 H). FTIR (KBr): $\tilde{\nu}$ = 3375 (s), 3334 (s), 3211 (m), 1624 (s), 1534 (s), 1478 (s), 1463 (s), 1447 (s), 1396 (w), 1348 (w), 1327 (w), 1296 (w), 1253 (m), 1213 (m), 1157 (m), 980 (w), 848 (w), 811 (w), 751 (m), 602 (w), 539 (w), 508 (w) cm^{-1}.

X-ray Crystallographic Study: Diffraction intensities for **1** and **2**, as well as Hpbm and Hapbm, were collected at 293 K on a Bruker Smart Apex CCD diffractometer (Mo-K_α radiation; λ = 0.71073 Å). Absorption corrections were applied with SADABS.[27] The structures were solved by direct methods and refined with full-matrix least-squares using the SHELXTL program package.[28] The organic hydrogen atoms were generated in ideal positions. Anisotropic thermal parameters were applied to all non-hydrogen atoms. Experimental details of the X-ray analyses are provided in Table 2, with selected bond lengths and angles listed in Table 3.
CCDC-258466 to -258468 (for **1**, **2**, and Hapbm, respectively) and -240084 (Hpbm) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Calculation Details: Based on the optimized geometries (selected optimized bond lengths and bond angles are listed in Table S2 in the Supporting Information), time-dependent density functional (TDDFT) calculations were performed at the B3LYP level with a 6-31G** basis set for C, H, N, and O atoms, and effective core potentials basis set LanL2DZ for Zn atoms, employing the Gaussian03 suite of programs.[29] The electron density diagrams of molecular orbitals were obtained with the Gaussview graphics program.

The Si–Ph bond of $PhSi[(CH_2)_3SiMe_2Bz]_3$ (**5**) is cleaved with triflic acid to give $TfOSi[(CH_2)_3SiMe_2Bz]_3$, which, in turn, reacts with triethylammonium chloride or potassium cyclopentadienide to give, respectively, $ClSi[(CH_2)_3SiMe_2Bz]_3$ (**8**) and $(C_5H_5)Si[(CH_2)_3SiMe_2Bz]_3$ (**10**). This strategy can be applied to the post-growth incorporation of nucleophiles to the focal point of carbosilane dendritic wedges. In this way, cyclopentadiene-functionalized dendritic wedges of second and third generation C_5H_5-G*n*-$[(CH_2)_3SiMe_2Bz]_x$ (*n* = 2, *x* = 9, **11**; *n* = 3, *x* = 27, **12**) have been obtained starting from Ph-G*n*-$[(CH_2)_3SiMe_2Bz]_x$ (**6**, **7**). The metallocenes $[\{(BzMe_2SiCH_2CH_2CH_2)_3SiC_5H_4\}_2MCl_2]$ (M = Ti, **14**; Zr, **15**) have also been obtained from **10** and their catalytic behavior in ethylene and propylene polymerization, using MAO as a cocatalyst, has been studied and compared to that of related non-dendritic complexes.

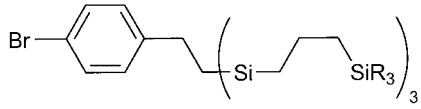
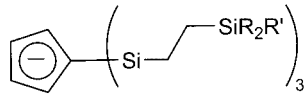
Introduction

The large number of dendrimers synthesized nowadays from a diversity of cores, repetitive units, and peripheral groups allows the design of macromolecules with tailored properties through the incorporation of suitable functions at the appropriate site of the dendritic molecule (i.e. core, framework, or periphery).[1] Transition metal catalysts are a good example of the relevance of the location of the functional group in the dendritic structure because of the different accessibility of the metal center to the substrate in core- and periphery-functionalized dendrimers.[2,3] In the vast majority of metal-functionalized carbosilane dendrimers the metal complexes reside in the periphery.[4] Some of the exceptions are represented by the metal complexes that van Leeuwen and al. have synthesized from phosphane ligands [triphenylphosphane, bis(diphenylphosphanyl)ferrocene (dppf), bis(diphenylphosphanyl)xanthene (xantphos), or *o*-(diphenylphosphanyl)phenol] located in the core of carbosilane dendrimers.[5] All these phosphanes have been obtained from a family of dendritic wedges whose first generation, **A**, is represented in Scheme 1 and which are grown from *p*-bromostyrene by the usual divergent methodology that alternates hydrosilylation and alkylation steps using $HSiCl_3$ and allylmagnesium bromide, respectively.[6] In the aforementioned dendritic phosphanes, prepared from the lithium derivative of **A**, a styrene spacer separates the phosphorus and the core silicon atoms.



A, R = allyl, Me



B, R = R' = Et; R = Ph, R' = Me

Scheme 1.

We have previously reported the synthesis of group 4 metallocenes derived from the first-generation dendron **B** that possesses a cyclopentadienide anion (Cp^-) directly linked to its focal point.[7] In contrast to the aryl bromide in **A**, the Cp group is not compatible with the hydrosilylation and alkylation steps and cannot be incorporated before the growth of the dendrimer. Here we describe a strategy for the post-synthetic modification of the focal point of a carbosilane dendritic wedge.

Results and Discussion

Fréchet introduced the term "dendritic wedge" in the description of the convergent strategy for the growth of dendrimers.[8] In this strategy, the dendrimer is assembled from the periphery and each successive generation is synthesized from a single reactive group located at the focal point of a dendritic wedge. The final reaction involves the attachment of the dendritic wedges to a core molecule. For this reason,

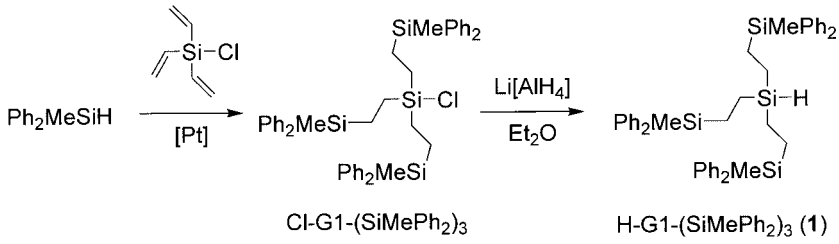
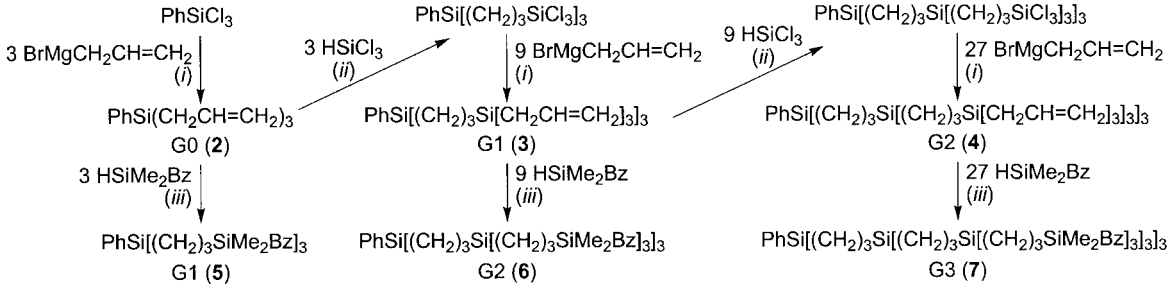


Scheme 2.

the convergent approach has been largely applied to the synthesis of core- or focal-point functionalized dendrimers. Carbosilane dendrimers are, in general, synthesized divergently by a repetitive sequence of hydrosilylation and alkylation steps.[6,9] The sequence of reactions depicted in Scheme 2 illustrates a possible route for the convergent preparation of carbosilane dendrimers in which the Si–Cl bond is reduced to Si–H instead of being alkylated as in a divergent synthesis. Thus, the carbosilane Cl-G1-$[(CH_2)_3SiMePh_2]_3$ was prepared by hydrosilylation of chlorotrivinylsilane with methyldiphenylsilane,[7] and reacted with lithium tetrahydridoaluminate to give H-G1-$[(CH_2)_3SiMePh_2]_3$ (**1**), the first-generation analog of the starting methyldiphenylsilane, quantitatively. The presence of a Si–H bond in **1** was confirmed by the septuplet observed in the ^1H NMR spectrum at $\delta = 3.64$ ppm ($^3J_{H,H} = 2.9$ Hz). Unfortunately, hydrosilylation of chlorotrivinylsilane with **1** always gave mixtures of the second-generation wedge Cl-G2-$[(CH_2)_3SiMePh_2]_3$ with partially hydrosilylated compounds, in spite of the variety of solvents, temperatures, and Pt catalysts (Speier, Karstedt, and Pt/C) tested. This result was not completely unexpected because it is known that both bulky and electron-donating substituents decrease the reactivity of silanes in the platinum-catalyzed hydrosilylation of olefins.[10] Both characteristics are combined in the silane **1** and in its progressively bulkier higher-generation analogs H-G*n*-$[(CH_2)_3SiMePh_2]_3$, which are required for this convergent strategy, in contrast to the divergent growth that uses activated silanes with electron-withdrawing chloro substituents.

The desired focal-point functionalization can also be achieved by an approach in which a protecting group is linked to the core before the dendrimer growth and eliminated at the end of the growing process. In the case of a carbosilane dendrimer, the phenyl group fulfills the main requirements of a silicon-core protector: it is inert towards hydrosilylation and alkylation, but forms bonds with silicon that can undergo protolysis to give a by-product that is easily separable from the dendrimer. Thus, G0, G1, and G2 compounds Ph-G*n*-$(CH_2CHCH_2)_x$ (**2**–**4**, respectively) with 3, 9, and 27 allyl end-groups, respectively, were synthesized from $PhSiCl_3$ by successive allylation and hydrosilylation steps (Scheme 3).[11] The ^1H NMR olefinic resonances at around $\delta = 4.8$ and 5.7 ppm were used to follow the progress of the critical hydrosilylation steps in order to determine their completion and, therefore, the absence of defects in the branches of the final products. The growth was terminated at the desired generation by using benzyldimethylsilane instead of trichlorosilane as the hydrosilylating agent to give Ph-G*n*-$[(CH_2)_3SiMe_2Bz]_x$ (Bz = $CH_2C_6H_5$, **5**–**7**). The reaction of allyl-terminated dendrimers with trichlorosilane in the presence of H_2PtCl_6 as a catalyst occurred smoothly at room temperature, whereas the reaction mixture had to be gently heated for the activation of the trialkylsilane $HSiMe_2Bz$ (^1H NMR monitoring). Dendrimers **5**–**7** were obtained as colorless oils after removal of the volatiles in vacuo and were purified by chromatography on a silica-gel column prior to subsequent use. After isolation, the yields ranged from 93 to 96% for allyl-terminated dendrimers **2**–**4** (for **3** and **4** the values correspond to overall yields from the allyl dendrimer of the previous generation) and 82–83% for **5**–**7**.

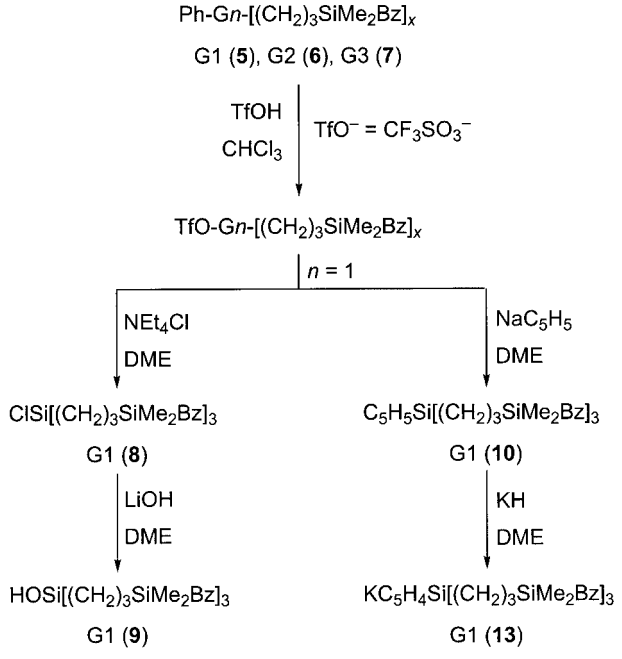
Acid-induced cleavage of the Ph–Si bond was attempted with boron trichloride in hexane,[12] HCl and catalytic amounts of aluminum trichloride in diethyl ether,[13] or triflic acid (trifluoromethanesulfonic acid, TfOH) in chloro-



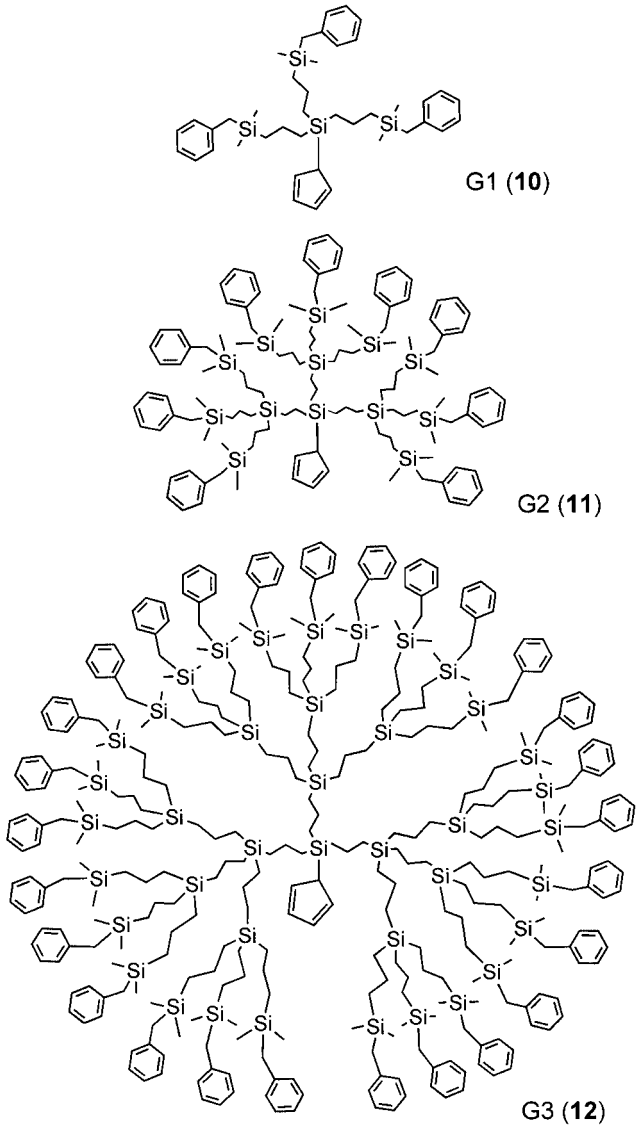
Scheme 3. Synthesis of carbosilane dendritic wedges **2**–**7** with a phenyl group attached to their focal point. Conditions: (*i*) diethyl ether, room temperature, overnight; (*ii*) solvent-free reaction, H_2PtCl_6 in 2-propanol, room temperature, 4 h; (*iii*) solvent-free reaction, H_2PtCl_6 in 2-propanol; see Exp. Sect. for details.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

form.[14] Boron trichloride failed to react with both allyl- and benzyldimethylsilyl-terminated compounds **2** and **5** at room temperature, and protic acids such as HCl or TfOH reacted at the same time with the terminal allyl groups of dendrimers Ph-G*n*-$(CH_2CH{=}CH_2)_x$ (**2**–**4**).[15] Cleavage of the Si–Ph bond with HCl was slow in diethyl ether at room temperature (^{1}H NMR evidence), whereas the Si–Ph bond of dendrimers Ph-G*n*-$[(CH_2)_3SiMe_2Bz]_x$ (**5**–**7**) was cleanly and readily cleaved with triflic acid at 0 °C in chloroform (Scheme 4), with the advantage that the triflate anion TfO^- is a good leaving-group in silyl triflates, undergoing exchange with a wide range of nucleophiles.[16] For the reactions described below, compounds TfO-G*n*-$[(CH_2)_3SiMe_2Bz]_x$ were used without isolation. As shown in Scheme 4, the reaction of $TfOSi[(CH_2)_3SiMe_2Bz]_3$ with triethylammonium chloride in dimethoxyethane (DME) gave $ClSi[(CH_2)_3SiMe_2Bz]_3$ (**8**). Other nucleophiles can be introduced at the focal-point position either from the chlorosilane or directly from the silyl triflate, as exemplified by the preparation of the silanol $HOSi[(CH_2)_3SiMe_2Bz]_3$ (**9**) or the cyclopentadiene $(C_5H_5)Si[(CH_2)_3SiMe_2Bz]_3$ (**10**). The ^{1}H NMR spectrum of **10** shows, at room temperature, broadened temperature-dependent resonances for both types of cyclopentadiene protons, those bonded to sp^2 (δ = 6.4–6.7 ppm) and those bonded to sp^3 carbons (δ = 2.9–3.5 ppm). The related trimethylsilylcyclopentadiene ($C_5H_5SiMe_3$), which is present as a mixture of the three possible isomers, also shows broadened temperature-dependent ^{1}H resonances, which are ascribed to the interconversion of ring protons and isomers by sigmatropic $SiMe_3$ and proton shifts.[17] The ^{1}H NMR behavior of **10** is clearly similar to that of $C_5H_5SiMe_3$, especially in the distribution and temperature dependence of the C(sp^3)–H resonances. Thus, the major isomer of **10** (ca. 70–75%) corresponds to the cyclopentadiene with a C(sp^3)–Si bond (Scheme 5) and gives a broad resonance at δ = 3.4 ppm, whereas the minor isomers show resonances at around δ = 3.0 ppm which are sharper at room temperature. The usefulness of the described methodology for the synthesis of higher-generation dendritic wedges has been demonstrated by the synthesis of the G2 and G3 cyclopentadienes **11** and **12** (Scheme 5). They were obtained as yellow oils in the same conditions described above for **10**, starting from the corresponding triflate TfO-G*n*-$[(CH_2)_3SiMe_2Bz]_x$. The ^{1}H NMR resonances in the cyclopentadiene sp^3 region are similar to those described above for **10**, although they are accompanied by the general broadening of resonances that the restricted mobility of protons causes in higher generations.



Scheme 4.



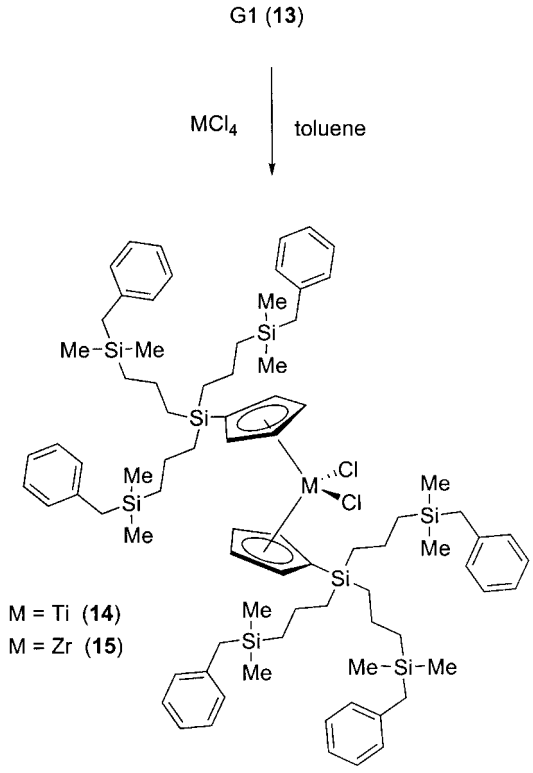
Scheme 5. Cyclopentadienes with carbosilane dendritic wedges of first (**10**), second (**11**), and third generation (**12**). Only the major isomers are represented.

Dendrimers **2**–**12** were characterized by elemental analysis and ^{1}H, ^{13}C{^{1}H}, and ^{29}Si{^{1}H} NMR spectroscopy. Three groups of methylene resonances are observed for the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$SiCH_2CH_2CH_2Si$ repeating unit in phenyl-protected dendrimers **5**–**7**, at $\delta \approx 0.8$ ppm for the methylene bonded to the core silicon, $\delta = 1.2$–1.3 ppm for the middle CH_2 groups, and $\delta \approx 0.5$ ppm for the rest. Only the core $SiCH_2$ resonance is affected by the modification of the focal-point group, and is progressively shifted to high field when Ph is replaced by Cl, OH, and C_5H_5. In the $^{29}Si\{^1H\}$ NMR spectra, a singlet is observed for every type of silicon atom present in the corresponding molecule. Mass spectra were obtained by ESI or APCI techniques for all the first-generation post-functionalized dendrimers **8**–**10**. Attempts to record MALDI-TOF mass spectra of second- and third-generation cyclopentadiene dendrimers **11** and **12** failed. The purity of phenyl-protected dendrimers **5**–**7**, as well as that of the post-modified cyclopentadienes **10**–**12**, was routinely checked by GPC chromatography in THF. Every chromatogram showed a unique peak with typical polydispersity values of about 1.02–1.03, according to the monodisperse nature of these molecules. As expected, the elution time of the dendrimers increases with the molecular weight. The molecular weights obtained after calibration with a standard of polystyrene were not in good agreement with the theoretical values because of the globular nature of dendrimers. However, a good linear relationship was shown between the logarithm of the theoretical molecular weights and the elution times on GPC traces ($R_2 = 0.984$).[18]

The first-generation cyclopentadienide **13** was synthesized as a potassium salt by reaction of **10** with KH in DME. Dendritic metallocenes **14** (Ti) and **15** (Zr) were subsequently obtained by reaction of two equivalents of cyclopentadienide **13** with $TiCl_4$ or $ZrCl_4$·2THF in toluene (Scheme 6). These products were isolated as red (Ti) or colorless (Zr) oils that were rather stable upon exposure to air. Upon activation with an excess of methylaluminoxane (MAO), complexes **14** and **15** catalyze the polymerization of ethylene. The results are summarized in Table 1 and compared with those of simple metallocenes $[(C_5H_5)_2MCl_2]$ (M = Ti, Zr) obtained under the same conditions. The activity is lowered by one order by the dendritic substituents in the titanocene catalyst, but noticeably there is no such decrease in the zirconocene case. We have previously reported a similar result with vinyl-type carbosilanes $[\{(Ph_2MeSiCH_2CH_2)_3SiC_5H_4\}_2MCl_2]$ (M = Ti, Zr), although in this example a small but significant decrease of 30% was observed for the zirconocene compound.[7] These results can be interpreted in steric terms by taking into account the bigger size of the zirconium atom, and the larger hindrance of vinyl-type carbosilanes when compared with the allyl type reported here. In polymerization of propylene (Table 1), the zirconium complex **15** displays a similar activity to that observed for $[(C_5H_5)_2ZrCl_2]$. Some degree of stereocontrol in the polymerization of α-olefins with metallocenes is, in principle, possible by restricting the rotation of the Cp ligand, for example by means of sterically demanding substituents.[19] The polypropylene obtained with **15**, at both 20 °C and –30 °C, shows the distribution of ^{13}C NMR resonances of a mainly atactic polymer,[20] similar to that obtained with $[(C_5H_5)_2ZrCl_2]$.



Scheme 6.

In view of these results, we tried the preparation of the second- and third-generation analogs of metallocenes **14** and **15**. Somewhat surprisingly, no reaction was observed between **11** or **12** and KH under the same conditions used for **10**. When *n*-buyllithium was employed instead as a deprotonating agent, the ^1H NMR spectra in C_6D_6 showed the disappearance of the resonances due to the $C(sp^3)$ protons, as expected for the formation of the lithium cyclopentadienides. However, the formation of either mono- or biscyclopentadienyl complexes was never observed when these

Table 1. Ethylene and propylene polymerization results with complexes **14** and **15**.[a]

Precatalyst	Ethylene Yield [g]	Activity [kg_{PE}/mol_M h]	Propylene Yield [g]	Activity [kg_{PP}/mol_M h]

solutions were reacted with $TiCl_4$ or $ZrCl_4$ in the usual solvents (toluene or THF for zirconium), with reaction times of up to two days and temperatures up to 50 °C. The reason for this failure − steric hindrance or inappropriate reaction conditions − is not clear to us at this stage.

Conclusions

The post-synthetic modification of the focal point of a dendrimer is useful for the chemistry of dendrimers and hyperbranched polymers because it permits the incorporation of more-reactive cores.[21] In this paper, we have demonstrated a methodology for such a modification of carbosilane dendrimers that is based on the protolysis of Si–Ph bonds with triflic acid and allows the linking of functional nucleophiles to the focal point of carbosilane wedges. In this way, we have synthesized dendritic cyclopentadienes up to the third generation. We are currently exploring the utility of this strategy for the modification of a variety of ligands.

Experimental Section

Reagents and General Techniques: All operations were performed under argon by using Schlenk or dry-box techniques. Solvents were dried and distilled under argon as described elsewhere.[22] Unless otherwise stated, reagents were obtained from commercial sources and used as received. $Na(C_5H_5)$ was prepared from freshly distilled cyclopentadiene and NaH in THF. $HSiMe_2Bz$ was synthesized from $HSiMe_2Cl$ and BzMgCl in diethyl ether. $ClSi(CH_2CH_2SiMePh_2)_3$ was prepared as previously reported.[7] ^1H, ^{13}C, and ^{29}Si NMR spectra were recorded on Varian Unity 300 or 500 Plus spectrometers. Chemical shifts (δ, ppm) are relative to $SiMe_4$, and were measured by internal referencing to the deuterated solvent (^{13}C and residual ^1H resonances), or by the substitution method (^{29}Si). Coupling constants (J) are given in hertz. The Analytical Services of the Universidad de Alcalá performed the C, and H analyses with a Heraeus CHN–O-Rapid microanalyzer, and the mass spectra with an Automass Multi, ThermoQuest. GPC analyses were carried out with a Varian Inert 9012 and 9065 Polychrom chromatograph, and Polymer Laboratories PL-ELS 1000 Light Scattering detector, using Polymer Laboratories Plgel columns and tetrahydrofuran (THF) as the eluent.

Synthesis of $HSi(CH_2CH_2SiMePh_2)_3$ (1): A solution of $ClSi(CH_2CH_2SiMePh_2)_3$ (1.00 g, 1.35 mmol) in 10 mL of diethyl ether was added to a mixture of lithium aluminum hydride (25 mg, 0.67 mmol) in diethyl ether (25 mL). After stirring the mixture for 6 h at room temperature, the excess of lithium aluminum hydride was hydrolyzed with a 5% solution of HCl in water, and the ethereal and aqueous phases were separated. The aqueous phase was extracted with diethyl ether (2×10 mL) and the ethereal fractions were collected and dried with anhydrous $MgSO_4$. Then, the solvent was removed in vacuo and the residue characterized as $HSi(CH_2CH_2SiMePh_2)_3$ (0.85 g, 89%) as a colorless oil. $C_{45}H_{52}Si_4$ (705.24): calcd. C 76.64, H 7.43; found C 76.31, H 7.39. ^1H NMR ($CDCl_3$): δ = 7.45 (m, 12 H, Ph), 7.32 (m, 18 H, Ph), 3.64 (sept, $^3J_{H,H}$ = 2.9, 1 H, Si*H*), 1.50 (s, 9 H, Me), 0.88 (m, 6 H, $HSiCH_2$), and 0.54 (m, 6 H, $CH_2SiMePh_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 137.1 (*ipso-Ph*), 134.5 (*meta-Ph*), 129.1 (*para-Ph*), 127.8 (*ortho-Ph*), 7.3 and 2.5 [$Si(CH_2)_2Si$], –5.1 (Me) ppm.

Synthesis of Ph-G*n*-(allyl)$_x$ (2–4): These compounds have been reported previously but complete preparative details were not given.[11] Here, the preparation of Ph-G2-$(allyl)_{27}$ (**4**) is described as representative. Ph-G1-$(allyl)_9$ (**3**; 3.7 g, 5.4 mmol) was added to an excess of trichlorosilane (10 mL, 99 mmol) in the presence of a 2×10^{-3} M solution of H_2PtCl_6 in 2-propanol (0.080 mL, 0.16 μmol) as catalyst. The solution was stirred for 4 h at room temperature and, after verification of the complete hydrosilylation of **3** by ^1H NMR spectroscopy, the excess of silane and other volatiles were removed under vacuum. Subsequently, the crude product was dissolved in diethyl ether (25 mL) and added dropwise (30 min) to an ice-cooled solution of allylmagnesium bromide (180 mmol) in diethyl ether (300 mL). When the addition was finished, the reaction mixture was allowed to warm to room temperature and the stirring was continued overnight. The excess of allylmagnesium bromide was then hydrolyzed with a concentrated aqueous solution of NH_4Cl (100 mL). The organic phase was separated by decantation and the aqueous solution was extracted again with diethyl ether (2×100 mL). The combined organic phase were dried with anhydrous $MgSO_4$, filtered, and the solvents evaporated in vacuo to yield **4** (10.7 g, 96%) as a colorless liquid that was pure by ^1H NMR spectroscopy.

Ph-G0-$(allyl)_3$ (**2**; 13.0 g, 96%) was obtained from $PhSiCl_3$ (9.5 mL, 59 mmol) and allylmagnesium bromide (200 mmol). Ph-G1-$(allyl)_9$ (**3**; 11.4 g, 93%) was obtained from Ph-G0-$(allyl)_3$ (**2**; 4.10 g, 18.0 mmol), trichlorosilane (10 mL, 99 mmol), and allylmagnesium bromide (190 mmol).

Ph-G0-$(allyl)_3$ (2): $C_{15}H_{20}Si$ (228.40): calcd. C 78.88, H 8.83; found C 78.80, H 8.81. ^1H NMR ($CDCl_3$): δ = 7.52 (m, 2 H, Ph), 7.36 (m, 3 H, Ph), 5.80 (m, 3 H, CH_2CH=CH_2), 4.89 (m, 6 H, CH_2CH=CH_2) 1.86 (m, 6 H, CH_2CH=CH_2) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 135.2 (*ipso*-Ph), 134.2 (CH_2CH=CH_2), 133.8 (*ortho*-Ph), 129.3 (*para*-Ph), 127.7 (*meta*-Ph), 114.3 (CH_2CH=CH_2), 19.5 (CH_2CH=CH_2) ppm. $^{29}Si\{^1H\}$ NMR ($CDCl_3$): δ = –7.90 ppm.

Ph-G1-$(allyl)_9$ (3): $C_{42}H_{68}Si_4$ (685.33): calcd. C 73.61, H 10.00; found C 73.57, H 9.98. ^1H NMR ($CDCl_3$): δ = 7.44 (m, 2 H, Ph), 7.34, (m, 3 H, Ph), 5.74 (m, 9 H, CH_2CH=CH_2), 4.84 (m, 18 H, CH_2CH=CH_2), 1.54 (m, 18 H, CH_2CH=CH_2), 1.37 (m, 6 H, $SiCH_2CH_2CH_2Si$), 0.84 (m, 6 H, $PhSiCH_2CH_2CH_2$), 0.66 (m, 6 H, $PhSiCH_2CH_2CH_2Si$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 137.2 (*ipso*-Ph), 134.1 (CH_2CH=CH_2), 133.7 (*ortho*-Ph), 128.6 (*para*-Ph), 127.4 (*meta*-Ph), 113.3 (CH_2CH=CH_2), 19.9 (CH_2CH=CH_2), 18.4, 17.6, and 16.7 [$Si(CH_2)_3Si$] ppm. $^{29}Si\{^1H\}$ NMR ($CDCl_3$): δ = –1.14 (3 Si), –4.01 (1 Si) ppm.

Ph-G2-$(allyl)_{27}$ (4): $C_{123}H_{212}Si_{13}$ (2056.1): calcd. C 71.85, H 10.39; found C 71.81, H 10.36. ^1H NMR ($CDCl_3$): δ = 7.42 (m, 2 H, Ph), 7.30 (m, 3 H, Ph), 5.74 (m, 27 H, CH_2CH=CH_2), 4.85 (m, 54 H, CH_2CH=CH_2), 1.55 (m, 54 H, CH_2CH=CH_2), 1.28 (m, 24 H, $SiCH_2CH_2CH_2Si$), 0.84 (m, 6 H, $PhSiCH_2CH_2CH_2$), 0.54 (m, 42 H, $PhSiCH_2CH_2CH_2Si$ and $SiCH_2CH_2CH_2Si$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 137.5 (*ipso*-Ph), 134.3 (CH_2CH=CH_2), 133.9 (*ortho*-Ph), 128.6 (*para*-Ph), 127.6 (*meta*-Ph), 113.4 (CH_2CH=CH_2), 19.8 (CH_2CH=CH_2), 18.6, 18.2, and 16.5 [G1-$Si(CH_2)_3Si$], 18.3, 17.6, and 16.7 [G2-$Si(CH_2)_3Si$] ppm. $^{29}Si\{^1H\}$ NMR ($CDCl_3$): δ = –4.21 (1 Si), 0.42 (3 Si), –1.02 (9 Si) ppm.

Synthesis of Ph-G*n*-[$(CH_2)_3SiMe_2Bz$]$_x$ (5–7): The preparation of Ph-G3-$[(CH_2)_3SiMe_2Bz]_{27}$ (**7**) is given as representative. An excess of benzyldimethylsilane (9.3 mL, 59 mmol) and a 2×10^{-3} M solution of H_2PtCl_6 in 2-propanol (0.080 mL, 0.16 μmol) were added to **4** (4.00 g, 1.95 mmol). The mixture was gently heated until reaction started (the solution became more viscous and turned slightly yellow) and then allowed to recover room temperature. The volatiles

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were evaporated under vacuum at room temperature and the residue was purified by flash chromatography on a silica gel column with hexane as eluent. Dendrimer **7** (9.86 g, 83%) was obtained as a colorless liquid.

Ph-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (**5**; 4.89 g, 82%) was obtained from benzyldimethylsilane (5.0 mL, 31.6 mmol) and **2** (2.00 g, 8.76 mmol); Ph-G2-[$(CH_2)_3SiMe_2Bz$]$_9$ (**6**; 7.68 g, 83%) was obtained from benzyldimethylsilane (7,0 mL, 44.2 mmol) and **3** (3.10 g, 4.53 mmol).

Ph-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (5): $C_{42}H_{62}Si_4$ (679.28): calcd. C 74.26, H 9.20; found C 74.21, H 9.19. ^{1}H NMR ($CDCl_3$): δ = 7.44 (m, 2 H, SiPh), 7.35 (m, 3 H, SiPh), 7.18 (m, 6 H, CH_2Ph), 7.05 (m, 3 H, CH_2Ph), 6.95 (m, 6 H, CH_2Ph), 2.04 (s, 6 H, CH_2Ph), 1.33 (m, 6 H, $CH_2CH_2CH_2$), 0.81 (m, 6 H, PhSi$CH_2CH_2CH_2$Si), 0.57 (m, 6 H, PhSi$CH_2CH_2CH_2$Si), –0.07 (s, 18 H, CH_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 140.4 (*ipso*-CH_2Ph), 137.9 (*ipso*-Ph), 134.0 (*meta*-Ph), 128.7 (*para*-Ph), 128.1 (*ortho*-CH_2Ph), 128.0 (*meta*-CH_2Ph), 127.6 (*ortho*-*Ph*), 123.8 (*para*-CH_2Ph), 27.7 (CH_2Ph), 19.6, 18.3, and 17.3 [Si(CH_2)$_3$Si], –3.51 (Me) ppm. ^{29}Si{^{1}H} NMR ($CDCl_3$): δ = 1.53 (3 Si), –3.99 (1 Si) ppm.

Synthesis of Cl-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (8): Compound **5** (1.00 g, 1.47 mmol) was dissolved in a small volume of chloroform (1 mL). Trifluoromethanesulfonic acid (0.14 mL, 1.6 mmol) was then added dropwise from a syringe to this solution previously cooled to 0 °C. Stirring was continued for 1 h at room temperature, the solvent was removed in vacuo, the residue was dissolved in dimethoxyethane (10 mL), and an excess of solid triethylammonium chloride (0.30 g, 2.2 mmol) was added. After stirring the reaction mixture for 2 h, the volatiles were removed in vacuo and the residue was extracted with hexane (10 mL), the mixture was filtered, and the solvent was evaporated to yield **8** (0.81 g, 86%) as a colorless oil. $C_{36}H_{57}ClSi_4$ (637.63): calcd. C 67.81, H 9.01; found C 67.35, H 9.10. MS (ESI–): *m*/*z* = 653 (calcd. for MOH^-: 653). ^{1}H NMR ($CDCl_3$): δ = 7.19 (m, 6 H, CH_2Ph), 7.04 (m, 3 H, CH_2Ph), 6.98 (m, 6 H, CH_2Ph), 2.06 (s, 6 H, $CH_2C_6H_5$), 1.37 (m, 6 H, Si$CH_2CH_2CH_2$Si), 0.79 (m, 6 H, ClSi$CH_2CH_2CH_2$Si), 0.57 (m, 6 H, ClSi$CH_2CH_2CH_2$), –0.04 (s, 18 H, Me) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 140.3 (*ipso*-CH_2Ph), 128.1 (*ortho*-CH_2Ph), 128.0 (*meta*-CH_2Ph), 123.9 (*para*-CH_2Ph), 25.7 ($CH_2C_6H_5$), 20.9, 19.1, and 17.6 [Si(CH_2)$_3$Si], –3.5 (Me) ppm. ^{29}Si{^{1}H} NMR ($CDCl_3$): δ = 30.50 (1 Si), 1.65 (3 Si) ppm.

Synthesis of HO-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (9): An excess of anhydrous lithium hydroxide (50 mg, 2.1 mmol) was added to a solution of **8** (0.50 g, 0.78 mmol) in dimethoxyethane (10 mL). After stirring the mixture for 3 h at room temperature, the solvent was removed in vacuo, the residue was extracted with hexane (10 mL), the mixture was filtered, and the solvent evaporated to yield **9** (0.41 g, 84%) as a colorless oil. Alternatively, compound **9** can be synthesized by hydrolysis of a solution of **8** in diethyl ether with several drops of water in the presence of an excess of triethylamine. $C_{36}H_{58}OSi_4$ (619.19): calcd. C 69.83, H 9.44; found C 69.43, H 9.43. MS (APCI–): *m*/*z* = 650 (calcd. for $MMeOH^-$: 650). ^{1}H NMR ($CDCl_3$): δ = 7.19 (m, 6 H, CH_2Ph), 7.04 (m, 3 H, CH_2Ph), 6.99 (m, 6 H, CH_2Ph), 2.06 (s, 6 H, $CH_2C_6H_5$), 1.33 (m, 6 H, Si$CH_2CH_2CH_2$Si), 1.20 (s, 1 H, O*H*), 0.61 and 0.54 (m, 12 H, Si$CH_2CH_2CH_2$Si), –0.05 (s, 18 H, Me) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 140.3 (*ipso*-CH_2Ph), 128.1 (*ortho*-CH_2Ph), 128.0 (*meta*-CH_2Ph), 123.8 (*para*-CH_2Ph), 25.8 ($CH_2C_6H_5$), 20.0, 19.5, and 17.7 [Si(CH_2)$_3$Si], –3.4 (Me) ppm. ^{29}Si{^{1}H} NMR ($CDCl_3$): δ = 15.49 (1 Si), 1.57 (3 Si) ppm.

Synthesis of C_5H_5-G*n*-[$(CH_2)_3SiMe_2Bz$]$_x$ (10–12): The preparation of C_5H_5-G3-[$(CH_2)_3SiMe_2Bz$]$_{27}$ (**12**) is given as representative. Compound **7** (10.0 g, 1.63 mmol) was dissolved in a small volume of chloroform (4 mL). Trifluoromethanesulfonic acid (0.245 g, 1.63 mmol) was added dropwise from a syringe to this solution previously cooled to 0 °C. Stirring was continued for 1 h at room temperature and then the solvent was removed in vacuo and the residue dissolved in dimethoxyethane (50 mL). Subsequently, solid NaC_5H_5 (0.144 g, 1.63 mmol) was added in a dry box. The reaction mixture was stirred for 3 h, the volatiles removed in vacuo, and the residue extracted with hexane (3 × 20 mL). After evaporation of the solvent, compound **12** (8.5 g, 85%) was obtained as a dark-yellow oil.

C_5H_5-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (**10**; 8.6 g, 80%) was obtained from **5** (11.0 g, 16.2 mmol), trifluoromethanesulfonic acid (2.43 g, 16.2 mmol), and NaC_5H_5 (1.43 g, 16.2 mmol). C_5H_5-G2-[$(CH_2)_3SiMe_2Bz$]$_9$ (**11**; 2.0 g, 80%) was obtained from **6** (2.50 g, 1.23 mmol), trifluoromethanesulfonic acid (0.184 g, 1.23 mmol), and NaC_5H_5 (0.108 g, 1.23 mmol).

Data for C_5H_5-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (10): $C_{41}H_{62}Si_4$ (667.27): calcd. C 73.80, H 9.37; found C 73.75, H 9.36. MS (ESI–): *m*/*z* = 666 (calcd. for $M–H^-$: 666). ^{1}H NMR ($CDCl_3$): δ = 7.19 (m, 6 H, CH_2Ph), 7.04 (m, 3 H, CH_2Ph), 6.96 (m, 6 H, CH_2Ph), 6.57, 3.42, and 2.96 (broad resonances, 5 H, C_5H_5), 2.05 (s, 6 H, $CH_2C_6H_5$), 1.27 (m, 6 H, Si$CH_2CH_2CH_2$Si), 0.53 and 0,46 (m, 12 H, Si$CH_2CH_2CH_2$Si), –0.06 (s, 18 H, Me) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 140.2 (*ipso*-CH_2Ph), 133.1 (C_5H_5), 129.9 (C_5H_5), 128.0 (*ortho*-CH_2Ph), 127.9 (*meta*-CH_2Ph), 123.8 (*para*-CH_2Ph), 49.7 (C_5H_5), 25.8 ($CH_2C_6H_5$), 19.7, 18.8, and 17.5 [Si(CH_2)$_3$Si], –3.3 (Me) ppm. ^{29}Si{^{1}H} NMR ($CDCl_3$): δ = 2.71 (1 Si), 1.54 (3 Si) ppm.

Data for C_5H_5-G2-[$(CH_2)_3SiMe_2Bz$]$_9$ (11): $C_{122}H_{194}Si_{13}$ (2026.0): calcd. Synthesis of KC_5H_4-G1-[$(CH_2)_3SiMe_2Bz$]$_3$ (13): In a dry box, solid potassium hydride (0.60 g, 15 mmol) was added to a solution of **10** (10 g, 15 mmol) in dimethoxyethane (50 mL). The reaction mixture was stirred overnight, filtered, and subsequently the solvent was evaporated in vacuo. Washing the resulting dark-yellow oil, which was insoluble in alkanes, with pentane (3 × 30 mL) yielded 8.7 g (82%) of pure **13**, which is stable enough to be characterized and stored for months in a dry box. MS (ESI+): *m*/*z* = 705 (calcd. for MH^+: 705). ^{1}H NMR (C_6D_6): δ = 7.24 (m, 6 H, CH_2Ph), 7.09 (m, 9 H, CH_2Ph), 6.01 (broad resonance, 4 H, C_5H_4), 2.20 (s, 6 H, $CH_2C_6H_5$), 1.64 (m, 6 H, $CH_2CH_2CH_2$), 0.90 (m, 12 H, $CH_2CH_2CH_2$), 0.17 (s, 18 H, Me) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 140.5 (*ipso*-CH_2Ph), 128.7 (*ortho*-CH_2Ph), 128.5 (*meta*-CH_2Ph), 124.5 (*para*-CH_2Ph), 114.0 (C_5H_5), 109.3 (C_5H_5), 26.6 ($CH_2C_6H_5$), 21.0, 20.8, and 20.3 [Si(CH_2)$_3$Si], –2.5 (Me) ppm; *ipso*-C_5H_4 not found. ^{29}Si{^{1}H} NMR (C_6D_6): δ = –12.03 (1 Si), 1.46 (3 Si) ppm.

Synthesis of [{C_5H_4-G1-[$(CH_2)_3SiMe_2Bz$]$_3$}$_2$TiCl$_2$] (14): A 0.20 M solution of $TiCl_4$ in toluene (3.0 mL, 0.60 mmol) was added from a syringe to a solution of the potassium cyclopentadienide **13** (0.85 g, 1.2 mmol) in toluene (20 mL). The mixture was stirred at room temperature overnight. After filtration, the solution was evaporated in vacuo to dryness. The crude red oil thus obtained was characterized as **14** (0.79 g, 91%). $C_{82}H_{122}Cl_2Si_8Ti$ (1451.3): calcd. C 67.86, H 8.47; found C 67.83, H 8.42. ^{1}H NMR ($CDCl_3$): δ = 7.17 (m, 6 H, CH_2Ph), 7.03 (m, 3 H, CH_2Ph), 6.95 (m, 6 H, CH_2Ph), 6.65 (pseudo t, AA′ part of an AA′BB′ spin system, 2 H, C_5H_4), 6.49 (pseudo t, BB′ part of an AA′BB′ spin system, 2 H, C_5H_4), 2.06 (s, 6 H, $CH_2C_6H_5$), 1.30 (m, 6 H, $SiCH_2CH_2CH_2Si$), 0.81 (m, 6 H, $C_5H_5SiCH_2CH_2CH_2Si$), 0.56 (m, 6 H, $C_5H_5SiCH_2CH_2CH_2Si$), –0.06 (s, 18 H, Me) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 140.1 (*ipso*-CH_2Ph), 129.2 (C_5H_4), 127.9 (*ortho*-CH_2Ph), 127.8 (*meta*-CH_2Ph), 123.6 (*para*-CH_2Ph), 119.1 (C_5H_4), 25.9 ($CH_2C_6H_5$), 20.0, 18.8, and 18.3, [Si(CH_2)$_3$Si], –3.1 (Me) ppm; *ipso*-C_5H_4 not found. ^{29}Si{^{1}H} NMR ($CDCl_3$): δ = –5.65 (1 Si), 1.53 (3 Si) ppm.

Synthesis of [{C_5H_4-G1-[$(CH_2)_3SiMe_2Bz$]$_3$}$_2$ZrCl$_2$] (15): Solid $ZrCl_4$·2THF (0.267 g, 0.71 mmol) was added, in a dry box, to a solution of **13** (1.00 g, 1.42 mmol) in toluene. The reaction mixture was stirred overnight, evaporated in vacuo, and extracted with hexane (3 × 10 mL). After filtration, the solvent was evaporated in vacuo to yield **15** (0.89 g, 84%) as a colorless oil. $C_{82}H_{122}Cl_2Si_8Zr$ (1494.66): calcd. C 65.89, H 8.23; found C 65.84, H 8.21. ^{1}H NMR ($CDCl_3$): δ = 7.19 (m, 6 H, CH_2Ph), 7.05 (m, 3 H, CH_2Ph), 6.95 (m, 6 H, CH_2Ph), 6.56 (pseudo t, AA′ part of an AA′BB′ spin system, 2 H, C_5H_4), 6.46 (pseudo t, BB′ part of an AA′BB′ spin system, 2 H, C_5H_4), 2.06 (s, 6 H, $CH_2C_6H_5$), 1.32 (m, 6 H, $SiCH_2CH_2CH_2Si$), 0.85 (m, 6 H, $C_5H_5SiCH_2CH_2CH_2Si$), 0.58 (m, 6 H, $C_5H_5SiCH_2CH_2CH_2Si$), –0.05 (s, 18 H, Me) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 140.1 (*ipso*-CH_2Ph), 127.9 (*ortho*-CH_2Ph), 125.5 (C_5H_4), 127.8 (*meta*-CH_2Ph), 123.6 (*para*-CH_2Ph), 115.5 (C_5H_4), 25.9 ($CH_2C_6H_5$), 19.9, 18.8, and 18.3 [Si(CH_2)$_3$Si], –3.1 (Me) ppm; *ipso*-C_5H_4 not found. ^{29}Si{^{1}H} NMR ($CDCl_3$): δ = –6.34 (1 Si), 1.54 (3 Si) ppm.

Ethylene and Propylene Polymerization: A 250-mL flask charged with toluene (50 mL) and equipped with a magnetic stirrer was evacuated and refilled with pre-dried ethylene or propylene gas four times. Whilst keeping the flask pressurized with the corresponding gas (1 bar) and stirring at room temperature, a toluene solution of methylaluminoxane (PMAO-IP 13% Akzo Nobel, 0.50 mL) was syringed through a septum. After 5 min, a toluene solution of the catalyst (0.50 mL, 2.5 mM) was injected into the flask with simultaneous starting of a stopwatch. The polymerization was quenched 10 min later by closing the gas feed, release of the overpressure, and addition of acidified methanol (4% v/v HCl). The mixture was stirred for 6 h and the polymer was filtered, washed with copious amounts of methanol, and dried in an oven to constant weight.

Synthesis and Structures of Bi(1,1-stannole)s

Masaichi Saito,*[a] Ryuta Haga,[a] and Michikazu Yoshioka[a]

Keywords: Metallacycles / Tin / UV/Vis spectroscopy

The synthesis and structures of bi(1,1-stannole)s are described. Treatment of 1-bromo-4-(dibromophenylstannyl)-1,3-butadiene with *tert*-butyllithium gives the bi(1,1-stannole) having a phenyl group on each tin atom, whereas treatment of 1-bromo-4-(tribromostannyl)-1,3-butadiene with phenyl- or bulky alkyllithiums gives the bi(1,1-stannole) having a phenyl or an alkyl group on each tin atom. The X-ray analysis of the *tert*-butyl-substituted bi(1,1-stannole) is also described. All bi(1,1-stannole)s display two shoulder absorption bands due to π–π^* and σ–π^* transitions.

Introduction

Group 14 metalloles,[1] or metallacyclopentadienes, have attracted much attention because of interest in them as a possible precursor for the preparation of conjugated polymers having unique electronic structures[2,3] as well as the potential aromaticity of their anions.[4] Since the successful synthesis of some oligo(1,1-silole)s[5,6] and poly(1,1-silole)s, they have been applied to organic electroluminescent (EL) devices.[7,8] Most recently, poly(1,1-germole) has also been reported.[9] In contrast to the silicon and germanium analogs, however, attempts to prepare oligo- and poly(1,1-stannole)s are still unknown. Although the synthesis and some simple reactions of stannoles have been reviewed,[1] even the synthesis of bi(1,1-stannole) has not yet been successful.

In the course of our studies on organotin compounds,[10] we have already reported that bromination of hexaphenylstannole (**1**) gives the ring-opened halogenated product **2** (Scheme 1).[11,12] We have also preliminarily reported that debrominative cyclization of **2** affords the bi(1,1-stannole).[13] We report herein the synthesis, structures, and physical properties of some bi(1,1-stannole)s.

Results and Discussion

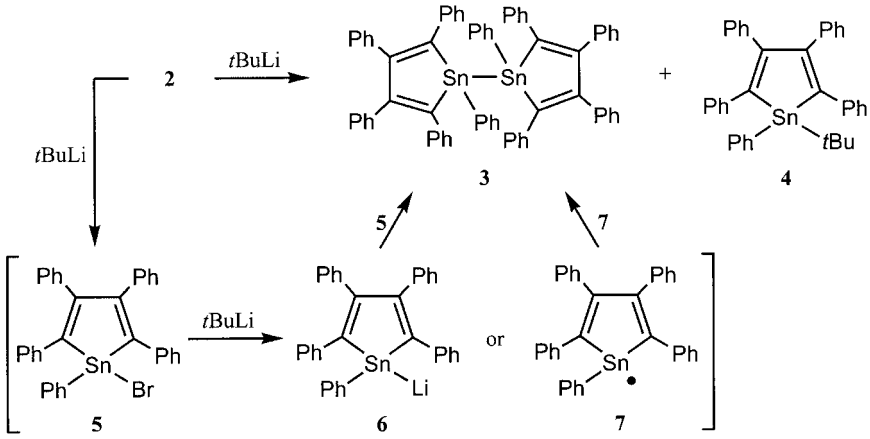
Synthesis of Bi(1,1-stannole) 3

Treatment of **2** with two equivalents of *tert*-butyllithium in THF at –100 °C gave a yellow solution. After usual workup, the mixture was chromatographed to give bi(1,1-stannole) **3** as yellow crystals in 58% yield together with stannole **4** (7%) (Scheme 2). To the best of our knowledge, compound **3** is the first example of bi(1,1-stannole). Two possible mechanisms for the formation of **3** are shown in Scheme 2. The initial step of the reaction is the formation of 1-bromo-1-phenylstannole (**5**), which reacts further with *tert*-butyllithium to give the stannole anion **6** or the stannole radical **7**. The stannole anion **6** then reacts with **5** to give **3**, while the stannole radical **7** couples to itself to also give **3**. Product **4** is formed by nucleophilic substitution at the tin atom of **5** by *tert*-butyllithium. Trapping of the intermediary ionic species **6** by addition of methyl iodide or chlorotrimethylstannane, expecting to obtain a methylated or a stannylated product, failed and the bi(1,1-stannole) **3** was obtained in 71 or 77% yield, respectively. Therefore, a radical mechanism for the formation of **3** is more likely, although the ionic mechanism cannot be ruled out entirely. The yield of **3** was improved (82%) when the reaction was carried out in diethyl ether, although the reason for the solvent-dependent product yield is not clear.

Synthesis of Bi(1,1-Stannole)s Having Various Substituents on the Tin Atom

The synthesis of other bi(1,1-stannole)s having various substituents on the tin atom was achieved by the reaction of 1-bromo-4-(tribromostannyl)-1,3-butadiene (**8**) with lithium reagents.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200500274

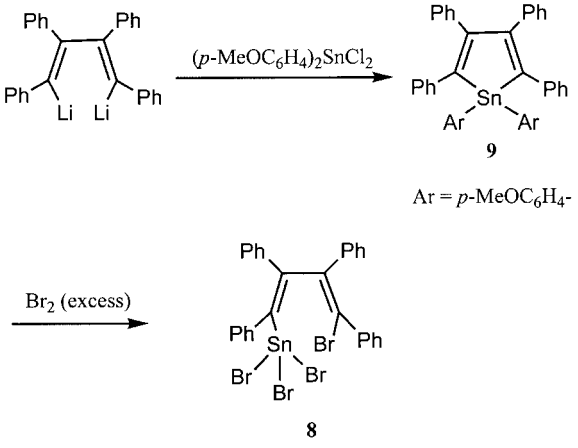


Scheme 2.

Synthesis of 1-Bromo-4-(tribromostannyl)-1,3-butadiene (8)

We attempted to synthesize **8** by the reaction of **1** or **2** with bromine. However, the reaction of **2** with bromine gave a complex mixture. Reaction of hexaphenylstannole (**1**) with excess bromine also gave a complex mixture containing 1,4-dibromo-1,2,3,4-tetraphenylbutadiene.[14]

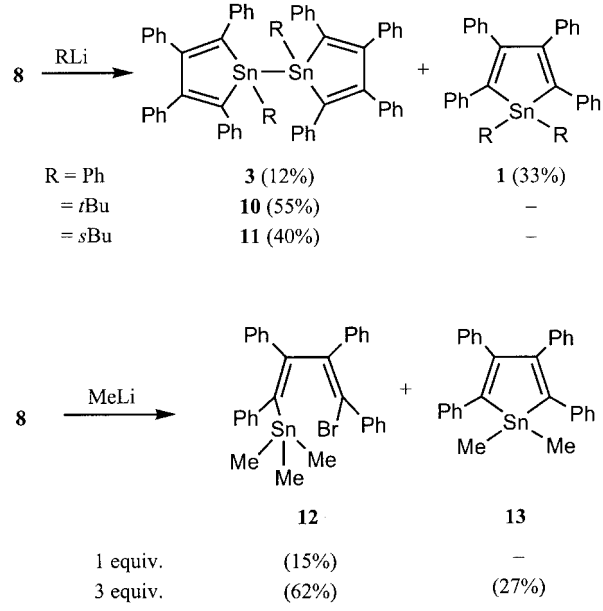
Since the *p*-methoxyphenyl group on the tin atom is known to be easily removed by halogenation,[15] the reaction of 1,1-di(*p*-methoxyphenyl)stannole (**9**) with bromine was examined. Compound **9** was prepared by the reaction of 1,4-dilithio-1,2,3,4-tetraphenylbutadiene with dichlorodi(*p*-methoxyphenyl)stannane[16] in 58% yield (Scheme 3). Reaction of **9** with bromine (1 equiv.) at –40 °C gave a complex mixture, and treatment of **9** with bromine (2 equiv.) at –20 °C afforded 1,4-dibromo-1,2,3,4-tetraphenylbutadiene (41%).[14] However, the reaction of **9** with excess bromine (10 equiv.) at room temperature gave **8** (96%). The structure of **8** was determined by NMR spectroscopy and elemental analysis (Scheme 3).



Scheme 3.

Reaction of 8 with Lithium Reagents: Synthesis of Bi(1,1-stannole)s

Treatment of **8** with phenyllithium (2 equiv.) afforded bi(1,1-stannole) **3** (12%) and hexaphenylstannole **1** (33%; Scheme 4). The preferential formation of **1** to **3** may be ascribed to the size of the lithium reagent. In fact, the reaction of **8** with bulkier *tert*-butyllithium (2 equiv.) rather than phenyllithium gave bi(1,1-stannole) **10** having a *tert*-butyl group on each tin atom as the sole product in 55% yield (Scheme 4). Reaction of **7** with *sec*-butyllithium (2 equiv.), a moderately bulky reagent, gave a bi(1,1-stannole) **11** having a *sec*-butyl group on each tin atom as a 1:1 diastereomeric mixture[17] in a relatively good yield (40%; Scheme 4). The diastereomeric ratio was estimated by signal intensities (δ = –60.59 and –60.57 ppm) in the ^{119}Sn NMR spectrum. Contrary to the bulky lithium reagent, the reaction of less bulky methyllithium (1 equiv.) with **8** gave 4-bromo-1,2,3,4-tetraphenyl-1-(trimethylstannyl)-1,3-butadiene (**12**) in 15% yield. Methyllithium would directly attack the tin to afford trimethyl derivative **12** (Scheme 4). Reaction of **8** with methyllithium (3 equiv.) gave **12** (62%) and 1,1-dimethylstannole **13** (27%; Scheme 4).



Scheme 4.

Structures of 3 and 10

Slow evaporation of the solvent from chloroform solutions of **3** and **10** gave X-ray quality crystals. The structure of **3** has been reported previously.[13] Because of the symmetrical structures of **3** and **10** with respect to the Sn–Sn bond, only a half moiety was refined. The ORTEP drawing of **10**, with selected bond lengths and angles, is shown in Figure 1. The length of the Sn–Sn bond is quite normal[18] at 2.7822(7) Å [2.7844(7) Å for **3**].[13] Each stannole ring has a nearly planar structure and is oriented in an *anti* fashion through the Sn–Sn bond probably due to steric reasons. The angle between the stannole plane and the Sn–Sn bond is 67° for **10** (74° for **3**).

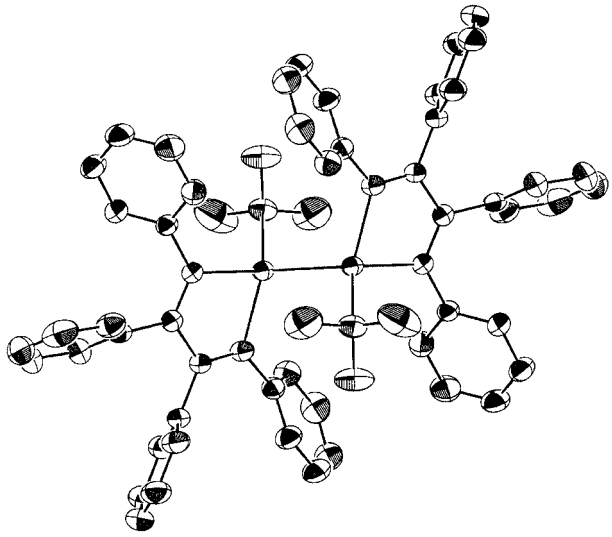

Figure 1. ORTEP drawing of **10** with thermal ellipsoid plots (40% probability for non-hydrogen atoms). Selected bond lengths [Å] and angles [°]: Sn(1)A–Sn(1)B 2.7822(7), Sn(1)A–C(1) 2.143(4), C(1)–C(2) 1.353(5), C(2)–C(3) 1.506(5), C(3)–C(4) 1.352(5), Sn(1)A–C(4) 2.157(4); C(1)–Sn(1)A–C(4) 83.28(14).

Spectroscopic Properties

In the ^{119}Sn NMR spectrum, each central tin atom of the compounds with the stannole skeleton resonates in the range from δ = –100 to –45ppm, in the same region as that of 1,1,2,3,4,5-hexaphenylstannole (δ = –88.7 ppm).[11] The tin atoms of alkyl-substituted bi(1,1-stannole)s **10** and **11** resonate to higher field than that of **3**, as is observed in normal distannanes (δ = –108.7 and –144.7 ppm for $Me_3SnSnMe_3$[19] and $Ph_3SnSnPh_3$,[20] respectively). The $^1J_{^{119}Sn,^{117}Sn}$ coupling constant of 2865 Hz for **3** is a normal value for distannanes (cf. 2748 Hz for $Bu_3SnSnBu_3$).[19] The UV/Vis absorption spectra for **3**, **10**, and **11** are shown in Figure 2. All bi(1,1-stannole)s display two shoulder absorption bands at around 320 and 370 nm. The latter band can be assigned to the π–π* transition of the stannole ring because a similar absorption band is found in 1,1,2,3,4,5-hexaphenylstannole (**1**; λ_{max} = 355 nm).[21] The π–π* transition of group 14 metalloles is observed in the same region, at around 360 nm, because the contributions of the diene moiety to both HOMO and LUMO are predominant rather than that of the metal moiety.[21] The shorter wavelength band can be assigned to the transition from σ(Sn–Sn) to π*(diene) because the corresponding band is absent in **1**. This absorption (320 nm) is red-shifted compared to that of a bi(1,1-silole) (300 nm)[7] because of the higher energy level of a σ(Sn–Sn) bond than that of a σ(Si–Si) bond.

Conclusions

Several bi(1,1-stannole)s combining two stannacyclopentadienyl units through an Sn–Sn bond have been synthe-

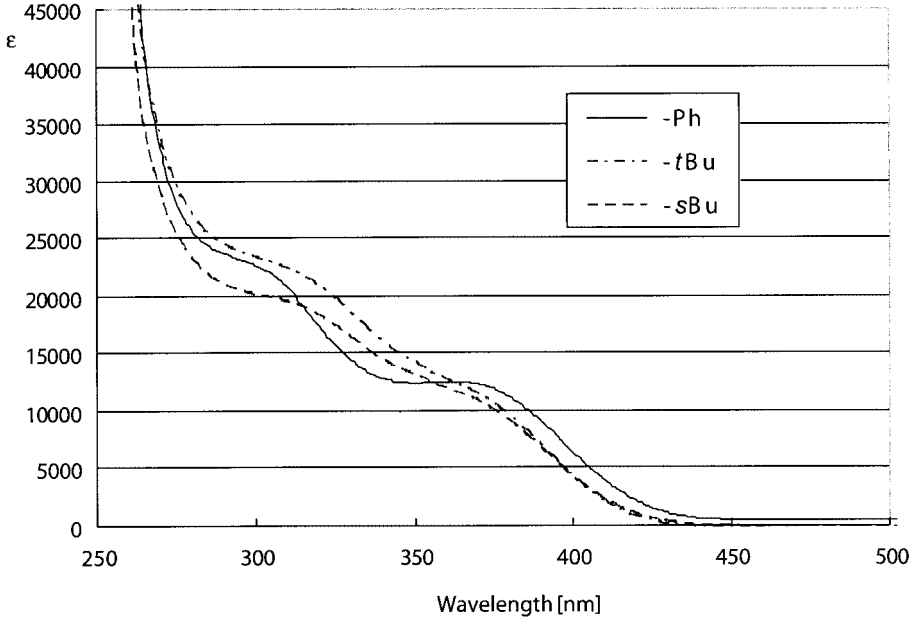

Figure 2. UV/Vis spectra of bi(1,1-stannole)s **3**, **10**, and **11**.

sized and characterized. The product yield in the formation of bi(1,1-stannole) by the reaction of 1-bromo-4-(tribromophenylstannyl)-1,3-butadiene with lithium reagent is dependent on the size of the lithium reagent used. The X-ray analysis of bi(1,1-stannole) shows a symmetrical structure with respect to the Sn–Sn bond. All bi(1,1-stannole)s display two shoulder absorption bands due to π–π* and σ–π* transitions.

Experimental Section

General Procedures: All reactions were carried out under argon. THF and diethyl ether used in the syntheses were distilled from sodium benzophenone ketyl under argon before use. ^{1}H (400 MHz) and ^{13}C NMR (100 MHz) spectra were recorded on a Bruker AM-400 or an ARX-400 spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. Although $^nJ_{Sn,^{13}C}$ couplings were observed in the ^{13}C NMR spectra as satellite signals, most of the $^nJ_{^{119}Sn-^{13}C}$ and $^nJ_{^{117}Sn-^{13}C}$ couplings could not be estimated separately because of line broadening. The multiplicities of the signals in the ^{13}C NMR spectra given in parentheses were deduced from DEPT spectra. ^{119}Sn NMR (149 MHz) spectra were recorded on a Bruker ARX-400 spectrometer in $CDCl_3$ with tetramethylstannane as an external standard. Column chromatography was carried out with Merck Kieselgel 60 (SiO_2). All melting points were determined on a Mitamura Riken Kogyo MEL-TEMP apparatus and are uncorrected. Electronic spectra were recorded on a JASCO V-560 UV/Vis spectrometer. Elemental analyses were carried out at the Microanalytical Laboratory of Molecular Analysis and Life Science Center, Saitama University.

Preparation of Bi(1,1-stannole) 3. (a) Method A (in THF): *tert*-Butyllithium (1.60 M in pentane; 3.2 mL, 5.12 mmol) was added at –100 °C to a THF (30 mL) solution of 1-bromo-4-(dibromophenylstannyl)-1,2,3,4-tetraphenyl-1,3-butadiene (**2**; 2030 mg, 2.56 mmol). After warming to room temperature over 4 h, the solvent was evaporated. The residue was subjected to column chromatography (hexane/ethyl acetate = 10:1) to afford bis(1,2,3,4,5-pentaphenylstannacyclopentadienyl) (**3**; 826 mg, 58%) and 1-*tert*-butyl-1,2,3,4,5-pentaphenylstannole (**4**; 103 mg, 7%).
3: M.p. 209 °C (decomp.) (recrystallized from dichloromethane/methanol). ^{1}H NMR: δ = 6.73–6.80 (m, 8 H), 6.84–6.89 (m, 8 H), 6.94–7.00 (m, 24 H), 7.13–7.20 (m, 4 H), 7.24–7.27 (m, 6 H) ppm. ^{13}C NMR: δ = 125.4 (d), 125.9 (d), 127.3 (d), 127.9 (d), 129.0 (d, $J_{Sn,C}$ = 53 Hz), 129.6 (d, $J_{Sn,C}$ = 22 Hz), 130.5 (d), 137.4 (d, $J_{Sn,C}$ = 10, 46 Hz), 138.7 (s), 140.5 (s, $J_{Sn,C}$ = 61 Hz), 142.4 (s, $J_{Sn,C}$ = 47 Hz), 145.9 (s, $J_{Sn,C}$ = 37, 334, 350 Hz), 154.3 (s, $J_{Sn,C}$ = 22, 81 Hz) ppm. ^{119}Sn NMR: δ = –99.3 ppm ($^1J_{^{119}Sn,^{117}Sn}$ = 2865 Hz). $C_{68}H_{50}Sn_2$ (1104.6): calcd. C 73.94, H 4.56; found C 73.30, H 4.31.
4: M.p. 160–161 °C (decomp.) (recrystallized from dichloromethane/methanol). ^{1}H NMR: δ = 1.37 (s, 9 H, $J_{Sn,H}$ = 75, 78 Hz), 6.79–6.80 (m, 4 H), 6.89–6.97(m, 12 H), 7.03–7.06 (m, 4 H), 7.30–7.37 (m, 3 H), 7.48–7.61 (m, 2 H) ppm. ^{13}C NMR: δ = 31.1 (q), 32.7 (s), 125.0 (d), 125.7 (d), 127.2 (d), 127.8 (d), 128.8 (d), 129.0 (d), 129.2 (d), 130.4 (d), 137.2 (d), 139.9 (s), 140.8 (s), 143.4 (s), 144.6 (s), 155.2 (s) ppm. ^{119}Sn NMR: δ = –59.9 ppm. $C_{38}H_{34}Sn$ (609.42): calcd. C 74.90, H 5.62; found C 74.90, H 5.58.

Method B (in Diethyl Ether): *tert*-Butyllithium (1.50 M in pentane; 3.4 mL, 5.10 mmol) was added at –100 °C to a diethyl ether (40 mL) solution of **2** (1999 mg, 2.52 mmol). After warming to room temperature over 4 h, the solvent was evaporated. The residue was subjected to column chromatography (ethyl acetate) followed by recrystallization from hexane and dichloromethane to afford **3** (1141 mg, 82%).

Attempt to Trap Intermediary Ionic Species with Methyl Iodide: *tert*-Butyllithium (1.48 M in pentane; 0.29 mL, 0.43 mmol) was added to a diethyl ether (4 mL) solution of **2** (114 mg, 0.14 mmol) at –100 °C. The color of the solution immediately turned yellow. Methyl iodide (0.05 mL, 0.80 mmol) was added to this solution. After warming to room temperature over 7 h, the solvent was evaporated. Recrystallization from hexane and dichloromethane gave **3** (56 mg, 71%).

Attempt to Trap Intermediary Ionic Species with Chlorotrimethylstannane: *tert*-Butyllithium (1.60 M in pentane; 0.24 mL, 0.38 mmol) was added to a diethyl ether (4 mL) solution of **2** (98 mg, 0.12 mmol) at –100 °C and a diethyl ether (2 mL) solution of chlorotrimethylstannane (30 mg, 0.15 mmol) was then added. After warming to room temperature over 4 h, the solvent was evaporated. Recrystallization from hexane and dichloromethane gave **3** (53 mg, 77%).

Preparation of 1,1-Di(*p*-methoxyphenyl)-2,3,4,5-tetraphenylstannole (9): A suspension of diphenylacetylene (4.40 g, 24.7 mmol) and lithium (171 mg, 24.7 mmol) in diethyl ether (17 mL) was stirred for 4 h at room temperature. A THF (15 mL) solution of di(*p*-methoxyphenyl)dichlorostannane[16] (4.11 g, 10.2 mmol) was added to the resulting suspension and the mixture was refluxed for 3 h. After removal of solvents, any material insoluble in dichloromethane was filtered off. After evaporation, the residue was subjected to column chromatography (hexane/ethyl acetate = 10:1) to give **9** (4.035 g, 58%). M.p. 200 °C (decomp.) (recrystallized from dichloromethane/hexane). ^{1}H NMR: δ = 3.81 (s, 6 H), 6.80–6.86 (m, 4 H), 6.89 (d, J = 8 Hz, 4 H), 6.92–7.05 (m, 16 H), 7.50 (d, J = 8 Hz, 4 H) ppm. ^{13}C NMR: δ = 55.0 (q), 114.9 (d, $J_{Sn,C}$ = 58 Hz), 125.3 (d), 125.8 (d), 127.3 (d), 127.8 (d), 128.3 (s), 129.3 (d, $J_{Sn,C}$ = 22 Hz), 130.3 (d), 138.3 (d, $J_{Sn,C}$ = 46 Hz), 140.7 (s, $J_{Sn,C}$ = 68 Hz), 142.5 (s, $J_{Sn,C}$ = 45 Hz), 143.0 (s), 154.4 (s, $J_{Sn,C}$ = 89 Hz), 160.7 (s) ppm. ^{119}Sn NMR: δ = –79.9 ppm. $C_{40}H_{34}O_2Sn$ (665.44): calcd. C 72.20, H 5.15; found C 72.30, H 4.93.

Reaction of 9 with Bromine (2 equiv.): A carbon tetrachloride (8 mL) solution of bromine (0.02 mL, 0.39 mmol) at –20 °C was added to a carbon tetrachloride (7 mL) solution of **9** (134 mg, 0.19 mmol). After warming to room temperature, the solvent was evaporated. The residue was recrystallized from dichloromethane and methanol to give 1,4-dibromo-1,2,3,4-tetraphenylbutadiene (39 mg, 41%).[14]

Reaction of 9 with Bromine (excess): A carbon tetrachloride (8 mL) solution of bromine (0.89 mL, 17.3 mmol) was added at room temperature to a dichloromethane (15 mL) solution of **9** (1200 mg, 1.74 mmol). The residue was recrystallized from dichloromethane and methanol to give 1-bromo-1,2,3,4-tetraphenyl-4-(tribromostannyl)-1,3-butadiene (**8**; 1328 mg, 96%). M.p. 167–168 °C (decomp.) (recrystallized from dichloromethane/hexane). ^{1}H NMR: δ = 7.06–7.16 (m, 4 H), 7.20–7.39 (m, 14 H), 7.48–7.53 (m, 2 H) ppm. ^{13}C NMR: δ = 128.0 (d), 128.1 (d), 128.2 (d), 128.3 (d), 128.56 (d), 128.58 (d), 128.9 (d), 129.0 (d), 129.8 (d), 129.9 (d), 130.1 (d), 130.8 (d), 136.4 (s), 136.6 (s, $J_{Sn,C}$ = 10 Hz), 136.8 (s), 138.8 (s), 141.0 (s, $J_{Sn,C}$ = 67 Hz), 144.1 (s), 156.69 (s, $J_{Sn,C}$ = 61 Hz) ppm. ^{119}Sn NMR: δ = –285.4 ppm. $C_{28}H_{20}Br_4Sn$ (794.78): calcd. C 42.32, H 2.54; found C 42.65, H 2.50.

Reaction of 8 with Phenyllithium: Phenyllithium (0.88 M in cyclohexane; 0.20 mL, 0.18 mmol) was added at –80 °C to a THF (3 mL) solution of **7** (70 mg, 0.09 mmol). After warming to room temperature over 3.5 h, the volatile substances were removed. After fil-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tration of material insoluble in dichloromethane, the filtrate was subjected to column chromatography (hexane/ethyl acetate = 10:1) to afford **1** (18 mg, 33%) and **3** (6 mg, 12%).

Reaction of 8 with *tert*-Butyllithium. Formation of Bi(1,1-stannole) 10: *tert*-Butyllithium (1.43 M in pentane; 1.1 mL, 1.57 mmol) was added at –95 °C to a THF (10 mL) solution of **8** (408 mg, 0.51 mmol). After warming to room temperature over 3 h, the volatile substances were removed. After removal of material insoluble in dichloromethane by filtration, the filtrate was recrystallized from dichloromethane and methanol to give bis(1-*tert*-butyl-2,3,4,5-tetraphenylstannacyclopentadienyl) (**10**; 150 mg, 55%). M.p. 270–300 °C (decomp.) (recrystallized from dichloromethane). ^{1}H NMR: δ = 1.10 (s, 18 H, $J_{Sn,H}$ = 85 Hz), 6.80–6.84 (m, 8 H), 6.87–7.04 (m, 32 H) ppm. ^{13}C NMR: δ = 31.6 (q), 35.2 (s), 124.9 (d), 125.6 (d), 127.2 (d), 127.7 (d), 129.6 (d), 130.7 (d), 140.9 (s), 143.5 (s), 148.5 (s), 154.2 (s) ppm. ^{119}Sn NMR: δ = –46.4 ppm. $C_{64}H_{58}Sn_2$ (1064.6): calcd. C 72.21, H 5.49; found C 71.54, H 5.37. The $J_{Sn,Sn}$ and $J_{Sn,C}$ satellites were not observed because of low solubility.

Reaction of 8 with *sec*-Butyllithium: *sec*-Butyllithium (0.96 M in pentane; 0.53 mL, 0.51 mmol) was added at –95 °C to a THF (3 mL) solution of **8** (136 mg, 0.17 mmol). After warming to room temperature over 7 h, the volatile substances were removed. After removal of material insoluble in dichloromethane by filtration, the filtrate was recrystallized from diethyl ether to give a 1:1 diastereomeric mixture of bis(1-*sec*-butyl-2,3,4,5-tetraphenylstannacyclopentadienyl) (**11**; 37 mg, 40%). M.p. 230–233 °C (decomp.) (recrystallized from dichloromethane/methanol). ^{1}H NMR: δ = 0.77 (t, J = 7 Hz, 6 H), 1.03–1.26 (m, 6 H), 1.47–1.58 (m, 4 H), 2.06–2.12 (m, 2 H), 6.76–6.78 (m, 8 H), 6.84–6.87 (m, 8 H), 6.91–6.95 (m, 16 H), 6.98–7.02 (m, 4 H) ppm. ^{13}C NMR: δ = 14.5 (q), 19.7 (q), 19.7 (q), 30.4 (t), 32.1 (d), 124.9 (d), 125.6 (d), 127.2 (d), 127.7 (d), 129.3 (d), 129.3 (d), 130.6 (d), 141.0 (s), 143.5 (s), 148.6 (s), 148.8 (s), 153.7 (s), 153.8 (s) ppm. ^{119}Sn NMR: δ = –60.59, –60.57 ppm. $C_{64}H_{58}Sn_2$ (1064.62): calcd. C 72.21, H 5.49; found C 71.58, H 5.46.

Reaction of 8 with Methyllithium (1 equiv.): Methyllithium (1.02 M in diethyl ether; 0.2 mL, 0.20 mmol) was added at –100 °C to a THF (5 mL) solution of **8** (163 mg, 0.21 mmol). After warming to room temperature, the volatile substances were removed. After removal of material insoluble in dichloromethane by filtration, the filtrate was subjected to column chromatography (hexane/ethyl acetate = 10:1) to give 4-bromo-1,2,3,4-tetraphenyl-1-(trimethylstannyl)-1,3-butadiene (**12**; 19 mg, 15%). M.p. 118 °C (decomp.) (recrystallized from dichloromethane/hexane). ^{1}H NMR: δ = 0.13 (s, 9 H, $J_{Sn,H}$ = 52, 54 Hz), 6.96–7.10 (m, 9 H), 7.13–7.23 (m, 9 H), 7.36–7.40 (m, 2 H) ppm. ^{13}C NMR: δ = –7.0 (q), 124.3 (s), 124.9 (d), 126.4 (d), 127.3 (d), 127.4 (d), 127.7 (d), 127.8 (d), 127.9 (d), 128.0 (d), 128.2 (d), 130.0 (d), 130.1 (d), 130.5 (d), 138.7 (s), 139.7 (s), 140.3 (s), 144.4 (s), 145.3 (s), 148.5 (s), 152.4 (s) ppm. ^{119}Sn NMR: δ = –36.2 ppm. $C_{31}H_{29}BrSn$ (600.20): calcd. C 62.04, H 4.87; found C 62.04, H 4.79.

Reaction of 8 with Methyllithium (3 equiv.): Methyllithium (1.02 M in diethyl ether; 0.4 mL, 0.41 mmol) was added at –90 °C to a THF (4 mL) solution of **8** (101 mg, 0.13 mmol). After warming to room temperature, the volatile substances and material insoluble in dichloromethane were removed. The residue (64 mg) contained 62% of **12** and 27% of 1,1-dimethylstannole **13** by ^{1}H NMR estimation.

Crystal and Experimental Data for 10: Crystals suitable for X-ray diffraction were obtained by slow evaporation of the solvent from a chloroform solution of **10**. Data for the X-ray crystallographic analysis were collected on a Mac Science MXC18K diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods using SIR[22] and refined by full-matrix least-squares techniques (SHELXL-97)[23] using all independent reflections (5672 reflections) for 298 parameters. The non-hydrogen atoms were refined anisotropically and all the hydrogen atoms were placed at calculated positions [d(C–H) = 0.96 Å]. R_1 = 0.042 [$I > 2\sigma(I)$, 5389 reflections], wR_2 = 0.097 (for all reflections), GOF = 1.094. The crystallographic data and details associated with data collection for **10** are given in Table 1.

Table 1. Crystallographic data for compound **10**.

Formula	$C_{64}H_{58}Sn_2$
Mol. mass	1064.52

A Platinium(II)-Based Molecular Light Switch for Proteins

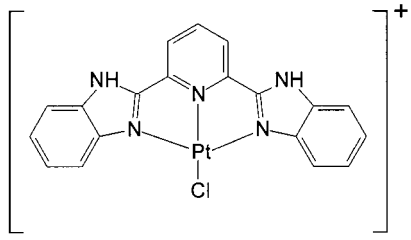
Vaidyanathan G. Vaidyanathan[a] and Balachandran U. Nair*[a]

Keywords: Fluorescent probes / Platinum / Proteins / Tridentate ligands

The platinum(II) complex $[Pt(bzimpy)Cl]^+$ (**1**) [bzimpy = 2,6-bis(benzimidazo-2-yl)pyridine] has been synthesized and characterized by FAB mass spectrometry and UV/Vis, NMR, and emission spectroscopy. Complex **1** emits weakly from its ^{3}MLCT state in aqueous solution but strongly in nonaqueous media. Complex **1** exhibits a molecular light switch effect with a drastic enhancement in its emission intensity and a 72-nm blue shift in the emission maxima in the presence of bovine serum albumin (BSA). Denaturation of BSA in the presence of 6 M urea leads to a decrease in the emission intensity of the complex, which suggests its binding to the hydrophobic pockets of the protein. In the presence of hemoglobin, however, quenching of the emission of the complex is observed due to its binding to Cys104 in subunit C and the resultant fluorescence resonance energy transfer from the platinum(II) complex to the heme.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

In recent years, there has been continuing interest in designing new molecules for the development of novel chemo- and biosensors. However, most of these studies deal with organic molecules as chemo- and biosensors. In recent times, considerable attention has been paid to the synthesis of inorganic chemosensors.[1] Although metal complexes exhibit luminescent behavior like organic molecules, the utility of these metal complexes as biosensors still remain sparse. In the last decade, Barton et al. have demonstrated that $[Ru(dppz)(bpy)_2]^{2+}$ behaves as a molecular light switch for DNA.[2] Despite extensive work on organic fluorophores such as 8-anilino-1-naphthalenesulfonic acid (ANS) as a probe to study the conformational changes of proteins,[3] no metal complex with a similar behavior has yet been reported.

Among the various transition metal ions, platinum plays a vital role in cancer research. While there are a number of reports on the interaction of platinum(II) complexes with DNA, there are relatively few reports on the binding of platinum(II) complexes to proteins.[4,5] Even though most platinum(II) complexes are nonluminescent at room temperature, a few of them have been exploited as chemosensors.[6] Recently, Grove et al. have discussed the vapochromic properties of $[Pt(Me_2bzimpy)Cl]^+$,[7] and Che et al. have recently demonstrated the use of PEG attached $[Pt(CNN)L]^+$ as a molecular light switch for proteins,[8] although studies pertaining to this complex have been limited to albumins. Very recently, the same group has demonstrated the molecular light switch effect specifically to human serum albumin (HSA) exhibited by a platinum(II) complex containing a cyclometalated ligand anchored to amino acids.[9] In this context, we have developed a new platinum-based biosensor with a tridentate ligand, bzimpy, $[Pt(bzimpy)Cl]^+$ (**1**). To the best of our knowledge, this is the first report of a platinum-based transition metal complex that mimics the behavior of an organic molecule such as ANS.



1

Complex **1** was isolated as its PF_6^- salt by refluxing a DMSO solution of bzimpy and K_2PtCl_4 in a 1:1 molar ratio. The absorption spectrum of **1** in DMSO exhibits intense bands at 320 and 380 nm due to an intraligand π–π* transition of the ligand bzimpy. A broad, featureless absorption band at 420 nm has been assigned to a ^{1}MLCT [Pt(5d)–π*(bzimpy)] transition similar to $[Pt(L18)Cl]^+$ [L18 = 2,6-bis(1-octadecylbenzimidazol-2-yl)pyridine].[10] Complex **1** exhibits a very broad and weak ^{3}MLCT emission centered at 625 nm in aqueous solution at room temperature upon excitation at 370 nm. The excited state lifetime of complex **1** is 0.19 μs in Tris buffer solution (pH 7.0) at 298 K. The excited state lifetime of complex **1** is less than that of other platinum(II) complexes such as PtPren and PtPrtmen, whose lifetimes are 4.2 and 3.6 μs, respectively.[11]

First, the effect of solvents on the emission spectrum of complex **1** was examined. On decreasing the polarity of the solvent, the emission maximum of the complexes shifts towards lower wavelength from 625 to 560 nm, with an increase in the emission intensity (Figure 1). This type of behavior has previously been observed for organic fluorophores such as ANS, where the emission maximum shifts to lower wavelength on decreasing the polarity of the solvent.[2] In order to investigate the molecular light switch effect of complex **1** in the presence of proteins, we investigated the emission properties of complex **1** with bovine serum albumin (BSA), chicken egg albumin, lysozyme, and hemoglobin. These proteins were chosen as they cover a range of hydrophobicity.

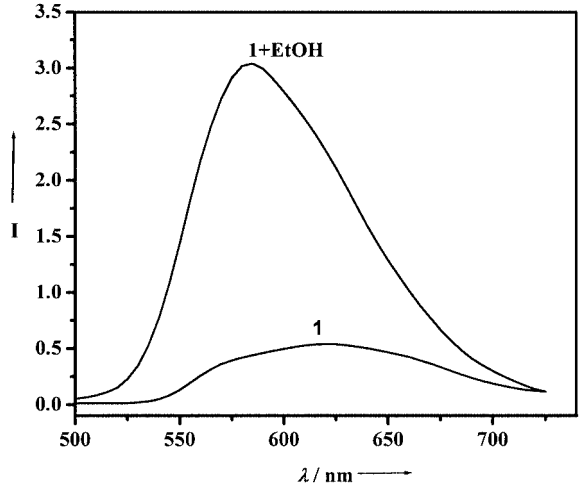

Figure 1. Emission spectra of **1** (50 μM) in the absence and presence of EtOH (λ_{ex} = 370 nm; 298 K; pH 7.0).

Interestingly, on addition of BSA (5 μM), the emission intensity of complex **1** (10 μM) increases 70-fold, with a drastic blue-shift of 72 nm in the emission maximum from 625 nm to 553 nm; the emission band gets sharper on increasing the amount of BSA (Figure 2). A similar behavior of the emission of complex **1** was observed in the presence of chicken egg albumin also. This enhancement in emission intensity has been ascribed to the binding of **1** in the hydrophobic pocket of serum albumin. The binding constants of **1** with BSA and egg albumin were calculated to be $(6.75 \pm 0.1) \times 10^4$ and $(5.4 \pm 0.1) \times 10^4$ M^{-1}, respectively, from the Scatchard plot, and the binding site size number was estimated to be one. Binding of complex **1** to lysozyme, however, resulted in only a marginal increase in its emission intensity. This is not surprising since lysozyme has a less hydrophobic region than the albumins. To understand the effect of albumin on the lifetime of the excited state of complex **1**, emission decay of the complex was monitored in the presence and absence of BSA (Figure 3). From the emission decay profile, the excited-state lifetime of the complex was estimated to be 1.89 μs in the presence of BSA.

Unlike in the case of BSA and lysozyme, the emission intensity of complex **1** decreases on addition of increasing

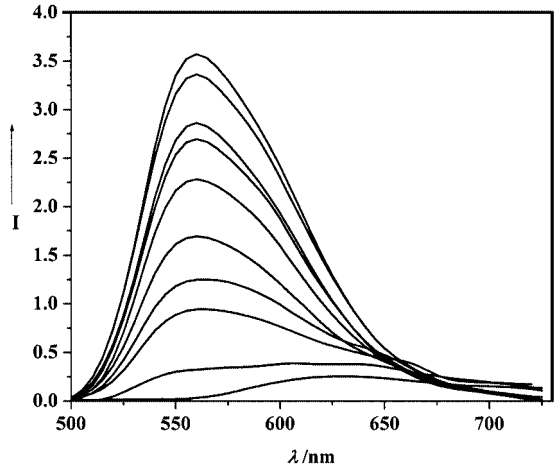

Figure 2. Emission spectra of **1** (10 μM) in the presence of BSA (0–5 μM) (λ_{ex} = 370 nm; pH 7.0).

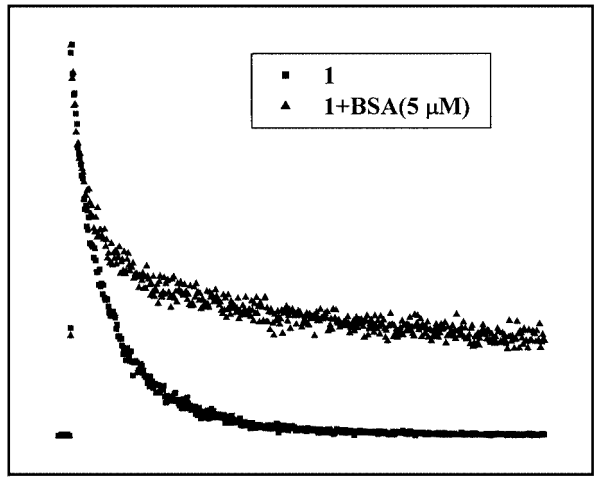

Figure 3. Decay profile of **1** (5 μM) in the absence and presence of BSA (5 μM) (298 K; pH 7.0).

amounts of hemoglobin (Figure 4). In hemoglobin protein, the hydrophobic pocket is occupied by the heme. If complex **1** binds to hemoglobin near the vicinity of heme, one can expect fluorescence resonance energy transfer (FRET) from complex **1** to the heme. This phenomenon of FRET will lead to quenching of the emission of **1** upon binding to hemoglobin. A careful examination of the crystal structure of hemoglobin shows that two sulfur-containing amino acids Met32 and Cys104 in subunit C are at a distance of 0.9 and 1.3 nm from the hydrophobic region where heme is present. Hence, binding of platinum(II) complex to these two sulfur sites will place complex **1** at the appropriate distance from heme for fluorescence energy transfer from **1** to the heme. As platinum(II) has a high affinity for sulfur,[12] complex **1** can be expected to bind to one of these two sulfur-containing amino acids of subunit C, resulting in the observed phenomenon of resonance energy transfer to heme.

In order to support the binding of complex **1** to the sulfur residues, we carried out the absorption titration of com-

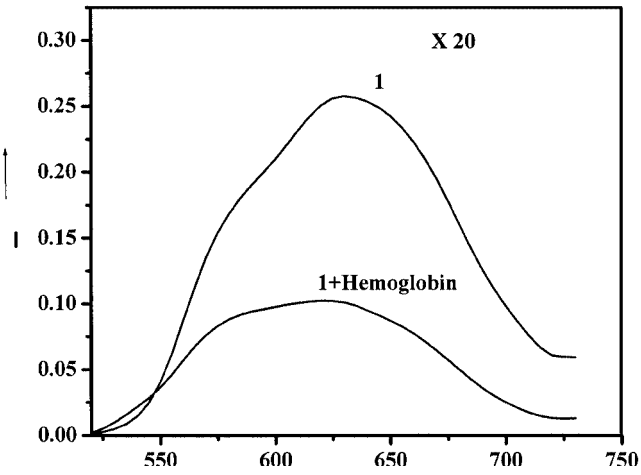

Figure 4. Emission spectra of **1** (50 μM) in the absence and presence of hemoglobin (5 μM) (λ_{ex} = 370 nm; 298 K, pH 7.0).

plex **1** with L-cysteine and L-methionine. Upon addition of increasing amounts of L-cysteine from 0 to 5 μM, the MLCT band of complex **1** shifted towards lower wavelength with the appearance of a new absorption band at 349 nm (Figure 5). The binding constant was determined from the following equation

$$[AA]/(\varepsilon_a - \varepsilon_f) = [AA]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_b - \varepsilon_f)$$

where [AA] is the concentration of amino acid and ε_a, ε_f, and ε_b correspond to A_{obsd}/[Pt], the molar extinction coefficient of the free platinum(II) complex, and the extinction coefficient for the platinum(II) complex in the fully bound form, respectively. A plot of [AA] vs. [AA]/($\varepsilon_a - \varepsilon_f$) gives K_b as the ratio of the slope to the intercept. The binding constant (K_b) was found to be $(3.3 \pm 0.2) \times 10^5$ M^{-1}. However, in the presence of L-methionine, there is no change in the absorption spectrum of complex **1**. The spectral titration

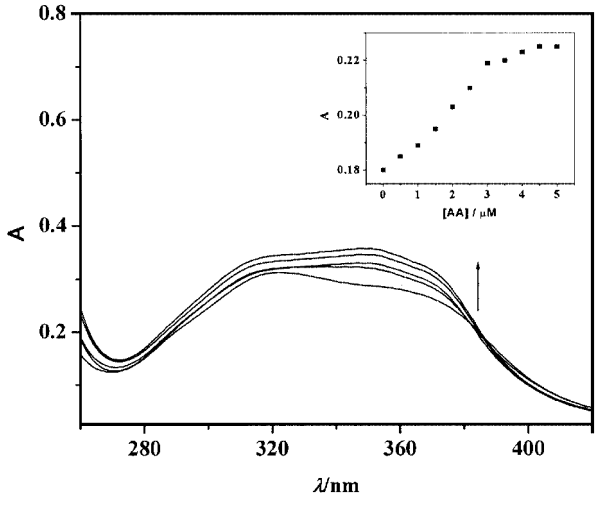

Figure 5. Absorption spectra of complex **1** (5 μM) in the absence and presence of L-cysteine (0–5 μM). Inset: plot of [AA] vs. absorbance at 349 nm.

studies reveal that [Pt(bzimpy)Cl]$^+$ binds more strongly to L-cysteine than to L-methionine. Hence, it can be concluded that complex **1** binds to Cys104 in the subunit C of hemoglobin.

To conclusively establish that complex **1** indeed binds to the hydrophobic regions of the protein, urea-unfolding experiments were carried out. Initially, the emission intensity of **1**-BSA adducts increases significantly with an increase in urea concentration and reaches a maximum at a urea concentration of 4.5 M. No further change in the emission intensity of the **1**-BSA adduct is observed with an increase in urea concentration up to 5 M. At 6 M urea, the emission intensity is the same as that of the native **1**-BSA adduct in the absence of urea. Beyond 6 M urea, however, there is a drastic decrease in the emission intensity of the adduct (Figure 6). Since BSA is a polypeptide with three domains (I, II, and III) extended through helices, the initial increase in emission intensity of the **1**-BSA adduct could be due to tight helical twisting in domain II of the BSA structure. The lack of any decrease in the emission intensity of the adduct in the presence of 4.5–5 M urea is indicative of the retention of the native-like conformation of domain II at this urea concentration. The marked decrease in emission intensity beyond 6 M urea and complete quenching beyond 7 M urea reveals the unfolding of the polypeptide chains followed by separation of domains from each other, which results in loss of hydrophobicity. The results observed here are similar to those observed for bilirubin binding to domain II of the BSA structure.[13] These results confirm that the binding of complex **1** to BSA is through the domain II hydrophobic cavity.

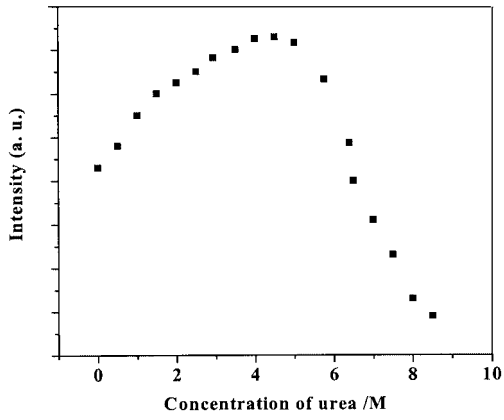

Figure 6. Unfolding of BSA incubated with **1** by urea (measured at 553 nm; λ_{ex} = 370 nm; 298 K).

In summary, we have shown that the present platinum(II) complex can be used as an extrinsic fluorophore for protein-binding studies. We hope that our findings will facilitate a significant development of metal-based sensors for biological applications. Further work is going on to study the uptake of this platinum(II) complex and its distribution in the cell, which can be monitored by fluorescence microscopy without addition of any external fluorophore.

Experimental Section

Materials: BSA (fraction V powder, lipid free, 66 kDa) and potassium tetrachloroplatinate(II) (K_2PtCl_4) were purchased from Sigma (St. Louis, MO, USA) and used as such without any further purification. 2,6-Pyridinedicarboxylic acid and *o*-phenylenediamine were purchased from Lancaster Chemicals. Tris(hydroxymethyl)aminomethane hydrochloride (Tris-HCl) was purchased from SRL Chemicals. All other reagents were of analytical grade. All the experiments were carried out at pH 7.0 at 25 °C.

Synthesis of [Pt(bzimpy)Cl]PF_6 (1): The ligand bzimpy was prepared as reported in the literature.[14] The platinum(II) complex was prepared by refluxing K_2PtCl_4 (0.48 g, 1 mmol) in DMSO for 2 h followed by the addition of bzimpy (0.311 g, 1 mmol). The resultant yellow precipitate was filtered and dried with diethyl ether. The yellow precipitate was dissolved in acetone and precipitated as its PF_6^- salt by addition of a saturated NH_4PF_6 solution. The yellow precipitate turns red on drying. Yield: 0.6 g (80%). MS: *m*/*z* = 541.5 $[M - Cl]^+$. $C_{19}H_{13}ClF_6N_5PPt$: calcd. C 33.23, H 1.91, N 10.2; found C 32.91, H 1.85, N 10.12. ^1H NMR [(D_6)DMSO]: δ = 8.32 (m, 1 H), 8.05 (d, 2 H), 8.02 (d, 2 H), 7.62 (d, 2 H), 7.33 (t, 2 H), 7.29 (t, 2 H) ppm.

Studies on the Interaction of the Platinum(II) Complex with BSA

Spectroscopic Measurements: All absorption spectra were measured with a Perkin–Elmer Lambda 35 double-beam spectrophotometer. To understand the binding of L-cysteine and L-methionine to complex **1**, the absorption spectra of complex **1** (5 μM) was monitored as a function of concentration of the two amino acids (0–5 μM). The concentration of L-cysteine and L-methionine was varied until there was no appreciable change in the spectrum of the metal complex.

Emission Studies: Steady-state emission studies of the platinum(II) complexes were carried out by varying the concentration of BSA ($0–5 \times 10^{-6}$ M) while keeping the concentration of metal complex constant. The metal complex was excited at 375 nm and emission was monitored between 500 and 850 nm. The binding constant of complex **1** with BSA was determined from the Scatchard plot.[15]

Time-resolved emission for the complex was determined with a picosecond-laser-excited TCSPC spectrometer. The excitation source was a tunable Ti-Sapphire laser (Tsunami Spectrophysics, USA) with a pulse width of less than 2 ps and a repetition rate of 82 MHz. Samples were excited at 370 nm and the emission was monitored with an MCP-PMT (Hamamatsu-C 4878) detector. The decay traces were deconvulated by using a non-linear least-squares analysis with IBH software.

Acknowledgments

V. G. V. thanks the CSIR for a research fellowship. The authors thank the National Center for Ultrafast Processes, Taramani, Chennai, for providing the facilities to carry out time-resolved emission experiments.

Mono and Bridged Azolium Picrates as Energetic Salts

Chuan-Ming Jin,[a] Chengfeng Ye,[a] Crystal Piekarski,[a] Brendan Twamley,[a] and Jean'ne M. Shreeve*[a]

Keywords: Azides / Heats of formation / Ionic liquids / Materials science / Nitrogen heterocycles

The energetic mono and bridged imidazolium, triazolium and tetrazolium picrates **7**–**10**, **14**, and **16**, the dipicrates **23**, **25**, and **26** and the dinitrates **24**, and **27** were synthesized by the quaternization of azolium derivatives (**1**, **2**, **13**, **15**, **19** and **20**) with picric acid and nitric acid or by metathesis of the corresponding quaternary salts (**3**, **6**, **21** and **22**) with silver picrate or silver nitrate. The structures of **14** and **16** were determined by single-crystal X-ray diffraction analysis confirming quaterization on the triazolium and tetrazolium rings. Their physical and thermodynamic properties were determined. In some cases, the salts are thermally stable to ca. 300 °C and they exhibit densities averaging ca. 1.6 g/cm^3. Nearly all have positive heats of formation with the highest calculated value, $\Delta_f H^o_m$ = 611.6 kJ/mol, found for 3-azido-1,4-dimethyl-1,2,4-triazolium picrate (**10**).

Introduction

Energetic materials are used extensively for both civilian and military applications. There are ongoing research programs worldwide to develop such new materials with higher performance or enhanced insensitivity to thermal or shock insults. In recent years, the synthesis of energetic, heterocyclic compounds have attracted considerable interest. Heterocycles generally have higher heats of formation, density, and oxygen balance than their carbocyclic analogues.[1–3]

Recently, a new class of energetic compounds containing a large number of nitrogen atoms has been studied. These high-nitrogen compounds form a unique class of energetic materials whose energy is derived from their very high positive heats of formation rather than from the combustion of the carbon backbone or the ring/cage strain. The high heat of formation is directly attributable to the large number of inherently energetic N–N and C–N bonds.[4–8]

Most often molecular compounds have been utilized in an energetic role, whereas we and others have recently demonstrated that heterocyclic-based energetic, low-melting salts appear to be of considerable value in this area.[9–13] Energetic materials that are salt-based often possess advantages over non-ionic molecules since these salts tend to exhibit lower vapor pressures and higher densities than their atomically similar non-ionic analogues. Five-membered nitrogen-containing heterocycles are traditional centers for energetic materials, and considerable attention is currently focused on energetic compounds based on azoles.[14,15] *N*-Aminoazolium salts are a family of compounds of increasing interest, since these substituted hetero rings when paired with nitrate or perchlorate anions form new, highly energetic salts.

We have synthesized energetic salts based on *N*-aminoazoles with concomitant determination of structural and thermal properties.[16–18] Increasing the number of nitrogen atoms in heterocycles results in considerable gain in the standard enthalpy of formation in the resulting compounds. The enthalpy criteria of energetic chemical systems are governed by their molecular structure. In moving from imidazole ($\Delta H_f°_{(cryst)}$ = 58.5 kJ/mol)[19] to 1,2,4-triazole ($\Delta H_f°_{(cryst)}$ = 109 kJ/mol) to tetrazole ($\Delta H_f°_{(cryst)}$ = 237.2 kJ/mol),[20] the variation in the trend of the heats of formation is increasingly positive The *N*-amino group behaves as an electron-withdrawing group in high-nitrogen heterocycles.[9]

High-nitrogen compounds containing polyazides possess even more positive heats of formation because their energy content rapidly increases with the number of energetic azido groups in the molecule. However, they tend to be extremely sensitive to spark, friction, and impact as well as to heat.[8] We have reported new energetic salts obtained by the quaternization of azido or nitro derivatives of imidazole, 1,2,4-triazole and substituted derivatives of tetrazole with nitric or perchloric acid or with iodomethane followed by metathesis reaction with silver nitrate or silver perchlorate.[17] While these compounds with azide-containing triazolium cations (nitrate or perchlorate anion) do exhibit marginally high positive heats of formation, recently reported molecular azides of triazine are considerably more energetic with considerably higher heats of formation, e. g., 2,4,6-triazido-1,3,5-triazine (+1053 kJ/mol) and 4,4′,6,6′-tetra(azido)azo-1,3,5-triazine (+2171 kJ/mol).[8]

 DOI: 10.1002/ejic.200500472

Another area of increasing interest is based on high-energy salts where both the cation and anion are high-nitrogen species.[8,21,22] This is a relatively new area where only a very few such compounds have been studied.[5,10b,22c] One of the more recent and exciting developments in high energy dense materials is salts with high-nitrogen content and with very high positive heats of formation which show remarkable insensitivity to electrostatic discharge, friction, and shock.

We have now extended our studies to salts with energetic mono and bridged azolium cations with picrate as the anion, and have determined their physical and thermodynamic properties. While the typical anions used in these systems are for example, nitrate, perchlorate, and dinitramide, until now their picrate analogues have not been synthesized. In our work, the physical and energetic properties of new picrate salts are compared with those of the salts formed with the former anions. The new salts reported here contain mono or dications and consequently, are either mono or dipicrates. These picrate salts combine an oxygen-rich anion with a high-nitrogen azolium cation thus providing the opportunity for high positive heats of formation. Although anhydrous picric acid tends to be unstable, and its impact and friction sensitivities are higher than that of TNT, many organic and inorganic picrate salts have been created and studied;[23] however, none consists of diazolium cations combined with picrate. The successful syntheses and characterization of these rather stable salts with moderately high positive enthalpies of formation are now reported.

Results and Discussion

Energetic salts, some of which are ionic liquids, have been prepared that contain substituted azolium cations (e. g., imidazolium, triazolium and tetrazolium) in combination with usually small energetic inorganic anions [e. g., NO_3^-, ClO_4^-, and $N(NO_2)_2^-$].[9,10c,16–18,24] Now we have replaced these simple inorganic species by introducing picrate as the energetic anion.

Triazolium or substituted triazolium picrates were prepared either by direct reaction with picric acid in methanol (**7**, **8**) or metathesis with silver picrate after quaternization of the parent triazole with methyl iodide (**9**, **10**) (Scheme 1). The triazolium iodides, **3** and **6**, were prepared based on the literature.[17,25] Although earlier we were able to quaternize azido-substituted triazoles with concentrated nitric or perchloric acid,[17] the analogous reactions of **4** and **5** with picric acid failed under a variety of conditions. This likely arises from the lower acidity of picric acid (pK_a of 0.3) compared to nitric acid (pK_a of –1.44) and with the concomitant decrease in the basicity of the triazolium ring because of the presence of the azide group. However, 3-azido-1,4-dimethyl-1,2,4-triazolium picrate (**10**) can be readily obtained from **6** which was metathesized with silver picrate (Scheme 1).

In their ^1H NMR spectra, all of the compounds **3**, **6**, **7**, and **8**–**10**, with the exception of **12** (shift at δ = 8.3 ppm), have chemical shifts downfield from δ = 9.3 ppm. The latter shifts indicate that these compounds were comprised of quaternized triazolium rings. However, quaternization of 3-amino-1,2,4-triazole (**11**) did not occur at the N-4 position in the triazolium ring, but rather compound **12** resulted from the ready protonation of the 3-amino group (Scheme 1). This same phenomenon was observed when concentrated nitric or perchloric acid was used, that is, a substituted ammonium salt ($RNH_3^+X^-$, X = NO_3^-, ClO_4^-) was formed analogous to **12**.

However, 4-amino-1,2,4-triazole (**13**) was readily quaternized with picric acid in methanol by protonating the ring at N-1 to give the triazolium salt **14** in high yield (Scheme 2). This is supported by signals at δ = 9.5 ppm and δ = 144.1 ppm in the ^1H NMR and ^{13}C NMR spectra, respectively. Additionally, the single-crystal X-ray structure corroborates the quaternization at N-1 (Figure 1).

These results are consistent with the literature where *N*-amino groups in nitrogen-rich heterocycles were quaternized in the ring, not at the *N*-amino group.[9,16,26] This apparently arises because the *N*-amino group acts as an electronegative, electron-withdrawing group in these triazolium systems in contrast to the cases where the triazolium derivatives contain *C*-amino group (s). However, surprisingly, quaternization of 5-amino-tetrazole (*C*-amino group)

Figure 1. (a) 30% Probability thermal ellipsoid plot of **14**. Only one conformation for the disordered NO_2 group is shown. Hydrogen atoms are shown but are unlabelled for clarity. (b) A packing diagram of **14**. Dashed lines indicate hydrogen bonding. Zig-zag sheets of triazolium cations tie the rows of picrates into a crosslinked 3D array.

(**15**) (Scheme 2) occurs at the N-4 position in the tetrazolium ring in high yield, and not at the amino group at C-5, to form the salt 5-amino-1,2,4-tetrazolium picrate (**16**). The single-crystal X-ray structure of compound **16** is given in Figure 2.

There is a paucity of energetic salts with bridged cations.[5] In order to examine the physical and thermodynamic properties of mono and diazolium salts containing a common anion, bridged bis(imidazolium) or bis(triazolium) methane compounds were obtained from the reaction of imidazole or triazole with dibromo- or dichloromethane under basic conditions and in the presence of a phase-transfer catalyst (Scheme 3).[27] These bridged azolium species, **19** and **20**, were either: 1) Reacted with picric or nitric acid to form the picrate **23**, or the nitrate **24**; however, compound **20** did not react with picric acid to give the corresponding dipicrate; or 2) quaternized with methyl iodide to give compound **21** and **22**,[27c] which were subsequently metathesized with silver picrate or nitrate forming compound **25**, **26** and **27**. Each of the picrate or nitrate salts was isolated in a yield >88%. Compound **27** is readily soluble in water, but **23**–**26** are not miscible with water. In general, all of these new picrate and nitrate salts are hydrolytically stable.

Physical characteristics and thermochemical properties of the new energetic ionic salts are given in Table 1. The effectiveness of an energetic compound is a function of many properties. Density is crucial since the more grams (mol) of material that can be loaded in a given space, the more efficient the energetic species is. High oxygen balance and a positive, Scheme 3, heat of formation increase the sensitivity of the material as well as performance since the specific impulse is proportional to the square root of heat of formation. For example, the heat of formation is 1075 kJ/mol, the density, 1.60 g/cm^3, and the oxygen balance, –56% are reported for an highly energetic salt, triaminoguanidinium 5,5′-azobis(1*H*-tetrazolate).[8]

Most of the picrates have good thermal stabilities ranging between 176 °C (**10**) and 313 °C (**25**) (TGA), melting points between 91 °C (**8**) and 215 °C (**23**) (DSC), and relatively high densities between 1.48 (**10**) and 1.85 (**16**) g/cm^3 (gas pycnometer). In fact, the latter approaches the density of HMX at 1.91 g/cm^3. However, in general, the bridged azolium picrates are somewhat more stable thermally than their monocationic picrate analogues as shown by their decomposition temperatures, e. g., **26**, T_d = 242 °C, is higher than **8**, T_d = 185 °C. Also, the picrates are more thermally stable than nitrates or perchlorates, e. g., 4-amino-1,2,4-triazolium picrate (**14**) decomposes at 228 °C compared with the nitrate and perchlorate which decompose at 181 °C and 208 °C, respectively.[18]

Similarly, compound **26** (picrate) decomposes at 242 °C, and compound **27** (nitrate) at 162 °C. However, while triazolium picrate (**7**) is thermally unstable at 196 °C, and the nitrate is stable only upto 182 °C, the perchlorate decomposes at 285 °C.[9] Compound **27**, a nitrate salt, exhibits properties of an energetic ionic liquid (T_g –15 °C). In general, the nitrate salt with same azolium cation has a lower

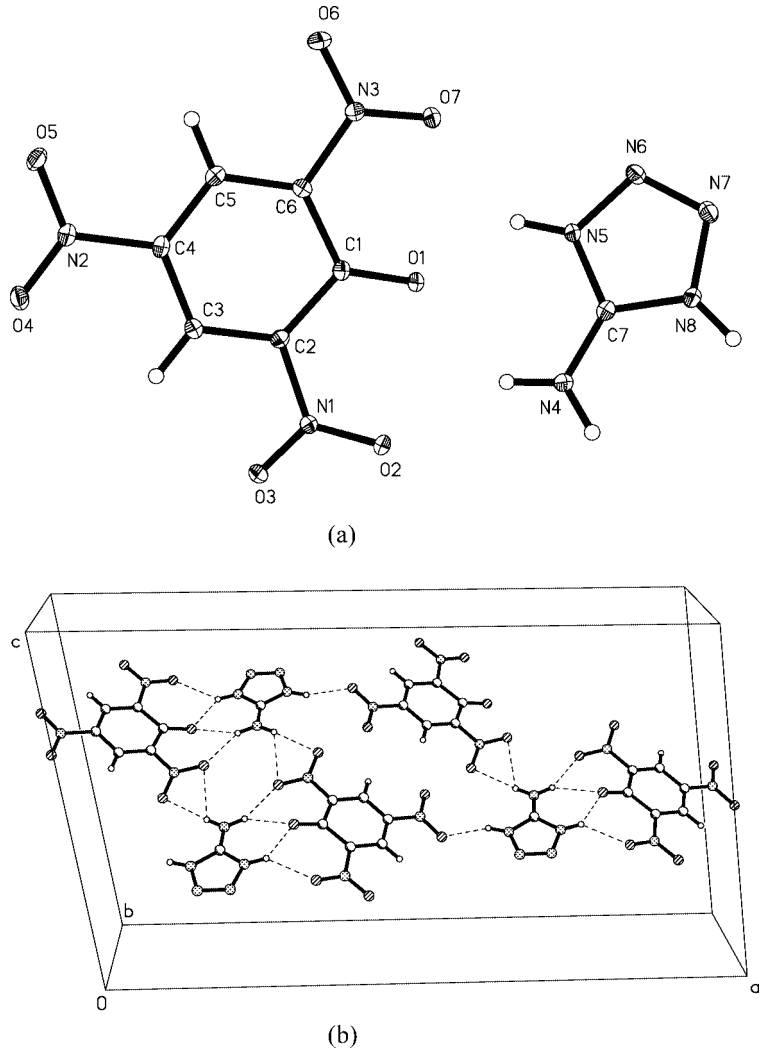

Figure 2. (a) 30% Probability thermal ellipsoid plot of **16**. Hydrogen atoms are shown but are unlabelled for clarity. (b) A packing diagram of **16**. Only one sheet section is shown. Hydrogen bonding is indicated by dashed lines.

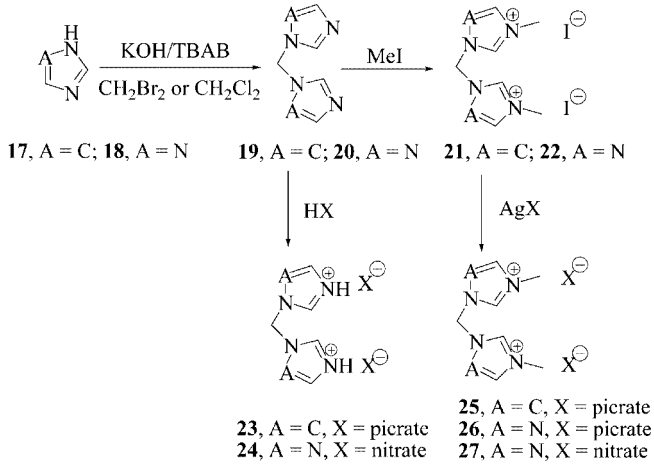

Scheme 3.

melting point than its picrate or perchlorate; e. g. compound **27** is liquid and compound **26** with T_m 216 °C. 4-Amino-1,2,4-triazolium picrate (**14**) with T_m = 197 °C is higher than the nitrate with T_m = 69 °C.[18] Unfortunately, we did not obtain ionic liquids based on picrate; only 1-methyl-1,2,4-triazolium picrate (**8**) with a melting point 91 °C falls into the ionic liquid class. The calculated oxygen balance values range from –36 to –93% which are reasonably close to those for TAG-AT (–73%), TNT (–74%) and picric acid (–43%) (Table 1) and slightly more negative than for HMX (–21%) and RDX (–22%). The molar enthalpy of formation for each sample, e. g., for compound **26**, was derived from the constant volume combustion energy using the following equation:

$\Delta_c H^o_m = \Delta_c U_m + \Delta nRT$ [$\Delta n = \sum n_i$ (products, g) – $\sum n_i$ (reactants, g)]

where $\sum n_i$ is the total molar amount of the gases in products or reactants.

The calculated heat of formation was based on the following reaction:

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[C_7H_{16}N_{12}O_{14}]^+[C_{12}H_4N_6O_{14}]^-$ (s) + 13/2 O_2 (g) → 19/2 CO_2 (g) + 8 H_2O (l) + 6 N_2 (g)

$\Delta_f H^o_m\{[C_7H_{16}N_{12}O_{14}]^+[C_{12}H_4N_6O_{14}]^-, (s)\} = \{19/2\Delta_f H^o_m[CO_2, (g)] + 8\Delta_f H^o_m[H_2O, (l)]\} - \Delta_c H^o_m\{[C_7H_{16}N_{12}O_{14}]^+[C_{12}H_4N_6O_{14}]^-, (s)\}$

Using the above formula and the literature values for the standard molar enthalpies of formation of CO_2 (g) and H_2O (l) [$\Delta_f H^o_m$ [CO_2, (g)] = –393.5 kJ/mol, $\Delta_f H^o_m$ [H_2O, (l)] = –285.8 kJ/mol],[28] $\Delta_f H^o_m$ for compound **26** was calculated to be 520.4 kJ/mol. All of the quaternary salts have positive heats of formation (ranging from 177.3 kJ/mol to 611.4 kJ/ mol) except for the imidazolium picrate derivatives **23** and **25** with heats of formation at –213.6 kJ/mol and –538.1 kJ/mol, respectively, and 1,1′-methylbis(4-methyltriazolium) dinitrate, and compound **27** with the heat of formation at –195.7 kJ/mol. Not surprisingly, picrate salts have higher heats of formation than the nitrate analogs, for example, $\Delta_f H^o_m$ of compound **26** is 520.4 kJ/mol and that of compound **27** is –195.7 kJ/mol; 4-amino-1,2,4-triazolium

picrate (**14**) at 468.8 kJ/mol is significantly more positive than the nitrate and the perchlorate salts at –109.7 and 298 kJ/mol, respectively.[17] Not unexpectedly 3-azido-1,4-dimethyl-1,2,4-triazolium picrate (**10**) with $\Delta_f H^o_m$ = 611.6 kJ/mol exhibits the most positive heat of formation in this group of energetic salts.

X-ray Crystallography

Compound **14** crystallizes in an orthorhombic space group, *Pbcn*, and compound **16** in the monoclinic *C*2/*c* space group. Both have eight formula units in the cell and in spite of the different space groups, display similar characteristics. Both consist of discrete crystallographically independent picrate anions and 4-amino-triazolium (**14**) or 5-imino-tetrazolium (**16**) cations. The protonation in compound **14** (part a in Figure 1), has occurred on one of the ring nitrogen atoms, N8, instead of the amino group. This NH^+ is involved in an asymmetric bifurcated hydrogen bond; N8···O1, 2.653(1) and N8···O7a, 2.950(5) Å. The double bonds appear to be localized in the triazolium in spite of the protonation, C7–N8, 1.297(2) Å and N9–C10, 1.296(2) Å. The dihedral angle between the triazolium group and the picrate is 78.4°. The packing diagram (part b in Figure 1) is more complex with rows of picrate anions hydrogen-bonded together by zig-zag sheets of triazolium cations into a cross-linked array. In **16**, the tetrazole double bonds also appear distinct, with N6–N7, 1.269(1) Å and an exocyclic amino C7–N4, 1.310(1) Å, (part a in Figure 2). The picrate and tetrazolium species have a much shallower angle to each other (dihedral angle of 21.9°) compared to **14**. The orientation of the tetrazolium cation to the anion also leads to an asymmetric bifurcated hydrogen bond between N5···O1, 2.624(1) Å, and N5···O7, 2.873(1) Å. Both amino hydrogen atoms are also involved in bifurcated hydrogen bonding, which help extend the system into isolated buckled sheets (part b in Figure 2). Although there are many picrate salts in the literature, there are relatively few associated with triazoles and tetrazoles. Only two of the four examples of each[29–32] display similar asymmetric bifurcated bonding between the tri/tetrazolium and the picrate (N···O, 2.62, 2.64 Å and 2.85, 2.90 Å). Crystallographic data for compounds **14** and **16** were listed in Table 2.

Conclusions

In summary, mono and bridged azolium picrate and nitrate salts were synthesized and their physical and thermochemical properties compared. The thermal stabilities of the salts are dipicrates > picrates > perchlorates > nitrates while the densities are found to average ca. 1.60 g/cm^3. Although it is not possible to quaternize 3-*C*-aminotriazole, the 4-aminotriazole easily reacted at N-1. In contrast, the 5-aminotetrazole (C-5) was readily quaternized at N-4. Their structures were confirmed by single-crystal X-ray analysis. The heats of formation values for picrates are more positive than for analogous nitrates and perchlorates. Oxygen balance values for the mono and bridged azolium picrates and dipicrates fall in the range of many common energetic materials.

Experimental Section

Caution: Although we have not experienced any problems in handling these compounds, their shock and impact sensitivity has not been determined. They should be handled with extreme care.

General Methods: The chemicals were obtained commercially. Silver picrate was prepared based on the literature.[33] A standard Schlenk line system was used for various manipulations. ^{1}H and ^{13}C NMR spectra were recorded on a spectrometer operating at 300 and 75 MHz, respectively, using [D$_6$]DMSO as solvent unless otherwise indicated. Chemical shifts are reported in ppm relative to TMS. DSC data were recorded by heating from 20 °C to 400 °C at 10 °C/min using a differential scanning calorimeter equipped with auto-cool and calibrated using indium. Thermogravimetric analysis (TGA) measurements were made by heating samples at 10 °C/min from 20 °C to 450 °C in a dynamic nitrogen atmosphere. Densities of solid salts were measured at room temperature using a gas pycnometer. The heat of combustion was determined using a semimicro oxygen bomb calorimeter. Elemental analyses were performed commercially. Electrospray mass spectra were recorded using Micromass LCT equipment.

Crystallography: Crystals of compound **14** and **16** were removed from the flasks. A suitable crystal was selected, attached to a glass fiber and placed in the low-temperature nitrogen stream. Data for **14** were collected at 297(2) K and for **16** were collected at 86(2) K using a Bruker/Siemens SMART APEX instrument (Mo-K_α radiation, λ = 0.71073 Å) equipped with a Cryocool NeverIce low temperature device. Data were measured using omega scans of 0.3° per frame for 5 seconds, and a hemisphere of data was collected for compound **14**. A total of 1471 frames were collected with a final resolution of 0.81 Å. The first 50 frames were recollected at the end of data collection to monitor for decay. And a full sphere of data was collected for **16**. A total of 2400 frames were collected with a final resolution of 0.77 Å. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART software[34] and refined using SAINTPlus[35] on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPlus software. Absorption corrections were applied using SADABS.[36] The structure was solved by direct methods and refined by least-squares method on F^2 using the SHELXTL program package.[37] The structure was solved in the space group *Pbcn* (no. 60) for **14** and *C*2/*c* (no. 15) for **16** by analysis of systematic absences. CCDC-271202 (for **14**) and CCDC-271203 (for **16**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

1,2,4-Triazolium Picrate (7): In 20 mL methanol were mixed 1,2,4-triazole (0.113 g, 1.6 mmol) and picric acid (0.373 g, 1.6 mmol). The mixture was stirred for 10 hours at 25 °C, and the solvent was removed under reduced pressure. The solid was washed with water (20 mL) and acetone (20 mL) to yield a dark-yellow solid **7** (0.453 g) in 95% yield. M.p. 169 °C. IR (KBr): $\tilde{\nu}$ = 3153, 3068, 2887, 1607, 1571, 1350, 1203, 628 cm^{-1}. ^{1}H NMR: δ = 11.8 (br. s, 2 H), 9.34 (s, 1 H), 9.32 (s, 1 H), 8.60 (s, 2 H) ppm. ^{13}C NMR: δ = 160.8, 143.3, 141.9, 125.3, 124.5 ppm. $C_8H_6N_6O_7$ (298.1): calcd. C 32.23, H 2.03, N 28.19; found C 31.99, H 2.06, N 28.43.

1-Methyl-1,2,4-triazolium Picrate (8): The procedure was the same as for compound **7** using **2** (0.083 g, 1.0 mmol) and picric acid (0.229 g, 1.0 mmol) at 25 °C for 8 hours. The residue was washed with water (20 mL) and dichloromethane (20 mL) to leave a light-yellow solid **8** (0.291 g) in 93% yield. M.p. 91 °C. IR (KBr): $\tilde{\nu}$ = 3143, 3074, 1608, 1538, 1322, 1274, 664 cm^{-1}. ^1H NMR ([D_6]acetone): δ = 9.42 (s, 1 H), 8.88 (s, 2 H), 8.66 (s, 1 H), 8.18 (br. s, 1 H), 4.21 (s, 3 H) ppm. ^{13}C NMR δ = 158.2, 145.4, 142.1, 140.6, 130.2, 124.9, 3.69 ppm. $C_9H_8N_6O_7$ (312.2): calcd. C 34.62, H 2.58, N 26.92; found C 34.25, H 2.61, N 27.26.

1,4-Dimethyl-1,2,4-triazolium Picrate (9): Silver picrate (0.336 g, 1.0 mmol) was added to **3** (0.225 g, 1.0 mmol) in 20 mL DMF to give a yellow precipitate. The mixture was filtered and solvent was removed from the filtrate under vacuum to leave a yellow solid. The latter was recrystallized from methanol and acetone (1:2) to give a pure yellow solid **9** (0.287 g) in 88% yield. M.p.141 °C. IR (KBr): $\tilde{\nu}$ = 3081, 2953, 1634, 1561, 1337, 1278, 786, 634 cm^{-1}. ^1H NMR δ = 9.97 (s, 1 H), 9.08 (s, 1 H), 8.58 (s, 2 H), 4.06 (s, 3 H), 3.89 (s, 3 H) ppm. ^{13}C NMR δ = 160.9, 145.3, 143.4, 141.8, 125.3, 124.4, 38.6, 34.0 ppm. $C_{10}H_{10}N_6O_7$ (326.2). MS (ESI): (+v e): *m*/*z* = 97.9 [M – Picrate] $^+$; (–v e): *m*/*z* = 227.9 [picrate] $^-$.

3-Azido-1,4-dimethyl-1,2,4-triazolium Picrate (10): The procedure was as used for **9** using **6** (0.18 g, 0.68 mmol) and silver picrate (0.224 g, 0.68 mmol) in 20 mL DMF to form a yellow solid. After removal of solvent, the residue was washed with acetone (30 mL) to leave a dark-yellow solid **10** (0.227 g) in 91% yield. M.p.106 °C. IR (KBr): $\tilde{\nu}$ = 3194, 3095, 2183, 1636, 1550, 1327, 1282, 702, 615 cm^{-1}. ^1H NMR: δ = 9.83 (s, 1 H), 8.59 (s, 2 H), 4.02 (s, 3 H), 3.62 (s, 3 H) ppm. ^{13}C NMR: δ = 161.3, 150.8, 144.1, 142.3, 125.6, 124.7, 39.5, 32.6 ppm. $C_{10}H_9N_9O_7$ (367.2): calcd. C 32.71, H 2.47, N 34.33; found C 32.45, H 2.40, N 33.50.

3-Amino-1,2,4-triazolium Picrate (12): The procedure was as used for **7** from **11** (0.084 g, 1.0 mmol) and picric acid (0.229 g, 1.0 mmol) in 40 mL methanol for 3 h at 45 °C to give a yellow powder **12** (0.298 g) in 95% yield. M.p. 235 °C. IR (KBr): $\tilde{\nu}$ = 3450, 3344, 3098, 1701, 1641, 1551, 1337, 1276, 708, 603 cm^{-1}. ^1H NMR: δ = 8.60 (s, 2 H), 8.32 (s, 1 H), 8.05 (br. s) ppm. ^{13}C NMR: δ = 160.9, 150.8, 141.9, 139.2, 125.3, 124.4 ppm. $C_8H_7N_7O_7$ (313.2): calcd. C 30.68, H 2.25, N 31.31; found C 30.52, H 2.11, N 31.89.

4-Amino-1,2,4-triazolium Picrate (14): Procedure was as used for **12** from **13** (0.094 g, 1.1 mmol) and picric acid (0.26 g, 1.1 mmol) at 45 °C for 6 h to give a yellow solid. Recrystallization from methanol (20 mL) to gave pure **14** (0.317 g) in 92% yield. M.p. 197 °C. IR (KBr): $\tilde{\nu}$ = 3363, 3260, 3122, 2988, 1610, 1543, 1336, 1266, 710, 619 cm^{-1}. ^1H NMR: δ = 9.49 (s, 1 H), 9.48 (s, 1 H), 8.60 (s, 2 H), 6.26 (br. s) ppm. ^{13}C NMR: δ = 160.9, 144.1, 141.9, 125.3, 124.4 ppm. $C_8H_7N_7O_7$ (313.2): calcd. C 30.68, H 2.25, N 31.31; found C 30.64, H 2.09, N 32.36.

5-Aminotetrazolium Picrate (16): Procedure was as used for **8** from **15** (0.124 g, 1.5 mmol) and picric acid (0.345 g, 1.5 mmol) in methanol (20 mL) at 50 °C for 12 h to form a yellow solid. Recrystallization from methanol and dichloromethane (1:2) produced pure **16** (0.424 g) in 90% yield. M.p. 147 °C. IR (KBr): $\tilde{\nu}$ = 3416, 3331, 3209, 2931, 1647, 1587, 1334, 1265, 734, 677 cm^{-1}. ^1H NMR δ = 8.60 (s, 2 H), 7.70 (br. s) ppm. ^{13}C NMR: δ = 160.8, 156.3, 141.9, 125.3, 124.4 ppm. $C_7H_6N_8O_7$ (314.2). MS (ESI): (+v e): *m*/*z* = 84.0 [M – Picrate – 2H] $^+$; (–v e): *m*/*z* = 227.9 [picrate] $^-$.

1,1′-Methylenebis(imidazolium) Dipicrate (23): Procedure was as for **7** from **19** (0.064 g, 0.5 mmol) and picric acid (0.229 g, 1.0 mmol) to give a yellow solid which was washed with acetone (10 mL) and dichloromethane (15 mL) to give a yellow powder **23** (0.288 g) in 95% yield. M.p. 215 °C. IR (KBr): $\tilde{\nu}$ = 3133, 3066, 1611, 1563, 1320, 1272, 709, 621 cm^{-1}. ^1H NMR: δ = 9.34 (s, 2 H), 8.60 (s, 4 H), 7.97 (s, 2 H), 7.74 (s, 2 H), 6.67 (s, 2 H) ppm. ^{13}C NMR: δ = 160.9, 141.9, 137.2, 125.3, 124.5, 121.6, 121.1, 58.0 ppm. $C_{19}H_{14}N_{10}O_{14}$ (606.4): calcd. C 37.63, H 2.33, N 23.10; found C 37.57, H 2.45, N 23.54.

1,1′-Methylenebis(triazolium) Dinitrate (24): Procedure was as for **7** from **20** (0.26 g, 2.0 mmol) and concentrated nitric acid (1.1 g, 70%wt) The solvent was removed in vacuo, the solid was washed with methanol (20 mL) to form a white solid **24** (0.536 g) in 97% yield. M.p. 153 °C. IR (KBr): $\tilde{\nu}$ = 3142, 3029, 1609, 1549, 1309, 1232, 715 cm^{-1}. ^1H NMR: δ = 10.22 (br. s), 9.25 (s, 2 H), 8.32 (s, 2 H), 6.78 (s, 2 H) ppm. ^{13}C NMR: δ = 150.6, 145.4, 60.0 ppm. $C_5H_8N_8O_6$ (276.2): calcd. C 21.75, H 2.92, N 40.37; found C 21.72, H 2.84, N 41.91.

1,1′-Methylenebis(3-methylimidazolium) Dipicrate (25): Procedure was as for **9** from **21** (0.13 g, 0.3 mmol) and silver picrate (0.2 g, 0.6 mmol) in 20 mL DMF to give a yellow solid. Recrystallization from methanol and acetone (1:3) gave pure **25** (0.172 g) in 90% yield. M.p. 184 °C. IR (KBr): $\tilde{\nu}$ = 3104, 3029, 1618, 1567, 1367, 1271, 734, 619 cm^{-1}. ^1H NMR: δ = 9.34 (s, 2 H), 8.60 (s, 4 H), 7.94 (s, 2 H), 7.79 (s, 2 H), 6.64 (s, 2 H), 3.91 (s, 6 H) ppm. ^{13}C NMR: δ = 160.7, 141.7, 137.9, 125.1, 124.4, 124.2, 121.9, 58.2, 36.2 ppm. $C_{21}H_{18}N_{10}O_{14}$ (634.4). MS (ESI): (+v e): *m*/*z* = 178.8 [M – Picrate] $^+$, 89 [M – 2 picrate] $^{2+}$/2; (–v e): *m*/*z* = 227.9 [picrate] $^-$.

1,1′-Methylenebis(4-methyltriazolium) Dipicrate (26): Procedure was as used for **9** from **22** (0.086 g, 0.2 mmol) and silver picrate (0.134 g, 0.4 mmol) to give an orange-yellow solid. Recrystallization from methanol (10 mL) gave pure **23** (0.114 g) in 89% yield. M.p. 216 °C. IR (KBr): $\tilde{\nu}$ = 3060, 1630, 1556, 1313, 1266, 705, 613 cm^{-1}. ^1H NMR: δ = 10.41 (s, 2 H), 9.29 (s, 2 H), 8.60 (s, 4 H), 7.19 (s, 2 H), 3.99 (s, 6 H) ppm. ^{13}C NMR: δ = 160.9, 146.6, 145.7, 141.9, 125.3, 124.3, 62.3, 34.7 ppm. $C_{19}H_{16}N_{12}O_{14}$ (636.4). MS (ESI): (+v e): *m*/*z* = 90.0 [M – 2 picrate] $^{2+}$/2; (–v e): *m*/*z* = 227.9 [picrate] $^-$.

1,1′-Methylenebis(4-methyltriazolium) Dinitrate (27): Compound **22** (0.189 g, 0.44 mmol) was mixed with silver nitrate (0.148 g, 0.88 mmol) in water (20 mL) to form a yellow precipitate. The suspension was filtered. The solvent was removed from the filtrate in vacuo to leave a colorless wax **27** (0.127 g) in 95% yield. M.p. –15.2 °C. IR (KBr): $\tilde{\nu}$ = 3116, 2986, 1637, 1588, 1352, 1233, 760, 617 cm^{-1}. ^1H NMR: δ = 10.46 (s, 2 H), 9.29 (s, 2 H), 7.17 (s, 4 H), 3.97 (s, 6 H) ppm. ^{13}C NMR: δ = 146.6, 145.9, 62.6, 34.6 ppm. $C_7H_{12}N_8O_6$ (304.2). MS (ESI): (+v e): *m*/*z* = 90.0 [M – 2NO_3^-]$^{2+}$/2; (–v e): *m*/*z* = 62.0 [NO_3] $^-$.

