Keywords: Iron / Long alkyl chains / Scanning tunneling microscopy / Highly oriented pyrolytic graphite / Nanopatterning / Self-assembly

The programmed self-assembly of a multimetallic grid-type supramolecular architecture and its hierarchical organization on graphite are described. The doubly functionalized 4,6-bis(2,2′-bipyridyl-6-yl)-2-phenylpyrimidine derivative **1**, equipped with $CH_2OC_{16}H_{33}$ moieties at the terminal pyridine rings, was designed as a new bis(tridentate) ligand and synthesized using Stille-type coupling reactions. Treatment of ligand **1** with $Fe(BF_4)_2{\cdot}6H_2O$ in $CHCl_3/CH_3CN$ led to the spontaneous formation of a [2×2]-grid-type Fe^{II} complex **2** in quantitative yield. The self-assembled tetranuclear complex **2** was adsorbed onto highly oriented pyrolytic graphite (HOPG) and studied by scanning tunneling microscopy (STM), which showed two morphologies of highly ordered two-dimensional arrays of the metallo-supramolecular architectures. The resulting monolayers of the grid-type complex **2** are much more stable than that obtained from the corresponding unsubstituted grid-type complex owing to the additional attractive forces between the hexadecyl moieties in **2** and the HOPG surface. Moreover, the reproducibility of the STM images of the hexadecyl-substituted grid **2** was strongly improved compared to the unsubstituted one. These results suggest that the introduction of long alkyl chains into metallo-supramolecular architectures would have general advantages for their organization and STM investigation on HOPG. Details of the preparation and the STM investigation of ligand **1** are also presented.

Introduction

The design and formation of ordered nanoscaled structures with functional properties have attracted considerable attention in materials science and nanotechnology.[1] A bottom-up approach based on the self-assembly of simple building units to nanometric-size objects is expected to be a powerful tool, instead of microfabrication as a top-down approach, for producing functional materials with great technological advantages. Especially interesting is a sequential application of different self-organization principles for the preparation of hierarchically structured materials. This would be realized by the controlled use of relatively strong, directional interactions (such as hydrogen bonds and coordinative interactions) as well as weak, nondirectional interactions (such as van der Waals force and hydrophobic interaction). In this study we examined the hierarchical organization of a self-assembled multimetallic supramolecular architecture on graphite.

We have previously shown that the self-assembly of bis(tridentate) ligands, based on terpyridine-like binding sites, with octahedrally coordinated metal ions such as Fe^{II}, Co^{II}, and Zn^{II} leads to [2×2]-grid-type complexes.[2–4] These complexes present interesting electronic, redox, and magnetic properties such as electronic interactions between the metal centers,[2] multilevel electrochemical reduction up to 10 reversible steps,[5] antiferromagnetic transition at low temperatures,[6] and spin crossover phenomena triggered by temperature, pressure, and light.[7] For technological application a further 2D or 3D ordering of these supramolecular complexes is required. Several strategies have been examined to obtain such ordered arrangement of the grid-type supramolecular architectures, including self-assembly at the air-water interface,[8] hydrogen-bonded crystal formation,[9] and adsorption on graphite.[10,11] An excellent method to visualize such assemblies with submolecular resolution on for example highly ordered pyrolytic graphite (HOPG) is represented by scanning tunneling microscopy (STM).[12] However, the stabilities of the monolayers obtained from unsubstituted [2×2]-grid-type complexes[10] and its pyridyl-

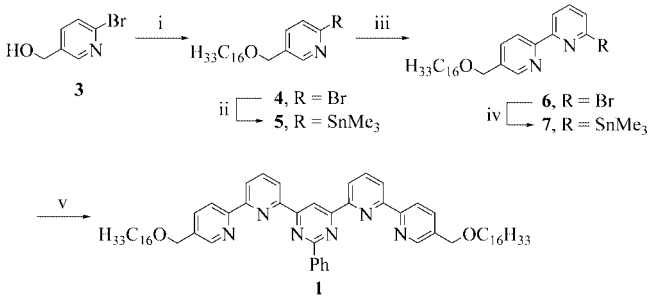
substituted derivatives[11] are low, and thus their STM images are obtained only with low reproducibility. To address these problems, we have designed as a new ligand 4,6-bis(2,2′-bipyridyl-6-yl)-2-phenylpyrimidine (**1**), equipped with $CH_2OC_{16}H_{33}$ moieties at the terminal pyridine rings. The long alkyl chains are expected to result in better adsorption on graphite.[13] Herein, we describe the details of the nanopatterning of HOPG by the long-chain-substituted [2×2]-grid-type complex **2**, together with the preparation and STM investigation of ligand **1**.

Results and Discussion

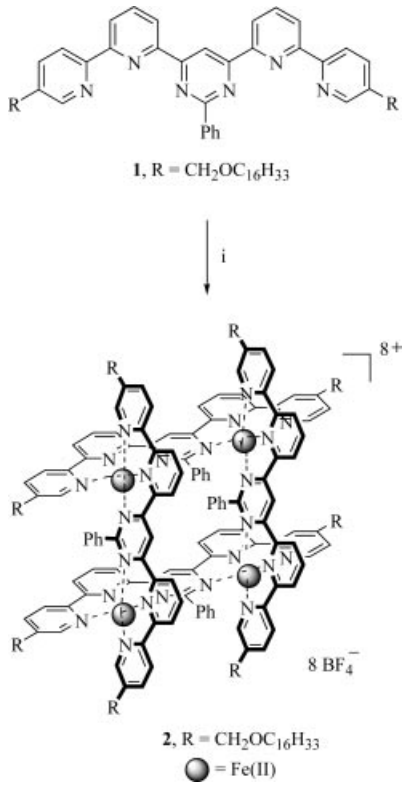
Synthesis of Ligand 1 and Self-Assembly of [2×2]-Grid-Type Fe^{II} Complex 2

The synthesis of the long-chain-substituted ligand **1** is outlined in Scheme 1. Deprotonation of 2-bromo-5-(hydroxymethyl)pyridine (**3**), which was readily accessible from commercially available 2-hydroxy-5-pyridinecarboxylic acid,[14] with sodium hydride in DMF followed by treatment with hexadecyl iodide afforded ether **4** in 66% yield. Stannylation of **4** with a hexamethyldistannane/$Pd(PPh_3)_4$ system in refluxing toluene produced **5**, which was in turn coupled with 2,6-dibromopyridine in the presence of $Pd(PPh_3)_4$ to afford bipyridine derivative **6** in 52% yield. Twofold Stille coupling of 4,6-dichloro-2-phenylpyrimidine[15] with 2 equiv. of **7**, which was prepared by stannylation of **6** with a hexamethyldistannane/$Pd(PPh_3)_4$ system, in refluxing toluene in the presence of $Pd(PPh_3)_4$ gave the desired ligand **1** in 57% yield.



Scheme 1. Synthesis of ligand **1**, i) NaH, DMF, then $C_{16}H_{33}I$; ii) $Me_3SnSnMe_3$, $Pd(PPh_3)_4$, toluene; iii) 2,6-dibromopyridine, $Pd(PPh_3)_4$; iv) $Me_3SnSnMe_3$, $Pd(PPh_3)_4$, toluene; v) 4,6-dichloro-2-phenylpyrimidine, $Pd(PPh_3)_4$.

Reaction of **1** with $Fe(BF_4)_2{\cdot}6H_2O$ in acetonitrile/chloroform (1:1) proceeded smoothly and cleanly to yield the corresponding [2×2]-grid-type complex **2** in quantitative yield, as similarly shown earlier for the formation of related complexes (Scheme 2).[2–4] The electrospray mass spectrum of **2** confirms its [2×2]-grid-like structure in solution.[16]



Scheme 2. Formation of the [2×2]-grid-type Fe^{II} complex **2**, i) $Fe(BF_4)_2{\cdot}6H_2O$, $CHCl_3/CH_3CN$ (1:1).

STM Investigation of Ligand 1 Adsorbed on HOPG

Self-assembly of ligand **1** on HOPG results in a highly ordered structure; the representative STM image of **1** is shown in Figure 1. Brighter and darker lamellae alternate within the image, where a bright color represents higher electron density. The periodicity of the lamellae is 55 Å. The brighter moiety exhibits a width of 25 Å and the darker moiety a width of 30 Å. The bright stripe shows a structured pattern with numerous small bright spots and is attributed to the aromatic rings. The darker stripe presents

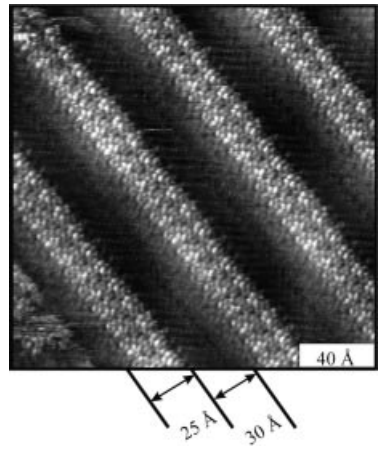

Figure 1. STM image of **1** on HOPG from 1,2,4-trichlorobenzene: Lamellar widths: 25 and 30 Å; V_{bias} = –362 mV, I_{set} = 23.8 pA.

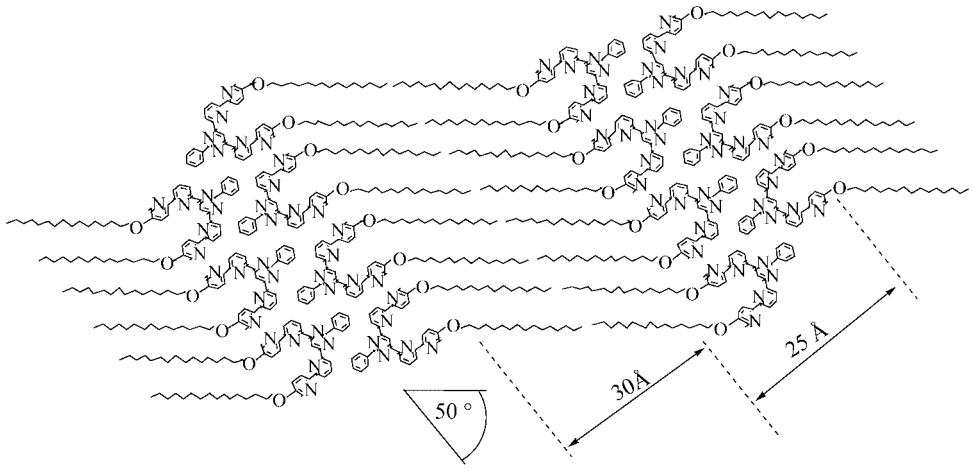

Scheme 3. Proposed model for the conformation and ordering of **1** on graphite.

.

an additional pattern of linear arrays of spots, which form an angle of 50° with the ribbons. These linear arrays are assigned to the alkyl chains in **1**. The image can be interpreted as a flat arrangement of the aromatic rings on the surface, which is expected for optimal contact between the monolayer and the basal plane of graphite. The alkyl chains in **1** are ordered commensurately with the graphite lattice.[13] The conformation of the aromatic units of **1** on the surface would be analogous to those observed for related compounds both in solution and in the solid state, i.e., a *transoid* conformation of the NC–CN bonds connecting the heterocycles, as indicated in our previous studies.[11,17–19] In the lower left corner of the STM image (Figure 1<yigr1>) a defect can be observed.

A plausible model for the arrangement of **1** on the surface is shown in Scheme 3. In this model, the bright stripes are formed by the aromatic part of two rows of molecules of **1**, which may be stabilized by weak intramolecular C–H···N interactions.[11,17–19] The alkyl chains form an angle of 50° with this stripe. From geometrical estimations the expected widths of the ribbons fit very well with the experimental values. The tilt angle of the alkyl chains with the main axis of the lamellae allows the optimal contact of ca. 4.5 Å between neighboring chains.[11] The comparison of the length of the alkyl chains in **1** and the observed width of the darker stripes in the image suggests a noninterdigitated assembly of the alkyl chains.

STM Investigation of [2×2]-Grid-Type Fe^{II} Complex 2 Assembled on HOPG

Representative STM images of the [2×2]-grid-type Fe^{II} complex **2** on HOPG are shown in Figure 2. The large scan area exhibits two domains of alternating brighter and darker ribbons (Figure 2a). On the first glimpse both domains seem to represent the same structure with changing preferred directions. A closer look reveals that the periodicities of the ribbons differ between 42 Å (domain A) and 23 Å (domain B), respectively, but both domains can be easily distinguished from the features of ligand **1** (Figure 1). Hence, we assume that **2** forms at the solution/HOPG interface at least two different morphologies. The formation of (pseudo)polymorphs[20] in 2D monolayers – sometimes depending on the solvent[21] – is known but the grid-like complexes of HOPG polymorphism were only observed in the case of different substituents in the periphery and in the center of the complexes, respectively.[10]

A detailed view of domain A (Figure 2b) shows that the brighter stripes are built from square-like entities with an edge length of 22 to 24 Å whereas the darker ribbons are structured by more narrow and broader stripes perpendicular to the ribbon direction. Because of the differences in electron density we attribute the brighter ribbons to the grid-like structure of the aromatic part of **2** and the darker bands to the alkyl substituents.

Regarding a reasonable model for the arrangement of **2** in domain A the fourfold symmetry of the square-like entities in Figure 2b gives hints for an arrangement of **2** with the C_4 axis perpendicular to the substrate surface (Scheme 4c). In Scheme 4a the geometrical dimensions of the grid core of **2** show that we expect an edge length for the squares without the alkyl chains of 18 Å. The larger size of the square-like shapes in Figure 2b suggests that each grid-like complex is rotated along the C_4 axis so that the ligands are no longer parallel and orthogonal, respectively, to the main direction of the bright stripes but form an angle of 20–30° and 110–120°, respectively (Scheme 4c). A further stripy fine structure of the square-like bright areas in the direction of one set of two parallel ligands per complex molecule with the above given angles supports this assumption. There is no optimal contact possible between the alkyl chains and the graphite surface due to the nonplanar structure of **2**. We suggest that the chains adopt a conformation similar to that shown in Scheme 4b, which exhibits the side view of one ligand molecule **1** in its conformation in complex **2**. Such conformation allows close contact between a part of an alkyl chain and graphite. The width of the darker ribbons of 18 Å is too small for a noninterdigitated arrange-

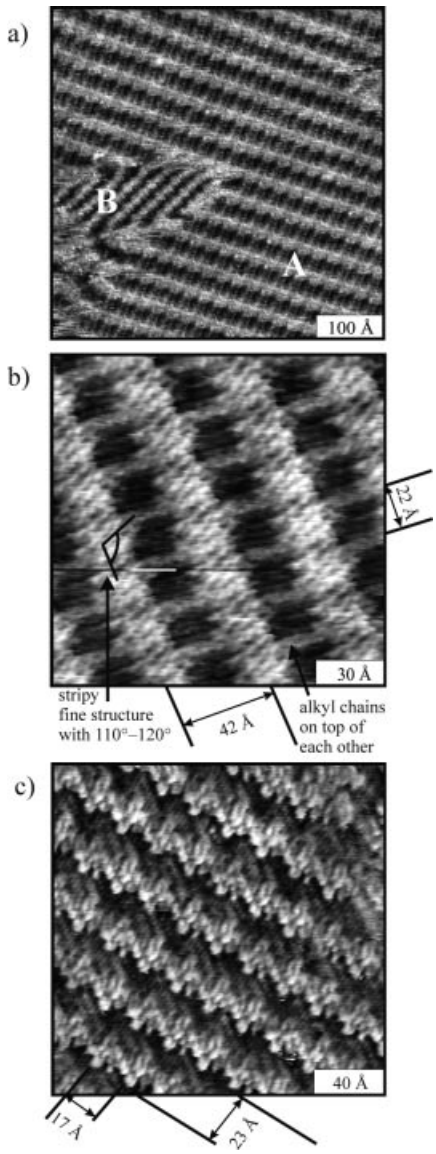

Figure 2. STM images of **2** on HOPG from 1,2,4-trichlorobenzene: Large-scan-area image with two different domains A and B (V_{bias} = –651 mV, I_{set} = 39.4 pA) (a), detailed view of domain A with a lamellar structure (periodicity: 42 Å) and a periodic fine structure within each lamella (periodicity: 22 Å), a stripy fine structure with an angle of ca. 115° with respect to the lamella axis is visible, too (V_{bias} = –410 mV, I_{set} = 36.6 pA) (b), detailed view of domain B with a lamellar structure (periodicity: 23 Å) and a periodic fine structure within each lamella (periodicity: 17 Å; V_{bias} = –344 mV, I_{set} = 44.1 pA) (c).

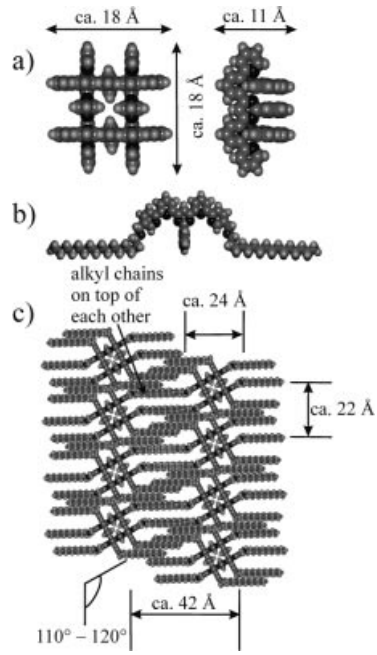
ment of the alkyl chains despite the above suggested conformation. Hence, we assume interdigitation which on the other side would lead, with the assumed orientation of the grid-like complexes, to a partial bumping of the alkyl chains (see Scheme 4c). Though the resolution of the STM image in Figure 2b does not give enough information on the exact ordering of the alkyl chains we suppose that at these positions the alkyl chains are approximately on top of each other. This might cause the contrast of brighter stripes within the darker ribbons in Figure 2b because of the topography and not primarily due to higher electron density.



Scheme 4. Proposed model for the arrangement of **2** on HOPG in domain A: top view of one grid-like complex along the C_2 axis (a, left), side view of one grid-like complex (a, right), side view of one ligand **1** with the proposed conformation of the alkyl chains ensuring close contact between the surface and the alkyl chains (b), top view of the arrangement of the grid-like complexes on HOPG (c).

A detailed view of domain B shows lamellae which are built from a bright and a dark band, the dark formed by fine stripes with an angle of 40° with respect to the ribbons (Figure 2c). Theses stripes are assigned to the alkyl chains. The bright parts are attributed to the high electron density aromatic moieties of complex **2** showing an additional fine structure with a periodicity of 17 Å.

Comparing with the much larger periodicity of the ribbons in domain A (42 Å, Figure 2b), we suggest an edge-on arrangement of the complexes on the graphite in domain B (periodicity 23 Å, Figure 2c), though we cannot assign unambiguously the fine structure of the bright parts to the structure of the grid-like complex. The edge-on arrangement of the complexes on the graphite may be accompanied by a tilt angle of up to 70° which would lead to a projected area of 17×18 Å (Scheme 5). This arrangement should lead to an improved contact between the two alkyl chains next to the graphite and the graphite surface at the expense of the other six alkyl chains which are bent to come at least partially into contact with the graphite surface. An additional consequence of such an arrangement is a stacking of the complexes which should be advantageous due to their highly charged character. Within one ribbon the complexes are assumed to be parallel to each other. Comparing adjacent ribbons a shift between two neighboring molecules of ca. 6 Å can be found which might be caused by the packing of the alkyl chains.

The two arrangements of complex **2** coexist on HOPG (see Figure 2a) but we do not yet know how the formation of one or the other morphology can be controlled. The

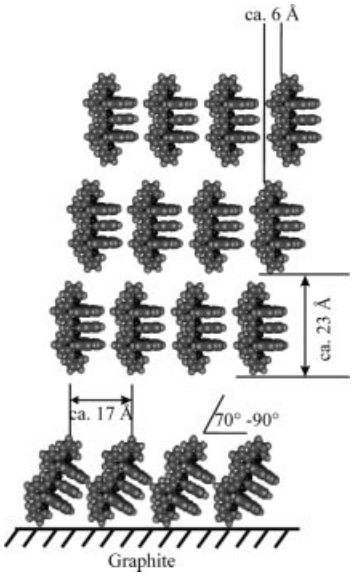

Scheme 5. Proposed model for the arrangement of **2** on HOPG in domain B: top view of the arrangement of the grid-like complexes (top), side view of the arrangement of the grid-like complexes parallel to the graphite surface with an angle of 70° resulting in a projected area of 17×18 Å (bottom). Only the grid cores are shown, the alkyl chains are omitted for clarity.

forms are stable enough not to be transformed into each other by the STM tip or any other external trigger present in the course of our STM experiments.

Conclusions

The doubly functionalized ligand **1**, having $CH_2OC_{16}H_{33}$ moieties at the terminal pyridine rings, was designed as a new bis(tridentate) ligand and synthesized. Treatment of **1** with $Fe(BF_4)_2{\cdot}6H_2O$ in $CHCl_3/CH_3CN$ led to the spontaneous formation of a [2×2]-grid-type Fe^{II} complex **2** in a quantitative yield. The STM investigations of both ligand **1** and the Fe^{II} complex **2** on graphite revealed their stable, regular arrangements on the surfaces. Complex **2** shows two different morphologies – a flat and an edge-on assembly of the grid-like complexes on HOPG. We do not yet know the factors determining the formation of one or the other arrangement. Importantly, stability of the monolayers of the long-chain-substituted complex **2**, and thus, reproducibility of their STM images have been significantly enhanced compared to the corresponding unsubstituted complex. Therefore, the present results suggest that the introduction of long alkyl chains into the ligand would be a useful strategy for the STM investigations of the related grid-type complexes as well as other metallo-supramolecular architectures on HOPG surfaces.

Experimental Section

General: Melting points were measured with a digital Electrotherma apparatus and are uncorrected. ^{1}H NMR spectra were recorded with a Bruker AC200 spectrometer in $CDCl_3$ at 200 MHz under ambient conditions; chemical shifts are given in ppm using TMS as reference. ^{13}C NMR spectra were recorded with a Bruker AC200 spectrometer in $CDCl_3$ at 50 MHz, also under ambient conditions; chemical shifts are given in ppm using the solvent peak as reference. Fast atom bombardment (FAB) mass spectra were recorded with a ZAB-HF VG spectrometer with *m*-nitrobenzyl alcohol as the matrix. Electrospray (ES) mass spectra were recorded with a triple quadrupole mass spectrometer Quattro II. The microanalyses were carried out at the Service Central de Microanalyse du CNRS, Faculté de Chimie, Strasbourg. Column chromatography was carried out on Merck silica gel 60 or Merck alumina activity II–III. 2-Bromo-5-(hydroxymethyl)pyridine (**3**)[14] and 4,6-dichloro-2-phenylpyrimidine[15] were prepared according to known procedures.

2-Bromo-5-(hexadecyloxymethyl)pyridine (4): To a suspension of sodium hydride (128 mg, 5.32 mmol, 60% dispersion in oil) in anhydrous DMF (6 mL) was added 2-bromo-5-(hydroxymethyl)pyridine (**3**)[14] (500 mg, 2.7 mmol) and the reaction mixture was stirred at room temperature for 1 h. The suspension was cooled to 0 °C and hexadecyl iodide (1.06 g, 3.0 mmol) was added to it. The mixture was then allowed to warm to room temperature and stirred for 44 h. After evaporation of the solvent, the residue was subjected to chromatography on silica gel eluting with hexane/EtOAc (4:1, v/v) to afford **4** as a colorless powder (723 mg, 66%). M.p. 47 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.84 (t, J = 6.7 Hz, 3 H, CH_3), 1.22 (m, 26 H, CH_2), 1.57 (quint, J = 6.7 Hz, 2 H, OCH$_2$CH_2), 3.44 (t, J = 6.4 Hz, 2 H, OCH_2), 4.42 (s, 2 H, C_{py}CH_2O), 7.41 (d, J = 8.2 Hz, 1 H, 4-H), 7.51 (dd, J = 8.2 and 2.4 Hz, 1 H, 3-H), 8.28 (d, J = 1.8 Hz, 1 H, 6-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.0, 22.6, 26.1, 29.3, 29.4, 29.6, 31.9, 69.4, 71.0, 127.8, 133.5, 137.8, 141.1, 149.2. MS (FAB): *m*/*z* (%) = 412.1 (100) $[M + H]^+$. IR (KBr): $\tilde{\nu}$ = 2954, 2916, 2851, 1586, 1566, 1473, 1458, 1388, 1110, 1089, 1026, 842, 824, 716, 630 cm^{-1}. $C_{22}H_{38}BrNO$ (412.46): calcd. C 64.20, H 9.31, N 3.41; found C 64.07, H 9.46, N 3.38.

2-Bromo-6-[5′-(hexadecyloxymethyl)pyrid-2′-yl]pyridine (6): A mixture of **4** (1 g, 2.42 mmol), hexamethyldistannane (880 mg, 2.66 mmol), and $Pd(PPh_3)_4$ (70 mg, 0.060 mmol) in toluene (16 mL) under argon was refluxed for 4 h. 2,6-Dibromopyridine (1.26 g, 5.32 mmol) and $Pd(PPh_3)_4$ (120 mg, 0.11 mmol) were added to the mixture and the reaction mixture was further refluxed under argon for 20 h. After evaporation of the solvent, the residue was subjected to chromatography on silica gel eluting with hexane/EtOAc (9:1, v/v) to afford **6** as a colorless powder (620 mg, 52%). M.p. 67 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.88 (t, J = 6.1 Hz, 3 H, CH_3), 1.25 (m, 26 H, CH_2), 1.56–1.72 (m, 2 H, OCH$_2$CH_2), 3.50 (t, J = 6.4 Hz, 2 H, OCH_2), 4.57 (s, 2 H, C_{py}CH_2O), 7.47 (dd, J = 7.9 and 1.2 Hz, 1 H, 3′- or 5′-H), 7.65 (t, J = 7.9 Hz, 1 H, 4′-H), 7.79 (dd, J = 8.2 and 2.4 Hz, 1 H, 3-H), 8.37 (dd, J = 7.6 and 0.9 Hz, 1 H, 3′- or 5′-H), 8.38 (d, J = 8.2 Hz, 1 H, 4-H), 8.62 (d, J = 2.1 Hz, 1 H, 6-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.0, 22.6, 26.1, 29.3, 29.4, 29.6, 31.8, 70.0, 70.8, 119.5, 120.9, 127.7, 134.7, 136.0, 139.0, 141.4, 148.3, 153.6, 157.1. MS (FAB): *m*/*z* (%) = 489.4 (100) $[M + H]^+$. IR (KBr): $\tilde{\nu}$ = 2953, 2916, 2849, 1600, 1570, 1545, 1470, 1434, 1387, 1124, 1026, 988, 801, 777, 754, 718, 672 cm^{-1}. $C_{27}H_{41}BrN_2O$ (489.54): calcd. C 66.25, H 8.44, N 5.72; found C 66.17, H 8.32, N 5.74.

4,6-Bis{6′-[5′′-(hexadecyloxymethyl)pyrid-2′′-yl]pyrid-2′-yl}-2-phenylpyrimidine (1): A mixture of **6** (300 mg, 0.61 mmol), hexamethyldistannane (221 mg, 0.64 mmol), and $Pd(PPh_3)_4$ (21 mg, 0.018 mmol) in toluene (4 mL) under argon was refluxed for 25 min. After evaporation of the solvent, the resultant crude stannylated product **7** was used for the following coupling reaction

without further purification. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.39 [s, 9 H, Sn(CH_3)$_3$], 0.89 (t, J = 6.1 Hz, 3 H, CH_3), 1.26 (m, 26 H, CH_2), 1.63 (quint, J = 6.7 Hz, 2 H, OCH_2CH_2), 3.50 (t, J = 6.4 Hz, 2 H, OCH_2), 4.57 (s, 2 H, $C_{py}CH_2O$), 7.44 (dd, J = 7.3 and 1.5 Hz, 1 H, 3′- or 5′-H), 7.64 (t, J = 7.3 Hz, 1 H, 4′-H), 7.80 (dd, J = 8.2 and 2.4 Hz, 1 H, 3-H), 8.27 (dd, J = 7.9 and 1.2 Hz, 1 H, 3′- or 5′-H), 8.54 (d, J = 7.9 Hz, 1 H, 4-H), 8.62 (d, J = 1.5 Hz, 1 H, 6-H). A mixture of **7** (334 mg, 0.58 mmol), 4,6-dichloro-2-phenylpyrimidine (**8**)[15] (66 mg, 0.29 mmol), and $Pd(PPh_3)_4$ (34 mg, 0.029 mmol) in toluene (5 mL) under argon was refluxed for 21 h. After evaporation of the solvent, the residue was taken up in $CHCl_3$ and filtered through a short pad of alumina. The solvent was evaporated, the residue was taken up in MeOH/acetone (1:1, v/v), and the precipitate formed was centrifuged off, washed with MeOH/acetone and dried in vacuo. The crude product thus obtained was further purified by column chromatography on alumina eluting with hexane/$CHCl_3$ (1:1, v/v) to afford **1** as a colorless powder (162 mg, 57%). M.p. 141 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.87 (t, J = 5.8 Hz, 6 H, CH_3), 1.24 (m, 52 H, CH_2), 1.67 (quint, J = 7.0 Hz, 4 H, OCH_2CH_2), 3.56 (t, J = 6.4 Hz, 4 H, OCH_2), 4.64 (s, 4 H, $C_{py}CH_2O$), 7.56–7.65 (m, 3 H, *m*- and *p*-H), 7.87 (d, J = 6.7 Hz, 2 H, 3′- or 5′-H), 8.05 (t, J = 7.9 Hz, 2 H, 4′-H), 8.60 (d, J = 7.9 Hz, 2 H, 3′- or 5′-H), 8.71–8.80 (m, 8 H, *o*-, 3′′-, 4′′- and 6′′-H), 9.62 (s, 1 H, 5-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.1, 22.7, 26.2, 29.3, 29.5, 29.6, 29.6, 29.6, 29.7, 29.8, 31.9, 70.3, 70.9, 111.5, 120.8, 121.7, 122.4, 128.4, 128.4, 130.6, 134.4, 136.0, 137.9, 137.9, 148.5, 153.8, 155.3, 155.4, 163.9, 164.1. MS (FAB): *m*/*z* (%) = 973.7 (100) $[M + H]^+$. IR (KBr): $\tilde{\nu}$ = 3060, 2918, 2850, 1720, 1556, 1540, 1471, 1377, 1263, 1115, 1022, 994, 814, 50, 718, 690, 652, 634 cm^{-1}. HR-MS (FAB): $C_{64}H_{89}N_6O_2$ (1022.51): calcd. *m*/*z* = 973.704702, found *m*/*z* = 973.705754 $[M + H]^+$.

[2×2]-Grid-Type Fe^{II} Complex (2): A mixture of **1** (5 mg, 5.14 μmol) and $Fe(BF_4)_2$·$6H_2O$ (1.73 mg, 5.14 μmol) in $CHCl_3$ (0.4 mL) and CH_3CN (0.4 mL) under argon was refluxed. The reaction was monitored by ^{1}H NMR spectroscopy and ES mass spectrometry and was proven to be completed after 15 h. Evaporation of the solvents afforded pure complex **2** in a quantitative yield as a dark green powder. ^{1}H NMR (200 MHz, $CDCl_3$/CD_3CN): δ = –17.8, –10.2, 0.0, 2.3, 2.8, 5.6, 7.3, 13.4, 14.2, 17.5, 55.5, 60.0, 66.4, 74.5. MS (ESI): *m*/*z* = 2318.7 $[M - 2\ BF_4]^{2+}$, 1517.0 $[M - 3\ BF_4]^{3+}$, 1116.4 $[M - 4\ BF_4]^{4+}$, 876.3 $[M - 5\ BF_4]^{5+}$.

STM Investigations: STM measurements were carried out under ambient conditions with a low-current RHK 1000 control system. STM imaging of the adlayers was performed at the internal interface between HOPG and a concentrated solution of the ligand **1**, dissolved in 1,2,4-trichlorobenzene, according to the procedure of Rabe.[13a] A drop of the solution was placed on a freshly cleaved HOPG surface, while the surface had already been scanned by STM under the conditions that allowed atomic resolution of the graphite surface structure. A potential of $U = \pm 1$ V was applied to the substrate. The scan rate was varied between 0.2 and 0.6 μm s^{-1}. The tunneling current set point was 8–20 pA. All images presented were obtained at constant current mode using a Pt/Ir (90:10) tip, which was mechanically sharpened. Complex **2** was dissolved in acetonitrile at a concentration less than 1 wt.-%. A drop of the solution was deposited on a freshly cleaved surface of graphite. The substrates were dried in the presence of acetonitrile vapor over 1 h (in a covered Petri dish with a few mL of acetonitrile next to the sample). Then the sample was taken out of the Petri dish and dried fully under ambient conditions. The molecular structure of the adlayer was probed by STM under air. The distances and angles were determined by using an internal calibration. The overall error of these determinations is estimated below ±5% for distances and angles.

Characterization by NMR Spectroscopy, X-ray Analysis and Cytotoxic Activity of the Ruthenium(II) Compounds $[RuL_3](PF_6)_2$ (L = 2-Phenylazopyridine or *o*-Tolylazopyridine) and $[RuL'_2L'']](PF_6)_2$ (L′, L′′ = 2-Phenylazopyridine, 2,2′-Bipyridine)

Keywords: Ruthenium / Tris(chelate) complexes / 2D NMR / Cytotoxicity

Tris(ligand) complexes $[RuL_3](PF_6)_2$ (L = 2-phenylazopyridine or *o*-tolylazopyridine) and mixed ligand $[RuL'_2L'']](PF_6)_2$ (L′ and L′′ are 2-phenylazopyridine or 2,2′-bipyridine) have been synthesized, structurally characterized and investigated for cytotoxic activity. These complexes are important to study the hypothesis that the compound α-$[Ru(azpy)_2Cl_2]$ (azpy = 2-phenylazopyridine) exhibits a high cytotoxicity due to its two *cis* chloride ligands, which might be exchanged for biological targets as DNA. Molecular structures of *mer*-$[Ru(azpy)_3](PF_6)_2$ (**1**) and *mer*-$[Ru(tazpy)_3](PF_6)_2$ (**5**) (tazpy = *o*-tolylazopyridine) have been determined by X-ray diffraction. Series of complexes $[RuL_3](PF_6)_2$ and $[RuL'_2L'']](PF_6)_2$ show interesting NMR spectroscopic data; e.g. the spectrum of *mer*-$[Ru(azpy)_3](PF_6)_2$ (**1**) shows extremely broadened resonances at room temp. but sharpened resonances at low temperature. In the ^1H NMR spectra of compounds $[Ru(azpy)_2(bpy)]^{2+}$ and $[Ru(bpy)_2(azpy)]^{2+}$ (bpy = 2,2-bipyridine), respectively, less broadened (room temp.) or completely sharp resonances (room temp.) occur in comparison to **1** (under same conditions). By selecting the right temperature and/or concentration, NMR spectra of these series of compounds have been resolved using 2D COSY and NOESY NMR spectroscopy. Remarkably, the cytotoxicity data against a series of human tumor cell lines (A498, EVSA-T, H226, IGROV, M19, MCF-7 and WIDR) show a moderate cytotoxicity for these series of tris(ligand) complexes. So, even though no chloride ligands are present in these tris(ligand) complexes, a considerable cytotoxic activity is observed. This would imply that the 2-phenylazopyridine ruthenium(II) complexes act by a completely different mechanism than the well-known cisplatin. This finding is important, because an anticancer compound acting via a different mechanism is a prerequisite in designing new anticancer drugs.

Introduction

The dichlorobis(2-phenylazopyridine)ruthenium(II) complexes, $[Ru(azpy)_2Cl_2]$ are under renewed investigation due to their cytotoxic activity in a panel of human tumor cell lines.[1,2] In particular the α configuration (Figure 1, α indicating the pairs of coordinating Cl, Npy and Nazo atoms in a mutual *cis*, *trans*, *cis* orientation) of the $[Ru(azpy)_2Cl_2]$ complexes is the most promising isomer, as this isomer displays a very high cytotoxicity, stability and a reasonable solubility.[1,2] The mechanisms underlying the cytotoxicity of the $[Ru(azpy)_2Cl_2]$ complexes and in particular of the α-$[Ru(azpy)_2Cl_2]$ are not known yet. In analogy to cisplatin[3] it has been hypothesized that two labile *cis* chloride ligands contribute to the overall activity of the compound, as in the tumor cell these labile chloride ligands will be replaced by water ligands and subsequently replaced by the nucleotides of the DNA. To confirm or reject this hypothesis it was decided to replace the chloride ligands of the *cis*-$[Ru(azpy)_2Cl_2]$ complexes by a third azpy or bpy ligand, unable to dissociate, and investigate this series tris(ligand)rutheni-

um(II) compounds for their cytotoxicity. This will result in a series of compounds, which will give more insights in the structure-activity relationships of these type of complexes.

Perhaps the most frequently considered binding interaction of heavy metals with DNA is that of coordinative binding to the bases of the DNA.[4] In addition to this interaction, intercalation is a common mode of association of small molecules with DNA; a flat aromatic heterocyclic moiety inserts and stacks in between the DNA base pairs.[4] Already in 1974 Lippard and co-workers[5,6] determined that platinum(II) complexes containing an aromatic heterocyclic ligand, such as terpyridine, could intercalate in DNA. This intercalation is not restricted to completely flat square-planar complexes, but partial intercalation of ligands coordinated to octahedral metal centers is also possible.[7] A ruthenium compound very thoroughly studied for its interaction with DNA is the tris(phenanthroline)ruthenium(II) complex. Depending on its enantiomeric form it binds to DNA by two non-coordinative modes, one described as a surface- or groove-bound interaction in the minor groove of the helix and the other appearing to be an intercalative interaction in the major groove of the helix.[4,7–9] However, the exact DNA binding mode of even a simple species like $[Ru(phen)_3]^{2+}$ remains an issue of debate.[10]

The compound $[Ru(azpy)_3](PF_6)_2$ theoretically exists in two different isomeric forms disregarding ΔΛ enantiomerism, i.e. the *mer* and *fac* isomers (Figure 2). The symmetry properties of the two isomers are markedly different; *fac*-$[Ru(azpy)_3](PF_6)_2$ belongs to the C_3 point group and hence has three equivalent azpy ligands. The *mer* isomer on the other hand is of C_1 symmetry, and all azpy ligands are inequivalent. The *fac* isomer formation of $[Ru(azpy)_3]^{2+}$ appears unlikely, also because previous studies have reported[11,12] that the *fac* isomer of $[Ru(azpy)_3]^{2+}$ is sterically unfavorable due to crowding of the three phenyl groups.

Several papers report the synthesis of $[Ru(azpy)_3]^{2+}$-like complexes. The first described[13] synthesis of $[Ru(azpy)_3]^{2+}$ dates from 1982; $[Ru(azpy)_3](PF_6)_2$ was synthesized using azpy and a crude mixture of isomers of $[Ru(azpy)_2Cl_2]$ with one isomer (probably α) in excess. The product is described as "a mixture" which has been characterized by IR and UV/Vis, which unfortunately does not say anything about the possible obtained *mer* or *fac* isomer(s). A one-pot synthesis using $RuCl_3$ and $[Ag(azpy)_2]^+$ as synthon has also been reported, but in this paper the possibility of the formation of both *fac* and *mer* isomers was not even discussed.[14] A recent publication appeared[11] after the present experimental work was carried out and showed the crystal structure of *mer*-$[Ru(azpy)_3](ClO_4)_2$. Except this crystal structure only a few more crystal structures of the type $[M(azpy)_3]^{n+}$ (with M any metal) have been reported, i.e. the rhenium structure[15] *fac*-$[Re(azpy)_3](ClO_4)$, the iron compound[16] $[Fe_2(CO)_2(4\text{-}CH_3\text{-}2\text{-phenylazopyridine})_3]$, the compound[11] *mer*-$[Ru(HL)_3](ClO_4)_2$ {HL = 2-[(4-(methoxyamino)phenyl)azopyridine} and the rhenium compound[17] *fac*-$[Re(apy)_3]I$ (apy = 2,2′-azobipyridine). Another type of tris(ligand) complexes are the mixed ligand complexes of the type $RuLL'_2$ (with L and L′ both didentate ligands with one of them containing the azo functionality) of which the crystal structures of $[Ru(bpy)(MeaaiMe)_2](ClO_4)_2$ [MeaaiMe = 1-methyl-2-(*p*-methylazo)imidazole], $[Ru(bpy)_2(p\text{-}MeaaiCH_2ph)](ClO_4)_2\cdot H_2O$, $[Ru(phen)(HaaiMe)_2](ClO_4)_2$, $[Ru(azpy)_2(H_2biim)](ClO_4)_2\cdot 3CH_2Cl_2$ (H_2Biim = 2,2′-biimidazole) and $[Ru(HL)(bpy)_2](ClO_4)_2$ {HL = 2-[(4-(arylamino)phenyl)azopyridine} are nice examples[11,18–21] of compounds structurally related to the series of compounds

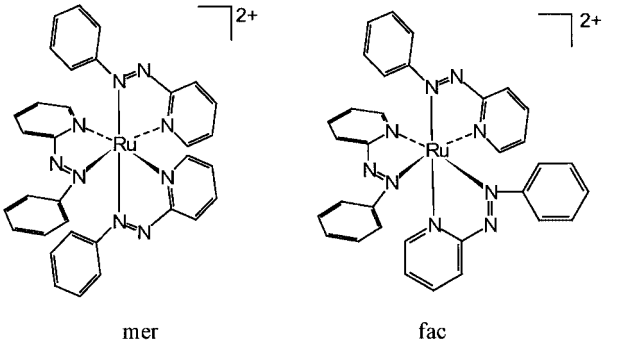

Figure 2. *mer*- and *fac*-$[Ru(azpy)_3]^{2+}$ (only Δ isomers shown).

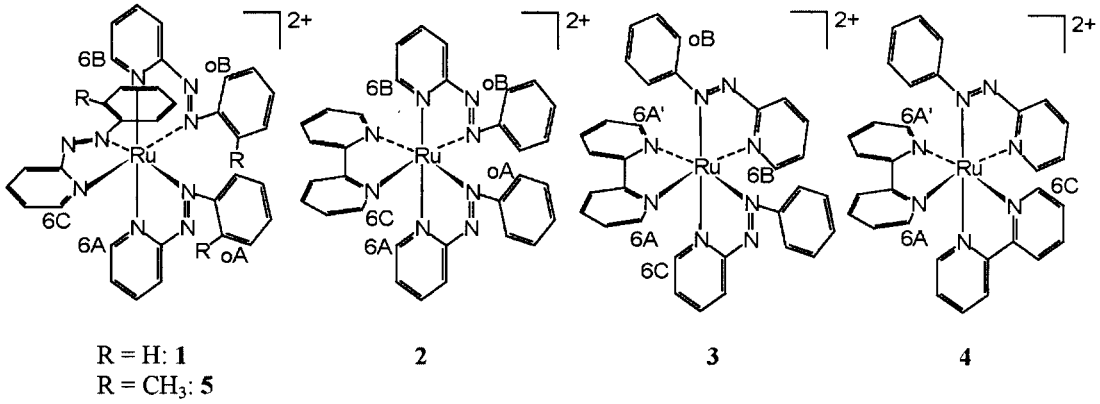

Figure 3. A series of tris(ligand) ruthenium(II) complexes (from left to right): mer-$[Ru(azpy)_3](PF_6)_2$ (**1**) and *mer*-$[Ru(tazpy)_3](PF_6)_2$ (**5**), α-$[Ru(azpy)_2(bpy)](PF_6)_2$ (**2**), β-$[Ru(azpy)_2(bpy)](PF_6)_2$ (**3**) and $[Ru(azpy)(bpy)_2](PF_6)_2$ (**4**); some hydrogen atoms, important for NMR assignments, are indicated.

described in this paper. Till now, no 2D NMR characterization or cytotoxicity tests have ever been reported on any kind of above mentioned tris(ligand) complexes.

To design new anticancer drugs and to develop structure-activity relationships for 2-phenylazopyridine ruthenium(II) complexes, a series (Figure 3) of newly synthesized tris(ligand) ruthenium(II) complexes, i.e. *mer*-[Ru(azpy)$_3$](PF$_6$)$_2$ (**1**), α-[Ru(azpy)$_2$(bpy)](PF$_6$)$_2$ (**2**), β-[Ru(azpy)$_2$(bpy)](PF$_6$)$_2$ (**3**), [Ru(azpy)(bpy)$_2$](PF$_6$)$_2$ (**4**) and *mer*-[Ru(tazpy)$_3$](PF$_6$)$_2$ (**5**, tazpy = *o*-tolylazopyridine) are synthesized and characterized by 2D NMR spectroscopy. X-ray diffraction analysis of **1** and **5** have been performed. The synthesis of these complexes is known from early work,[12,13,22] but the full NMR characterization using variable temperature NMR and 2D NMR techniques and especially the correlations made to antitumor research are new. The cytotoxicity of the complexes will be discussed in relation to the very cytotoxic dichlorobis(azpy)ruthenium(II) complexes.

Results and Discussion

General Considerations

One of the syntheses described in this paper is the synthesis of *mer*-[Ru(azpy)$_3$](PF$_6$)$_2$ from α-[Ru(azpy)$_2$(NO$_3$)$_2$] and azpy. Since only the *mer* isomer of [Ru(azpy)$_3$](PF$_6$)$_2$ has two azpy ligands positioned according to the α configuration (pairs of pyridine N atoms *trans* and Nazo atoms *cis*) this synthetic route theoretically excludes *fac* isomer formation, assuming that no isomerization[23] takes place. Moreover, *fac* isomer formation remains unlikely, also because previous studies have reported[11,12] that the *fac* isomer of [Ru(azpy)$_3$](PF$_6$)$_2$ is sterically unfavorable due to crowding of the three phenyl groups (vide infra). As anticipated only pure *mer*-[Ru(azpy)$_3$](PF$_6$)$_2$ was obtained.

Crystal Structures of 1 and 5

The cations of the crystal structures of *mer*-[Ru(azpy)$_3$](PF$_6$)$_2$ (**1**) and *mer*-[Ru(tazpy)$_3$](PF$_6$)$_2$ (**5**) are redrawn in Figure 4. For clarity, only the Λ enantiomers are shown, while the unit cell actually contains the Λ and Δ enantiomer. Furthermore the two PF_6^- counterions of which one is disordered have been omitted. The X-ray data of *mer*-[Ru(azpy)$_3$](ClO$_4$)$_2$ have been published by Das et al,[11] but has a different crystal system (monoclinic) and space group ($P2_1/c$) than **1** (resp. triclinic and $P\bar{1}$). However, the bond lengths of the cation of *mer*-[Ru(azpy)$_3$](ClO$_4$)$_2$ show a great deal of similarity with **1**. It is interesting to compare the X-ray data of **1** with *mer*-[Ru(tazpy)$_3$](PF$_6$)$_2$ (**5**) (see Figure 4). Crystallographic data of **1** and **5** are listed in Table 1. Selected bond lengths and angles of **1** and **5** are listed in Table 2 and Table 3, respectively.

In order to draw a comparison of the tris(ligand) complexes **1** and **5** with the related bis(azpy) complexes, like α-[Ru(azpy)$_2$Cl$_2$], α-[Ru(azpy)$_2$(NO$_3$)$_2$] and β-[Ru(azpy)$_2$Cl$_2$] (β indicating coordinating pairs Cl, Npy, Nazo in mutual *cis*, *cis cis* orientation), some distances within these complexes are listed in Table 4. In the crystal structures[24,25] of the bis(azpy) complexes the Ru–Nazo bonds were found to be significantly shorter than the Ru–Npy bonds. These short Ru–Nazo bonds can be attributed to substantial π-back bonding of the ruthenium through an azo nitrogen [Ru(t_{2g})-π*azpy]. In complexes **1** and **5** the lengths of the Ru–Nazo bonds are, on average, more similar to the Ru–Npy bond lengths. Therefore, no significant π-back bonding effects on the coordination bonds of **1** and **5** are visible. This is probably caused by a greater competition for Ru(t_{2g}) electrons in the tris(ligand) complexes. A *trans* N(azo)–M–N(azo) arrangement is quite rare as can be directly seen from the fact that from the five isomers of [Ru(azpy)$_2$Cl$_2$] the less common isomers, i.e.[26] δ-[Ru(azpy)$_2$Cl$_2$] and the

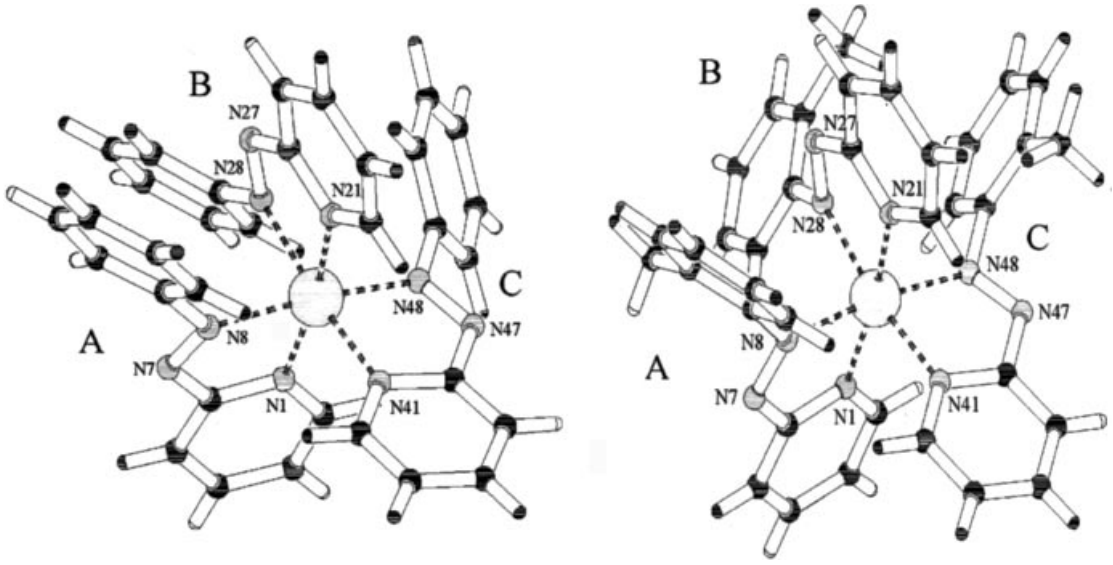

Figure 4. Crystal structures of **1** (left) and **5** (right). Only the Λ isomers are shown. To facilitate discussion the three (t)azpy ligands are denoted with A, B and C.

probable existing[27] ε-$[Ru(azpy)_2Cl_2]$ (δ indicating Cl, Npy and Nazo, *trans*, *trans*, *trans* and ε has the pairs of Cl, Npy and Nazo *cis*, *cis*, *trans*) have this *trans* Nazo-M–Nazo grouping. Also in the meridional tris(ligand) complexes this *trans* N(azo)–M–N(azo) arrangement occurs, e.g. the iron compound[16] $[Fe_2(CO)_2(4\text{-}CH_3\text{-}2\text{-phenylazopyridine})_3]$ and the compound[11] *mer*-$[Ru(azpy)_3](ClO_4)_2$. Especially in the *trans* Nazo–M–Nazo arrangement the two azo bonds are thought to compete for the back bonding of the Ru^{II} (4d) t2g electron density, resulting in, in theory, relatively long Ru–Nazo bond lengths.

^{1}H NMR Characterization of the Tris(ligand)ruthenium(II) Complexes

General Information

At room temperature, the resonances of the tris(ligand) complexes **1**,**2** and **5** were found to be significantly broadened at room temperature. The variable-temperature ^{1}H NMR spectra in $[D_6]$acetone of **1** and **2** are depicted in Figure 5. This broadening seems to be dependent on both concentration and temperature.

For example compound **1** shows really broad resonances at room temperature but cooling the sample results in marked sharpening of the resonances (Figure 5). Till now, no thorough NMR characterization has been reported about *mer*-$[Ru(azpy)_3]^{2+}$ type of compounds. For example the reported ^{1}H NMR spectrum of the compound[12] *mer*-$[Ru(tap)_3]^{2+}$ (tap = *m*-tolylazopyridine) shows two methyl resonances and the absence of one more methyl signal (as all three ligands in the *mer* isomer should be distinguishable) has been explained by the fact that in practice two rings become equivalent. By using pure β-$[Ru(tap)_2(H_2O)_2]^{2+}$ the occurrence of both *mer* and (a small amount of) *fac*-$[Ru(tap)_3]^{2+}$ have been reported which have been characterized by ^{1}H NMR spectroscopy.[12] However, this NMR characterization was not very clear. Only the high field region of the ^{1}H NMR spectrum was shown, which is quite inconvenient with respect to the broadening of especially the aromatic resonances observed for this type of complexes (vide infra).[12] Also the recent publication of Das et al. does not show any NMR spectroscopic data of *mer*-$[Ru(azpy)_3]$-

$(ClO_4)_2$. In general, for tris(ligand) complexes with 2-phenylazopyridine- or 2-phenylazoimidazole-like ligands only ^{1}H NMR chemical shift data are mentioned,[19–21,28] without performing 2D NMR experiments and no broadening is mentioned. In our opinion the ^{1}H NMR spectroscopic data of these very complicated spectra[19–21,28] are questionable. Therefore, an extensive description of the assignment of the tris(ligand) complexes mentioned in this paper using several 2D NMR techniques seems to be useful.

The ^{1}H NMR chemical shift values (600 MHz) of the complexes **1**, **2**, **3** and **4** (samples of **1** and **2** recorded at low temperatures) are listed in Table 5 (the resonances belonging to the azpy ligands are denoted with A, B or C, e.g. 6A or *o*B; the resonances belonging to the bpy ligands are denoted by only a number). The assignment of *mer*-[Ru(tazpy)$_3$](PF$_6$)$_2$ has not been attempted, as the broadening in this case was even more complicated probably due to additional steric hindrance due to the methyl group of the phenyl rings and under no conditions sharp resonances were observed. The assignment of the resonances of **1** at low temperature will be described in detail to show the common way of assigning such complicated spectra. It

Table 5. ^{1}H NMR chemical shift values (600 MHz) of **1**, **2**, **3** and **4** in [D_6]acetone. The spectrum of **1** has been recorded recorded at 183 K, 2 at 195 K and **3** and **4** at room temperature.

makes in a beautiful way use of the fact that in the compound *mer*-$[Ru(azpy)_3](PF_6)_2$, the azpy ligands are two-by-two in mutual α, β and ε configurations as shown in the bis(chelate) complexes $[Ru(azpy)_2Cl_2]$ and subsequently these configurations have known[26] interligand NOE cross-peaks. The use of these known geometries of $[Ru(azpy)_2Cl_2]$ complexes plays a key role in the assignment of compound **1.**

NMR Characterization of 1

The ^1H NMR spectrum of **1** (600 MHz) at low temperature and low concentration shows 16 well-resolved resonances some of which appear to be multiplet signals due to overlap of resonances (Figure S1, supporting information, for supporting information see also the footnote on the first page of this article). As **1** has C_1 symmetry, all three azpy ligands are inequivalent, resulting in 21 resonances, which have been fully assigned using 2D COSY and NOESY NMR spectroscopy.

First, from 2D COSY NMR the three sets of azpy pyridine signals and three sets of azpy phenyl signals have been distinguished. As in the NMR spectra only three sets of phenyl signals appear, the phenyl rings are assumed to rotate fast on the NMR time scale. The H6 protons of the azpy ligands were easily recognised from the smaller *J* coupling in comparison to the J coupling of the H3 atoms and appear at δ = 8.51, 8.70 and 9.06 ppm. The NOESY spectrum (Figure 6) shows several NOE cross peaks (Table S1, Supporting Information), i.e. one *o*-*o* coupling, one coupling between two H6 hydrogen atoms and four cross peaks between H6 and *ortho* resonances. The *mer*-$[Ru(azpy)_3]^{2+}$ backbone consists of pairs of azpy ligands of the isomeric bis(ligand) complexes, α-$Ru(azpy)_2$ (in Figure 4 these have been denoted as azpy ligand A and B), β-$Ru(azpy)_2$ (in Figure 4 these have been denoted as B and C) and ε-$Ru(azpy)_2$ (azpy ligands C and A in Figure 4). So because the azpy ligands A and B of **1** actually represent the α configuration, A6-*o*B and B6-*o*A NOEs are expected[24,26] in the 2D NOESY spectrum of **1**. Likewise, ligands B and C in **1** are expected[26] to display B6–C6 and *o*B-*o*C NOEs. The synthesis of the ε isomer, ε-$[Ru(azpy)_2Cl_2]$ has been reported in a short letter,[27] but no NMR spectroscopic data have been presented. Therefore the crystal structure of **1** is used to determine which NOE cross peaks are to be expected for this ε configuration. According to distances in the crystal structure of **1** the unknown ε-$Ru(azpy)_2$ backbone should give rise to 6C-*o*A (average distance of H46–H10 and H44–H14 = 4.0 Å) and 6A-*o*C cross peaks (average distance of H6–H47 and H6–H54 = 3.7 Å).

A close look in the NOESY spectrum shows that one of the H6 resonances (at, 8.70 ppm) gives cross peaks to two *ortho* signals. These NOEs unambiguously assign the resonance at δ = 8.70 ppm to correspond to the H6A atom giving cross peaks to *o*B and *o*C. In fact, the NOE 6A-*o*B is expected, as this is the known cross peak for the α configuration. The 6A-*o*C is a cross peak apparently occurring in the ε configuration, as was also likely from the crystal structure. How to discriminate between the *o*B and *o*C resonances? One of these *ortho* resonances is shifted upfield related to the other. The *o*B hydrogens are positioned within the shielding cone of pyridine ring A. For this reason the high-field resonance at δ = 7.02 ppm can be assigned to the *o*B hydrogens. A cross peak occurs between *o*B and *o*C in agreement with the β configuration. Two H6 resonances remain: the H6 resonances at δ = 8.51 and 9.06 ppm, which present a cross peak between each other. This 6B-6C NOE perfectly agrees with the β-$Ru(azpy)_2$ configuration. The signal at δ = 8.51 ppm is assigned to 6B, as this resonance is within the shielding cone of the pyridine ring of ligand C and so should appear at higher field.

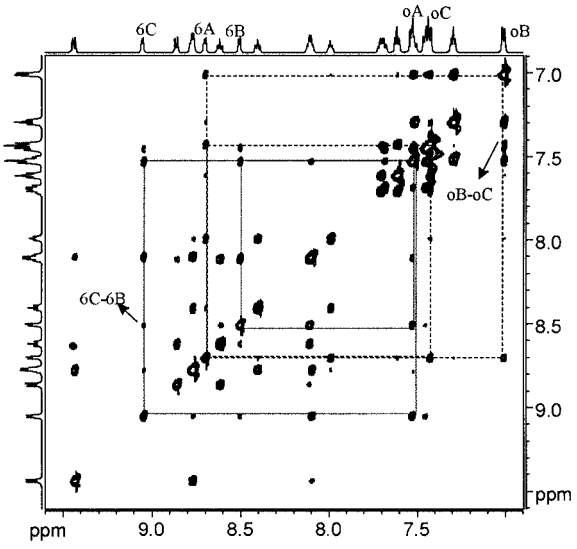

Figure 6. ^1H-^1H NOESY spectrum (600 MHz) and some assignments of the aromatic region of **1** in $[D_6]$acetone, 183 K. The dashed lines indicate the 6A-oB and 6A-oC NOEs. The dotted lines indicate the oA-6C and oA-6B NOEs. Arrows indicate the NOEs 6C-6B and oB-oC.

Two other NOE cross peaks observed in the 2D NOESY spectrum are the 6B-*o*A and 6C-*o*A NOEs. The first one is due to the α configuration of the ligands A and B, the second one is due to the ε configuration of ligands C and A.

NMR Characterization of 2

Interestingly, the ^1H NMR spectrum of **2** at room temperature shows partly sharp and partly broadened resonances (Figure 5). Cooling the NMR sample to 195 K all resonances sharpen. The ^1H NMR spectrum of **2** at 195 K shows only two sets of pyridine rings and one set of phenyl ring signals. Due to the C_2 axis present in this complex, the two azpy ligands are equivalent (A = B) and even the two pyridine rings of the bpy ligand are indistinguishable (see Figure 4). It appears to be difficult to assign the two sets of pyridine rings to either the bpy or the azpy ligand. An indication to assign properly the pyridine rings to either the azpy or the bpy ligand, is that the resonances of one pyridine ring are broadened at room temperature, whereas the other set of pyridine resonances is sharp at room temperature (Figure 5). As less broadening occurs introducing a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bpy ligand in these $[RuL_2L']^{2+}$ complexes (vide infra) it seems reasonable to assume that the broadened resonances correspond to the azpy ligand. Therefore, from the VT NMR studies (Figure 5) it follows that the sharp (at all temperatures) resonance at around 9.1 ppm corresponds to the H3 of bpy. Using COSY connectivities the other resonances are assigned.

The two most important NOE cross peaks that appear in the spectrum of **2** are (Figure S2, supp. inf.): 1) A NOE between the H6 resonance of one azpy ligand and the *ortho* resonance of the other azpy ligand (H6A–*o*B=H6B–*o*A) as A and B are forming the α configuration, and 2) a NOE between the H6 resonance of the bpy ligand and the *ortho* resonance of azpy (H6C-*o*A) which is a NOE due to the ε configuration (vide supra).

NMR Characterization of 3

The ^{1}H NMR assignment of β-$[Ru(azpy)_2(bpy)](PF_6)_2$ (**3**) is based on almost the same reasonings as used for **1**. The ^{1}H NMR of **3** (600 MHz) at room temperature shows all sharp resonances. However, also for this compound some signal broadening was observed at certain concentrations and temperatures, albeit not as extensively broadened as for example compound **1** (data not shown). Compound **3** consists again of pairs of ligands derived from known bis(ligand) moieties (Figure 3), which again can perfecly be used to assign the resonances properly. Ligand A and B form the α-Ru(azpy)(bpy) moiety. The 1D and 2D NOE data of α-$[Ru(azpy)(bpy)Cl_2]$ are just recently published.[29] Ligand B and C form the β-$[Ru(azpy)_2]$ moiety. Pyridine ring A (without prime) and ligand C form part of the ε-$Ru(azpy)_2$ backbone. In the 2D NOESY NMR spectrum (Figure S3, supp. inf.) one of the H6 resonances gives NOE cross peaks to two *ortho* resonances. These NOEs are assigned as the 6A-*o*B and 6A-*o*C NOEs in correspondence with the known cross peaks (H6-*o*) of the α-Ru(azpy)(bpy) moiety and ε-$Ru(azpy)_2$ configuration. Again the *o*B resonance is at higher field than the *o*C resonance as the *o*B hydrogens are in the shielding cone of pyridine ring A. Using the bpy H3-H3′ NOE, the other bpy pyridine ring can be assigned. The resonance 6A′ couples to two six resonances, i.e. 6B and 6C. As the chemical shifts of the protons 6B and 6C are almost identical they could not be assigned based on (de)shielding effects. Consequently, pyridine rings B and C could not be distinguished.

NMR Characterization of 4

The ^{1}H NMR of **4** shows all sharp resonances at room temperature and they remain sharp in the whole used temperature range. The ^{1}H-^{1}H 2D NOESY spectrum is shown in Figure S4, supp. inf. The H3-H3′ NOE of the bpy ligands has been used to assign the two bpy ligands. A simple ball and stick model shows that one of the bpy ligands has both its H6 hydrogen atoms in the shielding region of a pyridine ring, so the corresponding H6 resonances should both appear at high field. The other bpy ligand should have one H6 resonance at low field and one at high field (one H6 atom is in the shielding cone of a pyridine ring whereas the other H6 atom is above the azo bond, which gives less shielding). This allows the assignment of the resonances at δ = 8.05 and 7.72 ppm as H6A and H6A′ and the resonances at δ = 8.39 and 8.02 ppm as 6C and 6C′. Both H6C and H6A resonances give NOE cross peaks to the *ortho* resonance of the azpy ligand in agreement with the proposed structure of **4**.

Apparently, from the above-mentioned NMR spectroscopic data it is clear that the assignment of these kind of tris(ligand) complexes is quite complicated and the ^{1}H NMR assignment in literature of these kind of complexes is confusing, incomplete and sometimes erroneous.[19,21]

Variable Temperature and Concentration Studies

Although as yet not studied in detail, the concentration and temperature-dependent NMR spectra (300 MHz) show interesting differences between the complexes **1**, **2**, **3** and **4**. The temperature series of **1** at the lower concentration (Figure 5) results in sharper resonances at 193 K than in case of the higher concentration. The series of ^{1}H NMR spectra at various temperatures of **2** show less broadening in comparison to **1** and the differences between the two concentrations of **2** seem smaller. Finally the series of spectra of **3** also do show some signal broadening, which is comparable to **2**; one set of sharp resonances and one set of broadened reasonances (data not shown). In general, the comparison of **1** with **2** and **3** lead to the suggestion that introducing a bpy ligand in such tris(ligand) complexes results in a more rigid structure and consecutively less broadening. This is in agreement with the fact that the complexes $[Ru(azpy)(bpy)_2](PF_6)_2$ and $[Ru(bpy)_3](PF_6)_2$ do not show any signal broadening. Signal broadening in NMR occurring for this type of tris(ligand)ruthenium(II) complexes is not known in literature. For example in case of the related complex $[Ru(abpy)_3]^{2+}$ [(abpy = 2,2-azobis(pyridine)] ^{1}H NMR spectra data are reported, but no broadening has been mentioned.[28]

One mechanism that may be responsible for signal broadening in (azpy)ruthenium complexes is sterically hindered rotations of one or more phenyl rings.[30] In theory this implies that upon cooling the sample during the NMR experiment, the phenyl ring rotation becomes slower on the NMR time scale and at the lowest temperatures it is possible to stop the phenyl ring rotation (on the NMR time scale). This would result in distinct resonances for the *o* and *m* protons on one side of the phenyl ring and the *o* and *m* protons on the other side. However, the fact that such distinct resonances were not observed for any of the azpy-containing (tris)ligand complexes indicates that hindered rotations of phenyl rings are not responsible for the observed signal broadening. However, hindered tolyl-ring rotations might still be present in *mer*-$[Ru(tazpy)_3](PF_6)_2$, since upon cooling and diluting the NMR sample of this compound, no conditions were found which resulted in sharp resonances.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The fact that the broadening of the resonances of the tris(ligand) complexes is also dependent on concentration might suggest stacking or intermolecular interactions.

The possibility of ligand exchange/decoordination can be ruled out by the fact that no free ligand was observed at low temperatures and the fact that addition of free ligand did not influence the broadening of the signals.

Another explanation for the VT NMR results appears to lie in intramolecular rearrangements, which are known in the literature[31] to be able to result in NMR signal broadening. Nevertheless more research is needed to comprehend this phenomenon of signal broadening.

Cytotoxicity Tests

The complexes **1**, **2**, **3** and **4** have been tested for their cytotoxicity against a series of human tumor cell lines. The data are summarized in Table 6. Compound **1** shows in the cell lines EVSA-T and M19 quite a significant cytotoxicity, but in the other cell lines the IC_{50} values are moderate to low. Compound **2** exhibits in EVSA-T, M19 and MCF-7 a considerable cytotoxicity. Compound **3** displays only in the cell line M19 a considerable cytotoxicity and compound **4** still shows a considerable cytotoxicity in the cell lines EVSA-T and H226. Interesting to mention is that the compound $[Ru(bpy)_3](PF_6)_2$ does not show any cytotoxic effect under these circumstances (data not shown). It is important to note that the activity of these complexes cannot be caused by traces of starting materials, like for example α-$[Ru(tazpy)_2(NO_3)_2]$ or azpy. The former one shows an activity of approximately 8 μM[32] and the ligand azpy shows no cytotoxicity at all.[33] It is quite remarkable that this series of compounds **1**, **2**, **3** and **4** show a moderate cytotoxicity in some cell lines,[33] as these complexes do not have any anionic (chloride) ligands, to allow, after hydrolysis, coordination to DNA bases. This behavior might point to a class of very interesting ruthenium complexes acting by another mechanism than cisplatin and therefore opening the way to a new category of anticancer agents, agents which might be successful against cancer types where the old generation drugs appeared to be inactive. The activity of these tris(chelated) complexes might be caused by an intercalative interaction with DNA rather than a cisplatin-like covalent interaction with DNA. Interestingly just recently a publication appeared[34] concerning a series of tris(ligand) complexes $[Ru(L)_2(Y)]Cl_2$ with L bpy or phen and Y thiosemicarbazone-type of ligands. These complexes show a considerable antitumor activity in mice and therefore strengthening the fact that tris(ligand) complexes are a very important group of potential new ruthenium anticancer drugs.

Conclusions

Tris(ligand)ruthenium(II) azpy-like complexes show in many aspects interesting properties. The NMR spectroscopic data of the series of complexes $[RuL_3](PF_6)_2$ (L = 2-phenylazopyridine or *o*-tolylazopyridine) and $[RuL'_2L''](PF_6)_2$ (L′ and L′′ are 2-phenylazopyridine or 2,2′-bipyridine) show broadening of the resonances for especially the complexes **1**, **2** and **5**. This broadening appears to depend on temperature, concentration and steric hindrance within the complex. Choosing the right conditions, sharp resonances have been obtained and the complicated NMR spectra of these tris(ligand) complexes could be almost completely resolved. Especially the fact that these tris(chelated) complexes are build of pairs of known configurations (e.g. α-, β-, and ε-$Ru(azpy)_2$) with previously determined (2D) NMR spectroscopic data, allowed the assignment of almost all resonances of the tris(ligand) complexes.

The cytotoxicity data show that the complexes *mer*-$[Ru(azpy)_3](PF_6)_2$, α-$[Ru(azpy)_2(bpy)](PF_6)_2$, β-$[Ru(azpy)_2(bpy)](PF_6)_2$, and $[Ru(azpy)(bpy)_2](PF_6)_2$ have a moderate cytotoxicity in some particular cell lines. In general, the fact that these fully coordinated tris(chelated) complexes still show some activity, suggests intercalative properties responsible for eventual cell death. In conclusion, these complexes appear to act through another mechanism than the compound cisplatin, which indicates that in general these ruthenium 2-phenylazopyridine complexes are a very interesting class of anticancer complexes, conceivably being able to lead to a different type of anticancer drugs.

Experimental Section

Syntheses: The syntheses of the tris(ligand)ruthenium(II) complexes mentioned below are modifications of literature syntheses[12,13,22] for *mer*-$[Ru(azpy)_3]^{2+}$, $[Ru(azpy)_2(bpy)]^{2+}$ and $[Ru(azpy)(bpy)_2]^{2+}$ using *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ or α- and β-$[Ru(azpy)_2(NO_3)_2]$ as starting materials.[23,24,35]

***mer*-$[Ru(azpy)_3](PF_6)_2$ (1):** α-$[Ru(azpy)_2(NO_3)_2]$ (40.0 mg, $6.76\cdot10^{-5}$ mol) and azpy (37.4 mg, $2.04\cdot10^{-4}$ mol) were dissolved in water (5 mL) and methanol (5 mL). The red solution was refluxed for

one hour, during which time the solution turned red-brown. After cooling to room temperature, a concentrated aqueous solution of NH_4PF_6 (240 mg) was added, which led to the precipitation of a brown product. The brown product was washed with water and dried with diethyl ether, resulting in a yield of 38.0 mg (75%). $C_{33}H_{27}F_{12}N_9P_2Ru$ (940.1): calcd. C 42.1, H 2.9, N 13.4; found C 42.1, H 3.0, N 13.2.

α-[Ru(azpy)$_2$(bpy)](PF$_6$)$_2$ (2): α-[Ru(azpy)$_2$(NO$_3$)$_2$] (30.0 mg, $5.07\cdot10^{-5}$ mol) and bpy (23.8 mg, $1.47\cdot10^{-4}$ mol) were dissolved in water (5 mL) and methanol (5 mL). The purple solution was refluxed for 90 minutes, resulting in a brown solution. After cooling to room temperature, a concentrated aqueous solution NH_4PF_6 was added, which led to the precipitation of a red-brown product. This product was washed with water and diethyl ether and dried in vacuo with P_4O_{10}. Yield: 45.7 mg (99%). $C_{32}H_{26}F_{12}N_8P_2Ru$ (913.1): calcd. C 42.1, H 2.9, N 12.3; found C 43.6 H 3.0, N 12.6.

β-[Ru(azpy)$_2$(bpy)](PF$_6$)$_2$ (3): β-[Ru(azpy)$_2$(NO$_3$)$_2$] (20.0 mg, $3.38\cdot10^{-5}$ mol) and bpy (15.8 mg, $1.0\cdot10^{-4}$ mol) were refluxed for 1.5 hours in a mixture of water (3.5 mL) and of methanol (3.5 mL). During this time a color change from purple to red occurred. The resulting solution was filtered and a concentrated aqueous solution of NH_4PF_6 was added. A brown crystalline material formed within an hour. This product was collected by filtration and washed with water and diethyl ether. Yield: 22.7 mg (74%). $C_{32}H_{26}F_{12}N_8P_2Ru$ (913.1): calcd. C 42.1, H 2.9, N 12.3; found C 41.7, H 3.0, N 13.2.

[Ru(azpy)(bpy)$_2$](PF$_6$)$_2$ (4): *cis*-[Ru(bpy)$_2$Cl$_2$]·2H$_2$O (25.0 mg, $4.80\cdot10^{-5}$ mol) and azpy (44.0 mg, $2.40\cdot10^{-4}$ mol) were refluxed for 3.5 hours in water (5 mL), during which the solution changed color from yellow to red. The reaction mixture was filtered and a concentrated aqueous solution of NH_4PF_6 was added. A red precipitate could be collected, which was subsequently washed with small amounts of water and diethyl ether. Yield: 38.3 mg (90%). $C_{32}H_{25}F_{12}N_7P_2Ru\cdot1.5H_2O$ (925.1): calcd. C 40.8, H 3.1, N 10.8; found C 40.5, H 2.7, 10.9.

***mer*-[Ru(tazpy)$_3$](PF$_6$)$_2$ (5):** The precursor material α-[Ru(tazpy)$_2$(NO$_3$)$_2$] was prepared analogous to the synthesis[24] of α-[Ru(azpy)$_2$(NO$_3$)$_2$] with use of the ligand *o*-tolylazopyridine. α-[Ru(tazpy)$_2$(NO$_3$)$_2$] (20.0 g, $3.23\cdot10^{-5}$ mol) was refluxed with tazpy (19 mg, $9.6\cdot10^{-5}$ mol) in a mixture of methanol (5 mL) and water (5 mL) for one hour. A color change from violet to brown was noted and the solution was cooled to room temperature. A concentrated solution of NH_4PF_6 was then added, resulting in a brown precipitate, which was collected, washed with water, and dried in vacuo with P_4O_{10}. Yield: 24.6 mg (78%). $C_{36}H_{33}F_{12}N_9P_2Ru$ (982.1): calcd. C 44.00, H 3.38, N 12.83; found: C 44.0, H 3.1, N 12.9.

X-ray Crystal Structure Determination of 1 and 5: Crystals of suitable size were placed in the cold nitrogen stream of a Nonius KappaCCD diffractometer on rotating anode. Data were collected at 150 K, using Mo-K_α radiation (graphite monochromator, λ = 0.71073 Å). For **5** an absorption correction based on multiple measurements of symmetry-related reflections was applied (PLATON/MULABS,[36] T-range 0.898–0.950). The structures were solved by direct methods (SHELXS86,[37]) and refined on F^2 using full-matrix least-squares techniques (SHELXL-97-2,[38]). One of the PF_6 counterions in the crystal structure of **1** was refined with a two-site disorder model. Mild distance restraints were applied to enforce a reasonable geometry of the minor disorder component. Hydrogen atoms were included in the model on calculated positions, riding on their carrier atoms. The methyl groups of **5** were rotated along the C–C bond during refinement. All non-hydrogen atoms were refined with anisotropic displacement parameters with exception of the minor component atoms of the disordered counterion in **1**. Hydrogen atom displacement was described with a fixed isotropic parameter linked to the equivalent isotropic parameter of the carrier atom. Pertinent data for each of the structure determinations are given in Table 1. CCDC-251700 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Cyrstallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Physical Measurements: The NMR measurements were performed with a Bruker 300 DPX spectrometer and a 600 DPX spectrometer. Spectra were recorded in [D$_6$]acetone and calibrated on the solvent peak. 2D ^{1}H-^{1}H NOESY spectra were performed using the standard Bruker pulse sequences, with a mixing time of 0.8–1 s.

Cytotoxicity Tests. Determination IC$_{50}$ Values: For the determination of the IC_{50} values of the compounds **1**, **2**, **3** and **4** a panel of human tumor cell lines (MCF-7, EVSA-T, WIDR, IGROV, M19, A498 and H266) has been used. The in vitro cytotoxicity assays using these cell lines were performed at the Dr. Daniel den Hoed kliniek (Rotterdam Cancer Institute), Department of Medical oncology (Rotterdam, The Netherlands).

A stock solution of the test and reference compounds was used, which contained 1 mg compound/200 μL. The compounds were dissolved in DMSO. On the first day 150 μL of trypsinized tumor cells (1500–2000 cells/well) were plated in 96-wells flatbottom microtiter plates. The plates were preincubated 48 h at 37 °C, 8.5% CO_2 to allow the cells to adhere. On day 2, a threefold dilution sequence of ten steps was made in full medium, starting with the 1 mg compound/200 μL stock solution. Every dilution was used in quadruplicate by adding 50 μL to a column of four wells. On day 7 the incubation was terminated by washing the plate twice with PBS. Cytotoxicity was estimated by the microculture sulforhodamine B (SRB) test.[39] The absorbance was read at 540 nm using an automatic microplate reader (labsystems Multiskan MS). Data were used for construction of concentration response curves and determination of the IC_{50} value by use of Deltasoft 3 software.

Supporting Information (see also footnote on the first page of this article): ^{1}H NMR spectrum of **1** (Figure S1), 2D NOESY spectra of **2–4** (Figure S2–S4) and Table S1 showing NOE cross peaks for **1–4** (see also footnote on the first page of this article).

Acknowledgments

This work was supported by the Council for Chemical Sciences of the Netherlands Organization for Scientific Research (CW-NWO). We thank Johnson Matthey Chemicals (Reading, UK) for a generous loan of $RuCl_3\cdot3H_2O$. We thank C. Erkelens and A. W. M. Lefeber for assistance with the NMR pulse techniques. Dr. Dick de Vos is kindly acknowledged for facilitating determination of the IC_{50} values. Additional support from COST Action D20 allowing regular research exchanges to partner laboratories from EU countries is gratefully acknowledged.

Spectroscopy and Redox Behaviour of Dicopper(II) and Dinickel(II) Complexes of Bis(cyclen) and Bis(cyclam) Ligands

Sanae El Ghachtouli,[a] Cyril Cadiou,[a] Isabelle Déchamps-Olivier,[a] Françoise Chuburu,*[a] Michel Aplincourt,[a] Véronique Turcry,[b] Michel Le Baccon,[b] and Henri Handel[b]

Keywords: Copper / Nickel / Bis(cyclen) ligands / Bis(cyclam) ligands / Electrochemistry / EPR spectroscopy

The dinuclear Cu^{II} and Ni^{II} complexes of *meta*-xylyl and pyridyl biscyclen and biscyclam have been prepared and characterised in solution by means of UV/Visible spectra, electrochemical and EPR studies. X-ray structures of copper biscyclen complexes have been obtained. The comparison of all the data shows that the potentially coordinating N(*py*) pyridyl atom promotes the interaction between the two metal centers, whether it is spontaneously coordinated (biscyclen complexes) or not (biscyclam ones).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Tetraazamacrocyclic ligands like cyclen and cyclam are well known for their remarkable capacity to coordinate metallic ions. Their preorganisation, the flexibility of the macrocyclic framework and the soft character of the nitrogen donor atoms make the cyclic tetramines well suited for the complexation of d-block metals.[1] Thus, two of the properties of macrocyclic complexes that set them apart from the acyclic ones are selectivity in binding and kinetic stability with respect to dissociation. These features have been harnessed to develop macrocycles able to transport radioisotopic agents to a tumour site (^{64}Cu and ^{67}Cu for example).[2] Moreover, changes in the nitrogen (or carbon) substitution can determine their potential applications. In particular, functionalisation of cyclen by substituents such as acetate binding arms has led to a new class of ligands which are able to coordinate lanthanide cations especially Gd^{III}.[3] The corresponding complexes are developed and used as MRI contrast agents. Besides these medical applications, transition-metal complexes of tetraazamacrocycles in many respects, can be seen as metalloenzyme models, particularly when the ligand framework exhibits two or even three cavities. The corresponding bis- or tris-macrocycles may then be able to hold two or more metal centres in proximity, mimicking the multinuclear metal arrays at the active sites of the concerned metalloenzymes.[4] Since the length of the bridging groups controls the inter-metal ion distances, these ligands have been studied to examine the strength, more or less pronounced of the interaction between the metal centres. Kaden, Fabbrizzi and co-workers have shown through electrochemical and EPR studies of metallic bistetraazamacrocyclic complexes, that below an intermetallic distance of about 8 Å, metal–metal interactions can be detected.[5] In fact, in these studies the only parameter considered to tune the inter-metal distance is the spacer geometry. However, the flexibility of the macrocycle can induce favoured configurations of the cavity and then modifications of the metal coordination polyhedron. This factor may affect the intermetallic distance as well as topological modification of the ligand occurring during the redox process. Effectively, as recently shown for cyclam complexes the change in the metal redox state can be associated with their geometrical reorganisation.[6] Finally, the introduction of additional donor atoms on the intercycle spacer may interfere in the metal–metal distance due to selective coordination of one of the two metals to the linker.

In order to test the influence of these latter parameters, the preparation of dinuclear copper(II) and nickel(II) complexes based upon cyclen and cyclam cavities (Scheme 1) was improved and their electronic properties studied by means of electrochemical and EPR measurements.

Results and Discussion

Syntheses of Ligands and Complexes

The ligands $\mathbf{L^1}$ to $\mathbf{L^4}$ were synthesised according the bisaminal methodology[7] and the corresponding dinuclear complexes were obtained by addition of equimolar amounts of metallic salts (ClO_4 or BF_4 salts – see experimental section). Monocrystals suitable for an X-ray analysis were obtained for the copper complexes of cyclen ligands $\mathbf{L^1}$ and $\mathbf{L^2}$.

Structural Characterisation in the Solid State of Complexes $[Cu_2L^{1,2}]$

POV-ray depiction of $[Cu_2L^1]^{4+}$ complex is provided in Figure 1. The monocrystals were isolated by slow diffusion of a saturated sodium perchlorate solution into an aqueous solution of the complex. They show that two copper ions are coordinated by the four macrocyclic nitrogen atoms of each cyclen cavity and by a water molecule, leading to two pentacoordinate subunits linked together by a metaxylyl bridge. Selected bond lengths and angles are shown in Table 1. The Cu–NH bond lengths [2.016(5)–2.031(5) Å] are close to the ones in bis-*para*xylyl cyclen copper complex[8] while the bonds to the tertiary macrocyclic nitrogens are slightly longer [2.035(5)/2.046(5)] Å. This is certainly the consequence of the *N*-alkylation on these atoms as it is known that the M–N bond lengths are increased by *N*-alkyl substitution.[8–10] The copper coordination spheres are completed by oxygen donors from water molecules (one per copper ion) with Cu–O bond lengths of [2.142(4)/2.160(5)] Å. For each copper ion, the resulting geometry is based on a square planar pyramid, the metal ion being approximately at a distance of 0.50 Å from the base of the pyramid. At last for this complex, the intramolecular Cu–Cu distance is measured at 9.713 Å, while shorter intermolecular Cu–Cu distances are observed (7.333, 8.274, 9.582 Å).

The X-ray structure of the copper(II) complex of **L**[2] is provided in Figure 2 and relevant geometry details in Table 2. Monocrystals were grown by slow diffusion of diethylether in an acetonitrile solution of the tetrafluoroborate copper complex. Crystallographic analysis of $[Cu_2L^2(BF_4)](BF_4)_3$ shows the two copper ions to be pentacoordinate as expected for copper held in a cyclen cavity. The crystal structure underlines that the pyridyl nitrogen atom [N(*py*)] allows the discrimination of the two cavities since this atom is coordinated to only one of the two copper ions. Thus, the Cu(1) atom is bonded to the four nitrogen atoms of the first macrocyclic cavity [Cu–NH: from 2.019(7) to 2.033(7) Å; Cu–NR: 2.041(6) Å] and at a greater distance by the nitrogen atom of the pyridine ring [Cu–N(*py*): 2.266(6) Å]. The coordination of the N(*py*) atom certainly allows the formation of an efficient five-membered chelate ring which geometrically leads to a smaller N(*py*)-Cu–N angle, of 80.4(1)° for the N_1 nitrogen carrying the pyridine linker, compared to values of 95.4(3) to 129.6(3)° for the other three N(*py*)-Cu–N angles. In parallel, the Cu(2) atom is coordinated to the four nitrogen atoms of the second macrocyclic cavity [Cu–NH: from 2.021(7) to 2.038(7) Å; Cu–NR: 2.064(6) Å] and to a tetrafluoroborate anion [Cu–F: 2.135(6) Å]. The distances of the copper ions with regard to their corresponding macrocyclic cavities are about 0.54 Å (CuN_5 chromophore) or 0.51 Å (CuN_4 chromophore). The main consequence of the N(*py*) atom coordination to one of the two copper ions is the significant shortening of the intramolecular Cu–Cu distance since it is

Solution Properties

Electronic Absorption Spectroscopy

The UV/Visible absorption maxima of the complexes $[Cu_2\mathbf{L}]^{4+}$ and $[Ni_2\mathbf{L}]^{4+}$ ($\mathbf{L} = \mathbf{L^{1-4}}$) in water and acetonitrile are given as supporting information.

Copper Complexes: As commonly observed for these compounds, the featureless nature of the spectra makes difficult a detailed description of coordination geometries. Nevertheless, the main information resulting from the visible spectra of the copper biscyclen complexes ($[Cu_2\mathbf{L^{1,2}}]^{4+}$) are the following: for $[Cu_2\mathbf{L^1}]^{4+}$ whatever the solvent, the spectrum exhibits a broad band at 594 nm typical of a square based pyramidal copper complex (CuN_4S chromophore, S = solvent).[8] For $[Cu_2\mathbf{L^2}]^{4+}$, the spectrum is dissymmetrical and its deconvolution analysis shows that it is the superimposing of two spectra, the first one characteristic of a CuN_4S chromophore (with a band at 584–594 nm), the second one attributed to a CuN_5 chromophore[11] (shoulder between 684 and 735 nm, according to the solvent). Moreover, the presence of this shoulder indicates that the coordination of the pyridyl nitrogen N(*py*) to the copper ion is maintained in solution, whatever the pH conditions.

For the cyclam copper complexes $[Cu_2\mathbf{L^{3,4}}]^{4+}$, the absorption maxima at about 520 nm are typical of square planar copper complexes.[12] The lack of absorption at about 650 nm[13] is indicative of an absence of interaction between the pyridyl nitrogen atom N(*py*) and a copper ion for the $[Cu_2\mathbf{L^4}]^{4+}$ complex.

Nickel Complexes: For the nickel biscyclen complexes ($[Ni_2\mathbf{L^{1,2}}]^{4+}$) the UV/Visible spectra are indicative of octahedral coordination for the nickel in solution, solvent molecules occupying the free positions of the octahedron (chromophore NiN_4S_2).[14] Two bands are observed for both complexes in water and in acetonitrile corresponding to the predicted $^3A_{2g} \rightarrow {}^3T_{2g}$ (950–800 nm) and $^3A_{2g} \rightarrow {}^3T_{1g}$ (F) (560–500 nm) transitions for a d^8 metal ion under octahedral symmetry, the third transition $^3A_{2g} \rightarrow {}^3T_{1g}$ (P) (300–400 nm) being hidden by the stronger absorbance of the ligand ($\lambda < 300$ nm).

For the nickel cyclam complexes ($[Ni_2\mathbf{L^{3,4}}]^{4+}$), the solution visible spectra show a single band with the maximum in the range 450–470 nm, depending on both the complexes and the solvent. This signal is in accordance with the $[Ni(cyclam)]^{2+}$ spectrum ($\lambda = 459$ nm) and is consistent with the adoption by the metal of a square-planar geometry, the metal being perfectly fitted inside the macrocyclic cavity. In solution, the coexistence for $[Ni(cyclam)]^{2+}$complexes of square planar (low spin) and octahedral (high spin) geometries is well documented leading to a "yellow to blue" equilibrium between these species.[15] For the $[Ni_2\mathbf{L^{3,4}}]^{4+}$ complexes, we were not able to detect any additional peaks corresponding to octahedral nickel(II) ions. Two reasons may be responsible for that: either no octahedral complexes are present in solution or, because of low molar extinction coefficients, the octahedral complexes are difficult to detect. Finally, for $[Ni_2\mathbf{L^4}]^{4+}$, whatever the solvent and the pH conditions, the spectrum is identical and in addition similar to the one of $[Ni_2\mathbf{L^3}]^{4+}$. As for its copper homologue, this is indicative of an absence of interaction between the pyridyl nitrogen atom N(*py*) and the nickel.

Electrochemical Properties of the Bismacrocyclic Complexes

The binuclear $[Cu_2\mathbf{L}]$ and $[Ni_2\mathbf{L}]$ complexes ($\mathbf{L} = \mathbf{L^{1-4}}$) were all investigated by cyclic voltammetry in CH_3CN, the

working electrode being a glassy carbon disk and the Fc^+/Fc couple being used as a reference in acetonitrile.

Biscyclen Complexes: The cyclen cavity is not well adapted to stabilize +I and +III oxidation states for copper and nickel.[16] Therefore, it was not possible to obtain reproducible voltammograms, mainly because of the degradation of oxidised and reduced forms during the experiment.

Biscyclam Complexes: The copper complexes $[Cu_2\mathbf{L^3}]^{4+}$ and $[Cu_2\mathbf{L^4}]^{4+}$ show two irreversible bielectronic exchanges (one electron per metallic centre) separated by $\approx$ 2.40 V (Table 3). The anodic peaks happen respectively for $[Cu_2\mathbf{L^3}]^{4+}$ and $[Cu_2\mathbf{L^4}]^{4+}$at 1.25 V and 1.15 V while the cathodic ones happen at –1.21 V and –1.22 V. These values are in accordance with the ones measured for the monomeric [Cu(cyclam)]$^{2+}$ (1.02 V and –1.28 V), taking into account the incidence of the *N*-alkylation of the macrocyclic cavity on the redox potentials.[5d,17] In reduction, the two copper complexes exhibit a similar behaviour i.e. the $Cu^{II/I}$ process is irreversible and the reverse process is accompanied by a partial release of the metal, reported by an anodic peak at –0.60 V (Cu^0). In oxidation, the forward and reverse peak heights are inequivalent ($i_a >> i_c$), indicating that the electronic exchange $Cu^{II/III}$ is irreversible too. Moreover, the high anodic current wave detected for the first cycle, the decrease of its intensity when the number of cycles increased, and the apparition of a deposit at the electrode during the experiment show that the oxidated species $[Cu_2\mathbf{L^{3,4}}]^{6+}$ are highly unstable and react rapidly in the medium. This is consistent with observations generally done with copper tetraazamacrocyclic complexes.[18] We have checked that, as demonstrated by Fabbrizzi et al.,[5d] in concentrated perchloric acid solution (70%) at a Pt electrode, the Cu^{III} bistetraazamacrocyclic complexes become stable, at least at the time scale of the voltammetry experiment. In this special medium, the oxidation process is effectively quasi reversible ($i_a = i_c$). In order to have a greatest resolution of the signals associated with the consecutive redox events ($Cu^{II}\ Cu^{II} \rightarrow Cu^{II}\ Cu^{III} \rightarrow Cu^{III}\ Cu^{III}$) whose potentials are not very distant,[5d] differential pulse voltammetry (DPV) was used. The DPV profiles obtained for the two complexes in the oxidation scan are similar and exhibit a single wave peak. The measurements reproduce well the one already done by Fabbrizzi et al.[5d] for the $[Cu_2\mathbf{L^3}]^{4+}$ complex and indicate that for these two complexes the ring-to-ring distance is certainly too long to induce a two consecutive one-electron steps process.

Table 3. Electrochemical parameters for the $Cu_2\mathbf{L^3}$ and $Cu_2\mathbf{L^4}$ complexes.

	Oxidation potential	Reduction potential
$Cu_2\mathbf{L^3}$ (CH_3CN)[a]	E_p = 1.25 V	E_p = –1.21 V
$Cu_2\mathbf{L^4}$ (CH_3CN)[a]	E_p = 1.15 V	E_p = –1.22 V
$Cu_2\mathbf{L^3}$ ($HClO_4$, 70%)[b]	$E_{1/2}$ = 0.98 V (0.10 V)	–
$Cu_2\mathbf{L^4}$ ($HClO_4$, 70%)[b]	$E_{1/2}$ = 1.02 V (0.10 V)	–

[a] Potential values are given vs. Fc^+/Fc. [b] Potential values are expressed vs. SCE.

Cyclic voltammograms recorded for the nickel complexes $[Ni_2\mathbf{L^3}]^{4+}$ and $[Ni_2\mathbf{L^4}]^{4+}$ are reported in Figure 3. In reduction, the behaviour of the two complexes is quasi reversible and the $Ni^{II/I}$ system is electrochemically slow. The oxidation of the two complexes is more complicated since more than one CV wave is observed. Thus, for the complex $[Ni_2\mathbf{L^3}]^{4+}$ two oxidation potentials at 0.80 and 1.12 V are detected while the complex $[Ni_2\mathbf{L^4}]^{4+}$ shows two oxidation processes, the first one at 0.84 V and the second one split into two peaks at 1.03 and 1.18 V. For $[Ni_2\mathbf{L^3}]^{4+}$ the two CV waves are quasi reversible while for $[Ni_2\mathbf{L^4}]^{4+}$, the reversibility of the first system is very poor. It is noticeable that previous voltammetry experiments carried out for $[Ni_2\mathbf{L^3}]^{4+}$ [5d] have shown a simple oxidative behaviour since only the first system (0.80 V) was detected. As the purity of our complexes is satisfactory, one can think that in CH_3CN, two bismacrocyclic Ni^{II} species are successively oxidised. In $[Ni_2\mathbf{L^3}]^{4+}$ complex, the proportion of these two species is largely in favour of the first one while in $[Ni_2\mathbf{L^4}]^{4+}$ the proportion is similar. In CH_3CN, an increase of the temperature (298 K up to 313 K) results in growth of the second system at the expense of the first one (Figure 4a). When the CV waves are recorded at temperatures of 298 K down to 233 K (Figure 4b, Figure 5b), for both complexes the second system tends to disappear. It is also noticeable that for $[Ni_2\mathbf{L^4}]^{4+}$ the first system becomes more reversible. From these observations, it can be assumed that the oxidation of the first species is followed by a rearrangement. A temperature decrease can prevent this isomerisation and the vanishing at lower temperatures of the second oxidative system, would tend to show that the two oxidative processes are dependent on each other. As far as nickel(II) cyclam complexes are concerned, several stereoisomers have to be considered, according to the configuration of the macrocyclic cavity (Figure 6). There are five possible configurational isomers of planar complexes of the macrocyclic ligand cyclam:[19] RSRS (++++) i.e. type I, RSRR (+-++) i.e. type II, RRSS (+--+) i.e. type III, RSSR (++--) i.e. type IV, RRRR (+-+-) i.e. type V, where + indicates that the hydrogen of the NH is above the plane of the macrocycle and - indicates that it is below the plane.

A cluster analysis of Ni-14 membered tetraazamacrocycles found in the Cambridge Structural database[20] shows that the most frequent configurations encountered for these complexes are the type I and type III ones; the amount of these two forms can moreover vary according to the coordination shell geometry of the nickel and the macrocycle substitution. On certain conditions, isomerisation between type I and type III structures have been evidenced: for instance, the oxidatively induced isomerisation of type I [Ni(cyclam)]$^{2+}$ into type III has been reported,[6a] while in bistetraazamacrocyclic series, the isomerisation of the type III [Zn_2 (bis *para*-cyclam)] complex into the type I[21] has been described. Such an isomerisation can be proposed for the $[Ni_2\mathbf{L^3}]^{4+}$ and $[Ni_2\mathbf{L^4}]^{4+}$complexes. Unfortunately, the impossibility to isolate and characterise independently the supposed type III and type I isomers prevents any kinetic quantitative study of the equilibrium between these two

	1.18 V (0.10 V)	

Figure 3. Cyclic voltammetry at a glassy carbon disk (CH_3CN/Bu_4NPF_6, c = 0.1 mol L^{-1}; v = 100 mV s^{-1}) of millimolar solutions of $[Ni_2\mathbf{L^3}]^{4+}$ (dashed lines) and $[Ni_2\mathbf{L^4}]^{4+}$ (straight lines) and Differential Pulse Voltammetry of their oxidation system (10 mV step potential).

configurations. However, the variation of the CV traces with the scan sweep rate can be indicative (Figures 4c and 5a). Comparison of the CV traces shows that for $[Ni_2\mathbf{L^4}]^{4+}$ the increase of the sweep rate improves the reversibility of the first system. Moreover, during the same experiments, the second system is affected since it tends to disappear for both complexes. It is interesting to notice that changes observed by increasing the CV sweep rate are similar to the changes previously noted by lowering the temperature (Figure 4b and Figure 5b). It led us to propose a configurational equilibrium in solution, slightly shifted upon electrochemical oxidation between the type III and the type I isomers of $[Ni_2\mathbf{L^3}]^{4+}$ and $[Ni_2\mathbf{L^4}]^{4+}$ biscyclams. Voltammetric data alone cannot bring any geometrical information about the coordination shell and it is difficult to identify the structures formed upon the oxidation. However, by comparison of the gap between redox potentials determined for type III and type I isomers of [Ni(cyclam)]$^{2+}$[6a] one can propose for $[Ni_2\mathbf{L^3}]$ that the first system ($E_{½ox}$ = 0.80 V) corresponds to the oxidation of the two Ni ions held in a type III cavity while the second system ($E_{½ox}$ = 1.12 V) corresponds to the oxidation of the two Ni ions held in a type I cyclam cavity. The oxidative process can then be modelled as a classical square scheme, involving the electron-transfer reactions and the isomerisation processes (Scheme 2): the first oxidation peak corresponds to the electrogeneration of the type III $[Ni_2\mathbf{L^3}]^{6+}$ complex that undergoes a partial rearrangement to form the type I $[Ni_2\mathbf{L^3}]^{6+}$. Since the potential corresponding to the generation of the type I $[Ni_2\mathbf{L^3}]^{6+}$ is more positive than the redox potential of the $Ni^{II/III}$ in the type III complex, type I $[Ni_2\mathbf{L^3}]^{6+}$ species is immediately reduced into type I $[Ni_2\mathbf{L^3}]^{4+}$ species; this species is further oxidised at a more positive potential. This implies that the isomerisation process requires an elongation of the metal–nitrogen bonds of the tetraazamacrocycle, which readily takes place

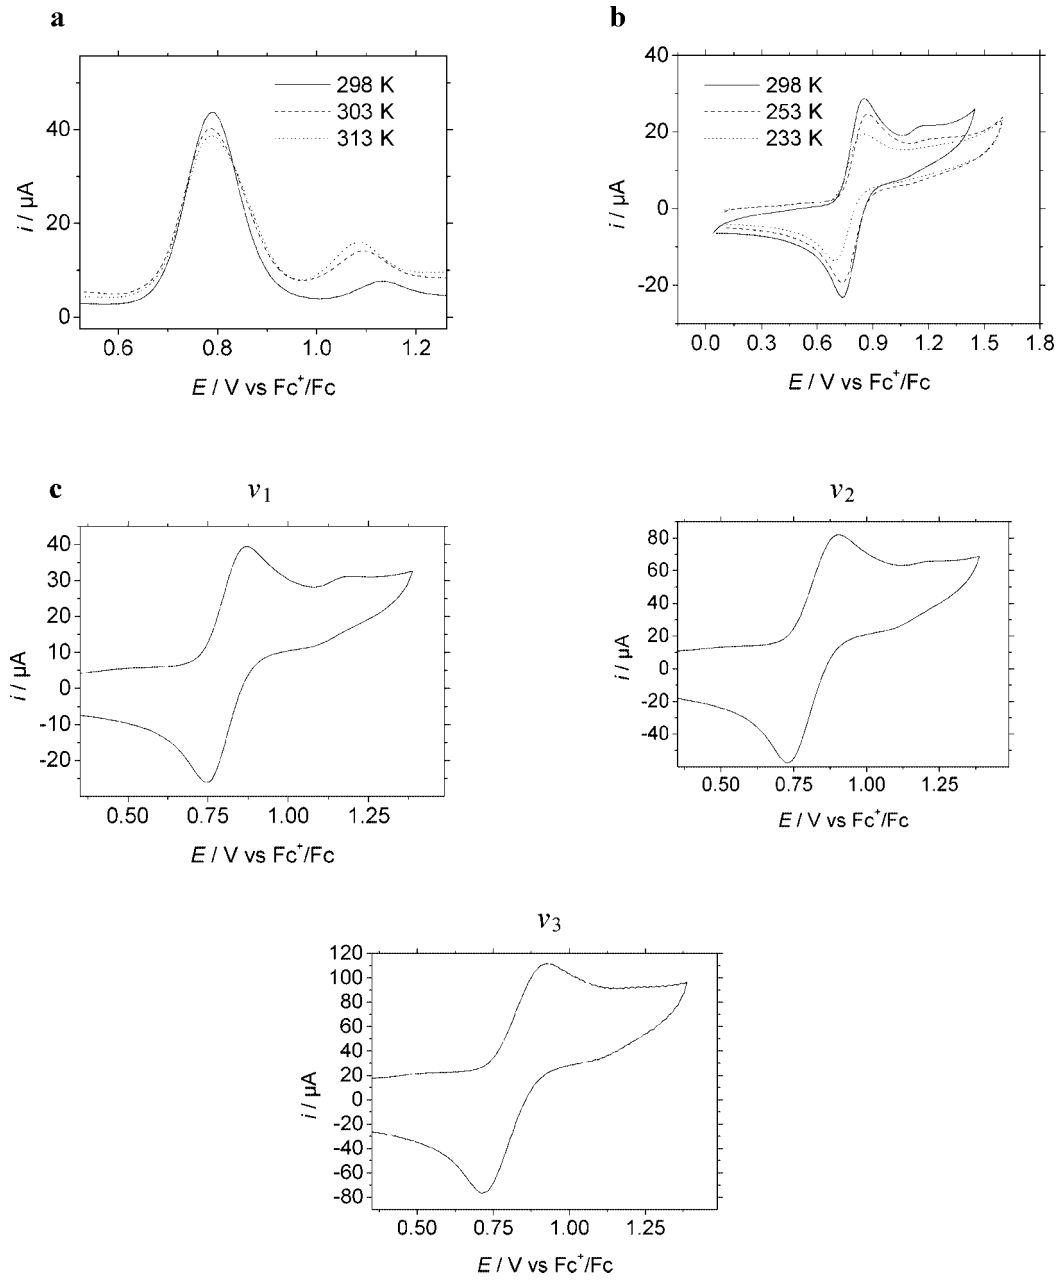

Figure 4. a: DPV profiles. b: CV curves of $[Ni_2\mathbf{L^3}]^{4+}$ at different temperatures. c: CV curves at v_1 = 100 mV s^{-1}, v_2 = 500 mV s^{-1}, v_3 = 1000 mV s^{-1}.

on cyclam derivatives by modification of the electron density on the metal, induced by the electrochemical oxidation $Ni^{II/III}$. Consequently, such isomerisation is negligible in acetonitrile without an electrochemical oxidation-reduction cycle. For complex $[Ni_2\mathbf{L^4}]^{4+}$, the electronic process is certainly more complicated than suggested by the square scheme since the oxidation peak of the supposed type I isomer is split. At this stage, only hypothesis can be formulated to interpret this signal. On the course of the (type III → type I) isomerisation process, a modification of the metal coordination sphere takes place as previously said. At the next step, the coordination of the nitrogen atom of the pyridine linker can occur on one of the two nickel centres, to lead to the oxidable type I $[Ni_2\mathbf{L^4}]^{4+}$ entity. This assumption is supported by the fact that most of the type I Ni^{II} complexes based on cyclam cavities are known to exhibit whether in a square planar or a square pyramidal configuration.[13,20] To test this proposal, modelling of type I $[Ni_2\mathbf{L^4}]^{4+}$ was improved in order to check the preferential equilibrium geometry of the complex. Whatever the type I starting geometry [N(*py*) coordinated or not], the most stable configuration corresponds to a situation where the nitrogen pyridyl atom is coordinated to one of the two nickel metals (Figure 7). Moreover, insofar as we can trust these calculations (because of the system size, the calculation level is restricted) the pyridinic nitrogen atom brings

the macrocycles and the metallic ions nearer (6.86 Å). Consequently, the two distinct peaks of the type I oxidation system can be assigned either to two different coordination modes of the two nickel ions (respectively NiN_5 and NiN_4) or to consecutive monoelectronic processes, the first one being assigned to the $Ni^{II/III}$ process at one of the metal centres, the second one to be ascribed to the one-electron oxidation at the other metal centre. Even if this last interpretation was previously proposed for a [Ni_2(biscyclam)] complex[5b] in which the metal centres are separated by 7.09 Å, none of these two propositions can be ruled out on the basis of electrochemical experiments.

EPR Spectroscopy of the Bismacrocyclic Complexes

The EPR spectra of the $[Cu_2\mathbf{L^{1-4}}]^{4+}$ complexes were recorded in DMF solution at 100 K in order to determine their *g* and *A* parameters (Figure 8). The simulated anisotropic EPR parameters are listed in Table 4. By way of comparison, the EPR parameters of the known acetate complexes $[Cu_2\mathbf{L^{1,3}}]^{4+}$[22] are also reported.

The X-band EPR spectra of frozen solutions exhibit a strong absorption at ≈ 3200 G, attributable to the allowed transitions $\Delta M_S = 1$. For the cyclam complexes $[Cu_2\mathbf{L^{3,4}}]^{4+}$ the EPR parameters are similar which means that the copper ions are held in an identical environment. The $g_{\|}$ values are found to be the same for both complexes, namely 2.182. These values are greater than the *g* ones, which is typical of axially symmetric d^9 copper complexes and a $d_{x^2-y^2}$ ground state.[23] The hyperfine coupling constants $A_{\|}$ (100 10^{-4} cm^{-1}) are as expected,[8,22] about half the value of the mononuclear complexes, in which the metal is held in a square planar environment. In the parallel region, the hyperfine system shows seven lines. This signal is typical of copper(II) dimers weakly coupled and can be interpreted as a triplet state spectrum originating from exchange-coupled pairs of copper(II) ions.[22] Thus, two series of seven lines are theoretically expected,[24] one for each allowed ΔM_S = 1 transition; they correspond to the hyperfine coupling between the two copper d^9 ions (I_{Cu} = 3/2). According to the zero-field splitting amplitude, the two septets can either overlap (weak D factor) or be shifted, even if in this case it is difficult to observe all the lines.[4c,5b] The simulation[25] of

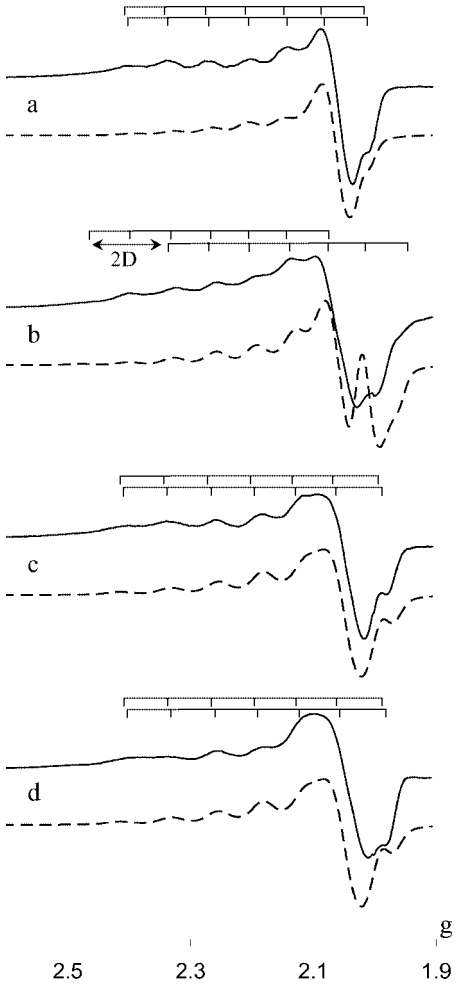

Figure 8. Experimental EPR spectra of biscyclen complexes. a: $[Cu_2\mathbf{L^1}](BF_4)_4$. b: $[Cu_2\mathbf{L^2}](BF_4)_4$ and of biscyclam complexes. c: $[Cu_2\mathbf{L^3}](BF_4)_4$. d: $[Cu_2\mathbf{L^4}](BF_4)$. Dotted spectra: simulated EPR spectra.

the spectrum can then help for the interpretation of the signals: for the complexes $[Cu_2\mathbf{L^{3,4}}]^{4+}$, the simulated spectra tend to demonstrate that the two septets overlap. This means that the exchange interaction between the two copper ions is weak. Nevertheless, the Cu^{II}–Cu^{II} interaction is present as shown by the existence of more than four hyperfine lines in the spectra of the $[Cu_2\mathbf{L^{3,4}}]^{4+}$ complexes and by

smaller values for $A_{\parallel}$.[4c,5,8,22,24] For an analogous series of xylyl-bismacrocyclic dicopper acetate complexes,[22] a second weak absorption at $\approx$ 1550 G was previously reported and assigned to the forbidden $\Delta M_S = 2$ transition. This transition was claimed as a further proof of intramolecular electron exchange between the two copper ions. Unfortunately, we were not able to highlight this signal for the two complexes $[Cu_2\mathbf{L^{3,4}}]^{4+}$ certainly because in these compounds the presence of a noncoordinating anion (BF_4^-) in solution prevents any strengthening of such interaction between the metal ions.

For the cyclen complexes $[Cu_2\mathbf{L^{1,2}}]^{4+}$, the comparison of the EPR parameters with the ones of the mononuclear $[Cu(cyclen)]^{2+}$ shows that $g_{\parallel}$ and $g_{\perp}$ are similar for all complexes. As already described for the cyclam complexes, the $A_{\parallel}$ values of $[Cu_2\mathbf{L^{1,2}}]^{4+}$ are half that determined for mononuclear $[Cu(cyclen)]^{2+}$. Moreover, the $g_{\parallel}$ parameters of $[Cu_2\mathbf{L^{1,2}}]^{4+}$ are higher than the ones of the cyclam analogues. This indicated that the coordination Scheme of copper ions in cyclen and cyclam is different. It is confirmed by the $A_{\parallel}$ values since, in cyclen complexes, the hyperfine coupling constants are smaller than the cyclam ones. It corresponds to a coordination of the copper ions outside the cyclen cavity, which is consistent with the crystal structure and the UV/Visible spectra of the complexes. Interestingly, the EPR spectrum of the pyridyl $[Cu_2\mathbf{L^2}]^{4+}$ complex exhibits more than seven lines in the parallel region. The simulated spectrum allows the proposal of an hyperfine system of nine lines. In this case, we assumed that the two septets are shifted by zero-field splitting 2D[24] and the simulation of the spectrum allowed the determination of a $D_{\parallel}$ parameter of 90 10^{-4} cm^{-1}. This value is tenfold increased compared to the ones simulated for the other complexes. This means that in the pyridyl $[Cu_2\mathbf{L^2}]^{4+}$ complex, the interaction between the metallic centres is stronger. From the D value, one can estimate the mean distance between the two paramagnetic cations, provided that the zero-field splitting is due to a pure dipole–dipole interaction:[24] from Equation (1) (Table 4), one obtains r_{Cu-Cu} = 7.03 Å for complex $[Cu_2\mathbf{L^2}]^{4+}$ in frozen DMF solution. This would indicate that in solution, the probable coordination of the pyridyl nitrogen shown by UV/Visible spectroscopy, would tend to move the two copper ions closer and then to favour exchange interaction between them.

Conclusions

The dinuclear Cu^{II} and Ni^{II} complexes based on biscyclen $\mathbf{L^{1,2}}$ or biscyclam $\mathbf{L^{3,4}}$ ligands have been studied. X-ray analysis of copper biscyclen complexes have shown that the pyridyl nitrogen atom [N(*py*)] coordinates one of the two copper ions. In solution, the comparison of the UV/Visible spectra of these two complexes indicates that the coordination of the N(*py*) atom is maintained, even upon acidification. The coordination of the N(*py*) atom leads to the shortening of the intermetallic copper–copper distance: as a result, the dipolar intermetallic interaction is promoted. This is underlined by the EPR spectrum of $[Cu_2\mathbf{L^2}]^{4+}$ complex, which exhibits in the parallel region nine equidistant lines (against seven for $[Cu_2\mathbf{L^1}]^{4+}$).

For the cyclam complexes, no evidence of the N(*py*) atom coordination to one of the two metal centres was found. However, EPR spectra of these dinuclear copper complexes show that a weak intermetallic interaction is still present since the parallel region of the spectra present seven equidistant lines. Nevertheless, for the corresponding nickel biscyclam complexes, electrochemical oxidation–reduction cycles, which promote a configurational rearrangement between type III and type I configurations of Ni biscyclam, can induce a coordination of the N(*py*) atom in the type I geometry. In this case, the strengthening of the metal–metal interaction is suggested by the splitting of the corresponding CV traces.

From this study, one can conclude that the existence of a potentially coordinating atom on the intercycle spacer can improve the metal–metal interaction. Consequently, bismacrocycles possessing more than one potentially coordinating atom on the spacer are currently under study.

Experimental Section

Syntheses: The metals salts were purchased from Aldrich. The other reagents were used as highest grade commercially available without further purification.

Ligand Synthesis: The synthesis and the characterisation of ligands $\mathbf{L^1}$ and $\mathbf{L^3}$ have been described previously elsewhere.[7] Ligands $\mathbf{L^2}$ and $\mathbf{L^4}$ have been synthesised according to the same procedure from cyclen or cyclam glyoxal ligands and 2,6-bis(bromomethyl)-pyridine.[26]

Ligand $\mathbf{L^2}$: Yield 69%. ^{13}C NMR ($CDCl_3$): δ = 44.4, 45.6, 46.3, 51.2, 60.5 (CH_2N), 121.1, 136.6, 158.4 (C_{ar}). Elemental analysis calcd. (%) for the hydrochloride salt of L^2: $C_{23}H_{45}N_9 \cdot 6HCl \cdot H_2O$: C 40.36, H 7.81, N 18.42; found: C 40.23, H 7.76, N 18.17.

Ligand $\mathbf{L^4}$: Yield 71%. ^{13}C NMR ($CDCl_3$): δ = 26.2–28.7 (CH_2CH_2N), 47.3, 47.9, 48.8, 49.1, 50.6, 53.2, 55.3, 59.5 (CH_2N), 120.9, 136.3, 158.6 (C_{ar}). Elemental analysis calcd. (%) for the hydrochloride salt of L^4: $C_{27}H_{53}N_9 \cdot HCl \cdot 2H_2O$: C 42.75, H 8.37, N 16.62; found: C 42.99, H 8.11, N 16.45.

Synthesis of $Cu_2L^1(ClO_4)_4{\cdot}4H_2O$: The neutral ligand ($5.2{\cdot}10^{-5}$ mol) was dissolved in distilled water (10 mL) followed by the addition of an ethanolic solution of the copper(II) perchlorate salt ($1.17{\cdot}10^{-4}$ mol). The blue solution was refluxed for 2 h and the solvents were evaporated under vacuum. The solid was washed twice with absolute ethanol. Elemental analysis calcd. (%) for $C_{24}H_{54}Cl_4Cu_2N_8O_{20}$: C 27.62, H 5.21, N 10.74; found: C 27.99, H 5.14, N 10.45.

This solid was further dissolved in water and the diffusion of an aqueous saturated sodium perchlorate solution produced monocrystals of $[Cu_2L^1(H_2O)_2](ClO_4)_4{\cdot}H_2O$, suitable for X-ray analysis.

Synthesis of $Cu_2L^{1-4}(BF_4)_4$ and $Ni_2L^{1-4}(BF_4)_4$: The neutral ligands ($5.2\ 10^{-5}$ mol) were dissolved in distilled water (10 mL) and aqueous solutions of copper(II) or nickel (II) salts ($1.17\ 10^{-4}$ mol in 5 mL) were added dropwise. The resulting solutions were heated at reflux for 2 h, the solvents were evaporated under vacuum afterwards. The solids were washed twice with absolute ethanol.

Elemental analysis for $Cu_2L^1(BF_4)_4{\cdot}2H_2O$: $C_{24}H_{50}B_4Cu_2N_8F_{16}O_2$ calcd. (%): C 30.12, H 5.27, N 11.71; found: C 29.99, H 5.02, N 12.39. $Cu_2\mathbf{L^2}(BF_4)_4$, $3H_2O$ $C_{23}H_{51}B_4Cu_2N_9F_{16}O_3$ calcd. Crystals of $Cu_2\mathbf{L^2}(BF_4)_4$ suitable for X-ray crystallography were obtained by slow diffusion of diethyl ether into an acetonitrile solution of the complex.

Spectroscopic Measurements: Electronic spectra in aqueous or acetonitrile solutions (10^{-3} mol L^{-1}) were all measured in the 300–900 nm range with a Lambda 6 Perkin–Elmer spectrophotometer. The acetonitrile solution of trifluoroacetic acid (0.1 mol L^{-1}) was prepared by dilution of trifluoroacetic acid Aldrich product at 99%. The acidification of acetonitrile copper complex solutions was obtained by successive additions of trifluoroacetic acid solution (100 μL).

The X-band EPR spectra (9.40 GHz) were recorded in DMF solutions at 100 K, with a Bruker spectrophotometer ELEXSYS 500. Simulations were carried out using the software Simfonia.[25]

Electrochemical Measurements: Voltammetric data were recorded with an Autolab with a PGSTAT12 potentiostat (ECO Chemie) associated to a conventional three electrodes electrochemical cell, the working electrode being a glassy carbon or platinum disk, a platinum plate being used as a counter electrode and in aqueous medium a saturated calomel electrode was used as the reference while in acetonitrile a silver electrode separated from the complex solution was used as a pseudo reference. In acetonitrile, the potential of the pseudo reference was measured vs. the ferricinium/ferrocene couple. Complexes concentrations were always close to 10^{-3} mol L^{-1} and in acetonitrile tetrabutylammonium hexafluorophosphate 10^{-1} mol L^{-1} was used as the supporting electrolyte. In concentrated perchloric acid solutions no additional electrolyte was employed.

Computational Details: The calculations have been performed using the Gaussian 98[27] program package. Both geometry and energy calculations were performed at the UHF/LANL2 MB level. Each molecular structure has been fully optimised and characterised as minimum by frequency analysis. Single point energy have further been calculated at the UB3LYP/LANL2DZ level [the LANL2DZ basis set as parameterised in Gaussian has been supplemented with polarisation function on nitrogen atoms (d_N = 0.80)].

Crystal Structure Determination: The crystal data were collected at 173 K with a Kappa CCD diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å).

The structures were solved by direct methods. After refinement of the non-hydrogen atoms, difference-Fourier maps revealed maxima of residual electron density close to positions expected for hydrogen atoms. Hydrogen atoms were introduced as fixed contributors at calculated positions [C–H = 0.95 Å, B(H) = 1.3 B_{eqv}]. Final difference maps revealed no significant maxima. All calculations were using the Nonius OpenMoleN package.[28] Neutral atom scattering factor coefficients and anomalous dispersion coefficients were taken from a standard source.

CCDC-261457 (for $[Cu_2\mathbf{L^1}(H_2O)_2]\cdot 4ClO_4\cdot 3H_2O$) and CCDC-261458 (for $[Cu_2\mathbf{L^2}BF_4]\cdot 3BF_4$) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Crystal data and details of the structure determination for $[Cu_2\mathbf{L^1}]\cdot(ClO_4)_4$ and $[Cu_2\mathbf{L^2}BF_4]\cdot(BF_4)_3$ are given in the following Table 5.

Acknowledgments

We thank Dr. A. de Cian (Université Louis Pasteur, Strasbourg, France) for the single-crystal X-ray analyses, Dr. Y. Frappart (Université René Descartes, Paris, France) for the EPR spectra. Dr. E. Derat (Université de Reims Champagne Ardenne, France) is gratefully acknowledged for helpful discussions in molecular modelling as well as the computational centre of "Université de Reims Champagne Ardenne" for computational facilities.

Sonochemical Synthesis and Characterization of $Ni(C_4H_6N_2)_6(PF_6)_2$, $Fe(C_4H_6N_2)_6(BF_4)_2$, and $Ni(C_4H_6N_2)_6(BF_4)_2$ in 1-Butyl-3-methylimidazole with Hexafluorophosphate and Tetrafluoroborate

Keywords: Ionic liquids / Sonochemistry / Iron / Nickel / Imidazole / X-ray powder diffraction / Structure analysis

This paper reports on the inorganic sonochemical synthesis of crystalline $Ni(C_4H_6N_2)_6(PF_6)_2$, $Fe(C_4H_6N_2)_6(BF_4)_2$, and $Ni(C_4H_6N_2)_6(BF_4)_2$ in the ionic liquids, 1-butyl-3-methylimidazolium hexafluorophosphate $(BMI)^+(PF_6)^-$ and 1-butyl-3-methylimidazolium tetrafluoroborate $(BMI)^+(BF_4)^-$. The structures of the compounds were determined and refined by using powder X-ray diffraction methods. The salts crystallize in the trigonal $P\bar{3}$ space group. IR, Raman and ^{19}F NMR spectroscopic studies confirm that the PF_6^- and BF_4^- anions are not bonded to the metal cations. Magnetic measurements reveal the paramagnetic nature of the complexes. Mössbauer investigations show that the iron atom in $Fe(C_4H_6N_2)_6(BF_4)_2$ is in the oxidation +2 state. The broad EPR signals, which reflect the octahedral symmetry of the nickel complexes, were measured for $Ni(C_4H_6N_2)_6(PF_6)_2$ and $Ni(C_4H_6N_2)_6(BF_4)_2$.

Introduction

Room-temperature ionic liquids (RTILs) have aroused increasing interest worldwide as solvents, templates, and charge-compensating groups for numerous types of reactions due to their unique physical properties.[1a–1d] There are only very few reports in the area of synthetic coordination chemistry in ionic liquids.[2–5]

Recently, we have presented a report on the inorganic sonochemical synthesis of a $Fe^{II}(1\text{-methylimidazole})_6(PF_6)_2$ in $(BMI)^+(PF_6)^-$ ionic liquid solvents.[6] The product was obtained as a result of the sonochemical decomposition of $Fe(CO)_5$ in $(BMI)^+(PF_6)^-$. The charge on the Fe^{II} ion in the complex is stabilized by the two PF_6^- anions originating from the ionic liquid. We found that the PF_6^- anions enter the final structure, wherein the ionic liquids act as clean and effective solvents for the crystallization of the complex. However, it is usually assumed that the ionic liquids are entirely innocuous and noncoordinating solvents.

In the current study, we have continued to explore inorganic sonochemical reactions in ionic liquids, and in this paper, we report the synthesis of iron and nickel complexes of 1-methylimidazole in two different ionic liquids (as solvents) under sonochemical conditions using carbonylmetal compounds as precursors. The precursors in all these cases are the corresponding carbonyl complexes [$Fe(CO)_5$ and $Ni(CO)_4$], which are not soluble in $(BMI^+)(PF_6^-)$ and $(BMI^+)(BF_4^-)$ ionic liquids. It is well known that pentacarbonyliron and tetracarbonylnickel yield amorphous iron and amorphous nickel when sonicated in decalin (or any other nonvolatile organic solvent) under argon.[7a,7b] On the other hand, the decomposition of $Fe(CO)_5$ and $Ni(CO)_4$ in decalin under oxygen yields amorphous metal oxides.[8] The sonochemical decomposition of these carbonyl complexes in $(BMI^+)(PF_6^-)$ and $(BMI^+)(BF_4^-)$ form crystalline products. The current paper demonstrates the generality of our previous study, and that in none of the four cases (two carbonyl complexes in two solvents) are metal oxides formed.

The sonochemical products of the decomposition of the carbonyl complexes in ionic liquids are crystalline. They differ from the amorphous products formed when the same reactions are performed in nonvolatile organic solvents. In the sonochemical reactions in ionic liquids, we found that the anions of the ionic liquid solvents serve as charge-compensating groups and cause the crystallization of the products.

Powder X-ray diffraction (PXRD) is used to investigate the crystal structure of the metal complexes synthesized un-

 DOI: 10.1002/ejic.200500024 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

der the sonochemical conditions. The synthesized inorganic complexes are characterized by C, H, N analysis and several spectroscopic methods, such as Mössbauer, IR, Raman, MS, EPR, and ^{19}F NMR. The thermal stability of the (*N*-methylimidazole)metal complexes and of ionic liquid solvents is studied with the help of thermal gravimetric analysis (TGA). The magnetic properties of the synthesized complexes of iron and nickel are also reported in this paper.

Results and Discussion

Powder XRD

The unit cell parameters (Table 1) of (1-methylimidazole)$_6$-Ni$(PF_6)_2$ (**A**), (1-methylimidazole)$_6$Fe$(BF_4)_2$ (**B**) and (1-methylimidazole)$_6$Ni$(BF_4)_2$ (**C**) were determined from PXRD peak positions. The initial atomic coordinates were derived from the structure models of (1-methylimidazole)$_6$-Fe$(PF_6)_2$,[6] (5-methylpyrazole)$_6$Ni$(ClO_4)_2$,[9] and (2-methyltetrazole)$_6$Ni$(BF_4)_2$,[10] whose unit-cell dimensions and PXRD patterns are analogous to those of **A**, **B** and **C**. The crystal structure of **A** was found to be identical to that of (1-methylimidazole)$_6$Fe$(PF_6)_2$.[6] The structure refinement was performed by applying the Derivative Difference Minimization (DDM)[11] method, in which derivatives of the profile difference are minimized, instead of the squared difference, which allows a full-profile refinement independently of the underlying background curve. The calculations were carried out using a computer code package based on a corrected and modified version of the Rietveld[12] refinement program DBWS.[13] The PXRD patterns of both **B** and **C** exhibited very complex background components caused, presumably, by an amorphous admixture and the structural faults discussed below, which made the application of DDM essential.

The PXRD structure refinement and the electron density map analysis of **B** and **C** revealed additional pseudo-positions of metal and fluorine atoms in the unit cell, which are related to the main ones by a mirror plane operation (x, y, $1/2 - z$). The presence of these positions was indicative of structural faults such as twin and/or line defects. The twinning and molecular disorder is known to be a typical phenomenon for structures of this type.[6,9,10,14a,14b] To allow for the presence of the faults, the structure model of **B** and **C** was constructed from two sub-sets of atomic positions related to each other by the mirror plane. The occupancies of the two sub-sets were refined independently for the anions and the cations applying the stoichiometric constraints. Atomic coordinates of methylimidazole were allowed to refine with soft constraints applied to the C–C and the C–N distances. The hydrogen atoms were added geometrically and refined using the riding model.

The structure refinement results are summarized in Tables 1, 2, 3 and 4. The final consistency between the observed and calculated PXRD profiles after the DDM structure refinement is illustrated in Figure 1. The crystal structure and the alternative positions of molecules in the unit cell are shown in Figures 2 and 3. The metal atoms in **A**, **B** and **C** have a typical octahedral coordination of six equivalent nitrogen atoms of the methylimidazole groups. The tetrafluoroborate anion has two alternative orientations with equal probabilities as follows from the occupancies of the respective atomic positions (Tables 2 and 3). The occupancies of the alternative pseudo-positions related to the (methylimidazole)metal complexes indicate a high concentration of the structural faults. The faults, in turn, may be responsible for the atomic disorder reflected in the high isotropic displacement parameters.

Mössbauer Spectroscopy and DC Magnetic Measurements

Mössbauer studies performed at room temperature (Figure 4) exhibit a single asymmetric quadrupole doublet [½eqQ = 0.558(5)] with an isomer shift of *IS* = 1.065(5) mm/s and a line width of 0.27 mm/s.[15] This relatively high *IS* value is assigned to Fe^{2+} in the high-spin state. The quadrupole splitting obtained is a result of the small distortion away from octahedral symmetry as discussed above. The narrow line width indicates clearly that, as far as the Fe ions are concerned, the measured sample is a single-phase material. The asymmetry in the doublet lines is due to a texture effect produced on the particles during the Mössbauer study.

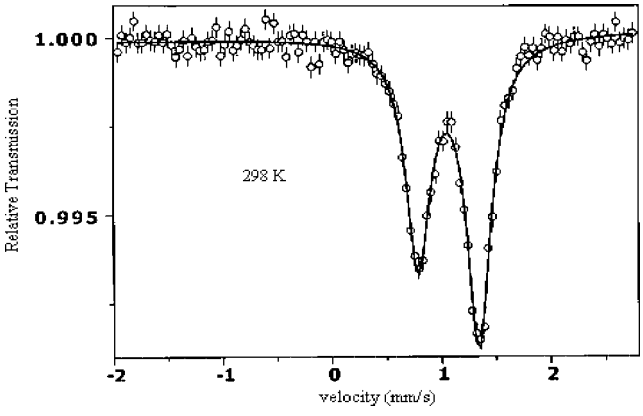

Figure 4. ^{57}Fe Mössbauer spectrum of $(C_4H_6N_2)_6Fe(BF_4)_2$ measured at 298 K.

In order to depict the high-spin state of Fe^{2+} ions in (1-methylimidazole)$_6$Fe(BF$_4$)$_2$, DC magnetic measurements were performed. DC magnetic measurements shown in Figure 5 conclusively confirm the high-spin state of Fe^{2+}, which is similar to the reports of high-spin Fe^{2+} compounds containing imidazole derivatives as ligands.[16a–16c] The temperature dependence of the susceptibility (measured at 1 T) have the typical paramagnetic shape down to 5 K, and adheres to the Curie–Weiss law: $\chi(T) = \chi_0 + C/(T - \theta)$, where χ_0 is the temperature-independent part of χ, C is the Curie constant, and θ is the Curie–Weiss temperature. The fit (solid line) yields: χ_0 = –0.0008 emu/mol Oe, C = 4.21(2) emu K/mol Oe and θ = –3.8(1) K. The linear isothermal magnetization (up to 1 T) shown in the inset confirms the paramagnetic nature at 5 K. The extracted paramagnetic effective moment is P_{eff} = 5.78 μ_B, a value which is midway between the common experimental 5.4 μ_B and the free ion P_{eff} = 6.7 μ_B (no spin-orbit coupling) for the high-spin state of Fe^{2+} ions.[17,18]

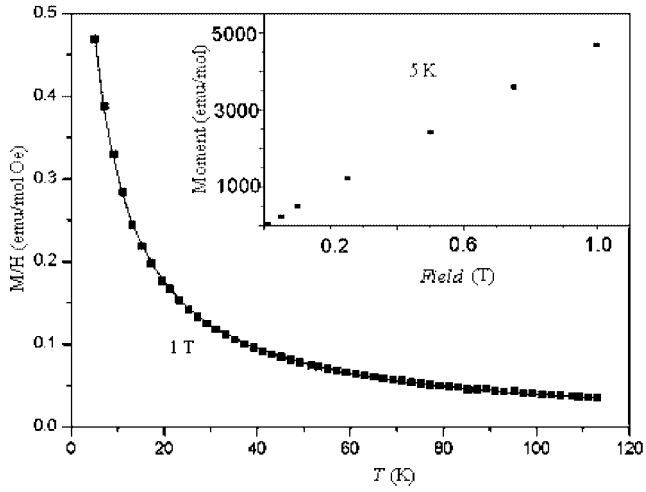

Figure 5. The DC magnetic susceptibility of $(C_4H_6N_2)_6Fe(BF_4)_2$ and linear $M(H)$ curve at 5 K.

Magnetic Measurements

The (imidazole)metal complexes show paramagnetic behavior[18,19] which can be seen in Figure 6. Higher magnetization values are measured for the (imidazole)iron complexes as compared to the (imidazole)nickel complexes, due to the different electronic ground-state configurations of the

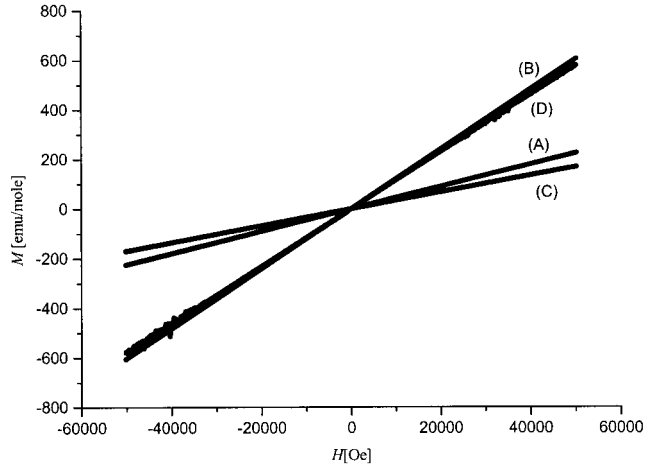

Figure 6. Comparison studies of the magnetization curve at room temperature for $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**), $(C_4H_6N_2)_6Fe(BF_4)$ (**B**)$_2$, $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**), and $(C_4H_6N_2)_6Fe(PF_6)$ (**D**).[6]

$Fe^{2+}(d^6)$ and $Ni^{2+}(d^8)$ ions in the complexes, with the theoretical spin magnetic moment (μ_s) values being d^6 = 4.90 B.M. and d^8 = 2.83 B.M., respectively. The (imidazole)-iron complexes shows similar magnetization properties whereas the (imidazole)nickel complexes are different. The change in magnetization can be observed due to interference of the orbital motion of the electron with the electric fields of the other atoms, ions, and molecules surrounding the metal ions.[20] The magnetizations of the synthesized (imidazole)metal complexes do not saturate in the range of the applied magnetic field.

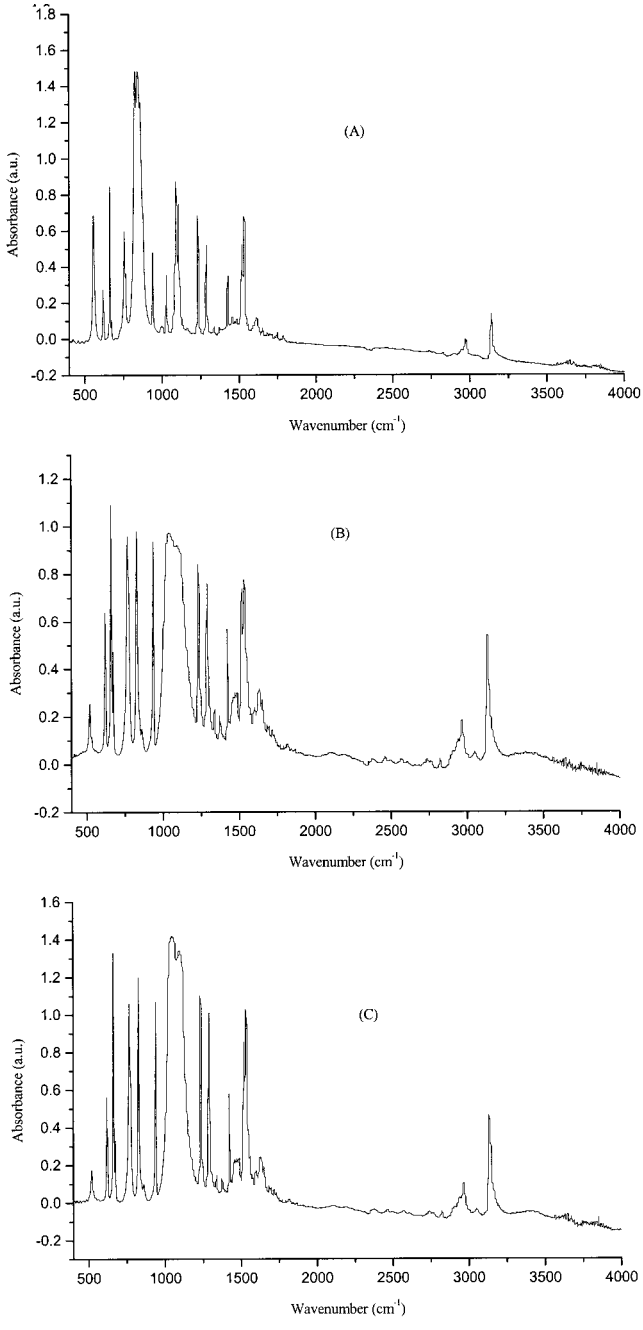

Figure 7. IR absorption spectra of the complexes $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**), $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**), and $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**).

Infrared and Raman Spectroscopy

The IR and Raman spectra are recorded for the iron and nickel complexes. They provide support to the characterization of the product by identifying the vibration of the ligands surrounding the central transition metal ion. The IR absorption spectra for the $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**), $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**) and $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**) are illustrated in Figure 7 (a, b, c). Table 5 shows the comparisons of the proposed assignments with those reported in the literature for the bands observed in the complexes of iron (**B**) and nickel (**A** and **C**).[18,19] The vibrational bands assigned to the organic ligand, $C_4H_6N_2$, are mostly blue-shifted, but some are assigned as shifted to the red. Our conclusion is that on average, the assigned bands illustrated in Table 5 are in good agreement with the interpretation of Reedijk,[18,19] Perchard and Novak.[20] The M–N vibrations are observed in the Raman spectra below 300 cm^{-1} and their locations agree with the literature values.[18,19] The IR and Raman active vibrations due to BF_4^- and PF_6^- anions are present in the spectra and also match the literature values.[21,22] Smaller shifts are observed for these bands, as compared with the literature values. The intense Raman line for the PF_6^- ion assigned to the symmetric mode ν_1 = 742 cm^{-1} is present in the $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**) spectra.[22] The IR and Raman active vibrations due to the BF_4^- ion for the $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**) and $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**) complexes are shown in Table 6. The Raman and IR measurements strengthen our assignment of the ligands surrounding the Fe and Ni ions. The observed vibration bands for the PF_6^- and BF_4^- anions confirm that the anions are not bonded to the metal ions.[19,23]

NMR Spectroscopy

^1H and ^{13}C NMR signals are probably too broad to be observed due to the paramagnetic properties of the iron and nickel complexes. The ^{19}F NMR spectrum [Figure 8 (a)] confirms the presence of PF_6^- in the $(C_4H_6N_2)_6Ni(PF_6)_2$ complex (**A**). The ^{19}F NMR spectra of $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**) and $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**) are presented in Figure 8 (b, c). The observed singlets (the coupling constant to boron is known to be very small in this anion[24]) have a shoulder deriving from the minor ^{10}B isotopomer (the isotope effect is 54 ppb). The NMR spectroscopic results reveal relatively narrow ^{19}F peaks. Thus, this demonstrates that the PF_6^- and BF_4^- anions are not bonded to the metal cations; see for instance ref.[25]

EPR Spectroscopy

The continuous wave electron paramagnetic resonance (cwEPR) spectroscopy is used to probe the point symmetry of the nickel complexes.

The EPR powder spectrum of (1-methylimidazole)$_6$-$Ni(PF_6)_2$ (**A**) and (1-methylimidazole)$_6Ni(BF_4)_2$ (**C**) at 3425G are presented in Figure 9 (a, b). These complexes

contain Ni^{2+} with $3d^8$ in octahedral symmetry, where the ground-term $^3A_{2g}$ nondegenerate state arises from the $(t_{2g})^6(e_g)^2$ configuration. Distortions from perfect octahedral symmetry result in a zero-field splitting of the three $S = 1A_{2g}$ terms ($m_s = 1$, 0, or –1). Transitional metal systems with $S = 1$ are often "EPR-silent" in the x-band EPR because of large zero-field splitting. The existence of an EPR spectrum Figure 9 (a, b) indicates a high symmetry about the metal atom, with a small zero-field splitting (less than the applied frequency, i.e. 9.7 GHz). The zero-field splitting arises from lowering, to some extent, the point symmetry from O_h, causing unequal magnetic field splitting, $m_s(-1) \leftrightarrow m_s(0)$ and $m_s(0) \leftrightarrow m_s(+1)$ transitions of the $^3A_{2g}$ ground state admixture with components of the nearest excited state, $^3T_{2g}$ [arises from the $(t_{2g})^5(e_g)^3$ configuration $^3T_{2g}$ state]. It is noticable that the two spectrum lines are very broad, which is commonly observed in concentrated paramagnetic samples.[9] Comparing the cwEPR spectrum of (1-methylimidazole)$_6$Ni$(PF_6)_2$ (**A**) with that of (1-methylimidazole)$_6$Ni$(BF_4)_2$ (**C**), we found that complex **C** shows more crystalline properties as complex **A**. The cwEPR spectra of the nickel complexes are consistent with powder spin-triplet systems reported in the literature.[9,18,19]

Thermal Analysis

To probe the mechanism of the reaction, we had to learn more about the thermal stability of the synthesized complexes, the precursors, and the ionic liquids. This was reached by studying the thermogravimetry analysis (TGA) of the products and the ionic liquids between 25 and 1000 °C with a heating rate of 3 °C min^{-1} under an N_2 flow. The TGA curve is shown in Figure 10 (a) for the $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**), $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**), $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**) and $(C_4H_6N_2)_6Fe(PF_6)_2$ (**D**) complexes. The TGA curve reveals that the anions affect the stability of the complexes.[26,27] The weight loss measured at a temperature of 250 °C, determined from the curve in Figure 10 (a), is 6.74% (0.28 mg) for **A**, 2.00% (0.11 mg) for **B**, 5.38% (0.23 mg) for **C** and 27.25% (1.01 mg) for **D**. The TGA curve shows that the BF_4^- anion complexes are more stable

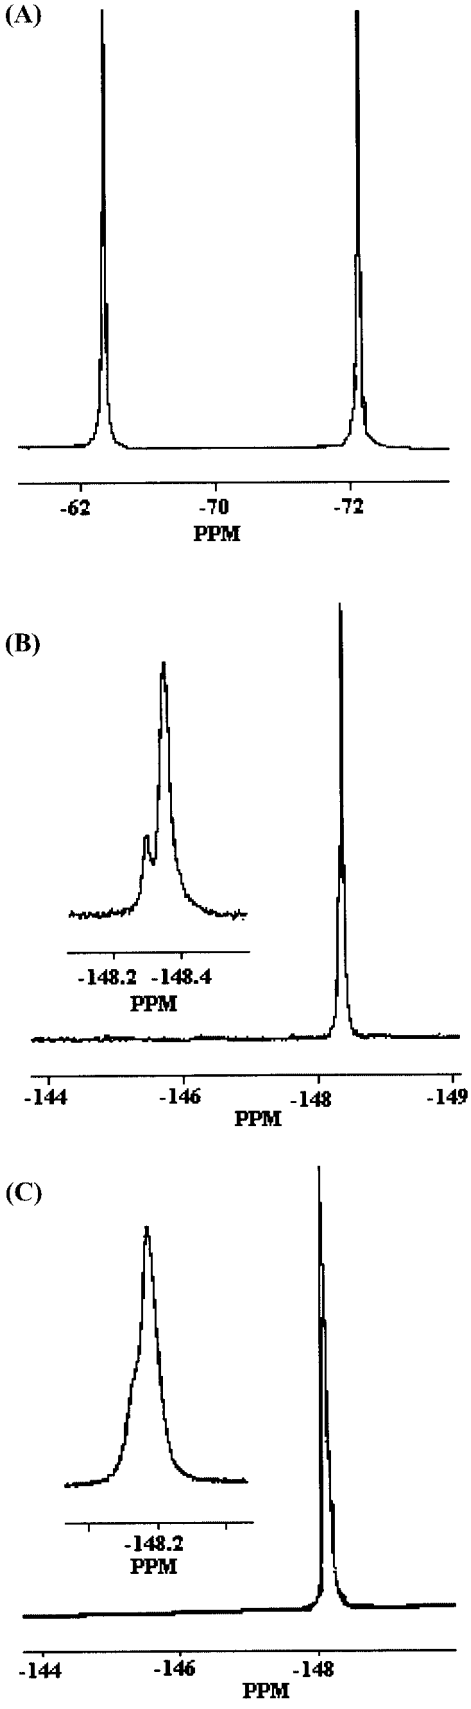

Figure 8. ^{19}F NMR spectra for $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**), $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**), and $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**).

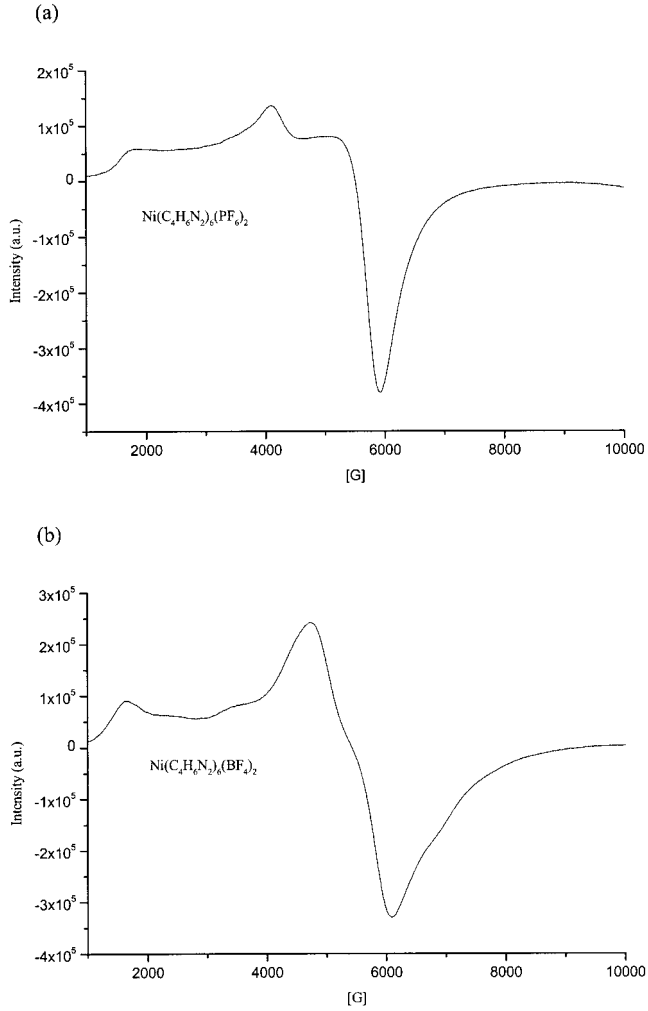

Figure 9. X-band EPR spectra of Ni^{2+} powder complexes at room temperature of $(C_4H_6N_2)_6Ni(PF_6)_2$ (a), and $(C_4H_6N_2)_6Ni(BF_4)_2$ (b).

than the PF_6^- anion complexes for both iron and nickel. The thermal stability of the ionic[28] liquids employed in our reactions, $(BMI^+)(PF_6^-)$ and $(BMI^+)(BF_4^-)$, were also studied using TGA between 25 and 1000 °C at a flow rate of 3 °C min^{-1} under N_2. The TGA graph of the ionic liquids is shown in Figure 10 (b), and the physical properties of the ionic liquid used for our reaction are summarized in Table 7. From Figure 10 (b) we observe at a temperature of 150 °C that there is no weight loss for the $(BMI^+)(PF_6^-)$ and $(BMI^+)(BF_4^-)$ ionic liquids. The decomposition temperature ranges of ionic liquids measured from TGA curves are found to be 332–516 °C $(BMI^+)(PF_6^-)$ and 309–528 °C $(BMI^+)(BF_4^-)$. The TGA curve confirms that the ionic liquids $(BMI^+)(PF_6^-)$ and $(BMI^+)(BF_4^-)$ are stable at the reaction temperature. They do not form a metal fluoride, or undergo any other decomposition at the reaction temperature.[29] It is therefore concluded from the TGA results that the ionic liquids react only as a result of the bubble's collapse.

Conclusions

The synthesis of transition metal complexes in ionic liquids under ultrasonic conditions has given a new direction to the chemistry of ionic liquids. In brief, the sonication products of 1-methylimidazole and carbonylmetal complexes in ionic liquids $(BMI^+)(PF_6^-)$ and $(BMI^+)(BF_4^-)$ (which act as solvents) form the complexes $(C_4H_6N_2)_6Fe(PF_6)_2$,[6] $(C_4H_6N_2)_6Ni(PF_6)_2$, $(C_4H_6N_2)_6Fe(BF_4)_2$, and $(C_4H_6N_2)_6Ni(BF_4)_2$ when sonicated in air. The interesting part of this reaction under ultrasound conditions is that there is no hydrolysis of PF_6 in the presence of metals, and there are no reports of metathesis or decomposition of cations to give different products. In these reactions the anions of the ionic liquids contribute to the final structure of the products, as was stated in our previous paper[6] and in ref.[30] The sonochemical products of Fe^{2+} and Ni^{2+} ions are octahedrally coordinated by six 1-methylimidazole molecules. The PF_6^- and BF_4^- anions act as charge-stabilizing agents in the formation of the crystals, which are characterized by the trigonal lattice with the $P\bar{3}$ space group. The PXRD structure analysis revealed a high concentration of twin and/or line defects in the crystals. Thus, ionic liquid solvents are effective as donors of anions for the cation stabilization under ultrasonic conditions. Although a tremendous amount of work has been carried out on applications of ionic liquids, there have been a few reports in recent years where ionic liquids are used in sonochemistry. In particular, much work is still needed to explore and utilize the fundamental chemistry and properties of these interesting liquids in sonochemistry.

Experimental Section

General: 1-Butyl-3-methylimidazolium hexafluorophosphate $(BMI^+)(PF_6^-)$ (96%), 1-butyl-3-methylimidazolium tetrafluoroborate $(BMI^+)(BF_4^-)$ (97%) and 1-methylimidazole were purchased from Aldrich. Pentacarbonyliron (99.5%) and tetracarbonylnickel (100%) were purchased from Strem Chemicals, USA; they were handled very carefully with safety precautions in an effective fume hood; refer to Material Safety Data Sheet (MSDS) for further information and safety measurements. PXRD data were collected with a Bragg–Brentano geometry using a DRON-4 diffractometer with a graphite secondary monochromator (Cu-K_α radiation, λ = 1.5418 Å) and a scintillation counter. The measurements were carried out at room temperature under air. A ^{57}Fe Mössbauer study of (1-methylimidazole)$_6Fe(BF_4)_2$ was performed at ambient temperature using a conventional constant acceleration drive and a 50 mCi ^{57}Co:Rh source. The experimental spectrum was analyzed by a least-squares fitting procedure, and the ^{57}Fe isomer shifts are relative to α-Fe, measured at room temperature. DC magnetic measurements were performed using a commercial (Quantum Design) super-conducting quantum interference device (SQUID) magnetometer. The magnetic measurements were performed with a Quantum Design MPMSXL SQUID magnetometer for $(C_4H_6N_2)_6Ni(PF_6)_2$ (**A**), $(C_4H_6N_2)_6Fe(BF_4)_2$ (**B**), $(C_4H_6N_2)_6Ni(BF_4)_2$ (**C**), and $(C_4H_6N_2)_6Fe(PF_6)_2$ (**D**). The magnetization was measured at room temperature as a function of an external field being swept up from –50 kOe to 50 kOe and down to –50 kOe in steps of 200 Oe. The IR absorption spectra of the complexes were recorded in the range of 400–4000 cm^{-1} by means of a Nicolet (Impact 410) spectrometer with KBr pellets (5 mg of sample in 500 mg of KBr). Raman spectroscopic measurements were carried out at room temperature with a Jobin Yvon Horiba Raman system. The 524 nm line of an Ar^+ laser was used as the excitation source. The Raman spectra were recorded in the range 100–4000 cm^{-1}. Powder samples

Table 7. Physical properties of the ionic liquids.

Ionic liquid	Decomposition temperature range (TGA)	Molecular weight [g/mol]	Density [g/ml]
1-Butyl-3-methylimidazolium hexafluorophoshate (96%)	332–516 °C	284.18	1.510
1-Butyl-3-methylimidazolium tetrafluoroborate (97%)	309–528 °C	226.02	1.320

were measured at room temperature with a Bruker EPR 100d X-band spectrometer, frequency 9.766 GHz, microwave power 6.34 mW.

Synthesis of the Complexes: The synthetic procedure for the metal complexes of 1-metylimidazole in an ionic liquid under ultrasonic conditions is reported in our previous communication.[6] All the metal complexes of 1-methylimidazole were crystallized from ethanol (due to high solute solubility).[31]

(1-Methylimidazole)$_6$Ni^{II}(PF$_6$)$_2$ (A): $Ni(CO)_4$ (6.18 mmol, 1.056 g) and 1-methylimidazole (24 mmol, 2 g) were dispersed in ionic liquid (BMI^+)(PF_6^-) (17.6 mmol, 5 g) under ultrasonic conditions. Transparent blue needle-shaped crystals (1.35 mmol, 1.141g) were obtained. $C_{24}H_{36}F_{12}N_{12}NiP_2$ (841.27): calcd. C 34.26, H 4.28, N 19.98; found C 34.70, H 4.47, N 19.73. ^{19}F NMR (188.3 MHz in [D$_6$]DMSO): δ = –70.25 (d, J_{PF} = 709 Hz) ppm (confirming the presence of PF_6^-). MS (DCI, FAB): *m*/*z* = 82 [$C_4H_6N_2$], 145 [PF_6].

(1-Methylimidazole)$_6$Fe^{II}(BF$_4$)$_2$ (B): $Fe(CO)_5$ (6.08 mmol, 1.192 g) and 1-methylimidazole (24 mmol, 2 g) were dispersed in ionic liquid (BMI^+)(BF_4^-) (22 mmol, 5 g) under ultrasonic conditions. Transparent needle-shaped crystals (2.16 mmol, 1.560g) were obtained. $C_{24}H_{36}B_2F_8FeN_{12}$ (722.09): calcd. C 39.88, H 4.98, N 23.26; found C 40.33, H 5.39, N 23.69. ^{19}F NMR (188.3 MHz in [D$_6$]-DMSO): δ = –148.35 ppm (confirming the presence of BF_4^-). MS (DCI, FAB): *m*/*z* = 82 [$C_4H_6N_2$], 87 [BF_4].

(1-Methylimidazole)$_6$Ni^{II}(BF$_4$)$_2$ (C): $Ni(CO)_4$ (6.18 mmol, 1.056 g) and 1-methylimidazole (24 mmol, 2 g) were dispersed in ionic liquid (BMI^+)(BF_4^-) (22 mmol, 5 g) under ultrasonic conditions. Transparent blue needle-shaped crystals (1.41 mmol, 1.024g) were obtained. $C_{24}H_{36}B_2F_8N_{12}Ni$ (724.95): calcd. C 39.72, H 4.96, N 23.17; found C 40.44, H 5.35, N 23.31. ^{19}F NMR (188.3 MHz in [D$_6$]DMSO): δ = –148.19 ppm (confirming the presence of BF_4^-). MS (DCI, FAB): *m*/*z* = 82 [$C_4H_6N_2$], 87 [BF_4].

1-D Open-Channeled 3-D Supramolecular Self-Assembled Frameworks Encapsulating Unprecedented Cyclic $(H_2O)_8$ Clusters or Solvent Molecules

Dong-sheng Li,[a,b] Yao-yu Wang,*[a] Xin-jun Luan,[a] Ping Liu,[a] Cai-hua Zhou,[a,b] Hai-rui Ma,[a] and Qiz-hen Shi[a]

Keywords: Hydroxybutanedioic acid / Copper / Bipyridine / Phenanthroline / Self-assembly / 1-D open channel

Two novel 1-D coordination polymers, $\{[Cu(Hhbd)(bpy)]\cdot 3H_2O\}_n$ (**1**) and $\{[Cu(Hhbd)(phen)]\cdot H_2O\cdot MeOH\}_n$ (**2**) [Hhbd = α-hydroxybutanedioicate dianion, bpy = 2,2′-bipyridine, phen = 1,10-phenanthroline], were rationally designed and synthesized with an identical construction strategy, using Hhbd ligands as bridges and chelating aromatic ligands as terminal ligands. Interestingly, the chelating aromatic ligand and the –OH groups of the Hhbd ligand play an important role in the self-assembly of the polymeric coordination chain by providing potential supramolecular recognition sites for π–π aromatic stacking and hydrogen-bond interactions, resulting in the self-assembly of the molecular double chains to give a 3-D supramolecular framework with 1-D open channels. More significantly, in **1** the host framework encapsulates unprecedented centrosymmetric cyclic $(H_2O)_8$ clusters that have a chair conformation and are connected into 1-D arrays by supramolecular association along the 1-D open channels. In contrast, the channels of **2** contain lattice water and disordered methanol molecules. TGA and XRPD show that the host frameworks of **1** and **2** are stable when the guest solvent molecules are removed from the channels. Variable-temperature magnetic susceptibility measurements for both complexes indicate the presence of weak antiferromagnetic exchange interactions between adjacent copper(II) ions.

Introduction

Research into self-assembling processes has recently become a rapidly growing area in supramolecular chemistry, biochemistry, and materials science.[1–4] Indeed, self-assembling processes are utilized by nature in many interesting chemical and biomolecular systems, such as in the folding of proteins and nucleic acids.[5–7] Moreover, the principles of self-assembly provide a new strategy for the rational design and synthesis of new supramolecular architectures, especially for the preparation of extended channel-containing metal-organic frameworks. Such systems are of potential utility for molecular recognition, ion exchange, gas storage, heterogeneous catalysis, and for the development of new magnetic materials.[8–10] Therefore, chemists have made significant efforts to introduce the self-assembling process into artificial systems.[11–13] As a result of this work, the self-assembly of organic, organometallic, and/or inorganic building blocks through metal-ligand binding, hydrogen bonds, or π–π interactions has become a powerful tool for the generation of large cage-like molecules and porous substances with channels.[14–18] Although important progress has been made in the construction of such assemblies by the exploitation of any one of these individual intermolecular interactions, a lot of research dealing with the combination of two or all three of them can still be carried out, allowing for the construction of an almost infinite number of new supramolecular entities.[19]

During the past decades, for materials chemists and especially for inorganic chemists, polycarboxylates have become one of the most used spacers in the synthesis of compounds that have potential applications as molecular-based magnetic materials, and for the preparation of porous materials that show host–guest behavior.[20–25] However, hydroxypolycarboxylic acids, although important as polycarboxylate ligands, have been seldom used to date. The unique features of hydroxypolycarboxylic acids have drawn our attention. First of all, these acids possess terminal carboxylic acid and hydroxyl groups that may be completely or partially deprotonated. This leads to a versatile coordination behavior, and as such, distinct bonding modes towards metal cations, such as nonchelating, chelating, and bridging modes can be realized.[26,27] Secondly, hydroxypolycarboxylic acids can act not only as hydrogen-bond acceptors, but also as hydrogen-bond donors to form new extended structures by means of additional hydrogen-bond interactions. Thirdly, some hy-

droxypolycarboxylic acids [*α*-hydroxybutanedioic acid (H_3hbd), 2,3-dihydroxybutanedioic acid (H_4dhbd), and 2-hydroxy-1,2,3-tricarballylic acid (H_4htb), etc.] are present in fruits and living cells, and they also play an important role in biological processes.[28–30]

Currently we are exploring the self-assembly of metal ions with ligands that are capable of forming hydrogen bonds and bringing about π–π interactions, and that behave as directional motifs capable of extending the dimensionality of the channel-containing product materials. In the present work, by using H_3hbd as the bridging ligand, and 2,2′-bipyridine (bpy) or 1,10-phenanthroline (phen) as terminal ligands, we have prepared two similar neutral 1-D coordination polymers, namely $\{[Cu(Hhbd)(bpy)]\cdot 3H_2O\}_n$ (**1**) and $\{[Cu(Hhbd)(phen)]\cdot H_2O\cdot MeOH\}_n$ (**2**) [Hhbd = *α*-hydroxybutanedioicate dianion]. Interestingly, under the direction of supramolecular recognition, and attraction through π–π aromatic stacking, and hydrogen-bond interactions provided by Hhbd and the aromatic chelating ligands, these 1-D chains may self-assemble to form molecular double chains that may also self-assemble to give a final 3-D framework that contains 1-D open channels. Unexpectedly, we found unprecedented cyclic $(H_2O)_8$ clusters encapsulated within the host framework of **1**. These clusters are connected into 1-D arrays along the 1-D open channels by supramolecular association.

Results and Discussion

Description of the Structures

{[Cu(Hhbd)(bpy)]·3H$_2$O}$_n$ (1)

A single-crystal X-ray structural analysis showed that **1** crystallizes in the monoclinic space group $P2_1/c$, with one copper(II) atom, one tridentate Hhbd ligand, one bpy ligand, and three lattice water molecules in each crystallographic unit. Each copper(II) atom is coordinated to three oxygen atoms from two different Hhbd ligands, and two nitrogen atoms from a chelating bpy ligand to give 3+1+1 distorted trigonal-bipyramidal geometry at the metal centers with a trigonality index $\tau = 0.93$.[31] Copper(II) is approximately coplanar with the equatorial plane defined by atoms O3, O5, N2, and shows a deviation of 0.0375 Å toward O1, as seen in part a of Figure 1. Selected bond lengths and angles are listed in Table 1, and are in close agreement with bond parameters previously reported for carboxylate and bpy containing copper(II) complexes.[32,33] In addition, the fact that the Cu–$O_{carboxyl}$ bonds [av.1.967(2) Å] are significantly shorter than the Cu–$O_{hydroxyl}$ bond [2.209(3) Å] indicates that the hydroxyl group of **1** is protonated; this is also found in many other *α*-hydroxycarboxylate complexes.[27,34]

It is worthwhile to note that the Hhbd dianion adopts an *R* conformation and bridges the copper centers to form 1-D polymeric chains running along the crystallographic *a* axis with an adjacent Cu···Cu distance of 7.013 Å (part b in Figure 1). The bpy ligands lie on one side of this chain in a parallel fashion. Interestingly, a pair of 1-D chains self-assemble to generate a molecular double chain under the direction of strong aromatic π–π interactions between the bpy units with a face-to-face distance of ca.3.375–3.422 Å (part c in Figure 1). There are significant C–H···O hydrogen bonds involving the bpy carbon atoms (C7) and the uncoordinated carboxyl oxygen atoms (O4) (C···O 3.357 Å, C–

H···O 164°), and these provide an additional attractive force between the strands.[35] To the best of our knowledge, the double chains represent the first example of perfect molecular double chains formed using hydroxypolycarboxylate ligands. Furthermore, neighboring pairs of double chains interact with each other through strong hydrogen bonds between the uncoordinated carboxyl oxygen atoms (O2) and the coordinated, protonated hydroxyl groups (O3) (O···O 2.676 Å, O–H···O 177°). These interactions form the final 3D framework that feature 1-D open channels when viewed along the crystallographic *a* axis (Figure 2). The approximate dimensions of these channels are 10.41 Å × 6.67 Å, which are large enough to encapsulate guest solvent molecules.

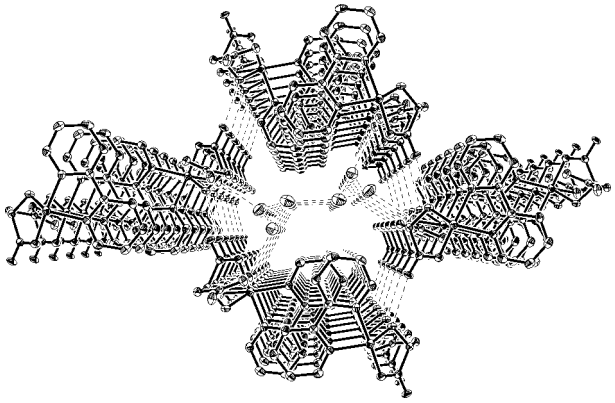

Figure 2. View of the 3-D supramolecular framework of **1** containing 1-D open channels encapsulating arrays of cyclic $(H_2O)_8$ clusters.

The most remarkable feature in **1** is that, in the 1-D open channels, the guest water molecules form a centrosymmetric cyclic $(H_2O)_8$ cluster that adopts a chair conformation (Figure 3). Two closely related isomers of nearly identical low-energy with S_4 and D_{2d} symmetries have been theoretically predicted for the $(H_2O)_8$ cluster.[36] Evidence for the existence of both of these isomers has been obtained from studies of gas-phase $C_6H_6(H_2O)_8$ and molecular beams.[37,38] However, only three kinds of $(H_2O)_8$ clusters, namely, the cubic cage-like $(H_2O)_8$ cluster with *Ci* symmetry, the icelike cyclic $(H_2O)_8$ cluster with –4*m*2 symmetry, and the opened-cube $(H_2O)_8$ cluster with centrosymmetric symmetry, have been found within different crystal hosts,[39–41] but no centrosymmetric cyclic $(H_2O)_8$ clusters have ever been reported.

Within the centrosymmetric cyclic $(H_2O)_8$ cluster only three water molecules are crystallographically unique. The hydrogen bond O···O distances range from 2.772 to 2.850 Å (mean value 2.799 Å), and are slightly longer than the average hydrogen bond length observed in icelike cyclic $(H_2O)_8$ clusters with –4*m*2 symmetry.[40] There is a narrow variation in the O···O···O angles, with an average value of 120.72°. These structural parameters are similar to those of cyclic $(H_2O)_6$ clusters.[42] Each water molecule in the cluster is involved in the formation of two hydrogen bonds with an adjacent water molecule. The water octamers are self-assembled along the channels, and are held together by

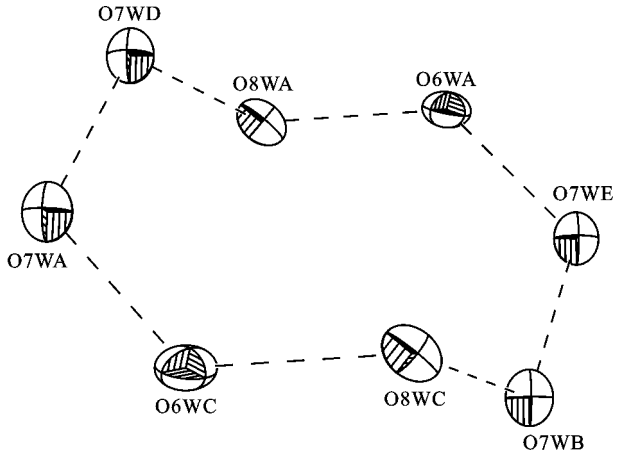

Figure 3. A centrosymmetric cyclic $(H_2O)_8$ cluster in **1** displaying a chair conformation. The view is along the crystallographic *b* axis; hydrogen bond O···O distances [Å] and O···O···O angles [°]: O7WA···O7WD 2.777(3), O7WA···O6WC 2.798(6), O6WC···O8WC 2.850(7), O8WC···O7WB 2.722(8), O6WC···O8WA 5.437(9); O7WD···O7WA···O6WC 118.65(11), O7WA···O6WC···O8WC 127.49(9), O6WC···O8WC···O7WB 125.85(10), O8WC···O7WB···O7WE 110.78(9).

O7W···O6W and O7W···O8W hydrogen bonds to give extended 1-D arrays consisting of eight-membered rings of water,which share a common side formed by an O7W···O7W hydrogen bond (Figure 4). Additionally, atoms O6W and O8W both donate a hydrogen bond towards a carboxyl oxygen atom situated on the Hhbd ligand of the host framework (O4, O5) (av.2.850 Å). These additional interactions play an important role incontributing to the stability of the 1-D cyclic $(H_2O)_8$ cluster arrays. The supramolecular association of water molecules into arrays is presumably enforced by the shape and the condition of the interior of the host's channel. These results further illustrate the structural diversity possible for water clusters and the sensitive dependence of their structures on the nature of their environment.

{[Cu(Hhbd)(phen)]·H_2O·MeOH}$_n$ (2)

Complexes **1** and **2** have the same space group, $P2_1/c$, and similar crystal data. The central copper(II) atoms in both complexes have the same coordination geometry, and the bond lengths and angles, as shown in Figure 5, part a, Table 1, are also similar. In other dicarboxylate complexes, such as the manganese maleate/diimine systems, and the copper ipa/diimine systems, the replacement of bpy with phen, a chelating aromatic ligand of a larger size, led to a dramatic change in the framework topologies.[33,43] In the study reported in this paper, we used phen instead of bpy, and having used similar reaction conditions, only the analogous neutral polymeric chains were formed in **2** (part b in Figure 5). However, there are some subtle differences between the two complexes; the aromatic π–π stacking interactions between the phen entities are stronger in **2** (the distance between the phen rings is ca.3.27–3.30 Å). Additionally, the 1-D open channels in the final 3-D host framework of **2** (ca. 9.97×4.67 Å),which are also formed through molecular double chains held together by $O_{hydroxyl}$–H···$O_{carboxyl}$ hydrogen bonds, are occupied by water and disordered methanol molecules (Figure 6). As shown above, the most critical factor to note for the two complexes is that their structural identity does not derive from their chemically very similar ancillary ligands, phen and bpy, but from the coordination geometry of their Hhbd ligands, in particular, of the hydroxyl groups bound to the central metal atom.

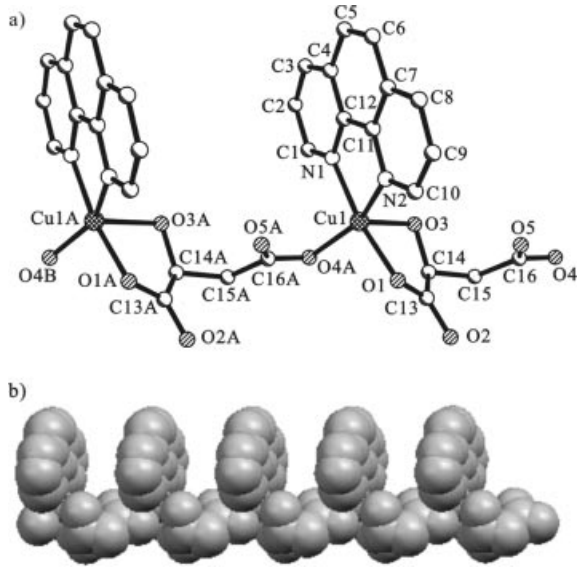

Figure 5. (a) Veiw of the coordination environment of the copper(II) atoms in **2**; (b) a neutral 1-D single-stranded polymeric chain.

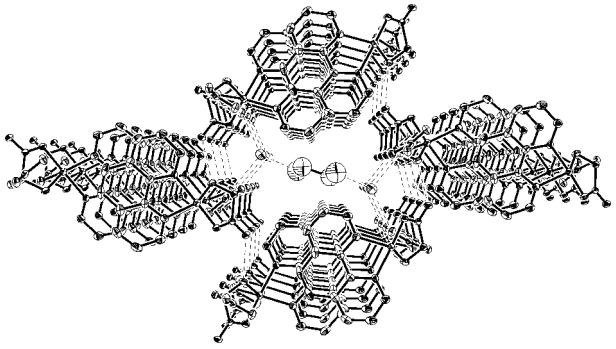

Figure 6. View of the 3-D supramolecular formwork of **2** with 1-D open channels containing the free water and disordered methanol molecules.

IR Spectra and TGA Analysis

The infrared spectra of the two complexes are quite similar, with a broad band centered at ca. 3420–3380 that is due to the –OH stretchingvibration of the water molecules involved in extensive hydrogen-bonding interactions.[44] Furthermore, the spectra exhibit the ν_{as}(OCO) and ν_s(OCO) vibrations of the carboxylate groups that occur at 1608 and 1393 cm^{-1} for **1** and at 1604 and 1403 cm^{-1} for **2**. $\Delta[\nu_{as(OCO)} - \nu_{s(OCO)}] > 200\ cm^{-1}$ for both complexes, a value that suggests that the carboxylate is coordinated in a monodentate fashion, This is in agreement with the crystal structure. Less significant absorption bands occur at 3050–2920 (stretching vibrations of the aromatic C–H groups), 860–720 (out-of-plane motion of the C–H groups of the pyridyl rings) and 570 cm^{-1} ($\nu_{(M-N)}$ vibration).

Thermogravimetric analysis (TGA) showed that the weight of **1** remains almost unchanged from 40 to 210 °C (first stage). The second stage occurs between 210 and 230 °C. A weight loss of 12.86% (calcd. 13.30%) over this range is attributed to the loss of three water molecules. When the temperature is above 235 °C, the product begins to lose the Hhbd and bpy ligands and then starts to decompose. In contrast to **1**, the lattice water and disordered methanol molecules of **2** are lost between 50 and 110 °C; the overall observed loss (11.67%) is in agreement with the calculated value (11.75%). When the temperature is above 240 °C, the complex begins to lose its ligands and then starts to decompose. These data analyses reveal that: (1) The free water and the disordered methanol molecules are removed from the channels of **2** in the range of 50–110 °C, whereas the coordinated phen and Hhbd ligands do not decompose over this temperature range. (2) The water molecules in **1** are involved in strong and extensive hydrogen-bond interactions, leading to the loss of water at higher temperatures. (3) The 1-D neutral polymeric chains of **1** and **2** are stable under 235 °C and 240 °C, respectively. In addition, after heating a sample of **1** at 230 °C, and a sample of **2** at 120 °C, for 2 h the guest solvent molecules are removed (the evacuated frameworks are defined as **1′** and **2′**, respectively). The X-ray power diffraction patterns of **1′** and **2′** are similar to those of **1** and **2**, although minor differences can be seen in the positions, intensities and widths of some peaks, indicating that the frameworks of **1** and **2** are retained after the removal of the guest species. On the other hand, it may also indicate that the 1-D open channels in **1** and **2** have the ability to absorb other hydrophilic small molecules. An investigation of these properties and the synthesis of other metal-Hhbd frameworks are underway.

Magnetic Properties

Variable-temperature magnetic susceptibility measurements over the 5–300 K range were carried out for **1** and **2**, and the plots of χ_M and $1/\chi_M$ vs. T are shown in Figure 7. Both $1/\chi_M$ vs. T plots are almost linear down to very low temperatures. Fitting the curves to the Curie–Weiss law $[1/\chi_M = (T - \theta)/C]$ gives a Curie–Weiss constant of C = 0.387 $cm^3 K mol^{-1}$ and a Weiss temperature, θ, of –0.431 K for **1** with an agreement factor of $R = 7.13 \times 10^{-4}$, and C = 0.420 $cm^3 K mol^{-1}$ and θ = –0.456 K for **2** with an agreement factor of $R = 4.07 \times 10^{-4}$, where $R = \Sigma[(1/\chi_M)_{obs} - (1/\chi_M)_{calc}]^2/\Sigma[(1/\chi_M)_{obs}]^2$. The θ values for the two complexes are indicative of weak antiferromagnetic interactions.[45,46] In order to evaluate the exchange interaction between neighboring copper(II) atoms, the experimental data were fitted using the expression (see below) obtained from the Bonner–Fisher calculation based on the effective spin Hamiltonian $H = -J\Sigma(S_iS_{i+1})$.[47]

$$\chi_M^{\ J} = \frac{N\beta^2 g^2 S(S+1)}{3kT}\frac{1+u}{1-u}$$

where

$$u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right]$$

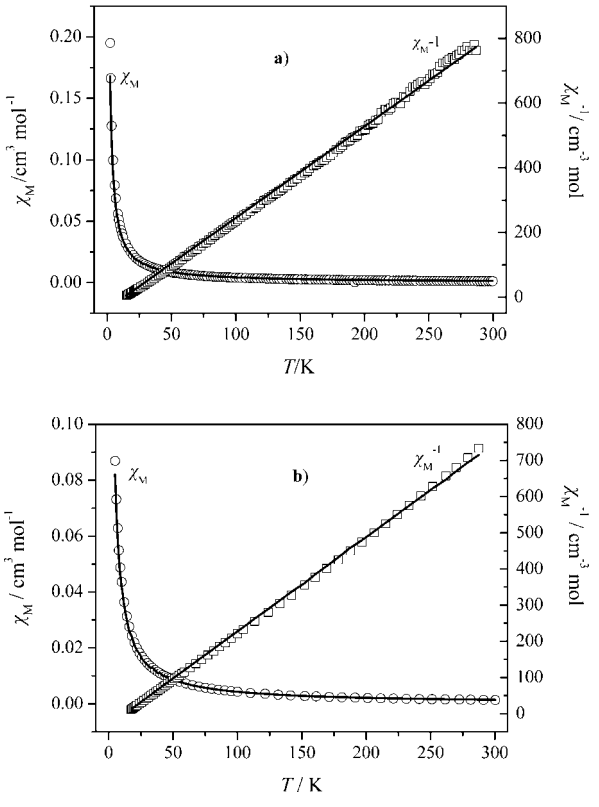

Figure 7. Experimental (○ and □) and fitted (–) curves showing the temperature dependence of χ_M and χ_M^{-1}. (a) for **1**; (b) for **2**.

Finally, this expression fits very well with the experimental susceptibilities of **1** and **2**, giving g = 2.09 and J = –0.487 cm^{-1} for **1** and g = 2.15 and J = –0.517 cm^{-1} for **2**. These very low J values are in agreement with the values of θ reported above. The antiferromagnetic interactions are obviously due to a long-range superexchange pathway between adjacent magnetic centers.[48,49]

Conclusion

In summary, two 3-D supramolecular frameworks with 1-D channels, $\{[Cu(Hhbd)(bpy)]\cdot 3H_2O\}_n$ (**1**) and $\{[Cu(Hhbd)(phen)]\cdot H_2O\cdot MeOH\}_n$ (**2**), were constructed from Hhbd-bridged 1-D chains of copper(II) units and chelating aromatic ligands. The Hhbd ligand adopts a coordination geometry identical to that observed for very similar ancillary chelating ligands. This results in the same structure topologies, in which the aromatic chelating ligand and the –OH groups of the Hhbd ligand play an important role in the self-assembly of the polymeric coordination chains by providing potential supramolecular recognition sites for π–π aromatic stacking and hydrogen-bond interactions. More significantly, in **1** the host framework encapsulates unprecedented centrosymmetric cyclic $(H_2O)_8$ clusters that adopt a chair conformation and are connected into 1-D arrays by supramolecular association.

Experimental Section

Synthesis of $\{[Cu(Hhbd)(bpy)]\cdot 3H_2O\}_n$ (1) and $\{[Cu(Hhbd)(phen)]\cdot H_2O\cdot MeOH\}_n$ (2): Reagents and solvents were purchased from commercial sources (Aldrich) and used as received. The two complexes were prepared in a similar way. Firstly, a sample of copper acetate monohydrate (0.40 g, 2 mmol) was dissolved in deionized water (15 mL). Secondly, *dl*-α-hydroxybutanedioic acid (H_3hbd) (0.29 g, 2.2 mmol) with either 2,2′-bipyridine (bpy) (0.33 g, 2.1 mmol) or 1,10-phenanthroline (phen) (0.42 g, 2.1 mmol) was suspended in MeOH (20 mL) and stirred at ambient temperature for 20 min. Thirdly, the MeOH solution was added slowly drop by drop to the previously prepared copper acetate solution with continuous stirring. The resulting mixture was then stirred for a further 40 min and then filtered. Finally, the blue filtrate solution was transferred to a tube and placed inside a conical flask containing acetone under air. After 13 d, blue crystals of **1** and **2** were manually harvested under the microscope and analyzed using single-crystal X-ray diffraction. Yield: 71% for **1** and 69% for **2**. (**1**) $C_{14}H_{18}CuN_2O_8$ (405.85): calcd. C 41.43, H 4.47, Cu 15.66, N 6.90; found C 41.40, H 4.45, Cu 15.60, N 6.88. (**2**) $C_{17}H_{18}CuN_2O_7$ (425.89): calad. C 47.94, H 4.26, Cu 14.92, N 6.58; found C 47.91, H 4.23, Cu 14.84, N 6.55.

Physical Measurements: Elemental analyses (C,H,N) were determined with a PE 2400 Elemental analyzer, and the analyses of the copper contents were performed on a Perkin–Elmer Optima 3300 DV ICP analyzer. Infrared spectra of KBr pellets were recorded with a BRUKER EQUINOX-55 spectrometer in the range of 4000–400 cm^{-1}. Thermal analyses were performed with a NETZSCH STA 449C microanalyzer with a heating rate of 10 °C min^{-1} under air. The XRPD patterns were recorded with a Rigaku D/Max 3III diffractometer with a scanning rate of 4 deg min^{-1}. Magnetic measurements were carried out on a polycrystalline sample with a SQUID magnetometer operating in the 5–

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

300 K temperature range with an applied field of 5 kOe. Diamagnetic corrections were estimated from the Pascal constants.

Crystal Data Collection and Refinement: Diffraction experiments for **1** and **2** were carried out with Mo-K_α radiation using a BRUKER SMART APEX-CCD diffractometer at 293(2) K. A summary of the crystallographic data and structure refinement details are given in Table 2. Both structures were solved by direct methods and refined with the full-matrix least-squares technique on F^2 using SHELXS-97[50] and SHELXL-97.[51] All non-hydrogen atoms were refined anisotropically. CCDC-261630 (for **1**) and CCDC-261631 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 2. Crystal data and structure refinement details for **1** and **2**.

Compound	**1**	**2**

Ru^{III} Complexes of Edta and Dtpa Polyaminocarboxylate Analogues and Their Use as Nitric Oxide Scavengers

Tim Storr,[a,b] Beth R. Cameron,*[a] Robert A. Gossage,[a,c] Helen Yee,[a] Renato T. Skerlj,[a] Marilyn C. Darkes,[a] Simon P. Fricker,[a] Gary J. Bridger,[a] Nathan A. Davies,[d] Michael T. Wilson,[d] Kevin P. Maresca,[e] and Jon Zubieta[e]

Keywords: Bioinorganic chemistry / Ruthenium / Polyaminocarboxylates / Nitric oxide scavenging

In this study a series of Ru^{III} complexes, chelated by analogues of ethylenediaminetetraacetic acid (edta) and diethylenetriaminepentaacetic acid (dtpa), were produced and tested for NO scavenging ability. Modifications to the edta and dtpa ligand frameworks were made in an effort to alter the reactivity, aqueous stability and pharmacokinetics of the resulting Ru^{III} complexes. The X-ray structure of the nitrosyl complex **38** confirms that the Ru^{III} complex **27** reacts with NO to form a linear {Ru–NO}[6] complex. The nitrosyl complex $[C_{15}H_{15}N_4O_{11}Ru]$ crystallized in the $P2_1/c$ space group with a = 12.731(3) Å, b = 10.894(2) Å, c = 14.241 (3) Å, β = 107.320(4)°, V = 1885.6(7) Å^3, and Z = 4. Kinetic studies on the reactions of **14** ($k = 2.38\times10^6$ M^{-1} s^{-1}) and **27** ($k = 2.30\times10^5$ M^{-1} s^{-1}) with NO exemplify the difference in chemical properties obtained by ligand framework manipulation. Binding constants of **14** ($K_B = 5\times10^6$ M^{-1}) and **27** ($K_B = 2\times10^5$ M^{-1}) with NO were also measured, indicating the tight binding of NO by the Ru^{III} complexes. The activity of the Ru^{III} complexes to scavenge nitric oxide was evaluated using RAW264 murine macrophage cells. Ligand analogues of edta that have a pyridine donor as part of the *N*,*N* chelate such as **20** and **24** exhibit similar scavenging activity to the parent compound. Ligand analogues of dtpa that have R groups at the central amine in place of the carboxylic acid such as **31**, **34**, and **37** are also efficient NO scavengers.

Introduction

The discovery that nitric oxide (NO) acts as a signaling molecule in the body has led to a significant amount of research concerning its function and also the role this small molecule plays in the physiology and pathophysiology of disease. As a testament to the importance of this work, Robert Furchgott, Ferid Murad, and Louis Ignarro were awarded the Nobel Prize in physiology or medicine for their pioneering work on NO. NO is produced in the body during the conversion of L-arginine to L-citrulline, a process catalyzed by the enzyme nitric oxide synthase (NOS).[1] A dysfunction in NO metabolism has been implicated in many disease states. For example, a decrease in NO production can lead to severe hypertension, a condition that is treated with vasodilators (NO donors) such as nitroprusside.[2] The overproduction of NO has been implicated to play a role in many disease states such as septic shock,[3] rheumatoid arthritis,[4] diabetes,[5] asthma,[6] and cancer.[7,8] One approach to attenuate the overproduction of NO is through the use of NOS inhibitors. There are several isoforms of NOS, and these can be divided into the Ca^{2+}-dependent [constitutive NOS (cNOS): nNOS and eNOS] and Ca^{2+}-independent (inducible NOS: iNOS). NOS inhibitors necessarily need to be specific for iNOS, to prevent any deleterious effects of inhibiting the essential constitutive NOS. An alternative strategy, eliminating the necessity of specific NOS inhibitors, is to use NO scavengers. Transition metal complexes such as pyridoxylated hemoglobin polyethylene (PHP)conjugates,[9] dinuclear copper complexes,[10] Fe dithiocarbamates[11] or Ru-containing[12,13] complexes have shown considerable potential as NO scavengers.

Ruthenium complexes have been investigated as immunosuppressive agents,[14] *anti*-tumour and *anti*-metastatic agents,[15–18] antiangiogenic agents,[19] and as nitric oxide (NO) scavengers.[2,12,20,21] Our research program has focused on the use of ruthenium complexes, and in particular Ru^{III} polyaminocarboxylate (PAC) complexes, as NO scavengers. An effective NO scavenger must meet certain criteria

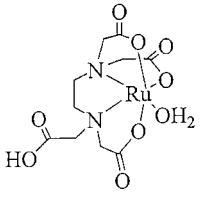
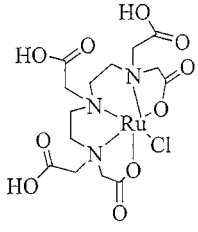
including (but not limited to) the following: (1) Fast NO reaction kinetics; (2) activity and stability in in vitro and in vivo biological systems; (3) low toxicity; (4) rapid clearance from the organism. The rich coordination chemistry of ruthenium allows for fine-tuning of all the necessary properties for an effective NO scavenger listed above through manipulation of the ligand framework. We have identified **AMD6245** and **AMD6221** as efficient NO scavengers in several disease models of varying pathophysiological complexity.[21–24] The PAC ligands bind to the ruthenium atom in a pentadentate fashion with the sixth coordination site being occupied by a water molecule or chloride ion.[12,25–27] In aqueous solution, a water molecule rapidly substitutes the chloride ion,[28,29] which in turn is a labile substituent that undergoes substitution with various ligands.[29–32] The Ru^{III}PAC complex reacts with NO to form a relatively inert Ru^{II}-$^{+}$NO species[12,33] making these compounds an attractive class of therapeutic agents. It is possible with the Ru^{III} complexes to control the compartmental localization of the NO scavenger by alteration of the multidentate ligand framework. Fine adjustment of lipophilicity, charge, and steric bulk offer potential avenues for enhancement of the pharmacological activity of these compounds. Indeed, while our two lead compounds **AMD6245** and **AMD6221** have shown significant activity, both exhibit drawbacks such as slow plasma clearance,[34] and nonselective reactivity (dimer formation,[35] and reactivity with thiols,[36–38] and N-heterocycles[29,39]) for the former, and fast plasma clearance[34] for the latter.



AMD6245



AMD6221

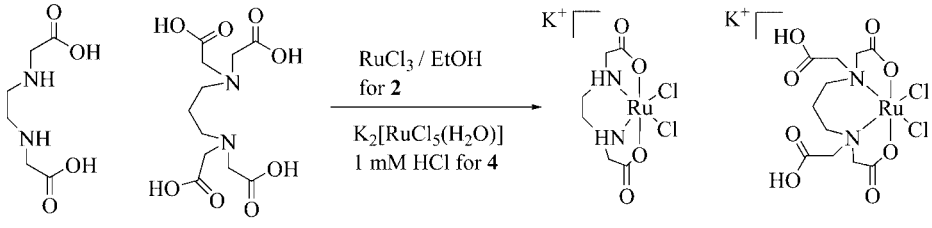
In an aerobic aqueous environment **AMD6245** is rapidly oxidized to form a μ-oxo Ru^{III}–Ru^{IV} dimer.[35] Dimer formation is particularly evident by a color change from yellow to green in solution, which occurs more rapidly under basic conditions. The mechanism is probably through an intermediate involving deprotonation of the coordinated H_2O molecule[35] (pK_a = 7.6). Although the in vitro NO scavenging ability does not appear to be affected by dimer formation, extra care is taken in formulation of **AMD6245** since the bioavailability of this dimer is not known. We therefore sought analogous ruthenium complexes that are less prone to oxidation/dimerization when in a formulated solution. This oxidation/dimerization does not appear to occur with **AMD6221** probably because the pK_a of the coordinated H_2O molecule (pK_a = 8.3)[40] is higher than that observed in **AMD6245**. Previously, we have shown that **AMD6245** has a significantly higher plasma C_{max} than **AMD6221** (74.5 μg/mL vs. 11.6 μg/mL) accompanied by a slower plasma clearance (1.13 mL/h vs. 19.9 mL/h) when administered as a single intravenous injection (20 mg/kg) in rats.[34] These studies suggest that the pharmacokinetic behaviour of Ru^{III} PAC complexes is influenced by the coordination environment of the Ru center as well as groups on the periphery (those not immediately bound to the metal center).

Herein, we report the synthesis and characterization of analogues of **AMD6245** and **AMD6221**. There were essentially two objectives to be achieved in the modification of the lead compounds **AMD6245** and **AMD6221**. First, modification of the ligand framework on **AMD6245** was undertaken to reduce dimer formation[35] and/or nonspecific reactivity.[29,36,37,39] It is this nonspecific reactivity with cellular components that is thought to reduce the NO scavenging ability of **AMD6245** in in vitro studies when compared to kinetic results and when compared to **AMD6221**. Second, modification of the **AMD6221** ligand framework was undertaken to increase lipophilicity, in an effort to prolong the activity of this complex in vivo. In both cases the NO scavenging ability of these compounds as well as the stability of the formulated solutions were evaluated using an in vitro RAW264 murine macrophage assay. Based on these results the most promising compounds will be further evaluated to determine the pharmacokinetic parameters.

Results and Discussion

Ligand Synthesis

The first approach at modification of the edta ligand framework to form symmetric analogs involved changing the number of carboxylate groups as in [{2-[(carboxymethyl)amino]ethyl}amino]acetic acid (**1**), or alternatively changing the ethylenediamine fragment to 1,3-propanediamine as in ({3-[bis(carboxymethyl)amino]propyl}-(carboxymethyl)amino)acetic acid (**3**).[41] (Scheme 1).

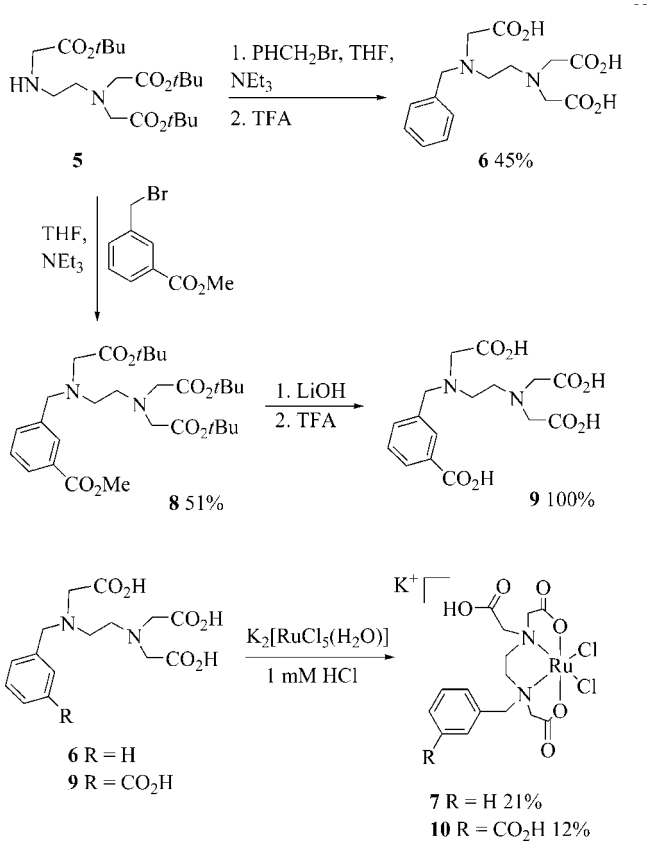


1 **3** **2** 22% **4** 24%

Scheme 1.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

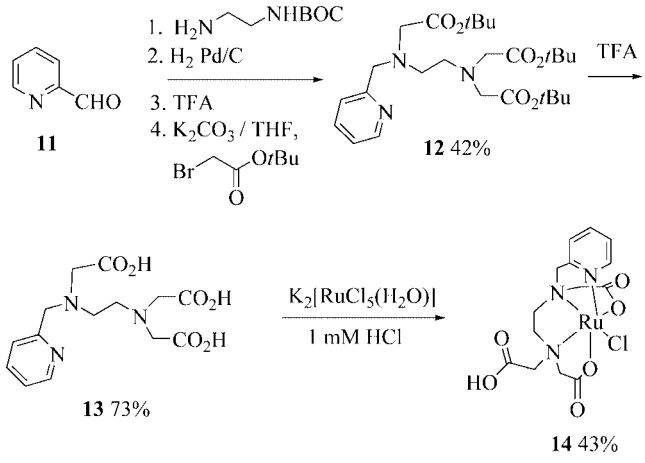
The synthesis of the first two nonsymmetrical edta analogs utilized compound **5**[42] as the starting point (Scheme 2). *N*-Alkylation of **5** with benzyl bromide under standard conditions and subsequent acid hydrolysis with trifluoroacetic acid afforded compound **6** in 45% overall yield. Similarly, *N*-alkylation with 3-bromomethylbenzoate afforded **8**, which was then deprotected over two steps to afford compound **9** in 50% overall yield.



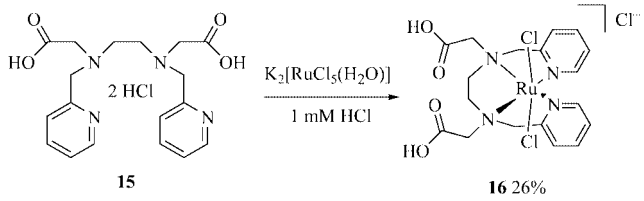
Scheme 2.

A second route, used to prepare the nonsymmetrical edta analog **13** (31% overall yield), which has a pendant pyridyl group, is a five-step procedure from pyridine-2-carbaldehyde (**11**) (Scheme 3). The main advantage of this method is that the starting materials are readily available (intermediate **5** is not required). Schiff-base formation between *N*-BOC ethylenediamine and pyridine-2-carbaldehyde followed sequentially by imine reduction and acid hydrolysis afforded a dark oil which was used without further purification. The three acid moieties were then added to this intermediate by *N*-alkylation with *tert*-butyl bromoacetate to afford compound **12**. Standard acid hydrolysis was then used to produce compound **13**. The symmetric ligand **15**, exhibiting two pendant pyridyl groups for metal binding, was synthesized by a literature method (Scheme 4).[43]

Edta ligand analogues, where one N atom of edta is replaced by a pyridyl N atom (**19, 23**), were prepared by multi-step synthetic routes as shown in Scheme 5. Reaction of methanesulfonyl chloride with methyl 6-(hydroxymethyl)pyridine-2-carboxylate[44] (**17**) afforded compound **18** in



Scheme 3.



Scheme 4.

near quantitative yield. Nucleophilic substitution of the mesylate group with iminodiacetic acid dimethyl ester followed by base (LiOH) hydrolysis of all three methyl esters to the corresponding carboxylic acid groups afforded the tricarboxylic acid ligand **19** in 39% overall yield**.** Ligand **23** was prepared in 4 steps in an overall yield of 38% from 6-(hydroxymethyl)pyridine-2-carbaldehyde[45] (**21**). Mesylation of the hydroxy group of **21** followed by *N*-alkylation with iminodiacetic acid di-*tert*-butyl ester[46] and subsequent reduction ($NaBH_4$) of the aldehyde group afforded compound **22**. Acid hydrolysis of the *tert*-butyl ester groups with trifluoroacetic acid (TFA) afforded compound **23** in 43% yield.

A significant amount of effort has been dedicated to developing structural analogs of dtpa due to the widespread use of this ligand in medical imaging.[47] Our intention in utilizing dtpa analogs in this study was to add lipophilicity in an effort to increase the plasma half-life and distribution of the Ru^{III} PAC compounds. Structural manipulations focused on removing charge, more specifically eliminating the acid functional group attached to the central N atom. Incorporation of a pyridyl moiety into the dtpa framework was realized with the synthesis of compound **26** (Scheme 6). Reaction of two equivalents of iminodiacetic acid dimethyl ester with 2,6-bis(bromomethyl)pyridine hydrogen bromide[48] **25** under basic conditions afforded the deprotected ligand **26** in one step in 71% yield. Due to the basic nature of the reaction mixture the compound was isolated as the tri-sodium salt. The 4-bromopyridyl-substituted derivative of this ligand has been reported,[46] which may provide a route to extensive structure-activity relationships (SAR) on complexes of this type.

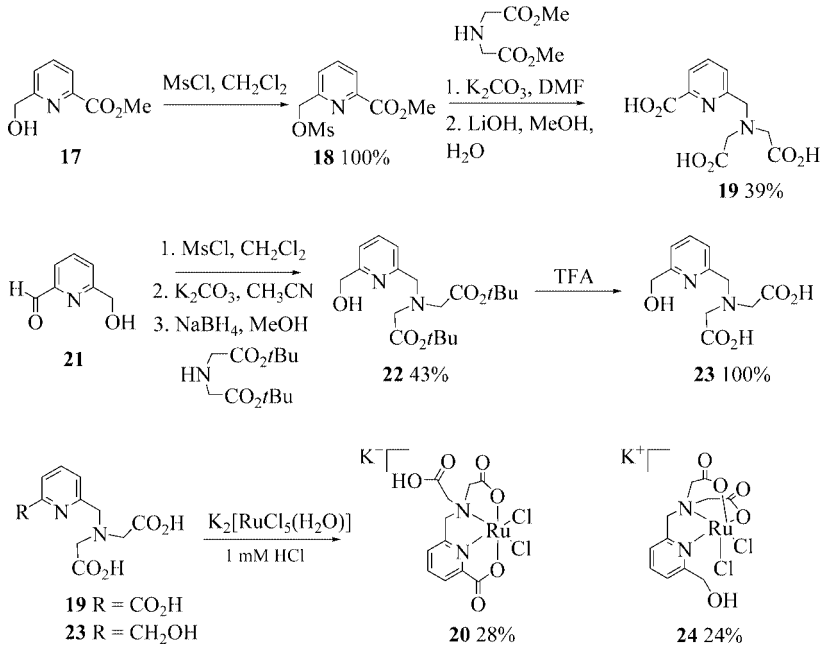
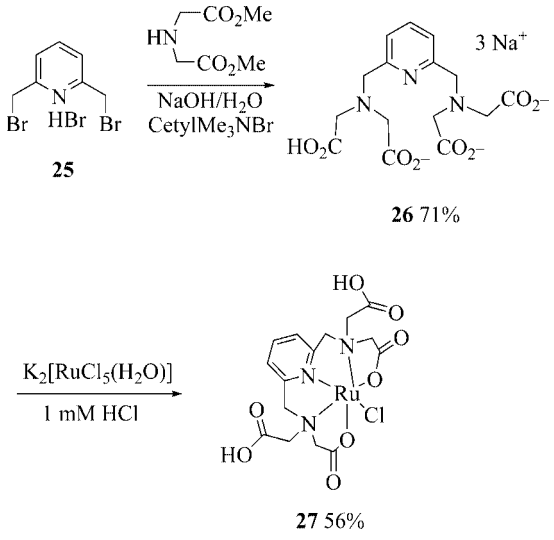
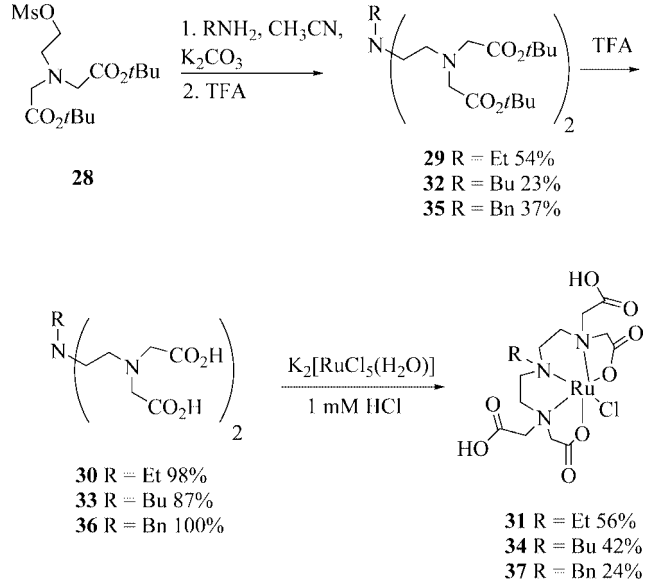


Scheme 5.



Scheme 6.

Dtpa analogs with various R groups attached to the central amine were also prepared as shown in Scheme 7. Using a similar synthetic strategy to that developed by Williams and Rapoport,[49] compounds **30** (R = ethyl), **33** (R = butyl), and **36** (R = benzyl) were prepared. The synthetic strategy is outlined using compound **30**. Two equivalents of compound **28** were reacted with ethylamine to afford the protected dtpa analog **29**. Standard TFA hydrolysis of the *tert*-butyl ester groups afforded compound **30** in 53% overall yield. The compounds described in this section were characterized by ^{1}H and ^{13}C NMR as well as mass spectrometry. Due to the extremely hygroscopic nature of the synthesized ligands, elemental analysis of the compounds was not carried out. Elemental analysis of the Ru complexes described in the next section was however used as a characterization tool.



Scheme 7.

Ru^{III} Complexes

The complexation of ruthenium to a PAC ligand was typically performed in 1 mM HCl heated to reflux using $K_2[RuCl_5(OH_2)]$[50] as the source of ruthenium. In only one circumstance (complex **2,** Scheme 1) was an alternate source of ruthenium ($RuCl_3$) used to prepare the complex. The complexes were often obtained by precipitation from the reaction mixture, however in a few instances chromatog-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

raphy was required for purification. The Ru^{III}PAC complexes were isolated as light yellow powders, and were found to be slightly soluble in water. The complexes were characterized by infrared spectroscopy (IR), mass spectroscopy (MS), elemental analysis, and in one case X-ray crystallography.

All edta-type complexes (except **14**) were characterized as the potassium salt with two chlorides bound to the metal center. The driving force for this type of structure is thought to be the mildly acidic (HCl) reaction conditions. The orientation of the two chloride ligands (*cis* or *trans*) is not known from the characterization data, however, the *cis* form is shown in the appropriate schemes. For compound **2**, stretching frequencies assigned to the coordinated carboxylates (CO_2^-; 1640 cm^{-1}), and the Ru–Cl[51] bonds (318 cm^{-1}) were visible. The absence of uncoordinated carboxylates (>1700 cm^{-1}) as well as the intact MS peak at *m/z* 346 $[M]^-$ lead to the structural formulation in Scheme 1. Mass spectroscopic data for all the Ru compounds are shown in Table 1. The calculated isotopic distribution pattern for each fragment matched the observed pattern. Compound **4** is also shown in Scheme 1, and was characterized in a similar fashion to **2** with the major difference being the presence of uncoordinated carboxylates (CO_2H, 1738 cm^{-1}) in the IR spectrum. The mass spectrum of compound **4** was informative; the fragmentation pattern showed the loss of a chloride ligand as well as two free acid moieties consistent with the proposed structure. Whether the two acid functions bound in compound **4** are from opposing N atoms to give a symmetric structure (as shown) or from a single N atom is unclear but exchange processes are most likely to occur in solution. The paramagnetic Ru^{III} center precluded NMR studies on any dynamic processes.

Complexes **7** and **10** are shown in Scheme 2. Strong absorptions in the IR spectrum (>1700 cm^{-1}) confirm the presence of uncoordinated carboxylate moieties in both complexes. For compound **7**, the presence of a $[M]^-$ peak (80% intensity) as well as an $[M - Cl - H]^-$ peak (100% intensity) in the ES-MS spectra confirms the structural interpretation and shows the facile loss of a chloride ion from the complex. This is to be expected as substitution for a chloride by water in aqueous solution would parallel the reactivity observed for **AMD6245**.[12] Only the $[M - Cl - H]^-$ peak (100% intensity) was present in the mass spectrum of compound **10**. The effect of adding another N atom, in the form of a pyridyl moiety, to form compound **14** was investigated as shown in Scheme 3. The structural formulation fits the general trend (vide supra) in that the Ru^{III} center exhibits a higher affinity for N donors over O-donors (acid groups) under the complexation conditions employed. This trend is further borne out with compound **16** (Scheme 4), synthesized from **15**,[43] which was concluded to have four N atoms bound based on the characterization data. The effect of substituting one edta N atom for a pyridyl moiety was also investigated as shown in Scheme 5. Compounds **20** and **24** were produced as their potassium salts. Elemental analysis and mass spectroscopic data are consistent with the proposed structures. An absorption due to an uncoordinated carboxylic acid was present in the IR of **20**, yet absent in **24**. The close proximity of the acid function attached to the pyridine in compound **20** most likely leads to the acid connectivity shown.

The four Ru^{III} dtpa analogs **27**, **31**, **34**, and **37** are shown in Scheme 6 and 7. All four compounds exhibit a Ru–Cl bond, two free acid functional groups, and three coordinated N atoms. The crystal structure of the product of the reaction of **27** with NO (Figure 1) further substantiates the structural interpretation. The mass spectroscopic data for the four Ru^{III} dtpa analogs (Table 1) showed similar molecular ions and fragmentation patterns to the parent complex **AMD6221**.[12] The presence of an $[M - Cl - 2H]^-$ peak with successive loss of carboxylate groups (44 mass units),

and in the case of **37** loss of a benzyl moiety (C_7H_7, 91 mass units), supports the proposed structures.

Reaction with NO

It is well documented that Ru^{III}PAC complexes react with small molecules such as NO.[33,52] As an example, compound **27** was treated with sodium nitrite in acid medium to form the Ru–NO complex **38**. Confirmation that compound **27** binds with NO in the proposed manner lies in the crystal structure of the nitrosyl complex (Figure 1). The structure consists of discrete mononuclear units, with the Ru site in a distorted octahedral environment defined by the amine donors N1 and N4 and the carboxylate oxygen donors O2 and O3 in the equatorial plane and the pyridine nitrogen N3 and the nitrosyl N1 occupying the axial positions. Consequently, one carboxylate group at each amine terminus adopts a pendant mode. Selected bond lengths and angles are given in Table 2. The structure clearly demonstrates a linear [∠Ru(1)–N(1)–O(1) = 175.8(4)°] {RuNO}[6] complex, where an electron is formally transferred from NO to Ru^{III}, so a Ru^{II}-$^{+}$NO assignment can be made. This complex coordinates in a similar fashion to the nitrosyl complex of **AMD6221** with the NpyN donor atoms coordinated in a meridonal geometric arrangement about the Ru center.[12] The difference is that the complex described here has one carboxylate from each N atom coordinated to the Ru, whereas with the nitrosyl complex of **AMD6221** one carboxylate from a terminal N atom and the carboxylate on the central N atom coordinate to the Ru center. This type of structure is not possible with **27** as the central carboxylate has been removed.

Table 2. Selected bond lengths [Å] and angles [°] for the nitrosyl complex **38**.

		O(1)–N(1)–Ru(1)	175.8(4)

The coordination sphere of Ru affects the rate of reaction with NO and the stability of the resultant nitrosyl complex. Stopped flow techniques similar to those for **AMD6245** and **AMD6221**[12,52] were used in order to investigate the reaction of select Ru^{III}PAC complexes with NO. A saturated nitric oxide aqueous solution was prepared by introducing a degassed buffer solution to a NO atmosphere (generated from sulfuric acid and sodium nitrite) and agitating to ensure saturation. Using this method NO solutions were obtained in a concentration range of 1.6–2.0 mM. UV/Vis spectral changes were monitored upon mixing solutions of candidate Ru compounds and NO. Second-order rate constants (k) and binding affinities (K_B) for complexes **14** and **27** are shown in Table 3 and compared with the parent compounds **AMD6245** and **AMD6221**, respectively. **AMD6245** is by the far the most efficient scavenger of NO in the absence of competing ligands. The extreme lability of this coordinated water molecule has been attributed to hydrogen bonding of the pendant carboxylate group to the water molecule thereby weakening the Ru–OH_2 bond and/or creating an open site for associative attack of the incoming ligand.[28] Alternatively, it has been proposed that the activation for associative attack of the incoming nucleophile is a result of the transient coordination of the pendant carboxylate group.[53,54] Modification of the coordination sphere can drastically change the rate of substitution. For instance, k is reduced at least one order of magnitude when a N_2O_4 coordination environment in **AMD6245** is changed to a N_2pyO_3 coordination environment as in **14**. The second-order rate constant for the reaction of **14** with NO was determined to be $2.38(\pm0.8)\times10^6$ M^{-1} s^{-1} at 20 °C (pH = 7.4; 50 mM phosphate buffer). A slight decrease in k = $2.30(\pm1.0)\times10^5$ M^{-1} s^{-1} at 20 °C (pH = 7.4; 50 mM phosphate buffer) is also observed when the N_3O_3 coordination environment of **AMD6221** is changed to a $NpyNO_3$ coordination sphere as in **27**. The binding constant of **14** (K_B = 5×10^6 M^{-1}) with NO was assessed by means of an UV/Vis titration (see supporting information; for supporting information see also the footnote on the first page of this article) and was found to be considerably lower than that of **AMD6245** and NO ($K_B > 10^8$ M^{-1}). The binding constant of **27** ($K_B = 2\times10^5$ M^{-1}) with NO was found to be identical to **AMD6221**. These results clearly demonstrate that manipulation of the ligand framework provides an opportunity to fine tune the chemical properties of the ruthenium complex to optimize the scavenging characteristics of the Ru^{III}PAC complexes. The stability and performance of the Ru complexes in an in vitro NO scavenging assay is however a much better indication of the potential utility of these compounds for their intended use as NO scavengers in vivo.

Table 3. Kinetic parameters for the reaction of selected Ru^{III}PAC complexes with NO.

Compound	Coordination sphere	k (M^{-1} s^{-1})	K_B (M^{-1})
AMD6245[a]	N_2O_4	$2.24\pm0.05\times10^7$ (7.3 °C)	$>10^8$
14	N_2pyO_3	$2.38\pm0.8\times10^6$ (20 °C)	$5\pm1.7\times10^6$
27	$NpyNO_3$	$2.30\pm1.0\times10^5$ (20 °C)	$2\pm0.75\times10^5$
AMD6221[a]	N_3O_3	3.0×10^5 (20 °C)	2×10^5

[a] Ref.[12]

NO Scavenging

The NO scavenging ability of the ruthenium complexes was evaluated using RAW264 murine macrophage cells. These cells are stimulated to produce NO by the addition of lipopolysaccharide (LPS) and interferon-γ (IFN-γ). In an aqueous biological environment NO reacts with O_2 to form nitrite and nitrate,[55] thus quantification of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

amount of nitrite produced in the cell media by the Griess assay[1] is an indirect but cost effective measurement of the amount of NO produced by the cells. The difference in the amount of nitrite in the cell media of cells in the presence or absence (control) of a ruthenium complex was used to evaluate the NO scavenging ability of the ruthenium complexes. To confirm the viability of the cells is not affected by the Ru compounds, a cytotoxicity assay was performed prior to the NO scavenging assay. The RAW264 murine macrophage cells (not stimulated to produce NO) were exposed to the Ru complex at concentrations of 12.5–100 μM under the same conditions that were used in the NO scavenging assay and the amount of cytotoxic effect measured by a 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) assay.[21] The Ru complexes were then evaluated for NO scavenging at the highest nontoxic concentration.

The results of the NO scavenging ability of the ruthenium complexes are presented in Table 4. Results for selected compounds are displayed in Figure 2. The change in the rate of NO substitution for selected analogs has been explored in kinetic studies discussed above. The NO scavenging assay using RAW264 murine macrophage cells addresses the activity of the compounds in relation to their NO scavenging ability in a biological milieu. Second, the ability of the formulated solutions to maintain NO scavenging activity upon storage can also be examined and this was addressed by monitoring the activity in the NO scavenging assay of a single stock solution over a two-week period. The observed in vitro NO scavenging ability of **AMD6245** (even at 2 weeks after the preparation of stock solutions) (Table 4) may be due to the presence of endogenous reductants capable of furnishing the monomer.

The results for the edta Ru^{III}PAC analogs clearly demonstrate the peripheral ligand effect on the NO scavenging ability of the metal complex. The limited activity of compound **2** may be due to a lack of a pendant carboxylic group to assist in the substitution reaction of the coordinated water molecule by NO.[31,56] It is not immediately obvious as to why compound **4** with pendant carboxy groups shows lower scavenging ability compared to **2**. Compound **7** was the only compound of the series to show toxicity and was thus tested for NO scavenging activity at a lower concentration. Even at a lower concentration (50 μM) compound **7** displayed suitable activity. Compound **10**, a close analog to **7**, was found to have minimal activity ($\Delta[NO_2^-] \approx 5$ μM). An interesting result is seen with the pyridyl edta analogues, **14, 16, 20,** and **24**. If the pyridine ring is incorporated into the structure such that it is part of the edta chelate where the N atom of the pyridine ring replaces one of the edta N atoms (**20, 24**), the NO scavenging ability is

similar to that of **AMD6245**. However, if the pyridine ring is a pendant coordinating group (**14, 16**) the NO scavenging ability appears to be almost twice that of **AMD6245** in this assay. Further investigation using the stability assay as described demonstrated that the activity of **14** and **16** is not maintained after dissolution for extended periods of time whereas complexes **20** and **24** show no change in their ability to scavenge NO when dissolved in solution over an extended period (see Figure 2).

Incorporation of the pyridine ring to form an analog of **AMD6221** is demonstrated with **27**. The N atom of the pyridyl ring in **27** replaces one of the N atoms of the dtpa ligand. In contrast to the situation with the edta analogues, this compound is less active than its parent and does not appear to maintain its activity when dissolved in solution over extended periods of time. The theory that the Ru complexes act as scavengers of nitric oxide is supported by the fact that compound **38**, the nitrosyl analog of **27**, does not lower the nitrite level from the control. This hypothesis has been demonstrated in detail for **AMD6221**.[20]

The best results were obtained when structural changes were made by replacement of the central carboxylic acid group of the dtpa ligand with alkyl or aromatic moieties as in **31, 34,** and **37**. The complexes were generally nontoxic and were quite effective in the NO scavenging assay ($\Delta[NO_2^-] > 20$ μM), with **31** being the most active ($\Delta[NO_2^-] > 38.5$ μM). This group of complexes also maintained their ability to scavenge NO when dissolved in solution over extended periods of time.

Conclusions

The ligand frameworks of **AMD6245** and **AMD6221** were modified in an effort to develop active alternatives exhibiting both NO scavenging ability and stability in formulated solution. Compounds with a pyridine ring as part of the *N*, *N* chelate of edta (**20**, **24**) are active alternatives to **AMD6245.** Changes to the **AMD6221** ligand framework afforded a group of compounds that have excellent NO scavenging ability and good stability when formulated as aqueous solutions. The compounds substituted with alkyl or aromatic groups at the central N atom (**31, 34, 37**) are good alternatives to **AMD6221** and further testing of these compounds is warranted.

Experimental Section

Materials and Equipment: Chemical reagents were purchased from Aldrich and used without further purification except $RuCl_3 \cdot H_2O$ which was purchased from Johnson Matthey. All solvents (anhydrous grade) were obtained from Aldrich and used as supplied. $K_2[RuCl_5(OH_2)]$,[50] ({3-[bis(carboxymethyl)amino]propyl}(carboxymethyl)amino)acetic acid (**3**),[41] *N*,*N*′-bis(2-pyridylmethyl)-ethylenediamine-*N*,*N*′-diacetic acid (**15**),[43] methyl 6-(hydroxymethyl)pyridine-2-carboxylate (**17**),[44] 6-(hydroxymethyl)pyridine-2-carbaldehyde (**21**),[45] iminodiacetic acid di-*tert*-butyl ester,[46] 2,6-bis(bromomethyl)pyridine hydrogen bromide (**25**),[48] and *N*-(hydroxyethyl)iminodiacetic acid di-*tert*-butyl ester[49] were prepared according to literature procedures. ^1H NMR and ^{13}C NMR spectra were recorded with a Bruker Avance 300 with chemical shifts referenced to $SiMe_4$. IR spectra (as CsI pellets) were recorded with a Mattson Galaxy Series 5000 FTIR spectrophotometer (only the relative intense bands are reported). Electrospray mass spectra (ES-MS) were recorded with a Bruker-HP Esquire-LC Ion Trap mass spectrometer and injected as aqueous solutions. Elemental analyses were performed by Atlantic Microlab, Inc. (Norcross, GA). Rate constants were determined using an Applied Photophysics DX17 stopped-flow spectrometer with a measured deadtime of 1 ms.

X-ray Diffraction Data Collection and Solution and Refinement of 38: Purple crystals of **38** were obtained from slow evaporation of an aqueous solution. The selected crystal of the complex **38** was studied with a Bruker diffractometer equipped with the SMART CCD system,[57] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The data collection was carried out at 90(5) K. The data were corrected for Lorentz polarization effects and absorption corrections were made using SADABS.[58] All calculations were performed using SHELXTL.[59] The structures were solved by direct methods and all of the non-hydrogen atoms were located from the initial solution. After locating all the non-hydrogen atoms in the structure, the model was refined against F^2, initially using isotropic and later anisotropic thermal displacement parameters until the final value of Δ/σ_{max} was less than 0.001. At this point the hydrogen atoms were located from the electron density difference map and a final cycle of refinements was performed, until the final value of Δ/σ_{max} was again less than 0.001. No anomalies were encountered in the refinement of the structure. The relevant parameters for crystal data, data collection, structure solution and refinement are summarized in Table 5, and important bond lengths and bond angles are presented in Table 2.

Table 5. Crystal data and structure refinement for nitrosyl complex **38**.

Chemical formula	$C_{15}H_{15}N_4O_{11}Ru$	Formula mass	528.38

[a] $R_1 = \Sigma(F_o - F_c)/F_o$. [b] $wR_2 = [\Sigma(F_o^2 - F_c^2)^2/\Sigma wF_o^2]^{1/2}$.

CCDC-251648 (for **38**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis of Complex 2 {[KRu(1-H$_2$)Cl$_2$]·2H$_2$O}: *N*-{2-[(Carboxymethyl)amino]ethyl}aminoacetic acid (**1**) (0.130 g, 0.74 mmol) was dissolved in EtOH (20 mL) and $RuCl_3 \cdot H_2O$ (0.155 g, 0.74 mmol) added. The mixture was heated to 60 °C during which time a precipitate formed. The solid was collected by filtration and washed with Et_2O to afford the desired product **2** (0.062 g, 22%) as a brown solid. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1640 (CO_2^-), 318 (Ru–Cl). ES-MS: *m*/*z* = 346 (100) [M]$^-$. $C_6H_{10}Cl_2KN_2O_4Ru \cdot 2H_2O$ (420.9): calcd. C 17.11, H 3.35, N 6.65, Cl 16.83; found C 17.40, H 3.76, N 6.80, Cl 17.20.

Synthesis of Complex 4 [KRu(3-H$_2$)Cl$_2$]: To a stirred solution of *N*-[{3-[bis(carboxymethyl)amino]propyl}-*N*-(carboxymethyl)aminoacetic acid[41] (**3**) (0.291 g, 0.54 mmol) dissolved in HCl (5 mL,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1 mM) was added $K_2[RuCl_5(H_2O)]$ (0.203 g, 0.54 mmol) and the reaction mixture was heated to 100 °C for 1.5 h. The solution was then cooled and a yellow powder was collected by filtration. The precipitate was washed with the mother liquor, ice-cold H_2O (2×10 mL), EtOH (3×5 mL), and Et_2O (3×5 mL) and dried in vacuo to afford the product complex **4** (0.075 g, 24%) as a yellow solid. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1738 (CO_2H), 1642 (CO_2^-), 316 (Ru–Cl). ES-MS: *m*/*z* = 440 $[M - Cl - H]^-$ (25), 404 $[M - 2Cl - 2H]^-$ (100), 360 (30) $[M - 2Cl - CO_2H]^-$, 316 (25) $[M - 2Cl - 2(CO_2H)]^-$. $C_{11}H_{16}Cl_2KN_2O_8Ru{\cdot}3H_2O$ (568.9): calcd. C 23.20, H 3.89, N 4.92, Cl 12.45; found C 22.97, H 3.67, N 4.80, Cl 12.15.

Synthesis of Complex 7 [KRu(6-H_2)Cl_2] via 5 and 6

***tert*-Butyl {[Bis(*tert*-butoxycarbonylmethyl)aminoethyl]amino}-acetate (5):** Compound **5** was prepared by an alternative method to that reported in the literature.[42] To a stirred solution of ethylenediamine (0.50 g, 8.30 mmol) in THF (70 mL) and triethylamine (3.34 g, 33.00 mmol) was added *tert*-butyl bromoacetate (4.90 g, 25.00 mmol) and the reaction mixture was stirred for 16 h at room temperature. The solvent was removed in vacuo and the residue was partitioned between CH_2Cl_2 (80 mL) and H_2O (50 mL). The separated aqueous phase was extracted with CH_2Cl_2 (2×80 mL) and the combined organic extracts were dried ($MgSO_4$) and the solvents evaporated in vacuo. The crude material was purified by column chromatography on silica gel (CH_2Cl_2/MeOH, 19:1) to afford the product **5** (0.887 g, 27%) as an oil. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.43 (s, 27 H), 2.63 (t, *J* = 6.0 Hz, 2 H), 2.84 (t, *J* = 6.0 Hz, 2 H), 3.28 (s, 2 H), 3.42 (s, 4 H) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 28.46, 28.51, 47.42, 51.84, 54.15, 56.41, 81.31, 81.36, 171.22, 171.68 ppm.