COVER PICTURE

The cover picture shows the structures of ferrocene-based phosphanyl-carboxylic acids that have been synthesized, characterized by various physicochemical methods, and further utilized as novel organometallic synthons, ligands in coordination compounds, and components of various catalytic systems over the last ten years that have passed since the discovery of the first representative. Some aspects of the chemistry of these and other related phosphanyl-ferrocenecarboxylic ligands addressed in the Microreview by P. Štěpnička on p. 3787 ff. are indicated in the centre of the cover picture, which is arranged in a chessboard-like manner to emphasize their close, and sometimes causal, relations and complementarity.

The Chemistry of Phosphanyl-ferrocenecarboxylic Ligands

Petr Štěpnička*[a]

Keywords: Ferrocene / Phosphanyl-carboxylic ligands / Coordination compounds / Catalysis / Phosphanes / Structure elucidation

The chemistry of ferrocene attracts considerable research interest even more than 50 years after its discovery, being stimulated mainly by applications of ferrocene ligands in catalysis. To the present day, the design of new ferrocene compounds ensued–sometimes by serendipity–the preparation of unprecedented coordination compounds and organometallic materials and, in the case of ferrocene compounds containing appropriate donor sets, led to numerous successful catalytic systems. This review provides a systematic survey of the chemistry of phosphanyl-ferrocenecarboxylic ligands as a specific class of hybrid ferrocene ligands that emerged about ten years ago, illustrating their synthesis, coordination behaviour, and catalytic applications. Attention is also paid to the structural chemistry of these functional ferrocene ligands. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

It has long been recognised that the introduction of a functional group into a ligand molecule changes its donor properties. Tuning ligand properties by means of the attached substituents proved exceptionally successful in the case of tertiary phosphanes. For instance, the application of carefully "tailored", functionalised phosphane ligands allows for the synthesis of coordination compounds with specific properties and helps in improving the efficacy and selectivity of transition metal mediated reactions.

Among the vast number of modified phosphane ligands reported to date, phosphanyl-carboxylic acids constitute a distinct class of ligands with unique properties.[1] Owing to the chemical properties of both heteroatom donor groups, phosphanyl-carboxylic donors possess great structural variability: the properties of the phosphane part can be varied considerably by changing the substituents at the phosphorus atom whereas the carboxy group can be converted into the corresponding carboxylate (pH-dependent coordination behaviour possible) or to numerous functional derivatives (typically esters and amides). This provides a relatively easy access to the families of related compounds as well as to entirely new types of ligands. Combination of the hard (carboxy) and soft (phosphane) donor groups[2] classify carboxy-phosphanes as typical examples of the so-called hybrid ligands.

The presence of the very different donor sites and chemical variability of the carboxy group enables phosphanyl-carboxylic ligands to coordinate to almost any metal ion and in diverse coordination modes. Soft metals commonly used in catalysis bind phosphanyl-carboxylic ligands predominantly as P-donors; coordination of the O-donor group results in relatively weaker dative bonds and may result in the

Petr Štěpnička was born in Liberec, Czech Republic in 1972. He studied inorganic chemistry at the Faculty of Science, Charles University in Prague (1990–1995), where he also received his Ph.D. for the work on phosphanyl-ferrocenecarboxylic acids with Professor Jaroslav Podlaha in 1998. After a postdoctoral fellowship at the Catalysis Research Center, Sapporo University in Japan with Professor Tamotsu Takahashi (1999), he returned to his alma mater and completed his habilitation in 2005, working in the field of phosphanyl-ferrocenecarboxylic ligands. His main research interests include the synthesis and studies on structural, coordination and catalytic properties of ferrocene compounds. He has authored more than 70 papers in reviewed journals.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

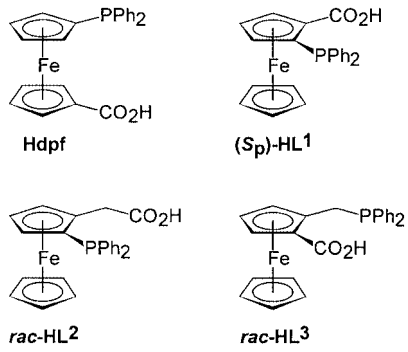
 DOI: 10.1002/ejic.200500485 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formation of hemilabile chelates.[1,3] This has a particular impact on the catalytic performance of these ligands since the metal–oxygen dative bonds can be cleaved by the substrate and formed again after the product of the catalytic process is expelled from the coordination sphere of the metal ion. Intermediate chelation makes the catalytic species more robust towards inhibitors and leads to stabilization of reaction intermediates, thus increasing the selectivity and stability of the catalytic system. Furthermore, the presence of carboxy groups increases the solubility of carboxy-phosphanes and their complexes in polar solvents, allowing us to perform some catalysed reactions even in water.[4] Representative examples of successful applications of phosphanyl-carboxylic ligands in catalysis include nickel-catalysed ethene oligomerisation (SHOP process),[5] palladium-catalysed co-dimerisation of ethene with styrene and alternating ethene/CO co-polymerization,[6] and rhodium-catalysed arene hydrogenation.[7] In addition, several chiral phosphanyl-carboxylic acids have been tested in palladium-catalysed enantioselective allylic alkylation.[8]

More recently, progress in organometallic chemistry initiated research on functionalised organometallic derivatives, particularly ferrocene compounds. During the studies involving ferrocene derivatives[9] it had been soon recognised that ferrocene donors differ in many respects from their "organic" counterparts. First, any ferrocene ligand is a coordination compound by itself and its coordination gives rise to multinuclear complexes. Second, the ferrocene molecule represents a conjugated, redox-active system.[9a,10] Monitoring the redox properties of the ferrocene unit within electronically communicating molecules may provide an insight into the nature of chemical interactions between the molecular parts, particularly changes accompanying the coordination of ferrocene donors. Besides, switching the oxidation state of the ferrocene unit may influence reactivity at the coordinated metal centre by changing donor properties of ferrocene ligands. Oxidation of the strongly electron-donating ferrocene moiety creates cationic ferricenium (and vice versa) whose electron-withdrawing character will be reflected by the considerably reduced donor ability of the ligand. Third, the ferrocene skeleton has a well-defined cylindrical shape. It is quite rigid against tilting of the cyclopentadienyl rings, the exception being some 1,1′-bridged derivatives (ferrocenophanes).[11] On the other hand, the energy barrier for the rotation of the rings along the molecular axis is usually very low.[12] This conformational flexibility is particularly important for 1,1′-disubstituted compounds, enabling a favourable arrangement of the donor groups.[13] Finally, ferrocene exhibits an exceptionally high chemical stability among organometallic compounds allowing many synthetic transformations to be performed. The basic synthetic methodology in ferrocene chemistry is well documented including many efficient routes to chiral compounds.[9]

The number of ferrocenylphosphanes bearing further functional groups has grown enormously over the past several decades and investigations into this area has led to the discovery of many useful ligands, some of them having practical importance. However, despite this effort, the field of mixed-donor ferrocene ligands is still strongly dominated by donors of N/P and P/P′ types that are accessible in a stereodefined form through diastereoselective metallation/functionalization of *C*-chiral ferrocene compounds {e.g., [1-(dimethylamino)ethyl]ferrocene, ferrocenyl-dihydrooxazoles, and -dioxanes} and subsequent functional group transformations.[9,14] Even though several potential ferrocene-containing O,P-donors have been reported in the literature, little attention has been paid to their coordination chemistry and catalytic applications.[14e]

Considering the effort devoted separately to the synthesis, coordination, and catalytic chemistry of phosphanyl-carboxylic ligands with purely organic backbones as well as to ferrocene ligands, it is somewhat surprising that ferrocene-containing phosphanyl-carboxylic acids had not been reported until 1996. Since then, a number of phosphanyl-ferrocenecarboxylic derivatives have emerged in the literature—however, as this review focuses exclusively on the synthesis, coordination chemistry, and catalytic and synthetic utility of phosphanyl-carboxylic acids derived from ferrocene, only compounds which have been studied as ligands and catalyst components are included. These comprise mainly—in chronological order—1′-(diphenylphosphanyl)ferrocenecarboxylic acid (Hdpf), its planarly chiral positional isomer, (S_p)-2-(diphenylphosphanyl)ferrocenecarboxylic acid [(S_p)-HL[1]], and homologues of the latter: *rac*-[2-(diphenylphosphanyl)ferrocenyl]acetic acid (*rac*-HL[2]) and *rac*-2-[(diphenylphosphanyl)methyl]ferrocenecarboxylic acid (*rac*-HL[3]; Scheme 1).



Scheme 1.

Compounds whose coordination and catalytic properties have not been studied systematically (albeit the compounds were often deemed "potentially useful ligands") and those serving just as reaction intermediates do not meet the scope of this review. Examples of such compounds (**1–4**) are shown in Scheme 2.[15] The same applies also for carboxy derivatives of 1,1′-diphosphaferrocene, e.g. to 3,3′,4,4′-tetramethyl-1,1′-diphosphaferrocene-2-carboxylic acid (**5**),[16] representing an alternative but still rather uncommon approach to phosphanyl-ferrocenecarboxylic donors.

1′-(Diphenylphosphanyl)ferrocenecarboxylic Acid (Hdpf)

Preparation and Further Synthetic Utilization

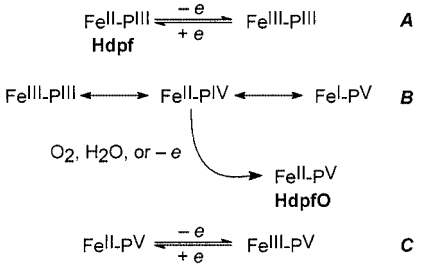
In the original synthesis of Hdpf (Scheme 3)[17] we made use of the ring opening in the strained ferrocenophane **6**[18] with phenyllithium to give 1′-(diphenylphosphanyl)lithioferrocene (**7**).[18b,19] In situ carboxylation of **7** with excess solid carbon dioxide and a subsequent acidification of the water-soluble part of the reaction mixture followed by recrystallization of the crude product afforded analytically pure Hdpf as an air-stable, rusty red-brown crystalline solid in typical yields around 80%. A similar methodology has been utilised for the synthesis[20] of 1′-(diphenylphosphanyl) ferrocenecarboxaldehyde (**8**).[21,22]

The acid was further converted into the corresponding phosphane oxide (HdpfO), methyl ester (Medpf), and reduced to alcohol **9** (Scheme 3).[20] A synthesis of Hdpf by stepwise metalation/functionalization of 1,1′-dibromoferrocene has been reported by Butler et al.[22]

In addition to the standard characterization, Hdpf and some related compounds were studied in detail by mass spectrometry[23] and by electrochemical methods.[17] In cyclic voltammograms in acetonitrile, Hdpf shows the expected one-electron oxidation to the corresponding ferricenium at $E^{\circ\prime}$ = +0.32 V vs. ferrocene/ferricenium reference, the shift to higher potential vs. the reference couple being in agreement with the electron-withdrawing nature of both substituents at the ferrocene unit (process **A** in Scheme 4). However, this electrochemical oxidation is followed by chemical complications, resulting in a pseudoreversible behaviour upon back-scan. The product of the following chemical steps was identified as the phosphane oxide HdpfO, an apparent product of the reactions between the electrogenerated ferricenium species and traces of oxygen and/or water. The presence of HdpfO is clearly reflected

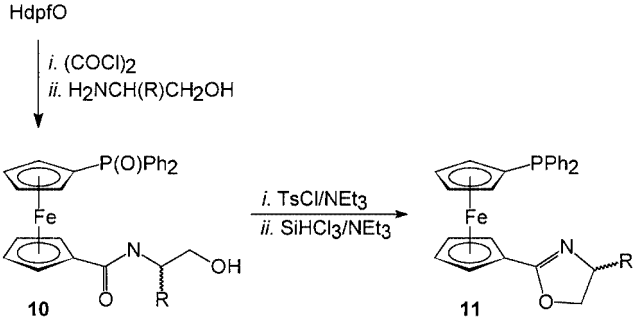
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

by an additional standard reversible ferrocene/ferricenium wave at more anodic potentials (**C** in Scheme 4). The overall behaviour of Hdpf in the anodic region can be formulated as an ECE process, though with some peculiar features: as the formation of HdpfO definitely involves an attack at the phosphorus atom, one may consider an electron transfer from the phosphorus to the electron-poor iron atom yielding a ferrocenyl-phosphonium cation-radical or its resonance form (see **B** in Scheme 4), which are more reactive at the phosphorus atom than Hdpf.[24] Similar ECE redox behaviour has been observed for 1,1′-bis(diphenylphosphanyl)ferrocene.[25] In contrast, nondissociating complexes with *P*-coordinated Hdpf exhibit normal reversible one-electron oxidations at the ferrocene unit (see below).



Scheme 4. Schematic depiction of the ECE electrochemical behaviour observed for Hdpf.

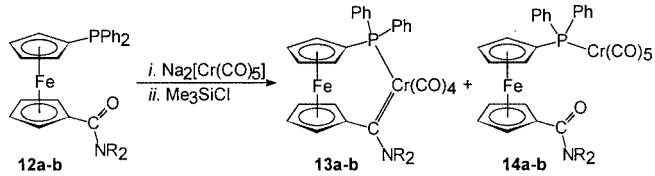
In the following work, Hdpf has been used[26] as a precursor for an alternative synthesis of chiral phosphanyloxazoline ligands (Scheme 5).[27] Due to an instability of the phosphanyl group under the reaction conditions, Hdpf was first converted to HdpfO. Then, the carboxy-phosphane oxide was treated with oxalyl chloride yielding the respective acid chloride, which was immediately treated with chiral β-amino alcohols to give amides **10**. Subsequently, the standard oxazoline ring closure reaction with **10** and deprotection of the phosphorus group gave [1′-(diphenylphosphanyl)ferrocenyl]oxazolines **11** (Scheme 5).



Scheme 5. Synthesis of ferrocenyl-oxazolines [R = (*S*)-*i*Pr, (*R*)-*i*Pr, (*S*)-*t*Bu, (*R*)-Ph].

Oxazolines **11** were tested in palladium-catalysed allylic substitution, giving nearly quantitative yields of the substitution products, though with a lower enantioselectivity than their analogues bearing both functional substituents on one cyclopentadienyl ring. The lowered selectivity can be ascribed to several intermediates with different conformation at the ferrocene unit participating in the catalysed reaction.[14c,27,28] This assumption is supported by spectral evidence and also by the fact, that the conformational equilibrium can be markedly influenced by introducing a stereogenic phosphorus atom.[29]

A different example of the synthetic usefulness of Hdpf represents the preparation of group-6 Fischer-type carbenes bearing the *P*-chelating 1′-(diphenylphosphanyl)ferrocenyl group.[30] In this case, Hdpf was first treated in the presence of peptide-coupling agents {1-hydroxybenztriazole/*N*-[3-(dimethylamino)propyl]-*N*′-ethylcarbodiimide} with secondary amines to give tertiary amides **12**. The reaction of amides **12** with $Na_2[Cr(CO)_5]$ and Me_3SiCl[31] afforded mixtures of the respective *P*-chelated carbenes **13** and phosphane complexes **14** (Scheme 6), which were easily separated by chromatography and fully characterised.



Scheme 6. Preparation of (carbene)chromium(0) compounds [NR_2 = NEt_2 (**a**) and morpholin-4-yl (**b**)].

A similar reaction between **12a** and $Na_2[W(CO)_5]$ under identical conditions (Scheme 7) is more complex, yielding a mixture of nonchelated carbene **15**, trinuclear "W_2Fe" complex **16** and the expected side-product **17**. Removal of **17** by chromatography and heating of the **15/16** mixture in toluene (80 °C, 4 h) afforded another mixture, whose components were separated by column chromatography and characterised as unreacted **16**, the *P*-chelated carbene **18**, and phosphanyl-carbaldehyde complex **19** resulting from decomposition of the carbenes.

The reaction course as observed for tungsten complexes provides strong evidence for a stepwise formation of the *P*-chelated carbenes. Somewhat surprisingly, an analogous reaction with $[Fe(CO)_4]^{2-}$ salts affords—in sharp contrast with the behaviour of organic amides[32]—exclusively the amidophosphane complex [$Fe(CO)_4$(**12a**-κ*P*)] (**20**).

A comparison of the crystal structures for **13a**, **13b**, **18**, and the nonchelated complex **16** (see Figure 1), which is void of possible structural constraints imposed by the chelation, clearly indicates that the $M(CO)_4$ units (M = Cr and W) perfectly fit into the pocket of the chelating ferrocene ligand and that the coordination causes no deformation within either part. An electrochemical study performed with **12a**–**b**, **13a**–**b**, and **14a**–**b** showed that the precursor amides **12** and the phosphane complexes **14a**–**b** behave as standard one ($Fe^{II/III}$) and two localised redox systems ($Fe^{II/III}$ and $Cr^{0/I}$), respectively, whereas the carbene complexes **13a**–**b** represent electronically coupled redox systems, where any redox change involves the entire molecule.

Coordination Chemistry and Catalytic Applications

As Hdpf was the first reported carboxy-ferrocenyl-phosphane, we turned our attention to studying its coordination behaviour towards selected metal ions in order to establish its coordination preferences, which could be expected to differ from the chemistry of either of the related donor-uniform ligands, (diphenylphosphanyl)ferrocene[33] and ferrocenecarboxylic acid.[34]

With soft metals, Hdpf coordinates as a simple tertiary phosphane. For instance, $K_2[PdCl_4]$ and $[Pd(cod)Cl_2]$ (cod = η^2:η^2-cycloocta-1,5-diene) reacted smoothly with 2 equiv. of Hdpf to give the bis(phosphane) complex *trans*-$[PdCl_2(Hdpf\text{-}\kappa P)_2]$ (**21a**). A similar reaction with $[Pd(cod)Br_2]$ gave *trans*-$[PdBr_2(Hdpf\text{-}\kappa P)_2]$ (**21b**). For the case of kinetically inert platinum(II), the isomers *trans*-$[PtCl_2(Hdpf\text{-}\kappa P)_2]$ (**22**) and *cis*-$[PtCl_2(Hdpf\text{-}\kappa P)_2]$ (**23**) were isolated depending on the precursor used.[35] According to the spectroscopic data, all compounds possess the expected square-planar arrangement, which was unambiguously corroborated by the structure determination for **22** and the adducts **21a**·$2CH_3CO_2H$, **22**·$2CH_3CO_2H$, and **23**·$(2+x)CH_2Cl_2$. Solvates **21a**·$2CH_3CO_2H$ and **22**·$2CH_3CO_2H$ obtained by recrystallisation from acetic acid are isostructural, forming molecular crystals built up of molecular triplexes formed by one complex molecule and two molecules of solvating acetic acid, bonded by double hydrogen bonds to the uncoordinated carboxy groups of the ligands (O···O 2.62 Å; Figure 2). The same type of intermolecular interaction is responsible for intermolecular aggregation in **22** and **23**·$(2+x)CH_2Cl_2$ but with a different outcome. The absence of polar solvate molecules in **22** leads to the formation of infinite hydrogen-bonded zig-zag chains (O···O 2.60–2.63 Å) whereas the molecules of **23** assemble by means of double hydrogen bonds into macrocyclic dimers (O···O 2.64 Å; Figure 2), whose conformation is further stabilised by graphite-like π···π stacking of the phenyl groups in *cis*-disposed ligands at a ring-centroid distance of 3.64 Å. The formation of closed supramolecular assembly $[\mathbf{23}]_2$ in the solvate **23**·$(2+x)CH_2Cl_2$ is very likely related to much lower polarity of the crystallization solvent.[35]

In contrast to the very stable palladium(II) and platinum(II) complexes, their nickel(II) analogues are prone to dissociative decomposition in polar solvents. In the series

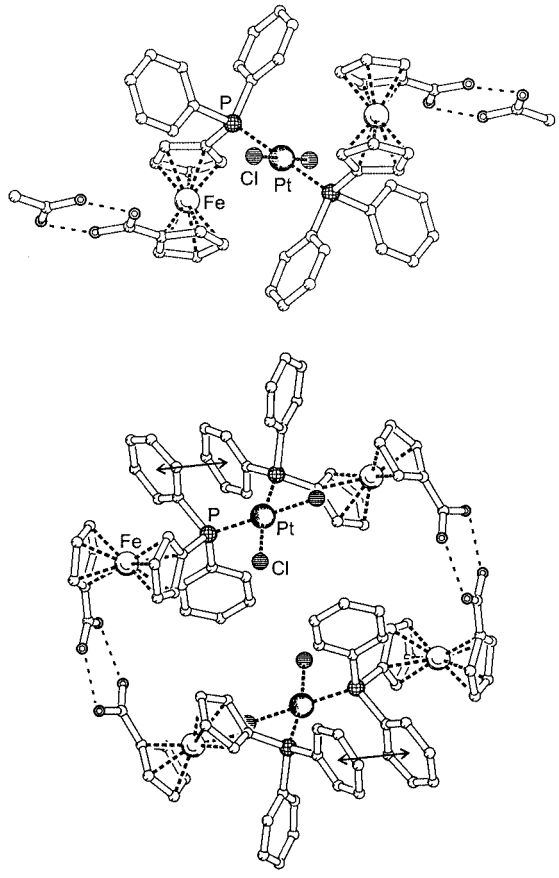

Figure 2. Views of the repeating units in the crystals of **22**·2CH_3CO_2H (top) and **23**·(2+*x*)CH_2Cl_2 (bottom). The O···O hydrogen bonds are shown as thin dashed lines and the π···π stacking interactions of the phenyl rings are indicated by double arrows. Hydrogen atoms and solvating dichloromethane (for the latter compound) are omitted for clarity.

[NiX_2(Hdpf-κ*P*)$_2$] [**24**, X = Cl (**a**), Br (**b**), I (**c**), and SCN-κ*N* (**d**)], the halide complexes **24a**–**c** are paramagnetic and tetrahedral whereas the thiocyanate **24d** is *trans*-square-planar and diamagnetic. Another nickel(II) complex, [Ni(dpf)$_2$] (**25**), was obtained by salt metathesis of nickel(II) sulfate with Nadpf. Compound **25** is an amorphous solid, practically insoluble in organic solvents and water. Hence, its formulation as a coordination polymer involving different nickel(II) sites and multidentate dpf$^-$ anions was based mainly on magnetic measurements and spectroscopic data (IR and photoelectron spectra).[36]

A similar situation has been observed for (Hdpf)mercury(II) complexes. The reaction of Hdpf with mercury(II) halides in acetic acid (bromide and chloride) or dichloromethane (iodide) gave two types of products depending on the stoichiometry of the starting materials: the trinuclear compounds [HgX_2(Hdpf-κ*P*)$_2$] (**26a**–**c**) and the dimeric, tetranuclear complexes [{Hg(μ-X)X(Hdpf-κ*P*)$_2$}$_2$] [**27a**–**c**; X = Cl (**a**), Br (**b**), and I (**c**)]. The complexes are insoluble in common solvents and decompose in strongly donating ones. The solvolytic equilibria are reflected, for example, by extensive broadening of the NMR resonances (spectra recorded for [D_6]DMSO solutions) and by the complexity of the electrochemical behaviour observed for a solution of the complexes in acetonitrile/*N*,*N*-dimethylformamide, explainable as a superposition of the redox response of the dissociated free ligand (see above) and (at least partly) solvolysed mercury complexes.[37]

The crystal structures of the bromide complexes, **26b** and the solvate **27b**·4CH_3CO_2H (Figure 3), revealed a tetrahedral coordination environment around the mercury ion, though with significant deviations from the regular geometry resulting from steric demands of the bulky carboxy-phosphane ligand (note: the overall structures are highly symmetric due to the imposed crystallographic symmetry). In both cases, the ligand carboxy groups do not participate in the coordination but instead take part in hydrogen bonding to either the carboxy group in a neighbouring ligand moiety resulting in infinite twisted chains (**26b**) or to the molecules of solvating acetic acid (**27b**·4CH_3CO_2H). The crystal packing of **27b**·4CH_3CO_2H, unlike the polymeric **26b**, is essentially molecular since two solvate molecules saturate the ligand carboxy groups while the remaining two form hydrogen-bonded dimers $(CH_3CO_2H)_2$ located in structural voids (Figure 3).[37]

Yet another example of carboxy groups of the *P*-coordinated Hdpf associating with solvating acetic acid molecules is the octanuclear heterocubane complex [(μ$_3$-I)$_4${Cu(Hdpf-κ*P*)}$_4$]·2CH_3CO_2H (**28**·2CH_3CO_2H), which is obtained upon refluxing CuI/Hdpf mixtures in glacial acetic acid. Notably, the reaction proceeds with the formation of the well-defined, stable solvate in a relatively broad range of the metal/ligand stoichiometry (Scheme 8).[38]

The structure of **28**·2CH_3CO_2H determined by X-ray crystallography revealed that the {Cu_4I_4} core is quite regular as far as bond lengths and angles are concerned but possesses no higher symmetry. In the crystal, the molecules of solvating acetic acid associate with the uncoordinated carboxy groups of ligands bonded at one face of the heterocubane core (O···O 2.62–2.65 Å). Likewise, the remaining ligand carboxy groups form the usual double hydrogen bridges but with the ligand carboxy groups from the neighbouring molecules (O···O 2.59 and 2.63 Å), thus linking the individual molecules in necklace-like zig-zag chains parallel to the crystallographic *c* axis (Scheme 8).

In further work we turned to mixed-donor carbonyl complexes involving group-6 metals [M(CO)$_5$(Hdpf-κ*P*)], where M = Cr (**29**), Mo (**30**), and W (**31**).[39] Complexes **29** and **31** have been synthesized in good yields by replacement of the weakly coordinated solvent in photogenerated intermediates [M(CO)$_5$(THF)] (THF = tetrahydrofuran), while **30** was obtained from the direct, thermally induced substitution of one carbonyl ligand with Hdpf in [Mo(CO)$_6$]. The compounds are sufficiently stable to be isolated in pure form albeit they slowly decompose in air and under daylight; their decomposition seems to be facilitated by the presence of the acidic carboxy function.

The formulation of compounds **29**–**31** is based mainly on spectroscopic data and further corroborated by the structure determination for **29**. An electrochemical study of the whole series by cyclic voltammetry showed that, upon rais-

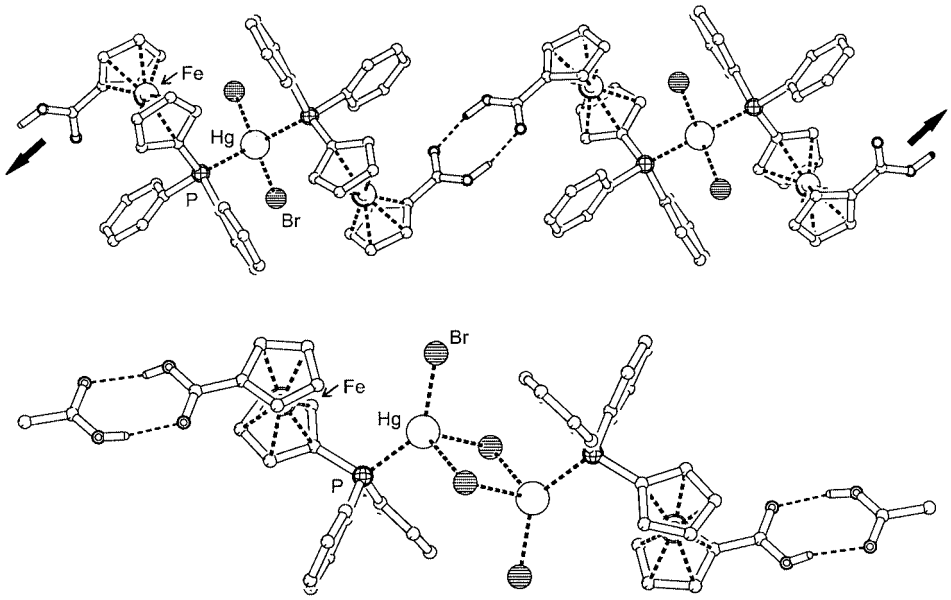

Figure 3. Views of the molecular structures of **26b** (top) and **27b**·$4CH_3CO_2H$ (bottom). The O···O hydrogen bonds are shown as dashed lines and the propagation of the chains in the structure of **26b** is indicated with arrows. The dimers $(CH_3CO_2H)_2$ present in the structure of the solvate are not shown for clarity.

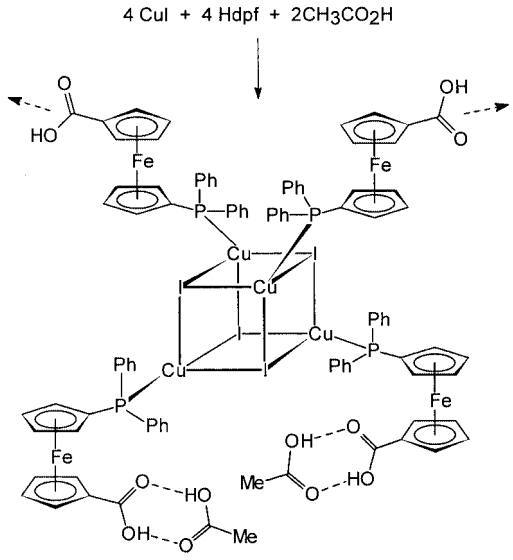

Scheme 8. Preparation and structure of the solvated heterocubane **28**·$2CH_3CO_2H$. Dashed arrows indicate where propagation of the infinite, hydrogen-bonded chains occurs.

ing the external potential, the complexes first undergo a ligand centred, reversible one-electron oxidation (ferrocene/ferricenium) followed by a group-6 metal centred redox process at more positive potentials. The position of the first wave is independent of the group-6 metal and shifted by ca. +180 mV with respect to uncoordinated Hdpf due to electron-density transfer from the ligand to the ligated metal ion. The reversibility of the first redox process indicates that the complexes are stable in both the usual and the oxidised forms under the conditions of measurement (dichloromethane solution, 0.1 $V s^{-1}$ scan rate), which contrasts with the redox behaviour of free Hdpf and solvolytically unstable mercury(II) complexes (see above).

Furthermore, Hdpf together with other phosphanes have been utilised as ligands in the synthesis of an extensive series of (alkoxycarbene)(η^6-hexamethylbenzene)ruthenium(II) compounds (Scheme 9).[40] The starting dichloro(phosphane) complexes **32a**–**d** were prepared by a bridge-splitting reaction from $[\{Ru(\mu\text{-}Cl)Cl(\eta^6\text{-}C_6Me_6)\}_2]$ and then converted into methoxycarbenes **33**. It is assumed that carbene formation starts with a removal of one chloride ligand with $NaPF_6$. The formed cationic, coordinatively unsaturated species coordinates one molecule of terminal alkyne giving an intermediate $[L_nRu(\eta^2\text{-}RC{\equiv}CH)]^+$, which isomerises to a cationic vinylidene complex $[L_nRu{=}C{=}CHR]^+$. Then, the carbene formation is completed by nucleophilic addition of methanol onto the electron-deficient vinylidene C-α atom. For carbenes with R′ = H, (trimethylsilyl)ethyne is used as the alkyne component because the C–Si bond is readily solvolysed under the reaction conditions.[41]

All compounds were characterised by standard spectral methods and the solid-state structure of the solvate **33da**·CH_2Cl_2 was determined by single-crystal X-ray diffraction. Even in this case double hydrogen bonds between carboxy groups of the *P*-coordinated ligand dominate the solid-state assembly, connecting into centrosymmetric dimers the enantiomeric cations (R_{Ru})- and (S_{Ru})-$[(\eta^6\text{-}C_6Me_6)RuCl(Hdpf\text{-}\kappa P)\{{=}C(OMe)CH_2Fc\}]^+$ (Fc = ferrocenyl) which are equally abundant in the racemic crystal (O···O 2.58 Å). In addition, the carboxy OH groups interact with the solvating dichloromethane, thus fixing the solvate in the structure by means of weak O–H···Cl hydrogen bonds, the O···Cl distance being 3.44 Å.

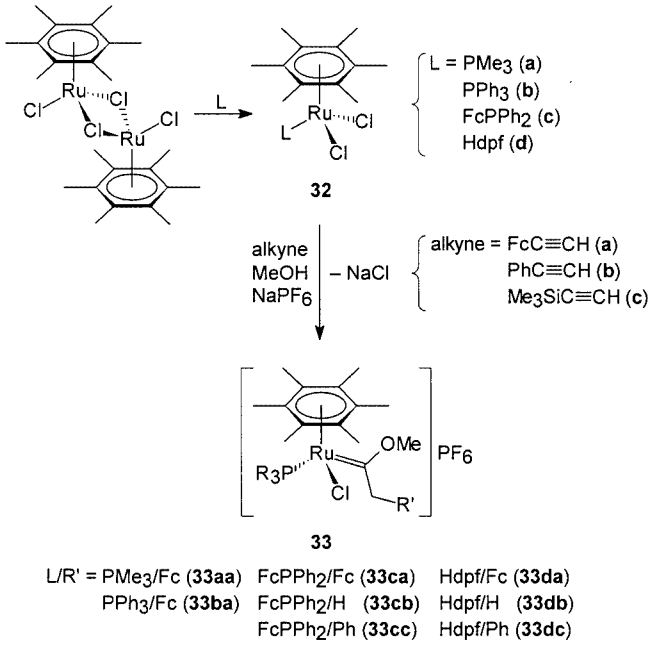

Scheme 9. Synthetic route to cationic (methoxycarbene)ruthenium compounds **33**.

The entire series of phosphane complexes **32** and carbenes **33** was studied by cyclic voltammetry in the anodic region. Analysis of the obtained data allowed for a comparison in both groups as well as across them; the observed trends undoubtedly deserve comment (Figure 4). As for the phosphane complexes, the compounds involving simple phosphanes, **32a** and **32b**, exhibit single redox waves attributable to the reversible oxidation at the central atom ($Ru^{II} \rightarrow Ru^{III}$). The potential of this process varies with the donor properties of the phosphane ligand: PPh_3 as a poorer σ-donor and better π-acceptor makes this oxidation more difficult [$E^{\circ\prime}$ = 0.39 (**32a**), 0.48 V (**32b**); the potentials are given relative to that of the internal ferrocene/ferricenium reference].

The presence of a ferrocenyl-phosphane in **32c** and **32d** is clearly reflected in the voltammograms by an additional one-electron ferrocene/ferricenium wave at lower potentials [$E^{\circ\prime}$ = 0.03 (**32c**), 0.28 V (**32d**)], an anodic shift for the latter compound being in agreement with the presence of an electron-withdrawing carboxy group (Figure 4). However, these redox potentials are slightly lower than those for free ligands, which is in a sharp contrast with the anodic shift typically accompanying coordination of these donors (cf. the data for **29**–**31**[39] and for the related $FcPPh_2$ complexes[42]). Nonetheless, this rather unexpected phenomenon can be explained by an efficient compensation of the ligand-to-metal σ-donation by π-back Ru → P bonding from the electron-rich ruthenium atom. At higher potentials, the ferrocene/ferricenium wave of the ligands is followed by the $Ru^{II} \rightarrow Ru^{III}$ oxidation−however, at much higher potentials than for **32a** and **32b** [$E^{\circ\prime}$ = 0.66 (**32c**), 0.68 V (**32d**)]. The origin of this anodic shift, which does not correspond with the strong electron-donating character of the ferrocene unit, can be accounted for by the preceding

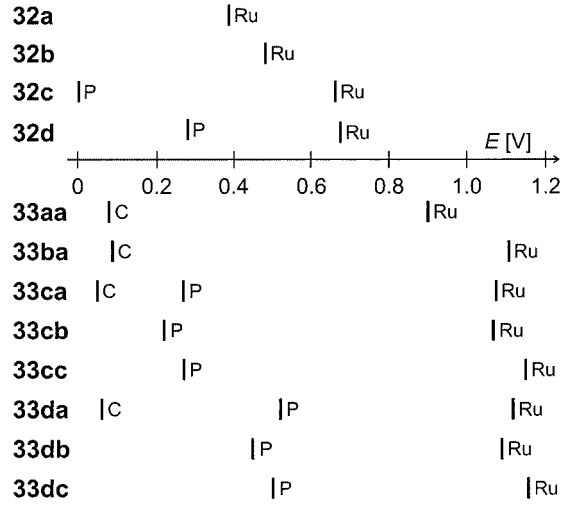

Figure 4. Chart diagram of the anodic redox potentials observed for **32** and **33** in dichloromethane solutions. The redox potentials were determined as an average of the anodic and cathodic peak potentials and given relative to the ferrocene/ferricenium reference. The values are distinguished as follows: the symbol **Ru** indicates a ruthenium-centred oxidation, while **C** and **P** denote the ferrocene/ferricenium potentials for carbene and phosphanyl-ferrocenyl groups, respectively. For compound labels see Scheme 9.

ligand oxidation converting the strongly electron-donating ferrocene into an electron-poor, cationic ferricenium. This change is naturally reflected by the donor properties of the whole phosphanyl-ferrocene ligand and is relayed onto the ruthenium centre (though perhaps in synergism with other factors).

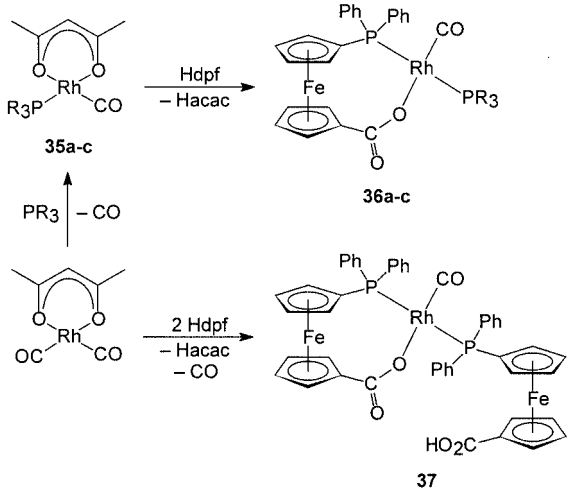
The redox behaviour of the carbenes is similar. However, the redox processes occur at higher potentials due to the cationic nature of these compounds (by ca. 0.5 V for the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ruthenium-centred oxidations, Figure 4). Another difference can be seen in the position of the ferrocene/ferricenium waves due to the phosphane ligands, which are shifted anodically by 0.24 V as compared to free ligands because the electron density lowering at the ferrocene unit following the coordination cannot be effectively compensated now by back-donation from the electron-poor ruthenium centres.

In summary, the data for compounds bearing the ferrocenyl-phosphanes (**32c**, **32d**, and the respective carbenes) clearly indicate electronic coupling between the ruthenium atom and the ferrocene ligand. On the contrary, the ferrocene unit located in the carbene part (**33aa**, **33ba**, **33ca** and **33da**) remains virtually unaffected by changes occurring in the rest of the molecule, which corresponds with the presence of a nonconjugated linker between the Ru atom and the (carbene)ferrocenyl group. A similar observation has been made also for (arene)ruthenium(II) complexes bearing Ru-coordinated ferrocenyl-phosphanes and ferrocenoyl groups at the terminus of a nonconjugated chain attached to the arene ligand.[43]

Interaction of rhodium(I) compounds with Hdpf leads to two types of complexes differing in coordination of the carboxy-phosphane ligand. The reaction of the dimeric complexes [{Rh(μ-X)(CO)$_2$}$_2$] with 4 equiv. of Hdpf gave the expected square-planar complexes with *P*-monodentate carboxy-phosphane, *trans*-[RhX(CO)(Hdpf-κ*P*)$_2$] [**34**, X = Cl (**a**) and Br (**b**)]. On the other hand, the reactions of Hdpf with rhodium(I) acetylacetonate complexes [Rh(acac)(CO)(L)] [**35**; L = PCy_3 (**a**), PPh_3 (**b**), and $FcPPh_2$ (**c**), acac = pentane-2,4,-dionate(1–)] afforded the corresponding square-planar complexes [Rh(CO)(L)(dpf-κ^2*O,P*)] (**36**) in which the phosphanyl-carboxylate anion dpf$^-$ coordinates as an *O,P*-chelating, bidentate ligand (Scheme 10). The formation of **36** from **35** and Hdpf represents an acid-base reaction with Hdpf acting as the proton donor to the leaving pentane-2,4-dione.[44]



Scheme 10. Preparation of rhodium(I) complexes with *O,P*-chelating phosphanyl-carboxylate dpf$^-$ [PR_3 = PCy_3 (**a**), PPh_3 (**b**), and $FcPPh_2$ (**c**); Cy = cyclohexyl].

Compounds **36a**–**c** are air-stable crystalline solids showing in their IR spectra the characteristic bands due to carboxylate groups ($\nu_{C=O}$ = 1602–1606 cm^{-1}; cf. 1666 cm^{-1} for Hdpf[17]) and the terminal carbonyl ligands ($\nu_{C\equiv O}$ = 1961–1965 cm^{-1}). For all compounds, the NMR spectra indicate *trans*-P–P arrangement around the rhodium atom, as was proven for **36a** by X-ray diffraction analysis (Figure 5).

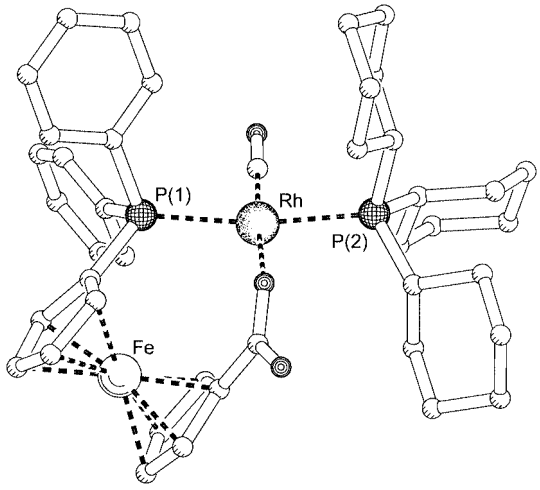


Figure 5. View of the molecular structure of **36a**. Hydrogen atoms are omitted.

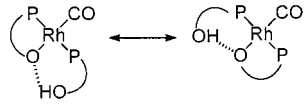
Replacing **35** with the dicarbonyl complex [Rh(acac)(CO)$_2$] in the reaction with Hdpf results in an immediate and exclusive formation of complex **37** (Scheme 10). The reaction proceeds with elimination of CO and acetylacetone, requiring 2 equiv. of Hdpf for 1 equiv. of the rhodium complex. For other molar ratios, the reaction stops when one of the starting materials is consumed: for instance, mixing of Hdpf and [Rh(acac)(CO)$_2$] in a 1:1 molar ratio affords an equimolar mixture of **37** and unreacted [Rh(acac)(CO)$_2$]. The IR spectra of **37** display bands assignable to the protonated (1703 cm^{-1}) and deprotonated (1551 cm^{-1}) carboxy group and the band of the terminal carbonyl ligand (1962 cm^{-1}). In contrast, ^{1}H and ^{13}C NMR show only one set of resonances due to "Hdpf" while the ^{31}P NMR spectrum features only one rhodium-coupled signal at δ_P = 20.2 ($^1J_{RhP}$ = 132 Hz) ppm, which is roughly half-way between the values observed for Hdpf in **34a**–**b** (δ_P = 22.2 ppm) and the dpf$^-$ anion in **35a**–**c** (δ_P = 18.4–18.7 ppm). Such a peculiar discrepancy was attributed to hemilabile coordination of the Hdpf/dpf$^-$ ligand pair where the two forms of ligand rapidly exchange the carboxy proton (Scheme 11). The exchange rate is sufficient to cause an averaging on the NMR time scale but definitely not in IR spectra, where both forms of the ligand are clearly observable.

Testing complexes **36a**, **36b** and **37** (pure or with various co-catalysts) and the related metal precursor/ligand mixtures [Rh(acac)(CO)$_2$]/*x*Hdpf, **35a**/Hdpf, **35b**/Hdpf, and



Scheme 11.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[RhH(CO)(PPh_3)_3]$/Hdpf in hydroformylation of 1-hexene has shown that most of these pre-catalysts are active, producing aldehyde mixtures in very good yields and with favourable *n*/*iso* ratios; halogen complexes **34a** and **34b** were practically inactive.[45]

Thus, complex **37** as such or generated in situ from $[Rh(acac)(CO)_2]$ and Hdpf represents an efficient hydroformylation catalyst precursor, not requiring any further co-catalyst; additional components may, however, be used to increase the reaction selectivity. For example, at a catalyst/1-hexene ratio of ca. 3.8×10^{-5} under 10 atm of CO/H_2 (1:1 mixture), pre-catalyst **37** gave isomeric heptanals in ca. 80% yield and *n*/*iso* ≈ 2 at 80 °C after 3 h, while the best *n*/*iso* ratio of 4.6 (without diminished yield) was achieved with the **37**/$P(OPh)_3$ system. Besides, complex **37** can be used repeatedly, cf. 84, 89, 83, 69, 48, 13% yields of aldehydes in six consecutive runs when the liquid part of the reaction mixture has been simply decanted from the catalyst residue (*n*/*iso* ratio ranged from 2.1 to 2.7). Spectral data indicate that **37** itself is not the catalytically active species but it is converted under the reaction conditions to the hydride $[RhH(CO)_2(Hdpf\text{-}\kappa P)_2]$.[45]

In our attempts to synthesize compounds featuring a form of Hdpf as an *O*-donor, we pursued the preparation of simple salts. Actually, the reaction of Hdpf with inorganic bases proceeded under the formation of carboxylate salts as evidenced by changes in the carbonyl stretching region of the IR spectra, but the products were ill-defined amorphous materials, tending to retain varying amounts of solvents.[46] Hence, whenever a dpf^- salt is required for synthesis, it is advantageous to generate it only in situ by treating Hdpf with an appropriate base.

The only example of exclusive carboxylate coordination for Hdpf is the paramagnetic titanocene carboxylate $[(\eta^5\text{-}C_5HMe_4)_2Ti(dpf\text{-}\kappa^2O,O')]$ (**38**) obtained by allowing equimolar amounts of "titanocene equivalent" $[(\eta^5\text{-}C_5HMe_4)_2Ti(\eta^2\text{-}Me_3SiC{\equiv}SiMe_3)]$ and Hdpf to react (Figure 6).[47] According to structural data, the dpf^- anion coordinates to the titanium ion as a simple carboxylate without any participation of the phosphane group: the carboxy plane nearly ideally bisects the titanocene fragment, the Ti–O bond lengths being 2.158 and 2.166 Å. Both metallocene units possess the expected geometry and are mutually rotated as exemplified by the dihedral angle subtended by the TiOO′ plane and the plane of the carboxy-substituted ferrocene cyclopentadienyl ring of ca. 25°.

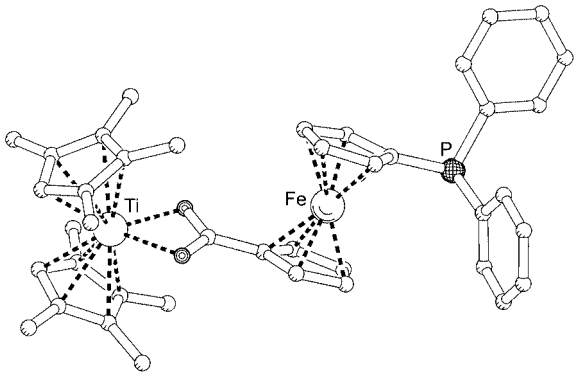


Figure 6. Molecular structure of bis(metallocene) complex **38**.

In order to elucidate the coordination properties of the methyl ester Medpf, we turned to palladium(II) complexes with chelate *C*,*N*-ligands (Scheme 12). The reaction of *ortho*-palladated dimeric complex **39** with Medpf gave the expected bridge-cleavage product **40**. However, the following attempts to synthesize *O*,*P*-chelate complexes failed. Removal of the halide ligand from **40** as well as the direct reaction of bis(acetonitrile) complexes **41** yielded only the phosphane complexes **42** with the acetonitrile molecule completing the coordination sphere around the palladium ion.[48]

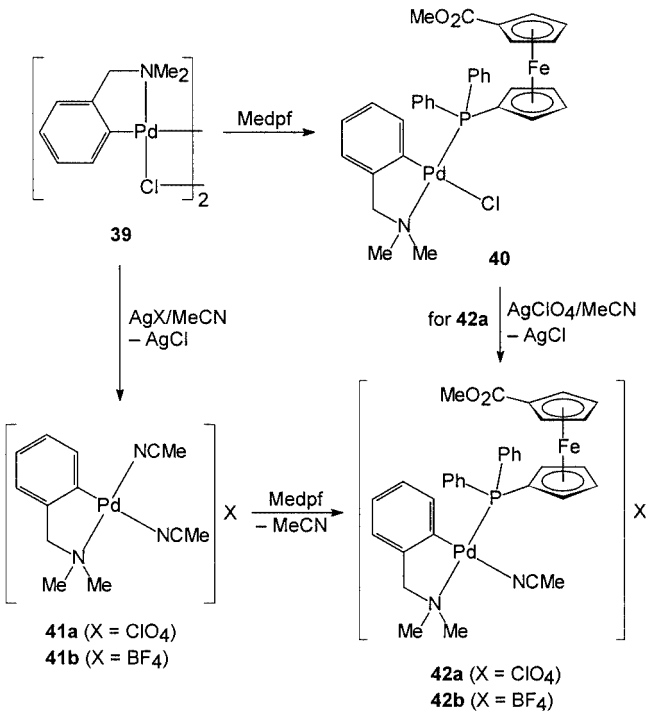
Compounds **40**, **42b**, and **21a** as well as some palladium(II) acetate/ligand mixtures (ligand = Hdpf, Medpf, and $FcPPh_2$) were tested as catalyst precursors for Suzuki–Miyaura cross-coupling of 4-bromotoluene and phenylboronic acid.[48] In all cases, the reaction proceeded with excellent isolated yields of 4-methylbiphenyl (≥ 80%). The most active catalysts proved to be the one generated in situ by mixing palladium(II) acetate with 2 equiv. of Hdpf or Medpf, which afforded the product in 96% isolated yield. The least active in the series tested proved to be the $[Pd(cod)Cl_2]$/2Hdpf mixture, a formal analogue to **21a**, which gave only 44% yield.

Recently, Hdpf was tested as an anchoring agent of a transition metal catalyst to a solid support. Treatment of mesoporous molecular sieves MCM-41 with Hdpf and, subsequently, with $[\{Ru(\mu\text{-}Cl)Cl(\eta^6\text{-}p\text{-cymene})\}_2]$ gave an Ru/Hdpf-modified sieve. Because the analytical data for Ru/Hdpf-MCM-41 implied an independent immobilization of the modifiers rather than a surface reaction, a similar material but without Hdpf was prepared from the dimeric ruthenium complex and the sieve. All these materials along with their molecular analogue $[\{RuCl_2(Hdpf\text{-}\kappa P)(\eta^6\text{-}p\text{-cymene})\}_2]$ (**43**) were tested as catalysts in the reaction of benzoic acid with propargyl alcohol to give 2-oxopropyl benzoate. The supported catalysts Ru-MCM-41 and Hdpf/Ru-MCM-41 proved less active than **43**, promoting a side reaction of propargyl alcohol, which further lowered the yield of the ester. In spite of some leaching of the catalytically active species from the solid support, the catalysts could be re-used without any apparent loss of catalytic activity.[49]

(S_p)-2-(Diphenylphosphanyl)ferrocenecarboxylic Acid

(S_p)-2-(Diphenylphosphanyl)ferrocenecarboxylic acid, (S_p)-HL^1, has been reported independently by three groups. The first mention dates back to the year 2000 when this compound was utilised as a chiral synthon for the preparation of chiral diamide ligands,[50] which were further tested in palladium-catalysed alkylation reactions[50a–50d] and the silver(I)-mediated formation of pyrroles.[50c] Notably, the acid itself proved to be a relatively poor ligand for the for-

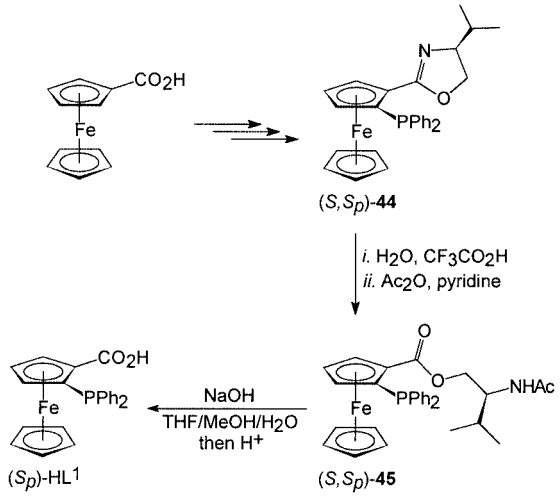
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 12.

mer reaction.[51] More recently, (S_p)-HL^1 has been employed as a chiral auxiliary (catalyst-directing group)[52] and its ester, (S_p)-MeL^1, utilised for the synthesis of ferrocenyl-oxazolines.[53]

The synthetic route leading to (S_p)-HL^1 as reported by all three groups was identical,[50a–50c,54] based the on a chiral protecting/*ortho*-directing group approach (Scheme 13). It starts with chiral ferrocenyl-oxazoline (S,S_p)-**44**, which is accessible in three steps (amidation, oxazoline ring closure, and diastereoselective lithiation/phosphanylation) from ferrocenecarboxylic acid in good yields and stereodefined form. The oxazoline was hydrolysed by the standard protocol: the oxazoline ring was first cleaved by action of aqueous trifluoroacetic acid to give an ammonium salt intermediate, which was directly converted into the more stable amido ester (S,S_p)-**45**. The following saponification of the ester amide with sodium hydroxide, acidification of the reaction mixture and chromatographic purification afforded (S_p)-HL^1 in 60–65% yields vs. (S,S_p)-**44**.



Scheme 13.

It should be noted that a similar methodology with the appropriate oxazolines furnished also 1′-(diphenylphosphanyl)-2-(trimethylsilyl)ferrocenecarboxylic acid,[50c] and esters of C_2-symmetric 2,2′-bis(diphenylphosphanyl)ferrocene-1,1′-dicarboxylic acid.[55] These compounds and amides relating to the later esters[56] were tested as ligands for palladium-catalysed allylic substitution.

Compared to the numerous catalytic applications of (S_p)-HL^1, the coordination chemistry of this carboxy-phosphane remains still unexplored. An exception are (arene)ruthenium(II) complexes with phosphanyl-carboxylate [(S_p)-L^1]$^-$, resulting from the reaction of [{Ru(μ-Cl)Cl(η^6-*p*-cymene)}$_2$] with 2 mol-equiv. of salt K[(S_p)-L^1] generated in situ by neutralization of (S_p)-HL^1 with the equivalent amount of KO*t*Bu. The reaction yields a kinetic 1:1 mixture of diastereoisomeric chelate complexes differing in configuration at the stereogenic ruthenium atom, (R_{Ru},S_p)-**46** and (S_{Ru},S_p)-**46**. However, this mixture undergoes a spontaneous epimerization in favour of the thermodynamically preferred isomer (R_{Ru},S_p)-**46**, which was isolated in 82% yield by crystallization over several days and structurally characterised (Scheme 14, Figure 7).[54]

Apparently, the thermodynamic driving force for this spontaneous equilibration is the destabilization of one of the diastereoisomers, (S_{Ru},S_p)-**46**, due to steric interactions

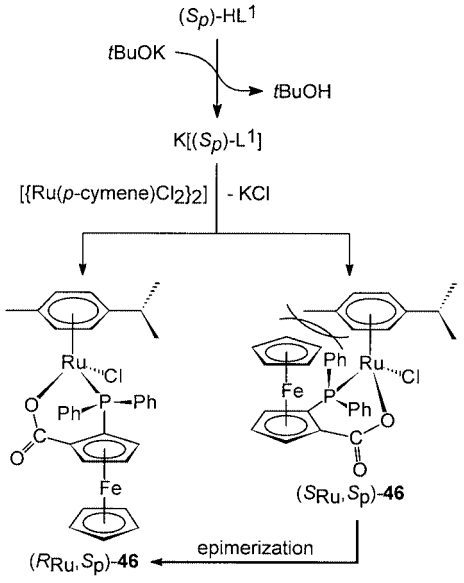

Scheme 14.

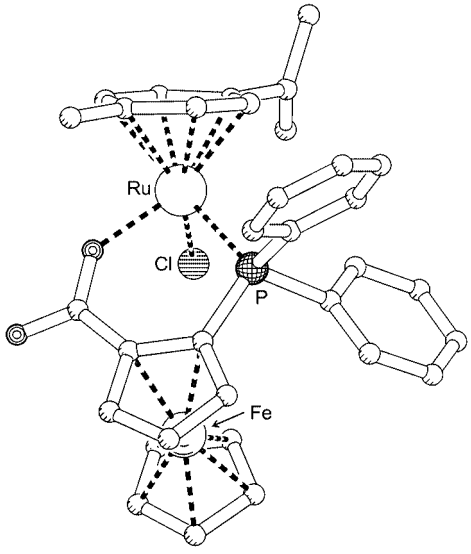

Figure 7. View of the molecular structure of (R_{Ru},S_p)-**46** as obtained for the solvate (R_{Ru},S_p)-**46**·0.7CH_2Cl_2. Molecules of solvating dichloromethane are not shown.

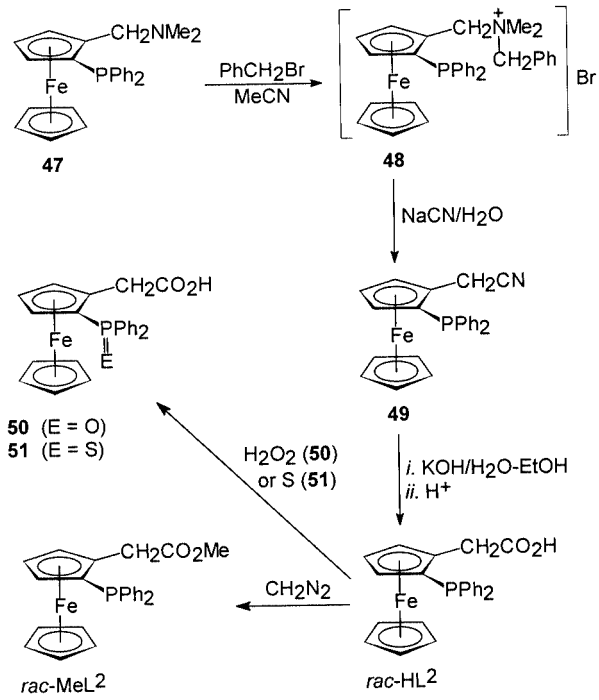
between the rigid ferrocene unit and the bulky η^6-arene ligand. The epimerization occurs most likely via Ru–O bond opening, followed by a rotation along of the ligand moiety into the sterically preferred position and the repetitive closure of the chelate ring. The hemilabile nature of the [(S_p)-L^1]$^-$ ligand evidently facilitates the isomerisation reaction.

rac-[2-(Diphenylphosphanyl)ferrocenyl]acetic Acid

rac-[2-(Diphenylphosphanyl)ferrocenyl]acetic acid, *rac*-HL^2, a formal homologue of (S_p)-HL^1, has been synthesized from the known precursor, *rac*-{[2-(diphenylphosphanyl)ferrocenyl]methyl}dimethylamine (**47**) (Scheme 15). The amine was converted by alkylation with benzyl bromide to ammonium salt **48**, which upon heating with aqueous sodium cyanide gave nitrile **49**. Hydrolysis of the nitrile followed by acidification of the reaction mixture and recrystallisation of the crude acid from aqueous acetic acid yielded *rac*-HL^2 as a yellow, air-stable solid (Scheme 16; ca. 63% yield from **47** over two steps; the salt does not need to be isolated). The acid was further converted into the respective phosphane oxide (**50**), phosphane sulfide (**51**), and methyl ester. The coordination ability of *rac*-HL^2 and *rac*-MeL^2 has been assessed in palladium(II) complexes.[57]



Scheme 15. Preparation of *rac*-HL^2 and its derivatives.

First, we studied palladium(II) complexes containing the 2-[(dimethylamino)methyl]phenyl-κ^2C^1,N spectator ligand (Scheme 16). The reaction of *rac*-MeL^2 with dipalladium precursor **39** gave the expected bridge-cleavage product **52**. Attempts to isolate a similar complex with *rac*-HL^2 failed due to consecutive reactions of the primary product analogous to **52**, most likely an acidolysis of the Pd–C bonds. The removal of the chloride ligand with silver(I) perchlorate from **52** gave cationic chelate complex **53**, which results also from a replacement of acetonitrile ligands in the cationic precursor **42a** (note: the same reaction but with Medpf proceeds with substitution of only one MeCN ligand, see above). The related complex containing the *O*,*P*-chelating [*rac*-L^2]$^-$ anion was obtained by treating dimer **39** with the stoichiometric amount of salt K[*rac*-L^2]$^-$ generated in situ from the acid and KO*t*Bu. The number, types and sequence of atoms within the "L^2-chelate" rings in **53** and **54** are identical and, hence the rings are structurally very similar, which is manifested also by practically identical ligand bite angles O–Pd–C of ca. 98°.[57]

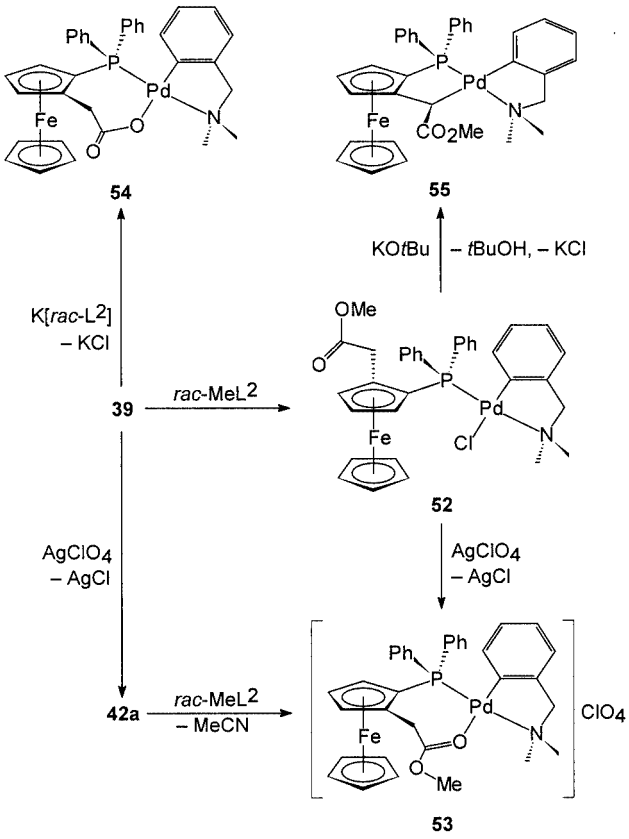
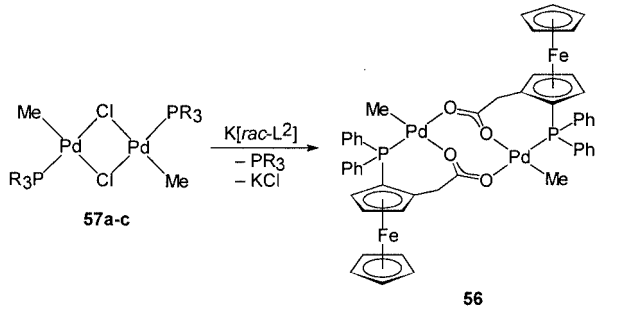


Scheme 16. Synthesis of {[(dimethylamino)methyl]phenyl-κ^2C^1,N}palladium(II) complexes with "L^2 family" ligands.

The reaction of **53** with sodium hydride or potassium *tert*-butoxide in THF provided bis(chelate) complex **55**. A formal dehydrohalogenation **53** → **55** can be rationalised by deprotonation at the activated ligand methylene group and a subsequent intramolecular substitution of the chloride ligand under preservation of the *trans*-P–N donor arrangement around the palladium ion. The reaction diastereoselectively creates a new chiral centre at the deprotonated carbon atom, producing the single diastereoisomer, $(S,R_p)/(R,S_p)$, from the racemic ester.[58] Compared to the related complexes with chelating $[R_2PCHCO_2Et]^-$ anions,[59] compound **55** is chemically very robust, inert to air, CO, SO_2, and some alkynes.

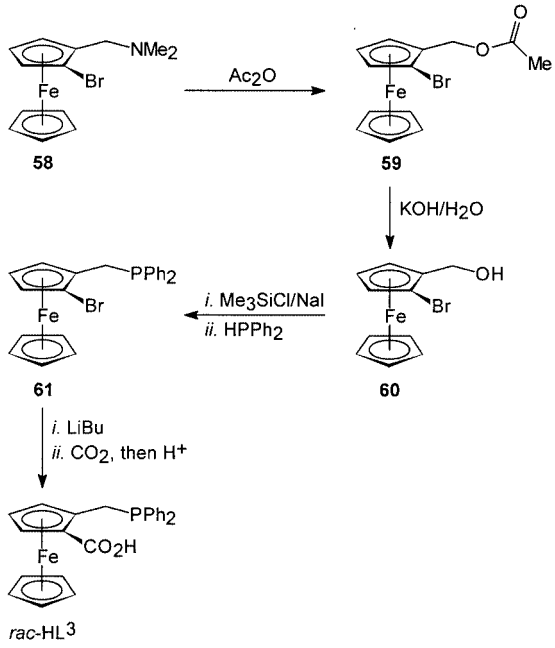


Scheme 17. Formation of dipalladium(II) complex **56** featuring a bridging tridentate $[rac\text{-}L^2]^-$ anion [PR_3 = PMe_3 (**a**), PPh_3 (**b**), and $PFur_3$, where Fur = fur-2-yl (**c**)].

Yet another coordination mode for the $[rac\text{-}L^2]^-$ anion exploiting all (classical) donor atoms has been observed for carboxylate-bridged dipalladium(II) complex **56** resulting from a reaction of dipalladium(II) complex **57** with K[*rac*-L^2] (Scheme 17). The formation of **56** likely involves a substitution of chloride ligands with the carboxylate and chelate-assisted replacement of monodentate phosphanes PR_3 with the phosphanyl group of the carboxylate ligand. Similarly to **55**, complex **56** results in a single diastereoisomer (R_p,S_p)-**56** (i.e., *meso*-form), combining both enantiomers of the racemic ligand in one complex molecule.[60]

rac-[2-(Diphenylphosphanyl) methyl]ferrocenecarboxylic Acid

The ligand *rac*-HL^3 or *rac*-[2-(diphenylphosphanyl) methyl]ferrocenecarboxylic acid is an isomer of the previously discussed compound *rac*-HL^2, differing in the position of the methylene spacer. It has been synthesized from *rac*-[(2-bromoferrocenyl)methyl]dimethylamine (**58**), which was converted to acetate **59** and then to bromo alcohol **60** (Scheme 18). Since the direct phosphanylation[61] commonly operative in ferrocene chemistry failed with compounds **58–60**, we sought for alternative methods. Fortunately, the key phosphanyl bromide **61** was obtained in excellent yield by treating alcohol **60** in acetonitrile with Me_3SiCl/NaI and then with Ph_2PH, as recently reported for some related compounds.[62] Metallation of **61** followed by carboxylation with carbon dioxide and chromatographic purification gave a good yield of *rac*-HL^3. For the sake of comparison with the *rac*-HL^2 family, the acid was further converted into the respective phosphane oxide **62**, phosphane sulfide **62**, and methyl ester *rac*-MeL^3.[63]



Scheme 18.

The coordination properties of *rac*-HL^3 and the respective ester have been studied up to the present only for rho-

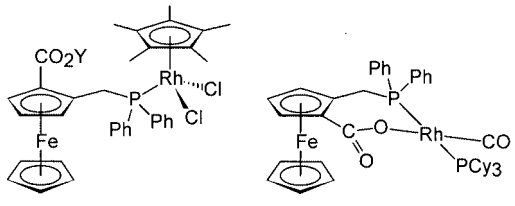
dium complexes (Scheme 19). (Cyclopentadienyl)rhodium(III) complexes with *P*-monodentate ligands (**64** and **65**) were prepared by bridge cleavage from [{Rh(μ-Cl)Cl(η^5-C_5Me_5)}$_2$] and the respective ligands. Attempts to synthesize *O*,*P*-chelated complexes by treating **64** with bases or from **65** by halide removal failed but, finally, the *O*,*P*-chelating coordination of the [*rac*-L^3]$^-$ anion was attained with a rhodium(I) complex **66** obtained from *rac*-HL^3 and **35a** (see also above).[63]



Scheme 19.

Structural Aspects

Hdpf, Medpf, and dpf$^-$ Complexes

The specific steric properties of the ferrocene moiety as mentioned above are obviously reflected in the spatial arrangement of complexes featuring Hdpf and the related forms of this ligand. The number of structurally characterised compounds (Table 1) enables us to draw some general conclusions about the ligand geometry. First, the ferrocene moieties remain quite regular, showing no deformation or tilting of the cyclopentadienyl rings: the maximum dihedral angle of the cyclopentadienyl planes of ca. 7.5° was observed for **29** and **23**·(2+*x*)CH_2Cl_2. Second, the rotation of the carboxy plane from the plane of its parent cyclopentadienyl ring (twist angle θ) does not usually exceed ca. 10°, the exceptions being **36a** (θ = 26°), **38** (θ = 19°) and one of the four ligand moieties in the structure of **28**·2CH_3CO_2H (θ = 16°). Whereas the carboxy rotation in **36a** apparently results from a compromise between the *O*,*P*-chelating coordination of the dpf$^-$ anion and the steric demands of the central atom, twisting of the carboxy group in **38** and **28**·2CH_3CO_2H is probably caused by crystal packing effects. However, in view of DFT calculations for ferrocenecarboxamide,[64] indicating that rotation of the amide moiety from the plane of its bonded cyclopentadienyl ring by as much as 30° reduces orbital interaction of their π-systems by approx. 14%, even such rotations of the carboxy plane do not destabilise the mentioned structures by precluding the carboxy-ferrocene conjugation.

Table 1. Conformation parameter τ for ferrocene units in the structurally characterised Hdpf derivatives and complexes.[a]

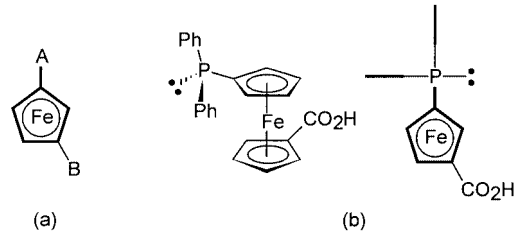
42b[48]	146

[a] Parameter τ is defined as the torsion angle (C^P–Cg^P–Cg^C–C^C), where Cg^P and Cg^C denote the centres of gravity of phosphanyl- (P) and carboxy-substituted (C) cyclopentadienyl rings, and C^P and C^C ring carbon atoms bearing the substituents. Absolute values for τ are given to eliminate chirality of the ligand moieties in the solid-state (see ref.[13]). Entries for all crystallographically independent ligand molecules are given where applicable.

The third but most varying parameter is the torsion angle τ (Table 1), which relates to the conformation of the 1,1′-disubstituted ferrocene core (see also ref.[13]). Of the 27 structurally characterised (H)dpf ligand moieties, twenty have τ in the range of 135–160°, i.e. around *anti*-eclipsed conformations [Scheme 20, (a); τ(AB) = 144°]. Such an arrangement apparently minimizes the steric interactions of the substituents at the ferrocene unit by bringing their centres of gravity (not the bonds to the substituents which would lead to *anti*-staggered conformations with τ = 180°) into a mutually opposite position [see side and top views in Scheme 20, (b)]. The minimum τ value of 60° was found for the chelate complex **36a**, where the proximity of both donor groups is enforced by the *O*,*P*-chelating coordination.



Scheme 20.

Energy changes associated with conformational alterations may be compensated for by an energy gain upon the formation of intermolecular bonds and a favourable crystal assembly.[65] This can be exemplified by six entries with τ = 68–118°, all featuring *P*-monodentate Hdpf, whose carboxy group takes part in the usual double hydrogen bridges to another ligand carboxy group or to solvating acetic acid.

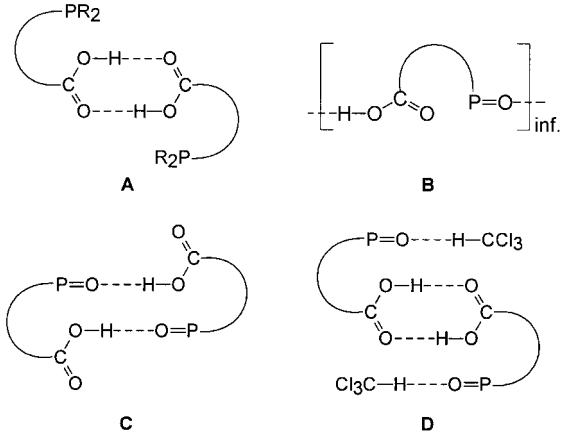
Intermolecular Interactions

The supramolecular architectures of crystalline organometallic solids are currently gaining increasing attention due to their relation to the rapidly growing research area of organometallic crystal engineering.[67] In this regard, ferrocene chemistry holds great potential for future developments because ferrocene molecules are usually stable, structurally well defined and, most importantly, capable of bearing various polar groups to be used as the structure-assembling tool.

The molecules of ferrocene phosphanyl-carboxylic ligands combine hard polar carboxy moieties with a nonpolar ferrocene skeleton and substituents at the phosphorus atom. Interactions between the polar parts are usually clearly detectable from the structural data and virtually dominate the crystal assembly. However, they operate together with the relatively weaker but important intermolecular forces such as, for example, C–H···X and C–H···π hydrogen bonds (X stands for a heteroatom), and π···π stacking interactions of the aromatic rings.[68]

The summary of the principal intermolecular interactions observed for the discussed ligands and their corresponding phosphane oxides and sulfides is given in Table 2. The phosphane derivatives typically assemble via double hydrogen bridges characteristic for carboxylic acids [Scheme 21, interaction **A**; notation according to graph set theory: $R^2_2(8)$[69]]. A similar assembly is usually encountered also for the respective phosphane sulfides whose thiophosphoryl sulfur atom cannot effectively compete for the hydrogen-bond donor with the carboxy oxygen atoms. On the other hand, the conversion of phosphanes into phosphane oxides is associated with an introduction of a strong hydrogen-bond acceptor, which further increases the structural variability. Among the ferrocene phosphanoyl-carboxylic acids which have been structurally characterised, HdpfO and (S_p)-**67** (see footnotes to Table 2) form one-dimensional zig-zag chains propagating by means of P=O···H–OC(=O) hydrogen bonds (Scheme 21, **B**) whilst **50** forms centrosymmetric cyclic dimers assembled via a pair of the similar P=O···H–OC(O) interactions (Scheme 21, **B**). In contrast, the solvated phosphane oxide **62**·$CHCl_3$ holds the structure of the parent carboxy dimer, forming additional hydrogen bonds to the solvate molecules [P=O···H–CCl_3: O···O 2.986(2) Å; Scheme 21, **D**].



Scheme 21. Hydrogen bonding patterns observed for phosphorus-substituted ferrocenecarboxylic acids.

Table 2. Hydrogen bond lengths for the carboxylic acids.[17,54,57]

Compound	Interaction[a]	*d*(O···O) [Å]
Hdpf	**A**	2.650(6), 2.653(6)[b] [c]
HdpfO	**B**	2.588(4)[b]
(S_p)-**67**[e]	**B**	2.556(4)[d]
rac-HL^2	**A**	2.646(2)[d]
50	**C**	2.596(3)[d]
51	**A**	2.649(2)[d]
rac-HL^3	**A**	2.629(3)[d]
62·$CHCl_3$	**D**	2.646(2)[d]
63·½CH_2Cl_2	**A**	2.663(2)[d]

[a] See text and Scheme 21 for definitions. [b] Determined at room temperature. [c] Entries for two crystallographically independent molecules. [d] Determined at 150 K. [e] (S_p)-2-(diphenylphosphanoyl)ferrocenecarboxylic acid, (S_p)-[HL^1O].

A situation similar to the free ligand has been observed also for a number of complexes with *P*-monodentate Hdpf: the ligand carboxy group typically forms characteristic double hydrogen bonds to an adjacent ligand moiety [**22**, **26b**, **23**·(2+*x*)CH_2Cl_2, **24d**·2$CHCl_3$, **28**·2CH_3CO_2H (see above), **29**, **33da**·CH_2Cl_2, **43**·CH_2Cl_2] or to solvating acetic acid [**21a**·2CH_3CO_2H, **22**·2CH_3CO_2H, **27b**·4CH_3CO_2H, **28**·2CH_3CO_2H (see above)]. In this regard, complex [PdCl{η^3-$CH_2C(CH_3)CH_2$}(Hdpf-κ*P*)] is a notable exception as it forms dimers through Pd–Cl···H–OC(=O) bonds [Cl···O 3.082(2) Å].[66]

Conclusions

The introduction of phosphanyl-ferrocenecarboxylic ligands about ten years ago brought some new aspects into the chemistry of mixed-donor ferrocene ligands. The particular combination of the functional groups and the ferrocene backbone makes these compounds chemically and structurally markedly diverse. Consequently, phosphanyl-ferrocenecarboxylic ligands represent very flexible donors, which typically offer several accessible, sometimes mutually interconvertible, coordination modes, and are capable of hemilabile coordination. From a practical viewpoint, phosphanyl-ferrocenecarboxylic derivatives hold much potential as perspective ligands for catalytic applications and as valuable synthons for the design of supramolecular organometallic materials. The results already obtained are promising and open up new areas for future research, ranging from the development of new ligands and complexes on one side to their applications in catalysis and material science on the other.

[12] The barrier of internal rotation of the cyclopentadiene rings in ferrocene in the gas phase has been established to ca. 4 kJ mol^{-1}, which is lower than the $N_A kT \approx 2.5$ kJ mol^{-1} at 298 K. For the reference, see: A. Haaland, J. E. Nilsson, *Acta Chem. Scand.* **1968**, *22*, 2653–2670.
[13] Fixing the conformations of 1,1′-disubstituted ferrocenes makes their molecules potentially chiral. However, this situation is restricted only to the solid state. In solution, the enantiomeric forms easily interconvert by rotation along the axis connecting the centres of the cyclopentadienyl rings and, hence, cannot be separated.

A Lutetium Cyclopentadienyl-Phosphazene Constrained Geometry Complex (CGC): First Isolobal Analogues of Group 4 Cyclopentadienyl-Silylamido CGC Systems[‡]

Konstantin A. Rufanov,*[a,b] Alex R. Petrov,[c] Vasili V. Kotov,[c] Frédéric Laquai,[c] and Jörg Sundermeyer*[c]

Dedicated to Prof. Dr. Herbert Schumann on the occasion of his 70th birthday

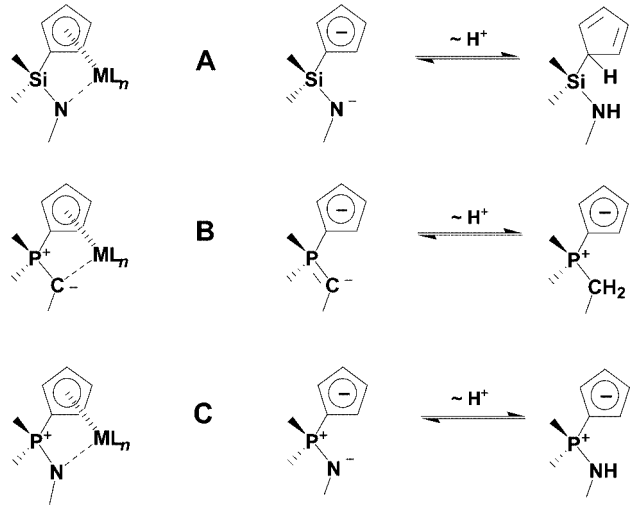
Keywords: Bridging ligands / Isolobal relationship / Phosphazenes / Constrained geometry complexes / Lutetium

$C_5Me_4HPMe_2$ reacts with 1-adamantyl azide to form the first example of a new family of cyclopentadienylideneaminophosphorane ligands (**1**). Metallation of **1** with $Lu(CH_2SiMe_3)_3(THF)_2$ leads to the first cyclopentadienyl-phosphazene CGC **2**, isolobal to known group 4 cyclopentadienyl-silylamido CGC systems.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Linked cyclopentadienyl-silylamido complexes of early transition metals,[1–4] the so-called "constrained-geometry" catalysts[5] (**A**; Scheme 1), have become one of the best developed classes of specially designed organometallics because of their industrial application as single-site olefin polymerisation catalysts.[4–6] Isolobal analogues of ligands **A** are the chelating cyclopentadienyl-phosphoranylidenes (**B**) and cyclopentadienyl-phosphazenes (**C**).[7]

We found that corresponding ligand systems (**B** and **C**, left) do exist in the thermodynamically more stable tautomeric form of cyclopentadienylidene-*P*-carbo- (**B**, right) and *P*-amino-phosphoranes (**C**, right). In the framework of our current studies on coordination and organometallic chemistry of organophosphorus(v) ligands with different O, S, Se, RN and RCH functionalities, synthesis and molecular structures of the type **B** ligand precursors have been recently developed and reported.[8] In this communication we present synthesis of the first example of type **C** ligands and a new CGC lutetium complex thereof along with their crystal structures.



Scheme 1. Isolobally related "constrained-geometry" complexes and corresponding ligand systems.

Results and Discussion

Synthesis of cyclopentadienylidene-phosphorane-C_5Me_4=PMe_2–NHAd (Ad = Adamantyl-1) (**1**) was achieved in 95% yield by the Staudinger reaction of the phosphane $C_5Me_4HPMe_2$, obtained in situ from C_5Me_4HLi and Me_2PCl (Scheme 2), with one equiv. of AdN_3. $^1H/^{13}C$ COSY was used for accurate assignment of all signals. It is

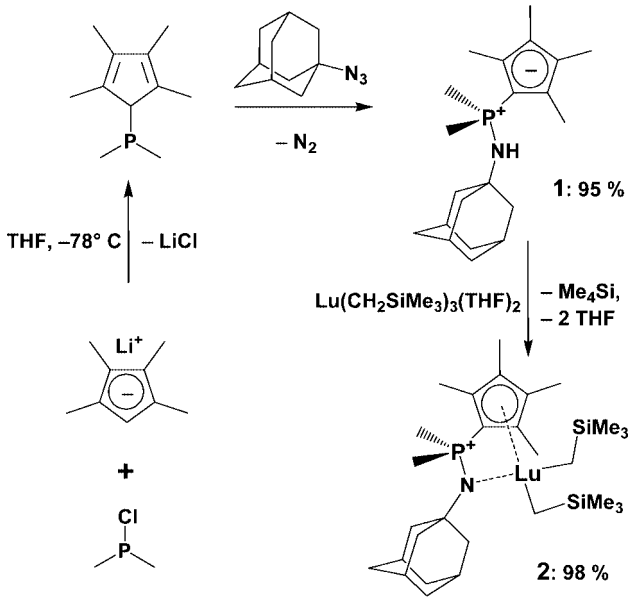
interesting to note that the N*H* proton appears shifted upfield at δ = 1.38 between the adamantyl-group CH_2 multiplets.[9] The highly pure ligand crystallises from THF/hexane mixtures as colourless plates. Simple metallation of **1** with $Lu(CH_2SiMe_3)_3(THF)_2$ in C_6D_6 at r.t. produced a new "constrained-geometry" lutetium complex [η^5:η^1-$C_5Me_4PMe_2NAd$]$Lu(CH_2SiMe_3)_2$ (**2**) in close to quantitative yield.[10]



Scheme 2. Synthesis of **1** and **2**.

Metallation of the ligand **1** (δ_P = 17.6) is accompanied by a shift to δ_P = 9.6. Molecules of THF do not coordinate to Lu in THF-containing solutions of **2**, as confirmed by the ^{1}H NMR spectrum: one set of signals of THF protons with distinct coupling is observed. Complex **2** is highly soluble in alkanes and crystallises upon slow evaporation of the reaction mixture at r.t. to give large colourless prisms. Both **1** and **2** are thermally rather stable; their molecular structures are shown in Figure 1.

A comparison of these two structures underlines an increase of the aromatic character of the Cp$^{\#}$ moiety coordinated to the Lu atom: the difference in C–C bond lengths within the Cp$^{\#}$ ring is 0.06 Å for **1** and 0.04 Å for **2**. P–C_{Me} and N–C_{Ad} bonds are only 0.01 Å longer in **2** than in **1**. The P–C_{Cp} bond in **2** is 0.05 Å longer than in **1**, whereas the P–N bond in **2** is almost the same value (0.06 Å) shorter than in **1**. The rather short Lu–N bond (2.28 Å) is much closer to the covalent Lu–N bond lengths (2.21 Å) than to the donor–acceptor ones (2.48 Å) found in the crystal structures of analogous Lu complexes – Cp*Lu(bipy)(NHDip)CH_2SiMe_3 and Cp*Lu(bipy)$(NHDip)_2$.[11] Lu–CH_2 (2.36 Å) and Lu–Cp$^{\#}_{cent}$ (2.33 Å) bond lengths lie in the typical range of Lu σ-alkyl and η^5-Cp* moieties.[11] The 101.2° value of the N–P–C_{Cp} angle is similar to that of N–Si–C_{Cp} in type **A** complexes. In combination with the large radius of Lu, a more open coordination sphere and as a consequence a small but probably nonbonding P···Lu distance (3.08 Å) about 0.7 Å shorter than the sum of the van der Waals radii of these elements (3.80 Å)[12] is observed.

Conclusions

We have introduced the new cyclopentadienyl-phosphazene ligand system **C** and used it for the design of rare earth metal organometallic chelate complexes of the constrained geometry type. A crystal structure analysis of lutetium bisalkyl (**2**) has been presented, confirming that the isolobal relation finds its counterpart in a structural relation to the well-known class of cyclopentadienyl-silylamido complexes of group 4 metals. Systematic synthetic, structural and reactivity aspects of type **B** and **C** ligand systems and a series of new organometallic complexes of *s*-, *p*-, *d*- and *f*-elements will be discussed in a forthcoming full account.[13]

[9] Possible explanation of this phenomenon consists in an effective π-shielding of N*H* proton with the C_5Me_4 group, which was partly confirmed by the X-ray structure of **1**, where this proton was located exactly under the phosphorane C_5-aromatic ring.

[10] **Synthesis of 1**: a solution of Me_2PCl (1.5 g, 15.5 mmol) in THF (10 mL) was added to a stirred suspension of C_5Me_4HLi (1.9 g, 14.7 mmol) in a 1:2 THF/hexane mixture (120 mL) for 0.5 h at –78 °C. The reaction mixture was allowed to stir overnight, warming up to r.t. LiCl was filtered off and all volatiles were removed in vacuo giving $C_5Me_4HPMe_2$ as a light yellow oil (2.2 g, 12.1 mmol, about 83% based on C_5Me_4HLi), which was dissolved in THF (10 mL) and treated with a solution of AdN_3 (2.2 g, 12.4 mmol) in THF (10 mL) at r.t. Thus the obtained yellow solution was allowed to stir with a gas-overpressure controller. During gas (N_2) liberation, the reaction solution gradually deepened in colour and after 4 h became dark brown. To complete the reaction it was warmed up to 50 °C for an additional 30 min. THF was removed in vacuo, yielding a light brown residue, which was treated with hexane (50 mL) and thoroughly washed with the same solvent (4 × 50 mL) to give, after drying in vacuo, a white powder of **1**. Yield 3.8 g (95% based on phosphane, 79% based on C_5Me_4HLi). ^{1}H NMR (300 MHz, C_6D_6, +23 °C): δ = 2.44 (s, 6H, C_5Me_4), 2.39 (s, 6H, C_5Me_4), 1.71 (br. s, 3H, CH_{Ad}), 1.40 [br. d, 6H, N–C(CH_2)$_3$], 1.35 (br. s, 1H, N*H*–Ad), 1.30 (br. m, 6H, CH–CH_2–CH), 1.25 [d, J(P,H) = 10 Hz, 6H, Me_2P]. ^{31}P NMR (121.5 MHz, C_6D_6, +23 °C): δ = 17.6 ppm. ^{13}C NMR (75.5 MHz, C_6D_6, +23 °C): δ = 119.7, 117.5 [d, d, J(P,C) = 19, J(P,C) = 18 Hz, *C*(Me)=*C*(Me)], 77.8 [d, J(P,C) = 125 Hz, P-C_{Cp}], 52.4 [d, J(P,C) = 4 Hz, P-NH-C_{ad}], 44.7 [d, J(P,C) = 4 Hz, N-C(CH_2)$_3$], 36.0 (s, CH-CH_2-CH) 29.9 (s, CH_{Ad}), 19.2 [d, J(P,C) = 70 Hz, Me_2P], 14.9 (s, C_5Me_4), 12.1 (s, C_5Me_4). EI-MS: 331, $\mathbf{1}^+$ (36%), 316, $\mathbf{1}^+$ – CH_3 (5%), 286, $\mathbf{1}^+$ – 3 CH_3 (11%), 196, $\mathbf{1}^+$ – Ad (20%). **Synthesis of 2**: a solution of **1** (330 mg, 1 mmol) in C_6D_6 (2 mL) was added to a solution of Lu(CH_2SiMe_3)$_3$(THF)$_2$ (580 mg, 1 mmol) in C_6D_6 (1 mL) at r.t. The pink-coloured solution obtained in this manner (0.6 mL) was transferred into a WILMAD 505-PS 7 NMR tube with a J. Young teflon valve. The rest of the reaction mixture was left in a glovebox for crystallisation at +25 °C giving, after evaporation of benzene, 540 mg of **2** in the form of colourless crystals in – together with the NMR sample – close to quantitative yield. ^{1}H NMR (300 MHz, C_6D_6, +23 °C): δ = 2.11 (s, 6 H, C_5Me_4), 2.04 (s, 6 H, C_5Me_4), 2.01 (br. s, 3 H, CH_{Ad}), 1.73 [br. d, 6 H, N-C(CH_2)$_3$], 1.56 (br. m, 6 H, CH-CH_2-CH), 1.15 [d, J(P,H) = 13 Hz, 6 H, Me_2P], 0.39 (s, 18 H, Me_3Si), –0.90 (q, ^2J = 20, ^4J = 10 Hz, 4 H, Lu-CH_2-Si). ^{31}P NMR (121.5 MHz, C_6D_6, +23 °C): δ = 9.6. ^{13}C NMR (75.5 MHz, C_6D_6, +23 °C): δ = 123.5, 121.5 [d, d, J(P,C) = 14, J(P,C) = 13 Hz, *C*(Me)=*C*(Me)], 83.8 [d, J(P,C) = 115 Hz, P-C_{ipso}], 54.1 [d, J(P,C) = 6 Hz, N-C_{ad}], 47.2 [d, J(P,C) = 8 Hz, N-C-(CH_2)$_3$], 38.3 (s, Lu-CH_2-Si), 36.3 (s, CH-CH_2-CH) 30.2 (s, CH_{Ad}), 21.9 [d, J(P,C) = 54 Hz, Me_2P], 13.9 (s, C_5Me_4), 11.8 (s, C_5Me_4), 4.9 (s, SiMe_3). EI-MS: 679, $\mathbf{2}^+$ (30%), 665.0, $\mathbf{2}^+$ – CH_2 (10%), 591.0, $\mathbf{2}^+$ – Me_4Si (16%). Satisfactory elemental analyses of **1** and **2** were obtained. General experimental details, NMR and EI-MS spectra as well as references on the syntheses of the starting reagents are collected in the Supporting Information; see also the footnote on the first page of this article.

Self-Assembly of 1-D Coordination Polymers Using Organometallic Linkers and Exhibiting Argentophilic Interactions $Ag^{I}\cdots Ag^{I}$

Jamal Moussa,[a] Kamal Boubekeur,[a] and Hani Amouri*[a]

Keywords: Coordination polymers / Silver / Self-assembly / Quinones / Metal-metal interactions

Treatment of the organometallic linkers [Cp*M(η^4-benzoquinone)] [M = Rh, L^{Rh}, (**1a**); M = Ir, L^{Ir} (**1b**)] with excess AgOTf provided the novel 1-D coordination polymers of the formula $\{[Ag_3(L^M)_2(CH_3CN)_2(OTf)][L^M](OTf)_2\}_n$ (**2a**,**b**). Single-crystal X-ray diffraction studies carried out on **2a** and **2b** showed that these polymers exhibit, as an outstanding feature, the presence of $d^{10}\cdots d^{10}$ argentophilic interactions between the silver atoms.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

The design and self-assembly of coordination frameworks exhibiting original architectures[1] and with potential applications as molecular wires,[2] in catalysis,[3] and ion encapsulation[4] offer exciting new prospects for researchers working in the area of material science.[5] Generally, coordination polymers are formed by self-assembly of organic spacers and transition metal ions of different geometrical structures.[6] In this work, we wish to report the 1-D coordination polymers $\{[Ag_3(L^M)_2(CH_3CN)_2(OTf)][L^M](OTf)_2\}_n$ (**2a**,**b**), based on silver coordination chemistry and using [Cp*M(η^4-benzoquinone)] [M = Rh, L^{Rh} (**1a**); M = Ir, L^{Ir} (**1b**)[7]] as organometallic linkers. Interestingly these coordination polymers **2a**,**b** display, as nodes, three silver ions in close proximity with Ag···Ag contacts of 3.3–3.7 Å (Figure 1).

Prior to this work the self-assembly of 1–3-D networks, was reported using the only known organometallic linker [(η^4-benzoquinone)$Mn(CO)_3$][Na].[8] However, none of these polymers contained silver cations. Thus, our 1-D polymers **2a**,**b** are the first coordination polymers with the neutral organometallic linkers [Cp*M(η^4-benzoquinone)] [M = Rh, L^{Rh} (**1a**); M = Ir, L^{Ir} (**1b**)] to be reported.[7] The current compounds differ completely in coordination and properties than those reported previously.

Treatment of [Cp*M(η^4-benzoquinone)] [M = Rh (**1a**); M = Ir (**1b**)] with excess $AgCF_3SO_3$ in CH_2Cl_2 provided a suspension, the solvent was removed under vacuum and the residue was recrystallized from CH_3CN/Et_2O to give golden crystals of **2a** and off-white crystals of **2b** in good yields (see Exp. Sect.). The spectroscopic data of **2a**,**b** are very similar. Thus, the IR spectra of **2a** and **2b** show the presence of two strong bands at 1266 and 1030 cm^{-1} and at 1267 and 1031 cm^{-1}, respectively, which are assigned to the triflate anions; furthermore, two absorptions are visible at 1593 and 1573 cm^{-1} for **2a** and at 1599 and 1580 cm^{-1} for **2b** which are attributed to the C=O groups of the coordinated benzoquinone. The ^1H NMR spectrum of **2a** recorded in [D_6]acetone shows the presence of two singlets at δ = 3.76 ppm assigned to the diene protons and at δ = 2.05 ppm attributed to the methyl protons of the (η^5-Cp*)Rh moiety, while **2b** shows the presence of a singlet at δ = 5.00 ppm for the diene protons and at δ = 2.06 ppm for the (η^5-Cp*)Ir moiety.

To ascertain the identity of these complexes **2a**,**b**, a single-crystal X-ray diffraction study was undertaken (Figure 2).[9] The structures of **2a** and **2b** show the formation of a 1-D coordination polymer. For example, **2b** consists of trimetallic silver nodes of formula $[Ag_3(L^{Ir})_2(CH_3CN)_2(OTf)]^{2+}$ which are linked through linear η^4-benzoquinone ligand L^{Ir} (**1b**). In this linear coordination polymer the trimetallic silver clusters constitute so-called secondary building units (SBUs) (Figure 1).[5] In each SBU, all silver atoms have tetrahedral configurations, the central silver atom Ag2, lies in a plane of symmetry, is coordinated to a triflate anion and to three quinone oxygen atoms while the other two silver atoms, which are symmetrically related, are linked to three quinone oxygen atoms and coordinated to CH_3CN (Figure 1). The Ag2···Ag1 distance between the central silver atom and the peripheral ones is 3.37 Å, indicative of an interatomic contact (sum of van der Waals radii of silver is 3.44 Å[10]), while the peripheral Ag1···Ag1 distance is 3.71 Å suggesting a weak interaction. Interestingly, the organometallic linker L^{Ir} adopts a boat conformation in **2b** with the quinone carbon atoms bent out of the diene plane while acting as a pentadentate ligand, and connecting five silver atoms such that one quinone oxygen atom is biden-

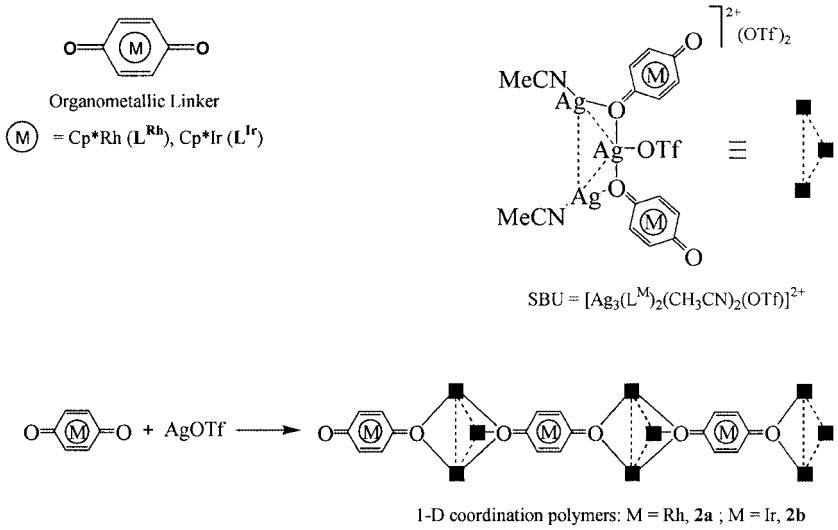

Figure 1. Self-assembly of 1-D polymers **2a**,**b** showing the secondary building units (SBUs) connected by the pentadentate organometallic linkers L^M; M = Rh (**1a**), Ir (**1b**).

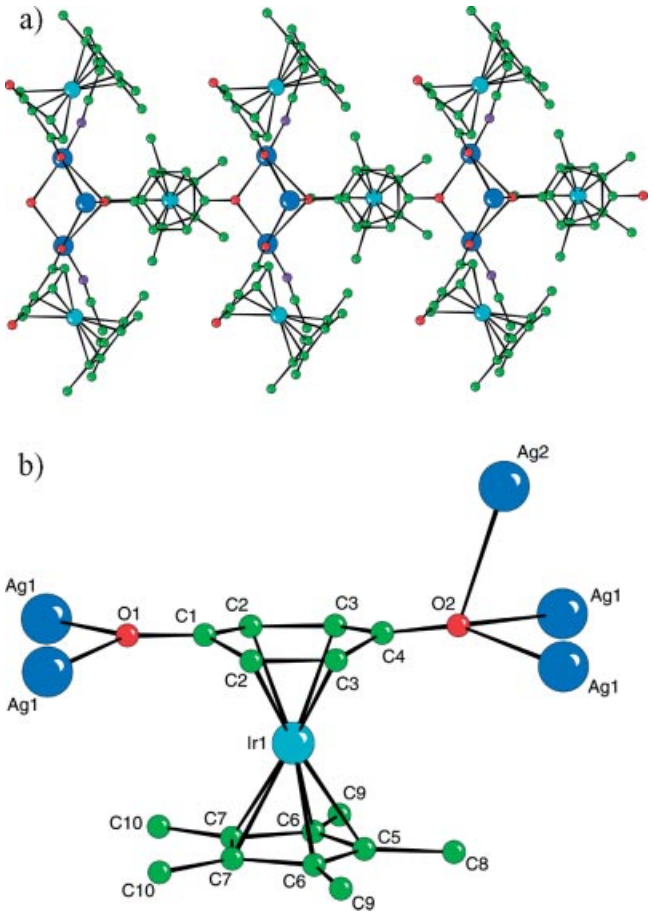

Figure 2. (a) X-ray structure of the 1-D polymer $\{[Ag_3(L^{Ir})_2(CH_3CN)_2(OTf)][L^{Ir}](OTf)_2\}_n$ (**2b**), the triflate anions are omitted for clarity. (b) View of the coordination environment of the pentadentate organometallic linker L^{Ir} in **2b**. Selected bond lengths [Å]: C1–O1 1.293(9), C4–O2 1.281(9), O1–Ag1 2.297(3), O2–Ag1 2.560(4), O2–Ag2 2.508(7), Ir1–C1 2.377(7), Ir1–C2 2.216(5), Ir1–C3 2.220(5), Ir1–C4 2.407(7).

tate (hinge angle θ = 11.85°) and the other one tridentate (hinge angle θ = 11.72°). Such coordination mode has not been reported before (Figure 2b).

Thus, each SBU is connected to the adjacent SBU via a bidentate quinone oxygen atom from one side and through a tridentate quinone oxygen atom from the opposite side, describing a unique architecture for the 1-D coordination polymers $\{[Ag_3(L^M)_2(CH_3CN)_2(OTf)][L^M](OTf)_2\}_n$ (**2a**,**b**).

Discrete trimetallic Ag^I complexes with $d^{10}\cdots d^{10}$ Ag···Ag interactions with luminescent properties continue to generate much interest.[11] The short metal–metal contacts found in these complexes are believed to play a dominant role in excited-state properties.[12] Thus, we intend in the near future to study the photophysical properties of our 1-D polymers **2a**,**b**.

In summary, we have reported a novel class of supramolecular coordination polymers with organometallic linkers exhibiting short argentophilic Ag···Ag interactions. These results illustrate successfully the role of the organometallic ligand linkers L^M (M = Rh, Ir) to produce a novel class of supramolecular species when combined with different metal ions of different geometries. The photoluminescence properties of our coordination polymers will be reported in due course.

Experimental Section

General: All experimental manipulations were carried out under argon using standard Schlenk tube techniques. ^{1}H NMR spectra were recorded with a Bruker AM 300 MHz. IR spectra were recorded as KBr discs with a bio-rad FT-IR spectrometer FTS 165. All solvents were distilled according standard procedures prior to use.

2a: To a suspension of AgOTf (51 mg, 0.2 mmol) in CH_2Cl_2 (15 mL) was added an orange solution of **1a** (35 mg, 0.1 mmol) in CH_2Cl_2 (15 mL). The suspension turned yellow immediately and a solid formed; this mixture was stirred at room temperature for 1 h

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and then the solvent was removed under vacuum, affording a yellow powder which was dried under vacuum and recrystallized by slow diffusion of diethyl ether into a CH_3CN solution to give golden crystals (yield 36 mg, 55%). This compound was identified as $\{[Ag_3(L^{Rh})_2(CH_3CN)_2(OTf)][L^{Rh}](OTf)_2\}_n$. ^1H NMR [300 MHz, $(CD_3)_2CO$]: δ = 2.05 (s, 15 H, Cp*), 3.76 (s, 4 H, benzoquinone) ppm. IR (KBr disc): $\tilde{\nu}$ = 1593, 1572 [ν(C=O)]; 1266 [ν(S–O)]; 1030 [ν(C–F)] cm^{-1}.

2b: To a suspension of AgOTf (80 mg, 0.3 mmol) in CH_2Cl_2 (15 mL) was added a pale yellow solution of **1b** (47 mg, 0.1 mmol). The suspension turned light brown immediately and a solid formed; this mixture was stirred at room temperature for 16 h and then the solvent was removed under vacuum, providing a brown powder which was dried under vacuum and recrystallized by slow diffusion of diethyl ether into a CH_3CN solution to give off-white crystals (yield 45 mg, 60%). This compound was identified as $\{[Ag_3(L^{Ir})_2(CH_3CN)_2(OTf)][L^{Ir}](OTf)_2\}_n$. ^1H NMR (300 MHz, CD_3CN): δ = 2.06 (s, 15 H, Cp*), 5.00 (s, 4 H, benzoquinone) ppm. IR (KBr disc): $\tilde{\nu}$ = 1593, 1572 [ν(C=O)]; 1267 [ν(S–O)]; 1031 [ν(C–F)] cm^{-1}.

An Unprecedented One-Dimensional Chain Constructed from β-Octamolybdate Clusters and Two Kinds of Silver Complex Fragments

Zhenyu Shi,[a] Xiaojun Gu,[a] Jun Peng,*[a] and Zhifeng Xin[a]

Keywords: Chainlike compound / Hydrothermal synthesis / Octamolybdate cluster / Ag complex

An unprecedented one-dimensional chainlike compound with green fluorescent emission, $(H_3O)[Ag_3(2,2'\text{-bpy})_2(phnz)_2(\beta\text{-}Mo_8O_{26})]$ (bpy = bipyridine, phnz = phenazine) has been synthesized under hydrothermal conditions. The compound is constructed from β-octamolybdate clusters linked through two kinds of silver-ligand subunits, $[Ag(2,2'\text{-bpy})(phnz)]^+$ and $[Ag(phnz)]^+$.

Introduction

The significant contemporary interest in the crystal engineering of inorganic-organic hybrid materials not only originates from their diverse structural flexibility, but also from their widely promising potential applications in catalysis, medicine, photochemistry and electromagnetism.[1] Up to now, although a number of inorganic-organic hybrid compounds have been reported,[1f,2] the design and synthesis of novel hybrid materials with highly specific and cooperative functions are still a great challenge. Recently, one synthetic strategy for controlling structure-function relationship has been extensively investigated by choosing suitable building blocks and exploiting the selected or designed organic ligands with the structure-directing properties during the preparation of inorganic-organic hybrid materials, in which the features of the components can be combined to form unique architectures and new properties.[3] An attractive choice of building blocks is polyoxometalate (POM) clusters which, similar to organic ligands, can coordinate to metal centers to construct novel inorganic-organic hybrids.[4] However, among the reported POM-based hybrids, few POM clusters bridged by silver complex fragments have been reported.[5] On the other hand, silver coordination polymers not only are good candidates for potential conducting materials, but also show interesting photophysical and photochemical properties.[6]

As is already known, aromatic chelate ligands such as 2,2′-bipyridine are capable of "passivating" metal sites via the N donors, thus inhibiting expansion of the polymeric frameworks.[7] The polycyclic aromatic bridging ligands such as phenazine with bigger steric hindrance can induce metal ions with flexible coordination spheres to form a complex with a lower coordination number.[1i,8] Therefore, the introduction of two such kinds of organodiamine ligands at a Ag^I site may lead to low-dimensional coordination polymers consisting of π–π stacking interactions and other intermolecular forces which contribute to the physical and chemical behavior of Ag^I complexes.

In this study, we choose 2,2′-bipyridine as a chelate ligand, phenazine as a bridging ligand and Ag^I as the secondary metal, to hydrothermally synthesize a novel one-dimensional chainlike compound with photoluminescence activity, $(H_3O)[Ag_3(2,2'\text{-bpy})_2(phnz)_2(\beta\text{-}Mo_8O_{26})]$ (bpy = bipyridine, phnz = phenazine). The compound represents the first example of octamolybdate clusters bridged by two kinds of organic aromatic amine ligands coordinated to Ag complex fragments.

Results and Discussion

Hydrothermal synthesis has been proved to be a powerful method for the construction of organic-inorganic hybrid materials. Although, in most cases, the reaction mechanisms under hydrothermal conditions are not clear and the control and prediction of crystal structures are difficult, the architecture of the final product directly depends on the interplay of the characteristics of metal ion, ligand, pH values and reaction temperature.[9] In the family of POMs, molybdenum polyoxoanions have received widespread attention owing to their different structures and versatile stoichiometry. It has been documented that the formation of different molybdenum oxoanion subunits can be controlled by the pH values.[3a,10] Generally, mononuclear molybdate $\{MoO_4\}$ exists in basic reaction conditions, while polyoxomolybdate clusters, such as $\{Mo_2O_7\}$, $\{Mo_3O_{10}\}$, $\{Mo_6O_{19}\}$ and $\{Mo_8O_{26}\}$, are most likely isolated under

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

acidic reaction conditions. The β-octamolybdate cluster anion is commonly crystallized from aqueous solutions of molybdate acidified to pH 3–4.

The single-crystal X-ray analysis reveals that the structure of the compound could be described as chains constructed from β-octamolybdates bridged by 2,2′-bipy- and phnz-coordinated Ag^I fragments. As shown in Figure 1, the centrosymmetric octamolybdate $\{Mo_8O_{26}\}$ moiety, which is built up from eight distorted $\{MoO_6\}$ edge-shared octahedrals, is a typical β-octamolybdate. The valence sum calculations show that all molybdenum atoms are in the +6 oxidation state.[11] According to the type of oxygen atoms bonded to the molybdenum atoms, the Mo–O bond lengths are divided into four categories: 1.692(5)–1.706(5) Å for Mo–O(t), 1.754(4)–2.267(4) Å for Mo–O(μ_2), 1.947(4)–2.340(4) Å for Mo–O(μ_3) and 2.135(4)–2.468(4) Å for Mo–O(μ_5) bonds, respectively. All these bond lengths are within the normal ranges and in close agreement with those described in the literature.[4]

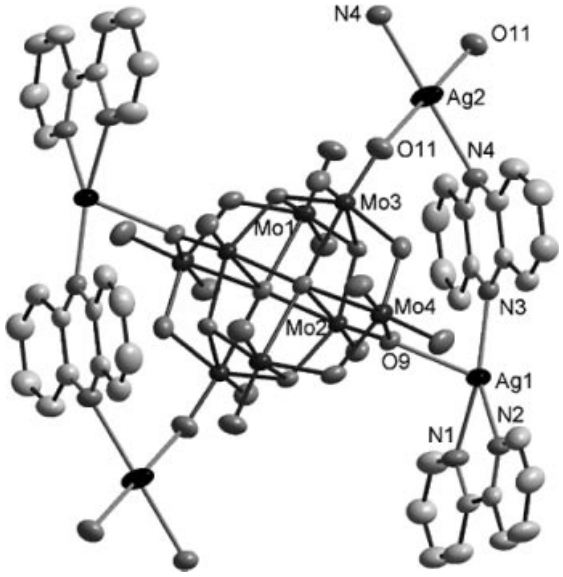

Figure 1. ORTEP drawing of the fundamental building block of the compound with the 50% probability level, showing the coordination environment around Ag and Mo. Only parts of atoms are labeled, and all the hydrogen atoms and water molecules are omitted for clarity.

There are two coordinated dinuclear Ag^I fragments around each β-octamolybdate cluster anion. Two crystallographically independent Ag sites comprise two different distinct environments (see Figure 1). One (Ag1) is coordinated by two nitrogen atoms (N1 and N2) from one 2,2′-bipy ligand, one nitrogen atom (N3) from one phnz ligand, and one bridging oxygen atom (O9) from one β-octamolybdate cluster to complete a trigonal-pyramidal coordination geometry (see Supporting Information, S1a). The atoms N1, N2, N3 and Ag1 nearly lie in the same plane [N3–Ag1–N2 = 144.3(2)°, N2–Ag1–N1 = 71.7(2)°, and N3–Ag1–N1 = 143.2(2)°], while the O9 atom is almost perpendicular to the plane, with the O9–Ag1–N3 angle of 81.5(2)°. The other (Ag2) is coordinated by two nitrogen atoms from two phnz ligands [Ag–N = 2.364(5) Å] and two terminal oxygen atoms from two β-octamolybdate clusters [Ag–O = 2.405(5) Å]. The N4–Ag2–O11 and N4#–Ag2–O11 angles are 82.38(2)° and 97.62(2)°, respectively. The sum of the four N–Ag–O angles is 360.00(4)°, which shows that the Ag(2) site exhibits a distorted square-planar coordination geometry (see Supporting Information, Figure S1b). As is already known, Ag^I generally adopts linear, trigonal, tetrahedral and octahedral coordination geometries, whereas the trigonal-pyramidal and square-planar coordination geometries are less reported. Furthermore, examples of two such kinds of coordination modes existing in the same Ag^I compound have not been documented. The two silver atoms (Ag1 and Ag2) are joined together by one phnz ligand, which acts as a bidentate bridging ligand.

The interesting structural feature of the compound is that β-octamolybdate clusters are linked together by Ag^I fragments through both terminal and bridging oxygen atoms to form a one-dimensional chain (see Figure 2). Interestingly, all the Ag^I ions in the same chain are coplanar. The adjacent one-dimensional chains in the compound are stacked into a two-dimensional supramolecular network (see Figure 3) through offset π–π aromatic stacking interactions with the closest face-to-face distance of ca. 3.40 Å. Protonated water molecules (Ow1) are positioned between the adjacent two-dimensional supramolecular networks and form the hydrogen bonding interactions with the terminal oxygen atoms coming from β-octamolybdate clusters, thus resulting in a three-dimensional supramolecular array (see Supporting Information, Figure S2). The typical hydrogen bonds are as follows: O(6)···Ow(1) 2.892 Å, Ow(1)···O(5) 2.854 Å, Ow(1)···O(8) 2.897 Å, Ow (1)···O(13) 3.001 Å.

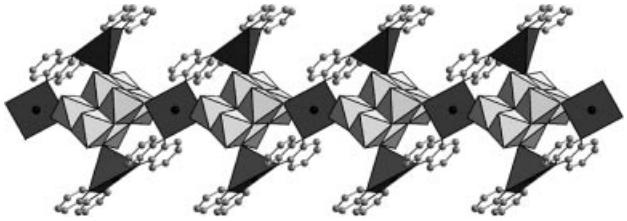

Figure 2. A view of the one-dimensional chain in the compound, all hydrogen atoms and water molecules are omitted for clarity.

Another interesting structural feature is that π–π stacking and Ag^I–π interactions coexist in the compound. To the best of our knowledge, no POM-based Ag^I complexes consisting of π–π stacking and Ag^I–π interactions have been reported. In the compound, the offset face-to-face distance is ca. 3.40 Å. The closest Ag···C contact between adjacent molecules is 3.37(2) Å, which is longer than those found for Ag^I complexes of other polycyclic aromatic compounds (see Figure 4).[6a]

In the infrared spectrum of the compound (as shown in Figure S3), the strong bands at 909, 831, 760, 691, 557 cm^{-1} are attributed to the μ(Mo=O) or μ(Mo–O–Mo) vibrations, while bands in the 1683–1419 cm^{-1} regions can be assigned to characteristic peaks of ligands 2,2′-bipy and phnz.

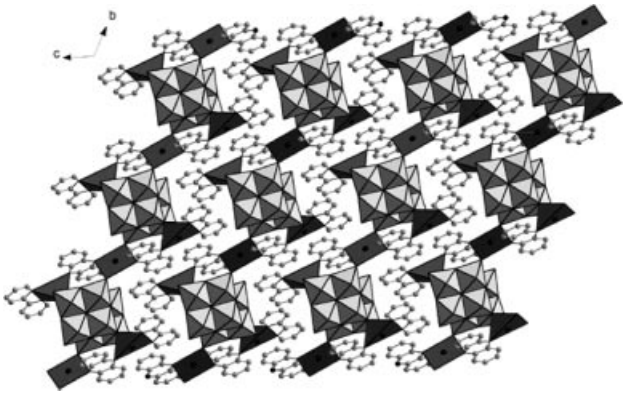

Figure 3. A view of the one-dimensional $\{Ag_3(2,2'\text{-bpy})_2(phnz)_2(\beta\text{-}Mo_8O_{26})\}^-$ chains linked into a two-dimensional layer through supramolecular interactions. All hydrogen atoms are omitted for clarity.

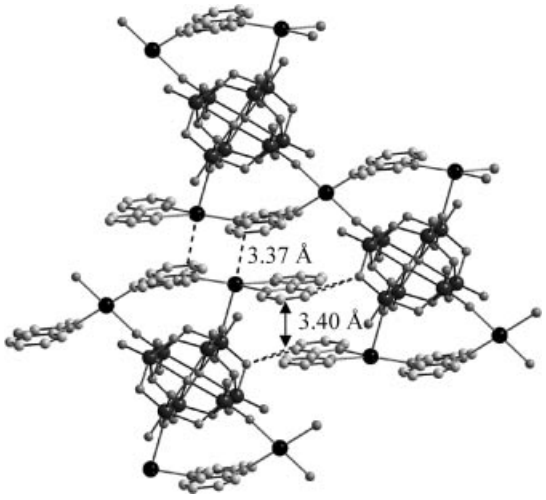

Figure 4. View of the compacted aromatic stacking interactions and significant interactions between the Ag^I ion and aromatic group in the compound.

The thermal gravimetric (TG) curve of the compound exhibits two steps of weight loss in the temperature range 30 to 700 °C (see Figure S4). The first weight loss of 0.63% in the temperature range 40–110 °C corresponds to the release of crystalline water. The second weight loss of 31.08% at 290–430 °C is ascribed to decomposition of organic ligands 2,2′-bipy and phnz. The total weight loss of 31.71% is in good accordance with the calculated value 31.52%.

Generally, Ag^I complexes may emit weak photoluminescence at low temperature.[6b] Whereas, at room temperature the compound in the powdered solid state displays intense photoluminescence with an emission maximum that occurs at 517 nm upon excitation at 420 nm (see Supporting Information, Figure S5). Comparably, the emission bands of the free ligands in the solid state are centered at about 394 nm (λ_{ex} = 330 nm) for 2,2′-bipy and 480, 512 nm (λ_{ex} = 445 nm) for phnz (see Figure S6). It is worth noting that the luminescent properties of the ligands 2,2′-bipy and phnz are very weak, therefore the strong photoluminescence of the compound may originate from the Ag^I–π interactions between Ag^I and the phnz ligand. Since the compound is insoluble in water and common solvents such as ethanol, acetone, acetonitrile and benzene, it may be a good candidate for solvent-resistant green fluorescent material.

In conclusion, a new one-dimensional chainlike compound with green fluorescent emission, constructed from β-octamolybdates linked by two kinds of organic aromatic amine ligands coordinated to Ag^I units, has been successfully synthesized. It represents the first example of POM-based inorganic-organic hybrids in which π–π stacking and Ag^I–π interactions coexist.

Experimental Section

Materials: All reagents and solvents for the syntheses were purchased from commercial and used as received.

Physical Methods: Elemental analyses (C, H, and N) were performed on a PerkinElmer 2400 CHN Elemental Analyzer. Ag and Mo were determined by a Leaman inductively coupled plasma (ICP) spectrometer. IR spectra were obtained on Alpha Centaurt FT/IR spectrometer with KBr pellets in the 400–4000 cm^{-1} region. The TG analyses were performed on a Perkin–Elmer TGA7 instrument in flowing N_2 with a heating rate of 10 °C min^{-1}. Excitation and emission spectra were obtained on a Cary Eclipse.

Synthesis of $(H_3O)[Ag_3(2,2'\text{-bpy})_2(phnz)_2(\beta\text{-}Mo_8O_{26})]$: A mixture of $(NH_4)_6Mo_7O_{24}{\cdot}2H_2O$ (0.4140 g, 0.335 mmol), $AgNO_3$ (0.1138 g, 0.67 mmol), 2,2′-bpy (0.1046 g, 0.67 mmol), phnz (0.0603 g, 0.335 mmol) and H_2O (12 mL) in a mol ratio of 1:2:2:1:2000 was sealed in a Teflon-lined stainless autoclave and heated at 165 °C for 5 days. Yellow crystals of the compound were filtered, washed with water and dried at room temperature. Yield 0.162 g (33% based on silver). Initial pH, 3.8; final pH, 3.3. Elemental analysis for the compound $C_{44}H_{35}Ag_3Mo_8N_8O_{27}$ (2198.91): calcd. C 24.02, H 1.59, N 5.10, Ag 14.73, Mo 34.92; found C 23.96, H 1.46, N 5.18, Ag 14.67, Mo 34.88. IR (KBr): $\tilde{\nu}$ = 3446 (m), 1683 (m), 1558 (m), 1540 (m), 1521 (m), 1490 (m), 1472 (m), 1437 (m), 1419 (m), 909 (m), 831 (w), 760 (w), 691 (m), 557 (w) cm^{-1}.

X-ray Crystallography: Crystal data for the compound was collected on a Rigaku R-AXIS RAPID IP diffractometer, with Mo-K_α-monochromated radiation (λ = 0.71073 Å) at 293 K. An empirical absorption correction was applied.[12] The structure was solved by directed methods and refined by full-matrix least-squares on F^2 using the SHELXTL crystallographic software package.[13] All the non-hydrogen atoms were refined anisotropically. Ow1 was located from difference maps and refined anisotropically, while the hydrogen atoms attached to Ow1 were not located. The positions of hydrogen atoms on carbon atoms were calculated theoretically. Selected bond lengths and angles are listed in Table S1 (see Supporting Information). Crystal data: $C_{44}H_{35}Ag_3Mo_8N_8O_{27}$, triclinic, $P\bar{1}$, M_r = 2198.91 g mol^{-1}, a = 10.132(2) Å, b = 12.106(2) Å, c = 13.283(3) Å, α = 114.43(3)°, β = 107.76(3)°, γ = 90.76(3)°, V = 1394.3(5) $Å^3$, Z = 1, D_c = 2.615 g cm^{-3}, $F(000)$ = 1045, θ range 2.61–27.48°. A total of 9334 reflections were collected and 6204 were independent (R_{int} = 0.0293). The final refinement including hydrogen atoms converged to R = 0.0456, wR = 0.0944, $(\Delta\rho)_{max.}$ = 0.98 e $Å^{-3}$ (0.72 Å from Mo4), $(\Delta\rho)_{min.}$ = –0.98 e $Å^{-3}$ (0.88 Å from Ag2).

CCDC-267510 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Tuning of Copper(I)–Dioxygen Reactivity by Bis(guanidine) Ligands

Sonja Herres-Pawlis,[a] Ulrich Flörke,[a] and Gerald Henkel*[a]

Dedicated to Professor H. W. Roesky on the occasion of his 70th birthday

Keywords: Bioinorganic chemistry / Copper / Guanidine ligands / Ligand design / O–O activation

A series of bis(guanidine) ligands designed for use in biomimetic coordination chemistry, namely bis(tetramethylguanidino)-, bis(dipiperidinoguanidino)-, and bis(dimethylpropyleno)propane (btmgp, $DPipG_2p$ and $DMPG_2p$, respectively), has been extended to include bis(dimethylethyleneguanidino)propane ($DMEG_2p$), which has both N^{amine} atoms of each guanidine functionality connected by a short ethylene bridge, as a member. From this series, a family of novel bis(guanidine)copper(I) compounds – $[Cu_2(btmgp)_2][PF_6]_2$ (**1**), $[Cu_2(DPipG_2p)_2][PF_6]_2$ (**2**), $[Cu_2(DMPG_2p)_2][PF_6]_2$ (**3**), and $[Cu_2(DMEG_2p)_2][PF_6]_2 \cdot 2MeCN$ (**4**) – has been synthesised. Single-crystal X-ray analysis of **1**–**4** demonstrated that these compounds contain dinuclear complex cations that contain twelve-membered heterocyclic $Cu_2N_4C_6$ rings with the Cu atoms being more than 4 Å apart. Each copper atom is surrounded by a set of two N-donor functions from different ligands, resulting in linear N–Cu–N coordination sites. Depending on their individual substitution patterns, the guanidine moieties deviate from planarity by characteristic propeller-like twists of the amino groups around their $N–C^{imine}$ bonds. The influence of these groups on the reactivity of the corresponding complexes **1**–**4** with dioxygen was investigated at low temperatures by means of UV/Vis spectroscopy. The reaction products can be classified into μ-η^2:η^2-peroxodicopper(II) or bis(μ-oxo)dicopper(III) complex cations that contain the $\{Cu_2O_2\}^{2+}$ core portion as different isomers. The electronic properties of the specific bis(guanidine) ligands are discussed from the viewpoint of their σ-donor and π-acceptor capabilities, and it is shown that μ-η^2:η^2-peroxodicopper(II) complexes are stabilised relative to the bis(μ-oxo)dicopper(III) ones if π conjugation within the guanidine moieties is optimised.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Dioxygen binding in biology is controlled by appropriately designed transition metal active sites. Investigations directed towards an understanding of the mechanisms and a transformation of such processes to technical applications are among the most important research objectives not only in bioinorganic chemistry but also in numerous and diverse arrays of catalytic oxidation reactions.[1–7]

From X-ray structure determinations of the blood dioxygen carrier hemocyanin (for example in arthropods and molluscs)[7,8] it is known that the protein active sites consist of μ-η^2:η^2-peroxodicopper(II) units where each copper ion binds three supporting exogenic N-donor functions originating from histidine imidazole groups. Spectroscopic comparisons suggest that this binding mode occurs also in tyrosinases (phenol → *o*-quinone)[9] and catechol oxidases (*o*-catechol → *o*-quinone).[10,11] $Cu–O_2$ (1:1) adducts are suggested to be involved in the activities of dopamine β-hydroxylase,[12] peptidylglycine α-hydroxylating monooxygenase[1b] and amine oxidases,[12,13] and units containing three copper atoms are found in multicopper oxidases (MCOs) that reduce O_2 to water.[9a]

An understanding of the nature of these reactive intermediates is essential in order to use their principles in coordination chemistry directed towards catalytic applications. Considerable progress towards this aim has been attained through examination of the dioxygen reactivity of synthetic Cu^I complexes, which has resulted in the characterisation of a variety of systems containing μ-η^2:η^2-peroxodicopper(II), bis(μ-oxo)dicopper(III) and bis(μ_3-oxo)tricopper(III,II,II) complex topologies (Figure 1).

A key research objective has been to understand how supporting ligand structural features influence the relative stabilities and interconversions of these species, and especially the effects that control the equilibrium between the P- and O-core that are relevant to proposed metalloprotein active-site intermediates. It has been shown that both units can be supported by neutral, multidentate N-donor ligands and that ligand structural elements (e.g., size of substituents, donor type, bite angle, denticity) play a critical role in determining which units form and how they react.[1,2]

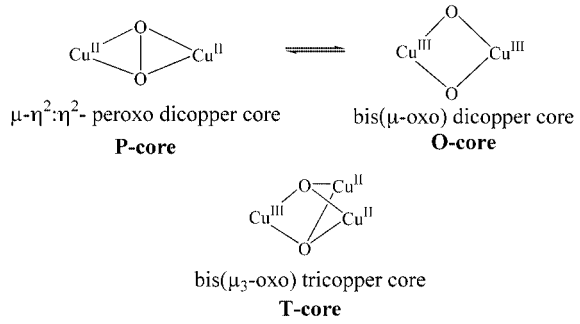

Figure 1. Topologies of Cu/O_2 species where each Cu atom is bonded to both O atoms simultaneously.

The majority of model complexes that imitate the native system make use of tridentate N-donor ligands for copper complexation. These ligands are able to stabilise the Cu_2O_2 core portion by forming square-pyramidal CuO_2N_3 coordination sites with more weakly bonded axial N-donor functions.[3,14,15] However, model complexes that mimic tyrosinase activity are not necessarily dependent on these facial-capping ligands. As has been shown by Stack et al., bidentate N-donor ligands are also capable of forming complexes containing the heterocyclic Cu_2O_2 core portion.[4,16,17] The associated square-planar CuO_2N_2 coordination sites are expected to be more accessible for external substrates that may act as targets for catalytic oxygenation reactions.[18–20] Following this approach, peralkylated diamine ligands have been used to stabilise either the bis(μ-oxo)dicopper(III) (O-core complexes) or the μ-η^2:η^2-peroxodicopper(II) core portion (P-core complexes) depending on the type of substituents.[2a] These systems exhibit tyrosinase-like reactivity as they insert oxygen into C–H bonds. Although the O-core has yet not been detected in enzymatic systems, its relevance for hydroxylation activity seems likely because the equilibria between P- and O-core states proven for model complexes have to be taken into account.[3,16,21–23]

In our search for bifunctional N-donor ligands able to stabilise unusually high metal oxidation states we extended our interest towards guanidine-type systems. Following this approach, bis(tetramethylguanidino)propane (btmgp) was synthesised as the first member of a series of bifunctional peralkylated guanidine ligands designed for use in biomimetic coordination chemistry.[24–26] Attempts to modify the guanidine moieties resulted in the successful preparation of the novel derivatives bis(dimethylpropyleneguanidino)propane ($DMPG_2p$), bis(dipiperidylguanidino)propane ($DPipG_2p$) and bis(dimethylethyleneguanidino)propane ($DMEG_2p$) (Figure 2).[27a,27c]

In this paper we describe a series of dinuclear copper(I) complexes containing these ligands and their reaction behaviour towards molecular oxygen. Depending on the residues attached to the guanidine systems, the resulting Cu_2O_2 species are either bis(μ-oxo)dicopper(III) or μ-η^2:η^2-peroxodicopper(II) complexes.

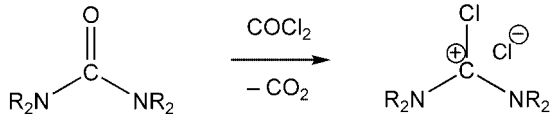
Results and Discussion

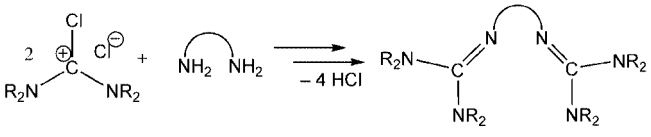
Synthesis of the Ligands

The synthesis of the ligands was accomplished according to a general procedure that allows the condensation of almost every urea with an amine to form a guanidine compound via the corresponding Vilsmeier salt.[27b] The Vilsmeier salt is obtained in good yield by reaction of the substituted urea with phosgene in toluene or acetonitrile (Scheme 1).



Scheme 1. Generation of the Vilsmeier salts.

The reaction of the Vilsmeier salt with propylene-1,3-diamine, in the presence of triethylamine as an auxiliary base, leads to the corresponding guanidine after deprotonation of the initially formed hydrochloride (Scheme 2). Separation from the by-product Et_3NHCl is accomplished by adding 1 equiv. of NaOH per guanidine functionality and removing the resulting NEt_3 and solvent under reduced pressure. The hydrochloride is not isolated but deprotonated in a two-phase system of MeCN/50% aqueous KOH in order to obtain the pure free base, which needs no further purification.



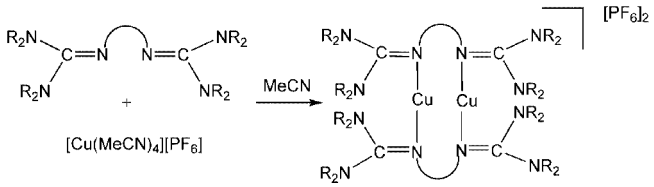
Scheme 2. Reaction between the Vilsmeier salt and the bis(amine).

Synthesis of the Copper Complexes

The complexes were synthesised in good yields by combining $[Cu(MeCN)_4][PF_6]$ with 1.05 equiv. of the bis(guani-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dine) ligand in dry acetonitrile and stirring for 30 min (Scheme 3). The resulting complex salts **1**–**4** are soluble in polar aprotic media such as MeCN, CH_2Cl_2 and THF, but insoluble in diethyl ether and hydrocarbons.



Scheme 3. Complexation of $[Cu(MeCN)_4][PF_6]$ with bis(guanidine) ligands.

All compounds are extremely sensitive to air and moisture due to the high proton affinity of guanidines, which is caused by delocalisation of the positive charge in the guanidine moiety.

Crystal Structures

Single crystals of compounds **1**–**4** suitable for X-ray crystallography were grown by slow diffusion of diisopropyl ether into acetonitrile solutions. The results of the structural analyses are shown in Figures 3, 4, 5, and 6, respectively, while selected bond lengths and angles are collected in Table 1; parameters relating to the data collection and refinement can be found in the Experimental Section.

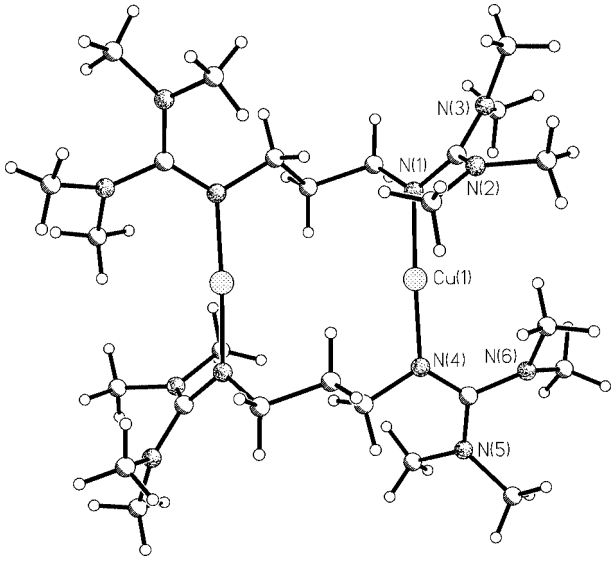


Figure 3. Structure of the $[Cu_2(btmgp)_2]^{2+}$ moiety in crystals of **1**.

The dinuclear complex cations present in all four compounds exhibit molecular ring structures with significant differences in the folding of their propylene chains and in their corresponding interligand H···H separations passing through the centroids of the molecules. The copper centres show almost linear twofold coordination from two N-donor atoms of different ligands with N–Cu–N angles of 176.66(9), 176.77(15), 177.15(6), and 175.29(9)° for **1**–**4**, respectively. The centroids of the molecules lie on crystallographic inversion centres, resulting in perfectly planar

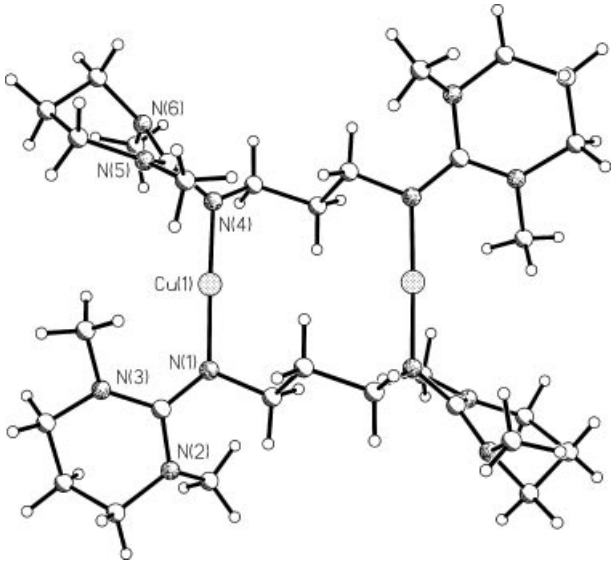

Figure 5. Structure of the $[Cu_2(DMPG_2p)_2]^{2+}$ moiety in crystals of **3**.