[{2-[Benzyl(carboxymethyl)amino]ethyl}carboxymethylamino]acetic Acid (6): To a stirred solution of compound **5** (0.734 g, 1.80 mmol) and triethylamine (0.382 g, 3.60 mmol) in THF (10 mL) was added benzyl bromide (0.316 g, 1.8 mmol) and the reaction was stirred at 35 °C for 22 h. The solvent was removed in vacuo and the residue was partitioned between CH_2Cl_2 (10 mL) and saturated aqueous $NaHCO_3$ (10 mL). The separated aqueous phase was extracted with CH_2Cl_2 (2×10 mL), and the combined organic extracts were dried ($MgSO_4$) and the solvents evaporated in vacuo. The crude material was purified by column chromatography on silica gel (hexanes/EtOAc, 7:1), to afford the ester-protected precursor (0.496 g, 55%) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.40 (s, 18 H), 1.42 (s, 9 H), 2.80–2.88 (m, 4 H), 3.24 (s, 2 H), 3.44, (s, 4 H), 3.80 (s, 2 H), 7.21–7.34 (m, 5 H) ppm. The ester-protected precursor (0.496 g, 1.00 mmol) was dissolved in TFA (12.6 g, 100 mmol) and the solution was stirred at room temperature for 16 h. The solvent was removed in vacuo and the residue was lyophilized from an aqueous solution to afford the product **6** (0.454 g, 82%) as a white solid. ^{1}H NMR (300 MHz, CD_3OD, 25 °C): δ = 3.10 (t, *J* = 6.0 Hz, 2 H), 3.39–3.45 (br. s, 6 H), 4.09 (s, 2 H), 4.59 (s, 2 H), 7.47–7.50 (m, 3 H), 7.57–7.60 (m, 2 H) ppm. ^{13}C NMR (300 MHz, CD_3OD, 25 °C): δ = 50.59, 53.04, 56.26, 60.90, 130.66, 131.42, 132.01, 132.78, 169.39, 175.74 ppm.

Preparation of 7: The title compound **7** (0.046 g, 21%) was prepared as a yellow solid from **6** (0.210 g, 0.38 mmol) and $K_2[RuCl_5(H_2O)]$ (0.142 g, 0.38 mmol) by a procedure analogous to that described for **4**. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1726 (CO_2H), 1641 (CO_2^-), 391 (Ru–Cl). ES-MS: *m*/*z* = 494 (80) $[M]^-$, 458 (100) $[M - Cl - H]^-$. $C_{15}H_{18}Cl_2KN_2O_6Ru{\cdot}2H_2O$ (568.9): calcd. C 31.64, H 3.89, N 4.92, Cl 12.45; found C 31.63, H 3.96, N 4.77, Cl 13.03.

Synthesis of Complex 10 [KRu(9-H_2)Cl_2] via 8 and 9

Methyl 3-{[{2-[Bis(*tert*-butoxycarbonylmethyl)amino]ethyl}(*tert*-butoxycarbonylmethyl)amino]methyl}benzoate (8): The title compound **8** (0.115 g, 51%) was prepared as a colorless oil from compound **5** (0.165 g, 0.41 mmol) and 3-bromomethylbenzoate (0.094 g, 0.41 mmol) by a procedure analogous to that described for the first step of compound **6**. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.40 (s, 18 H), 1.43 (s, 9 H), 2.79–2.86 (m, 4 H), 3.25 (s, 2 H), 3.40 (s, 4 H), 3.83 (s, 2 H), 3.87 (s, 3 H), 7.35 (dd, *J* = 6.0, 9.0 Hz, 1 H), 7.55 (d, *J* = 9.0 Hz, 1 H), 7.89 (d, *J* = 6.0 Hz, 1 H), 7.95 (s, 1 H) ppm.

3-{[{2-[Bis(carboxymethyl)amino]ethyl}(carboxymethyl)amino]-methyl}benzoic Acid (9): To a stirred solution of **8** (0.771 g, 1.40 mmol) in MeOH (19 mL) and H_2O (6 mL) was added lithium hydroxide (0.236 g, 5.60 mmol) and the reaction was stirred at room temperature for 16 h (in the absence of light) and then the solvent was evaporated in vacuo. This intermediate was used directly in the next step without further purification. The residue was dissolved in TFA (8.30 g, 73.00 mmol) and stirred for 16 h then evaporated in vacuo. Ethanol was added to the residue, the resulting suspension was filtered, and the product lyophilized to afford white solid compound **9** (1.04 g, 100%). ^{1}H NMR (300 MHz, CD_3OD, 25 °C): δ = 3.15 (t, *J* = 6 Hz, 2 H), 3.43–3.48 (br. s, 6 H), 4.09 (s, 2 H), 4.64 (s, 2 H), 7.59 (dd, *J* = 6.0, 9.0 Hz, 1 H), 7.85 (d, *J* = 6.0 Hz, 1 H), 8.12 (d, *J* = 9.0 Hz, 1 H), 8.26 (s, 1 H) ppm. ^{13}C NMR (300 MHz, CD_3OD, 25 °C): δ = 50.47, 53.65, 54.16, 60.01, 65.74, 130.65, 132.05, 132.30, 133.13, 133.48, 136.67, 168.93, 169.07, 175.12 ppm. ES-MS: *m*/*z* = 369 $[M + H]^+$.

Preparation of 10: Compound **10** (0.051 g, 12%) was prepared as a yellow solid from **9** (0.377 g, 0.60 mmol) and $K_2[RuCl_5(H_2O)]$ (0.236 g, 0.60 mmol) by a procedure analogous to that described for compound **4**. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1709 (CO_2H), 1639 (CO_2^-), 389 (Ru–Cl). ES-MS: *m*/*z* = 502 (100) $[M - Cl - H]^-$. $C_{16}H_{18}Cl_2KN_2O_8Ru{\cdot}5H_2O$ (667.0): calcd. C 28.79, H 4.23, N 4.20, Cl 10.62; found C 28.63, H 3.69, N 4.29, Cl 11.08.

Synthesis of Complex 14 {[Ru(13-H_2)Cl]} via 11 and 12

***tert*-Butyl *N*-(*tert*-Butoxycarbonylmethyl)-*N*-{2-[(*tert*-butoxycarbonylmethyl)(pyridin-2-ylmethyl)amino]ethyl}aminoacetate (12):** To a solution of pyridine-2-carbaldehyde (**11**) (3.20 g, 30.0 mmol) in benzene (50 mL) was added *N*-BOC-ethylenediamine (5.26 g, 33 mmol) and the mixture was heated to reflux with stirring in a Dean–Stark apparatus for 1.5 h. The reaction mixture was evaporated to dryness, dissolved in MeOH (50 mL) and 5% Pd/C was added (0.5 g). The mixture was hydrogenated at 50 psi with a Parr apparatus overnight. The mixture was filtered through celite, and the filtrate was evaporated to give the pyridine intermediate (≈ quantitative). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.40 (s, 9 H), 2.75–2.85 (m, 2 H), 3.20–3.35 (m, 2 H), 3.90 (s, 2 H), 5.30 (br. s, 1 H), 7.10–7.20 (m, 1 H), 7.30–7.36 (m, 1 H), 7.60–7.70 (m, 1 H), 8.50–8.60 (m, 1 H) ppm. The pyridine intermediate (5.08 g) was dissolved in CH_2Cl_2 (30 mL) and TFA (30 mL) was added. The mixture was allowed to continue stirring overnight at room temperature and then evaporated to give a dark oil. ^{1}H NMR [300 MHz, $(CD_3)_2SO/D_2O$, 25 °C]: δ = 3.10–3.20 (m, 2 H), 3.20–3.30 (m, 2 H), 4.48 (s, 2 H), 7.40–7.45 (m, 2 H), 7.80–7.90 (m, 1 H), 8.60 (m, 1 H) ppm. This intermediate was used without further purification in the next step. To a solution of the oil from above in DMF (80 mL) was added K_2CO_3 (27.9 g, 10.0 equiv.) followed by *tert*-butyl bromoacetate (8.95 mL, 3.0 equiv.) and the mixture was stirred at room temperature for 48 h. The reaction mixture was filtered through celite and the filtrate was evaporated to give a dark oil. Purification by column chromatography on silica gel (CH_2Cl_2/MeOH, 19:1) gave the tri-*tert*-butyl ester (4.14 g, 42% for two steps) **12** as a light yellow oil. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.35–1.50 (m, 27 H), 2.83–2.86 (m, 4 H), 3.37 (s, 2 H), 3.43 (s,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

4 H), 3.95 (s, 2 H), 7.10–7.20 (m, 1 H), 7.52 (d, J = 7.5 Hz, 1 H), 7.64 (dt, J = 7.5, 1.7 Hz, 1 H), 8.51 (d, J = 4.7 Hz, 1 H) ppm.

***N*-Carboxymethyl-*N*-{2-[(carboxymethyl)(pyridin-2-ylmethyl)-amino]ethyl}aminoacetic Acid (13):** The title compound **13** (3.24 g, 73%) was prepared as a yellow solid from **12** (4.14 g, 8.35 mmol) and TFA (30 mL) by a procedure analogous to the hydrolysis step for compound **6**. ^{1}H NMR (300 MHz, D_2O, 25 °C): δ = 3.00–3.15 (m, 2 H), 3.20–3.30 (m, 2 H), 3.59 (s, 4 H), 4.04 (s, 2 H), 4.51 (s, 2 H), 7.50 (m, 1 H), 7.61 (d, J = 7.7 Hz, 1 H), 7.98 (dt, J = 7.7, 1.6 Hz, 1 H) 8.63 (d, J = 5.0 Hz, 1 H). $C_{14}H_{19}N_3O_6$·1.8TFA: calcd. C 39.83, H 3.95, N 7.92; found C 38.85, H 4.19, N 8.06.

Preparation of 14: Complex **14** (0.26 g, 43%) was prepared as a yellow/orange solid from **13** (0.75 g, 1.30 mmol) and $K_2[RuCl_5(OH_2)]$ (0.5 g, 1.3 mmol) by an analogous procedure to that described for compound **4**. IR (CsI) $\tilde{\nu}$ (cm^{-1}): 1730 (CO_2H), 1688, 1618 (CO_2^-), 320 (Ru–Cl). ES-MS: m/z = $C_{14}H_{17}ClN_3O_6Ru$·0.5H_2O (469.0): calcd. C 35.87, H 3.87, N 8.96, Cl 7.56; found C 35.86, H 3.79, N 8.98, Cl 7.58.

Synthesis of Complex 16 {[Ru(15-H_2)Cl_2]Cl}: To a solution of compound **15** (H_2bped·2HCl)[43] (1.0 g, 2.50 mmol) in water (10 mL, pH = 4) was added a solution of $K_2[RuCl_5(OH_2)]$ (0.838 g, 2.50 mmol) in HCl (minimum volume, 1 mM). The reaction mixture was heated to reflux temperature for 1.5 h. The dark green solution was reduced to approximately one half the original volume and on slow evaporation a yellow-orange solid precipitated from the reaction mixture. This was collected by filtration and re-crystallised from H_2O/EtOH to yield orange microcrystalline solid **16** (0.37 g, 26%). IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1726 (CO_2H). ES-MS: m/z = 458 (100) [M – 2Cl – 2H]$^+$, 414 (50) [M – 2Cl – H – CO_2H]$^+$, 370 (75) [M – 2Cl – 2(CO_2H)]$^+$. $C_{18}H_{22}Cl_3N_4O_4Ru$ (565.0): C 38.21, H 3.92, N 9.90, Cl 18.80; found C 38.21, H 3.96, N 9.90, Cl 18.79.

Synthesis of Complex 20 {[KRu(19-H_2)Cl_2]} via 18 and 19

Methyl 6-(Methylsulfonyloxymethyl)pyridine-2-carboxylate (18): To a stirred solution of compound **17**[44] (0.220 g, 1.30 mmol) and triethylamine (0.400 g, 4.00 mmol) in CH_2Cl_2 (13 mL) cooled in an ice bath was added dropwise methanesulfonyl chloride (0.180 g, 1.60 mmol). After 30 min the reaction was quenched with saturated aqueous $NaHCO_3$ (15 mL) and the aqueous phase was separated and extracted with CH_2Cl_2 (3×15 mL). The combined organic extracts were dried ($MgSO_4$) and the solvent was evaporated in vacuo to afford product **18** (0.347 g, 100%) as a yellow-orange oil. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.15 (s, 3 H), 4.01 (s, 3 H), 5.44 (s, 2 H), 7.70 (d, J = 6.0 Hz, 1 H), 7.92 (dd, J = 6.0, 9.0 Hz, 1 H), 8.12 (d, J = 9.0 Hz, 1 H) ppm.

6-{[Bis(carboxymethyl)amino]methyl}pyridine-2-carboxylic Acid (19): To a stirred solution of compound **18** (0.323 g, 1.3 mmol) and iminodiacetic acid dimethyl ester (0.191 g, 1.2 mmol) in DMF was added K_2CO_3 (0.359 g, 2.6 mmol) and the reaction mixture was stirred at 35 °C for 16 h. The solvent was removed in vacuo and partitioned between H_2O (10 mL) and CH_2Cl_2 (15 mL). The aqueous portion was extracted with CH_2Cl_2 (3×15 mL), and the combined organic extracts were dried ($MgSO_4$) and the solvents evaporated in vacuo. The crude material was purified by column chromatography (CH_2Cl_2/MeOH, 19:1) on silica gel to afford the ester-protected precursor (0.200 g, 49%) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.70 (s, 6 H), 3.97 (s, 3 H), 4.16 (s, 4 H), 5.36 (s, 2 H), 7.51 (d, J = 9.0, 1 H), 7.84 (dd, J = 6.0, 9.0, 1 H), 8.02 (d, J = 6.0 Hz, 1 H) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 49.48, 52.63, 53.32, 68.46, 124.46, 124.79, 138.25, 155.93, 157.31, 165.88, 170.09 ppm. To a 0 °C solution of the ester-protected precursor (0.200 g, 0.65 mmol) in MeOH (19 mL) and H_2O (6 mL) was added LiOH·H_2O (0.270 g, 6.4 mmol). The mixture was stirred at room temperature for 17 h in the absence of light. The solution was acidified with 2 N HCl and the solvent was removed in vacuo. The crude material was purified on Dowex cation exchange resin (H^+ form, 50W-200 mesh) to afford product **19** (0.172 g, 78%). ^{1}H NMR (300 MHz, D_2O, 25 °C): δ = 4.02 (s, 2 H), 4.15 (s, 2 H), 5.39 (s, 2 H), 7.95 (d, J = 7.5 Hz, 1 H), 8.25 (d, J = 7.2 Hz, 1 H), 8.46 (dd, J = 7.2, 7.5 Hz, 1 H) ppm. ^{13}C NMR (300 MHz, D_2O, 25 °C): δ = 50.27, 50.56, 127.02, 128.74, 147.29, 152.83, 156.73, 173.22, 173.46 ppm. ES-MS: m/z = 313 [M + H]$^+$.

Preparation of 20: Compound **20** (0.064 g, 28%) was prepared as a yellow solid from **19** (0.157 g, 0.48 mmol) and $K_2[RuCl_5(H_2O)]$ (0.172 g, 0.46 mmol) by a procedure analogous to that described for compound **4**. IR (CsI): $\tilde{\nu}$ (cm^{-1}) = 1709 (CO_2H), 1632, 1607 (CO_2^-), 341 (Ru–Cl). ES-MS: m/z = 402 (100) [M – Cl – H]$^-$. $C_{11}H_{10}Cl_2KN_2O_6Ru$·2$H_2O$ (512.9): calcd. C 25.74, H 2.75, N 5.46, Cl 13.81; found C 25.56, H 2.64, N 5.06, Cl 12.97.

Synthesis of Complex 24 [KRu(19-H_2)Cl_2] via 22 and 23

***tert*-Butyl *N*-(*tert*-Butoxycarbonylmethyl)-*N*-{[6-(hydroxymethyl)pyridin-2-yl]methyl}aminoacetate (22):** The mesylate intermediate (3.61 g, 100%) was prepared as a brown oil from 6-(hydroxymethyl)pyridine-2-carbaldehyde (**21**)[45] (2.30 g, 1.7 mmol), methanesulfonyl chloride (2.12 g, 1.8 mmol), and triethylamine (5.08 g, 50 mmol) by an analogous procedure to that described for compound **18**. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 3.15 (s, 3 H), 5.43 (s, 2 H), 7.70 (m, 1 H), 7.97 (m, 2 H), 10.05 (s, 1 H) ppm. Reaction of the mesylate (3.61 g, 1.7 mmol) with di-*tert*-butyl iminodiacetate[46] (3.706 g, 1.5 mmol) following conditions similar to the first step in the synthesis of compound **19** afforded, after column chromatography on silica gel (hexanes/EtOAc, 4:1), the aldehyde as a colorless oil (2.25 g, 45%). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.46 (s, 18 H), 3.50 (s, 4 H), 4.14 (s, 2 H), 7.85 (m, 1 H), 7.94 (m, 1 H), 10.05 (s, 1 H) ppm. The aldehyde (2.25 g, 6.2 mmol) was reduced in MeOH (60 mL) under nitrogen with sodium borohydride (0.235 g, 6.2 mmol). The reaction was heated to 60 °C with stirring, and after 1 h the solvent was removed in vacuo and the residue was partitioned between H_2O (30 mL) and CH_2Cl_2 (30 mL). The aqueous phase was separated and extracted with CH_2Cl_2 (3×40 mL) and the combined organic extracts were dried ($MgSO_4$) and the solvents evaporated in vacuo to afford the product **22** (2.16 g, 38% for 3 steps) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.46 (s, 18 H), 3.48 (s, 4 H), 3.98 (t, J = 4.5 Hz, 1 H), 4.05 (s, 2 H), 4.72 (d, J = 4.5 Hz, 2 H), 7.08 (d, J = 6.0 Hz, 1 H), 7.53 (d, J = 9.0 Hz, 1 H), 7.66 (dd, J = 6.0, 9.0 Hz, 1 H) ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 28.57, 56.22, 59.88, 64.13, 81.47, 119.04, 122.02, 137.64, 158.25, 158.65, 170.90 ppm. ES-MS: m/z = 367 [M + H]$^+$.

***N*-Carboxymethyl-*N*-{[6-(hydroxymethyl)pyridin-2-yl]methyl}aminoacetic Acid (23):** Compound **23** (0.492 g, 100%) was prepared as a white solid from **22** (2.10 g, 5.7 mmol) and TFA (10 mL) by a procedure analogous to the hydrolysis step for compound **6**. ^{1}H NMR (300 MHz, D_2O, 25 °C): δ = 3.64 (s, 4 H), 4.28 (s, 2 H), 4.85 (s, 2 H), 7.69 (br. s, 2 H), 8.27 (t, J = 8.0 Hz, 1 H) ppm. ^{13}C NMR (300 MHz, D_2O, 25 °C): δ = 55.98, 60.07, 123.75, 125.19, 147.02, 152.72, 155.65, 174.85 ppm. ES-MS: m/z 255 [M + H]$^+$.

Preparation of 24: The title compound **24** (0.035 g, 24%) was prepared as a yellow solid from **23** (0.152 g, 0.32 mmol) and $K_2[RuCl_5(H_2O)]$ (0.118 g, 0.32 mmol) by a procedure analogous to compound **4**. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1657, 1630 (CO_2^-), 316 (Ru–Cl). ES-MS: m/z = 446 (100) [M – H + Na]$^-$. $C_{11}H_{12}Cl_2KN_2O_5Ru$·

$2H_2O$ (498.9): calcd. C 28.64, H 3.71, N 6.07, Cl 15.37; found C 28.44, H 3.67, N 6.02, Cl 15.36.

Synthesis of Complex 27 [Ru(26-H_2)Cl] via 26: Trisodium ({6-[bis-(carboxymethyl)amino]methyl}pyridin-2-ylmethyl}carboxymethyl-amino)acetate (**26**). An aqueous solution of sodium hydroxide (30 mL, 10 mM), 2,6-bis(bromomethyl)pyridine hydrogen bromide (**25**)[48] (1.0 g, 2.9 mmol), iminodiacetic acid dimethyl ester (0.934 g, 5.8 mmol), and cetyltrimethylammonium bromide (0.21 g, 0.58 mmol) was stirred at room temperature for 3 days. A white precipitate formed which was removed by filtration and the filtrate was evaporated to give a white solid. This solid was purified by recrystallisation from water and ethanol to give the desired compound **26** as the sodium salt (0.9 g, 71%). ^{1}H NMR (300 MHz, D_2O, 25 °C): δ = 3.27 (s, 8 H), 3.93 (s, 4 H), 7.30 (d, J = 7.5 Hz, 2 H), 7.80 (t, J = 7.8 Hz, 1 H) ppm.

Preparation of 27: The title compound **27** (0.550 g, 56%) was prepared as a yellow solid from **26** (0.781 g, 1.8 mmol) and $K_2[RuCl_5(OH_2)]$ (0.670 g, 1.8 mmol) by a procedure analogous to compound **4**. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1734 (CO_2H), 1649 (CO_2^-), 350 (Ru–Cl). ES-MS: m/z = 466 (40) [M – Cl – 2H]$^-$, 423 (65) [M – Cl – H – CO_2H]$^-$, 379 (45) [M – Cl – 2(CO_2H)]$^-$, 334 (100) [M – Cl – 3(CO_2H)]$^-$. $C_{15}H_{17}ClN_3O_8Ru{\cdot}2.5\,H_2O$ (549.0): calcd. terial that had not dissolved was removed by filtration, and the solvent was removed in vacuo from the filtrate. The residue was dissolved in a minimal amount of water and upon slow evaporation at room temperature a solid was formed. The solid was collected by filtration, washed with MeOH and dried in air to afford complex **38** (0.074 g, 82%). Suitable crystals for X-ray diffraction were obtained by slow evaporation of an aqueous solution. IR (CsI) $\tilde{\nu}$ (cm^{-1}) = 1898 (NO), 1736 (CO_2H), 1616 (CO_2^-). ^1H NMR (300 MHz, D_2O/K_2CO_3, 25 °C): δ = 4.23–4.56 (m, 8 H), 5.21 (ABq, 4 H), 7.96 (d, 2 H), 8.41 (t, 1 H) ppm. ES-MS: *m/z* = 498 $[M]^-$. $C_{15}H_{16}N_4O_9Ru\cdot 3.5\,H_2O$ (561.0): calcd. C 32.15, H 4.14, N 10.00; found C 32.15, H 3.97, N 9.91.

Kinetic Studies

Determination of Binding Constants: On addition of an aqueous NO solution to a solution of a complex an absorbance change is observed in the near-UV region of the spectrum which is utilized to determine the binding stoichiometry of NO to Ru^{III} and to obtain an estimate of the binding affinity. The binding constants were determined from plots of the fractional saturation, *Y*, against the total concentration of NO added. *Y* is defined as $Y = (A - A_0)/(A_\infty - A_0)$, where A_0 and A_∞ are absorbances at a selected wavelength (λ) in the absence and presence of saturating NO and A is the absorbance (at λ) after the addition of a sub-saturating concentration of NO. The monitoring wavelength was selected for each complex to ensure the largest change in ΔA on NO binding, this was between 280 and 350 nm depending on the complex under study. All spectra were recorded using a Hewlett–Packard 8451 diode array spectrophotometer (Agilent UK).

Determination of Rate Constants: The kinetics of NO binding to Ru complexes were determined using an Applied Photophysics DX17 stopped-flow spectrometer with a measured dead time of 1 ms. In the stopped flow experiment the temperature was maintained within ±0.1 °C. One syringe was charged with a solution of NO (100 μM)[12] and one with the ruthenium complex (100 μM) so that the final concentration of complex was 50 μM after mixing. Both the NO and complex solutions were prepared in potassium phosphate buffer (100 mM) at pH = 7.4. The calculated rate constants are determined from an average of at least 6 experiments (see supporting information for the spectrophotometric curves, for supporting information see also the footnote on the first page of this article).

RAW 264 Murine Macrophage Assay for NO Scavenging by Ruthenium Complexes: RAW264 cells were cultured on 24 well plates (2×10^6 cells/well) in 2 mL Eagle's minimal essential medium. The cells were activated by the addition of 10 μg/mL *E.coli* 0111:B4 lipopolysaccharide (Sigma L2630) and 100 IU/mL mouse recombinant IFN-γ. The production of nitric oxide was estimated from the amount of nitrite in the medium after 18 h using the Greiss assay as described previously.[21] To estimate the NO scavenging ability of the ruthenium complexes, the nitrite accumulation was measured under the following conditions: 1) Nonactivated cells, 2) LPS/IFN-γ activated cells and 3) LPS/IFN-γ activated cells treated with appropriate amount of Ru complex. The cells were activated to produce NO in the presence of the appropriate ruthenium complex (100 μM or nontoxic concentration) and the results are reported as the change in the amount of nitrite produced between treated cells (condition 3) and nontreated cells (condition 2). The experiment was repeated on stock solutions of the ruthenium complexes that were stored at 4 °C for one and two weeks. Control experiments were performed to show that ruthenium complexes were not cytotoxic at the concentrations used in this study, as determined from an MTT assay.[20]

The **Supporting Information** available (see also the footnote on the first page of this article) includes the UV/Vis plots used to determine the binding constants (K_B) of compounds **14** and **27** with NO.

Preparation of an $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ Electrode Material From a New Li–Co–Ni Mixed-Citrate Precursor

Yodalgis Mosqueda,[a] Eduardo Pérez-Cappe,[b] Pilar Aranda,[c] and Eduardo Ruiz-Hitzky*[c]

Keywords: Citrates / Electrode materials / Lithium batteries / Mixed-valent compounds / Oxides

A new chemical route to prepare the mixed oxide $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$, which is a member of the well-known Li-Ni-Co-O family that is of interest as an electrode material for rechargeable lithium batteries, from a mixed citrate is reported. In a first step the new citrate $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$, is synthesized, which, after thermal decomposition, gives the layered mixed-oxide phase $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$. This oxide has been characterized by chemical analysis, XRD, FTIR, SEM, and DTA, revealing an "ideal" trigonal α-$NaFeO_2$ type structure with a well-ordered distribution of Li and Ni ions in different lattices. Thermoelectric power and four-point electrical conductivity measurements indicate a nonactivated conductivity mechanism of a small polaron. The $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ compound prepared by this so-called "citrate route" has a better reversibility of Li-insertion in charge–discharge cycles than related phases reported previously.

Introduction

Among the $LiMO_2$ (M = V, Cr, Mn, Co, Ni) series, the $Li_x(Ni_{1-y}Co_y)_{1-x}O_2$ family shows structures based on either cubic close packed (fcc) or distorted (fcc) oxygen lattices.[1–3] These families of oxides exhibit very interesting physical and electrochemical properties that have made most of them applicable as positive electrodes in high-energy-density batteries.[4–8] The $Li_x(Ni_{1-y}Co_y)_{1-x}O_2$ system exhibits several advantageous properties in comparison to the $LiNiO_2$ and $LiCoO_2$ end members, such as higher capacity, lower material cost, better thermal stability, and superior rechargeable performance.[9–11] One of the key requirements to obtain a good electrode material within this family of compounds is to reach a good cationic order of Ni and Li ions in different structural sites. However, many authors have reported the presence of divalent nickel ions (r = 0.68 Å) at the lithium sites (r = 0.74 Å) in the nickel-rich phases because this element in its trivalent oxidation state is relatively unstable and, due to its small ionic size (r = 0.56 Å) fits better in the lithium octahedral position.[12–14] This can be seen by XRD and IR spectroscopy. In this way, strong overlap in the (006)/(012) and (018)/(110) couples of diffraction lines, as well as a (003)/(104) integrated intensity ratio lower than 1.2, indicate the presence of cationic disorder.[12,13] Moreover, the characteristic IR pattern in oxides with well-ordered cationic distribution, which consists of the presence of two well-individualized IR characteristic regions for the vibration modes of LiO_6 (300–200 cm^{-1}) and $M^{3+}O_6$ (650–400 cm^{-1}) sites, is lost.[15,16] When the lithium ions surrounding the nickel divalent ions are preferentially deintercalated, the oxidation process of extra nickel ions, i.e. from the divalent (r = 0.68 Å) to the trivalent state (r = 0.56 Å), takes place. On reversing polarity in the charge–discharge cycles, these lithium ions can no longer fit back into their sites due to octahedral distortion, and therefore the electrochemical cyclability is limited.[12,17,18]

Taking into account the above observations, one of the strategies for preparing materials with better cycling properties has been directed towards new routes of synthesis to produce trigonal ($R\bar{3}m$) Ni-rich phases with an ordered distribution of Li^+ and M^{3+} ions in the octahedral sites. Synthetic methods that lead to small-particle-size materials are also of interest because they favor the ionic and electronic diffusion in the cathode material intergrain frontiers, as well as the overpotential decrease of the ionic transfer across the cathode/electrolyte interface.[19,20] Chemical methods involving salts after precipitation and convenient thermal treatments have been the strategies for the preparation of small-particle-size oxides. In this way, the so-called citrate method has been employed in the preparation of multicomponent oxides (perovskites, spinels, ferrites, etc.) to produce materials with a high chemical homogeneity and small particle size.[21–30] This method involves the precipitation of citrate salts at controlled pH and concentration ratio of the involved ions, followed by their thermal decomposition. The Pechini process[26] for the synthesis of mixed oxides is one of the different reported pathways in which polyhydroxy alcohols are used to produce the esterification of

complex mixtures of citrates to give a polymeric resin, which is decomposed above 400 °C.[21,23–26] However, the formation of a dense and rigid resin intermediate of citric acid and ethylene glycol, which leads to crystallite agglomeration during pyrolysis, has been found to be a critical problem of this approach.[25] A modified Pechini method has been reported recently by Julien et al.,[30] in which a gel precursor is prepared by addition of citric acid to a mixture of the metal acetates followed by heating at 800 °C to obtain the micro-sized $LiNi_{0.6}Co_{0.4}O_2$ phase. Alternative routes[27–30] are based on the higher solubility of the citrate salts in ethanol vs. water, as reported by Zhecheva and coworkers[29] for the preparation of $LiCoO_2$ powders with small particle size. These authors showed that the chelating ability of citric acid, and therefore its ability to form complexes with metal ions, is highly dependent on the ions' concentration. Thus, concentrated lithium-cobalt-citrate solutions (1:1:2, Li:Co:citric acid) lead to the formation of a homogeneous $(NH_4)_3LiCo(C_6H_5O_7)_2$ citrate. The thermal decomposition of this amorphous citrate yields a $LiCoO_2$ phase with an "ideal" trigonal α-$NaFeO_2$-type structure.[29]

Although the method employed by Zhecheva et al.[29] is efficient for the preparation of lithium cobalt oxides, there is no evidence of its application to systems involving other metal such as nickel, or when a substitution of cobalt by nickel must take place. The aim of the present work is to extend Zhecheva's method[29] to the synthesis of $LiNi_{0.8}Co_{0.2}O_2$ by using, in this case, a new precursor consisting of a mixed nickel-cobalt citrate of appropriate stoichiometry. We intend to optimize the synthesis conditions to reach a well-defined crystalline phase of the mixed citrate that could produce the ideal trigonal Li-Co-Ni oxide (rich in nickel) by a new chemical route followed by thermal decomposition. As is reported below, the resulting oxide has a $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ composition whose structural and electrochemical features are studied in comparison with the phase of similar composition ($Li_{0.8}Ni_{0.8}Co_{0.2}O_2$) prepared by a ceramic method.

Results and Discussion

Preparation and Structural Characterization of the Precursor Citrate and the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ Phase

During the preparation of the precursors of the Li-Co-Ni mixed oxides we observed that attempts to prepare the mixed citrates of a selected stoichiometry in the presence of lithium salts always resulted in mixtures of amorphous and crystalline Li-Co and Li-Ni phases, except when the pH and the concentration of the solutions were strictly controlled. Therefore, based on the experimental results of Zhecheva et al.[29] applied to lithium–transition metal (Co or Ni) citrate single-phase preparations, we estimated what would be the optimum pH value to obtain the Li-Co-Ni tridentate citrate as a single phase with a 1:1:2 Li:(Co-Ni):citrate ratio. The variation of the concentration of citrate (Cit) species vs. pH (Figure 1) is obtained by solving the three equilibrium equations of citric acid dissociation in water.[31]

$$H_3Cit\ (aq) \rightleftharpoons H_2Cit^-\ (aq) + H^+\ (aq);\ K_a = 8.4\times10^{-4} \quad (1)$$

$$H_2Cit^-\ (aq) \rightleftharpoons HCit^{2-}\ (aq) + H^+\ (aq);\ K_a = 1.8\times10^{-5} \quad (2)$$

$$HCit^{2-}\ (aq) \rightleftharpoons Cit^{3-}\ (aq) + H^+\ (aq);\ K_a = 4\times10^{-6} \quad (3)$$

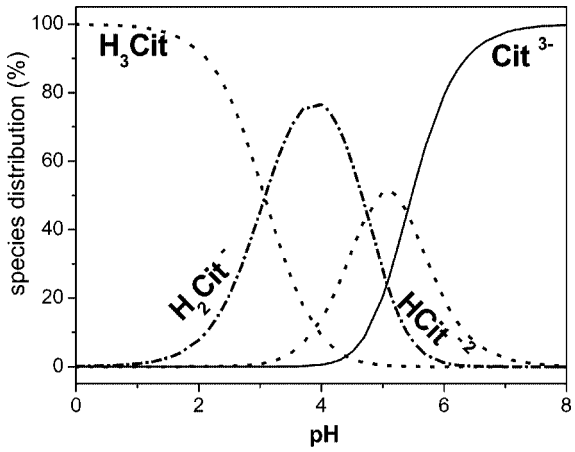

Figure 1. Phase diagram of citric acid species as a function of pH (calculated for a total citric acid concentration of 1 mol L^{-1}).

The distribution diagram of equilibrium species for citric acid shows that the Cit^{3-} species predominate around pH 7. To favor the presence of such species it is necessary to increase the pH, which in our case is achieved by adding the Li^+ ions as carbonate and, finally, aqueous ammonia solution to adjust to pH 7. Under these conditions Cit^{3-}, Li^+, Co^{2+}, Ni^{2+}, and NH_4^+ species are present, thus making possible the precipitation of the mixed citrate containing Li^+ and NH_4^+ ions, which act as counterions as with other reported ammonium metal citrates, such as $(NH_4)_4M(C_6H_5O_7)_2$ (M = Co, Zn, and Cu), studied by Zhecheva,[29] Swanson,[32] and Both,[33] respectively.

The mixed citrate $(NH_4)_3LiNi_{0.8}Co_{0.8}(C_6H_5O_7)_2$ obtained at pH 7 (see Experimental Section) precipitates as a blue-green solid when the resulting solution is dried. The elemental analysis (CHN) of the solid (C 28.40, N 9.19, H 4.12) is in good agreement with the calculated values (C 28.93, N 8.51, H 4.42). The STEM-EDX analysis of this sample for different particles of the solid shows Ni/Co, O/Ni, O/Co, and O/C atomic ratios of about 3.79, 4.56, 18.90, and 1.53, respectively, which indicate good homogeneity of the sample compositions.

The formation of a citrate salt is clearly revealed by IR spectroscopy (Figure 2) as the characteristic vibration bands of the carboxylic groups of the citric acid at 1740 cm^{-1} and 1690 cm^{-1} ($\nu_{C=O}$), 1420 cm^{-1} ($\nu_{CO} + \delta_{OH}$ in plane), and 930 cm^{-1} (δ_{OH} out plane) are replaced by the two characteristic antisymmetric and symmetric stretching vibration bands of carboxylate groups at 1576 cm^{-1} and 1385 cm^{-1}, respectively.[29,34] It is well known that the position and separation between ν_{as} and ν_s stretching vibrations of COO^- can be used to establish the coordination mode of the carboxylate anions around the metal ion.[35–37] The presence of the band assigned to the symmetric vibration

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mode below 1400 cm^{-1} – it appears at 1385 cm^{-1} in the citrate synthesized here – suggests the coordination of the carboxylate as a bidentate ligand. The large band centered at 3190 cm^{-1} (Figure 2) can be assigned to the ν_{OH} stretching vibrations of perturbed 2-hydroxy groups, thus indicating the participation of such hydroxyls in the metal coordination. The bands at 1190 cm^{-1} and 1138 cm^{-1} correspond to the ν_{CO} stretching vibration modes of these tertiary alcohol groups.[34]

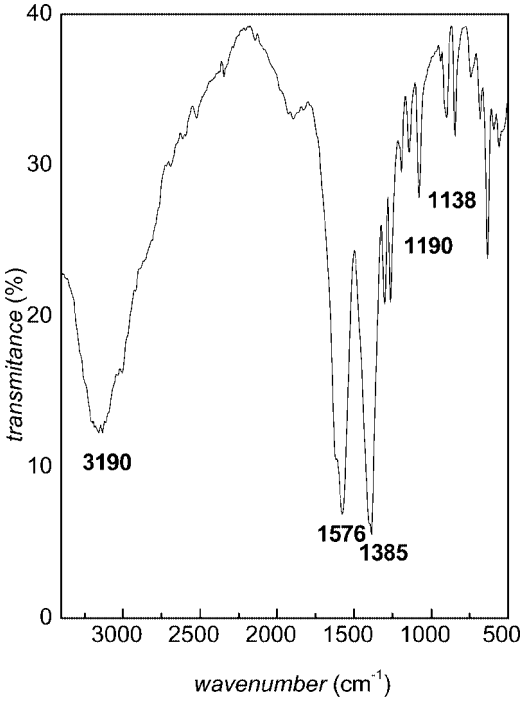

Figure 2. IR spectrum of the citrate $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$.

Figure 3 shows the XRD patterns of the mixed Li-Co-Ni citrate obtained at pH 7 (considered as the optimal acidity conditions) and another citrate obtained at pH 6. This latter solid exhibits a poor diffractogram, suggesting the presence of the citrate together with other phases, including amorphous materials. It is important to remark that thermal decomposition of both citrates results in different crystalline Li-Ni-Co mixed oxides with rhombohedral symmetry ($R\bar{3}m$).

The XRD patterns (Figure 3 c and d) are similar to those reported in the literature for $Li_{1-x}[Ni_{(x-y)}Ni_x]Co_{1-y}O_2$,[1–3,7,8,10,12,13] but a clear splitting of the (006) and (012) reflections as well as the (018) and (110) diffraction lines is observed for the oxide obtained from the citrate prepared at pH 7. This observation indicates that the corresponding mixed oxide has an α-$NaFeO_2$-type structure with a better ordered cationic distribution[12,13] than the oxide prepared from the citrate obtained at pH 6. The presence of NiO and Co_3O_4 phases that could take part in the resulting product can be discarded as their more intense XRD diffraction peaks do not appear in the patterns. Some of them could be overlapped by the most intense signals of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ mixed oxide but the other reflections are not detected in the background.

The XRD profiles of the ordered Li-Ni-Co mixed oxide as well as its new citrate precursor (pH 7) were indexed with the CELREF V3 computer program.[38] The unit-cell parameters in the hexagonal system (space Group: $R\bar{3}m$) are a = 0.2841 and c = 1.4070 nm, $\alpha = \gamma = 90°$, $\beta = 120°$ (calculated from the structural data in Table S1 in the Supporting Information). These parameters are not far from those of the $LiNi_{0.8}Co_{0.2}O_2$ oxide prepared by a ceramic route (a = 0.2867, c = 0.1416 nm, $\alpha = \gamma = 90°$, $\beta = 120°$ by Rougier[12] and a = 0.2862, b = 0.1412 nm, $\alpha = \gamma = 90°$, β

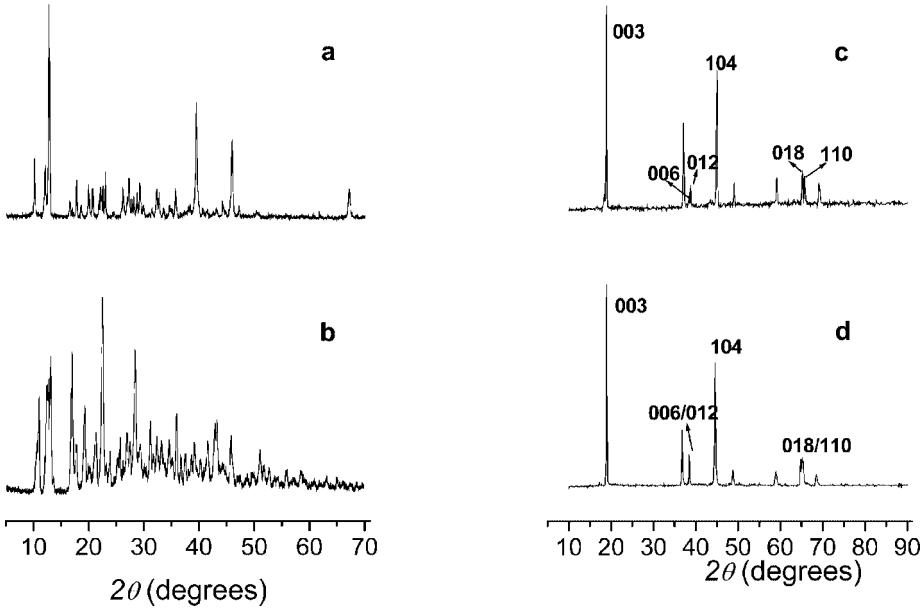

Figure 3. XRD patterns of the Li-Ni-Co citrate precursors obtained in this work at pH 7 (a) and pH 6 (b), and of the mixed Li-Ni-Co oxides obtained by thermal decomposition at 750 °C from the corresponding citrate prepared at pH 7 (c) and pH 6 (d).

= 120° in this work) or from those of $LiNi_{0.6}Co_{0.4}O_2$ reported by Julen et al.[30] by a sol-gel route (a = 0.2839, c = 0.1409 nm, $\alpha = \gamma = 90°$, $\beta = 120°$). For the precursor (citrate synthesized at pH 7) the unit-cell parameters in the monoclinic system ($P2_1/m$ space group) are a = 0.8839, b = 1.3768, c = 0.9057 nm, $\beta = 114.9°$ (powder X-ray diffraction data given in Table S2 in the Supporting Information).

The DTA and TG curves (Figure 4) of the citrate prepared at pH 7 show an endothermic peak at 140 °C, which is accompanied by a weight loss that was assigned to a first NH_3 loss according to TG/MS results (see Figure 1 in the Supporting Information). The complex endothermic peak observed between 170 °C and 240 °C accompanied by the second weight loss was assigned to loss of the residual NH_3 molecules and also the well known transformation of citrate $(C_6H_5O_7)^{3-}$ into *cis*-aconitate $(C_6H_3O_6)^{3-}$ and a water molecule.[21,25,29] Above 300 °C several exothermic processes take place accompanied by drastic weight losses due to the vigorous combustion reactions of the residual organic matter. The total weight loss for $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ is about 82%, which agrees well with the calculated values for a final product of composition $LiNi_{0.8}Co_{0.2}O_2$ (80.5%).

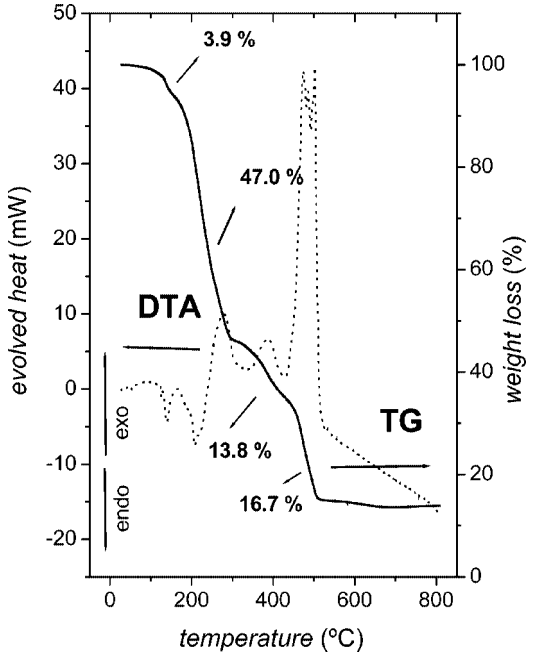

Figure 4. TG and DTA curves of the citrate $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ heated in air.

The thermal evolution of the citrate synthesized at pH 7 was also followed by XRD with the objective to determine at what temperature this precursor is transformed into the lamellar mixed oxide with trigonal structure. Figure 5 shows that the citrate precursor gives the Li-Ni-Co-O-phase at 750 °C.

The citrate thermal decomposition at 750 °C for 30 hours gives a well-ordered $Li_xNi_{0.8}Co_{0.2}O_2$ material of composition 4.98% Li, 47.91% Ni, and 12.16% Co (see analytical data in Table S3 in the Supporting Information) that fits well with the ideal $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase (Li 5.08%, Ni

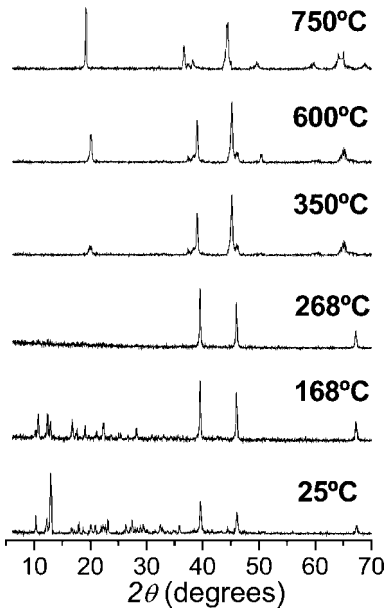

Figure 5. Evolution of the XRD patterns with temperature of the $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ citrate precursor until transformation into the trigonal Li-Ni-Co-O mixed-oxide phase at 750 °C.

49.12%, Co 12.33%). From iodometric titration we deduced a mean oxidation state of +3 for both cobalt and nickel, i.e. Co^{III} and Ni^{III}. This result indicates that the loss of Li^+ does not lead to the formation of Ni^{2+} ions as some authors have proposed.[39] Moreover, in the present case the loss of Li^+ provokes the oxidation of Ni^{3+} and Co^{3+} to the +4 oxidation state, as will be discussed later in relation to the electrical characterization of the mixed oxide. The high temperature used during the citrate–oxide transformations could be responsible for the loss of lithium from the solids.

Figure 6 shows the IR spectrum of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase in the 200 to 800 cm^{-1} region. As observed in related Li-Co-Ni mixed oxides, the number of resolved IR bands (4 bands: 2 A_{2U} and 2 E_U) corresponds to that predicted for a rhombohedral structure.[3,15,16] In our case the band at 256 cm^{-1} can be ascribed to the LiO_6 stretching vibrations, and the absorption bands between 500–700 cm^{-1} can be assigned to vibrations of the $M^{3+}O_6$ octahedral species. In addition, that the spectrum may be divided into two parts suggests the occurrence of distinct LiO_6 and $M^{3+}O_6$ vibrational frequencies,[15,16] which agrees well with the existence of an ordered ion distribution in a distorted rock-salt structure which corresponds to the interpretation of the XRD results.

The SEM image of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase (Figure 7) shows the agglomeration of fine particles with a homogeneous particle-size distribution (ca. 1 mμ). It is expected that the particle size should diminish with a shorter reaction time, thus favoring the Li ion diffusivity,[30,39,40] which is very important for rechargeable lithium-ion battery applications.[19,20] However, it has been observed that under such conditions the order in the distribution of the ions, for instance Li^+ and M^{3+} ions, may be not reached. So, to achieve good electrochemical properties it is necessary to establish

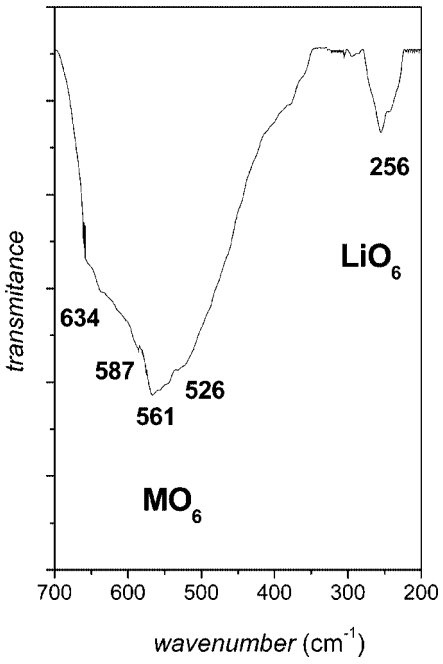

Figure 6. IR spectrum of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase obtained after thermal decomposition in air of the $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ citrate precursor at 750 °C for 30 h.

a compromise in the preparation conditions to allow the formation of a well-ordered phase with a relatively small size particle. In the case of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase synthesized from the mixed citrate, the particle size is smaller than in the $Li_{0.8}Ni_{0.8}Co_{0.2}O_2$ phase (0.5–20 μm) also obtained in this work by the classical ceramic route. This is also applicable for comparison to other Li-Co-Ni phases obtained from sol-gel precursors followed by calcination at 700–800 °C, such as $LiNi_{0.5}Co_{0.5}O_2$ (3 μm, at 800 °C for 10 h),[9] $LiNi_{0.25}Co_{0.75}O_2$ (1–10 μm at 800 °C for 2 h),[39] and $LiNi_{0.6}Co_{0.4}O_2$ (1 μm, at 700 °C for 4 h).[30]

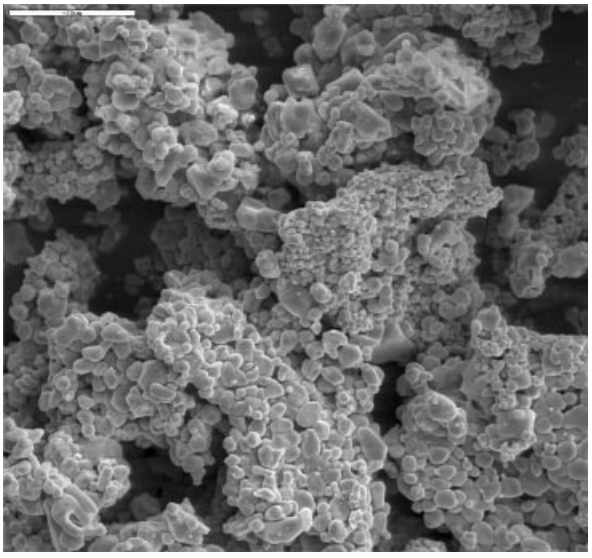

Figure 7. SEM image of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase obtained after thermal decomposition in air of the $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ citrate precursor at 750 °C for 30 h.

The study of sample composition carried out by STEM-EDX analysis of different particles shows a high homogeneity in the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase, with Ni/Co, O/Ni, and O/Co ratios in the 4.09–4.15, 0.70–0.61, and 2.57–2.60 ranges of composition, respectively.

Electrical and Electrochemical Characterization of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ Phase

Figure 8 shows the evolution of the thermoelectric power of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ compound with temperature. All are positive values that are almost independent of the temperature in the studied range. This behavior has been attributed to a small polaron Ni^{3+}-O^{2-}-Ni^{4+}-type transport mechanism, where there is no thermal activation of the number of carriers.[10,40,41] This behavior can be explained by considering the actual lithium content in this sample ($x = 0.7$), hence the loss of the ideal Li^+ stoichiometry may be compensated by the presence of Ni^{4+}/Ni^{3+} couples.[41]

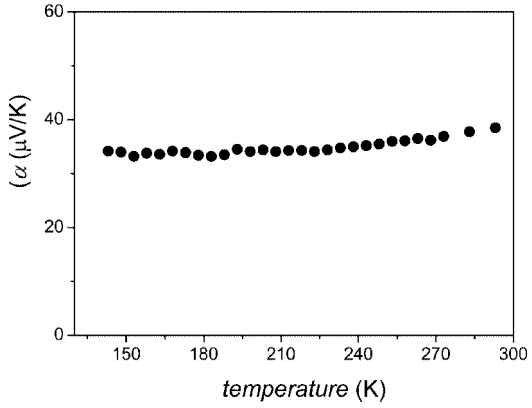

Figure 8. Variation of the thermoelectric power with temperature in the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase obtained after thermal decomposition in air of the $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ citrate precursor at 750 °C for 30 h.

Previous studies[10,41] have confirmed that, during lithium deintercalation, trivalent nickel ions, rather than trivalent cobalt ions, are preferentially oxidized to the tetravalent state. To unambiguously confirm this behavior a detailed study of the electronic transport properties was carried out during lithium extraction. From a general point of view, nickel oxidation must lead to small polaron-type conductivity, while cobalt oxidation must lead to a tendency to electronic delocalization through the t^2–t^2 overlapping.

Saadoune and Delmas[41] have studied different compositions of $Li_xNi_{0.8}Co_{0.2}O_2$ ($x > 0.5$) and have observed that there is no change in the transport mechanism. Our results for the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase prepared from the citrate precursor are very similar to theirs and confirm an activated character with an activation energy of 0.17 eV in the electrical conductivity (Figure 9). This result confirms the electronic localization in this phase, which is in good agree-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment with the presence of Ni^{4+} ions in the material and therefore the existence of Ni^{4+}-O^{2-}-Ni^{3+} hopping. Considering the actual composition of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase, it must be assumed that there are a significant number of Ni^{4+} ions, leading to the presence of holes in the Ni^{4+}/Ni^{3+} narrow band and the respective decrease of the Ni^{4+}-O^{2-}-Ni^{3+} distance as a resulting of the higher valence of Ni^{4+}, which makes the Ni^{3+}-O^{2-}-Ni^{4+} hopping easier. Finally, it should be noted that our $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ presents a good conductivity value in the 10^{-2} S cm^{-1} range, which is one of the requirements for applications in secondary lithium batteries.

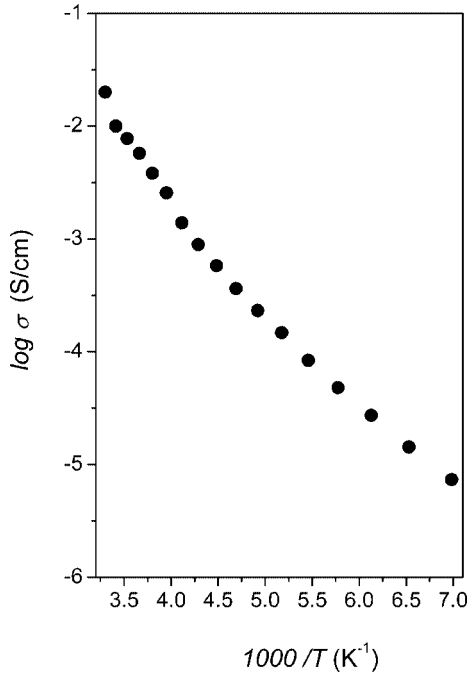

Figure 9. Variation of the electrical conductivity with temperature in the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase obtained after thermal decomposition in air of the $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ citrate precursor at 750 °C for 30 h.

The first charge and discharge curves of the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase used as a positive electrode (without any addition of conductive carbon due to its good electrical conductivity) are illustrated in Figure 10, in which the Li content has been varied in the $0.7 \geq x \geq 0.4$ composition domain whilst operating at a 70 μA cm^{-2} current density. This graphic shows that the electrochemical process is well reversible, with the coulombic efficiency of the first discharge process being about 96% of the first charge one. The monotonous increment of the voltage vs. composition curve suggests the occurrence of a monophasic reaction in the charge/discharge process, as has been reported by several authors.[1,7,29,30] On the contrary, for the material obtained by the traditional ceramic method ($Li_{0.8}Ni_{0.8}Co_{0.2}O_2$), the first insertion/deinsertion lithium cycle exhibits a very poor percentage of recovered lithium (about 50%), i.e. a poor reversibility.

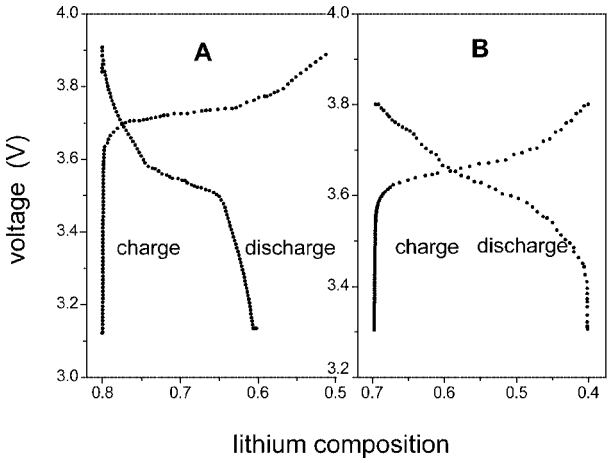

Figure 10. First charge/discharge cycle of (a) the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase (Li/$LiClO_4$ (PC/EC)/$Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ cell) and (b) the $Li_{0.8}Ni_{0.8}Co_{0.2}O_2$ phase prepared by the ceramic method (Li/$LiClO_4$ (PC/EC)/$Li_{0.8}Ni_{0.8}Co_{0.2}O_2$ cell), both at 70 μA cm^{-2}.

The low polarization effect observed is in good agreement with the lithium content determined from chemical analysis ($x = 0.7$), because it is known that when x becomes close to 1 the ionic conductivity decreases as the number of available sites for Li^+ ion diffusion becomes very small, leading to a strong polarization effect.[41]

Figure 11 shows a plot of the $-dx/dV$ values vs. the potential for the first charge/discharge cycle of the cell prepared from the $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ phase. The occurrence of a single step of extraction and insertion of lithium from the cathode suggests the existence of a unique phase in our compound, in contrast to the $Li_{0.75}Ni_{0.8}Co_{0.2}O_2$ ceramic phase already reported by Saadone and Delmas.[41] In this last case, the observed minimum in the dx/dV plot is associated with order–disorder transitions during the insertion/deinsertion of the Li^+ ions.

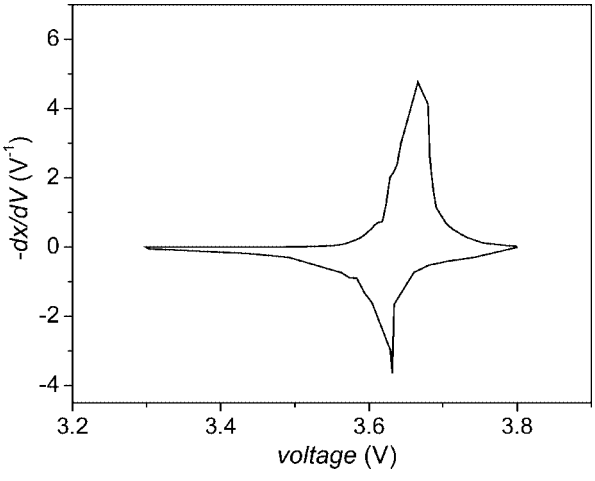

Figure 11. Derivative curve ($-dx/dV$) vs. voltage for the first charge/discharge cycle of the Li/$LiClO_4$(PC/EC)/$Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ cell. In the derivative term, x represents the content of Li.

The excellent cyclability of this cell, at least for the first four charge/discharge processes, is shown in Figure 12. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

data show a specific capacity of 80 mAh g^{-1}, corresponding to the insertion/extraction of 0.3 Li^+. The experimental conditions were selected in order to ensure that the lithium insertion never goes lower than 0.4 moles to avoid irreversible phase transformations. This limitation implies that the maximum amount in the lithium content was that of the starting oxide, i.e. $x = 0.7$.

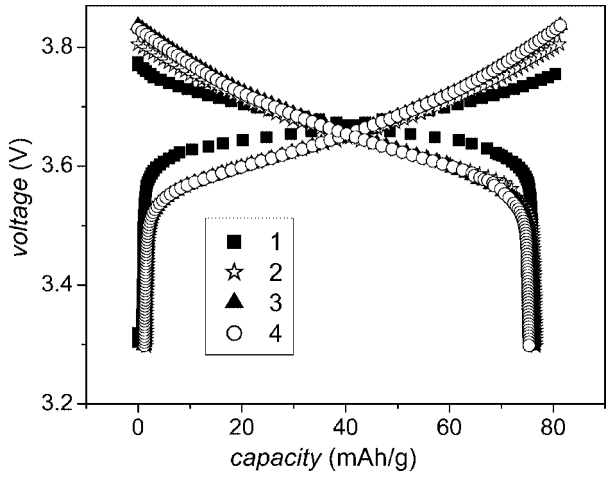

Figure 12. Galvanostatic cycling curves of the Li/$LiClO_4$ (PC/EC)/$Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ cell at a constant current density of 70 μA cm^{-2}. The Li content has been varied in the $0.7 \geq x \geq 0.4$ composition domain.

The theoretical capacity calculated for a variation of $\Delta x = 0.6$ in the lithium content for a similar cell prepared with materials of the same family compounds is about 160 mAh g^{-1},[29,30,41] which is equivalent to the value of 80 mAh g^{-1} obtained by us for $\Delta x = 0.3$ extracted and reinserted.

Concluding Remarks

The main requirement to obtain a Ni-rich phase such as $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ with well-ordered cationic distribution of Li and Ni from citrate precursors is the pH control in the precursor synthesis to form a unique phase of the mixed citrate. Working at unsuitable pH conditions results in a mixture of citrate phases which, after thermal decomposition, gives rise to mixed oxides presenting a disordered Li/Ni cationic distribution.

The $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ oxide prepared from the mixed citrate $(NH_4)_3LiNi_{0.8}Co_{0.2}(C_6H_5O_7)_2$ shows good electrical conductivity that is high enough to ensure the required behavior as an electrode material for convenient electrochemical insertion/deinsertion of lithium without addition of conductive carbon.

Comparing the results of electrochemical behavior towards Li insertion/deinsertion of $Li_{0.7}Ni_{0.8}Co_{0.2}O_2$ as an electrode material with that of the already reported $Li_{0.75}Ni_{0.8}Co_{0.2}O_2$ phase prepared by a ceramic method shows that the novel phase presents an enhanced performance in the cyclability properties.

Experimental Section

The Li-Co-Ni citrate with a Li/Co/Ni/citric acid stoichiometry ratio of 1:0.2:0.8:2, respectively, was synthesized by adding Li_2CO_3 (1.92 g; Merck) to a mixture of aqueous solutions of $Co(NO_3)_2 \cdot 6H_2O$ (11.98 g; Riedel-de Haën) and $Ni(NO_3)_2 \cdot 6H_2O$ (2.98 g; Aldrich) to reach the 1:4 Co/Ni stoichiometry selected. A saturated solution of citric acid (Aldrich) was then added dropwise to this mixture, which was stirred rapidly until a clear solution was obtained. Afterwards, the pH was adjusted to 7 with aqueous ammonia (6 M; Merck) and the mixture was heated at 80 °C for 4 h. This thermal treatment produced the formation of a blue-green precipitate, which was isolated, washed with ethanol, and dried at 100 °C in air. The solid was characterized and then used to prepare the mixed oxide by heating at 750 °C for 30 h. For comparative purposes, a $Li_xNi_{0.8}Co_{0.2}O_2$ phase was prepared by a conventional ceramic route based on the thermal decomposition of stoichiometric mixtures of $Ni(NO_3)_2 \cdot 6H_2O$, $Co(NO_3)_2 \cdot 6H_2O$, and $Li(OH) \cdot H_2O$ at 400 °C and subsequent solid-state reaction in air at 750 °C for 30 h.[3]

The elemental analyses (CHN) were performed with a Perkin–Elmer 240C microanalyzer. The Li, Ni, and Co contents were determined with an ICP-AES spectrometer Perkin–Elmer Optima 3300. The mean oxidation state of cobalt and nickel was determined by iodometric titration. The XRD patterns were recorded with a Philips PW1710 diffractometer using Cu-K_α radiation from 10° to 90° (2θ) at 2° min^{-1}. The temperatures for the programmed recording of XRD patterns (5 °C min^{-1}) during the heating of the citrate precursor carried out in the Anton Paar high temperature chamber of the diffractometer, were selected from the DTA and TG curves of the sample obtained in a Seiko SSC/5200 analyzer (5 °C min^{-1} heating rate from room temperature to 900 °C in air). The TG/MS measurement were carried out with a Thermostatar Baltzers Instrument coupled to a Seiko SSC/5200 TG-DTA System using 100 mL min^{-1} He flux, heating from 25 to 600 °C at 2 °C min^{-1}. The Infrared spectra of the citrate precursor (KBr pellets) and mixed oxides (polyethylene pellets) were recorded with an ATI MATTSON Genesis Series FTIR spectrometer in the 400–4000 cm^{-1} region and a Perkin–Elmer FTIR spectrophotometer model 567 in the 200–700 cm^{-1} region, respectively. The morphology, particle-size distribution, and purity of the phases were studied with a SEM Zeiss DSM-960 microscope coupled with an EDX Tacor-Northen Serie Z-II spectrometer operating at 20 kV and a STEM LEO-910 microscope also coupled with an EDX system.

Thermoelectric power and four-point conductivity measurements in the –133 to 20 °C temperature range were carried out simultaneously using a homemade apparatus described elsewhere.[42] Pellets of pressed powder (7 tons cm^{-2}) were sintered at 700 °C for 4 h in air. The electrochemical measurements were carried out in Li/$LiClO_4$(PC/EC)/$Li_xNi_{0.8}Co_{0.2}O_2$ cells. The positive electrode consists of sintered pellets (0.13 cm diameter) pressed at 3 tons cm^{-2} of the pure mixed oxide (i.e., without addition of carbon as electric conductor). The cells, assembled in an argon-filled dry box, were galvanostatically cycled under low current density (70 μA cm^{-2}) in the $0.7 \geq x \geq 0.4$ and $0.8 \geq x \geq 0.4$ lithium composition ranges for the oxides prepared by the chemical and ceramic methods, respectively.

A New Spherical Metallacryptate Compound $[Na\subset\{Cu_6(Thr)_8(H_2O)_2(ClO_4)_4\}]\cdot ClO_4\cdot 5H_2O$: Magnetic Properties and DFT Calculations

Sheng-Chang Xiang,[a] Sheng-Min Hu,[a] Jian-Jun Zhang,[a] Xin-Tao Wu,*[a] and Jun-Qian Li[b]

Keywords: Spherical metallacryptate / Magnetic properties / Density functional calculations / Broken symmetry / Threonine

The hexanuclear copper(II) complex with threoninato acid has been synthesized. Its structure can be described as an octahedron cage with D_{2h} symmetry in which six copper ions are bound by eight threoninato acids with a $[3.1_12_23_10]$ coordination mode and one Na^+ cation being captured within the center of the cage. In contrast with other hexanuclear copper compounds containing amino acids, the title compound has a prolate Cu_6 octahedron with the longest axial distance and a rectangle equatorial plane, as well as special coordinated perchlorate ions. Compared with classic cryptate, hexanuclear copper(II) compounds with amino acids can be regarded as a new topologic type of spherical macrotricyclic metallacryptates [2,2,2,2] whose cages have a high selectivity for sodium ions. The analysis of magnetic susceptibility data shows that the threoninato compound has a ground state with spin $S = 3$. The computing coupling constant between the equatorial Cu centers and the axial ones is 4.4 cm^{-1}, calculated by using DFT methods for a model compound. This is close to three known experimental values of 1.39, 0.56 or 0.43 cm^{-1} for complexes with 4-hydroxy-L-prolinato, L-prolinato or L-threoninato acid as ligands, respectively. The dominant ferromagnetic interactions for these complexes can be essentially attributed to the orthogonality between the magnetic orbitals, d_{xz} or d_{yz} orbitals for the equatorial Cu^{II} centers and $d_{x^2-y^2}$ orbitals for the axial ones.

Introduction

The crown ether[1] is one of the classic synthetic ionophores, and the discovery of its cation-binding properties launched the rich field of host-guest chemistry.[2] While increasing the denticity of the crowns through construction of three-dimensional cavities, the cryptands[3] increase the binding affinities of the crowns for alkali metals. Using hydroxamic acid [e.g., salicylhydroxamic acid (SHI)] or oxime as ligands to stabilize the metallacrown ring, Pecoraro[4] synthesized a series of metallacrown analogs by introducing the heteroatom substitution approach which incorporates transition metal ions and nitrogen atoms into the methylene positions of the crown ethers. Once transition metals have been incorporated into metallacrowns they tend to have some interesting properties, which are not found in the simple organic crowns, such as redox activity, strong absorption spectra, and paramagnetism. Pecoraro[5] has obtained a cylindrical metallacryptate $Na[(Na(DMF)_3)_2\{[Na_{0.5}[Ga(SHI)]_4]_2(\mu_2\text{-}OH)_4\}]$, whose $[Na_{0.5}[Ga(SHI)]_4]_2$ metal cycles can be fused together through bridging hydroxides to form bicyclic metallacrowns. The cavity thus formed can selectively bind sodium cations. Another type of the inorganic analogs of cryptates,[6] based on a polyoxometalate framework, shows selectivity for lanthanides.

As the basic building units of proteins, amino acids are ubiquitous and indispensable ligands in biology, and it has been proven that amino acids are excellent ligands for the construction of 3d–4f heteronuclear clusters.[7,8] We[9] have also obtained two hexanuclear copper complexes with two amino acids, glycine (Gly) and L-proline (Pro), respectively, which also have a cavity that binds the sodium cation. Another hexanuclear copper analog with 4-hydroxy-L-proline (hpro) has been synthesized by Winpenny,[10] which is ferromagnetically coupled, yielding an $S = 3$ spin ground state. Bu[11] has produced a one-dimension analog $\{Cu_6Na\}_n$ chain by using 1,5-diazacyclooctane-*N*,*N*′-diacetate acid as the ligand. In this paper, we wish to report a new hexanuclear copper complex $[Na\subset\{Cu_6(Thr)_8(H_2O)_2(ClO_4)_4\}]\cdot ClO_4\cdot 5H_2O$ (**1**) with threoninato acid (Thr) as an inorganic analog of cryptands, which binds sodium cations through eight oxygen atoms of the carboxylate groups of eight threoninato acids.

The aims of this work, from a new viewpoint, are to recognize hexanuclear copper compounds with amino acids as a new type of spherical macrotricyclic metallacryptates, and to study the influence of the various ligands on the structure and magnetic properties of this family. Furthermore,

the magnetic properties of these complexes are firstly calculated by employing $\{Cu_6(Gly)_8\}^{4+}$ as a model by using the broken-symmetry approach[12] with density functional theory (DFT). Finally the nature of magnetic exchange for these complexes is explained from the scope of orbital interaction.

Results and Discussion

Structural Description

Part (a) of Figure 1 shows the skeleton structure of **1**. Selected interatomic distances and bond angles for compound **1** are collected in Table 1, respectively. As shown in Figure 1, a Na^+ ion is trapped in the center of a $\{Cu_6(Thr)_8\}$ cage, whose structure may be described as a four-blade propeller. The central metal ion is surrounded by eight carboxylate oxygen atoms which link it to the copper atoms of four $[Cu(Thr)_2]$ units with a mean Na–O distance 2.576 Å. The four units then use their spare carboxylate oxygen atoms to coordinate to the two Cu^{II} centers at the axial vertices, respectively (each Cu^{II} center coordinates to four carboxylate oxygen atoms and the mean Cu_a–O distance is about 1.959 Å). The square pyramidal configuration of the axial Cu^{II} atom is completed by the coordination of a water molecule from the apical position (Cu_a–O_w distances are 2.246 and 2.290 Å, respectively). If the weak interaction is not considered, each equatorial Cu^{II} ion of the cluster has a coordination number (CN) of four and its coordination geometry can be described as square planar. The average Cu_e–O and Cu_e–N distances are 1.949 Å and 1.971 Å, respectively. The six Cu^{II} centers of this cluster form an octahedron with idealized D_{2h} symmetry, the sodium ion being therefore approximately octahedrally surrounded by copper. The four equatorial Cu atoms provide a rectangular plane of the octahedron with two side lengths (the nearest Cu_e–Cu_e distances) of 5.162 and 4.789 Å, but not a square plane as in other amino acid compounds.[9,10] The average distance between axial and equatorial copper atoms is 5.012 Å. Although threoninato acid is a tetradentate ligand, it actually acts as a tridentate ligand by utilizing its amino and carboxylate groups to chelate one Cu^{II} ion and bridge another, as shown in part (b) of Figure 1. The coordination mode indicated by the Harris notation[13] is $[3.1_12_23_10]$.

Four of the five perchlorate ions lie between the propellers formed by the four $[Cu(Thr)_2]$ units as shown in Figure 2. Because the structure of the $[Cu_6]$ unit is distorted, these four perchlorate ions, as the linkages, are not symmetrically equivalent, so that the four Cu^{II} atoms located at the equatorial vertices of a non-binding octahedron provide a rectangular plane, not a square one as for other amino acid compounds. Two oxygen atoms from half of these ions are weakly coordinated to two Cu centers from $[Cu(Thr)_2]$ units, occupying the axial positions of their tetragonally

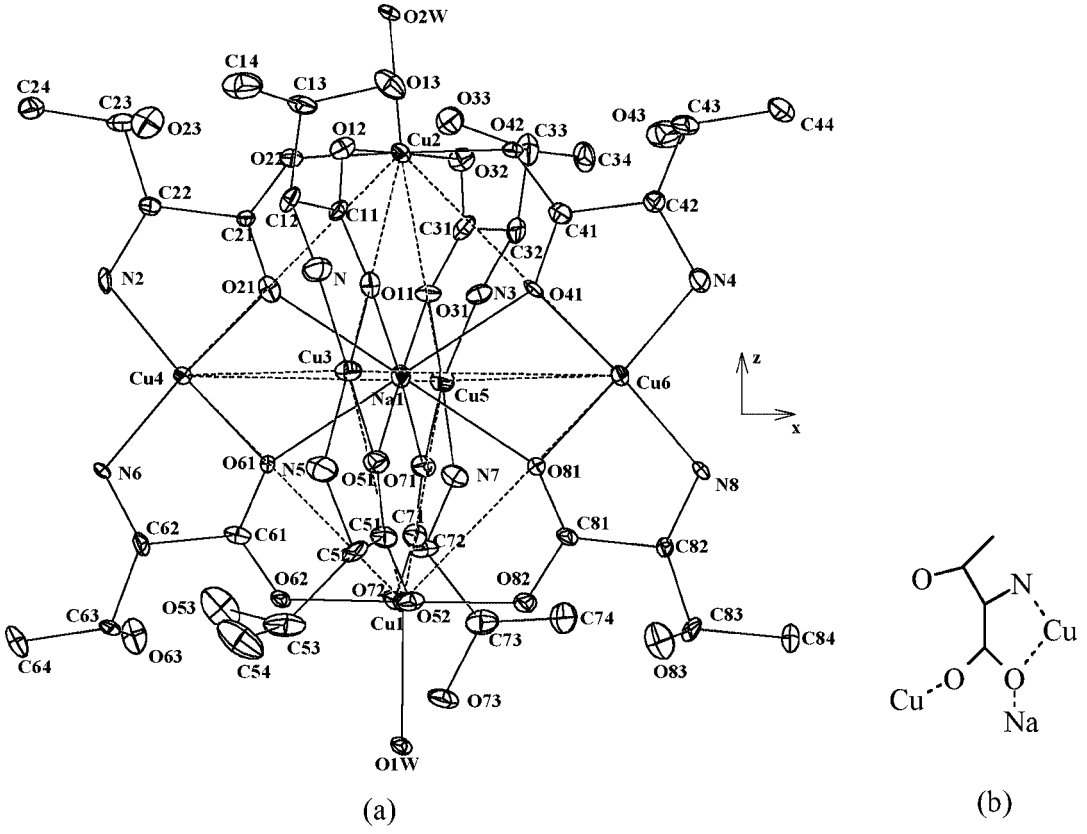

Figure 1. (a) ORTEP view of **1** shows the coordination geometries of Cu^{II} and threoninato acid with vibration ellipsoids at the 30% probability level. Hydrogen atoms are omitted for clarity. (b) The coordination mode $[3.1_12_23_10]$ of threoninato ligand indicated by the Harris notation.

elongated octahedral environment, which gives a long side of the rectangle (5.162 Å). The other ClO_4^- ions, however, bind to two Cu^{II} atoms through only one O-donor of its oxygen atoms, which supplies a short side (4.789 Å). As the location barrage, the distances between the Cu_e and O atoms of single-O-donor perchlorate ions are longer than those between the Cu_e and O atoms of two-O-donor ones. The four perchlorate ions act as the fixed interaction of propellers, which makes the skeleton of **1** more stable. The fifth ClO_4^- ion and several water molecules in the periphery have large thermal parameters in contrast with the skeleton atoms.

Some parameters for hexanuclear copper compounds with different amino acids are collected in Table 2. Different ligands lead to the large structural differences, including space group, shape of the octahedron, axial ligand and coordination modes of the perchlorate ions. *catena*-$[Na\subset Cu_2\{Cu(hpro)_2\}_4(ClO_4)_5]\cdot 4H_2O$ is a one-dimensional compound based on the $\{NaCu_6\}$ unit with hydroxyl groups from hpro ligands as the bridge, whereas others are zero-dimensional clusters with solvents, OH^- or perchlorate ions as axial ligands. In glycine complexes, there are two different $\{Cu_6Na\}$ units, one of them with one more Na^+ ion outside the cage. The hpro compound has a compressed octahedron with the shortest axial Cu_a–Cu_a distance forming the chain, while complex **1** has a prolate octahedron with the longest axial distance and a rectangle equatorial plane occurring with the perchlorate ions at the corners. From the Na–O distances, it can be seen that the size and inclusion ability of these octahedron cages are uniform, even though there are many distinctions among the hexanuclear compounds with various amino acids.

New Spherical Metallacryptate [2,2,2,2]

Figure 3 shows that on substituting the Cu_a–O linkage for the bridging N–C units of the classical cryptate [2,2,2] and the O–Cu_e–O linkage for the $[OCH_2CH_2O]$ units, because of their similar O–O distance (2.79 and 2.73 Å,[14] respectively), hexanuclear copper(II) compounds with amino acids can be seen as a new type of spherical macrotricyclic metallacryptate [2,2,2,2]. The four equatorial Cu^{II} ions are a way of bringing the eight oxygen atoms into the

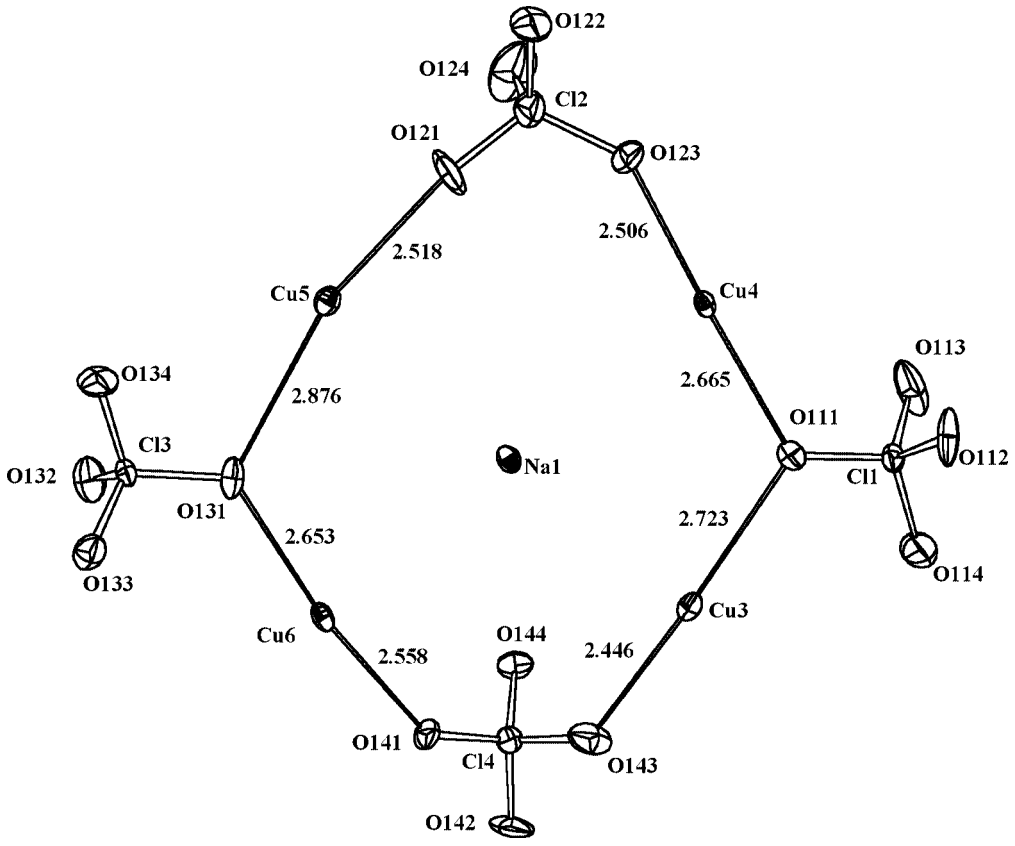

Figure 2. Coordination modes of the four perchlorate ions and the distances [Å] between equatorial Cu^{II} atoms and coordination oxygen atoms of perchlorate ions with vibration ellipsoids at the 30% probability level.

right positions to function as a non-metal cryptate that binds the center sodium cation, while the two axial metal ions use the directionality of the d orbitals to bring the ligands into a definite geometry as the bridging N atoms in the cryptate. The employment of d orbitals results in the enhancement of the connection number of the bridging atoms from three to four. Subtracting the shortest diagonal O–O distance of the cage (O41–O61, 5.098 Å) with the double bonding radii of the oxygen atoms (2 × 1.16 Å),[15] we can estimate that the cavity radius of compound **1** is 1.39 Å, similar to the ionic radius (1.32 Å[16]) of the Na^+ cation with a coordination number (CN) of eight. Winpenny et al.[10] has considered that this kind of cage can selectively bind the Na^+ cation even in the presence of excess Li^+, K^+, Ca^{2+}, La^{3+} or Lu^{3+}, whose ionic radii with a CN of eight are 1.06, 1.65, 1.26, 1.30 and 1.12 Å, respectively.[16] We have still obtained the title compound even in the presence of excess Y^{3+} (1.16 Å)[16] or trivalent rare earth ions. The cryptate [2,2,2], with a cavity size of 1.4 Å, can bind many kinds of metal ions besides alkali or alkaline earth metals to form complexes.[17] The replacement of the bridging N atoms with metal atoms increases the connection number of bridging atoms and thus alters the topological structure of the cryptate, which can further improve the selectivity of the cavity to sodium.

Magnetochemistry

Temperature-dependent magnetic susceptibilities of **1** are measured from ground crystalline samples in the temperature ranges of 4–300 K under a constant magnetic field of 10000 G and are shown in Figure 4 in the forms of χ_m vs. T and $\chi_m T$ vs. T per Cu_6 unit. At room temperature (300 K), the $\chi_m T$ value is 1.7 emu mol^{-1} K for **1**, compared with the expected values 2.25 emu mol^{-1} K for six spin-only Cu^{II} ions (S = 1/2, g = 2). The difference may result from the diamagnetic contribution of the compound. Upon cooling, **1** shows a continuous slight increase in $\chi_m T$, and a subsequent much sharper increase below ca. 25 K, suggesting that overall **1** is ferromagnetic, as confirmed by the positive Weiss constant (10.8 K). In order to investigate the exchange interaction of **1**, a model Heisenberg Spin-Hamiltonian is employed [Equation (1)].

$$H = -2J'(S_1 + S_2)(S_3 + S_4 + S_5 + S_6) \quad (1)$$

J' is the exchange coupling constant between the equatorial Cu atoms and the axial Cu ones, and S_i is the spin operator of each Cu center whose suffix is identical to that shown in Figure 1. From the model and the Van Vleck equation,[18] the molar susceptibilities of **1** can be deduced

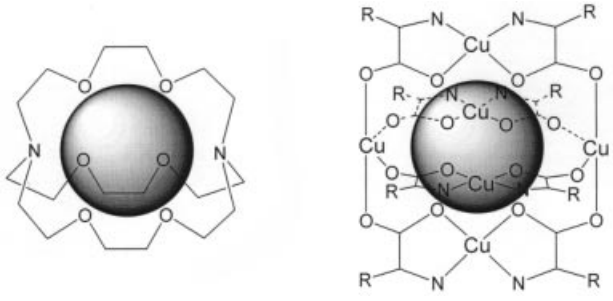

Figure 3. The classic cryptate [2,2,2] (left) and spherically metallacryptate [2,2,2,2] (right). The latter has macrotricycles made up of four blades and the equatorial cycle of perchlorate ions as shown in Figure 2 as an example. The central sphere represents a sodium cation. R is the substitution group of the amino acids or H atom for glycine.

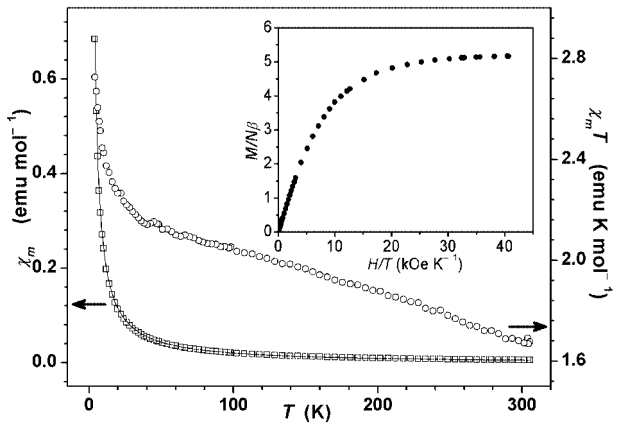

Figure 4. Plot of experimental χ_m vs. T (left) and $\chi_m T$ vs. T (right) for compound **1**. The solid line represents the fitted results. In the inset is a plot of $M/N\beta$ vs. H/T for **1** indicating the spin ground state, $S_T = 3$.

as in Equation (2) with the addition of the sample's diamagnetic contribution χ_{dia} by use of the Kambe vector coupling method,[19] which originates from a total of 20 spin states ranging in spin values from 0 to 3.

$J = J'/k$, and k is the Boltzmann constant, g the Landé factor. After the best least-squares fit to the experimental data, the parameters are given as: $g = 2.01$, $J' = 0.43\ cm^{-1}$ and $\chi_{dia} = -2.60$ (10^{-3} emu mol^{-1}) with a final agreement factor $R = 2.32\times10^{-6}$ [$R = \Sigma(\chi_m^{obsd.} - \chi_m^{calcd.})^2/\Sigma(\chi_m^{obsd.})^2$].

Attempts to fit the data by employing the method proposed by Belorizky[20] for octahedron clusters, which includes the coupling between the equatorial metal ions as

$$\chi_m = \frac{3}{8}\times\frac{g^2[28\exp(4J/T) + 30\exp(2J/T) + 16\exp(-2J/T) + 2\exp(-6J/T) + 20]}{T[7\exp(4J/T) + 15\exp(2J/T) + 14\exp(-2J/T) + 3\exp(-4J/T) + 3\exp(-6J/T) + 22]} + \chi_{dia} \quad (2)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

well as the next nearest interactions, gives the same values for g, J' and χ_{dia} as above. But the next nearest interactions and the coupling through the perchlorate ions are so small that they can be regarded as negligible. The coupling constant of **1** agrees with that of the prolinato compound,[10] 0.56 cm^{-1}. The positive J' value indicates that **1** has a ground state with spin $S = 3$, which is also proven by the $M/N\beta$ vs. H/T plot in the inset of Figure 4 with a saturation value for $M_S/N\beta$ of about 5.2.

DFT Studies

The computational strategy adopted in previous theoretical studies[21] for exchange coupling binuclear complexes is adapted to the hexanuclear complexes by using an approach that Ruiz[22] proposed. The approach consists of evaluating the exchange coupling constant J_{ij} between two paramagnetic metal centers i and j in the hexanuclear molecule by calculating the energy difference between the triplet and broken-symmetry states of a model molecule in which metal atoms are substituted by diamagnetic Zn^{2+} cations in all positions but i and j. Then the coupling constant is given below by employing a phenomenological Heisenberg Hamiltonian $H_{ij} = -2J_{ij}\cdot S_i\cdot S_j$;

$$J_{ij} = \frac{E_{BS} - E_{TS}}{S(S+1)} = \frac{E_{BS} - E_{TS}}{2} \quad (3)$$

where the total spin $S = S_1 + S_2 = 1$ for the triplet state, and the energy of the broken-symmetry solution is taken as an approximation to that of the singlet state. The procedure keeps with the proposal of Perdew and co-workers,[23] who suggest that the broken-symmetry single determinant is the correct solution of the Kohn–Sham equations for the singlet state. The triplet energy of the model compounds is gained from the single point energy calculation with the convergence parameter 10^{-8}. The energy of the broken-symmetry states is obtained by investigating the stability of the singlet solution with respect to a symmetry-broken solution, which is carried out by means of the formalism developed by Bauernschmitt and Ahlrichs,[24] as implemented in *Gaussian* 03[25] by the keyword STABLE with the option OPT. If the singlet B3LYP solution is unstable, the program finds the symmetry-broken B3LYP solution, which yields the energy of broken-symmetry states.

In order to simplify the computing work and make the theoretical result representative, the $\{Cu_6(Gly)_8\}^{4+}$ is employed as a model to investigate the magnetic properties of hexanuclear Cu^{II} compounds with amino acids. Its structural data are obtained from CCDC-165331. Because of the symmetry, the coupling constants J_{ij} are only calculated for $i = 1$. After metal atoms are replaced with diamagnetic Zn^{2+} cations in all positions but i and j, the four values of J_{ij} are obtained from equation (c) as shown in Table 3. All of them are positive, indicating that the interaction between the axial copper atoms and the equatorial ones is ferromagnetic. The average value, +4.4 cm^{-1}, is near to three known sets of experimental data, 1.39, 0.56 or 0.43 cm^{-1} for complexes with hpro, Pro or Thr as ligands, respectively.

Table 3. Exchange coupling constants J_{ij} (cm^{-1}) and energies (a.u.) of the triplet (E_{TS}) and broken-symmetry states (E_{BS}) for the $\{Cu_2Zn_4(Gly)_8\}^{4+}$ model compounds. 1 and 2 represent the two axial metal atoms and 3 to 6 the four equatorial ones, respectively.

i,j	E_{BS}	E_{TS}	J_{ij}
1,3	–12665.6168369	–12665.6167647	7.9
1,4	–12665.6186476	–12665.6185943	5.8
1,5	–12665.6181018	–12665.6180721	3.2
1,6	–12665.6168756	–12665.6168696	0.6

Exchange coupling in carboxylate-bridge complexes is largely determined by the conformation of the bridge and the interaction between the d orbitals of the metal and the bridge.[26] As has been shown in the few well-characterized Cu^{II} complexes bridged by *syn-anti* carboxylate groups, a *syn-anti* conformation of the (Cu–O–C–O′–Cu′) bridge is unfavorably oriented to give a strong overlap between the magnetic orbitals of the copper atoms.[27] For dinuclear copper carboxylates, the magnetic orbitals belong to the Cu $d_{x^2-y^2}$ orbital.[28] But for the hexanuclear Cu^{II} complexes with amino acids, the coordination geometry around each equatorial Cu^{II} ion is an elongated octahedron, the Cu^{II} unpaired electron can be mainly described by the d_{xz} or d_{yz} metallic orbital defined by the short bonds of the Cu–amino acid units; the x and z direction is shown in part (a) of Figure 1. Whereas the coordination geometry around each axial copper(II) ion is a square pyramid with their magnetic orbitals primarily being ascribed to the $d_{x^2-y^2}$ metallic orbital. The planes of the magnetic orbitals d_{xz} or d_{yz} of the equatorial Cu^{II} ions are nearly perpendicular to those of the $d_{x^2-y^2}$ planes of the two axial Cu^{II} ions, which provides a favorable orientation for the orthogonality of the magnetic orbitals, thus causing a dominant ferromagnetic interaction. The values of the magnetic coupling for these amino acid compounds are within those observed in the copper complexes[26,29,30] with bridging *syn-anti* carboxylate groups (0.37–14 cm^{-1}).

Experimental Section

General: All starting materials are of reagent grade and used without further purification. Elemental analyses were carried out by the Elemental Analysis Lab of our Institute. Magnetic measurements were carried out with a Quantum Design PPMS model 6000 magnetometer.

Synthesis of 1: $Cu(ClO_4)_2\cdot 5H_2O$ (0.353 g, 1 mmol) was dissolved in 10 mL of H_2O, followed by the addition of threonine (0.119 g, 1 mmol). The pH value of the above solution was then carefully adjusted by slow addition of 0.1 M aqueous NaOH until the precipitate that had formed remained (pH ≈ 5.5). The mixture was then filtered and the filtrate was placed in a desiccator with phosphorus pentoxide. Blue prismatic crystals were obtained several weeks later and isolated by filtration, washed with cold water, and dried in the air. Yield 0.11 g (44.6% based on threonine). $C_{32}H_{78}Cl_5Cu_6N_8NaO_{51}$ (1972.50): calcd. C 19.49, H 3.99, N 5.68; found C 19.26, H 3.83, N 6.09.

Structure Determination and Refinement: A blue prismatic single crystal with approximate dimensions of 0.20 mm × 0.15 mm

× 0.10 mm was mounted on a glass fiber. X-ray diffraction intensity data were collected on a Rigaku Mercury CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by using an ω scan mode at 130.15 K. A total of 22772 reflections were collected within $3.01 \leq \theta \leq 25.03°$, yielding 9896 unique reflections (R_{int} = 0.0621), of which 8718 were considered as observed ($I > 2\sigma(I)$). The crystal structure was solved by direct methods with the Siemens *SHELXTL*^{TM} version 5 package of crystallographic software[15] and refined by full-matrix least-squares refinement on F^2. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms on all carbon and nitrogen atoms were generated symmetrically, allowed to ride on their respective parent atoms and included in the structure factor calculations with assigned isotropic thermal parameters but not refined. The final $R = \Sigma||F_o| - |F_c|| / \Sigma|F_o|$, and $Rw = \{\Sigma[w(F_o^2 - F_c^2)^2] / \Sigma w(F_o^2)^2\}^{1/2}$ ($w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$). The crystallographic data are summarized in Table 4.

CCDC-252441 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Computational Details: All calculations have been performed by means of the *Gaussian* 03 suite of ab initio programs[25] using the B3LYP DFT method in which Becke's hybrid exchange functional[31] and the correlation functional[32] of Lee, Yang, and Parr are combined. A basis set of triple-ζ quality[33] is used for the Cu and Zn atoms and of double-ζ quality[34] for other atoms in all calculations.

A Study Using X-ray Absorption and Emission Spectroscopy of Dioxygen-Binding Xerogels Incorporating Cyclam Units Complexed with Copper Salts

José Goulon,*[a] Chantal Goulon-Ginet,[a,b] Andrei Rogalev,[a] Fabrice Wilhelm,[a] Nicolas Jaouen,[a] Delphine Cabaret,[c] Yves Joly,[d] Géraud Dubois,[e,f] Robert J. P. Corriu,[g] Gabriel David,[e] Stéphane Brandès,[e] and Roger Guilard*[e]

Keywords: X-ray absorption spectroscopy / Tetraazamacrocyclic ligand / Dioxygen binding / Peroxo ligand / Copper

X-ray absorption spectroscopy was used to elucidate how hybrid xerogels complexed with $CuCl_2$ could reversibly bind molecular dioxygen. Difference EXAFS analyses at the Cu K-edge suggest that dioxygen could bridge two Cu atoms in a μ-η^1:η^1 peroxo-like conformation with unequal Cu···O distances. Only the short distance (R_{Cu-O1} = 1.86 ± 0.01 Å) was unambiguously determined and looks typical of a Cu^{II} site. The Cu···Cu internuclear distances would be rather long: $R_{Cu-Cu} \approx 4.0$ Å (3.9 Å) for the oxygenated (oxygen-free) xerogels. Cl K-edge EXAFS spectra revealed the pre-existence in the oxygen-free xerogels of Cu^{I} sites with short Cl–Cu bonds (2.11 ± 0.03 Å). Pentacoordinate Cu^{II} sites with a longer Cl–Cu bond (2.45 ± 0.03 Å) were also identified. Another signal at a further distance (2.73 ± 0.03 Å) suggests that the Cl ions could bridge mixed-valence $\{Cu^{I},Cu^{II}\}$ sites. In oxygenated xerogels complexed with $CuCl_2$, ca. 75% of the Cu atoms would be singly bound to dioxygen while the signature of the pentacoordinate Cu^{II} sites would totally vanish. Substituting $CuBr_2$ for $CuCl_2$ yields xerogels with a poor capability to bind dioxygen. This is remarkably correlated with a decrease of the signatures at R_{Cu-O1} = 1.86 Å and R_{Cu-Cu} = 4.0 Å. EXAFS spectra of the oxygen-free xerogel complexed with $CuBr_2$ again exhibit signatures assigned to short (2.30 Å)/long (2.49 Å) Cu–Br bonds as expected for mixed-valence $\{Cu^{I},Cu^{II}\}$ systems. Inactive xerogels prepared with metallated cyclams seem to undergo a structural change during hydrolysis and polycondensation. Deconvoluted XANES spectra of the active xerogels exhibit a strong pre-edge resonance which is characteristic of mixed-valence Cu^{I} sites. This interpretation was supported by ab initio XANES simulations carried out beyond the muffin-tin approximation.

Introduction

In the past decade, nanostructured organic-inorganic hybrid polymers have attracted much attention because these novel materials offer unique combinations of optical, physical[1,2] or chemical[3–5] properties. It was a stimulating challenge for chemists to prepare hybrid polymers chelating metal cations in such a way that the metal would still be accessible for catalytic activity. Starting from the consideration that saturated polyazamacrocycles, especially the 1,4,8,11-tetraazacyclotetradecane (cyclam), had a strong capability to bind transition metal cations,[6–10] two partner groups (located in Dijon and Montpellier) settled upon incorporating cyclam units within silica matrices prepared by a sol-gel process.[11–13] Two strategies illustrated in Scheme 1 were explored:[13]

(A) The hydrolysis and polycondensation of $[Cu(cyclam)]^{2+}$ or $[Co(cyclam)]^{2+}$ alkoxysilylated complexes quantitatively produced hybrid polymers incorporating the metallated cyclam units.

(B) The hydrolysis and polycondensation of the alkoxysilylated (uncomplexed) cyclam precursors was performed first and the metal salt (e.g. $CuCl_2$) was then incorporated into the hybrid xerogel (Scheme 1).

Interestingly, it was found that, in the case of $CuCl_2$, the materials prepared by routes (A) and (B) had different spectrochemical properties reflecting different structures. Typically, xerogels of type (A) had a strong X-band EPR signal at 3200 G with a broad linewidth ($g \approx 2.15$) at room tem-

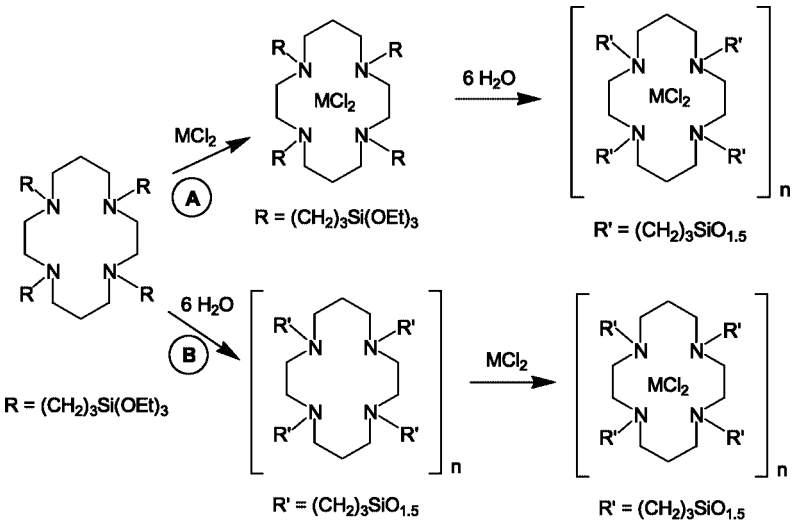

Scheme 1. Alternative routes to yield metallated hybrid xerogels following Route (A) and Route (B).

perature and at 100 K. This signal was assigned to Cu^{II} centers, but this broad signal vanished for xerogels of type (B). In contrast, xerogels of type (B) exhibited a much weaker signal at 1550 G ($g \approx 4.40$), which often characterizes dicopper interactions associated with a dinuclear structure. What made this structural problem even more interesting was the discovery that xerogels prepared by route (B) could bind (and possibly activate) molecular dioxygen whereas xerogels prepared by route (A) were essentially inactive. Recent tests have confirmed that the ability of xerogels of type (B) to bind dioxygen would be as high as for hemocyanin (Hc).

We tried to elucidate the puzzling structure of xerogels of type (B) using X-ray absorption and the XANES spectra were compared with ab initio simulations performed with an advanced code (FDMNES) that offered a double benefit. First, we could control the charge transfer from the ligand toward the metal, this option being useful here to describe the contribution of the neutral cyclam ligands. Second, we were not constrained to using spherically averaged muffin-tin potentials as with standard codes. The latter advantage is particularly sensible for covalent bonding.

Results and Discussion

Coordination Geometry: EXAFS Studies

The structural information contained in EXAFS spectra is often difficult to decipher. Analyses become most delicate when destructive interferences cause major spectral distortions and a loss of information.[14,15] Global fits can be either misleading or simply unreliable due to large correlations. Even with such complicated problems, the strength of EXAFS stems from its very high sensitivity to small structural changes and this is precisely what we tried to exploit with difference analyses. It is indeed recommended that the consistency of the analyses be checked by combining EXAFS spectra collected adifferent absorption edges.

EXAFS analyses of model compounds **1** = Cu(TPP), **3** = $[Cu(tmc)](BF_4)_2$ and **6** = [Cu(tpc)Cl]Cl are detailed only in the supporting information section. This preliminary study was very helpful because it made the limits of a direct data reduction fully transparent even though high quality data were collected over a wide spectral range. Given the highly symmetrical (D_{4h}) geometry of the copper porphyrin, the FT spectra of **1** offer a rich pattern of signatures which justified refined analyses, taking the multiple scattering paths into account. In contrast, the poor rigidity of the 14-membered saturated macrocyclic ligand restricted the information that could be extracted from the EXAFS spectra of complexes **3** and **6**. In the hexacoordinate species **3**, dynamic distortions of the axial and equatorial bonds can be predicted from the Jahn–Teller theorem[16] and were found to cause significant spectral distortions. Compound **6** was initially expected to be pentacoordinate, the copper ion being shifted away from the average plane of the four nitrogens with some trigonal distortion also arising from the ligand field. Published crystal structures of related pentacoordinate Cu complexes[17–19] raised a troublesome question regarding the true chemical formulation of compound **6**. Such pentacoordinate complexes were systematically found to be mixed-valence complexes due to the presence of linear anions $[Cl{-}{-}{-}Cu^{I}{-}{-}{-}Cl]^{-}$. The problem is that EXAFS is critically sensitive to the presence of such anions in which the short Cu^{I}–Cl bond (2.116 Å) is comparable to the Cu^{II}–N bond (2.13 Å). Destructive interferences between these two EXAFS signals are expected, the practical result being a loss of intensity of the Cu---N signature. This is a typical circumstance where, in our experience, analyses based only on fits would dangerously fail because the mathematical problem is poorly defined.[14,15] In combining the EXAFS spectra of species **6** recorded at both the Cu and Cl K-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

edges, we could produce strong evidence of the contributions of the linear anion $[Cl{-}{-}{-}Cu^{I}{-}{-}{-}Cl]^{-}$. This was received as a strong warning that standard fitting procedures may not be suitable to analyze the EXAFS spectra of our xerogels.

Active Xerogels Complexed with $CuCl_2$

In this paper, reactive materials towards dioxygen binding will be considered as "active" systems while unreactive solids in an ambient atmosphere will be called "inactive". Our strategy was first to compare the Cu K-edge FT EXAFS spectra of the oxygenated xerogel **XB2** with the oxygen-free xerogel **XB1**, both xerogels being complexed with $CuCl_2$. The relevant FT spectra $Im\tilde{\chi}_N(R)$ are displayed in Figure 1A. For model compound **3**, the FT spectra exhibit strong signatures which can be assigned unambiguously to the {Cu···N} and {Cu···Cα1} single scattering paths involving the cyclam ring with R_{Cu-N} = 2.02(2) Å and $R_{Cu-C\alpha1}$ = 2.8(8) Å. Since these signatures are nicely superimposed for the two xerogels, we were led to the first conclusion that the coordination geometry of the cyclam macrocycle can hardly be heavily altered in the oxygenated xerogel **XB2**. It thus became attractive to envisage difference analyses. We have reproduced in Figure 1B the FT spectra $Im\tilde{\chi}_N(R)$ and $|\tilde{\chi}_N(R)|$ obtained by Fourier transforming the difference EXAFS signal of a virtual species [**XB2-XB1**].

The most striking feature in Figure 1B is a sharp, nicely resolved peak which we assigned to a short Cu–O1 bond. The corresponding distance would be much too short to reflect any realistic distortion of the cyclam macrocycle. This led us to incorporate the phase shifts and scattering amplitudes of a Cu···O shell, calculated with FEFF8.9 for a cluster that has the structure of a well-characterized Cu–dioxygen model compound, into the optical FT.[20] Then by using a standard single shell fit, we could refine the distance: R_{Cu-O1} = 1.855 ± 0.005 Å, the Debye–Waller factor: $[\sigma_{Cu-O1}]^2$ = 0.00086 Å^2 and the average number density of bound oxygen atoms: N_{Cu-O1} = 0.76 ± 0.06 per copper site. The distance R_{Cu-O1} is much shorter than any Cu^{II}–OH bond length (1.97–2.02 Å) in copper hydroxyhalide minerals[21–25] like atacamite, paratacamite or in active phases of supported catalysts used for oxychlorination of ethylene.[26–28] In contrast, our R_{Cu-O1} distance compares remarkably well with the Cu–O bond lengths of Cu–dioxygen complexes of known crystal structures.[29,30] For instance, it is very close to the distance R_{Cu-O1} = 1.852 Å or R_{Cu-O1} = 1.868 Å found respectively in the end-on dinuclear μ-*trans* peroxo dicopper complex of Karlin[31,32] and Susuki[33] in which the dioxygen molecule is bound to two copper sites. If we accept that this may also be true for xerogel **XB2**, then our fit led us to expect the fraction of bound dioxygen molecules per copper site to be of the order of ca. 38%. It is quite remarkable that this value is nicely consistent with earlier measurements of oxygen adsorption which had established that the fraction of bound dioxygen should be near 40%. Note that the Cu···O1 signal could be seen directly in the FT spectrum of xerogel **XB2** displayed in Figure 1(A). Unfortunately, it interferes with the negative sidelobe of the intense Cu···N signal that makes the assignment problematic.

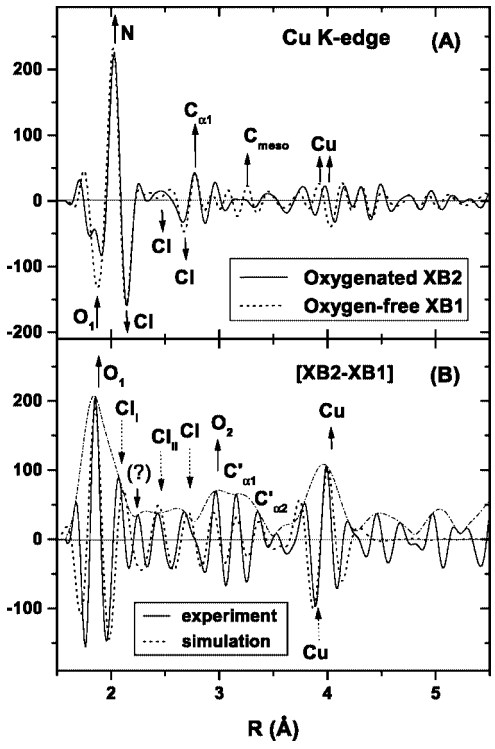

Figure 1. (A) Comparison of the Cu K-edge FT spectra $Im\tilde{\chi}(R)$ of xerogel **XB2**$[CuCl_2]/O_2$ (solid line) and of xerogel **XB1**$[CuCl_2]/N_2$ (dotted line). Arrows indicate where weak contributions of bridging chloride ions may interfere in xerogel **XB1**. (B) Cu K-edge FT spectra $Im\tilde{\chi}(R)$ (solid line) and $|\tilde{\chi}(R)|$ (dot-dashed line) of the difference signal of [**XB2** (oxygenated) – **XB1** (oxygen-free)]. A simulated FT difference EXAFS spectrum $Im\tilde{\chi}(R)$ (dotted line) is also reproduced which was calculated using a structure derived from Figure 3(A).

In the difference FT spectrum $|\tilde{\chi}_N(R)|$ shown in Figure 1B, there is another strong signature peak near 4 Å. We have assigned this signal to the derivative of a single scattering Cu···Cu EXAFS signal, resulting from a small variation of the distance R_{Cu-Cu} when dioxygen is bound to copper. At this stage, we would like to stress that this signal cannot be an experimental artefact since it is present in all difference analyses performed with individual scans. Clearly, the assignment of such a weak Cu···Cu EXAFS signal in the FT spectra displayed in Figure 1(A) would again be problematic because it is feared that this signal could interfere with the intense contributions of multiple-scattering paths involving the nitrogen atoms of the cyclam ligand. This is where a difference analysis can offer a decisive simplification of the spectra. Based on our experience, only a heavy scatterer like a copper atom could give such a strong signature at a long distance in the FT difference spectrum.

A simulation of the difference spectrum that is also reproduced in Figure 1(B) supports our interpretation. Using phase-shifts and scattering amplitudes calculated with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

FEFF8.9 for the same Cu–dioxygen model compound,[20] the best agreement was obtained for $R_{Cu-Cu} = 3.99 \pm 0.03$ Å; $[\sigma_{Cu-Cu}]^2 = 0.0032$ Å^2 in the oxygenated xerogel **XB2**; $R_{Cu-Cu} = 3.89 \pm 0.02$ Å; $[\sigma_{Cu-Cu}]^2 = 0.0032$ Å^2 in the oxygen-free xerogel **XB1**. The number density $N_{Cu-Cu} = 0.76$ was found (within the experimental uncertainty) to be equal to N_{Cu-O1}, which indeed supports the consistency of our assignment. Multiple scattering (MS) paths involving the coordination shell and the central atom are well-known sources of complication in the analyses of the EXAFS spectra at long distances but they should not play a major role here because: (i) the contribution of the MS paths involving copper and the nitrogen atoms of the first shell should cancel out in the difference as well as the contribution of the single scattering (SS) paths; (ii) MS paths involving oxygen or chlorine atoms cannot contribute to a signal that would be as intense or even more intense than the contribution of the first shell SS path. These considerations were supported by many more simulations, which are not reproduced in this paper.

Insight into the dioxygen species that is formed in the oxygenated xerogel **XB2** can also be drawn from solution chemistry of copper(I) complexes or from a systematic review of the crystal structures of Cu–dioxygen complexes.[29,30] The oxygenation of Cu^I complexes can generate three types of 2:1 Cu/O_2 species: an end-on *trans*-1,2-peroxodicopper(II), a side-on μ-η^2:η^2-peroxodicopper(II) and a bis(μ-oxo)dicopper(III) complex. The nature of the species that forms is primarily dictated by the denticity of the ligand.[30] In particular, the oxygenation of Cu^I complexes of sterically unhindered tetradendate tripodal ligands exclusively produces μ-1,2-peroxo complexes. Beyond denticity, other factors such as chelate ring size, nature of the donor atoms, electronic effects, steric demands and geometry are secondary in most cases. It appears that the internuclear distance R_{Cu-Cu} found for xerogel **XB2** would be significantly longer than the Cu···Cu distances in side-on dinuclear μ-η^2:η^2-peroxo copper complexes but shorter than in the end-on dinuclear *trans* μ-η^1:η^1-peroxo copper complex of Karlin et al.[31] ($R_{Cu-Cu} = 4.36$ Å). A side-on conformation should be ruled out for two reasons: (i) each dioxygen molecule would contribute to four equivalent Cu–O1 bonds and the signal at 1.86 Å should thus be twice as intense as what we found; (ii) for a coplanar side-on conformation, there is a limit ($R_{Cu-Cu} \approx 3.6$ Å) beyond which the four equivalent Cu–O1 bonds would split into two groups of unequal distances: $R_{Cu-O1} \leq R_{Cu-O2}$ and the end-on arrangement gains a higher probability.

Because no Cu/O_2 intermediate has been characterized, upon oxygenation in solution, for a tetrasubstitued cyclam copper(I) complex, one has to rely on comparisons with other tetradendate systems. In this regard, the aliphatic tetraamine ligands derived from tris(2-aminoethyl)amine (tren) are considered as good models of the immobilized cyclams although the former are not macrocyclic.[33–35] These ligands form μ-1,2-peroxodicopper(II) species, and accordingly, it is more likely that the reaction of xerogel **XB1** and dioxygen leads to the formation of an end-on μ-1,2-peroxodicopper(II) complex, in conformity with the EXAFS results. Yet, the Cu–Cu distance of 4.0 Å, shorter than in structurally characterized μ-1,2-peroxodicopper(II) complexes, suggests a distorted arrangement of the peroxo moiety.

We may then raise the subsidiary question whether there is any additional information available in the difference spectrum that could give us some indication about R_{Cu-O2}. We wish to underline that the following exercise is far more speculative than the previous assignments of the Cu···O1 and Cu···Cu signatures. We tried to assign the single scattering contribution of the second oxygen to the (next) most intense peak of the FT difference spectrum, i.e. to a signal peak at $R_{Cu-O2} \approx 2.96$ Å. One could find a few arguments supporting this very speculative assignment: (i) the signal had the expected phase for a Cu···O shell; (ii) this signal also shows up in the FT spectrum of xerogel **XB2** displayed in Figure 1(A) and, thus, cannot be an experimental artefact; (iii) to remain consistent with $R_{Cu-Cu} \approx 4$ Å, we have added the constraint: $R_{Cu-O2} \leq 3.02$ Å, but steric hindrance from the carbon atoms of the *N*-propyl groups would make distances $R_{Cu-O2} \leq 2.7$ Å very unlikely. A tentative estimation of the Cu–O1–O2 angle is possible only if we assume that the distance $d_{O1-O2} = 1.432$ Å as in the end-on peroxo structure of Karlin et al.[31] To a first approximation, one would calculate a bent angle Cu–O1–O2 of 127.7° to be compared with 108° in the structure of Karlin et al.[31] Recall that Kitajima et al.[20] predicted that, for pentacoordinate copper sites, the end-on dinuclear μ-η^1:η^1-peroxo-like structure should be the most favorable structure with Cu–O–O angles of the order of 130°. Our speculative assignment of the signal peaking at ca. 2.96 Å to the Cu···O2 single scattering path had another geometrical implication in that the distance Cu···Cu would be too short to enable the sequence of four atoms {Cu1···O1···O2···Cu2} be coplanar. From elementary 3D geometry considerations, we found that the directions of the Cu1–O1 and Cu2–O2 bonds should be rotated by ca. 93° with respect to each other. This would be required to minimize the steric hindrance between the two macrocyclic ligands.

We have implicitly suggested so far that dinuclear sites {Cu1;Cu2} should pre-exist in the oxygen-free xerogel **XB1**. Supporting arguments were found in the EXAFS spectra recorded at the Cl K-edge. The Cl K-edge FT spectra $\mathrm{Im}\tilde{\chi}_N(R)$ of the oxygen-free and oxygenated xerogels **XB1** and **XB2**, respectively, are shown in Figure 2(A) whereas difference FT spectra of the virtual species [**XB1**-**XB2**] are displayed in Figure 2(B). Here, the optical FT spectra were systematically corrected using the phase shifts and scattering amplitudes of a Cl···Cu shell. We carefully checked the consistency of our E_0 value with respect to earlier analyses of other model compounds involving Cl···Metal distances. At short distances, there are unbalanced contributions of Cu^I sites and pentacoordinate Cu^{II} sites with well-resolved signatures peaking at: $R_{Cl-Cu^I} = 2.11 \pm 0.03$ Å, and $R_{Cl-Cu^{II}} = 2.44 \pm 0.03$ Å, respectively. Interestingly, we also found a well-defined signal at a long distance: $R_{Cl-Cu} \geq 2.71 \pm 0.03$ Å which seems to agree with our suspicion

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that the Cl^- ions could asymmetrically bridge the copper sites.

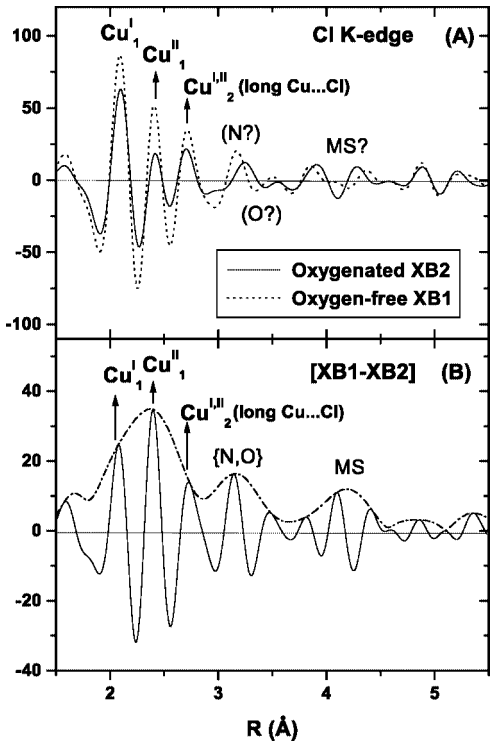

Figure 2. (A) Comparison of the Cl K-edge FT EXAFS spectra $Im\tilde{\chi}(R)$ of xerogel **XB2**[$CuCl_2$]/O_2 (solid line) and of xerogel **XB1**[$CuCl_2$]/N_2 (dotted line). Arrows mark the expected Cl···Cu distances for Cu^I–Cl and Cu^{II}–Cl bonds. The signal at 2.7 Å would be consistent with a Cl anion bridging mixed-valence $\{Cu^I,Cu^{II}\}$ sites. (B) Cl K-edge FT spectra $Im\tilde{\chi}(R)$ (solid line) and $|\tilde{\chi}(R)|$ (dot-dashed line) of the difference EXAFS signal of [**XB1** (oxygen-free) – **XB2** (oxygenated)].

Thus, we were led to seriously consider the existence of mixed-valence Cu^I and Cu^{II} sites. Note that the long distance $R_{Cl–Cu_2}$ looks quite comparable with distances (e.g. 2.674–2.707 Å) reported for chloride ions bridging mixed-valence dinuclear $\{Cu^I,Cu^{II}\}$ sites.[36] Such distances are, however, only slightly shorter than the distances (2.71–2.76 Å) found for chloride ions symmetrically bridging two Cu^{II} sites in copper hydroxychloride minerals[21,23,24] (e.g. atacamite). Cl K-edge EXAFS data are not accurate enough to discriminate between these two structural options. However, from the estimated Cu1···Cu2 distance in the deoxy-xerogel **XB1** ($R_{Cu1–Cu2} \approx 3.89$ Å), one would predict the bridging angle Cu1–Cl–Cu2 to be either 97° or 105° depending on whether Cu1 is taken as a Cu^I or a pentacoordinate Cu^{II} site. This compares rather well with the bridging angle (92°) reported for chloride ions in mixed-valence dinuclear $\{Cu^I,Cu^{II}\}$ sites.[36]

Concentrating on the FT spectrum of the oxygenated xerogel **XB2**, we found [Figure 2(A)–2(B)] only a modest amplitude reduction of the Cu^I–Cl signal while the signature of the pentacoordinate Cu^{II}–Cl site vanished completely. This rather astonishing result was confirmed a posteriori by re-investigating the Cu K-edge FT difference spectra. From Figure 1(B) we identified a positive peak at $R_{Cu^{II}–Cl} \approx 2.44$ Å together with a poorly resolved side-peak at $R_{Cu^I–Cl} \approx 2.10$ Å. There might still be an additional signal correlated with the long Cl··Cu2 distance ($R_{Cu–Cl} \approx 2.7$ Å) but it would be interfering with the signal, which we had previously assigned to the Cu1···O2 signature. These various Cu···Cl signatures are expected to appear as positive peaks in the FT difference spectrum of [**XB2-XB1**] as a consequence of the difference in the phase shifts of oxygen and chlorine scattering atoms. As far as we are concerned, the main interest of this exercise was essentially to probe the self-consistency of our assignments in the difference analyses.

At this stage, we tried to summarize in Figure 3 the possible structures of the Cu sites in the active xerogels. According to our analyses, up to four different Cu sites could coexist in xerogels **XB1** and **XB2**. In Figure 3(A), we sketched what a dinuclear site corresponding to the dioxygen adduct in **XB2** could look like. There is probably a small shift (≈ 0.2 Å ?) of the Cu atoms out of the average nitrogen plane and, most likely, also a trigonal distortion of the Cu^I–N bonds but there is no hope as yet of extracting this information from the EXAFS spectra. Moreover, any distortion of this type referring to the cyclam ligand should already pre-exist in the oxygen-free xerogel. From Figure 3(A), we realized that steric hindrance of the carbons (Cα) located on the same side of the cyclam as the dioxygen adduct should probably define the most stable configuration.

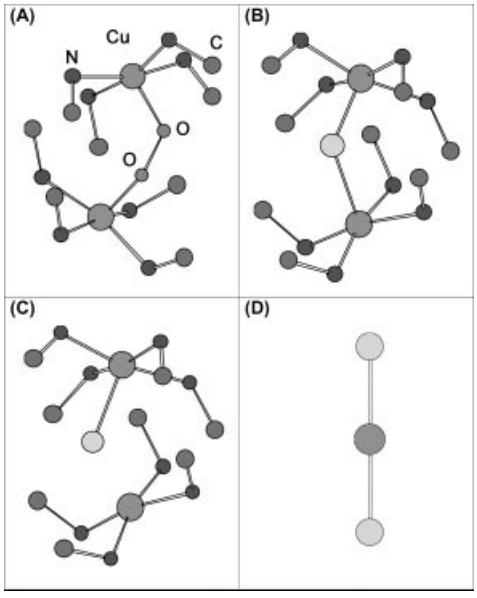

Figure 3. (A) Stereogeometry of the dinuclear μ-η^1:η^1 peroxo-like Cu site consistent with the difference EXAFS analysis with: $R_{Cu–O1}$ = 1.855 Å; $R_{Cu–O2}$ = 2.965 Å; $R_{Cu–Cu}$ = 3.988 Å. The Cu atoms were arbitrarily shifted by 0.2 Å from the average 4-N plane whereas the Cu–O bond had to be tilted by 10° with respect to the cyclam axes in order to minimize the steric hindrance of the carbons. (B) Stereogeometry of the postulated mixed-valence $\{Cu^I,Cu^{II}\}$ dinuclear site in xerogel **XB1**. (C) Stereogeometry of tetra- and pentacoordinate Cu^{II} sites coexisting only in xerogel **XB1**. (D) Linear counterion [Cl---Cu^I---Cl] identified in species **6**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

With regards to the oxygen-free xerogel, a dinuclear site in which a chloride ion would bridge two pentacoordinate copper atoms with a formal valence of 1.5 would be unstable since the system would spontaneously evolve towards configurations sketched in Figure 3(B) and (C). The dinuclear configuration of Figure 3(B) would be most convincing for a mixed-valence $\{Cu^{I},Cu^{II}\}$ species, i.e. with a pentacoordinate Cu^{I} site, a short Cu^{I}–Cl bond (2.11 Å) and a long distance Cl–Cu^{II} (2.7 Å). In the configuration of Figure 3(C), the Cu^{II} site would be pentacoordinate with the intermediary bond length $R_{Cu^{II}–Cl} \approx 2.44$ Å and the bare, tetracoordinate Cu^{I} site could easily be oxidized. Dynamic exchanges between configurations (B) and (C) would require only a small translation of the bridging chlorine atom. Last but not least, EXAFS cannot rule out at this stage the presence of linear anions $[Cl{-}{-}{-}Cu^{I}{-}{-}{-}Cl]^{-}$ [Figure 3(D)] as discussed for complex **6** (see Supporting Information).

Building on these considerations, we have generated a simulated spectrum, which approaches the experimental Cu K-edge FT difference spectrum of Figure 1(B) reasonably well. Indeed, we do not pretend that the structural problem has been solved but, at least, we come up with a model that is consistent with all EXAFS analyses. For convenience, we assumed that the signals observed at $R \approx 3.15$ Å could be assigned to the shortest intermolecular distance Cu2···C′α3. The parameters defining the scattering paths contributing to the simulated difference spectrum displayed in Figure 1(B) are listed in Table S1 of the supporting information section. The contribution of the MS paths was found to be marginal in this exercise.

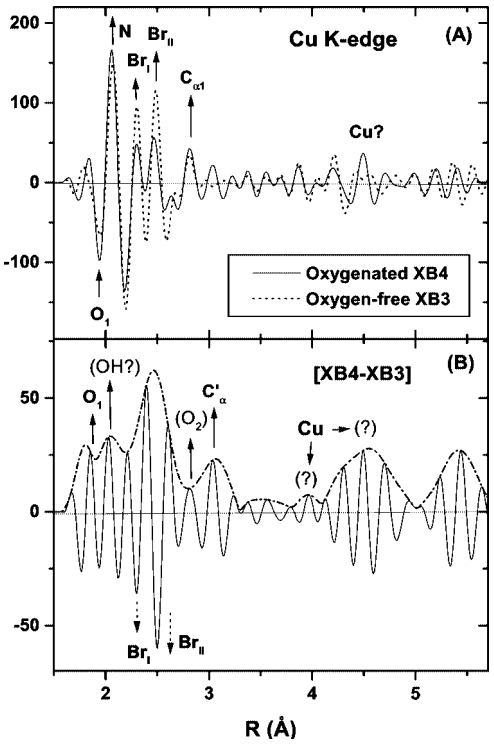

Figure 4. (A) Comparison of the Cu K-edge FT EXAFS spectra $Im\tilde{\chi}(R)$ of xerogel **XB4**$[CuBr_2]/O_2$ (solid line) and xerogel **XB3**$[CuBr_2]/N_2$ (dotted line). The split contributions of the Cu^{I}–Br and Cu^{II}–Br bonds are identified as (Br_I) and (Br_{II}). (B) Cu K-edge FT spectra Im $\tilde{\chi}(R)$ (solid line) and $|\tilde{\chi}(R)|$ (dot-dashed line) of the difference EXAFS signal of [**XB4** (oxygenated) – **XB3** (oxygen-free)]. Note the weaker amplitude of the Cu···O_1 signal.

Xerogels of Type (B) Complexed with $CuBr_2$

The Cu K-edge FT EXAFS spectra $Im\tilde{\chi}_N(R)$ of the oxygenated xerogel **XB4** and of the oxygen-free xerogel **XB3** complexed with $CuBr_2$ are compared in Figure 4(A). The FT difference spectra of the virtual species [**XB4**–**XB3**] is again reproduced in Figure 4(B). On comparing the FT spectra displayed in Figure 1(A) and Figure 4(A), it would appear that the peak assigned to the Cu···N distances is less intense and slightly shifted towards long distances in the xerogels complexed with $CuBr_2$, the average bond length increasing from 2.02Å to ca. 2.06 Å. In the FT spectrum of the oxygen-free xerogel **XB3**, there is clear evidence that bromine atoms are present in the coordination shell of copper and a refined EXAFS analysis suggested that two different Cu–Br bond lengths should be envisaged. The shortest one ($R = 2.30 \pm 0.02$ Å) would again fall very close to the Cu–Br bond length of the linear anion[37] $[Br{-}{-}{-}Cu^{I}{-}{-}{-}Br]^{-}$ and would be shorter than the Cu–Br bond length[38] in $[Cu^{I}–Br_3]^{2-}$; the long distance ($R = 2.49 \pm 0.02$ Å) would be typical of a pentacoordinate Cu^{II} complex.[39] These two resolved signals were identified as Br_I and Br_{II} in Figure 4(A) and Figure 4(B). Thus, there is again a strong indication that mixed-valence $\{Cu^{I},Cu^{II}\}$ sites[40–42] could be present in these xerogels, the signature of the Cu^{I} site being definitively less intense than the signature of the Cu^{II} site.

Independent chemical tests had previously established that the capability of xerogel **XB3** to fix dioxygen was rather poor as compared to xerogel **XB1**. This could be correlated with our observation that the difference FT spectrum of Figure 4(B) exhibits only a very weak signal at the short distance $R_{Cu–O1} = 1.86$ Å where we expect the characteristic signature of the formation of the same end-on dinuclear μ-η^1:η^1-peroxo structure discussed in the previous section.

It should be noted that the difference signals in Figure 4(B) are much less intense than in Figure 1(B). Also, the situation looks more confusing at further distances where the signature at $R_{Cu–Cu} = 3.99$ Å is now very weak whereas new signatures show up at 4.2–4.5 Å. This is not completely unexpected since: (i) the amount of dinuclear peroxo-like complex is certainly heavily reduced; (ii) we would have been suspicious if we had found the same internuclear Cu···Cu distance for the oxygen-free xerogels complexed either with $CuBr_2$ (**XB3**) or with $CuCl_2$ (**XB1**). Anyhow, the signals that show up at 4.2–4.5 Å are weak on the scale of Figure 1(B) and we clearly approach the noise limit of difference analyses.

Nevertheless, one may question why the structural changes between xerogels **XB4** and **XB3** should be so small. One could speculate that, in the presence of trapped water molecules, the dioxygen adduct would be partly and irreversibly decomposed to yield $Cu^{I,II}$–OH bonds (1.87/2.00 Å), with the OH^{-} anions replacing the released bromide anions. This would explain the presence of imperfectly

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

resolved signatures at 1.86/1.99 Å in Figure 4(B). Note that one would also expect longer Cu···Cu distances if there is no more bridging Br^- anion.

Inactive Xerogels Complexed with $CuCl_2$

The FT spectra $Im\tilde{\chi}_N(R)$ of the inactive xerogel **XA1** and of the oxygen-free, active xerogel **XB1** are now compared in Figure 5A. The strong signal peaking at 2.002 Å in the FT spectrum of **XA1** is most likely to be assigned once again to Cu···N distances. If one assumes that this peak refers to the average R_{Cu-N} bond length, then the corresponding bond length would be shorter than in the active xerogel **XB1** ($R_{Cu-N} \approx 2.022$ Å) and also much shorter than in model compound **6** or in its silylated precursor ($R_{Cu-N} \approx 2.13$ Å). In EXAFS, a shorter bond length is most often correlated with a stronger intensity but, quite paradoxically, the intensity of the Cu···N signal in the inactive xerogel **XA1** is reduced by ca. 30% with respect to xerogel **XB1**. In fact the intensity of the Cu···N peak is similar to the intensity of the Cu···N peak in **6** in which we pointed out the role of a destructive interference. The FT spectrum of xerogel **XA1** exhibits a well resolved negative signal peaking at 2.28 Å which one might be tempted to assign to a Cu···Cl distance. Unfortunately, such a speculative assignment would not make any sense because all crystal structures reported so far show that in pentacoordinate Cu^{II} complexes the Cu–Cl bond length is of the order of $R_{Cu-Cl} \approx 2.44$–2.47 Å as discussed earlier and illustrated by model compound **6**. There are still signatures in the FT spectrum of **XA1** which could be perfectly assigned to Cu···Cα1 and Cu···Cα2 single scattering paths and would indicate that the copper atoms are coordinated to the cyclam although the conformation of the macrocyclic ligand is certainly not the same as in the active xerogels.

We suspect that, in xerogel **XA1**, the EXAFS signal of the Cu···N distances are heavily distorted by destructive interferences within the coordination polyhedron. The negative side-lobes of the Cu···N peak are anomalously small and distorted which fuelled our suspicions. In a desperate attempt to recover some structural information lost in destructive interferences, we tried to display in Figure 5(B) the difference spectra of the virtual species [**XA1-XB1**] and [**XA1-XB2**]. The rather strong intensity of the signatures found in the FT difference spectrum of [**XA1-XB1**] confirms that the copper environment is fundamentally different in these two xerogels but, at this stage, a detailed interpretation of the difference spectrum is hopeless. If we restrict ourselves to the coordination shell, we may conjecture that there should be at least two additional signatures interfering with the Cu···N signal in the EXAFS spectrum of the inactive xerogel **XA1**: (i) the first one peaking at ca. 1.9 Å looks most typical of Cu···OH distances; (ii) the second one peaking at ca. 2.15 Å might well reflect a distortion of the cyclam macrocycle resulting in two sets of Cu···N bond lengths, e.g. 2.03 Å and 2.15 Å. It has been pointed out a while ago by Barefield and Wagner[6] that macrocycles with tertiary amines such as tetramethylcyclam could accommodate a sixth ligand at short distance with a significant folding of the macrocycle resulting in two pairs of nonequal Cu–N bonds. Such an interpretation could perhaps be consistent with the FT difference spectra of Figure 5(B). However, this is one interpretation amongst several. At a purely speculative level, we also considered the case of a dinuclear copper site now bridged with two OH^- anions. This model would explain why xerogel **XA1** could not bind anymore dioxygen. The present EXAFS study was nevertheless worth the time and effort involved: (i) it gave the experimental proof that xerogels **XA1** and **XB1** have fairly different local structures; (ii) and also that subtle changes in the coordination geometry of the cyclam would yield strong Cu···N residual signatures around 2.0(3) Å in the FT difference spectra. A contrario, the latter point supports the consistency of our difference analysis of xerogels **XB1** and **XB2**.

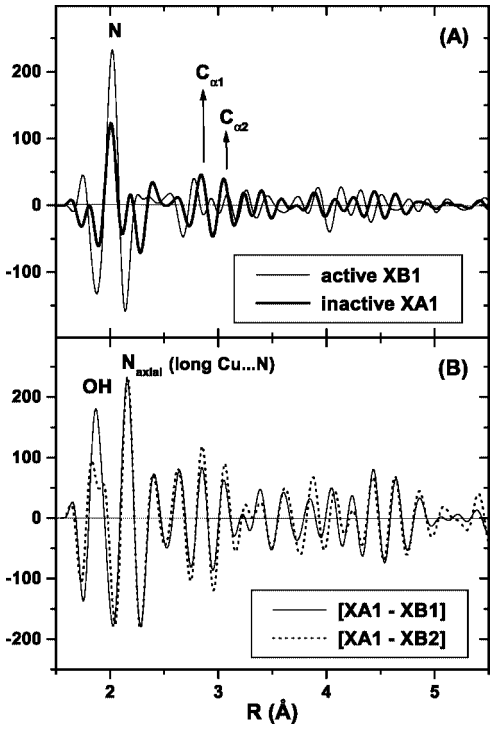

Figure 5. (A) Comparison of the FT spectra $Im\tilde{\chi}(R)$ of the inactive xerogel **XA1**[$CuCl_2$]/air (thick line) and active xerogel **XB1**[$CuCl_2$]/N_2 (solid line). Note the poor intensity of the (distorted) Cu···N signal of the inactive xerogel **XA1**. (B) FT spectra $Im\tilde{\chi}(R)$ of the difference EXAFS of [**XA1** (inactive) – **XB1** (oxygen-free)] (solid line) and of [**XA1** (inactive) – **XB2** (oxygenated)] (dotted line). Note the well-resolved contributions of the interfering signatures assigned to additional Cu···O and Cu···N single scattering paths.

Valence and Ligand Field Information

XANES Spectra as Fingerprints

We have regrouped in Figure 6(A) the deconvoluted Cu K-edge XANES spectra of all active xerogels, i.e the oxygen-free xerogels **XB1**[$CuCl_2$] or **XB3**[$CuBr_2$] and the oxygenated species **XB2**[$CuCl_2$]/O_2 or **XB4**[$CuBr_2$]/O_2. We have also added, on the same plot, the Cu K-edge XANES spectrum of the inactive xerogels **XA1**[$CuCl_2$]/Air. All spectra

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were recorded over the same energy range and were deconvoluted with the same parameters (i.e. ΔE_G; ΔE_L). Therefore, there is no extra difficulty in comparing deconvoluted spectra. Noticeably, the Cu K-edge XANES spectra of all active xerogels have the same morphology. The most characteristic features were labeled from (A) to (F). Quantitative information regarding the peak energy and relative intensity of the near-edge features (A)–(E) are summarized in Table 2S (supporting information section). Most striking is the very sharp "white line" (C) peaking at 8985.33 eV, the intensity of which decreases by only ca. 15% in air or dioxygen. In all XANES spectra, there is a shoulder labeled (D) which peaks at 8987.4 eV. It is particularly well resolved in the spectra of xerogels **XB1**[$CuCl_2$] and **XB2**[$CuCl_2$]. Much weaker but still quite real are the pre-edge structures (A) and (B) found at 8980.4 eV and 8983.3 eV, respectively. In the case of the inactive xerogel **XA1**, the white line (C) is not only shifted towards high energy but its intensity is reduced in the ratio 3:1 whereas the shoulder (D) seems to become progressively smaller.

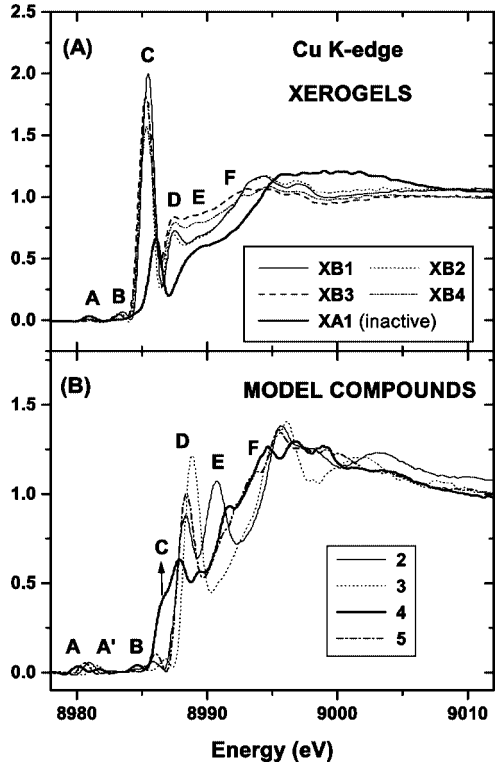

Figure 6. Numerically deconvoluted Cu K-edge XANES spectra. (A) XANES spectra of active xerogels: **XB1**[$CuCl_2$]/N_2; **XB2**[$CuCl_2$]/O_2; **XB3**[$CuBr_2$]/N_2 and **XB4**[$CuBr_2$]/O_2. The XANES spectrum of the inactive xerogel **XA1**[$CuCl_2$]/Air is also shown for comparison. The strong pre-edge resonance (C) is a characteristic feature of all XANES spectra of active xerogels. (B) Note the absence of any sharp resonance (C) in the Cu K-edge XANES spectra of various $[Cu(cyclam)]^{2+}$ complexes with variable coordination geometries: **2** = $Cu(cyclam)(ClO_4)_2{\cdot}0.5H_2O$; **3** = $[Cu(tmc)](BF_4)_2$; **4** = $[Cu(tmc)Cl](BF_4)$; **5** = $[Cu(dmdpc)](BF_4)_2$.

The Cu K-edge XANES spectra of model compounds **2**–**5** were regrouped in Figure 6(B). Clearly, the XANES spectra of tetra-, penta- or hexacoordinate cyclam complexes are quite different. The case of the pentacoordinate complex **4** is particularly relevant here since it was found to exhibit a marked analogy with the XANES spectrum of freshly prepared samples of the silylated precursor. We wish to stress that the sharp white line (C) is very weak in the XANES spectrum of such a pentacoordinate Cu^{II} complex.

The Cl K-edge XANES spectra of the oxygen-free xerogel **XB1** and of the oxygenated sample **XB2** are shown in Figure 7(A). We included on the same plot the Cl K-edge XANES spectrum of **6** which, according to the EXAFS study, should be a pentacoordinate complex of Cu^{II} contaminated with some fraction of the linear anion $[Cl{-}{-}{-}Cu^{I}{-}{-}{-}Cl]^{-}$. It immediately appears from Figure 7(A) that the morphology of the Cl K-edge XANES spectra of xerogels **XB1** and **XB2** is similar. Interestingly, the modest intensity of the pre-edge resonance labeled "A" peaking at 2819 eV in the case of complex **6** is very weak in the case of the active xerogels.

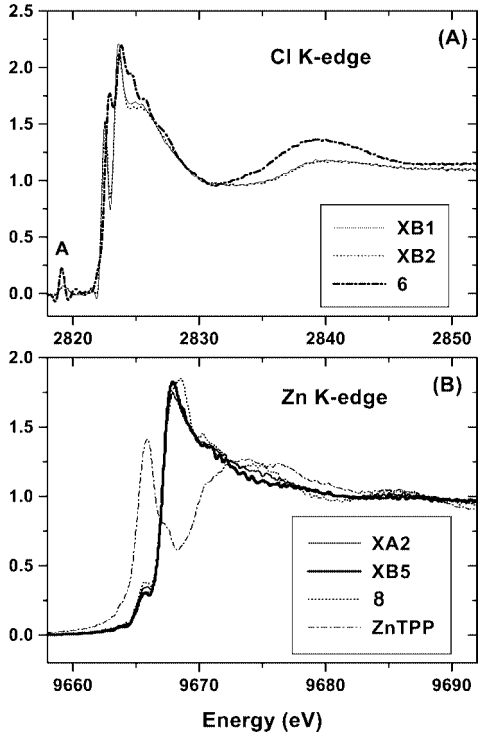

Figure 7. (A) Deconvoluted Cl K-edge XANES spectra of the active xerogels **XB1**[$CuCl_2$]/N_2 and **XB2**[$CuCl_2$]/O_2. The Cl K-edge XANES spectrum of the mixed-valence $\{Cu^{I},Cu^{II}\}$ complex **6** is also shown. It exhibits only a weak pre-edge resonance (A) at 2819 eV that vanishes for Cu^{I} compounds. (B) Deconvoluted Zn K-edge XANES spectra of xerogels **XA2**[$ZnCl_2$]/Air, **XB5**[$ZnCl_2$]/Air and of the zinc complex **8**. The XANES spectrum of Zn(TPP) was added as a reference.

This resonance was reported by Hedman et al.[43] to reflect the amount of ligand character in the antibonding orbital $(1 - \alpha^2)^{1/2}(Cu\ 3d_{x^2-y^2}) - \alpha(Cl\ 3p)$ of Cu^{II} compounds. In Cu^{I} compounds as well as in the linear anion $[Cl{-}{-}{-}Cu^{I}{-}{-}{-}Cl]^{-}$, this resonance should become much weaker because the Cu 3d orbitals should become nearly filled just as in the case of the Zn 3d orbitals of $ZnCl_2$. Figure 7(A) would thus confirm that the copper atoms in xerogels **XB1** or **XB2**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

could hardly be "standard" Cu^{II} sites, as already anticipated from their EXAFS spectra.

The Zn K-edge XANES spectra of xerogels **XA2**[$ZnCl_2$], **XB5**[$ZnCl_2$] and of the silylated zinc complex **8** are displayed in Figure 7(B). The XANES spectrum of the zinc porphyrin Zn(TPP) was included as a reference. Substituting $ZnCl_2$ for $CuCl_2$ yields xerogels of type (A) and (B) that may still be slightly different but the differences in their XANES spectra become much more subtle. Here the XANES spectra of the xerogels are dominated by a single, sharp white line peaking at 9669 eV. The very weak pre-edge shoulder is consistent with a limited contribution of 3d atomic orbitals of Zn to the empty excited states. Obviously there seems to be a much stronger charge transfer from the metal to the porphyrin dianion in the case of Zn(TPP).

Simulation of XANES Spectra

In the previous section, the XANES spectra were used as sensitive fingerprints of the coordination geometry and electronic structure of the Cu sites in the xerogels. One may wonder whether ab initio simulations could help us to correlate quantitatively the observed changes with the electronic structure and the geometrical arrangement of the cyclam units. We will concentrate on two questions: (i) can we reproduce the very sharp, intense resonance (C) peak at 8986.8 eV? (ii) can we find any reliable indication that Cu^{I} sites exist in xerogels of type (B)? This is important because there is no known example of dioxygen reversibly bound to true Cu^{II} sites. We compare in Figure 8(A), Figure 8(B) and Figure 8(C), the deconvoluted experimental XANES spectra of model compounds **1**, **2** and **5** with simulated XANES spectra calculated with the MSW option of the code FDMNES, i.e. using muffin-tin potentials and the Xα functional density for exchange correlation. In each case, the geometry of the molecular cluster is systematically shown.

For the copper porphyrin **1**, we used the same muffin-tin radii as Case and Karplus[44] who already stressed that the ground state, formally written as Cu^{II} ($3d^9$) could easily transform into Cu^{I} ($3d^{10}$) by charge transfer excitation. As illustrated with Figure 8(A), the agreement between the deconvoluted experimental spectrum and our simulation looks encouraging. The simulated spectrum of Figure 8(A) reproduces the strong pre-edge resonance which was found to be highly sensitive to the charge transfer from the aromatic pyrrole towards the copper atom. The best agreement with the experimental results was obtained from the following occupation of the valence atomic orbitals: [Cu $3d^{9.40}$, $4s^{0.20}$; N $(2s2p)^{4.97}$; $C_{pyrrole}$, C_{meso} $(2s2p)^{4.10}$, C_{phenyl} $(2s2p)^{3.98}$] whereas the muffin-tin zero had to be adjusted to $V0_{imp}$ = –16.0 eV. It is not surprising that the MS calculation cannot reproduce the relative amplitudes and linewidths of the various shape resonances (especially beyond the edge) because the deconvolution is not perfect, whereas the FDMNES code takes into account only the real part of the Hedin–Lundqvist exchange-correlation potential but not its imaginary part.

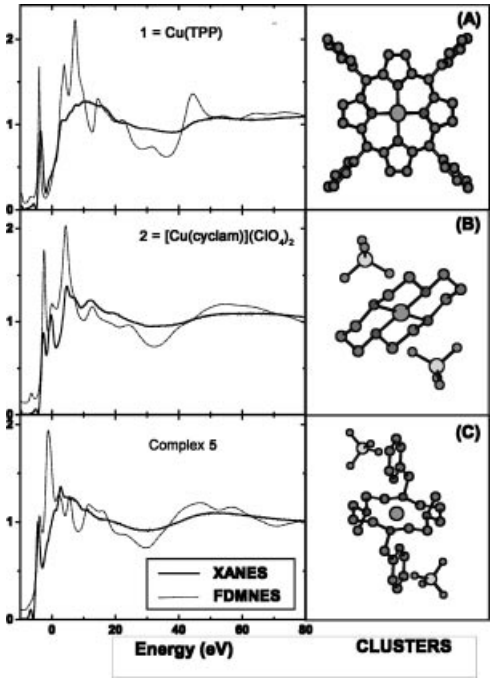

Figure 8. MSW simulations of the XANES spectra of model compounds: (A) **1** = Cu(TPP); (B) **2** = [Cu(cyclam)]$(ClO_4)_2$·0.5H_2O; (C) **5** = [Cu(dmdpc)]$(BF_4)_2$. Deconvoluted experimental spectra are shown again for comparison.

As illustrated with Figure 8(B) and Figure 8(C), our simulations of the XANES spectra of complexes **2** and **5** also look rather encouraging. Here, we expect a different charge delocalization because the cyclam macrocycles are neutral whereas the porphyrin macrocycle is a dianion. We kept the same muffin-tin radii as for the simulation of the copper porphyrin but we changed the occupation of the valence atomic orbitals. Since the crystal structure of species **2** is unknown, we incorporated the crystal structure of **2′** = [Cu(cyclam)]$(ClO_4)_2$, in which the two perchlorate anions are only very weakly bound at long distances, into our calculation. Nevertheless, Figure 8(B) reveals that the simulated XANES spectrum of species **2′** is very similar to the experimental spectrum of complex **2** which implies that **2** is most likely tetracoordinate. We used the following occupancy of the valence atomic orbitals: [Cu $3d^{9.46}$, $4s^{0.26}$; N $(2s2p)^{4.74}$; O_{axial} $(2s2p)^{6.40}$], the muffin-tin zero being now arbitrarily adjusted to $V0_{imp}$ = –18.5 eV. Note that the resonance doublet in the edge is remarkably well reproduced. For the hexacoordinate complex **5**, the best agreement with the experimental spectrum was obtained with the following occupation of the valence atomic orbitals: [Cu $3d^{9.72}$, $4s^{0.22}$; N_{equat} $(2s2p)^{4.64,\ 4.71}$; N_{axial} $(2s2p)^{4.92}$], the muffin-tin zero now being shifted to $V0_{imp}$ = –21.5 eV.

In contrast, we systematically failed to reproduce the XANES spectra of the xerogel **XB1**. In particular, we never succeeded in reproducing the sharp resonance (C) peaking at 8985.4 eV. These negative results led us to envisage that the XANES spectrum of xerogel **XB1** should result from two contributions; the first one being formally associated with a Cu^{I} ($3d^{10}$) site and the second one to a Cu^{II} ($3d^9$)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

site. This required us to perform two consecutive calculations, i.e. one for each individual copper site. The difficulty is that we need a consistent calibration of the energy scale of these two spectra. Unfortunately, standard multiple scattering calculations are not reliable enough for such an exercise because the muffin-tin zero (V0) depends on the different occupation of the valence orbitals for a given copper site. This stimulated us to run the FDM option of the FDMNES code since no muffin-tin approximation is made, V0 will no longer be defined. In order to avoid a prohibitive computing time, we have performed a test calculation with a simplified dinuclear cluster in which the two copper atoms were asymmetrically bridged by one chlorine atom. The macrocyclic ligand surrounding each absorbing site was restricted to four nitrogen atoms and twelve α carbons. For the first calculation, the absorbing atom was the Cu^{I} site ($1s^1$; $3d^{10}$; $4s^{0.1}$; $4p^{0.2}$), the Cu^{II} site ($1s^2$; $3d^9$; $4s^{0.1}$; $4p^{0.2}$) contributing as a scattering atom; for the second calculation, the role of the two sites was exchanged. For simplicity, no screening effect was taken into account for the Cu^{I} site. With regards to the other scattering atoms, we extrapolated the population of the atomic orbitals from previous calculations, i.e. N_{equat} $(2s2p)^{4.58,4.60}$; Cl $(3s3p)^{7.84}$; C $(2s2p)^{4.04}$. The calculated atomic photo-ionization energies of the Cu^{I} and Cu^{II} sites were ε_{ii} = 9071.24 eV and 9059.964 eV, respectively.

The XANES spectra simulating the resolved contributions of equipopulated $\{Cu^{I};Cu^{II}\}$ sites are compared in Figure 9 in which we also reproduced the XANES spectrum of xerogel **XB1**. Since it is a usual trend of FDM calculations to generate sharp resonance lines, we found it preferable to numerically convolute the simulated XANES spectra with Lorentzian lineshapes centered at the Fermi energy E_F (Lorentzian half-width: Γ = 0.1–0.2 eV). The key conclusion is that resonances (A) (B), (C), (D) are most likely to be assigned to Cu^{I} sites, whereas resonances (E), (F) should involve the Cu^{II} site. We would like to emphasize that this is the first simulation in which resonance (C) could be reproduced with a strong intensity and we observed that this line would not depend so much on the internuclear distance $R_{Cu–Cu}$.

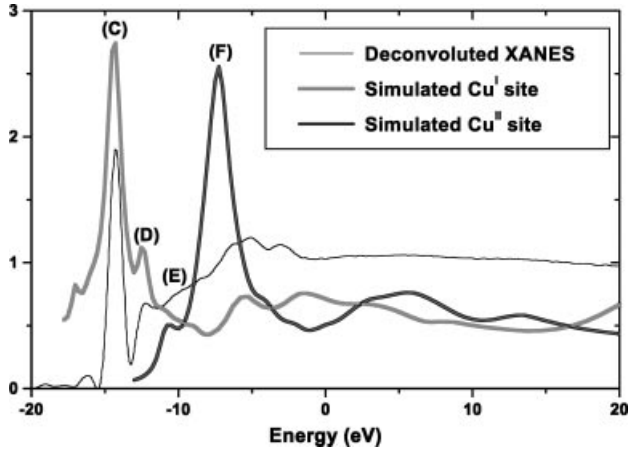

Figure 9. Simulated XANES spectra of mixed-valence $\{Cu^{I};Cu^{II}\}$ sites. The resolved contributions of the Cu^{I} and Cu^{II} sites were simulated using the *Finite Difference* option of the code FDMNES. A deconvoluted XANES spectrum of xerogel **XB1** is reproduced again for comparison. Note that resonance (C) is most likely to be assigned to the Cu^{I} site.

Conclusion

FT difference analyses at the Cu K-edge gave a strong indication that, in the oxygenated xerogel **XB2**, dioxygen would bridge two copper atoms in a kind of end-on μ-η^1:η^1 peroxo-like conformation with a short Cu–O1 distance: $R_{Cu–O1}$ = 1.855 ± 0.005 Å but with a rather long internuclear distance: $R_{Cu–Cu} \approx$ 4.0 Å. The number density $N_{Cu–O1}$ = 0.75 ± 0.1 agrees fairly well with independent measurements of O_2 adsorption (38% per copper site). There is no doubt that in both the oxygenated (**XB2**) and the oxygen-free (**XB1**) xerogels the Cu atoms are still complexed by the cyclam units. This is proved by the presence in the FT spectra of each individual xerogel of characteristic signatures assigned to the Cu···N and Cu···Cα1 single scattering paths at typical distances: $R_{Cu–N}$ = 2.02(2) Å and $R_{Cu–Cα1}$ = 2.8(8) Å, respectively. Interestingly, there is no evidence of a structural rearrangement affecting the coordination of the cyclam macrocycle in the oxygenated xerogel. This may not be so surprising if the substituted macrocycle is totally immobilized within the rigid inorganic polymeric structure of the xerogel. This could explain the reactivity of these xerogels towards dioxygen and why dioxygen is bound almost reversibly.

If we retain the model of an end-on peroxo-like conformation, then one should also observe the weaker signature of a second single scattering path at a longer Cu···O2 distance. The best we could do was to assign, in a purely speculative way, this Cu···O2 signature to a residual signal found in the difference spectrum at $R_{Cu–O2}$ = 2.9(6) Å. If this assignment is correct, then the Cu–O1–O2 angle was estimated to be ca. 128° in noticeable agreement with arguments previously developed by Kitajima et al.[20] However, we wish to underline that the corresponding deductions relative to the stereogeometry of the complex are indirect and remain speculative.

The Cl K-edge EXAFS study turned out to be particularly informative in the case of the active xerogels **XB1** and **XB2**. It established that, in the oxygen-free xerogel **XB1**, we had pentacoordinate Cu sites with both short Cu^{I}–Cl bonds ($R \approx$ 2.11 ± 0.03 Å) and typical Cu^{II}–Cl bonds ($R \approx$ 2.44 ± 0.03 Å). Chloride ions may well asymmetrically bridge dinuclear, mixed-valence copper sites as suggested by the detection in the FT spectra of a characteristic signal at a long distance ($R \geq$ 2.7 Å). We found it somewhat amazing that in the oxygenated xerogel **XB2**, the amplitude of the Cu^{I}–Cl signal decreased by ca. 20% while the signature of the pentacoordinate Cu^{II}–Cl site vanished. This result was confirmed a posteriori by the FT difference analysis at the Cu K-edge once it became possible to identify the Cu···Cl signatures. Note that the released chloride anions are most probably disordered and could hardly contribute to any detectable EXAFS signal.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Substituting $CuBr_2$ for $CuCl_2$ yields xerogel **XB3**, known to be much less reactive. Such poor activity could be correlated with a cut by ca. 50% in the intensity of the $Cu\cdots O_1$ signal (R = 1.86 Å) in the FT difference spectrum of [**XB4**-**XB3**] where **XB4** denotes the relevant oxygenated xerogel. However, we found an additional signal at $R \approx 1.98$ Å which we assigned tentatively to the Cu^{II}–OH bond of a pentacoordinate mononuclear Cu site. Inactive xerogels prepared with metallated cyclams by route (A) were also found to have a fairly different structure. It seems that a major structural change had occurred during hydrolysis and polycondensation and it was speculated that a folded conformation of the cyclam would allow the copper atom to accommodate the coordination of two OH^- anions at short distances ($R \geq 1.9$ Å) while maintaining two short ($R \approx 2.00$ Å) and two long ($R \approx 2.15$ Å) Cu–N bonds. At this stage, no refined interpretation of the EXAFS spectra of the xerogels prepared by means of route (A) is possible.

Deconvoluted XANES spectra of all xerogels prepared by route (B), i.e. by incorporating $CuCl_2$ into the hybrid xerogel, exhibit a strong pre-edge resonance at 8985.4 eV which seems to be associated with the Cu^I site of a mixed-valence $\{Cu^I,Cu^{II}\}$ structure. Simulations of the XANES spectra of a number of model compounds were carried out with the standard MSW option of the code FDMNES and gave rather encouraging results. In contrast, we systematically failed to reproduce the XANES spectrum of xerogel **XB1** using the standard MSW approach. This is not too surprising since this XANES spectrum is expected to be the superposition of the individual contributions of Cu^I and Cu^{II} sites. Unfortunately, the relative chemical shift of the Cu^I and Cu^{II} pre-edge resonances cannot be reproduced accurately enough with MSW codes relying on the crude muffin-tin approximation. A very encouraging result was nevertheless obtained using the Finite Differences option of the advanced code FDMNES. A preliminary simulation carried out beyond the muffin-tin approximation allowed us to assign unambiguously the strong pre-edge resonance (C) at 8985.4 eV to a Cu^I site.

Experimental Section

Materials: The active/inactive xerogels were complexed with $CuCl_2$, $CuBr_2$ or $ZnCl_2$:

XA1 = Xerogel type (A)[$CuCl_2$]/Air **XA2** = Xerogel type (A)[$ZnCl_2$]/air

XB1 = Xerogel type (B)[$CuCl_2$]/N_2 **XB2** = Xerogel type (B)[$CuCl_2$] + O_2

XB3 = Xerogel type (B)[$CuBr_2$]/N_2 **XB4** = Xerogel type (B)[$CuBr_2$] + O_2

XB5 = Xerogel type (B)[$ZnCl_2$]/air

All details concerning the synthesis of the metallated xerogels can be found elsewhere.[11–13] Samples **XB1**-**XB4** were handled in vacuo in tight cells and filled in glove boxes. Model compounds used as reference for the XANES or EXAFS study included: **1** = Cu(TPP); **2** = Cu(cyclam)$(ClO_4)_2\cdot 0.5H_2O$; **3**[45] = [Cu(tmc)]$(BF_4)_2$; **4**[46] = [Cu(tmc)Cl](BF_4); **5**[46] = [Cu(dmdpc)]$(BF_4)_2$; **6** = [Cu(tpc)Cl]Cl; **7** = [Cu(tpsc)Cl]Cl; **8** = [Zn(tpsc)Cl]Cl. TPP denotes the (*meso*-5,10,15,20-tetraphenylporphyrinato) macrocyclic dianion; cyclam is the 1,4,8,11-tetraazacyclotetradecane ligand; tmc refers to the 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane macrocycle; dmdpc refers to the 1,8-dimethyl-4,11-bis(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane ligand; tpc and tpsc denote the 1,4,8,11-tetrapropyl-1,4,8,11-tetraazacyclotetradecane and the 1,4,8,11-tetrakis(trimethylsilylpropyl)-1,4,8,11-tetraazacyclotetradecane macrocycle, respectively.

Instruments and Methods: X-ray absorption and emission spectra were recorded with the ESRF beamline ID12.[47] The X-ray source is a helical undulator which, for the present project, was operated in the linear polarization mode. In order to scan EXAFS spectra over 2000 eV, we used the so-called "*gap-scan*" technique[48] which consists of optimizing the magnetic gap of the undulator during a scan of the monochromator in such a way that the energy of the monochromatic photons always matches the peak intensity of the undulator spectrum. The monochromator was equipped with a pair of Si (111) crystals cooled down to 152 K. The energy resolution was very close to the intrinsic limits, i.e. $\Delta E \approx 0.40$ eV at the Cl K-edge; $\Delta E \approx 1.56$ eV (1.72 eV) at the Cu (Zn)K-edges. The energy calibration was consistent with the SSRL criterion assigning the first inflexion point of the Cu foil XANES spectrum to 8980.3 eV.[49] Vertically focusing double mirrors (VFM) allowed us to keep the level of unwanted harmonics well below 5 orders of magnitude. EXAFS or XANES spectra were systematically recorded in the (integrated) Fluorescence Yield (FY) mode. Sample pellets were inserted in a vacuum-tight sample holder and were excited by the incident X-ray beam through a 12.5 μm thin Kapton window (5 mm active diameter). The sample holder (cooled down to 80 K) was itself located inside a high vacuum fluorescence chamber equipped with eight low noise photodiodes arranged in the backscattering geometry and collecting the fluorescence photons emitted over a wide solid angle. X-ray emission spectra were recorded in the spectral ranges of the Cu $K\beta_{1,3}$ (and $K\beta_{2,5}$) fluorescence lines using a high resolution spectrometer equipped with a spherically bent Si (220) crystal analyzer operated with the 440 reflection at a Bragg angle of 46.17°. The analyzer energy scale was calibrated against that of the double crystal monochromator by measuring the elastic scattering line of the reference sample **1**.

EXAFS Data Collection and Analyses: High quality Cu K-edge EXAFS spectra were recorded on model compounds **1** = Cu(TPP), **3** = [Cu(tmc)]$(BF_4)_2$ and **6** = [Cu(tpc)Cl]Cl as well as on xerogels **XA1**, **XB1**, **XB2**, **XB3** and **XB4**. For each sample, several long scans (2500 data points) were collected at low temperature (T = 80 K) over a very wide energy range [i.e. 8944–10941 eV]. No radiation damage was detected and all accumulated spectra could be averaged. EXAFS oscillations could be detected up to k = 20–22 $Å^{-1}$ in $k.\chi(k)$ spectra (Figures S1–S3 in the Supporting Information), even for the xerogels in which the metal concentration was rather low. We found a double benefit in collecting EXAFS data over a wide range in the momentum space: (i) the resolution of the FT spectra in the direct space was maximized; (ii) the identification of the signatures of heavy scattering atoms (i.e. Cu, Br or Cl) in the FT spectra by varying k_{max} in the window function was easier.

EXAFS spectra were also recorded at the Cl K-edge for xerogels **XB1** and **XB2**. The presence of a weak potassium K-edge signal at 3610 eV (associated with trace amounts of this element nonuniformly distributed over the Kapton window) in the spectra required us to truncate the $k\cdot\chi(k)$ spectra for $k \geq 14.4$ $Å^{-1}$ (see Figure S4 in the Supporting Information). A very weak argon K edge at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3200 eV was identified which was treated as a second order perturbation.

The EXAFS analyses followed standard procedures detailed elsewhere.[14] The spectra recorded in FY detection mode were systematically corrected for self-absorption.[14,50] Throughout this paper, phase and amplitude corrected "optical" FT spectra[14] were displayed. Phase shifts and backscattering amplitudes were generated using the code FEFF8.9.[51,52] Numerical fitting methods in both the direct and reciprocal spaces[14] were also available as options in our EXAFS data analysis package.

XANES: Numerical Deconvolution and ab initio Simulations: The convoluted effects of the core hole lifetime and of the finite energy resolution of the monochromator resulted in smooth but broad Voigt lineshapes, which restricted the possibility of resolving and assigning the pre-edge and shape resonances in the experimental XANES spectra. Following a strategy pioneered at the ESRF by Loeffen et al.,[53] the experimental XANES spectra were deconvoluted numerically in order to recover narrow lineshapes. The price to be paid was an artificial increase of the noise level in the XANES spectra. XANES spectra were simulated with the advanced code FDMNES which offers two options:

(i) Multiple Scattered Wave (MSW) calculations can be carried out with muffin-tin potentials spherically averaged in the atomic or outer-sphere regions but only volume-averaged in the interstitial region. In practice, the averaged muffin-tin zero ($V0_{imp}$) is a critical parameter that needs to be carefully adjusted. Muffin-tin radii can be automatically determined from standard prescriptions (e.g. using the Norman criterion[54]). Local electronic densities were obtained by superposition of atomic contributions but the Clementi–Roetti atomic wave functions[55] can be replaced by external wave functions taking into account relativistic effects (as in FEFF8.10). The occupancy of the valence orbitals can be artificially altered in order to simulate charge transfers between atoms that are no longer neutral. The Coulomb potential was then calculated by solving the Poisson equation where the energy dependent exchange-correlation potential was approximated either by a standard Xα functional density or by the real part of a Hedin–Lundqvist functional.[56]

(ii) In the finite-difference method (FDM)[57] the Schrödinger equation was solved over a grid of discrete points in a spherical volume centered at the absorbing atom. There is no need to introduce any artificial spherical symmetry or to define any interstitial region. This is most appreciable in the case of directional covalent bonding. In the present study, the lack of an arbitrarily defined muffin-tin zero was essential in order to accurately determine the contribution of Cu^{I} and Cu^{II} sites. The occupancy of the valence orbitals was artificially altered to simulate charge transfers between atoms just as in the MSW option. Unfortunately, FDM calculations resulted in a dramatic increase in computing time, which required us to perform our calculations on the powerful NEC SX-5 machine of the CNRS in Orsay (IDRIS).

Supporting Information Available (see also footnote on the first page of this article): This includes: (i) selected *raw* experimental EXAFS spectra; (ii) a detailed EXAFS study of model compounds **1**, **3** and **6**; (iii) Figure S7 illustrating the quality of the single shell fit of the Cu–O1 signal in the FT difference spectrum; (iv) Table S1 listing the parameters of scattering paths contributing to the simulated FT difference spectrum displayed in Figure 1(B); (v) a comparison of numerically deconvoluted and raw Cu K-edge XANES spectra for the model compound **1** as well as for all xerogels complexed with $CuCl_2$; (vi) Table S2 listing the peak energy and relative intensities of the resolved resonances (A)–(E).

Acknowledgments

This work is part of a joint collaboration supported by AIR-LIQUIDE and the French C.N.R.S. The allocation of 220 hours of free computing time on the NEC SX-5 machine of the IDRIS computing center in Orsay was greatly appreciated.

Partly fluorinated trialkoxysilyl-substituted carboxylic acids $(RO)_3Si(CH_2)_3N(R')C(O)(CF_2)_3COOH$ (**3a**: R = Et, R′ = H; **3b**: R = R′ = Me) have been prepared in a straightforward synthesis from the respective trialkoxysilyl-substituted primary and secondary amines and hexafluoroglutaric anhydride. Treatment with silver(I) oxide yields the corresponding silver carboxylates **4a**,**b** which have been thoroughly characterized in solution and in the solid state, including an X-ray crystallographic analysis of **4a**. The molecular structure of **4a** consists of archetypal carboxylate-bridged disilver(I) pairs with a strong closed-shell Ag–Ag (d^{10}–d^{10}) interaction and a unique intramolecular bond between a silyl ether group and the metal ion. In addition the amide oxygen atoms are involved in H-bonding and in intermolecular silver coordination, giving rise to an unusual two-dimensional network structure. Silyl-free acid $iPr_2NC(O)(CF_2)_3COOH$ (**5**) and its silver salt **6** have been prepared and structurally characterized for comparison. It is shown that the trialkoxysilyl tail in **4a**,**b** allows for convenient attachment of these silver complexes to silica surfaces, as is corroborated by DRIFT measurements. The immobilized silver carboxylates **7a**,**b** exhibit remarkable stability and are expected to open an easy access to a wide variety of SiO_2-grafted transition metal catalysts via transfer of the carboxylate ligand in simple exchange reactions.

Introduction

For several decades, the immobilization of homogeneous catalysts has been a major topic and has been pursued in various academic and industrial laboratories.[1] Stimulus for this comes from the great benefits of combining the advantages of homogeneous (high activity, high selectivity, high reproducibility) and heterogeneous (easy separation and recovery of the catalyst from the reaction mixture) catalysis.[2]

One of the major drawbacks of homogeneous catalysts is the need for separation of the relatively expensive catalysts from the reaction mixture at the end of the process. A solution to this separation problem is the use of immobilized homogeneous catalysts, which can be recovered from the reaction mixture by simple filtration or centrifugation and then, potentially, be reused.[3,4] In addition to this separation advantage, the catalytic performance of the immobilized catalysts, e.g. stability and selectivity, are sometimes improved compared to their homogeneous analogs.[5,6] Therefore, there is a growing need to develop more efficient and practical immobilization methods.

The most widely used method of immobilization of homogeneous transition metal catalysts is the binding of at least one of the catalyst ligands to a solid support via a covalent bond. Immobilization can be done either on inorganic or organic polymer support materials. Inorganic materials such as silica have many advantages compared to the organic materials: high chemical stability, high mechanical stability, no swelling properties, excellent thermal stability and an almost unlimited access to tailor-made particles including tailor-made surfaces.[7] A common and easy method for the immobilization of functionalities on SiO_2 surfaces is the reaction of alkoxysilyl-substituted functionalities with the OH groups of silica.[5,7] However, the number of available alkoxysilyl-substituted catalyst ligands is limited – especially alkoxysilyl-substituted anionic ligands are very rare. Thus there is great interest in new and versatile building blocks, which can easily be covalently combined with the support material on one side and with the metal atom of the homogeneous catalyst on the other.

Many homogeneous catalysts based on e.g. ruthenium, rhodium, tungsten, cobalt, palladium or copper contain halogen atoms, which do not participate in the catalytic cycle.[8–10] Replacement of those halogen atoms by other ligands such as anionic carboxylates has recently been explored for several catalyst systems.[11–13] It has often been observed that the catalytic performance of the carboxylate-

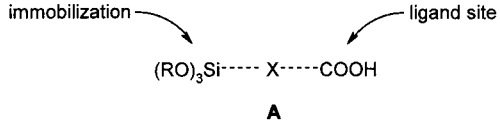
substituted catalysts is in the same range as the parent halogen-substituted catalysts. Therefore, we were searching for new type **A** building blocks bearing two functionalities (Scheme 1): an immobilizable alkoxysilyl-group and an accessible carboxylic acid group that after deprotonation may act as a ligand towards transition metal ions. Silver salts of these functional carboxylates are sought as suitable synthons that will allow subsequent attachment of the metal complex fragment via halide exchange, forming the respective silver halide.



Scheme 1.

With respect to the spacer X, fluorinated moieties are of particular interest, since they may provide favorable solubility and higher stability of the silver salts and of the resulting metal carboxylate complexes. In addition, electron-withdrawing carboxylates have proven superior in various catalytic processes.[12–14]

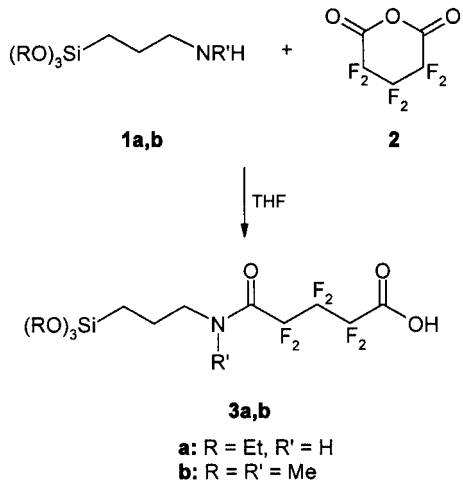
In this contribution, we report on the synthesis and spectroscopic properties of two new partly fluorinated trialkoxysilyl-substituted silver(I) carboxylates with a type **A** backbone. A related fluorinated silver(I) carboxylate lacking the silyl group has been prepared for comparison, and unusual structural features of these complexes in the solid state are described. It should be noted that silver(I) carboxylates have been intensively studied for their rich and diverse structural chemistry in the solid state,[15–17] and silver(I) complexes with fluorinated carboxylates have previously attracted interest as potential precursors for chemical vapor deposition (CVD) yielding metallic silver layers.[18–20]

Results and Discussion

Synthesis and Spectroscopy

Partly fluorinated trialkoxysilyl-substituted carboxylic acids **3** were prepared in almost quantitative yields by the reaction of the trialkoxysilyl-substituted primary amine **1a** and secondary amine **1b** with hexafluoroglutaric anhydride (**2**) in tetrahydrofuran (Scheme 2). The reactions have to be carried out in the absence of water to avoid hydrolysis of the silyl function, which is catalyzed by acidic protons. Products **3a** and **b** can be isolated as colorless oils or used in situ in the next step of the synthetic sequence. Compound **3a** has been mentioned previously but was not isolated.[13]

IR spectra of acids **3a**,**b** (Table 1) show the characteristic bands for $\tilde{\nu}_{as}$(COO) at 1775 cm^{-1} (**3a**) or 1781 cm^{-1} (**3b**) and for $\tilde{\nu}_{s}$(COO) at 1445 cm^{-1} (**3a**) or 1464 cm^{-1} (**3b**) as well as



Scheme 2. Synthesis of the trialkoxysilyl-functionalized carboxylic acids **3**.

strong absorptions for the C–F stretches around 1165 cm^{-1}. As expected for an *N*-monosubstituted amide,[21] **3a** features two bands at 1703 and 1549 cm^{-1} (amide I and amide II, respectively), while a single band at 1679 cm^{-1} is observed for *N*,*N*-disubstituted amide **3b**. Distinct ^{1}H, ^{13}C, and ^{19}F NMR signals for the *E* and *Z* amide isomers are detected for **3b**, revealing an *E*/*Z* ratio of 0.62:1 at 297 K.

Table 1. Characteristic IR spectral frequencies in cm^{-1}.

[a] $\Delta\tilde{\nu} = \tilde{\nu}_{as}$(COO) – $\tilde{\nu}_{s}$(COO) for the silver(I) carboxylate. [b] assignment of $\tilde{\nu}_{as}$(COO) and $\tilde{\nu}$(CON) is tentative, hence no value for $\Delta\tilde{\nu}$ is included. n.a. = not assignable because of SiO_2 absorptions.

Conversion of carboxylic acids **3** into the appropriate silver(I) carboxylates **4** can be achieved by reacting the respective acid **3a**,**b** with silver(I) oxide in MTBE. Alternatively, acids **3** generated in situ from the respective amine **1a**,**b** and hexafluoroglutaric anhydride (**2**) can be directly converted into **4a**,**b** by the addition of silver(I) oxide in MTBE (Scheme 3). Following the latter method the reaction mixture was stirred overnight at room temperature in the dark. After filtration and removal of the solvent, complex **4a** was obtained as a colorless solid while **4b** was isolated as a colorless oil.

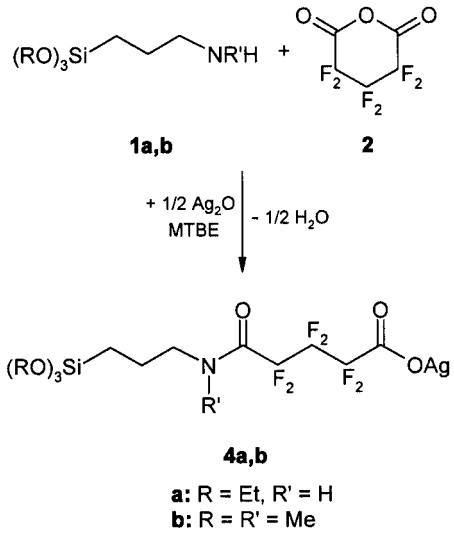
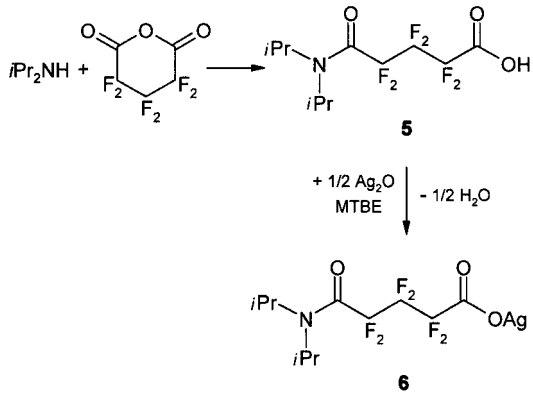


Scheme 3. Synthesis of the trialkoxysilyl-functionalized silver carboxylates **4**.

Formation of the silver carboxylate complexes **4a**,**b** is confirmed by the absence of $\tilde{\nu}_{as}$(COO), $\tilde{\nu}_{s}$(COO) vibrations for the free acids and the appearance of distinct $\tilde{\nu}_{as}$(COO) and $\tilde{\nu}_{s}$(COO) stretches around 1680 and 1395 cm^{-1} (Table 1).[22] In contrast, the characteristic bands for the amide functions in **4a**,**b** are barely shifted from their position in **3a**,**b**.[23] The separation of the $\tilde{\nu}_{as}$(COO) and $\tilde{\nu}_{s}$(COO) stretches of around $\Delta\tilde{\nu}$ = 290 cm^{-1} for **4a** may indicate a bridging carboxylate coordination (compare the crystallographic results, vide infra).[23,24] As noted previously, however, the precise type of carboxylate coordination cannot be proposed on the basis of the $\Delta\tilde{\nu}$ parameter.[19,24] Formation of silver carboxylate complexes is further corroborated by a significant low-field shift of the carboxylic ^{13}C NMR resonance from around 160.8 ppm in the acids **3a**,**b** to around 163.8 ppm in **4a**,**b**. At the same time the ^{13}C NMR resonance for the amide group is almost unchanged at around 158.7 ppm.

Proper solvent selection is critical for the formation of pure products **4**. While the reaction mixture is colorless in MTBE and a colorless product is isolated from this solvent, the reaction mixture turns yellow in THF and a deeply yellow product is obtained in the latter case. The color of the product remains yellow even after complete removal of THF. All attempts to further purify these yellow products or to identify the colored species failed. However, the highly colored impurity can only be present in trace amounts, since X-ray crystallographic analyses of the materials **4a** obtained from both solvents gave identical results (vide infra) and the IR spectra of KBr pellets of both materials are basically identical ($\Delta\tilde{\nu} \approx 294\ cm^{-1}$). In contrast to MTBE, THF appears to coordinate to the silver ions in **4a** in solution, since ^{1}H NMR spectroscopic experiments in CD_2Cl_2 reveal a slight shift of the THF solvent signal to lower field. Furthermore, IR absorptions for the $\tilde{\nu}_{as}$(COO) and $\tilde{\nu}_{s}$(COO) stretches of **4a** measured in either THF or MTBE solution show significant differences (Table 1), with $\Delta\tilde{\nu}$ being 300 cm^{-1} in THF while being 251 cm^{-1} in MTBE (amide I and amide II bands for **4a** are quite similar in the two solvents). If isolated as pure compounds **4a** and **4b** are stable at room temperature and show no significant light sensitivity. Upon heating the color of solid **4a** and **4b** changes from colorless via red to brown, and at 160 °C formation of a silver film occurs. In solution, compounds **4** start to decompose under light at room temperature within several days. No decomposition is observed when keeping the solution at –20 °C under exclusion of light.

In order to investigate the influence of the alkoxysilyl group on the stability and structural features of type **4** compounds, an analog of **4** devoid of the alkoxysilyl group has been synthesized from the route shown in Scheme 4. The alkoxysilyl-free acid **5** can be readily prepared from diisopropylamine and hexafluoroglutaric anhydride in dichloromethane. Crystallization from dichloromethane/hexane at room temperature gave colorless X-ray quality crystals of **5**. Attempts to carry out the synthesis of **5** in MTBE or THF leads to the formation of the diamide $iPr_2NC(O)(CF_2)_3C(O)NiPr_2$.



Scheme 4. Synthesis of the silyl-free carboxylic acid **5** and the silver carboxylate **6**.

Addition of **5** to a suspension of silver(I) oxide in MTBE leads to the formation of the silyl-free silver(I) carboxylate **6** (Scheme 4). After stirring the reaction mixture in the dark for 4 h at room temperature, the colorless product is conveniently isolated by filtration followed by removal of the solvent. Crystals of **6** could be obtained by diffusion of hexane into a saturated solution of the crude product in chloroform. If carried out in THF instead of MTBE the color of the reaction solution turned yellow and a yellow product was isolated, just like the observation made with the earlier described silver(I) carboxylates **4a** and **4b**. IR spectral features of **6** are quite similar if measured either in THF or MTBE solution or as KBr pellets, showing a single broad band for $\tilde{\nu}_{as}$(COO) and $\tilde{\nu}(CO)_{amide}$ at ca. 1680 cm^{-1} and a $\tilde{\nu}_{s}$(COO) band at ca. 1380 cm^{-1}. Compared to the alkoxysilyl-containing silver(I) carboxylates **4** the silyl-free silver(I) carboxylate **6** exhibits much lower thermal stability and much higher light sensitivity. **6** cannot be handled in air due to its strong hygroscopic behavior, and it decomposes within minutes under exposure to light in both solution and

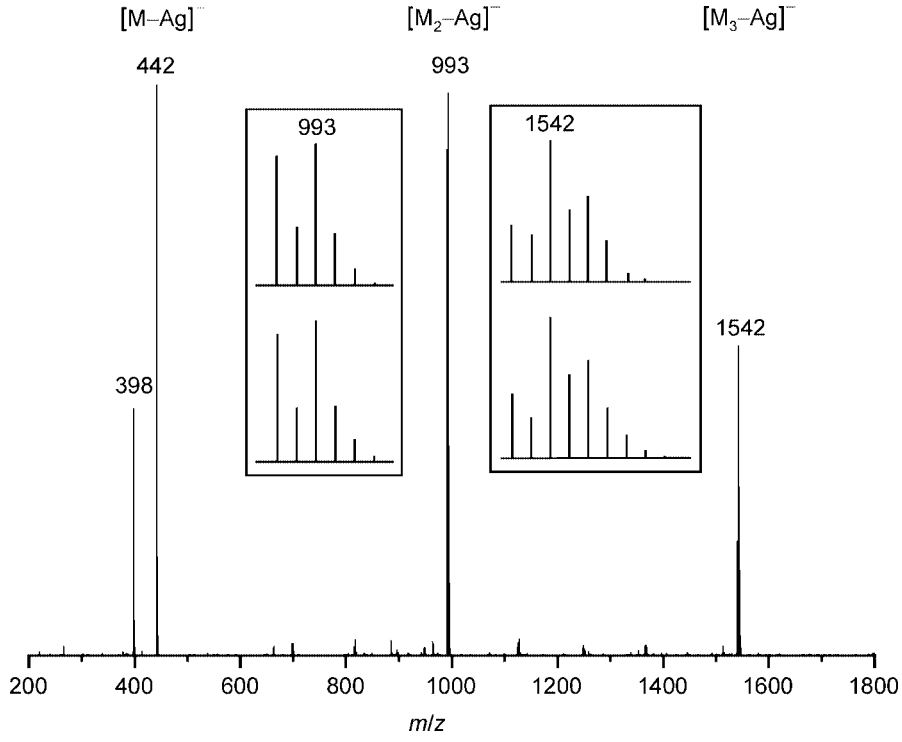

Figure 1. Part of the negative ion ESI mass spectrum of **4a**. The insets show the experimental (upper) and calculated (lower) isotopic distribution pattern for distinct ions $[M_x - Ag]^-$ (x = 2, 3).

as a solid. Upon heating **6** decomposes at around 95 °C turning into a dark colored solid.

Positive ion ESI mass spectra of acetonitrile solutions of all silver carboxylate complexes **4a**, **4b**, and **6** show a prominent peak for simple $[Ag(NCMe)_2]^+$, but minor signals characteristic for various ions $[M_x + Ag]^+$ (x = 1–3) or $[M_x + Na]^+$ (x = 1, 2) are also discernible, thus suggesting the presence of oligomeric aggregates in solution. This is most apparent from the negative ion ESI mass spectrum of **4a** depicted in Figure 1, where all major peaks can be clearly assigned to ions $[M_x - Ag]^-$ (x = 1–3). Aggregation also takes place in the solid state, as is described in the following section.

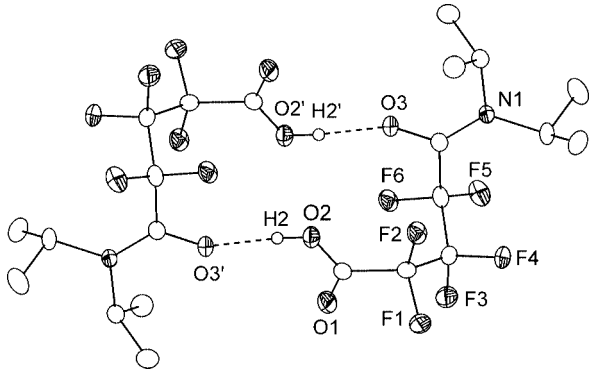

Figure 2. ORTEP plot (30% probability thermal ellipsoids) of the molecular structure of **5**. For the sake of clarity all hydrogen atoms except H2 have been omitted. Selected atom distances [Å] and angles [°]: O2–H2 0.85(3), H2···O3′ 1.75(3), O2···O3′ 2.595(2); O2–H2···O3′ 175(3). Crystal Structures

Silver complexes **4a** and **6** have been investigated by X-ray crystallography in order to fully understand their distinct spectroscopic and mass-spectrometric features and to rationalize the different thermal stability and light sensitivity of the alkoxysilyl-substituted and silyl-free silver(I) carboxylates **4** and **6**, respectively. For comparison, the structure of acid **5** has also been determined crystallographically and is shown in Figure 2. Molecular structures of **4** and **6** are depicted in Figure 3, Figure 4 (complex **6**), Figure 5, and Figure 6 (complex **4a**), along with selected atom distances and bond angles.

In the solid state carboxylic acid **5** exists as a dimer composed of two acid molecules that are linked via intermolecular hydrogen bonding (Figure 2). The hydrogen bond occurs between the carboxylic group as an H-donor and the amide-O atom as an H-acceptor, forming an unusual 16-membered ring structure. Though dimer or catemer formation of carboxylic acids via hydrogen bonds between two acid functionalities (**B**; Scheme 5) is an archetypal structural motif and is a mainstay of organic crystal engineering,[25,26] carboxylic acid association involving other groups

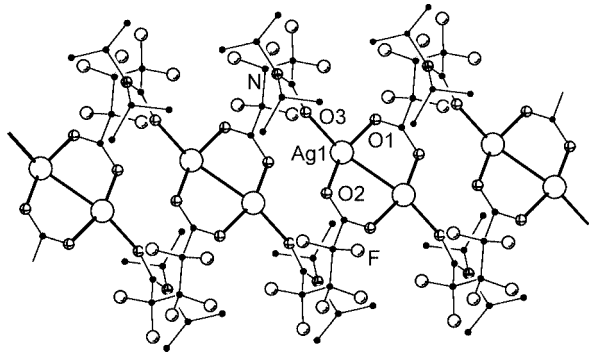

Figure 4. Plot of the chain structure of **6**. For the sake of clarity all hydrogen atoms have been omitted.

such as, e.g., a carbonyl or amide is rather rare if both groups are present in the same molecule.[27]

Reaction of **5** with Ag_2O gives yellow crystals of **6**. The structure consists of carboxylate-bridged metal-pairs **C**, featuring a strong closed-shell interaction that leads to a short Ag–Ag distance of 2.94 Å (Figure 3). Such interactions are quite common for the heavier coinage metals, and metal-metal distances of comparable magnitude have been reported for numerous compounds.[28] Since the coordination sphere of the Ag^+ ions in type **C** dimeric units is generally not satisfied by the two oxygen atoms, coordination of additional donors typically leads to polymeric or oligomeric arrays, and silver carboxylate dimers **C** have thus been exploited as building blocks for the assembly of extended coordination networks.[29] In the present case the Ag–Ag pairs are coated by their two acid molecules, and these pairs constitute subunits of a chain structure that is created through intermolecular coordination of the amide oxygen atoms to next neighbor metal pairs (Figure 4). Taking into account the closed-shell interaction and the coordination of three oxygen atoms, each silver is found in a strongly distorted

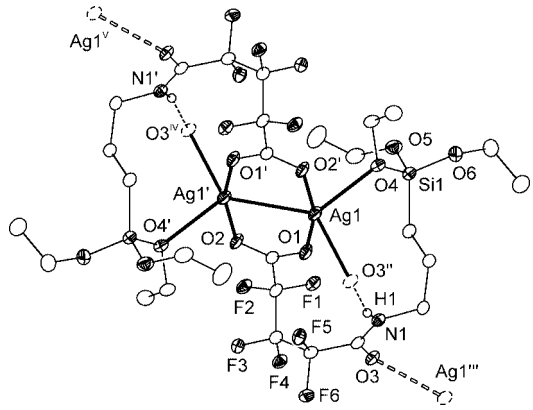

Figure 5. ORTEP plot (30% probability thermal ellipsoids) of the molecular structure of **4a**. For the sake of clarity all hydrogen atoms except H1 have been omitted. Scheme 5.

square-planar environment [distance to the least-squares planes of the four surrounding atoms is 0.415(1) Å].

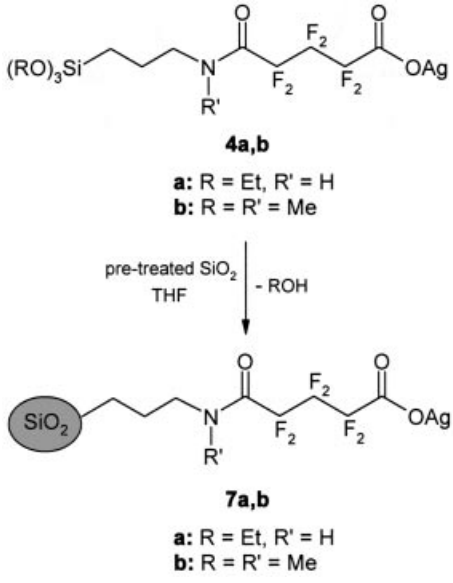
A similar type **C** motif with d^{10}–d^{10} interaction and a short Ag–Ag distance of 2.97 Å is also observed for **4a**. In contrast to **6**, however, the silver ions in **4a** show a distorted trigonal-bipyramidal coordination environment, because a silyl ether group is involved in metal ion binding [*d*(Ag1–O4) = 2.606(2) Å, Figure 5]. Oxygen atoms from the car-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

boxylic acid functionalities occupy the axial positions, whereas the adjacent silver ion, an amide oxygen atom and an oxygen atom from the silyl ether group make up the equatorial positions. Direct coordination of silyl ethers to transition metal atoms is quite rare and **4a** is one of the very few structurally characterized examples for the heavier group 11 elements. To the best of our knowledge, **4a** is the only silver compound with a distance between the metal center and the oxygen atom of a Si–O–C fragment which is distinctly below 3 Å.[30] Like in **4a** the Ag–Ag pairs are coated by acid molecules, and additional coordination of oxygen atoms from two adjacent dimeric building blocks results in the formation of a two-dimensional network structure (Figure 6). Each of these amide oxygen atoms at the same time acts as a hydrogen-bond acceptor for the N–H protons of an adjacent amide.

Immobilization

Immobilization of the silver(I) carboxylates **4** onto silica was performed by a pre-treatment step of the silica material followed by the actual immobilization step (Scheme 6). First the silica was successively washed with methanol, dichloromethane and hexane in order to remove any impurities from the SiO_2, and the treated material was dried at 200 °C under high vacuum for 4 h to achieve thermal desorption of physically adsorbed water molecules from the silica gel surface.



Scheme 6. Immobilization of **4** onto silica gel.

Silver(I) carboxylates **4** were subsequently attached to the silica surface by adding a solution of **4** in THF to a silica/THF suspension and stirring the reaction mixture at room temperature for 21 h in the dark. Immobilized silver(I) carboxylates **7a** and **b** were isolated as white solids by filtration and thoroughly washed with THF and hexane. The combined filtrates were evaporated under vacuum and checked for any remaining starting material. No residual **4** was detected, thus confirming that complete immobilization had occurred. This corresponds to an immobilization ratio of 0.1 mmol of **4** per g of SiO_2 and accordingly 5 wt.-% of **4**, which is a good ligand loading rate for a potential subsequent transformation of the silver(I) carboxylates into powerful immobilized catalysts.[31–33] Immobilized silver(I) salts **7** show remarkable stability when taking into account that stabilization of their homogeneous silver(I) precursors **4** occurred by aggregation, which is necessarily reduced upon covalent immobilization of **4** on the silica surface. The immobilized silver(I) salts **7** start to decompose under light at room temperature within several days; when kept under the exclusion of light they can be stored over a period of a few weeks without decomposition. Upon heating, the color of **7** changes from white to yellow (90 °C) to brown (180 °C).

DRIFT (Diffuse Reflectance Infra-red Fourier Transform) measurements of **7a**,**b** confirm the adsorption of the silver carboxylate compounds onto the silica. The pre-treated silica shows, inter alia, the expected sharp peak at 3747 cm^{-1} for isolated noninteracting silanol groups and broad bands at 1993, 1862, 1625, 1195, 980, and 845 cm^{-1} for the H–O–H (adsorbed water) and Si–O–Si modes of silica itself.[34–36] While these features remain unchanged in **7a**,**b**, additional peaks appear at 1713, 1664 and 1539 cm^{-1} (**7a**) or 1669 cm^{-1} (**7b**). This is close to the position of the $\tilde{\nu}_{as}$(COO) and $\tilde{\nu}$(CON) modes of the respective precursor compounds **4a**,**b** (Table 1), in agreement with nondestructive adsorption of complexes **4a**,**b** onto the silica.

Conclusions and Outlook

A straightforward synthetic approach is reported for some new silver(I) carboxylates that incorporate a partly fluorinated tail with an appended trialkoxysilyl substituent. The silver carboxylate complexes have been thoroughly characterized both in solution and in the solid state and have been found to form oligonuclear or polymeric assemblies that are based on archetypal carboxylate-bridged disilver(I) units with short d^{10}–d^{10} interactions. Inter alia, an unusual coordination of an alkoxysilyl oxygen atom towards silver has been discovered.

The trialkoxysilyl anchor enables a convenient attachment of complexes **4a**,**b** to silica surfaces. The future potential of the newly prepared immobilizable type **4** compounds and immobilized type **7** compounds is summarized in Scheme 7. The development of the flexible fluorinated silver carboxylates reported in this work is expected to open an easy access to a wide variety of SiO_2-grafted transition metal species **E** (M = transition metal complex fragment) via simple exchange reactions. Metal exchange may be carried out either before [route (**a**)] or after [route (**b**)] the immobilization step, depending on the specific requirements of the particular system. Since separation of the insoluble silver halides from the silica-bound catalyst may pose a problem, the former route (**a**) should in most cases be advantageous.

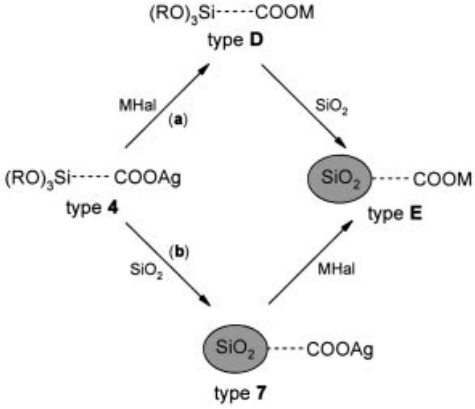

Scheme 7.

A detailed evaluation of various type **E** immobilized transition metal complexes in catalytic reactions will be reported in due course.

Experimental Section

General Remarks: All operations were carried out under argon using standard vacuum and Schlenk techniques or in a glovebox under argon (Labmaster 130, MBraun, Germany). All solvents were dried and purified by passing them through suitable drying columns or by employing standard drying agents.[37,38] 3-(Triethoxysilyl)propylamine (Fluka), 3-(methylamino)propyltrimethoxysilane (ABCR), hexafluoroglutaric anhydride (ABCR), diisopropylamine (Merck) and silver(I) oxide (Merck) were used as received. All stoichiometric calculations involving silica gel (KG 60, Merck) are based on an average surface area of 510 $m^2 g^{-1}$. ^1H and ^{13}C NMR spectra were recorded with a Bruker DPX 250 Advance, Bruker AMX 300 or Bruker DRX 500 Advance at ambient temperature. Data are given in ppm relative to solvent signals for ^1H and ^{13}C NMR spectra or relative to an external standard for ^{19}F NMR experiments ($CFCl_3$ at 0 ppm). IR spectra were recorded with a Bruker Equinox 55 FT-IR instrument as KBr pellets, as films between KBr plates or in solution using a CaF_2 cell. DRIFT measurements (Diffuse Reflectance Infra-red Fourier Transform) were recorded with a Bruker IFS-66 FT-IR instrument; the samples were scanned 256 times. Elemental analyses were measured with a Vario EL. Melting points were obtained with a BÜCHI capillary apparatus B-540. Mass spectra were collected with a Finnigan MAT 8200 (EI, 70 eV) or a Finnigan MAT LCQ (ESI).

$(EtO)_3Si(CH_2)_3N(H)C(O)(CF_2)_3COOH$ (3a):[13] Hexafluoroglutaric anhydride (**2**) (192 μL, 1.40 mmol) dissolved in THF (7.5 mL) was added dropwise to a solution of 3-(triethoxysilyl)propylamine (**1a**) (331 μL, 1.40 mmol) in THF (7.5 mL). The mixture was stirred for 30 min at room temperature, and all volatiles were then removed under reduced pressure at 25 °C. **3a** was isolated as a colorless oil. [KG 60]–$(CH_2)_3$N(H)C(O)$(CF_2)_3$COOAg (7a): Silica gel (KG 60) was washed successively with methanol, dichloromethane and hexane and was dried at 200 °C under full vacuum for 4 h. A solution of $(EtO)_3Si(CH_2)_3N(H)C(O)(CF_2)_3COOAg$ **(4a)** (113.2 mg, 0.2 mmol) in THF (10 mL) was added to a suspension of the pretreated KG 60 (2000 mg) in THF (20 mL). After stirring for 21 h at room temperature in the dark the functionalized silica gel was isolated by filtration with subsequent washing using THF and *n*-hexane. Drying overnight under full vacuum afforded 2089.9 mg of [KG 60]–$(CH_2)_3$N(H)C(O)$(CF_2)_3$COOAg (**7a**). Remaining $(EtO)_3Si(CH_2)_3N(H)C(O)(CF_2)_3COOAg$ **(4a)** was not found in the filtrates. Carbon analysis: found 0.8%, which corresponds to 0.1 mmol **4a** per g KG 60 (5 wt.-%). IR (DRIFT): $\tilde{\nu}$ = 1713 (w), 1664 (w), 1539 (w) cm^{-1}.

[KG 60]–$(CH_2)_3N(Me)C(O)(CF_2)_3COOAg$ (7b): Analogous to the preparation of **7a**, KG 60 (2030 mg) in THF (20 mL) and $(MeO)_3Si(CH_2)_3N(Me)C(O)(CF_2)_3COOAg$ **(4b)** (106.1 mg, 0.2 mmol) in THF (10 mL) were used. Drying overnight under full vacuum afforded 2127.1 mg of [KG 60]–$(CH_2)_3N(Me)C(O)(CF_2)_3COOAg$ (**7b**). Remaining $(MeO)_3Si(CH_2)_3N(Me)C(O)(CF_2)_3COOAg$ **(4b)** was not found in the filtrates. Carbon analysis: found 1.0%, which corresponds to 0.1 mmol **4b** per g KG 60 (5 wt.-%). IR (DRIFT): $\tilde{\nu}$ = 1669 (m) cm^{-1}.

X-ray Crystallographic Study: X-ray data were collected with a STOE IPDS II diffractometer (graphite monochromated Mo-K_α radiation, λ = 0.71073 Å) by use of ω scans at –140 °C (Table 2). The structures were solved by direct methods and refined on F^2 using all reflections with SHELX-97.[39,40] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms not involved in hydrogen bonding were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 Å^2. The positional and isotropic thermal parameters of the nitrogen-bonded hydrogen atom H1 in **4a** and the oxygen-bonded H2 in **5** were refined without constraints. Face-indexed absorption corrections were performed numerically with the program X-RED.[41]

CCDC-259720 (for **4a**), -259721 (for **5**) and -259722 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Design, Preparation and Characterization of the Adducts of the Bis-Amido Cobalticinium Complex $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2][PF_6]$ with Fumaric and Maleic Acids

Dario Braga,*[a] Stefano L. Giaffreda,[a] Marco Polito,[a] and Fabrizia Grepioni*[a]

Keywords: Organometallic complexes / Amides / Hydrogen bonding / Crystal engineering / Supramolecular chemistry

The supramolecular hydrogen-bonded adducts obtained by treating the cationic bis-amido complex $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2]^+$ with fumaric and maleic acid are investigated and their modes of aggregation in the solid state are explored. It is shown that the bis-amido organometallic complex can be mono- and di-protonated in the reaction with the dicarboxylic acids, leading to the formation of complex, mixed-anion supramolecular salts containing either the dication $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}$, $[\mathbf{1}H]^{2+}$, or the trication $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}$, $[\mathbf{1}H_2]^{3+}$. The derivatives of the reaction with fumaric acid, namely, $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$, $[\mathbf{1}H]^{2+}\cdot PF_6^-\cdot 1/2[\text{fumarate}]^{2-}$, and $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$, $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$, contain either the dianion $[\text{fumarate}]^{2-}$ or the hydrogen-bridged supramolecular trianion $[H(\text{fumarate})_2]^{3-}$, depending on the amide/acid stoichiometric ratio. In the case of maleic acid, on the other hand, the possibility of intramolecular hydrogen-bond formation generates exclusively salts of the hydrogen maleate anions, namely, $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[\text{Hmaleate}]^-$, $2[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[\text{Hmaleate}]^-$, $2[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}\cdot 3[PF_6]^-\cdot 3[\text{Hmaleate}]^-\cdot 2H_2O$, $2[\mathbf{1}H_2]^{3+}\cdot 3[PF_6]^-\cdot 3[\text{Hmaleate}]^-\cdot 2H_2O$ and $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}\cdot 2[PF_6]^-\cdot[\text{Hmaleate}]^-\cdot H_2O$, $[\mathbf{1}H_2]^{3+}\cdot 2[PF_6]^-\cdot[\text{Hmaleate}]^-\cdot H_2O$, in which the hydrogen maleate anions act as bridges between the protonated bis-amido organometallic sandwiches.

Introduction

In the context of crystal engineering,[1] organometallic molecules and ions are beginning to attract an increasing interest since organometallic molecules and molecular ions combine the supramolecular bonding capacity of organic molecules with the presence of metal atoms. The number of possible combinations of the valence, spin and charge states of the metal atoms with the coordination geometries and supramolecular bonding capacity of functionalised organometallic complexes is virtually unlimited.[2] One of the important issues in this area of chemistry is that of being able to design, synthesize and ultimately exploit the topological properties of solid-state materials based on coordination compounds, whether linked together to form supramolecular complexes or joined in extended coordination networks through space.[3] The goal is to achieve an intelligent control of the recognition and assembly processes that lead from molecular or ionic components to superstructures,[4] hence from individual to collective chemical and physical properties.[5]

In recent years, we have directed our efforts,[6] together with others,[7] towards the exploration of the area of organometallic supramolecular solid-state chemistry and crystal engineering. While many organic compounds often utilized by the crystal engineer are commercially available and can be used directly in supramolecular assembly experiments, this is not so with organometallic species, which need, most often, to be synthesized on purpose.

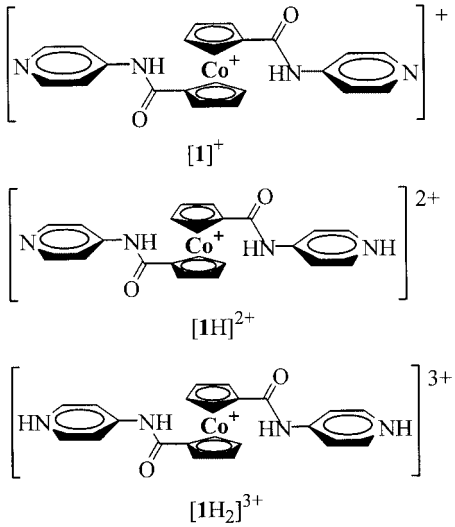
With this idea in mind, we have begun to prepare, also in collaboration with others, novel organometallic building blocks with adequate supramolecular-bonding functionalities for the construction of target architectures.[8] We have focused our strategy on the possibility of adding hydrogen bonding donor/acceptor groups to robust sandwich complexes. The rationale for this choice is that the hydrogen bond is the strongest of the non-covalent interactions and the one that best combines strength and directionality.[9] Strength is synonym of cohesion and stability, while directionality implies topological control and selectivity, which are fundamental prerequisites for a successful control of the aggregation processes.[10]

It is now well demonstrated that coordination ligands functionalised with –COOH and –OH groups form essentially the same type of hydrogen-bonding interactions, whether as part of organic molecules or as part of metal

complexes.[2,7,11] This is not surprising, as hydrogen bonds formed by such strong donor and acceptor groups are at least one order of magnitude stronger than most non-covalent interactions. In terms of topology, dicarboxylic acid molecules allow construction of supramolecular networks because of the twin hydrogen-bonding function. We have extensively exploited this feature by using sandwich organometallic dicarboxylic acids such as $[Fe(\eta^5\text{-}C_5H_4COOH)_2]$, $[Co(\eta^5\text{-}C_5H_4COOH)_2]^+$ and $[Cr(\eta^6\text{-}C_6H_5COOH)_2]$.[12] The cobalt cationic complex, in particular, has proved to be extremely versatile for applications in solid–solid and solid–gas reactions.[13]

Recently, we have expanded this chemistry towards organometallic bis-amido complexes. We have reported the solid-state investigation of the bis-amido cobalticinium complex $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2][PF_6]$, $[\mathbf{1}]^+[PF_6]^-$, together with its utilization in the formation of a hydrogen-bonded adduct with ferrocene dicarboxylic acid, namely, $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2][Fe(\eta^5\text{-}C_5H_4COOH)_2][PF_6]$.[14] It is worth stressing that $[\mathbf{1}]^+$ possesses, at least in principle, both the capacity of acting as a cationic di-base for protonation and hydrogen-bond formation, as well as that of acting as a coordination ligand. In this study we explore the first of these characteristics. The downside of this is feature is that the counterion (in all cases discussed herein the $[PF_6]^-$ anion) is also "carried through" the acid–base reaction and the subsequent crystallization, thereby decreasing the level of predictability of the supramolecular architectures resulting from acid-base aggregation. As it will be seen in the following section, our compounds can be described as hetero-anionic salts, that is, containing both $[PF_6]^-$ and the anions obtained from deprotonation of fumaric and maleic acids of the protonated bis-amide $[\mathbf{1}]^+$.

In this paper we describe the results obtained from the reactions between $[\mathbf{1}]^+[PF_6]^-$ and the dicarboxylic fumaric and maleic acids. The idea is that of using the –COOH groups of the two acids as a probe of the hydrogen-bonding capacity of the organometallic complex $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2]^+$. Our interest stems from the observation that the cationic starting material can, at least in principle, behave both as a mono- and as a di-protonic acceptor at the two N-termini (thus leading to the formation of di- and tri-cationic complexes, see Scheme 1). These protonated forms can form hydrogen bonds with suitable acceptors. Furthermore, the presence of the two –(CO)NH amido groups confers additional hydrogen-bonding capacity to the molecule.



Scheme 1. The cationic bis-amide complex $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2]$, $[\mathbf{1}]^+$, together with the di- and tri-cationic species $[\mathbf{1}H]^{2+}$ and $[\mathbf{1}H_2]^{3+}$ obtained by mono- and di-protonation of the two N-termini.

Results and Discussion

As pointed out above, the organometallic amide $[\mathbf{1}]^+$ can exist in solution in three different forms depending on the degree of protonation, that is, $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2]^+$, $[\mathbf{1}]^+$, $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5C_5H_4CONHC_5H_4NH)]^{2+}$, $[\mathbf{1}H]^{2+}$, and $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}$, $[\mathbf{1}H_2]^{3+}$. In the reaction with acids, the degree of protonation can be generally "tuned" by varying the base/acid molar ratio. Of the three cations, only the structure of $[\mathbf{1}]^+$ has been reported before and we refer the reader to the previous publication,[14] while the structures of the mono-protonated and di-protonated compounds have not yet been reported. Since the supramolecular structure of $[\mathbf{1}H]^{2+}$ is related to the following discussion, we shall first describe the packing of the dication $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}$, $[\mathbf{1}H]^{2+}$, while the tri-cation $[\mathbf{1}H_2]^{3+}$ will be seen in the structure of the adducts discussed below. Selected hydrogen bonding parameters for $[\mathbf{1}H]^{2+}$, as well as for all the other species described herein, are reported in Table 1.

The dication $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}$, $[\mathbf{1}H]^{2+}$, has been crystallized as its $[PF_6]^-$ salt in the form $2[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot 4[PF_6]^-\cdot H_2O$, $2[\mathbf{1}H]^{2+}\cdot 4[PF_6]^-\cdot H_2O$. The most interesting feature is that the dication forms hydrogen-bonded dimers in the solid state via N–H···N interactions, as shown in Figure 1. The resulting supramolecular aggregate is thus a tetracation "held together" by two N–H···N hydrogen bonds [N(4)···N(3) 2.715(4), N(8)···N(6) 2.738(4) Å, for the two crystallographically independent units shown in Figure 1].

It is worth noting that one of the tetracations is hydrogen-bridged with two water molecules [N···O 2.943(5) Å] and both cations also interact with the $[PF_6]^-$ anions, establishing N–H···F hydrogen-bonding interactions with the amidic N–H units [N···F distances in the range 3.025(4)–3.072(5) Å], as shown in Figure 2.

Reactions with Fumaric Acid

Even though it is possible to envisage several stoichiometric molar ratios between base and acid in the reaction of $[\mathbf{1}]^+$ with acids (see Table 1), our experiments show that

only two stoichiometries yield crystalline aggregates, namely, $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$, $[\mathbf{1}H]^{2+}\cdot PF_6^-\cdot 1/2[\text{fumarate}]^{2-}$, and $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$, $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$, obtained from the 2:1 and the reverse 1:2 amide/acid ratios, respectively. Amide/acid ratios 2:1, 1:1 and 1:1.5 all yielded the fumarate derivative $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$, while the ratios 1:2 and 1:3 both yielded the hydrogen fumarate derivative $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$. Why other stoichiometries, in particular the 1:1, are not obtained, is difficult to say. One should keep in mind, however, that the acid/base protonation equilibrium in solution is not the only aspect that may influence the final solid-state product stoichiometry. Solubility equilibria, for example, may favour one species over another, while kinetic aspects may have a role in the formation of long-living crystal nuclei in solution.

In the cases yielding $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$, $[\mathbf{1}H]^{2+}\cdot PF_6^-\cdot 1/2[\text{fumarate}]^{2-}$, the diprotic acid is able to protonate two molecules of the amide, raising the charge of the organometallic moiety from +1 to +2. This product is formed with stoichiometric ratios of up to 1:1.5 (which, incidentally, implies that there is unreacted fumaric acid that precipitates together with the crystals of the adduct). Above 1:1.5 the protonation equilibrium changes: the excess of fumaric acid leads to complete protonation of the bis-amido complex, to a total cationic charge of +3 and formation of the complex $[\mathbf{1}H_2]^{3+}$. The resulting material $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$ is crystallized together with a protonated water molecule (see below). The expected product, $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[\text{fumarate}]^{2-}$, corresponding to the stoichiometric ratio 1:1 was not isolated.

Thus, the two crystals $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$ and $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+$ contain the diprotonated and the triprotonated organometallic complexes, respectively. In spite of this difference, the two complexes show interesting structural relationships in the solid state:

i) The organometallic complexes in both the $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$ and the $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(\text{fumarate})_2]^{3-}\cdot H_3O^+\cdot H_2O$ crystals adopt a *cisoid* (eclipsed) conformation of the Cp-pyridyl ligands.

ii) In $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[\text{fumarate}]^{2-}$ the monoprotonated amide forms a cyclic dimer with another complex through N–H···N hydrogen bonds [N(3)···N(4) 2.669(7) Å], as shown in Figure 3.

iii) The dimers are linked together in a zigzag fashion by the interaction of the deprotonated fumarate dianions and the outer amido N–H groups (see Figure 3) [N(1)···O(3) 2.809(6), N(2)···O(4) 2.703(6) Å]. Each carboxylate unit "pinches" the two N–H groups of one complex; in such a way the organometallic cation and the fumarate dianion interact via four N–H···O bonds.

iv) In the case of $[\mathbf{1}H_2]^{3+}$, on the other hand, a dimer cannot form because both N-termini are protonated, nonetheless the complex retains the eclipsed geometry of the ligands and substituents (see part a of Figure 4). The pyridyl NH groups interact through hydrogen bonding with the $[H_3O]^+$ cation and the water molecule [N(3)···O(100) 2.690(4) and N(4)···O(200) 2.743(4) Å], which in turn interact with each other [O(100)···O(200) 2.829(4) Å]. The $[H_3O]^+$ cation and the water molecule are also hydrogen bonded to the $[H(\text{fumarate})_2]^{3-}$ anions (see part b of Figure 4) [O(100)···O(6) 2.703(4), O(100)···O(8) 2.739(4), O(200)···O(5) 2.976(5) Å].

v) The trications $[\mathbf{1}H_2]^{3+}$ are linked together by a supramolecular anion formed by a hydrogen fumarate unit and a fumarate dianion. Since the proton is mid-way along the

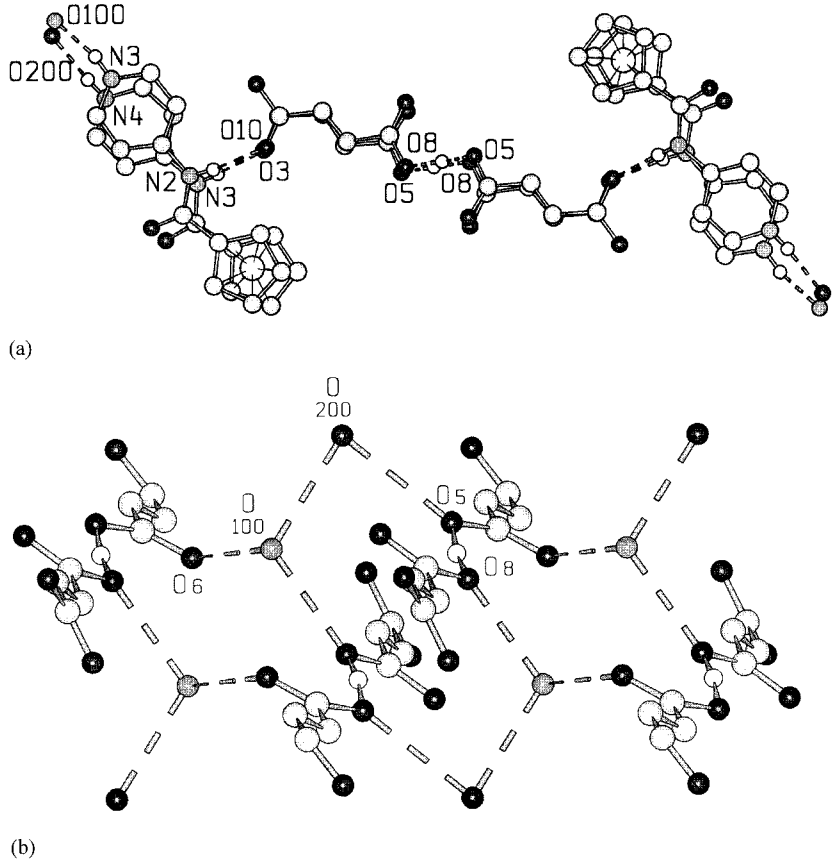

Figure 4. (a) In crystalline $[\mathbf{1}H_2]^{3+}\cdot[PF_6]^-\cdot[H(fumarate)_2]^{3-}\cdot H_3O^+\cdot H_2O$ the trications are linked together by a supramolecular anion formed by a hydrogen fumarate unit and a fumarate dianion. Since the proton is mid-way along the O···O bond in this unit, it is more appropriate to describe the systems as a superanion $[H(fumarate)_2]^{3-}$, with an O(5)···O(8) separation of 2.466(4) Å. (b) The $[H_3O]^+$ cation and the water molecule interact via hydrogen bonding with each other [O(100)···O(200) 2.829(4) Å] and with the $[H(fumarate)_2]^{3-}$ anion [O(100)···O(6) 2.703(4), O(100)···O(8) 2.739(4), O(200)···O(5) 2.976(5) Å]. [H_{CH}, H_{water} and $H_{[H_3O]^+}$ atoms not shown for clarity].

O···O bond [O(5)···O(8) 2.466(4) Å], it is more appropriate to describe the system as a superanion of formula $[H(fumarate)_2]^{3-}$.

vi) On both sides the supramolecular trianion $[H(fumarate)_2]^{3-}$ interacts with the amido N–H groups, as observed in $[\mathbf{1}H]^{2+}$ with N(1)···O(3) and N(2)···O(10) separations of 2.763(4) and 2.965(5) Å, respectively.

Reactions with Maleic Acid

In terms of supramolecular bonding capacity and hydrogen-bond formation, maleic acid differs from fumaric acid-mainly in the fact that mono-deprotonation leads in general to formation of an intramolecular hydrogen bond. As a consequence of the intramolecular hydrogen-bonding formation the carboxylate groups are available only for hydrogen-bonding acceptance.

The structure of $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$, $2[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$, is reminiscent of those of the mono-protonated amide salt $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot 4[PF_6]^-\cdot H_2O$ and of the hydrogen fumarate salt $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[maleate]^{2-}$. These systems have in common the presence of hydrogen bond dimers in the solid state (see Figure 5). The N–H···N

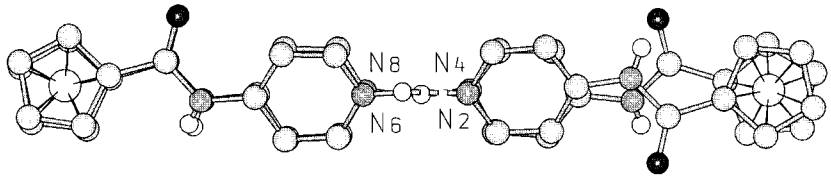

Figure 5. The hydrogen bonded dimer in crystalline $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$, $2[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$. Note how the amido groups are eclipsed in one of the two dications and staggered in the other. [H_{CH}, H_{water} and $H_{[H_3O]^+}$ atoms not shown for clarity].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

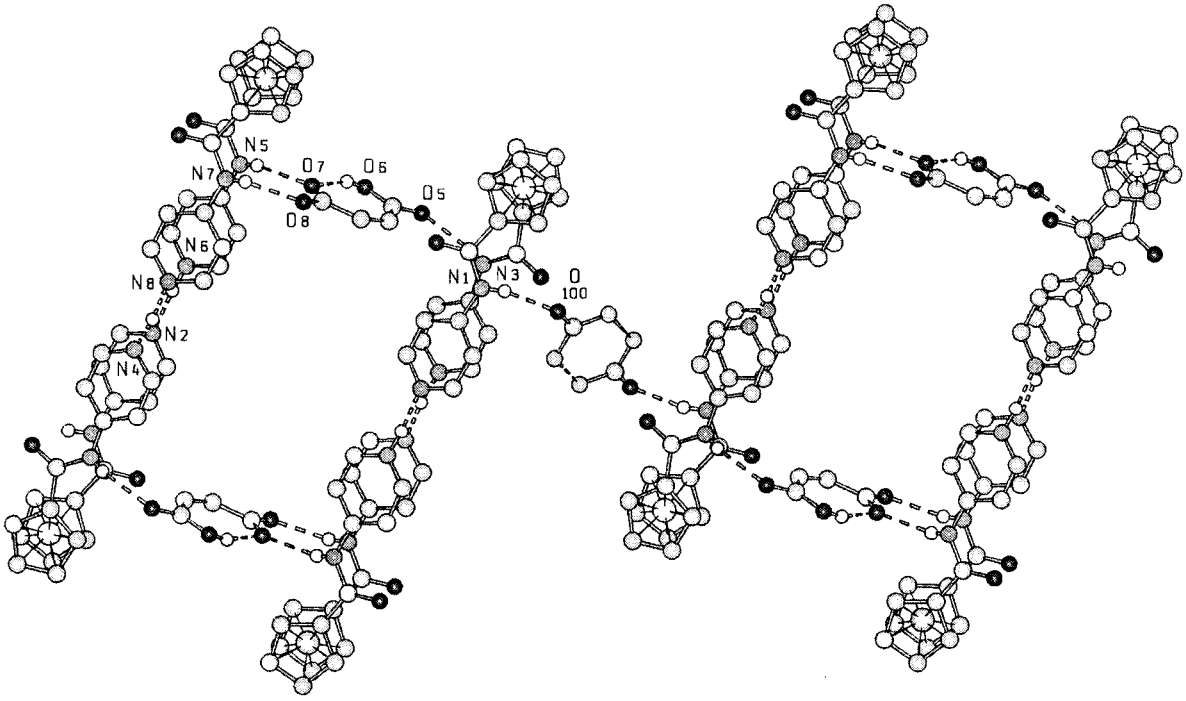

Figure 6. The structure of $2[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$ shows the presence of hydrogen-bonded dimers in the solid state of the type observed for $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)(\eta^5\text{-}C_5H_4CONHC_5H_4NH)]^{2+}\cdot[PF_6^-]_4\cdot H_2O$, as well as the hydrogen fumarate salts $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[fumarate]^{2-}$. Note, however, that the amido groups are eclipsed in one of the two di-cations and staggered in the other (see Figure 5). The "dimers of dimers" are held together by a hydrogen oxalate anion, which is disordered over two orientations (only one of the two images is shown here for clarity). [H_{CH}, H_{water} and $H_{[H_3O]^+}$ atoms not shown for clarity].

separations are comparable in length [N(4)···N(8) 2.688(6); N(6)···N(2) 2.686(6) Å]. Note, however, that the amido groups are eclipsed in one of the two dications and staggered in the other. This difference seems to suggest that in solution the complex is present with both, possibly dynamically interconverting conformations, which are frozen out at the stage of crystallization. It is also noteworthy that compound $2[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$ is the only case, in this study, where the Cp-amido ligands show both the staggered and eclipsed relative orientations of the C(=O)NH units. The arrangement of the hydrogen maleate anions provides a possible rationale for the difference. As shown in Figure 6, the hydrogen maleate anions provide two types of bridges between neighbouring dimers.

Because of the mentioned scarcity of hydrogen-bonding donor sites, the interaction links have to utilize the amido N–H groups. The structure can be described as formed of "dimers of dimers" held together by two ordered hydrogen maleate anions, for a total of six N–H···O interactions [N(3)···O(5) 2.923(5), N(5)···O(7) 2.916(6), N(7)···O(8) 2.836(6) Å]. The N(1)–H(100) donor group, which is not involved in the "dimer of dimer" formation, can thus be used to link together the "dimers of dimers" through the disordered hydrogen maleate [N(1)···O(100) 2.832(6) Å] (see Figure 6). This picture also provides a rationale for the disorder observed in the latter hydrogen maleate anion, which is oriented randomly in two positions around the crystallographic inversion centre.

Let us now consider the cases of compounds $2[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}\cdot 3[PF_6]^-\cdot 3[Hmaleate]^-\cdot 2H_2O$, $2[\mathbf{1}H_2]^{3+}\cdot 3[PF_6]^-\cdot 3[Hmaleate]^-\cdot 2H_2O$, and $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4NH)_2]^{3+}\cdot 2[PF_6]^-\cdot[Hmaleate]^-\cdot H_2O$, $[\mathbf{1}H_2]^{3+}\cdot 2[PF_6]^-\cdot[Hmaleate]^-\cdot H_2O$. These two crystalline materials, in spite of the different stoichiometry, bear some close structural relationships. In both systems the intramolecular hydrogen maleate anion acts as a bridge between two trications (compare Figure 7 and Figure 8) by accepting hydrogen-bond donation from the protonated pyridine N-terminus and from the amido N–H system of two distinct cations [N···O distances in the range 2.789(5)–2.923(7) Å]. The hydrogen maleate bridges thus generate an extended network of alternating cations and anions, thanks also to the rotational freedom about the Cp–Co–Cp axis. In addition to this, in compound $2[\mathbf{1}H_2]^{3+}\cdot 3[PF_6]^-\cdot 3[Hmaleate]^-\cdot 2H_2O$ the two hydrogen maleates that do not act as bridges still interact each with an organometallic cation via NH···O hydrogen bonds [N(5)···O(10), N(8)···O(9), N(1)···O(13) Å] (Figure 7) and establish hydrogen-bonding interactions with the water molecules [O···O distances in the range 2.771(5)–2.936(5) Å].

Note how the hydrogen maleate anion acts as a bridge between trications forming an extended network. [H_{CH}, H_{water} and $H_{[H_3O]^+}$ atoms not shown for clarity]

Conclusions

The aim of this study was to explore the supramolecular bonding capacity of the cationic bis-amide complex $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2][PF_6]$, $[\mathbf{1}]^+[PF_6]^-$, towards the dicarboxylic fumaric and maleic acids. The idea was to use the –COOH groups as a probe of the hydrogen-bonding capacity of the organometallic complex.

In previous studies we have extensively investigated the behaviour of organometallic dicarboxylic acids, such as, $[Fe(\eta^5\text{-}C_5H_4COOH)_2]$, $[Co(\eta^5\text{-}C_5H_4COOH)_2]^+$ and $[Cr(\eta^6\text{-}C_6H_5COOH)_2]$[12] towards a variety of organic and inorganic acids or bases. The results of these studies have led us to the successful exploitation of the acid/base behaviour of one such species, namely the zwitterionic form $[Co(\eta^5\text{-}C_5H_4COOH)(\eta^5\text{-}C_5H_4COO)]$, obtained by deprotonation of the cobalticinium cationic acid, in heterogeneous reactions with vapours of acids and bases.[13,15] In a parallel investigation we have studied the reactivity of neutral disubstituted pyridyl and pyrimidyl ferrocenyl species towards acids and metal complexes.[16] With the present work we intended to extend these findings to a new class of supramolecular synthons, namely that of cationic bis-amido complexes, of which $[Co^{III}(\eta^5\text{-}C_5H_4CONHC_5H_4N)_2]^+$ is the prototype.[17]

In the course of this investigation we have shown that both fumaric and maleic acids are sufficiently strong as to protonate the pyridine moiety. However, in the case of maleic acid, formation of the intramolecular hydrogen bond yields compounds that contain only the hydrogen maleate monoanion, while in the case of fumaric acid, both the completely deprotonated fumarate dianion and the supramolecular trianion formed by one hydrogen fumarate mono-anion and one fumarate dianion were obtained.

In terms of organometallic moieties, most adducts, but not all, contain the dimer formed by the monoprotonated dication $[\mathbf{1}H]^{2+}$ and are held together by intercation N–H···N hydrogen bonds between a protonated and a free pyridyl N atom, while the O-atom acceptors on the fumarate and hydrogen maleate anions appear to be involvedexclusively in interactions with the amido –(CO)N–H hydrogen-bond donors. Only in the case of $[\mathbf{1}H_2]^{3+}\cdot 2[PF_6]^-\cdot[Hmaleate]^-\cdot H_2O$ an interaction between the N-atom and the acid is observed.

Further studies are in progress to utilize the bis-amido complexes in the formation of complexes of complexes, for applications in coordination chemistry and crystal engineering.

Experimental Section

All reactants were purchased from Aldrich and used without further purification. Reagent grade solvents and bidistilled water were used.

Synthesis of $[\mathbf{1}H]^{2+}\cdot 2[PF_6]^-$: $[\mathbf{1}H]^{2+}$ was synthesized following a procedure, slightly modified, reported by Beer and Stokes.[18]

Synthesis of $[\mathbf{1}]^+\cdot[PF_6]^-$: $[\mathbf{1}H]^{2+}$ was treated with a 0.1 M solution of NH_3, in order to obtain deprotonation of the two pyridine moieties. Elementary analysis: calcd. C 46.01, N 9.55, H 3.16; found C 46.04, N 9.53, H 3.12.

Synthesis of $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[fumarate]^{2-}$: $[\mathbf{1}]^+\cdot[PF_6]^-$ (0.11 mmol) and fumaric acid, $C_4H_2O_4$ (0.11 mmol) were dissolved in 5 mL of water. Crystals suitable for single-crystal X-ray diffraction were obtained by slow evaporation of water. The same compound was obtained after reaction of $[\mathbf{1}]^+\cdot[PF_6]^-$ (0.11 mmol) with $C_4H_2O_4$ (0.5 and 1.5 mmol; 2:1 and 1:1.5 reagents ratio, respectively). Elemen-

tary analysis: calcd. C 45.59, N 8.86, H 3.19; found C 45.57, N 8.85, H 3.20.

Synthesis of $[1H_2]^{3+}\cdot[PF_6]^-\cdot[H(fumarate)_2]^{3-}\cdot H_3O^+\cdot H_2O$: $[1]^+\cdot[PF_6]^-$ (0.11 mmol) and fumaric acid, $C_4H_2O_4$, (0.22 mmol) were dissolved in 5 mL of water. Crystals suitable for single-crystal X-ray diffraction were obtained by slow evaporation of water. The same compound was obtained after reaction of $[1]^+\cdot[PF_6]^-$ (0.11 mmol) with $C_4O_4H_2$ (0.33 mmol; 1:3 reagents ratio). Elementary analysis: calcd. C 42.77, N 6.65, H 3.59; found C 42.78, N 6.63, H 3.60.

Synthesis of $2[1H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[maleate]^{2-}$: $[1]^+\cdot[PF_6]^-$ (0.22 mmol) and maleic acid, $C_4H_2O_4$, (0.11 mmol) were dissolved in 5 mL of water. Crystals suitable for single-crystal X-ray diffraction were obtained by slow evaporation of water. Elementary analysis: calcd. C 43.12, N 8.04, H 2.86; found C 42.14, N 80.02, H 2.86.

Synthesis of $2[1H_2]^{3+}\cdot 3[PF_6]^-\cdot 3[Hmaleate]^-\cdot 2H_2O$: $[1]^+\cdot[PF_6]^-$ (0.11 mmol) and maleic acid, $C_4H_2O_4$, (0.22 mmol) were dissolved in 5 mL of water. Crystals suitable for single-crystal X-ray diffraction were obtained by slow evaporation of water. Elementary analysis: calcd. C 40.21, N 6.69, H 2.83; found C 40.22, N 6.70, H 2.83.

Synthesis of $[1H_2]^{3+}\cdot 2[PF_6]^-\cdot[Hmaleate]^-\cdot H_2O$: $[1]^+\cdot[PF_6]^-$ (0.11 mmol)and an excess of maleic acid, $C_4H_2O_4$, were dissolved in 5 mL of water. Crystals suitable for single-crystal X-ray diffraction were obtained by slow evaporation of water. Elementary analysis: calcd. C 36.64, N 6.57, H 2.72; found C 36.62, N 6.55, H 2.72.

Crystal Structure Determination: Crystal data for all compounds were collected on a Bruker ApexII CCD diffractometer. Crystal data and details of measurements are summarised in Table 2. Common to all compounds: Mo-*Kα* radiation, λ = 0.71073 Å, monochromator: graphite. Data for $2[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$ were collected at 293 K, all other data were collected at 273 K. SHELX97[19a] was used for structure solution and refinement based on F^2. Non-hydrogen atoms were refined anisotropically. The $[PF_6]^-$ anion in $[\mathbf{1}H]^{2+}\cdot[PF_6]^-\cdot 1/2[fumarate]^{2-}$ is disordered over two positions (refined with an occupancy ratio of 80:20) around the F1–F5 axis. One of the two $[Hmaleate]^-$ ions in $[\mathbf{1}H]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2[Hmaleate]^-$ is disordered over two equivalent positions around an inver-

Table 2. sion centre, and was difficult to model; the position of the independent carbon atom and of the oxygen atom involved in the intramolecular hydrogen bond could not be separated well from those of the second, inverted image; the refinement was then done by attributing an average C/O scattering factor to the two atoms. All hydrogen atoms bound to nitrogen and oxygen atoms were located by difference Fourier syntheses. Only the hydrogen atoms bound to the water molecule in $2[\mathbf{1H}]^{2+}\cdot 4[PF_6]^-\cdot H_2O$ and $[\mathbf{1H_2}]^{3+}\cdot 2[PF_6]^-\cdot$ [Hmaleate]$^-\cdot H_2O$, and the H_{COOH} hydrogen in the disordered maleate monoanion in $2[\mathbf{1H}]^{2+}\cdot 5/2[PF_6]^-\cdot 3/2$[Hmaleate]$^-$ could not be located. Hydrogen atoms bound to carbon atoms were added in calculated positions. SCHAKAL99[19b] was used for the graphical representation of the results. The program PLATON[19c] was used to calculate the hydrogen-bonding interactions reported in Table 1.

Grafting Poly(4-vinylpyridine) with a Second-Order Nonlinear Optically Active Nickel(II) Chromophore

Ugo Caruso,[a] Roberto Centore,*[a] Barbara Panunzi,[b] Antonio Roviello,*[a] and Angela Tuzi[a]

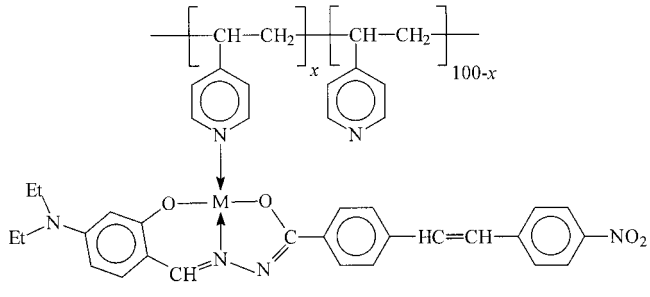
Keywords: N ligands / Nickel / Nonlinear optics / Poly(4-vinylpyridine)

Metal-containing polymers are obtained by grafting commercial poly(4-vinylpyridine) (average molecular weight 60000 or 160000) with a Ni^{II} chromophore complex. The metal-containing chromophore was obtained from a tridentate benzoylhydrazine ligand. Chromophore fragments were grafted onto the polymer by formation of a coordinative bond between the metal and the pyridinic nitrogen. Two acentric mononuclear Ni^{II} complexes containing pyridine as an additional ligand, in a square-planar or in an octahedral environment, have been prepared and characterised also by single-crystal X-ray analysis. The chemical and thermal properties of the model complexes and of the grafted polymers were examined and compared with those of Cu^{II}- and Pd^{II}-based ones, in particular with reference to their NLO properties.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Metallopolymers are a very attractive class of materials because of their widespread applications.[1a–1c] In particular, polymers bearing metallic chromophores are of current interest in the area of nonlinear optically (NLO) active materials.[2a,2b] Considerable effort has been directed toward molecular engineering of second order NLO-active coordination complexes that can be covalently bonded to a polymeric system. There are many examples in the recent literature of polymers with a metal-containing chromophoric moiety in the main chain or as side groups.[3a–3c] In particular, researchers aim to produce materials with high NLO responses that are easy to synthesise and are chemically and thermally stable.

Recently, we have developed a new approach to second-order NLO active metallopolymers based on grafting metallochromophores onto preformed (and commercially available) coordinating polymers, such as poly(4-vinylpyridine).[4a–4c] Metallochromophores are obtained by coordination of suitable metal ions to push-pull *N*-salicylidene-*N′*-aroylhydrazine-type tridentate ligands. An example of a polymer based on this approach is shown in Scheme 1 (M = metal atom).



Scheme 1.

It is likely that the coordination properties of the metal have an effect on the properties of the grafted polymer. In fact, in the case of expansion of the coordination sphere of the metal from square planar to penta- or hexacoordinate environments, a partial cross-linking (by coordination) can occur in the polymer system. This, in turn, should affect some polymer properties related to second order NLO applications, such as the glass-transition temperature and the time stability of the orientational order induced during the poling process and its extent. Up to now we have restricted our investigation to Cu^{II}- and Pd^{II}-containing metallopolymers, for which the coordination geometry expected and most frequently found is square planar, so that coordinative cross-linking of the polymers should not be expected. Actually, for model complexes of Cu^{II} with some ligands having a longer conjugation path, crystallographic evidence for weak interaction of the square-planar coordinated metal with an additional pyridine molecule, leading to pseudo-pentacoordinate complexes, has been observed.[4a–4c]

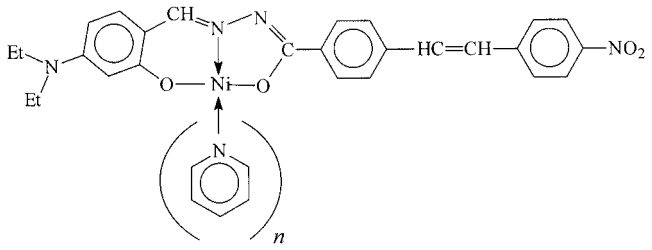
To the best of our knowledge, only a few reports of nickel-based NLO active polymers have appeared,[5a–5c] and some of these deal with host–guest-type systems.[6a,6b] In this paper we report a detailed investigation of the polymer system shown in Scheme 1 and containing Ni^{II} as the metal ion, for which a greater relevance of hexacoordination of the metal can be expected. In addition, the crystal structures of the model complexes (pyridine adducts) shown in Scheme 2 are also reported.



Scheme 2.

Results and Discussion

A general outline of the synthetic route to the new nickel-grafted polymers is shown in Scheme 3.

The model complex [Ni(L)Py] was synthesised as described in the Experimental Section. Its DSC heating curve shows only a broad endothermic signal starting at about 250 °C, corresponding to loss of the coordinated pyridine. No melting was observed under the polarizing microscope up to decomposition (about 345 °C, as detected by TGA analysis). The second-order molecular nonlinearity of [Ni(L)Py] was determined by the EFISH technique. The result obtained, $\mu\beta = 850 \times 10^{-48}$ esu, indicates a moderate activity and is consistent with results we have reported for Cu^{II} and Pd^{II} complexes containing the same ligand or closely related ligands ($\mu\beta$ between 1100×10^{-48} and 1500×10^{-48} esu[4a,4c]).

Recrystallisation of [Ni(L)Py] from THF/hexane gave brick-red prismatic crystals suitable for X-ray analysis that confirmed the square-planar coordination of nickel by the tridentate ligand and one pyridine molecule; a solvent (THF) molecule is also included in the crystal lattice. Remarkably, the same complex, when recrystallised by evaporation from pyridine, gave dark-violet crystals that, in about two hours at room temperature, turned to dark red, undergoing about 33% weight loss. Subsequent structural analysis confirmed that the dark-violet crystals contain the hexacoordinate complex [Ni(L)Py_3], in which two additional pyridine molecules are coordinated to the metal in apical positions, and pointed out the presence of a large amount of solvent of crystallisation in the crystals (2.5 pyridine molecules for each complex molecule). Since the crystals easily lose the solvent at room temperature, and also some coordinated pyridine on heating, as evidenced by the complex TGA pattern, the X-ray structural analysis for this complex was necessarily performed at low temperature (–100 °C).

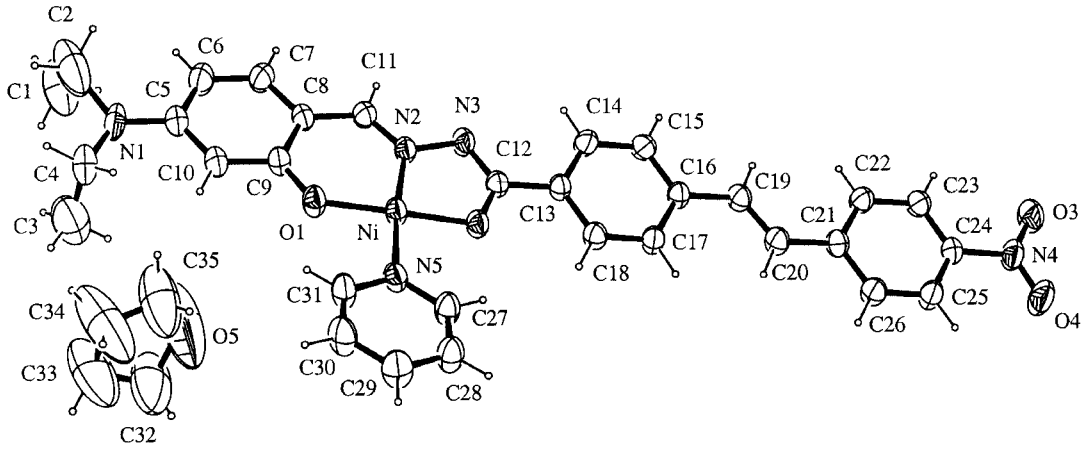

Figure 1. ORTEP view of [Ni(L)Py]. Thermal ellipsoids are at the 30% probability level. The THF solvent molecule is also shown.

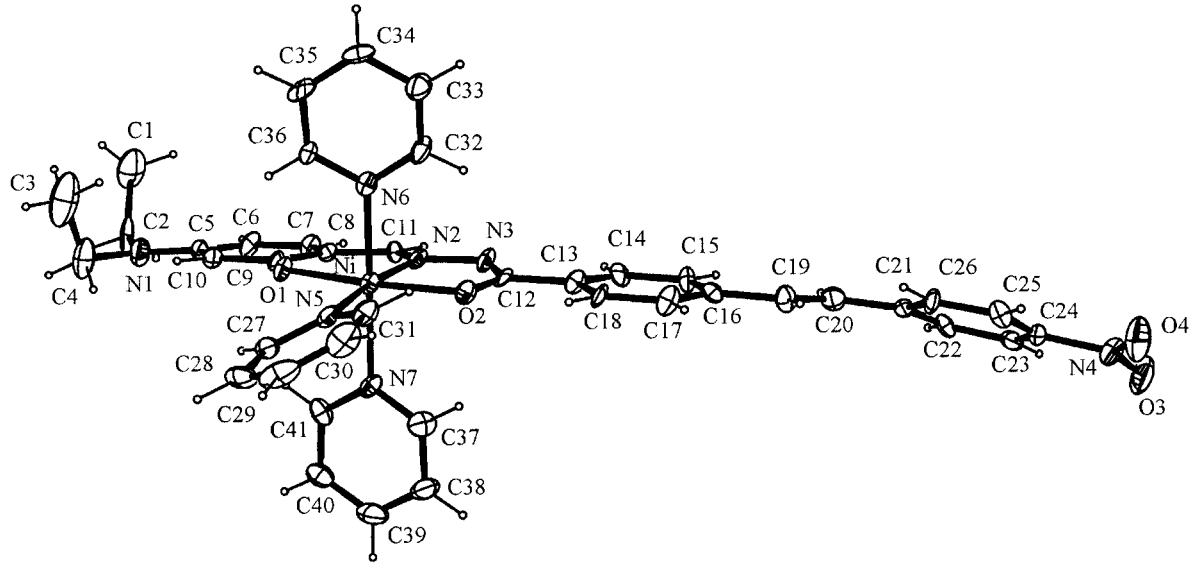

Figure 2. ORTEP view of [Ni(L)Py_3]. Thermal ellipsoids are at the 30% probability level. Pyridine solvent molecules are not shown.

The molecular structures of complexes [Ni(L)Py] and [Ni(L)Py_3] are shown in Figures 1 and 2 respectively. Selected bond lengths and angles are given in Table 1.

As evidenced by the C–O and C–N bond lengths (see Table 1), and in accordance with analogous compounds,[4a–4c] the tridentate ligand is present in its enol form in both complexes. It adopts a substantially planar conformation in the first complex, while a small torsion of the nitrophenyl group around the C20–C21 bond is present in the second (see Table 1). The coordination geometry is different in the two complexes: it is square planar in [Ni(L)Py], with general geometric features very close to those observed for analogous Cu^{II} and Pd^{II} compounds,[4a–4c] whereas in [Ni(L)Py_3] the metal is hexacoordinate with a fairly regular octahedral coordination geometry, with the tridentate ligand and one pyridine in the equatorial positions, while two additional pyridine molecules occupy the axial positions at the same mean distance (shorter than those recorded for analogous pseudo-pentacoordinate Cu^{II} complexes[4a–4c]). As compared to the square-planar complex, the distances between the metal and ligands are slightly longer in the octahedral complex, as expected. The mean plane of the (N5, C27–C31) coordinated pyridine is twisted by about 22° with respect to the equatorial coordination plane, while the mean planes of the two axial pyridines are twisted by about 18° with respect to each other. Solvent molecules are present in the crystal packing of both compounds, and this seems to be necessary in order to get crystallisation. In particular, in [Ni(L)Py_3] the pyridine solvent molecules are placed into channels running parallel to the *c* axis across the crystal, and this could explain why these molecules are easily lost even at room temperature. One pyridine solvent molecule lies on the binary axis along *c*, while the other two are placed near the screw axis parallel to *c*. Although crystals of [Ni(L)Py_3] are acentric (space group *Fdd*2), no relevant NLO activity

is expected for them because the molecules are elongated perpendicularly to the polar binary axis, which gives rise to an antiparallel arrangement of the push–pull fragments.

As far as the thermal behaviour of the hexacoordinate species is concerned, the TGA curve of [Ni(L)Py_3] above 100 °C (when the crystallisation pyridine molecules and both the axial pyridine molecules are lost) is the same as that of the square-planar complex [Ni(L)Py], as shown in Figure 3. From 220 to 250 °C a weight loss of about 11% is observed due to removal of coordinated pyridine from the square-planar complex and formation of a species that is stable up to 330 °C, which does not melt before decomposition. The elemental analysis of that species (a red crystalline product) is compatible with formation of the dinuclear [$Ni_2(L)_2$] species. Its TGA curve is shown in Figure 4. This behaviour suggests a good way to obtain [$Ni_2(L)_2$] species, since the methods described previously for other M^{II} ions[3c, 4a-4c] do not give products with a satisfactory degree of purity. Thermal treatment of [Ni(L)Py] at 270 °C for 3 min gave the dinuclear species quantitatively, which was then used in the grafting reaction onto the poly(4-vinylpyridine) (PVPy) backbones.

Grafted polymers were obtained by a bridge-splitting reaction of [$Ni_2(L)_2$] and anchoring of the Ni(L) fragments directly onto the pyridine nitrogens of the PVPy chains, as described previously.[4a–4c] Since a suitable choice of the molecular weight of the polymer backbone and of the grafting percentage of chromophoric fragment allows us to tune the spectroscopic, rheological, and thermodynamic properties of the final materials, two different compositions in complex (35% and 60% by weight) and two different molecular weights of PVPy (60000 and 160000) were studied. The latter choice was made in order to gain more viscous systems that are useful in the spin-coating deposition of polymeric thin films.

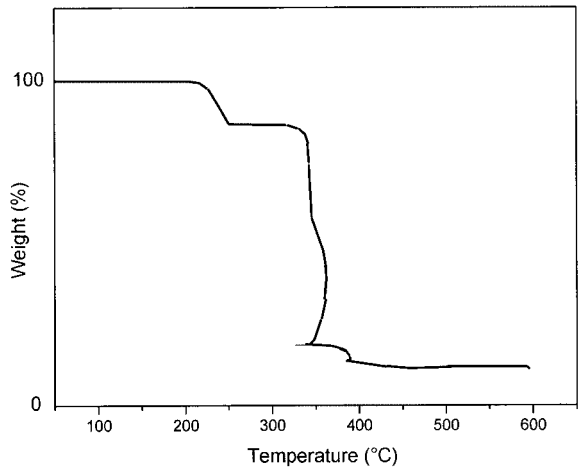

Figure 3. TGA curve of [Ni(L)Py] at a heating rate of 20 °C min^{-1}.

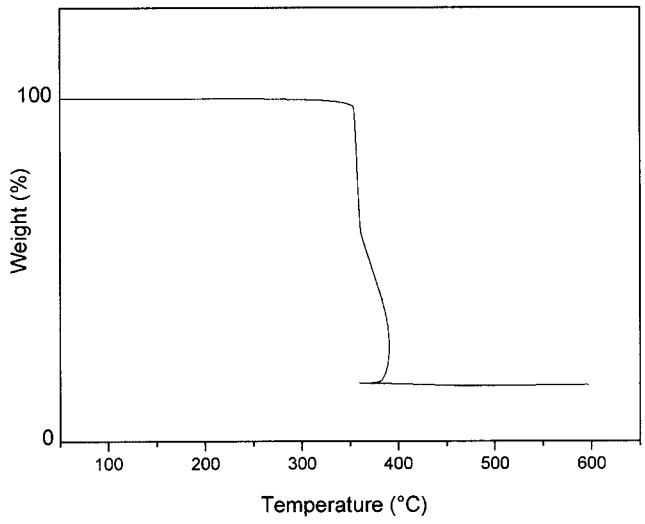

Figure 4. TGA curve of [$Ni_2(L)_2$] at a heating rate of 20 °C min^{-1}.

All the grafted PVPy samples are soluble in DMF and in *N*-methyl-2-pyrrolidinone. The ^{1}H NMR spectra of the four grafted PVPy samples, recorded in DMF solution, show broad peaks due to the high molecular weight of the polymers. No sharp peak pertaining to a free low-molecular-weight complex is detected. The signal at about δ = 8.5 ppm, due to the *ortho* hydrogen of the coordinated pyridine nitrogen, which occurs at about δ = 8.2 ppm in free PVPy and a peak at about δ = 3.4 ppm due to the –CH_2–*N*-φ protons in the chromophore, are the only significant resonances.

[a] Glass-transition temperature. [b] Decomposition temperature (5% weight loss) in air. [c] Inherent viscosity (c = 50.0 mg mL^{-1}) in NMP at 60 °C. [d] Calculated metal content as NiO. [e] Experimental metal content as NiO. [f] Molar extinction coefficient. [g] Absorption maxima. [h] Coordinated fragment (as NiL) content calculated from absorbance values (on the basis of the absorbance of the dinuclear complex). [i] Dried at 200 °C.

The most relevant UV/Vis and thermodynamic data of the polymers are reported in Table 2. The values of the molar extinction coefficient from the UV/Vis spectra recorded in $CHCl_3$ solutions follow the chromophore content.

The glass-transition temperatures (T_g) increase with the grafting amount, and they are independent of the molecular weight of the polymer backbone. Remarkably, in this case we note a higher increase of the T_g with respect to analogous Cu^{II}- and Pd^{II}-grafted polymers.[4a–4c] In particular, the T_g values for both [Ni(L)35PVPy60] and [Ni(L)35PVPy160] are 53 °C above the value for free PVPy and those of [Ni(L)60PVPy60] and [Ni(L)60PVPy160] 98 °C above this value. For the Cu^{II}- and Pd^{II}-grafted PVPy (same ligand L), increases of 48 °C for both the 35% grafted polymers and only 74 °C for both the 60% ones were observed.[7]

UV/Vis absorption spectra for the mononuclear and the dinuclear species, the ligand and a metallated polymer (the curve for [Ni(L)35PVPy60] is reported as an example) are shown in Figure 5. As expected, the UV/Vis absorption pattern and λ_{max} value for the free ligand L are very different from those pertaining to the species containing L as a tridentate ligand, i.e. the mononuclear square-planar complex, the dinuclear complex and the grafted polymers, which are essentially identical. These spectra are also very similar to those we have recorded for complexes containing the same ligand and Cu^{II} or Pd^{II} metal ions.[4a] The UV/Vis spectra of the octahedral species are complicated by the various equilibria between adducts with different coordination geometry occurring in solution and also depend on the donor capability of the solvent.

The DSC curves for the two commercial PVPy samples and the corresponding grafted polymers are given in Figure 6. It should be noted that the signal due to the glass transition for a sample dried at 200 °C is very sharp (about 30 °C) in all cases. The larger increase in the T_g as compared with Cu^{II} and Pd^{II} systems[4a–4c] may be correlated with the tendency of the Ni^{II} ion to add two other pyridine molecules, thus promoting a stronger interaction between the polymer chains. Other experimental evidence of this behaviour is the observation that the solutions in which the grafting reaction was performed, and also the 10% solutions obtained by dissolving the metallated polymers at 200 °C to prepare spin-coated thin film samples, yield a gel upon quick cooling to room temperature.

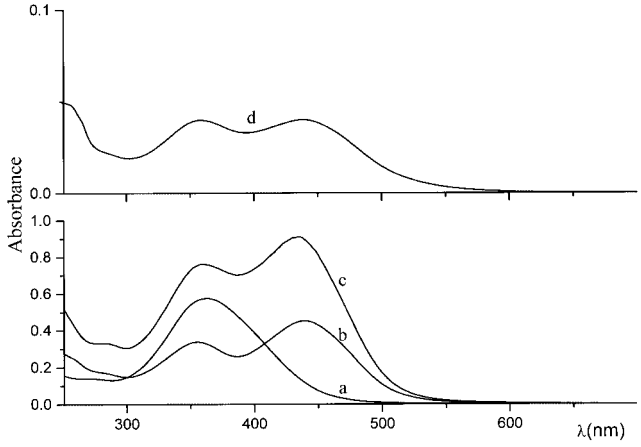

Figure 5. UV/Vis absorption spectra of L (curve a), [Ni(L)Py] (curve b), [$Ni_2(L)_2$] (curve c) and [Ni(L)35PVPy60] (curve d).

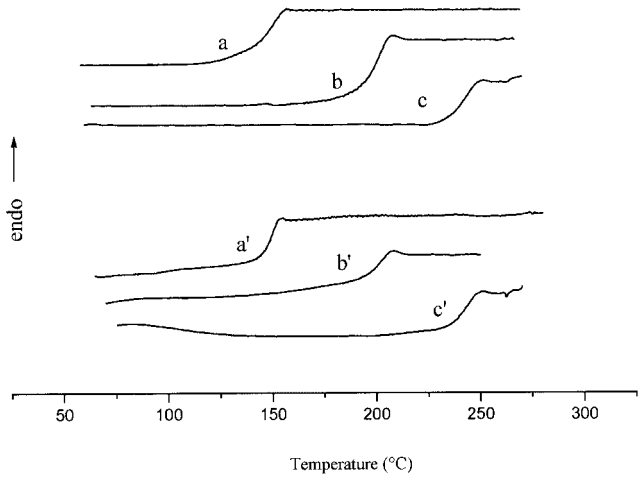

Figure 6. DSC curves (10 °C min^{-1}, N_2 atmosphere) for PVPy 60000 (a), [Ni(L)35PVPy60] (b), and [Ni(L)60PVPy60] (c), and PVPy 160000 (a′), [Ni(L)35PVPy160] (b′) and [Ni(L)60PVPy160] (c′).

Another point that is probably also related to the pyridine–metal interactions is the increase of the inherent viscosities with the grafting percentage with respect to that of free **PVPy**. In contrast, the inherent viscosities of the Cu^{II}-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and Pd^{II}-grafted PVPy samples decrease with the metal content.[4a–4c]

Thermal treatments of polymer samples simulating poling conditions (i.e. annealing near or above the T_g for 30 min) do not produce appreciable changes in their thermal behaviour. No evidence of crystallinity was detected in the subsequent DSC heating runs or by optical observations under a polarizing microscope. On a sample deposited as a thin film on a glass slide by the spin-coating technique from hot NMP solution, a transparent homogeneous surface was observed. X-ray spectra recorded for the untreated polymer samples show only haloes typical of an amorphous phase.

The high T_g values, the good thermal stability (decomposition temperatures are generally over 330 °C) and the absence of structured phases make these metallated polymers promising as materials for second order NLO applications. Moreover, the ability to establish interactions between the polymer chains (by metal coordination) could be used to obtain a kind of cross-linking at temperatures lower than the T_g, thus providing a stabilisation of the polar order of the chromophore units that is higher than in the analogous Cu^{II}- and Pd^{II}-grafted PVPy samples.

Conclusions

The use of a fragment containing the nickel(II) ion bound to a tridentate ligand in the preparation of grafted poly(4-vinylpyridine) samples for nonlinear optics affords significant improvements in the properties of the final materials. The ability of Ni^{II} to enlarge its coordination sphere is evidenced by the isolation and structural determination of a tetracoordinate square-planar model complex and of the corresponding hexacoordinate octahedral complex (resulting from addition of two other pyridine molecules to the first complex). The crosslinking related to the coordination expansion is reflected in the higher glass-transition temperatures of this series of metallated polymers and in the increase of their inherent viscosities. This should enhance the poling time stability.

Experimental Section

Materials: All solvents, poly(4-vinylpyridine) (PVPy; M_n = 60000 and 160000 uma), 4-diethylamino-2-hydroxybenzaldehyde, 4-nitrocinnamic acid and nickel(II) perchlorate hexahydrate are commercially available (Aldrich) and were used without purification.

Physical Measurements: Phase-transition temperatures and enthalpies were measured using a differential thermal analyzer DSC Perkin–Elmer Pyris (scanning rate 10 °C min^{-1}, nitrogen flow). Optical observations were performed with a Zeiss Axioscop polarizing microscope equipped with an FP90 Mettler temperature heating stage. UV/Vis absorption spectra were recorded at room temperature with a Jasco V-560 Spectrophotometer in DMF. IR spectra were recorded with a JASCO FP-750 apparatus. Thermogravimetric analysis was performed in air with a TA Instruments SDT 2960 with simultaneous DSC-TGA recording. ^1H NMR spectra were recorded by Varian spectrometers operating at 200 MHz or at 300 MHz. X-ray diffraction patterns were recorded on a flat film camera (Ni-filtered Cu-K_α radiation). The inherent viscosities of polymers (NMP solutions at 60.0 °C) were measured with an Ubbelohde viscometer.

Synthesis: Synthetic pathways for the metallated polymers [Ni(L)-PVPy] and for the dinuclear complex $[Ni_2(L)_2]$ and mononuclear complex [Ni(L)Py] are reported in Scheme 3. The synthesis of the ligand L has already been described by us.[4a]

[Ni(L)Py]: A solution of nickel(II) perchlorate hexahydrate (2.5 g, 6.84 mmol) in 20 mL of water was added at about 100 °C to a solution of L (3.0 g, 6.54 mmol) in 100 mL of pyridine. The resulting solution was stirred at 100 °C for about 10 min, after which time a dark-red solid precipitated upon further addition of water (about 80 mL). This solid was recovered by filtration and washed three times with water, then dried at 110 °C. Yield: 3.46 g (89%). Decomposition occurs before melting. $C_{31}H_{29}N_5NiO_4$: calcd. C 62.59, H 5.04, N 11.78; found C 62.58, H 4.98, N 11.68. Recrystallisation from $CHCl_3$/heptane gave brick-red crystals of [Ni(L)Py]. Single crystals for X-ray diffraction analysis were obtained from THF solution. ^1H NMR (200 MHz, $CDCl_3$, Me_4Si): δ = 8.68 (d, 2 H), 8.20 (d, 2 H), 7.92 (d, 2 H), 7.76 (s, 1 H), 7.63 (d, 2 H), 7.48 (m, 4 H), 7.19 (m, 3 H), 6.22 (s, 1 H), 6.17 (s, 2 H), 3.346 (q, 4 H), 1.17 (t, 6 H) ppm.

[Ni(L)Py_3]: Dark-violet crystals of the hexacoordinate complex were obtained by slow evaporation of a pyridine solution of [Ni(L)Py]. The sample was stored at room temperature under pyridine atmosphere for further characterisations.

[$Ni_2(L)_2$]: This dinuclear complex was obtained by thermal treatment of the mononuclear complex [Ni(L)Py] at 270 °C for 3 min. The resulting dark-red crystals were used without further treatment. Yield: quantitative. Decomposition occurs before melting. $C_{52}H_{48}N_8Ni_2O_8$: calcd. C 60.56, H 4.85, N 10.87; found C 60.44, H 4.80, N 10.79.

Ni(L)PVPy: Four polymers {[Ni(L)35PVPy60], [Ni(L)60PVPy60], [Ni(L)35PVPy160] and [Ni(L)60PVPy160]} were obtained by grafting the fragment Ni(L) (at 35% and 60% by weight) onto two PVPy samples (60000 and 160000 average molecular weight). The polymers were prepared following a synthetic procedure already described by the authors,[4b] by dissolving the appropriate amount of PVPy (previously dried at 200 °C) in DMF and the dimeric complex $[Ni_2(L)_2]$ in DMF and blending and stirring the solution for 25 min at 90 °C. The polymer that precipitated upon addition of water was washed twice with vigorous stirring and dried at 120 °C. The yield was quantitative.

[Ni(L)35PVPy160]: Calcd. C 72.37, H 6.02, N 12.46; found C 71.00, H 6.16, N 12.22.

[Ni(L)35PVPy60]: Calcd. C 72.37, H 6.02, N 12.46; found C 70.38, H 6.12, N 12.08.

[Ni(L)60PVPy60]: Calcd. C 68.26, H 5.57, N 11.84; found C 67.80, H 5.60, N 11.85.

[Ni(L)60PVPy160]: Calcd. C 68.26, H 5.57, N 11.84; found C 67.65, H 5.68, N 11.76.

X-ray Analysis: X-ray data collection for [Ni(L)Py] was performed at room temperature on an Enraf–Nonius MACH3 diffractometer in the ω/θ scan mode, using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). Cell parameters were obtained from a least-squares fit of the θ angles of 25 reflections in the range 7.04° $\leq \theta \leq$ 8.95°. A semi-empirical absorption correction (ψ scans) was applied.

Data collection for $Ni(L)Py_3$ was performed at low temperature (–100 °C) on a Bruker–Nonius kappa CCD diffractometer (Mo-K_α

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

radiation, phi scans + omega scans to fill the asymmetric unit). Cell parameters were obtained from a least-squares fit of the θ angles of 30 reflections in the range $6.02° \leq \theta \leq 9.89°$. A semi-empirical absorption correction (multiscan, SADABS) was applied.

Both structures were solved by direct methods and refined anisotropically by the full-matrix least-squares method on F^2 against all independent measured reflections (SHELXS and SHELXL program of the SHELX 97 package[8]). H atoms were placed in calculated positions as riding on their carriers atoms. Max. residual electron density 0.691 (–0.424) e Å^{-3} for [Ni(L)Py] and 0.315 (–0.333) e Å^{-3} for [Ni(L)Py$_3$]. Some crystal, collection and refinement data are reported in Table 3.

CCDC-249658 (for [Ni(L)Py]) and CCDC-249659 (for [Ni(L)Py$_3$]) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

NLO Characterisation: The second-order optical nonlinearity of [Ni(L)Py] was determined by the EFISH technique, in chloroform, by measuring the $\mu_g\beta$ dot product of the chromophore, where μ_g is the ground state permanent dipole moment and β the (vector) quadratic hyperpolarizabilty of the molecule. The light source was a Q-switched Nd:Yag laser whose emission at 1.06 μm was shifted to 1.907 μm by stimulated Raman scattering in a high-pressure hydrogen cell. The measurements were calibrated relative to a quartz wedge: the experimental value of $d_{11}^{quartz} = 1.2 \times 10^{-9}$ esu at 1.06 μm was extrapolated to 1.1×10^{-9} esu at 1.907 μm. A detailed description of the experimental apparatus is given elsewhere.[9]

Acknowledgments

We thank the CIMCF of the Università di Napoli "Federico II" for X-ray (MACH 3) and NMR facilities and the C.R.d.C. "Nuove Tecnologie per le attività produttive" (Regione Campania, Italy) for the Nonius kappa-CCD diffractometer. Financial support from MIUR (Italy) within FIRB2001 grant is also acknowledged. Thanks are due to Dr. Alain Fort of IPCMS-CNRS GONLO of Strasbourg (France) for help with the EFISH measurements.

[1]Borahafnocenophanes: Synthesis, Structure and Catalytic Activity

Holger Braunschweig,*[a] Mario Kraft,[a] Krzysztof Radacki,[a] and Sascha Stellwag[a]

Keywords: Boron / Hafnium / Metallocenophanes / *ansa*-Metallocenes / Ethylene polymerisation

Various [1]borahafnocenophanes of the general formula $[R_2NB(\eta^5\text{-}C_5H_4)_2HfCl_2]$ [R = CH_3, **13**; R = C_2H_5, **14**; R_2 = $(CH_2)_5$, **15**] were synthesised in high yields by a convenient two-step, one-pot synthesis, and their constitution in solution elucidated from multinuclear NMR spectroscopic data. Suitable single crystals of complexes **13** and **15** were subjected to X-ray diffraction studies, thus providing the first structural data of [1]borahafnocenophanes. The catalytic activity of the new complexes in the Ziegler–Natta polymerisation of ethylene was studied and compared to that of corresponding [1]borazirconocenophanes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Over the past few decades Group 4 metallocenophanes have been studied intensively due to their potential as Ziegler–Natta-type catalysts for the polymerisation of olefins.[1] By tailoring the ligand framework and the *ansa*-bridge in particular, highly active and, with respect to the polymerisation of propene, highly stereoselective catalysts were designed.[2–4] R_2C, R_4C_2 and R_2Si bridges have been commonly incorporated.[5–7] The introduction of a boranediyl bridge, i.e. a $B{=}NR_2$ moiety, is believed to be of some advantage with respect to the catalytic performance of such *ansa* complexes, since the small boron atom imposes high rigidity, and therefore has a potential to improve the stereoselectivity of the catalyst, especially at higher temperature, where the polymerization is usually performed. In addition, a three coordinate boron atom is to some extent Lewis-acidic, a fact that is believed to enhance the activity of the Group 4 metal centre. Thus, [1]borametallocenophanes and related constrained-geometry complexes (CGC)[8] of Ti and Zr were put into focus very recently.[9,10] Shapiro and Reetz reported the first [1]borazirconocenophanes **1** and **2**,[11] which displayed a phenylboranediyl-moiety linking the two η^5-coordinated ligands. These complexes, however, could only be obtained as adducts with Et_2O, THF, SMe_2 or PMe_3 (Figure 1), therefore cancelling the Lewis acidity of the boron atom. Rufanov et al. reports the isolation of a metallocenophane incorporating a base-free three-coordinate boron bridge,[12] although these results are not reproducible and the complex is poorly characterized. Hence, the validity of this assignment is still in question.[10] Attempts to synthesise analogous zirconocene complexes in the absence of Lewis-bases have so far failed.[11] The reaction of **1** with $Li[C_6F_5]$ was reported by Lancaster to yield the corresponding anionic *ansa*-zirconocene **3**.[13]

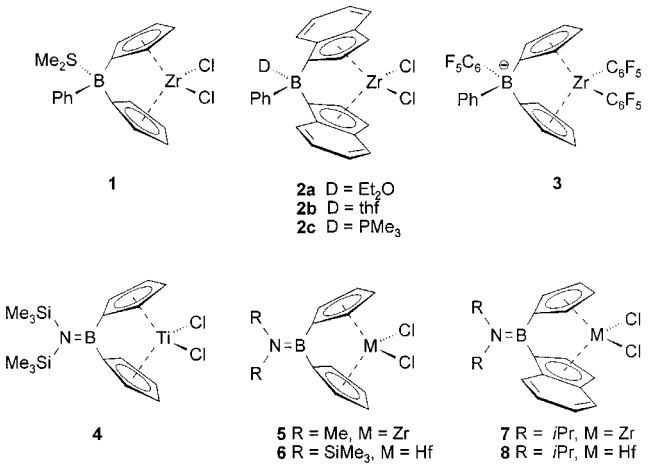

Figure 1. Boron-bridged metallocenes of Ti, Zr, and Hf.

In 1999 we reported on the titanium complex **4** as the first base-free [1]borametallocenophane of Group 4,[14] and in the same year we and Ashe extended the use of the aminoboranediyl-bridge to the synthesis of the corresponding zirconium complexes.[15,16] Subsequently, the chemistry of base-free [1]borazircono- and titanocenophanes was developed to some extent, providing evidence for their enhanced properties as Ziegler–Natta-type catalysts.[8,14–19] In sharp contrast to those Ti- and Zr-based *ansa* complexes, knowledge of corresponding [1]borahafnocenophanes is restricted to the brief spectroscopic characterisation of only two examples, $[(Me_3Si)_2NB(\eta^5\text{-}C_5H_4)_2HfCl_2]$ (**6**) and $[iPr_2NB(\eta^5\text{-}C_5H_4)(\eta^5\text{-}C_9H_6)HfCl_2]$ (**8**).[15] Structural studies, as well as information on their performance as catalysts, however, remained elusive.

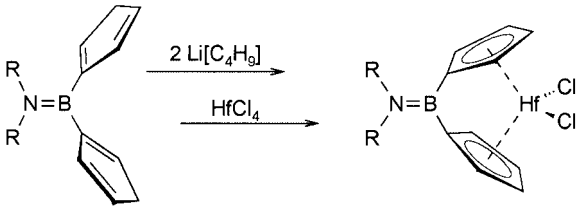
In this paper we address this deficiency and report on a series of new [1]borahafnocenophanes, their characterisation in the crystalline state and their use as catalysts for the polymerisation of ethylene.

Results and Discussion

As described earlier the reaction of amino(dihalo)borane R_2NBX_2 (R = Me, *i*Pr, $SiMe_3$; X = Cl, Br) with two equiv. of Na[C_5H_5] leads straightforwardly to the respective amino(biscyclopentadienyl)borane in excellent yields.[17] The reaction of Et_2NBBr_2 (**9**) and $(CH_2)_5NBBr_2$ (**10**) with 2 equiv. Na[C_5H_5] gave, at reaction times of 16 h, $Et_2NB(\eta^1\text{-}C_5H_5)_2$ (**11**) and $(CH_2)_5NB(\eta^1\text{-}C_5H_5)_2$ (**12**), respectively, in almost quantitative yields [Equation (1)]. The constitution in solution of the biscyclopentadienyl ligand precursors has been studied and reported elsewhere.[17] As shown in Equation (1), in the initial product the boron is bound to a sp^3-hybridised carbon, yielding the kinetically favoured product; below room temperature a sigmatropic proton rearrangement takes place to give the thermodynamically favoured product.

The rearrangement process leads to two new isomers per Cp-ring in which boron is bound to sp^2-hybridised carbon atoms. The rearrangement is not reversible, presumably due to interactions between the vinylic π-electrons of the adjacent carbon atoms with the empty p_z-orbital of boron. A nomenclature to distinguish between the three isomers was introduced, describing the positions of the double bonds in the Cp ring with respect to the boron atom: **a**llylic/**a**llylic (aa), **v**inylic/**a**llylic (va) and **v**inylic/**h**omoallylic (vh).[17] In biscyclopentadienylborane systems 6 isomers are theoretically possible (aa/aa, aa/va, aa/vh, va/va, va/vh and vh/vh), however only the three isomers in which boron is bound to a sp^2-hybridised carbon (va/va, va/vh and vh/vh) are expected at ambient temperatures. Due to these isomeric mixtures the resulting ^1H and the ^{13}C NMR spectra of both ligand precursors (**11** and **12**) are complex. A low field shift of around 10 ppm in the ^{11}B NMR was reported for $R_2NB(\eta^1\text{-}C_5H_5)_2$ (R = Me, *i*Pr, $SiMe_3$) compared to the corresponding amino(dihalo)boranes;[15,17] for **11** and **12** similar shifts to lower field compared to the parent boranes were observed.

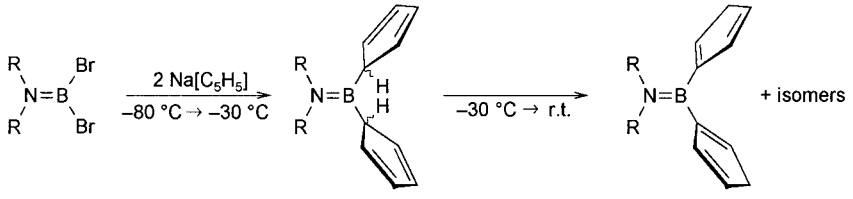
The hafnium complexes $[Me_2NB(\eta^5\text{-}C_5H_4)_2HfCl_2]$ (**13**), $[Et_2NB(\eta^5\text{-}C_5H_4)_2HfCl_2]$ (**14**) and $[(CH_2)_5NB(\eta^5\text{-}C_5H_4)_2HfCl_2]$ (**15**) are obtained according to Equation (2) in a convenient two-step, one-pot reaction, starting from the ligand precursors $R_2NB(\eta^1\text{-}C_5H_5)_2$ and 2 equiv. BuLi and subsequent treatment with $HfCl_4$. The dimetallation of the ligand precursor is carried out at –80 °C with subsequent warming to ambient temperatures, yielding quantitatively the dilithiated Cp derivative that is treated in situ with $HfCl_4$ at low temperature. Complexes **13**, **14** and **15** are sparingly soluble in toluene but soluble in CH_2Cl_2 and proved to be stable in the solid state towards decomposition over weeks when stored at room temperature.



13 R = CH_3
14 R = C_2H_5
15 R,R = $-(CH_2)_5-$ (2)

The structure of **13**–**15** in solution was derived from multinuclear NMR spectra, showing the expected two pseudo triplets in the ^1H NMR spectra for the AA′BB′ spin system of the cyclopentadienyl protons at δ = 5.66, 6.73 (**13**), 5.65, 6.73 (**14**) and 5.31, 6.33 ppm (**15**). The carbon signals for the Cp-rings in the ^{13}C NMR spectra are all in the same range at 110 and 125 ppm, respectively. The signals for the C_{ipso} of the Cp ring could not be detected in the room temperature ^{13}C NMR spectra of **13**–**15** due to quadrupolar $^{13}C\text{-}^{11}B$ coupling.[20] Virtually unaffected by the complexation of the ligand is the ^{11}B NMR signal of **13**–**15**, as reported before.[8]

Pale yellow crystals of **13** and **15** suitable for X-ray diffraction were obtained from toluene at –35 °C (Figure 2). Their crystal structures are compared with those of the complexes $[(\eta^5\text{-}C_5H_5)_2HfCl_2]$[21] (**16**), $[Me_2C(\eta^5\text{-}C_5H_4)_2HfCl_2]$[22] (**17**) and $[Me_2Si(\eta^5\text{-}C_5H_4)_2HfCl_2]$[23] (**18**). All bond lengths and angles discussed here are summarised



kinetically favoured product thermodynamically favoured product

Introducing the bridging unit causes changes in the geometry of the molecule with respect to the parent compound **16**. The *tilt angle* α increases with the incorporation of smaller bridging atoms, according to the trend C > B > Si; an α value of 53.5° is found for **16**, 57.7° for **18**, 64.7° for **13**, 64.9 for **15** and 70.1° for **17**. Virtually the same trend is found for the angle δ, being of 129.2° for **16**, 127.6° for **18**, 121.7° for **15**, 121.4° for **13** and 117.1° for **17**, respectively, highlighting the close relationship between α and δ. Furthermore, it is interesting to consider the values of θ for the four structures. These indicate a smaller deviation from the ideal tetrahedral angular value (109°) in **17** than in **18**, according to the smaller covalent radius of C with respect to Si. This results in a shorter C_{ipso}–E (E = C, **17**; E = Si, **18**) bond and a larger θ value for **17** (99.4°) than **18** (93.7°). The corresponding angles for **13** and **15** are 105.2(3)° and 105.5(2)°, respectively, reflecting the distortion of these complexes (a value of θ = 120° would be expected given the sp^2-hybridization of B). However, a direct comparison of the angle θ for the 4 structures is not possible, due to the different hybridisation of the bridging atoms.

An important factor for the polymerisation activity is the position of the metal centre relative to the Cp-centroids, which is described by the angle δ (Figure 3, part b). The polymerisation activities might increase when the metal protrudes from the wedge created by the Cp-ligands, due to a better accessibility of the metal centre to the incoming olefin. As expected, there is a relationship between the *tilt angle* α and the distance (*d*) of the metal from the vector connecting the Cp-centroids. The differences in the values *d* for the new compounds with respect to the parent complex, expressed in per cent, demonstrate the effect of the bridging moiety.[22] In **16** the distance *d* is 0.935 Å; a similar value is found for **18** (0.964 Å), with a change of 3.1%, while in the carbon bridged complex **17** the metal protrudes 1.134 Å (21.3%) away from the Cp-Cp vector. In both boron bridged complexes **13** and **15** the hafnium centre displays similar deviations with respect to its position in **16**, 1.066 Å (14.0%) and 1.061 Å (13.5%).

The B–N distance is typical for a corresponding double bond [1.369(5) Å for **13** and 1.371(4) Å for **15**] and similar to that found in the Zr complex $[Me_2NB(\eta^5\text{-}C_5H_4)_2ZrCl_2]$ (**5**) (B–N distance 1.384 Å). The angle θ in the compounds **13** and **15** [105.2(3)° and 105.5(2)°] is virtually the same as

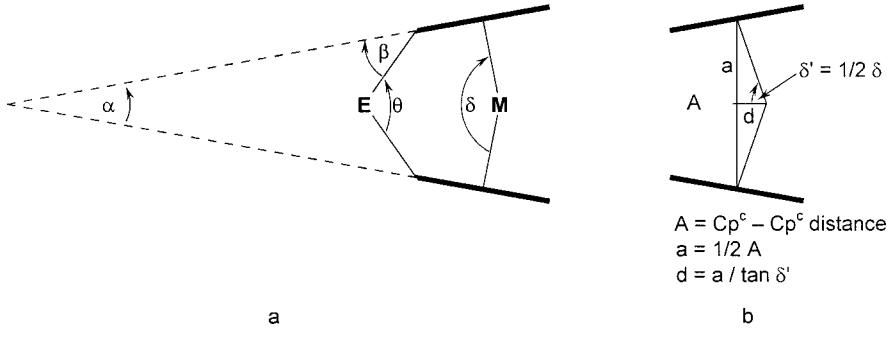

Figure 3. Structural parameter of *ansa*-metallocenes.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that observed in **5** (105.9°), as is the *tilt angle α* (**13**, 64.7°, **15**, 64.9° and **5**, 65.5°). The remaining structural parameters of **13** and **15**, especially those related to bond length and angles at the metal centre, are similar to those of **5**, reflecting the similar size of Zr and Hf.

The structural changes in the so-called *unstrained* complexes **13** and **15** compared to the parent complex **16**, are less pronounced then those observed in related *strained ansa*-metallocenes.[24] The small boron bridge in [1]boraferrocenophanes causes a more pronounced change in the geometric parameters compared to the parent ferrocene, e.g. *tilt angles* of about 32° are usually observed in [1]boraferrocenophanes.[25]

Polymerisation of Ethylene

The [1]borahafnocenophanes **13** and **14** were studied as catalysts for the polymerisation of ethylene. After activation with a 4500 fold excess of MAO the complexes polymerise ethylene at slightly elevated temperature with an activity of about 260 $kg_{PE}·mol_{Hf}^{-1}·h^{-1}$. As to be expected from studies on various Zr- and Hf-based catalyst systems,[2,26,27] the activity displayed here is lower than that of corresponding [1]borazirconocenophanes by a factor of 7.[28] However, the molecular masses (M_w) of the obtained PE-samples as determined by GPC-methods were found to be 19200 $g·mol^{-1}$ for **13** and 34500 $g·mol^{-1}$ for **14**, thus being significantly higher than in the case of Zr.

Conclusions

The synthetic method described in this paper and previously reported for titanium and zirconium complexes provides a general route to Group 4 [1]borametallocenophanes. Determination of the first crystal structures of [1]borahafnocenophanes **13** and **15** allows for a direct comparison of important structural parameters to those of corresponding complexes of Ti and Zr. It is now demonstrated that [1]borametallocenophane complexes of all three Group 4 metals can act as active catalysts in olefin polymerisation when sufficiently activated. The activity of [1]borahafnocenophanes was found to be lower than that of comparable zirconium complexes, but the resulting polymers are characterised by a higher molecular weight. Studies on the catalytic behaviour of Group 4 [1]borametallocenophanes as a function of the steric and electronic properties of the ligand framework are ongoing.

Experimental Section

All manipulations were carried out under dry argon with common Schlenk techniques. Solvents were dried with a solvent purification system (SPS) from M. Braun columns and stored under argon over molecular sieves; reagents were dried and purified by standard procedures. Dibromo(diethylamino)borane,[29] dibromo(piperidino)borane,[30] Me_2NB-(η^1-C_5H_5)$_2$[17] and Na[C_5H_5][31] were obtained according to literature procedures. Li[C_4H_9] and $HfCl_4$ were obtained commercially and used without further purification. NMR: Bruker Avance 200 at 64.21 MHz (^{11}B, $BF_3·OEt_2$ in C_6D_6 as external standard), Bruker Avance 400 at 400.13 MHz (^{1}H, internal standard TMS), 100.61 MHz (^{13}C{^{1}H}, APT, internal standard TMS).

Mass spectra were recorded with a Thermo Finnigan Trio 1000 and with a Finnigan MAT 8200. Elemental analyses (C, H, N) were obtained from a Carlo–Erba elemental analyzer, model 1160. The polymerisation experiments were carried out in a 500-mL glass autoclave from Büchi.

$Et_2NB(\eta^1\text{-}C_5H_5)_2$ (11): $(C_2H_5)_2NBBr_2$ (1.75 g, 7.20 mmol) is added to a suspension of Na[C_5H_5] (1.21 g, 14.40 mmol) in hexane (40 mL) at –80 °C. The mixture is allowed to come to ambient temperature and is subsequently stirred for 16 h. Insoluble materials are removed by centrifugation and the solvent is removed in vacuo yielding 1.45 g (94%) **11** as a yellow oil. ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C, isomeric mixture of **va/va**, **va/vh** and **vh/vh**): δ = 1.11, 1.16, 1.20 [t, ^3J(H,H) = 7.02 Hz, 18 H, CH_3], 3.05, 3.09, 3.12 (m, 12 H, CH_{2Cp}), 3.21, 3.26, 3.36 (q, $^3J_{H,H}$ = 7.02 Hz, 12 H, CH_2), 6.3–6.7 (m, 18 H, CH_{Cp}) ppm. ^{11}B NMR (64 MHz, CD_2Cl_2, 25 °C): δ = 37.9 ppm. ^{13}C NMR (100 MHz, CD_2Cl_2, 25 °C, isomeric mixture of **va/va**, **va/vh** and **vh/vh**): δ = 16.23, 16.40, 16.41 (CH_3), 43.23, 43.67, 43.77, 44.17, 46.85, 46.94 (CH_2, CH_{2Cp}); 131.97, 133.21, 133.26, 135.89, 137.13, 137.26, 137.35, 138.95, 141.74 (CH_{Cp}) ppm. MS: *m*/*z* (%) = 213 (75) [M^+], 198 (100) [M^+ – CH_3], 148 (60) [M^+ – C_5H_5], 141 (35) [M^+ – $(C_2H_5)_2$], 77 (92) [$C_5H_6B^+$]. $C_{14}H_{20}BN$ (213.13): calcd. C 78.90, H 9.46, N 6.57; found C 79.32, H 9.57, N 6.37.

$(CH_2)_5NB(\eta^1\text{-}C_5H_5)_2$ (12): As described for **11**, Na[C_5H_5] (1.44 g, 16.20 mmol) is suspended in hexane (40 mL) and reacted with $(CH_2)_5NBBr_2$ (2.07 g, 8.10 mmol) at –80 °C. Insolubles are removed by centrifugation and all volatiles are removed in vacuo, yielding 1.68 g (92%) **12** as a yellow oil. ^{1}H NMR (400 MHz, C_6D_6, 25 °C, isomeric mixture of **va/va**, **va/vh** and **vh/vh**): δ = 1.3–1.5 (m, 18 H, CH_{2pip}), 2.90, 3.00, 3.08 (m, 12 H, CH_{2Cp}), 3.2–3.4 (m, 12 H, CH_{2pip}), 5.5–7.2 (m, 18 H, CH_{Cp}) ppm. ^{11}B NMR (64 MHz, C_6D_6, 25 °C): δ = 36.8 ppm. ^{13}C NMR (100 MHz, C_6D_6, 25 °C, isomeric mixture of **va/va**, **va/vh** and **vh/vh**): δ = 26.14, 26.18, 29.27, 29.32, 29.37, 43.75, 47.17, 47.46, 50.66, 50.99, 51.34 (CH_{2pip}, CH_{2Cp}), 132.36, 132.45, 133.80, 133.84, 136.31, 137.36, 138.02, 138.15, 139.07, 139.63, 141.37, 141.95 (CH) ppm. MS: *m*/*z* (%) = 225 (75) [M^+], 166 (88) [M^+ – C_5H_5], 77 (100) [C_5H_6B], 65 (35) [C_5H_5]. $C_{15}H_{20}BN$ (225.14): calcd. C 80.02, H 8.95, N 6.22; found C 80.38, H 8.73, N 6.48.

$[Me_2NB(\eta^5\text{-}C_5H_4)_2HfCl_2]$ (13): A solution of $Me_2NB(\eta^1\text{-}C_5H_5)_2$ (0.98 g, 5.30 mmol) in hexane (40 mL) is treated at –80 °C with Li[C_4H_9] (4.24 mL, 10.60 mmol). After warming up to ambient temperature the mixture was stirred for further 16 h. The resulting suspension is centrifuged and the solid washed with 40 mL hexane, suspended in toluene, and then treated with $HfCl_4$ (1.70 g, 5.30 mmol) at –80 °C. The pale yellow reaction mixture is allowed to come to room temperature and stirred for 16 h, insolubles are removed by centrifugation and the solution is concentrated and stored at –35 °C. 1.93 g (84%) **13** was isolated as pale yellow crystals. ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 3.11 (s, 6 H, CH_3), 5.66 (pt, 4 H, CH_{Cp}), 6.73 (pt, 4 H, CH_{Cp}) ppm. ^{11}B NMR (64 MHz, CD_2Cl_2, 25 °C): δ = 37.7 ppm. ^{13}C NMR (100 MHz, CD_2Cl_2, 25 °C): δ = 40.33 (CH_3), 110.13, 124.67 (CH_{Cp}) ppm. MS: *m*/*z* (%) = 433 (100) [M^+], 418 (16) [M^+ – CH_3], 397 (11) [M^+ – HCl], 389 (27) [M^+ – $(CH_3)_2N$], 368 (49) [M^+ – C_5H_5], 353 (28) [M^+ – C_5H_5 – CH_3]. $C_{12}H_{14}BCl_2HfN$ (432.46): calcd. C 33.33, H 3.26, N 3.24; found C 33.71, H 3.74, N 3.03.

[$Et_2NB(\eta^5\text{-}C_5H_4)_2HfCl_2$] (14): As described for **13**, $Et_2NB(\eta^1\text{-}C_5H_5)_2$ (1.08 g, 4.80 mmol) was treated at –80 °C with $Li[C_4H_9]$ (3.84 mL, 9.60 mmol) and subsequently with $HfCl_4$ (1.54 g, 4.80 mmol). Compound **14** was obtained as a pale yellow microcrystalline material (1.53 g, 69%). ^1H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 1.27 (t, $^3J_{H,H}$ = 7.20 Hz, 6 H, CH_3), 3.45 (q, $^3J_{H,H}$ = 7.20 Hz, 4 H, CH_2), 5.65 (pt, 4 H, CH_{Cp}), 6.73 (pt, 4 H, CH_{Cp}) ppm. ^{11}B NMR (64 MHz, CD_2Cl_2, 25 °C): δ = 38.1 ppm. ^{13}C NMR (100 MHz, CD_2Cl_2, 25 °C): δ = 16.20 (CH_3), 43.72 (CH_2), 109.89, 124.58 (CH) ppm. MS: *m/z* (%) = 461 (100) [M^+], 389 (56) [$M^+ - (C_2H_5)_2N$], 353 (44) [$M^+ - (C_2H_5)_2N - HCl$]. $C_{14}H_{18}BCl_2HfN$ (460.51): calcd. C 36.51, H 3.94, N 3.04; found C 36.84, H 4.29, N 2.78.

[$(CH_2)_5NB(\eta^5\text{-}C_5H_4)_2HfCl_2$] (15): As described for **13**, $(CH_2)_5NB(\eta^1\text{-}C_5H_5)_2$ (0.86 g, 3.80 mmol) was treated at –80 °C with 2.5 M $Li[C_4H_9]$ (2.96 mL, 7.60 mmol) and subsequently with $HfCl_4$ (1.22 g, 3.80 mmol). Compound **15** was obtained as a pale yellow microcrystalline material (1.35 g, 78%). Recrystallisation from toluene yielded single crystals suitable for X-ray diffraction. ^1H NMR (400 MHz, C_6D_6, 25 °C): δ = 1.1–1.3 (m, 6 H, CH_{2pip}), 3.00 (m, 4 H, CH_{2pip}), 5.31 (pt, 4 H, CH_{Cp}), 6.66 (pt, 4 H, CH_{Cp}). ^{11}B NMR (64 MHz, C_6D_6, 25 °C): δ = 36.8. ^{13}C NMR (100 MHz, C_6D_6, 25 °C): δ = 24.76, 28.19, 49.50 (CH_{2pip}), 109.64, 124.48 (CH_{Cp}). MS: *m/z* (%) = 474 (38) [M^+], 438 (100) [$M^+ - HCl$], 351 (55) [$M^+ - HCl - (CH_2)_5N$]. $C_{15}H_{18}BCl_2HfN$ (472.52): calcd. C 38.13, H 3.84, N 2.96; found C 38.51, H 4.19, N 2.63.

Polymerization: A 500-mL glass autoclave equipped with a 15 mL dropping funnel was charged with toluene (200 mL) and methylaluminoxan solution (30 mL, 10 wt.-% in toluene). A solution of the complex (5 mL) in toluene ($2\cdot10^{-3}$ M) was placed in the dropping funnel. The autoclave was pressurized with ethylene until a pressure of 2 bar was reached, simultaneously the temperature was raised to 60 °C. The polymerization was initiated by adding the complex to the toluene/MAO solution. At all times of the polymerization experiment the ethylene pressure was constantly maintained at 2 bar. The polymerization was stopped by ventilation of the autoclave and adding acidic methanol (30 mL) to quench the excess of MAO. The resulting mixture was stirred in methanol (800 mL) for 1 h and then filtered and dried at 90 °C, giving the polyethylene as a white powder, which was analyzed by high temperature gel permeation chromatography.

Crystal Structure Determination: The crystal data of **13** and **15** were collected at Bruker APEX diffractometer with CCD area detector and graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods, refined with the SHELX software package (G. Sheldrick, University of Göttingen, 1997) and expanded using Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned idealized positions and were included in structure factor calculations. **Crystal Data for 13:** $C_{12}H_{14}BCl_2HfN$ M_r = 432.44, pale yellow block, 0.28 × 0.18 × 0.17, monoclinic, space group *P*21/*n*, *a* = 11.4561(9) Å, *b* = 10.0071(8) Å, *c* = 12.0774(9) Å, β = 105.013(1)°, *V* = 1337.32(18) Å^3, *Z* = 4, $\rho_{calcd.}$ = 2.148 g·cm^{-3}, μ = 8.174 cm^{-2}, *F*(000) = 816, *T* = 193 K; R_1 = 0.0188, w_R = 0.0491, 2649 independent reflections [$2\theta \leq 52.16°$] and 154 parameters. **Crystal Data for 15:** $C_{22}H_{26}BCl_2HfN$ M_r = 564.64, pale yellow plates, 0.23 × 0.23 × 0.10, triclinic, space group *P*–1, *a* = 9.752(2) Å, *b* = 11.627(3) Å, *c* = 11.884(3) Å, *a* = 118.441(3)°, β = 101.620(3)°, γ = 101.310(3)°, *V* = 1091.8(4) Å^3, *Z* = 2, $\rho_{calcd.}$ = 1.717 g·cm^{-3}, μ = 5.028 cm^{-2}, *F*(000) = 552, *T* = 173 K; R_1 = 0.0191, w_R = 0.0483, 4298 independent reflections [$2\theta \leq 52.1°$] and 244 parameters.

CCDC-260992 and -260993 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

COVER PICTURE

The cover picture shows an allegory of bioinorganic chemistry and biomimetic studies. Here, the metalloprotein (human Mn-SOD, PDB-code 1MSD) is posing for the painter. As a bioinorganic chemist, he is designing new molecules that would reproduce this protein activity; he is testing the activity of these molecules and deciphering mechanisms. Here, we show the structure of a small Mn^{II} complex that has been studied for its SOD-like activity by pulsed radiolysis. In the painting, the UV/Vis trace of a multipulse experiment at 300 nm is shown, with successive spikes and plateaus. An overall increase in the absorbance of the successive plateaus is observed. The asterisks indicate irradiations. Simulations of the individual growth of the spikes, of the individual decrease down to the plateau and of the overall increase of the absorbance for the successive plateaus leads to the proposition of a mechanism. This is the triangular cycle shown in the painting, involving an $\{MnOO\}^6$ adduct between Mn^{II} and superoxide. This label, $\{MnOO\}^6$, is proposed by analogy with the nomenclature used for iron–nitroxide adducts. Each event indicated in the cycle has been proven. Moreover, this study shows unambiguously that the Mn^{II} compound displays a catalytic activity for superoxide dismutation. Details are presented in the article by J.-P. Renault, C. Policar et al. on p. 2789ff. In the original picture by Magritte, the inset in the lower right-hand corner, is entitled "La clairvoyance" (clear-sightedness) and was painted in 1936.

A Nonanuclear Ni^{II} Cluster with a 1,2,4-Triazolo[4,3-*a*]pyrimidine Derivative

Sawsan Salameh,[a] Mohammad Abul-Haj,[a] Miguel Quirós,*[b] and Juan M. Salas[b]

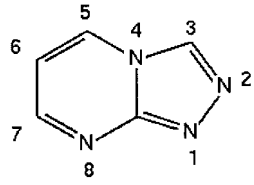
Keywords: Cluster compounds / Nickel / Triazolopyrimidine / Magnetic properties

This article describes the nickel cluster compound $[Ni_9L_8(OH)_6(NH_3)_4(H_2O)_8](NO_3)_4{\cdot}8H_2O$, where **L** represents the anionic form of the ligand 7,8-dihydro-1,2,4-triazolo[4,3-*a*]-pyrimidin-7-one. The structure of the cation of this compound is rather complicated, involving nine metal atoms, eight bridging organic ligands, bridging hydroxyl groups, and terminal ammonia and water molecules. The central nickel atom lies on a crystallographic inversion centre, while the other eight define two disorted "cubane-like" $[Ni_4(OH)_3]^{5+}$ subclusters. Each subcluster is linked to the central atom by three triple bridging organic ligands. Additional **L** ligands bridge two external metal atoms in each subcluster. The variation with temperature of the magnetic susceptibility of the compound indicates the presence of both ferromagnetic and antiferromagnetic interactions; the latter is predominant.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The condensation of a 1,2,4-triazole ring and another of a pyrimidine molecule may give rise to four different families of heterocyclic, bicyclic compounds. Among these, the thermodynamically more stable, and hence the most studied ones, are 1,2,4-triazolo[1,5-*a*]pyrimidines, which bind to metal atoms in a number of different ways to give rise to different structural motifs.[1] More bonding possibilities arise if the positions of the nitrogen atoms in the heterocycle are interchanged, defining the isomeric families 1,2,4-triazolo[1,5-*c*]pyrimidines,[2] 1,2,4-triazolo[4,3-*a*]pyrimidines,[3] and 1,2,4-triazolo[4,3-*c*]pyrimidines.[4] These are far less thermodynamically stable, and isomerisation processes (Dimroth rearrangement) are possible on heating, possibly catalysed by acidic or basic pH conditions,[5] so working with any of these families is potentially more difficult.

Our research group has just started to explore the coordination possibilities of one of these families, namely the 1,2,4-triazolo[4,3-*a*]pyrimidines, which differ from the 1,5-*a* derivatives in the position of one of the nitrogen atoms of the triazole ring, which is separated as far as possible from the pyrimidine ring, is subject to less steric hindrance, and is contiguous to the other external imidazole nitrogen atom. The skeleton of this family of compounds, as well as the numbering scheme used for identifying their atoms, is shown in Scheme 1.



Scheme 1.

The first metal complex of one of these derivatives (with an exocyclic oxo group in position 7) is a silver dimer recently published by us.[6] In this complex the ligand bridges the metal atoms through the two nitrogen atoms of the triazole ring. Following this research line, we have started to explore the behaviour of this ligand towards metal atoms of the first transition series. We used a pH high enough to deprotonate the nitrogen atom of the pyrimidine ring, which usually carries the acidic proton (N8), so that it could become a new binding site, and we have been successful in obtaining a crystalline solid with nickel(II) in ammonia aqueous solution. The solid is a nonanuclear cluster, and the metal atoms are bridged by organic ligands and hydroxyl groups, which transmit both ferromagnetic and antiferromagnetic interactions.

Results and Discussion

The main feature of the crystal structure of the title compound is the presence of centrosymmetric clusters built from nine nickel atoms, eight **L** ligands, six hydroxo groups, four ammonia molecules and eight water molecules. Discrete clusters with nine metal atoms are not very frequently observed, nevertheless, a number of nonanuclear nickel compounds have been described with different bridging li-

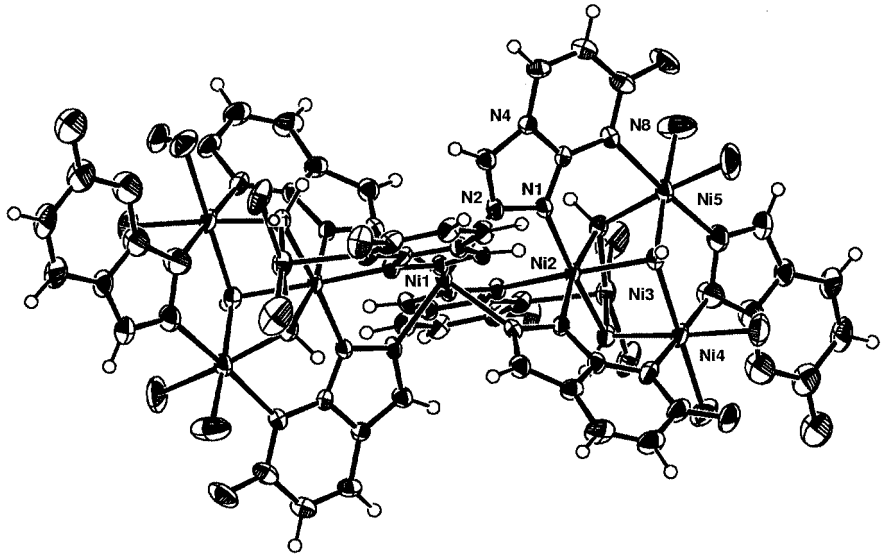

Figure 1. Molecular structure of the $[Ni_9L_8(OH)_6(NH_3)_4(H_2O)_8]^{4+}$ cluster according to X-ray analysis. Both halves are related by a crystallographic inversion centre. Non-hydrogen atoms are represented by ellipsoids at the 50% probability level. Only the metal atoms on one side of the central metal atom, and the nitrogen atoms of one of the organic ligands have been labelled for clarity.

gands and different topologies,[7,8] some of them involving hydroxo groups.[9,10]

Two crystallographically independent clusters are present in the unit cell, but they are chemically equivalent and subsequently will be described jointly. The quality of the crystal data is not high enough for a very accurate structural determination and, in fact, some ambiguity remains in the assignment of the water and ammonia molecules. Additionally, some of the nitrate counteranions and interstitial water molecules are poorly defined and have been introduced into the structural model with partial occupancy (see Exp. Sect.).

A view of one of these clusters is shown in Figure 1. The nickel atom placed at the centre of the cluster (Ni1) lies on a crystallographic inversion centre, and is octahedrally coordinated to by the nitrogen atom in position 2 of the six different **L** moieties. The environment of this atom has approximate D_{3d} symmetry, and the Ni1···N2 distances are in the range of 2.07–2.11 Å.

On each side of this central atom, a $Ni_4(OH)_3$ subcluster is placed. Nickel and oxygen atoms in this subcluster form a cubane-like backbone with one of the vertices missing. Each hydroxyl group bridges three nickel atoms, one of these (Ni2) is close to the centre of the cluster (distance Ni1···Ni2, 3.65–3.66 Å) and is linked to the three hydroxyl groups, whereas the other three (Ni3, Ni4 and Ni5, which we will refer to as the "external" nickel atoms from here onward) are linked to only two hydroxyl groups each. The "cubane" is heavily distorted with the external metal atoms, which are adjacent to the empty vertex,separated outwards from their ideal positions. This is reflected in the bond angles around the hydroxyl oxygen atoms, which are in the 92.0–96.0° range if Ni2 is considered, and in the 113.9–125.5° range if it is not. The distortion of the "cubane" is also seen in the intermetallic distances, 2.97–3.03 Å for Ni2···Ni(external), and 3.36···3.64 Å for Ni(external)··· Ni(external). Nickel···oxygen distances (the edges of the cube) are in the range of 2.04–2.08 Å for Ni2–OH, and 2.00–2.06 Å for Ni(external)–OH bonds.

Several examples of structures containing Ni_4O_4 "cubane-like" clusters can be found in the bibliography; in most of them, the oxygen atoms belong to methoxy groups,[11] or to more complex organic molecules,[12] but surprisingly, very few have bridging hydroxo groups.[13] The Ni–O distances in these species are around 2.0–2.1 Å, and the cubes are usually quite distorted with angles above and below 90° around the oxygen and nickel atoms, respectively; the actual degree of distortion clearly is conditioned by the presence of other ligands. On the other hand, the only examples of "incomplete" Ni_4O_3 cubanes that we have found are those linked by extra oxygen bridges to other metal atoms, thus they are just portions of more complex Ni–O skeletons.[14]

The six organic ligands coordinated to the central metal atom join it to both cubane-like subclusters (three ligands to each), and act as triple bridges through the nitrogen atoms at positions 2, 1 and 8: N2 is linked to Ni1 as previously said, N1 is linked to Ni2 and N8 is linked to Ni3, Ni4 or Ni5. Atom Ni2 is then coordinated to the three hydroxyl oxygen atoms, and the N1 atom of the three organic ligands in an approximate C_{3v} environment.

An additional triazolopyrimidine ligand is present on each side of the cluster bridging two of the "external" metal atoms (namely Ni4 and Ni5) through the two nitrogen atoms of the triazole ring (N1 to Ni4 and N2 to Ni5). The coordination environments of the three external nickel atoms are completed by two water or ammonia molecules: those attached to Ni3 have been assigned as ammonia, and those attached to Ni4 and Ni5 as water, although these as-

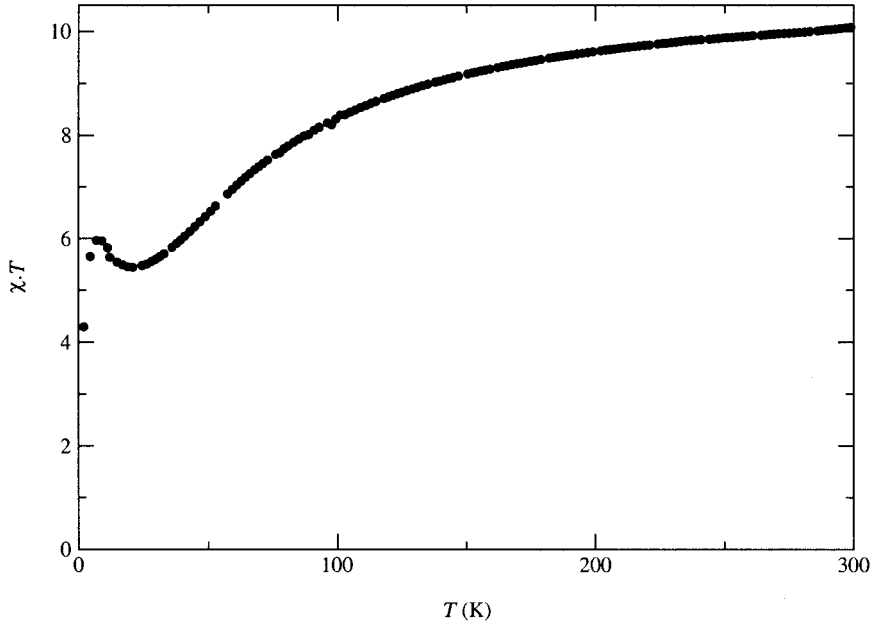

Figure 2. Variation with temperature of the magnetic susceptibility of the title compound, represented as a χT vs. T curve (χ in emu per mol of clusters).

signments are far from being certain (see Exp. Sect.). An octahedral environment is completed in this way for Ni4 and Ni5, whereas a not very frequently observed square-pyramidal environment is found for Ni3. For this atom, the sixth position is not available since the above-mentioned organic ligand attached to Ni4 and Ni5 is orientated in that direction preventing either water or ammonia from occupying that position.

If a comparison is made between the geometries of all the organic ligands in the title compound and those in the previously mentioned silver dimeric complex,[6] in which the ligand is in the neutral form, the most noticeable differences are the lengthening of the C7–O7 bond (from 1.221 to 1.24–1.30 Å) and, probably more significantly, the closing of the C7–N8–C8 angle (from 122.0 to 116–117°), a consequence of the N8 deprotonation. This is true for both triple bridging and double bridging ligands, supporting the idea that all are anionic. The non-coordinated N8 atom of the double bridging ligand forms an intramolecular hydrogen bond with one of the water molecules attached to Ni4 [distances 2.743(9) and 2.862(11) Å].

The magnetic susceptibility of the compound has been measured in the 2–300 K temperature range. The results are shown in Figure 2, in the form of a χT vs. T plot. The product χT steadily decreases with T reaching a minimum at 20 K. It then increases reaching a maximum at 8 K before decreasing sharply at very low temperature. This behaviour indicates that both ferromagnetic and antiferromagnetic interactions are taking place, the latter being predominant. The decrease at very low T may be attributed to antiferromagnetic intermolecular interactions. After normalising the χT value where $T \rightarrow \infty$ to 1, the normalised values at different temperatures are 0.89 (300 K), 0.48 (minimum at 19 K), 0.53 (maximum at 8 K), and 0.38 (at 2 K, the lowest temperature used).

Due to the low symmetry of the cluster, with five structurally different types of metal atoms, a large number of different coupling constants are expected (at least ten, even if those between atoms on different sides of the central metal atom are neglected). Deriving an expression for χ as a function of temperature from the resulting complex spin Hamiltonian, and fitting the many adjustable parameters to the experimental data, would be a very difficult task (if possible at all), so the values of the coupling constants have not been determined, and not even their signs (that indicate which pairs interact ferromagnetically and which antiferromagnetically) have been deduced.

The data above 50 K obey the Curie–Weiss law very well. The linear fitting of $1/\chi$ vs. T yields a value of –35.4(3) K for θ (somehow quantifying the strong antiferromagnetic interactions that prevail in this region), and an effective magnetic moment per nickel atom as $T \rightarrow \infty$ of 3.166(1) B.M. (g = 2.24).

Experimental Section

Reagents were obtained from standard commercial sources; organic reagents were of synthetic grade and inorganic reagents of analytical grade. The ligand 7,8-dihydro-1,2,4-triazolo[4,3-*a*]pyrimidin-7-one hemihydrate was synthesised as described previously.[6,15] Microanalysis of C, H and N were performed with a Fisons Instruments EA-1008 analyser. Magnetic susceptibility measurements were made with a SQUID MPMS-XL Quantum Design magnetometer, at the Universidad Complutense (Madrid), using a magnetic field of 1.00 T. Diamagnetic corrections were applied.

Synthesis of the Nickel Complex: Nickel chloride hexahydrate (0.238 g, 1 mmol) and 7,8-dihydro-1,2,4-triazolo[4,3-*a*]pyrimidin-7-one (LH) hemihydrate (0.145 g, 1 mmol) were dissolved in separate aliquots of 1 M aqueous ammonia (10 mL). Both solutions were mixed, and the resulting blue solution was left to stand so that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the excess ammonia was eliminated. Deep blue crystals of the title compound, suitable for X-ray work, were obtained. Elemental analysis of $C_{40}H_{74}N_{40}Ni_9O_{42}$ $[Ni_9\mathbf{L}_8(OH)_6(NH_3)_4(H_2O)_8](NO_3)_4 \cdot 8H_2O$ (2315.5): calcd. C 20.75, H 3.22, N 24.20; found C 20.7, H 3.5, N 24.2.

Crystallography: Data for a single crystal of the title complex (dimensions, $0.28 \times 0.15 \times 0.06$ mm) were collected at room temperature with a Bruker SMART APEX CCD system with Mo-K_α radiation (λ = 0.7107 Å). Data were corrected for absorption (multiscan, transmission range, 0.6667–0.8775). The structure was solved by Direct Methods. According to the elemental analysis data, four ammonia molecules are present per cluster, but the quality of the crystal data does not allow us to unambiguously distinguish between water and ammonia molecules. The Fourier peaks attached to the square-pyramidal Ni atom (Ni3) have been assigned as ammonia because of the coordination polyhedron of this atom, and because more favourable thermal parameters are obtained in this way, but of course, this assignment cannot be taken as granted (other assignments or possible disordered situations cannot be discarded). The structure was refined anisotropically (except for hydrogen atoms, disordered water molecules and two poorly defined nitrate anions) on F^2 using SHELXL-97.[16] Hydrogen atoms of the heterocycle and of the hydroxyl groups were placed at ideal positions, and those of the water and ammonia molecules were ignored. Isotropic thermal parameters for all H atoms were fixed to 1.2 times the equivalent isotropic thermal parameter of their parent atoms.

Crystal Data for $[Ni_9L_8(OH)_6(NH_3)_4(H_2O)_8](NO_3)_4 \cdot 8H_2O$: Triclinic, space group $P\bar{1}$, a = 11.0481(5), b = 18.2700(8), c = 21.3860(9) Å, α = 65.966(1) β = 83.287(1), γ = 86.043(1)°, V = 3914.4(3) Å^3, Z = 2, D_{calc} = 1.963 Mg/m^{-3}, μ = 2.237 mm^{-1}, 45862 reflections (17819 unique) collected (θ range 1.25–28.45°), wR_2 = 0.2454, R[12041 data with $I > 2\sigma(I)$] = 0.0808.

CCDC-265692 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Structural Transformations and Magnetic Effects Induced by Solvent Exchange in the Spin Crossover Complex $[Fe(bpp)_2][Cr(bpy)(ox)_2]_2$

Mari Carmen Giménez-López,[a] Miguel Clemente-León,[a] Eugenio Coronado,*[a] Francisco M. Romero,*[a] Sergiu Shova,[b][‡] and Jean-Pierre Tuchagues[b]

Keywords: Spin crossover / Iron / Solvent sensing / Hydration / Magnetic properties

Structural, thermal, magnetic and solvent-exchange properties of the spin crossover compound $[Fe(bpp)_2][Cr(bpy)(ox)_2]_2$ containing paramagnetic anions are given. This complex salt **1** crystallises as a dihydrate with two inequivalent (high-spin and low-spin) Fe^{II} sites. The dehydrated compound is a spin-crossover material with $T_{1/2}\uparrow$ = 369 K and $T_{1/2}\downarrow$ = 353 K. Rehydration takes place without loss of crystallinity, yielding a polymorph (**2**) with 100 % high-spin Fe^{II} sites. The different high-spin fractions in **1** and **2** have been correlated to structural changes in the Fe^{II} second coordination sphere. The magnetic response to the presence of different sorbed molecules has also been explored.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

The spin crossover between the diamagnetic low-spin (LS, S = 0) and the paramagnetic high-spin (HS, S = 2) states in iron(II) complexes has attracted much interest.[1] Although the purely molecular origin of the effect is clearly established by its observation in solution, cooperativity plays a key role in the solid state, where the phenomenon may be accompanied by a structural phase transition. The transition is triggered by a given external perturbation (light irradiation, pressure or temperature change) and the response (change of the optical and magnetic properties) may be observed abruptly with a hysteretic behaviour. These materials can then be considered as bistable systems suitable for practical applications.

In the search of increasing cooperativity, high-dimensional structures have been designed in which the functional molecular units are linked by bridging ligands.[2] Using this strategy, some nanoporous frameworks displaying spin crossover effects that are influenced by the reversible exchange of solvate molecules have been obtained.[3] Another approach relies on hydrogen bonding. In this context, the abrupt and hysteretic spin transitions of $[Fe(bpp)_2]X_2$ complex salts [bpp = 2,6-bis(pyrazol-3-yl)pyridine; X = anion] are well documented.[4] The amino groups of the pyrazolyl moieties can set up hydrogen bonds with its environment and this gives rise to a cooperative behaviour and a marked dependence of the spin transition on the nature of the anion and the extent of hydration.[5] This family of compounds may provide good candidates for the study of solvation effects in spin crossover that can lead to interesting applications in molecular sensing. Further, these salts exhibit Light-Induced Excited Spin State Trapping (LIESST) effects at high temperatures with relatively long lifetimes of the photoinduced metastable states.[6] In this report, we give evidence for the strong dependence of the electronic configuration of the Fe^{2+} cations on the exchange of guest solvent molecules in the salt $[Fe(bpp)_2][Cr(bpy)(ox)_2]_2$ (**1**) (bpy = 2,2′-bipyridine; ox = oxalate dianion). The complex anion has been chosen for its ability to form hydrogen bonds and π–π stacking interactions.[7]

Compound **1** crystallises as a dihydrate $[Fe(bpp)_2][Cr(bpy)(ox)_2]_2{\cdot}2H_2O$ and its structure[8] comprises isolated $[Fe(bpp)_2]^{2+}$ and $[Cr(bpy)(ox)_2]^-$ complexes and water molecules. Two crystallographically independent octahedral iron(II) sites, Fe(1A) and Fe(1B), were found (Figure 1a). Both sites have a pseudo C_{2v} symmetry, with the tridentate bpp ligand binding to the iron ion in meridional positions. The Fe(1A) coordination sphere is consistent with high-spin Fe^{II}, with Fe–N bond lengths lying in the range 2.146(2)–2.210(2) Å. In contrast, the Fe–N bond lengths of the Fe(1B) site are typical low-spin values, lying in the range 1.921(2)–1.976(2) Å. Several examples of coexistence of HS and LS species in the same compound have been reported. In these cases, the different iron centres adopt similar ligand-binding geometries but different second coordination spheres.[9] We observed a similar behaviour: the four non-coordinating N–H groups of complex **A** (Figure 1a) are hydrogen-bonded to three $[Cr(bpy)(ox)_2]^-$ anions and one water molecule, whereas complex **B** is connected to four $[Cr(bpy)(ox)_2]^-$ anions. Since the oxalate oxygen atom of the

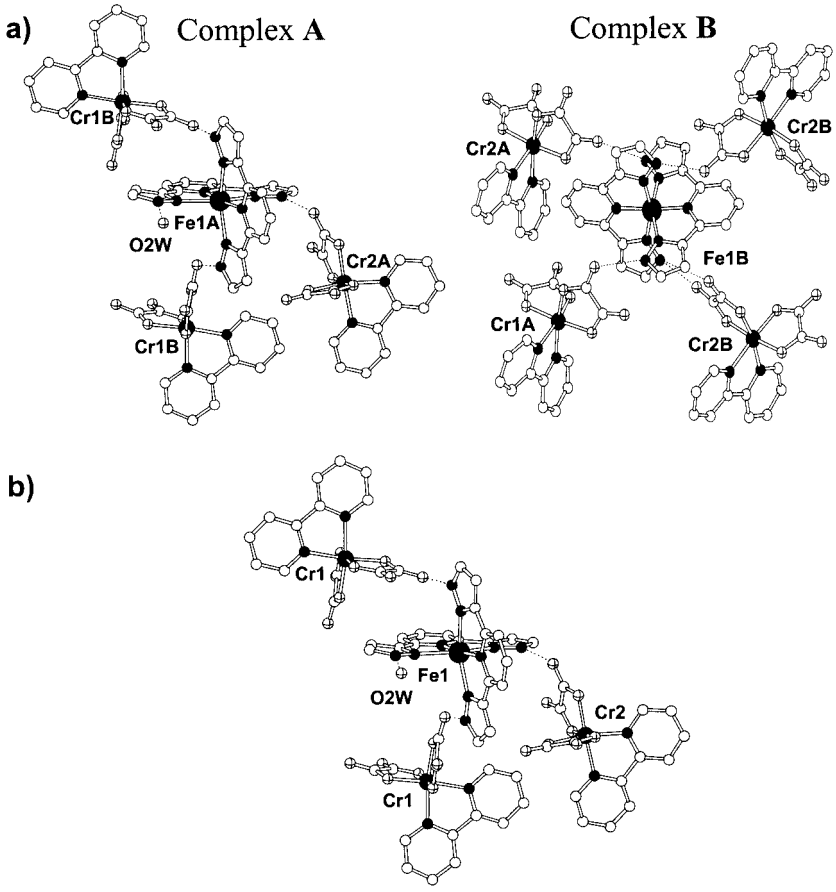

Figure 1. View of the crystal structure of the hydrated salt $[Fe(bpp)_2][Cr(bpy)(ox)_2]_2 \cdot 2H_2O$ showing the first and second coordination spheres of the Fe^{2+} cations; a) original sample (**1**), b) rehydrated sample (**2**).

anion is a better hydrogen-bonding acceptor than water, the electron density of the non-coordinating nitrogen atoms of **B** is increased with respect to **A**. This leads to stronger donor–metal σ-interaction, favouring the LS state for complex **B**.

The magnetic properties of **1** are in agreement with this structural analysis. The product of the molar magnetic susceptibility with the temperature, $\chi_M T$, (Figure 2, curve 1) shows a nearly constant value of 5.5 emu·K·mol^{-1} from 50 K to room temperature, in agreement with the presence of half of the Fe^{2+} ions in the HS state and two Cr^{3+} ions per formula unit. At temperatures above 320 K, $\chi_M T$ decreases and reaches a minimum at 356 K, followed by an increase to a value of 7 emu·K·mol^{-1} at 400 K, indicating that 100% of the Fe sites are HS at this temperature. On cooling now the compound (curve 2) below 300 K, a $\chi_M T$ value of 3.7 emu·K·mol^{-1} is observed, as expected for two uncorrelated Cr^{3+} ions with all the iron(II) centres in the LS configuration. Successive temperature cycles (heating and cooling modes, Figure 2) reveal that the preheated sample displays a spin crossover behaviour with $T_{1/2}\uparrow$ = 369 K and $T_{1/2}\downarrow$ = 353 K.

The thermogravimetric analysis (TGA) of **1** (Figure 3a) indicates a weight loss of about 3% upon heating of the compound in the 300–380 K range. This is clearly a dehydration process that corresponds to the loss of two water molecules. The DSC measurement of the original sample (Figure 3b, curve 1) shows two different endothermic processes that can be attributed to dehydration. In the cooling mode (curve 2), the dried sample exhibits an exothermic feature at 354 K, characteristic of a high-spin to low-spin transition. This process was masked in the measurement of

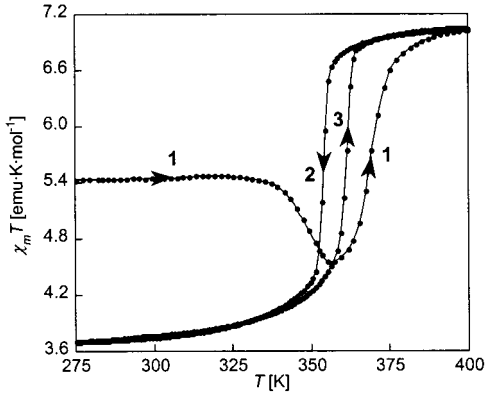

Figure 2. Temperature dependence of $\chi_M T$ for compound **1** in the 275–400 K range. Curve 1: original sample in the heating mode. Curves 2 and 3: subsequent temperature cycle (cooling and heating modes, respectively).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the original hydrated sample and it can be also characterised by the sharp endothermic peak observed in the heating mode (curve 3) at 358 K.

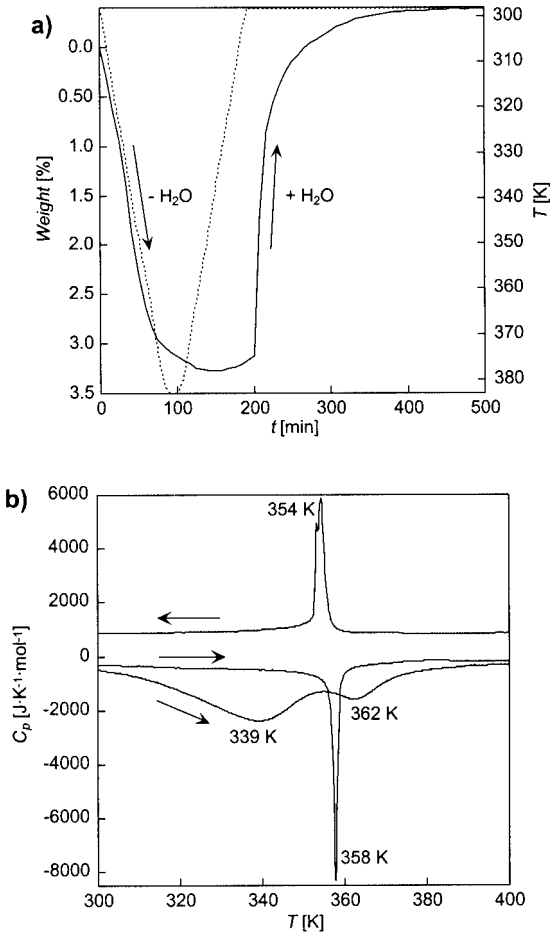

Figure 3. a) Thermogravimetric analysis of compound **1** showing the dehydration-rehydration process. The weight loss of the sample was measured in the 300–380 K range at a constant heating rate of 1 K/min. Then the sample was allowed to cool in an ambient atmosphere. b) Differential scanning calorimetry of **1** in the range of 300–400 K. Curve 1: original sample in the heating mode. Curves 2 and 3: subsequent temperature cycle (cooling and heating modes, respectively).

Based on the thermal and magnetic studies, it is possible to conclude that the initial sweeping-rate-dependent decrease of $\chi_M T$ is due to a change of spin accompanying the dehydration, while the abrupt increase/decrease of $\chi_M T$ observed at higher temperatures is associated to a spin transition of the dehydrated compound. This behaviour is typical of $[Fe(bpp)_2]X_2$ salts.[9] The main difference here is that the spin transition is pushed to very high temperatures as compared to previous examples. Removal of water molecules may allow a fourth $[Cr(bpy)(ox)_2]^-$ anion to be located in the second coordination sphere of Fe(1A), giving rise to a strong stabilisation of the LS state.

Rehydration of a dried sample of **1** proceeds readily and the total weight of the original sample can be recovered in a few minutes (Figure 3a). Surprisingly, the rehydrated sample and the original sample show different magnetic behaviours. Below 50 K, both samples exhibit a continuous increase of $\chi_M T$ with increasing temperature. This can be attributed to zero-field splitting and spin-orbit coupling effects, although intermolecular interactions between the different spin carriers cannot be discarded. From 50 K to room temperature (Figure 4a), the $\chi_M T$ value of the rehydrated sample is equal to 7.5 emu·K·mol^{-1}, suggesting that all the Fe^{2+} cations are in the HS state. As shown for the original sample, loss of water causes a sudden decrease of $\chi_M T$ above room temperature. By further heating, the spin transition characteristic of the dehydrated sample is again observed. TGA and DSC studies confirm again the hypotheses based on the magnetic behaviour. The markedly different magnetic properties of the original and rehydrated samples are very interesting: the magnetic measurements reflect the history of the dehydration-rehydration process.

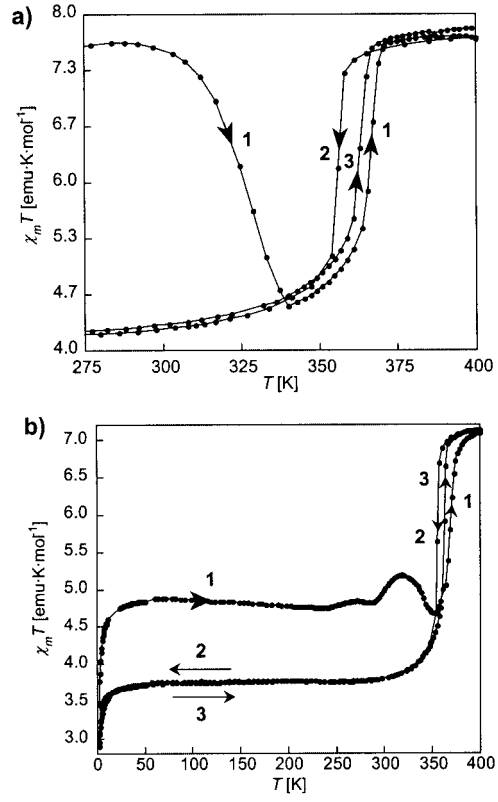

Figure 4. Temperature dependence of $\chi_M T$ for rehydrated (a) and MeOH-solvated (b) samples in the 2–400 K range. Curves 1: first treatment in the heating mode. Curves 2 and 3: subsequent temperature cycles (cooling and heating modes, respectively).

Temperature-dependent X-ray diffraction data suggest that this process occurs without drastic changes in the crystal structure. This prompted us to study the crystal structure of the rehydrated phase. For this purpose, a single crystal of **1** was heated to 343 K under dry nitrogen until constant loss of weight in a TGA instrument. Afterwards, the crystal was kept in ambient atmosphere to allow rehydration and the structure of the rehydrated single crystal

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was solved by X-ray diffraction measurements (Figure 1b). The resulting compound **2** is also a dihydrate and it retains the same crystal symmetry.[10] One of the unit cell parameters is halved and only one independent Fe^{II} site is now present. Its environment is very similar to that observed for the HS site Fe(1A) of the original compound, with Fe–N bond lengths in the 2.145(3)–2.204(3) Å range and the second coordination sphere containing three $[Cr(bpy)(ox)_2]^-$ anions and one water molecule hydrogen-bonded to the pyrazolyl moieties. Hence, after rehydration the two crystallographically independent high-spin Fe(1A) and low-spin Fe(1B) sites become equivalent and a 100% content of HS species is observed.

These findings suggest that spin crossover materials can be very sensitive to exchangeable guest solvent molecules such as alcohols, which are able to form hydrogen bonds. In principle, it could be possible to correlate the nature of the absorbed solvent with the magnetic properties; in such a way that spin crossover could be used as a molecular probe. As an example, **1** has been dehydrated and resolvated with methanol. The solvation process can be easily monitored in a TGA apparatus. An increase of weight corresponding to the absorption of one MeOH molecule was observed. Magnetic measurements of this methanol-solvated sample (Figure 4b) show a distinct behaviour with respect to the rehydrated material. The $\chi_M T$ value at 200 K is 4.8 emu·K·mol^{-1} and corresponds to 33% Fe^{II} centres in the HS state. This value remains nearly constant on increasing the temperature. At 330 K, desolvation starts and $\chi_M T$ decreases to a minimum value at 350 K.[11] Further heating results in a sudden increase of the magnetic signal that corresponds to the spin transition of the desolvated sample. Successive temperature cycles reveal the same magnetic behaviour than that observed for the dehydrated material.

To summarize, the dry material at room temperature exhibits only the paramagnetism of the Cr^{III} centres, with all the Fe^{2+} ions in their LS configuration. Upon exposure to ambient moisture, the compound undergoes a spin crossover to an HS phase. This transition can be correlated to the replacement of a $[Cr(bpy)(ox)_2]^-$ anion by a water molecule in the second coordination sphere of the Fe^{2+} cations. In contrast, treatment of a dry sample with dry methanol vapours yields a material with only 33% of the Fe^{II} sites in the HS configuration.

Clearly, the magnetic properties of this spin crossover compound are very sensitive to the presence of different solvates. This is a well-known effect that has recently drawn special attention in the field of crystal engineering.[12] However, there are only a few qualitative studies on the influence of absorption of solvent molecules in the spin states of dry compounds.[13] These studies lack of any structural evidence. The present work provides a deeper insight into the spin changes associated with different resolvation processes. As compared to previously reported examples based on high-dimensional networks, our approach relies simply on hydrogen bonding. Further work will be devoted to study the influence of the paramagnetic anion on the solvent sensing properties.

Experimental Section

General: All chemicals and solvents were used as received. $Ba[Cr(bpy)(ox)_2]_2\cdot 3H_2O$ and bpp were synthesized according to previously described methods.[14,15]

$[Fe(bpp)_2][Cr(bpy)(ox)_2]_2\cdot 2H_2O$ (1): A solution of bpp (140 mg, 0.66 mmol) and $FeSO_4\cdot 7H_2O$ (92 mg, 0.33 mmol) in 40 mL of MeOH was added to a suspension of $Ba[Cr(bpy)(ox)_2]_2\cdot 3H_2O$ (361 mg, 0.33 mmol) in 30 mL of water. The resulting mixture was stirred for 2 h to promote complete precipitation of $BaSO_4$, which was removed by filtration. After a few days, large red crystals were obtained by slow concentration of the mother liquor. Yield: 199 mg (53%). IR (KBr): $\tilde{\nu}$ = 3544 (w), 3444 (w), 3127 (m), 2921 (m), 1711 (vs), 1679 (vs), 1653 (vs), 1609 (s), 1370 (s), 803 (m), 773 (m), 543 (m), 415 (w) cm^{-1}. $C_{50}H_{38}Cr_2FeN_{14}O_{18}$ (1282.8): calcd. C 46.82, H 2.99, N 15.29; found C 46.82, H 2.93, N 15.08; calcd. Cr/Fe 66.6:33.3, found 65.8/34.2.

Physical Measurements: Dc magnetic susceptibility measurements were performed on polycrystalline samples using a magnetometer (Quantum Design MPMS-XL-5) equipped with a SQUID sensor. Variable-temperature measurements were carried out in the temperature range 2–400 K in a magnetic field of 0.1 T. The temperature sweeping rate was the same for the experiments performed on the original and methanol-solvated samples: 0.5 K·min^{-1} (2–10 K), 1 K·min^{-1} (10–50 K), 5 K·min^{-1} (50–200 K), 2 K·min^{-1} (200–400 K). For the rehydrated sample, the last change in the sweeping rate was set to 340 K. Thermogravimetric measurements were carried out with a Mettler Toledo TGA/SDTA 851 apparatus in the 298–1373 K temperature range under nitrogen and at a scan rate of 5 K·min^{-1}. The dehydration-rehydration process was monitored by heating the ground sample under a stream of nitrogen from 298 to 383 K (1 K·min^{-1}). Then, the system was kept at this temperature during 20 min to allow complete loss of water molecules. Afterwards, the sample was cooled to 298 K. At this point, the stream of nitrogen was replaced by a stream of humid air to allow complete rehydration of the sample. For the solvation experiment, a stream of nitrogen saturated with dry methanol was used. The total flux of nitrogen was constant during the experiments. After saturation (constant weight), the samples were quickly introduced in the SQUID apparatus, protecting them from the environment. Heat capacity measurements under nitrogen were performed in a Mettler Toledo DSC 821e apparatus with warming and cooling rates equal to 4 K·min^{-1} from 253 to 423 K. IR transmission measurements of KBr pellets were recorded at room temperature with a Nicolet Avatar 320 FT-IR spectrophotometer in the range 4000–400 cm^{-1}. C,H,N elemental analyses were carried out in a CE instruments EA 1110 CHNS analyzer. The Cr/Fe ratios were measured with a Philips ESEM X230 scanning electron microscope equipped with an EDAX DX-4 microsonde.

[8] Crystal data for **1**: $C_{100}H_{76}Cr_4Fe_2N_{28}O_{36}$, M = 2565.59, crystal dimensions: 0.50×0.45×0.05 mm, triclinic, $P\bar{1}$, a = 15.5434(15), b = 17.723(2), c = 20.985(2) Å, α = 102.002(12), β = 103.291(11), γ = 103.299(12), V = 5263.4(9) Å^3, Z = 2, $\rho_{calcd.}$ = 1.629 Mg m^{-3}, μ(Mo-K_α) = 0.769 mm^{-1}. A dark-red plate-like single crystal of **1** was used for data collection at 180 K with a Stoe Imaging Plate Diffractometer System (IPDS) diffractometer equipped with a graphite-monochromated Mo-K_α radiation source (λ = 0.71073 Å), and an Oxford Cryostream Cooler Device. Data were collected using the φ rotation movement with a crystal-to-detector distance of 70 mm (φ = 0.0–250°, Δφ = 1.4°). Of 52754 measured reflections, 19375 (4.14° < 2θ < 52.20°) were independent (R_{int} = 0.0470) and used to refine 1812 parameters. Semiempirical absorption corrections were made based on equivalent reflections with the program MULTISCAN.[16] The structure was solved by direct methods using SHELXS-97[17] and refined by full-matrix least squares on F_o^2 with SHELXL-97[18] with anisotropic displacement parameters for non-hydrogen atoms. All H atoms attached to carbon atoms were introduced in idealized positions (d_{CH} = 0.96 Å) using the riding model with their isotropic displacement parameters fixed at 120% of their riding atom. Positional parameters of the hydrogen atoms of three solvate water molecules were obtained from difference Fourier syntheses and verified by the geometric parameters of hydrogen bonds. O(4w) molecules, which are positioned in hydrophobic cavities, are disordered among two positions with a 0.6:0.4 ratio of the occupancy factors. There are no short intermolecular contacts from O(4w) which can be characterized as possible H-bonds. The hydrogen atoms for this water molecule were not localized. There is only one short intermolecular contact [O4w···O(2B) = 2.826 Å], which can be characterized as possible H-bond. R_1 = 0.0419 for 14420 reflections with $I \geq 2\sigma(I)$, wR_2 = 0.1071; R_1 = 0.0623, wR_2 = 0.1194, GOF = 0.984 for all data. Max./min. residual peaks in the final difference map: 0.955/–0.482 e·Å^{-3}. CCDC-258048 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[10] Crystal data for **2**: $C_{50}H_{38}Cr_2FeN_{14}O_{18}$, M = 1282.79, crystal dimensions: 0.20×0.12×0.05 mm, triclinic, $P\bar{1}$, a = 9.04700(10), b = 15.6410(2), c = 20.6980(3) Å, α = 102.5530(5), β = 102.0710(5), γ = 103.9340(5), V = 2666.95(6) Å^3, Z = 2, ρ_{calc}d. = 1.597 Mg m^{-3}, μ(Mo-K_α) = 0.758 mm^{-1}. A dark-red plate-like single crystal of **2** was used for data collection with a Nonius Kappa CCD diffractometer (4.34° < 2θ < 55.32°) equipped with a graphite-monochromated Mo-K_α radiation source (λ = 0.71073 Å). Data collection was performed at 180 K. Of 22949 measured reflections, 12198 were independent (R_{int} = 0.0403) and used to refine 793 parameters. The structure was solved by direct methods (SIR97)[19] and refined against F^2 with a full-matrix least-squares algorithm using SHELXL-97[18] and the WinGX (1.64) software package.[20] All non-hydrogen atoms were refined anisotropically. H-atoms were added in calculated positions and refined riding on the corresponding atoms except H atoms of –NH groups and water molecules. H-atoms of –NH groups were located by difference Fourier maps and refined isotropically. H-atoms of water molecules were calculated on the basis of geometry and force-field considerations using the CALC-OH program[21] and refined isotropically fixing the H–H and H–O distances. Final R [$I > 2\sigma(I)$]: R_1 = 0.0538, wR_2 = 0.1505; final R (all data): R_1 = 0.0933, wR_2 = 0.1961. Max./min. residual peaks in the final difference map: 0.700/–1.230 e·Å^{-3}. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.
[11] Between 300 and 330 K, a slight increase of the magnetic signal is observed. This behaviour is also observed in a blank measurement performed with a sample dehydrated in the TGA equipment and then transferred to the SQUID instrument. Besides this accident, the magnetic behaviour of this sample is the same as that observed in curves 2 and 3 for dry samples. This accident is most probably due to the presence of humidity within the equipment.

A Pulse Radiolysis Study of Catalytic Superoxide Radical Dismutation by a Manganese(II) Complex with an N-Tripodal Ligand

Stéphanie Durot,[a] François Lambert,[a] Jean-Philippe Renault,*[b] and Clotilde Policar*[a]

Keywords: Bioinorganic chemistry / Enzyme models / Manganese / Superoxide dismutase / SOD mimic / Pulsed radiolysis / MnOO adduct

This article presents a pulse radiolysis study of the reactivity of a SOD-mimic Mn^{II} complex $[Mn^{II}(IPG)]^+$ **1** with superoxide. It uses an improved set-up with a circulating cell. It provides convergent pieces of evidence that **1** catalyses efficiently the dismutation of superoxide. Three sets of experiments are described: (1) Transient formation and decay of an adduct labeled $\{MnOO\}^6$ were studied. (2) A multi-pulse experiment showed a reproducible behaviour upon successive superoxide pulses. (3) Superoxide decay was monitored at 270 nm to provide an overall kinetic constant. A mechanism is proposed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

The superoxide radical anion ($O_2^{\cdot-}$), produced by the one-electron reduction of dioxygen, has been shown to be a highly toxic species.[1–6] It is known to be involved in oxidative stress.[2,7–9] Superoxide dismutases (SOD) catalyze $O_2^{\cdot-}$ dismutation into dioxygen and hydrogen peroxide and constitute an endogenous protection.[2–5,10] Since superoxide has been shown to play an important role in several diseases, low-molecular-weight SOD mimics have potential use as pharmaceutical agents.[8,9,11] Synzymes[12] can also enlighten the understanding of the natural enzyme catalytic mechanism. A wide range of putative catalysts for superoxide dismutation has been reported.[4,9,13] SOD activity is usually estimated on the basis of indirect activity tests, such as the Mc-Cord Fridovich test.[10] These tests are informative, as they provide a quantification of the activity in conditions close to physiological, but they may lead to errors in the interpretation of results, as previously shown.[9,14,15] According to us and others,[9,14,16] both indirect and direct methods are necessary, as they provide complementary information. In the indirect methods, superoxide is provided at a constant rate and at concentrations close to what is encountered during oxidative stress. This provides a test for the ability of the putative SOD mimic to be useful under physiological situations. However, in most cases it is difficult to distinguish between a catalyst and a scavenger. With direct methods, as superoxide can be used in large excess relative to the putative SOD mimic, unambiguous characterization of the catalyst and the scavenger is accomplished. However, direct methods for the determination of catalytic rate constants, including stopped-flow and pulse radiolysis, are rarely used.[9,13,15–17]

In this work, we provide convergent pieces of evidence by pulse radiolysis that a manganese(II) complex **1**, $[Mn(IPG)(MeOH)]_n(PF_6)_n$ (IPG^- = *N*,*N*-(2-pyridylmethyl[(1-methylimidazol-2-yl)methyl]glycinate, see Figure 1), catalyses the dismutation of superoxide. The crystal structure of complex **1** and its reactivity towards superoxide both in anhydrous DMSO and in aqueous medium have been previously reported.[18,19] It displays a good SOD-like activity, as shown by the McCord–Fridovich test (IC50 = $(2.0 \pm 0.2) \times 10^{-6}$ mol L^{-1} or k_{cat} = $(2.9 \pm 0.3) \times 10^6$ mol^{-1} L s^{-1}).[19,20] In the present article, three sets of experiments are described with different purposes: (a) transient formation and decay of an adduct between Mn and superoxide were studied under conditions for which $[\mathbf{1}]_0 > [O_2^{\cdot-}]_0$. (b) A multi-pulse experiment showed a reproducible behaviour upon successive $O_2^{\cdot-}$ pulses. (c) Superoxide decay was monitored at 270 nm under conditions for which $[\mathbf{1}]_0 < [O_2^{\cdot-}]_0$ to provide an overall kinetic constant.

The superoxide radical was produced in oxygenated aqueous solutions by pulse radiolysis,[21] and its direct reaction with the putative SOD mimic was monitored by UV/Visible spectrophotometry. High-energy ionizing radiation generates primary radicals ($H^{\cdot}$, e^{-}_{aq}, $HO^{\cdot}$), that are rapidly and quantitatively converted into either superoxide $O_2^{\cdot-}$ or its protonated form hydroperoxyl $HO_2^{\cdot}$, in the presence of either formate or alcohols.[22,23] Propan-2-ol was chosen as formate might coordinate to manganese. The aqueous solution was driven at a constant rate through the UV/Visible microcell, where it was irradiated for a short time period. The irradiation frequency (1 Hz) was chosen so that between two pulses the solution was totally renewed. Absorbance was averaged over 100 pulses. This technique provides an improvement of the signal-to-noise ratio, relative to the single-pulse experiments generally used.[4,16,17,24]

The reaction of **1** with superoxide was studied over a wide range of time scales (from 10^{-6} to 1 s). Experiments were performed at pH 7.8 (5 mM phosphate buffer) in order to allow comparison with the previous indirect test.[19]

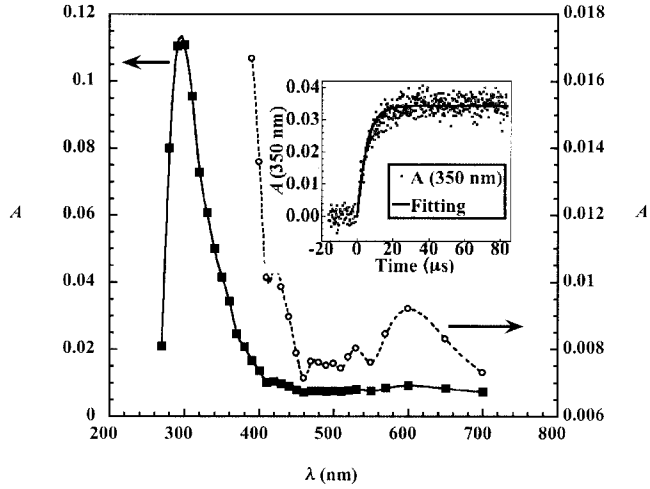

Figure 2. Difference absorption spectrum of the transient T formed during the reaction of **1** with superoxide 40 μs after the pulse. T decays with a half-life of ca. 0.04 s. Squares refer to the left axis and circles to the right axis. [**1**] = 10^{-3} mol L^{-1}; propan-2-ol 0.1 mol L^{-1}; phosphate buffer 5 mmol L^{-1}; irradiation pulse 1 μs; [$O_2^{\cdot-}$] = 7.3×10^{-5} mol L^{-1}; averaging over 100 pulses; flux 1 mL min^{-1}; irradiation frequency 1 Hz. Inset: kinetic trace at 350 nm, fitted by $A = A_0[1 - \exp(-k_{app}t)]$.

1. Self-Decay of Superoxide

First, it was checked that the self-decay of $O_2^{\cdot-}$ followed a second order rate law, as expected for the auto-dismutation of superoxide. The observed rate constant had a value of 1.3×10^5 mol^{-1} L s^{-1}, consistent with that reported in the literature[23] at pH 7.8 (1.0×10^5 mol^{-1} L s^{-1}).

2. Reaction of 1 with Superoxide under Conditions for which $[1]_0 > [O_2^{\cdot-}]_0$: Search for an Intermediate

Absorbance was monitored at different wavelengths during the reaction between **1** and $O_2^{\cdot-}$, under conditions where $[1]_0 > [O_2^{\cdot-}]_0$ [conditions (A): $[1]_0 = 10^{-5}$, 2.5×10^{-5}, 5×10^{-5}, 10^{-4} and 5×10^{-4} mol L^{-1} and $[O_2^{\cdot-}]_0 = 1.3\times10^{-6}$ mol L^{-1} and conditions (B): $[1]_0 = 5\ 10^{-4}$ mol L^{-1} and 10^{-3} mol L^{-1} and $[O_2^{\cdot-}]_0 = 7.3\times10^{-5}$ mol L^{-1}]. The difference absorption spectrum of a transient T, recorded 40 μs after the pulse, showed an intense peak at 300 nm and a smaller peak at 600 nm, as shown in Figure 2. Figure 2 inset shows the kinetic trace of transient formation at 350 nm. A rate constant, k_1, for the formation of the transient T was derived, $(2.2\pm0.3)\times10^8$ mol^{-1} L s^{-1}).

T can reasonably be ascribed to an adduct between $[Mn(IPG)]^+$ and $O_2^{\cdot-}$. No assignment of the oxidation state of manganese and oxygen (neither Mn^{II} and superoxide nor Mn^{III} and peroxide) is made here. We suggest to label it $\{MnOO\}_n$ (with $n = 6$ here), by analogy to Enemark and Feltham $\{FeNO\}_n$ nomenclature: n represents the number of d electrons from the metal center and the π* single electron from superoxide.[1,25] Such adducts have already been described for reactions involving Mn^{II} complexes and superoxide, by pulse radiolysis[16,23,24,26,27] and stopped-flow[28] studies. Complexes with an oxygenated coordination sphere (sulfate, formate, pyrophosphate,[26] phosphate,[24] aqua[27]) form adducts labeled $[MnO_2]^+$ characterised by an absorption maximum at 260–270 nm. The adduct observed with the complex $[Mn^{II}(TPAA)](PF_6)_2$ (TPAA = tris[2-[*N*-(2-pyridylmethyl)amino]ethyl]amine, a heptadentate nitrogen ligand) exhibits absorption maxima at 290 and 310 nm.[16] Although protonated species (MnOOH) have been previously considered,[24,26] we, and others,[24,27] excluded them on the basis of the published pK_a for (MnOOH/MnOO) (2.5 to 5.5).[24,26] Complex **1** shows an N_3O_1 coordination sphere. The absorption maximum for T at 300 nm is thus in the expected range. Furthermore, its formation rate constant is consistent with rate constants reported for similar adducts, ranging from 7.5×10^6 mol^{-1} s L^{-1} to 4.4×10^8 mol^{-1} L s^{-1}.[16,23,24,26–29] In addition, the existence of an intermediate $\{MnOO\}^6$ is consistent with reactivity studies previously performed in anhydrous DMSO. A di-μ-oxo dimer $[(IPG)Mn^{III}(O)_2Mn^{IV}(IPG)]^+$ has been obtained upon addition of 0.5 equiv. of superoxide on the manganese complex, and characterised by using UV/Visible spectroscopy and EPR. Its formation has been rationalised by the reaction of a postulated adduct $\{MnOO\}^6$ with the remaining monomeric manganese(II) complex.[19]

3. Multipulse Experiment on a Noncirculating Solution: Is the Behaviour of the Complex towards Superoxide Reproducible?

Experiments were recorded at different time scales ($t \le 8.4\times10^{-5}$ s, $t \le 8.4\times10^{-4}$ s, $t \le 8.4\times10^{-3}$ s, $t \le 8.4\times10^{-2}$ s), indicating that the transient T decays with a half-life of about 0.04 s.

To obtain more information on the mechanism of the reaction of **1** with $O_2^{\cdot-}$ and check the reproducibility of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

behaviour of **1** towards $O_2^{\cdot-}$, a multi-pulse experiment[30] was performed. 11 repeated irradiations were applied to a noncirculating complex solution. This solution thus received successive doses of superoxide, approximately 0.75 equiv. each.

The trace recorded at 300 nm is provided in Figure 3. After the superoxide pulse, an absorption peak S (for spike) was observed with a decrease and a stabilisation of the absorbance on a plateau P. This behaviour was reproducibly recorded up to 11 times, and the absorbance reached a higher level on successive plateaus. It should also be noted that the size of the peak was decreasing upon repetitive pulses.

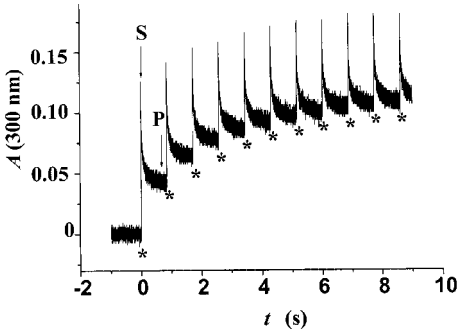

Figure 3. Variation of absorbance with time at 300 nm, during a multipulse experiment. [**1**] = 10^{-4} mol L^{-1}; propan-2-ol 0.1 mol L^{-1}; phosphate buffer 5 mmol L^{-1}; irradiation pulse 1 μs; [$O_2^{\cdot-}$] = 7.3×10^{-5} mol L^{-1}; irradiation frequency 1 Hz. Arrows indicate the first spike S and the plateau P. Stars indicate irradiations.

Difference absorption spectra, obtained at the spike S (2.6 ms ≤ t ≤ 22.6 ms) and at the plateau P (800 ms ≤ t ≤ 820 ms) after the first pulse are shown in Figure 4 and compared to that of the short time transient T. The S and P spectra are both characterised by an intense absorption maximum at 280 nm. It was checked that both S and P spectra are reproducibly obtained after each further pulse. The comparison of spectra labelled S, P and T seems to indicate that at the spike S, the solution is a mixture of the transient T and of the product characterised by the spectrum measured at the plateau P. The absorbance decay after the spike was completed within 0.5 s, and had a half-life (0.02 s) of the same order of magnitude as the half-life of the transient T.

A tentative attempt was made to analyse and simulate the behaviour of the successive plateaus.[31] This behaviour can be described by a catalytic cycle, involving an adduct {MnOO}^{6} as the transient T [ε_T(300 nm)[32] = 1500 L mol^{-1} cm^{-1}] and a species R responsible for the residual absorbance at the plateaus (Scheme 1). Electrochemical oxidation of the manganese(II) complex **1** leads to a yellow solution, whose UV/Visible spectrum is consistent with the main peaks observed at the plateaus.[33] The species R may thus be ascribed to the manganese(III) complex [Mn^{III}(IPG)]$^{2+}$ (a rough estimation from the electrochemical generation leads to an ε_P(300 nm) of about 1800 L mol^{-1} cm^{-1}). A simple ping-pong mechanism cannot reproduce the behaviour of the plateaus upon successive irradiations: as

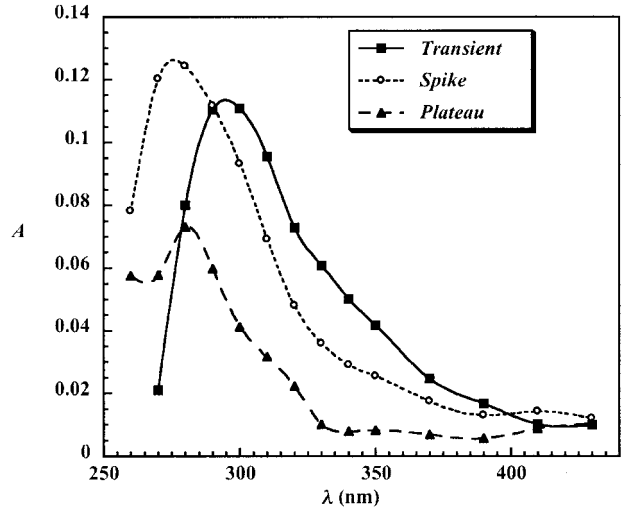

Figure 4. Difference absorption spectra of the solution during the reaction of **1** with superoxide. Absorbance was read at the top of the spike S (2.6 ms ≤ t ≤ 22.6 ms) and at the plateau P (800 ms ≤ t ≤ 820 ms) after the first pulse. The spectrum of transient T is added for the sake of comparison. [**1**] = 10^{-4} mol L^{-1}; propan-2-ol 0.1 mol L^{-1}; phosphate buffer 5 mmol L^{-1}; irradiation pulse 1 μs; [$O_2^{\cdot-}$] = 7.3×10^{-5} mol L^{-1}; irradiation frequency 1 Hz.

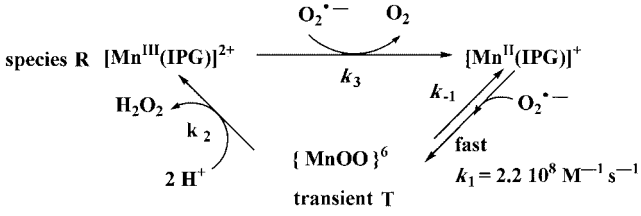
ε_P(300 nm) and ε_T(300 nm) are close, the decay in absorbance to reach the plateau P cannot be assigned solely to the formation of [Mn^{III}(IPG)]$^{2+}$. A pathway back to Mn^{II} has to be considered (see Scheme 1).



Scheme 1. Proposed reaction scheme for the reaction of **1** with superoxide. It consists of a catalytic cycle involving a manganese(II)–superoxide adduct as a transient and a manganese(III) complex as the species R responsible for the spectrum at the plateau.

From the schematic mechanism in Scheme 1, an iterative formula for X_n, representing the fraction of Mn^{II} at plateau n can be derived, see Equation (1).

$$X_{n+1} = X_n - \frac{k_1 X_n \times 0.75}{k_3(1-X_n)+k_1X_n} \times \frac{k_2}{k_{-1}+k_2} + \frac{k_3(1-X_n)\times 0.75}{k_3(1-X_n)+k_1X_n} \quad (1)$$

The second term stands for the fraction of transient T decaying back to [Mn^{II}(IPG)]$^+$ (k_{-1}), as T may decay either to [Mn^{II}(IPG)]$^+$ (k_{-1}) or to [Mn^{III}(IPG)]$^{2+}$ (R) (k_2). The third term stands for the transformation of [Mn^{III}(IPG)]$^{2+}$ (R) to [Mn^{II}(IPG)]$^+$, which is assumed here to be complete. At each pulse, 0.75 equiv. of superoxide is introduced into the system.

The best fit, up to the sixth iteration, (see Figure 5) was obtained for $k_1 = 3k_3$ and $k_{-1} = 2.2k_2$.[34]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

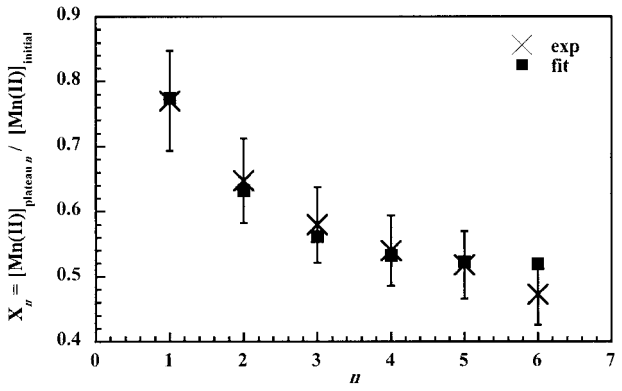


Figure 5. Cross marks: iterative values for the Mn^{II} fraction at plateau *n*, deduced from the absorbance measured at the plateau, assuming only **1** and $[Mn^{III}(IPG)]^{2+}$ are present at the plateau (error arbitrarily fixed at 10%). Square marks: simulation using successive iterations for X_n (see text).

4. Superoxide Decay at 270 nm under Conditions for which $[1]_0 < [O_2^{\cdot-}]_0$: Overall Catalytic Rate Constant

The catalytic nature of the reaction was confirmed by following the decay of the absorbance of superoxide at 270 nm in the presence of **1**, with $[1]_0 < [O_2^{\cdot-}]_0$ ($[1]_0 = 2\times10^{-7}$ mol·L^{-1} and 10^{-5} mol·L^{-1} and $[O_2^{\cdot-}]_0 = 7.3\times10^{-5}$ mol·L^{-1}). It should be noted that only a limited range of concentrations for **1** were informative, as the adduct {MnOO}^{6} itself absorbs at that wavelength.

The decay of superoxide is faster at high concentrations of complex **1** and follows apparent first-order kinetics. The deduced catalytic rate constant $k_{cat} = 3.8\pm0.2\times10^6$ mol^{-1}Ls^{-1} is of the same order of magnitude as that calculated from the indirect xanthine-xanthine oxidase-cytochrome c test ($2.9\pm0.3\times10^6$ mol^{-1}Ls^{-1}).[19]

Conclusions

This pulse radiolysis study allows us to propose a catalytic mechanism involving a transient adduct {MnOO}^{6}, and a manganese(III) complex for the reaction of complex **1** with superoxide. These two species were characterised by their differential absorption spectra. The formation rate of the adduct is among the fastest reported in the literature. The multipulse experiment showed unambiguous reproducible behaviour upon successive superoxide pulses (up to 11). Complex **1** efficiently catalyses the dismutation of superoxide with a rate constant equal to 1% of that of the manganese superoxide-dismutase. The present study provides convergent pieces of evidence for catalytic activity. To complete the mechanistic scheme suggested here for the reactivity of the manganese(II) compounds, further research is now underway on the reactivity of the Mn^{III} species. Moreover, further research to improve the catalytic activity of the manganese SOD mimics is now in progress.

Experimental Section

The pulse radiolysis experiments were carried out with a 10 MeV Titan β linear accelerator at the Laboratory of Radiolysis, CEA Saclay. Pulses from 5 ns to 1 μs are available, and the pulse frequency is adjustable. A 10 ns pulse corresponds to a 20 Gray dose. Solutions saturated with oxygen are driven in a quartz circulating microcell (spectral path length 1 cm, volume 400 μL) at a constant flux (1 mL/min). The spectroscopic and temporal analysis is mediated by an optical fibre, linked to a monochromator, then to a photomultiplicator and lastly to a Tektronix numerical oscilloscope allowing the observation of the temporal evolution of absorbance. Absorbance was averaged over 100 pulses as it provides an improvement of the signal-to-noise ratio, relative to the single-pulse experiments generally used. The amount of superoxide generated during pulse radiolysis was established by the absorbance value at 260 nm, assuming that $\varepsilon_{260} = 1940$ L mol^{-1} cm^{-1}.[23]

Measurements were carried out in a 5 mmol L^{-1} phosphate buffer, propan-2-ol 100 mmol L^{-1} at pH 7.8 and 25 °C at different concentrations of Mn^{II} complex. Solutions were oxygen saturated by bubbling O_2 for at least 60 min. A 1 μs-pulse, generating a 7.3×10^{-5} mol L^{-1} superoxide concentration, was imposed upon the solution. The irradiation frequency was 1 Hz, so that the cell content was totally renewed between two pulses. The disappearance of superoxide was followed at 270 nm (($\varepsilon_{270} = 1479$ L mol^{-1} cm^{-1} at pH 7.8 and 23 °C[21]). Spectra are differential, the reference absorbance being recorded before irradiation.

Rates were derived assuming either second-order kinetics corresponding to the self-dismutation of superoxide ($A = A_0/[1 + k_{obs}A_0t)]$) or pseudo-first-order kinetics in the presence of the complexes ($A = A_0[\exp(-k_{obs}t)] + B$, and $k_{obs} = k_{cat}$ [complex]). Simulations of kinetic traces are performed using Gepasi3 (self-dismutation) or Kaleidagraph (complex catalysed dismutation; see the Supporting Information for a Figure providing k_{obs} = f([**1**]); see also the footnote on the first page of this article).

[20] From the measured IC50 values, it is possible to calculate a rate constant value, which is independent of both detector concentration and nature. At the IC50 concentration, superoxide reacts at the same speed with cytochrome c and the putative SOD-mimic. Then, $k = k_{cytc} \times [cytc]/IC50$.[35] In the case of cytochrome c Fe^{III} as detector, k_{cytc}(pH 7.8; 21 °C) = $2.6\ 10^5\ mol^{-1}\ L\ s^{-1}$.[36].

[32] Estimate assuming that 100% of **1** has been converted into the transient over the first 40 ms.
[33] The electrochemical generation of the Mn^{III} species was done in a two-compartment cell, with a three-electrode set up (working electrode: vitreous carbon (15 cm^2), reference electrode: SCE, KCl sat., counter electrode: Pt grid) collidine/collidinium buffer (50 mM, pH 7.5) (collidine: 2,4,6-pyridine) in MeOH, $[Mn(IPG)^+]$ = 2 mM, potential of the electrolysis: 1V/SCE). The Mn^{III} was unstable and the Mn^{II} species was recovered within a few hours.
[34] The quality of the fit was greatly decreased after the sixth iteration (not shown). This could be due to several experimental factors: cumulative doses, bleaching by UV analysis light, accumulation of hydrogen peroxide and the oversimplified description in the scheme of the reactivity of the Mn^{III} species (R).

The Relationship between the Structure and Magnetic Properties of Bioinspired Iron(II/III) Complexes with Schiff-Base-Like Chelate Ligands, Part I: Complexes with Dianionic [N_4] Macrocycles

Birgit Weber[a][‡] Indira Käpplinger,[a] Helmar Görls,[a] and Ernst-G. Jäger*[a]

Keywords: Bioinorganic chemistry / Iron / Macrocycles / Magnetic properties / Schiff bases

The molecular structures and the spin ground-state of the iron(II/III) complexes **Fe1**, **Fe2** and **Fe3**, which contain dianionic macrocyclic [N_4] ligands derived from substituted acetylacetaldehydes and 1,2-diamines, have been investigated by X-ray analysis and temperature-dependent susceptibility measurements, respectively. The iron(II) complexes **Fe^{II}1** (which is dimeric by intermolecular coordination of one peripheral carbonyl group), **Fe^{II}1MeOH**, **$(Fe^{II}L)_2$dabco** (L = **1**, **2**, **3**; dabco = 1,4-diazabicyclo[2.2.2]octane) and the iron(III) complex **Fe^{III}1Cl** are pentacoordinate and have an intermediate-spin ground-state at room temperature (S = 1 for Fe^{II}; S = 3/2 for Fe^{III}). The intermediate-spin state was confirmed by DFT-MO calculations for **Fe^{II}1MeOH** and **Fe^{III}1Cl** and is also in agreement with the Mössbauer data of **Fe^{II}1** and ESR measurements of **Fe^{III}1Cl**. The iron centre in **Fe^{II}2** is nearly square-planar and shows a strong decrease of the magnetic moment below $T \approx 250$ K. This is probably due to an S = 0 to S = 1 spin-crossover or, more likely, to intermolecular antiferromagnetic interactions (shortest Fe–Fe distance of 3.4 Å). A new pair of octahedral iron(II/III) complexes with an N-heterocyclic axial ligand, **$Fe^{II}3(Py)_2$**/[**$Fe^{III}3(Py)_2$**]PF_6, could be crystallised. In contrast to the previously described pairs **$Fe^{II}1(Him)_2$**/[**$Fe^{III}1(Him)_2$**]PF_6 and **$Fe^{II}2Py_2$**/[**$Fe^{III}2Py_2$**]ClO_4, the orientation of the planes of the axial ligands is nearly independent of the oxidation step of the central atom. Octahedral derivatives with biologically relevant anions as axial ligands have been crystallised for the first time, namely [$BzEt_3N$][**$Fe^{III}1(NCS)_2$**], [Et_4N][**$Fe^{III}2(CN)_2$**]$(H_2O)_{0.5}$, Na[**$Fe^{III}2(NO_2)_2$**]$(MeOH)_2(H_2O)_{0.5}$ and [**$Fe^{III}2(NO_2)OH_2$**](MeOH). The latter shows a magnetic moment of $\mu_{eff} \approx 2.85\ \mu_B$ at room temperature, which decreases to 1.85 μ_B at lower temperature. This indicates an incomplete S = 1/2 to S = 3/2 spin-crossover, which is probably due to the presence of H_2O as a weak axial ligand.

Introduction

Iron is known to be a ubiquitous biometal with a great variety of metabolic functions.[1] Many iron-containing proteins are derived from haem with the porphyrinato macrocycle as a typical dianionic equatorial [N_4] ligand. The unique biological role of (porphyrin)iron compounds may be one reason for the unbroken interest in this important class of molecules over nearly a century. This is reflected in the countless number of papers and many extensive reviews, monographs and handbooks.[2] Compared with the porphyrins, including such variations as expanded porphyrins, confused porphyrins etc., there are only a few other examples of similar [N_4] macrocycles that can act as dianionic equatorial ligands. Besides the synthetic porphyrins and their tetrabenzotetraaza derivatives, the phthalocyanines and complexes with tetradentate [N_2O_2]-coordinated dianions of *N*,*N*-bridged salicylaldimines (e.g. "salen") have been investigated extensively, and in part quite successfully, as models for the active sites of haem proteins. For instance, the reversible uptake of dioxygen − the main function of haemoglobin − was realized with simple "(salen)Co" much earlier[3] than with (porphyrin)iron compounds detached from the protein; the first catalysts of technical relevance for cytochrome-P450-like oxygenation reactions were derived from (salen)Mn.[4]

During the last decades we have created a pool of chelate complexes[5] with ligand systems that can be subdivided into the three basic structures given in Scheme 1. All these compounds are structural or functional models of active sites of metalloenzymes: Type **I**, which is formally most related to porphyrins, contains tetradentate twofold negatively charged macrocyclic ligands with an [N_4] donor set and a more or less extended π-system. [The special ligand Me_4TAA, first published in 1969 as its nickel complex (Me_4TAA)Ni[6] and today known in complexes with nearly all transition elements and many main group metals,[7] has been characterised by F. A. Cotton: "The latter bears many similarities to porphyrinato systems, but its chemical behav-

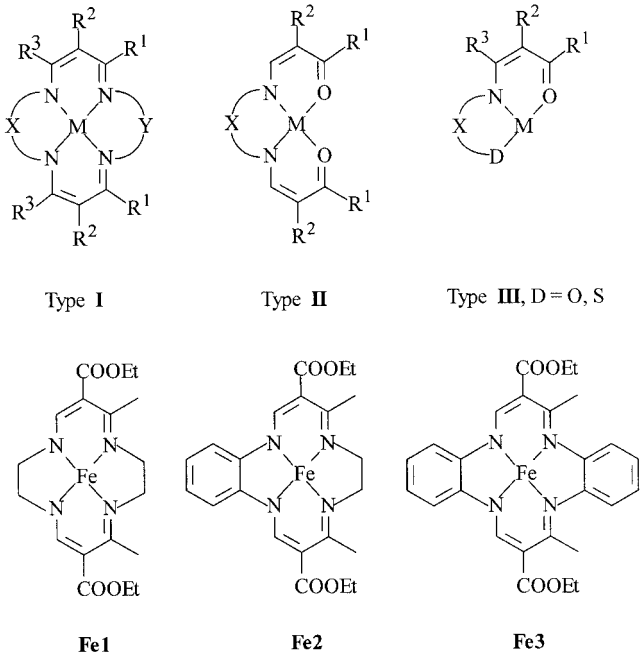
iour seems to be even more diverse."[7b]] Type **II** is derived from dianionic open-chain ligands with an [N_2O_2] coordination sphere ("salen" is a special case with a fused benzene ring for $R^1 + R^2$). Type **III** is derived from tridentate dianions; the coordinatively highly unsaturated formula unit promotes the formation of oligonuclear structures[8] similar to those found in biological systems. Previous investigations on cobalt, copper and nickel complexes of types **I**, **II** and **III** have already shown that the variation of the *N*,*N*′-bridges X, Y and the substituents R^{1-3} can be used to control properties such as the electronic state of the central atom,[9] the redox potentials,[10,11a,11d,11e] the affinity of vacant axial coordination sites towards additional ligands,[11] as well as the binding and activation of dioxygen,[5b,12] carbon dioxide[13] or nitric oxide.[14] These results indicated that the macrocycles **I** and, in some respect, also the complexes **II** share many common characteristics with porphyrins, but marginal ligand variations can dramatically change the behaviour. This situation is particularly typical of the chemistry of the iron complexes.



Scheme 1. Formulae of basic chelate complexes studied in our laboratory (**I**–**III**) and formulae of macrocyclic iron complexes used in this work (**Fe1**–**Fe3**). The arabic numbers represent the dianion of the macrocyclic ligand $\mathbf{H_2L}$ ($\mathbf{L^{2-}}$ = **1**, **2**, **3**). **Fe1a** denotes the more hydrophilic variant of **Fe1** with acetyl (COMe) instead of the ester groups COOEt. The abbreviation $\mathbf{Me_4TAA}$ ("tetramethyldibenzo*tetraaza*[14]*annulene*") is used for $\mathbf{L^{2-}}$ in type **I** with X = Y = *o*-phenylene, $R^1 = R^3$ = Me, and R^2 = H. The basic macrocycles **FeL** and the axial ligands [MeOH, dabco (μ-1,4-diazabicyclo[2.2.2]-octane), Py (pyridine), N-MeIm (*N*-methylimidazole), I^- etc.] are given in bold (with the exception of the tables); all other components of the formula units or within the lattice are given in plain characters.

Busch et al.,[15a,15b] Holm et al.[15c,15d] and Goedken et al.[16] have described iron(II/III) complexes of type **I** with R^2 = H or Ph. The parent compound of **Fe1** (R^2 = H) has been characterised as a square-planar intermediate-spin (S = 1) complex[15a] that gives an octahedral diadduct, probably with a high-spin (S = 2) ground state, in pyridine solution. No addition of imidazole − a very characteristic reaction of (porphyrin)iron compounds − could be observed. Even in our earlier reports[17] we accentuated the high tendency of the carbonyl-substituted derivative **Fe1** to give octahedral low-spin diadducts, especially with imidazole. Many such derivatives have been isolated as solids and could be characterised by X-ray structure analysis and susceptibility measurements.[18] The existence of others (also with biologically relevant anions such as nitrite and sulfite[19b]) could be proved in solution by spectrophotometric titration.[19] In this respect, the carbonyl-substituted derivative **Fe1** is more closely related to porphyrins than the parent compound. On the other hand, several pentacoordinate iron(III) halides of type **I** have been described as intermediate-spin (S = 3/2) complexes,[15,20] whereas the derivative $\mathbf{Fe(Me_4TAA)Cl}$ has a high-spin (S = 5/2) ground state, just as most halides of (porphyrin)iron(III) compounds. The formation of various pentacoordinate halides and pseudo-halides **Fe1X** (X = F, Cl, Br, I, N_3^-, SCN^-) has been monitored by spectrophotometric equilibrium studies in two-phase systems,[21] but their spin state is uncertain in some cases. In contrast, all the pentacoordinate nitrosyl derivatives **FeLNO** (**L** = **1**, **2**, **3**) have an S = 1/2 ground state, just as the analogous (porphyrin)iron compounds.[22]

The existence of coordinatively unsaturated species that are able to reversibly bind additional axial ligands, as well as the possibilities of changing the oxidation number and the spin state of the central atom, are key features of many haem proteins. For instance, the iron(II) atom in deoxygenated haemoglobin has an effective coordination number of five as the bonding to the nitrogen atom of the imidazole ring of the "proximal" histidine group causes a strong displacement from the [N_4] plane of the equatorial porphyrin; the ground state is high spin (S = 2). After oxygenation, the central atom is best described as six-coordinate low-spin (S = 1/2) iron(III) in a weakly distorted octahedral environment, antiferromagnetically coupled with the unpaired electron of an axially coordinated superoxide radical ion. For comparison with our macrocycles we are therefore mainly interested in structural and magnetic information as a function of the coordination number and the oxidation state of iron in these complexes.

This paper is focused on (i) the spin state of complexes with coordination number less than 6, (ii) the dependence of the orientation of axial N-heterocycles in octahedral diadducts on the oxidation state of the central atom, and (iii) attempts to isolate adducts with biologically relevant anions as solids for structural and magnetic studies.

Results and Discussion

Syntheses and General Characterisation

In contrast to the analogous nickel and copper compounds, the iron complexes of type **I** cannot be synthesised

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

by a direct metal-templated condensation of the precursor complexes of type **II** with diamines. The best synthetic method is the reaction of an iron(II) salt, chiefly the acetate, with the free ligands $\mathbf{H_2 1}$, $\mathbf{H_2 2}$ and $\mathbf{H_2 3}$, respectively, which can be obtained by demetallation of the copper(II) complexes. The synthesis of the basic iron(II) complexes **Fe1**,[17b,17c,21] **Fe2**[10d] and **Fe3**[23] has been described previously. However, since all these publications are in German in mainly non-international, and in part no longer available, journals, and also because some steps of the ligand syntheses have been modified to prevent the use of gaseous hydrogen sulfide, we will give a summary of the syntheses in the Experimental Section.

Adducts of the iron(II) complexes with axial ligands were obtained by adding an excess of the corresponding ligand to the reaction mixture during the synthesis of the iron(II) complex. The products precipitated upon slow cooling of the reaction mixture. In some cases mono- and/or diadducts were formed depending on the concentrations and the temperature regime.[17b,17c] Diffusion procedures are better suited for diadduct formation starting from the isolated parent complexes. The air sensitivity of the iron(II) complexes is strongly dependent on the type of additional axial ligands and decreases in general from **Fe1** to **Fe3**. This sequence is in agreement with the redox potentials of the complexes.[5c,10d]

The iron(III) complexes are best prepared starting from the iron(II) derivatives by in-situ oxidation with iodine in the presence of an excess of sodium iodide to promote the precipitation of the iodide **FeLI**.[20,21] The latter is a good precursor for a large range of iron(III) derivatives with different axial ligands.[5c,18] Carbon tetrachloride is a suitable Cl donor to yield the chloride derivatives **FeLCl**. All the iron(III) complexes are relatively air-stable but water-sensitive, especially in the presence of primary or secondary amines (piperidine!) or phosphonic acid esters as axial ligands. Here, hydrolysis and/or radical redox processes occur. All complexes are therefore best handled under dry argon.

Intermediate-Spin Complexes with Coordination Numbers 4, 4+1 and 5

Crystals suitable for X-ray structure analysis were obtained for the solvent-free iron(II) complexes **Fe1** and **Fe2**. Only one stable solvate with an O-donor, **Fe1MeOH**, could be crystallised. The previously described crystalline 1:1 solvates of **Fe1** with the N-donors ammonia or pyridine[17b] decompose even at room temperature under dry argon. Attempts were made with the alternative N-donor 1,4-diazabicyclo[2.2.2]octane (dabco) and, in all cases, good crystals

Table 1. Spin state (*S*), room-temperature magnetic moment (μ_{eff}) and bond lengths [Å] and angles [°] within the first coordination sphere of macrocyclic iron(II/III) complexes with coordination numbers (*CN*) 4, 4+1 and 5.

of the bridged complexes **(FeL)$_2$dabco** (**L** = **1**, **2**, **3**) were obtained. With imidazole and its derivatives the octahedral diadducts **FeL(HIm)$_2$** are strongly favoured. Sub-stoichiometric amounts of imidazole result in the formation of polymeric species.[17b,17c] In contrast, several iron(II) complexes of the general type **II** give mononuclear mono- and diadducts with imidazole.[5a] Additionally to the known pentacoordinate iron(III) complex **Fe^{III}1I** with axial iodide,[20] all the chlorides **Fe^{III}LCl** were isolated as solids, but only **Fe^{III}1Cl** gave crystals of sufficient quality. Selected parameters of the molecular structures and the magnetic moments at room temperature are listed in Table 1. The data of **Fe1I**,[20] **Fe1NO**,[22] **Fe(Me$_4$TAA)**,[16a] **Fe(Me$_4$TAA)CO**[16c] and **Fe(Me$_4$TAA)Cl**[16b] are included for comparison. The atom numbering in the table corresponds to that given in Figure 1. Figure 2 shows the molecular structures of selected examples, if possible approximately in the same projection of the basic chelate ring.

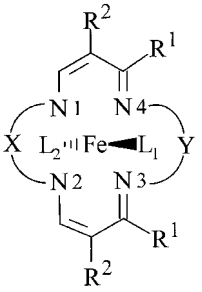

Figure 1. Unified atom numbering scheme used in Tables 1 and 3 for the equatorial donor atoms.

At first sight, the new data show few characteristic differences. The room-temperature magnetic moments are in satisfactory agreement with former measurements using a Gouy balance[17b] for **Fe1** (3.38 μ_B), **Fe1MeOH** (3.37 μ_B), **Fe1NH$_3$** (3.12 μ_B), **Fe1Py** (3.08 μ_B), and **Fe1I** (4.07 μ_B).[17c] These values are all higher to a greater or lesser degree than the spin-only value of 2.83 μ_B for two (S = 1) and 3.87 μ_B for three (S = 3/2) unpaired electrons, but all of them are within the region expected for intermediate-spin iron(II) and iron(III) complexes.[15a] (The reason for the increased values is probably a contribution of an orbital magnetic moment, due to an unsymmetrical population of the d_{xz} and d_{yz} orbitals, see also Figure 7.)

The iron atom has an approximately square-planar coordination sphere in **Fe2**. The central atom in all the other complexes is pentacoordinate with an approximately square-pyramidal geometry − in **Fe1** by intermolecular coordination of one of the peripheral carbonyl groups (*CN* = 4+1).The bond lengths and angles within the first coordina-

tion sphere, including those of the octahedral complexes described in the next sections (cf. Table 3), reflect the rules formerly elaborated for a large number of our macrocyclic iron complexes:[5a] the Fe–N distances within the equatorial plane are, for low-spin and intermediate-spin complexes, nearly independent of the type of equatorial ligand $\mathbf{L^{2-}}$, the coordination number and the oxidation state of the central atom [average of 16 significant mean values from Tables 1 and 3 of 191(1) pm]. Larger differences exist between the Fe–N distances on the non-methylated side (N1, N2) and the methylated side (N3, N4) of the six-membered chelate rings [average of 32 significant values in each case: 189(1) and 192(1) pm, respectively]. The distances to the axial ligands are always longer than those within the equatorial plane. This is in contrast to the conditions in the case of many derivatives of (porphyrin)iron compounds and is obviously due to the higher effective field strength, which is accompanied by shorter equatorial Fe–N distances, of the ligands $\mathbf{L^{2-}}$ (**L** = **1**, **2**, **3**). The displacement of the central atom from the best equatorial [N_4] plane in pentacoordinate complexes is more obvious in the presence of relatively strong axial ligands with short distances to the iron atom (Cl^- > dabco > MeOH > COOEt) but there is no clear correlation. Interestingly, a small but significant displacement is also observed for the iron atom in $\mathbf{Fe^{II}2}$, which is directed towards the neighbouring iron atom in the asymmetric unit (Fe–Fe distance of 335 pm).

Two selected prototypes of complexes with a quite different behaviour are included in Table 1. The first one, the nitrosyl derivative **Fe1NO**, which we interpreted as $\mathbf{(Fe^{III})^{+}NO^{-}}$,[22a] has a temperature-independent $S = 1/2$ spin ground state. The axial Fe–N distance of 173 pm is shorter than the equatorial Fe–N bonds, which are approximately in the same range as for the other complexes. These deviations can be explained by assuming a very strong ligand field of the axial NO^- ligand. The other one, the pentacoordinate chloride complex **Fe(Me$_4$TAA)Cl**, which has a magnetic moment of 5.95 μ_B,[16b] is undoubtedly a high-spin iron(III) complex and resembles the behaviour of the pentacoordinate halides of (porphyrin)iron compounds. This is also reflected in an average Fe–N distance of over 200 pm that is typical for high-spin iron(II/III) complexes such as those of the general type **II**.[5a,22] Taking into account that the similar complex $\mathbf{Fe3^{III}Cl}$ is clearly an intermediate-spin complex (μ_{eff} = 4.20 μ_B at room temperature; structure data unfortunately not available), the difference indicates a lower field strength of the ligand **Me$_4$TAA**. The reason for this could be the stronger "saddle-shaped" distortion of the macrocycle, caused by the two additional methyl groups in R^3, and/or the absence of the peripheral carbonyl group in R^2, which increases the π-acceptor strength of the ligand and the effective charge of the central atom in the other complexes. In agreement with this idea, **Fe(Me$_4$TAA)** forms derivatives with carbon monoxide and other strong π-acceptors as axial ligand much more easily than **Fe3**.[16c,16d]

On closer inspection, the structural nuances of the complexes are reflected in the temperature dependence of the magnetic behaviour. Selected examples are depicted in Figure 3.

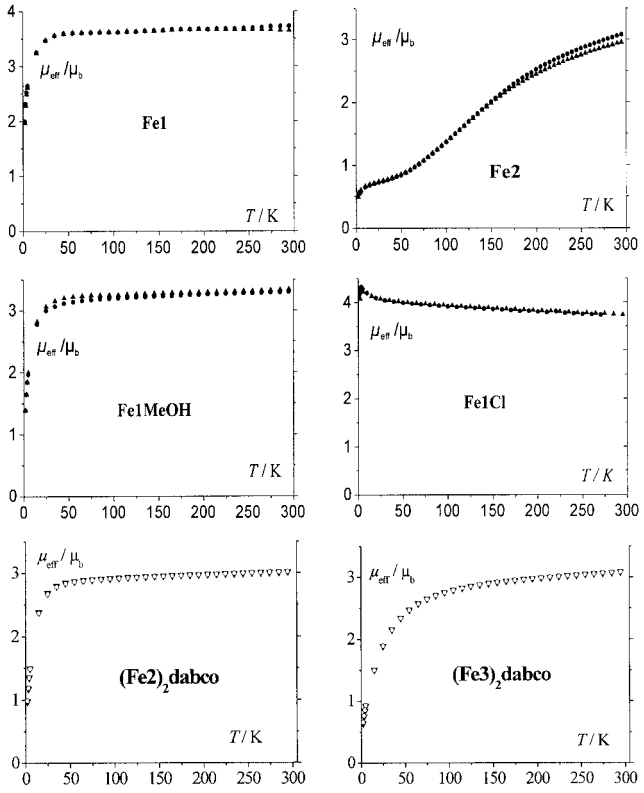

Figure 3. Temperature dependence of the effective magnetic moment of selected macrocyclic iron complexes: **Fe2** (*CN* = 4), **Fe1** (*CN* = 4+1), **Fe1MeOH**, **Fe1Cl**, **(Fe2)$_2$dabco**, **(Fe3)$_2$dabco** (all *CN* = 5). All measurements were carried out at 0.2 and 0.5 T.

With the exception of **Fe1Cl**, the magnetic moment decreases at lower temperature. **Fe2** shows a characteristic sigmoid curve progression which is apparent even at room temperature (Figure 3). This peculiarity can be explained as an incomplete and smooth transition into the low-spin $S = 0$ state, accompanied by antiferromagnetic interactions between two iron atoms (as mentioned above, the lattice of **Fe2** consists of pairs of two molecules with an iron–iron distance of 335 pm, which is short enough for direct interactions). The relatively steep decrease of the magnetic moment of several complexes at $T < 20$ K (left side of Figure 3) is not quite clear because the shortest Fe–Fe distance in the lattice is quite long (for **Fe1** and **Fe1MeOH** > 650 pm). In the case of the dinuclear iron(II) complex **(Fe3)$_2$dabco** the decrease of the magnetic moment starts already at $T < 150$ K. The Fe–Fe distances within the dinuclear unit are nearly identical for all **(FeL)$_2$dabco** derivatives (729, 725, and 727 pm for **L** = **1**, **2**, and **3**, respectively), but the Fe–Fe distances between the dinuclear units in the lattice are significantly shorter, especially for **(Fe3)$_2$dabco** (524, 528, and 421 pm for **L** = **1**, **2**, and **3**, respectively). This could explain the different behaviour of the latter.

The strong influence of the equatorial ligand is reflected in the zero-field Mössbauer spectra of solid samples of the

solvent-free complex **Fe1**. The spectrum at 4.2 K is given in Figure 4. The observed quadrupole splitting of ΔE_Q = 3.37 mm s^{-1} (isomer shift δ = 0.32 mm s^{-1}) is very large for an iron(II) complex, even if a square-planar coordination sphere is considered. The data for similar complexes are given in Table 2. ΔE_Q appears to increase with increasing σ-donating ability (basicity) of the equatorial ligand. This is in agreement with earlier observations revealing a stronger σ-donor ability of the ligands **1**–**3** in comparison to similar porphyrin ligands.

[a] At room temperature.

The ESR spectrum of a frozen solution of **Fe1Cl** in toluene at 10 K is given in Figure 5. The g values (g_y^{eff} = 4.594, g_x^{eff} = 3.486 and g_z^{eff} = 2.039) can be assigned to the population of the ground-state (S = 1/2) Kramers doublet of the S = 3/2 system. The signal at 6.203 is due to small (μ-oxo?) impurities. The signal intensity of the impurity increases with decreasing temperature. The spectrum is similar to those reported for **Fe1I**,[20] although with slightly shifted g values, which can be assigned to a different rhombicity parameter E/D (D = axial, E = rhombic zero-field splitting parameter) of around 0.1 for the chloride complex (0.22 for the iodide adduct). In contrast to **Fe1I**, the chloride complex **Fe1Cl** is not ESR-silent in the solid state. A broad signal is observed at around g = 4.7, which can be explained by differences in the molecular packing in the crystal.

The intermediate-spin state of the iron(III) complexes is also reflected in the characteristic shifts of the resonances in the ^{1}H NMR spectra. As an example, the spectrum of

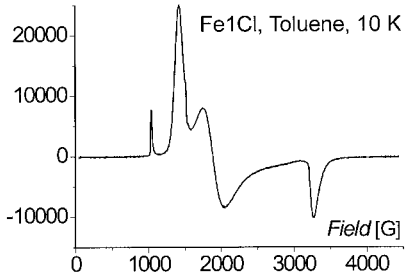

Figure 5. ESR spectrum of **Fe^{III}1Cl** in frozen toluene solution at 10 K.

Fe1Cl in toluene at 45 °C is given in Figure 6. With the help of predictions about the signal shifts based on literature proposals[25] and the signal intensities a clear assignment is possible. The observed paramagnetic shift can be interpreted by taking only the contact shift into account. The temperature dependence of the shifts obeys the Curie law.

Molecular orbital calculations based on the molecular structure were performed for **Fe1MeOH** and **Fe1Cl** to confirm the intermediate-spin ground state. Similar calculations were also performed for **Fe1I** and, for better comparison, the coordinate system was chosen the same way. The z axis of the molecular coordinate system was chosen in the direction of the axial ligand bond with the iron atom located at the origin of the coordinate system. The x and y axes are directed between the equatorial nitrogen atoms so that the σ-bonds with the equatorial ligand are formed by the $3d_{xy}$ orbital of the iron atom. The results of the spin-polarized calculations for **Fe1MeOH** are given in Figure 7.

The MO diagram of **Fe1Cl** is similar to that of **Fe1I** discussed in detail previously,[22] and is therefore not displayed here. Small differences are found in the bonding conditions between the iron atom and the axial ligand. In the case of the iodide adduct, covalent interactions between the $3d_{z^2}$ (σ-bonding) and $3d_{xz,yz}$ (weakly π-antibonding) orbitals of the iron atom and the $5p_z$ orbital of the axial ligand are present, while the $5p_{x,y}$ orbitals of the iodide ion are nearly non-bonding. In case of the chloride adduct π-interactions between the $3p_{x,y}$ orbitals of the chloride ion and the $3d_{xz,yz}$ orbitals of the iron atom are present and are more pronounced than in the case of the iodide adduct. This explains the hypsochromic shift of the typical LTMCT (equatorial *l*igand-*t*o-*m*etal *c*harge *t*ransfer) band in the UV/Vis spectrum of the chloride complex relative to the iodide one.[21]

The intermediate-spin state of **Fe1MeOH** is clearly mirrored in the molecular orbital diagrams. The unoccupied d_{xy} orbital responsible for the σ-bond with the equatorial ligand is clearly separated from the other four d orbitals and the strong interaction with the macrocycle leads to a reduced iron contribution. The interactions with the axial ligand (methanol) are not reflected in the MO diagrams, thereby indicating a very weak bond. The pattern of the MO energies is actually more similar to the typical pattern of a square-planar coordination than a square-pyramidal one, therefore the coordination number of the iron atom can also be described as 4+1.

Orientation of Axial N-Heterocycles in Octahedral Complexes

One of the biological functions of b-type cytochromes is to switch the direction of charge-transfer processes depending on the potential. The active site contains haem with two axial imidazole rings of histidine. The voltage-dependent change of the orientation of the heterocyclic planes could be a possible mechanism for the switching. Former X-ray studies on the pair **Fe^{II}1(HIm)$_2$** and [**Fe^{III}1(HIm)$_2$**]-PF_6 gave evidence for such a charge-dependent reorientation of the imadazole planes,[18a] but it was not possible to clarify the role of the intermolecular hydrogen bonds in this case. Later on, an overview of the orientation of axial ligand planes in octahedral homo- and heteroligand diadducts of fifteen iron(II/III) complexes was given.[18b] We have now successfully crystallised **Fe^{II}3(Py)$_2$** and **[Fe^{III}3(Py)$_2$]**-PF_6, the first pair of complexes derived from the basic complex **Fe3**. The structures of both complexes are depicted in Figure 8 (right side), together with those of **Fe^{II}2Py$_2$** and [**Fe^{III}2Py$_2$**]ClO_4 (left side) for comparison. The corresponding bond lengths and angles are summarised in Table 3.

Addition of two neutral nitrogen ligands at the axial coordination sites of the macrocyclic iron complexes leads to low-spin complexes. The spin state was confirmed by ESR investigations in the case of the iron(III) complexes.[18b,19c] The iron atom is surrounded by six nitrogen atoms, resulting in a relatively symmetric close coordination sphere with an approximate D_{4h} symmetry. [d] See ref.[18b] [e] The quality of the data is not sufficient and we are only publishing the conformation of the molecule, although distances and angles are similar to those of the other complexes. [f] Because of the disorder of the second axial NO_x ligand and the diamagnetism of the compound, the correct composition is uncertain.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pounds with similar axial ligands are also low-spin complexes, while complexes with sterically demanding axial ligands such as benzimidazole or 2-methylimidazole are high spin due to the small energetic splitting of the iron 3d orbitals.[26,27] Similar high-spin diadducts of our macrocycles have not been obtained up to now.

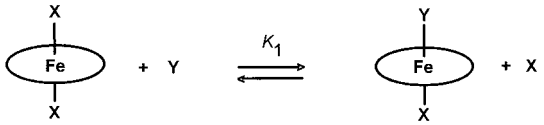
The iron atom is situated in the $[N_4]$ plane of the equatorial ligand. The average $Fe–N_{eq}$ bond lengths (190–192 pm) for both pairs in Figure 8 are in the range typical for all of our low-spin and intermediate-spin complexes, but significantly shorter than in similar (porphyrin)iron complexes (196–200 pm).[28] The change of the oxidation state of the iron atom from +2 to +3 leads to an almost negligible shortening of the equatorial bond lengths. A slight lengthening of these bonds in octahedral complexes of **Fe1** in comparison with the square-planar and pentacoordinate complexes can be explained by the increased electron density at the central atom. The bond lengths between the iron atom and the axial ligands are in the region 200–204 pm, similar to those in low-spin (porphyrin)iron complexes, and are independent of the oxidation state of the central atom.

The most characteristic difference between the structures of both pairs in Figure 8 is the orientation of the planes of the axial pyridine rings. In the case of **Fe^{II}2(Py)$_2$** both pyridine rings are nearly coplanar and are directed at the centre carbon atom of the six-membered chelate rings, similar to the case of **Fe^{II}1(Him)$_2$**. The angle between their planes amounts to only 9°. In the iron(III) derivative [**Fe^{III}2(Py)$_2$**]-ClO_4, however, both planes of the pyridine rings are twisted more in the direction at the equatorial N-atoms and the five-membered rings, and the angle between them is now 79°. This finding suggests that the similar behaviour of the pair **Fe^{II}1(Him)$_2$**/[**Fe^{III}1(Him)$_2$**]PF_6 is not necessarily a result of reorganisation of intermolecular hydrogen bonds. In contrast, the planes of the pyridine rings in the pair **Fe^{II}3(Py)$_2$** and [**Fe^{III}3(Py)$_2$**]PF_6 remain in a nearly unchanged orientation with an angle of 90° and 80°, respectively; they are independent of the oxidation state of the central atom. This is a consequence of the "saddle-shaped" distortion of the twofold phenylene-bridged equatorial ligand that allows only one energetically favoured orientation of the planes of the axial pyridine rings (perpendicular to each other) along the "trough" on each side.

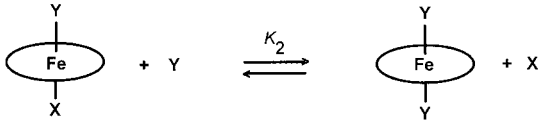
All attempts to crystallise the iron(II) counterparts of [**Fe^{III}1(Py)$_2$**]PF_6 and [**Fe^{III}1(N-Meim)$_2$**]ClO_4 (Table 3) were unsuccessful.

Octahedral Complexes with Biologically Relevant Anions as Axial Ligands

Extended spectrophotometric equilibrium studies of the equilibria (1) and (2),[5a,5c,18b,19] particularly with the more hydrophilic complex **Fe1a**, have provided conclusive proof of the existence of octahedral iron(III) complexes [**Fe^{III}1aXY**] in solution with a large number of axial ligands, including anions as hydroxide, sulfite, nitrite, cyanide, thiocyanate, and even such "exotic" ligands as $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$.[19a] In several cases, for example X = HIm, Y = CN^-, strong stabilizing interactions between both axial ligands have been detected.



(1)



(2)

In view of the fact that anionic and mixed axial ligands play a key role in the chemistry of haem enzymes, we were interested in obtaining structural information for such complexes, especially to determine whether interactions between axial ligands through the central atom are reflected in the structural parameters. Unfortunately, attempts to isolate pure crystals failed in most cases, therefore only a few examples are presented here.

One of the many functions of haem enzymes in biological systems is the activation of small molecules and ions such as nitric oxide (NO), nitrite (NO_2^-) or sulfite (SO_3^{2-}). There has been a renewed interest in the biological nitrogen cycle with the discoveries of the biomedical functions of nitric oxide[29,30] and the clarification of the X-ray structure of the haem enzyme cytochrome c nitrite reductase.[31] This development increased the interest in model compounds with manageable electronic interactions to obtain a better understanding of the coherences of the biological activity of these small molecules. An overview of the properties of nitrosyliron complexes of ligand types **I** and **II** has been published.[22] A dinitrite adduct and several mononitrite adducts (with occupation of the sixth coordination site by other ligands) of "picket-fence" porphyrins have been prepared and several attempts have been made to describe the iron–nitrite bond.[32a–32d] All of these compounds are low-spin iron(III) complexes.

The reaction of our macrocyclic iron(II) complexes with nitrite under inert conditions yields the corresponding nitrosyliron complex as the main product, according to Equation (3), in all three cases. This was proved by ESR spectroscopy and by preparing **Fe1^{15}NO** using ^{15}N-labelled $NaNO_2$.

$$2\,\mathbf{Fe1} + 3\,NO_2^- + H_2O \rightarrow \mathbf{Fe1NO} + [\mathbf{Fe1(NO_2)_2}]^- + 2\,OH^- \quad (3)$$

The reaction of the iron(III) complexes with nitrite in organic solvents is even more complex. Although the spectrophotometric titration of [**Fe^{III}1a**]$^+$ clearly indicates the existence of a dinitrito and a mixed hydroxo-nitrito derivative in alkaline aqueous solution,[19b] all attempts to crystallise such derivatives of **Fe1** failed. Upon exclusion of air, the isolated reaction product of **Fe1Cl** or **Fe1I** in methanol is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the corresponding nitrosyl complex according to Equation (4). On the other hand, **Fe1NO** reacts in methanol or pyridine with air to give the nitrite adduct [Equation (5)]. The existence of a mono- and dinitrite adduct has been proved by UV/Vis spectroscopy.[22] Similar reactions have been found for ferric porphyrin complexes.[34]

$$\mathbf{Fe1}^{+} + 2\,NO_2^{-} \rightarrow \mathbf{Fe1NO} + NO_3^{-} \quad (4)$$

$$\mathbf{Fe1NO} + 1/2\,O_2 + D \rightarrow \mathbf{Fe1(NO_2)D};\ D = Py,\ MeOH \quad (5)$$

For **Fe2** it was possible, starting from the corresponding iodide or chloride complex, to isolate a nitrite diadduct and a few crystals of a mixed adduct with one nitrite ion and one water molecule as axial ligand *trans* to the nitrite ion. The molecule structures are given in Figure 9a, b. In both complexes the iron atom has a nearly octahedral coordination sphere and is located in the plane of the macrocycle. The Fe–N_{eq} and Fe–N_{NO_2} distances are similar to those of other diadducts. The oxygen atoms of the nitrite ligands point towards the six-membered chelate ring and, in the case of the diadduct, both nitrite groups are coplanar. The coordination of water in the case of the monoadduct is interesting. This has been postulated in many quantum-chemical investigations but has never been described in detail. The relatively large distance of 206 pm between the iron atom and the bound water molecule suggests a weak coordination.

While the nitrite diadduct is a pure low-spin complex over the whole temperature range, the nitrite monoadduct performs a spin transition between the S = 1/2 and S = 3/2 states. Such spin transition behaviour has already been reported for other six-coordinate iron(III) complexes[35a,35b] and is also typical of some nitrosyliron complexes of type **II**.[22,35c,35d] The effective moments plotted against temperature are given for both compounds in Figure 10.

Calculations based on the SCC-Xα method did confirm the S = 1/2 configuration as the ground state for both complexes. The energy difference to the S = 3/2 first excited state of **[Fe2(NO$_2$)OH$_2$]**(MeOH) is, at around 20 kJ mol^{-1}, small for this program. (The expected value at room temperature is significantly lower, but experience with the program used shows that the obtained values are within this region for this program.[40]) Therefore an admixture of this state and the ground state at room temperature is plausible. Another possibility is an interaction between both spin states that would explain the room-temperature effective moment of 2.82 μ_B, which is significantly lower than the expected spin-only value of 3.87 μ_B. Similar effects have been described in the literature for other iron(III) complexes.[36] Measurements of the effective magnetic moment at higher temperatures are not possible as the complex decomposes with loss of water. On the basis of these calculations it could be shown that the overlap population between Fe and O_{H_2O} decreases by 60% during the spin transition. The resulting pentacoordinate complex should be an intermediate-spin complex similar to the corresponding iron(III) halide complexes.

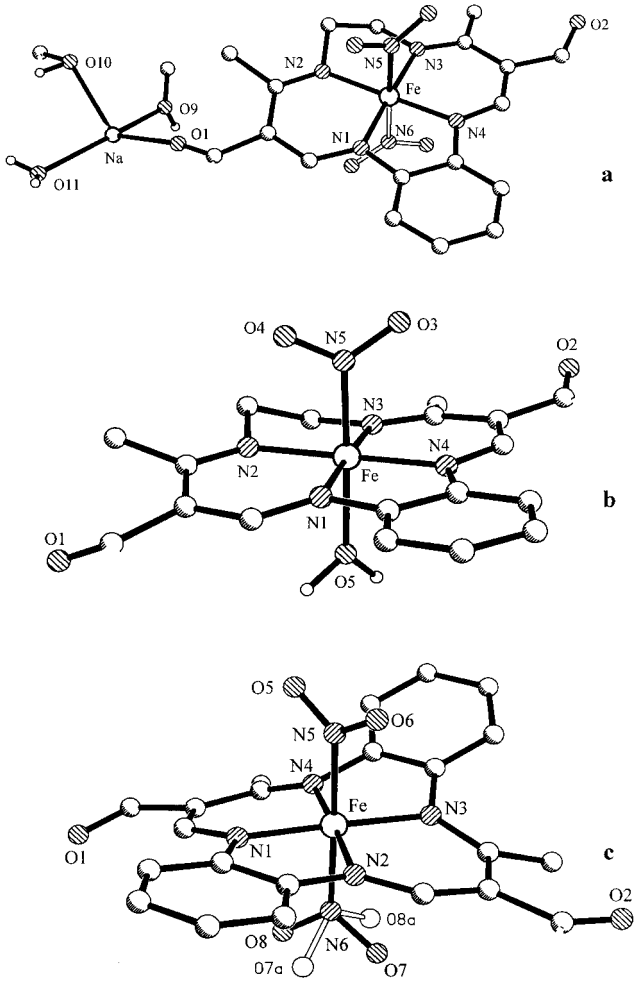


Figure 9. Molecule structures of (a) Na[**Fe^{III}2(NO$_2$)$_2$**](MeOH)$_2$(H$_2$O)$_{0.5}$, (b) [**Fe^{III}2(NO$_2$)OH$_2$**] and (c) [**Fe^{III}3(NO$_2$)NO$_x$**]$^-$. Ethoxy groups are omitted.

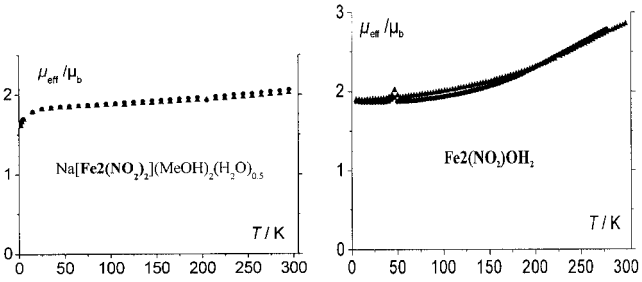

Figure 10. Temperature dependence of the effective magnetic moment of Na[**Fe^{III}2(NO$_2$)$_2$**](MeOH)$_2$(H$_2$O)$_{0.5}$ (left) and [**Fe^{III}2(NO$_2$)OH$_2$**] (right). The measurements were carried out at 0.2 and 0.5 T.

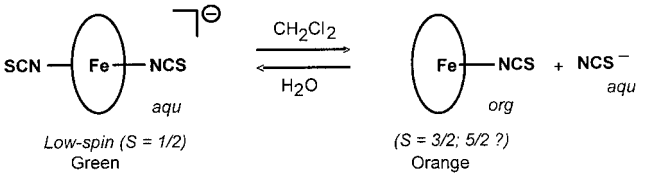
For **Fe3** − the complex most similar to (porphyrin)iron compounds − a derivative with the approximate composition (nBu$_4$N)$_2$[**Fe3(NO$_2$)NO$_x$**](NO$_2$)(H$_2$O), with one axial nitrite and one other axial NO_x ligand has been crystallised. Unfortunately, the latter is disordered in such a manner that it was impossible to decide between an NO_2 with two and an NO with four orientations. Additionally, the presence of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

potential cations and anions in the lattice makes it more difficult to clearly define the charge of the central unit. The diamagnetism of the crystals suggests a neutral complex [**Fe^{III}3(NO$_2$)NO**] with low-spin iron(III), antiferromagnetically coupled with the nitrosyl radical. This interpretation agrees with the distances and angles within the central unit. Mixed axial nitrite-nitrosyl coordination has also been found in iron(II)[32e] and iron(III)[32d] complexes with "picket-fence" porphyrins.

The thiocyanate anion is of interest not only because of its biological relevance but also because it is, along with azide, one of the pseudo-halides that give heterogeneous equilibria with [**Fe^{III}1a**]$^+$ [Equation (6)] between aqueous and lipophilic phases accompanied by a "structural mimicry":



(6)

While the green product, in agreement with its EPR spectrum, is doubtless an octahedral low-spin iron(III) complex, the orange one, which is stable only in lipophilic solvents such as dichloromethane, benzene or toluene, has not been unambiguously characterised to date. Unfortunately, all attempts to obtain pure crystals of this product also failed. Crystals suitable for X-ray structure determination were only obtained for the diadduct [BzEt$_3$N][**Fe^{III}1(NCS)$_2$**].

The only examples of thiocyanato adducts of (porphyrin)-iron compounds described in the literature are a pentacoordinate monoadduct of high-spin iron(III)[37] and a hexacoordinate low-spin complex with pyridine as second axial ligand.[38] Cationic macrocyclic iron(II/III) complexes with neutral equatorial ligands easily form thiocyanato diadducts.[39] Thus, the complex [BzEt$_3$N][**Fe1(NCS)$_2$**] is the first macrocyclic iron complex with an anionic [N$_4$] ligand and two axially bound thiocyanate ligands (Figure 11).

For a proper description, the adduct has to be referred to as a diisothiocyanato complex, which is also the case for the corresponding porphyrin monoadducts. The linear coordination of the thiocyanate ion is confirmed by the Fe–N$_{ax}$–C$_{ax}$ angles of 171° and 179°. The Fe–N distances are comparable with those in cationic complexes described previously. The only conspicuous feature of the complex is the arrangement of the free ester groups of the equatorial ligand, where both carbonyl oxygen atoms point to the unsubstituted site of the ligand. For all other complexes of this ligand type characterised by X-ray structure analysis, at least one, but mostly both, of the terminal carbonyl oxygen atoms are directed towards the methyl group. The low-spin state of the iron(III) atom was confirmed by ESR spectroscopy (*g* values: 1.973, 2.125, 2.162).[18]

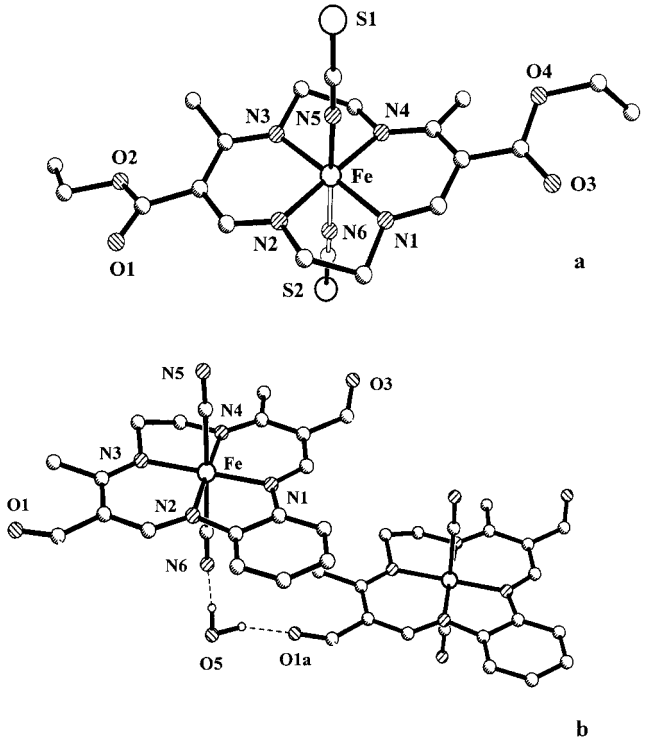


Figure 11. Molecule structures of (a) [**Fe^{III}1(NCS)$_2$**]$^-$ and (b) [**Fe^{III}2(CN)$_2$**]$^-$(H$_2$O)$_{0.5}$ (cations omitted for clarity).

An octahedral anionic complex with two cyanide ions as axial ligands, [Et$_4$N][**Fe^{III}2(CN)$_2$**] could be crystallised with the unsymmmetrically bridged macrocycle.

Dicyanide complexes are well documented and characterised in the literature.[41,42] The question as to whether the cyanide ion is bound to the iron atom through the carbon or the nitrogen atom was decided in favour of the carbon atom (the difference of the *R*1 values, the resulting C–N bond length and the remaining electron density were considered). This result fits with results in the literature. The distances between the iron atom and the equatorial nitrogen atoms are, with an average of 192 pm, slightly longer than those of other octahedral iron(III) complexes and are more comparable with those found for iron(II) complexes. Compared with the isothiocyanate diadduct, the axial bond lengths are also long and more similar to pyridine adducts. These differences in the bond lengths lead to the conclusion that in the case of cyanide as axial ligand, additional negative charge is localised at the iron atom (and therefore delocalised over the macrocyclic ligand), resulting in a lengthening of the bonds. In the case of the larger thiocyanate ion, the negative charge is localised on the easily polarizable sulfur rather than the iron atom, resulting in shorter bond. The low-spin state of the iron(III) atom was confirmed by ESR spectroscopy. In contrast to neutral octahedral complexes the ground-state electron configuration of the cyanide diadduct is $(d_{xz},d_{yz})^4(d_{xy})^1$. The same results can be found for comparable cyanide diadducts in the literature.[41,42]

Conclusions

The results described above confirm the close relation of our macrocycles with porphyrins, but they also indicate some special features. In general, the anions $\mathbf{L^{2-}}$ (**L** = **1**, **2**, **3**) seem to be stronger ligands for iron than most porphyrinato systems. The reasons for this could be: (i) the stronger basicity and σ-donor ability of the four nitrogen donor atoms, especially in the case of **L** = **1**; (ii) the presence of the electron-withdrawing carbonyl groups in conjugation with the π-system of the six-membered chelate rings, which promote potential π-backbonding and increase the effective charge of the central atom, especially when **L** = **2** and **3**, where the π-system is extended over one phenylene ring (the second phenylene in **3** is hardly included in the conjugation); (iii) the smaller hollow within the cavity of the 14-membered macrocycle, which is better suited for the radii of iron(II/III) in lower spin states.

The pronounced tendency to stabilize the intermediate-spin ground state in iron(II/III) complexes with coordination numbers below six, even when similar compounds are in a high-spin state [e.g. **Fe^{III}(Me$_4$TAA)Cl** or the halides of (porphyrin)iron compounds], is a typical feature of the ligands $\mathbf{L^{2-}}$. Intermediate spin (S = 1) was found in the iron(II) complexes **Fe2** (CN = 4, planar), **Fe1** (CN = 4+1 by weak intermolecular coordination of the ester carbonyl group), **Fe1MeOH** and the bridged complexes **(FeL)$_2$dabco** (**L** = **1**, **2**, **3**; all CN = 5, square-pyramidal). The preference to bind axial O-ligands − MeOH or even such a weak O-donor as COOEt − indicates that the iron atom in **Fe1** is the "hardest" central atom in the series **FeL**. The magnetic behaviour of the iron(II) complexes at lower temperature is often determined by intermolecular interactions in the lattice: **Fe2**, with the shortest Fe–Fe distance of 335 pm, shows a sigmoid decrease of the magnetic moment, whereas **(Fe3)$_2$dabco**, where the *inter*molecular Fe–Fe distance (421 pm) is much shorter than the *intra*molecular distance (727 pm), shows a steep decrease of the moment starting already at around 150 K. The complexes **FeLCl** (**L** = **1**, **2**, **3**) and the iodide **Fe1I** represent the iron(III) case of intermediate-spin (S = 3/2) behaviour. The intermediate-spin state could be confirmed by Mössbauer spectrometry for **Fe1**, by ESR and NMR spectroscopy for **Fe1Cl**, and by DFT-MO calculations for **Fe1MeOH**, **Fe1Cl** and, previously, for **Fe1I** (see refs.[22b,22c] for more calculations).

The pair **Fe^{II}3(Py)$_2$**/[**Fe^{III}3(Py)$_2$**]PF_6 was characterised as a third example of potential "voltage-dependent molecular switches" based on octahedral low-spin iron(II/III) complexes with N-heterocycles as axial ligands. Comparison with the pairs **Fe^{II}1(HIm)$_2$**/[**Fe^{III}1(HIm)$_2$**]PF_6 and **Fe^{II}2(Py)$_2$**/[**Fe^{III}2(Py$_2$)**]ClO_4 resulted in the conclusions that: (i) the charge-dependent change of the orientation of the axial planes is not necessarily accompanied by reorganisation of intermolecular hydrogen bonds, and (ii) the "saddle-shaped" distortion of the ligand **3** allows only orientation of the axial planes perpendicular to each other; no charge-dependent twist of these planes is possible. Other new octahedral low-spin complexes with axial N-heterocycles are [**Fe^{III}1(Py)$_2$**]PF_6 and [**Fe^{III}1(N-MeIm)$_2$**]ClO_4, but unfortunately their iron(II) counterparts could not be obtained as suitable crystals.

Octahedral low-spin derivatives of the macrocyclic iron complexes **FeL** with biologically relevant anions as axial ligands have been crystallised for the first time, although their existence in solution was proved many years ago. Reactions with nitrite resulted in the anionic diadduct [**Fe^{III}2(NO$_2$)$_2$**]$^-$ with pentacoordinate sodium as counterion, and, more interestingly, in the neutral mixed-ligand complex [**Fe^{III}2(NO$_2$)OH$_2$**]. The presence of water as a relatively weak axial ligand results in a temperature-dependent admixing of low-spin (favoured at low temperature) and, possibly, intermediate-spin species. DFT-MO calculations agree with this interpretation. With cyanide and thiocyanate ions the octahedral low-spin diadducts [Et_4N][**Fe2(CN)$_2$**] and [$BzEt_3N$][**Fe1(NCS)$_2$**] could be crystallised. Unfortunately, it was not possible to obtain pure crystals of the pentacoordinate neutral counterpart of the latter, **Fe^{III}1(NCS)**, which exists together with the anionic diadduct in an equilibrium of distribution between a lipophilic and an aqueous phase.

With regard to the existence of high-spin iron(II/III) complexes and to the processes of spin conversion, some of the iron complexes of type **II** are more closely related to (porphyrin)iron compounds than the macrocycles **I**. This will be the subject of a following paper.

Experimental Section

General Procedures and Instrumentation: If not stated differently, all syntheses were carried out under argon using Schlenk tube techniques. All solvents were purified as described in the literature[43] and distilled under argon. Magnetic measurements of pulverized samples were performed with a Quantum Design MPMSR-5s SQUID magnetometer in a temperature range from 1.7 to 400 K, with the exception of **Fe2Cl** and **Fe3Cl**. All measurements were carried out at two field strengths (0.2 and 0.5 T). Diamagnetic corrections were made using values calculated with tabulated Pascal constants (as a rule, suitable values can be estimated as $\chi_{dia} \approx 0.6 \times 10^{-6} M_{complex}$). The measurements of the highly air-sensitive iron(II) compounds were repeated several times under strongly inert conditions to ensure that the samples remain in the iron(II) state during preparation. For comparison, an additional sample was measured after exposure to air. ESR investigations were carried out with an ESP 300E (Bruker) instrument at liquid-nitrogen temperature with the solid or in solution (methanol, toluene) or equipped with an N_2/He-flow cryostat from 4.2 K up to room temperature. Molecular orbital calculations were carried out in a local density approximation (LDA) by the spin-polarized self-consistent-charge (SCC-)Xα method.[44,45]

Syntheses: The syntheses of the free ligands are summarised in Scheme 2 for **H$_2$1** and **H$_2$2** and in Scheme 3 for **H$_2$3**. All steps of the ligand syntheses were carried out in air. From a thermodynamic point of view, the driving force of the complex formation starting from the free ligand, as well as of the reverse protolysis of the complex, depends on the competition between two protons and the divalent metal ion to bind the anion of the deprotonated ligand:

$$M^{2+} + 2HL \rightleftharpoons ML + 2H^+ \quad (7)$$

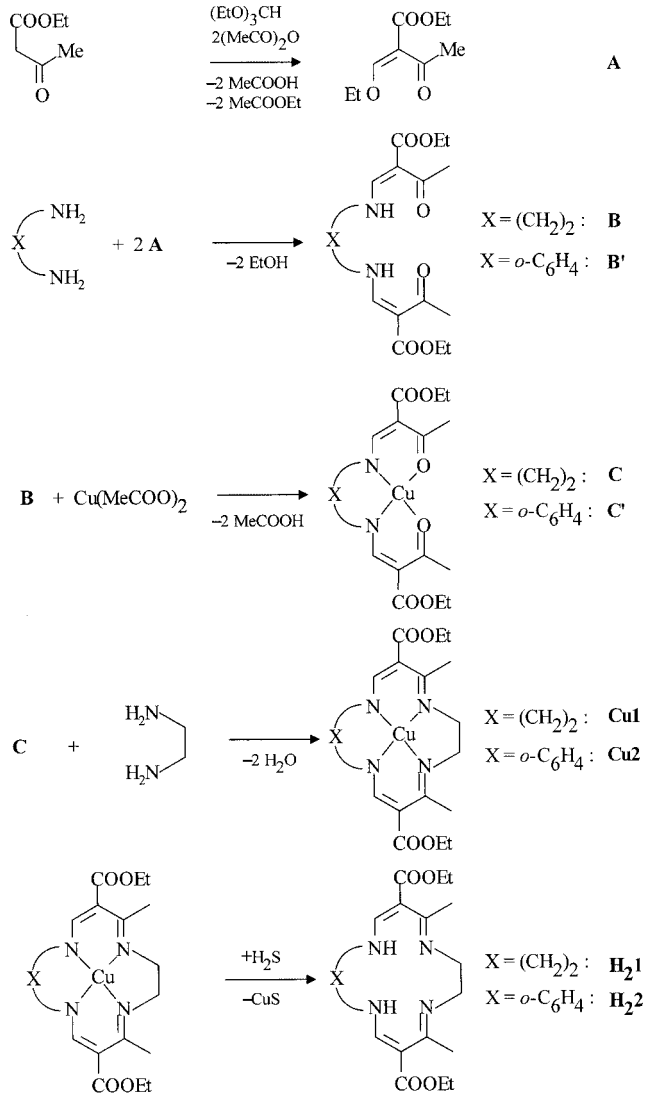
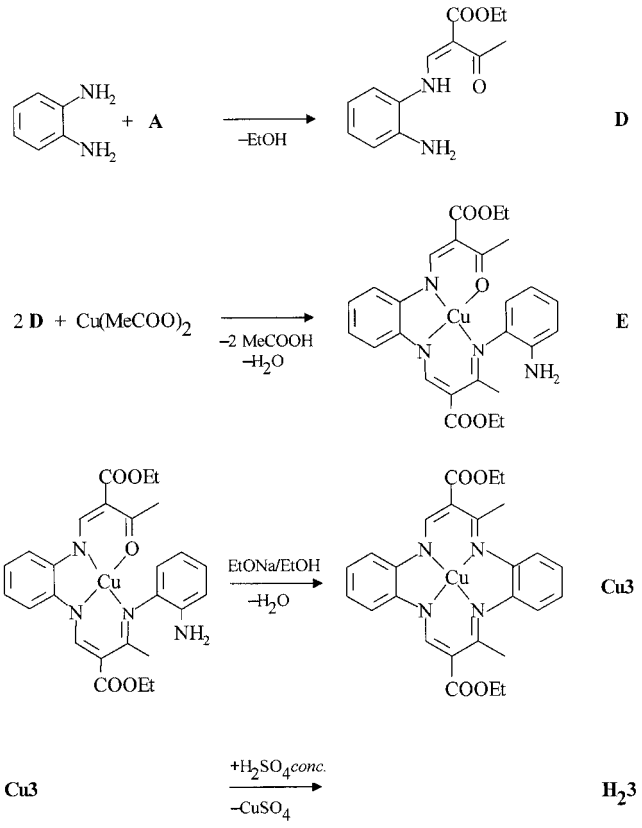


Scheme 2. Syntheses of the free macrocyclic ligands H_2**1** and H_2**2**.



Scheme 3. Synthesis of the free macrocyclic ligand H_2**3**. The Cu-driven condensation of two molecules **D** is expected to give the *anti* isomer of the copper complex **E** with respect to the methyl groups. The X-ray analysis of **E** confirms, however, the depicted *syn* structure.[14b]

The key step of the syntheses of the free ligands is a template reaction using the copper(II) ion as template, followed by the demetallation of the macrocyclic copper complex. The different conditions of the demetallation reflect the different properties of the ligands: the release of the protonated macrocycle H_2**3** from **Cu3** is possible by dissolving it in sulfuric acid without any auxiliary reagent. This is obviously due to the relatively low stability of the copper complex **Cu3**, where the copper(II) ion is too large for the small hollow of the rigid anion $\mathbf{3}^{2-}$. To obtain the ligands H_2**1** and H_2**2**, addition of the auxiliary reagent hydrogen sulfide is necessary to remove the copper ion. Different reaction conditions are also typical for the formation of iron complexes. As in the case of porphyrins, iron(II) is easier to incorporate into the macrocycles than iron(III). The complex **Fe1** was formed nearly quantitatively in a fast reaction using a 1:1 ratio of ligand and iron(II) acetate, even under moderate basic conditions. For the complexes **Fe2** and **Fe3** an excess of the iron(II) salt is necessary to prevent contamination by the free ligand. Additionally, the complex formation requires an increase of the reaction time from a few minutes (**Fe1**) to 2–3 h (**Fe2**) or 10–11 h (**Fe3**). This increase reflects the kinetic effect of the increasing rigidity of the ligand structures.

Syntheses of the Macrocyclic Ligands

6,13-Bis(ethoxycarbonyl)-7,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraene ($H_2$1):[17b,46b] The preparation of this ligand by a template synthesis of the copper complex **Cu1**, followed by demetallation with hydrogen sulfide in dilute sulfuric acid and precipitation with sodium hydroxide, gave the free ligand in nearly quantitative yield. However, to prevent the use of gaseous hydrogen sulfide, the latter can be replaced by precipitation from homogeneous solution by in situ hydrolysis with thioacetamide. In this case the yield of the last step drops to about 45%.

Compound A:[47] Ethyl acetoacetate (130 g, 1 mol), acetic anhydride (204 g, 2 mol) and triethyl orthoformate (148 g, 1 mol) were refluxed together for 40 min. The low-boiling side-products were distilled off at normal pressure until foggy clouds appeared in the reaction vessel. The main product was then obtained by fractionatal vacuum distillation (b.p. 145–150 °C at 2 kPa). The purity of the oily, colourless to bright greenish-yellow product was determined by GC analysis. Yield: 140.1 g (75%).

Compound B:[33] Compound **A** (140.1 g, 0.75 mol) was dissolved in methanol (130 mL) and freshly distilled ethylenediamine (22.8 g, 0.379 mol), dissolved in methanol (130 mL), was then slowly added to the solution. The reaction mixture was stirred vigorously and the ligand precipitated immediately. The colourless product was filtered off and recrystallised from ethanol or dioxane. Yield: 94 g (77%).

Compound C:[33] Compound **B** (10 g, 0.029 mol) and copper acetate monohydrate (5.9 g, 0.035 mol, finely pulverized) were mixed and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

heated in DMF or ethanol (500 mL) to reflux for 30 min. After cooling, violet crystals precipitated that were filtered off, washed with methanol and dried. Yield: 10.1 g (85%).

Cu1:[46a] Compound **C** (50 g, 0.12 mol) was dissolved in ethylenediamine (100 mL, dried and freshly distilled from solid potassium hydroxide) and heated to reflux until the colour had changed from deep blue to brownish-violet (15–30 min). After cooling, the product was filtered off and washed with water. Yield: 38.5 g (72%).

$H_2$1:[17b,46b] **Cu1** (2.0 g, 0.0047 mol) was suspended in methanol (10 mL) and stirred for 15 min. Ice-cold (0 °C) dilute sulfuric acid (ca. 2 M, 40 mL) was then added to the suspension. After 1 min, thioacetamide (4.2 g, 0.056 mol) was added to the suspension and the reaction mixture was stirred for a further 3 min. The suspension was filtered through a fluted filter paper into a calculated volume of ice-cold sodium hydroxide solution (ca. 4 M) such that the mixture became neutral or weakly basic after addition of all of the acidic filtrate. The free ligand was filtered off and washed with water until a nearly neutral pH was obtained. The crude material was recrystallised from methanol as fine colourless needles. Yield: 0.8–1 g (47–58%).

6,13-Bis(ethoxycarbonyl)-7,12-dimethylbenzo[*b*]-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraene ($H_2$2): Cu2 was synthesised in analogy to **Cu1** using 1,2-phenylenediamine instead of ethylenediamine in step **B**.[10d,33]

$H_2$2:[10d] **Cu2** (2.0 g, 0.0042 mol) was suspended in methanol (10 mL) and stirred for 15 min. Ice-cold (0 °C) sulfuric acid (5 M, 40 mL) was then added to the suspension. After 1 min, thioacetamide (4.2 g, 0.056 mol) was added to the suspension and the reaction mixture was stirred for a further 3 min. The suspension was then filtered into ice-cold sodium hydroxide (4 M, 100 mL) taking care to ensure that the solution did not warm up. The free ligand was filtered off and washed with water until a nearly neutral pH was obtained. The crude material was dissolved in a little dioxane and reprecipitated with distilled water to obtain yellow crystals. Yield: 0.8–1 g (45–60%).

6,13-Bis(ethoxycarbonyl)-7,12-dimethyldibenzo[*b*,*i*]-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraene ($H_2$3):[23a] In earlier reports, the complexes **M3** (M = Cu, Co)[23c] and the intermediates **E**[23b] were postulated as isomeric structures with an *anti* configuration of the methyl groups attached to the six-membered chelate rings. However, the X-ray structural analysis of the free ligand **$H_2$3** and the nitrosylcobalt complex **Co3NO** proved the *syn* structure.[14b]

Compound D:[23b] A suspension of *o*-phenylenediamine (12 g, 0.11 mol) in ethanol (100 mL) was heated to reflux. Compound **A** (18.6 g, 0.1 mol) was slowly added to the solution and the mixture was refluxed for 20 min. After cooling, compound **D** precipitated as yellow needles that were collected and recrystallised twice from methanol or ethanol. Yield: 13.14 g (53%). M.p. 84 °C.

Compound E:[23b] Compound **D** (24.8 g, 0.1 mol) was heated to reflux in methanol (200 mL) and a suspension of finely ground copper acetate monohydrate (9.98 g, 0.05 mol) in methanol (150 mL) was slowly added to the solution. The suspension was refluxed for approximately 6 h. After cooling, the product was filtered off immediately, washed with methanol and dried. Yield: 23.56 g (87%).

Cu3:[23c] Compound **E** (6.68 g, 0.012 mol) was heated to reflux in dry ethanol (150 mL). Metallic sodium (0.31 g, 0.013 mol), dissolved in dry ethanol (50 mL), was slowly added to the suspension and the mixture refluxed for 6 h. After cooling, the product was filtered off immediately, washed with cold methanol and dried. Yield: 5.99 g (96%).

$H_2$3:[23a] **Cu3** (2 g, 0.0038 mol) was suspended in cooled concentrated H_2SO_4 (50 mL) where it underwent a colour change from brown to yellow. The suspension was added dropwise to a water/ice mixture, taking care to ensure the solution did not warm up. The free ligand precipitated as yellow needles that were collected on a paper filter, washed with water until a neutral pH was obtained, and dried at room temperature. The crude material was dissolved in a little dioxane and reprecipitated with distilled water to obtain yellow crystals. Yield: 1.2–1.4 g (70–80%).

Syntheses of the Iron(II) Complexes

[6,13-Bis(ethoxycarbonyl)-7,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraenato(2–)]iron(II) (Fe1):[17b] Iron(II) acetate (2.08 g, 11.9 mmol) and **$H_2$1** (4.30 g, 11.8 mmol) were dissolved in methanol (60 mL) and refluxed for 1 h. After standing overnight, the red precipitate was collected and dried in vacuo. Yield: 2.27 g (46%). $C_{18}H_{26}FeN_4O_4$ (418.27): calcd. C 51.68, H 6.27, N 13.40; found C 48.34, H 6.09, N 12.22; the discrepancy between the calcd. and found values is due to the high air sensitivity of the complex. IR (Nujol): $\nu_{C=O}$ = 1671 cm^{-1}. MS (DEI): *m*/*z* (%) = 418 (100) [M^+], 373 (15) [$M^+ - OC_2H_5$], 344 (5) [M^+ – COOEt].

[6,13-Bis(ethoxycarbonyl)-7,12-dimethylbenzo[*b*]-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraenato(2–)]iron(II) (Fe2):[10d] Iron(II) acetate (0.76 g, 4.4 mmol) and **$H_2$2** (1.27 g, 3.1 mmol) were suspended in methanol (20 mL) and refluxed for 6 h. The black product was collected, washed with a small volume of methanol and dried in vacuo. Yield: 1.14 g (77%). $C_{22}H_{26}FeN_4O_4$ (466.31): calcd. C 56.66, H 5.62, Fe 11.98, N 12.02; found C 55.23, H 5.52, Fe 12.1, N 12.24; the discrepancy between the calcd. and found values is due to the high air sensitivity of the complex. IR (Nujol): $\nu_{C=O}$ = 1676 cm^{-1}. MS (DEI): *m*/*z* (%) = 43 (100), 466 (50) [M^+].

[6,13-Bis(ethoxycarbonyl)-7,12-dimethyldibenzo[*b*,*i*]-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraenato(2–)]iron(II) (Fe3):[23a] Iron(II) acetate (1.33 g, 7.7 mmol) and **$H_2$3** (2.29 g, 5.0 mmol) were suspended in methanol (20 mL) and refluxed for 12 h. The black product was collected, washed with a small volume of methanol and dried in vacuo. Yield: 2.24 g (88%). $C_{26}H_{26}FeN_4O_4$ (514.35): calcd. C 60.71, H 5.09, N 10.89; found C 59.95, H 5.09, N 11.01. IR (Nujol): $\nu_{C=O}$ = 1686 cm^{-1}. MS (DEI): *m*/*z* (%) = 514 (100) [M^+], 486 (20) [$M^+ - C_2H_4$], 468 (15) [$M^+ - OC_2H_5$].

Dinuclear Adducts with Bridging 1,4-Diazabicyclo[2.2.2]octane (dabco)

(Fe1)$_2$dabco: Iron(II) acetate (0.31 g, 1.8 mmol) and 0.65 g of **$H_2$1** were dissolved in 20 mL of methanol and refluxed for 20 min. After cooling, a solution of dabco (0.2 g, 1.8 mmol) in 5 mL of methanol was slowly added to the solution. Slow crystallisation overnight yielded red needles suitable for X-ray structure analysis. The product was collected, washed with a little ice-cold methanol and dried in vacuo. Yield: 0.33 g (39%). $C_{36}H_{52}Fe_2N_8O_8 \cdot C_6H_{12}N_2$ (948.73): calcd. C 53.71, H 6.80, N 14.77; found C 52.48, H 6.59, N 14.78. IR (Nujol): $\nu_{C=O}$ = 1673, 1652 cm^{-1}. MS (DEI): *m*/*z* (%) = 112 (100) [M^+(dabco)], 418 (90) [M^+(**Fe1**)]. DTG: Up to 250 °C loss of 11.3% (calcd. for 1 dabco: 11.8%); decomposition at 300 °C.

(Fe2)$_2$dabco: Fe2 (0.5 g, 1.1 mmol) was suspended in 20 mL of methanol. Then, 1.3 mL of a 1 M solution of dabco in methanol was added to the suspension and left standing for slow crystallisation. After 2 d, red-black needles were obtained. The product was collected, washed with a little methanol and dried in vacuo. Yield: 0.3 g (55%). $C_{44}H_{52}Fe_2N_8O_8 \cdot C_6H_{12}N_2$ (1044.8): calcd. C 57.48, H 6.18, N 13.42; found C 56.60, H 6.12, N 13.41. IR (Nujol): $\nu_{C=O}$ = 1674 cm^{-1}. MS (DEI): *m*/*z* (%) = 112 (100) [M^+(dabco)], 466 (10) [M^+(**Fe2**)]. DTG: Up to 100 °C loss of 11.3% (solvent in the crys-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tal), up to 300 °C loss of 12.4% (calcd. for 1 dabco: 10.7%); decomposition at 350 °C.

$(Fe3)_2$dabco: Fe3 (0.65 g, 1.3 mmol) was suspended in 40 mL of methanol. Then, 1.8 mL of a 1 M solution of dabco in methanol was added to the suspension and left standing for slow crystallisation. After 2 d, black needles were obtained. The product was collected, washed with a little methanol and dried in vacuo. Yield: 0.45 g (61%). $C_{52}H_{52}Fe_2N_8O_8{\cdot}C_6H_{12}N_2$ (1140.9): calcd. C 61.06, H 5.65, N 12.28; found C 58.96, H 5.90, N 12.03. IR (Nujol): $\nu_{C=O}$ = 1686 cm^{-1}. MS (DEI): *m*/*z* (%) = 42 [fragment], 112 (90) [M^+(dabco)], 514 (10) [M^+(**Fe3**)]. DTG: Up to 250 °C loss of 9.7% (calcd. for 1 dabco: 9.8%); at 350 °C decomposition.

Syntheses of the Iron(III) Complexes: The syntheses of the iron(III) iodide complexes **Fe1I**[19c,21] and **Fe2I**[10d] have been described previously.

[6,13-Bis(ethoxycarbonyl)-7,12-dimethyl-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraenato(2–)]iron(III) Chloride (Fe1Cl): Fe1 (1.36 g, 3.3 mmol) was suspended in tetrachloromethane (20 mL) for 2 d. The CCl_4 was then removed by cold vacuum distillation and the obtained solid was recrystallised from methanol. The precipitate was filtered off and dried in vacuo. The mother solution was allowed to stand overnight to produce single crystals of **Fe1Cl** suitable for X-ray crystallography. Yield: 1.04 g (69%). $C_{18}H_{26}ClFeN_4O_4$ (453.72): calcd. C 47.65, H 5.78, N 12.35; found C 44.81, H 5.37, N 11.50. IR (Nujol): $\nu_{C=O}$ = 1680 cm^{-1}. MS (DEI): *m*/*z* (%) = 28 (100), 453 (10) [M^+], 418 (30) [M^+ – Cl]. DTG: Decomposition at 170 °C.

[6,13-Bis(ethoxycarbonyl)-7,12-dimethylbenzo[*b*]-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraenato(2–)]iron(III) Chloride (Fe2Cl): Fe2 (0.67 g, 1.4 mmol) was suspended in tetrachloromethane (20 mL) for 2 d. The CCl_4 was then removed by cold vacuum distillation and the solid product was recrystallised from methanol. The precipitate was filtered off and dried in vacuo. Yield: 0.59 g (84%). $C_{22}H_{26}ClFeN_4O_4$ (501.764): calcd. C 52.66, H 5.22, N 11.17; found C 52.52, H 4.89, N 11.45. IR (Nujol): $\nu_{C=O}$ = 1685 cm^{-1}. MS (DEI): *m*/*z* (%) = 36 (100), 501 (50) [M^+], 466 (20) [M^+ – Cl].

[6,13-Bis(ethoxycarbonyl)-7,12-dimethyldibenzo[*b*,*i*]-1,4,8,11-tetraazacyclotetradeca-5,7,12,14-tetraenato(2–)]iron(III) Chloride (Fe3Cl): Fe3 (0.96 g, 1.9 mmol) was suspended in tetrachloromethane (30 mL) for 2 d. The CCl_4 was then removed by cold vacuum distillation and the solid was recrystallised from methanol. The precipitate was filtered off and dried in vacuo. Yield: 0.87 g (83%). $C_{26}H_{26}ClFeN_4O_4$ (549.80): calcd. C 56.79, H 4.77, N 10.19; found C 55.60, H 4.61, N 10.48. IR (Nujol): $\nu_{C=O}$ = 1697 cm^{-1}. MS (DEI): *m*/*z* (%) = 31 (100), 549 (90) [M^+], 514 (15) [M^+ – Cl].

Synthesis of Diadducts of Iron(II/III) Complexes

$Fe3(Py)_2$: Fe3 (40 mg) was dissolved in pyridine (7 mL) and a layer of heptane (10 mL) was added over the pyridine solution. After a few days, a fine black-red crystalline precipitate was obtained. $C_{26}H_{26}FeN_4O_4{\cdot}2C_5H_5N$ (672.55): calcd. C 64.3, H 5.4, N 12.5; found C 64.4, H 5.2, N 12.4.

$[Fe3(Py)_2]PF_6$: Fe3I (30 mg) was dissolved in pyridine (15 mL) and then a solution of NH_4PF_6 in methanol (2 M) was added dropwise until a precipitate was obtained. $C_{26}H_{26}FeN_4O_4{\cdot}2C_5H_5N{\cdot}PF_6$ (817.52): calcd. C 52.9, H 4.4, N 10.3; found C 52.8, H 4.6, N 10.1. MS (DEI): *m*/*z* (%) = 79 (100) [pyridine], 514 (<1) [M^+(**Fe3**)].

$[Fe1(Py)_2]PF_6$: Fe1I (30 mg) was dissolved in a solution of pyridine in benzene (1 M, 15 mL) and then a solution of NH_4PF_6 in methanol (2 M) was added dropwise to the solution until a precipitate was obtained. $C_{18}H_{26}FeN_4O_4{\cdot}2C_5H_5N{\cdot}PF_6$ (721.44): calcd. C 46.6, H 5.0, N 11.7; found C 46.6, H 4.9, N 11.5. MS (DEI): *m*/*z* (%) = 79 (100) [pyridine], 418 (19) [M^+(**Fe1**)].

$[Fe1(N\text{-}MeIm)_2]ClO_4(H_2O)$: Fe1I (30 mg) was dissolved in a solution of *N*-methylimidazole in methanol (1.4 M, 15 mL). A solution of $NaClO_4$ in water was added dropwise to the solution until a precipitate was obtained. $C_{18}H_{26}FeN_4O_4{\cdot}2C_4H_6N_2{\cdot}ClO_4{\cdot}H_2O$ (693.90): calcd. C 44.6, H 5.7, N 16.0; found C 61.4, H 5.9, N 13.5. MS (DEI): *m*/*z* (%) = 82 (100) [*N*-methylimidazole], 418 (25) [M^+(**Fe1**)].

$Na[Fe2(NO_2)_2](MeOH)_2(H_2O)_{0.5}$: Fe2Cl (0.032 g, 0.05 mmol) was suspended in methanol (5 mL). A solution of sodium nitrite in methanol/water (1 M, 5 mL) was then added. After a few days, black crystals were obtained. The product was collected, washed with a little methanol and dried in vacuo. Yield: 0.01 g (40%). IR (Nujol): $\nu_{C=O}$ = 1665 cm^{-1}. MS (ESI neg.): *m*/*z* (%) = 512 (100) [M^-(**$Fe2(NO_2)$**)], 558.1 (50) [M^-{**$Fe2(NO_2)_2$**}].

The following procedures were carried out only with the aim of obtaining crystals suitable for X-ray investigations. No yield is given and the main product in the solution may have another identity. Crystal growth was accomplished by using a temperature gradient or different solubility in different solvents. The choice of the counterion may be crucial for crystallisation of the compound. Dropwise addition of nonpolar solvents (*n*-heptane and *n*-hexane are not suitable) can also be used for crystallisation. The addition of water may be used as a last alternative in the case of water-miscible solvents.

$(BzEt_3N)[Fe1(SCN)_2]$: Fe1I (30 mg) was dissolved in 15 mL of a saturated solution of $(BzEt_3N)SCN$ in water/methanol (1:1).

$Et_4N[Fe2(CN)_2](H_2O)_{0.5}$: Fe2I (30 mg) was dissolved in a saturated solution of Et_4NCN in water (15 mL). The mixture was heated and filtered while still hot.

$[Fe2(NO_2)OH_2](MeOH)$: Fe2I (30 mg) was dissolved in methanol (15 mL). The solution was added dropwise to a heated saturated solution of nBu_4NNO_2 in water/methanol (4:1).

$(nBu_4N)_2[Fe3(NO_2)NO_x](NO_2)(H_2O)$: Fe3I (40 mg) was dissolved in dichloromethane (30 mL) and 5 mL of this solution was added to a saturated solution of nBu_4NNO_2 in methanol.

Crystal Structure Determination: The intensity data for the compounds were collected with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarisation effects, but not for absorption.[48a,48b] The structures were solved by direct methods (SHELXS[49]) and refined by full-matrix least-squares techniques against F_o^2 (SHELXL-97[50]). The hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[50] Na[**$Fe2(NO_2)_2$**]$(MeOH)_2(H_2O)_{0.5}$ shows a disordered methanol and water molecule with the same oxygen position. This disorder could be solved. The data for compound **Fe1Cl** are not of adequate quality, although the esd's are good enough to be discussed in this paper. For **Fe2**, $[Fe3(Py)_2]PF_6$ and $(nBu_4N)_2$[**$Fe3(NO_2)NO_x$**]$(NO_2)(H_2O)$ we are only publishing the conformation of the central complex unit and the crystallographic data; we will not deposit the data with the Cambridge Crystallographic Data Centre. XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

Crystal Data for Fe1:[51] $C_{18}H_{26}FeN_4O_4$, M_r = 418.28 g mol^{-1}, brown prism, size 0.32×0.20×0.12 mm, monoclinic, space group $P2_1/c$, a = 12.5031(4), b = 11.0732(4), c = 27.4969(6) Å, β = 92.798(2)°, V = 3802.4(2) $Å^3$, T = –90 °C, Z = 8, $\rho_{calcd.}$ =

1.461 g cm^{-3}, μ(Mo-K_α) = 8.25 cm^{-1}, F(000) = 1760, 11872 reflections in h(–16/16), k(–14/13), l(–34/33), measured in the range 1.63° $\leq \theta \leq$ 27.47°, completeness for θ_{max} 90.8%, 7906 independent reflections, R_{int} = 0.028, 5880 reflections with $F_o > 4\sigma(F_o)$, 508 parameters, 0 restraints, $R1_{obs}$ = 0.050, wR^2_{obs} = 0.127, $R1_{all}$ = 0.075, wR^2_{all} = 0.142, GOOF = 0.988, largest difference peak/hole: 0.446/–0.409 e Å^{-3}.

Crystal Data for Fe1MeOH:[51] $C_{19}H_{30}FeN_4O_5$, M_r = 450.32 g mol^{-1}, brown prism, size 0.10 × 0.09 × 0.08 mm, monoclinic, space group $P2_1/n$, a = 7.3249(2), b = 29.5441(9), c = 9.7511(3) Å, β = 94.912(2)°, V = 2102.46(11) Å^3, T = –90 °C, Z = 4, $\rho_{calcd.}$ = 1.423 g cm^{-3}, μ(Mo-K_α) = 7.55 cm^{-1}, F(000) = 952, 8074 reflections in h(–9/9), k(–38/38), l(–12/12), measured in the range 2.76° $\leq \theta \leq$ 27.49°, completeness for θ_{max} 97.2%, 4694 independent reflections, R_{int} = 0.033, 3559 reflections with $F_o > 4\sigma(F_o)$, 271 parameters, 0 restraints, $R1_{obs}$ = 0.038, wR^2_{obs} = 0.093, $R1_{all}$ = 0.060, wR^2_{all} = 0.105, GOOF = 0.838, largest difference peak/hole: 0.349/–0.283 e Å^{-3}.

Crystal Data for Fe2: $C_{22}H_{26}FeN_4O_4$, triclinic, space group $P\bar{1}$, a = 13.019(3), b = 13.753(3), c = 13.757(3) Å, α = 103.28(3), β = 117.00(3), γ = 97.04(3)°, V = 2061.7(8) Å^3, T = –90 °C, Z = 4, F(000) = 976, 5550 measured reflections, 5192 independent reflections, R_{int} = 0.045, 3598 reflections with $I > 2\sigma(I)$, 535 parameters, 0 restraints, $R1$ = 0.162, wR^2 = 0.338, GOOF = 1.052, largest residual electron density: 1.129 e Å^{-3}. Due to technical problems, the measurement stopped too early and reflections at high θ angles are missing. Therefore, the anisotropy refinement and hydrogen atoms were set aside resulting in a dissatisfactory $R1$ value and a high remaining maximum electron density.

Crystal Data for Fe1Cl:[51] $C_{18}H_{26}ClFeN_4O_4$, M_r = 453.73 g mol^{-1}, brown prism, size 0.20 × 0.18 × 0.12 mm^3, monoclinic, space group $P2_1/n$, a = 13.5466(6), b = 7.8215(4), c = 18.5515(9) Å, β = 96.539(3)°, V = 1952.83(16) Å^3, T = –90 °C, Z = 4, $\rho_{calcd.}$ = 1.543 g cm^{-3}, μ(Mo-K_α) = 9.42 cm^{-1}, F(000) = 948, 7129 reflections in h(–17/15), k(–10/9), l(–23/24), measured in the range 3.42° $\leq \theta \leq$ 27.52°, completeness for θ_{max} 96.2%, 4320 independent reflections, R_{int} = 0.065, 3701 reflections with $F_o > 4\sigma(F_o)$, 257 parameters, 0 restraints, $R1_{obs}$ = 0.130, wR^2_{obs} = 0.207, $R1_{all}$ = 0.156, wR^2_{all} = 0.216, GOOF = 1.248, largest difference peak and hole: 1.009/–1.123 e Å^{-3}.

Crystal Data for Fe3(Py)$_2$:[51] $C_{36}H_{36}FeN_6O_4$, triclinic, space group $P\bar{1}$, a = 10.6327(3), b = 12.0421(4), c = 14.7871(5) Å, α = 66.015(2), β = 71.582(2), γ = 66.368(2)°, V = 1558.09(9) Å^3, T = –90 °C, Z = 2, F(000) = 704, 12217 measured reflections, 7108 independent reflections, R_{int} = 0.028, 6385 reflections with $I > 2\sigma(I)$, 424 parameters, 0 restraints, $R1$ = 0.044, wR^2 = 0.103, GOOF = 1.016, largest residual electron density: 0.421 e Å^{-3}.

Crystal Data for [Fe3(Py)$_2$]PF$_6$: $C_{36}H_{36}F_6FeN_6O_4P$, orthorhombic, space group $Pbca$, a = 16.840(3), b = 20.335(4), c = 20.857(4) Å, V = 7142(3) Å^3, T = –90 °C, Z = 8, μ(Mo-K_α) = 5.65 cm^{-1}, F(000) = 3368. The data are not of the best quality and so we are publishing only the conformation of the molecule, although the distances and angles are of plausible size.

Crystal Data for [Fe1(Py)$_2$]PF$_6$:[51] $C_{28}H_{36}F_6FeN_6O_4P$, monoclinic, space group $P2_1/n$, a = 9.211(2), b = 14.861(3), c = 24.180(5) Å, β = 100.51(3)°, V = 3254.2(11) Å^3, T = 20 °C, Z = 4, F(000) = 1492, 8631 measured reflections, 4697 independent reflections, R_{int} = 0.028, 3596 reflections with $I > 2\sigma(I)$, 442 parameters, 0 restraints, $R1$ = 0.052, wR^2 = 0.138, GOOF = 1.067, largest residual electron density: 0.436 e Å^{-3}.

Crystal Data for [Fe1(N-MeIm)$_2$]ClO$_4$(H$_2$O):[51] $C_{26}H_{40}ClFeN_8O_9$, monoclinic, space group $P2_1/n$, a = 14.897(1), b = 13.613(1), c = 16.096(1) Å, β = 95.950(7)°, V = 3246.6(4) Å^3, T = –90 °C, Z = 4, F(000) = 1468, 12274 measured reflections, 7233 independent reflections, R_{int} = 0.082, 4759 reflections with $I > 2\sigma(I)$, 425 parameters, 0 restraints, $R1$ = 0.131, wR^2 = 0.238, GOOF = 1.140, largest residual electron density: 0.552 e Å^{-3}.

Crystal Data for (BzEt$_3$N)[Fe1(NCS)$_2$]:[51] $C_{33}H_{48}FeN_7O_4S_2$, monoclinic, space group $P2_1/n$, a = 11.7266(2), b = 24.7177(6), c = 12.7940(2) Å, β = 96.551(1)°, V = 3684.19(12) Å^3, T = –90 °C, Z = 4, F(000) = 1540, 7450 measured reflections, 7450 independent reflections, 5659 reflections with $I > 2\sigma(I)$, 487 parameters, 0 restraints, $R1$ = 0.056, wR^2 = 0.118, GOOF = 1.055, largest residual electron density: 0.415 e Å^{-3}.