Cu_2N_4 moieties. The corresponding Cu–N, N=C, N–C and propyl-bridge C–C distances vary only very slightly from **1** to **4** and are almost identical (averaged values in the order from **1** to **4**): Cu–N: 1.877, 1.866, 1.869, 1.875 Å; N=C: 1.319, 1.309, 1.324, 1.314 Å; C–N(guanidine): 1.358, 1.364, 1.357, 1.359 Å; N–C(propyl): 1.474, 1.471, 1.474, 1.474 Å; C–C(propyl): 1.523, 1.513, 1.523, 1.517 Å. The Cu–N–C and N–C–C ring angles vary slightly in a non-systematic manner, the C–C–C angles are 111.6(2)°, 115.6(3)°, 112.4(1)° and 112.7(2)° for **1**–**4**. These differences may be traced back to variations in the Cu···Cu separations [4.121(1), 4.723(1), 4.358(1), and 4.488(1) Å, respectively]. In **1**, the $N=C(N)_2$ planes of the guanidine moieties are nearly perpendicular to each other with a dihedral angle of 86.3°. For **3**, **2**, and **4** these angles decrease to 80.0°, 71.5° and 68.4°, respectively.

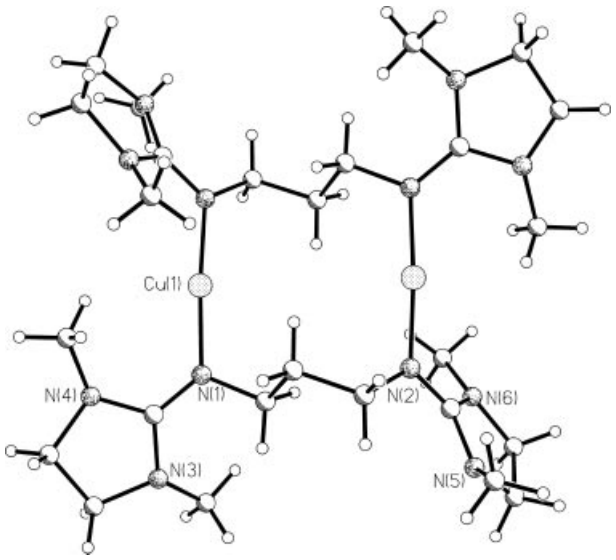

Figure 6. Structure of the $[Cu_2(DMEG_2p)_2]^{2+}$ moiety in crystals of **4**.

Table 1. Selected distances and angles of the complex cations in crystals of **1**–**4**.

Distances [Å]	1	2	3	4
Cu···Cu	4.121(1)	4.723(1)	4.358(1)	4.488(1)
Cu–N^{imine}	1.876(2)	1.876(3)	1.872(1)	1.878(2)
	1.878(2)	1.856(3)	1.867(1)	1.873(2)
N=C	1.323(3)	1.320(5)	1.323(2)	1.310(3)
	1.315(3)	1.297(4)	1.325(2)	1.318(3)
H···H[a]	3.37	2.30	3.26	3.00
Angles [°]				
N^{imine}–Cu–N^{imine}	176.7(1)	176.8(1)	177.2(1)	175.3(1)
N^{amine}–C–N^{amine}	116.0(2)	114.7(4)	117.5(1)	110.0(2)
	116.8(2)	116.0(4)	117.6(1)	110.9(2)

[a] Shortest H···H contact between parallel propylene spacer groups; the H–H vector passes through the centroid of the corresponding complex cation.

Compared with the free ligands $DMPG_2p$ and $DPipG_2p$,[27a] the C=N bonds in **2** and **3** are clearly elongated by about 0.04 Å, whereas the remaining geometric ring parameters show no relevant influence from copper complexation. The $N=C(N)_2$ planes in these ligands show dihedral angles of 23.1 and 31.5°.

Compared with the complexes **1**–**3** (116.4, 115.4, and 117.6°, respectively), the N^{amine}–C–N^{amine} angle in **4** is diminished to 110.5° as the short ethylene linker in the $DMEG_2p$ ligand introduces steric strain.

Table 2 summarises the dihedral angles between the CN_3 guanidine plane and the C^{imine}–N^{amine}–$(C^{alkyl})_2$ planes within the guanidine moieties in the crystalline free bases and in the solid complex salts. It is assumed that the deviation of an individual angle from the mean value mainly reflects packing forces of the crystals. In solution, however, these angles are not subjected to anisotropic interactions with the solvent. For that reason, the following discussion is based on the assumption that the mean angle found in the crystalline state comes close to the situation in solution.

Table 2. Dihedral angles [°] between the CN_3 guanidine plane and the C^{imine}–N^{amine}–$(C^{alkyl})_2$ planes (mean values and ranges of individuals).

Compound	Angle [°]
btmgp	n/a
$DPipG_2p$	40.7 [39.2–42.7]
$DMPG_2p$	25.9 [19.7–31.8]
$DMEG_2p$	n/a
$[Cu_2(btmgp)_2][PF_6]_2$ (**1**)	34.1 [32.3–35.9]
$[Cu_2(DPipG_2p)_2][PF_6]_2$ (**2**)	37.6 [32.2–43.2]
$[Cu_2(DMPG_2p)_2][PF_6]_2$ (**3**)	24.8 [16.7–33.5]
$[Cu_2(DMEG_2p)_2][PF_6]_2$ (**4**)	17.4 [12.7–23.1]

UV/Vis Spectra

Upon reaction of **1** and **2** with O_2, intensive LMCT absorption bands at 300 (ε = 15600) and 390 nm (ε = 17200 $M^{-1}cm^{-1}$) are observed which are characteristic for all O-core complexes known so far (Figure 7).[28a] These species are unstable even at –80 °C in dichloromethane. The initial red solutions change to bluish-green upon warming up to room temperature within 1–2 h.

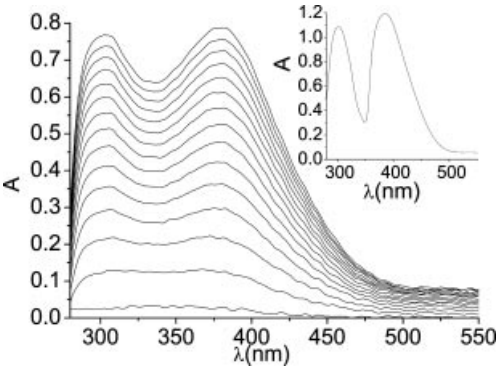

Figure 7. Time-dependent UV/Vis absorption spectra (every 2 min) observed upon introduction of O_2 gas into a CH_2Cl_2 solution of **2** (0.25 mM, –80 °C) during 30 min; inset: spectrum after 2 h (0.33 mM).

Compound **3** reacts with O_2 in dichloromethane with predominant formation of a P-core complex which can be identified by LMCT absorptions at 350 (ε = 21200) and at 550 nm (ε = 900 $M^{-1}cm^{-1}$). The band at about 300 nm (ε = 13500 $M^{-1}cm^{-1}$) originates from O-core components that are formed concomitantly with the P-core (Figure 8). The O-core absorption at 390 nm is not resolved.

In contrast, reaction of **3** with O_2 in acetonitrile at –40 °C results in the immediate formation of an O-core complex, as shown by the UV/Vis absorption bands at 290 (ε = 13000) and 390 nm (ε = 15800 $M^{-1}cm^{-1}$; Figure 9). With MeCN as solvent, the equilibrium between P- and O-core is shifted almost completely to the O-core side. These results show that coordinating solvents are better suited to stabilise the O-core than non-coordinating ones, and thus confirm the reports of other groups.[1a,2,3a]

Treatment of a 0.2 mM solution of **4** in CH_2Cl_2 with dioxygen at –80 °C resulted in a green colour of the solution. At higher concentrations, the solution turns dark brown. The UV/Vis spectrum observed 1 h after introduction of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

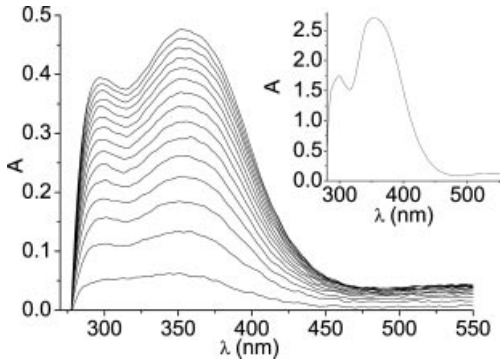

Figure 8. Time-dependent UV/Vis absorption spectra (every 2 min) observed upon introduction of O_2 gas into a CH_2Cl_2 solution of **3** (0.2 mM, –80 °C) during 30 min; inset: spectrum after 2 h (0.5 mM).

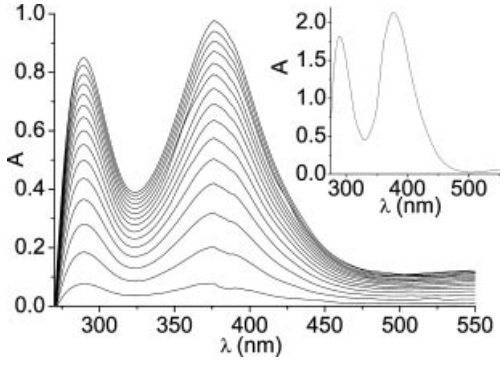

Figure 9. Time-dependent UV/Vis absorption spectra (every 30 s) observed upon introduction of O_2 gas into an MeCN solution of **3** (0.25 mM, –40 °C) during 8 min; inset: spectrum after 1 h (0.5 mM).

molecular oxygen is shown in Figure 10. The spectrum is dominated by a strong absorption band at 355 nm (ε = 17000 $M^{-1}cm^{-1}$) indicative of the predominant formation of the P-core complex. The shoulder at 320 nm (ε = 9500 $M^{-1}cm^{-1}$) is assigned to the formation of O-core contributors.

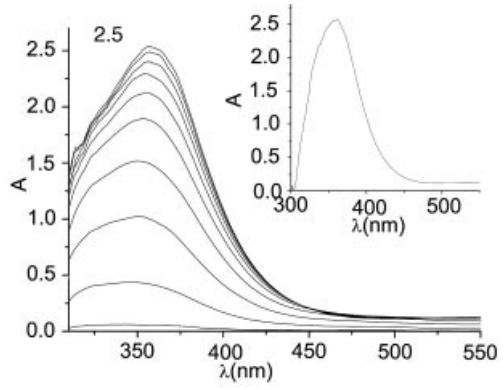

Figure 10. Time-dependent UV/Vis absorption spectrum (every 2 min) observed upon introduction of O_2 gas into a solution of **4** in MeCN/CH_2Cl_2 (1:10) (0.5 mM, –80 °C) during 30 min, inset: spectrum after 1 h (0.25 mM).

Kinetic Aspects

The increase in the absorption bands during the reaction of **1**–**3** with dioxygen in excess obeys first-order kinetics (Figure 11). Moreover, the same first-order rate constants were obtained for reactions starting from different concentrations of **3** in CH_2Cl_2. This observation indicates that the reaction of the copper(I) complexes with oxygen is first-order with respect to the copper complex but of zero-order with respect to O_2 if it is used in excess. The activation parameters ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) for the formation of the O-core complexes of **1** and **2** and the P-core complex of **3** were determined from the temperature dependence of k (–40 to –80 °C). The first-order rate constants (k) determined at –80 °C and the activation parameters for the formation of the copper–dioxygen species are summarised in Table 3. The kinetic data given below are in accordance with comparable systems reported in the literature, which exhibit small activation enthalpies and very negative activation entropies.[22,23] A small activation enthalpy is indicative of the high driving force for the reaction of a copper(I) complex with dioxygen, whereas a negative activation entropy is the result of a reaction where two molecules are combined to form a new one.

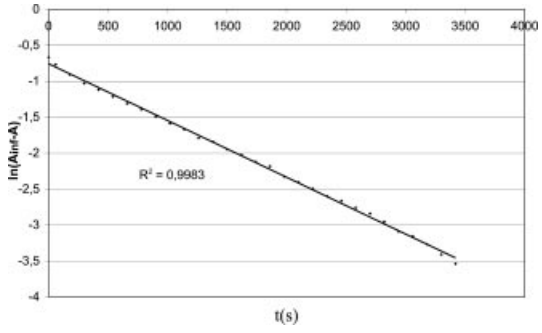

Figure 11. First-order plot based on the absorption change at 350 nm (P-core) for the reaction of **3** at –80 °C with O_2.

Table 3. Kinetic data for the formation of copper–dioxygen species (first-order kinetics).[28b]

Compound	k_1 [s^{-1}]	$\Delta H^{\ddagger}$ [kJ mol^{-1}]	$\Delta S^{\ddagger}$ [J mol^{-1} K^{-1}]
$[Cu_2(btmgp)_2][PF_6]_2$ (**1**)	$1.6(1)\times10^{-1}$	9(1)	–210(5)
$[Cu_2(DPipG_2p)_2][PF_6]_2$ (**2**)	$6.3(3)\times10^{-5}$	42(1)	–104(3)
$[Cu_2(DMPG_2p)_2][PF_6]_2$ (**3**)	$7.9(3)\times10^{-4}$	12(1)	–230(2)

In comparison with **1** and **3**, complex **2** shows a higher activation enthalpy and a smaller negative activation entropy, which can be traced back to the steric demands of the piperidyl units.

Electrochemistry

The copper(I) complexes **1**–**4** were also investigated cyclovoltammetrically to determine their redox activities. In the course of these measurements, irreversible oxidation waves at about –0.2 V attributable to the oxidation of Cu^{I} to Cu^{II} are observed for all the complexes (Table 4). This behaviour is not surprising as the initially linear coordination of Cu^{I} requires subsequent rearrangement processes on changing the oxidation state of copper.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 4. Cyclovoltammetric data (MeCN/TBAP, 2 mm glassy carbon/NHE, v = 100 mV s^{-1}, 25 °C).

Copper complex (+1/+2)	E_{ox} [V]
$[Cu_2(btmgp)_2][PF_6]_2$ (**1**)	–0.18
$[Cu_2(DPipG_2p)_2][PF_6]_2$ (**2**)	–0.29
$[Cu_2(DMPG_2p)_2][PF_6]_2$ (**3**)	–0.21
$[Cu_2(DMEG_2p)_2][PF_6]_2$ (**4**)	–0.23

Interestingly, no correlation between the oxidation potentials of the copper(I) complexes **1**–**4** and their abilities to stabilise P- or O-core complexes could be found.

Mechanism of the Reaction with Oxygen

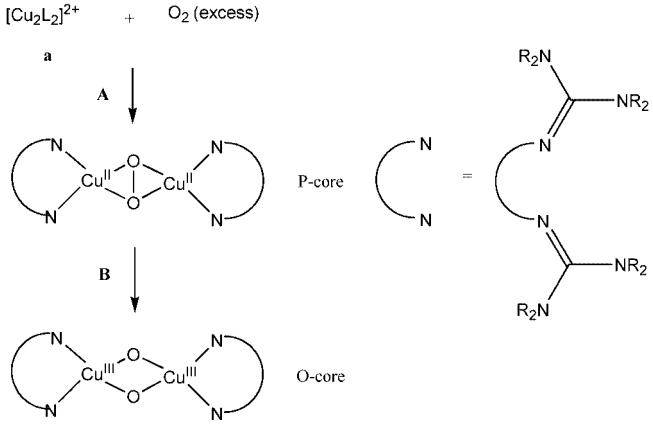
The observed reaction with molecular oxygen has to be associated with a rearrangement of the bis(guanidine) ligands because the target area of this reaction is affected by significant H···H interactions between protons belonging to adjacent propylene spacers. This interaction is shown by the dashed line in Figure 4 (complex cation **2**). The corresponding ligand conformation represents the maximum stretch of the propylene spacer, which leads to a maximum intraligand N···N separation of 4.821 Å. On going to shorter N···N separations, as realised in the complex cations **1**, **3** and **4**, the propylene chain folds up and allows longer H···H contacts, as can be seen from Table 1 and Figures 3, 5 and 6, respectively. This would principally facilitate potential oxygen insertion, but is in contradiction with the requirements of the resulting $N_2Cu_2O_2N_2$ moiety, which demands intraligand N···N distances of at least 5.5 Å.[27c] Thus, the situation under discussion does not allow any insertion of oxygen into this region without rearrangement of the ligands.

Based on the kinetic data, we propose the following mechanism for the reaction with molecular oxygen (Scheme 4): the Cu^I precursor (complex **a**) reacts in a sequence of first-order reactions with an excess of dioxygen to form the P-core complex. The oxygen uptake within step **A** is rate-determining. In the cases of **1** and **2**, the P-core complexes are less stable than their O-core counterparts, so that the reaction proceeds immediately via step **B**. In the case of **3**, the P-core complex is more stable, and its formation was investigated kinetically.

Reaction step **A** also includes the rearrangement of the bis(guanidine) moieties from nonchelating ligands into chelating ones. The corresponding reaction path is currently under investigation.

σ-Donor and π-Acceptor Capabilities of the Ligands

In order to explain the reaction behaviour of the copper(I) complexes with molecular oxygen, we have to look at the special coordination properties of the guanidine ligands described above. The dihedral angles within the guanidine moieties are decisive for the discussion of these coordination properties (vide supra). Depending on the residues attached to the guanidine systems, the resulting Cu_2O_2 species



Scheme 4. Proposed mechanism of the reaction of **1**–**4** with dioxygen.

are either bis(μ-oxo)dicopper(III) or μ-η^2:η^2-peroxodicopper(II) complexes, or mixtures of both. The direction in which the equilibrium is driven depends on the degree of planarisation of the guanidine moieties. Within a guanidine residue, the observed structure is predominantly the result of an interplay of two major driving forces, one of them determined by electronic and the other by steric interactions.

Both types of interaction are competing against each other: as the p-orbitals of the peripheral $N^{amine}C_3$ portions search for reasonably good π-interactions with the central CN_3 unit, this prerequisite demands one common plane containing all the involved C and N atoms. On the other hand, the spatial demands of the substituents at the amine nitrogen atoms require propeller-like twists of the NC_3 portions around their N–C^{imine} bonds, which thus prevents a coplanar arrangement with the central CN_3 group. Furthermore, we observed pyramidalisation tendencies of the peripheral $N^{amine}C_3$ portions, which are amplified if both N atoms are part of a heterocyclic ring, as in $DMPG_2p$ and $DMEG_2p$. The degree of pyramidalisation depends on the steric strain in the heterocycle but has no influence on the coordination properties.

It turned out that the result of the interplay between electronic (π-p conjugation) and steric forces (repulsion of the substituents, Figure 12) is decisive for the equilibrium between the bis(μ-oxo)- and the μ-η^2:η^2-peroxodicopper core. Small dihedral angles between adjacent $N^{amine}C_3$ and CN_3 units, indicative of a good conjugation of the π-orbitals in the guanidine moiety, favour the μ-η^2:η^2-peroxodicopper core, whereas moderately larger ones induce a shift of the equilibrium towards the formation of the bis(μ-oxo)dicopper state.

A bonding description of the P-core has been developed by a detailed correlation of spectral features, structural parameters and theoretical calculations by Solomon et al.[9] Furthermore, it is reported that strictly σ-donating ligands should be better suited to stabilise O-core complexes, whereas ligands with π-acceptor properties should favour the formation of their P-core counterparts.[2a,3a]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

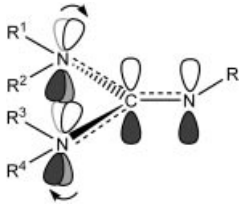


Figure 12. Competition of p-π conjugation and steric repulsion within the guanidine centre; arrows indicate twist from ideal conjugation (pale grey).

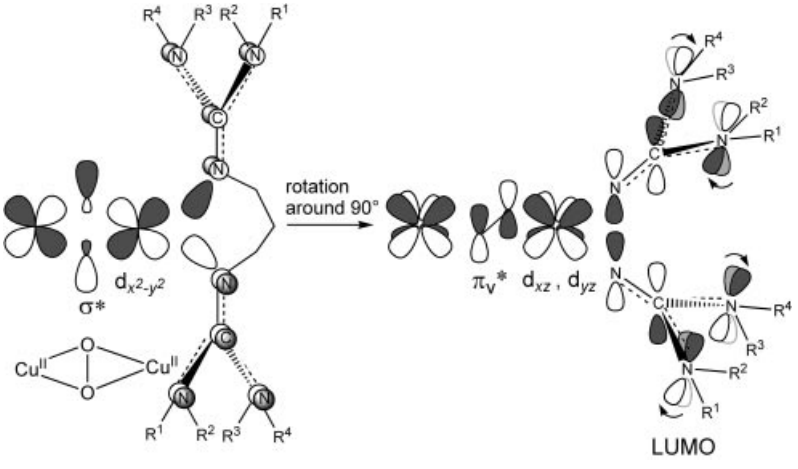
The bonding situation comprising a bis(guanidine) ligand attached to the $\{Cu_2O_2\}^{2+}$ core portion is illustrated in Scheme 5. In an attempt to elucidate the principal factors that control the P-core/O-core equilibrium, we correlated the degree of conjugation within the guanidine moiety with the reaction behaviour of the corresponding copper(I) complex towards oxygen. This correlation applies to bis(guanidine) ligands with propylene backbones. In the σ-plane (Scheme 5, left), the interaction of the σ-lobes of the coordinating imine nitrogen atoms with the Cu^{II} $d_{x^2-y^2}$ orbital is denoted. Orthogonally to the σ-plane, the empty π*-orbitals (Scheme 5, right) of the guanidine moieties, representing the LUMO, possess the correct symmetry to accept electron density from the filled d_{xz} and d_{yz} orbitals of Cu^{II}. In the next step, electron density from the peroxide π_v*-orbital can now be transferred into the partially depleted d_{xz} and d_{yz} orbitals of Cu^{II}. At this stage, the degree of p-π conjugation within the guanidine system is of interest. Enhanced p-π overlap lowers the energy of the LUMO of the guanidine residue and makes it more accessible for π-back-donation. In consequence, small modifications of the ligand geometries that change the guanidine conjugation are suited to influence the equilibrium between P- and O-core complex states. In the ligands $DMPG_2p$ and $DMEG_2p$, the alkylene linkers tie the amine nitrogen atoms together and the average guanidine dihedral angles are therefore very small (vide supra). The guanidine conjugation is thus enhanced. However, in btmgp and $DPipG_2p$ the NR_2 moieties are twisted around their N^{amine}–C^{imine} bonds, and the guanidine conjugation is hindered. For that reason, the LUMO is raised in energy, and back-donation is diminished. Now, the σ-donating effect of the imine nitrogen atoms dominates the coordination and the O-core is stabilised.

Conclusions

The novel dipod ligand bis(dimethylethyleneguanidino)-propane ($DMEG_2p$) has been synthesised for use in biomimetic coordination chemistry. $DMEG_2p$ belongs to a new class of bis(guanidine) ligands whose Cu^I complexes are well suited to activate molecular oxygen. Due to their ability to delocalise the positive charge over the guanidine moiety, these ligands are able to stabilise high metal oxidation states, which are established in a variety of copper complexes containing the $\{Cu_2O_2\}^{2+}$ core portion. The analysis of the bonding situation comprising this site attached to a bis(guanidine) residue reveals that the coordination properties of the imine N-donor atoms depend on the substitution pattern within the guanidine moieties. Thus, it is possible to influence the reactivity of the bis(guanidine)copper(I) complexes towards molecular oxygen directly by introducing appropriately designed substituents. Sterically demanding alkyl groups raise the energy of the LUMO, which has the appropriate symmetry to accept electrons from the $\{Cu_2O_2\}^{2+}$ core portion and thus destabilise the P-core state within these complexes. On the other hand, integrating both amine groups of a guanidine residue into a five- or six-membered ring favours the P-core over the O-core state by strengthening the π-conjugation within the ligand and thus lowering the energy of the LUMO. Based on these interrelations between steric features of the ligands and the electron distribution within the $\{Cu_2O_2\}^{2+}$ core portions of dinuclear Cu_2O_2 complexes, new insights into the mechanism of dioxygen activation are provided and strategies towards ligand modification can be developed which are directed towards tailored reaction systems capable of hydroxylating substrates in pre-defined positions.



Scheme 5. Bonding situation comprising a bis(guanidine) ligand attached to the $\{Cu_2O_2\}^{2+}$ core portion.

Experimental Section

General Remarks: All manipulations were performed under pure dinitrogen (99.996%) dried with P_4O_{10} using Schlenk techniques or a glovebox and with absolute solvents. Solvents were purified according to literature procedures and also kept under nitrogen. Triethylamine and 1,3-diaminopropane were used as purchased from Fluka. $[Cu(MeCN)_4][PF_6]$, the Vilsmeier salts and the ligands btmgp, $DMPG_2p$ and $DPipG_2p$ were prepared according to literature procedures.[24,27]

Physical Measurements: Spectra were recorded with the following spectrometers: NMR: Bruker AMX 300 and Avance 500, respectively. IR: Nicolet P510. UV: Perkin–Elmer Lambda 45 in combination with the Hellma UV/Vis low-temperature fibre optic interface (1-cm path length cell), excess O_2, Lauda RL 6 CP cryostat. Copper(I) solutions were transferred into the UV low-temperature cell with a steel capillary under argon pressure. MS (EI, 70 eV): Saturn 2. The elemental analysis for $DMEG_2p$ was performed with a Perkin–Elmer 2400 analysator. Microanalyses for **1**–**4** were performed at the Mikroanalytisches Labor, Ilse Beetz, Kronach, Germany. Cyclic voltammetry (CV) was performed with the electrochemical device Metrohm E 505 equipped with a potentiostat Model VersaStat by EG&G in combination with the PC program Electrochemical Analysis Software 3.0 Model 250 by EG&G. The electrochemical cell was operated under argon, with glassy carbon, glassy carbon and saturated Ag/AgCl serving as working, counter and reference electrodes, respectively. CV curves were obtained at scan rates of 100 mV s^{-1} at 25 °C in MeCN/0.1 M nBu$_4$NPF$_6$. As the complexes are extremely air-sensitive, the copper(I) solutions were transferred into the CV cell with a steel capillary under argon pressure.

Caution! Phosgene is a severe toxic agent that can cause pulmonary embolism and, in the case of prolonged exposure, may be lethal. Use only in a well-ventilated fume hood.

Chloro-*N*,*N*′-bis(1-piperidyl)formamidinium Chloride: According to a literature procedure,[27b] phosgene was passed at 0 °C through a solution of Bis(1-piperidyl) ketone (Aldrich, 12.5 g, 63.8 mmol) in dry MeCN (200 mL) for 30 min. The reaction mixture was stirred at room temperature for 6 h and at 40 °C for another 36 h. After the mixture had cooled down to room temperature, the solvent was evaporated under reduced pressure in order to obtain the product as colourless, slowly crystallising oil. Yield: ca.70% (112 g, 44.7 mmol).

Chloro-*N*,*N*′-ethylene-*N*,*N*′-dimethylformamidinium Chloride: Phosgene was passed at 0 °C through a solution of 1,3-dimethyl-2-imidazolidinone (Fluka, 68.5 g, 600 mmol) in dry toluene (300 mL) for 50 min. The reaction mixture was stirred at room temperature for 2 h and at 40 °C for another 12 h. After the mixture had cooled down to room temperature, the white precipitate formed was collected by filtration, washed three times with dry diethyl ether, and dried in vacuo. Yield: 95% (96 g, 570 mmol).

***N*,*N*′-Bis(1,3-dimethylimidazolidin-2-ylidene)propane-1,3-diamine [Bis(dimethylethyleneguanidino)propane, $DMEG_2p$]:** A solution of chloro-*N*,*N*′-ethylene-*N*,*N*′-dimethylformamidinium chloride (6.76 g, 40 mmol) in dry MeCN (80 mL) was added dropwise, with vigorous stirring, to an ice-cooled solution of 1,3-diaminopropane (1.48 g, 20 mmol) and triethylamine (5.57 mL, 4.04 g, 40 mmol) in dry MeCN (40 mL). After 3 h at reflux, a solution of NaOH (1.6 g, 40 mmol) in water (10 mL) was added. Solvents and Et_3N were then evaporated under vacuum. In order to deprotonate the bis(hydrochloride), 50 wt% KOH (aq., 25 mL) was added and the free base was extracted into the MeCN phase (3 × 25 mL). The organic phase was dried with Na_2SO_4 on charcoal. After filtration through Celite, the solvent was evaporated under reduced pressure. The pure product was obtained as a colourless oil which crystallised after 2 months as needles suitable for X-ray diffraction; yield: 95% (5.05 g, 19 mmol). ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 1.57 (m, 2 H, CH_2), 2.60 (s, 12 H, CH_3), 2.95 (br., 8 H, CH_2), 3.26 (t, ^3J = 6.7 Hz, 4 H, CH_2) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C): δ = 32.1 (C_a), 36.3 (CH_3), 45.0 (C_b), 49.3 (CH_2), 157.3 (C_{gua}) ppm. IR (film NaCl): $\tilde{\nu}$ = 2931 s, 2831 s, 1660 vs. [ν(C=N)], 1651 vs. [ν(C=N)], 1485 s, 1435 m, 1422 m, 1384 m, 1336 w, 1263 m, 1241 w, 1113 w cm^{-1}. EI-MS: *m*/*z* (%) = 266.2 (39) [M$^+$], 249 (4) [M$^+$ – CH_3], 205 (5), 152 (10), 140 (60) [$CH_2CH_2N{=}CN_2C_4H_{10}^+$], 126 (80) [$CH_2N{=}CN_2C_4H_{10}^+$], 114 (100) [$H_2N{=}CN_2C_4H_{10}^+$], 98 (32), 84 (25), 70 (24). $C_{13}H_{26}N_6$ (266.4): calcd. C 58.61, H 9.84, N 31.55; found C 58.93, H 9.58, N 31.49.

$[Cu_2(btmgp)_2][PF_6]_2$ (1): $[Cu(MeCN)_4][PF_6]$ (372 mg, 1 mmol) was added to a stirred solution of btmgp (284 mg, 1.05 mmol) in MeCN (15 mL). After 30 min of stirring, diethyl ether (20 mL) was added to obtain the colourless product, yield: 90% (430 mg). Crystals suitable for X-ray diffraction were grown by slow diffusion of diethyl ether into an MeCN solution of **1**. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 2.01 (s, MeCN), 2.28 (m, 2 H, H_b), 2.89 (s, 12 H, CH_3), 2.91 (s, 12 H, CH_3), 3.32 (m, 4 H, H_a) ppm. IR (KBr): $\tilde{\nu}$ = 3435 w, 2953 m [ν(CH)], 2931 m [ν(CH)], 2881 m [ν(CH)], 2853 w [ν(CH)], 1564 s [ν(C=N)], 1558 s [ν(C=N)], 1539 s [ν(C=N)], 1477 m [δ(CH)], 1464 m [δ(CH)], 1456 m, 1427 m, 1416 m, 1408 m, 1398 s [ν(C=N)], 1362 m [ν(C=N)], 1337 vw, 1240 w, 1169 m [ν(C=N)], 1161 w, 1123 w, 1070 m [ν(C=N)], 1024 w, 1011 w, 899 w, 876 m, 839 vs, 779 w, 557 m cm^{-1}. UV/Vis (CH_2Cl_2): λ_{max} (ε) = no bands; shoulder at 360 nm (233 M^{-1} cm^{-1}). $C_{26}H_{60}Cu_2F_{12}N_{12}P_2$ (957.9): calcd. C 32.60, H 6.31, N 17.55; found C 32.66, H 6.39, N 17.52.

$[Cu_2(DPipG_2p)_2][PF_6]_2$ (2): $[Cu(MeCN)_4][PF_6]$ (372 mg, 1 mmol) was added to a stirred solution of $DPipG_2p$ (452 mg, 1.05 mmol) in MeCN (15 mL). After 30 min of stirring, diethyl ether (20 mL) was added to obtain the colourless product, yield: 82% (524 mg). Crystals suitable for X-ray diffraction were grown by slow diffusion of diisopropyl ether into an MeCN solution of **2**. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ = 1.48–1.58 (m, 24 H, Pip-CH_2), 1.71 (q, ^3J = 7.0 Hz, 2 H, CH_2), 3.05 (t, ^3J = 7.0 Hz, 16 H, Pip-CH_2), 3.55 (t, 4 H, CH_2) ppm. ^{13}C NMR (125 MHz, CD_3CN, 25 °C): δ = 24.0 (Pip), 25.2 (Pip), 25.6 (Pip) 33.8 (C_a), 47.6 (C_b), 49.3 (Pip), 160.2 ($C_{quat.}$) ppm. IR (KBr): $\tilde{\nu}$ = 2934 m, 2852 m, 1626 s [ν(C=N)], 1554 s [ν(C=N)], 1548 s [ν(C=N)], 1491 m [ν(C=N)], 1440 m, 1372 m, 1341 w, 1261 w, 1253 m 1236 w, 1211 w, 1203 w, 1163 m, 1114 w, 1078 m, 1023 m, 1016 w, 985 w, 907 w, 839 vs. [ν(P–F)], 787 m, 705 w, 581 w, 555 m cm^{-1}. $C_{50}H_{92}Cu_2F_{12}N_{12}P_2$ (1278.4): calcd. C 46.98, H 7.25, N 13.15; found C 46.99, H 7.22, N 13.19.

$[Cu_2(DMPG_2p)_2][PF_6]_2$ (3): $[Cu(MeCN)_4][PF_6]$ (372 mg, 1 mmol) was added to a stirred solution of $DMPG_2p$ (308.7 mg, 1.05 mmol) in MeCN (15 mL). After 30 min of stirring, diethyl ether (20 mL) was added to obtain the colourless product, yield: 86% (433 mg). Crystals suitable for X-ray diffraction were grown by slow diffusion of diisopropyl ether into an MeCN solution of **3**. ^{1}H NMR (500 MHz, CD_3CN, 25 °C): δ = 1.62 (m, 2 H, CH_2), 1.71 (m, 4 H, CH_2), 2.95 (s, 12 H, CH_3), 3.15 (m, 8 H, CH_2) ppm. ^{13}C NMR (125 MHz, CD_3CN, 25 °C): δ = 22.3 (CH_2), 34.8 (C_a), 40.1 (CH_3), 46.3 (C_b), 49.7 (CH_2), 160.6 ($C_{quat.}$) ppm. IR (KBr): $\tilde{\nu}$ = 2953 s, 2919 s, 2864 s, 2831 m, 1564 vs. [ν(C=N)], 1552 vs. [ν(C=N)], 1537 vs. [ν(C=N)], 1473 s, 1453 s, 1419 s, 1403 vs. [ν(C=N)], 1376 s, 1354 s, 1325 s, 1313 s, 1272 w, 1236 s, 1206 w, 1162 w, 1113 w, 1084 m, 1050 m, 1014 m, 837 vs. [ν(P–F)], 769 s, 557 s, 511 m cm^{-1}.

Crystal Structure Analyses: Crystal data for compounds **1**–**4** are presented in Table 5. X-ray diffraction data were collected with a Bruker-AXS SMART APEX CCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å). Data reduction and absorption correction were performed with SAINT and SADABS.[29] The structures were solved by direct and conventional Fourier methods and all non-hydrogen atoms refined anisotropically with full-matrix least-squares procedures based on F^2 (SHELXTL[29]). Hydrogen atoms were derived from difference Fourier maps and placed at idealised positions, riding on their parent C atoms, with isotropic displacement parameters U_{iso}(H) = 1.2U_{eq}(C) and 1.5U_{eq}(C methyl). All methyl groups were allowed to rotate but not to tip. Compound **4** contains two MeCN solvent molecules per unit cell. CCDC-273408 (**1**), -273409 (**2**), -273410 (**3**), and -273411 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Stable Nickel Catalysts for Fast Norbornene Polymerization: Tuning Reactivity

Juan A. Casares,[a] Pablo Espinet,*[a] José M. Martín-Alvarez,[a] Jesús M. Martínez-Ilarduya,[a] and Gorka Salas[a]

Keywords: Homogeneous catalysis / As ligands / Sb ligands / Nickel / Polymerization / Norbornene / Pentafluorophenyl

The air-stable complexes *trans*-[Ni($C_6Cl_2F_3$)$_2$L$_2$] (L = $SbPh_3$, **1**; $AsPh_3$, **2**; $AsCyPh_2$, **3**; $AsMePh_2$, **4**; PPh_3, **5**) have been synthesized by arylation of [$NiBr_2$(dme)] (dme = 1,2-dimethoxyethane) in the presence of the corresponding ligand L (for compounds **1**–**4**) or by ligand substitution starting from **1** (for compound **5**). The structures of **1**, **2**, and **5** have been determined by X-ray diffraction and show an almost perfect square-planar geometry in all cases. Their catalytic activity in insertion polymerization of norbornene have been tested showing a strong dependence of the yield and molecular mass of the polymer on the ligand used and the solvent. High yield and high molecular mass values are obtained using complexes with ligands easy to displace from Ni^{II} ($SbPh_3$ is the best) and noncoordinating solvents. Complexes **1**–**3** are suggested as convenient bench-catalysts to have available in the lab.

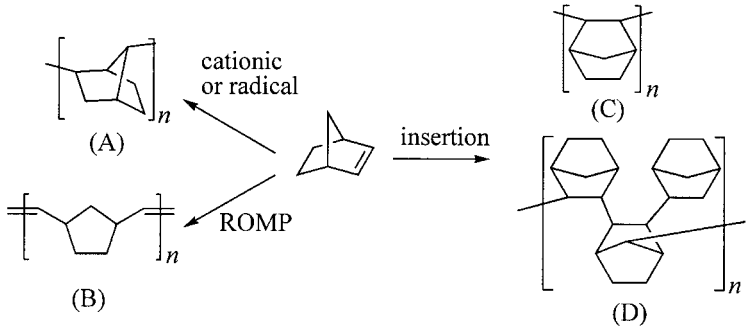
Introduction

The increasing interest in the polymerization of cyclic olefins is due to the attractive properties of these polymers, which show high glass transition temperatures, high optical transparency, low dielectric constant and low birefringence. Starting from norbornene (bicyclo[2.2.1]hept-2-ene) and norbornene derivatives, different classes of polymers can be obtained by selecting polymerization conditions that drive the reaction by cationic or radical pathways, by ring-opening metathesis, or by insertion routes (Scheme 1).[1]

Cationic polymerization of norbornene results in the formation of low molecular mass polymers with rearranged norbornanediyl units in the backbone (A). Metal catalyzed ring-opening metathesis polymerization (ROMP) of norbornene derivatives yields polymers containing unsaturations in the backbone (B). Metal-catalyzed insertion polymerization of norbornene, either with early transition metallocene complexes or with late transition organometallics can lead to two different structures, one strictly linear containing norbornanediyl units (C), and another in which norbornanediyl and rearranged norbornanediyl with appended norbornanediyl units alternate (D).[1,2]

A number of nickel complexes are very efficient catalysts for the vinyl polymerization of norbornene, for the copolymerization of functionalized norbornenes, and also for the copolymerization of norbornene with ethene.[1,3–9] Usually the polymerization requires a nickel(II) catalyst and an organometallic co-catalyst [typically methylaluminoxane or



Scheme 1.

$B(C_6F_5)_3$],[1,3,7,8,10] but a few nickel organometallics (cationic allyl complexes such as [Ni(η^3-crotyl)(1,4-COD)]PF_6, some phenyl derivatives, and [Ni(C_6F_5)$_2$(η^6-toluene)]), are very efficient without co-catalyst.[1,8,9] Noteworthy, although the use of monodentate ligands, particularly phos-

phanes, has been reported in the patent literature,[11] most of the catalysts used are stabilized by multidentate chelating ligands.

In this paper we report the synthesis of complexes *trans*-$[Ni(C_6Cl_2F_3)_2L_2]$ (L = $SbPh_3$, $AsPh_3$, $AsCyPh_2$, $AsMePh_2$, or PPh_3) and their catalytic activity in insertion polymerization of norbornene. In these compounds the monodentate ligands are able to stabilize the complexes allowing their manipulation as solids in the air, but are labile and weak enough to give highly active catalytic systems in solution.

Results and Discussion

Synthesis and Behavior in Solution

The reaction of $[NiBr_2(dme)]$ (dme = 1,2-dimethoxyethane) with $Li(C_6Cl_2F_3)$ and L (molar ratio 1:1:2.2) in diethyl ether affords the yellow air-stable complexes *trans*-$[Ni(C_6Cl_2F_3)_2L_2]$ (L = $SbPh_3$, **1**; $AsPh_3$, **2**; $AsCyPh_2$, **3**; $AsMePh_2$, **4**) (Scheme 2). With PPh_3 this procedure affords *trans*-$[Ni(C_6Cl_2F_3)_2(PPh_3)_2]$ (**5**) along with a number of by-products, not further identified, which lowered the yield. Thus, complex **5** is better prepared by the reaction of **1** with PPh_3 in chloroform (molar ratio 1:2), followed by solvent evaporation, and removal of the displaced ligand $SbPh_3$ with diethyl ether. In fact *trans*-$[Ni(C_6Cl_2F_3)_2(SbPh_3)_2]$ is a fairly general precursor for other $[Ni(C_6Cl_2F_3)_2L_2]$ complexes.

$AsCyPh_2$	**3**
$AsMePh_2$	**4**
PPh_3	**5**

Scheme 2.

All the complexes reported in this paper are *trans* isomers. The structures of **1**, **2** and **5** have been determined by X-ray diffraction. They are very similar and only the structure of **5** is shown in Figure 1. Crystallographic data are given in Table 3 (see Experimental Section). Selected interatomic distances and angles are shown in Table 1. The complexes crystallized in the P-1 group with one molecule in the asymmetric unit for compound **5**, and just half a molecule in the asymmetric unit for compounds **1** and **2**. The three compounds are almost perfectly square planar, with angles between adjacent donor atoms very close to 90° and the two haloaryl ligands mutually *trans*. The Ni–C bond lengths are very similar to those found in the two *trans*-bis(pentafluorophenyl)nickel complexes reported to date (1.939 Å in both $[Ni(C_6F_5)_2(PMePh_2)_2]$ and $[Ni(C_6F_5)_2(CNtBu)_2]$).[18,20] The Ni–P distances [2.2467(9) and 2.2544(8) Å] are in the upper limit of the range found in the Cambridge Structural Database for *trans*-bis(triphenylphosphane)nickel complexes (2.220–2.253 Å).[12] The Ni–As and Ni–Sb distances cannot be compared to reference values in the literature because the Ni complexes with $AsPh_3$ or $SbPh_3$ reported (one with each ligand) are not structurally similar.[13,14] The haloaryl rings are almost perpendicular to the coordination plane in the three molecules, with tilting

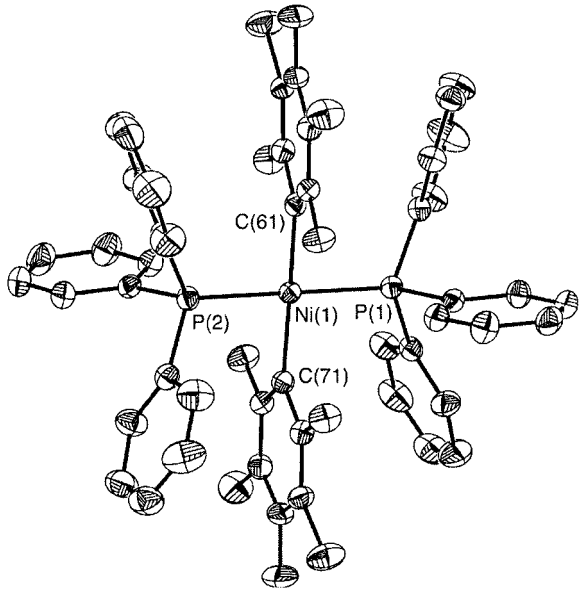

Figure 1. ORTEP diagram of the molecular structure of complex *trans*-$[Ni(C_6Cl_2F_3)_2(PPh_3)_2]$ (**5**). All hydrogen atoms have been omitted for clarity. Atoms are shown as displacement ellipsoids enclosing 30% probability density.

angles ranging from 83.2(2) to 89.3(2)°. The phosphane ligands are staggered and one phenyl ring on each phosphane is parallel to one haloaryl ring.

The stereochemical preferences of complexes $[Ni(aryl)_2L_2]$ are strongly dependent on the nature of L. Electronically, the *cis* isomers, avoiding *trans* arrangements of substituents with high *trans*-influence, should be preferred, and this is often determinant for Pd and Pt complexes.[15] However, steric factors seem important in the smaller Ni. In fact, structures containing some of the ligands used here have *cis* feature L–Ni–L angles noticeably larger than 90°,[16] indicating steric repulsion between the ligands. This suggests that the preference for the *trans* isomer found here must be largely associated to a minimization of steric repulsions. Related complexes with arylphosphanes also show a preference for *trans* stereochemistry, as found for $[Ni(C_6F_5)_2(PMePh_2)_2]$,[17,18] and $[Ni(4\text{-}C_6BrF_4)_2(PMePh_2)_2]$ in solution ($CDCl_3$ or CD_2Cl_2) and in the solid state.[19] $[Ni(4\text{-}C_6BrF_4)_2(PMePh_2)_2]$ is formed as a mixture of the *cis* and *trans* isomers which slowly converts completely into the most stable *trans* isomer. On the other hand, for complexes involving less sterically demanding ligands, such as $[PPh_3Me][Ni(C_6F_5)_2Br(CO)]$, $[Ni(C_6F_5)_2(CO)_2]$, and $[Ni(C_6F_5)_2(THF)_2]$, only the *cis* isomer is obtained.[20] The NMR spectra of **1**–**5** in $CDCl_3$ show the presence of just one compound in solution. The spectra at room temperature are coincident with those recorded at 213 K on samples dissolved at low temperature, supporting the suggestion that the signals arise from the *trans* isomer present in the solid state.

Complexes **1**–**5** are stable in the solid state and can be stored for long periods, but they decompose slowly in solution in $CDCl_3$ or [D$_6$]acetone at 298 K (in times much larger than the polymerization reactions). The decomposition is faster for **1** than for **2**–**4**, and is very slow for **5**. The major F-containing decomposition product is the coupling compound $C_6Cl_2F_3$–$C_6Cl_2F_3$ (**6**), along with small amounts of $C_6Cl_2F_3H$ (**7**) and other very minor noncharacterized products. A similar decomposition pattern has been reported for related pentafluorophenyl derivatives.[21]

Catalyzed Polymerization of Norbornene

The catalytic reactions were carried out under nitrogen at room temperature. In CH_2Cl_2 the polymerization started in seconds without cocatalysts, producing a white precipitate of polymer. After 30 min the reactions were quenched pouring the reacting mixtures over MeOH. Data concerning the polymers obtained are reported in Table 2. No attempts were made to optimize the yield or M_w of the polymer. Polymerization runs using **1** as a catalyst under air gave the same results.

The ^{13}C NMR spectra of the polynorbornene obtained in these experiments were identical to that reported by Barnes et al. using $[Ni(dpm)_2]/AlEt_3/B(C_6F_5)_3$ (dpm = 2,2,6,6-tetramethyl-3,5-heptanedionate) and (pentafluorophenyl)nickel complexes as catalysts. The absence of resonances in the 20–24 ppm region has been taken as indicative of *exo*-enchained norbornene-based polymers, generated by an insertion mechanism.[9] The ^{19}F NMR spectra in $CDCl_3$ showed mainly three 1:1:1 signals (–112.0, –115.3, –115.5 ppm), together with signals due to the coupling product **6** and smaller signals due to the hydrolysis product **7**, which remain adsorbed to the polymer, and to unidentified products (–105.1, –106.0, –111.9 ppm). Repeated washing with toluene removes the signals of **6** and **7**, but not the other minor signals. The chemical shifts of the 1:1:1 signals are typical of a $C_6Cl_2F_3$ group bonded to a carbon atom and can be assigned to the perhaloaryl group bonded to the polymer. The chemical shift of the $C_6Cl_2F_3$ fluorine nuclei are very sensitive to the group substituents.[22] A similar effect has been observed in the ^{19}F NMR of the pentafluorophenyl group bonded to metal or to carbon atoms.[23] The presence of three signals indicates that the two F_{ortho} atoms are nonequivalent because the rotation of the $C_6Cl_2F_3$ group around the phenyl *ipso*-carbon–norbornene carbon single bond is hindered according to the results reported by Barnes et al.[9] In the case of the $C_6Cl_2F_3$ group the chemical shifts for F_{ortho} and F_{para} do not permit us to assign them unambiguously and an attempt to correlate (hence recognize) the F_{ortho} atoms by spin saturation transfer at 323 K was unsuccessful, revealing that there is no detectable exchange of the two F_{ortho} signals at this temperature. In our compounds we do not see a splitting of any of the F_{ortho} signals, a phenomenon which was reported in the case of C_6F_5 by Barnes et al.[9] This may well be because of the fact that all chemical shift differences are smaller in our system.

Table 2. Norbornene polymerization catalyzed by **1**–**5** (reaction conditions unless otherwise stated: 9.2 mmol of norbornene and 4.6 μmol of catalyst in 3 mL of CH_2Cl_2; reaction time: 30 min).

Entry	Catalyst	Yield [%]	$M_w/10^5$	M_w/M_n
1	**1**	90	12.59	2.4
2	**2**	75	6.06	4.6
3	**3**	72	6.05	4.9
4	**4**	3	2.11	2.1
5	**5**	traces	0.1	
6	**1**[a]	–	–	
7	**1**[b]	17	0.99	
8	**1**[c]	0	–	
9	**1**[d]	18	0.1	

[a] Solvent: acetone. [b] Solvent: acetone; reaction time: 24 h. [c] 5-Norbornene-2-carboxaldehyde instead of norbornene. [d] A 3:1 mixture of norbornene/5-norbornene-2-carboxaldehyde instead of norbornene.

A clear dependence of the yield of the polymer on the ligand in the catalysts is observed: the yield in polymer is high for complexes with $SbPh_3$, $AsPh_3$, and $AsCyPh_2$, but drops dramatically for $AsMePh_2$ and PPh_3. The very high yield and M_W found with complex **1** ($SbPh_3$ as the ligand) are comparable to that found previously for the three component catalyst $[Ni(dpm)_2]/AlEt_3/B(C_6F_5)_3$.[9] The higher stability in the solid state of **1** compared to $[Ni(C_6F_5)_2(\eta^6\text{-toluene})]$, which is air and moisture sensitive, is advantageous. The influence of the ligand on the reaction can be understood assuming that equilibria 1 and 2 govern the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

concentration of the active species in solution. Ligands that are better donors and have less steric requirement shift these equilibria to the left, making the complexes inactive.

$$[Ni(C_6Cl_2F_3)_2L_2] + NB \rightleftharpoons [Ni(C_6Cl_2F_3)_2(NB)L] + L \quad (1)$$

$$[Ni(C_6Cl_2F_3)(P)L_2] + NB \rightleftharpoons [Ni(C_6Cl_2F_3)(P)(NB)L] + L \quad (2)$$

(P = polymer chain)

The effect of the bulkiness of the ligand on the properties of the polymer has been studied by Lipian et al. for cationic allylpalladium(II) complexes with selected phosphanes as the catalyst.[24] For these catalysts the bulkier the phosphane the lower the molecular mass of the polymer, while high conversion is always observed. The opposite trend is observed here comparing complexes **3** (containing $AsCyPh_2$) and **4** (containing $AsMePh_2$). This suggests a different ligand role for both types of catalyst. While no ligand dissociation is required in the palladium complexes employed by Lipian et al. (the bulkier phosphane is simply hindering more norbornene coordination or insertion), in complexes **1**–**5** the displacement of one ligand by the entering norbornene is required to carry out the polymerization process. For similar electronic characteristics displacement of a bulkier ligand $AsCyPh_2$ in equilibria 1 and 2 is favored compared to the displacement of $AsMePh_2$ and this turns out to be the dominant fact. Similarly, the molecular mass of the polymer increases with the same ligands that increase the overall yield of the reaction.

The reaction between **1** and norbornene in CD_2Cl_2 was monitored by ^{19}F NMR (norbornene:**1** = 200:1). No signals of Ni complexes containing $C_6Cl_2F_3$ other than **1** were detected throughout the experiment. This suggests that **1** is a precatalyst, from which the catalyst is formed in a small nonobservable proportion. At low temperature (–60 °C) no reaction takes place at an observable rate. At –10 °C the white polymer starts to precipitate from the solution and very broad $C_6Cl_2F_3$ signals appear corresponding to the ones mentioned earlier. At 0 °C the solution becomes very viscous in a few minutes, giving rise to a broadening of all the signals in the spectrum.

The polymerization of O-functionalyzed norbornenes with Ni catalysts has been reported in the literature, although using a higher catalyst/monomer ratio.[8] Even in these conditions the yield and M_w values are low, and the authors attribute the low reactivity of O-functionalyzed norbornenes in part to the coordinating ability of the oxygen. Examples of the poisoning effect of palladium catalysts due to the coordination of the O-donor groups of functionalyzed norbornenes have been recently reported.[27]

The polymerization of 5-norbornene-2-carboxaldehyde was attempted with **1** as the catalyst, but no reaction was observed after 30 min, in agreement with the observations just discussed. Moreover, 5-norbornene-2-carboxaldehyde inhibits the polymerization in mixtures with norbornene and only a small amount of oligomers is obtained (Table 2, entries 8 and 9). The reaction of 5-norbornene-2-carboxaldehyde with **1** was monitored by ^{19}F NMR spectroscopy. In a 1:1 ratio no reaction takes place. If the ratio of the monomer is increased up to 100:1 no new signals of Ni-bonded $C_6Cl_2F_3$ groups appear, but weak peaks of organic $C_6Cl_2F_3$ arise. Apparently, the aldehyde group is not able to stabilize any Ni intermediate formed after norbornene insertion into the C–Ni bond, nor is the carboxylic group able to displace the $SbPh_3$ ligands coordinated to nickel, at least in a detectable extension. At room temperature the oligomerization of the monomer takes place slowly in the NMR tube, giving very broad signals due to $C_6Cl_2F_3$ bonded to carbon.

Further support of the detrimental effect of the presence of O-donors in norbornene polymerizations, whether intramolecular (O-functionalyzed norbornenes) or external (O-containing solvents) is provided by the results found for polymerization of norbornene in acetone: No polymerization of norbornene was observed after 30 min at 25 °C. Only after 24 h could a small amount of polynorbornene be detected (Table 2, entries 6 and 7). In other words, the catalytic activity is severely reduced, although not completely suppressed, in acetone. The small amount of white polymer precipitated from the acetone solution after 24 h at 25 °C was dissolved in $CDCl_3$ and showed in the ^{19}F NMR spectrum the same signals of $C_6Cl_2F_3$ discussed for the polymers obtained in CH_2Cl_2. However, the M_w of this polymer (Table 2 entry 7) is much lower than the M_w of the polymers obtained in CH_2Cl_2.

^{19}F NMR spectra of solutions of **1** in acetone revealed a complicated equilibrium between four different complexes, arising from partial substitution of $SbPh_3$ by acetone or water, with only 2% remaining as complex **1**.[25] The interpretation of this is that the most active catalyst in solution is complex **1**, which has a lower concentration in an acetone solution than in noncoordinating solvents, hence showing a reduced activity. Moreover, the substitution equilibria 1 and 2, which give rise to the species on which insertion takes place, are now further disfavored by the presence of considerable concentrations of free ligand, displaced from **1** by solvent or water. The rate corresponding to direct catalysis by aquo or acetone complexes is likely to be negligible, given the strong ligation of these O-donor ligands to Ni. This interpretation fits well with the general hypothesis that oxygen donors block the Ni catalyst.[8,24,26,27]

Conclusions

The results show that some *trans* diaryl nickel complexes containing monodentate ligands, stable and easy to store and handle, are very efficient catalysts for norbornene polymerization. There is a strong dependence of the yield and molecular mass of the polymer on the ligand used: yields and M_w's are higher for complexes with $SbPh_3$ (the best), $AsPh_3$, and $AsCyPh_2$, which are ligands easy to displace from Ni^{II}, but ligands more strongly bonded to the metal, such $AsMePh_2$ or PPh_3 (the worst) give less efficient catalysts. The inability of the complexes to polymerize substituted norbornene containing O-donor groups is related to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the fact that the norbornene olefin bond is not able to displace the O-coordinating ligands even under high concentration conditions. Finally, the use of coordinating O-donor solvents or water is extremely detrimental.

In view of their catalytic activity in norbornene polymerization, their thermal and air stability, and their easy preparation, compounds **1**–**3** are choice reagents to have available.

Experimental Section

General Methods: All reactions were carried out under N_2 except when stated otherwise. Solvents were distilled using standard methods. The starting compound [$NiBr_2$dme],[28] the ligand $AsMePh_2$,[29] and solutions of $LiC_6Cl_2F_3$ were prepared by published methods.[30] Combustion CHN analyses were made with a Perkin–Elmer 2400 CHN microanalyzer. IR spectra were recorded with a Perkin–Elmer FT 1720 X spectrophotometer. Molecular masss of polymer were determined with a Waters SEC system equipped with a refractive index detector, using a three-column bed operating at 40 °C in $CHCl_3$ and calibrated to polystyrene narrow distribution standards. GS-MS data were obtained with a Hewlett–Packard 6890N gas chromatograph mass spectrometer (5973).

NMR spectra: ^{1}H NMR (300.16 MHz), ^{19}F NMR (282.4 MHz), and ^{31}P NMR (121.4 MHz) spectra were recorded with Bruker ARX 300 and AC 300 instruments equipped with a VT-100 variable-temperature probe. Chemical shifts are reported in ppm from $SiMe_4$ (^{1}H), CCl_3F (^{19}F), or H_3PO_4 (85%) (^{31}P) with positive shifts downfield, at ambient probe temperature unless otherwise stated. *J* values are given in Hz. ^{13}C NMR were registered as ^{1}H-^{13}C correlation experiments, which were made with a HMQC sequence with BIRD selection and GARP decoupling during acquisition. Chemical shifts of quaternary carbons are not listed in the experimental data.

Synthesis of $AsBrPh_2$: A solution of $LiAsPh_2$ was prepared from Li (0.557 g, 80.25 mmol), and $AsPh_3$ (9.187 g, 30.00 mmol) in THF (60 mL) as reported in the literature.[31] The solution was filtered with a cannula, cooled to –80 °C and Br_2 (3.1 mL, 60.50 mmol) was added very slowly. The solution was left to warm up to room temperature whilst stirring, whereupon it changed from deep red to orange. Then, solvent was removed and the resulting black residue was treated with CH_2Cl_2 (20 mL) and a saturated solution of NH_4Br in water (40 mL). The organic layer was decanted and the aqueous layer was subsequently extracted with CH_2Cl_2 (2 × 10 mL). Organic layers were dried with anhydrous $MgSO_4$, filtered and the solvent was vacuum evaporated. $AsBrPh_2$ (yellow oil) was obtained from the resulting residue after distillation at 170 °C and 5 mbar. Yield: 4.438 g (48%). $C_{12}H_{10}AsBr$ (309.04): calcd. C 46.64, H 3.26; found C 46.32, H 3.07. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.67–7.63 (m, 4 H), 7.44–7.40 (m, 6 H) ppm. ^{13}C NMR ($CDCl_3$, 293 K): δ = 134.5, 133.3, 130.8, 129.6 ppm.

Synthesis of $AsCyPh_2$: A solution of MgCyCl in diethyl ether (35 mL) was prepared refluxing Mg (0.509 g, 20.94 mmol) and CyCl (2.0 mL, 16.86 mmol) for 6 h. The mixture was then cooled in an ice bath and a solution of $AsBrPh_2$ (2.321 g, 7.51 mmol) in THF (20 mL) was slowly added dropwise over 15 min. The stirring was maintained for another 30 min. The system was opened to air and acidified water (30 mL) was added. The organic layer was decanted and the aqueous layer was extracted with diethyl ether (3 × 10 mL). The organic solution was dried with anhydrous $MgSO_4$ and filtered and the solvent was vacuum evaporated. $AsCyPh_2$ was obtained as a yellow oil. After one day at –20 °C it became a white crystalline solid. Yield: 1.898 g (81%). $C_{18}H_{21}As$ (312.29): calcd. C 69.23, H 6.78; found C 68.79, H 6.57. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.50 (m, 4 H, Ph), 7.38–7.31 (m, 6 H, Ph), 2.33 (m, 1 H, C*H*, Cy), 1.77 (m, 5 H, Cy), 1.32 (m, 5 H, Cy) ppm. ^{13}C NMR ($CDCl_3$, 293 K): δ = 139.4, 133.6, 128.4, 128.2 ppm.

Synthesis of *trans*-[$Ni(C_6Cl_2F_3)_2(SbPh_3)_2$] (1): *n*-Butyllithium (8.5 mL of 1.2 M solution in hexane, 10.20 mmol) was added dropwise to a solution of 1,3,5-$C_6Cl_3F_3$ (2.402 g, 10.20 mmol) in dry Et_2O (50 mL), at –78 °C. After the reaction mixture was stirred at this temperature for 1 h, $SbPh_3$ (4.322 g, 12.24 mmol) and [$NiBr_2$(dme)] (1.574 g, 5.10 mmol) were added, and the suspension obtained was stirred overnight and allowed to warm to room temperature. Wet Et_2O (20 mL) was added and the suspension evaporated to dryness. The residue was extracted with $CHCl_3$ (60 mL) and the filtrate was evaporated to 5 mL, treated with ethanol (20 mL), and concentrated to 20 mL. The resulting suspension was filtered and the yellow solid washed with ethanol and air dried. Yield: 2.94 g (50%). $C_{48}H_{30}Cl_4F_6NiSb_2$ (1164.78): calcd. C 49.50, H 2.60; found C 49.14, H 2.76. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.34–7.25 (m, 30 H, Ph) ppm. ^{19}F NMR ($CDCl_3$, 293 K): δ = –87.47 (s, 4 F, F_{ortho}), –119.46 (s, 2 F, F_{para}) ppm.

Synthesis of *trans*-[$Ni(C_6Cl_2F_3)_2(AsPh_3)_2$] (2): To a solution of $LiC_6Cl_2F_3$ prepared from $C_6Cl_3F_3$ (1.181 g, 5.02 mmol) and BuLi (5.02 mmol) at –78 °C, were added $AsPh_3$ (1.837 g, 6.00 mmol) and [$NiBr_2$(dme)] (0.772 g, 2.50 mmol), the brown suspension obtained was stirred for 12 h and allowed to warm to room temperature. After that time the flask was opened to the air and wet diethyl ether (15 mL) was added in order to hydrolyze the organolithium excess. The solution was filtered and the resulting red solution was concentrated until dryness. The residue was treated with $CHCl_3$ (30 mL), the obtained suspension was filtered, and the resulting orange solution was concentrated until dryness. The crude product was recrystallized from $CHCl_3$/EtOH. Yield: 1.39 g (52%). $C_{48}H_{30}As_2Cl_4F_6Ni$ (1071.10): calcd. C 53.82, H 2.82; found C 53.06, H 2.94. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.7–7.1 (m, 30 H, Ph) ppm. ^{19}F NMR ($CDCl_3$, 293 K): δ = –89.05 (s, 4 F, F_{ortho}), –120.34 (s, 2 F, F_{para}) ppm.

Synthesis of *trans*-[$Ni(C_6Cl_2F_3)_2(AsCyPh_2)_2$] (3): Prepared as described for **2** but using $AsCyPh_2$ (1.891 g, 6.00 mmol) instead of $AsPh_3$. Yield: 1.323 g (49%). $C_{48}H_{42}As_2Cl_4F_6Ni$ (1083.20): calcd. C 53.22, H 3.91; found C 52.94, H 3.60. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.4–7.0 (m, 20 H, Ph), 2.11 (m, 2 H, C*H*, Cy), 1.88–0.88 (m, 20 H, Cy) ppm. ^{19}F NMR ($CDCl_3$, 293 K): δ = –88.75 (s, 4 F, F_{ortho}), –120.08 (s, 2 F, F_{para}) ppm.

Synthesis of *trans*-[$Ni(C_6Cl_2F_3)_2(AsMePh_2)_2$] (4): Prepared as described for **2** but using $AsMePh_2$ (1.465 g, 6.00 mmol) instead of $AsPh_3$. Yield: 0.834 g (35%). $C_{38}H_{26}As_2Cl_4F_6Ni$ (946.96): calcd. C 48.20, H 2.77; found C 47.82, H 2.71. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.31 (m, 20 H, Ph), 1.57 (s, 6 H, Me) ppm. ^{19}F NMR ($CDCl_3$, 293 K): δ = –90.29 (s, 4 F, F_{ortho}), –119.69 (s, 2 F, F_{para}) ppm.

Synthesis of *trans*-[$Ni(C_6Cl_2F_3)_2(PPh_3)_2$] (5): To a solution of PPh_3 (0.0787 g, 0.30 mmol) in $CHCl_3$ (20 mL) solid **1** (0.175 g, 0.15 mmol) was added. After complete dissolution of the nickel compound, the solution was stirred for 30 min, filtered through Celite®, and then the solvent was evaporated to dryness. The solid residue was washed with *n*-hexane (4 × 10 mL) to remove the $SbPh_3$, filtered and vacuum dried. Yield 0.128 g (87%). $C_{48}H_{30}Cl_4F_6NiP_2$ (983.21): calcd. C 58.64, H 3.07; found C 58.31, H 3.00. ^{1}H NMR ($CDCl_3$, 293 K): δ = 7.50 (m, 4 H, Ph), 7.29 (m, 2 H, Ph), 7.19 (m, 4 H, Ph) ppm. ^{19}F NMR ($CDCl_3$, 293 K): δ =

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

–89.04 (t, $^4J_{P-F}$ = 2.7 Hz, 4 F, F_{ortho}), –121.21 (t, $^6J_{P-F}$ = 3.4 Hz, 2 F, F_{para}) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293 K): δ = 22.4 (m) ppm.

Synthesis of $C_6Cl_2F_3$–$C_6Cl_2F_3$ (6): A solution of **1** (1.400 g, 1.20 mmol) in chloroform (250 mL) was refluxed for 12 h. The resulting brown suspension was evaporated to dryness and the residue was chromatographed (silica gel/hexane). The fraction corresponding to the first eluted compound was evaporated to dryness giving a white solid. Yield: 0.303 g (62%). $C_{12}Cl_4F_6$ (399.93): calcd. C 36.04; found C 36.20. GS-MS: *m*/*z* = 397.8 $[M]^+$. ^{19}F NMR ($CDCl_3$, 293 K): δ = –107.48 (m, 1 F, F_{para}), –110.78 (m, 2 F, F_{ortho}) ppm.

Synthesis of $C_6Cl_2F_3H$ (7): To a solution of $LiC_6Cl_2F_3$ prepared from $C_6Cl_3F_3$ (1.000 g, 4.25 mmol) and BuLi (4.25 mmol) at –78 °C, was added H_2O (0.300 g, 16.65 mmol). The mixture was allowed to warm to room temperature, dried with $MgSO_4$, and the solvents evaporated to dryness, yielding a colorless oil. Yield: 0.717 g (84%). GS-MS: *m*/*z* (%) = 199.9 $[M]^+$. ^1H NMR ($CDCl_3$, 293 K): δ = 6.91 (td, $^3J_{H,F}$ = 8.6 Hz, $^5J_{H,F}$ = 2.4 Hz, 1 H) ppm. ^{19}F NMR ($CDCl_3$, 293 K): δ = –110.64 (m, 1 F, F_{para}), –112.04 (dd, $^3J_{H,F}$ = 8.6 Hz, $^4J_{F-F}$ = 1.8 Hz, 2 F, F_{ortho}) ppm.

Polymerization Experiments: All the polymerization catalysis reactions were carried out under N_2, in Schlenk flasks (25 mL) reacting norbornene with a monomer:catalyst ratio of 2000:1. In a typical experiment norbornene (866.3 mg, 9.2 mmol) was dissolved in deoxygenated CH_2Cl_2 (3 mL). To the stirred solution the solid catalyst (4.9 mg of **2**, 4.6 μmol) was added. The reaction started immediately, giving polynorbornene as a white precipitate (the reaction is better done in a round-bottomed flask, since the heat generated by the reaction makes the solvent boil). The stirring was maintained for 30 min and the reaction mass was poured into MeOH (100 mL). The polymer was filtered, washed several times with MeOH and vacuum dried. Yield: 650 mg (75%). NMR spectroscopic data of the polymers. ^{13}C DEPT NMR spectra ($CDCl_3$) of the polymers were recorded, and in all cases a similar spectra were obtained with broad signals at the following chemical shifts, δ = 54–45 (CH), 45–38 (CH), 38–34 (CH_2), 34–28 (CH_2) ppm.

Experimental Procedure for X-ray Crystallography: Suitable single crystals were mounted in glass fibers, and diffraction measurements were made with a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å).[32] Intensities were integrated from several series of exposures, each exposure covering 0.3° in ω, the total data set being a hemisphere.[33] Absorption corrections were applied, based on multiple and symmetry-equivalent measurements.[34] The structure was solved by direct methods and refined by least-squares on massed F^2 values for all reflections (see Table 3).[35] All non-hydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints. Hydrogen atoms were taken into account at calculated positions and their positional parameters were refined. Refinement proceeded smoothly to give R_1 = 0.0423 based on the reflections with $I > 2\sigma(I)$ and wR_2 = 0.0965 for all data. Complex neutral-atom scattering factors were used.[36] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications with the following deposition numbers: CCDC-262216, -262215, and -262214 for complexes **1**, **2**, and **5**, respectively. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk).

Supporting Information: Two ORTEP figures for compounds **1** and **2** are provided as Supporting Information (see also the footnote on the first page of this article).

Reversible Bond Formation and Cleavage of the Oxo Bridge of $[Ru_2(\mu\text{-}O)(dioxolene)_2(btpyxa)]^{3+}$ [btpyxa = 2,7-Di-*tert*-butyl-9,9-dimethyl-4,5-bis(2,2′:6′,2′′-terpyrid-4′-yl)xanthene] Driven by a Three-Electron Redox Reaction

Tohru Wada[a] and Koji Tanaka*[a]

Keywords: Electronic structure / O ligands / Oxidation / Reduction / Ruthenium

The bis(chlororuthenium) complex $[Ru_2Cl_2(3,6\text{-}tBu_2sq)_2(btpyxa)](PF_6)_2$ [**1**]$(PF_6)_2$ [3,6-tBu_2sq = 3,6-di-*tert*-butyl-1,2-benzosemiquinone; btpyxa = 2,7-di-*tert*-butyl-9,9-dimethyl-4,5-bis(2,2′:6′,2′′-terpyrid-4′-yl)xanthene] and the oxo-bridged diruthenium complex $[Ru_2(\mu\text{-}O)(3,6\text{-}tBu_2sq)_2(btpyxa)](PF_6)_3$ [**2**]$(PF_6)_3$ were synthesized, and the redox behavior of these complexes, which contain a non-innocent dioxolene ligand, was investigated by electrochemical and electrospectrochemical methods. Dicationic $[\mathbf{1}]^{2+}$ undergoes two successive metal-centered one-electron and a simultaneous two-electron ligand-based redox reaction at $E_{1/2}$ = +0.13 and +0.09 and $E_{1/2}$ = –0.75 V (vs. SCE), respectively, in CH_2Cl_2. The UV/Vis/NIR spectrum of tricationic $[\mathbf{2}]^{3+}$ shows an intervalence-transition (IT) band at 1333 nm (ε = 1.52×10^4 M^{-1} cm^{-1}) in a near-IR region together with two CT bands at 766 (ε = 2.21×10^4 M^{-1} cm^{-1}) and 586 nm (ε = 1.13×10^4 M^{-1} cm^{-1}) in CH_2Cl_2. The mixed-valence complex of $[\mathbf{2}]^{3+}$ with an Ru^{IV}–O–Ru^{III} core is reversibly oxidized and reduced to the Ru^{IV}–Ru^{IV} and Ru^{III}–Ru^{III} oxidation states at $E_{1/2}$ = +0.63 and –0.01 V, respectively, in CH_2Cl_2. On the other hand, three-electron reduction of [**2**]$(PF_6)_3$ is accompanied by the cleavage of the Ru–O–Ru bond at E_p = +0.02 V to give $[\{Ru(OMe)(3,5\text{-}tBu_2sq)\}\{Ru(OH_2)(3,5\text{-}tBu_2sq)\}(btpyxa)]^+$ in MeOH.

Introduction

Much attention has been paid to transition-metal complexes with non-innocent ligands such as dioxolenes, dithiolenes, and benzoquinonediimines due to their unique electronic,[1] magnetic,[2] and structural[3] properties that derive from pπ–dπ interactions between the metals and such ligands. Ruthenium–dioxolene complexes, in particular, have strong pπ–dπ interactions because of the close orbital energies between the central metal and the dioxolene ligand. Indeed, the electronic structures of ruthenium–dioxolene complexes are characterized in terms of charge distribution due to delocalization of π-electrons over the central metal and the ligand.[4,5] We have demonstrated that the dioxolene ligand in $[Ru(L)(3,5\text{-}tBu_2sq)(trpy)]^{2+}$ [L = OH_2,[6] CO,[7] 3,5-tBu_2sq (3,5-di-*tert*-butyl-1,2-benzosemiquinone), trpy (2,2′:6′,2′′-terpyridine)] exerts an unusually strong influence on the electronic states of the ligand L. For example, an aqua ligand of $[Ru^{III}(OH_2)(3,5\text{-}tBu_2sq)(trpy)]^{2+}$ dissociates two protons under strongly basic conditions to give the corresponding terminal ruthenium oxo complex $[Ru^{II}(O^{\cdot-})(3,5\text{-}tBu_2sq)(trpy)]^0$ without forming a μ-oxo diruthenium complex (Scheme 1).[6] EPR measurements revealed the radical character of the oxo ligand of the resultant oxo complex. Unusual oxyl radical formation results from intramolecular one-electron transfer from the doubly deprotonated aqua ligand of $[Ru^{III}(OH_2)(3,5\text{-}tBu_2sq)(trpy)]^{2+}$ to the Ru^{III}-semiquinone framework. A similar conversion of two hydroxyl ligands into two oxyl radicals in the bis(ruthenium–dioxolene) complex $[Ru_2(OH)_2(3,6\text{-}tBu_2q)_2(btpyan)]^{2+}$ [3,6-tBu_2q = 3,6-di-*tert*-butyl-1,2-benzoquinone, btpyan = 1,8-bis(2,2′:6′,2′′-terpyrid-4′-yl)anthracene], in which two ruthenium-dioxolene frameworks are fixed in a face-to-face conformation by the rigid btpyan ligand, enabled the catalytic four-electron oxidation of water through O–O bond formation by the radical coupling of the two oxyl radical ligands.[8]

We synthesized two new complexes, a bis(chlororuthenium–dioxolene) complex $[\mathbf{1}]^{2+}$ and a μ-oxo-bis(ruthenium–dioxolene) complex $[\mathbf{2}]^{3+}$ bridged by 2,7-di-*tert*-butyl-9,9-dimethyl-4,5-bis(2,2′:6′,2′′-terpyrid-4′-yl)xanthene (btpyxa) in which two terpyridines are linked by a xanthene skeleton (Scheme 2). The two terpyridine units bridged by a xanthene and an anthracene moiety in btpyxa and btpyan, respectively, are not able to rotate freely because of their steric repulsions.[8,9] The distinct difference between btpyxa and btpyan is that the sp^3 carbon and oxygen atoms at the 9- and 10-position of xanthene, respectively, in the former

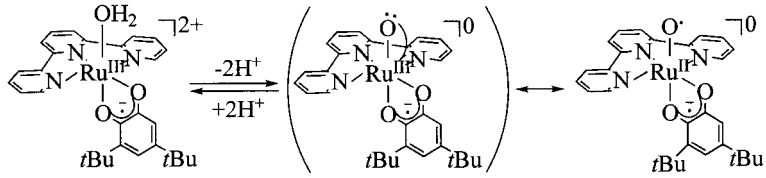
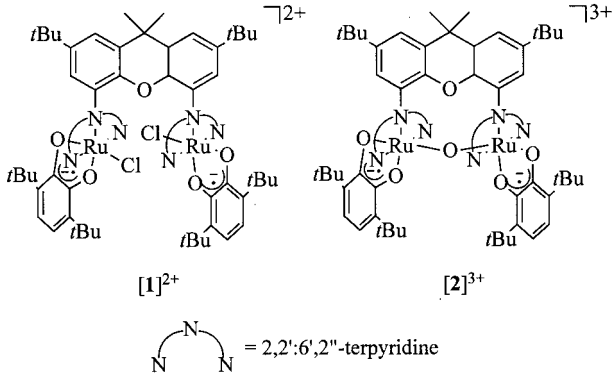


Scheme 1. Acid-base equilibrium of the aqua complex $[Ru(OH_2)(3,5\text{-}tBu_2sq)(trpy)]^{2+}$ and the oxyl radical complex $[Ru(O)(3,5\text{-}tBu_2sq)(trpy)]^{0}$.

give flexibility of the unit, whereas the anthracene in the latter has a rigid planar structure. Complexes $[\mathbf{1}]^{2+}$ and $[\mathbf{2}]^{3+}$ have the same skeleton fixed by btpyxa, but their electronic states and redox behavior are quite different from each other. We will report here the electronic structures of the diruthenium complexes and redox reactions accompanied with the Ru–O–Ru bond cleavage.



Scheme 2. Schematic structures of $[\mathbf{1}]^{2+}$ and $[\mathbf{2}]^{3+}$.

Results and Discussion

Syntheses and Electronic Structures

The reaction of $[Ru_2Cl_6(btpyxa)]$ with two equivalents of 3,6-di-*tert*-butylcatechol in the presence of *t*BuOK in MeOH gave a purple solution, presumably due to the formation of a bis[ruthenium(II) semiquinone] complex under N_2. The purple solution gradually turned blue upon exposure to air. The crude product was purified by column chromatography on alumina and subsequent treatment with aqueous NH_4PF_6. The product is a dicationic diruthenium complex containing two chloride ligands $\{[\mathbf{1}](PF_6)_2\}$. The UV/Vis/NIR spectrum of $[\mathbf{1}](PF_6)_2$ in CH_2Cl_2 [Figure 1(a)] shows a strong band at 598 nm ($\varepsilon = 1.93 \times 10^4\ M^{-1}cm^{-1}$) assignable to a charge-transfer (CT) band resulting from the $Ru^{III}(sq)$ (sq = semiquinone) framework by analogy with the electronic spectra of the analogous $[Ru^{III}(OH_2)(3,5\text{-}tBu_2sq)(trpy)]$.[6b] The resonance Raman spectrum of $[\mathbf{1}](PF_6)_2$ exhibits two strongly enhanced bands at 1357 and 1158 cm^{-1} upon excitation at 632.8 nm, whereas the intensities of these bands decrease upon excitation at 514.5 nm. In addition, the stretching modes of the semiquinone of $[Ru^{III}(OH_2)(3,5\text{-}tBu_2sq)(trpy)]^{2+}$ are found at 1353 and 1167 cm^{-1}.[6b] The strong absorption band of $[\mathbf{1}]^{2+}$ at 598 nm, therefore, is reasonably assigned to the CT band of the $Ru^{III}(sq)$ core. Thus, two ruthenium-dioxolene frameworks of $[\mathbf{1}]^{2+}$ have the $Ru^{III}(sq)$ oxidation state, although the contribution of an $Ru^{II}(q)$ (q = quinone) framework cannot be ignored in the electronic structure of $[\mathbf{1}]^{2+}$.

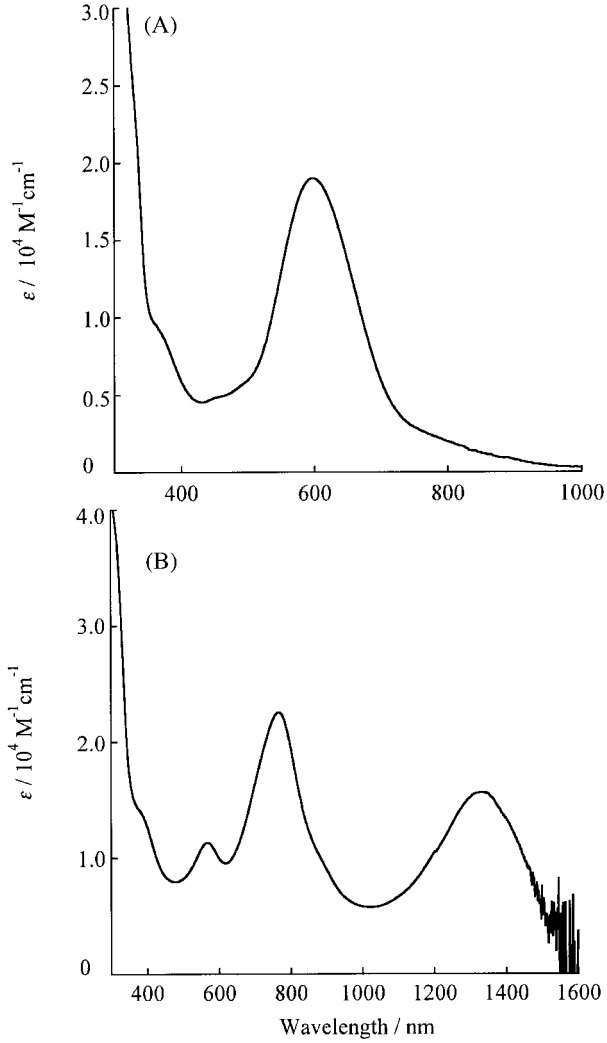


Figure 1. UV/Vis/NIR spectra of (A) $[\mathbf{1}](PF_6)_2$ and (B) $[\mathbf{2}](PF_6)_3$ in CH_2Cl_2.

We noticed the formation of a small amount of an oxo-bridged diruthenium complex $[\mathbf{2}]^{3+}$ as a minor product in the reaction of $[Ru_2Cl_6(btpyxa)]$ with 3,6-di-*tert*-butylcatechol in MeOH. The yield of $[\mathbf{2}](PF_6)_3$ was dependent on

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

contamination of water in MeOH, suggesting that the bridging oxygen of $[\mathbf{2}]^{3+}$ comes from H_2O. The reaction of $[Ru_2(\mu\text{-}O)Cl_2(btpyxa)]$ with 3,6-di-*tert*-butylcatechol in the presence of a large excess of KOAc, followed by treatment with $NaPF_6$ in MeOH, gave $[\mathbf{2}](PF_6)_3$ in a low yield of 11%. The fact that no oxo-bridged species (Ru–O–Ru) were detected in the synthesis of the 1,8-bis(terpyridyl)anthracene-bridged complex $[Ru_2(OH)_2(3,6\text{-}t\text{Bu}_2\text{sq})_2(btpyan)]^{2+}$[8] is explained by the greater flexibility of the xanthene skeleton of btpyxa compared with the anthracene in btpyan. The UV/Vis/NIR spectrum of $[\mathbf{2}](PF_6)_3$ [Figure 1(b)] in CH_2Cl_2 shows a strong band at 1333 nm ($\varepsilon = 1.52\times10^4$ M^{-1}cm^{-1}) assigned to the intervalence-transition (IT) band (vide infra) in the near-IR region, with two CT bands at 766 ($\varepsilon = 2.21\times10^4$ M^{-1}cm^{-1}) and 586 nm ($\varepsilon = 1.13\times10^4$ M^{-1}cm^{-1}) in the visible region. The appearance of the IT band at 1333 nm indicates that $[\mathbf{2}]^{3+}$ is a mixed-valence complex. The contribution of $[(sq)Ru^{III}\text{–}O\text{–}Ru^{IV}(sq)]^{3+}$, therefore, is much higher than other resonance forms such as $[(q)Ru^{II}\text{–}O\text{–}Ru^{III}(q)]^{3+}$, $[(cat)Ru^{IV}\text{–}O\text{–}Ru^{IV}(sq)]^{3+}$ (cat = catecholato), etc. in the electronic structure of $[\mathbf{2}]^{3+}$.

Redox Behavior of $[\mathbf{1}]^{2+}$ and $[\mathbf{2}]^{3+}$ in CH_2Cl_2

The cyclic voltammogram (CV) of $[\mathbf{1}](PF_6)_2$ in CH_2Cl_2 shows three pairs of anodic and cathodic waves in a potential range from +0.8 to –1.3 V (vs. SCE; Figure 2).

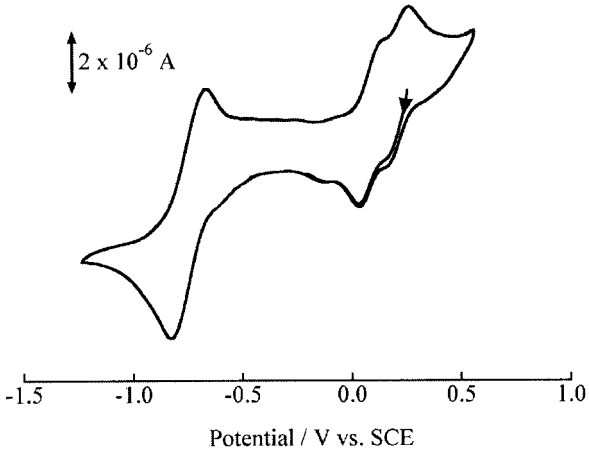

Figure 2. CV of $[\mathbf{1}](PF_6)_2$ in CH_2Cl_2 containing $n\text{Bu}_4NClO_4$ (0.1 M) as an electrolyte under N_2. The arrows indicate the rest potential of the solution and the direction of scan.

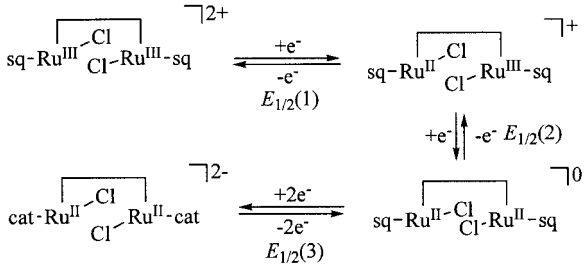
Based on the rest potential (+0.26 V) of $[\mathbf{1}]^{2+}$ in CH_2Cl_2, the two quasi-reversible redox couples at $E_{1/2}(1) = +0.13$ and $E_{1/2}(2) = +0.09$ V are associated with the metal-centered redox reactions. The redox couple at $E_{1/2}(3) = -0.75$ V with large peak currents is consistent with a dioxolene-based redox reaction due to its similarity to the redox potential of the analogous monomer [RuCl(3,5-$t\text{Bu}_2$sq)(trpy)].[5] The bulk electrolysis of $[\mathbf{1}]^{2+}$ in CH_2Cl_2 at +0.00 V consumes 2.03 F mol^{-1} of electricity. In addition, 2.01 F mol^{-1} of electricity also passes in the subsequent electrolysis of the resultant solution at –0.75 V.[10] The two redox reactions at $E_{1/2} = +0.13$ and +0.09 V apparently result from a one-electron transfer process because of the similarity of the peak currents of both redox waves (Figure 2). On the other hand, the redox couple at –0.75 V is a simultaneous two-electron transfer. The redox reactions at $E_{1/2}(1) = +0.13$, $E_{1/2}(2) = +0.09$, and $E_{1/2}(3) = -0.75$ V are summarized in Scheme 3.



Scheme 3. Redox reactions of $[\mathbf{1}]^{2+}$ in CH_2Cl_2.

The equilibrium constant (K_d) for the disproportionation reaction of $[\mathbf{1}]^+$ is defined by Equations (1) and (2).[11] The K_d calculated from $\Delta E_{1/2} = E_{1/2}(2) - E_{1/2}(1) = -0.04$ V is 0.21, which proves that the mixed-valence complex $[\mathbf{1}]^+$ ($Ru^{II}\text{–}Ru^{III}$) exists as an equilibrium mixture of $[\mathbf{1}]^{2+}$ and $[\mathbf{1}]^0$ in solution.

$$2[\mathbf{1}]^+ \overset{K_d}{\rightleftarrows} [\mathbf{1}]^0 + [\mathbf{1}]^{2+} \quad (1)$$

$$E_{1/2}(2) - E_{1/2}(1) = \frac{RT}{F}\ln K_d \quad (2)$$

Electrospectroscopy of $[\mathbf{1}]^{2+}$ in CH_2Cl_2 (Figure 3) also provides valid information about the $[\mathbf{1}]^{2+}/[\mathbf{1}]^+$ and $[\mathbf{1}]^+/[\mathbf{1}]^0$ redox reactions.

The CT band at 598 nm of $[\mathbf{1}]^{2+}$ decreases by half in the electrochemical reduction at +0.10 V and a new band appears at 882 nm, which is assigned to a CT band resulting from the $Ru^{II}(sq)$ moiety. The 598-nm band disappears completely in the electrolysis at –0.10 V and the 882-nm band is shifted to 866 nm with an increase in its absorbance. The shift of the CT band from 598 nm to 882 nm and then to 866 nm upon the reduction of $[\mathbf{1}]^{2+}$ at +0.10 V and –0.10 V is ascribed to the changes of the electronic structures from $[(sq)ClRu^{III}\text{–}Ru^{III}Cl(sq)]^{2+}$ to $[(sq)ClRu^{III}\text{–}Ru^{II}Cl(sq)]^0$ through $[(sq)ClRu^{II}\text{–}Ru^{III}Cl(sq)]^+$. Further reduction of $[\mathbf{1}]^0$ at –1.0 V completely extinguished the 866-nm band of $[(sq)ClRu^{II}\text{–}Ru^{II}Cl(sq)]^0$. Taking into account that the $Ru^{II}(cat)$ framework, with a fully occupied Ru t_{2g} and π orbital (π* orbital of quinone), has no CT band between Ru and the dioxolene ligand, the $[\mathbf{1}]^0/[\mathbf{1}]^{2-}$ couple at –0.75 V is assigned to the simultaneous two-electron reduction of $[(sq)ClRu^{II}\text{–}Ru^{II}Cl(sq)]^0$ to $[(cat)ClRu^{II}\text{–}Ru^{II}Cl(cat)]^{2+}$. The spectral changes in the redox cycle between $[\mathbf{1}]^{2+}$, $[\mathbf{1}]^+$, $[\mathbf{1}]^0$, and $[\mathbf{1}]^{2-}$ take place reversibly, since re-oxidation of a CH_2Cl_2 solution of $[\mathbf{1}]^{2-}$ at +0.4 V fully restored the spectrum of $[\mathbf{1}]^{2+}$. It is worthy of note that $[\mathbf{1}]^{2+}$ displays two Ru^{II}/Ru^{III} redox couples at $E_{1/2}(1) = +0.13$ and $E_{1/2}(2) = +0.09$ V, while the two semiquinone ligands of $[\mathbf{1}]^0$ are reduced to catecholato ones at the same potential. However,

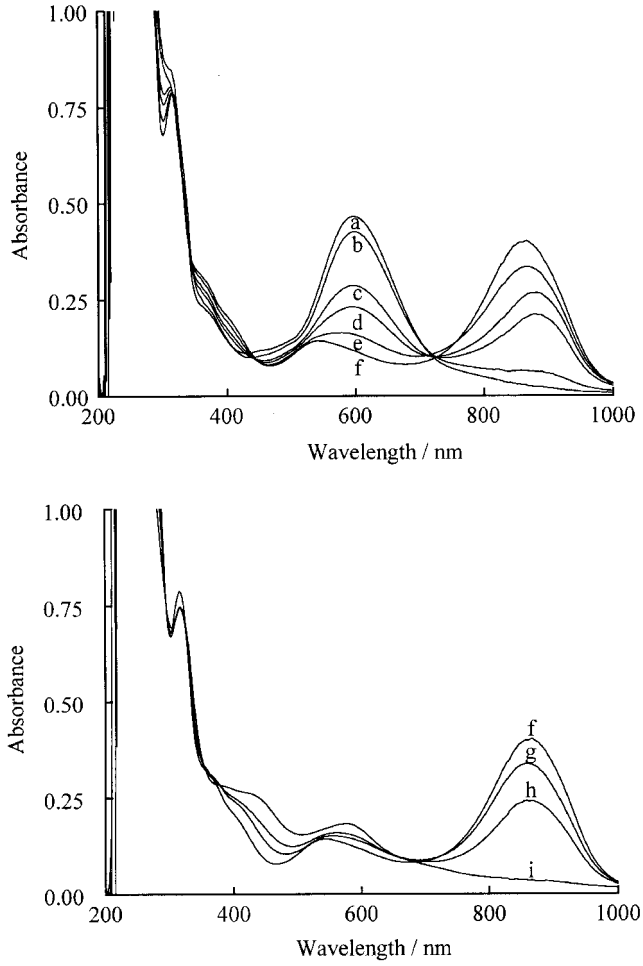

Figure 3. UV/Vis/NIR spectra of $[\mathbf{1}](PF_6)_2$: a) before electrolysis and after electrolysis at b) +0.20 V, c) +0.15 V, d) +0.10 V, e) +0.05 V, f) 0.00 V, g) –0.70 V, h) –0.80 V, and i) –0.90 V in CH_2Cl_2 containing nBu$_4$NClO$_4$ (0.1 M) as an electrolyte.

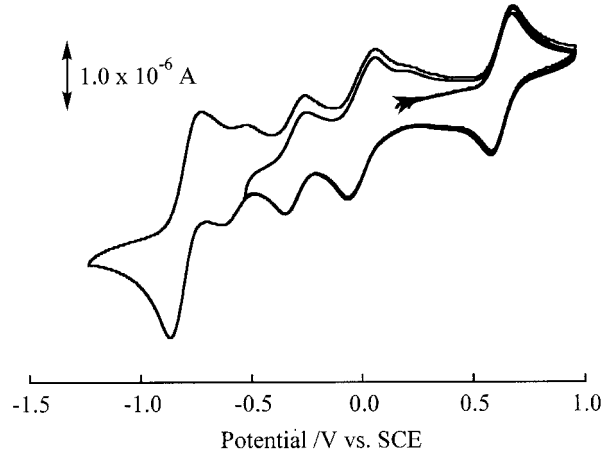

Figure 4. CV of $[\mathbf{2}](PF_6)_3$ in CH_2Cl_2 containing nBu$_4$NClO$_4$ (0.1 M) as an electrolyte under N_2. The arrows indicate the rest potential of the solution and the direction of scan.

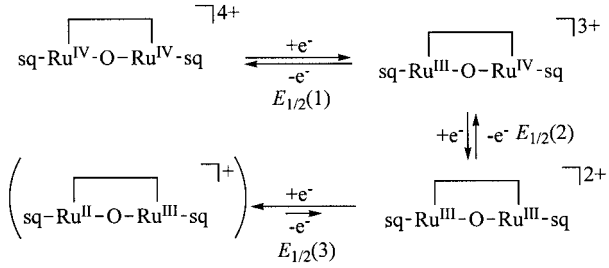
the IT band associated with $[\mathbf{1}]^+$, which was generated by the bulk electrolysis of $[\mathbf{1}]^{2+}$ at +0.10 V in CH_2Cl_2, was not detected at all in the region from 500 to 2200 nm. Meyer at al. have demonstrated that electrostatic effects caused by charge differences of dinuclear complexes result in a discrepancy of the redox potentials of two redox sites by about 20–60 mV.[12] The absence of the IT band of $[\mathbf{1}]^{2+}$ and a small potential difference between the two Ru^{II}/Ru^{III} redox couples (ΔE = 40 mV), therefore, may be ascribed to electrostatic effects, although an electronic interaction between the two Ru atoms of the $[(sq)Ru^{II}Cl\ ClRu^{III}(sq)]^+$ framework cannot be ruled out completely.

The oxo-bridged diruthenium complex $[\mathbf{2}]^{3+}$ exhibits a strong IT band at 1333 nm and two strong CT bands at 766 and 578 nm, as described above. The actual electronic structure of $[\mathbf{2}]^{3+}$ is approximated by $[(sq)Ru^{III}–O–Ru^{IV}(sq)]^{3+}$, since the strong electron-donating ability of the μ-oxo group in $[\mathbf{2}]^{3+}$ would stabilize higher oxidation states of Ru. Indeed, the redox behavior of $[\mathbf{2}]^{3+}$ is very different from that of $[\mathbf{1}]^{2+}$ (compare Figures 2 and 4).

The CV of $[\mathbf{2}]^{3+}$ (Figure 4) shows four quasi-reversible redox couples at $E_{1/2}(1)$ = +0.63, $E_{1/2}(2)$ = –0.01, $E_{1/2}(3)$ = –0.30, and $E_{1/2}(4)$ = –0.80 V. The redox reactions at $E_{1/2}(1)$ = +0.63 and $E_{1/2}(2)$ = –0.01 V were assigned to the $[(sq)Ru^{III}–O–Ru^{IV}(sq)]^{3+}/[(sq)Ru^{IV}–O–Ru^{IV}(sq)]^{4+}$ and the $[(sq)Ru^{III}–O–Ru^{IV}(sq)]^{3+}/[(sq)Ru^{III}–O–Ru^{III}(sq)]^{2+}$ couples, respectively, on the basis of the rest potential of the solution (E_{rest} = +0.21 V). The pattern and the potential of the redox couple at $E_{1/2}(1)$ = –0.80 V of $[\mathbf{2}]^{3+}$ are close to those of the simultaneous two-electron reduction of the two semiquinone ligands of $[\mathbf{1}]^{2+}$. Therefore, the redox reaction at $E_{1/2}(3)$ = –0.30 V is correlated with the $[(sq)Ru^{III}–O–Ru^{III}(sq)]^{2+}/[(sq)Ru^{III}–O–Ru^{II}(sq)]^+$ couple. The redox reactions of $[\mathbf{2}]^{3+}$ in CH_2Cl_2 are summarized in Scheme 4.



Scheme 4. Redox behavior of $[\mathbf{2}]^{3+}$ in CH_2Cl_2.

The changes of the oxidation states of $[\mathbf{2}]^{3+}$ were followed by UV/Vis/NIR spectroscopy. The one-electron oxidation of $[\mathbf{2}]^{3+}$ at +0.80 V resulted in disappearance of the bands at 1333 and 766 nm and generation of a new band at 656 nm. The electrochemical reduction of $[\mathbf{2}]^{3+}$ at –0.25 V also caused a disappearance of the same bands and the generation of a strong band at 872 nm (Figure 5). These spectral changes between $[\mathbf{2}]^{2+}$, $[\mathbf{2}]^{3+}$, and $[\mathbf{2}]^{4+}$ occur reversibly depending on the electrolysis potentials.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

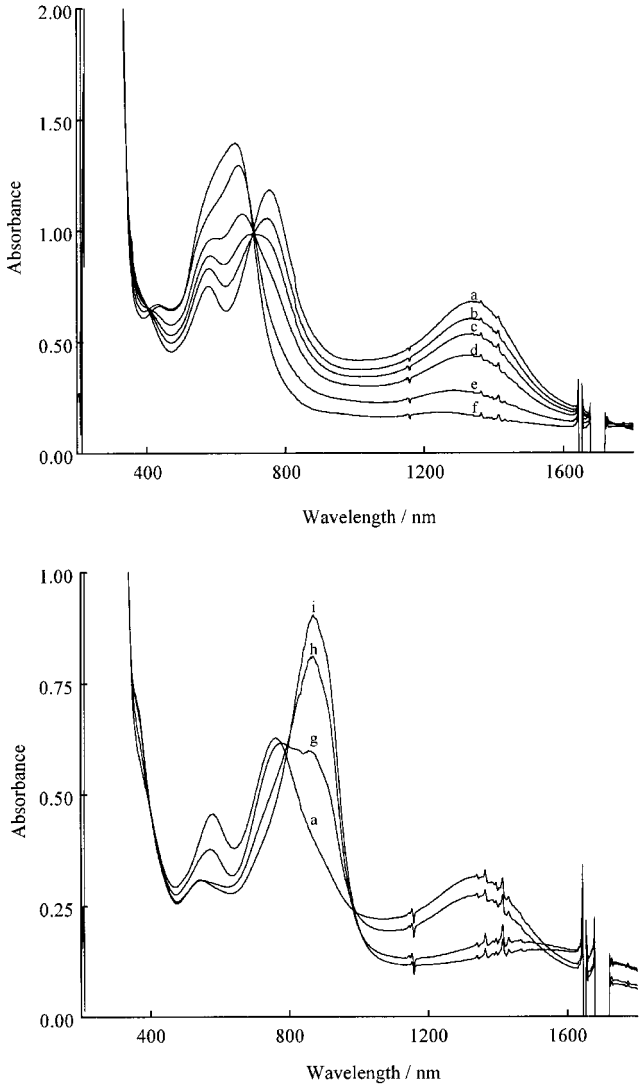


Figure 5. UV/Vis/NIR spectra of [**2**](PF$_6$)$_3$: a) before electrolysis and after electrolysis at b) +0.40 V, c) +0.50 V, d) +0.60 V, e) +0.70 V, f) +0.80 V, g) +0.00 V, h) –0.10 V, and i) –0.25 V in CH_2Cl_2 containing nBu$_4$NClO$_4$ (0.1 M) as an electrolyte.

If [**2**]$^{2+}$ has the [(sq)Ru^{III}–O–Ru^{III}(sq)]$^{2+}$ core, the monocation [**2**]$^{+}$ would also be a mixed-valence metal complex. The controlled potential electrolysis of [**2**]$^{3+}$ at –0.60 V in CH_2Cl_2, however, induced fragmentation reactions of the complex, as re-oxidation of the resultant solution at –0.20 V did not recover the spectrum of [**2**]$^{2+}$.[13] The decomposition of the mixed-valence complex [**2**]$^{+}$ may be caused by the fragility of the Ru^{III}–O–Ru^{II} bond (vide infra). It is worthy of note that the mixed-valence complex [**2**]$^{3+}$, with the [(sq)-Ru^{III}–O–Ru^{IV}(sq)]$^{3+}$ core, is quite stable in solution, since the disproportionation constant of [**2**]$^{3+}$ [Equation (2)] is negligibly small ($K_d = 1.5\times10^{-11}$) in contrast to that of [**1**]$^{+}$ ($K_d = 0.21$).

Redox Behavior of [2]$^{3+}$ in MeOH

The fragility of the highly reduced form of [**2**]$^{3+}$ becomes more prominent in MeOH. In contrast to the CV of [**2**]$^{3+}$ in CH_2Cl_2, the complex exhibits four redox couples in a potential range from +1.0 to –1.0 V in MeOH or CF_3CH_2OH[14] (Figure 6).

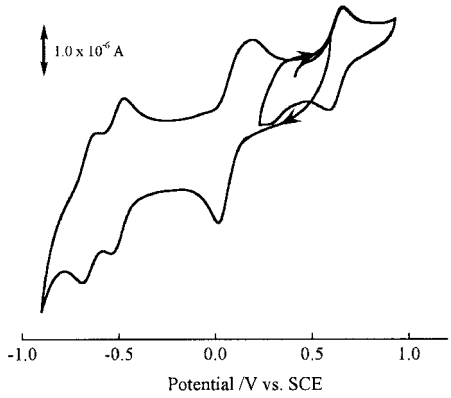

Figure 6. CV of [**2**](PF$_6$)$_3$ in MeOH and CF_3CH_2OH containing nBu$_4$NClO$_4$ (0.1 M) as an electrolyte under N_2. The arrows indicate the rest potentials of the solution and the direction of scan.

The rest potential (E_{rest} = +0.38 V) and the redox potential of the quasi-reversible couple [$E_{1/2}$(1) = +0.66 V] in CF_3CH_2OH are quite close to those in CH_2Cl_2, suggesting the stability of [**2**]$^{4+}$ as well as [**2**]$^{3+}$ in CF_3CH_2OH and MeOH. On the other hand, a peak current of the cathodic wave at E_{pc} = +0.02 V in MeOH is much larger than that of the redox couple at $E_{1/2}$(1) = +0.66 V. Indeed, the controlled potential electrolysis of [**2**]$^{3+}$ at –0.30 V in MeOH consumes 2.96 F mol^{-1} of electricity. Despite the occurrence of such an unusual three-electron reduction of [**2**]$^{3+}$ at E_{pc} = +0.02 V, the pattern of the CV of Figure 6 remained unchanged in multi-potential sweeps in a range of +0.70 V to –0.90 V. We therefore concluded that [**2**]$^{3+}$ undergoes three-electron reduction and oxidation reactions at E_{pc} = +0.02 V and E_{pa} = +0.2 V(broad) in MeOH. The reversible conversion between [**2**]$^{3+}$ and the three-electron oxidation products was also evidenced by the electronic absorption spectra, since the bands of [**2**]$^{3+}$ at 1330 and 766 nm disappeared during the controlled potential electrolysis at –0.30 V in MeOH with generation of two new bands at 848 and 876 nm (Figure 7).

Re-oxidation of the resultant solution at +0.40 V recovered the electronic absorption spectrum of [**2**]$^{3+}$. Taking into account that the three-electron reduction of [**2**]$^{3+}$ takes place at E_{pc} = +0.02 V in MeOH, chemical reduction of [**2**]$^{3+}$ was conducted by treatment with $Na_2S_2O_3$ (excess) in MeOH/H_2O (1:1 v/v) and a dark-purple product was obtained as a PF_6 salt in a 66% yield. The electronic absorption spectra of the product shows two strong CT bands at 848 and 876 nm, suggesting the existence of two types of Ru^{II}(sq) frameworks, and the pattern of the spectrum is fully consistent with that of the electrochemically three-electron-reduced form of [**2**]$^{3+}$ in MeOH. The ESI mass spectra[15] (Figure 8) show a signal at m/z = 738, which corresponds to the summation of the molecular weights of [**2**]^{0} + CH_3OH + H^+ with a composition that is consistent with the elemental analysis of the product.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

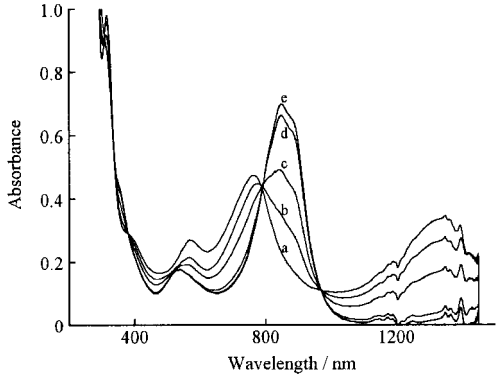

Figure 7. UV/Vis/NIR spectra of [**2**]$(PF_6)_3$: a) before and after electrolysis at b) +0.10 V, c) 0.00 V, d) –0.10 V, and e) –0.20 V in MeOH containing nBu$_4$NClO$_4$ (0.1 M) as an electrolyte under N_2.

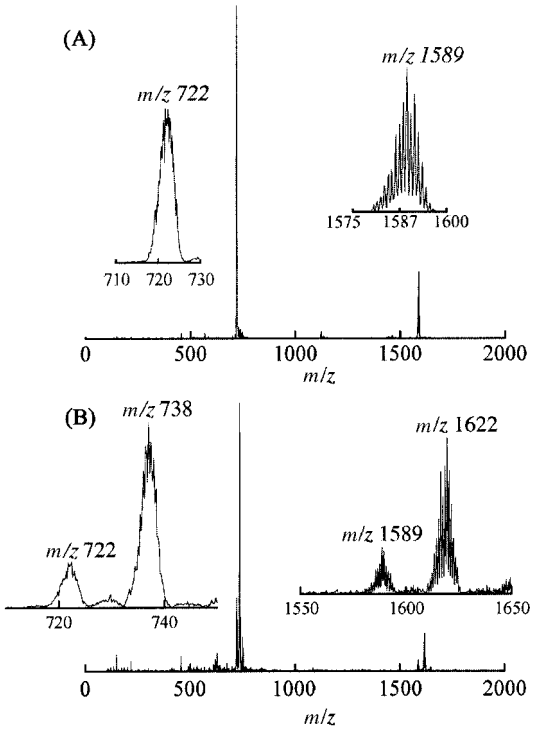

Figure 8. ESI mass spectra of (A) [**2**]$(PF_6)_3$ and (B) [**3**](PF_6) in MeOH.

Based on a combination of the ESI-MS measurements and the UV/Vis/NIR spectra, the most reasonable structure of the product is [{$Ru^{II}(OH_2)$(3,6-tBu$_2$sq)}{Ru^{II}(OMe)(3,6-tBu$_2$sq)}(btpyxa)](PF_6) {[**3**](PF_6)} [Equation (3)].

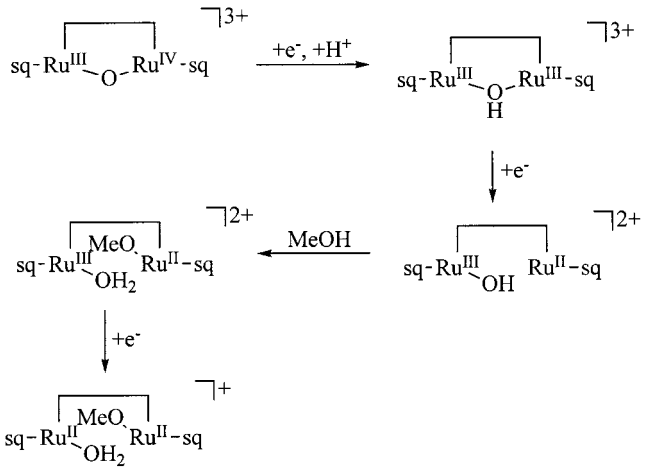
$$\left[(sq)Ru^{III}\text{–}O\text{—}Ru^{IV}(sq)\right]^{3+} + 3e^- + H^+ + CH_3OH \rightleftharpoons \left[(sq)Ru^{II}(OH_2)\ (MeO)Ru^{II}(sq)\right]^{+} \quad (3)$$

[**2**]$^{3+}$ [**3**]$^{+}$

Chemical reduction of [**2**]$^{3+}$ with a large excess of $Na_2S_2O_3$ in CF_3CH_2OH in place of MeOH gave only [**2**]$^{2+}$ on the basis of ESI-MS and UV/Vis/NIR measurements; the monocationic dimer bearing Ru–OH and Ru–OCH_2CF_3 moieties was not detected at all in the reaction mixtures. The cavity generated by btpyxa may be too small for an attack of CF_3CH_2OH at Ru.

It is worthy of note that the conversion between [**2**]$^{3+}$ and [**3**]$^{+}$ triggered by the three-electron redox reaction takes place reversibly on the CV timescale. Such an unusual reaction can be explained in terms of the fragility of the Ru^{II}–O–Ru^{III} and Ru^{II}–O–Ru^{II} frameworks and the stability of the Ru^{III}–O–Ru^{III} and Ru^{III}–O–Ru^{IV} ones due to the strong electron-donating ability of the μ-oxo ligand. In addition, the flexibility of the btpyxa ligand must play a key role in the smooth μ-oxo bond formation and cleavage reactions. Degradation of the two-electron-reduced form of [**2**]$^{3+}$ ([**2**]$^{+}$) in CH_2Cl_2, therefore, is correlated with the lability of the Ru^{II}–O–Ru^{III} group of [**2**]$^{+}$ in MeOH.

A proposed mechanism for the formation of [**3**]$^{+}$ is depicted in Scheme 5. A one-electron reduction of [**2**]$^{3+}$ at +0.02 V in MeOH will induce protonation of the bridging O atom of [**2**]$^{2+}$, which causes an anodic shift of the reduction potential of the resultant [(sq)Ru^{III}–O(H)–Ru^{III}-(sq)]$^{3+}$. As a result, the latter undergoes further one-electron reduction to generate [(sq)Ru^{II}–O(H)-Ru^{III}(sq)]$^{2+}$ at the same potential. Taking into account that [(sq)Ru^{II}–O–Ru^{III}(sq)]$^{+}$ is not stable in CH_2Cl_2, the Ru–O(H)–Ru bond of [(sq)Ru^{II}–O(H)–Ru^{III}(sq)]$^{2+}$ will be immediately cleaved and the resultant vacant coordination site of Ru attacked by MeOH, which is accompanied by protonation of the Ru–OH group. Such protonation would also cause an anodic shift of the reduction potential of the [{$Ru^{III}(OH_2)$-(sq)}{Ru^{II}(OMe)(sq)}]$^{2+}$ framework. Thus, simultaneous three-electron reduction of [**2**]$^{3+}$ in MeOH is ascribed to a successive one-electron reduction coupled with proton transfer.



Scheme 5. A proposed mechanism for the reduction of [**2**]$^{3+}$ in MeOH.

The distance between the carbons at the 4- and 5-positions of btpyxa was determined as 4.56 Å by an X-ray structural analysis of [PtCl(btpyxa)]$^{+}$, in which the xanthene skeleton is planar probably due to π-π stacking of two

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trpy planes.[9] On the other hand, the Ru···Ru interatomic distance and the Ru–O–Ru bond angle of the oxo-bridged dimer $[(bpy)_2(OH_2)Ru–O–Ru(OH_2)(bpy)_2]^{4+}$ are 3.708(1) Å and 165.4(3)°.[16] The xanthene framework in the present μ-oxo dimers, therefore, must deviate largely from linear in order to accept two Ru(sq)(trpy) moieties connected by the μ-oxo bond. On the contrary, dinuclear Ru complexes bridged by btpyan, with the rigid anthracene plane, are practically impossible to fit bent Ru–O–Ru bonds. This view reasonably explains why ruthenium dimers bridged by btpyxa form μ-oxo bonds whereas those with btpyan cannot accommodate a bent Ru–O–Ru bond. The unusual simultaneous three-electron redox reaction of $[\mathbf{2}]^{3+}$, which is accompanied by the formation and cleavage of the oxo bridge connecting the two [Ru(trpy)(sq)] frameworks, is therefore ascribed to the synergic effects of participation of proton transfer in the redox reaction, the flexibility of btpyxa, and the high affinity of the μ-oxo bond for high oxidation states of Ru.

Conclusions

Bis(chlororuthenium–semiquinone) $[\mathbf{1}](PF_6)_2$ and μ-oxobis(ruthenium–semiquinone) $[\mathbf{2}](PF_6)_3$ complexes, bridged with btpyxa, have been prepared and their redox behavior investigated. The electronic states of $[\mathbf{1}](PF_6)_2$ and $[\mathbf{2}](PF_6)_3$ were expressed by $[(sq)ClRu^{III}–Ru^{III}Cl(sq)]^{2+}$ and $[(sq)Ru^{III}–O–Ru^{IV}(sq)]^{3+}$, respectively, based on the ESI-MS, elemental analysis, and UV/Vis/NIR spectra. Dicationic $[\mathbf{1}]^{2+}$ undergoes two successive metal-centered one-electron reactions and a ligand-based simultaneous two-electron redox reaction at $E_{1/2}$ = +0.13, +0.09, and –0.75 V (vs. SCE), respectively, in CH_2Cl_2. The mixed-valence state of $[\mathbf{2}]^{3+}$ is quite stable because the ruthenium–semiquinone moieties of $[\mathbf{2}]^{3+}$ interact strongly with each other through the oxo bridge. The mixed-valence complex $[\mathbf{2}]^{3+}$ can be reversibly oxidized and reduced to and from the $Ru^{IV}–Ru^{IV}$ and $Ru^{III}–Ru^{III}$ oxidation states at $E_{1/2}$ = +0.63 and –0.01 V, respectively in CH_2Cl_2. On the other hand, $[\mathbf{2}]^{3+}$ undergoes a three-electron reduction accompanied by cleavage of the Ru–O–Ru bond at E_p = +0.02 V, and $[\{Ru(OMe)(3,5\text{-}tBu_2sq)\}\{Ru(OH_2)(3,5\text{-}tBu_2sq)\}(btpyxa)]^+$ is formed in MeOH. The unusual reversible Ru–O–Ru bond cleavage and formation during the three-electron redox reaction can be ascribed not only to the stability and fragility of the μ-oxo bond at high and low oxidation states of the Ru centers, respectively, but also to the flexibility of btpyxa.

Experimental Section

General Remarks: $RuCl_3·3H_2O$ was purchased from Furuya Metal Co., Ltd., NH_4PF_6 and $Na_2S_2O_3$ from Wako Pure Chemical industries, Ltd. 3,6-Di-*tert*-butylcatechol[17] and btpyxa[9] were synthesized according to literature procedures. All solvents were purified by distillation.

UV/Vis/NIR spectra were recorded on a Shimazu UVPC-3100 UV/Vis/NIR scanning spectrophotometer. ESI mass spectra were measured with a Shimazu LCMS-2010 liquid chromatograph mass spectrometer and Waters Micromass LCT. Elemental analyses were carried out at the Research Center for Molecular-Scale Nanoscience. Cyclic voltammetry (CV) was performed with an ALS/Chi model 660 electrochemical analyzer. CVs were recorded in CH_2Cl_2 or MeOH containing 0.1 mol dm^{-3} of nBu$_4$NClO$_4$ as an electrolyte at a scan rate of 50 mV s^{-1} at 298 K using a glassy carbon disk as the working electrode, a Pt wire as the counter electrode, and Ag/$AgNO_3$ (0.01 M) as the reference electrode. All potentials were converted to SCE ($E_{SCE} = E_{Ag/Ag+} + 0.330$ V). Spectroelectrochemical measurements of UV/Vis/NIR spectra were conducted in CH_2Cl_2 or MeOH containing 0.1 mol dm^{-3} of nBu$_4$NClO$_4$ as an electrolyte using a thin-layer optical cell (path length: 0.5 mm) with a platinum minigrid working electrode sandwiched between the two glass sides of an optical cell, a platinum counter electrode, and an Ag/$AgNO_3$ reference electrode. A Hokuto Denko HA-501 potentiostat and a Shimazu UV-3100PC UV/Vis/NIR scanning spectrophotometer were used. Controlled-potential electrolysis was carried out in CH_2Cl_2 or MeOH at room temperature under N_2 in an electrolysis cell consisting of three compartments: one for the glassy carbon plate (15 mm × 30 mm), the second for a platinum counter electrode (15 mm × 30 mm), which was separated from the working electrode cell by an anion-exchange membrane, and the third for an Ag/$AgNO_3$ reference electrode.

$[Ru_2Cl_6(btpyxa)]$: A dehydrated MeOH solution (30 mL) containing $RuCl_3·3H_2O$ (133 mg, 0.50 mmol) and btpyxa (200 mg, 0.25 mmol) was deoxygenated with a stream of nitrogen gas for 30 min and the solution was then refluxed for 3 h under N_2. The dark brown solid precipitate was filtered off and washed with MeOH (5 mL, three times) and acetone (5 mL, three times) to remove unreacted $RuCl_3$ and btpyxa, and then dried in vacuo. Yield: 204 mg (68%). $C_{53}H_{48}Cl_6N_6ORu_2$ (1199.9): calcd. C 53.05, H 4.03, N 7.00; found C 53.12, H 4.11, N 6.82.

$[Ru_2Cl_2(3,6\text{-}tBu_2sq)_2(btpyxa)](PF_6)_2$ $\{[\mathbf{1}](PF_6)_2\}$: An MeOH suspension (30 mL) containing $[Ru_2Cl_6(btpyxa)]$ (200 mg, 0.17 mmol) and 3,6-di-*tert*-butylcatechol (83 mg, 0.37 mmol) was deoxygenated with a stream of nitrogen gas for 30 min in a 100-mL flask. A deoxygenated MeOH solution (30 mL) of *t*BuOK (124 mg, 1.11 mmol) was then added to the suspension by syringe under N_2 and the reaction mixture was stirred for 24 h at room temperature under N_2. Insoluble $[Ru_2Cl_6(btpyxa)]$ gradually dissolved and the solution became dark-purple. The reaction mixture was then exposed to air. The dark-purple solution turned dark-blue in color in 2 h. After evaporation of the solution to dryness under reduced pressure, the product was purified by column chromatography using Alumina N super-I (ICN Biomedicals GmbH) and acetone/EtOH as an eluent. An aqueous solution of NH_4PF_6 was added to the dark-blue fraction. Concentration of the solution under reduced pressure gave a dark-blue powder, which was separated by filtration and dried in vacuo. Yield: 97 mg (32%). ESI-MS: m/z = 749 ($[\mathbf{1}]^{2+}$). $C_{81}H_{88}Cl_2F_{12}N_6O_5P_2Ru_2$ (1788.6): calcd. C 54.39, H 4.96, N 4.70; found C 54.40, H 5.01, N 4.66.

$[Ru_2(\mu\text{-}O)Cl_4(btpyxa)]·3H_2O$: An MeOH/$H_2O$ (80:20) solution (30 mL) containing $RuCl_3·3H_2O$ (133 mg, 0.50 mmol) and btpyxa (200 mg, 0.25 mmol) was deoxygenated with a stream of nitrogen gas for 30 min, after which time the solution was heated at reflux for 3 h under N_2. The dark-brown hot solution was filtered and evaporated to 10 mL under reduced pressure. The brown solid precipitate was filtered off and washed with cold MeOH (1 mL, three times) to remove unreacted $RuCl_3$ and btpyxa. Yield: 195 mg (65%). $C_{53}H_{54}Cl_4N_6O_5Ru_2$ (1199.0): calcd. C 53.09, H 4.54, N 7.01; found C 52.21, H 4.52, N 6.88.

$[Ru_2(\mu\text{-}O)(3,6\text{-}t\text{Bu}_2\text{sq})_2(\text{btpyxa})](PF_6)_3$ {[2]$(PF_6)_3$}: An MeOH solution (30 mL) containing $[Ru_2(\mu\text{-}O)Cl_4(\text{btpyxa})]$ (150 mg, 0.13 mmol) and 3,6-di-*tert*-butylcatechol (63 mg, 0.29 mmol) was deoxygenated with a stream of nitrogen gas for 30 min in a 100-mL flask. A deoxygenated MeOH solution (50 mL) of KOAc (852 mg, 8.7 mmol) was then added to the solution by syringe under N_2. The reaction mixture was stirred for 24 h at room temperature under N_2. The reaction mixture gradually turned dark-purple, and it was then exposed to air. The solution's color turned black in 2 h. After evaporation of the solution to dryness under reduced pressure, an aqueous solution of NH_4PF_6 was added to the methanolic solution (5 mL) of the residue. The resultant black powder was filtered and purified by column chromatography using Alumina N super-I (ICN Biomedicals GmbH) and CH_2Cl_2 as the eluent. Evaporation of acetone from the black fraction gave a black powder, which was filtered and dried in vacuo. Yield: 25 mg (11%). ESI-MS: *m*/*z* = 1589 $\{[\mathbf{2}](PF_6)\}^+$, 722 ($[\mathbf{2}]^{2+}$), 481 ($[\mathbf{2}]^{3+}$).[15] $C_{81}H_{88}F_{18}N_6O_6P_3Ru_2$ (1794.6): calcd. C 51.79, H 4.72, N 4.47; found C 51.64, H 4.80, N 4.65.

Chemical Reduction of [2]$(PF_6)_3$: An aqueous solution (5 mL) of $Na_2S_2O_3$ (10 mg, excess) was added to an MeOH solution (5 mL) of [**2**]$(PF_6)_3$ (10 mg, 5.6 μmol) and the solution was stirred for a few minutes. Evaporation of the solution under reduced pressure precipitated a dark-purple powder of [{Ru(OMe)(3,6-$t\text{Bu}_2$sq)}-{Ru(OH_2)(3,6-$t\text{Bu}_2$sq)}(btapyxa)](PF_6) {[**3**](PF_6)}, which was filtered and dried in vacuo. Yield: 6 mg (66%). ESI-MS: *m*/*z* = 1622 $\{[\mathbf{3}](PF_6)\}^+$, 738 ($[\mathbf{3}]^{2+}$).[13] $C_{82}H_{92}F_6N_6O_7PRu_2$ (1620.8): calcd. C 60.73, H 5.78, N 5.18; found C 60.62, H 5.80, N 4.98.

Acknowledgments

We are grateful to Dr. Hideo Kakimi and Dr. Hiroshi Yamasu of Jasco International Co., Ltd. for the ESI-TOF MS measurements.

[10] The difference in the redox potential between the $[\mathbf{1}]^{2+}$/ $[\mathbf{1}]^+$ and $[\mathbf{1}]^+$ /$[\mathbf{1}]^0$ couples ($\Delta E_{1/2}$ = 0.04 V) is too small to form pure $[\mathbf{1}]^+$ in the bulk electrolysis. So, bulk electrolysis was conducted at 0 V. Accordingly, disproportionation of $[\mathbf{1}]^+$ to $[\mathbf{1}]^{2+}$ and $[\mathbf{1}]^0$ [Equation (1)] has no influence on the number of electrons consumed in the electrolysis.

[12] R. W. Callahan, G. M. Brown, T. J. Meyer, *Inorg. Chem.* **1975**, *14*, 1443–1453.

[13] The controlled-potential electrolysis of $[\mathbf{2}]^{2+}$ at –0.60 V in CH_2Cl_2 resulted in disappearance of the 872-nm band of $[\mathbf{2}]^{2+}$ and generation of a weak, broad band at 864 nm. Re-oxidation of the solution at –0.25 V, however, did not recover the spectrum of $[\mathbf{2}]^{2+}$ nor produce any strong absorption bands in the visible region. This result implies the dissociation of the dioxolene ligands of $[\mathbf{2}]^+$ during the electrochemical reduction.

[14] CF_3CH_2OH was used as a solvent for the CV of $[\mathbf{2}]^{3+}$ instead of MeOH because MeOH is oxidized above ca. +0.8 V in the conditions of CV.

[15] The trication was not detected in the ESI mass spectrum of [**2**]$(PF_6)_3$ in MeOH or CH_2Cl_2 using a normal electrospray ionization probe because $[\mathbf{2}]^{3+}$ is readily reduced to $[\mathbf{2}]^{2+}$ under the experimental conditions used. The signals of $[\mathbf{2}]^{3+}$ were, however, detected as a cluster ion with solvent at 30 °C by ESI-TOF MS employing a Nanoflow-ESI probe with an orthogonal acceleration time-of-flight (Waters–Micromass). The monocation was not detected in the ESI-mass spectrum of [**3**](PF_6) in MeOH because $[\mathbf{3}]^+$ is readily oxidized to $[\mathbf{3}]^{2+}$, which was detected as the monocation $\{[\mathbf{3}](PF_6)\}^+$.

Bifunctional Bioorganometallic Iridium(III)–Platinum(II) Complexes Incorporating Both Intercalative and Covalent DNA Binding Capabilities

Susan Gençaslan[a] and William S. Sheldrick*[a]

Keywords: Iridium / Platinum / Peptides / DNA binding / Bioinorganic chemistry

The DNA binding of bifunctional Ir^{III}–Pt^{II} complexes containing $[(\eta^5\text{-Cp}^*)Ir(dppz)]^{2+}$ and $[Pt(terpy)]^{2+}$ or *trans*-$[PtL_2L']^{2+}$ fragments (L = NH_3, L′ = DMF; L = H_2O, L′ = NH_3) bridged by flexible κ*S*:κ*N*(amino)-coordinated methionine-containing peptides has been studied by UV/Vis and CD spectroscopy. Stable intercalative binding of the Ir^{III} fragment of the complexes $[\{(\eta^5\text{-Cp}^*)Ir(dppz)\}(\mu\text{-peptide-}\kappa S{:}\kappa N)\{Pt(terpy)\}](CF_3SO_3)_4$ (**5**) (peptide = H-Gly-Gly-Phe-Met-OH; H-Gly-OH = glycine, H-Phe-OH = L-phenylalanine, H-Met-OH = L-methionine) and **6** [peptide = H-$(Ala)_4$-Met-OH; H-Ala-OH = L-alanine] is indicated by their steady decrease in absorbance at maxima between 350 and 390 nm on titration with CT DNA and by the bathochromic shifts of these maxima. Binding constants K_b of $1.4(4)\times10^6$ M^{-1} for both **5** and **6** and site sizes *s* of 2.8(1) and 2.2(1), respectively, are in accordance with this monofunctional mode. Both peptide chain length and the site(s) of the labile Pt^{II} substituents DMF or H_2O play an important role in determining the degree of intercalation of the Ir^{III} fragment and the extent of helix distortion caused by simultaneous covalent binding of Pt^{II} centres for the DNA interaction of the complexes $[\{(\eta^5\text{-Cp}^*)Ir(dppz)\}(\mu\text{-peptide-}\kappa S{:}\kappa N)\{trans\text{-}(PtL_2L')\}]^{4+}$ **7**–**10**. Whereas both **9** and **10** (L = H_2O, L′ = NH_3; peptide = H-Gly-Met-OH or H-Gly-Gly-Met-OH) exhibit a high degree of bifunctional binding [**9**, K_b = $1.1(5)\times10^6$ M^{-1}, *s* = 1.3(1); **10**, K_b = $1.4(7)\times10^6$ M^{-1}, *s* = 2.1(1)], CD spectroscopy indicates that a more pronounced reorganisation of the DNA helix is required for the former complex with its shorter peptide. Effective intercalation is also observed for **8** (L = NH_3, L′ = DMF; peptide = H-Gly-Gly-Met-OH) but not for **7** with the analogous Pt^{II} fragment but a shorter bridging peptide (H-Gly-Met-OH).

Introduction

Multinuclear platinum complexes containing two or more square-planar platinum(II) centres capable of covalent binding to DNA nucleobases represent a relatively new class of anticancer agents.[1–3] They have been shown to exhibit activity in cancer cell lines with intrinsic resistance to cisplatin and can also overcome acquired resistance to this successful antitumor drug, presumably as a result of their participation in long-range interstrand DNA adducts. Length, conformational flexibility, total charge and hydrogen-bonding donor capacity of the linking ligands (e.g. 1, *n*-diaminoalkanes) have been identified by Farrell[1,2] as paramount factors in the design of multinuclear platinum drugs.

A modified approach to the polynuclear concept involves the design of bifunctional complexes with two distinct DNA binding capabilities connected by a rigid or flexible bridging moiety. For instance octahedral ruthenium(II) and square-planar platinum(II) centres have been linked in the heterodinuclear complexes $[\{cis\text{-}RuCl_2(Me_2SO)_3\}(\mu\text{-}H_2N(CH_2)_4NH_2)\{cis\text{-}PtCl_2(NH_3)\}]$[4] and [(terpy)Ru(μ-dtdeg)PtCl]Cl_3 {terpy = 2,2′:6′,2′′-terpyridine, dtdeg = bis[4′-(2,2′:6′,2′′-terpyridyl)]diethyleneglycol ether}.[5] However, the light-sensitive and highly reactive former complex proved to be unsuitable as a DNA binding probe and the latter complex exhibited a lower cytotoxicity towards cisplatin-sensitive cell lines in comparison to $[PtCl(terpy)]\cdot2H_2O$, presumably due to the fact that its ruthenium moiety can only participate in electrostatic DNA interactions. Attempts to improve on the effectiveness of cisplatin have also involved the tethering of intercalating acridine[6,7] and phenazine[8,9] groups to platinum(II) centres. The presence of an intercalative chromophore leads both to a marked increase in the rate of DNA platination and to an altered sequence specificity.[7,9] Metallointercalators such as $[Pt(terpy)]^{2+}$[10,11] or $[Ru(dppz)(phen)_2]^{2+}$ (dppz = dipyrido[3,2-*a*:2′,3′-*c*]phenazine)[12] have also been linked to identical fragments to afford bifunctional complexes with high DNA binding affinities. The use of dppz-containing compounds to promote intercalative DNA binding is well documented.[13]

We have recently demonstrated that bioorganometallic metallointercalators of the type $[(\eta^5\text{-Cp*})Ir(dppz)(peptide)]^{n+}$ (*n* = 1–3)[14] and $[(\eta^6\text{-arene})Ru(dppz)(peptide)]^{n+}$ (*n* = 1–3; arene = C_6H_6, $Me_3C_6H_3$, C_6Me_6)[15] exhibit strong side-on intercalative binding into DNA with equilibration constants K_b of up to 5.5×10^6 M^{-1}. Following initial

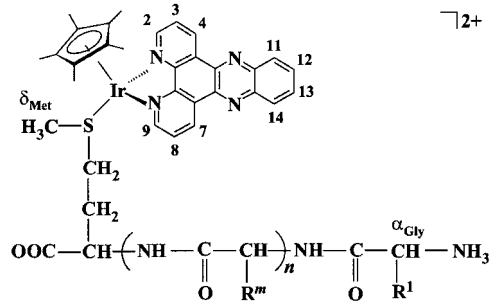
chemospecific κ*S* coordination of the organometallic [(η^5-Cp*)Ir(dppz)]$^{2+}$ or [(η^6-arene)Ru(dppz)]$^{2+}$ fragment in complexes of methionine-containing peptides, a second similar or different metal fragment can be introduced by employing either the terminal amino function or the donor atom of a suitable side chain as the additional binding site. The feasibility of this concept has been demonstrated for [{(η^5-Cp*)Ir(dppz)}$_2$(μ-H-Met-Met-OH-κ*S*:κ*S*′)](CF$_3$SO$_3$)$_4$ and [{(η^5-Cp*)Ir(dppz)}(μ-H-Gly-Met-OH-κ*S*:κ*N*$_G$){Pt(terpy)}](CF$_3$SO$_3$)$_4$.[16] We now extend the design strategy to iridium(III)–platinum(II) complexes exhibiting an intercalating [(η^5-Cp*)Ir(dppz)]$^{2+}$ moiety tethered to a *trans*-[PtL$_2$L′] (L = NH$_3$, H$_2$O;L′ = DMF, NH$_3$) fragment. To the best of our knowledge, such compounds of the type [{(η^5-Cp*)Ir(dppz)}(μ-peptide-κ*S*:κ*N*){*trans*-(PtL$_2$L′)}]$^{4+}$ represent the first examples of bifunctional complexes containing both a metallointercalator and a covalent DNA binding capability.

Results and Discussion

Monofunctional Starting Compounds [(η^5-Cp*)Ir(dppz)(peptide-κ*S*)](CF$_3$SO$_3$)$_2$ 3 and 4

The bioorganometallic starting compounds of the type [(η^5-Cp*)Ir(dppz)(peptide-κ*S*)](CF$_3$SO$_3$)$_2$ [peptide = H-Gly-Met-OH,[16] H-Gly-Gly-Met-OH,[14] H-Gly-Gly-Phe-Met-OH (**3**), H-(Ala)$_4$-Met-OH (**4**)] were prepared as described previously for H-Gly-Met-OH[16] and H-Gly-Gly-Met-OH[14] by initially refluxing [(η^5-Cp*)Ir(acetone)$_3$](CF$_3$SO$_3$)$_2$ (**1**)[17] with dppz in CH$_3$OH/CH$_2$Cl$_2$ for 2 h. Addition of the appropriate peptide in CF$_3$COOH to the resulting [(η^5-Cp*)Ir(acetone)(dppz)](CF$_3$SO$_3$)$_2$ solution leads to formation of the desired complexes [(η^5-Cp*)-Ir(dppz)(peptide-κ*S*)](CF$_3$SO$_3$)$_2$ (Scheme 1). Strongly acidic conditions (CF$_3$COOH) are, however, necessary to achieve chemospecific κ*S* coordination of the methionine side chains in the presence of non-protected terminal amino or carboxylate groups. After stirring at 50 °C for 18 h and volume reduction, the products can be precipitated by addition of diethyl ether. The remaining solution contains a residual quantity of [(η^5-Cp*)Ir(CF$_3$COO)(dppz)](CF$_3$SO$_3$) (**2**), which could be subsequently crystallised in low yield.



3 $R^3 = CH_2\text{-}C_6H_5$, $R^2 = R^1 = H$ ($n = 2$; $m = 2, 3$)
4 $R^1 - R^4 = CH_3$ ($n = 3$; $m = 2, 3, 4$)

Scheme 1.

As depicted in Figure 1, complex **2** exhibits an interplanar angle of 56.1° between its Cp* and dppz ring systems and contains a κ*O*-coordinated trifluoroacetate ligand with an Ir–O2 distance of 2.156(7) Å. Although individual [(η^5-Cp*)Ir(CF$_3$COO)(dppz)]$^+$ cations dimerise through π–π interactions of their parallel phenanzine ligands in the crystal structure of **2** (Figure 2), more extensive base stacking is prevented by the steric requirements of the Cp* and CF$_3$COO$^-$ ligands. An interplanar distance of 3.48 Å is observed for the dppz ring systems within such cation pairs. Dimerisation of complexes containing the [(η^5-Cp*)-Ir(dppz)]$^{2+}$ fragment will, of course, be expected in solution and also possibly as an external binding mode on the DNA surface for the bifunctional complexes studied in the present work. This prompted us to determine the dimerisation constant K_D for [(η^5-Cp*)Ir(dppz)(H-Gly-Gly-Met-OH-κ*S*)](CF$_3$SO$_3$)$_2$ as a typical monofunctional member of this class of bioorganometallic compounds.

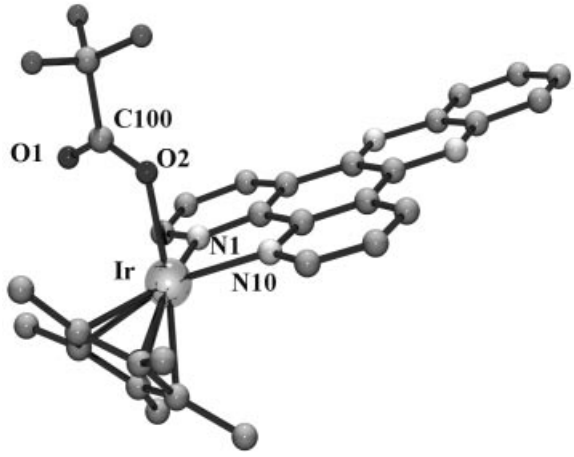


Figure 1. Molecular structure of the cation of [(η^5-Cp*)-Ir(CF$_3$COO)(dppz)](CF$_3$SO$_3$) (**2**): Selected bond lengths [Å] and angles [°]: Ir–N1 2.109(8), Ir–N10 2.106(8), Ir–O2 2.156(7), Ir–C 2.158(4)–2.198(4), C100–O1 1.20(2), C100–O2 1.26(1), N1–Ir–N10 77.4(3), N1–Ir–O2 84.6(3), N10–Ir–O2 82.9(3).

The [(η^5-Cp*)Ir(dppz)(H-Gly-Gly-Met-OH)]$^{2+}$ cation displays two characteristic absorption maxima at 364 and 382 nm for the π–π* transitions of its dppz ligand. At very low concentrations (10 μM or lower) in a 10 mM phosphate buffer at pH = 7.2, the molar absorption coefficients ε_{364} and ε_{382} are independent of the cation concentration, i.e. **2** is present as a monomer. The observed hypochromic shifts in the ε values for the concentration range 10–180 μM (Figure 3) are indicative of increasing intermolecular dipole–dipole interactions between dppz ligands and thereby of dimerisation. Using the equation of Schwarz et al.,[18] a dimerisation constant K_D of 6.4×10^3 M^{-1} was determined on the basis of a regression analysis for ($\varepsilon_M - \varepsilon_{obsd.}$) ($\lambda$ = 382 nm) in the concentration range 10–250 μM. Respective values of 13395 L·mol^{-1}·cm^{-1} and 8894 L·mol^{-1}·cm^{-1} were obtained for the molar absorption constants ε_M and ε_D of the monomer and dimer. These represent a relative decrease in absorption $\Delta A/A$ at 382 nm of 25.4%. The strength of the base stacking for the large planar dppz ligands of [(η^5-Cp*)Ir(dppz)(H-Gly-Gly-Met-OH)]$^{2+}$ is underlined by

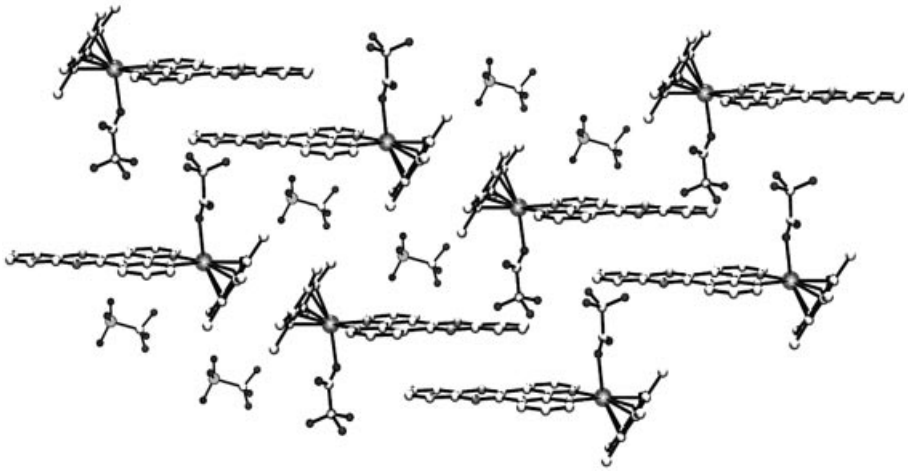

Figure 2. Dimerisation of the $[(\eta^5\text{-Cp*})Ir(CF_3COO)(dppz)]^+$ cations of **2** in the crystal lattice.

comparing its K_D value with the lower values of 4×10^3 and 5×10^2 M^{-1} for [PtCl(terpy)]Cl[19] and proflavine.[18]

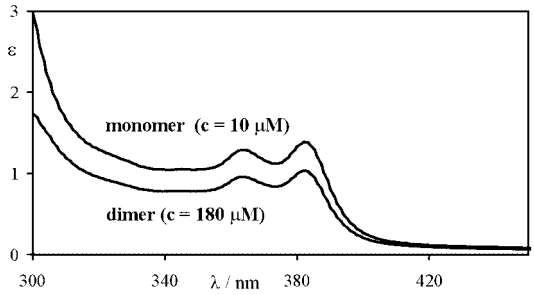

Figure 3. Dimerisation of the $[(\eta^5\text{-Cp*})Ir(dppz)(H\text{-}Gly\text{-}Gly\text{-}Met\text{-}OH)]^{2+}$ cations in a phosphate buffer at pH = 7.2 as demonstrated by the hypochromic shift of the molar absorption coefficients ε ($L \cdot mol^{-1} \cdot cm^{-1}$) in the wavelength range 300–420 nm.

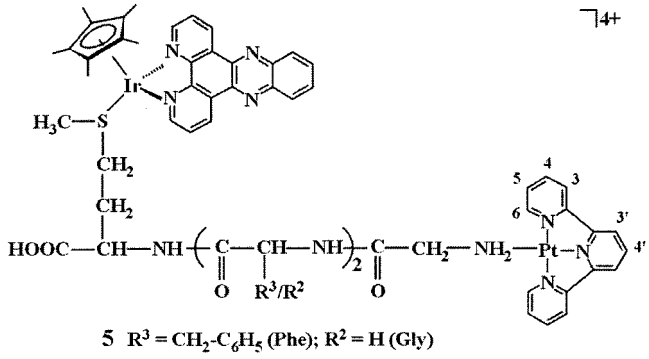
Bifunctional Iridium(III)–Platinum(II) Metallointercalators 5 and 6

The bifunctional iridium(III)–platinum(II) metallointercalators $[\{(\eta^5\text{-Cp*})Ir(dppz)\}(\mu\text{-H-Gly-Gly-Phe-Met-OH-}\kappa S{:}\kappa N_G)\{Pt(terpy)\}](CF_3SO_3)_4$ (**5**) and $[\{(\eta^5\text{-Cp*})Ir(dppz)\}(\mu\text{-H-(Ala)}_4\text{-Met-OH-}\kappa S{:}\kappa N_G)\{Pt(terpy)\}](CF_3SO_3)_4$ (**6**) (Figure 4) are prepared by addition of **3** or **4**, respectively, to an aqueous $[Pt(OH_2)(terpy)](CF_3SO_3)_2$ solution. All four complexes were characterised by elemental analysis, FAB mass spectrometry, ^{1}H and ^{13}C NMR, IR and UV/Vis spectroscopy. Downfield ^{1}H NMR shifts of 0.10 ppm are observed for the signals of the Cp* methyl protons of the κ*S*-coordinated $[(\eta^5\text{-Cp*})Ir(dppz)]^{2+}$ fragments in **3**–**6** in comparison to the δ value of 1.74 for this singlet in a CD_3OD solution of the chloro complex $[(\eta^5\text{-Cp*})Ir(Cl)(dppz)](CF_3SO_3)$.[14] In contrast, the signals of the methionine δ-CH_3 protons adjacent to the coordinated thioether sulfur atoms in the met-containing complexes exhibit a more pronounced opposite upfield shift from typical values of ca. 2.10 ppm in the free peptide to resonance positions in the range δ = 1.79–1.81 ppm. As previously noted for both $[(\eta^5\text{-Cp*})Ir(dppz)]^{2+}$ and $[(\eta^6\text{-arene})Ru(dppz)]^{2+}$ derivatives[14,15] this behaviour represents a striking reversal of the typical positive shift displayed by the signals of the δ-CH_3 protons in analogous half-sandwich organometallic complexes without a chelating aromatic ligand such as dppz.[20,21] The shielding cone of the neighbouring dppz ligand may well be responsible for this anomalous upfield shift in **3**–**6**.



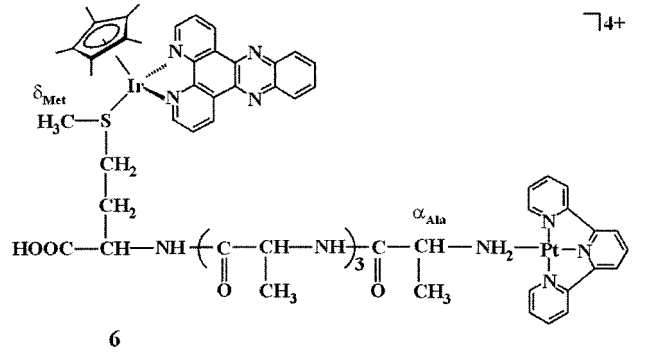


Figure 4. Tetracations of the bifunctional complexes **5** and **6**.

Additional κ*N* coordination of the $[Pt(terpy)]^{2+}$ fragment by the terminal amino group of the peptide ligands in **5** and **6** leads to significant upfield shifts in the δ values of the H6

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and H5 protons from their resonance positions of δ = 9.00 and 7.86 ppm in [PtCl(terpy)]Cl (CD_3OD solution). Respective shifts of δ = 8.83/8.88 and 7.82 ppm are observed for the bifunctional complexes. Further clear evidence for κ*N* coordination is also provided by the characteristic upfield shifts recorded for the signals of the adjacent α proton(s) of the terminal amino acid residue in **5** and **6**. Whereas the α_{Gly1} singlet exhibits only a modest shift from δ = 3.65 ppm in the free peptide to 3.61 ppm upon coordination in **5**, a striking move from δ = 3.94 to 3.72 ppm is observed for signal of the α_{Ala1} proton in **6**.

DNA Binding Studies for 3–6

A pronounced decrease in absorbance at 364 and 382 nm and the bathochromic shifts of these absorption maxima (Figure 5) on UV/Vis titration of 20 μM solution of **3**–**6** with calf thymus DNA (CT DNA) are clearly indicative of dppz intercalation into DNA. In contrast to the hypochromic shifts $-\Delta A/A$ of 32.1–38.7% for **3**–**6** at 382 nm with their associated red shifts of 5 nm, a much smaller decrease in absorbance of only 12.2 or 11.0%, respectively, is observed for the terpyridine ligand at its 343 nm maximum in **5** and **6**, which remains unshifted. As no correction for the increase in DNA absorbance at 343 nm (due to its 15-fold increase in concentration during the UV/Vis titration) was made, it is reasonable to assume that terpyridine intercalation will not be of great significance for the binding of **5** and **6**. Absorption data collected at 382 nm for **3**–**6** were fitted by least squares using the non-cooperative non-specific binding model by Bard and Thorp.[22,23] Best fits were obtained for the intrinsic binding constants K_b and the average binding site sizes *s* listed in Table 1. Both these parameters and the melting temperature shifts ΔT_m for **3** and **4** are closely similar to the values of $1.2(1)\times10^6$ M^{-1} (K_b), 1.6 (*s*) and 6.9 °C (ΔT_m) previously reported for the analogous compound [(η^5-Cp*)Ir(dppz)(H-Gly-Gly-Met-OH-κ*S*)](CF$_3$SO$_3$)$_2$.[14] We chose the longer oligopeptides H-Gly-Gly-Phe-Met-OH and H-(Ala)$_4$-Met-OH in the hope that these might enable long-range bis-intercalation of their bifunctional complexes **5** and **6** into the DNA helix.

However, as simultaneous intercalation of both the aromatic ligands of the [(η^5-Cp*)Ir(dppz)]$^{2+}$ and [Pt(terpy)]$^{2+}$ fragments would be predicted to afford significantly higher binding constants and site sizes [i.e. the average number of nucleobase pairs between the specific or middle binding position of neighbouring mono- or bis-metallointercalators, respectively], the calculated values of 1.4×10^6 M^{-1} and 2.8(1)/2.2(1) for K_b and *s* in **5** and **6** are clearly in accordance with effectively exclusive [(η^5-Cp*)Ir(dppz)]$^{2+}$ mono-intercalation. We have previously reported similar binding constants [$1.5(1)\times10^6$ M^{-1} and $3(3)\times10^6$ M^{-1}] and site sizes (2.6, 2.9) which also indicate only mono-intercalation of the Ir^{III} fragment for two likewise intercalators [{(η^5-Cp*)-Ir(dppz)}$_2$(μ-H-Met-Met-OH-κ*S*:κ*S*′)](CF$_3$SO$_3$)$_4$ and [{(η^5-Cp*)Ir(dppz)}(μ-H-Gly-Met-OH-κ*S*:κ*N*$_G$){Pt(terpy)}]-(CF$_3$SO$_3$)$_4$.[16] These values, taken together with the successful fitting of the UV/Vis data for all complexes in a wide complex/DNA molar ratio {*r* = 0.067–1.0 with [DNA] = M(nucleotide)} indicate that the DNA binding mode of such metallointercalators must be effectively independent of the number of amino acid residues. Whereas the extended aromatic system of dppz preferentially intercalates into DNA, the stabilising role of the smaller terpyridine ligands will presumably be restricted to intermolecular base stacking on the DNA surface. The relatively limited decrease in absorbance at the terpy maximum (λ = 343 nm) observed during UV/Vis titrations is in accordance with this binding description (Figure 5). Interestingly, the highest K_b and *s* values were determined for the H-Gly-Met-OH complex, thereby suggesting that such surface π–π interactions may, indeed, be more favourable for the [Pt(terpy)]$^{2+}$ moiety when bridged to the Ir^{III} fragment by this shorter peptide.

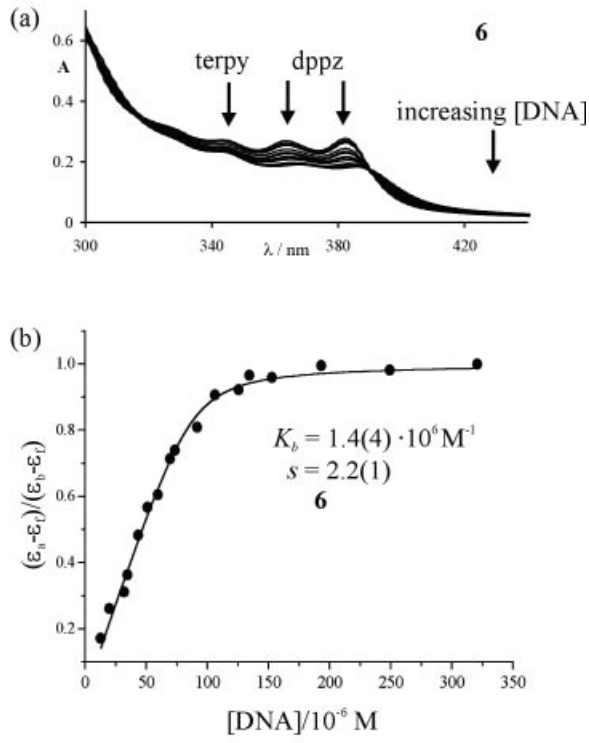

Figure 5. (a) UV/Vis spectra for the titration of [{(η^5-Cp*)Ir(dppz)}-[μ-(Ala)$_4$-Met-OH-κ*S*:κ*N*]{Pt(terpy)}](CF$_3$SO$_3$)$_4$ **6** (20 μM) in a 10 mM phosphate buffer (pH = 7.2) with CT DNA [0–300 μM (nucleotide)]; (b) the best least-squares fit for **6**/DNA to the non-cooperative non-specific binding model by Bard and Thorp.[22,23]

Table 1. Binding constants K_b, site sizes *s* and melting temperature shifts ΔT_m for the interaction of CT DNA with complexes **3**–**6** in a 10 mM phosphate buffer at pH = 7.2.

Complex	K_b [M^{-1}]	s	ΔT_m [°C]

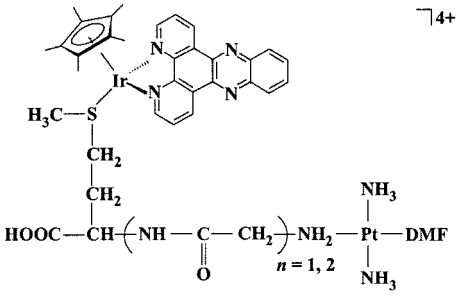
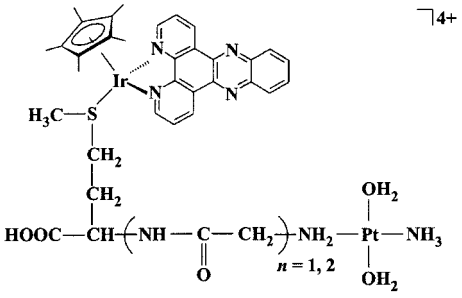
Bifunctional Iridium(III)–Platinum(II) Complexes 7–10 with Both Intercalative and Covalent DNA Binding Capabilities

Treatment of the appropriate monofunctional starting compound $[(\eta^5\text{-Cp*})Ir(dppz)(peptide\text{-}\kappa S)](CF_3SO_3)_2$ with *trans*-$[Pt(DMF)_2(NH_3)_2](NO_3)_2$ in DMF affords the bifunctional complexes $[\{(\eta^5\text{-Cp*})Ir(dppz)\}(\mu\text{-peptide-}\kappa S{:}\kappa N_{G1})(trans\text{-}\{Pt(NH_3)_2DMF\})](CF_3SO_3)_2(NO_3)_2$ (peptide = H-Gly-Met-OH **7**, H-Gly-Gly-Met-OH **8**) shown in Figure 6. The required *trans*-$[Pt(DMF)_2(NH_3)_2](NO_3)_2$ is prepared in situ by addition of 2 equiv. of $AgNO_3$ to *trans*-$[PtCl_2(NH_3)_2]$ in DMF solution followed by filtration of the precipitated AgCl. Retention of the κ*S* coordination mode by the $[(\eta^5\text{-Cp*})Ir(dppz)]^{2+}$ fragment is confirmed by the characteristic ^{1}H NMR upfield shifts of the methionine δ-CH_3 singlets to δ = 1.79 ppm in **7** and **8**. Replacement of the Ir^{III} fragment by *trans*-$[Pt(DMF)(NH_3)_2]$ would, in contrast, lead to a downfield shift for the signals of these protons from δ ≈ 2.10 ppm in the free peptides to a value in the range δ = 2.3–2.5 ppm.[24,25] Coordination of the Pt^{II} moiety by the N-terminal glycine (Gly1) amino function in **7** and **8** is indicated by the pronounced upfield shifts of the α_{Gly1} singlets from δ = 3.72/3.75 ppm in the free peptides to δ = 3.64/3.62 ppm in the bifunctional complexes. The resonances of the *trans*-sited DMF ligand (CD_3OD solution) are observed with appropriate integral values at δ = 2.84, 2.98 (CH_3) and 7.96 (CH) in **7** and 2.85, 2.97 (CH_3) and 7.96 (CH) ppm in **8**.



7, n = 1; **8**, n = 2



9, n = 1; **10**, n = 2

Figure 6. Tetracations of the bifunctional complexes **7**–**10**.

Bifunctional organometallic compounds of the type $[\{(\eta^5\text{-Cp*})Ir(dppz)\}(\mu\text{-peptide-}\kappa S{:}\kappa N_{G1})(trans\text{-}\{Pt(NH_3)(OH_2)_2\})][Et_4N](CF_3SO_3)_5$ **9** and **10** are prepared by reaction of the starting compounds $[(\eta^5\text{-Cp*})Ir(dppz)(peptide\text{-}\kappa S)](CF_3SO_3)_2$ with $(Et_4N)[PtCl_3(NH_3)]$ in aqueous solution following initial precipitation and removal of AgCl on treatment of the Pt^{II} complex with 3 equiv. of $Ag(CF_3SO_3)$. Although the molecular ions, themselves, could not be detected by FAB mass spectrometry, the bridging μ-1κ*S*:2κN_{Gly1} coordination mode is clearly confirmed for the peptides H-Gly-Met-OH (**9**) and H-Gly-Gly-Met-OH (**10**) by the pronounced ^{1}H NMR upfield shifts of their δ_{Met}-CH_3 and α_{Gly1}–CH_2 singlets to δ = 1.79/3.64 and 1.81/3.64 ppm, respectively. The much stronger *trans* effect of NH_3 in comparison to the aqua ligands (E_t values 200:1)[26] leads to exclusive κ*N* coordination of the peptide amino group in *trans* position to the ammine ligand in **9** and **10**. Sharp singlets for Me α_{Gly1}–CH_2 protons are also in accordance with the presence of only the *trans* isomer.

Before turning in detail to DNA interaction studies of the bifunctional complexes **7**–**10** with their complementary covalent and intercalative binding capabilities, it is necessary to consider possible competitive substitution reactions for the nucleobase nitrogen atoms, i.e. whether Ir^{III} or Pt^{II} will be preferred as coordination partners. The kinetics of nucleobase binding was, therefore, studied by ^{1}H NMR in an exemplary manner for the reaction of **7** with the model purine base 9-ethylguanine at a 1:2 molar ratio in a 10 mM phosphate buffer (pH = 7.2) at T = 298 K (Figure 7). As indicated by the rapid growth in the free DMF CH singlet at δ = 7.94 ppm in comparison to the declining resonance at δ = 7.90 ppm (coordinated DMF), substitution by the hydrogen- or dihydrogenphosphate buffer anions is relatively rapid. The extent of the subsequent slow replacement of the new anionic ligand by κ*N*7-coordinated 9-ethylguanine can be gauged by the integral ratio of the H8 resonances at δ = 8.32 (coordinated) and 7.80 (free) ppm. After 5 d, ca. 90% of **7** is converted into $[\{(\eta^5\text{-Cp*})Ir(dppz)\}(\mu\text{-H-Gly-Met-OH-}\kappa S{:}\kappa N_{G1})[trans\text{-}\{Pt(9\text{-ethylguanine})(NH_3)_2\}]]^{4+}$ (**11**) depicted in Figure 8. Exclusive Pt^{II} coordination is confirmed by the unchanged resonance positions and integral values for the dppz and δ_{Met} protons after this period of time.

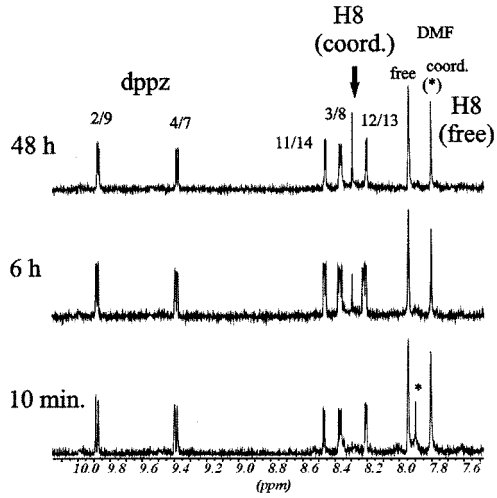


Figure 7. Aromatic region of the ^{1}H NMR spectrum of a 1:2 reaction mixture of **7** (c = 5 mM) and 9-ethylguanine in a 10 mM phosphate buffer at pH = 7.2 and T = 298 K.

UV/Vis DNA Binding Studies for 7–10

The interaction of **7**–**10** with CT DNA was studied by UV/Vis titrations, DNA melting temperature determinations and CD spectroscopy. As for **3**–**6**, hypo- and bathochromic shifts were observed for the dppz absorption maxima at 363 and 382 nm on increasing the DNA/complex molar ratio from 1:1 to 15:1. Although ca. 90–95% of the total decrease in absorbance $\Delta A/A$ at 382 nm is achieved within 2 min, it takes between 8 (complex **7**) and 40 h (complex **9**) for the DNA/complex reaction mixtures to reach an equilibrium. This behaviour is in striking contrast to **3**–**6**, for which $-\Delta A/A$ reaches its maximum value within 2 min, and indicates that a slow structural reorganisation and binding optimisation must take place for **7**–**10** following rapid initial intercalation and/or surface base stacking. All UV/Vis spectra employed for the determination of binding constants and site sizes were measured after equilibration, i.e. after no further change in the monitored absorbance at 382 nm was recorded.

DNA binding parameters for **7**–**10** are listed in Table 2. As satisfactory least-squares fits (Figure 9) could be obtained in all cases for the absorption data using the model by Bard and Thorp[22,23] non-cooperative non-specific binding can be assumed for the interaction of the complexes with CT DNA. The low $-\Delta A/A$ value of 27.5% and the physically unrealistic site size (s = 0.9) of less than one base pair between binding sites indicate that only a limited degree of intercalation is achieved by **7** with its dipeptide bridging ligand H-Gly-Met-OH. A comparison of these values with those of the monofunctional complex [(η^5-Cp*)-Ir(dppz)(H-Gly-Met-OH-κ*S*)]$(CF_3SO_3)_2$[27] [$-\Delta A/A$ = 45.1%, $K_b = 1.9(7)\times10^6$ M^{-1}, s = 2.2(1)], for which equilibration is reached within 2 min, suggests that coordination of the Pt^{II} centres by DNA nucleobases must be rapid for **7**. Exclusive initial intercalation of the [(η^5-Cp*)Ir-(dppz)]$^{2+}$ fragment (as observed for the monofunctional complex), followed by a slow increase in κ*N* coordination of the group 10 metal and a concomitant reduction in the degree of intercalation, would otherwise lead to a slow decline in $\Delta A/A$ from a maximum value of ca. 45.1%[27] after 2 min.

Table 2. $-\Delta A/A$ (for λ = 382 nm), binding constants K_b, site sizes s, melting temperature shifts ΔT_m and induced circular dichroism Θ (for λ = 300 nm) for the interaction of CT DNA with complexes **7**–**10** in a 10 mM phosphate buffer at pH = 7.2.

Complex	$-\Delta A/A$ [%]	K_b [M^{-1}]	s	ΔT_m [°C]	[Θ] [deg·cm^2·dmol^{-1}]
7	27.5	$1.1(2)\times10^6$	0.9(1)	8.2	-1.5×10^3
8	35.2	$4(3)\times10^6$	2.4(2)	11.2	-2.9×10^3
9	43.9	$1.1(5)\times10^6$	1.3(1)	17.2	-3.8×10^3
10	38.5	$1.4(7)\times10^6$	2.1(1)	17.2	-3.8×10^3

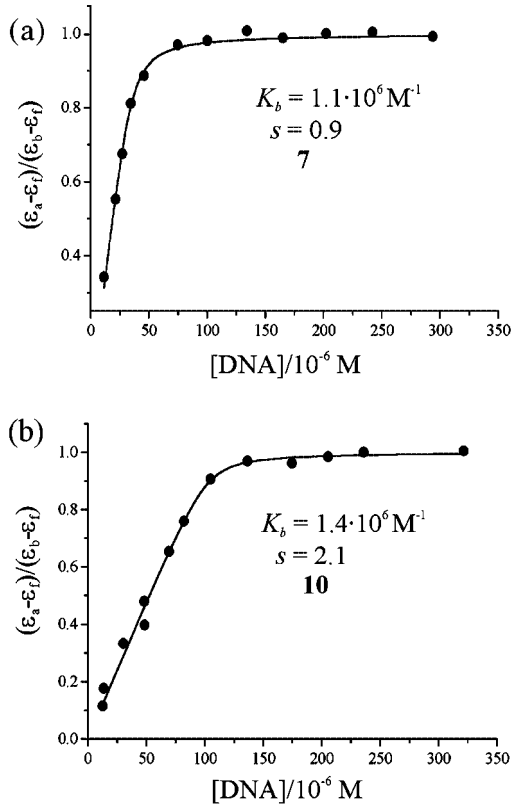

Figure 9. Best least-squares fits to the model by Bard and Thorp[22,23] for complexes **7** and **10**.

Circular Dichroism DNA Binding Studies for 7–10

In contrast to **7**, the much higher $-\Delta A/A$ and s values of 35.2% and 2.4(2), respectively, for **8** indicate that this complex with its longer bridging peptide, H-Gly-Gly-Met-OH, is apparently capable of combining both κ*N* coordination of the DNA nucleobases by the *trans*-[$Pt(NH_3)_2$(peptide-κ*N*)]$^{2+}$ fragment and effective intercalation of the [(η^5-Cp*)-Ir(dppz)(peptide-κ*S*)]$^{2+}$ moiety. Characteristic changes in the observed circular dichroism (CD) spectrum of DNA provide a means of monitoring both conformational changes for the biopolymer and possible intercalation or groove binding of an interacting metal complex.[28,29] As depicted for CT DNA in Figure 10, a negative band at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

246 nm and a positive band at 275 nm due to base stacking are observed for a B-DNA helix. Addition of the metallointercalator [(η^5-Cp*)Ir(dppz)(H-Gly-Gly-Met-OH-κ*S*)](CF_3SO_3)$_2$ at a complex/DNA molar ratio of r = 0.1 leads to a small reduction in the negative Cotton effect at 246 nm and a small hypsochromic shift of 3 nm for the positive band to 272 nm, thereby indicating only minor distortion of the B helix. The additional negative-induced CD band at 300 nm must presumably be caused by the intercalation of the dppz ligands into the DNA helix.[29]

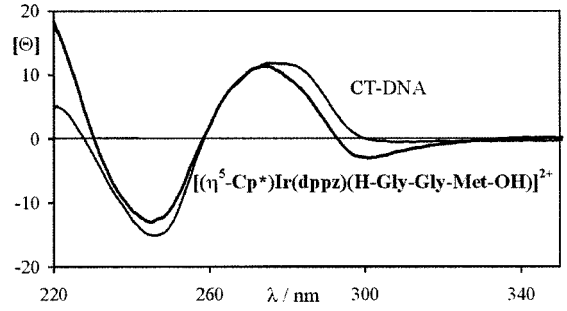

Figure 10. CD spectra of CT DNA and a mixture of [(η^5-Cp*)-Ir(dppz)(H-Gly-Gly-Met-OH-κ*S*)](CF_3SO_3)$_2$ and DNA [molar ratio (1:10)] in a 10 mM phosphate buffer (pH = 7.2) after 48 h incubation at 295 K.

Figure 11 compares the CD spectra of the bifunctional complexes **7** and **8** with CT DNA at a molar ratio of 0.1. The significantly higher degree of intercalation for **8** leads to a molar ellipticity ([Θ] = -2.9×10^3 deg·cm^2·dmol^{-1} for λ = 300 nm) that is almost twice as large as that recorded for the less effective metallointercalator **7** ([Θ] = -1.5×10^3 deg·cm^2·dmol^{-1} for λ = 300 nm). In the case of the former complex, the small but significant increase in [Θ] for the positive CD band at 276 nm may be attributed to additional

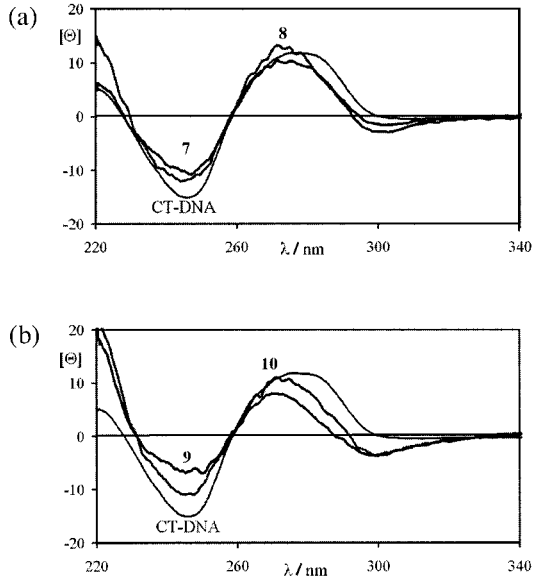

Figure 11. CD spectra of (a) complexes **7** and **8** and (b) complexes **9** and **10** with CT DNA at a complex/[DNA] molar ratio of 1:10 in a 10 mM phosphate buffer (pH = 7.2) at 295 K after 48 h incubation. [Θ] values are given in deg·cm^2·dmol^{-1}·10^3.

stabilisation of base stacking in the helix due to the combination of both dppz intercalation (see Figure 10) and covalent binding of the Pt^{II} centres. In contrast, the decrease in [Θ] for **7** at this wavelength is comparable with that previously reported for [PtCl(dien)]Cl[30] and can, therefore, be regarded as being indicative for monodentate Pt^{II} coordination with a significantly lower degree of intercalation. The large decrease in the negative [Θ] values at 246 nm in both **7** and **8** in comparison to [(η^5-Cp*)Ir(dppz)(H-Gly-Gly-Met-OH-κS)](CF_3SO_3)$_2$ (Figure 10) may be due to the fourfold positive charge of the bifunctional complexes, which could lead to a change in the helical conformation. A schematic illustration of a possible long-range simultaneous covalent and intercalative binding mode for complex **8** with s = 2.0 (calcd. 2.4) is given in Figure 12a.

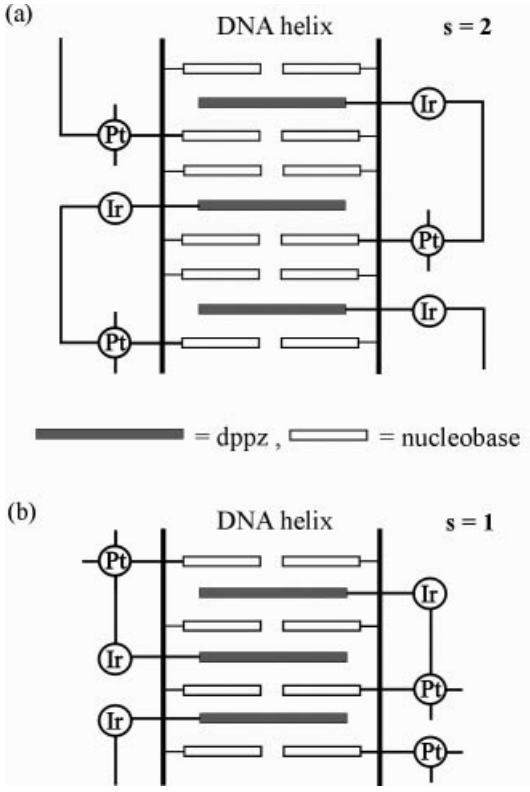

Figure 12. Schematic depictions of possible simultaneous covalent and intercalative binding modes; (a) for **8** with s = 2.0 (calcd. 2.4); (b) for **9** with s = 1.0 (calcd. 1.3).

The *cis* positions of the labile aqua ligands relative to the coordinating amino groups of the peptide ligands in **9** and **10** might be expected to favour a high degree of simultaneous covalent and intercalating DNA binding even for the shorter dipeptide of **9**. Experimental support for this hypothesis is provided by their induced molar ellipticity [Θ] at λ = 300 nm (-3.8×10^3 deg·cm^2·dmol^{-1}) and by the high values of $-\Delta A/A$ (43.9, 38.5%) and K_b (1.1×10^6, 1.4×10^6 M^{-1}) observed for their UV/Vis titrations with CT DNA at 382 nm. The former parameters are particularly interesting for **9**, as they indicate highly effective dppz intercalation for a low average site size of only 1.3 base pairs. In contrast to **10**, for which only the negative band at 247 nm is signifi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cantly influenced by metal binding, marked decreases in the intensity are observed for both the positive and negative bands in the CD spectrum recorded for **9**/DNA at a 1:10 molar ratio. The magnitude of these decreases is similar to those observed for *trans*-$[PtCl_2(NH_3)_2]$,[30] which can disturb the DNA helix by participation in *trans*-bidentate binding. However, the characteristic bathochromic shifts of the CD band at maxima for this coordination mode are missing for both **9** and **10**. It can be concluded that **9** and **10** must both exhibit a high degree of simultaneous covalent and intercalative DNA binding and that a more pronounced reorganisation of the DNA conformation is required to achieve this goal with complex **9** with its shorter linking peptide. The high melting temperature shifts ΔT_m of 17.2 °C for the interaction mixtures **9**/DNA and **10**/DNA result presumably from increased electrostatic stabilisation of the double helix due to the presence of an additional $[Et_4N]^+$ cation. The schematic depiction of possible simultaneous covalent and intercalative binding for **9** violates the general rule of the neighbour-exclusion principle,[31] that intercalative binding can only occur at every other base pair ($s \geq 2$). Neighbour-exclusion violating structures are more rigid[32] and support for this type of structure is provided by the pronounced helix distortions evident from the CD spectra of the interaction mixture **9**/DNA (Figure 11b).

The present work, therefore, confirms that bifunctional complexes of the type $[\{(\eta^5\text{-Cp*})Ir(dppz)\}(\mu\text{-peptide-}\kappa S{:}\kappa N)\{trans\text{-}(PtL_2L')\}]^{4+}$ with flexible bridging peptide ligands are capable of simultaneous covalent and intercalative DNA binding. Both the chain length of the peptide backbone and the position of the labile ligands in the square-planar Pt^{II} coordination sphere are shown to exhibit an important influence on the degree of intercalation and the extent of helix distortion.

Experimental Section

General: All manipulations and reactions were performed under argon in carefully dried solvents using standard Schlenk techniques. FTIR: Perkin–Elmer 1760X as KBr discs. CD: Jasco J-715 in the range 220–400 nm for 1:10 complex/[DNA] mixtures [DNA concentration in M(nucleotide)] in a 10 mM phosphate buffer at pH = 7.2. FAB MS: Fisons VG Autospec with 3-nitrobenzyl alcohol as the matrix. ^1H and ^{13}C NMR spectroscopy: Bruker DRX 400 with chemical shifts reported as δ values relative to the signal of the deuterated solvent. ^{13}C NMR signals for the CF_3SO_3 anions are observed in the range δ = 121.8–122.8 (q) ppm and are not listed for individual complexes. Elemental analyses: Vario EL of Elementar Analysensysteme GmbH. $IrCl_3{\cdot}xH_2O$, K_2PtCl_4, *cis*-$[PtCl_2(NH_3)_2]$ and *trans*-$[PtCl_2(NH_3)_2]$ were purchased from Chempur, $Ag(CF_3SO_3)$ and $AgNO_3$ from Acros and peptides, with the exception of H-$(Ala)_4$-Met-OH, from Bachem. The mentioned pentapeptide was prepared by solid-state synthesis, $[\{(\eta^5\text{-Cp*})IrCl\}_2(\mu\text{-Cl})_2]$,[33] [PtCl(terpy)]Cl[34] and dipyrido[3,2-*a*:2′,3′-*c*]-phenazine (dppz)[35] in accordance with literature procedures. Subsequent treatment of an acetone solution of $[\{(\eta^5\text{-Cp*})IrCl\}_2(\mu\text{-Cl})_2]$ with 4 equiv. of $Ag(CF_3SO_3)$ and filtration of the resulting AgCl precipitate afforded the starting compound $[(\eta^5\text{-Cp*})Ir(acetone)_3](CF_3SO_3)_2$ (**1**).[17] $[(\eta^5\text{-Cp*})Ir(dppz)(H\text{-Gly-Met-OH-}\kappa S)](CF_3SO_3)_2$[16] and $[(\eta^5\text{-Cp*})Ir(dppz)(H\text{-Gly-Gly-Met-OH-}\kappa S)](CF_3SO_3)_2$ were prepared from **1** and the relevant peptide in a manner previously described for the latter complex.[14] $(Et_4N)[PtCl_3(NH_3)]$ was obtained according to a literature procedure on treating *cis*-$[PtCl_2(NH_3)_2]$ with $(Et_4N)Cl{\cdot}H_2O$.[36]

$[(\eta^5$-Cp*)Ir(dppz)(H-Gly-Gly-Phe-Met-OH-κS)$](CF_3SO_3)_2$ (3): The ligand dppz (56.5 mg, 0.2 mmol) was added to **1** (159.8 mg, 0.2 mmol) in CH_3OH/CH_2Cl_2 (10 mL) and the resulting solution stirred at reflux for 2 h. After addition of H-Gly-Gly-Phe-Met-OH (82.1 mg, 0.2 mmol) in CF_3COOH (1.5 mL) and stirring at 50 °C for 18 h, the volume was reduced to 3 mL. The product was precipitated by addition of diethyl ether, washed and dried in vacuo. Yield 181.9 mg (69%). $C_{48}H_{51}F_6IrN_8O_{11}S_3$ (1318.3): calcd. C 43.7, H 3.9, N 8.5, S 7.3; found C 43.3, H 3.8, N 8.4, S 7.3. FAB MS: *m*/*z* (%) = 1319 (17) $[M]^+$, 1168 (10) $[M - OTf]^+$, 1019 (44) $[M - 2\ OTf]^+$. ^1H NMR (CD_3OD): δ = 1.79 (s, 3 H, δ Met), 1.84 (s, 15 H, CH_3 Cp*), 1.9–2.1 (mm, 4 H, β and γ Met), 2.93, 3.14 (m, 2 H, β Phe), 3.65, 3.69 (2s, 4 H, α Gly1, α Gly2), 4.29 (m, 1 H, α Phe), 4.36 (m, 1 H, α Met), 7.15 (m, 4 H, Phe), 7.24 (s, 1 H, Phe), 8.11 (m, 2 H), 8.43 (m, 2 H), 8.49 (dd, 2 H), 9.37 (dd, 2 H), 10.04 (dd, 2 H, dppz) ppm. ^{13}C NMR (CD_3OD): δ = 8.6 (CH_3 Cp*), 17.0 (δ Met), 30.6 (β Met), 33.7 (γ Met), 38.2 (β Phe), 41.6, 43.4 (α Gly), 51.0 (α Met), 56.2 (α Phe), 97.2 (Cp*), 127.8, 129.6, 130.3 (Phe), 130.4, 130.9 (dppz), 131.0 (Phe), 133.8, 134.3, 139.2, 140.6, 144.3, 151.3, 155.2 (dppz), 168.1, 171.1, 172.7, 173.6 (COO, NHCO) ppm. IR: $\tilde{\nu}$ = 3436 vs. (NH), 1737, 1675 s (ν CO), 1545, 1499 (δ NH) cm^{-1}.

$[(\eta^5$-Cp*)Ir(dppz)[H-$(Ala)_4$-Met-OH-κS]$](CF_3SO_3)_2$ (4): Preparation as for **3** with H-$(Ala)_4$-Met-OH (86.7 mg, 0.2 mmol). Yield 139.5 mg (52%). $C_{47}H_{56}F_6IrN_9O_{12}S_3$ (1341.4): calcd. C 42.1, H 4.2, N 9.4, S 7.2 (%); found C 42.3, H 3.8, N 9.1, S 6.7 (%). DNA Binding Studies of 3–10: The thermal denaturation temperature T_m of 1:10 complex/DNA mixtures was determined in a 10 mM phosphate buffer at pH = 7.2. Melting curves were recorded at 260 nm with a Lambda 15 Perkin–Elmer spectrometer connected with a temperature controller (Haake FS thermostat). A ramp rate of 0.25 °C min^{-1} was used over the range 25–97 °C. T_m values were calculated by determining the midpoints of the melting curves from the first-order derivatives. Experimental ΔT_m values are estimated to be accurate within ±1. Concentrations of CT DNA were determined spectrophotometrically using the molar extinction coefficient ε_{260} = 6600 M^{-1} cm^{-1}.[37] All absorption titrations were performed at room temperature. After sonication, buffered solutions of CT DNA gave a ratio of UV absorbance A_{260}/A_{280} of ca. 1.90, indicating that DNA was sufficiently free of protein.[38] 20 μM solutions of the individual metal complexes were treated with DNA over a range of molarities from 20 to 400 μM (nucleotide). All UV/Vis spectra were measured after equilibration, i.e. no further change in monitored absorbance. Titration curves were constructed from the fractional change in the absorbance as a function of DNA concentration according to the model by Bard and Thorp[22,23] for non-cooperative non-specific binding for one type of discrete DNA binding site.

$$(\varepsilon_a - \varepsilon_f)/(\varepsilon_b - \varepsilon_f) = (b - \{b^2 - 2K_b{}^2C_t[\mathrm{DNA}]/s\}^{1/2})/2K_bC_t \quad (1)$$

Equation (1) was used to fit the absorption data by least-squares refinement of binding constants (K_b) and site sizes (s) with $b = 1 + K_bC_t + K_b[\mathrm{DNA}]/2s$, where ε_a is the extinction coefficient observed at a given DNA concentration, ε_f the extinction coefficient of the complex in the absence of DNA, ε_b the extinction coefficient

of the complex when fully bound to DNA (i.e. no absorption change on further addition of DNA), K_b the equilibrium constant in M^{-1}, C_t the total metal complex concentration, [DNA] the DNA concentration in M(nucleotide), and s the binding site size. Values of ε_b were obtained by extrapolation from the y intercept of plots of $\varepsilon_a/\varepsilon_f$ vs. 1/[DNA]. The K_b and s values of Tables 1 and 2 are those for the best least-squares fits to the individual UV/Vis titration curves using the program ORIGIN 6.0.

X-ray Structural Analysis of 2: $[(\eta^5\text{-Cp*})Ir(CF_3COO)(dppz)](CF_3SO_3)$, $C_{31}H_{25}F_6IrN_4O_5S$, M = 871.8, triclinic, space group $P\bar{1}$ (no. 2), a = 8.701(2), b = 11.535(2), c = 16.603(3) Å, α = 103.60(3), β = 90.93(3), γ = 102.21(3)°, V = 1579.2(5) Å^3, Z = 2, $D_{calcd.}$ = 1.833 g·cm^{-3}, μ(Mo-K_α) = 4.376 mm^{-1}; Siemens P4 diffractometer; graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystal size: 0.46 × 0.30 × 0.12 mm; ω-scan in the range $2\theta \leq 50°$ ($-10 \leq h \leq 10$, $0 \leq k \leq 13$, $-19 \leq l \leq 19$), 5683 reflections collected, 5406 independent reflections (R_{int} = 0.051); semiempirical absorption corrections with ψ-scans; max./min. transmission 0.716/0.373; 428 parameters refined; R_1 = 0.057 for 4326 reflections with $I > 2\sigma(I)$, $wR_2 = \{[\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o)^2]\}^{1/2}$ = 0.136 for all data; min./max. residual electron density 1.82/–1.83 e·Å^{-3}. Anisotropic temperature factors for all non-hydrogen atoms with the exception of the disordered F atoms of the CF_3COO^- ligand, which exhibit s.o.f. values of 0.8 and 0.2.[39]

Secondary Periodicity in the Tetrahalogeno Complexes of the Group 13 Elements

Kinga Frąckiewicz,[a] Marian Czerwiński,[b] and Sławomir Siekierski*[a]

Keywords: Quantum calculations / Electronic structure / Group 13 elements / Halogeno complexes / Secondary periodicity

The M–X distances, the charges on the M and X atoms and the natural electron configurations in the hypothetical MX_4^- molecules, where M is a group 13 element and X = F, Cl, Br, I, have been investigated by quantum calculations. The computed distances are compared with the experimental data, mostly in the $Bu_4N[MX_4]$ salts. We found that: (1) down group 13 both the experimental and calculated M–X distances, the charge on the M atom and the sum of the populations of the M valence orbitals show zigzag variations produced by the filled 3d and 4f shells and by the relativistic effects in the 6s and $6p_{1/2}$ orbitals; (2) the experimental distances are shorter than the calculated values due, at least in part, to libration of the MX_4^- anions in the salts; (3) both the charge on M and the sum of the populations of M valence orbitals point to a highly covalent character of the B–X bonds (except for the B–F bond) and much less covalent character of the M–X bonds formed by the heavier members of the group. In the Al–Tl range the covalent character of the M–X bonds oscillates, and it strongly decreases on passing from the MCl_4^- to MF_4^- complexes; (4) the M–X distances (X = Cl, Br, I) are close to the sum of the respective covalent radii, whereas the M–F distances are significantly shorter because of considerable admixture of ionic bonding.

Introduction

It has been known for a long time that changes in some chemical properties are not uniform down the groups of p-block elements. For instance, despite the general trend of decreasing stability of the highest oxidation state $AsCl_5$ is, in contrast to $SbCl_5$, highly unstable,[1] $HBrO_4$ shows unexpectedly strong oxidizing properties and BrF_7 is, in contrast to IF_7, not known. These and other non-uniform changes in chemical properties, termed secondary periodicity or zigzag behaviour by Biron,[2] result from changes in the valence orbitals. Figure 1 shows for the group 13 elements that the *n*s and *n*p orbital radii and the covalent radius do not increase uniformly down the group but show an oscillatory, saw-tooth or zigzag variation. The orbital radii shown in Figure 1 are those calculated by Desclaux[3] and the covalent radii were taken from the literature.[4] It has been proposed by several authors[5] that the zigzag changes in orbital radii, energies and ionisation potentials of p-block elements result from incomplete shielding of the nuclear charge for valence electrons by the filled 3d shell (the first anomaly at row 4) and by the filled 4f shell (the second anomaly at row 6). Relativistic effects, which for the 6th row were found to be as important as the lanthanide contraction,[5b,5c] additionally shift Tl toward In.

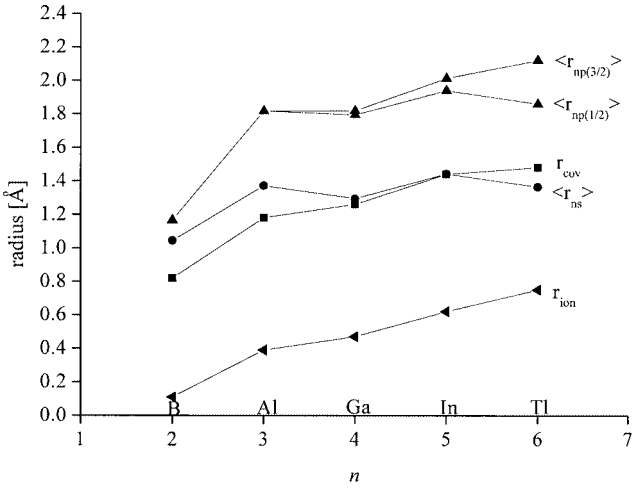

Figure 1. Expectation orbital radii in the atoms, $<r_{nl}>$, M^{3+} ionic radius, r_{ion} (CN = 4), and covalent radius, r_{cov}, for the group 13 elements.

The zigzag changes in the radii of valence orbitals should be more or less reproduced by changes in interatomic distances in compounds formed by the p-block elements. Therefore, one can expect a significant increase in the M–X interatomic distance for the group 13 elements when Al is substituted for B, a decrease or small increase in M–X between Al and Ga, a relatively large increase between Ga and In and again a decrease or small increase between In and Tl. However, such a pattern of changes would only be

observed provided the M–X bonds are essentially covalent. That is because the ionic radius, r_{ion} (CN = 4), in contrast to the covalent radius, r_{cov}, shows only a rudimental zigzag behaviour (see Figure 1).

The experimental M–H, M–C and M–Cl distances in the MX_k molecules formed by the elements of groups 13–17 have been compiled and discussed by Haaland.[6] In the above formula the subscript k is equal to one for group 17, two for group 16, three for groups 13 and 15 and four for group 14. The reported distances indeed show zigzag changes, which become less and less conspicuous as one moves from group 13 to group 17, and which seem to be independent of the X atom. The only experimental data which cover all elements of group 13 are those for the M–C bonds in the $M(CH_3)_3$ molecules.[6] These data show a large, very small, relatively large and again a small increase in the M–C distance within the B–Al, Al–Ga, Ga–In and In–Tl pairs, respectively (see Figure 2). Apart from experimental studies on the M–C bond length, the M–X distances in MH, MH_3, MF and MF_3 molecules formed by the group 13 elements have been computed by Schwerdtfeger et al.[7] The computed distances in the MH_3 and MF_3 (also in MH and MF) molecules repeat quite well the zigzag variation found experimentally for the M–C distances (Figure 2). However, in contrast to the M–H and M–C bonds, the M–F bond length in MF_3 (also in MF) increases significantly between Al and Ga (see Figure 2), which may be due to a more ionic character of the M–F bond. That the M–F bond is distinctly more ionic than the M–H bond is shown by the metal charge, q_m, which in TlF_3 is almost twice as large as that in TlH_3.[7] Up to now, variation in the M–X distances down the groups of p-block elements has been studied only for uncharged molecules. Therefore, it was interesting to find out whether the M–X distances in the MX_4^- ions, where M is a group 13 element and X = F, Cl, Br, I, also show a distinct zigzag variation. One could presume that in the MX_4^- ions the negative charge and the coordination

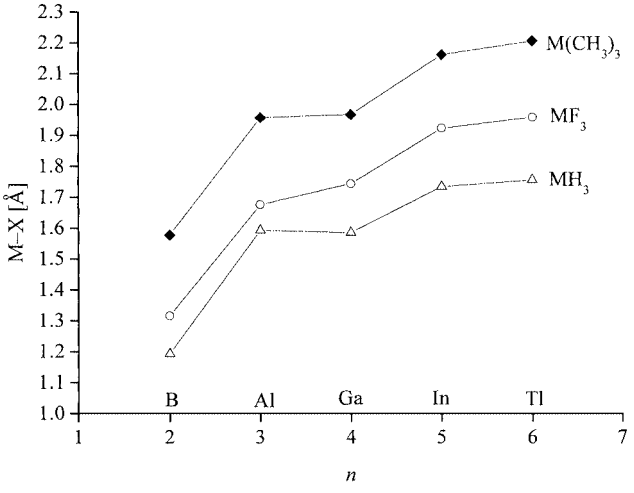

Figure 2. Experimental M–C[6] and calculated M–H and M–F[7] distances in the $M(CH_3)_3$, MH_3 and MF_3 molecules formed by the group 13 elements.

number four would confer considerable ionic character on the M–X bond. This would make the M–X distance depend more on the ionic radius than on the radii of the outermost s and p orbitals. If so, the M–X distance, like r_{ion}, would show only a feeble zigzag variation (see Figure 1). Moreover, one can also presume that this variation would be more distinct for the MI_4^-, MBr_4^- and MCl_4^- than for the MF_4^- complexes. This is because calculations show that the metal charge, q_m, is 0.67 in TlI_3 (TlI_3 is the hypothetical D_{3h} molecule), 1.08 in $TlBr_3$, 1.06 in $TlCl_3$ and 2.03 in MF_4^-,[7] and lower metal charge means less ionic character of the M–X bond. One can expect a similar or even more conspicuous dependence of q_m on X in the MX_4^- ions. In order to check these presumptions we have carried out calculations on the hypothetical gaseous MX_4^- molecules (M = B, Al, Ga, In, Tl and X = F, Cl, Br, I) and compared the calculated M–X distances with the experimental data, mostly in the tetrabutylammonium salts of the MX_4^- anions.

Results and Discussion

M–X Bond Lengths

The experimental M–X distances in the MX_4^- complexes and the computed distances in the hypothetical gaseous MX_4^- molecules (X = F, Cl, Br, I) formed by the group 13 elements are shown in Table 1 and Figure 3. The experimental M–X distances in the tetrabutylammonium salts of $AlBr_4^-$, GaX_4^- (X = Cl, Br, I), InI_4^- and TlX_4^- (X = Cl, Br) are those reported in our previous papers.[8–10] The Al–I, In–X (X = Cl, Br) and Tl–I distances in the tetrabutylammonium salts were taken from other papers.[11–13] Since we have found no data on the $Bu_4N[BX_4]$ and $Bu_4N[AlCl_4]$ salts, the B–Cl and the Al–Cl distances are those in HP(2-methylphenyl)$_3$[BCl_4][14] and $H_2PMe_2[AlCl_4]$.[15] The B–F distance is the average of the distances in $Me_4N[BF_4]$,[16] $Me_3PhN[BF_4]$[17] and $Pr_4N[BF_4]$,[18] whereas the Al–F distance is that in $Ph_4P[AlF_4]$.[19] Comparison of the average Tl–Cl distance in the tetramethylammonium salt[20] with that in the tetrabutylammonium salt[8] (2.416 Å and 2.393 Å, respectively) and of the Al–Cl distance in the $LiAlCl_4$ and $CsAlCl_4$ salts[21] (2.137 Å and 2.119 Å) shows that the effect of the cation on the M–X distance is within about 0.02 Å. This makes it possible to study the secondary periodicity in the M–X distance using the data from MX_4^- salts of different cations. We have also found no experimental data on the B–X distances in the BX_4^- complexes (X = Br, I) and we failed to synthesise the corresponding tetrabutylammonium salts. However, comparison of the data for the $Bu_4N[MX_4]$ salts shows that in the Al–Tl range the differences in the distances |M–Br| – |M–Cl| and |M–I| – |M–Cl|, are independent of M within about 0.015 Å. This allowed us to estimate the B–Br and B–I distances from the experimental B–Cl distance. Since each MX_4^- anion in the $Bu_4N[MX_4]$ salts is surrounded by five Bu_4N^+ cations, which form a highly distorted trigonal bipyramid, the anions are also distorted and show either two pairs of M–

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

X distances (orthorhombic system) or four different M–X distances (monoclinic system),[8] with the difference between the longest and shortest M–X distance being about 0.015 Å. In the salts of cations other than the Bu_4N^+ cation the MX_4^- tetrahedra are also distorted. Therefore, the experimental M–X distances collected in Table 1 and the experimental distances in Figures 3, 6 and 7 are average values. Since the hypothetical gaseous tetrahedral MX_4^- molecules are free from any external influence they show only one M–X distance.

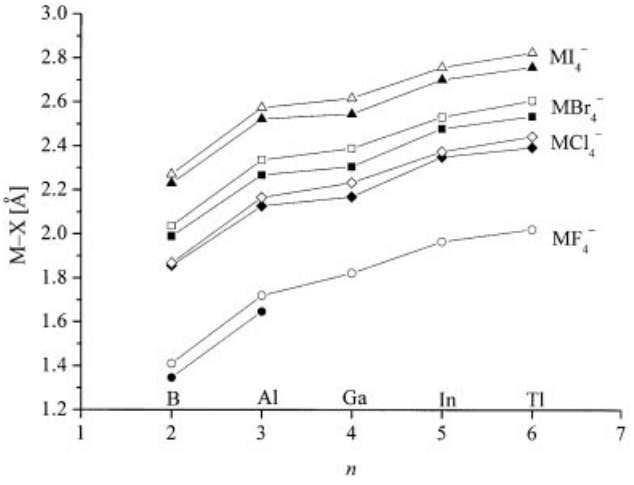

Figure 3. Experimental (filled symbols) and calculated (open symbols) M–X distances in the MX_4^- anions formed by the group 13 elements (X = F, Cl, Br, I).

It follows from the data in Table 1 and Figure 3 that the M–X distances calculated by the MP2/MBW method with the 2d polarisation function are longer than the experimental distances by about 0.05 Å on average. The B–X, Al–X and Ga–X distances (X = F, Cl, Br) calculated by the MP2/6-311+G* method and the M–Cl distance (M = Al, Ga, In, Tl) calculated by the MP2/MBW method with the 2s/2p/1d basis set are also longer than the experimental value by about 0.04 Å. Irrespective of the method, the biggest differences for each X are observed for gallium and thallium. This is because large-core pseudopotential calculations without including core-polarisation effects overestimate the Ga–X and Tl–X distances in particular. Three major factors may be responsible for the difference between the experimental and calculated M–X distances. The first is libration of the MX_4^- anion in the salt, which makes the experimental M–X distance shorter than that in the free MX_4^- molecule[22] that is the subject of the calculations. The second factor is electrostatic interaction in the salt between the MX_4^- anion and the "infinite" number of consecutive coordination shells containing alternately the Bu_4N^+ cations and the MX_4^- anions. This interaction may either expand or shrink the MX_4^- anion, depending on the number of cations and anions in each shell and on the shell radius. Obviously, the first shell, which contains cations, increases the M–X distance because there is a positive charge on the M atom and a negative charge on the X atom. The following shells alternately decrease and increase the M–X distance. However, because of the complex geometry of the system and the great number of shells that must be taken into account, calculation of the final outcome is unfeasible. The third factor may be a systematic error in the M–X distances calculated by the MP2/MBW method. Indeed, a comparison of calculated[7] and experimental[23] distances in the gaseous MH and MF molecules, where M = B, Al and In, shows that the calculated distances are longer than the experimental by about 0.015 Å on average. However, it is important to note that both the experimental and computed distances show a similar zigzag variation down the group, although it is slightly less conspicuous in the calculated distances. This is because, as pointed out above, calculations overestimate the Ga–X and Tl–X distances in particular. In the range from Cl to I the zigzag variation in the M–X bond length seems to be almost independent of the halogen atom and resembles that observed for the MH_3, $M(CH_3)_3$ and MF_3 molecules, (see Figure 2). This similarity shows that the electronegativity of the ligand atom, the number of ligands and the charge on the molecule do not substantially affect the zigzag variation in the M–X distances. However, more detailed examination of changes in the calculated M–X distances (see Table 1 and Figure 3) shows that the zigzag variation in MF_4^- is less conspicuous than in the remaining MX_4^- molecules, which suggests a more ionic character of the M–F bond.

Charges on the Atoms and Natural Electron Configurations

Table 2 shows the calculated atomic charges on the M and X atoms in the MX_4^- molecules, and Figure 4 is a plot of the charge on the metal atom as a function of the row number. The atomic charges were calculated using the B3LYP method with the LANL2DZ basis set. The charge on M and the charge on X, the latter multiplied by four, add almost exactly to –1. Figure 4 shows that the charge on the metal atom, q_m, in each complex increases strongly between B and Al, whereas in the range from Al to Tl it only shows large oscillations. Except for the BCl_4^-/BBr_4^- pair, q_m increases when Br is substituted for I, Cl for Br and F for Cl. The increase in q_m between MCl_4^- and MF_4^- is more than twice as large as that between MI_4^- and MCl_4^-, which points to the singular properties of the fluorine complexes. Table 3 shows the natural electron configurations of the M and X atoms in the MX_4^- molecules; the sum of the populations of the s and p valence orbitals in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the M atoms, calculated from the electron configurations, is plotted as a function of the row number in Figure 5. Except for boron, the $(n + 1)$s orbitals are practically not occupied and the population of the $(n + 1)$p orbitals is, on average, smaller than 0.03. It is important to note that both q_m and the sum of populations (the latter reflected in the x-axis) show a zigzag variation similar to that in the M–X distance, although it is much more conspicuous. Since both the low value of q_m and the high population of the valence orbitals of the metal atom mean more covalent character of the M–X bonds we conclude that: (1) the B–X bonds are highly covalent, except for the B–F bond, which is significantly less covalent; (2) bonding becomes much less covalent in the Al–Tl range, where the bond character shows strong oscillations. These oscillations are generated by the filled 3d shell (bonding becomes more covalent for Ga than for Al) and by the joint effect of the filled 4f shell and relativistic effects in the 6s and $6p_{1/2}$ orbitals (bonding becomes more covalent for Tl than for In); (3) for each M bonding becomes less covalent on passing from the MI_4^- to MCl_4^- complexes and much less covalent on passing from the MCl_4^- to MF_4^- complexes.

Correlation Between the M–X Distance and the Covalent Radius

Since in the Al–Tl range the ionic radius, r_{ion} (CN = 4), shows only a weak zigzag variation (see Figure 1), one can-

not expect the experimental M–X distance to depend linearly on r_{ion}, as documented in Figure 6. On the other hand, a comparison of the data in Figures 1 and 4 shows that the covalent radius and the average M–X distance in the MX_4^- ions change in a very similar way down group 13, so that a linear correlation between the two can be expected. Figure 7 shows the experimental M–X distance in the MX_4^- complexes as a function of the sum of the covalent radii of the M and X atoms $[r_{cov}(M) + r_{cov}(X)]$. We can see from Figure 7 that for X = Cl, Br, I the experimental M–X distance depends linearly on the sum of the covalent radii. Moreover, the M–X distance is very close to the sum of the respective covalent radii. On the other hand, the experimental B–F and Al–F distances suggest a separate downward-shifted linear plot for the MF_4^- complexes. In order to show that all M–F distances form a separate lower-lying linear branch we have additionally plotted the calculated M–F distances in Figure 7. Since these are greater than the experimental values (as are the calculated M–Cl, M–Br and M–I distances), their position clearly shows that all experimental M–F distances would form a separate

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lower-lying branch. It is worthy to note that the M–C and M–H distances in the $M(CH_3)_3$ and MH_3 molecules[6,7] also form a common linear plot, with the M–X distance close to the sum of the respective covalent radii, whereas the M–F distances in the MF_3 molecules[7] belong to a separate lower-lying branch (see Figure 8). That the length of the M–F bond is considerably shorter than that expected from the sum of the covalent radii results from a significant admixture of ionic bonding. Using somewhat outdated but visual language, one can say that the decrease in the M–F bond length results from the resonance between the covalent and ionic structures.

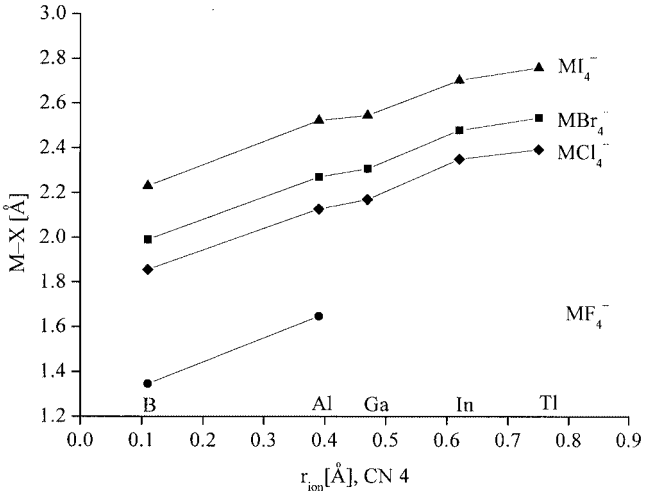

Figure 6. The experimental M–X distance in the MX_4^- anions as a function of the ionic radius, r_{ion} (CN = 4). M is a group 13 element and X = F, Cl, Br, I.

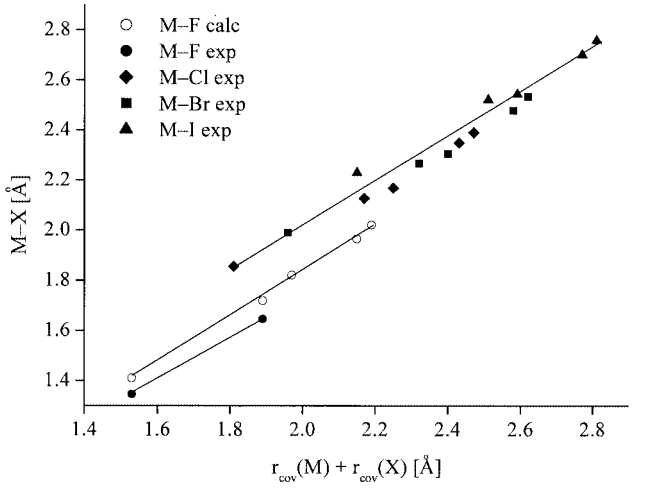

Figure 7. Experimental and calculated M–X distances in the MX_4^- molecules as a function of the sum of the covalent radii [r_{cov}(M) + r_{cov}(X)]. M is a group 13 element and X = F, Cl, Br, I.

Changes in the Unit Cell Volumes

The $Bu_4N[MX_4]$ salts of the group 13 elements studied till now crystallise for each M either in the *Pnna* (X = Cl, Br) or in the $P2_1/n$ (X = I) space groups.[8] Therefore, for a given X the zigzag variation in the M–X distance, i.e. in the volume of the MX_4^- anion, results in a similar variation in the unit cell volume (Figure 9). Because of the interaction between the MX_4^- anion and the five Bu_4N^+ cations from the nearest coordination shell, the zigzag variation in the volume of the anion generates zigzag variation in the anion-to-cation distance, i.e. in the M–N distance. For example, according to the data for the $Bu_4N[MI_4]$ salts,[8] the average M–N distance is equal to 6.584, 6.581, 6.630 and 6.622 Å, for Al, Ga, In and Tl, respectively. Since there is a decrease, an increase and again a decrease in the M–N distance for the consecutive pairs of elements, these data indeed show a distinct zigzag variation in the M–N distance. However, it should be noticed that the overall increase in the M–X distance in the $Bu_4N[MX_4]$ salts between Al and Tl is equal to 0.237 Å, whereas the respective increase in the M–N distance is equal to only 0.037 Å This is because the X atoms are located near the end-atoms of the butyl chains, where

there is enough space for the X atom to change its position without significantly moving the whole Bu_4N^+ cation.

Conclusions

We can draw the following conclusions from our calculations and from the available experimental data.

(1) In group 13 both the experimental M–X distances in the MX_4^- salts (mainly tetrabutylammonium salts) and the computed M–X distances in the hypothetical gaseous MX_4^- molecules (X = F, Cl, Br, I) show almost the same zigzag variation down the group, although slightly less conspicuous in the calculated values. This is because large-core pseudopotential calculations without including core-polarisation effects overestimate the Ga–X and Tl–X distances in particular. The variation in both the experimental and calculated bond length in the MX_4^- ions is similar to those in the MH_3, $M(CH_3)_3$, MF_3, MH and MF molecules. This means that the general pattern of changes in the metal-to-ligand distance down the group 13 is not substantially affected by the electronegativity of the ligand atom, the coordination number of the M atom or the charge on the molecule. However, a comparison of the calculated M–X distances in the MX_4^- molecules shows a less distinct zigzag variation in the M–F distance, which points to a more ionic character of the M–F bonds.

(2) The experimental M–X distances are shorter (on average by about 0.05 Å) than the calculated values. The main reason seems to be libration of the MX_4^- anions in the salts, which is absent in the hypothetical gaseous MX_4^- molecules. Moreover, the MP2/MBW method may slightly overestimate the calculated M–X distances. On the other hand, interaction of the MX_4^- anion with a large number of the coordination shells containing alternately cations and anions may either increase or decrease the experimental M–X distance, i.e. either decrease or increase the difference between the calculated and experimental M–X distances. However, the final outcome for many shells is difficult to calculate.

(3) Both the charge on the M atom, q_m, and the sum of the populations of M valence orbitals show very distinct zigzag variations down group 13, which points to the highly covalent character of the M–X bond formed by boron (except for the B–F bond) and distinctly less covalent for the heavier members of the group. The bond character oscillates strongly in the range from Al to Tl due to the filled 3d shell and to the joint effect of the filled 4f shell and relativistic effects in the 6s and $6p_{1/2}$ orbitals. The covalent character of the bond decreases between the MI_4^- and MCl_4^- complexes for all the group 13 elements and decreases significantly on passing from the MCl_4^- to MF_4^- complexes.

(4) The M–X bond length (X = Cl, Br, I) is close to the sum of the covalent radii. The much greater ionic character of the M–F bond, documented by the high value of q_m, low population of metal valence orbitals and less-conspicuous zigzag variation in the calculated M–F distances, makes the M–F bond length significantly shorter than the sum of the covalent radii.

(5) The M–X distances in the simple MX_k molecules (X = H, CH_3, Cl) formed by the group 14–17 elements show a zigzag variation[6] down each group similar to that in the MX_4^- complexes discussed in this paper. Since we have shown that the zigzag variation in the M–X distance for the MX_4^- complexes correlates with changes in the charge on the central atom and with changes in the population of its valence orbitals, we presume that the contribution from covalent bonding in the MX_k molecules of groups 14–17 changes in a way similar to that found for the MX_4^- complexes of the group 13 elements.

Calculations

In quantum calculations we used the nonrelativistic Hartree–Fock (NRHF) method[24] as well as the Kohn–Sham Density Functional Theory (DFT),[25] and methods which take into account relativistic effects through the use of a relativistic effective core potential (RECP). Calculations carried out in the frame of the NRHF method include electron correlation by Møller–Plesset (MP2)[26] for the 6-311+G* basis set.[27] To take into account relativistic effects we used the Stuttgart/Dresden basis sets and pseudopotentials adjusted to Wood–Boring data (MBW).[28] In the DFT method we chose a hybrid potential of the type B3LYP[29] and carried out calculations for all atoms using the LANL2DZ basis set.[30] Additionally, for all elements we introduced two polarisation functions of the d type whose orbital exponents are given by Huzinaga.[31] In the frame of the methods with pseudopotential we assumed that electrons in the closed shells enter into the core, thereby designating its effective potential. Using the MP2/MBW method with the 2d polarisation function we determined the global optimum geometry with regard to distances and angles for all the MX_4^- molecules, where M = B, Al, Ga, In, Tl and X = F, Cl, Br, I. In order to compare the geometries obtained in this way we carried out calculations using the MP2/6-311+G* method with the basis set which takes into account polarisation and dispersive effects to the greatest possible extent. Because of problems with availability of the 6-311+G* basis sets for heavier atoms, the optimum geometry in this method could only be obtained for the MX_4^- molecules, where M = B, Al, Ga and X = F, Cl, Br. For M = B, Al, Ga, In, Tl and X = Cl we also carried out calculations using the MP2/MBW method and the Stuttgart/Dresden basis sets complemented by the 2s/2p/1d set with one polarisation function of the d type, for which the orbital exponent is given by Huzinaga.[31] Using this method we obtained somewhat better agreement between the calculated and experimental distances in comparison with those obtained by the MP2/MBW method with the 2d polarisation function. However, because of problems with availability of the basis sets we were only able to carry out calculations for the MCl_4^- molecules. For the optimised geometry we calculated the charges on the atoms in the studied molecules by the B3LYP/LANL2DZ method. This method, in contrast to the MP2/MBW method, gives charges on the atoms, which are compatible with changes in the M–X distance and in the occupation of metal valence orbitals. We determined the natural electron configurations of the M and X atoms based on the procedure of natural orbital analysis.[32] The calculations were carried out with the Gaussian 98 package.[33]

Synthesis, Electronic Characterisation and Significant Second-Order Non-Linear Optical Responses of *meso*-Tetraphenylporphyrins and Their Zn^{II} Complexes Carrying a Push or Pull Group in the β Pyrrolic Position

Elisabetta Annoni,[a] Maddalena Pizzotti,*[a] Renato Ugo,[a] Silvio Quici,[b] Tamara Morotti,[b] Maurizio Bruschi,[c] and Patrizia Mussini[d]

Keywords: Cyclic voltammetry / Nonlinear optics / Porphyrins / UV/Vis spectroscopy / Zinc

This work describes the synthesis and characterisation by electronic absorption spectroscopy, cyclic voltammetry and by a solvatochromic investigation of *meso*-tetraphenylporphyrins and their Zn^{II} complexes substituted at the β pyrrolic position by a pseudo-linear, π-delocalised organic linker carrying either an electron-withdrawing (pull) or electron-donating (push) group. The second-order NLO response of these push-pull porphyrinic chromophores has been investigated by the EFISH technique working with a non-resonant incident wavelength of 1.907 μm. The porphyrin ring substituted at the β pyrrolic position by an electron-acceptor π-system behaves as a significant donor group, comparable to a ferrocenyl group or to a phthalocyanine. Unexpectedly, the porphyrin ring substituted at the β pyrrolic position with an electron-donor π-system shows a larger and significant second-order NLO response.

Introduction

A wide variety of push-pull organic π-conjugated chromophores have been extensively investigated, both theoretically and experimentally, for their significant second-order optical nonlinearities.[1–3] When compared to organic chromophores, pseudo-linear coordination and organometallic chromophores may offer additional electronic features, acting on the second-order non-linear optical (NLO) response, such as intense charge-transfer transitions (ligand to metal and vice versa) at relatively low energy that are easily tuneable by changing the oxidation state of the metal, its coordination sphere and stereochemistry.[4] Attempts have been made to design two-dimensional push-pull chromophores based on π-delocalised macrocycles such as porphyrins and metalloporphyrins,[5,6] metallophthalocyanines[7a] and subphthalocyanines,[7b,7c] and metallotriazolohemiporphyrazines.[8] Porphyrins and their metal complexes offer some additional advantages, such as good thermal and chemical stability, acceptable solubility for the determination of dipole moments and their second-order molecular NLO response and relatively easy synthetic pathways for the preparation of various architectures.[9] The highly polarisable π ring, with strong π→π* transitions,[10] of push-pull metal porphyrins asymmetrically substituted in the 5- and 15-positions, has been proposed as an excellent linker of the pseudo-linear push-pull chromophore.[11] This latter point was experimentally confirmed by Therien et al.,[6a,6b] Ng et al.[6c] and recently also by some of us.[6d] However, to the best of our knowledge, no-one, with the exception of two rather preliminary communications,[12] has experimentally investigated whether the π system of porphyrins or metalloporphyrins can act as a donor or acceptor group of a pseudo-linear push-pull chromophore. Depending on the number of π electrons, π orbitals, and on the heteroatom electronegativities, heterocyclic rings can act as electron-rich (donor) or electron-poor (acceptor) systems.[13] Pyrrole, with six π electrons and five π orbitals, is an electron-rich π system. Thus, a porphyrinic chromophore with four pyrrole rings may be considered, at first glance, as a π-electron-rich system in which electron-rich and electron-poor carbon atoms may be identified.[14] In order to experimentally prove some interesting theoretical suggestions,[14] we investigated the second-order NLO response of push-pull pseudo-linear chromophores based on a 5,10,15,20-tetraphenylporphyrin, either as free base or as Zn^{II} complex, carrying a push or a pull group linked to the β pyrrolic position through a π-delocalised spacer. One major prob-

lem with push-pull π-delocalised macrocycles is the correct determination of their molecular second-order NLO response. The quadratic hyperpolarizability of asymmetric porphyrins and their metal complexes has been measured by HRS (Hyper-Rayleigh Scattering),[6a] Stark effect[6b] and by EFISH (Electric Field Induced Second Harmonic) generation techniques.[5,6c,6d] Depending on the incident wavelength, these measurements can be affected by resonance enhancements[6a,6d] and in the case of the HRS technique also by a fluorescent contribution to the second harmonic.[6a]

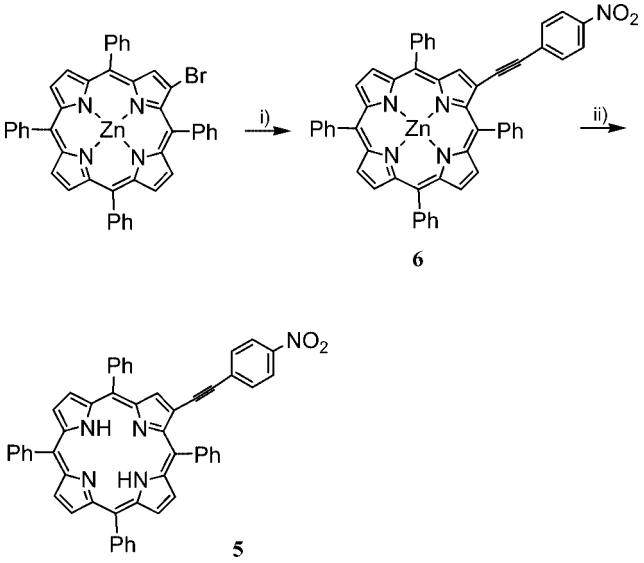
In order to avoid both these effects, the second order NLO responses of compounds investigated in this work were measured by the EFISH technique working at a non-resonant incident wavelength of 1.907 μm. In addition, density functional theory (DFT)[15] calculations were carried out in order to confirm experimental dipole moments and to define the best structural geometries using the BP86 functional[16] and an all-electron valence triple-ξ basis set with polarisation functions on all atoms.[17]

Results and Discussion

Synthesis of Porphyrins and Their Zn^{II} Complexes

The asymmetric 5,10,15,20-tetraphenylporphyrins and their Zn^{II} complexes investigated in this work are reported in Figure 1.

Porphyrin **1** was synthesised by reaction of 2-bromo-5,10,15,20-tetraphenylporphyrin, obtained by bromination of 5,10,15,20-tetraphenylporphyrin (TPP) with *N*-bromosuccinimide, first with Ni(acac), then with CuCN[18] to afford the Ni^{II} complex of **1**, and finally by controlled demetallation with concentrated sulfuric acid. Its Zn^{II} complex **2** was obtained by reaction of **1** with $Zn(OAc)_2$.[19] Porphyrin **3** was obtained by reaction of the Zn^{II} complex of TPP with I_2 and $AgNO_3$ to afford **4**,[20] followed by demetallation with concentrated HCl. Complex **6** was obtained by a Sonogashira coupling reaction of the Zn^{II} complex of 2-bromo-5,10,15,20-tetraphenylporphyrin with 4-nitrophenylacetylene in refluxing THF/Et_3N, using $[PdCl_2(PPh_3)_2]$ and CuI as catalysts, followed by demetallation with CF_3COOH in CH_2Cl_2 at room temperature to give porphyrin **5** (Scheme 1).



Scheme 1. i) 4-Nitrophenylacetylene, $[PdCl_2(PPh_3)_2]$ (cat), THF/NEt_3, reflux; ii) CF_3COOH, CH_2Cl_2, room temp., 20 h.

Porphyrins **7** and **11**, which are already known,[21] were synthesised by a new and easier method based on the Wittig condensation of 2-formyl-5,10,15,20-tetraphenylporphyrin (**13**) with (4-nitrobenzyl)triphenylphosphonium bromide and [4-(dibutylamino)benzyl]triphenylphosphonium chloride respectively (Scheme 2).

Reactions were carried out in CH_2Cl_2 at room temperature in the presence of solid NaOH as base to afford, after purification by column chromatography, a mixture of (*E*)-

and (*Z*)-isomers. From this mixture the pure (*E*)-isomers **7** and **11** were obtained, in 58% and 69% yields respectively, by repeated crystallisation from CH_2Cl_2/MeOH. Porphyrin **13** was prepared in 70% yield by Vilsmeier formylation of the commercially available Ni complex of TPP (Scheme 2) following a modification of the procedure reported in the literature.[22] (4-Nitrobenzyl)triphenylphosphonium bromide was easily obtained, in quantitative yield, by quaternisation of triphenylphosphane with 4-nitrobenzylbromide in refluxing toluene, while (4-dibutylamino)benzyltriphenylphosphonium chloride was prepared from (4-dibutylamino)benzyl alcohol, obtained by reduction of (4-dibutylamino)benzaldehyde with $NaBH_4$, by adapting a procedure reported in the literature.[23] The Zn^{II} complexes **8** and **12** were obtained in quantitative yield by treating porphyrins **7** and **11**, respectively, with $Zn(OAc)_2$ in $CHCl_3$/MeOH.[19] Porphyrin **9**, bearing a (1*E*,3*E*)-butadiene linker in the β position, was prepared by Wittig condensation of 4-nitrocinnamaldehyde with the phosphonium salt **16** in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as base (Scheme 3).

The preparation of the phosphonium salt **16** was carried out, starting from the aldehyde **13**, according to the synthetic scheme reported in a preliminary communication by Bonfantini and Officer in 1993.[24] However the detailed experimental procedure was never published, hence a careful description of the synthesis and characterisation of intermediate porphyrins **14**, **15** and **16** is given in the Experimental Section.

Again, treatment of the free porphyrin **9** with $Zn(OAc)_2$ in $CHCl_3$/MeOH at reflux afforded the Zn^{II} complex **10** in quantitative yield. All porphyrins and their Zn^{II} complexes were characterised by elemental analysis, ^1H NMR spectroscopy and mass spectrometry

Electronic Absorption, Emission Spectra and Solvatochromic Behaviour

Metal complexation of tetraarylporphyrins increases the ring microsymmetry from D_{2h} to D_{4h}, with a parallel decrease of the number of Q absorption bands from four to two.[10,25,26] Although the introduction of a substituent in the β pyrrolic position should produce a lowering of the D_{4h} microsymmetry, the usual decrease of the number of Q bands from four to two was reported when comparing porphyrin **7** and its Ni^{II} complex.[21] For porphyrin **1** and its Cu^{II} complex, a decrease of the number of Q bands from four to three was originally published,[18] but later a decrease from four to two was reported when comparing porphyrins **1** and **3** with their Cu^{II} complexes.[25] When comparing porphyrins **1** and **3** with their Zn^{II} complexes **2** and **4**, we observed a decrease of the number of Q bands from four to three, with complete disappearance of the Q_α band above 600 nm but with a weak Q_β band at higher energy still detectable (Table 1 and Figure 2).[27]

A similar decrease of the number of Q bands was observed when comparing porphyrins **5** and **7** with their Zn^{II}

[a] H_2TPP = 5,10,15,20-tetraphenylporphyrin. [b] Values obtained by irradiation at the Soret wavelength and at the lower energy Q_β band (in parentheses). [c] Values were obtained according to the equation $\Delta\nu_{1/2} = f/4.33\times10^{-9}\cdot\varepsilon$ (F. L. Pilar, *Elementary Quantum Chem.*, McGraw-Hill Book Comp., **1968**) where f is the oscillator strength and ε is the maximum extinction coefficient (values in parentheses are graphically measured[28]). [d] Slightly different values of λ_a are given in ref.[21] [e] An absorption band at 406 nm (logε = 4.65) was also detected for **2**, while **1** showed only a shoulder of the B band at higher energy.

complexes **6** and **8**.[27] However, when comparing porphyrin **9** with its Zn^{II} complex **10**, with the electron-withdrawing nitro group further away from the β pyrrolic carbon atom, the number of Q bands decreases from four to two (Table 1 and Figure 4). The above observations would suggest a significant electronic asymmetry of the porphyrin ring when the nitro group is linked to the β pyrrolic position directly or through an arylethenyl or an arylethynyl bridge. This suggestion is also supported by the asymmetry of the B Soret band, with evidence for a shoulder at lower energy (see Figure 3 and Figure 4) and by its bandwidth increase (Table 1).[26]

However, when an electron-donating dibutylamino group is linked to the β pyrrolic position through an arylethenyl linker, the Soret B band remains quite symmetric and its bandwidth does not increase significantly (Table 1). Interestingly, in the spectra of **1** and **2** we also observed an absorption band ($\log\varepsilon = 4.5$) close to the Soret B band but at higher energy (Figure 2 and Table 1) that has not been reported in previous investigations.[25]

The modulation of the π valence orbital levels of porphyrins and metalloporphyrins by substitution at the β pyrrolic position was investigated by a combination of cyclic voltammetry and electronic absorption spectroscopy.[25] A similar approach was later applied when comparing porphyrins **7** and **11** (the latter with a dimethylamino instead of a dibutylamino group) and their Ni^{II} complexes.[21] Electronic transitions from the a_{1u} and a_{2u} HOMO to the e_g LUMO orbitals in porphyrins and their metal complexes cause B and Q absorption bands whose wavelengths and oscillator strengths are defined by the interaction configuration between the a_{1u} and a_{2u} orbitals and therefore by their relative energies.[10] These latter are reported to be affected by substitution at the β pyrrolic position; the effect is more pronounced for the a_{1u} orbital, which has a non-vanishing electron density on both the α and β pyrrolic carbon atoms.[25] For porphyrin **7** and its Ni^{II} complex, with the nitro group not directly linked to the β pyrrolic position, the perturbation of the energy of the a_{1u} orbital has been suggested to be modest.[21] On the contrary, the decrease of Q bands from four to three upon complexation of **7** with Zn^{II}, together with the significant asymmetry of the B band and parallel increased bandwidth, would suggest a significant perturbation of the porphyrin π orbitals. Due to the π delocalised nature of the substituent at the β pyrrolic position, this effect could not be originated only by an inductive perturbation of the energy levels of the a_{1u} and a_{2u} frontier orbitals. As already suggested for porphyrin **7**,[21] this perturbation could be mainly due to the conjugation of the π orbitals of the linker with the π orbitals of the pyrrolic ring, which may induce some charge-transfer character to porphyrin $\pi \rightarrow \pi^*$ transitions that are no longer totally centred

on the porphyrin ring,[28] as supported by the increased bandwidth of the Soret B band.[26] In agreement with this hypothesis, the available structural data indicate, at least for the arylethenyl linker, that the porphyrin core and the styryl group are essentially coplanar,[21,29] a structural feature which should promote a facile interaction of the π orbitals of the linker with the porphyrin π orbitals. Such a nearly planar arrangement was confirmed as the best geometry, by an ab initio DFT method, for the Zn^{II} complexes **8** and **12** and the related porphyrins **7** and **11** (see below).

The effects of substituents upon the relative energies of the frontier orbitals a_{1u} and a_{2u} of metal porphyrin complexes may be evaluated, in a first instance, by the Shelnutt analysis,[28] which correlates the energies of the B and Q_α transitions with the ratio of the square of their transition dipole moments. Shelnutt suggests that the closer in energy the a_{1u} and a_{2u} orbitals are, the smaller the ratio of the square of the transition dipole moments of the Q_α and B transitions, respectively, and the difference in energy $E_B - E_{Q\alpha}$.

The substitution at the β pyrrolic position in the Zn^{II} porphyrin complexes investigated in this work produces a substantial increase of both $E_B - E_{Q\alpha}$ and the ratio of the square of the transition dipole moments of the Q_α and B transition, respectively, with respect to the parent complex ZnTPP (Table 2). Such an increase is more relevant when the π-delocalised substituent carries the strong donor dibutylamino group. This evidence adds further support to a significant perturbation of the energies of the a_{1u} and a_{2u} orbitals, which shift further apart. However, the so-called Shelnutt analysis[28] must be taken with some caution because different linkers may introduce different charge-transfer character to B or Q_α transitions, or to both of them.

In order to produce more evidence for a significant electronic perturbation, we also investigated the trends of a parameter of the electronic absorption spectra of Zn^{II} porphyrin complexes that is independent of the extent of the configurational interaction of the a_{1u} and a_{2u} orbitals. This is the centre of gravity of the B and Q_α bands, defined as $E = ½(E_B + E_{Q\alpha})$, which is an indication of the relative perturbation of the energy levels of the a_{1u} and a_{2u} frontier orbitals.[25] A red shift of the centre of gravity with respect to CuTPP of about 350–700 cm^{-1} has been found for the substitution in the β pyrrolic position with a series of electron-withdrawing groups, while the red shift is much smaller (about 20–400 cm^{-1}) with electron-donating groups.[25] We have found a relevant blue shift of about 1500 cm^{-1} (Table 2) with respect to ZnTPP for complexes **4**, **6**, **8** and **10** carrying a nitro group directly or indirectly bound to the β pyrrolic carbon atom. The centre of gravity appears to be quite independent of the different nature and length of the π linker (Table 2). On the contrary, the centre of gravity of complex **12**, with a π linker carrying an electron-donating dibutylamino substituent, shows a completely different trend with a limited red shift of about 300 cm^{-1} (Table 2). The above observations suggest not only the presence of a perturbation, but also a completely opposite trend when passing from an electron-withdrawing to an electron-donating π delocalised substituent.[25] In conclusion, we have produced a significant and complementary body of evidence for a significant electronic perturbation of the π porphyrin system by β pyrrolic substitution with a π delocalised linker carrying a push or pull group. In order to confirm the role of π conjugation, which should introduce some charge-transfer character to both the B and Q absorption bands, we carried out a solvatochromic investigation using a set of solvents of increasing polarity, excluding those that show strong donor or hydrogen-bonding properties (see Experimental Section), so that mainly the orientational effect of the solvent polarity (and not hydrogen bonding or strong basic ligation) dependency was studied. With this limitation a poor solvatochromic behaviour of the B band of porphyrin complexes was usually reported.[30,31] However, the solvatochromic behaviour of the B band becomes significant for a series of Zn^{II} complexes of various isomers of H_2TPP bearing two NO_2 groups in different β pyrrolic positions.[32]

We have produced clear evidence for a significant solvatochromic behaviour of both B and Q_β (in porphyrins the Q band is at higher energy) bands for porphyrins and their Zn^{II} complexes investigated in this work when carrying a π delocalised linker (Table 3). With the exception of porphyrin **9**, the Soret B band is always shifted to higher energy (blue shift) with increasing polarity of the solvent when a nitro group is linked through a π spacer (Table 3).

The strength of the charge-transfer character, deduced from the absolute value of $\Delta\mu_{eg}$ (difference between excited and ground state dipole moments), which is negative for blue-shifted bands, is relatively small for porphyrins **5**, **7**

[a] H_2TPP is 5,10,15,20-tetraphenylporphyrin. [b] Not significantly solvatochromic.

and **9** but becomes more relevant for their Zn^{II} complexes **6** and **8**, with an abrupt increase for complex **10** (Table 3). The Q_β band of porphyrins **5**, **7** and **9**, which is only slightly shifted to lower energy (red shift) with increasing polarity of the solvent, becomes blue shifted in the Zn^{II} complexes **6** and **10** or remains unchanged in **8** (Table 3). As already reported,[32] the solvatochromic behaviour becomes insignificant when the nitro group is directly linked to the β pyrrolic position, suggesting that the solvatochromism must be ascribed to a charge-transfer process originated by a significant perturbation of the π frontier orbitals of the porphyrin ring through conjugation with π delocalised substituents (Table 3). Porphyrin **11**, with an arylethenyl linker carrying a dibutylamino group, and its Zn^{II} complex **12** show an unexpectedly significant solvatochromism, blue shifted for **12** and red shifted for **11**, of both B and Q_β bands. In this latter case it is difficult, however, to suggest that this solvatochromic behaviour may be due to a charge-transfer process involving conjugation of the π-delocalised linker and the porphyrin ring, since their B bands are symmetric with no increase of the bandwidth.[26] In this latter case the perturbation of the π system of the porphyrin, which influences the polarity of both the ground and excited states, probably involves the strongly donor dibutylamino group.

All porphyrins and their Zn^{II} complexes investigated in this work show a neat fluorescent emission band when irradiated either at the Soret B band or at the Q_β band. The intensity of the emission for both porphyrins and their Zn^{II} complexes is more relevant when the Soret B band is irradiated. Porphyrin **3** and its Zn^{II} complex **4**, with the nitro group directly bound to the β pyrrolic position, show, as already reported,[33] only one diffuse emission band (Table 1). The same behaviour is shown by the Zn^{II} complex **12**, with a dibutylamino group linked to the β pyrrolic position through an arylethenyl linker. The wavelength of the emission bands of both porphyrins and their Zn^{II} complexes is affected by the length of the π-delocalised linker, while it is not too affected by the substituents (Table 1). As with the absorption B and Q_β bands, the emission bands are also solvatochromic.

In conclusion, our detailed investigation of the electronic spectra and their solvatochromic behaviour has produced strong evidence for a significant perturbation of the π porphyrin ring by β pyrrolic substitution with a π-delocalised linker carrying a donor or acceptor group. This perturbation involves the conjugation of both the π orbital systems, as confirmed by the solvatochromic behaviour of both B and Q_β bands, but the significant excitation processes due to conjugation are different if the π-delocalised linker carries a push or a pull group.

Voltammetric Investigation

The anodic oxidation of porphyrins and their Zn^{II} complexes investigated in this work takes place by two reversible one-electron steps.[34,35] For porphyrin **11** and its Zn^{II} complex **12**, which carry a dibutylamino group, in addition to the two main peaks we noticed a small oxidation prewave located before the second (for **11**) and the first (for **12**) main oxidation peak (Table 4). Porphyrins **5**, **7** and **11**, with a different *para* substituent on the phenyl ring or a different π system connecting the phenyl group to the porphyrin ring, show the following oxidisability sequence for the first oxidation steps: **11** >> **7** > **5** (Table 4).

A significantly lower oxidation potential for the first oxidation step has already been reported for a porphyrin structurally related to **11** that carries a dimethylamino instead of a dibutylamino group.[21] For this latter porphyrin the second oxidation step was reported not to be reversible, while we found that for **11** it is reversible and not at significantly lower oxidation potential with respect to porphyrins **5** and **7** (Table 4). As a consequence, for porphyrin **11** it is better to take into account, when comparing its oxidisability with that of other porphyrins, the second oxidation step, which seems to be centred, as for other porphyrins, on the HOMO energies of the porphyrin π core. In fact, as already suggested,[21] the first step of oxidation of **11** could be centred off the HOMO energies of the porphyrin π core, probably at the dibutylamino functionality. The higher oxidisability of **11** and the slightly lower oxidisability of **5** with respect

[a] Reversibile monoelectronic peaks are italicised. [b] Prewaves are in parentheses.

to **7** (Table 4) can be interpreted as an increased stabilisation due to a significant perturbation, produced by the substituents carrying an electron-withdrawing nitro group, on the energy levels of the HOMO electrons, which stabilizes the π core of the porphyrin ring.

This effect is in agreement with a conjugation between the π system of the linker and the π orbitals of the porphyrin ring as proposed above. The slightly higher oxidisability of **7** with respect to **5** can be interpreted in terms of the higher efficiency of the triple bond of the linker in transmitting the perturbation of the electron-withdrawing nitro group to the porphyrin π core.

When a porphyrin ring is complexed to a metal like Zn^{II}, irrespective of the working medium and of the porphyrin structure, a fairly constant difference in the range from –0.31 to –0.16 V between the first oxidation potential of the Zn^{II} complex and that of its parent porphyrin has been reported.[35,36] This range of negative values is shown by two of the three couples investigated in this work: –0.24 V for **6** vs. **5** and –0.23 V for **8** vs. **7** (Table 4). When comparing **12** and **11**, the difference turns out to be –0.27 V only if taking into account the oxidation prewave of the Zn^{II} complex, while when comparing the first "regular" peak the difference (–0.03 V) appears to be anomalously low. However, when taking into account the second oxidation peak, as suggested above, the expected difference of –0.22 V is found. This is additional evidence that the first oxidation peak in porphyrin **11** does not involve the HOMO electrons of the π porphyrin core. The difference $\Delta E_{(ox–red)}$ between the first oxidation and the first reduction process of porphyrins and their Zn^{II} complexes has been reported to be always within 2.25 ± 0.15 V (Kadish's relationship), as expected for a strictly ring-based process of oxidation and reduction.[35] For porphyrins **5** and **7**, the $\Delta E_{(ox–red)}$ values obey Kadish's relationship (2.16 V and 2.26 V respectively), while again for porphyrin **11** this difference is only 1.69 V, if we consider the first "regular" reduction peak. It becomes 2.05 V, as expected, when the second reduction peak is taken into account. For Zn^{II} complexes **6**, **8** and **12** the values of $\Delta E_{(ox–red)}$ deviate from Kadish's relationship (1.88 V for **6**, 1.96 V for **8** and 1.91 V for **12** when taking into account the first oxidation peak; the value becomes 2.07 V for **12** if we consider the second oxidation peak). It thus appears that the π levels of the Zn^{II} porphyrins investigated in this work are quite affected by the perturbation induced by the π system of the linker mainly when it carries a nitro group. Complexation of porphyrins to Zn^{II} results in a significant anticipation, with respect to the parent porphyrin, of both the first and second oxidation potentials, according to a relevant increase of the negative charge on the porphyrin ring (Table 4). However, complexation to Ni^{II} of porphyrin **7** results in only a slight difference of the oxidation potentials with respect to those of the parent porphyrin (e.g. +0.03 V for the first oxidation peak, 0.00 V for the second one),[21] in agreement with the suggestion of Kadish et al.[35] of a higher induction parameter of Ni^{II} (1.8) with respect to Zn^{II} (1.5), resulting in a negative charge on the porphyrin ring that is much less significant for the Ni^{II} complexes. Finally, although the detection of three or four one-electron reduction waves is usually reported for porphyrins and their metal complexes when working with an acceptably broad cathodic window,[37,38] in the present work, due to the less broad window when working in CH_2Cl_2 as solvent, we observed only the first two reduction peaks and only the first one for **6** and **7**. All the potentials but one (namely those of porphyrin **11**) fall within the expected range of 0.42 ± 0.03 V of difference between the first and the second reduction potential, namely 0.42 V for **5** (averaging between the first reduction peak and its shoulder), 0.40 V for **8**, 0.52 V for **11** and 0.40 V for **12**. The first reduction step appears to be clearly monoelectronic and reversible only for Zn^{II} complexes **6** and **8**.

As a conclusion, the voltammetric investigation has confirmed a perturbation of the HOMO levels of the porphyrin π core due to conjugation with the π orbitals of the linker bound to the β pyrrolic position. This perturbation is more significant if the π linker carries a nitro group and if the Zn^{II} ion is complexed to the porphyrin ring. When the π linker carries a donor dibutylamino group the perturbation of the π levels of the porphyrin ring is not only lower, but the HOMO levels are centred on the dibutylamino group.

Dipole Moments

Although the experimental determination of the dipole moment by the Guggenheim method[39] was not reproducible for the push-pull porphyrins and their metal complexes investigated previously, such that it was always calculated by semi-empirical methods,[5,6] we obtained quite reproducible experimental measurements, with the exception of porphyrin **11** and its Zn^{II} complex **12** (see Exp. Sect.). Porphy-

rins **5**, **7** and **9**, which carry a linker with a nitro group, show a dipole moment comparable to that of their Zn^{II} complexes **6**, **8** and **10**. The nature of the linker, either phenylethynyl, phenylethenyl or even phenylbutan-1,3-dienyl, does not induce a significant effect on the order of magnitude of the experimental dipole moment (Table 5). The best geometries and dipole moments were calculated theoretically by an ab initio approach based on the density functional theory (DFT)[15,16] using an extended basis set[17] (see Experimental Section for details). The calculated optimised geometries always support a quite planar arrangement of the π porphyrin ring and the π system of the organic linker.

The calculated dipole moments of the two isomeric structures of asymmetric porphyrins **3**, **5**, **7**, **9** and **11** are quite similar, thus the data reported in Table 5 are mean values. They are in good agreement with the experimental ones with the exception of the couple **9** and **10**. For porphyrin **11** and its Zn^{II} complex **12** the calculated dipole moments are, as expected, rather low and with inversion of polarity (Table 5). In this latter case, complexation to Zn^{II} induces a slight lowering of the dipole moment with respect to the free porphyrin, in agreement with an increased negative charge on the porphyrin ring acting as acceptor. As expected, the opposite effect is calculated and observed experimentally for the couples **5** and **6**, **7** and **8**, and **9** and **10** (Table 5). The order of magnitude of the dipole moments of porphyrins **5**, **7** and **9** and their Zn^{II} complexes **6**, **8** and **10**, with a linker carrying a nitro group, supports a significant electronic asymmetry.

In conclusion, according to theoretical calculations the substitution of the electron-withdrawing nitro group by the strongly electron-donating dibutylamino group introduces a lower electronic asymmetry with a completely opposite polarity. Therefore, we have further evidence that, already in the ground state, the conjugation of the π systems produces a completely opposite electronic effect: the porphyrin ring acts as an electron donor if the linker carries a nitro group, while it acts as an electron acceptor if the linker carries a dibutylamino group. This ambivalent picture of the ground-state electronic density of the porphyrins and their Zn^{II} complexes investigated in this work can be better measured when comparing their dipole moments and ^1H NMR chemical shifts with those of a series of (*E*)-stilbene structures (Table 6).

If compared to the benzene ring, the porphyrin ring, as such or as a Zn^{II} complex, behaves as a much better acceptor and a slightly better donor on the basis of both dipole moments and chemical shifts of the protons of the (*E*)-double bond when linked through the β pyrrolic position. It shows, however, lower donor properties than a benzene ring carrying a dimethylamino group in the *para* position. Therefore, already in the ground state, a porphyrin ring substituted in the β pyrrolic position with a push or pull aryl ethenyl system shows a relevant ambivalent role as donor or acceptor.

Determination of the Quadratic Hyperpolarizability by the EFISH Technique

The EFISH technique[40] allows the determination of the second-order NLO response, γ_{EFISH}, of a solute. In order to avoid resonance enhancement, we worked with an off-resonance incident wavelength of 1.907 μm (see Experimental Section).

In highly π conjugated two dimensional molecules, such as porphyrins and phthalocyanines, the electronic contribution to γ_{EFISH} in Equation (3) (see Experimental Section) cannot, at first instance, be ignored.[5c,41] However, for asymmetrically substituted phthalocyanines, structurally related to our porphyrinic chromophores, carrying an arylethenyl or an arylbutadienyl spacer with a nitro group in the *para* position, the electronic contribution to γ_{EFISH} was evaluated to be much smaller than the dipolar orientational one.[41] In accordance, we neglected the electronic contribution during the evaluation of EFISH $\beta_{1.907}$ from γ_{EFISH}.

Our push-pull porphyrinic chromophores are characterised by a dipole moment axis directed quite parallel to the π linker axis, as confirmed by our DFT calculations on the dipole moments and best geometries. It follows that a charge-transfer process involving the π linker, which may control the second-order NLO response, is probably located quite parallel to this axis, as in traditional two-dimensional, pseudo-linear, organometallic push-pull chromophores.[42] If so, the component of β_{vec} along the dipole moment axis, that is EFISH $\beta_{1.907}$ (see Experimental Section), should be quite coincident with β_{vec}, which is the vectorial part of the quadratic hyperpolarizability tensor. EFISH $\beta_{1.907}$ turns out to be small for porphyrin **3** and for the Zn^{II} complexes **2** and **4**, with the electron-withdrawing group linked directly to the β pyrrolic position (Table 5). The order of magnitude of the quadratic hyperpolarizabilities of **3** and **4** is in agreement with that of a structurally related porphyrin and its Zn^{II} complex but carrying completely fluorinated aromatic rings in *meso* positions, although in this latter case the quadratic hyperpolarizability was measured with the HRS technique (Hyper Raleigh Scattering) working with a resonant incident wavelength of 1.064 μm.[12b] In this latter case, on the basis of solvatochromic evidence the major contribution to the second-order NLO response was attributed to a charge-transfer process from the porphyrin ring (as donor) to the nitro group linked to the β pyrrolic carbon atom (as acceptor) along the dipole moment axis, as assumed above.[43] The very low second-order NLO response of chromophores **2**–**4** is in accordance with the assumption that acceptor groups appended to an electron-rich centre, like the β position of the porphyrin ring, should not produce large NLO responses.[13,14] The values of EFISH $\beta_{1.907}$ increase upon introduction of a π-delocalised linker between the β pyrrolic position of the porphyrin ring and the electron-withdrawing nitro group (Table 5). As in structurally related pseudo-linear, organometallic, push-pull chromophores[42] and in structurally related push-pull phthalocyanines,[41] EFISH $\beta_{1.907}$ increases slightly upon increasing the length of the linker or by substitution of a triple bond with an (*E*)-double bond. We have also shown that EFISH $\beta_{1.907}$ always decreases slightly on going from the free porphyrin to its Zn^{II} complex, with the exception of the couple **9** and **10**, which show comparable values (Table 5).

This limited effect of coordination to Zn^{II} is in agreement with the assumption that the second-order NLO response is controlled by a charge-transfer process, favoured by conjugation, from the occupied π levels of the pyrrolic ring, acting as a push system, to the π* antibonding orbitals of the linker. In fact, this latter process should be scarcely affected by coordination of the porphyrin to Zn^{II}, which mainly influences the energy of the a_{2u} porphyrin orbital, with nodes at the metal centre and little electron density on the *exo* pyrrole positions.[10,25]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The positive value of the second-order NLO response of porphyrins with a nitro group linked to the β pyrrolic position by a π linker (**5**, **7**, **9** and **6**, **8**, **10**) also supports the role of such a charge-transfer process, which is characterised by the same polarity of the dipole moment.[42]

Interestingly, the values of EFISH $\beta_{1.907}$ of our porphyrinic chromophores **5**–**10** are comparable to that of structurally related chromophores based on the phthalocyanine ring.[41]

A larger and still positive second-order NLO response, confirmed by a series of experimental determinations in two different laboratories (see Experimental Section), was found by substitution of the nitro group with the strongly electron donating dibutylamino group as in porphyrin **11** and its Zn^{II} complex **12**. The second-order NLO response increases by complexation to Zn^{II} (Table 5). This response of both **11** and **12** cannot be due to a charge-transfer process, as above, from the occupied π orbitals of the pyrrolic ring to the π* antibonding orbitals of the π linker, since this process should produce a negative second-order NLO response as its polarity is opposite to that of the calculated dipole moment.[42] It is known that in push-pull NLO molecules the nature of the π conjugation can alter the electron donating ability of push substituents.[13] Thus, we can tentatively propose that the high EFISH $\beta_{1.907}$ values of both **11** and **12** are due to a relevant increase of the electronic effects of the donor properties of the dibutylamino group induced by an extended π system involving the porphyrin ring, possessing π segments that are either electron rich or electron poor.[14] The conjugation process of the overall π system of the linker with the extended π system of the porphyrin ring should stabilize the π* antibonding levels, thus producing a shift of the n→π* transition, which is the main origin of the second order NLO response, to much lower energy. In accordance with this hypothesis, this latter transition, which is usually located around 370–390 nm in *para*-dimethylaminostilbazoles,[42] is absent in the electronic spectra of both **11** and **12**, thus supporting a relevant red shift, probably under the large B band or even under the Q bands at much lower energy. In any case, our experimental observations are in agreement with the suggestion, based on a theoretical approach, of Marks, Ratner et al.[14] that the linkage to the electron-rich β pyrrolic position of a π system carrying a strong electron donating dibutylamino group may be the origin of some depletion of electron density on the donor and thereby of the reduction of the ground-state polarisation with an increase of the effective strength of the donor substituent and thereby of the second-order NLO response.[14] The significant increase of EFISH $\beta_{1.907}$ by coordination of **11** to Zn^{II} is in agreement with this hypothesis because complexation introduces a significant increase of the electron density on the porphyrinic ring, as confirmed by our voltammetric investigation. The significant second-order NLO response cannot be attributed to a aggregation process, which was discarded by a careful spectroscopic investigation carried out over a large range of concentrations.

Finally, the static quadratic hyperpolarizability EFISH, β_0, was calculated with the two-levels model,[44] according to Equation (1), assuming that the major charge-transfer process affecting the second-order NLO response is under the Soret B band.

$$\beta_0 = \beta_{1907}\left[1-\left(\frac{2\lambda_{max}}{1907}\right)^2\right]\left[1-\left(\frac{\lambda_{max}}{1907}\right)^2\right] \quad (1)$$

The dominant role of the Soret B band is supported by its significant charge-transfer character in all our porphyrinic chromophores, as evidenced by the solvatochromic investigation (Table 3) and by its high intensity. Any contribution due to the Q bands, in particular the Q_β band, which is not only slightly solvatochromic, but also of much lower intensity, should be much less relevant.

Obviously, the application of the two-levels model to an extended two-dimensional π system, although already applied to porphyrins[6a,6b] and phthalocyanines,[41] is quite debatable. Therefore, the β_0 values calculated by this approach should be considered only for their order of magnitude.

Conclusions

In this work we have produced, for the first time, clear evidence for a significant perturbation of the energy of the π electron core of the porphyrin ring due to conjugation between the porphyrinic π system, when substituted at the β pyrrolic position with a π delocalised linker carrying a nitro group, and the π system of the linker itself. The asymmetric shape and increased bandwidth of the B band, the Shelnutt analysis,[28] the trend of the centre of gravity of the B and Q_α bands and the sensitivity of the first two voltammetric oxidation steps, which involve the HOMO orbitals, with respect to the nature of the π linker, all support this perturbation, where the porphyrin ring, because of the electron-richness of the β position,[14] acts as an electron donor. This effect seems to be less relevant when the π linker carries a dibutylamino group. In this latter case the HOMO orbitals are centred on this group. Therefore, we have produced clear evidence that, already in the ground state, the porphyrin ring shows an ambivalent character, acting also as an acceptor, as supported, for instance, by the value and polarity of the dipole moments of porphyrin **11** and its Zn^{II} complex **12**, both of which have a linker carrying the strongly electron-donating dibutylamino group.

In the electron excitation process, the significant conjugation of the π levels of both the porphyrin ring and linker facilitates a charge transfer from the occupied π levels of the porphyrin π core, acting as a push group, to the antibonding π* orbitals of the linker carrying the pull nitro group, thus producing positive values of EFISH $\beta_{1.907}$ of the chromophores either as porphyrins (**5**, **7** and **9**) or as their Zn^{II} complexes (**6**, **8** and **10**) (Table 5). Evidence for a charge-transfer process from the porphyrin ring is also provided by the significant solvatochromic behaviour of both B and Q_β bands and by the asymmetric shape and

increased bandwidth of the B band of chromophores **5**–**10**.

In order to evaluate the unknown push properties of the β position of the porphyrin ring we can compare, for instance, the quadratic hyperpolarizability EFISH $\beta_{1.907}$ of the push-pull chromophore **8** with that of structurally related push-pull chromophores having an organic aryl moiety or an organometallic system like ferrocene as push groups (Figure 5). The EFISH $\beta_{1.907}$ of **8** is comparable to that of the chromophore carrying a ferrocenyl push group[45] but much smaller than the organic chromophore with *para*-dimethylamino as the push group.[46] A similar trend is observed for the porphyrinic chromophore having a butadienyl linker like the Zn^{II} complex **10**, which shows a value of EFISH $\beta_{1.907}$ comparable to that of the structurally related chromophore carrying a push ferrocenyl group,[45] but much smaller than that of the organic chromophore with the *para*-dimethylamino push group.[46] Not very different is the trend with respect to the structurally related organic chromophore when the linker is acetylenic (Figure 5).

Figure 5. Quadratic hyperpolarizability ($\beta_{1.907}$) of some organic and organometallic push-pull systems measured in $CHCl_3$ by the EFISH technique at an incident wavelength of 1.907 μm.

Therefore, *meso*-tetraphenylporphyrins and their Zn^{II} complexes, carrying in the β pyrrolic position a π-delocalised linker with an electron-withdrawing nitro group, behave, in a push-pull chromophore, as a push group similar to the ferrocenyl group.

The ambivalent character of the porphyrin ring in the porphyrins and their Zn^{II} complexes investigated in this work is confirmed also by properties involving excited states, like the second-order NLO response. The lack of bandwidth increase of the B band, its symmetry and the lower perturbation of the centre of gravity of the B and Q_α bands for both **11** and **12** do not produce evidence for an excitation process involving a significant charge-transfer from the π porphyrin core to the π linker, as occurs in the series of chromophores **5**–**10**. On the contrary, the significant positive EFISH $\beta_{1.907}$ values of **11** and **12** would suggest an effective screening of the ground-state polarisation induced by the electron-rich β pyrrolic position of the porphyrin ring, which behaves as a kind of acceptor and increases, in the excitation process, the donor properties of the dimethylamino push group.[14]

Experimental Section

All the commercially available solvents and chemicals were of reagent-grade quality and, unless otherwise stated, were used without further purification. Porphyrin **3**,[20] its Zn^{II} complex **4**[20] and 4-nitrophenylacetylene[47] were prepared according to literature methods. ^1H NMR spectra were recorded on a Bruker AC-300 Spectrometer in $CDCl_3$ as solvent. Electronic spectra were obtained in $CHCl_3$ with a Jasco V-530 Spectrometer. Emission spectra were obtained in $CHCl_3$ with a Jasco FP-777 spectrofluorimeter. FAB-MS measurements were performed with an analytical VG 7070 EQ instrument. Elemental analyses were carried out in the Analytical Laboratories of the Department of Inorganic, Metallorganic and Analytical Chemistry of Milan University. Dipole moments were determined in $CHCl_3$ solution with a WTW-DM01 dipolmeter (dielectric constant) coupled with a Pulfrich Zeiss PR2 refractometer (refractive index) according to the Guggenheim method.[39]

Cyclic Voltammetry: Cyclovoltammetric investigations (CV) were carried out on carefully deaerated solutions with a station including an AMEL 2049 potentiostat/galvanostat, an AMEL 568 function generator and a Lynseis LY16100-II *x*/*y* recorder. The working solutions were made up with HPLC-grade CH_2Cl_2 and tetrabutylammonium perchlorate (TBAP; >99% Fluka) at concentrations ranging from 3×10^{-4} M to 7×10^{-4} M. Data were obtained at different potential scan rates (ranging from 0.02 to 0.5 $V\,s^{-1}$) working with two different electrodes: (a) an AMEL glassy carbon disk electrode (GC, 2 mm diameter), and (b) a platinum wire electrode (Pt, 1 cm length, 0.05 cm diameter), using a platinum counter-electrode and a saturated calomel electrode (SCE) as reference. The nearly identical voltammograms indicate that the electrode materials have no catalytic effect on the oxidation process.

The electrochemical reversibility and electron number of each well-defined peak were checked by classical tests,[48] including analysis of the I_p vs. $v^{1/2}$ characteristics, the E_p vs. log*v* characteristics, the ($E_p - E_{p/2}$) vs. log*v* characteristics and the "stationary", step-like waves obtained by convolutive analysis of the original CV characteristics.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Solvatochromic Investigation: The solvatochromic behaviour of the Soret B and Q_β bands was investigated by using a set of polar, nonprotic and only weakly donor solvents (CH_3CN, acetone, dichloroethane, CH_2Cl_2, THF, ethyl acetate, $CHCl_3$, toluene, CCl_4, cyclohexane, *n*-hexane). The values of $\Delta\mu_{eg}$, the difference between the dipole moments of the excited and of the ground state, were obtained from the Mc Rae equation (2)[49] evaluating the radius of the cavity, *a*, occupied by the solute in the solvent empirically from the molecular weight:

$$\nu_a = \nu_a^{\,g} + A\frac{2(n^2-1)}{a^3(2n^2-1)} + B\left(\frac{\varepsilon-1}{\varepsilon+2} - \frac{n^2-1}{n^2+2}\right); \quad B = \frac{-2\mu\Delta\mu_{eg}}{hca^3} \qquad (2)$$

where ν_a and $\nu_a^{\,g}$ are the frequencies of the absorption maximum in a given solvent and in the gas phase, respectively, μ is the dipole moment, *a* is the radius of the cavity (cm), and ε and *n* are the solvent dielectric constant and refractive index, respectively. Since in the determination of $\Delta\mu_{eg}$ of both B and Q_β bands we were not interested in their absolute value, but only in their order of magnitude and sign, the use of the molecular weight for a rather approximate assignment of the value of *a* (cavity radius) to rather flat molecules, such those studied in this work, may be considered acceptable.

EFISH Measurements: EFISH measurements were performed in our department in $CHCl_3$ solutions, as a function of concentration, working at an incident wavelength of 1.907 μm using a Q-switched Nd:YAG laser with a 60- and 20-ns pulse duration, manufactured by Atalaser. The 1.907 μm fundamental wavelength was obtained by Raman shifting of the 1.064 μm emission of the Q-switched Nd:YAG laser in a high pressure hydrogen cell (60 bar). A liquid cell with thick windows in the wedge configuration was used to obtain the Maker fringe pattern (harmonic intensity variation as a function of liquid cell translation).[40] In the EFISH experiments the incident beam was synchronised with a DC field applied in order to break the centrosymmetry of the solution. The apparatus for the EFISH measurements was a prototype made by SOPRA (France).

From the concentration dependence (10^{-3}–10^{-4} M) of the harmonic signal with respect to that of the pure solvent, the NLO responses EFISH β_λ, were determined from the calculated γ_{EFISH}, according to Equation (3):

$$\gamma_{EFISH} = \frac{\mu\beta_\lambda(-2\omega;\omega,\omega)}{5kT} + \gamma(-2\omega;\omega,\omega,0) \qquad (3)$$

where γ_{EFISH} is the sum of a cubic electronic contribution $\gamma(-2\omega;\ \omega,\ \omega,\ 0)$ and of a quadratic orientational contribution $\mu\beta_\lambda$ $(-2\omega;\ \omega,\ \omega)/5kT$, where μ is the dipole moment and EFISH β_λ is the projection along the dipole moment direction of the vectorial component β_{vec} of the tensorial quadratic hyperpolarizability, β, at the incident wavelength λ.

Computational Methods: The optimised geometry of porphyrins as two geometric isomers and of their Zn^{II} complexes was determined at an ab initio level using the DFT (Density Functional Theory) approach[15] adopting the BP86 functional[16] and an all-electron valence triple-ξ basis set with polarisation functions on all atoms (TZVP).[17] The ab initio DFT approach was undertaken because previous experiences[6d] have shown that semi-empirical Hamiltonians like MNDO or AM1 do not produce optimised geometries for the extended π conjugation when the linker is based on a styryl or phenylbutadienyl structure. A loss of planarity of the π linker and therefore a decrease of the π conjugation is usually the final result.

The final geometry of all the porphyrinic systems investigated, either as the free-base porphyrin or its Zn^{II} complex, shows a good planarity of the π linker with the π system of the porphyrinic moiety. The values of the dipole moments moduli and components were finally computed using the Turbomole suite of programs[50] in connection with the resolution of the identity (RI) approximation.[51]

Synthesis of Porphyrins and Their Zn^{II} Complexes

2-Bromo-5,10,15,20-tetraphenylporphyrinatonickel(II): 2-Bromo-5,10,15,20-tetraphenylporphyrin (205 mg, 0.296 mmol) was dissolved in slightly warmed 1,2-dichloroethane (30 mL) whilst stirring, then $Ni(acac)_2$ (84 mg, 0.326 mmol) was added. After 45 minutes the complete disappearance of the starting porphyrin was evidenced by TLC (*n*-hexane/toluene, 7:3) and by the change of the colour of the reaction mixture from brown to red and finally to orange. After removal of the solvent in vacuo, the crude product was crystallised with CH_2Cl_2/pentane and washed with pentane to afford the complex in quantitative yield.

2-Cyano-5,10,15,20-tetraphenylporphyrin (1): This porphyrin was prepared by demetallation of its Ni^{II} complex, synthesised according to a literature procedure.[18] 2-Cyano-5,10,15,20-tetraphenylporphyrinatonickel(II) (50 mg) was dissolved in 95% H_2SO_4 (2 mL) with magnetic stirring. The green solution was slowly added to a saturated solution of $(NH_4)_2CO_3$ and the dark brown suspension was filtered. The mother liquor was extracted with CH_2Cl_2 (2 × 60 mL), and the organic phase was washed with H_2O, dried with Na_2SO_4 and the solvents evaporated to dryness. The residue was purified by column chromatography (silica gel, CH_2Cl_2/*n*-hexane, 1:1) to afford 43 mg (94%) of pure **1** as a dark brown powder. ^{1}H NMR (300 MHz, $CDCl_3$): δ = –2.80 (br. s, 2 H, NH), 7.71–7.81 (m, 12 H, $H_{m,pPh}$), 8.16–8.19 (m, 8 H, H_{oPh}), 8.74 (s, 2 H, $H_{pyrrolic}$), 8.90–8.98 (m, 4 H, $H_{pyrrolic}$), 9.36 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 420 (5.29), 517 (3.79), 552 (3.21), 605 (3.53), 593 (3.23), 648 (3.20) nm. $C_{45}H_{29}N_5$ (639): calcd. C 84.48, H 4.57, N 10.95; found C 84.40, H 4.73, N 10.94. MS-FAB(+): *m*/*z* = 640 $[M + 1]^+$.

2-Nitro-5,10,15,20-tetraphenylporphyrin (3): A solution of the Zn^{II} complex **4** (68.3 mg, 0.094 mmol) in 50 mL of CH_2Cl_2 was stirred at room temperature with 1.5 mL of concentrated HCl for 5 min, then the pH was raised to 7–8 by addition of NEt_3. The brown solution was transferred into a separating funnel and washed with H_2O, the organic phase was separated, dried with Na_2SO_4, evaporated and the residue purified by column chromatography (silica gel, toluene) to afford pure **3** (quantitative yield) as a violet powder. ^{1}H NMR (300 MHz, $CDCl_3$): δ = –2.58 (br. s, 2 H, NH), 7.71–7.83 (m, 12 H, $H_{m,pPh}$), 8.20–8.29 (m, 8 H, H_{oPh}), 8.91–9.05 (m, 6 H, $H_{pyrrolic}$), 9.07 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 427 (5.24), 527 (4.14), 560 (3.56), 605 (3.53), 665 (3.88) nm. $C_{44}H_{29}N_5O_2$ (659): calcd. C 80.10, H 4.43, N 10.62; found C 80.40, H 4.42, N 10.60. MS-FAB(+): *m*/*z* = 660 $[M + 1]^+$.

2-[2-(4-Nitrophenyl)ethyn-1-yl]-5,10,15,20-tetraphenylporphyrin (5): A solution of Zn^{II} complex **6** (60 mg, 0.073 mmol) and trifluoroacetic acid (1 mL) in CH_2Cl_2 (25 mL) was stirred at room temperature for 12 h. The volatiles were removed in vacuo to afford a dark-green residue which was dissolved in CH_2Cl_2 (100 mL) and carefully washed with a 5% aqueous solution of $NaHCO_3$ (2 × 50 mL) and with H_2O (2 × 50 mL), dried with Na_2SO_4 and the solvents evaporated to dryness. The residue was crystallised from CH_2Cl_2/*n*-hexane to afford 52 mg (94%) of **5** as a red-brown powder. ^{1}H

NMR (300 MHz, $CDCl_3$): δ = –2.65 (br. s, 2 H, NH), 7.49 (AA′BB′, 2 H, H_{Ar}), 7.60–7.83 (m, 12 H, $H_{m,pPh}$), 8.15–8.22 (m, 10 H, 8H_{oPh}, 2H_{Ar}), 8.78–8.91 (m, 6 H, $H_{pyrrolic}$), 9.13 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 430 (5.26), 525 (4.31), 562 (3.83), 601 (3.78), 657 (3.68) nm. $C_{52}H_{33}N_5O_2$ (759): calcd. C 82.19, H 4.38, N 9.22; found C 81.75, H 4.40, N 8.96. MS-FAB(+): *m*/*z* = 760 $[M + 1]^+$.

2-[(1*E*)-2-(4-Nitrophenyl)ethen-1-yl]-5,10,15,20-tetraphenylporphyrin (7): Solid NaOH (400 mg, 10 mmol) was added to a solution of (4-nitrobenzyl)triphenylphosphonium bromide (596 mg, 1.25 mmol) and 2-formyl-5,10,15,20-tetraphenylporphyrin (**13**; 160 mg, 0.25 mmol) in 30 mL of 1,2-dichloroethane and the resulting suspension was heated at reflux and stirred for 8 h. Then, the reaction mixture was diluted with 150 mL of CH_2Cl_2, washed with 100 mL of H_2O and the organic phase was separated, dried with Na_2SO_4 and the solvents evaporated. The residue was purified by column chromatography (silica gel, CH_2Cl_2) to afford 160 mg of product as a mixture 80:20 of (*E*)- and (*Z*)-isomers. This mixture was purified by crystallisation from CH_2Cl_2/CH_3OH to afford 110 mg (58%) of pure (*E*)-isomer **7**. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.60 (br. s, 2 H, NH), 7.11 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.29 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.30 (d, *J* = 8.6 Hz, 2 H, H_{Ar}), 7.74–7.86 (m, 12 H, $H_{m,p}$), 8.14–8.24 (m, 10 H, 8H_{oPh}, 2H_{Ar}), 8.70–8.82 (m, 6 H, $H_{pyrrolic}$), 9.01 (br. s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 431 (5.31), 525 (4.34), 569 (4.13), 602 (3.94), 659 (3.47) nm. $C_{52}H_{35}N_5O_2$ (761): calcd. C 81.9, H 4.64, N 9.20; found C 81.6, H 4.62, N 9.16. MS-FAB(+): *m*/*z* = 762 $[M + 1]^+$.

2-{(1*E*)-2-[4-(Dibutylamino)phenyl]ethen-1-yl}-5,10,15,20-tetraphenylporphyrin (11): Solid NaOH (480 mg, 12 mmol) was added to a solution of [4-(dibutylamino)benzyl]triphenylphosphonium bromide (258 mg, 0.5 mmol) and 2-formyl-5,10,15,20-tetraphenylporphyrin (**13**; 193 mg, 0,3 mmol) in 25 mL of CH_2Cl_2, and the resulting suspension was stirred at room temperature for 4 h. Then, the reaction mixture was purified by column chromatography (silica gel, CH_2Cl_2) to afford 205 mg of product as a 9:1 mixture of (*E*)- and (*Z*)-isomers. This product was crystallised from CH_2Cl_2/*n*-pentane to give 175 mg (69%) of pure (*E*)-isomer **11**. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.60 (br. s, 2 H, NH), 1.01 (t, *J* = 7.20 Hz, 6 H, $CH_{3\ butyl}$), 1.20–1.70 (m, 4 H, $2CH_{2\ butyl}$), 3.34 (t, *J* = 7.60 Hz, 4 H, NCH_2), 6.60 (d, *J* = 8.80 Hz, 2 H, H_{Ar}), 6.72 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.12 (d, *J* = 8.80 Hz, 2 H, H_{Ar}), 7.28 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.65–7.88 (m, 12 H, $H_{m,pPh}$), 8.15–8.30 (m, 8 H, H_{oPh}), 8.65–8.85 (m, 6 H, $H_{pyrrolic}$), 8.96 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 422 (5.36), 521 (4.41), 579 (4.16), 603 (4.14), 660 (3.71) nm. $C_{60}H_{53}N_5$ (843): calcd. C 85.37, H 6.33, N 8.30; found C 85.0, H 6.35, N 8.26. MS-FAB(+): *m*/*z* = 844 $[M + 1]^+$.

2-[(1*E*,3*E*)4-(4-Nitrophenyl)-1,3-butadienyl]-5,10,15,20-tetraphenylporphyrin (9): 1,8-Diazabicyclo[5.4.0]-undec-7-ene (DBU; 509 mg, 3.34 mmol) was added to a solution of the phosphonium salt of the tetraphenylporphyrin **16** (52 mg, 0.0562 mmol) and 4-nitrocinnamaldehyde (12 mg, 0.0674 mmol) in CH_2Cl_2 (5 mL), and the mixture was maintained under magnetic stirring and at room temperature for one hour. The product was isolated by column chromatography (silica gel; toluene/cyclohexane, 9:1) and further purified by crystallisation from CH_2Cl_2/*n*-hexane to afford 38 mg (86%) of pure **9** as a purple solid. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.56 (s, 2 H, NH), 6.40 (d, 1 H, H_{butyl}), 6.74 (d, 2 H, H_{butyl}), 7.17 (m, 1 H, H_{butyl}), 7.54 (d, 2 H, H_{Ar}), 7.78 (m, 12 H, $H_{o,pPh}$), 7.79 (m, 6 H, $H_{pyrrolic}$), 8.15 (d, *J* = 6.98 Hz, 2 H, H_{Ar}), 8.23 (m, 8 H, H_{mPh}), 8.95 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis (CH_2Cl_2): λ_{max} (logε) = 425 (5.03), 523 (4.21), 572 (4.07), 601 (3.86), 665 (3.51) nm. $C_{54}H_{37}N_5O_2$ (787): calcd. C 82.32, H 4.73, N 8.89; found C 82.0, H 4.60, N 8.70. MS-FAB(+): *m*/*z* = 788 $[M + 1]^+$.

Synthesis of Zn^{II} Complexes: Zn^{II} complexes **2**, **8**, **10** and **12** were synthesised following the general procedure described in the literature.[19] In a typical preparation, the free porphyrin (100 mg) was dissolved in slightly warmed $CHCl_3$ (50 mL) and a solution of $Zn(OAc)_2{\cdot}2H_2O$ (free porphyrin/metal salt = 1:3) in MeOH (5 mL) was then added. The mixture was heated at reflux for 2 h and the progress of the reaction was monitored by TLC. After removal of the solvent in vacuo, the crude product was purified by crystallisation or by washing with methanol.

2-Cyano-5,10,15,20-tetraphenylporphyrinatozinc(II) (2): The violet powder was crystallised from CH_2Cl_2/*n*-pentane. Yield: 98%. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.60–7.80 (m, 12 H, $H_{m,pPh}$), 8.12–8.20 (m, 8 H, H_{oPh}), 8.87–8.93 (m, 6 H, $H_{pyrrolic}$), 9.46 (br. s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 427 (5.62), 518 (3.57), 555 (4.20), 593 (4.02) nm. $C_{45}H_{27}N_5Zn$ (702): calcd. C 76.87, H 3.87, N 9.96; found C 76.52, H 3.88, N 9.92. MS-FAB(+): *m*/*z* = 703 $[M + 1]^+$.