Crystal Data for Et$_4$N[Fe2(CN)$_2$](H$_2$O):[51] $C_{32}H_{48}FeN_7O_5$, monoclinic, space group $P2_1/n$, a = 11.1860(2), b = 11.8490(4), c = 25.0733(9) Å, β = 92.355(2)°, V = 3320.5(5) Å^3, T = –90 °C, Z = 4, F(000) = 1420, 13220 measured reflections, 7482 independent reflections, R_{int} = 0.062, 4899 reflections with $I > 2\sigma(I)$, 446 parameters, 0 restraints, $R1$ = 0.063, wR^2 = 0.119, GOOF = 1.010, largest residual electron density: 0.436 e Å^{-3}.

Crystal Data for [Fe2(NO$_2$)OH$_2$](MeOH):[51] $C_{23}H_{29}FeN_6O_{10}$, orthorhombic, space group $Pna2_1$, a = 16.273(1), b = 11.6454(7), c = 13.8026(7) Å, V = 2615.7(3) Å^3, T = –90 °C, Z = 4, F(000) = 1180, 5725 measured reflections, 5725 independent reflections, 4004 reflections with $I > 2\sigma(I)$, 344 parameters, 1 restraint (origin of the unit cell), $R1$ = 0.077, wR^2 = 0.138, GOOF = 1.031, largest residual electron density: 0.507 e Å^{-3}.

Crystal Data for Na[Fe2(NO$_2$)$_2$](MeOH)$_2$(H$_2$O)$_{0.5}$:[51] $C_{46.4}H_{67.2}Fe_2N_{12}Na_2O_{22}(CH_4O)_2$, M_r = 1366.89 g mol^{-1}, red-brown prism, size 0.12 × 0.10 × 0.09 mm, monoclinic, space group $P2_1/n$, a = 11.3381(3), b = 13.3795(6), c = 21.1046(8) Å, β = 102.522(2)°, V = 3125.4(2) Å^3, T = –90 °C, Z = 2, $\rho_{calcd.}$ = 1.452 g cm^{-3}, μ(Mo-K_α) = 5.65 cm^{-1}, F(000) = 1431, 11116 reflections in h(–14/14), k(–14/17), l(–27/27), measured in the range 1.89° $\leq \theta \leq$ 27.48°, completeness for θ_{max} 98.8%, 7082 independent reflections, R_{int} = 0.033, 5071 reflections with $F_o > 4\sigma(F_o)$, 419 parameters, 0 restraints, $R1_{obs}$ = 0.0546, wR^2_{obs} = 0.1280, $R1_{all}$ = 0.0886, wR^2_{all} = 0.146, GOOF = 0.962, largest difference peak/hole: 0.845/–0.619 e Å^{-3}.

Solvent-Mediated Redox Transformations of Ytterbium Bis(indenyl)-diazabutadiene Complexes

Alexander A. Trifonov,*[a] Elena A. Fedorova,[a] Vladimir N. Ikorskii,[b] Sebastian Dechert,[c][‡] Herbert Schumann,[c] and Mikhail N. Bochkarev[a]

Keywords: Diazadiene ligands / N ligands / Radical ions / Ytterbium

The reactions of diamagnetic $[(C_9H_7)_2Yb(THF)_2]$ (**2**) and [*rac*-$(CH_2\text{-}1\text{-}C_9H_6)_2Yb(THF)_2$] (**3**) with *t*BuN=CH–CH=N*t*Bu (DAD) in toluene result in the formation of the paramagnetic complexes $[(C_9H_7)_2Yb(DAD)]$ (**4**) and [*rac*-$(CH_2\text{-}1\text{-}C_9H_6)_2Yb$(DAD)] (**5**), respectively. The IR, UV/Vis, and ^{1}H NMR spectroscopic data, the magnetic properties, and the single-crystal X-ray diffraction studies of **4** and **5** indicate that in the solid state and in noncoordinating media both complexes are ytterbium(III) derivatives containing the DAD radical-anion, whereas the ^{1}H NMR and UV/Vis spectra of solutions of **4** and **5** in the coordinating solvent THF give evidence for divalent ytterbium. Recrystallization of **4** and **5** from THF/hexane results in the recovery of the starting ytterbium complexes **2** and **3** due to an unusual redox substitution of the radical anion of diazabutadiene by THF in the coordination sphere of ytterbium.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

During the past two decades, 1,4-disubstituted diazadienes have attracted considerable attention as useful ligands in transition metal chemistry due to their redox and coordination properties. The lone electron pair at both nitrogen atoms and the π-electrons of the C=N bonds allow theese molecules to act both as an n- and a π-electron donor. They can also coordinate metal atoms both as a neutral ligand[1] and, based on their quite pronounced electron affinity,[2] as a radical anion[3] or dianion[4] by accepting one or two electrons from the metal. Especially the ligand substituted at the nitrogen atoms with the bulky *tert*-butyl group (DAD) has been widely employed for the synthesis of stable complexes of electropositive lanthanides.[5] Considering the reduction state and the coordination mode of the DAD ligand, these compounds can be divided into two main groups. The first group contains homo- and hetero-ligated compounds containing the DAD radical anion coordinated to the lanthanide atom through two nitrogen atoms,[5] while in the second group the doubly reduced enediamido fragment is 2σ:π-bonded to the central metal atom.[6] Due to the low energy of the π*-orbital of diazadiene ligands,[2c] their complexes with ytterbium, a metal which has two stable oxidation states with a low Yb^{II}/Yb^{III} transformation potential,[7] are of particular interest with respect to intramolecular metal–ligand electron transfers. In our previous studies we have synthesized and structurally characterized the homoleptic ytterbium(III) complex $[(DAD)_3Yb]$ (**1**).[5c] In order to explain the results obtained for **1** from variable temperature magnetic measurements, a temperature-induced valence tautomerism has been suggested. Thus, complex **1** is assumed to exist as the divalent ytterbium derivative $[Yb^{II}(DAD^{-\cdot})_2(DAD^0)]$ at temperatures of 5 to 15 K, while in the temperature range 80 to 300 K the complex is transformed into the trivalent ytterbium compound $[Yb^{III}(DAD^{-\cdot})_3]$. Continuing our studies on intramolecular redox processes in DAD ytterbium complexes, we report here on unusual solvent-mediated redox transformations of the bis(indenyl)diazabutadieneytterbium complexes $[(Ind)_2Yb(DAD)]$.

Results and Discussion

The addition of *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene (DAD) in THF to THF solutions of $[(\eta^5\text{-Ind})_2Yb(THF)_2]$ [Ind = C_9H_7 (**2**), *rac*-$(CH_2\text{-}1\text{-}C_9H_6)$ (**3**)][8] does not cause any change in the color of the reaction mixtures and the ^{1}H NMR spectra of these mixtures show superposition of the spectra of the Yb^{II} complexes and of free DAD. Evapora-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200401014

tion of the solvent in vacuo leaves a deep-red solid which, on addition of toluene, dissolves with formation of a brown (for **2**) or greenish-black solution (for **3**). The ^{1}H NMR spectra of these solutions show a set of broadened signals indicative of the presence of paramagnetic Yb^{III} species and radical anionic [DAD]$^{-\cdot}$ (Scheme 1).

2, 4 X = no bridge; two seperated C_9H_7 ligands
3, 5 X = CH_2-CH_2

Scheme 1.

Cooling of the concentrated toluene solutions causes precipitation of the complexes [(η^5-Ind)$_2$Yb^{III}(DAD$^{-\cdot}$)] [Ind = C_9H_7 (**4**), *rac*-(CH_2-1-C_9H_6) (**5**)], which were isolated as dark-brown (**4**) and greenish-black (**5**) crystalline solids in yields of 74 and 81%, respectively. Both complexes are highly air- and moisture-sensitive, moderately soluble in toluene, and less soluble in hexane.

Crystals suitable for single-crystal X-ray diffraction studies were obtained by slow cooling of toluene solutions of **4** and **5** to –20 °C. Complex **5** crystallizes as a toluene solvate [*rac*-(CH_2-1-C_9H_6)$_2$Yb(DAD)](C_7H_8)$_{0.5}$. The molecular structures of **4** and **5** are depicted in Figures 1 and 2, respectively; crystal and structural refinement data are listed in Table 1.

In both compounds, the ytterbium atom is η^5-coordinated by the two cyclopentadienyl units of the indenyl ligands and the two nitrogen atoms of the radical anionic DAD ligand and adopts the geometry of a distorted tetrahedron. Complex **5** exists in the crystalline state only in the racemic form. The Yb–Cp$_{Centr.}$ distances in **4** [2.376(3) and 2.383(3) Å] as well as in **5** [2.371(2) and 2.383(2) Å] are shorter than those in the starting Yb^{II} complexes **2** [2.457(1) Å][9a,9b] and **3** [2.43(3)–2.45(3) Å][8b] and are close to the values reported for the indenylytterbium(III) derivatives [(1-C_4H_7-4,7-$Me_2C_9H_4$)$_2$Yb(μ-Cl)$_2$Li(THF)$_2$] [2.333(3) and 2.336(4) Å][10a] and [*meso*-(CH_2-1-C_9H_6)$_2$YbN($SiMe_3$)$_2$] [2.328(3) and 2.332(3) Å].[10b] The shortening of the Yb–Cp$_{Centr.}$ distances in **4** and **5** compared to those in **2** and **3** indicates the oxidation of the ytterbium atom from Yb^{II} to Yb^{III}.[11] However, in both cases the magnitude of the shortening is considerably less than would be expected on the basis of the difference in the ionic radii of Yb^{II} and Yb^{III} (0.155 Å). Further, it should be noted that the values of the Yb–Cp$_{Centr.}$ bond lengths in **4** and **5** lie between the corresponding values of [Cp$_2$Yb(DAD)] [2.324(7) and 2.334(4) Å][5g] and [Cp*$_2$Yb(DAD)] [2.401(2) and 2.414(2) Å][5h] and reflect the comparable steric demand of the cyclopentadienyl, pentamethylcyclopentadienyl, and indenyl ligands. Whereas the two Yb–N bond lengths in **4** [2.318(5) and 2.335(5) Å] as well as in **5** [2.321(4) and 2.343(5) Å] differ significantly between each other, the values still lie between the corresponding, almost equal values of [Cp$_2$Yb(DAD)] [2.309(9) and 2.306(9) Å][5g] and [Cp*$_2$Yb(DAD)] [2.385(4) and 2.394(3) Å].[5h] The Yb–N bond lengths in **4** and **5** are comparable to the lengths of the Yb^{III}–N coordination bonds in the compounds [Cp*$_2$Yb(bipy)] (2.32 Å),[12d] [{Cp*$_2$Yb(bipy)}$^+$-{Cp*$_2$YbCl$_2$}$^-$] (2.37 Å),[12d] [{Cp*$_2$Yb(phen)}$^+$(I)$^-$-(CH_2Cl_2)] (2.36 Å),[12d] and [Cp$_2$Yb($PzMe_2$)-($HpzMe_2$)] [2.360(6), 2.414(6) Å],[12e] but are much longer than the covalent Yb^{III}–N bonds in [(η^5-C_9H_7)$_2$YbN-($SiMe_3$)$_2$] [2.160(5), 2.163(5) Å],[12a] [(η^5-MeC_5H_4)$_2$Yb-(NPh_2)] [2.216(5) Å],[12b] [(η^5-MeC_5H_4)$_2$Yb(NPh_2)(THF)] [2.287(6) Å],[12b] and [{Li(THF)$_4$}{Yb(NPh_2)$_4$}] [2.188(9)–2.2401(9) Å].[12c] The bond lengths within the DAD ligand of **4** and **5** should indicate its radical-anionic character since an electron transfer to the LUMO of the ligand is expected to cause delocalization of the charge over the whole conjugated NCCN fragment, which involves changes in the bond lengths. Compared to the N=C [1.267(2) Å][13] and C–C bond lengths [1.467(2) Å][13] in the free DAD molecule, the N=C bonds in the DAD ligands of **4** [1.323(8) and 1.309(8) Å] and **5** [1.324(7) and 1.331(6) Å] are substantially elongated, while the C–C bonds [**4**: 1.412(9), **5**: 1.429(7) Å] are shortened and close to the values of aromatic carbon–carbon bonds.[14] This bonding situation is similar to that described for [Cp*$_2$Sm(DAD)],[5d] [Cp$_2$Yb(DAD)],[5g] and [Cp*$_2$Yb(DAD)],[5h] and proves the radical-anionic character of the DAD ligand in **4** and **5**. In summary, the struc-

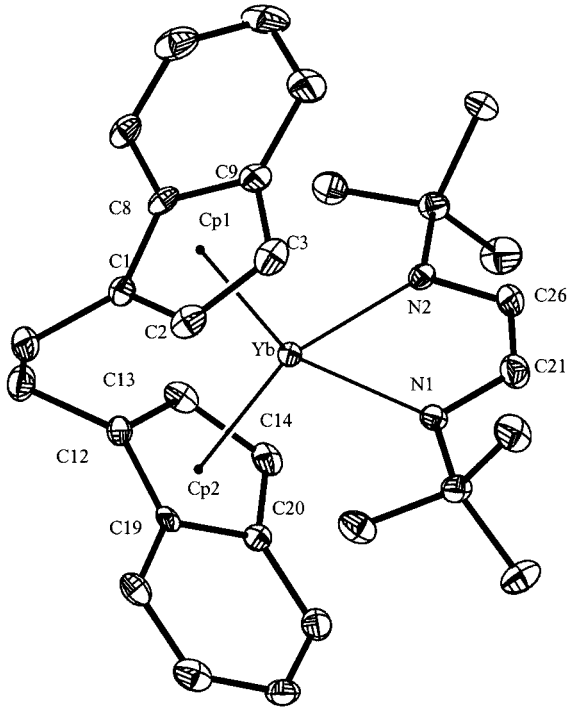

Figure 2. ORTEP diagram (30% probability thermal ellipsoids) of [*rac*-(CH_2-1-C_9H_6)$_2$Yb(DAD)] (**5**) showing the non-hydrogen-atom numbering scheme. Hydrogen atoms have been omitted for clarity. Relevant bond lengths [Å] and angles [°]: Yb–$Cp1_{Cent.}$ 2.371(2), Yb–$Cp2_{Cent.}$ 2.383(2), Yb–C1 2.646(5), Yb–C2 2.605(5), Yb–C3 2.623(5), Yb–C8 2.704(5), Yb–C9 2.719(5), Yb–C12 2.652(5), Yb–C13 2.590(5), Yb–C14 2.632(5), Yb–C19 2.750(5), Yb–C20 2.730(5), Yb–N1 2.321(4), Yb–N2 2.343(5), N1–C21 1.324(7), N2–C26 1.331(6), C21–C26 1.420(7); $Cp1_{Cent.}$–Yb–$Cp2_{Cent}$ 120.05(8), N1–Yb–N2 75.33(15).

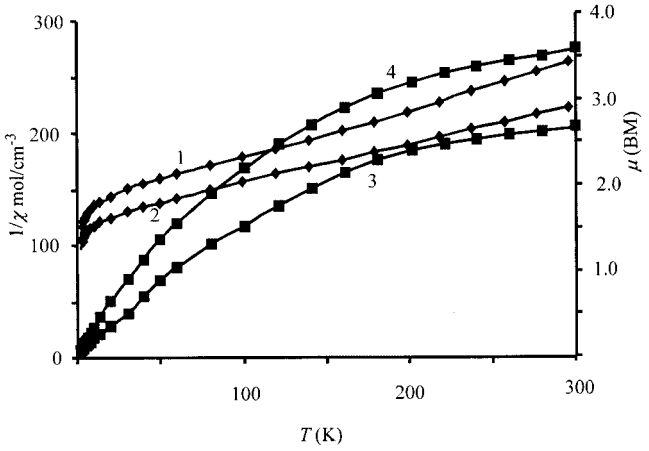

Figure 3. Thermal dependence of $1/\chi$ vs. T [K] and μ vs. T [K] for [(C_9H_7)Yb(DAD)] (**4**; curve 1: μ vs. T; curve 3: $1/\chi$ vs. T) and [*rac*-(CH_2-1-C_9H_6)$_2$Yb(DAD)] (**5**; curve 2: μ vs. T; curve 4: $1/\chi$ vs. T) at 5 kOe.

tural parameters of **4** and **5** are in agreement with the trivalent oxidation state of the ytterbium atom and the radical-anionic character of the DAD ligand. Unexpectedly, **4** and **5** are ESR silent in the temperature range 173 to 300 K in the solid state as well as in toluene solution. This fact is attributable either to a substantial broadening of the signal of the DAD radical anion in the field of the paramagnetic Yb^{III} ion or to antiferromagnetic coupling of the spin carriers.

Magnetic measurements of crystalline samples of **4** and **5** were carried out at 5 kOe in the temperature range 2 to 300 K. Plots of $1/\chi$ vs. T and μ vs. T are shown in Figure 3.

For **4** as well as for **5**, the measurements show a nonlinear dependence of the reciprocal value of the magnetic susceptibility χ as a function of temperature. The effective magnetic moments of the complexes increase from 1.6 μ_B (**4**) and 1.5 μ_B (**5**) at 2 K to 3.4 μ_B (**4**) and 3.0 μ_B (**5**) at 300 K. The values of the effective magnetic moments of **4** and **5** in benzene solution at 300 K, estimated according to the published procedure,[15] are in agreement with the data obtained for the crystalline samples by the SQUID method. The Yb^{III} ion has the electronic configuration $4f^{13}$ and is paramagnetic. The expected magnetic moment of Yb^{III} complexes is 3.8 μ_B at 5–30 K and 4.5 μ_B at 90–300 K;[16] the experimental values range from 3.4 to 4.9 μ_B.[17] An Yb^{III} complex that also contains a radical anion, as is suggested for **4** and **5**, should show a magnetic moment of 4.8 μ_B at room temperature provided that the spins of the two unpaired electrons do not interact. However, the experimental values of the magnetic moments obtained for **4** and **5** are considerably lower than the predicted ones, which could be caused either by redox tautomerism between paramagnetic [$(Ind)_2Yb^{III}(DAD^{\cdot-})$] and diamagnetic [$(Ind)_2Yb^{II}(DAD^0)$] molecules or antiferromagnetic coupling of the two unpaired electrons in [$(Ind)_2Yb^{III}(DAD^{\cdot-})$]. Recently, Andersen and co-workers studied the Yb^{III} complexes [Cp^*_2Yb(bipy)], [{1,3-t-$Bu_2C_5H_3$}$_2$Yb(phen)], and [Cp^*_2Yb(phen)] which contain an organic radical anion similar to **4** and **5**. They found effective magnetic moments at 300 K of 2.4, 3.4, and 4.0 μ_B, respectively. In order to interpret the low magnetic moments of these compounds, antiferromagnetic coupling between the spin carriers was postulated.[12d] Antiferromagnetic coupling between trivalent rare-earth ions and paramagnetic semiquinone ligands has been found also to be dominating for the series of complexes [Ln(DTBSQ)($HBPz_3$)$_2$] [Ln = Er, Tb, Dy, Yb; DTBSQ = 3,5-di-*tert*-butylsemiquinone, $HBPz_3$ = hydrotris(pyrazolyl)borate].[18] Hatfield and co-workers have described a strong exchange coupling between the lanthanide ions and the phthalocyaninato radical in bis(phthalocyaninato)lanthanide sandwich compounds [(Pc^{-2})Ln^{III}(Pc^{-1})] (Ln = Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu). The value of the room-temperature magnetic moment for trivalent ytterbium antiferromagnetically coupled with an organic radical anion was calculated to be 3.46 μ_B.[19] Taking those results into account, the analysis of the $1/\chi$ vs. T and μ vs. T plots suggests that an antiferromagnetic spin interaction is a plausible reason for the low magnetic moments of **4** and **5**; however the available data do not allow us to exclude definitely the existence of redox tautomers.

The IR spectrum of neutral DAD shows two characteristic and strong absorption bands at 1620 and 1200 cm^{-1},

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which are assigned to the ν(C=N) and ν(C–N) vibrations, respectively. In the IR spectra of **4** and **5** the absorption at 1200 cm^{-1} is still very strong, but the band at about 1600 cm^{-1} is very weak, which identifies the DAD ligand as a radical anion. The infrared data of **4** and **5** are consistent with those of [Cp$_2$Yb(DAD)][5g] and [Cp*$_2$Yb(DAD)],[5h] complexes which also contain the radical-anionic DAD ligand.

The UV/Vis spectra of **4** and **5** in hexane show strong absorptions at 318 and 335 nm, respectively, which correspond well with the strong band of (DAD$^{-\cdot}$)Na$^+$ at 325 nm, but differ from that of neutral DAD at 285 nm, thus giving further proof of the radical-anionic character of the DAD ligand (Figure 4). In contrast, the spectra of **4** and **5** recorded in the coordinating solvent THF at room temperature show evidence for the formation of free DAD and the respective THF-coordinated indenylytterbium(II) complexes [(C$_9$H$_7$)$_2$Yb(THF)$_2$] and [*rac*-(CH$_2$-1-C$_9$H$_6$)$_2$Yb(THF)$_2$].

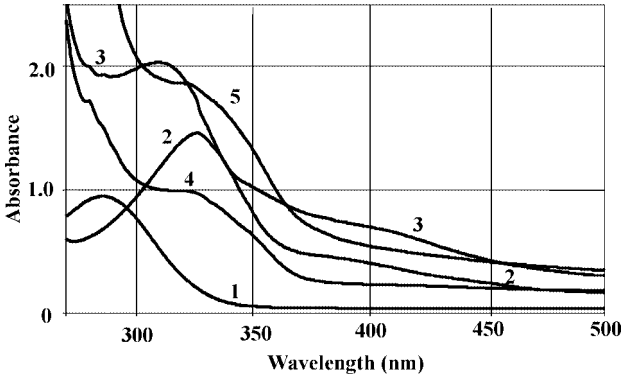

Figure 4. UV/Vis spectra. 1: DAD in hexane; 2: DAD$^{-\cdot}$Na$^+$ in THF; 3: [(C$_9$H$_7$)$_2$Yb(DAD)] (**4**) in hexane; 4: [(C$_9$H$_7$)$_2$Yb(DAD)] (**4**) in THF; 5: [(C$_9$H$_7$)$_2$Yb(THF)$_2$] (**2**) in THF.

According to the paramagnetism of **4** and **5**, their ^{1}H NMR spectra recorded in [D$_6$]benzene at 25 °C show a set of broadened signals that are substantially shifted with respect to those of comparable diamagnetic complexes (Figure 5 and Figure 6). The *tert*-butyl groups and the imino groups of the DAD ligand each gives rise to a singlet at δ = 27.90 (**4**) and 34.21 ppm (**5**) and a broad singlet at δ = –28.74 (**4**) and –18.53 ppm (**5**), respectively. The signals for the protons of the indenyl units appear at δ = 12.16, 10.41, –18.42, and –39.25 ppm in the intensity ratio of 2:2:2:1 for **4**, and at δ = 36.01, 32.74, 23.79, –0.85, –9.90, and –84.34 ppm with equal intensity for **5**. The proton signals of the ansa-ethylene group in **5** appear as two singlets at δ = –21.76 and –23.04 ppm. Variable temperature ^{1}H NMR measurements (–60 to 20 °C) of **4** in [D$_8$]toluene solution reveal a considerable temperature dependence of the chemical shift value of the imino protons (Figure 7), only a slight temperature dependence of the chemical shift value of the *tert*-butyl protons, and no temperature dependence of the chemical shift values of the indenyl protons.

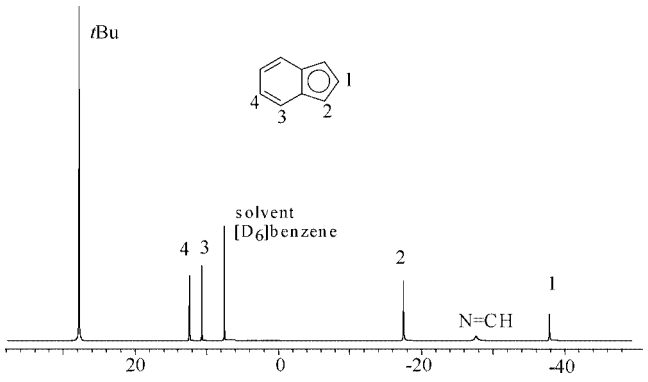

Figure 5. ^{1}H NMR spectrum of [(C$_9$H$_7$)$_2$Yb(DAD)] (**4**) in [D$_6$]benzene at 20 °C.

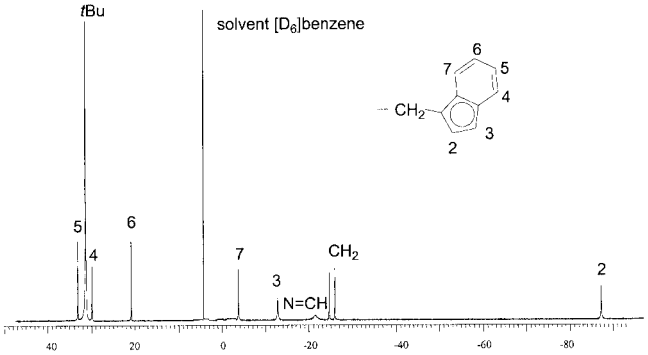

Figure 6. ^{1}H NMR spectrum of [*rac*-(CH$_2$-1-C$_9$H$_6$)$_2$Yb(DAD)] (**5**) in [D$_6$]benzene at 20 °C.

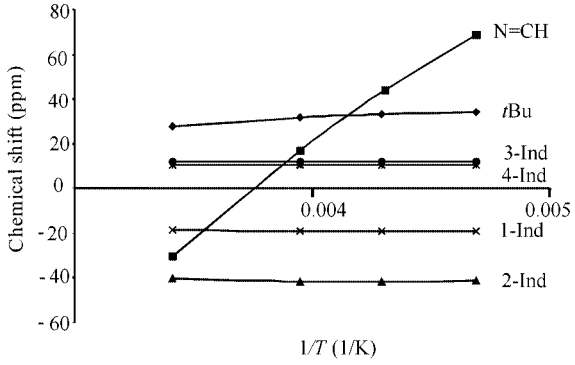

Figure 7. Variable temperature ^{1}H NMR spectroscopic data for [(C$_9$H$_7$)$_2$Yb(DAD)] (**4**) in [D$_8$]toluene: δ vs. 1/*T*.

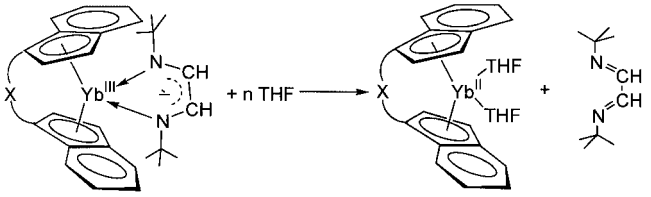
The nature of the solvent influences the ^{1}H NMR spectra of **4** and **5** dramatically. Thus, in contrast to the ^{1}H NMR spectra of solutions of **4** and **5** in aromatic hydrocarbons, the spectra of solutions in the coordinating solvent [D$_8$]-THF show the sharp signals of DAD^0 and diamagnetic [(C$_9$H$_7$)$_2$Yb^{II}(THF)$_2$] or [*rac*-(CH$_2$-1-C$_9$H$_6$)$_2$Yb^{II}(THF)$_2$], respectively. It is worth noting that in the ^{1}H NMR spectra of solutions of **4** and **5** in [D$_8$]THF at 25 °C, recorded just after the preparation of the samples, the signals assigned to the diamagnetic Yb^{II} metallocenes (δ = 0 to 9 ppm) are still broad; they change to sharp signals with resolved coupling patterns only after about 6 h. The spectra of **4** and **5** in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CD_2Cl_2 cannot be recorded since the complexes react with this solvent.

In order to isolate the indenylytterbium(II) species that is present in the THF solutions, we added hexane at 20 °C to concentrated THF solutions of **4** and **5** and isolated the starting ytterbium(II) metallocenes $[(C_9H_7)_2Yb^{II}(THF)_2]$ (**2**) and [*rac*-$(CH_2$-1-$C_9H_6)_2Yb^{II}(THF)_2$] (**3**) in high yields (82 and 73%, respectively). *N*,*N*′-Di-*tert*-butyl-1,4-diazabutadiene was identified and isolated from the mother liquor by chromatographic methods in almost quantitative yields (Scheme 2).



Scheme 2.

The above results allow the conclusion that complexes **4** and **5** exist as indenyl derivatives of trivalent ytterbium coordinated by the *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene radical anion $[(Ind)_2Yb^{III}(DAD^{-\cdot})]$ in the crystalline state as well as in noncoordinating solvents. Dissolution of **4** or **5** in coordinating solvents like THF causes displacement of the radical-anionic DAD ligand by THF molecules. This process implies an electron transfer from the diazadiene radical anion to the ytterbium(III) ion, resulting in the oxidation of the ligand to neutral DAD and reduction of Yb^{III} to Yb^{II}, followed by substitution of the neutral DAD ligand by two THF molecules. An analogous reductive substitution process has been established for the complex [Cp^*_2Yb-(DAD)], but not for [Cp_2Yb(DAD)] because of its shorter Yb–N distances.[5h] One can suppose that steric repulsion of the bulky indenyl and *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene ligands will be decisive for the examined reactions and the elongation and weakening of the Yb–N bonds in **4** and **5**. Hence, the energy of the Coulombic interaction between the $[(Ind)_2Yb^{III}]^+$ cationic species and the radical anion of diazadiene $DAD^{-\cdot}$ is comparable with that of the coordination bonds between Ind_2Yb^{II} and THF, and, as a result, the DAD ligand redox substitution becomes feasible. A similar behavior towards THF has been described by Evans and co-workers for decamethylsamarocene complexes with aromatic polycyclic ligands.[20] However, unlike the indenylytterbium complexes **4** and **5**, the samarium derivatives cannot be regenerated by removal of THF and addition of aromatic or aliphatic solvents.

Experimental Section

All experiments were performed in evacuated tubes, using standard Schlenk techniques, with rigorous exclusion of traces of moisture and air. THF, benzene, toluene, and hexane were purified by distillation from sodium/benzophenone ketyl and were condensed in vacuo prior to use. Indene (commercially available) was used after drying over molecular sieves. Commercially available 1,2-bis(indenyl)ethane was used as purchased (Dalchim). IR spectra were recorded as Nujol mulls on a Specord M80 spectrophotometer, and NMR spectra on a Bruker DPX200 spectrometer in [D_6]benzene, [D_8]THF, or [D_5]pyridine at 298 K. Chemical shifts for ^1H and ^{13}C NMR spectra were referenced internally using the residual solvent resonances and are reported relative to TMS. The UV/Vis spectra were recorded in evacuated quartz cuvettes on a Perkin–Elmer Lambda 25 spectrophotometer. The ESR spectra were measured on a Bruker ER 200D-1SRC instrument. GC analyses were performed with a Tzvet 530 gas chromatograph. Magnetic susceptibility measurements of solid samples were carried out on a SQUID magnetometer MPMS-5S from Quantum Design at 5 kOe. Magnetic measurements in benzene solution were performed according to the published procedure[15] on a Bruker DPX200 spectrometer. Lanthanide metal analyses were carried out by complexometric titration.

Synthesis of $[(C_9H_7)_2Yb(THF)_2]$ (2): A solution of indene (1.35 g, 11.68 mmol) in THF (10 mL) was added to a suspension of the naphthalene complex $[(C_{10}H_8)Yb(THF)_2]$ (2.60 g, 5.84 mmol) in THF (40 mL) and the reaction mixture was heated to 60 °C and stirred vigorously for 12 h. The resulting brown solution was filtered, THF was evaporated, and naphthalene was sublimed in vacuo at 60 °C. The solid residue was washed with hexane (2 × 20 mL) and recrystallized from THF/toluene (1:5 v/v). The precipitate was washed with cold toluene and dried in vacuo at room temperature to yield **2** as ruby-red crystals (2.36 g, 74%). $C_{26}H_{30}O_2Yb$ (547.5): calcd. C 57.03, H 5.52; found C 56.59, H 5.99. ^1H NMR (200 MHz, [D_5]pyridine): δ = 1.73 (m, 8 H, THF), 3.59 (m, 8 H, THF), 5.74 (d, $^3J_{H,H}$ = 3.2 Hz, 4 H, Ind), 6.2 (t, $^3J_{H,H}$ = 3.0 Hz, 2 H, Ind), 6.65 (m, 4 H, Ind), 7.31 (m, 4 H, Ind) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, [D_5]pyridine): δ = 25.8 (THF), 67.9 (THF), 95.7 (Ind), 117.7 (Ind), 117.9 (Ind), 121.4 (Ind), 127.5(Ind) ppm. IR (KBr, Nujol): $\tilde{\nu}$ = 3060 cm^{-1} (w), 1320 (s), 1040(s), 860 (s), 760(s), 720 (s).

Synthesis of $[(CH_2$-1-$C_9H_6)_2Yb(THF)_2]$ (3): A solution of 1,2-bis-(indenyl)ethane (1.03 g, 4.02 mmol) in THF (10 mL) was added to a suspension of the naphthalene complex $[(C_{10}H_8)Yb(THF)_2]$ (1.79 g, 4.02 mmol) in THF (30 mL) and the reaction mixture was heated to 60 °C and stirred vigorously for 16 h. The resulting brown solution was filtered, THF was evaporated, and naphthalene was sublimed in vacuo at 60 °C. The solid residue was washed with hexane (2 × 20 mL) and recrystallized from THF/toluene (1:5 v/v). The precipitate was washed with cold toluene and dried in vacuo at room temperature to yield **3** as ruby-red crystals (1.89 g, 82%). $C_{28}H_{32}O_2Yb$ (573.6): calcd. C 58.63, H 5.62; found C 58.97, H 5.31. ^1H NMR (200 MHz, [D_5]pyridine): δ = 1.74 (br. s, 8 H, THF), 2.97 (s, 2 H, CH_2), 3.33 (s, 2 H, CH_2), 3.56 (br. s, 8 H, THF), 5.61 (d, $^3J_{H,H}$ = 4.0 Hz, 1 H, Ind), 5.75 (d, $^3J_{H,H}$ = 4.0 Hz, 1 H, Ind), 6.31 (m, 2 H, Ind), 6.48–6.69 (m, 4 H, Ind), 7.12 (m, 2 H, Ind), 7.55 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, Ind), 7.66 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, Ind) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, [D_5]pyridine): δ = 25.8 (THF), 28.6 (CH_2), 28.7 (CH_2), 67.9 (THF), 94.5 (Ind), 94.8 (Ind), 112.4 (Ind), 115.1 (Ind), 117.1 (Ind), 117.3 (Ind), 119.1 (Ind), 119.8 (Ind), 121.0 (Ind), 121.2 (Ind), 123.9 (Ind), 125.3 (Ind), 125.6 (Ind), 127.2 (Ind), 127.8 (Ind) ppm. IR (KBr, Nujol): $\tilde{\nu}$ = 3060 cm^{-1} (w), 1320 (s), 1040(s), 860 (s), 760(s), 720 (s).

Synthesis of $[(C_9H_7)_2Yb(DAD)]$ (4): A solution of DAD (0.15 g, 0.89 mmol) in THF (2 mL) was added to a solution of **2** (0.49 g, 0.89 mmol) in THF (10 mL). The reaction mixture was stirred for

Synthesis of [*rac*-(CH$_2$-1-C$_9$H$_6$)$_2$Yb(DAD)](C$_6$H$_5$CH$_3$)$_{0.5}$ (5): Similar to the procedure described for **4**, compound **5** was obtained from DAD (0.25 g, 1.49 mmol) in THF (5 mL) and **3** (0.86 g, 1.49 mmol) in THF (10 mL). Recrystallization from toluene afforded **5** as greenish-black crystals (0.77 g, 81%). $C_{33.5}H_{40}N_2Yb$ (643.7): calcd. C 62.50, H 6.26, Yb 26.88; found C 62.88, H 6.62, Yb 26.34. ^{1}H NMR (200 MHz, [D$_6$]benzene, 20 °C): δ = 36.01 (s, 2 H, 5-Ind), 34.21 (s, 18 H, Me$_3$C), 32.79 (s, 2 H, 4-Ind), 23.79 (s, 2 H, 6-Ind), –0.86 (s, 2 H, 7-Ind), –9.90 (s, 2 H, 3-Ind), –18.53 (s, 2 H, N=CH), –21.76 (s, 2 H, CH$_2$), –23.04 (s, 2 H, CH$_2$), –84.34 (s, 2 H, 2-Ind) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 3050 cm^{-1} (w), 1585 (w), 1370 (s), 1255 (s), 1200 (s), 780 (s), 7450 (s).

X-ray Crystallographic Study: The crystal data and details of data collection are given in Table 1. X-ray data were collected at –100 °C on a Siemens SMART CCD diffractometer (graphite monochromated Mo-K_α radiation, λ = 0.71073 Å, ω-scan technique) fitted with an area-detector. The structures were solved by direct methods using SHELXS-97[21] and refined on F^2 using all reflections with SHELXL-97.[22] The toluene solvent molecule in **5** is disordered about a crystallographic center of inversion. The C–C distances between ring carbon atoms were restrained to be equal. The atoms of the disordered part in **5** were refined isotropically, all other non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned using an isotropic displacement parameter of 0.08 Å^2. SADABS[23] was used to perform area-detector scaling and absorption corrections. The geometrical aspects of the structure were analyzed using the PLATON program.[24]

CCDC-257892 (**4**) and -257893 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Anion Template Effect and the Polymerization Degree – Diversity through Flexibility

Kalle I. Nättinen,[a,b] Paulo E. N. de Bairos,[a,c] Petri J. Seppälä,[a] and Kari T. Rissanen*[a]

Keywords: Crystal engineering / N ligands / Zeolite analogues / Self-assembly / Transition metals

Two 2D (**M1** and **M2**) and one 1D (**M3**) metal-organic frameworks (MOFs) have been prepared from pyridine functionalized tetradentate ligand tetrakis(nicotinoxymethyl)methane **TNM** with silver tetrafluoroborate, nickel chloride, and copper hexafluorophosphate. **M1** manifests a previously unpresented mode of 4,4 threefold parallel interpenetration for 2D MOFs. Large channels (vdW diameter 9.4 Å) through eclipsed 2D layers of **M2** were observed. While the open space percentage in the noninterpenetrated **M2** was 38.0 %, the triple interpenetration of the sheets of **M1** reduced the void to 10.8 %. With the same ligand and a similar, weakly coordinating anion as that in **M1**, the structure **M3** was rendered one-dimensional. The result is explained partly by the flexibility of the **TNM** ligand and partly by the lack of a suitable bridging solvent.

Introduction

Since the beginning of crystal engineering,[1] there has been a search for reliable methods to predict and control the product of crystal syntheses. The study of the crystal structures has a dual focus: the analysis of the obtained structures and the prediction of yet to be formed crystals. Meticulous analysis of the crystal structures together with the growing understanding of weak intermolecular interactions such as the CH···O and π-interactions have made it possible to have some control over the outcome of the crystallizations. With yet another compound, some properties of the crystal – centrosymmetricity and porosity being good examples – can be dictated, although complete control still escapes the chemist in many cases. The efforts made to accumulate this knowledge have been documented to general crystal structure databases such as IUCR[2] for inorganic and CSD[3] for organic structures, as well as more specific databases including the metal-organic framework database of interpenetrated frameworks by S. R. Batten,[4] and the topological analysis of the CSD database of Proserpio et al.[5] etc. Our interests lie within the creation of noninterpenetrated metal-organic structures, MOFs,[6–8] their properties and the control of their dimensionality. The prevention of interpenetration can be achieved by using templates (e.g. solvents), bulky ligands, or as in our case, bulky, weakly coordinating anions such as PF_6^-, BF_4^-, or ClO_4^-.[9] The use of these anions indeed seems to block the formation of interpenetrated 3D frameworks,[10,11] but also often results in a network with lower dimensionality. The lowered dimensionality renders the results less useful for applications since the covalent bonding throughout the framework in 3D structures principally stands for higher thermal stability. In this work we examine the reasons behind the lowered dimensionality and the role of the bulky anions as templates for the frameworks.

Results and Discussion

The tetradentate ligand **TNM** is by nature more chelating than the **TINM** (tetrakis(isonicotinoxymethyl)methane): the pyridyl nitrogens are sterically more hindered, thereby rendering the formation of 3D MOFs more difficult (Scheme 1). We have previously shown the synthesis of 3D MOFs possible using the **TNM** ligand. However, this requires an additional bridging element, the methanol molecules, in order to create the 3D connectivity. The frameworks with lower dimensionality are predominantly achieved when using the **TNM** ligand and the bulky anions BF_4^- and PF_6^-, and also in structures with smaller coordinative anions.[12]

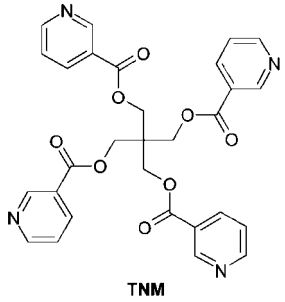
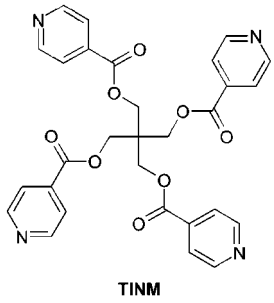


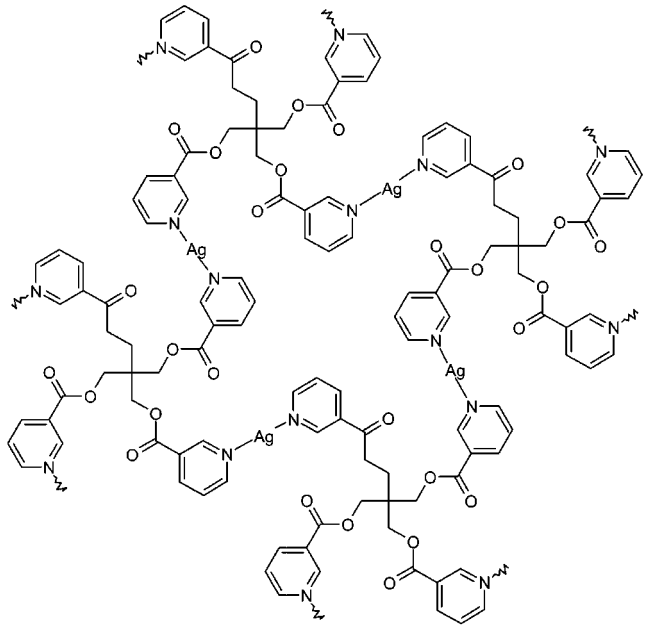


Scheme 1.

The flexibility of the **TNM** ligand allows the enveloping of the anions within the frameworks and the formation of MOFs with anions of different sizes. The result is a variety of topologies differing from those obtained by the small coordinative anions. The use of the Ag^{I} cation resulted in a 2D structure, which was also the case with the use of the Ni^{II} cation. The use of Cu^{I} without the presence of methanol prevented the formation of the Cu–MeOH–Cu bridged structure[12] – a 1D structure was formed instead.

The Threefold Interpenetrated 2D Layer Structure M1

The ligands are located in two sheets, forming the top and bottom of the polymeric layer (Scheme 2). The Ag^{I} cations, being located in the top, bottom, and middle of the layer, bridge the ligand sheets together, resulting in a 1.5 nm layer (Scheme 2 and Figure 1). There are two Ag^{I} cations with different coordination environments. The Ag1 cations bridging the **TNM** ligands in the top and bottom of the layers have a distorted square-planar coordination with the two pyridyl ligands [Ag–N distances of 2.167(1) and 2.174(2) Å] coordinated to opposite sides of the Ag^{I} and two BF_4^- anions [Ag–F distances 2.883(2) and 2.947(2) Å] on the sides of the axis formed by the py-Ag-py coordination. The distortion of the coordination sphere manifests itself by the fluorides of the BF_4^- being positioned above the plane of the Ag^{I} cation and the pyridyl nitrogens. This is explained by the steric repulsion of the layer of threefold interpenetrated frameworks which pushes the anions above the optimum arrangement. Interestingly, the pyridyl ligands are not eclipsed but arranged nearly perpendicularly. The square-planar coordination sphere of the Ag2 cations in the middle of the layer in **M1** is arranged in a similar way to the Ag1 in the top and bottom of the layer: two pyridyl nitrogens [Ag–N distances of 2.101(1) and 2.146(2) Å] and two loosely bound fluorides of the neighboring BF_4^- anions [Ag–F distances 3.029(1) and 3.370(2) Å]. The coordination sphere is nondistorted. The pyridyl ligand conformation is eclipsed, as usual for opposing pyridyl ligands (Figure 2).[12] The Ag2 is "sandwiched" between two neighboring pyridyl rings which are positioned so that an octahedral environment for Ag2 is formed. The Ag2–C distances to the carbons of these pyridyl rings are 3.164 and 3.218 Å. On the basis of molecular modeling calculations (energy minimization)[13] comparing the coordination environments of Ag1 and Ag2 (two pyridyl rings and two BF_4^-) the environment of Ag2 is more stable, even without the added stability of the "sandwich" pyridyl rings. This result is backed up by the obvious distortion from the optimum square-planar geometry of Ag1 and the results of CSD[3] searches showing the predominance of the eclipsed geometry. However, the conformation of the pyridyl ligands around the Ag^{I} cations is primarily dictated by the connectivity of the framework.



Scheme 2. A schematic presentation of **M1** without the BF_4^- anions.

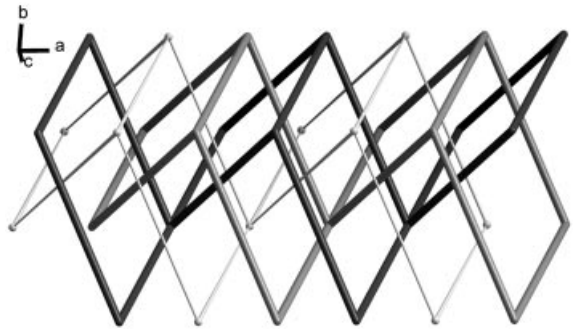


Figure 1. A schematic presentation of the threefold interpenetration of the 4,4 nets of **M1**. Only central carbon atoms and the connections between them are shown.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

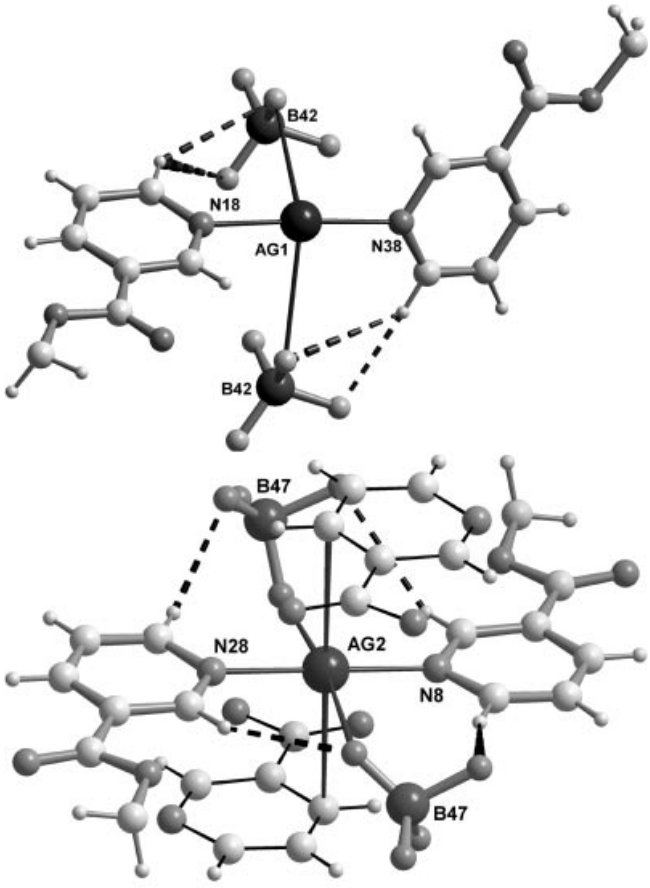

Figure 2. The coordination spheres of Ag1 and Ag2, showing the weak hydrogen bonds between the pyridyl hydrogen atoms and the fluorides of the BF_4^-. The shortest weak CH···F bond for those BF_4^- around the Ag1 is 2.365(2) Å (H39···F44) and for the BF_4^- around the Ag2 2.351(5) Å (H29···F50). The pyridyl rings on top and bottom of the Ag2 and their interactions with the Ag2 are also shown.

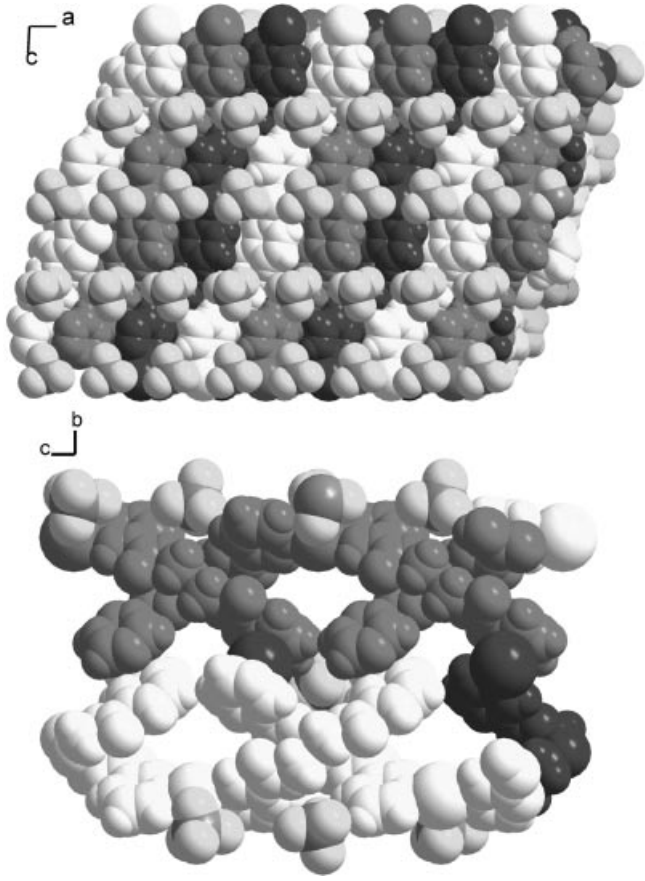

Figure 3. A space-filling presentation of **M1** along the *b* and *a* axis, showing the interpenetration of the layers and the channels along the *a* axis. The BF_4^- anions are shown only in the middle one of the three horizontally adjacent cavities shown in the lower figure. The three separate layers are shown in light, medium, and dark grey.

This explains the unfavored coordination geometry of the Ag1.

The BF_4^- anions are in close vicinity to the Ag^I cations, resulting in sparse anion layers between the polymeric frameworks and also channels (filled with anions) inside the layers. The 4,4 topology 2D sheets are threefold parallel interpenetrated (Figure 1), however, not completely consuming the open space of the framework. Besides the channels containing the BF_4^- anions, an additional set of channels remains along the *a* axis (Figure 3). The disordered solvent that could not be localized from the cavities was treated with SQUEEZE/BYPASS.[14]

The threefold parallel interpenetration of two-dimensional 4,4 nets is already known.[15–18] However, the mode of interpenetration of **M1** is previously unpresented. This mode is due to the use of the flexible tetradentate ligand which provides new geometrical possibilities for the network. In our previous work we presented a noninterpenetrated 2D structure with four **TNM** ligands coordinated to each Cu^{II} cation.[12] The use of Ag^I with two coordination sites for the **TNM** ligand makes the network of **M1** looser: the smallest loop in **M1** consists of eight ligand arms plus the metal coordination (56 bonds), whereas in our previous 2D **TNM** structure, the size of the loop (28 bonds) was half that of the **M1**. The amount of counter anions per metal cation is also halved in **M1**. The larger loops and reduced number of anions are the reasons for the threefold interpenetration in **M1**.

The 2D Layer Structure M2

We have previously synthesized a 3D MOF from **TINM** and $NiCl_2$[12] and respectively shown that the **TNM** ligand is unable to form a 3D MOF with a coordinative anion (and without the aid of an additional bridging component).[12,10] However, the formation of structures with lower dimensionality is possible with these components: 1 and 2D structures have already been obtained.[12,19] Here we present an eclipsed 2D layer structure with large pores (5.0 × 8.1 Å) through the crystal lattice along the *a* axis and smaller pores along the *b* and *c* axes (Scheme 3 and Figure 4). Similarly with the $CoCl_2$ structure reported earlier,[19] the net-

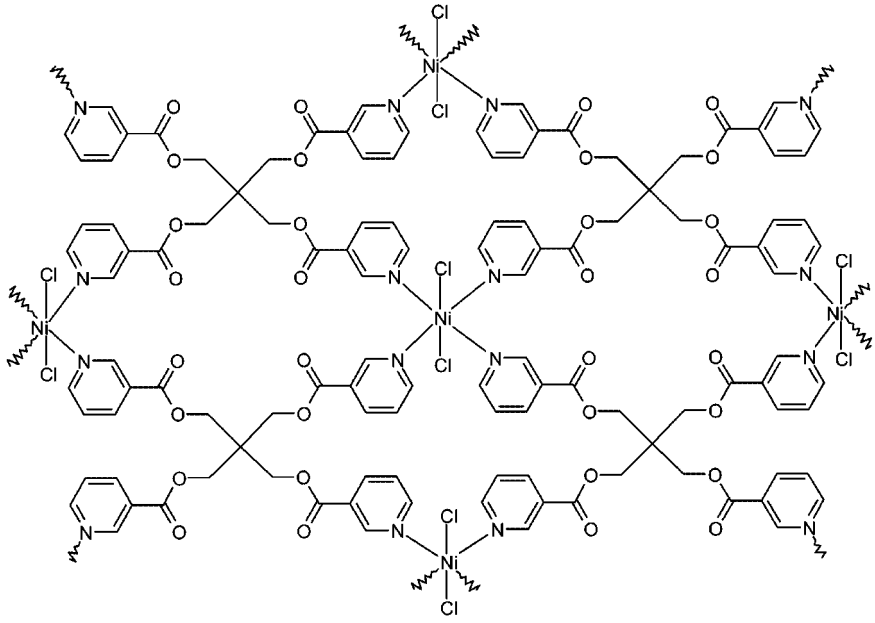

Scheme 3. A schematic presentation of **M2**.

work complies with the 4,4 topology with alternating nodes of the ligand central carbons and the Ni^{II} cations. The angles and distances between the nodes are presented in Figure 5.

The chloride anions are coordinated to the Ni^{II} cations in a 35.6 and 35.8° angle to the normal of the plane formed by the Ni^{II} cations in one layer. The octahedral coordination sphere of the Ni^{II} cations is tilted sideways (see Figure 4 and Figure 5) in order to minimize the repulsion of the chloride anions of neighboring layers. The layers are held together by weak hydrogen bonds between the chloride anions, the carbonyls, and the aromatic hydrogens. The attractive interactions are neither very strong nor numerous, resulting in the disorder of the molecule. The disorder was modeled by splitting the two arms (the carbonyl group and the pyridyl rings) of the independent half of the ligand into two positions. The population parameters of these halves were refined and then fixed to the refined values for the refinement of their temperature factors. The disordered solvent was treated with SQUEEZE/BYPASS.[20] The solvent accessible void for the structure was 30.0%.[20]

The 1D Chain Structure M3

The use of **TNM** together with the $Cu(PF_6)_2$/$Cu(OH)_2$/$CuPF_6$ and in the absence of MeOH resulted in a 1D MOF structure. Each chain is composed of two parallel rows of **TNM** ligands with paired, linear conformation. The pyridyl groups of the parallel rows are superimposed and bridged together by the Cu^{I} cations with the N–Cu–N axis perpendicular to the direction of the polymeric chain (Scheme 4). The PF_6^- and OH^- anions and the coordinated water molecules are enveloped in the wrinkles of the heavily puckered chains. The puckering is due to the linear coordination of the *meta*-isomer pyridyl rings to the Cu^{I} (Figure 6).

The neighboring chains are held together by the CH···O interactions between the aromatic hydrogens and the car-

bonyl oxygens as well as the π···π and van der Waals interactions. We have previously reported a 3D structure prepared from the same reagents.[10] However, in this previously reported structure the 1D chains were bridged together by the solvent methanol molecules. The absence of an additional bridging component like methanol in the preparation of **M3** prevents the formation of higher dimensionality products. The disorder around the square-planar coordination sphere of the Cu^{I} cations excludes the detailed discussion of the coordination bond lengths. The disorder was treated by setting geometrical restraints on the ligand. Furthermore, the disordered solvent was treated with SQUEEZE/BYPASS.[20]

Conclusions

The choice of the anions is critical for the topology of the resulting framework. In spite and because of the flexibility of the **TNM** and **TINM** ligands, the frameworks obtained with bulky noncoordinative anions are systematically different from those obtained with small coordinative anions. The flexibility of these ligands allows the tight enveloping of the anions within the forming framework or in other words, the templation of the frameworks by the anions. The use of $AgBF_4$ with **TNM** resulted in the formation of a threefold interpenetrated 2D network **M1**. The use of Ni^{II} instead of Co^{II} did not change the topology of the formed 2D frameworks.[19] However, unlike in the previous Co^{II} structure, the layers were eclipsed, which resulted in large channels (vdW diameter 9.4 Å) through the 2D layers of **M2**. The lack of a suitable bridging solvent (to allow polymerization in the 2nd and 3rd dimension) in the **M3** rendered the structure one-dimensional. As usual, the interpenetration was found to consume the available open space in **M1** resulting in a low value of 10.8%. In the noninterpenetrated structure **M2** the open space percentage was 38.0%.

Experimental Section

Materials and Measurements: All commercially available chemicals are of reagent grade and used as received without further purification. **TNM** and $Cu(PF_6)_2/Cu(OH)_2/CuPF_6$ were synthesized as previously reported.[10,21] The purity of **M1**–**2** was confirmed by elemental analysis, whereas the EA of **M3** gave inaccurate results due to the decomposition of the structure in air. Transferring the crystals directly from the mother liquid to the perfluorinated oil used in the single-crystal X-ray diffraction experiments, the decomposition was prevented and the diffraction experiment was enabled.

The Threefold Interpenetrated 2D Layer Structure M1: In a solution of **TNM** (22 mg, 39.5 μmol) dissolved in MeOH (3 mL) was added $AgBF_4$ (16 mg, 82.2 μmol) in water (1.5 mL). The solution was slowly allowed to evaporate, and the crystalline solid was collected from the solution before complete evaporation of the solvents and dried in air. Yield: 29%. $C_{29}H_{24}Ag_2B_2F_8N_4O_8$ + 8 H_2O: calcd. C 32.0, H 3.7, N 5.1; found C 31.9, H 2.9, N 5.0.

The 2D Layer Structure M2: A MeOH solution of **TNM** (1.5 mL, 14.4 mM) was carefully layered on top of a THF solution of $NiCl_2{\cdot}6H_2O$ (1.5 mL, 15 mM). The solutions were slowly allowed to diffuse and the crystalline solid was collected from the interface of the solvents and dried overnight in air. Yield: 57%. $C_{29}H_{24}Cl_2N_4NiO_8$ + 2 MeOH: calcd. C 49.6, H 4.3, N 7.5; found C 49.2, H 4.2, N 7.4.

The 1D Chain Structure M3: To a solution of **TNM** (6 mg, 10.8 μmol) dissolved in MeCN (1.5 mL) was added a saturated

water solution of $Cu(PF_6)_2/Cu(OH)_2/CuPF_6$ (5 mL). The solution was slowly allowed to evaporate, and the crystalline solid was collected from the solution before complete evaporation of the solvents and dried in air. Yield: 54%.

X-ray Crystallographic Study: The single-crystal X-ray diffraction was done with a Nonius–Kappa CCD diffractometer with graphite-monochromatized Mo-K_α (λ = 0.71073 Å) radiation. The Collect software system was used in the measurement and DENZO-SMN[22] in the processing of the data. The structures were solved and refined by full-matrix least squares on F^2 with the WinGX-software package utilizing SHELXS97 and SHELXL97 modules.[23–25] Hydrogen atoms were refined by a riding model. Absorption correction was not performed for any of the complexes. The graphic presentations of the structures were created with the software Diamond.[26] The crystallographic parameters for the structures **M1**–**M3** are presented in Table 1.

CCDC-256787–256789 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Slowly Exchanging *cis*-PtA_2B_2 Atropisomers with A_2 = Chiral Diamine Ligands and B = 5,6-Dimethylbenzimidazole

Manuela Trani,[a] Francesco Cannito,[b] Giovanni Natile,*[c] Patricia A. Marzilli,[d] and Luigi G. Marzilli*[d]

Keywords: Cisplatin / Anticancer drug / Platinum complexes / Chiral diamines / 5,6-Dimethylbenzimidazole

cis-PtA_2G_2 complexes, in which A_2 is a bidentate amine ligand and G is a unidentate guanine derivative bound to platinum through N7, are simple models of the G-G cross-link DNA lesion formed by the anticancer drug cisplatin. Rotation of the G bases about the Pt–N7 bonds is usually rapid except for bulky amine ligand(s). This paper concerns *cis*-$PtA_2(Me_2Bzm)_2$ adducts [A_2 = 2,2′-bipiperidine (Bip) and *N*,*N*,*N*′,*N*′-tetramethyl-2,3-diaminobutane (Me_4DAB); Me_2Bzm = 5,6-dimethylbenzimidazole] for which the interconversion among possible rotamers (one HH and two HT) is slow on the NMR time scale. The amounts of the rarely observed HH conformer were 52 and 37 % at 5 °C for $BipPt(Me_2Bzm)_2$ and $Me_4DABPt(Me_2Bzm)_2$, respectively, and increased to 60 and 44 % at 50 °C. This result represents the first reported clear evidence for the existence of the HH atropisomer in *cis*-PtA_2B_2 adducts (B = G or Me_2Bzm base) with fully substituted diamines, such as Me_4DAB or Me_4EN (Me_4EN = *N*,*N*,*N*′,*N*′-tetramethyl-1,2-diaminoethane). The lack of an O-substituent on the C4 atom of Me_2Bzm (corresponding to C6 of G) undoubtedly allows for a relatively stable HH conformer. Thermodynamic parameters confirm the crucial role of the substituents in positions 4 and 6 of the base systems (for Me_2Bzm and G derivatives, respectively) in determining the stability of different rotamers. The greater abundance of the HH rotamer for $BipPt(Me_2Bzm)_2$ than for $Me_4DABPt(Me_2Bzm)_2$ indicates that an increase in the steric bulk of the carrier ligand favors the HT rotamers over the HH rotamer. For both $BipPt(Me_2Bzm)_2$ and $Me_4DABPt(Me_2Bzm)_2$ adducts, the major HT rotamer has the six-membered ring of each Me_2Bzm ligand on the more crowded side of the *cis* amine with respect to the platinum coordination plane: the N–CH_2– group in Bip and the N–Me_{eq} (N–Me_{eq} = quasi-equatorial N–Me) in Me_4DAB adducts. The latter result is in complete agreement with previous findings from our laboratories concerning $BipPtG_2$ and $Me_4DABPtG_2$ compounds and gives further support to the view that the major HT rotamer is stabilized by the six-membered ring of each base canted toward the *cis* base.

Introduction

Cisplatin [*cis*-$PtCl_2(NH_3)_2$] is one of the most widely used drugs in the treatment of several cancers.[1,2] Its precise mechanism of action is not completely understood, but it is known to target primarily nuclear DNA, forming a critical lesion by cross-linking two adjacent guanine bases or an adenine and a guanine base of the same strand.[1–6] A serious limitation in studies of adducts between Pt anticancer drugs and DNA is the fluxional character of these adducts. We have called this limitation the "dynamic motion problem."[7]

We have been investigating *cis*-PtA_2G_2 complexes, in which A_2 is a bidentate amine ligand designed to possess steric bulk near the *cis* coordination sites and G is a unidentate guanine derivative bound to platinum through N7.[7–14] In these models the interconversion between rotamers (by rotation around the Pt–N7 bonds) is slow on the NMR time scale,[15] and thus the presence of different rotamers can be detected by NMR spectroscopy. The G bases can be in a head-to-head arrangement (HH), in which both H8 atoms lie on the same side of the coordination plane, or in a head-to-tail arrangement (HT), in which the H8 atoms lie on opposite sides of the coordination plane (ΛHT and ΔHT, Scheme 1).

For $BipPtG_2$ and $Me_2DABPtG_2$ adducts (Bip = 2,2′-bipiperidine, Me_2DAB = *N*,*N*′-dimethyl-2,3-diaminobutane; C_2-symmetrical ligands are obtained for *S*,*R*,*R*,*S* or *R*,*S*,*S*,*R* configurations at the four stereocenters located on the N, C, C, and N atoms of the chelate ring, Scheme 2), the HT conformers typically dominated over the HH conformer.[11,12,16,17] This dominance was attributed to interligand interactions, which were classified as "first-to-first," "first-to-second," and "second-to-second" sphere com-

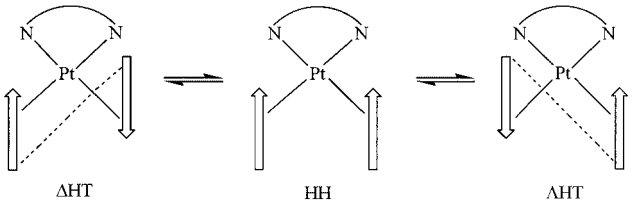
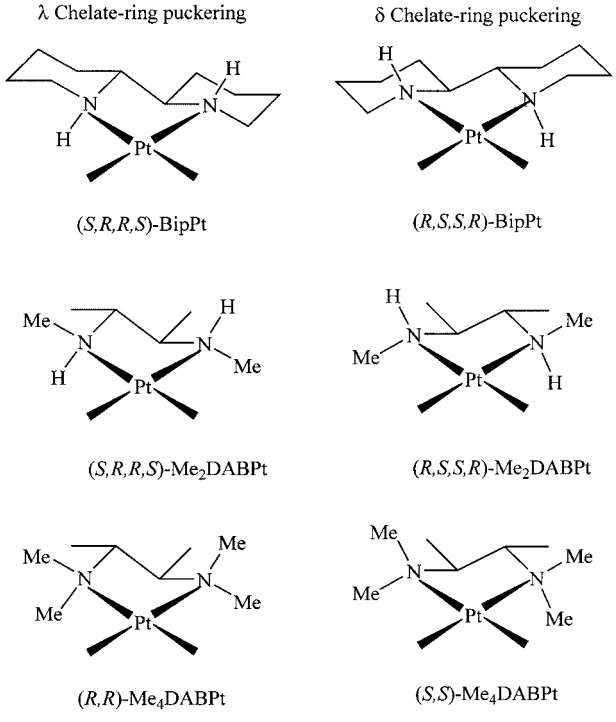


Scheme 1. Schematic representation of HH, ΔHT, and ΛHT atropisomers for *cis*-PtA_2B_2 complexes.

munications.[17,18] The latter two types of interactions involve phosphate groups,[11,12,17,18] and in this study we examine adducts lacking this group in order to focus on first-to-first sphere communications (FFC). FFC are interligand interactions involving portions of the ligands close to the metal center. Base-to-base interactions and H-bonding interactions between G O6 and N–H of a *cis* amine fall into this category. For C_2-symmetrical Bip and Me_2DAB ligands the latter interaction should favor the HT rotamer having the O6 atom of each G near the N–H of the *cis* amine, and on the opposite side of the platinum coordination plane from the N–CH_2– or the N–Me group. One HT rotamer was in fact favored but, contrary to our expectations, the O6 of each guanine of this major rotamer was near the N–CH_2– or the N–Me group of the *cis* amine, not near the N–H group.



Scheme 2. Schematic representation of Bip, Me_2DAB, and Me_4DAB ligands coordinated to a platinum(II) moiety.

In the NMR spectra of $BipPtG_2$ and $Me_2DABPtG_2$ complexes, the H8 signal of the major HT rotamer is more downfield than the H8 signal of the minor HT rotamer. This result is an indication that in the major HT rotamer the H8 proton of each guanine is pointing farther away from the *cis* G (so that it experiences a smaller shielding effect from the *cis* G) as the six-membered ring of each guanine moves toward the *cis* guanine ("6-in" orientation). The HH rotamer has one H8 signal more downfield than the H8 signal of the major HT form (HH_d base), and the second H8 signal more upfield than the H8 signal of the minor HT conformer (HH_u base). The latter signal must belong to a guanine having H8 pointing toward the *cis* G and embedded in its shielding cone; therefore this guanine must have the "6-out" orientation.

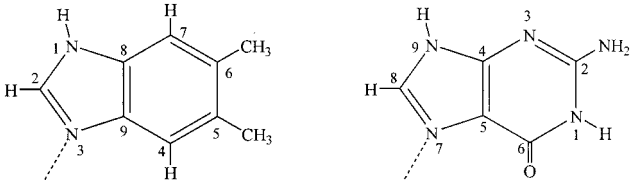
The "6-in" orientation of the *cis* G's in HT conformers of $BipPtG_2$ and $Me_2DABPtG_2$ adducts has implications relevant to the stability of the conformers. For example, the interaction between the H8 atom of each G and the *cis* amine will be smaller when H8 is on the side of the N–H than when it is on the side of the N–CH_2– or the N–Me of the *cis* amine with respect to the platinum coordination plane. Therefore the conformer with H8 near the N–H of the *cis* amine will be favored and will have the six-membered ring of each guanine on the same side as the N–CH_2– or the N–Me group of the *cis* amine. The fact that the "6-in" orientation of *cis* guanines is favored suggests strongly that this orientation allows better base-base, dipole-dipole (the H8 of one guanine closer to the O6 of the second guanine), and stacking interactions.

In the HH rotamer, the "6-out" guanine (with a shielded H8) has the six-membered ring on the same side of the coordination plane as the N–H of the *cis* amine (whereas the second guanine has the six-membered ring near the N–CH_2– or the N–Me of the *cis* amine). The smaller steric interaction of the former guanine with the *cis* amine allows the "6-out" orientation to occur, and as a consequence the negatively charged O6 atom of this "6-out" guanine is farther from the O6 atom of the *cis* G.

More recently, in order to achieve a better understanding of systems lacking N–H groups, studies were conducted on adducts with the carrier ligand, Me_4DACH (Me_4DACH = *N*,*N*,*N*′,*N*′-tetramethyl-1,2-diaminocyclohexane).[19] The dissymmetry of Me_4DACH with respect to the platinum coordination plane is very small (each diamine N-donor has methyls on both sides of the coordination plane), which makes the ligand fundamentally different from the Bip and Me_2DAB ligands previously investigated. As Cramer found in his classic study on Me_4ENPtG_2 adducts (Me_4EN = *N*,*N*,*N*′,*N*′-tetramethyl-1,2-diaminoethane, G = Guo),[15] no HH rotamer was observed at equilibrium in any of the $Me_4DACHPtG_2$ adducts; moreover, the H8 chemical shifts are very similar for the major and the minor HT rotamers. The absence of a significant amount of HH rotamer could be a consequence of the bulk produced on both sides of the coordination plane by the four N–Me groups. This bulk on both sides of the coordination plane does not allow "6-out" canting of at least one G, which is required for minimizing O6···O6 electrostatic repulsions.[20] Moreover, two $Me_4DACHPt(5'\text{-}GMP)_2$ ΔHT rotamers were shown by X-ray crystallography to have a "6-in" orientation of the two G's in spite of the opposite chiralities of the Me_4DACH ligands in the two compounds.[21]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Despite the many studies conducted on cisplatin models, numerous questions remain unanswered. In an effort to achieve a better understanding of the factors influencing formation and stability of conformers in models of the cisplatin-DNA cross-link, we undertook a study of *cis*-PtA_2-$(Me_2Bzm)_2$ complexes (A_2 = Bip and Me_4DAB; Me_2Bzm = 5,6-dimethylbenzimidazole; Scheme 3). Me_2Bzm lacks the O substituent on the C4 atom (corresponding to C6 of purines); therefore, a comparison between Me_2Bzm and G adducts allows us to unravel the role of such an oxygen atom in the formation and stability of conformers. Moreover, Me_2Bzm has several "probe protons" on its periphery that might help in assessing the ligand canting.[22]



Scheme 3. Shorthand drawings of 5,6-dimethylbenzimidazole and guanine bases.

Results

[*rac*-BipPt($Me_2Bzm)_2$]$^{2+}$ Complex: The lack of chirality in the Me_2Bzm ligands renders indistinguishable the NMR spectroscopic data obtainable for [*rac*-BipPt-$(Me_2Bzm)_2]^{2+}$ and for the single enantiomers [(*R*,*S*,*S*,*R*)-BipPt$(Me_2Bzm)_2]^{2+}$ and [(*S*,*R*,*R*,*S*)-BipPt$(Me_2Bzm)_2]^{2+}$; therefore, only the NMR spectroscopic data concerning the *rac* isomer (used in higher concentration) will be described. The ^{1}H NMR spectrum of [*rac*-BipPt$(Me_2Bzm)_2]^{2+}$ (in D_2O at pH 6 and 5 °C) exhibited four sets of signals for each proton (Figure 1 shows the H2 region), indicating the presence of one HH and two HT conformers. Complete assignment of the signals for each conformer (Table 1) was possible on the basis of a ^{1}H/^{1}H ROESY experiment carried out at 5 °C. In the ^{1}H/^{1}H ROESY spectrum, the H2 signal at δ = 8.57 ppm had an NOE cross-peak to the H2 signal at δ = 8.42 ppm, allowing the assignment of these signals to the HH conformer (HH_d and HH_u denote the HH base having the H2 signal downfield and upfield with respect to the H2 signal of the major HT rotamer, respectively). The other two signals at δ = 8.54 and 8.38 ppm must belong to the major HT (MHT) and minor HT (mHT) rotamers, respectively. The H2 signal of the major HT conformer at δ = 8.54 ppm had an NOE cross-peak to the H4 signal at δ = 8.16 ppm; similarly, the H2 signal of the minor HT conformer at δ = 8.38 ppm had an NOE cross-peak to the H4 signal at δ = 8.18 ppm. Therefore, the H4 signals at δ = 8.16 and 8.18 ppm were assigned to the major and minor HT conformers, respectively. The remaining two H4 signals belonging to the HH rotamer (8.08 and 8.29 ppm) were assigned to the HH_d and HH_u bases of the HH rotamer, respectively, on the basis of the opposite relationship in chemical shift between the H2 and H4 protons.

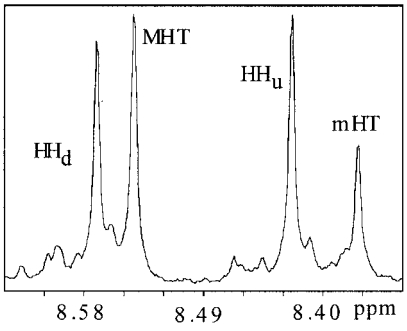


Figure 1. H2 region of the ^{1}H NMR spectrum of [*rac*-BipPt$(Me_2Bzm)_2]^{2+}$ at 5 °C.

Table 1. ^{1}H NMR Shifts (ppm) of Me_2Bzm for [*rac*-BipPt$(Me_2Bzm)_2]^{2+}$ at 5 °C and pH 6.

	MHT[a]	mHT[a]	HH_d[a]	HH_u[a]
H2	8.54	8.38	8.57	8.42
H4	8.16	8.18	8.08	8.29
H7	7.29	7.37	7.21	7.26
Me5	2.42	2.49	2.21	2.47
Me6	2.24	2.34	2.01	2.20

[a] MHT = equivalent bases of the major head-to-tail conformer; mHT = equivalent bases of the minor head-to-tail conformer; HH_d = base of the HH conformer with downfield H2; HH_u = base of the HH conformer with upfield H2.

NOE cross-peaks between H4 and Me5 signals, between Me5 and Me6 signals, and between Me6 and H7 signals were used to complete the assignments of the Me_2Bzm protons (Supporting information; for supporting information see also the footnote on the first page of this article). NOE cross-peaks between the H4 signals of Me_2Bzm and the N–CH_2– signals of Bip allowed us to assign the Δ or Λ conformations to the HT rotamers and to identify the orientation of each base in the HH rotamer. The H4 signal at δ = 8.16 ppm belonging to the major HT conformer had a cross-peak to the N–CH_2– signal of the Bip ligand at δ = 2.78 ppm. Therefore, the major HT rotamer has the Me_2Bzm six-membered rings close to the *cis* N–CH_2– groups of the Bip ligand [this corresponds to the rotamer having the ΔHT conformation in the (*R*,*S*,*S*,*R*) adduct and the ΛHT conformation in the (*S*,*R*,*R*,*S*) adduct]. It follows that the minor HT rotamer must have the six-membered ring of each Me_2Bzm near the N–H of the *cis* amine corresponding to ΛHT and ΔHT conformations for the (*R*,*S*,*S*,*R*) and (*S*,*R*,*R*,*S*) adducts, respectively. The H4 signal at δ = 8.08 ppm belonging to the HH_d base of the HH conformer also had a cross-peak to the N–CH_2– signals of the Bip ligand at δ = 2.78 ppm, therefore the HH_d base of the HH rotamer has the six-membered ring near the *cis* N–CH_2– group of Bip. Thus, the HH_u base of the HH rotamer must have the six-membered ring close to the N–H of the *cis* amine.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

When the temperature was increased from 5 to 50 °C, a change in the ratio of conformers was observed and the HH conformer became more favored. The respective percentages of HH, major HT, and minor HT conformers were 52, 31, and 17, at 5 °C; 57, 30, and 13, at 35 °C; and 60, 28, and 12, at 50 °C.

[(*R*,*S*,*S*,*R*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ and [(*S*,*R*,*R*,*S*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ Complexes: The reason for preparing derivatives with pure enantiomeric Bip ligands was to investigate their CD spectra. The CD spectrum at pH 6 of [(*R*,*S*,*S*,*R*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ exhibits positive bands around 300 and 260 nm and negative bands around 285, 240, and 210 nm. On the other hand, the CD spectrum at pH 6 of [(*S*,*R*,*R*,*S*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ shows negative bands at 300 and 260 nm and positive bands at 285, 240, and 210 nm (Figure 2). The CD spectra of *cis*-Pt(Me_2Bzm)$_2$ adducts are not expected to be similar to those of *cis*-PtG_2 adducts because of the different nature of the $\pi \rightarrow \pi^*$ electron transitions; however, the trends observed for chiral BipPt(Me_2Bzm)$_2$ adducts at long wavelengths (>230 nm) resemble the trends observed for $BipPtG_2$ adducts. For instance, the CD spectrum of (*R*,*S*,*S*,*R*)-BipPt(5′-GMP)$_2$ at neutral pH exhibits a negative band at 288 nm and a positive band at 254 nm (which were identified as characteristic of a ΔHT conformation); conversely, the CD spectrum of (*S*,*R*,*R*,*S*)-BipPt(5′-GMP)$_2$ exhibits a positive band at 288 nm and a negative band at 254 nm (which were identified as characteristic of a ΛHT conformation).[12] Therefore, the CD spectra are in agreement with a dominant ΔHT rotamer for [(*R*,*S*,*S*,*R*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ and a dominant ΛHT rotamer for [(*S*,*R*,*R*,*S*)-BipPt(Me_2Bzm)$_2$]$^{2+}$. This result is in full agreement with the NMR investigation showing that the major rotamer had the ΔHT conformation for [(*R*,*S*,*S*,*R*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ and the ΛHT conformation for [(*S*,*R*,*R*,*S*)-BipPt(Me_2Bzm)$_2$]$^{2+}$.

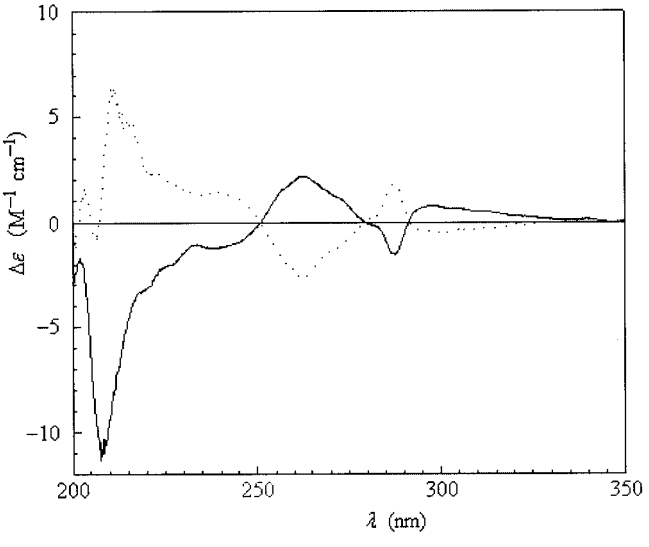

Figure 2. CD spectra of [(*R*,*S*,*S*,*R*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ (solid line) and [(*S*,*R*,*R*,*S*)-BipPt(Me_2Bzm)$_2$]$^{2+}$ (dotted line) collected at room temperature and pH 6.

[*rac*-Me_4DABPt(Me_2Bzm)$_2$]$^{2+}$ Complex: As for the Bip complexes, the lack of chirality in the Me_2Bzm ligand renders the NMR spectroscopic data obtained for [*rac*-Me_4DABPt(Me_2Bzm)$_2$]$^{2+}$ identical to those obtained for complexes with individual Me_4DAB enantiomers. Therefore, only the NMR spectroscopic data concerning the *rac* isomer (used in higher concentration) will be described. The ^{1}H NMR spectrum of [*rac*-Me_4DABPt(Me_2Bzm)$_2$]$^{2+}$ (D_2O, pH 6.5, 5 and 25 °C) had four sets of signals, indicating the presence of one HH (with inequivalent bases) and two HT conformers (each one with equivalent bases) as expected (Figure 3). Complete assignment of signals for each conformer (Table 2 and Table 3) was possible on the basis of ^{1}H/^{1}H NOESY and ^{1}H/^{13}C HMQC experiments, and on the basis of previous results from these laboratories on the (*S*,*S*)-Me_4DABPt(3′-GMP)$_2$ adduct.[23]

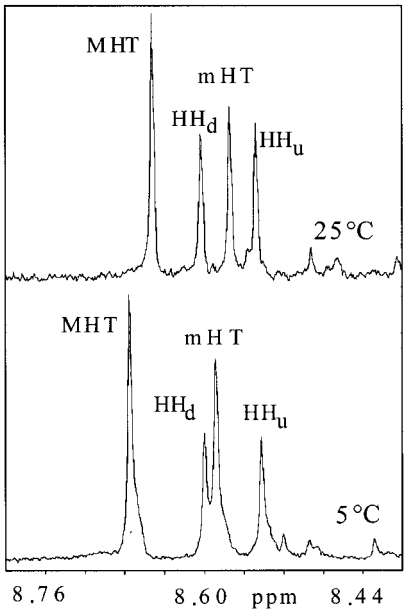

Figure 3. H2 region of the ^{1}H NMR spectra of [*rac*-Me_4DABPt(Me_2Bzm)$_2$]$^{2+}$ at 5 (bottom) and 25 °C (top).

In the ^{1}H/^{1}H NOESY spectrum of [*rac*-Me_4DABPt(Me_2Bzm)$_2$]$^{2+}$ at 5 °C, the intense H2 signal at δ = 8.67 ppm had a cross-peak to the intense H4 signal at δ = 8.17 ppm; thus, these resonances were assigned to the major HT rotamer. The less intense H2 signal at δ = 8.59 ppm had a cross-peak to the less intense H4 signal at δ = 8.19 ppm; thus, these resonances were assigned to the minor HT rotamer. The two H2 signals of equal intensity at δ = 8.60 and 8.54 ppm must belong to the HH rotamer (HH_d and HH_u bases, respectively). The H4 signals at δ = 8.27 and 8.28 ppm must also belong to the HH rotamer. Their assignment to the HH_u and HH_d bases, respectively, was possible on the basis of NOE cross-peaks between the H4 protons and the *cis* amine N–Me's as described in the following paragraph. NOE cross-peaks be-

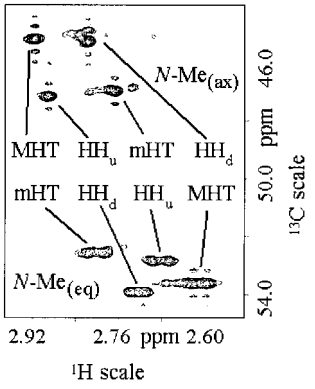

Figure 4. N–Me region of the ^{1}H/^{13}C HMQC spectrum (25 °C) of [*rac*-$Me_4DABPt(Me_2Bzm)_2]^{2+}$.

tween H4 and Me5 signals, between Me5 and Me6 signals, and between Me6 and H7 signals were used to complete the assignments of the Me_2Bzm signals (Supporting Information).

Assignment of the Δ and Λ conformations to the two HT rotamers and of the HH_d and HH_u bases in the HH rotamer was derived from the relative positions of the H2 (five-membered ring) and H4 (six-membered ring) protons with respect to the N–Me_{ax} and N–Me_{eq} (quasi-axial and quasi-equatorial N–Me groups of the carrier ligand, respectively) as revealed by the ^{1}H/^{1}H NOESY spectrum.[24] The latter experiment depends on the assignment of the proton resonances to the axial and equatorial N–Me's of the Me_4DAB ligand. This assignment was made on the basis of a previous investigation carried out in these laboratories on the (*S*,*S*)-$Me_4DABPt(3'\text{-GMP})_2$ adduct,[23] showing that the equatorial N–Me resonances have ^{13}C NMR chemical shifts at ca. 53 ppm, while the axial N–Me resonances have ^{13}C NMR chemical shifts at ca. 46 ppm. Therefore the ^{1}H/^{13}C HMQC experiment reported in Figure 4 was sufficient to distinguish between axial and equatorial N–Me signals.

The strong NOE cross-peaks observed between the H2 and the N–Me_{ax} signals and between the H4 and the N–Me_{eq} signals for the major HT conformer provide evidence that the six-membered ring of each base is near the N–Me_{eq} group of the *cis* amine; thus, the MHT rotamer has the ΔHT conformation for the [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct and the ΛHT conformation for the [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct. Likewise, strong NOE cross-peaks between the H2 and the N–Me_{eq} signals and between the H4 and the N–Me_{ax} signals for the minor HT conformer are indications that the six-membered ring is close to the N–Me_{ax} group of the *cis* amine, a situation which corresponds to the mHT atropisomer having the ΛHT conformation in the [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct and the ΔHT conformation in the [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct. For the HH rotamer, a strong NOE cross-peak between H2 and N–Me_{ax} signals for the HH_d base indicates that this base has the six-membered ring near the N–Me_{eq} of the *cis* amine. The H4 signal at δ = 8.28 ppm has a NOE cross-peak to an equatorial N–Me signal (δ = 2.69 ppm); thus, it is assigned to the HH_d base. On the other hand, a strong NOE cross-peak between the H2 and the N–Me_{eq} signals for the HH_u base indicates that this base has the six-membered ring close to the N–Me_{ax} of the *cis* amine. The H4 signal at δ = 8.27 ppm has a NOE cross-peak to an axial N–Me signal (δ = 2.85 ppm); thus, it is assigned to the HH_u base. The H2/N–Me and H4/N–Me regions of ^{1}H/^{1}H NOESY spectra for [*rac*-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ are reported in Figure 5 and Figure 6, respectively.

As found also for the [*rac*-$BipPt(Me_2Bzm)_2]^{2+}$ adduct, the percentages of the different [*rac*-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ conformers depend on temperature. The relative abundances of the HH, major HT, and minor HT conformers were 37, 39, and 24, at 5 °C; 42, 35, and 23, at 25 °C; and 44, 35, and 21, at 50 °C.

[(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ and [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ Complexes: CD data for both [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ and [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adducts have been collected. The CD spectrum at pH 6 of [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ exhibits positive bands around 300, 275, and 210 nm, and a negative band at 240 nm. In contrast, the CD spectrum at pH 6 of [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ shows negative bands at 300, 275, and 210 nm, and a positive band at 240 nm (Figure 7). Thus, the CD spectra of [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ and [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ resemble those observed for [(*R*,*S*,*S*,*R*)-$BipPt(Me_2Bzm)_2]^{2+}$ and [(*S*,*R*,*R*,*S*)-$BipPt(Me_2Bzm)_2]^{2+}$ only for wavelengths above 230 nm, while they are rather different for wavelengths below 230 nm. Moreover, for wavelengths above 230 nm the Cotton effect is dominated by coupling between $\pi \rightarrow \pi^*$ transitions of *cis* bases and can be diagnostic for the Λ or Δ conformation of the dominant HT rotamer.[21] Thus for the Me_4DAB complexes also, as previously observed for the Bip adducts, the CD spectra are in agreement with the dominance of the ΔHT conformation for [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ and of the ΛHT conformation for [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$. This result is in full agreement with the NMR spectroscopic data showing that the major HT rotamer had the Δ conformation in the [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct and the Λ conformation in the [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct.

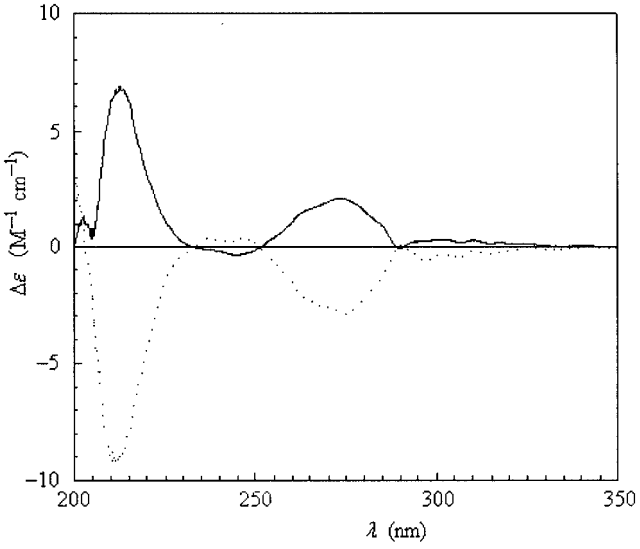

Figure 7. CD spectra of [(*S*,*S*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ (solid line) and [(*R*,*R*)-$Me_4DABPt(Me_2Bzm)_2]^{2+}$ (dotted line) collected at room temperature and pH 6.

From the percentages of individual rotamers at different temperatures the activation parameters for the equilibria HH ⇄ MHT and HH ⇄ mHT have been evaluated and the values are reported in Table 4.

Table 4. Enthalpy (ΔH, kJ·mol^{-1}) and Entropy (ΔS, J K^{-1} mol^{-1}) for the Equilibria HH ⇄ MHT and HH ⇄ mHT (K_{MHT} = [MHT]/[HH]; K_{mHT} = [mHT]/[HH]) in *cis*-PtA_2B_2 Complexes.[a]

Discussion

Base Canting in *cis*-PtA_2B_2 Adducts: The G H8 signals are generally used as a probe for assessing the degree and direction ("6-in" or "6-out") of base canting in *cis*-PtA_2G_2 adducts.[25] In the HH conformer of $BipPtG_2$ and $Me_2DABPtG_2$ adducts (with C_2-symmetry of the bidentate ligand), one base generally has low canting, while the other base is strongly canted. For the highly canted base, the six-membered ring moves toward the *cis* amine, and the H8 atom moves toward the *cis* G. Because of the ring-current anisotropy of the *cis* G, the H8 signal of the canted G experiences an upfield shift. The H2 of Me_2Bzm is in a position corresponding to that of H8 of a G base; therefore, the canting can be deduced from the position of the H2 ^1H

NMR resonance of [*cis*-$PtA_2(Me_2Bzm)]^{2+}$ adducts. Moreover, for the Me_2Bzm ligand, the H4 and Me5 shifts can also be used to confirm the direction and degree of canting.

Of particular significance is the very small difference in H2 chemical shifts of the HH rotamer of [BipPt-$(Me_2Bzm)_2]^{2+}$ (δ = 0.15 ppm) when compared to that of the H8 signals of the HH rotamer of $BipPtG_2$ species (ca. 1.3 ppm). For *cis*-PtG_2 adducts unfavorable electrostatic and steric interactions between O6 atoms of *cis* G's are likely in the HH rotamer, for which the O6···O6 distance can be estimated to be smaller than the sum of the van der Waals radii for guanines orthogonal to the platinum coordination plane.[26] Some relief from unfavorable electrostatic and steric interactions can be achieved if one or both G's can be canted "6-out". Such a canting is possible in $BipPtG_2$ as well as in $Me_2DABPtG_2$ adducts because one G in the HH rotamer has the six-membered ring adjacent to the N–H of the *cis* amine. The "6-out" canting of this guanine will not only be allowed by the small steric interaction between the six-membered ring of the guanine and the N–H of the *cis* amine, but might also be favored by H-bond formation between the G-O6 and the amine N–H.

The main difference between G and Me_2Bzm bases resides in the absence, in the latter case, of the oxygen substituent. The absence of such a substituent greatly reduces the steric and electrostatic interactions between *cis*-bases, which therefore can both be "quasi orthogonal" to the coordination plane.

For $BipPtG_2$ adducts,[12] the H8 signal of the major HT conformer was 0.3 to 0.5 ppm downfield from the H8 signal of the minor HT conformer (depending upon the G base and the pH); in contrast, in $[BipPt(Me_2Bzm)_2]^{2+}$ the difference in chemical shift between the H2 signals of the major and minor HT rotamers is only 0.16 ppm. For HT conformers of *cis*-PtG_2 adducts base canting is driven by dipole-dipole interactions. Calculations show that a "6-in" canting of the two guanines (up to 20° rotation about the Pt–N7 bond, starting from the plane of each guanine orthogonal to the coordination plane) will bring the H8 of each guanine closer to the O6 of the *cis* guanine with consequent increase in stability of the rotamer.[28] This situation is probably attained in the MHT rotamer of $BipPtG_2$ and $Me_2DABPtG_2$ compounds, in which the H8 atom of each guanine is on the same side as the N–H of the *cis* amine with respect to the coordination plane. In contrast, in the minor HT rotamer of $BipPtG_2$ and $Me_2DABPtG_2$ compounds such a "6-in" canting of the two guanines is limited by steric interaction between the H8 of each guanine and the *N*-alkyl substituent on the *cis* amine, both on the same side of the coordination plane. With respect to the MHT rotamer, the smaller "6-in" canting of the two guanines in mHT causes both a lower stability of this rotamer and a greater shielding of the H8 protons, which therefore resonate at higher field.

In the Me_2Bzm adducts there is no strong dipole-dipole interaction of the type just described for the G adducts. Any dipole-dipole interaction should be weak. The absence of a strong driving force to base canting explains why the separation between the H2 resonances of HT rotamers is smaller in Me_2Bzm adducts than in G adducts.

As mentioned, information about canting can also be gained from the H4 and Me5 signals of Me_2Bzm. The H4 and Me5 signals of the major HT rotamer were slightly upfield with respect to the corresponding signals for the minor HT rotamer ($\Delta\delta$ of 0.02 and 0.07 ppm for H4 and Me5, respectively). The differences in chemical shift between the two H4 and between the two Me5 signals of the HH rotamer were 0.21 and 0.26 ppm, respectively (Table 1). As expected, the trend in chemical shifts for H4 and Me5 is opposite to that for H2 because canting that brings H2 closer to the *cis* base will bring H4 and Me5 farther from the *cis* base and vice-versa.

As observed in the case of $[BipPt(Me_2Bzm)_2]^{2+}$, for $[Me_4DABPt(Me_2Bzm)_2]^{2+}$ the separations between the two H2 signals of the HH rotamer (δ = 0.06 ppm) and between the H2 signals of the two HT conformers (δ = 0.08 ppm) are also small (Table 2). The explanation given for the former complex applies also to the latter.

The slightly greater separation between the two H2 resonances of the HH rotamer and between the H2 resonances of the two HT rotamers for the $[BipPt(Me_2Bzm)_2]^{2+}$ vs. the $[Me_4DABPt(Me_2Bzm)_2]^{2+}$ adduct is in agreement with the former complex having a greater canting freedom for one Me_2Bzm ligand of the HH rotamer (the Me_2Bzm having the six-membered ring adjacent to the N–H of the *cis* amine) and for the two Me_2Bzm ligands of one HT rotamer (the rotamer having the H2 of each Me_2Bzm near the N–H of the *cis* amine). However, as already pointed out, the degree of canting observed in the $[BipPt(Me_2Bzm)_2]^{2+}$ adduct is far smaller than that observed in the $BipPtG_2$ adducts because in the latter case the steric and electrostatic repulsion between the O6's of the *cis* G's in the HH conformer or the electrostatic attraction between the O6 of one G and the H8 of the *cis* G in the HT rotamers drives the tilting of the guanine(s).

Comparison with Base Canting in Re or Ru Metal Complexes Containing *cis*-Benzimidazole Ligands: The current work complements our previous studies on Re and Ru complexes containing *cis* Me_3Bzm (Me_3Bzm = 1,5,6-trimethylbenzimidazole) ligands.[22,27] For $[Re_2O_3Cl_4(Me_3Bzm)_4]$,[27] the four Me_3Bzm ligands have an HH-HT-HH arrangement. The central HT arrangement was formed by pseudo-bridging "stacked" Me_3Bzm ligands (designated as Me_3Bzm^s), while the peripheral HH arrangements were formed by one Me_3Bzm^s base and one of the two equivalent "terminal" Me_3Bzm bases (designated as Me_3Bzm^t). The structure showed that the two Me_3Bzm^t bases were highly canted with respect to the two Me_3Bzm^s bases. In the ^1H NMR spectrum the H2 signal of the Me_3Bzm^t bases was ≈ 1.3 ppm downfield from that of the Me_3Bzm^s H2 signal; the H4 and Me5 signals showed the opposite trend. The high degree of canting of the Me_3Bzm^t bases with respect to the Me_3Bzm^s bases was attributed to the electrostatic attraction between the positively charged H2 of Me_3Bzm^t and the negatively charged O and Cl groups in the core of the dimer.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

For *cis*,*cis*,*cis*-[$RuCl_2(Me_2SO)_2(Me_3Bzm)_2$] ($Me_2SO$ = dimethyl sulfoxide)[22] one HT and one HH form were observed in solution. For the HH conformer, the H2 signal of the uncanted Me_3Bzm base that is *cis* to the Cl atoms was 1.5 ppm downfield with respect to the H2 signal of the canted Me_3Bzm base that is *cis* to the Me_2SO groups. Opposite trends were observed for the H4 and Me5 signals. In the X-ray structure of the HH conformer, the Me_3Bzm close to the Me_2SO groups was highly canted, with the H2 atom pointing toward the Me_3Bzm base close to the Cl atoms. The six-membered ring of the canted Me_3Bzm ligand was inserted between the two *cis* Me_2SO ligands so as to avoid steric interaction with the bulky Me_2SO groups. This insertion causes the H2 atom to move toward the *cis* Me_3Bzm. The latter Me_3Bzm is kept in a fixed position because of favorable electrostatic attraction between its H2 and the two *cis* Cl ligands.

The results obtained with the Re and Ru complexes emphasize the role of electrostatic interactions in determining the canting of Me_2Bzm/Me_3Bzm ligands. Electrostatic interactions of this type are not present in the platinum complexes investigated here, which, in fact, show little or negligible canting.

Distribution of Conformers: The HH rotamer, disfavored in most of the previously studied *cis*-PtG_2 adducts,[17] is the most favored conformer for [$BipPt(Me_2Bzm)_2$]$^{2+}$ and [$Me_4DABPt(Me_2Bzm)_2$]$^{2+}$ complexes, and its stability increases with increasing temperature. The HH:HT ratio was 1.1 at 5 °C and 1.5 at 50 °C for [$BipPt(Me_2Bzm)_2$]$^{2+}$, whereas the maximum observed HH:HT ratio was 0.8 for $BipPt(1\text{-Me-}5'\text{-GMP})_2$ complexes and was generally less than 0.3 for N1 unmethylated guanine adducts.[17]

Dipole–dipole interactions appear to play a crucial role in determining the stability of the HT rotamers in G complexes. Such interactions favor the HT rotamers over the HH rotamer because in the former case the positive end of one dipole (near the H8 atom) can approach the negative end of the second dipole (near the O6 atom). Moreover, the H8 and O6 atoms of *cis* guanines can approach each other more closely if each guanine is canted "6-in". The HH rotamer is formed in small yield in $BipPtG_2$ and $Me_2DABPtG_2$ complexes and is practically absent in the $Me_4DACHPtG_2$ adducts. In the former cases, one G (that having the six-membered ring adjacent the N–H of the *cis* amine) can be canted "6-out" so as to bring the O6 atom of one G farther from the O6 atom of the *cis* G. Such a "6-out" canting is not possible in the $Me_4DACHPtG_2$ complex because of steric interaction between the six-membered ring of each guanine and the adjacent Me-substituent on the *cis* amine; therefore, no HH rotamer is formed.

The absence of dipole-dipole interaction in Me_2Bzm adducts makes the HH and the two HT rotamers comparable in stability, with the consequence that the three rotamers are found in comparable amounts.

The slightly greater percentage of the HH rotamer for [$BipPt(Me_2Bzm)_2$]$^{2+}$ than for [$Me_4DABPt(Me_2Bzm)_2$]$^{2+}$ can be explained by the presence in the former case of a smaller steric interaction between the two six-membered rings of the Me_2Bzm ligands: for the HH rotamer these rings are on the same side of the coordination plane. In fact, in the Bip complex one Me_2Bzm has the six-membered ring on the same side of the plane as the N–H of the *cis* amine and thus the Me_2Bzm can be canted "6-out"; in contrast, in the Me_4DAB complex, both Me_2Bzm ligands have the six-membered ring on the side of one N–Me of the *cis* amine, a situation which greatly reduces the possibility of canting. However, even in the Me_4DAB complex, one Me_2Bzm (the one having the six-membered ring on the side of the plane as the "quasi axial" N–Me of the *cis* amine) can be canted "6-out" slightly more than the other Me_2Bzm (the one having the six-membered ring on the same side of the plane as the "quasi equatorial" N–Me). As a consequence, the H2 proton of the former base is more shielded by the *cis* base and resonates at higher field (HH_u) than the other (HH_d).

In both the Bip and Me_4DAB complexes with two *cis* G's or two *cis* Me_2Bzm ligands, one HT rotamer is more abundant than the other. Moreover, the major HT rotamer has the H8 or H2 signals (for G and Me_2Bzm adducts, respectively) downfield from that of the minor HT rotamer, an indication that these protons are less shielded by the *cis* base in the major HT rotamer than in the minor HT rotamer and that the two bases are more canted "6-in" in MHT than in mHT. Why the Me_2Bzm bases tend to be canted "6-in" in the HT rotamers is not clear. One possibility is that a stacking interaction can take place between *cis* Me_2Bzm bases. Therefore, as in the case of *cis* guanines, a "6-in" canting of the two bases is preferred because it ensures better stacking. Moreover, the canting can be greater when H2 is adjacent to the N–H (Bip complex) or to the "quasi axial" N–Me (Me_4DAB complex) of the *cis* amine than when H2 is adjacent to the N–CH_2– or to the "quasi equatorial" N–Me of the *cis* amine.

Thermodynamic Parameters: Both the MHT and mHT rotamers have lower enthalpy and entropy than the HH rotamer (Table 4). Therefore, the higher entropy of the HH rotamer leads to the preference of this isomer over the MHT and mHT forms. The values of ΔH and ΔS for the MHT and mHT rotamers are more dispersed in the Bip than in the Me_4DAB complex. This greater dispersion can be easily understood by keeping in mind that in the former case the two HT rotamers are more different (the six-membered ring of Me_2Bzm is on the side of the N–CH_2– of the *cis* amine in one rotamer and on the side of the N–H of the *cis* amine in the other rotamer) than in the latter case (both rotamers have the six-membered ring of each Me_2Bzm on the side of a N–Me of the *cis* amine).

For both the Bip and Me_4DAB complexes, the MHT rotamer has higher enthalpy and entropy than the mHT rotamer, and this greater entropy makes the former rotamer favored. The opposite trend was observed in the related $Me_2DABPtG_2$ complexes (G = 9-ethylguanine, 3′-GMP, and 5′-GMP)[29] for which the major HT rotamer was always lower in enthalpy and entropy than the minor HT rotamer, and the lower enthalpy was responsible for the greater abundance of the former rotamer with respect to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the latter. This appears to be a major difference between Me_2Bzm and G derivatives and can be correlated to the presence, in corresponding positions of the base ring-systems, of a proton (H4) in one case and of an oxygen (O6) in the latter case.

Conclusions

Comparisons of analogous complexes containing two *cis* Me_2Bzm or two *cis* guanine ligands have clarified the factors influencing the properties of the guanine complexes. Electrostatic interactions between *cis* G's have been found to be the major driving force in base canting. The repulsion between O6 of *cis* G's is responsible for the "6-out" canting of at least one G in the HH rotamer. On the other hand, electrostatic attraction between the O6 of one G and the H8 of the *cis* G and base stacking are responsible for the preferential "6-in" canting of the two G's in the HT rotamer. The "6-out" canting of a base in the HH rotamer may be impeded by steric interaction between the six-membered ring of this base and a substituent on the *cis* amine. Similarly, the "6-in" canting of each base in the HT rotamer may be limited by steric interaction between the H8 of the base and a substituent on the *cis* amine.

The role of electrostatic interactions is greatly reduced in *cis*-$PtA_2(Me_2Bzm)_2$ complexes, as compared to the *cis*-PtA_2G_2 analogs, because the Me_2Bzm bases lack an oxygen substituent. Nevertheless, for both types of complexes the six-membered rings of the two bases are found on the most crowded side of the *cis* amine with respect to the coordination plane for the major HT rotamer. Also, for both types of complexes the major HT has the signal for the five-membered ring proton (H2 for Me_2Bzm and H8 for G) less shielded than the signal of that proton of the minor HT. As previously concluded for *cis*-PtA_2G_2 analogs, these findings are clear indications that for Me_2Bzm complexes also the major HT rotamer has more canted "6-in" bases than the minor HT rotamer and that such a greater canting is favored by smaller steric interactions between the H2 proton of each base and substituents on the *cis* amine. In the absence of major electrostatic interactions, the driving force for such a "6-in" canting of the two Me_2Bzm bases is likely to be base-stacking.

Thermodynamic parameters confirm the crucial role played by the H4 and O6 substituents (for Me_2Bzm and G derivatives, respectively) in determining the stability of different rotamers.

Experimental Section

Materials: 5,6-Dimethylbenzimidazole was purchased from Aldrich. (*R*,*S*,*S*,*R*)-BipPt$(NO_3)_2$, (*S*,*R*,*R*,*S*)-BipPt$(NO_3)_2$, *rac*-BipPt$(NO_3)_2$,[24] (*S*,*S*)-Me_4DABPt$(NO_3)_2$, (*R*,*R*)-Me_4DABPt$(NO_3)_2$, and *rac*-Me_4DABPt$(NO_3)_2$ were synthesized as described elsewhere.[23]

Preparation of $[Me_4DABPt(Me_2Bzm)_2]^{2+}$ Complexes: Stock solutions of (*R*,*S*,*S*,*R*)-BipPt$(NO_3)_2$, (*S*,*R*,*R*,*S*)-BipPt$(NO_3)_2$, (*S*,*S*)-Me_4DABPt$(NO_3)_2$, and (*R*,*R*)-Me_4DABPt$(NO_3)_2$ (4 mM) and of *rac*-BipPt$(NO_3)_2$ and *rac*-Me_4DABPt$(NO_3)_2$ (ca. 8 mM) were prepared in D_2O. NMR samples were prepared by adding 300 μL of complex solution into an NMR tube containing a suspension of 5,6-Me_2Bzm in 350 μL of H_2O (Me_2Bzm:Pt = 2.3). The pH was adjusted to 6 with 1% DNO_3. The reaction, monitored by ^1H NMR spectroscopy (23 °C), required several days (at, 55 °C) for completion.

NMR Spectroscopy: 1D NMR spectroscopic data were collected with Unity Varian 600 MHz and Inova 600 MHz instruments. A selective presaturation pulse was employed to suppress the HDO resonance, and the residual HDO peak was used as reference. FID's were accumulated for 64 scans.

2D experiments were performed in D_2O with a Unity Varian 600 MHz spectrometer. 2048 × 512 Matrices were collected at 5 °C for rotational nuclear Overhauser (ROESY) and $^1H/^1H$ nuclear Overhauser (NOESY) experiments (spectral window of ca. 6000 Hz in both dimensions), 2048 × 256 Matrices were collected at 25 °C for $^1H/^{13}C$ heteronuclear multiple-quantum coherence experiments (HMQC).

Circular Dichroism (CD) Spectroscopy: Solutions (ca. 0.04 mM) for CD experiments were prepared by diluting 30 μL of the NMR solution into 3 mL of H_2O. CD spectra were recorded at room temperature from 350 to 200 nm on a JASCO J-600 CD spectropolarimeter.

Thermodynamic Parameters: The equilibrium constants (K_{MHT} = [MHT]/[HH] and K_{mHT} = [mHT]/[HH]) were evaluated from the percentages of the different rotamers at different temperatures. The plots of $\ln K_{MHT}$ and $\ln K_{mHT}$ as a function of $1/T$ were linear within the experimental errors, and from their slopes and intercepts the values of ΔH and ΔS for the transformations were evaluated. The estimated thermodynamic parameters are listed in Table 4.

Supporting Information (see footnote on the first page of this article): Assignment of the Me5, Me6, and H7 signals of the Me_2Bzm ligand for $[rac\text{-BipPt}(Me_2Bzm)_2]^{2+}$ and $[rac\text{-}Me_4DABPt(Me_2Bzm)_2]^{2+}$. Equilibrium constants K_{MHT} and K_{mHT} at different temperatures and plots of the logarithm of the equilibrium constants as a function of $1/T$.

[25] In previous related papers from our laboratories the expression "canted G base" was used to mean a G whose H8 experiences an upfield shifting effect caused by the ring-current anisotropy of the *cis* base (J. Kozelka, M. H. Fouchet, J. C. Chottard, *Eur. J. Biochem.* **1992**, *205*, 895–906). Conversely, the expression "uncanted base" was used to mean a G whose H8 is positioned away from the *cis* G and, therefore, is less shielded. In this paper the expression "canting" has been used to mean exclusively the sloping of a guanine plane on the coordination plane.
[26] The calculation has been performed starting from the X-ray structure of $Me_4DACHPtG_2$ ΔHT rotamer (ref.[21]) and rotating the two G's about the Pt–N7 bonds so as to have an HH conformer with guanine bases orthogonal to the coordination plane. Under these conditions the O6···O6 distance was found to be ca. 2.0 Å (sum of the van der Waals radii ca. 3.0 Å).

Structural Features of Titanium Complexes of Salicylaldiminato Derivatives of Amino Acids

Jens Müller,[a] Gerald Kehr,[a] Roland Fröhlich,[a] and Gerhard Erker*[a]

Keywords: Chelate ligands / Titanium / Tridentate ligands / Metallamacrocycles / Catalytic hydrocyanation

Condensation of salicylaldehyde with amino acid derivatives gave the salicylaldimine derivatives **3** that reacted with $TiCl_4$ with release of HCl to yield the chelate complexes [(SalPhgOMe)$TiCl_3$] (**4a**), [(SalValOMe)$TiCl_3$] (**4b**), and the dipeptide derivative [(SalAlaValOMe)$TiCl_3$] (**4d**). The complex [(Sal*PhgOMe)$TiCl_3$] (**4c**) was prepared analogously starting from 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde and phenylglycine methyl ester. Complex *rac*-**4a** was characterized by X-ray diffraction and shown to feature a typical structure where the monoanionic ligand is tridentate, coordinating to the central titanium atom through both the phenolate oxygen atom and the ester carbonyl oxygen atom as well as through the imine nitrogen atom. A hydrolyzed carboxylate analogue of **4a** exhibits an analogous central structural framework. In this case, however, the overall structure of *rac*-**5a** was found to be a metallacyclic tetramer where four titanium atoms bind four such tridentate ligands.

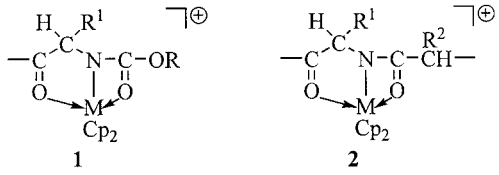
Introduction

Group 4 metal complexes of peptide derivatives are receiving an increased interest lately. This section of the field of coordination chemistry[1] has become of increasing importance with regard to a variety of ongoing developments. Thus, titanium–protein complexes may play a role in the cancerostatic potential of some organometallic complexes of this light Group 4 element.[2,3] Titanium as well as zirconium complexes of modified peptide ligands have found some useful applications in enantioselective catalysis.[4,5] Heterogenized oligopeptide–zirconium complexes have been thought to exhibit an enzyme-like behavior in some organophosphate hydrolysis reactions,[6] to mention a few such recent developments and observations in this growing field.[7]

We had recently studied the chemistry and the structural features of the reaction products between [Cp_2TiMe^+] or [Cp_2ZrMe^+] cations with a variety of oligopeptide derivatives.[8,9] Addition and subsequent liberation of methane eventually resulted in a variety of stable products that all showed the structural motif of a tridentate chelate complex framework (see Scheme 1). In some cases a carbonyl group of a protective group (e.g. Boc) was involved (**1**), in other cases it was the C=O group of the next amino acid building block that made up one of the fused chelate ring systems (**2**).



Scheme 1.

It was the question whether we had here observed a special structural feature of a specific class of Group 4 metallocene–peptide complexes or if the observed structural motif in the systems **1/2** was an example of a general structural type in this area of coordination chemistry. For that reason we have investigated a number of remotely related titanium complexes derived from very electrophilic Group 4 metal components. We actually found favoured related structural frameworks in systems that were obtained from the reactions of $TiCl_4$ with salicylaldiminato derivatives of amino acids and dipeptides. Some representative examples are described and discussed in this article.

Results and Discussion

We have prepared a small series of salicylaldimine ligands (**3a**–**d**) by treatment of salicylaldehyde with the hydrochlorides of the respective amino acid methyl esters in dichloromethane with the aid of triethylamine.[10] For this study we have employed the amino acids (L)-phenylglycine and (L)-valine. For the synthesis of **3c** we have used 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde as the coupling component. The chelate ligand **3d** was prepared by condensation

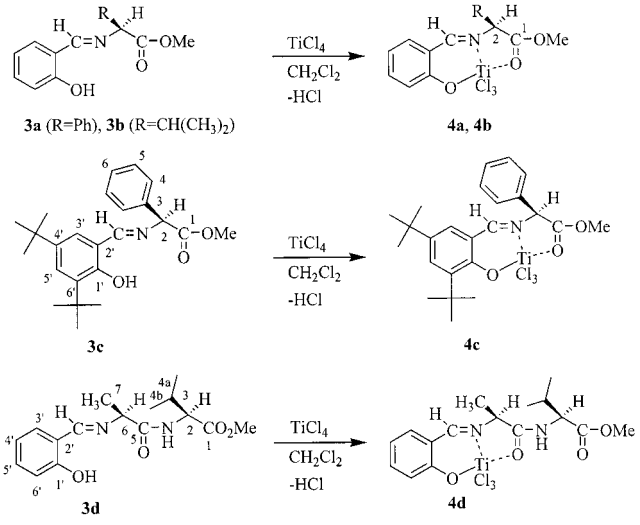
Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

of salicylaldehyde with the peptide derivative HAlaValOMe (employed as the TFA adduct).

Treatment of the ligand system **3a** with $TiCl_4$ proceeded cleanly in dichloromethane solution with cleavage of HCl (Scheme 2). After a reaction time of ca. 1.5 h, the complex formation was complete. After workup, the product **4a** was isolated as a red solid in ca. 90% yield. The corresponding titanium complexes [(SalValOMe)$TiCl_3$] (**4b**), [(Sal*PhgOMe)$TiCl_3$] (**4c**), and the dipeptide-derived product [(SalAlaValOMe)$TiCl_3$] (**4d**) were synthesized analogously by treatment of the free HO-containing ligands with $TiCl_4$ in dichloromethane with cleavage of 1 equiv. of HCl. The reactions were practically quantitative, and these products were isolated in yields between 85% and 96%.



Scheme 2.

The complexes **4a**–**d** were characterized spectroscopically (see below) and by C,H,N elemental analyses. Single crystals of **4a** were obtained from a saturated THF solution at –22 °C, which allowed characterization by an X-ray crystal structure analysis (see Figure 1). The (SalPhgOMe) system is sensitive to racemization, and it seems that the racemate of the corresponding Ti complex (*rac*-**4a**) crystallizes much easier than its pure enantiomers. Therefore, we have only obtained single crystals of *rac*-**4a** (and consequently also of its derivative *rac*-**5a**) for the X-ray crystal structure analyses, despite numerous attempts to crystallize the enantiomerically pure compounds. Therefore, the degree of enantiomeric purity of the complexes **4**, derived from single amino acids, must remain open at this time. In the case of the dipeptide derivative **4d**, we only observed a single diastereoisomer by NMR spectroscopy, which indicates that enantiomerization at the proximal amino acid (Ala) in this (and probably the related **4b**) system, seems not to be a serious problem under the applied conditions. The ligands **3a** (SalPheOMe) and **3b** (SalValOMe) crystallized as the pure enantiomers (for details see the Exp. Sect. and the Supporting Information; for Supporting Information see also the footnote on the first page of this article).

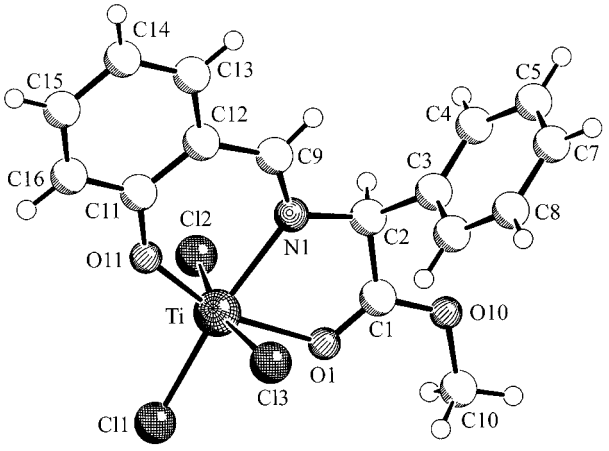


Figure 1. View of the molecular structure of the [(SalPhgOMe)-$TiCl_3$] complex *rac*-**4a**; selected bond lengths [Å] and angles [°]: Ti–Cl1 2.265(1), Ti–Cl2 2.327(1), Ti–Cl3 2.319(1), Ti–N1 2.177(2), Ti–O1 2.111(2), Ti–O11 1.797(2), C1–O10 1.303(3), C1–C2 1.507(3), C2–C3 1.520(3), C2–N1 1.482(3), N1–C9 1.281(3), C9–C12 1.448(3), C11–O11 1.346(3); Cl1–Ti–Cl2 93.9(1), Cl1–Ti–Cl3 94.7(1), Cl1–Ti–N1 171.3(1), Cl1–Ti–O1 96.5(1), Cl1–Ti–O11 104.1(1), Cl2–Ti–Cl3 165.3(1), Cl2–Ti–N1 84.6(1), Cl2–Ti–O1 83.9(1), Cl2–Ti–O11 95.3(1), Cl3–Ti–N1 85.1(1), Cl3–Ti–O1 83.3(1), Cl3–Ti–O11 94.2(1), N1–Ti–O1 74.9(1), N1–Ti–O11 84.5(1), O1–Ti–O11 159.4(1), Ti–O1–C1 119.8(1), O1–C1–O10 123.5(2), O1–C1–C2 121.9(2), O10–C1–C2 114.5(2), C1–C2–N1 106.2(2), C2–N1–C9 118.0(2), Ti–N1–C2 116.1(1), Ti–N1–C9 125.9(1), Ti–O11–C11 141.0(1). For additional values see the text.

In complex *rac*-**4a** the (SalPhgOMe) ligand binds to the titanium atom through the phenolic oxygen atom, the imine nitrogen atom and the ester carbonyl oxygen atom. The core atoms of this tridentate chelate ligands are oriented close to planar. The bond between Ti and the phenolic oxygen atom O11 is short [1.797(2) Å] and the corresponding Ti–O11–C11 angle [141.0(1)°] is substantially enlarged.[11] The Ti–N1 linkage amounts to 2.177(2) Å, with the C9–N1 bond [1.281(3) Å] being in the typical C=N double bond range.[12] The nitrogen atom N1 shows a trigonal-planar coordination geometry [Ti–N1–C9: 125.9(1)°, Ti–N1–C2: 116.1(1)°, C9–N1–C2: 118.0(2)°]. The Ti–O1 distance is 2.111(2) Å, and the corresponding C1–O1–Ti angle was found at 119.8(1)°. The C1–O1 length [1.229(3) Å] is in the typical carbonyl C=O double bond range. The adjacent C1–O10 bond is much longer at 1.303(3) Å.

The coordination geometry at the central titanium atom is distorted octahedral. There is a pronounced *trans* effect: The Ti–Cl1 bond (*trans* to N1) is much shorter [2.265(1) Å] than the Ti–Cl2 [2.327(1) Å] and Ti–Cl3 [2.319(1) Å] bonds. The three *trans* angles amount to 171.3(1)° (Cl1–Ti–N1), 165.3(1)° (Cl2–Ti–Cl3) and 159.4(1)° (O1–Ti–O11). Ten of the twelve *cis* angles are within a narrow range between 83.3(1)° and 96.5(1)°. Only the N1–Ti–O1 angle is markedly smaller at 74.9(1)°, which probably is a typical feature of the five-membered chelate substructure. Consequently, the adjacent O11–Ti–Cl1 angle is widened to 104.1(1)°.

Complex **4a** seems to adopt a similar structure in solution. The ^{13}C NMR spectra clearly indicate the coordina-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion of the ester carbonyl group. On going from the ligand (**3a**: δC1 = 171.1 ppm) to the complex **4a** (δC1 = 182.3 ppm) this carbonyl carbon resonance is shifted to larger δ values by $\Delta\delta$ = +11.2 ppm. This is very characteristic for the formation of a Ti–O=C metal coordination.[8,9] The coordination is also evidenced by a similar shifting of the adjacent OCH_3 resonances on going from **3a** to **4a** (^{1}H: $\Delta\delta$ = +0.48 ppm; ^{13}C: $\Delta\delta$ = +6.8 ppm; see Table 1). The evidence for the imine coordination to the titanium atom comes from a comparison of the ^{15}N NMR spectra. Complex **4a** features a ^{15}N NMR imine nitrogen resonance at δ = –104.9 ppm, which is shifted by $\Delta\delta$ = –16.3 ppm relative to the noncoordinated **3a** reference. In contrast, the increased coordination number of the imine nitrogen atom in **4a** does not lead to very characteristic differences in the ^{13}C ($\Delta\delta$ = –1.9 ppm) or ^{1}H NMR spectra. The complexes **4b**–**d** show similar spectroscopic features (see Table 1), so that we must assume analogous solution structures of these compounds featuring tridentate salicylaldimine/amino acid derived chelate ligands.

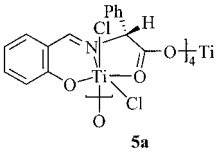
During an attempt to crystallize complex **4a** from dichloromethane, apparently some of the compound was unintendedly hydrolyzed and single crystals of the Ti–chelate carboxylate complex *rac*-**5a** were isolated (see Scheme 3). In the crystal state this complex attains an interesting tetranuclear structure (see Figures 2 and 3) in which the chelate carboxylates have become connected in a metallacyclic fashion by means of a bridging octahedrally coordinated quartet of titanium atoms. The coordination of each of the four subunits is chemically equivalent, although crystallographically slightly different. Again, we find the same structural framework motif that was already observed in the related monomeric complex **4a** (see above). This shall be illustrated with the subunit A in the tetramer of **5a** in the crystal.

The substructures of *rac*-**5a** feature the typical array of Ti–O/N bonds at their distorted octahedral Ti atom. In the subunit A of *rac*-**5a** the Ti–O3 bond length is 1.803(4) Å, which is almost as short as the respective bond in *rac*-**4a** (see above). The Ti–N1 linkage in *rac*-**5a** amounts to 2.164(5) Å, the adjacent C3–N1 double bond has a length of 1.274(7) Å. The O1–Ti distance in *rac*-**5a** was found at 2.002(4) Å, and the C1–O1 bond [1.267(6) Å] is in the typical carboxylate C=O bond range.[12] The C1–O2 distance in the Ti–carboxylate is in a similar range [1.247(6) Å]. The O2(A)–Ti1(B) bond length amounts to 2.054(4) Å. The Ti1(A)–O2(D) distance is 2.086(4) Å. Together with the pair of remaining chloride ligands [Ti–Cl1: 2.262(2) Å; Ti–Cl2: 2.261(2) Å] this completes the distorted octahedral co-



Scheme 3.

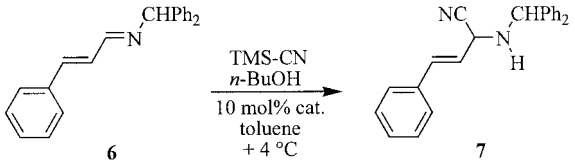
ordination geometry around the central titanium atom of this subunit. As expected, the three *trans* angles deviate in a typical manner from the ideal 180° [O3A–Ti1A–O1A: 157.3(2)°; O2D–Ti1A–Cl2A: 173.7(1)°; N1A–Ti1A–Cl1A: 169.4(1)°]. The *cis* angles are in a narrow range between 83.6(2)° and 97.6(2)°, again with the exception of the small O1A–Ti1A–N1A angle inside the five-membered ring substructure of the chelate [75.0(2)°]. As previously observed for the structure of *rac*-**4a**, this also leads to an increased O3A–Ti1A–Cl1A angle [104.2(2)°] in the Ti–carboxylate *rac*-**5a**.

The complexes **4** were briefly checked for their catalytic activity. For this characterization we used the hydrocyanation reaction of **6** to yield **7** (see Scheme 4), a system that was described previously by Hoveyda et al.[5,13] The complexes **4b**–**d** were employed. They all were more active than the in situ catalyst, generated by treatment of **3b** with $Ti(OiPr)_4$. Not unexpectedly, we did not observe any asymmetric induction with any of these simple catalyst systems under the applied reaction conditions at +4 °C.[4,5] However, the conversion of **6** to **7** showed very low *ee* values of ca. 6–9%, when carried out with the **4b** catalyst system at –78 °C.



Scheme 4.

Conclusions

This study has shown that $TiCl_4$ reacts with the salicylaldimine derivatives **3** with cleavage of HCl to give tridentate chelate complex structures of a type which is reminiscent of the oligopeptide–metallocene cation complexes that we had obtained and structurally characterized previously (see Scheme 1).[8,9] It seems that the electrophilic Group 4 metals in general favour the formation of such tridentate chelate structures whenever it is possible. In the case of the peptide-derived systems **1** and **2** (see above) tridentate chelate complex frameworks were formed, featuring anellated five- and four-membered ring structures, whereas in the case of the systems **4** the salicylaldimine moiety was involved in the formation of a closely related framework built up of anellated six- and five-membered chelate ring systems. Since these chelate structures form so easily, it can probably be assumed that similar structures are also readily available in the reactions of such ligand precursors with e.g. $Ti(OiPr)_4$. It may be that such structures play an important role in the respective catalyst systems, as proposed,[5] although in the previous studies the catalysts were usually generated in situ and not isolated or structurally characterized. Since the isolated complexes **4** are catalytically active, it may be tempting to actually prepare, isolate and structurally characterize such a catalyst by using an optimized longer oligopeptide-derived ligand system known from the literature[5] to gain direct experimental evidence of the stereochemical features of such active catalyst systems.

Experimental Section

General Remarks: Reactions with air- and moisture-sensitive compounds or reagents were carried out under argon using Schlenk-type glassware or in a glovebox. Solvents were dried and distilled under argon prior to use. For additional general information, including a list of the instruments used for physical characterization of the compounds see refs.[8,9] For the atom numbering scheme used in the NMR listings, see Scheme 2. Most NMR assignments were secured by additional 2D NMR experiments [^1H-^{15}N ghmbc experiment based on an $^nJ(^{15}N,^1H)$ coupling constant of 5 Hz].[14]

X-ray Crystal Structure Analyses: Data sets were collected with Enraf Nonius CAD4 and Nonius KappaCCD diffractometers, in case of Mo radiation, equipped with a rotating anode generator. Programs used: Data collection EXPRESS (Nonius B.V., **1994**) and COLLECT (Nonius B.V., **1998**), data reduction MolEN (K. Fair, Enraf–Nonius B. V., **1990**) and Denzo-SMN (Z. Otwinowski, W. Minor, *Methods in Enzymology*, **1997**, *276*, 307–326), absorption correction for CCD data SORTAV (R. H. Blessing, *Acta Crystallogr.* **1995**, *A51*, 33–37; R.H. Blessing, *J. Appl. Crystallogr.* **1997**, *30*, 421–426) and Denzo (Z. Otwinowski, D. Borek, W. Majewski, W. Minor, *Acta Crystallogr.* **2003**, *A59*, 228–234), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Crystallogr.* **1990**, *A46*, 467–473), structure refinement SHELXL-97 (G. M. Sheldrick, University of Göttingen, **1997**), graphics SCHAKAL (E. Keller, **1997**) and DIAMOND (K. Brandenburg, University of Bonn, **1997**). CCDC-261081, -261082, -261560 and -261561 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Preparation of the Salicylaldimines

SalPhgOMe (3a): Triethylamine (2.48 g, 24.6 mmol, 1.05 equiv.) was added to a suspension of HCl·H–Phg–OMe (3.00 g, 24.6 mmol, 1.05 equiv.) in dichloromethane (40 mL). After addition of salicylaldehyde (4.71 g, 23.4 mmol, 1.00 equiv.), the colour of the solution turned yellow and the reaction mixture was stirred at room temperature overnight. The solution was washed twice with water and the organic layer dried with magnesium sulfate. Removal of the solvent (at ca. +5 °C to avoid racemisation) led to a yellow solid (5.36 g, 19.9 mmol, 85%). Single crystals for the X-ray crystal structure analysis were obtained by crystallisation from ethanol at –22 °C. M.p. 65.6 °C. $C_{16}H_{15}NO_3$ (269.3): calcd. C 71.63, H 5.61, N 5.20; found C 71.33, H 5.63, N 5.22. $[\alpha]_D^{20} = -26.8$ ($c = 0.3$, $CHCl_3$). IR (KBr): $\tilde{\nu}$ = 2949, 2743, 2675, 2492, 1749, 1629, 1576, 1496, 1464, 1440, 1405, 1315, 1281, 1258, 1209, 1167, 1150, 1127, 1092, 1060, 1036, 982, 854, 776, 758, 742, 731, 697, 612, 561, 521 cm^{-1}. ^1H NMR (300.1 MHz, CD_2Cl_2, 298 K): δ = 13.06 (s, 1 H, OH), 8.40 (s, 1 H, CH=N), 7.46–7.26 (m, 7 H, H_{phenyl}), 6.98–6.89 (m, 2 H, H_{phenyl}), 5.20 (s, 1 H, 2-H), 3.75 (s, 3 H, OCH_3) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 171.1 (C-1), 167.4 (CH=N), 161.4 (C–OH), 137.7, 133.3, 132.4, 129.3, 128.8, 128.2, 119.6, 117.3 (C_{phenyl}), 75.1 (C-2), 53.0 (OCH_3) ppm. GHMBC (60.8/599.8 MHz, CD_2Cl_2, 298 K): δ (^{15}N)/δ(^1H) = –88.6/13.06, 8.40, 5.20 (CH=*N*/1′-O*H*, C*H*=N, 2-H) ppm.

SalValOMe (3b): According to the preparation of **3a**, HCl·H–ValOMe (3.00 g, 17.9 mmol) was treated with triethylamine (1.81 g,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

17.9 mmol) and salicylaldehyde (2.08 g, 17.0 mmol) to yield **3b** as a yellow solid (3.32 g, 14.1 mmol, 83%). Single crystals for the X-ray crystal structure analysis were obtained by crystallisation from a 1:1 mixture of pentane/diethyl ether at –22 °C. M.p. 34.9 °C. $C_{13}H_{17}NO_3$ (235.3): calcd. C 66.36, H 7.28, N 5.95; found C 66.37, H 7.26, N 5.85. $[\alpha]_D^{20}$ = –38.4 (*c* = 1.0, $CHCl_3$), IR (KBr): $\tilde{\nu}$ = 2955, 2344, 1736, 1625, 1573, 1493, 1455, 1429, 1409, 1338, 1368, 1331, 1305, 1276, 1196, 1173, 1137, 1115, 1060, 1032, 1020, 977, 880, 847, 762, 736, 675, 663, 601, 549, 461 cm^{-1}. ^1H NMR (300.1 MHz, CD_2Cl_2, 298 K): δ = 13.11 (s, 1 H, OH), 8.33 (s, 1 H, CH=N), 7.40–7.30 (m, 2 H, H_{phenyl}), 6.97–6.85 (m, 2 H, H_{phenyl}), 3.77 (d, ^3J = 6.3 Hz, 1 H, 2-H), 3.74 (s, 3 H, OCH_3), 2.38 (m, 1 H, CH_{iPr}), 0.97 (d, ^3J = 6.8 Hz, 6 H, 2 CH_3) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, CD_2Cl_2, 298 K): δ = 172.2 (C-1), 167.5 (CH=N), 162.0 (C–OH), 133.5, 132.5, 119.4, 117.7 (C_{phenyl}), 78.5 (C-2), 52.7 (OCH_3), 32.7 (CH_{iPr}), 19.9, 18.7 (2 CH_3) ppm.

Sal*PhgOMe (3c): Triethylamine (173 mg, 1.70 mmol, 1.00 equiv.) was added to a solution of HCl·H–Phg–OMe (344 mg, 1.70 mmol, 1.00 equiv.) in ethanol (20 mL). After addition of 3,5-di-*tert*-butyl-2-hydroxybenzaldehyde (400 mg, 1.70 mmol, 1.00 equiv.), the reaction mixture was stirred at room temperature for 3 d. The solvent was removed and the residue taken up in dichloromethane (20 mL). The yellow solution was washed twice with an aqueous 5% $NaHCO_3$ solution (20 mL) and once with water (20 mL). The organic layer was dried with magnesium sulfate and removal of the solvent led to 532 mg (1.39 mmol, 82%) of a yellow solid. M.p. 93.0 °C. $C_{24}H_{31}NO_3$ (381.5): calcd. C 75.56, H 8.19, N 3.67; found C 75.43, H 8.27, N 3.44. $[\alpha]_D^{20}$ = –6.9 (*c* = 0.16, CH_2Cl_2). IR (KBr): $\tilde{\nu}$ = 3482, 3417, 2961, 2869, 1752, 1630, 1474, 1452, 1439, 1391, 1365, 1322, 1274, 1252, 1200, 1161, 1087, 1065, 835, 726, 696, 504 cm^{-1}. ^1H NMR (599.8 MHz, CD_2Cl_2, 298 K): δ = 13.49 (s, 1 H, OH), 8.42 (s, 1 H, CH=N), 7.48 (m, 2 H, 4-H), 7.43 (AB, ^4J = 2.4 Hz, 1 H, 5′-H), 7.41 (m, 2 H, 5-H), 7.36 (m, 1 H, 6-H), 7.12 (AB, ^4J = 2.4 Hz, 1 H, 3′-H), 5.20 (s, 1 H, 2-H), 3.76 (s, 3 H, OCH_3), 1.46 [s, 9 H, 6′–$C(CH_3)_3$], 1.30 [s, 9 H, 4′-$C(CH_3)_3$] ppm. $^{13}C\{^1H\}$ NMR (150.8 MHz, CD_2Cl_2, 298 K): δ = 171.3 (C-1), 168.6 (CH=N), 158.3 (C-1′), 140.9 (C-4′), 137.9 (C-3), 137.1 (C-6′), 129.3 (C-5), 128.8 (C-6), 128.2 (C-4), 128.2 (C-5′), 127.0 (C-3′), 118.2 (C-2′), 75.0 (C-2), 52.9 (OCH_3), 35.3 [6′-*C*(CH_3)$_3$], 34.4 [4′-*C*(CH_3)$_3$], 31.5 [4′-C(*C*H$_3$)$_3$], 29.5 [6′-C(*C*H$_3$)$_3$] ppm.

SalAlaValOMe (3d): Triethylamine (320 mg, 3.16 mmol, 1.05 equiv.) was added to a solution of TFA·H–Ala–Val–OMe (1.00 mg, 3.16 mmol, 1.05 equiv.) in ethanol (20 mL). After addition of salicylaldehyde (367 mg, 3.01 mmol, 1.00 equiv.), the reaction mixture was stirred at room temperature for 2 d. The solvent was removed and the residue taken up in dichloromethane (20 mL). The yellow solution was washed twice with an aqueous 5% $NaHCO_3$ solution (20 mL) and once with water (20 mL). The organic layer was dried with magnesium sulfate and removal of the solvent led to 692 mg (2.26 mmol, 75%) of a yellow oil. $C_{16}H_{22}N_2O_4$ (306.4): calcd. C 62.73, H 7.24, N 9.14; found C 62.72, H 7.05, N 9.05. $[\alpha]_D^{20}$ = +112.0 (*c* = 0.1, CH_2Cl_2). IR (KBr): $\tilde{\nu}$ = 3426, 2965, 2926, 2869, 2365, 1739, 1669, 1626, 1587, 1517, 1465, 1435, 1369, 1317, 1283, 1204, 1152, 1034, 912, 756, 626 cm^{-1}. ^1H NMR (499.8 MHz, C_6D_6, 298 K): δ = 12.85 (s, 1 H, OH), 7.53 (s, 1H CH=N), 7.02 (m, 1 H, 6′-H), 7.00 (m, 1 H, 4′-H), 6.80 (ABCD, ^3J = 7.7, ^4J = 1.4 Hz, 1 H, 3′-H), 6.64 (ABCD, ^3J = 7.5, ^4J = 1.6 Hz, 1 H, 5′-H), 6.61 (d, ^3J = 8.7 Hz, 1 H, NH), 4.77 (m, 1 H, 2-H), 3.64 (q, ^3J = 6.8 Hz, 1 H, 6-H), 3.17 (s, 3 H, OCH_3), 2.03 (m, 1 H, 3-H), 1.34 (d, ^3J = 6.9 Hz, 3 H, 7-H), 0.85 (d, ^3J = 6.9 Hz, 3 H, 4a-H), 0.77 (d, ^3J = 6.9 Hz, 3-H, 4b-H) ppm. $^{13}C\{^1H\}$ NMR (125.7 MHz, C_6D_6, 298 K): δ = 172.0 (C-1), 171.5 (C-5), 167.1 (CH=N), 161.6 (C-1′), 133.2 (C-4′), 132.3 (C-3′), 119.0 (C-5′), 118.9 (C-2′), 117.5 (C-6′), 68.6 (C-6), 57.1 (C-2), 51.5 (OCH_3), 31.4 (C-3), 20.9 (C-7), 19.0 (C-4a), 17.5 (C-4b) ppm.

Preparation of the Titanium Complexes

[(SalPhgOMe)TiCl$_3$] (4a): $TiCl_4$ (1.10 g, 5.79 mmol, 1.00 equiv.) was added to a solution of SalPhgOMe (**3a**) (1.56 g, 5.79 mmol, 1.00 equiv.) in dichloromethane (20 mL). The colour of the solution immediately turned red. After stirring at room temperature for 1.5 h, the solvent was removed and the red solid (2.75 g, 5.21 mmol, 90%) dried in vacuo. Single crystals for the X-ray crystal structure analysis were obtained by crystallisation from THF at –22 °C. Decomp. 207.4 °C. $C_{16}H_{14}Cl_3NO_3Ti{\cdot}1.25CH_2Cl_2$ (528.7): calcd. C 39.19, H 3.15, N 2.65; found C 39.56, H 3.04, N 2.61. $[\alpha]_D^{20}$ = –43.2 (*c* = 0.25, CH_2Cl_2). IR (KBr): $\tilde{\nu}$ = 3439, 3062, 2960, 2870, 1649, 1616, 1596, 1560, 1496, 1475, 1453, 1370, 1273, 1251, 1228, 1156, 1123, 1051, 1030, 1005, 921, 841, 763, 734, 703, 661, 586, 551, 456, 427 cm^{-1}. ^1H NMR (499.8 MHz, CD_2Cl_2, 298 K): δ = 7.99 (d, ^4J = 2.0 Hz, 1 H, CH=N), 7.66 (ABCD, ^3J = 8.5, ^4J = 2.0 Hz, 1 H, 5′-H), 7.51 (m, 5 H, 4-H, 5-H u. 6-H), 7.39 (ABCD, ^3J = 8.5, ^4J = 1.5 Hz, 1 H, 3′-H), 7.19 (ABCD, ^3J = 8.5, ^4J = 1.0 Hz, 1 H, 4′-H), 6.91 (ABCD, ^3J = 8.5 Hz, 1 H, 6′-H), 5.99 (d, ^4J = 2 Hz, 1 H, 2-H), 4.23 (d, ^5J = 2 Hz, 3 H, OCH_3) ppm. $^{13}C\{^1H\}$ NMR (125.7 MHz, CD_2Cl_2, 298 K): δ = 182.3 (C-1), 165.2 (CH=N), 162.1 (C-1′), 137.8 (C-5′), 135.7 (C-3′), 133.6 (C-3), 130.8 (C-5), 130.4 (C-4 u. C-6), 125.8 (C-2′), 125.6 (C-4′), 114.9 (C-6′), 75.6 (C-2), 58.8 (OCH_3). GHMBC (60.8/599.8 MHz, CD_2Cl_2, 298 K): δ (^{15}N)/δ (^1H) = –104.9/7.99 (CH=*N*/C*H*=N) ppm.

X-ray Crystal Structure Analysis of *rac*-4a: Formula $C_{16}H_{14}Cl_3NO_3Ti{\cdot}3C_4H_8O$, *M* = 638.84, red crystal 0.35 × 0.20 × 0.15 mm, *a* = 10.396(1), *b* = 19.708(1), *c* = 15.139(1) Å, β = 91.83(1)°, *V* = 3100.2(4) $Å^3$, $\rho_{calcd.}$ = 1.369 g cm^{-3}, μ = 5.75 cm^{-1}, empirical absorption correction (0.824 ≤ *T* ≤ 0.919), *Z* = 4, monoclinic, space group $P2_1/c$ (No. 14), λ = 0.71073 Å, *T* = 198 K, ω- and φ-scans, 20865 reflections collected (±*h*, ±*k*, ±*l*), [(sinθ)/λ] = 0.66 $Å^{-1}$, 7378 independent (R_{int} = 0.037) and 5630 observed reflections [$I \geq 2\sigma(I)$], 353 refined parameters, *R* = 0.048, wR_2 = 0.121, max./min. residual electron density 0.46/–0.47 e·$Å^{-3}$, hydrogen atoms calculated and refined as riding atoms.

[(SalValOMe)TiCl$_3$] (4b): According to the preparation of **4a**, SalValOMe (**3b**) (500 mg, 2.13 mmol) was treated with $TiCl_4$ (403 mg, 2.13 mmol) to yield **4b** as a red solid (850 mg, 2.04 mmol, 96%). Decomp. 207.4 °C. $C_{13}H_{16}Cl_3NO_3Ti{\cdot}1/3CH_2Cl_2$ (416.8): calcd. C 38.42, H 4.03, N 3.36; found C 38.48, H 3.93, N 3.50. $[\alpha]_D^{20}$ = +204.4 (*c* = 0.125, CH_2Cl_2). IR (KBr): $\tilde{\nu}$ = 2966, 2934, 2874, 1752, 1643, 1598, 1460, 1399, 1377, 1318, 1273, 1251, 1227, 1155, 1123, 1098, 1055, 984, 920, 844, 759, 663, 558, 456, 416 cm^{-1}. ^1H NMR (599.8 MHz, CD_2Cl_2, 298 K): δ = 8.35 (s, 1 H, CH=N), 7.69 (ABCD, ^3J = 7.8, ^4J = 1.5 Hz, 1 H, 5′-H), 7.63 (ABCD, ^3J = 7.8, ^4J = 1.5 Hz, 1 H, 3′-H), 7.25 (ABCD, ^3J = 7.8, ^4J = 1.2 Hz, 1 H, 4′-H), 6.89 (ABCD, ^3J = 7.8 Hz, 1 H, 6′-H), 4.62 (dd, ^3J = 5.9, ^4J = 0.8 Hz, 1 H, 2-H), 4.32 (s, 3H OCH_3), 2.64 (m, 1 H, 3-H), 1.20 (d, ^3J = 6.8 Hz, 3 H, 4a-H), 1.16 (d, ^3J = 6.8 Hz, 3 H, 4b-H) ppm. $^{13}C\{^1H\}$ NMR (150.8 MHz, CD_2Cl_2, 298 K): δ = 183.5 (C-1), 164.2 (CH=N), 162.0 (C-1′), 137.7 (C-5′), 135.8 (C-3′), 125.8 (C-2′), 125.5 (C-4′), 114.9 (C-6′), 78.0 (C-2), 58.4 (OCH_3), 34.7 (C-3), 20.7 (C-4a), 19.0 (C-4b) ppm.

[(Sal*PhgOMe)TiCl$_3$] (4c): According to the preparation of **4a**, Sal*PhgOMe (**3c**) (200 mg, 0.52 mmol) was treated with $TiCl_4$ (100 mg, 0.52 mmol) to yield **4c** as a red solid (330 mg, 0.44 mmol, 85%). Decomp. 336.5 °C. $C_{24}H_{30}Cl_3NO_3Ti{\cdot}2.5CH_2Cl_2$ (747.1): calcd. C 42.60, H 4.72, N 1.87; found C 42.95, H 4.58, N 2.18. $[\alpha]_D^{20}$ = –27.3 (*c* = 0.08, CH_2Cl_2). X-ray Crystal Structure Analysis of *rac*-5a: Formula $C_{15}H_{11}Cl_2NO_3Ti{\cdot}CH_2Cl_2$, M = 456.97, red crystal 0.25 × 0.10 × 0.07 mm, a = 14.182(1), b = 14.401(1), c = 19.735(1) Å, α = 75.70(1), β = 89.91(1), γ = 85.97(1)°, V = 3895.5(4) Å^3, $\rho_{calcd.}$ = 1.558 g cm^{-3}, μ = 10.02 cm^{-1}, empirical absorption correction (0.788 ≤ T ≤ 0.933), Z = 8, triclinic, space group $P\bar{1}$ (No. 2), λ = 0.71073 Å, T = 198 K, ω- and φ-scans, 37081 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.62 Å^{-1}, 15775 independent (R_{int} = 0.058) and 10717 observed reflections [$I \geq 2\ \sigma(I)$], 912 refined parameters, R = 0.080, wR_2 = 0.214, max./min. residual electron density 1.84/–0.97 e·Å^{-3} in the region of the solvent molecules, phenyl group C21B–C26B refined with split positions, some of the solvent molecules heavily disordered, refinement with split positions did not improve the model, hydrogen atoms calculated and refined as riding atoms.

Catalytic Hydrocyanation Reactions: The catalyst (0.043 mmol) was dissolved in toluene(2 mL) under argon. After stirring at room temperature for 10 min, imine **6** (0.43 mmol)[13] was added and the mixture was cooled to 4 °C. After an equilibration time of 20 min, trimethylsilyl cyanide (0.85 mmol) was added and a solution of *n*-butanol (0.64 mmol) in toluene (2 mL) was added through a syringe pump over a period of 10 h. After further stirring at 4 °C for 14 h, the reaction was quenched by the addition of diethyl ether (5 mL). Filtration through a plug of silica gel, removal of the solvent and crystallisation from a 1:1 mixture of diethyl ether/pentane at –22 °C yielded the product. Enantiomeric analysis was carried out by HPLC (Kromasil, KR100-5CHI-TBB, 250 × 4.6 mm, flow 0.5 mL/min, *n*-hexane) after a reaction time of 12 and 24 h, respectively. Details are provided with the Supporting Information.

Supporting Information (see also footnote on the first page of this article): Additional spectroscopic data of the compounds **3** and **4**; X-ray crystal structure analyses of the compounds **3a** and **3b**; details of the catalytic hydrocyanation reactions.

Reactions of Zirconocene Bis(trimethylsilyl)acetylene Complexes with Fluorinated Pyridines: C–H vs. C–F Bond Activation

Ulrike Jäger-Fiedler,[a] Perdita Arndt,[a] Wolfgang Baumann,[a] Anke Spannenberg,[a] Vladimir V. Burlakov,[b] and Uwe Rosenthal*[a]

Keywords: Zirconocene / C–F bond activation / C–H bond activation / Organometallics / Heterocycles

The zirconocene complexes $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (**1a**: L = THF; **1b**: L = pyridine) and the ethylene bis(tetrahydroindenyl) complex *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (**2**) react with 2,3,5,6-tetrafluoropyridine with C–H bond activation to produce the 4-substituted pyridyl complexes with agostic alkenyl groups $Cp'_2Zr(4\text{-}C_5NF_4)[\text{–}C(SiMe_3)=CH(SiMe_3)]$ ($Cp'_2 = Cp_2$) (**3**) and (Cp'_2 = ebthi) (**4**). With 2,3,4,6-tetrafluoropyridine, after C–H bond activation, complex **2** yields two isomers of the 5-substituted pyridyl complex *rac*-(ebthi)$Zr(3\text{-}C_5NF_4)[\text{–}C(SiMe_3)=CH(SiMe_3)]$ with agostic alkenyl groups, **5a** and **5b**. With pentafluoropyridine complex **1b** gives, after dissociation of the bis(trimethylsilyl)acetylene (btmsa), C–F bond activation at the 4-position and formation of $Cp_2Zr(4\text{-}C_5NF_4)F$ (**6**). Complex **1b** reacts with 3-chloro-2,4,5,6-tetrafluoropyridine by means of a preferred C–Cl activation to give $Cp_2Zr(3\text{-}C_5NF_4)Cl$ (**7**). These results are in contrast to the reactions of the titanium complex $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ which, with 2,3,5,6-tetrafluoropyridine, gave C–F activation in preference to C–H activation. With pentafluoropyridine, C–F bond activation at the 2-position was found rather than at the 4-position.

Introduction

Among reactions of different titanocene and zirconocene complexes of bis(trimethylsilyl)acetylene $Cp_2M(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (M = Ti, without L; M = Zr, L = THF, pyridine), the activation of seemingly unreactive bonds by the pentamethylcyclopentadienyl complexes $Cp^*_2M(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (M = Ti, Zr) and the ethylene bis(tetrahydroindenyl) complexes *rac*-(ebthi)$M(\eta^2\text{–}Me_3SiC_2SiMe_3)$ (M = Ti, Zr) has been described by us in some reviews.[1–10] For example, cleavage of C–H, C–C (Cp-ring opening, cleavage of butadiynes), Si–C, P–C, N–H, N–C, N–N, Si–O, N–O, C–O, C–S and C–B bonds gave complexes with potential applications in stoichiometric and catalytic reactions.

The inertness of fluorocarbons is a consequence of the great strength of the C–F bond which arises from the small size and the high electronegativity of the fluorine atom. Nevertheless, the activation of several types of carbon–fluorine bonds by transition metal complexes has been summarised in many reviews.[11–16]

Examples of the activation of C–F bonds by electron-deficient group 4 transition-metal species of zirconium and titanium with subsequent C–F bond cleavage are relatively rare. One of the first examples for titanium was reported by Stone et al. who isolated $Cp_2Ti(C_6F_5)F$ upon pyrolysis of $Cp_2Ti(C_6F_5)_2$.[17] Later Burk and coworkers described the elimination of a cyclopropane $(CH_2)_2CR_2$ and the formation of a titanocene-fluoro-dienone complex $Cp_2Ti(F)[(O\text{–}C(CCF_3)_3C=CF_2)]$ by F-abstraction in the reaction of a tetrakis(trifluoromethyl)cyclopentadienone-titanacyclobutane complex $[Cp_2Ti(CH_2)_2CR_2][O=C(CCF_3)_4]$.[18] Beckhaus and coworkers described the complete defluorination of trifluoromethyl-substituted Cp-ligands by titanium amide complexes.[19] More recently similar reactions were described by Deck et al. for the corresponding pentafluorophenyl substituents of cyclopentadienyl and indenyl ligands.[20] Hessen and coworkers reported that the complex $[Cp^*_2Ti(\eta^1\text{-}FC_6H_5)][BPh_4]$ reacts with trifluorotoluene to yield 1,2-diphenyl-1,1,2,2-tetrafluoroethane and $Cp^*_2TiF_2$.[21] Stoichiometric and catalytic C–F bond activations for the aromatisation of cyclic perfluorocarbons were achieved using titanocene and zirconocene, generated from Cp_2MCl_2 (M = Ti, Zr) and $Mg/HgCl_2$ or Cp_2ZrCl_2 and $Al/HgCl_2$.[22]

Zirconocene generating systems such as Cp_2ZrPh_2 or $Cp_2ZrCl_2/2\ n$BuLi can defluorinate perfluorodecalin to perfluoronaphthalene.[23] 2-Fluoro- and 3-fluoropyridine can also be defluorinated by various complexes such as Cp'_2MCl_2 (M = Ti, Zr, Hf; Cp′ = Cp, Cp*) in combination with different aluminium compounds acting as reducing agents.[24] In a series of outstanding papers, Jones and co-

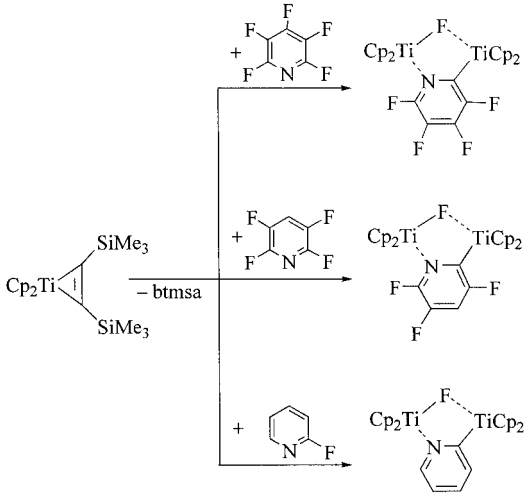
workers described the activation of several types of C–F bonds in alkanes, arenes and olefins using $Cp^*_2ZrH_2$. The published mechanistic investigations showed different pathways depending on the substrate used.[25–31] Caulton et al. showed that Cp_2ZrHCl reacts with fluoroethylene with formation of Cp_2ZrFCl, $Cp_2Zr(CH_2CH_3)Cl$ and Cp_2ZrF_2.[32] In the case of zirconium, hydride complexes were mostly used in C–F bond activation reactions. One exception was the reaction of *rac*-(ebthi)Zr(Me)(NH*t*Bu) with pentafluoropyridine published by Bergman and coworkers. Using the monomeric imidozirconocene complex [*rac*-(ebthi)-Zr=N*t*Bu], they observed activation of the *ortho* C–F bond and the formation of an amininopyridinato complex *rac*-(ebthi)ZrF(-N*t*Bu-2-C_5NF_4).[33]

In the light of the surprising results concerning zirconocene difluorides and alkyl monofluorides in the catalytic polymerisation of olefins,[34–37] we began to question whether the above mentioned alkyne complexes could activate C–F bonds to form the zirconocene fluoro complexes by C–F bond cleavage. These investigations were also extended to cover the question of whether hydride complexes (Zr–H systems, formed by reactions of systems containing Zr–F and Al–H bonds) could cleave the C–F bonds of $B(C_6F_5)_3$.[38,39]

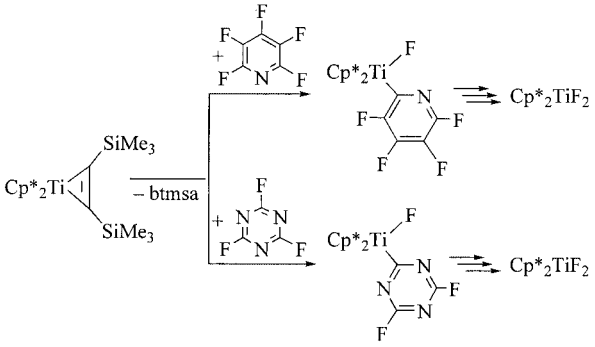
In this work we extended and compared the investigations of Beckhaus and his group concerning reactions of our titanium reagents[1–10] $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ and $Cp^*_2Ti(\eta^2\text{–}Me_3SiC_2SiMe_3)$ towards pyridine and fluorinated pyridines with the reactions of the corresponding zirconocene complexes. In this paper we describe the reactions of the zirconocene complexes $Cp_2Zr(L)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (**1a**: L = THF, **1b**: L = pyridine) and the ethylene bis(tetrahydroindenyl) complex *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ towards fluorinated pyridines. These reactions were used to probe any differences in the behaviour between the bis(trimethylsilyl)acetylene complexes of Ti and Zr.

Results and Discussion

Very recently, Beckhaus and coworkers published a series of excellent examples of reactions of titanocene bis(trimethylsilyl)acetylene complexes with different N-heterocyclic compounds.[40–43] In these reactions, the complexes $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ and $Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ act as sources of titanocene "Cp_2Ti" and permethyltitanocene "Cp^*_2Ti" after dissociation of the alkyne. They react differently with pyridine and fluorinated pyridines (Scheme 1 and Scheme 2). Under C–H activation, $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ and pyridine give an H-bridged binuclear titanium fulvalene derivative. 2-Fluoropyridine reacts with $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ by means of C–F activation to give an F-bridged binuclear titanium complex. It is remarkable that no C–H activation product was found in this case. With $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$, pentafluoropyridine gives a similar perfluorinated product.



Scheme 1.



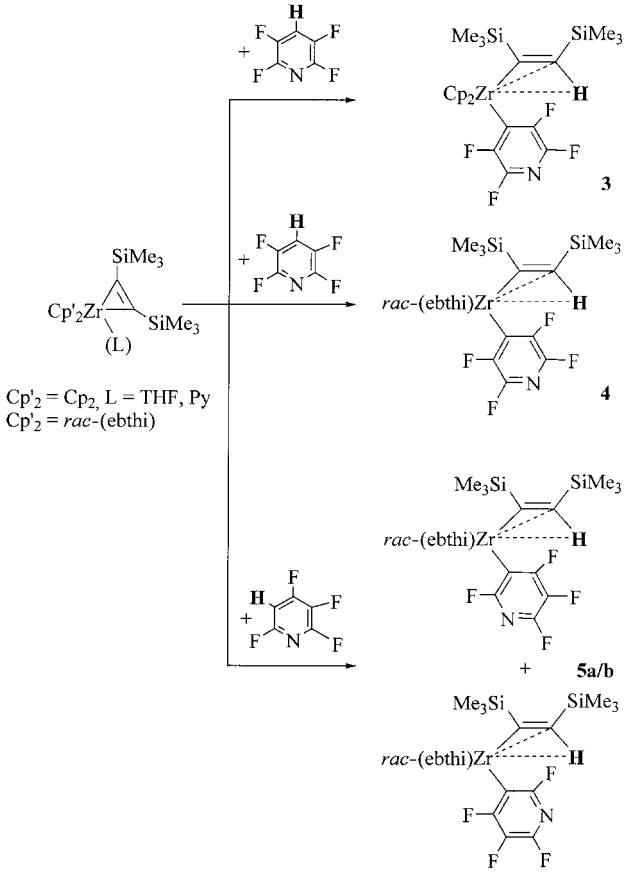
Scheme 2.

With $Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ the pentafluoropyridine forms, after C–F activation, a mononuclear titanium(IV) monofluoro complex $Cp^*_2Ti(2\text{-}C_5NF_4)F$ as an intermediate, as demonstrated by ^1H and ^{19}F NMR spectroscopic measurements. The latter complex reacts with an excess of the substrate to give the difluoride complex $Cp^*_2TiF_2$. A similar reaction was found for the cyanuric fluoride (Scheme 2).

In addition to C–F activation after elimination of the bis(trimethylsilyl)acetylene, there is another pathway for the reactions of the corresponding zirconocene complexes **1** and **2** with fluorinated pyridines. Upon C–H activation and without alkyne elimination, formation of agostic alkenyl complexes was observed. Both possibilities represent the typical reactions of these metallocene bis(trimethylsilyl)-acetylene complexes (Scheme 3).

The zirconocene complex $Cp_2Zr(THF)(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (**1a**) and the ethylene bis(tetrahydroindenyl) complex *rac*-(ebthi)$Zr(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (**2**) react with 2,3,5,6-tetrafluoropyridine by means of C–H bond activation to produce the complexes $Cp'_2Zr(4\text{-}C_5NF_4)$[–C(SiMe$_3$)=CH(SiMe$_3$)] ($Cp'_2 = Cp_2$) (**3**) and ($Cp'_2$ = ebthi) (**4**) (Scheme 3) containing both fluorosubstituted pyridyl groups metallated in the 4-position and agostic alkenyl groups. With 2,3,4,6-tetrafluoropyridine complex **2** yields,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



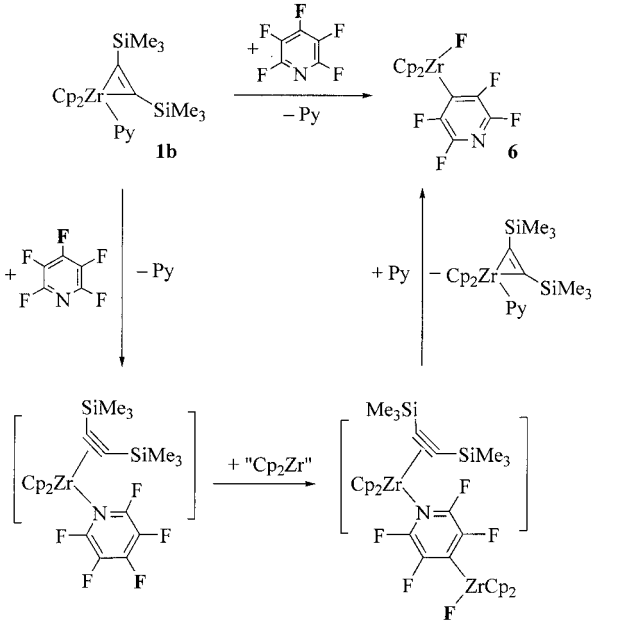
Scheme 3.

after C–H bond activation, two isomers **5a** and **5b** (1 to 2 ratio) of the corresponding complex *rac*-(ebthi)Zr(3-C_5NF_4)[–C($SiMe_3$)=CH($SiMe_3$)] bearing fluorosubstituted pyridyl substituents metallated in the 5-position as well as agostic alkenyl groups (Scheme 3).

With pentafluoropyridine and **1b**, elimination of bis(trimethylsilyl)acetylene and C–F bond activation in the 4-position was observed with subsequent formation of Cp_2Zr(4-C_5NF_4)F (**6**) (Scheme 4). As described in this work, in the case of zirconium such a species was isolated whereas in the above mentioned reaction of $Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with pentafluoropyridine the respective C–F activation reaction resulted in formation of a similar mononuclear titanium(IV) mono-fluoro complex $Cp^*_2Ti(2\text{-}C_5NF_4)F$ only as an intermediate which reacts to give the difluoride $Cp^*_2TiF_2$ (see Scheme 2).

According to these results, C–H activation is preferable to C–F activation for zirconium. For zirconium, the attack for C–F bond activation occurs in the 4-position and not in the 2-position as described for titanium. Both positions are activated but in the case of zirconium the 4-position is favoured.

It is possible to explain the favoured reaction at the 4-position for zirconium by invoking a bimolecular reaction with precoordination of the pentafluoropyridine as an N-donor and a subsequent attack of a second zirconocene moiety at the 4-position (Scheme 4). Coordination of the

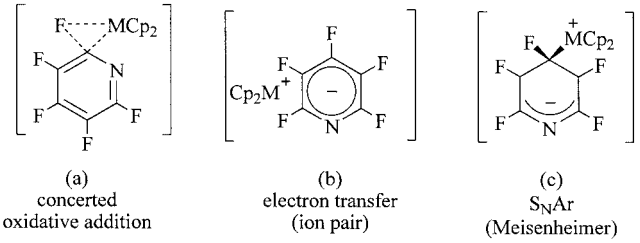


Scheme 4.

pyridine or such a precoordination of the pentafluoropyridine is generally impossible for the complex $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ because of the smaller sized titanium atom.

It is reasonable to assume that the above mentioned C–H bond activation of 2,3,5,6-tetrafluoropyridine in complexes containing a fluorosubstituted pyridyl metallated in the 4-position could also proceed via a similar precoordination. In contrast, the unsubstituted pyridine in complex **1b** did not show such reactivity since it has no H-atoms in the 4-position which could be activated.

Another explanation for the favoured reaction at the 4-position follows from suggestions by Jones, Braun and Perutz (Scheme 5).[15,44] The observed preference for C–F bond activation in the 2-position for titanium provides evidence for concerted oxidative addition of the pyridine by means of a three-centred transition state (a). An electron transfer reaction pathway through a tight ion pair (b) or an S_NAr type nucleophilic mechanism via a Meisenheimer intermediate (c) would result in an attack at the 4-position of the pentafluoropyridine as found for zirconium.

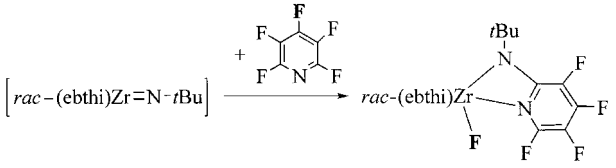


Scheme 5.

These results for the activation in the 4-position are also in contrast to the above mentioned reaction very recently described by Bergman[33] in which *rac*-(ebthi)Zr(Me)(NH*t*Bu) reacts with pentafluoropyridine via the monomeric imidozirconocene complex [*rac*-(ebthi)Zr=N*t*Bu]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

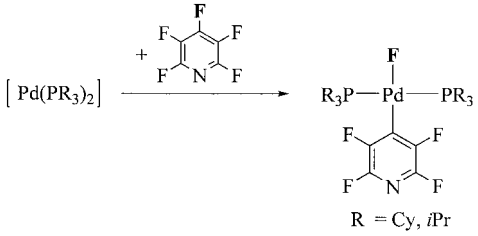
to afford the amininopyridinato complex *rac*-(ebthi)ZrF-(–N*t*Bu-2-C_5NF_4) with activation of the *ortho* C–F bond (Scheme 6).



Scheme 6.

On the other hand, Bergman described only N-donor coordination for the unsubstituted pyridine and no C–H bond activation whereas the imidozirconocene complex [*rac*-(ebthi)Zr=N*t*Bu] reacted, for example with benzene, with activation of the C–H bond and formation of the complex *rac*-(ebthi)Zr(Ph)NH*t*Bu.[33]

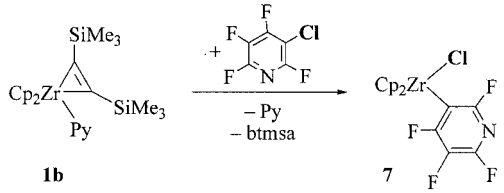
The activation of pentafluoropyridine in the 4-position with formation of $L_nM(4\text{-}C_5NF_4)F$ complexes was shown by Perutz and Braun to be typical for Ni,[44] Pd,[45] Rh[46] and Pt.[47] An example of reactions of this type is shown in Scheme 7.



Scheme 7.

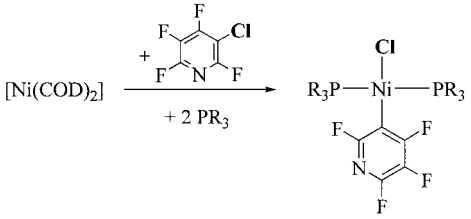
One can conclude from these results that the chemo- and regioselectivity of the C–H and C–F bond activations in reactions of fluorinated pyridines depends on the *metals* (C–F for Ti, C–H for Zr; 2-position for Ti, 4-position for Zr and Ni) and the *ligands* (Zr: 2-position for L = imido, 4-position for L = alkyne).

For the purpose of comparing the different reactivities of C–F and C–Cl bonds in halogenated pyridines, we found that complex **1b** reacts with 3-chloro-2,4,5,6-tetrafluoropyridine by means of a preferred C–Cl activation to give $Cp_2Zr(3\text{-}C_5NF_4)Cl$ (**7**) (Scheme 8). This result is very similar to that described by Perutz and Braun for the reaction of Ni^0 complexes with 3-chloro-2,4,5,6-tetrafluoro-pyridine (Scheme 9).[44]



Scheme 8.

In general, the preferred reactivity of C–Cl bonds over C–F bonds is not restricted to the 3-position of the 3-chloro-2,4,5,6-tetrafluoro-pyridine. Traces of 2-chloro-3,4,5,6-tetrafluoro-pyridine contained in our batch of pentafluoro-pyridine also reacted with complex **2** with preferred C–Cl bond activation to give the complex *rac*-(ebthi)-$Zr(2\text{-}C_5NF_4)Cl$.[48]



Scheme 9.

NMR-Spectroscopic and Molecular Structure Data

Unfortunately, all of the new compounds are only sparingly soluble in aromatic hydrocarbons so that in most cases the detection of the fluorinated carbon atoms was unsuccessful. However, the presence of the fluorinated pyridines is evident from their ^{19}F NMR signals. The most characteristic NMR spectroscopic and molecular structural feature of compounds **3** and **4** is the agostic interaction of the alkenyl group Zr–Cα=CβH. This alkenyl unit shows ^1H-NMR signals at rather low fields and the ^{13}C-NMR signals of Cα appear at low field whereas the Cβ signals are located upfield of the normal olefinic range. Typical for the additional agostic interaction is the very small coupling constant $^1J_{C\beta\text{-}H}$ (96 Hz in **3**, 97 Hz in **4** and 100 Hz in **5**). In the molecular structure, acute Zr–Cα–Cβ angles and short Zr–Cβ bond lengths reflect this special type of interaction. All these features have been previously observed in similar complexes such as $[Cp_2Zr\{\text{–}C(SiMe_3)=CH(SiMe_3)\}]_2[\mu\text{-}C\equiv C]$ (**A**),[49] [*rac*-(ebthi)Zr(C≡C-2-Py){–C(SiMe$_3$)=CH(SiMe$_3$)}] (**B**)[49] and the β-propiolactamate $[Cp_2Zr(\text{–}NC_3H_4O)\{\text{–}C(SiMe_3)=CH(SiMe_3)\}]$ (**C**)[50] which are all typical zirconocene σ-alkenyl complexes with agostic Cβ–H···Zr interactions (Table 1).

In the ^{19}F NMR spectra of complexes **3**, **4**, **5**, **6** and **7** the shifts for the fluorine substitutents on the pyridine ring are in the low field region for uncoordinated fluoroaromatics (ca. –100 ppm) and are not shifted to the extreme high field as found for the fluoro bridged Zr–F–C groups (ca. –200 ppm).[51] The signal for the fluoride at zirconium was found at 1.3 ppm for complex **6**. This is in the range typically seen for other zirconocene fluorides (ca. 20–30 ppm).[52]

The increased steric demand of the *rac*-ebthi ligand system is responsible for restricted rotation of the pyridyl group about the Zr–C bond. For the Cp complex **3** only two ^{19}F resonances were found whereas the ebthi complex **4** exhibits four (an exchange between the otherwise equivalent *ortho* or *meta* fluoro substituents by pyridyl rotation does not occur). Therefore, two possible and different orientations of the asymmetric 5-pyridyl substituent are the most probable explanation for the presence of two isomeric forms

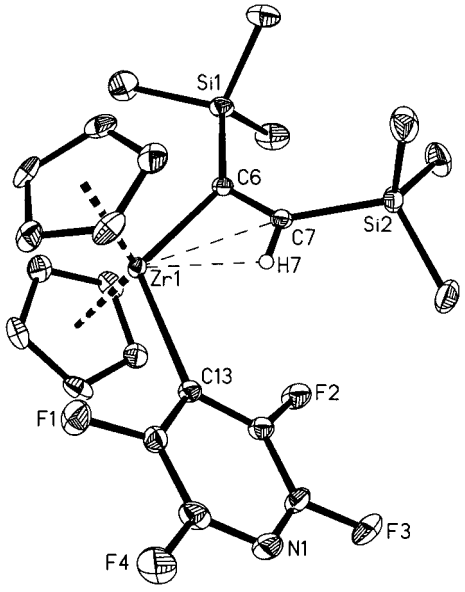

Figure 1. Molecular structure of complex **3**. Hydrogen atoms (except H7) are omitted for clarity. The thermal ellipsoids correspond to the 30% probability level. Selected bond lengths [Å] and angles [°]: Zr1–C6 2.247(2), Zr1–C7 2.554(2), Zr1–H7 2.14(2), Zr1–C13 2.432(2); Zr1–C6–C7 87.3(2), C7–C6–Si1 131.8(2), C6–C7–Si2 137.4 (2).

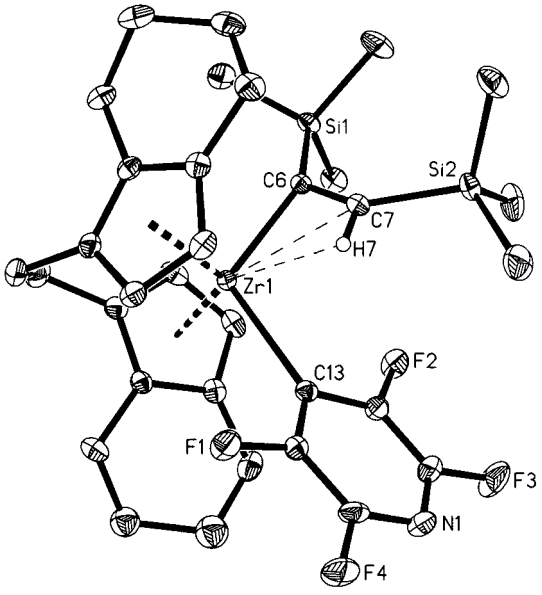

Figure 2. Molecular structure of complex **4**. Hydrogen atoms (except H7) are omitted for clarity. The thermal ellipsoids correspond to the 30% probability level. Selected bond lengths [Å] and angles [°]: Zr1–C6 2.257(2), Zr1–C7 2.556(2), Zr1–H7 2.16(3), Zr1–C13 2.426(2); Zr1–C6–C7 86.8(2), C7–C6–Si1 128.0(2), C6–C7–Si2 137.6 (2).

of **5** (Scheme 3). Accordingly, differences show up for the proton signal of the agostic CH group: it appears as a *triplet* in **3** (coupling to two fluorine atoms made equivalent by pyridyl rotation) but only as a *doublet* in **4** and **5**.

Complexes **3**, **4**, **6** and **7** were investigated by X-ray crystallography. The crystallographic data are presented in Table 2 and the molecular structures are shown in Figure 1, Figure 2, Figure 3 and Figure 4, respectively. Complexes **3**, **4**, **6** and **7** display the general feature of bent metallocenes and show no interactions between the fluoro substituents of the pyridine ring and the central atom. Complexes **3** and **4** are characterised by a molecular geometry typical for species containing agostic interactions of the alkenyl group Zr–Cα=CβH (Table 1). Notable features are Zr–Cα bonds in the range of a single bond, Cα–Cβ distances in the range typical for double bonds and a very small Zr–Cα–Cβ angle which indicates the additional interaction of the H(Cβ) with the central zirconium atom (Figure 1 and Figure 2). The tetrafluoropyridyl ring σ-bonded at the 4-position exhibits relatively long Zr–C single bond lengths [Zr1–C13 = 2.432(2) Å in **3** and 2.426(2) Å in **4**].

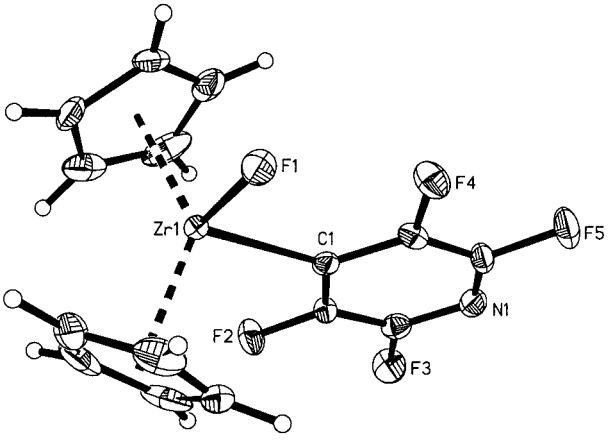

Figure 3. Molecular structure of complex **6**. The thermal ellipsoids correspond to the 30% probability level. Selected bond lengths [Å] and angles [°]: Zr1–C1 2.347(3), Zr1–F1 1.946(2); F1–Zr1–C1 99.38(9).

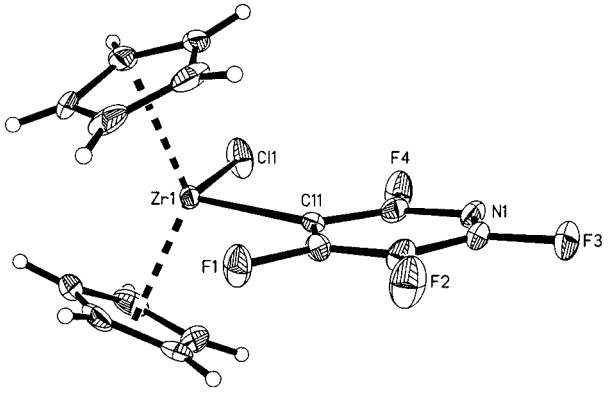

Figure 4. Molecular structure of complex **7**. The thermal ellipsoids correspond to the 30% probability level. Selected bond lengths [Å] and angles [°]: Zr1–C11 2.353(5), Zr1–Cl1 2.422(1); Cl1–Zr1–C11 104.9(1).

The molecular structure of complex **6** is depicted in Figure 3. The tetrafluoropyridyl ring σ-bonded at the 4-position in the molecule has shorter Zr–C bond lengths [Zr1–C13 = 2.347(3) Å] compared with **3** and **4** mentioned above. The observed Zr1–F1 bond length of 1.946(2) Å and the C1–Zr1–F1 angle of 99.38(9)° are in the same range as found in other zirconocene fluoro complexes. For example, some bond lengths were observed in the complex $Cp_2Zr(F)(C_6F_5)$ [Zr–C = 2.346 Å and Zr–F = 1.946 Å].[25] The monofluoride [(η^5-tetrahydroindenyl)$_2$Zr(F)(CH_2CH_2-2-Py)] [Zr–C = 2.377(3) Å] and the difluoride [(η^5-tetrahydroindenyl)$_2ZrF_2$] [Zr–F = 1.946(2) and 1.974(2) Å] exhibit comparable bond lengths.[52]

In the molecular structure of complex **7** (Figure 4), the bond length for Zr1–C11 [2.353(5) Å] is the same as that found for complex **6**. The observed Zr1–Cl1 bond length of 2.422(1) Å corresponds well with that found in other complexes of this type, e.g. Cp*$_2$Zr(Cl)($CH_2CH{=}CH_2$) (Zr–C = 2.324 Å and Zr–Cl =2.436 Å).[53]

Conclusions

Using the reactions presented we have documented that zirconocene bis(trimethylsilyl)acetylene complexes are able to activate C–H, C–F and C–Cl bonds of differently substituted pyridines. Whereas the corresponding titanocene bis(trimethylsilyl)acetylene complexes react with elimination of the alkyne and preferential C–F bond activation with formation of binuclear Ti^{III} complexes, an additional reaction possibility exists for zirconium in which the alkyne can remain part of the complex and form, after C–H bond activation, Zr^{IV} complexes with agostic σ-alkenyl groups. The latter is a typical example of the different reactivity between titanocene and zirconocene bis(trimethylsilyl)acetylene complexes. For titanium, a favourable elimination of the alkyne with formation of Ti^{III} complexes can be observed whereas for zirconium no elimination of the alkyne occurs but, instead, the formation of Zr^{IV} complexes.

Experimental Section

General: All operations were carried out under argon with standard Schlenk techniques. Prior to use, solvents were freshly distilled from sodium tetraethylaluminate and stored under argon. Deuterated solvents were treated with sodium or sodium tetraethylaluminate then distilled and stored under argon. Fluorinated pyridines were dried over molecular sieves and degassed before use. The following spectrometers were used: Mass spectrometry: AMD 402; NMR spectroscopy: Bruker ARX 400 (^{1}H, ^{13}C) and Bruker AC 250 (^{19}F) instruments. Chemical shifts were referenced to signals of the solvents used which were [D_6]benzene (δ_H = 7.16, δ_C = 128.0 ppm) and [D_8]toluene (δ_H = 2.03, δ_C = 20.4 ppm). The ^{19}F NMR spectra were referenced to external $CFCl_3$. The spectra were assigned with the help of DEPT experiments. Melting points were measured in sealed capillaries using a Büchi 535 apparatus. Elemental analyses were performed using a Leco CHNS-932 elemental analyser.

X-ray Crystallographic Study of Complexes 3, 4, 6 and 7: Data were collected with a STOE-IPDS-diffractometer using graphite-mono-

chromated Mo-K_α radiation. The structures were solved by direct methods (SHELXS-86)[54] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93).[55] XP (BRUKER AXS) was used for structure representations.

CCDC-263968 (for **3**), -263969 (for **4**), -263970 (for **6**) and -263971 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Preparation of Complex 3: Complex **1a** (266 mg, 0.5 mmol) was dissolved in THF/*n*-hexane (ca. 1 to 3, 10 mL) and treated with 2,3,5,6-tetrafluoropyridine (115 μL, 1.14 mmol) while stirring. After 2 h at 60 °C the brown solution had become green and a grey precipitate had formed. After filtration, the precipitate was recrystallised from THF/*n*-hexane at –32 °C. Filtration gave a yield of 160 mg of colourless crystals (51%). M.p. 147 °C (dec.). $C_{23}H_{29}F_4NSi_2Zr$ (542.87): calcd. C 50.89, H 5.38, N 2.58; found C 50.98, H 5.30, N 2.55. ^{1}H NMR (C_6D_6): δ = 0.15 (t, $J_{H,F}$ = 0.7 Hz, 9 H, β-$SiMe_3$), 0.25 (s, 9 H, α-$SiMe_3$), 5.34 (s, 10 H, Cp), 6.65 (t, $J_{H,F}$ = 3.9 Hz, 1 H, CH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 0.2 (t, $J_{C,F}$ = 1.6 Hz, β-$SiMe_3$), 2.0 (α-$SiMe_3$), 101.1 ($^1J_{C,H}$ = 96.2, $J_{C,F}$ = 1.8 Hz, β-CH), 108.1 (Cp), 146.0, 143.6 (2 m, CF), 162.8 (t, $^2J_{C,F}$ = 57 Hz, *p*-C), 218.8 (t, $J_{C,F}$ = 1.5 Hz, α-C) ppm. ^{19}F{^{1}H} NMR (C_6D_6): δ = –96.5 (AA′XX′), –110.5 (AA′XX′) ppm. ^{29}Si NMR (C_6D_6): δ = –3.2 ($^2J_{Si,H}$ = 3 Hz (CH) and 6.6 Hz (Me), β-Si), –6.9 ($^2J_{Si,H}$ = 6.4, $^3J_{Si,H}$ = 19 Hz, α-Si) ppm. Preparation of Complex 4: This was prepared as described above starting from complex **2** (300 mg, 0.57 mmol) and 2,3,5,6-tetrafluoropyridine (230 μL, 2.3 mmol) in *n*-heptane. At 80 °C the solution became red-brown and a yellow precipitate formed which was filtered off to give complex **4**. The yield was 161 mg (42%). M.p. 197 °C (dec.). $C_{33}H_{43}F_4NSi_2Zr$ (675.19): calcd. C 58.54, H 6.40, N 2.07; found C 58.28, H 6.62, N 1.99. ^{1}H NMR (C_6D_6): δ = 0.14 (d, $J_{H,F}$ = 0.7 Hz, 9 H, β-$SiMe_3$), 0.40 (s, 9 H, α-$SiMe_3$), 0.65–2.59 (20 H, CH_2), 5.15 (t, $J_{H,F} \approx {}^3J_{H,H} \approx$ 2.4 Hz, 1 H, CH), 5.87 (t, $J_{H,F} \approx {}^3J_{H,H} \approx$ 3.0 Hz, 1 H, CH), 5.97 (dd, $J_{H,F} \approx$ 1.5, $^3J_{H,H} \approx$ 2.7 Hz, 1 H, CH), 6.27 (d, $J_{H,F}$ = 4.5 Hz, 1 H, =CHβ), 6.45 (d, $^3J_{H,H}$ = 2.7 Hz, 1 H, CH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 0.9 (β-$SiMe_3$), 3.4 (α-$SiMe_3$), 21.8, 22.1, 22.3, 22.7, 23.3 (2 C), 24.1, 25.6 (d, $J_{C,F} \approx$ 1 Hz), 27.7, 28.5 (10×CH_2), 100.1, 103.3 (d, $J_{C,F}$ = 4.0 Hz), 105.3, 106.4 (d, $J_{C,F}$ = 10.5 Hz) (4×CH), 115.4 ($^1J_{C,H}$ = 96.8, $J_{C,F}$ = 4.4 Hz, β-CH), 120.8, 122.1 (d, $J_{C,F} \approx$ 1 Hz), 122.7 (d, $J_{C,F} \approx$ 1 Hz), 125.7, 129.4, 129.6 (6×quat. C), 223.6 (d, $J_{C,F}$ = 4.4 Hz, α-C) ppm; the C atoms of the pyridine were not found. ^{19}F{^{1}H} NMR (C_6D_6): δ = –95.7 (m), –97.4 (m), –112.6 (m), –114.6 (m) ppm. MS: *m*/*z* 675 $[M]^+$, 524 $[M - C_5F_4N]^+$, 504 $[M - C_8H_{19}Si_2]^+$, 354 $[M - C_5F_4N - C_8H_{19}Si_2]^+$.

Preparation of Complexes 5a/b: These were prepared as described above starting from complex **2** (243 mg, 0.43 mmol) and 2,3,4,6-tetrafluoropyridine (49 μL, 0.48 mmol) in *n*-heptane (10 mL). After 1.5 h at 60 °C the green solution had become red-brown and a yellow precipitate had formed which was filtered off to give a 1:2 mixture of complexes **5a** and 5**b**. Yield 233 mg (75%). M.p. 180–181 °C (dec.). $C_{33}H_{43}F_4NSi_2Zr$ (675.19): calcd. C 58.54, H 6.40, N 2.07; found C 58.30, H 6.28, N 2.01. ^{1}H NMR (C_6D_6): **5a**: δ = 0.15 (s, 9 H, β-$SiMe_3$), 0.40 (s, 9 H, α-$SiMe_3$), 0.6–2.7 (20 H, CH_2), 5.17 (t, $J_{H,F} \approx {}^3J_{H,H} \approx$ 2.6 Hz, 1 H, CH), 5.83 (t, $J_{H,F} \approx {}^3J_{H,H} \approx$ 3.0 Hz, 1 H, CH), 5.99 (dd, $J_{H,F} \approx$ 1.5, $^3J_{H,H} \approx$ 2.9 Hz, 1 H, CH), 6.40 (d, $J_{H,F}$ = 3.7 Hz, 1 H, =CHβ), 6.42 (d, $^3J_{H,H}$ = 2.8 Hz, 1 H, CH) ppm. **5b**: δ = 0.18 (s, 9 H, β-$SiMe_3$), 0.41 (s, 9 H, α-$SiMe_3$), 0.6–2.7 (20 H, CH_2), 5.18 (t, $J_{H,F} \approx {}^3J_{H,H} \approx$ 2.6 Hz, 1 H, CH), 5.80 (t, $J_{H,F} \approx {}^3J_{H,H} \approx$ 3.0 Hz, 1 H, CH), 5.95 (dd, $J_{H,F} \approx$ 1.6, $^3J_{H,H} \approx$ 2.6 Hz, 1 H, CH), 6.39 (d, $J_{H,F}$ = 3.7 Hz, 1 H, =CHβ), 6.45 (d, $^3J_{H,H}$ = 2.8 Hz, 1 H, CH) ppm. ^{13}C{^{1}H} NMR (C_6D_6): **5a**: δ = 0.9 (β-$SiMe_3$), 3.4 (α-$SiMe_3$), 21.9, 22.2, 22.4, 22.8, 23.3 (2 C), 23.9, 25.6, 27.8, 28.3 (10×CH_2), 99.7, 104.2 (d, $J_{C,F}$ = 4.2 Hz), 105.1, 106.7 (d, $J_{C,F}$ = 11.0 Hz) (4×CH), 116.1 (d, $J_{C,F}$ = 3.3 Hz, =CHβ), 120.5, 121.7 (d, $J_{C,F} \approx$ 1 Hz), 122.9 (d, $J_{C,F} \approx$ 1 Hz), 125.7, 129.5, 129.6 (6×quat. Ethylene Homo- and Copolymerization Activity of a Series of [ONNO]-Type Amine Bis(phenolate) Based Vanadium(II–V) Catalysts

Christian Lorber,*[a] Fabien Wolff,[a] Robert Choukroun,[a] and Laure Vendier[a]

Keywords: Vanadium / Amine (bis)phenolates / Polymerization / Copolymer / Crystal structure / Olefins

The synthesis and structural characterization of new paramagnetic amine bis(phenolate) [ONNO]-vanadium(III) and -vanadium(II) complexes, V^{III}(acac)[ONNO], V^{III}(Cl)(THF)[ONNO], and V^{II}(TMEDA)[ONNO], is described. These compounds complete the family of [ONNO]-vanadium(IV/V) complexes previously reported. The members of the [ONNO]-vanadium family at various oxidation states that range from vanadium(II) to vanadium(V), in association with $EtAlCl_2$ cocatalyst, were studied in the polymerization of ethylene and in the copolymerizations of ethylene-1-hexene and ethylene-norbornene. Poly(ethylene-*co*-1-hexene) and poly(ethylene-*co*-norbornene) were produced with co-monomer content of up to 11 mol-% and 29 mol-% for 1-hexene and norbornene, respectively.

Introduction

In the past decade, a tremendous amount of effort has been devoted to the design of new "non-metallocene" group 4 transition metal complexes because of their importance as α-olefin polymerization catalysts.[1] Particularly, chelating diamide,[1a,2–4] dialkoxide,[1a,5–6] or phenoxyimine[7,8] ligands have been extensively studied as rigid supporting environments for titanium and zirconium complexes, which has resulted in the emergence of a great deal of novel and useful chemistry, including the discovery of highly active olefin polymerization precatalysts. Among these new ligands, chelating, dianionic [ONNO]-type amine bis(phenolate) ligands associated with group 4 metal complexes[5] have proven to be highly active 1-hexene polymerization catalysts, and in some cases, even isospecific living polymerization was possible.[5a] Recently yttrium-[ONNO] complexes have been reported for their catalytic activity in the ring-opening polymerization of ε-caprolactone.[9]

Vanadium-based catalysts in homogeneous Ziegler–Natta polymerization have been known for about half a century.[10] Although generally less active, their use presents a number of interesting advantages over group 4 metal catalysts:[11] (i) the synthesis of high molecular weight polymers with narrow polydispersity, (ii) the preparation of ethylene/α-olefin copolymers with high α-olefin incorporation, and (iii) the preparation of syndiotactic polypropylene. The major reason for the low activity of these systems is their deactivation during the polymerization process, probably due to reduction of the catalytically active vanadium species to low-valent, less active or inactive species. Nevertheless, $V(acac)_3$ is currently employed in the synthesis of EP (ethylene–propylene) and EPDM (ethylene–propylene–diene monomer) elastomers.

As part of an ongoing study of vanadium chemistry with various supporting ligands,[12] and in particular of vanadium complexes for olefin polymerization, we have recently used ancillary diamido ligands with sterically demanding protecting groups[13] or imido ligands[14] on vanadium(IV) complexes as a way to overcome the problem of catalyst deactivation by stabilization of the formal oxidation state of the vanadium center. Following this approach, we recently described the synthesis of a series of oxo-vanadium(V)[15] and vanadium(IV)[16] complexes with the ancillary amine bis(phenolate) [ONNO]-type ligand (Figure 1) that are of the type V^{V}(=O)(X)[ONNO] {X = O*i*Pr (**1**), N_3 (**2**), Cl (**3**) and V^{IV}(Y)[ONNO] (Y = O*i*Pr (**4**), Cl (**5**)}, and we demonstrated interesting features in the solution and the solid-state structure of these unprecedented complexes. To complete our study on this new family of complexes, we wish to report here on the synthesis, and structural characterization, of new vanadium(III) and vanadium(II) complexes supported by [ONNO]-type bis(phenoxy)amine ligand, and to compare their ethylene homo- and copolymerization activity with other members of the vanadium(II–V) complex family.

Results and Discussion

In previous articles we have described the synthesis of [ONNO]-type amine bis(phenolate) complexes of oxo-vanadium(V) [**1**–**3**] and vanadium(IV) [**4**–**5**].[15,16] Although vanadium complexes with oxidation numbers from +3 to +5 are known to catalyze ethylene polymerization, the active spe-

cies is probably a vanadium(III) complex. Vanadium(II) species are generally considered inactive. To verify this point, we decided to prepare vanadium(III) and vanadium(II) compounds containing the [ONNO] ligand and to test the whole family of [ONNO]-vanadium complexes as olefin polymerization catalysts.

Synthesis of the Vanadium(III) and Vanadium(II) Complexes

Reacting V(acac)$_3$ with 1 equiv. of [ONNO]H$_2$ in toluene at 80 °C for 14 h afforded, after workup, the desired vanadium(III) complex V(acac)[ONNO] (**6**) as an orange solid with 87% yield (Scheme 1). Accordingly, **6** is a d^2-paramagnetic, NMR-silent compound with an effective magnetic moment μ_{eff} of 2.91 μ_B at 20 °C.

$$V(acac)_3 + [ONNO]H_2 \xrightarrow[-\ 2\ acacH]{toluene,\ 80\,°C} \underset{\mathbf{6}}{V(acac)[ONNO]}$$

Scheme 1. Synthesis of trivalent complex V(acac)[ONNO].

When 1 equiv. of K$_2$[ONNO] was slowly added to a THF solution of VCl$_3$(THF)$_3$ at ambient temperature there was an immediate reaction (Scheme 2). After careful workup and recrystallization in THF/toluene–pentane, yellow crystals of V(Cl)(THF)[ONNO] (**7**) were obtained (yield 31%). As for **6**, complex **7** is NMR-silent, and room temperature magnetic susceptibility measurements gave a μ_{eff} of 2.87 μ_B.

$$VCl_3(THF)_3 + K_2[ONNO] \xrightarrow[-\ 2\ KCl]{THF,\ r.t.} \underset{\mathbf{7}}{V(Cl)(THF)[ONNO]}$$

Scheme 2. Synthesis of trivalent complex V(Cl)(THF)[ONNO].

An entry to the [ONNO]-vanadium(II) chemistry was successfully achieved by reacting the vanadium(II) precursor VCl$_2$(tmeda)$_2$ [tmeda *N*,*N*,*N*′,*N*′-tetramethylethylenediamine] with 1 equiv. of K$_2$[ONNO] at room temperature whilst stirring in THF for 2 h to give red crystals of complex V(tmeda)[ONNO] (**8**) (Scheme 3). Complex **8** is a high-spin d^3-paramagnetic, NMR-silent compound with a μ_{eff} of 3.90 μ_B at 20 °C.

$$VCl_2(tmeda)_2 + K_2[ONNO] \xrightarrow[-\ 2\ KCl\ -\ tmeda]{THF,\ r.t.} \underset{\mathbf{8}}{V(tmeda)[ONNO]}$$

Scheme 3. Synthesis of divalent complex V(tmeda)[ONNO].

X-ray Structure Determination

During the course of our investigation, crystals of [ONNO]H$_2$ were obtained from a cold dichloromethane/pentane solution (–20 °C), and we report its molecular structure with an ORTEP diagram shown in Figure 2.[17] The main features of the solid-state structure is the tripodal configuration that adopts the ligand framework; this arrangement seems to arise from three intramolecular hydrogen-bond interactions between O1–HO1···N1 (2.05 Å, 146.0°), O1–HO1···O2 (2.54 Å, 130.4°), and O2–HO2···N2 (2.03 Å, 151.6°).

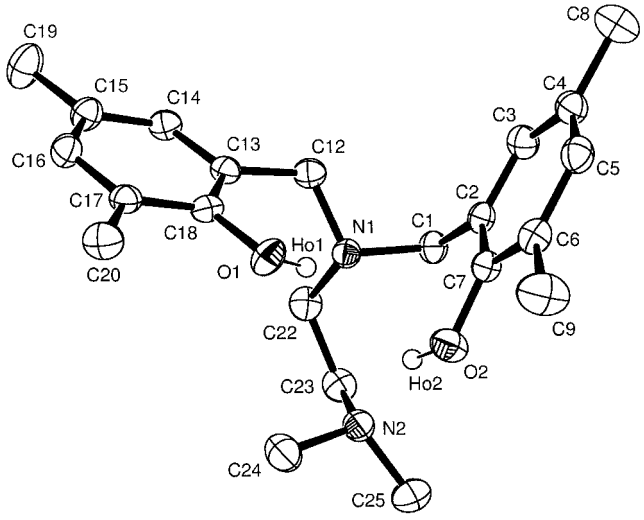

Figure 2. Ortep drawing of the molecular structure of [ONNO]H$_2$ showing 50% probability ellipsoids. Hydrogen atoms are omitted for clarity. Selected parameters (bonds, Å; angles, °): N1–C12 1.467(3), N1–C1 1.482(3), N1–C22 1.473(3), C18–O1 1.371(2), C7–O2 1.367(2), N2–C23 1.462(3), N2–C24 1.467(3), N2–C25 1.465(3), O1–H···N1 2.05, O1–H1···O2 2.54, O2–H2···N2 2.03, O1–H–N1 146.0, O1–H1–O2 130.4, O2–H2–N2 151.6.

Crystals of all three complexes (**6**–**8**) were obtained: red-orange crystals of **6** were obtained by careful layering a toluene solution of **6** with pentane, yellow crystals of **7** by low-temperature crystallization in THF/toluene–pentane solution, and red crystals of **8** by layering a toluene solution of **8** with pentane. The thermal ellipsoid plots are depicted in Figure 3, Figure 4, and Figure 5, with a comparison of selected bond lengths and angles in Table 1. Complex **8** presents two independent molecules in the cell with very similar structural parameters; therefore only one of these molecules will be described here. The solid-state structures confirm our first formulations: complexes **6**–**8** are mononuclear complexes, containing an octahedrally coordinated vanadium(III) center surrounded by a tetradentate [ONNO] ligand and one acac ligand (**6**), a chlorine atom and a THF solvate

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molecule (**7**), and tmeda ligand (**8**). With regard to the [ONNO] ligand, in all complexes, the two phenolate rings have a *trans* configuration, and both amino-nitrogen donor atoms are coordinated to the metal center; these features are ones that they share with their group 4- and other vanadium-[ONNO] analogues.[5b,5d–f,15,16] Bonding distances between the metal center and the O and N donors of [ONNO] are in the range typically observed for such complexes: (i) V–O(phenoxide) distances are ca. 1.9–2.0 Å, which is slightly longer than those of higher oxidation state [ONNO]-vanadium(v/iv) analogues by about 0.1 Å,[14,15] (ii) the two vanadium–nitrogen bonds formed between the metal center and the tripodal amino-N atom and the dimethylamino sidearm N atom have distances that range from 2.13 to 2.32 Å. Bonds formed by vanadium and the additional ligands are typical: V–O(acac) approximately 2.00 Å (in **6**), V–Cl1 = 2.377(2) Å (in **7**), V–O(THF) = 2.131(4) Å (in **7**), and V–N(TMEDA) = 2.302(8) and 2.383(8) Å (in **8**).

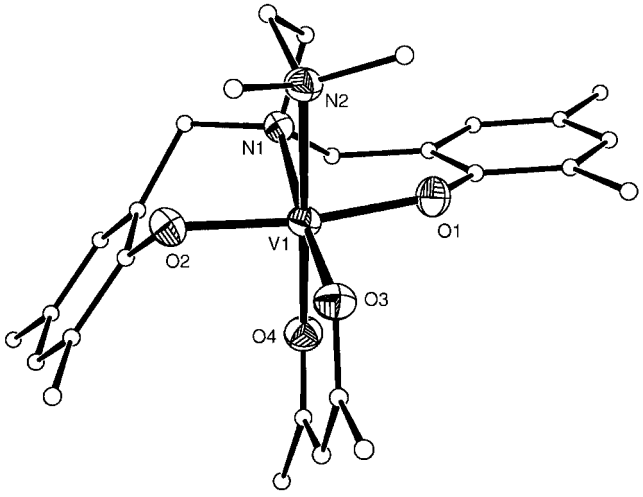

Figure 3. Ortep drawing of the molecular structure of **6** showing 50% probability ellipsoids (except on C atoms for clarity) and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

The crystals of **7** contain the isomer with the chlorine atom *trans* to the dimethylaminoethyl sidearm and the THF ligand *trans* to the tripodal nitrogen atom of [ONNO]. However, because of the paramagnetism of the complex and the impossibility of recording its NMR spectrum we cannot exclude the presence of the other isomer (with the Cl atom *trans* to the tripodal N atom) in solution.

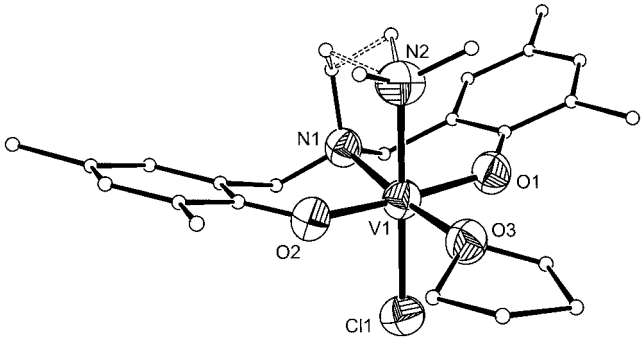

Figure 4. Ortep drawing of the molecular structure of **7** showing 50% probability ellipsoids (except on C atoms for clarity) and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

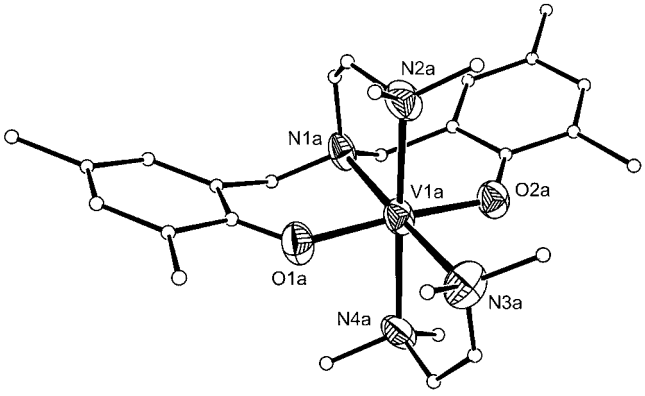

Figure 5. Ortep drawing of the molecular structure of molecule A of **8** showing 50% probability ellipsoids (except on C atoms for clarity) and partial atom-labeling schemes. Hydrogen atoms are omitted for clarity.

Interestingly, the configuration of the [ONNO] fragment in the crystal structure of **6** is very different from that of **7** and **8**. The configuration of the [ONNO] ligand in **7** and **8**

[a] X1 = X2 = O_{acac} (**6**) or N_{tmeda} (**8**); X1 = Cl, X2 = O_{THF} (**7**). [b] For independent molecule A. [c] Angle defined by the two planes containing the two phenolate aromatic rings; the + sign refers to a folding away from the NMe_2 sidearm, whereas the – sign refers to a folding towards the NMe_2 sidearm.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is symmetry related [the two aromatic rings of the bis(phenolate) framework (without the sidearm)]; the phenolate groups of the [ONNO] framework fold in towards the pendant (dimethylamino)ethyl sidearm, and the angle between the two planes of the aromatic rings are approximately –142° (**7**) and –151° (**8**) [the minus sign refers to a folding towards the NMe_2 sidearm; in contrast, the folding away from the NMe_2 sidearm has a positive sign]. In contrast, the phenolate groups of the [ONNO] ligand of **6** fold back away from the pendant (dimethylamino)ethyl sidearm; the angle δ between the two planes of the aromatic rings is now about +116° with a molecular structure that has two non-symmetry-related phenolate rings. Such a helicoidal distortion of the tripodal amino nitrogen donor atom induces a lower symmetry in the ligand framework of **6**, as already observed in the solid-state structure of two other [ONNO]-vanadium complexes,[15,16] and seems to arise from the presence of an O-ligated anionic ligand (alkoxo, oxo, acac) in a *trans* position to the (dimethylamino)ethyl sidearm nitrogen donor atom. Figure 6 presents a summary of the geometry of all the [ONNO]-vanadium compounds that we have prepared.

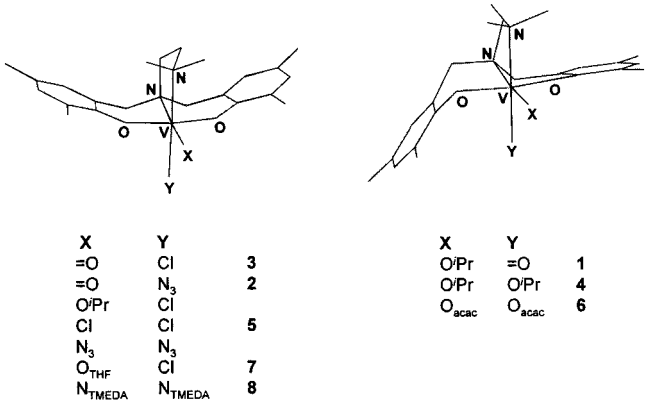

Figure 6. Symmetrical and non-symmetrical geometry in [ONNO]-Vanadium(II–IV) complexes.

Homopolymerization Studies

Together with the [ONNO]-vanadium complexes that present oxidation states of +5 and +4 reported by us in previous articles,[15,16] we are now introducing a family of vanadium complexes that are supported by the same ancillary ligand and that stabilize four oxidation states of the metal center (from +2 to +5), which allows us the opportunity to evaluate their activity toward the homopolymerization of ethylene, propene, and 1-hexene.

Ethylene Polymerization

Preliminary studies conducted on **6** with MAO cocatalyst (500 equiv.) under 1 bar of ethylene failed to produce polyethylene. We had already observed such behavior with other vanadium catalysts that do not possess V–Cl bonds.[14] Moreover, it is well known that vanadium catalysts give higher polymerization activities or polymers with lower polydispersity indices upon activation with simple chloroalkylaluminum reagents (such as $EtAlCl_2$ or Et_2AlCl) rather than MAO.[11b,11c,14,18,19] As a result, all of our further studies were conducted with $EtAlCl_2$ as cocatalyst.

The catalyst activity of the vanadium(II–V) complexes **1**–**8** of the [ONNO] ligand for the polymerization of ethylene has been evaluated under the same set of conditions of 10 equiv. of $EtAlCl_2$ under 1 atm of ethylene at 20 °C in toluene (except for catalysts **2** and **3** that are not soluble in toluene, and these reactions were thus conducted in dichloromethane). The results are summarized in Table 2 and are classified by the oxidation states of the catalysts; a comparison with standard V-based catalysts VCl_4, VCl_4·DME, and $V(acac)_3$ tested in our hands under the same experimental conditions is also presented.

Under these conditions, [ONNO]-vanadium(V) complexes **2** and **3** exhibit modest activities ranging from 17 to 22 $kg_{PE}\,mol^{-1}{}_{[V]}\,h^{-1}$, a number comparable to other vanadium systems described in the literature.[1a,11,14,18] This modest activity may be attributable to the use of dichloromethane as solvent; catalyst **1** gives a much higher produc-

tivity of 272 $kg_{PE}\,mol^{-1}_{[V]}\,h^{-1}$. Polymer properties are typical of high molecular weight (M_w = 1.18–7.16 × 10^5 $g\,mol^{-1}$), high density polyethylenes [HDPE] (T_m = 134–139 °C), and a reasonably narrow, unimodal polydispersity indice, M_w/M_n = 2.65, is observed with **1**.

Under the above conditions, the activities of the vanadium(IV)-[ONNO] catalysts **4** and **5** are much higher; 474 $kg_{PE}\,mol^{-1}_{[V]}\,h^{-1}$ (**4**) and 62 $kg_{PE}\,mol^{-1}_{[V]}\,h^{-1}$ (**5**). Meanwhile, polydispersity indices are very low (2.00 and 2.03, respectively), which suggests that the active species is well defined, and the [ONNO] ligand remains coordinated to the metal during the catalytic process. Melting temperatures are again very high (ca. 139 °C) corresponding to HDPE.

Vanadium(III)-[ONNO] catalyst **6** is a particularly efficient catalyst; as with **4**, a rapid initial polymerization occurs, which results in the solidification of the solution with formation of a gel of PE in less than 2 min (activity = 436 $kg_{PE}\,mol^{-1}_{[V]}\,h^{-1}$). This problem could be partly resolved by conducting the reaction in pentane. We then observe a slightly lower productivity, but a gain in the polydispersity (3.33 in toluene versus 2.63 in pentane), and a high molecular weight polymer (M_w = 1.00 × 10^6 $g\,mol^{-1}$). Interestingly, ethylene polymerization with the other vanadium(III) catalyst **7** is a little bit slower than with **6**, although the low polydispersity (2.24) suggests again a well-defined active species.

Finally, vanadium(II) complex **8** gives poor yields of PE. As expected, this confirms that this reduced oxidation state of the vanadium center gives only inactive or less active polymerization catalysts. Nevertheless, one cannot exclude that the absence of activity is due to the presence of the chelating TMEDA ligand at the metal center, and additional polymerization experiments with vanadium(III–V) catalysts in the presence of TMEDA will be necessary to address this point.

Although clear trends are not easily apparent (except for the V^{II} state that is inactive), the following conclusion can be drawn: (i) catalysts **2**, **3**, **5**, and **7** with V–Cl or V–N_3 bonds give lower activities relative to catalysts **1**, **4**, and **6** that have alkoxide or acac ligands, (ii) the activities and quality of the polyethylenes obtained with catalysts **1**, **4**, and **6** (with oxidation states +5 to +3) are very similar. This could suggest that these different systems involve a similar catalytically active species that is most probably a [ONNO]-vanadium(III) complex (in the case of **1** and **4**, resulting from the reduction of the V^V or V^{IV} center by the aluminum cocatalyst). Clearly, further studies will be needed to clarify these points.

Propene and 1-Hexene Homopolymerization

Unfortunately, none of the [ONNO]-vanadium complexes could catalyze propene polymerization at 20 °C, even under 4 bar propene, using $EtAlCl_2$ as cocatalyst (V/Al = 1:10). This is surprising as the $V(acac)_3/EtAlCl_2$ system is known to initiate living propene polymerization,[20] but this may result from the strong steric hindrance of the tetradentate dianionic [ONNO] ligand.

Less surprisingly, we were unable to polymerize 1-hexene with our catalysts, even at high temperatures (70 and 135 °C). To the best of our knowledge, V-based catalysts reported for such a reaction are very rare.[21]

Ethylene Copolymerization Studies

The copolymerization of ethylene with α-olefins is a common means of generating polyethylenes with controlled crystallinity and density. These polymers are known as linear low-density polyethylenes (LLDPE). The introduction of short-chain branches originating from the co-monomer decreases the crystallinity and melting temperature of the copolymer as the co-units interfere with crystallization and reduce the size of crystallites. Preliminary studies of the copolymerization of ethylene with 1-hexene and norbonene with our new vanadium compounds are described below.

The copolymerization of ethylene with 1-hexene was conducted at ambient temperature in toluene with complexes **1** and **4**–**7** in the presence of $EtAlCl_2$ cocatalyst (V/Al = 1:10), under 2 bar ethylene with a ratio of 1:800 for catalyst/1-hexene, and was compared to that of $V(acac)_3$ (see Table 3).

Although **7** did not produce any polymer, a white polymeric material was obtained with the other catalysts **1** and **4**–**6**. The ^{13}C NMR spectra (370 K) of the resulting polymers reveals that these catalysts produced poly(ethylene-*co*-hexene)s (EH) typical of EH block copolymers, and the polyethylene sequences are separated by isolated hexene units (no HH dyads are observed; Figure 7 shows a

Table 3. Results of ethylene–1-hexene copolymerization [conditions: catalyst (0.01 mmol) in 10 mL of toluene; $EtAlCl_2$ cocatalyst (10 equiv.); ethylene (2 bar); 1-hexene (8 mmol); time of polymerization 30 min run].

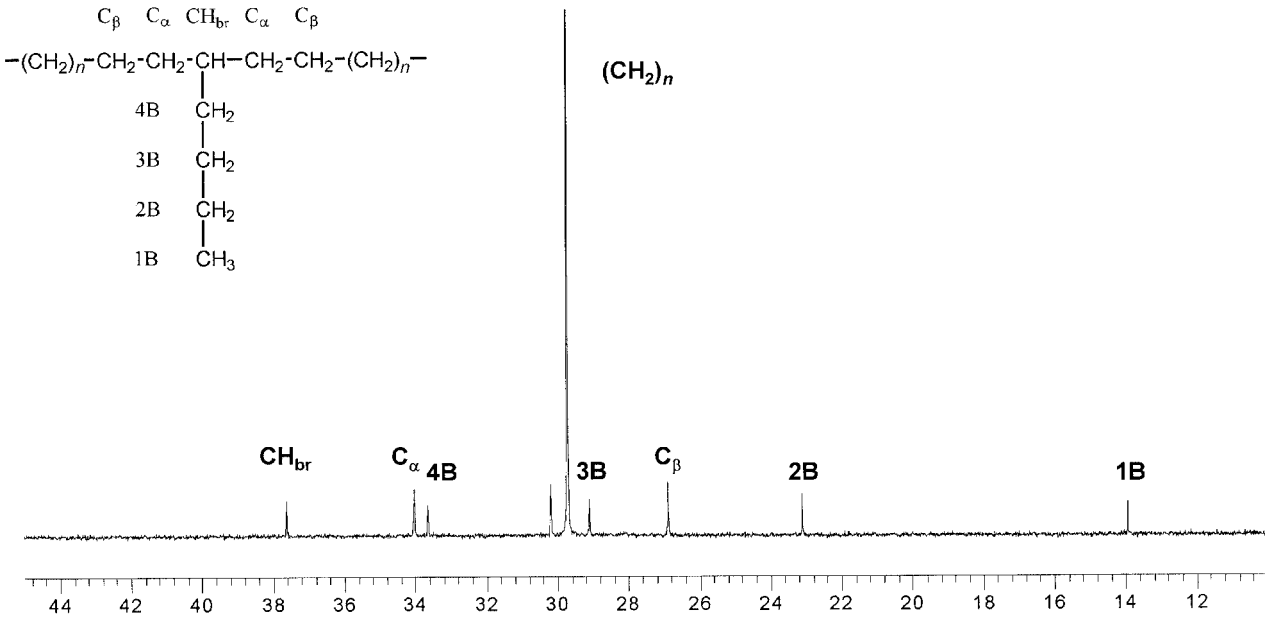

Figure 7. ^{13}C NMR spectrum [370 K, 1,2,4-trichlorobenzene/[D_2]tetrachloroethane] of the ethylene–*co*-1-hexene polymer made using **6**/$EtAlCl_2$.

$^{13}C\{^1H\}$ NMR spectrum of an EH copolymer obtained using **6**/$EtAlCl_2$).

The integration of the signals of 1-hexene versus ethylene in the ^{13}C NMR spectra of these EH copolymers allowed us to determine the 1-hexene incorporation ratio into the copolymers.[22] This value was found to be relatively modest, ca. 4 mol%, with catalysts **1**, **4** and **5**, and slightly higher with **6** (7.4 mol%). Increasing the ethylene pressure to 4 bar (with catalyst **6**) resulted in a decrease in catalyst productivity, whereas (logically) the 1-hexene content diminished to 8.8 mol%. Conversely, lowering the ethylene pressure to 1 bar decreased the activity with incorporation of more 1-hexene units (10.6%). These conditions have not been optimized; in particular, we have also noticed an increase in the 1-hexene content and productivity of **6** by working in a pentane solution.

In all cases, the EH copolymers have a low molecular weight M_w of 32×10^3 (with **1**), 73×10^3 (with **4**) and 71×10^3 (with **6**), but with different molecular weight distributions; the EH copolymers produced by **1** and **4** have a broad molecular weight distribution [PDI = 4.26 (bimodal), and 3.53 for **1**, and **4**, respectively], whereas narrow unimodal polydispersity indices are obtained with **6** at various ethylene pressures [PDI = 1.90 (1 bar), 1.70 (2 bar), and 2.07 (4 bars)].

The effect of the incorporation of 1-hexene into the copolymer on the melting behavior of the EH copolymer is illustrated in Figure 8, which shows the DSC endotherms obtained after step-crystallization of the copolymers made using **6**/$EtAlCl_2$. Furthermore, it has been established that 1-hexene does not enter the crystal lattice of PE, therefore, a DSC analysis can give an idea of the heterogeneity in the co-monomer distribution.[23,24] The DSC thermograms of the EH copolymers show five to six melting temperature values ranging from ca. 63 °C to ca. 111 °C. According to these endotherms, and those found in the literature,[23,24] separations based on different populations of crystalline lamellae have occurred, depending on the amount and distribution of 1-hexene units in the molecular chain ("intrachain heterogeneity"). Long polymer segments recrystallize into larger crystals, which melt at higher temperatures, whereas short segments form small crystals, which melt at lower temperatures. Each peak of the DSC curve corresponds to one type of polymer fraction, which could have a different amount and distribution of short-chain branching in the PE chain.

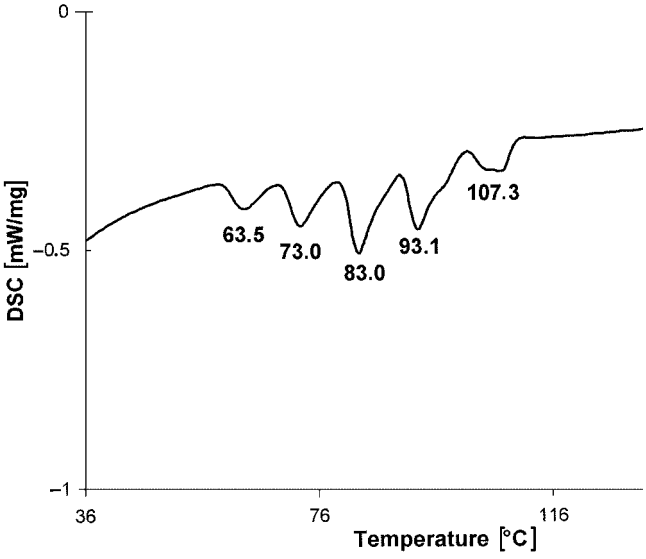

Figure 8. DSC thermogram obtained for an ethylene–*co*-1-hexene polymer made using **6**/$EtAlCl_2$.

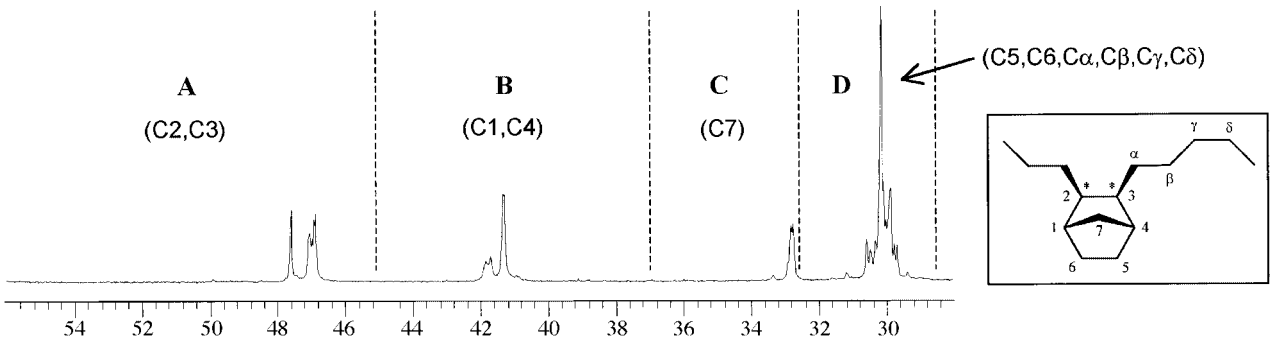

Figure 9. ^{13}C NMR spectrum [370 K, 1,2,4-trichlorobenzene–[D_2]tetrachloroethane] of the ethylene–*co*-norbornene polymer made using **6**/$EtAlCl_2$ (ethylene 1 bar).

As materials, poly(ethylene-*co*-norbornene)s possess rather interesting properties (high glass transitions, good chemical and heat resistance, and excellent transparency) that make them promising, in particular, for their potential applications in optoelectronics. Under the above conditions used to produce the poly(ethylene-*co*-hexene) [room temperature, and 1–4 bar ethylene, in the presence of norbornene], preliminary studies show that **6** associated with $EtAlCl_2$ (V/Al = 1:10) presents an interesting catalytic activity for ethylene–norbornene copolymerization (Table 4): activity = 292 $kg_{copolymer}\,mol^{-1}\,h^{-1}$ at 2 bar ethylene. The resultant polymer was poly(ethylene-*co*-norbornene) with a similar overall ^{13}C NMR spectrum (see Figure 9), high norbornene content (14–29 mol%),[25] and a microstructure that possesses no norbornene repeat units and contains both *meso* and *racemo* alternating ethylene–norbornene sequences as well as isolated norbornene units. More details on the copolymerization behavior of these systems will be described elsewhere.

Table 4. Results of ethylene–norbornene copolymerization [conditions: catalyst (0.01 mmol) in 10 mL of toluene; $EtAlCl_2$ cocatalyst (10 equiv.); ethylene (1–4 bar); 1-hexene (8 mmol); time of polymerization 15 or 30 min run].

Conclusions

We described the synthesis and molecular structure of three new amine(bisphenolate) complexes of vanadium(II) and (III). We used the whole family of [ONNO]-vanadium complexes, from vanadium(II) to vanadium(V), as ethylene polymerization catalysts in association with the $EtAlCl_2$ cocatalyst. To the best of our knowledge, this is the first comprehensive study of a catalytic polymerization system with a single ancillary ligand set to stabilize such a broad scale of oxidation states of the metal center.

Preliminary studies show that some of these new complexes are efficient catalysts for ethylene-α-olefin copolymerization, producing poly(ethylene-*co*-1-hexene) and poly(ethylene-*co*-norbornene) with high α-olefin content. These promising results still need to be optimized, and future studies are in progress to determine the best catalytic conditions (temperature, ethylene pressure, co-monomer and cocatalyst concentration), as well as the effect of halogenated compounds as activity enhancers.[26] These studies will appear in due course. From our preliminary polymerization results, and because it is easily prepared from commercially available $V(acac)_3$, $V^{III}(acac)$[ONNO] appears as the most interesting complex for further studies. Our study also confirms the importance of the vanadium(III) as the active species in V-based catalytic systems.