2-[(1*E*)-2-(4-Nitrophenyl)ethen-1-yl]-5,10,15,20-tetraphenylporphyrinatozinc(II) (8): The blue-violet powder was washed with *n*-hexane and a small amount of MeOH in order to eliminate the excess of $Zn(OAc)_2$. Yield: 90%. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.18 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.24 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.37 (d, *J* = 8.6 Hz, 2 H, H_{Ar}), 7.76- 7.85 (m, 12 H, $H_{m,pPh}$), 8.19–8.28 (m, 10 H, 8H_{oPh}, 2H_{Ar}), 8.82–8.96 (m, 6 H, $H_{pyrrolic}$), 9.16 (br. s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 432 (5.20), 526 (3.77), 558 (4.35), 597 (4.13) nm. $C_{52}H_{33}N_5O_2Zn$ (824): calcd. C 75.70, H 4.04, N 8.49; found C 75.4, H 4.03, N 8.45. MS-FAB(+): *m*/*z* = 825 $[M + 1]^+$.

2-[(1*E*,3*E*)4-(4-Nitrophenyl)1,3-butadienyl]-5,10,15,20-tetraphenylporphyrinatozinc(II) (10): The dark green powder was washed with *n*-hexane and a small amount of MeOH in order to eliminate the excess of $Zn(OAc)_2$. Yield 90%. ^1H NMR (300 MHz, $CDCl_3$): δ = 6.40 (d, 1 H, H_{butyl}), 6.75 (d, 2 H, H_{butyl}), 7.14 (dd, 1 H, H_{butyl}), 7.55 (d, 2 H, H_{Ar}), 7.78 (m, 12 H, $H_{m,pPh}$), 8.15 (d, 2 H, H_{Ar}), 8.24 (m, 8 H, H_{oPh}), 8.88 (m, 6 H, $H_{pyrrolic}$), 9.07 (br. s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis (CH_2Cl_2): λ_{max} (logε) = 430 (4.94), 559 (4.11), 599 (3.98) nm. $C_{54}H_{35}N_5O_2Zn$ (850): calcd. C 76.20, H 4.14, N 8.23; found C 76.20, H 4.05, N 8.01. MS-FAB(+): *m*/*z* = 851 $[M + 1]^+$.

2-{(*1E*)-2-[4-(Dibutylamino)phenyl]ethen-1-yl}-5,10,15,20-tetraphenylporphyrinatozinc(II) (12): The dark powder was washed with *n*-hexane and a small amount of MeOH in order to eliminate the excess of $Zn(OAc)_2$. Yield: 85%. ^1H NMR [300 MHz, $(CD_3)_2CO$]: δ = 1.02 (t, *J* = 7.2 Hz, 6 H, CH_3), 1.45–1.51 (m, 4 H, CH_2), 1.60–1.73 (m, 4 H, CH_2), 3.41 (t, *J* = 7.2 Hz, 4 H, CH_2N), 6.69 (d, *J* = 8.8 Hz, 2 H, H_{Ar}), 6.82 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.14 (d, *J* = 8.8 Hz, 2 H, H_{Ar}), 7.22 (d, *J* = 16.0 Hz, 1 H, $H_{ethenyl}$), 7.72- 7.88 (m, 12 H, $H_{m,pPh}$), 8.15–8.30 (m, 8 H, H_{oPh}), 8.70–8.90 (m, 6 H, $H_{pyrrolic}$), 9.01 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 422 (5.20), 556 (4.08), 601 (3.97) nm. $C_{60}H_{51}N_5Zn$ (906): calcd. C 79.47, H 5.63, N 7.73; found C 79.60, H 5.61, N 7.70. MS-FAB(+): *m*/*z* = 907 $[M + 1]^+$.

2-Nitro-5,10,15,20-tetraphenylporphyrinatozinc(II) (4): A solution of $AgNO_3$ (97.8 mg, 0.576 mmol) in 20 mL of CH_3CN and a solution of I_2 (75 mg, 0.295 mmol) in 20 mL of CH_2Cl_2 were rapidly added to a solution of 5,10,15,20-tetraphenylporphyrinatozinc(II) (301 mg, 0.434 mmol) in 80 mL of CH_2Cl_2/CH_3CN (1:1, v/v); the resulting mixture was stirred at room temperature, under nitrogen, in the dark, for two hours. The reaction mixture was filtered, the solvent was evaporated in vacuo and the residue was purified by

column chromatography (silica gel, CH_2Cl_2) to afford 71.7 mg (22%) of a violet powder. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.67–7.95 (m, 12 H, $H_{m,pPh}$), 8.19–8.22 (m, 8 H, H_{oPh}), 8.98–9.00 (m, 6 H, $H_{pyrrolic}$), 9.22 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 425 (5.28), 522 (3.41), 555 (4.00), 598 (3.80) nm. $C_{44}H_{27}N_5O_2Zn$ (722): calcd. C 73.08, H 3.76, N 9.69; found C 73.20, H 3.89, N 9.80. MS-FAB(+): m/z = 723 $[M + 1]^+$.

2-[2-(4-Nitrophenyl)ethyn-1-yl]-5,10,15,20-tetraphenylporphyrinatozinc(II) (6): A mixture of 2-bromo-5,10,15,20-tetraphenylporphyrinatozinc(II) (150 mg, 0.182 mmol), $[PdCl_2(PPh_3)_2]$ (19 mg, 0.027 mmol), CuI (15.4 mg, 0.0081 mmol), 4-nitrophenylacetylene (61.5 mg, 0.42 mmol) and triethylamine (3 mL) in 40 mL of THF was heated at reflux under nitrogen, in the dark, for 5 h. The solvent was evaporated in vacuo and the residue was purified by column chromatography (silica-gel, toluene/cyclohexane, 1:1) to afford 63 mg (42%) of pure **6** as a dark-violet powder. ^1H NMR (300 MHz, $CDCl_3$): δ = 7.50 (d, J = 8.79 Hz, 2 H, H_{Ar}), 7.61–7.83 (m, 12 H, $H_{m,pPh}$), 8.17–8.22 (m, 10 H, 8H_{oPh}, 2H_{Ar}), 8.65–8.93 (m, 6 H, $H_{pyrrolic}$), 9.27 (br. s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 431 (5.30), 521 (3.60), 557 (4.25), 594 (4.03) nm. $C_{52}H_{31}N_5O_2Zn$ (822): calcd. C 75.87, H 3.80, N 8.51; found C 76.2, H 3.89, N 8.35. MS-FAB(+): m/z = 823 $[M + 1]^+$.

2-Formyl-5,10,15,20-tetraphenylporphyrin (13): A solution of dimethylformamide (2 mL) and phosphoryl chloride (2 ml) in 10 mL of 1,2-dichloroethane was left at room temperature and stirred magnetically for 30 min. After this time, a solution of tetrakis-5,10,15,20-tetraphenylporphyrinatonickel(II) (300 mg, 0.449 mmol) in 100 mL of 1,2-dichloroethane was added and the reaction mixture was refluxed for 24 h. The dark-green solution was then evaporated to dryness and the residue was treated, while cooling with an ice bath, with 10 mL of 96% H_2SO_4 to afford a green viscous solution, which was diluted with a saturated aqueous solution of CH_3COONa until the pH was basic. The product was extracted with CH_2Cl_2 (3 × 150 mL), the organic phase was washed with aqueous 5% NaOH (100 mL) and then with H_2O (150 mL) and the solvents evaporated in vacuo to afford 320 mg of crude product. Purification by column chromatography (silica gel, CH_2Cl_2) afforded 220 mg (70%) of pure **13** as a purple solid. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.60 (br. s, 2 H, NH), 7.64–7.84 (m, 12 H, $H_{m,pPh}$), 7.95–8.05 (m, 2 H, H_{oPh}), 8.12–8.28 (m, 6 H, H_{oPh}), 8.65–8.81 (m, 2 H, $H_{pyrrolic}$), 8.85–8.87 (m, 4 H, $H_{pyrrolic}$), 9.23 (br. s, 1 H, $H_{pyrrolic}$), 9.42 (s, 1 H, CHO) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 432 (5.47), 526 (4.21), 568 (3.80), 605 (3.70), 664 (3.83) nm. $C_{45}H_{30}N_4O$ (642): calcd. C 84.09, H 4.70, N 8.72; found C 84.35, H 4.83, N 8.79. MS-FAB(+): m/z = 643 $[M + 1]^+$.

2-Hydroxymethyl-5,10,15,20-tetraphenylporphyrin (14): A sample of 2-formyl-5,10,15,20-tetraphenylporphyrin (**13**; 375 mg, 0,583 mmol) was dissolved in 50 mL of refluxing dry tetrahydrofuran, then $NaBH_4$ (609 mg, 16.1 mmol) was added and the suspension was stirred for 15 min. The reaction mixture was cooled to room temperature, 100 mL of H_2O was added in order to eliminate the excess of $NaBH_4$, then the reaction mixture was transferred into a separating funnel and extracted with 100 mL of $CHCl_3$. The organic phase was separated, dried with Na_2SO_4 and evaporated under reduced pressure. The residue was purified by crystallisation with CH_2Cl_2/*n*-hexane to afford 335 mg (89%) of pure **14** as a purple solid. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.75 (br. s, 2 H, NH), 1.95 (t, 1 H, exchange with D_2O), 4.88 (d, J = 5.06 Hz, 2 H, CH_2O), 7.64–7.80 (m, 12 H, $H_{m,pPh}$), 8.08–8.11 (m, 2 H, H_{oPh}), 8.17–8.22 (m, 6 H, H_{oPh}), 8.50–8.61 (m, 2 H, $H_{pyrrolic}$), 8.75 and 8.87 (m, 4 H, $H_{pyrrolic}$), 8.94 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 419 (5.71), 515 (4.27), 549 (3.77), 589 (3.74), 645 (3.50) nm. $C_{45}H_{32}N_4O$ (644): calcd. C 83.83, H 5.00, N 8.69; found C 83.9, H 5.02, N 8.72. MS-FAB(+): m/z = 645 $[M + 1]^+$.

2-(Chloromethyl)-5,10,15,20-tetraphenylporphyrin (15): A solution of thionyl chloride (0.13 g, 1.36 mmol) in 5 mL of Et_2O was slowly added, keeping the temperature in the range 0–5 °C, to a stirred solution of porphyrin **14** (87.5 mg, 0.136 mmol) and pyridine (0.13 g, 1.63 mmol) in 30 mL of Et_2O. Once the addition was complete, the temperature was raised to room temperature and the reaction mixture was stirred for 30 min. The mixture was then transferred into a separating funnel, diluted with 100 mL of CH_2Cl_2 and washed with water (70 mL) and aqueous 5% $NaHCO_3$ (60 mL). The organic phase was dried with Na_2SO_4 and the solvents evaporated in vacuo to afford 95 mg of residue, which was purified by crystallisation from CH_2Cl_2/*n*-pentane to give 85 mg (95%) of a purple solid. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.79 (br. s, 2 H, NH), 4.79 (s, 2 H, CH_2Cl), 7.64- 7.75 (m, 12 H, $H_{m,pPh}$), 8.10–8.25 (m, 8 H, H_{oPh}), 8.65 (d, J = 4.87 Hz, 2 H, $H_{pyrrolic}$), 8.78–8.87 (m, 4 H, $H_{pyrrolic}$), 8.96 (s, 1 H, $H_{pyrrolic}$) ppm. UV/Vis ($CHCl_3$): λ_{max} (logε) = 420 (5.54), 516 (4.26), 550 (3.84), 592 (3.73), 650 (3.81) nm. $C_{45}H_{31}ClN_4$ (662): calcd. C 81.50, H 4.71, N 8.45; found C 81.15, H 4.78, N 8.49. MS-FAB(+): m/z = 663 $[M + 1]^+$, 628 $[M – Cl]^+$.

[2-(5,10,15,20-Tetraphenylporphyrin-2-yl)methylene]triphenylphosphonium Chloride (16): A solution of porphyrin **15** (75.1 mg, 0.113 mmol) and triphenylphosphane (240 mg, 0.9 mmol) in 50 mL of $CHCl_3$ was refluxed under magnetic stirring for 16 h. The solvent was then evaporated in vacuo, the residue was washed with *n*-hexane in order to remove the excess of PPh_3, and the purple solid residue was dried to afford 84 mg (80%) of pure **16**. ^1H NMR (300 MHz, $CDCl_3$): δ = –2.78 (br. s, 2 H, NH), 5.31 (d, J = 15 Hz, 2 H, CH_2P), 7.10- 7.20 (m, 6 H, 3 $H_{m,pPh}$ + 3 $H_{pAr–P}$), 7.22–7.35 (m, 5 H, 3 $H_{o\ Ar–P}$ + 2 H_{oPh}), 7.41 (d, J = 7.2 Hz, 2 H, 2 H_{oPh}), 7.50–7.95 (m, 18 H, 3 $H_{oAr–P}$ + 6 $H_{mAr–P}$ + 9 $H_{m,pPh}$), 8.10–8.20 (m, 4 H, 4H_{oPh}), 8.34 (d, J = 3.6 Hz, 1 $H_{pyrrolic}$), 8.45 (d, J = 4.9 Hz, 1 $H_{pyrrolic}$), 8.70–8.90 (m, 5 $H_{pyrrolic.}$) ppm. UV/Vis (CH_2Cl_2): λ_{max} (logε) = 423 (5.60), 519 (4.26), 556 (3.72), 595 (3.69), 652 (3.70) nm. $C_{63}H_{46}ClN_4P$ (924): calcd. C 81.76, H 5.01, N 6.05; found C 81.50, H 5.03, N 6.10. MS-FAB(+): m/z = 889 $[M – Cl]^+$, 627 $[M – Cl – PPh_3]^+$.

4-(Dibutylamino)benzyl Alcohol: A sample of 4-(dibutylamino)-benzaldehyde (2.33 g, 10 mmol) was dissolved in 100 mL of 96% EtOH. Then, $NaBH_4$ (760 mg, 20 mmol) was added and the suspension was stirred at reflux for 2 h. The reaction mixture was evaporated in vacuo, the residue was taken up into a separating funnel with 60 mL of H_2O and 100 mL of Et_2O and the organic phase was separated. The aqueous phase was extracted with Et_2O (2 × 50 mL). The organic phase was dried with $MgSO_4$ and the solvents evaporated to dryness to afford 2.28 g (97%) of pure product as a thick, colourless oil. ^1H NMR (200 MHz, $CDCl_3$): δ = 0.95 (t, J = 7.2 Hz, 6 H, CH_3), 1.25–1.45 (m, 5 H, CH_2 + OH), 1.45–1.65 (m, 4 H, CH_2), 3.26 (t, J = 7.2 Hz, 4 H, CH_2N), 4.54 (d, J = 5.7 Hz, 2 H, CH_2O), 6.62 (d, J = 8.8 Hz, 2 H, AA′BB′), 7.20 (d, J = 8.8 Hz, 2 H, AA′BB′) ppm.

[4-(Dibutylamino)benzyl]triphenylphosphonium Chloride: A suspension of 4-(dibutylamino)benzyl alcohol (1.18 g, 5 mmol) in 20 mL of CH_3CN, cooled to 0 °C, was saturated with gaseous HCl until a light yellow solution had formed. This solution was heated at reflux and stirred for 40 h. The reaction mixture was evaporated in vacuo, the residue was taken up in a separating funnel with 120 mL of CH_2Cl_2, washed with aqueous 10% Na_2CO_3 (2 × 30 mL) and 50 mL of brine. The organic phase was dried with $MgSO_4$ and the solvents evaporated to dryness to give a white solid residue which

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was ground with Et_2O and filtered to give 2.41 g (93%) of a white solid. ^1H NMR (200 MHz, $CDCl_3$): δ = 0.95 (t, J = 7.2 Hz, 6 H, CH_3), 1.18–1.35 (m, 4 H, CH_2), 1.35–1.55 (m, 4 H, CH_2), 3.16 (t, J = 7.2 Hz, 4 H, CH_2N), 5.14 (d, J = 13 Hz, 2 H, CH_2P^+), 6.36 (d, J = 8.8 Hz, 2 H, AA′BB′), 6.82 (dd, J = 8.8, J = 2.5 Hz, 2 H, AA′BB′), 7.55–7.80 (m, 15 H, H_{phenyl}) ppm.

Nitrate- and Nitrite-Assisted Conversion of an Acetonitrile Ligand Into an Amidato Bridge at an $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ Core: Electrochemistry of the Amidato Complex $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^+$

Marc Le Hénanf,[a] Christine Le Roy,[a] François Y. Pétillon,[a] Philippe Schollhammer,[a] and Jean Talarmin*[a]

Keywords: Bridging ligands / Cyclic voltammetry / Electrochemistry / Molybdenum / S ligands

Treatment of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ (**1**$^+$) with NO_3^- or NO_2^- results in the conversion of one terminally bound acetonitrile ligand into an amidato bridge. The reaction produces $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^{0/+}$ (**2**$^{0/+}$) and involves the formation of an intermediate, which was detected by cyclic voltammetry but which could not be isolated, and which likely arises from the substitution of the NO_x anion for one MeCN ligand. The electrochemical behaviour of **2**$^+$ was studied by cyclic voltammetry in THF and MeCN. The reduction of **2**$^+$ in the presence of acid (HBF_4/H_2O or HBF_4/Et_2O) in these solvents leads to the release of the amidate bridge. Controlled-potential electrolysis of **2**$^+$ in MeCN in the presence of acid produces **1**$^+$ quantitatively; the charge consumed (>1 F mol^{-1} of **1**$^+$) indicates that electrons are also used to reduce protons. This was confirmed by the formation of **2**$^+$ (in variable amounts depending on the conditions) on treating **2** with acid.

Introduction

Complexes with the $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ core have been shown to sustain transformations of various unsaturated substrates.[1–3] The electrochemical reduction of a complex containing a $\mu\text{-}\eta^1,\eta^1$-coordinated phenyldiazene ligand in the presence of acid results in the cleavage of the N=N bond and the release of ammonia and aniline.[2] During this reduction, the nitrogenous moiety undergoes a coordination change, most probably at the hydrazido(1–) stage, from a $\mu\text{-}\eta^1,\eta^1$ to a $\mu\text{-}\eta^1$ geometry.[2] This has been recently confirmed by a theoretical study of the different steps of the reduction process.[4] Similarly, the electrochemical reduction in the presence of protons of a complex bearing a $\mu\text{-}\eta^1,\eta^2$-vinylidene ligand affords a $\mu\text{-}\eta^1$-coordinated carbyne derivative.[3]

These examples, which illustrate the ability of the $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ entity to adjust to the electronic properties of various unsaturated ligands in different coordination modes, prompted us to examine the possibility of reducing nitrate and nitrite at this site. Nitrate and nitrite are known to adopt various modes of coordination to metal centres,[5–8] including, respectively, $\mu\text{-}\eta^1,\eta^1$-(*O*,*O*) and $\mu\text{-}\eta^1,\eta^1$-(*N*,*O*) binding to bimetallic units. It has been suggested that the nature of the metal-coordinated atom(s) may influence the nature of the reduction products of nitrate and nitrite.[9] In the case of the nitrite ion, the possibility of an asymmetrical $\mu\text{-}\eta^1,\eta^1$-(*N*,*O*) coordination to a bimetallic fragment is particularly attractive since this might allow the reductive cleavage of an N–O bond, with conservation of an M–O bond and *without* the release of NO, which would circumvent the difficulty of re-binding this molecule for further reduction. Several examples of $\mu\text{-}\eta^1,\eta^1$-(*N*,*O*) coordination of NO_2^- have been reported,[5,6,7a] and in some cases the nitrite (nitrate) complex was obtained by substitution of NO_2^- (NO_3^-) for MeCN ligands.[5,6] We therefore examined the reaction of the bis(acetonitrile) complex $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ (**1**$^+$)[10] with nitrate and nitrite. However, these reactions did not produce NO_3^- or NO_2^- derivatives, but the amidato complex, $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^{0/+}$ (**2**$^{0/+}$), which we already knew to arise from hydration of one acetonitrile ligand in **1**$^+$, and which we fully characterized in a previous study.[11] An example of a nitrite-promoted hydration of acetonitrile has previously been reported.[12] In this case, coordination of the nitrite anion to a $\{Cr(\mu\text{-}OH)_2Cr\}$ core resulted in the cleavage of one hydroxy bridge and attack of this on a non-coordinated acetonitrile molecule. The coordinated nitrite was released upon formation of the amidato bridge.[12]

In this paper, we report the reactions of **1**$^+$ with NO_3^- and NO_2^- as well as the electrochemical behaviour of the reaction product, the amidato complex **2**$^{0/+}$.

Results and Discussion

Reaction of NO_3^- or NO_2^- with $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ ($\mathbf{1}^+$)

The bis(acetonitrile) complex $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ ($\mathbf{1}^+$) undergoes two diffusion-controlled, reversible, one-electron oxidation steps ($E_{1/2}^{ox1}$ = –0.20 V; $E_{1/2}^{ox2}$ = 0.45 V) and an irreversible reduction (E_p^{red} = –2.2 V) in MeCN/$[NBu_4][PF_6]$.[10,13] $\mathbf{1}^+$ is stable in this electrolyte, as shown by control CVs[13] over a period of several hours. Addition of a large excess of NO_3^- to a solution of $\mathbf{1}^+$ in MeCN/$[NBu_4][PF_6]$ leads to drastic changes of the cyclic voltammogram: the two reversible oxidations and the irreversible reduction of $\mathbf{1}^+$ are replaced by two oxidation and two reduction steps, the relative intensities of which change with time. After several minutes, two couples with $E_{1/2}^{ox}$ = 0 V and $E_{1/2}^{red}$ = –0.81 V have developed at the expense of the other two redox systems with $E_{1/2}^{ox}$ = 0.27 V and E_p^{red} = –1.3 V.

In THF/$[NBu_4][PF_6]$, a solution of $\mathbf{1}^+$ instantly turns from red-orange to yellow upon addition of one equivalent of NO_3^-. The CV recorded immediately after mixing (Figure 1a) shows that the reversible oxidations of $\mathbf{1}^+$ ($E_{1/2}^{ox1}$ = –0.25 V; $E_{1/2}^{ox2}$ = 0.37 V in THF/$[NBu_4][PF_6]$) are replaced by two oxidation ($E_{1/2}^{ox}$ = 0.01 V; $E_{1/2}^{ox}$ = 0.24 V) and two reduction steps ($E_{1/2}^{red}$ = –0.80 V; E_p^{red} = –1.37 V), very similar to those observed in MeCN. After about two hours stirring, the redox systems with $E_{1/2}^{ox}$ = 0.24 V and E_p^{red} = –1.37 V have almost completely disappeared (Figure 1b). The metal-containing product, which possesses the same redox potentials as the amidato complex $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^+$ ($\mathbf{2}^+$; $E_{1/2}^{ox}$ = 0 V; $E_{1/2}^{red}$ = –0.80 V) [11] in THF and MeCN electrolytes, could not be separated from the supporting electrolyte. However, the nature of the product was confirmed by the ^{1}H NMR spectrum of the compound obtained by reaction of $\mathbf{1}^+$ with NO_3^- in THF without supporting electrolyte, and treatment of the reaction mixture with $NaBH_4$ before work-up. The ^{1}H NMR spectrum showed that the reduced amidato complex **2**[11] had formed under these conditions.

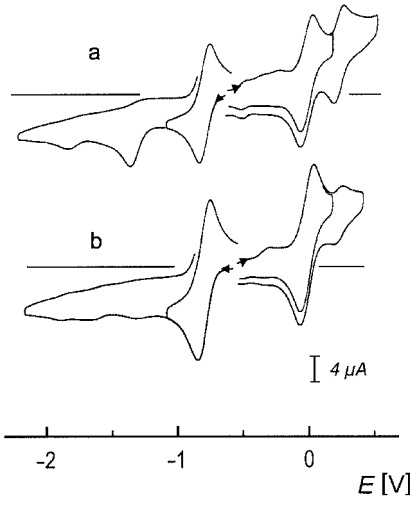

Figure 1. Cyclic voltammetry of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ ($\mathbf{1}^+$; 1.1 mM) in THF/$[NBu_4][PF_6]$ a) immediately after addition of 1 equiv. of $[NBu_4][NO_3]$, and b) after 2 h stirring (vitreous carbon electrode, v = 0.2 V s^{-1}; potentials are against ferrocene/ferrocenium).

Similar experiments were performed with nitrite (Figure 2). Although the reaction of $\mathbf{1}^+$ with NO_2^- is faster than with NO_3^-, a CV recorded immediately after addition of one equivalent of $\mathbf{1}^+$ to a THF solution of NO_2^- (Figure 2, a) allowed the detection of an intermediate with $E_{1/2}^{ox}$ = 0.21 V and E_p^{red} = –1.39 V, in addition to the final product $\mathbf{2}^+$ (Figure 2, b). Different to the reaction with NO_3^-, the amidato complex formed upon reaction of $\mathbf{1}^+$ with nitrite is present as a mixture of the neutral and cationic forms (**2**/$\mathbf{2}^+$; Figure 2, b). Voltammetry at a rotating disc electrode confirmed this. The nature of the metal product was again ascertained by comparison of the ^{1}H NMR spectrum of the complex isolated (after reduction by $NaBH_4$) from the reaction carried out in THF in the absence of supporting electrolyte, with that of an authentic sample of **2**. The reaction of $\mathbf{1}^+$ with NO_3^- or NO_2^- can be represented as shown in Scheme 1. The CVs in Figures 1b and 2b show that minor co-products, which we have not attempted to characterize, are also present.

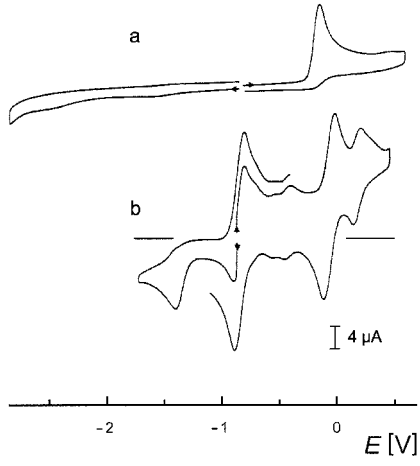

Figure 2. Cyclic voltammetry of a solution of $[NBu_4][NO_2]$ (1 mM) in THF/$[NBu_4][PF_6]$ a) before, and b) immediately after addition of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ ($\mathbf{1}^+$; 1 mM, 1 equiv.) (vitreous carbon electrode, v = 0.2 V s^{-1}; potentials are against ferrocene/ferrocenium).

In THF, $\mathbf{2}^+$ (or **2**) is not formed from $\mathbf{1}^+$ in the absence of NO_x^- on the timescale of the experiments described above. Therefore, these ions clearly promote the formation of the amidato complex $\mathbf{2}^+$ (or **2**). Two different properties of NO_x^- might explain their role in the reaction. The first possibility is that NO_x^- acts as a ligand, replacing one of the MeCN groups of $\mathbf{1}^+$. Coordination and reduction of nitrate or nitrite ions by oxo transfer to a metal centre have been reported.[14] In the case of transition-metal nitrite complexes, transfer of an oxygen atom to an organic substrate has also been observed, the NO_2^- ligand being N-bound (*nitro* coordination) to the metal.[15] In the present study, the similarity of the redox potentials of the intermediates

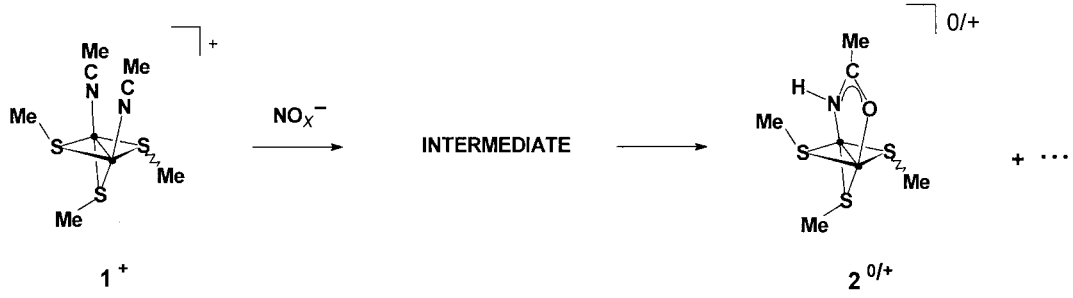

Scheme 1. ● = MoCp; x = 2 or 3.

detected during the course of the reaction of $\mathbf{1}^+$ with either nitrate or nitrite suggests that the intermediates should be similar, that is with a *nitrito* coordination of NO_2^-. The amidato complex would then result from a sequence of reactions that includes the release of an $NO_{(x-1)}$ species (neutral or anionic) and the transfer of a proton or of a H atom from the environment. The release of a nitrite *anion* in the reaction of $\mathbf{1}^+$ with NO_3^- is unlikely since we did not detect the oxidation peak of NO_2^- (see Figure 2, a) by CV after completion of the reaction of $\mathbf{1}^+$ with NO_3^- (Figure 1, b). The fact that $\mathbf{2}^+$ is formed by treating $\mathbf{1}^+$ with NO_3^- while a mixture of $\mathbf{2}/\mathbf{2}^+$ results from the reaction of $\mathbf{1}^+$ with NO_2^- might arise from homogeneous redox steps involving nitrogen oxides released in the reactions.

The second possibility is that the NO_x^- anion acts as a base [HNO_3/NO_3^-: pK_a = 8.89 in MeCN].[16] Since the experiments were not conducted under rigorously anhydrous conditions, residual water in the solvent might be involved. Thus, deprotonation of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)(H_2O)]^+$, a possible precursor of $\mathbf{2}^+$, by nitrate or nitrite would lead to a hydroxo ligand and thus promote the formation of $\mathbf{2}^+$ (or **2**). This would be similar to the postulated mechanism of hydrolytic reactions catalysed by enzymes possessing two metal ions in close proximity at the active site. It is thought that the metal centres in these enzymes act cooperatively, the role of one of them being to modify the pK_a of a bound water molecule, thus generating a hydroxide ligand that attacks the substrate present at the neighbouring metal centre.[17,18] Similar reactions can involve mononuclear complexes. The metal-promoted hydrolysis of a nitrile ligand in the side chain of a tetrazamacrocyclic Cu complex has been reported recently.[19]

If this is the case in our study, the intermediate detected in the reaction of $\mathbf{1}^+$ with NO_x ions would be either a hydroxo complex or a species derived therefrom. However, it is not clear why such an intermediate would be longer-lived when generated by the reaction of $\mathbf{1}^+$ with NO_3^- than when it arises from the reaction of $\mathbf{1}^+$ with nitrite.

In order to discriminate between the above possibilities, we conducted two types of experiments, namely the reaction of $\mathbf{1}^+$ with a base (Et_3N: pK_a = 18.5 in MeCN)[20] and, the reaction of $\mathbf{1}^+$ with a weakly basic, oxygen-containing anion ClO_4^- [$HClO_4/ClO_4^-$: pK_a = 1.6 in MeCN].[21]

The reaction of $\mathbf{1}^+$ with Et_3N (1.2 equiv.) was monitored by cyclic voltammetry in THF/$[NBu_4][PF_6]$. Although the characteristic couples of $\mathbf{1}^+$ were replaced by reversible systems at –0.67 V and 0.67 V on addition of Et_3N, the CV did not show the formation of an intermediate such as the one observed on treatment with nitrate or nitrite. Small reversible couples around –0.8 V and 0 V suggested that only a small amount of the amidato complex might be produced. Therefore, it appears unlikely that $\mathbf{2}^{+/0}$ results from the deprotonation of an aqua precursor. It is worth noting that reaction of $\mathbf{1}^+$ with chloride, the basicity of which is very similar to that of nitrate (HCl/Cl^-: pK_a = 8.94 in MeCN),[16] produces the known $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(\mu\text{-}Cl)]$ complex by the substitution of Cl^- for a MeCN ligand.[10]

The CV of $\mathbf{1}^+$ in MeCN is not affected by the presence of a large excess of ClO_4^- (supporting electrolyte: $[NEt_4][ClO_4]$). On the contrary, the CV of $\mathbf{1}^+$ recorded in THF/$LiClO_4$ or in THF/$[NBu_4][PF_6]$ in the presence of ClO_4^- is totally different from that obtained in the absence of perchlorate. The characteristic redox couples of $\mathbf{1}^+$ are not observed in the presence of ClO_4^-. Instead, redox systems similar to those present after addition of NO_x^- to a solution of $\mathbf{1}^+$ are detected. A small amount of $\mathbf{2}^+$, characterized by a reduction around –0.8 V and an oxidation at 0 V, is present in solution (Figure 3, a), and its concentration increases slowly with time.

The major compound present in a THF solution of $\mathbf{1}^+$ in the presence of ClO_4^- could not be isolated. It clearly arises from a reaction between the metal complex and perchlorate. That the redox potentials of this species ($E_{1/2}^{ox}$ = 0.23 V, E_p^{red} = –1.27 V in THF/Li[ClO_4]; $E_{1/2}^{ox}$ = 0.23 V, E_p^{red} = –1.4 V in THF/$[NBu_4][PF_6]$ + 2 equiv. ClO_4^-) are close to those of the intermediate observed upon addition of NO_x^- to $\mathbf{1}^+$ suggests that the nature of the metal compound responsible for these couples is similar in each case. However, whereas the amidato complex is formed essentially quantitatively from the intermediate observed upon treating $\mathbf{1}^+$ with NO_3^- or with NO_2^- (**2** is also formed in the latter case) within a few minutes (NO_2^-) or a few tens of minutes (NO_3^-), formation of the amidato complex $\mathbf{2}^+$ from the perchlorate intermediate is very much slower, while that of **2** requires an electrochemical reduction step.

The control experiments with Et_3N and ClO_4^- demonstrate that the basic properties of the reactant, that is its ability to deprotonate coordinated water, are not essential to the formation of $\mathbf{2}^{+/0}$. It is therefore unlikely that the residual water of the solvent plays a pivotal part in the pro-

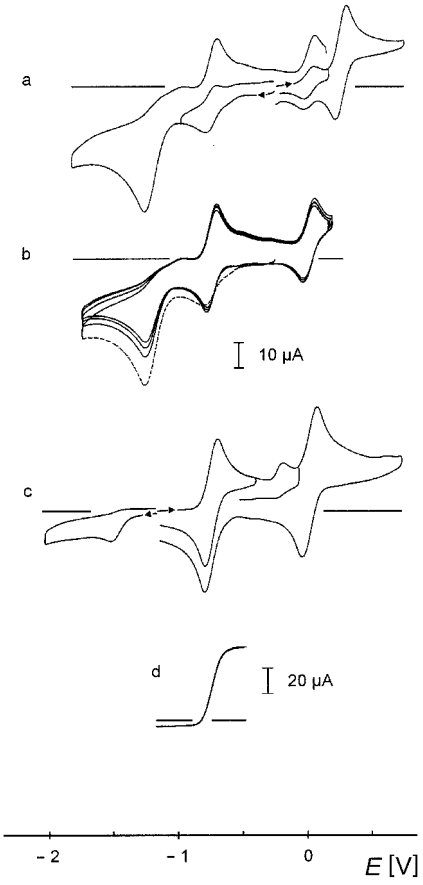

Figure 3. Cyclic voltammetry of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)_2]^+$ ($\mathbf{1}^+$; 2 mM) in THF/$LiClO_4$ recorded immediately after the addition of the metal complex (a); the curve in b) represents repetitive scans in the potential range –1.8/0.2 V and the dashed curve is the first negative-going scan; the cyclic voltammogram in (c) and the RDE voltammogram in (d) were obtained after controlled-potential electrolysis of the solution in b) at –1.4 V on a graphite cathode (n = 2 F per mol of $\mathbf{1}^+$) (vitreous carbon electrode, v = 0.2 V s^{-1}; potentials are against ferrocene/ferrocenium).

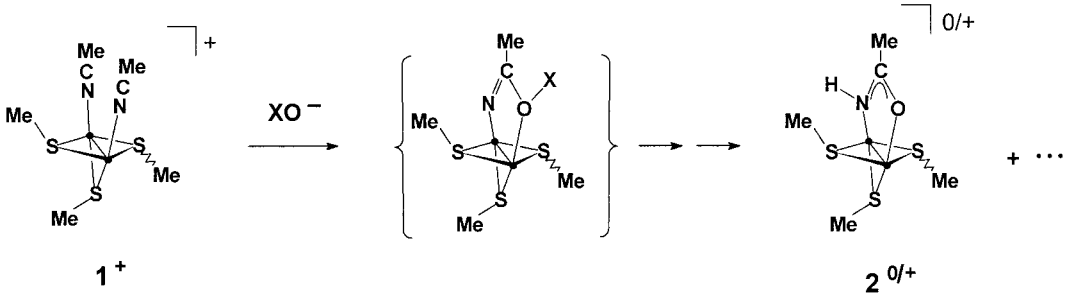
cess on the timescale of the electrochemical experiments.That the amidate derivative was obtained upon treatment of $\mathbf{1}^+$ with different oxo anions strongly suggests that the oxygen atom in $\mathbf{2}^{+/0}$ comes from the XO^- moiety bound to a metal centre (X = NO, NO_2 or ClO_3).

Metal complexes containing perchlorate ligands have been reported.[18,22] However, in these compounds ClO_4^- can generally be substituted by a variety of ligands, in contrast to what is observed here: addition of a large excess of acetonitrile has no effect on the CV shown in Figure 3a. Therefore, it is unlikely that the species observed in THF in the presence of perchlorate arises from the simple substitution of ClO_4^- for one MeCN ligand in $\mathbf{1}^+$. Rather, an intermediate such as the one shown in Scheme 2 can be envisaged. The absence of a perchlorate derivative in MeCN/$[NEt_4][ClO_4]$ would then arise from the worse coordinating ability of ClO_4^- as compared to acetonitrile.

The reduced amidato complex **2** is generated from the intermediate formed in the reaction of $\mathbf{1}^+$ with perchlorate by reduction at –1.3 V (Figures 3a and b). This was confirmed by voltammetry of the catholyte after controlled-potential electrolysis (E_{el} = –1.4 V, graphite cathode), as shown in Figures 3c and 3d. However, the charge consumed to produce **2** was between 1.4 and 2 F per mol of $\mathbf{1}^+$, while $\mathbf{2}^+$ was the major product formed after the transfer of about 1 F per mol of $\mathbf{1}^+$. Assuming that the intermediate is as shown in Scheme 2, the formation of $\mathbf{2}^+$ in the early stage of the electrolysis would be consistent with a (one-electron) reductive elimination of X^- (e.g. ClO_3^-) accompanied (or followed) by a protonation step. The reduction of $\mathbf{2}^+$ ($E_{1/2}^{red}$ = –0.8 V) at the electrolysis potential completes the reduction process. A small amount of an unknown product is also present after electrolysis (Figure 3c).

It has been shown that coordinated nitriles can be attacked by carbonate to produce an amide derivative with the release of CO_2.[23] Oxyfunctionalizations of coordinated nitriles with various oxygen-containing substrates have also been reported.[24] A direct attack of XO^- (X = NO, NO_2 or ClO_3) on one of the MeCN ligands of $\mathbf{1}^+$ could also take place. However, this possibility appears less likely on the basis of the experiments carried out in MeCN, since the formation of $\mathbf{2}^+$ from $\mathbf{1}^+$ and NO_3^- is slower than in THF or requires a large excess of nitrate, while no reaction occurred in the presence of ClO_4^-, even when used in very large excess (supporting electrolyte). The fact that the redox potentials of the intermediates detected in the reactions of $\mathbf{1}^+$ with NO_2^-, NO_3^- or ClO_4^- are very similar in THF suggests that they must be closely related. While the intermediate formed by treating $\mathbf{1}^+$ with nitrate and nitrite produces $\mathbf{2}^{+/0}$ within a relatively short time, it appears longer-lived when obtained by reaction of $\mathbf{1}^+$ with perchlorate. As the intermediate could not be isolated from the solution, its nature is not known and the reason for this difference could



Scheme 2. Postulated intermediate in the reaction of $\mathbf{1}^+$ with XO^- (X = NO_2, NO or ClO_3). ● = MoCp.

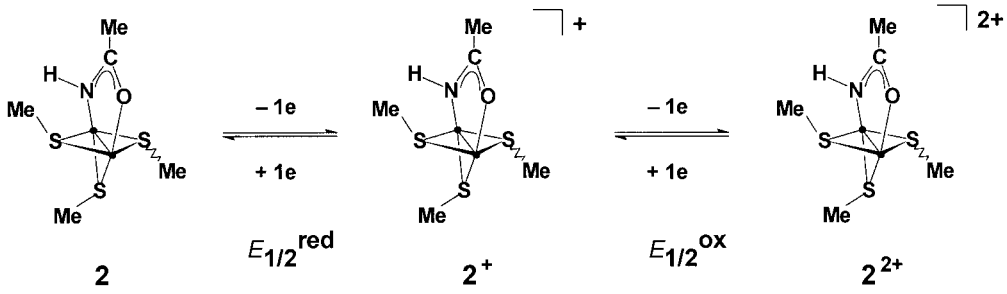

Scheme 3. ● = MoCp.

not be elucidated. However, if the precursor of the amidato complex is as shown in Scheme 2, the different lifetimes might indicate that the X–O bond is stronger for X = Cl than for X = N.

The reactivity of $\mathbf{1}^+$ reveals the occurrence of a bimetallic effect in the $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ moiety. Treatment of $\mathbf{1}^+$ with chloride or trifluoroacetate produces complexes where the anion occupies a bridging position.[10,32] This indicates that the remaining MeCN ligand in the likely intermediate $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(MeCN)X]$ (X = Cl, CF_3CO_2) is released upon X bridging. Despite the ability of NO_3^- and NO_2^- to adopt bridging coordination modes,[5,6,7a] this was not observed at the $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ core, and the amidato complex $\mathbf{2}^+$ (and **2**) was obtained instead. Therefore, it appears that the reactivity (the lability) of the acetonitrile bound to one Mo atom is affected by the nature of the ligand present at the adjacent metal centre of the $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ site.

Electrochemistry of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^{0/+}$ ($\mathbf{2}^{0/+}$)

Several compounds containing an amidato ligand are known,[17,18,25] although no electrochemical study of such a complex has been reported so far, to the best of our knowledge. We now report the electrochemistry of $\mathbf{2}^{0/+}$ in THF and MeCN containing $[NBu_4][PF_6]$. We paid special attention to the reduction of $\mathbf{2}^+$ in the presence of acid in order to investigate the mechanism of the release of the amidato ligand as acetamide.[11]

Complex $\mathbf{2}^+$ undergoes diffusion-controlled, one-electron reduction and oxidation steps in both solvents (Scheme 3). Controlled-potential electrolysis at –1.0 V afforded the neutral compound **2** essentially quantitatively[26] after transfer of 1 F per mol of $\mathbf{2}^+$.

The CV of $\mathbf{2}^+$ in MeCN/$[NBu_4][PF_6]$ (Figure 4, a) is strongly affected by the presence of protons, although the changes only concern the reduction step, which becomes irreversible and shifts by about 100 mV towards positive potentials (Figure 4, b). This is indicative of the occurrence of a follow-up reaction (EC process)[13,27,28] under these conditions.

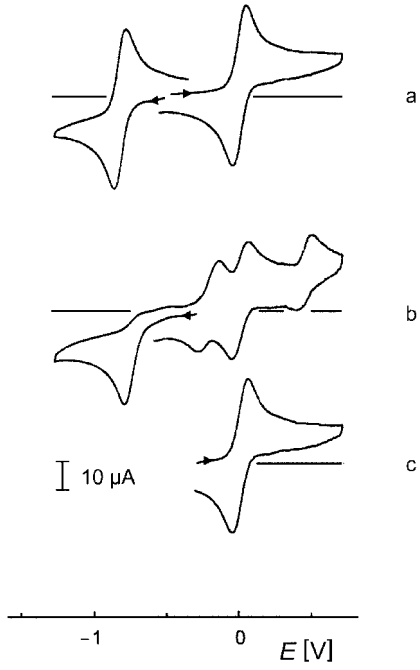

Figure 4. Cyclic voltammetry of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^+$ ($\mathbf{2}^+$; 1 mM) in MeCN/$[NBu_4][PF_6]$ a) before, and b) and c) after addition of an excess of HBF_4/H_2O (vitreous carbon electrode, v = 0.2 V s^{-1}; potentials are against ferrocene/ferrocenium).

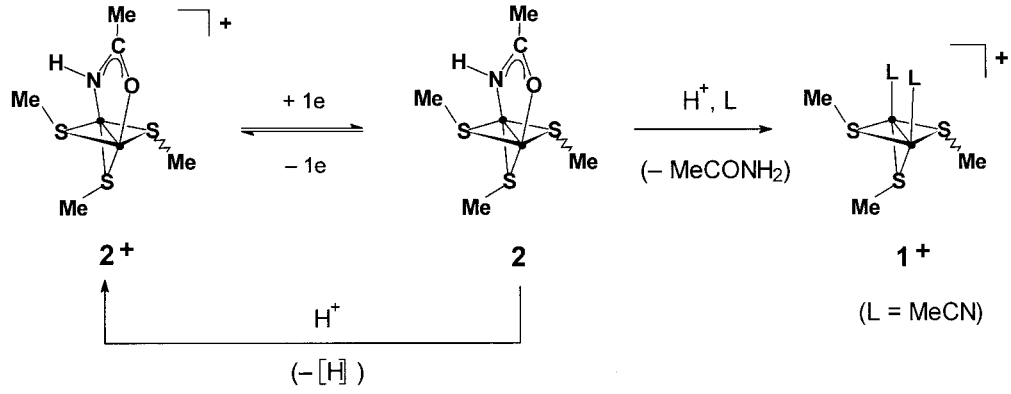
The reduction of $\mathbf{2}^+$ in the presence of acid in MeCN/$[NBu_4][PF_6]$ affords a product that was identified as $\mathbf{1}^+$ from its redox systems detected on the return scan (Figure 4, b). Controlled-potential electrolysis at –0.9 V effectively produces $\mathbf{1}^+$. However, the CV recorded after the passage of 1 F per mol of $\mathbf{2}^+$ demonstrates that $\mathbf{2}^+$ is still present in solution; conversion of $\mathbf{2}^+$ to $\mathbf{1}^+$ is almost complete (>90%)[26] only after the transfer of about 1.5 F per mol of $\mathbf{2}^+$. While these experiments are entirely consistent with previous ones showing that protonation of **2** in MeCN produces $\mathbf{1}^+$ and acetamide,[11] they also suggest that part of the charge consumed during electrolysis is used to reduce protons. This can be described as shown in Scheme 4.

In contrast to what is observed in MeCN/$[NBu_4][PF_6]$, addition of two equivalents of HBF_4/H_2O to a THF/$[NBu_4][PF_6]$ solution of $\mathbf{2}^+$ did not lead to a significant change of the cyclic voltammogram. However, in the pres-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4. ● = MoCp.

ence of larger amounts of acid (10–20 equiv. HBF_4/H_2O or HBF_4/Et_2O), the reduction of $\mathbf{2}^+$ in this solvent occurs according to an EC process, as shown by the decrease of the anodic-to-cathodic peak current ratio $[(i_p^a)/(i_p^c)^{red}]$, and by the presence of a product (**3**) detected by its redox steps on the return scan at $E_{1/2}$ = –0.43 V and 0.21 V (Figure 5, b; note that the presence of acid has no effect on the oxidation, cf. Figure 5, c).

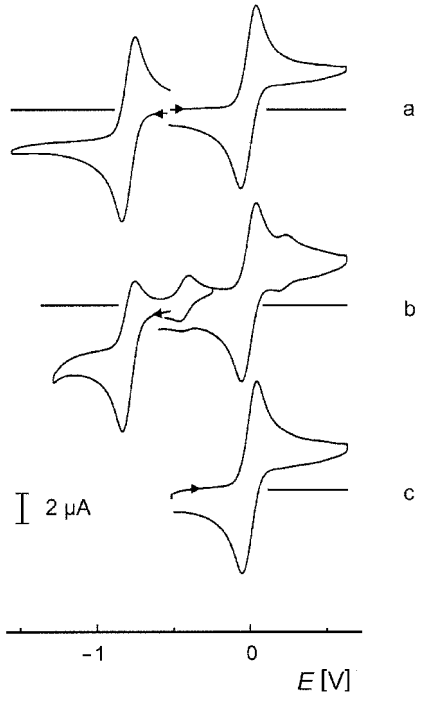


Figure 5. Cyclic voltammetry of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^+$ ($\mathbf{2}^+$; 1 mM) in THF/$[NBu_4][PF_6]$ a) before, and b) and c) after addition of a large excess (17 equiv.) of HBF_4/Et_2O (vitreous carbon electrode, v = 0.05 V s^{-1}; potentials are against ferrocene/ferrocenium).

Cyclic voltammetry after controlled-potential reduction of $\mathbf{2}^+$ in the presence of acid (10 equiv. HBF_4/Et_2O) in THF shows that a substantial amount of the starting material $\mathbf{2}^+$ is still present along with product **3** after the passage of 2 and 3 F per mol of $\mathbf{2}^+$ (ca. 60% and 50% $\mathbf{2}^+$ present, respectively).[26] This clearly shows that the charge diverted to reduce protons (see Scheme 4) is larger in THF than in MeCN. Consistent with this, addition of H^+ to an electrogenerated solution of **2** in THF leads to the formation of $\mathbf{2}^+$ along with product **3** (Figure S1c in the Supporting Information). Complex **3** decomposed upon work-up. However, its reaction with acetonitrile affords $\mathbf{1}^+$.[29] This indicates that **3** retains the $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ core and possesses labile ligand(s) bound to the metal centres. Species such as $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(L)(L')]^+$ (L, L′ = THF and/or H_2O), or a derivative retaining the acetamide ligand, $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(NH_2COMe)(L)]^+$ (L = THF or H_2O), are possible. It should be noted that protonation of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(\mu\text{-}NH_2)]$ with HBF_4/H_2O in MeCN affords $\mathbf{1}^+$, while a product tentatively assigned as $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(NH_3)(THF)]^+$ [$E_{1/2}^{ox}$ = –0.39 V and 0.31 V] was obtained by protonation with HBF_4/Et_2O in THF.[30]

As mentioned above, a major difference between the CV experiments carried out in THF and in MeCN lies with the detection of **2** in the former solvent, even in the presence of a large excess of acid. The addition of MeCN to an acidic THF solution of $\mathbf{2}^+$ leads to the CV detection of $\mathbf{1}^+$ instead of **3** on the reverse scan (see Figures 6a and b), without a change in the characteristics of the reduction process $[(i_p^c)^{red}, (i_p^a/i_p^c)^{red}]$, that is, without a change in the overall kinetics of the following chemical reaction(s). Therefore, the solvent-dependence of the kinetics of the reduction of $\mathbf{2}^+$ in the presence of acid does not originate in the solvent-binding step itself. This would be consistent with the fact that $\mathbf{1}^+$ is formed from **3**.

Monitoring the course of the reaction of **2** with a large excess of acid by amperometry at a rotating disc electrode (E = –0.6 V, on the plateau of the first oxidation of **2**) indicates[31] the existence of an equilibrium between **2** and a protonated intermediate, which would be shifted by the slower conversion of the intermediate into products [$\mathbf{2}^+$ (with loss of an H atom) and **3** or $\mathbf{1}^+$ (with the release of the amidato bridge upon L binding) in THF or MeCN respectively] (Scheme 5).[32]

The possibility of releasing the amidato bridge upon electrochemical reduction of $\mathbf{2}^+$ in the presence of 10–20 equiv. of acid in THF was confirmed by controlled-potential electrolyses performed in the presence of an excess of substrate

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

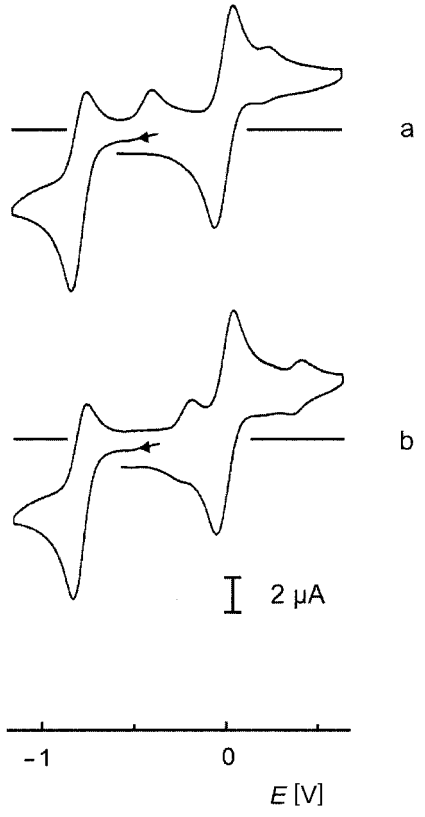

Figure 6. Cyclic voltammetry of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]^+$ (**2**$^+$; 1 mM) in THF/$[NBu_4][PF_6]$ in the presence of a large excess (17 equiv.) of HBF_4/Et_2O a) before, and b) after addition of MeCN (vitreous carbon electrode, $v = 0.05\ V\,s^{-1}$; potentials are against ferrocene/ferrocenium).

(10 equiv. *t*BuNC). Under these conditions, the bis(isocyanide) analogue of **1**$^+$ was obtained in about 80% yield[26] along with **2**$^+$, after the transfer of more than 2 F per mol of **2**$^+$. The nature of the product was confirmed by comparison of its redox potentials with those of an authentic sample of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(t\text{BuNC})_2]^+$.[34]

Conclusions

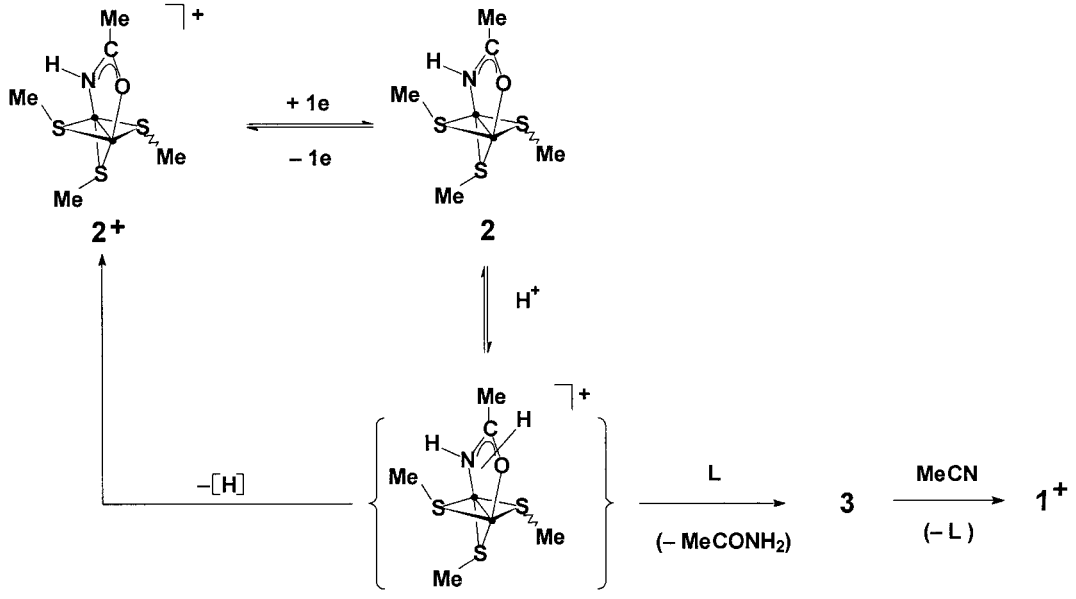
The results reported in this paper illustrate an original oxyfunctionalization of an acetonitrile bound to a bimetallic sulfur core $\{Mo_2(Cp)_2(\mu\text{-}SMe)_3\}$ by oxygen-containing anions, XO^- (X = NO, NO_2, ClO_3), which initially arises from substitution (or less likely direct attack) of MeCN by XO^-, and produces the amidate complex **2**$^{0/+}$.

The electrochemical reduction of **2**$^+$ in the presence of acid demonstrates that the amidate bridge can be released, since **1**$^+$, the precursor of **2**$^+$, is regenerated when the reactions are carried out in MeCN. Because **2**$^+$ is also formed from **1**$^+$ in a wet atmosphere,[11] the present results exemplify the possibility of a cyclic conversion of acetonitrile into acetamide.

Experimental Section

Methods and Materials: All experiments were carried out under an inert atmosphere using Schlenk techniques. THF was purified as described previously.[33] Acetonitrile (Merck, HPLC grade) was used as received. The fluoroboric acid [diethyl ether complex and aqueous solution (Aldrich)], was used as received. The preparation and the purification of the supporting electrolyte $[NBu_4][PF_6]$ and the electrochemical equipment were as described previously.[33] All the potentials quoted in the text and figures are relative to the ferrocene-ferrocenium couple; ferrocene was added as an internal standard at the end of the experiments. ^{1}H NMR spectra were recorded on a Bruker AC300 spectrometer. Shifts are relative to tetramethylsilane as an internal reference. Complexes $[Mo_2(Cp)_2(\mu\text{-}SMe)_3(L)_2]^+$ (L = MeCN, *t*BuNC) were synthesised as described previously.[10,34]

Preparation of $[Mo_2(Cp)_2(\mu\text{-}SMe)_3\{\mu\text{-}\eta^1,\eta^1\text{-}OC(Me)NH\}]$ (2) by treatment of 1$^+$ with NO_x^- (x = 2, 3): In a typical experiment, a



Scheme 5. ● = MoCp; the species in brackets was not detected.

mixture of $\mathbf{1}^+$ (0.0565 g, 8.9×10^{-5} mol) and $[NBu_4][NO_3]$ (0.1445 g, 4.7×10^{-4} mol, 5.3 equiv.) in 15 mL of THF was stirred under dinitrogen for 3 h. After filtration, the solution was taken to dryness. The solid was dissolved in MeCN and $NaBH_4$ was added in excess (0.017 g, 4.5×10^{-4} mol, 5 equiv.). The solution was stirred for 30 min and then filtered to remove a brown precipitate. The volume of the solution was reduced to 2 mL under reduced pressure, and addition of Et_2O (15 mL) led to the formation of a white precipitate. The latter was removed by filtration, and the solution was taken to dryness. The solid residue was dried under vacuum. The ^1H NMR spectrum of the solid demonstrated that the amidate complex **2** had formed. CV of the NMR sample showed the presence of **2**, with a small amount of $\mathbf{2}^+$ resulting from the oxidation of the neutral complex ($E_{1/2}{}^{ox} = -0.8$ V).

A similar procedure was followed for the reaction of $\mathbf{1}^+$ with nitrite. $[NBu_4][NO_2]$ (0.0182 g, 6.3×10^{-5} mol) and $\mathbf{1}^+$ (0.0418 g, 6.6×10^{-5} mol) were dissolved in THF (15 mL). The solution was stirred for about 1 h, after which time it was taken to dryness. The solid was dissolved in MeCN (10 mL) and an excess of $NaBH_4$ (0.0164 g, 4.3×10^{-4} mol, 6.6 equiv.) was added. After a few minutes stirring, the solvent was evaporated under reduced pressure. Et_2O (10 mL) was added to the residue, and after 10 min stirring the solution was filtered and taken to dryness. The solid was stirred for 10 min in pentane (5 mL), and, after evaporation of the solvent, the solid was dried under vacuum. As above, the ^1H NMR spectrum of the solid demonstrated that the amidate complex **2** had formed.

[26] The yield of the reduction of $\mathbf{2}^{+}$ was calculated by comparing the peak current of the reactant to that of the product, assuming identical diffusion coefficients.

[27] a) A. J. Bard, L. R. Faulkner, *Electrochemical Methods. Fundamentals and Applications*, John Wiley & Sons, New York, **1980**, chapter 11, pp 429–485; b) E. R. Brown, R. F. Large, in *Techniques of Chemistry*, vol. I – *Physical Methods of Chemistry*, Part IIA (Ed.: A. Weissberger), John Wiley & Sons, New York, **1971**, chapter 6, pp 423–530.

[28] The variations of the current function $[i_p^{red}(H^+)/v^{1/2}]$ associated with the reduction peak of $\mathbf{2}^{+}$ in the presence of acid $[i_p^{red}(H^+)]$ against scan rate, and the peak current ratio of the reduction in the presence and in the absence of protons $[i_p^{red}(H^+)/i_p^{red} \approx 1.1]$ are consistent with the transfer of a single electron in the reduction in the presence of acid. Also, the fact that the oxidation of $\mathbf{2}^{+}$ is not affected by the presence of H^+ (Figure 4, c) indicates that $\mathbf{2}^{+}$ is not protonated, and that the change in the reduction step arises from the protonation of electrogenerated **2** (EC process).

[29] Addition of MeCN to the solution in Figure S1c (see Supporting Information) results in the conversion of product **3** into $\mathbf{1}^{+}$. This indicates (see part b in Figure 6) that $\mathbf{1}^{+}$ is most probably formed from **3**, with no change in the reduction mechanism due to the presence of MeCN.

[30] F. Y. Pétillon, P. Schollhammer, J. Talarmin, *J. Chem. Soc., Dalton Trans.* **1997**, 4019–4024.

[31] The oxidation current measured at the rotating disc electrode drops to the background level on addition of H^+ to **2** in MeCN, which shows that **2** is removed very rapidly from the solution. In contrast, after an initial abrupt fall of about 30% on adding H^+ to a THF solution of **2**, the oxidation current decreases more slowly.

[32] The mechanism in Scheme 5 was used for CV simulations (VirtualCV 1.0, written by A. Laouénan, is available on the web). The main characteristics of the CVs in Figures 6a and 6b $\{[(i_p^a/i_p^c)^{red}\ \mathbf{2}^{+}]$, $[i_p^a(\mathbf{3})$ or $(\mathbf{1}^{+})/i_p^c(\mathbf{2}^{+})]\}$ were reproduced assuming that $\mathbf{1}^{+}$ is formed from **3**.[29] The solvent-dependence of the overall kinetics (see Figures 4b and 5b) was simulated by an increase of the forward rate constant for protonation, and of the second-order rate constant for the solvent-binding step, on going from THF to MeCN. This is entirely consistent with the fact that HBF_4/H_2O (i.e. H_3O^+) and HBF_4/Et_2O should be stronger acids in MeCN than in THF, and with the properties of MeCN compared to THF as a ligand for the metal sites in this type of complexes. The fact that the amount of $\mathbf{2}^{+}$ formed on reacting **2** with H^+, and that the charge used to reduce protons upon electrolysis of acidic solutions of $\mathbf{2}^{+}$, are larger in THF than in MeCN is assigned to the smaller rate constant of the substrate-binding step (Scheme 5) in the former. This is consistent with the fact that protonation of **2** in MeCN produces $\mathbf{1}^{+}$ with little $\mathbf{2}^{+}$.

Coordination Chemistry of *N*,*N*,*N*′,*N*′-Tetraethylpyridine-2,6-dithiocarboxamide (*S*-dept) – X-ray Crystal Structures and Magnetic Properties of [Co(*S*-dept)X_2] (X = Br, I, and NCS)

Keywords: *N*,*N*,*N*′,*N*′-Tetraethylpyridine-2,6-dithiocarboxamide / X-ray crystallography / IR / Zero-field splitting / EPR

Mononuclear cobalt(II) complexes [Co(*S*-dept)X_2] [X = Br (**1**), I (**2**) and NCS (**3**)] were synthesized using *N*,*N*,*N*′,*N*′-tetraethylpyridine-2,6-dithiocarboxamide (*S*-dept), and characterised by conductivity, spectral and single-crystal X-ray diffraction studies. These studies reveal that the compounds consist of discrete monomeric molecules in which the cobalt atoms are five-coordinate in an environment that is best described as being distorted square-pyramidal. In dimethylformamide the iodo complex shows significant ionic dissociation (1:1 electrolyte) and its crystal field absorption spectrum is interpretable in terms of an octahedral structure [Co(*S*-dept)$(DMF)_2$I]$^+$. The temperature dependence of the magnetic susceptibility data is indicative of a high-spin compound with an important zero-field splitting. The best fit was obtained with $|D| = 20.5\ cm^{-1}$ and $g = 2.53$ for **1**, $|D| = 14.2\ cm^{-1}$ and $g = 2.38$ for **2** and $|D| = 17.7\ cm^{-1}$ and $g = 2.35$ for **3**. The X-band EPR spectra at low temperature is also characteristic of an $S = 3/2$ state with important zero-field splitting. The most important band appears at low fields (ca. 1200 G).

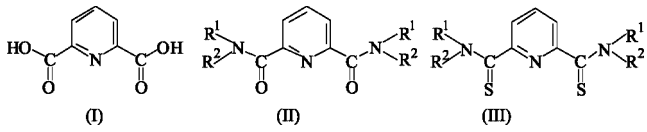
Introduction

There has been a growing interest in the development of coordination chemistry of nonmacrocyclic multidentate ligands derived from pyridine-2,6-dicarboxylic acid (I).[1,2] The symmetrical tertiary amide side arms at the 2- and 6-positions of the central pyridine ring provide a variety of novel *ONO*-tridentate receptors for binding to metal ions (II).[2] The inflexibility of the ligand in these systems has been one of the important factors leading to the isolation of low-symmetry five-coordinate complexes of Cu^{II}, Co^{II}, Ni^{II}[3–6] and nine-coordinate complexes of lanthanide ions.[2] Steric and electronic consequences brought by peripheral substitutions to the terminal carboxamide side arms have been well illustrated by Piguet et al.[2] on the complexation of Ln^{III} ions. Recently, we have extended these studies to ligands containing C=S instead of C=O bonds on the side arms at the 2- and 6-positions, i.e., ligands containing an *SNS* set of donor atoms (III).[7,8] Deviations from idealized geometries would be naturally expected because of the bulky alkyl groups on the nitrogen atoms and may cause structural constraints. *N*,*N*,*N*′,*N*′-Tetraethylpyridine-2,6-dithiocarboxamide [R^1, R^2 = Et in (III); *S*-dept] coordinates through the planar *SNS* set of donor atoms. Our recent studies on (*S*-dept)$_2MCl_2$ (M = Co and Cu) complexes have revealed significant structural differences between the two complexes.[7,8] The copper complex is composed of cationic and anionic dimers: $[Cu_2Cl_2(\mu$-*S*-dept$)_2][Cu_2Cl_4(\mu$-Cl$)_2]$. The cationic fragment exhibits an unusual Cu–Cu disposition taking place through bridging sulfur atoms, observed only in a few Cu^{II} complexes.[8] The coordination geometry around each Cu center is approximately distorted square-pyramidal. On the other hand, the cobalt complex[7] is built up of [Co(*S*-dept)(Cl)]$^+$ and $[Co_2Cl_4(\mu\text{-}Cl)_2]^{2-}$ ions. The cobalt ion in the cation has a distorted square-planar geometry. The cationic units are stacked over each other in a staggered manner so that each cobalt ion interacts weakly with a sulfur atom of a unit above and below it.



Spectrophotometric, magnetic and electrical conductivity measurements had been reported for a large number of five-coordinate complexes of cobalt(II).[9–27] In most cases, the magnetic moment was only measured at room temperature, in order to determine the spin-sate of the system [high-spin ($S = 3/2$) or low-spin ($S = 1/2$)]. For some compounds the

magnetic measurements at different temperatures were reported but not the X-ray crystal structure.[20,21] In other cases, the X-ray crystal structure was reported, but not the study of $\chi_M = f(T)$.[9–13,24,25,27,28]

To the best of our knowledge, very few high-spin five-coordinate Co^{II} complexes are structurally and magnetically characterized. Some of them are polynuclear systems[29–32] and their magnetic properties are due to the interaction between the Co^{II} ions. Only 3 mononuclear complexes are reported in the literature with the structural data and magnetic study (χ vs. T): [Co{(*t*Bu)(Me)salmdptn}],[22] [Co(saloph)(2-MeImd)][23] and $[Co(L^5)_2(H_2O)]$[26] with HL^5 = *N*-(2-chloro-6-methylphenyl)pyridine-2-carboxamide.

In this paper, we describe the crystal structure and magnetic properties of [Co(*S*-dept)X_2] (X = Br, I and NCS) compounds. The present work is aimed to determine the steric influence of the *SNS* set of donor atoms of *S*-dept on the geometry of the complexes. Our studies have revealed significant structural differences between [Co(*S*-dept)-$(NCS)_2$] and its nickel analogue.[33]

Five-coordinated mononuclear Co^{II} (d^7) complexes can be high-spin (S = 3/2), low-spin (S = 1/2) or a temperature-induced spin-transition can be observed. For high-spin Co^{II} complexes the study of the magnetic properties allows to find the value of the zero-field splitting parameters. In this work, we report the temperature dependence of the magnetic susceptibility and the fit of the experimental data allows finding the parameters of the zero-field splitting. The EPR spectra in frozen solution is also reported.

Results and Discussion

These complexes are obtained in good yield by mixing equimolar amounts of *S*-dept and the appropriate salt in anhydrous EtOH. The compounds are air- and moisture-stable and are readily soluble in the common organic solvents such as $CHCl_3$, CH_2Cl_2, and 1,2-dichloroethane. The tridentate nature of the ligand and the fact that the complexes are practically undissociated in chloroform and dichloromethane solutions suggest penta-coordination around the metal ion in these solvents. In CH_3CN and DMF solutions, the iodo complex **2** shows significant dissociation and molar conductivities are in the range typical of 1:1 electrolytes.[35] The complex most probably ionizes to give $[Co(S\text{-dept})I]^+_{solv}$ and I^- in these solutions. The conductivity data clearly show that the dissociation is less extensive for the bromo and thiocyanato complexes and molar conductivities are significantly less than the values expected for 1:1 electrolytes.

The expected positive shifts in position and changes in intensity of the principal IR bands of the pyridine ring are interpreted in favour of the coordination of *S*-dept through the pyridine ring nitrogen atom[36] in the complexes. Bands at 1263, 990, and 818 cm^{-1} may be considered as having significant contribution from C=S vibrations, based on comparison of the spectra of *O*-deap and *S*-dept. These bands show a slight downward shift in frequency in these complexes indicating coordination of the sulfur atoms. The presence of a band at 2062 cm^{-1} in **3** is consistent with *N*-bonded terminal thiocyanato groups.[37] The corresponding ν(CS) modes are obscured by ligand vibrations.[38,39]

The close similarity between the crystal-field spectra of the solid compounds (Br and NCS derivatives) and of their solutions in $CHCl_3$ indicates that these compounds retain the same structure (see Table 4). Compounds **1**, **2**, and **3** each show four distinct bands which are consistent with five-coordinate high-spin cobalt(II) complexes.[14–16] The spectra can be correlated with those of the complexes Co(MABenNEt_2)Cl_2,[17] Co(Et_4dien)X_2 (X = Cl, Br, I, N_3, and NCS),[15] Co(Me_5dien)Cl_2[18,19] and Co(Et_4dien)Cl_2.[11] The complexes **1**–**3** show a common band at ca. 625 nm which is assigned to the $^4A_{2'}(F) \rightarrow {}^4A_{2'}(P)$ transition. This band is characteristic of five-coordinate complexes irrespective of the nature of the donor atoms and the true geometry of the complex.[16] Their electronic spectra also show solvent dependence. In DMF solutions, the spectra are consistent with Co^{II} in an octahedral configuration, probably formed by coordination of DMF. In DMF solution, the iodo complex is, however, strongly conducting, probably one of the iodine atoms is dissociated to give [Co(*S*-dept)$(DMF)_2I]^+$ and free iodide ions. Complexes **1** and **3** are non-conducting in DMF and may be formulated as [Co(*S*-dept)(DMF)X_2] (X = Br and NCS).

Crystal Structures of [Co(S-dept)X_2] [X = Br (1), I (2), and NCS (3)]

The molecular structures and the atom labelling scheme of the complexes are shown in Figures 1, 2, and 3. Selected bond lengths and angles are listed in Table 1. The three complexes consist of monomeric molecules with a five-coordinate stereochemistry resulting from bonding to terdentate *S*-dept ligand and the other two positions are occupied by two X groups (Br, I or terminal *N*-bonded NCS). The geometry about the cobalt atom may be described either as square-pyramidal or trigonal-bipyramidal, depending on the parameter, $\tau = \beta - \alpha/60$ (β is defined as the larger of the basal angles and α is the remaining angle).[39] When τ is 0, the coordination is square-pyramidal; however for a trigonal-bipyramidal configuration τ is 1, and is often reported as a percent value. The τ values for **1** [β = N(1)–Co(1)–Br(2), 159.66(17)° and α = S(2)–Co(1)–S(1), 137.96(9)°], **2** [β = N(1)–Co(1)–I(2), 166.19(12)° and α = S(1)–Co(1)–S(2), 131.58(7)°], and **3** [β = N(5)–Co(1)–N(1), 164.27(18)° and α = S(1)–Co(1)–S(2), 138.76(6)°] are 36.2, 57.7, and 42.5%, respectively. Complexes **1**–**3** may be considered as distorted square-pyramidal. The anions differ in the angles with the metal atom which destroys the two-fold rotational symmetry of the molecules. The torsion angles between the pyridine ring (C1,C2,C3,C4,C5 and N1) and the thioamide planes (C1,C6,S1,N2 and C5,C11,S2,N3) are: 45.4(1) and 35.9(1) for **1**, 38.8(1) and 35.9(1) for **2**, and 38.8(1) and 52.1(1) for **3**. There appears to be no correlation between the angle of rotation of thioamide groups and the pyridine

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ring. However, the conformation of the ligand seems to be dependent on the size of the anion. The conformation of iodide and thiocyanate complexes are almost identical with methyl carbon atoms C13 and C15 being on the same side of the amide group, whereas C8 and C10 are on opposite sides of the plane. In the case of the bromide complex the methyl groups C8 and C10 as well as C13 and C15 are on the opposite sides with respect to the thioamide plane.

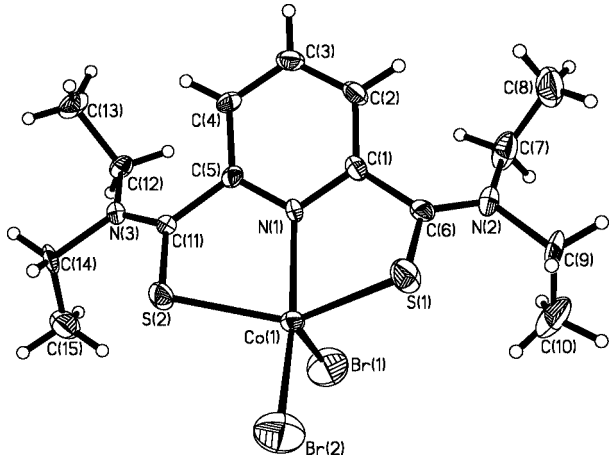

Figure 1. Perspective view of complex **1** with atom numbering scheme (thermal ellipsoids at 50% probability level).

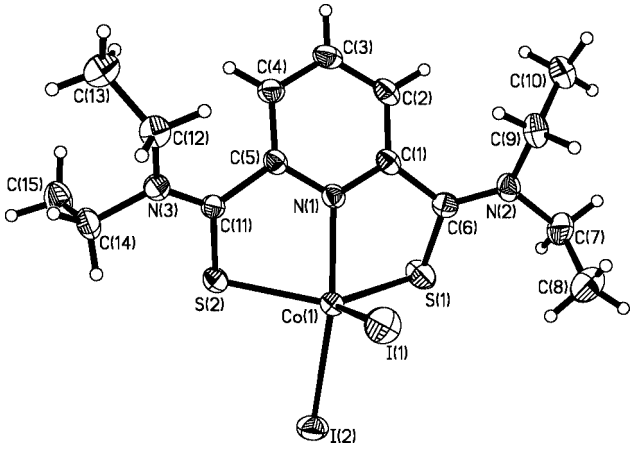

Figure 2. Perspective view of complex **2** with atom numbering scheme (thermal ellipsoids at 50% probability level).

In the structure of **1** the bromine atom Br(1) occupies the apical position and sulfur atoms S(1), S(2), pyridine N(1) and Br(2) form the base of the pyramid. The mean plane through these atoms indicates that the atoms are 0.205, 0.203, –0.238, and –0.170 Å, respectively, above and below the mean plane. The Co ion is –0.607 Å below the mean plane defined by these four atoms. Similarly, in the structure of **2** the iodine atom I(1) occupies the apical position and sulfur atoms S(1), S(2), pyridine N(1) and I(2) form the base of the pyramid. The mean plane through these atoms indicates that the atoms are 0.307, 0.328, –0.396, and –0.239 Å, respectively, above and below the mean plane. The Co ion is –0.599 Å below the mean plane defined by these four atoms.

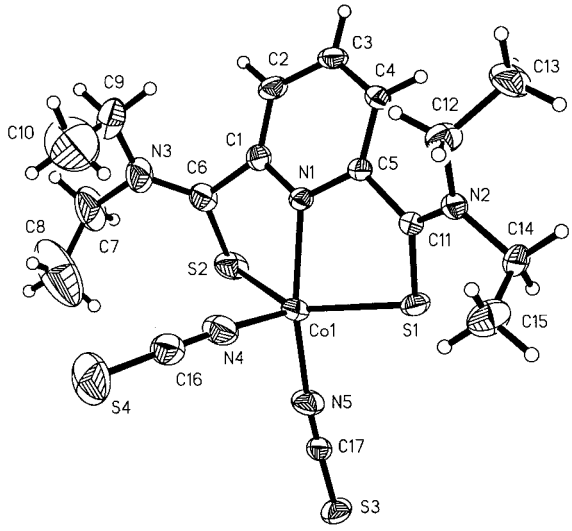

Figure 3. Perspective view of complex **3** with atom numbering scheme (thermal ellipsoids at 50% probability level).

The isothiocyanate nitrogen atom N(4) occupies the apical position and sulfur atoms S(1) and S(2), pyridine N(1) and thiocyanate N(5) form the base of the pyramid. The mean plane through N(1), N(5), S(1), S(2) indicates that these atoms are 0.39, 0.52, –0.05, –0.08 Å, respectively, above and below the mean plane. The Co ion is 0.74 Å above the mean plane defined by these four atoms. It is interesting that the Co–NCS linkages in **3** are bent with Co–N(5)–C(17) and Co–N(4)–C(16) angles of 171.0(5) and 167.0(6), respectively. It has been observed by others[40,41] that this linkage may be either linear or angular, with examples of M–N–C angles falling in the range 141–174°. The non-linearity of this type may be attributed to steric factors.[21] It also suggests electron density localisation on the donor nitrogen atom such that a canonical form **I** contributes to the structure.[40,42]

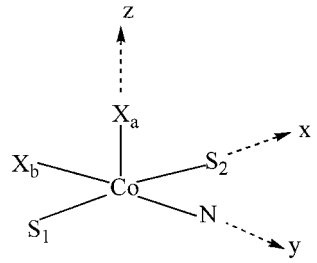
Co

I

It has been known that interactions of cobalt and nickel thiocyanates with terdentate ligands provide complexes of different stereochemistry.[35,43] Our present results provide ample evidence that cobalt has a greater tendency than nickel to give monomeric five-coordinate complexes rather than octahedral complexes.

Extended Hückel Calculations

The compounds reported here show a $CoNS_2X_2$ core, with significant differences in the Co–ligand distances. Compound **3** shows a CoN_3S_2 core, with three short Co–N distances (ca. 2.1 Å) and two long Co–S (ca. 2.4 Å) (*x*-axis) distances (see Scheme 1). Compound **1**, with a $CoNBr_2S_2$ core, has one short Co–N (ca. 2.1) and four long Co–S and Co–Br (ca. 2.4 Å) (*yz*-plane) distances. Finally, for compound **2** with a $CoNI_2S_2$ core, we observe one short Co–N (ca. 2.1 Å), two long Co–S (ca. 2.4 Å) (*x*-axis), and two very long Co–I distances with values in the range ca. 2.6–2.7 Å. Then, from the point of view of bond lengths, compound **3** shows a more regular core, with short Co–L distances, while compound **2** shows the most irregular core, with long Co–L distances.



Scheme 1.

Extended Hückel calculations with the crystallographic coordinates of compounds **1**–**3** were carried out with the CACAO program.[44] Due to the absence of symmetry in these complexes a full split of the five d orbitals is obtained and a great delocalisation towards the ligands is observed in all cases. There are at least nine MOs with a cobalt contribution >15%.

High-spin Co^{II} compounds show three singly occupied molecular orbitals (SOMOs). The highest energy SOMO shows a significant contribution of the $x^2 - y^2$ orbital of the cobalt ion and has a σ*-character with the ligands in the basal plane (S_1, N, S_2, and X_b), while the next SOMO is constituted essentially by the z^2 of the cobalt ion and the p orbital of the monodentate ligand in apical position (X_a) (or the non-bonding π_{nb} orbital of the NCS ligand). The lowest energy SOMO shows a significant contribution of the *xz* orbital of the Co^{II} ion and of the p orbitals of S_1 and S_2. In the iodide complex (and in minor proportion in

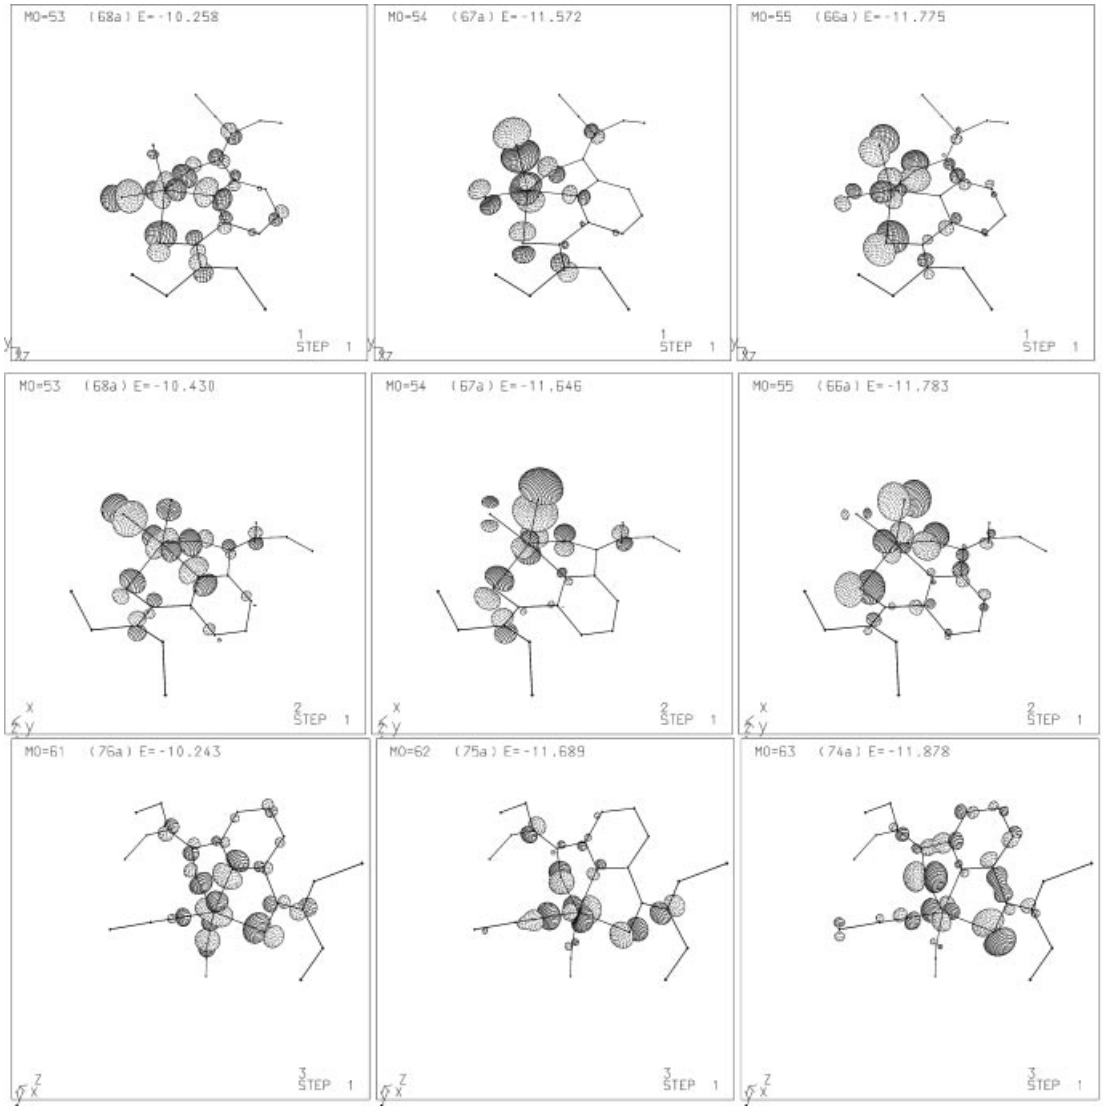

Figure 4. SOMOs for compound **1** (top), **2** (centre), and **3** (bottom).

the bromide complex) a considerable contribution of the apical ligand is also observed (Table 2, Figure 4).

Due to the distortions in the geometry, the *xz*, *yz*, and *xy* orbitals of the Co^{II} ions contribute to several MOs. However, these results confirm the description of the structure of these compounds as a distorted square pyramid. The energy of σ_a* is similar for the three compounds, while σ_b* is more stabilized for compound **2**, which shows a major distortion to the trigonal-bipyramidal geometry, than for **1** and **3** (Figure 5).

One of the limitations of the extended Hückel calculations is the non-inclusion of the inter-electronic repulsions; nevertheless, from a qualitative point of view, we can consider for each compound, a similar pairing energy in each orbital, and from the energy diagram shown in Figure 5, we can find an approximate value for the relative energies of the different excited states (E1–E6). From these results, we can propose, for the three compounds, the presence of several excited states close in energy to the ground state (ca. 5000 cm^{-1}, E1–E3 and E4) (Table 3). These states would

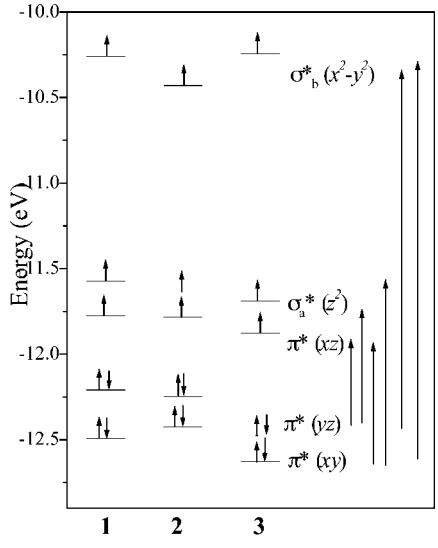

Figure 5. MO energy diagram for compounds **1**–**3**.

correspond to the different transitions $\pi^* \rightarrow \pi^*$ and $\pi^* \rightarrow \sigma a^*$ (z^2), and the transition $\pi^* \rightarrow \sigma b^*$ ($x^2 - y^2$) should appear at higher energy (ca. 16000 cm^{-1}).

Magnetic Properties

The magnetic susceptibility of **1**–**3** was measured in the range 2–300 K (Figure 6). In all cases, the $\chi_M T$ product decreases with the temperature. The shape of the three graphs is similar, but for compound **1**, we found higher $\chi_M T$ values. The room-temperature values of $\chi_M T$ = 3.03 cm^3 mol^{-1} K (for **1**) and 2.7 cm^3 mol^{-1} K (for **2** and **3**) differ from the spin-only value $\chi_M T$ = 1.87 cm^3 mol^{-1} K for S = 3/2 (high-spin Co^{II} complexes) which indicates an orbital contribution to the g-values. On lowering the temperature, $\chi_M T$ decreases, and under 50 K $\chi_M T$ falls drastically. The shape of the $\chi_M T$ vs. T graph is indicative of an important zero-field splitting. Owing to spin-orbit coupling, the S = 3/2 state is split into two Kramer's doublets ($M_s = \pm 1/2, \pm 3/2$), separated by 2D, with D being the axial zero-field splitting parameter. Formally, the magnetic behaviour can be treated as an S = 3/2 spin state under the action of the spin Hamiltonian $H = D[S_z^2 - S(S + 1)/3] + g_{\parallel}\beta Hz S_z + g_{\perp}\beta(H_x S_x + H_y S_y)$. The expression of the magnetic susceptibilities χ_M [with $\chi_M = (\chi_{\parallel} + 2\chi_{\perp})/3$] is derived from this Hamiltonian.[45] With the aim to fit the low-temperature values, it was necessary to modify the equation, including the term of the intermolecular magnetic interactions zJ, where J is the interaction parameter between two nearest neighbour magnetic species and z is the number of nearest neighbours around a given magnetic molecule in the crystal lattice. Then the equation used to fit the experimental data is

$$\chi_M T = \frac{TNg^2\beta^2 F(D,T)}{3kT - zJ \cdot F(D,T)}$$

where

$$F(D,T) = \frac{1}{4}\left[\frac{1+9\exp(-2D/kT)}{1+\exp(-2D/kT)}\right] + 2kT\left(\frac{(\frac{1}{kT}) + \frac{3}{4D} - \frac{3}{4D}\exp(-2D/kT)}{1+\exp(-2D/kT)}\right)$$

The best fits were obtained with $|D|$ = 20.5 cm^{-1}, g = 2.53, zJ = –0.50 cm^{-1} and $R = 1.8 \cdot 10^{-4}$ (**1**); $|D|$ = 14.2 cm^{-1}, g = 2.38, zJ = –1.67 cm^{-1} and R = 2.7 10^{-4} (**2**); $|D|$ = 17.7 cm^{-1}, g = 2.35, zJ = –1.23 cm^{-1} and R = 2.9 10^{-4} (**3**). As it can be seen in Figure 6, compounds **2** and **3** show similar $\chi_M T$ values, while compound **1** shows at room temperature a higher $\chi_M T$ value, indicative of a large g value. The best fit of the experimental data also corresponds to a largeer D value for **1** than for **2** or **3**.

As it has been indicated, very few high-spin five-coordinate Co^{II} complexes are structurally and magnetically characterized. Only three mononuclear complexes are reported in the literature with the structural data and magnetic study (χ vs. T): [Co{(*t*Bu)(Me)salmdptn}] (with D = –38.9 cm^{-1}, E = 1.7 cm^{-1}, g_x = 1.68, g_y = 1.89, g_z = 3.21 and zJ = –1.0 cm^{-1}),[22] [Co(saloph)(2-MeImd)] (with $|D|$ = 22.6 cm^{-1}, g = 2.14),[23] and [Co(L^5)$_2$(H_2O)] with HL^5 = *N*-(2-chloro-6-methylphenyl)pyridine-2-carboxamide (Curie–Weiss law between 80–300 K).[26] The study of the magnetic properties of [Co(Salpad)$_2$(t-MeStpy)] (D = 16.57 cm^{-1}, g = 2.39),[20] [Co(H_2fsa)$_2$(phn)(t-MeStpy)] (spin equilibrium),[20] and [Co(bzimpy)Cl_2] (D = 73.4 cm^{-1}, E = 3.28 cm^{-1}, zJ = –0.205 cm^{-1})[21] are also reported in the literature, but to the best of our knowledge, the crystal structure of these compounds is not published.

In spite of the limited number of mononuclear Co^{II} compounds with five-coordination which have been structurally and magnetically characterized, two facts could be discussed: the stabilization of the spin state S = 3/2 and the magnitude of the zero-field splitting.

Cobalt(II) complexes with Schiff-base ligands could be high-spin or low-spin. In a comparative study of five-coordinate Co^{II} complexes of the types [Co(salen)L] and [Co(saloph)L] reported by Kennedy et al.,[23] the authors note an increase of the out-of-plane displacement of the Co^{II} ion from ca. 0 Å for low-spin complexes to ca. 0.45 Å for the high-spin compounds [Co(saloph)(2-MeImd)] (0.45 Å)[23] and [Co(3-MeOsalen)(H_2O)] (0.43 Å).[28] The three compounds reported in this paper show a high-spin configuration and all of them show an important out-of-plane displacement of the Co^{II} ion of ca. 0.6–0.74 Å. The high value

[a] $g = (gx + gy + gz)/3$. [b] $\tau = 1$: trigonal-bipyramid; $\tau = 0$: square pyramid.[38] [c] This work.

of this displacement could be attributed to the different nature of the ligands in the basal plane: N_2O_2 for salen and saloph and NS_2X for compounds **1**–**3**. The presence of a voluminous donor-atom ligand favors the distortion and stabilize the $S = 3/2$ state.

In the same way, Hitchaman showed[46] that increasing distortions from a square-pyramidal geometry could lead to a rapid decrease in the quartet-state energy, especially when $\beta > 102°$ ($\beta = L_{ax}$–Co–N angle). For the three compounds reported in this paper, the largest β angle is found for the iodo complex **2** with $\beta = 107°$ (major distortion to the trigonal-bipyramidal geometry); for **1** and **3** the β angle is slightly more than 90° (91.7° and 93.6°, respectively).

In comparison with the Schiff-base complexes, compounds **1**–**3** show a major distortion in the geometry: the presence of the *S*-dept ligand, with its sulfur atom coordinated to the Co^{II} ion favors the out-of-plane displacement of the metal center. Due to the tridentate character of the *S*-dept ligand, the fourth position of the basal plane is occupied by a monodentate ligand, consequently a major flexibility of the geometry could be attended. The most voluminous monodentate ligand, iodide, leads to a major distortion from the square-pyramidal to the trigonal-bipyramidal geometry. Therefore, in the reported compounds [Co(S-dept)X_2] (**1**–**3**) both ligands, *S*-dept and X, favor the stabilization of the $S = 3/2$ state in preference to the $S = 1/2$ state.

For systems with an $S = 3/2$ state, the magnetic anisotropy due to the non-spherical distribution of the spin density is enhanced by the low symmetry of the five-coordinate chromophore. The D values found for compounds **1**–**3** are of the same order as reported for other five-coordinate Co^{II} complexes with $S = 3/2$. Attempts to correlate the zero-field splitting parameter (D) with the structural distortions are hard, due to the limited number of compounds of this kind reported in the literature. Compounds **1**–**3** show quite smaller D and g values than [Co{(*t*Bu)(Me)salmdptn}][22] and [Co(saloph)(2-MeImd)][23] (Table 4).

It is difficult to interpret the differences in the zero-field splitting parameters for five-coordinate Co^{II} complexes. The magnitude of D and g values is influenced by the second-order spin-orbit coupling, λ and $1/\Delta_i$, where λ is the spin-orbit coupling constant and Δ_i the energy gap between ground state and excited states. The expression of the axial ZFS parameter $D = f(\lambda, 1/\Delta_i)$ for different ions and geometries could be found in a recent review about the zero-field splitting in metal complexes.[47] For Co^{II} ions, the equation for the d^7 ion in a tetrahedral environment is also described in this paper, but not for a five-coordinate complex.

For a free Co^{II} ion $\lambda = -180$ cm^{-1}. But this parameter is sensitive to the covalence of the bond. Compounds **1**–**3** with the *S*-dept ligand must show a greater degree of covalence than the compounds with Schiff-base ligands. Thus, a lower $|\lambda|$ value must be expected for compounds **1**–**3**. Complex **2** with iodide as monodentate ligand, should show a maximum covalence in the Co–X bonds, and consequently the small $|\lambda|$ value must correspond to this compound.

On the other hand, the D value is sensitive to the proximity of excited states with orbital contribution. Several factors influence the energy gaps, Δ_i, such as the bond covalence, the kind of donor atom and the distortions in geometry. In spite of the limitations of the extended Hückel calculations, the presence of several excited states at low energy could be attended. However, the inter-electronic repulsion must be different for the three complexes, due to the presence of different X ligands (Br, I, NCS), and it is not precise to compare the energy values of the excited states postulated in Table 3. The presence of excited states at low energy contributes to the D value, but it is not possible to rationalize their effect.

Compounds formed by voluminous donor ligands such as *S*-dept or iodide, could contribute to diminish the zero-field splitting (small $|D|$ values). Compounds **1**–**3** show lower values than the compounds with Schiff-base ligands.[22,23] Therefore, complex **2** containing S-dept and iodide exhibits the lowest $|D|$ value.

On the other hand, it is difficult to correlate the distortion of the coordination polyhedron with the zero-field splitting parameter. For the two complexes with Schiff-base ligands the compound with major distortion from the square-pyramidal geometry (larger τ) show a larger D value, while for the three complexes reported here with the *S*-dept ligand, the maximum τ value corresponds to compound **2**, with the lowest value of the zero-field splitting parameter.

EPR Spectra

The EPR spectra of powdered samples and of frozen CH_2Cl_2 solution of **1**–**3** were recorded at different temperatures. Only below 100 K was the EPR signal significant, due to the relaxation effects.

The EPR spectra of powdered samples show in all cases a very broad band, with a better resolution at 4 K. The most intense features were found at low field, in the region of 2000 G. In frozen solution the three compounds show very similar spectra (Figure 7) with the most intense feature

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at ca. 1200 G ($g \approx 5.5$). The position of this band is similar for the three compounds (1150 G for **1**, 1250 G for **2**, and 1180 G for **3**). Another small feature was observed at 2760 G. The low-field signal can be attributed to $g_{\perp}$ and the small signal centred at ca. 2800 G to $g_{\|}$. These spectra are characteristic of a high-spin Co^{II} complex, with S = 3/2 and a large zero-field splitting ($D > g\beta H$), as occurs in compounds **1**–**3** whose $|D|$ values are between 14–21 cm^{-1}.

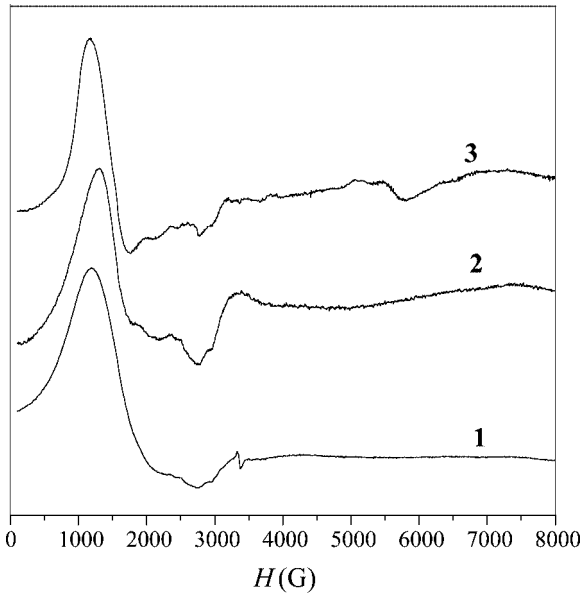

Figure 7. X-band EPR spectra of frozen CH_2Cl_2 solutions of complexes **1**–**3**.

Conclusions

In this work we have reported the synthesis and characterization of three new five-coordinate Co^{II} complexes. In all cases, the coordination polyhedron of the Co^{II} ion is a distorted square pyramid, with an electronic configuration of high-spin. Although there is no correlation between the angle of rotation of thioamide groups and the pyridine ring, the conformation of the ligand is dependent on the size of the anion. The compounds show major distortion in the geometry with a large out-of-plane displacement of the Co^{II} ion of ca. 0.6–0.74 Å. The distortion of the geometry, due to the *S*-dept ligand with voluminous donor atoms, could explain the stabilization of the S = 3/2 state than the S = 1/2 state.

Important zero-filed splitting is observed, as it could be expected for high-spin Co^{II} compounds. The D value seems to be very sensitive to the nature of the ligand. The compounds reported in the literature, with a CoO_2N_2 core show larger $|D|$ values than compounds **1**–**3**, with a $CoNS_2X_2$ core. The smallest value corresponds to compound **2** containing more diffuse donor atoms ($CoNS_2I_2$ core) with maximum covalence of the Co–L bonds.

The EPR spectra at low temperature show two bands, at low fields, characteristic of systems with an S = 3/2 ground state and an important zero-field splitting, as is the case for Co^{II} compounds.

Experimental Section

Materials: All reactions were carried out under anhydrous conditions. Solvents were dried using standard techniques. Absolute ethanol (AR quality, Hayman Ltd.) and pyridine-2,6-dicarboxylic acid (Fluka) were used as supplied. *N*,*N*,*N*′,*N*′-Tetraethylpyridine-2,6-dithiocarboxamide was prepared as described earlier.[7,8]

Synthesis of the Complexes [Co(S-dept)X_2] [X = Br (1), I (2) and NCS (3)]: $CoCl_2$ (3 mmol), dissolved in anhydrous ethanol (20 mL), was added to a solution of KBr or KI or KSCN (each 6 mmol) in ethanol (20 mL). The mixture was refluxed for about 4 h. The white precipitate of KCl was removed by filtration and *S*-dept (3 mmol), dissolved in ethanol (20 mL), was added to the solution. After refluxing for about 4–5 h, **1**, **2** and **3** were obtained as dark green solids on keeping at room temperature. The complexes were crystallized from anhydrous ethanol by slow concentration at room temperature. **1:** Yield 1.36 g (86%). M.p. 210 °C. $C_{15}H_{23}Br_2CoN_3S_2$ (528): calcd. Selected IR frequencies (KBr disk [cm^{-1}]): ν̃ = 2062, 1600, 1580, 1530, 1460, 1438, 1410, 1315, 1277, 1259, 1187, 1164, 1144, 1094, 1072, 1010, 980, 909, 812, 722, 668, 640, 562, 478, 456, 424.

Physical Methods: Elemental analyses (C,H,N) were carried out with a Perkin–Elmer model 2400 CHN elemental analyzer at the SAIF, Panjab University. Bromide and iodide anions were determined by precipitation as silver salts and sulfur by precipitation as $BaSO_4$. IR spectra were recorded as KBr pellets with a Perkin–Elmer RX-1 FTIR spectrophotometer. Molar conductances were measured using a Digital conductivity bridge, Model CC601.The UV/Vis spectra were recorded with a JASCO V-530 UV/Vis spectrophotometer in a 1-cm matched quartz cell. The diffuse reflectance spectra of powdered samples were recorded with a Hitachi Model 330 integrating sphere reflectance spectrophotometer in the 185–2600 nm region, using magnesium oxide as reference. Magnetic susceptibility measurements, for polycrystalline samples of **1**–**3**, were performed with a Quantum Design SQUID MPMS-XL susceptometer, working in the range 2–300 K under magnetic fields of 2000 G, at the "Servei de Magnetoquímica" (Universitat de Barcelona). Pascal's constants were used to estimate the diamagnetic

corrections. The fits were performed by minimizing the function $R = \Sigma[(\chi_M T)_{exp} - (\chi_M T)_{cal}]^2/\Sigma(\chi_M T)_{exp}^2$. EPR spectra for **1**–**3** were recorded at X-band (9.4 GHz) frequency with a Bruker ESP-300E spectrometer from room temperature to 4 K, at the "Servei de Magnetoquímica" (Universitat de Barcelona).

X-ray Crystallography: Crystallization of **1**, **2** and **3** by slow concentration of their saturated ethanolic solutions at room temperature yielded good single crystals. Intensity data were collected with a Siemens P4 single-crystal diffractometer equipped with a molybdenum sealed tube (λ = 0.7173 Å) and highly oriented graphite monochromator. Table 5 shows the unit cell parameters and data measurement details. The parameters associated with the structure of **1** are as follows: Crystal size 0.24 × 0.20 × 0.16 mm. The lattice parameters and standard deviations were obtained by least-squares fit to 40 reflections $10.085° < 2\theta < 30.312°$ The data were collected by the 2θ-θ scan mode with a variable scan speed ranging from 2.0 to a maximum of 60° min^{-1}. Three reflections were used to monitor the stability and orientation of the crystal and were measured after every 97 reflections. Their intensities showed only statistical fluctuations during 40.28 h of X-ray exposure time. The data were collected for Lorentz and polarisation factors and an empirical absorption correction based on the ψ-scan method was applied. The structure was solved by direct methods using SHELX-97[34] and also refined on F^2 using the same one. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included in the ideal positions with fixed isotropic U values and were riding on their respective non-hydrogen atoms. A weighting scheme of the form $w = 1/[(\sigma^2F_o^2) + (ap)^2 + bp]$ with a = 0.1606 and b = 8.27 was used. The refinement converged to a final R value of 0.0747 (wR_2 = 0.22 for 3012 reflections) [$I > 2\sigma(I)$]. The final difference map was featureless. The data collection procedure, structure solution and refinement for compounds **2** and **3** were essentially the same as for **1**. The parameters associated with the structures are as follows: **2:** 40 reflections $(0.420° < 2\theta < 30.118°)$ for an accurate cell parameter determination, crystal size 0.28 × 0.24 × 0.19 mm, a total of 46.90 h of X-ray exposure time, R = 0.0383 (wR_2 = 0.1093 for 3342 reflections) [$I > 2\sigma(I)$] with a = 0.0572 and b = 10.73 in weighting scheme. **3:** 40 reflections $(0.420° < 2\theta < 30.118°)$ for an accurate cell parameter determination, crystal size 0.20 × 0.20 × 0.10 mm, a total of 48 h of X-ray exposure time, R = 0.0535 (wR_2 = 0.1422 for 3602 reflections) [$I > 2\sigma(I)$] with a = 0.0811 and b = 1.8505 in above mentioned weighting scheme. A summary of the crystal parameters, experimental details and refinement results are listed in Table 5. CCDC-254292 (**1**), -254293 (**2**), and -254294 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Keywords: Bridging ligands / Cyanides / P ligands / Platinum / Self-assembly

The dinuclear complex $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(NCCH_3)_2]$ (**1**) is described and fully characterised. Complex **1** reacts with 2,2′-bipyrimidine and *cis*-$[M(C_6F_5)_2(THF)_2]$ to form the di-, tri- and tetranuclear complexes **2**, **3** and **4**, respectively, depending on the ratio of reagents and the type of metal (M = Pt, Pd). Complex **1** reacts with KCN to form the anionic dinuclear complex $[PPh_3(CH_3)]_2[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(CN)_2]$ (**6**). Complex **6** acts as a metalloligand towards *cis*-$[M(C_6F_5)_2(THF)_2]$ or **1** to yield the corresponding hexanuclear or octanuclear complexes **7**, **8** and **9**. The structure of $[PPh_3(CH_3)]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2Pd(C_6F_5)_2\}_2]$ (**8**) has been established by X-ray diffraction.

Introduction

The use of transition metal centres and coordination chemistry for directing the formation of complex structures has evolved into one of the most widely used strategies for organizing molecular building blocks into supramolecular arrays.[2–7] The directional-bonding approach, or "molecular library", involves the assembly of large metal-containing structures wherein the metal centres act as highly directional corner or side units in the resulting geometric shapes or polyhedra. This approach uses a blocking ligand to protect coordination sites at the metal centre, thus controlling the positions available for the binding of bridging ligands and enabling the construction of the desired architecture. This type of research began with the use of mononuclear coordination centres, especially Pd^{II} and Pt^{II},[8–10] but considerable success has since been achieved by using dimetallic entities instead.[11,12] In the course of our research in phosphido derivatives we have prepared several polynuclear complexes that contain the "$(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt$" fragment.[13–19] In some cases the precursor for this fragment is the complex $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(S)_2]$[20] (S = solvent) which has been prepared in situ but never isolated. In this paper we describe the isolation of the dinuclear derivative $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(NCCH_3)_2]$ (**1**) and we study its coordination chemistry towards different ligands with the aim of establishing its synthetic potential as a building block for species with predefined geometric shapes.

Results and Discussion

The addition of $AgClO_4$ to an acetone/acetonitrile solution of $[Bu_4N]_2[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}Cl)\}_2]$ (molar ratio 2:1) results in the precipitation of silver chloride; $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(NCCH_3)_2]$ (**1**) is isolated as a white, stable solid from the mother liquors. The ^{19}F NMR spectrum shows a signal with platinum satellites for the *o*-F atoms and the resonances due to *m*- and *p*-F atoms (higher field) appear overlapped, with the expected 2:3 intensity ratio confirming the equivalence of both C_6F_5 groups. The ^{31}P NMR spectrum shows a signal (δ = –143.8 ppm) with platinum satellites for the two equivalent P atoms. The chemical shift appears at high field, indicating that both PPh_2 ligands are supporting two metal centres not involved in M–M bonds [3.443(1) Å]. Two values of $^1J_{Pt,P}$ (1927 and 2454 Hz for Pt^1 and Pt^2, respectively) can be calculated from the platinum satellites (see Scheme 1 for atom numbering). The assignment of each value to Pt^1 or Pt^2 can be carried out considering the great *trans* influence of the C_6F_5 group and comparing the values with those obtained in other similar pentafluorophenyl derivatives.[21] The IR spectrum shows, in the 800 cm^{-1} region, two absorptions of similar intensity due to the X-sensitive mode of the C_6F_5 groups, in agreement with the presence of the "*cis*-$Pt(C_6F_5)_2$" fragment,[22,23] and two absorptions in the 2300 cm^{-1} region due to ν(CN) of the coordinated acetonitrile. All significant spectroscopic data are given in the Exp. Sect.

The crystal structure of complex **1** was determined by X-ray diffraction and is shown in Figure 1. During the resolu-

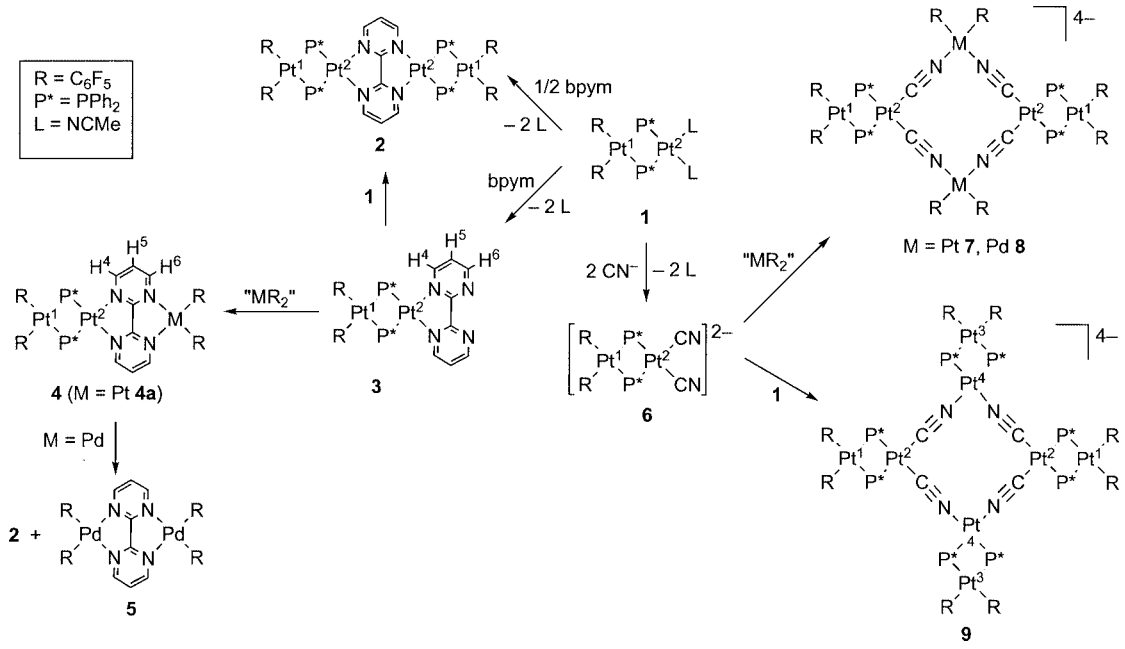

Scheme 1.

tion of the structure, two essentially identical molecules of **1** were found in the asymmetric part of the unit cell and we will discuss only one of them now. Selected bond lengths and angles are listed in Table 1. Complex **1** is a dinuclear complex (Figure 1) in which the two Pt atoms are bridged by two diphenylphosphido ligands. The square-planar environments of the metal centres are completed by two *cis*-pentafluorophenyl groups in the case of Pt(1), and two *cis*-acetonitrile ligands in the case of Pt(2). The two acetonitrile moieties are practically linear, as expected, and the bond lengths and angles fall in the range usually found for this ligand coordinated to Pt.[24–28] The molecular skeleton $C_2PtP_2PtN_2$ is not planar. The angle between the perpendicular lines to the best square planes formed by the Pt atoms and the atoms directly bonded to them is 33.94(4)°.

The well-known stability of Pt–C_6F_5 bonds and the Pt(μ-PPh_2)$_2$Pt skeleton, and the lability of the Pt–N (acetonitrile) bonds, make complex **1** an excellent dinuclear starting material with a 90° angle between the "open-coordination sites".

Reaction of 1 with 2,2′-Bipyrimidine

In order to explore the potential of complex **1** as a precursor for self-assembly chemistry, we started the study by

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

substituting the two acetonitrile ligands in **1** with 2,2′-bipyrimidine (bpym), a ligand with four N donor atoms that can be used as a linker of the building blocks.[29–32] Addition of bpym to an acetone solution of **1** in a 1:2 molar ratio (see Scheme 1) gave the linear tetranuclear complex $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}bpym)Pt(\mu\text{-}PPh_2)_2Pt(C_6F_5)_2]$ (**2**). This process is facilitated by both the sp^2 hybridisation at the N atoms, the chelate effect of the ligand and the high insolubility of **2**. Nevertheless, when the ligand is added in a 1:1 molar ratio the dinuclear complex $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(bpym)]$ (**3**) is obtained. The bpym ligand in **3** is coordinated in a terminal chelating mode, and thus the other two N atoms can be used for further coordination. Complex **2** can be obtained by the addition of **1** to solutions of **3** in acetone (1:1 molar ratio).

With the aim of synthesising asymmetric derivatives we added *cis*-$[M(C_6F_5)_2(THF)_2]$ (M = Pt, Pd) to CH_2Cl_2 solutions of **3** (1:1 molar ratio); the results are different for M = Pt or Pd. In the first case the two donor N atoms of **3** coordinate to the added platinum centre and the asymmetric, linear, trinuclear derivative $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}bpym)Pt(C_6F_5)_2]$ (**4a**) crystallises from the solution. However, the reaction of **3** with *cis*-$[Pd(C_6F_5)_2(THF)_2]$ does not yield the heteronuclear complex $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}bpym)Pd(C_6F_5)_2]$ (**4b**) but rather a mixture of **2** and $[(C_6F_5)_2Pd(\mu\text{-}bpym)(C_6F_5)_2]$ (**5**),[33] which were identified by IR spectroscopy. The two complexes can be easily separated from this solid by dissolving **5** in acetone. The ^1H NMR spectra of **3** and **4a** show, in addition to PPh_2 groups, three resonances due to the H^4, H^5 and H^6 atoms of the bpym ligand, as expected for these asymmetric compounds. The ^{19}F NMR spectra of **3** shows three signals (2 *o*-F, 2 *m*-F, *p*-F) due to the equivalence of both C_6F_5 groups, while complex **4a** shows, as expected, the signals due to both types of inequivalent C_6F_5 groups (see Exp. Sect.). The ^{31}P NMR spectra of **3** and **4a** show the same pattern as **1**.

In the IR spectra of complexes **2** and **3** two absorptions of the same intensity due to the X-sensitive mode of the C_6F_5 groups are observed in the 800 cm^{-1} region, in agreement with the presence of the "*cis*-$M(C_6F_5)_2$" fragment.[22,23] For complex **4a** four absorptions due to the two different "*cis*-$M(C_6F_5)_2$" fragments are observed. In addition, two intense sharp peaks of nearly equal intensity at approximately 1580 and 1560 cm^{-1} (ring stretching modes of bpym) characterise the terminal-chelating mode of the bpym ligand in complex **3**. The presence of the bis(chelating) mode (complexes **2**, **4a** and **5**), however, is indicated either by an asymmetric doublet or a single strong broad feature in the same range.[34]

All our attempts to obtain a single crystal of the tetranuclear complex **2** suitable for X-ray diffraction purposes failed, probably due to its insolubility. Although we obtained single crystals of the asymmetric complex **4a** and collected data for two different crystals, in both cases the value of *R* was not satisfactory, thus the structure of **4a** cannot be fully described. However, the skeleton of the molecule and the connectivity of the atoms are as expected.

Reaction of 1 with Cyanide

The cyanide ligand can act as a linear linker in polynuclear systems that exhibit fascinating structures and properties.[35–41] Although the design of molecular entities has produced large rings, stars, boxes, cages and clusters involving cyanide bridging ligands, only a few examples with platinum centres in their structure have been reported.[42–47] With the aim of synthesising other homo- or heteronuclear square molecules we decided to use the cyanide ligand as: a) it can easily act as a terminal ligand, thus allowing a designed synthesis through a two-pot process; b) although some bent cyanide bridges are known,[48] this group is usually rigid and linear when acting as a bridging ligand; and c) their anionic nature allows the synthesis of anionic molecular squares. Although we have recently reported some examples of anionic heterometallic squares,[42] these molecules are usually neutral or cationic with a high charge.

The addition of KCN to acetone solutions of **1** in a 2:1 molar ratio (a methyltriphenylphosphonium salt was also added to facilitate the crystallisation) yielded the dinuclear complex $[PPh_3(CH_3)]_2[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(CN)_2]$ (**6**) in which the cyanide groups act as terminal ligands. The two N atoms of **6** are bonded to other *cis*-blocked metal centres to form the expected squares. The reaction of *cis*-$[M(C_6F_5)_2(THF)_2]$ (M = Pt, Pd) with CH_2Cl_2 solutions of the metalloligand **6** (1:1 molar ratio) gave the hexanuclear anionic macrocycles $[PPh_3(CH_3)]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2M(C_6F_5)_2\}_2]$ (M = Pt, **7**; Pd, **8**). Similarly, the reaction of **6** and **1** (1:1 molar ratio) afforded the octanuclear complex $[PPh_3(CH_3)]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)Pt(\mu\text{-}PPh_2)_2Pt(C_6F_5)_2\}_2]$ (**9**; Scheme 1). The ^{19}F NMR spectrum of **6** shows three signals in a 2:2:1 intensity ratio and the low-field signal, due to the *o*-F atoms, shows platinum satellites. This is the expected pattern for **6** in which both C_6F_5 groups are equivalent. In agreement with the formulation given in Scheme 1, the ^{19}F NMR spectrum of **7** exhibits two signals in the *o*-F region (2:2 intensity ratio), two high-field multiplets for the *m*-F (2:2 intensity ratio) and two different signals for the *p*-F atoms (1:1 intensity ratio), thus confirming the presence of two non-equivalent C_6F_5 rings (C_6F_5 *trans* to CN and C_6F_5 *trans* to P). The spectrum of **8** is analogous, but one *m*-F signal appears overlapped with that of the *p*-F one. Moreover, only one signal, with platinum satellites, is observed for the two types of *o*-F atoms (C_6F_5 bonded to platinum or to palladium), thereby indicating that they are isochronous. This was unambiguously confirmed by considering the intensity ratio of the platinum satellites and the central signal (1:10:1). For complex **9**, the two different *o*-F atoms are isochronous and the signals due to *m*-F atoms are overlapped. Nevertheless, the presence of two inequivalent C_6F_5 groups is unambiguously demonstrated by the two well-separated *p*-F signals (see Exp. Sect.). The ^{31}P NMR spectrum of **6** shows one high-field signal with platinum satellites (1:8:17:8:1 intensity ratio) for the P atoms of the diphenylphosphido groups. The two doublets expected for the two isotopomers in which one platinum centre is ^{195}Pt (22.3% abundance each one) are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

overlapped, ;indicating equal coupling constants between the equivalent P atoms and the inequivalent Pt^1 and Pt^2 centres. This is in agreement with the easily observed signals due to the isotopomer in which the two metal centres are ^{195}Pt (11.3% abundance). The same spectral pattern is observed for complexes **7** and **8**, thus indicating that the coordination of the N atoms of the CN ligand in **6** to the metal centre of the "*cis*-$M(C_6F_5)_2$" fragment (M = Pt, Pd) does not perceptibly change the magnetic environment of the Pt^1 and Pt^2 centres. The octanuclear macrocycle **9** shows two different types of diphenylphosphido ligands: the PPh_2 groups bridging Pt^1 and Pt^2 centres, both with two Pt–C bonds (fragment from **6**), and the PPh_2 groups bridging Pt^3 and Pt^4 centres, with two Pt^3–C and two Pt^4–N bonds (fragment from **1**). The ^{31}P NMR spectrum of **9** exhibits, in the high-field region, two signals with platinum satellites. The signal at δ = –161.0 ppm shows a pattern similar to the one observed for **6**–**8** and can be assigned to the P atoms of the "$Pt^1(\mu\text{-}PPh_2)_2Pt^2$" fragment, while two different values of $^1J_{Pt,P}$ (1899 and 2400 Hz) can be extracted from the signal at δ = –157.9 ppm; this signal can be assigned to the P atoms of the "$Pt^3(\mu\text{-}PPh_2)_2Pt^4$" fragment. The assignment of both $^1J_{Pt,P}$ values (see Exp. Sect.) was carried out by comparison with the corresponding values observed in **1**, **3** and **4a**.

The relevant feature of the IR spectra of **6**–**9** is the presence of two sharp absorptions at 2122 and 2113 cm^{-1} in **6** (terminal cyanide), which are assigned to ν(C≡N), and their significant shift towards higher frequencies in the squares **7**, **8** and **9** (bridging cyanide).[49] In all cases the absorptions observed in the 800 cm^{-1} region indicate the presence of "*cis*-$M(C_6F_5)_2$" fragments.[22,23]

Figure 2a shows the structure of the anion in complex **8**. Selected bond lengths and angles are given in Table 2. The X-ray structure establishes the presence of the hexanuclear complex anion $[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2Pd(C_6F_5)_2\}_2]^{4-}$ and four $[PPh_3(CH_3)]^+$ cations along with three molecules of acetone and one molecule of *n*-hexane as lattice solvent. The platinum atoms are bonded to two diphenylphosphido ligands, which act as bridges between both metal centres, and to two C_6F_5 ligands in the case of Pt(2) or to two CN bridging ligands in the case of Pt(1). The N atoms of the cyanide are coordinated to the Pd atoms, which complete their coordination with two C_6F_5 groups in *cis* positions. The distances and angles in each coordination sphere are within the expected values. The maximum deviation of the metal atoms with respect to their best least-squares plane is 0.046 Å in the case of Pt(2). The C_6F_5 rings are essentially perpendicular to their coordination planes, with angles ranging from 77.0 to 91.4°. The coordination planes of Pt(1) and Pd(1) are essentially coplanar (4.8°), while the coordination plane of Pt(2) forms an angle of 22.1° with that of Pt(1). The Pt(1) and Pd(1) atoms form an almost perfect square, with edges of 5.19 and 5.21 Å, in which the CN ligands are located, defining an open cavity which is not large enough to accommodate the bulky cations or solvent molecules (see Figure 2b).

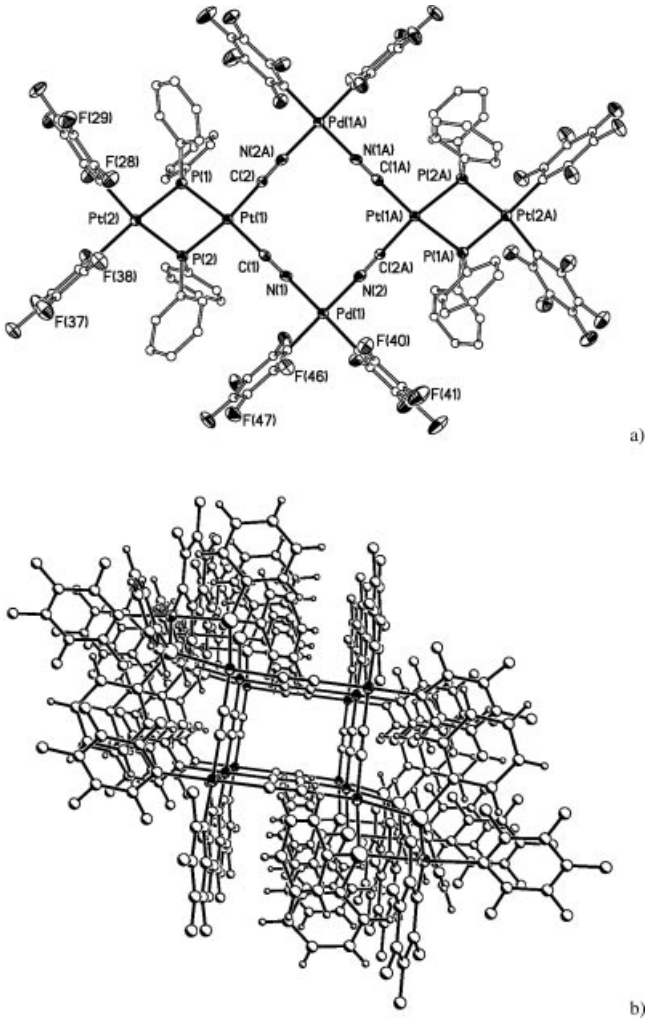

Figure 2. a) Structure of the anion of $[PPh_3Me]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2Pd(C_6F_5)_2\}_2]$ (**8**). b) Packing diagram of the anions in **8**, showing how the cores of the molecular squares stack to form an infinite tunnel.

Table 2. Selected bond lengths [Å] and angles [°] for $\{(PPh_3Me)_2[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2Pd(C_6F_5)_2]\}_2\cdot 3Me_2CO\cdot$*n*-hexane (**8**·3$Me_2CO$·*n*-hexane).

We also tried to obtain an X-ray structure of complex **9** but unfortunately only poor quality crystals were obtained after many crystallisation attempts. The X-ray data measured with the diffractometer had a very low intensity, which was almost non-existent at 2θ angles $> 40°$. Thus, only a set of poor quality data could be obtained and therefore only the connectivity of the complex was established. The skeleton is rather different to that of **8** since the central core is not planar but angular, as schematized in Figure 3.

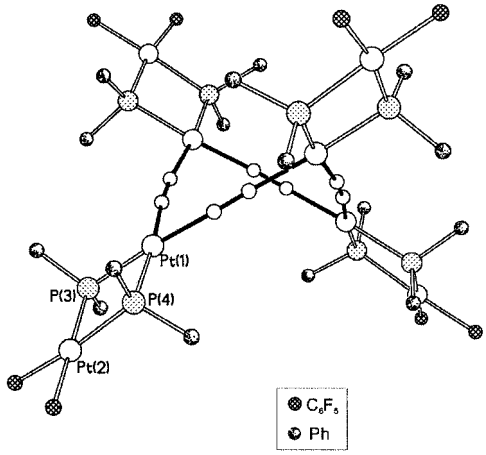

Figure 3. Structure of the anion of $[PPh_3Me]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2Pt(\mu\text{-}PPh_2)_2Pt(C_6F_5)_2\}_2]$ (**9**).

Conclusion

Complex **1**, in which the two acetonitrile ligands can be easily replaced, can be considered as a neutral dinuclear building block with "open-coordination sites" at 90°. The study involves the design of one-dimensional complexes with both diphenylphosphido and bpym ligands and two-dimensional molecules with diphenylphosphido and cyanide ligands. The anionic dinuclear complex **6** is used as a metalloligand towards neutral mononuclear or dinuclear species. This is a straightforward route for the preparation of homo- or heterometallic species. The choice of neutral entities,"$(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt$" and "$M(C_6F_5)_2$", and an anionic linker, cyanide, allowed us to synthesize the tetraanionic squares **7**, **8** and **9**, even though the complexes with this molecular architecture that have been reported so far are usually cationic or neutral species.

Experimental Section

General Procedures: C, H and N analysis was performed with a Perkin–Elmer 240B microanalyser. IR spectra were recorded with a Perkin–Elmer Spectrum One spectrophotometer (Nujol mulls between polyethylene plates in the range 4000–350 cm^{-1}). NMR spectra were recorded with a Varian Unity 300 instrument with $SiMe_4$, $CFCl_3$ and 85% H_3PO_4 as external references for ^1H, ^{19}F and ^{31}P, respectively. Conductivities (acetone, $c \approx 5 \times 10^{-4}$ M) were measured with a Philips PW 9509 conductimeter. Literature methods were used to prepare the starting materials $[Bu_4N]_2[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}Cl)\}_2]$[21] and *cis*-$[M(C_6F_5)_2(THF)_2]$ (M = Pt, Pd).[50]

Caution! *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared, and these should be handled with great caution.*

Preparation of $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(NCCH_3)_2]$ (1): $AgClO_4$ (0.150 g, 0.723 mmol) was added to a solution of $[Bu_4N]_2[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}Cl)\}_2]$ (1.000 g, 0.364 mmol) in acetone (10 mL) and acetonitrile (10 mL). The mixture was stirred at room temperature for 4 h, filtered, and the resulting solution was concentrated to ca. 5 mL, whereupon **1** crystallised as a white solid. *i*PrOH (5 mL) was added and the mixture was stirred for 1 h. Complex **1** was collected by filtration and washed with 2 mL of *i*PrOH. Yield: 0.651 g (76%). $C_{40}H_{26}F_{10}N_2P_2Pt_2$ (1176.8): calcd. C 40.82, H 2.22, N 2.38; found C 40.98, H 2.03, N 2.59. IR (nujol mull): $\tilde{\nu}$ = 782 and 774 (X-sensitive C_6F_5 group),[22,23] 2323, 2294 (N≡C) cm^{-1}. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –166.0 (6 *m*- + *p*-F), –114.7 ($^3J_{Pt,F}$ = 301 Hz, 4 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –143.8 ($J_{Pt^1,P}$ = 1927, $J_{Pt^2,P}$ = 2454 Hz) ppm.

Preparation of $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}bpym)Pt(\mu\text{-}PPh_2)_2Pt(C_6F_5)_2]$ (2): 2,2′-bpym (0.013 g, 0.084 mmol) was added, with stirring, to a colourless solution of **1** (0.200 g, 0.169 mmol) in acetone (15 mL) and **2** began to precipitate as a yellow solid. After 45 min stirring, **2** was filtered off, washed with 1 mL of acetone and vacuum-dried. Yield: 0.161 g (81%). $C_{80}H_{46}F_{20}N_4P_4Pt_4$ (2347.6): calcd. C 41.00, H 1.97, N 2.38; found C 41.49, H 1.84, N 2.17. IR (nujol mull): $\tilde{\nu}$ = 784, 776 (X-sensitive C_6F_5 group), 1581 (bpym) cm^{-1}. Complex **2** is not soluble enough in usual organic solvents for NMR studies.

Preparation of $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(bpym)]$ (3): 2,2′-bpym (0.013 g, 0.084 mmol) was added to a colourless solution of **1** (0.100 g, 0.084 mmol) in acetone (15 mL). After 15 h of stirring at room temperature, the orange solution was concentrated almost to dryness and $CHCl_3$ (3 mL) was added while stirring. Complex **3** crystallised as a yellow solid, which was filtered off and washed with 1 mL of $CHCl_3$. Yield: 0.085 g (81%). $C_{44}H_{26}F_{10}N_4P_2Pt_2$ (1252.9): calcd. C 42.14, H 2.07, N 4.47; found C 41.74, H 1.85, N 4.16. IR (nujol mull): $\tilde{\nu}$ = 783, 775 (X-sensitive C_6F_5 group), 1580, 1556 (bpym) cm^{-1}. ^1H NMR (300 MHz, [D$_6$]acetone, 22°C): δ = 7.68 (t, $J_{H^5,H^{4,6}}$ = 5.2 Hz, 2 H^5-bpym), 8.36 (br. d, 2 H^6-bpym), 9.32 (br. d, 2 H^4-bpym) ppm. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –166.1 (2 *p*-F), –165.9 (4 *m*-F), –114.2 ($^3J_{Pt,F}$ = 301 Hz, 4 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –125.6 ($J_{Pt^1,P}$ = 1859, $J_{Pt^2,P}$ = 2390 Hz) ppm.

Preparation of $[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}bpym)Pt(C_6F_5)_2]$ (4a): *cis*-$[Pt(C_6F_5)_2(THF)_2]$ (0.053 g, 0.078 mmol) was added to a yellow solution of **3** (0.100 g, 0.079 mmol) in CH_2Cl_2 (10 mL). The colour of the solution changed to brown, while a solid began to crystallise. After 15 min of stirring, the brown solid **4a** was filtered off and washed with 1 mL of CH_2Cl_2. Yield: 0.071 g (50%). $C_{56}H_{26}F_{20}N_4P_2Pt_3$ (1782.1): calcd. C 37.70, H 1.45, N 3.10; found C 37.90, H 1.47, N 2.74. IR (nujol mull): $\tilde{\nu}$ = 816, 808, 782, 774 (X-sensitive C_6F_5 group), 1585 (bpym) cm^{-1}. ^1H NMR (300 MHz, [D$_6$]acetone, 22°C): δ = 8.00 (t, $J_{H^5,H^{4,6}}$ = 5.4 Hz, 2 H^5-bpym), 8.58 (br. d, 2 H$^{6/4}$-bpym), 9.08 (br. d, 2 H$^{4/6}$-bpym) ppm. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –168.0 (6 *m* + *p*-F), –166.0 (4 *m*-F), –163.5 (2 *p*-F), –120.1 ($^3J_{Pt,F}$ = 459 Hz, 4 *o*-F), –116.0 ($^3J_{Pt,F}$ = 300 Hz, 4 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –128.6 ($J_{Pt^1,P}$ = 1868, $J_{Pt^2,P}$ = 2414 Hz) ppm.

Preparation of $[PPh_3(CH_3)]_2[(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(CN)_2]$ (6): KCN (0.030 g, 0.460 mmol) was added to a solution of **1** (0.200 g,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.170 mmol) in acetone (10 mL) and the mixture was stirred at room temperature for 15 h. $[PPh_3(CH_3)]ClO_4$ (0.128 g, 0.339 mmol) was then added and the mixture was concentrated to dryness. CH_2Cl_2 (10 mL) was added to the white residue and then filtered. The solution was concentrated to ca. 1 mL, *i*PrOH (10 mL) was added and **6** crystallised as a white solid which was filtered off, washed with 2 mL of *i*PrOH and vacuum-dried. Yield: 0.211 g (73%). $C_{76}H_{56}F_{10}N_2P_4Pt_2$ (1701.38): calcd. C 53.65, H 3.31, N 1.64; found C 53.80, H 2.98, N 1.60. IR (nujol mull): $\tilde{\nu}$ = 782, 773 (X-sensitive C_6F_5 group), 2122, 2113 ν(C≡N) cm^{-1}. Λ_M = 91 $\Omega^{-1}cm^2mol^{-1}$. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –166.4 (2 *p*-F), –164.6 (4 *m*-F), –111.7 ($^3J_{Pt,F}$ = 323 Hz, 4 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –150.3 ($J_{Pt^{1,2},P}$ = 1820 Hz, PPh_2), 27.2 (PPh_3CH_3) ppm.

Preparation of $[PPh_3CH_3]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)_2M(C_6F_5)_2\}_2]$. M = Pt (7): *cis*-$[Pt(C_6F_5)_2(THF)_2]$ (0.060 g, 0.089 mmol) was added to a solution of **6** (0.150 g, 0.088 mmol) in CH_2Cl_2 (10 mL) and the solution was stirred for 1.5 h. The solvent was evaporated to leave 2 mL while a white solid began to crystallise and $CHCl_3$ (5 mL) was added. Complex **7** was filtered off and washed with 1 mL of cold $CHCl_3$. Yield: 0.134 g (68%). $C_{176}H_{112}F_{40}N_4P_8Pt_6$ (4461.2): calcd. C 47.38, H 2.53, N 1.25; found C 47.03, H 2.03, N 1.19. IR (nujol mull): $\tilde{\nu}$ = 810, 800, 783, 773 (X-sensitive C_6F_5 group), 2164 br. ν(C≡N) cm^{-1}. Λ_M = 106 $\Omega^{-1}cm^2mol^{-1}$. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –166.8 (4 *p*-F), –166.6 (4 *p*-F), –166.3 (8 *m*-F), –166.1 (8 *m*-F), –117.7 ($^3J_{Pt,F}$ 505 = Hz, 8 *o*-F), –114.4 ($^3J_{Pt,F}$ = 333 Hz, 8 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –157.2 ($J_{Pt^{1,2},P}$ = 1831 Hz, PPh_2), 23.1 (PPh_3CH_3) ppm. **M = Pd (8):** This complex was obtained [yield: 0.070 g (56%)] according to a similar procedure to that used for **7** from **6** (0.100 g, 0.058 mmol) and *cis*-$[Pd(C_6F_5)_2(THF)_2]$ (0.034 g, 0.058 mmol). $C_{176}H_{112}F_{40}N_4P_8Pd_2Pt_4$ (4283.8): calcd. C 49.35, H 2.63, N 1.31; found C 49.57, H 2.44, N 1.25. IR (nujol mull): $\tilde{\nu}$ = 797, 784, 774 (X-sensitive C_6F_5 group), 2164, 2157 ν(C≡N) cm^{-1}. Λ_M = 162 $\Omega^{-1}cm^2mol^{-1}$. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –166.0 (4 *p*-F), –164.5 (8 *m*-F), –163.1 (12 *m* + *p*-F), –112.2 (8 *o*-F), –112.2 ($^3J_{Pt,F}$ = 328 Hz, 8 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –154.8 ($J_{Pt^{1,2},P}$ = 1835 Hz, PPh_2), 26.9 (PPh_3CH_3) ppm.

Preparation of $[PPh_3CH_3]_4[\{(C_6F_5)_2Pt(\mu\text{-}PPh_2)_2Pt(\mu\text{-}CN)\}_4]$ (9): Complex **1** (0.056 g, 0.048 mmol) was added to a solution of **6** (0.080 g, 0.048 mmol) in acetone (10 mL) and the solution was stirred at room temperature for 15 h. The solvent was evaporated to leave ca. 2 mL and $CHCl_3$ (8 mL) was added and the mixture concentrated to ca. 5 mL. Complex **9** crystallised as a white solid which was filtered off and washed with 1 mL of $CHCl_3$. Yield: 0.076 g (57%). $C_{224}H_{152}F_{40}N_4P_{12}Pt_8$ (5592.2): calcd. C 48.12, H 2.70, N 1.00; found C 48.30, H 2.31, N 0.77. IR (nujol mull): $\tilde{\nu}$ = 781, 771 (X-sensitive C_6F_5 group), 2152 br. ν(C≡N) cm^{-1}. Λ_M = 91 $\Omega^{-1}cm^2mol^{-1}$. ^{19}F NMR (282.4 MHz, [D$_6$]acetone, 22°C): δ = –167.5 (4 *p*-F), –167.3 (4 *p*-F), –166.2 (12 *m*-F), –165.6 (4 *m*-F), –114.0 ($^3J_{Pt,F}$ = 317 Hz, 16 *o*-F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_6$]acetone, 22°C): δ = –161.0 ($J_{Pt^{1,2},P}$ = 1843 Hz, PPh_2), –157.9 ($J_{Pt^{3},P}$ = 1899, $J_{Pt^{4},P}$ = 2400 Hz, PPh_2), 23.0 (PPh_3CH_3) ppm.

Structural Analysis of Complexes 1·Me_2CO and 8·3Me_2CO·*n*-hexane: Crystal data and other details of the structure analysis are presented in Table 3. Single crystals were mounted on quartz fibres in a random orientation and held in place with a fluorinated oil. Data collection was performed at 100 K with a Bruker Smart CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) with a nominal crystal-to-detector distance of 6.0 cm. Unit-cell dimensions were determined on the basis of the positions of 9622 (**1**) or 7283 (**8**) reflections from the main dataset. For **1**, a hemisphere of data, based on three ω-scans runs (starting ω =

–28°) at φ values 0, 90, and 180 with the detector at 2θ = 28°, was collected. At each of these runs, frames (606, 435 and 230 respectively) were collected at 0.3° intervals and 10 s per frame. For **8**, a complete sphere of data was collected based on three ω-scans runs at φ values of 0, 120 and 240. At each of these runs, 606 frames were collected at 0.3° intervals and 30 s per frame. The diffraction frames were integrated using the SAINT package[51] and corrected for absorption with SADABS.[52] Lorentz and polarisation corrections were also applied. The structures were solved by direct methods. All non-hydrogen atoms of the complexes were assigned anisotropic displacement parameters. The hydrogen atoms were constrained to idealised geometries and assigned isotropic displacement parameters equal to 1.2- or 1.5-times the U_{iso} values of their respective parent atoms. After all atoms of the molecules had been located, there still remained some areas of electron density that were modelled as the lattice solvent. Final difference electron density maps showed, only in the case of **8**, some peaks above 1 e Å^{-3} (max. 2.69, largest diff. hole –1.07), most of them close to the heavy metal atoms and with no chemical meaning, others were located in the solvent area. The crystals lost solvent very rapidly and because of this their quality was not good. The structures were refined using the SHELXL-97 program.[53] CCDC-268963 (**1**) and -268963 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Vertex-Sharing Water Tape Consisting of Cyclic Hexamers

Bao-Qing Ma,*[a] Hao-Ling Sun,[a] and Song Gao*[a]

Keywords: Water aggregates / Cyanides / Hydrogen bonds

A 1D water tape consisting of vertex-sharing cyclic water hexamers has been observed, which represents a subunit of ice structure.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Water is recognized as being essential for life processes, but its actual role in these processes is relatively poorly understood.[1] The obstacle lies in the diversity of hydrogen-bonding associations of water molecules, as reflected by a large number of polymorphous forms of ice. Discrete small clusters, as the basic units of water structure, have been widely investigated both experimentally and theoretically, because their structural information holds considerable promise for the understanding of the behavior of bulk water and processes in biological systems.[2] This realization has prompted enormous studies on the water structures trapped in different environments and great progress has been made regarding structural characterization in hydrate clathrates.[3–7]

One-dimensional water morphologies including chains and tapes constitute an important form of water, which plays a significant role in many fundamental biological processes as "proton wires".[8] Helical water chains have also been observed in crystal hosts.[9] From a structural point of view, the polymeric water morphologies have a close relationship with bulk water, especially those containing a cyclic water hexamer, which is one of the dominant components in liquid water and the building unit of ice I_h. Two-dimensional water layers consisting of hexameric rings with different conformations such as boat, chair, or hybrid chair/boat have been observed in several cases.[10] Although extended tapes containing hexamers have been reported recently, they actually comprise fused tetramers and hexamers[11] rather than sole hexamers. In this context, we report herein a 1D tape-like water structure consisting of vertex-sharing cyclic hexamers, which is hosted within the complex $[Fe(bipy)_2(CN)_2]\cdot 2.5H_2O$ (**1**) (bipy = 2,2′-bipyridine). The tape is a fragment of ice I_h and can be viewed as a simple model of ice structure.

Results and Discussion

Description of the Structure of 1

An ORTEP view of compound **1** is shown in Figure 1. Selected bond lengths and angles are given in Table 1. The compound consists of one $Fe(bipy)_2(CN)_2$ moiety and two and a half water molecules. The ferricyanide moiety has been widely used for the preparation of molecule-based magnetic materials[12] and recent interest has been focused on the versatile cyanide fragments with capping ligands to diversify the structures and properties.[13] The Fe atom in **1** is coordinated by four N atoms from two chelating 2,2′-bipy molecules [Fe–N1 = 2.004(2); Fe–N2 = 1.978(2); Fe–N3 = 1.987(2); Fe–N4 = 1.962(2) Å] and two C atoms from two *cis* cyanide groups [Fe–C21 = 1.915(2); Fe–C22 = 1.910(2) Å], forming an essentially octahedral coordination environment, which is similar to its analogue, $[Fe(1,10\text{-phen})_2(CN)_2]\cdot 3H_2O$.[14] The corresponding bond lengths are in agreement with those in $[Fe(1,10\text{-phen})_2(CN)_2]\cdot 3H_2O$. The Fe atom and cyanide groups are almost linear, with the Fe–C21–N5 and Fe–C22–N6 bond angles being 176.6(8) and 176.0(8)°, respectively. The C21–Fe–C22 bond angle is

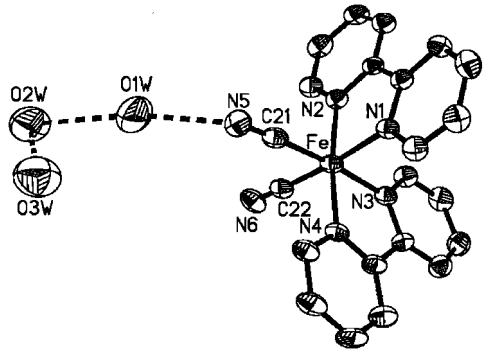

Figure 1. Molecular structure of compound **1**.

87.52°, consistent with that in complex $[Fe(1,10\text{-phen})_2(CN)_2]\cdot 3H_2O$ (88.61°). The dihedral angles between the two pyridine rings of each 2,2′-bipy (N1–N2; N3–N4) are 7.88(62) and 5.17(21)°, respectively, and the two 2,2′-bipy molecules are almost perpendicular, with an intersecting angle of 86.37°.

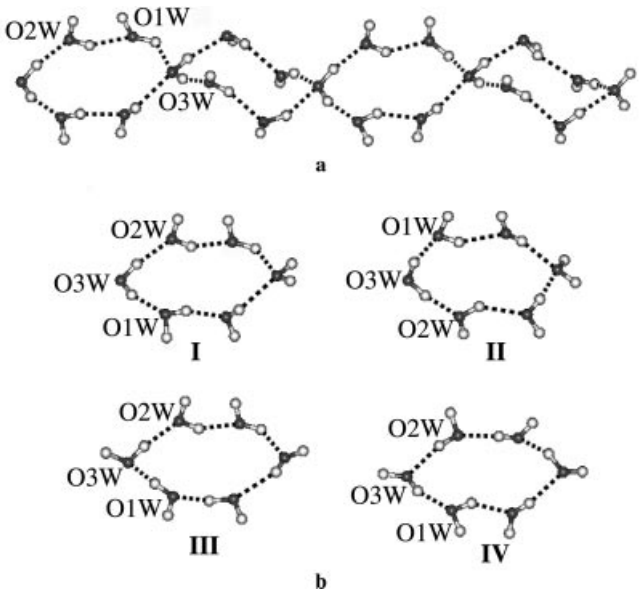

Figure 2. (a) 1D water tape assembled from cyclic hexamers by sharing one vertex. Hydrogen bonds [Å]: O1W···O2W*a* = 2.952(4); O1W···O3W = 2.920(3); O2W···O3W = 2.808(3); $a = -x, -y + 1, -z$. (b) Four different hydrogen-bonding patterns presented in the water tape due to imposed symmetry restriction.

Interestingly, two and a half independent water molecules associated with hydrogen bonds form a cyclic hexamer, which is center-symmetric and adopts a chair conformation (Figure 2a). The average O···O distance of 2.89 Å is close to the value in liquid water (2.85 Å),[15] but longer than that in ice I_h (2.759 Å).[16] Compared with those discrete water hexamers recently observed in the solid states, the distance is slightly shorter than that found in a planar hexamer (2.905 Å)[5b] trapped in an organic compound, however it is longer than that housed in a metal-organic framework.[17] The bond angles in the hexamer vary from 80.5 to 132.9°, which considerably deviates from the corresponding value of 109.3° for preferred tetrahedral geometry in hexagonal ice, implying that the flexibility of hydrogen bonds allows efficient perturbation enforced by the surrounding environments.

Theoretical calculation predicts that hexamer represents the transition from 2D cyclic to 3D cage structure with a cage isomer as a stable configuration.[2a] Other less stable conformers including boat, chair, and quasiplanar, have also been experimentally observed. The chair-shaped hexamers described here are not discrete, but self-assembled into a one-dimensional tape by sharing a vertex, which is located on a twofold axis parallel to the [010] direction (Figure 2a). The adjacent hexamers are tilted with an intersecting angle of 28°. The shared water serves as double hydrogen-bond donors and acceptors with a tetrahedral geometry, which is a quite common configuration for the oxygen atom in ice and liquid water. The remaining two water molecules participate in three hydrogen-bonding interactions as double donors and single acceptor, reminiscent of the water surface or interface, where deficient hydrogen-bonded water molecules are present. Recent spectroscopic experiments also demonstrated that significant numbers of oxygen atoms in liquid water are less than four coordinate.[18] As imposed by the symmetry (space group *C*2/*c*), the hydrogen atoms, except for those bonded to a peripheral host, are disordered, as commonly found in ice structure, and there are four possible hydrogen-bonding patterns, as illustrated in Figure 2b. This reflects the anomalous nature of water due to flexible hydrogen bonds. Four hydrogen atoms related by a twofold axis on O3W have half occupancy. O1W and O2W water molecules each have a full-occupancy hydrogen atom that is hydrogen bonded to the host, while the intratape hydrogen atoms are positionally disordered with half occupancy. The bridging O3W has a typical tetrahedral geometry for a water molecule with O3W···O1W and O3W···O2W distances being 2.904(4) and 2.799(3) Å, respectively.

In contrast to frequently observed discrete water tetrameric, pentameric, and hexameric clusters, the connection of these clusters into a tape-like motif is relatively rare. Very recently, a 1D tape consisting of vertex-sharing water tetramers has been reported[19] and we discovered two water tapes made up of vertex-sharing and edge-sharing pentamers.[6a,20] Water tapes consisting of mixed water rings including fused hexamers and tetramers trapped in an organic compound, 2,4-bimethyl-5-aminobenzo[*b*]-1,8-naphthyridine,[11a] and a metal-organic complex, $[Ag_2(ophen)_2]_2\cdot 6H_2O$ [Hophen = 1*H*-[1,10]phenanthrolin-2-one], have also been observed.[11b] The currently described water tape built from vertex-sharing hexamers represents an important development of this kind of motif. We are unaware of any other reported water tapes made of sole water hexamers, though 1D chains consisting of cyclic hexameric chair conformers linked by metal ions have been reported in the complexes $[M(H_2biim)_2(H_2O)_2](ina)_2\cdot 4H_2O$ (M = Zn, Co; H_2biim = 2,2′-biimidazole; ina = isoniconate).[21] Considering a pivotal position of the hexamer in the water structure, our water tape could provide insight into the mysterious veil

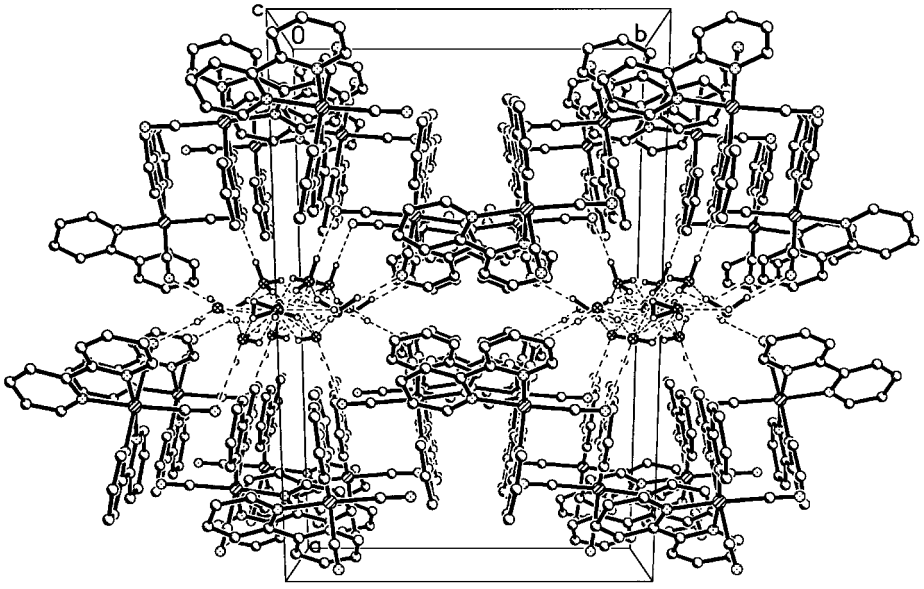

Figure 3. The packing diagram of **1** viewed along crystallographic *c* axis, showing 1D channels in which water tapes are included. Hydrogen atoms on the host are omitted for clarity. Hydrogen bonds [Å]: O1W···N5 = 2.850(3); O2W*a*···N6 = 2.918 (2); *a* = –*x*, –*y* + 1, –*z*.

of water. To simplify the ice structure, one can reduce its dimension to 2D sheet, to 1D tape, to 0D cluster. The 1D tape lies in between 2D sheet and 0D cluster and can be either edge- or vertex-sharing, which not only is a simple model with respect to 2D sheet, but also has close approximation to ice with respect to the discrete hexameric cluster.

These 1D water tapes are anchored within the channels produced by the host packing. The perpendicular arrangement of the two coordinated 2,2′-bipy molecules around the Fe atom in **1** leads to a rectangular channel with approximate dimensions of 5 × 8 Å parallel to the [001] direction (Figure 3). This channel size appears to adapt the water tape well, as opposed to the "armchair" and zigzag water chains which are hosted within the channels of 6.63 × 3.44 Å and 4.80 × 3.02 Å, respectively.[22] By comparison, a linear water trimer cluster is filled within the channel formed in the compound $[Fe(1,10\text{-phen})_2(CN)_2]\cdot 3H_2O$,[14] which has a similar structure to **1**. The small channel size due to the presence of the bulky 1,10-phen ligands prevents further aggregation of water clusters, and no water tape was observed, indicating the influence of the host environment on the water structure. The cyanide groups from $[Fe(2,2'\text{-bipy})_2(CN)_2]$ units point inward to the channels and form hydrogen bonds with the free hydrogen atoms available to O1W and O2W water molecules. The O···N separation from water tapes to cyanide groups are 2.850(3) and 2.918(2) Å, which are comparable to those in the interior of the tape.

Thermogravimetric Analysis

Thermogravimetric analysis was done with an LT-1 model thermobalance. Compound **1** showed a weight loss of 9.59% below 100 °C, which corresponds to the lattice water molecules, in agreement with the calculated value of 9.62%. It also demonstrates that water tapes are loosely anchored within the host. At 220 °C, the complex began to lose the ligands and decomposed completely at 355 °C. The processes of decomposition are very complicated. The final residue (observed 18.84%) is assigned as Fe_2O_3 (calculated 18.20%).

Conclusions

A novel water tape structure featuring vertex-sharing cyclic hexamers has been structurally determined. Characterization of water morphologies in crystal hydrates is rapidly growing into a new field. Although the control of water clusters of different nuclearity is impossible at the current stage, a judicious choice of hosts could be helpful to trap novel water morphologies. This study and our recent finding of an octameric cluster in a cyanide-bridged f-d complex[23] imply that the cyanide compound might be a good promoter to induce water aggregations.

Experimental Section

Synthesis of 1: Compound **1** was prepared by the literature method.[24] Column-shaped single crystals suitable for X-ray diffraction were obtained through recrystallization of **1** in methanol after 2 weeks.

Crystallography: Crystal data and refinement parameters are summarized in Table 2. Data collection was performed with an Enraf–Nonius CAD-4 Mach3 diffractometer with graphite-monochromated Mo-K_α radiation. A dark red single crystal with approximate dimensions of 0.12 × 0.15 × 0.30 mm^3 was chosen. Unit cell was determined from 25 indexed reflections in the range 8.32–14.97°. Intensity data were collected using ω-2θ-scan mode in the range 1.67 ≤ θ ≤ 27.02°. Of the 5793 reflections measured, 4624 were found

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to be unique (R_{int} = 0.1146). An absorption correction based on ψ scan was applied to the data during data reduction. No decay correction was applied. The structure was solved by the heavy atom method and refined by a full-matrix least-squares technique based on F^2 using the SHELXL 97 program[25]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms on 2,2′-bipy molecules were placed in geometrically calculated positions and refined isotropically. Hydrogen atoms on water molecules were located from difference Fourier maps and refined by fixing the O–H bond length to 0.96 Å and the isotropic temperature factors to a value of 1.5 times that of the oxygen atoms. CCDC-255296 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Molecular Recognition – Allosterism Generated by Weak Host–Guest Interactions in Molecular Rectangles

James D. Crowley,[a] Ian M. Steele,[a] and Brice Bosnich*[a]

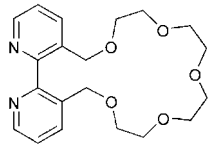
Keywords: Host–guest systems / Molecular recognition / Allosterism / Self-assembly / Supramolecular chemistry

Two metal-based molecular rectangles that bear two identical binding sites form 1:2 host–guest adducts with a pair of analogous planar Pt^{2+} complexes. The larger of the two guests shows no binding allosterism with either of the two rectangles, but substantial positive allosterism is observed when the smaller guest binds to the rectangles. It is proposed that the smaller guest is better accommodated in the binding sites of the receptor and that this leads to allosterism. Various experiments, including ^{1}H NOESY spectroscopy, support the supposition that the smaller guest is better incarcerated in the receptors.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

1. Introduction

Allosterism is commonly deployed by biological systems for controlling and regulating function. In these systems, the binding of a substrate usually engenders conformational or other changes in the receptor so that the subsequent binding of the same substrate at other identical sites is either of enhanced or of decreased stability. The mechanisms that generate positive or negative allosterism are subtle, and they are poorly understood in complicated systems. There have been numerous model systems developed,[1] starting with the classical experiments of Rebek.[2] Rebek devised several allosteric systems, including **1**.



1

The bipyridyl-bound complex [(**1**)W(CO)$_4$] is a (kinetically) stable molecule. Using a U-tube where water is separated by CH_2Cl_2, it was found that the free ligand **1** transported K^+ in preference to Na^+, but that the tungsten complex caused these preferences to be reversed. It was assumed that the transport preference is related to the stability of the alkali ion in the crown-ether site. The bipyridyl that binds to the tungsten generates a different preferred conformation for the crown ether from that adopted by the free ligand **1**. Thus, the tungsten bound to the bipyridyl is mechanically coupled to the crown ether site, leading to different binding affinities of the alkali metals. Following from this work, there have been numerous examples of allosterism involving dinuclear ligands, where the insertion of a metal into one site leads to increased or diminished binding of a second metal in the other site.[1] Some of these systems have been especially sophisticated, some involve allosteric control of catalysis.[1] In some respects, generating allosterism by homo- or heterotopic coordination of metals has a well-understood logic, which relies on the positioning of coordinating ligands for binding to metals with commensurate stereochemical demands. These aspects are cogently presented in Kramer's review.[1]

The next level of complexity in synthetic modeling was in deploying weak (directional) hydrogen bonding for mechanical coupling. The first example of allosterism generated by hydrogen bonding was reported by Hunter[3] who synthesized a host with two identical hydrogen bonding sites for the guest, quinone. In $CHCl_3$ solution, positive allosterism was observed for the two homotopic sites of the host. The allosterism was modest; the successive constants were $K_1 = 14\ M^{-1}$ and $K_2 = 28\ M^{-1}$. Later, a similar hydrogen-bonding homoditopic receptor was found to give positive allosterism for a single guest.[4] More recently, a carefully designed homoditopic system was found capable of giving high positive allosterism for a variety of guests.[5] Differences of 33:1 between the two constants were reported.

As far as we are aware, no examples of allosterism involving weak, poorly directional forces, such as π–π interactions, have been reported.[1e] This paper reports cases where weak molecular recognition forces lead to positive allosterism.

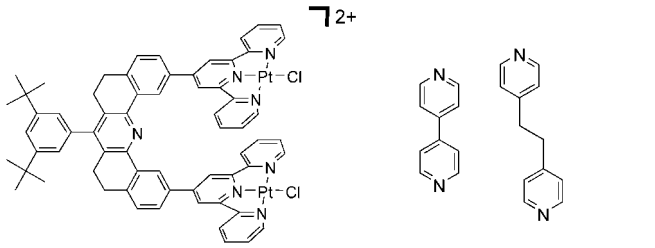
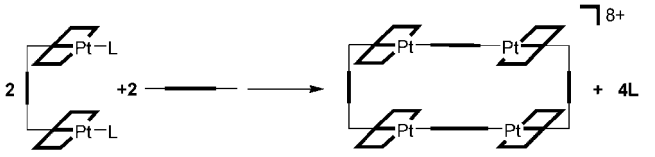
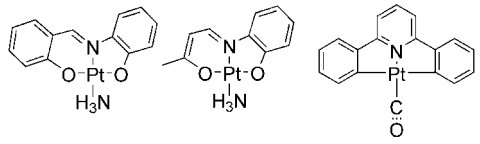
2. Receptors and Guests

Molecular rectangles bearing two identical sites were used for investigating allosterism. The molecular cleft **2** is joined by the linkers **3** or **4** to give the molecular rectangles as shown schematically in Equation (1). The three potential metal-containing guests, **5**, **6**, and **7**, were investigated in order to study allosterism. With receptor **2**, both of the guests **5** and **6** form stable 1:1 host–guest complexes in solution.[6,7]

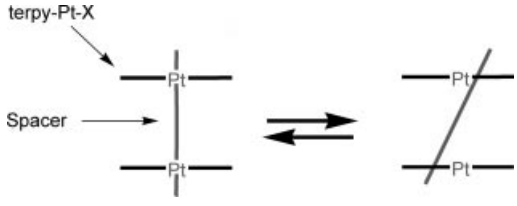




(1)



Crystal structures and NOE experiments[6,7] show that the guests **5** and **6** lie within the molecular cleft of **2**. In the solid state, and probably also in solution, the guests **5** and **6** engage in weak Pt–Pt interaction with the receptor **2**. The maximum separation between the face-to-face terpy-Pt-X units of receptor **2** is about 7.2 Å. The crystal structure shows that this interplanar separation is contracted to 6.557 Å in order to accommodate guest **5** in **2**.[6] This contraction is achieved by the concerted rotation of the terpy-Pt-X units about the spacer unit as shown in Scheme 1.



Scheme 1.

Addition of the guests **5** or **6** to solutions of the molecular rectangles will lead to stepwise incarceration of the guests into the molecular clefts. Upon the addition of the first guest, the terpy-Pt-linker unit separation is likely to contract to accommodate the guest. When this happens, the other terpy-Pt-linker unit separation is also likely to contract, because the sites are mechanically coupled by the linkers **3** and **4**. Linker **4** is less rigid than linker **3** and this may lead to less rigid mechanical coupling of the sites. Thus it is conceivable that after the insertion of one guest into a site, the other site may become better organized to accept the second guest because of conformational changes induced by the first adduct formation. If this is the case, then positive allosterism might be observed in host–guest adducts of the rectangles. The reason for including **7**[8] as a guest will become apparent later.

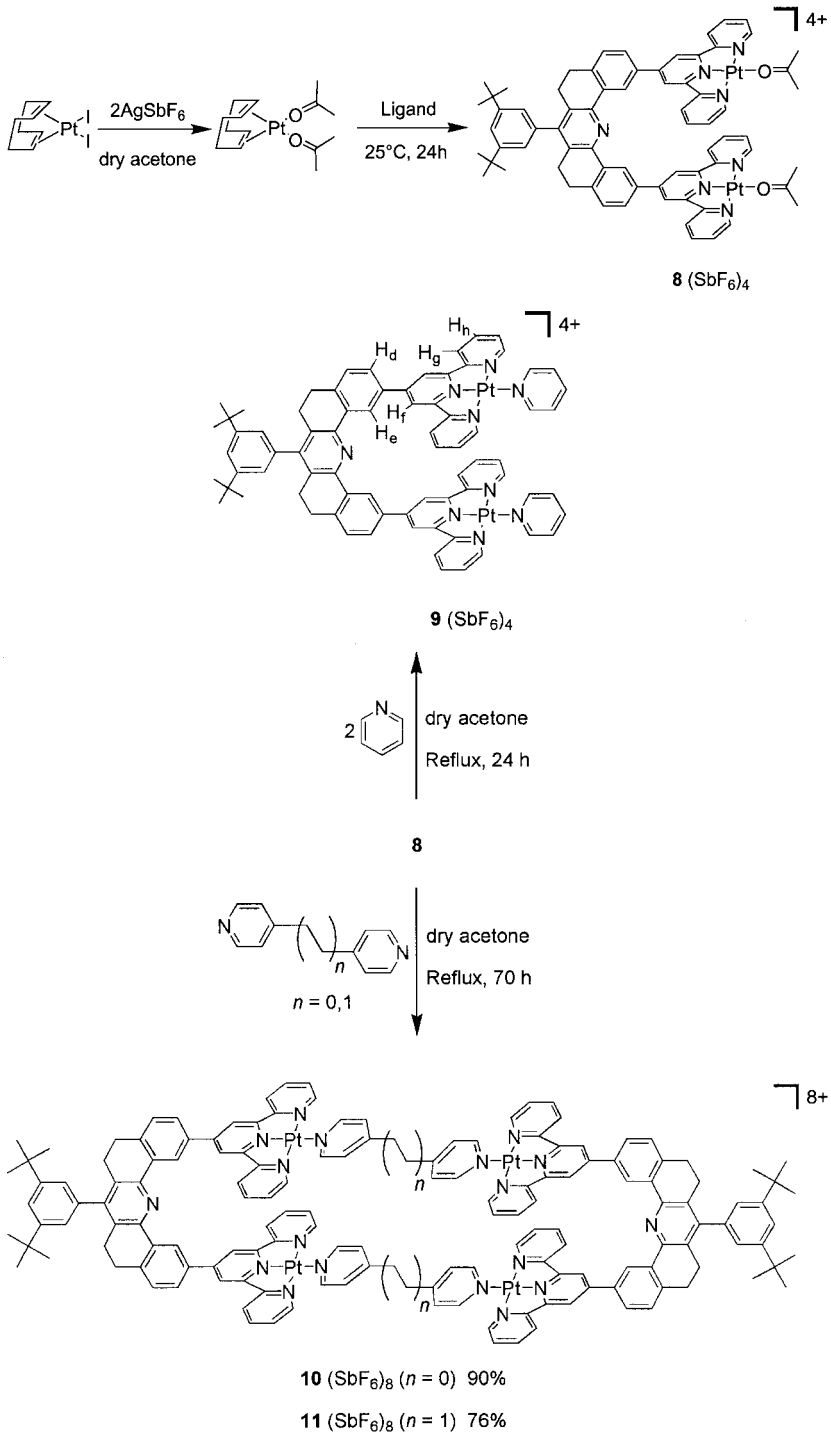
The preparation of the receptor ligand in **2** has been described elsewhere[9] as was the preparation of **5**,[6] **6**,[7] and **7**.[8] Because the reactions of Pt^{2+} complexes are usually kinetically slow, the procedure outlined in Scheme 2 was used for incorporating Pt^{2+} into the two terpy sites of the ligand. The rate of Pt^{2+} incorporation is enhanced by the trans-effect of the olefins and by the fact that presumably labile acetone ligands are being substituted. The reactions are carried out under anhydrous conditions to avoid the formation of nonlabile hydroxo complexes. Solutions of the dipyridine compound **9** and of the two rectangles are kinetically stable at room temperature and below. This behavior contrasts with that of the analogous Pd^{2+} compounds,[10] which are kinetically labile in solution at room temperature. The two rectangles in dimethyl formamide (DMF) solutions give ESI-MS spectra[11] that are devoid of fragmentation and show ion peaks that are consistent with the proposed structures, which, in turn, are confirmed by the peak isotopic distribution of the 2+ ions (Supporting Information). Furthermore, the ^1H NMR spectra of the two rectangles are in full accord with the proposed structures (Supporting Information). There seems little doubt that the molecular rectangles have been correctly identified.

3. Host–Guest Formation

All of the host–guest adduct investigations were carried out in [D_7]DMF solutions at 60 °C. DMF was used because it is a poorly coordinating solvent, and, at 60 °C in this solvent, all of the ^1H NMR spectral peaks are sharp for both the host and the guest. By following the change in chemical shift for certain protons as a function of the mol ratio of host to guest, the stoichiometry of the binding and the binding constants were determined.[12]

As expected, either guest, **5** or **6**, formed 1:1 host–guest adducts with receptor **9** (see Figure 6). The stability constants are listed in Table 1. The smaller value of the stability constant for the **9**–**6** adduct may be related to the smaller π-surface of guest **6**. For both host–guest complexes, complexation-induced chemical shifts are observed for the (internal) H_e but not for the (outer) H_d protons (see Scheme 2), indicating that the guest resides within the molecular cleft. Upon host–guest formation, the color changes

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2.

to deep red from the light yellow of the components (see Figure 5). The ESI-MS of the host–guest adducts gives peaks for the free receptor, in addition, strong peaks are observed for the 1:1 host–guest adducts formed by **9** with **5** (see Figure 7) and with **6**.

The stabilities of the host–guest adducts **9**–**5** and **9**–**6** should be related in some respects to the first association constants for the two molecular rectangles **10** and **11** (Scheme 2). At 60 °C in [D_7]DMF solution, a 1:2 host–guest complex was found to form between the molecular rectangle **10** and the guest **5** (see Figure 9). As expected, host–guest formation is signaled by the appearance of a deep red color (see Figure 8). ESI-MS of the host–guest adduct, **10**–(**5**)$_2$, provides peaks for the free rectangle, for the receptor with one guest associated, and for the 1:2 host–guest adduct (see Figure 10). Similar ESI-MS data are observed for all rectangle adducts listed in Table 1, and in all cases, host–guest formation is signaled by the appearance

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of red-colored solutions. The two statistically adjusted microscopic stability constants[13] for the adduct are listed in Table 1 together with the ratio of the stability constants, K_2/K_1. No allosterism is observed for this system: the two constants are the same within experimental error. The absence of allosterism for rectangle **10** could be connected with the rigidity of the linker, which may hinder appropriate mechanical coupling between the two sites. Rectangle **11** has a more flexible linker, and this circumstance might allow favorable conformational adjustment at the binding sites. The two microscopic stability constants for the host–guest adduct **11**–(**5**)$_2$ are listed in Table 1. Again, no allosterism is observed within experimental error. Interestingly, the association constants for the adducts **10**–(**5**)$_2$ and **11**–(**5**)$_2$ are the same within experimental error. The absence of allosterism in either of these cases might suggest that the structure of the guest may influence whether or not allosterism is observed. It was supposed that a smaller guest such as **6** might fit better into the molecular clefts of the rectangles, and, as a consequence, better mechanical coupling between the two binding sites may ensue.

The pairs of stability constants for the 1:2 host–guest adducts **10**–(**6**)$_2$ and **11**–(**6**)$_2$ are given in Table 1. Positive allosterism is observed for both adducts, the **11**–(**6**)$_2$ system having the larger cooperative enhancement.

Table 1. Microscopic stability constants (M^{-1}) for host–guest formation in [D_7]DMF at 60 °C.

Adduct	Host–Guest Stoichiometry	K_1 [M^{-1}]	K_2 [M^{-1}]	Ratio K_2/K_1
9–**5**	1:1	3760 ± 600	–	–
9–**6**	1:1	1160 ± 200	–	–
10–(**5**)$_2$	1:2	4100 ± 200	4200 ± 100	1.02
11–(**5**)$_2$	1:2	3800 ± 300	4400 ± 100	1.15
10–(**6**)$_2$	1:2	1450 ± 200	5200 ± 400	3.58
11–(**6**)$_2$	1:2	1250 ± 200	5600 ± 400	4.58

The free energy associated with the first stability constant (K_1) of the adducts **10**–(**6**)$_2$ and **11**–(**6**)$_2$ incorporates the free energy of the conformational rearrangement that leads to allosterism. Thus one might expect that the stability constant for the analogous uncoupled adduct, **9**–**6**, would be larger than the first constants for **10**–(**6**)$_2$ and **11**–(**6**)$_2$. The formation constants for the **9**–**6** adduct and the first association constants (K_1) for the **10**–(**6**)$_2$ and **11**–(**6**)$_2$ adducts are essentially the same (Table 1). Similarly, even though the adducts **10**–(**5**)$_2$ and **11**–(**5**)$_2$ show no allosterism, their first constant (K_1) is essentially the same as the constant (K) found for the 1:1 adduct, **9**–**5**. We discuss these observations later but we can provide no plausible explanation for the results.

The fact that the 1:2 adducts **10**–(**5**)$_2$ and **11**–(**5**)$_2$ show no allosterism whereas the 1:2 adducts **10**–(**6**)$_2$ and **11**–(**6**)$_2$ do may, as we have suggested, be connected with the ability of the receptors to accommodate the smaller guest **6**. ^{1}H NOE experiments suggest that this may be the case.

4. ^{1}H NOE Experiments on the Host–Guest Adducts, 10–(5)$_2$ and 10–(6)$_2$

The ^{1}H NOESY experiments[14] were carried out in [D_7]DMF solutions at 60 °C. The results for the **10**–(**5**)$_2$ and **10**–(**6**)$_2$ host–guest adducts are illustrated in Figure 1 and Figure 2, respectively. Since the rectangles have symmetry operations that interchange the protons H_e and H_d with the corresponding protons of the spacer, the symmetry-related protons are not shown. It will be seen that the two systems (Figures 1 and 2) show different ^{1}H NOESY cross-peaks, but both spectra clearly demonstrate that the guests reside only within the molecular clefts. The two guests **5** within rectangle **10** show cross-peaks between the protons, H_e and H_k, of the rectangle and the "back" (H_s, H_r, H_q, H_p and H_o) and "front" (H_v, NH_3) protons of the guest. The guests are shown in one pair of orientations, but the cross-peaks clearly indicate that several orientations of the guest within the clefts exist for the **10**–(**5**)$_2$ adduct. For the 1:2 host–guest adduct, **10**–(**6**)$_2$, the ^{1}H NOESY data clearly show that the guests exist in one preferred orientation as illustrated in Figure 2, where the ammine ligands of the guests point at the 4,4′-dipyridyl linkers.

It will be noted that for both adducts (Figures 1 and 2) some protons of the guest show no cross-peaks with the host. Given that NOE cross-peaks are generally observed at distances of less than about 3.5 Å,[14] the orientation of the guests in the rectangle **10** is roughly as shown in Figure 1, where the *ortho*-amino phenolate residue probably resides, to some extent, outside of the cleft. The several mutual orientations of the two guests within the rectangular receptor are probably interchanged by intermolecular exchange because scale molecular models suggest that the receptor site does not appear to be large enough to allow for intramolecular rotation of the guest.

Because of the interaction of the *ortho*-protons of the pyridine ligands of the linker with those of the flanking pyridyl ligands of the terpy-Pt unit, the pyridine ligand planes of the linker are expected to lie roughly perpendicular to the terpy-Pt units. The barrier to rotation of the linker pyridine ligands cannot be high, because, even at –90 °C in acetone solution, rapid rotation of the pyridine ligands occurs on a ^{1}H NMR time scale (500 MHz).[10] At 60 °C in [D_7]DMF, the 1:2 host–guest adducts also show rapid rotation of the linker pyridine ligands, but the preferred orientation of the pyridine planes is likely to be perpendicular to the terpy-Pt^{2+} plane. Scale molecular models indicate that when the planes of the linker pyridine ligands lie roughly perpendicular to the terpy-Pt plane, the guests, especially **5**, cannot be fully accommodated within the molecular clefts of the rectangles. It is probable that guest incarceration does not provide sufficient energy to cause the planes of the linker pyridine groups to approach planarity with the terpy-Pt units to open the cleft cavity. Thus, we suggest that the pyridine ligands of the linkers are the main steric impediment to complete incarceration of guest **5**. As shown in Figure 2, guest **6** has only one predominant orientation within the host. Presumably the smaller size of **6** relative to **5** al-

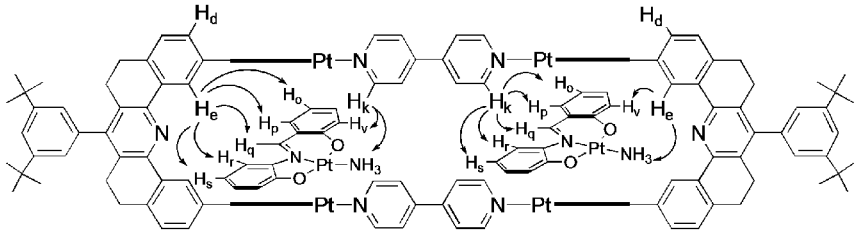

Figure 1. Cross-peaks observed for the 1:2 host–guest adduct **10**–(**5**)$_2$ in [D$_7$]DMF at 60 °C.

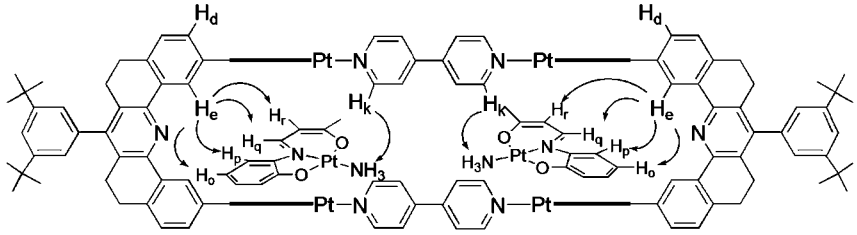

Figure 2. Cross-peaks observed for the 1:2 host–guest adduct **10**–(**6**)$_2$ in [D$_7$]DMF at 60 °C. Possible cross-peaks with the guest methyl group were not investigated.

lows the former to fit better within the cleft. As for the case of the adduct between **2** and **5**,[6] where the guest also has a single orientation and the crystal structure reveals Pt–Pt interaction, it is suggested that Pt–Pt interaction exists for the 1:2 adduct **10**–(**6**)$_2$. These observations suggest that the observed allosterism may depend on how well the guests are accommodated within the hosts, and Pt–Pt interaction may possibly fix the orientation of the guest, which may also contribute to favorable mechanical coupling. The arguments given above depend on the assumption that the disposition of the linker pyridine groups prevents the full accommodation of guests having the dimensions of **5** or larger. Since the barrier to pyridine ligand rotation is unknown, it is possible to argue that the guests could cause the linker pyridine groups to rotate so as to accommodate the guest. This postulate implies that the free energy of host–guest formation is sufficient to overcome the major part of the linker pyridine rotational barrier. In order to explore this matter further, we have studied the host–guest behavior of the much larger guest **7**[8,15] with **10**.

5. Host–Guest Formation of 10 with 7

The receptor **2** forms a bright red 1:2 host–guest complex with the guest **7**, where one guest lies within the molecular cleft and the other guest lies on the outer faces of the terpy-Pt-Cl units.[15] The Pd^{2+} rectangle analogous to **10** forms a red 1:4 host–guest complex with 9-methylanthracene (**12**).[16] In this case, two of the guests lie in the two molecular clefts, and the other two guests are associated with the outer faces of the terpy-Pd-linker units. In [D$_7$]DMF at 60 °C, addition of **7** to the rectangular receptor **10** causes a slightly visible change in color, and ESI-MS data show only ions corresponding to the receptor (Supporting Information). ^{1}H NMR spectral shift titration indicates that a 1:4 host–guest complex is formed (Supporting Information). Inspection of the host protons whose chemical shifts change upon host–guest formation suggests that guest **7** does not occupy the molecular clefts of receptor **10**. This was confirmed by ^{1}H NOESY spectra at 60 °C in [D$_7$]DMF, where only the receptor protons H$_d$ and H$_k$ (but not H$_e$)

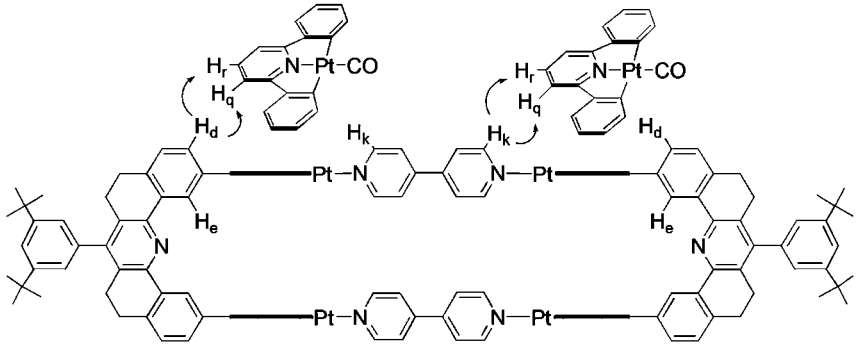

Figure 3. Cross-peaks observed for the 1:4 host–guest adduct **10**–(**7**)$_4$ in [D$_7$]DMF at 60 °C. Only two guests are shown, one for each of the two orientations.

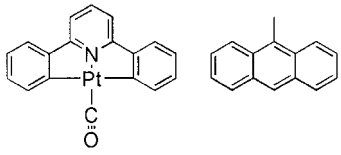
have cross-peaks to the protons of the guest (Figure 3). The ^{1}H NMR spectrum indicates that the 4,4′-dipyridyl linkers are rapidly rotating so that both of the protons adjacent to the pyridine nitrogen atoms have cross-peaks with the guest. The observed cross-peaks (Figure 3) indicate that the guest adopts two orientations, as evidenced by the interaction of both H_d and H_k with H_r and H_q. Since a 1:4 host–guest complex is formed, it is not possible to obtain the four stability constants, but it is clear that guest **7** does not occupy the molecular clefts of **10** to any significant degree. These data support our supposition that the pyridine ligands of the linkers restrict access to the molecular cleft and that it is possible that a guest of the size of **5** may have difficulty in being fully incarcerated in the clefts. As a consequence, it may be that in such circumstances there is only weak mechanical coupling between the sites.



7 **12**

6. X-ray Diffraction Studies

We have attempted to obtain suitable crystals for X-ray diffraction from the host–guest complexes formed by the molecular rectangles **10** and **11** and the two guests **5** and **6** as well as the guest-free rectangles **10** and **11**. Except for crystals formed by the host–guest adduct **10**–(**5**)$_2$, none of the other solids diffracted in a manner suitable for structure determination. The crystals of **10**–(**5**)$_2$ were formed from methyl ethyl ketone by methanol diffusion. The crystals diffracted but they were disordered, and only an outline of the molecular rectangle structure could be obtained. The crystallographic data are listed in Table 2, and the derived structure is shown in Figure 4. The solvent molecules, the SbF_6^- counter ions, the guest molecules, and the di-*tert*-butyl phenyl substituents on the spacers are very disordered and are not shown in Figure 4.

The positions of the guest molecules were indicated by the electron density of the Pt^{2+} ions, which appear in the two molecular clefts and on the outside faces of the four terpy-Pt-linker units of the rectangle. The disorder may arise from this multiple occupancy of these sites. Attempts to crystallize the **10**–(**5**)$_2$ with two extra equivalents of **5** in the hope of occupying all of the guest sites with molecules of **5** failed.

The molecular rectangle is in a *meso* conformation with one spacer in the *R*,*R* and the other in the *S*,*S* configuration. The bonding of the linkers to the Pt^{2+} atoms is not ideal, and the 4,4′-dipyridyl linkers are buckled in order to link to the Pt^{2+} atoms (see lower structure in Figure 4). Presumably this linker strain would be relieved for the rectangle **11** that carries the more flexible 4,4′-dipyridylethane (**4**) linker. The planes of the pyridine groups of the linkers are essentially perpendicular to the plane of the terpy-Pt^{2+} units, a geometry that was inferred from the modeling of the rectangles. Adjacent planes of the terpy-Pt^{2+} units of each cleft are nearly parallel to each other, and the interplanar separation is about 6.9 Å. The "width" of a pyridine (from hydrogen to corresponding hydrogen) is about

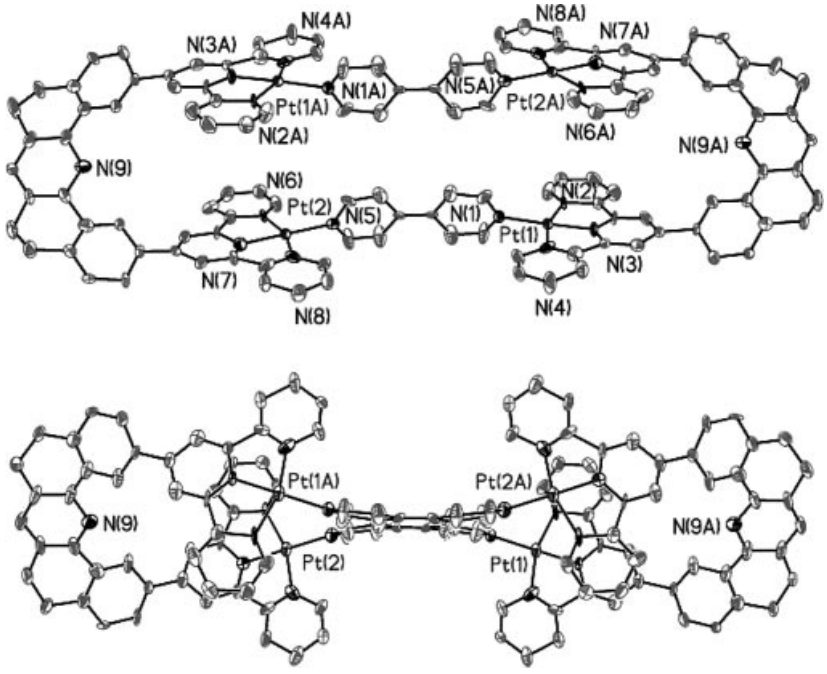


Figure 4. ORTEP diagrams of the "core" of the molecular rectangle. Above, a "side" view, below a "top" view. The disordered guest molecules **5**, the *tert*-butyl-containing phenyl rings of the spacer, the SbF_6^- ions, and the solvents of crystallization have been omitted for clarity. The thermal ellipsoids are shown at 50% probability.

5 Å. Thus, the corresponding pyridine groups of neighboring linkers have nearest approach distances of about 1.9 Å if the pyridine groups of different linkers are aligned as is nearly the case (Figure 4). A separation of this magnitude will not allow a guest to reside between pyridine groups and would not allow a large guest such as **7** to fit into the molecular cleft. The interplanar separation of the terpy-Pt^{2+} units is uncharacteristically large. Usually, this separation is 6.8 Å or less,[17] and the separation in the present system is at the outer limits of π–π stacking distances. There does not seem to be any steric impediment to the contraction of the parallel terpy-Pt^{2+} units to a separation of 6.7 Å. A smaller guest such as **6** may cause this interplanar separation contract more.

7. Discussion

Understanding the origins of allosterism in multimetallic ligand systems and even in hosts bearing hydrogen bonds is relatively simple in outline. This is so for the former because the coordination geometries of metals and the requirements of the ligands are understood. For the latter systems, the geometry of hydrogen bonding with given substrates is usually understood, and, consequently, there are plausible rationalizations that can be advanced on the basis of the directions of the hydrogen bonds. With systems that rely on weak, poorly directional π–π or similar interactions, attempts to rationalize the allosterism are more difficult. This is the case even for the present rectangles that appear to provide a simple mechanism for mechanical coupling between sites. Whereas substantial positive allosterism was observed for the 1:2 host–guest complexes **10**–(**6**)$_2$ (K_2/K_1 = 3.58) and **11**–(**6**)$_2$ (K_2/K_1 = 4.58), the energy differences between the two constants are small. For the former, the free energy difference is 0.65 kcal mol^{-1}, and for the latter the difference is 1.01 kcal mol^{-1}. It is therefore difficult to ascribe these small energy differences to specific interactions of conformational changes for complicated hosts such as the present rectangles. Despite these difficulties, work on allosterism generated by weak interactions is important because biological systems rely on the concerted orchestration of these weak forces.

Experimental Section

Procedures: All reagents were obtained from commercial suppliers and were used without further purification. All reactions were performed under argon, unless otherwise specified. Electronic absorption spectra were obtained with a Perkin–Elmer Lambda 6 UV/Vis spectrophotometer. Elemental analyses were performed by Desert Analytics, Inc., Tucson, Arizona. ^{1}H and ^{13}C NMR spectra were recorded with a Bruker DRX500 Fourier transform spectrometer at 300 K, unless specified otherwise. Proton and carbon chemical shifts, *δ*, are reported in ppm, referenced to TMS. Coupling constants, *J*, are reported in Hertz. APCI-MS and ESI-MS were obtained with an Agilent 1100 MSD LC-MS. Acetonitrile was dried with CaH_2, tetrahydrofuran (THF) was dried with potassium/benzophenone ketyl, diethyl ether (Et_2O) was dried with sodium/benzophenone ketyl, dichloromethane (CH_2Cl_2) was dried with CaH_2, and triethylamine (TEA) was dried with CaH_2. Thin-layer chromatography was carried out using precoated silica gel (Whatman PE SIL G/UV) or precoated aluminum oxide (J. T. Baker, aluminum oxide IB-F). Silica gel 60 Å (Merck, 230–400 mesh) and aluminum oxide 58 Å (either activated, basic, Brockman I or activated, neutral, Brockman I) were used for chromatography as indicated. Celite is J.T. Baker Celite 503. The receptor ligand **L**[9] and the guests **5**,[6] **6**,[7] and **7**[8] were prepared by methods previously described. The linkers 4, 4′-dipyridyl (**3**) and 4, 4′-dipyridylethane (**4**), and [(COD)PtI_2] were obtained from the Sigma–Aldrich Chemical Co. and were used without further purification.

[$LPt_2(Py)_2$][SbF_6]$_4$, Receptor 9: The following procedure must be performed with rigorous exclusion of water. A dried 25-mL flask was charged with $AgSbF_6$ (0.185 g, 0.538 mmol) dissolved in anhydrous acetone (10 mL). To a suspension of [(COD)PtI_2] (0.150 g, 0.269 mmol) in dry acetone (5 mL) was added the colorless solution of the silver salt. Upon addition, the COD complex rapidly dissolved and AgI precipitated. The reaction was stirred for 1 h at room temperature, with brief sonication midway through this period. The AgI was removed by Schlenk filtration through a fine-porosity frit under argon. The receptor ligand **L** (0.126 g, 0.135 mmol) was added to the clear solution. The ligand dissolved rapidly, and the color of the solution changed to orange-yellow. The reaction was stirred at room temperature for 24 h, during which time the color became less orange. Pyridine (0.026 g, 0.028 mL, 0.330 mmol) was added to the solution, and the reaction mixture was heated at reflux (70 °C). The mixture was stirred at this temperature for 24 h. The solvent was then removed under reduced pressure to yield a yellow solid, which was slurried in cold methanol and recovered by filtration. It was washed with cold methanol (1 × 5 mL), ether (1 × 5 mL), and pentane (2 × 5 mL), then dissolved in acetone (5 mL) and filtered through Celite. The product was crystallized by vapor diffusion of diethyl ether into the acetone solution. The receptor **9** was recovered by filtration and was washed with diethyl ether (1 × 5 mL) followed by pentane (2 × 3 mL). Yield = 0.280 g (86%). ^{1}H NMR ([D_6]acetone, 27 °C, 500 MHz): *δ* = 1.41 (s, 18 H), 2.86 (t, *J* = 6.55 Hz, 4 H), 3.16 (t, *J* = 6.75 Hz, 4 H), 7.23 (d, *J* = 1.68 Hz, 2 H), 7.65–7.69 (m, 3 H),

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.93 (t, J = 6.79 Hz, 4 H), 8.05–8.08 (m, 4 H), 8.15 (d, J = 7.55 Hz, 4 H), 8.48 (t, J = 7.88 Hz, 2 H), 8.57 (t, J = 7.65 Hz, 4 H), 8.89 (d, J = 7.75 Hz, 8 H), 9.17–9.19 (m, 4 H), 9.32 (d, J = 5.09 Hz, 4 H) ppm. $C_{75}H_{65}F_{24}N_9Pt_2Sb_4$ (2425.54): calcd. C 37.14, H 2.70, N 5.20; found C 37.33, H 2.94, N 4.96. ESI-MS: a series of peaks were observed that were consistent with $[M - n(SbF_6)]^{n+}$ (n = 1–4): for example, 370.2 [**9** – 4(SbF_6)]$^{4+}$, 572.3 [**9** – 3(SbF_6)]$^{3+}$, 976.0 [**9** – 2(SbF_6)]$^{2+}$, 2188.9 [**9** – 1(SbF_6)]$^{+}$.

Pt Molecular Rectangle Formed with 4,4′-Dipyridyl (10): The following procedure must be performed with rigorous exclusion of water. A dried 25-mL flask was charged with $AgSbF_6$ (0.185 g, 0.538 mmol) dissolved in anhydrous acetone (10 mL). To a suspension of [(COD)PtI_2] (0.150 g, 0.269 mmol) in dry acetone (5 mL) was added the colorless solution of the silver salt. Upon addition, the COD complex rapidly dissolved and AgI precipitated. The reaction was stirred for 1 h at room temperature, with brief sonication midway through this period. The AgI was removed by Schlenk filtration under argon. The receptor ligand **L** (0.126 g, 0.135 mmol) was added to the clear solution. The ligand dissolved rapidly, and the color of the solution changed to orange-yellow. The reaction was stirred at room temperature for 24 h, during which time the color became less orange. The linker 4,4′-dipyridyl (0.021, 0.135 mmol) was added to the solution, and the reaction mixture was heated at reflux (70 °C). The mixture was stirred at this temperature for 2 d. At the end of this period, the solvent was removed under reduced pressure to yield a yellow solid, which was slurried in cold methanol and recovered by filtration. It was washed with methanol (1 × 5 mL), ether (1 × 5 mL), and pentane (2 × 5 mL), then dissolved in acetone (5 mL) and filtered through Celite. The product was crystallized by vapor diffusion of diethyl ether into the acetone solution. The molecular rectangle was recovered by filtration and was washed with diethyl ether (1 × 5 mL) and pentane (2 × 3 mL). Yield = 0.296 g (91%). ^{1}H NMR ([D_6]acetone, 27 °C, 500 MHz): δ = 1.42 (s, 36 H), 2.84 (t, J = 6.55 Hz, 8 H), 3.10 (t, J = 6.61 Hz, 8 H), 7.23 (d, J = 1.68 Hz, 4 H), 7.65 (t, J = 1.63 Hz, 2 H), 7.68 (d, J = 7.86 Hz, 4 H), 7.86 (t, J = 6.63 Hz, 8 H), 8.02 (d, J = 5.05 Hz, 8 H), 8.14 (dd, J_1 = 1.80 Hz, J_2 = 7.75 Hz, 4 H), 8.65–8.68 (m, 16 H), 8.96 (d, J = 7.95 Hz, 8 H), 9.29 (s, 8 H), 9.36 (d, J = 1.67 Hz, 4 H), 9.65 (d, J = 6.46 Hz, 8 H) ppm. $C_{130}H_{126}F_{48}N_{18}Pt_4Sb_8$ (4847.04): calcd. C 37.17, H 2.62, N 5.20; found C 37.46, H 2.69, N 5.06. ESI-MS: a series of peaks were observed that were consistent with $[M - n(SbF_6)]^{n+}$ (n = 2–6): for example, 571.5 [**10** – 6(SbF_6)]$^{6+}$, 733.2 [**10** – 5(SbF_6)]$^{5+}$, 975.0 [**10** – 4(SbF_6)]$^{4+}$, 1379.1 [**10** – 3(SbF_6)]$^{3+}$, 2187.8 [**10** – 2(SbF_6)]$^{2+}$.

Pt Molecular Rectangle Formed with 4,4′-Dipyridylethane (11): A procedure analogous to that above was used. One equivalent of 4,4′-dipyridylethane (0.025 g, 0.135 mmol) was added to the dry acetone solution formed after the reaction of $AgSbF_6$ with [Pt(COD)I_2], and the reaction mixture was heated at reflux (70 °C). The mixture was stirred at this temperature for 2 d. The solvent was removed under reduced pressure to yield a yellow solid, which was slurried in cold methanol and recovered by filtration. It was washed with methanol (1 × 5 mL), ether (1 × 5 mL), and pentane (2 × 5 mL), then dissolved in acetone (5 mL) and filtered through Celite. The product was crystallized by vapor diffusion of diethyl ether into the acetone solution. The molecular rectangle was recovered by filtration and was washed with diethyl ether (1 × 5 mL) and pentane (2 × 3 mL). Yield = 0.290 g (76%). ^{1}H NMR ([D_6] acetone, 27 °C, 500 MHz): δ = 1.42 (s, 36 H), 2.86 (t, J = 6.83 Hz, 8 H), 3.10 (t, J = 6.44 Hz, 8 H), 3.51 (s, 8 H), 7.23 (d, J = 1.65 Hz, 4 H), 7.66 (t, J = 1.69 Hz 2 H), 7.70 (d, J = 7.80 Hz, 4 H), 7.97–8.00 (m, 8 H), 8.07–8.10 (m, 20 H), 8.25 (dd, J_1 = 1.80 Hz, J_2 = 7.75 Hz, 4 H), 8.60–8.65 (m, 8 H), 8.98 (d, J = 8.06 Hz, 8 H), 9.27 (d, J = 6.43 Hz, 4 H), 9.34 (s, 8 H), 9.42 (d, J = 1.89 Hz, 4 H). $C_{154}H_{134}F_{48}N_{18}Pt_4Sb_8$ (4903.15): calcd. C 37.72, H 2.75, N 5.14; found C 37.42, H 2.49, N 5.05. ESI-MS: a series of peaks were observed that were consistent with $[M - n(SbF_6)]^{n+}$ (n = 2–6): for example, 581.8 [**11** – 6(SbF_6)]$^{6+}$, 745.5 [**11** – 5(SbF_6)]$^{5+}$, 990.3 [**11** – 4(SbF_6)]$^{4+}$, 1399.1 [**11** – 3(SbF_6)]$^{3+}$, 2216.3 [**11** – 2(SbF_6)]$^{2+}$.

Host–Guest Interaction of Receptor 9 with 5: The procedure for stoichiometry determination employed for the host–guest adduct formed between **9** and **5** is representative. A series of solutions of **9** (1.75 mM) in dry [D_7]DMF containing varying amounts of **5** (0.23 mM to 11.4 mM) were prepared and were examined by ^{1}H NMR spectroscopy (60 °C). The host in [D_7]DMF solution is orange, as is the guest. The host–guest mixtures vary in color from orange-red to deep red (Figure 5). The mol ratio method[12] was applied, and the stoichiometry of the association was found to be one guest molecule per one host molecule (Figure 6). The data were analyzed using a curve-fitting procedure,[6] and K_1 was found to be 3670 ± 560 M^{-1}. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with $[M - n(SbF_6)]^{n+}$ and $[M{\cdot}G - n(SbF_6)]^{n+}$ (n = 1–4): for example, 370.2 [**9** – 4(SbF_6)]$^{4+}$, 476.6 [**9·5** – 4(SbF_6)]$^{4+}$, 572.3 [**9** – 3(SbF_6)]$^{3+}$, 713.1 [**9·5** – 3(SbF_6)]$^{3+}$, 976.0 [**9** – 2(SbF_6)]$^{2+}$, 1188.4 [**9·5** – 2(SbF_6)]$^{2+}$ (Figure 7).

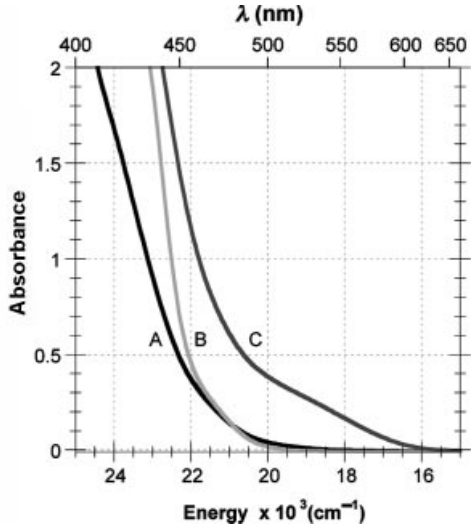

Figure 5. Absorption spectra for **9** (A, 1.75 mM), **5** (B, 2.05 mM), and a 1:1 solution (C) of **9** (1.75 mM) and **5** (1.89 mM). The experiments were performed at 25 °C in dry DMF.

Host–Guest Interaction of Receptor 9 with 6: The procedure was analogous to that used above. The stoichiometry of the association was found to be one guest molecule per one host molecule (Supporting Information). K_1 was found to be 1160 ± 210 M^{-1}. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with $[M - n(SbF_6)]^{n+}$ and $[M{\cdot}G - n(SbF_6)]^{n+}$ (n = 1–4): for example, 370.2 [**2** – 4(SbF_6)]$^{4+}$, 467.1 [**9·6** – 4(SbF_6)]$^{4+}$, 572.3 [**9** – 3(SbF_6)]$^{3+}$, 701.5 [**9·6** – 3(SbF_6)]$^{3+}$, 976.0 [**9** – 2(SbF_6)]$^{2+}$, 1170.3 [**9·6** – 2(SbF_6)]$^{2+}$.

Host–Guest Interaction of Molecular Rectangle 10 with 5: The procedure for stoichiometry determination employed for the host–guest adduct formed between **10** and **5** is representative. A series of solutions of **10** (1.65 mM) in dry [D_7]DMF containing varying amounts of **5** (0.25 mM to 23.4 mM) were prepared and were examined by ^{1}H NMR spectroscopy (60 °C). The host in [D_7]DMF solution is orange, as is the guest. The host–guest mixtures vary in

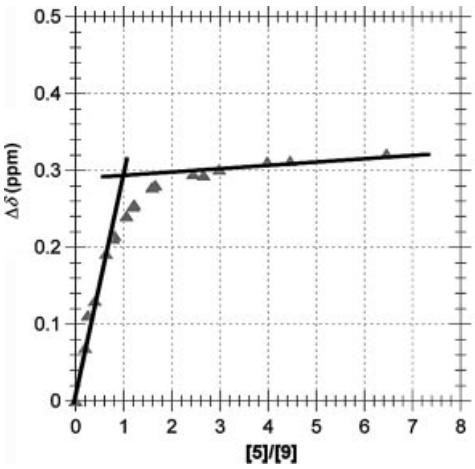

Figure 6. ^{1}H NMR stoichiometry titration for the host–guest complex formed between **9** and **5**. The experiments were performed at 60 °C in [D_7]DMF. The concentration of **9** was held constant at 1.75 mM, and the concentration of **5** was varied between 0.23 mM and 11.4 mM. The plot refers to the proton H_h (see Scheme 2).

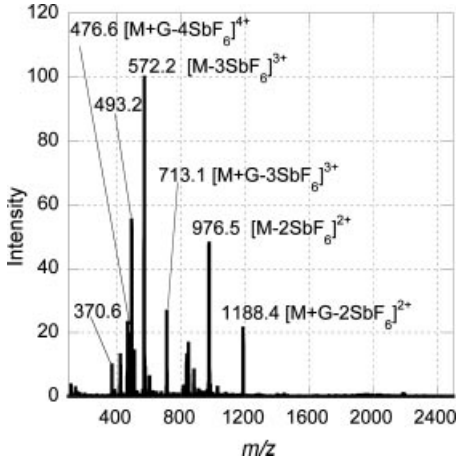

Figure 7. ESI-MS (DMF, 1.75 mM) of the host–guest complex formed between **9** and **5**, *m*/*z* = 370.6 [**9** – 4SbF_6]$^{4+}$, 476.6 [**9·5** – 4SbF_6]$^{4+}$, 572.3 [**9** – 3SbF_6]$^{3+}$, 713.1 [**9·5** – 3SbF_6]$^{3+}$, 976.5 [**9** – 2SbF_6]$^{2+}$, 1188.4 [**9·5** – 2SbF_6]$^{2+}$.

color from orange-red to deep red (Figure 8). The stoichiometry of the association was found to be two guest molecules per one host molecule (Figure 9). Equilibrium constants were determined using a previously described algorithm.[9] The microscopic value of K_1 was found to be 4100 ± 400 M^{-1}, and K_2 was 4200 ± 200 M^{-1}. K_2/K_1 = 1.02. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with [M – *n*(SbF_6)]$^{n+}$, [M·G – *n*(SbF_6)]$^{n+}$ and [M·2G – *n*(SbF_6)]$^{n+}$ (*n* = 2–5): for example, 733.1 [**10** – 5(SbF_6)]$^{5+}$, 975.7 [**10** – 4(SbF_6)]$^{4+}$, 1081.3 [**10·5** – 4(SbF_6)]$^{4+}$, 1187.4 [**10**–(**5**)$_2$ – 4(SbF_6)]$^{4+}$, 1379.4 [**10** – 3(SbF_6)]$^{3+}$, 1520.7 [**10·5** – 3(SbF_6)]$^{3+}$, 1662.3 [**10**–(**5**)$_2$ – 3(SbF_6)]$^{3+}$, 2187.5 [**10** – 2(SbF_6)]$^{2+}$ (Figure 10).

Host–Guest Interaction of Molecular Rectangle 11 with 5: The procedure was analogous to that used above. The stoichiometry of the association was found to be two guest molecules per one host molecule (Supporting Information). K_1 was found to be 3800 ± 300 M^{-1}, and K_2 was 4400 ± 200 M^{-1}. K_2/K_1 = 1.15. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with [M – *n*(SbF_6)]$^{n+}$, [M·G – *n*(SbF_6)]$^{n+}$ and [M·2G – *n*(SbF_6)]$^{n+}$ (*n* = 2–5): for example, 744.5 [**11** – 5(SbF_6)]$^{5+}$, 990.4 [**11** – 4(SbF_6)]$^{4+}$, 1095.4 [**11·5** – 4(SbF_6)]$^{4+}$, 1201.4 [**11**–(**5**)$_2$ – 4(SbF_6)]$^{4+}$, 1398.2 [**11** – 3(SbF_6)]$^{3+}$, 1539.2 [**11·5** – 3(SbF_6)]$^{3+}$, 1680.7 [**11**–(**5**)$_2$ – 3(SbF_6)]$^{3+}$, 2215.6 [**11** – 2(SbF_6)]$^{2+}$, 2428.1 [**11**–(**5**)$_2$ – 2(SbF_6)]$^{2+}$ (Supporting Information).

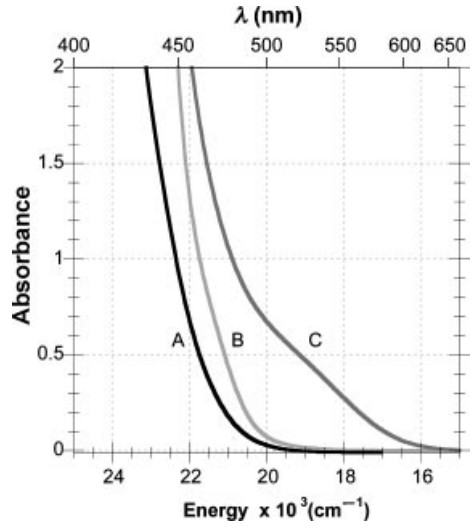

Figure 8. Absorption spectra for **10** (A, 1.65 mM), **5** (B, 3.45 mM), and a 1:2 solution (C) of **10** (1.65 mM) and **5** (3.55 mM). The experiments were performed at 25 °C in dry DMF.

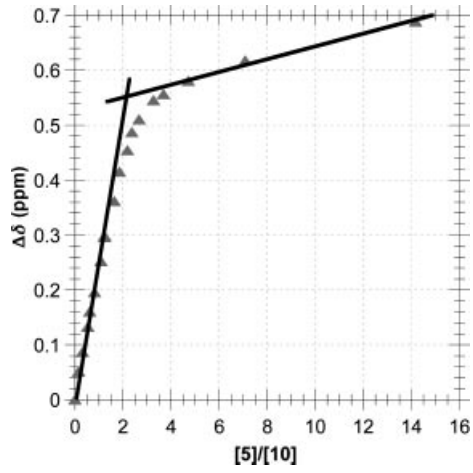

Figure 9. ^{1}H NMR stoichiometry titration for the host–guest complex formed between **10** and **5**. The experiments were performed at 60 °C in [D_7]DMF. The concentration of **10** was held constant at 1.65 mM, and the concentration of **5** was varied between 0.25 mM and 23.4 mM. The plot refers to the proton H_h (see Scheme 2).

Host–Guest Interaction of Molecular Rectangle 10 with 6: The procedure was analogous to those described above. The stoichiometry of the association was found to be two guest molecules per one host molecule (Supporting Information). K_1 was found to be 1450 ± 200 M^{-1}, and K_2 was 5200 ± 400 M^{-1}. K_2/K_1 = 3.58. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with [M – *n*(SbF_6)]$^{n+}$ and [M·2G – *n*(SbF_6)]$^{n+}$ (*n* = 3–5): for example, 888.1 [**10**–(**6**)$_2$ – 5(SbF_6)]$^{5+}$, 975.4 [**10** – 4(SbF_6)]$^{4+}$, 1169.2 [**10**–(**6**)$_2$ – 4(SbF_6)]$^{4+}$, 1379.3 [**10** – 3(SbF_6)]$^{3+}$, 1638.0 [**10**–(**6**)$_2$ – 3(SbF_6)]$^{3+}$, 2186.9 [**10** – 2(SbF_6)]$^{2+}$ (Supporting Information).

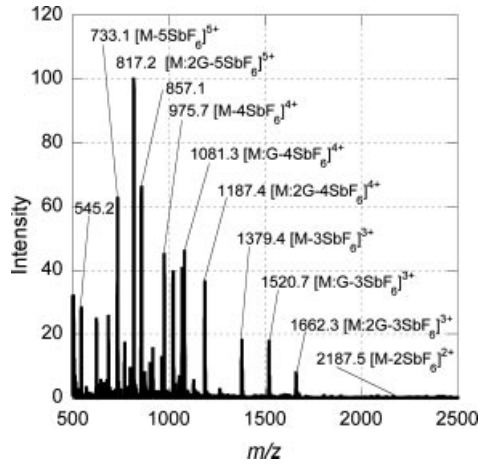

Figure 10. ESI-MS (DMF, 1.65 mM) of the host–guest complex formed between **10** and **5**, 733.1 [**10** – 5(SbF_6)]$^{5+}$, 975.7 [**10** – 4(SbF_6)]$^{4+}$, 1081.3 [**10·5** – 4(SbF_6)]$^{4+}$, 1187.4 [**10**–(**5**)$_2$ – 4(SbF_6)]$^{4+}$, 1379.4 [**10** – 3(SbF_6)]$^{3+}$, 1520.7 [**10·5** – 3(SbF_6)]$^{3+}$, 1662.3 [**10**–(**5**)$_2$ – 3(SbF_6)]$^{3+}$, 2187.5[**10** – 2(SbF_6)]$^{2+}$.

host molecule (Supporting Information). K_1 was found to be 1250 ± 200 M^{-1}, and K_2 was 5600 ± 400 M^{-1}. K_2/K_1 = 4.58. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with [M – n(SbF_6)]$^{n+}$, [M·G – n(SbF_6)]$^{n+}$ and [M·2G – n(SbF_6)]$^{n+}$ (n = 3–5): for example, 710.2 [**11**–(**6**)$_2$ – 6(SbF_6)]$^{6+}$, 744.5 [**11** – 5(SbF_6)]$^{5+}$, 929.1 [**11**–(**6**)$_2$ + 2DMF – 5(SbF_6)]$^{5+}$, 990.1 [**11** – 4(SbF_6)]$^{4+}$, 1026.9 [**11** + 2DMF – 4(SbF_6)]$^{4+}$, 1086.4 [**11·6** – 4(SbF_6)]$^{4+}$, 1183.3 [**11**–(**6**)$_2$ – 4(SbF_6)]$^{4+}$, 1398.2 [**11** – 3(SbF_6)]$^{3+}$, 2215.6 [**11** – 2(SbF_6)]$^{2+}$ (Supporting Information).

Host–Guest Interaction of Molecular Rectangle 10 with 7: The procedure was analogous to that used above. The mol ratio method[12] was applied, and the stoichiometry of the association was found to be four guest molecules per one host molecule (Supporting Information). Because of the high host–guest stoichiometry, the binding constants could not be determined. ESI-MS ([D_7]DMF): a series of peaks were observed that were consistent with [M – n(SbF_6)]$^{n+}$(n = 2–6): for example, 571.5 [**10** – 6(SbF_6)]$^{6+}$, 733.2 [**10** – 5(SbF_6)]$^{5+}$, 975.0 [**10** – 4(SbF_6)]$^{4+}$, 1379.1 [**10** – 3(SbF_6)]$^{3+}$, 2187.8 [**10** – 2(SbF_6)]$^{2+}$. No peaks due to the host–guest adducts were observed (Supporting Information).

Crystallographic Structural Determination for the Host–Guest Adduct Formed from 10 and 5: Crystals of the complex were grown by dissolving a 1:2 mixture of host **10** and guest **5** in methyl ethyl ketone and vapor diffusing with methanol for seven days at –4 °C.

Data Collection: A red, brick-shaped fragment (0.20 × 0.15 × 0.15 mm) was selected under a stereomicroscope while immersed in Fluorolube oil to avoid possible reaction with air. The crystal was removed from the oil using a tapered glass fiber that also served to hold the crystal for data collection. The crystal was mounted and centered on a Bruker SMART APEX system at 100 K. Rotation and still images showed the diffractions to be sharp. Frames separated in reciprocal space were obtained and provided an orientation matrix and initial cell parameters. Final cell parameters were obtained from the full data set.

A "full sphere" data set was obtained which samples approximately all of the reciprocal space to a resolution of 0.84 Å using steps of 0.3° in ω and 30-s integration times for each frame. Data were collected at 100 K. Integration of intensities and refinement of cell parameters were performed with SAINT.[18] Absorption corrections were applied using SADABS[18] based on redundant diffractions.

Structure Solution and Refinement: The space group was determined as $P\bar{1}$ on the basis of systematic absences and intensity statistics. Patterson methods were used to locate some Pt atoms and repeated-difference Fourier maps allowed recognition of many carbon atoms. It soon became clear that the expected SbF_6 and other Pt atoms were either not located or located as split atoms. While the C units became obvious, considerable difficulties were encountered in locating some C atoms, particularly those associated with the split Pt atoms or in expected solvent. The F atoms of the SbF_6 groups were either not found or found with poor geometry. It was concluded that there is severe disorder for the anions, solvent, and guest Pt units. Sb and Pt guest positions were usually located and their occupancy refined. Some F atoms were assigned but in general SbF_6 units were not complete. Although anisotropic refinement for the C framework was possible, some terminal C atoms showed poor geometry. No H location was attempted. Final refinement was anisotropic for all C, N, and Pt atoms of the framework. Some thermal parameters were unusual, but overall the framework was consistent with that expected. All ORTEP diagrams have been drawn with 50% probability ellipsoids. The final R value of approximately 14% directly results from the inability to locate the anions and guest molecules.

The CIF file CCDC 267851 [for **10**–(**5**)$_2$] contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: The Supporting Information contains the ^{1}H NMR stoichiometry plots, ESI-MS, UV/Vis spectra, COSY, and NOESY spectra for the host–guest adducts.

Synthesis and Relaxivity Studies of a Gadolinium(III) Complex of ATP-Conjugated DO3A as a Contrast Enhancing Agent for MRI

S. James Ratnakar[a] and Vedhamonickom Alexander*[a]

Keywords: Gadolinium / Imaging agents / Macrocyclic ligands / N ligands

A gadolinium(III) complex of adenosine 5′-triphosphate (ATP)-appended DO3A has been synthesized in order to attain higher relaxivity and to reduce the in vivo toxicity. DO3A (**2**) was synthesized as the exclusive product by a single step direct trialkylation of cyclen with chloroacetic acid in water (pH 10, –4 °C). ATP was then covalently appended to the DO3A framework through a propyl linker. The 3-bromopropane spacer appended DO3A (**3**) was synthesized by the reaction of DO3A with 1,3-dibromopropane in water/DMF in the presence of triethylamine as proton scavenger. The ATP-appended DO3A (DO3A-Pr-ATP) was synthesized by the reaction of **3** with ATP in water at room temperature. [Gd(DO3A-Pr-ATP)(H_2O)$_2$] (**4**) was synthesized by the reaction of DO3A-Pr-ATP with gadolinium(III) perchlorate hydrate in water. The X- and Q-band EPR spectra of **4** contain a broad band with no hyperfine splitting at both room temperature and liquid nitrogen temperature. The *g*-values are 2.167 and 2.033 at X- and Q-band, respectively. The magnetic moment of **4** is 7.45 BM which is close to the value for free Gd^{III} ion. The longitudinal relaxivity, r_{1p}, of [Gd(DO3A-Pr-ATP)(H_2O)$_2$] is 6.51 $mM^{-1}s^{-1}$ (24 MHz and 35 ± 0.1 °C), which is higher than that of [Gd(DOTA)(H_2O)]$^-$ (r_{1p} = 3.56 $mM^{-1}s^{-1}$, 20 MHz, 39 °C, pH 7.3) and [Gd(DO3A)(H_2O)$_2$] (r_{1p} = 4.8 $mM^{-1}s^{-1}$, 20 MHz, 40 °C). The higher relaxivity of **4** than for other systems with q = 2 is due to the increase in the molecular dimension of the complex by the conjugation of ATP. The relaxivity of **4** at pH 8.4 (TRIS buffer) decreases to 5.64 $mM^{-1}s^{-1}$, probably due to a change in the hydration number by the replacement of the coordinated water molecules by TRIS. The r_{1p} relaxivity of **4** in the presence of β-cyclodextrin is 8.97 $mM^{-1}s^{-1}$ due to the increase in the molecular weight and dimension of the inclusion complex formed by the noncovalent host–guest interaction of the ATP pendant arm with the hydrophobic cavity of β-cyclodextrin. The transverse relaxivity, r_{2p}, of **4** is 7.48 $mM^{-1}s^{-1}$ (24 MHz and 35 ± 0.1 °C). The r_{2p}/r_{1p} ratio of 1.16 indicates that **4** is a T_1-weighted contrast agent. The ATP moiety remains as an extended pendant arm and does not bind with the metal ion, nor does it block the coordination sites for the inner-sphere water molecules.

Introduction

MRI is a state-of-the-art, noninvasive imaging modality in clinical medicine, as exemplified by the award of the 2003 Nobel Prize for medicine to Professor Paul C. Lauterbur (Biomedical Magnetic Resonance Laboratory, University of Illinois) and Professor Sir Peter Mansfield (University of Nottingham) for their seminal discoveries concerning the use of magnetic resonance to visualize different structures leading to the development of modern MRI.[1] An MRI image is a three dimensional signal intensity map of the spatially encoded proton signal of the in vivo water molecules in a given volume element (voxel). The movement of protons from one position to another during the relaxation experiment alters the signal intensity and therefore the moving blood has no detectable signal. It is common to increase the contrast of the image by administering MRI contrast agents (CAs),[2] which enhance the longitudinal and transverse relaxation rates of the water protons which contribute to the intensity of the MRI signal and thus to the contrast of the image. The first example of a paramagnetic substance used for tissue discrimination in MRI was provided by Lauterbur et al.[3] The in vitro and in vivo chemical results reported by Tweedle et al.[4] support the usefulness of strongly chelated Gd^{III} complexes as CAs, and since then Gd^{III} complexes of polyaminocarboxylate ligands have been widely studied.[2a,2e,2f]

Proton relaxivity by Gd^{III}-based CAs is governed by the magnetic coupling interaction of the unpaired electrons of the metal ion and the water proton nuclei by a through-space dipole–dipole mechanism[5] and is interpreted using the Solomon–Bloembergen–Morgan (SBM) theory.[6] Relaxivity is determined by several parameters,[5d,7] and higher relaxivity may be obtained by increasing the correlation time, τ_c, which modulates the dipole–dipole relaxation mechanism. It depends on the exchange lifetime (k_{ex} = $1/\tau_m$) of the coordinated water molecules, the electronic relaxation times ($T_{1e,2e}$), and the rotational correlation time (τ_R) of the complex. One of the practical approaches to gain higher relaxivity by gadolinium-based contrast agents

is increasing τ_R by increasing the size and molecular weight of Gd^{III} chelates by covalent or noncovalent interaction with macromolecules. Examples of Gd^{III} chelates bound to macromolecules include the HSA adduct of the Gd complex of benzyloxy-α-propionic acid substituted DOTA (r_{1p} = 56 $mM^{-1}s^{-1}$),[8] the Gd complex of a *p*-bromobenzyloxy-substituted pyridine macrocycle (r_{1p} = 8.25 $mM^{-1}s^{-1}$), its HSA adduct (r_{1p} = 48 $mM^{-1}s^{-1}$), and its noncovalent adduct with poly-β-cyclodextrin (r_{1p} = 36 $mM^{-1}s^{-1}$),[9] the squaric ester substituted DO3A linked to polyornithine (r_{1p} = 29 $mM^{-1}s^{-1}$),[10] Gd-DTPA-polylysine[11] (r_{1p} = 13 $mM^{-1}s^{-1}$ and 32 $mM^{-1}s^{-1}$ at pH 8), the Gd dendrimer of the DTPA-functionalized second-generation starburst dendrimer (r_{1p} = 234 $mM^{-1}s^{-1}$ at 25 MHz),[12] the Gd complex of *p*-nitrophenyl-substituted DOTA (r_{1p} = 5.4 $mM^{-1}s^{-1}$, 20 MHz, 25 °C, pH 7.3),[13] the HSA adduct of MS-325 (r_{1p} = 50.8 $mM^{-1}s^{-1}$, 20 MHz),[14] the glucitol-conjugated DO3A (r_{1p} = 5.19 $mM^{-1}s^{-1}$),[15] Gd chelates of *p*-bromobenzyl- and *p*-phosphonatomethylbenzanilido-substituted DO3A (r_{1p} = 7.9 $mM^{-1}s^{-1}$ and 10.7 $mM^{-1}s^{-1}$, respectively), and their HSA adducts (r_{1p} = 24.0 $mM^{-1}s^{-1}$ and 21.0 $mM^{-1}s^{-1}$, respectively),[16] and the multiple Gd-DO3A chelates covalently attached to a polysaccharide backbone (r_{1p} = 14.4 $mM^{-1}s^{-1}$ for each Gd, 20 MHz, 39 °C).[17]

The gadolinium(III) chelates approved by the FDA for human imaging are $(NMG)_2[Gd(DTPA)(H_2O)]$[18] (Magnevist, Schering), $(NMG)[Gd(DOTA)(H_2O)]$[19] (Dotarem, Guerbet), $[Gd(DTPA\text{-}BMA)(H_2O)]$[20] (Omniscan, Nycomed), $[Gd(HP\text{-}DO3A)(H_2O)]$[21] (ProHance, Bracco), $[Gd(DO3A\text{-}Butrol)(H_2O)]$[22] (Gadovist, Schering), and $[Gd(BOPTA)(H_2O)]$[23] (MultiHance, Bracco). New classes of MRI contrast agents[24] such as blood pool agents,[25] targeting CAs,[24] and smart contrast agents such as those that are pH-sensitive,[10,25i,26] oxygen-pressure (pO_2) responsive,[27] enzyme responsive,[28] and metal ion concentration dependent[29] are now emerging.

Clinical MRI applications continue to evolve rapidly. This drives the need for more efficient and pathology-specific contrast agents that will increase the potential of MRI as a diagnostic tool. Increasing the molecular weight of a Gd^{III} chelate with two inner-sphere water molecules by conjugating with a biomacromolecule would lead to a biocompatible CA with high relaxivity. Such chelates with high tissue-specific targeting moieties are able to provide improved image contrasts even at a lower concentration than normally required. DO3A is a well-suited ligand framework for functionalization due to the unique secondary amine nitrogen of the macrocyclic ring. Furthermore, biomacromolecule-appended DO3A is expected to exhibit the same stability as that of the parent DO3A. Herein we report the synthesis and relaxivity studies of gadolinium(III) complex of adenosine 5′-triphosphate appended DO3A.

Results and Discussion

Synthesis of the Ligand

1,4,7-Tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (DO3A) (2)

DO3A was synthesized in a single-step direct N-alkylation of cyclen with chloroacetic acid in a 1:3 molar ratio in 69.58% yield. The reaction was carried out at –4 °C and gradually heated to 50 °C over 4 h. The pH of the medium was maintained at 10 throughout the reaction. DO3A was first synthesized by Tweedle et al.[30] by the reaction of cyclen with chloroacetic acid in water at pH 10. The reaction afforded both DO3A and DOTA and the separation was carried out by ion-exchange chromatography. Tweedle et al.[21a] have also reported the synthesis of DO3A by the alkylation of monoprotected cyclen (*p*-toulenesulfonyl or formyl group) with chloroacetic acid followed by deprotection.

Linker-Appended DO3A (3)

DO3A is a heptadentate ligand with three acetate arms and a unique secondary amine nitrogen on the ring. The bromopropyl linker appended DO3A (**3**) was synthesized by the N-alkylation of DO3A with 1,3-dibromopropane in the presence of triethylamine as proton scavenger in DMF/water at room temperature. The use of triethylamine as a base leads to the formation of its hydrobromide salt along with **3**, which is removed by washing with methanol. The reaction is illustrated in Scheme 1.

ATP-Appended DO3A (DO3A-Pr-ATP)

ATP was appended onto the DO3A framework through the bromopropyl linker by the reaction of **3** with ATP in a

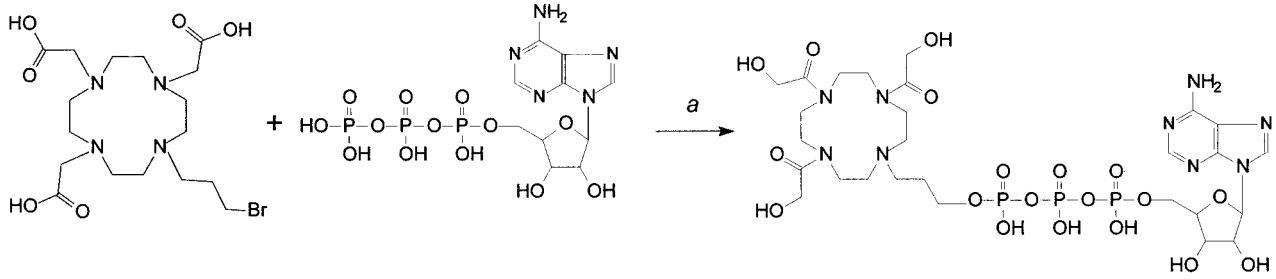

Scheme 2. Synthesis of DO3A-Pr-ATP. Conditions: (a) water, room temp., 36 h.

1:1 molar ratio in water at room temperature (Scheme 2). The reaction of **3** with the commercially available disodium salt of ATP yielded DO3A-Pr-ATP along with sodium bromide as the side product. Since both are soluble in water the isolation of the free ligand becomes difficult. Therefore, the free form of ATP, recovered from its disodium salt by passing an aqueous solution through a cation exchange resin and eluting with water, was reacted with **3**. DO3A-Pr-ATP was isolated as a white solid by adding methanol.

Spectroscopic Studies

Infrared Spectrum

The IR spectrum of DO3A-Pr-ATP shows a broad peak at 3420.1 cm^{-1} assignable to the ν_s(OH) vibration. The peaks at 2926.5 and 1476.8 cm^{-1} are assignable to the ν_s(CH) and δ_s(CH) vibrations, respectively. The sharp peaks at 1700 and 1635.4 cm^{-1} are due to the ν_s(C=O) and δ_s(NH) vibrations, respectively. The sharp peak at 1507.1 cm^{-1} is

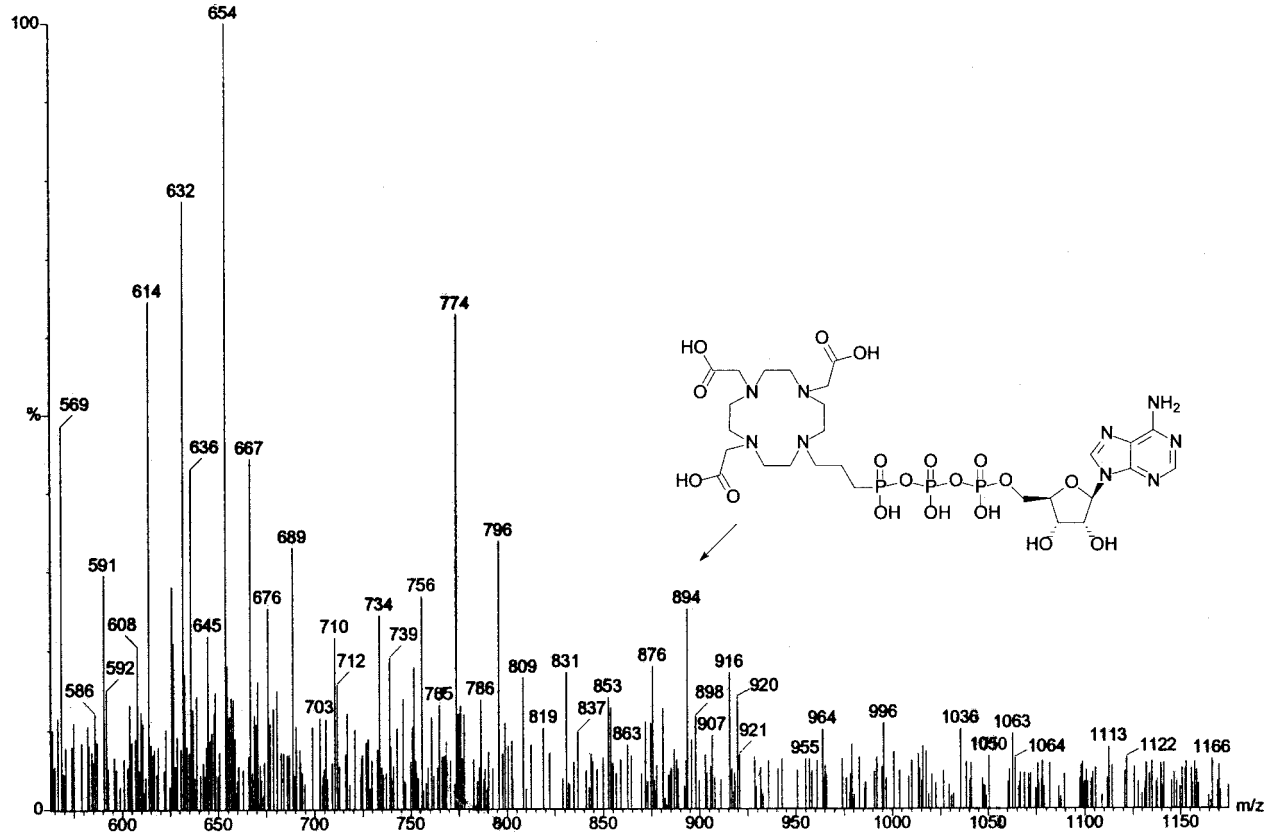

Figure 1. ESI mass spectrum of 10-[3-(adenosine 5′-triphosphate)oxypropyl]-1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (DO3A-Pr-ATP).

assigned to the ν_s(C–O) vibration of the ether linkage between the DO3A and ATP. The peak at 1087.6 cm^{-1} is assigned to the ν_s(C–N) vibration. The bands at 1228.4 and 900 cm^{-1} are assigned to the ν_s(P=O) and ν_s(P–O) vibrations, respectively.[31] The IR spectrum of the complex contains the characteristic absorption bands of the ligand except for the OH vibrations of the carboxylic acid. The band at 1608.8 cm^{-1} in the complex is typical of the COO functionality.[32]

ESI Mass Spectrum

The ESI mass spectrum of DO3A-Pr-ATP shows a peak at *m*/*z* = 894 for the molecular ion $[M + 1]^+$ ($C_{27}H_{47}N_9O_{19}P_3$). The peak at *m*/*z* = 756 is assignable to the species $[M - C_5H_7N_5]^+$ ($C_{22}H_{39}N_4O_{19}P_3$) formed by the loss of the adenine moiety of ATP. The peak at *m*/*z* = 654 is assignable to the species $[M - C_9H_{13}N_5O_3]^+$ ($C_{18}H_{33}N_4O_{16}P_3$) formed by the loss of the furan moiety of ATP. The peak at *m*/*z* = 348 is assignable to the species $[M - C_{13}H_{19}N_5O_{13}P_3]^+$ ($C_{14}H_{28}N_4O_6$) formed by the loss of the phosphate group of ATP and the propyl linker group. The ESI mass spectrum of DO3A-Pr-ATP is depicted in Figure 1.

^{1}H NMR Spectrum

The ^{1}H NMR spectrum of DO3A-Pr-ATP in D_2O shows resonances for the methylene protons of the cyclen framework as a multiplet at δ = 3.10–3.4 ppm (12 H, NCH_2CH_2N). The triplet at δ = 3.58–3.63 ppm (*J* = 5.5 Hz, 2 H) is assigned to the OCH_2 protons of the linker that is bonded to ATP. The resonance at δ = 4.37 ppm (6 H, CH_2COO) is assigned to the methylene protons of acetate arms. The triplet centered at δ = 4.25 ppm (1 H) is assigned to the proton of the furan ring of the adenine moiety. The doublet at δ = 4.49–4.65 ppm (2 H) is assigned to the OCH_2 protons of the ATP unit. The signals at δ = 2.25 ppm are assigned to the protons of the propyl linker. The resonances at δ = 8.37, 8.54 (m, 2 H), and 6.07 ppm (m, 1 H) are assigned to the aromatic protons of the adenine moiety. The ^{1}H NMR spectrum of DO3A-Pr-ATP is depicted in Figure 2.

^{13}C NMR Spectrum

The ^{13}C NMR spectrum of DO3A-Pr-ATP in D_2O has a signal at δ = 174.52 ppm assignable to the carboxylic acid carbon. The signals at δ = 152.90–145.57 ppm are assignable to the carbon atoms of the adenine group of ATP. The resonances at δ = 68.43 (OCH_2), 77.38 (OCH_2), and 87.14 ppm are assignable to the C_2, C_3, and C_4 carbons, respectively, of the furan ring. The signal at δ = 34.78 ppm is assignable to the β-CH_2 carbon of the propyl linker. The resonance at δ = 52.99 ppm is due to the methylene carbon of the propyl linker bonded to the nitrogen of the macrocycle. The signal at δ = 68.43 ppm is assigned to the methylene carbon attached to the phosphate group of ATP. The higher chemical shift of this carbon compared to the other two methylene carbons of the linker is indicative of its attachment to the terminal phosphate group of ATP. The signal at δ = 52.99 ppm is assignable to the ethylenic carbon of the macrocyclic framework. The resonance at δ = 57.23 ppm is assignable to the methylene carbon of the acetate arm.

^{31}P NMR Spectrum

The ^{31}P NMR spectrum of DO3A-Pr-ATP in D_2O shows three distinct signals due to the three phosphate groups of ATP in different environments. The signal at δ = 130.20 ppm is assigned to the central phosphate and the signal at δ = 107.35 ppm is assignable to the phosphate attached to the propyl spacer. The signal at δ = 119.30 ppm is assigned to the phosphate that is attached to the furan group of ATP.

Mass Spectrum of [Gd(DO3A-Pr-ATP)(H_2O)$_2$]

The ESI mass spectrum shows a cluster of peaks at *m*/*z* = 1081 assignable to the molecular ion $[M - 2]^+$ $[Gd(C_{27}H_{41}N_9O_{19}P_3)(H_2O)_2]$. The peak at *m*/*z* = 793 is assignable to $[M - C_{11}H_{17}N_5O_5]^+$ $[Gd(C_{17}H_{27}N_4O_{16}P_3)]$, the species formed by the loss of the adenine moiety. The peak at *m*/*z* = 734 is assignable to the species $[M - C_{12}H_{21}N_5O_7]^+$ $[Gd(C_{15}H_{24}N_4O_{14}P_3)]$ formed by the loss of the acetate group. The peak at *m*/*z* = 578 is assignable to the species $[M - Gd(C_{12}H_{20}N_5O_7)]^+$ ($C_{15}H_{25}N_4O_{14}P_3$) formed by the loss of Gd^{III}. The peak at *m*/*z* = 483 is assignable to $[M - Gd(C_{12}H_{20}N_5O_{11}P)]^+$ ($C_{15}H_{25}N_4O_{10}P_2$), the species formed by the loss of one phosphate group. The peak at *m*/*z* = 168 is assignable to $[M - Gd(C_{19}H_{29}N_5O_{21}P_3)]^+$ ($C_8H_{16}N_4$), the species formed by the loss of acetate groups and the propyl linker. The MALDI-TOF mass spectrum shows a peak at *m*/*z* = 1043.80 (100%) assignable to the molecular ion $[M - 2H_2O]^+$ $[Gd(C_{27}H_{41}N_9O_{19}P_3)]$, which further confirms the formation of the complex. The MALDI TOF mass spectrum of [Gd(DO3A-Pr-ATP)(H_2O)$_2$] is given in Figure 3.

EPR Spectra and Magnetic Moment of [Gd(DO3A-Pr-ATP)(H_2O)$_2$]

The X- and Q-band EPR spectra consist of a broad band with no hyperfine splitting at room temperature or at liquid nitrogen temperature. The *g*-value at X-band is 2.167 and at Q-band is 2.0333. The *g*-value at 77 K is 2.103 (X-band). The broad band shows that the dipolar interaction of the metal ion is small. The magnetic moment of [Gd(DO3A-Pr-ATP)(H_2O)$_2$] is 7.5 BM which is close to the value for the free gadolinium(III) ion (7.85 BM).

Relaxivity Studies

Longitudinal Relaxivity (r_{1p})

The ligand DO3A-Pr-ATP has the DO3A framework with an extended ATP pendant arm. It coordinates to the metal ion through four nitrogen donors of the macrocycle and three carboxylate oxygens. Two inner-sphere water molecules complete the coordination geometry. The complex [Gd(DO3A-Pr-ATP)(H_2O)$_2$] (**4**) is expected to have the same coordination geometry as that of [Gd(DO3A)(H_2O)$_2$]. The longitudinal relaxivity of **4** is 6.51 $mM^{-1}s^{-1}$ (normal-

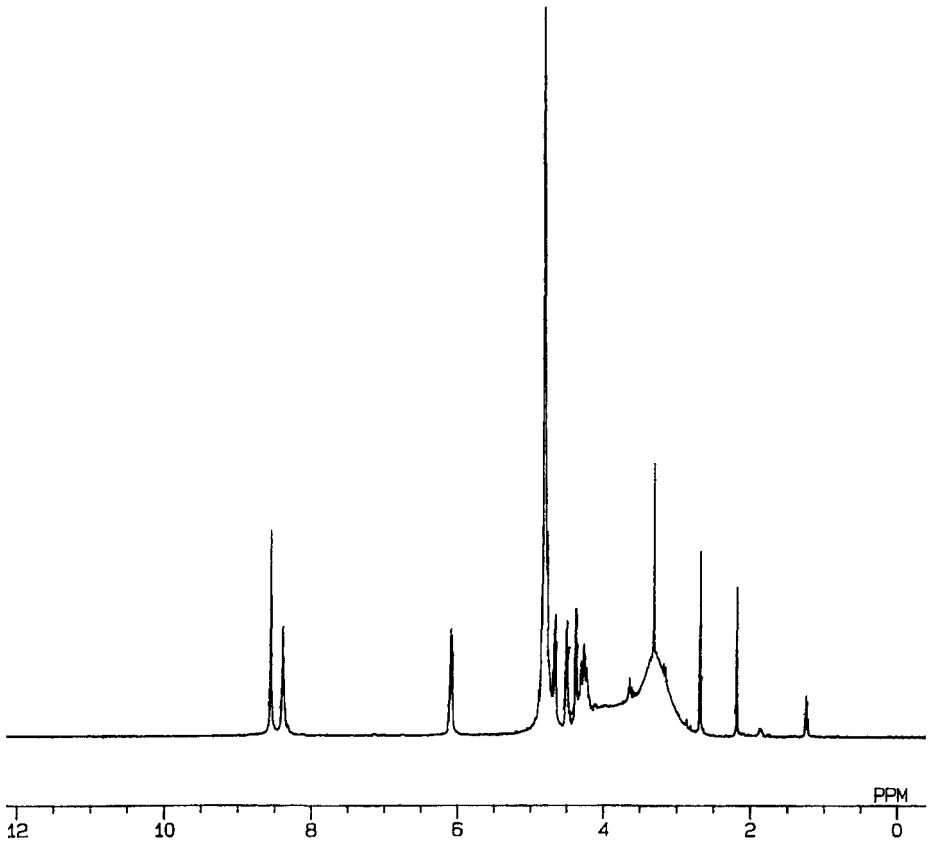

Figure 2. ^{1}H NMR spectrum of 10-[3-(adenosine 5′-triphosphate)oxypropyl]-1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (DO3A-Pr-ATP).

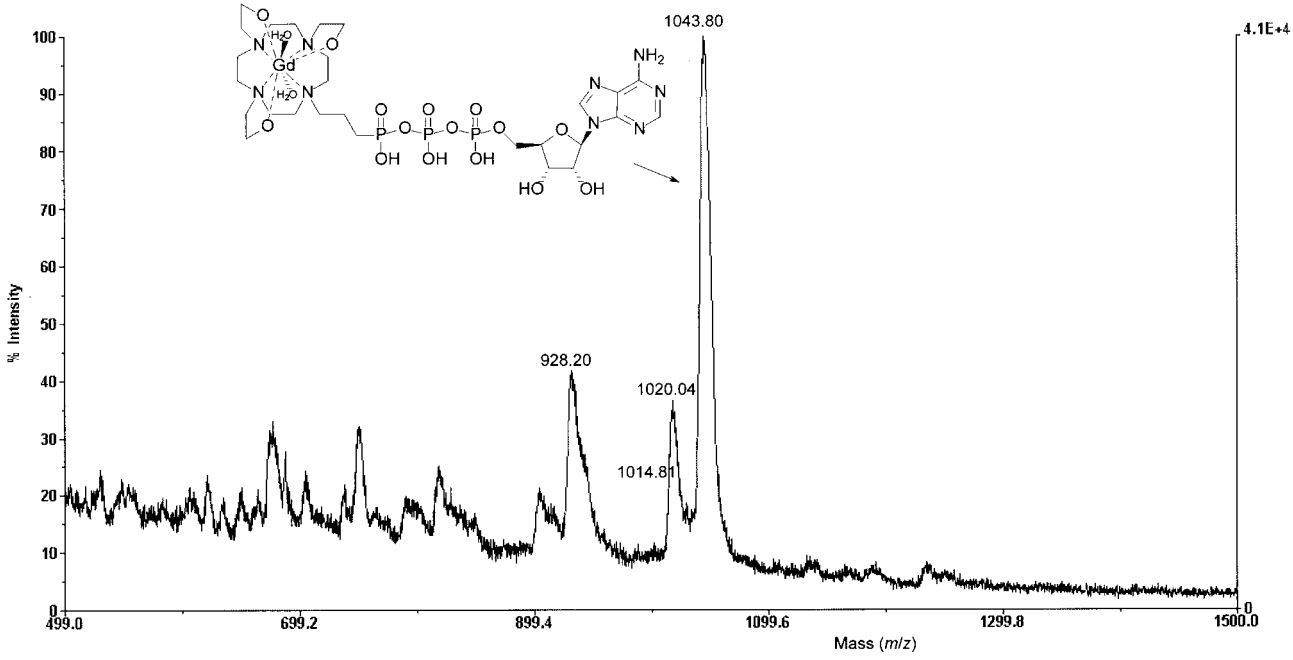

Figure 3. MALDI TOF mass spectrum of [Gd(DO3A-Pr-ATP)(H_2O)$_2$] (**4**).

ized to 1 mM). The contribution by the inner-sphere mechanism to the overall relaxivity is approximately 1.7 mM^{-1} s^{-1} per coordinated water molecule.[2a,2d] The higher longitudinal relaxivity of **4** than that of [Gd(DOTA)(H_2O)]$^-$ (r_{1p} = 3.56 mM^{-1} s^{-1}, 20 MHz, 39 °C, pH 7.3),[15] a q = 1 system, and [Gd(DO3A)(H_2O)$_2$] (r_{1p} = 4.8 mM^{-1} s^{-1} at 20 MHz, 40 °C),[33] a q = 2 system, is attributed not only to the presence of two inner-sphere water molecules bound to the me-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tal ion, but also to the longer rotational correlation time, τ_R, due to the increase in the molecular dimensions of the complex by the conjugation of ATP. As the molecular tumbling rate is reduced by increasing the molecular dimension, the dipole–dipole interaction between the paramagnetic metal ion and the water proton is efficient and, as a result, a greater paramagnetic effect is transferred to the bulk solvent (water). Tweedle et al.[34] have shown that the relaxivity of Gd^{III} complexes increases with increasing molecular weight. The outer-sphere contribution to overall relaxivity is approximately 2.3–2.5 $mM^{-1}s^{-1}$ deduced on the basis of the relaxivity of Gd^{III} complexes with no inner-sphere water molecules ($q = 0$).[35]

Longitudinal Relaxivity in the Presence of β-Cyclodextrin

The longitudinal relaxivity of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ increases to 8.97 $mM^{-1}s^{-1}$ in the presence of β-cyclodextrin. This is attributed to the formation of an inclusion complex through a nonbonding interaction between the ATP pendant arm and β-cyclodextrin with a concomitant increase in the molecular dimension and τ_R of the complex, which leads to an enhancement in relaxivity. An aqueous solution of β-cyclodextrin (50 mM) under the same experimental conditions does not show enhancement of water proton relaxivity. The concentration of β-cyclodextrin was maintained at 50-times the concentration of the complex to ensure the formation of the inclusion complex. Aime and co-workers[36] have reported that the formation of ternary inclusion complexes between the hydrophobic cavity of β-cyclodextrin and Gd^{III} chelates leads to a 10-fold increase of r_{1p}. Many complexes form inclusion complexes with β-cyclodextrin through noncovalent interactions between the substituent and β-cyclodextrin cavity.[9] The nature of the substituent also plays an important role. Aime et al.[13] have reported a large K_D (dissociation constant) value as a consequence of the poor fit of the substituent into the β-cyclodextrin cavity compared to complexes with no substituent. The presence of the substituent in the *para* position of the phenyl ring is expected to strengthen the binding and favor the formation of the inclusion complex.[37] Thus, the enhancement of the relaxivity of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ in the presence of β-cyclodextrin is attributed to the formation of the inclusion complex by a noncovalent host–guest interaction between the free amine group in the *para* position of the phenyl ring of ATP and the hydrophobic cavity of β-cyclodextrin. A plot of the concentration of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ vs. $1/T_1$ in the presence and absence of β-cyclodextrin is given in Figure 4.

pH Dependence of the Relaxivity

The relaxivity of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ at pH 8.4 (TRIS buffer) is 5.64 $mM^{-1}s^{-1}$, which is one unit lower than the relaxivity of the complex without pH adjustment (pH 5.4). The hydration number of the metal plays an important role on relaxivity. $[Gd(H_2O)_8]^{3+}$ has a q value of 8 or 9 and exhibits a relaxivity of 11.8 $mM^{-1}s^{-1}$. As the q value decreases, the relaxivity also decreases. Sherry et al.[38] have observed that the decrease in relaxivity at higher pH is due to the competition of the hydroxide ion for coordination to the Gd^{III} ion. The decrease in the relaxivity of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ at higher pH may be due to the replacement of bound water molecules by TRIS.

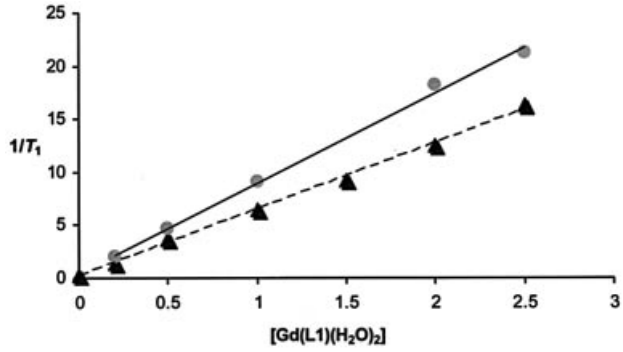

Figure 4. A plot of concentration of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ vs. T_1^{-1} in the presence (●) and in the absence (▲) of β-cyclodextrin.

Transverse Relaxivity (r_{2p})

The transverse relaxivity of $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ is 7.48 $mM^{-1}s^{-1}$ (24 MHz and 35 ± 0.1 °C), which is higher than that of $[Gd(DOTA)(H_2O)]^-$ (r_{2p} = 4.57 $mM^{-1}s^{-1}$, 20 MHz). The r_{2p}/r_{1p} ratio for $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ is 1.16, showing that the complex is a T_1-weighted contrast agent. The maximum signal intensity attained is determined by the r_{2p}/r_{1p} ratio, with the highest signal intensity occurring when the ratio is unity.

Conclusions

In this work, the synthesis and relaxivity studies of a Gd^{III} complex of adenosine 5′-triphosphate conjugated DO3A has been reported. The increase in the molecular weight of the chelate leads to an increase in the r_{1p} and r_{2p} relaxivities due to the slow tumbling rate of the complex in solution. The covalent attachment of ATP causes the complex to remain intact under different experimental conditions and it is expected to be biocompatible and nontoxic. $[Gd(DO3A\text{-}Pr\text{-}ATP)(H_2O)_2]$ is expected to reduce the in vivo clearance rate due to its noncovalent interaction with blood serum albumin and could be used as an intravascular contrast agent as the persistence of the complex in blood would be higher. Thus, there is a wide scope for studying the interaction and relaxivity of this complex in the presence of blood serum albumin to evaluate its suitability as a blood pool agent. Furthermore, the ATP-conjugated derivative is particularly interesting since the NH_2 group provides a site for further modification of the ligand or covalent attachment of a substituent. The appended ATP does not bind with the central metal ion or block the coordination site of the inner-sphere water molecules and remains as an extended pendant arm. It is worthwhile to study the behavior of this complex in response to biological events such as enzyme action. The advent of attaching metal complexes to larger biological molecules has created a new

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

realm of research in the field of bioconjugates. Conjugates of chelates with biological macromolecules that have affinity for specific tissues can be employed to study specific biological processes and physiological function. Design of MRI contrast agents that remain in the body for longer time and target specific tissues is a need for the future.

Experimental Section

Chemicals: Triethylenetetraamine (99%), *p*-toluenesulfonyl chloride, 1,2-dibromoethane, 1,3-dibromopropane, chloroacetic acid, xylenol orange, β-cyclodextrin, Celite, anhydrous potassium carbonate, and TRIS (Fluka) were used as such. Adenosine 5′-triphosphate disodium salt (Aldrich) was converted into the free form by passing through Amberlite IR120 (H^+, strongly acidic) (Aldrich) cation exchange resin and eluting with triply distilled water. The resin was washed with distilled water five times before use. Triethylamine, perchloric acid (Merck, India), sodium hydroxide and potassium hydroxide pellets (Rankem, India), and gadolinium(III) carbonate (Indian Rare Earths Ltd.) were used as such. $Gd(ClO_4)_3 \cdot nH_2O$ was prepared from gadolinium(III) carbonate and perchloric acid in water. The perchlorate salt was recrystallized from triply distilled water prior to use. Cyclen was synthesized by the method of Chavez and Sherry.[39] The solvents were purified by the standard procedures.[40]

Physical Measurements: Infrared spectra were recorded on a Perkin–Elmer Spectrum RX-I FT-IR spectrometer in the range of 4000–400 cm^{-1} using KBr pellets. Potassium bromide (FT IR grade, Aldrich) was used to make pellets. FAB mass spectra were recorded on a Jeol SX-102/DA 6000 mass spectrometer/data system using argon (6 kV, 10 mA) as the FAB gas. The accelerating voltage was 10 kV and the spectra were recorded at room temperature using *m*-nitrobenzyl alcohol as the matrix. Electrospray ionization mass spectra were recorded with a Micromass Quattro-II Triple Quatrapole mass spectrometer. The sample was dissolved in water and introduced into the ESI capillary using a 5-μL syringe pump. The ESI capillary was set at 3.5 kV with a cone voltage of 40 V. CHN microanalyses were carried out using Perkin–Elmer 2400 Series II CHNS/O Elemental Analyzer interfaced with a Perkin–Elmer AD 6 Autobalance. Helium (analytical grade) was used as the carrier gas. Analytical and preparative HPLC analysis were carried out using Varian PrepStar 218 (Varian Instruments Inc., USA) binary gradient solvent delivery module with an inline three channel degasser Model 2000 for solvent delivery. A Rheodyne injector valve (20 μL) was used for the sample injection. HPLC column (250 × 4.6 mm × 1/4 in Valco, Microsorb-MV 100-5 C18) (analytical) and DYNAMAX HPLC column (250 × 10.0 mm, Microsorb 300–10 C18) (preparative) were used. UV/Visible detector Model 345 operating in the range 190–1100 nm was used. The fractions were collected using a Model 704 fraction collector. EPR spectra were recorded on a Jeol instrument at Q-band (34.5 MHz) and X-band (9.4 MHz) with a scan range of 8000 g and the field was set at 12500 T. Magnetic susceptibility measurements were carried out on EG&G PAR Model 155 vibrating sample magnetometer at 25 °C. ^1H NMR spectra were recorded in D_2O and $CDCl_3$ (9.995 atom% D, Aldrich) on a Jeol GSX-400 multinuclear NMR spectrometer working at 400 MHz at 25 °C. The ^{13}C NMR spectra were recorded at 100 MHz using a Jeol GSX-400 instrument. The ^{31}P NMR spectra were recorded at 162 MHz.

Longitudinal Relaxivity (r_{1p}) Measurements: The longitudinal relaxivity of the Gd^{III} complex was determined from the spin-lattice relaxation time, T_1. The T_1 measurements were carried out on a Maran wide line NMR (Resonance Instruments Ltd., UK) operating at 24 MHz and 35 ± 0.1 °C. The temperature was controlled using a temperature console. The complex solutions in triply distilled water were placed in a 10-mm stoppered quartz tube and the instrument parameters were optimized for each T_1 measurement. The T_1 measurements were made using the standard inversion recovery pulse sequence (180°–τ–90°) with phase-sensitive detection[41] with varying τ values ranging from 50 μs to 6 s for each concentration of the complex. The computer program Winfit was used to plot the time vs. signal intensity to get an exponential plot and the T_1 values were calculated from the plot. A delay of at least 5 T_1 was maintained in between successive pulses to allow the complete return of the spin system to equilibrium. The T_1 values for five different concentrations of the complex were measured. A plot of $1/T_1$ vs. concentration of the complex gave a straight line and the slope was taken as the longitudinal relaxivity r_{1p}. The longitudinal relaxivity at pH 8.5 was measured by maintaining the pH by adding TRIS buffer. The longitudinal relaxivity in the presence of β-cyclodextrin was determined by adding aqueous solution of a known amount of β-cyclodextrin and keeping the solution overnight at ambient temperature to attain equilibrium. Six different concentrations (0.2, 0.5, 1.0, 1.5, 2.0, and 2.5 mM) of the complex in water were used for relaxivity measurements.

Transverse Relaxivity (r_{2p}) Measurements: The transverse relaxivity, r_{2p}, was determined from the spin–spin relaxation time T_2. A standard CPMG (Carl–Purcel–Meiboon–Gill) pulse sequence (90°–τ–180°)[42] with a τ value of 50 μs was used to determine T_2. The computer program Winfit was used to plot the time vs. signal intensity to get an exponential curve and T_2 was calculated from the graph. The T_2 values for six different concentrations were measured. The transverse relaxivity was calculated from the slope of the regression line, obtained by the plot of the concentration of the complex vs. $1/T_2$ by a least-squares fitting method. Six different concentrations (0.2, 0.5, 1.0, 1.5, 2.0, and 2.5 mM) of the complex were prepared in triply distilled water.

1,4,7-Tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (DO3A) (2): Chloroacetic acid (2.820 g, 30 mmol) in 20 mL of water was placed in a double-walled, round-bottomed flask, connected to a cryostat maintained at –4 °C, and aqueous sodium hydroxide (5 N) was added dropwise whilst stirring until the pH reached 5. Cyclen sulfate (3.684 g, 10 mmol) in water (50 mL) was neutralized with 5 N sodium hydroxide and added to the chloroacetic acid solution in the flask whilst stirring at –4 °C. The pH of the mixture was increased to 10 by the addition of 5 N aqueous sodium hydroxide. The solution was maintained at –4 °C with constant stirring whilst maintaining pH 10 by the frequent addition of 5 N aqueous sodium hydroxide for 3 h. The contents of the flask were transferred to another round-bottomed flask, fitted with a double surface condenser, and slowly heated to room temperature for 5 h while maintaining a pH of 10. The solution was further heated to 50 °C over a period of 4 h and the temperature was maintained for 8 h at pH 10. The solution was cooled to room temperature and loaded onto a column containing Amberlite IR 120 (H^+, strongly acidic) cation exchange resin and eluted with deionized water. The solvent was removed under reduced pressure in a rotary evaporator and the resulting white solid was washed with dry acetone and methanol, filtered, and dried in a vacuum desiccator. The purity of DO3A was checked by HPLC (R_f = 3.244, H_2O/CH_3CN 9:1 *v*/*v*); yield 69.58%; m.p. 260 °C. IR (KBr): $\tilde{\nu}$ = 3406.5 cm^{-1} ν_s(OH), 2964.0 ν_s(CH), 1723.0 ν_s(C=O), 1623.6 δ(NH), 1459.8 ν(CH), 1391.6 δ(OH), 1212.3 ν_s(CO), 1087.0 ν_s(CN), 985 δ(CH), 720 δ_r(CH). MS (70 eV, EI): *m*/*z* (%) = 344 (80) $[M - 2]^+$ ($C_{14}H_{24}N_4O_6$),

329 (50) $[M - NH]^+$ ($C_{14}H_{23}N_3O_6$), 302 $[M - C_2NH_3]^+$ ($C_{12}H_{20}N_3O_6$), 243 (20) $[M - C_4H_7NO_2]^+$ ($C_{10}H_{17}N_3O_4$), 185 (50) $[M - C_6H_9NO_4]^+$ ($C_8H_{15}N_3O_2$), 57 (100) ($C_2H_2O_2$). ^{1}H NMR (400 MHz, D_2O, TMS): δ = 3.21 (m, 12 H, CH_2), 3.39 (m, 4 H, N–CH_2), 3.60 (s, 6 H, CH_2COOH), 3.9 (d, 1 H, J = 5.3 Hz, NH) ppm. ^{13}C NMR (100.34 MHz, D_2O): δ = 42.5 (CH_2), 47.8 (N–CH_2), 52.06 (CH_2COOH), 174.5 (COOH) ppm. $C_{14}H_{26}N_4O_6$ (346.08): calcd. C 48.58, H 7.51, N 16.18; found C 48.14, H 7.43, N 15.94.

10-Bromopropyl-1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (3): DMF (30 mL) and 5 drops of triethylamine were added, whilst stirring, to a solution of DO3A (3.45 g, 10 mmol) in 60 mL of distilled water in a round-bottomed flask, kept over a rotamantle, and the mixture was heated to 80 °C. The temperature was maintained at 80 °C for 1 h with stirring. 1,3-Dibromopropane (2.01 g, 10 mmol) in 10 mL of DMF was then added slowly and the reaction mixture was stirred for 36 h at 80 °C. The mixture was filtered and the filtrate was evaporated in a rotary evaporator to dryness. The solid compound that separated out was washed with dry methanol to remove triethylamine hydrobromide salt and then with acetone. The white solid was dried in a vacuum desiccator and recrystallized from water. The purity of **3** was checked by HPLC (R_f = 4.20, H_2O/CH_3CN, 3:2 *v*/*v*); yield 67%; m.p. 290 °C (dec). IR (KBr): $\tilde{\nu}$ = 3432.2 cm^{-1} ν_s(OH), 2954.0 ν_s(CH),1692.0 ν_s(C=O), 1460.3 δ(CH), 1385.4 δ(OH), 1214.4 ν_s(CO), 1087.3 ν_s(CN), 980.7 δ(CH), 699.4 δ_r(CH). MS (FAB): *m*/*z* = 466 $[M - 1]^+$ ($C_{17}H_{30}N_4O_6Br$), 341 $[M - C_3H_9Br]^+$ ($C_{14}H_{21}N_4O_6$), 284 $[M - C_5H_{11}O_2Br]^+$ ($C_{12}H_{20}N_4O_4$), 255 $[M - C_7H_{16}O_2Br]^+$ ($C_{10}H_{15}N_4O_4$). ^{1}H NMR (400 MHz, D_2O, TMS): δ = 2.63 (m, 2 H, CH_2), 3.23 (m, 12 H, CH_2), 3.41 (s, 6 H, N–CH_2), 3.84 (CH_2COOH) ppm. ^{13}C NMR (100.34 MHz, D_2O): δ = 36.84 (N-CH$_2$-*C*H$_2$), 52.73 (*C*H$_2$), 58.28 (*C*H$_2$COOH) 174.31 (*C*OOH) ppm. $C_{17}H_{31}BrN_4O_6$ (467.01): calcd. C 43.71, H 6.63, N 11.99; found C 43.18, H 6.33, N 11.53.

10-[3-(Adenosine5′-triphosphate)oxypropyl]-1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (DO3A-Pr-ATP): Adenosine 5′-triphosphate disodium salt (0.551 g, 1 mmol) was dissolved in 5 mL of water and passed through a column packed with Amberlite IR-120 (H^+, strongly acidic) cation exchange resin and eluted with distilled water. The linker-appended DO3A (**3**; 0.466 g, 1 mmol) in 25 mL of water was added to the eluent, which contains free ATP, and stirred for 24 h at room temperature. The solvent was removed under reduced pressure in a rotary evaporator whilst maintaining the bath temperature below 40 °C. The vitreous solid that separated out became white upon the addition of methanol and was washed with acetone, dried in a vacuum desiccator, and stored in a refrigerator. The purity of DO3A-Pr-ATP was checked by HPLC (R_f = 6.11, H_2O/CH_3CN, 9:5 *v*/*v*); yield 53.4%; m.p. 153 °C (dec). IR (KBr): $\tilde{\nu}$ = 3420.1 cm^{-1} ν_s(OH), 2926.5 ν_s(CH), 1476.8 δ_s(CH), 1700 ν_s(C=O), 1635.4 δ_s(NH), 1507.1 ν_s(C–O), 1087.6 ν_s(C–N), 995 δ(C–H), 719.8 δ_r(C–H), 1228.4 ν_s(P=O), 900 ν_s(P–O). C 36.31, H 5.15, N 14.10; found C 36.14, H 4.96, N 13.94.

[Gd(DO3A-Pr-ATP)(H$_2$O)$_2$] (4): Gadolinium(III) perchlorate hydrate (0.11 g, 0.25 mmol) was added to a solution of DO3A-Pr-ATP (0.22 g, 0.25 mmol) in 30 mL of water and stirred at room temperature for 36 h. Dowex cation exchange resin (10 g) was added to the reaction mixture and stirred for 15 min at room temperature and the absence of uncomplexed Gd^{III} ions was confirmed by testing the solution with xylenol orange indicator.[43] The solution was filtered to remove solid particles and the filtrate was distilled off under reduced pressure in a rotary evaporator to dryness. The white solid was recrystallized from triply distilled water. The purity of the complex was checked by HPLC (single peak, retention time 4.420 (H_2O/CH_3CN, 9:1, *v*/*v*); yield 59.09%; m.p. 175 °C (dec). IR (KBr): $\tilde{\nu}$ = 3303.4 cm^{-1} ν_s(OH), 1608.8 (COO), 1410.6 δ_s(OH), 1238.0 ν_s(P=O), 909 ν_s(P–O). MS (ESI): *m*/*z* = 1081 $[M - 2]^+$ $[Gd(C_{27}H_{41}N_9O_{19}P_3)(H_2O)_2]$, 793 $[M - C_{11}H_{17}N_5O_5]^+$ $[Gd(C_{17}H_{27}N_4O_{16}P_3)]$, 734 $[M - C_{12}H_{21}N_5O_7]^+$ $[Gd(C_{15}H_{24}N_4O_{14}P_3)]$, 578 $[M - Gd(C_{12}H_{20}N_5O_7)]^+$ ($C_{15}H_{25}N_4O_{14}P_3$), 483 $[M - Gd(C_{12}H_{20}N_5O_{11}P)]^+$ ($C_{15}H_{25}N_4O_{10}P_2$), 168 $[M - Gd(C_{19}H_{29}N_5O_{21}P_3)]^+$ ($C_8H_{16}N_4$). $Gd(C_{27}H_{43}N_9O_{19}P_3)(H_2O)_2$ (1083.05): calcd. C 29.94, H 4.33, N 11.63; found C 29.68, H 4.25, N 11.46.

Supporting Information Available (see footnote on the first page of this article): Chart S1. Gadolinium(III) chelates approved by FDA for human imaging. FAB mass spectroscopic data of 10-(3-bromopropyl)-1,4,7-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane (Figure S1), T_1 values for different concentrations of $[Gd(L1)(H_2O)_2]$ (Table S1), the plot of concentration of $[Gd(L1)(H_2O)_2]$ vs. $1/T_1$ (r_{1p} relaxivity measurements) (Figure S2), T_1 values for different concentrations of $[Gd(L1)(H_2O)_2]$ in the presence of β-cyclodextrin (Table S2), the plot of concentration of $[Gd(L1)(H_2O)_2]$ vs. $1/T_1$ in the presence of β-cyclodextrin (Figure S3), T_1 values for different concentrations of $[Gd(L1)(H_2O)_2]$ at pH 8.4 (Table S3), and a plot of concentration of $[Gd(L1)(H_2O)_2]$ vs. $1/T_1$ (r_{1p} relaxivity measurements at pH 8.4; Figure S4).

Acknowledgments

This research was carried out with the financial support of the Board of Research in Nuclear Sciences (BRNS), Department of Atomic Energy, Government of India. We thank Dr. V. K. Manchanda, Head, Radiochemistry Division, Bhabha Atomic Research Center, Mumbai-400085, for his support. We thank Dr. Venkat Manohar, Measurements Science Division, Unilever Research India, Bangalore, for providing facilities for relaxivity measurements.

Synthesis, Characterization and Molecular Structures of Yttrium Trifluoroacetate Complexes with O- and N-Donors: Complexation vs. Hydrolysis

Jianyong Zhang,[a] Stéphanie Morlens,[a] Liliane G. Hubert-Pfalzgraf*[a] and Dominique Luneau[b]

Keywords: Carboxylate ligands / Fluorinated ligands / N ligands / Superconductors / Yttrium

Dehydration and complexation reactions of $[Y(TFA)_3(H_2O)_3]$ (**1**; TFA = O_2CCF_3) were investigated with O- and N-donor ligands in order to obtain suitable precursors for MOD (Metal Organic Deposition). Anhydrous adducts such as $[Y_2(\mu,\eta^2\text{-}TFA)_4(\eta^1\text{-}TFA)_2(OHC_2H_4O\textit{i}Pr)_4]$ (**3**), $[Y_2(\mu,\eta^2\text{-}TFA)_4(\eta^1\text{-}TFA)_2(OHC_2H_4OC_2H_4OMe)_2]$ (**4**), or $[Y(TFA)_3(triglyme)]$ (**5**) were isolated. The reactions with N-donor ligands are more complex and afford mixed-ligand derivatives such as $[Y(TFA)_3(H_2O)_2(LL)]_m$ [LL = TMEDA (**9**), $Me_2NC_2H_4NMeC_2H_4NMe_2$ (**10**)] and, in the case of primary amines, yttrium oxohydroxo derivatives such as $[H_3O][Y_3(\mu_3\text{-}OH)(\mu\text{-}O)_3(\eta^1\text{-}TFA)_3(H_2O)_6(en)_3]$ (**6**; en = $NH_2C_2H_4NH_2$). All complexes were characterized by elemental analysis, FT-IR, and by single-crystal X-ray diffraction for **3**, **4**, and **6**. All structurally characterized complexes contain on eight-coordinate Y centers. Perfluorobutyrate and difluoroacetate derivatives were also prepared.