Experimental Section

General Remarks: Starting materials for ligand synthesis were purchased from Aldrich Inc. or Fluka Inc. and used as received. All experiments requiring a dry atmosphere were performed using standard Schlenk line or drybox techniques under argon. Solvents were refluxed and dried over appropriate drying agents under argon, collected by distillation, and stored in the drybox over 4 Å molecular sieves. The ligand [ONNO]H_2 was prepared according to a known synthesis.[5e] K_2[ONNO] was prepared by adding excess K into a THF solution of [ONNO]H_2, filtering and evaporating to dryness. $V(acac)_3$ was purchased from Fluka. $EtAlCl_2$ (25 mol-% in toluene) was purchased from Aldrich. All vanadium precursors $VCl_3(THF)_3$ and $VCl_2(tmeda)_2$ were prepared as published previously.[27,28] [ONNO]-vanadium(V) and -vanadium(IV) complexes were prepared according to published syntheses.[15,16] NMR spectroscopic data were recorded with a AMX-400 spectrometer, and referenced internally to residual protonated-solvent (^1H) resonances and are reported relative to tetramethylsilane (δ = 0 ppm). Pseudo-quantitative ^{13}C NMR spectra of the copolymers were obtained at 370 K in 1,2,4-trichlorobenzene/[D_2]tetrachloroethane containing approximately 3 mg of $Cr(acac)_3$ to reduce T_1 (inverse-gated, $d1$ = 5 s). Co-monomer incorporation was measured by integration of characteristic signals. Elemental analyses were performed at the Laboratoire de Chimie de Coordination (Toulouse, France). Magnetic susceptibility data were collected on powdered samples of the different compounds with use of a homemade Faraday-type automatic magnetometer with mercury tetra(thiocyanato) cobaltate susceptibility at 20 °C, $16.44 \times 10^{-6}\,cm^3\,mol^{-1}$). Diamag-

netic corrections were applied by using Pascal's constants as described previously.[12b] Size exclusion chromatography (SEC) analyses were carried out at the CNRS-LCPO laboratory (Bordeaux-Pessac, France) and at Polimeri Europa (Milan, Italy) in 1,2,4-trichlorobenzene at 140 °C relative to polystyrene standards. DSC thermograms of the polymers were measured on a DSC 204 Netzsch apparatus using a modified method.[29] The polymer sample was melted in a DSC crucible at 170 °C under nitrogen (10 °C/min). It was then successively annealed under nitrogen at descending temperature stages, starting from the melt by steps of 10 °C to reach 20 °C (with isotherms of 2 h between 110 and 60 °C). The cooled sample was then heated at 5 °C/min from 20 to 200 °C (the melting temperature values T_m and the heat of fusion (ΔH_f) were taken from the second heating curve).

Synthesis of V^{III}(acac)[ONNO] (6): To a solution of V(acac)$_3$ (100 mg, 0.29 mmol) in toluene (2 mL) was added [ONNO]H$_2$ (102 mg, 0.29 mmol) in portions at room temperature. The reaction mixture was heated at 80 °C for 14 h, after which the volatiles were removed under vacuum. The resulting orange solid was washed with pentane (3 × 5 mL) and dried under vacuum. Yield: 128 mg, 87%. μ_{eff} (20 °C) = 2.91 μ_B. $C_{27}H_{37}N_2O_4V$ (504.54): calcd. C 64.27, H 7.39, N 5.55; found C 64.02, H 7.24, N 5.69.

Synthesis of V^{III}(Cl)(THF)[ONNO] (7): K$_2$[ONNO] (174 mg) was slowly added in portions to a solution of VCl$_3$(THF)$_3$ (150 mg, 0.41 mmol) in THF (2 mL). The solution was left at ambient temperature whilst stirring overnight. Volatiles were removed under vacuum. The resulting solid was extracted with toluene, the solution was filtered through Celite and dried in vacuo. The solid was washed with pentane and dried under vacuum. Crystallization from a THF/toluene–pentane solution (room temperature and then at –20 °C) afforded yellow crystals of **7**. Yield: 65 mg, 31%. μ_{eff} (20 °C) = 2.87 μ_B. $C_{26}H_{38}ClN_2O_3V$ (512.99): calcd. C 61.87, H 7.47, N 5.46; found C 62.07, H 7.15, N 5.11.

Synthesis of V^{II}(tmeda)[ONNO] (8): K$_2$[ONNO] (366 mg) was slowly added in portions to a solution of VCl$_2$(TMEDA)$_2$ (300 mg, 0.84 mmol) in THF (4 mL), whilst stirring. After 2 h at room temperature, the volatiles were removed under vacuum. The resulting solid was extracted with toluene (5 mL), the solution was filtered through Celite and slowly layered with pentane (7 mL). Red crystals of **8** were obtained and dried under vacuum. Yield: 200 mg, 46%. μ_{eff} (20 °C) = 3.90 μ_B. $C_{28}H_{46}N_4O_2V$ (521.63): calcd. C 63.47, H 8.89, N 10.74; found: C 63.40, H 8.70, N 10.66.

Typical Ethylene Polymerization Catalyses: A 10 mL toluene solution of catalyst (5 mg) was flushed under 1 bar ethylene. The AlEtCl$_2$ (10 equiv. of a 1 M solution in toluene) cocatalyst dissolved in toluene (1.5 mL) was added to initiate the polymerization, and the ethylene pressure was maintained constant during the polymerization. The polymerization was stopped by adding methanol (5 mL), and the polyethylenes were filtered, washed with methanol, water and acetone, and dried for 48 h at 80 °C.

Typical Ethylene-α-olefin Copolymerization Catalyses: A 10 mL toluene solution of catalyst (5 mg) and 1-hexene (680 mg) [or norbornene (760 mg)] was flushed under 2 bar ethylene. The AlEtCl$_2$ (10 equiv. of a 1 M solution in toluene) cocatalyst dissolved in toluene (1.5 mL) was added to initiate the polymerization, and the ethylene pressure was maintained constant during the polymerization. The polymerization was stopped by adding methanol (5 mL), and the polyethylenes were filtered, washed with methanol, water and acetone, and dried for 48 h at 80 °C.

Crystal Structure Determination of [ONNO]H$_2$ and 6–8: (Table 5) For the four compounds, data were collected at low temperature (T = 180 K) with a Stoe Imaging Plate Diffraction System (IPDS), equipped with an Oxford Cryosystems Cryostream Cooler Device and using a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Final unit cell parameters were obtained by means of a least-squares refinement of a set of 8000 well-measured reflections, and the crystal decay was monitored during data collection by measuring 200 reflections by image; no significant fluctuation of intensities was observed. Structures were solved by means of

direct methods with the programs SIR92/97,[30] and subsequent difference Fourier maps and models were refined by least-squares procedures on F^2 by using SHELXL-97[31] integrated in the package WINGX version 1.64,[32] and empirical absorption corrections were applied to the data.[33] All hydrogen atoms were located on differences Fourier maps and introduced in the refinement as fixed contributors using a riding model with an isotropic thermal parameter fixed at 20% higher than those of the C sp^2 atoms and 50% for the C sp^3 atoms to which they were connected. Methyl groups they were refined with the torsion angle as a free variable. For the three compounds, all non-hydrogen atoms were anisotropically refined, and in the last cycles of refinement, weighting schemes were used, where weights are calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$. In the case of compound **6**, with a polar space group ($P2_1$), SHELXL automatically generates floating origin restraints to fix the X-ray 'centre of gravity' of the structure in the polar axis direction (in the case of $P2_1$, with unique axis *b*, the polar axis is *Y*). Complex **8** presents two independent molecules in the cell with very similar structural parameters. The crystal structure of **8** refined to a high *R* factor because of poor quality, probably as a result of multilayer-type crystals (considering the reciprocal), which could not be treated as twin crystals. The resulting R_{int} was very high (13.93%), which explains the poor final *R* value. The final residues (with low values $+0.90 < Q < -0.95$) are all located close to the metal centers.

CCDC-263761, –263762, –263763 and CCDC-263764 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Multidimensional Cyanide-Bridged Heterometallic Fe^{II}–Cu^{I} and Homometallic Cu^{I} Coordination Polymers from Solvothermal Reactions Involving either $K_3[Fe(CN)_6]$ or KCN as the Source of Cyanide Anions

Enrique Colacio,*[a] Ahderrahmane Debdoubi,[b] Raikko Kivekäs,[c] and Antonio Rodríguez[a]

Keywords: Coordination polymers / Copper / Cyanides / Heterometallic complexes / Solvothermal synthesis

The reaction between $K_3[Fe(CN)_6]$, $CuCl_2{\cdot}2H_2O$ and 1,10-phenanthroline (phen) under hydrothermal conditions gives rise to the formation of the 3D cyanide-bridged heterometallic Fe^{II}–Cu^{I} complex $[Fe(CN)_4(phen)_2Cu_2]$ (**1**). Its 3D network structure is constructed from two types of fused cyanide-bridged 10- and 14-metal-membered centrosymmetric rings (Fe_2Cu_8 and Fe_2Cu_{12}), which are defined by the general sequences $\{(Cu^I)_4\text{-}Fe^{II}\text{-}(Cu^I)_4\text{-}Fe^{II}\}$ and $\{(Cu^I)_6\text{-}Fe^{II}\text{-}(Cu^I)_6\text{-}Fe^{II}\}$, respectively. The copper(I) and iron(II) atoms exhibit distorted triangular planar and distorted octahedral coordination environments, respectively. Complex **1** is the first example of a 3D cyanide-bridged bimetallic complex prepared by hydrothermal methods. The use of methanol as solvent, KCN as source of cyanide anions and 2,2′,6,6′-bipyrimidine as the bridging ligand results in the isolation of the 2D homometallic copper(I) complex $[Cu_2(CN)_2(bpym)]{\cdot}H_2O$ (**2**). Its structure consists of neutral 2D (6,3) honeycomb layers in the *ab* plane made of fused $Cu_6(CN)_4(bpym)_2$ rings, in which the copper(I) atoms exhibit a distorted tetrahedral geometry. The layers are interdigitated in such a way that the bpym ligands lie above and below the ring cavities of neighbouring networks, with an ABCD repeat sequence of layers. Water molecules are located in the free space between the A/D and B/C layers. Under the same conditions as used for **1**, but with 4-methyl-2,2′,6,6′-bipyrimidine 2-oxide instead of phen, the 3D complex $[Cu_2(CN)_2(mbpym]$ (**3**) was obtained (mbpym = 4-methyl-2,2′,6,6′-bipyrimidine). During the reaction the oxygen atom of the *N*-oxide group is eliminated and the novel ligand mpym formed. Its structure consists of distorted tetrahedral copper(I) atoms connected by cyanide and mpym bridging ligands to give rise to a 3D chiral network.

Introduction

Research on multidimensional polymetallic coordination polymers is currently of great interest because of their fascinating structural diversity and potential applications as functional materials in fields such as electrical conductivity, molecule-based magnets, molecular absorption, ion-exchange, heterogeneous catalysis, etc.[1] Among these materials, cyanide-bridged bimetallic complexes deserve special attention as they exhibit, among others, interesting electrochemical, zeolitic, magnetic and photomagnetic properties.[2] These compounds can be prepared either by assembling cyanometallates and metal complexes or by multicomponent self-assembly of cyanide, metal ions and multidentate ligands. Although the majority of these systems are still being prepared by conventional solution routes, attention has recently turned to solvothermal techniques. In this regard, we and others have recently reported homo- and heterometallic cyanide-bridged complexes, which were assembled through hydrothermal reactions with azine and diazine ligands and either CuCN or hexacyanometallate anions as sources of cyanide anions.[3–8] As an extension of our work in this field, in this paper we report three novel coordination polymers that have been constructed from simple phenanthroline and bipyrimidine ligands, namely $[Fe(CN)_4(phen)_2Cu_2]$ (**1**; phen = 1,10-phenanthroline), $[Cu_2(CN)_2(bpym]{\cdot}H_2O$ (**2**; bpym = 2,2′-bipyrimidine) and $[Cu_2(CN)_2$ (mbpym)] (**3**; mbpym = 4-methyl-2,2′-bipyrimidine).

Results and Discussion

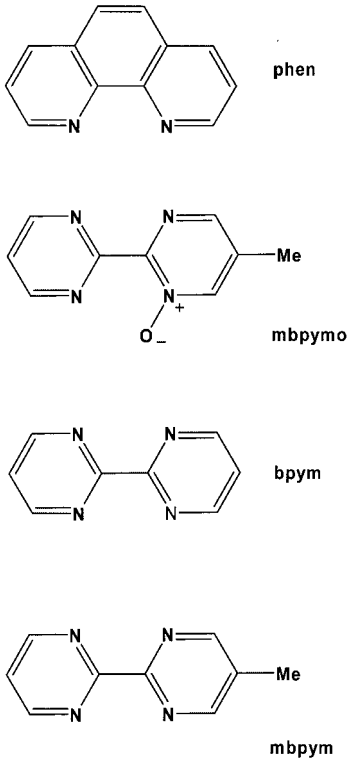
Solvothermal reactions are typically carried out in the 100–260 °C temperature range under autogenous pressure. Under these conditions, the reduced viscosity of the solvent enhances diffusion processes, thus favouring the solvent extraction of solids, the self-assembly of the precursors and the crystal growth from the solution. In fact, a rich variety of 1D to 3D polymetallic systems with intriguing structures and topologies have been recently prepared by solvothermal

 DOI: 10.1002/ejic.200401000

reactions, the great majority of them being hometallic in nature. The complexity of these reactions, in principle, prevents the control and prediction of crystal structures. Nevertheless, it is clear from empirical observations that the architecture of these multidimensional materials depends strongly on the subtle interplay between the characteristics of the metal ion (oxidation state, coordination preferences, plasticity of the coordination sphere, available coordination positions, redox capability, etc.), ligand (type and number of donor groups, bridging capability, connectivity, steric constraints, etc.) and reaction conditions (temperature, heating time, solvent, etc.). In this regard, Zubieta's group has prepared in the last few years a variety of multidimensional cyano-bridged complexes with simple diimine ligands. For these systems both changes of the ligand and the steric constraints imposed by the ligand substituents often give rise to the formation of quite different architectures.[4] As expected, a change in the reaction stoichiometry and/or counterion may also have a direct influence on the structure of the final product. For instance, the hydrothermal reaction of $Cu(CH_3COO)_2{\cdot}H_2O$, $K_3[Fe(CN)_6]$ and phen in a 2:1:1.5 molar ratio give rise to the 1D homometallic compound $[Cu_6(CN)_6(phen)_4]$.[5] However, the use of $CuCl_2{\cdot}2H_2O$ instead of $Cu(CH_3COO)_2{\cdot}H_2O$ and a 1:1:1 molar ratio allowed us to isolate $[Fe(CN)_4(phen)_2Cu_2]$ (**1**), an interesting 3D bimetallic complex. As far as we know, this compound is only the second example of a cyano-bridged bimetallic complex prepared by solvothermal techniques, and the first example of such a compound exhibiting a 3D structure.

While chelating donor ligands, such as phen, act as passivating agents by blocking metal coordination sites, bridging ligands are expected to favour the propagation of the structure. In a previous paper,[3] we reported that the solvothermal reaction of $K_3[Fe(CN)_6]$, $CuCl_2{\cdot}2H_2O$ and bpym, a bisdidentate ligand, in methanol leads to a 2D material made of honeycomb layers with alternating bpym and cyanide bridges. However, under the same solvothermal conditions, the use of KCN instead of $K_3[Fe(CN)_6]$ as a source of cyanide anions resulted in the formation of a different 2D homometallic compound $[Cu_2(CN)_2(bpym)]{\cdot}H_2O$ (**2**).

Recently, we have prepared the compound 4-methyl-2,2′-bipyrimidine 2-oxide (mbpymo, see Scheme 1), which, in principle, might bridge two metal ions to produce polynuclear complexes. However, all attempts to obtain this kind of compound were unsuccessful.[9] In view of this, we decided to use hydrothermal methods to force their preparation. Thus, by following the same synthetic procedure as that for **2**, but using $K_3[Fe(CN)_6]$ instead of KCN, the 3D complex $[Cu_2(CN)_2(mbpym)]$ (**3**), which contains cyanide and 4-methyl-2,2′-bipyrimidine (mbpym) bridging ligands was obtained (when KCN is used as a source of cyanide anions no definite compound could be isolated). During the hydrothermal reaction the *N*-oxide group of the ligand is lost and mbpym formed. This fact, and the reduction of iron(III) and copper(II) ions to iron(II) and copper(I), respectively, are a consequence of the high pressure and temperature used in the hydrothermal reactions for preparing complexes **1**–**3**. Cyanide groups, from either KCN or the dissociation of $[Fe(CN)_6]^{3-}$, are probably responsible for the reduction process, yielding cyanogen as the oxidation product. Moreover, it is well known that copper(I) cyanide species are more stable at elevated temperatures and pressures than those of copper(II).[4]



Scheme 1.

X-ray Structures

The asymmetric unit of the structure of **1**, together with the atomic labelling scheme, is given in Figure 1; selected bond lengths and angles are gathered in Table 1. The structure is constructed from two types of 10-metal-membered (Fe_2Cu_8) and two types of 14-metal-membered (Fe_2Cu_{12}) centrosymmetric rings, which fuse out of plane into an intricate 3D network. Within these rings, which are defined by the general sequences $\{(Cu^I)_4\text{-}Fe^{II}\text{-}(Cu^I)_4\text{-}Fe^{II}\}$ and $\{(Cu^I)_6\text{-}Fe^{II}\text{-}(Cu^I)_6\text{-}Fe^{II}\}$, respectively, the metal centres are bridged by cyanide groups (Figure 1, middle). The Fe_2Cu_8 rings are similar to those observed in the 2D Fe^{II}–Cu^I compound $[Fe(bipy)_2(CN)_4Cu_2]$.[3] There are four independent Cu^I atoms in the structure, all of which exhibit a distorted trigonal-planar geometry with Cu–X bond lengths and X–Cu–X angles (X = C or N) in the ranges 1.872–1.975 Å and 104.49(12)–140.68(13)°, respectively. Each of these Cu^I atoms is connected by cyanide groups to two Cu^I atoms and one Fe^{II} atom, with Cu···Cu and Cu···Fe distances in the ranges 4.8736(6)–4.9456(6) Å and 4.7773(8)–4.9683(6) Å, respectively. There are two crystallographically independent Fe^{II} atoms in the structure (Fe1 and Fe2),

which exhibit a distorted octahedral FeN_4O_2 coordination environment. Each Fe^{II} atom is coordinated by four nitrogen atoms belonging to two bidentate phen ligands and to two carbon atoms from cyanide groups, these latter bridging each Fe^{II} atom to two Cu^{I} atoms and displaying a *cis* orientation. As expected for the Fe–CN–Cu coordination, the Fe–C–N angles [171.3(3)–177.3(3)°] are closer to linearity than the Cu–N–C angles [148.5(3)–165.3(2)°]. This is due to the stronger covalent interaction between C and Fe^{II} atoms. The bond lengths and angles in the Fe(CN)(phen) unit are similar to those found for the $Fe(bipy)(CN)_2$ unit in the 2D compound $[Fe(bipy)_2(CN)_4Cu_2]$ and the molecular squares $[Fe_2Cu_2(\mu\text{-}CN)_4(bipy)_6](PF_6)_4\cdot 2H_2O$ and $[Fe_2Co_2(\mu\text{-}CN)_4(bipy)_6]\cdot 2CHCl_3\cdot CH_3NO_2$.[10]

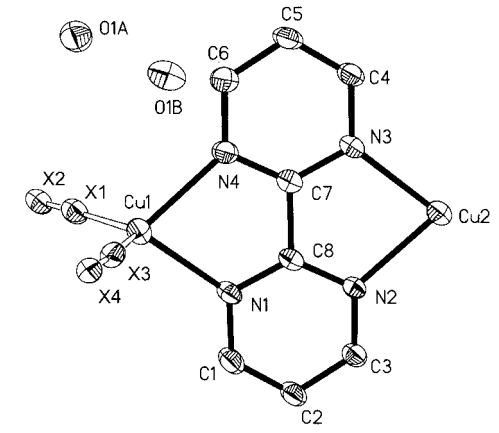
[a] Equivalent positions: $x - 1/2, -y + 3/2, z + 1/2$. [b] $-x + 1, -y + 2, -z + 1$. [c] $-x + 3/2, y - 1/2, -z + 3/2$.

The Fe1 and Fe2 centres are chiral and display opposite absolute configurations, therefore the crystal as a whole is racemic. One of the Fe_2Cu_8 rings contains two Fe1 atoms and the other one two Fe2 atoms, with approximate dimensions 11×18 Å^2 and 8×18 Å^2, respectively. The Fe_2Cu_{12} rings containing Fe1 and Fe2 have approximate dimensions 8×23 Å^2 and 13×25 Å^2. Cavities created by the out-of-plane fusion of the rings are filled by the coordinated phen ligands. Within the rings the maximum deviation from the mean plane corresponds to the iron(II) atoms. It should be noted that **1** is the first example of a 3D cyanide-bridged bimetallic complex prepared by hydrothermal methods.

We have shown that the related 2D Fe^{II}–Cu^{I} bimetallic compound $[Fe(bipy)_2(CN)_4Cu_2]$[3] exhibits a high spin:low spin equilibrium with 96% of the Fe^{II} atoms in the low-spin state ($S = 0$) at room temperature. Likewise, it has been shown recently that a series of cyanide-bridged Fe^{II}–M systems (M = Pd^{II}, Pt^{II}, Ni^{II}, Au^{I}, Ag^{I}) exhibit thermal-, pressure-, and light-induced spin crossover transitions.[11] In the case of **1**, however, the magnetic measurements reveal that the compound is diamagnetic at room temperature, thus indicating that the ligand field is strong enough to force all the Fe^{II} atoms to be in the low-spin state.

The structure of **2** (Figure 2) is very similar to that previously reported by us for the dehydrated compound $[Cu_2(CN)_2(bpym)]$[3] and consists of neutral 2D(6,3) honeycomb layers in the *ab* plane made of fused $Cu_6(CN)_4(bpym)_2$ rings and water molecules. The structure can be alternatively described as constructed from zig-zag $\{Cu(CN)\}_4$ chains linked by bisdidentate bridging bpym ligands generating the (6,3) net topology. Selected bond lengths and angles are given in Table 2. Two major differences between the structure of **2** and its dehydrated complex are observed: a) in **2**, the mean plane of the bpym ligand is almost perpendicular to the layers, with a dihedral angle of 90.2° (or 89.8°), whereas in the dehydrated complex this dihedral angles is only 73°; b) in **2**, the layers are stacked in such a way that bpym ligands are interdigitated and aligned above and below one sheet with the cavities in neighbouring layers, giving rise to an ABCD repeat pattern of layers (Figure 3). The bpym ligands of layers A and B are parallel.



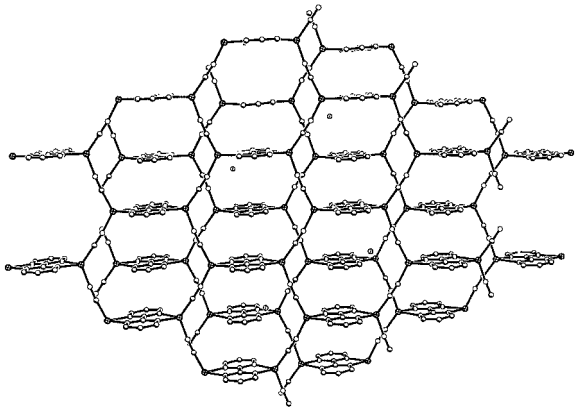


Figure 2. Perspective view of the asymmetric unit of **2** with the disordered CN bridging groups labelled as X (top). View down the *c* axis of two neighbouring layers with the same orientation of the bpym ligands (bottom).

[a] Equivalent positions: x, $y + 1$, z. [b] $x - 1/2$, $y + 1/2$, z.

Likewise, the mean planes of the layers C and D are also parallel but form a dihedral angle of 47.5° with those of layers A and B. Thus, layers are arranged in couples, with interlayer distances of about 4 Å and 6 Å for layers of the same couple (AB and CD) and different couples (BC and DA), respectively. In **2**, however, the repeat pattern of layers is of the ABAB type. Water molecules are located in the free space between the layers of different couples.

In **2**, Cu1 and Cu2 exhibit distorted tetrahedral coordination environments, which are formed by the coordination of two bridging cyano groups and one bridging bisdidentate bpym ligand, with Cu–X(cyano) (X = C or N) and Cu–N(bpym) bond lengths in the ranges 1.873(7)–1.909(7) Å and 2.102(4)–2.140(4) Å, respectively. As expected, the small bite of the bpym ligands leads to distorted tetrahedral coordination geometries with bond angles in the range 78.04(15)–125.7(2)°. The Cu···Cu distances across the cyanide ligands are 4.9431(12) Å and 4.9614(12) Å, whereas that across the bpy ligand is 5.6686(11) Å. The Cu_6 ring

has approximate dimensions of 8.8×11 Å^2, with Cu···Cu distances across the ring in the range 9.917(17)–10.9254(16) Å.

The asymmetric unit of the structure of $[Cu_2(mbpym)(CN)_2]$ (**3**) is given in Figure 4; selected bond lengths and angles are listed in Table 3. There are two crystallographically independent distorted tetrahedral copper(I) atoms in the structure, which are coordinated, as in **2**, by two bridging cyano groups and one bisdidentate bridging mbpym ligand. In contrast to **2**, the join of the Cu^I atoms does not take place in the same plane, therefore the structure is 3D. When viewed down the *a* axis, the structure seems to be made of fused hexagonal rings (Figure 4, middle). However, a closer examination reveals that these rings are not closed (Figure 4, bottom), and the Cu atoms are distributed in the *a* direction in a spiral manner leading to a 3D chiral network with hexagonal channels of approximate dimensions 9×9.5 Å^2. The space filling is achieved by orientation of the mbpym ligands in such a way that the methyl groups lie on the channels. The bond lengths and angles are similar to those observed in **2**. The Cu···Cu distance across the mbpym is 5.7311(10) Å, whereas the Cu···Cu distances across the cyanide ligands are 4.9526(9) Å and 4.9590 (9) Å.

Concluding Remarks

From the above results the following conclusions can be drawn: (i) The use of hexacyanoferrate(III) as a precursor together with $CuCl_2 \cdot 2H_2O$ and polydentate ligands in simple hydrothermal reactions allows the isolation of homo- and heterometallic cyanide-bridged complexes with intriguing 3D architectures. (ii) The introduction of sterically demanding substituents in the bisdidentate ligand bpym leads to the formation of different structures (compound **2** vs. compound **3**). (iii) Solvothermal chemistry is a versatile and useful synthetic tool to prepare cyanide-bridged polymers.

Solvothermal reactions between other cyanometallate precursors, metal salts and a wide variety of polydentate ligands are currently under examination in our laboratory.

Experimental Section

4-Methyl-2,2′-bipyrimidine was prepared by condensation of 2-cyanopyrimidine with hydroxylamine·HCl and further condensation with 3-ethoxy-2-methylpropenal.[9] The rest of the reagents are commercially available and were used without further purification.

$[Fe(CN)_4(phen)_2Cu_2]$ (1): A mixture of $CuCl_2 \cdot 2H_2O$ (0.21 g, 1.22 mmol), phen (0.22 g, 1.22 mmol), $K_3[Fe(CN)_6]$ (0.4 g, 1.22 mmol) and water (8 mL) was added to a Teflon-lined stainless steel Parr acid digestion vessel and heated at 180 °C for 2 d under autogenous pressure. Slow cooling of the resulting solution to room temperature afforded dark red crystals of **1**. Yield: 0.22g (55%). IR (KBr): ν_{CN} = 2090, 2096 and 2119 cm^{-1}. $C_{28}H_{16}Cu_2N_8Fe$: calcd. C 51.90, H 2.49, N 17.31; found C 51.55, H 2.56, N 17.09. A Fe/Cu ratio of 0.51 was determined by SEM (scanning electron microscopy).

$[Cu_2(CN)_2(bpym] \cdot H_2O$ (2): Dark red crystals of **2** were grown from the hydrothermal treatment of $CuCl_2 \cdot 2H_2O$ (0.054 g, 0.32 mmol), 2,2′-bipyrimidine (0.050 g, 0.32 mmol), KCN (0.123 g, 1.92 mmol) and methanol (8 mL) in the same conditions as for **1**. Yield: 0.026g (47%). IR (KBr): ν_{CN} = 2116 cm^{-1}. $C_{10}H_8Cu_2N_6O$: calcd. C 33.78, H 2.27, N 23.65; found C 33.75, H 2.09, N 23.75.

$[Cu_2(CN)_2(mbpym]$ (3): This compound was prepared as dark red crystals under the same hydrothermal conditions as above with $CuCl_2 \cdot 2H_2O$ (0.098 g, 0.57 mmol), 4-methyl-2,2′-bipyrimidine 2-oxide (0.1 g, 0.57 mmol), $K_3[Fe(CN)_6]$ (0.189 g, 0.57 mmol) and methanol (8 mL). Yield: 0.032g (32%). IR (KBr): ν_{CN} = 2071 cm^{-1}. $C_{11}H_8Cu_2N_6$: calcd. C 37.58, H 2.30, N 23.92; found C 37.51, H 2.36, N 23.52.

Physical Measurements: Elemental analyses were carried out at the Instrumentation Scientific Centre of the University of Granada on a Fisons–Carlo–Erba analyser model EA 1108. IR spectra were recorded on a MIDAC progress IR spectrometer using KBr pellets.

X-ray Crystallography: Single-crystal diffraction data for **1**–**3** were measured on a Bruker Smart Apex diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). All data sets were corrected for Lorentz and polarisation effects, and absorption corrections were made with SADABS.[12] A total of 45034, 7827 and 7832 reflections giving 7791, 2902 and 3101 unique reflections were collected (R_{int} = 0.0402, 0.0359 and 0.0260) for **1**, **2** and **3**, respectively.

The structures were solved by direct methods and refined on F^2 with the SHELXL97 program.[13] For each compound, refinement of each CN bridge between two Cu^I atoms indicated disordering with respect to the C and N termini. When site occupation parameters of the bridging CN atom positions did not differ markedly from the ratio 50:50 the parameters were fixed to 50% C and 50% N. The disordered CN atom positions are labelled in tables and drawings with X1, X2, X3 etc. For example, in compound **1** the first atom position: 0.5 N6a + 0.5 C26b = X1; second 0.5 N6b + 0.5 C26a = X2; third 0.5 N7a + 0.5 C27b = X3, etc. For all structures, the non-hydrogen atoms were refined with anisotropic displacement parameters and the hydrogen atoms were treated as riding atoms using the SHELX97 default parameters.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

For **1**, the asymmetric unit of the structure consists of four Cu^{I} atoms, two Fe^{II} atoms, eight cyanide ions and four phen ligands. Four of the cyanide ions bridging the copper atoms are disordered.

For **2**, in addition to the disordered bridging cyanide groups, the oxygen atom of the water molecule is disordered over two sites. Site occupation parameters for the atoms were refined, but the hydrogen atom of the disordered water molecule could not be reliably located.

Complex **3** has a lot of pseudo-symmetry and the structure can be solved and refined both in centrosymmetric space group *C*2/*c* and in non-centrosymmetric space group *Cc*. Site occupation parameters for each disordered CN atom position were fixed to 50% C and 50% N for both space groups. Refinement in the centrosymmetric space group resulted in a partly disordered mbpym ligand, whereas refinement in the non-centrosymmetric space group gave a fully ordered ligand. As the *R*1 value of 0.0732 in the centrosymmetric space group is markedly higher than that of 0.0477 in the non-centrosymmetric space group we report here the structure in the lower symmetry space group *Cc*. The structure of **2** was refined as a racemic mixture. The crystal data for **1** to **3** are summarised in Table 4.

Synthesis, Structure and Spectroscopic Properties of Novel 9,10-Bis{[6-(diphenylphosphanyl)-2-pyridylmethyl]propylaminomethyl}anthracene-Bridged Group 11 Metal (M = Cu^I and Ag^I) Dinuclear Complexes

Hu Xu,[a] Feng-Bo Xu,*[a] Qing-Shan Li,[a] Wei-Guo Duo,[a] Hai-Bin Song,[a] and Zheng-Zhi Zhang*[a]

Keywords: Dinuclear complexes / Phosphanyl-pyridine ligands / Copper / Silver / Charge transfer interaction / Dual emission

Dinuclear complexes $[M_2(\mu\text{-BPNNAn})]X_2$ (M = Cu^I, X = ClO_4^- **1**, X = BF_4^- **2**; M = Ag^I, X = BF_4^- **3**, X = ClO_4^- **4**) have been prepared by treating 9,10-bis{[6-(diphenylphosphanyl)-2-pyridylmethyl]propylaminomethyl}anthracene (BPNNAn) with $M(CH_3CN)_4X$ in CH_2Cl_2. The structures of complexes **1**, **2** and **3** have been determined by single-crystal X-ray diffraction studies. In the complexes, BPNNAn acts as a chelating ligand and two metal ions riding on two bridgehead carbon atoms in the anthracene group leads to the deformation of the anthracenyl ring. The Cu–Arene charge transfer interaction is observed from the nonfluorescent emission of Cu complex **1**, while the Ag complex **3** exhibits dual emission at high concentrations in a CH_2Cl_2 solution.

Introduction

In recent years increasing interest, focused on phosphanyl-pyridine ligands as building blocks, stems from its ability to form hetero- or homonuclear metal complexes.[1] The typical representative 2-(diphenylphosphanyl)pyridine (dppy) has been widely used to synthesize dppy-bridged dinuclear species because of the short bite between the two donor atoms and the poor flexibility.[2] On the other hand, anthracenyl rings exist in a great deal of organic compounds as a good fluorophore. These types of compounds have been applied as a fluorescence chemosensor for small molecules or metal ions.[3] Therefore, we wish to associate two dppy units with an anthracenyl group through long chain spacers to form a polydentate ligand and to explore the change in fluorescence after the bonding to metal atoms. Herein we report the novel dinuclear complexes $[M_2(\mu\text{-BPNNAn})]X_2$ (M = Cu, X = ClO_4^- **1**, X = BF_4^- **2**; M = Ag, X = BF_4^- **3**, X = ClO_4^- **4**) constructed from the polydentate phosphanyl-pyridyl ligand 9,10-bis{[6-(diphenylphosphanyl)-2-pyridylmethyl]propylaminomethyl}-anthracene (BPNNAn) and Group 11 metals. The Cu complexes are formed through charge transfer interactions and Ag complexes give dual fluorescence emission at high concentrations in CH_2Cl_2 solution.

Results and Discussion

BPNNAn was prepared from 9,10-bis(propylaminomethyl)anthracene, 6-(bromomethyl)-2-chloropyridine and lithium diphenylphosphide by two-step reactions. In the ligand molecule, two dppy units are linked together through an eight atom chain. Meanwhile, there are two lone-pair electrons belonging to two tertiary N atoms associated with the dppy units by a methylene spacer. Hence, it is potentially a polydentate ligand. Its Group 11 dinuclear complexes $[M_2(\mu\text{-BPNNAn})]X_2$ (M = Cu, X = ClO_4^- **1**, X = BF_4^- **2**; M = Ag, X = BF_4^- **3**, X = ClO_4^- **4**) were obtained by the reaction of BPNNAn with $M(CH_3CN)_4X$ (M = Cu or Ag; X = ClO_4^- or BF_4^-) in a 1:2 mol ratio and are stable in air and moisture in the solid state, and soluble in dichloromethane and acetone (Scheme 1).

Slow evaporation of a solution of complex **1** in acetone and ethyl acetate yields bright yellow crystalline material, which has been determined as **1**·2CH_3COCH_3 (Figure 1a) by a single-crystal X-ray diffraction study. Using similar methods, bright yellow crystalline **2**·1.5$ClCH_2CH_2Cl$ and pale green crystalline **3**·2CH_3OH (Figure 1b, only one of the two independent molecules is shown) can be obtained. The detailed crystallographic data and structural refinements for **1**, **2** and **3** are summarized in Table 1.

It can be envisaged that two dppy units contained in BPNNAn occur at a relatively extended distance to relieve their mutual repulsion. However, after coordination with the group 11 metals (M = Cu, Ag) a great conformational change of the ligand takes place. BPNNAn acts as a chelating ligand, in which the dppy-N and tertiary N atoms from

one arm and the P atom from the other simultaneously capture one of the M atoms. Each metal center exhibits a three coordinated trigonal pyramidal geometry. The two metal atoms ride on the two bridgehead carbon atoms in the anthracene group as shown in Figure 2 (only displaying complex **1**). Such a coordination mode leads to a remarkable structural change in the anthracenyl ring. To relieve the steric repulsion, the 9,10-carbon atoms of the anthracenyl ring are markedly bent towards the two metal cores, out of the coplanar configuration, and form dihedral angles of 20.1° (**1**) and 9.3° (10.8°) (**3**) between the side benzene rings in the anthracenyl units. The values are larger than that of 7.7° in our mono-Cu–η^6–arene complex.[4] For the same reason *n*-propyl groups on the tertiary N atoms and two phenyl rings on the P atoms stretch away from the M cores in a linear direction as much as possible. The dinuclear cations of **1** (Figure 1a), and **3** (Figure 1b) possess the C_2-symmetric structures. No interaction is observed between cations and anions. Selected bond lengths [Å] and angles [°] for complexes **1**, **2** and **3** are summarized in Table 2.

[a] Symmetry transformations used to generate equivalent atoms: #2 $-x + 1, y, -z + 3/2$.

Apart from the two tertiary N atoms, two dppy units in a head-to-tail mode forming an eight-membered ring $M_2P_2N_2C_2$, which has an eclipsed conformation, bridge the metal atoms. The torsion angle P(1)–Cu(1)–Cu(2)–P(2) of 117.8° for **1** is much smaller than that of 125.2°(128.3°) for **3**. While in $[Ag_2(\mu\text{-}L^1)_2(MeCN)_2]^{2+}$ [L^1 = 2-(diphenylphosphanyl)-6-(pyrazol-1-yl)pyridine],[5] $[Cu_2(\mu\text{-}L)_2(MeCN)_2]^{2+}$ (L = 6-(diphenylphosphanyl)-2,2′-bipyridine)[6] and $[Cu_2(\mu\text{-}L^1)_2(MeCN)_2]^{2+}$ [L^1 = 2-(diphenylphosphanyl)-6-(pyrazol-1-yl)pyridine],[7] the similar eight-membered rings are staggered conformations.

The Cu···Cu distance 2.9734(16) Å for **1** is close to the sum of the van der Waals radii of Cu^I centers and lies towards the longer distances of the known Cu–Cu bonds [2.639(2)–2.938(2) Å] for dinuclear Cu^I complexes.[8] The value is slightly longer than that of 2.721(3) Å in $[Cu_2(\mu\text{-dppy})_3(MeCN)]^+$[9] and much shorter than those of 3.584(1) Å, 3.625(1) Å and 3.941(2) Å in $[Cu_2(\mu\text{-dppy})_2(MeCN)]^+$,[10] $[Cu_2(\mu\text{-}L^1)_2(MeCN)_2]^{2+}$ [L^1 = 2-(diphenylphosphanyl)-6-(pyrazol-1-yl)pyridine][7] and $[Cu_2(\mu\text{-}L)_2(MeCN)_2]^{2+}$ (L = 6-(diphenylphosphanyl)-2,2′-bipyridine),[6] respectively.

The Ag···Ag separation of 3.0874(19) Å [3.0963(16) Å] in **3** is slightly shorter than that of 3.145 Å in $[Ag_2(dppy)_2]^{2+}$[11] and 3.162(1)–3.223(1) Å in $[Ag_3\{HC(PPh_2)_3\}_2]^{3+}$.[12] And the value compares with those found in $[Ag_2(\eta^1\text{-dppy})(\mu\text{-dppy})_2]^{2+}$ [3.072(1) Å],[13] $[Ag_2Cl_2(dppy)_3]$ [3.074(2) Å][14] and $[Ag_2(dpm)_2(NO_3)_2]$ (3.085 Å) [dpm = bis(diphenylphosphanyl)methane].[15] But the Ag···Ag distance of **3** is slightly longer than that of 2.964(1) Å reported in $[Ag_2(\mu\text{-}L^1)_2(MeCN)_2]^{2+}$ [L^1 = 2-(diphenylphosphanyl)-6-(pyrazol-1-yl)pyridine],[5] which indicates the possibility of a weak Ag···Ag bond. Since the value of 3.30 Å represents the upper limit for the Ag···Ag interactions in coordination compounds,[16] it can be concluded that Ag···Ag interactions are present in complex **3**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In addition, there is an intramolecular π-π stacking interaction between two phenyl rings on two P atoms that are nearly orthogonal to the anthracene mean plane. They stack partially with separations of 3.33 Å and 3.47 Å (3.39 Å) for **1** and **3**, respectively. The π-π stacking interactions may be one of the reasons for drawing two metal atoms together that are located close to one another. The distance of the center of the M···M to the anthracene central ring in **1** is 2.9 Å, while the corresponding value in **3** is 3.2 Å. When $[M_2(\mu\text{-BPNNAn})]X_2$ react with Na_2S, the free ligand BPNNAn can be recovered quantitatively by removing the coordinated Cu or Ag atoms from the polydentate complexes (Scheme 1).

Compared with the free ligand, the fluorescence emission intensity of $[M_2(\mu\text{-BPNNAn})]X_2$ changes dramatically. The spectrum of BPNNAn in CH_2Cl_2 solution (1.0×10^{-5} M) at room temperature displays the expected strong emission peak for the anthracenyl fluorophore centered at 431 nm. Complex **1** in CH_2Cl_2 gives a feeble emission, while **3** gives a moderately strong peak (Figure 3). What is more interesting is that a broad new emission peak, centered at 460 nm, emerges, except for the anthracenic emission of **3**. The new emission for **3** is dependent on concentration and is ascribable to the formation of excimer type intermolecular complexes resulting from the interaction between the two anthracenyl rings. When the concentration is very low, the emission peak results mainly from the anthracenyl ring. With the increase of the concentration, the excimer emission gradually appears and becomes dominant (Figure 4). Therefore, we propose that there is a series of conversion processes for **3** in the CH_2Cl_2 solution. Firstly, the Ag···Ag bond separates away from the anthracenyl unit and the deformation of the anthracenyl ring forms **3′**. Then the combining of two **3′** forms the dimer. But in the low concentration range, **3′** cannot efficiently form the dimer, which generates a new emission. At high concentration, the dimer occurs in larger quantities than both **3** and **3′**. So the new emission dominates in the emission spectrum in Ag complexes at high concentration (Scheme 2). As for **1** the feeble emission shows the formation of a charge transfer complex in the Cu complex,[17] in which the charge transfer interaction is fairly strong and prevents **1** from forming the analogs of **3′**. On the other hand, complex **1** does not generate the dual emission as **3** does, which also further proves the presence of the aforementioned Cu–Arene charge transfer interaction in Cu complexes. Besides, we also observe the fluorescence emission intensity change process for the solution of BPNNAn in CH_2Cl_2 containing $Cu(CH_3CN)_4ClO_4$ of different concentrations (Figure 5). With the increasing concentration of Cu^I, the fluorescence emission intensity of the solution descends gradually until the emission becomes weak. Recording the fluorescence intensity against the ratio

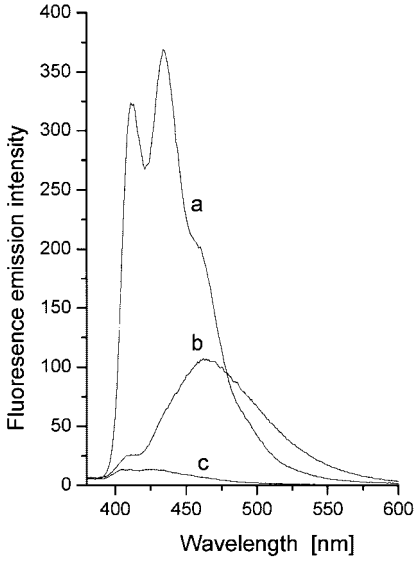

Figure 3. Fluoresence emission spectra of **a** (BPNNAn), **b** (**3**) and **c** (**1**) (λ_{ex} = 360 nm) at 298 K in CH_2Cl_2 (1.0×10^{-5} M).

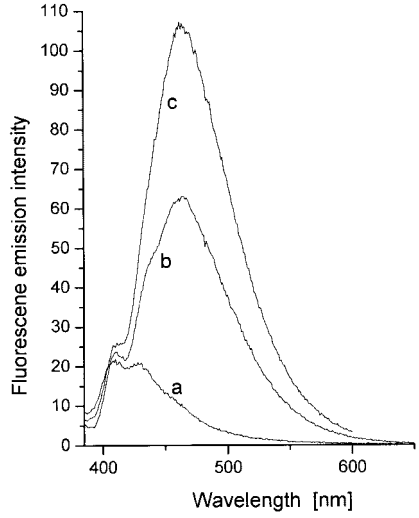

Figure 4. Fluorescene emission intensity of **3** in different concentrations of a CH_2Cl_2 solution: (a) 1.0×10^{-6} M, (b) 5.0×10^{-6} M, (c) 1.0×10^{-5} M.

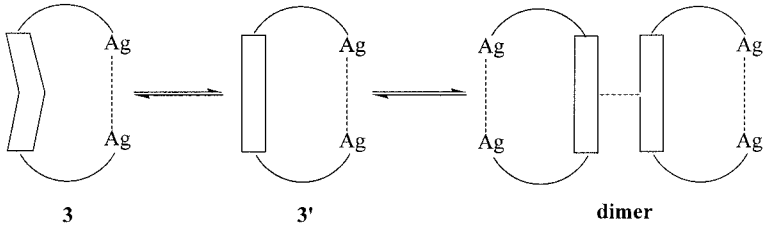

Scheme 2. Conversion process of **3** in CH_2Cl_2 solution.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[Cu^I] to [**1**], we get a corresponding curve, which indicates that a compound like **1** will only be formed in the end if sufficient Cu^I exists in solution (Figure 6).

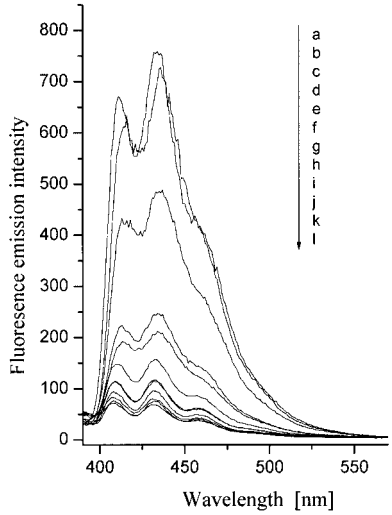

Figure 5. Fluorescence emission spectra (λ_{ex} = 360 nm) of solutions containing $Cu(CH_3CN)_4ClO_4$ of different concentrations in a CH_2Cl_2 solution of BPNNAn (1.0×10^{-5} M) (a = 0×10^{-5} M, b = 0.2×10^{-5} M, c = 0.4×10^{-5} M, d = 0.6×10^{-5} M, e = 0.8×10^{-5} M, f = 1.0×10^{-5} M, g = 1.2×10^{-5} M, h = 1.4×10^{-5} M, i = 1.6×10^{-5} M, j = 1.8×10^{-5} M, k = 2.0×10^{-5} M, l = 2.2×10^{-5} M).

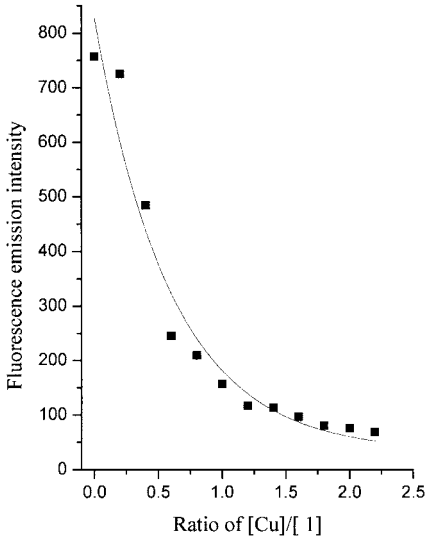

Figure 6. Plot of the recorded relation of fluorescence intensity at 431 nm against the ratio of [Cu^I] to [**1**] (1.0×10^{-5} M) in CH_2Cl_2.

There is a hemilabile coordination mode in these structures, which makes the study of the catalytic activity of these BPNNAn systems with the late transition metals highly feasible. The work in this field is presently under way.

Conclusions

We have prepared a new polydentate phosphane ligand BPNNAn and obtained its Group 11 dinuclear complexes **1**, **2**, **3** and **4**, in which anthracene planes are remarkably bent. Complexes [M_2(μ-BPNNAn)]X_2 react with Na_2S to release quantitatively the free ligand BPNNAn. Cu···Arene charge transfer interactions in the Cu complexes exist, which leads to nonfluorescence emission of the complexes, while Ag complexes, which possess Ag···Ag bonds, generate dual fluorescence emission under the same conditions.

Experimental Section

General Procedures: All reactions were carried out under prepurified argon using standard Schlenk or vacuum line techniques unless stated otherwise. The solvents were purified by standard methods. ^1H and ^{31}P NMR spectra were recorded on a Bruker AC-300 NMR spectrometer. Elemental analyses were measured by using a Perkin–Elmer 2400C Elemental Analyzer. The fluorescence spectroscopy was measured with a Cary Eclipse fluorescence spectrophotometer.

CAUTION: Metal perchlorates are potentially explosive in reactions with organic compounds and proper care should always be taken.

Preparation of 9,10-Bis[(6-chloro-2-pyridylmethyl)propylaminomethyl]anthracene (L): 6-(bromomethyl)-2-chloropyridine (4.54 g, 22 mmol) and K_2CO_3 (5.52 g, 40 mmol) were added to a solution containing 9,10-bis(propylaminomethyl)anthracene (3.0 g, 10 mmol) in MeCN (80 mL). The resulting mixture was stirred at refluxing temperature for 3 days while being exposed to air. This solution was cooled and then filtered through Celite. The solvent was removed in vacuo and water (50 mL) was added. The aqueous phase was extracted with CH_2Cl_2 (3×40 mL) and the organic phase dried with anhydrous Na_2SO_4 overnight. Most of the CH_2Cl_2 was removed under vacuum and ether was added. Cooling to –10 °C yielded a pale yellow solid, which was recrystallized with dichloromethane-haxane to afford **L**. Yield: 2.64 g (46.2%). ^1H NMR (300 MHz, $CDCl_3$): δ = 8.48–8.51(q, 4 H, An*H*) (An = Anthracene), 7.42–7.46(q, 4 H, An*H*), 7.19–7.24(t, 2 H, Py*H*) (Py = Pyridine), 6.99–7.02(d, 2 H, Py*H*), 6.86–6.89(d, 2 H, Py*H*), 4.55(s, 4 H, AnCH_2), 3.61(s, 4 H, NCH_2Py), 2.54–2.59(t, 4 H, CH_2CH$_2$CH$_3$), 1.57–1.69(m, 4 H, CH$_2$CH_2CH$_3$), 0.76–0.81(t, 6 H, CH$_2$CH$_2$CH_3) ppm. Elemental analysis for $C_{34}H_{36}Cl_2N_4$ (571.6 g): calcd. C 71.45, H 6.30, N 9.81; found: C 71.44, H 6.42, N 9.72.

Preparation of BPNNAn: A solution of *n*BuLi in hexane (4 mL, 1.88 M) was added dropwise to a solution of Ph_2PH (1.29 g, 6.94 mmol) in THF (15 mL) at 0 °C with stirring and the resulting solution was stirred for half an hour at this temperature. Then the mixture was added dropwise to a solution of **L** (1.80 g, 3.15 mmol) in THF (20 mL) at –78 °C and the mixture was allowed to warm slowly to room temperature and continuously stirred for 5 h, after which the solution was refluxed for 2 h. After cooling, the solvent was removed in vacuo and water (50 mL) was added. The aqueous phase was extracted with CH_2Cl_2 (3×30 mL) and the organic phase dried with anhydrous Na_2SO_4 overnight. Most of the CH_2Cl_2 was removed under vacuum and the residue was cooled to 0 °C for 8 h to afford a light yellow solid BPNNAn. Yield: 1.6 g (57.4%). ^1H NMR(300 MHz, $CDCl_3$): δ = 8.52–8.55 (q, 4 H, An*H*), 7.43–7.46 (q, 4 H, An*H*), 7.23–7.35 (m, 22 H, Ph*H* and Py*H*), 7.04–7.07(d, 2 H, Py*H*), 6.75–6.78(d, 2 H, Py*H*), 4.60(s, 4 H, AnCH_2), 3.76(s, 4 H, NCH_2Py), 2.54–2.59(t, 4 H, CH_2CH$_2$CH$_3$), 1.57–1.68(m, 4 H, CH$_2$CH_2CH$_3$), 0.73–0.78 (t, 6 H, CH$_2$CH$_2$CH_3) ppm. ^{31}P NMR (300 MHz, $CDCl_3$): δ = –4.42 (s) ppm. Elemental analysis for $C_{58}H_{56}N_4P_2$ (871.1 g): calcd. C 79.90, H 6.43, N 6.43; found: C 79.81, H 6.22, N 6.55.

Preparation of Complex $[Cu_2(\mu\text{-BPNNAn})](ClO_4)_2$ (1): Solid $[Cu(MeCN)_4][ClO_4]$ (0.107 g, 0.328 mmol) was added to a solution of BPNNAn (0.143 g, 0.164 mmol) in CH_2Cl_2 (20 mL) with stirring at –30 °C. The resulting solution was allowed to warm slowly to room temperature and stirred continuously for 2 h at this temperature. Subsequent diffusion of diethyl ether into the concentrated solution gave complex **1** as a yellow powder. Yield: 0.09 g (45.69%). ^{31}P NMR (300 MHz, $[D_6]$DMSO): δ = 12.80(s) ppm. Elemental analysis for $C_{58}H_{56}Cl_2Cu_2N_4O_8P_2 \cdot 2CH_3C(O)CH_3$ (1313.1 g): calcd. C 58.49, H 5.18, N 4.26; found: C 58.18, H 5.45, N 4.25.

Preparation of Complex $[Cu_2(\mu\text{-BPNNAn})](BF_4)_2$ (2): Complex **2**, as a bright yellow powder, was synthesized by BPNNAn (0.110 g, 0.126 mmol) and $[Cu(MeCN)_4][BF_4]$ (0.079 g, 0.251 mmol) by the same procedure as used for **1**. Yield: 0.112 g (74.67%). ^{31}P NMR (300 MHz, $[D_6]$DMSO): δ = 12.82(s) ppm. Elemental analysis for $C_{58}H_{56}Cu_2B_2N_4F_8P_2 \cdot 1.5ClCH_2CH_2Cl$ (1320.1 g): calcd. C 55.45, H 4.70, N 4.24; found: C 55.05, H 4.91, N 4.47.

Preparation of Complex $[Ag_2(\mu\text{-BPNNAn})](BF_4)_2$ (3): Complex **3**, as a pale yellow powder, was synthesized by BPNNAn (0.143 g, 0.164 mmol) and $[Ag(MeCN)_4][BF_4]$ (0.118 g, 0.328 mmol) by the same procedure as used for **1**, but in darkness. Yield: 0.120 g (57.97%). ^{31}P NMR (300 MHz, $[D_6]$DMSO): δ = 21.97 ppm. Elemental analysis for $C_{58}H_{56}Ag_2B_2N_4F_8P_2 \cdot 2CH_3OH$ (1324.5 g): calcd. C 54.36, H 4.83, N 4.23; found: C 54.30, H 4.74, N 4.07.

Preparation of Complex $[Ag_2(\mu\text{-BPNNAn})](ClO_4)_2$ (4): Complex **4**, as a pale yellow powder, was synthesized by BPNNAn (0.143 g, 0.164 mmol) and $[Ag(MeCN)_4][ClO_4]$ (0.122 g, 0.328 mmol) by the same procedure as used for **1**, but in darkness. Yield: 0.150 g (71.09%). ^{31}P NMR (300 MHz, $[D_6]$DMSO): δ = 22.04 ppm. Elemental analysis for $C_{58}H_{56}Ag_2Cl_2N_4O_8P_2$ (1285.8 g): calcd. C 54.12, H 4.35, N 4.35; found: C 53.76, H 4.43, N 4.03.

Reaction of Complexes with Na_2S: A solution of excess $Na_2S \cdot 9H_2O$ in distilled water (5 mL) was added to a solution of **1** (58 mg, 0.048 mmol) in acetone (15 mL) with stirring and a black precipitate was immediately produced. Stirring was continued for 30 min and a white solid was generated. CH_2Cl_2 (15 mL) was added to the solution and stirring continued until the white solid disappeared. The black precipitate was filtered and the solvent was removed under vacuum. The residue was recrystallized from CH_2Cl_2-diethyl ether to give BPNNAn. Yield: 30 mg (71.4%).

Similar reactions for complex **2**, **3** and **4** can be undertaken to give BPNNAn quantitatively.

X-ray Crystallography: The structures of **1**, **2** and **3** were solved by direct methods and all non-hydrogen atoms were subjected to anisotropic refinement by full-matrix least-squares on F^2 using the SHELXTL package. Data collection was performed at room temperature with a Bruker SMART 1000 CCD diffractometer operating at 50 kV and 20 mA using Mo-K_α radiation (0.71073 Å). An empirical absorption correction was applied using the SADABS program. All hydrogen atoms were generated geometrically (C–H bond lengths fixed at 0.96 Å), assigned appropriate isotropic thermal parameters and included in structure factor calculations.

CCDC-244084, -258486 and -258487 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The Fenton Reaction in Aerated Aqueous Solutions Revisited

Sandra Rachmilovich-Calis,[a] Alexandra Masarwa,[a] Naomi Meyerstein,[b] and Dan Meyerstein*[a,c]

Keywords: Alcohols / Chain reactions / Dioxygen / Oxidation / Fenton reaction / Iron

The oxidation of alcohols in aerated acidic aqueous solutions by the Fenton reagent is a chain reaction. The length of the chain depends linearly on the number of CH_nOR (n = 1 or 2) groups in the alcohol. The reaction is accelerated by increasing the concentration of $Fe(H_2O)_6^{2+}$, but this cation is also active in at least one of the termination steps of the chain reaction. Addition of ethanol to a solution containing sucrose shortens the chain length. Saturation with dioxygen, instead of air, increases the chain length. An increase in alcohol concentration increases the chain length up to a limiting value. A complicated mechanism, which is in agreement with all these observations, is proposed. However, efforts to simulate the mechanism succeed only in simulating the $Fe(H_2O)_6^{3+}$ yield, but indicate that the observed process is considerably faster than the predicted one. In the latter the rate-determining step is the Fenton reaction, the rate constant of which is well known.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

In 1894 Fenton reported that alcohols are oxidized in the presence of H_2O_2 and $Fe(H_2O)_6^{2+}$.[1] After more than 110 years of further research the active intermediate in, and detailed mechanism of, this kind of reactions are still ambiguous and repeatedly discussed in many publications and reviews.[2–9] In 1934 Haber and Weiss[10] suggested that the key step in this process is:

$$H_2O_2 + Fe(H_2O)_6^{2+} \rightarrow {}^{\cdot}OH + OH^- + Fe(H_2O)_6^{3+} \quad (1)$$

This reaction and its analogous reactions

$$H_2O_2 + M^nL_m \rightarrow {}^{\cdot}OH + OH^- + M^{n+1}L_m \quad (2)$$

the "Fenton-like" reactions, play an important role in a variety of catalytic and biological processes. In biology this reaction is believed to be the main source of the ROS (Reactive Oxygen Species) in the cell[11–13] that cause a variety of diseases, for example cancer, arteriosclerosis, essential hypertension, Alzheimer's disease, amyloidosis, osteoarthritis, etc.[14,15]

However, detailed kinetic studies indicate that hydroxyl radicals are not formed in all these reactions.[3,4,16–23] The detailed mechanism seems to involve one of the following routes:[19]

$$H_2O_2 + M^nL_m \leftrightharpoons L_mM^n{\cdot}H_2O_2 \text{ or } L_{m-1}M^n{\cdot}H_2O_2 + L \quad (3)$$

followed by:

$$L_{m-1}M^n \cdot H_2O_2 \xrightarrow{+L} M^{n+1}L_m + {}^{\cdot}OH + OH^- \quad (4a)$$

$$L_{m-1}M^n \cdot H_2O_2 \rightarrow L_{m-1}M^{n+2}{=}O + H_2O \quad (4b)$$

$$L_{m-1}M^n \cdot H_2O_2 \xrightarrow{+RH} M^{n+1}L_m + R^{\cdot} + H_2O + OH^- \quad (4c)$$

$${}^{\cdot}OH + RH \rightarrow R^{\cdot} + H_2O \quad (5)$$

$$L_{m-1}M^{n+2}{=}O + {>}RH \xrightarrow{+L} M^{n+1}L_m + R^{\cdot} + OH^- \quad (6)$$

Thus, in the presence of an organic substrate, RH, ultimately the same radicals $R^{\cdot}$ are formed. The results point out that the choice of the route to $R^{\cdot}$ depends on the nature of M, L, RH and its concentration, and on the medium, for example the pH.[3,4,19,24,25] Recent results indicate that for $M_nL_m = Fe(H_2O)_6^{2+}$ reaction (4b) is the dominant pathway.[16–18,26]

We decided recently to use the Fox assay[27] to determine the concentrations of H_2O_2 and hydroperoxides in biological samples. In this assay, the yield of Fe^{III} is measured by the absorption of its complex with xylenol orange. The addition of alcohols to the aerated reaction mixture increases the Fe^{III} yield. Thus, for example, in solutions containing 0.1 M sorbitol the yield is $[Fe(H_2O)_6^{3+}]/[H_2O_2] = 14$. This result clearly points out that the $[Fe(H_2O)_6^{3+}]$ is formed in a chain reaction. Two mechanisms have been suggested in the literature for this process. The first, suggested by Wolff,[27] is as follows:

[a] Department of Chemistry, Ben-Gurion University of the Negev, Beer-Sheva, Israel
[b] Department of Physiology, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel
[c] Department of Biological Chemistry, College of Judea and Samaria, Ariel, Israel
E-mail: danmeyer@bgumail.bgu.ac.il
Fax: +972-3-906-7440
Tel: +972-3-906-6153

$$H_2O_2 + Fe(H_2O)_6^{2+} \rightarrow HO^{\cdot} + OH^- + Fe(H_2O)_6^{3+} \quad (7)$$

$$HO^{\cdot} + R_2CHOH \rightarrow H_2O + R_2C^{\cdot}OH \quad (8)$$

$$R_2C^{\cdot}OH + O_2 \rightarrow R_2C(OO^{\cdot})OH \quad (9)$$

$$R_2C(OO^{\cdot})OH \rightarrow R_2C{=}O + HO^{\cdot}_2 \quad (10)$$

$$HO^{\cdot}_2 + Fe(H_2O)_6^{2+} \rightarrow H_2O_2 + Fe(H_2O)_6^{3+} \quad (11)$$

However, it is difficult to suggest which reaction terminates this chain process as the rates of reactions (8), (9), (10), and (11) are known and are high. Thus, second-order reactions between the radicals are not expected to compete with these reactions.

The second mechanism, proposed by Gebicki,[28] has reaction (12) instead of (11) in the reaction mechanism [reactions (7)–(10) are analogous to Wolff]:

$$2\ HO^{\cdot}_2 \rightarrow H_2O_2 + O_2 \quad (12)$$

This mechanism is clearly wrong as it predicts a yield of $[Fe(H_2O)_6^{3+}]/[H_2O_2]$ of 2.

We decided, therefore, to investigate the mechanism of this reaction in detail. The results indeed point out that the mechanism is considerably more complicated, although some of its aspects remain unresolved.

Results and Discussion

Initially, the effect of $Fe(H_2O)_6^{2+}$ concentration on the kinetics of the FOX assay with the substrate sucrose was studied. The results (Figure 1) are quite surprising. As expected, the rate of the process increases with $Fe(H_2O)_6^{2+}$ concentration. However the yield of $Fe(H_2O)_6^{3+}$ clearly decreases with the increase of $Fe(H_2O)_6^{2+}$ concentration, in other words the results point out that $Fe(H_2O)_6^{2+}$ is involved in at least one of the chain-termination steps. This termination step cannot be due to the competition between reactions (13) and (8a).

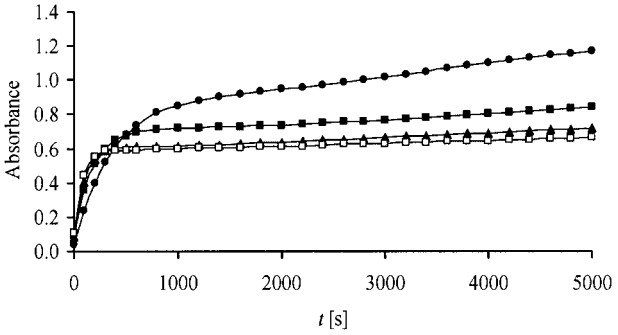

Figure 1. Kinetic measurements for different concentrations of iron(II) ammonium sulfate. The test solutions contained 10 mM sucrose, 2 μM H_2O_2, and the FOX reagent at a concentration of 250 μM (●), 400 μM (■), 600 μM (▲), and 800 μM (□) of iron(II) ion in air-saturated solutions.

$$^{\cdot}OH + Fe(H_2O)_6^{2+} \xrightarrow{H^+} H_2O + Fe(H_2O)_6^{3+} \quad (13)$$

with $k_{13} = 3.0 \times 10^8\ M^{-1}s^{-1}$,[29]

$$R_2CHOH + HO^{\cdot} \rightarrow R_2C^{\cdot}OH + H_2O \quad (8a)$$

with $k_{8a} = 2.3 \times 10^9\ M^{-1}s^{-1}$,[30] as even at the highest $[Fe(H_2O)_6^{2+}]$, $k_{13}[Fe(H_2O)_6^{2+}]$ is only 1.5% of k_{8a}[sucrose].

In the second set of experiments the effect of the nature of the organic solute on the yield of $Fe(H_2O)_6^{3+}$ was studied. The yield of Fe^{III} increases with the number of CH_nOX groups. The results are summarized in Table 1 and Figure 2. These results again clearly demonstrate that a competition between reactions (13) and (8) cannot determine the chain length. As recent results[16–18] point out that the Fenton reaction in acidic solutions proceeds via:

$$Fe(H_2O)_6^{2+} + H_2O_2 \rightarrow (H_2O)_5Fe^{IV}{=}O^{2+} + H_2O \quad (4b')$$

it seemed reasonable to suggest that the chain length is determined by the competition between reactions (14) and (15):

$$(H_2O)_5Fe^{IV}{=}O^{2+} + Fe(H_2O)_6^{2+} \xrightarrow{2\ H^+} 2\ Fe(H_2O)_6^{3+} \quad (14)$$

$$(H_2O)_5Fe^{IV}{=}O^{2+} + R^1R^2HCOH \rightarrow 2\ Fe(H_2O)_6^{3+} + {}^{\cdot}CR^1R^2(OH) \quad (15)$$

The specific rates of these reactions are unknown, although it is reasonable to suggest that reaction (14) proceeds via an inner-sphere mechanism and, as the specific rate of water exchange of $Fe(H_2O)_6^{2+}$, reaction (16), is $3.2 \times 10^6\ M^{-1}s^{-1}$,[31]

$$Fe(H_2O)_6^{2+} + H_2O^* \rightarrow Fe(H_2O)_5(H_2O^*)^{2+} + H_2O \quad (16)$$

it is estimated that $k_{14} \leq 3 \times 10^6\ M^{-1}s^{-1}$.

It is not unreasonable to suggest that k_{15} increases linearly with the number of CH_nOX groups. Therefore, the simplest mechanism that explains the results is that outlined in reactions (4b′)–(14) below. All the reactions in this group, with the exception of reactions (15) and (14), are known reactions. Furthermore, reaction (14) has been proposed in the literature[16] and reactions analogous to reaction (15) have also been proposed.[16,36]

$$Fe(H_2O)_6^{2+} + H_2O_2 \leftrightharpoons [(H_2O)_5Fe^{II}{\cdot}H_2O_2] \rightarrow (H_2O)_5Fe^{IV}{=}O^{2+} + H_2O \quad (4b')$$

with $k = 56\ M^{-1}s^{-1}$ [16]

$$(H_2O)_5Fe^{IV}{=}O^{2+} + R^1R^2CHOH \rightarrow Fe(H_2O)_5(OH)^{2+} + R^1R^2C^{\cdot}OH\ (\equiv R^{\cdot}) \quad (15)$$

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \quad (9')$$

with $k \geq 1 \times 10^9\ M^{-1}s^{-1}$ [32]

$$RO_2^{\cdot} \rightarrow R^1R^2C{=}O + HO^{\cdot}_2 \quad (10')$$

with $400\ s^{-1} < k < 2600\ s^{-1}$ [33,34]

$$RO_2^{\cdot}\backslash HO^{\cdot}_2 + Fe(H_2O)_6^{2+} \leftrightharpoons (H_2O)_5Fe^{III}{-}OOR^{2+} \quad (17)$$

with $k > 2 \times 10^6\ M^{-1}s^{-1}$, $K \approx 200\ M^{-1}$ [35]

$$(H_2O)_5Fe^{III}{-}OOR^{2+} \xrightarrow{H^+} Fe(H_2O)_6^{3+} + HOOR \quad (18)$$

with $k \approx 1500\ M^{-1}s^{-1}$ [35]

Diethyl ether	1	3.6×10^9	4.6	
Dioxane	2[b]	2.8×10^9	4.9	

[a] Average of several determinations, error limit ±10%. [b] The CH_2OX groups are not adjacent.

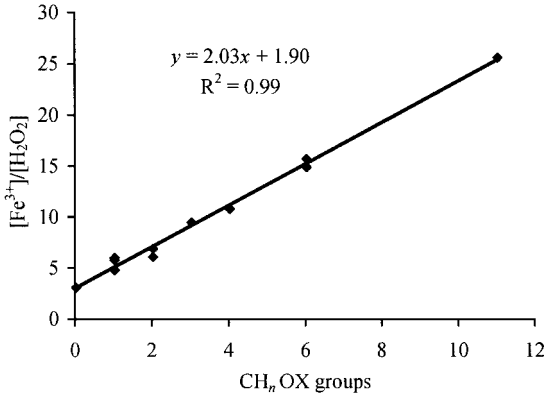

Figure 2. The influence of substrate structure [number of CH_nOX (n = 1 or 2) groups] on the chain length in the FOX assay. The test solutions contained 2–7 μM H_2O_2, 100 mM organic substrate, and the FOX reagent in air-saturated solutions.

$$(H_2O)_5Fe^{III}–OOR^{2+} + Fe(H_2O)_6^{2+} \rightarrow (H_2O)_5Fe^{IV}=O^{2+} + Fe(H_2O)_6^{3+} + ROH \quad (19)$$

with $k \approx 5\times10^5$ $M^{-1}s^{-1}$ [35]

$$(H_2O)_5Fe^{IV}=O^{2+} + Fe(H_2O)_6^{2+} \xrightarrow{2\,H^+} 2\,Fe(H_2O)_6^{3+} \quad (14)$$

with $k < 3\times10^6$ $M^{-1}s^{-1}$.

In order to check the validity of this mechanism, the effect of the concentration of the organic substrate on the yield of $Fe(H_2O)_6^{3+}$ was measured; the results for ethanol and sucrose are presented in Figure 3. The results point out that the yield of $Fe(H_2O)_6^{3+}$ initially increases with $[R^1R^2HCOH]$, as expected, but surprisingly reaches a limiting value at high substrate concentrations. These results indicate that at low $[R^1R^2HCOH]$ the competition between reactions (14) and (15) influences the chain length, but this competition has no effect at high concentrations. Indeed, a careful analysis of Figure 1 shows that the effect of $[Fe(H_2O)_6^{2+}]$ on the yield of $Fe(H_2O)_6^{3+}$ is large at low $[Fe(H_2O)_6^{2+}]$ and reaches a limiting value at higher concentrations. These results suggest that another termination step contributes to the mechanism. This conclusion is supported by the effect of adding C_2H_5OH to reaction mixtures containing sucrose (Figure 4). The results clearly demonstrate that the addition of ethanol shortens the chain length rather than extending it as predicted in reactions (4b′)–(14). This effect might be due to the fact that, in principle, two types of radicals R· are formed: a) a terminal α,ω radical ·CH(CHR′OH)OH (≡ $^{\cdot}R^1$), b) a β radical ·C(CHR′OH)(CHR′′OH)OH (≡ $^{\cdot}R^2$).

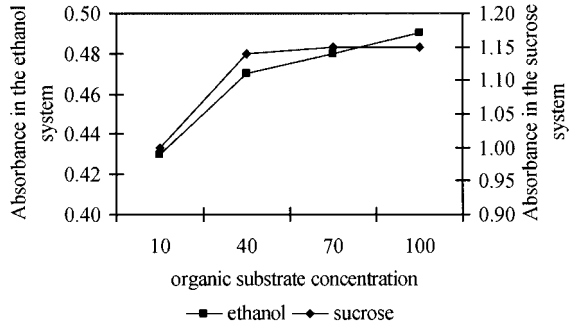

Figure 3. The influence of increasing concentrations of ethanol and sucrose on the absorbance of $Fe^{III}XO$ formed. The test solutions contained 5 μM H_2O_2 with 10–100 mM ethanol and 2 μM H_2O_2 with 10–100 mM sucrose and the FOX reagent in air-saturated solutions.

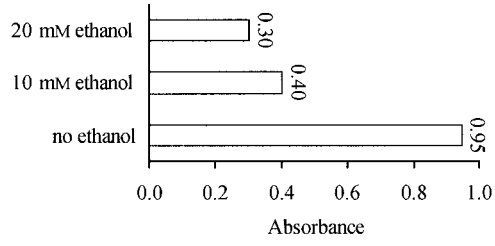

Figure 4. The absorbance of $Fe^{III}XO$ formed in sucrose-containing solutions in the presence of different concentrations of ethanol. The test solutions contained 10 mM sucrose, 2 μM H_2O_2, the FOX reagent, and 0–20 mM of ethanol in air-saturated solutions.

Both these radicals react with dioxygen to yield the $R^iO_2^{\cdot}$ radicals. However, these eliminate $HO_2^{\cdot}$ at considerably different rates

$$^{\cdot}O_2CH(CHR'OH)OH \rightarrow HO_2^{\cdot} + CH(O)(CHR'OH) \quad (10'a)$$

with k = 400 s^{-1} [33,34]

$$^{\cdot}O_2C(CHR'OH)(CHR''OH)OH \rightarrow HO_2^{\cdot} + C(O)(CHR'OH)(CHR''OH) \quad (10'b)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with $k = 2600\ s^{-1}$ [33,34]

For sugars, there is an additional, faster elimination step for the group next to the ether linkage ($k > 7000\ s^{-1}$).[33,34]

All the $HO_2^{\cdot}$ radicals contribute to the chain process via reactions (17), (18), and (19). However the $RO_2^{\cdot}$ radicals, which are longer lived for the $^{\cdot}O_2CH(CHR'OH)OH$ radicals (α,ω-attack), yield some $HO_2CH(CHR'OH)OH$ via reaction (18). The latter product is usually unstable and might decompose by reaction (20)[37]

$$HO_2CH(CHR'OH)OH \rightarrow C(O)(CHR'OH)OH + H_2O \text{ or } HC(O)(CHR'OH) + H_2O_2 \quad (20)$$

The decomposition into the acid is acid catalyzed, whereas the aldehyde analog preferably forms in more basic solutions and at higher temperatures.[37] Thus, part of reaction (20), which competes with reaction (4b′), is clearly a termination step. This mechanism also explains the role of $Fe(H_2O)_6^{2+}$ in shortening the chain length at high $[HCR^1R^2OH]$. Under these conditions the competition between reaction (10) and reaction (17) is clearly a function of $[Fe(H_2O)_6^{2+}]$ and, as reaction (17) is partially followed by reactions (18) and (20), reaction (17) contributes to a termination step. This contribution of $Fe(H_2O)_6^{2+}$ to the termination step is limited by the fact that reaction (19) competes with reaction (18) and reaction (4b′) with reaction (20).

This reaction scheme also explains the effect of the number of CH_nOX groups on the $Fe(H_2O)_6^{3+}$ yield: clearly, with more CH_nOX groups the ratio $[R^{2\cdot}]/[R^{1\cdot}]$ increases. This decreases the contribution of reaction (20), which is partially a termination step. In order to check this hypothesis the effect of pentaerythritol was checked. The result, Table 1, clearly demonstrates that the chain length corresponds to four CH_nOH groups, even though they are not adjacent. However, it should be noted that the rate of $HO_2^{\cdot}$ elimination from $^{\cdot}O_2CH(OH)C(CH_2OH)_3$ is not known and might be considerably higher than that of $R'O_2^{\cdot}$ radicals. It should be noted that there is a large variety in the rates of $HO_2^{\cdot}$ elimination reactions;[33,34,38,39] the source of these differences is not yet fully understood.[33,34,38,39]

When the solutions were saturated with O_2, instead of air, the yield of $Fe(H_2O)_6^{3+}$ increased (Table 2). In these experiments, only the yield was measured as they were performed in sealed syringes. The effect is small, though significant, for one CH_nOX group, and increases somewhat for a larger number of CH_nOX groups. The effect of differing oxygen concentrations on a system containing ethanol was noted previously.[40] As reaction (9′) is very fast, and as $k[^{\cdot}R+Fe(H_2O)_6^{2+}]$ is about three orders of magnitude slower[41] and $[O_2]$ is at least two orders of magnitude larger than that of any of the intermediates, the dioxygen effect cannot be attributed to an acceleration of reaction (9′). Thus, one has to conclude that the dioxygen effect in the ethanol system is due to the reaction of dioxygen with one of the reactive intermediates. No such reaction is known and a plausible one is:

Table 2. The effect of oxygen on the yields in the FOX assay for different substrates (comparison of air- and oxygen-saturated solutions). The test solutions contained 2 μM H_2O_2, the FOX assay, and 100 mM organic substrate (ethanol, glycerol, sorbitol, and sucrose).

Increase on oxygen saturation	$[Fe^{III}]/[H_2O_2]$ (oxygen)[a]	$[Fe^{III}]/[H_2O_2]$ (air)[a]	CH_nOX groups	Substrate
None	–	1.9	1.9	0
Ethanol	+26%	6.2	4.9	1
+56%	12.2	7.8	3	glycerol
+50%	24.2	16.1	6	sorbitol
+48%	42.4	28.6	11	sucrose

[a] Single determination, error limit ±15%.

$$(H_2O)_5Fe^{III}–OOR^{2+} + O_2 \underset{H^+}{\rightarrow} (H_2O)_5Fe^{IV}–OOR^{3+} + HO_2^{\cdot} \quad (21)$$

followed by:

$$(H_2O)_5Fe^{IV}–OOR^{3+} \overset{H_2O}{\rightarrow} Fe(H_2O)_6^{3+} + RO_2^{\cdot} \quad (22)$$

or by:

$$(H_2O)_5Fe^{IV}–OOR^{3+} \overset{H^+}{\rightarrow} (H_2O)_5Fe^{VI}=O^{4+} + ROH \quad (23)$$

Reaction (21) might compete with reaction (18) and thus elongate the chain length. Alternatively, the reaction occurring could be:

$$Fe^{IV} + O_2 \rightarrow Fe^{V} + O_2^{\cdot-} \quad (24)$$

although the relative redox potentials do not support this possibility. Oxidation of $PFe^{IV}=O$ by H_2O_2 to $PFe^{III}–O_2^{\cdot-}$ has been suggested in the literature.[42–44]

The larger dioxygen effect for systems with more than or equal to two CH_nOX groups is attributed to the competition between reactions (9) and reactions (25) (β-elimination of water from 1,2-diol-type radicals):[38]

$$^{\cdot}CH(CHR'OH)OH \rightarrow O=CH(C^{\cdot}HR') + H_2O \quad (25a)$$

$$^{\cdot}C(CHR'OH)(CHR''OH)OH \rightarrow O=C(C^{\cdot}HR')(CHR''OH) + H_2O \quad (25b)$$

Reactions (25) are acid catalyzed and, at pH 1.8, the experimental pH, the rate for the glycol radical, for example, is $2.5 \times 10^3\ s^{-1}$.[45] Reaction (25) competes slightly with reactions (9), the rate of which in air saturated solutions is around $7 \times 10^5\ s^{-1}$.[32] The radicals formed in reactions (25) form peroxyl radicals, which do not eliminate $HO_2^{\cdot}$ radicals. Clearly, reactions (25) do not occur for radicals derived from alcohols with one CH_nOX group or nonadjacent CH_nOX groups.

In kinetic simulations the general trend of the reactions ($[Fe^{II}]$, [substrate] effect) could be modeled reasonably well by including only the group of reactions (4b′)–(14) outlined above. Reactions for α,ω and β radicals were differentiated and the option included that part of the formed ROOH leads to a termination reaction instead of being returned to the cycle. These reactions do not include any explanations for the [dioxygen] effect and therefore this effect could not be modeled. The reactions (21–25) could not be incorpo-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rated in the simulations as the calculations proved to be too complicated. The simulations could be fitted to the $Fe(H_2O)_6^{3+}$ yields but the kinetics were always considerably slower than the observed ones. This stems from the fact that reaction (4b) is the rate-determining step and the rate constant of this reaction is well known.

Finally, it should be noted that when ROOH peroxides other than H_2O_2 are used, the yield of $Fe(H_2O)_6^{3+}$ is considerably lower.[27,46] This suggests that in these reactions the yield of $(H_2O)_5Fe^{IV}=O^{2+}$ is considerably lower than in the H_2O_2 system. This suggests that either $R^3O^{\cdot}$ radicals are formed in these reactions, which might be true also for reaction (19), or that reaction (4c) takes place in these systems to produce another mixture of $R^{\cdot}$ radicals than reaction (15). $R^3O^{\cdot}$ radicals might decompose via:[47]

$$CHR'R''O^{\cdot} \xrightarrow{\text{fast}} {}^{\cdot}CR'R''OH \quad (26)$$

This is, for example, expected to happen for fatty acid hydroperoxides, which are formed biologically, or for the radical formed from $(CH_3)_3COOH$ via:

$$C(CH_3)_3O^{\cdot} \rightarrow C(CH_3)_2O + {}^{\cdot}CH_3 \quad (27)$$

with $k = 2.0 \times 10^3\ s^{-1}$,[48] etc.

Concluding Remarks

This study clearly demonstrates that the mechanism of the Fenton reaction and Fenton-like reactions, in aerated aqueous solutions containing organic substrates, is considerably more complex than assumed so far. It seems reasonable to propose that reactions analogous to reaction (17) occur also in nonaqueous media. Therefore, also in these media the mechanisms of the Fenton process are probably considerably more complicated than proposed.[6,49–52]

The results point out that the yield of Fe^{III} depends on the nature of the peroxide and the nature of all the organic compounds present in the solution. Thus, the use of the FOX assay for the determination of the total peroxides in biological samples is difficult if at all feasible.

Finally, it is tempting to speculate that analogous reactions in biological systems might lead to considerable deleterious biological processes by damaging sugars bound to the membranes of cells[13] and/or to the sugar moieties in RNA and DNA.

Experimental Section

Materials: All the chemicals purchased from Sigma or Aldrich were of A.R. grade and therefore used without further purification. The water used was deionized and was further purified with a Millipore Milli-Q setup with a final resistivity of >10 MΩ

Preparation of the FOX Reagent: The FOX reagent containing iron(II) ammonium sulfate, H_2SO_4, xylenol orange, and an organic substrate was mixed with hydrogen peroxide to give final concentrations of 2–9 μM hydrogen peroxide, 250–800 μM iron(II) ion, 25 mM H_2SO_4, 100 μM xylenol orange (XO), and 10–100 mM organic substrate. The solutions were incubated for 40 min at room temperature. The absorbance was read at 560 nm. All spectra were run against blanks containing the FOX reagent. In some experiments, the XO was added only after 40 min for the analytical determination of the Fe^{III} yield.

UV/Vis measurements were carried out with a Hewlett–Packard Diode Array spectrophotometer model 8452A, which enables measurements in the range of 190–820 nm at a resolution of ±2 nm.

Determination of the H_2O_2 Concentration: The concentration of H_2O_2 was determined using the iodide method.[53] A stock solution containing KI, NaOH, and ammonium heptamolybdate was mixed with a second stock solution containing potassium hydrogenphthalate to give final concentrations of 0.08 M KI, 3.2×10^{-5} M ammonium heptamolybdate, and 0.02 M potassium hydrogen phthalate (final pH 4.0). The final solution was then mixed with H_2O_2 at concentrations ranging between 1×10^{-6} and 1×10^{-5} M. Addition of H_2O_2 leads to the production of I_3^- via the following reactions:

$$2\ I^- + H_2O_2 + 2\ H^+ \rightarrow I_2 + 2\ H_2O \quad (28)$$

$$I_2 + I^- \rightleftharpoons I_3^- \quad (29)$$

The absorbance of I_3^- was measured at 352 nm (ε = 26500 $M^{-1}\,cm^{-1}$).

Rate Simulations: Kinetic simulations were performed in order to evaluate the effects of H_2O_2, Fe^{II}, and organic substrate concentrations and the input rates and pattern of the mechanism. The simulations explored the formation kinetics of Fe^{III} and were compared to the experimental results. The kinetic calculations were performed with the Pro-Kineticist II program by Applied Photophysics.

Acknowledgments

This study was supported in part by grants from the Israel Science Foundation and from the Budgeting and Planning Committee of The Council of Higher Education and the Israel Atomic Energy Commission. D. M. wishes to express his thanks to Mrs. Irene Evens for her ongoing interest and support.

Organotin-Substituted Crown Ethers for Ditopic Complexation of Anions and Cations[‡]

Gregor Reeske,[a] Markus Schürmann,[a] Burkhard Costisella,[a] and Klaus Jurkschat*[a]

Dedicated to Prof. W.-W. Du Mont on the occasion of his 60th birthday

Keywords: Ditopic complexation / Host-guest chemistry / NMR spectroscopy / X-ray crystallography / Tin

The syntheses of the organotin-substituted crown ethers *m*-($Ph_2XSnCH_2CH_2$)-15-benzocrown-5 (**2**, X = Ph; **3**, X = I; **4**, X = Cl; **5**, X = NCS) and the salt [*m*-($Ph_3SnCH_2CH_2$)-15-benzocrown-5·Na]$^+SCN^-$ (**2a**) are reported. Compounds **2a** and **4** (as its aqua complex **4**·H_2O) are characterized by single-crystal X-ray diffraction sudies. Multinuclear NMR spectroscopy and electrospray mass spectrometry reveal the triorganotin chloride **4** to be a ditopic host towards sodium rhodanide. This statement is further supported by the ability of compound **4** to transport sodium rhodanide through an organic membrane.

Introduction

The simultaneous recognition and sensing of anions and cations is a new area of increasing research activities.[1,2] Practical applications of ion-pair recognition range from complexation of zwitterionic amino acids and peptides,[3,4] the transport of ion pairs across biological membranes[5–12] to solubility enhancement of ion pairs in nonpolar solvents for ion extraction.[13] Ion-pair receptors known so far are based on the combination of crown compounds or calixarenes with (i) ammonium groups exploiting hydrogen bonding[14,15] or (ii) Lewis acidic groups.[16–20] Straightforward examples of the latter case involve the work of Reetz et al.[18a] on an organoboron-substituted crown ether, and Willem et al.[18b] who reported the sodium rhodanide complex of triorganotin carboxylates containing the [18]crown-6 and [15]crown-5 substituents. However, an essential shortcoming of the latter compounds is the kinetic lability of the tin–carboxylate bond, which makes the corresponding zwitterionic complexes unstable in solution.[18b]

In continuation of our own studies on organotin halides as Lewis acids for selective complexation of anions[21–23] we report here the synthesis and structures of kinetically more stable carbon-bonded organotin-functionalized crown ethers and demonstrate that such compounds are able to complex and transport sodium rhodanide in nonpolar organic solvents.

Results and Discussion

Synthetic Aspects and Molecular Structures in the Solid State

The reaction of 4-vinylbenzo-15-crown-5[24,25] (**1**) with triphenyltin hydride provided [2-(6,7,9,10,12,13,15,16-octahydro-5,8,11,14,17-pentaoxabenzocyclopentadec-2-yl)ethyl]-triphenylstannane (**2**) as a colorless oil (Scheme 1).

Treatment of the tetraorganostannane **2** with 1 molequiv. of iodine gave the triorganotin iodide **3**. The latter was quantitatively converted into its chloride derivative **4** by reaction with AgCl in acetonitrile over a period of 14 d. The reaction of triorganotin iodide **3** with AgSCN in CH_3CN gave the triorganotin rhodanide **5** in quantitative yield.

The treatment of **2** with NaSCN in ethanol provided the corresponding sodium rhodanide complex **2a** as a colorless solid. Single crystals of **2a** suitable for X-ray diffraction analyses were obtained by recrystallization from dichloromethane/*n*-hexane.

The molecular structure of **2a** is shown in Figure 1 and selected geometric parameters are collected in Table 1.

The sodium cation is coordinated by five oxygen atoms with Na–O distances ranging between 2.317(7) and 2.469(6) Å. These values are in line with those reported for similar compounds.[18] The rhodanide anion is located close

to the sodium cation with an Na–N distance of 2.344(9) Å. The tin atom shows the expected tetrahedral configuration.

Crystallization of the triorganotin chloride **4** at –5 °C from CH_2Cl_2/Et_2O (1:2) in the presence of air moisture afforded single crystals of the aqua complex $4 \cdot H_2O$ as its CH_2Cl_2 solvate.

The molecular structure of $4 \cdot H_2O$ is shown in Figure 2, selected geometric parameters are collected in Table 2.

Table 2. Selected bond lengths [Å] and angles [°] for $4 \cdot H_2O$.

The compound crystallizes monoclinically with one molecule in the unit cell. The tin atom in $4 \cdot H_2O$ is pentacoordinate and adopts a distorted trigonal-bipyramidal configuration [geometrical goodness $\Delta(\Sigma\vartheta) = 68.5°$].[26,27] The equatorial positions are occupied by C(1), C(11), C(21) and the axial positions by Cl(1) and the water oxygen atom. The tin atom is displaced by 0.22 Å from the plane defined by C(1), C(11), C(21) in the direction of Cl(1). The Sn(1)–Cl(1) and Sn–O(6W) distances of 2.453(1) and 2.469(4) Å, respectively, are comparable with those of other aqua complexes of organotin chlorides.[28,29] In CH_2Cl_2 solution, compound

4·H_2O shows a dissociation equilibrium between **4**·H_2O and **4** + H_2O. The equilibrium is fast on the NMR time-scale with the population of **4** + H_2O dominating at room temperature (δ^{119}Sn = 2 ppm). However, at –70 °C the aqua complex **4**·H_2O dominates (δ^{119}Sn = –155 ppm). These results are supported by NOE decoupling experiments at different temperatures. At room temperature the water proton resonance shows a large NOE to the resonances of the crown ether ring suggesting hydrogen bonding to the oxygen atoms of the latter. Upon lowering of the temperature, this NOE becomes smaller, which implies a larger distance between the crown ether protons and the water protons.

Complexation Studies

In comparison to the organotin-substituted crown ether **2**, the ^{13}C NMR spectrum of its sodium complex **2a** shows low-field shifts of approximately 2 ppm for the crown ether carbon resonances. The same effect was observed for the ^{13}C NMR spectrum ($CDCl_3/CD_3CN$, 4:1) of the chlorodiphenylstannyl-substituted crown ether **4** to which 1 mol-equiv. of sodium tetraphenylborate ($NaBPh_4$) had been added. This clearly indicates complexation of the sodium cation by the crown ether. The ^{119}Sn NMR spectrum of the same solution showed a single resonance at δ = –9.2 ppm indicating, as expected, no coordination of the tetraphenylborate anion.

The ^{119}Sn NMR spectrum at –70 °C of a CD_2Cl_2 solution of the triorganotin chloride **4,** to which 1 mol-equiv. of $[(Ph_3P)_2N]Cl$ had been added, showed a single resonance at δ = –198 ppm indicating the in situ formation of the dichlorotriorganostannate [**4**·Cl][$(Ph_3P)_2N$] (**4a**). In a similar manner, addition of $n$$Bu_4NSCN$ to a solution of the triorganotin rhodanide **5** afforded, in situ, the complex [**5**·SCN][$n$$Bu_4N$] (**5a**). Its ^{119}Sn NMR spectrum at –70 °C showed a single resonance at δ = –253 ppm. The ^{119}Sn NMR spectrum at –70 °C of a solution of the chlorodiphenylstannyl-substituted crown ether **4**, to which 1 mol-equiv. of Bu_4NSCN had been added, showed three resonances at δ = –198 ppm (signal a, integral 18), –216 ppm (signal b, integral 69) and –253 ppm (signal c, integral 13). Addition of a further 3 mol-equiv. of Bu_4NSCN changed the integral ratios of signals (a), (b) and (c) to 9, 69, and 21, respectively. Signals (a) and (c) are assigned to **4a** and **5a**, respectively, whereas signal (b) is tentatively assigned to [**4**·SCN][$n$$Bu_4N$] (**4b**). The latter assignment is supported by the observation of the same ^{119}Sn chemical shift of a CD_2Cl_2 solution of the triorganotin rhodanide **5** to which 1 mol-equiv. of $[(Ph_3P)_2N]Cl$ had been added, and by the fact that organostannate complexes of type $[R_3SnXY]^-$ are more stable than their corresponding symmetrically substituted derivatives $[R_3SnX_2]^-$ and $[R_3SnY_2]^-$.[30] The ^{119}Sn NMR spectra at room temperature of all the solutions mentioned above showed no resonances, indicating fast exchange between the species present in the corresponding samples.

The ^{119}Sn NMR spectrum at room temperature of a solution of the triorganotin chloride **4** in CD_2Cl_2 to which 1 mol-equiv. of NaSCN had been added showed in comparison to compound **4** a low-frequency-shifted single broad resonance at δ = –225 ppm ($\nu_{1/2}$ = 2013 Hz) which at –60 °C shifted to δ = –248 ppm ($\nu_{1/2}$ = 937 Hz). The ^{13}C NMR spectrum of the same solution showed $^1J(^{13}C\text{-}^{117/119}Sn)$ coupling constants of 595/621 and 716/751 Hz to the Sn–CH_2 and Sn–C_i carbon atoms, respectively, that are larger than the corresponding couplings of 426/446 and 540/566 Hz measured for compound **4**. Both the ^{119}Sn chemical shifts and the $^1J(^{13}C\text{-}^{117/119}Sn)$ coupling constants clearly indicate the tin atom in the complex [**4**·NaSCN] to be pentacoordinate. The ultimate evidence for the coordination of the rhodanide anion to the tin atom stems (i) from the observation of a $^2J(^{13}C\text{-}^{117/119}Sn)$ coupling of 59 Hz to the rhodanide carbon atom and (ii) from an HMBC correlation experiment showing a ^5J coupling of the *o*-phenyl protons to the rhodanide carbon atom. The binding of the sodium cation to the crown ether oxygen atoms is clearly evidenced by similar high-frequency shifts of the ^{13}C resonances for the crown ether carbon atoms as observed for the sodium complex **2a** (see above).

These results unambiguously prove that the chlorodiphenylstannyl-substituted crown ether **4** is a ditopic receptor simultaneously binding the sodium cation and rhodanide anion.

This statement obtains further support from electrospray mass spectrometry (ESMS) and transport experiments. Thus, the ESMS spectrum (negative mode) of a solution of the triorganotin chloride **4** to which NaSCN had been added showed mass clusters at m/z = 685.14 and 766.22 which are assigned to $[\mathbf{5} + SCN]^-$ and $[\mathbf{5} + 2\ SCN + Na]^-$, respectively. In the positive mode the spectrum showed a major mass cluster at m/z = 650.05 which is assigned to $[\mathbf{5}\cdot Na]^+$. Minor mass clusters at m/z = 569.07 and 609.06 were also present which were assigned to $[\mathbf{4} - Cl]^+$ and $[\mathbf{4} - Cl + OH + Na]^+$, respectively.

The transport properties of the chlorodiphenylstannyl-substituted crown ether **4** were investigated by a U-tube experiment (Figure 3).

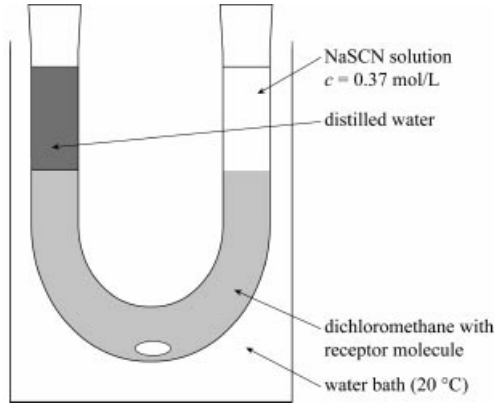

Figure 3. Schematic presentation of the U-tube experiment.

Figure 4 demonstrates the superior capability of compound **4** over triphenyltin chloride and the unsubstituted 15-benzocrown-5 to transport NaSCN from an aqueous

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phase through a dichloromethane layer into another aqueous phase. This apparently becomes possible by the simultaneous complexation of the sodium cation and the rhodanide anion by the ditopic host **4**.

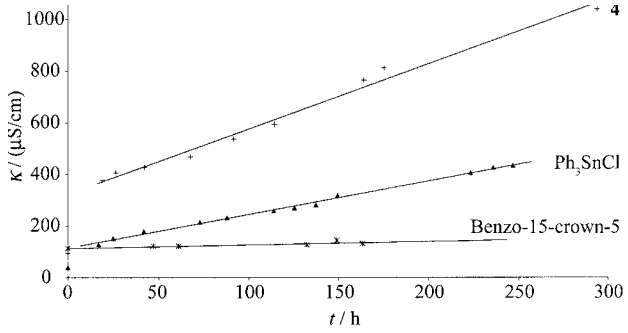

Figure 4. Plot of the electric conductivity vs. time illustrating the different ability of the triorganotin chloride **4**, triphenyltin chloride, and the unsubstituted crown ether benzo-15-crown-5 to transport sodium rhodanide through a dichloromethane layer. The concentration of **4**, Ph_3SnCl as well as that of the crown ether was 0.0268 mol/L.

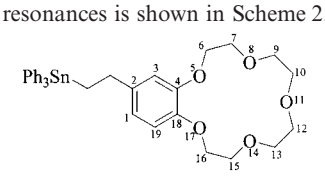
Conclusions

Linking a chlorodiorganostannyl moiety via a dimethylene spacer with a crown ether was shown to provide the robust ditopic host **4** for the complexation of sodium rhodanide. It even serves for the efficient extraction of the latter from an aqueous solution. Given the large variety of crown ethers and related compounds such as azacrowns and cryptands on the one hand and the experience with mono- bi- and multicentered organometal-based Lewis acids on the other, the concept of combining representatives of these classes of compounds in one molecule appears to be promising for designing tailor-made hosts for the complexation of any salt.

Experimental Section

General Methods: All solvents were purified by distillation under nitrogen from appropriate drying agents. The hydrostannylation was carried out under nitrogen. 4-Vinylbenzo-15-crown-5[24,25] and triphenyltin hydride[31] were synthesized as described in the literature. The NMR experiments were carried out with Bruker DRX 500, Bruker DRX 400, DPX 300, Varian Nova 600 and Varian Mercury 200 spectrometers. Chemical shifts δ are given in ppm and are referenced to the solvent peaks with the usual values calibrated against tetramethylsilane (^1H, ^{13}C) and tetramethylstannane (^{119}Sn). The numbering of the carbon atoms applied for the assignment of the ^{13}C resonances is shown in Scheme 2.



Scheme 2.Numbering scheme for the assignment of the ^{13}C NMR resonances.

The ability of compound **4** to transport the rhodanide anion through an organic phase was investigated by U-tube experiments as shown in Figure 3. The conductivity was determined with an apparatus of the type LF530 from the company Wissenschaftlich-Technische Werkstätten. The cell was calibrated at 20 °C with an NaCl standard solution. The rhodanide transported to the aqueous layer was identified by reaction with iron(III).

Complexation Studies: The samples for ^1H, ^{13}C and ^{119}Sn NMR spectroscopy were prepared by dissolving the triorganotin chloride **4** (ca. 80 mg) and the corresponding amounts of $NaBPh_4$, nBu_4NSCN and NaSCN in deuterated solvents. The ^1H (400.1 MHz) and ^{13}C (100.6 MHz) spectra were recorded at 303 K whereas the ^{119}Sn (149.4 MHz) NMR spectra were recorded at both 303 and 208 K. NaSCN was dried in vacuo (10^{-3} Torr) at 100 °C for several days and stored under nitrogen. $NaBPh_4$ and nBu_4NSCN were stored in a desiccator.

Crystallography: Crystals of **2a** were grown from ethanol and of **4**·H_2O from a CH_2Cl_2/Et_2O solution at –5 °C. Crystallographic data are collected in Table 3. Intensity data for the colorless crystals were collected with a Nonius KappaCCD diffractometer with graphite-monochromated Mo-K_α radiation. The data collections covered almost the whole sphere of the reciprocal space with 2 (**2a**), 4 (**4**·H_2O) sets at different κ angles and 203 (**2a**), 424 (**4**·H_2O) frames by ω-rotation (Δ/ω = 1°) at 2×90 s (**2a**), 70 s (**4**·H_2O) per frame. Crystal decay was monitored by repeating the initial frames at the end of the data collection. After analysis of the duplicate reflections, there was no indication of any decay. The structures were solved by direct methods (SHELXS97[32]) and successive difference Fourier syntheses. Refinement applied full-matrix least-squares methods (SHELXL97[33]). The H atoms were placed in geometrically calculated positions using a riding model with U_{iso} constrained at 1.2 times U_{eq} of the carrier C atom, whereas the H atoms [H(6W1), H(6W1)] (**4**·H_2O) bonded to the water molecule O(6W) were located in the difference Fourier map and refined isotropically. In **2a** there are two C atoms disordered over two sites with occupancies of 0.5 [C(42), C(43), C(43′), C(44′)], whereas C(43′) is refined isotropically. In **4**·H_2O one Cl atom of the solvent molecule CH_2Cl_2 is disordered over two sites with occupancies of 0.9 [Cl(3) and 0.1 Cl(3′)]. Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from ref.[34] The figures were created by SHELXTL.[35] CCDC-248340 (**2a**) and -248341 (**4**·H_2O) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[2-(6,7,9,10,12,13,15,16-Octahydro-5,8,11,14,17-pentaoxabenzocyclopentadec-2-yl)ethyl]triphenylstannane (2): 4-Vinylbenzo-15-crown-5 (12.8 g, 44 mmol) and AIBN (115 mg) were added to Ph_3SnH (26.7 g, 41 mmol). The mixture was stirred at 70 °C for 12 h. After cooling to room temperature, CH_2Cl_2 (40 mL) was added and the solution was filtered through Celite. The filtrate was concentrated to give a yellow oil. The latter was purified by column chromatography (silica gel, CH_2Cl_2). Elution with ethanol gave 16.9 g (60%) of **2** as a slightly yellow oil. ^1H NMR (400.1 MHz, $CDCl_3$, 300 K): δ = 1.80 [t, $^3J(^1H\text{-}^1H)$ = 7.7, $^3J(^1H\text{-}^{117/119}Sn)$ = 54.5 Hz, 3 H, Sn–CH_2], 2.93 [t, $^3J(^1H\text{-}^1H)$ = 7.7, $^2J(^1H\text{-}^{117/119}Sn)$ = 56.9 Hz, 2 H, CH_2–Ar], 3.72–3.79 [m, 8 H, H(9)–H(13)], 3.82–3.85 [m, 2 H, H(7)], 3.87–3.93 [m, 2 H, H(15)], 3.94–3.98 [m, 2 H, H(6)], 4.07–4.10 [m, 2 H, H(16)], 6.62 {d, ^3J[H(1)-H(19)] = 2.0 Hz, 1 H, H(19)}, 6.66 {dd, ^3J[H(1)-H(19)] = 2.0, ^4J[H(1)-H(3)] = 8.2 Hz, 1 H, H(1)}, 6.73 {d, ^4J[H(1)-H(3)] = 8.2 Hz, 1 H, H(3)}, 7.32–7.45 (m, 15 H, $SnPh_3$) ppm. $^{13}C\{^1H\}$ NMR (100.6 MHz, $CDCl_3$, 300 K): δ = 13.1 [$^1J(^{13}C\text{-}^{117/119}Sn)$ = 383 Hz, Sn–CH_2], 32.0 [$^2J(^{13}C\text{-}^{117/119}Sn)$ = 18 Hz, CH_2–Ar], 69.1 [C(6)], 69.7 [C(16)], 69.8 [C(7)],

On the Structure of Nonastannide Clusters in Liquid and Solid State

Jan Rosdahl,[a] Thomas F. Fässler,[b] and Lars Kloo*[a]

Keywords: EXAFS spectroscopy / Cluster compounds / Polyanions / Solid-state structures / Ab initio calculations

The nonastannide clusters have been investigated using EXAFS, NMR and Raman spectroscopy as well as quantum chemical calculations explicitly considering a model cationic field and solid-state statistics. NMR spectroscopic and EXAFS results are basically identical to those previously published and consistent with a fluctional model of the cluster. The quantum chemical calculations show that there is no significant difference in energy between the two model geometries, C_{4v} and D_{3h}, and that the vibrational frequencies are very low, clearly indicating that the cluster is expected to be fluctional. The solid-state statistics show that both model geometries can be used to describe all known nonastannide structures with reasonable success, illustrating that the classification of the nonastannide clusters in terms of specific symmetries is entirely arbitrary.

Introduction

Homoatomic clusters of the main-group elements, E_n, is a group of molecules that have attracted some interest over the last decades.[1–3] This is partly due to the fact that these clusters are considered to form one of many extensions to the exciting borane chemistry. However, when using heavier atoms the bonds become more flexible with regards to acceptable bond lengths and angles, as compared to the lighter elements. Good candidates for investigating such flexibility effects are the nine-vertex clusters with C_{4v} or D_{3h} symmetry, such as E_9^{4-} or E_9^{3-} (E = Ge, Sn or Pb), due to their highly related geometries. In order to simplify the matter somewhat, we will mainly focus on the nonastannide clusters.

Over the last three decades, several crystallographic structures containing Sn_9^{4-} or Sn_9^{3-} have been reported.[4–15] Several of these have been classified as having a C_{4v} geometry, as expected according to Wade's rules for a *nido* cluster such as Sn_9^{4-}.[16] However, some appear to adopt a D_{3h} geometry, which is typical for a *closo* geometry and expected for Sn_9^{2-}, but it is most certainly not the correct geometry for a *nido* cluster such as Sn_9^{4-}. The same has been observed for other elements and is not considered to be unusual, yet unexplained. Many of the structure determinations indicate that there is some "disorder" in the structure and sometimes the structure is described in terms of going from C_{4v} geometry towards D_{3h}, or vice versa. The description is, nevertheless, still very static and often neglects the information contained in the anisotropic displacement parameters (ADPs), which we will show is unfortunate.

The prediction of the dynamic behavior of Sn_9^{4-} is at least as old as one of the first structures and was later complemented by a NMR spectroscopic investigation in solution.[5,17] However, the energy barrier for the fluctional behavior of the cluster was never determined, despite the low temperatures used during the experiments. This fluctional behaviour can even be retained when incorporating $Pt_2(PPh_3)$ into the cluster,[18] while other additions are more questionable with regards to the fluctional behaviour.[19,20]

Many of the early theoretical results for nonastannide clusters are based on extended Hückel calculations and they all report that the C_{4v} geometry is more stable than D_{3h}.[21,22] This is in good agreement with both earlier and more recent results,[5,20] but the opposite result can also be obtained, indicating that the difference in energy is very small.[23]

Since the description of the behaviour of nonastannide clusters in solution and solid state is so inconsistent, we believe that one of them can not be entirely correct. In order to get a more coherent description of the nature of these clusters, we have conducted an investigation involving EXAFS, NMR and Raman spectroscopy as well as quantum chemical calculations explicitly considering the effect of the cationic field and solid-state statistics.

Results and Discussion

Spectroscopy

The NMR spectroscopic results for the nonastannide cluster in ethylenediamine (en) solution are essentially the

same as those previous obtained, showing a heptet at a chemical shift of +1208 ppm and J = 264 Hz for the tin-potassium system in ethylenediamine, thus confirming the fluctional behaviour of the clusters in solution.[17,24] The integrated satellite peak intensities also confirm this interpretation, since the number of neighbours in the cluster is determined to be between four and five, as expected for a fluctional nine-atomic cluster that is close to both C_{4v} and D_{3h} symmetry.

The Raman spectroscopic results for the nonastannide cluster in en solution are also similar to previous results, displaying a peak at 155 cm^{-1} for the sample containing K and Sn with a ratio of 1:1.[25] This peak is assigned to the symmetrical breathing mode of vibration. Similar spectra were observed for the Na:Sn system. Furthermore, the position of the peak and the number of observed bands are not conclusive for either geometry.

EXAFS measurements have been conducted for three different samples corresponding to an en solution with Sn_9^{4-}, a solid with Sn_9^{4-} and a solid with Sn_9^{3-}. The expected result would be that all three samples should exhibit significantly different EXAFS patterns, since these three systems were chosen to represent three different classes, a fluctional cluster, a cluster with rigid C_{2v} geometry and a cluster with rigid D_{3h} geometry. However, all three samples give rise to very similar EXAFS traces, as can be seen in Figure 1 and Figure 2. The EXAFS pattern for the solution is somewhat more limited in resolution than those of the solids. Despite this, the similarities are hard to ignore. Furthermore, the EXAFS results for the two solids are almost identical to each other and thus consistent with a fluctional cluster model also in solid state (see Figure 1).

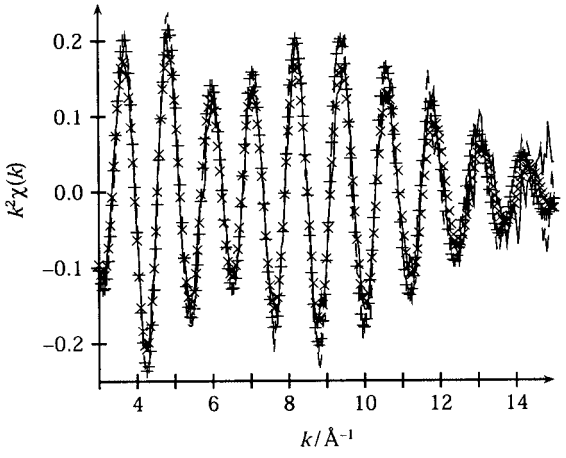

Figure 1. The reduced EXAFS data for the two solid model compounds. The solid line corresponds a solid with Sn_9^{3-}, while the dashed line corresponds to a solid with Sn_9^{4-}. The fitted models for the two samples are shown as × and +, respectively.

All three EXAFS traces can be fitted with a single Sn–Sn path, with a Sn–Sn distance of 3.06(4), 2.974(5)and 2.987(8) Å for the solution with Sn_9^{4-}, the solid with Sn_9^{4-} and the solid with Sn_9^{3-}, respectively. The problem with detecting longer distances is also consistent with a fluctional cluster model, since the largest variations are obtained for

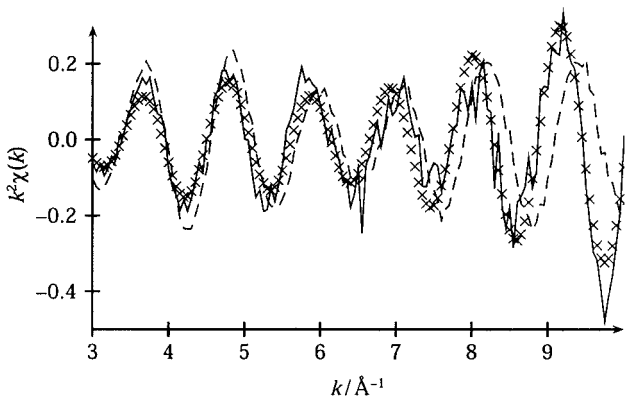

Figure 2. The reduced EXAFS data for the solution with Sn_9^{4-} (solid line) and fitted model (×). For comparison, the dashed line shows the solid with Sn_9^{4-}.

the longest Sn–Sn distances, thus dampening them below the level of noise. However, the longer Sn–Sn distances are present when calculating theoretical EXAFS spectra with rigid models of Sn_9^{4-}, both C_{4v} and D_{3h} geometries, and this is the only difference between experiment and theory (see Figure 3).

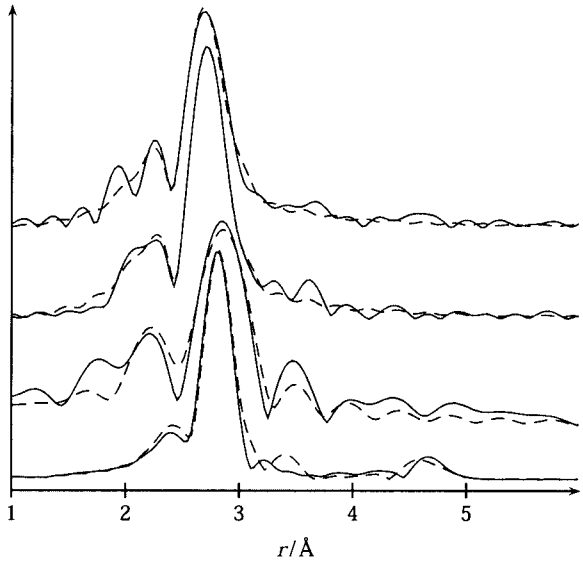

Figure 3. The radial distribution functions of the EXAFS data, fitted models and theoretical models. They are from top to bottom: solid sample with Sn_9^{3-} (solid line) and fitted model (dashed line); solid sample with Sn_9^{4-} (solid line) and fitted model (dashed line); solution with Sn_9^{4-} (solid line) and fitted model (dashed line); theoretical Sn_9^{4-} cluster with C_{4v} (solid line) and D_{3h} geometry (dashed line).

Solid-State Statistics

Several crystal structures of nonastannides are known, obtained at various temperatures and with different compositions.[4–15] The most common way to determine the symmetry of a cluster, when it is not very obvious, is to compare the angle and distance ratios with the idealised geometries.[26,9] A more blunt approach is to simply investigate the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

histogram of intramolecular Sn–Sn distances, which exhibits some of the expected similarities with the EXAFS results, see Figure 3 and Figure 4. If the ratio between the number of distances that fall in the two regions $2.55 \leq d_{Sn-Sn} < 3.95$ and $3.95 \leq d_{Sn-Sn} \leq 5.15$, where d_{Sn-Sn} is the Sn–Sn distance in Å, is 7:5 (21:15) the cluster is classified as being more of D_{3h} type, while a ratio of 5:4 (20:16) is obtained for clusters being more of C_{4v} type. A naive explanation for the above ratios would be that a D_{3h} structure is expected to have 21 shorter distances; 12 between the capping atoms and the closest atoms in the prism, 6 within the triangles in the prism and 3 for the edges in the prism, and 15 longer distances. A similar reasoning for C_{4v} results in 20 shorter distances; 4 between the capping atom and the upper square, 4 within the lower square, 8 between the squares and 4 within the upper square, and 16 longer distances. However, both these approaches only consider the static positional information from the crystal structure determination and totally neglects the information in ADPs, which often constitute a large portion of the information of a crystallographic study.

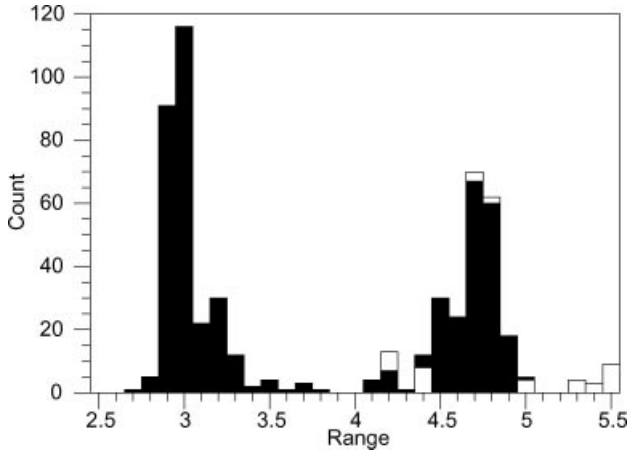

Figure 4. Histogram over intra (filled) and inter (open) molecular Sn–Sn distances.

We believe that the ADPs must be considered in order to get a more complete and dynamic picture of a solid-state structure. Therefore, we suggest that the symmetry of a cluster should be examined and possibly determined by fitting the idealised models to the crystallographic data, while considering the anisotropic displacement parameters. A nice feature with this approach is that the size of the ellipsoids needed to enclose the model using the experimental data will give an unbiased value of how good the fit is.

Since it is only necessary, more or less, to displace four of the nine atoms in order to change the symmetry from C_{4v} to D_{3h} or vice versa, it is evident that the remaining five atoms ought to fit both models reasonably well, which is clearly seen in Table 1, where the median of the fit never is worse than 30%. Moreover, ellipsoids with 80% probability is sufficient to include any of the two models in any of the structures, and ellipsoids with 50% probability will do the same for nearly half of the structures. This is also the level of the probability surfaces presented in most articles reporting solid-state structures.

The fit is generally better for the C_{4v} geometry compared to the D_{3h} one, mainly due to the extra parameter in the fit which is absent in the latter case. Furthermore, it can be seen that structures containing Sn_9^{3-} are better described in terms of a D_{3h} geometry than a C_{4v}, as expected, while structures containing Sn_9^{4-} often are better described in terms of a C_{4v} geometry. However, there are exceptions. Both models can be used, with reasonable success, to describe any of the nonastannide structures reported so far,

Table 1. Part of the statistical data for the various fits. The size of the ellipsoid needed to include the model is given in % and the distance between the experimental and the corresponding model position is given as d [Å].

[a] Better solutions exist for the combined model, $x\ C_{4v} + (1 - x)\ D_{3h}$, when x adopts a negative value. However, these were discarded since the fit was considered to be good enough even when x was limited to $0 \leq x \leq 1$. [b] This is for the structure where six of the atoms are labeled by an extra A and refined isotropically. [c] This is for the structure where six of the atoms are labeled by an extra B and refined.

clearly showing that the clusters are fluctional also in solid state and not only in solution (see Figure 5).

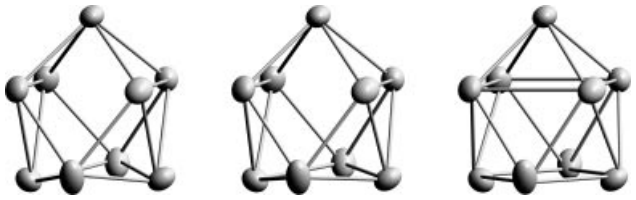

Figure 5. The three different models fitted to the same experimental data. They are from left to right; D_{3h}, C_{2v} and C_{4v}. The three-fold rotation axis in the case of D_{3h} is aligned horizontally. The crystallographic data being illustrated corresponds to $(K^+$-[18-crown-6]$)_3$-$[K^+][Sn_9]^{4-}$(en).[9]

An interesting feature of all the structures is that all tin atoms are located at general positions. This shows that all the clusters have unique geometries that are not directly enforced by the symmetry of the space group and that the different geometries most likely reflects the true nature of the clusters.

Theory

The calculational results clearly show that there is essentially no difference in energy between the two model symmetries, C_{4v} and D_{3h}, regardless the choice of basis set or theoretical method. The difference in energy between C_{4v} and D_{3h} being –3.5, –0.8 and +4.7 kJ·mol^{-1} at HF, B3LYP and MP2 levels, respectively, with the smallest basis set. The difference in energy is even smaller using larger basis sets, indicating that larger basis sets are required in order to properly describe the electron delocalisation in the cluster. Moreover, the preferred geometry appears to be dependent of the level of the calculation, illustrating the delicate balance between the different geometries in question. In addition, the vibrational frequencies are very low, highlighting that the potential energy surface is extremely flat for the two models (Table 2). Similar results have previously been reported, including the lead cluster congener.[20,27]

The obtained vibrational frequencies are lower than the experimentally observed ones, indicating that the harmonic oscillator approximation is not optimal.[25,20] Assuming that frequencies are reasonably correct, it immediately follows that the molecule will have several vibrational states occupied even at quite low temperatures. The most important vibrational mode is the lowest mode, the B_1 or E′, depending on the symmetry, whose vibrating motion is in the direction towards the alternative symmetry, see Figure 6. This shows that regardless of which of the two symmetries the cluster adopts it will always, as lowest vibrational mode, be vibrating in a manner that is directed towards the other symmetry. In this context it is noteworthy to remember that vibrational excitations correspond to larger oscillation amplitudes.

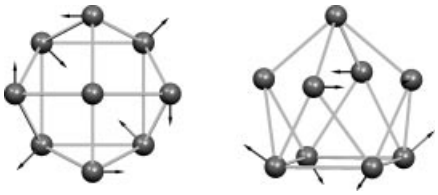

Figure 6. The displacement vectors for the lowest vibration mode of the theoretical model with C_{4v} geometry. In the left figure, the cluster is viewed upon along the C_4 axis, while in the right figure it is viewed almost perpendicularly to the C_4 axis.

The obtained vibrational frequencies are not particularly dependent on the choice of basis set, but the intensities are. This wouldn't be a problem if the relative intensities were

Table 2. Vibrational frequencies for the two model compounds at different levels of theory. Imaginary frequencies are shown as negative numbers and correspond to transition states (saddle points).

left almost intact, but this is unfortunately not the case. However, a general trend is that the intensities increase with increasing number of diffuse functions in the basis set, which easily can be explained with the increased flexibility of the electron cloud.

The cationic field, introduced in an attempt to mimic more normal solid-state conditions for the cluster, leaves the vibrational frequencies almost unaffected, while having a significant impact on the total energy by mainly shifting the potential energies for the nuclei and electrons, resulting in a bound HOMO in a majority of the cases, see Figure 7 and Figure 8.

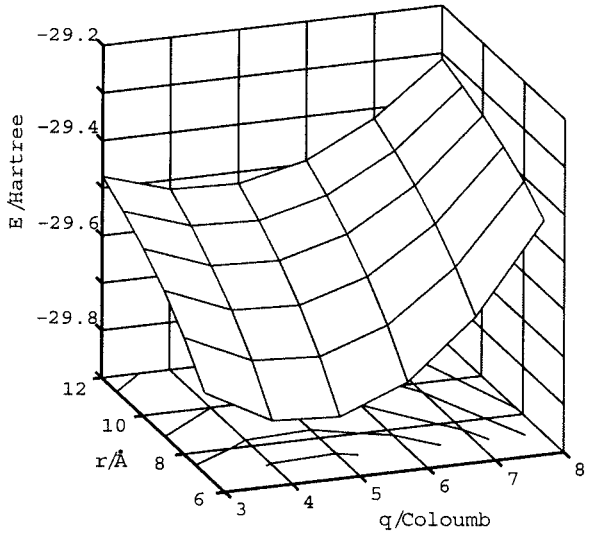

Figure 7. The variation of the total energy with respect to the radius and the charge of the cationic field for a Sn_9^{4-} cluster with C_{4v} geometry. The corresponding Figure for the D_{3h} geometry is virtually identical and thus not explicitly shown.

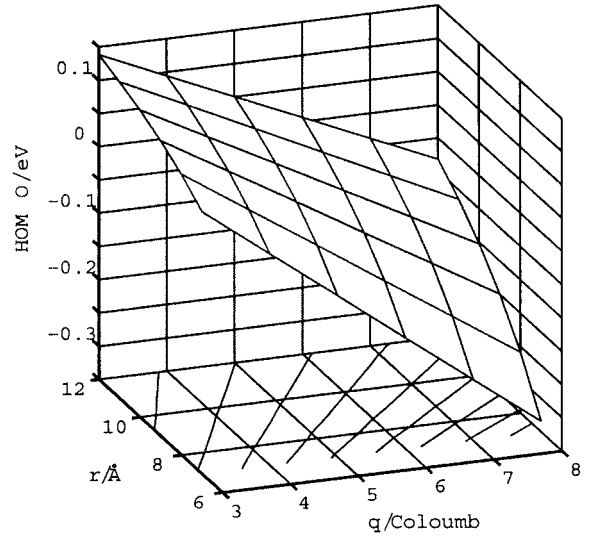

Figure 8. The variation of the HOMO energy level with respect to the radius and the charge of the cationic field for a Sn_9^{4-} cluster with C_{4v} geometry. The corresponding Figure for the D_{3h} geometry is virtually identical and thus not explicitly shown.

The ELF results are also practically unaffected by the field, and the differences are well within the expected accuracy of calculation.[28] Moreover, the iso-surfaces exhibit the same size, shape and location for the different cationic fields considered within the model geometries. This shows that the skeletal electrons are almost unaffected by the cationic field, thus leaving the polyhedral framework practically intact. When comparing iso-surfaces for the two model geometries, it becomes evident that they do not differ much at all, the largest difference in the enclosed iso-surface volumes is never larger than 2.2 Å^3 and this is less than 5% of the total volume in question (see Figure 9 and Figure 10).

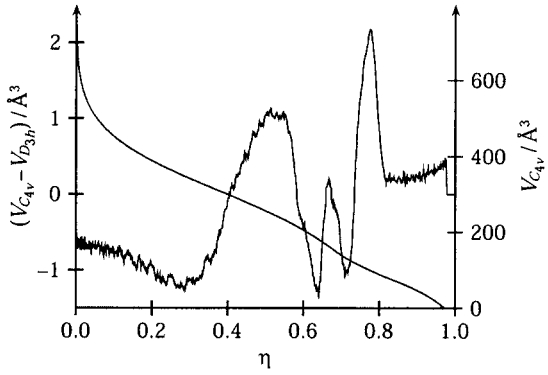

Figure 9. The difference in the enclosed iso-surface volumes between the C_{4v} and D_{3h} models together with the enclosed surface volume for the C_{4v} model at various η.

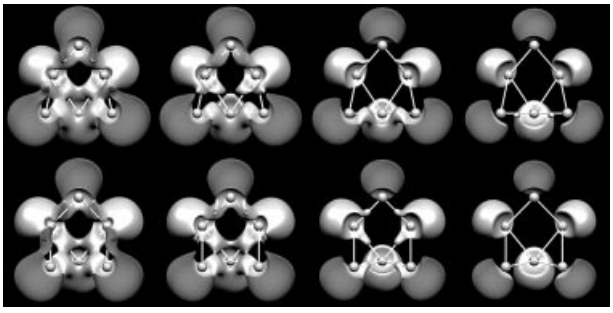

Figure 10. The iso-surfaces at η = 0.66, 0.69, 0.76 and 0.81, from left to right, for the optimised C_{4v} (upper) and D_{3h} geometry (lower). The surfaces are sliced through a σ_v mirror plane coinciding with the plane of the paper, i.e. the four-fold rotation axis for the C_{4v} model is aligned vertically in the plane of the paper and the three-fold rotation axis for the D_{3h} model is aligned horizontally in the plane of the paper.

Moreover, the preferred total charge for the field is about +5, slightly higher than the corresponding charge of the anionic cluster.

Conclusions

The nonstannide clusters are probably best viewed upon as highly fluctional, almost liquid-like drops that retain their fluctional behavior even in solid state and at low temperatures. Due to this fluctionality of the cluster it becomes superficial to discuss the symmetry of the cluster, since the only information known so far is the vibrational average and not the static ideal that is so vital for the discussion.

Experimental Section

Chemicals: Ethylenediamine (en, Merck, for synthesis, 99%) was refluxed with sodium for several hours, distilled under nitrogen and stored with molecular sieves before being used. Potassium metal (Alpha, 99.95%), sodium metal (Alpha, 99.95%) and tin metal (Baker, 99.98%) was used as purchased. The two solid samples, $(K^+$-[2,2,2]crypt$)_3[Sn_9]^{3-}$ and $(K^+$-[18-crown-6]$)_3[K^+][Sn_9]^{4-}$(en), were prepared as described elsewhere.[10,9]

Syntheses: The alloys were made by fusing the elements in a dry pyrex tube at 250 °C and with the molar ratios 10:1, 5:1, 1:1, 1:5 and 1:10 between potassium or sodium and tin. Ethylenediamine was added to the tube after the reaction was completed and the reaction mixture was allowed to equilibrate for 24 hours before further analysis of the solution. All work was carried out in a glove box with a dry nitrogen atmospehere (< 1 ppm O_2, < 1 ppm H_2O) due to the alloys sensitivety to oxygen.

NMR Spectroscopy: NMR spectra were recorded with a Varian Unity 300 MHz spectrometer operating at 111.87 MHz for ^{119}Sn. Chemical shifts are given with respect to $SnCl_4$ at +150 ppm.

Raman Spectroscopy: Raman spectra were obtained with a Bio-Rad Fourier Transform Raman system, employing the 1024 nm radiation of an infrared Nd:YAG laser. 4 cm^{-1} resolution was used.

EXAFS: X-ray absorption (EXAFS) data were recorded at the Stanford Synchrotron Radiation Laboratory (SSRL), using beam line 4 at 3.0 GeV and 50–90 mA. Monochromatic radiation was obtained from a Si(220) double crystal monochromator. High-order harmonics were rejected by 50% detuning. Incident and transmitted X-rays were monitored with argon-filled ion chambers. Six scans were made for all samples. The solid samples were contained in a cell of 1 mm thickness with Kapton film as windows, internally referenced by the K-edge of a tin foil to 29.2 keV. The liquid sample was contained in a cell of 2 mm thickness with Kapton film as windows and the fluorescence was detected with a Ge-detector after passing through an Ag filter. The FEFF program was employed to calculate the Sn–Sn phase shift and amplitude functions, which were used in the non-linear, least-squares fit of the k^3-weighted EXAFS data.[29,30]

Solid-State Statistics: The models were fitted to the crystallographic data with an in-house developed program, using the least-squares method minimising:

$$\sum_i \Delta X_i^T U_i^{-1} \Delta X_i$$

where ΔX_i is the positional difference between the model and the crystallographic data and U_i is the anisotropic displacement parameter for the i:th atom. Three different models were considered, C_{4v}, D_{3h} and a mixture of the two, $x\ C_{4v} + (1 - x)\ D_{3h}$. The last model was mainly used for determining the ratio between the two other ones, when the two models are oriented in such way that the combined model will have C_{2v} symmetry. Both models were fitted simultaneously to the data in order to limit the possibility of obtaining unrealistic results.

Common for all models is that there are three parameters related to the orientation of the model relative to the data. In addition, there are four and three parameters related to the size and shape of the C_{4v} and D_{3h} models, respectively. The combined model has an additional parameter related to the mixing of the two previous models. Thus, in total there are 7, 6 and 11 parameters that are fitted for the C_{4v}, D_{3h} and $x\ C_{4v} + (1 - x)\ D_{3h}$ models, respectively.

Calculations: All quantum chemical calculations, except the Electron Localisation Functions (ELF), were performed using Gaussian98 (rev. A7) with a variety of computers.[31] ECP-based basis sets were used for tin, employing the Stuttgart group, quasi-relativistic ECP's (46 and 28 core electrons) and slightly modified valence spaces;[32] (14s10p2d1f)/[3s3p2d1f] and (14s10p3d2f)/[4s4p3d2f] for the 46 core electron ECP, and (12s12p8d2f1g)/[6s6p3d2f1g] for the 28 core electron ECP.[33,34] Calculations were performed at Hartree–Fock (HF), B3LYP and 2nd-order Møller–Plesset perturbation theory (MP2) level and vibrational frequency calculations were performed.

The ELF calculations were performed using the TopMod program package.[28,35] The grid was chosen so that the distance between the borders and the closest atom was at least 6.0 a.u., and the step size was never larger than 0.1 a.u. The ELF iso-surfaces were visualised with the program Molekel.[36,37]

The cationic field was entered as point charges located at the vertices of a truncated icosahedron, more known as a buckyball or a football. The radius was varied between 7.0 and 12.0 Å at 1.0 Å interval and the point charges were uniformly assigned so that the total charge was varied between 3.0 and 8.0 Coulomb at 1.0 Coulomb interval. The center of the truncated icosahedron was aligned with the center of the molecule and a five-fold rotation axis was aligned with the rotational axis of the highest order of the molecule and another five-fold rotation axis was aligned with a suitable mirror plane, thus assuring that both symmetries are broken by the cationic field.

Acknowledgments

We are grateful to The Swedish Research Council and EU RTN for supporting this work. The authors thank Per Persson, Umeå University, for helpful discussions. Portions of this research were carried out at the Stanford Synchrotron Radiation Laboratory, a national user facility operated by Stanford University on behalf of the U.S. Department of Energy, Office of Basic Energy Sciences.

An Unexpected Crystal-Chemical Principle for the Pyrochlore Structure

Terrell A. Vanderah,*[a] Igor Levin,[a] and Michael W. Lufaso[a]

Keywords: Pyrochlore / Displacive disorder / Bismuth zinc niobates / Phase equilibria

Phase equilibrium studies of the Bi–Zn–Nb–O system show that pyrochlore does not form at chemical compositions predicted by the traditional formula for this crystal structure, $A_2B_2O_6O'$, where A denotes large (8-coordinated, e.g. Bi^{3+}) and B small (6-coordinated, e.g. Zn^{2+}, Nb^{5+}) cation sites. Instead, pyrochlore forms only at compositions with excess B cations which, surprisingly, occupy the large A-cation sites. Reports of similar behavior in other pyrochlores suggest a previously unrecognized inherent structural feature (displacive disorder) which allows the formation of a large family of cubic pyrochlores with small B cations occupying up to ca. 25 % of the large A-cation sites. Many pyrochlores can now be synthesized by deliberately combining large and small metal ions on the A sites.

Introduction

The mineral pyrochlore, $(Na,Ca)_2Nb_2O_6(OH,F)$, was named in 1826 from the Greek for *fire* and *green* because some specimens turned green upon ignition.[1] *Pyrochlore* also denotes a large group of 22 crystallographically similar minerals that are highly diverse chemically[2] and widely distributed geologically. The general formula is $\mathbf{A_{1\rightarrow2}B_2O_6(O,OH,F)\cdot}\boldsymbol{n}\mathbf{H_2O}$, where, in geological specimens, **A** is a relatively large cation (Ca, K, Ba, Y, Ce, Pb, U, Sr, Cs, Na, Sb^{3+}, Bi, and/or Th; radii larger than or equal to ca. 1.0 Å) and **B** is a smaller cation (Nb, Ta, Ti, Sn, Fe, and/or W); the seventh anion position in the crystal structure can be occupied by O^{2-}, OH^-, and/or F^-.[1]

A large number of pyrochlore analogs have been synthesized with an amazing variety of chemical compositions and exploitable properties.[3–9] These include ferroelectricity,[4,10,11] temperature-stable high-permittivity properties,[12,13] fast-ion oxygen conductivity,[6–8] and a wide variety of electrical properties including metallic conductivity, semiconductivity, superconductivity, and electronic phase transitions.[4,5,14–18] The threefold symmetry of the metal arrangement in the crystal structure leads to interesting and diverse magnetic-ordering properties such as ferromagnetism, antiferromagnetism, and spin-glass behavior;[19–21] colossal magnetoresistance (CMR) has also been observed.[22,23] Pyrochlores are known to exhibit catalytic properties,[6] optical properties of interest for pigments and luminescent materials,[6,24] and refractory properties resulting in their consideration as host ceramics for nuclear waste immobilization.[4,25]

The remarkable variety of properties obtainable with the pyrochlore crystal structure reflects its inherent chemical and structural versatility. This non-molecular arrangement[4,5,26,27] is unusual in that it can be considered as two relatively independent, interpenetrating three-dimensional frameworks (Figure 1). The $A_2B_2O_7$ overall formula for ideal oxide pyrochlores is often written as $A_2B_2O_6O'$ (or $A_2B_2O_6X$) to distinguish the oxygen atoms (or anions) in the two different networks. The ideal cubic structure is highly symmetrical, crystallizing in space group $Fd\bar{3}m$ (No. 227), with four crystallographically distinct sites occupied by the A (site 16*d*), B (site 16*c*), O (site 48*f*), and O′ (site 8*b*) ions. Symmetry fixes the positions of all ions except those in 48*f*, which have a single variable parameter along the *x*-direction. The extensive compositional ranges known for pyrochlore compounds reflect the versatility of the A_2O' substructure: "defect" pyrochlores form readily since this network can be partially occupied or even completely absent, as in the pyrochlore-type polymorph of WO_3 (W_2O_6).[29] In addition, the O′ position can be occupied by anions other than O^{2-} such as OH^-, F^-,[30] and S^{2-},[31] forming oxyhydroxide, oxyfluoride, and oxysulfide pyrochlores. A number of non-oxide pyrochlores are known[27,32] including chlorides[33] and fluorides.[34,35] The pyrochlore structure is therefore highly "tailorable"; e.g., the identities and oxidation states of the B-cations, which play a leading role in electronic properties, can be controlled by achieving electroneutrality through deliberate choices of the A and O′ ions and their concentrations.

Although solid-state chemists realize that ions are not hard spheres with fixed sizes, the use of *structure field maps*[36] to predict the crystalline arrangement of new complex oxides has been moderately successful, especially given the scarcity of theoretical tools. For a given crystal structure, the map is constructed empirically from known com-

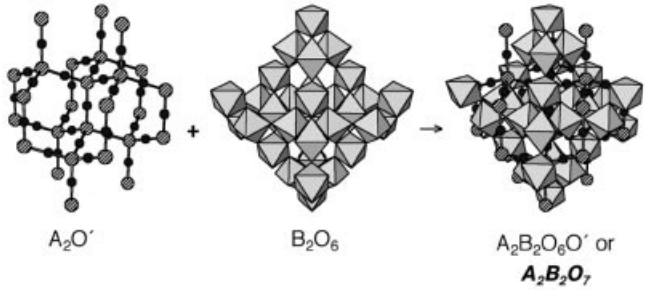

Figure 1. The ideal crystal structure of pyrochlore represented as two interpenetrating networks. Small black spheres denote A cations, large hatched spheres represent O′ oxygen anions, and gray octahedra contain B cations with oxygen atoms located at the six vertices. The A_2O' network corresponds to that of anticristobalite-type[28] Cu_2O, featuring four-coordinate O′ ions and two-coordinate A cations. The B_2O_6 framework consists of $[BO_6]$ octahedra sharing all vertices to form large cavities. The structures are interwoven such that the O′ ions of the A_2O' network occupy the centers of these cavities, while the A cations reside in puckered hexagons formed by oxygen atoms in the B_2O_6 framework. The final coordination number of the A cations is eight including the two oxygen atoms in the A_2O' network, which cap the puckered hexagonal ring above and below.

pounds by plotting the ionic radii[37] of the A vs. the B cations; new compounds may form the same structure if the radii of the proposed A and B cations correspond to a point in the observed stability field. The use of structure field maps and cation radius ratios to predict the formation of pyrochlores has been somewhat successful for ideal formulations.[4,8,38–41] For example, for $A^{3+}{}_2B^{4+}{}_2O_7$ pyrochlores, the A cation can be as small as Lu^{3+} (0.977 Å) or as large as Bi^{3+} (1.17 Å), while the radii of the B cations fall between ca. 0.58 and 0.72 Å.[4] The approach has been less useful for pyrochlores with substitutions on the A and B sites;[6,42] nevertheless, there is general agreement that the A cation must be appreciably larger than the B cation for the structure to form.

In the late 1990s, pyrochlore-containing Bi–Zn–Nb–O materials attracted considerable attention as they were found to exhibit properties suitable for embedded (miniaturized) temperature-stable capacitors and filters.[12,43] The composition of the pyrochlore phase was given in numerous reports as $Bi_{1.5}Zn_{1.0}Nb_{1.5}O_7$, which incited considerable controversy since this would require half of the small Zn^{2+} cations (radius 0.74 Å) to be mixed with the much larger Bi^{3+} ions on the A sites of the structure [i.e., $Bi_{1.5}Zn_{0.5}(Zn_{0.5}Nb_{1.5})O_7$, B-site cations in parentheses]. The size of Zn^{2+}, which is rarely observed with coordination numbers higher than 6, falls well outside the structure field maps for the A site cations in ideal pyrochlores.[4,40] Subsequently, the composition $Bi_{1.5}Zn_{1.0}Nb_{1.5}O_7$ was shown to be a two-phase mixture of pyrochlore and ZnO; however, a pure single-phase cubic pyrochlore was indeed obtained at the composition $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$,[44] which also requires a considerable concentration of Zn^{2+} on the A sites.

A structural determination of $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$[44] revealed static displacive disorder in the A_2O' portion of the structure and concluded a structural formula of $Bi_{1.5}Zn_{0.42}\square_{0.08}(Zn_{0.50}Nb_{1.5})O_{6.92}$. The A sites were assumed to be occupied by a (disordered) mixture of Bi^{3+}, Zn^{2+}, and vacancies (□); observation of reflections with Miller indices 442, forbidden for an ideal pyrochlore, required lower-symmetry positions for the A and O′ ions, even though the average structure retains cubic symmetry [$Fd\bar{3}m$, a = 10.5616(1) Å] The combined displacements (Figure 2) of the A (0.39 Å) and O′ (0.46 Å) ions change the coordination number of the A cations from 8 to (5 + 3), thus permitting the smaller Zn^{2+} ion to achieve a chemically reasonable environment, with fewer nearest oxygen neighbors, by local correlations of the displaced ions, as

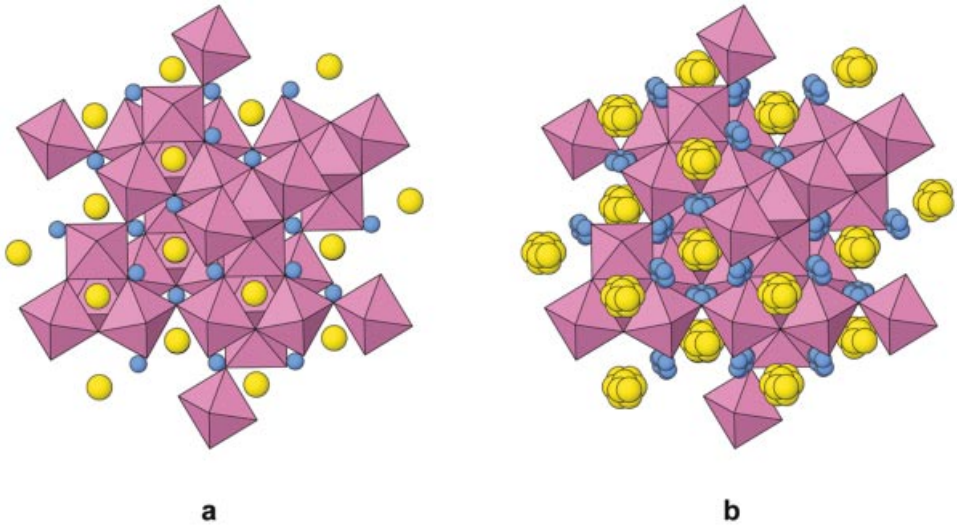

Figure 2. Comparison of the ideal (**a**) pyrochlore structure (Figure 1) and actual (**b**) structure determined for $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$, with displacive disorder in the A_2O' network.[44] Blue spheres represent A cation sites, yellow spheres represent the O′ oxygen sites (bonds in the A_2O' network have been omitted for clarity), and red octahedra denote the B_2O_6 framework. In part **b**, a disordered mixture of Bi^{3+}, Zn^{2+}, and vacancies is distributed randomly among the six equivalent sites represented by each toroid of blue spheres; cuboctahedral clusters of yellow spheres denote the 12 possible displaced positions for the O′ ions.

subsequently confirmed by a detailed study of diffuse scattering.[45] Single-crystal X-ray diffraction analysis[46] also confirmed the displacively disordered structural model for $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$. Interestingly, vibrational spectroscopic studies suggest that the glass-like dielectric behavior observed for $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$ is caused by this displacive disorder.[44,47] The present study of the equilibrium phase diagram for the Bi_2O_3–ZnO–Nb_2O_5 system was carried out to elucidate the compositional range of this highly unusual pyrochlore as well as its thermodynamic compatibility with other phases in the system.

Results and Discussion

Subsolidus phase relations obtained for the Bi_2O_3–ZnO–Nb_2O_5 system are shown in Figure 3. The previously reported binary phase equilibria for the perimeter systems (Bi_2O_3–Nb_2O_5,[48–50] Bi_2O_3–ZnO,[51] ZnO–Nb_2O_5[52,53]) were confirmed in the present study, with the exception of the Bi_2O_3–Nb_2O_5 system above 0.75 Bi_2O_3 (represented here as a solid solution extending to Bi_2O_3) which we did not investigate in detail. This region apparently forms a series of modulated fluorite superstructures;[49] differences in the reported diagrams likely arise from variations in cooling methods and whether specimens were examined by X-ray or electron diffraction methods.

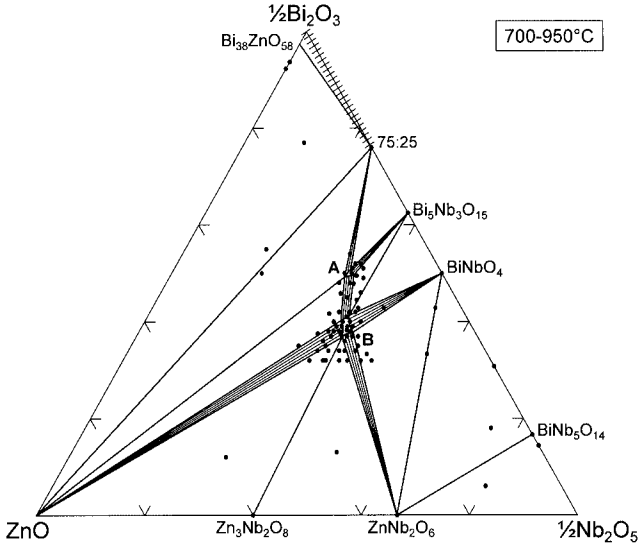

Figure 3. Subsolidus phase equilibrium diagram in air for the Bi_2O_3–ZnO–Nb_2O_5 system. Black dots denote the compositions of specimens prepared in the study; concentrations are on a molar fraction basis. Ternary phase formation is limited to zirconolite (A) and pyrochlore (B), both of which form single-phase solid solution regions. As shown, zirconolite forms thermodynamically stable mixtures with pyrochlore, ZnO, the 75:25 Bi_2O_3:Nb_2O_5 solid solution, and $Bi_5Nb_3O_{15}$. Bi–Zn–Nb–O pyrochlores will form stable mixtures with zirconolite, $Bi_5Nb_3O_{15}$, $BiNbO_4$, $ZnNb_2O_6$, $Zn_3Nb_2O_8$, and ZnO. Temperature-stable dielectric ceramics are processed in the two-phase region indicated between zirconolite (A) and pyrochlore (B).

Only two ternary phases were found to form in the Bi_2O_3–ZnO–Nb_2O_5 system, monoclinic zirconolite[54,55] (A) and cubic pyrochlore (B) (Figure 3). Observable shifts in their X-ray powder diffraction patterns indicated that both compounds are nonstoichiometric and form solid solution regions. Pyrochlore does not form at the conventionally predicted composition $Bi_2Zn_{2/3}Nb_{4/3}O_7$, which falls in the zirconolite region A. Instead, pyrochlore forms at substantially lower Bi concentrations in this chemical system. The present results indicate, in fact, that the single-phase field for the pyrochlore structure falls *completely outside* compositions predicted for conventional pyrochlores, i.e., those with Bi^{3+} on the A sites and a Zn^{2+}/Nb^{5+} mixture on the B sites, as shown in Figure 4. We conclude that the unconventional placement of small B-type cations such as Zn^{2+} on the large A-cation sites, accompanied by displacive disorder in the A_2O' network, is *required* for stabilization of the pyrochlore structure in the Bi–Zn–Nb–O system.

A number of reports found in the literature suggest that displacive disorder in the A_2O' network is an inherent feature of the pyrochlore structure. Nearly thirty years ago, a detailed structural study of $Sn^{2+}{}_{1.76}(Ta_{1.56}Sn^{4+}{}_{0.44})O_{6.54}$[56] found that Sn^{2+} was displaced 0.38 Å from the ideal A-cation positions, nearly the same as in $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$. These authors mention observation of the "forbidden" 442 reflection as "glaring" evidence of deviation from the ideal pyrochlore structure. Similar behavior was found for $Bi_{1.74}Ti_2O_{6.62}$, again with Bi^{3+} displacements of 0.38 Å,[57] and also for the stoichiometric compound $Bi_2Ti_2O_7$.[58] Pyrochlore-type $Tl_2Nb_2O_{6+x}$ compounds were also found to exhibit Tl ion displacements, apparently dynamic at room temperature.[59] Numerous titanate and zirconate pyrochlores with rare earth A-cations are known to exhibit characteristic diffuse intensity distributions[60] analogous to those observed for β-cristobalite (SiO_2), which features atoms in the same positions as the A_2O' network of pyrochlore. A study of $La_2Zr_2O_7$ concluded that the La^{3+} ions do not occupy the ideal A sites, but are dynamically disordered around an annulus perpendicular to the O′–La–O′ linear unit.[60] This behavior is analogous to the orientational disorder of the [SiO_4] tetrahedra in β-cristobalite, which results in typical Si–O bond lengths and angles as opposed to the chemically unreasonable values in the average structure. Similar improvements in bond lengths are achieved for La^{3+} in the pyrochlore $La_2Zr_2O_7$ by this mechanism;[60] the annulus containing the La positions occurs in the same plane as the toroids of six possible A sites in $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$ (Figure 2, part b).

The unconventional substitution of small B-type cations on the A sites of pyrochlore has also been previously observed; the present results as well as several other reports suggest that up to about 25% of the A sites in the $A_2B_2O_6O'$ structure can be substituted with small, typically B-site cations. Examples include the ferroelectric oxysulfide pyrochlore $Cd_{2-x}Zn_xNb_2O_6S$,[31] and the series $Bi_{2-x}B_xRu_2O_{7-y}$ (B = Mn, Co, Ni, Cu, Zn, Mg), with x-values as high as 0.5.[16] Similar cubic pyrochlores have been reported with Nb instead of Ru; i.e., $Bi_{1.5}MNb_{1.5}O_7$ (M = Cu, Mg, Mn, Ni), which would require half of the small M cations to be mixed with Bi^{3+} on the A sites.[61] These re-

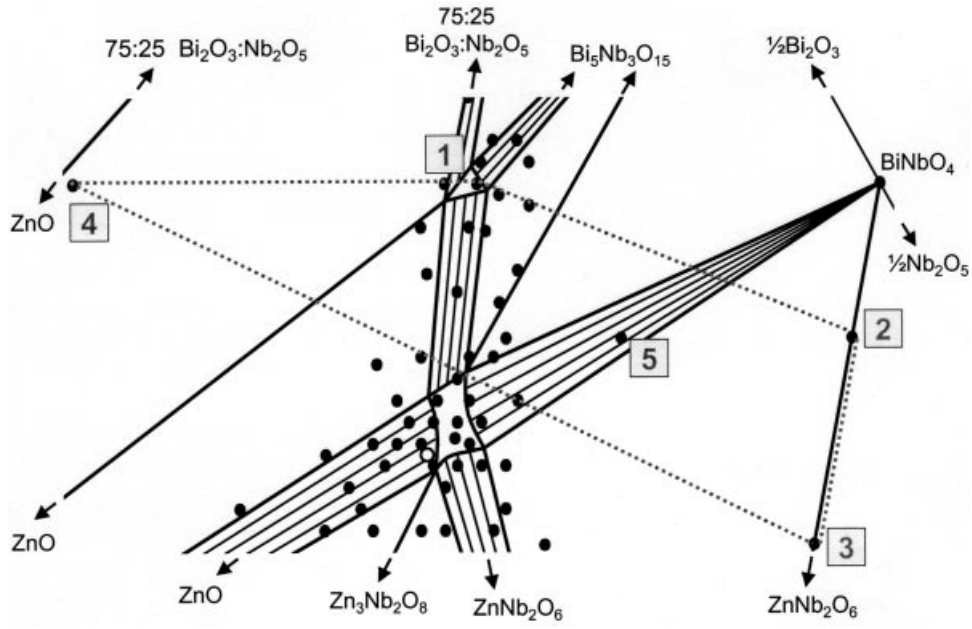

Figure 4. Magnified portion of the Bi_2O_3–ZnO–Nb_2O_5 phase equilibrium diagram (Figure 3), emphasizing the regions of zirconolite and pyrochlore phase formation. The zirconolite structure forms at compositions within the small triangle containing the composition $Bi_2Zn_{2/3}Nb_{4/3}O_7$ (1). The cubic pyrochlore phase forms within the four-sided region below zirconolite. Joins (lines) emanate from the curved sides and vertices of this region to compounds that form thermodynamically stable two-phase mixtures with pyrochlore. The dotted line connects compositions 1 ($Bi_2Zn_{2/3}Nb_{4/3}O_7$), 2 ($Bi_{1.5}Zn_{0.166}Nb_{1.833}O_7$), 3 ($BiZn_{1/3}Nb_{5/3}O_6$), and 4 ($Bi_2Zn_{4/3}Nb_{2/3}O_6$) to outline the compositional field in which conventional pyrochlores and/or defect pyrochlores are expected to form (5 = $Bi_{1.5}Zn_{0.5}Nb_{1.5}O_{6.5}$); i.e., with no Zn^{2+} ions on the A sites. The single-phase region found for pyrochlore is seen to fall *completely outside* this field, indicating that the structure only forms at compositions with excess B cations that are accommodated on A sites. The open circle in the two-phase ZnO-pyrochlore field corresponds to the composition $Bi_{1.5}Zn_{1.0}Nb_{1.5}O_7$, given in numerous reports as the stoichiometry of the pyrochlore phase, but which actually lies outside the single-phase region.

ports do not include detailed X-ray powder diffraction data; however, all of these cubic pyrochlores should exhibit displacive disorder in the A_2O' network to provide chemical accommodation of the small B-type cations – their X-ray powder diffraction patterns should exhibit weak forbidden reflections such as the 442, which can be indexed using the reported $Fd\bar{3}m$ cubic unit cells, but which serve as (easily overlooked) diagnostic flags for the displacement of atoms to lower-symmetry positions in the space group.

The present study confirmed observation of weak peaks at the positions of the diagnostic 442 reflections in the powder diffraction patterns for pyrochlore phases forming in the systems Bi–M–Nb–O with M = Co, Fe, Ni, Mn, Cu, and Cr, as shown in Figure 5. As in the Bi–Zn–Nb–O system, the pyrochlore phase in these systems does *not* form as a pure compound at conventional formulations (i.e. $Bi_2Co_{2/3}Nb_{4/3}O_7$, $Bi_2Ni_{2/3}Nb_{4/3}O_7$, Bi_2FeNbO_7, Bi_2MnNbO_7, $Bi_2Cu_{2/3}Nb_{4/3}O_7$, or Bi_2CrNbO_7). Recent phase equilibrium studies of the Bi_2O_3–Mn_2O_3–Nb_2O_5 and Bi_2O_3–Fe_2O_3–Nb_2O_5 systems[62] found that, similar to the Bi_2O_3–ZnO–Nb_2O_5 system (Figure 3), the pyrochlore single-phase fields occur at substantially lower Bi concentrations than the conventional formulas, and at compositions requiring the mixing of B-type Mn and Fe cations on the A-sites with Bi^{3+}. Furthermore, *all* X-ray powder diffraction patterns for pyrochlore and pyrochlore-containing specimens in these studies exhibited clearly observable 442 reflections. We conclude that, as for the Bi–Zn–Nb–O system, the occurrence of displacive disorder in the A_2O' network is *required* for the formation of pyrochlore in the Bi–Mn–Nb–O and Bi–Fe–Nb–O chemical systems. We refer to these as misplaced-displacive cubic pyrochlores – pyrochlores which exhibit misplacement of traditionally octahedral B-site cations onto the larger A-sites, accompanied by displacive disorder in the A_2O' substructure to facilitate lower coordination numbers for the smaller species.

A structural study of the cubic pyrochlores $Bi_2Ru_2O_7$, $Bi_{1.6}Cu_{0.4}Ru_2O_7$, and $Bi_{1.6}Co_{0.4}Ru_2O_7$[14] confirmed static displacive disorder in both the A and O′ sites for all three compounds, and proposed that this was a common feature of $A_2B_2O_7$ pyrochlores having a lone electronic pair on the A-site cation (e.g. Bi^{3+}, Pb^{2+}, Tl^+). Similar conclusions were drawn for the series $Bi_{2-y}Yb_yRu_2O_{7-\delta}$[18] and $Bi_{2-x}(CrTa)O_{7-y}$[63] More generally, we suggest that this is an inherent feature of the chemically versatile pyrochlore structure which occurs to accommodate cations with shapes (i.e. lone pairs) or sizes (i.e. typical B-type cations) that are non-ideal for the coordination environment provided by the rigid B_2O_6 framework. This more general principle is demonstrated in the Ca-Ti–Nb–O system, which forms a cubic pyrochlore near the composition $Ca_{1.5}Ti_{1.5}NbO_7$ [=$Ca_{1.5}Ti_{0.5}(TiNb)O_7$].[64] Structural studies of single crystals of $Ca_{1.5}Ti_{1.5}NbO_7$ and also isostructural $Ca_{1.5}Ti_{1.5}TaO_7$[65] revealed displacive disorder in both the A and O′ positions

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

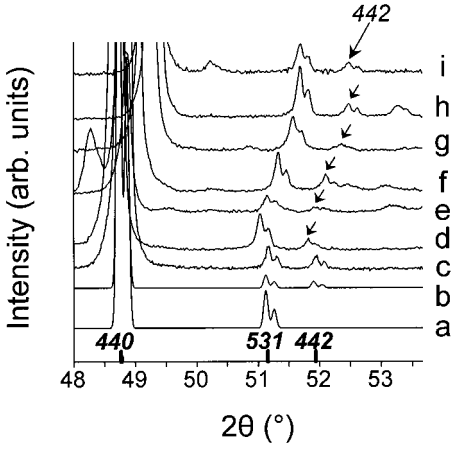

Figure 5. Selected regions of X-ray powder diffraction patterns showing that pyrochlore phases in the Bi–M–Nb–O systems (M = Zn, Co, Fe, Ni, Mn, Cu, and Cr) all exhibit weak peaks at the positions of the 442 reflections, diagnostic for displacive disorder in the A_2O' network. Patterns a) and b) are calculated for $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$ assuming the ideal (a) pyrochlore structure (shown in part **a** of Figure 2), and (b) using the refinement results with static disordered displacements in the A and O′ sites[42] (see part **b** of Figure 2); the latter calculated pattern matches the experimentally observed pattern for $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$ (c). The 442 reflection occurs just below 52° 2θ for the Zn compound and is forbidden in the ideal pyrochlore structure (a). This reflection is seen in all of the other patterns (at slightly shifted 2θ-values reflecting different unit cell volumes) for equilibrated specimens with nominal compositions (d) $Bi_2Co_{2/3}Nb_{4/3}O_7$, (e) $Bi_2Ni_{2/3}Nb_{4/3}O_7$, (f) Bi_2FeNbO_7, (g) Bi_2MnNbO_7, (h) $Bi_2Cu_{2/3}Nb_{4/3}O_7$, and (i) $Bi_{4/3}CrNbO_6$. Although pyrochlore is the major phase in these specimens, it does not form as a single phase at these conventional formulations.

of the cubic pyrochlore structures; the Ti^{4+} ions in the A_2O' network were displaced 0.7 Å from the ideal A sites, resulting in chemically reasonable bond lengths to five oxygen atoms, while Ca^{2+} ions remained in the ideal positions. Interestingly, the $Ca_{1.5}Ti_{1.5}NbO_7$ pyrochlore was found to exhibit dielectric relaxation similar to that of $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$,[47] suggesting that displacive disorder, not the presence of Bi^{3+}, gives rise to this phenomenon.

Conclusions

Realizing that the pyrochlore structure can accommodate small B-type metals on up to 25% of the large A-sites by displacive disorder, solid state chemists are no longer restricted to the formula $A_2B_2O_6O'$ in the preparation of pyrochlore-type compounds with yet unknown, potentially useful properties. Many compounds can now be synthesized and/or modified by deliberate combinations of large and small metal ions on the A-sites. Since large A cations and smaller B-type cations tend to be electronically dissimilar, electrical and magnetic properties should be strongly affected by mixing them in the A_2O' network.[14] Ionic conductivity properties should also depend strongly on the occurrence of B cations, vacancies, and displacive disorder in the A_2O' network. For the theoretical community, the challenge remains to understand why some chemical systems *only* form so-called misplaced-displacive cubic pyrochlore phases, even though conventional crystal chemistry suggests that normal pyrochlores should form.

Experimental Section

Approximately 80 polycrystalline specimens (3–4 g each) were prepared in air by solid-state reactions using Bi_2O_3 (99.999%), ZnO (99.99%), and Nb_2O_5 (99.999%). Prior to each heating, each sample was mixed by grinding with an agate mortar and pestle for 15 min, pelletized, and placed on sacrificial powder of the same composition on Pt foil supported by alumina ceramic. After an initial overnight calcine at 800 °C (below the m.p. of Bi_2O_3, 825 °C) multiple 4-hour heatings (with intermediate grinding and re-pelletizing) were carried out at 950–980 °C. (Exceptions were low-melting specimens with Bi contents above 90 mol-% $BiO_{1.5}$, which were not heated above 700 °C). Samples were furnace-cooled to ca. 700 °C and then air-quenched on the bench-top. Typically, three to five heatings were required to attain equilibrium, which was presumed when no further changes could be detected in the weakest peaks observed in the X-ray powder diffraction patterns. Thermogravimetric analyses (TGA) of pure ZnO and Bi_2O_3 in flowing air indicated no significant weight loss below 1000 °C for Bi_2O_3 and about 1200 °C for ZnO. For the pyrochlore phase of composition $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$, TGA under flowing oxygen indicated congruent-like melting at ca. 1185 °C coinciding with the onset of appreciable volatility. Single pyrochlore-type crystals were easily obtained by heating $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$ powder in a Pt capsule (sealed by welding) to 1275 °C, followed by slow-cooling (5 °C/h) to below the freezing point.

Polycrystalline pyrochlore-containing specimens in the Bi–M–Nb–O systems (M = Co, Ni, Fe, Mn, Cu, and Cr) were synthesized as above at the following chemical compositions, with reagents and final soak temperatures in parentheses: $Bi_2Co_{2/3}Nb_{4/3}O_7$ (Co_3O_4, spectroscopic grade, pre-analyzed by TGA, 925 °C), $Bi_2Ni_{2/3}Nb_{4/3}O_7$ (NiO, 99.998%, 925 °C), Bi_2FeNbO_7 (Fe_2O_3, reagent grade, 925 °C), Bi_2MnNbO_7, ($MnCO_3$, reagent grade, pre-analyzed by TGA, 885 °C), $Bi_2Cu_{2/3}Nb_{4/3}O_7$ (CuO, reagent grade, 825 °C), and $Bi_{4/3}CrNbO_6$ (Cr_2O_3, reagent grade, 975 °C). All specimens, when equilibrated, were mixtures containing pyrochlore as the major phase.

Phase assemblages in the Bi_2O_3–ZnO–Nb_2O_5 system were ascertained using the disappearing phase method[66,67] and X-ray powder diffraction data obtained with a Philips[68] diffractometer equipped with incident Soller slits, a theta-compensating slit and graphite monochromator, and a scintillation detector. Samples were mounted in welled glass slides. Patterns were collected at ambient temperatures using Cu-K_α radiation over the range 3–70° 2θ with a 0.02° 2θ step size and a 2 s count time. Intensity data measured as relative peak heights above background were obtained using the DATASCAN software package, and processed using JADE. For unit cell refinements, observed 2θ line positions were first corrected using SRM 660, LaB_6,[69] as an external calibrant. Lattice parameters were refined using JADE (2θ values, Cu-$K_{\alpha1}$ = 1.540593 Å).

Unit cell parameters and compositions for several single-phase pyrochlore specimens are given in Table 1. The present data suggest that the limiting compositions of the pyrochlore phase field, located at the four cusps (corners) in Figure 4, are approximately $Bi_{1.64}Zn_{0.33}(Zn_{0.52}Nb_{1.48})O_7$ (highest Bi-content), $Bi_{1.61}Zn_{0.39}(Zn_{0.55}Nb_{1.46})O_7$, $Bi_{1.48}Zn_{0.44}(Zn_{0.44}Nb_{1.56})O_7$ (highest Nb-content), and $Bi_{1.47}Zn_{0.52}(Zn_{0.48}Nb_{1.52})O_7$ (lowest Bi-content,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

highest Zn-content). During synthesis, the pyrochlore phase formed early in partially reacted samples and was readily purified within the single-phase region, suggesting high thermodynamic stability.

Table 1. Compositions, cubic unit cell parameters (***a***, space group $Fd\bar{3}m$, #227), and structural formulas for single-phase pyrochlore specimens. These compositions correspond to the points within the four-sided pyrochlore region shown in Figure 4. The structural formulas have been normalized to seven oxygen atoms (full occupancy of the O′ site) for purposes of comparison. Parentheses denote cations in the octahedral B-sites.

Composition	*A* [Å]	Structural formula
$Bi_{1.50}Zn_{0.91}Nb_{1.54}O_7$	10.551(1)	$Bi_{1.50}Zn_{0.45}(Zn_{0.46}Nb_{1.54})O_7$
$Bi_{1.52}Zn_{0.93}Nb_{1.52}O_7$	10.555(1)	$Bi_{1.50}Zn_{0.45}(Zn_{0.48}Nb_{1.52})O_7$
$Bi_{1.55}Zn_{0.91}Nb_{1.51}O_7$	10.553(1)	$Bi_{1.55}Zn_{0.42}(Zn_{0.49}Nb_{1.51})O_7$
$Bi_{1.60}Zn_{0.93}Nb_{1.47}O_7$	10.564(1)	$Bi_{1.60}Zn_{0.40}(Zn_{0.53}Nb_{1.47})O_7$
$Bi_{1.63}Zn_{0.88}Nb_{1.47}O_7$	10.571(1)	$Bi_{1.63}Zn_{0.35}(Zn_{0.53}Nb_{1.47})O_7$

Acknowledgments

We thank R. S. Roth for helpful discussions, L. P. Cook for thermogravimetric analyses, J. Suh for technical assistance, and P. K. Schenk and N. Swanson for graphical representation of the phase diagram data.

N-Donor Ligand Coordination Polymers of Cu^{II}, Zn^{II}, and Cd^{II} Obtained at Elevated Temperature and Pressure

Hélène Casellas,[a] Chiara Massera,[b] Patrick Gamez*[a] Anna Maria Manotti Lanfredi,[b] and Jan Reedijk*[a]

Keywords: Coordination polymers / N ligands / Multidirectional ligands / Chain structures / Pi interactions

Reactions of Copper(II), Zinc(II), and Cadmium(II) nitrate with 2,4,6-tris(dipyridin-2-ylamino)-1,3,5-triazine (dpyatriz) at elevated temperature and pressure lead to new 1D coordination polymers which exhibit solid-state structures significantly different from those obtained at room temperature and atmospheric pressure. In addition, these coordination compounds exhibit unusual anion–π interactions.

Introduction

Supramolecular interactions are important in several fields of contemporary chemistry. Supramolecules are often self-assembled systems by means of a variety of interactions which may interplay. In crystal engineering, synergistic effects between intermolecular non-covalent interactions are of great importance and must be regarded as a single interrelated entity. The targeted molecular self-assembly of coordination architectures from tailored molecular components is a potential route to novel one-, two-, and three-dimensional networks.[1,2] The preparation of polymeric complexes can be accomplished by using rationally designed polydentate ligands. Many advanced 2D and 3D metallosupramolecular structures[3] have been generated in this way with encouraging applications in catalysis,[4] drug design,[5] separation studies,[6] gas storage,[7] and molecular recognition.[8] Furthermore, their preparation has highlighted another consideration: it is not only the building blocks that are important, but also the experimental parameters such as solvent, temperature, pressure, etc. used during the synthesis may lead to different species.[9] For example, the reaction of $Cu^{I}Br$ with 2,2′-dipyridyl under ambient conditions leads to a 1:1 adduct, while a polymeric structure is formed at 170 °C and autogenous pressure.[10]

In the course of research investigations to prepare triazine-based coordination polymers and study their physical and catalytic properties,[11–13] the ligand 2,4,6-tris(dipyridin-2-ylamino)-1,3,5-triazine (dpyatriz) has been synthesized (Figure 1).[14,15] Coordination compounds of Cu^{II} and Zn^{II} nitrate with dpyatriz obtained at room temperature and normal pressure in acetonitrile have been recently reported.[11,16] In this paper, new coordination polymers obtained from dpyatriz and various metal nitrates in acetonitrile at 105 °C in a closed pressure tube are described, showing significantly different coordination networks, as well as uncommon supramolecular interactions.

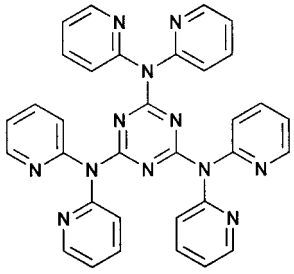

Figure 1. 2,4,6-Tris(dipyridin-2-ylamino)-1,3,5-triazine (dpyatriz).

Results and Discussion

Reaction of $Cu(NO_3)_2{\cdot}3H_2O$ in acetonitrile with dpyatriz yields light-blue parallelepipeds of $[Cu_2(dpyatriz)(NO_3)_4](H_2O)$ (**1**), whose crystal structure was determined by X-ray diffraction (Figure 2). The dinuclear building blocks consist of one pentacoordinate copper ion Cu(1) involved in the self-assembly of the coordination polymer and one isolated pentacoordinate copper ion Cu(2). Cu(1) is in a square-pyramidal geometry ($\tau = 0.167$)[17] with N(6) in an axial position (Table 1). The basal plane is formed by three N-coordinating 2-pyridyl moieties [N(5), N(11), and N(12)] from two didentate dipyridylamine units belonging to a symmetry-related dpyatriz ligand. The in-plane Cu–N dis-

tances can be regarded as normal (Table 1). The fourth position is occupied by the oxygen atom O(1) of a nitrate counter-anion. The angles around Cu(1) in the basal plane are close to 90°, varying from 83.7(3) to 93.5(3)° (Table 2). Cu(2) is also in a square-pyramidal geometry ($\tau = 0.137$).[17]

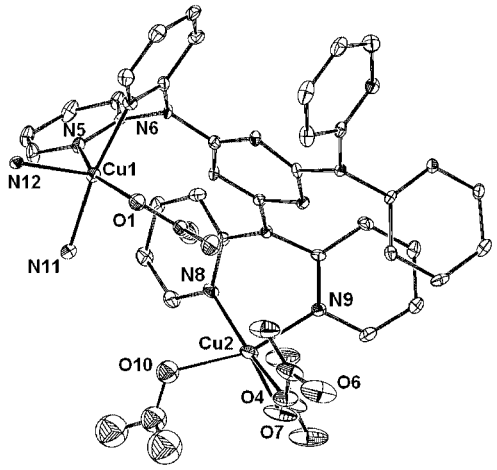

Figure 2. ORTEP plot of the repeating unit of **1**, where the N11 and N12 atoms belong to a symmetry-related unit. The water molecule and the hydrogen atoms are omitted for clarity; thermal ellipsoids are at the 20% probability level.

The basal plane around Cu(2) is constituted of two nitrogen atoms N(8) and N(9), from a dipyridylamine group, and two oxygen atoms O(7) and O(10), from two nitrate anions (one of these oxygen atoms is statistically distributed over two different positions indicated with O10 and O10′). The in-plane Cu–N distances are in the usual range, as well as the Cu–O distances (Table 1).[18] The axial position is occupied by the oxygen atom O(4) from a third coordinated nitrate ion, at a somewhat longer distance. The angles around Cu(2) in the basal plane vary from 86.1(5) to 95.9(4)° (Table 2). In addition, a water molecule O(18) is present in the crystal lattice (not depicted in Figure 2). This water molecule is hydrogen-bonded to the oxygen atom O(6a) of a nitrate group coordinated to Cu(2a) of an adjacent polymer chain [O(1S)–H···O(6a) 2.931(8) Å] (Figure 3).

This dinuclear copper complex makes up a 1D zigzag polymer through the coordination of Cu(1) by a dipyridylamine moiety from an adjacent repeating unit (Figure 3). Most interestingly, a quite different 1D ladder coordination polymer has been obtained from $Cu(NO_3)_2 \cdot 3H_2O$ and dpyatriz in acetonitrile, at room temperature and atmospheric pressure.[11] The different crystal packing observed in the present study is obviously due to the higher temperature and pressure used during the crystallisation process. This result illustrates the difficulty to predict a crystal structure. Indeed, crystal growth involves several intermolecular synergistic noncovalent interactions between all synthons,[19] i.e. ligands, metal ions, anions and solvents, which have certainly to be considered for a better crystal structure prediction. In addition, the temperature and the pressure applied during the crystallisation are clearly important and should also be taken into account.

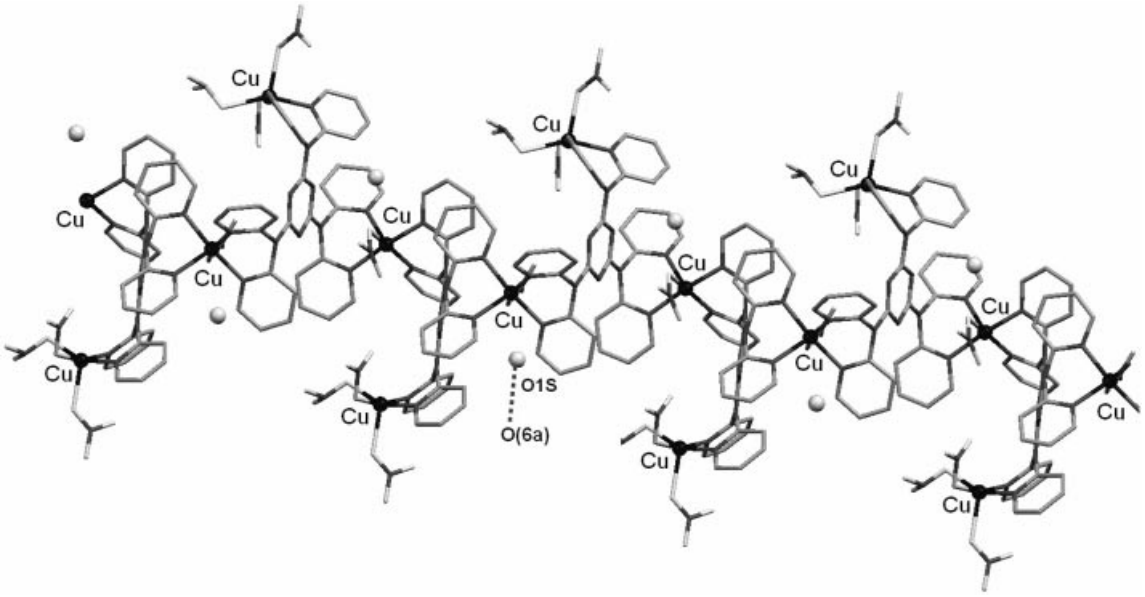

Figure 3. Representation of the copper(II) 1D zigzag coordination polymer.

Another very interesting feature of this high-temperature-prepared supramolecular species is the interaction between the oxygen atom O(2) of the nitrate anion coordinated to Cu(1) and the π-cloud of a 1,3,5-triazine ring, with a centroid···O(2) distance of 3.67(1) Å and an angle of the centroid···O(2) axis to the plane of 67.7(3)° (Figure 4). Noncovalent anion–π interactions are quite uncommon and have only recently been discovered, owing to the electron-donating character of an anion which is expected to lead to repulsive interactions with aromatic π-clouds.[20,21] This type of interactions has been first demonstrated by NMR studies.[22–24] Several recent articles have reported theoretical calculations on the binding of uncoordinated anions with electron-deficient triazine derivatives, indicating energetically favorable noncovalent interactions.[21,25,26] Very recently, first crystallographic evidences of such interactions has been described between 1,3,5-triazine groups and free anions.[27,28] The present compound reveals the possible interaction between a nitrate and an electron-poor aromatic ring.

A different, but related coordination polymer has been obtained by reaction of $Zn(NO_3)_2{\cdot}6H_2O$ and dpyatriz in

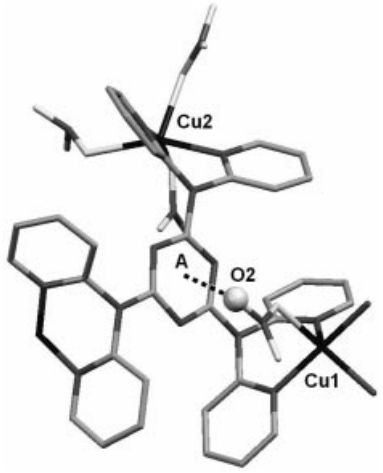

Figure 4. Oxygen–π interaction in **1** between a nitrate anion and an *s*-triazine ring. A···O(2) = 3.67(1) Å; triazine plane–A–O(2) axis = 67.7(3)°.

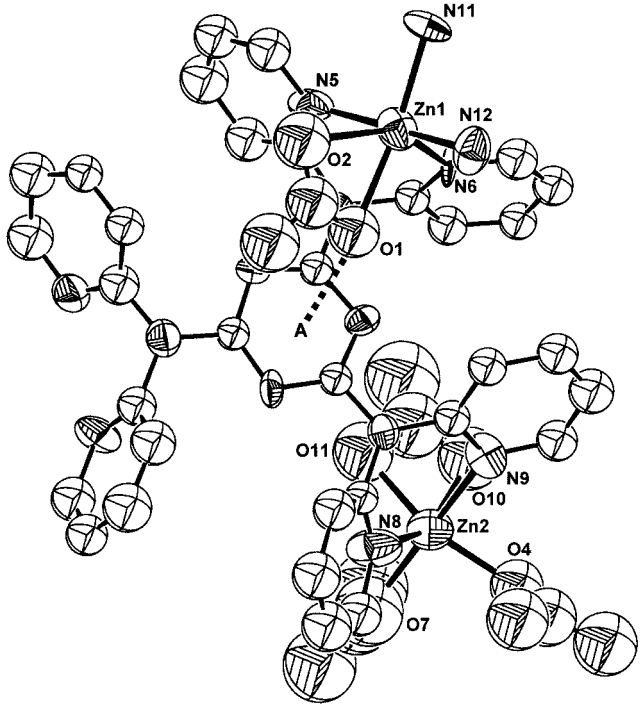

Figure 5. ORTEP plot of the repeating unit of **2** where the N11 and N12 atoms belong to a symmetry-related unit. The water molecule and the hydrogen atoms are omitted for clarity; thermal ellipsoids are at the 50% probability level. A···O(1) = 3.11(3) Å; triazine plane–A–O(2) axis = 67.2(5)°.

acetonitrile at the same temperature. The dinuclear repeating unit of the zig-zag polymer present in the compound $[Zn_2(dpyatriz)(NO_3)_4](H_2O)$ (**2**) is depicted in Figure 5.

Zn(1), which is involved in the self-assembly of the coordination polymer, is in a highly distorted octahedral environment, due to the coordination of the nitrate anion in a didentate fashion. The basal plane of the octahedron is formed by two N-coordinating pyridine rings [N(6) and N(11)] of two symmetry-related dpyatriz ligands, and by two oxygen atoms, O(1) and O(2), of a nitrate ion. The in-plane Zn–N distances can be regarded as normal (Table 1).[29] The large in-plane Zn–O distances stem from the didentate coordination mode of the anion which induces a great distortion. The axial positions are taken up by two N-donors, N(5) and N(12), of two symmetry-related dipyatriz ligands. The angles around Zn(1) in the basal plane vary from 56.6(6) to 107.7(6)°, showing once again the important distortion resulting from the particular coordination of the nitrate ion (Table 2). Zn(2) is in a distorted octahedral geometry as well. The basal plane is constituted of one N-atom N(8) from a pyridine group at a normal distance (Table 1). The remaining positions are occupied by three O-atoms, O(4), O(10), and O(11), of two nitrate ions. The axial positions are occupied by one N-atom, N(9), of a pyridine group and by the O-atom O(7) of a third nitrate ion. The angles around Zn(2) in the basal plane are far from 90°, varying from 61.2(7) to 118.0(6)°, due to the didentate binding mode of one nitrate ion (Table 2). In addition, a water molecule is present in the crystal lattice.

This dinuclear zinc complex represents the repeating unit of a 1D zigzag polymer closely related to the one obtained with copper(II) nitrate (Figure 3). A completely different coordination compound, i.e a tetranuclear zinc(II) complex, has been reported as obtained at room temperature and ambient pressure from the same reactants,[16] just like in the case of the copper polymer.

Like the copper coordination polymer, the zinc polymer exhibits anion–π interactions. Indeed, anion–π interactions are realised between the oxygen atom O(1) of the didentate nitrate anion coordinated to Zn(1) and the 1,3,5-triazine ring with a centroid···O(1) distance of 3.11(3) Å and an angle of the centroid···O(1) axis to the plane of 67.2(5)° (Figure 5).

Finally, the reaction of $Cd(NO_3)_2{\cdot}4H_2O$ in acetonitrile at 105 °C with dpyatriz yields colorless diamond-shaped crys-

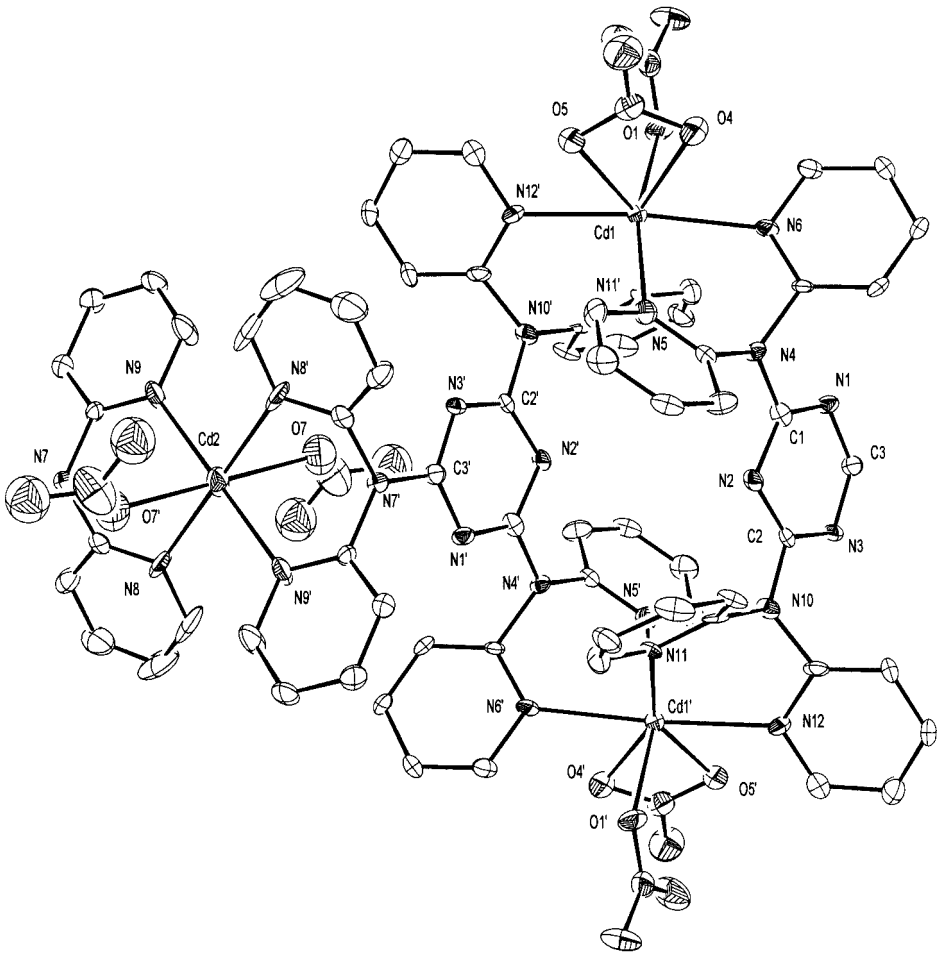

Figure 6. ORTEP view of the building block (containing two asymmetric units) forming the polymeric chain. Hydrogen atoms are omitted for clarity; thermal ellipsoids are at the 20% probability level.

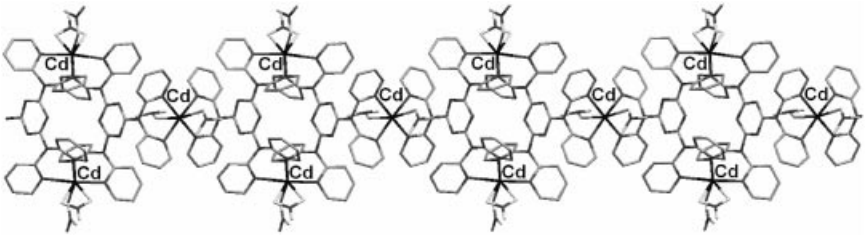

Figure 7. Representation of the cadmium(II) 1D linear coordination polymer.

tals of $[Cd_3(dpyatriz)_2(NO_3)_6]$ (**3**) whose crystal structure was determined by X-ray diffraction (Figure 6).

Cd(1) shows a pentagonal bypiramid configuration due to the coordination of a nitrate ion acting as a chelating ligand. The basal plane of the bipyramid is constituted by three *N*-pyridyl donor atoms, N(6), N(11′), and N(12′), of two didentate dipyridylamine groups belonging to different dpyatriz ligands and by two oxygen atoms, O(4) and O(5), of the chelating anion (Table 1). The in-plane Cd–N distances are normal; the large in-plane Cd–O distances are due to the chelating nitrate ion. The axial positions are occupied by one N-donor atom, N(5), of a dipyridylamino group and by an oxygen atom, O(1), of a monodentate nitrate ion. The angles around the cadmium(II) ion in the basal plane vary from 73.2(2) to 82.7(2)° with the exception of the O(4)–Cd(1)–O(5) angle of 49.8(2)°, distorted because of the chelating behaviour of the nitrate ion (Table 2). Cd(2), which lies on an inversion center, is in an octahedral environment constituted of four N-coordinating 2-pyridyl groups located in the basal plane [N(8) and N(9)], and two axially coordinated O-atoms of two monodentate nitrate ions [O(7)]. The in-plane Cd–N distances are typical as well as the axial Cd–O bond length (Table 1).[30] The angles around Cd(2) in the basal plane vary from 83.6(2) to 96.9(3)° (Table 2).

This trinuclear cadmium unit represents the building block of a 1D linear polymer through the coordination of Cd(2) by a dipyridylamino moiety of an neighbouring repeating unit (Figure 7).

Electron–π interactions further stabilize the polymer chains. Indeed, the symmetrically related oxygen atoms O(8) and O(8′) of the monodentate nitrate ions coordinated to Cd(2) are strongly interacting with electron-poor triazine rings with a short centroid···O distance[21] of 3.26(1) Å (Figure 8, A and A′). The angle of the centroid···O axis to the plane is 79.9(2)°. In addition, the remaining oxygen atoms of the anions, O(9) and O(9′), are interacting with pyridine groups of dipyridylamino units, probably due to the fact that the pyridine rings involved are coordinated to a cadmium ion, thus enhancing their electron-poor character (Figure 8, B and B′). The centroid···O distance is 3.58(2) Å and the centroid···O axis to the plane angle is 49.0(3)°. To the best of our knowledge, this is the first crystallographic example of such nitrate–pyridine π-cloud interactions. The distances and angles observed are far from the theoretical calculated values for the extensively studied model system *s*-triazine anion.[21,26] Unfortunately, no theoretical investigations have been yet performed on the *less electron-deficient, dissymmetric* pyridine ring, but one would rationally anticipate *longer ring–anion bonds* as well as an *optimal plane–axis angle inferior to 90°*.

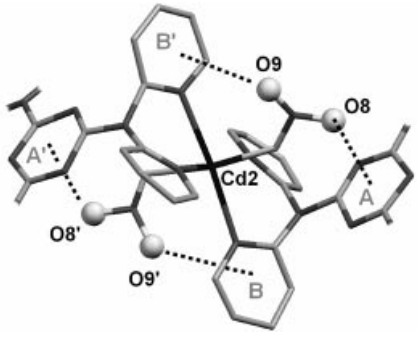

Figure 8. π interactions in **3** between the oxygen atoms of nitrate anions and electron-deficient 1,3,5-triazine and pyridine rings. A···O(8) = 3.26(1) Å; triazine plane–A–O(8) axis = 79.9(2)°. B′···O(9) = 3.58(2) Å; pyridine plane–B′–O(9) axis = 49.0(3)°.

Conclusions

In conclusion, the supramolecular molecules **1**, **2**, and **3** have been obtained at elevated temperature and pressure. The polymeric complexes show anion–π interactions, and experimental evidence of coordinated nitrate anions interacting with triazine or pyridine rings is described, demonstrating the possible existence of anion–π interactions. In addition, the high temperature and pressure applied during their synthesis resulted in notably different crystal structures when compared to those of the coordination compounds prepared from the same reactants, at room temperature and atmospheric pressure.

Experimental Section

General Remarks: Infrared spectra were collected with a Perkin–Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate Diamond ATR as a sample support. Vis/NIR spectra were measured with a Perkin–Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. Elemental analyses were performed at the Microanalytical Laboratory of the Leiden Institute of Chemistry, The Netherlands. X-band EPR spectra were recorded with a JEOL electron spin resonance spectrometer, equipped with an Esprit 330 data system, at room temperature and at 77 K, with dpph as an internal reference (g = 2.0036).

Preparation of $[Cu_2(dpyatriz)(NO_3)_4](H_2O)$ (1): $Cu(NO_3)_2{\cdot}3H_2O$ (7.1 mg, 0.0293 mmol) was added to a suspension of dpyatriz (11.5 mg, 0.0195 mmol) in acetonitrile (6 mL). After dissolving the copper salt, the closed pressure tube was placed in an oven at 105 °C. Single crystals of **1** suitable for X-ray analysis were obtained as light-blue needles at 105 °C after 2 d. Yield: 16 mg (83%). $C_{33}H_{26}Cu_2N_{16}O_{13}$ (981.78): calcd. C 40.37, H 2.67, N 22.83; found C 39.85, H 2.21, N 22.17. IR (neat): $\tilde{\nu}$ = 1607, 1558, 1471, 1374, 1278, 1005, 772, 668 cm^{-1}. UV/Vis (reflectance): λ = 262 (LMCT), 643 and 975 (d–d transitions) nm. Solid-state EPR: g = 2.12 (room temp.), 2.11 (77 K).

Preparation of $[Zn_2(dpyatriz)(NO_3)_4](H_2O)$ (2): $Zn(NO_3)_2{\cdot}6H_2O$ (8.1 mg, 0.0273 mmol) was added to a suspension of dpyatriz (10.7 mg, 0.0182 mmol) in acetonitrile (6 mL). After dissolving the zinc salt, the closed pressure tube was placed in an oven at 105 °C. Single crystals of **2** suitable for X-ray analysis were obtained as colorless parallelepipeds at this temperature after 2 d. Yield: 14 mg (77%). $C_{33}H_{26}Zn_2N_{16}O_{13}$ (985.44): calcd. C 40.22, H 2.66, N 22.74; found C 39.98, H 2.28, N 22.62. IR (neat): $\tilde{\nu}$ = 3080, 1608, 1558, 1378, 1286, 1022, 771, 667 cm^{-1}. UV/Vis (reflectance): λ = 269 (LMCT) nm.

Preparation of $[Cd_3(dpyatriz)_2(NO_3)_6]$ (3): $Cd(NO_3)_2{\cdot}4H_2O$ (9.3 mg, 0.0301 mmol) was added to a suspension of dpyatriz (11.8 mg, 0.0200 mmol) in acetonitrile (12 mL). After dissolving the cadmium salt, the closed pressure tube was placed in an oven at 105 °C. Colorless diamond-shaped single crystals of **3** suitable for X-ray analysis were obtained at 105 °C in a pressure tube after 3 d. Yield: 17 mg (91%). $C_{66}H_{48}Cd_3N_{30}O_{18}$ (1886.54): calcd. C 42.01, H 2.54, N 22.26; found C 41.89, H 2.28, N 21.64. IR (neat): $\tilde{\nu}$ = 3082, 1603, 1550, 1378, 1292, 1014, 768, 664 cm^{-1}. UV/Vis (reflectance): λ = 288 (LMCT) nm.

X-ray Crystallographic Study: The molecular structures were determined by single-crystal X-ray diffraction methods. Crystallographic and experimental details for the different structures are summarized in Table 3. Intensity data and cell parameters were recorded at room temperature (293 K) with a Bruker AXS Smart 1000 single-crystal diffractometer (Mo-K_α radiation), equipped with a CCD area detector. The data reductions were performed using the SAINT[31] and SADABS[32] programs. The structures were solved by direct methods using the SIR97 program[33] and refined on F_o^2 by full-matrix least-squares procedures, using the SHELXL-97 program.[34] Most of the non-hydrogen atoms were refined with anisotropic atomic displacements. The hydrogen atoms were included in the refinement at idealized geometries (C–H 0.95 Å) and refined "riding" on the corresponding parent atoms. The weighting scheme used in the last cycle of refinement was $w = 1/[\sigma^2(F_o^2) + (0.0347P)^2]$ (**1**), $w = 1/[\sigma^2(F_o^2) + (0.0411P)^2]$ (**2**) and $w = 1/[\sigma^2(F_o^2) + (0.0400P)^2 + 6.1257P]$ (**3**), where $P = (F_o^2 + 2F_c^2)/3$. Molecular geometry calculations were carried out using the PARST97 program.[35] All calculations were carried out with a DIGITAL Alpha Station 255 computer. CCDC-255636 (**1**), -255637 (**2**), and -255638 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors thank COST Action D21/003/2001 for allowing regular exchange of preliminary results within a European network before publication and the Dutch National Research School Combination Catalysis (HRSMC and NIOK) for financial support. Exchange visits with the groups of Profs. E. Hahn and B. Krebs (Westfälische Wilhelms-Universität, Münster) through an NWO and DFG grant in the framework of the joint Graduierten-Kolleg are thankfully acknowledged.

Synthesis, Structure and Luminescence Properties of Four Novel Terbium 2-Fluorobenzoate Complexes

Xia Li,[a] Zhuo-Yong Zhang,[a] and Ying-Quan Zou*[b]

Keywords: Fluorinated ligands / Luminescence / O ligands / Terbium

Four new complexes $[Tb(2\text{-}FBA)_3\cdot(2\text{-}HFBA)\cdot H_2O]_2$ (**1**), $\{[Tb(2\text{-}FBA)_3\cdot(4,4'\text{-}bpy)\cdot H_2O]_3\}_n$ (**2**), $[Tb(2\text{-}FBA)_3\cdot(2,2'\text{-}bpy)]_2$ (**3**), and $[Tb(2\text{-}FBA)_3\cdot phen\cdot CH_3CH_2OH]_2\cdot[Tb(2\text{-}FBA)_3\cdot phen]_2$ (**4**) (2-HFBA: 2-fluorobenzoic acid; 4,4′-bpy: 4,4′-bipyridine; 2,2′-bpy: 2,2′-bipyridine; phen: 1,10-phenanthroline) have been synthesized and characterized by X-ray diffraction analysis. Complex **1** is a dimeric molecule with a one-dimensional supramolecular structure formed by hydrogen bonds. Complex **2** is an infinite one-dimensional polymer chain formed by bridging carboxylato groups; its 2D framework structure is formed by hydrogen bonds. The structure of complex **3** contains three independent binuclear molecules in the asymmetric unit. In two of them, two Tb^{3+} ions are held together by four 2-FBA groups, with two of them in a bidentate-bridging mode and the other two in a chelating-bridging mode. In the third, two Tb^{3+} ions are held together by four 2-FBA groups, all of which are in the bidentate-bridging mode. One 2-FBA group and one 2,2′-bpy chelate to one Tb^{3+} ion, resulting in coordination numbers of the central terbium ion of nine and eight, respectively. The structure of complex **4** contains two nonequivalent binuclear molecules in the asymmetric unit – $[Tb(2\text{-}FBA)_3\cdot phen\cdot CH_3CH_2OH]_2$ and $[Tb(2\text{-}FBA)_3\cdot phen]_2$. In the former, the Tb^{3+} ion is surrounded by eight atoms, five O atoms from five 2-FBA groups, one O atom from one ethanol molecule and two N atoms from phen, and the 2-FBA groups act in monodentate and bridging coordination modes. In the latter, the Tb^{3+} ion is coordinated by nine atoms, seven O atoms from five 2-FBA groups and two N atoms of phen, and the 2-FBA groups link the Tb^{3+} ion in chelating, bridging, and chelating-bridging coordination modes. Complexes **1**, **3**, and **4** emit a bright green light under UV light in the solid state. There are four emission peaks in the luminescence spectra at 488, 543, 584, and 618 nm, corresponding to the $^5D_4\rightarrow{}^7F_6$, $^5D_4\rightarrow{}^7F_5$, $^5D_4\rightarrow{}^7F_4$, and $^5D_4\rightarrow{}^7F_3$ transitions, respectively, of the Tb^{3+} ion.

Introduction

Most terbium complexes emit intense green fluorescence and have potential applications in fluorescent probes and in electroluminescent devices.[1,2] The luminescent intensities of lanthanide complexes depend on their ligands, and some lanthanide carboxylate complexes have good luminescent properties. This kind of lanthanide complex has been studied in recent years due to the variety of structural types and potential applications in catalysis and luminescent probes, etc.[1–4] We are interested in the structural chemistry of these complexes. Many structural studies on lanthanide carboxylate complexes have been reported. In lanthanide monocarboxylate complexes, the carboxylate groups are coordinated simultaneously to the lanthanide ion in different modes, namely monodentate, chelating, bridging, and bridging-chelating modes. Consequently, the complexes are often mononuclear, dinuclear dimers, polymeric chains, or network structures. Generally, lanthanide complexes with only a monoacid form coordination polymers with bridging carboxylato groups, such as $[Nd(3\text{-}CH_3C_6H_4COO)_3]$ and $[Tb(3\text{-}CH_3C_6H_4COO)_3]$,[5] $[Nd(2\text{-}CH_3OC_6H_4COO)_3\cdot 4H_2O]$,[6] $[Eu(4\text{-}CH_3C_6H_4COO)_3]$,[7] and $[Eu(2,3\text{-}DMOBA)_3]_n$ (2,3-DMOBA = 2,3-dimethoxybenzoate).[8] However, lanthanide complexes with a monoacid and 1,10-phenanthroline (phen) or 2,2′-bipyridine (2,2′-bpy) are commonly dimeric molecules with a bridging linkage of the carboxylato groups, such as in $[Eu(4\text{-}CH_3C_6H_4COO)_3(phen)]$,[9] $[Sm_2(4\text{-}CH_3C_6H_4COO)_6(2,2'\text{-}bpy)_2]$,[10] $[Eu(m\text{-}CH_3C_6H_4COO)_3(phen)](H_2O)$,[11] and $[Eu_2(3,4\text{-}DMBA)_6\cdot(phen)_2]$ (3,4-DMBA = 3,4-dimethylbenzoate).[12] In these complexes, the phen or 2,2′-bpy ligand coordinates to the metal in a chelating mode to form a stable five-membered ring. Lanthanide carboxylate complexes containing 2,2′-bpy or phen have interesting structures, with both high stability and intense fluorescence.[9–12] 4,4′-Bipyridine (4,4′-bpy), however, coordinates to the metal with one or two N atoms, and is weaker than phen or 2,2′-bpy. In this paper terbium and 2-fluorobenzoic acid (2-HFBA) have been used to synthesize a new complex $[Tb(2\text{-}FBA)_3\cdot(2\text{-}HFBA)\cdot$

$H_2O]_2$ (**1**). When 4,4′-bpy, 2,2′-bpy, or phen was added to the complexes, new mixed-ligand terbium complexes with interesting structures were obtained, namely $\{[Tb(2\text{-}FBA)_3 \cdot (4,4'\text{-}bpy) \cdot H_2O]_3\}_n$ (**2**), $[Tb(2\text{-}FBA)_3 \cdot (2,2'\text{-}bpy)]_2$ (**3**), and $[Tb(2\text{-}FBA)_3 \cdot phen \cdot CH_3CH_2OH]_2 \cdot [Tb(2\text{-}FBA)_3 \cdot phen]_2$ (**4**). Crystal analysis showed that complex **1** is a dimeric molecule, whereas complex **2** is a polymer in which 4,4′-bpy coordinates to Tb^{3+} ion and the 2-FBA groups coordinate to the Tb^{3+} ion in only one bidentate-bridging mode. The structure of complex **3** contains three independent binuclear molecules, and the structure of complex **4** contains two nonequivalent binuclear molecules. These structural features are rare in lanthanide carboxylate complexes. Complexes **1**, **3**, and **4** emit intense green fluorescence.

Results and Discussion

Structural Description of $[Tb(2\text{-}FBA)_3 \cdot (2\text{-}HFBA) \cdot H_2O]_2$ (1)

The structure of complex **1** is shown in Figure 1 (part a), which shows that the Tb^{3+} ion is coordinated by seven oxygen atoms from 2-FBA groups, one oxygen atom from one 2-HFBA ligand, and one oxygen atom from water, giving a coordination number of nine. The two Tb^{3+} ions are linked together by four bridging carboxylato groups to form a centrosymmetric dimeric unit, which is rare for lanthanide carboxylate complexes. The majority of known lanthanide complexes containing a monoacid display a one-dimensional polymer chain, such as in $[Tb(3\text{-}CH_3C_6H_4COO)_3]$,[5] $[Nd(2\text{-}CH_3OC_6H_4COO)_3 \cdot 4H_2O]$,[6] and $[Eu(2,3\text{-}DMOBA)_3]_n$.[8] The distance between two Tb^{3+} ions is 3.951(3) Å (Table 1). All the 2-FBA groups are coordinated to the Tb^{3+} ion and can be classified into three different coordination modes: the carboxylato groups O5–C15–O6 are in a chelating mode, in which two O atoms coordinate to the same Tb^{3+} ion, the carboxylato groups O1–C1–O2 are in a bridging mode, in which two O atoms coordinate to two different Tb^{3+} ions to form a bidentate bridge, and the carboxylato groups O3–C8–O4 are in a chelating-bridging mode, in which two O atoms chelate one Tb^{3+} ion and one of them also simultaneously links to another Tb^{3+} ion, forming a tridentate bridge. The 2-HFBA ligand binds in a monodentate mode through a single oxygen atom to the Tb^{3+} ion. It is not common to observe a monodentate carboxylic acid ligand coordinated to a lanthanide center. The Tb–O bonds have an average length of 2.436 Å and the O–Tb–O bond angles lie in the range 50.2(2)–148.7(3)°. There is a bonding water molecule (O9) at a distance of 2.410(7) Å to the Tb^{3+} ion, which takes part in hydrogen bonds with the coordinated oxygen of carboxylato groups and the fluorine atoms in the benzene ring [O9–H9A···O5 ($-x + 1$, $-y$, $-z + 2$) with d(O9···O5) = 2.754 Å and ∠O9–H9A–O5 = 166.16°; O9–H9B···F2 ($-x + 1$, $-y$, $-z + 2$) with d(O9···F2) = 3.047 Å and ∠O9–H9B–F2 = 153.38°] to form a one-dimensional supramolecular chain (Figure 1, part b). This case is different from the three complexes with a one-dimensional polymeric structure mentioned above.

Structural Description of $\{[Tb(2\text{-}FBA)_3\cdot(4,4'\text{-bpy})\cdot H_2O]_3\}_n$ (2)

The structure of complex **2** is shown in Figure 2 (part a), which shows that each terbium ion is connected by six oxygen atoms from six 2-FBA groups, one oxygen atom from water, and one nitrogen atom from a 4,4′-bpy molecule. The 2-FBA groups coordinate the terbium ion in only a bidentate-bridging mode. Complexes in which carboxylato groups coordinate a metal in only one coordination mode, such as $[Nd(3\text{-}CH_3C_6H_4CO_2)_3]$[5] and $[Eu(4\text{-}CH_3C_6H_4COO)_3]$.[7] in which the carboxylato groups adopt only one bridging-chelating mode, are not common. Two adjacent Tb^{3+} ions are connected by four bridging O1–C1–O2 and O3–C8–O4 groups to form a dimeric unit. These dimeric units are linked by two simple bridging carboxylato groups (O5–C15–O6) to form a one-dimensional polymer chain along the [1,0,0] direction. The distances between two adjacent Tb^{3+} ions in the polymer chain are 4.269 Å (Tb1···Tb1A) within the dimeric unit and 5.637 Å between the dimeric units (Table 2). The Tb1A···Tb1···Tb1B angle is 159.1°, and the $Tb–O_{carboxyl}$ distances range from 2.470(4) Å to 2.513(4) Å, with a mean value of 2.492 Å. The O–Tb–O bond angles are in the range 71.70(14)–143.71(14)°, and the $Tb–O_{water}$ bond length is 2.566(4) Å. The 4,4′-bpy ligand coordinates to Tb^{3+} ion through one N atom. There is a bonding nitrogen atom (N1) of 4,4′-bpy at a distance of 2.851(5) Å to the Tb^{3+} ions. The two pyridyl rings are not coplanar, and have a dihedral angle of 146.0°. The uncoordinated N atom of 4,4′-bpy forms a hydrogen bond with coordinated water [O7–H7A···N2B, with d(O7···N2B) = 2.857 Å and ∠O7–H7A–N2B = 170.0°]. Adjacent 1D chains are interlinked by these hydrogen bonds to form a two-dimensional supramolecular network structure along the [1,0,1] direction (Figure 2, part b). Complex **2** is different from the complex $[Tb_2(O_2CPh)_6(4,4'\text{-bpy})]_n$,[1] in which 4,4′-bpy bridges two different metals with two N atoms. Complex **2** is also different from the complexes $\{[Eu(m\text{-MOBA})_3\cdot 2H_2O]1/2(4,4'\text{-bpy})\}_\infty$ (*m*-MOBA = *m*-methoxybenzoate)[13] and $\{[Eu(\alpha\text{-FURA})_3\cdot 2H_2O]\cdot NO_3\cdot(4,4'\text{-Hbpy})\}_\infty$ (α-FURA = α-furoate),[14] in which the 4,4′-bpy molecule does not coordinate to the metal. Lanthanide carboxylate complexes containing coordinated 4,4′-bpy are less common due to the weak coordination of 4,4′-bpy in this kind of complex.

Structural Description of $[Tb(2\text{-}FBA)_3\cdot(2,2'\text{-bpy})]_2$ (3)

The structure of complex **3** is shown in Figure 3 (a, b and c). It is dimeric and, interestingly, there are three independent molecules in the asymmetric unit, in which each molecular unit is dimeric with an inversion center. Each $Tb1^{3+}$ ion is coordinated by nine atoms, seven oxygen atoms from five 2-FBA groups and two nitrogen atoms of one 2,2′-bpy ligand (Figure 3, part a). They adopt a distorted monocapped square-antiprism arrangement, with atoms O3, O5, O4A, and O6A forming the upper and O1, O2, N1, and N2 the lower square-planes with a dihedral angle between them of 4.4°; atom O4 caps the upper plane. The 2-FBA ligands act in chelating, bridging, and chelating-bridging modes. Two Tb1 ions are held together by four 2-FBA groups, with two of them in a bidentate bridging mode, and the other two in a chelating-bridging mode. In addition, each terbium ion is also chelated by one 2-FBA group and one 2,2′-bpy ligand. The Tb1···Tb1A distance is 4.137 Å (Table 3). The Tb1–O bond lengths range from 2.28(8) to 2.91(9) Å, with an average length of 2.459 Å. It is reasonable that the Tb1–O4 distance, 2.91 Å, of the tridentate bridging carboxylato group is the largest due to O3–C18–O4–Tb1 being an unstable four-membered ring. This feature has been observed in other lanthanide carboxylate complexes. The O–Tb1–O angles vary considerably in the range 53.00(3)–150.00(3)°, but they are not uncommon

for lanthanide carboxylate complexes. The 2,2′-bpy ligand coordinates to the Tb^{3+} ion in a conventional chelation mode with two N atoms, forming a five-membered ring. The two pyridyl rings of the 2,2′-bpy ligand are not coplanar and form a dihedral angle of 12.2° in the dimer. The Tb1–N bond lengths are similar, with an average value of 2.56 Å, and the N–Tb1–N bond angle is 62(3)°.

Each $Tb2^{3+}$ ion is eight-coordinate, with six oxygen atoms from five 2-FBA groups and two nitrogen atoms from one chelating 2,2′-bpy ligand (Figure 3, part b). The two terbiums in the dimer are held together by four 2-FBA groups, all with a bidentate-bridging coordination mode, and each terbium ion is further bonded to one chelating 2-FBA group and one 2,2′-bpy molecule. Thus, each terbium ion has a distorted square-antiprism coordination geometry with O7, O8, N3, and N4 forming one square face and O9, O11, O10A, and O12A the other. The dihedral angle between the two faces is 4.6°. The 2-FBA ligands coordinate the terbium ion in chelating and bidentate-bridging coordination modes. Obviously, the structures given in Figure 3 (part b) and Figure 3 (part a) are different with respect to the different linking modes of the four 2-FBA groups to the two terbium ions. The Tb2···Tb2A distance is 4.260 Å. The Tb2–O distances vary in the range 2.35(7) to 2.48(8) Å, with an average value of 2.372 Å, and the O–Tb2–O angles range from 53.00(3) to 149.00(3)°. The average Tb2–N distance is 2.53 Å and the N–Tb2–N angle is 62(4)°. The dihedral angle between the two pyridyl rings of the 2,2′-bpy molecule is 6.0°.

As shown in Figure 3 (part c), the $Tb3^{3+}$ ion is coordinated by nine atoms, seven oxygen atoms from five 2-FBA groups and two nitrogen atoms of one 2,2′-bpy ligand. The coordination polyhedron of the $Tb3^{3+}$ ion is a distorted monocapped square-antiprism, which is quite similar to that of the $Tb1^{3+}$ ion in Figure 3 (part a) but differs from that of the Tb2 ion in Figure 3 (part b). The distance be-

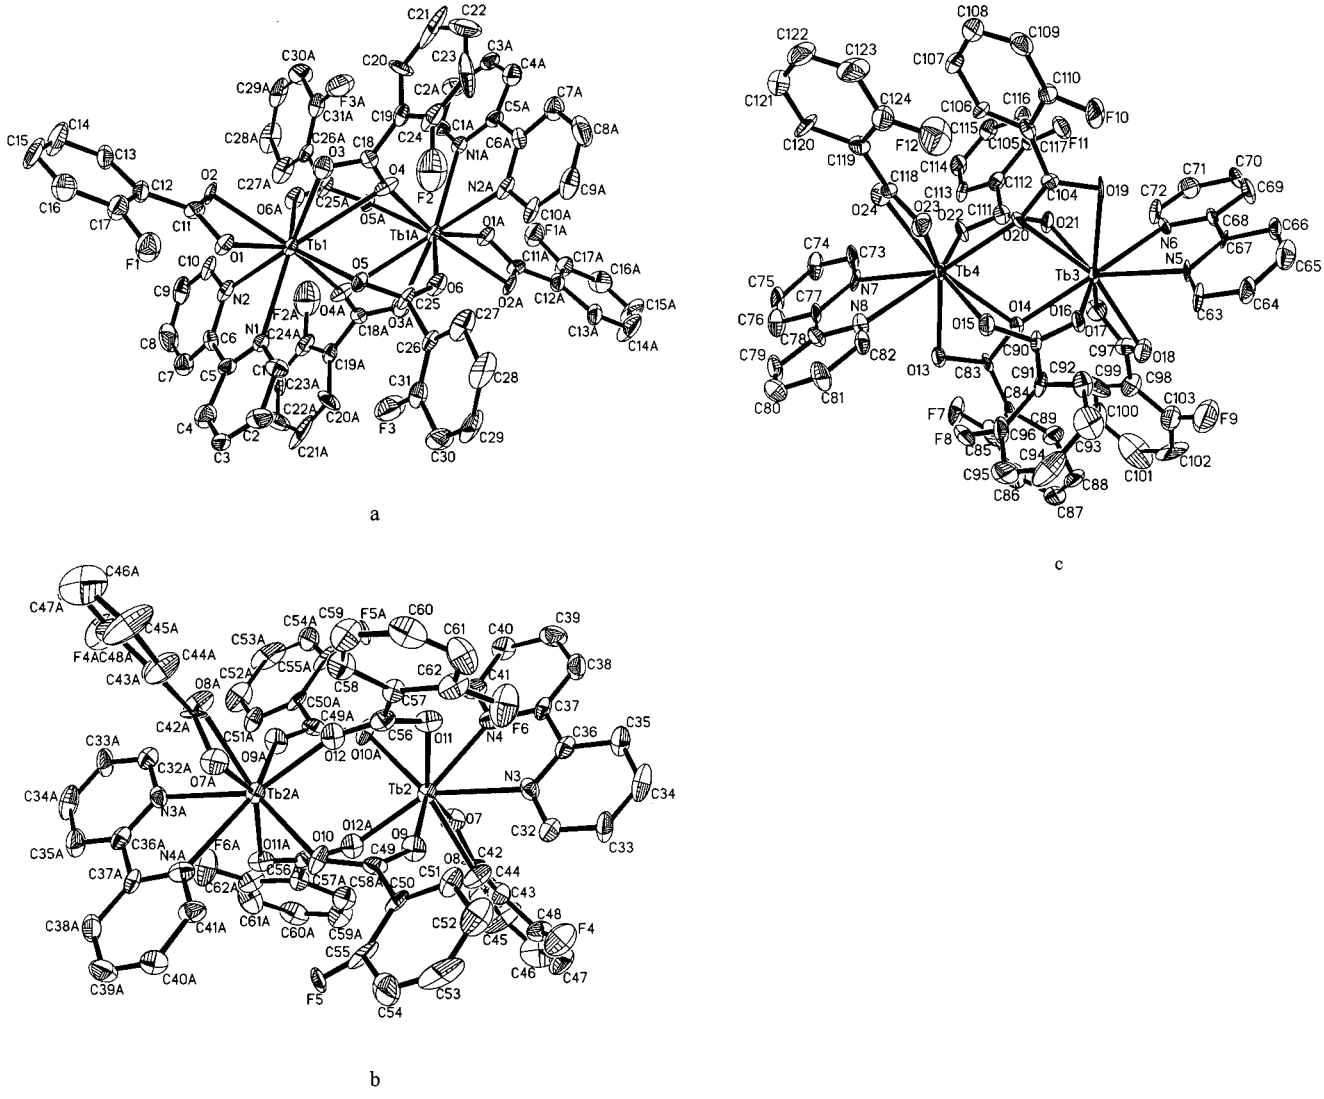

Figure 3. Molecular structures of the complex **3**. (a), (b), and (c) show three different structures. All hydrogen atoms have been omitted for clarity; the thermal ellipsoids are shown at the 30% probability level.

tween the two central terbium ions (Tb3···Tb4) is 3.951 Å. The average Tb3–O and Tb3–N bond lengths are 2.436 Å and 2.56 Å, respectively. The O–Tb3–O angles range from 53.00(3) to 144.00(3)°; the N–Tb3–N angle is 63(3)°. The two pyridyl rings of 2,2′-bpy in the dimer are not coplanar, and have a dihedral angle of 10.1°.

The structure of complex **3** contains three independent centrosymmetric units [Figure 3, parts a–c]. Figure 3 (part b) is different from Figure 3 (part a) or Figure 3 (part c) owing to the different bonding mode of the carboxyl groups, similar to the previously reported complex [Eu_2(*p*-$CH_3C_6H_4COO$)(phen)$_2$], which contains two nonequivalent binuclear molecules.[9] The mean Tb1–O distance (2.459 Å) in Figure 3 (part a) is longer than that of Tb2–O (2.372 Å) in Figure 3 (part b), and the distance between the central metal ions Tb1···Tb1A (4.137 Å) in Figure 3 (part a) is shorter than that of Tb2···Tb2A (4.260 Å) in Figure 3 (part b). A similar feature in the following discussion for complex **4** can be found due to the different bonding mode of the carboxyl groups. The Tb1–O mean distance in Figure 3 (part a) is close to that of Tb3–O (2.436 Å) in Figure 3 (part c), and the distance between the central metal ions Tb1···Tb1A in Figure 3 (part a) is close to that of Tb3···Tb4 (3.951 Å) in Figure 3 (part c) due to the similar coordination environments of $Tb1^{3+}$ and $Tb3^{3+}$. The corresponding O–Tb–O bond angles for the three molecules are in agreement with each other. For coordinated 2,2′-bpy, the two pyridyl rings are not coplanar in the complex, although the Tb–N bond lengths and the N–Tb–N bond angles for the three molecules are in good agreement.

Structural Description of a phen-Containing Terbium 2-Fluorobenzoate Complex with Two Different Compositions, [Tb(2-FBA)$_3$·phen·CH_3CH_2OH]$_2$ and [Tb(2-FBA)$_3$·phen]$_2$ (4)

The structure of complex **4** is shown in Figure 4 (parts a and b). Obviously, the structure of complex **4** contains two nonequivalent binuclear molecules, namely [Tb(2-FBA)$_3$·phen·CH_3CH_2OH]$_2$ (Figure 4, part a) and [Tb(2-FBA)$_3$·phen]$_2$ (Figure 4, part b); both dimers are centrosymmetric.

Figure 4 (part a) shows that four 2-FBA groups function as a bridge and connect two terbium ions to form a dimeric molecule with a Tb1···Tb1A separation of 4.423 Å. Each $Tb1^{3+}$ ion is further bonded to a monodentate 2-FBA group, one chelated phen, and one ethanol molecule to give a coordination number of eight. The $Tb1^{3+}$ ion is in a distorted square-antiprism arrangement in which the dihedral angle between the top (atoms O1, O5, O2A, O6A) and bottom (atoms O3, O7, N1, N2) planes is 3.0°. The 2-FBA groups link the $Tb1^{3+}$ ion in monodentate and bidentate-bridging coordination modes. The Tb1–O(carboxyl) distances are in the range 2.30(4) to 2.43(4) Å, with an average distance of 2.348 Å, and the O–Tb1–O(carboxyl) angles range from 72.90(13) to 144.9(13)° (Table 4). The bond length for the oxygen atom of the ethanol molecule to the terbium ion is 2.575 Å. The coordinated ethanol molecules

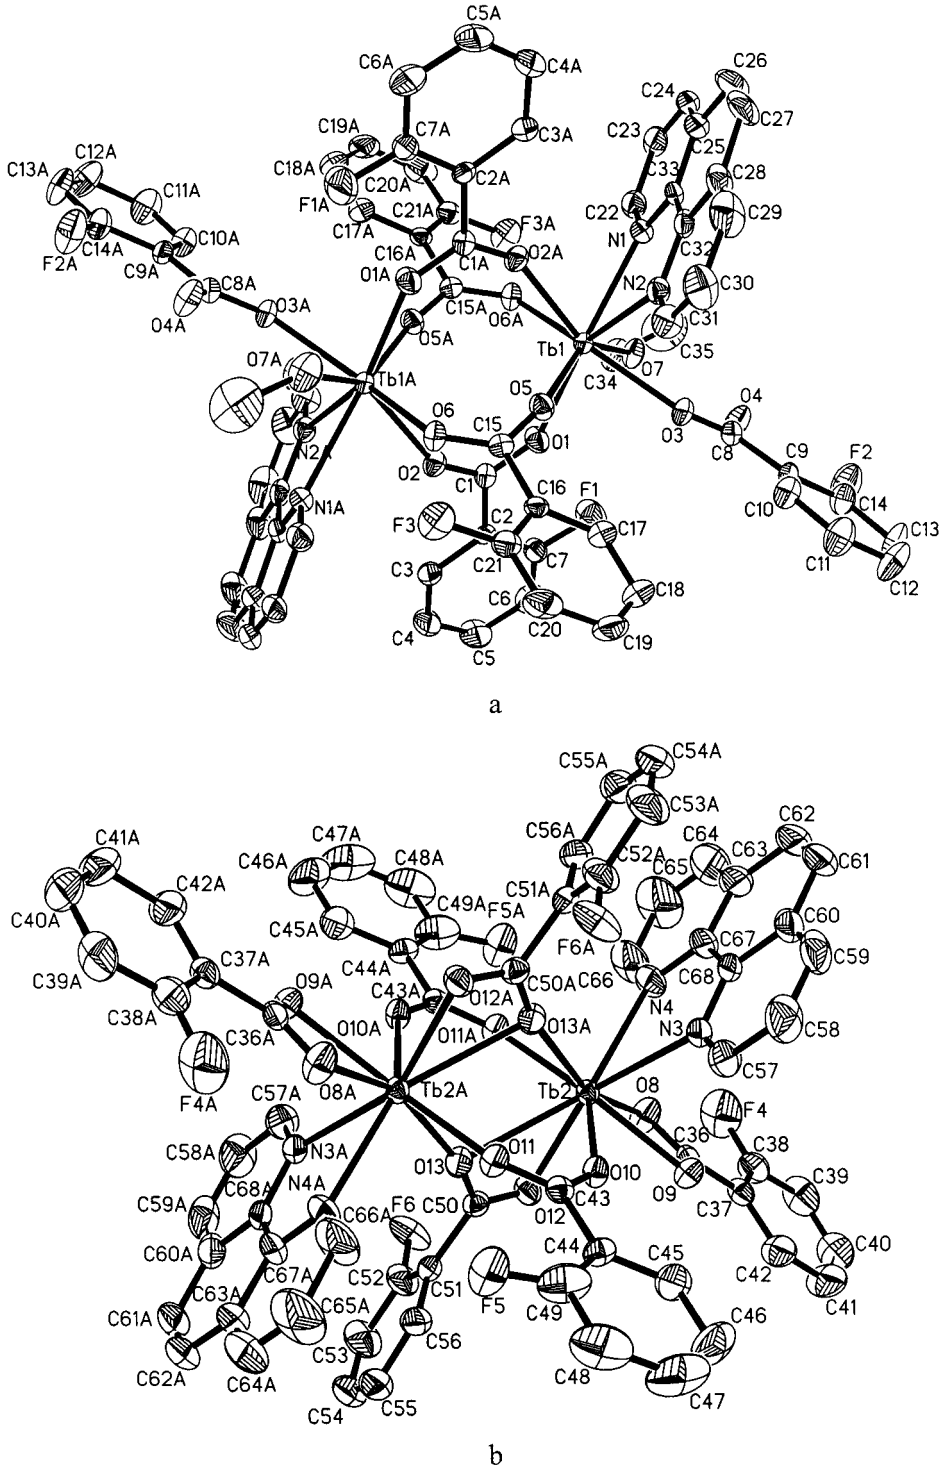

Figure 4. Molecular structures of complex **4**. (a) and (b) show two different structures. All hydrogen atoms have been omitted for clarity; the thermal ellipsoids are shown at the 30% probability level.

form hydrogen bonds with uncoordinated carboxyl oxygen atoms (O7–H7···O4, with an O7···O4 distance of 2.578 Å and O7–H7···O4 angle of 136.18°). The phen ligand acts as a typical chelating ligand coordinating to the terbium ion, with an average Tb1–N distance of 2.43 Å and N–Tb1–N angle of 63.7(16)°.

Figure 4 (part b) shows that the $Tb2^{3+}$ ion is surrounded by nine atoms, seven oxygen atoms from five 2-FBA groups and two nitrogen atoms from one phen molecule. The $Tb2^{3+}$ ion is in a distorted monocapped square-antiprism configuration. Atoms O10, O12, O11A, and O13A and O8, O9, N3, and N4 form the upper and lower square-planes,

respectively, with a dihedral angle between them of 8.2°; atom O13 caps the upper plane. The 2-FBA ligands act in chelating, bidentate-bridging, and chelating-bridging modes. Two terbium ions are connected by four 2-FBA groups − two bidentate-bridging and two chelating-bridging − to give a Tb2···Tb2A distance of 3.985 Å. In addition, each terbium ion is chelated by one 2-FBA group and one phen ligand. Obviously, Figure 4 (part b) is unlike Figure 4 (part a) but quite similar to Figure 3 (part a) and Figure 3 (part c). The Tb2–O bond lengths range from 2.30(4) to 2.71(4) Å, with an average distance of 2.439 Å, and the O–Tb2–O angles range from 52.5(14) to 155.7(16)°. The phen molecule chelates the terbium ion with an average Tb2–N bond length of 2.60 Å and N–Tb2–N angle of 62(2)°.

However, there are very few cases where two molecules with two different compositions and structures exist in an asymmetric unit. By comparing Figure 4 (part b) with Figure 4 (part a), their formulas, the coordination environment of central ion and coordination mode of carboxylato groups are different. The differences result in different distances of Tb–O(carboxyl) and Tb···Tb. The mean Tb2–O(carboxyl) distance of 2.439 Å in Figure 4 (part b) is longer than that of Tb1–O(carboxyl) (2.348 Å) in Figure 4 (part a), and the distance between the central metal ions (Tb2···Tb2A) (3.985 Å) in Figure 4 (part b) is shorter than that between Tb1 and Tb1A (4.423 Å) in Figure 4 (part a). A similar feature was observed in complex **3**. The fact that Ln^{3+} ions are bridged by chelating-bridging carboxylato groups results in a larger Ln–O distance and a smaller Ln–Ln distance.

Figure 3 (parts a, b and c) and Figure 4 (part b) exhibit common structures of lanthanide carboxylate complexes with 2,2′-bpy or phen, in which the carboxylate groups coordinate to lanthanide in different modes, such as monodentate, chelating-bidentate, bidentate-bridging, and tridentate-bridging. Generally, ternary lanthanide complexes containing a monoacid and 2,2′-bpy or phen are centrosymmetric dimers with a coordination number at the metal of eight or nine. The structure of eight-coordinate complexes is the same as that in Figure 3b, where two metal ions are linked together by four carboxylato groups with a bidentate-bridging coordination mode, and each metal ion is also chelated by one carboxylato group and one 2,2′-bpy or phen molecule, such as in $[Sm_2(4\text{-}CH_3C_6H_4COO)_6(2,2'\text{-}bpy)_2]$,[10] $[Eu(m\text{-}CH_3C_6H_4COO)_3(phen)](H_2O)$,[11] and $[Eu_2(3,4\text{-}DMBA)_6(phen)_2]$.[12] The structure of nine-coordinate complexes is the same as those in Figure 3 (parts a and c) and Figure 4 (part b), where two metal ions are linked together by four carboxylato groups with bidentate-bridging and chelating-bridging modes, and each metal ion is also chelated by one carboxylato group and one 2,2′-bpy or phen ligand, such as in $[Eu(2,3\text{-}DMOBA)_3{\cdot}bpy]_2$ (2,3-DMOBA = 2,3-dimethoxybenzoate),[15] $[Ln_2(O_2CCH_3)_6(phen)_2]$ (Ln = Ce, Gd),[16] and $[La_2(propionato)_6(2,2'\text{-}bpy)_2]$.[17] Eight- or nine-coordinate complexes are formed depending on the different bridges over the two central metal ions of the four carboxyl groups, namely whether the four carboxylato groups are all in a bidentate-bridging mode or two of them are in a bidentate-bridging mode and the other two in a chelating-bridging mode. The phen or 2,2′-bpy molecule coordinates to the metal in conventional chelation through two N atoms to form a five-membered ring. However, although the two phenyl rings are coplanar in the phen complexes since this molecule is rigid, the two pyridyl rings are not coplanar in 2,2′-bpy complexes since this is a flexible ligand.

Fluorescence Spectra

The complexes **1**, **3**, and **4** emit a bright-green light in the solid state under UV light. Fluorescence was observed in the range of 400–700 nm by selective excitation at 353 nm, as shown in Figure 5 (parts a, b, and c). There are four main emission peaks in the luminescence spectra at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

488, 543, 584, and 618 nm, corresponding to the transition between the first excited state ($^5D_4$) and the ground-state multiplet ($^7F_{6-3}$) of the Tb^{3+} ion, namely $^5D_4 \rightarrow {}^7F_6$, $^5D_4 \rightarrow {}^7F_5$, $^5D_4 \rightarrow {}^7F_4$, and $^5D_4 \rightarrow {}^7F_3$, respectively. The most intense emission band is at 543 nm. The luminescence spectra of complexes **1** and **3** are similar to that of complex **4**. The splits observed in the emission bands correspond to $^5D_4 \rightarrow {}^7F_6$, $^5D_4 \rightarrow {}^7F_5$. Shoulder peaks at 486 nm, 542 and 548 nm were observed. The nonluminescence of complex **2** may be due to 4,4′-bpy coordinating in a monodentate manner, which means that the ligand-to-metal energy transfer processes are not effective.

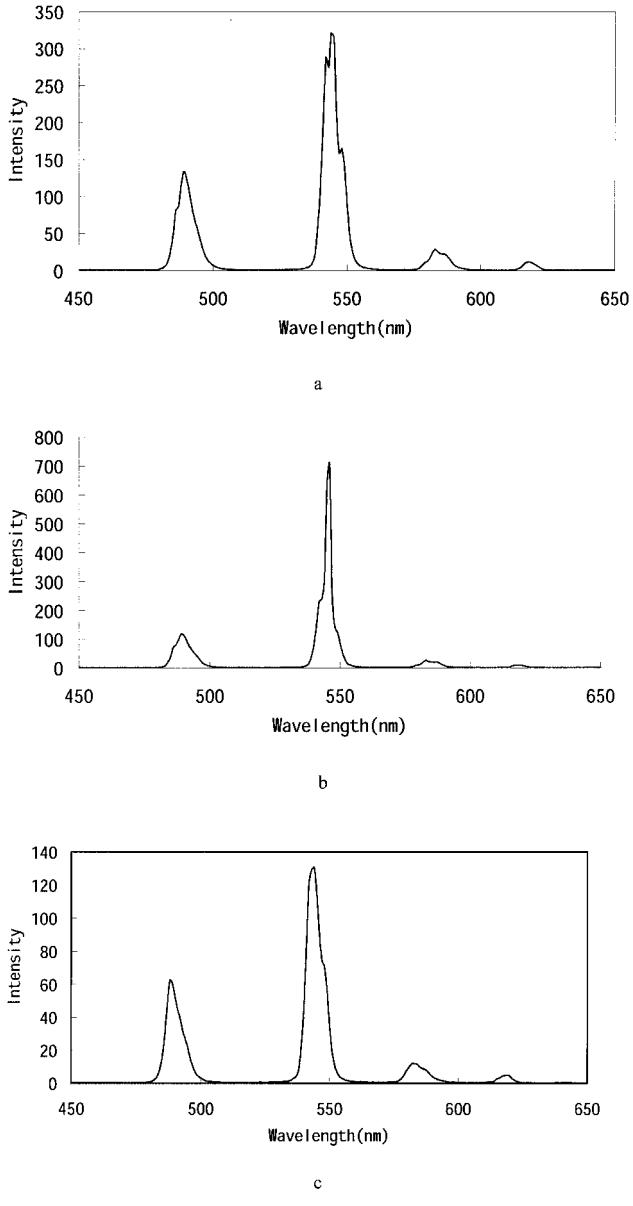

Figure 5. The fluorescence spectra of complexes **1** (a; λ_{exc} = 353 nm), **3** (b; λ_{exc} = 353 nm), and **4** (c; λ_{exc} = 353 nm).

Conclusion

The complexes discussed above were constructed based on terbium and 2-fluorobenzoic acid, with 4,4′-bpy, 2,2′-bpy, or phen acting as co-ligands to generate terbium complexes with various structures. Complex **1** is a dimeric molecule, unlike the majority of known lanthanide complexes containing a monoacid, which are one-dimensional polymers. Complex **2** is one of the very few lanthanide complexes containing a coordinated 4,4′-bpy molecule, complex **3** contains three independent binuclear molecules, and complex **4** contains two different binuclear molecules. Several other structural features of these complexes are of particular importance. In particular, complexes **1**, **3**, and **4** exhibit good fluorescence properties.

Experimental Section

Fluorescence Spectroscopy: Fluorescence spectra were measured on an F-4500 FL spectrophotometer in the solid state at room temperature.

$[Tb(2\text{-}FBA)_3 \cdot (2\text{-}HFBA) \cdot H_2O]_2$ (1): 2-Fluorobenzoic acid (1.5 mmol) was dissolved in the appropriate amount of ethanol. The pH of the solution was controlled in the range 6–7 by addition of 2 M NaOH solution. An ethanolic solution of $TbCl_3 \cdot 6H_2O$ (0.5 mmol) was then added dropwise. The mixture was heated under reflux with stirring for 3 h. Single crystals were obtained from the mother liquor after a month at room temperature. Yield: 0.0969 g (26.39%). $C_{56}H_{38}F_8O_{18}Tb_2$ (1468.7): calcd. C 45.80, H 2.61; found C 45.39, H 3.00.

$[Tb(2\text{-}FBA)_3 \cdot (4,4'\text{-}bpy) \cdot H_2O]_n$ (2): 2-Fluorobenzoic acid (1.5 mmol) was dissolved in the appropriate amount of ethanol. The pH of the solution was controlled in the range 6–7 by addition of 2 M NaOH solution. An ethanolic solution of 4,4′-bipyridine (0.5 mmol) and an ethanolic solution of $TbCl_3 \cdot 6H_2O$ (0.5 mmol) were then added dropwise, successively. The mixture was heated under reflux with stirring for 2 h. Single crystals were obtained from the mother liquor after seven weeks at room temperature. Yield: 0.1200 g (31.98%). $C_{62}H_{44}F_6N_4O_{14}Tb_2$ (1500.9): calcd. C 49.62, H 2.96, N 3.73; fC 51.18, H 3.06, N 4.32.

$[Tb(2\text{-}FBA)_3 \cdot (2,2'\text{-}bpy)]_2$ (3): When 2,2′-bpy was used instead of 4,4′-bpy, complex **3** was obtained. Yield: 0.1959 g (53.50%). $C_{124}H_{80}F_{12}N_8O_{24}Tb_4$ (2929.64): calcd. C 50.84, H 2.75, N 3.82; found C 50.82, H 3.06 N, 3.80.

$[Tb(2\text{-}FBA)_3 \cdot phen]_2$ and $[Tb(2\text{-}FBA)_3 \cdot phen \cdot CH_3CH_2OH]_2$ (4): When phen was used instead of 4,4′-bpy, complex **4** was obtained. Yield: 0.1983 g (50.89%). $C_{136}H_{92}F_{12}N_8O_{26}Tb_4$ (3117.9): calcd. C 52.39, H 2.97, N 3.59; found C 52.75, H 2.69, N 3.61.

X-ray Crystallographic Study: X-ray crystal data collection for the complexes was performed on a Bruker Smart 1000 CCD diffractometer with monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 K (Table 5). Semi-empirical absorption corrections were applied using the SADABS program. All calculations were carried out with SHELXS-97 and SHELXL-97.[18,19] The structures were solved by direct methods and refined on $|F|^2$ by full-matrix least-squares methods.

CCDC-250512, -250511, -250513, and -250514 (for **1**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Fragmentation of Alkoxo(catecholato)vanadium(V) Complexes $[(C_6H_4O_2)V(OR^1)(OR^2)]^+$ in the Gas Phase

Malgorzata Kaczorowska[a] Detlef Schröder,*[a] and Helmut Schwarz[a]

Keywords: Alkoxo complexes / Catecholates / Elimination / Hydrogen migration / Vanadium

Electrospray ionization (ESI) mass spectrometry is used to investigate the gas-phase dissociation behavior of vanadium(V) complexes $[(C_6H_4O_2)V(OR^1)(OR^2)]^+$ containing two identical or different alkoxy groups (R^1, R^2 = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7 and *t*-C_4H_9) and a catecholato ligand ($C_6H_4O_2$). The fragmentation reactions of the complexes are studied by collision-induced dissociation (CID) and labeling experiments. For $[(C_6H_4O_2)V(OR^1)(OR^2)]^+$ cations with alkoxo groups larger than methyl, a trend for preferential evaporation of hydrocarbon fragments is observed, followed by expulsion of neutral alcohols. Further, the CID spectra of all complexes show a signal which can be assigned to the complex $[(C_6H_4O_2)VO]^+$.

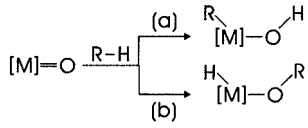
Introduction

Over the past years, interest in transition-metal oxides has grown steadily, due to the promising role which these compounds play in heterogeneous catalysis.[1] Metal oxides often serve as catalysts which are characterized by high selectivities and activities in many processes.[2] An important group of transition-metal catalysts are vanadium oxides,[3] used, for example, in the oxidation of sulfur dioxide in the industrial production of sulfuric acid and for the oxidation of hydrocarbons, e.g. propane and *n*-butane, to valuable products such as maleic acid and its anhydride. With respect to the oxidation of saturated hydrocarbons, mixed vanadium oxide/vanadium phosphate oxide (VPO) is of particular interest as a catalyst.[4]

Interest in transition-metal alkoxides arises from their potential role in metal-mediated oxidation reactions. High-valent transition-metal oxo complexes have been recognized to enable activations of C–H or O–H bonds in many important chemical and biological processes.[5] In general, C–H bond activation of alkanes by a transition-metal oxide [M]=O can occur in two different ways (Scheme 1). The first conceivable route (a) is transfer of a hydrogen atom from a C–H bond to the oxygen atom concomitant with bonding of the alkyl residue to the metal atom. The alternative reaction (b) involves C–O bond formation which yields a metal alkoxide concomitant with an additional metal–hydrogen bond.

For many reactions of transition-metal oxides with alkanes it is not easy to predict a clear preference for one of these routes. Experimental data needed for such a prediction are often not available because many of the relevant species are either difficult to isolate or elusive. Theoretical approaches are an attractive alternative under these circumstances, although application of quantum mechanical calculations to coordinatively unsaturated transition-metal compounds is all but trivial. In particular, many reactions of transition-metal oxides involve many low-lying excited electronic states.[6–9] Theoretical investigations of the activation of methane by the bare metal oxide cation FeO^+, which serves as a prototype for C–H bond activation of alkanes by transition-metal oxides in the gas phase,[6,10] predict preference of reaction (a), but route (b) is also not too energy-demanding and is conceivable as well.[11] Further, the formation of alkoxometal complexes has been proposed in the reactions of oxides of group V–VIII transition metals with methanol.[12] Metal alkoxides are also important intermediates in the dihydroxylation of olefins by OsO_4,[13] and reactions of the chromium dioxide cation with hydrocarbons in the gas phase.[14] With respect to our particular interest in vanadium alkoxides, the presence of $VOCH_3$ units has been considered essential for the selective oxidation of methanol to formaldehyde.[15,16]



Scheme 1.

In this article, we present an experimental study of composite vanadium(V) cations in the gas phase, which contain two identical or different alkoxy groups. The interest is focused on the examination of the effects of the substituents on the dissociation behavior of the complexes. More simple vanadium complexes like trimethylvanadate have been suc-

[a] Institut für Chemie der Technischen Universität Berlin, Strasse des 17. Juni 135, 10623 Berlin, Germany

cessfully examined before by various spectrometric means.[17] For our investigation, we aimed at producing vanadium(v) complexes of the type $[(L)V(OR^1)(OR^2)]^+$ in the gas phase, where R^1, R^2 = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, and *t*-C_4H_9. Our first choice for the ligand L to which the vanadium atom is connected by two single bonds through oxygen atoms was $[(C_2H_4O_2)V(OR^1)(OR^2)]^+$, where $C_2H_4O_2$ corresponds to glycolate. In this case, however, the fragmentations were not unequivocal, because several of the fragment ions observed can be assigned to dissociation of alkoxy groups as well as to the dissociation of the glycolate unit. Therefore, we switched to the more robust catechol ligand, for which such a problem does not exist (see below). Our focus lies on alkoxovanadium(v) complexes, which might be formed as transient intermediates in the oxidation of alkanes by vanadium oxides, because low-valent vanadium oxide cations and clusters cannot oxidize alkanes.[18–21]

In the experiments, electrospray ionization (ESI) mass spectrometry is employed, a technique which permits transfer of ionic complexes into the gas phase directly from solution, with a variable degree of desolvation or fragmentation. The possibility of analyzing the complexes in the gas phase in the absence of solvent provides essential information about ion structures and stoichiometries. Understanding of the gas-phase chemistry of transition-metal alkoxides can therefore provide insight into their fundamental properties at a molecular level and might thereby help to explain their behavior in the condensed phase.

Results

ESI of $VOCl_3$,dissolved in different alcohols and mixtures of alcohols with a small amount of catechol, leads to the formation of the desired vanadium(v) complexes $[(C_6H_4O_2)V(OR^1)(OR^2)]^+$. The abundances of the ions of interest critically depend on the concentration of catechol as well as the mixing ratio of the alcohols. If the concentration of catechol in the solution is too high, complexes with a $[(C_6H_4O_2)V(C_6H_4O_2)]^+$ core prevail. Likewise, the yields of the mixed alkoxy complexes are poor, when the concentration of the second alcohol is too small, as formation of $[(C_6H_4O_2)V(OR^1)_2]^+$ prevails.

In the cation ESI spectra of $VOCl_3$ in methanol with catechol under soft ionization conditions, the monocationic vanadium(v) complexes shown in Scheme 2 are observed. In structure **I**, the metal center V^V is connected with the aromatic ring through the oxygen atoms of catechol and forms an additional double bond with the vanadyl oxygen atom. This cation appears in the mass spectra of all mixtures examined.

The CID spectrum of mass-selected **I** (*m*/*z* = 175) shows a mass difference of Δ*m* = –28 (Table 1), which may be assigned to expulsion of CO or C_2H_4; given the $VC_6H_4O_3^+$ stoichiometry of **I**, loss of C_2H_4 appears unlikely, however. By analogy, Δ*m* = –44 is assigned to loss of CO_2. The CID spectra of **I** recorded at higher collision energies are dominated by VO^+ with additional signals corresponding to Δ*m* = –28, –44, –56, and –72, which can be assigned to CO, CO_2, two molecules of CO, and possibly CO + CO_2, respectively. For the cation **II** (*m*/*z* = 193), containing two hydroxy groups, the main process upon CID is loss of a water molecule (Δ*m* = –18), which formally leads to **I**. Likewise the strong signal for Δ*m* = –32 evolving in the case of complex **III** (*m*/*z* = 207) can be assigned to the loss of methanol. Similar to cation **III**, the CID spectra of complex **IV** containing two methoxy groups bound to a vanadium(v) center are characterized by the elimination of methanol (Δ*m* = –32), which can be explained by the mechanism depicted in Scheme 3. The key step corresponds to a hydrogen migration from the carbon atom of one to the oxygen atom of the second methoxy group. This scenario also accounts for the experimentally observed loss of formaldehyde (Δ*m* = –30). The CID spectrum is dominated, however, by the expulsion of a CH_3 radical (Δ*m* = –15), a process which is unique for the complex with R^1 = R^2 = CH_3; the fragment with Δ*m* = –45 is assigned to a combined loss of CH_3 + CH_2O. The CID spectra of mass-selected $[(C_6H_4O_2)V(OCD_3)_2]^+$ fully confirm theses conclusions in that preferential eliminations of CD_3 (Δ*m* = –18), CD_2O (Δ*m* = –32), and CD_3OD (Δ*m* = –36) are observed.

Table 1. Neutral losses (given as mass differences, Δ*m*) observed upon CID of the mass-selected cations **I–IV**, generated by ESI of $VOCl_3$ with catechol in methanol. Data given relative to the base peak (100) of the CID products at E_{lab} = 3 eV.

The CID spectra of the mixed methoxy complexes $[(C_6H_4O_2)V(OCH_3)(OC_2H_5)]^+$, $[(C_6H_4O_2)V(OCH_3)(OC_3H_7)]^+$ and $[(C_6H_4O_2)V(OCH_3)\{OC(CH_3)_3\}]^+$ are dominated by losses of corresponding alkenes generated from the larger alkoxy group, i.e. C_2H_4, C_3H_6, and C_4H_8, respectively (Table 2). Alkene elimination leads to the formation of **III**, prior to further degradation to structure **I** (Scheme 4). Minor dissociation pathways correspond to the expulsion of alcohols: methanol and ethanol from $[(C_6H_4O_2)V(OCH_3)(OC_2H_5)]^+$, methanol and propanol for the $[(C_6H_4O_2)V(OCH_3)(OC_3H_7)]^+$ complex, and finally,

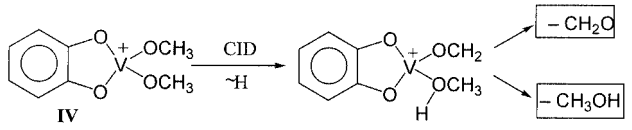
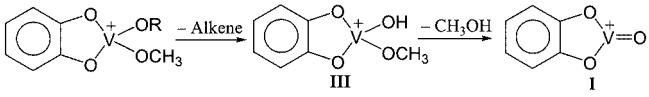
[a] Ratio of hydrogen transfer according to routes (c) and (d), see Scheme 6 and text for details. [b] In addition, a consecutive loss of CH_3 and CH_2O is observed [Δm (%) = –45 (30)]. [c] Poor abundances of $[M^+]$ formed upon ESI; the value given is an upper limit derived from the noise level.



Scheme 3.

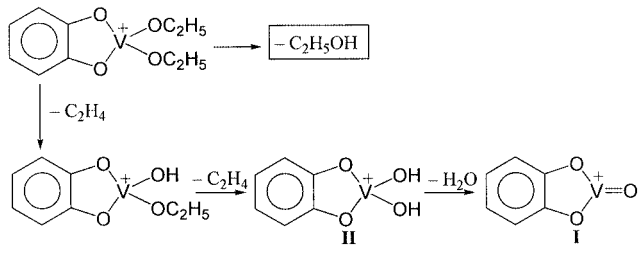
methanol and *tert*-butyl alcohol for the cation-$[(C_6H_4O_2)V(OCH_3)(OC(CH_3)_3)]^+$, respectively. For the latter complex, also loss of water is observed (Δm = –18). The CID spectra of mass-selected $[(C_6H_4O_2)V(OCH_3)(OCH_2CD_3)]^+$ generated from [2,2,2-D_3]ethanol reveal a preferential combined elimination of $C_2H_2D_2$ (Δm = –30) and CH_3OD (Δm = –63). The labeling experiments thereby confirm that the key reactions under CID of mixed methoxy complexes correspond to losses of alkenes according to Scheme 4.



Scheme 4.

The CID spectra of mass-selected $[(C_6H_4O_2)V(OCH_3)\{OCH(CH_3)_2\}]^+$ are also characterized by the elimination of C_3H_6, but the reaction does not dominate in this case. Instead, the major fragmentation is associated with an expulsion of methanol (Δm = –32), along with smaller amounts of $(CH_3)_2CHOH$ (Δm = 60).

Similar to the complexes containing one methoxy group and another larger alkoxy group, expulsion of ethene (Δm = –28) predominates upon CID of mass-selected $[(C_6H_4O_2)V(OC_2H_5)_2]^+$; expulsion of ethanol is observed also (Δm = –46). Possible pathways for the neutral losses upon CID of $[(C_6H_4O_2)V(OC_2H_5)_2]^+$ are presented in Scheme 5, which also suggest the formation of **II** by a consecutive loss of a second C_2H_4 unit followed by the elimination of H_2O to finally yield **I**. Note that the route via **II** is impossible for the complexes with a methoxy ligand as shown in Scheme 4, because alkene elimination is not feasible for R = CH_3. Upon CID of mass-selected $[(C_6H_4O_2)V(OC_2H_5)(OC_2D_5)]^+$, eliminations of C_2H_4 (Δm = –28) and C_2D_4 (Δm = –32) compete with each other with an apparent kinetic isotope effect (KIE) of 2.3 ± 0.1 associated with H-migration from the β-carbon atom in the course of alkene elimination. The significant magnitude of the KIE implies that C–H bond activation is rate-determining, as expected.[22,23]



Scheme 5.

The CID spectra of mixed complexes containing one ethoxy group are dominated by expulsion of alkenes from the larger alkoxy group: C_3H_6 for $[(C_6H_4O_2)V(OC_2H_5)(OC_3H_7)]^+$ as well as $[(C_6H_4O_2)V(OC_2H_5)\{OCH(CH_3)_2\}]^+$ cations and C_4H_8 for $[(C_6H_4O_2)V(OC_2H_5)\{OC(CH_3)_3\}]^+$, respectively, along with smaller amounts of corresponding alcohols (Table 2).

The fragmentations of $[(C_6H_4O_2)V(OC_3H_7)_2]^+$ and $[(C_6H_4O_2)V\{OCH(CH_3)_2\}]^+$ are very similar to each other. In both cases, the major CID signal corresponds to the loss of C_3H_6 (Δm = –42). As a result, cations containing one hydroxy group $[(C_6H_4O_2)V(OH)(OC_3H_7)]^+$ and $[(C_6H_4O_2)V(OH)\{OCH(CH_3)_2\}]^+$ are formed. These ions undergo a second loss of C_3H_6 (Δm = –84) to yield structure **II**, which can then expel water to finally afford **I**. Likewise, the CID spectra of $[(C_6H_4O_2)V(OC_3H_7)\{OC(CH_3)_3\}]^+$ and $[(C_6H_4O_2)V\{OCH(CH_3)_2\}\{OC(CH_3)_3\}]^+$ are quite similar and characterized by the elimination of C_4H_8 fragments

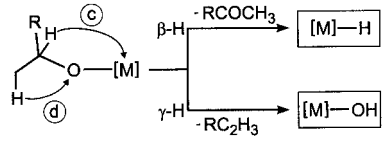
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(*m*/*z* = 235) along with small amounts of neutral *tert*-butyl alcohol. For $[(C_6H_4O_2)V(OC_3H_7)\{OC(CH_3)_3\}]^+$ an additional signal is present at *m*/*z* = 249, which can be assigned to the expulsion of C_3H_6 (Table 2). The fragmentation of the vanadium(V) complex with two *tert*-butoxy groups under CID conditions leads to predominant formation of the $[(C_6H_4O_2)V\{OC(CH_3)_3\}(OH)]^+$ concomitant with neutral butene. Also in this case, formation of complex **I** is observed at elevated collision energies.

Discussion

The comparison of the CID patterns of the various alkoxovanadium(V) complexes described above allows some general trends in reactivity to be derived. As a first and obvious conclusion, the dimethoxy complex $[(C_6H_4O_2)V(OCH_3)_2]^+$ is considered as being unique in that it cannot undergo olefin loss and instead expels a methyl radical which is only observed for this particular complex. Formally, the expulsion of $CH_3^{\cdot}$ affords a free valence at the remaining oxygen atom, thus formally leading to a hypervalent vanadium compound or an oxygen-centered radical. However, catechol can be considered to act as a redox-active ligand[24] in that electronic rearrangement may lead to an $OV(OCH_3)^+$ cation coordinated to an *ortho*-quinone ligand, i.e. a formal vanadium(IV) complex. For the other complexes, a clear trend for the preferential evaporation of hydrocarbon fragments from the larger alkoxy group is observed, followed by evaporation of neutral alcohol ligands (R^1OH and R^2OH).

In recursion to the above results, it is interesting to consider the fragmentation processes occurring upon CID in terms of one of two possible routes. Quite obviously, the trends among the various alkoxovanadium cations depend on the structure of the alkoxy groups. For a more detailed consideration, some kind of categorization of the reactions observed is required. Let us therefore distinguish between β-hydrogen transfer to afford a ketone [route (c)] and γ-hydrogen transfer to afford an alkene [route (d)] (Scheme 6). By analogy to ample previous findings on gaseous transition-metal alkoxides,[14,25–28] a hydridometal species is proposed in route (d); note, however, that in the particular case of the $[(C_6H_4O_2)V(OR)(OR')]^+$ complexes studied here, a metal hydride does not need to be involved as an intermediate because hydrogen transfer can directly occur to the other alkoxo group.[17] Within this framework for classification of the fragmentations observed experimentally, the reactions which lead to expulsions of neutral alcohols as well as carbonyl compounds are considered as belonging to route (c). Likewise, alkene losses are assigned to route (d). Similarly, the resulting consecutive products are attributed to the corresponding primary reactions of either routes, e.g. $\Delta m = -84$ in the case of R^1, $R^2 = OC_3H_7$ corresponds to the sequential elimination of two propene units. The last column of Table 2 shows the (normalized) ratio of the routes (c) and (d); other fragmentations, such as the loss of CH_3 from the dimethoxy derivative, are neglected in this comparison. For almost all complexes studied here, the contribution of route (d) is much higher than that of route (c). Exceptions are R^1, $R^2 = CH_3$, of course, for which route (d) is impossible, and the ions containing an *isopropyl* unit for which the amount of route (c) is enhanced. When the competition among the substituents is considered, the β-hydrogen-transfer steps according to route (c) show a small discrimination between R^1 and R^2 with a slight preference for the elimination of the smaller alcohol. In contrast, route (d) is much more specific in that a high preference for the elimination of the larger alkene is observed. These differential substituent effects can be understood on the basis of the mechanisms proposed above. Thus, in route (c), one substituent must serve as hydrogen donor while the other one acts as hydrogen acceptor and is then lost as an alcohol. By such, the substituent effects counterbalance each other. In the olefin elimination according to route (d), however, only one alkoxo group is involved and formation of the more substituted alkene is favored, as expected.



Scheme 6.

Conclusion

Electrospray mass spectrometry allows the generation of cationic alkoxovanadium(V) complexes $[(C_6H_4O_2)V(OR^1)(OR^2)]^+$, bearing a catecholate unit ($C_6H_4O_2$) as ligand. For all vanadium(V) complexes described above, a trend for the preferential evaporation of hydrocarbon fragments from alkoxy groups larger than CH_3 is observed, followed by evaporation of neutral alcohol ligands (R^1OH and R^2OH). The subsequent fragments formed at elevated collision energies still contain the catecholato ligand, suggesting a common $[(C_6H_4O_2)VO]^+$ core. The results demonstrate that the bond between vanadium(V) and catechol is much stronger than those between the metal center and the alkoxo groups.

With respect to the role of vanadium in oxidation catalysis, the mass-spectrometric studies reported in this work suggest mononuclear vanadium(V) centers to be of limited use for the conversion of alcohols with β-H atoms into the corresponding carbonyl compounds because alkene elimination can obviously compete quite efficiently.

Experimental Section

The experiments were performed using a commercial VG BIO-Q mass spectrometer equipped with an ESI source followed by a tandem mass spectrometer of QHQ configuration (Q = quadrupole, H = hexapole).[29] All examined ionized vanadium(V) complexes were generated by ESI of dilute methanolic solutions of $VOCl_3$, the appropriate alcohol(s), and catechol. All solutions were introduced

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

into the ESI source through a silica capillary with a syringe pump (3 μL/min). For each ion studied, the instrument parameters were optimized for maximum ion abundances. Nitrogen was used as a nebulizer and drying gas at a source temperature of 80 °C. Collision induced dissociation (CID) experiments were performed with xenon as a collision gas at a pressure of approximately $3 \cdot 10^{-4}$ mbar, and several collision energies (E_{lab} from 0 to 30 eV). For the CID experiments, the ions were mass-selected using Q1, allowed to interact with the collision gas in the hexapole collision cell, and the ionic products were then analyzed by scanning Q2. The cations observed in all solvents used can be divided into two major categories: vanadium-containing cations and metal-free cations; the latter are of no interest in this study, except that they were tried to be kept minimal in order to increase the yields of metal-containing ions. For all species, the number of ligands of the formed solvated cations depends on the cone voltage in the ESI source which determines the softness or hardness of the ionization conditions. All vanadium(v) complexes presented here are formed at a cone voltage of U_c = 20 eV, which corresponds to gentle ionization conditions where multiply ligated ions prevail. At $U_c > 80$ V, diatomic VO^+ prevails for all mixtures studied.

Novel Indenylzirconium Complexes as Supported Catalysts in the Polymerization of Ethylene

Carlos Alonso-Moreno,[a] Antonio Antiñolo,[a] Fernando Carrillo-Hermosilla,[a] Pedro Carrión,[a] Isabel López-Solera,[a] Antonio Otero,*[a] Sanjiv Prashar,[b] and José Sancho[c]

Keywords: Metallocene / Zirconium / Homogeneous catalysis / Supported catalysts / Polymerization / Ethylene

A series of substituted indene {C_9H_7R-3 [R = $CH_2CH_2CH_2OSiMe_3$ (**1**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**2**), $CH_2CH_2CH_2OSiMe_2tBu$ (**3**)]}, and *ansa*-indene compounds {$Me_2Si(C_9H_6R\text{-}3)_2$-1 [R = $CH_2CH_2CH_2OSiMe_3$ (**4**)], $Me_2Si(C_9H_6R\text{-}3)$-1(C_5HMe_4) [R = $CH_2CH_2CH_2OSiMe_3$ (**5**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**6**), $CH_2CH{=}CH_2$ (**7**), $CH_2CH_2CH_2OSiMe_2tBu$ (**8**)]} have been prepared. The lithium derivatives of **1**–**8** were employed in the synthesis of the indenylzirconium complexes [$Zr(\eta^5\text{-}C_9H_6R\text{-}1)_2Cl_2$] [R = $CH_2CH_2CH_2OSiMe_3$ (**17**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**18**), $CH_2CH_2CH_2OSiMe_2tBu$ (**19**)], *rac*-[$Zr\{Me_2Si(\eta^5\text{-}C_9H_5R\text{-}3)_2\text{-}1\}Cl_2$] [R = $CH_2CH_2CH_2OSiMe_3$ (**20**)], [$Zr\{Me_2Si(\eta^5\text{-}C_9H_5R\text{-}3)\text{-}1(\eta^5\text{-}C_5Me_4)\}Cl_2$] [R = $CH_2CH_2CH_2OSiMe_3$ (**21**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**22**), $CH_2CH{=}CH_2$ (**23**), $CH_2CH_2CH_2OSiMe_2tBu$ (**24**)] and [$Zr(Me_2Si\{\eta^5\text{-}C_9H_5(CH_2CH_2CH_2O)\text{-}3\}\text{-}1\{\eta^5\text{-}C_5Me_4\})Cl$] (**21a**). The alkyl complexes [$Zr(Me_2Si\{\eta^5\text{-}C_9H_5(CH_2CH_2CH_2O)\text{-}3\}\text{-}1\{\eta^5\text{-}C_5Me_4\})Me$] (**25**) and [$Zr\{Me_2Si(\eta^5\text{-}C_9H_5R\text{-}3)\text{-}1(\eta^5\text{-}C_5Me_4)\}Me_2$] [R = $CH_2CH_2CH_2OSiMe_2tBu$ (**26**)] have been synthesized by the reaction of the corresponding *ansa*-zirconocene derivative with the alkyl Grignard reagent. The molecular structure of [$(Zr\{C_9H_6(CH_2CH_2CH_2O)\text{-}1\}Cl_2)_2(Zr\text{–}O)$] (**17a**), a subproduct in the formation of **17** has been determined by single-crystal X-ray diffraction studies. The indenylzirconium complexes **17–24** have been immobilized on partially dehydroxylated SiO_2, and these supported systems used to polymerize ethylene in the presence of methylaluminoxane. The catalytic activity of these compounds in both homogeneous and heterogeneous polymerization is reported.

Introduction

On the basis of production data for 2000, 85–95 million tons of polyolefins (essentially homopolymers and copolymers of ethylene and propylene) were produced globally. The worldwide polypropylene capacity is approximately 34 million tons, all of which is made with supported catalysts. Sixty percent of polyethylene is made with supported catalysts, bringing the current market for polyolefins produced on supported catalysts to a total of 65–70 million tons per year. This already impressive market is still in full growth.[1,2]

Metallocene/MAO catalytic systems are highly efficient in producing polyolefins with defined microstructures and narrow molecular weight distributions,[3,4] although to date, these systems have generally been applied in solution. However, for most industrial applications, it is desirable to employ these catalysts in gas-phase reactions in order to take advantage of existing heterogeneous polymerization plant infrastructure and thus avoiding the costly modification needed for incorporating homogeneous systems. The single-site catalysts therefore need to be immobilized on a solid support in order to be active in gas-phase processes. Supported single-site catalysts are presently being used worldwide in the annual production of 1 billion kg of polyethylene.

The most common method of applying metallocene compounds to heterogeneous polymerization is to support the complexes on inorganic solids (in most cases silica gel).[5–7] There are four different routes to supported catalysts: (i) Direct adsorption of the metallocene on the carrier surface leading to physisorption or chemisorption of the metallocene (direct heterogenization). (ii) Direct adsorption of the metallocene/MAO adduct on the support. (iii) Initial adsorption of MAO to the support followed by adsorption of the metallocene (indirect heterogenization). (iv) Covalent bonding between the ligands of the metallocene complex and the carrier surface followed by activation with external MAO.

Several metallocene compounds containing functional groups linked to cyclopentadienyl or indenyl ligands have

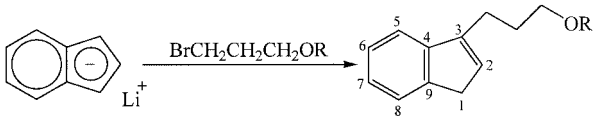
been described.[8] One of the most promising methods to obtain supported catalysts comes from the reaction between the functional group of these metallocene complexes and another functional group on the solid surface (route iv). This option was applied to obtain some supported mono- or bis(cyclopentadienyl) derivatives.[8b,9–11] When silica is employed as a support, the surface hydroxy groups have frequently been used for immobilizing the catalyst although they can also cause some decomposition of the metallocene complex. A strained siloxane group generated by dehydroxylation has been shown to react with alkoxysilane groups,[12] and this reactivity opens up the possibility of supporting metallocene complexes with pendant alkoxy or silyloxy groups on dehydroxylated silica.

In this paper we describe the synthesis and characterization of a series of alkoxy- and silyloxy-substituted indene compounds and their zirconium(IV) derivatives, and the successful immobilization of the metallocene catalysts on dehydroxylated silica.

Results and Discussion

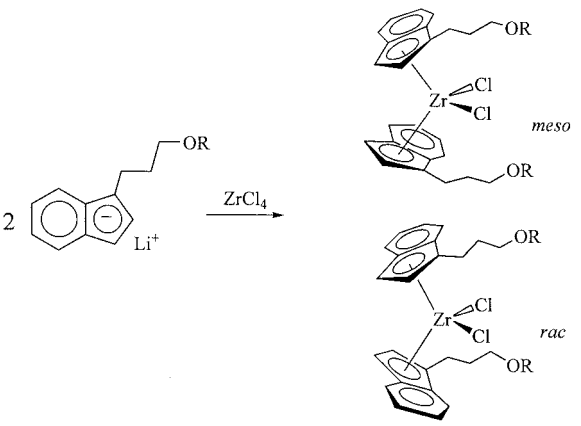
The preparation of the substituted indene precursors C_9H_7R-3 [R = $CH_2CH_2CH_2OSiMe_3$ (**1**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**2**), $CH_2CH_2CH_2OSiMe_2tBu$ (**3**)] was achieved by the reaction of $BrCH_2CH_2CH_2OR$ (R = $SiMe_3$, $CH_2C_6H_5$, $SiMe_2tBu$) and indenyllithium [Equation (1)]. ^1H NMR spectroscopy showed the isolated product of **1–3** to be virtually exclusively the 3-isomer (>98%). The 1-H signal for **1–3** was observed as a doublet, at $\delta \approx 3.2$ ppm, corresponding to two protons and 2-H as a triplet, at $\delta \approx 6.1$ ppm, corresponding to one proton. In addition, **1–3** were characterized by electron impact mass spectrometry (see Exp. Sect.).



R = $SiMe_3$ (**1**), CH_2Ph (**2**), $SiMe_2tBu$ (**3**) (1)

Compounds **1–3** were lithiated in the normal manner with *n*-butyllithium giving the lithium derivatives $Li(C_9H_6R$-1) [R = $CH_2CH_2CH_2OSiMe_3$ (**9**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**10**), $CH_2CH_2CH_2OSiMe_2tBu$ (**11**)]. Compounds **9–11** were treated with $ZrCl_4$ to yield the zirconocene complexes $[Zr(\eta^5$-C_9H_6R-1$)_2Cl_2]$ [R = $CH_2CH_2CH_2OSiMe_3$ (**17**), $CH_2CH_2CH_2OCH_2Ph$ (**18**), $CH_2CH_2CH_2OSiMe_2tBu$ (**19**)] [Equation (2)].

The substituted indenyl ligands are prochiral and can yield two diastereomers for the zirconocene complexes. A *re*,*re* or *si*,*si* attachment gives rise to the two enantiomers of the *rac* diastereomer, whereas a *re*,*si* attachment leads to the *meso* diastereomer.[13–15] The synthetic approach employed in this study gave, as shown by NMR spectroscopy, a 1:1 *rac*/*meso* isomer ratio.



R = $SiMe_3$(**17**), CH_2Ph (**18**), $SiMe_2tBu$ (**19**) (2)

^1H and ^{13}C NMR spectra of **17–19** exhibit two sets of signals in a 1:1 ratio, corresponding to the presence of both distereomers (see Exp. Sect.). The characterization was simplified by the fact that the *rac* isomer has C_2 symmetry which makes the two indenyl rings equivalent. This is also true for the *meso* isomer because of a mirror plane. In the ^1H NMR spectra of **17–19**, the protons in position 2 and 3 of the indenyl ligand showed only vicinal coupling and were thus observed as doublets in the ^1H NMR spectra. It was possible to assign the 2-H and 3-H signals to their respective diastereomers using NOE experiments. An interesting observation is that for a sample containing a mixture of the diastereomers, the "inner-pair" of 2-H and 3-H doublets were assigned to the *rac* isomer, whereas for the *meso* isomer the two doublets were the "outer-pair". Because of the complex nature caused by overlapping signals we were not able to assign the multiplet systems observed for the protons of both the pendant chain and the indenyl C_6 fragment to their respective diasteromers.

During the preparation of **17**, a minor product was, at times, detected. We were able to isolate this subproduct, $[(Zr\{C_9H_6(CH_2CH_2CH_2O)-1\}Cl_2)_2(Zr$–$O)]$ (**17a**), by fractional recrystallization and characterize it by single-crystal X-ray diffraction studies. The molecular structure and atomic numbering scheme are shown in Figure 1. Selected bond lengths and angles for **17a** are given in Table 1.

The structure consists of a dinuclear complex of zirconium. The metal atoms are bound to the indenyl ligand in an η^5 mode, to the oxygen atoms of the pendant chains which bridge the two zirconium atoms, and to two chlorine atoms in a four-legged piano-stool conformation. The indenyl ligands are in a *trans* disposition.

During the preparation of **9** it is possible that a second lithiation occurs at the oxygen atom of the pendant chain with the elimination of $nBuSiMe_3$ to give $Li[C_9H_6(CH_2CH_2CH_2OLi)$-1]. If this subproduct is present when the reaction of **9** is carried out with $ZrCl_4$, the presence of **17a** may be detected in the isolated product [Equation (3)].

The bridged bis(indene) compound, $\{Me_2Si[(C_9H_6$-R-3$)$-1$]_2\}$ (**4**) (R = $CH_2CH_2CH_2OSiMe_3$), was prepared by

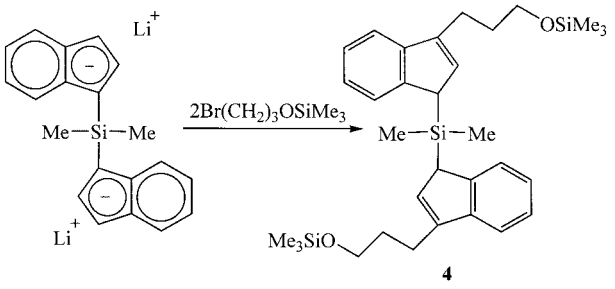
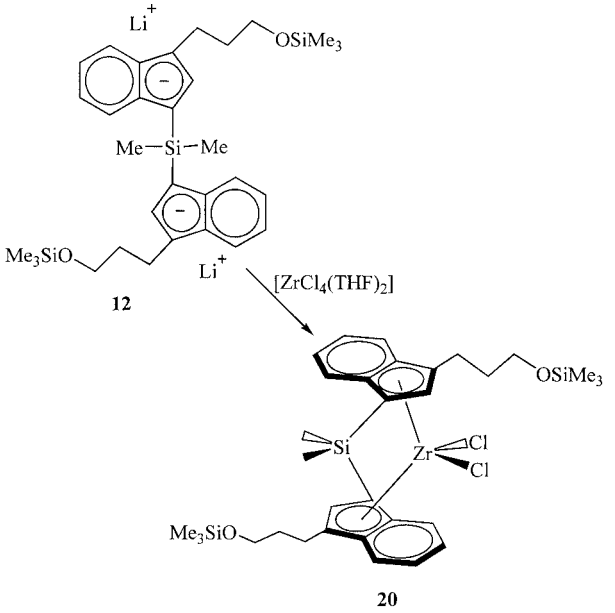
(3)

the reaction of 2 equiv. of $BrCH_2CH_2CH_2OSiMe_3$, with $Li_2[Me_2Si(C_9H_6)_2$-1] and isolated as a mixture of its *meso* and *rac* isomers [Equation (4)].



(4)

^{1}H NMR spectroscopy showed the isolated product of **4** to be virtually exclusively (>98%) the symmetrically substituted indene isomer. In addition, **4** was characterized by electron impact mass spectrometry (see Exp. Sect.). Double deprotonation of **4** with2 equiv. of *n*-butyllithium gave the corresponding dilithium derivative, $Li_2[Me_2Si(C_9H_5R\text{-}3)_2$-1] (**12**) (R = $CH_2CH_2CH_2OSiMe_3$), whose reaction with $[ZrCl_4(THF)_2]$ in toluene gave the *ansa*-indenyl complex, [Zr{$Me_2Si(\eta^5$-C_9H_5R-3)$_2$-1}Cl_2] [R = $CH_2CH_2CH_2OSiMe_3$ (**20**)], exclusively as the *rac* isomer [Equation (5)]. Use of $[ZrCl_4(THF)_2]$ as the zirconium source has been suggested to modify the ratio of the diastereomers formed.[14] This proposal is reinforced by the observation that the reaction of **12** with $ZrCl_4$ gave **20** as a 3:2 *rac*/*meso* mixture.

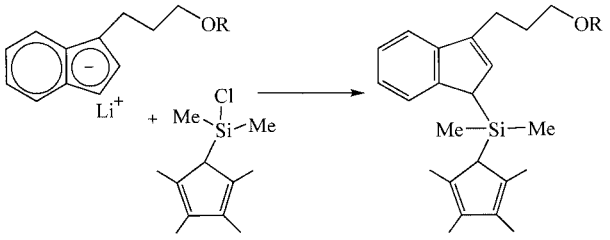


(5)

Compound **20** was characterized by NMR spectroscopy. The proton signal assignments were made according to a procedure using ^{1}H and ^{13}C NMR correlated spectroscopy (HETCOR) (see Exp. Sect.).

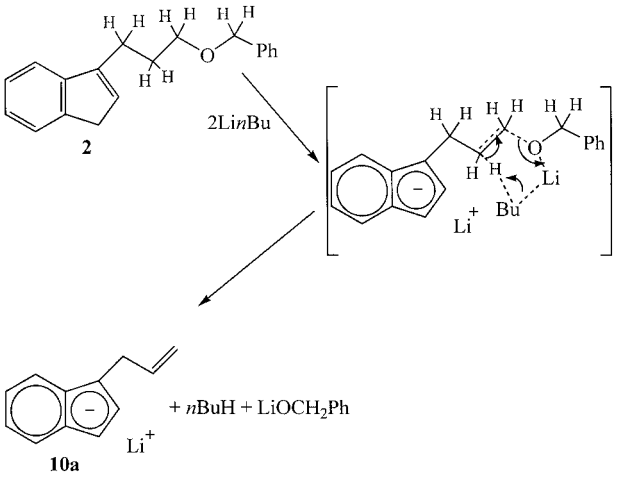
The preparation of the asymmetrically substituted *ansa* ligand precursors [$Me_2Si(C_9H_6R$-3)-1(C_5HMe_4)] [R = $CH_2CH_2CH_2OSiMe_3$ (**5**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**6**),

$CH_2CH_2CH_2OSiMe_2tBu$ (**8**)] was achieved by the reaction of $Me_2Si(C_5Me_4H)Cl$ and the corresponding lithium derivatives **9**–**12** [Equation (6)].



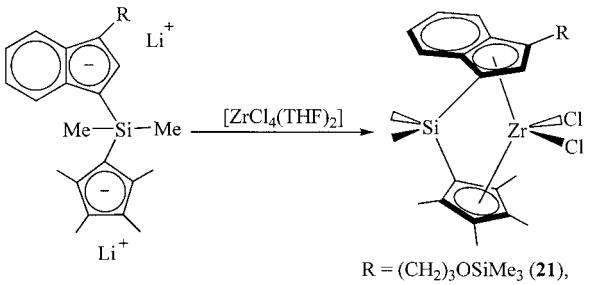
R = $SiMe_3$ (**5**), CH_2Ph (**6**), $SiMe_2tBu$ (**8**) (6)

The reaction of **2** with an excess of *n*BuLi gave the lithium derivative $Li[C_9H_6(CH_2CH{=}CH_2)\text{-}1]$ (**10a**) by a bimolecular elimination [Equation (7)]. The subsequent reaction of **10a** with $Me_2Si(C_5Me_4H)Cl$ yielded the asymmetrically substituted *ansa* ligand precursor, $\{Me_2Si[C_9H_6(CH_2CH{=}CH_2)\text{-}3]\text{-}1(C_5HMe_4)\}$ (**7**). ^1H NMR spectroscopy showed the isolated products **5**–**8** to be virtually exclusively (>98%) the regioisomer where the $SiMe_2$ *ansa* bridge is situated in position 1 in both the indenyl and cyclopentadienyl moieties. In addition, **5**–**8** were characterized by electron impact mass spectrometry (see Exp. Sect.).



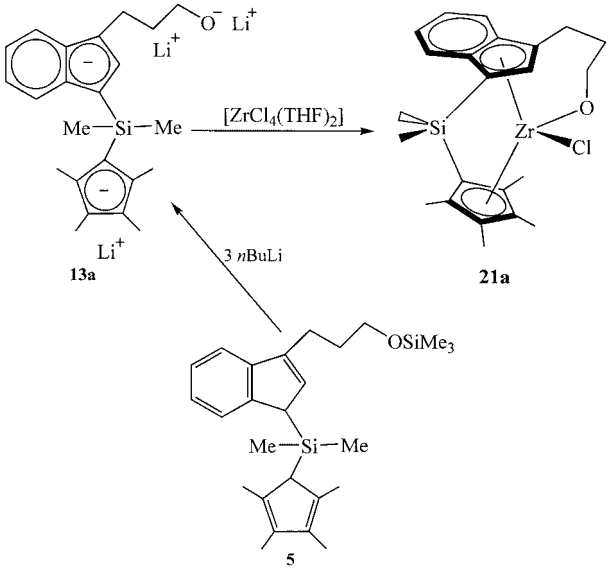
(7)

Compounds **5**–**8** were then lithiated in the normal way with *n*-butyllithium to give the corresponding dilithium derivatives, $Li_2[Me_2Si(C_9H_5R\text{-}3)\text{-}1(C_5Me_4)]$ [R = $CH_2CH_2CH_2OSiMe_3$ (**13**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**14**), $CH_2CH{=}CH_2$ (**15**), $CH_2CH_2CH_2OSiMe_2tBu$ (**16**)] whose reaction with $[ZrCl_4(THF)_2]$ gave the *ansa*-zirconocene complexes $[Zr\{Me_2Si(\eta^5\text{-}C_9H_5R\text{-}3)\text{-}1(\eta^5\text{-}C_5Me_4)\}Cl_2]$ [R = $CH_2CH_2CH_2OSiMe_3$ (**21**), $CH_2CH_2CH_2OCH_2C_6H_5$ (**22**), CH_2CHCH_2 (**23**), $CH_2CH_2CH_2OSiMe_2tBu$ (**24**)] [Equation (8)].



R = $(CH_2)_3OSiMe_3$ (**21**), $(CH_2)_3OCH_2Ph$ (**22**), $CH_2CH{=}CH_2$ (**23**), $(CH_2)_3OSiMe_2tBu$ (**24**) (8)

When the lithiation reaction of **5** was carried out in the presence of excess of *n*-butyllithium, the trilithium derivative, $Li_2\{Me_2Si[C_9H_5(CH_2CH_2CH_2OLi)\text{-}3]\text{-}1(C_5Me_4)\}$ (**13a**) was formed through the elimination of the $SiMe_3$ moiety [Equation (9)]. Compound **13a** was characterized by ^1H NMR spectroscopy which confirmed the loss of the $SiMe_3$ group. The reaction of **13a** with $[ZrCl_4(THF)_2]$ gave the *ansa*-zirconocene complex $[Zr(Me_2Si\{\eta^5\text{-}C_9H_5(CH_2CH_2CH_2O)\text{-}3\}\text{-}1\{\eta^5\text{-}C_5Me_4\})Cl(Zr\text{–}O)]$ (**21a**), where the oxygen atom of the pendant chain is directly bonded to the metal center [Equation (9)].



(9)

Compounds **21**–**24** were characterized spectroscopically (see Exp. Sect.). The ^1H NMR spectra show the lack of symmetry in these chiral complexes, with four singlets being observed for the cyclopentadienyl methyl groups, two singlets for the *ansa*-bridge methyl groups, a singlet for the proton of the indenyl C_5 ring and four multiplets corresponding to the protons of the C_6 ring of the indenyl moiety. In addition signals were observed for the pendant alkyl chain.

The alkyl derivatives, $[Zr(Me_2Si\{\eta^5\text{-}C_9H_5(CH_2CH_2CH_2O)\text{-}3\}\text{-}1\{\eta^5\text{-}C_5Me_4\})Me(Zr\text{–}O)]$ (**25**) and $[Zr\{Me_2Si(\eta^5\text{-}C_9H_5R\text{-}3)\text{-}1(\eta^5\text{-}C_5Me_4)\}Me_2]$ [R = $CH_2CH_2CH_2OSi$-

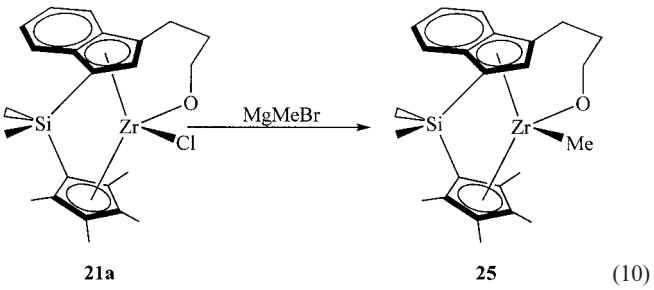
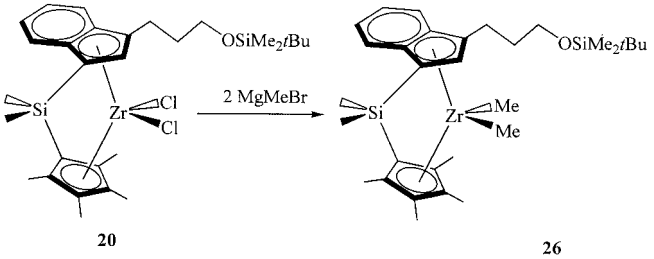
Me_2tBu (**26**)] were prepared by the reaction of the Grignard reagent MeMgBr with the corresponding mono- or dihalo *ansa*-zirconocene complexes **21a** and **24**, respectively [Equations (10) and (11)]. Compounds **25** and **26** were characterized by spectroscopic methods (see Exp. Sect.). The ^1H NMR spectrum for **25** is similar to that recorded for its parent compound **21a** but in addition a singlet for the metal-bonded methyl group is observed. For **26**, two signals, assigned to the inequivalent metal-bonded methyl groups, were recorded.



21a **25** (10)



20 **26** (11)

Figure 2 shows IR spectra corresponding to the reaction between a toluene solution of [Zr{$Me_2Si(\eta^5$-C_9H_5R-3)-1(η^5-C_5Me_4)}Cl_2] [R = $CH_2CH_2CH_2OSiMe_2tBu$ (**17**)] and the surface of a partially dehydroxilated silica, after removal of solvent (see Exp. Sect.). The spectrum of silica preheated at 773 K has a sharp band at 3747 cm^{-1} (assigned to isolated OH groups) with a small broad shoulder at 3670 cm^{-1}, which can be attributed to silanols that are perturbed due to interparticle contact[16] or to OH groups retained deep within the pores[17] (Figure 2a). The magnitude of the silanol number, which is independent of the origin and structural characteristics of amorphous silica, is considered to be ca. 1.8 OH nm^{-2} for a silica dehydroxylated at 733 K.[18] Bands at 1866 cm^{-1} and 1640 cm^{-1} are combination and overtone bands of Si–O network bonds. After contact with the metallocene solution and removal of the solvent (Figure 2b), new bands can be seen in the 2900 and 1400 cm^{-1} regions and these correspond to stretching and bending modes of the cyclopentadienyl ligands. The OH groups that were initially isolated are now partially perturbed, generating broad ν(OH) bands at lower frequencies due to an interaction with the cyclopentadienyl π-electron system through

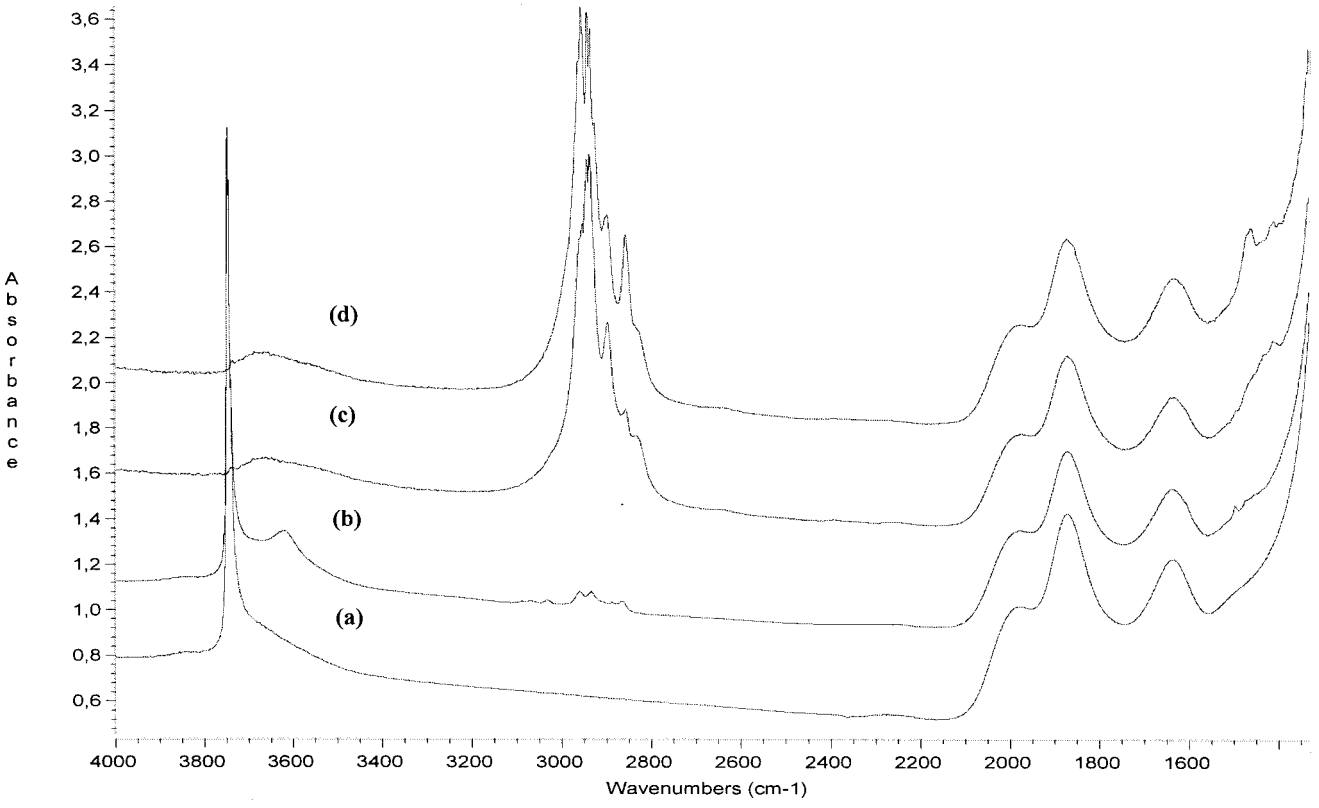


Figure 2. (a) SiO_2 dehydroxylated; (b) after grafting of **17**; (c) after addition of MAO; (d) after contact with C_2H_4.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydrogen bonding.[19] The total intensity of the band due to the hydroxy groups was slightly modified after the addition of an excess of metallocene solution, a situation also observed by dos Santos and co-workers in the reaction between partially dehydroxylated silica and [Zr(η^5-C_5H_4-*n*Bu)$_2$Cl$_2$].[20]

It is well established that the surface hydroxy group density on silica decreases with thermal activation as a result of an increase in the number of siloxane reactive bridges. These strained groups can activate covalent bonds such as the Si–O bond in silicon ethers or N–H in ammonia.[21] We could propose a similar behavior with our silicon ether metallocene derivatives. Similar results were found in the reaction of [Zr(η^5-C_5H_5)$_2$Cl$_2$] and dehydroxylated silica.[22]

The behavior of the catalyst system after the addition of the MAO cocatalyst was also studied by FT-IR spectroscopy. The IR spectrum of a sample of **17**-SiO_2 treated with MAO (Al/Zr = 100) is shown in Figure 2c. After addition of MAO at room temperature, the infrared band attributed to the isolated silanol groups (at 3747 cm^{-1}) disappeared completely, indicating a reaction between some basic methyl groups of MAO and the acidic silanol moieties of the silica. New infrared bands were observed in the ν(CH) region (one intense band at 2940 cm^{-1} and three weak bands at 2898, 2856 and 2838 cm^{-1}). These signals were assigned to stretching vibrations of the C–H bonds of the methyl groups in MAO. The grafted MAO should be able to activate neighboring surface zirconocene molecules.[23] The catalytic activity of **17**-SiO_2, after treatment with MAO, towards ethylene polymerization was confirmed, using FT-IR spectroscopy, by monitoring the appearance of vibrations due to polyethylene in the regions 3000–2800 and 1500–1300 cm^{-1} (Figure 2d). Intense bands were observed at 2970, 2850 and 1380 cm^{-1}, which correspond to the ν(CH) and δ(CH) vibrations of polyethylene, respectively.

The polymerization of ethylene, under homogeneous conditions and using **9**–**13** and **15**–**17** as the catalyst, with metal/MAO catalyst ratios of 1:100 (in order to compare with supported catalysts) or 1:500, has been carried out. The polymerization experiments were carried out at 70 °C and at an olefin pressure of 1.5 bar. The results of the experiments are given in Table 2.

In all the cases, as expected, higher activities were found for the 500:1 Al/Zr ratio. The highest catalytic activities were recorded for **19**, **22** and **23**. In comparison, **20** gave a notably low catalytic activity. The activities recorded for the *ansa*-zirconocene complexes **22** and **23** are higher than their unsubstituted analogue, [Zr{Me_2Si(η^5-C_9H_6)(η^5-C_5Me_4)}-Cl_2], although **24** gave a similar value. Only compound **19** shows a higher value than its corresponding unsubstituted reference complex.

The complexes **17**–**24** were supported on dehydroxylated silica and, in the presence of MAO (Zr/Al 1:100), were employed as heterogeneous catalysts in the polymerization of ethylene. The experiments were carried out at 70 °C and at an olefin pressure of 1.5 bar and the results are given in Table 3.

The amount of supported metallocene was verified by surface elemental analyses (Zr). The average results of several samples are summarized in Table 3.

Supported substituted complexes **17**, **21**, and **24** show similar or higher activities than their reference unsubstituted complexes. We could propose that, at least in these cases, more active surface species were obtained than those obtained from "conventional" unsubstituted complexes. Later complexes could be fixed on the surface by reaction between Zr–Cl moieties and Si–OH acidic groups, to give strong Zr–O–Si bonding, hard to activate by MAO. In contrast, the new complexes could be fixed by the reaction be-

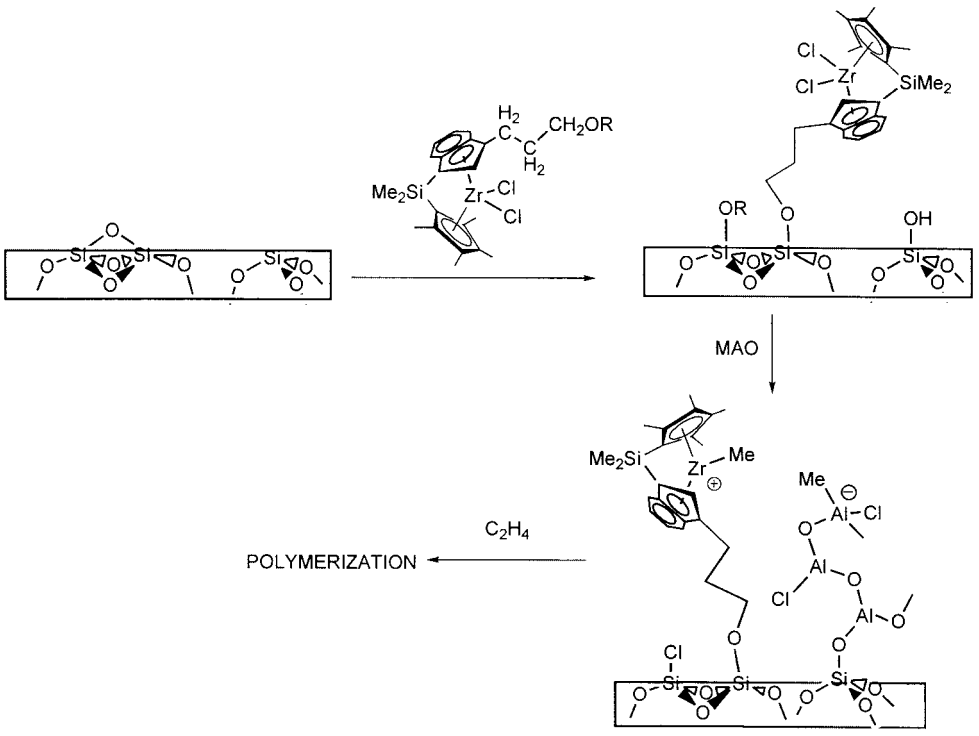

Scheme 1. Proposed mechanism in the immobilization of the catalyst at the siloxane bridge and its subsequent activation with MAO.

tween the $(CH_2)_2OR$ group and the siloxane bridges, to give surface species, which remember the structure of the analogous molecular complexes, to give more active catalysts (Scheme 1).

In addition, it is noteworthy that supported complexes **17**, **21** and **24** show similar or higher activities than their corresponding homogeneous catalysts, with a 100:1 Al/Zr ratio, showing both the advantages of supporting the complexes (reduced MAO addition to activate), and the use of pendant reactive chains (more active species).

Conclusions

We have carried out the synthesis of indenyl-containing zirconium complexes with pendant chains capable of interacting with dehydroxylated silica. We have successfully immobilized the complexes on silica and tested the activity of these supported catalysts in the polymerization of ethylene and compared the results with the reference unsubstituted complexes.

Experimental Section

General Remarks: All reactions were prepared using standard Schlenk tube techniques under dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before use. $[ZrCl_4(THF)_2]$, $ZrCl_4$, C_9H_8, $Me_2Si(C_5HMe_4)Cl$, $SiMe_2Cl_2$, $BrCH_2CH_2CH_2OH$ and $(Me_3Si)_2NH$ were purchased from Aldrich and used directly. Grace Davison XPO 2407 silica (200 m^2/g, according to data from supplier) was dehydroxylated under vacuum (10^{-2} Torr) at 773 K for 16 h, cooled and stored under dry nitrogen. Ethylene (Alphagaz), iBu_3Al (TIBA, Aldrich) and MAO (EURECENE, 10, Crompton) were used without further purification. ^1H and ^{13}C spectra were recorded with Varian UNITY FT-300, Varian GEMINY FT-400 and Varian INNOVA FT-500 spectrometers and referenced to the residual deuterated solvent. Microanalyses were carried out with a Perkin–Elmer 2400 microanalyzer. Mass spectrometric analyses were performed with a Vg Autospec instrument or a Hewlett–Packard 5988A (m/z = 50–1000) (electron impact). Infrared spectra were recorded with a Nicolet Magna 550-FT spectrophotometer using an infrared cell equipped with CaF_2 or KBr windows; this setup allowed in situ studies. A total of 32 scans were typically accumulated for each spectrum (resolution 2 cm^{-1}). The samples consisted of ca. 20 mg of silica pressed into a self-supported disc of 1 cm diameter. The samples were dehydroxylated at 773 K for 16 h. Zirconocene grafting was performed using a 10^{-2} M solution of the metallocene in toluene to give approximately 1% Zr/SiO_2. The samples were warmed at 333 K for 1 h, washed with toluene and dried in vacuo at 343 K until no further change was observed (sublimation of the excess complex was observed).

Preparation of $C_9H_7(CH_2CH_2CH_2OSiMe_3)$-3 (1): $BrCH_2CH_2CH_2OSiMe_3$ (9.04 g, 43.04 mmol) was added to a solution of $Li(C_9H_7)$ (5.25 g, 43.04 mmol) in Et_2O at –78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 15 h. The solvent was removed in vacuo and hexane (100 mL) was added. The mixture was filtered and the solvent removed from the filtrate under reduced pressure to yield the title compound as a yellow oil. Compound **1** was purified by flash distillation (8.47 g, 80%). ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 0.20 (s, 9 H, $OSiMe_3$), 1.65 and 2.08 (2 m, each 2 H, $CH_2CH_2CH_2O$), 3.40 (m, 2 H, 1-H), 3.82 (t, J = 6.3 Hz, 2 H, CH_2OSiMe_3), 6.32 (m, 1 H, 2-H), 7.26 and 7.33 (2 t, J = 7.3 Hz, each 1 H, 5-H and 8-H), 7.50 and 7.58 (2 d, J = 7.3 Hz, each 1 H, 6-H and 7-H) ppm. EI MS: m/z (%) = 246 (30) [M^+, $C_9H_7(CH_2CH_2CH_2OSiMe_3)^+$], 130 (100) [$M^+ - C_9H_7$], 115 (24) [$M^+ - CH_2CH_2CH_2OSiMe_3$].

Preparation of $Li_2[Me_2Si(C_9H_5R\text{-}3)_2\text{-}1]$ (R = $CH_2CH_2CH_2OSiMe_3$) (12): The synthesis of **12** was carried out in an identical manner to **9**: **4** (5.00 g, 9.11 mmol) and *n*BuLi (1.60 M in hexane) (13.67 mL, 21.86 mmol). Yield (4.00 g, 78%). $C_{32}H_{46}Li_2O_2Si_3$ (560.8): calcd. C 68.53, H 8.27; found C 68.21, H 8.24.

Preparation of $Li_2[Me_2Si(C_9H_5R\text{-}3)\text{-}1(C_5Me_4)]$ (R = $CH_2CH_2CH_2OSiMe_3$) (13): The synthesis of **13** was carried out in an identical manner to **9**: **5** (5.00 g, 11.77 mmol) and *n*BuLi (1.60 M in hexane) (17.65 mL, 28.25 mmol). Yield (4.16 g, 81%). $C_{26}H_{38}Li_2OSi_2$ (436.6): calcd. C 71.52, H 8.77; found C 71.33, H 8.71.

Preparation of $Li_2\{Me_2Si[C_9H_5(CH_2CH_2CH_2OLi)\text{-}3]\text{-}1(C_5Me_4)\}$ (13a): The synthesis of **13a** was carried out in an identical manner to **9**: **5** (5.00 g, 11.77 mmol) and *n*BuLi (1.60 M in hexane) (22.10 mL, 35.31 mmol). Yield (3.13 g, 72%).^{1}H NMR (400 MHz, C_6D_6/[D$_8$]THF, 25 °C): δ = –0.30 and –0.58 (2 s, each 3 H, SiMe_2), 1.68, 1.70, 1.82 and 1.86 (4 s, each 3 H, C_5Me_4), 1.76 and 2.59 (2 m, each 2 H, CH_2CH_2CH$_2$O), 3.53 (t, J = 6.3 Hz, 2 H, CH_2OSiMe$_3$), 6.14 (s, 1 H, 2-H), 6.98 (m, 2 H, 5-H, 8-H), 7.29 (m, 2 H, 6-H, 7-H) ppm. $C_{23}H_{29}Li_3OSi$ (370.40): calcd. C 74.58, H 7.89; found C 74.12, H 7.92.

Preparation of $Li_2[Me_2Si(C_9H_5R\text{-}3)\text{-}1(C_5Me_4)]$ (R = $CH_2CH_2CH_2OCH_2Ph$) (14): The synthesis of **14** was carried out in an identical manner to **9**: **6** (5.00 g, 10.57 mmol) and *n*BuLi (1.60 M in hexane) (15.85 mL, 25.36 mmol). Yield (3.27 g, 68%). $C_{30}H_{36}Li_2OSi$ (454.6): calcd. C 79.27, H 7.98; found C 79.34, H 7.96.

Preparation of $Li_2[Me_2Si(C_9H_5R\text{-}3)\text{-}1(C_5Me_4)]$ (R = $CH_2CH{=}CH_2$) (15): The synthesis of **14** was carried out in an identical manner to **9**: **7** (5.00 g, 14.95 mmol) and *n*BuLi (1.60 M in hexane) (22.43 mL, 35.88 mmol). Yield (4.14 g, 80%). $C_{23}H_{28}Li_2Si$ (346.4): calcd. C 79.74, H 8.15; found C 79.29, H 8.11.

Preparation of $Li_2[Me_2Si(C_9H_5R\text{-}3)\text{-}1(C_5Me_4)]$ (R = $CH_2CH_2CH_2OSiMe_2tBu$) (16): The synthesis of **13** was carried out in an identical manner to **9**: **8** (5.00 g, 10.71 mmol) and *n*BuLi (1.60 M in hexane) (16.10 mL, 25.70 mmol). Yield (4.00 g, 78%). $C_{29}H_{44}Li_2OSi_2$ (478.7): calcd. C 72.76, H 9.26; found C 72.54, H 9.17.

Preparation of $[Zr\{\eta^5\text{-}C_9H_6(CH_2CH_2CH_2OSiMe_3)\text{-}1\}_2Cl_2]$ (17): Toluene (100 mL) was added to a solid mixture of $ZrCl_4$ (1.15 g, 4.95 mmol) and Li[$C_9H_6(CH_2CH_2CH_2OSiMe_3)$-1] (**9**) (2.50 g, 9.90 mmol). The resulting pale yellow solution was stirred for 15 h. The mixture was filtered and the solvent removed in vacuo to yield a yellow oil of the title complex (1.87 g, 58%). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, two isomers): δ = 0.15, 0.18 (2 s, each 18 H, 4×OSiMe_3), 1.60–2.00 and 2.60–3.15 (2 m, each 8 H, 4×CH_2CH_2CH$_2$O), 3.45–3.80 (2 m, each 4 H, 4×CH_2OSiMe$_3$), 5.75 (d, J = 3 Hz, 2 H, *meso*-3-H), 5.88 (d, J = 3 Hz, 2 H, *rac*-3-H), 6.13 (d, J = 3 Hz, 2 H, *rac*-2-H), 6.37 (d, J = 3 Hz, 2 H, *meso*-2-H), 7.20–7.70 (m, 16 H, 4×5-H–8-H) ppm. ^{13}C{^{1}H} (75 MHz, $CDCl_3$, 25 °C, two isomers): δ = –0.3 (OSiMe_3), 24.3 and 24.6 (*C*H$_2$CH$_2$CH$_2$O), 30.5 (CH$_2$*C*H$_2$CH$_2$O), 61.9 (*C*H$_2$OSiMe$_3$), 99.1 (*meso*-C-3), 99.29 (*rac*-C-3), 120.2 (*meso*-C-2), 121.8 (*rac*-C-2), 118.8–139.0 (C-5–C-8) (C-4, C-9 not observed) ppm. EI MS: *m*/*z* (%) = 652 (13) [M$^+$, Zr($C_9H_6CH_2CH_2CH_2OSiMe_3)_2Cl_2^+$], 297 (100) [M$^+$ – $C_9H_6CH_2CH_2CH_2OSiMe_3$ – Cl]. $C_{30}H_{42}Cl_2O_2Si_2Zr$ (652.95): calcd. C 55.18, H 6.48; found C 55.36, H 6.45.

Preparation of $[Zr\{\eta^5\text{-}C_9H_6(CH_2CH_2CH_2OCH_2Ph)\text{-}1\}_2Cl_2]$ (18): The synthesis of **18** was carried out in identical manner to **17**. $ZrCl_4$ (1.16 g, 4.96 mmol) and Li[$C_9H_6(CH_2CH_2CH_2OCH_2Ph)$-1] **10** (2.50 g, 9.91 mmol). Yield: 2.33 g, 68%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, two isomers): δ = 1.84–2.07 and 2.40–3.13 (2 m, each 8 H, 4×CH_2CH_2CH$_2$O), 3.36–3.62 (m, 8 H, 4×CH_2OCH$_2$Ph), 4.03–4.58 (2 m, each 4 H, 4×OCH_2Ph), 5.68 (d, J = 3 Hz, 2 H, *meso*-3-H), 5.88 (d, J = 3 Hz, 2 H, *rac*-3-H), 6.10 (d, J = 3 Hz, 2 H, *rac*-2-H), 6.33 (d, J = 3 Hz, 2 H, *meso*-2-H), 7.14–7.68 (m, 36 H, 4×5-H–8-H and 4×OCH$_2$*Ph*) ppm. ^{13}C{^{1}H} (75 MHz, $CDCl_3$, 25 °C, two isomers): δ = 24.4 and 24.7 (*C*H$_2$CH$_2$CH$_2$O), 29.9 (CH$_2$*C*H$_2$CH$_2$O), 69.4 (*C*H$_2$OCH$_2$Ph), 72.9 (OC*H*$_2$Ph), 99.1 (*meso*-C-3), 99.3 (*rac*-C-3), 120.4 (*meso*-C-2), 122.0 (*rac*-C-2), 117.9–144.4 (C-5–C-8 and OCH$_2$*Ph*) (C-4, C-9 not observed) ppm. EI MS: *m*/*z* (%) = 688 (15) [M$^+$, Zr($C_9H_6CH_2CH_2CH_2OCH_2Ph)_2Cl_2^+$], 388 (73) [M$^+$ – $C_9H_6CH_2CH_2CH_2OCH_2Ph$ – Cl], 261 (100) [M$^+$ – $C_9H_6CH_2CH_2CH_2OCH_2Ph$ – 2 Cl – CH$_2$Ph]. $C_{38}H_{38}Cl_2O_2Zr$ (688.84): calcd. C 66.26, H 5.56; found C 66.46, H 5.52.

Preparation of $[Zr\{\eta^5\text{-}C_9H_6(CH_2CH_2CH_2OSiMe_2tBu)\text{-}1\}_2Cl_2]$ (19): The synthesis of **19** was carried out in identical manner to **17**. $ZrCl_4$ (0.99 g, 4.25 mmol) and Li[$C_9H_6(CH_2CH_2CH_2OSiMe_2tBu)$-1] (**11**) (2.50 g, 8.49 mmol). Yield: 1.66 g, 53%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, two isomers): δ = 0.03, 0.05 (2 s, each 12 H, OSiMe_2), 0.89, 0.91 (2 s, each 18 H, OSiMe$_2$*tBu*), 1.57–1.87 and 2.62–3.04 (2 m, each 8 H, 4×CH_2CH_2CH$_2$O), 3.57–3.71 (m, 8 H, 4×CH_2OSiMe$_2$*t*Bu), 5.68 (d, J = 3 Hz, 2 H, *meso*-3-H), 5.84 (d, J = 3 Hz, 2 H, *rac*-3-H), 6.07 (d, J = 3 Hz, 2 H, *rac*-2-H), 6.30 (d, J = 3 Hz, H, *meso*-2-H), 7.16–7.63 (m, 16 H, 4×5-H–8-H) ppm. ^{13}C{^{1}H} (75 MHz, $CDCl_3$, 25 °C, two isomers): δ = –5.2 (OSi*Me*$_2$*t*Bu), 24.1 and 24.4 (*C*H$_2$CH$_2$CH$_2$O), 26.0 (OSiMe$_2$*tBu*), 32.3 (CH$_2$*C*H$_2$CH$_2$O), 62.3 (*C*H$_2$OSiMe$_2$*t*Bu), 99.0 (*meso*-C-3), 99.2 (*rac*-C-3), 120.39 (*meso*-C-2), 212.89 (*rac*-C-2), 120.5–139.3 (C-5–C-8) (C-4, C-9 not observed) ppm. EI MS: *m*/*z* (%) = 737 (15) [M$^+$ Zr($C_9H_6CH_2CH_2CH_2OSiMe_2tBu)_2Cl_2^+$], 699 (14) [M$^+$ – Cl], 261 (100) [M$^+$ – $C_9H_6CH_2CH_2CH_2OSiMe_2tBu$ – Cl – SiMe$_2$*t*Bu]. $C_{36}H_{54}Cl_2O_2Si_2Zr$ (773.11): calcd. C 58.66, H 7.38; found C 58.39, H 7.33.

Preparation of *rac*-$[Zr(Me_2Si\{\eta^5\text{-}C_9H_5(CH_2CH_2CH_2OSiMe_3)\text{-}3\}_2\text{-}1,1')Cl_2]$ (20): Toluene (100 mL) was added to a solid mixture of [$ZrCl_4(THF)_2$] (2.06 g, 5.47 mmol) and Li$_2$\{Me$_2$Si[C_9H_5-(CH$_2$CH$_2$CH$_2$OSiMe$_3$)-3]$_2$-1,1′\} (**12**) (3.09 g, 5.47 mmol). The resulting pale yellow solution was stirred for 15 h. The mixture was filtered and the filtrate concentrated (10 mL) and cooled to –30 °C to yield an orange solid of the title complex (1.16 g, 30%). ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 0.09 (s, 18 H, 2×OSiMe_3), 1.12 (s, 6 H, SiMe_2), 1.77 and 2.86 (2 m, each 4 H, 4×CH_2CH_2CH$_2$O), 3.55 (m, 4 H, 2×CH_2OSiMe$_3$), 5.81 (s, 2 H, 2×2-H), 7.05 and 7.30 (2 t, J = 8.6 Hz, each 2 H, 2×6-H and 7-H), 7.40 and 7.53 (2 d, J = 8.6 Hz, each 2 H, 2×5-H and 8-H) ppm. ^{13}C{^{1}H} (75 MHz, $CDCl_3$, 25 °C): δ = –1.2 (SiMe_2), –0.2 (OSiMe_3), 24.7, (*C*H$_2$CH$_2$CH$_2$O), 32.9 (CH$_2$*C*H$_2$CH$_2$O), 62.3 (*C*H$_2$OSiMe$_3$), 77.4 and 85.4 (C-1 and C-3) (C-4, C-9 not observed), 117.2 (C-2), 124.5, 124.9, 126.7 and 126.8 (C-5–C-8) ppm. $C_{32}H_{46}Cl_2O_2SiZr$ (709.1): calcd. C 54.20, H 6.54; found C 54.35, H 6.57.

Preparation of $[Zr(Me_2Si\{\eta^5\text{-}C_9H_5(CH_2CH_2CH_2OSiMe_3)\text{-}3\}\text{-}1\{\eta^5\text{-}C_5Me_4\})Cl_2]$ (21): Toluene (100 mL) was added to a solid mixture of [$ZrCl_4(THF)_2$] (2.46 g, 6.53 mmol) and Li$_2$\{Me$_2$Si[C_9H_5-(CH$_2$CH$_2$CH$_2$OSiMe$_3$)-3]-1(C_5Me_4\} (**13**) (2.57 g, 6.53 mmol). The resulting pale yellow solution was stirred for 15 h. The mixture was filtered and the filtrate concentrated to 10 mL and cooled to –30 °C to yield yellow solid of the title complex (0.76 g, 20%). ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 0.08 (s, 9 H, OSiMe_3), 0.94 and 1.17 (2 s, each 3 H, SiMe_2), 1.90, 1.94, 1.95 and 2.00 (4 s, each 3 H, C_5Me_4), 1.98 and 3.00 (2 m, each 2 H, CH_2CH_2CH$_2$O), 3.63 (m, 2

Preparation of [Zr(Me$_2$Si{η^5-C$_9$H$_5$(CH$_2$CH$_2$CH$_2$OSiMe$_2$*t*Bu)-3}-1{η^5-C$_5$Me$_4$})Cl$_2$] (24): The synthesis of **24** was carried out in identical manner to **21**. Li$_2${Me$_2$Si[C$_9$H$_5$(CH$_2$CH$_2$CH$_2$OSiMe$_2$*t*Bu)-3]-1(C$_5$HMe$_4$)} (**16**) (2.56 g, 5.36 mmol) and [ZrCl$_4$(THF)$_2$] (2.02 g, 5.36 mmol). Yield 1.00 g, 30%. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 0.08 (s, 6 H, OSiMe_2*t*Bu), 0.96 and 1.18 (2 s, each 3 H, SiMe_2), 0.90 (s, 9 H, OSiMe_2*tBu*), 1.90, 1.93, 1.94 and 2.00 (4 s, each 3 H, C$_5Me_4$), 1.85 and 3.02 (2 m, each 2 H, CH_2CH_2CH$_2$O), 3.64 (m, 2 H, CH_2OSiMe$_2$*t*Bu), 5.61 (s, 1 H, 2-H), 7.05 and 7.33 (2 t, J = 8.6 Hz, each 1 H, 6-H and 7-H), 7.48 and 7.60 (2 d, J = 8.6 Hz, each 1 H, 5-H and 8-H) ppm. ^{13}C{^{1}H} (125 MHz, $CDCl_3$, 25 °C): δ = –5.0 (OSiMe_2*t*Bu), 1.4 and 1.7 (SiMe_2), 12.4, 12.7, 14.9, 15.5 (C$_5Me_4$), 25.1 ($CH_2CH_2CH_2O$), 26.2 and 18.6 (OSiMe$_2$*tBu*), 33.1 ($CH_2CH_2CH_2O$), 62.8 (CH_2OSiMe$_2$*tBu*), 116.7 (C-2), 124.6 and 125.7 (C-5 and C-8), 126.3 and 126.5 (C-6 and C-7), 84.6, 95.9 (C-1, C-3) (C-4, C-9 not observed), 119.2–138.1 (C_5Me$_4$) ppm. $C_{29}H_{44}Cl_2OSi_2Zr$ (627.0): calcd. C 55.56, H 7.07; found C 55.61, H 7.08.

Preparation of [Zr(Me$_2$Si{η^5-C$_9$H$_5$(CH$_2$CH$_2$CH$_2$O)-3}-1{η^5-C$_5$Me$_4$})Me(*Zr–O*)] (25): The synthesis of **25** was carried out in identical manner to **26**. MgMeBr (3 M in THF) (0.21 mL, 0.63 mmol) and **21a** (0.30 g, 0.63 mmol). Yield: 0.24 g, 83%. ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = –1.13 (s, 3 H, Zr–*Me*), 0.67 and 0.71 (2 s, each 3 H, SiMe_2), 1.70, 1.84, 1.87 and 2.03 (4 s, each 3 H, C$_5Me_4$), 1.56 and 2.65 (2 m, each 2 H, CH_2CH_2CH$_2$O), 3.89 (m, 2 H, CH_2O), 5.97 (s, 1 H, 2-H), 6.91 and 7.14 (2 t, J = 8.6 Hz, each 1 H, 6-H and 7-H), 7.32 and 7.36 (2 d, J = 8.6 Hz, each 1 H, 5-H and 8-H) ppm. ^{13}C{^{1}H} (125 MHz, C_6D_6, 25 °C): δ = –3.1 and –3.0 (SiMe_2), 10.7, 11.8, 14.0 and 14.6 (C$_5Me_4$), 24.5 (Zr–*Me*), 25.9 ($CH_2CH_2CH_2O$), 32.0 ($CH_2CH_2CH_2O$), 68.3 (CH_2O), 115.7 (C-2), 123.9 and 124.0 (C-5 and C-8), 126.1 and 126.2 (C-6 and C-7), 82.20, 93.11 (C-1, C-3) (C-4, C-9 not observed), 117.66–128.74 (C_5Me$_4$) ppm. $C_{24}H_{32}OSiZr$ (455.8): calcd. C 63.24, H 7.08; found C 63.34, H 7.09.

Preparation of [Zr(Me$_2$Si{η^5-C$_9$H$_5$(CH$_2$CH$_2$CH$_2$OSiMe$_2$*t*Bu)-3}-1{η^5-C$_5$Me$_4$})Me$_2$] (26): MgMeBr (3 M in THF) (0.38 mL, 1.15 mmol) was added to a solution of **24** (0.30 g, 0.48 mmol) in THF (50 mL) at –78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 4 h. The solvent was removed in vacuo and hexane (25 mL) added. The mixture was filtered and the solvent was removed from the filtrate in vacuo to yield the title complex (0.24 g, 87%). ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = –1.42 and –0.36 (2 s, each 3 H, Zr–*Me*), 0.04 (s, 6 H, OSiMe_2*t*Bu), 0.98 and 1.83 (2 s, each 3 H, SiMe_2), 0.97 (s, 9 H, OSiMe_2*tBu*), 1.61, 0.50, 0.67 and 1.74 (4 s, each 3 H, C$_5Me_4$), 1.80 and 3.00 (2 m, each 2 H, CH_2CH_2CH$_2$O), 3.55 (m, 2 H, CH_2OSiMe$_2$*t*Bu), 5.45 (s, 1 H, 2-H), 6.88 and 7.16 (2 t, J = 8.6 Hz, each 1 H, 6-H and 7-H), 7.26 and 7.57 (2 d, J = 8.6 Hz, each 1 H, 5-H and 8-H) ppm. ^{13}C{^{1}H} (125 MHz, C_6D_6, 25 °C): δ = –5.0 (OSiMe_2*t*Bu), 11.5 and 25.5 (SiMe_2), 1.0, 1.3, 14.9, 18.4 (C$_5Me_4$), 24.6 ($CH_2CH_2CH_2O$), 25.5 and 21.4 (OSiMe$_2$*tBu*), 33.7 ($CH_2CH_2CH_2O$), 36.5 and 36.7 (Zr–*Me*), 62.3 (CH_2OSiMe$_2$*tBu*), 117.5 (C-2), 126.3 and 124.2 (C-5 and C-8), 124.0 and 127.7 (C-6 and C-7), 80.11, 90.38 (C-1, C-3) (C-4, C-9 not observed), 120.8–129.5 (C_5Me$_4$) ppm. $C_{31}H_{50}OSi_2Zr$ (586.1): calcd. C 63.52, H 8.60; found C 63.68, H 8.64.

X-ray Crystal-Structure Determination of [(Zr{C$_9$H$_6$-(CH$_2$CH$_2$CH$_2$O)-1}Cl$_2$)$_2$(*Zr–O*)] (17a): Intensity data were collected with a NONIUS-MACH3 diffractometer equipped with a graphite monochromator and a Mo-K_α radiation source (λ = 0.71073 Å) using an $\omega/2\theta$-scan technique. The final unit-cell parameters were determined from 25 well-centered reflections and refined by least-squares methods. Data were corrected for Lorentz and polarization effects but not for absorption. The structure was solved by direct methods using the SHELXS computer program[24]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and refined on F^2 by full-matrix least squares (SHELXL-97).[25] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in calculated positions and were refined with an overall isotropic temperature factor using a riding model. Weights were optimized in the final cycles. Crystallographic data are given in Table 4. CCDC-259059 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]^{0.5}$.

Homogeneous Polymerization Experiments: Polymerizations were carried out in a 1-L glass reactor using toluene as a solvent (250 mL). Catalysts (33 μmol) were treated with the appropriate quantity of a solution of MAO in toluene (10% Al) for 15 min. Toluene (230 mL), TIBA scavenger (2 mL) and activated catalyst were introduced, in this order, into the reactor and the temperature was fixed at 343 K. The nitrogen was removed and a continuous flow of ethylene (1.5 bar) was introduced over 30 min. The reaction mixture was then quenched by the addition of acidified methanol. The polymer was collected by filtration, washed with methanol and dried under vacuum at room temperature for 24 h.

Heterogeneous Polymerization Experiments: The supported catalysts were prepared under an inert gas using Schlenk techniques and a glove-box. A solution of the zirconocene complex (quantity needed to obtain a theoretical level of 1% Zr/SiO_2) in toluene (30 mL) was added to partially dehydroxylated silica (1.00 g) and the mixture was stirred at 333 K for 16 h. The slurries were filtered through fritted discs and washed with toluene (10×20 mL). The resultant solids were carefully washed with toluene and dried under vacuum. Polymerizations were carried out in a 1-L glass reactor using toluene as a solvent (250 mL). The supported catalysts (approx. 300 mg) were treated with the appropriate quantity of a solution of MAO in toluene (10% Al) for 15 min. The solvent and the volatiles were removed in vacuo. Toluene (230 mL), TIBA scavenger (2 mL) and activated catalyst in freshly distilled toluene (20 mL) were introduced, in this order, into the reactor and the temperature was fixed at 343 K. The nitrogen was removed and a continuous flow of ethylene (1.5 bar) was introduced over 30 min. The reaction mixture was then quenched by the addition of acidified methanol. The polymer was collected by filtration, washed with methanol and dried under vacuum at room temperature for 24 h.

Synthetic Applications of Lawesson's Reagent in Reactions with Cu^{I} Alkoxides

Weifeng Shi[a] and Alexander Rothenberger*[a]

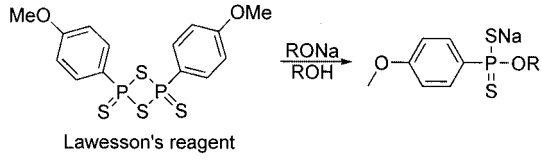
Dedicated to Prof. Reinhart Ahlrichs on the occasion of his 65th birthday

Keywords: Metal alkoxide / P ligands / S ligands / Elimination

The reaction of Lawesson's reagent with CuO*t*Bu and tertiary phosphanes produced the complexes $[Cu_2(\mu_2\text{-}ArS_2P\text{–}O\text{–}PS_2Ar)(PPh_3)_4]$ (**1**) (Ar = *p*-C_6H_4OMe) and $[Cu_4\{Ar(\mu_2\text{-}S)_2P\text{–}O\text{–}P(\mu_2\text{-}S)_2Ar\}_2(dppa)_2]$ (**2**) (dppa = $Ph_2PNHPPh_2$) in high yields. The ligand $[ArS_2P\text{–}O\text{–}PS_2Ar]^{2-}$ is the first of a new family of dianionic P/S ligands.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Coordination chemistry with phosphorus- and sulfur-containing ligands is still an active area of research.[1] The motivation for research in this field is diverse and includes the use of thio-functionalised organophosphorus compounds as additives to vulcanisation processes, as precursors for CVD processes and as insecticides.[2–4] Recent activities in this field made use of silyl esters of diphenylphosphanyldithioic and phenyltrithiophosphonic acid as starting materials for coinage metal clusters.[5] Also the coordination chemistry of other P/S-containing anions, e.g., phosphorodithioato and -selenolato anions $[(RO)_2PE_2]^-$ (R = organic group; E = S, Se), with transition metal cations has received much attention.[6] Lawesson's reagent,[7] widely known as a powerful thionation reagent in organic synthesis, offers another route to complexes containing P/S-based anionic ligands (Scheme 1).[8]

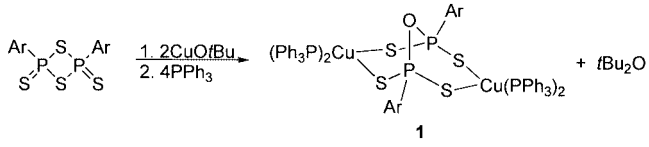


Scheme 1. Synthesis of sodium phosphonodithioate salts (R = Me, Et, *i*Pr).

Metathesis of the sodium phosphonodithioate salts (Scheme 1) gave rise to several metal complexes.[8] The generated *O*-alkyl (4-methoxyphenyl)phosphonodithioato ligands are bidentate and chelate metal atoms via the S atoms, whilst the introduced alkoxide group is not involved in coordination. As part of a wider study of the reactivity of late transition metal alkoxides, we have studied reactions of CuO*t*Bu with Lawesson's reagent in aprotic solvents and report here the first results.

Results and Discussion

When Lawesson's reagent was heated with 2 equiv. of CuO*t*Bu in toluene, a yellow precipitate was formed which dissolved upon addition of PPh_3. Crystallization from a mixture of dichloromethane and pentane gave, to our surprise, no phosphane-stabilised copper(I) phosphonodithioate, which could have been regarded as analogous compound to the sodium phosphonodithioate salts prepared by Woollins et al. (Scheme 1).[8] Instead, the Cu^{I} pyrophosphonodithioate $[Cu_2(\mu_2\text{-}ArS_2P\text{–}O\text{–}PS_2Ar)(PPh_3)_4]$ (**1**) (Ar = *p*-C_6H_4OMe) was obtained in 80% yield (Scheme 2).



Scheme 2. Synthesis of **1** (Ar = *p*-C_6H_4OMe).

The structure of **1** was initially determined by X-ray analysis (Figure 1). The dianionic ligand $[ArS_2P\text{–}O\text{–}PS_2Ar]^{2-}$ generated in the reaction of CuO*t*Bu with Lawesson's reagent bridges two $[Cu(PPh_3)_2]^+$ ions. Compound **1** is consists of two puckered annulated six-membered $[CuS_2P_2O]$ rings and an organic shell of phenyl rings of the PPh_3

 DOI: 10.1002/ejic.200500220 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ligands (each one disordered over two positions; 50:50) and *p*-C_6H_4OMe groups from Lawesson's reagent. The Cu^I centres show a distorted tetrahedral coordination environment.

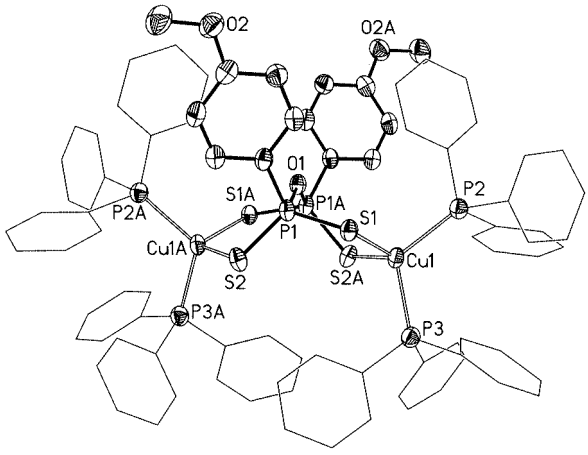

Figure 1. Molecular structure of **1** in the solid state (ellipsoids at 50% probability level; hydrogen atoms are omitted for clarity; label A denotes symmetry operation $-x + 1, y, -z - 1/2$). Selected bond lengths [Å] and angles [°]: Cu(1)–P(3) 2.3181(15), Cu(1)–P(2) 2.3193(14), Cu(1)–S(1) 2.3643(14), Cu(1)–S(2A) 2.3749(15), P(1)–O(1) 1.640(2), P(1)–S(2) 1.9909(17), P(1)–S(1) 1.9927(16); O(1)–P(1)–S(2) 110.33(12), O(1)–P(1)–S(1) 110.01(7), S(2)–P(1)–S(1) 117.41(8), P(1A)–O(1)–P(1) 130.3(3).

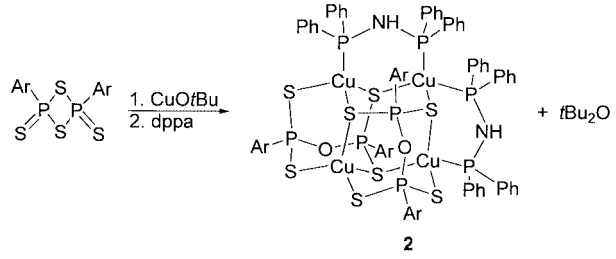
The P–O and P–S distances in **1** are in good agreement with values observed in $[K_2(C_{10}H_6)PS_2(\mu\text{-}O)PS_2]$, which is the closest related compound to **1**.[9] The $^{31}P\{H\}$ NMR spectrum was recorded from crystals of **1** dissolved in $CDCl_3$ (verified by redetermination of the unit cell). Resonances at $\delta = 91.5$ ppm for the generated $[ArS_2P\text{–}O\text{–}PS_2Ar]^{2-}$ dianion and at $\delta = -3.6$ ppm for coordinated PPh_3 ligands were observed and the IR spectrum showed a strong band at $\tilde{\nu}_{as}(P\text{–}O\text{–}P) = 841\ cm^{-1}$. The detailed mechanism of the formation of the $[ArS_2P\text{–}O\text{–}PS_2Ar]^{2-}$ dianion in **1** is difficult to confirm. We propose the initial formation of an intermediate Cu^I phosphonodithioate salt $[ArP(OtBu)S_2Cu]$, which instantly decomposes to form tBu_2O and **1**. It was impossible to isolate and characterize intermediate complexes. The separation of tBu_2O from the solvent toluene cannot be achieved by distillation, and in GC/MS experiments tBu_2O was not detected due to large solvent excess. The reaction was therefore performed in C_6D_6 and all volatile products were distilled off. Redistillation into an NMR tube afforded a sample containing tBu_2O formed in the reaction (Supporting Information; for Supporting Informations see also the footnote on the first page of this article). Reactions of CuO*t*Bu with Lawesson's reagent in the presence of several different phosphane ligands were also performed. Addition of dppa (dppa = $Ph_2PNHPPh_2$) afforded the tetranuclear complex $[Cu_4\{Ar(\mu_2\text{-}S)_2P\text{–}O\text{–}P(\mu_2\text{-}S)_2Ar\}_2(dppa)_2]$ (**2**) (Scheme 3, Figure 2).



Scheme 3. Synthesis of **2** (Ar = *p*-C_6H_4OMe; dppa = $Ph_2PNHPPh_2$).

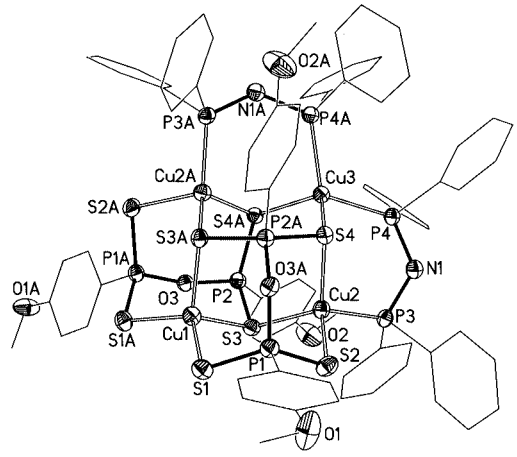


Figure 2. Molecular structure of **2** in the solid state (ellipsoids at 50% probability level; hydrogen atoms are omitted for clarity). Label A denotes symmetry operation $-x - 1, y, -z + 3/2$. Selected bond lengths [Å] and angles [°]: Cu(1)–S(1) 2.2958(16), Cu(1)–S(3) 2.3394(19), Cu(2)–P(3) 2.2209(19), Cu(2)–S(3) 2.3178(16), Cu(2)–S(4) 2.337(2), Cu(2)–S(2) 2.3570(17), Cu(3)–P(4) 2.3318(18), Cu(3)–S(4) 2.3641(16), S(1)–P(1) 1.994(2), S(2)–P(1) 1.990(3), S(3)–P(2) 2.011(2), S(4)–P(2A) 2.027(2), P(1)–O(3A) 1.662(5), P(2)–O(3) 1.613(4), P(2)–S(4A) 2.027(2), P(3)–N(1) 1.707(6), P(4)–N(1) 1.709(5); O(3A)–P(1)–S(2) 109.66(19), O(3A)–P(1)–S(1) 110.14(17), S(2)–P(1)–S(1) 118.99(12), O(3)–P(2)–S(3) 108.20(18), S(3)–P(2)–S(4A) 119.43(10), P(3)–N(1)–P(4) 127.3(3), P(2)–O(3)–P(1A) 136.3(3).

In the solid state **2** consists of two fused adamantane cage frameworks in which two $[ArS_2P\text{–}O\text{–}PS_2Ar]^{2-}$ dianions coordinate the Cu atoms Cu(1,2,2A). Cu(3) is located in the periphery of the cluster and two dppa ligands complete the remaining coordination sites of Cu(2,2A,3). Like in **1**, Cu atoms in **2** exhibit distorted tetrahedral coordination environments but the new ligand $[Ar(S)_2P\text{–}O\text{–}PS_2Ar]^{2-}$ now bridges two Cu atoms via the S atoms S(3,3A,4,4A), whilst the remaining S atoms S(1,1A,2,2A) are coordinated to one Cu atom each. Spectroscopic data and observed bond lengths in **2** verify the uniform composition of crystals of **2** and can be compared with **1** or $[K_2(C_{10}H_6)PS_2(\mu\text{-}O)PS_2]$.[9]

Conclusions

The results presented here show that the reaction of the Cu^I alkoxide CuO*t*Bu and Lawesson's reagent in toluene produces Cu^I complexes containing the new dianionic ligand

$[ArS_2P–O–PS_2Ar]^{2–}$ in high yield. Currently, investigations in this area are extended to different Lawesson-type reagents, metal alkoxides and phosphane ligands. Studies of the influence of organic substituents of transition metal alkoxides on the fragmentation of Lawesson-type reagents will be the subject of future work in this area. Compounds **1** and **2** are the first representatives of a range of metal complexes currently prepared using these ligands and illustrate that a variety of coordination modes is to be expected.

Experimental Section

General Remarks: All operations were carried out under purified dinitrogen. Toluene was dried with sodium, dichloromethane was dried with CaH_2, pentane was dried with $LiAlH_4$ and freshly distilled. Chemicals were purchased from Aldrich. Cu*O*t*Bu and dppa were prepared according to published procedures.[10,11]

1: To a solution of Lawesson's reagent (202 mg, 0.50 mmol) in toluene (12 mL) was added dropwise a solution of Cu*O*t*Bu (136 mg, 1.00 mmol) in toluene (10 mL). The resulting yellow solution was refluxed for about 5 h during which time a color change to brown and the formation of a yellow precipitate was observed. The precipitate was dissolved by addition of a solution of PPh_3 (524 mg, 2.0 mmol) in toluene (10 mL). The solvent was removed under reduced pressure. Addition of CH_2Cl_2 (3 mL) and pentane (5 mL) and storage of the solution at room temp. for 1 d produced colorless crystals; yield 0.68 g (81%); m.p. 194 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 7.9–6.7 (m., 19 H, ar. H), 3.8 (s, 3 H, OCH_3) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 161.5–113.1 (ar. C), 55.3 (s, OCH_3) ppm. ^{31}P NMR (162 MHz, $CDCl_3$, 25 °C, 65% H_3PO_4): δ = 91.2 (s, $ArPS_2O$), –3.6 (s, $CuPPh_3$) ppm. IR (KBr): $\tilde{\nu}$ = 3046 w, 1593 s, 1431 (P–C), 1250 s, 1105 s, 841 s (P–O–P), 657 s (P=S) cm^{-1}. $C_{86}H_{74}Cu_2O_3P_6S_4$ (1594.2): calcd. C 64.6, H 4.6; found C 64.4, H 4.6.

2: To a solution of Lawesson's reagent (202 mg, 0.50 mmol) in toluene (12 mL) was added dropwise a solution of Cu*O*t*Bu (136 mg, 1.00 mmol) in toluene (10 mL). The resulting yellow solution was refluxed for about 5 h during which time a colour change to brown and the formation of a yellow precipitate was observed. The precipitate was dissolved by addition of a solution of dppa (385 mg, 1.00 mmol) in toluene (10 mL). The solvent was removed under reduced pressure. Addition of CH_2Cl_2 (3 mL) and pentane (5 mL) and storage of the solution at room temp. for 1 d produced colorless crystals of **2**; yield 0.42 g (79%); m.p. 201 °C. ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 8.1–6.9 (m., 24 H, ar. H), 5.4 (s, 1 H, NH, next to peak of CH_2Cl_2), 3.9–3.8 (s, 3 H, OCH_3) ppm. ^{13}C NMR (100 MHz, CD_2Cl_2, 25 °C): δ = 162.2–113.5 (10 C, ar. C), 55.8 (s, 1 C, OCH_3) ppm. ^{31}P NMR (162 MHz, CD_2Cl_2, 25 °C, 65% H_3PO_4): δ = 89.1 (s, $ArPS_2O$), 38.3 (br. s, $NPPh_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3297 w (N–H), 3051 w, 1596 s, 1435 s (P–C), 1258 s, 1107 s, 880 bs (P–O–P), 694 s (P=S) cm^{-1}. $C_{76}H_{68}Cu_4N_2O_6P_8S_8$ (1859.8): calcd.C 48.9, H 3.7; found C 49.3, H 3.8.

X-ray Crystallographic Study: Data for **1** and **2** were collected with a STOE IPDS II diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods and refined by full-matrix least squares on F^2 (all data) using the SHELXTL program package.[12] Hydrogen atoms were placed in calculated positions, non-hydrogen atoms were assigned anisotropic thermal parameters. Disordered components were refined with isotropic thermal parameters. Crystal data for **1**: $C_{86}H_{74}Cu_2O_3P_6S_4CH_2Cl_2$; M = 1681.52; monoclinic, space group $C2/c$; Z = 4; a = 22.431(5), b = 13.711(3), c = 26.435(5) Å, β = 104.20(3)°; V = 7882(3) Å^3; T = 100(2) K; $F(000)$ = 3472; $D_{calcd.}$ = 1.417 g·cm^{-3}. 29604 reflections measured, of which 8548 were unique (R_{int} = 0.0485); 238 parameters; final wR_2 = 0.2063 (all data); R_1 = 0.0742 [$I > 2\sigma(I)$]; largest difference peak/hole 2.446/–1.145 e·Å^{-3}. Crystal data for **2**: $C_{76}H_{68}Cu_4N_2O_6P_8S_83CH_2Cl_2$ M = 2130.51; monoclinic, space group $C2/c$, Z = 4; a = 18.457(4), b = 19.747(4), c = 24.311(5) Å, β = 93.66(3)°; V = 8843(3) Å^3; T = 100(2) K; $F(000)$ = 4328; $D_{calcd.}$ = 1.600 g cm^{-3}. 13293 reflections measured, of which 7876 were unique (R_{int} = 0.0460); 509 parameters; final wR_2 = 0.2042 (all data); R_1 = 0.0682 [$I > 2\sigma(I)$]; largest difference peak/hole 0.995/–1.633 e·Å^{-3}. CCDC-263199 and -263200 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see footnote on the first page of this article): NMR spectra of tBu_2O formed during the reaction.

COVER PICTURE

The cover picture shows the potential energy curves for a generic valence tautomeric complex with a schematic representation emphasizing the intramolecular electron transfer between the metal ion and the ligand, which can be induced by different external stimuli such as temperature, pressure or irradiation. The diagram is accompanied by a representation of the different redox-active ligands involved in valence tautomerism that are presented in the Microreview by E. Evangelio and D. Ruiz-Molina on p. 2957 ff.

Valence Tautomerism: New Challenges for Electroactive Ligands

Emilia Evangelio[a] and Daniel Ruiz-Molina*[a]

Keywords: Valence tautomerism / Electroactive / Intramolecular electron transfer / Bistability / Switch

Valence tautomeric complexes combine redox-active ligands and transition metal ions with two or more accessible oxidation states, exhibiting two nearly degenerated electronic states with localized electronic structures. Charge distribution in such electronic isomers has an appreciable sensitivity to the environment so an external perturbation, like photons, temperature and/or pressure, may lead to an intramolecular electron transfer between both redox active units and therefore to a reversible interconversion between the two degenerated electronic states. Moreover, since each electronic isomer exhibits different optical, electronic and/or magnetic properties, these complexes are being proposed as candidates for future use in molecular electronic devices and switches. Most of the valence tautomeric complexes reported thus far are based on quinone or quinone-type ligands with a series of transition metal ions such as Co, Cu, Ni and Mn. Nevertheless, in the last few years, the number of electroactive ligands identified to be active in valence tautomeric complexes is being expanded by including new radical ligands such as polychlorotriphenylmethyl, phenoxyl or tetraphenylporphyrin radicals.

Introduction

Development of molecular-scale systems that exhibit intramolecular electron-transfer phenomena induced by external stimuli has attracted considerable attention.[1] The interest is twofold. First, the possibility of inducing a reversible change in the electronic distribution of a molecular system opens the door to their potential use in information storage and integrated molecular-sized devices. And second, from a theoretical point of view, to study the role of various parameters governing the intramolecular electron transfer (IET) rates. Mixed-valence systems are excellent candidates for such studies since they contain at least two redox sites with different oxidation states linked by a bridge that medi-

Emi Evangelio was born in Barcelona, Spain, in 1977. She studied Chemistry at the University of Barcelona where she received her laureate degree in 2002 and Masters degree in 2004 with the work "Organometallic Compounds of Platinum(II) and Platinum(IV) Derivatives from Phenanthrene and Anthracene". She is currently busy with a PhD at the Institut de Ciència de Materials de Barcelona. Her research is devoted to structural, magnetic and optical properties of catechol compounds and derivatives.

Daniel Ruiz-Molina obtained his PhD in 1996 at the Institut of Materials Science of Barcelona (ICMAB) working with Prof. J. Veciana. His work focused on the controlled synthesis of dendrimers and magnetic organic materials. In 1997, he joined Hendrickson's Group at UCSD as a postdoctoral research fellow for three years. His project involved the synthesis and characterization of new molecular switches and single-molecule magnets. Since July 2001, he holds a permanent position at the ICMAB. His main interests are the preparation and characterization of multifunctional molecular materials and switches (optical, magnetic and electric properties) and the preparation of molecular ordered arrays on surfaces (2D) for molecular electronics.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ates the transfer of electrons from one site to the other.[2] Depending on the strength of the interaction between the redox centers, Robin and Day[3] classified the mixed-valence systems into three main groups. The potential energy curves for the three types of mixed-valence compounds, which represent the systems for any geometry along the nuclear coordinate, are shown in Figure 1.

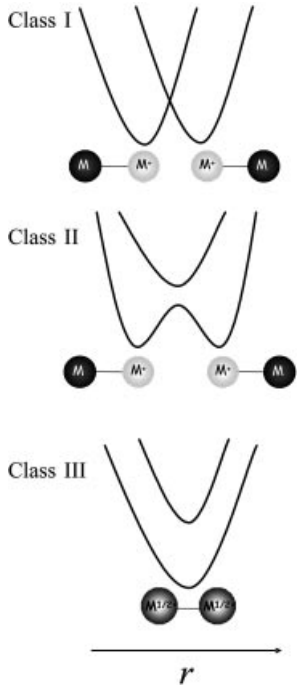

Figure 1. Potential energy curves for mixed-valence systems. The curves are arranged into three main groups according to the Robin and Day classification. In Class I the interaction between the redox centers is negligible; in Class II the interaction between the redox centers is weak or moderate and in Class III the electronic interaction is so intense that the electron is completely delocalized over the molecule.

In the Class I mixed-valence systems the interaction between the redox centers is zero or extremely weak and, therefore, the system only exhibits the properties of the isolated redox units. Even if the molecule acquires sufficient activation energy to reach the intersection region, the probability of electron exchange would be negligible. On the contrary, in Class III mixed-valence systems the electronic interaction is so intense that the electron is completely delocalized over the entire molecule. Then, the properties of each isolated unit are no longer observed and new properties associated with the delocalized species appear. Finally, for Class II systems the interaction between the redox centers is moderate. The electronic interaction has almost no effect on the potential energy curves in the vicinity of the equilibrium geometries but causes mixing in the vicinity of the crossing point. In other words, the electron is vibrationally localized in one of the redox centers due to the presence of an activation energy barrier (ΔG), although such a barrier may be overcome by an external optical or thermal stimulus, to promote an IET process.

The study of molecular mixed-valence class II systems was initiated by Taube's seminal work on compounds such as $[(NH_3)_5Ru\text{-bridge-}Ru(NH_3)_5]^{5+}$. Since then, most of the mixed-valence complexes that have been shown to exhibit intramolecular electron-transfer phenomena are homo- and heteronuclear metallic complexes where the two metal atoms with different oxidation states are connected through an organic bridging ligand.[4] From them, ruthenium complexes and ferrocene moieties have been widely used thanks to their great stability, ease of oxidation and their kinetic inertness.[5] Mixed-valence molecular systems where the electro-active units are pure organic groups have so far received less attention, probably due to their high instability,[6] although for these systems electron transfer could be fine-tuned in a far more precise manner thanks to the flexibility of organic synthesis. The different types of electroactive organic units used thus far are: i) anion radicals derived from conjugated diquinones and diimides,[7] ii) cation radicals derived from bis(tetrathiafulvalenes),[8] iii) cation radicals derived from bis(hydrazines),[9] iv) quinoid groups[10] and v) ion radicals derived from π-conjugated polyarylmethyl/polyarylamines[11] and polychlorotriphenylmethyl radicals.[12] In most of these cases the intramolecular electron transfer is mediated through an organic bridge and only in a few cases does it take place through a bridging metal ion.[13]

Finally, a third type of class II mixed-valence systems is the heterogeneous complexes combining both redox-active ligands and transition metal ions. Some complexes with non-innocent electro-active ligands exhibit a reversible intramolecular electron transfer between the metal ion and the ligand, leading to an internal charge redistribution and therefore to the existence of two different electronic isomers. This family of complexes, termed Valence Tautomeric (VT), is of considerable interest. First, they are unique model systems, which provide insight into the basic factors affecting intramolecular electron transfer in coordination complexes. And second, from an applied perspective, the large changes in the optical, structural, and magnetic properties that often accompany the valence tautomeric interconversion have potential applications in bistable molecular switching materials and devices. In this review, we will first give a brief introduction to the concepts of valence tautomerism, its origin, physical properties and interconversion mechanisms. In a subsequent section, we will make a compendium of the different redox-active ligands used thus far in valence tautomeric complexes, and we will finally mention some new ideas based on the combination of valence tautomeric equilibrium with additional redox reactions involved with the redox-active ligand.

Valence Tautomerism

Valence tautomeric metal complexes with at least two redox-active centers, the metal ion and an electro-active ligand, are characterized by the existence of two electronic isomers (valence tautomers) with different charge distribu-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tions, and consequently, different optical, electric and magnetic properties. The interconversion between the different electronic isomers is accomplished by a reversible intramolecular electron transfer involving the metal ion and the redox active ligand, analogous with that observed for Prussian blue analogs.[14] A schematic representation of valence tautomerism together with the corresponding potential energy curve plotted as a function of the nuclear coordinate, is shown in Figure 2.

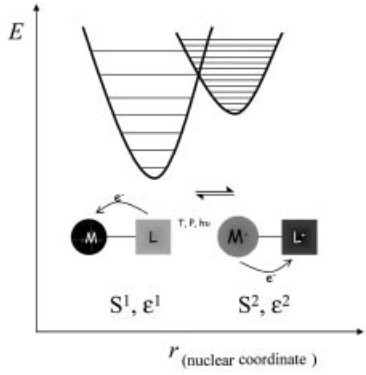

Figure 2. Potential energy curves for a valence tautomeric complex with a schematic representation emphasizing the intramolecular electron transfer between the metal ion and the ligand.

One of the first descriptions of valence tautomerism and an excellent example of the above mentioned charge distribution sensitivity is exhibited by the cobalt bis(quinone) complex [Co^{III}(3,5-DTBCat)(3,5-DTBSQ)(bpy)] (**1**), where 3,5-$DTBCat^{2-}$ and 3,5-$DTBSQ^{-}$ refer, respectively, to the catecholate (Cat^{2-}) and semiquinonate (SQ^{-}) forms of 3,5-di-*tert*-butyl-o-quinone, and bpy is 2,2′-bipyridine.[15] In solution, the equilibrium in Equation (1) can be induced by variations of temperature and monitored by magnetic measurements and spectroscopic techniques such as UV/Vis, NMR and/or EPR spectroscopy.[16]

$$[Co^{III}(3,5\text{-DTBCat})(3,5\text{-DTBSQ})(bpy)]\ (\mathbf{1},\ ls\text{-}Co^{III}) \rightleftharpoons [Co^{II}(3,5\text{-DTBSQ})_2(bpy)]\ (\mathbf{1},\ hs\text{-}Co^{II}) \quad (1)$$

For instance, a solution of complex **1** in toluene at low temperatures shows a band at 600 nm characteristic of the **1**, *ls*-Co^{III} tautomer. An increase of temperature promotes an intramolecular electron transfer so the **1**, *ls*-Co^{III} converts into the **1**, *hs*-Co^{II} tautomer as one of the ligands is oxidized by one electron from a Cat^{2-} to an SQ^{-} ligand. As a consequence, the intensity of the 600 nm band decreases and a band at 770 nm characteristic of the **1**, *hs*-Co^{II} tautomer increases in intensity (see Figure 3). Accompanying the optical changes, variations in the magnetic response are also observed. The **1**, *ls*-Co^{III} isomer has an $S = 1/2$ ground state whereas the **1**, *hs*-Co^{II} isomer has an $S = 2$ ground state.

This interconversion is an entropy-driven process, analogous with the extensively studied low-spin to high-spin crossover phenomena. The large entropy gain arises from: 1) a gain in electronic entropy due to the higher spin state degeneracy of the *hs*-Co^{II} form and 2) the higher density of vibrational states of the *hs*-Co^{II} form due its longer metal-ligand bond lengths. Thus thermal population of tautomeric states is dictated by the Gibbs free energy expression shown in Equation (2). At low temperatures, $T\Delta S$ is negligible compared to ΔH, and consequently if $\Delta H > kT$ only the *ls*-Co^{III} state is populated. An increase in the temperature will increase the $T\Delta S$ contribution, making it non-negligible and favoring the population of the *hs*-Co^{II} state, up to a critical temperature T_c where $\Delta G = 0$ and $\Delta H = T\Delta S$. A further increase in the temperature will change the sign of ΔG.

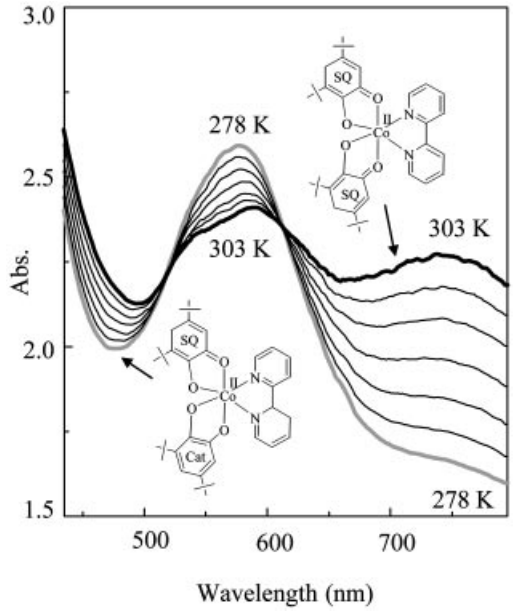

Figure 3. Temperature dependence of the electronic absorption spectrum of a CH_2Cl_2 solution of complex **1**.

$$\Delta G = \Delta G_{hs\text{-}Co^{II}} - \Delta G_{ls\text{-}Co^{III}} = \Delta H - T\Delta S \quad (2)$$

It is important to emphasize that whereas most of the valence tautomeric complexes reported thus far exhibit a temperature-dependent interconversion in solution, the number of examples exhibiting a valence-tautomeric interconversion in the solid state is rather limited. For this, the presence of solvate molecules within the crystalline network and their effects on the phonon relaxation, play a critical role. For instance, a plot of the magnetic susceptibility vs. temperature for a sample of complex **2** recrystallized from four different solvents is shown in Figure 4. In this figure it is shown that for complex [Co^{III}(3,5-DTBSQ)(3,5-DTBCAT)(phen)]·$C_6H_5CH_3$ (**2**), the tautomeric interconversion between the **2**, *ls*-Co^{III} and **2**, *hs*-Co^{II} isomers can be reversibly driven with temperature and monitored by large changes in the magnetic susceptibilities, with an interconversion that occurs abruptly within a narrow temperature range of ca. 30 °C. On the contrary, a polycrystalline sample recrystallized from ethanol has a μ_{eff} value essentially independent of the temperature and close to the value of 1.7 μ_B expected for the low-spin isomer. For samples recrystallized from acetonitrile and dichloromethane, incomplete transitions were observed (see Figure 4).[17]

Moreover, since valence tautomeric complexes are electronically labile, they exhibit significant vibronic interactions and therefore an appreciable sensitivity to the environment. As a consequence, intramolecular electron transfer can be induced not only by temperature variations but also by irradiation or pressure.

Light-Induced Tautomerism

Adams et al. reported results of the first picosecond time-resolved optical experiments on valence tautomeric complexes in solution.[18] In such work, pulsed laser photolysis, both on the picosecond (90 ps pulse) and the nanosecond (24 ns pulse) time-scales, were carried out for a series of complexes with the general formula [Co(3,5-DTBSQ)$_2$-(N-N)]. The authors showed that when the complex is in the *ls*-Co^{III} form, a laser pulse could it excite it to a LMCT excited state. Such excited states experience a rapid intersystem crossing to the *hs*-Co^{II} state with a subsequent electron recombination to finally yield the *ls*-Co^{III} isomer. At room temperature, the rate of *hs*-Co^{II} to *ls*-Co^{III} conversion (k_{bvt}) ranges from 6.1×10^7 to 6.7×10^8 s^{-1} and its temperature dependence follows an Arrhenius-like behavior in the 140–300 K range. However, below 140 K, deviations from linearity are seen, most likely due to the involvement of quantum mechanical tunneling. Valence tautomerism for this family of complexes was also shown to take place in the solid state after illumination at low temperatures.[19] For instance, variations on the μ_{eff} vs. T plot of [Co^{III}(3,5-DTBSQ)(3,5-DTBCAT)(phen)]·C_6H_5Cl (**2**) before and after illumination are shown in Figure 5.[20] Similar interconversion in the solid state has been reported by Dei et al. for the new dinuclear complex [{Co(cth)}$_2$(dhbq)](PF$_6$)$_3$ (**3**), both by irradiation with a laser connected to the SQUID magnetometer and by reflectivity spectra.[21] Their results showed that the light-induced phenomenon is perfectly reversible although the photoinduced population rate corresponds to only 43% of the sample, most likely due to opacity phenomena.

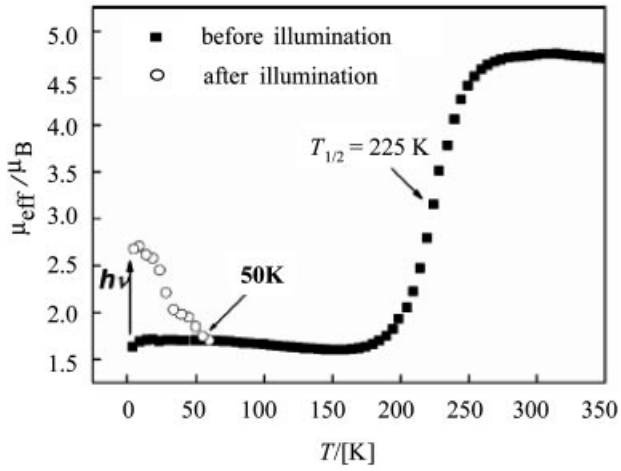

Figure 5. Plot of the χT product as a function of temperature T for complex **3** measured before and after irradiation at 647 nm. The bump at 45 K on the irradiation curve is a result of a small amount of oxygen.

Finally, additional femtosecond spectroscopic experiments by Neuwahl et al. in a simple cobalt-dioxolene derivative in solution demonstrated the involvement of not two but at least three states in a two-step process for a valence tautomeric interconversion in solution.[22] Besides the Co^{III}-Cat and Co^{II}-Sq pairs involved in the tautomerism, the third species may originate from several possible electronic isomers, such as a Co^{III}-Cat species with divergent electronic congurations or a low-spin Co^{II}-Sq isomer, which is expected to be characterized by a triplet electronic ground state.

Pressure-Induced Tautomerism

The X-ray structure analysis of complex **2** at three different temperatures (137, 238 and 295 K) revealed an average metal-ligand bond length increase of 0.18 Å on passing from the **2**, *ls*-Co^{III} to the **2**, *hs*-Co^{II} tautomer. As shown in Figure 6, such a change is due to a drastic change in the population of the antibonding e_g* orbitals.

Such increase of the molecular size when passing from the low-spin to the high-spin isomer has also been used to modulate valence tautomerism by pressure effects.[23] Verdaguer et al.[24] studied the nonsolvated complex **2** and its related solvated form [Co^{II}(3,5DTBSQ)$_2$(phen)]·$C_6H_5CH_3$ by EXAFS and XANES. EXAFS data indicated that the **2**, *hs*-Co^{II} tautomer has bond lengths of Co–O = 2.08 Å and Co–N = 2.13 Å whereas the **2**, *ls*-Co^{III} tautomeric complex is smaller with Co–O = 1.91 Å and Co–N = 1.93 Å. Both complexes could be reversibly driven from the larger **2**, *hs*-Co^{II} tautomer to the smaller **2**, *ls*-Co^{III} tautomeric form upon application of pressure, within the 0.075–0.700 GPa

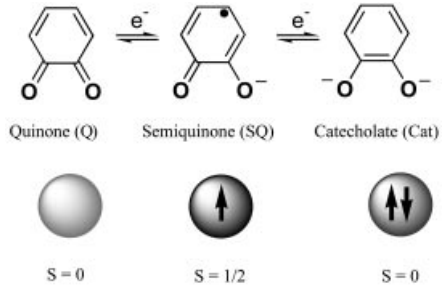
range for the solvated form and 0.10–2.5 GPa for the non-solvated form. In addition to EXAFS and XANES, pressure-induced valence tautomerism has also been recently monitored by changes in the magnetic response.[25]

Redox-Active Ligands

So far, many different types of redox-active ligands have been described in the literature. Among them are π-conjugated molecules with coordinating capabilities such as quinone-types,[26] crown-ethers,[27] ferrocene,[28] tetrathiafulvalenes derivatives,[29] and polymers/oligomers,[30] such as polyanilines and polythiophenes.[31] However, we must emphasize that even though the number of metal complexes based on redox-active ligands is considerable, those exhibiting valence tautomerism are rather limited since they must simultaneously satisfy two conditions: 1) the degree of covalency in the interaction between metal ion and electroactive ligand must be low, and 2) the energy of their frontier orbitals must be similar.[32] In other words, it is necessary that these complexes exhibit localized electronic structures, low orbital mixing, and a small energy difference between the two electronic tautomers. Most of the valence tautomeric complexes reported thus far are based on quinone or quinone-type ligands with a series of transition metal ions. Nevertheless, in the last few years the number of electroactive ligands inducing valence tautomerism is being expanded by including new electroactive ligands such as schiff-base, phenoxyl, tetraphenylporphyrin and polychlorotriphenylmethyl radicals. Examples of each case are revised below.

Quinone Ligands

Metal dioxolene complexes have been the subject of a vigorously growing and fascinating research field for a long time due to their rich structural, physical and chemical properties.[33] In addition to exhibiting valence tautomerism, the subject of the present review, several other interesting features such as the design of paramagnetic molecules with predetermined spin topologies[34] and activation of small molecules like O_2 and N_2 have also been described.[35] Most of these interesting features are related to their rich redox activity, since they are "noninnocent" electroactive ligands that may exist as neutral quinones (Q), radical semiquinones (SQ^{-}) or dianionic catecholates (Cat^{2-}) (Scheme 1), although in valence tautomeric complexes they are only found in the SQ^{-} and Cat^{2-} forms due to the limiting binding ability of the quinone ligand.[36] Charge localization within the metal-quinone chelate ring has been observed for different transition metal complexes (cobalt, manganese, nickel and copper among them),[37] allowing the observation in some cases of valence tautomerism. However, in other cases such as for ruthenium complexes, charge distribution is less clear and a delocalized electronic structure may be an appropriate description.[16]



Scheme 1.

Cobalt Complexes

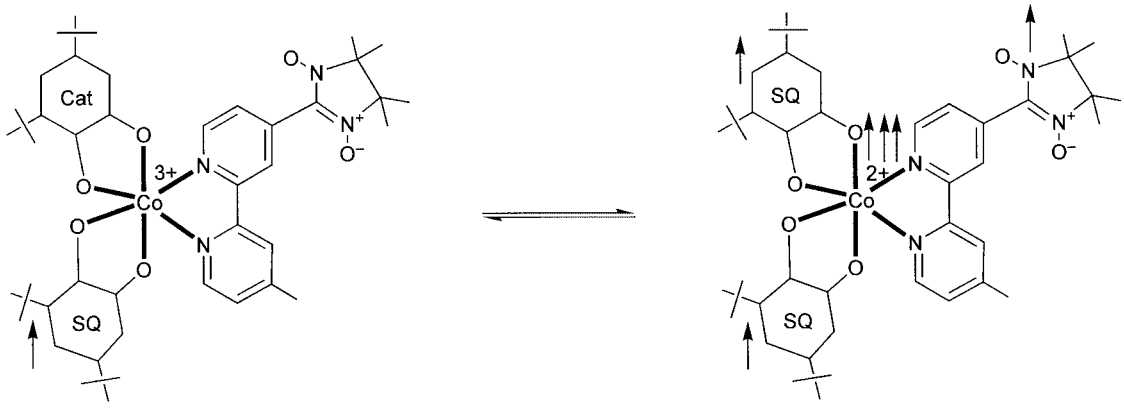
The best investigated family of quinone-based valence tautomeric complexes is that of cobalt-dioxolene molecules, where the valence tautomeric interconversion involves an intramolecular electron transfer between a six-coordinate cobalt ion and a coordinated dioxolene ligand. The simplest cobalt-quinone complexes undergoing valence tautomerism belong to the family of ionic complexes with the general formula [ML(diox)]Y, where L = tetraazamacrocycle ancillary ligand, diox = 9,10-dioxophenantrene and Y = PF_6, BPh_4, I.[25] Such complexes undergo a temperature- and pressure-induced intramolecular electron-transfer equilibrium with a transition temperature that varies with the volume and coulombic interaction of the counterion Y. Moreover, substitution of CH_2Cl_2 solvent molecules with their deuterated analogs drastically modifies its magnetic properties giving rise to a thermal hysteresis, an important issue if future technological applications are envisaged for these molecular systems.[38]

Before the previous monodioxolene complexes were reported, most cobalt complexes shown to exhibit valence tautomerism were of the general formula [Co(N-N)$(Q)_2$], where N-N is a diazine ligand, Q = 3,5- and 3,6-di-*tert*-butylcatecholato or semiquinone form. Several interesting features have been observed for this family of complexes, among them a marked effect of the nature of the quinone and ancillary ligands on the tautomerism. For instance, whereas in complex [Co(bpy)(3,6-DBSQ)(3,6-DBCat)] bipyridine ligands of adjacent molecules stack to form a one-dimensional lattice resulting in a remarkable photomechanical effect upon irradiation, replacement by the 3,5-di-*tert*-

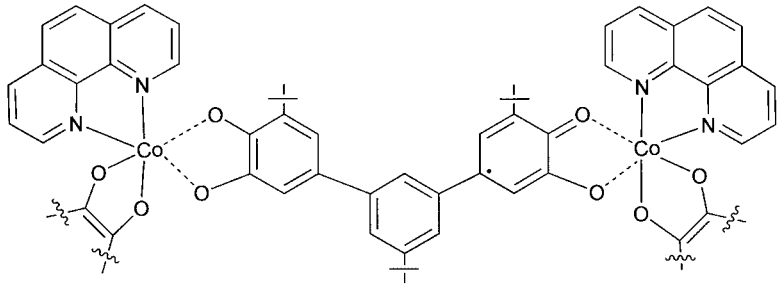
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

butylcatecholato induces a dimerization. As far as the ancillary ligand is concerned, Hendrickson et al.[39] and Pierpont et al.[40] have also concluded that it is possible to systematically control valence tautomerism by changing the counterligand chelate ring flexibility and their donor abilities. Another interesting example has been described by Awaga et al., who reported valence tautomerism in the spin-labeled complex [Co(nnbpy)(3,5-DTBSQ)$_2$] (**4**), where nnbpy is a bipyridine substituted nitronyl nitroxide radical. Even though the temperature dependence of the magnetic susceptibility indicates a tautomeric interconversion above 250 K, the radical ligand behaves as a Curie spin over the whole temperature region.[41] A schematic representation of the valence tautomerism observed for complex **4** is shown in Scheme 2.

In addition to variations in the number and nature of the electroactive and counter ligands, different polynuclear tautomeric complexes have also been reported (see Scheme 3). For instance, Dei et al. reported the dinuclear complex [{Co(cth)}$_2$(dhbq)](PF$_6$)$_3$ (**3**) that undergoes a gradual thermal tautomeric transition at around 175 K and quantitative photoconversion.[21] Pierpont et al. followed this approach to establish the photomechanical polymer [Co(pyz)(3,6-DBQ)$_2$]$_n$ (**5**). This coordination polymer exhibited a temperature-induced tautomeric interconversion in the solid state that is derived from a mechanical process



Scheme 2.



6

due to variations on the bond lengths although no hysteresis effects were observed.[42] On the contrary, such hysteresis was observed more recently by Schultz et al., who used a bis-bidentate ligand to obtain the coordination polymer $[Co(phen)L]\cdot 0.5CH_2Cl_2$ (**6**). This cobalt-dioxolene polymer exhibits the necessary cooperative properties that lead to thermal hysteresis in a valence tautomeric equilibrium, even though the transition could be classified as gradual.[43]

Copper Complexes

Some copper complexes containing dioxolene ligands may yield, under the right conditions, the valence tautomeric interconversion shown in Equation (3) and Figure 7.[44]

$$[Cu^{II}(DTBCat)(L)] \rightleftharpoons [Cu^{I}(DTBSQ)(L)] \quad (3)$$

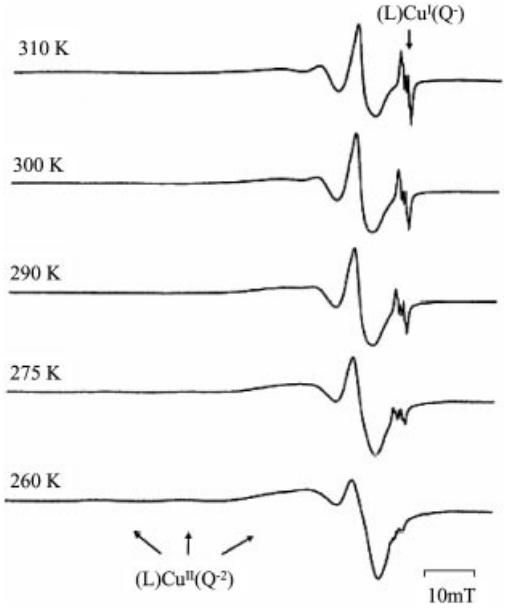

Figure 7. EPR spectra illustrating the temperature-dependent redox isomerism (**3**), with L = mtb and Q = 3,5-di-*tert*-butyl-*o*-quinone, in THF solution.

One of the first examples of valence tautomerism involving the Cu^{II}/Cu^{I} pair was reported in a copper containing amine oxidase enzyme that catalyzes the oxidation of amines to aldehydes,[45] an important process involved in relevant biological functions such as growth regulation and tissue maturation. Indeed, the oxidation of primary amines to aldehydes takes place through a two-electron reduction of O_2 to H_2O_2 catalyzed by the active copper center of the homodimeric enzyme. For this to be achieved and to circumvent spin conservation problems an interconversion from its initial Cu^{II}-catecholate form to the Cu^{I}-semiquinone form, mediated by an intramolecular electron transfer between both units, takes place. Dooley et al. presented evidence for the generation of such a Cu^{I}-semiquinone natural form on several amine oxidases under anaerobic conditions by taking advantage of the very different EPR characteristics (*g* factor and hyperfine-coupling constants) between the pairs Cu^{II}/diamagnetic ligand and Cu^{I}/radical ligand.[45] These studies suggested that the Cu^{I}-semiquinone and the Cu^{II}-catecholate forms are in equilibrium; the Cu^{II}-catecholate form being more stable at low temperatures and the Cu^{I}-semiquinone form at high temperatures.

These exciting results and other biological and commercial processes have motivated the synthesis and characterization of different copper-quinone synthetic models. These studies have shown that the electronic distribution in a series of complexes with the general formula $[(Q^{n-})Cu^{n+}L]$ depends on the donor or acceptor characteristics of the ligand L. With strong π-acceptor ligands, such as L = CO, CNR, PR_3 or AsR_3, the Cu^{I}-semiquinone form is favored, whereas the use of non π-acceptor ligands, such as amine ligands, favors the Cu^{II}-semiquinone form.[46] For instance, Kaim et al. have reported the use of a thioether ligand that favors the Cu^{I}-semiquinone form to induce sensitive valence tautomerism in paramagnetic copper complexes related to amine oxidase enzymes.[47] Similar studies have also been done by Speier et al., who described the existence of valence tautomerism for the species $[Cu(py)_2(PhenQ)_2]$ (**7**).[48] The temperature dependence of the isotropic ESR spectrum of complex **7** in a pyridine solution indicates that at 373 K the complex is in the form $[Cu^{I}(PhenSQ)]$ whereas at 233 K the $[Cu^{II}(PhenCat)]$ tautomer is present, exclusively.

Manganese Complexes

A few years after the first report on cobalt tautomerism, similar temperature-dependent shifts in electronic spectra were observed for a related complex of manganese.[49] The main difference is that valence tautomerism in this case involves three different tautomeric forms associated with three different oxidation states where the manganese ions can be found. Complex $[Mn(py)_2(3,5\text{-}DBCat)_2]$ (**8**) experienced a reversible change in color from the intense purple of the Mn^{IV} form to the pale green-brown characteristic color of the Mn^{II} form. The interconversion takes place through a Mn^{III} form, which usually exhibits similar colors to that of the Mn^{IV} form, as confirmed later in the solid state[50] and in solution.[51] More recently, valence tautomerism in an adduct of a tetrazamacrocycle complex of manganese with a single *o*-benzoquinone ligand has also been reported.[52] The tautomeric interconversion involves two species with nearly degenerate electronic states and a strong sensitivity to variations of the counterion.

Iron and Nickel Complexes

Very recently, two new examples of nickel and iron-quinone complexes have been reported to exhibit valence tautomerism. Tanaka et al. reported complexes $[Ni(PyBz_2)(tBu_2SQ)]PF_6$ (**9**) and $[Ni(MePyBz_2)(tBu_2Cat)]PF_6$ (**10**) as the first examples for the successful control of valence tautomerism between the Ni^{II}-SQ and Ni^{III}-Cat frameworks.[53] Moreover, drastic differences in the electronic states of both complexes are observed due to the steric effects induced by the *o*-methyl group in the $MePyBz_2$ ligand, which weakens the coordination of the pyridine moiety to the nickel ion compared with the unsubstituted $PyBz_2$ ligand. On the other hand, Banerjee et al. reported a semiquinone-cate-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

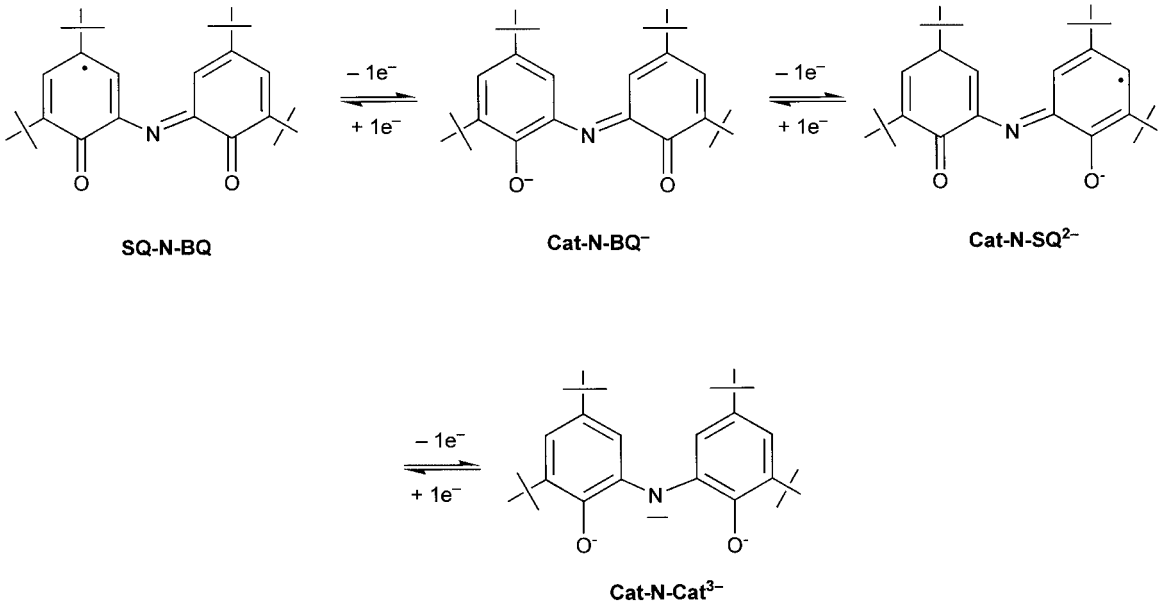
cholate based mixed valence complex [Fe(bispicen)-(Cl_4Cat)(Cl_4SQ)]·DMF (**11**), for which valence tautomerism has been followed by electronic absorption spectroscopy. The tautomer Fe^{III}-(Cl_4Cat)(Cl_4SQ) is favored at low temperatures, while at an elevated temperature, the Fe^{II}-(Cl_4SQ)$_2$ tautomeric form dominates. This is the first example where a mixed valence semiquinone/catecholate iron(III) complex undergoes intramolecular electron transfer.[54]

Phenoxyl Ligands

Transition metal complexes in which one or more of the ligands is present as a phenoxyl radical have attracted much interest due to their broad occurrence in technical processes[55] and enzymatic metalloproteins such as galactose oxidase (GAO)[56] or glyoxal oxidase (GLO).[57] Phenoxyl radicals are monovalent oxygen radical species that exhibit delocalization of the unpaired electron over the aromatic ring and in most cases *ortho* and *para* substituents that give steric protection.[58] For instance, it has been shown that *tert*-butyl substituents at the *ortho* and *para* positions of the phenolates facilitate one-electron oxidation to the corresponding phenoxyl radicals, because these substituents decrease the oxidation potential of the phenolates and provide enough steric bulk to suppress bimolecular decay reactions of the generated phenoxyl radicals.[59] Several groups have prepared metal-phenoxyl complexes giving new insights into the chemical factors that govern the generation and stability of this type of radicals,[60] among those worth mentioning are the ones produced by Wieghardt et al. They have established that bidentate *O,N*-coordinated *o*-aminophenolato ligands can be found in one of the following different protonation and oxidation levels: *o*-imidophenolate(2$^-$) anions, *o*-iminobenzosemiquinonate(1$^-$) radical monoanions or even *o*-iminobenzoquinone. All these forms can exist in coordination compounds as confirmed by low-temperature X-ray crystallography.[61] In addition, *o*-iminobenzosemiquinonate(1$^-$) anions are paramagnetic (S = 1/2) ligands that couple either ferro- or antiferromagnetically when coordinated to a paramagnetic transition metal ion, depending on the symmetry of the magnetic d orbital of the metal ion.

A further step has been the study and characterization of *O,N*-coordinated type ligands containing two phenolate donor groups. These ligands, in addition to producing phenoxyl radicals in the presence of air, exhibit better chelating capabilities and good π-donor atoms that stabilize higher oxidation states,[62] which has allowed the observation of valence tautomerism in some of their complexes. The advantages of valence tautomeric Schiff-base complexes over transition metal complexes with *o*-quinone ligands are considerable. First, valence tautomeric Schiff-base complexes display higher stabilities relative to atmospheric oxygen in solution and in the solid state. Second, the differences between the optical properties of isomers involved in the valence tautomerism of the cobalt Schiff-base complex are enhanced when compared to those observed for cobalt complexes with *o*-quinone ligands. Third, the Schiff-base ligand exhibits a richer electrochemical behavior since it can exist in different oxidation forms, ranging from +1 to –3, which may lead to stable coordination complexes with several metal ions in a variety of oxidation states. For instance, the tridentate ligand [(2-hydroxy-3,5-di-*tert*-butyl-1-phenyl)imino]-3,5-di-*tert*-butyl-1,2-benzoquinone ligand (Cat-N-BQ), may in principle exist in different oxidation states although it usually coordinates in the mononegative Cat-N-BQ or dinegative Cat-N-SQ radical forms (see Scheme 4).[63]

Using such a ligand, in 1988 Pierpont et al. reported the new complex [Co^{III}(Cat-N-BQ)(Cat-N-SQ)] (**12**), although at that time no evidence for tautomeric interconversion was shown to take place.[64] A few years later, the temperature



Scheme 4.

dependence of the spectral and magnetic properties of solutions of this compound in nonpolar solvents suggested the existence of the valence tautomeric equilibrium shown in Equation (4). The temperature dependence of the ^{1}H NMR spectrum of a [D_8]toluene solution of complex [Co^{III}(Cat-N-BQ)(Cat-N-SQ)] is shown in Figure 8.[65]

$$[Co^{III}(Cat\text{-}N\text{-}BQ)(Cat\text{-}N\text{-}SQ)] \rightleftharpoons [Co^{II}(Cat\text{-}N\text{-}BQ)_2] \quad (4)$$

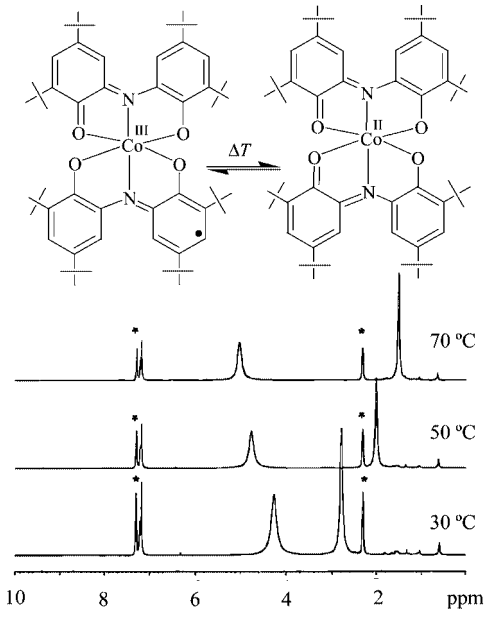


Figure 8. Temperature dependence of the ^{1}H NMR spectrum of a [D_8]toluene solution of [Co(Cat-N-BQ)(Cat-N-SQ)]. The observed signals are due to the *tert*-butyl groups of the ligand. Resonances associated with ring protons are not shown.

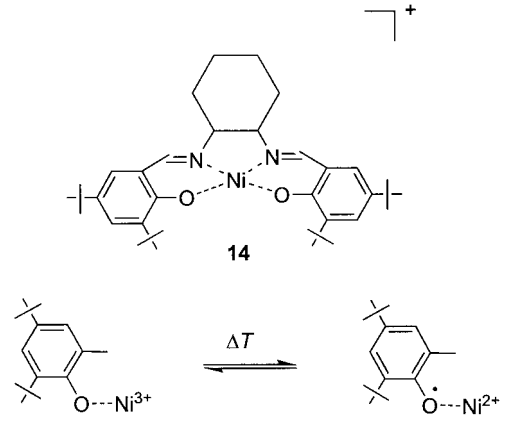
The interconversion temperature (T_c) was determined to be close to 300 K by the ratio between the enthalpy and the entropy changes in solution but no tautomerism was observed in the solid state, as evidenced by the lack of changes in the variable-temperature magnetic susceptibility data. This fact was initially attributed to the lack of solvate molecules within the crystalline network, which are assumed to impart a "softness" to the lattice that makes it possible to appreciate the dimensional change in the complex. However, in subsequent work, the same authors showed that complex **12** exhibits a tautomeric interconversion in the solid state but at much higher temperatures than in solution.[66] The large difference between the interconversion T_c in the solid state and in solution is suggested to come from the entropy changes associated with the modifications of vibronic interactions.

Valence tautomerism has also been reported for the related manganese complex [Mn^{IV}(Cat-N-SQ)$_2$] (**13**). In this case, valence tautomerism involves three different tautomeric isomers associated with the three different oxidation states in which the manganese ion can be found: Mn^{IV}, Mn^{III} and Mn^{II}.[67] Variable-temperature magnetic susceptibility data for a crystalline sample of complex **13** is characterized by a constant μ_{eff} value of 1.9 μ_B consistent with the formulation [Mn^{IV}(Cat-N-SQ)$_2$] (**13**, Mn^{IV}). This fact evidenced the lack of valence tautomerism for complex **13** in the solid state, at least in the temperature range studied. For this reason, variable-temperature magnetic susceptibility data for a [D_8]toluene solution of complex **13** were recorded. From 5 to 270 K complex **13** exhibits a constant μ_{eff} value of 1.8–1.9 μ_B in solution, characteristic of the **13**, Mn^{IV} tautomer. Then, from 270 to 360 K the value of μ_{eff} increases gradually to a value of 4.8 μ_B, which is over the spin-only value of 3.9 μ_B (g = 2) expected for the **13**, Mn^{III} isomer but below that expected for the **13**, Mn^{II} tautomer (5.9 μ_B). Since the tautomeric interconversion in solution usually occurs gradually over a large temperature range (>80–100 °C) it was impossible to completely shift the tautomeric equilibrium to the [Mn^{II}(Cat-N-Q)$_2$] isomer. Further support of the existence of the valence tautomerism shown in Scheme 4 was provided by variable temperature electronic absorption spectra for a toluene solution of complex **13** in the 293–353 K temperature range.

In addition to the Schiff-base ligands previously described and in the course of studies on metal-phenoxyl radical complexes, Shimazaki et al. have recently reported that the one-electron oxidized form of a new mononuclear nickel(II)-bis(salicylidene)diamine complex exhibits valence tautomerism. Indeed, the one-electron oxidation of **14** has been found to be temperature dependent in CH_2Cl_2 yielding the corresponding Ni^{III}-phenolate complex at $T < -120$ °C and the Ni^{II}-phenoxyl radical species at $T > -100$ °C, which is regarded as a tautomerism of the oxidation states governed by temperature.[68] A schematic representation for the tautomeric equilibrium of this species in solution is shown in Scheme 5.



Scheme 5.

Polychlorotriphenylmethyl Radicals

Perchlorotriphenylmethyl radicals (PTM) have their central carbon atom, where most of the spin density is localized, sterically shielded by an encapsulation with six bulky chlorine atoms that increases its life expectancy and thermal and chemical stability.[69] Moreover, the cyclic voltammetry of perchlorotriphenylmethyl radicals shows the formation of two different stable ionic species that correspond

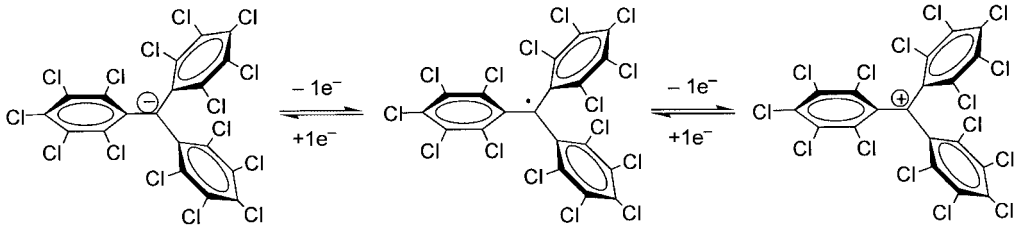
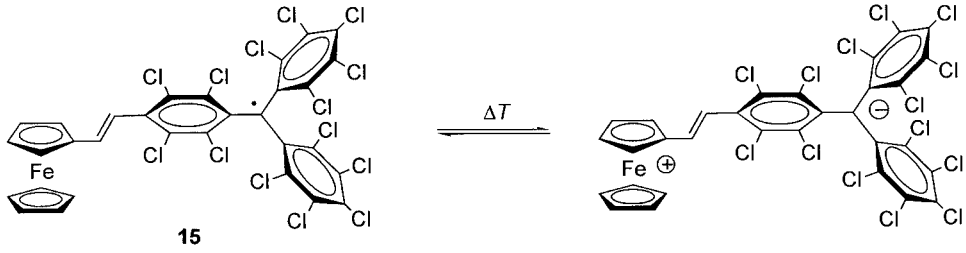


Scheme 6.



Scheme 7.

to the oxidation and reduction of this radical (see Scheme 6). This allows the corresponding anions and cations to be obtained, either chemically or electrochemically, both in solution and in solid state, which also show considerable stabilities in accordance with the steric shielding of their central carbon atoms. Such persistence as well as the particular structural and conformational characteristics of radicals of this family, has enabled them to be functionalized in order to build pure organic open-shell dendrimers with high-spin ground states[70] and pure-organic mixed-valence molecular wires exhibiting intramolecular electron-transfer phenomena.[71]

More recently, Veciana et al. have described the use of perchlorotriphenylmethyl radicals, properly functionalized with carboxylic groups, to obtain complexes combining paramagnetic metal ions and pure organic radicals as ligating sites. Even though this approach has been successfully used to obtain novel mononuclear[72] and extended transition metal complexes exhibiting nonconventional structural motifs, such as nanoporous frameworks with exotic magnetic behavior,[73] no valence tautomerism has been reported on such complexes so far. Nevertheless, the same authors did report valence tautomerism on a new family of molecular systems comprising PTM radicals and ferrocene

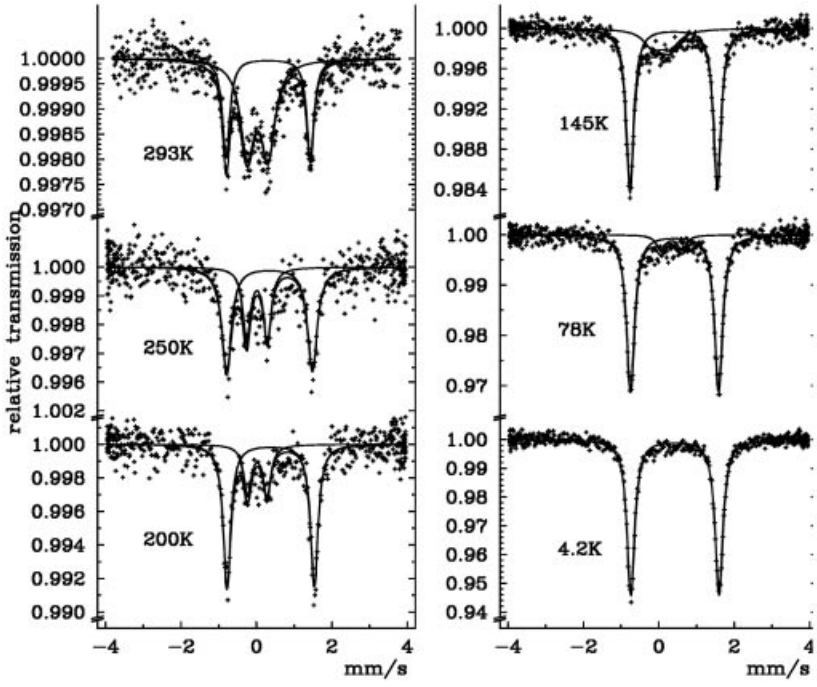


Figure 9. ^{57}Fe Mössbauer spectra of radical **15** as a function of temperature, showing the interconversion between the Fe^{III} and Fe^{II} redox states.

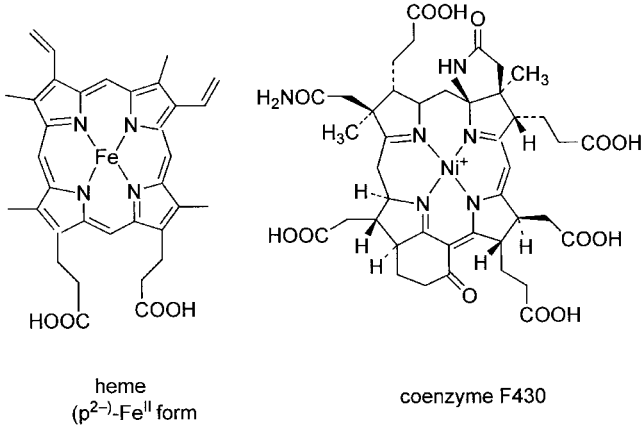
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

units (see Scheme 7).[74] Ferrocene chromophores are interesting not only because of their electron donor capacities and rich electrochemistry but also because they are electroactive species whose oxidation state can be controlled by means of a chemical or electrochemical stimulus, with their oxidized states being of open-shell character.

As far as we know, this is the only example described, so far, where valence tautomerism was followed by variable-temperature Mössbauer experiments. The ^{57}Fe Mössbauer spectra of radical **15** as a function of temperature are shown in Figure 9. As can be seen in this figure, the Mössbauer spectrum of **15** exhibited a temperature-dependent behavior, in solid state, that is in agreement with the observation of a temperature-dependent intramolecular electron transfer from the ferrocene center to the radical as shown from left to right in Scheme 7. The conversion appears to be gradual up to room temperature and fully reversible as confirmed by repetitive temperature-variable Mössbauer experiments.

Metalloporphyrins

The cation radicals of metalloporphyrins have been extensively studied because they serve as model systems for biological-redox intermediates. In these systems, the formation of a ring vs. a metal centered cation is determined by factors such as the intrinsic redox potentials of the porphyrin ring and metal center, the number and type of ligands on the metal ion and the nature of the solvent. Thanks to such electronic lability, some metalloporphyrins are susceptible to exhibiting valence tautomerism. A well-recognized case is the heme system, in which the porphinoid macrocyclic ligand can participate directly in the electron-transfer process, or nickel complexes of porphinoid ligands related to the function of factor F430 in the methane-releasing coenzyme M reductase.[75] A drawing of the heme and coenzyme F430 are shown in Scheme 8.



Scheme 8.

In addition to the occurrence in natural systems, in 1975 Dolphin et al. showed the existence of a reversible intramolecular electron transfer in an oxidized nickel tetraphenylporphyrin (TPP).[76] The reversible temperature-dependent transformation can be described as shown in Equation (5).

$$[Ni^{II}(TPP)]^{\cdot+}\ ClO_4^- \rightleftharpoons [Ni^{III}(TPP)]^+\ ClO_4^- \quad (5)$$

At room temperature, oxidation of complex Ni(TPP) (where TPP = tetraphenylporphyrin) yields a green solution associated with the electronic form $[Ni^{II}(TPP^{\cdot})^+]$ with a π-cation radical. Upon freezing at 77 K, the green solution becomes orange. These spectral changes are consistent with conversion to a low-spin $[Ni^{III}(TPP)]^+$ (S = 1/2) in which the unpaired electron resides in a metal ion orbital, as confirmed by temperature-dependent ESR spectroscopy. Kadish et al. also studied electron-transfer mechanisms of five different nickel(II) porphyrins by replacing the phenyl groups with alkyl groups, all of them exhibiting a temperature-dependent valence tautomerism.[77] In addition to variations on the porphyrin ring, it has been proposed that axial ligation also plays a significant role in mediating the tautomerism. For instance, Bocian et al.[78] have shown based on spectroscopic data that relatively stable $[Ni^{III}(TPP)]^+$ can be obtained, even at ambient temperatures, when coordinating ligands such as THF, py and CH_3CN, are present. The spectroscopic data indicate that the conversion to Ni^{III} species is facilitated by mixing of the metal ion and porphyrin ring orbitals, the latter of which contains the hole in the π-cation form.

Redox-Tuned Valence Tautomerism

The redox activity of the ligands not only allows for the existence of valence tautomerism but also for additional switching capacities resulting from an electrochemical process. Such a strategy has been shown to be very useful for the systematic tuning of the critical temperature (T_c), at which there are equal amounts of both tautomers, as well as of the net magnetic moments and optical properties of the tautomeric isomers. Different examples of redox-tuned valence tautomerism are revised below.

Quinone Ligands

A study of the influence of the temperature on the cyclic voltammetric behavior of complex $[Co^{III}$(3,5-DTBCat)(3,5-DTBSQ)(bpy)] (**1**, *ls*-Co^{III}) revealed interesting features. This was the first time that changes in the redox properties of both isomers were followed.[79] As shown in Figure 10, at 273 K the **1**, *ls*-Co^{III} tautomer shows two well-defined processes at $E_{1/2}$ of –0.34 and +0.25 V vs. Ag wire. The redox couple observed at $E_{1/2}$ = –0.34 V is associated with the reduction of the semiquinone ligand to the catecholate form, whereas the second redox process is characteristic of the oxidation of the catecholate ligand to the semiquinone form. As the temperature is increased, slight shifts of the redox processes into the direction of more positive potentials and the apparition of new redox processes at approximately $E_{1/2}$ = –0.75 and +0.40 V, are observed. Since the tautomeric interconversion in solution occurs gradually

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

over a large temperature range, it was impossible to completely shift the tautomeric equilibrium to the **1**, *hs*-Co^{II} isomer. For this reason, the voltammetric response of complex [Co^{III}(3,5-DTBCat)(3,5-DTBSQ)(phen)] (**2**) at different temperatures was also studied (see Figure 10). The cyclic voltammogram of **2** in CH_2Cl_2 at 273 K shows a similar pattern to that observed for **1** at 303 K with a mixture of **2**, *ls*-Co^{III} and **2**, *hs*-Co^{II} since it exhibits a lower temperature interconversion. As the temperature is increased, **2**, *ls*-Co^{III} converts completely into the **2**, *hs*-Co^{II} tautomer, whose cyclic voltammogram shows a one-reduction process at $E_{1/2}$ = –0.20 V vs. Ag wire, and two irreversible one-electron oxidation processes. The reduction process is associated with the reduction of the two semiquinone ligands to the catecholate form whereas the oxidation processes are mostly associated with the irreversible oxidation of the semiquinone ligand to the quinone form and to the oxidation of the metal center.

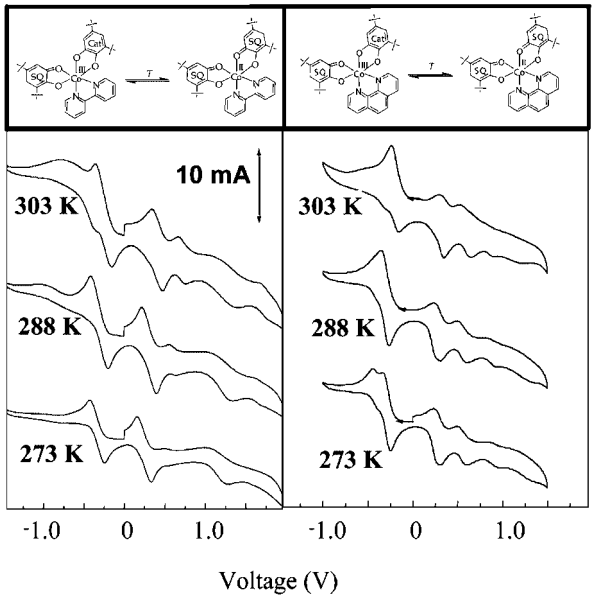


Figure 10. Variable-temperature electrochemical experiments for complexes **1** and **2** in CH_2Cl_2.

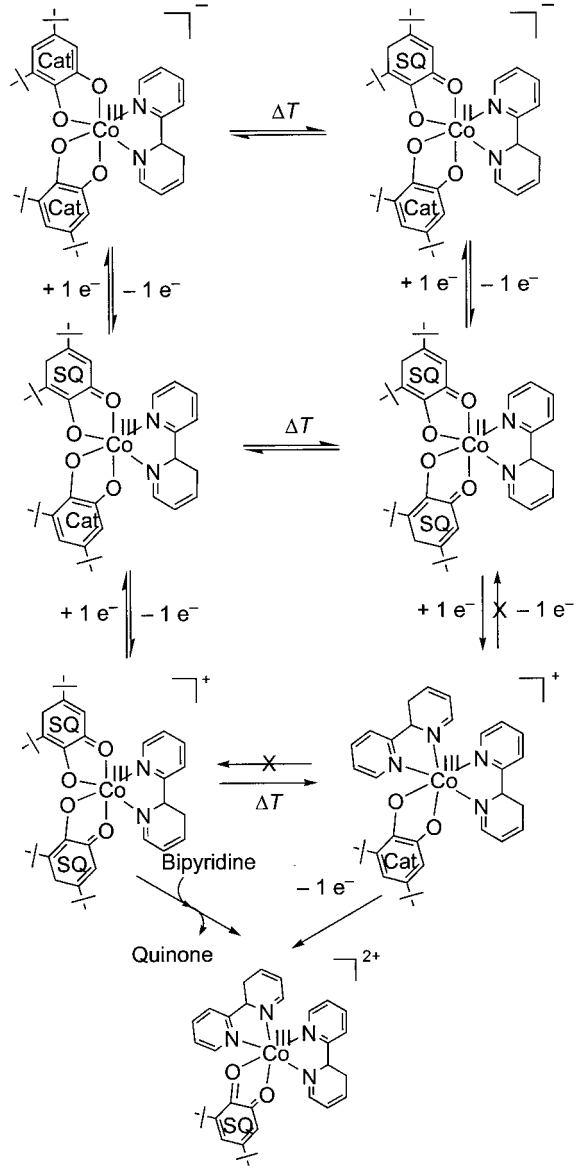
Such temperature-dependent redox behavior was also used to selectively oxidize or reduce each one of the tautomeric isomers.[80] Reduction of [Co^{III}(3,5-DTBCat)(3,5-DTBSQ)(bpy)] in CH_2Cl_2 at 273 K with 1 equivalent of $CoCp_2$ yielded [Co^{III}(3,5-DTBCat)$_2$(bpy)][$CoCp_2$] (**1**$^-$, *ls*-Co^{III}) as a dark-green microcrystalline material, whereas reduction of the corresponding high-spin isomer [Co^{II}(3,5-DTBSQ)$_2$(bpy)] (**1**, *hs*-Co^{II}) yielded a purple microcrystalline material characterized as [Co^{II}(3,5-DTBCat)(3,5-DTBSQ)(bpy)][$CoCp_2$] (**1**$^-$, *hs*-Co^{II}). Moreover, the electronic absorption spectra of **1**$^-$, *ls*-Co^{II} and **1**$^-$, *hs*-Co^{II} in acetone exhibited a temperature dependence consistent with the valence-tautomeric equilibrium shown in Scheme 9. This allowed the establishment of an array of four states showing different optical and magnetic ground states, controlled by two temperature-controlled valence-tautomeric equilibria and two reversible redox processes. The possibility of entering the cycle at each state and advancing through the square array in a clockwise and counter-clockwise direction was also established.



Scheme 9.

Such an array was not obtained for the corresponding oxidized species. Indeed, complex **1**, *ls*-Co^{III} was oxidized by a H_2O_2/HCl mixture yielding an olive-green microcrystalline material characterized as [Co^{III}(3,5-DTBSQ)$_2$(bpy)]·Cl (**1**$^+$, *ls*-Co^{III}). However, oxidation of complex **1**, *hs*-Co^{II} with 1 equivalent of $AgBF_4$ surprisingly yielded [Co(3,5-DTBCat)(bpy)$_2$](BF_4)·2CH_2Cl_2 (**16**). A feasible mechanism for obtaining complex **16** is shown in Scheme 9. Single oxidation of one semiquinone to the quinone form occurs, but the resulting quinone ligand is not basic enough to interact with first-row transition metal ions and therefore the ligand is lost to introduce a new bipyridine ligand that keeps the octahedral coordination around the cobalt ion. A similar mechanism was found for the double oxidation of **1**, *ls*-Co^{III} by $AgBF_4$ and **1**, *hs*-Co^{II} by a mixture of $HClO_4/H_2O_2$ to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

yield in both cases $[Co^{III}(3,5\text{-DTBSQ})(bpy)_2]\cdot X_2$, where X = BF_4 or ClO_4, respectively.[81]

Phenol Ligands

To avoid the low donor capabilities of quinone ligands, Rovira et al. established an array of four states based on the oxidation of the tautomeric complex $[Co^{III}(Cat\text{-}N\text{-}BQ)(Cat\text{-}N\text{-}SQ)]$ (**12**).[82] The advantage of this complex lies in the rich electrochemical behavior of the Schiff-base ligand, which can exist in up to five different oxidation forms, ranging from +1 to –3. Its cyclic voltammogram shows a one-electron oxidation process at $E_{1/2}$ = +0.18 V and a reversible one-electron reduction at $E_{1/2}$ = –0.38 V, both being associated with electrochemical processes occurring at ligand-based orbitals. Potential controlled electrolysis experiments demonstrated the reversibility of both redox processes, indicating no structural changes such as ligand loss or decomposition on the time-scale of the experiment. Therefore, the charged species formed from partial oxidation of complex **12** was generated chemically. Interestingly, the variable-temperature absorption spectra of a toluene solution of complex $[Co^{III}(Cat\text{-}N\text{-}BQ)_2]^+$ (**12**$^+$) shows the existence of an equilibrium consistent with the existence of a temperature-induced valence tautomerism [Equation (6)].

$$[Co^{III}(Cat\text{-}N\text{-}BQ)_2]^+ \rightleftharpoons [Co^{II}(Cat\text{-}N\text{-}BQ)(SQ\text{-}N\text{-}BQ)]^+ \quad (6)$$

This allowed the establishment of an array of four states showing different optical and magnetic ground states by using a reversible oxidation process as an additional stimulus. In a further step, to expand the number of states within the array, Ruiz-Molina et al. converted the valence tautomeric equilibrium of complex $[Mn^{IV}(Cat\text{-}N\text{-}SQ)_2]$ (**13**, Mn^{IV}) by an additional reversible oxidation process to an array of six states. The cyclic voltammogram of complex **13** shows two oxidation processes at $E_{1/2}$ = +0.68 V and $E_{1/2}$ = +0.15 V and a reversible reduction at $E_{1/2}$ = –0.46 V (vs. Ag wire), which have been identified as electrochemical processes involving ligand-based orbitals. Therefore, the charged species **13**$^+$ formed from partial oxidation of complex **13** was generated chemically. Moreover, the variable-temperature magnetic susceptibility data and electronic spectroscopy for a [D_8]toluene solution of a toluene solution was consistent with the valence tautomerism shown in Equation (7).

$$[Mn^{IV}(Cat\text{-}N\text{-}Q)(Cat\text{-}N\text{-}SQ)]^+ \rightleftharpoons [Mn^{III}(Cat\text{-}N\text{-}Q)_2]^+ \rightleftharpoons [Mn^{II}(Cat\text{-}N\text{-}Q)(SQ\text{-}N\text{-}Q)]^+ \quad (7)$$

Polychlorotriphenylmethyl Radicals

The polychlorotriphenylmethyl radical **17**, derived from the valence tautomeric complex **15**, by replacing the ferrocene unit by a permethylated ferrocene, has been converted into an array of three redox states that exhibit distinct physical properties by reduction into their diamagnetic anionic form **17**$^-$ and/or oxidation into the ferrocenium radical derivative **17**$^+$.[83] Interest in these molecular systems is considerable since they not only exhibit variations in color and magnetic properties but also show nonlinear optical responses due to their octupolar nature and their donor-acceptor dyad topology. Indeed, the color of the [K([18]-crown-6)]$^+$**17**$^-$ salt is deep purple, radical **17** is brown, the **17**$^+$$BF_4^-$ salt is yellow, and the hydrocarbon **17**-H is pale pink. In accordance with their distinct colors, the optical absorption spectra of the three species **17**, **17**$^+$, **17**$^-$ show striking differences. Among them, is a remarkable broad intervalence charge-transfer (IVCT) absorption band in the NIR region observed for radical **17**, centered at 1520 nm which is associated with an intramolecular electron transfer from the ferrocene donor unit to the radical acceptor unit (the PTM unit). On the other hand the IVCT band is absent, in agreement with the lack of electron-donor character of the organometallic unit when it is oxidized or reduced. The dynamic hyperpolarizabilities of these three species were measured by hyper-Rayleigh scattering (HRS) experiments. In accordance with the presence of an intense IVCT band, radical **17** gives a large nonlinear optical response with a dynamic hyperpolarizability value β = $545(\pm 30)\times 10^{-30}$ esu. This value is reduced almost ninefold to $66(\pm 7)\times 10^{-30}$ esu for **17**$^+$, and even more for the carbanion **17**$^-$ which has a β = $30(\pm 3)\times 10^{-30}$ esu. The magnetic properties of the three species that have been studied are also different. Thus, while [K([18]crown-6)]$^+$**17**$^-$ is diamagnetic, the paramagnetic susceptibility of compounds **17** and **17**$^+$BF4$^-$ in the solid state between 4–300 K showed quasi-ideal paramagnetic behavior with effective magnetic moments of 1.72 for **17** and 2.50 μ_B for **17**$^+$BF4$^-$ at 300 K; as expected for systems with S = 1/2 and S = 2×1/2 units.

To demonstrate the complete reversibility of the redox reactions of radical **17**, several oxidation and reduction cycles were performed. As shown in Figure 11, the optical

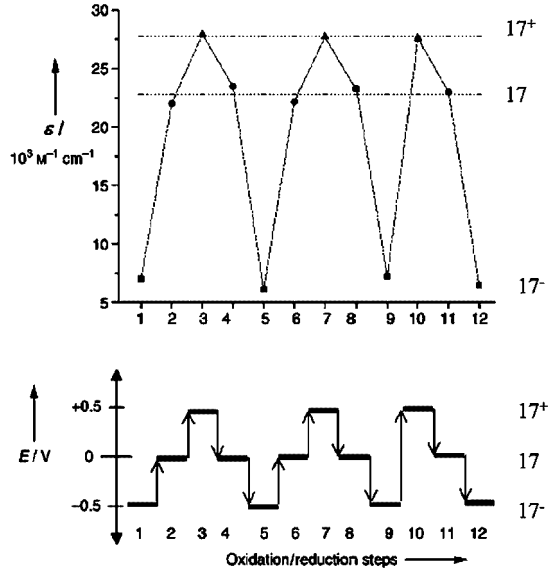


Figure 11. Cyclic stepwise oxidations and reductions carried out in THF with a chronoamperometric technique monitoring the changes in the visible spectrum for **17**-H, [K([18]crown-6)]$^+$**17**$^-$, **17**, and **17**$^+$$BF_4^-$.

spectrum was recorded, after each step, and could be fully recovered after each cycle. Analogous switching behavior was also detected with EPR spectroscopy by studying the magnetic response in solution of the redox-switchable molecular array. Such chemical transformations along with the conversions by electrical stimuli led us to expect a plethora of signal transduction mechanisms should this molecular switchable array be used as a molecular logic gate. Therefore, radical **17** appeared as an ideal candidate for developing a multiproperty three-state switching molecular device governed by electrical and/or thermal inputs.

Extending the NHC Concept: C–C Coupling Catalysis by a Pd^{II} Carbene (*r*NHC) Complex with Remote Heteroatoms

Sabine K. Schneider,[a] Patric Roembke,[b] Gerrit R. Julius,[b] Christoph Loschen,[c] Helgard G. Raubenheimer,*[b] Gernot Frenking,*[c] and Wolfgang A. Herrmann*[a]

Keywords: Carbene ligands / C–C Coupling / Density functional calculations / Homogeneous catalysis

A palladium complex, *trans*-Cl(PPh_3)$_2$Pd{C^a-*cyclo*-C_6H_4-*o*-N(Me)C=C^bH}(C^a–C^b), that contains a carbene ligand with remote heteroatoms (*r*NHC) is much more active in certain C–C coupling reactions than comparably simple NHC- and phosphane-containing precatalysts. The *r*NHC ligand binds strongly by electrostatic as well as orbital interaction to the metal.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Carbon–carbon bond formation with palladium complexes as catalysts is a key step in the synthesis of organic chemicals, natural products as well as in a variety of industrial processes.[1–3] Important examples of such catalysis are found in the Suzuki and Heck reaction types.[4,5] Activity in this area is presently characterized by a search for new ligands and, not independent thereof, the collection of mechanistic information.[6] Phosphanes have been the ligands of choice and are still further investigated.[1,7] However, numerous studies have been undertaken in the recent past to overcome their limitations and replace them by ligands that afford stable compounds while avoiding unwanted side reactions and aiming at even increased activities.[8] Recent successes include the use of N-heterocyclic carbenes (NHC's) as ligands in the precursor complexes.[9–11]

Very few N-heterocyclic-coordinated carbene ligands with remote heteroatoms (*r*NHC's) are known[12] (related, but without remote heteroatoms are α-N carbenes derived from pyridine[13] or azoles[14]). The recent discovery of the exceptional stability and complex dynamics of such Pd^{II} and Pt^{II} compounds[15] encouraged a study to establish their potential use as precatalysts in coupling reactions. Herein we report on a series of comparative Mizoroki–Heck (M–H) and Suzuki–Miyaura (S–M) couplings that involve a number of phosphane and NHC complexes, and the cationic complex chloro(2-methoxy-*N*-methylquinolin-4-yl)-bis(triphenylphosphane)palladium(II) (**1**), that has been described in detail before.[15] A more meaningful comparison of competitive activities with the most effective systems in the literature, will only be possible after steric effects have been incorporated into **1** and other *r*NHC ligands. In this preliminary report we show that such ligand types certainly have potential as precatalysts and also describe a quantum mechanical comparison between NHC and *r*NHC model ligands and complexes. Descriptions of the ligand electronic structures as well as the metal–ligand bonding in NHC and the "newcomer" *r*NHC complex types are extracted from DFT calculations at the RI-BP86/SVP level.[16]

The catalyst precursors, all prepared according to standard procedures and screened for their activity and efficiency in well-known M–H and S–M reactions, are shown in Figure 1 and the results obtained in Table 1 and Table 2. These reactions do not represent troublesome couplings but

[d] For Entries 8–12 compare also Figure 2.

simple ones using relatively simple catalytic systems to allow a comparison on an electronic (and not steric) basis and to show that *r*NHC ligands deserve further attention. The data indicate clearly the superiority of the stable *r*NHC complex which gives relatively high conversions even at low concentration. Under the reported conditions TON's of 9.1×10^5 in the M–H and 3.2×10^6 in the S–M coupling are reached. Catalyst loading in the latter situation, however, is too low and affects the efficiency of the process. Arylchlorides couple successfully at 0.5% loading level of the *r*NHC complex according to M–H, and at 1.0% in the S–M reaction without any evidence of palladium black formation, even after stirring for 24 hours.

An even better picture of the relative catalyst activities emerged from the time-conversion curves in Figure 2 and Figure 3 determined under similar conditions for the two types of C–C coupling respectively.

The two sets of curves are remarkably similar,[10] and the *r*NHC complex, which requires no induction period, comes out on top of the chosen series again. Cationic charge (or alternatively, the number of phosphane ligands present) on the complex is not an important parameter for the halophosphane compounds **4** and **5**, but differentiate clearly between NHC complexes **2** and **3**.

To better understand from a chemical viewpoint the reasons behind the relatively high activity of the *r*NHC complex in comparison with a simple cationic NHC complex, we theoretically analyzed their metal–carbene bonds. First, the geometries of the model compounds **1M** and **2M** with phenyl (on P) and methyl (on N and O) substituents replaced by hydrogen atoms, were optimized at the RI-BP86/SVP level.[16]

For this study the crystal and molecular structures of **2** – prepared similarly to **1**[15] (compare also ref.[17]) – were determined. Crystal data and calculated geometries are given as Supporting Information (for details see also the footnote on the first page of this article). The agreement between calculated and experimental bond lengths is quite good. Both methods indicate similar Pd–C(carbene) bond lengths, but a significantly larger *trans* influence is exhibited by the *r*NHC ligand (experimental Pd–Cl bond length 0.044 Å longer in **1** than in **2**)

We used different methods for extracting chemical bonding information in **1M** and **2M**. Figure 4 shows the most important frontier orbitals of the two simplified free carbene ligands *r*NHC and NHC. The σ-donor HOMO orbital in *r*NHC is 1.28 eV higher in energy than in NHC. HOMO-1, the highest-lying occupied π-orbital, has a much larger coefficient at the carbene C-atom in NHC than in *r*NHC affording a higher electron population at the C(carbene) p(π) AO in NHC (0.66) than in *r*NHC (0.53) which is disadvantageous for M–L π back donation in the former complex. The LUMO of NHC (not shown) is a π* orbital of the C=C double bond which has a node at the C(carbene) atom. The next low-lying π-acceptor orbital, LUMO+1, has a large coefficient at the C(carbene) p(π) AO. The π-acceptor LUMO of *r*NHC is lower in energy than the LUMO+1 of NHC but it is much more delocalized. The increase in the p(π) AO population on the carbene carbon atom of *r*NHC after formation of the complex **1M** ($\Delta q\pi$ = 0.28 e) is larger than in NHC ($\Delta q\pi$ = 0.20 e) and suggests that this ligand may also be a somewhat stronger π-acceptor than the latter species.

A deeper insight into the metal–carbene bonding situation results from an energy decomposition analysis (EDA)[17,19] of **1M** and **2M** (Table 3). The metal–carbene interactions in the *r*NHC carbene complex, **1M**, are significantly stronger (ΔE_{int} = –107.6 kcal/mol) than in **2M** (ΔE_{int} =

[a] Ratio of aryl halide/phenylboronic acid/K_2CO_3 = 1:1.2:1.5; solvent: xylene; T = 130 °C. [b] GC yield using diethylene glycol/di-*n*-butyl ether as internal standard. [c] Cs_2CO_3 was used as base. [d] For Entries 8–12 compare also Figure 3.

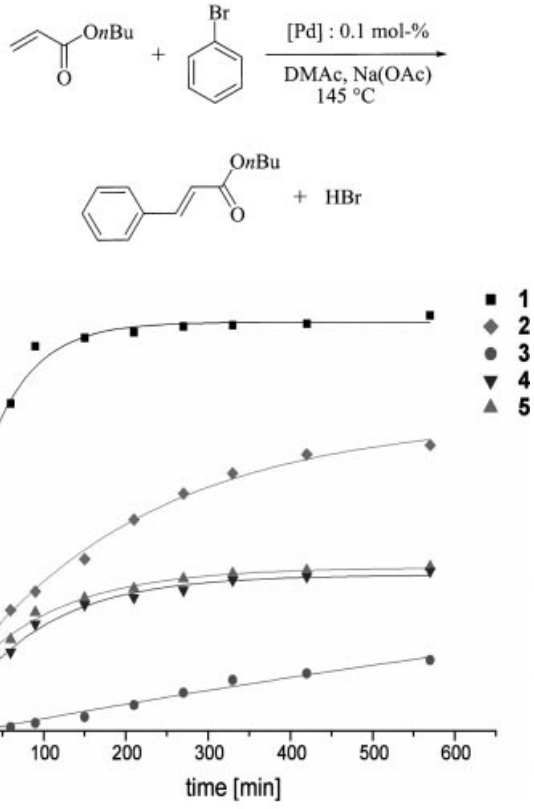

Figure 2. Time-conversion-curves: Mizoroki–Heck reaction.

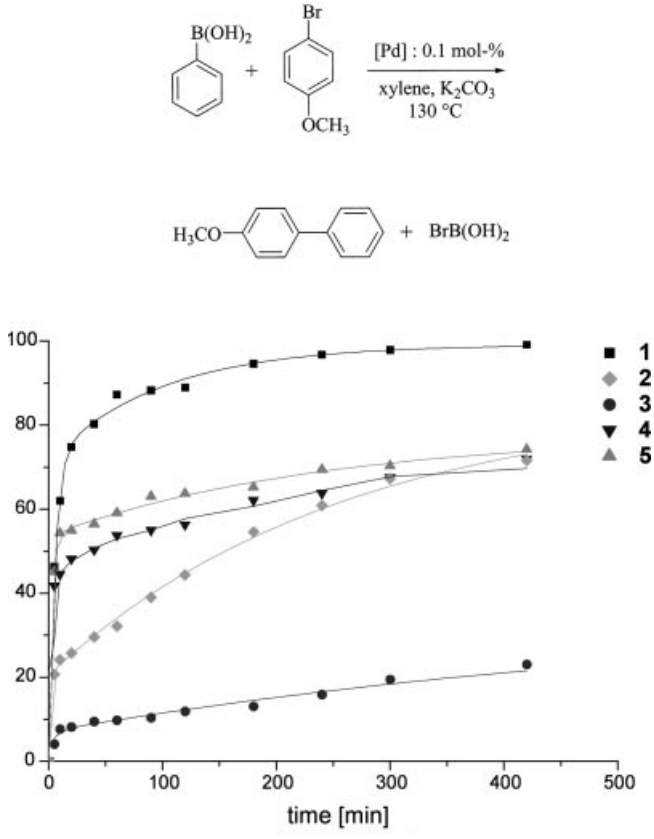

Figure 3. Time-conversion-curves: Suzuki–Miyaura reaction.

–85.5 kcal/mol). The rather small calculated geometry relaxation of the fragments (ΔE_{prep}) indicates that the former complex also has a bond dissociation energy of ca. 20 kcal/mol higher than the latter (also compare a related discussion involving other carbene complexes by one of us[20]).

The metal–carbene bonding in both complexes comes mainly from classical electrostatic interactions, ΔE_{elstat}, which contribute ca. 70% to the attractive forces.

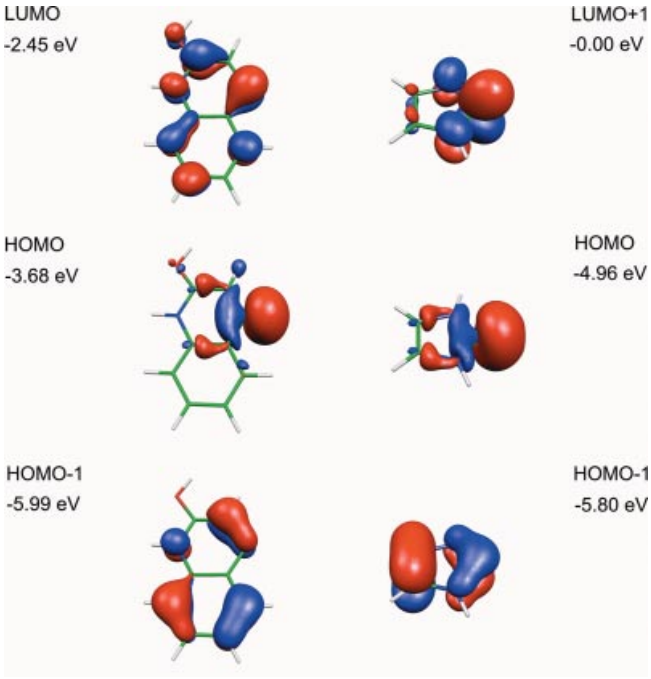

Figure 4. Frontier orbitals of the free model carbenes *r*NHC (left) and NHC (right).

Table 3. Energy decomposition analyses of **1M** and **2M**.[a]

	1M		**2M**	
ΔE_{int}	–107.6		–85.5	
ΔE_{Pauli}	184.9		157.9	
ΔE_{elstat}	–204.6	(69.9%)	–171.8	(70.6%)
ΔE_{orb}	–87.9	(30.1%)	–71.5	(29.4%)
a′	–72.8	(82.8%)	–60.4	(84.5%)
a′′	–15.1	(17.2%)	–11.1	(15.5%)
ΔE_{prep}	3.6		2.4	
$\Delta E = -D_e$	–104.0		–83.1	

[a] Energy given in kcal mol^{-1}.

The most interesting part of the EDA is the breakdown of the total orbital interaction term, $\Delta E_{orb,}$ into orbital contributions of different symmetry (Table 3). The EDA calculations of complexes **1M** and **2M** were carried out with C_s symmetry, which means that the strength of the σ-bonding is given by the a′ orbitals while π-bonding is given by the a′′ orbitals. The former contribution is clearly more important [72.8 kcal/mol (82.8%) in **1M** and 60.4 kcal/mol (84.5%) in **2M**] than π-bonding [15.1 kcal/mol (17.2%) in **1M** and 11.1 kcal/mol (15.5%) in **2M**].

In conclusion, this study, using palladium as central metal, has shown that a carbene-type ligand with no heteroatom in the immediate vicinity of the carbon donor atom activates the metal centre significally more than comparable simple N-heterocyclic carbenes. No serious dichotomy arises when Heck- and Suzuki-type conversions are compared. The exceptionally strong metal–carbene bond in such a complex – as determined by quantum chemical DFT calculations – is mainly due to very strong metal–ligand electrostatic attraction as well as an energetically higher-lying σ-HOMO on the ligand that overlaps well and donates electrons readily.

All our results are in accordance with an *r*NHC ligand that remains attached to the central metal during the catalytic cycle and indicate that catalytic activity could be increased by further ligand tailoring, especially an increase in steric bulk.[11,21] Finally we anticipate that this work will provide an impetus for further study and that the new class of ligands will find application in other important catalytic processes and should, individually, be considered as useful alternatives to NHC′s as we shall show in future reports.

Experimental Section

The preparation of the catalyst precursor complex **2** is described in the Supporting Information, **3**[11a] as well as **4**[22] were prepared according to literature procedures and **5** is commercially available.

Heck Reaction: A constant ratio of sodium acetate (3.00 mmol, 246 mg) and aryl halide (2.00 mmol, e. g. 315 mg bromobenzene) as well as 100 mg diethylene glycol/di-*n*-butyl ether were placed in a Schlenk tube equipped with a stirring bar under argon. Then 3.00 mmol of *n*-butyl acrylate (0.43 mL) and 2 mL degassed DMAc were added. After 10 min at the desired temperature, the catalyst solution was added against a positive stream of argon. To terminate the reaction the mixture was allowed to cool to room temperature and 3 mL of aqueous HCl added. The water phase was extracted thrice with 2 mL of dichloromethane and the organic fraction dried with $MgSO_4$. Conversions and yields were determined by GC-MS using diethylene glycol/di-*n*-butyl ether as internal standard.

Suzuki Reaction: Phenylboronic acid (2.40 mmol, 293 mg) and potassium carbonate (3.00 mmol, 415 mg) were placed in a Schlenk tube equipped with a stirring bar under argon. Aryl halide (2.00 mmol; e. g. 374 mg bromoanisole), 100 mg diethylene glycol/di-*n*-butyl ether and 2 mL degassed xylene were added. After thermostating at 130 °C for 10 min, the catalyst solution was added against a positive stream of argon. To end the reaction, the mixture was cooled to room temperature and 3 mL of water added. The water phase was extracted three times with 2 mL of diethyl ether and the organic phases dried with $MgSO_4$.

Two Novel Cadmium Polymeric Metallamacrocyclic Complexes Constructed from a Pyridylmethyl-Functionalized Tetraaza Ligand

Zhen Ma,[a,b] Zhongning Chen,[a] and Rong Cao*[a]

Keywords: Cadmium complexes / Crystal structures / Macrocyclic compounds / Hydrothermal method

A new octadentate ligand L was synthesized by tetrafunctionalization of 1,4,8,11-tetraazacyclotetradecane (L^1, cyclam) with 4-pyridylmethyl groups and its two novel cadmium polymeric metallamacrocyclic complexes, $[Cd_3L_{1.5}(C_6H_5O_7)_2{\cdot}6H_2O]_n$ (**1**) and $[CdCl_2L_2{\cdot}2.5H_2O]_n$ (**2**), were obtained by hydrothermal methods.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Macrocyclic and macrobicyclic compounds attract increasing interests of chemists owing to their interesting structures, properties and important roles in coordination chemistry and many other fields, such as material chemistry and medicinal chemistry.[1–6] Unlike polyoxa macrocyclic and macrobicyclic compounds, polyaza compounds can be functionalized by several groups, such as alkynyl,[7] phosphanylmethyl,[8] carboxyl,[9] and heterocyclic groups[10] on their secondary N-sites and thereby show some novel properties in coordination, electro-, photoluminescent and catalytic chemistry. Hence, we recently started the investigation on the complexes constructed from functionalized polyaza ligands, in order to prepare some novel structures and study their applications in material and medicinal chemistry. In this communication, we will report a new tetrafunctionalized octadentate ligand L and its two novel cadmium polymeric metallamacrocyclic complexes, $[Cd_3L_{1.5}(C_6H_5O_7)_2{\cdot}6H_2O]_n$ (**1**) and $[CdCl_2L_2{\cdot}2.5H_2O]_n$ (**2**), which were obtained by hydrothermal methods.

The ligand (L) was synthesized by the reaction of 1,4,8,11-tetraazacyclotetradecane (cyclam, L^1) with 4-pyridylmethyl chloride according to a previously reported procedure (Figure 1).[10] Complex **1** was obtained from the hydrothermal reaction of cadmium nitrate, L and sodium citrate. Single-crystal X-ray analysis illustrates that **1** is an interesting polymeric metallamacrocyclic complex. There are three crystallographic independent Cd^{2+} ions: Cd(1) is coordinated by five oxygen and two nitrogen atoms in a pentagonal-bipyrimidal geometry, Cd(2) is coordinated by five oxygen and one nitrogen atoms in an octahedral geometry, while Cd(3) is coordinated by six oxygen and one nitrogen atoms in a pentagonal-bipyrimidal geometry. The citrate ligand shows an η^1-η^2-η^2-η^3-μ_4 coordination mode to connect four central metal ions by its six oxygen donors of three carboxylic groups and a hydroxy group (Supporting Information, Figure S1). One oxygen atom of it is uncoordinated and two oxygen donors coordinate to two central ions. The ligand L adopts two coordination modes: one acts as tetradentate ligand to coordinate four cadmium ions by its four pyridyl nitrogen atoms (η^1-μ_4, L^a), the other as bidentate ligand to two cadmium ions by its two *para*-pyridyl nitrogen atoms (η^1-μ_2, L^b) (Figure 1). The most striking feature of **1** is that its structure is built from seven interesting metallacycle units. The three Cd^{2+} ions form a novel M_3O_3 trinuclear heterocyclohexane-like metallacycle by the connection of citrate ligands (first metallacycle unit, C1; Figure 2). Every two of such trinuclear units are bridged by two citrate ligands to form a hexanuclear unit with a dinuclear 14-membered metallamacrocycle (C2; Figure 2). Every hexanuclear unit is connected with two other neighboring hexanuclear units by two citrate ligands to form columns of the structure with a dinuclear 12-membered metallamacrocycle (C3; Figure 2). Although several similar examples[11–16] of structures of the Cd_3O_3 unit have been reported, the major conformation is a heterocubane,[12,14,15] different from that in **1**. The fourth metallamacrocycle is a dinuclear 21-membered one formed by the linkage of two trinuclear Cd_3O_3 units through the two neighboring pyridyl

arms of an L^a ligand with the distance between the two Cd ions [Cd(1) and Cd(3)] being 6.546 Å (C4; Figure 3). The fifth macrocycle is a hexanuclear 50-membered metallamacrocycle (C5) formed by the linkage of four trinuclear units through four pyridyl arms from two L^a ligands in a parallelogram-type geometry as shown in Figure 3. The four corners of the parallelogram are occupied by cadmium ions, the side lengths are 15.293 and 11.092 Å, while the diagonals are 13.584 and 23.006 Å. The sixth macrocycle is a tetranuclear 42-membered parallelogram metallamacrocycle formed by the linkage of two trinuclear units through two L^b ligands (C6; Figure 3), the sides of the parallelogram are 3.761 and 20.160 Å and the diagonals are 20.434 and 20.582 Å. The seventh macrocycle is an octanuclear 68-membered parallelogram metallamacrocycle formed by the linkage of six trinuclear Cd_3O_3 units through two L^b ligands (C7), the sides of the parallelogram are16.448 and 20.161 Å and the diagonals are 21.343 and 29.974 Å. The columns formed by the hexanuclear units are linked by L^a and L^b ligands to result in a three-dimensional conforma-

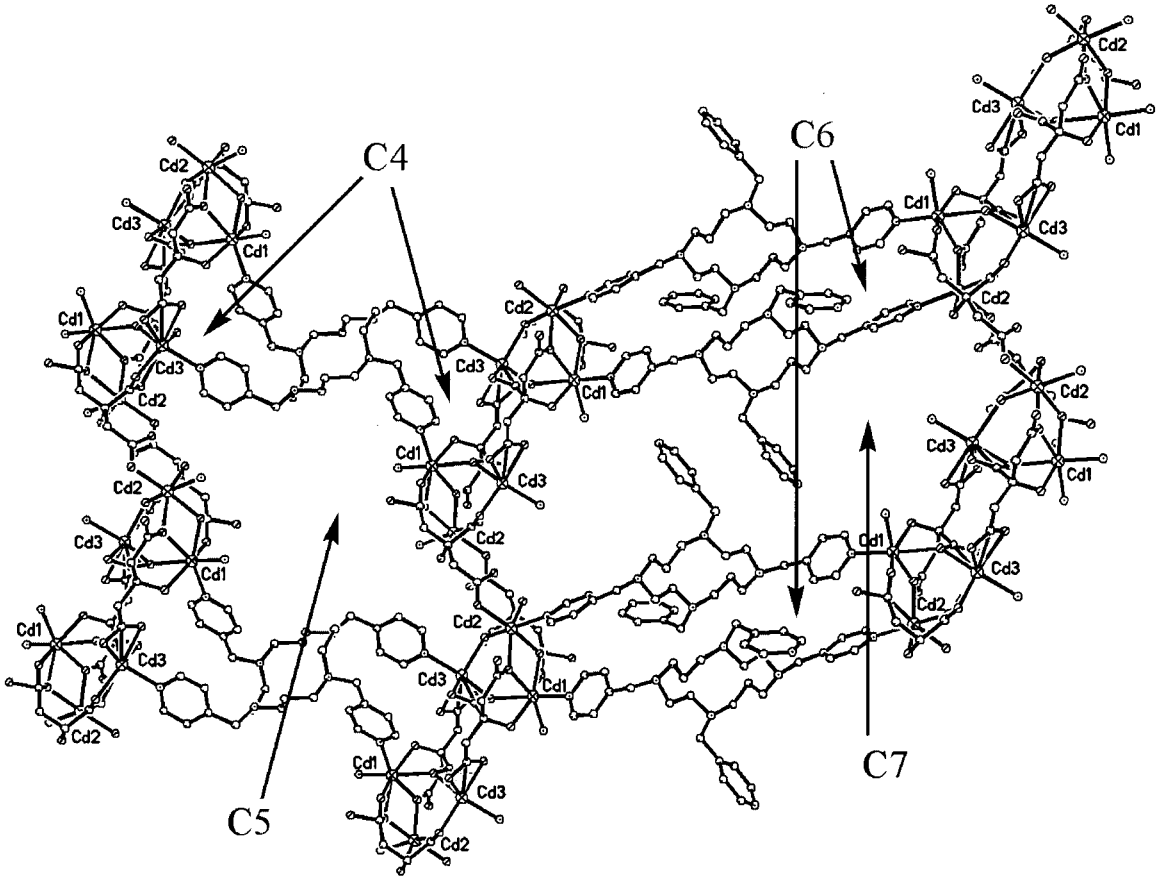

Figure 3. Molecular structure of complex **1**. Some molecules of L are omitted for clarity. There are four types of metallamacrocycles shown in this Figure: C4 and C5 (left) and C6 and C7 (right).

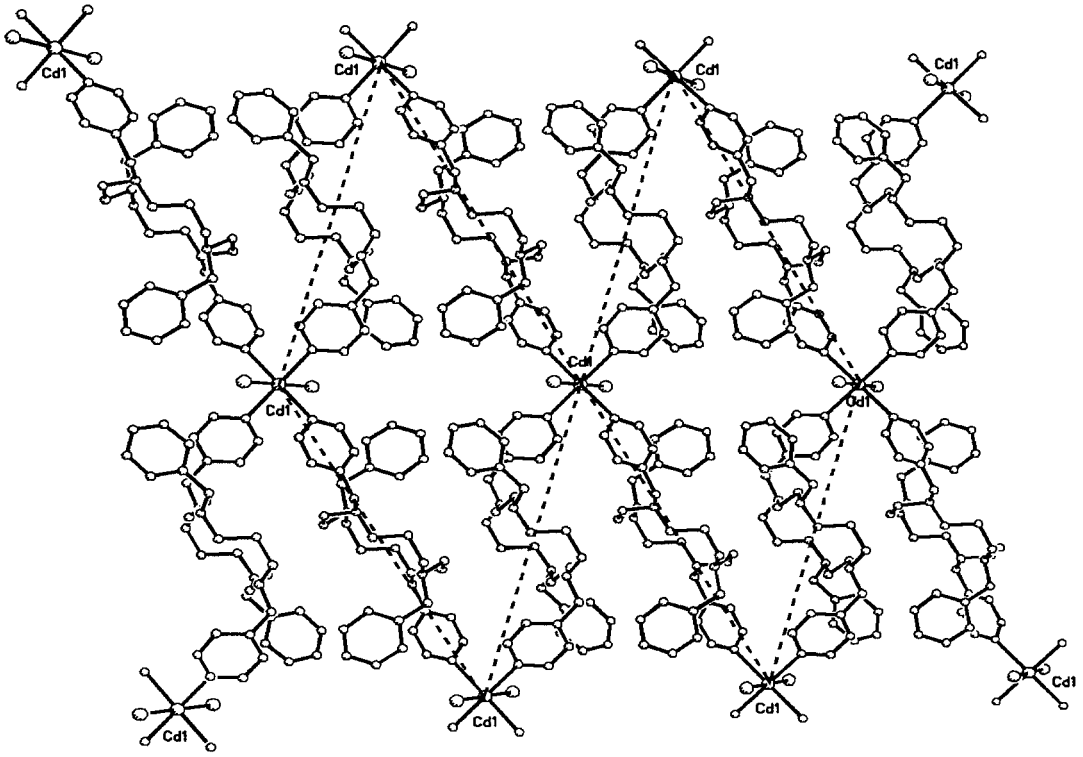

Figure 4. Molecular structure of complex **2**. Selected bond lengths [Å]: Cd(1)–N(6) 2.355(3), Cd(1)–N(5) 2.441(3), Cd(1)–Cl(1) 2.6145(9).

tion. Water molecules as guests exist in the structure and there are intermolecular hydrogen bonds O–H···O between neighboring water molecules.

Interestingly, when $CdCl_2$ was used as reactant, complex **2** was isolated, where no citrate ligands are observed because of the strong coordination ability of chloride ions to cadmium ions. A similar reaction without citrate ligand also resulted in **2**. This means that no substitution reaction between chloride ions and citrate ligands occurred under these hydrothermal conditions, and the citrate ligand did not play an important role in the formation of **2**. Compound **2** is a two-dimensional polymeric structure composed of $CdCl_2$ and ligand L (Figure 4). The ligand L shows only one conformation with two pendant pyridyl groups coordinated to cadmium ions and the other two being free (η^1-μ_2, L^b; Figure 1). In this structure, the cadmium ions are coordinated by four nitrogen atoms from four pyridyl groups of L^b and two chloride ions in a distorted octahedral geometry. The two chloride ions occupy the two apical positions and the basal plane consists of the four nitrogen atoms. The basic unit of this structure is a tetranuclear 76-membered metallamacrocycle in which four $CdCl_2$ units are connected by four L^b units in a parallelogram geometry with the two sides being 18.739 and 16.728 Å and the two diagonals being 13.508 and 32.856 Å. The metallamacrocycles are further extended into a planar structure by sharing cadmium ions. In both complexes **1** and **2**, the ligand L functions as a bridging ligand with the cyclam unit being uncoordinated, similar to the observation in the gold complex of *N*-phosphanylmethyl-functionalized cyclam reported by Che et al.[17]

In summary, two novel cadmium polymeric metallamacrocyclic complexes have been prepared from pyridyl-functionallized 1,4,8,11-tetraazacyclotetradecane by a hydrothermal method; different cadmium reactants influence the structures of the complexes dramatically. Further studies are underway and will be reported in a full paper.

Experimental Section

Synthesis of the Free Ligands L^1 and L: L^1 was prepared according to a reported procedure.[18] Free ligand L was prepared by tetrafunctionalization of L^1 with 4-pyridylmethyl chrolide according to a revised reported procedure.[10] Yield 41%; M.p. 152–153 °C. $C_{34}H_{44}N_8$ (564.77): calcd. C 72.30, H 7.85, N 19.84; found C 72.33, H 7.96, N 19.50. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ =1.77 (s, 4 H, a), 2.53 (s, 8 H, b), 2.61 (s, 8 H, c), 3.41 (s, 8 H, –CH_2–pyr), 7.24 (d, J = 3.5 Hz, 8 H, aryl), 8.47 (d, J = 4.0 Hz, 8 H, aryl) ppm. EI-MS: *m/z* (%) = 567.2, 566.3, 565.2 (100), 356.8, 256.4, 242.2, 178.7. IR (KBr disk): $\tilde{\nu}$ = 3073 (w), 3020 (w), 2958 (s, br.), 2797(m), 1596 (s), 1559 (m), 1467 (m), 1414 (s), 1366 (m), 1248 (m), 1155 (m), 1121 (m), 1103 (m), 1041 (m), 799 (s) cm^{-1}.

Synthesis of Complex 1: A mixture of $Cd(NO_3)_2{\cdot}4H_2O$ (0.044 g, 0.14 mmol), L (0.040 g, 0.071 mmol), $Na_3C_6H_5O_7{\cdot}2H_2O$ (0.021 g, 0.071 mmol), and distilled water (20 mL) was sealed in a 25-mL stainless steel reactor with Teflon liner and heated at 110 °C for 3 d. Colorless crystals of **1** were isolated by mechanical separation from the mixture of **1** and unidentified white powder. The yield of **1** was 12% based on Cd^{2+}. $C_{63}H_{88}Cd_3N_{12}O_{20}$ (1670.65): calcd. C 45.29, H 5.31, N 10.06; found C 45.32, H 5.29, N 10.02.

Synthesis of Complex 2: A mixture of $CdCl_2{\cdot}2.5H_2O$ (0.032 g, 0.14 mmol), L (0.040 g, 0.071 mmol), $Na_3C_6H_5O_7{\cdot}2H_2O$ (0.021 g, 0.071 mmol), and distilled water (20 mL) was sealed in a 25-mL

stainless steel reactor with Teflon liner and heated at 110 °C for 3 d. Colorless crystals of **2** were isolated by mechanical separation from a mixture of **2** and unidentified white powder. The yield of **2** was ca. 35% based on $CdCl_2$. $C_{68}H_{93}CdCl_2N_{16}O_{2.50}$ (1357.88): calcd. C 60.14, H 6.90, N 16.51; found C 60.23, H 6.85, N 16.26.

X-ray Crystallography: Crystal data for L: $C_{34}H_{44}N_8$ (564.77), monoclinic, space group $P2_1/n$, T = 130(2) K, a = 5.9649(4), b = 11.7400(7), c = 21.839(2) Å, β = 96.586(4)°, V = 1519.3(2) Å^3, Z = 2, $D_{calcd.}$ = 1.235 g·cm^{-3}, $F(000)$ = 608, μ(Mo-K_α) = 0.076 mm^{-1}, colorless from methanol, 0.75 × 0.50 × 0.25 mm, θ range for data collection 3.31–27.48°, 11320 collected, 3462 unique and 3150 observed (R_{int} = 0.0265) reflections, 190 parameters, R = 0.0435 and wR = 0.1049 for observed reflections with $I > 2\sigma(I)$, GOF = 1.058, $(\Delta\rho)_{max}$ = 0.262, $(\Delta\rho)_{min}$ = –0.205 e/Å^{-3}. Crystal data for **1**: $C_{63}H_{88}Cd_3N_{12}O_{20}$ (1670.65), triclinic, space group $P\bar{1}$, T = 130(2) K, a = 13.104(4), b = 16.448(5), c = 18.682(6) Å, α = 104.619(3), β = 102.754(1), γ = 106.923(2)°, V = 3534.2(18) Å^3, Z = 2, $D_{calcd.}$ = 1.570 g·cm^{-3}, $F(000)$ = 1708, μ = 0.974 mm^{-1}, colorless from water, 0.50 × 0.25 × 0.15 mm, θ range 3.02–25.00°, 22192 collected, 12317 unique and 10957 observed (R_{int} = 0.0220) reflections, 904 parameters, R = 0.0507 and wR = 0.1143 for observed reflections with $I > 2\sigma(I)$, GOF = 1.051, $(\Delta\rho)_{max}$ = 1.720, $(\Delta\rho)_{min}$ = –0.870 e/Å^{-3}. Crystal data for **2**: $C_{68}H_{93}CdCl_2N_{16}O_{2.50}$ (1357.88), triclinic, space group $P\bar{1}$, T = 130(2) K, a = 9.469(3), b = 13.271(4), c = 13.508(4) Å, α = 80.028(7), β = 78.940(8), γ = 86.796(7)°, V = 1640.3(8) Å^3, Z = 1, $D_{calcd.}$ = 1.375 g·cm^{-3}, $F(000)$ = 715, μ = 0.474 mm^{-1}, colorless, 0.30 × 0.25 × 0.05 mm, θ range 2.38–25.00°, 10544 collected, 5735 unique and 4813 observed (R_{int} = 0.0393) reflections, 411 parameters, R = 0.0483 and wR = 0.1013 for observed reflections with $I > 2\sigma(I)$, GOF = 1.093, $(\Delta\rho)_{max}$ = 0.873, $(\Delta\rho)_{min}$ = –0.472 e/Å^{-3}. Data collections for the three compounds were performed with a Rigaku Mercury-CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The data sets were collected at 130 K (ω-scan mode). The structures of the three compounds were solved by direct methods, the metal atoms were located from the E-maps, and other non-hydrogen atoms were derived from the successive difference Fourier syntheses and refined anisotropically. All hydrogen atoms were theoretically located. The structures were refined on F^2 by full-matrix least squares using the SHELXTL-97 program package. CCDC-262561, -262562, and -262563 (for L, **1**, and **2**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: Coordination modes of the citrate ligand (Figure S1); structural figures of the two complexes (Figures S2–S10); molecular structure (Figure S11), ^{1}H NMR spectrum (Figure S12), and EI mass spectrum (Figure S13) of ligand L.

Reactions of enantiopure (*S*)-[(η^5-C_5H_5)Re(NO)(PPh_3)(=CH_2)]$^+$ PF_6^- [(*S*)-**2**] and $PH_2CH_2(CH_2)_nCH_2PH_2$ (0.5 equiv.) give ($S_{Re}S_{Re}$)-[(η^5-C_5H_5)Re(NO)(PPh_3){$CH_2PH_2CH_2(CH_2)_n$-$CH_2PH_2CH_2$}(Ph_3P)(ON)Re(η^5-C_5H_5)]$^{2+}$ $2PF_6^-$ [*n* = 0/1, ($S_{Re}S_{Re}$)-**3/4**; 65–62/77–58 %]. Reaction of racemic **2** (BF_4^- salt) and $PH_2(CH_2)_2PH_2$ (0.5 equiv.) gives the *meso* and *rac* diastereomers of **3** (BF_4^- salts) in 28 % and 38 % yields after crystallization. Treatments of ($S_{Re}S_{Re}$)-**3/4** with *t*BuOK and then (*S*)-**2** give the tetrarhenium complexes ($S_{Re}S_{Re}S_{Re}S_{Re}$)[{(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)}$_2${$PHCH_2(CH_2)_n$-CH_2PH}{(CH_2)(Ph_3P)(ON)Re(η^5-C_5H_5)}$_2$]$^{2+}$ $2PF_6^-$ [*n* = 0/1, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8**; 89–88/98–87 %]. The crystal structure of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** is determined and its conformation analyzed. Reactions of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** and *t*BuOK give air-sensitive diphosphanes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-{(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)}$_2${$PCH_2(CH_2)_nCH_2P$}{(CH_2)(Ph_3P)(ON)Re(η^5-C_5H_5)}$_2$ [*n* = 0/1, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10**; 92/62 %]. Additions of (a) PhIO give the corresponding dioxides (72/62 %), and (b) [$Rh(NBD)_2$]$^+$ PF_6^- give the corresponding chelates [(P–P)Rh(NBD)]$^+$ PF_6^- (75/82 %) (NBD = norbornadiene). These catalyze hydrogenations of protected dehydroamino acids and hydrosilylations of propiophenone with only modest enantioselectivities. Similar results are obtained when ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10** are applied in rhodium-catalyzed conjugate additions of aryl boronic acids, or palladium-catalyzed allylic alkylations.

Introduction

For some time, we have been interested in incorporating metal fragments into donor ligands that can be used in metal-catalyzed reactions – in other words, bimetallic catalysts in which one metal remains a "spectator" with respect to bond-breaking and bond-making.[1–4] This has in part been inspired by the immensely useful ferrocene-containing ligands, many of which are chiral and regularly applied in a variety of enantioselective catalytic transformations.[5] It would seem logical that other chiral metal fragments could also possess suitable – and perhaps superior – architectures for asymmetric induction. Furthermore, as described in several recent papers,[1,4b,6] eighteen-valence-electron complexes that feature a donor atom in the α or β position (e. g., L_nMPR_2: or $L_nMCH_2PR_2$:) are much more basic and nucleophilic than organic analogs that lack the metal (:PR_3). This is largely due to repulsive interactions involving the lone pair and occupied metal-based orbitals.[7] Hence, there are also opportunities for unusual electronic effects that may aid bond activation.

In previous papers, we have exploited these steric and electronic phenomena in reactions that result in new stereocenters,[2] and those that do not.[4] Other groups are also making important contributions to the design and application of non-ferrocenyl metal-containing ligands in catalysis.[8] We have often but not exclusively[4b] used the easily resolved[9] chiral rhenium fragment [(η^5-C_5H_5)Re(NO)(PPh_3)]$^+$ (**I**). Two types of bidentate ligands have been prepared, as illustrated by the diphosphanes **II** and diamine **IIIa** in Figure 1. In the first, the rhenium is part of the chelate backbone. In the second, two rhenium fragments are positioned exocyclic to the chelate backbone. The former gives rhodium complexes that catalyze hydrogenations and hydrosilylations with good to excellent enantioselectivities.[2a,2b,2e] The latter also gives metal complexes,[3] but these were not extensively investigated as catalysts, in part because the nitrogen atoms are configurationally labile stereocenters that can lead to multiple diastereomers upon chelation.