Introduction

Perfluorocarboxylate derivatives have been used as a source of fluorides by pyrolysis for glasses,[1] as a source of metal films for late transition metals, especially silver, by CVD techniques,[2] and have been considered for high Tc superconductors.[3] Trifluoroacetate (TFA) derivatives are currently used for elaboration of high Tc superconductor coatings by MOD (Metal Organic Deposition),[4a] a low-cost approach by comparison with vacuum approaches such as MOCVD (Metal Organic Chemical Vapour Deposition).[4b] This strategy proceeds via the formation of barium fluoride, thus avoiding the formation of more stable barium carbonate, during the thermal decomposition. However, the synthesis of the Ba, Y and Cu trifluoroacetates in situ starting from commercial acetates has led to lack of reproducibility in the quality of the coatings. This has been attributed to the volatility of the copper(II) derivative during the subsequent thermal treatment as well as to the presence of water. Lanthanide and yttrium trifluoroacetates associated with Al or Zn alkyls have also attracted interest as catalysts in various polymerization processes.[5] Although a large number of lanthanide trifluoroacetate complexes have been reported, often for their luminescence properties, few of them are anhydrous. Most of them are mixed-ligand species such as $[Ln(TFA)_3L_2(H_2O)]$ [L = pyzNO (pyrazine *N*-oxide)[6] or aza (2-azacyclononane)[7]] but species such as $[Ln(TFA)_3(DMF)_2]$ (LL = bipy, *o*-phen)[8] are also known. Structural characterization remains scarce, although such adducts display a large structural diversity, as represented by the $[Ln(TFA)_3(TMSO)_2]$ (TMSO = tetramethylene sulfoxide) derivatives,[9] which form infinite chains of dimers for Ln = La but discrete dimers for Ln = Nd, as well as $[Sm_2(\mu,\eta^2\text{-}TFA)_4(\eta^1\text{-}TFA)_2(aza)_2(H_2O)_2]\cdot 2aza$,[7] ionic compounds for the $Ln(TFA)_3(HMPA)_3$ adducts (Ln = La, Nd, Er) which are not isomorphous and are based on $[Er(\eta^1\text{-}TFA)_2(HMPA)_4]^+$, $[Er(\eta^1\text{-}TFA)_2(HMPA)_2(H_2O)_3]^+$ or $[Nd(\eta^2\text{-}TFA)_2(HMPA)_4]^+$ cations stabilized by a TFA counteranion.[10] Studies on yttrium derivatives remain quite scarce despite their interest in materials science.

We wish to report here the synthesis and characterization of yttrium fluorocarboxylate adducts with O- and N-donor ligands of various denticity. The anhydrous adducts $[Y_2(TFA)_6(OHC_2H_4O\textit{i}Pr)_4]$ (**3**) and $[Y_2(TFA)_6(OHC_2H_4OC_2H_4OMe)_2]$ (**4**) and the ionic hydroxide derivative $[H_3O][Y_3(\mu_3\text{-}OH)(\mu\text{-}O)_3(\eta^1\text{-}TFA)_3(H_2O)_6(en)_3]$ (**6**; en = $NH_2C_2H_4NH_2$) have been structurally characterized.

Results and Discussion

The synthetic routes and reactivity of yttrium trifluoroacetate derivatives were investigated. The various compounds were isolated in high yields and characterized by

 DOI: 10.1002/ejic.200500156

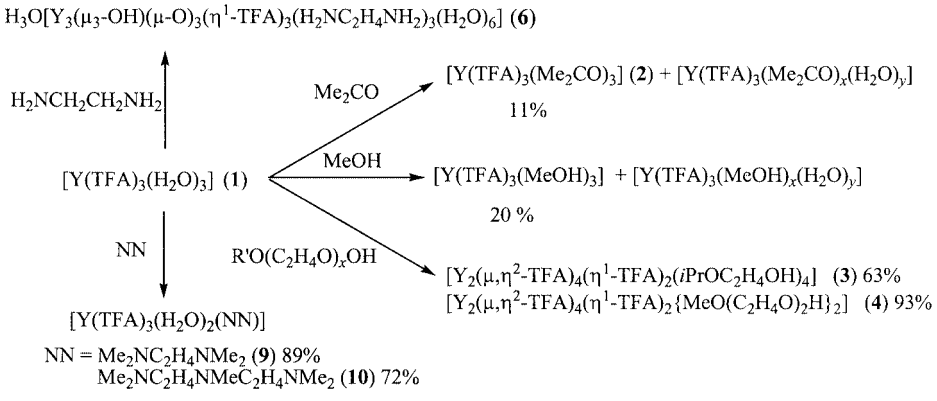
elemental analysis and FT-IR and ^{1}H NMR spectroscopy. $[Y_2(TFA)_6(OHC_2H_4OiPr)_4]$ (**3**), $[Y_2(TFA)_6(OHC_2H_4OC_2H_4OMe)_2]$ (**4**), and $[H_3O][Y_3(\mu_3\text{-}OH)(\mu\text{-}O)_3(\eta^1\text{-}TFA)_3(H_2O)_6(en)_3]$ (**6**; en = $NH_2C_2H_4NH_2$) were also characterized by single-crystal X-ray diffraction.

Synthesis of Y Derivatives by Ligand Exchange and Thermal Dehydration

The classical, cost-efficient synthesis of yttrium trifluoroacetate by reacting the oxide with trifluoroacetic acid in refluxing toluene[11] proceeds with formation of water as by-product to afford the hydrate $[Y(TFA)_3(H_2O)_3]$ (**1**). The presence of residual oxide was ascertained by absorption bands at 561 and 461 cm^{-1} in the IR spectrum. Recrystallization of **1** from diethyl ether allowed elimination of Y_2O_3. Attempts to remove the water molecules (48 h, 140 °C, 10^{-4} Torr) were unsuccessful, probably due to the strong hydrogen bonding between the water molecules and the fluorinated ligand.[12] More efficient dehydration of **1** could be achieved at 200 °C in a furnace but some decomposition was observed and the anhydrous $Y(TFA)_3$ is very hygroscopic due to its high Lewis acidity. Methyl orthoformate has been used for the dehydration of $LnCl_3{\cdot}xH_2O$,[13] therefore its potential to dehydrate **1** was evaluated. If the preceding reaction was carried out in the presence of methyl orthoformate (stoichiometry 1:3), a different product was formed. The presence of methanol in the coordination sphere was confirmed by the reaction with $[Y(TFA)_3(H_2O)_3]$ in refluxing methanol, which gives $[Y(TFA)_3(MeOH)_x]$ (20%) and the partially dehydrated adduct $[Y(TFA)_3(MeOH)_x(H_2O)_y]$. Attempts to use acetone as a ligand for access to anhydrous TFA derivatives, as reported for $[Cu_2(TFA)_4]_\infty$,[14] afforded the very hygroscopic species $[Y(TFA)_3(Me_2CO)_3]$ (**2**) in low yield, the major species being a mixture of $[Y(TFA)_3(H_2O)_x(Me_2CO)_y]$ complexes which could not be crystallized out. $[Y(CHF_2CO_2)_3(H_2O)_3]$ was also prepared from the oxide and CHF_2CO_2H but, in contrast to **1**, it was insoluble in THF. Anhydrous perfluorobutyrate $[Y(O_2CC_3F_7)_3]$ (**11**) was prepared from the oxide even in the absence of a dehydrating reagent. However, high yields required long reactions times (3 d) and careful work-up due to its high volatility under vacuum. In contrast, the hydrate $[Y(O_2CC_3F_7)_3(H_2O)_2]$ (**12**) was obtained easily in nearly quantitative yield from $[Y_2(CO_3)_3(H_2O)_3]$ in refluxing toluene.

Ligand-exchange reactions with various polydentate N- or O-donors were more efficient and yielded dehydrated, partially dehydrated, or hydrolyzed adducts in either toluene or THF at room temp. Dissolution of **1** generally required an excess of ligand, especially in toluene. The O- and N-donor ligands behaved quite differently in their potential to give water-free adducts. Exchange reactions with *i*PrOC_2H_4OH, $MeOC_2H_4OC_2H_4OH$, and triglyme ($MeOC_2H_4OC_2H_4OC_2H_4OMe$) provided water-free $[Y_2(TFA)_6(iPrOC_2H_4OH)_4]$ (**3**), $[Y_2(TFA)_6(MeOC_2H_4OC_2H_4OH)_2]$ (**4**), and $[Y(TFA)_3(MeOC_2H_4OC_2H_4OC_2H_4OMe)]$ (**5**), respectively (Scheme 1).

The reactions between $[Y(TFA)_3(H_2O)_3]$ and N-donor Lewis bases (B) were more complex than those with O-donor ligands. Exchange reactions with TMEDA and $Me_2NC_2H_4NMeC_2H_4NMe_2$ provided the partially dehydrated complexes $[Y(TFA)_3(H_2O)_2(Me_2NC_2H_4NMe_2)]$ (**9**) and $[Y(TFA)_3(H_2O)_2(Me_2NC_2H_4NMeC_2H_4NMe_2)]$ (**10**), respectively. However, in the presence of primary amines such as $H_2NC_2H_4NH_2$ (en), $H_2NC_2H_4NMe_2$, $H_2NC_2H_4NHC_2H_4NH_2$, and $H_2NC_2H_4NHC_2H_4OH$, part of the trifluoroacetate ligand was converted into a BH^+TFA^- salt to afford hydrolyzed metallic derivatives. In the case of ethylenediamine, the metallic species corresponds to an anionic trinuclear oxohydroxide $[Y_3(\mu_3\text{-}OH)(\mu\text{-}O)_3(\eta^1\text{-}TFA)_3(H_2O)_6(en)_3]^-$ stabilized by H_3O^+ as counterion, all metals being eight-coordinate (see below). Adducts with similar formulae were obtained with other primary amines, namely the tridentate $NH_2C_2H_4NHC_2H_4X$ (X = NH_2, OH) ligands, although these compounds were devoid of water. The various yttrium oxohydroxide trifluoroacetate complexes were often contaminated by some trifluoroacetate ammonium salts which were difficult to separate by crystallization or by sublimation. These results show that reactions between **1** and tertiary amines afford partially dehydrated adducts, while those with primary amines give



Scheme 1. Reactivity of **1** toward some O- and N-donors (all reactions at room temp.).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydrolyzed products. The formation of **6** according to Equation (1) supposes the presence of more water than that resulting from **1**, the additional water molecules being provided either by the solvent or, more likely, by the hygroscopic character of **1**. An hydroxy Pr trifluoroacetate $[Pr_2(TFA)_3(OH)(15\text{-crown-}5)_2][Pr_2(TFA)_8]$ has been reported by treatment of $[Pr(TFA)_3(H_2O)_3]$ with 15-crown-5.[15]

Physical Characteristics and Thermal Behavior

The various complexes display very intense broad absorption bands in their FT-IR spectra − generally two − at around 1290–1100 cm^{-1} corresponding to the C–F vibrations.[16,17] Additional sharp bands due to the coordinated Lewis base are present as well but they are shifted downfield with respect to the free ligand, as illustrated for

$$3\,[Y(TFA)_3(H_2O)_3] + 6\,H_2NC_2H_4NH_2 + 2\,H_2O \longrightarrow H_3O[Y_3(\mu_3\text{-}OH)(\mu\text{-}O)_3(\eta^1\text{-}TFA)_3(H_2O)_6(en)_3] + 3\,[H_3NC_2H_4NH_3](TFA)_2 \quad (1)$$

en = $H_2NC_2H_4NH_2$

Table 1. IR data [cm^{-1}] of the various yttrium fluorocarboxylate adducts.

Compound	$\nu(CO_2)$ $\nu_{as}(CO_2)$	$\nu_s(CO_2)$	ν(M–O)	ν(OH) [ν(NH)]	Observation

the alcohol adducts **3** and **4**. The absorption bands characteristic of the carboxylate ligands appear generally as several bands for the $\nu_{as}(CO_2)$ stretch, with some around 1740–1715 cm^{-1} and some at lower frequencies around 1680–1600 cm^{-1}, suggesting trifluoroacetate ligands displaying different coordination modes such as bridging or bridging-chelating and monodentate (Table 1). Similar patterns have been observed for $[Sm_2(\mu,\eta^2\text{-TFA})_4(\eta^1\text{-TFA})_2(aza)_4(H_2O)_2]\cdot 2aza$[7] and $[LaCu(bdmmpH)(bdmmp)(\mu\text{-}OH)(TFA)_3]_2$ [bdmmpH = 2,6-bis(dimethylaminomethyl)-4-methylphenol].[18] The absorption band at 1682 cm^{-1} for **6** and **8**, for instance, suggests the presence of monodentate TFA, in agreement with the frequency found for the dangling TFA of $[Y(\eta^1\text{-TFA})_2(H_2O)_6][TFA]$(18-crown-6).[19] The presence of η^1-TFA ligands is also evidenced by the reduction of the intensity of the $\nu_s(CO_2)$ absorption bands around 1403 cm^{-1}. The presence of water molecules in the coordination sphere of the complexes with the N-donor ligands (**9** and **10)** is evidenced by bands between 3350 and 3700 cm^{-1}.

The TGA patterns (N_2, 1 atm) of the perfluorobutyrate derivatives **11** and **12** account for their volatility. They decompose into yttrium fluoride and oxofluoride, respectively. Compound **12** decomposes between 320 and 370 °C after loss of water (up to 210 °C), whereas **11** decomposes between 270 and 310 °C.

Anhydrous metal trifluoroacetate derivatives are less soluble in organic media than their hydrated counterparts, and the yttrium derivatives are also less soluble than the barium derivatives.[17] Complexation with organic ligands improves their solubility and the complexes have good solubility in polar solvents such as THF, DME, and alcohols. All the anhydrous yttrium trifluoroacetate complexes are slightly hygroscopic. As expected, the solubility in organic media also increases with the length of the fluoroalkyl chain, the solubility of $[Y(PFB)_3(H_2O)_2]$ in MeOH, for example, is thus much better than that of $[Y(TFA)_3(H_2O)_3]$. Both compounds are actually more soluble in MeOH than in *i*PrO-C_2H_4OH. The low solubility of the various fluoroacetate compounds in nonpolar solvents precluded access to useful ^1H or ^{19}F NMR spectroscopic data (extensive dissociation was generally observed in CD_3OD).

Molecular Structures of $[Y_2(TFA)_6(R'OH)_x]$ (R' = *i*PrOC$_2$H$_4$, x = 4; R' = MeOC$_2$H$_4$OC$_2$H$_4$, x = 2) and of $[H_3O][Y_3(\mu\text{-}O)_3(\mu_3\text{-}OH)(TFA)_3(en)_3(H_2O)_6]$

Compounds **3**, **4**, and **6** were characterized by low-temperature single-crystal X-ray diffraction. The structures of complexes **3** and **4** with the O-donor ligands are depicted in Figures 1 and 2, respectively. Two independent molecules (**3a** and **3b**) having similar metric parameters are present in the unit cell of **3**. Selected bond lengths and angles are collected in Table 2 and Table 3 for **3** and **4**, respectively. The Y–TFA adducts with O-donor Lewis bases are dinuclear. Their molecular structure is based on a $Y_2(\mu,\eta^2\text{-TFA})_4(\eta^1\text{-TFA})_2$ core, the coordination sphere being completed by neutral ligands in order to achieve eight-coordination for the metals. As a result, the adduct **3** with isopropoxyethanol shows two different coordination modes, namely monodentate η^1- and bidentate η^2- for the alcohol, whereas 2-propoxyethoxyethanol ($HOC_2H_4OC_2H_4OMe$) is tridentate in **4**. The Y–O bond lengths range from 2.280(3) to 2.437(3) Å in **4**. The Y-μ,η^2-O(TFA) bonds [av. 2.329(5) and 2.334(3) Å for **3** and **4**, respectively] are longer than the corresponding Y-η^1-O(TFA) ones [2.301(5) and 2.300(3) Å]. As observed for an η^1-TFA barium derivative, the C–O bonds are slightly elongated by coordination [1.256(3) vs. 1.193(3) Å]. The coordination polyhedra of Y correspond to a square prism and a distorted square antiprism for **3** and **4**, respectively. The Y···Y distances have values of 4.484(2) (av.) and 4.464(5) Å for **3** and **4** respectively. They are thus longer than the Ln···Ln distances in $[Sm_2(\mu,\eta^2\text{-TFA})_4(\eta^1\text{-TFA})_2(aza)_4(H_2O)_2]\cdot 2aza$[7] and $[Nd_2(\mu,\eta^2\text{-TFA})_4(\eta^2\text{-TFA})_2(TMSO)_2]$[9] despite the smaller size of the metal, and also much longer than for $[Y_2(TFA)_6(bdmap)_2]^{2-}$ [bdmap = 1,3-bis(dimethylamino)-2-propoxide {$OCH(CH_2NMe_2)_2$}].[20] The bridging coordination mode of the trifluoroacetate ligand is quite common for homometallic as well as heterometallic compounds such as $[(\mu\text{-}TFA)_2Ln(\mu\text{-}CF_3CHO_2)AlR_2(THF)_2]_2$ (Ln = Nd, Y, Eu). The Y···F distances (>4.5 Å) account for the absence of Y···F interactions in the solid state, in contrast to the lanthanide fluorinated alkoxides.[17b] Octacoordination appears as the preferred coordination number for all structurally characterized yttrium trifluoroacetate derivatives.

Compound **6** crystallizes in the rhombohedral space group $R\bar{3}$ as a trinuclear anion and a H_3O^+ hydroxonium cation with the overall formula $[H_3O][Y_3(\mu_2\text{-}O)_3(\mu_3\text{-}OH)(TFA)_3(en)_3(H_2O)_6]$. The anion has C_3 symmetry, with the O3 oxygen atom (μ_3-OH) and the H_3O^+ ion both located on the C_3 axis, with O3 capping the trinuclear $[Y_3(\mu\text{-}O)_3(\mu_3\text{-}OH)]^{+2}$ unit (Figure 3). Selected bond lengths and angles are collected in Table 4. The Y–O bond lengths spread over the range 2.217(12) to 2.65(2) Å and follow the order Y–μ-O < Y–μ_3-OH < Y–η^1-O(TFA) < Y–Ow(H_2O). For the latter, two types of Y–Ow distances [2.49(2) and 2.64(2) Å] are observed. The Y–η^1-O(TFA) bond lengths of 2.44(2) Å (av.) are much longer than those in **3** and **4** despite the identical coordination numbers. The Y···O distances involving the dangling oxygen atoms have values of 3.636 Å. The Y–N bond distances [2.55(2) Å] are comparable to those observed, for instance, for $[Y_2(thd)_4(\mu,\eta^2\text{-bdmap})_2]$ (thd = 2,2,6,6-tetamethylheptane-3,5-dionate).[20] The Y···Y distance of 3.778(3) Å is in agreement with the data reported for the previous compound or for $[Cp_6Y_3(\mu\text{-}OMe)_3(\mu_3\text{-}H)_2Li_2(THF)_6]$.[21] It is much shorter than for **3** or **4**, where the metals are bridged by the trifluoroacetate ligands, but longer than for most other polynuclear yttrium alkoxides. The TFA and ethylenediamine ligands are located below the Y_3 plane on the same side as the hydroxide ligand, whereas the hydroxonium cation is located on the same side as the water molecules. As for the other derivatives, the structure of **6** displays no short Y···F (>5.127 Å)

or μ_3-OH···F (>4.44 Å) interactions. In contrast, one observes two quite short N···F interactions, namely N1···F1 and N1···F3, with values of 3.744 and 3.821 Å respectively. These N···F interactions are much shorter than those observed, for instance, for [Ce{OCH$(CF_3)_2\}_4$(tmeda)] (4.137–4.259 Å).[22] The Y···O(H_3O) distance of 4.793(3) Å excludes the presence of ion pairs. The O(H_3O)···O(H_2O, O1w) distance of 3.26 Å shows that no strong hydrogen bonding exists. Metal complexes containing the hydroxonium cation remain scarce. Some examples are represented

by $[H_3O][Re_3Cl_{10}(H_2O)_2],5H_2O$[23] and by [18-crown-6]$(H_3O)_2(Hf_2F_{10}\cdot 2H_2O)\cdot 4H_2O$.[24] Trinuclear neutral metal oxocarboxylate cores $[M_3(\mu_3\text{-}O)(TFA)_6(H_2O)_3]$ (M = Fe, Co, Mn, Ni) are quite common and have been used as building blocks for extended arrays.[25] On the other hand, reactions between fluoroacetates and amines are known to form ionic species, as observed, for instance, for bismuth with species such as $[(BH)_2Bi(\eta^1\text{-}TFA)_5]$ (B being pyridine or diamines such as TMEDA or other tertiary diamines) where the cations interact with the dangling oxygen of the trifluoroacetate ligands by H-bonding (Figure 4).[26]

No reaction was observed between Y and Ba trifluoroacetate derivatives, for instance in methanol. This was also confirmed by the fact that the reaction between $[Ba(OH)_2(H_2O)_8]$, yttrium oxide, trifluoroacetic acid, and methyl orthoformate in refluxing toluene gave a mixture of the homometallic species $[Ba(TFA)_2]_m$, $[Y(TFA)_3(H_2O)_3]$ and $[Y(TFA)_3(MeOH)_x(H_2O)_y]$ (IR evidence). In contrast, functional alcohols such as amino alcohols were able to promote the formation of heteronuclear assemblies.[27]

Experimental Section

All manipulations were routinely performed under argon using Schlenk tubes and vacuum line techniques. Solvents were purified by standard methods. Trifluoroacetic (TFAH), perfluorobutyric (PFBH) and difluoroacetic acids (Aldrich) were stored over molecular sieves. $[Y(TFA)_3(H_2O)_3]$ (**1**) was prepared by reacting the oxide with TFAH in refluxing toluene.[11] IR spectra were recorded as Nujol or as Fluorolub mulls on an IR-FTS 45 spectrometer. Elemental analyses were done at the Centre de Microanalyses du CNRS. IR data and general properties are collected in Table 1.

$[Y(TFA)_3(Me_2CO)_3]$ (2): Complex **1** (0.815 g, 1.69 mmol) was added to acetone (20 mL). Concentration after 2 d gave colorless crystals of **2**. $C_{15}H_{18}F_9O_9Y$ (602.19): calcd. C 29.92, H 3.01, found C 30.03, H 3.10.

$[Y_2(TFA)_6(i\text{PrOC}_2H_4OH)_4]$ (3): $i\text{PrOC}_2H_4OH$ (1.38 mL, 12.0 mmol) was added to a suspension of **1** (0.72 g, 1.5 mmol) in toluene (20 mL). After stirring for 14 h, concentration gave colorless crystals of **3** (0.60 g, 63%). $C_{32}H_{48}F_{18}O_{20}Y_2$ (1272.5): calcd. C 30.20, H 3.80; found C 30.15, H 3.92.

$[Y_2(TFA)_6(MeOC_2H_4OC_2H_4OH)_2]$ (4): $MeOC_2H_4OC_2H_4OH$ (0.43 mL, 3.6 mmol) was added to a suspension of **1** (0.58 g, 1.2 mmol) in toluene (20 mL). After stirring for 14 h, filtration gave a solid, which was redissolved in THF to yield colorless crystals of **4** (0.61 g, 93%). $C_{22}H_{24}F_{18}O_{18}Y_2$ (1096.2): calcd. C 24.11, H 2.21; found C 24.33, H 2.34.

$[Y(TFA)_3(MeOC_2H_4OC_2H_4OC_2H_4OMe)]$ (5): Triglyme (0.5 mL, 2.74 mmol) was added to a solution of **1** (0.658 g, 1.37 mmol) in THF (15 mL). After stirring at room temp. for 14 h, concentration gave colorless crystals of **5** (0.52 g, 63%). $C_{14}H_{18}F_9O_{10}Y$ (606.18): calcd. C 27.74, H 2.99; found C 27.94, H 3.10%.

$[H_3O][Y_3(\mu_3\text{-}OH)(\mu\text{-}O)_3(TFA)_3(H_2NC_2H_4NH_2)_3(H_2O)_6]$ (6): A procedure similar to that of **5** but with ethylenediamine (0.66 mL, 9.92 mmol) and **1** (0.60 g, 1.24 mmol) in THF (15 mL) gave **6** (0.43 g). $C_{12}H_{40}F_9N_6O_{17}Y_3$ (978.18): calcd. C 14.73, H 4.12, N 8.5; found C 16.20, H 4.30, N 9.15. ^1H NMR (CD_3OD): δ = 2.67 (s, 12 H, CH_2), 3.2 (s, Me) ppm. The product was sometimes contaminated with $[H_3NC_2H_4NH_3][TFA]_2$, thus precluding good analytical data.

$[H_3O][Y_3O(OH)_3(TFA)_3(H_2NC_2H_4NHC_2H_4X)_3]$ [X = NH_2 (7) and X = OH (8)]: These complexes were prepared by a procedure similar to **6**.

7: $C_{18}H_{45}F_9N_9O_{11}Y_3$ (1001.3): calcd. C 21.95, H 4.53, N, 12.59; found C 23.48, H 4.12, N 13.20.

8: $C_{18}H_{42}F_9N_6O_{14}Y_3$ (1004.3): calcd. C 21.53, H 4.22, N 8.37; found C 21.72, H 4.35, N 8.55.

$[Y(TFA)_3(H_2O)_2(Me_2NC_2H_4NMe_2)]$ (9) and $[Y(TFA)_3(H_2O)_2(Me_2NC_2H_4NMeC_2H_4NMe_2)]$ (10): Prepared by a procedure similar to **4**. Yields: 89% for **9** and 72% for **10**.
9: $C_{12}H_{20}F_9N_2O_8Y$ (580.19): calcd. C 24.84, H 3.47, N 4.93; found C 24.38, H 3.46, N 4.86.
10: $C_{15}H_{27}F_9N_3O_8Y$ (637.29): calcd. C 28.27, H 4.27, N 6.59; found C 28.15, H 4.13, N 6.70.

Treatment of **1** (0.67 g, 1.39 mmol) with $Me_2NC_2H_4NH_2$ (0.46 mL, 4.16 mmol) in toluene or THF (20 mL) gave needles of $Me_2NC_2H_4NH_3$·TFA as the only crystalline species. IR: $\tilde{\nu}$ = 1683 cm^{-1} s, 1586 m, 1518 m, 1463 s, 1424 m; 598 w, 542 w, 520 w. X-ray data: a = 6.427(1), b = 18.124(4), c = 8.753(2) Å, β = 101.58(3)°, V = 998.8 Å^3, space group $P2_1/c$.

$[Y(O_2CC_3F_7)_3]$ (11): Perfluorobutyric acid (1.5 mL, 10.5 mmol) was added to a suspension of Y_2O_3 (0.39 g, 1.74 mmol) in toluene (15 mL). After refluxing for 3 d, filtration and recrystallization from Et_2O gave **11** by condensation into a cold trap during evaporation under vacuum (0.94 g, 75%). $C_{12}F_{21}O_6Y$ (728.00): calcd. C 19.8; found C 19.7.

$[Y(H_2O)_2(O_2CC_3F_7)_3]$ (12): Perfluorobutyric acid (3.3 mL, 25.3 mmol) was added to a suspension of $Y_2(CO_3)_3$·$3H_2O$ (1.74 g, 4.2 mmol) in toluene (30 mL). After refluxing for 24 h, the precipitate was filtered, washed with hexane, and recrystallized from Et_2O to give **12** (6.10 g, 95%). $C_{12}H_4F_{21}O_8Y$ (764.03): calcd. C 18.86, H 0.53, found C 19.05, H 0.62.

$[Y(O_2CCHF_2)_3(H_2O)_3]$ (13): The same procedure as for **1** applied to Y_2O_3 (452 mg, 2.0 mmol) and CHF_2CO_2H (0.4 mL, 6.0 mmol) in refluxing toluene for 32 h. Recrystallization from THF (75%). $C_6H_9F_6O_9Y$ (428.03): calcd. C 16.84, H 2.12, found C 16.92, H 2.22.

All compounds were soluble in polar media (alcohols, THF, DME) but insoluble in $CHCl_3$ or hydrocarbons (aliphatic and aromatic).

X-ray Crystallography of 3, 4, and 6: Suitable crystals of **3**, **4**, and **6** were grown directly from the reaction media. X-ray single-crystal diffraction data were collected with a Nonius Kappa CCD diffractometer. The data were processed with the DENZO reduction software package.[28] An absorption correction (XABS2)[29] was applied to the data of compound **3**. The structures were solved and refined on F^2 using SHELXTL.[30] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the final refinement model in calculated positions with isotropic thermal parameters. The distribution of the C–F bond lengths is quite large due to disorder phenomena, which are also illustrated by high thermal factors. Crystal structure and refinement data are summarized in Table 5.
CCDC-227441 (for **3**), -227442 (for **4**), and -244549 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis, Characterization, and Electrochemical Properties of Dinuclear Complexes Assembled from Asymmetric Co^{III} Bis(dioximates) and Boronic Acids

Renata Dreos,*[a] Patrizia Siega,[a] Silvia Scagliola,[a] Lucio Randaccio,*[a] Giorgio Nardin,[a] Claudio Tavagnacco,[a] and Manuela Bevilacqua[a]

Keywords: Boronic acid / Cobalt / Dioximes / Enantioselectivity / Electrochemistry

Bis(methylphenylglyoximate)cobalt(III) complexes exist both as *cis* and *trans* isomers due to the asymmetry of the equatorial ligand, and, when the axial ligands are different, the *trans* isomer is chiral. The reaction of racemic *trans*-$[CH_3Co(mpgH)_2py]$ (**1**) with either 3- or 4-pyridylboronic acid affords dimeric units arranged on a crystallographic symmetry center such that the pyridyl nitrogen of one moiety coordinates to the Co atom of the symmetry-related unit. In principle, three structurally different dimeric species (two homodimers and one heterodimer) can be obtained. Time-resolved ^1H NMR spectra of a 1:1 mixture of racemic **1** and either 3- or 4-pyridylboronic acid in $CDCl_3/CD_3OD$ show that the reaction does not converge toward a unique species in solution. Nevertheless, X-ray structures show that the heterochiral dimers are the only products that crystallize from the reaction mixture. The nature of the dioximate side groups does not affect the geometry of the dimeric arrangements assembled by 4-pyridylboronic acid ("molecular box"). On the contrary, the geometry of the species assembled by 3-pyridylboronic acid varies from the "molecular parallelogram" obtained from the bis(dimethylglyoximates) to the highly squeezed "molecular box" obtained from bis(methylphenylglyoximates). Cyclic voltammetry studies show that the metal centers in the dimeric species do not interact with each other and undergo a simultaneous redox process. However, depending on the geometry of the systems, the redox process involves a single four-electron reduction for **3** and **5** or two consecutive two-electron reduction steps for **4** and **6**.

Introduction

Organobis(dimethylglyoximato)cobalt(III) complexes {organocobaloximes, $[CH_3Co(dmgH)_2L]$, where L is a neutral ligand} have been extensively studied, mainly for their interest as vitamin B_{12} models,[1] but also for their use as polymerization catalysts[2] and as templates in organic synthesis.[3] Some examples of cobalt complexes with dioximato ligands other than $dmgH_2$, such as glyoximates (gH),[4] dicyclohexylglyoximates (chgH),[5] and diphenylglyoximates (dpgH),[6] are known. Derivatives containing mixed equatorial ligand sets, which include one dpgH and either a dmgH or chgH, have also been reported.[7] To the best of our knowledge, only two reports exist of cobalt complexes with the asymmetric methylphenylglyoximate ligand (mpgH).[8]

Organocobaloximes with either one or both of the intramolecular OHO bridges replaced by organoboryl groups are well known and have recently been reviewed.[9] We have used organobis(dimethylglyoximate)- and organobis(diphenylglyoximate)cobalt(III) complexes as building blocks in the assembly of supramolecular systems.[10] Indeed, functionalized aromatic boronic acids have been shown to efficiently direct the assembly of organocobaloximes through the reaction of the $B(OH)_2$ group with the oxime bridge of one cobaloxime molecule, with simultaneous coordination of the donor atom to the cobalt of another cobaloxime.[10] Products of different nuclearity and geometry have been obtained, depending on the geometry of the boronic acid used as linker (L^1, L^2, and L^3, Scheme 1). The most relevant consequence of replacing the methyl groups by phenyl groups in the equatorial ligand is a change of the nuclearity of the supramolecular species assembled with 3-aminophenylboronic acid (L^3): a molecular triangle was obtained starting from $[CH_3Co(dmgH)_2L]$ (Scheme 1), whereas a dimeric species was obtained from $[CH_3Co(dpgH)_2L]$ (Scheme 2), the trimeric arrangement being prevented by the steric hindrance of the phenyl groups.[11]

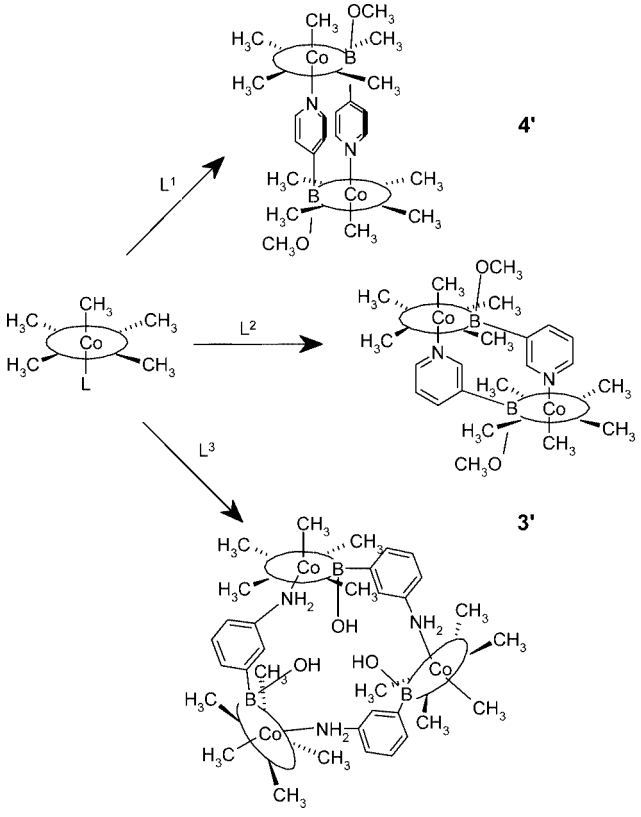
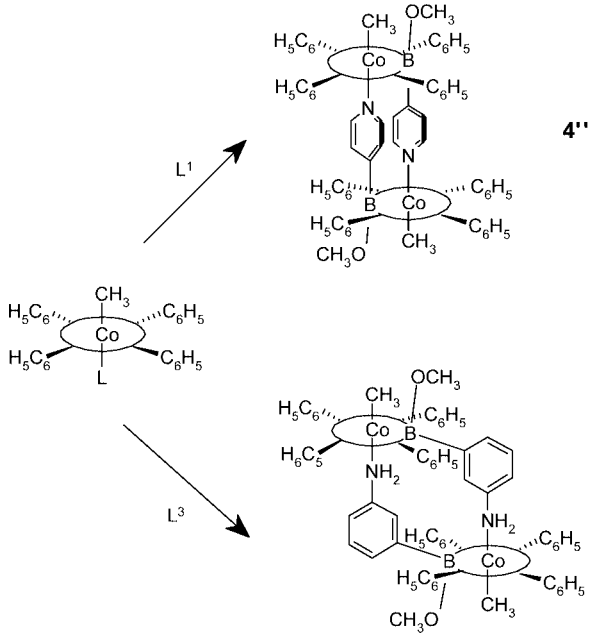


Scheme 1.



Scheme 2.

In order to systematically study how the steric bulk of the chelate affects the geometry of the assembled species, we have extended our investigation to bis(methylphenylglyoximato) complexes. These complexes exist both as *cis* and *trans* isomers due to the asymmetry of the equatorial ligand, and, when the axial ligands are different, the *trans* isomer is chiral. Therefore *trans*-[CH_3Co(mpgH)py] can be applied as a chiral building block in larger molecular systems.

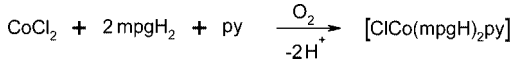
Here we report a study of the systems assembled from *trans*- and *cis*-[CH_3Co(mpgH)py] with 3- and 4- pyridylboronic acid, which includes the characterization of the dimeric aggregates formed both in solution and in the solid state and an investigation of their electrochemical properties.

Results and Discussion

Synthesis of the Organometallic Complexes

The ligand was prepared by addition of a tenfold excess of hydroxylamine hydrochloride, dissolved in water and neutralized with an equimolar amount of NaOH, to a methanolic solution of 1-phenyl-1,2-propanedione 2-oxime, as shown in Scheme 3.

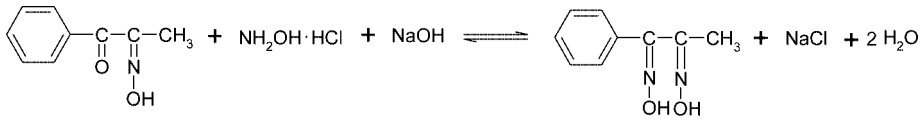
[ClCo(mpgH)$_2$py] was prepared by direct air oxidation of $CoCl_2$ in the presence of $mpgH_2$ and pyridine (Scheme 4). The ^{1}H NMR spectrum showed that the reaction product is a mixture of the *cis* and *trans* isomers.



Scheme 4.

Small quantities of the pure isomers could be separated by stratification of *n*-heptane over a $CDCl_3$ solution of the mixture in an NMR tube. After slow diffusion, two different kinds of crystals deposited on the walls of the tube and were manually separated. The ^{1}H NMR spectrum in $CDCl_3$ allowed identification of the *cis* and *trans* isomers, as the *cis* isomer gives rise to two singlets for the nonequivalent oximic protons, whereas only one signal is shown by the *trans* isomer. Integration of the signals of the equatorial methyls in the spectrum of the reaction mixture revealed that the *trans* isomer is the more abundant product of the synthesis. This isomer is chiral and exists in two enantiomeric forms.

The synthesis of the organometallic derivatives was carried out starting from the mixture of the *cis*- and *trans*-[ClCo(mpgH)$_2$py] isomers by reduction with $NaBH_4$ followed by the oxidative addition of CH_3I (Scheme 5). The product always remained a mixture of isomers, but not nec-



Scheme 3.

essarily in the same ratio as in the starting mixture. *trans*-[CH_3Co(mpgH)py] (**1**) and *cis*-[CH_3Co(mpgH)py] (**2**) were separated by fractional crystallization from CH_2Cl_2/CH_3OH (1:1) and characterized by ^{1}H NMR spectroscopy and X-ray structural analysis.

$$[ClCo^{III}(pmgH)_2py] \xrightarrow[NaOH]{NaBH_4} [Co^{I}(pmgH)_2py]^-$$

$$[Co^{I}(pmgH)_2py]^- \xrightarrow{CH_3I} [CH_3Co^{III}(pmgH)_2py]$$

Scheme 5.

The chiral *trans* isomer was isolated as a racemic mixture of the A and C enantiomers.[12]

Synthesis of the Supramolecular Species

The reactions were performed in a mixture of solvents (chloroform/methanol, 1:6), because the starting complexes **1** and **2** are poorly soluble in methanol although a hydroxylic solvent is necessary for the formation of hydroxyboronate species containing a tetrahedral boron.[10b] X-ray quality crystals were obtained from solutions containing a racemic mixture of the *trans* derivative **1** and either 3-pyridylboronic acid (**3**) or 4-pyridylboronic acid (**4**). Small crystals, not of X-ray quality, were also obtained from the reactions of the *cis* isomer **2** with 3-pyridylboronic acid and 4-pyridylboronic acid (**5** and **6**, respectively) These were identified by ESI MS and ^{1}H NMR spectroscopy in noncoordinating solvents.

The formation of the supramolecular species from **1** was monitored in solution by ^{1}H NMR spectroscopy. When an equivalent amount of 3-(or 4-)pyridylboronic acid was added to the racemic mixture of *trans*-[CH_3Co(mpgH)py] in $CD_3OD/CDCl_3$ (1:1) at a pH of about 5, the ^{1}H NMR spectrum consisted of a complicated pattern of peaks, which did not simplify on standing for two weeks, attesting to the presence of several species besides **3** (or **4**; Figure S1). Removal of the solvent under vacuum yielded a mixture of products, which was not further characterized. However, if the solvent was left to evaporate slowly from the solution, the crystals deposited on the walls of the NMR tubes consisted of pure **3** (or **4**). Redissolution of **3** (or **4**) in $CD_3OD/CDCl_3$ (1:1) resulted in a partial and slow decomposition of the supramolecular species (Figure S2).

X-ray Structures

ORTEP drawings of **1** and **2** are shown in Figure 1 together with their numbering scheme. Both **1** and **2** crystallize in a centrosymmetric space group with four molecules per unit cell. The equatorial ligand in **1** is nearly planar, the two dioximato moieties (excluding the phenyl side groups) making an interplanar angle of 1.9(3)°. The dioximato moieties in **2** are slightly bent towards the axial methyl group, making an interplanar angle of 6.2(1)°. The axial py ring is oriented with respect to the equatorial ligand in such a way as to nearly bisect the oxime bridges (orientation A) in **1**, whereas in **2** it is rotated by 17° towards N1 with respect to the orientation in **1**. No appreciable differences were detected in the coordination bond lengths and angles. Table 1 shows a comparison of the measured coordination distances with those reported for other methyl derivatives having different dioximate ligands. No evidence of a structural *cis*-influence is apparent.

The crystal of **3** is built up by dimeric units arranged on a crystallographic symmetry center and methanol solvent. The dimeric unit (Figure 2a) is formed by two enantiomeric *trans*-[$CH_3Co(mpgH)_2$] moieties held together by two 3-pyridylboronic acid residues. This arrangement results in a *meso* species whose geometry is similar to that found in the analogous bis(dimethylglyoximato) derivative **3′**.[10a] The C–C_{Me} and C–C_{Ph} units are not coplanar, the C_{Me} and C_{Ph} atoms being about 0.2 Å out of the mean plane of the five-membered rings. In **3′**, the C–C_{Me} bonds are nearly coplanar, with the C_{Me} less than 0.1 Å out of the five-membered rings. The 3-pyridyl residue coordinated to the Co′ atom is tilted by 167° (177° in **3′**) with respect to the equatorial plane, as measured by the Co′–N5–C22 angle. Thus, the two symmetry-related 3-py rings, which are essentially coplanar in **3′**, are still parallel in **3** but displaced by 1.45 Å. As a consequence, the "molecular parallelogram" in **3′** approaches a highly squeezed "molecular box" in **3**. Nevertheless, the dimensions of the Co···B···Co′···B′ parallelogram in **3** are not significantly different from those in **3′**, with a decrease of more than 2° in the B···Co···B′ angle (Table 1). As for **3′**, the 3-py mean plane in **3** is oriented in such a way as to nearly bisect the oxime bridge of the equatorial moiety (orientation A). The coordination bond lengths and angles do not differ significantly from those reported in **3′**. The axial Co–C and Co–N distances are compared in Table 1.

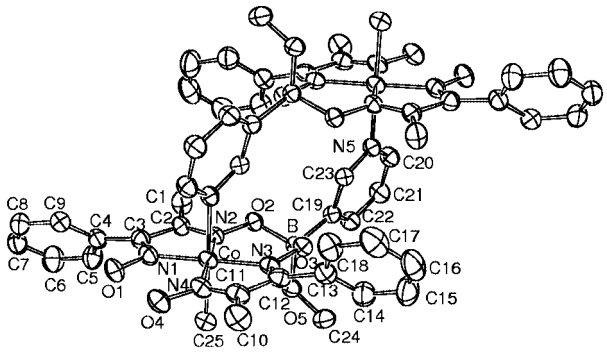
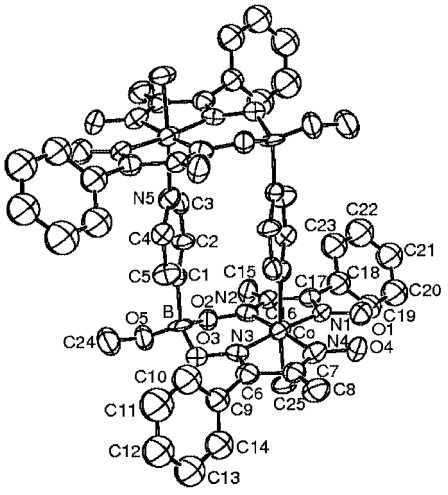
Table 1. Selected bond lengths [Å] of the mononuclear complexes **1** and **2** and the dinuclear complexes **3** and **4** compared with the corresponding distances for other methyl derivatives containing different dioximate ligands.

	Co–C	Co–N	Co–N_{eq} (mean)
1	1.976(6)	2.045(6)	1.872(5)
2	1.994(4)	2.057(3)	1.882(3)
$[CH_3Co(dmgH)_2py]$[13]	1.998(5)	2.068(3)	
$[CH_3Co(dpgH)_2py]$[6b]	1.997(4)	2.053(4)	1.884(3)
3	2.003(3)	2.074(3)	1.875(3)
3′[10a]	1.985(9)	2.069(8)	1.869(8)
4	2.010(9)	2.104(5)	1.884(9)
4′[10b]	2.00(1)	2.08(1)	1.87(1)
4′′[10c]	2.013(4)	2.068(3)	1.879(3)

The crystal of **4** is built up by dimeric units arranged on a crystallographic symmetry center (ORTEP diagram in Figure 2b). The dimer is formed by two enantiomeric *trans*-$[CH_3Co(mpgH)_2]$ moieties held together by two 4-pyridylboronic acid residues as for **3**. This arrangement results in a *meso* species whose geometry is very similar to those found in the analogous derivatives **4′**[10b] and **4′′**,[11] which contain dmgH and dpgH units, respectively. This result shows that the nature of the dioximate side substituents does not affect the geometry of such a dimeric arrangement ("molecular box"); the two symmetry-related 4-py rings face each other at an interplanar distance of about 3.4 Å.



a



b

Figure 2. ORTEP drawing (thermal ellipsoids at 30% probability) and labeling scheme for **3** (a) and **4** (b).

In all these dinuclear species, the axial 4-py ring nearly bisects the five-membered rings of the equatorial moiety (orientation B, rotated by about 90° with respect to orientation A found in **3** and **3′**). The resulting approximate Co···B···Co′···B′ rectangle in **4** has Co···B and B···Co′ sides of 3.22 and 6.61 Å, respectively, and a B···Co′···B′ angle of 87.3°. A comparison with the corresponding figures in **4′**[10b] and **4′′**[11] show that the side substituents in **4** lead to a more regular rectangle. The coordination bond lengths and angles do not differ appreciably from those found in **4′** and **4′′**; the axial Co–C and Co–N distances are given in Table 1. A comparison of these data shows that the axial Co–N distances are not appreciably affected by the dioximato side substituents in either the mononuclear or in the series of dinuclear compounds. However, it seems that the Co–N_{ax} distance (and possibly that of Co–C) is slightly lengthened in the dinuclear species.

Characterization of the Supramolecular Species in Solution

The ESI mass spectra of the supramolecular species **3**, **4**, **5**, and **6** in CH_2Cl_2/HCOOH (1%) show that the base peaks

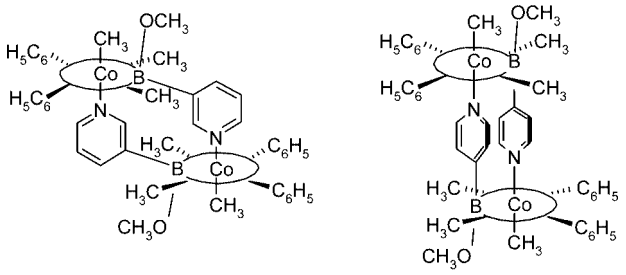
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for the molecular ions [M + H^+] correspond to protonated dimeric species held together by two pyridylboronic acids, with the residual B(OH) groups esterified by methanol.

The ^{1}H NMR spectra of **3** and **4** in $CDCl_3$ show similar features except for the signals of pyridine. Only one set of signals is evident, as a consequence of the presence of a symmetry center. The axial methyl, the B(OCH_3), and the residual oximic protons give rise to three singlets, whereas the phenyl protons appear as a multiplet. The two singlets for the equatorial methyls confirm the insertion of a single boryl bridge. The three py protons of **3** give rise to three signals in the range δ = 7.25–8.30 ppm. The signal of the *ortho* NC*H*C(CH)B proton is notably shifted to lower field (δ = 9.6 ppm) with respect to the corresponding proton of free 3-pyridylboronic acid (δ = 8.6 ppm in CD_3OD), due to the deshielding effect of the magnetic anisotropy of the parallel pyridyl ring. The pyridyl protons of **4** appear as four doublets in the range δ = 6.72–7.09 ppm and are all nonequivalent as a consequence of the assembly and of the hindered rotation. The remarkable upfield shift of these protons with respect to the corresponding proton of the free 4-pyridylboronic acid (δ = 8.05 and 8.47 ppm in D_2O)[10b] is due to the shielding effect of the two facing pyridyl rings.

These results are entirely consistent with the solid-state structure, thereby suggesting that **3** and **4** are stable in solution in aprotic solvents − they neither dissociate nor are in equilibrium with species having different nuclearity.

The ^{1}H NMR spectra of **5** and **6** in $CDCl_3$ are very similar to those of **3** and **4**, respectively. The main differences are the presence of only one singlet for the equatorial methyls in both **5** and **6** and the internal equivalence of the *ortho* and the *meta* protons of pyridine in **6**. Both these results are consistent with the presence of a mirror plane bisecting the OHO and the OBO bridges. In the *cis* isomer **2**, the insertion of the boronic acid may occur either in the OHO bridge near to the methyl groups or in that near to the phenyl groups. The close proximity of the resonances of the equatorial methyl groups of **5** and **6** to the resonances of CH_3C=NOB in **3** and **4**, respectively, and the presence of a cross-peak between B(OCH_3) and the equatorial CH_3 group in the ROESY spectrum, strongly support the former hypothesis. The proposed structures for **5** and **6**, very similar to those of **3** and **4**, are depicted in Scheme 6.



5 **6**

Scheme 6.

Electrochemistry

The electrochemical behavior of both the mononuclear complexes **1** and **2** and the dinuclear species **3**–**6** was investigated by cyclic voltammetry in CH_2Cl_2 containing 0.05 M tetra-*n*-butylammonium perchlorate (TBAP). This solvent proved to be suitably solubilizing for all the compounds and its conductivity is still sufficiently high to allow routine voltammetric studies.[14] This solvent-supporting electrolyte system allows a potential scan from +1.4 to –1.9 V vs. SCE.

The behavior of the *trans*- and *cis*-[CH_3Co(mpgH)$_2$py] isomers is very similar, so the following discussion refers equally to both derivatives. The CV of the mononuclear species **1** and **2** show three signals (Figure 3 and Table 2). The reduction peak **b** (E_{pc} = –1.625 V in both cases, at 100 mV s^{-1} scan rate) shifts toward more negative values at increasing scan rate and has no anodic counterpart up to 1 V s^{-1}. A further peak couple, **a** and **a′**, is visible at more positive potentials and is independent of the reduction peak **b**. In fact, it also develops if the CV is carried out in a range not including peak **b**, such as 0 V → +1.4 V → 0 V. The linear dependence of the height of the peaks **a** and **a′** on the square root of the scan rate, the ratio between the cathodic and the anodic peak current, i_{pa}/i_{pc} (equal to 1), the constancy of (E_{pc} + E_{pa})/2, and the difference E_{pa} – E_{pc} (equal to 110 mV at 100 mV s^{-1}) all show that this peak couple corresponds to a quasi-reversible monoelectronic process.[15] This is assigned to a Co^{III}/Co^{IV} electron transfer in

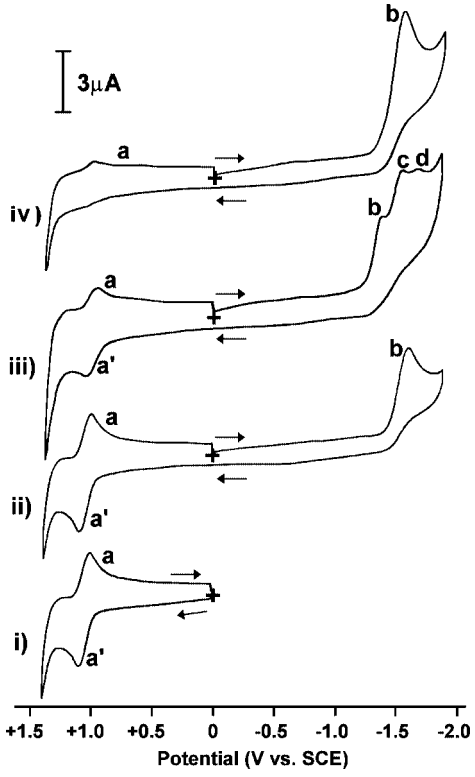


Figure 3. Cyclic voltammetry at a scan rate of 100 mV s^{-1} in CH_2Cl_2 + TBAP (0.05 M) at T = 0.0 °C. i) and ii) complex **2**; iii) complex **6**; iv) complex **5**. Scans are made in the range 0 to 1.4 to 0 V for i) and 0 to –1.9 to +1.4 V to 0 V for ii), iii) and iv).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which the oxidized species is stable in the CV time range.[16] On the basis of a comparison of the peak currents, the reduction peak **b** is attributed to a dielectronic Co^{III}/Co^{I} reduction, followed by a relatively fast chemical reaction, which gives no more electroactive species (EC mechanism).[15]

Table 2. Summary of E_p potentials at a scan rate of 100 mV s^{-1} in CH_2Cl_2 (TBAP 0.05 M) at 0.0 °C.

Complex	E_{pa}(**a**)	E_{pc}(**a**)	E_{pc}(**b**)	E_{pc}(**c**)	E_{pc}(**d**)
1	+1.08	+0.97	–1.625	–	–
3	+1.05[a]	+0.95	–1.57	–	–
4	–	–	–1.41	–1.60	–
2	+1.09	+0.98	–1.625	–	–
5	+1.05[a]	+0.96	–1.575	–	–
6	+1.04	+0.93	–1.40	–1.56	–1.67

[a] Very low.

The cyclic voltammograms of the dinuclear species assembled with 3-pyridylboronic acid (**3** and **5**) show one cathodic signal **b** (E_{pc} = –1.57 V in both cases at 100 mV s^{-1}) without any anodic counterpart and a couple of low peaks **a** and **a′**, independent of the cathodic peak, at more positive potentials (Table 2 and Figure 3). The cyclic voltammograms of the dinuclear species assembled with 4-pyridylboronic acid (**4** and **6**) both show a couple of cathodic peaks that lack the anodic counterpart at 100 mV s^{-1}: E_{pc} (**b**) = –1.41 and E_{pc} (**c**) = –1.60 V for **4** and E_{pc} (**b**) = –1.40 and E_{pc} (**c**) = –1.56 V for **6**. A very low and scarcely reproducible reduction peak **d** is present in the complex **6** at more negative value, but it was not investigated further. In addition, both species exhibit a further couple of peaks at more positive potential for both of them, but for complex **4** the signals are too low to determine the peak potential.

Therefore, in the dinuclear species, the chemically equivalent and noninteracting metal centers undergo the redox processes simultaneously at the same potential. It is noteworthy that, by comparison of the peak heights and the CV shape,[17] it is possible to attribute two consecutive two-electron reduction steps for **4** and **6** and a single four-electron reduction step for **3** and **5.** It has previously been reported that the electrochemical reduction of a series of organocobaloximes in aprotic solvents, such as dimethyl sulfoxide, dimethylformamide, and acetonitrile, takes place in two separate steps, but in pyridine or in the presence of strong donor species, a single two-electron step is observed.[18] In the present case, 3- and 4-pyridylboronic acids have very similar donor properties, but the orientation of the pyridyl ring in the dinuclear species is different. Indeed, the 3-pyridyl ring has the orientation A in **3** and **5**, whereas the 4-pyridyl ring has the orientation B in **4** and **6**. The latter orientation results in a lengthening of the Co–N bond (Table 1) and, in consequence, an apparent weakening of the electron-donor power of 4-pyridylboronic acid.

The reduction peak potentials of the monomers **1** and **2** are always more negative than that of the supramolecular species **3**–**6**. This behavior can be attributed to the stronger electron-donor power of pyridine with respect to the pyridylboronic acid due to the electron-withdrawing effect of the boron atom on the pyridyl ring.

Conclusion

The reaction of racemic **1** with either 3- or 4-pyridylboronic acid can produce three structurally different dimeric species (two homodimers AA and CC and one heterodimer AC), but only the heterochiral dimers **3** (or **4**) crystallize from the reaction mixture. As the time-resolved ^{1}H NMR spectra of the reaction mixture do not show convergence toward a unique species in solution, the high enantiospecificity of the assembly has to be attributed to a preferential crystallization rather than to an enantiomeric self-recognition in solution.[19] Examples of preferential crystallization have been reported previously and have been attributed to an interplay of enthalpic, entropic, and crystal-packing factors.[20] Furthermore, both **3** and **4** are stable when dissolved in $CDCl_3/CD_3OD$, showing that the dissociation process in solution is quite slow. The slowness of both the formation and the dissociation process reflects the fact that the covalent O–B–O moiety has to be broken in this process.[21]

X-ray structural results show that the nature of the dioximate side substituents does not affect the geometry of the dimeric arrangements assembled by 4-pyridylboronic acid ("molecular box"). On the contrary, the geometry of the species assembled by 3-pyridylboronic acid varies from the "molecular parallelogram" obtained from the bis(dimethylglyoximates) to the highly squeezed "molecular box" obtained from methylphenylglyoximates.

Cyclic voltammetry studies show that the metal centers in the dimeric species do not interact with each other and undergo a simultaneous redox process. However, depending on the geometry of the systems, the redox process involves a single four-electron Co^{III}/Co^{I} step for **3** and **5** or two consecutive two-electron steps Co^{III}/Co^{II} and Co^{II}/Co^{I} for **4** and **6**.

Experimental Section

General Remarks: ^{1}H NMR spectra were recorded with a Jeol EX-400 and referenced to residual solvent protons. Electrospray mass spectra were recorded in positive mode using an API 1 mass spectrometer (Perkin–Elmer). All reagents and solvents were obtained commercially and were used without further purification, unless otherwise stated.

Electrochemical Measurements: Cyclic voltammetry was performed with an Amel 551 potentiostat, equipped with positive feedback, driven by an Amel 568 function generator. The signals were recorded on an Amel 863 x-y recorder with a potential reproducibility of ±3 mV. A three-electrode system was used. The working electrode was a 2-mm-diameter glassy carbon disk (EG&G), which was polished with 0.3 and 0.05 micron Micropolish (Buehler) and sonicated in CH_2Cl_2 solution before any measurement. The reference was an SCE (saturated NaCl) electrode, separated from the solution by a glass frit filled with a 0.05 M solution of TBAP (Fluka) in CH_2Cl_2. The counter electrode was a Pt wire. The mea-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

surements were performed on 1×10^{-3} M solutions of the complexes in CH_2Cl_2 (Carlo Erba). The commercial solvent was shaken with H_2SO_4, water, and $NaHCO_3$ (5% solution) and then distilled from CaH_2 under argon. Dried TBAP (0.05 M) was used as supporting electrolyte. The temperature was maintained at 0 °C and oxygen was removed by bubbling nitrogen that had first been pre-saturated with the solvent.

Synthesis of the Ligand $mpgH_2$: Hydroxylamine hydrochloride (21 g, 30 mmol) was dissolved in water (30 mL) and neutralized with an equimolar amount of NaOH. A methanolic solution of 1-phenyl-1,2-propanedione 2-oxime (5 g, 30 mmol in 80 mL) was added and the mixture was heated under reflux for 3 h. The precipitate was collected by filtration and washed with water and chloroform to give a white product. Yield: 4.25 g (78%). $C_9H_{10}N_2O_2$ (178.19): calcd. C 60.7, H 5.66, N 15.7; found C 60.3, H 5.77, N 15.7. ESI-MS (60 V, CH_3OH): calcd. for $mpgH_2$ 178.188; found 179.1 (100%). ^{1}H NMR (400 MHz, [D$_6$]DMSO, TMS): δ = 2.02 (s, 3 H, C*H*$_3$), 7.14 (d, $^3J_{H,H}$ = 8.3 Hz, 2 H, *ortho* Ph), 7.20–7.43 (m, 3 H, *meta* and *para* Ph), 11.42 (s, 1 H, CH_3C=NO*H*), 11.46 (s, 1 H, PhC=NO*H*) ppm.

Synthesis of [ClCo(mpgH)$_2$py]: The ligand $mpgH_2$ (1.9 g, 11 mmol) was added to a suspension of $CoCl_2 \cdot 6H_2O$ (1.3 g, 5.5 mmol) in ethanol (60 mL). The suspension was heated and stirred in the presence of air for 40 min. After the addition of py (0.9 mL, 11 mmol) to the resulting solution, the mixture was cooled to room temperature in a stream of air. After 2 h, a yellowish microcrystalline precipitate was collected by filtration. The ^{1}H NMR spectrum showed that the precipitate was a mixture of the *cis* and *trans* isomers in a ratio of about 1:1.2. Yield: 2.07 g (71.3%). $C_{23}H_{23}ClCoN_5O_4$ (527.85): calcd. C 52.3, H, 4.39, N 13.2; found C 52.8 H, 4.46, N 12.8. Small quantities of the isomers could be separated by stratification of *n*-heptane over a $CDCl_3$ solution of the mixture in an NMR tube. After slow diffusion, two different kinds of crystals deposited on the walls of the tube and were separated manually. The dark-brown crystals corresponded to the *trans* isomer, whereas the dark-yellow crystals corresponded to the *cis* isomer. ***trans*-[ClCo(mpgH)$_2$py]:** ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 2.32 (s, 6 H, equatorial C*H*$_3$), 7.28 (m, 2 H, *meta* py), 7.45 (m, 10 H, equatorial phenyls), 7.75 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, *para* py), 8.42 (d, $^3J_{H,H}$ = 5.2 Hz, 2 H, *ortho* py), 18.07 (s, 2 H, O*H*O) ppm. ***cis*-[ClCo(mpgH)$_2$py]:** ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 2.34 (s, 6 H, equatorial C*H*$_3$), 7.26 (m, 2 H, *meta* of py), 7.41 (m, 10 H, equatorial phenyls), 7.75 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, *para* of py), 8.4 (d, $^3J_{H,H}$ = 5.6 Hz, 2 H, *ortho* of py), 18.32 (s, 1 H, O*H*O), 18.52 (s, 1 H, O*H*O) ppm.

Synthesis of [CH$_3$Co(mpgH)$_2$py]: NaOH (1 pellet in 2 mL of water) and a twofold excess of py (0.18 mL, 1.9 mmol) were added to a suspension of [ClCo(mpgH)$_2$py] (mixture of *cis* and *trans* isomers in a ratio of 1:1.2; 0.50 g, 0.95 mmol) in 130 mL of methanol. The resulting solution was deaerated by bubbling nitrogen. $NaBH_4$ (0.054 g, 1.42 mmol), dissolved in the minimum amount of water, and CH_3I (0.15 mL, 1.89 mmol) were then added in sequence. The solution was stirred at room temperature under nitrogen for 30 min and then the solvent was evaporated in vacuo. The orange crystals were collected by filtration. The ^{1}H NMR spectrum showed that the precipitate was a mixture of the *cis* and *trans* isomers, in a ratio of about 1:1.2. The isomers were separated by fractional crystallization from CH_3OH/CH_2Cl_2 (1:1), exploiting the lower solubility of the *trans* isomer. ***trans*-[CH$_3$Co(mpgH)$_2$py] (1):** Yield: 0.188 g (36%). $C_{24}H_{26}CoN_5O_4$ (507.43): calcd. C 56.8, H 5.16, N 13.8; found C 55.7, H 5.06, N 13.6. ESI-MS (60 V, MeOH): *m*/*z* calcd. for *trans*-[CH$_3$Co(mpgH)$_2$py] 507.428; found 508.0 (60%); further peaks: *m*/*z* (%) = 530.0 (68) [M + Na$^+$], 429.0 (96) [M – py], 451.0 (100) [M + Na$^+$ – py]. ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.14 (s, 3 H, axial C*H*$_3$), 2.05 (s, 6 H, equatorial C*H*$_3$), 7.25–7.45 (m, 12 H, *meta* py and equatorial phenyls), 7.79 (t, $^3J_{H,H}$ = 7.6 Hz,

1 H, *para* py), 8.77 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, *ortho* py), 18.20 (s, 2 H, O*H*O) ppm. ***cis*-[$CH_3Co(mpgH)_2py$] (2):** Yield: 0.124 g (27%). $C_{24}H_{26}CoN_5O_4$ (507.43): calcd. C 56.8, H 5.16, N 13.8; found C 56.7, H 5.40, N 14.0. ESI-MS (60 V, MeOH): *m*/*z* calcd. for *cis*-[$CH_3Co(mpgH)_2py$] 507.428; found 508.0 (24%); further peaks: *m*/*z* (%) = 529.9 (28) [M + Na^+] , 429.1 (80) [M – py], 451.0 (100) [M + Na^+ – py]. ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.12 (s, 3 H, axial C*H*$_3$), 2.08 (s, 6 H, equatorial C*H*$_3$), 7.25–7.42 (m, 12 H, *meta* of py and equatorial phenyls), 7.79 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, *para* of py), 8.75 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, *ortho* of py), 18.39 (s, 1 H, O*H*O), 18.56 (s, 1 H, O*H*O) ppm.

Synthesis of 3: A solution of 3-pyridylboronic acid (12 mg, 0.098 mmol in 6 mL of MeOH) was added to a solution of *trans*-[$CH_3Co(mpgH)_2py$] (0.050 g, 0.098 mmol in 1 mL $CHCl_3$) The pH was adjusted to 5.5 with concentrated $HClO_4$ and NaOH. The solution was filtered and set aside in a beaker covered with Parafilm. After some days, small orange crystals of **3**, suitable for X-ray analysis, appeared and were collected by filtration. Yield: 33.2 mg (62%). $C_{50}H_{54}B_2Co_2N_{10}O_{10}$ (1094.5): calcd. C 54.8, H 4.97, N 12.8; found C 55.3, H 5.10, N 12.7. ESI-MS (90 V, CH_2Cl_2/HCOOH 1%): *m*/*z* calcd. for **3** 1094.5; found 1095.4 (100%). ^{1}H NMR (400 MHz, $CDCl_3$, TMS: δ = 1.45 (s, 6 H, axial C*H*$_3$), 1.79 (s, 6 H, C*H*$_3$C=NOH), 2.01 (s, 6 H, C*H*$_3$C=NOB), 3.31 (s, 6 H, OC*H*$_3$), 7.12–7.74 (m, 22 H, *meta* of py and equatorial phenyls), 7.90 (d, $^3J_{H,H}$ = 6.8 Hz, 2 H, *ortho* of py), 8.30 (d, $^3J_{H,H}$ = 5.4 Hz, 2 H, *para* of py), 9.60 (s, 2 H, *ortho* of py), 18.54 (s, 2 H, O*H*O) ppm.

Synthesis of 4: The synthesis was performed as described above using 4-pyridylboronic acid instead of 3-pyridylboronic acid. Yield: 17 mg (32%). $C_{50}H_{54}B_2Co_2N_{10}O_{10}$ (1094.5): calcd. C 54.8, H 4.97, N 12.8; found C 54.3, H 5.03, N 12.3. ESI-MS (90 V, CH_2Cl_2/HCOOH 1%): *m*/*z* calcd. for **4** 1094.5; found 1095.4 (100%). ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.28 (s, 6 H, axial C*H*$_3$), 2.27 (s, 6 H, C*H*$_3$C=NOH), 2.51 (s, 6 H, C*H*$_3$C=NOB), 3.22 (s, 6 H, OC*H*$_3$), 6.72(d, $^3J_{H,H}$ = 5.4 Hz, 2 H, *meta* of py), 6.83(d, $^3J_{H,H}$ = 5.4 Hz, 2 H, *meta* of py), 7.05 (d, $^3J_{H,H}$ = 5.4 Hz, 2 H, *ortho* of py), 7.09 (d, $^3J_{H,H}$ = 5.4 Hz, 2 H, *ortho* of py), 7.45–7.65 (m, 20 H, phenyls), 17.89 (s, 2 H, O*H*O) ppm.

Synthesis of 5: A solution of 3-pyridylboronic acid (12 mg, 0.098 mmol in 6 mL of MeOH) was added to a solution of *cis*-[$CH_3Co(mpgH)_2py$] (0.050 g, 0.098 mmol in 1 mL of $CHCl_3$) and the pH was adjusted to 5.5. The solution was filtered and allowed to stand in a beaker covered with Parafilm for2 d. Then, the solvent was evaporated under atmospheric pressure and the orange solid collected by filtration. Yield: 22.3 mg (41%). $C_{50}H_{54}B_2Co_2N_{10}O_{10}$ (1094.5): calcd. C 54.8, H 4.97, N 12.8; found C 53.0, H 4.50, N 11.8. ESI-MS (90 V, CH_2Cl_2/HCOOH 1%): *m*/*z* calcd. for **5** 1094.5; found 1095.2 (100%). ^{1}H NMR (400 MHz, $CDCl_3$, TMS: δ = 1.49 (s, 6 H, axial C*H*$_3$), 1.99 (s, 12 H, C*H*$_3$C=NOB), 3.44 (s, 6 H, OC*H*$_3$), 7.30–7.50 (m, 22 H, *meta* of py and equatorial phenyls), 8.09 (d, $^3J_{H,H}$ = 7.1 Hz, 2 H, *ortho* of py), 8.46 (d, $^3J_{H,H}$ = 5.5 Hz, 2 H, *para* of py), 9.72 (s, 2 H, *ortho* of py), 18.56 (s, 2 H, O*H*O) ppm.

Synthesis of 6: A solution of 4-pyridylboronic acid (12 mg, 0.098 mmol in 6 mL of MeOH) was added to a solution of *cis*-[$CH_3Co(mpgH)_2py$] (0.050 g, 0.098 mmol in 1 mL of $CHCl_3$) and the pH was adjusted to 5.5. The solution was filtered and allowed to stand in a beaker covered with Parafilm for 2 d. Then, two drops of water were added and the solvent evaporated under atmospheric pressure. The orange solid was collected by filtration. Yield: 6.3 mg (12%). $C_{50}H_{54}B_2Co_2N_{10}O_{10}$ (1094.5): calcd. C 54.8, H 4.97, N 12.8; found C 53.8, H 5.41, N 11.7. ESI-MS (90 V, CH_2Cl_2/HCOOH 1%): *m*/*z* calcd. for **6** 1094.5; found 1095.4 (80%). ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.28 (s, 6 H, axial C*H*$_3$), 2.53 (s, 12 H, C*H*$_3$C=NOB), 3.37 (s, 6 H, OC*H*$_3$), 6.84 (d, $^3J_{H,H}$ = 6.3 Hz, 4 H, *meta* of py), 7.16 (d, $^3J_{H,H}$ = 6.3 Hz, 4 H, *ortho* of py), 7.45–7.55 (m, 20 H, equatorial phenyls), 17.94 (s, 2 H, O*H*O) ppm.

Structure Determinations: Single crystals suitable for X-ray data collection were obtained as reported above. Data for the crystals of compounds **1** and **4**, being of small size and, in the case of **4**, also of poor quality, were collected at 200 K and 293 K, respectively, using a rotating copper-anode generator working at 45 kV and 95 mA, equipped with an Enraf Nonius KCCD diffractometer; 88 images for **1** and 176 for **4** were collected (crystal-to-detector distance of 42 mm) with 6° oscillation and 20 s/° exposure time for CCD image. The data were processed, scaled, and merged with the programs DENZO and SCALE-PACK.[22] Data for the crystals of compounds **2** and **3** were collected at 293 K and 150 K, respectively, with a Nonius DIP 1030 H System, using graphite-monochromated Mo-K_α radiation. For both compounds a total of 30 frames were collected using the Xpress program[23] over half of reciprocal space, with a rotation of 6° about the axis. A Mac Science Image Plate (diameter = 300 mm) was used and the crystal-to-plate distance was fixed at 90 mm. The determination of unit-cell parameters, integration of reflection intensities, and data scaling were performed using the programs DENZO and SCALE-PACK. All structures were solved by direct methods,[24] followed by Fourier syntheses and refined by full-matrix least squares (on F^2) cycles.[25] The H atoms were not refined but were included at calculated positions in the final refinements. A suite of programs[26] was also used for the geometrical and final calculations. Crystal and refinement data are given in Table 3. CCDC-264667 to -264670 (**1**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: Time-resolved ^{1}H NMR spectra relative to the formation and decomposition of **3**, ^{1}H NMR spectra of **1**–**6**, and ESI mass spectra of **3**–**6**.

[12] The stereochemical description of the two enantiomers has been achieved by using the configuration index, the priming convention, and the chirality symbols based on the priority sequence (A/C stereochemical descriptors) [A. von Zelewski, *Stereochemistry of Coordination Compounds*; Wiley, Chichester, **1996**; J. G. Leigh, *Nomenclature of Inorganic Chemistry*, Blackwell, Oxford, **1990**]. For practical purposes, the C_2 axis of the molecule has been chosen as the reference axis with the view from py (having a lower priority number than CH_3) to the metal atom. The complete stereochemical description of the C enantiomer is therefore OC-6-41′-C and that of the A enantiomer OC-6-41′-A.

Octahedral Hexahydroxo Rhenium Cluster Complexes $[Re_6Q_8(OH)_6]^{4-}$ (Q = S, Se): Synthesis, Structure, and Properties

Spartak S. Yarovoi,[a] Yuri V. Mironov,[a] Dmitry Y. Naumov,[a] Yuri V. Gatilov,[b] Svetlana G. Kozlova,[a,c] Sung-Jin Kim,[d] and Vladimir E. Fedorov*[a]

Keywords: Rhenium / Hexahydroxo complexes / Cluster compounds / Electronic structure / Luminescence

Two novel rhenium cluster compounds, $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ (**1**) and $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ (**2**), containing octahedral cluster chalcogenide anionic complexes $[Re_6Q_8(OH)_6]^{4-}$ with terminal hydroxo ligands have been synthesized by the reaction of $Re_6Q_8Br_2$ (Q = S, Se) with molten KOH. Two chalcohalide compounds, one known ($Cs_4[Re_6S_8Br_6]\cdot 2H_2O$, **3**) and another new ($Cs_3[Re_6Se_8Cl_6]\cdot 2H_2O$, **4**), were prepared by reactions of **1** and **2** with CsX and HX (X = Br, Cl) in an aqueous solution. Compounds **1**, **2**, and **4** have been characterized by the single-crystal X-ray diffraction method. Compounds **1** and **2** are crystallized in triclinic space group $P\bar{1}$ with one formula unit in the cell of dimensions a = 8.4936(8) Å, b = 8.9101(11) Å, c = 10.5940(13) Å, α = 77.935(11)°, β = 75.933(9)°, γ = 71.244(10)°, V = 728.9(1) Å^3 (compound **1**) and a = 8.613(1) Å, b = 8.996(1) Å, c = 10.057(1) Å, α = 78.587(2)°, β = 77.811(2)°, γ = 71.728(2)°, V = 715.9(2) Å^3 (compound **2**). Compound **4** crystallizes in the monoclinic space group $P2_1/n$ with two formula units in the cell of dimensions a = 9.819(3) Å, b = 12.925(4) Å, c = 11.756(4) Å, β = 113.38(3)°, V = 1369.6(8) Å^3. Compounds **1** and **2** display luminescent properties.

Introduction

The chemistry of octahedral rhenium cluster complexes with cluster core $\{Re_6Q_8\}^{2+}$ (Q = S, Se, Te) is in a stage of rapid development.[1] Some solids like $Re_6Q_8X_2$ (Q = S, Se; X = Cl, Br)[2] or Re_6Te_{15}[3] containing similar cluster cores prepared by high temperature solid-state reactions are characterized by extended intercluster bonding. A large number of articles have appeared within the last few years that have reported the preparation of molecular cluster complexes of the $Re_6Q_8L_6$ type (L = Cl, Br, I, or different organic ligands).[4] One way of preparing molecular cluster complexes is the excision reaction through interaction of polymeric solids such as $Re_6Q_8X_2$ or Re_6Te_{15} with molten salts. A similar strategy for the preparation of chalcocyanide complexes $[Re_6Q_8(CN)_6]^{4-}$ by reactions of Re_6Te_{15} or $Re_6Q_8X_2$ with molten KCN have been used earlier.[5] Very recently we suggested molten KOH as a new reaction medium: the reaction of $Re_6Se_8Br_2$ with molten KOH at 280 °C results in formation of the unusual cluster core $\{Re_6Se_4O_4\}^{2+}$, found in $Cs_{11}(H_3O)[Re_6Se_4O_4Cl_6]_3\cdot 4H_2O$.[6] Further investigation of reactions of $Re_6Q_8X_2$ with molten KOH results in the preparation of three new cluster compounds: $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ (**1**), $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ (**2**), and $Cs_3[Re_6Se_8Cl_6]\cdot 2H_2O$ (**4**), and one known: $Cs_4[Re_6S_8Br_6]\cdot 2H_2O$ (**3**). All new compounds were characterized by X-ray single-crystal analysis.

Results

Syntheses

Compounds **1** and **2** containing hexahydroxo complexes $[Re_6Q_8(OH)_6]^{4-}$ (Q = S, Se) were obtained from $Re_6S_8Br_2$ (for **1**) and $Re_6Se_8Br_2$ (for **2**) in molten KOH at 280 °C and 200 °C respectively in open vessels following recrystallization of the compounds from water. The only rhenium octahedral cluster complex with OH^- groups as terminal ligands, $[Re_6S_8(OH)_2(H_2O)_4]\cdot 12H_2O$, was described earlier.[7] Compounds **3** and **4** were obtained from aqueous solutions of compounds **1** and **2** by adding CsX and HX and further crystallization. Crystals of diamagnetic compound **3** are orange. Paramagnetic compound **4** crystallizes from the solution as black crystals.

Structures

The structures of the cluster anions $[Re_6Q_8(OH)_6]^{4-}$, where Q = S (**1**) or Se (**2**) (Figure 1), are similar to the well-known octahedral complexes of $[Re_6Q_8L_6]^{4-}$ type with L = Cl^-, Br^-, I^-, CN^-. There is a nearly regular Re_6 octahedron residing inside a Q_8 (S, Se) cube with the distances Re–Re in the range 2.5906(9)–2.5846(8) Å (**1**) and 2.6085(6)–2.6155(6) Å (**2**) and Re–(μ_3-Q) in the range 2.407(4)–2.420(3) Å (**1**) and 2.527(1)–2.545(1) Å (**2**). Six terminal OH^- ligands are coordinated to Re atoms with bond lengths Re–O 2.07(1)–2.09(1) Å (**1**) and 2.081(6)–2.088(6) Å (**2**). Whereas the Re–Re and Re–(μ_3-Q) bond lengths increase in the order $Re_6S_8 < Re_6Se_8$, the Re–O bond lengths do not appear to vary.

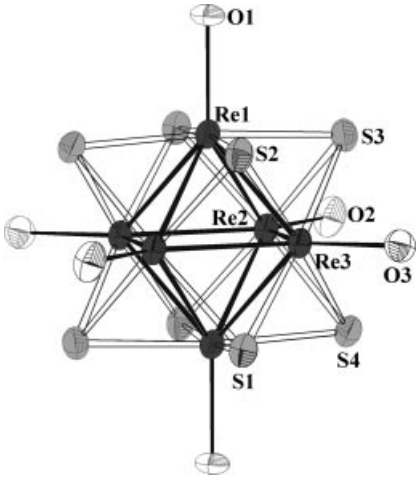

Figure 1. View of the cluster anion $[Re_6(\mu_3\text{-}S)_8(OH)_6]^{4-}$ in **1**. Displacement ellipsoids are drawn at the 50% probability level.

Compound **4** was studied by single-crystal X-ray analysis; the structure of compound **3** was described earlier.[8] The structure of the oxidized cluster anion $[Re_6Se_8Cl_6]^{3-}$ (Figure 2) is also similar to the well-known octahedral complexes $[Re_6Q_8L_6]^{4-}$ where L is a typical acidoligand (Cl^-, Br^-, I^-, CN^-). In the cluster core $\{Re_6Se_8\}$ there is a system of Re–Re and Re–(μ_3-Se) bonds, with lengths in the range 2.606(1)–2.615(1) Å and 2.497(3)–2.525(3) Å, respectively. Six terminal Cl^- ligands are coordinated to Re atoms with bond lengths of 2.414(7)–2.427(6) Å.

To confirm the presence of OH^- groups in the compounds, a solid-state NMR investigation has been carried out at 180 K for $K_4[Re_6Q_8(OH)_6]\cdot 8H_2O$. The wide-line ^1H NMR spectrum was recorded by sweeping the frequency in the neighborhood of 22.8 MHz using a home-made NMR spectrometer with signal accumulation. The experimental NMR spectrum is simulated reasonably by two spectral lines (Figure 3). One line is a classic Pake's line with the parameters: $a = 23.0 \pm 0.5$ kHz and $\beta_1 = 7.4 \pm 0.1$ kHz; these parameters are typical characteristics for H_2O without self-diffusion.[9] The other line is a single one, which can be attributed to H atoms of OH^- groups. This line is simulated

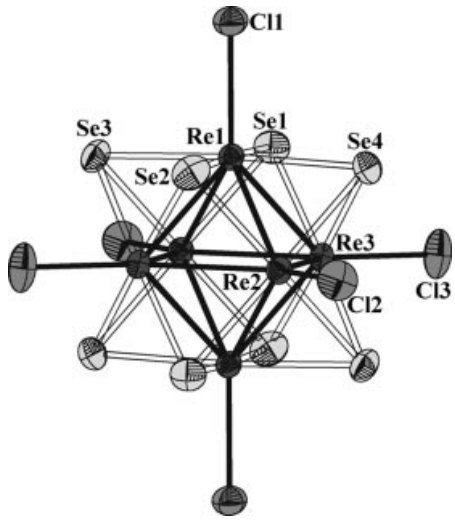

Figure 2. View of the cluster anion $[Re_6(\mu_3\text{-}Se)_8Cl_6]^{3-}$ in **4**. Displacement ellipsoids are drawn at the 50% probability level.

by the Gaussian function with $\beta_2 = 7.5 \pm 0.1$ kHz.[10] The ratio of the integral intensities of the two lines (I_2/I_1) is $R = 0.36 \pm 0.02$, which is very close to the composition of $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$. Analogous results were obtained for $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$: $a = 24.5 \pm 0.5$ kHz and $\beta_1 = 9.3 \pm 0.1$ kHz; $\beta_2 = 8.4 \pm 0.1$ kHz and $R = 0.30 \pm 0.02$.

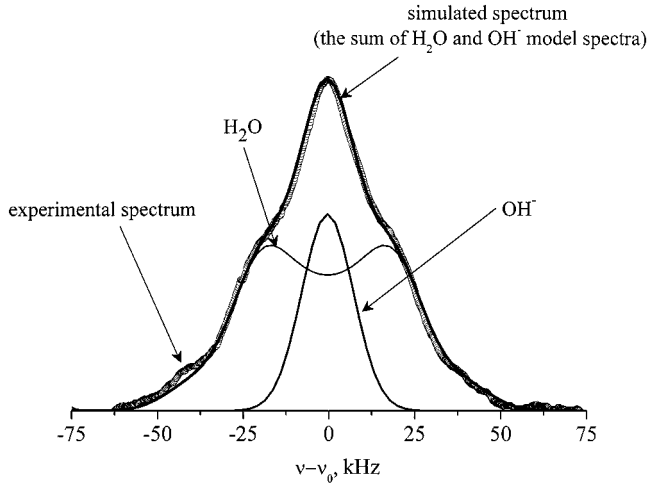

Figure 3. Experimental ^1H NMR absorption at 180 K for $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and the calculated spectra for H_2O and OH^- and their sum. For $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ the figure is analogous.

The most interesting feature of compound **4** is the oxidized state of the cluster core $\{Re_6Se_8\}^{3+}$, where the number of cluster valence electrons is equal to 23. It is known that diamagnetic complexes $[Re_6Q_8L_6]^{4-}$ containing 24 valence electrons in the Re_6 cluster can be transformed into 23-electron paramagnetic $[Re_6Q_8L_6]^{3-}$ forms. The stability of a sulfur-containing complex in comparable experimental conditions can be explained by its higher electrochemical potential in the redox process. For example, it is known that for chalcocyanide complexes $[Re_6Q_8(CN)_6]^{4-}$ the electrochemi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cal potentials of a similar one-electron oxidation reaction are in decreasing order as S > Se > Te; thus for aqueous solutions $E_{1/2}$ are equal to 1.07, 0.82, and 0.53 V respectively for sulfur-, selenium-, and tellurium-containing complexes.[11] Thus, a selenium-containing cluster anion can be oxidized in aqueous solutions rather easily.

The formation of the oxidized anion $[Re_6Se_8Cl_6]^{3-}$ was confirmed by both X-ray analysis (by determination of number of cations in the structure) and magnetic measurements, which showed paramagnetic behavior with one unpaired electron per cluster (see Supporting Information). Simple and high-yield synthesis of this compound opens a path for preparing other compounds containing an oxidized paramagnetic cluster complex. This is rather useful, because oxidized clusters are the most proper starting compounds for the preparation of Re_6 complexes with organic ligands in comparison with rather inert 24-electron complexes.

As seen from our experiments, the hexahydroxo complexes $[Re_6Q_8(OH)_6]^{4-}$ are good precursors for different reactions. They can be transformed into neutral aqua-hydroxo complexes of the type $[Re_6Q_8(OH)_2(H_2O)_4]\cdot nH_2O$. Reactions with halide ions give chalcohalide complexes $[Re_6Q_8L_6]$ where L = Cl, Br, I; in principle, a similar approach for synthesis of chalcohalide complexes may be applied for different variations of μ_3-S or μ_3-Se in the cluster core with terminal Cl, Br, or I ligands. Here we have synthesized only the combinations of S/Br and Se/Cl as the most evident samples in the structure analysis. Beside the substitution of terminal OH^- groups in $[Re_6Q_8(OH)_6]^{4-}$ it is possible to substitute inner μ_3-Q ligands in the cluster core. The first example of a similar reaction is preparation of the compound $Cs_{11}(H_3O)[Re_6Se_4O_4Cl_6]_3\cdot 4H_2O$, containing the cluster core $\{Re_6Se_4O_4\}$.[6] In contrast to easy substitution of terminal OH groups, which is performed in solution, the substitution of inner μ_3-Q ligands in the cluster core requires higher temperatures: for example, substitution of selenium with oxygen was carried out in molten KOH at 280 °C. Finally, selenium-containing complexes can be converted easily in solution in oxidized form.

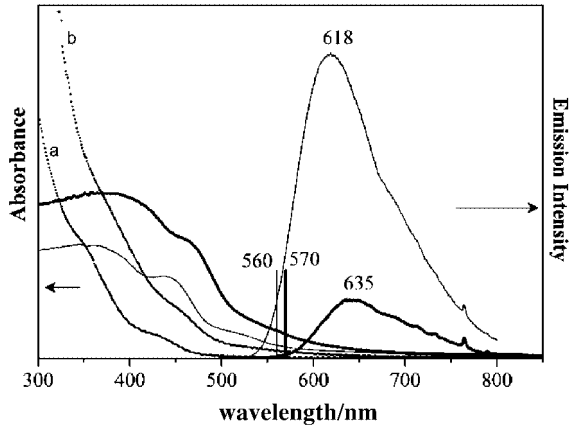

Figure 4. Electronic absorption spectra (at the left) of solids $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ (thin line), $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ (bold line), and their aqueous solutions (dots a and b), and emission luminescent spectra (on the right) of solids $K_4[Re_6S_8(OH)_6]$ (thin line) and $K_4[Re_6Se_8(OH)_6]$ (bold line). Spectral intensities are normalized. Vertical lines show the forbidden transitions.

Luminescence Properties

Luminescence properties of solid samples of **1** and **2** were recorded at room temperature in wavelength range from 500 to 700 nm. Upon excitation at 440 nm, solid samples of **1** and **2** display photoluminescence with λ_{max} at 618 and 635 nm, respectively (Figure 4). The luminescence spectra of aqueous solutions for both compounds are very similar.[12]

Electronic Structure

The optimized calculated values of the geometric parameters of the $[Re_6Q_8L_6]^{n-}$ complexes are in good qualitative agreement with X-ray experimental data. The highest occupied molecular orbitals (HOMO) of diamagnetic $[Re_6S_8(OH)_6]^{4-}$ and $[Re_6Se_8(OH)_6]^{4-}$ complexes are very much alike (Figure 5). The electronic structure of the HOMO ($21e_g$) in the $[Re_6S_8(OH)_6]^{4-}$ cluster anion in general terms corresponds to the quantum calculations of the electronic structure of related complexes, $[Re_6Q_8L_6]^{4-}$ with Q = S, Se and L = Cl, Br, I, CN.[13] The highest occupied orbitals, $18t_{2u}$ and $24e_g$, in the $[Re_6Se_8(OH)_6]^{4-}$ cluster anion have an energy separation of 0.0015 eV. The use of the SAOP GGA functional[14] revealed that the energy separation is 0.019 eV. In this case it is difficult to predict which one of these orbitals is HOMO in reality. It is interesting to note that this is the first example when the HOMO of $Re_6Q_8L_6$ complexes has a t_{2u} symmetry. The LUMO of both clusters have the symmetry eg [22eg (S) and 25eg (Se)]. The similar result for HOMO may be an artifact, but it challenges further wide theoretical and experimental investigations. In particular, it is well known that luminescent properties of $[Re_6Q_8L_6]^{4-}$ complexes are determined by the frontier orbital symmetry.[13e] For these complexes the HOMO (eg)–LUMO (a_{1g} or t_{1g}) transitions are characterized as forbidden electronic dipole transitions. If the HOMO has t_{2u} symmetry, the HOMO–LUMO transition is allowed and decreasing luminescent excitement may be expected. As can be seen from the luminescent properties of **1** and **2** (Figure 4), this prediction takes place here. Notice that the related complexes $[Re_6Se_8(CN)_6]^{4-}$ showed much stronger emissions than $[Re_6S_8(CN)_6]^{4-}$.[15]

The calculated HOMO–LUMO energy gaps are 2.20 and 2.17 eV, the binding energies are –158.0 and –152.3 eV, and ionization potentials (IP) are –6.1 and –5.9 eV for $[Re_6S_8(OH)_6]^{4-}$ and $[Re_6Se_8(OH)_6]^{4-}$ complexes respectively. (IP = –4.5 eV for the $[Re_6Se_8Cl_6]^{4-}$ complex.) The charge distribution of calculated octahedral clusters is presented in Table 1.

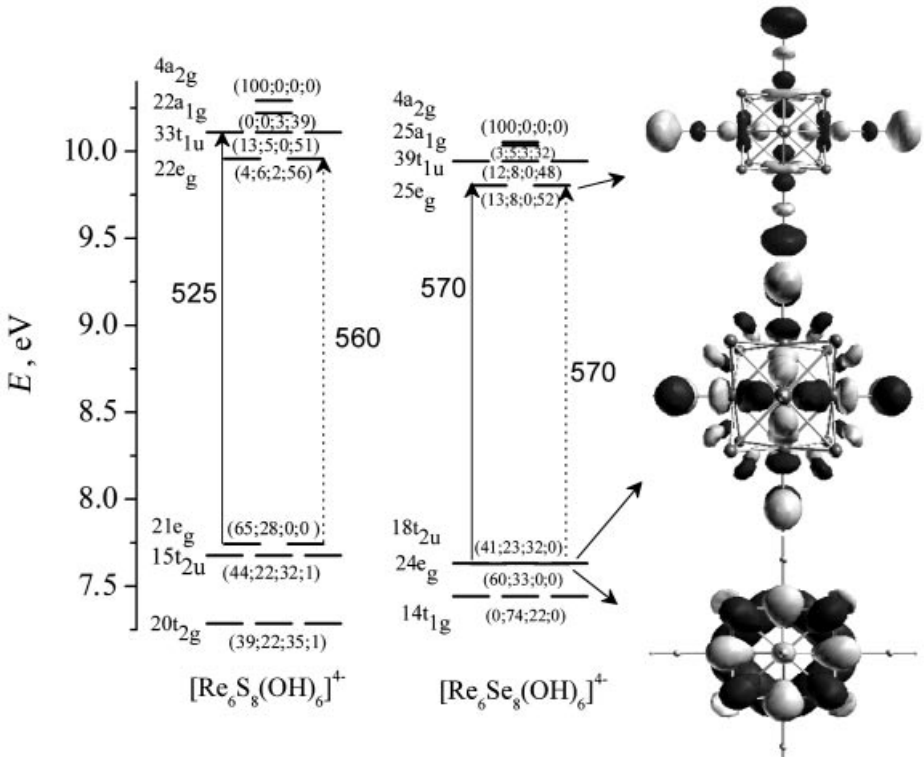

Figure 5. The energy level diagram and schematic figures of MO calculated at the DFT level of theory for $[Re_6S_8(OH)_6]^{4-}$ and $[Re_6Se_8(OH)_6]^{4-}$ complexes. The numbers and symmetry types of the calculated MOs are indicated. Numbers in brackets indicate the percentage of the valent orbitals: 5d Re; 3p S; 4p Se; 2p O; and 1s H, respectively. Arrows show the electronic forbidden (dotted lines) and allowed (solid lines) transitions.

Table 1. The charge distribution in the $[Re_6Q_8L_6]^{4-}$ (Q = S, Se; L = OH, Cl) complexes.

Complex	Re	Q	O; (Cl)	H
$[Re_6S_8(OH)_6]^{4-}$	0.118	–0.283	–0.447	0.039
$[Re_6Se_8(OH)_6]^{4-}$	0.099	–0.276	–0.439	0.041
$[Re_6Se_8Cl_6]^{3-}$	0.069	–0.115	–0.416	–
$[Re_6Se_8Cl_6]^{4-}$	0.054	–0.179	–0.481	–

Experimental Section

$Re_6S_8Br_2$ and $Re_6Se_8Br_2$ were prepared as described.[2] All other reagents were commercially available products of reagent grade quality and were used as purchased. All experiments were performed in an open vessel in air.

$K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ (1) and $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ (2): Compounds **1** and **2** were obtained by heating $Re_6Q_8Br_2$ (Q = S, Se) (1 g) and KOH (1.5 g) at 280 °C (**1**) and 200 °C (**2**) in carbon glass vessels for 30 min in air. After cooling, the resulting melt was washed with *i*PrOH (3 × 20 mL portions), dissolved in water (30 mL), filtered, evaporated to 7 mL by heating, and cooled to room temperature. After 12 h red crystals were filtered off and air-dried. Yields: $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ (0.78 g, 66%), $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ (0.9 g, 79%). Electron microprobe analysis (EMA): $K_{4.0}Re_6S_{8.0}$ (**1**), $K_{4.1}Re_6Se_{7.98}$ (**2**).

$Cs_4[Re_6S_8Br_6]\cdot 2H_2O$ (3) and $Cs_3[Re_6Se_8Cl_6]\cdot 2H_2O$ (4): Compounds **3** and **4** were obtained by heating $Re_6Q_8Br_2$ (Q = S, Se) (1 g) and KOH (1.5 g) at 280 °C (**3**) and 200 °C (**4**) in carbon glass vessels for 30 min in air. After cooling, the resulting melt was washed with *i*PrOH (3 × 20 mL portions), dissolved water (50 mL), and filtered. CsBr (1 g, for **3**) or CsCl (1 g, for **4**), and 10 mL of concentrated HBr (for **3**) or HCl (for **4**) were added to the solutions and boiled for 10 min. After this the solutions were filtered and evaporated to 20 mL and cooled to room temperature. After 12 h the orange crystals of **3** or black crystals of **4** were filtered off and air-dried. Yields: $Cs_4[Re_6S_8Br_6]\cdot 2H_2O$ (1.1 g, 70%); $Cs_3[Re_6Se_8Cl_6]\cdot 2H_2O$ (0.91 g, 58%). EMA: $Cs_{4.0}Re_6S_{7.98}Br_{6.1}$ (**3**), $Cs_{3.1}Re_6Se_{7.9}Cl_{6.1}$ (**4**).

X-ray Crystallography: Single-crystal X-ray diffraction data were collected on compounds **1**, **2**, and **4** with the use of graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 273 K (**1** and **4**) and 170 K (**2**) with Enraf Nonius CAD4 (**1**), Bruker Smart CCD with the operating program SMART (**2**) and Siemens P4 (**4**) diffractometers. All structures were solved by direct methods by means of the SHELX-97 program set and were refined by full-matrix least-squares techniques.[16] An empirical absorption correction was applied by measuring three azimuthal scan curves for compound **1**. Face indexed absorption correction was performed numerically with the use of XPREP for compounds **2** and **4**. The program SADABS (**4**) was then employed to make incident beam and decay corrections.

$K_4Re_6S_8(OH)_6\cdot 8H_2O$ (1): M = 1776.26, crystal size 0.25 × 0.20 × 0.15 mm, triclinic space group $P\bar{1}$, a = 8.4936(8) Å, b = 8.9101(11) Å, c = 10.5940(13) Å, α = 77.935(11)°, β = 75.933(9)°, γ = 71.244(10)°, V = 728.9(1) Å^3, Z = 1, $\rho_{calcd.}$ = 4.120 g cm^{-3}, μ = 26.011 mm^{-1}, $2 < \theta < 24.98°$, T = 293(2) K. Reflections: 2746 collected, 2557 unique (R_{int} = 0.0186), 2105 observed [$I > 2\sigma(I)$]; 158 parameters refined with R = 0.0439 [$I > 2\sigma(I)$], wR_2 = 0.1218 (all data), Gof = 1.032, residual electron density: +3.983, –2.509 e Å^{-3}.

$K_4Re_6Se_8(OH)_6\cdot 8H_2O$ (2): (M = 2151.46), crystal size 0.12 × 0.06 × 0.02 mm, triclinic space group $P\bar{1}$, a = 8.613(1) Å, b =

8.996(1) Å, c = 10.057(1) Å, α = 78.587(2)°, β = 77.811(2)°, γ = 71.728(2)°, V = 715.9(2) Å^3, Z = 1, $\rho_{calcd.}$ = 4.990 g cm^{-3}, μ = 36.058 mm^{-1}, 2.09 < θ < 28.20°, T = 170(2) K. Reflections: 4461 collected, 3174 unique (R_{int} = 0.0186), 2461 observed [$I > 2\sigma(I)$]; 146 parameters refined with R = 0.0329 [$I > 2\sigma(I)$], wR_2 = 0.0941 (all data), Gof = 0.992, residual electron density: + 2.783, –2.382 e Å^{-3}.

$Cs_3[Re_6Se_8Cl_6]\cdot 2H_2O$ (4): (M = 2396.34), crystal size 0.24 × 0.19 × 0.18 mm, monoclinic space group $P2_1/n$, a = 9.819(3) Å, b = 12.925(4) Å, c = 11.756(4) Å, β = 113.38(3)°, V = 1369.6(8) Å^3, Z = 2, $\rho_{calcd.}$ = 5.811 g cm^{-3}, μ = 41.554 mm^{-1}, 2.3 < θ < 29.99°, T = 293(2) K. Reflections: 4202 collected, 3993 unique (R_{int} = 0.0445), 2861 observed [$I > 2\sigma(I)$]; 116 parameters refined with R = 0.0782 [$I > 2\sigma(I)$], wR_2 = 0.2203 (all data), Gof = 1.027, residual electron density: + 5.211, –9.385 e Å^{-3}.

Computational Details: Density functional calculations (DFT) were carried out on $[Re_6Q_8(OH)_6]^{4-}$ models using the ADF2002 code.[14] The local-exchange VWN correlation potential was used for the local density approximation (LDA),[17] and Becke's nonlocal corrections to the exchange energy[18] and Perdew's nonlocal corrections to the correlation energy were added.[19] The zeroth-order relativistic approximation (ZORA) method was used to account for the scalar relativistic effects.[20] The STO basic set without core potentials was used for all atoms (ZORA/TZ2P). The octahedral O_h symmetry was imposed on the full geometry optimization of the ground electronic states for $[Re_6Q_8(OH)_6]^{4-}$ models, a prototype of the analyzed clusters. Calculations of the electronic-binding energy have been performed for the reactions 6 Re + 8 Q + 6 O + 6 H + 4 e^- → $[Re_6Q_8(OH)_6]^{4-}$. The ionization potentials were computed as the energy differences between the $[Re_6Q_8L_6]^{3-}$ and $[Re_6Q_8L_6]^{4-}$, IP = $\Delta E_3 - \Delta E_4$. The atomic net charges for several $[Re_6Q_8(OH)_6]^{n-}$ complexes have been obtained using the Hirshfeld analysis.[21]

Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository CSD-number filenames 415278 (for **1**), 415279 (for **2**), and 415280 (for **4**).

Acknowledgments

Synthesis, Crystal Structures and Photophysical Properties of Novel Tetranuclear Cadmium(II) Schiff-Base Complexes

Wing-Kit Lo,[a] Wai-Kwok Wong,*[a,b] Wai-Yeung Wong,[a,b] and Jianping Guo[a]

Keywords: Cadmium / Crystal structures / Phosphorescence / Schiff bases

The synthesis and structural characterisation of some new tetranuclear cadmium(II) Schiff-base complexes were described. Reaction of the hexadentate Schiff-base ligands (H_2L) with an excess of cadmium(II) acetate, $Cd(OAc)_2$, furnished novel tetracadmium complexes of the general formula $[Cd_4(L)_2(OAc)_4]$, which exhibit an interesting three-dimensional cage-like structure of four ligand-supported cadmium atoms. All of the complexes were fully characterised by spectroscopic (FTIR, NMR and FAB MS) methods and their molecular structures were confirmed by single-crystal X-ray analysis. The X-ray crystal structures of these tetranuclear Schiff-base complexes represent the first structurally characterised examples of this kind for the cadmium triad. These new complexes were found to display rich photophysical properties and they all exhibited low-temperature phosphorescence in the frozen state.

Introduction

Beside supramolecular[1] and bioinorganic studies,[2] cadmium complexes also play an important role in luminescence research.[3] Numerous luminescent polynuclear transition metal complexes of d^{10} transition metals such as Zn^{II}, Cd^{II}, Cu^{I}, Ag^{I}, Au^{I}, and so forth, have been reported.[4] The use of Cd^{II} complexes as luminescence materials has an added advantage because the coordination environment of Cd^{II} is different from other d^{10} transition metals. The coordination number of Zn^{II}, Ag^{I}, Au^{I} and Cu^{I} is usually 4–5 and rarely greater than 6. On the other hand, the coordination number of Cd^{II} lies between 6 and 8, which allows the Cd^{II} complexes to exhibit a special structure and the potential for different structure-related properties, as compared to the other d^{10} metal complexes. Harvesting of the triplet state emission in molecular and polymeric materials has become an important topic nowadays, and metal complexes play an important role in this area. Most of the research is focused on the expensive d-metals (Pt, Ir, Au, etc.) [4,5] and the lanthanide metal complexes.[6] Very recently, phosphorescence has been observed in some Hg^{II} systems.[5d,5e,5f] However, there are relatively few reports on the phosphorescence emission of the analogous cadmium complexes. Schiff-base zinc(II) complexes have been shown to be effective emitters;[7] however, reports on the luminescent properties of Schiff-base cadmium(II) complexes are very rare. In fact, the use of Schiff-base cadmium complexes as potential luminescent materials has great research merits in that they can be prepared on a large scale and are more cost-effective.

Bermejo and co-workers reported the preparation of three-dimensional cage-like Schiff-base Zn complexes by using an electrochemical reaction with hexadentate ligands.[8] In this report, a series of tetranuclear Schiff-base cadmium complexes of the general formula $[Cd_4(L)_2(OAc)_4]$ were prepared by the reaction of the hexadentate Schiff-base ligands H_2L with excess $Cd(OAc)_2$. Under the same reaction conditions, $Zn(OAc)_2$ gave only the mononuclear Schiff-base complexes [ZnL].[9] A possible explanation here is that the coordination number of Zn^{II} ranges normally from 4 to 5, and the inner N_2O_2 cavity of the Schiff-base ligand already provides a tetradentate environment, meaning further extension of the structure from the metal centre is less favourable. On the other hand, the coordination number of Cd^{II} is usually 6–8, and the inner N_2O_2 cavity is only 4, which enables an extension of its structure to the neighbouring complex, forming an interesting tetranuclear cage-like structure.

Results and Discussion

Synthesis and Characterisation

It has been reported that the electrochemical reaction of the cadmium anode with *N*,*N*′-bis(3-hydroxysalicylidene)-ethylene-1,2-diamine (H_4L', L′ = tetraanionic ligand), a potentially hexadentate Schiff base, gave polymeric dinuclear cadmium(II) complexes of the general formula $[Cd_2(L')(H_2O)_2]_n$, whose solid-state structure has not been

determined.[8b] However, when the corresponding 3-methoxy derivative *N*,*N*′-bis(3-methoxysalicylidene)ethylene-1,2-diamine H_2L (L = dianionic ligand), also a potentially hexadentate Schiff base, was treated with a threefold excess of cadmium(II) acetate in refluxing absolute ethanol overnight, the resultant clear solution, upon workup, gave yellow, air-stable crystalline tetranuclear Schiff-base cadmium(II) complexes of the general formula $[Cd_4(L)_2(OAc)_4]$ [L = L^1 (**1**), L^2 (**2**), L^3 (**3**)] in around 50% yield (Scheme 1). All attempts to isolate other products from the solution mixture have met with little success so far. Compounds **1**–**3** gave satisfactory elemental analyses and collated spectroscopic data (IR, ^{1}H NMR and FABMS) of these complexes are in good agreement with their formulation. Full details are given in the Exp. Sect. In their FAB (positive mode) mass spectrum, all three compounds exhibit a mass peak corresponding to $[M - OAc]^+$ at *m*/*z* = 1277, 1589 and 1637 for **1**, **2** and **3**, respectively, for ^{79}Br and ^{112}Cd. The complexes are soluble in polar organic solvents such as CH_2Cl_2 and $CHCl_3$. All of them exhibit a broad peak in their ^{1}H NMR spectrum at $\delta \approx 8.4$ for their imino protons (–C*H*=N–). Their solid-state IR spectrum also exhibit strong absorption bands corresponding to $\nu_{C=N}$ and $\nu_{C=O}$ at about 1635 and 1460 cm^{-1}, respectively, which are similar to those reported for the 3-hydroxy analogue.[8b] Conductivity measurements showed that complexes **1**–**3** behave as electrolytes in methanol and non-electrolytes in chloroform. This indicates that these complexes dissociate one or more of their coordinated acetate ligands to form cations in methanol and remain neutral and undissociated in chloroform.

Scheme 1. Synthesis of compounds **1**–**3**.

The molecular structures of **1** and **3** were ascertained by X-ray crystallography and were found to be structurally very similar. Perspective drawings of **1** and **3** are shown in Figures 1 and 2, respectively, and selected bond lengths and bond angles are given in Tables 1 and 2. Structural analysis revealed that all the Cd atoms of such tetranuclear complex are seven-coordinate and are linked together by the hexadentate Schiff-base ligands. The Cd(1) and Cd(2) atoms form a distorted square base with the two phenolic oxygen atoms [O(2) and O(6)] and each of the latter atoms behaves as a μ_3-O ligand coordinating with the other two Cd atoms [Cd(3) and Cd(4)]. The Cd(1) [or Cd(2)] atom is further linked to the Cd(4) [or Cd(3)] atom by a bridging tridentate acetate ligand. Each of the Cd(3) and Cd(4) atoms is further coordinated to a bidentate acetate ligand to give an overall neutral cage-like tetranuclear structure. The distance between each Cd atom falls in the range of 3.555–5.907 Å, which precludes any significant metal–metal interaction. Presumably, aggregation of the four cadmium atoms in the structures of **1** and **3** is triggered by the use of large cadmium atoms that tend to favour high coordination numbers and the multidentate nature of the Schiff-base ligands in our study. The Cd–N bond lengths lie within 2.324(3)–2.356(3) Å for **1** and 2.294(15)–2.354(11) Å for **3**, which are similar to those reported previously.[10] For **1** and **3**, the Cd–O bond lengths of the two complexes span a wide range of 2.248(3)–2.589(3) Å and 2.229(9)–2.552(9) Å, respectively, and this is probably a manifestation of the difference in the nature of the O-donor group in these complexes.

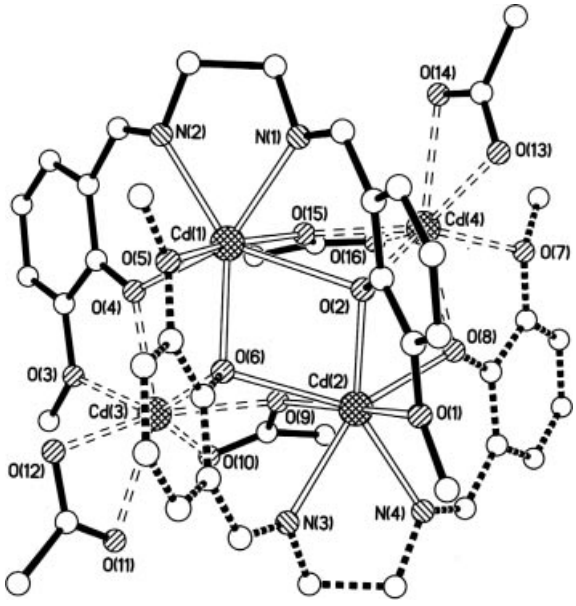

Figure 1. Molecular structure of **1**. Only atoms within the metal coordination core are labelled.

Photophysical Properties

The photophysical properties of **1**–**3** in $CHCl_3$ have been studied and the relevant data are summarised in Table 3. The absorption bands between 240 and 380 nm can be assigned to $\pi \rightarrow \pi^*$ transitions of the Schiff-base ligands. The room-temperature emission of compounds **1**–**3**, with lifetimes (τ) ranging from 0.8 to 1.2 ns and quantum yields (Φ_{em}) of $3.8–5.9 \times 10^{-3}$, can be assigned to the intraligand emission. The absorption, emission and excitation spectra of **1**–**3** are shown in Figures 3, 4 and 5. The room-tempera-

ture excitation spectrum of **3** (monitored at 472 nm) is identical to its 77 K excitation spectrum (monitored at 508 nm), indicating that both the room-temperature and 77 K emission features have the same origin. The absorption, excitation and emission bands are slightly red-shifted upon attachment of a bromide or a *p*-tolyl substituent. Figure 6 depicts the 77 K emission spectra of **1**–**3** in a glassy state. Time-resolved spectra and lifetime measurements showed that both ligand-centred singlet (^{1}LC) and triplet (^{3}LC) emissions coexist at 77 K, with the shoulder being the ^{1}LC fluorescence (τ = 3.4–6.0 ns) and the main peak in the lower energy regime being the ^{3}LC phosphorescence (τ = 10.9–44.2 ms). The ^{3}LC emission was not observed at room temperature even in an oxygen-free solvent system. At room temperature, thermal vibrations, which were minimised at 77 K, can efficiently quench the ^{3}LC transition. Comparing the relative intensity of the ^{1}LC with ^{3}LC emission at 77 K, we observe that the intersystem crossing (ISC) efficiency follows the order **3** > **2** > **1**. On the other hand, the ^{1}LC emission quantum efficiency is in the order **1** > **2** > **3**, which shows that an increase in conjugation or the presence of a heavy bromine substituent can enhance the ISC efficiency, and thus effectively suppress the ^{1}LC emission.

Concluding Remarks

To the best of our knowledge, complexes **1**–**3** constitute the first examples of tetranuclear Schiff-base cadmium complexes of this type and these compounds can display strong triplet-state emission induced by the heavy-atom effect of cadmium. Structural characterisations of **1** and **3** are particularly interesting and we were able to build up polymetallic Schiff-base complexes assembled through the high-coordinate large cadmium atoms and the multidentate ligands. Work is in progress to enhance such triplet emission by structural modifications of the Schiff-base ligands. Comparative analyses of these Schiff-base cadmium complexes with their lower zinc(II) congeners are worthy of serious investigations and are expected to give equally interesting results in the area of luminescent metallated materials.

Experimental Section

General Procedures: Solvents and starting materials were purchased commercially and used without further purification unless otherwise stated. The hexadentate Schiff-base ligands H_2L^1, H_2L^2 and H_2L^3 were prepared according to the literature method.[9] Elemental analyses (C, H, N) were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, China. Electronic absorption spectra in the UV/Vis region were recorded with a Hewlett Packard 8453 UV/Vis spectrophotometer, steady-state visible fluorescence and photoluminescence excitation spectra with a Photon Technology International (PTI) Alphascan spectrofluorimeter, and visible decay spectra with a pico-N_2 laser system (PTI Time Master) with λ_{ex} = 337 nm. Quantum yields of visible emissions were computed according to a literature method[11] using quinine sulfate in 0.1 N H_2SO_4 as the reference standard (Φ = 0.55 in air-equilibrated water).[12] Infrared spectra (KBr pellets) were recorded with a Nicolet Nagna-IR 550 spectrometer and NMR spectra with a JEOL EX270 spectrometer. Chemical shifts of ^{1}H and ^{13}C NMR spectra were referenced to internal deuteriated solvents and then recalculated to $SiMe_4$ (δ = 0.00 ppm). Low-resolution mass spectra (LRMS) were obtained with a Finnigan MAT SSQ-710 spectrometer in the positive FAB mode. Conductivity measurements were carried out with a DDS-11 conductivity bridge for 10^{-4} mol dm^{-1} solutions either in CH_3OH or CH_3CN. ***Caution:*** Cadmium complexes are toxic, and all experiments involving these reagents should be carried out in a well-vented hood.

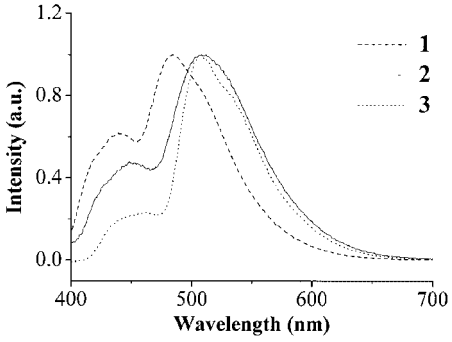

Figure 6. Photoluminescence spectrum of **1**, **2** and **3** at 77 K.

Preparation of $[Cd_4(L^1)_2(OAc)_4]$ (1): Excess $Cd(OAc)_2 \cdot 2H_2O$ (2.80 g, 10.5 mmol) was added to a suspension of H_2L^1 (1.062 g, 3.23 mmol) in absolute ethanol. The resultant reaction mixture was refluxed overnight to give a clear yellow solution. The solution was filtered and the solvents were evaporated to dryness to give a yellow solid. The solid was washed with deionised water, redissolved in a $CHCl_3/CH_3OH$ mixture and the resulting solution was filtered. The filtrate was allowed to concentrate slowly at room temperature to give yellow crystals of $\mathbf{1} \cdot CH_3OH$ in about a week. Yield: 2.214 g (51%). M.p. > 300 °C. ^{1}H NMR ($CDCl_3$): δ = 1.78 (br. s, 12 H, CH_3COO), 3.73 (m, 4 H, NCH_2), 3.80–3.98 (m, 12 H, OCH_3), 4.35 (m, 4 H, NCH_2), 6.37–6.51 (m, 4 H, Ph-*H*), 6.77–6.80 (m, 8 H, Ph-*H*), 8.41 (m, 4 H, C*H*=N) ppm. IR (KBr): $\tilde{\nu}$ = 3423 s, 1633 s, 1558 s, 1450 s, 1415 s, 1288 m, 1215 s, 1099 m, 970 m, 743 m cm^{-1}. FABMS (positive mode): *m*/*z* = 1277 ([M – OAc]$^+$ for ^{112}Cd). $C_{44}H_{48}Cd_4N_4O_{16} \cdot CH_3OH$ (1370.56): calcd. C 39.44, H 3.82, N 4.09; found C 39.13, H 3.78, N 4.05.

Preparation of $[Cd_4(L^2)_2(OAc)_4]$ (2): The synthesis of **2** followed the same procedures as for **1** except that $Cd(OAc)_2 \cdot 2H_2O$ (0.471 g, 1.77 mmol) and H_2L^2 (0.312 g, 0.58 mmol) were used instead. Yel-

low crystals of **2**·CH_3OH were obtained. Yield: 0.481 g (50%). M.p. > 300 °C. ^{1}H NMR ($CDCl_3$): δ = 1.75 (br. s, 12 H, CH_3COO), 3.70 (m, 4 H, NCH_2), 3.82–3.96 (m, 12 H, OCH_3), 4.28 (m, 4 H, NCH_2), 6.88–6.97 (m, 8 H, Ph-*H*), 8.32 (m, 4 H, C*H*=N) ppm. IR (KBr): $\tilde{\nu}$ = 3423 m, 1635 s, 1542 m, 1456 s, 1401 m, 1286 m, 1233 s, 1211 s, 1094 m, 977 m, 773 m, 688 m cm^{-1}. FABMS (positive mode): *m*/*z* = 1589 ([M – OAc]$^+$ for ^{79}Br and ^{112}Cd). $C_{44}H_{44}Br_4Cd_4N_4O_{16}$·$CH_3OH$ (1686.15): calcd. C 32.05, H 2.87, N 3.32; found 32.53, H 2.85, N 3.45.

Preparation of [$Cd_4(L^3)_2(OAc)_4$] (3): Similarly, a mixture of $Cd(OAc)_2$·$2H_2O$ (0.434 g, 1.78 mmol) and H_2L^3 (0.270 g, 0.53 mmol) was used here to give, after workup, yellow crystals of **3**·$3H_2O$ in 46% yield (0.417 g). M.p. > 300 °C. ^{1}H NMR ($CDCl_3$): δ = 1.81 (br. s, 12 H, CH_3COO), 2.37 (br. s, 12 H, Ph-CH_3), 3.72 (m, 4 H, NCH_2), 3.92–4.06 (m, 12 H, OCH_3), 4.40 (m, 4 H, NCH_2), 6.37–6.51 (m, 4 H, Ph-*H*), 7.03–7.40 (m, 24 H, Ph-*H*), 8.55 (m, 4 H, C*H*=N) ppm. IR (KBr): $\tilde{\nu}$ = 3428 m, 1634 s, 1558 s, 1457 s, 1405 s, 1269 m, 1202 m, 985 m, 815 m, 772 m cm^{-1}. FABMS (positive mode): *m*/*z* = 1637 ([M – OAc]$^+$ for ^{112}Cd). $C_{72}H_{72}Cd_4N_4O_{16}$·$3H_2O$ (1753.07): calcd. C 49.33, H 4.48, N 3.20; found C 49.54, H 4.49, N 3.11.

X-ray Crystallography: Pertinent crystallographic data and other experimental details are summarised in Table 4. Crystals of **1** and **3** suitable for X-ray diffraction studies were grown by slow concentration of a solution of the respective compound in CH_3OH. Intensity data were collected at 293 K with a Bruker Axs SMART 1000 CCD area-detector diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The collected frames were processed with the software SAINT[13] and an absorption correction was applied (SADABS)[14] to the collected reflections. The structures of all compounds were solved by direct methods (SHELXTL)[15] and refined against F^2 by full-matrix least-squares analysis. All non-hydrogen atoms were refined anisotropically for these structures. Hydrogen atoms were generated in their idealised positions and allowed to ride on their respective parent carbon atoms. CCDC-241608 (**1**) and -241609 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis, Structure, and Properties of Zirconium and Hafnium Complexes Containing η^2-Pyrazolato Ligands

Elena Sebe,[a] Ilia A. Guzei,[a,c] Mary Jane Heeg,[a] Louise M. Liable-Sands,[b] Arnold L. Rheingold,[b,d] and Charles H. Winter*[a]

Keywords: Group-4 transition metals / Zirconium / Hafnium / Pyrazolato ligands / N ligands / Intramolecular hydrogen bond

Treatment of tetrakis(dimethylamido)zirconium with four equiv. of 3,5-dimethylpyrazole, 3,5-di-*tert*-butylpyrazole, or 3,5-diphenylpyrazole in refluxing toluene afforded tetrakis(η^2-3,5-dimethylpyrazolato)zirconium (86%), tetrakis(η^2-3,5-di-*tert*-butylpyrazolato)zirconium (88%), and tetrakis(η^2-3,5-diphenylpyrazolato)zirconium (85%), respectively, as colorless crystalline solids. The analogous hafnium complexes were prepared through treatment of hafnium tetrachloride with four equiv. of the potassium salts of 3,5-dimethylpyrazolate, 3,5-di-*tert*-butylpyrazolate, or 3,5-diphenylpyrazolate in tetrahydrofuran to afford tetrakis(η^2-3,5-dimethylpyrazolato)hafnium (75%), tetrakis(η^2-3,5-di-*tert*-butylpyrazolato)hafnium (58%), and tetrakis(η^2-3,5-diphenylpyrazolato)hafnium·toluene (38%), respectively, as colorless crystalline solids. X-ray crystal structures of representative members of these complexes revealed monomeric species containing four η^2-pyrazolato ligands and approximate dodecahedral geometry about the metal centers. Treatment of tetrakis(η^2-3,5-dimethylpyrazolato)hafnium with 3,5-dimethylpyrazole in a 1:1 molar ratio afforded tris(η^2-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazole)hafnium as colorless crystals (84%). Tris(η^2-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazole)hafnium contains three η^2-3,5-dimethylpyrazolato, one η^1-3,5-dimethylpyrazolato, and one η^1-3,5-dimethylpyrazole ligands. The η^1-3,5-dimethylpyrazolato and η^1-3,5-dimethylpyrazole ligands are connected through a N–H···N hydrogen bond. Tetrakis(η^2-3,5-dimethylpyrazolato) hafnium did not form an adduct with pyridine or tetrahydrofuran, suggesting that the formation of a hydrogen bond is important to the stability of adducts. Attempted sublimation of all of the new pyrazolato complexes led to some decomposition, as evidenced by the formation of the free pyrazoles in the sublimates and significant amounts of nonvolatile residues. This work greatly expands the number of zirconium and hafnium complexes that contain η^2-pyrazolato ligands.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Thin films of binary zirconium and hafnium phases are of significant interest, in view of their useful properties and important applications. Hafnium oxide and hafnium silicate have much higher dielectric constants compared to silicon dioxide, and are among the best candidates to replace silicon dioxide as gate dielectric materials in future microelectronics devices.[1] Analogous zirconium phases are also of interest for similar applications.[1] Zirconium nitride (ZrN, Zr_3N_4) and hafnium nitride (HfN, Hf_3N_4) have potential uses that include hard coatings[2] and barrier layers in microelectronics devices.[3] To allow film growth by chemical vapor deposition and related techniques, it is necessary to have volatile complexes that react with additional reagents to afford the desired phases. Since zirconium and hafnium halides have low vapor pressures, there has been considerable investigation of metal–organic and inorganic hafnium complexes with useful vapor pressures. Precursors that have been investigated for the deposition of zirconium and hafnium oxide and related oxide materials contain various ligands that include alkoxide,[4] nitrate,[5] dialkylamido,[6] and others.[7] The growth of zirconium and hafnium nitride films by CVD methods has been much less explored, and has largely employed dialkylamido–based precursors.[8]

Our group and others have been exploring the coordination chemistry of pyrazolato ligands with metals across the periodic table.[9,10] In 1997, we reported the synthesis, structure, and molecular orbital calculations of titanium(IV) complexes that contain terminal η^2-pyrazolato ligands.[10d] In particular, the molecular orbital calculations predicted that filled in-plane nitrogen-based orbitals interact with empty d-orbitals on the titanium(IV) ion. Based upon this

bonding model, η^2-pyrazolato ligand coordination was predicted to be general in a wide variety of metal complexes. Subsequently, we and others have demonstrated η^2-pyrazolato ligand coordination in many transition metal, main group, and lanthanide complexes.[9,10]

As part of our goals related to further exploration of η^2-pyrazolato ligand coordination among the transition metals and the design of new volatile film growth precursors, we set out to explore zirconium and hafnium pyrazolato complexes. Herein we report the synthesis, structure, and properties of a series of monomeric zirconium(IV) and hafnium(IV) complexes that contain η^2-pyrazolato ligands. The thermal stability and volatility of these complexes are described. In addition, tetrakis(η^2-3,5-dimethylpyrazolato) hafnium forms a novel adduct with 3,5-dimethylpyrazole. There have been few reports of zirconium and hafnium pyrazolato complexes.[10c,11,12] Meyer and co-workers reported a homoleptic zirconium complex with four bulky η^2-pyrazolato ligands.[11] We have reported the synthesis and structure of several zirconium and hafnium complexes that contain pyrazolato ligands,[12] but have not published any structural studies of the homoleptic pyrazolato complexes.

(2)

Results and Discussion

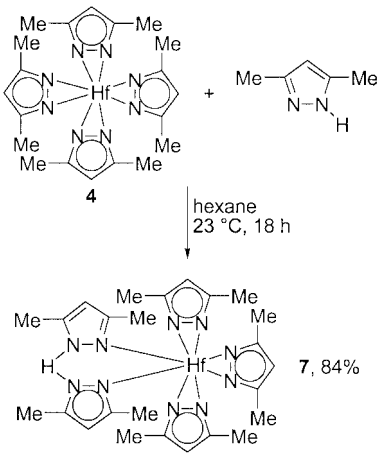
Synthetic Chemistry

Treatment of tetrakis(dimethylamido)zirconium with four equiv. of 3,5-dimethylpyrazole, 3,5-di-*tert*-butylpyrazole, or 3,5-diphenylpyrazole in refluxing toluene afforded tetrakis(η^2-3,5-dimethylpyrazolato)zirconium (**1**, 86%), tetrakis(η^2-3,5-di-*tert*-butylpyrazolato)zirconium (**2**, 88%), and tetrakis(η^2-3,5-diphenylpyrazolato)zirconium (**3**, 85%), respectively, as colorless crystalline solids [Equation (1)]. We have previously reported that treatment of group 4 and 5 metal chlorides with potassium pyrazolato salts constitutes an excellent synthetic route to the corresponding group 4 and 5 pyrazolato complexes.[12,13] Accordingly, salt metathesis routes to hafnium pyrazolato complexes were explored. Treatment of hafnium tetrachloride with 4 equiv. of the potassium salts of 3,5-dimethylpyrazolate,[12b] 3,5-di-*tert*-butylpyrazolate,[13] or 3,5-diphenylpyrazolate[13] in tetrahydrofuran at ambient temperature for 18 h afforded tetrakis(η^2-3,5-dimethylpyrazolato)hafnium (**4**, 75%), tetrakis(η^2-3,5-di-*tert*-butylpyrazolato)hafnium (**5**, 58%), and tetrakis(η^2-3,5-diphenylpyrazolato)hafnium·toluene (**6**·C_7H_8, 38%), respectively, as colorless crystalline solids [Equation (2)]. Complexes **1**–**3** were alternatively prepared by salt metathesis routes similar to those for **4**, **5**, and **6**·C_7H_8. The isolated yields of **1**–**3** were similar to those obtained by protonolysis reactions from tetrakis(dimethylamido)zirconium.

The structural assignments for **1**–**5** and **6**·C_7H_8 were based upon spectral and analytical data. In addition, X-ray crystal structure determinations were carried out for **1**, **3**, **4**, and **6**·C_7H_8, as described below. Complexes **1**, **3**, **4**, and **6**·C_7H_8 are monomeric in the solid state, with four η^2-pyrazolato ligands and eight-coordinate metal centers. They are stable indefinitely at ambient temperature under dry argon or nitrogen. The ^1H and $^{13}C\{^1H\}$ NMR spectra of **1**–**5** and **6**·C_7H_8 are consistent with the solid-state structures, and reveal the expected resonances for one type of pyrazolato ligand. In the dodecahedral structures of **1**–**5** and **6**·C_7H_8, the 3- and 5-substituents on each pyrazolato ligand are in different chemical environments. The fact that only one type of chemical environment is observed in the NMR spectra of **1**–**5** and **6**·C_7H_8 indicates that the pyrazolato ligand substituents are undergoing rapid site exchange on the NMR timescale. Such site exchange probably occurs through a sliding motion of the η^2-pyrazolato ligands across the faces of the dodecahedral molecular structures, which interchanges the two types of sites and is presumably a very low energy process.

During several attempts to crystallize **4** from polar solvents such as tetrahydrofuran or diethyl ether, a new complex was obtained that had a much more complicated ^1H NMR spectrum than that of **4**. A crystal structure determination, as described below, established that this new complex was tris(η^2-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazole)hafnium (**7**). Complex **7** probably corresponds to a hydrolysis product of **4**. It is less soluble and more crystalline than **4**, and crystallizes selectively from the polar solvents. Since **7** could only be obtained in low and variable yields by this process, an independent synthesis was developed. Treatment of **4** with one equiv. of 3,5-dimethylpyrazole in hexane at ambient temperature for 18 h afforded **7** in 84% yield as a colorless powder [Equation (3)].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



(3)

The structural assignment for **7** was based upon spectral and analytical data, as well as an X-ray crystal structure determination, as described below. Further treatment of **7** with 3,5-dimethylpyrazole or treatment of **4** with 2 or more equiv. of 3,5-dimethylpyrazole did not lead to new complexes, and only **7** and free 3,5-dimethylpyrazole were isolated. Treatment of **1** with 3,5-dimethylpyrazole under conditions similar to the preparation of **7** afforded a species with a ^{1}H NMR spectrum that was similar to that of **7**. However, attempted crystallization of this material afforded only crystals of **1**. Treatment of **4** with pyridine in hexane, followed by crystallization, afforded only **4**. Complex **4** also did not form an isolable adduct with tetrahydrofuran. The ^{1}H NMR spectrum of **4** at ambient temperature in [D_8]toluene in the presence of pyridine (1 equiv.) showed no evidence for the formation of a pyridine adduct. Treatment of **3** or **6**·C_7H_8 with 3,5-diphenylpyrazole (1 equiv.) in [D_8] toluene showed no evidence for adduct formation, and crystallization always afforded pure **3** or **6**·C_7H_8. Similarly, there was no evidence for adduct formation between **2** or **5** and 3,5-di-*tert*-butylpyrazole.

In the solid state, complex **7** contains three η^2-3,5-dimethylpyrazolato, one η^1-3,5-dimethylpyrazolato, and one η^1-3,5-dimethylpyrazole ligands, as described below. The η^1-3,5-dimethylpyrazolato and η^1-3,5-dimethylpyrazole ligands are connected through a N–H···N hydrogen bond. At 20 °C in [D_2]dichloromethane (**7** is much more soluble in this solvent than in toluene), the ^{1}H NMR of **7** exhibited one slightly broad resonance for the methyl groups at δ = 2.17 ppm, one slightly broad resonance at δ = 5.99 ppm for the pyrazolato core C–*H* fragment, and a very broad resonance at δ = 10.3 ppm for the pyrazole N–*H* group. This spectrum indicates that proton exchange between the pyrazole and four pyrazolato ligands and site exchange among the pyrazolato ligands are fast on the NMR timescale at 20 °C. At –93 °C in [D_2]dichloromethane, the ^{1}H NMR was much more complicated. Resonances due to pyrazole N–*H* groups were observed at δ = 16.88, 16.58, 13.70, and 11.19 ppm. If the solid-state structure of **7** is maintained in solution, a single pyrazole N–*H* resonance should be observed. In the pyrazolato core C–*H* resonance region, nine singlets of various intensities were observed between δ = 5.48–6.30 ppm, compared to the five expected resonances if the molecular structure of **7** were maintained in solution. In the methyl resonance region, at least 20 singlets were observed between δ = 0.89–2.35 ppm. The ^{1}H NMR spectrum at –93 °C demonstrates that **7** exists as a mixture of at least several complexes in solution.

Volatility and Thermal Stability Study

Complexes **1**–**7** were evaluated for their volatility and thermal stability in order to assess their potential viability as film growth precursors. Sublimation was observed beginning at about the temperatures at which the free pyrazoles sublime (3,5-dimethylpyrazole, 45 °C/0.05 Torr; 3,5-diphenylpyrazole, 150 °C/0.05 Torr; 3,5-di-*tert*-butylpyrazole, 80 °C/0.05 Torr). For **1**–**5** and **6**·C_7H_8, the sublimed material consisted of the free pyrazole along with smaller amounts of **1**–**5** and **6**·C_7H_8. There were substantial amounts of nonvolatile residues at the conclusion of the sublimations. Sublimation of **7** at 50–60 °C/0.05 Torr afforded 3,5-dimethylpyrazole as the sublimate. This behavior is consistent with thermal decomposition of **1**–**7** during sublimation, and thus these complexes are unlikely to serve as useful film growth precursors under thermal source delivery conditions.

X-ray Crystal Structures

X-ray crystal structures of **1**, **3**, **4**, **6**·C_7H_8, and **7** were determined to establish the geometries about the metal centers and the bonding modes of the pyrazolato ligands. Experimental crystallographic data are summarized in Table 1. Selected bond lengths and angles are given in Table 2. Perspective views of **4** and **7** are presented in Figure 1 and Figure 2. The coordination spheres of **1**, **3**, and **6**·C_7H_8 are similar to that of **4**, so a representative perspective view is only given for **4**.

The molecular structures of **1**, **3**, **4**, and **6**·C_7H_8 consist of monomeric complexes, with four η^2-pyrazolato ligands bonded to each metal center and approximate dodecahedral geometry. The metal–nitrogen distances [**1**, 2.162(5)–2.226(5); **3**, 2.173(2)–2.212(2); **4**, 2.137(8)–2.206(7); **6**·C_7H_8, 2.156(4)–2.191(4) Å] are consistent with idealized η^2-pyrazolato ligand bonding. These bond lengths are comparable for the zirconium and hafnium complexes, due to similar sizes of the zirconium(IV) (r = 0.72 Å for six coordination[14]) and hafnium(IV) (r = 0.71 Å for six coordination[14]) ions. The metal ions in **1**, **3**, **4**, and **6**·C_7H_8 lie approximately in the C_3N_2 planes of the pyrazolato ligand cores, and thus the filled in-plane nitrogen-based orbitals are involved in bonding. The pyrazolato nitrogen–nitrogen bond lengths in **1**, **3**, **4**, and **6**·C_7H_8 vary from 1.37–1.40 Å, while the nitrogen–metal–nitrogen bite angles of the pyrazolato ligands range between 36.3–37.3°.