This situation – which can be desirable for some purposes but undesirable for others – is easily circumvented, as shown in ligand **IV**. Now four rhenium fragments are present, arrayed such that the donor atoms are no longer stereocenters. Accordingly, in this paper we describe (1) an

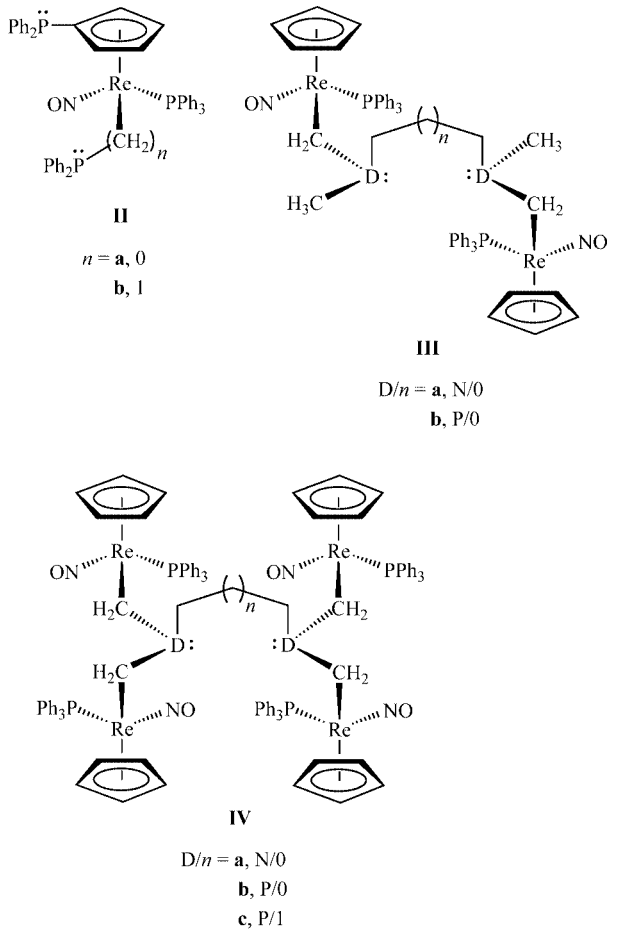

Figure 1. Evolution of families of chiral chelating ligands based upon the chiral rhenium fragment $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^+$ (**I**).

efficient and convenient route to diphosphanes of the type **IVb**,**c**, (2) the structural characterization of a diprotonated derivative, (3) the formation of dioxide and rhodium derivatives, and (4) exploratory catalytic reactions. These ligands can be regarded as derivatives of 1,2-bis(dimethylphosphanyl)ethane (DMPE) and 1,3-bis(dimethylphosphanyl)-propane (DMPP), the prototypical electron-rich 1,2- and 1,3-diphosphanes in coordination chemistry.[10]

Results

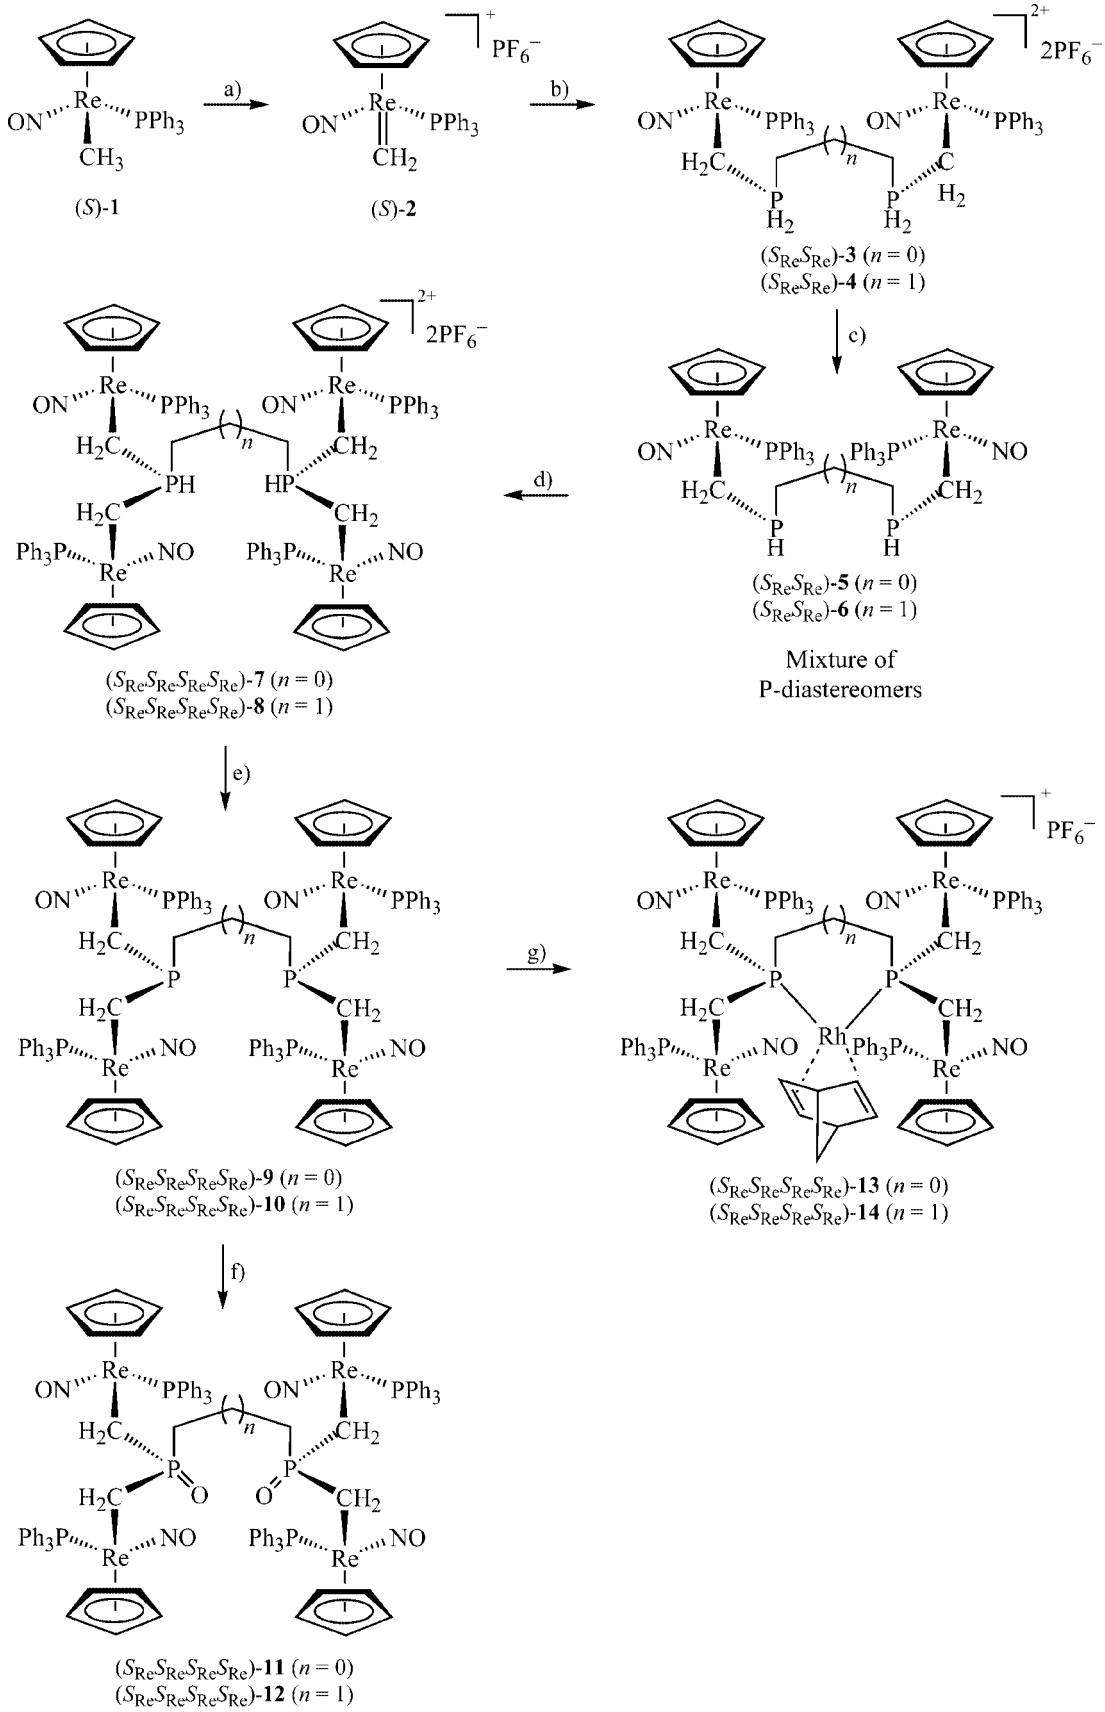
1. Dirhenium Complexes: The diprimary diphosphanes $PH_2CH_2(CH_2)_nCH_2PH_2$ (n = 0, 1) were purchased or prepared from the corresponding dibromides by published Arbuzov/reduction sequences.[11] As shown in Scheme 1, the enantiopure methyl complex (*S*)-$(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_3)$ [(*S*)-**1**][12,13] and trityl salt Ph_3C^+ PF_6^- were reacted in CH_2Cl_2 at –60 °C to generate the methylidene complex (*S*)-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(=CH_2)]^+$ PF_6^- [(*S*)-**2**].[14] Then a half-equivalent of $PH_2CH_2(CH_2)_nCH_2PH_2$ was added. Workups gave the diphosphonium salts $(S_{Re}S_{Re})$-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)\{CH_2PH_2CH_2(CH_2)_n\text{-}CH_2PH_2CH_2\}(Ph_3P)(ON)Re(\eta^5\text{-}C_5H_5)]^{2+}$ $2PF_6^-$ [n = 0/1, $(S_{Re}S_{Re})$-**3/4**][13] as yellow needles or powders in 65–62% and 77–58% yields. Both products were thermally stable and tolerated several hours in air. They were soluble in most polar organic solvents (CH_2Cl_2, DMF, ethanol, THF, dioxane) and insoluble in aliphatic or aromatic hydrocarbons.

Complexes $(S_{Re}S_{Re})$-**3/4** and all other new compounds below were characterized by IR and NMR (^1H, ^{13}C, ^{31}P) spectroscopy, mass spectrometry, and microanalysis, as summarized in the experimental section. The two rhenium moieties gave a single set of NMR signals. The ^1H NMR spectra showed two doublets of multiplets for the diastereotopic PHH′ protons, each with distinct ^1J(H,P) values. The ^{13}C NMR spectra exhibited P*C*H_2C signals (18.9/24.0 ppm) that were coupled to both protonated phosphorus atoms; that in $(S_{Re}S_{Re})$-**4** was particularly well-resolved [dd, ^1J(C,P) = 39, ^3J(C,P) = 15 Hz]. A number of chemical shift trends were evident, as analyzed elsewhere.[10a]

As shown in Scheme 2, a similar sequence was conducted with $PH_2(CH_2)_2PH_2$ and the *tetrafluoroborate* salt of the *racemic* methylidene complex, $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)\text{-}(=CH_2)]^+$ BF_4^- (**2′**). The less soluble *meso* diastereomer $(S_{Re}R_{Re})$-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)\{CH_2PH_2(CH_2)_2PH_2\text{-}CH_2\}(Ph_3P)(ON)Re(\eta^5\text{-}C_5H_5)]^{2+}$ $2BF_4^-$ [$(S_{Re}R_{Re})$-**3′**] precipitated from the reaction mixture and was isolated in 28% yield. This material was insoluble in all common solvents except DMSO. The *rac* diastereomer $(S_{Re}S_{Re},R_{Re}R_{Re})$-**3′** was isolated from the supernatant in 38% yield. The configurational assignments followed from the close similarity of the NMR and IR data for the latter diastereomer (especially the ^{13}C $ReCH_2$ signals) with those of non-racemic $(S_{Re}S_{Re})$-**3**.

As shown in Scheme 1, $(S_{Re}S_{Re})$-**3/4** were treated with *t*BuOK in THF. This gave bright orange solutions of the disecondary diphosphanes $(S_{Re}R_{Re})$-$(\eta^5\text{-}C_5H_5)Re(NO)\text{-}(PPh_3)\{CH_2PHCH_2(CH_2)_nCH_2PHCH_2\}(Ph_3P)(ON)Re(\eta^5\text{-}C_5H_5)$ [n = 0/1, $(S_{Re}S_{Re})$-**5/6**]. Since two phosphorus stereocenters are generated, ^{31}P NMR spectra of $(S_{Re}S_{Re})$-**5** were recorded in situ. In the absence of special kinetic or thermodynamic phenomena,[15] three diastereomers would be expected: $S_{Re}S_PS_PS_{Re}$, $S_{Re}R_PR_PS_{Re}$, and $S_{Re}S_PR_PS_{Re}$ (identical with $S_{Re}R_PS_PS_{Re}$). The last should exhibit two *P*CH_2 signals; the others, which have a C_2 axis, should give only one. The ^{31}P NMR spectrum showed four signals {δ [^1J(P,H)]: –29.6 (189), –32.3 (189), –36.1 (201), –36.4 (201) ppm} in an area ratio of 21:21:40:18. If it is assumed that the two peaks of equal intensity arise from $(S_{Re}S_PR_PS_{Re})$-**5**, a 42:40:18 mixture of diastereomers is obtained. Given this poor selectivity, no attempts were made to deconvolute the other NMR signals, and the mixtures were used directly for subsequent chemistry. The phosphorus inversion barriers are believed to be high, as supported by data for related compounds below.

2. Tetrarhenium Complexes: Following an extraction/filtration step, crude $(S_{Re}S_{Re})$-**5/6** were added to a cold solution of enantiopure (*S*)-**2** in CH_2Cl_2. As shown in Scheme 1, workups gave the ditertiary diphosphonium salts $(S_{Re}S_{Re}S_{Re}S_{Re})$-$[\{(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_2)\}_2\text{-}\{PHCH_2(CH_2)_nCH_2PH\}\{(CH_2)(Ph_3P)(ON)Re(\eta^5\text{-}C_5H_5)\}_2]^{2+}$



Scheme 1. Syntheses of tetrarhenium complexes; a) Ph_3C^+ PF_6^-, CH_2Cl_2, –60 °C; b) $PH_2CH_2(CH_2)_nCH_2PH_2$ (n = 0, 1), CH_2Cl_2, –60 to 25 °C; c) *t*BuOK, THF or CH_2Cl_2, 25 °C; d) (*S*)-**2**, CH_2Cl_2, –60 to 25 °C; e) *t*BuOK, THF, 25 °C; f) air or PhIO, CH_2Cl_2 or THF, 25 °C; g) $[Rh(NBD)_2]^+$ PF_6^-, THF, 25 °C.

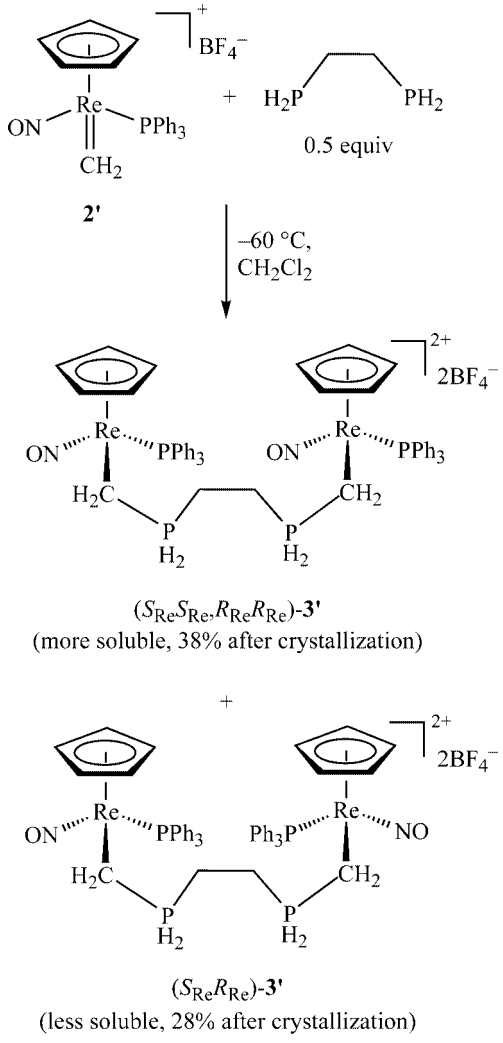

Scheme 2. Syntheses of the racemic and *meso* diphosphonium salt **3′**.

$2PF_6^-$ [n = 0/1, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8**].[13] These lack the phosphorus stereocenters of the precursors. The former was isolated as red prisms in 89–88% yields, and the latter as a yellow-orange powder in 98–87% yields. Both could be stored for months under ambient conditions, and were characterized analogously to the dirhenium analogs. They were soluble in CH_2Cl_2, acetone, THF, and 1,2-difluorobenzene, and insoluble in alcohols, ether, benzene, and alkanes.

The two L_nReCH_2 groups on each phosphorus atom of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** are diastereotopic, and related to those on the other phosphorus atom by a C_2 axis. Thus, two sets of NMR signals were observed. For example, ^{13}C NMR spectra showed two signals for the Re*C*H_2P*C*H_2Re carbons, and ^1H NMR spectra four multiplets for the ReC*HH′*PC*H′′H′′′*Re protons. As illustrated with ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** in Figure 2 (top), ^{31}P NMR spectra exhibited two PPh_3 signals. For all tetrarhenium complexes, the ^{31}P NMR coupling patterns are best approximated by non-first-order AA′BB′ CC′ spin systems, with CC′ representing the phosphorus atoms of the $PCH_2(CH_2)_nCH_2P$ moiety. The apparent triplets of the PPh_3 groups of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** could be duplicated in simulations, and the broad singlet of the PCH_2 group is interpreted as an unresolved triplet. Various chemical shift trends are analyzed elsewhere.[10a]

Complexes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** were reacted with *t*BuOK under rigorous oxygen-free conditions. Workups gave the title ditertiary diphosphanes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-{(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)}$_2${$PCH_2(CH_2)_nCH_2P$}{(CH_2)-(Ph_3P)(ON)Re(η^5-C_5H_5)}$_2$ [n = 0/1, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10**][13] as highly air sensitive, analytically pure red powders in 92% and 62% yields. Solutions could be kept for several hours at room temperature under argon. In contrast, the related monorhenium monophosphanes (η^5-C_5H_5)Re-(NO)(PPh_3)(CH_2PR_2) are stable in air for several hours, with even solutions showing only minor decomposition.[4a] Complexes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10** were characterized similarly to the others described above. The diastereotopic L_nReCH_2 groups gave separate NMR signals, as exemplified by the ^{31}P NMR spectrum of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** in Figure 2. Mass spectra showed only oxidation products.

In principle, the diastereotopic L_nReCH_2 groups can be exchanged via a phosphorus inversion/bond rotation sequence. Inversion barriers for tertiary organophosphanes are typically 28–36 kcal mol^{-1} (120–150 kJ·mol^{-1}).[16] Thus, NMR spectra of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** were recorded at elevated temperatures. However, no coalescence phenomena were observed in [D_8]toluene at 110 °C, conditions under which the complex has a half-life of ca. 10 min. From the frequency differences of the diastereotopic cyclopentadienyl (^1H, ^{13}C) and PPh_3 (^{31}P) groups, lower limits of 19.0–20.4 kcal mol^{-1} (79.4–85.5 kJ·mol^{-1}) could be calculated for the phosphorus inversion barrier ($\Delta G^{\ddagger}_{383\ K}$). This is much higher than the 14–16 kcal mol^{-1} typically found for analogous pyramidal metal phosphido complexes, L_nMPR_2.[17,18]

3. Derivatives of Tetrarhenium Diphosphanes and other Reactions: As shown in Scheme 1, when ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** was worked up in air, the diphosphane dioxide ($S_{Re}S_{Re}S_{Re}S_{Re}$)-{(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)}$_2$-{$PO(CH_2)_2PO$}{$(CH_2)(Ph_3P)(ON)$Re(η^5-C_5H_5)}$_2$ [($S_{Re}S_{Re}S_{Re}S_{Re}$)-**11**] was isolated in 95% yield. Alternatively, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** were sequentially treated with *t*BuOK and the oxygen atom donor PhIO. Workups gave ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**11/12** in 72% and 62% yields, with the latter containing small amounts of Ph_3PO. Both complexes were yellow-orange powders that could be stored under ambient conditions for months without decomposition. As shown in Figure 2, the ^{31}P NMR signal of the PO group of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**11** was 53 ppm downfield of the corresponding signal in ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9**, and coupled to the phosphorus atoms of the PPh_3 groups [^3J(P,P) = 17 Hz].

Next, the preparation of rhodium chelate complexes of the tetrarhenium diphosphanes was investigated. Thus, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** were sequentially treated with *t*BuOK and $[Rh(NBD)_2]^+$ PF_6^- under rigorous inert atmosphere conditions (NBD = norbornadiene). As shown in Scheme 1, workups gave the target complexes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-[({(η^5-

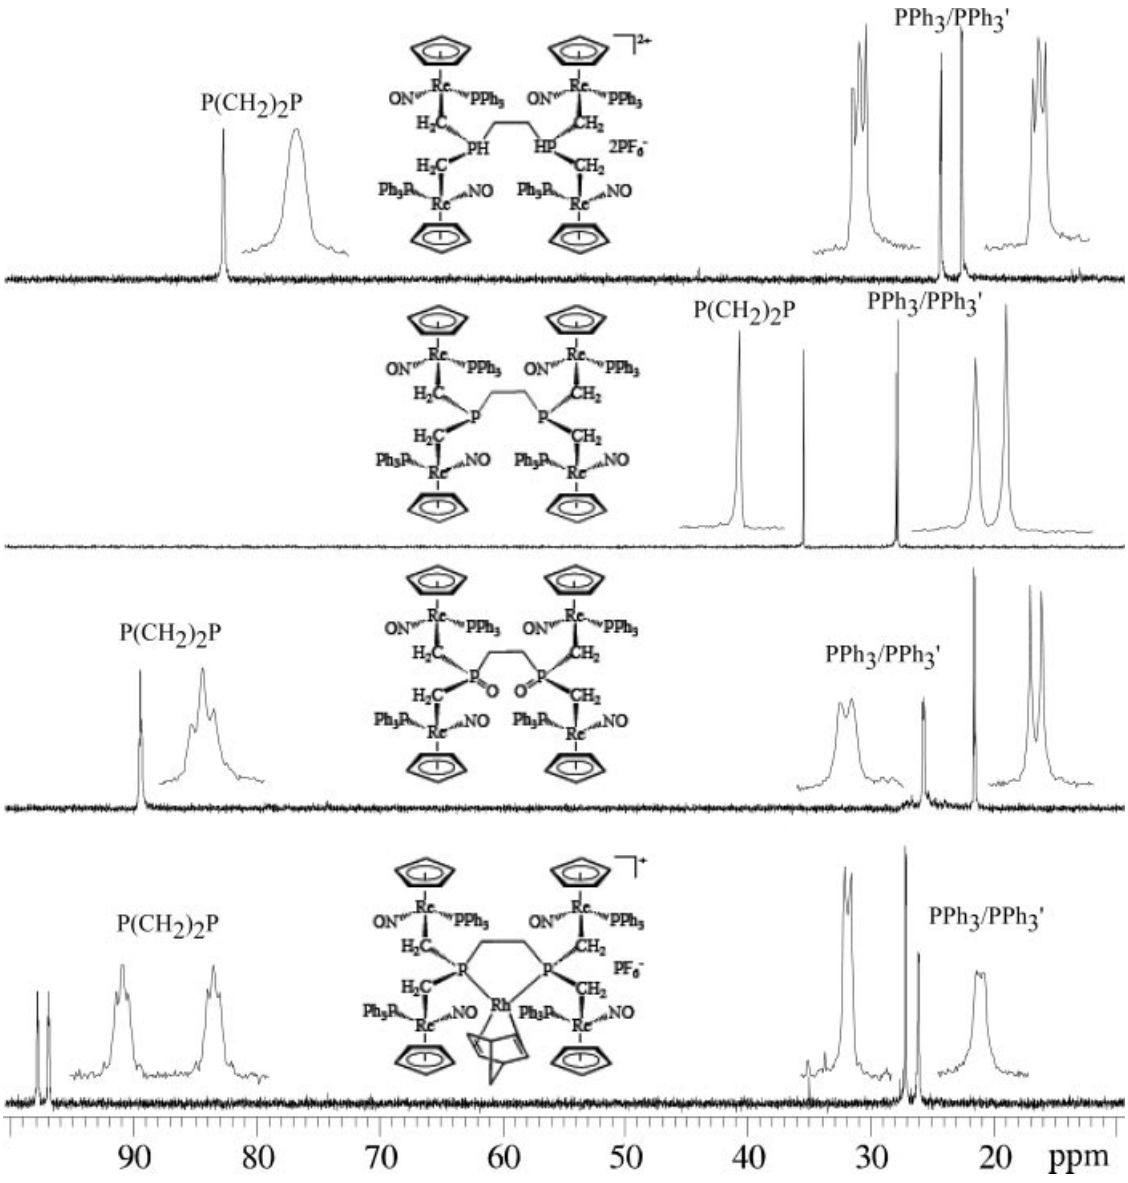

Figure 2. $^{31}P\{^{1}H\}$ NMR spectra of tetrarhenium complexes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**, -**9**, -**11**, and -**13** (from top to bottom).

C_5H_5)Re(NO)(PPh_3)$(CH_2)\}_2\{PCH_2(CH_2)_nCH_2P\}\{(CH_2)$-$(Ph_3P)(ON)Re(\eta^5$-$C_5H_5)\}_2)Rh(NBD)]^+$ PF_6^- [n = 0/1, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13/14**] as analytically pure red-brown powders in 75% and 82% yields. The mass spectra exhibited molecular ions with the correct isotope distributions. The ^1H and ^{13}C NMR spectra showed diagnostic signals for the NBD ligand. As illustrated in Figure 2, ^{31}P spectra displayed rhodium couplings [^1J(P,Rh) = 150–142 Hz] that confirmed the P–Rh–P chelate. Chemical shift trends, including ^{31}P NMR ring size effects, are analyzed elsewhere.[10a]

Finally, we sought to probe the Brønsted basicities of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10** with respect to related monorhenium complexes. Thus, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**, the monorhenium phosphonium salt $[(\eta^5$-$C_5H_5)Re(NO)(PPh_3)(CH_2PPh_2H)]^+$ PF_6^-,[4a] and *t*BuOK were combined in a 1:2:2 mol ratio in an NMR tube. After 1 h, all of the ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** remained. However, the monorhenium complex had been completely converted into the conjugate base (η^5-C_5H_5)Re-(NO)(PPh_3)(CH_2PPh_2). These data strongly suggest that the second L_nReCH_2 moiety on each phosphorus atom in ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10** further enhances the Brønsted basicity, and the equilibrium sketched in Scheme 3 can be formulated.

4. Catalysis: The tetrarhenium diphosphanes **9/10** were evaluated as ligands in several metal catalyzed transformations. Reactions previously examined with rhodium chelates of the monorhenium diphosphanes **II** (Figure 1)[2a,2b,2e] were studied first. Thus, the protected dehydroamino acids **15a**–**c** shown in Equation (1) of Scheme 4 were hydrogenated in the presence of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13** or -**14** that had been generated in situ from ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** or -**8**, *t*BuOK, and $[Rh(NBD)_2]^+$ PF_6^-. Reactions were complete over the course of 1–2 days at 75 °C under 8 bar of H_2. However, rhodium adducts of **II** were active at room temperature and under 1 bar of H_2. Furthermore, the enantioselectivities were poor, with the DMPP-type complex ($S_{Re}S_{Re}S_{Re}S_{Re}$)-

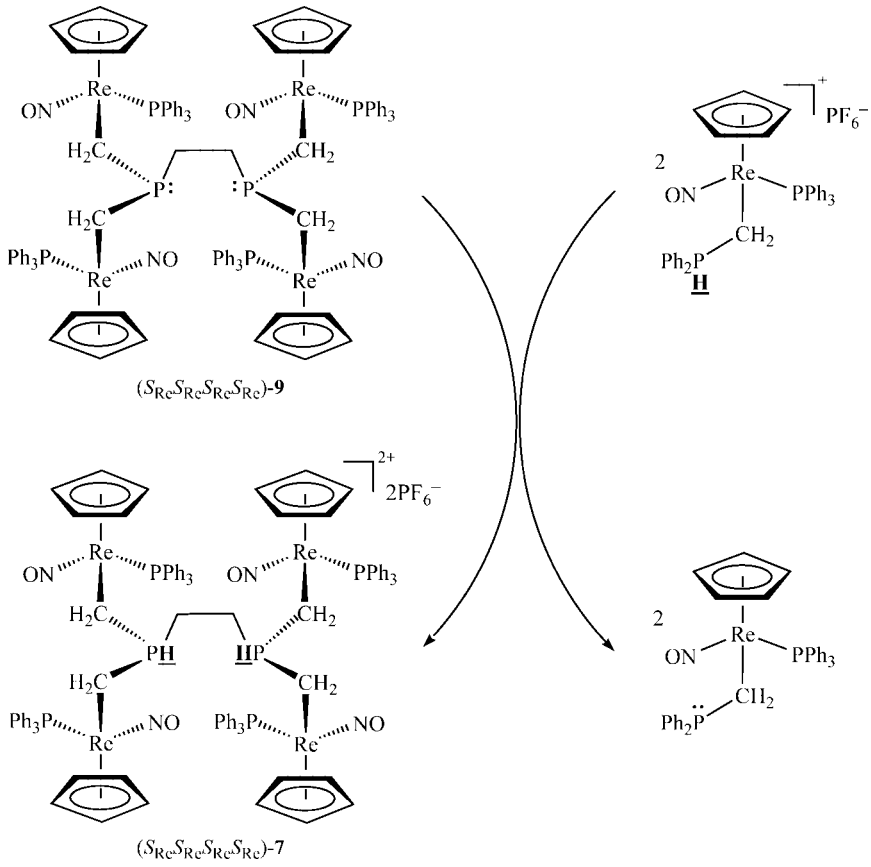

Scheme 3. Relative Brønsted basicities.

14 slightly better than the DMPE-type complex ($S_{Re}S_{Re}$-$S_{Re}S_{Re}$)-**13** (33–30% vs. 12% *ee*).

As shown in Equation (2) of Scheme 4, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13** was next evaluated as a catalyst for the hydrosilylation of propiophenone (**17**). Reactions with Ph_2SiH_2 were monitored by NMR, and required 6–14 days to reach 85–75% conversions. The silyl ether **18** was deprotected to the alcohol, which was racemic by chiral GC analysis. Under similar conditions, rhodium adducts of **II** gave complete reactions within 12 h, and *ee* values of 62–38%.[2e] Interestingly, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13** that had been isolated was less active than that generated in situ. Parallel experiments with Mes_2SiH_2 gave analogous results. This suggests that some of the activity associated with the catalysts generated in situ may arise from by-products, as opposed to ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13/14**.

Equation (3) of Scheme 4 shows another type of rhodium-catalyzed reaction, the conjugate addition of an arylboronic acid to an enone.[19] These are commonly carried out in dioxane/water mixtures at 100 °C with catalysts generated in situ from Rh(acac)($H_2C{=}CH_2$)$_2$ and a chelating diphosphorus donor ligand. We first verified earlier reports that (*S*)-BINAP is an effective ligand for the addition of phenylboronic acid to 2-cyclohexen-1-one (**19**).[20] GC and HPLC analysis indicated the formation of 3-phenylcyclohexanone (**20**) in >99% yield and >99% *ee*. However, under analogous conditions, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** and ($R_{Re}R_{Re}R_{Re}R_{Re}$)-**10** (generated in situ) gave **20** in only 8–7% yields (48–41% conversions) and 38–2% *ee*. The ligand (*R*)-**IIb** (Figure 1) was therefore tested, and afforded **20** in 30% yield (65% conversion) and 40% *ee*.

Many chiral chelating ligands have proven effective in palladium-catalyzed enantioselective allylic alkylations.[21] As shown in Equation (4) of Scheme 4, the condensation of dimethyl malonate with the allylic acetate **21** was probed using a standard set of conditions. Control experiments with racemic BINAP and (*S*)-BINAP gave the substitution product **22** in 61–47% yields (unoptimized) after flash chromatography. Analysis of the latter by chiral HPLC indicated a 94% *ee*. Analogous reactions with ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** and ($R_{Re}R_{Re}R_{Re}R_{Re}$)-**10** gave **22** in 47–37% yields but *ee* values of only 2%. The ligand (*R*)-**IIb** afforded a 16% *ee*. Hence, the title ligands give disappointing *ee* values in all reactions assayed, as further detailed elsewhere.[10b] They can therefore be regarded as *un*privileged ligands,[22] and possible factors are analyzed below.

5. Structural Data: The crystal structure of a CH_2Cl_2 disolvate of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** was determined as summarized in Table 2 and the experimental section. The unit cell was tetragonal, with four molecules of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** and belonging to the space group $P4_22_12$. Key metrical parameters are summarized in Table 1. The structure of the dication is depicted in Figure 3, together with *one* of the two PF_6^- anions. The dication features a C_2 axis at the midpoint of the C3/C3A bond and perpendicular to the idealized P–C3–C3A–P plane. This exchanges pairs of atoms such as

Scheme 4. Summary of catalytic reactions.

Re1/Re1A, Re2/Re2A, P3/P3A, and C3/C3A. Three of the fluorine atoms of the PF_6^- ion in Figure 3 are disordered (F33, F34, F35), but only the average positions are shown.

The most striking feature of the dication is the grouping of the bulky PPh_3 ligands in the same hemisphere. An up/down motif that would minimize steric interactions might have been intuitively expected. Consequently, a cavity is defined by the four cyclopentadienyl rings in the opposite hemisphere. This provides a pocket for the disordered PF_6^- anion. The P30–F34 bond is directed towards the PCH_2CH_2P bridge, and forms F–H–P hydrogen bonds with both PH groups (2.55 Å from the average position for F34 to the calculated hydrogen positions). The non-disordered fluorine atoms F31 and F31A form very slightly longer F–H–P hydrogen bonds with H3 and H3A, respectively.

The structures of many related molecules with $ReCH_2X$ linkages have been studied in solution and the solid state.[3,14,23–26] The Re–CH_2 and CH_2–X conformations often have an important bearing upon diastereomer equilibria and reaction stereoselectivity. Thus, Newman-type pro-

torsion angles (**V**, –145.2°; **VI**, –147.5°). This places the X group between the smaller cyclopentadienyl and nitrosyl ligands, which is the least congested interstice on rhenium.

Complexes are also known in which the X group bears three sterically differentiated substituents (L/M/S). Typically, the largest group (L) exhibits a torsion angle near 180°, such that the Re–CH_2 and X–L bonds are *anti*.[3,23–25] This is evident in the partial structure **V**, where there is a large CH_2Re substituent and a Re1–C1–P3–C2 torsion angle of –165.5. The overall result is a "*W*"-shaped five-atom Ph_3P–*Re*–CH_2–*P*–CH_2Re conformation. However, the situation in **VI** is different. Now the medium CH_2CH_2 group occupies the terminus of the "*W*"-segment (P2–Re2–C2–P3–C3). The large CH_2Re substituent is roughly gauche to the Re2–C2 bond, as reflected by a Re2–C2–P3–C1 torsion angle of 74.0°. Possible implications are analyzed below.

In efforts to better understand the modest enantioselectivities in Scheme 4, crystal structures of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13/14** were sought. All attempts to grow suitable single crystals were unsuccessful. Racemates are often easier to crystallize than enantiopure compounds. However, as easily seen from Scheme 2, the use of racemic rhenium building blocks would give intractable mixtures of diastereomers. Thus, the enantiomers ($S_{Re}S_{Re}S_{Re}S_{Re}$)- and ($R_{Re}R_{Re}R_{Re}R_{Re}$)-**7** were independently synthesized, mixed in a 1:1 ratio, and treated with *t*BuOK and then $[Rh(NBD)_2]^+$ PF_6^-. However, no crystals of racemic **13** could be obtained, even after adding a 10-fold excess of the BAr_F^- anion.

Discussion

1. Design Elements: Scheme 1 establishes the ready availability of a novel new class of diphosphane ligands that contain four symmetrically-disposed chiral-at-rhenium substituents and are based upon 1,ω-bis(dimethylphosphanyl)-alkane carbon skeletons. This methodology can likely be extrapolated to many types of derivatives, such as pentamethylcyclopentadienyl analogs or species with still longer methylene bridges. The overall yields of the ditertiary diphosphonium salts ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** from commercially available $Re_2(CO)_{10}$ (25%/22%) are similar to those of **II-a**,**b**,[2b] which compares well with most of the widely applied chiral ferrocene-based ligands.[5] Since ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7/8** can be stored for indefinite periods, they represent convenient depots for the very air sensitive title diphosphanes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10**.

The title diphosphanes can also be viewed in the evolutionary context of Figure 5. The structure **VII** embodies the essential features of DIOP, the classic chiral diphosphane introduced by Kagan in 1971.[27] The stereocenters can be moved closer to the phosphorus atoms as in **VIII**, a well-known example of which is CHIRAPHOS.[28] In **IX**, the phosphorus atoms become stereocenters, as exemplified by DIPAMP, another very early chiral diphosphane.[29] In later efforts, stereocenters were introduced exocyclic to the chelate backbone. Structure **X** corresponds to the DuPHOS ligand family,[30] in which the phosphorus atoms are no longer stereogenic. Motif **XI** can be viewed as a hybrid with both phosphorus and exocyclic stereocenters, and corresponds to **IIIb** in Figure 1. Finally, **XII** represents our new family of chiral diphosphanes.

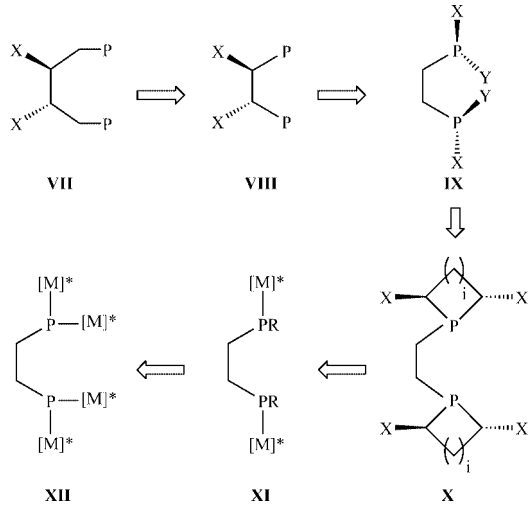

Figure 5. Motifs for chiral chelating diphosphanes. [M]* = "chiral-at-metal" group.

Surprisingly, we have not been able to locate any reports of diphosphanes with analogous arrays of four homochiral substituents. The most readily envisioned cases would involve substituents derived from the chiral pool. Unlike most chiral pool compounds, both enantiomers of the chiral rhenium building blocks are equally available. Therefore, both enantiomers of our ligands are easily accessed. There are also possibilities for other diastereomers, all of which are depicted schematically in Figure 6 using standard formalisms for systems with constitutionally equal stereocenters.[31] The shaded and unshaded circles in formulae **i**–**vii** denote mirror images of the chiral fragments. There are six chiral stereoisomers (**i**–**iii** with enantiomers a/b) and four *meso*-stereoisomers (**iv**–**vii**). Of the latter, **iv** and **v** possess a center of inversion (*i*) and two mirror planes, whereas **vi** and **vii** have only one mirror plane.

In seven of the ten isomers, at least one phosphorus atom is pseudoasymmetric.[32] These are designated with P_r and P_s chirality descriptors in Figure 6.[31] The many consequences of pseudoasymmetric atoms have been analyzed in detail. One requirement is that the configurations, here at phosphorus, remain invariant upon reflection through a mirror plane (e. g., **iia** vs. **iib**; **iiia** vs. **iiib**). Those in *meso* **iv**–**vi** are stereogenic but achirotopic since they lie on a local symmetry plane and permuting two rhenium fragments generates another *meso* form. Formula **ia** corresponds to the isomers synthesized in Scheme 1, ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10**. For illustration purposes, **v** would correspond to the structure shown in Figure 6.

Practical syntheses of these other diastereomers will require some serendipity, but should be possible. Consider the diastereomers ($S_{Re}S_{Re}$,$R_{Re}R_{Re}$)-**3′** and ($S_{Re}R_{Re}$)-**3′** in Scheme 2, which are easily separated. Subsequent reaction of the diphosphane corresponding to ($S_{Re}R_{Re}$)-**3′** with

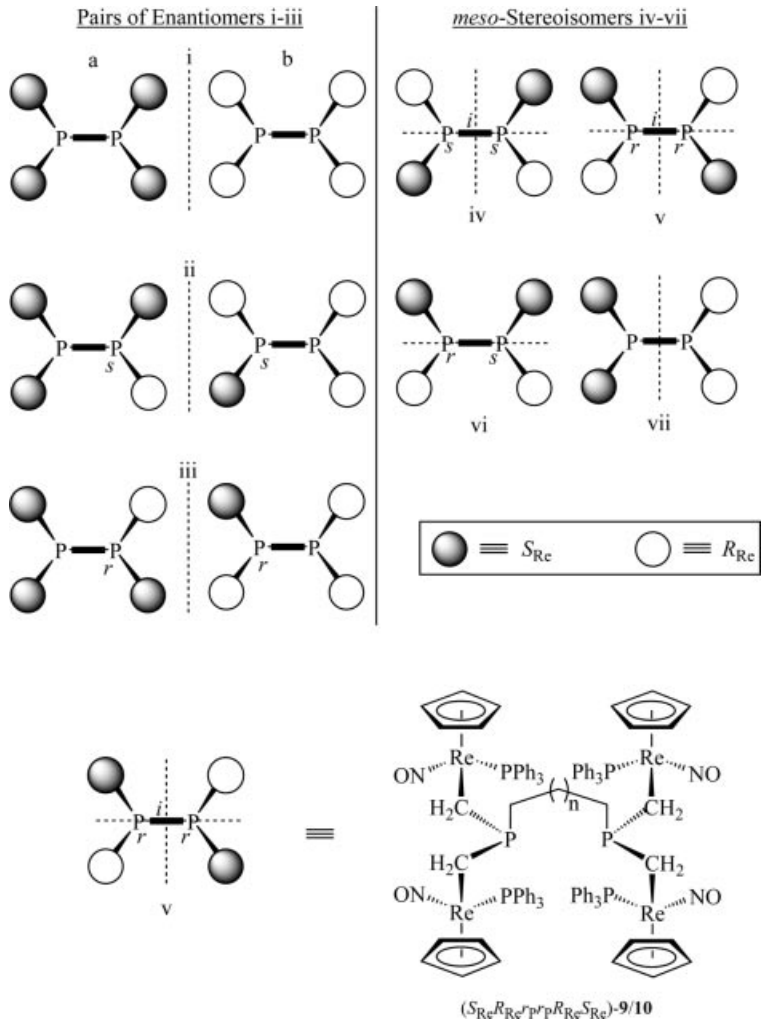

Figure 6. Possible stereoisomers of tetrarhenium diphosphanes. The descriptors *r* and *s* denote pseudoasymmetric phosphorus atoms, and *i* a center of inversion.

enantiopure rhenium methylidene complex **2** would yield only two non-racemic diastereomers, one of the type **ii** and the other of the type **iii**. This likely represents a tractable separation, and would allow all chiral stereoisomers to be secured. On the other hand, an analogous sequence with ($S_{Re}S_{Re}$,$R_{Re}R_{Re}$)-**3′** would be less useful, resulting in the known diastereomer **i**, and as many as three *meso* diastereomers (**iv**–**vi**).

2. Structure and Catalysis: The congested nature of the tetrarhenium systems is obvious in the crystal structure of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** (Figure 3). Despite this, the diphosphane ligands ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10** and $[Rh(NBD)_2]^+$ PF_6^- react to form the stable rhodium chelates ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13/14**. Bulky ligands and/or sterically restricted binding pockets can be favorable for asymmetric catalysis. However, the rates and *ee* values for enantioselective hydrogenations and hydrosilylations (Scheme 4) are much lower than those with analogous rhodium chelates of the diphosphanes **IIa**,**b** (Figure 1). One possible explanation is that the ligands in ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13/14** are simply too voluminous to allow effective catalysis. The residual activities might be due in part to achiral rhodium-containing decomposition products, which would be consistent with the modest *ee* values. One probe would be to test related complexes with only two chiral rhenium fragments, such as could be derived from **IIIb** (Figure 1). However, as noted above, multiple diastereomers are possible due to the phosphorus stereocenters.

The performances of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** and ($R_{Re}R_{Re}R_{Re}R_{Re}$)-**10** in rhodium-catalyzed conjugate additions of aryl boronic acids and palladium-catalyzed allylic alkylations are also disappointing (Scheme 4). In both reactions, catalysts are commonly generated in situ, and there is the question whether analogous species are formed from ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9** and ($R_{Re}R_{Re}R_{Re}R_{Re}$)-**10**. The aqueous conditions associated with the former reaction are a possible complicating factor. The diphosphane **IIb**, which we view as sterically less congested, also gives *ee* values distinctly lower than those of benchmark ligands. This leads us to believe that both classes of ligands are simply not

XIII (meso) **XIV** **XV** ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**

Figure 7. Conformations of compounds with Ph_3P–Re–CH_2–X–CH_2–Re–PPh_3 linkages.

competitive with existing systems. However, we note in passing that a DIOP derivative has been prepared with four P-ferrocenyl substituents.[33] The rhodium chelate catalyzes the hydrogenation of itaconic acid with reasonable enantioselectivities (40% *ee*).

The conformational features of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** highlighted in Figure 4 can be compared to those in related complexes. The crystal structure of the *meso* sulfonium salt ($S_{Re}R_{Re}$)-[{(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)}$_2$(SCH_3)]$^+$ I^- has been determined, and the conformation of the cation is depicted in **XIII** in Figure 7.[23] The seven-atom P–Re–CH_2–S–CH_2–Re–P linkage adopts an extended "*VVV*"-shape, with *anti* relationships between the bulkiest groups (*Ph*$_3$*P*–Re vs. CH_2–*S* and *Re*–CH_2 vs. S–*C*H_2*Re*). The sulfur atom is a pseudoasymmetric, and can assume a "matched" configuration such that the small lone pair is *syn* to both larger cyclopentadienyl ligands, and the medium CH_3 substituent is *syn* to both smaller nitrosyl ligands.

Since the rhenium atoms in ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** have the same configuration, a conformation analogous to that in **XIII** is not possible. The conformation **XIV** would maintain *anti* relationships between the bulkiest groups (*Ph*$_3$*P*–Re vs. CH_2–*P* and *Re*–CH_2 vs. P–*C*H_2*Re*) and a "*VVV*" shape. However, now the medium *C*H_2CH_2 substituent on phosphorus is forced into a *syn* relationship with one of the larger cyclopentadienyl ligands. This unavoidable "mismatch" raises the steric energy, and the alternative conformation **XV** is found in the crystal instead. Here, the ReCH_2–P bond has been rotated to bring the *Re*–CH_2 group *anti* to the P–*C*H_2CH_2 group, as in the partial structure **VI** (Figure 4). We therefore speculate that diastereomers of **7/8** of the types **ii** or **iii** (Figure 6), in which the type of "matched" relationship in **XIII** can be maintained on one of the two phosphorus atoms, may afford less congested and therefore superior catalysts.

Despite the inauspicious beginning in Scheme 4, we continue to believe that the tetrarhenium complexes in Scheme 1 should have useful applications in enantioselective catalysis, especially for reactions that involve fundamentally different mechanisms. For example, chiral phosphane oxides, diphosphane dioxides, and related species are very useful nucleophilic catalysts for enantioselective condensations of appropriate allylsilanes with carbonyl compounds.[34] High *ee* values can be obtained, and ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**11/12** represent attractive candidates for such chemistry. Furthermore, we have recently found that the rhenium-containing monophosphane (η^5-C_5H_5)Re(NO)(PPh_3)(CH_2PPh_2) effects enantioselective Baylis–Hillman reactions.[35] Thus, this general class of complexes has a promising future in catalysis, as will be detailed in future reports from this laboratory.

3. Conclusion

The types of chelating ligands available that contain the chiral rhenium fragment **I** have been significantly augmented by the new 1,2- and 1,3-diphosphanes ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**9/10**. These electron-rich, DMPE/DMPP derivatives are efficiently synthesized as outlined in Scheme 1, and are readily converted to diphosphane dioxides and rhodium chelate complexes. However, they have not proved to be effective ligands for metal-catalyzed enantioselective reactions in the cases examined to date. This may be due to their considerable bulk, as reflected by the crystal structure of a diprotonated derivative. Nonetheless, metal-containing ligands continue to make a major impact in enantioselective catalysis,[1,5] and additional applications of the compounds reported herein remain under investigation.

Experimental Section

General: Most general procedures, chemical purifications, and instruments were identical with those in a recent full paper.[4a] Further information is provided elsewhere.[10] HPLC was conducted using a ThermoQuest instrument package (pump/autosampler/detector P4000/AS 3000/UV 6000LP). Solvents were freshly dried before use, as detailed in the supporting information; for supporting information see also the footnote on the first page of this article. Purification steps new to this study: 2-cyclohexen-1-one (95+%, Aldrich), vacuum-distilled; H_2O (reaction cosolvent), freeze-pump-thaw degassed (3 cycles); KOAc (Merck), dried 24 h at 120 °C.

[(η^5-C_5H_5)Re(NO)(PPh_3){$CH_2PH_2CH_2(CH_2)_nCH_2PH_2CH_2$}-($Ph_3P$)(ON)Re($\eta^5$-$C_5H_5$)]$^{2+}$ 2X$^-$ (*n*/X = 0/PF_6, 3; 0/BF_4, 3′; 1/PF_6, 4): (**A**) A Schlenk flask was charged with (*S*)-**1** (0.327 g,

[({(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)}$_2${$PCH_2(CH_2)_nCH_2P$}{(CH_2)-(Ph_3P)(ON)Re(η^5-C_5H_5)}$_2$)Rh(NBD)]$^+$ PF_6^- [*n* = 0/1, 13/14 (see Scheme 1)**]:** (**A**) A glass vial was charged with ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**·(CH_2Cl_2)$_2$ (0.124 g, 0.0447 mmol) and THF (5 mL) in a glove box. Then *t*BuOK (1.0 M *in* THF; 0.107 mL, 0.11 mmol) was added dropwise with stirring. The vial was sealed with a screw cap. After 30 min, the solvent was removed by oil pump vacuum. The orange powder was extracted with toluene (5 mL) in a glove box. The extract was passed through a PTFE syringe filter. Then [Rh(NBD)$_2$]$^+$ PF_6^- (0.0193 g, 0.0447 mmol)[40] was added with stirring. After 1 h, pentane (20 mL) was added dropwise. After 30 min, the precipitate was collected by filtration and dissolved in $CHCl_3$ (5 mL). A layer of pentane was gently added. After 2 days, the supernatant was decanted and the red-brown powder dried by oil pump vacuum to give ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**13**·($CHCl_3$)$_2$ (0.093 g, 0.032 mmol, 75%). M. p. 230–235 °C (dec). $C_{105}H_{100}F_6N_4O_4P_8Re_4Rh$·($CHCl_3$)$_2$ (2899.3): calcd. C 44.33, H 3.55, N 1.93; found C 44.26, H 3.86, N 1.72. MS (FAB, 3-NBA): *m*/*z* (%) = 2529 (6) [M]$^+$, 558 (100) [(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2)]$^+$.

Relative Brønsted Basicities: A 5-mm NMR tube was charged with ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7** (0.0196 g, 0.0075 mmol), [(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2PPh_2H)]$^+$ PF_6^- (0.0133 g, 0.015 mmol),[4a] and CD_2Cl_2 (0.60 mL) in a glove box. A reference ^{31}P{^{1}H} NMR spectrum was recorded. Then *t*BuOK (1.0 M in THF; 0.015 mL, 0.015 mmol) was added. The orange solution became darker. After 1 h, a ^{31}P{^{1}H} NMR spectrum showed complete conversion of [(η^5-C_5H_5)Re(NO)(PPh_3)(CH_2PPh_2H)]$^+$ PF_6^- to (η^5-C_5H_5)Re(NO)(PPh_3)(CH_2PPh_2) and no reaction of ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**.

Hydrogenations: A Fisher–Porter bottle was charged with **7** or **8** (0.012 mmol) and THF (10 mL) in a glove box, and *t*BuOK (1.0 M in THF; 0.028 mL, 0.028 mmol) was added with stirring. After 5 min, [Rh(NBD)$_2$]$^+$ PF_6^- (0.0043 g, 0.010 mmol)[40] was added, giving an orange solution. After 30 min, **15** (2.00 mmol; Scheme 4) and THF (10 mL) were added. The bottle was closed under argon and purged with H_2 (75 psi, 3 ×). The mixture was vigorously stirred under H_2 (120 psi, 8 bar, 75 °C). After 1–2 h, **16** was isolated by a standard workup.[2b,2e] Configurations and enantiomeric purities were determined as described previously.[2b,2e]

Hydrosilylations: A glass vial was charged with **7** or **8** (0.0052 mmol) and THF (5 mL) in a glove box, and *t*BuOK (1.0 M *in* THF; 0.0125 mL, 0.012 mmol) was added with stirring. After 5 min, [Rh(NBD)$_2$]$^+$ PF_6^- (0.0022 g, 0.0050 mmol)[40] was added. After 30 min, **17** (0.184 g, 1.00 mmol; Scheme 4), and Ar_2SiH_2 (1.2 mmol) were added, and the vial sealed with a screw cap. The sample was stirred (24–26 °C, glove box). Aliquots were dissolved in $CDCl_3$ and the ^{1}H NMR signals of **17** integrated against those of **18**.[2e] After 14 days, a saturated solution of K_2CO_3 in methanol was added (1 mL). After 1 h, the solvents were removed by oil pump vacuum and the residue filtered through a silica gel column (4 × 1 cm) using hexanes. This gave crude 1-phenyl-1-propanol, the enantiomeric purity of which was assayed by GC (Lipodex-E).

Conjugate Additions: A Schlenk tube was charged with **7** or **8** (0.0144 mmol) and dioxane (1 mL) in a glove box, and *t*BuOK (1.0 M in THF, 0.03 mL, 0.03 mmol) was added with stirring. After 30 min, Rh(acac)(H_2C=CH_2)$_2$ (0.0031 g, 0.012 mmol)[42] was added, giving a brown mixture. After 30 min, phenylboronic acid (0.244 g, 2.00 mmol) and **19** (0.039 mL, 0.039 g, 0.40 mmol; Scheme 3) were added. After 15 min, H_2O (0.100 mL) was added, giving a brown solution. The sample was stirred under argon at 100 °C. After 5 h, the dark brown solution was cooled to room temperature. Saturated aqueous $NaHCO_3$ (5 mL) was added. The organic layer was separated. The aqueous layer was extracted with CH_2Cl_2 (3 × 5 mL). The combined organic phases were dried ($MgSO_4$). Hexanes (10 mL) were added, and the solution was filtered through a silica gel pad (2 × 3 cm) using hexanes/EtOAc (5:1 v/v, 2 × 5 mL; this removes rhodium complex). Decane (0.039 mL, 0.029 g, 0.20 mmol; internal standard) was added to the filtrate. The yield of **20** was assayed by GC (OPTIMA-5). The solution was filtered through a silica gel column using hexanes/EtOAc (5:1 v/v) and the enantiomeric purity was assayed by HPLC (Chiralcel OD). NMR: See Supporting Information.

Allylic Alkylations: A Schlenk tube was charged with **7** or **8** (0.0180 mmol) and CH_2Cl_2 (1 mL) in a glove box, and *t*BuOK (1.0 M in THF, 0.054 mL, 0.054 mmol) was added with stirring. After 5 min, [Pd(η^3-C_3H_5)Cl]$_2$ (0.0027 g, 0.0074 mmol) was added, followed by a solution of **21** (0.0757 g, 0.300 mmol; Scheme 4)[43] in CH_2Cl_2 (1 mL). A vial was charged with dimethyl malonate (0.103 mL, 0.119 g, 0.901 mmol), CH_3(C=NTMS)OTMS (0.220 mL, 0.183 g, 0.900 mmol), KOAc (0.0015 g, 0.015 mmol), and CH_2Cl_2 (1 mL). This mixture was added dropwise to the Schlenk tube with stirring. After 24 h, ether (15 mL) was added. The mixture was washed with cold, saturated aqueous NH_4Cl (2 × 7.5 mL), dried (Na_2SO_4), and concentrated by rotary evaporation. Flash chromatography on silica gel (1.5 × 17 cm, 3:1 v/v, hex-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

anes/EtOAc, R_f = 0.68) gave a slightly yellow oil that when dried by oil pump vacuum afforded **22** as white solid. The enantiomeric purity was analyzed by HPLC (Chiralcel OD). NMR: See Supporting Information.

X-ray Crystallography: Data were collected on ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**·$(CH_2Cl_2)_2$ (see above) as outlined in Table 2. Cell parameters were obtained from 10 frames using a 10° scan and refined with 12270 reflections. Lorentz, polarization and absorption corrections were applied.[44] The space group was determined from systematic absences and subsequent least-squares refinement. The structure was solved by direct methods. The parameters were refined with all data by full-matrix-least-squares on F^2 using SHELXL-97.[45] Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were fixed in idealized positions using a riding model. Scattering factors were taken from the literature.[46] The asymmetric unit contained a half molecule of the tetrarhenium complex. Three fluorine atoms of one PF_6^- anion (F33, F34, and F35) were disordered about a symmetry axis and were refined with an occupancy ratio of 50:50. The rhenium configuration was established by Flack's *x* parameter [found: –0.018(7); theory for correct and inverted structures: 0 and 1].[47]

Table 2. Crystallographic data for ($S_{Re}S_{Re}S_{Re}S_{Re}$)-**7**·$(CH_2Cl_2)_2$.

Molecular formula	$C_{100}H_{98}Cl_4F_{12}N_4O_4P_8Re_4$
Molecular mass	2782.18
Temp. of collection [°C]	–100(2)
Diffractometer	KappaCCD
Radiation [Å]	Mo-K_α
Crystal system	tetragonal
Space group	$P4_22_12$
Unit cell dimensions:

The Reductive Elimination of Methane from *ansa*-Hydrido(methyl)metallocenes of Molybdenum and Tungsten: Application of Hammond's Postulate to Two-State Reactions

José-Luis Carreón-Macedo,[a] Jeremy N. Harvey,*[a] and Rinaldo Poli*[b]

Keywords: Density functional theory / Metallocenes / Minimum energy crossing points / Hammond's postulate / Spin crossover reactivity

The energetic profile of the methane reductive elimination from a selected number of hydrido(methyl)molybdenocene and -tungstenocene derivatives has been calculated by DFT methods. The calculations were carried out for the $CH_2(C_5H_4)_2M$ (*a*-M), $SiH_2(C_5H_4)_2M$ (*a*-H_2Si–M), and Si$Me_2(C_5Me_4)_2M$ (*a*-Me_2Si–M*) *ansa*-metallocene systems for M = Mo, W. They include the full optimization of minima [the hydrido(methyl) starting complexes, M(H)(CH_3), the intermediate methane complexes, M(CH_4), and the metallocene products in the singlet and triplet configurations, (^{3}M and ^{1}M)], transition states (for the methyl hydride reductive elimination, M–TS_{ins}, and for the hydrogen exchange, M–TS_{exch}), and the minimum energy crossing point (M–MECP) leading from the singlet methane complexes to the corresponding triplet metallocenes. The results are compared with those previously obtained for the simpler $(C_5H_5)_2M$ (Cp_2M) systems (J. C. Green, J. N. Harvey, and R. Poli, *J. Chem. Soc., Dalton Trans.* **2002**, 1861). The calculated energy profiles, notably the relative energies of M–TS_{ins} and M–MECP, are in agreement with available experimental observations for the *a*-Me_2Si–M* systems. The comparison of the energies and geometries of the rate-determining M–TS_{ins} and M–MECP structures with those of the thermodynamically relevant minima for the various systems show the applicability of Hammond's postulate to two-state reactions. However, one notable exception serves to show that the principle is only quantitatively reliable when all the potential energy surfaces for the set of analogous reactions have similar shapes.

Introduction

The reductive elimination of alkyl hydride complexes to liberate a molecule of saturated alkane is a fundamental step in catalytic hydrogenation,[1,2] whereas the reverse process is relevant for the functionalization of hydrocarbons.[3,4] Both have been topics of intense investigation.[5–7] A particular class of compounds that has attracted considerable attention is the family of the Group 6 metallocenes, Cp′$_2$M(H)(R) (M = Mo, W; Cp′ = any cyclopentadienyl ligand),[8–13] in particular with R = CH_3, involving the formation and/or activation of methane. An interesting feature of this family (shared with other systems) is that the 16-electron complex Cp′$_2$M has a different spin state – a triplet – from that of the diamagnetic Cp′$_2$M(H)(R).[14–17] Thus, the process that interconverts the two complexes is a two-state reaction.[18] Experimental work suggests that the elimination of methane from Cp′$_2$M(H)(CH_3) proceeds via σ-CH_4 intermediates, Cp′$_2$M(η^2-CH_4) where the CH_4 ligand coordinates through the electrons of one σ-C–H bond, because scrambling processes between the hydride and the methyl H atoms have sometimes been found by deuterium labeling experiments to be competitive or faster than the elimination process. Theoretical studies have addressed this issue and confirmed the existence of such intermediates, which possess a singlet ground state like the alkyl(hydrido) reagent.[15,17] In addition, these studies have identified the transition states leading to the H exchange and the oxidative addition.

However, to fully understand the reaction coordinate leading to the elimination products, it is also necessary to explicitly determine the minimum energy crossing point (MECP) between the singlet and triplet surfaces. As shown schematically in Figure 1, crossing occurs during the elimination process of the CH_4 ligand from the coordination sphere of the intermediate σ-CH_4 complex, M(CH_4), leading to the triplet metallocene, ^{3}M.[17] There are two possible limiting scenarios. In the first one (part a of Figure 1), the insertion transition state (M–TS_{ins}) leading from the M(CH_4) intermediate to the hydrido(methyl) complex, M(H)(Me), has a lower energy than the MECP (M–MECP). When this is the case, provided the exchange of the coordinated C–H bond for the methane ligand also occurs through a lower energy transition state (M–TS_{exch}) than the M–MECP, the hydrogen scrambling process is faster than

the methane elimination. This situation can be kinetically defined as a pre-equilibrium between the starting M(H)(Me) complex and the intermediate M(CH_4) complex, followed by rate-limiting methane dissociation, in which the overall rate is controlled by the M–MECP energy. In the second scenario (part b of Figure 1), the energy of M–TS_{ins} is higher than the M–MECP. In this case, the methane elimination is kinetically a one-step process determined by the M–TS_{ins} energy, and no H scrambling is observed. In our previous computational study of this phenomenon for the simple metallocenes of Mo and W, Cp_2M,[17] which included the explicit calculation of M–TS_{ins} and M–MECP geometries and energies, we found that E(M–TS_{ins}) > E(M–MECP) for Cp_2Mo [31.0 and 4.3 kJ mol^{-1}, respectively, relative to the M(CH_4) intermediate], whereas the two energies are comparable for Cp_2W (9.8 and 9.1 kJ mol^{-1}). Thus, the Mo system corresponds to the situation (b) whereas the W analogue shows an intermediate behavior. Analogous calculations on the *ansa* system [$CH_2(C_5H_4)_2$]W (*a*-W), on the other hand, resulted in situation (a): E(M–TS_{ins}) = 4.4 kJ mol^{-1} and E(M–MECP) = 17.3 kJ mol^{-1}. The corresponding *ansa*-molybdenum system (*a*-Mo) was not explored in detail.

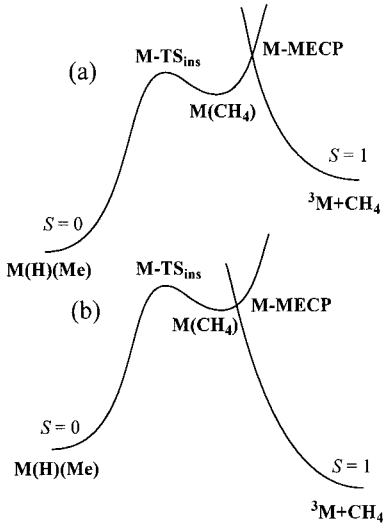

Figure 1. Reaction coordinate leading from $Cp'_2M(H)(CH_3)$ to Cp'_2M + CH_4. (a) E(M–TS_{ins}) < E(MECP); (b) E(M–TS_{ins}) > E(M–MECP).

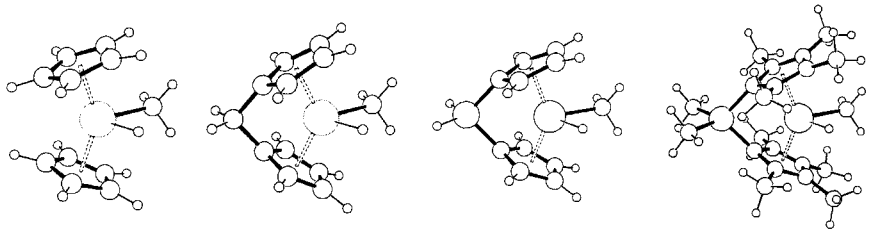
Recent elegant work by Parkin et al. has provided experimental evidence, through the determination of kinetic isotope effects (KIE), for the occurrence of these two limiting situations with the methane or benzene reductive eliminations of [$Me_2Si(C_5Me_4)_2$]Mo(H)(Ph) and [$Me_2Si(C_5Me_4)_2$]-W(H)(R) where R = Me, Ph. Whereas the molybdenum system is characterized by a normal KIE, i.e. $k_H/k_D > 1$, the tungsten systems exhibit an overall inverse KIE which derives from a combination of an inverse equilibrium isotope effect (EIE) for the reductive-elimination step, and a near-zero KIE for the spin-forbidden methane dissociation step. The KIE for the reductive-elimination step is, like for the Mo case, normal, but it does not determine the overall KIE because it is not the rate-limiting step.[13] This can be expressed in other terms; the nature of the bonding of the key hydrogen (or deuterium) atom at the different stationary points along the reaction coordinate is qualitatively the same in the Mo and W cases. Bonding is fairly tight for the starting metal hydride (in the M–H or M–D bond), then becomes looser at the elimination TS, where H (D) is only partly bonded to M and C, then is at its tightest in the strong C–H (or C–D) bond which is present in the intermediate, the MECP and the products. This difference in bonding leads to differences in zero-point energies, which together with the fact that the overall bottleneck to the reaction is different in the two cases, explains the isotopic effects. Thus, the normal KIE for the decomposition of the Mo complex corresponds to the situation illustrated in Figure 1(b), whereas the overall inverse KIE observed for the W complexes results from an energetic profile as shown in Figure 1(a).

This difference was attributed by Parkin et al. to the relative stability of the starting [$Me_2Si(C_5Me_4)_2$]M(H)(R) and final [$Me_2Si(C_5Me_4)_2$]M complexes (here represented as *a*-Me_2Si–W* or *a*-Me_2Si–Mo*), implicitly invoking Hammond's principle for the relative energy of the two critical points. However, this hypothesis was not accompanied by a computational verification. In a separate contribution, Parkin et al. have reported calculations of the relative energy of the TS and crossing point for the W system, the crossing point having a marginally higher energy (ca. 33 kcal mol^{-1}) than the TS (30.1 kcal mol^{-1}).[19] The study, however, does not report similar calculations for the Mo system. In addition, the crossing point was estimated by a procedure that



Scheme 1.

we have termed the "partial optimization method",[20] which is more approximate than the explicit calculation of the MECP. The purpose of the present study is to complete the comparison of the *ansa*-[$CH_2(C_5H_4)_2$]M (M = Mo, W) systems, to compare these systems with the simpler metallocenes that we have previously described,[17] and to analyze the TS and MECP energies and geometries in more detail, in light of Hammond's postulate. In addition, we extend and apply the same analysis to the simplified systems [$H_2Si(C_5H_4)_2$]Mo (*a*-H_2Si–Mo), [$H_2Si(C_5H_4)_2$]W (*a*-H_2Si–W), and finally to the experimentally reported systems *a*-Me_2Si–W* and *a*-Me_2Si–Mo*. The labels used throughout this contribution contain a first part to identify the metallocene core (the generic M in Figure 1), and a second part to identify the way in which this interacts with the methane molecule, following the pattern shown in Figure 1. Views of the hydrido(methyl) derivatives for all systems investigated in this study, and the corresponding labels, are given in Scheme 1.

Results and Discussion

Cp_2M and *a*-M Systems

The new results reported here complete a previous study of ours, dealing with the reductive-elimination process of CH_4 from hydrido(methyl) derivatives of Cp'_2M, where Cp′ = Cp (Cp_2M) or Cp'_2 = $CH_2(C_5H_4)_2$ (*a*-M) and M = Mo and W.[17] In that study, DFT calculations were carried out with the B3LYP functional and two different basis sets. The complete set of critical points along the reaction pathway (including M–TS_{ins} and M–MECP) was determined only with the simpler LANL2DZ basis set, whereas a more sophisticated basis set, where the C and H atoms were described by polarized 6-31G** basis functions, was used only to recalculate all local minima. In addition, all the calculations were carried out using the standard B3LYP level of density functional theory. In recent work, we have found that relative energetics obtained for organometallic species, especially the spin-state splitting between high- and low-spin states, can depend quite strongly on the functional used.[21–23] We therefore decided to validate the method used in our previous work by considering larger basis sets and other DFT functionals, for one of the systems under consideration, i.e. [$CH_2(C_5H_4)_2$]W (*a*-W). These results are summarized in Table 1.

As can be seen, the four sets of calculations using the B3LYP and B3PW91 hybrid functionals yield very similar results. The binding energy of the *a*-W(CH_4) intermediate is slightly lower with the small basis set, and slightly larger with the B3PW91 functional, but the differences are smaller than the expected error levels in both cases. Somewhat larger differences are noted between the hybrid functionals and the gradient-corrected BP86 functional. These differences can all be interpreted in terms of a relatively larger stabilization of the triplet fragment with the hybrid functionals than with BP86. This type of behavior is fairly general[21] and can be attributed to the admixture of Hartree–Fock exchange in hybrid functionals which favors the high-spin state. Even here, though, the differences between methods are only of the order of 10–15 kJ mol^{-1}, and would be unlikely to affect the qualitative conclusions. We have therefore carried out the rest of this work using the simpler B3LYP/LANL2DZ and B3LYP/6-31G** calculations.

In our earlier work, as well as locating some of the stationary points only with the smaller LANL2DZ basis, no TS and MECPs were calculated, with either basis, for the *ansa*-Mo system, [$CH_2(C_5H_4)_2$]Mo (*a*-Mo). We have now completed the study of these four systems by calculating all missing TS and MECPs at both levels, see Table 2.

We shall discuss here only the relevant new points. For the more basic features of this system, we refer the reader to our previous contribution.[17] The relative energies at the two computational levels are in relatively good agreement within the singlet state. The 6-31G** basis set leads to somewhat lower triplet-singlet gaps for the 16-electron Mo systems, whereas nearly identical gaps are found at the two levels for the two W systems. The 6-31G** calculations lead, for all systems, to significantly lower M–TS_{ins} energies relative to the M(CH_4) complex, whereas the relative energy of the M–MECP is less affected. We shall provide a more detailed discussion of the relative energetics and geometries only on the basis of the 6-31G** results. These are given in Figures 2 and 3. However, the considerations would be the same on the basis of the LANL2DZ results.

For all systems, M–TS_{exch} is very low, leading to fast scrambling of the C–H bonds in the M(CH_4) intermediate. Only for the *a*-W system, is the H exchange barrier higher

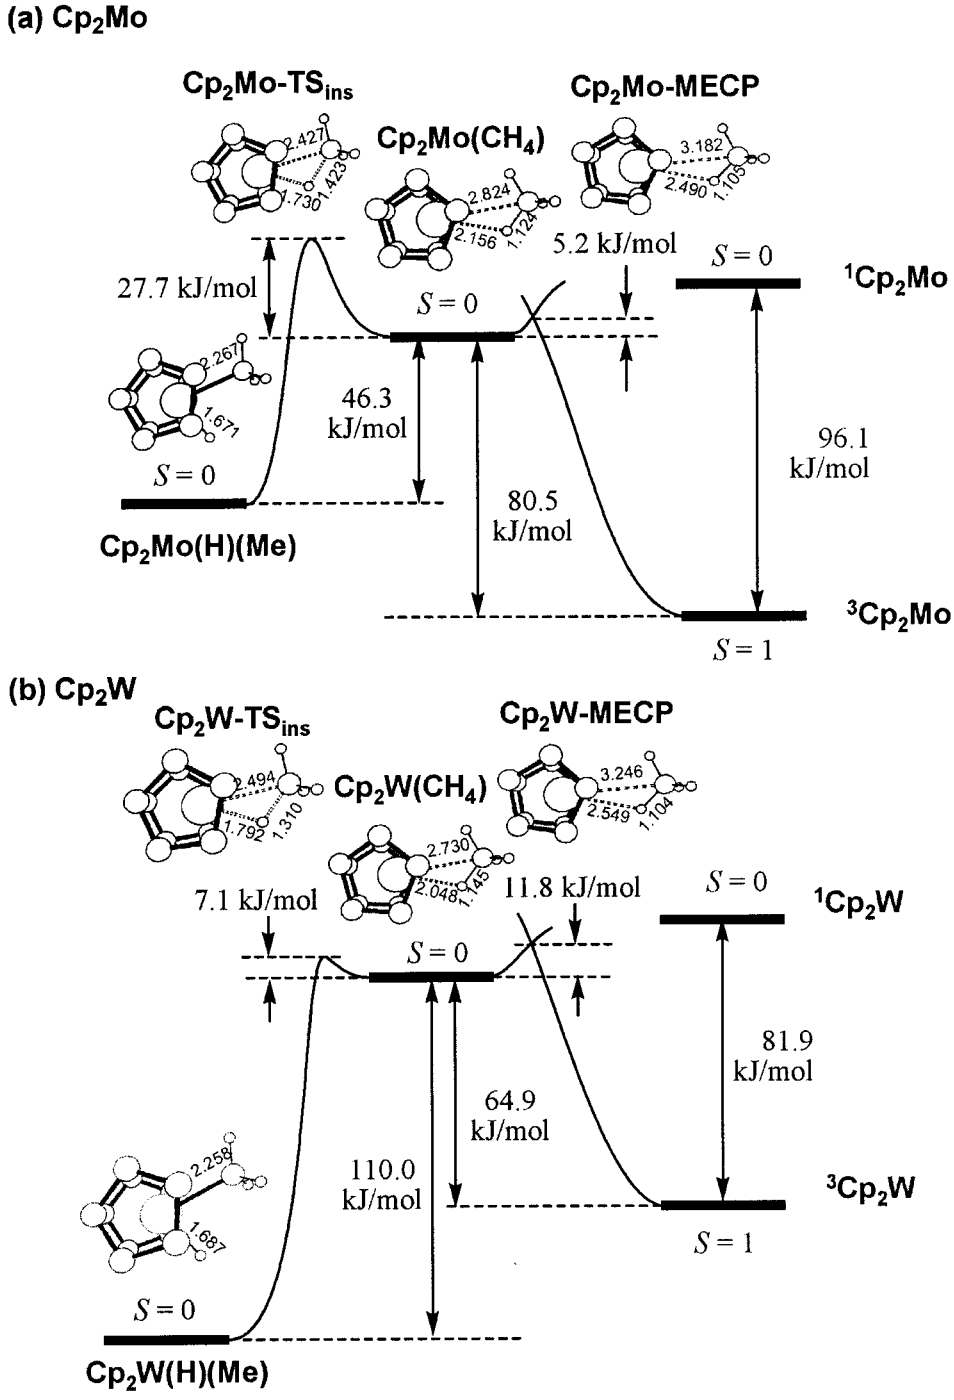

Figure 2. Reaction coordinate for the CH_4 oxidative addition to Cp_2M, with simplified views and selected bonding parameters [Å] for the relevant optimized structures. The H atoms on the cyclopentadienyl rings have been omitted for clarity. All energies are at the B3LYP/6-31G** level.

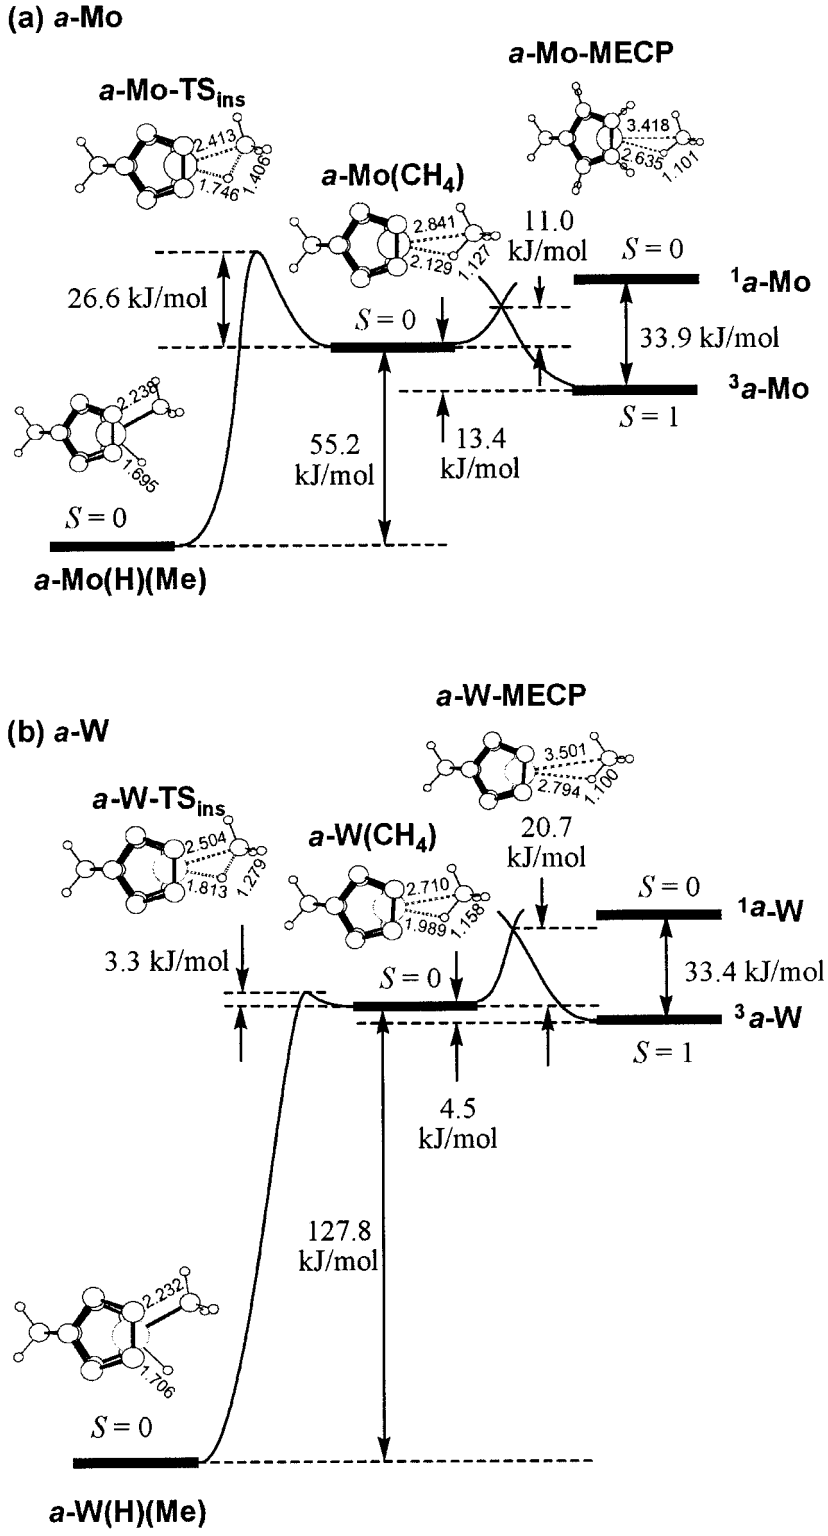

Figure 3. Reaction coordinate for the CH_4 oxidative addition to *a*-M, with simplified views and selected bonding parameters [Å] for the relevant optimized structures. The H atoms on the cyclopentadienyl rings have been omitted for clarity. All energies are at the B3LYP/6-31G** level.

than the insertion barrier (6.4 vs. 3.3 kJ mol^{-1}), but scrambling is still favorable relative to CH_4 dissociation, as experimentally verified for the $Me_2C(C_5H_4)_2W$ system.[12] As we will discuss further on, this is concordant in terms of the high barrier induced by the M–MECP. The M–TS$_{exch}$ geometry is in all cases symmetrical with identical M–H distances and a planar MH_2C arrangement with overall C_{2v} symmetry, in agreement with a previous report.[15]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

For the Cp_2M systems (Figure 2), the qualitative picture remains the same as previously shown on the basis of the LANL2DZ calculations. For the Mo system, the oxidative addition barrier (TS) is much higher than the M–MECP [27.7 vs. 5.2 kJ mol^{-1}, relative to the M(CH_4) intermediate]. For the W system, the M–TS_{ins} is slightly lower than the M–MECP (7.1 vs. 11.8 kJ mol^{-1}), whereas these two energies are closer at the LANL2DZ level. Experimentally, H exchange and CH_4 elimination were found to be competitive, the H exchange barrier being slightly lower.[9] No experimental data is available to be compared with the Mo system. For the *ansa* systems (Figure 3), the CH_4 elimination is again more favorable than the oxidative addition for Mo, whereas oxidative addition is now strongly preferred for the W system. This picture is in qualitative agreement with the experimental observation of H-scrambling processes for $Me_2C(C_5H_4)_2W(H)(CH_3)$, whereas no methane elimination occurs under the same conditions.[12]

a-H_2Si–M and *a*-Me_2Si–M* Systems

The calculations on these two systems were only carried out at the B3LYP/6-31G** level. The energy results are reported in Table 3, while selected geometrical parameters are given in Figures 4 and 5 for the *a*-H_2Si–M and *a*-Me_2Si–M* systems, respectively, together with a representation of the reaction coordinates for the reductive elimination and dissociation processes. Qualitatively, the picture does not differ too much from that of the *a*-M system for either metal.

Both *ansa*-silylene systems display similar energetics to the corresponding *a*-M system for the reductive elimination step leading to the σ-methane complex, but with greater energy gains upon methane dissociation. This fact can be related to the greater facility, for the silylene systems, to better relax the metallocene scaffold, because of the greater size of the silicon atom. This is particularly notable in the triplet state, because this benefits more than does the singlet state, from an energetic point of view, from a parallel geometry. The *a*-M system, on the other hand, is constrained by the smaller C atom to remain in a more strained, and therefore energetically less favorable geometry. The M–TS_{exch} energy is lower than the M–TS_{ins} energy for the two Mo systems and higher for the two W systems. In all cases, however, it is lower than the M–MECP energy. This is in agreement with the occurrence of H-scrambling processes between the hydride and the methyl ligands for the W system.

Comparison of Energies and Geometries for the MECP and Insertion TS

A full comparison of the four systems leads to a satisfactory rationalization of the relative barriers on the basis of Hammond's postulate concerning the relation between exothermicity and barrier height. The metal insertion into the C–H bond (C–H oxidative addition), starting from the M(CH_4) intermediate, has a smaller barrier for the group of W metallocenes (1.8–7.1 kJ mol^{-1} range), for which the process is more exothermic, and a greater one for the Mo group (22.9–27.7 kJ mol^{-1} range), for which the thermodynamics is less favorable. Within each group, the M–TS_{ins} barrier follows approximately the expected trend, for the W group, it decreases steadily from Cp_2W (7.1 kJ mol^{-1}) to *a*-Me_2Si–W* (1.8 kJ mol^{-1}) following the increase of energy gain, then it increases again for *a*-W. For the Mo group, it is highest for Cp_2Mo, which has the smallest energy gain, and lowest for *a*-Me_2Si–Mo* with the greatest energy gain. There is a small inversion of trend between the *a*-H_2Si–Mo and *a*-Mo systems.

The M–TS_{ins} geometry becomes more and more reactant-like (shorter C–H, longer M–C and M–H distances) as the barrier decreases, as expected on the basis of Hammond's postulate. The trend is quite clear within the W group, the only inversion being witnessed for the W–C distance between Cp_2W and *a*-H_2Si–W. Within the Mo series, the C–H bond length follows the order of the energy gain (1.423 Å for Cp_2Mo > 1.414 Å for *a*-H_2Si–Mo > 1.406 Å for *a*-Mo > 1.388 Å for *a*-Me_2Si–Mo*), rather than the order of the insertion barriers. On the other hand, the Mo–C distance is unexpectedly longer for Cp_2Mo–TS_{ins} (2.427 Å), whereas the Mo–H distance is anomalously long, relative to the rest of the series, in *a*-Mo–TS_{ins}. Overall, the energetic and structural trends are very much in line with expectations, on the basis of the oxidative addition thermodynamics and Hammond's postulate.

The same considerations hold true for the CH_4 dissociation process, which involves the spin-inversion phenomenon. For any pair of metallocenes containing the same ligand, the process is slightly more exothermic for Mo and the dissociation barrier (determined by the spin-inversion pro-

cess) is correspondingly smaller. Within each group of metallocenes containing the same metal, the barrier steadily decreases with an increase of energy gain for the *ansa* systems in the order *a*-M > *a*-H_2Si–M > *a*-Me_2Si–M* (W: 20.7, 14.9 and 11.8 kJ mol^{-1} vs. 4.5, 24.2 and 37.4 kJ mol^{-1}; Mo: 11.0, 6.4 and 5.2 kJ mol^{-1} vs. 13.4, 36.8 and 41.4 kJ mol^{-1}). On going further to the Cp_2M system, at first sight surprisingly, the further increase in the methane dissociation energy is not accompanied by a further decrease in the dissociation barrier, which takes exactly the same values as for the corresponding *a*-Me_2Si–M* system for each metal. This is due to the fact that methane dissociation is anomalously exothermic for this system, due to the relaxation energy associated with moving the two Cp rings parallel to one another. In the MECP region, the presence of the methane molecule prevents both singlet and triplet states from adopting this parallel configura-

tion, so that the local slope and curvature of the potential energy surfaces resemble those for the constrained *ansa*-C and -Si systems. The additional stabilization of the triplet only intervenes well beyond the MECP, and hence has no effect on the relative energy of the latter. The MECP geometry becomes correspondingly more reactant-like as the barrier decreases. As for the oxidative addition TS examined above, there are a few exceptions, but the general trend is well respected. In particular, the trends of C–H, M–C and M–H distances are as expected within the *ansa*-W series. Particularly notable are the trends between the methylene- and the silylene-bridged systems for both metals.

This comparison shows that Hammond's principle can successfully be applied as an approximate guide to predic-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ting barrier heights and geometries for reaction steps involving a change in spin state. Although there are, a priori, no reasons why the principle should not apply in such cases, this does not appear to be a generally appreciated phenomenon. We previously discussed Hammond's postulate to rationalize trends in spin-isomerization barriers for a series of *para*-substituted phenyl cations,[24] but there do not appear to have been other mentions in the context of spin-forbidden processes.

The exception mentioned above for the Cp_2M systems shows that, as for the more usual application to adiabatic reactions, the principle is only quantitatively reliable when all the potential energy surfaces for the set of analogous reactions have similar shapes. Where the endo- or exothermicity of one of the reactions considered is due to a feature of the potential energy surface which is not present in the other cases, and is not situated in the TS_{ins} or MECP region, deviations from the Hammond's principle predictions can be expected so some care should be taken when applying it to novel situations.

Conclusions

This study completes a previous one[17] in terms of the relative barriers to oxidative addition and elimination from (σ-CH_4)metallocene complexes, and extends it to silylene-bridged *ansa* systems that have been the subject of recent experimental studies.[13] The comparison of the reaction barriers for the various systems considered in this study has shown that the relative barriers for both one-state and two-state processes can be generally related to the reaction energetics through the application of Hammond's postulate. Though minor differences can be related to changes in the ligand system (*ansa* vs. non-*ansa*, methylene- vs. silylene-bridged), a major effect on the energetic profile and on the related kinetic response is that of the nature of the metal center. The calculation shows that the change of kinetic behavior for the same methane reductive elimination process from a hydrido(methyl) complex (i.e. from normal to inverse KIE from an Mo complex to the W analog)[13] is regulated not only by changes in the energy of the reductive elimination TS, but also by changes, quantitatively as important, in the energy of the methane dissociation MECP.

Computational Methods

The bulk of the computations were carried out using the well-established B3LYP hybrid density functional level of theory, as implemented in the Gaussian03[25] program package. The calculations were carried out using two different basis sets: (i) with the standard LANL2DZ basis set for all atoms, which includes an ECP on the W and Mo atoms; (ii) with a similar basis which includes polarization functions. Specifically, the LANL2DZ ECP and basis were retained on the metal atoms, but the standard 6-31G** basis was used on C and H (referred to as "6-31G**" henceforth). All structures were fully optimized, with the optimization of the MECPs being carried out by a combination of Gaussian and the shell script/Fortran code of one of the authors.[26,27] Geometry optimizations without symmetry constraints, backed up in several cases by computation of vibrational frequencies, showed all structures studied here to have at least C_S symmetry, with some belonging to higher point groups. Accordingly, the MECP optimizations were carried out within C_S symmetry. To further test the accuracy of the chosen method, we carried out additional calculations on the $[CH_2(C_5H_4)_2]W$ system only. Specifically, we characterized the singlet and triplet fragment, the σ-CH_4 intermediate and the methyl hydride product, using a larger basis set, with the SDD pseudopotential and associated basis set on W, and the 6-311++G** basis sets for the C and H atoms. Full geometry optimization was carried out with these basis set combinations and the B3LYP functional was used in the main body of the work, with additional single-point energies calculated using the same basis set, at the B3LYP geometries, with the B3PW91 and BP86 density functionals. None of the reported energies include a correction for zero-point energy, as this is difficult to obtain at the MECPs. Nevertheless, frequencies have been calculated for all other stationary points, and used to identify them as minima or transition states.

Hybrid 2D and 3D Frameworks Based on ε-Keggin Polyoxometallates: Experiment and Simulation

Anne Dolbecq,*[a] Caroline Mellot-Draznieks,[a] Pierre Mialane,[a] Jérôme Marrot,[a] Gérard Férey,[a] and Francis Sécheresse[a]

Keywords: Molybdenum / Organic–inorganic hybrid materials / Polyoxometallates / Simulation

The ε-Keggin polyoxomolybdate {ε-$PMo^{V}_{8}Mo^{VI}_{4}O_{40-x}(OH)_x$-$M_4$} is a versatile building unit, with M being either a Zn^{II} or a La^{III} capping ion located at the vertices of a slightly distorted tetrahedron. The charge of the Keggin unit depends on the number of protonated oxo bridging ligands, which has been shown to vary from 0 to 5. The Keggin entity can thus be either an anion (M = Zn, x = 0) or a cation (M = La, x = 3–5). The Zn derivative has been generated in situ by hydrothermal synthesis and forms a 2D material built from the connection of the cations by 4,4′-bipyridine ligands linked to the capping Zn^{II} ions. The reaction of the chloride salt of the La derivative with di-, tri- and tetrasubstituted benzenecarboxylate ligands has allowed us to isolate 2D and 3D materials. The 3D materials seem to be the first examples of hybrid open frameworks based on Keggin building blocks. The 3D framework built from the connection of ε-Keggin units by trimesate ions exhibits tunnels filled only by water molecules, which can be partly removed and reintroduced at room temperature. Besides these experimental results, simulation has allowed us to generate two virtual hybrid structures derived from those of known silicates by replacing the Si ions by hypothetical ε-Keggin cations and the *O*-bridging ligands by terephthalate ions, thus showing that 3D frameworks with large pores can be envisioned in the chemistry of hybrid organic–inorganic materials based on ε-Keggin units and motivating further experimental investigations.

Introduction

Metal–organic frameworks[1] constitute a recent class of materials with open architectures built from metal ions linked together by organic bridging ligands, most of the time carboxylate ions.[2] These compounds have attracted much interest because of their potential applications in catalysis, gas storage and separation. Their structures can be classified according to the dimensionality of the inorganic network.[3] The largest family contains metal–organic frameworks with discrete inorganic building blocks. Two factors determine the geometry and the size of the cavities, namely the symmetry and size of the molecular units and the nature of the organic ligand. For example, Yaghi et al. have shown that the volume of the cavities increases dramatically when the bridging organic ligand is lengthened.[4] Another way to expand the lattice, known as "scale chemistry",[5] is to increase the size of the inorganic building blocks, which are so far limited to a small number of metal ions. We have recently reported the synthesis of a novel polyoxocation, $[\varepsilon\text{-}PMo^{V}_{8}Mo^{VI}_{4}O_{36}(OH)_4\{La(H_2O)_4\}_4]^{5+}$, which is a mixed-valence ε-Keggin-type polyoxometallate (POM) core capped by four lanthanum ions located at the vertices of a slightly distorted tetrahedron.[6] The La^{III} ions are connected to the molybdenum ions by three triply bridging oxygen atoms and their coordination sphere is completed by disordered water molecules. The overall symmetry of the polyoxocation is tetrahedral. Two examples of transition metal cations (Zn^{II}, Ni^{II}) capping reduced ε-Keggin cores have also been reported.[7] The water molecules bound to transition metal or rare-earth cations capping the POM core can be potentially substituted by N- or O-donor ligands, which opens the way to the design of a new family of hybrid organic–inorganic materials. We have recently obtained the first members of this family, namely two 1D materials formed by the connection of the POMs by squarate or glutarate ligands, respectively.[8] Nevertheless, owing to the overall tetrahedral symmetry of the inorganic cation, 3D materials can be envisioned, which can lead eventually to porous frameworks. We describe in this paper our first results in the synthesis of 2D and 3D frameworks with the ε-Keggin building unit, synthesised by two different ways, namely hydrothermal techniques, which have led to $Na(C_{10}H_{10}N_2)[\varepsilon\text{-}PMo_{12}O_{40}Zn_4(H_2O)_2(C_{10}H_8N_2)_3]\cdot 10H_2O$ (**1**), and standard bench conditions, which have allowed us to isolate $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5La_4(C_8H_4O_4)_3]\cdot 41H_2O$ (**2**), $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5\{La(H_2O)_3\}_4(C_9H_3O_6)_2]\cdot 44H_2O$ (**3**) and [ε-

$PMo_{12}O_{37}(OH)_3\{La(H_2O)_4\}_4(C_{10}H_2O_8)]\cdot 24H_2O$ (**4**). The synthetic routes to obtain the different compounds described in this paper are summarised in Figure 1. Besides these experimental results, we also report here the simulation of two phases built from the connection of a hypothetical ε-Keggin core, capped by pentacoordinate transition metal ions, by a rigid dicarboxylate ligand − the terephthalate ligand − in order to demonstrate the potentiality of this molecular building block for the design of hybrid organic–inorganic materials with large pores.

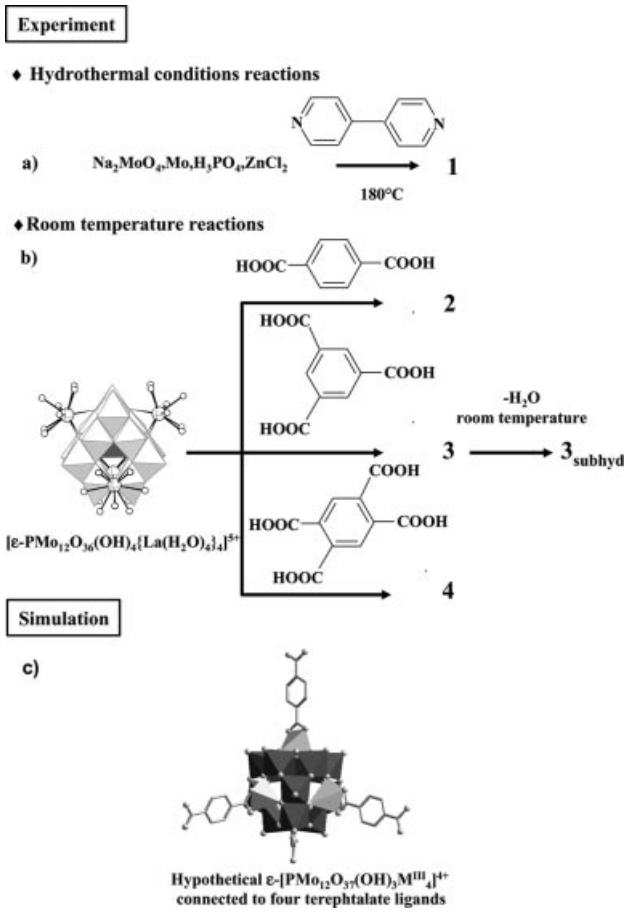

Figure 1. The synthetic conditions used to obtain a) **1** in a hydrothermal "one-pot" synthesis and b) **2**, **3** and **4** from the $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_4\}_4]^{5+}$ precursor. Note that for $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_4\}_4]^{5+}$ the four water molecules are disordered on the lanthanum ions; c) polyhedral representation of the hypothetical ε-Keggin ion with pentahedral capping transition ions used for the simulation.

Results and Discussion

Synthesis

The synthesis of the hybrid materials with ε-Keggin building units was performed according to two different procedures: the first one exploits hydrothermal conditions and the second one is based on the substitution of water molecules bound to the lanthanum ions of the inorganic precursor by carboxylate groups of the organic ligand (Figure 1). We first chose Zn^{II} ions as capping transition metal ions in hydrothermal reactions because of their ability to adopt low coordination numbers and thus favour the 1:2 POM:ligand stoichiometry. 4,4′-Bipyridine was selected as ligand because it is neutral and thus it should have a greater affinity for the most probable anionic ε-Keggin core capped with divalent Zn ions than the terephthalate ligand. Single crystals of $Na(C_{10}H_{10}N_2)[\varepsilon\text{-}PMo_{12}O_{40}Zn_4(H_2O)_2(C_{10}H_8N_2)_3]\cdot 10H_2O$ (**1**) were obtained from the reaction of a mixture of Na_2MoO_4, Mo as reducing agent, H_3PO_4, $Zn(CH_3COO)_2$ and 4,4′-bipyridine in water adjusted to pH 6.5, and heated at 180 °C. The ε-Keggin core capped with Zn^{II} ions is generated in situ and connects three different neutral bidentate ligands to generate a 2D material. Although the synthetic conditions are quite different, especially the Zn:ligand ratio and the nature of the precursors, the structure of **1** (see below) is close to that of a 2D material reported recently.[7b]

Despite numerous attempts, single crystals of $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5La_4(C_8H_4O_4)_3]\cdot 41H_2O$ (**2**) of suitable quality for X-ray diffraction could not be obtained, and only microcrystalline powders were formed by slow addition of an aqueous solution of terephthalic acid to a methanolic solution of $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_{2.5}Cl_{1.25}\}_4]\cdot 27H_2O$.[6] Elemental analysis indicates that the stoichiometry of the hybrid compound is one ε-Keggin ion for three terephthalate ligands. The structure of **2** is thus certainly very close to that of **1**, with terephthalate ligands in place of bipyridine and La^{III} ions replacing Zn^{II} ions, as also suggested by the similarity of their experimental powder diffraction patterns (Figure 3, b). However, the poor quality of the experimental diagram of **2** prevents any further investigation of the structure.

Single crystals of $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5\{La(H_2O)_3\}_4(C_9H_3O_6)_2]\cdot 44H_2O$ (**3**) were grown by slow evaporation, at room temperature, of a CH_3OH/H_2O solution containing the chloride salt of the ε-Keggin precursor and a stoichiometric amount of trimesate ions. The determining factors for the crystallisation process are the CH_3OH/H_2O ratio, the pH of the trimesate solution and the stoichiometry of the reaction. Compound **3** rapidly loses water at room temperature to give $\mathbf{3_{subhyd}}$. Single crystals of $[\varepsilon\text{-}PMo_{12}O_{37}(OH)_3\{La(H_2O)_4\}_4(C_{10}H_2O_8)]\cdot 24H_2O$ (**4**) were obtained in a similar manner except that a pure water solution was used instead of a mixture of CH_3OH and H_2O. In the presence of an excess of ligand, and/or if the pH is too high, only microcrystalline powders precipitate.

The infrared spectra of **1**, **2**, $\mathbf{3_{subhyd}}$ and **4** are very similar in the 970–500 cm^{-1} region, where characteristic Mo=O and Mo–O vibrations are found. The bands of **2**, $\mathbf{3_{subhyd}}$ and **4** in the 1650–1350 cm^{-1} domain are characteristic of the O–C–O vibrations of the coordinated ligand.

Structure of $Na(C_{10}H_{10}N_2)[\varepsilon\text{-}PMo_{12}O_{40}Zn_4(H_2O)_2(C_{10}H_8N_2)_3]\cdot 10H_2O$ (1)

The ε-Keggin unit is similar to the building unit encountered in the 1D solids with glutarate and squarate ligands,[8]

Mo···Mo[d]	2.882(3)–2.869(3) [2.875]	3.1326(13) [3.133]	3.1476(11)–3.1501(10) [3.149]

[a] Mean values are indicated in square brackets. [b] O_a refers to an oxygen atom of the central cavity bound to the phosphorus atom; O_b and O_c refer to bridging oxygen atoms; O_d refers to a terminal oxygen atom. [c] Mo–O distances for O atoms bridging two Mo atoms of the Keggin core with two corresponding Mo–O distances longer than 2.0 Å. [d] Mo···Mo distances between 2.80 and 3.20 Å.

and in the 3D materials **3** and **4** (see below) except that the Mo^V and Mo^{VI} ions are not all localised, as observed previously. Indeed, while valence bond calculations[9] (Table S1, Supporting Information) indicate clearly that Mo1, Mo6 and Mo7 are Mo^V ions, in agreement also with their short intermetallic Mo–Mo bonds (Table 1), the four Mo^{VI} ions and four Mo^V ions remaining are delocalised over eight centres. The Mo–Mo distances for these ions (Table 1) are intermediate between Mo^V–Mo^V (ca. 2.6 Å) and Mo^{VI}···Mo^{VI} bonds (ca. 3.2 Å). The $[\varepsilon\text{-}PMo^V_8Mo^{VI}_4O_{40}]^{11-}$ core is stabilized by four Zn^{II} capping ions and this entity is thus formally anionic. Due to the smaller ionic radii of the Zn^{II} ions compared to the La^{III} ions, and consequently shorter Zn–O distances (Table 2 and Table S2 in the Supporting Information), the volume occupied by the ε-Keggin core is far smaller when it is capped by Zn^{II} ions. A rough estimation, using the mean distance between the central phosphorus atom and the atoms of the ligands L coordinated to the Zn^{II} or La^{III} ions as the radius of a sphere, leads to a volume of 775 $Å^3$ for the Zn derivative ($d_{P\cdots L} \approx 5.7$ Å) and 1630 $Å^3$ for the La derivative ($d_{P\cdots L} \approx 7.3$ Å).

	4
La–O(POM)	2.452(5)–2.676(5) [2.556]
La–O(H_2O)	2.499(6)–2.758(12) [2.610]
C–O	1.207(10)–1.293(10) [1.254]

[a] Mean values are indicated in square brackets.

Three different coordination modes are encountered in **1**. Thus, Zn1 is pentacoordinate, being bound to three oxygen atoms of the ε-Keggin core and two nitrogen atoms of two 4,4′-bipyridine ligands (Figure 2), Zn2 is bound to three oxygen atoms of the Keggin core, one nitrogen atom of a bipyridine ligand and two additional water molecules, and is thus hexacoordinate, and Zn3 only bears one extra ligand, i.e. a bypiridine molecule, and is tetracoordinate (Figure 2). In the (*a*,*b*) plane, one ε-Keggin unit is connected to four adjacent units through four bipyridine molecules linked to Zn1 ions, thus forming a double chain (Figure 3, a). These double chains stack along the *c* axis and are connected to neighbouring ones by bipyridine ligands linked to the Zn2 and Zn3 ions, thus forming a double plane. Intersecting tunnels along the *b* and *c* directions are generated, however the adjacent planes interpenetrate (Figure 3, a) and the material does not exhibit any porosity. Furthermore, disordered sodium ions and free protonated bipyridine ions are found as counterbalancing cations.

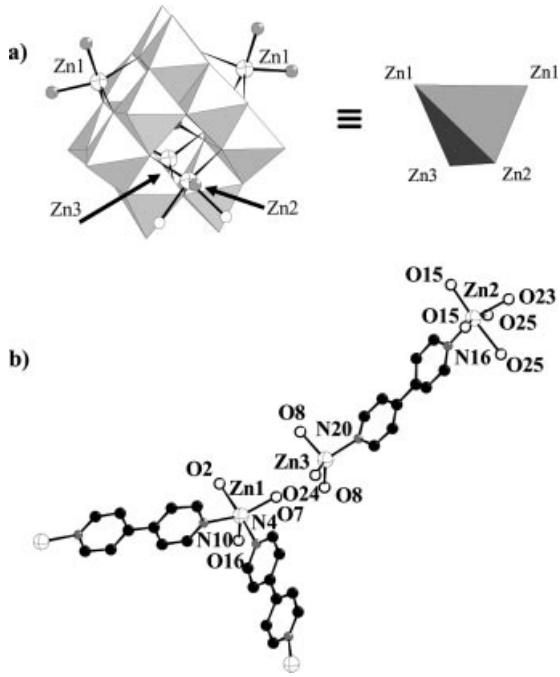

Figure 2. a) Representation of the building unit in **1**, showing the three different coordination modes of the Zn^{II} capping ions and its overall tetrahedral symmetry; b) labelling scheme of the Zn^{II} centres and their ligands.

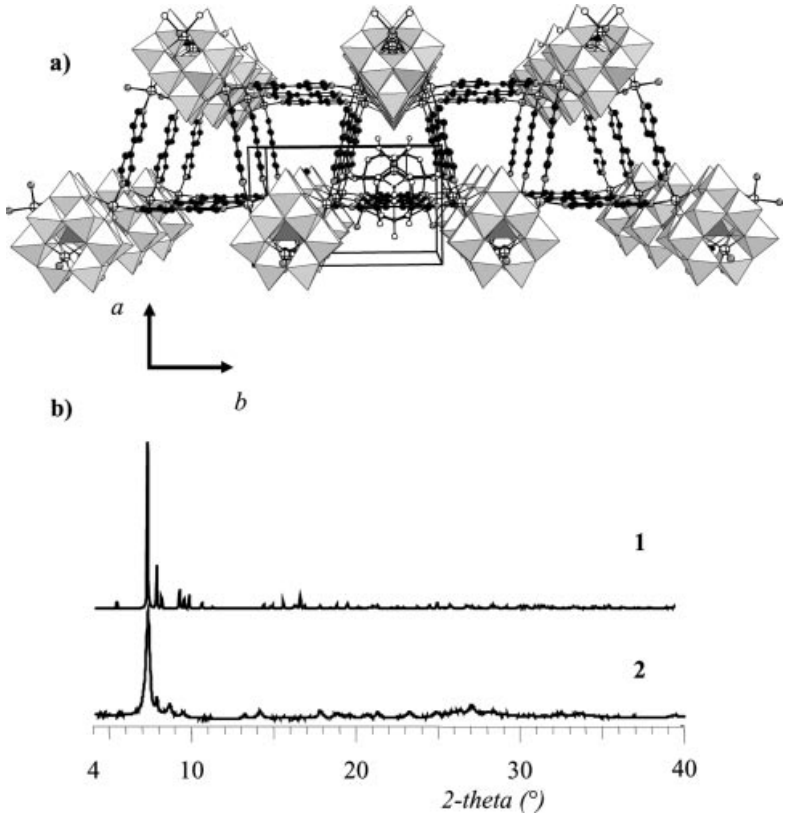

Figure 3. a) View of the double chains in the (*a*,*b*) plane formed by the connection of ε-Keggin units by bipyridine ligands; the connection along the *c* axis ensure the formation of planes. The position of an ε-Keggin cation (ball and stick representation) belonging to an adjacent double plane is also shown. Non-coordinated water molecules and bipyridinium counterions have been omitted for clarity. b) Comparison of the simulated powder pattern of **1** and the experimental powder pattern of **2**.

Structure of $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5\{La(H_2O)_3(C_9H_3O_6)_2\}]\cdot 44H_2O$ (3)

Crystals of **3** rapidly become amorphous when left in air. X-ray analysis was therefore performed on a single crystal of **3** sealed in a capillary tube. Compound **3**, which exhibits a three-dimensional structure, crystallises in the non-centrosymmetric space group $P2_12_12$. One organic ligand connects three different polyoxocations through La–O bonds, two carboxylate groups adopt a chelating mode while one pendent oxygen atom (O26) remains in the third one (Figure 4, a). The quite short C–O distance [C9–O26 = 1.258(14) Å] of the pendent group indicates that this group is non-protonated. This bonding mode of the trimesate ligand has been encountered a few times.[10] Each lanthanum ion bears three additional water molecules, and the lanthanum ion connected to the bridging carboxylate group (La1) is also connected to another trimesate ligand, therefore the La1 ions are enneacoordinate whereas the La2 ions are only octacoordinate. The geometrical features within the polyoxometallate core are slightly affected by the coordination to organic ligands. As observed for the polymeric structure with squarate and glutarate ions,[8] among the twelve Mo ions, eight Mo^V ions form Mo–Mo bonds ($d_{Mo-Mo} \approx 2.6$ Å, Table 1) while the remaining four are Mo^{VI} centres ($d_{Mo\cdots Mo} \approx 3.2$ Å). Valence bond calculations (Table S1, Supporting Information) confirmed the oxidation state of the Mo ions

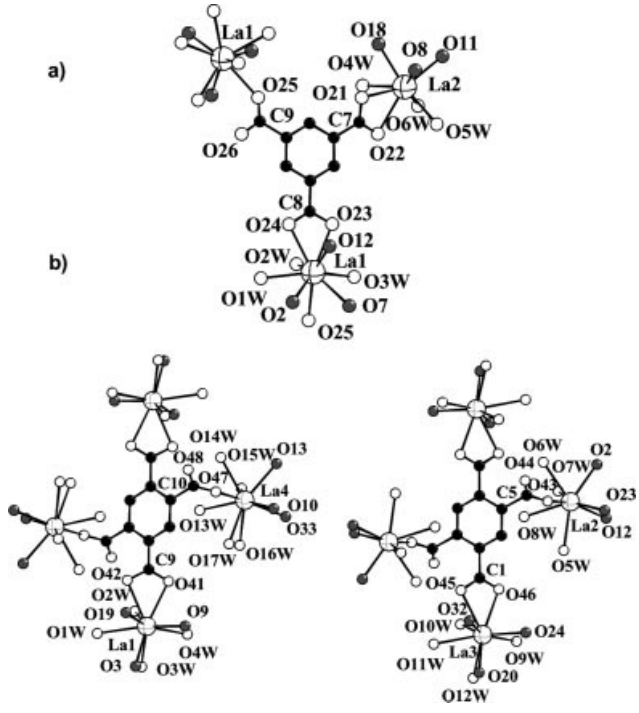

Figure 4. Bonding mode of a) the trimesate ligand in **3** and b) the pyromellitic ligands in **4**; the oxygen atoms bound to the POM core are represented as grey spheres.

and allowed us to localise four protons on bridging oxygen atoms of the POM core. In order to respect the electroneutrality, one additional proton is assumed to be delocalised over the four remaining μ_2-oxygen atoms of the POM. Indeed, it is well known that the basicity of a Keggin polyoxomolybdate increases when it is reduced, and the doubly bridging oxygen atoms are the preferred protonation sites.[11] The connection of the polyoxocations by the tridentate ligands generates a neutral 3D framework with 1D channels running along the *c* axis (Figure 5). The channels have rectangular free apertures of 6.1 × 7.2 Å, as estimated from the interatomic distances between atoms delimiting the channels and taking into account their van der Waals radii. These channels are filled with clusters of disordered water molecules that form intricate hydrogen bonds with other water molecules of the clusters and the oxygen atoms of the polyoxocation.

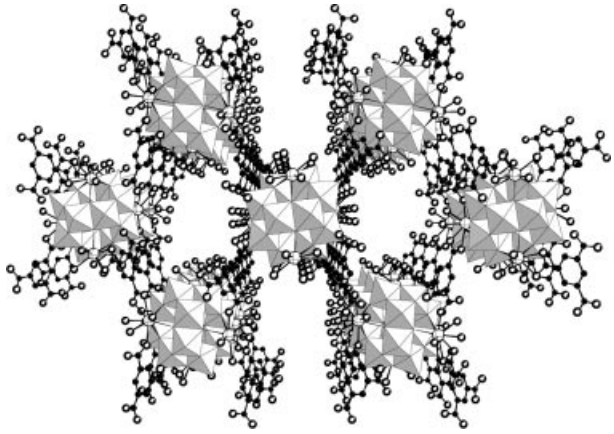

Figure 5. Perspective view of the 3D structure of **3** showing the channels along the *c* direction. Non-coordinated water molecules have been omitted for clarity.

Structure of $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5\{La(H_2O)_3\}_4(C_{10}H_2O_8)]\cdot 24H_2O$ (4)

Compound **4** crystallises in the centrosymmetric $P\bar{1}$ space group. The asymmetric unit contains a POM polyoxocation and two halves of the organic ligand, in agreement with the 1:1 stoichiometry. Each ligand is bound to four lanthanum ions from four distinct POMs (Figure 4, b). Like in **3**, there are two different connecting modes of the carboxylate groups: two are chelating and two are only monodentate C–O groups. The O–C–O groups are almost perpendicular to the plane of the organic molecule. La2 and La1 are connected to monodentate C–O groups, and La2 bears four additional water molecules in addition to the three oxygen atoms of the POM and is thus octacoordinate while La1 has a supplementary water molecule and is nonacoordinate. La3 and La4 are bound to chelating carboxylate groups and are both nonacoordinated. The geometrical features within the POM are similar to those in **3** (Table 1). The connection of one POM to the organic ligands by La–O–C bonds generates a 3D material that contains small channels running along the *b* axis that are filled, as in **3**, by disordered water molecules (Figure 6).

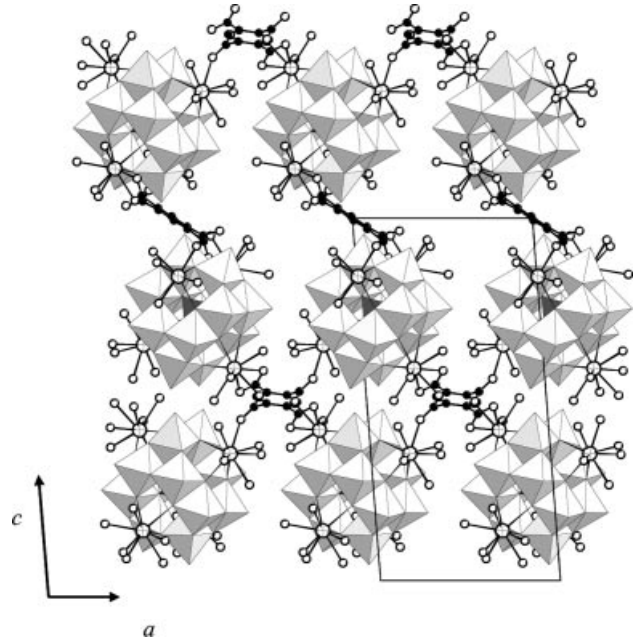

Figure 6. View of the 3D structure of **4** along the *b* axis. Non-coordinated water molecules have been omitted for clarity.

Subhydrate of 3

The stability of **3** was investigated first by a simple treatment at room temperature. The X-ray powder diffraction pattern of freshly filtered, ground crystals of **3** does not exactly fit the calculated powder pattern obtained from the single-crystal X-ray diffraction experiment (Figure 7). Indeed, the first peak is observed for a 2θ value of 6.10° (Figure 7, d), while the first peak in the calculated powder pattern is obtained for a 2θ value of 5.93° (Figure 7, b). This powder pattern progressively evolves with time; the first peak broadens and shifts toward higher 2θ values, while the position of the other ones remains approximately unchanged (Figures 7, e and f). No further change is observed after a few hours at room temperature, indicating that the partial dehydration of **3** is achieved to give $\mathbf{3_{subhyd}}$. When a drop of water is added to the powder sample of $\mathbf{3_{subhyd}}$, the X-ray powder pattern changes and the position of the first peak (Figure 7, c) now matches the position of the first peak in the calculated powder pattern (Figure 7, a). This experiment shows that the dehydration at room temperature is reversible.

Despite the poor quality of the experimental X-ray powder pattern, we tried to simulate the structure of the dehydrated sample $\mathbf{3_{subhyd}}$ by lattice energy minimisations[20] to reproduce the positions of the experimental diffraction peaks. This simulation allowed us to calculate the cell parameters of the dehydrated sample and showed that the contraction mainly affects the *a* parameter.[12] The channels shrink upon dehydration, in agreement with a hydrophobic

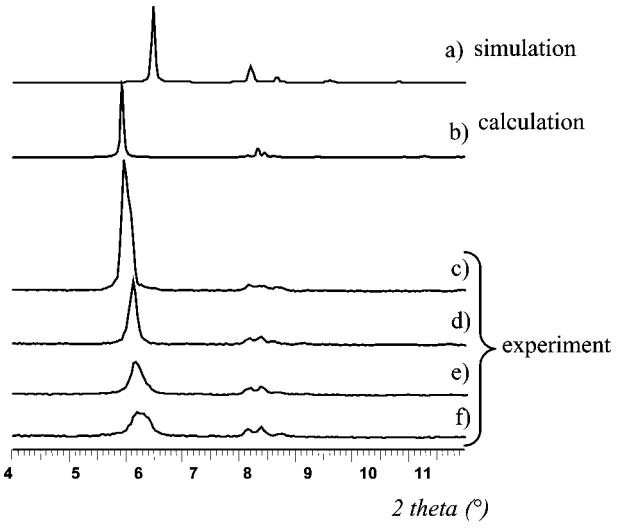

Figure 7. a) Simulated diffraction powder pattern of $\mathbf{3}_{\mathbf{subhyd}}$; b) calculated diffraction powder pattern from the single-crystal X-ray diffraction structure of **3**. Experimental diffraction powder pattern: c) $\mathbf{3}_{\mathbf{subhyd}}$ to which a drop of water has been added, d) **3** freshly filtered (t = 5 min), e) t = 30 min, f) t = 2 h.

character, as a consequence of the presence of aromatic rings on the channel walls. The difference between the volumes of **3** and $\mathbf{3}_{\mathbf{subhyd}}$ (reduction of 12%) leads to an estimated number of water molecules lost by the dehydration at room temperature of 17, assuming that a hydrogen-bonded water molecule occupies a volume of 40 Å^3. The thermogravimetric analysis (TGA) curve performed on $\mathbf{3}_{\mathbf{subhyd}}$ (Figure S1) shows an initial weight loss of 16.0% (calcd. 16.1) attributable to the loss of 32 water molecules trapped within the channels. The second weight loss of 9.6% (calcd. 9.4) corresponds to the loss of water molecules bound to the lanthanum ions and to the formation of oxides. This is in agreement with the following formula [ε-$PMo_{12}O_{35}(OH)_5$-$\{La(H_2O)_3\}_4(C_9H_3O_6)_2$]·$32H_2O$ for $\mathbf{3}_{\mathbf{subhyd}}$, while elemental analysis is more in favour of 27 hydration water molecules (see Experimental Section).

The presence of tunnels filled only with water molecules motivated a measurement of the surface area. Nevertheless, after activation of the sample at 70 °C a BET nitrogen adsorption measurement performed on $\mathbf{3}_{\mathbf{subhyd}}$ revealed a low surface area (ca. 14 $m^2 g^{-1}$), thus confirming the X-ray thermodiffractometry experiment, which shows that the structure collapses. At variance with the dehydration at room temperature and ambient pressure, the dehydration under vacuum is therefore irreversible.

The description of the four hybrid organic–inorganic materials **1**–**4** based on the ε-Keggin unit shows the complexity of these systems. However, an important feature arises from this study: Keggin ions can be used as inorganic bricks to build up hybrid open frameworks. To the best of our knowledge, it indeed seems that this has been found here for the first time. This is probably due to the possibility for ε-Keggin ions to be tetrahedrally decorated by four cations, which act as points of anchorage for linking organic species, and also means that the serendipity which often governs the POM:ligand stoichiometry can be surpassed by the introduction of computer prediction of possible Keggin-based hybrid frameworks. In order to tentatively rationalise what family of open frameworks compounds could be envisioned, the following section describes our first simulation results.

Computational Section

In the current search for new and interesting hybrid open frameworks, the predictability of the framework architecture and its resulting dimensionality are essential. It is highly valuable to consider how systematic approaches may be computationally developed for producing new hybrid frameworks, with the desire of developing virtual libraries that might be accessible through synthesis. With this in mind, some of us (C.M-D, G.F.), have made important efforts to introduce a computational prediction of crystal structures using the concept of building units.[5] The resulting AASBU method (Automated Assembly of Secondary Building Units)[13] was initially devoted to inorganic structures, but the applicability of the method in the realm of hybrid solids has been demonstrated recently.[14] The key feature of the method lies in the use of pre-defined organic and inorganic building units together with pre-defined connection points on each type of unit. The simulations explore their assembly in 3D space through a cascade of simulated annealing and minimisation steps. Indeed, this simulation approach focuses on the capacity of the organic and inorganic sub-units to generate infinite networks, resulting in a list of candidate periodic crystalline arrangements and their respective space group, cell parameters and atomic coordinates.

One of the key points for the success of the method is the knowledge of the chemical conditions associated with the existence of a given building block in the solution. In the same way as we demonstrated the existence of Cr_3–μ_3-O clusters,[14c] the [ε-$PMo^{V}_8Mo^{VI}_4O_{36}(OH)_4$-$\{La(H_2O)_4\}_4$]$^{5+}$ Keggin ion has been characterised in solution.[6] Its recurrence in experimental crystal structures is a clear evidence that the Keggin ion may be regarded as a building unit, the condensation of which with an appropriate organic linker might lead to a whole series of hybrid infinite networks. This section presents an attempt to produce hybrid infinite networks computationally by assembling Keggin inorganic units with a carefully chosen organic counterpart and to demonstrate the capacity of the simulation approach for generating hybrid open-framework candidates that are all built from the same pre-defined Keggin ion and organic ligand, in other words hybrid polymorphs.

In the present computational work, we selected terephthalic acid as a good candidate to generate hypothetical Keggin-based hybrid structures owing to its rigid carbon skeleton and its simple bidentate character. The use of 4,4′-bipyridine would have led to similar results. The isolated Keggin ion offers four anchorage points to the carboxylate function through its four capping M ions, which are placed

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at the corners of a virtual tetrahedron (M is chosen here as a trivalent M^{III} ion). The Keggin–terephthalic acid linkages therefore lead to pentacoordinate M^{III} cations, where each M cation is coordinated to three oxygen atoms of the Keggin ion and two oxygen atoms of the carboxylate ligand. This ε-Keggin cation, with four pentacoordinate capping transition metal ions, is currently a hypothetical ion which has never been isolated but which is chosen here in order to simplify the calculations. Interestingly, considering that each Keggin ion may connect to four terephthalic acids in the four directions of a tetrahedron (Figure 1), the infinite connection of alternating Keggin ions and terephthalic acids is deemed to lead to four-connected networks similar to those observed in dense silicates such as quartz or microporous silicates such as zeolites,[15] all of which contain corner-sharing SiO_4 tetrahedra.

In the present work, the simulation of two candidate hybrid structures is presented. Using the above analogy with silicates, we assembled the Keggin ion and terephthalate ligands in 3D space to simulate two upper hybrid analogues which correspond to the quartz-α and LTA augmented nets.[16] Indeed, according to O'Keeffe et al., each augmented net possesses the same topology as two existing silicates or aluminosilicates: quartz-α ($P3_22_1$, a = 4.90 Å, c = 5.40 Å) and zeolite LTA ($Fm\bar{3}c$, a = 24.61 Å). Both frameworks result from the corner-sharing arrangement of SiO_4 tetrahedra. The crystallographic position of the Si atoms of the silicate structures is indicative of the required positioning of each Keggin ion centre, while the crystallographic position of the oxygen atoms is indicative of the required positioning of the centre of the organic molecule ensuring the linkage between two adjacent Keggin ions. Indeed, this construction process fully uses the analogy between the Si–O–Si linkages typically found in silicates and the metal–ligand–metal linkages found in metal–organic frameworks. The important size of the Keggin ion and of the organic molecule in comparison with that of Si and O atoms requires an extension of the size of each unit cell. The cell size of quartz-α increases to $a \approx 30$ Å, while that of zeolite LTA to more than 130 Å, keeping the Si and O atoms at the same crystallographic positions. In a subsequent step, the replacement of each independent Si and O atom by a Keggin ion and an organic ligand, respectively, was performed in each unit cell, resulting in two hybrid crystal structures with the same chemical composition [ε-$PMo_{12}O_{37}(OH)_3(M^{III})_4](O_2C\text{-}C_6H_4\text{-}CO_2)_2$. In some cases, these steps required a lowering of the initial symmetry. As a final step, the two hybrid crystal structures were submitted to lattice energy minimisations by allowing the atomic positions and the cell parameters to relax. Short-range interactions were calculated with the UFF forcefield.[17] The electrostatic contribution was calculated with an Ewald summation by using partial charges obtained from the charge equilibration method.[18] The simulations were performed using the Cerius2 suite of software[19] on an Octane SGI R12000 workstation operating at 300 MHz.

Energy-minimised structures of the quartz-type and of the LTA-type are shown in Figures 8 and 9, respectively, together with their simulated X-ray powder diffraction pattern (Cu-K_α respectively). The hybrid LTA-type Keggin dicarboxylate converged with cell parameters of a = 119.25 Å, while that of the minimised quartz-type Keggin-dicarboxylate possesses cell parameters of a = 25.93 Å and c = 24.20 Å. The quartz-type structure (Figure 8) can be described as a 3D network of Keggin cations connected by terephthalate ligands to form exclusively distorted 6-rings, directly emanating from the quartz topology. Hence it is a

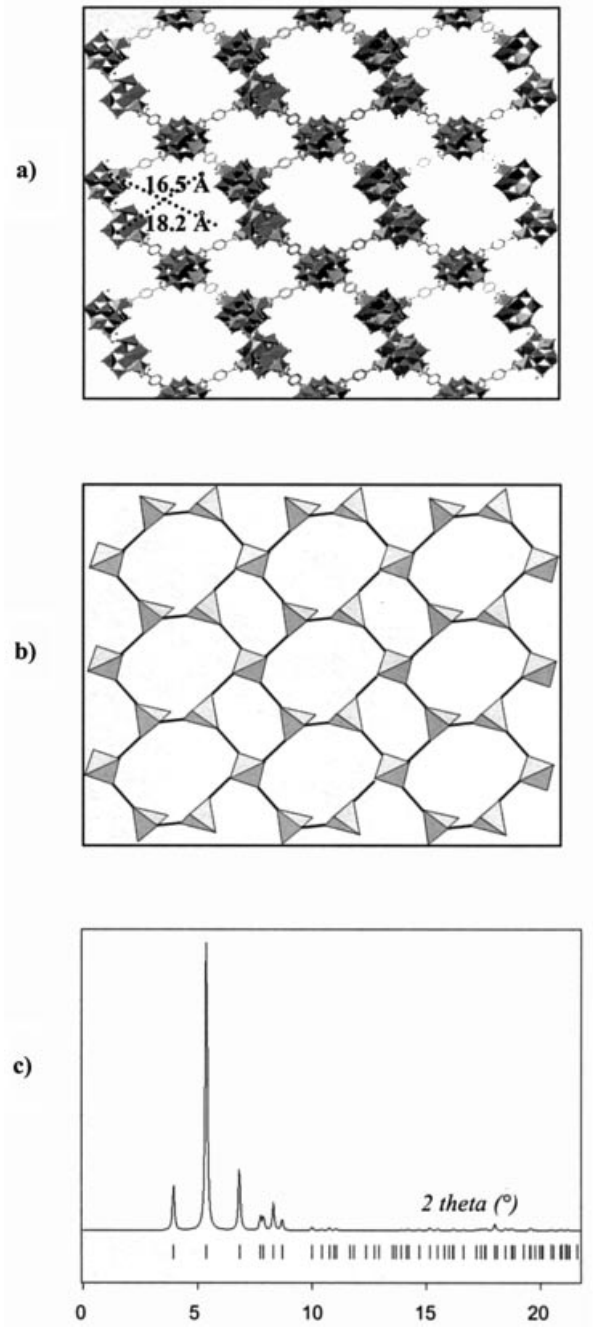

Figure 8. a) Projection along the a axis of the energy minimised structure of the quartz-α type; b) schematic view with ε-Keggin units represented by tetrahedra and terephthalate ligands by rods; c) simulated X-ray powder diffraction pattern (Cu-K_α).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

porous hypothetical structure which forms channels delimited by six Keggin ions with accessible diameters of 16.5×18.3 Å. The LTA-type structure (Figure 9) contains small cages (sodalite-type cages) made of 6-rings of Keggin ions and 4-rings, visible at the centre of Figure 9. Their assembly along each direction generates a bigger cage (here called supercage), made of 4-, 6- and 8-rings, four of which are visible at each corner of Figure 9. These supercages communicate with one another through 8-rings, the connection of which generates channels with larget dimensions (ca. 40 Å of diameter from one terephthalate to the opposite one). The inner diameter of the supercage is around 84 Å. These lattice energy calculations are a preliminary study to a more extended work on the relative stabilities of Keggin-containing hybrid frameworks. We believe that these two hypothetical structures are indicative of the viability of such open-framework architectures.

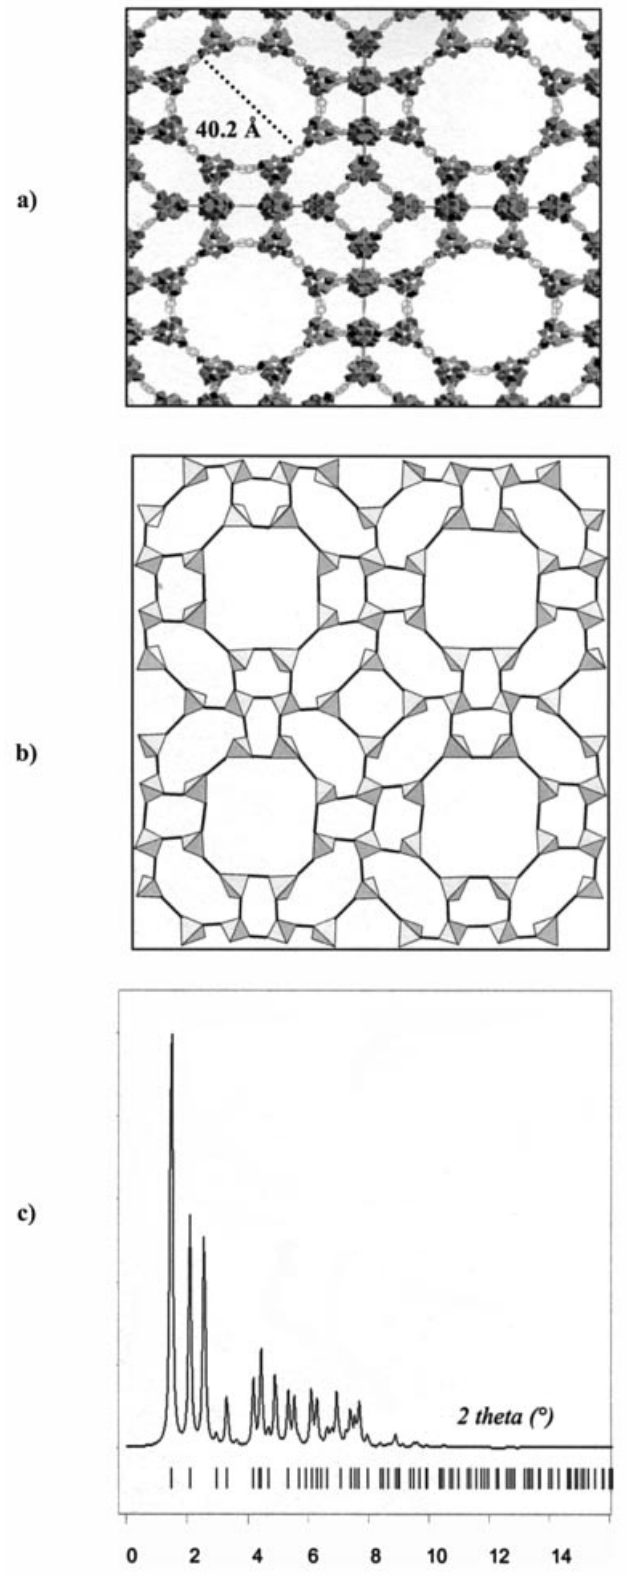

Figure 9. a) Projection along the *c* axis of the energy minimised structure of the zeolite LTA type, b) schematic view with ε-Keggin units represented by tetrahedra and terephthalate ligands by rods, c) simulated X-ray powder diffraction pattern (Cu-K_α).

Conclusions

This study demonstrates that it is possible to build extended frameworks containing a polyoxomolybdate building unit, under mild or hydrothermal conditions, with POM:ligand ratios ranging from 1:3 to 1:1. Two important features of the Keggin core dictate the nature of the final product: its charge related to the valence of the capping ion and the protonation states and also the coordination adopted by the capping ion. The synthesis of the materials described in this paper proves that a large family of original extended frameworks can be isolated, even though no stable porous materials have been obtained so far, and the simulation results show that the materials built from the connection of an ε-Keggin inorganic building unit and rigid linkers can potentially exhibit very large pores. It is now the chemist's role to investigate the synthesis of such phases. We will adopt two strategies: at room temperature we will continue to develop the reactions of the $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\text{-}\{La(H_2O)_4\}_4]^{5+}$ polyoxocation with rigid polycarboxylates. We also are planning to investigate the replacement of lanthanum ions by rare-earth cations with smaller coordination numbers, such as Yb^{3+}. These rare-earth centres would be bound to a lower number of water molecules and the stability of the framework could therefore be improved. The second strategy will take advantage of hydrothermal conditions for the synthesis of porous materials with the aim of obtaining phases close to the simulated ones. The ε-Keggin core capped with transition metal cations (Fe^{III}, Ru^{III}, Mn^{III},...) will be generated in situ in the presence of O- or N-donor ligands. Furthermore, as demonstrated by recent results from our group, even if no single crystals are isolated and provided the X-ray powder pattern is of suitable quality, simulation combined with X-ray powder diffraction could allow us to determine the structure of these hybrids. Finally, the incorporation of POMs into hybrid organic–inorganic materials could lead to interesting applications. Indeed, these solids could combine the properties of POMs with those of porous materials, thereby opening-up a new perspective in the field of catalysis by POM-based compounds.

Experimental Section

General: All chemicals were used as purchased without purification. Elemental analysis was performed by the Service Central d'Analyse of CNRS 69390 Vernaison France. Infrared spectra were recorded with an IRFT Magna 550 Nicolet spectrophotometer at 0.5 cm^{-1} resolution, using the technique of pressed KBr pellets. X-ray powder diffraction data were collected with a Siemens D5000 diffractometer equipped with Cu-K_α radiation. The BET surface area analysis was performed with a Micrometrics ASP200 porosimeter. TGA experiments were performed under air (5°C/min) using a TA Instrument type 2050 analyzer apparatus.

Synthesis of $Na(C_{10}H_{10}N_2)[\varepsilon\text{-}PMo_{12}O_{40}Zn_4(H_2O)_2(C_{10}H_8N_2)_3]\cdot 10H_2O$ (1): A mixture of $Na_2MoO_4\cdot 2H_2O$ (0.47 g, 1.94 mmol), Mo (0.030 g, 0.31 mmol), $Zn(OOCCH_3)_2$ (0.16 g, 0.73 mmol), 4 M H_3PO_4 (46 μL, 0.18 mmol), 4,4′-bipyridine (0.06 g, 0.38 mmol) and water (5 mL; pH adjusted to 6.5 with 1 M NaOH) was sealed in a Teflon-lined reactor which was kept at 180 °C for 60 h. Black parallelepipedic crystals for single-crystal X-ray diffraction were hand selected from a product mixture. Crystals for elemental analysis were isolated by decantation after sonication and washed with EtOH (0.200 g, 36% yield in crystals, based on Mo). IR (KBr pellets): $\tilde{\nu}$ = 1541 s, 1505 s, 1409 s, 1299 w, 1018 w, 961 m, 934 s, 838 w, 815 m, 772 s, 754 s, 699 w, 599 s, 514 w cm^{-1}. $C_{40}H_{58}Mo_{12}N_8NaO_{52}PZn_4$ (2949.7): calcd. C 16.29, Mo 39.03, N 3.80, Na 0.78, P 1.05, Zn 8.87; found C 13.26, Mo 38.93, N 3.06, Na 1.04, P 1.05, Zn 10.75.

Synthesis of $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5La_4(C_8H_4O_4)_3]\cdot 41H_2O$ (2): $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_{2.5}Cl_{1.25}\}_4]\cdot 27H_2O$ (0.100 g, 3.2×10^{-5} mol) was dissolved in CH_3OH (5 mL). A solution of 6×10^{-3} M terephthalic acid (16 mL, 9.6 10^{-5} mol) adjusted to pH 6.0 was then added dropwise. The resulting microcrystalline burgundy powder (0.100 g, yield 86.5% based on molybdenum) was filtered and washed with H_2O and EtOH. IR (KBr pellets): $\tilde{\nu}$ = 1639 s, 1541 s, 1505 m, 1409 s, 1299 w, 961 m, 934 s, 838 w, 815 m, 772 m, 754 s, 699 w, 599 m, 514 m cm^{-1}. $C_{24}H_{99}La_4Mo_{12}O_{93}P$ (3613.88): calcd. C 7.98, La 15.37, Mo 31.85, P 0.86; found C 8.41, La 15.25, Mo 31.37, P 0.90.

Synthesis of $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5\{La(H_2O)_3(C_9H_3O_6)_{0.5}\}_4]\cdot 44H_2O$ (3): Crystals were obtained by slow evaporation of a solution of $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_{2.5}Cl_{1.25}\}_4]\cdot 27H_2O$ (0.050 g, 1.6×10^{-5} mol) dissolved in CH_3OH (5 mL) to which a 10^{-2} M trimesic acid solution (1.6 mL, 1.6×10^{-5} mol), adjusted to pH 3.9 with 1 M NaOH, was added. After two days red parallelepipedic single crystals of **3** (14 mg, yield 28% based on Mo) were filtered off. The crystals were left for two days in air in an open beaker to give **3** $_{subhyd}$. IR (KBr pellets): $\tilde{\nu}$ = 1611 s, 1554 s, 1435 s, 1369 s, 1263 w, 1113 w, 966 m, 932 s, 812 m, 758 s, 685 m, 602 m, 529 s cm^{-1}. $[\varepsilon\text{-}PMo_{12}O_{35}(OH)_5\{La(H_2O)_3(C_9H_3O_6)_{0.5}\}_4]\cdot 27H_2O$ ($C_{18}H_{89}La_4Mo_{12}O_{91}P$, 3499.7): calcd. C 6.17, La 15.88, Mo 32.90, P 0.89; found C 6.32, La 15.90, Mo 32.75, P 0.87.

Synthesis of $[\varepsilon\text{-}PMo_{12}O_{37}(OH)_3\{La(H_2O)_4\}_4(C_{10}H_2O_8)]\cdot 24H_2O$ (4): Single crystals were obtained by slow evaporation of a 4 mL solution of $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_{2.5}Cl_{1.25}\}_4]\cdot 27H_2O$ (0.020 g, 0.65×10^{-5} mol) to which a 5×10^{-3} M pyromellitic acid solution (1.3 mL, 0.65×10^{-5} mol) was added. After a few days red parallelepipedic crystals were collected by filtration (0.016 g, yield 75% based on molybdenum). IR (KBr pellets): $\tilde{\nu}$ = 1625 s, 1545 s, 1492 m, 1433 m, 1385 s, 1328 w, 1141 w, 966 m, 932 s, 812 m, 758 s, 685 m, 602 m, 529 s cm^{-1}. $C_{10}H_{77}La_4Mo_{12}O_{84}P$ (3279.6): calcd. C 3.66, La 16.94, Mo 35.10, P 0.94; found C 4.09, La 16.61, Mo 34.95, P 0.91.

X-ray Crystallography: Intensity data collection was carried out with a Siemens SMART three-circle diffractometer equipped with a CCD detector using monochromatic Mo-K_α radiation (λ = 0.71073 Å). The absorption correction was based on multiple and symmetry-equivalent reflections in the data set using the SADABS program[20] based on the method of Blessing.[21] The structure was solved by direct methods and refined by full-matrix least-squares

Synthesis, Properties and Molecular Structure of [Ru(tpm)(bpy)(CH_3CN)](PF_6)$_2$ (tpm = tris(1-pyrazolyl)methane, bpy = 2,2′-bipyridine) – Another Example of Nitrile Hydrolysis Promoted by Ruthenium(II)[‡]

Néstor E. Katz,*[a] Florencia Fagalde,[a] Noemí D. Lis de Katz,[a] María G. Mellace,[a] Isabel Romero,[b] Antoni Llobet,*[c] and Jordi Benet-Buchholz[d]

Keywords: Scorpionate ligands / Ruthenium / Bipyridines / Hydrolysis / Acetonitrile complexes

The synthesis and isolation of [Ru(tpm)(bpy)(CH_3CN)](PF_6)$_2$ (tpm = tris(1-pyrazolyl)methane; bpy = 2,2′-bipyridine) in good yield is described. This new Ru^{II} complex has been spectroscopically (IR, UV/Vis, emission) and electrochemically (cyclic voltammetry) characterized. Its solid-state structure has been solved by means of X-ray diffraction analysis and shows a distorted octahedral geometry where, as expected, the tpm ligand occupies three facial coordination sites, the bpy ligand chelates two further sites, and the CH_3CN ligand saturates the coordination sphere of the Ru metal center. Electrochemical and spectroscopic results indicate that the CH_3CN ligand acts as a moderately strong π-acceptor. The capacity of the coordinated CH_3CN ligand to undergo basic hydrolysis is also described. A second-order rate constant $k_{obs} = 1.3 \times 10^{-3}$ M^{-1} s^{-1} (T = 25 °C) has been obtained by following the UV/Vis absorption changes over time; the activation parameters obtained over the temperature range 17.0–40.0 °C are: $\Delta H^{\ddagger} = 74 \pm 4$ kJ mol^{-1} and $\Delta S^{\ddagger} = -54 \pm 12$ J mol^{-1} K^{-1}. These results are compared and discussed with regard to related complexes described in the literature that are also capable of carrying out this reaction. The results presented here make it possible to characterize the electronic and steric factors further and understand how they influence the basic hydrolysis of the coordinated CH_3CN ligand.

Introduction

The hydrolysis of nitriles to amides promoted by transition metals is a subject of interest with industrial and pharmacological applications.[1] Coordination of nitriles to transition metals in high or medium oxidation states normally increases the electrophilicity of the unsaturated nitrile C atom, thus promoting the addition of a great variety of nucleophiles.[1c] When the metal ion is in a low oxidation state, promotion is usually not observed. Thus, Ru^{III} is a much better mediator than Ru^{II} for nitrile hydrolysis.[2,3] The selective hydrolysis of nitriles to amides can also be achieved electrochemically.[4]

When the coligands coordinated to Ru^{II} are strong π-acceptors, such as polypyridines, one would expect an enhancement of the rate constant for nitrile hydrolysis. We could demonstrate[5] a quite unusual effect for a transition metal in oxidation state +2: the Ru^{II}(trpy)(bpy) moiety (trpy = 2,2′:6′:2″-terpyridine; bpy = 2,2′-bipyridine) can accelerate the hydrolysis of acetonitrile to acetamide in basic solutions by a factor of ca. 3×10^3. This result was accounted for by the extensive π-backbonding from Ru^{II} to the polypyridyl ligands.

We describe in this work the synthesis and physicochemical properties of the PF_6^- salt of the new complex [Ru(tpm)(bpy)(CH_3CN)]$^{2+}$ (tpm = tris(1-pyrazolyl)methane). In order to extend our knowledge of the enhancement effect of Ru^{II}, we also report on the hydrolysis of coordinated acetonitrile in this species. The structural and kinetic results obtained can be compared to those determined before for the complex [Ru(trpy)(bpy)(CH_3CN)]$^{2+}$[5,6] in order to understand how the different electronic and geometric constraints influence their reactivity.

The structures of the bpy, tpm and trpy ligands are shown in Scheme 1.

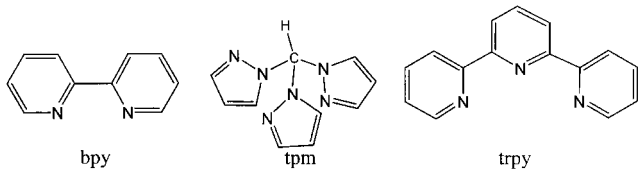

Scheme 1.

Results and Discussion

Synthesis

The synthetic route to $[Ru(tpm)(bpy)(CH_3CN)](PF_6)_2$ involves the substitution of the labile H_2O ligand in the known complex $[Ru(tpm)(bpy)(H_2O)](PF_6)_2$. In order to investigate the hydrolysis in basic solutions, the PF_6^- salt was metastasized to a Br^- salt, so that a higher solubility could be achieved.

UV/Vis and IR spectra

Figure 1 shows the electronic spectrum of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$. The UV spectrum in CH_3CN shows intraligand $\pi\rightarrow\pi^*$ absorption bands between 200 and 300 nm. In the visible region, bands due to MLCT (metal-to-ligand charge transfer) transitions $d_\pi(Ru)\rightarrow\pi^*$ (bpy) are observed at λ_{max} = 397 nm ($\varepsilon = 3.8\times10^3$ M^{-1}cm^{-1}) and 440 nm ($\varepsilon = 2.7\times10^3$ M^{-1}cm^{-1}). These values are lower than those corresponding to $[Ru(tpm)(bpy)(py)]^{2+}$ (py = pyridine; λ_{max} = 416 and 466 nm),[7] but similar to those of $[Ru(tpm)(py)(4,4'\text{-}(C(O)OC_2H_5)_2\text{-}bpy)]^{2+}$ (λ_{max} = 393 and 446 nm),[7] which leads to the conclusion that introducing a nitrile group into the coordination sphere of the $Ru(tpm)(bpy)^{2+}$ moiety has the same effect as introducing strong π-electron-withdrawing substituents into the 4,4′-positions of bpy. The higher π-acceptor capacity of CH_3CN relative to py has also been encountered when comparing the properties of Ru^{II} complexes containing 1,4,7-trithiacyclonane and 1,10-phenanthroline.[8]

On the other hand, the nitrile stretching frequency in the IR spectrum (of a KBr pellet) of $[Ru(tpm)(bpy)(CH_3CN)](PF_6)_2$ ($\tilde{\nu}_{C\equiv N}$ = 2282 cm^{-1}) is shifted to a higher frequency relative to the free ligand ($\tilde{\nu}_{C\equiv N}$ = 2254 cm^{-1}; $\Delta\tilde{\nu}_{C\equiv N}$ = 28 cm^{-1}). If we compare this result to the decrease in $\tilde{\nu}_{C\equiv N}$ observed in the IR spectrum of $[Ru(NH_3)_5(CH_3CN)](ClO_4)_2$, with respect to the free ligand ($\Delta\tilde{\nu}_{C\equiv N}$ = –15 cm^{-1}),[9] a strongly diminished π-back-bonding effect from Ru^{II} to the nitrile group caused by competition with 2,2′- bpy is inferred for the complex studied here.

Electrochemical Measurements

The cyclic voltammetry in CH_3CN, with 0.1 M TBAH [tetrakis(*n*-butyl)ammonium hexafluorophosphate] as a supporting electrolyte shows in the oxidative range of potential a reversible redox wave for the Ru^{III}/Ru^{II} couple at $E_{1/2}$ = 1.28 V (vs. SCE). Figure S1 shows the cyclic voltammogram. The values of λ_{max} and $E_{1/2}$ are consistent with those of similar complexes with strong π-accepting ligands, such as $[Ru(tpm)(bpy)(pz)]^{2+}$ (pz = pyrazine; λ_{max} = 392 and 457 nm; $E_{1/2}$ = 1.26 V).[10]

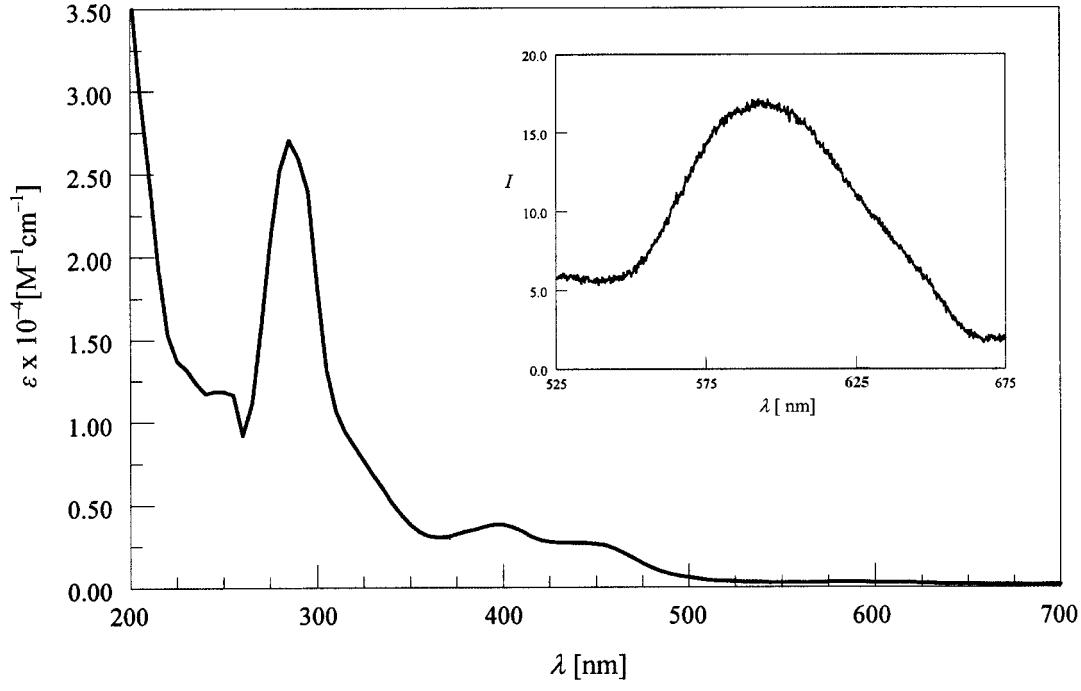

Figure 1. UV/Visible spectrum of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$, in CH_3CN, at room temperature. The inset shows the emission spectrum of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$ in CH_3CN, at room temperature (λ_{exc} = 440 nm).

Luminescence Properties

The inset in Figure 1 shows the emission spectrum of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$ at room temperature in CH_3CN. The value of λ_{em} = 591 nm (at λ_{exc} = 440 nm) is similar to that determined for $[Ru(tpm)(bpy)(BPE)]^{2+}$ [BPE = *trans*-1,2-bis(4-pyridyl)-ethylene]: λ_{em} = 606 nm at λ_{exc} = 400 nm in CH_3CN[10] providing additional evidence of the behavior of CH_3CN as a stronger π-electron-accepting group than py.[8]

X-ray Structure

Figure 2 shows the ORTEP diagram for the cation $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$. The crystal data are presented in the Supporting Information. The metal center adopts a pseudo-octahedral geometry with 3 N atoms (N1, N3, N5) from the tpm ligand coordinated in a facial manner. The 2,2′-bpy (N7, N8) acts as a chelating ligand, while the sixth position is occupied by the nitrogen atom (N9) of CH_3CN.

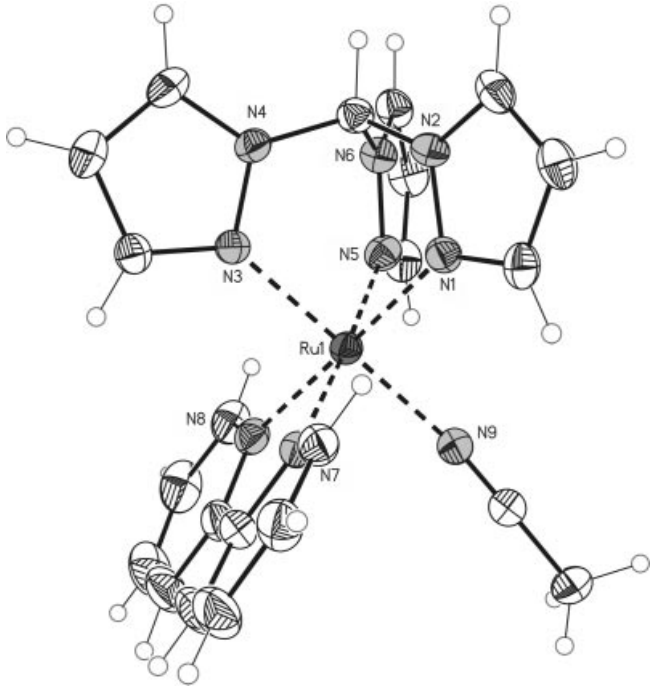

Figure 2. ORTEP-plot view (ellipsoids drawn at 50% probability) of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$, together with its labeling scheme. Selected bond lengths [Å] and angles [°]: Ru(1)–N(9), 2.0295(18); Ru(1)–N(7), 2.044(2); Ru(1)–N(3), 2.0500(17); Ru(1)–N(8), 2.053(2); Ru(1)–N(5), 2.068(2); Ru(1)–N(1), 2.069(2); N(9)–Ru(1)–N(7), 89.03(8); N(9)–Ru(1)–N(3), 179.65(7); N(7)–Ru(1)–N(3), 90.73(8); N(9)–Ru(1)–N(8), 87.00(8); N(7)–Ru(1)–N(8), 78.64(8); N(3)–Ru(1)–N(8), 92.70(7); N(9)–Ru(1)–N(5), 93.45(8); N(7)–Ru(1)–N(5), 176.51(8); N(3)–Ru(1)–N(5), 86.78(8); N(8)–Ru(1)–N(5), 99.03(8); N(9)–Ru(1)–N(1), 94.24(8); N(7)–Ru(1)–N(1), 98.86(8); N(3)–Ru(1)–N(1), 86.05(8); N(8)–Ru(1)–N(1), 177.20(9); N(5)–Ru(1)–N(1), 83.42(8).

The Ru–N bond lengths, as well as the bonding angles, are within the range found for similar complexes.[10] The Ru^{II}–N9 bond length, 2.029(18) Å, is closer to a Ru^{III}–N bond length (2.025Å in $[Ru(NH_3)_5(PhCN)]^{3+}$)[11] than to a Ru^{II}–N bond length (1.954 Å in $[Ru(NH_3)_5(PhCN)]^{2+}$).[11] The competition of bpy and CH_3CN for the electron density of Ru^{II} makes this metal more electropositive than in the corresponding ammine complexes.

Kinetics of Nitrile Hydrolysis

Figure 3 shows the consecutive spectra obtained at pH = 13.0, I = 0.1 M and T = 25 °C of an aqueous solution of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$. The MLCT absorption bands at λ_{max} = 397 and 440 nm are shifted to 440 and 510 nm, respectively. Isosbestic points are observed at 410 and 320 nm. These changes are indicative of a hydrolysis process followed by a ligand-substitution reaction. In effect, the observed rate constant is several orders of magnitude higher than that expected for a simple substitution of CH_3CN. As shown in Figure 3, the process is completed in less than 2 hours, while ligand replacements in Ru^{II} polypyridyl complexes normally take several days at room temperature.[5] The final product is coincident with that of the ion $[Ru(tpm)(bpy)(OH)]^{+}$; in effect, when 1 drop of concentrated HCl was added to this complex, two bands developed at λ_{max} = 427 and 494 nm, values identical to those expected for $[Ru(tpm)(bpy)(OH_2)]^{2+}$.[12] The process is not catalytic, since the substitution rate of H_2O for CH_3CN in $[Ru(tpm)(bpy)(OH_2)]^{2+}$ is expected to be very slow.[13] It is well known[4] that coordinated amides are rapidly released from the coordination sphere of Ru^{II} and that they undergo further hydrolysis to carboxylic acids and ammonia in basic solutions.[1c,3] It should be noted, however, that the lifetime of amido-bonded complexes can be increased by using polydentate ligands such as cyclam.[14]

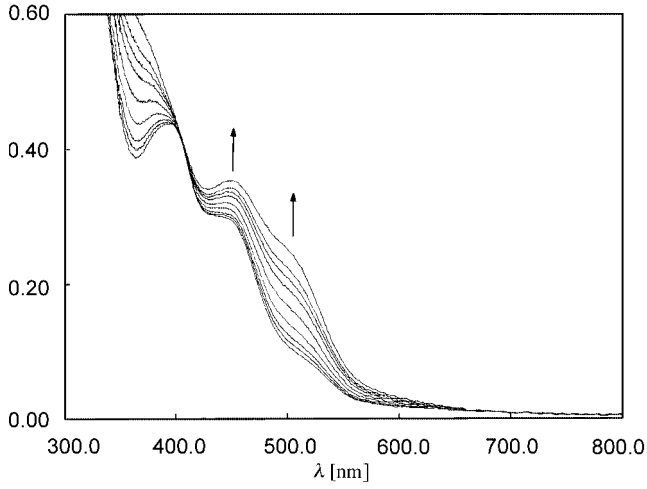

Figure 3. Spectra obtained in aqueous basic solutions of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$ at times t = 0, 3, 7, 15, 27, 41, 50, 60 and 81 min ([Ru] = 1.2×10^{-4} M; pH = 13; I = 0.1 M; T = 25 °C).

The pseudo-first-order rate constants k_{obs} depend linearly on the concentration of OH^-: $k_{obs} = k_{OH}[OH^-]$ (Figure S2). Table 1 shows the second-order rate constants for acetonitrile hydrolysis (k_{OH}) in several Ru complexes (including that of the free ligand). As shown in Table 1, the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rate constant for the basic hydrolysis of $[Ru(tpm)(bpy)(CH_3CN)](PF_6)_2$ is 1.3×10^{-3} M^{-1} s^{-1} at 25 °C. Therefore, the Ru^{II}(tpm)(bpy) group accelerates the reaction by a factor of 10^3 with respect to the free ligand, an enhancement effect that is lower than that of $Ru^{III}(NH_3)_5$, but higher than that of $Ru^{II}(NH_3)_5$. The value is also ca. 4 times lower than that of the corresponding Ru^{II}(trpy)(bpy) complex, although the values are within the same order of magnitude and intermediate in the wide range of hydrolysis rate constants reported in the literature.[1b]

Table 1. Rate constants for basic hydrolyses of CH_3CN in several ruthenated species, at 25 °C.

Complex	k_{OH}[M^{-1} s^{-1}]	Reference
CH_3CN	1.6×10^{-6}	[2]
$[Ru(NH_3)_5(CH_3CN)]^{2+}$	$<6\times10^{-5}$	[2]
$[Ru(tpm)(bpy)(CH_3CN)]^{2+}$	1.3×10^{-3}	This work
$[Ru(trpy)(bpy)(CH_3CN)]^{2+}$	4.6×10^{-3}	[4]
$[Ru(NH_3)_5(CH_3CN)]^{3+}$	2.2×10^{2}	[2]

The variation of $\ln(k_{OH}/T)$ with $1/T$ is displayed in Figure 4. From Eyring's rate equation,[15] values of $\Delta H^{\ddagger}$ = (74 ± 4) kJ mol^{-1} and $\Delta S^{\ddagger}$ = (–54 ± 12) J mol^{-1} K^{-1} are determined, which are typical for an associative mechanism. Metal-catalyzed nitrile hydrolyses normally have negative activation entropies, since bimolecular processes are involved.[16]

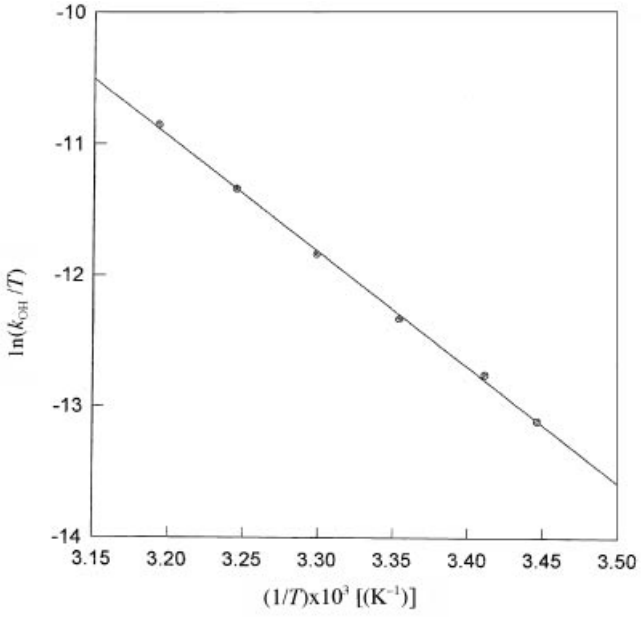

Figure 4. Eyring's plot for the basic hydrolysis of CH_3CN in $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$.

Since trpy is a better π-acceptor than tpm, as evidenced by the higher $E_{1/2}$ values of $[Ru(trpy)(bpy)(L)]^{2+}$ complexes than those of $[Ru(tpm)(bpy)(L)]^{2+}$ complexes,[17,10] one would expect a more energy-demanding hydrolysis process for the latter species, when L = CH_3CN. However, the measured activation enthalpy is the same as that of the trpy species ($\Delta H^{\ddagger}$ = 74 kJ mol^{-1}).[5] On the other hand, the activation entropy is highly negative and much lower than that of the trpy species ($\Delta S^{\ddagger}$ = –42 J mol^{-1} K^{-1}),[5] thus accounting for its lower reaction rate. These entropy differences can be explained by considering the steric constraints imposed by the facial geometry of coordinated tpm. In contrast to the meridional geometry of trpy in $[Ru(trpy)(bpy)(CH_3CN)]^{2+}$,[6] the structure of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$ (see Figure 2) shows that two of the tpm rings protrude out of the metal-coordinated plane containing the N1, N5, N7, and N8 atoms, thus making the attachment of the hydroxide group to the coordinated nitrile group more entropy-demanding.

Conclusion

The new complex $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$ presents spectral, electrochemical, and photophysical properties similar to analogous species with strong π-electron-accepting groups. Although the Ru^{II}(tpm)(bpy) moiety can also promote the hydrolysis of coordinated CH_3CN by a factor of 10^3 relative to free CH_3CN, the effect is less than that previously observed with the Ru^{II}(trpy)(bpy) moiety, because of the steric constrains imposed by the facial geometry of tpm.

Experimental Section

Materials: All reagents were obtained from Aldrich Chemical Co. and used without further purification. CH_3CN was freshly distilled for electrochemical measurements.

Preparations: All synthetic manipulations were routinely performed under nitrogen using Schlenk tubes and vacuum line techniques. Electrochemical experiments were performed in the dark under N_2 or Ar with degassed solvents.

Synthesis of $[Ru(tpm)(bpy)(CH_3CN)](PF_6)_2$: $[Ru(tpm)(bpy)(H_2O)](PF_6)_2$ (55 mg) prepared as described before,[12] was dissolved in CH_3CN (15 mL) and refluxed for 3 h. The solution was cooled to room temperature, and diethyl ether (100 mL) was added. The orange precipitate that formed was collected on a frit, washed with cold ether, and dried in vacuo over P_4O_{10}. Yield: 36 mg (64%). Elemental analysis: calcd. C 32.9, H 2.6, N 15.7; found C 33.1, H 2.7, N 15.0. IR: $\tilde{\nu}_{C\equiv N}$ = 2282 cm^{-1}. UV/Vis in CH_3CN: λ_{max}, nm (ε, M^{-1} cm^{-1}) = 397(3.8×10^3), 440 (2.7×10^3), 520 (7.2×10^2). $E_{1/2}$ = 1.28 V (vs. SCE).

The Br^- salt of the ion $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$ was obtained by dissolving the PF_6^- salt (25 mg) in acetone (2 mL) and adding nBu$_4$NBr (500 mg) previously dissolved in acetone (2 mL). The precipitate was collected by filtration, washed with cold acetone, and dried in vacuo over P_4O_{10}. Yield: 17 mg (80%).

Equipment: All chemicals were reagent grade and used as received. UV/Visible spectra were recorded with a Shimadzu UV-160A spectrophotometer, equipped with a thermostatted cell compartment. IR spectra (of KBr pellets) were measured using a double-beam Perkin–Elmer 983G spectrophotometer. Chemical analyses were done at INQUIMAE, University of Buenos Aires, Argentina. Fluorescence measurements were determined with a Shimadzu RF-5301 PC spectrofluorometer in CH_3CN at room temperature. Cyclic voltammetry experiments were carried out in CH_3CN, 0.1 M TBAH [tetrakis(*n*-butyl)ammonium hexafluorophosphate] on a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

BAS Epsilon EC apparatus with a conventional three-electrode array, consisting of vitreous C as the working electrode, platinum wire as the auxiliary electrode and Ag/AgCl (3 M KCl) as the reference electrode. Ar was bubbled through the solutions prior to photophysical and electrochemical measurements.

Doubly distilled water was used for all kinetic determinations. pH measurements were carried out with a precision of ± 0.05 pH units, using a Metrohm 744 pH meter. The hydrolysis reactions were studied under pseudo-first-order conditions at temperatures between 17 °C and 40 °C, and pH values between 12.1 and 13.1 (NaOH). The ionic strength was fixed at I = 0.1 M (KCl). A fresh solution of $[Ru(tpm)(bpy)(CH_3CN)](Br)_2$ in water was used for each set of experiments. Absorbance (A) vs. time (t) data were recorded at λ = 510 nm. Duplicate or triplicate runs were made at each value of pH and temperature. The pseudo-first-order rate constants were determined by least-squares fits of $\ln(A_t - A_\infty)$ vs. t, which were linear for more than 3 half-lives. The estimated error in the base hydrolysis rate constants (k_{OH}) is ± 5%.

X-ray Structure Determination: Crystals of $[Ru(tpm)(bpy)(CH_3CN)](PF_6)_2$ were grown by slow diffusion of diethyl ether into a concentrated solution of $[Ru(tpm)(bpy)(pz)](PF_6)_2$[10] in CH_3CN at room temperature. Molecular formula $C_{22}H_{21}F_{12}N_9P_2Ru$, M = 802.49, orthorhombic, a = 12.88244(6), b = 13.4952(5), c = 16.3986(7) Å, V = 2850.9(2) Å^3, space group $P2_12_12_1$, Z = 4, μ = 0.775 mm^{-1}, $d_{calcd.}$ = 1.870 g cm^{-3}. The measurement was made with a Siemens P4 diffractometer equipped with a SMART-CCD-1000 area detector, a MACScience Co. rotating anode with Mo-K_α radiation, a graphite monochromator and a Siemens low temperature device LT2 (T = –120 °C). The measurements were made in the range 1.95 to 31.52°. 44178 reflections were collected, of which 9061 are unique (R_{int} = 0.0726). Full sphere data collection ω and φ scans. Programs used: Data collection Smart V. 5.060 (Bruker AXS, 1999), data reduction Saint + Version 6.02 (Bruker AXS 1999) and absorption correction SADABS (max/min transmission: 1.000000/0.578248, Bruker AXS 1999). Structure solution and refinement was performed using SHELXTL Version 5.10 (Sheldrick, Universtität Göttingen, Göttingen, Germany, 1998). The structure was solved by direct methods and refined by full-matrix least-squares against F^2. All calculated hydrogen positions are free refined. Final R_1 [$I > 2\sigma(I)$] = 0.0331 and $wR(F^2)$ [$I > 2\sigma(I)$] = 0.0719. The number or refined parameters was 472.

CCDC-264142 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information Available: CIF magnetic files together with additional electrochemical (Figure S1. Cyclic voltammogram of $[Ru(tpm)(bpy)(CH_3CN)]^{2+}$, in CH_3CN, 0.1 M TBAH, v = 200 mV/s) and kinetic (Figure S2. Dependence of the hydrolysis rate constants k_{obs} on [OH^-], at 25 °C) data (See footnote on the first page of this article.).

Self-Assembled Triorganotin(IV) Moieties with 1,3,5-Benzenetricarboxylic Acid: Syntheses and Crystal Structures of Monomeric, Helical, and Network Triorganotin(IV) Complexes

Chunlin Ma,*[a,b] Yinfeng Han,[a] Rufen Zhang,[a] and Daqi Wang[a]

Keywords: Crystal engineering / Helical structures / Networks / Self-assembly / Tin

A series of novel triorganotin(IV) complexes of the type $[(R_3Sn)_3(TMA)]\cdot Y\cdot L$ [R = CH_3, Y = $3CH_3OH$ (**1**); R = CH_3, Y = $2CH_3OH$ (**2**); R = $C_6H_5CH_2$ (**3**); R = *o*-F-$C_6H_4CH_2$ (**4**); R = *o*-Cl-$C_6H_4CH_2$ (**5**); R = C_6H_5, L = CH_2Cl_2 (**6**); R = C_6H_5, L = $EtOH\cdot 2H_2O$ (**7**); R = C_6H_5, L = $Et_2O\cdot CH_2Cl_2$ (**8**); H_3TMA = 1,3,5-benzenetricarboxylic acid] and $[(CH_3)_3Sn]_2(HTMA)\cdot H_2O$ (**9**) have been synthesized. All complexes were characterized by elemental analysis and by IR, ^1H, ^{13}C, and ^{119}Sn NMR spectroscopy. Except for **4** and **5**, all complexes were also characterized by X-ray crystallography. Complex **1** possesses a network structure where TMA acts as a tridentate ligand coordinated to three trimethyltin(IV) moieties and three methanol molecules that are involved in a hydrogen-bond system, whereas **2** possesses a helical structure where TMA acts as a tetradentate ligand coordinated to three trimethyltin(IV) ions and two methanol molecules that bend into the helical turn in the intra-helix hydrogen-bond system. Complexes **3**–**8** are monomeric structures where TMA acts as a hexadentate ligand coordinated to triorganotin(IV) ions and **9** possesses a network structure where TMA acts as a tetradentate ligand coordinated to trimethyltin(IV) ions and water molecules in the hydrogen-bond system that links the neighboring layers into a 3D network.

Introduction

In the last years, metal-directed self-assembly[1] has produced fascinating results in two topical areas dealing respectively with the deliberate construction of molecular interlocked/intertwined species, like rotaxanes, catenanes, knots, and helicates,[2,3] and the crystal engineering of extended 2D and 3D networks.[4,5] Conformationally flexible ligands are typical building elements in the former area, while in the latter essentially rigid rod-like organic units are usually employed to connect the metal centers. In particular, multi-benzenecarboxylate ligands have been shown to be good building blocks in the design of self-assembly complexes with desired topologies owing to their rich coordination modes.[6–10] In spite of the rich coordination chemistry exhibited by transition metals with these ligands,[11–17] relatively little is known with respect to the synthesis and the formal coordination of discrete organotin(IV) complexes with these ligands. Therefore, exploring whether organotin(IV) complexes with these ligands can help the construction of novel structure is of interest.

In this work, we selected H_3TMA and the triorganotin(IV) ion on the basis of the following considerations: (a) it has three carboxylic acid groups that may be completely or partially deprotonated, inducing rich coordination modes and allowing interesting structures with higher dimensions; (b) it can act not only as a hydrogen-bond acceptor but also as a hydrogen-bond donor, depending upon the number of deprotonated carboxyl groups; (c) some of the carboxyl groups may not lie in the phenyl ring plane upon complexation to metal ions owing to space hindrance, thus it may connect metal ions in different directions; (d) it possesses high symmetry that may be helpful for the crystal growth of the product formed; (e) triorganotin(IV) ions have a high affinity for hard donor atoms, and ligands containing oxygen atoms, especially carboxylic ligands, are usually employed in the architectures for polymeric complexes. Recently, we began to assemble H_3TMA and triorganotin(IV) ions and hope the rich information stored in H_3TMA will induce novel polymeric structures constructed by tin(IV) centers. Herein we report the syntheses and characterizations of nine triorganotin(IV) complexes constructed from H_3TMA. With a 1:3:3 molar ratio of H_3TMA:EtONa:R_3SnCl we obtained eight trinuclear complexes (**1**–**8**) of the type $[(R_3Sn)_3(TMA)]\cdot Y\cdot L$ [R = CH_3, Y = $3CH_3OH$ (**1**); R = CH_3, Y = $2CH_3OH$ (**2**); R = $C_6H_5CH_2$ (**3**); R = *o*-F-$C_6H_4CH_2$ (**4**); R = *o*-Cl-$C_6H_4CH_2$ (**5**); R = C_6H_5, L = CH_2Cl_2 (**6**); R = C_6H_5, L = $EtOH\cdot 2H_2O$ (**7**); R = C_6H_5, L

 DOI: 10.1002/ejic.200500152

= $Et_2O{\cdot}CH_2Cl_2$ (**8**)], and with a 1:2:2 ratio a 3D network **9** was obtained with the formula $[(CH_3)_3Sn]_2(HTMA){\cdot}H_2O$.

Results and Discussion

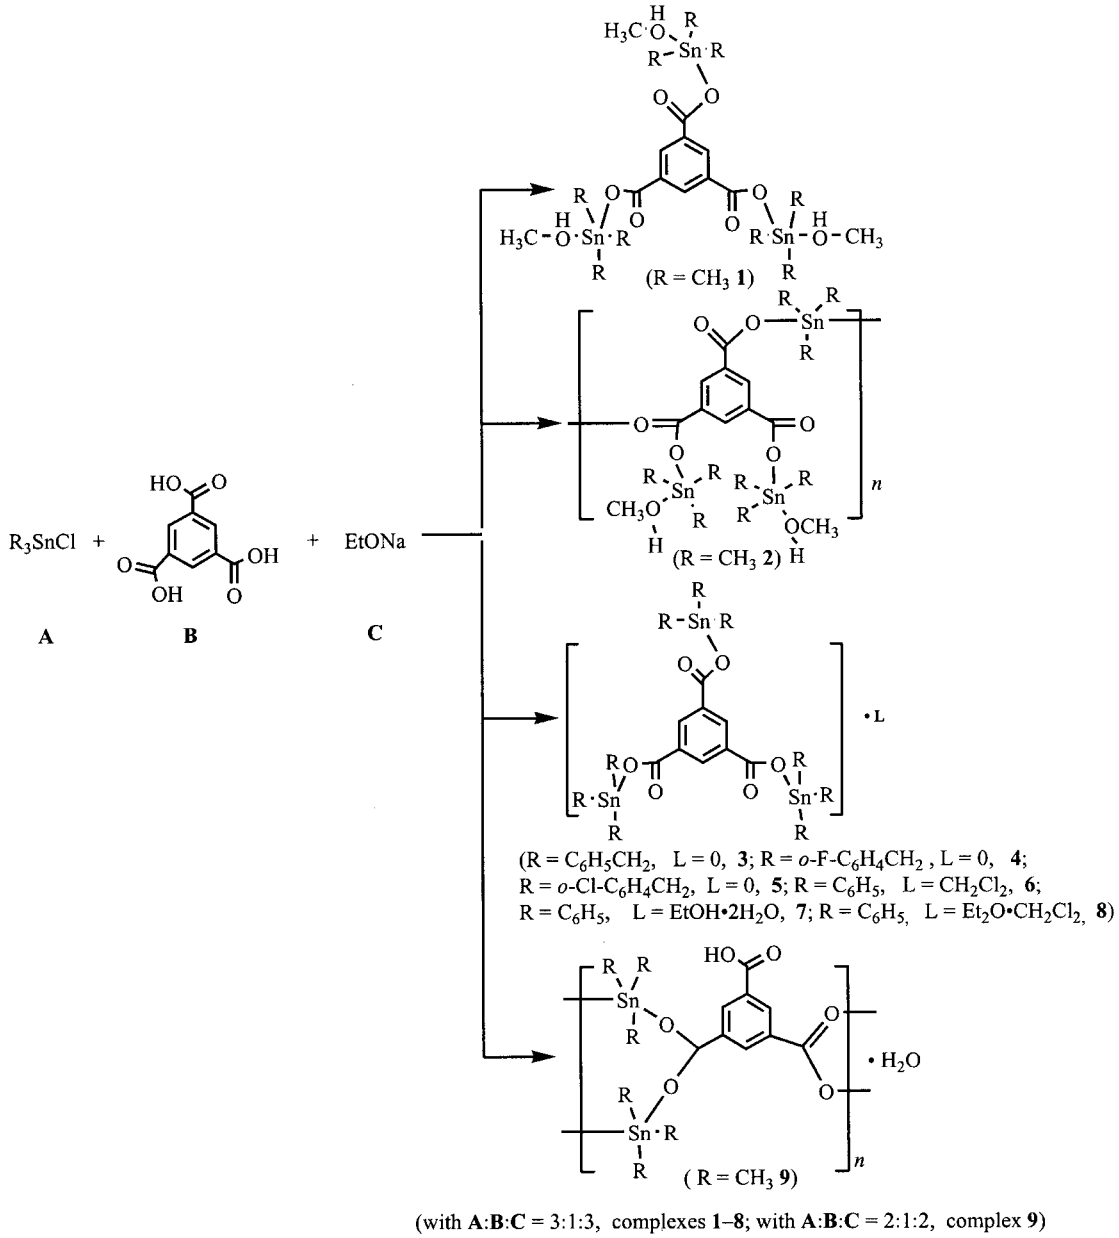
Reactions of H_3TMA and sodium ethoxide with triorganotin(IV) chlorides in a 1:3:3 or 1:2:2 stoichiometry afford the air-stable complexes **1**–**8** or **9**, respectively. The synthetic procedures are shown in Scheme 1.

Spectroscopic Studies

IR Spectroscopy

The stretching frequencies of interest are those associated with the C(O)O, Sn–C, and Sn–O groups. The strong absorption in the region 468–496 cm^{-1}, which is absent in the spectrum of the free ligand, is assigned to the Sn–O stretching mode. All these values are consistent with those detected in a number of organotin(IV)–oxygen derivatives.[18,19]

In organotin carboxylate complexes, IR spectroscopy can provide useful information concerning the coordination mode of the carboxyl group. When the carboxylic group coordinates the tin atom in a monodentate manner, the difference between the wavenumbers of the asymmetric and symmetric carboxylic stretching bonds (mode I), $\Delta\nu[\nu_{asC(O)O^-} - \nu_{sC(O)O^-})$ is greater than that observed for ionic complexes. When the ligand chelates (mode II), $\Delta\nu$ is considerably smaller than that for ionic complexes, while for asymmetric bidentate coordination the value is in the



Scheme 1.

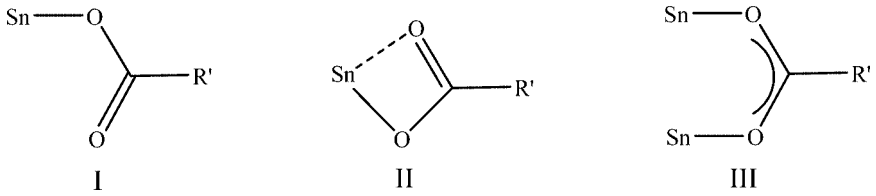

Scheme 2. Different coordination modes of the carboxylate group.

range characteristic of monodentate coordination.[20] The characteristic wavenumber difference for mode III is larger than that for chelated ions and nearly the same as observed for ionic complexes (Scheme 2).

Based on the above results, it was possible to distinguish the coordination mode of the $C(O)O^-$ group. The magnitude of $\Delta\nu$ of about 170 cm^{-1}, compared with those for the corresponding sodium salts, reveals that the carboxylate ligands function as bidentate ligands under the conditions employed.[21,22] This is also consistent with the X-ray diffraction study (see below).

NMR Spectroscopy

The ^1H NMR spectra show the expected integration and peak multiplicities. In the spectrum of the free ligand, the resonance observed at about δ = 10.51 ppm, which is absent in the spectra of the complexes, indicates the replacement of the carboxylic acid proton on complex formation. The chemical shifts of the signals for the methyl groups (δ = 0.81–1.01 ppm) and the phenyl group (δ = 7.21–7.76 ppm) appear at the same position as in the ligands. The $^2J_{Sn,H}$ values of trimethyltin derivatives **1** and **2** (68.6 and 69.4 Hz, respectively) are similar to those previously reported for five-coordinate trigonal bipyramidal tin(IV) adducts.[23]

The ^{13}C NMR spectra of all complexes show a significant downfield shift of all carbon resonances compared with the free ligand because of an electron density transfer from the ligand to the acceptor. Although at least two different types of carboxyl groups are present, only a single resonance is observed for the COO group in the ^{13}C NMR spectra. A possible reason for this is that either accidental magnetic equivalence of the carbonyl carbon atoms occurs or the separations between the sets of resonance are too small to be resolved.

The ^{119}Sn NMR spectra of **1** and **2** show only one signal, typical of a five-coordinate species, which is in accordance with their structures in the solid state.[24] However, the chemical shift for **9** (δ = –55.0 ppm) is within the range corresponding to a coordination number of 4 (δ = –60 to +200 ppm),[24] so it can reasonably be assumed that the structure of **9** in solution is probably different from that observed in the solid state.

Crystal Structure of $[(Me_3Sn)_3(TMA)]\cdot 3CH_3OH$ (1)

The molecular structure is illustrated in Figures 1 and 2 and selected bond lengths and bond angles are given in Table 1. Complex **1** is a two-dimensional polymer in the crystalline state. All the Sn atoms are five-coordinate with a trigonal bipyramidal structure by coordinating an additional methanol group. The axial ligand–tin–axial ligand angles [O(1)–Sn(1)–O(3) = 172.60(18)°, O(4)–Sn(2)–O(6) = 174.97(19)°, and O(7)–Sn(3)–O(9) = 174.7(2)°] suggest that the structures are near to a normal trigonal bipyramid. Intermolecular hydrogen-bond interactions between the methanol and the oxygen atom of an adjacent molecule [O(3A)–H···O(2) = 2.703 Å, O(6B)–H···O(8) = 2.694 Å, and O(9C)–H···O(5) = 2.608 Å] result in the formation of a two-dimensional network.

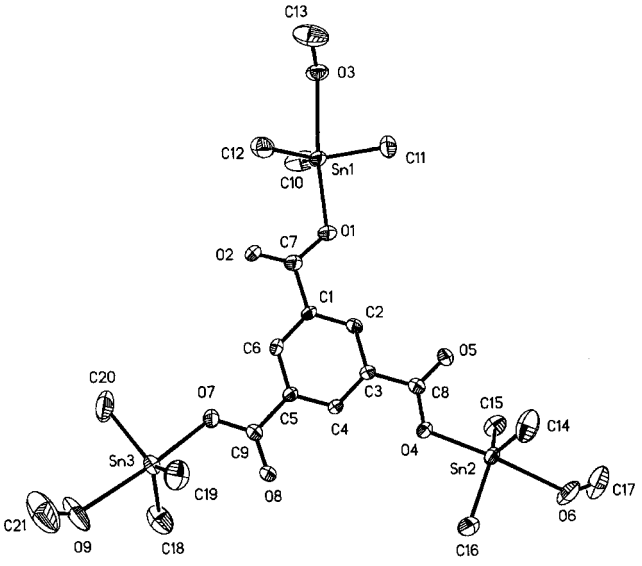

Figure 1. The molecular structure of **1**.

Crystal Structure of $[(Me_3Sn)_3(TMA)]\cdot 2CH_3OH$ (2)

The molecular structure of complex **2** is illustrated in Figures 3 and 4 and selected bond lengths and bond angles are given in Table 1. The asymmetric unit of **2** consists of $[(Me_3Sn)_3(TMA)]\cdot 2CH_3OH$ as the building block. There are two types of independent Sn atoms: the geometry at Sn(1) atom is trigonal bipyramidal with a bridging carboxyl group (O1 and O6A) and the geometries at Sn(2) and Sn(3) are trigonal bipyramidal with coordinating methanol group. The O(1)–Sn(1)–O(6)#1 [$-x$, $-y$, z + 1/2; 168.7(3)°], O(3)–Sn(2)–O(7)#2 [x, y – 1, z; 175.1(3)°], and O(5)–Sn(3)–O(8) [171.0(3)°] angles suggest that the structures are near to an ideal trigonal bipyramid. There are also two types of carboxylate groups, one of which is bidentate and the other monodentate. Due to the anisobidentate coordination mode of the carboxylate groups to the tin atoms, two groups of

different Sn–O bond lengths are found, one group corresponding to Sn–O bonds of covalent character [2.156(9)–2.160(7) Å] and the other group corresponding to Sn–O bonds of coordinative character (2.548 Å). Bond lengths of 2.114(3)–2.208(2) Å and 2.381(2)–2.57(1) Å, respectively, have been measured in related trimethyltin carboxylates.[25] Also, there are two methanol molecules in the coordination sphere, with Sn–O bond lengths of 2.462 Å and 2.568 Å, respectively, which are comparable in strength to the intramolecular tin–oxygen bonds and close in length to the sum of the covalent radii of tin and oxygen (2.13 Å),[26] which is recognized as a coordinative bond.

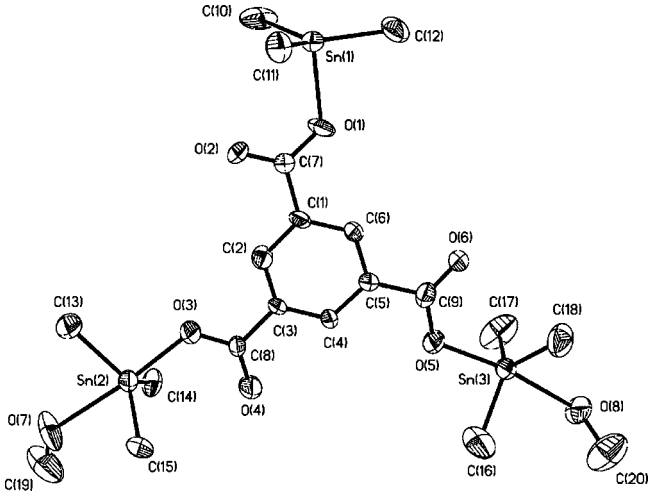

Figure 3. The molecular structure of **2**.

The structure shows that the Sn(1) ion is arranged in an infinite single helix with intervening TMA^{3-} ligands even though the ligand has no intrinsic tendency to form helical structures. The helical structure of **2** is a result of metal–organic ligand interactions coupled with the stereoelectronic characteristics of the ligand and the conditions prevailing during the synthesis. The helix has two distinct

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

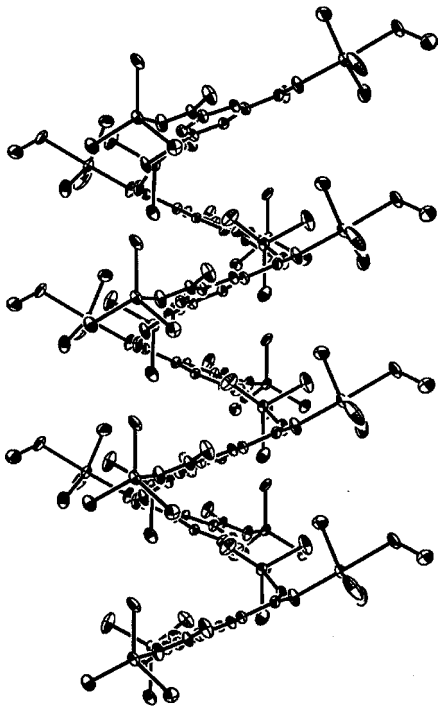

Figure 4. The helical structure of **2**.

Sn···Sn distances of 5.810 and 6.771 Å. The stability of the final helical structure relies on the coordinative bonds that each metal makes with the ligand. The helix is further organized into a metal–organic framework structure through inter-helix hydrogen bonding interactions to form a curved three-dimensional network.

The oxygen–oxygen distances in the crystal are also within the hydrogen-bonding range.[27] Hydrogen bonding is one of the main factors in the construction of supramolecular systems, and there are a variety of such linkages between the oxygen atoms of the carboxylic and coordinated methanol molecules. The packing is such that the oxygen of the coordinated methanol molecule forms two hydrogen bonds with the carboxylic oxygen atom of an adjacent molecule, which means that in the crystal there are a series of parallel helical chains that are linked by hydrogen bonds between coordinated CH_3OH and carboxylic oxygen atoms, which run through each other.

Crystal Structures of $[\{(C_6H_5CH_2)_3Sn\}_3(TMA)]$ (3), $[\{(C_6H_5)_3Sn\}_3(TMA)]\cdot CH_2Cl_2$ (6), $[\{(C_6H_5)_3Sn\}_3(TMA)]\cdot EtOH\cdot 2H_2O$ (7), and $[\{(C_6H_5)_3Sn\}_3(TMA)]\cdot Et_2O\cdot CH_2Cl_2$ (8)

The molecular structures of complexes **3**, **6**, **7**, and **8** are illustrated in Figures 5, 6, 7, and 8, respectively, and se-

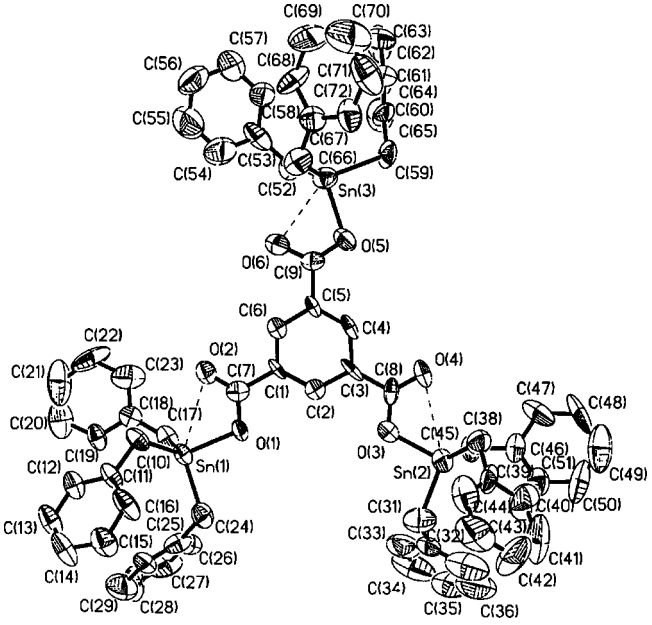

Figure 5. The molecular structure of **3**.

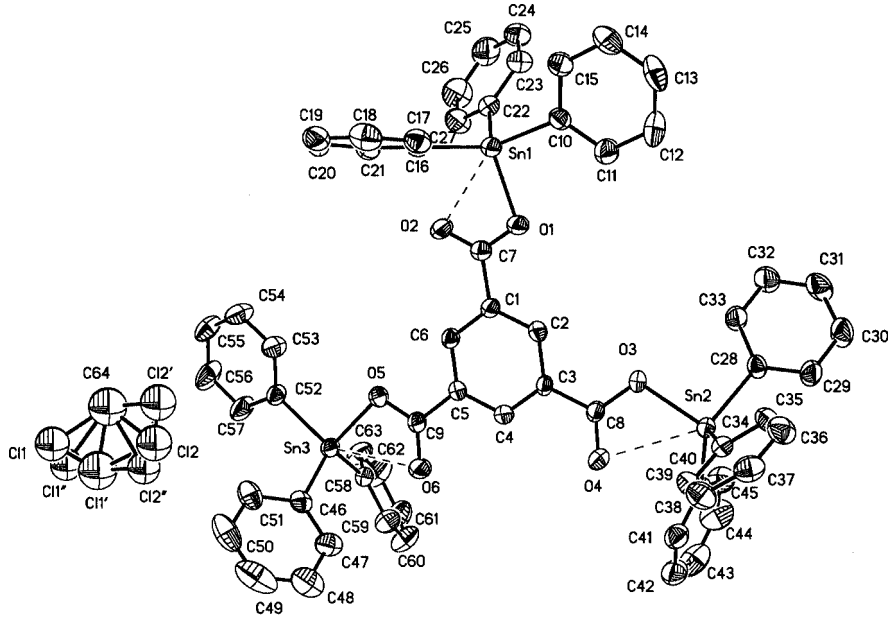

Figure 6. The molecular structure of **6**.

lected bond lengths [Å] and angles [°] are listed in Table 2. Trinuclear triphenyltin or tribenzyltin carboxylate of H_3TMA possesses a monomeric structure. For the complexes, it can be seen that the Sn(1)–O(1), Sn(2)–O(3), and Sn(3)–O(5) bond lengths (2.052–2.097 Å) lie in the range of 2.038(9)–2.115(6) Å that has been reported as the Sn–O covalent bond length, which proves that the oxygen atoms are coordinated to the tin atoms by a strong chemical bond. The intramolecular distances Sn(1)···O(2), Sn(2)···O(4), and Sn(3)···O(6) are in the range 2.634–2.916 Å. Although these distance are considerably longer than the normal Sn–O covalent bond length, they lie in the range of Sn···O distances of 2.61–3.02 Å which have been confidently reported for intramolecular bonds.[28,29] As the oxygen atoms of the carboxylate are involved in a weak coordinative interaction with tin along one of the tetrahedral faces, the structure distortion for the tin atoms in **3** and **6**–**8** is best described as a capped tetrahedron.

Crystal Structure of $[\{(CH_3)_3Sn\}_2(HTMA)]\cdot H_2O$ (9)

The molecular structure of **9** is illustrated in Figure 9. It consists of infinite ribbons extending through the cell in the *b* direction, as indicated in Figure 10. Bond lengths and bond angles are given in Table 3. The trimethyltin(IV) groups are situated in special positions in the crystallographic mirror planes and are linked by a carboxylate; each TMA ligand in **9**, in turn, employs its two bidentate carboxylic groups to coordinate to four metal centers. Thus, four ligands are linked by four metal centers into a 24-membered macrocycle, which is further linked to eight nearest-neighbor Sn centers by four independent TMA ligands to give rise to a lattice plane with a cavity of 10.441–10.445 Å. All the tin atoms possess the same coordination environment. The coordination about the tin atom is only slightly distorted from a regular trigonal bipyramidal geometry. The angles O(3)#1–Sn(1)–O(1) 169.62(15)° and O(2)–Sn(2)–O(4)#2 171.48(16)° are close to a linear arrangement. The sum of the angles subtended at the tin atom in the trigonal plane is 358.3° for Sn(1) and 359.9° for Sn(2), so that the atoms Sn(1), C(10), C(11), and C(12) and Sn(2), C(13), C(14), and C(15) are almost in the same plane. The Sn–C distances [2.100(6)–2.118(7) Å] are equal within experimental error and close to the single-bond value for trigonal bipyramidal tin.[30]

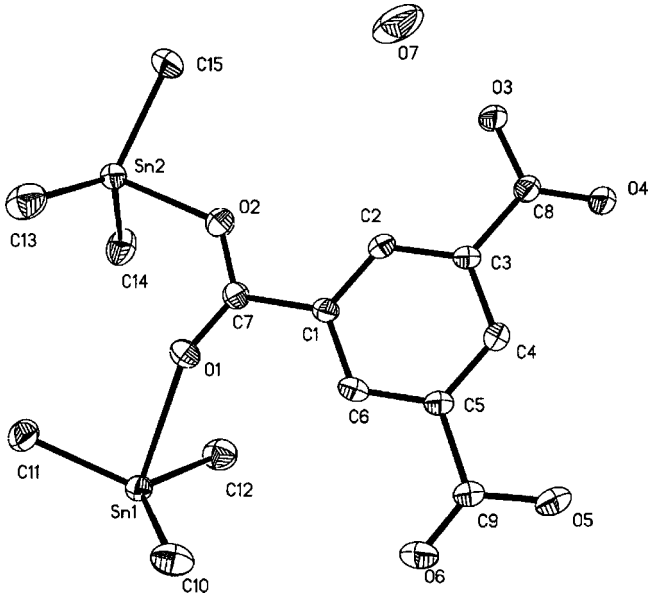

Figure 9. The molecular structure of **9**.

Interestingly, the $[\{(CH_3)_3Sn\}_2(HTMA)]\cdot H_2O$ groups are joined together by hydrogen bonds to form a three-dimensional network. The crystallization water molecule is linked to the O(3) atom to form a hydrogen bond [O(7)–H···O(3)] and to the O(5) and O(6) atoms from the neighboring $[(CH_3)_3Sn]_2(HTMA)\cdot H_2O$ group to form a further two hydrogen bonds [O(7)–H···O(6A) and O(7)···O(5A)–H(5A), respectively]. Viewed along the *a* axis, each layer $[(CH_3)_3Sn]_2(HTMA)\cdot H_2O$ is linked to an adjacent $[(CH_3)_3Sn]_2(HTMA)\cdot H_2O$ unit leading to an infinite network of intermolecular O···H–O hydrogen bonds. Thus, these networks are further organized into metal–organic framework structures through inter-network hydrogen bonding interactions that form a curved three-dimensional network.

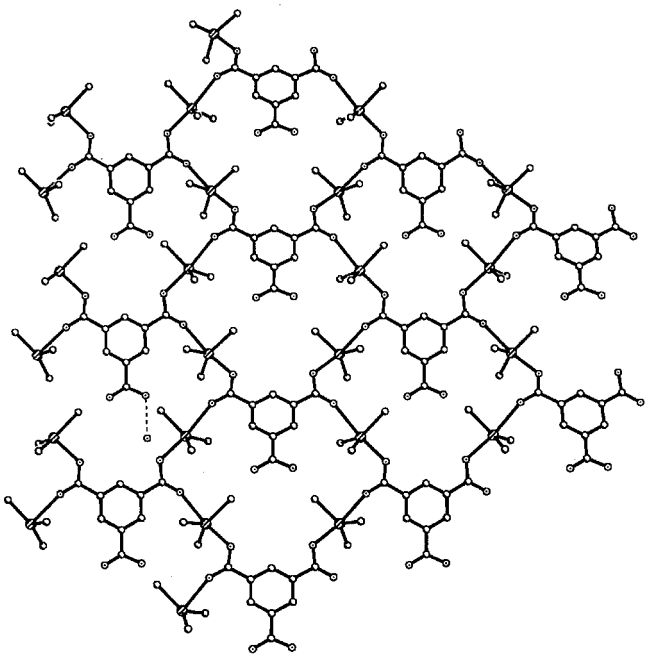

Figure 10. The network structure of **9**.

Conclusions

In summary, by carefully controlling the reaction conditions we have found that H_3TMA is a versatile building block for the construction of metal–organic complexes by complete or partial deprotonation of its carboxyl groups. Despite using a 1:3:3 molar ratio of H_3TMA, EtONa, and $(PhCH_2)_3SnCl$ (or Ph_3SnCl), we couldn't obtain a product similar to the polymeric structure of complex **2**. In general, in the crystalline state these complexes generally adopt either a polymeric structure with a five-coordinate tin atom or a discrete five-coordinate form.[21,31] Trimethyltin benzoates mainly assume one-dimensional associated arrangements, whereas triphenyltin benzoates generally exist in a discrete five-coordinate form. A delicate energy balance is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

present between the two forms, although the greater electronegativity of a phenyl group than a methyl group has been cited as a factor influencing the formation of the discrete form, as it gives more access to an axial position of a trigonal bipyramid.[31] A polymeric structure for tribenzyl or triphenyl carboxylates is associated with an electron-withdrawing R group. The contribution of either steric or electronic factors has been discussed by Holmes et al.[31] From structural data accumulated so far, the relative ligand electronegativity appears to be an important factor in determining whether the discrete structural form or the chain form is observed.[32] The axial tin–ligand bond lengths in both forms are subject to variations depending on the substitute electronegativity, ring strain, hydrogen bonds, and steric interactions.

Experimental Section

Materials and Measurements: Trimethyltin chloride, triphenyltin chloride, and 1,3,5-benzenetricarboxylic acid are commercially available and were used without further purification. Tribenzyltin chloride, tri(*o*-chlorobenzyl)tin chloride, and tri(*o*-fluorobenzyl)-tin chloride were prepared by a standard method reported in the literature.[33] The melting points were obtained with Kofler micro-melting point apparatus and are uncorrected. IR spectra were recorded on a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. ^{1}H, ^{13}C, and ^{119}Sn NMR spectra were recorded on Varian Mercury Plus 400 spectrometer operating at 400, 100.6, and 149.2 MHz, respectively. The spectra were acquired at room temperature (298 K) unless otherwise specified; ^{13}C spectra are broadband proton decoupled. The chemical shifts are reported in ppm with respect to the references and are stated relative to external tetramethylsilane (TMS) for ^{1}H and ^{13}C NMR, and to neat tetramethyltin for ^{119}Sn NMR spectroscopy. Elemental analyses were performed with a PE-2400II apparatus.

Synthesis of [{(CH$_3$)$_3$Sn}$_3$(TMA)]·3CH$_3$OH (1) and [{(CH$_3$)$_3$Sn}$_3$(TMA)]·2CH$_3$OH (2): The reaction was carried out under nitrogen. H_3TMA (0.210 g, 1 mmol) and sodium ethoxide (0.204 g, 3 mmol) were added to a Schlenk flask and stirred for 0.5 h. Trimethyltin chloride (0.600 g, 3 mmol) was then added and the reaction mixture was stirred for 10 h at 40 °C. After filtration, the solvent was evaporated in vacuo. Yield: 78%. Rhombic crystals of **1** and block crystals of **2** were obtained from methanol solution.

X-ray Crystallographic Studies: Crystals were mounted in Lindemann capillaries under nitrogen. Diffraction data were collected on a Smart CCD area-detector with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). A semi-empirical absorption correction was applied to the data. The structures were solved by direct methods using SHELXS-97 and refined against F^2 by full-matrix least-squares using SHELXL-97. Hydrogen atoms were placed in calculated positions. Crystal data and experimental details of the structure determinations are listed in Table 4.
CCDC-256334 (for **1**), -249847 (for **2**), -226854 (for **3**), -248292 (for **6**), -230982 (for **7**), -236567 (for **8**), and -252043 (for **9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Keywords: Arsenic / Crystal structure / Electrochemistry / Palladium / Polyoxometalates / Tungsten

The monopalladium(II)-substituted $[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]^{10-}$ (**1**) and the tripalladium(II)-substituted $[Cs_2Na(H_2O)_8Pd_3(\alpha\text{-}AsW_9O_{33})_2]^{9-}$ (**2**) were synthesized in aqueous acidic medium (pH 4.8) by reaction of Pd^{2+} ions with $[As_2W_{19}O_{67}(H_2O)]^{14-}$ and $[\alpha\text{-}AsW_9O_{33}]^{9-}$, respectively. The dimeric polyanions **1** and **2** were characterized by complete elemental analysis, FTIR, and electrochemistry. Single-crystal X-ray analysis was carried out on $Cs_3Na_7[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]\cdot 1.5NaCl\cdot 22H_2O$ (**1a**), which crystallizes in the triclinic system, space group $P\bar{1}$, with a = 13.2465(16) Å, b = 16.873(2) Å, c = 23.080(3) Å, α = 107.315(2)°, β = 95.025(3)°, γ = 98.040(3)°, and Z = 2; $Cs_3Na_6[Cs_2Na(H_2O)_8Pd_3(\alpha\text{-}AsW_9O_{33})_2]\cdot NaCl\cdot 15H_2O$ (**2a**) crystallizes in the monoclinic system, space group $P2_1/m$, with a = 13.1842(5) Å, b = 19.6584(7) Å, c = 18.2377(6) Å, β = 100.7660(10)°, and Z = 2. Polyanion **1** is composed of two $[\alpha\text{-}AsW_9O_{33}]^{9-}$ fragments connected by a $WO(H_2O)$ unit, one square-planar palladium atom and two sodium ions, leading to a sandwich-type structure with C_s symmetry. Polyanion **2** also consists of two $[\alpha\text{-}AsW_9O_{33}]^{9-}$ moieties, but these are linked by three equivalent, square-planar Pd^{2+} ions, one sodium ion and two cesium ions, leading to a sandwich-type structure with C_{2v} symmetry. A cyclic voltammetric study of polyanion **2** in a pH 5 medium shows a Pd^0 deposition process on the glassy carbon electrode surface. The corresponding wave and the waves for the tungsten redox processes could be separated clearly. The thickness of the film increases with the number of potential cycles or the duration of potentiostatic electrolysis. The deposited film proved to be very stable and efficient in the electrocatalytic reduction of dioxygen. Polyanion **1** was not sufficiently stable in solution to warrant electrochemical characterization.

Introduction

Polyoxometalates (POMs) are a well-known class of metal–oxygen cluster species with a diverse compositional range and structural variety, and therefore, they attract increasing attention worldwide.[1] Although POMs have been known for about 200 years, a large number of novel polyoxoanions with different size, composition and structure are still being discovered.[2–4] The fascinating properties of POMs allow to envisage applications in different fields including catalysis, medicine and materials science.[5–7] Therefore, systematic structural design of novel POMs and derivatization of known POMs continue to be a considerable focus in the ongoing research in POM chemistry. Most POMs are composed of early transition metal MO_6 ($M = W^{6+}$, Mo^{6+}, etc.) octahedra and main group XO_4 ($X = P^V$, Si^{IV}, etc.) tetrahedra. The most famous POMs are probably the Keggin (e.g. $PW_{12}O_{40}^{3-}$) and the Wells–Dawson (e.g. $P_2W_{18}O_{62}^{6-}$) ions.[2]

The existence of As^{III}-containing POMs has been known for several years.[8] The lone pair of electrons on the heteroatom does not allow the closed Keggin unit to form, which has resulted in some unexpected structures, e.g. $[NH_4As_4W_{40}O_{140}Co_2(H_2O)_2]^{23-}$, $[As_4W_{20}O_{72}(H_2O)_2]^{12-}$, $[H_2AsW_{18}O_{60}]^{7-}$, and $[AsW_8O_{30}AsOH]^{7-}$.[9] A few years ago, Pope et al. reported on $[As_{12}Ce_{16}(H_2O)_{36}W_{148}O_{524}]^{76-}$, which also is the largest polyoxotungstate known to date.[10] This supramolecular polyanion is composed of 12 (α-AsW_9O_{33}) and four (W_5O_{18}) units. More recently, Kortz et al. reported on the second largest tungstoarsenate known to date, $[As_6W_{65}O_{217}(H_2O)_7]^{26-}$.[11] This species consists of four inner (β-AsW_9O_{33}) and two outer (α-AsW_9O_{33}) fragments that are linked by a total of 11 corner-sharing WO_6 octahedra.

The nonatungstoarsenate(III) $[\alpha\text{-}AsW_9O_{33}]^{9-}$ was discovered by Tourné et al. in 1973,[8a] and since then, the interaction of this trivacant ligand with transition-metal ions has been studied. Such work has resulted predominantly in di-

meric, sandwich-type structures, and the first member of this class ($[Cu_3(H_2O)_2(\alpha\text{-}AsW_9O_{33})_2]^{12-}$) was reported by Hervé et al. in 1982.[12] Since then a number of isostructural derivatives have been characterized: $[M_3(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{12-}$ (M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) and $[(VO)_3(\alpha\text{-}AsW_9O_{33})_2]^{11-}$.[13] Very recently, Kortz et al. described the first example of a sandwich-type species with four transition metals, $[Cu_4K_2(H_2O)_8(\alpha\text{-}AsW_9O_{33})_2]^{8-}$.[14] Recently, tetrasubstituted sandwich-type POMs based on the $[\beta\text{-}AsW_9O_{33}]^{9-}$ fragment have also been reported, e.g. $[M_4(H_2O)_{10}(\beta\text{-}AsW_9O_{33})_2]^{6-}$ (M = Fe^{3+}, Cr^{3+}).[15]

The 19-tungstodiarsenate(III) $[As_2W_{19}O_{67}(H_2O)]^{14-}$ was also reported by Tourné et al. in 1973,[8a] and its structure was recently confirmed by Kortz and coworkers.[11] This polyanion consists of two $[\alpha\text{-}AsW_9O_{33}]^{9-}$ fragments, which are linked by an additional tungsten center, resulting in a dilacunary species. The interaction of $[As_2W_{19}O_{67}(H_2O)]^{14-}$ with di- and trivalent transition-metal and main-group elements has been investigated by different groups and has resulted in disubstituted products $[M_2As_2W_{19}O_{67}(H_2O)_3]^{n-}$ (n = 10, M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, VO^{2+}; n = 8, M = Mn^{3+}, Fe^{3+}, Ga^{3+}).[13a, 16]

The 20-tungstodiarsenate(III) $[As_2W_{20}O_{68}(H_2O)]^{10-}$ was first reported by Hervé et al. who synthesized this as a monolacunary species from the dilacunary precursor $[As_2W_{19}O_{67}(H_2O)]^{14-}$.[17] The same authors also studied the interaction of $[As_2W_{20}O_{68}(H_2O)]^{10-}$ with first-row transition-metal ions, which leads to the monosubstituted products $[MAs_2W_{20}O_{68}(H_2O)_2]^{8-}$ (M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, VO^{2+}).[17] Recently, Kortz et al. reported on the ytterbium derivative $[YbAs_2W_{20}O_{68}(H_2O)_3]^{7-}$.[18]

All of the above sandwich-type structures can be considered to be derivatives of Jeannin's 21-tungstodiarsenate(III) $[As_2W_{21}O_{69}(H_2O)]^{6-}$, which consists of two $[\alpha\text{-}AsW_9O_{33}]^{9-}$ fragments linked by a belt of three tungsten atoms.[19]

Organotin-substituted tungstoarsenates(III) of this structural type have also been prepared. Pope et al. reported on tetrasubstituted $[\{C_6H_5Sn)_2O\}_2H(AsW_9O_{33})_2]^{9-}$,[20] and later, Kortz et al. prepared disubstituted $[(C_6H_5Sn)_2As_2W_{19}O_{67}(H_2O)]^{8-}$.[21] Very recently, Kortz et al. synthesized the first diorganotin-substituted tungstoarsenate(III), $[\{Sn(CH_3)_2(H_2O)_2\}_3(\beta\text{-}AsW_9O_{33})]^{3-}$, which self-condenses in the solid state leading to the hybrid organic–inorganic 2D material $(CsNa_2[\{Sn(CH_3)_2\}_3(\beta\text{-}AsW_9O_{33})]\cdot 7H_2O)_\infty$.[22]

For many years, POM researchers have attempted to incorporate 4d and 5d elements, in general, and Pd, in particular, in lacunary POMs because of the highly interesting catalytic properties of such species. For a long time the two Pd^{II}-containing polyoxotungstates $[Pd_3(A\text{-}PW_9O_{34})_2]^{12-}$ [23] and $[WZnPd_2(H_2O)_2(B\text{-}\alpha\text{-}ZnW_9O_{34})_2]^{12-}$ [24] have been the only known members of this class, and both were not structurally characterized by X-ray diffraction. Nevertheless, it has been demonstrated that these POMs have excellent catalytic properties for the selective and efficient transformation of organic substrates.[25] In 1994, Angus–Dunne et al. reported on the synthesis and structure of $[Pd_2W_{10}O_{36}]^{8-}$, which represents the first palladium(II)-substituted isopolytungstate.[26] In 2001, Krebs et al. reported on the structure of the tripalladium-substituted tungstotellurate $[Pd_3(TeW_9O_{33})_2]^{10-}$, but without providing any synthetic or crystallographic details.[6]

Recently, we also engaged in the synthesis of polyoxotungstates substituted by noble metals (e.g. Pd, Ru). We already reported on the two novel $Ru^{II}(dmso)_3$-supported polyanions $[HW_9O_{33}Ru^{II}_2(dmso)_6]^{7-}$ and $[Ru(dmso)_3(H_2O)XW_{11}O_{39}]^{6-}$ (X = Ge, Si).[27] Furthermore, we investigated the possibility of forming the Pd^{II} analogs of our tricopper(II)-substituted derivatives $[Cu_3(H_2O)_3(\alpha\text{-}XW_9O_{33})_2]^{12-}$ (X = As^{III}, Sb^{III}).[13a] This proved to be possible, and very recently, we reported on the synthesis and electrochemistry of the first structurally characterized palladium(II)-substituted heteropolyanion $[Cs_2Na(H_2O)_{10}Pd_3(\alpha\text{-}SbW_9O_{33})_2]^{9-}$.[28] We have also already reported on the structure and electrochemistry of the Pd^{II}-substituted tungstosilicate $[Cs_2K(H_2O)_7Pd_2WO(H_2O)(A\text{-}\alpha\text{-}SiW_9O_{34})_2]^{9-}$.[29]

Here we report on two novel palladium(II)-substituted tungstoarsenates(III).

Results and Discussion

Synthesis and Structure

The novel palladium(II)-substituted, dimeric tungstoarsenate(III) $[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]^{10-}$ (**1**) has been synthesized by reaction of $PdCl_2$ with $K_{14}[As_2W_{19}O_{67}(H_2O)]$ in aqueous acidic medium and isolated as a mixed cesium–sodium salt. Polyanion **1** represents only the third example of a structurally characterized palladium-substituted heteropolytungstate.[28,29] The sandwich-type **1** consists of two lacunary B-α-$[AsW_9O_{33}]^{9-}$ Keggin fragments linked by a Pd atom and a $WO(H_2O)^{4+}$ moiety, which leads to a structure with nominal C_s symmetry (see Figure 1 and Figure 2). Alternatively, **1** can be described as a $[As_2W_{19}O_{67}(H_2O)]^{14-}$ fragment that has taken up a palladium atom. We originally expected incorporation of two palladium atoms in dilacunary $[As_2W_{19}O_{67}(H_2O)]^{14-}$. However, it is not clear why this precursor picks up only one rather than the expected two palladium centers. Surprisingly, the third addenda atom position in the central belt of **1** is occupied by a sodium ion (Na2). Interestingly, Na2 is five-coordinate and is bonded by four terminal oxo groups [Na2···O 2.24–2.34(2) Å] of the two Keggin units in **1** and another terminal oxo group [Na2···O 2.42(3) Å] of W19, resulting in a square-pyramidal coordination sphere. Only one of the resulting three vacancies between W19, Na2 and the palladium atom is occupied by an additional sodium ion Na1. This Na1 is six-coordinate and is bonded by four bridging oxo groups [Na1···O 2.50–2.52(2) Å] of **1** and two terminal water molecules [Na1···O 2.41–2.48(3) Å] resulting in an octahedral coordination sphere. The orientation of Na1 in the belt of **1** is not all that surprising, as crystal structures of several 3d transition-metal derivatives have also revealed the presence of sodium ions in analogous positions. In the di- and tri-transition-metal-substituted derivatives $[M_2(H_2O)_2WO(H_2O)Na_3(H_2O)_6(\alpha\text{-}AsW_9O_{33})_2]^{7-}$ (M = Co^{2+}, Zn^{2+}, Mn^{2+}) and $[M_3(H_2O)_3Na_3(H_2O)_6(\alpha$-

$AsW_9O_{33})_2]^{9-}$ (M = Mn^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}), three sodium ions were observed in the central belt in equivalent positions.[13] In the monophenyltin derivative $[(C_6H_5Sn)_2Na(H_2O)_2As_2W_{19}O_{67}(H_2O)]^{7-}$, a sodium ion was found between the two tin atoms.[21] Finally, in Pope's $[(C_6H_5Sn)_3Na_3(H_2O)_6(\alpha\text{-}SbW_9O_{33})_2]^{6-}$, three sodium ions are located in the central belt in addition to the three C_6H_5Sn groups.[20]

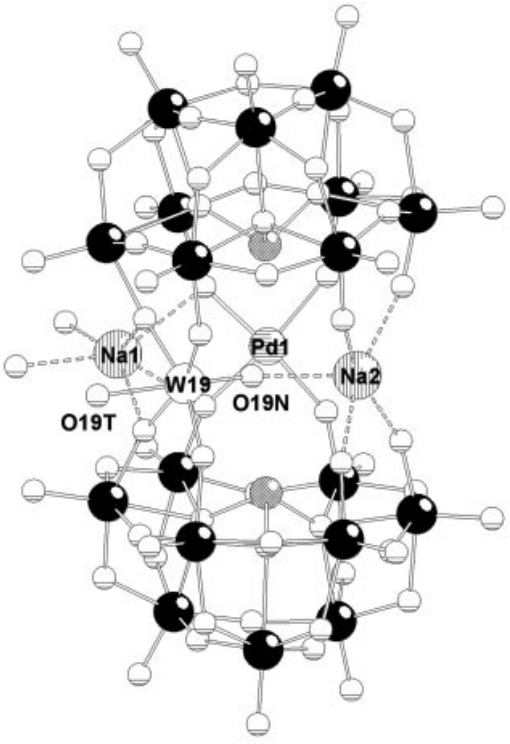

Figure 1. Ball and stick representation of $[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]^{10-}$ (**1**) showing labels for some selected atoms in the central belt. The shading of the remaining atoms is as follows: tungsten (black), arsenic (cross-hatched), and oxygen (white).

Bond valence sum analysis[30] reveals that in polyanion **1** the *trans*-related terminal ligands of the unique tungsten linker are arranged so that the water molecule is *external* [W19–O19T 2.27(2) Å] and the oxo ligand is *internal* [W19–O19N 1.72(2) Å], see Figure 1. This is in complete agreement with all other compounds containing the $[As_2W_{19}O_{67}(H_2O)]$ fragment, including the precursor itself.[11,13a,16] Interestingly, the situation is reversed for the dipalladium(II)-substituted $[Cs_2K(H_2O)_7Pd_2WO(H_2O)(A\text{-}\alpha\text{-}SiW_9O_{34})_2]^{9-}$ ($Pd_2Si_2W_{19}$) which our group reported very recently.[29] This species is composed of two (A-α-SiW_9O_{34}) Keggin moieties linked by a $WO(H_2O)$ group and two equivalent, square-planar Pd^{2+} ions, leading to a sandwich-type structure with C_{2v} symmetry. In $Pd_2Si_2W_{19}$, the central tungsten atom has the terminal oxo group in the *external* position, and the *trans*-related water molecule is pointing towards the inside of the central polyanion cavity. This observation allows for the conclusion that the two lone pairs of electrons associated with the As^{III} heteroatoms in **1** and **2** exhibit steric and electronic constraints which do not allow the existence of a long, *internal* $W–OH_2$ bond.

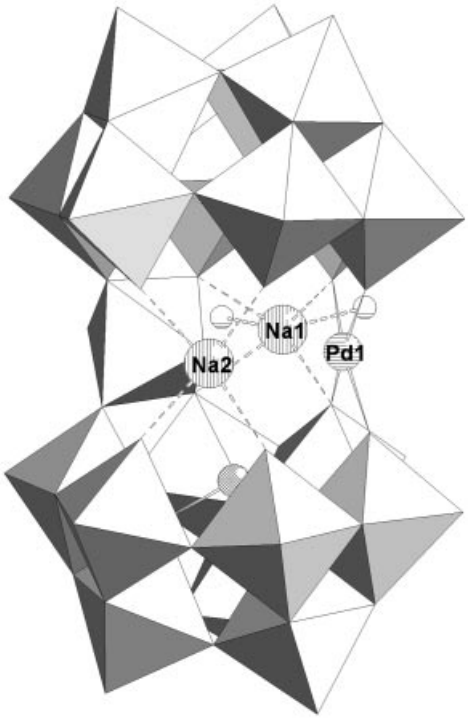

Figure 2. Combined polyhedral/ball and stick representation of **1**. The polyhedra represent WO_6 and the shading of the balls is as follows: arsenic (cross-hatched) and oxygen (white).

We also report on the tripalladium(II)-substituted, dimeric tungstoarsenate(III) $[Cs_2Na(H_2O)_8Pd_3(\alpha\text{-}AsW_9O_{33})_2]^{9-}$ (**2**), which has been synthesized by reaction of $PdCl_2$ with $Na_9[\alpha\text{-}AsW_9O_{33}]$ in aqueous acidic medium and isolated as a mixed cesium–sodium salt. Polyanion **2** is composed of two ($\alpha\text{-}AsW_9O_{33}$) units linked by three square-planar Pd^{2+} ions (see Figure 3). Therefore, **2** represents the arsenic(III) analog of $[Cs_2Na(H_2O)_{10}Pd_3(\alpha\text{-}SbW_9O_{33})_2]^{9-}$ ($Pd_3Sb_2W_{18}$), which we reported very recently.[28] Both of these tripalladium-substituted, sandwich-type species exhibit the same kind of bonding of the palladium atoms to the two Keggin fragments. Specifically, each palladium atom is bound to two oxo groups of the same W_3O_{13} triad of each Keggin unit. Interestingly, this is very different from the structurally related 3d transition-metal derivatives $[(M(H_2O)_3(\alpha\text{-}AsW_9O_{33})_2]^{9-}$ (M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+}).[13] The latter exhibit transition-metal centers which are bound by two oxo groups of two different W_3O_{13} triads of each Keggin unit. We believe that the difference in the coordination geometry of the incorporated transition-metal center (square-planar for Pd^{II} versus square pyramidal for Cu^{II} or Zn^{II}) determines which bonding mode is preferred. It must be re-emphasized that this conclusion applies to tungstoarsenates(III). Interestingly, Krebs et al. observed a "non-eclipsed" bonding mode of the three palladium centers in $[Pd_3(TeW_9O_{33})_2]^{10-}$, which indicates that the type of heteroatom may also influence the bonding mode of the palladium ions to the two Keggin caps.[6]

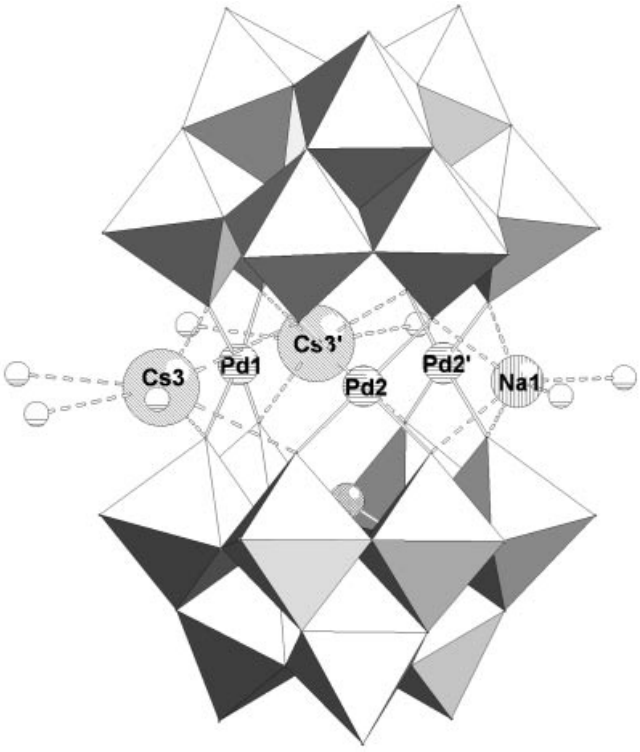

Figure 3. Combined polyhedral/ball and stick representation of $[Cs_2Na(H_2O)_8Pd_3(\alpha\text{-}AsW_9O_{33})_2]^{9-}$ (**2**) showing labels for the heavy atoms in the central belt. The polyhedra represent WO_6 and the shading of the remaining atoms is as follows: arsenic (cross-hatched) and oxygen (white).

The central belt of **2** is completed by two Cs^+ and a Na^+ ion, which occupy the vacancies between the adjacent palladium centers, resulting in a polyanion with idealized C_{2v} symmetry (see Figure 3). The two symmetry-equivalent cesium ions Cs3 and Cs3′ are coordinated to four oxo groups of **2** [Cs···O 3.065–3.168(13) Å] and three oxo groups of a neighboring polyanion [Cs···O 3.069–3.245(13) Å]. As expected, the sodium ion Na1 is six-coordinate and is bonded by four bridging oxo groups [Na1···O 2.448–2.449(16) Å] of **2** and two terminal water molecules [Na1···O 2.40(3) Å], resulting in an octahedral coordination sphere.

The synthetic procedure for **2** is very similar to that of $Pd_3Sb_2W_{18}$, which was prepared by interaction of $Pd(CH_3COO)_2$ with $Na_9[\alpha\text{-}SbW_9O_{33}]$.[28] Polyanion **2** was synthesized in good yield in a simple one-pot procedure by interaction of $PdCl_2$ with $Na_9[\alpha\text{-}AsW_9O_{33}]$ in aqueous acidic medium (pH 4.8). Interestingly, we have not been able to synthesize **2** using $Pd(CH_3COO)_2$ as a palladium source. In fact, reaction of $Pd(CH_3COO)_2$ with $Na_9[\alpha\text{-}AsW_9O_{33}]$ in aqueous acidic medium (pH 4.8) resulted in **1**. As described above, we were eventually able to identify a more rational synthetic procedure for **1** using the dilacunary precursor $[As_2W_{19}O_{67}(H_2O)]^{14-}$ (see also Experimental Section).

Nevertheless, it is somewhat surprising that the two pure, water soluble, commercially available palladium(II) salts $PdCl_2$ and $Pd(CH_3COO)_2$ react differently with the same lacunary polyoxoanion precursor $[\alpha\text{-}AsW_9O_{33}]^{9-}$, resulting in two different products **1** and **2**.

Electrochemistry

The instability of **1** precludes any interesting study of its electrochemical behavior on a well-defined species.