The molecular structure of **7** consists of monomeric molecules containing three η^2-3,5-dimethylpyrazolato, one

η^1-3,5-dimethylpyrazolato, and one η^1-3,5-dimethylpyrazole ligands bound to each hafnium center. There is an intramolecular hydrogen bond between the hydrogen atom bonded to N(2) of the η^1-3,5-dimethylpyrazole ligand and N(8) of the η^1-3,5-dimethylpyrazolato ligand. The overall geometry about the hafnium center can be considered as pentagonal bipyramidal, with the nitrogen atoms of two η^2-3,5-dimethylpyrazolato and one η^1-3,5-dimethylpyrazolato ligands corresponding to the equatorial plane. The center of the nitrogen–nitrogen bond of the η^2-3,5-dimethylpyrazolato ligand containing N(9) and N(10) and the coordinated nitrogen atom of the 3,5-dimethylpyrazole ligand correspond to the axial groups. The hafnium–nitrogen bond lengths for the η^2-3,5-dimethylpyrazolato ligands fall between 2.138(4)–2.251(3) Å, and these values are similar to those observed in **1**, **3**, and **4**. The η^2-3,5-dimethylpyrazolato ligand containing N(5) and N(6) has slightly asymmetric hafnium–nitrogen bond lengths of 2.138(4) and 2.251(4) Å, respectively. This slight asymmetry may arise from steric interactions between the methyl group containing C(14) and the η^1-3,5-dimethylpyrazole ligand. The hafnium–nitrogen bond lengths for the η^1-3,5-dimethylpyrazolato and 3,5-dimethylpyrazole ligands are 2.229(4) and 2.373(4) Å, respectively. The longer hafnium–nitrogen bond length for the 3,5-dimethylpyrazole ligand is consistent with its assignment as a neutral donor. The nitrogen–nitrogen bond lengths vary from 1.360(5)–1.390(5) Å. The nitrogen–hafnium–nitrogen bite angles of the η^2-3,5-dimethylpyrazolato ligands range between 36.45(13)–37.41(14)°, and are identical to the values for **1**, **3**, **4**, and **6**·C_7H_8.

Comments on 1–7

The results described herein extend our previous studies of homoleptic titanium(IV) pyrazolato complexes[10d,10e] to

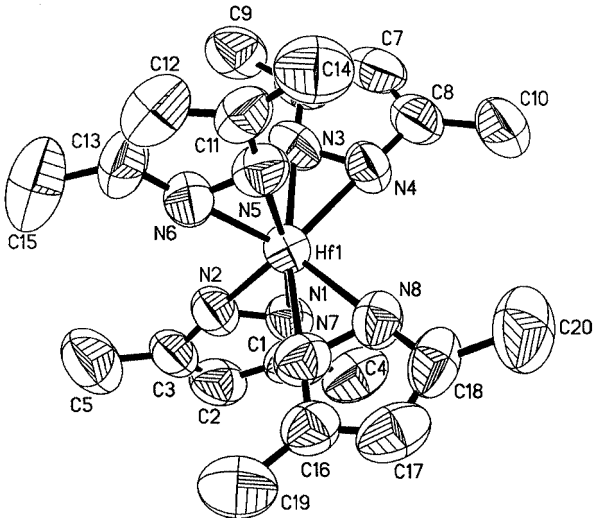

Figure 1. Perspective view of tetrakis(η^2-3,5-dimethylpyrazolato)-hafnium (**4**) with probability ellipsoids at the 50% level.

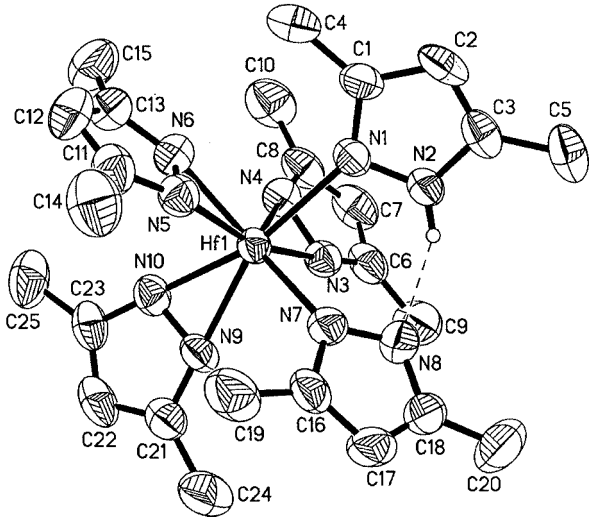

Figure 2. Perspective view of tris(η^2-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazole)hafnium (**7**) with probability ellipsoids at the 50% level.

the heavier group 4 elements zirconium and hafnium. $[Zr(R'_2pz)_4]$ (R′ = fluorenylmethyl) is the only other homoleptic heavier group 4 pyrazolato complex that has been structurally characterized.[11] It possesses approximate dodecahedral geometry about each zirconium ion, with zirconium–nitrogen bond lengths that range between 2.158(3)–2.210(3) Å. Thus, in spite of the bulky fluorenylmethyl substituents in the 3- and 5-positions of the pyrazolato ligands in $Zr(R'_2pz)_4$, essentially idealized η^2-pyrazolato ligands are observed. The combined results suggest that η^2-pyrazolato ligand coordination should be very common in zirconium(IV) and hafnium(IV) complexes. Excluding complexes containing tris(pyrazolyl)borate and related ligands (which possess μ–η^1:η^1-pyrazolato ligands), mixed ligand zirconium(IV) and hafnium(IV) pyrazolato complexes that have been structurally characterized to date are consistent with this prediction. For example, $[Cp_2Zr(pz)(THF)]^+BPh_4^-$ contains an η^2-pyrazolato ligand with zirconium–nitrogen bond lengths of 2.182(8) and 2.207(8) Å.[10c] $Hf(tBu_2pz)_3Cl$ contains η^2-pyrazolato ligands with hafnium–nitrogen bond lengths that range between 2.132(5)–2.162(8) Å.[12a] The metal–nitrogen bond lengths in these complexes are very similar to those observed in **1**, **3**, **4**, and **6**·C_7H_8. We have previously carried out molecular orbital calculations on the model pyrazolato complex $Ti(Me_2pz)Cl_3$,[10e] and noted that the η^2-pyrazolato ligand bonding occurs through overlap of filled symmetric and antisymmetric in-plane nitrogen-based orbitals with empty d-orbitals on the titanium center. Thus, the metal ion lies approximately in the C_3N_2 plane to maximize overlap with the in-plane nitrogen-based orbitals. The crystal structures of **1**, **3**, **4**, and **6**·C_7H_8 are consistent with this bonding model.

A surprise that emerged from this study is the formation and unusual structure of **7**. There was spectroscopic evidence in solution for a similar adduct derived from addition of 3,5-dimethylpyrazole to **1**. However, **1** crystallized selectively from these solutions, which indicates that adduct formation with 3,5-dimethylpyrazole is subtly balanced energetically with the crystallization of **1**. There was no evidence for formation of adducts between **4** and pyridine or tetrahydrofuran, either in the solution or the solid state. Accordingly, it appears that the N–H···N hydrogen bond is a key feature of the stability of **7**. Similar pyrazolato-pyrazole adducts bridged by N–H···N hydrogen bonds have been reported.[15]

Experimental Section

General: All manipulations were performed under argon using either glovebox or Schlenk line techniques. Hexane was distilled from P_2O_5, toluene was distilled from sodium, and tetrahydrofuran was distilled from purple solutions of sodium benzophenone ketyl. Tetrakis(dimethylamido)zirconium and hafnium tetrachloride were purchased from Strem Chemicals, Inc. and were used as received. 3,5-Dimethylpyrazole and 3,5-diphenylpyrazole were purchased from Aldrich Chemical Company and were sublimed prior to use. 3,5-Di-*tert*-butylpyrazole[16] and the potassium pyrazolate salts[12b,13] were prepared according to literature procedures. We previously briefly described the synthesis and characterization of **2** and **5**,[12a] but did not describe structural data or reactivity. ^1H and $^{13}C\{^1H\}$ NMR were obtained at 300, 400, 75, or 100 MHz in the indicated solvents. Infrared spectra were obtained using Nujol as the medium. Elemental analyses were performed by Midwest Microlab, Indianapolis, Indiana. Melting points were obtained with a Haake–Buchler HBI digital melting point apparatus and are uncorrected.

Preparation of Tetrakis(η^2-3,5-dimethylpyrazolato)zirconium (1): A 100 mL Schlenk flask was charged with 3,5-dimethylpyrazole (0.288 g, 3.00 mmol), toluene (35 mL), and was fitted with a reflux condenser. A solution of tetrakis(dimethylamido)zirconium (0.200 g, 0.759 mmol) in toluene (2 mL) was injected into the Schlenk flask using a syringe. The reaction mixture was then refluxed for 2 h. Upon cooling to room temperature, the volatile components were removed under reduced pressure to give an off-white solid. This solid was then extracted with hexane (20 mL), and the hexane extract was filtered through a 2-cm pad of Celite on a coarse frit to afford a clear, colorless solution. Removal of the vola-

tile components under reduced pressure afforded **1** as a white crystalline solid (0.304 g, 86%). An analytical sample was obtained by recrystallization from a hexane solution at –20 °C, which afforded **1** as colorless crystals; m. p. 151–152 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 3108 (w), 1568 (w), 1524 (s), 1440 (s), 1423 (s), 1366 (m), 1341 (w), 1320 (w), 1306 (w), 1262 (w), 1159 (w), 1116 (m), 1035 (w), 1004 (m), 959 (m), 790 (m), 729 (m), 684 (w) cm^{-1}. ^1H NMR ([D$_6$]benzene, 22 °C): δ = 2.17 (s, 24 H, C–C*H*$_3$), 5.97 (s, 4 H, pyrazolato C*H*) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 22 °C): δ = 12.88 (s, C–*C*H$_3$), 112.18 (s, pyrazolato *C*H), 145.82 (s, *C*–CH$_3$) ppm. $C_{20}H_{28}N_8Zr$ (471.72): calcd. C 50.92, H 5.98, N 23.75; found C 50.26, H 5.87, N 23.08.

Preparation of Tetrakis(η^2-3,5-di-*tert*-butylpyrazolato)zirconium (2): In a fashion similar to the preparation of **1**, treatment of tetrakis-(dimethylamido)zirconium (0.200 g, 0.759 mmol) with 3,5-di-*tert*-butylpyrazole (0.540 g, 3.00 mmol) afforded **2** as a white crystalline solid (0.534 g, 88%). An analytical sample was obtained by recrystallization from a hexane solution at –20 °C, which afforded **2** as colorless crystals; m. p. 226 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 3108 (w), 1589 (s), 1570 (s), 1248 (m), 1206 (w), 968 (w), 953 (w), 866 (m), 844 (m), 754 (w), 696 (w) cm^{-1}. ^1H NMR ([D$_6$]benzene, 22 °C): δ = 1.24 [s, 72 H, C(C*H*$_3$)$_3$], 6.34 (s, 4 H, pyrazolato C*H*) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 22 °C): δ = 30.82 [s, C(*C*H$_3$)$_3$], 32.30 [s, *C*(CH$_3$)$_3$], 105.98 (s, pyrazolato *C*H), 159.31 [s, *C*–C(CH$_3$)$_3$] ppm. $C_{44}H_{76}N_8Zr$ (808.37): calcd. C 65.38, H 9.48, N 13.86; found C 63.42, H 9.22, N 12.77.

Preparation of Tetrakis(η^2-3,5-diphenylpyrazolato)zirconium (3): In a fashion similar to the preparation of **1**, treatment of tetrakis(dimethylamido)zirconium (0.200 g, 0.759 mmol) with 3,5-diphenylpyrazole (0.660 g, 3.00 mmol) afforded **3** as a white crystalline solid (0.616 g, 85%). An analytical sample was obtained by recrystallization from a hexane solution at –20 °C, which afforded **3** as colorless crystals; m. p. 240 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 3102 (w), 1407 (w), 1366 (s), 1335 (m), 1262 (m), 1170 (w), 1156 (w), 1101 (m), 1074 (m), 1057 (w), 1023 (m), 971 (m), 918 (w), 804 (m), 761 (s), 723 (s), 691 (s) cm^{-1}. ^1H NMR ([D$_6$]benzene, 22 °C): δ = 6.92 (s, 4 H, pyrazolato C*H*), 6.98 (s, 24 H, *meta*- and *para*-C*H* of C$_6$H$_5$), 7.77 (s, 16 H, *ortho*-C*H* of C$_6$H$_5$) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$] benzene, 22 °C): δ = 109.41 (s, pyrazolato *C*H), 126.69 (s, *para*-*C*H of C$_6$H$_5$), 128.10 (s, *meta*-*C*H of C$_6$H$_5$), 128.72 (s, *ortho*-*C*H of C$_6$H$_5$), 132.18 (s, *ipso*-*C* of C$_6$H$_5$), 150.72 (s, pyrazolato *C*–C$_6$H$_5$) ppm. $C_{60}H_{44}N_8Zr$ (968.25): calcd. C 74.43, H 4.58, N 11.57; found C 74.49, H 4.62, N 11.53.

Preparation of Tetrakis(η^2-3,5-dimethylpyrazolato)hafnium (4): A 100 mL Schlenk flask was charged with hafnium tetrachloride (0.200 g, 0.624 mmol), potassium 3,5-dimethylpyrazolate (0.335 g, 2.50 mmol), and tetrahydrofuran (50 mL). The cloudy colorless reaction mixture was stirred at ambient temperature for 18 h. Then, the volatile components were removed under reduced pressure to give a white solid. This solid was extracted with hexane (80 mL), and the hexane extract was filtered through a 2-cm pad of Celite on a coarse frit to afford a colorless clear solution. Removal of the volatile components under reduced pressure afforded **4** as a white crystalline solid (0.262 g, 75%). An analytical sample was obtained by recrystallization from a hexane solution at –20 °C, which afforded **4** as colorless crystals; m. p. 149–150 °C. IR (Nujol): $\tilde{\nu}$ = 3110 (w), 1524 (m), 1366 (m), 1341 (w), 1323 (w), 1310 (w), 1262 (m), 1170 (w), 1154 (w), 1115 (m), 1037 (w), 1006 (m), 960 (m), 789 (s), 731 (s), 724 (s) cm^{-1}. ^1H NMR ([D$_6$]benzene, 22 °C): δ = 2.16 (s, 24 H, C–C*H*$_3$), 6.08 (s, 4 H, pyrazolato C*H*) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 22 °C): δ = 13.32 (s, C–*C*H$_3$), 112.99 (s, pyrazolato *C*H), 146.15 (s, *C*–CH$_3$) ppm. $C_{20}H_{28}HfN_8$ (558.99): calcd. C 42.97, H 5.05, N 20.05; found C 42.89, H 5.01, N 20.05.

Preparation of Tetrakis(η^2-3,5-di-*tert*-butylpyrazolato)hafnium (5): In a fashion similar to the preparation of **4**, treatment of hafnium tetrachloride (0.200 g, 0.624 mmol) with potassium 3,5-di-*tert*-butylpyrazolate (0.545 g, 2.50 mmol) afforded **5** as a white crystalline solid (0.295 g, 58%). An analytical sample was obtained by recrystallization from a toluene solution at –20 °C, which afforded **5** as colorless crystals; m. p. 202 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1527 (m), 1509 (m), 1366 (s), 1304 (m), 1260 (s), 1230 (m), 1206 (w), 1094 (s), 1024 (s), 993 (m), 801 (s), 721 (m) cm^{-1}. ^1H NMR ([D$_6$] benzene, 22 °C): δ = 1.23 [s, 72 H, C(C*H*$_3$)$_3$], 6.46 (s, 4 H, pyrazolato C*H*) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 22 °C): δ = 30.71 [s, C(*C*H$_3$)$_3$], 32.22 [s, *C*(CH$_3$)$_3$], 106.02 (s, pyrazolato *C*H), 159.14 [s, *C*–C(CH$_3$)$_3$] ppm. $C_{44}H_{76}HfN_8$ (895.63): calcd. C 59.01, H 8.55, N 12.51; found C 59.14, H 8.46, N 12.32.

Preparation of Tetrakis(η^2-3,5-diphenylpyrazolato)hafnium·Toluene (6·C$_7$H$_8$): In a fashion similar to the preparation of **4**, treatment of hafnium tetrachloride (0.200 g, 0.624 mmol) with [K(Ph$_2$pz)-(THF)]$_6$ (0.645 g, 0.325 mmol) afforded a white crystalline solid. Recrystallization of this solid from a toluene solution at –20 °C afforded **6**·C$_7$H$_8$ as colorless crystals (0.274 g, 38% based upon the potassium pyrazolato reagent); m. p. 239–240 °C (dec; toluene loss observed at 110 °C). IR (Nujol): $\tilde{\nu}$ = 1366 (s), 1303 (w), 1260 (s), 1170 (m), 1153 (m), 1097 (s), 1021 (s), 974 (w), 802 (s), 760 (m), 723 (s) cm^{-1}. ^1H NMR ([D$_6$]benzene, 22 °C): δ = 6.92 (s, 4 H, pyrazolato C*H*), 6.98 (s, 8 H, *para*-C*H* of C$_6$H$_5$), 7.00 (s, 16 H, *meta*-C*H* of C$_6$H$_5$), 7.72 (m, 16 H, *ortho*-C*H* of C$_6$H$_5$) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 22 °C): δ = 109.15 (s, pyrazolato *C*H), 126.62 (s, *para*-*C*H of C$_6$H$_5$), 127.95 (s, *meta*-*C*H of C$_6$H$_5$), 128.34 (s, *ortho*-*C*H of C$_6$H$_5$), 132.08 (s, *ipso*-*C* of C$_6$H$_5$), 150.33 (s, pyrazolato *C*–C$_6$H$_5$) ppm. In addition, resonances due to free toluene were observed in the ^1H and $^3C\{^1H\}$ NMR spectra. $C_{67}H_{52}HfN_8$ (1147.66): calcd. C 70.12, H 4.57, N 9.76; found C 70.09, H 4.64, N 9.47.

Preparation of Tris(η^2-3,5-dimethylpyrazolato)(η^1-3,5-dimethylpyrazolato)(η^1-3,5-dimethyl-pyrazole)hafnium (7): A 100 mL Schlenk flask was charged with **4** (0.254 g, 0.454 mmol), 3,5-dimethylpyrazole (0.044 g, 0.458 mmol), and hexane (50 mL). The colorless mixture was stirred at ambient temperature for 18 h. Then, the solution was filtered through a 2-cm pad of Celite on a coarse frit to afford a clear, colorless solution. The volatile components were removed under reduced pressure to afford **7** as a white crystalline solid (0.250 g, 84%). An analytical sample was obtained by recrystallization from a hexane solution at –20 °C, which afforded **7** as colorless crystals; m. p. 71 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 3248 (m, ν_{NH}), 3205 (m, ν_{NH}), 3135 (m, ν_{NH}), 3110 (m), 3040 (m), 1671 (m), 1622 (m), 1595 (m), 1568 (m), 1524 (m), 1485 (s), 1441 (s), 1418 (s), 1345 (s), 1307 (s), 1260 (s), 1155 (m), 1146 (m), 1112 (s), 1099 (s), 1029 (s), 1016 (s), 1007 (s), 958 (m), 862 (m), 833 (m), 791 (s), 730 (m), 703 (s), 659 (m) cm^{-1}. ^1H NMR ([D$_6$]benzene, 22 °C): δ = 2.12 (broad s, 30 H, C*H*$_3$), 5.89 (broad s, 5 H, pyrazolato and pyrazole C*H*), 13.0 (very broad s, 1 H, N*H*) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 22 °C): δ = 12.56 (s, C–*C*H$_3$), 108.31 (s, pyrazolato and pyrazole *C*H), 144.95 (s, *C*–CH$_3$) ppm. $C_{25}H_{36}HfN_{10}$ (655.13): calcd. C 45.84, H 5.54, N 21.38; found C 45.67, H 5.54, N 21.06.

X-ray Crystallographic Structure Determinations for 1, 3, 4, 6·C$_7$H$_8$, and 7: Crystalline samples of all air sensitive compounds were mounted in sealed thin-walled glass capillaries under nitrogen for X-ray data collection. The single-crystal X-ray diffraction experiments for **1** and **3** were performed with a Siemens P4 diffractometer with Mo-K_α radiation and graphite monochromator. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were treated as idealized contributors. Data-

sets for **4**, **6**·C_7H_8, and **7** were collected at room temperature with a Bruker P4/CCD diffractometer equipped with Mo radiation. For each collection, a full sphere of data was collected at 10 s/frame with 0.2° between each frame. The frame data were integrated with the manufacturer's SMART and SAINT software.[17] Absorption corrections were applied with Sheldrick's SADABS program[17] and each structure was solved and refined using the programs of SHELXL-97.[18] The crystal structures of compounds **4**, **6**·C_7H_8, and **7** consist of discrete monomeric neutral complexes. Complex **4** crystallizes as colorless flat squares. The hydrogen atoms were placed in calculated positions. Complex **6**·C_7H_8 crystallizes as colorless mounds that were grown together. A cut fragment was used for data collection and a dataset was extracted with Sparks' GEMINI software.[17] One molecule of toluene solvent per hafnium ion is present in the model. The hydrogen atoms were placed in calculated positions. Complex **7** crystallizes as colorless blocks. All atoms occupy general positions in the unit cell. The hydrogen atoms were placed in observed and calculated positions.

CCDC-269335 (for **1**), -269336 (for **3**), -269337 (for **4**), -269338 (for **6**·C_7H_8), and -269339 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK; Fax: (+44)-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk.

Zirconium and Hafnium Complexes with (Allylsilyl)(η-amidosilyl)-η^5-cyclopentadienyl Ligands: Synthesis, Structure and Reactivity

Cristina Ramos,[a] Pascual Royo,*[a] Maurizio Lanfranchi,[b] Maria Angela Pellinghelli,[b] and Antonio Tiripicchio[b]

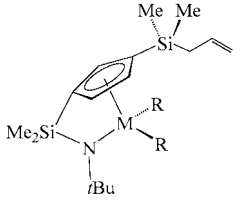
Keywords: Insertion / Isocyanides / Hafnium / Metallocenes / Zirconium

The disubstituted cyclopentadiene $C_5H_4(SiMe_2Cl)[SiMe_2(CH_2CH=CH_2)]$ was isolated by reaction of the lithium salt $[Li\{C_5H_4SiMe_2(CH_2CH=CH_2)\}]$ with $SiMe_2Cl_2$. It was then treated with NH_2tBu and $LiNH(2,6\text{-}Me_2C_6H_3)$ to give the (aminosilyl)cyclopentadienes $C_5H_4[SiMe_2(CH_2CH=CH_2)][SiMe_2(NHR)]$, which were further deprotonated to their dilithium salts $[Li_2\{1\text{-}SiMe_2NR\text{-}3\text{-}SiMe_2(CH_2CH=CH_2)C_5H_3\}]$ (R = *t*Bu, 2,6-$Me_2C_6H_3$). Reactions of the metal halides $ZrCl_4(THF)_2$ and $HfCl_4$ with these dilithium salts, followed by alkylation of the resulting dichloro complexes, afforded the (η^1-amidosilyl)-η^5-cyclopentadienyl complexes $[M\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}NR)[SiMe_2(CH_2CH=CH_2)]\}X_2]$ (R = *t*Bu, 2,6-$Me_2C_6H_3$; X = Cl, Me, CH_2Ph; M = Zr, Hf). Only the bis(iminoacyl) complexes $[M\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}Nt\text{Bu})[SiMe_2(CH_2CH=CH_2)]\}\{\eta^2\text{-}CR=N(2,6\text{-}Me_2C_6H_3)\}_2]$ (M = Zr, Hf; R = Me, CH_2Ph) could be isolated when the dialkylzirconium and -hafnium complexes were treated with CN(2,6-$Me_2C_6H_3$); these were slowly transformed into the C–C-coupled diazametallacyclopentene compounds $[M\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}Nt\text{Bu})[SiMe_2(CH_2CH=CH_2)]\}\{\eta^1\text{-}N(2,6\text{-}Me_2C_6H_3)\text{-}CR=CR\text{-}\eta^1\text{-}N(2,6\text{-}Me_2C_6H_3)\}]$ (R = Me, CH_2Ph, M = Zr; R = Me, M = Hf) when their toluene solutions were heated to 70 °C–80 °C for long periods (2–4 d). The structural characterisation of all of the new compounds is described and the molecular structure of the dimeric dichlorozirconocene $[ZrCl(\mu\text{-}Cl)\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}Nt\text{Bu})[SiMe_2(CH_2CH=CH_2)]\}]_2$, was determined by X-ray diffraction methods.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Many reports[1–9] have described the dynamics of the ion pairs formed by activation of a precursor metallocene with various Lewis acids, which are assumed to be the species responsible for the metallocene-catalysed alkene polymerisation[5,10–15] and considered to be the cornerstone of its efficiency and stereocontrol. Several strategies have been used to stabilize the intermediate cationic alkyl alkene metallocene[10,16–21] and (η^1-amidosilyl)-η^5-cyclopentadienyl[3,22–30] d^0 group-4 metal complexes. We have reported[31,32] the formation of alkyl alkene metallocene cations through η^2-coordination of the alkene moiety of an allylsilyl group tethered to the cyclopentadienyl ring. In order to study the formation and reactivity of the corresponding (η^1-amidosilyl)-η^5-cyclopentadienyl cationic compounds reported elsewhere, we synthesised and characterised disubstituted (allylsilyl)(amidosilyl)cyclopentadienyl group 4 metal complexes of the type represented in Scheme 1. These compounds are described in this paper, along with the insertion reactions of isocyanides into their metal–alkyl bonds and C–C coupling reactions of the resulting iminoacyl derivatives.



Scheme 1.

Results and Discussion

Successful synthesis of the disubstituted cyclopentadiene containing the two required aminosilyl $[SiMe_2(NHt\text{Bu})]$ and allylsilyl $[SiMe_2(CH_2CH=CH_2)]$ functionalities was achieved by first introducing the allylsilyl group[33] followed by metallation and reaction of the resulting lithium (allylsilyl)cyclopentadienide salt[31,32] with $SiMe_2Cl_2$ to give the disilylated cyclopentadiene $C_5H_4(SiMe_2Cl)[SiMe_2(CH_2CH=CH_2)]$ (**1**, Scheme 2), which was isolated as a yellow liquid.

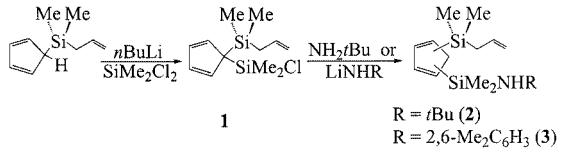


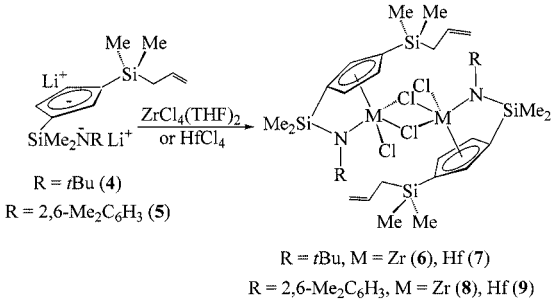
Scheme 2.

Further aminolysis of the chorosilyl derivative **1** by reaction with the primary amine NH_2tBu or metathesis with $LiNH(2,6\text{-}Me_2C_6H_3)$ afforded the disilylated cyclopentadienes $C_5H_4[SiMe_2(CH_2CH{=}CH_2)][SiMe_2(NHR)]$ (R = *t*Bu **2**, 2,6-$Me_2C_6H_3$ **3**), which were isolated as oily yellow and orange liquids, respectively. The chlorosilyl derivative **1** was identified by ^1H NMR spectroscopy as a unique 1,1-isomer. However, formation of the 1,3-isomer is favoured for the aminosilyl compounds **2** and **3** due to the presence of the sterically more demanding amino substituents (see Exp. Sect.).

The mixture of isomers of the disilylcyclopentadienes **2** and **3** was metallated by treatment with 2 equiv. of *n*BuLi to give the dilithium salts, which were isolated as white solids containing one single component and were identified by ^1H NMR spectroscopy as the 1,3-isomer $[Li_2\{1\text{-}SiMe_2NR\text{-}3\text{-}SiMe_2(CH_2CH{=}CH_2)C_5H_3\}]$ (R = *t*Bu **4**, 2,6-$Me_2C_6H_3$ **5**). Their ^1H NMR spectra show the three ring-proton signals expected for an asymmetric molecule, whereas the diastereotopic methyl groups of both silyl fragments and the diastereotopic methylene protons of the allylsilyl fragment are observed as two singlets (see Exp. Sect.).

A direct synthesis based on halide metathesis, when the metal tetrahalides were treated with 1 equiv. of the dilithium salts **4** and **5**, was used to transfer the (amidosilyl)cyclopentadienyl ligand, as shown in Scheme 3. Reaction of **4** with $ZrCl_4(THF)_2$ or $HfCl_4$ in toluene at room temperature yielded the "constrained-geometry" complexes $[MCl(\mu\text{-}Cl)\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}N\mathit{t}Bu)[SiMe_2(CH_2CH{=}CH_2)]\}]_2$ (M = Zr **6**, Hf **7**), which were isolated in high yield as a yellow crystalline solid (**6**) and an oily orange solid (**7**) and characterised by elemental analysis (**6**), NMR spectroscopy and X-ray diffraction methods (**6**). Analogous reactions using the dilithium salt of the corresponding (2,6-dimethylphenyl) amido ligand **5** were carried out in the hope of obtaining improved crystallinity of the resulting metal compounds.[34] However, the new dichloro complexes $[MCl(\mu\text{-}Cl)\{\eta^5\text{-}C_5H_3[SiMe_2\text{-}\eta^1\text{-}N(2,6\text{-}Me_2C_6H_3)][SiMe_2(CH_2CH{=}CH_2)]\}]_2$ (M = Zr **8**, Hf **9**) were always obtained as oily orange and white solid products, respectively, which easily decomposed with elimination of free amine; consequently, they were difficult to purify, giving rather low yields (lower than 30%) after purification. These compounds were not studied further.

The ^1H and ^{13}C NMR spectra of the silylamido derivatives **6**–**9** show three multiplets (^1H) and five resonances (^{13}C) for the Cp ring protons and carbon atoms and four singlets (^1H and ^{13}C) for the two diastereotopic silylmethyl groups; two of the multiplets were occasionally observed as overlapped signals in the ^1H NMR spectrum. The ^1H NMR



Scheme 3.

spectra of all the complexes show the typical pattern of the allyl substituent, which consists of one high-field multiplet for the $SiCH_2$ protons at δ = 1.7–1.8 ppm, one multiplet at δ = 5.6–5.8 ppm for the internal olefinic proton and one multiplet for the two external olefinic protons at δ = 4.8–4.9 ppm. The ring C_{ipso} resonance for compounds **6**–**9** appears at higher field than those of the other carbon atoms, consistent with the (amidosilyl)cyclopentadienyl ligands adopting a chelate coordination mode with the metal centre.[35] This NMR behaviour may suggest the presence of mononuclear structures of the silylamido derivatives **6**–**9** in solution, for which the enantiotopic 1,3-disilylcyclopentadienyl ring faces are responsible for the asymmetry of these molecules. However, it could also be consistent with a centrosymmetric dimeric diastereoisomer with two equivalent Cp-silylamido systems, which is formed by two mononuclear units held together by a pair of bridging chloro ligands. Both mono- and dinuclear structures exhibit two non-equivalent chloro ligands, one of which is localised under the allyldimethylsilyl substituent of the cyclopentadienyl ligand in the mononuclear structure or is the terminal ligand in the dinuclear compound.

The dimeric structure of complex **6** in the solid state was determined by X-ray diffraction methods on a single crystal obtained from a hexane solution cooled to –35 °C. The same dimeric structure may be tentatively assigned to all of the other complexes **7**–**9** in the solid state, as shown in Scheme 3. Typical signals due to coordinated THF were observed in the ^1H and ^{13}C NMR spectra of the more electron-deficient complex **8** containing the less basic amido ligand.

A view of the molecular structure of complex **6**, together with the atomic labelling scheme, is shown in Figure 1. Selected bond lengths and angles are given in Table 1. The crystal structure consists of discrete chloro-bridged centrosymmetric dimeric molecules of $[ZrCl(\mu\text{-}Cl)\{\eta^5\text{-}C_5H_3(SiMe_2\text{-}\eta^1\text{-}N\mathit{t}Bu)[SiMe_2CH_2CH{=}CH_2]\}]_2$. Each zirconium atom is bound to the cyclopentadienyl ring in a slightly asymmetric fashion [Zr–C bond lengths are in the range 2.441(6)–2.557(7) Å, while the Zr–CT distance is 2.187(8) Å, where CT is the centroid of the ring], to the nitrogen atom of the silylamido moiety [Zr–N = 2.042(6) Å], to a terminal chlorine atom [Zr–Cl2 = 2.457(2) Å] and to two bridging chlorine atoms [Zr–Cl1 = 2.645(2) and Zr–Cl1′ = 2.653(2) Å]. The Zr atom is in a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

four-legged piano-stool arrangement if the centroid of the cyclopentadienyl ring is taken into consideration. The value of the Zr–N bond length is consistent with double-bond character and falls in the range (2.034–2.088 Å) retrieved from the Cambridge Structural Database files for pentacoordinate Zr complexes containing the ZrClCpSiN(amido) moiety.[36–45] The almost equal bridging Zr–Cl distances are significantly longer than the terminal Zr–Cl distance, and this last bond length again falls in the range 2.432–2.529 Å retrieved from the CSD files for similar complexes. To the best of our knowledge, the only chloro-bridged dimeric zirconium complex found in the literature containing a (amidosilyl)cyclopentadienyl moiety is (*R*,*R*)-[ZrCl(μ-Cl)]{η^5:η^1-$C_5Me_4SiMe_2NCH(Me)(Ph)$}$_2$,[39] where the Zr–Cl bridging bond lengths are significantly different. The *trans* influence of the amido nitrogen and chlorine coordinating atoms seem similar in **6**, and the bridging Zr–Cl bond lengths are not significantly different.

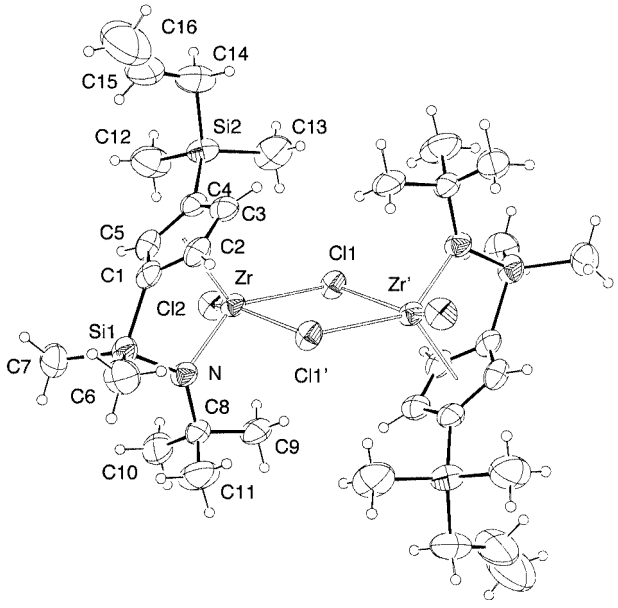


Figure 1. ORTEP drawing of the molecular structure of **6** in the solid state; thermal ellipsoids are drawn at the 30% probability level.

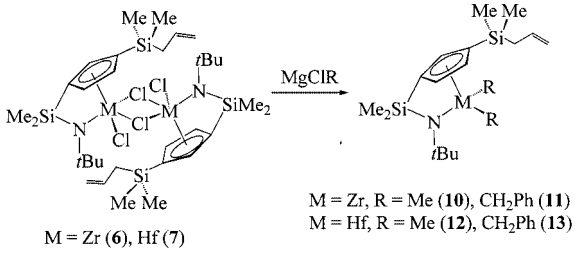
The C1 atom that bears the amidosilyl arm is pyramidally distorted, as shown by the sum of bond angles (350.8°) as in the other chloro(amidosilyl)cyclopentadienyl complexes,[36–45] and in the doubly silylamido-bridged cyclopentadienyltitanium complex,[46] while the C4 atom that bears the allylsilyl arm is weakly pyramidally distorted (the sum of the bond angles is 359.3°). The Si1 and Si2 atoms are out of the Cp plane by –0.845(2) and 0.250(3) Å, respectively.

In spite of having non-equivalent chloro ligands, none of these zirconium and hafnium complexes showed selective reactions when they were treated with alkylating agents. As shown in Scheme 4, reactions of complexes **6** and **7** with 2 equiv. of MgClR (R = Me, CH_2Ph) in hexane at room temperature gave the dialkyl complexes [M{η^5-$C_5H_3(SiMe_2$-η^1-N*t*Bu)[$SiMe_2(CH_2CH{=}CH_2)$]}R_2] (M = Zr, R = Me **10**, CH_2Ph **11**; M = Hf, R = Me **12**, CH_2Ph **13**), which were isolated as brown and orange oily solids, respectively, and identified by elemental analysis and NMR spectroscopy. In addition to the same features discussed above for the precursor dichloro complexes, the non-equivalency of the two alkyl groups of these asymmetric molecules is easily demonstrated by their ^{1}H and ^{13}C NMR spectra. The spectra of the methyl complexes **10** and **12** show two singlets (^{1}H) and two resonances (^{13}C) for the two non-equivalent, metal-bonded methyl groups, whereas four doublets (^{1}H) for the two diastereotopic methylene protons and two resonances (^{13}C) for the methylene carbon atom are observed for each non-equivalent, metal-bonded benzyl group of the benzyl derivatives **11** and **13**.



Scheme 4.

Insertion of isocyanide into one of the two non-equivalent metal–alkyl bonds of these dialkyl compounds may afford mixtures of two diastereomers, unless for diastereoselective reactions.[47] However, when 1 equiv. of CN(2,6-$Me_2C_6H_3$) was added to the toluene solutions of the dialkyl(amidosilyl)cyclopentadienyl compounds **10**–**13**, the initially formed 16-electron iminoacyl compounds could not be detected by NMR spectroscopy because they react very easily to give the bis(iminoacyl) complexes by further insertion into the second metal–alkyl bond. This behaviour is in contrast to that observed for metallocene-type complexes for which the monoiminoacyl complexes are 18-electron species, which do not undergo further insertion into the second metal–alkyl bond.

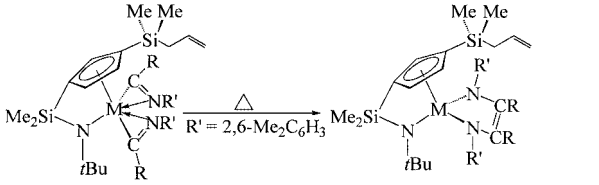
Therefore these insertion reactions were complete when toluene solutions of the dialkyl complexes **10**–**13** were treated with two equivalents of 2,6-xylyl isocyanide at room temperature to give the corresponding bis(iminoacyl) compounds[48] [M{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)[$SiMe_2$(CH_2CH=CH_2)]}{η^2-CR=N(2,6-$Me_2C_6H_3$)}$_2$] (M = Zr, R = Me **14**, CH_2Ph **15**; M = Hf, R = Me **16**, CH_2Ph **17**) which were isolated as red and orange oily products and identified by elemental analysis and NMR and infrared spectroscopy.

As shown in Scheme 5 the bis(iminoacyl) complexes **14**–**16** were slowly converted into the C–C-coupled compounds.[49] This transformation was complete when their toluene solutions were heated at 70 °C–80 °C for long periods (2 d for **18** and **19** and 4 d for **20**) in sealed tubes to give the diazametallacyclopentene complexes [M{η^5-C_5H_3($SiMe_2$-η-N*t*Bu)[$SiMe_2$(CH_2CH=CH_2)]}-{η-N(2,6-$Me_2C_6H_3$)CR=CR-η-N(2,6-$Me_2C_6H_3$)] (R = Me, M = Zr **18**, Hf **19**; R = CH_2Ph, M = Zr **20**). Complexes **18**–**20** were isolated as red (**18**) and brown (**19**, **20**) oily products and identified by NMR and IR spectroscopy. The ^{1}H and ^{13}C NMR spectra of all of these iminoacyl (**14**–**17**) and enediamido (**18**–**20**) compounds correspond to the asymmetric molecules expected from the enantiotopic character of the disilylcyclopentadienyl ligand (see Exp. Sect.). The presence of four methyl resonances (occasionally overlapped) for the [(2,6-dimethylphenyl)imino]acyl groups indicates that rotation around the N–aryl bond is avoided.



M = Zr, R = Me (**14**), CH_2Ph (**15**)
M = Hf, R = Me (**16**), CH_2Ph (**17**)

M = Zr, R = Me (**18**), CH_2Ph (**19**)
M = Hf, R = Me (**20**)

Scheme 5.

Compounds **14**–**17** contain the iminoacyl ligand η^2-coordinated to the metal centre as shown by their spectroscopic data. The signals observed in the ^{1}H NMR spectra for the alkyl and methylene(benzyl) groups migrated to the inserted aryl isocyanide are shifted downfield (by about 2 ppm) with respect to the values observed for the metal-bonded groups of the precursor dialkyl complexes. In contrast, the ^{13}C NMR resonance of the alkyl carbon atom is shifted to higher field (by about 10 ppm for Zr and 20 ppm Hf) on insertion. The most remarkable feature observed in the NMR spectra of these complexes is the chemical shift of the resonance due to the iminoacyl carbon atoms, which is shifted downfield at δ = 250–268 ppm. Another important spectroscopic feature that allows the assignment of the iminoacyl coordination mode in solution is the stretching ν(C=N) frequency of the iminoacyl bond observed in the IR spectra at 1540–1555 cm^{-1}, which corresponds to the η^2-coordinated iminoacyl ligands.[50] The ^{1}H NMR resonances due to the migrated alkyl groups in the C–C coupled enediamido complexes **18**–**20** are shifted downfield with respect to those observed for the starting bis(iminoacyl) compounds, whereas the ^{13}C NMR signals due to the enediamido sp^2-carbon atoms are observed at δ = 111–112 ppm.

Conclusions

Dichloro- and dialkyl(amidosilyl)cyclopentadienyl zirconium and -hafnium complexes of the type [M{η^5-C_5H_3[$SiMe_2$(CH_2CH=CH_2)]($SiMe_2$-η-NR)}X_2] with the allyldimethylsilyl-substituted cyclopentadienyl ligand have been isolated in high yields by conventional synthetic methods and characterised by NMR spectroscopy and X-ray diffraction methods.

The two non-equivalent chloro and alkyl ligands of these asymmetric molecules do not show diastereoselective reactions, so that alkylation of the dichloro complexes only gives dialkyl derivatives, and insertion of CN(2,6-$Me_2C_6H_3$) into the metal–alkyl bonds only afforded bis(iminoacyl) compounds. Formation of monoalkyl and monoiminoacyl complexes could not be detected in any of these reactions. NMR spectroscopic studies revealed that the iminoacyl ligand is η^2-coordinated in all of these compounds with the nitrogen atom always occupying the internal coordination site. C–C coupling reactions between the two iminoacyl ligands are very slow processes that give quantitative yields of the diazametallacyclopentene complexes after heating the toluene solutions of the bis(iminoacyl) complexes at 70–80 °C for 2–4 d.

Experimental Section

General Considerations: All manipulations were performed under argon using standard Schlenk and high-vacuum line techniques or a glovebox model MO40-2. Solvents were pre-dried and purified by distillation under argon from an appropriate drying agent (sodium for toluene, sodium/potassium alloy for hexane and sodium/benzophenone for diethyl ether and THF) before use. Deuterated solvents were stored over activated molecular sieves (4 Å) in Teflon-valved flasks and previously degassed by several freeze-pump-thaw cycles. NH_2tBu (Aldrich) was dried with sodium and distilled prior to use. $SiMe_2$(CH_2CH=CH_2)Cl (Aldrich), $SiMe_2Cl_2$ (Aldrich), *n*BuLi (Aldrich), $HfCl_4$ (Merck), MgClMe (Aldrich) and MgCl(CH_2Ph) (Aldrich) were purchased from commercial sources and used without further purification. C_5H_5[$SiMe_2$(CH_2CH=CH_2)],[51] [Li{$C_5H_4SiMe_2$(CH_2CH=CH_2)}],[51] and $ZrCl_4(THF)_2$[52] were prepared according to literature procedures. C, H and N microanalyses were performed with a Perkin–Elmer 240B. Unreliable elemental analytical data are not given for some highly soluble and air-sensitive compounds which could not be crystallised and were isolated as spectroscopically pure oily products. NMR spectra, measured at 25 °C, were recorded with a Varian Unity 300 (^{1}H NMR at 300 MHz and ^{13}C NMR at 75 MHz) spectrometer. ^{1}H and ^{13}C chemical shifts are reported in δ units relative to TMS standard.

Synthesis of C_5H_4($SiMe_2$Cl)[$SiMe_2$(CH_2CH=CH_2)] (1): $SiMe_2Cl_2$ (5.7 mL, 47 mmol) was added to a THF (100 mL) solution of [Li{η^5-$C_5H_4SiMe_2$(CH_2CH=CH_2)}] (8.0 g, 47 mmol), cooled to –78 °C and the mixture was stirred at room temperature for 16 h. The solvent was then removed under vacuum and the residue was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

extracted into hexane (2 × 50 mL). After filtration and evaporation of the solvent under reduced pressure, compound **1** was isolated as a yellow liquid (9.81 g, 38.18 mmol, 82% yield). $C_{12}H_{21}ClSi_2$ (256.92): calcd. C 56.10, H 8.24; found C 55.88, H 8.36. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.05 (s, 6 H, SiMe_2), 0.23 (s, 6 H, SiMe_2), 1.47 (d, J = 8.1 Hz, 2 H, SiCH_2), 4.86 (m, 2 H, CH=CH_2), 5.65 (m, 1 H, CH=CH_2), 6.57 (m, 2 H, C_5H_4), 6.81 (m, 2 H, C_5H_4) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = –2.9 (SiMe_2), 1.5 (SiMe_2), 22.8 (SiCH_2), 58.3 (C_5H_4, C_{ipso}), 113.9 (CH=CH_2), 133.1 (C_5H_4), 134.6 (C_5H_4), 134.9 (CH=CH_2) ppm. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.04 (s, 6 H, SiMe_2), 0.10 (s, 6 H, SiMe_2), 1.47 (d, J = 8.1 Hz, 2 H, SiCH_2), 4.86 (m, 2 H, CH=CH_2), 5.63 (m, 1 H, CH=CH_2), 6.40 (m, 2 H, C_5H_4), 6.64 (m, 2 H, C_5H_4) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = –2.9 (SiMe_2), 1.7 (SiMe_2), 22.6 (SiCH_2), 58.0 (C_5H_4, C_{ipso}), 113.6 (CH=CH_2), 132.8 (C_5H_4), 134.3 (C_5H_4), 134.7 (CH=CH_2) ppm.

Synthesis of C_5H_4[SiMe$_2$(CH$_2$CH=CH$_2$)][SiMe$_2$(NH*t*Bu)] (2): NH_2tBu (11.5 mL, 109 mmol) was added to a solution of **1** (14 g, 54.5 mmol) in THF at –78 °C. The mixture was slowly warmed to room temperature and stirred for 15 h. After removal of the solvent under vacuum, the residue was extracted into hexane and the ammonium chloride salt was removed by filtration. Product **2** was obtained as a yellow liquid (12.48 g, 42,51 mmol, 78% yield). $C_{16}H_{31}NSi_2$ (293.60): calcd. C 65.46 H, 10.64, N 4.77; found C 64.44, H 10.68, N 4.48. Major isomer: ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = –0.14 (s, 3 H, SiMe_2), –0.01 (s, 3 H, SiMe_2), 0.26 (s, 3 H, SiMe_2), 0.36 (s, 3 H, SiMe_2), 0.60 (br. s, 1 H, NH), 1.08 (s, 9 H, CMe_3), 1.45 (m, 2 H, SiCH_2), 3.23 (br. s, 1 H, C_5H_4), 4.93 (m, 2 H, CH=CH_2), 5.69 (m, 1 H, CH=CH_2), 6.60, 6.81, 6.89 (m, 3 H, C_5H_4) ppm. Minor isomer: ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.05 (s, 6 H, SiMe_2), 0.07 (s, 6 H, SiMe_2), 0.66 (br. s, 1 H, NH), 1.15 (s, 9 H, CMe_3), 1.74 (m, J = 8.1 Hz, 2 H, SiCH_2), 4.93 (m, 2 H, CH=CH_2), 5.88 (m, 1 H, CH=CH_2), 6.46, 6.72 (m, 3 H, C_5H_4) ppm.

Synthesis of C_5H_4[SiMe$_2$(CH$_2$CH=CH$_2$)][SiMe$_2$NH(2,6-Me$_2$C$_6$H$_3$)] (3): Compound **1** (13 g, 53 mmol) was added at room temperature to a suspension of LiNH(2,6-$Me_2C_6H_3$) (6.7 g, 53 mmol) in hexane (100 ml) and the mixture was stirred for 16 h. LiCl was filtered off and the solvent was removed from the resulting solution to give an orange oil which was identified as **3** (14.5 g, 42.4 mmol, 80% yield). Major isomer: ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = –0.20 (s, 3 H, SiMe_2), 0.01 (s, 3 H, SiMe_2), 0.14 (s, 3 H, SiMe_2), 0.34 (s, 3 H, SiMe_2), 1.39 (m, 2 H, SiCH_2), 2.15 (s, 6 H, C_6H_3 Me_2), 2.54 (br. s, 1 H, NH), 3.07 (br. s, 1 H, C_5H_4), 4.92 (m, 2 H, CH=CH_2), 5.68 (m, 1 H, CH=CH_2), 6.40–7.00 (m, C_5H_4 + C_6H_3) ppm. Minor isomer: ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.05 (s, 3 H, SiMe_2), 0.10 (s, 3 H, SiMe_2), 0.23 (s, 3 H, SiMe_2), 0.28 (s, 3 H, SiMe_2), 1.70 (m, 2 H, SiCH_2), 2.22 (s, 6 H, C_6H_3 Me_2), 2.54 (br. s, 1 H, NH), 2.92 (br. s, 1 H, C_5H_4), 4.92 (m, 2 H, CH=CH_2), 5.68 (m, 1 H, CH=CH_2), 6.40–700 (m, C_5H_4 + C_6H_3) ppm.

Synthesis of [Li$_2${1-SiMe$_2$N*t*Bu-3-SiMe$_2$(CH$_2$CH=CH$_2$)C$_5$H$_3$}] (4): A 1.6 M solution of *n*BuLi in hexane (17 ml, 28 mmol) was added dropwise to a solution of **3** (4 g, 14 mmol) in diethyl ether at –78 °C. The reaction mixture was warmed to room temperature and stirred for 4 h. The solvent was removed under reduced pressure to yield a solid, which was washed with hexane. The yellow solid was dried under vacuum and was characterised as **3** (3.85 g, 12.6 mmol, 90% yield). $C_{16}H_{29}Li_2NSi_2$ (305.47): calcd. C 62.91, H 9.57, N 4.59; found C 62.19, H 9.78, N 4.04. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.30 (s, 6 H, SiMe_2), 0.46 (s, 6 H, SiMe_2), 1.18 (s, 9 H, CMe_3), 1.83 (m, 2 H, SiCH_2), 4.89 (m, 2 H, CH=CH_2), 6.04 (m, 1 H, CH=CH_2), 6.65 (m, 1 H, C_5H_3), 6.80 (m, 1 H, C_5H_3), 6.90 (m, 1 H, C_5H_3) ppm.

Synthesis of [Li$_2${1-SiMe$_2$N(2,6-Me$_2$C$_6$H$_3$)-3-SiMe$_2$(CH$_2$CH=CH$_2$)-C$_5$H$_3$}] (5): A suspension of **3** (14 g, 41 mmol) in diethyl ether was treated at –78 °C with a 1.6 M hexane solution of *n*BuLi (51 mL, 82 mmol). The mixture was stirred at room temperature for 4 h and the solvent was then removed under vacuum to give a yellow solid which, after being washed with hexane (2 × 50 mL) and dried under vacuum, was identified as the dilithium salt **5** (13 g, 36.9 mmol, 90% yield). $C_{20}H_{29}Li_2NSi_2$ (353.51): calcd. C 67.95, H 8.27, N 3.96; found C 67.18, H 8.02, N 3.95. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.32 (s, 6 H, SiMe_2), 0.57 (s, 6 H, SiMe_2), 1.85 (m, 2 H, SiCH_2), 2.75 (s, 6 H, C_6H_3 Me_2), 4.90 (m, 2 H, CH=CH_2), 6.05 (m, 1 H, CH=CH_2), 6.75–7.45 (m, C_5H_3 + C_6H_3) ppm.

Synthesis of [Zr{η^5-C$_5$H$_3$(SiMe$_2$-η^1-N*t*Bu)[SiMe$_2$(CH$_2$CH=CH$_2$)]}Cl$_2$] (6): Toluene at –78 °C was added to a mixture of **4** (3 g, 9.8 mmol) and $ZrCl_4(THF)_2$ (3.7 g, 9.8 mmol) also cooled to –78 °C. The reaction mixture was warmed to room temperature and was stirred for 16 h. The toluene was removed under vacuum and the residue was extracted into hexane. The solvent volume was reduced and the solution was cooled to –40 °C to give yellow crystals which were isolated by filtration (2.67 g, 5.89 mmol, 60% yield). $C_{16}H_{29}Cl_2NSi_2Zr$ (453.71): calcd. C 42.36, H 6.44, N 3.09; found C 42.90, H 6.42, N 3.05. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.33 (s, 6 H, SiMe_2), 0.55 (s, 6 H, SiMe_2), 1.37 (s, 9 H, CMe_3), 1.77 (m, 2 H, SiCH_2), 4.86 (m, 2 H, CH=CH_2), 5.74 (m, 1 H, CH=CH_2), 6.44 (t, 1 H, C_5H_3), 6.58 (t, 1 H, C_5H_3), 7.02 (t, 1 H, C_5H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = –3.6 (SiMe_2), –3.3 (SiMe_2), 0.5 (SiMe_2), 0.9 (SiMe_2), 23.7 (SiCH_2), 32.5 (CMe_3), 57.1 (CMe$_3$), 111.9 (C_5H_3, C_{ipso}), 113.7 (CH=CH_2), 126.1 (C_5H_3), 127.1 (C_5H_3), 132.9 (C_5H_3, C_{ipso}), 133.5 (CH=CH_2) ppm.

Synthesis of [Hf{η^5-C$_5$H$_3$(SiMe$_2$-η^1-N*t*Bu)[SiMe$_2$(CH$_2$CH=CH$_2$)]}Cl$_2$] (7): Toluene cooled to –78 °C was added to a mixture of **4** (1.5 g, 4.9 mmol) and $HfCl_4$ (1.6 g, 4.9 mmol) also at –78 °C. The reaction mixture was stirred while it was warmed to room temperature. After the solution had been stirred overnight, the toluene was removed under reduced pressure and the residue was extracted into hexane. The solution was filtered and the solvent was removed to give **7** as an orange oil (1.59 g, 2.95 mmol, 60% yield). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.32 (s, 3 H, SiMe_2), 0.33 (s, 3 H, SiMe_2), 0.56 (s, 6 H, SiMe_2), 1.31 (s, 9 H, CMe_3), 1.77 (m, 2 H, SiCH$_2$), 4.89 (m, 2 H, CH=CH_2), 5.77 (m, 1 H, CH=CH_2), 6.35 (t, 1 H, C_5H_3), 6.49 (t, 1 H, C_5H_3), 6.97 (t, 1 H, C_5H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = –3.6 (SiMe_2), –3.3 (SiMe_2), 0.8 (SiMe_2), 1.2 (SiMe_2), 23.7 (SiCH_2), 33.2 (CMe_3), 55.6 (CMe$_3$), 111.8 (C_5H_3, C_{ipso}), 113.7 (CH=CH_2), 124.5 (C_5H_3), 125.6 (C_5H_3), 126.0 (C_5H_3), 131.6 (C_5H_3, C_{ipso}), 133.5 (CH=CH_2) ppm.

Synthesis of [Zr{η^5-C$_5$H$_3$[SiMe$_2$-η^1-N(2,6-Me$_2$C$_6$H$_3$)][SiMe$_2$(CH$_2$-CH=CH$_2$)]}Cl$_2$] (8): Toluene (100 mL) was added at –78 °C to a mixture of solid dilithium salt **5** (2 g, 5.66 mmol) and $ZrCl_4$·2THF (2.13 g; 5.66 mmol) and the mixture was then stirred at room temperature for 16 h. After filtration of the resulting LiCl, the solvent was removed under vacuum and the residue was extracted into hexane (2 × 50 mL). The solution was concentrated by evaporation of the solvent under reduced pressure and cooled to –35 °C to give compound **8** as an orange oily solid (0.91 g, 1.70 mmol, 30% yield). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = –0.04 (s, 3 H, SiMe_2), 0.12 (s, 3 H, SiMe_2), 0.38 (s, 3 H, SiMe_2), 0.39 (s, 3 H, SiMe_2), 1.52 (m, 2 H, SiCH_2), 1.80 (t, 4 H, C_2H_4), 2.10 (s, 3 H, C_6H_3 Me_2), 2.24 (s, 3 H, C_6H_3 Me_2), 3.70 (t, 4 H, OC_2H_4), 4.78 (m, 2 H, CH=CH_2), 5.61 (m, 1 H, CH=CH_2), 6.50 (t, 1 H, C_5H_3), 6.77 (t, 1 H, C_5H_3), 6.83 (t, 1 H, C_5H_3), 6.70–7.00 (m, 3 H, C_6H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = –2.7 (SiMe_2), –2.6 (SiMe_2), –0.4 (SiMe_2), 0.2 (SiMe_2), 20.3 (C_6H_3 Me_2), 20.6 (C_6H_3 Me_2), 24.8

($SiCH_2$), 25.3 (C_2H_4), 68.5 (OC_2H_4), 113.2 (CH=CH_2), 116.7 (C_5H_3, C_{ipso}), 122.4 (C_5H_3), 124.2 (C_5H_3), 127.8 (C_5H_3), 127.8, 129.8, 130.0, 130.7, 132.4 (C_6H_3), 134.2 (C_5H_3, C_{ipso}), 134.9 (CH=CH_2), 151.2 (C_6H_3, C_{ipso}) ppm.

Synthesis of [Hf{η^5-C_5H_3[$SiMe_2$-η^1-N(2,6-$Me_2C_6H_3$)][$SiMe_2$(CH_2-CH=CH_2)]}Cl_2] (9): Toluene (100 mL) was added at room temperature to a mixture of **5** (2 g, 5.66 mmol) and $HfCl_4$ (1.81 g, 5.66 mmol). The mixture was stirred for 16 h and the solvent was then removed under reduced pressure to give a residue which was extracted into hexane (2 × 50 mL) to separate the LiCl formed. The resulting solution was concentrated and cooled to –35 °C overnight to give a colourless solid identified as **9** (1.0 g, 1.7 mmol, 30% yield). $C_{20}H_{29}Cl_2HfNSi_2$ (589.02): calcd. C 40.78, H 4.96, N 2.38; found C 40.77, H 5.09, N 2.23. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.36 (s, 3 H, SiMe_2), 0.39 (s, 3 H, SiMe_2), 0.51 (s, 3 H, SiMe_2), 0.55 (s, 3 H, SiMe_2), 1.80 (m, 2 H, SiCH_2), 2.11 (s, 3 H, C_6H_3 Me_2), 2.14 (s, 3 H, C_6H_3 Me_2), 4.88 (m, 2 H, CH=CH_2), 5.77 (m, 1 H, CH=CH_2), 6.64 (t, 1 H, C_5H_3), 6.80 (t, 1 H, C_5H_3), 7.07 (t, 1 H, C_5H_3), 6.82–7.02 (m, 3 H, C_6H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 25 °C): δ = –3.0 (SiMe_2), –2.7 (SiMe_2), 0.1 (SiMe_2), 0.3 (SiMe_2), 19.6 (C_6H_3 Me_2), 19.7 (C_6H_3 Me_2), 24.2 (SiCH_2), 114.3 (CH=CH_2), 117.9 (C_5H_3, C_{ipso}), 123.9 (C_5H_3), 125.6 (C_5H_3), 125.8 (C_5H_3), 126.6–128.6 (C_6H_3), 133.7 (CH=CH_2), 142.5 (C_6H_3, C_{ipso}) ppm.

Synthesis of [Zr{η^5-C_5H_3[$SiMe_2$-η^1-N*t*Bu][$SiMe_2$(CH_2CH=CH_2)]}-Me_2] (10): A solution of MgClMe in THF (3.3 mL, 10 mmol) was added to a solution of **6** (2.3 g, 5.1 mmol) in hexane cooled to –78 °C. The reaction mixture was slowly warmed to room temperature and then stirred for 16 h. The solution was filtered and the solvent was removed under reduced pressure to give **10** as a brown oil (1.3 g, 3.1 mmol, 60% yield). $C_{18}H_{35}NSi_2Zr$ (412.87): calcd. C 52.37, H 8.54, N 3.39; found C 52.74, H 9.13, N 3.04. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.15 (s, 3 H, ZrMe_2), 0.17 (s, 3 H, ZrMe_2), 0.26 (s, 3 H, SiMe_2), 0.27 (s, 3 H, SiMe_2), 0.35 (s, 6 H, SiMe_2), 1.36 (s, 9 H, CMe_3), 1.70 (m, 2 H, SiCH_2), 4.92 (m, 2 H, CH=CH_2), 5.80 (m, 1 H, CH=CH_2), 6.27 (t, 1 H, C_5H_3), 6.36 (t, 1 H, C_5H_3), 6.72 (t, 1 H, C_5H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = –2.9 (SiMe_2), –2.7 (SiMe_2), 1.5 (SiMe_2), 2.0 (SiMe_2), 24.9 (SiCH_2), 34.2 (CMe_3), 35.1 (ZrMe_2), 35.7 (ZrMe_2), 55.5 (CMe$_3$, C_{ipso}), 107.1 (C_5H_3, C_{ipso}), 113.9 (CH=CH_2), 122.8 (C_5H_3), 124.8 (C_5H_3), 125.2 (C_5H_3), 126.8 (C_5H_3, C_{ipso}), 134.6 (CH=CH_2) ppm.

Synthesis of [Zr{η^5-C_5H_3[$SiMe_2$-η^1-N*t*Bu][$SiMe_2$(CH_2CH=CH_2)]}-(CH_2Ph)$_2$] (11): A 2 M THF solution of MgClBz (5 mL, 10 mmol) was added at –78 °C to a hexane solution of the dichloro complex **6** (2.3 g, 5.1 mmol). The mixture was stirred for 16 h while it was warmed to room temp. After filtration to separate $MgCl_2$, the solvent was removed under vacuum to give **11** as a brown oil (1.73 g, 3.06 mmol, 60% yield). ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.22 (s, 3 H, SiMe_2), 0.24 (s, 3 H, SiMe_2), 0.34 (s, 3 H, SiMe_2), 0.36 (s, 3 H, SiMe_2), 1.11 (s, 9 H, CMe_3), 1.60 (m, 2 H, SiCH_2), 1.50 (d, J = 11.0 Hz, 1 H, CH_2Ph), 1.71 (d, J = 10.3 Hz, 1 H, CH_2Ph), 2.10 (d, J = 11.2 Hz, 1 H, CH_2Ph), 2.15 (d, J = 10.1 Hz, 1 H, CH_2Ph), 4.92 (m, 2 H, CH=CH_2), 5.72 (m, 1 H, CH=CH_2), 6.18 (t, 1 H, C_5H_3), 6.25 (t, 1 H, C_5H_3), 6.52 (t, 1 H, C_5H_3), 6.86–7.18 (m, 10 H, C_6H_5) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = –2.7 (SiMe_2), –2.4 (SiMe_2), 1.5 (SiMe_2), 2.1 (SiMe_2), 25.3 (SiCH_2), 33.7 (CMe_3), 54.4 (ZrCH_2), 54.7 (CMe$_3$, C_{ipso}), 57.6 (ZrCH_2), 109.7 (C_5H_3, C_{ipso}), 114.0 (CH=CH_2), 122.4, 124.1, 125.4 (C_5H_3), 126.8, 127.7, 128. 3, 129.6, 129.7 (C_6H_5), 134.4 (CH=CH_2), 145.5, 145.9 (C_6H_5, C_{ipso}) ppm.

Synthesis of [Hf{η^5-C_5H_3[$SiMe_2$-η^1-N*t*Bu][$SiMe_2$(CH_2CH=CH_2)]}-Me_2] (12): A 3 M THF solution of MgClMe (2.9 mL, 8.8 mmol) was added at –78 °C to a solution of the dichloro complex **7** (2.4 g, 4.4 mmol) in hexane. The reaction mixture was stirred for 16 h while it was warmed slowly to room temp. The solution was filtered and the solvent removed under reduced pressure to give complex **12** as an orange oil (1.32 g, 2.64 mmol, 60% yield). $C_{18}H_{35}HfNSi_2$ (500.14): calcd. C 43.23, H 7.05, N 2.80; found C 43.09, H 7.51, N 2.67. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.00 (s, 3 H, HfMe_2), 0.03 (s, 3 H, HfMe_2), 0.24 (s, 3 H, SiMe_2), 0.26 (s, 3 H, SiMe_2), 0.38 (s, 6 H, SiMe_2), 1.32 (s, 9 H, CMe_3), 1.68 (m, 2 H, SiCH_2), 4.91 (m, 2 H, CH=CH_2), 5.78 (m, 1 H, CH=CH_2), 6.20 (t, 1 H, C_5H_3), 6.27 (t, 1 H, C_5H_3), 6.67 (t, 1 H, C_5H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = –2.6 (SiMe_2), –2.4 (SiMe_2), 2.0 (SiMe_2), 2.4 (SiMe_2), 25.2 (SiCH_2), 35.1 (CMe_3), 47.1 (HfMe_2), 48.0 (HfMe_2), 55.0 (CMe$_3$, C_{ipso}), 107.9 (C_5H_3, C_{ipso}), 114.3 (CH=CH_2), 122.9 (C_5H_3), 125.2 (C_5H_3), 125.7 (C_5H_3), 126.9 (C_5H_3, C_{ipso}), 134.9 (CH=CH_2) ppm.

Synthesis of [Hf{η^5-C_5H_3[$SiMe_2$-η^1-N*t*Bu][$SiMe_2$(CH_2CH=CH_2)]}-(CH_2Ph)$_2$] (13): The same procedure described to prepare **11** was applied using a 2 M THF solution of MgClBz (4.4 mL, 8.8 mmol) and **7** (2.4 g, 4.4 mmol) to give **13** as an orange oil (1.72 g, 2.64 mmol, 60% yield). $C_{30}H_{43}HfNSi_2$ (652.34): calcd. C 55.24, H 6.64, N 2.15; found C 55.23, H 5.99, N 2.28. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.22 (s, 3 H, SiMe_2), 0.24 (s, 3 H, SiMe_2), 0.38 (s, 3 H, SiMe_2), 0.41 (s, 3 H, SiMe_2), 1.19 (s, 9 H, CMe_3), 1.40 (d, J = 12.5 Hz, 1 H, CH_2Ph), 1.47 (d, J = 11.5 Hz, 1 H, CH_2Ph), 1.63 (m, 2 H, SiCH_2), 1.84 (d, J = 12.5 Hz, 1 H, CH_2Ph), 1.96 (d, J = 11.7 Hz, 1 H, CH_2Ph), 4.83 (m, 2 H, CH=CH_2), 5.69 (m, 1 H, CH=CH_2), 5.91 (t, 1 H, C_5H_3), 6.19 (t, 1 H, C_5H_3), 6.28 (t, 1 H, C_5H_3), 6.77–7.20 (m, 10 H, C_6H_5) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = –2.8 (SiMe_2), –2.6 (SiMe_2), 1.4 (SiMe_2), 2.0 (SiMe_2), 25.0 (SiCH_2), 34.5 (CMe_3), 56.4 (CMe$_3$, C_{ipso}), 71.2 (HfCH_2), 73.5 (HfCH_2), 109.2 (C_5H_3, C_{ipso}), 114.0 (CH=CH_2), 122.0, 122.5, 125.3 (C_5H_3), 126.5, 126.7, 128. 2, 128.7, 128.8 (C_6H_5), 134.4 (CH=CH_2), 147.0, 147.3 (C_6H_5, C_{ipso}) ppm.

Synthesis of [Zr{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)[$SiMe_2$(CH_2CH=CH_2)]}-{η^2-CMe=N(2,6-$Me_2C_6H_3$)}$_2$] (14): A solution of **10** (1.0 g, 2.42 mmol) in toluene (50 mL) was treated with a toluene (20 mL) solution of CN(2,6-$Me_2C_6H_3$) (0.63 g, 4.84 mmol) at room temperature. The mixture was stirred for 3 h and the solvent was then removed under vacuum. The residue was extracted into pentane (40 mL) and the solution was filtered and concentrated under reduced pressure to give a red oily product identified as compound **14** (1.31 g, 1.94 mmol, 80% yield). ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.11 (s, 3 H, SiMe_2), 0.25 (s, 3 H, SiMe_2), 0.70 (s, 6 H, SiMe_2), 1.11 (s, 9 H, CMe_3), 1.62 (m, 2 H, SiCH_2), 1.89 (s, 3 H, N$Me_2C_6H_3$), 1.93 (s, 6 H, N$Me_2C_6H_3$), 1.96 (s, 3 H, N$Me_2C_6H_3$), 2.05 (s, 3 H, CMe_2), 2.12 (s, 3 H, CMe_2), 4.90 (m, 2 H, CH=CH_2), 5.76 (m, 1 H, CH=CH_2), 6.33 (t, 1 H, C_5H_3), 6.53 (t, 1 H, C_5H_3), 6.61 (t, 1 H, C_5H_3), 6.90–7.00 (m, 6 H, C_6H_3) ppm. ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, 25 °C): δ = –2.7 (SiMe_2), –2.5 (SiMe_2), 3.9 (SiMe_2), 4.6 (SiMe_2), 18.4, 18.7, 18.9, 19.6 (N$Me_2C_6H_3$), 24.2 (SiCH_2), 25.5, 25.6 (CMe_2), 35.3 (CMe_3), 55.8 (CMe$_3$, C_{ipso}), 113.4 (CH=CH_2), 114.5 (C_5H_3, C_{ipso}), 119.2, 121.4, 121.7 (C_5H_3), 125.3–129.9 (C_6H_3), 135.1 (CH=CH_2), 146.9, 147.4 (NC), 253.0, 257.1 (CMe$_2$) ppm.

Synthesis of [Zr{η^5-C_5H_3($SiMe_2$-η^1-N*t*Bu)[$SiMe_2$(CH_2CH=CH_2)]}-{η^2-C(CH_2Ph)=N(2,6-$Me_2C_6H_3$)}$_2$] (15): A toluene (10 mL) solution of CN(2,6-$Me_2C_6H_3$) (0.37 g, 2.83 mmol) was added to a solution of **11** (0.80 g, 1.42 mmol) in toluene (40 mL) and the mixture was stirred at room temperature overnight. The solvent was re-

39.2 (CH_2Ph), 55.5 (CMe_3, C_{ipso}), 112.8 (N*C*=*C*N), 113.2 (CH=*C*H_2), 117.3, 119.4 (C_5H_3, C_{ipso}), 123.3, 123.8, 124.8 (C_5H_3), 125.8–129.4 (C_6H_3, C_6H_5), 134.7 (*C*H=CH_2), 138.6, 139.1, 149.4, 149.8 (C_6H_3, C_6H_5, C_{ipso}) ppm.

X-ray Structure Determination of [ZrCl(μ-Cl){η⁵-C_5H_3($SiMe_2$-η¹-N*t*Bu)[$SiMe_2$($CH_2CH=CH_2$)]}]₂ (6): Crystals of compound **6** were obtained by crystallisation from hexane, and a suitably sized crystal in a Lindemann tube was mounted on a Philips PW 1100 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystallographic and experimental details are summarised in Table 2. No decay was observed during the data collection. A semi-empirical method of absorption correction was applied (maximum and minimum values for the transmission coefficient were 1.000 and 0.665).[53] The structure was solved by direct methods (SIR97)[54] and refined by least squares against F_o^2 (SHELXL-97).[55] All the non-hydrogen atoms were refined anisotropically and the hydrogen atoms were introduced from geometrical calculations and refined using a riding model. The programs PARST[56] ad ORTEP[57] were also used. CCDC-273336 (**6**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 2. Crystal data and structure refinement for **6**.

Empirical formula	$C_{32}H_{58}Cl_4N_2Si_4Zr_2$
Formula mass	907.40
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system, space group	monoclinic, $P2_1/a$
Unit cell dimensions	a = 14.412(9) Å b = 12.300(6) Å, β = 92.29(2)° c = 12.784(6) Å
Volume	2264(2) Å^3
Z, calculated density	2, 1.331 Mg m^{-3}
Absorption coefficient	0.825 mm^{-1}
F(000)	936
Crystal size	0.45 × 0.25 × 0.20 mm
Theta range for data collection	3.19–24.00°
Limiting indices	$-16 \le h \le 16$, $0 \le k \le 14$, $0 \le l \le 14$
Reflections collected/unique	3729/3563 [R(int) = 0.0971]
Completeness to θ = 24.00	99.8%
Absorption correction	empirical
Max./min. transmission	1.000/0.665
Refinement method	full-matrix least squares on F^2
Data/restraints/parameters	3563/0/199
Goodness-of-fit on F^2	0.857
Final R indices [$I > 2\sigma(I)$]	R_1 = 0.0514, wR_2 = 0.1102
R indices (all data)	R_1 = 0.1346, wR_2 = 0.1372
Largest diff. peak and hole	0.444 and –0.503 e Å^{-3}

Acknowledgments

Financial support of our work by MEC (project MAT2004-02614) and DGU-CM (project GR/MAT/0622/2004) is gratefully acknowledged.

Effects of pyridyl-ring alkylation on complexation of Mn^{II}, Fe^{II}, Ni^{II}, Cu^{II} and Zn^{II} by chelators based on *r*-1,*c*-3,*c*-5-triaminocyclohexane (tach) have been studied. The chelators studied are *N*,*N*′,*N*′′-tris[(*x*-alkyl-2-pyridyl)methyl] derivatives of tach, where the ring substituents are 3-Me, 4-Me, 5-Me, 6-Me or 6-MeO ("tach-*x*-Rpyr"). Dicationic complexes were synthesized for most combinations of the above five metals and five chelators, using ClO_4^-, NO_3^-, Cl^-, or $CF_3SO_3^-$ as counterions. Their bonding, structure, and aqueous lability were analyzed by UV/Vis/NIR spectroscopy, magnetic moment determination, HPLC, and single-crystal X-ray crystallography. The striking features are seen in the 6-alkylated complexes, where steric repulsions between the 6-substituents at the threefold axis of the pseudo-octahedral coordination sphere result in a substantially weakened metal–ligand interaction. In the $[M(tach\text{-}6\text{-}Rpyr)]^{2+}$ series of divalent Mn, Ni, Cu and Zn, effects of these repulsions include bond angle and length distortions, decrease of the coordination number to five, shifts of d-d electronic transitions to lower energies, and spin-free complexes of the bound metal ion. Aqueous lability studies by HPLC agree with the spectroscopic findings. The bonding properties of the other tach-*x*-Mepyr chelators (x = 3, 4, 5) closely resemble the unalkylated parent tachpyr in solution. Similarly in the X-ray studies, $[Zn(tach\text{-}3\text{-}Mepyr)]^{2+}$ resembles $[Zn(tachpyr)]^{2+}$. The cytotoxicities of the chelators toward human breast cancer cells (MCF7) at a fixed chelator concentration of 16 μM show time-dependent induction of cell death in the order tach-3-Mepyr $>\approx$ tach-4-Mepyr $>$ tach-5-Mepyr $>$ tachpyr, whereas tach-6-Mepyr and tach-6-MeOpyr had no effect on the cells. The depressed cytotoxicities of the latter two are attributed to inability to bind Fe^{II} or Zn^{II} strongly.

Introduction

The tripodal aminopyridyl chelator tachpyr {*r*-1,*c*-3,*c*-5-tris[(2-pyridylmethyl)amino]cyclohexane} has been shown to readily complex divalent 3d transition metal ions;[1–4] tachpyr and its derivatives are under consideration as chemotherapeutic agents.[5–7] It is strongly cytotoxic to a variety of tumor cells as seen by an IC_{50} of 4.8 μM toward cultured bladder tumor cells. It is also preferentially toxic, showing a sevenfold decrease in IC_{50} in cancer cells relative to normal cells.[8] We have recently shown that it binds Zn^{II} and Fe^{II} in cells, and that the binding of Fe^{II} in vitro is accompanied by redox processes.[9] Metal complexes are well known to promote oxidative damage by catalyzing production of $HO^{\cdot}$, $O_2^{\cdot-}$, or other species collectively termed reactive oxygen species (ROS). We therefore pursue the hypotheses that tachpyr may affect cells by causing depri-

vation of essential biometals and/or that the complexes formed may go on to catalyze oxidative damage, particularly those of redox-active bioavailable metals such as Fe and Cu.

Study of pyridyl-ring-alkylated tachpyr variants appeared appropriate in order to change electronic properties or induce steric hindrance in tachpyr and its derivatives. Herein we focus on the ability of such derivatives to bind divalent biometals as seen from the coordination geometries and the electronic properties of $[M^{II}(tach\text{-}x\text{-}Rpyr)]^{2+}$ (Scheme 1; M = Mn, Fe, Ni, Cu, Zn; R = Me where x = 3–6 and R = MeO where x = 6). The electronic structure in solution has been studied by spectroscopy, and solid-state structures have been studied by single-crystal X-ray crystallography. Aqueous formation processes have been studied by electronic spectroscopy, and the lability of isolated complexes has been investigated by reversed-phase HPLC. Cytotoxicities of tach-*x*-Rpyr in human breast cancer (MCF7) cells are reported and the relationship of metal chelation to biological effects is discussed. In toxicity studies, tach-3-Mepyr, tach-6-Mepyr and tach-6-MeOpyr emerged as most interesting, tach-3-Mepyr due to more rapid onset of toxicity and the tach-6-Rpyr derivatives due to lack of toxicity, hence, these have received greater scrutiny in the present work.

Results and Discussion

Complexation Processes and Products

To investigate steric and electronic effects resulting from variation of the metal ion in the series **1*x***, **2*x***, **3*x***, **4*x*** and **5*x*** and of chelator in the series **#a**, **#b**, **#c**, **#d**, **#e** (Scheme 1), binding of Mn^{II}, Fe^{II}, Ni^{II}, Cu^{II}, and Zn^{II} by tach-*x*-Mepyr (x = 3, 4, 5, and 6) and tach-6-MeOpyr was studied in aqueous and nonaqueous solution. Isolation of complexes proceeded straightforwardly in MeOH by reaction of equimolar amounts of ligands and metal ion salts of counterions Cl^-, ClO_4^-, NO_3^- and $CF_3SO_3^-$ followed by precipitation with Et_2O. The counterion ClO_4^- provided superior material for X-ray study, while the other counterions were preferred for most solution studies due to greater aqueous solubility. Due to the ability of Fe^{II} to mediate oxidation of bound tachpyr,[2] all studies with this metal ion were conducted under anaerobic conditions. To study solution chemistry of alkylated tach chelators, complexation of Fe^{II}, Ni^{II}, Cu^{II} and Zn^{II} ions was carried out generally in water (for all tach-3-Mepyr and tach-6-Mepyr cases and most others; MeOH for a few cases) and the resulting solutions were analyzed. Adequate concentrations for analysis, ca. 5×10^{-2} M were obtained with all counterions except ClO_4^-. The appropriate physical methods were employed including UV/Vis/NIR spectroscopy, ^1H NMR spectroscopy, HPLC and solution magnetic moment determination. The electronic spectra from solution complexation closely resembled those of isolated complexes **2a**–**4e** in MeCN (Table 1 and Exp. Sect.). Mn^{II} complexation was generally not possible in aqueous media, and tach-6-Mepyr complexes were labile under HPLC conditions in some cases (see below). The spectral analyses of the solutions were consistent with six-coordination in all cases except $[Cu(tach\text{-}6\text{-}MeOpyr)]^{2+}$ which is discussed later.

HPLC studies provided good qualitative indications of lability trends and lipophilicities as a function of chelator and metal ion. The method very clearly distinguished metal

[a] All Fe^{II} and Ni^{II} complex spectra measured in MeCN; all Cu^{II} spectra measured in MeOH except [Cu(tach-6-Mepyr)]$(ClO_4)_2$ and [Cu(tach-6-MeOpyr)]$(ClO_4)_2$ which were measured in H_2O. [b] In the case of d-d transitions, assignments of pseudo-octahedral complexes are made in the O_h point group while the square-pyramidal Cu^{II} complexes are given as transitions between individual orbitals according to literature conventions.

complex from metal chelator and was particularly appropriate for study of Zn^{II} and Mn^{II} speciation where Vis/NIR spectroscopy is not available.[1,9] Due to their polarity the metal complexes eluted at 12 to 15 min, whereas free chelator retention times were upwards of 20 min. The separation was improved by isocratic elution with a mobile phase of 90% Et_3N/HOAc buffer and 10% MeOH in order to clearly discriminate complexes of different metal ions with the same chelator.

The Mn^{II} complexes **1d** and **1e** could be prepared in MeOH, but they dissociated completely under HPLC analysis, as expected given the poor match of size and hard–soft acid–base properties as well as the steric effects of 6-substitution of the coordinating pyridine ring. The $[Zn(tach\text{-}6\text{-}Mepyr)]^{2+}$ complex **5d** was also labile, but $[Zn(tach\text{-}3\text{-}Mepyr)]^{2+}$ (**5a**) and $[Zn(tachpyr)]^{2+}$ (**5f**) yielded clean single peaks, indicative of inertness.

Ring alkylation of tachpyr increased lipophilicity of chelators and complexes as shown by RP-HPLC studies in the gradient mode. Thus, the free chelator tachpyr and $[Zn(tachpyr)]^{2+}$ eluted at substantially shorter times (18.8 min and 8.4 min) than the respective alkylated compounds tach-3-Mepyr and $[Zn(tach\text{-}3\text{-}Mepyr)]^{2+}$ (22.9 min and 14.6 min).

^1H NMR spectra of complexes **2a**–**c** and **5a**–**e** are consistent with the octahedral-enforcing nature of tach-framework chelators as previously shown in $[Ni(tachpyr)]^{2+}$, $[Zn(tachpyr)]^{2+}$ and $[Ga(tachpyr)]^{3+}$.[4] Characteristic patterns of proton–proton coupling between cyclohexyl H atoms indicate "closed", complexed tach as opposed to "open" tach.[1] The two methylene protons of the coordinated pendant arms are diastereotopic, indicating that the arms of these complexes are twisted about the metal ion in the Δ or Λ configuration, and Δ–Λ interconversion does not occur on the NMR time-scale at room temperature, also as previously found for $[M(tachpyr)]^{2+}$ (M = Fe^{II}, Zn^{II}, Ga^{III}, In^{III}).[1,2,18]

In total, synthetic and physical studies demonstrate the alkylated derivatives of tachpyr to be effective chelators of Fe^{II}, Ni^{II}, Cu^{II} and Zn^{II}, while Mn^{II} is not bound in aqueous media, and some of the 6-alkylated tachpyr variants are labile in aqueous media.

Electronic Structure

To examine metal-complex structures in solution and assess effects of pyridyl substituents at various positions, the UV/Vis/NIR spectra of the Fe^{II}, Ni^{II}, and Cu^{II} complexes were measured, assigned, and compared with other amino/pyridyl–metal compounds (Table 1). The spectral assignments for Ni^{II} and Cu^{II} complexes were made as previously reported for their complexes of tachpyr and *N*-alkylated tachpyr derivatives.[1,3] The Fe^{II} complexes **2a**–**c** exhibit a large absorption band at 22600–23100 cm^{-1} with a weak low-energy shoulder at 17400–18200 cm^{-1}. We assign the intense absorption to a metal-to-ligand charge-transfer band ($d\pi \rightarrow p\pi^*$) typical of LS Fe^{II} complexes with π-acceptor ligands.[19–22] This absorption appears to mask all d-d transitions except the low-energy shoulder that is generally assigned as the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition in LS Fe^{II} or Co^{III} complexes.[20,23]

Comparison across the chelate tach-*x*-Mepyr series shows that 6-substituted ligands have weaker field strength toward Fe^{II}, Ni^{II}, and Cu^{II}, while methyl substitution at the 3, 4, and 5 positions on the pyridine rings has no notable effect on the field strength relative to tachpyr. Thus, the 6-substituted Ni^{II} complexes **3d** and **3e** have lower d-d transition energies as compared to the 3-, 4- and 5-substituted compounds **3a**–**c**. In the Fe^{II} series, 6-substitution causes a shift of Fe^{II} from low-spin (LS) to high-spin (HS) state. The Fe^{II} complexes **2d** and **2e** contain a considerably weaker MLCT band around 28500 cm^{-1} with a slight shoulder to lower energy. The MLCT band is weaker as is typical for HS Fe^{II}.[20] Additionally there is a very weak absorption at 11100–11800 cm^{-1}. This absorption is assigned to a $^5T_{2g} \rightarrow {}^5E_g$ transition, as is seen in $[Fe([12]aneN_3py_3)]^{2+}$ and other HS Fe^{II} complexes.[19,20,22]

Alkylation of the pyridyl 6-position leads to a five-coordinate complex in the case of Cu^{II}. The UV/Vis/NIR spectrum of $[Cu(tach\text{-}6\text{-}MeOpyr)]^{2+}$ **4e** displays a low energy shoulder indicative of five-coordination as seen for $[Cu(tach\text{-}6\text{-}Mepyr)]^{2+}$ (**4d**).[3] We obtain a satisfactory fit to three Gaussian peaks (Figure 1) which we assign to the $d_{z^2} \rightarrow d_{x^2-y^2}$, $d_{xy} \rightarrow d_{x^2-y^2}$, and $d_{xy,yz} \rightarrow d_{x^2-y^2}$ transitions in order of increasing energy as has been shown for aqueous $[Cu(tach\text{-}Et_3)(H_2O)_2]^{2+}$ and other square-pyramidal Cu^{II} complexes.[24–26] The molar absorptivities of the component peaks are relatively high, ca. 25–160 M^{-1} cm^{-1} as is typical of d-d transitions of square-pyramidal copper complexes where parity-forbidden Laporte selection rules are relaxed by lowered symmetry.[27]

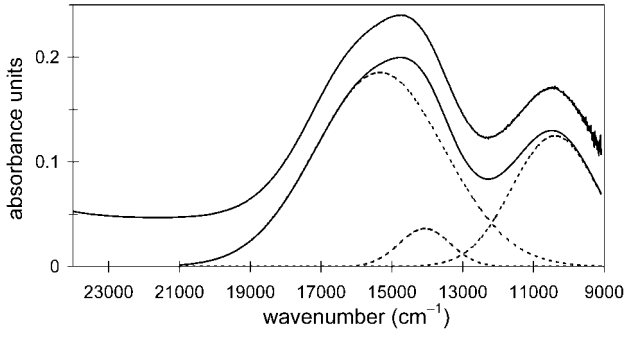

Figure 1. Resolution of the electronic spectrum of $[Cu(tach\text{-}6\text{-}MeOpyr)](ClO_4)_2$ (aq) into bands (L to R, dotted lines): $d_{xz,yz} \rightarrow d_{x^2-y^2}$, $d_{yz} \rightarrow d_{x^2-y^2}$ and $d_{z^2} \rightarrow d_{x^2-y^2}$. The calculated spectrum in the range 21000–9000 cm^{-1} is shown as a solid line and the experimental spectrum at 0.04 absorbance units above.

Overall, the weakened interactions between the 6-substituted ligands and the divalent metal centers that are seen here result in a substantially weakened ligand field as seen from coordination number, spin state, or d-d electronic transitions of the bound metal ion. The effects are due to steric hindrance produced by the methyl or methoxy groups when the pyridyl rings are brought into proximity in the closed conformation of the chelator.

Cytotoxicity Studies

The cytotoxicities of tach-*x*-Mepyr (*x* = 3–6) and of tach-6-MeOpyr were studied against a tachpyr control (Figure 2). Using a fixed concentration of chelator (16 μM), extent of cell death in the first 24 h varied considerably, whereas at the 72 h timepoint all chelators except tach-6-Mepyr and tach-6-MeOpyr had caused loss of 75–80% of cell viability. The lack of toxicity in the 6-substituted chelators is as expected because their metal-binding properties are sterically hindered as demonstrated by the solution UV/Vis spectra. However, there are significant differences in rate of cell killing, in the order tach-3-Mepyr $>\approx$ tach-4-Mepyr $>$ tach-5-Mepyr $>$ tachpyr. There is no corresponding variation in the ligand-field strength as a function of alkylated position on pyridine.

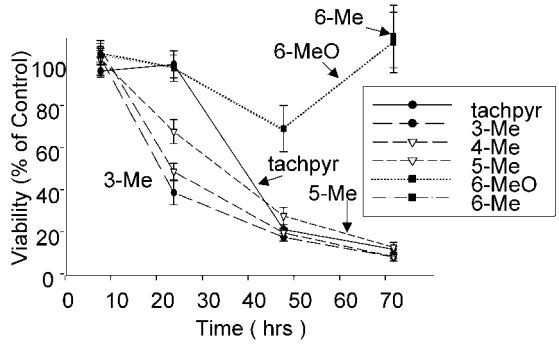

Figure 2. MCF7 cells were treated with 16 μM tach-*x*-Rpyr for the indicated times (8, 24, 48 and 72 h) and viability assessed using an MTT assay as described in Exp. Sect. Viability was expressed as percent survival relative to the control cells, which were untreated. Means and standard errors of 3 independent experiments are shown. In the case of 6-methyl-tachpyridine, only the 72 h timepoint was assessed.

Structural Studies

To elucidate the influences of the metal ion and alkylation of the pyridine rings of tachpyr upon bonding in the complexes, we undertook crystallographic studies of selected complexes. These studies focused on 6-alkylated and

[a] In structures with two independent molecules per asymmetric unit, pairs of corresponding distances or angles are given in brackets.

3-alkylated pyridyl derivatives because of their particular influences on lability or biological activity. The salient findings are presented in Table 2, and views of selected complex cations are shown in Figures 3, 4, 5, 6 and 7.

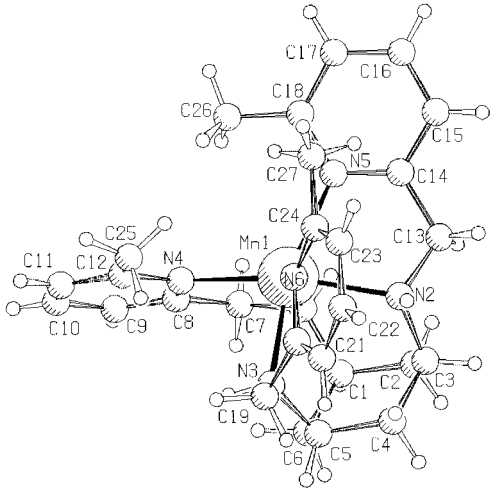

Figure 3. Projection along the N6–Mn bond of one cation in the asymmetric unit of $[Mn(tach\text{-}6\text{-}Mepyr)](ClO_4)_2\cdot 0.5H_2O\cdot 0.5MeOH$ (**1d**·$0.5H_2O$·0.5MeOH) (PLUTO) showing that the pyridyl ring C21•••C24 is not coplanar with the N6–Mn1 bond.

The M–N(amino) bond lengths of the complexes are generally comparable to the unalkylated analogues $[M(tachpyr)]^{2+}$ (M = Ni^{II}, Zn^{II}, Mn^{II})[1] and to other aminopyridyl ligands. They correlate well with the divalent metal ionic radii; as the six-coordinate ionic radius[28,29] increases from Ni^{II} (0.83 Å) to Zn^{II} (0.88 Å) to Mn^{II} (0.97 Å), the M–N bond lengths increase as well.

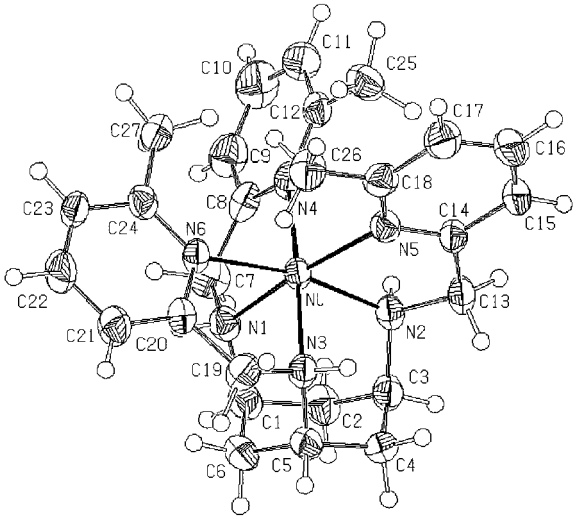

Figure 4. ORTEP view of the complex cation of $[Ni(tach\text{-}6\text{-}Mepyr)](NO_3)_2\cdot 0.5Et_2O$ (**3d′**·$0.5Et_2O$) (50% probability ellipsoids).

From the structural standpoint, 3-alkylation has little effect on complexation geometry in the solid state. The M–N bond lengths and the twist angle of $[Zn(tach\text{-}3\text{-}Mepyr)]^{2+}$ (**5a**) (Figure 6) are very comparable to those of $[Zn(tachpyr)]^{2+}$.[4]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

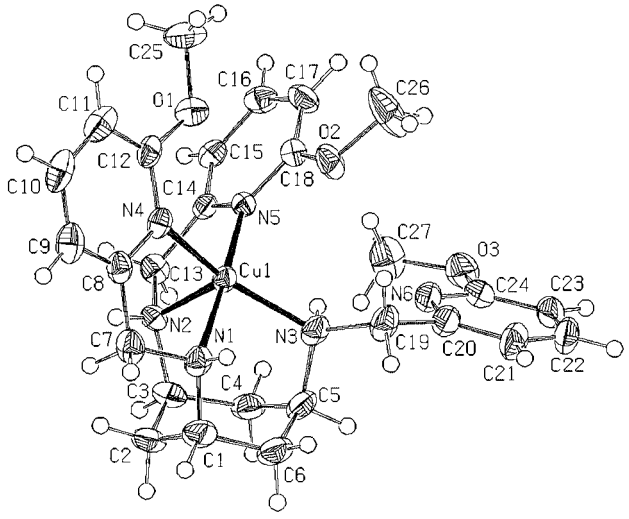

Figure 5. ORTEP view of one molecule in the asymmetric unit of $[Cu(tach\text{-}6\text{-}MeOpyr)](ClO_4)_2$ (**4e**) (50% probability ellipsoids).

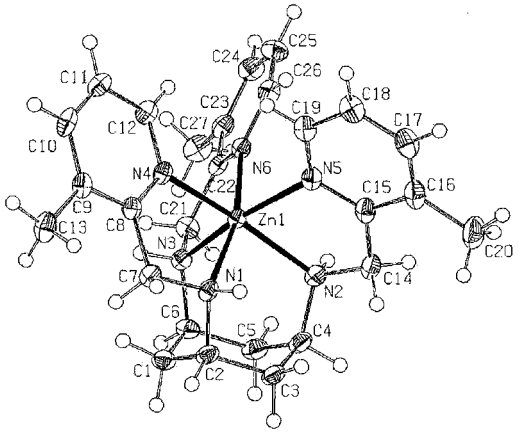

Figure 6. ORTEP view of one molecule in the asymmetric unit of $[Zn(tach\text{-}3\text{-}Mepyr)](NO_3)_2{\cdot}2MeOH{\cdot}0.5H_2O$ (**5a**·2MeOH·0.5H_2O) (50% probability ellipsoids).

However, the M–N(pyridyl) distances vary substantially in the 6-alkylated compounds. Elongations of the $Mn–N_{(py)}$ bond lengths due to steric hindrance may be uniform as seen in the cations $[Ni(tach\text{-}6\text{-}Mepyr)]^{2+}$ (**3d′**) (Figure 4) and $[Mn(tach\text{-}6\text{-}MeOpyr)]^{2+}$ (**1e**) or non-uniform as in $[Zn(tach\text{-}6\text{-}Mepyr)]^{2+}$ (**5d′**) (Figure 7) and $[Mn(tach\text{-}6\text{-}Mepyr)]^{2+}$ (**1d**) (Figure 3). The Ni^{II} complex **3d′** shows a uniform elongation (i.e., $Ni^{II}–N_{(py)}$ distances increase similarly) by roughly 0.11 Å relative to $[Ni(tachpyr)]^{2+}$ for all three $N_{(py)}$ donor atoms. In contrast, the Zn^{II} complex **5d′** shows two lesser elongations (ca. 0.050 Å) of the $Zn–N_{(py)}$ bonds and one very long bond with an elongation of ca. 0.38 Å. In the non-uniform elongation case, it is notable that the plane of the pyridyl ring is not coplanar with the longest $M^{II}–N_{(py)}$ bond; thus, the lone pair of the pyridyl N atom is directed away from the metal center. This is illustrated by a projection of $[Mn(tach\text{-}6\text{-}Mepyr)]^{2+}$ along the (longest) Mn1–N6 bond in Figure 3.

The compound $[Cu(tach\text{-}6\text{-}MeOpyr)](ClO_4)_2$ (**4e**) is five-coordinate in the solid state (Figure 5), consistent with the

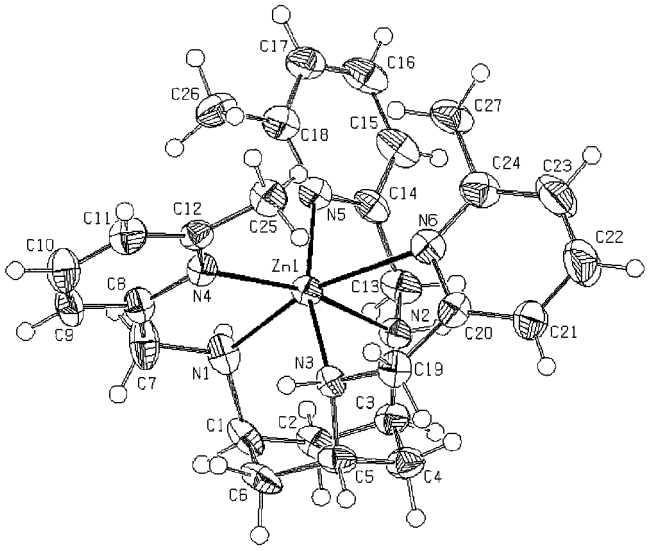

Figure 7. ORTEP view of one molecule in the asymmetric unit of $[Zn(tach\text{-}6\text{-}Mepyr)](ClO_4)_2{\cdot}0.5H_2O{\cdot}0.5MeOH$ (**5d′**·0.5H_2O·0.5MeOH) (50% probability ellipsoids).

assigned aqueous structure. This complex has four shorter bonds and one longer bond as expected in Jahn–Teller-distorted Cu^{II}, and previously observed in $[Cu(tach\text{-}6\text{-}Mepyr)](ClO_4)_2$ (**4d**).[3] The shorter bond lengths of **4e** [range 1.994(3) to 2.102(3) Å] compare favorably to those of **4d** [range 2.001(3)–2.103(3) Å] (Table 2), and the long distances [average of 2.171(3) Å in two molecules in the asymmetric unit] are somewhat shorter than in **4d** [2.216(3) Å]. Sterically crowded Cu^{II} is well known to assume coordination geometries varying from square-based pyramidal to trigonal-bipyramidal. In these cases the coordination geometry may be described by the in-plane angular distortion $\tau = (\beta - \alpha)/60°$, where β and α are the two basal angles formed by the *trans* ligands and the metal ion. The ideal square pyramid is defined by $\tau = 0$ and the trigonal bipyramid by $\tau = 1$.[30] The shape of Cu^{II} compound **4e** is closer to a square-based pyramid with an average $\tau = 0.26$ whereas **4d** has a more distorted intermediate shape, with $\tau = 0.58$.

In the case of Mn^{II}, the 6-substitution of the pyridyl ring makes the trigonal-prismatic geometry less favorable than distorted octahedral, as shown by comparison of trigonal twist angle (Φ) values in $[Mn(tach\text{-}6\text{-}Mepyr)]^{2+}$ (**1d**) and $[Mn(tach\text{-}6\text{-}MeOpyr)]^{2+}$ (**1e**) to $[Mn(tachpyr)]^{2+}$.[1] The Φ value is the angle by which the triangles of pyridyl N atoms and amino N atoms are staggered, as viewed down the pseudo-C_3 axis. The octahedron possesses perfect staggering with an angle $\Phi = 60°$ and the trigonal prism is perfectly eclipsed with $\Phi = 0°$. The value of Φ for $[Mn(tachpyr)]^{2+}$ is 2.5° while values of Φ for **1d** and **1e** are 52.6° and 44.8°, respectively. The drastic change in Φ reflects the closeness of 6-substituents to each other in a trigonal prism. It was observed in $[Mn(tachpyr)]^{2+}$ that extension of the pendant arms into a planar arrangement [i.e., making the N(H)–CH_2–(2-pyridyl) framework planar], to achieve a trigonal-prismatic coordination sphere, allowed the most favorable bite angles for a large metal ion. However, in the trigonal

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

prism the groups at the 6-pyridyl position must point directly at each other. Thus, **1d** and **1e** attain larger Φ values because sterics make the trigonal-prismatic geometry unfavorable in this case. Additionally, binding a metal ion into the trigonal-prismatic geometry of an aminopyridyl tach chelator causes severe distortions of the coordination geometry of the tach nitrogen atoms, forcing them into a trigonal-pyramidal geometry (with H at the apex of the pyramid).[1] In **1d** similarly to **5d**, the third arm is forced away from the other two at a greater Mn–N bond length, and it is unable to attain good overlap of the N(py) lone pair with Mn^{II} (Figure 3). In **1e**, steric effects do not seem as great, and the average N(py)–Mn bond length is marginally shorter than that of $[Mn(tachpyr)]^{2+}$ (Table 2).

Conclusions

The 6-position has a considerable effect on metal-binding properties in tach-6-Mepyr due to steric interactions amongst 6-substituents in metal-bound tach-6-Rpyr. On the other hand, there appears to be little electronic effect of 3-, 4-, or 5-alkylation on ligand-field strength in the tach-*x*-Mepyr series, nor any steric effect of 3-alkylation. The biological differences between tach-3-Mepyr and tachpyr appear to derive from other factors such as a difference in rate of metal ion binding, or formation constants of metal–ligand interaction, or other parameters specific to the Fe^{II} complexes. Studies of formation constants and complexation reactivities to compare the interactions of Zn^{II} and Fe^{II} with tach-3-Mepyr and tachpyr are therefore in progress.

Experimental Section

General: Full physical characterization of complexes was carried out with material prepared and isolated using nonaqueous solvents without optimization of yields. Aqueous complexation studies are described by a general procedure for each metal. X-ray crystallography was carried out on the isolated complexes from nonaqueous media. Cytotoxicity studies were performed with phosphate-buffered saline solutions of the free chelators, which were prepared as reported.[3,10]

Materials and Methods: All the materials cited below were of research grade or spectro-quality grade in the highest purity available and were generally obtained from commercial sources and used without further purification except Et_2O. Et_2O was distilled from Na and used immediately. $[D_6]$DMSO was obtained from Cambridge Isotope Laboratories. UV/Vis/NIR solution electronic spectra were measured using a Varian Cary 5 or a Varian Cary 50-Bio UV/Vis spectrometer with 1- or 3-mL quartz cuvettes (1 cm path length). Solid-phase Vis spectra were obtained with a model RSA-HP-53 reflectance spectroscopy attachment (Labsphere, Inc.) to an HP8453 diode-array instrument. All solution UV/Vis/NIR spectra are presented in Table 1; deconvolutions of Cu^{II} spectra were performed using Microcal Origin 6.0 software. Electrospray ionization (ESI) mass spectra in the positive ion detection mode were obtained with a Finnegan LCQ Classic instrument with dual optical Paul traps and Picoview nanospray source. Fast-atom bombardment mass spectra (FAB-MS) were taken with an Extrel 4000 instrument in the positive ion detection mode. Samples were desorbed from mixtures of DMSO and Magic Bullet ("MB"). Calculations from the program developed by Scientific Instrument Services (http://www.sisweb.com/cgi-bin/mass10.pl, accessed August 2, 2004) aided in assignment of peaks. ^{1}H NMR spectra were obtained using a Bruker AM360 instrument or a Varian Mercury 400 MHz instrument. Chemical shifts are reported in ppm on the δ scale relative to TMS. Magnetic moments were determined using Evans' method.[11] Elemental analysis was performed by Atlantic Microlabs (Atlanta, Georgia). Drying was accomplished in air or under reduced pressure (ca. 10^{-2} Torr) with a standard Schlenk line. All work with Fe^{II} was conducted with standard Schlenk or glovebox techniques under prepurified N_2 or Ar due to the oxidation sensitivity of the complexes.[12]

CAUTION: Perchlorate salts can be explosive and should be handled with care. No explosions occurred during the course of this work.

Metal Complex Syntheses

[Mn(tach-6-Mepyr)](ClO$_4$)$_2$·H$_2$O (1d·H$_2$O): A colorless solution of $Mn(ClO_4)_2{\cdot}6H_2O$ (0.0899 g, 2.48×10^{-4} mol) in MeOH (2 mL) was added to a pale yellow solution of tach-6-Mepyr (0.110 g, 2.48×10^{-4} mol) in MeOH (2 mL) affording yellow prisms suitable for X-ray diffraction (shown to be **1d**·1/2MeOH·1/2H$_2$O). The crystals were isolated and dried under reduced pressure giving a pale yellow solid. The solid was washed with MeOH (5 mL) and Et_2O (5 mL) and dissolved in MeCN followed by vapor-phase diffusion of Et_2O generating yellow prisms. The prisms were isolated and dried under reduced pressure affording a yellow solid in 73.9% yield (0.128 g, 1.83×10^{-4} mol). MS (ESI): m/z = 498 [M – 2 ClO_4^- – H^+], 598 [M – ClO_4]. μ_{eff} (DMSO, 25 °C) = 5.79 B.M. $C_{27}H_{38}Cl_2MnN_6O_9$ (715.15): calcd. C 45.26, H 5.35, N 11.73; found C 44.93, H 5.16, N 11.98.

[Mn(tach-6-Mepyr)](CF$_3$SO$_3$)$_2$ (1d′): A solution of $Mn(CF_3SO_3)_2{\cdot}6H_2O$ (0.083 g, 1.8×10^{-4} mol) in MeOH (2 mL) was added to a pale yellow solution of tach-6-Mepyr (0.079 g, 1.8×10^{-4} mol) in MeOH (2 mL) giving a pale yellow solution. Addition of dry Et_2O (20 mL) to this solution gave a pale-yellow oil that was isolated by decantation and triturated to a light tan powder with Et_2O (2 × 20 mL). The powder was dried under reduced pressure, then taken up in MeOH (3 mL) and subjected to vapor-phase diffusion of Et_2O to provide colorless prisms that were isolated and dried under reduced pressure affording a 46% yield (0.066 g, 8.3×10^{-5} mol) of white prisms. HPLC (gradient mode): Identical to free ligand at $R_t \approx$ 21.0 min. MS (FAB/glycerol): m/z = 648 [M – $CF_3SO_3^-$]$^+$. $C_{29}H_{36}F_6MnN_6O_6S_2$ (797.14): calcd. C 43.67, H 4.55, N 10.54; found C 43.62, H 4.51, N 10.50.

[Mn(tach-6-MeOpyr)](CF$_3$SO$_3$)$_2$ (1e): A solution of $Mn(CF_3SO_3)_2{\cdot}6H_2O$ (0.058 g, 1.3×10^{-4} mol) in MeOH (2 mL) was mixed with a pale yellow solution of tach-6-MeOpyr (0.059 g, 1.2×10^{-4} mol) in MeOH (2 mL), giving a pale yellow solution. Addition of dry Et_2O (20 mL) to this solution gave a pale yellow oil that was isolated by decantation and triturated to a white powder with Et_2O (2 × 20 mL). The powder was dried under reduced pressure, then taken up in MeOH (3 mL) and subjected to vapor-phase diffusion of Et_2O to provide colorless prisms (**1e**·MeOH) suitable for X-ray diffraction. The prisms were isolated and dried under reduced pressure affording a 58% yield (0.059 g, 7.0×10^{-5} mol) of white prisms. μ_{eff} (DMSO, 25 °C) = 5.70 B.M. MS (FAB/gly): m/z = 696 [M – $CF_3SO_3^-$]$^+$, 532 [M –2 $CF_3SO_3^-$ – CH_3^+]$^+$. HPLC (gradient mode): identical to free ligand at R_t = 23.7 min. $C_{29}H_{36}F_6MnN_6O_9S_2$ (845.13): calcd. C 41.19, H 4.29, N 9.94; found C 41.03, H 4.33, N 9.86.

[Fe(tach-3-Mepyr)]Cl_2·1.5H_2O (2a·1.5H_2O): A pale green solution of $FeCl_2$·4H_2O (0.0070 g, 3.53 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-3-Mepyr (0.0155 g, 3.48 × 10^{-5} mol) in MeOH (1 mL) producing a brown-yellow solution. Et_2O (2 mL) was added and the solution let stand for 48 h at 10 °C producing clusters of carmine red needles. Product was isolated and dried under reduced pressure affording deep red needles. ^{1}H NMR (400 MHz, [D_6]DMSO, 25 °C): δ = 7.59, 7.15, 6.91 (d, dd, d, 3 H, 3-MeC_5H_3N), 5.29 (br. t, 1 H, N*H*CH_2), 4.23, 4.02 (dd, dd, 2 H, NHC*H*$_2$py, diastereotopic), 2.95 (br. s, 1 H, cyclohexyl methine *H*), 2.37 (s, 3 H, C*H*$_3$py), 2.12 (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.84 (br. d, 1 H, axial cyclohexyl methylene *H*). $C_{27}H_{39}Cl_2FeN_6O_{1.5}$ (597.19): calcd. C 54.25, H 6.58, N 14.07; found C 54.17, H 6.22, N 13.76.

[Fe(tach-4-Mepyr)]Cl_2·1.5H_2O (2b·1.5H_2O): A pale green solution of $FeCl_2$·4H_2O (0.0110 g, 5.53 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-4-Mepyr (0.0244 g, 5.49 × 10^{-5} mol) in MeOH (1 mL) affording a brown-yellow solution. Slow Et_2O diffusion produced several deep red microcrystals. The supernatant was decanted and the microcrystals were dried under reduced pressure. ^{1}H NMR (400 MHz, [D_6]DMSO, 25 °C): δ = 7.42, 7.17, 6.86 (s, d, d, 3 H, 4-MeC_5H_3N), 5.45 (br. t, 1 H, N*H*CH_2), 4.43, 4.19 (dd, dd, 2 H, NHC*H*$_2$py, diastereotopic), 3.21 (br. s, 1 H, cyclohexyl methine *H*), 2.37 (s, 3 H, C*H*$_3$py), 2.02 (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.79 (br. d, 1 H, axial cyclohexyl methylene *H*). $C_{27}H_{39}Cl_2FeN_6O_{1.5}$ (597.19): calcd. C 54.25, H 6.58, N 14.07; found C 54.56, H 6.16, N 13.86.

[Fe(tach-5-Mepyr)]Cl_2·H_2O (2c·H_2O): A pale green solution of $FeCl_2$·4H_2O (0.0108 g, 5.43 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-5-Mepyr (0.0235 g, 5.28 × 10^{-5} mol) in MeOH (1 mL) creating a brown-yellow solution. Addition of Et_2O (ca. 20 mL) produced a slightly cloudy solution that yielded carmine red needles upon standing one week. The supernatant was decanted and the product was allowed to air dry giving deep red needles. ^{1}H NMR (400 MHz, [D_6]DMSO, 25 °C): δ = 7.65, 7.49, 6.78 (d, d, s, 3 H, 5-MeC_5H_3N), 5.57 (br. t, 1 H, N*H*CH_2), 4.43, 4.12 (dd, dd, 2 H, NHC*H*$_2$py), 3.13 (br. s, 1 H, cyclohexyl methine *H*), 2.08 (partially obscured) (s, 3 H, C*H*$_3$py), 2.09 (partially obscured) (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.81 (br. d, 1 H, axial cyclohexyl methylene *H*). $C_{27}H_{38}Cl_2FeN_6O$: calcd. (588.18) C 55.08, H 6.51, N 14.28; found C 54.73, H 6.45, N 13.88.

[Fe(tach-6-Mepyr)]$(ClO_4)_2$·H_2O (2d·H_2O): A yellow solution of $Fe(ClO_4)_2$·6H_2O (0.0160 g, 4.41 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-6-Mepyr (19.5 g, 4.39 × 10^{-5} mol) in MeOH (1 mL) producing a dark red solution. During 24 h at 5 °C red needles precipitated from the solution. Removal of the supernatant and air-drying produced bright red needles. μ_{eff} (DMSO, 25 °C) = 5.46 B.M. at 25 °C. $C_{27}H_{38}Cl_2FeN_6O_9$ (716.14): calcd. C 45.24, H 5.35, N 11.73; found C 45.45, H 5.31, N 11.61.

[Fe(tach-6-MeOpyr)]Cl_2·1.5H_2O (2e·1.5H_2O): A pale green solution of $FeCl_2$·4H_2O (0.0113 g, 5.68 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-6-MeOpyr (0.0276 g, 5.61 × 10^{-5} mol) in MeOH (1 mL) producing a yellow solution. Addition of ca. 15 mL of Et_2O produced a slightly cloudy solution that deposited yellow prisms upon standing 48 h. The supernatant was decanted and the product allowed to air-dry resulting in bright yellow prisms. μ_{eff} (DMSO, 25 °C) = 5.77 B.M. at 25 °C. $C_{27}H_{39}Cl_2FeN_6O_{4.5}$ (645.17): calcd. C 50.22, H 6.09, N 13.02; found C 50.21, H 6.10, N 12.84.

[Ni(tach-3-Mepyr)]$(ClO_4)_2$ (3a): A pale green solution of $Ni(ClO_4)_2$·6H_2O (0.0169 g, 4.62 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-3-Mepyr (0.0204 g, 4.59 × 10^{-5} mol) in MeOH (1 mL) affording a pale purple-pink solution. Pink needles formed after 24 h. The supernatant was decanted and the solid was washed with Et_2O and dried, producing pale pink needles (0.0191 g, 59.3%). MS (ESI, MeOH): *m*/*z* = 501 = [M – 2 ClO_4^- – H^+], 601 [M – ClO_4^-]. $C_{27}H_{36}Cl_2N_6NiO_8$ (700.13): calcd. C 46.20, H 5.17, N 11.97; found C 46.43, H 5.28, N 12.06.

[Ni(tach-4-Mepyr)]$(ClO_4)_2$ (3b): A pale green solution of $Ni(ClO_4)_2$·6H_2O (0.0159 g, 4.35 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-4-Mepyr (0.0197 g, 4.43 × 10^{-5} mol) in MeOH (1 mL) producing a pink solution. Small pink needles were produced by Et_2O diffusion into the MeOH solution. These crystals were isolated, washed with Et_2O, dried under reduced pressure, and taken up in MeOH (1 mL). Et_2O diffusion into the MeOH solution yielded pink needle clusters that were isolated and dried affording a pink solid (0.0184 g, 59.2%). MS (ESI, MeOH): *m*/*z* = 501 [M – 2 ClO_4^- – H^+], 601 [M – ClO_4^-]. $C_{27}H_{36}Cl_2N_6NiO_8$ (700.13): calcd. C 46.20, H 5.17, N 11.97; found C 46.31, H 5.14, N 11.94.

[Ni(tach-5-Mepyr)]$(ClO_4)_2$ (3c): A pale green solution of $Ni(ClO_4)_2$·6H_2O (0.0162 g, 4.42 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-5-Mepyr (0.0200 g, 4.50 × 10^{-5} mol) in MeOH (1 mL) producing a purple-pink solution. Slow diffusion of Et_2O produced light pink microcrystals. The microcrystals were isolated, washed with Et_2O, dried under reduced pressure, and taken up in MeOH (1 mL). Diffusion of Et_2O into the MeOH solution produced pink needles that were isolated, washed with Et_2O, and dried producing pink needles (0.0221 g, 70.2%). MS (ESI, MeOH): *m*/*z* 501 [M – 2 ClO_4^- – H^+], 601 [M – ClO_4^-]. $C_{27}H_{36}Cl_2N_6NiO_8$ (700.13): calcd. C 46.20, H 5.17, N 11.97; found C 46.21, H 5.13, N 11.76.

[Ni(tach-6-Mepyr)]$(ClO_4)_2$·H_2O (3d·H_2O): A pale green solution of $Ni(ClO_4)_2$·6H_2O (0.0169 g, 4.62 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-6-Mepyr (0.0203 g, 4.57 × 10^{-5} mol) in MeOH (1 mL) affording a dark yellow solution. Small light brown needles along with a yellow-brown oil formed after 24 h. The supernatant was decanted, the needles and oil were washed with Et_2O, and the needles were isolated and dried under vacuum (0.0046 g, 14%). MS (ESI, MeOH): *m*/*z* = 501 [M – 2 ClO_4^- – H^+], 601 [M – ClO_4^-]. μ_{eff} (DMSO, 25 °C) = 3.8 B.M. $C_{27}H_{38}Cl_2N_6NiO_9$ (718.14): calcd. C 45.03, H 5.32, N 11.65; found C 45.37, H 5.32, N 11.63.

[Ni(tach-6-Mepyr)]$(NO_3)_2$ (3d′): A pale yellow solution of tach-6-Mepyr (0.0839 g, 1.89 × 10^{-4} mol in MeOH, 2 mL) was added to a pale green solution of $Ni(NO_3)_2$·6H_2O (0.0549 g, 1.89 × 10^{-4} mol) in MeOH (2 mL) affording a peach solution. After adding Et_2O (12 mL) and standing for 2 h, pale lavender microcrystals formed which were isolated, washed with CH_3CN, and dried under reduced pressure to a pale violet solid. This was dissolved in MeOH followed by vapor diffusion of Et_2O, affording pale violet prisms of an ether adduct (**3d′**·0.5Et_2O) that were suitable for X-ray crystallography. These were isolated and dried to a pale violet solid (0.0828 g, 69.8%). MS (FAB/DMSO/NBA): *m*/*z* = 502 [M – 2 NO_3^-]. UV/Vis/NIR (MeOH): λ_{max} (ε) = 10800 (23.2), 12300 (13.7), 17800 cm^{-1} (7.8 cm^{-1} M^{-1}). μ_{eff} = 3.087 B.M. at 25 °C. $C_{27}H_{36}N_8NiO_6$ (626.21): calcd. C 51.35, H 5.80, N 17.83; found C 51.70, H 5.78, N 17.86.

[Ni(tach-6-MeOpyr)]$(ClO_4)_2$ (3e): A pale green solution of $Ni(ClO_4)_2$·6H_2O (0.0167 g, 4.57 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-6-MeOpyr (0.0208 g, 4.23 × 10^{-5} mol) in MeOH (1 mL) producing a pale violet solution. The violet prisms that deposited after 24 h were isolated, washed with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Et_2O, and dried under vacuum (0.0150 g, 47.3%). MS (ESI, MeOH): *m/z* = 549 [M – 2 ClO_4^- – H^+], 649 [M – ClO_4^-]. μ_{eff} (DMSO, 25 °C) = 3.1 B.M. $C_{27}H_{36}Cl_2N_6NiO_{11}$ (748.12): calcd. C 43.25, H 4.84, N 11.21; found C 43.09, H 4.94, N 11.11.

[Cu(tach-3-Mepyr)](ClO$_4$)$_2$ (4a): A blue solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.0267 g, 7.21 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-3-Mepyr (0.0315 g, 7.09 × 10^{-5} mol) in MeOH (1 mL). A light indigo-blue precipitate formed that redissolved immediately to a blue solution. Slow Et_2O diffusion into the solution produced shiny blue prisms that were isolated and recrystallized from MeCN (4 mL) by vapor-phase diffusion of Et_2O (0.0419 g, 84.0%). MS (FAB/DMSO/MB): *m/z* = 606 [M – ClO_4^-]. UV/Vis/NIR (solid): λ_{max} = 14700 cm^{-1}. $C_{27}H_{36}Cl_2CuN_6O_8$ (705.13): calcd. C 45.86, H 5.13, N 11.89; found C 45.86, H 5.15, N 11.99.

[Cu(tach-4-Mepyr)](ClO$_4$)$_2$·H$_2$O (4b·H$_2$O): A blue solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.0258 g, 6.96 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-4-Mepyr (0.0310 g, 6.97 × 10^{-5} mol) in MeOH (1 mL). A blue precipitate formed that immediately redissolved to a blue solution. Slow Et_2O diffusion into the solution formed a blue oil which was triturated to a powder with Et_2O and recrystallized from MeOH by vapor-phase diffusion of Et_2O providing blue plates (0.0240 g, 48.8%). MS (FAB/DMSO/MB): *m/z* = 606 [M – ClO_4^-]. UV/Vis/NIR (solid): λ_{max} = 15100 cm^{-1}. $C_{27}H_{38}Cl_2CuN_6O_9$ (723.14): calcd. C 44.73, H 5.28, N 11.59; found C 44.64, H 5.10, N 11.19.

[Cu(tach-5-Mepyr)](ClO$_4$)$_2$ (4c): A blue solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.0264 g, 7.12 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-5-Mepyr (0.0322 g, 7.24 × 10^{-5} mol) in MeOH (1 mL). A light blue precipitate formed that immediately redissolved to a blue solution. Slow Et_2O diffusion into the solution formed a blue oil which was triturated to a powder with Et_2O and recrystallized from MeOH by vapor-phase diffusion of Et_2O providing blue needles (0.0376 g, 74.8%). MS (FAB/DMSO/MB): *m/z* = 606 [M – ClO_4^-]. UV/Vis/NIR (solid): λ_{max} = 15200 cm^{-1}. $C_{27}H_{36}Cl_2CuN_6O_8$ (705.13): calcd. C 45.86, H 5.13, N 11.89; found C 46.16, H 5.28, N 11.64.

[Cu(tach-6-MeOpyr)](ClO$_4$)$_2$ (4e): A blue solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.0229 g, 6.18 × 10^{-5} mol) in MeOH (1 mL) was added to a pale yellow solution of tach-6-MeOpyr (0.0306 g, 6.22 × 10^{-5} mol) in MeOH (1 mL). A light blue precipitate formed that immediately redissolved to a blue solution. Slow Et_2O diffusion into the solution formed a blue oil which was triturated to a powder with Et_2O and recrystallized from MeCN (2 mL) by vapor-phase diffusion of Et_2O giving shiny blue needles suitable for X-ray crystallography (0.0365 g, 78.3%). MS (FAB/DMSO/MB): *m/z* = 654 [M – ClO_4^-], 493 (free tach-6-MeOpyr). UV/Vis/NIR (solid): λ_{max} = 10204, 15060 cm^{-1}. $C_{27}H_{36}Cl_2CuN_6O_{11}$ (753.11): calcd.C 42.95, H 4.81, N 11.13; found C 43.12, H 4.80, N 11.17.

[Zn(tach-3-Mepyr)](NO$_3$)$_2$·2H$_2$O (5a·2H$_2$O): A solution of $Zn(NO_3)_2 \cdot 6H_2O$ (0.0335 g, 1.126 × 10^{-4} mol) in MeOH (2 mL) was mixed with a pale yellow solution of tach-3-Mepyr (0.0502 g, 1.129 × 10^{-4} mol) in MeOH (2 mL) with no obvious change observed. Diffusion of Et_2O into the solution overnight gave clusters of colorless needles. The product was isolated, washed with Et_2O, and dried under reduced pressure affording white needles (0.0364 g, 5.74 × 10^{-5} mol, 51.0%). Suitable crystals for X-ray diffraction (shown to be **5a**·2MeOH·0.5H_2O) were grown from MeOH by vapor-phase diffusion of Et_2O. ^{1}H NMR (360 MHz, [D$_6$]DMSO, 25 °C): δ = 7.91, 7.76, 7.42 (d, d, dd, 3 H, 3-MeC_5H_3N), 4.41 (br. t, 1 H, N*H*CH_2), 4.05, 3.95 (dd, dd, 2 H, MepyCH_2N, diastereotopic), 3.29 (br. s, 1 H, cyclohexyl methine *H*), 2.32 (partially obscured) [s, 3 H, (CH_3)py], 2.34 (partially obscured) (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.88 (br. d, 1 H, axial cyclohexyl methylene *H*). MS (ESI): *m/z* = 507 [M – 2 NO_3^- – H^+], 570 [M – NO_3^-]. HPLC (gradient mode): R_t = 14.6 min (free ligand R_t = 22.9 min). $C_{27}H_{40}N_8O_8Zn$ (668.23): calcd. C 48.40, H 6.02, N 16.72; found C 48.15, H 6.06, N 16.66.

[Zn(tach-4-Mepyr)](NO$_3$)$_2$ (5b): A solution of $Zn(NO_3)_2 \cdot 6H_2O$ (0.0284 g, 6.16 × 10^{-5} mol) in MeOH (1 mL) was mixed with a pale yellow solution of tach-4-Mepyr (0.0278 g, 6.25 × 10^{-5} mol) in MeOH (1 mL), giving a pale yellow solution. Diffusion of Et_2O overnight gave colorless needle clusters. The product was isolated, washed with Et_2O, and dried under reduced pressure affording white needles (0.0235 g, 3.71 × 10^{-5} mol, 60.2%). ^{1}H NMR (360 MHz, [D$_6$]DMSO, 25 °C): δ = 7.68, 7.46, 7.34 (d, s, dd, 3 H, 4-MeC_5H_3N), 4.60 (br. t, 1 H, N*H*CH_2), 4.07 (m, 2 H, MepyCH_2N, diastereotopic), 3.26 (br. s, 1 H, cyclohexyl methine *H*), 2.48 (s, 3 H, CH_3py), 2.32 (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.86 (br. d, 1 H, axial cyclohexyl methylene *H*). MS (FAB/DMSO/MB): *m/z* = 507 [M – 2 NO_3^- – H^+], 570 [M – NO_3^-]. $C_{27}H_{36}N_8O_6Zn$ (632.20): calcd. C 51.15, H 5.72, N 17.68; found C 51.11, H 5.75, N 17.61.

[Zn(tach-5-Mepyr)](NO$_3$)$_2$·3H$_2$O (5c·3H$_2$O): A solution of $Zn(NO_3)_2 \cdot 6H_2O$ (0.0203 g, 6.82 × 10^{-5} mol) in MeOH (1 mL) was mixed with a pale yellow solution of tach-5-Mepyr (0.0301 g, 6.77 × 10^{-5} mol) in MeOH (1 mL), giving a colorless solution. Diffusion of Et_2O into the solution overnight gave a colorless oil. Trituration produced a white precipitate. The product was isolated, washed with Et_2O, and dried under reduced pressure affording a white powder (0.0345 g, 5.44 × 10^{-5} mol, 80.4%). ^{1}H NMR (360 MHz, [D$_6$]DMSO, 25 °C): δ = 7.95, 7.60, 7.52 (d, s, d, 3 H, 5-MeC_5H_3N), 4.59 (br. t, 1 H, N*H*CH_2), 4.07 (qd, 2 H, MepyCH_2N, diastereotopic), 3.23 (br. s, 1 H, cyclohexyl methine *H*), 2.29 (partially obscured) (s, 3 H, CH_3py), 2.33 (partially obscured) (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.86 (br. d, 1 H, axial cyclohexyl methylene *H*). MS (FAB/gly): *m/z* = 507 [M – 2 NO_3^- – H^+], 570 [M – NO_3^-]. $C_{27}H_{42}N_8O_9Zn$ (686.24): calcd. C 47.14, H 6.15, N 16.29; found C 47.18, H 6.11, N 15.96.

[Zn(tach-6-Mepyr)](NO$_3$)$_2$·H$_2$O (5d·H$_2$O): A solution of $Zn(NO_3)_2 \cdot 6H_2O$ (0.0423 g, 1.42 × 10^{-4} mol) in MeOH (2 mL) was mixed with a pale yellow solution of tach-6-Mepyr (0.0614 g, 1.38 × 10^{-4} mol) in MeOH (2 mL), giving a pale yellow solution. Adding Et_2O directly into the solution and waiting 18 h gave a white solid. The product was isolated, washed with Et_2O, and dried under reduced pressure affording a white solid (0.0143 g, 2.26 × 10^{-5} mol, 16.3%). ^{1}H NMR (360 MHz, [D$_6$]DMSO, 25 °C): δ = 7.89, 7.37, 7.31 (t, d, d, 3 H, 6-MeC_5H_3N), 4.23 (br. m, 1 H, N*H*CH_2), 4.20, 4.09 (d, d, 2 H, MePyCH_2N, diastereotopic), 3.08 (br. s, 1 H, cyclohexyl methine *H*), 2.16 (s, 3 H, C$H_3C_5H_3$N), 2.10 (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.82 (br. d, 1 H, axial cyclohexyl methylene *H*). MS (FAB/NBA/DMSO): *m/z* = 570 [M – NO_3^-], 507 [M – 2 NO_3^- – H^+]. HPLC (gradient): labile, identical to free tach-6-Mepyr at $R_t \approx$ 21.3 min. $C_{27}H_{38}N_8O_7Zn$ (650.22): calcd. C 49.74, H 5.87, N 17.19; found C 49.30, H 5.91, N 17.15.

[Zn(tach-6-Mepyr)](ClO$_4$)$_2$·H$_2$O (5d′·H$_2$O) and [Zn(tach-6-Mepyr)](ClO$_4$)$_2$·0.5MeOH·0.5H$_2$O (5d′·0.5MeOH·0.5H$_2$O): A pale yellow solution of tach-6-Mepyr (0.0540 g, 1.22 × 10^{-4} mol) in MeOH (4 mL) was added to a solution of $Zn(ClO_4)_2 \cdot 6H_2O$ (0.0493 g, 1.22 × 10^{-4} mol) in EtOH (4 mL) affording a white precipitate. After standing for 1 h, the precipitate was isolated and washed with Et_2O and MeOH. This was dried under reduced pressure affording a white solid in 60.3% yield (0.0569 g, 8.05 × 10^{-5} mol). Single crystals suitable for X-ray crystallography (shown to be

5d′·1/2MeOH·1/2H_2O) were obtained by Et_2O diffusion into an MeOH solution of the complex. ^1H NMR ([D_6]DMSO, 25 °C): δ = 7.89, 7.36, 7.34 (t, d, d, 3 H, $CH_3C_5H_3N$), 4.22, 4.05 (m, d, 3 H, diastereotopic methylene H's of MePyCH_2N and NHCH_2), 3.07 (br. s, cyclohexyl methine *H*), 2.15 (s, 3 H, CH_3C$_5$H$_3$N), 2.13 (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.82 (br. d, 1 H, axial cyclohexyl methylene *H*). MS (FAB/glycerol): *m*/*z* = 507 [M – 2 ClO_4^- – H^+]. $C_{27}H_{38}Cl_2N_6O_9Zn$(724.14): calcd. C 44.61, H 5.27, N 11.56; found C 44.58, H 5.41, N 11.74.

[Zn(tach-6-MeOpyr)](NO$_3$)$_2$ (5e): A solution of $Zn(NO_3)_2$·$6H_2O$ (0.0212 g, 7.13 × 10^{-5} mol) in MeOH (1 mL) was mixed with a colorless solution of tach-6-Mepyr (0.0364 g, 7.39 × 10^{-5} mol) in MeOH (1 mL) giving a colorless solution. Diffusion of Et_2O overnight produced colorless needles that were isolated, washed with Et_2O, and dried under reduced pressure affording white needles (0.0232 g, 3.36 × 10^{-5} mol, 47.1%). ^1H NMR (360 MHz, [D_6]DMSO, 25 °C): δ = 7.99, 7.10, 6.92 (t, d, d, 3 H, 6-OMeC$_5$H$_3$N), 4.39 (d, 1 H, NHCH_2), 4.14, 3.95 (dd, dd, 2 H, MeOpyCH_2N), 3.28 (s, 3 H, CH_3O), 3.13, (br. s, 1 H, cyclohexyl methine *H*), 2.24 (br. d, 1 H, equatorial cyclohexyl methylene *H*), 1.81 (br. d, 1 H, axial cyclohexyl methylene *H*). MS (FAB//NBA/DMSO): *m*/*z* = 618 [M – NO_3^-]. $C_{27}H_{36}N_8O_9Zn$ (680.19): calcd. C 47.56, H 5.32, N 16.43; found C 47.30, H 5.24, N 16.17.

[Zn(tachpyr)](CF$_3$SO$_3$)$_2$ (5f): A solution of $Zn(CF_3SO_3)_2$ (0.063 g, 1.7 × 10^{-4} mol) in MeOH (2 mL) was mixed with a pale yellow solution of tachpyr (0.070 g, 1.7 × 10^{-4} mol) in MeOH (2 mL), giving a pale yellow solution. Vapor-phase diffusion of Et_2O into this solution gave colorless needles after 18 h, which were isolated by decantation of solvent, washed with Et_2O and dried under reduced pressure affording an 82% yield (0.110 g, 1.4 × 10^{-4} mol) of white needles. ^1H NMR ([D_6]DMSO, 25 °C): MS (ESI, MeOH): *m*/*z* = 617 [M – $CF_3SO_3^-$], 469 [M – 2 $CF_3SO_3^-$ + H^+]$^+$. HPLC (gradient mode): R_t = 8.4 min (free ligand R_t = 18.8 min). HPLC (isocratic mode): R_t = 5.0 min. $C_{26}H_{30}F_6N_6O_6S_2Zn$ (764.09): calcd. C 40.76, H 3.95, N 10.97; found C 40.92, H 3.87, N 10.96.

Solution-Phase Complexation: Solution complexation studies for Fe^{II}, Ni^{II}, and Cu^{II} were carried out by combining aqueous or methanolic M^{II} and ligand solutions followed by spectroscopic analysis as described below; tach-*x*-Mepyr (*x* = 3, 4, 5 and 6) were easily dissolved in water while acidic conditions were required for tach-6-MeOpyr to dissolve (6 equiv. HCl). M^{II} (aq) was added to the chelator solution resulting in immediate complexation except in the case of tach-6-MeOpyr where 6 equiv. of NaOH was needed. Their spectra agreed well with those of the isolated metal complexes in MeCN (Table 1).