In contrast, **2** will increase the steadily expanding series of the very few Pd-containing heteropolyanions characterized by cyclic voltammetry. With the exception of $K_{12}[WZnPd^{II}_2(H_2O)_2(ZnW_9O_{34})_2]\cdot 38H_2O$, which was studied by Neumann et al.,[25a] and an allusion to the electrochemistry of $K_2Na_6[Pd_2W_{10}O_{36}]\cdot 22H_2O$,[26] only two polyanions $[Cs_2Na(H_2O)_{10}Pd_3(\alpha\text{-}SbW_9O_{33})_2]^{9-}$ ($Pd_3Sb_2W_{18}$)[28] and $[Cs_2K(H_2O)_7Pd_2WO(H_2O)(A\text{-}\alpha\text{-}SiW_9O_{34})_2]^{9-}$ ($Pd_2Si_2W_{19}$)[29] have been characterized to date by cyclic voltammetry. In the latter two examples, cyclic voltammetric studies show deposition of Pd^0 on the glassy carbon electrode surface, giving a film with a particularly well-behaved hydrogen sorption/desorption pattern.

In anticipation of future comparisons, essentially with its Sb-analog $Pd_3Sb_2W_{18}$,[28] polyanion **2** was studied by cyclic voltammetry in 0.4 M (CH_3COO^- + CH_3COOH) pH 5 buffer. Figure 4 shows the pattern observed for a 2×10^{-4} M solution of **2**. For a sequential description of the voltammogram in Figure 4, the potential domain can be divided into two parts. In the domain from –0.1 V to –0.520 V, the first broad cathodic peak observed roughly between –0.300 V and –0.360 V vs. SCE features the Pd^0 deposition process, which is ill-separated from the reduction of the W centers. This behavior is much the same as observed previously for the closely related $Pd_3Sb_2W_{18}$, but differs from that obtained for $PdSO_4$ solutions. With the present complex **2**, the second potential domain starting from –0.1 V to + 1.0 V in the positive potential direction and back to –0.1 V represents unambiguously the oxidation of the deposited Pd surface, followed by the reduction of the oxide. With $PdSO_4$, a broad drawn-out deposition wave was obtained, which is in agreement with the usual observation that the deposition can be performed in a large potential domain.[31] Whatever the Pd-containing compound, the subsequent, sharp cathodic peak with a sharp and narrow anodic counterpart features the hydrogen sorption/desorption processes. It is noteworthy that the film built from **2** shows the same remarkable hydrogen sorption/desorption characteristics obtained previously with $Pd_3Sb_2W_{18}$,[28] thus underscoring the excellent quality of the deposited film, compared with direct deposition from $PdSO_4$.

Typically, the potential cycling program in Figure 4 ensured that the deposition of Pd^0 on the electrode surface was restricted to the potential domain between + 0.2 V and –0.52 V. Alternatively, film deposition can be realized by potentiostatic electrolysis at –0.5 V. The rate at which the film became thicker increases with the more negative value of the potential selected for the cathodic end of the cyclic potential scan or, alternatively, with the more negative value chosen for controlled potential electrolysis. As expected, the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

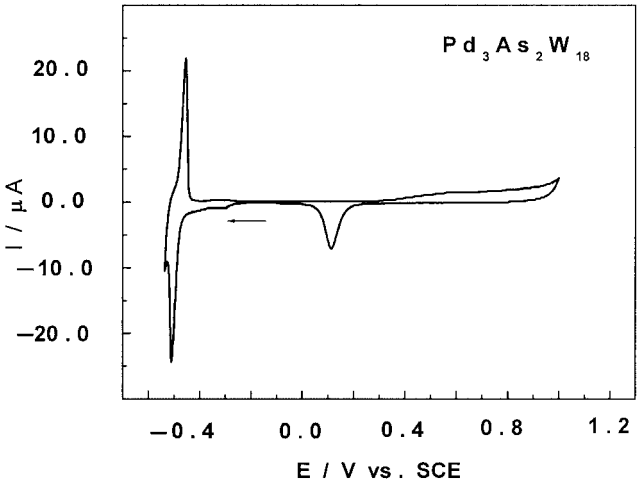

Figure 4. Representative cyclic voltammogram observed upon continuous cycling at a glassy carbon electrode of a 2×10^{-4} M solution of **2** in 0.4 M (CH_3COO^- + CH_3COOH) pH = 5 buffer. The potential variation was between –0.520 V and + 1.0 V. The arrow indicates the direction of the first scan, which starts at –0.1 V. Working electrode: glassy carbon; reference electrode: SCE; scan rate: 2 mV s^{-1}.

thickness increases also with the number of cycles or the duration of potentiostatic electrolysis. These observations parallel the literature results for Pd^0 deposition from ions in solution.[31] The domain starting from –0.1 V to + 1.0 V in the positive potential direction and back to –0.1 V represents unambiguously the oxidation of the deposited Pd surface, followed by reduction of the oxide. This part of the pattern is exactly the same as that obtained previously with $Pd_3Sb_2W_{18}$.[28]

The stability and robustness of the film deposited from **2** was tested in the following way. After deposition of a film on the glassy carbon surface, the electrode was taken out of the solution, copiously rinsed with Millipore water, left for some time in the open air, and then soaked in pure supporting electrolyte (pH = 5). The pattern obtained in Figure 4 is exactly reproduced, except for the broad "first" deposition wave which is missing. This pattern could be cycled several times without observing any changes. This experiment demonstrates the perfect stability of the film. A rough estimate of the film thickness in Figure 4 can be calculated. Typically, the building of the film shown in Figure 4 necessitates 263×10^{-6} C, which corresponds to about 1.3×10^{15} Pd atoms. With an atomic radius of 140 pm for Pd,[32] a monolayer of these atoms would cover an area of 8.1×10^{-5} m^2. With an electrode surface area of 7.07×10^{-6} m^2, the deposited film corresponds to about eleven monolayers.

In short, results gathered from the pertinent literature[31] suggest that Figure 4 features the characteristics of the deposition behavior of Pd^0 on the glassy carbon electrode surface. As a complementary cross-check, we were interested in verifying whether these surfaces display the electrocatalytic behavior that is usually expected for Pd^0 films. The electrocatalytic reduction of dioxygen was studied for this purpose. Figure 5 shows the superposition of the voltammograms obtained with the deposited Pd^0 film in the pure pH 5 electrolyte, and after bubbling air and pure dioxygen, separately, through the solution. It must be noted that no reduction of dioxygen occurred on the glassy carbon surface alone in the potential domain explored.[33] In contrast, a very efficient reduction of dioxygen was observed on the Pd^0-modified surface as can be inferred from the relatively positive potential location of the process. The catalytic process was efficient enough for the voltammograms to be polarogram-shaped. Furthermore, the plateau currents scale up roughly with the concentration of dioxygen in solution. Typically, a thin Pd^0 film comprising roughly six monolayers was used for the experiments shown in Figure 5. Actually, several film thicknesses were used, and a very efficient dioxygen reduction process was observed no matter what the film thickness. Finally, prolonged cycling of these electrodes in the presence of dioxygen did not induce any deactivation of the surfaces.

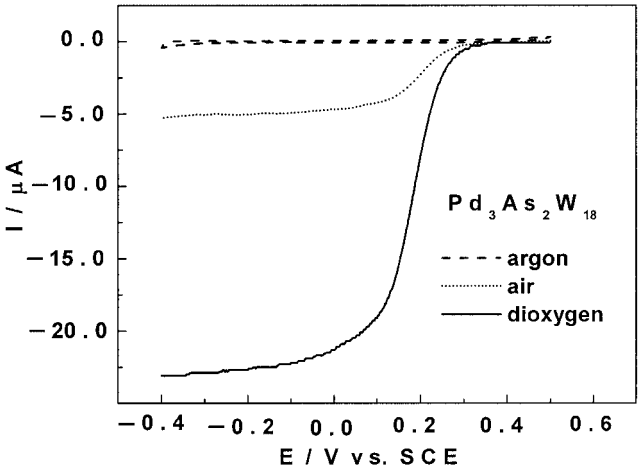

Figure 5. Cyclic voltammetry characterization, in 0.4 M (CH_3COO^- + CH_3COOH) pH = 5 buffer, of the electrocatalytic reduction of dioxygen on a thin film of Pd^0 (6 monolayers) deposited by **2** on a glassy carbon electrode; reference electrode: SCE; scan rate: 2 mV s^{-1}. The polarogram-shaped cyclic voltammograms were obtained with the Pd^0 film in pure supporting electrolyte deaerated with argon after air and pure dioxygen were bubbled, separately, through the solution.

Conclusions

We have synthesized the novel monopalladium(II)-substituted $[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]^{10-}$ (**1**) and the tripalladium(II)-substituted $[Cs_2Na(H_2O)_8Pd_3(\alpha\text{-}AsW_9O_{33})_2]^{9-}$ (**2**). These polyanions represent the first examples of structurally characterized palladium(II)-substituted tungstoarsenates(III). Both **1** and **2** were prepared in simple, one-pot procedures by reaction of Pd^{2+} ions with $[As_2W_{19}O_{67}(H_2O)]^{14-}$ and $[\alpha\text{-}AsW_9O_{33}]^{9-}$, respectively, in aqueous acidic medium (pH 4.8). Polyanion **2** represents the arsenic(III) analog of $[Cs_2Na(H_2O)_{10}Pd_3(\alpha\text{-}SbW_9O_{33})_2]^{9-}$ ($Pd_3Sb_2W_{18}$), and it is also stable in a large pH domain (pH 0–5). Polyanion **1** is much less stable in solution, which can be rationally explained by structural considerations. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

backbone of **1** is composed of two $[\alpha\text{-}AsW_9O_{33}]^{9-}$ fragments connected by a $WO(H_2O)^{4+}$ unit, which represents the well-known $[As_2W_{19}O_{67}(H_2O)]^{14-}$ fragment. However, **1** has only one palladium(II) center incorporated rather than the expected two, and furthermore, this polyanion exhibits an additional, highly unusual feature: the third addenda atom position in the central belt of **1** is occupied by a sodium ion. This is completely unprecedented for this structural subclass of polyanions and probably explains the low stability of **1** in solution. In fact, polyanion **1** could be considered as a monolacunary species, and it also appears like an intermediate in the formation of the hypothetical dipalladium(II)-substituted $[Pd_2WO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]^{10-}$, which we have not been able to isolate to date. Furthermore, our synthetic work in this direction is aimed at the synthesis of the antimony(III) analog of **1** with the suggested formula $[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}SbW_9O_{33})_2]^{10-}$and of the dipalladium tungstoantimonate(III) $[Pd_2WO(H_2O)(\alpha\text{-}SbW_9O_{33})_2]^{10-}$.

Both polyanions **1** and **2** were electrochemically investigated, but the low stability of **1** in the aqueous solutions tested in this work precluded a reliable study. On the other hand, cyclic voltammetry of **2** in a pH 5 medium resulted in the deposition of a Pd^0 film on the glassy carbon electrode surface. The voltammogram showed a particularly sharp hydrogen sorption/desorption as observed previously with the closely related $Pd_3Sb_2W_{18}$. The glassy carbon surface modified by deposition of Pd^0 from **2** proved to be stable and remarkably efficient for the electrocatalytic reduction of dioxygen, at least in the pH 5 medium used here.

Experimental Section

Synthesis

The polyanion precursors $Na_9[\alpha\text{-}AsW_9O_{33}]$ and $K_{14}[As_2W_{19}O_{67}(H_2O)]$ were synthesized according to the published procedures.[8a,11] The identity of the products was confirmed by infrared spectroscopy. All other reagents were used as purchased without further purification.

$Cs_3Na_7[Na_2(H_2O)_2PdWO(H_2O)(\alpha\text{-}AsW_9O_{33})_2]\cdot 1.5NaCl\cdot 22H_2O$ (1a): A sample of $PdCl_2$ (0.040 g, 0.23 mmol) was dissolved in NaAc buffer (20 mL of 0.5 M solution, pH 4.8) while stirring. $K_{14}[As_2W_{19}O_{67}(H_2O)]$ (0.50 g, 0.095 mmol) was then added. The solution was heated to 80 °C for about 1 h and filtered after it had cooled, and then CsCl (0.5 mL of 1.0 M solution) was added to the red filtrate. Slow evaporation at room temperature led to 0.34 g (yield 60%) of a red crystalline product after about two weeks. IR: 944 (m), 893 (s), 796 (s), 746 (vs), 608 (w), 503 (w), 462 (w), 435 (w) cm^{-1}. **1a**: calcd. As 2.5, Cl 0.9, Cs 6.7, Na 4.1, Pd 1.8, W 58.6; found As 2.3, Cl 0.6, Cs 6.7, Na 3.8, Pd 1.5, W 57.7.

$Cs_3Na_6[Cs_2Na(H_2O)_8Pd_3(\alpha\text{-}AsW_9O_{33})_2]\cdot NaCl\cdot 15H_2O$ (2a): A sample of $PdCl_2$ (0.06 g, 0.34 mmol) was dissolved in NaAc buffer (20 mL of 0.5 M solution, pH 4.8) while stirring. $Na_9[\alpha\text{-}AsW_9O_{33}]$ (0.50 g, 0.20 mmol) was then added. The solution was heated to 80 °C for about 1 h and filtered after it had cooled, and then CsCl (0.5 mL of 1.0 M solution) was added to the red filtrate. Slow evaporation at room temperature led to 0.30 g (yield 49%) of a brown crystalline product after about two weeks. IR: 955 (sh), 938 (m), 897 (m), 860 (sh), 782 (vs), 730 (m), 685 (m), 516 (w), 483 (w), 448 (w) cm^{-1}. **2a**: calcd. As 2.4, Cl 0.6, Cs 10.8, Na 3.0, Pd 5.2, W 54.0; found As 2.5, Cl 0.5, Cs 10.4, Na 2.8, Pd 4.7, W 54.9.

All elemental analyses were performed by Kanti Labs Ltd. in Mississauga, Canada. The IR spectra were recorded with a Nicolet Avatar FTIR spectrophotometer in KBr pellets.

X-ray Crystallography

A crystal of **1a** was mounted on a glass fiber for indexing and to collect intensity data at 200 K on a Bruker D8 SMART APEX CCD single-crystal diffractometer using Mo-K_α radiation (λ = 0.71073 Å). Direct methods were used to solve the structure and to locate the heavy atoms (SHELXS97). The remaining atoms were then found from successive difference maps (SHELXL97). The final cycle of refinement, including the atomic coordinates, anisotropic thermal parameters (all W, Pd, Cs, Na, As, Cl atoms) and isotropic thermal parameters (all O atoms) converged at $R = 0.102$ and $R_w = 0.230$ [$I > 2\sigma(I)$]. No hydrogen atoms were included in the refinement. In the final difference map, the deepest hole was –10.945 e Å^{-3} and the highest peak 9.592 e Å^{-3}. The residual electron density is located exclusively near the tungsten atoms. Routine Lorentz and polarization corrections were applied and an absorption correction was performed using the SADABS program.[34]

A crystal of compound **2a** was mounted on a glass fiber for indexing and to collect intensity data at 150 K on a Rigaku Saturn 70 CCD single-crystal diffractometer using Mo-K_α radiation (λ = 0.71070 Å). Direct methods were used to solve the structure and to locate the heavy atoms (SHELXS97). The remaining atoms were then found from successive difference maps (SHELXL97). The final cycle of refinement, including the atomic coordinates, anisotropic thermal parameters (all W, Pd, Cs, Na, As, Cl atoms) and isotropic thermal parameters (all O atoms) converged at $R = 0.080$ and $R_w = 0.216$ [$I > 2\sigma(I)$]. No hydrogen atoms were included in the refinement. In the final difference map, the deepest hole was –7.319 e Å^{-3} and the highest peak 5.813 e Å^{-3}. Routine Lorentz and polarization corrections were applied and an absorption correction was performed using the MULTISCAN program.[35] Crystallographic data for **1a** and **2a** are summarized in Table 1.

Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-415125 (**1a**) and CSD-415128 (**2a**).

Electrochemistry

General Methods and Materials: Pure water was used throughout. It was obtained by passing through a RiOs 8 unit followed by a Millipore-Q Academic purification set. All reagents were of high-purity grade and were used as purchased without further purification. The UV/Visible spectra were recorded on a Perkin–Elmer Lambda 19 spectrophotometer with 2×10^{-5} M solutions of the relevant polyanion. Matched 1.000 cm optical path quartz cuvettes were used. The compositions of the various media were as follows: for pH 0: HCl or H_2SO_4; for pH 1 to 3: 0.2 M Na_2SO_4 + H_2SO_4; for pH 4 and 5: 0.4 M CH_3COONa + CH_3COOH; for pH 6 and 7: 0.4 M NaH_2PO_4 + NaOH.

Electrochemical Experiments: The same media as those used for UV/Visible spectroscopy were used for the electrochemical investigation, but the polyanion concentration was 2×10^{-4} M. The solutions were deaerated thoroughly for at least 30 min with pure argon and kept under a positive pressure of this gas during the experiments. All cyclic voltammograms were recorded at a scan rate of 2 mV s^{-1}, unless otherwise stated. The source, mounting, and polishing of the glassy carbon (GC, Tokai, Japan) electrodes has been

described before.[36] The glassy carbon samples had a diameter of 3 mm. The electrochemical set-up was an EG & G 273 A driven by a PC with the M270 software. Potentials are quoted against a saturated calomel electrode (SCE). The counter electrode was platinum gauze with a large surface area. All experiments were performed at room temperature.

Stability Studies: We tried to identify conditions at which polyanions **1** and **2** were stable enough to allow for electrochemical studies. For this purpose, the UV/Vis spectrum of each compound was monitored as a function of pH over a period of at least 24 h at room temperature. This delay was selected as a compromise between the time needed for electrochemical characterization of the complexes and that for eventual long-lasting or preparative-scale catalytic or electrocatalytic processes. Only spectra reproducible with respect to shape, absorbance, and wavelength location over this period of time were considered to indicate complete stability. At these conditions, **2** shows complete stability from pH 0 through to 5. It is interesting to compare this stability domain to that of the closely related polyanion $Pd_3Sb_2W_{18}$, which is stable from pH 0 to 7.[28] Provisionally, this difference might be attributed to the different heteroatoms Sb versus As. A complementary cross-check of these suggested stabilities was obtained by electrochemical experiments: the complete voltammetric study for each pH value lasts, typically, between 8 and 10 h. Perfect reproducibility of the voltammogram obtained for a selected potential scan rate was observed and taken as a complementary criterion of stability. In contrast to the behavior of **2**, no satisfactory stability domain could be determined for **1** in aqueous solution, despite efforts to modify the composition of the supporting electrolytes.

Interplay between Nitrones and (Nitrile)Pd^{II} Complexes: Cycloaddition vs. Complexation Followed by Cyclopalladation and Deoxygenation Reactions

Nadezhda A. Bokach,[a,b] Artem A. Krokhin,[b,c] Alexey A. Nazarov,[c] Vadim Yu. Kukushkin*[b] Matti Haukka,[d] João J. R. Fraústo da Silva,[a] and Armando J. L. Pombeiro*[a]

Keywords: Palladium / Nitrone complexes / Nitrile complexes / 1,3-Dipolar cycloaddition / Cyclometalation

The reaction between the nitrone *p*-MeC$_6$H$_4$CH=N(Me)O and *trans*-[PdCl$_2$(RCN)$_2$] (R = Ph, Me) in the corresponding RCN (or of the nitrone in neat RCN in the presence of PdCl$_2$) proceeds at 45 °C (R = Ph) or reflux (R = Me) for 1 d and allows the isolation of the Δ^4-1,2,4-oxadiazoline complexes [PdCl$_2$\{N^a=C(R)ON(Me)C^{b}H(C$_6$H$_4$Me-*p*)\}$_2$(N^a–C^b)] (R = Ph **1**; R = Me **2**) in ca. 50 and ca. 15 % yields, respectively. The reaction time can be drastically reduced by focused microwave irradiation of the reaction mixture. In CH$_2$Cl$_2$ or acetone, this reaction proceeds in another direction to achieve the unstable nitrone complex [PdCl$_2$\{ON(Me)=CH(C$_6$H$_4$Me-*p*)\}$_2$] (**3**), which was characterized by electrospray mass spectrometry, IR and ^{1}H NMR spectroscopy. Complex **3** is the first representative of (nitrone)Pd^{II} compounds and is the key intermediate in at least two further reactions, i.e. cyclopalladation to give the dimeric complex [Pd$_2$(μ-Cl)$_2$\{ON(Me)=C(H)C$_6$H$_3$Me-*p*\}$_2$] (**5**; 30 % isolated yield) and deoxygenation of the nitrone to furnish the imine compound [PdCl$_2$\{N(Me)=CH(C$_6$H$_4$Me-*p*)\}$_2$] (**4**). The palladium complexes **1**, **2**, **4** and **5** were characterized by C, H, and N analyses, FAB-MS, IR, ^{1}H and ^{13}C\{^{1}H\} spectroscopy, while **4** and **5** additionally by X-ray crystallography.

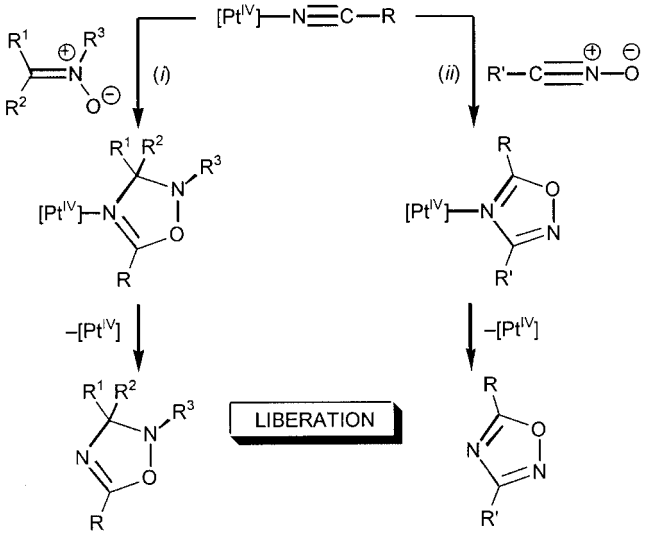
Introduction

In organic chemistry, 1,3-dipolar cycloadditions are reactions of paramount importance for the synthesis of a great variety of heterocycles.[1–5] One of the most promising subdirections of research in this area includes metal control of the interplay between various dipolarophiles and dipoles. Indeed, metal-mediated cycloadditions have been the object of extensive investigations in the past decade and substantial progress has been achieved in both stoichiometric and catalytic approaches.[5–8] In the overwhelming majority of these works, *alkenes* have been employed as dipolarophiles, whereas application of *organonitriles* for these purposes was investigated to an incomparably lesser degree.[6,7] Recently we found that significant activation of nitriles−even typically unreactive ones bearing an electron-donor R group in RCN−toward cycloadditions of both allyl anion (i.e., nitrones,[8–11] route *i* in Scheme 1) and propargyl/allenyl anion type (i.e., nitrile oxide,[12,13] route *ii*) dipoles[1,2] can be reached by their ligation to a Pt^{IV} center, while Pt^{II} displays little effect[10] on the reaction. Subsequent liberation of the ligands allowed the metal-mediated synthesis of these two classes of heterocycles.



Scheme 1.

As a continuation of our project on reactions of metal-activated nitriles in general[6,14] and 1,3-cycloadditions[8–13] in particular, we have chosen (nitrile)Pd^{II} complexes as di-

polarophiles and observed a palladium-mediated [2 + 3] cycloaddition of a nitrone to achieve (Δ^4-1,2,4-oxadiazoline)-Pd^{II} complexes. A recent brief report[15] on the occurrence of this type of reaction for the benzonitrile complex [$PdCl_2(PhCN)_2$], including an indication that the analogous acetonitrile compound is unreactive, prompted us to display our own results in this field. In contrast to that work, we have observed not only that the [2 + 3] cycloaddition proceeds for [$PdCl_2(MeCN)_2$] but also that other types of reactions, i.e. cyclopalladation and nitrone deoxygenation, take place in these systems. The occurrence of the latter two processes, which were not previously observed in the chemistry of nitrones, explains the lack of selectivity of the cycloaddition and provides further insight into understanding the effect of the metal center upon the cycloaddition.

Results and Discussions

We chose to study the reaction of palladium(II) complexes *trans*-[$PdCl_2(RCN)_2$], bearing nitriles with acceptor (R = Ph) and donor (R = Me) substituents, with a stable nitrone, *p*-$MeC_6H_4CH{=}N(Me)O$, as the dipole/ligand.

Palladium(II)-Mediated 1,3-Dipolar Cycloaddition

The reaction between the nitrone *p*-$MeC_6H_4CH{=}N(Me)O$ and PhCN mediated by a Pd^{II} center was performed by two similar, although technically distinct, routes (Scheme 2, routes **A** and **B**).

In the first route (**A**), both $PdCl_2$ and the nitrone *p*-$MeC_6H_4CH{=}N(Me)O$ were reacted in a suspension of neat PhCN, while in the second route (**B**) the nitrile complex *trans*-[$PdCl_2(PhCN)_2$],[16] dissolved in the corresponding nitrile, was treated with the nitrone. In both routes, the reaction proceeds at 45 °C for 1 d (or for 4 h under 20 W microwave irradiation) and the isolated yield of the Δ^4-1,2,4-oxadiazoline complex [$PdCl_2\{N^a{=}C(Ph)ON(Me)C^bH(C_6H_4\text{-}Me\text{-}p)\}_2(N^a\text{–}C^b)$] (**1**), prepared by the two methods, is almost the same (ca. 50%) irrespective of whether conventional or microwave conditions are applied.

The reaction of $PdCl_2$ with neat PhCN is well known and it constitutes a method for the preparation of *trans*-[$PdCl_2(PhCN)_2$].[16] Hence, it is not surprising that the reaction rates and the isolated yields are similar for both routes, because the first route conceivably includes the formation of [$PdCl_2(PhCN)_2$] (upon dissolution of $PdCl_2$ in PhCN) followed by the cycloaddition of the nitrone. Despite the similarity of the synthetic approaches **A** and **B**, the obvious advantage of the former method is that it allows us to obtain complex **1** starting directly from $PdCl_2$ and omitting the unnecessary step of the isolation of *trans*-[$PdCl_2(PhCN)_2$].

The complex **1** gave satisfactory microanalysis for the PhCN solvate and the expected fragmentation/isotopic pattern in FAB-MS$^+$ ([M – Cl]$^+$ and [M – 2 HCl]$^+$). In the IR spectrum, the complex exhibits a strong band at 1649 cm^{-1} from ν(C=N) of the heterocycle and 2231 cm^{-1} from ν(C≡N) of the solvate. In the ^{1}H NMR spectrum, the Δ^4-1,2,4-oxadiazoline ring displays signals in the aromatic range from 8.62 to 7.32 ppm, two Me groups appear at 2.90 and 2.43, and the C*H* signal emerges at δ = 5.82 ppm. Excess of Ph's from the solvated PhCN were detected in the spectrum by integration. All our data agree well with the previously reported formulation.[15] In addition, we performed an X-ray analysis of **1** and it is indicated that the *R*,*R*- and *S*,*S*-Δ^4-1,2,4-oxadiazoline ligands are in the mutu-

ally *trans*-positions (see Figure 1 and deposited data). Unfortunately, the rather poor quality of crystals precluded a detailed comparison of the geometrical parameters.

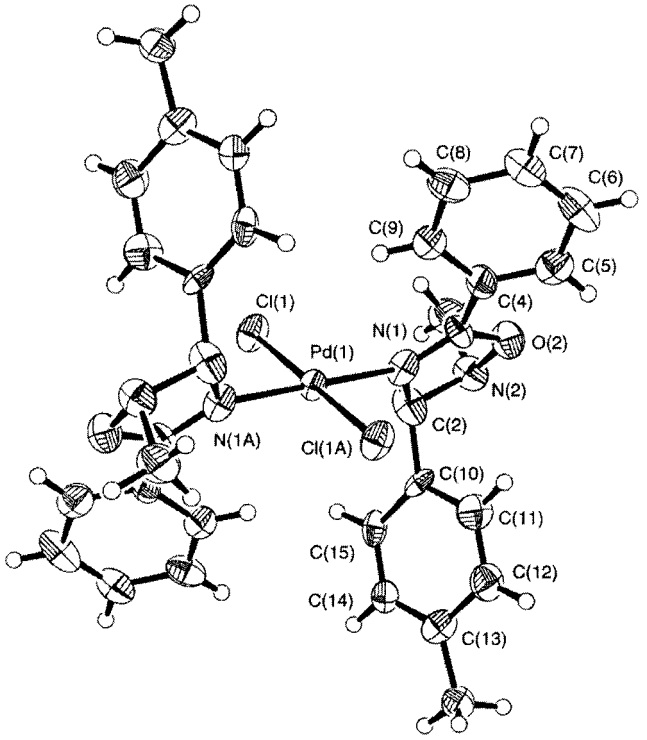

Figure 1. ORTEP view of **1**.

Previously, it has been reported that the acetonitrile complex $[PdCl_2(MeCN)_2]$ is unreactive toward the nitrone *p*-$MeC_6H_4CH=N(O)Me$ even under relatively harsh conditions (80 °C, 1 week).[15] In contrast to that report, in our hands, an interplay between the nitrone *p*-$MeC_6H_4CH=N(O)Me$ and $[PdCl_2(MeCN)_2]$ (or with $PdCl_2$) in MeCN (Scheme 2, **A** and **B**) upon reflux for 1 d (or, 20 min at ca. 80 °C under 70 W microwave irradiation) results in the formation of a broad mixture of products, where the complex **2**, derived from the 1,3-dipolar cycloaddition is formed in 10–15% ^{1}H NMR yield [integration is based on the C*H*(R) proton of the ring which usually emerges in a very specific region from 5.0 to 6.0 ppm]. The complex $[PdCl_2\{N^a=C(Me)ON(Me)C^bH(C_6H_4Me\text{-}p)\}_2$-$(N^a–C^b)]$ (**2**) was isolated as a solid and characterized as the bis-hydrate (see Exp. Sect.). Microwave irradiation of the reaction mixture did not improve the selectivity of the cycloaddition but allowed the dramatic reduction of the reaction time.

Coordination of the Nitrone and Subsequent Reactions

In general, dissociation of RCN from (nitrile)Pd^{II} complexes in non-nitrile solutions (vs. nitrile ones), similar to that described for weak electrolytes by the Ostwald dilution law, increases and consequently the amount of ligated RCN decreases thus favouring the substitution via the expected dissociative mechanism. Thus, to increase the fraction of reactions other than the cycloaddition and to understand the lack of selectivity, indicated in the previous section, we studied the reaction between $[PdCl_2(RCN)_2]$ complexes and the nitrone *p*-$MeC_6H_4CH=N(O)Me$ in dichloromethane and acetone. Indeed, in these experiments we did not detect complexes **1** and **2** but the complex $[PdCl_2\{\underline{O}N(Me)=CH(C_6H_4Me\text{-}p)\}_2]$ (**3**) (Scheme 2, route **C**), which originates from the substitution, was isolated. Although **3** is unstable even in the solid state and undergoes further reactions in solutions (see later) we succeeded to characterize this product by electrospray mass spectrometry ($[M - HCl]^+$ and $[M - 2HCl]^+$ ions were observed). In the IR spectrum of **3**, the ν(C=N) stretching vibration is shifted to a higher frequency (by, 14 cm^{-1}), while the ν(N–O) stretch is shifted to a lower frequency (by 10 cm^{-1}) vs. those signals in the free nitrone and these observations favour *O*-coordination of the nitrone to a Pd^{II} center.

Complexes with *O*-bound nitrones as ligands are known although scarce. These species can be formed (*i*) in the direct reaction of a nitrone and a metal complex at various metal centers such as *hard* (U^{VI},[17] Zn^{II},[18,19] Sn^{IV},[20] Ti^{IV},[15,21] Zr^{IV}),[15] *soft* (Au^{I},[22] Au^{III},[22] Ag^{I})[19] and *borderline* (Ni^{II},[23] Cu^{II}, Mn^{II}, Co^{II}, Fe^{II}, Fe^{III},[24,25] and Ru^{II}- and Os^{II}-[26] porphyrines) Lewis acids and (*ii*) in a metal-mediated process, e.g. by reaction of a carbene ligand with nitrosoarenes at an Fe^{II} center[27] or by addition of 2-methyl-2-nitrosopropane to coordinated ethylene[28] at a Pt^{II} center. To the best of our knowledge, the complex **3** is the first representative of a (nitrone)Pd^{II} compound.

We believe that the nitrone complex **3** can be the key intermediate in at least two further reactions, which are observed in this work, i.e. cyclopalladation to give the dimeric complex $[Pd_2(\mu\text{-}Cl)_2\{\underline{O}N(Me)=C(H)C_6H_3Me\text{-}p\}_2]$ **5** (Scheme 2, route **D**) and deoxygenation of the nitrone to furnish the imine compound $[PdCl_2\{N(Me)=CH(C_6H_4Me\text{-}p)\}_2]$ **4** (Scheme 2, route **E**). Thus, **5** is released as crystals (yield is 30%) when the reaction mixture is kept in CH_2Cl_2 for 3 d at room temperature (Figure 2).

The dimer **5** was characterized by X-ray crystallography. Both palladium atoms form a square-planar arrangement with two mutually *trans* cyclometalated nitrones. The deviation of the metallacycle planes Pd(1)C(1)C(7)C(8)N(1)O(1) from the Pd(1)Cl(1)Pd(1A)Cl(1A) plane is 22.36°. The bond lengths Pd–Cl (*trans* to O) [2.3234(6) Å] and Pd–Cl (*trans* to C) [2.4712(6) Å] are normal and agree well with other palladium(II) halogen-bridged complexes.[29] The difference in the Pd–Cl bond lengths *trans* to O or *trans* to C are due to a strong ground state *trans*-influence of C-bonded ligands.[30] The bond length C(8)–N(1) [1.289(3) Å] is a double one[31] and the bond length N(1)–O(1) [1.331(2) Å] has a value that falls in the range of typical N–O bond lengths in *N*-oxides.[31]

The data on stability of nitrone metal complexes are quite limited in the literature and the only relevant information so far reported is for the iron complexes $[Cp(CO)_2Fe\{\underline{O}N(Ar)=CH(Ar')\}]^+$ which are light- and moisture-sensitive and decompose to the imine ArN=CH(Ar′) (by *deoxygenation*; the reducing agent was not verified[27]) and

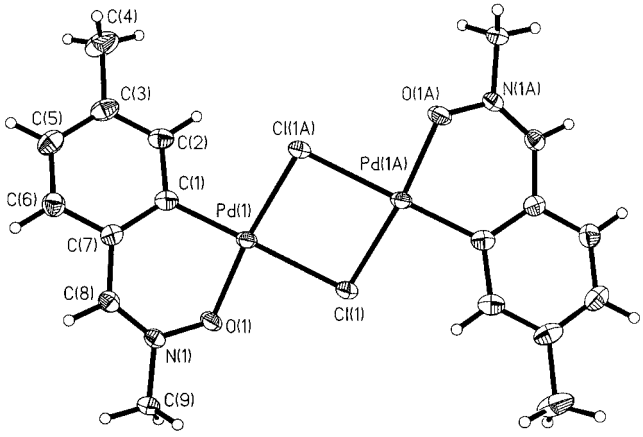

Figure 2. Thermal ellipsoid view of complex **4** with atomic numbering scheme. Thermal ellipsoids are drawn with 50% probability. Selected bond lengths [Å] and angles [°]: Pd(1)–N(1) 2.024(5), Pd(1)–Cl(1) 2.3058(16), N(1)–C(1) 1.250(8), N(1)–C(9) 1.469(8), C(1)–C(2) 1.473(10), N(1)–Pd(1)–Cl(1) 90.53(15), Pd(1)–N(1)–C(1) 126.7(5), Pd(1)–N(1)–C(9) 113.3(4), N(1)–C(1)–C(2) 126.8(6).

to aldehyde O=CH(Ar′) (by *hydration*) along with some unidentified iron-containing products.[27] In accord with this report, we isolated (by mechanical separation of crystals obtained from evaporation of a CH_2Cl_2/Et_2O solution of the residue of the reaction mixture $PdCl_2$–*p*-MeC_6H_4CH=N(O)Me–PhCN) the aldimine compound $[PdCl_2\{N(Me)=CH(C_6H_4Me\text{-}p)\}_2]$ (**4**) (Scheme 2, route **E**; Figure 3) which was characterized by X-ray diffraction study. In complex **4**, the palladium atom is in a square-planar arrangement and two aldimine ligands are mutually *trans*. The value of the C(1)–N(1) [1.250(8) Å] bond length is in the typical double bond range[31] and the Pd–Cl [2.3057(16) Å] bonds are normal.[31]

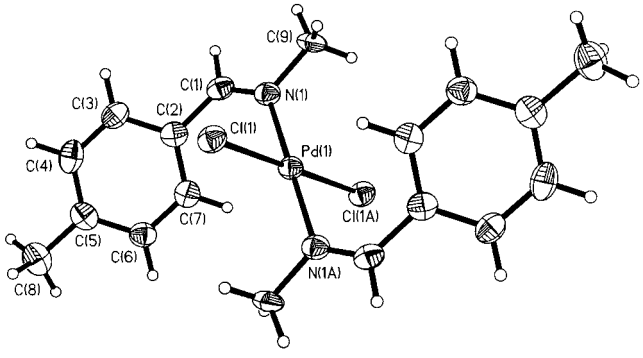

Figure 3. Thermal ellipsoid view of complex **5** with atomic numbering scheme. Thermal ellipsoids are drawn with 50% probability. Selected bond lengths [Å] and angles [°]: Pd(1)–C(1) 1.973(4), Pd(1)–O(1) 1.996(3), Pd(1)–Cl(1) 2.4696(12), N(1)–O(1) 1.333(4), C(1)–Pd(1)–O(1) 92.21(15), C(1)–Pd(1)–Cl(1A) 94.65(13), O(1)–Pd(1)–Cl(1) 87.82(8), Pd(1)–Cl(1)–Pd(1A) 94.73(4).

A possible rationale for the formation of **4** is deoxygenation of the parent nitrone, whereupon the appropriate aldimine MeN=CH(C_6H_4Me-*p*) coordinates to a Pd^{II} center. Indeed, the deoxygenation of nitrones involving metal centers is known and includes $CoCl_2{\cdot}6H_2O$/Sm,[32] $AlCl_3{\cdot}6H_2O$–THF/Zn,[33] $TiCl_4$/NaI,[34] $(CF_3CO)_2O$/NaI[35] reductive systems, or $TiCl_3$.[36] In the first four cases, these systems are believed to involve initial activation of the N–O group of nitrone by an electrophilic reagent followed by the reduction. In the latter case, $TiCl_3$ plays the role of both activator and reducing reagent. Our palladium(II) systems could, in principle, reduce nitrones in a similar way insofar as they contain an activating center, i.e. Pd^{II} (Scheme 2, **C**), and a reducing reagent, e.g. the aldehyde O=(H)-C(C_6H_4Me-*p*), detected in the reaction mixture by NMR method, formed upon metal-mediated hydrolysis of the nitrone.

Final Remarks

The results obtained in this work could be considered from at least two perspectives. From the viewpoint of 1,3-dipolar cycloaddition it is worthwhile to note that (*i*) even the rather electron-deficient nitrile PhCN in the free state does not react with the nitrone (allyl anion type dipole[2]) under the reaction conditions described above. Furthermore, a structurally similar nitrone, i.e. PhCH=N(O)Me, reacts with PhCN under harsh conditions (110 °C, 10 d) giving the corresponding oxadiazoline in 57% yield;[37] (*ii*) in the synthetic experiments we did not observe a significant difference in reactivities toward the cycloaddition between the corresponding palladium(II)- (this work) and platinum(II) (ref.[9]) complexes $[MCl_2(PhCN)_2]$, albeit conditions are not strictly similar (1 d, 40 °C, in PhCN for the Pd^{II} complex and 1 d, 20–25 °C, in CH_2Cl_2 for the Pt^{II} complex). The opposite holds true for the cycloaddition of nitrile oxides (a propargyl/allenyl anion type dipole[2]) to nitriles in $[MCl_2(RCN)_2]$ complexes where the activation of RCN species, toward the cycloaddition, is higher at a Pd^{II} center. A similar trend has been observed by Lippert et al.[38] for nucleophilic addition of water to nitriles ligated to $[M(en)_2]^{2+}$ moieties; the rate of the hydrolysis found for M = Pd^{II} was substantially larger than for M = Pt^{II}. This *difference* in activation between the two metal centers toward nitrile oxides and *similarity* toward nitrones deserves further investigations directed to the understanding of such relative behaviors and the development of a strategy for the metal-mediated 1,3-dipolar cycloaddition.

From the viewpoint of coordination of nitrones, we observed that the more labile Pd^{II} center (vs. the kinetically inert Pt^{II} and Pt^{IV} centers) reacts to a comparable degree with both dipolarophile and dipole and the latter interaction, i.e. ligation of the nitrone to a Pd^{II} center (observed in this work for the first time), inhibits the 1,3-dipolar cycloaddition by coordination of the oxygen atom of the dipole.

In general, the directing of the reaction of nitriles with nitrones to a cycloaddition or a complexation route depends on a delicate balance between donor/acceptor properties of substituents at both dipolarophile and dipole, activating power of the metal center toward cycloaddition and its substitution inertness/lability toward interaction with the reactants. From this perspective the Pd^{II} center occupies an

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

intermediate position between such a substitutionally inert strong RCN activator as a Pt^{IV} center (where only efficient cycloaddition of both nitrones and nitrile oxides[8] was observed) and kinetically labile (nitrile)Ti^{IV} and (nitrile)Zr^{IV} systems (where only displacement of nitriles by nitrones was reported[15]).

Experimental Section

Materials and Instrumentation: Solvents and the nitriles were obtained from commercial sources and used as received. The complexes $[PdCl_2(RCN)_2]$ (R = Me,[39] Ph[16]) and the nitrone[40] were prepared as described previously. Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (NBA) matrices of the samples with 8 keV (ca. $1.28\,10^{15}$ J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Electrospray ionization mass spectra were recorded with a Bruker Esquire 3000 in positive ion mode. Infrared spectra (4000–400 cm^{-1}) were recorded with a JASCO FT/IR-430 instrument in KBr pellets. ^1H and $^{13}C\{^1H\}$ NMR spectra were measured on Bruker DPX 300 and Varian UNITY 300 spectrometers at ambient temperature.

X-ray Crystal Structure Determinations: Crystals were immersed in cryo-oil, mounted in a Nylon loop and measured at a temperature of 100 K or 120 K. The X-ray diffraction data was collected by a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å). The Denzo-Scalepack[41] program package was used for cell refinements and data reduction. The structures were solved by direct methods using the SHELXS-97 or SIR2000 programs.[42,43] A multiscan absorption correction based on equiv. reflections (XPREP in SHELXTL v. 6.14)[44] was applied to all of the data (the $T_{min.}/T_{max.}$ values were 0.7887/0.9215, 0.10130/0.16564, and 0.8169/0.9055 for **1**, **4**, and **5**, respectively). Structural refinements were carried out using SHELXL-97 with the WinGX graphical user interface.[45,46] All of the hydrogens were placed in idealized positions and constrained to ride on their parent atom. The crystallographic data of **4** and **5** are summarized in Table 1. The selected bond lengths and angles of **4** and **5** are shown in Figure captions. The structure solution of **1** is not satisfactory and therefore the crystallographic details are only given as supplementary material (for details see below).

Table 1. Crystallographic data for complexes **4** and **5**.

CCDC-262709 to -262711 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthetic Work and Characterization

Reaction of $PdCl_2$ with *p*-$MeC_6H_4CH=N(O)Me$ in PhCN: Nitrile (0.5 mL) was added to a mixture of $PdCl_2$ (12 mg, 0.068 mmol) and the nitrone *p*-$MeC_6H_4CH=N(O)Me$ (22.4 mg, 0.150 mmol) and the suspension formed left to stand for 1 d at 45 °C. During this time the solid $PdCl_2$ was completely dissolved to give a yellow solution. Then the solvent was removed under vacuum at 50 °C and the oily residue was crystallized under Et_2O (five 2-mL portions) and dried under a stream of nitrogen at room temperature. The reaction can be performed starting from $[PdCl_2(PhCN)_2]$ under the same reaction conditions. The reaction between $PdCl_2$ and *p*-$MeC_6H_4CH=N(O)Me$ in PhCN is complete after 4 h under microwave irradiation (20 W, 50 °C).

$[PdCl_2\{N^a=C(Ph)ON(Me)C^bH(C_6H_4Me\text{-}p)\}_2(N^a–C^b)]$ (1): Yield 50%. $C_{32}H_{32}Cl_2N_4O_2Pd$ (682.0): calcd. C 56.36, H 4.73, N 8.22; found C 58.75, H 5.03, N 8.37%. Calcd. for $C_{32}H_{32}Cl_2N_4O_2Pd\cdot 2/3PhCN$: C 58.68, H 4.74, N 8.71. FAB-MS: *m*/*z* = 647 [M – Cl]$^+$, 609 [M – 2HCl]$^+$. FT-IR (KBr, selected bands): $\tilde{\nu}$ = 1649 (s) ν(C=N) cm^{-1} (ref.[15] 1632 vs. in KBr). ^1H NMR ($CDCl_3$): δ = 8.62 (d, 2 H, *m*-Ar), 7.55 (m, 5 H, Ph), 7.32 (d, 2 H, *o*-Ar), 5.82 (br. s, 1 H, CH), 2.90 (br. s, 3 H, NMe), 2.43 (s, 3 H, *p*-Me) ppm. (ref.[15] 8.68, 7.63, 7.48, 7.40, 7.30, 5.87, 2.95, 2.44 ppm. $CDCl_3$). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 164.74 (C=N), 133.43, 130.46, 129.40, 128.84 and 128.41 (Ph and Ar), 93.76 (CH), 45.75 (NMe), 21.45 (*p*-Me) ppm (ref.[15] 164.3, 139.4, 133.0, 130.4, 129.3, 129.1, 128.7, 128.6, 128.1, 122.5, 93.8, 46.0, 21.5 ppm; $CDCl_3$).

Among other compounds formed in the mixture we succeeded in identifying the aldehyde *p*-$MeC_6H_4C(H)=O$ [^1H NMR ($CDCl_3$): δ = 9.94 (s), 7.76 (d), 7.30 (d), and 2.42 (s)]. In addition, crystals of $[PdCl_2\{N(Me)=CH(C_6H_4Me\text{-}p)\}_2]$ (**4**) suitable for an X-ray study were obtained by slow evaporation of a CH_2Cl_2/Et_2O solution of the residue obtained from the reaction mixture PhCN–$PdCl_2$–*p*-$MeC_6H_4CH=N(O)Me$.

Reaction of $PdCl_2$ (or $[PdCl_2(MeCN)_2]$) and *p*-$MeC_6H_4CH=N(O)Me$ in MeCN: MeCN (5 mL) was added to a mixture of $PdCl_2$ (12.4 mg, 0.07 mmol) (or $[PdCl_2(MeCN)_2]$, 18.1 mg, 0.070 mmol) and *p*-$MeC_6H_4CH=N(O)Me$ (21.0 mg, 0.14 mmol) and it was refluxed on stirring for 1 d, whereupon the solvent was removed in vacuo at room temperature to give a brown powder. ^1H NMR monitoring of the latter shows that the cycloaddition product is formed in 10–15% yield. The powder was treated with two 2-mL portions of Et_2O, the yellow solution was separated from the brown powder by filtration and then the filtrate was evaporated under vacuum at room temperature to give a yellow oily residue that was rapidly washed with cold Et_2O (0.5 mL) and dried again under vacuum at room temperature to give **2**. The reaction can also be performed under focused microwave irradiation (15–20 min, 100 W) and the oxadiazoline complex is formed also in ca. 10–20% yield.

$[PdCl_2\{N^a=C(Me)ON(Me)C^bH(C_6H_4Me\text{-}p)\}_2(N^a–C^b)]\cdot 2H_2O$ (2): Isolated yield is 12%. $C_{22}H_{32}Cl_2N_4O_4Pd$ (557.8): calcd. C 44.50, H 5.43, N 9.43; found C 44.60, H 5.30, N 9.71. FAB-MS: *m*/*z* = 521 [M – HCl]$^+$. FT-IR (KBr, selected bands): $\tilde{\nu}$ = 1650 (s) ν(C=N) cm^{-1}; water of crystallization was observed in the IR spectrum in well-dried KBr (3460 br). ^1H NMR ($CDCl_3$): δ = 7.47 (d, 2 H, *m*-Ar), 7.21 (d, 2 H, *o*-Ar), 5.62 (br. s, 1 H, CH), 2.82 (br. s, 3 H, NMe), 2.45 (s, 3 H, Me), 2.40 (s, 3 H, *p*-Me) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 166.53 (C=N), 139.19 (*p*-), 130.08 (C_{ipso}), 129.26 and

128.14 (*o*- and *m*-), 91.51 (br., CH), 46.09 (NMe), 21.36 (*p*-Me), 13.78 (Me) ppm.

Reaction of $[PdCl_2(MeCN)_2]$ with *p*-$MeC_6H_4CH=N(O)Me$ in CH_2Cl_2 and Acetone: The nitrone *p*-$MeC_6H_4CH=N(O)Me$ (0.21 mmol) was added to a solution of $[PdCl_2(MeCN)_2]$ (26 mg, 0.10 mmol) in CH_2Cl_2 or acetone (1 mL) at room temperature. The reaction mixture became dark orange within several min, then it was allowed to stay for 2–3 h without stirring. A dark-red solution was formed, the solvent was evaporated under a stream of N_2 and the dark residue washed with Et_2O (two 2-mL portions) and dried in air and then under vacuum at room temperature. In the NMR spectrum of the residue, signals that can be attributed to the nitrone complex $[PdCl_2\{\underline{O}N(Me)=C(H)C_6H_4Me\text{-}p\}_2]$ and the corresponding aldehyde *p*-$MeC_6H_4C(H)O$ were detected. No traces of acetamide or acetic acid, corresponding to MeCN, were detected. Satisfactory elemental analyses can not be obtained because of hydrolytic and redox decomposition of the nitrone complex $[PdCl_2\{\underline{O}N(Me)=C(H)C_6H_4Me\text{-}p\}_2]$. If the reaction mixture is left standing at room temperature for 3 d, the solution becomes slightly lighter and orange-yellow crystals of $[Pd_2(\mu\text{-}Cl)_2\{\underline{O}N(Me)=C(H)C_6H_3Me\text{-}p\}_2]$ are released on the top of the flask. The yield of the cyclometalated product **5** is ca. 30%.

$[PdCl_2\{\underline{O}N(Me)=CH(C_6H_4Me\text{-}p)\}_2]$ (3): MS (ESI+): *m*/*z* = 441 [M – Cl], 403 [M – 2Cl – H]. FT-IR (KBr, selected bands): $\tilde{\nu}$ = 3012, 2944 (w) ν(C–H), 1601 (s) ν(C=N), 1159 (*m*-s) ν(N–O) cm^{-1}; in the free nitrone 1587 (s) ν(C=N), 1167 (*m*-s) ν(N–O) cm^{-1}. ^1H NMR ([D$_6$]acetone): δ = 8.20 (d, 7.8 Hz, 2 H, *m*-Ar), 8.08 (s, 1 H, CH), 7.33 (d, 7.8 Hz, 2 H, *o*-Ar), 3.99 (s, 3 H, NMe), 2.39 (s, 3 H, *p*-Me) ppm. Complex **3** was also detected, by ^1H NMR method, in the reaction between the nitrone and $[PdCl_2(PhCN)_2]$.

$[Pd_2(\mu\text{-}Cl)_2\{\underline{O}N(Me)=C(H)C_6H_3Me\text{-}p\}_2]$ (5): $C_{18}H_{20}Cl_2N_2O_2Pd_2$ (580.1): calcd. C 37.27, H 3.48, N 4.83; found C 37.48, H 3.60, N 4.61. FT-IR (KBr, selected bands): $\tilde{\nu}$ = 1628 (m) ν(C=N), 1582 (s) ν(C=C), 1155 (*m*-s) ν(N–O) cm^{-1}; in the free nitrone 1587 (s) ν(C=N), 1167 (*m*-s) ν(N–O) cm^{-1}. The solid complex is insoluble in the most common deuterated solvents and it reacts with [D$_6$]DMSO to give a solution with the following spectrum, i.e. ^1H NMR ([D$_6$]DMSO): δ = 8.39 (s, 1 H, CH); 7.75 (d, *m*-Ar); 7.14 (d, *o*-Ar); 6.97 (s, *m*-Ar); 3.81 (s, 3 H, NMe); 2.21 (s, 3 H, *p*-Me) ppm.

Acknowledgments

This work has been supported by the Fundação para a Ciência e a Tecnologia (FCT), Portugal, and its POCTI program (POCTI/QUI/43415/2001 project) (FEDER funded) and the Russian Fund for Basic Research (grants 03–03–32363 and 05–03–32140). N.A.B. and V.Yu.K. express gratitude to the POCTI program, Portugal for the grant SFRH/BPD/11448/2002 (N.A.B.) and a grant for Cientista Convidado/Professor at the Instituto Superior Técnico (V.Yu.K.). N.A.B., M.H., and V.Yu.K. would like to thank the Academy of Finland for financial support. V.Yu.K. is very much obliged to ISSEP for the Soros Professorship (2001–2004) and the Royal Society of Chemistry for a Grant for International Authors. The authors also thank NATO for the Collaborative Linkage Grant PST.CLG.979289.

Synthesis and Characterization of Heterotrinuclear Complexes of Nickel and Palladium with Pyridinecarboxylate as Bridging Ligands

José Ruiz,*[a] María Dolores Santana,*[a] Abel Lozano,[a] Consuelo Vicente,[a] Gabriel García,[a] Gregorio López,[a] José Pérez,[b] and Luis García[b]

Keywords: Palladium / Nickel / Pyridinecarboxylate / Heterotrinuclear complexes / Mononuclear complexes

Heterotrinuclear pyridinecarboxylate complexes of nickel(II) and palladium(II) of the types [Ni(mcN$_3$)(pyridinecarboxylate)]$_2${μ-[Pd(C$_6$F$_5$)$_2$]}(PF$_6$)$_2$ [mcN$_3$ = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene (Me$_3$-mcN$_3$) or 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene (Me$_4$-mcN$_3$)] have been prepared by two different routes. The corresponding monomeric pyridinecarboxylate complexes of nickel and the monomeric pyridinecarboxylic acid/ester complexes of palladium have also been prepared. The crystal structures of two precursors [Ni(Me$_4$-mcN$_3$)(NC$_5$H$_4$-3-COO)]PF$_6$ and *cis*-[Pd(C$_6$F$_5$)$_2$(NC$_5$H$_4$-4-CH$_2$COOCH$_3$)$_2$] have been established by X-ray diffraction.

Introduction

Pyridinecarboxylate ligands tend to bind metal ions with both, pyridine and carboxylate groups to form extended networks, where the carboxylate groups balance the metal charges.[1–6] The deliberate, stepwise and controlled synthesis of molecular squares and dinuclear macrocycles using pyridinecarboxylates as spacers has been recently reported by Hor et al.[7]

The versatile carboxylate anion can adopt a wide range of bonding modes including monodentate, symmetric and asymmetric chelating and bidentate and monodentate bridging.[8] It is generally agreed that the carboxylate complexes of the 3d elements, including several examples of nickel derivatives, play an important role in biochemistry.[9]

In this paper we report the preparation by two different routes and the spectroscopic behavior of heterotrinuclear pyridinecarboxylate complexes of nickel and palladium in which the two nickel(II) ions are in a pentacoordinate environment. The corresponding monomeric pyridinecarboxylate complexes of nickel and the monomeric pyridinecarboxylic acid/ester complexes of palladium have also been prepared.

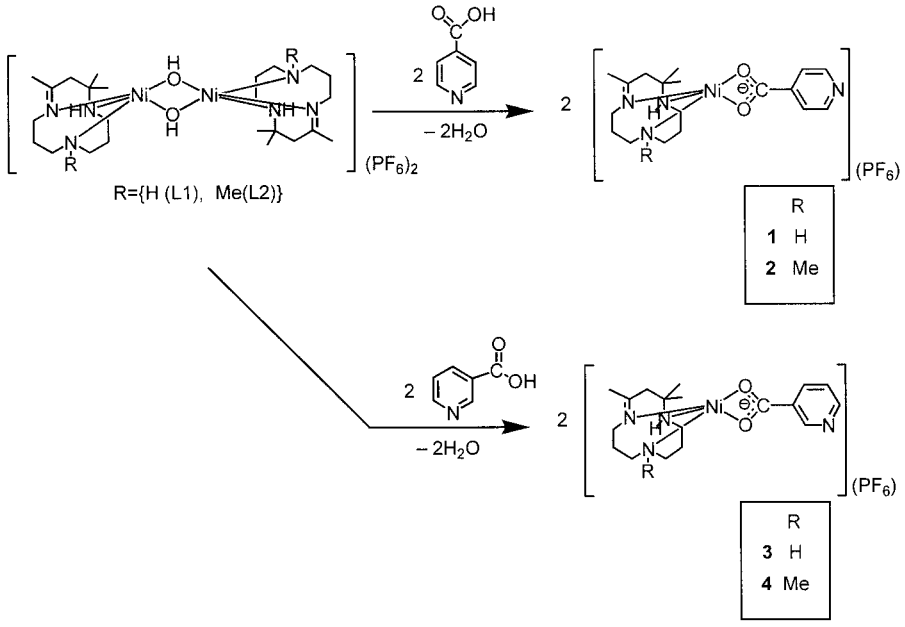
Results and Discussion

Synthesis and Characterization of Monomeric Pyridinecarboxylate Complexes of Nickel(II)

The reaction between [Ni(mcN$_3$)(μ-OH)]$_2$(PF$_6$)$_2$ [mcN$_3$ = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene (Me$_3$-mcN$_3$) or 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene (Me$_4$-mcN$_3$)] and carboxylic acids [HA = isonicotinic (Hisonic) or nicotinic (Hnic) acid] leads to the formation of the carboxylate complexes [Ni(mcN$_3$)(A)](PF$_6$) **1**–**4** shown in Scheme 1.

The acid-base reaction occurs at room temperature in acetone with the concomitant liberation of water. This synthetic method has previously been used for the preparation of pentacoordinate nickel(II) complexes containing N,S-donor,[10] oxamidate,[11] hydroxamate,[12] and pyridonate ligands,[13] as well as phosphate esters and phosphinate derivatives.[14]

Complexes **1**–**4** are air-stable both in the solid state and in solution. They have been characterized by partial elemental analyses, FAB$^+$ mass spectrometry and spectroscopic (IR, UV/Vis, and ^{1}H NMR) methods. The IR spectra of complexes **1**–**4** show characteristic absorptions for the mcN$_3$ ligands:[12,14] 3287–3121 cm^{-1} for $\tilde{\nu}$(N–H), ca. 1660 cm^{-1} for $\tilde{\nu}$(C=N), and two strong bands as a result of the PF$_6^-$ ion at 840 and 560 cm^{-1}. The κ^2-coordination mode in compounds **1**–**4** is revealed by the IR spectra, which contain symmetric OCO stretching bands at ca. 1550 cm^{-1}.[15,16] The κ^2-coordination mode in **4** was authenticated by an X-ray crystal structure determination (vide infra). The electronic spectra of **1**–**4** are quite similar and show two d-d transitions in acetone solution with $\lambda_{max} \approx$



Scheme 1. Monomeric nickel complexes.

63 (ca. 80 $M^{-1}cm^{-1}$) and 390 nm (ca. 200 $M^{-1}cm^{-1}$) which could be assigned to $^3B_1(F) \rightarrow {}^3E(F)$ and $^3B_1(F) \rightarrow {}^3A_2, {}^3E(P)$ transitions, respectively. Both λ_{max} values and molar absorptivities are consistent with a pentacoordinate environment around the nickel(II) center.[17]

NMR Spectroscopic Study of Complexes 1–4

All of the complexes exhibit sharp hyperfine-shifted ^1H NMR signals in acetone solution in the 370 to –35 ppm chemical shift range. The ^1H NMR spectra of complexes **1**–**4** show the resonance line pattern observed for the mcN_3 ligands that was assigned on the basis of previous studies of (macrocycle)nickel complexes[10–14] and from the temperature dependence of the resonances. A representative ^1H NMR spectrum for complex **4** is shown in Figure 1. The α-methylene proton signals shift downfield whereas the β-methylene proton signals shift upfield with regard to the diamagnetic position.[18] Moreover, the signals of the equatorial protons are expected to experience larger contact shifts than those of the axial protons[19] and therefore the most downfield resonances are due to α-CH_{eq} and the most upfield ones to β-CH_{eq}. The isotropically shifted ^1H NMR signals observed for the methyl groups [2-Me, 4-Me(a,b), and 9-Me-N] and phenyl groups of carboxylates can be initially assigned by inspection of their peak areas. All the resonances of the phenyl rings are downfield to TMS in accordance with a dominant σ-delocalization pattern of spin density, consistent with the ground state of nickel(II), although the unpaired electrons could polarize the net spin density in the d_π orbitals. A similar behavior has been observed elsewhere.[20] Curie plots of proton resonances of complex **4** in [D_6]acetone are shown in Figure 2. These plots illustrate the general tendency for the contact shifts to increase more rapidly at lower temperatures and exhibit a temperature dependence closely proportional to T^{-1}.

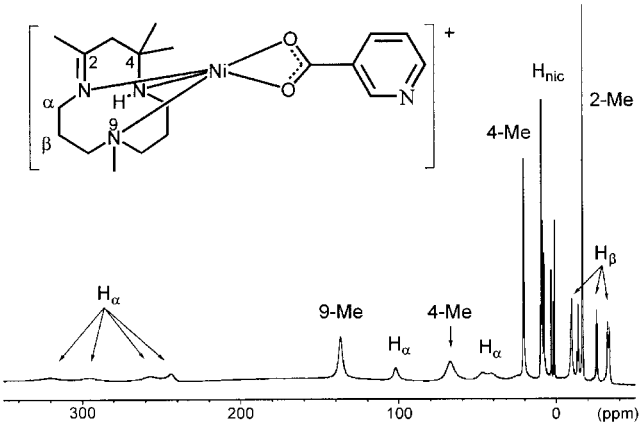


Figure 1. ^1H NMR spectra (in [D_6]acetone solution at room temperature) of complex **4**.

Description of the Crystal Structure of Complex 4

The crystal structure of the cation of complex **4** is shown in Figure 3. Selected geometric data are given in Table 1. In each crystallized cation of complex **4**, the nickel atom is five-coordinate, with a square-pyramid arrangement of the chelating atoms. The Reedijk τ parameter[21] (τ = 0 and 1 for square-pyramidal and trigonal-bipyramidal structures, respectively) shows a value of 0.005. The three nitrogen atoms of the N_3 macrocycle are found at the apical position and two adjacent basal ones, whereas the other two basal positions correspond to the *O,O′*-carboxylate group. The basal plane is formed by N(1), N(2), O(1), and O(2), with an r.m.s. deviation of fitted atoms of 0.0108 Å. The Ni atom is 0.3054(13) Å above the corresponding basal plane towards the apical N(3) atom. The coordinated macrocycle exhibits a chairlike conformation for the two six-membered rings that do not contain the C=N bond. This is the most

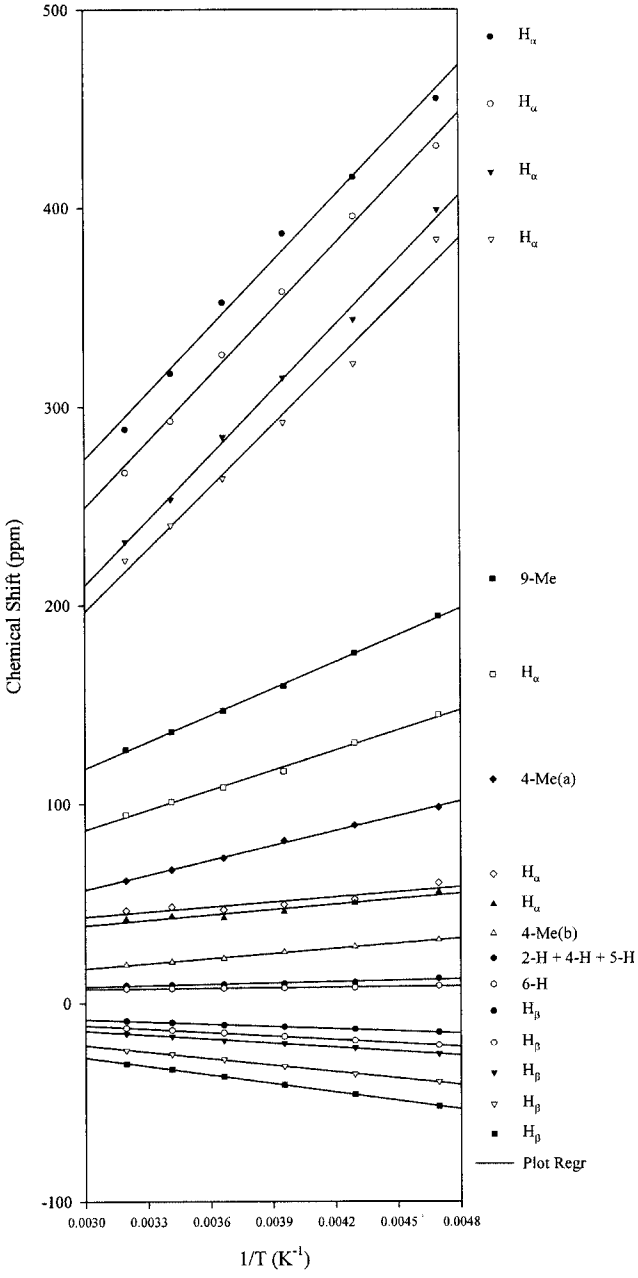

Figure 2. Curie plots of proton resonances of complex **4**.

frequent conformation in complexes having these macrocycles.[13] The Ni–O bond lengths in **4** are close to each other [2.085(2)–2.129(2) Å]. The carboxylate ligands are bonded in a symmetric (or almost) chelating mode with a $\Delta O = \{[Ni–O(2)] – [Ni–O(1)]\}$ value of 0.034 Å. There is a classical intermolecular hydrogen bonding between N(2)–H(2) and N(4) of a neighbor cation generated by ($–x + 2$, $–y + 2$, $–z$) symmetry operation, and a "non-classical" hydrogen bonding between C(16)–H(16) and O(2), generated by the same symmetry operation. The hydrogen bonds of complex **4** are summarised in Table 2 (see Figure 4). These bond lengths are comparable to those reported for other crystallographically characterized nickel carboxylate complexes with a distorted square-pyramidal[22] or octahedral[22–24] geometry. The bite angle of the carboxylate anion shows a value of 62.76(8)°. The torsion angle between the pyridine ring and the nickel-bound carboxylate group is 2.27(8)°. This is the first crystal structure of a pentacoordinate (nicotinato)nickel(II) complex (3D search using the Cambridge Structural Database, CSD version 5.25, July 2004 release).

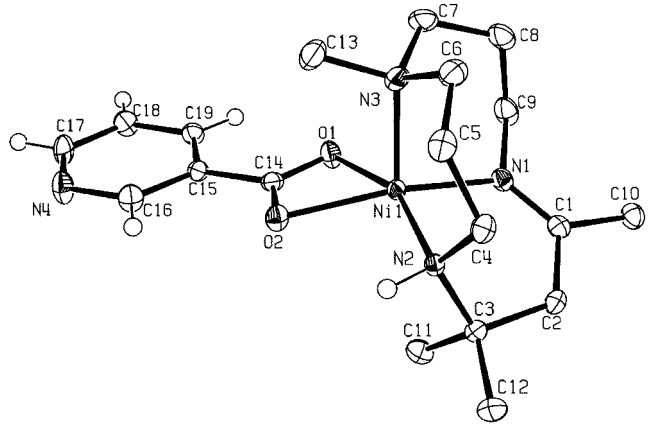

Figure 3. ORTEP drawing of complex **4** showing the atom numbering scheme. Displacement ellipsoids are drawn at the 50% probability level. For clarity hydrogen atoms of the macrocycle are omitted.

Synthesis and Characterization of Monomeric Pyridinecarboxylic Acid/Ester Complexes of Palladium(II)

The labile complex *cis*-$[Pd(C_6F_5)_2(PhCN)_2]$ has been used as starting material for the preparation of several palladium complexes.[25–28] When *cis*-$[Pd(C_6F_5)_2(PhCN)_2]$[29] was treated with the pyridinecarboxylic acids NC_5H_4-4-COOH (isonicotinic), NC_5H_4-3-COOH (nicotinic) or NC_5H_4-4-CH_2COOH (in methanol), complexes **5**–**7** were obtained in high yields (Scheme 2). Complexes **5**–**7** are all white, air-stable solids. Their IR spectra show the characteristic absorptions of the C_6F_5 group ($\tilde{\nu}$ = 1630 m, 1490 vs, 1050 s, 950 vs cm^{-1})[30] and a split band at $\tilde{\nu} \approx 800\ cm^{-1}$ assigned to the *cis*-$Pd(C_6F_5)_2$ moiety.[31,32] The IR spectra of **5** and **6** show the expected strong ν(C=O) band at $\tilde{\nu} \approx 1720\ cm^{-1}$, a frequency that is typical for aromatic carboxylic acids.[33,34] In complex **7** the ν(C=O) band is observed at $\tilde{\nu} = 1744\ cm^{-1}$. The ^{19}F NMR spectra of complexes **5**–**7** show the presence of two equivalent freely rotating C_6F_5 rings giving three resonances with relative intensities of 4:2:4 due to the *ortho*-, *para*-, and *meta*-F atoms, respectively. The ^1H NMR spectrum of complex **7** shows the methoxy resonance of the pyridinecarboxylic ester ligands at δ = 3.66 ppm.

Description of the Crystal Structure of Complex 7

Figure 5 depicts the structure of the neutral palladium complex. Selected bond lengths and angles are given in Table 3. The coordination around Pd is square-planar. The N1, N2, C1, and C7 atoms form a perfect plane with the Pd atom 0.0037(7) Å above this plane. The angle between the two C_6F_5 rings is 90.72(7)° and the angle between the two N-donor ligands is 90.16(5)°. The Pd–N distances lie within the range reported in complexes containing the $\{Pd(C_6F_5)_2N_2\}$ moiety, such as $[Pd(C_6F_5)_2\{NH{=}CMe_2\}_2]$,[25] $[Pd(C_6F_5)_2\{NH{=}C(OMe)Me\}_2]$[35] and $[Pd(C_6F_5)_2(pz\cdots H\cdots pz)]$ (pz = pyrazolate).[27] The Pd–C_6F_5 bond lengths are in the range found in the literature for (pentafluorophenyl)palladium complexes.[36–38] In addition, there are some interconnections by hydrogen bonds involv-

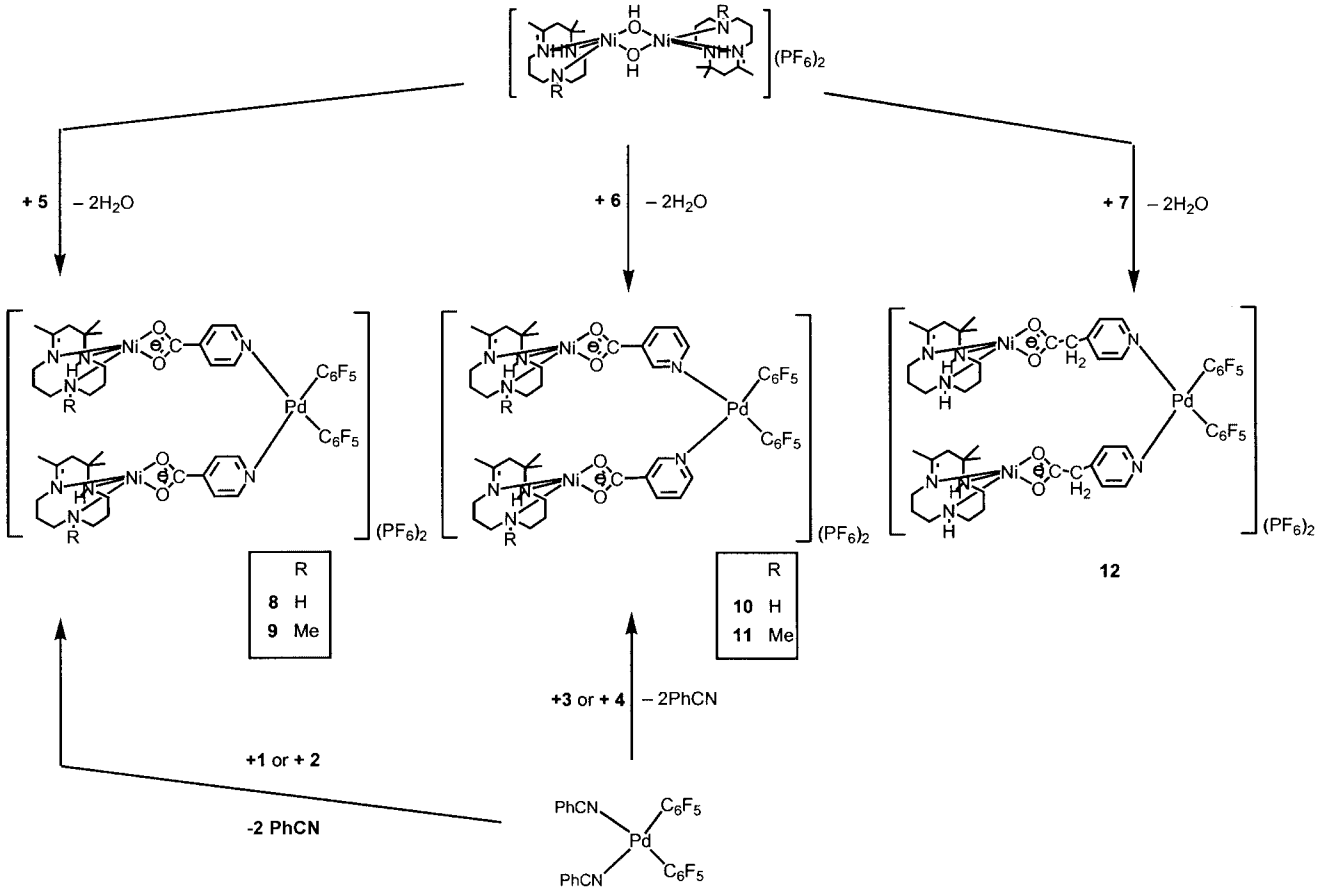
Synthesis and Characterization of Heterotrinuclear Pyridinecarboxylate Complexes of Nickel(II) and Palladium(II)

Heterotrinuclear pyridinecarboxylate complexes of nickel(II) and palladium(II) of the types $[Ni(mcN_3)(pyridinecarboxylate)]_2\{\mu\text{-}[Pd(C_6F_5)_2]\}(PF_6)_2$ (mcN_3 = Me_3-mcN_3 or Me_4-mcN_3) **8**–**12** have been prepared by two different routes (Scheme 3). The first method is based on the reaction of the monomeric pyridinecarboxylate complexes of nickel(II) $[Ni(mcN_3)(A)](PF_6)$ **1**–**4** with the labile complex *cis*-$[Pd(C_6F_5)_2(PhCN)_2]$, which takes place with the concomitant release of PhCN. The second method is based on the treatment of the monomeric pyridinecarboxylic derivatives of palladium(II) **5**–**7** with the hydroxo complex $[Ni(mcN_3)(\mu\text{-}OH)]_2(PF_6)_2$ (mcN_3 = Me_3-mcN_3 or Me_4-mcN_3). Complexes **8**–**12** are air-stable both in the solid state and in solution. They were characterized by partial elemental analyses, FAB^+ mass spectrometry and spectroscopic (IR and ^1H NMR) methods. The IR spectra of complexes **8**–**12** show characteristic absorptions for the mcN_3 ligands,[12,14] the absorption of the pyridinecarboxylate ligands, the characteristic absorptions of the C_6F_5 group[30] and a split band at $\tilde{\nu} \approx 800\ cm^{-1}$ assigned to the *cis*-$Pd(C_6F_5)_2$ moiety.[31,32] Two strong bands as a result of the PF_6^- ion at $\tilde{\nu}$ = 840 and 560 cm^{-1} are also observed.

NMR Study of Complexes 8–12

The ^{19}F NMR spectra of complexes **8**–**12** show the presence of two equivalent freely rotating C_6F_5 rings giving three resonances with relative intensities of 4:2:4 due to the *ortho*-, *para*-, and *meta*-F atoms, respectively. The ^1H NMR spectra of the complexes **8**–**12** also show relatively sharp and well-resolved resonances for the macrocyclic protons as well as the expected resonance line pattern. The magnitudes of these shifts are also similar to those observed for the



Scheme 3. Heterotrinuclear complexes.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corresponding monomeric pyridinecarboxylate derivatives of nickel (**1**–**4**). However, the coordination to the *cis*-$Pd(C_6F_5)_2$ moiety through the nitrogen atom of pyridinecarboxylate disturbs the spin density into the pyridine ring and the shifts of pyridinecarboxylate in heterotrinuclear derivatives are in general larger than in monomeric complexes. The temperature dependence of the shifts of **11** in Figure 6 follows the established pattern, with the shifts moving away from the diamagnetic position and increasing with T^{-1}.

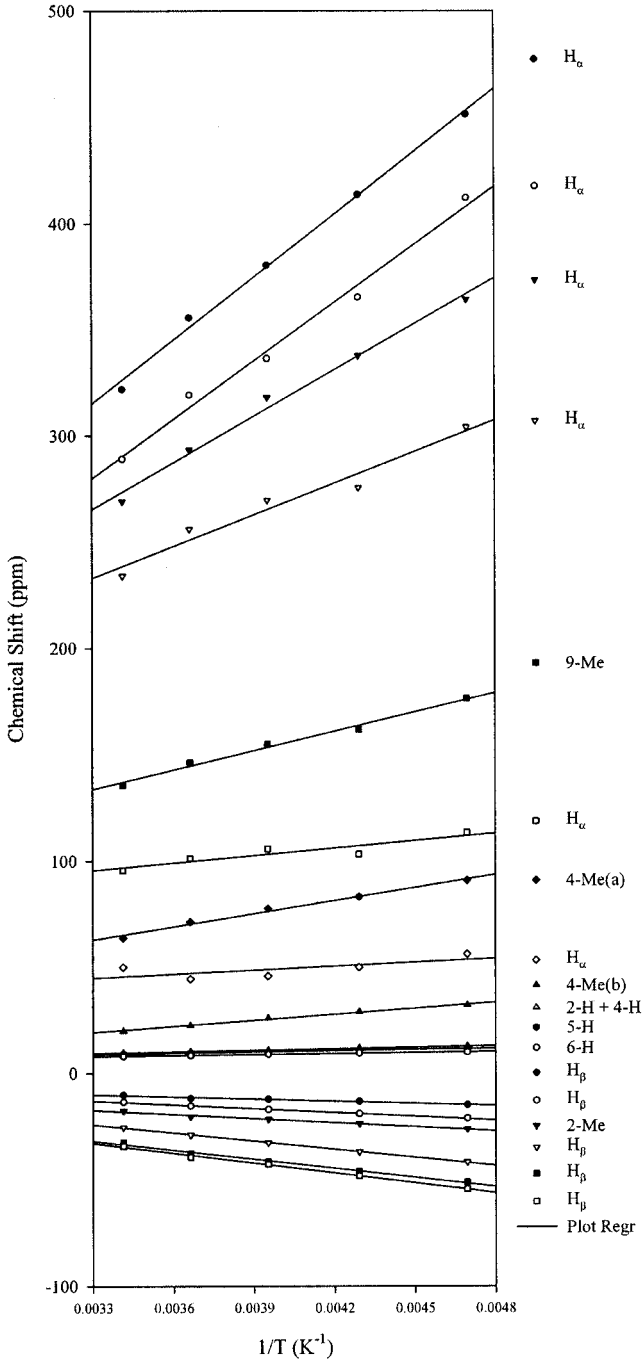


Figure 6. Curie plots of proton resonances of complex **11**.

Experimental Section

General Methods: The C, H, N analyses were performed with a Carlo Erba model EA 1108 microanalyzer. The ^1H and ^{19}F NMR spectra were recorded with a Bruker AC 200E, Bruker AC 300E or Bruker AV-400 spectrometer, using $SiMe_4$ or $CFCl_3$ as standards, respectively. IR spectra were recorded with a Perkin–Elmer 16F PC FT-IR spectrophotometer using Nujol mulls between polyethylene sheets. Fast-atom bombardment (FAB) mass spectra were run with a Fisons VG Autospec spectrometer operating in the FAB^+ mode. The UV/Vis spectra (in acetone) were recorded with a UNICAM 520 spectrophotometer equipped with matched quartz cells in the 300–800 nm range. The chemicals were purchased from Aldrich and were used without further purification. Solvents were dried and distilled by general methods before use. The starting compound $[\{Ni(Me_3\text{-}mcN_3)(\mu\text{-}OH)\}_2](PF_6)_2$ and its 9-methyl derivative,[40,41] as well as *cis*-$[Pd(C_6F_5)_2(PhCN)_2]$[29] were prepared by procedures described elsewhere.

Preparation of Complexes

Complexes 1 and 3: NC_5H_4-4-COOH or NC_5H_4-3-COOH (0.30 mmol) was added to a solution of $[Ni(Me_3\text{-}mcN_3)(\mu\text{-}OH)]_2(PF_6)_2$ (100 mg, 0.15 mmol) in acetone (25 mL). The mixture was stirred overnight at room temperature and the solvent was partially evaporated under reduced pressure. On addition of diethyl ether, the blue-green complexes precipitated and were filtered off, washed with diethyl ether and air-dried. **1:** Yield: 115 mg (92%). $C_{18}H_{29}F_6N_4NiO_2P$ (537): calcd. C 40.25, H 5.44, N 10.43; found C 39.96, H 5.71, N 10.14. MS (FAB^+): *m*/*z* (%) = 391 (100) $[M^+]$. IR (nujol): $\tilde{\nu}$ = 3286, 3268 (NH), 1650 (C=N), 1548 (OCO) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 290.8 (H_α), 263.0 (H_α), 192.3 (H_α, 2 H), 161.4 (H_α), 85.0 (H_α, 2 H), 57.3 (H_α), 38.7 (4-Me, 3 H), 22.7 (4-Me, 3 H), 9.6 (Hisonic, 4 H), –11.0 (H_β), –13.3 (H_β, 2 H), –15.2 (H_β), –17.3 (H_β), –20.3 (2-Me, 3 H), –33.0 (H_β) ppm. **3:** Yield: 117 mg (94%). $C_{18}H_{29}F_6N_4NiO_2P$ (537): calcd. IR (nujol): $\tilde{\nu}$ = 1705 (C=O), 796, 784 (Pd–C_6F_5) cm^{-1}. ^{1}HNMR [$(CD_3)_2CO$, TMS]: δ = 9.21 (s, 2 H, 2-H), 8.99 (d, J_{HH} = 5 Hz, 2 H, 6-H), 8.48 (d, J_{HH} = 7 Hz, 2 H, 4-H), 7.72 (dd, J_{HH} = 5 Hz, 2 H, 5-H) ppm. ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –117.0 (d, 4 F_o, J_{om} = 28.0 Hz), –163.2 (t, 2 F_p, J_{mp} = 17.0 Hz), –165.5 (m, 4 F_m). **7:** Yield: 85 mg (74%). $C_{28}H_{18}F_{10}N_2O_4Pd$ (743): C 45.3, H 2.4, N 3.8; found C 44.9, H 2.5, N 3.8. MS (FAB^+): *m/z* (%) = 575 (100) [$M^+ – C_6F_5$]. IR (nujol): $\tilde{\nu}$ = 1744 (C=O), 795, 783 (Pd–C_6F_5) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 8.64 (d, J_{HH} = 6 Hz, 4 H, 2,6-H), 7.47 (d, J_{HH} = 6 Hz, 4 H, 3,5-H), 3.79 (s, 4 H, $PhCH_2$), 3.66 (s, 6 H, CH_3) ppm. ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –116.8 (d, 4 F_o, J_{om} = 28.0 Hz), –163.7 (t, 2 F_p, J_{mp} = 20.0 Hz), –165.8 (m, 4 F_m) ppm.

Complexes 8 and 10. Method 1: $Pd(C_6F_5)_2(PhCN)_2$ (45.3 mg, 0.07 mmol) was added to a solution of complex **1** or **3** (0.14 mmol) in acetone (25 mL). The mixture was stirred at room temperature for 24 h. The solution was concentrated under reduced pressure and the addition of diethyl ether caused the precipitation of a pale blue solid, which was collected by filtration, washed with diethyl ether and air-dried. Yields: 100 mg (94%) (for **8**) and 97 mg (91%) (for **10**). **Method 2:** $[Ni(Me_3\text{-}mcN_3)(\mu\text{-}OH)]_2(PF_6)_2$ (63.1 mg, 0.073 mmol) was added to a solution of complex **5** or **6** (50.1 mg, 0.073 mmol) in acetone (15 mL) and the resulting solution was refluxed for 5 h. The solvent was partially evaporated under reduced pressure. On addition of Et_2O, the blue complexes precipitated and were filtered off and air-dried. Yields: 81 mg (73%) (for **8**) and 78 mg (70%) (for **10**). **8:** $C_{48}H_{58}F_{22}N_8Ni_2O_4P_2Pd$ (1515): calcd. C 38.1, H 3.9, N 7.4; found C 37.7, H 3.9, N 7.4. MS (FAB^+): *m/z* (%) = 391 (100) $[Ni(Me_3\text{-}mcN_3)(isonic)]^+$. IR (nujol): $\tilde{\nu}$ = 3285, 3271 (NH), 1658 (C=N), 1548 (OCO), 795, 778 (Pd–C_6F_5) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 254.0 (H_α), 236.3 (H_α, 2 H), 168.5 (H_α), 156.3 (H_α), 101.3 (H_α, 2 H), 72.8 (H_α), 54.5 (4-Me, 3 H), 16.3 (4-Me, 3 H), 10.7 (2-H + 6-H, 2 H), 8.8 (3-H + 5-H, 2 H), –12.3 (H_β, 2 H), –14.2 (H_β), –17.3 (H_β), –17.6 (2-Me, 3 H), –24.6 (H_β), 28.8 (H_β), –31.5 (H_β) ppm. ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –72.0 (d, 12 F, PF_6^-, J_{FP} = 708 Hz), –116.8 (d, 4 F_o, J_{om} = 24.5 Hz), –163.5 (t, 2 F_p, J_{mp}= 20.7 Hz), –165.7 (m, 4 F_m) ppm. ^{31}P NMR ([D_6]acetone, H_3PO_4): δ = –143.5 (sept, 2 P, J_{PF} = 707 Hz) ppm. **10:** $C_{48}H_{58}F_{22}N_8Ni_2O_4P_2Pd$ (1515): calcd. C 38.1, H 3.9, N 7.4; found C 37.8, H 3.9, N 7.4. MS (FAB^+): *m/z* (%) = 391 (100) $[Ni(Me_3\text{-}mcN_3)(nic)]^+$, 1367 (2) [$M^+$]. IR (nujol): $\tilde{\nu}$ = 3288, 3275 (NH), 1658 (C=N), 1556 (OCO), 795, 778 (Pd–C_6F_5) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 224.1 (H_α, 2 H), 207.1 (H_α), 96.2 (H_α, 2 H), 73.8 (H_α), 52.1 (4-Me, 3 H), 22.8 (H_α), 16.4 (4-Me, 3 H), 12.3 (H_α), 9.7 (2-H + 4-H, 2 H), 9.4 (5-H), 8.6 (6-H), –11.9 (H_β, 2 H), –14.3 (H_β), –17.9 (2-Me, 3 H), –24.6 (H_β), –28.9 (H_β), –32.1 (H_β) ppm. ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –71.9 (d, 12 F, PF_6^-, J_{FP} = 712 Hz), –116.2 (d, 4 F_o, J_{om} = 22.5 Hz), –162.7 (t, 2 F_p, J_{mp} = 25.4 Hz), –164.8 (m, 4 F_m) ppm. ^{31}P NMR ([D_6]acetone, H_3PO_4): δ = –143.6 (sept, 2 P, J_{PF} = 709 Hz) ppm.

Complexes 9 and 11. Method 1: $Pd(C_6F_5)_2(PhCN)_2$ (45.3 mg, 0.07 mmol) was added to a solution of complex **2** or **4** (0.14 mmol) in acetone (25 mL). The mixture was stirred at room temperature for 24 h. The solution was concentrated under reduced pressure and the addition of diethyl ether caused the precipitation of a pale blue solid, which was collected by filtration, washed with diethyl ether and air-dried. Yields: 105 mg (97%) (for **9**) and 96 mg (89%) (for **11**). **Method 2:** $[Ni(Me_4\text{-}mcN_3)(\mu\text{-}OH)]_2(PF_6)_2$ (65.3 mg, 0.073 mmol) was added to a solution of complex **5** or **6** (50.1 mg, 0.073 mmol) in acetone (15 mL) and the resulting solution was refluxed for 5 h. The solvent was partially evaporated under reduced pressure. On addition of Et_2O, the blue complexes precipitated and were filtered off and air-dried. Yields: 79 mg (70%) (for **9**) and 86 mg (76%) (for **11**). **9:** $C_{50}H_{62}F_{22}N_8Ni_2O_4P_2Pd$ (1542): calcd. C 38.9, H 4.2, N 7.3; found C 38.5, H 4.4, N 7.3. MS (FAB^+): *m/z* (%) = 405 (100) $[Ni(Me_4\text{-}mcN_3)(isonic)^+]$, 1395 (1) [$M^+$]. IR (nujol): $\tilde{\nu}$ = 3269 (N–H), 1657 (C=N), 1547 (OCO), 797, 780 (Pd–C_6F_5) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 317.7 (H_α), 259.8 (H_α), 242.9 (H_α), 210.5 (H_α, 2 H), 128.9 (9-Me, 3 H), 92.5 (H_α), 87.8 (H_α, 2 H), 56.9 (4-Me, 3 H), 19.0 (4-Me, 3 H), 11.4 (2-H + 6-H, 2 H), 10.4 (3-H + 5-H, 2 H), –10.4 (H_β, 2 H), –12.9 (H_β), –18.3 (2-Me, 3 H), –25.0 (H_β), –30.4 (H_β), –35.2 (H_β) ppm. ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –71.6 (d, 12 F, PF_6^-, J_{FP} = 708 Hz), –116.7 (d, 4 F_o, J_{om} = 24.5 Hz), –163.4 (t, 2 F_p, J_{mp} = 20.7 Hz), –165.6 (m, 4 F_m) ppm. ^{31}P NMR ([D_6]acetone, H_3PO_4): δ = –143.3 (sept, 2 P, J_{PF} = 708 Hz) ppm. **11:** $C_{50}H_{64}F_{22}N_8Ni_2O_4P_2Pd$ (1542): calcd. C 38.9, H 4.2, N 7.3; found C 38.4, H 4.2, N 7.1. MS (FAB^+): *m/z* (%) = 405 (100) $[Ni(Me_4\text{-}mcN_3)(nic)^+]$, 1394 (1) [$M$]$^+$. IR (nujol): $\tilde{\nu}$ = 3270 (NH), 1657 (C=N), 1547 (OCO), 797, 785 (Pd–C_6F_5) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 310.6 (H_α), 287.5 (H_α), 249.7 (H_α), 233.5 (H_α), 134.4 (9-Me, 3 H), 95.6 (H_α, 2 H), 63.5 (4-Me, 3 H), 48.8 (H_α, 2 H), 19.8 (4-Me, 3 H), 9.7 (2-H + 4-H, 2 H), 9.3 (5-H), 8.2 (6-H), –9.8 (H_β, 2 H), –13.3 (H_β), –17.1 (2-Me, 3 H), –25.0 (H_β), –32.2 (H_β), –33.4 (H_β) ppm. ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –71.2 (d, 12 F, PF_6^-, J_{FP} = 712 Hz), –116.2 (d, 4 F_o, J_{om} = 26.4 Hz), –162.3 (t, 2 F_p, J_{mp} = 16.9 Hz), –164.6 (m, 4 F_m) ppm. ^{31}P NMR ([D_6]-acetone, H_3PO_4): δ = –143.3 (sept, 2 P, J_{PF} = 691 Hz) ppm.

Complex 12: $[Ni(Me_3\text{-}mcN_3)(\mu\text{-}OH)]_2(PF_6)_2$ (63.1 mg, 0.073 mmol) was added to a solution of complex **7** (54.2 mg, 0.073 mmol) in acetone (15 mL) and the resulting solution was refluxed for 5 h. The solvent was partially evaporated under reduced pressure. On addition of Et_2O, the blue complexes precipitated and were filtered off and air-dried. **12:** Yield: 96 mg (85%). $C_{50}H_{62}F_{22}N_8Ni_2O_4P_2Pd$ (1543): calcd. C 38.9, H 4.1, N 7.3; found C 38.5, H 4.3, N 7.0. MS (FAB^+): *m/z* (%) = 405 (100) $[Ni(Me_3\text{-}mcN_3)(PyOAc)]^+$, 1397 (15) [$M^+ + 1 + PF_6$]. IR (nujol): $\tilde{\nu}$ = 3289, 3266 (NH), 1661 (C=N), 1558 (OCO), 795, 783 (Pd–C_6F_5) cm^{-1}. ^1H NMR [$(CD_3)_2CO$, TMS]: δ = 230.2 (H_α, 2 H), 207.4 (H_α), 196.4 (H_α), 185.5 (H_α), 174.3 (H_α), 103.2 (H_α, 2 H), 56.3 (4-Me, 3 H), 19.7(–CH_2–, 2 H), 16.8 (4-Me, 3 H), 8.8 (2-H + 6-H, 2 H), 7.4 (3-H + 5-H, 2 H), –12.0 (H_β, 2 H), –15.1 (H_β), –16.4 (2-Me, 3 H), –23.9 (H_β), 28.8 (H_β, 2 H). ^{19}F NMR [$(CD_3)_2CO$, TMS]: δ = –72.0 (d, 12 F, PF_6^-, J_{FP} = 709 Hz), –116.2 (d, 4 F_o, J_{om} = 25.4 Hz), –163.1 (t, 2 F_p, J_{mp} = 16.9 Hz), –164.8 (m, 4 F_m) ppm. ^{31}P NMR ([D_6]acetone, H_3PO_4): δ = –143.6 (sept, 2 P, J_{PF} = 708 Hz) ppm.

X-ray Data Collection and Structure Determination: Data collection was performed with a Bruker Smart CCD diffractometer with a nominal crystal–detector distance of 4.5 cm. Diffraction data were collected based on an ω-scan. A total of 1371 (**7**) and 2524 (**4**) frames were collected at 0.3° intervals and 10 s per frame. The diffraction

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

frames were integrated using the SAINT package[42] and corrected for absorption with SADABS.[43] The crystallographic data are shown in Table 5. The structures were solved by direct methods[44] and refined anisotropically on F^2.[44] Hydrogen atoms were introduced in calculated positions. CCDC-256615 (**4**) and -256616 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Keywords: Adduct / Gold(I) / Carbene / Acetylide

The reaction of Au(CO)Cl with 1,3-di-*tert*-butylimidazol-2-ylidene and 1,3-dimesitylimidazol-2-ylidene in toluene at room temperature results in CO evolution and readily affords in high yield the adducts **1a** and **1b**, respectively. The reaction of **1a** and **1b** with ethynylmagnesium chloride in THF yields **2a** and **2b**, respectively. The crystal structures of **1a**, **1b**, and **2a** were determined.

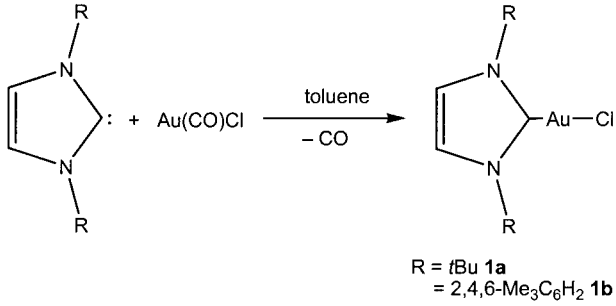
Introduction

Recently there has been a resurgence of interest in the chemistry of gold compounds in general and that of gold(I) compounds in particular. A major driving force for this interest has been the utility of soluble gold compounds in various applications ranging from precursor for gold nanoparticles[1,2] to drugs,[3] and catalysts.[4–6] Among Au^I compounds, there has been considerable success in the preparation of alkynyl gold complexes. These are among the most stable organogold complexes.[7] Although dinuclear complexes such as $R_3PAuC{\equiv}CAuPR_3$ have been known for some time,[8,9] Schmidbaur and co-workers have recently isolated terminal acetylides of gold in the form of gold ethynyl complexes $RAuC{\equiv}CH$ (R = $MePH_2$, Me_3P).[10] A key factor in this successful assembly is the utility of appropriate phosphane ligands in stabilizing such compounds. It has also been shown that these compounds can be used as reliable synthons in crystal engineering owing to strong and predictable aurophilic [Au^I–Au^I] interactions.[11] Another interesting aspect of these complexes has been the ability to exhibit rich photophysical and photochemical behaviour.[12–15]

One of the key challenges in Au^I chemistry remains the availability of reasonably stable synthons, which would allow simple substitution reactions. The use of sterically hindered N-heterocyclic carbenes[16] for such a purpose was regarded as ideal.[17,18] Accordingly, in this paper we describe a facile one-step, high yield synthesis of a lipophilic gold(I)-N-heterocyclic carbene complex LAuCl. We also demonstrate the synthetic utility of the latter by preparing the terminal acetylide $LAuC{\equiv}CH$. The X-ray crystal structures of LAuCl and $LAuC{\equiv}CH$ are described. During the preparation of this manuscript Baker and co-workers reported the synthesis of LAuCl **1a** complex by transmetallation of LAgCl and $(Me_2S)AuCl$.[19]

Results and Discussion

The reaction of Au(CO)Cl with a stoichiometric amount of N-heterocyclic carbene (1,3-di-*tert*-butylimidazol-2-ylidene or 1,3-dimesitylimidazol-2-ylidene) in toluene at room temperature results in a vigorous evolution of carbon monoxide and the formation of the corresponding carbene adducts **1a** and **1b**, respectively (Scheme 1). Thus this synthetic method represents a viable and rational route for the preparation of N-heterocyclic carbene adducts of Au^I.



Scheme 1. Synthesis of Au^I N-heterocyclic carbene complexes.

Compounds **1a** and **1b** have been unambiguously characterized by means of spectroscopic, spectrometric, and crystallographic techniques. Both **1a** and **1b** are colorless crystalline solids and are thermally stable. They decompose

[a] Institut für Anorganische Chemie der Georg-August-Universität Göttingen,

with melting at 170 °C and 210 °C respectively. The EI mass spectrum of **1a** revealed that the most intense peak appears at *m*/*z* 320 and corresponds to the loss of one *tert*-butyl group and the chlorine atom from the molecular ion. A similar peak at *m*/*z* 303 in **1b** is due to [M^+ – Cl – Au – H]. The ^{1}H NMR spectrum of **1a** exhibits two singlets (δ = 1.83 and 7.26 ppm) for the protons of the *tert*-butyl groups and (HC=CH) of the carbene. They are shifted downfield relative to the 1,3-di-*tert*-butylimidazol-2-ylidene (δ = 1.51 and 7.06 ppm). The resonances of *o*-Me and *p*-Me in **1b** (δ = 1.75 and 2.13 ppm) are observed upfield relative to the carbene (δ = 2.08 and 2.31 ppm) whereas the (HC=CH) protons in **1b** (δ = 7.46 ppm) are found downfield relative to the carbene (δ = 7.07 ppm). A weak ^{13}C NMR resonance (δ = 167.6 ppm for **1a**) can be assigned to the carbene carbon atom. However, in case of **1b** no resonance downfield to 150 ppm was detected which could be assigned to the carbene carbon.

Single crystals of **1a** and **1b** suitable for X-ray structural analysis were obtained from their toluene solutions. Compound **1a** crystallizes with one molecule of toluene. The molecular structures of **1a** and **1b** are shown in Figure 1 and Figure 2, respectively, and selected metric parameters are given in Table 1. Compound **1a** crystallizes in the monoclinic space group $P2_1/c$ whereas compound **1b** in the orthorhombic space group *Fdd*2, respectively. The X-ray crystal structures of **1a** and **1b** reveal that the compounds are monomeric adducts of the N-heterocyclic carbene Au^I chloride, no Au^I–Au^I interactions were observed.

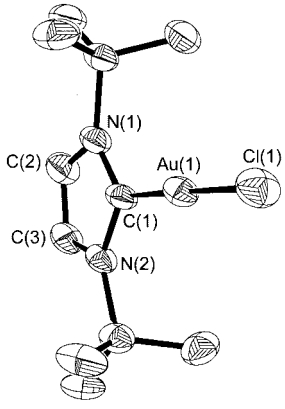

Figure 1. Molecular structure of **1a**. Toluene molecule and hydrogen atoms are omitted for clarity, thermal ellipsoids are shown with 50% probability.

The Au–Cl distances 2.290(2) Å in **1a** and 2.281(4) Å in **1b** are shorter than the Au–Cl distance in [Au(Me$_2$-bimy)Cl] [2.338(2) Å][17] but comparable to that in {PhCH$_2$N(CH)$_2$N(COPh)C}AuCl [2.286(2) Å][18] and [Au(Me$_2$-imyl)Cl] [2.288(3) Å].[20] The Au–C bond lengths 1.983(8) Å in **1a** and 1.933(1) Å in **1b** are similar to those found in [Au(Me$_2$-bimy)Cl][17] [1.985(1) Å], {PhCH$_2$N(CH)$_2$N(COPh)C}AuCl[18] [1.970(1) Å] and in [Au(Me$_2$-imyl)Cl][20] [1.98(1) Å]. The average N–C(1) distance of the ligand in **1a** 1.369 Å and 1.377 Å in **1b** are similar to those observed in [Au(Me$_2$-bimy)Cl] (1.371 Å)[17] and in

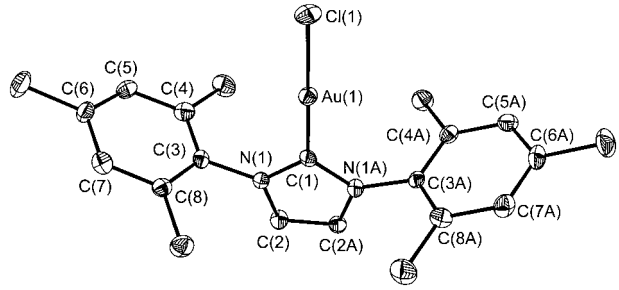

Figure 2. Molecular structure of **1b**. Hydrogen atoms are omitted for clarity, thermal ellipsoids are shown with 50% probability.

Table 1. Selected bond lengths [Å] and angles [°] of **1a**, **1b**, and **2a**.

	1a	**1b**	**2a**
Au(1)–C(1)	1.983(8)	1.933(1)	2.05(1)
Au(1)–Cl(1)	2.290(2)	2.281(4)

* N(2) corresponds to N(1A) and C(3) corresponds to C(2A) in case of **1b**.

{PhCH$_2$N(CH)$_2$N(COPh)C}AuCl (1.355 Å).[18] The N(1)–C(1)–N(2) angles within the N_2C_3 five-membered ring of the carbene ligand in **1a** 104.5(7)° and 102.6(9)° in **1b** are similar to that in {PhCH$_2$N(CH)$_2$N(COPh)C}AuCl 104.4(1)° but are slightly smaller than those in [Au(Me$_2$-bimy)Cl][17] 108(1)° and in [Au(Me$_2$-imyl)Cl][20] [106(10)°]. In the crystal lattice **1a** forms an extended network through agostic interaction of Au with one proton of the *t*Bu group from neighbouring molecule (2.96 Å) and also interacts with one *o*-H of the solvating toluene molecule (3.06 Å) present in the crystal lattice (Figure 3). These are in the range 1.95–3.20 Å reported for similar H···Au interactions.[21] In the case of **1b** all aromatic hydrogens are involved in hydrogen bonds. Hydrogen atoms on C(7) and C(7A) are bonded by agostic interactions to Au from two different neighbouring molecules with a H···Au distance of 3.18 Å which is comparable to the values in the range 1.95–3.20 Å reported for similar H···Au interactions[21] but slightly longer than those in **1a**. Hydrogen atoms present on C(5), C(5A), C(2) and C(2A) are bonded to Cl atoms of neighbouring molecules in a symmetrical manner as shown in Figure 4. The corresponding H···Cl distances are 2.88 Å and 2.90 Å which agrees with the reported values of intermediate to long range intermolecular interactions.[21,22]

Reaction of the adducts **1a** and **1b** with ethynylmagnesium chloride in THF smoothly affords the corresponding gold(I) ethynyls **2a** and **2b** in good yields (Scheme 2). Compounds **2a** and **2b** decompose with melting at 155 °C and

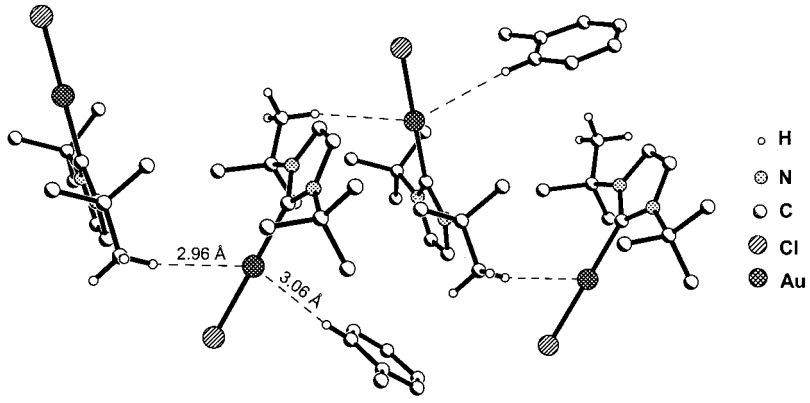

Figure 3. Perspective view of the agostic interactions of Au with *o*-H of the toluene molecule and with H atom of *t*Bu of the carbene ligand in the crystal state of **1a**, forming a zig-zag chain.

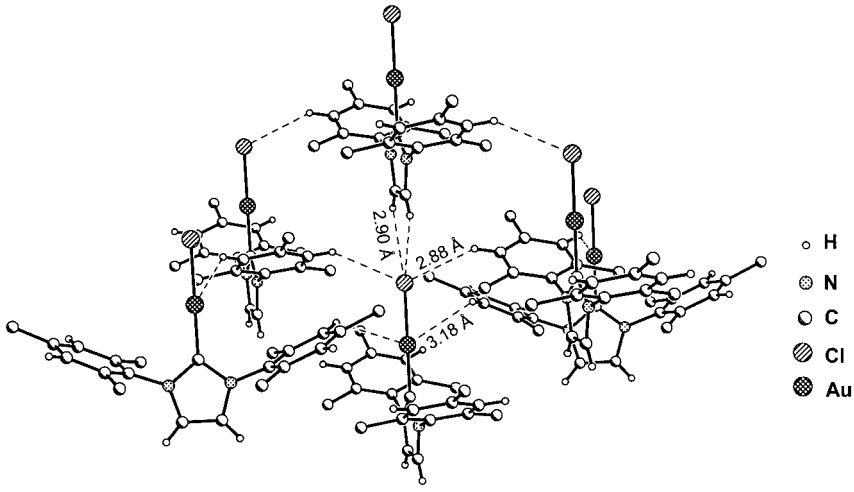

Figure 4. Perspective view of the chain formation through the agostic interaction of the aromatic protons of the carbene ligand with Au and Cl atoms in **1b**.

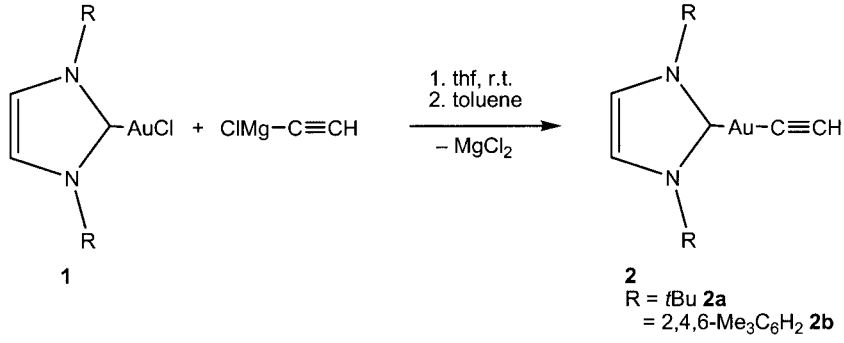
240 °C respectively. The EI mass spectrum of **2a** revealed the molecular ion peak as the most intense one (*m*/*z* 402), whereas the ion at *m*/*z* 303 in **2b** is the most intense peak and corresponds to the loss of Au and C_2H_2 units from the molecular ion. The IR spectrum of **2a** shows a sharp band (1979 cm^{-1}) which can be attributed to the ethynyl stretching frequency. The corresponding stretching mode for **2b** appears at 1982 cm^{-1}. The ^1H NMR spectrum of **2a** shows the ethynyl proton to resonate at δ = 1.22 ppm whereas the same proton in **2b** resonates at δ = 0.86 ppm. The resonances of the carbene ligand in **2a** and **2b** are shifted downfield relative to the free carbenes. The ^1H NMR spectrum of **2a** shows two singlets (δ = 1.84 and 7.29 ppm) for the protons of the *tert*-butyl groups and (HC=CH) of the carbene. They are shifted downfield relative to the free carbene, (δ = 1.51 and 7.06 ppm). The resonances of *o*-Me and *p*-Me in **2b** (δ = 2.13 and 2.34 ppm) are observed downfield (δ = 2.08 and 2.31 ppm) as well as the (HC=CH) protons



Scheme 2. Synthesis of the monomeric terminal ethynyl Au^I complexes **2a** and **2b**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in **2b** (δ = 7.38 ppm) relative to the free carbene (δ = 7.07 ppm). A weak ^{13}C NMR resonance (δ = 187.9 ppm for **2a**) can be assigned to the N–C–N carbon atom and it is shifted downfield relative to **1a** (δ = 167.6 ppm).

Single crystals of **2a** suitable for X-ray structural analysis were obtained from its toluene solution. Repeated efforts to obtain a better data set for **2a** were not successful due to the fast crystal decomposition caused by liberation of the solvating toluene molecules. The most optimistic dataset is reported here. The molecular structure of **2a** is shown in Figure 5 and selected metric parameters are given in Table 1. Compound **2a** is isomorphous to **1a**. The X-ray crystal structure of **2a** reveals that the compound is a monomeric adduct of the N-heterocyclic carbene Au^I acetylide with no Au^I–Au^I interactions. The Au(1)–C(12) distance of 2.04(2) Å in **2a** is similar to that of [($MePh_2P$)AuC≡CH] 2.008(4) Å.[10] The C(12)–C(13) distance of the ethynyl moiety in **2a** [1.11(2) Å] is comparable to that in [($MePh_2P$)AuC≡CH] [1.187(6) Å].[10] The Au(1)–C(12)–C(13) angle of 171.3(2)° in **2a** is comparable to that in [($MePh_2P$)AuC≡CH] [178.9(4)°].[10] The C(1)–Au(1)–C(12) angle in **2a** is close to linearity. The N(1)–C(1)–N(2) angle [107(1)°] is slightly wider than that of the parent compound **1a** [104.5(7)°]. The H····Au agostic interactions observed in the crystal of **2a** are analogous to that of **1a** (Figure 6). Thus the contacts are 2.97 Å and 3.12 Å corresponding to the *o*-H of toluene and H atom of *t*Bu group of the carbene. Due to the disordered toluene molecule in **2a** in two positions with occupancy ratio 87:13 the 2.97 Å distance is attributed to the major 87% part and 3.04 Å distance is attributed to the minor 13% part.

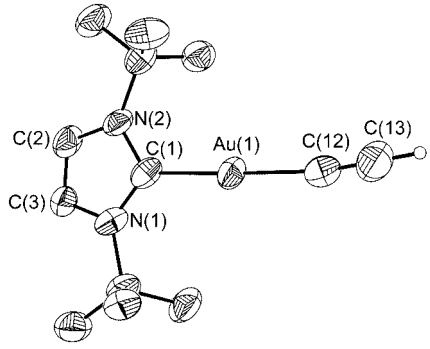


Figure 5. Molecular structure for **2a**. Only the hydrogen atom on the ethynyl group is shown. The toluene molecule is omitted for clarity, thermal ellipsoids are shown with 50% probability.

In summary, we have demonstrated a single step synthesis of N-heterocyclic carbene adducts of gold(I) chloride. The utility of complexes thus synthesized stems from the stability of these complexes which have been used to prepare the first N-heterocyclic carbene gold(I) ethynyl which contains a terminal –C≡CH group.

Experimental Section

All manipulations were performed under a dry and oxygen free atmosphere (N_2 or Ar) using Schlenk line and glove box techniques. Solvents were purified according to conventional procedures and were freshly distilled prior to use. Au(CO)Cl,[23] 1,3-di-*tert*-butylimidazol-2-ylidene and 1,3-dimesitylimidazol-2-ylidene[24] were synthesized according to literature.

Synthesis of (1,3-Di-*tert*-butylimidazol-2-ylidene)gold(I) Chloride (1a): In a glove box a 100 mL Schlenk flask was charged with Au(CO)Cl (1.90 g, 7.30 mmol) and topped with a dropping funnel containing 1,3-di-*tert*-butylimidazol-2-ylidene (1.31 g, 7.25 mmol). Toluene (50 mL) was added to the dropping funnel and the resulting solution was added dropwise to the flask at room temperature. The mixture was stirred until the CO evolution had ceased. It was filtered and the residue was washed with toluene (30 mL). The combined filtrate was concentrated until the compound begins to crystallize and then kept at 0 °C for two days to afford colorless crystals of (1,3-di-*tert*-butylimidazol-2-ylidene)gold(I) chloride **1a** (1.8 g), the mother liquor afforded another crop (0.6 g), combined yield 2.48 g, 83%, m.p. 170 °C (decomp.). $C_{11}H_{20}AuClN_2$ (412): calcd. C 32.04, H, 4.84, N, 6.79; found C 32.27, H, 5.01, N, 6.80. EI-MS: *m/z* (%) 412 (44) [M^+], 376 (14) [M^+ – H – Cl], 356 (14) [M^+ – *t*Bu – H], 320 (100) [M^+ – Cl – *t*Bu], 264 (36) [M^+ – 2 *t*Bu –

IR (KBr, Nujol): $\tilde{\nu}$ = 1982, 1730, 1606, 1559, 1484, 1409, 1376, 1339, 1290, 1234, 1164, 1028, 926, 852, 755, 705, 629, 574 cm^{-1}.

X-ray Structure Determinations for 1a, 1b, and 2a: A suitable crystal of each compound was mounted on a glass fiber and coated with paraffin oil. Diffraction data for **1a** and **2a** were collected on a Siemens-Stoe AED2 four-circle instrument and the measurements were made with graphite-monochromated Mo-*K*α radiation (λ = 0.71073 Å). Data for **1b** was obtained on Bruker three circle diffractometer equipped with a SMART 6000 CCD detector using

mirror monochromated Cu-$K\alpha$ radiation (λ = 1.54178 Å) (Table 2). Compound **1b** was refined as a recemic twin with ratio of the components 35.3:64.7. The structures were solved by direct methods using SHELXS-97[25] and refined against F^2 on all data by full-matrix least-squares with SHELXL-97[26]. All non-hydrogen atoms were refined anisotropically. The disordered toluene molecule in **2a** was refined with distance and geometry restrains and restrains for anisotropic displacement parameters. Neutral-atom scattering factors (including anomalous scattering) were taken from the International Tables for X-ray Crystallography. Hydrogen atoms were included at geometrically calculated positions except for protons of the methyl group of disordered toluene molecule in **2a** and refined using a riding model.

Identification of Copper(II) Binding Sites in the Aminoglycosidic Antibiotic Neomycin B

Małgorzata Jeżowska-Bojczuk,*[a] Wojciech Szczepanik,[a][‡] Stefano Mangani,[b] Elena Gaggelli,[b] Nicola Gaggelli,[b] and Gianni Valensin[b]

Keywords: Bioinorganic chemistry / Aminoglycoside antibiotics / Neomycin B / N,O ligands / Copper

Protonation and copper(II) coordination properties of neomycin B were studied in solution by potentiometry, NMR, UV/Vis, CD, and EPR spectroscopy, XAS and mass spectrometry. Mono- and dinuclear complexes were found depending on the metal-to-ligand molar ratio. Neomycin B anchors Cu^{II} ions above pH 5.0 with an NH_2 group from ring B. Simultaneously, the second amino group of the same ring and the hydroxyl group of ring A complete the binding set of donors. With an increase in pH the remaining $-NH_3^+$ functional groups in the neomycin B molecule are deprotonated without affecting the complexation pattern. However, these groups, particularly the ones located in the D-ring of the antibiotic, may coordinate the second copper(II) ion when the metal is present in excess. We have proved this process with the use of potentiometry, CD and especially mass spectrometry.

Introduction

Neomycins are aminoglycoside antibiotics produced by *Streptomyces fradiae* as a mixture of three analogues A, B and C. Only neomycin B is used in therapy and it is active against gram-negative aerobic bacteria and *Staphylococcus.* It is topically or orally applied, mainly prior to surgical interventions of the intestine. Parenteral administration of the drug may result in oto- and nephrotoxic effects much more acute than for any other aminoglycoside.[1] A possible explanation was recently provided in our studies,[2] showing that (i) neomycin has the highest potency in cleaving $tRNA^{Phe}$ and (ii) the Cu^{II}-neomycin complex disproportionates H_2O_2 to hydroxyl radicals, as well as oxidizes plasmid DNA with the highest efficiency.

Coordination of aminoglycosides by Cu^{II} ions was extensively investigated[3–6] and evidence was reached for copper selectively yielding high stability complexes over other transition metal ions.[7] Although not present at very high levels intracellularly, the amount of copper(II) in the plasma reflects the state of health of the organism. Under circumstances when antibiotics are applied (e.g. inflammation), the serum level of copper may drastically increase,[8] probably as a result of leukocyte activation that releases even micromolar amounts of copper and iron as well.[9] Increased concentrations of Cu^{II} ions in selected tissues are also observed during the appearance of cancer, anemia[10] or hyperthyroidism.[11] Thus chelation of the metal by xenobiotics, e.g. drugs, may occur in vivo.

The coordination abilities of neomycin B (Figure 1) have not been thoroughly investigated to date. Formation of solid polymeric complexes has been observed with selected transition metal ions but without any evidence of amino groups being involved in binding.[12] The characteristics of the Cu^{II} complex of neomycin B in solution have also been delineated, but the final determined structure concerns only the coordination of neamine,[13] a subunit of neomycin B

(see rings A and B, Figure 1). The aim of the current study is to gain deeper insight into the Cu^{II}-neomycin binding equilibria depending upon pH and metal ion-to-antibiotic molar ratio.

Results and Discussion

Protonation of Neomycin B

The protonation constants calculated on the basis of potentiometric titrations are presented in Table 1. They correspond to six amino groups present in this hexaprotic antibiotic molecule. Both amino sugar rings (A and D) and the 2-deoxystreptamine ring (B) contain two amino group substituents. Only the pentose ring (C) has no protonating function (Figure 1). The location of the amino groups causes equal distribution of the positive charge within the neomycin B molecule.

Table 1. Protonation and stability constants of neomycin B and its copper(II) complexes.

Protonation constants of neomycin B			Stability constants of Cu^{II}-neomycin B		
species	log β	pK	species	log β	pK
LH_6	46.575(2)	5.69	CuH_3L	31.80(4)	–
LH_5	40.885(2)	7.02	CuH_2L	26.24(1)	5.56
LH_4	33.865(2)	7.603	CuHL	19.02(1)	7.22
LH_3	26.262(3)	8.147	CuL	10.94(1)	8.08
LH_2	18.115(2)	8.745	$CuH_{-1}L$	1.97(1)	8.97
LH	9.370(2)	9.370	$CuH_{-2}L$	–7.99(1)	9.96

Almost all pK_a values are typical for amino functions and fit the characteristic range 7–9 (Table 1), except the first one which is much lower (pK_a = 5.69) in agreement with previous ^{15}N NMR spectroscopic measurements.[14] Such low values of the first deprotonation constant were also found for all other aminoglycosides studied so far: 6.0 for geneticin[3] and kanamycin A[4] that have a +4 charge at low pH, and 5.7 for the +5 charged kanamycin B[5] and tobramycin.[6] Neomycin with its six amines has an almost identical value for this constant as do the pentaprotic antibiotics. Therefore, the decrease in the first pK_a of the aminoglycosides is likely to arise from a local electrostatic interaction between neighboring NH_3^+ groups within the same ring,[4,5,14] rather than from the overall charge of the entire molecule.

All the successive deprotonations are separated from one another by only ca. 0.6 log units (Table 1). The statistics on the deprotonation of bifunctional molecules indicate that each of the two processes is almost parallel (the "ideal" statistical log value is 0.6[15]). ^{15}N NMR spectroscopy allowed us to calculate the pK values and assign them to each amino group of the antibiotic molecule.[14] In spite of diverse experimental conditions, the calculated constants agree with our determinations.

Copper(II) Complexation by Neomycin B

Neomycin B offers more potential possibilities for copper(II) chelation when compared with previously investigated aminoglycoside antibiotics.[3–6] This antibiotic forms six complexes with cupric ion in the pH range 5.5 to 10. At a 1:1 molar ratio or at an excess of the antibiotic, only monomeric complexes are formed in solution, as confirmed by potentiometry and mass spectrometry measurements (Table 1 and Table 2). The first minor species, which starts to occur at pH ca. 5, has CuH_3L stoichiometry (H_6L represents the fully protonated ligand). It is a common feature of the Cu^{II}-aminoglycoside complexes that the binding process is accompanied by a two-proton loss, which results from chelate ring formation by the amine nitrogen and a neighboring hydroxyl oxygen with simultaneous deprotonation of the latter. Cu^{II} anchoring then proceeds at the 3 amino group of the deoxystreptamine ring B due to its lowest deprotonation constant value.[14] In the case of neomycin B there is an additional deprotonation of another amine function. This event is very likely to occur at one of the bisaminated rings (A or D) due to the mentioned electrostatic interaction, but not in ring (B), where Cu^{II} is already bound. A {N,O} type chelation therefore occurs, with deprotonation of another amine, without its involvement in coordination. However, the CuH_3L species exists at too low

Table 2. Summary of the observed ESI-MS ions (m/z) at pH 8.0 {$(NH_4)_2CO_3$, 5 mM} for neomycin B (L) and its Cu^{II} complex. Concentrations: Cu^{II} 0.25 or 0.5 mM and L 0.25 mM.

a fraction (12% of total Cu^{II} amount, Figure 2) to allow unambiguous delineation of its characteristics.

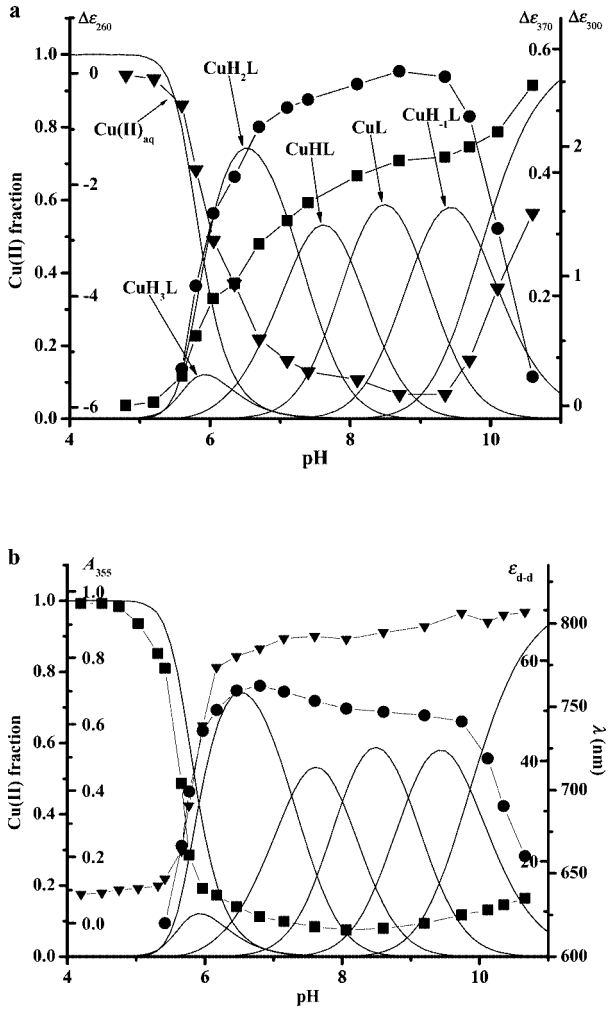

Figure 2. The speciation diagram for the Cu^{II}-neomycin B system with CD spectral parameters overlaid (a): $\Delta\varepsilon$ of CT bands at: 260 nm (▼), 300 nm (■) and 370 nm (●), as well as UV/Vis spectra parameters overlaid (b): ε (▼) and λ (■) of d-d band and shoulder at 355 nm (●). $\Delta\varepsilon$ and ε are in M^{-1} cm^{-1}.

This form is followed by a major species, CuH_2L complex, which prevails over the first at almost the same pH range. The stability constants of both complexes differ by ca. 5.6 log units, in agreement with the deprotonation of another amine nitrogen. However, this value is too low for a spontaneous proton loss and seems to be forced by another electron pair acceptor. If this further deprotonation proceeds at the same ring, where Cu^{II} is already bound, then another deprotonated nitrogen will also be engaged in the coordination process and {N,N,O} type chelation will occur. The results, obtained from spectroscopic measurements confirm that the CuH_2L species involves two nitrogen atoms coordinated to the central metal ion.

In order to establish the coordination pattern of this species unambiguously, ^1H and ^{13}C NMR spectroscopic methods were applied. The chemical shifts (ppm) of neomycin B are summarized in Table 3. Spectral assignment was achieved by COSY and ROESY experiments, by ^{13}C ^1H 2D shift correlated maps and by comparison with reference data.[16,17] Addition of copper to the solution of neomycin and pH adjustment to 6.8, where the CuH_2L complex reaches its maximum concentration, were not very effective in enhancing the nuclear relaxation rates. This fact is reflected by the relatively small values of R_{1p} (Table 4), where R_{1p}, the paramagnetic contribution to the spin-lattice relaxation is defined by Equation (1).

Table 3. ^1H and ^{13}C NMR chemical shift (ppm) of neomycin B 9.9 mM in D_2O at pH 6.8 (value uncorrected for the isotopic effect), T = 298 K and with TSP-d_4 as internal reference standard.

$$R_{1p} = R_{1obs} - R_{1f} = \frac{p_b}{R_{1M}^{-1} + \tau_M} \quad (1)$$

where: R_{1obs} and R_{1f} are the spin-lattice relaxation rates measured in the presence and in the absence of the metal respectively, τ_M is the exchange lifetime from the bound to the free state, p_b is the molar fraction of the bound ligand, and R_{1M} is the spin-lattice relaxation rate of the copper-bound ligand. R_{1M} is accounted for by the following simplified equation [Equation (2)] reporting the dipole-dipole interaction, as provided by the Solomon–Bloembergen–Morgan theory.[18]

$$R_{1M} = \frac{1}{10}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\hbar^2\gamma_I^2\gamma_S^2}{r^6}\left\{\frac{\tau_c}{1+(\omega_I-\omega_S)^2\tau_c^2} + \frac{3\tau_c}{1+\omega_I^2\tau_c^2} + \frac{6\tau_c}{1+(\omega_I+\omega_S)^2\tau_c^2}\right\} \quad (2)$$

where: μ_0 is the vacuum permeability, γ_I and γ_S are the nuclear and electron magnetogyric ratios, ω_I and ω_S are the proton and electron Larmor frequencies, respectively, r is the proton–Cu^{II} distance and τ_c is the effective correlation time.

The proton spin-lattice relaxation rates were selectively affected, as also reported in Table 4, while no sizeable

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

change in chemical shift was detected. The relatively larger R_{1p} values experienced by the 2_{ax}, 2_{eq}, 5 and 1′ protons suggest that rings A and B of neomycin B are directly involved in the coordination of the Cu^{II} ion. ^{13}C paramagnetic relaxation rates, together with potentiometric data (Table 1 and Table 5), moreover suggest the 1 and 3 deprotonated amino groups (ring B) and 4′ deprotonated hydroxyl group (ring A) as the possible donor set.

Table 4. Paramagnetic contributions to proton longitudinal relaxation rates (R_{1p}, s^{-1}) of neomycin B, 9.9 mM in D_2O at pH 6.8 (value uncorrected for the isotopic effect), T = 298 K. Contributions were calculated as the difference between the R_1 values in the presence (R_{1obs}) and in the absence (R_{1f}) of $Cu(NO_3)_2$ [ratio Cu^{II}-neomycin: 1:100] and converted into copper-proton distances r_{Cu-H} through Equations (1) and (2) using $\tau_C = 2.73 \times 10^{-10}$ s and $\tau_M = 6.00 \times 10^{-4}$ s. Missing values are due to overlap among protons of the same ring.

The correlation time in Equation (2) is generally determined by rotation of the metal complex. The reorientational dynamics of the complex was approximated by evaluating the motional correlation time of the free antibiotic in a water solution. This was accomplished by measuring the value of the cross-relaxation rate, σ, of the 2_{ax} and $2_{equiv.}$ protons of the ring B by means of Equation (3).[19]

$$\sigma = R^{bsel} - R^{sel} = \frac{1}{10}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\gamma_H^4 \hbar^2}{r^6}\left(\frac{6\tau_c}{1+4\omega_H^2\tau_c^2} - \tau_c\right) \quad (3)$$

where: r is the distance between vicinal protons (0.177 nm), and R^{bsel} and R^{sel} are the double- and single-selective spin-lattice relaxation rates, respectively. The value obtained was $\tau_c = 0.27 \pm 0.05$ ns at 298 K.

As stated in Equation (1), exchange of the ligand between free and bound states must be considered. In fact

Table 5. Paramagnetic contributions to carbon longitudinal relaxation rates (R_{1p}, s^{-1}) of neomycin B 9.9 mM in D_2O at pH 6.8 (value uncorrected for the isotopic effect), T = 298 K. Contributions were calculated as the difference between the R_1 values in the presence (R_{1obs}) and in the absence (R_{1f}) of $Cu(NO_3)_2$ [ratio Cu^{II}-neomycin B: 1:100] and converted into copper-carbon distances r_{C-Cu} [nm].

R_{1M}, the structure-sensitive parameter, can be directly obtained from Equation (2) only in cases where fast exchange conditions ($R^{-1}_{1M} >> \tau_M$) prevail. The unusually small, although diverse, R_{1p} values suggest, by themselves, occurrence of a slow-intermediate exchange region, where R^{-1}_{1M} is equal or slightly smaller than τ_M. This being the case, both R^{-1}_{1M} and τ_M would contribute to R_{1p}. The contribution of exchange was measured by the temperature dependence of R_{1p}, which is well known in the literature.[20]

The temperature dependencies of the R_{1p} values of some protons are shown in Figure 3. The plots suggest that slow exchange conditions prevail (this justifies the relatively small paramagnetic effects), but that R_{1p} is close to its maximum where intermediate exchange conditions dominate. The exchange rates were calculated by fitting the initial part of the temperature dependent R_{1p} data (where $R_{1p} \approx p_b k_{off} = p_b/\tau_M$, τ_M being the exchange lifetime) with the Eyring equation [Equation (4)].[20]

$$\tau_M^{-1} = \frac{kT}{h} e^{-\frac{\Delta G^\#}{RT}}$$

$$\ln[R_{1p}] = \ln\left[p_b \frac{kT}{h}\right] - \frac{\Delta G^\#}{RT} \quad (4)$$

where: $\Delta G^\#$ is the free energy of activation for the dissociation process and p_b is approximated to the [Cu^{II}]/[neomycin B] ratio. An average value of $\tau_M = 0.60 \pm 0.03$ ms could be calculated.

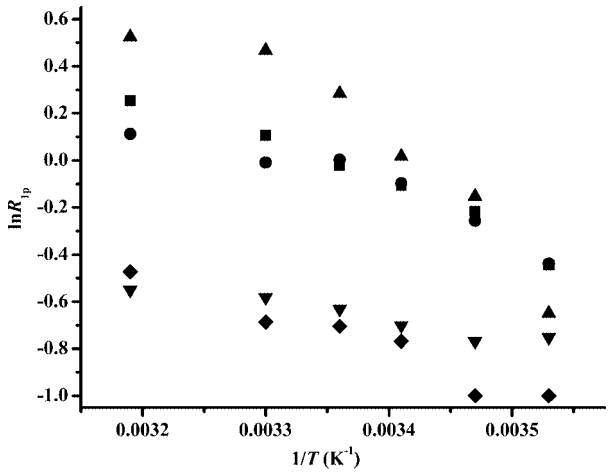

Figure 3. Temperature dependencies of paramagnetic relaxation rates (R_{1p}) of selected protons of neomycin B (9.9 mM) in D_2O (pH 6.8), in the presence of Cu^{II} ions at a concentration of 0.099 mM: 2_{ax} of ring B (■); 2_{eq} of ring B (●); 1′ of ring A (▲); 1″ of ring C (▼); 1‴ of ring D (♦).

Introducing the exchange time value into Equation (1) allowed us to extract all R_{1M} values from the R_{1p} ones. Since Equation (2) provides R_{1M} as a function of τ_c/r^6, taking the value of τ_c for the free ligand to be 0.27 ± 0.05 ns at 298 K, allowed us to calculate all copper–proton and copper–carbon distances, also shown in Table 4 and Table 5. The approximation used is not expected to introduce large errors in the calculated distances because the r^6 dependence minimizes even large errors (up to 50%) in the motional correlation time. The distances were then used as restraints in order to calculate the structure of the Cu^{II}-neomycin B complex in aqueous solution at pH 6.8. The suggested structure was supported by molecular mechanics and dynamics: an energy-minimized molecular model of Cu^{II}-neomycin B complex (Figure 4) was obtained by using the HYPERCHEM graphics package. The stick model of the complex shows the Cu^{II} ion bound to the two deprotonated amino groups of ring B, the 4′ deprotonated hydroxyl group of ring A and a water molecule added to reach the minimum set of donors. The 3‴-OH (ring D) and the 3-NH_2 (ring B) were found at a typical hydrogen bonding distance, such that further stabilization of the complex may be hypothesized. The obtained structure suggests that neomycin B wraps around Cu^{II} in a way that leaves the metal ion exposed to the water medium.

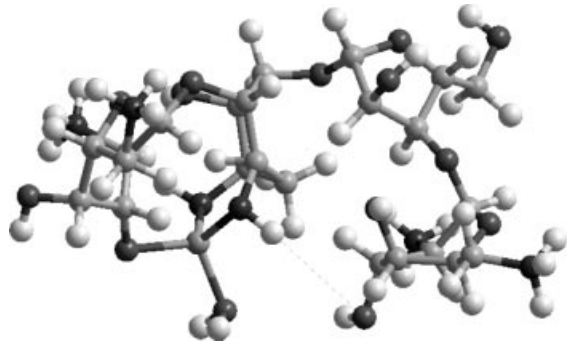

Figure 4. Structural model of the Cu^{II}-neomycin B 1:1 complex in water solution. The dashed line represents the hydrogen bond.

The above coordination model of CuH_2L is also supported by other spectroscopic methods (Table 6). The values of the A_{II} and g_{II} parameters calculated from the EPR spectra confirm the number of nitrogen donors around the metal ion. Moreover, the parameters of charge-transfer bands (CD, UV/Vis) and d-d bands (UV/Vis) change significantly with an increase in the concentration of this species (see Figure 2). The formation of two positive and one negative Cotton effects in the CD spectra (Figure 2, part a, Table 6) is observed. The effects at 260 and 300 nm most probably correspond to $NH_2 \rightarrow Cu^{II}$ CT transitions and those at 370 nm to the $O^- \rightarrow Cu^{II}$ one. The distinct shoulder on electronic absorption spectra around 355 nm suddenly appears around pH 5.5 and its intensity also increases with the rise of the CuH_2L fraction (Figure 2, part b). The d-d band parameters obtained from UV/Vis spectra reflect these changes, while the intensity of this band in the CD spectra is very low and remains at this level until about pH 10 (Figure 2, part b). It is worth stressing that all applied spectroscopic methods show persistence of spectral parameters with the appearance of the following three species. With an increase of pH to 9 solutions containing CuHL, CuL and $CuH_{-1}L$ complexes give very similar spectra. All these species differ from each other by the proton contents only. The values of their deprotonations fit the range 7–9, characteristic for amine group deprotonation.

Table 6. Spectroscopic parameters of particular complex forms of Cu^{II}-neomycin B, 1:1 system.

Species	UV/Vis[a]		CD[a]		EPR[b]	
	λ	ε	λ	$\Delta\varepsilon$	$A_{\parallel}$	$g_{\parallel}$
			700[c]	–0.23		
CuH_2L + CuHL +	616	65	370[d]	+0.54	184	2.24
CuL + $CuH_{-1}L$	356[sh]	270	300[e]	+1.77		
			261[e]	–5.51		

[a] λ [nm], ε and $\Delta\varepsilon$ [M^{-1} cm^{-1}]. [b] A_{II} [Gs]. [c] d-d transition band. [d] CT: $O^- \rightarrow Cu^{II}$. [e] CT: $NH_2 \rightarrow Cu^{II}$, [sh] shoulder.

At about pH 10, the solution of the Cu^{II}-neomycin complex changes its color from deep blue to violet. CD spectra obtained under these conditions present a total disappearance of the charge-transfer band at 370 nm and a distinct decrease of the band intensity at around 260 nm, probably suggesting the stepwise hydrolysis of the bound neomycin molecule, as already reported.[13] Mass spectra recognize this process already at pH 8.0, though to a very low extent (Table 2).

Two-Centered Cu^{II}-Neomycin B Complexes

A unique feature of the copper(II)-neomycin system is the formation of two-centered complexes, occurring at excess concentrations of the metal ion. Such complexes appear below pH 6, although in the pH range 4–6 mononuclear species also occur (Figure 5). However, their concentration

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

does not exceed 15% of the total amount of Cu^{II}. It is worth noting that species having the stoichiometry CuH_5L and CuH_4L, present in this system, do not appear in potentiometric titrations for the equimolar Cu^{II}-antibiotic system. It therefore seems likely that either the double excess of Cu^{II} ions over neomycin favors its deprotonation, and subsequent coordination to the metal, or the concentration of both complexes in the 1:1 system is too low for pH-metric detection. Table 7 shows the stability constants for dinuclear species, while Figure 5 presents the course of CD spectral parameters depending on the pH of the solution. The $\Delta\varepsilon$ values of d-d transition bands both for 1:1 and 2:1 systems are overlaid on the speciation diagram for the dinuclear Cu^{II}-neomycin complexes. Apparently, with an excess of the metal ion, an increase of the d-d band intensity follows the formation of the two-centered complexes. Around pH 7.5, where only the 2:1 complexes exist in solution, the CD parameters are stable (Figure 5).

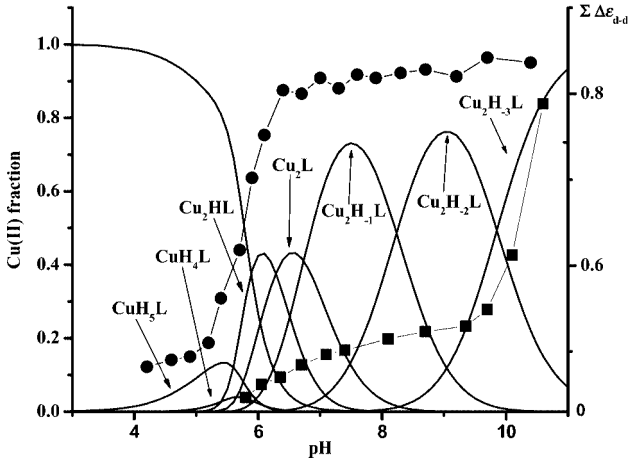

Figure 5. The speciation diagram for Cu^{II}-neomycin B complex at 2:1 molar ratio with $\Delta\varepsilon$ of d-d bands on CD spectra obtained for the 1:1 (■) and 2:1 (●) systems overlaid.

$Cu_2H_{-2}L$	2.65(6)
$Cu_2H_{-3}L$	–7.19(2)

In order to ascertain the possibility of a Cu–Cu interaction, XAS spectra were obtained. Figure 6 shows the edge region of the spectra of the studied samples indicating different copper environments while keeping the edge energy values characteristic of Cu^{II} constant, as judged by the position of the main transition at about 8990 eV. The edge shape is characteristic for Cu^{II} complexed to nitrogen or oxygen donors.[21] The 1s-3d pre-edge absorption at ca. 8980 eV are all extremely small and indicate centrosymmetric Cu^{II} binding sites as present in Jahn–Teller distorted tetragonal or square-planar copper complexes.[22] Hence we conclude that the concentrated samples (1 and 2), regardless of the molar ratio, show similar edges resembling that of the free Cu^{II}_{aq}, while the 2 mM sample (3) displays 1s-4p transitions at about 8988 eV and more complex white line transitions (see Figure 6).

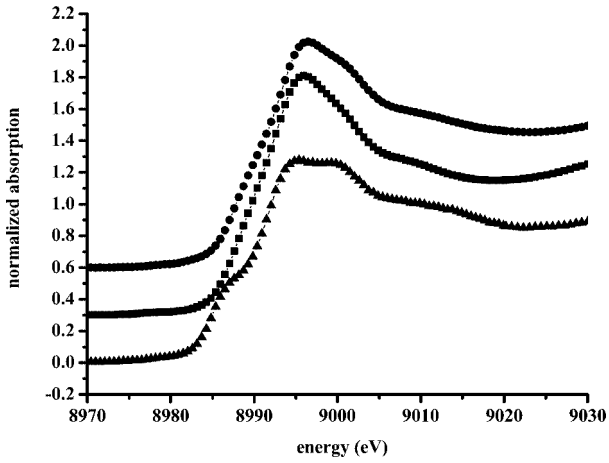

Figure 6. Comparison of the X-ray absorption edges for the Cu^{II}-neomycin B 2:1 complex, Cu^{II} 100 mM (■), Cu^{II}-neomycin B 2:1 complex, Cu^{II} 2 mM (▲) and Cu^{II}-neomycin B 1:1 complex, Cu^{II} 100 mM (●).

The EXAFS spectrum of the Cu^{II}-neomycin B complex 2:1, (100 mM, sample 1) together with its Fourier transform is reported in Figure 7, parts a,b. The spectrum is characteristic of all light O/N type scatterers and, despite the presence of slight distortions due to multiple scattering effects from outer shell atoms, it can be well simulated without introducing multiple scattering contributions into the calculations. The contribution to the total EXAFS of the first shell ligand can be evaluated in four O/N divided into two shells of two donors at 1.94(1) Å and two donors at 2.02(1) Å (see Table 8). Adding a further shell of two N/O atoms at 2.74(2) Å significantly improves the fit leading to a classical Jahn–Teller distorted elongated octahedron for the Cu^{II} coordination. As already indicated by the edge shape the EXAFS spectrum of sample 2 (Cu^{II}-neomycin B 1:1 complex, 100 mM) as with the previous one, can be simulated by a 4+2 type of Cu^{II} coordination consisting of four N/O atoms at 1.98(1) Å and two N/O atoms at 2.32 Å and 2.83 Å, respectively.

Due to the low copper concentration the spectrum of sample 3 (Cu^{II}-neomycin B 2:1 complex, 2 mM) is much noisier than the others. However, the EXAFS (Figure 8, a) displays features, which can be reproduced only by introducing multiple scattering (MS) path contributions from atoms lying in a rigid scaffold containing almost colinear arrangements of atoms. Together with the shape of the edge region, this evidences a significantly different Cu^{II} coordination with respect to the same complex in a more concentrated solution (sample 2). Here Cu^{II} is bound to two N/O atoms at 1.96(1) and 2.00(1) Å and two N/O atoms at 1.91(1) and 1.96(1) Å. The outer shell features evident in the spectrum Fourier transform (Figure 8, b) can be adequately modeled by the MS from outer shell atoms bound

to a rigid, bidentate, N/O type ligand. The presence of MS effects makes it impossible to detect the probable presence of two axial O/N ligands between 2.3–2.8 Å as seen in samples 1–2.

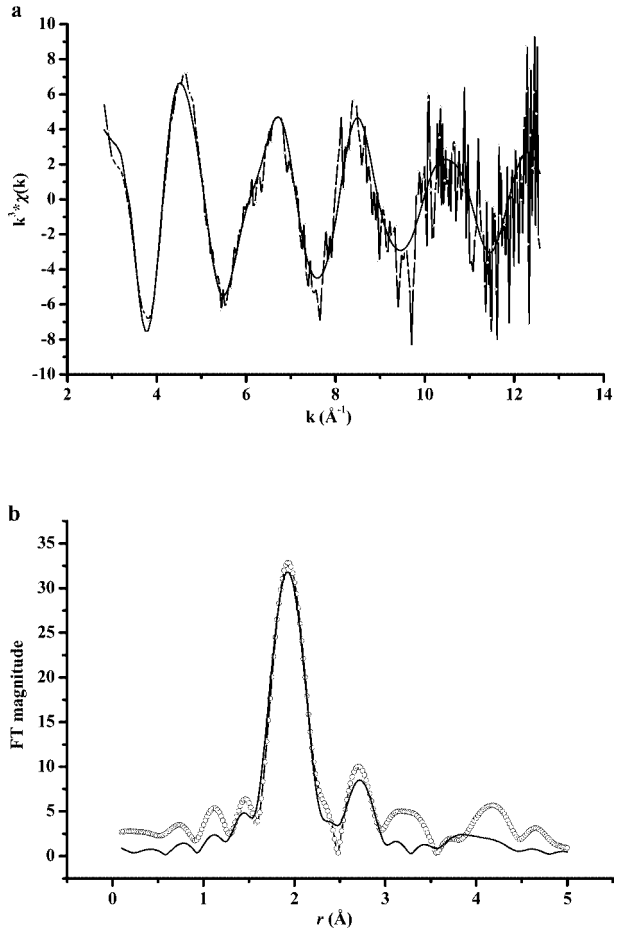

Figure 8. Comparison of experimental (open circles) and theoretical (continuous line) EXAFS data (a) and of their Fourier transform (b) for the Cu^{II}-neomycin B 2:1 complex at 2 mM concentration. The fitting parameters are reported in Table 8.

EXAFS is able to detect metal-metal distances when they are in the 3.5–4.0 Å range. Furthermore, at longer distances the Cu–Cu scattering in nonordered systems like solutions is very weak and can be hidden in the background due to the scattering of light atoms (C, N, O), lying at about the same distance from the metal.[23] However, there is no evidence of Cu–Cu scattering in the case of the neomycin complexes. If there are two Cu atoms bound per neomycin molecule, they should be located at distances larger than 3.5 Å. Lack of the spin relaxation on the EPR spectra, which were obtained under the same conditions, confirms that both metal ions are separated and are most probably located at different rings of the antibiotic.

Mass spectrometry brings additional evidence for the Cu^{II}_2-neomycin complex formation. The distinct peak at *m*/*z* of ca. 739 is observed (Table 2). Its intensity is intermediate but several further peaks originating from the variety of adducts occur at higher values of *m*/*z*. The peaks with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

m/*z* ca. 788, 820, 840, 857 and 918 correspond with adducts formed by two Na, two K, perchlorate, Na + sulfate and three carbonate ions, respectively (data not shown in Table 2).

Conclusions

The results obtained indicate that neomycin B, compared with the other previously investigated aminoglycosides, binds copper(II) ions with the highest affinity. The reason that it happens may be found within the binding pattern. Three-ring aminoglycosides, i.e. kanamycin A and B, tobramycin or geneticin, coordinate Cu^{II} ion mostly by their terminal amino sugar donors and not by the amines of the deoxystreptamine residue, in contrast with what has been presently demonstrated in the case of the four-ring neomycin. Cu^{II} coordination by the donors of this ring not only leads to an increase in stability of the complexes but also leaves the amino groups of the A and D rings uninvolved in any interaction with the metal ion. As a consequence, at excess copper(II) concentrations, a second metal ion may be bound by neomycin B, most probably at a site provided by ring D. In fact, none of its donor groups is directly involved in the coordination process of the first Cu^{II}, while ring A donates a hydroxyl group for axial complex stabilization. Formation of dinuclear species is a unique feature of neomycin B within all of the Cu^{II}-aminoglycoside systems investigated so far.

Experimental Section

Materials: Neomycin B, $CuCl_2$, $Cu(ClO_4)_2$, $Cu(NO_3)_2$, KNO_3, $NaClO_4$, 1,2-ethanediol, DCl, NaOD, TSP-d_4, 3-(trimethylsilyl)-[2,2,3,3-d_4] propionate sodium salt and all other simple chemicals were purchased from Sigma Chemical Co. (St. Louis, MO). Deuterium oxide (99.95%) was obtained from Spectra2000 s.r.l.

Potentiometry: Potentiometric titrations of neomycin B and its complexes with Cu^{II} in the presence of 0.1 M KNO_3 were performed at 25 °C using pH-metric titrations over the pH range 3–12 (Molspin automatic titrator, Molspin Ltd, Newcastle upon Tyne, UK) with 0.1 M NaOH as titrant. Changes in pH were monitored with a combined glass-Ag/AgCl electrode (ATI Russell pH Ltd, Fife, Scotland) calibrated daily in hydrogen ion concentrations by HNO_3 titrations.[24] Samples contained 1 mM neomycin B and Cu^{II}: antibiotic molar ratios of 1:1, 1:2 and 2:1 were used. The data were analyzed using the SUPERQUAD program.[25] Standard deviations computed by the SUPERQUAD program refer to random errors only.

Electronic Absorption (UV/Vis): The electronic absorption spectra were recorded at 25 °C with a Beckman DU-650 (Beckman, Palo Alto, CA) spectrophotometer over the spectral range of 200–900 nm, in a 1 cm cell. The samples contained a 2.5 mM Cu^{II}-neomycin B complex at a 1:1 molar ratio. The experiments were performed in 0.1 M $NaClO_4$ to keep a constant ionic strength, analogous to that used in the potentiometric titrations.

CD Spectroscopy: The spectra were recorded at 25 °C with a Jasco J-715 spectropolarimeter (JASCO, Japan Spectroscopic Co., Hiroshima, Japan), over the range of 200–800 nm, using a 0.5-cm cell. Samples contained a 1:1 or 2:1 Cu^{II}-to-neomycin B ratio at complex concentration of 2.5 mM. For the electronic absorption spectroscopic measurements a 0.1 M aqueous $NaClO_4$ solution was used. The spectra are expressed in terms of $\Delta\varepsilon = \varepsilon_l - \varepsilon_r$, where ε_l and ε_r are molar absorption coefficients for left and right circularly polarized light, respectively.

EPR Spectroscopy: The spectra of the Cu^{II} complex with neomycin B were recorded at 77 K with a Bruker ESP 300E spectrometer (Karlsruhe, Germany) at the X-band frequency (9.3 GHz). 1,2-ethanediol: water (1:2) was used as solvent in the low-temperature experiments to obtain homogeneity of the frozen samples. The concentrations of Cu^{II} in the samples were of 5 mM and Cu^{II}-to-neomycin B molar ratios were 1:1 and 2:1.

NMR Spectroscopy: Neomycin B solutions were made in deuterium oxide (99.95%), adjusted to a 0.1 M ionic strength with KNO_3 and carefully deoxygenated through a freezing-vacuum pumping-sealing-thawing procedure. The desired concentration of copper ions was achieved by using a stock solution of copper nitrate in deuterium oxide (molar ratio Cu^{II}-neomycin: 1:100). The pH was adjusted with either DCl or NaOD. NMR spectroscopic experiments were carried out at 14.1 T and at a controlled temperature (±0.1 K) with a Bruker Avance 600 spectrometer equipped with a Silicon Graphics workstation. TSP-d_4 was used as the internal reference standard. The proton resonance assignment was obtained by COSY and ROESY experiments. Rotating frame Overhauser enhancement spectroscopy (ROESY) was performed at a mixing time of 300 ms and the radio-frequency strength for the spin-lock field was 1.9 KHz. 2D ^1H ^{13}C HSQC shift correlation spectra were obtained in order to detect and assign ^{13}C NMR spectra at relatively low concentrations. Proton spin-lattice relaxation rates ($R_1 = 1/T_1$) were measured with the inversion recovery pulse sequence or with a combination of it with 2D TOCSY, when imposed by resolution limits. This was obtained by introducing a ^1H 180° pulse followed by a variable delay in front of the TOCSY sequence. Relaxation rates were calculated with regression analysis of the initial recovery curves of longitudinal magnetization components, leading to errors in the range of ±3%. A DANTE pulse train was used to measure selective proton spin-lattice relaxation rates.[26]

Molecular Mechanics and Dynamics Calculations: Molecular structures were generated by the HYPERCHEM software package [HYPERCHEM, Hypercube release 7.5 for Windows; Hypercube Inc.: Waterloo, ON, 2002], implemented on a Pentium 120 MHz PC. Charges were calculated by ZINDO-1 semi-empirical methods, and the model was then subjected to 25 ps unrestrained molecular dynamics at 300 K with the MM+ force field. The H–Cu and C–Cu distances, as obtained by NMR spectroscopic experiments, were introduced as restraints for the final 25 ps MD run at 300 K.

XAS Data Collection and Analysis: XAS data at the copper edge were collected at DESY (Hamburg, Germany) with the EMBL bending magnet beam line D2 equipped with a Si(111) double crystal monochromator with an energy resolution of 1.6 eV at 8980 eV. The DORIS-III storage ring was operated under normal conditions (4.5 GeV, 90–140 mA). The second monochromator crystal was detuned to 50% of its peak intensity in order to reject higher harmonics. Ionization chambers in front of and behind the sample were used to monitor the beam intensity. The sample cells were mounted in a 2-stage Displex cryostat (modified Oxford instruments) and kept at 20 K during data collection.

The samples used for data collection are as follows:

1. Cu^{II}-neomycin B complex at a 2:1 molar ratio, Cu^{II} conc. 100 mM

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2. Cu^{II}-neomycin B complex at a 1:1 molar ratio, Cu^{II} conc. 100 mM

3. Cu^{II}-neomycin B complex at a 2:1 molar ratio, Cu^{II} conc. 2 mM

For samples 1 and 2 the data were collected at the copper edge (ca. 8990.0 eV at the edge jump inflection point) by monitoring the sample absorption, while for the more dilute sample 3 the Cu-K_α fluorescence was detected with an energy discriminating 13 element Ge solid state detector (Canberra). The Bragg reflections of a static Si(220) crystal in back-reflection geometry have been used for the absolute energy calibration of the copper spectra.[22] For samples 1 and 2 three to eight spectra were collected for each sample from 8410 to 9810 eV with variable step widths. In the XANES and EXAFS regions steps of 0.3 and 0.6–1.5 eV were used, respectively. For sample 3 only two scans could be collected and the final spectrum resulted from the averaging. The scans spanned the 8500–9810 eV energy range with variable steps in the different regions of the spectrum. After inspection of each scan for edge consistency, the data were normalized by the edge jump and averaged. The EXAFS was then extracted by subtracting the slowly varying atomic background fitted with a cubic spline. Data reduction to extract the EXAFS spectrum was based on standard procedures and performed with the EXPROG software package.[27] The full, k^3 weighted, EXAFS spectra have been compared with theoretical simulations obtained by utilizing the rapid curved multiple scattering theory implemented in the set of programs EXCURVE 9.20.[28] The whole spectrum was analyzed by simulation by varying the atom types and the coordination numbers and iteratively refining the distance (R) and the Debye–Waller factor ($2\sigma^2$) for each atomic shell. The quality of the fit was assessed by the goodness of fit function through the parameter ε^2 which accounts for the degree of over determinacy[29] and by the R factor as defined within EXCURVE 9.20.[28] The pre-edge peak (1s-3d electronic transition at ca. 8980 eV) areas were calculated by subtracting an arctangent function from the normalized edge spectra and integrating over the range 8975–8985 eV.

Mass Spectrometry: The mass spectra were obtained with a Finnigan Mat TSQ 700 instrument (Thermo-Finnigan, Bremen, Germany), using the ESI (electro-spray ionization) technique with N_2 as carrier gas, and flow-rate of 2 μL/min. Three kinds of samples were investigated at pH 8.0 (adjusted with acetic acid and ammonium carbonate): free neomycin B and Cu^{II}-neomycin B complex at 1:1 and 2:1 ratios. All samples were prepared as water solutions. Then methanol was added to a final concentration of 50%, in order to decrease surface tension during sample evaporation. Final sample concentrations were: neomycin B, 0.25 mM and Cu^{II}, 0.25 or 0.5 mM.

A Straightforward Route to Copper/Zinc Oxide Nanocomposites: The Controlled Thermolysis of $Zn[Cu(CN)_3]$

Yanzhi Guo,[a] Rainer Weiss,[a] and Matthias Epple*[a]

Keywords: Cyanides / Copper / Zinc / Thermochemistry / EXAFS spectroscopy

Copper–zinc nanocomposites were prepared by thermolysis of copper–zinc cyanides under mild conditions. Two different routes were used for the preparation of the cyanide complex: A batch precipitation method and the continuous overflow precipitation method. The thermolysis of the cyanides was studied in-situ by thermogravimetry coupled with infrared spectroscopy (TG-IR) and by thermogravimetry coupled with mass spectroscopy (TG-MS). The structure of the nanocomposites was investigated by X-ray powder diffraction (XRD) and extended X-ray absorption fine structure (EXAFS). Geometric models were suggested on the atomic scale based on EXAFS results for the precursor, the mixed oxides (CuO/ZnO), and the reduced copper–zinc samples (Cu/ZnO, i.e. catalyst for methanol synthesis). In the batch precipitation method, the influence of temperature on the morphology of the thermolysis products was explored. In the continuous overflow method, the morphology of the Cu–Zn cyanide complex was investigated as a function of concentration and residence time. A high solution concentration and a short residence time (equivalent to a high flow rate) led to smaller particles.

Introduction

Copper–zinc oxide nanocomposites can be obtained in a variety of morphologies, including thin films,[1] nanowires[2] and nanoparticles.[3] High surface area copper/zinc oxide is an active catalyst for methanol synthesis, for water-gas shift reactions, and for various hydrogenations.[4] It is widely accepted that zinc oxide can improve the dispersion of copper and thereby the catalytic activities.[5] Copper–zinc oxide nanocomposites are usually prepared by co-precipitation from aqueous solutions. Typically, a mixed solution of copper and zinc salts (usually nitrates or acetates) is prepared and the precipitation of both carbonates is induced by addition of sodium or ammonium carbonate whilst stirring, followed by drying and calcination.[6–9] The particle size and crystallinity of the products can be adjusted by the pH, the concentration, the stirring rate, the duration of precipitation and aging, and the calcination conditions.[10] Pollard et al.[4] used the minerals georgeite $[Cu_5(CO_3)_3(OH)_4{\cdot}6H_2O]$ and azurite $[Cu_3(CO_3)_2(OH)_2]$ as precursors for copper–zinc mixed oxides. Recently, a nonaqueous organometallic route was developed by Hambrock et al.[11] and uniform copper–zinc nanoparticles were obtained. They used $Cu[OCH(Me)CH_2NMe_2]$ and Et_2Zn as precursors. The thermolysis was carried out in the coordinating solvent hexadecylamine at elevated temperatures and nano-scale colloidal copper–zinc systems with different zinc contents were obtained. Zhou et al.[2] prepared copper–zinc nanowires by heating CuI_2 and ZnI_2 in a dynamic oxygen atmosphere. A self-catalysed vapour-liquid-solid growth mechanism was suggested.

Polymeric metal cyanides represent a homogeneous mixture of the individual metals on the atomic length scale. The heterogeneous mixing of individual compounds is therefore avoided. The controlled thermolysis of these compounds can be carried out at comparatively low temperature due to the presence of a suitable organic leaving group, i.e. the cyanide in the precursors. A higher temperature is usually required in conventional syntheses to achieve a sufficiently fast diffusion. We have shown that the composition as well as the crystal structure of the bimetallic Fe–Sn and Ru–Sn composites can be fine-tuned by the thermolysis conditions such as time, temperature and the atmosphere.[12–14] Such systems are suitable precursors for the preparation of bimetallic nanocomposites that incorporate the initially blended metals.

Recently we adopted the continuous overflow method for the preparation of calcium phosphate nanoparticles from solution.[15] The particle size, morphology and crystallinity can be adjusted by the process parameters, mainly the residence time (the flow rate of the solutions), and the concentration of the solutions. It was therefore the aim of this work to prepare a suitable cyanide precursor for the Cu/ZnO system and to control its morphology by different crystallisation methods. Thereby, the properties of the final product should be adjustable.[16–18]

Result and Discussion

For the preparation of the Cu–Zn cyanide complex, there are two possible routes as shown in Equations (1), (2) and (3). In both cases, tetrahedral $[Zn(CN)_4]^{2-}$ is formed in the first step (1). Subsequently, both reactions (2) and (3) are likely to occur. Because the stability constant of $[Zn(CN)_4]^{2-}$ (4×10^{19} M^{-4})[19] is smaller than that of $[Cu(CN)_4]^{2-}$ (1×10^{27} M^{-4}),[20] the latter compound is preferred in equilibrium. However, the oxidation state of $[Cu(CN)_4]^{2-}$ is not stable leading to a reduction of Cu^{II} to Cu^{I}. Thus, a transient state of $[Cu(CN)_3]^{2-}$ can be assumed, followed by the formation of $Zn[Cu(CN)_3]$ as precipitate and the release of $(CN)_2$ into the gas phase.

$$4\ CN^- + Zn^{2+} \rightarrow [Zn(CN)_4]^{2-} \quad (1)$$

$$[Zn(CN)_4]^{2-} + Cu^{2+} \rightarrow Cu[Zn(CN)_4]\ \downarrow \quad (2)$$

$$[Zn(CN)_4]^{2-} + Cu^{2+} \rightarrow Zn[Cu(CN)_4] \rightarrow Zn[Cu(CN)_3]\downarrow + \tfrac{1}{2}\ (CN)_2\ \uparrow \quad (3)$$

Batch-Wise Preparation and Thermolysis

For the Cu–Zn cyanide complex prepared by the batch precipitation method, elemental analysis gave 17.5 wt.-% C, 20.2 wt.-% N, 30.3 wt.-% Cu and 31.2 wt.-% Zn. This corresponds to a Cu/Zn/CN molar ratio of 1:1:3.1. We conclude that $Zn[Cu(CN)_3]$ (calcd. 17.4 wt.-% C, 20.3 wt.-% N, 30.7 wt.-% Cu and 31.6 wt.-% Zn) is the main component of the precipitates and a small amount of $Cu[Zn(CN)_4]$ (calcd. 20.6 wt.-% C, 24.0 wt.-% N, 27.3 wt.-% Cu and 28.1 wt.-% Zn) is also present. The infrared spectra of this complex support this assumption (Figure 1). The strong peak at 2155 cm^{-1} is the contribution of CN groups bound (via carbon) to Cu^{I}.[21] An additional contribution at 2217 cm^{-1} is attributed to CN bound (via carbon) to Zn.[22] It is obvious that $Zn[Cu(CN)_3]$ is dominating in the prepared cyanides due to its high peak intensity in the spectra.

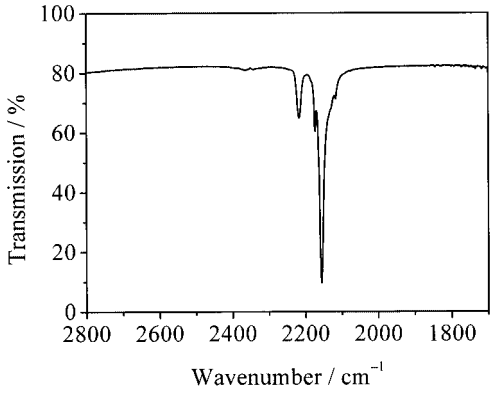

Figure 1. Infrared spectra of $Zn[Cu(CN)_3]$, prepared by the batch precipitation method.

The thermolysis of the copper–zinc complex was studied by thermogravimetric analysis coupled with infrared spectroscopy (TG-IR). When heated up under oxygen, the decomposition of the copper–zinc complex started at about 300 °C (Figure 2, part a). Two steps at about 440 °C and 510 °C can be derived from the TG weight loss curve. The weight loss ceased at about 530 °C. At 1000 °C, only CuO/ZnO was present, as shown by XRD. The total weight loss was about 23%. From the weight loss it can be deduced that the precursor consists of $Zn[Cu(CN)_3]$ (a theoretical weight loss of 22.2% for a complete transformation to CuO/ZnO) rather than $Cu[Zn(CN)_4]$ (a theoretical weight loss of 30.9%). This is in good agreement with the elemental analysis. Two exothermal peaks in the DTA curve correspond to the two steps in the weight loss curve, indicating oxidative combustion.

The infrared spectra in Figure 2 (part b) correspond to the evolved gas phase during heating. The contribution of

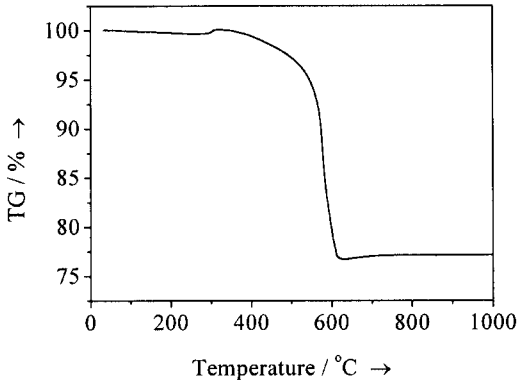
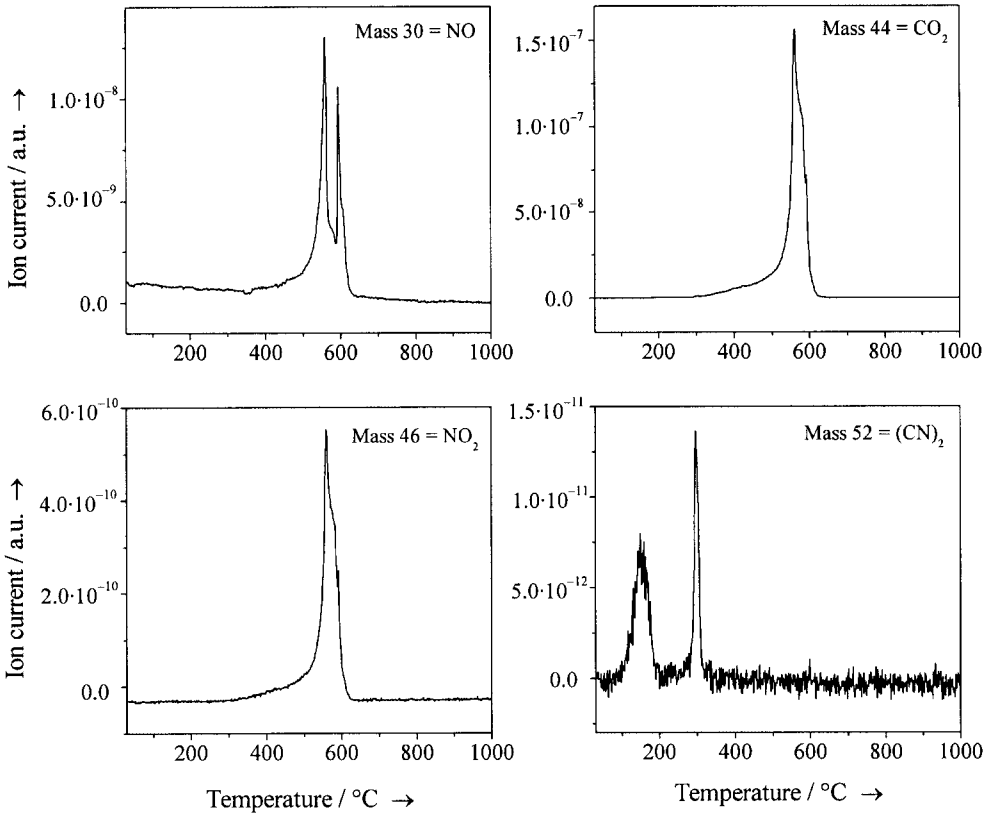
cyanides (CN, at 2343 cm^{-1}) appeared first. Carbon dioxide (C=O, 2360/2312/671 cm^{-1}) was subsequently released at elevated temperature, showing again the two steps at about 440 °C and 510 °C, indicated by the two maxima in the time-resolved spectra.

Another experiment was carried out with thermogravimetric analysis coupled with mass spectroscopy (TG-MS). Air was used as oxidizing gas and the copper–zinc complex was heated from room temperature to 1000 °C. The weight loss started at about 300 °C and stopped at around 620 °C (Figure 3, part a). The thermolysis was shifted to higher temperature compared with the TG-IR results because oxygen was replaced by air and the heating rate was increased from 5 K min^{-1} to 10 K min^{-1}. The total weight loss was



(a)



(b)

Figure 3. (a) Thermogravimetric analysis of $Zn[Cu(CN)_3]$ under air, (b) the corresponding time-resolved mass spectra of four different masses in the released gases (heating rate 10 K min^{-1}).

about 24 wt.-%. The mass spectra in Figure 3 (part b) clearly show the release of gaseous species. Cyanogen [$(CN)_2$: mass 52] was released at low temperatures in two steps, corresponding to the low intensity of the cyanide peak in the IR spectra. The initial "dip" in the TG curve at around 300 °C can be related to a non-oxidative elimination of cyanogen. The release of carbon dioxide, nitrogen monoxide and nitrogen dioxide at higher temperatures occurred in two steps, indicated by two peaks or a broad peak with a shoulder.

The XRD patterns of the thermolysis products under air at different temperatures are shown in Figure 4, part a. Copper oxide and zinc oxide are present. With rising thermolysis temperature, the height of the peaks increased and their width decreased, indicating an increasing particle size (a better crystallinity). The three oxides samples of Figure 4, (part a) were then reduced at 250 °C in H_2/N_2 to Cu/ZnO. The effects of the initial thermolysis temperatures under air are also represented in the XRD patterns of the reduced samples (Figure 4, part b).

EXAFS analysis was performed to investigate the crystal structure of the copper zinc cyanide complex (no single crystals could be obtained so far), of the oxide mixtures (CuO/ZnO), and of the reduced samples (Cu/ZnO). Figure 5 (part a) shows the Cu *K*-edge EXAFS Fourier transform magnitudes (FTs) of the complex $Zn[Cu(CN)_3]$. The nearest neighbours derived from the FTs were fit as 3 carbon atoms at 1.92 Å (Table 1, part a). Another carbon atom appeared at a larger distance, at 2.37 Å. This can be ascribed to different Cu–CN bonds.[21] In this case the coordination polyhedron around Cu can be described as deformed trigonal pyramid with one CN group at a larger distance. The corresponding nitrogen atoms in cyanide appear at 3.12 Å (3 N) and 3.71 Å (1 N), respectively. The Zn *K*-edge EXAFS Fourier transform magnitude of the complex is shown in Figure 5, part b. As nearest neighbours of zinc, 4 nitrogen atoms are present in a distance of 1.93 Å (Table 1, part b). The second peak indicates the corresponding carbon atoms of the cyanide group at 3.22 Å. In both EXAFS spectra (Cu and Zn), a metallic neighbour can be fit in a

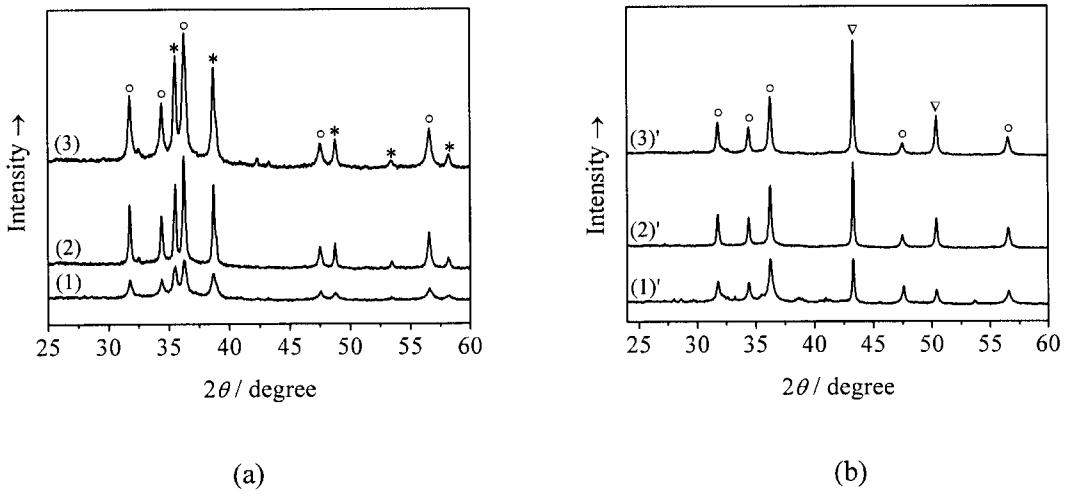

Figure 4. (a) XRD patterns of CuO/ZnO obtained by oxidation of $Zn[Cu(CN)_3]$ at 300 °C (1), 400 °C (2) and 500 °C (3) for 3 hours; (b) XRD patterns of Cu/ZnO obtained by reduction of the corresponding oxide mixtures under H_2/N_2 for 3 hours at 250 °C. The marked peaks correspond to ZnO (o), CuO (*) and Cu (∇).

distance of 5.1 to 5.2 Å. By EXAFS, we cannot distinguish between a copper neighbour and a zinc neighbour, but the given stoichiometry suggests a network which consists of Cu–C–N–Zn units that connect fourfold-coordinated Cu and Zn centres.

Table 1. Fit parameters for the Cu *K*-edge (a) and Zn *K*-edge (b) EXAFS spectra of $Zn[Cu(CN)_3]$ prepared by the batch precipitation method.

(a) $Zn[Cu(CN)_3]$	*R* [Å]	Coordination number	$\sigma^2 \cdot 10^3$ [Å^2]
Cu – 3 C	1.92	3.1	3.3
Cu – C	2.37	1.0	2.8
Cu – 3 N	3.12	3.2	0.1
Cu – N	3.71	1.4	4.2
Cu – 4 Zn	5.12	4.2	5.9
(b) $Zn[Cu(CN)_3]$	*R* [Å]	Coordination number	$\sigma^2 \cdot 10^3$ [Å^2]
Zn – 4 N	1.93	4.4	6.6

Zn – 4 Cu	5.20	4.3	5.8

In the Cu *K*-edge FTs of the CuO/ZnO mixture (Figure 6, part a), the shells of Cu–O and Cu–Cu in CuO are clearly present, supporting the X-ray diffraction data (Table 2, part a).[23] Figure 6 (part b) shows the Cu *K*-edge FTs of the reduced samples (Cu/ZnO). The Cu–Cu distances of the first shell are in the range of 2.69–2.74 Å (Table 2, part b), and compare well to that of the bulk metal (2.56 Å). The coordination numbers were about 12, also in agreement with the cubic close packing of the bulk metal. The second shell of copper was at a distance of about 3.5 Å with a coordination number of 6. The weak peaks at about 1.5 Å may result from CuO or Cu_2O (in bulk Cu_2O the first coordination number is 2 and the Cu–O distance is 1.84 Å; see also the results for CuO).[24] Possibly, this is the result of an oxidation of the copper surface due to exposure to air before the EXAFS measurement.

The morphology of the Cu–Zn cyanide complex and the thermolysis products were studied by scanning electron microscopy (Figure 7, parts a–d). The initial complex crystallized as micrometer-scale platelets which were destroyed

by the following thermolysis. The diameter of the agglomerates decreased at higher thermolysis temperatures, in contrast to the crystallite size determined by XRD, which increased with increasing temperatures. However, the macroscopic morphology is not directly related to the internal domain size.

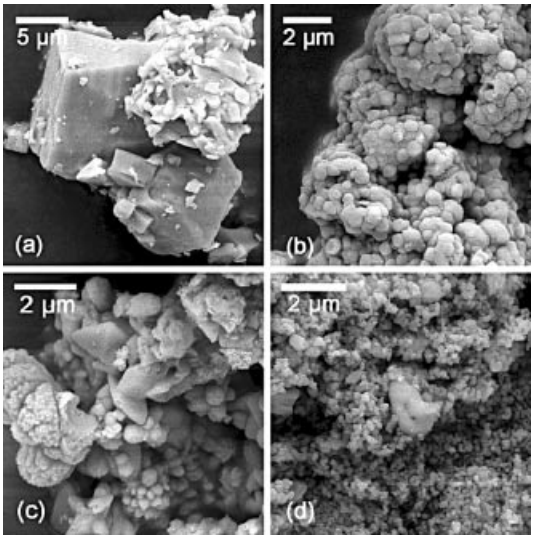

Figure 7. SEM images of $Zn[Cu(CN)_3]$ from batch preparation (a) and its thermolysis products (CuO/ZnO) obtained under air for 3 h at 300 °C (b), 400 °C (c), 500 °C (d), respectively.

Continuous Overflow Preparation

In the continuous overflow precipitation method, the properties of the product can be better controlled in comparison to the simple batch-wise crystallisation. Main variation parameters are the residence time and the concentrations.

We studied the morphology of the Cu–Zn cyanide complex as a function of the solution concentration and the average residence time (related to the flow rate), respectively. First, the concentration was varied at a constant flow rate. It can be seen in Figure 8 parts a–c) that with increasing concentrations of Cu^{2+} and $[Zn(CN)_4]^{2-}$, the complex morphology changed from platelets to spherical particles and the size decreased. Second, the residence time was varied at a constant concentration. This effect is obvious (Figure 8, parts d–f): A shorter residence time led to smaller particles. Hence, we can conclude that higher concentration and low residence time (or high flow rate) both lead to smaller spherical (nano-)particles instead of well-crystalline microcrystals (platelets). Elemental analysis of the sample in Figure 8 (part f) gave a Cu/Zn/CN ratio of 1:1:3.04 (16.8 wt.-% C, 19.6 wt.-% N, 29.0 wt.-% Cu, and 30.6 wt.-% Zn), which indicates that $Zn[Cu(CN)_3]$ was still the main component of the precipitates obtained by continuous overflow method, even at the highest concentration and the shortest residence time.

Conclusions

In summary, a batch-wise and a continuous synthesis method were applied to the precipitation of the copper–zinc coordination compound $Zn[Cu(CN)_3]$. Structurally, this compound consists of Cu–C–N–Zn units that bridge Cu and Zn centres (both in fourfold coordination). With the continuous overflow precipitation method, fine spherical particles are obtained at high solution concentration and short residence time (or a high flow rate). The thermolysis of the cyanides was studied in-situ by TG-IR and TG-MS. Under oxidizing conditions, cyanogen is lost only at lower temperature whereas at higher temperature, thermal decomposition to carbon and nitrogen oxides occurs. The product is a 1:1 mixture of CuO and ZnO which can be reduced to Cu/ZnO, a well-known catalyst.

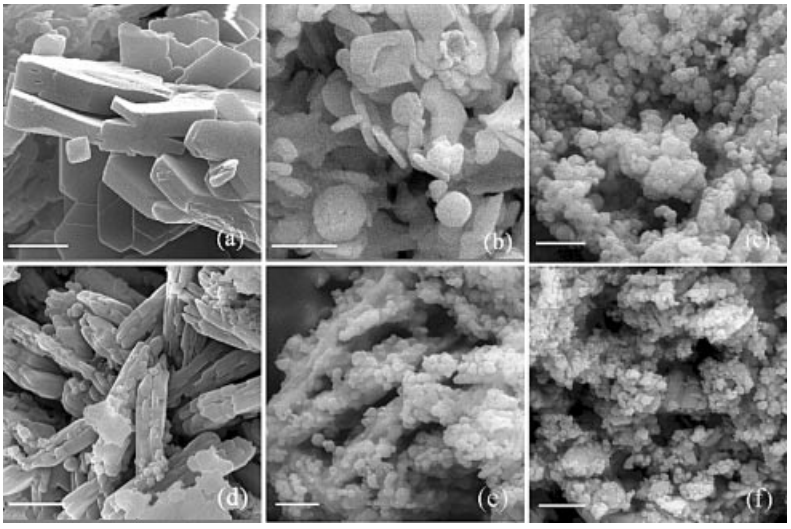

Figure 8. SEM images of $Zn[Cu(CN)_3]$ prepared by continuous overflow method with different $[Zn(CN)_4]^{2-}$ concentrations (residence time of 30 s), i.e., 0.05 mol L^{-1} (a), 0.3 mol L^{-1} (b), 0.4 mol L^{-1} (c) and different residence time (constant concentration of 0.4 mol L^{-1}), i.e., 140 s (d), 30 s (e), 15 s (f). Cu^{2+} and $[Zn(CN)_4]^{2-}$ were always present in stoichiometric ratios (1:1). Scale bar: 1 µm.

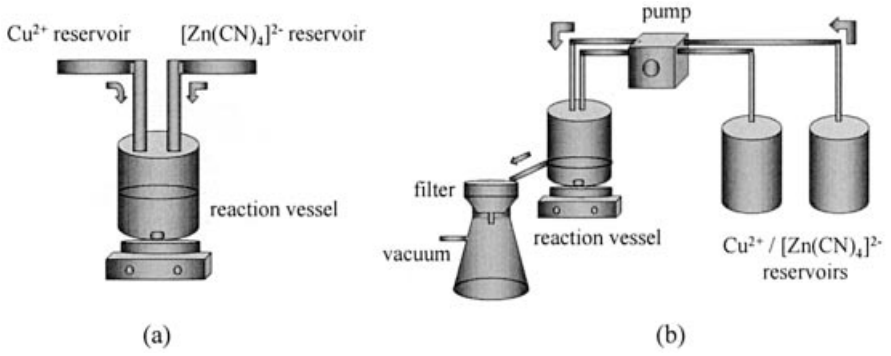

Figure 9. Schematic setups of the batch precipitation method (a) and the continuous overflow method (b).

Experimental Section

In the batch precipitation method (Figure 9, part a), $[Zn(CN)_4]^{2-}$ was prepared by mixing aqueous solutions of zinc sulfate and potassium cyanide. Copper(II) sulfate was then added whilst stirring and copper zinc cyanide was obtained as precipitate. In the continuous overflow precipitation method (Figure 9, part b), the aqueous solutions of $K_2[Zn(CN)_4]$ and $CuSO_4$ were pumped at different flow rates (giving different residence time) into a stirred precipitation vessel at room temperature. The overflowing suspension was immediately filtered. The precipitate was dried overnight under air at room temperature and stored in sealed vials until further characterization. All reagents were used in stoichiometric amounts, i.e. $n(Cu) = n(Zn)$.

The controlled thermolysis of the cyanides was carried out in a horizontal quartz tube reactor with an inner diameter of 30 mm. The thermal decomposition was carried out under air at 300, 400 and 500 °C for 3 hours. The mixed oxides were then reduced under hydrogen/nitrogen (5:95, *v*:*v*) at 250 °C for 3 hours.

Combined thermogravimetry-infrared spectroscopy (TG-IR) was carried out with a Netzsch STA 409 TG-DTA/DSC apparatus connected to a Bruker Vertex 70 infrared system for in-situ gas analysis. Samples were heated from room temperature to 1000 °C at a rate of 5 K min^{-1} under O_2 at a flow rate of 50 mL min^{-1}. The evolved gases were monitored in-situ by infrared spectroscopy (IR). The infrared spectra were all corrected for background absorption. Background spectra were recorded at room temperature before the start of the experiment with the cavity filled by flow gas. Thermogravimetry-mass spectroscopy (TG-MS) was carried out with a TGA 7 Perkin–Elmer thermobalance coupled to a quadrupole mass spectrometer (OmniStar™, Pfeiffer). The sample was heated up with 10 K min^{-1} under synthetic air (20.5% oxygen in nitrogen) at a flow rate of 100 mL min^{-1}.

X-ray diffraction was carried out at room temperature at beamline B2 at the Hamburger Synchrotronstrahlungslabor (HASYLAB) at Deutsches Elektronen Synchrotron (DESY), Hamburg, Germany.

The morphology of the thermolysis products was studied by scanning electron microscopy (LEO Gemini 1530). Extended X-ray absorption fine structure (EXAFS) spectroscopy was carried out at beamline E4 at HASYLAB/DESY. The programs SPLINE and XFIT[25] were used for quantitative data evaluation. Theoretical standards were computed with the program FEFF 6.01a.[26] The amplitude reduction factor S_o^2 was fixed to 1. Variation parameters were the bond lengths, the coordination numbers, the Debye-Waller factors (σ^2), and the zero-energy correction (E_o).

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft within the scope of the Collaborative Research Center SFB 558: Metal–substrate interactions in heterogeneous catalysis. We are grateful for Prof. M. Muhler for TG-MS measurements. We thank J. Gering for experimental assistance. Synchrotron beamtime by HASYLAB at DESY was generously provided.

Influence of 2-Aminopyridine on the Formation of Molybdates under Hydrothermal Conditions

Katikaneani Pavani[a] and Arunachalam Ramanan*[a]

Keywords: Hydrothermal synthesis / N ligands / Molybdenum / Crystal structure

The hydrothermal reaction of an aqueous ammonium heptamolybdate solution with first-row transition metal salts in the presence of 2-aminopyridine at around 180 °C and under autogenous pressure yields several molybdates, such as the 1D chains in $(C_5N_2H_7)_4Mo_8O_{26}$ (**1**), zero-dimensional $(C_5N_2H_7)_6Mo_7O_{24}\cdot 3H_2O$ (**2**), and the first synthesis of Lindgrenite $[Cu_3Mo_2O_8(OH)_2$ (**3**)] The structures of these materials were established by single-crystal and powder X-ray diffraction techniques. The crystal structures of wolframite-based $MnMoO_4$ (**4**) and $ZnMoO_4$ (**5**) were established by powder X-ray diffraction. The role of 2-aminopyridine (2-ampy) in the formation of the different solids under hydrothermal conditions is discussed.

Introduction

Molybdenum oxide based materials are of contemporary interest due to their promising applications in the area of catalysis, sorption, electrical conductivity, magnetism, photochemistry, sensors, and energy storage.[1–5] Among these, transition-metal-containing molybdates are attractive candidates due to their structural, electronic, and catalytic properties.[6–10] For example, β-$FeMoO_4$ and $Fe_2(MoO_4)_3$ have been employed in the synthesis of formaldehyde from methanol on a commercial scale, and Fe–Mo–O catalysts exhibit good activity for the oxidation of toluene to benzaldehyde.[11] In addition, it has been found that β-$FeMoO_4$ is a very good precursor of catalysts for hydrodesulfurization (HDS) processes,[12] and cobalt and nickel molybdates are important components of industrial catalysts for the partial oxidation of hydrocarbons and precursors in the synthesis of catalysts for hydrodesulfurization (HDS). Manganese- and nickel-containing molybdates are also potential electrode materials in rechargeable lithium batteries.[13] In recent times, soft chemistry routes, including hydrothermal reactions, have been commonly employed for the manipulation of hybrid molybdates in the presence of organic molecules as structure directors. The role of organic amines has been extensively investigated in the formation of discrete polyoxometalate clusters to three-dimensional networks of molybdenum oxide based materials.[14–20] It is well known that when polyoxomolybdate(POM)-based solids are crystallized from aqueous solution (either under ambient or hydrothermal conditions) in the presence of organic amines, organic/inorganic hybrid salts are invariably formed. These may be salts between organic cations and discrete polyoxomolybdate anions or composite solids with extended POM anions incorporated with organic cations. If an additional transition metal ion is present, the metal complex can either be present as a countercation or as part of the extended network linking POM cluster anions. An examination of the synthetic methodologies reported in the literature suggests that there have been very few attempts to rationalize the reactivity pattern in the formation of these solids. It is important to examine the role of organic amines in a systematic fashion to understand the critical issues involved in controlling the reaction and hence the structure of molybdates, even though hydrothermal reactions are commonly termed as "black-box" in nature. This paper is an attempt in this direction to identify the phases formed in the presence of an organic amine by employing identical reaction conditions and varying only the nature of the metal. We preferred the aromatic diamine 2-aminopyridine ($pK_a \approx 6.9$) as it forms weak complexes with transition metals and hence is readily labile in the presence of hydroxy ligands (Scheme 1) during hydrolysis and condensation reactions to produce an –M–O–Mo–O–M– network. Also, the amine has good solubility in aqueous solution and is hydrothermally stable. This paper describes the synthesis and characterization of several molybdates and proposes a rational model to explain the influence of 2-aminopyridine on their formation under hydrothermal conditions.

Results and Discussion

Powder X-ray diffraction analysis showed that single-phase crystalline molybdates were obtained only from the reactions containing manganese, cobalt, nickel, copper, or

zinc. In the case of iron(II) chloride, hydrothermal treatment led to amorphous products. Table 1 lists the experimental conditions applied for the hydrothermal synthesis of molybdates, along with phase identification as established by powder and single-crystal X-ray diffraction. Scheme 2 shows the molybdates that were crystallized under hydrothermal conditions in the presence of 2-ampy. In all cases the yields were much higher than 70% (based on molybdenum) and the compounds were isolated as single phases, as determined by thermal studies and powder XRD. The powder X-ray diffraction patterns of $MnMoO_4$ (**4**) and $ZnMoO_4$ (**5**) are similar and the cell parameters and intensities correspond to the Wolframite structure reported in the literature.[21–23] In the case of cobalt and nickel, we obtained a polyoxometalate-based solid **2** that does not contain cobalt or nickel. Hydrothermal treatment of ammonium heptamolybdate and 2-ampy in the absence of a transition metal led to another new solid **1**. The crystal structures of solids **1** and **2** were further established by single-crystal X-ray diffraction. The hydrothermal reaction of ammonium molybdate solution with copper(II) ions in the presence of 2-ampy resulted in the formation of the pure Lindgrenite phase $Cu_3Mo_2O_8(OH)_2$ (**3**). Interestingly, this is the first laboratory synthesis and characterization of the mineral Lindgrenite. Both powder and single-crystal X-ray diffraction data of the product are consistent with the previously reported

crystal structure of the mineral.[24] This solid does not contain 2-ampy and, in its absence, the hydrothermal reaction yields the well-known hexagonal molybdate $(NH_4)_x$-$Mo_6O_{18}{\cdot}yH_2O$ (**6**).[25,26] However when the reaction was carried out with MoO_3 as a starting precursor it resulted in the formation of compound **2**, which is based on a heptamolybdate cluster**.** This indicates that the heptamolybdate phase is stable under these conditions. Thermal analysis of the solids was carried out under nitrogen (Figure 1). $MnMoO_4$(**4**) and $ZnMoO_4$(**5**) do not show any significant weight loss, thus confirming that they are anhydrous substances. In case of **3**, a broad weight loss in the temperature range 175–400 °C shows the loss of one water molecule to give a final composition of $Cu_3Mo_2O_9$. Both **1** and **2** lose their water molecules and organic groups in multiple steps. Weight loss up to 500 °C is probably due to the loss of water and organic groups and corresponds to the composition determined from single-crystal X-ray analysis.

Crystal Structure of 1

The crystal structure of **1** consists of 2-ampy cations and infinite anionic molybdenum oxide chains that are built from edge-sharing octamolybdate clusters $[Mo_8O_{28}]$ (Figure 2a). The $\{Mo_8O_{26}\}_\infty$ chains propagate along the *a*-axis (Figure 2d). Each chain is surrounded by six others (Figure 3). The interchain regions are filled with 2-ampy cations that participate in extensive, strong hydrogen bonding with cluster oxygen atoms. Each Mo_8O_{28} cluster is hydrogen-bonded to four 2-ampy cations through the terminal oxygen atoms O3 and O10 of the cluster. The crystal data are pro-

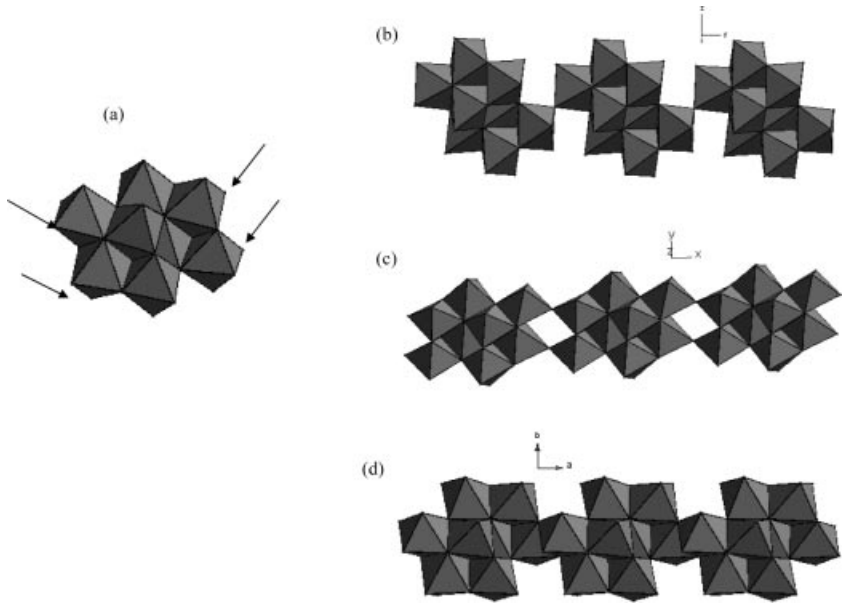

Figure 2. (a) Polyhedral representation of the octamolybdate. Sites through which the subunits are linked into infinite chains in **1** are denoted with arrows. (b) The linkage of octamolybdates through common corners to form chains with the $(Mo_8O_{27})_n^{6n-}$ composition. (c) The linkage of octamolybdates is through pairs of Mo–O–Mo bridges to form a molybdenum oxide chain with the $(Mo_8O_{26})_n^{4n-}$ composition. (d) The linkage of octamolybdates through common edges to form chains with the $(Mo_8O_{26})_n^{4n-}$ composition as in the case of **1**.

vided in Table 2. The Mo–O distances are significantly different due to multiple bonding character and range from 1.687(3) to 2.504 (3) Å. The octamolybdate chains found in **1** are similar to those in two other tetramolybdates, namely $K_2Mo_4O_{13}$[27] and $(NH_4)_2Mo_4O_{13}$.[28] Two other octamolybdates with a slightly different composition, namely $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$ and $(C_4H_{12}N_2)_3Mo_8O_{27}$ ($C_4H_{12}N_2$ = piperazinium ion),[29] and a polymeric octamolybdate [$(MeNC_5H_5)_4Mo_8O_{26}$] reported by Zubieta et al.[30] are also known. The composition of the polymeric solid depends upon the connectivity pattern between the basic octamolybdate fragments. In $(MeNC_5H_5)_4Mo_8O_{26}$, the octamolybdate subunits are connected by linear and symmetrical Mo–O–Mo bridges into infinite chains (Figure 2c), while in $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$ and $(C_4H_{12}N_2)_3Mo_8O_{27}$, the octamolybdate subunits share common corners (Figure 2b). The linkage of octamolybdate blocks through common edges, i.e., the connectivity mode encountered in $(C_5N_2H_7)_4[Mo_8O_{26}]$ (**1**), again results in an $[Mo_8O_{26}]^{4-}$ stoichiometry for the chains (Figure 2d).

Crystal Structure of 2

The crystal structure of $(C_5N_2H_7)_6Mo_7O_{24}\cdot 3H_2O$ (**2**) is that of a heptamolybdate $[Mo_7O_{24}]^{6-}$ based solid. The Mo_7O_{24} cluster anion contains a central $\{Mo_3O_8\}$ core

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

built of three edge-shared MoO_6 octahedral units arranged in a 1×3 rectangular array; two MoO_6 units from above and two from below share the equatorial oxygen atoms at the apices of the octahedra in the rectangle. Each Mo^{VI} atom in the Mo_7O_{24} cluster has a distorted octahedral geometry with an Mo–O bond length in the range of 1.702(3)–2.298(2) Å for terminal and bridging oxygen atoms. Each $Mo_7O_{24}^{6-}$ anion is surrounded by six 2-ampy cations (Figure 4). Each cluster anion exhibits strong H-bonding with six of the 2-ampy cations and only terminal oxygen atoms participate in this H-bonding. Although all six 2-ampy cations are involved in H-bonding, only two of them connect the clusters into an extended 1D chain (Figure 5). The water molecules present also form strong H-bonds among themselves as well as with cluster oxygen atoms. This solid is identical to that reported in the literature, except that we have grown it under hydrothermal conditions.[31] All the bond angles and distances are consistent with Mo_7O_{24} clusters observed in previous reports.[32–34]

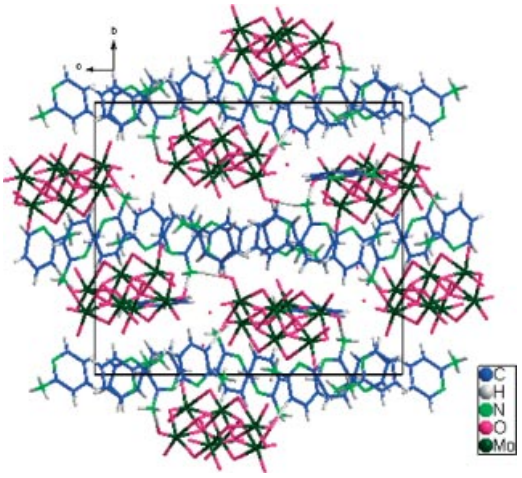

Figure 4. $\{Mo_7O_{24}\}^{6-}$ cluster anions exhibiting H-bonding with water and 2-aminopyridinium cations in **2**.

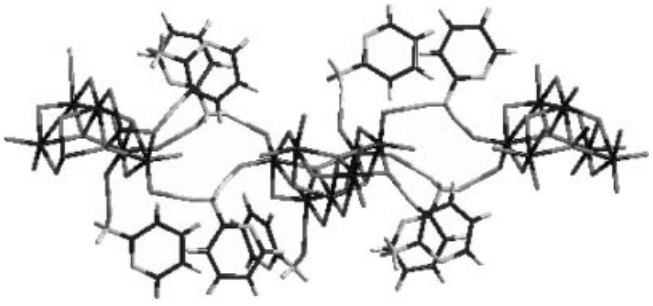

Figure 5. View showing the infinite 1D chain formation of $\{Mo_7O_{24}\}^{6-}$ clusters via the strong H-bonding with 2-aminopyridium cations in **2**.

Crystal Structure of 3

The single-crystal structural analysis of **3** is very similar to that of the naturally occurring mineral Lindgrenite solved by Hawthorne et al.[24] The vanadium analog of **3** has also been reported recently.[35] There are two asymmetric copper atoms in the crystal structure of the synthetic analog of Lindgrenite $[Cu_3Mo_2O_8(OH)_2]$, one of which occurs at the special position, as well as one asymmetric molybdenum and five asymmetric oxygen atoms which all occupy the general position (4e). While the molybdenum atoms are coordinated by four oxygen atoms in a pseudo-tetrahedral arrangement, the copper atoms are pseudo-octahedrally coordinated by oxygen atoms. There is a strong Jahn–Teller distortion around both copper centers, with considerable extension of the apical bonds when compared with the equatorial bonds. The two hydrogen atoms are bonded to O1 and O4. A prominent feature of the Lindgrenite structure is the strips of edge-sharing CuO_6 octahedra that run parallel to the *c*-axis (Figure 6). These strips are cross-linked by MoO_4 tetrahedra that share corners with the CuO_6 octahedra; each MoO_4 tetrahedron links three strips together, with the fourth linkage occurring along the length of one of the strips (Figure 7).

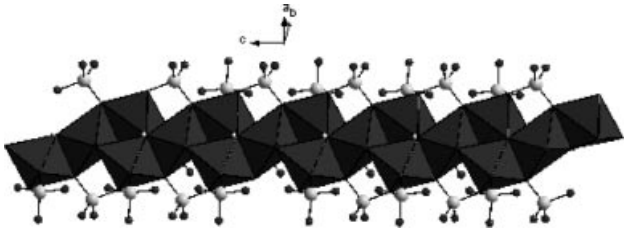

Figure 6. Strips of edge-sharing CuO_6 octahedra running parallel to the *c*-axis in **3**.

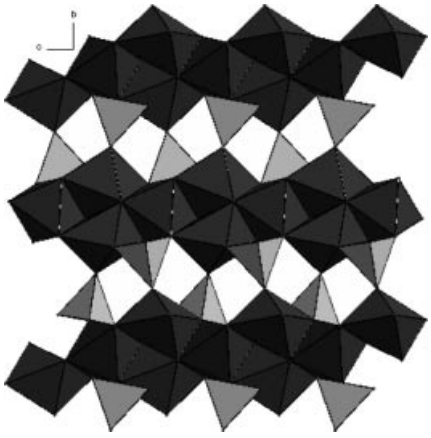

Figure 7. Crystal structure of Lindgrenite (**3**) viewed along the *c*-axis.

Crystal Structures of 4 and 5

The powder X-ray diffraction patterns of $MnMoO_4$ (**4**) and $ZnMoO_4$ (**5**) are isostructural and suggest a Wolframite structure based on the cell parameters and intensities. We did not succeed in obtaining suitable single crystals under our reaction conditions. Both the molybdenum and manganese or zinc atoms in the Wolframite structure are octahedrally coordinated. Each octahedron has two short, two

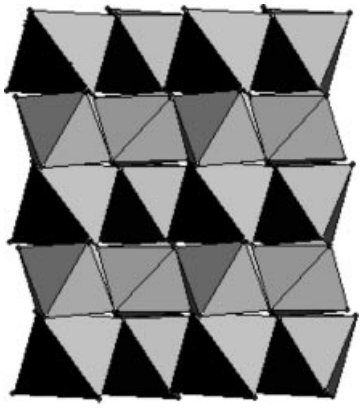

Figure 8. Crystal structural of $MMoO_4$ (M = Mn and Zn).

medium, and two long metal–oxygen bonds (Figure 8). The metal atoms occupy special positions while the oxygen atoms are at general positions. The octahedra are highly distorted with angles ranging from 72.9 (1) to 101.7 (1)° in the molybdenum-containing octahedron and from 75.7(1) to 110.6(2)° in the manganese one. Compounds **4** and **5** have also been synthesized earlier by other groups.[21–23] To the best of our knowledge, however, this is the first report of a low-temperature hydrothermal method for the synthesis of $MnMoO_4$ and $ZnMoO_4$.

Chemistry of the Formation of Molybdates by Hydrothermal Treatment

When heptamolybdates are dissolved in aqueous solution in the presence of 2-ampy (pH ≈ 6.0), other molybdate species such as $[MoO_3(OH)]^-$, $MoO_2(OH)_2(H_2O)_2$, $[Mo_8O_{26}]^{4-}$, and $[H_2Mo_8O_{28}]^{6-}$ may form due to a slight change in the pH and ionic strength of the medium, although heptamolybdate is the predominant cluster at equilibrium. The equilibrium species will change considerably when the aqueous molybdate solution is subjected to hydrothermal treatment.

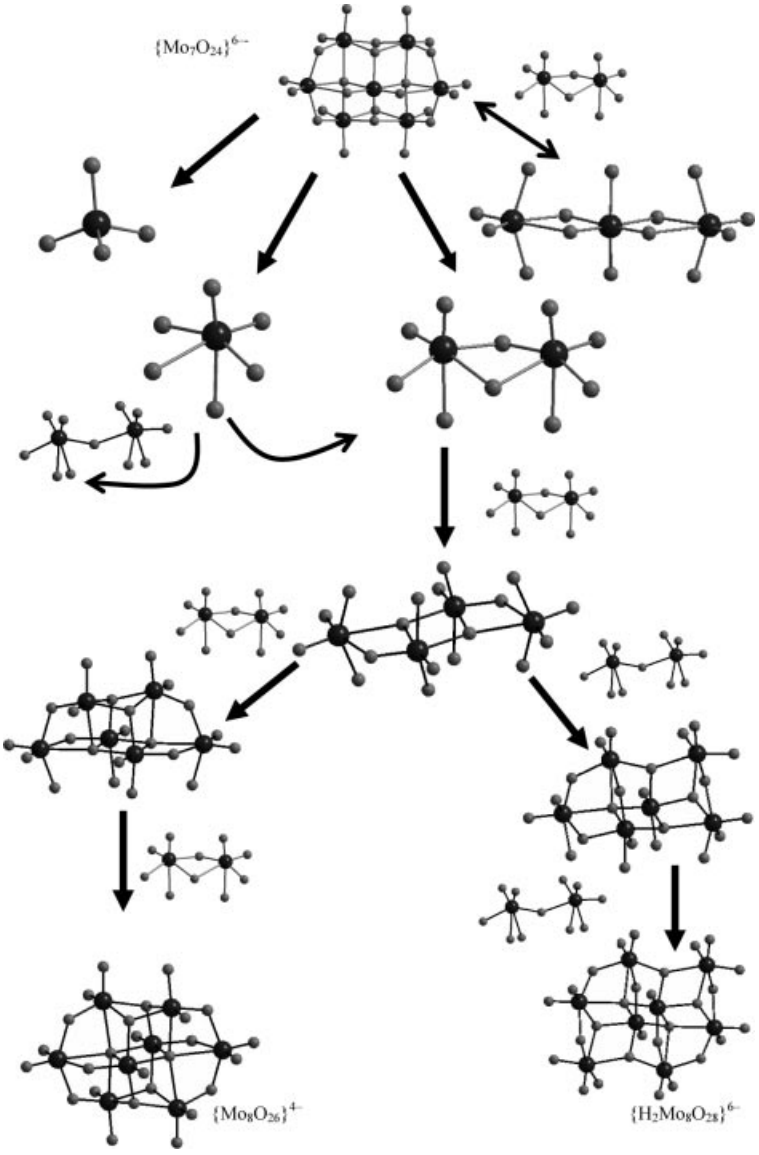

Figure 9. Hypothetical pathway for the self-assembly of polyoxomolybdate cluster anions from heptamolybdates.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Under these conditions, crystallization of a salt or a solid will be dominated by the electrostatic interactions between the polyoxomolybdate anions and the organic cations; secondary interactions taking place between the hydrated metal ions and other minor molybdate cluster anions, along with noncovalent interactions such as hydrogen bonding, may also influence the structure. On the basis of the solids obtained in this study, it is reasonable to assume that the heptamolybdate cluster anion dominates the equilibrium as long as the reaction is carried out under self-assembly conditions at room temperature without the addition of acid or hydrothermal treatment. In addition, other metal ions in the medium (such as cobalt or nickel) do not compete with the organic ligand (2-ampy in our case). As the larger anion prefers a larger cation, we invariably obtain a salt based on heptamolybdate $[Mo_7O_{24}]^{6-}$ along with the organic cation as in **2**. Since heptamolybdates are hardly protonated, the packing of the final solids is influenced by the hydrogen-bonding interaction between the anions, cations and water molecules, as demonstrated in the structure of **2**. The presence of weakly acidic cobalt or nickel hydrates is responsible for keeping the heptamolybdate clusters stable in solution. The reaction carried out in the absence of these metal ions results in the formation of **1**. Under slightly acidic conditions, the heptamolybdate undergoes fragmentation into smaller units, including MoO_4 and MoO_6 units. A few of these smaller fragments of oxomolybdenum clusters can reassemble to form larger clusters such as $[Mo_8O_{26}]^{4-}$, $[H_2Mo_8O_{28}]^{6-}$, etc. (Figure 9). The cluster $[H_2Mo_8O_{28}]^{6-}$, with its large negative charge, is not completely stable in aqueous solution and under hydrothermal conditions tends to condense to form 1D polymeric chains of the composition $[Mo_8O_{26}]^{4-}{}_\infty$; in the presence of 2-ampy, the solid **1** crystallizes out. A similar framework is also known with K^+ and NH_4^+ cations. When we carried out a hydrothermal reaction of MoO_3 rather than ammonium heptamolybdate with 2-ampy, we obtained only the heptamolybdate cluster based solid **2**. Incidentally, **2** was also obtained when a hydrothermal reaction was carried out in the presence of nickel and cobalt ions. This suggests that the formation of POM clusters such as $[H_2Mo_8O_{28}]^{6-}$ and $[Mo_7O_{24}]^{6-}$ depends on the nature of the starting molybdenum precursor. The reactions occurring in the presence of manganese, copper, and zinc favor a shift in equilibrium towards MoO_x^{n-} species. In the case of Mn and Zn, a Wolframite-based $MMoO_4$ structure is stabilized. Unlike other metal ions, copper(II) ions tend to form polymeric chains[36–38] at around this pH, and these readily react with MoO_4^{2-} ions to give Lindgrenite (**3**). However, hydrothermal treatment of ammonium heptamolybdate with copper(II) ions in the absence of 2-ampy results in ammonium-intercalated hexagonal molybdates. We have previously shown that hexagonal molybdates are the most stable phases formed under hydrothermal conditions in the presence of monovalent alkali metal or ammonium ions.[26] Since we also obtained the Lindgrenite phase from the hydrothermal reaction of sodium molybdate and copper chloride solution (pH ≈ 6), 2-ampy provides a suitable pH for the fragmentation of heptamolybdates into tetrahedral MoO_4. The results reported here suggest that 2-ampy has a major influence on the formation of transition metal molybdates.

Conclusions

The hydrothermal reaction of aqueous ammonium heptamolybdate with manganese, cobalt, nickel, copper, or zinc ions in the presence of 2-aminopyridine results in the formation of several crystalline molybdates. A weak base such as 2-aminopyridine can act as a buffer and form weaker complexes with the transition metal, thus preventing its hydrolysis in aqueous solution. The hydrothermal medium can further influence the condensation of the protonated oxomolybdate clusters or the formation of metal molybdates.

Experimental Section

Syntheses: All chemicals were obtained from Aldrich and used without further purification. $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ (0.625 mmol) was mixed with an appropriate amount of transition metal M^{2+} salts (M = Mn, Fe, Co, Ni, Cu, Zn; 5 mmol) and 2-ampy (7.5 mmol) in 18 mL of distilled water (1000 mmol). In order to rationalize the influence of 2-ampy, we also carried out a blank reaction as above without the transition metal chloride. The mixture was transferred into a 30-mL Teflon-lined acid digestion reactor and heated at 180 °C for 2 d and then cooled slowly to room temperature. The pH of the reaction before and after was found to be about 6 in all cases. To investigate the influence of 2-ampy when the molybdenum source is MoO_3, the reaction was carried out by heating the mixture of MoO_3 and 2-ampy in the molar ratio 1:1.5 under the same conditions. In all the cases, the products were washed with water and dried in air at room temperature. All the solids were analyzed by powder X-ray diffraction (Bruker AXS diffractometer with Cu-K_α radiation) for crystallinity and phase identification. TG analyses were carried out with a Perkin–Elmer TGA7 system on well-ground samples under a nitrogen flow with a heating rate of 10 °C min^{-1}. In all cases the phase purity of the samples was established by simulating powder X-ray diffraction patterns on the basis of the single-crystal structure data.

X-ray Crystallography: Single-crystal diffraction studies were carried out with a Bruker SMART CCD diffractometer with Mo-K_α (λ = 0.71073Å) radiation at 28 °C for **1**–**3**. Table 1 lists the experimental parameters used for the single-crystal structure analyses. The software SADABS was used for absorption correction and SHELXTL for space-group and structure determination and refinements.[39,40] The molybdenum atoms were located first and then the remaining atoms were deduced from subsequent difference Fourier syntheses. The hydrogen atoms were located using geometrical constraints. All the atoms except H were refined anisotropically. Least-squares refinement cycles on F^2 were performed until the model converged. Experimental and crystal data are provided in Tables 1 and 2, respectively. CCDC-245096 (**1**) and -249182 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Further details of the crystal-structure investigation for **3** may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number ICSD-415059.

Synthesis and Crystal Structures of $[W(3,6\text{-dichloro-1,2-benzenedithiolate})_3]^{n-}$ (n = 1, 2) and $[Mo(3,6\text{-dichloro-1,2-benzenedithiolate})_3]^{2-}$: Dependence of the Coordination Geometry on the Oxidation Number and Counter-Cation in Trigonal-Prismatic and Octahedral Structures

Hideki Sugimoto,*[a] Yuuki Furukawa,[a] Makoto Tarumizu,[a] Hiroyuki Miyake,[a] Koji Tanaka,[b] and Hiroshi Tsukube[a]

Keywords: Coordination modes / Molybdenum / S ligands / Salt effects / Tungsten

The novel complexes $(Et_4N)_2[W(bdtCl_2)_3]$ (**1a**), $(Ph_4P)_2[W(bdtCl_2)_3]$ (**1b**), $(Et_4N)[W(bdtCl_2)_3]$ (**2a**), $(Ph_4P)[W(bdtCl_2)_3]$ (**2b**), $(C_5NH_6)[W(bdtCl_2)_3]$ (**2c**), and $(Et_3NH)_2[Mo(bdtCl_2)_3]$ (**3a**) ($bdtCl_2$ = 3,6-dichloro-1,2-benzenedithiolate) were prepared and characterized by X-ray crystallographic, UV/Vis spectroscopic, and electrochemical methods. Versatile geometrical changes around the tungsten centers were observed. The trigonal-prismatic structure of the tungsten center in $(Et_4N)_2[W(bdtCl_2)_3]$ (**1a**) is changed to an intermediate structure between trigonal prismatic and octahedral upon solid-state oxidation of the complex to $(Et_4N)[W(bdtCl_2)_3]$ (**2a**). Replacement of the counter-cation of $(Et_4N)_2[W(bdtCl_2)_3]$ (**1a**) with Ph_4P^+ also resulted in geometrical changes and somewhat of an octahedral contribution is included in $(Ph_4P)_2[W(bdtCl_2)_3]$ (**1b**). However, almost the same coordination structures are present in the series of structures $(Et_4N)[W(bdtCl_2)_3]$ (**2a**), $(Ph_4P)[W(bdtCl_2)_3]$ (**2b**), and $(C_5NH_6)[W(bdtCl_2)_3]$ (**2c**), with an oxidation number of +5. These structures adopt an intermediate geometry between trigonal prismatic and octahedral. No geometrical change was observed upon changing the metal center from tungsten to molybdenum in $[M(bdtCl_2)_3]^{2-}$ (M = W and Mo).

Introduction

In recent years, much attention has been directed toward the synthesis of metal complexes containing dithiolene ligands. This interest is primarily due to their utility in magnetic materials, superconductors, nonlinear optical materials, luminescent sensors, and enzyme catalytic centers.[1–4] The synthetic routes to tungsten and molybdenum complexes with dithiolene ligands have been extensively developed,[5,6] and their tris(dithiolene) complexes have been well characterized.[7] These tris(dithiolene) complexes show interesting characteristics in terms of both reversible electron-transfer reactions and geometrical variations around the metal centers. Although six-coordinate metal complexes generally exhibit an octahedral coordination geometry to minimize ligand interactions, it is well known that tris(dithiolene) complexes of molybdenum and tungsten can adopt both octahedral (OCT) and trigonal-prismatic (TP) structures (Scheme S1 in the Supporting Information).[7]

According to the classification of Beswick et al., the coordination geometries are found to largely depend on the nature of the coordinated dithiolene ligands.[7] $[M(mnt)_3]^{2-}$ (M = W and Mo; mnt = 1,2-dicyano-1,2-ethylenedithiolate) complexes[8] adopt intermediate structures between OCT and TP [OCT/TP = average of the values for θ/60 and (90 – φ)/(90 – 55) = 53% for M = Mo and W],[7] whereas $[M(S_2C_2Me_2)_3]^{2-}$ (M = W and Mo; $S_2C_2Me_2$ = 1,2-dimethylethylene-1,2-dithiolate) complexes[9] primarily adopt TP structures (OCT/TP = 1% for M = W and 2% for Mo).[7] When the bdt ligand is employed (bdt = benzene-1,2-dithiolate), $[W(bdt)_3]^{2-}$ structures largely depend on these counter-cations. The $(Ph_4As)_2[W(bdt)_3]$ structure[10] is intermediate between TP and OCT (OCT/TP = 44%),[7] whereas $(Et_4N)_2[W(bdt)_3]$[11] adopts a TP structure (OCT/TP = 2%).[7] The oxidation numbers of the metal centers also have an effect on the geometries. Examples of structurally characterized M^{IV}, M^{V}, and M^{VI} complexes with the same dithiolene ligands and counter-cations are limited to $(Et_4N)_n[M(S_2C_2Me_2)_3]^{0/-/2-}$ (M = W and Mo, n = 0, 1, and 2),[9,12] but all the six complexes adopt near TP geometries.[7] On the other hand, $[W(bdt)_3]^{0/-/2-}$ [10–14] and $[W(S_2C_2Ph_2)_3]^{0/-}$ ($S_2C_2Ph_2$ = 1,2-phenylethylene-1,2-dithiolate)[15] structures adopt variable geometries ranging from OCT/TP = 0% to OCT/TP = 62% (former), and from 39% to 2% (latter).[7] Because these complexes have different

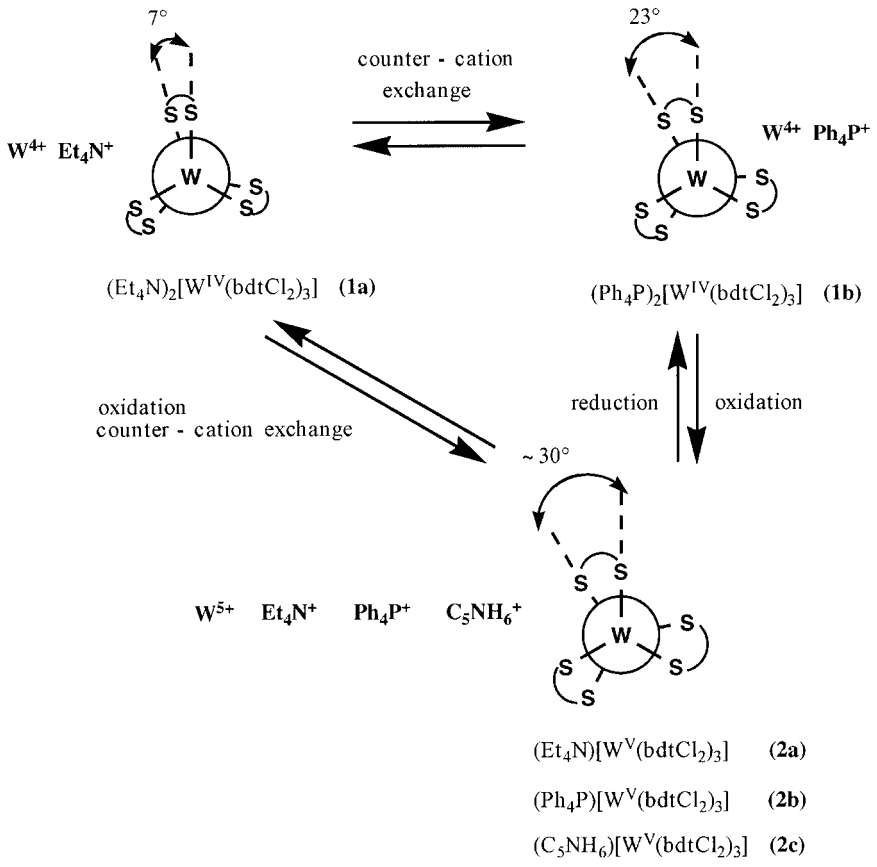

Scheme 1. Diagram showing geometrical changes.

counter-cations, including $Me_2Ph_2P^+$, Me_4N^+, Et_4N^+, Ph_4As^+, and $PhCH_2(Et)_3N^+$, and the effects of the oxidation number and counter-cation on the geometry still remain unclear, we have systematically characterized a series of $[M(dithiolene)_3]^{-/2-}$ (M = W and Mo) complexes containing the same counter-cations but weaker electron-donating dithiolene ligands than $S_2C_2Me_2$. The structural comparison between the tris($bdtCl_2$) complexes of tungsten and molybdenum ($bdtCl_2$ = 3,6-dichloro-1,2-benzenedithiolate) $(Et_4N)_2[W(bdtCl_2)_3]$ (**1a**), $(Ph_4P)_2[W(bdtCl_2)_3]$ (**1b**), $(Et_4N)[W(bdtCl_2)_3]$ (**2a**), $(Ph_4P)[W(bdtCl_2)_3]$ (**2b**), $(C_5NH_6)[W(bdtCl_2)_3]$ (**2c**), and $(Et_3HN)_2[Mo(bdtCl_2)_3]$ (**3a**) reveals new insights into the factors governing the structures of tris(dithiolene) complexes (Scheme 1).

Results and Discussion

Structural Characterization

Figures 1, 2, and 3 show the crystal structures of the anionic tungsten(IV) complexes **1a** and **1b**, and the molybdenum(IV) complex **3a**, respectively, and Figures 4, 5, and 6 show those of the tungsten(V) complexes **2a**–**2c**, respectively. The metal centers of all anions are coordinated to six sulfur atoms from three $bdtCl_2$ ligands, and all the anions interact with the counter-cations through C–H···S bonds (3–3.6 Å). The crystal structure of **2c** reveals that the pyridinium cation stacks between the aromatic phenyls of two anions (ca. 3.5 Å) to form a chain structure (not shown). The θ and φ values (see Experimental Section) given in Scheme S1 are good indications for a geometry between TP (θ = 0° and φ = 90°) and OCT (θ = 60° and $\varphi \approx$ 55°). The values of our new complexes and related complexes taken from the literature are listed in Table 1.

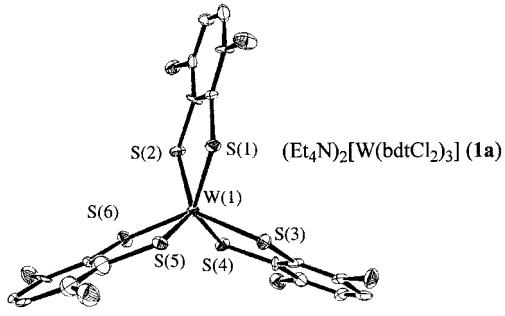

Figure 1. Structure of anion part of **1a** with 50% probability thermal ellipsoids. Selected bond lengths [Å] and angles [°]: W(1)–S(1) 2.374(5), W(1)–S(2) 2.381(5), W(1)–S(3) 2.382(4), W(1)–S(4) 2.358(5), W(1)–S(5) 2.372(4), W(1)–S(6), 2.378(5); S(2)–W(1)–S(1) 81.2(2), S(4)–W(1)–S(1) 141.3(2), S(6)–W(1)–S(1) 131.1(2), S(3)–W(1)–S(2) 128.4(2), S(4)–W(1)–S(2) 82.9(2), S(5)–W(1)–S(2) 139.5(2),S(4)–W(1)–S(3) 81.4(2), S(6)–W(1)–S(3) 141.2(2), S(5)–W(1)–S(4) 130.6(2), S(6)–W(1)–S(5) 81.3(2).

The tungsten(IV) center in **1a** adopts an almost TP structure (θ = 7°, φ = 86°, and OCT/TP = 12%; Scheme S1).
